Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary. Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility. With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Contributors

Ariane M. Abcarian, MD
Attending Surgeon
Division of Colon and Rectal Surgery
Cook County Health
Assistant Professor
Department of Surgery
Rush University Medical Center
Chicago, Illinois
Management of Hemorrhoids

Herand Abcarian, MD, FACS
Professor of Surgery
University of Illinois Hospital and Health Sciences System
John H. Stroger Jr. Hospital of Cook County
Chicago, Illinois
Management of Hemorrhoids

Mohamad A. Abdulhai, MD
Colon and Rectal Surgeon
Department of Surgical Oncology
Banner MD Anderson Cancer Center
Phoenix, Arizona
Surgical Management of Colon Cancer

Christopher J. Abularrage, MD
Associate Professor
Division of Vascular Surgery and Endovascular Therapy
Johns Hopkins Hospital
Baltimore, Maryland
Diabetic Foot

Ali F. AbuRahma, MD, FRCS, FACS, RVT, RPVI
Professor and Chief
Vascular and Endovascular Surgery
Director, Vascular Fellowship and Residency Programs
Department of Surgery
Robert C. Byrd Health Sciences Center
West Virginia University
Medical Director, Vascular Laboratory
Charleston Area Medical Center
Charleston, West Virginia
Femoropopliteal Occlusive Disease

Zachary T. AbuRahma, DO
Assistant Professor of Vascular Surgery
Charleston Area Medical Center
West Virginia University
Charleston, West Virginia
Femoropopliteal Occlusive Disease

David B. Adams, MD
Distinguished University Professor Emeritus
Department of Surgery
Medical University of South Carolina
Charleston, South Carolina
Pancreas Divisum and Other Variants of Dominant Dorsal Duct Anatomy

Laura M. Adams, MD
Associate Physician and Surgeon
Department of Surgery
UC San Diego
La Jolla, California
Endocrine Changes with Critical Illness

Reid B. Adams, MD
S. Hurt Watts Chair and Professor
Department of Surgery
University of Virginia
Charlottesville, Virginia
Management of Liver Hemangioma

Adeseye Adekeye, MD, PhD
Assistant Professor
Department of Surgery
Thomas Jefferson University
Philadelphia, Pennsylvania
Advances in Neoadjuvant and Adjuvant Therapy for Early-Stage Breast Cancer

Gina L. Adrales, MD, MPH, FACS
Associate Professor
Department of Surgery
Johns Hopkins School of Medicine
Baltimore, Maryland
Management of Inguinal Hernia

Gillian M. Ahrendt, MD
Resident
Department of Orthopaedic Surgery
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania
Management of Primary Sclerosing Cholangitis

Steven A. Ahrendt, MD
Professor
Department of Surgery
Division of Surgical Oncology
University of Colorado
Denver, Colorado
Management of Primary Sclerosing Cholangitis

Nita Ahuja, MD, MBA, FACS
Professor and Chair
Department of Surgery
Yale School of Medicine
Professor
Department of Pathology
Yale–New Haven Hospital
New Haven, Connecticut
Management of Adrenal Cortical Tumors

Venkata S. Akshintala, MD
Assistant Professor
Division of Gastroenterology
Johns Hopkins University School of Medicine
Baltimore, Maryland
Management of Hepatic Encephalopathy

Mohammad Al Efishat, MD, FSSO
Complex Surgical Oncology, HPB Fellow
Department of Surgery
Johns Hopkins Hospital
Baltimore, Maryland
Management of Intrahepatic, Perihilar, and Distal Extrahepatic Cholangiocarcinoma

Hasan B. Alam, MD
Loyal and Edith Davis Professor and Chair
Department of Surgery
Northwestern University Feinberg School of Medicine
Surgeon-in-Chief
Northwestern Memorial Hospital
Chicago, Illinois
Initial Assessment and Resuscitation of the Trauma Patient

Vance L. Albaugh, MD, PhD
Assistant Professor of Metabolic Surgery
Metamor Institute
Pennington Biomedical Research Center
Staff Surgeon
Metabolic and Bariatric Surgery
Franciscan Missionaries of Our Lady
Baton Rouge, Louisiana
Cardiovascular Disease Risk Reduction After Bariatric Surgery

Katherine Albutt, MD, MPH
Assistant Professor
Division of Trauma, Emergency Surgery, and Surgical Critical Care
Massachusetts General Hospital
Boston, Massachusetts
Current Management of Rectal Injury

Yewande Alimi, MD, MHS
Assistant Professor
Department of Surgery
Georgetown University School of Medicine
Washington, DC
Loss of Domain in Abdominal Wall Reconstruction

Wilson M. Alobuia, MD, MS
General Surgery Resident
Stanford University
Stanford, California
Management of Pheochromocytoma

Ranim Alsaad, MD
General Surgery Resident
Johns Hopkins Hospital
Baltimore, Maryland
Ischemic Colitis
Pregnancy and Breast Cancer Management

Emanuela Silva Alvarenga, MD
Clinical Associate Staff
Colon and Rectal Surgery
Cleveland Clinic Florida
Weston, Florida
Rectovaginal Fistula

John C. Alverdy, MD, FACS, FSIS
Sara and Harold Lincoln Thompson Professor of Surgery
Executive Vice Chair
Department of Surgery
The University of Chicago Pritzker School of Medicine
Chicago, Illinois
Management of Acute Necrotizing Pancreatitis

Avani Amin, MD
Instructor of Medicine
Division of Hospital Medicine
Section of Palliative Medicine
Johns Hopkins University School of Medicine
Baltimore, Maryland
Surgical Palliative Care

Ciro Andolfi, MD, FACS
Pediatric Surgeon
Department of Surgery
The University of Chicago Pritzker School of Medicine
Chicago, Illinois,
Pediatric Surgeon
Department of Surgery
Les Hôpitaux Civils de Colmar
Colmar, France
Management of Cysts, Tumors, and Abscesses of the Spleen

Lauren Antognoli, MD
Surgical Resident
Luminis Health Anne Arundel Medical Center
Annapolis, Maryland
Management of Primary Chest Wall Tumors

Pathik Aravind, MD
Resident Physician
Yale University School of Medicine
New Haven, Connecticut
Treatment Trends in Locally Recurrent and Metastatic Breast Cancer

Margaret W. Arnold, MD
Program Director
General Surgery
MedStar Baltimore
Baltimore, Maryland;
Associate Professor
Department of Surgery
Georgetown School of Medicine
Washington, DC
Treatment of Claudication

Chady Atallah, MD
Assistant Professor
Department of Surgery
Johns Hopkins Medical Institutions
Baltimore, Maryland
Management of Radiation-Induced Injury to the Small and Large Bowel
Management of Pruritus Ani

Andrea L. Axtell, MD, MPH
Surgical Fellow
Division of Thoracic Surgery
Massachusetts General Hospital
Boston, Massachusetts
Management of Tracheal Stenosis

Nilofer Azad, MD
Associate Professor
Department of Gastrointestinal Oncology
Johns Hopkins Medical Institutions
Baltimore, Maryland
Neoadjuvant and Adjuvant Therapy for Colorectal Cancer

Omaira Azizad, MD
Assistant Professor
Anesthesiology and Pain Management
University of Texas Southwestern Medical Center
Dallas, Texas
ERAS Protocols for General Surgery

Alison M. Bales, MD
Fellow
Department of Surgery
Indiana University
Indianapolis, Indiana
Management of Pulmonary Parenchymal Injury

Adrian Barbul, MD
Professor
Department of Surgery
Vanderbilt University Medical Center
Professor
Department of Surgery
Nashville Veterans Affairs Hospital
Nashville, Tennessee
Is Nasogastric Intubation Necessary After Alimentary Tract Surgery?

Philip S. Barie, MD, MBA, MCCM, FSIS, FIDSA, FACS, MAMSE
Professor Emeritus of Surgery
Division of Trauma, Burns, Critical and Acute Care
Weill Cornell Medical College
New York, New York
Burn Wound Management

Emilie C. Barnes, MD
Department of Surgery
University of North Carolina
Chapel Hill, North Carolina
Management of Tumors of the Anal Region

Stephen L. Barnes, MD, FACS
Chair, Hugh E Stephenson Department of Surgery
University of Missouri
Columbia, Missouri
Abdomen That Will Not Close

Erica Barnett, BA
MD Candidate
Department of Surgery
Harvard Medical School
Boston, Massachusetts
Management of Acute Cholangitis

Reva Basho, MD
Assistant Professor
Medical Oncology
Cedars-Sinai Medical Center
Director, Women's Cancer Research
Ellison Institute for Transformative Medicine
Los Angeles, California
Molecular Targets in Breast Cancer

Gary A. Bass, MD, MSc, MBA, PhD, FEBS (EmSurg)
Assistant Professor
Division of Traumatology, Surgical Critical Care, and Emergency Surgery
University of Pennsylvania
Philadelphia, Pennsylvania
Acute Kidney Injury in the Injured and Critically Ill

Richard J. Battafarano, MD, PhD
Associate Professor and Chief
Division of Thoracic Surgery
Johns Hopkins Medical Institutions
Baltimore, Maryland
Management of Paraesophageal Hernia Repair

Solange Bayard, MD
General Surgery
NewYork-Presbyterian/Weill Cornell Medicine
New York, New York
Surgical Management of the Axilla

Marshall S. Bedine, MD
Assistant Professor
Department of Medicine
Division of Gastroenterology and Hepatology
Johns Hopkins Medical Institutions
Baltimore, Maryland
Management of Acute Colonic Pseudo-Obstruction (Ogilvie's Syndrome)

Kevin E. Behrns, MD
Chief Medical Officer and Professor
Department of Surgery
University of Florida
Leesburg, Florida
Genetic Testing and High-Risk Pancreatic Cancer Screening

Lauren Beliveau, MD
Vascular Fellow
Baylor Heart and Vascular Hospital
Dallas, Texas
Brachiocephalic Reconstruction

Elizabeth R. Benjamin, MD, PhD
Associate Clinical Professor
Department of Surgery
Emory University
Trauma Medical Director
Grady Memorial Hospital
Atlanta, Georgia
Management of Traumatic Liver Injury

David Berger, MD
Associate Professor
General and Gastrointestinal Surgery
Harvard Medical School
Massachusetts General Hospital
Boston, Massachusetts
Management of Acute Cholangitis

James H. Black III, MD, FACS
David Goldfarb MD Professor of Surgery
Vascular Surgery and Endovascular Therapy
Johns Hopkins School of Medicine
Chief, Vascular Surgery and Endovascular Therapy
Johns Hopkins Hospital
Baltimore, Maryland
Management of Thoracic and Thoracoabdominal Aortic Aneurysms

Alex B. Blair, MD
Surgical Resident
Johns Hopkins Hospital
Baltimore, Maryland
Management of Gastric Adenocarcinoma

Shivanand Bomman, MD
Gastroenterology Research Fellow
Center for Digestive Health
Virginia Mason Franciscan Health
Seattle, Washington
Pancreatic Ductal Disruptions Leading to Pancreatic Fistula, Pancreatic Ascites, or Pancreatic Pleural Effusion

Morgan Bonds, MD
Assistant Professor
Department of Surgery
University of Oklahoma Health Sciences Center
Oklahoma City, Oklahoma
Management of Gallstone Ileus

Marylise Boutros, MD, FRCSC, FACS
Associate Professor
Department of Surgery
McGill University
Attending Surgeon
Colorectal Surgery
Jewish General Hospital
Montreal, Quebec
Management of Clostridioides Difficile Colitis

Justin Brilliant, MD
Resident Physician
Johns Hopkins Hospital
Baltimore, Maryland
Management of Refractory Ascites

L.D. Britt, MD, MPH, DSc (Hon), FACS, FCCM
Henry Ford Professor and Edward J. Brickhouse Chairman
Department of Surgery
Eastern Virginia Medical School
Norfolk, Virginia
Blunt Abdominal Trauma

Sacha P. Broccard, MD
Resident
Mayo Clinic
Jacksonville, Florida
Surgical Management of the Polyposis Syndromes

Malcolm V. Brock, MD
Professor
Division of Thoracic Surgery
Johns Hopkins Medical Institutions
Baltimore, Maryland
Esophageal Function Tests
Mediastinal Masses

Ryan C. Broderick, MD
Assistant Professor
Department of Surgery
Division of Minimally Invasive Surgery
UC San Diego
La Jolla, California
Management of Acute Cholecystitis

Stephen R. Broderick, MD, MPHS
Assistant Professor
Department of Surgery
Johns Hopkins Medical Institutions
Baltimore, Maryland
Management of Barrett's Esophagus

Lawrence B. Brown, MD, MPH, MHS
General Surgery Resident
Johns Hopkins University
Baltimore, Maryland
Gastrointestinal Tubes for Feeding and Decompression

Jill C. Buckley, MD
Professor
Department of Urology
UC San Diego Health System
San Diego, California
Renal and Ureteral Traumatic Injuries

Corinne Bunn, MD
Resident
Loyola University Medical Center
Chicago, Illinois
Buerger's Disease (Thromboangiitis Obliterans)

Mark S. Burke, MD, FACS
Attending Surgeon
Plastic and Reconstructive Surgery
Erie County Medical Center
Buffalo, New York
Breast Reconstruction Following Mastectomy: Considerations, Techniques, and Outcomes, Part 2

Richard A. Burkhart, MD
Associate Professor
Departments of Surgery and Oncology
Johns Hopkins Hospital and Johns Hopkins University
Baltimore, Maryland
Intraductal Papillary Mucinous Neoplasms of the Pancreas

Michael S. Burnim, MD
Fellow
Division of Pulmonary and Critical Care Medicine
Johns Hopkins University School of Medicine
Baltimore, Maryland
COVID-19 and Health Care Delivery in a Pandemic

William Reece Burns, MD
Assistant Professor
Department of Surgery
Johns Hopkins School of Medicine
Baltimore, Maryland
Management of Intrahepatic, Perihilar, and Distal Extrahepatic Cholangiocarcinoma

Errol L. Bush, MD, FACS
Surgical Director
Advanced Lung Disease and Transplant Program
Associate Professor
Division of Thoracic Surgery
Johns Hopkins University
Baltimore, Maryland
Extracorporeal Membrane Oxygenation for Respiratory Failure

Ronald W. Busuttil, MD, PhD
Distinguished Professor Emeritus and Executive Chair
Department of Surgery
Founding Chief
Division of Liver and Pancreas Transplantation
David Geffen School of Medicine at University of California Los Angeles
Los Angeles, California
Management of Budd-Chiari Syndrome

Jo Buyske, MD
CEO and President
American Board of Surgery
Adjunct Professor
Department of Surgery
University of Pennsylvania Perelman School of Medicine
Philadelphia, Pennsylvania
The American Board of Surgery Certifying (Oral) Examination

Kristine E. Calhoun, MD
Professor
Director of Medical Student Surgical Education
University of Washington School of Medicine
Seattle, Washington
Ductal and Lobular Carcinoma in situ of the Breast

Nicholas A. Calotta, MD
Resident Physician
Plastic and Reconstructive Surgery
Johns Hopkins School of Medicine
Baltimore, Maryland
Nonmelanoma Skin Cancers
Management of Cutaneous Melanoma

Richard P. Cambria, MD
Robert R. Linton Professor of Vascular and End-Vascular Surgery
Harvard Medical School
Division of Vascular and Endovascular Surgery
St. Elizabeth Medical Center
Boston, Massachusetts
Open Repair of Abdominal Aortic Aneurysms
Endovascular Treatment of Abdominal Aortic Aneurysms

Melissa S. Camp, MD, MPH
Assistant Professor
Department of Surgery
Johns Hopkins Hospital
Baltimore, Maryland
Breast Implant-Associated Anaplastic Large Cell Lymphoma

Yilin (Linda) Cao, MD
Resident Physician
Department of Radiation Oncology and Molecular Radiation Sciences
Johns Hopkins University School of Medicine
Baltimore, Maryland
Neoadjuvant and Adjuvant Therapy for Colorectal Cancer

Ned Z. Carp, MD
Barbara Brodsky Chief of Surgery and Chair
Department of Surgery
Lankenau Medical Center
Wynnewood, Pennsylvania
Management of Male Breast Cancer

Fabio Casciani, MD
Department of Surgery
University of Pennsylvania Perelman School of Medicine
Philadelphia, Pennsylvania
Management of Complications After the Whipple Procedure

Elliot L. Chaikof, MD, PhD
Johnson and Johnson Professor of Surgery
Department of Surgery
Harvard Medical School
Chair, Roberta and Stephen R. Weiner Department of Surgery
Beth Israel Deaconess Medical Center
Boston, Massachusetts
Popliteal and Femoral Artery Aneurysm

Ahmed Chatila, MD
Fellow
Department of Gastroenterology and Hepatology
University of Maryland
Baltimore, Maryland
Pneumatosis Intestinalis and the Importance for the Surgeon

Sophia Y. Chen, MD, MPH
Resident Physician
Johns Hopkins University School of Medicine
Baltimore, Maryland
Management of Radiation-Induced Injury to the Small and Large Bowel

Albert Chi, MSE, MD
Associate Professor
Division of Trauma, Critical Care, and Acute Care Surgery
Oregon Health & Science University
Portland, Oregon
Fluid and Electrolyte Therapy

Timothy D. Chilton, DO
Resident Physician
Vascular and Endovascular Surgery
St. Louis University
St. Louis, Missouri
Management of Infected Grafts

Walter Cholewczynski, MD
Associate Chairman of Surgery
Director of Surgical Critical Care
Department of Surgery
Bridgeport Hospital
Bridgeport, Connecticut;
Clinical Assistant Professor
Department of Surgery
Yale School of Medicine
New Haven, Connecticut
Antibiotics in Surgical Critical Care

Michael A. Choti, MD, MBA
Chief, Department of Surgery
Banner MD Anderson Medical Center
Phoenix, Arizona
Surgical Management of Colon Cancer

Joani Christensen, MD
Assistant Professor
Department of Surgery
Washington University in St. Louis School of Medicine
St. Louis, Missouri
Lymphedema

Adrienne N. Christopher, MD
Resident Physician
Thomas Jefferson University Hospital
Clinical Research Fellow
Division of Plastic Surgery
University of Pennsylvania Hospital
Philadelphia, Pennsylvania
Use of Various Meshes in Hernia Repair

Anna Chudnovets, MD
General Surgery Specialist
Department of Surgery
Johns Hopkins Medical Institutions
Baltimore, Maryland
Preoperative Bowel Preparation: Is It Necessary?

Jose R. Cintron, MD
Chairman, Division of Colon and Rectal Surgery (Retired)
John H. Stroger Hospital of Cook County
Associate Professor (Retired)
University of Illinois College of Medicine at Chicago
Chicago, Illinois
Surgical Management of Constipation

Bryan M. Clary, MD, MBA
Professor and Chair
Department of Surgery
UC San Diego
San Diego, California
Management of Acute Cholecystitis

Jordan M. Cloyd, MD
Surgical Oncologist
Department of Surgery
Ohio State University
Columbus, Ohio
Management of Colorectal Liver Metastases

Christine S. Cocanour, MD, FACS, FCCM
Professor
Department of Surgery
Division of Trauma
UC Davis
Sacramento, California
Catheter Sepsis in the Intensive Care Unit

Raul Coimbra, MD, PhD
Surgeon-in-Chief
Division of Trauma, Surgical Critical Care, and Burns
Riverside University Health System Medical Center
Riverside, California;
Professor
Department of Surgery
Loma Linda University
Loma Linda, California
Chest Wall Trauma, Hemothorax, and Pneumothorax

Salih Colakoglu, MD
Assistant Professor
Plastic and Reconstructive Surgery
Johns Hopkins Hospital
Baltimore, Maryland
Breast Reconstruction Following Mastectomy: Indications, Techniques, and Results, Part I

Julie A. Conyers, MD, MBA, FACS
Surgeon, Trauma Acute Care Surgery
UC Health
Colorado Springs, Colorado;
Chief Medical Officer
Pikes Peak Regional Hospital
Woodland Park, Colorado
Endoscopic Therapy for Esophageal Variceal Hemorrhage

Vice Chair for Education
Department of Surgery
Chair, Department of Medical Education
UT Health San Antonio Long School of Medicine
San Antonio, Texas
The American Board of Surgery Certifying (Oral) Examination

Danielle K. DePeralta, MD
Assistant Professor
Surgical Oncology
Northwell Health
New York, New York
Management of Malignant Liver Tumors

Niraj M. Desai, MD
Assistant Professor
Department of Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland
Transplantation of the Pancreas

Melissa Louise DeSouza, MD
Surgeon
Foregut and Bariatric Surgery
The Oregon Clinic
Portland, Oregon
Management of Disorders of Esophageal Motility

Lauren M. DeStefano, MD
Breast Surgical Oncologist
Department of Surgery
Cedars-Sinai Medical Center
Los Angeles, California
Ductal and Lobular Carcinoma in situ of the Breast

Laurence P. Diggs, MD
Chief Resident
Rutgers Robert Wood Johnson University School of Medicine
New Brunswick, New Jersey
Management of Gastrointestinal Stromal Tumors

Conor Dillon, DO
Instructor, General Surgery
Homer Stryker School of Medicine
Western Michigan University
Kalamazoo, Michigan
Surgical Site Infections

Joseph DiNorcia, MD
Associate Professor
Recanati/Miller Transplantation Institute
Icahn School of Medicine at Mt. Sinai
New York, New York
Management of Budd-Chiari Syndrome

Gerard M. Doherty, MD
Moseley Professor and Chair of Surgery
Harvard Medical School
Surgeon-in-Chief and Crowley Family Chair
Brigham and Women's Hospital
Boston, Massachusetts
Nontoxic Goiter

James M. Donahue, MD
Associate Professor
Department of Surgery
University of Alabama at Birmingham
Birmingham, Alabama
Management of Esophageal Perforation

Joy Zhou Done, MD, MHS
Resident
Johns Hopkins
Baltimore, Maryland
PET Scanning in the Management of Colorectal Cancer
Treatment Trends in Locally Recurrent and Metastatic Breast Cancer

Jay J. Doucet, MD, MSc, FACS, FRCSC
Professor
Department of Surgery
UC San Diego
San Diego, California
Endocrine Changes with Critical Illness

Quan-Yang Duh, MD
Professor and Chief
Section of Endocrine Surgery
UC San Francisco
Attending Surgeon
VA Medical Center
San Francisco, California
Management of Thyroid Nodules

Mark D. Duncan, MD, FACS
Associate Professor
Division of Surgical Oncology
Johns Hopkins Medical Institutions
Associate Professor
Department of Oncology
Miller Coulson Academy of Clinical Excellence
Baltimore, Maryland
Management of Gastric Adenocarcinoma

Mark A. Eckardt, MD
Surgical Resident
Yale School of Medicine
New Haven, Connecticut
Management of Adrenal Cortical Tumors

Barish H. Edil, MD
Professor and Chair
Department of Surgery
University of Oklahoma
Oklahoma City, Oklahoma
Management of Gallstone Ileus

David T. Efron, MD
Professor
Department of Surgery
University of Maryland Shock Trauma Center
Medical Director and Chief of Trauma
RA Cowley Shock Trauma Center
University of Maryland School of Medicine
Baltimore, Maryland
Emergency Department Resuscitative Thoracotomy

Jonathan E. Efron, MD
Professor of Surgery and Urology
Johns Hopkins University
Baltimore, Maryland
Management of Toxic Megacolon

Anne P. Ehlers, MD, MPH
Senior Fellow
University of Washington
Seattle, Washington
Endoscopic Treatment of Barrett's Esophagus

Daniel L. Eisenson, MD
Resident
Johns Hopkins University School of Medicine
Baltimore, Maryland
Management of Hepatic Abscess

S. James El Haddi, MD, MS
General Surgery Resident
Oregon Health & Science University
Portland, Oregon
Fluid and Electrolyte Therapy

Mohamad El Moheb, MD
General Surgery Resident
University of Virginia
Charlottesville, Virginia;
Postdoctoral Research Fellow
Massachusetts General Hospital
Boston, Massachusetts
Use of Opioids in the Postoperative Period

Ramy El-Diwany, MD, PhD
Resident
Johns Hopkins University School of Medicine
Baltimore, Maryland
Management of Small Bowel Tumors

James K. Elsey, MD, FACS
Professor
Department of Surgery
Medical University of South Carolina
Charleston, South Carolina
Management of Abdominal Aortic Aneurysm with Concomitant Nonvascular Abdominal Pathology

Joel Elterman, MD, FACS
Associate Clinical Professor
Department of Surgery
University of Colorado School of Medicine
Anschutz Medical Campus
Fort Collins, Colorado;
Trauma and Acute Care Surgery
Medical Center of the Rockies
Loveland, Colorado
Septic Response and Management

Johns Hopkins School of Medicine
Baltimore, Maryland
Incisional, Epigastric, and Umbilical Hernias

David W. McFadden, MD, MBA
Murray-Heilig Chairman and Professor
Department of Surgery
University of Connecticut
Farmington, Connecticut
Management of Zollinger-Ellison Syndrome

Sean P. McGuire, MD
General Surgery Resident
Indiana University
Indianapolis, Indiana
Management of Cystic Disorders of the Bile Ducts

Christopher R. McHenry, MD, FACS
Vice Chair, Department of Surgery
Metro Health Medical Center
Professor
Department of Surgery
Case Western Reserve University School of Medicine
Cleveland, Ohio
Management of Thyroiditis

Erin E. McIntosh, MD
Resident Physician
Department of Surgery
St. Elizabeth's Medical Center
Boston, Massachusetts
Open Repair of Abdominal Aortic Aneurysms

Genevieve B. Melton-Meaux, MD, PhD
Professor
Department of Surgery
University of Minnesota
Minneapolis, Minnesota
Management of Colorectal Polyps

Avedis Meneshian, MD
Assistant Professor
Department of Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland,
Thoracic Surgeon
Anne Arundel Medical Center
Annapolis, Maryland
Management of Primary Chest Wall Tumors

Raman Menon, MD
Colon and Rectal Surgery
Swedish Medical Center
Seattle, Washington
Anal Condyloma

Thomas S. Metkus Jr., MD, PhD
Assistant Professor
Departments of Surgery and Medicine
Johns Hopkins University
Baltimore, Maryland
Cardiovascular Pharmacology

Fabrizio Michelassi, MD
Lewis Atterbury Stimson Professor and Chairman
Department of Surgery
Weill Cornell Medical College
Surgeon-in-Chief
NewYork-Presbyterian Hospital/Weill Cornell Medical Center
New York, New York
Use of Strictureplasty in Crohn's Disease

Shruti Mony, MBBS
Department of Gastroenterology and Hepatology
Johns Hopkins University
Baltimore, Maryland
Enteral Stents in the Treatment of Colonic Obstruction

Katherine A. Morgan, MD, FACS
Professor and Chief
Division of Gastrointestinal and Laparoscopic Surgery
Medical University of South Carolina
Charleston, South Carolina
Gallstone Pancreatitis

Department of Surgery
University of Chicago
Chicago, Illinois
Management of Acute Necrotizing Pancreatitis

Carol D. Morris, MD, MS
Division Chief, Orthopaedic Oncology
Vice Chair, Clinical Operations
Department of Orthopaedic Surgery
Johns Hopkins Medicine
Baltimore, Maryland
Management of Soft Tissue Sarcomas

Christopher R. Morse, MD
Assistant Professor
Thoracic Surgery
Massachusetts General Hospital
Harvard University
Boston, Massachusetts
Management of Acquired Esophageal Respiratory Tract Fistula

Ashok Muniappan, MD
Thoracic Surgeon
Department of Surgery
Massachusetts General Hospital
Boston, Massachusetts
Management of Tracheal Stenosis

Peter Muscarella II, MD
Gastrointestinal Surgery
Niagara Falls Memorial Medical Center
Niagara Falls, New York
Management of Lower Gastrointestinal Bleeding

Matthew Mutch, MD
Chief, Section of Colon and Rectal Surgery
Associate Professor
Department of Surgery
Washington University in St. Louis
St. Louis, Missouri
Management of Rectal Cancer

Juan A. Muñoz-Largacha, MD
Cardiothoracic Surgery Fellow
Division of Cardiothoracic Surgery
University of Alabama at Birmingham
Birmingham, Alabama
Management of Esophageal Perforation

Arthur J. Nam, MD, MS
Associate Professor
Plastic and Reconstructive Surgery
R Adams Cowley Shock Trauma Center
Baltimore, Maryland
Necrotizing Skin and Soft Tissue Infections

Amol Kumar Narang, MD
Assistant Professor
Department of Radiation Oncology and Molecular Sciences
Johns Hopkins University School of Medicine
Baltimore, Maryland
Intraoperative Radiation for Pancreatic Cancer

Isam W. Nasr, MD
Assistant Professor
Department of Surgery
Johns Hopkins University
Baltimore, Maryland
Repair of Pectus Excavatum

James T. Nawalaniec, MD
General Surgery Resident
Massachusetts General Hospital
Boston, Massachusetts
Management of Acquired Esophageal Respiratory Tract Fistula

Matthew A. Nehs, MD
Assistant Professor
Department of Surgery
Brigham and Women's Hospital
Harvard Medical School
Boston, Massachusetts
Nontoxic Goiter

Adam Nelson, MD
Assistant Professor
Department of Surgery
University of Arizona
Tucson, Arizona
Use of Resuscitative Endovascular Balloon Occlusion of the Aorta in Resuscitation of the Trauma Patient

Brenda S. Nettles, DNP, MS, ACNP-BC, CNE
Assistant Professor
School of Nursing
Acute Care Nurse Practitioner
Division of Surgical Oncology
Johns Hopkins Hospital
Baltimore, Maryland
Surgical Palliative Care

Lisa Ann Newman, MD, MPH
Professor, Department of Surgery
NewYork-Presbyterian Hospital/Weill Cornell Medical Center
Chief, Division of Breast Surgery
Director, NewYork-Presbyterian Hospital Network Interdisciplinary Breast Program
Medical Director and Founder
International Center for the Study of Breast Cancer Subtypes
Weill Cornell Medicine
New York, New York
Surgical Management of the Axilla

Nariman Nezami, MD
Associate Professor
Division of Vascular and Interventional Radiology
Department of Diagnostic Radiology and Nuclear Medicine
University of Maryland School of Medicine
Associate Professor
Experimental Therapeutics Program
University of Maryland Marlene and Stewart Greenebaum Comprehensive Cancer Center
Baltimore, Maryland
Transarterial Therapies for Primary and Metastatic Liver Tumors

Dennis C. Nguyen, MD
Assistant Professor
Plastic and Reconstructive Surgery
Washington University School of Medicine
St. Louis, Missouri
Evaluation and Management of the Patient with Craniomaxillofacial Trauma

Hien T. Nguyen, MD, MBA
Director of the Comprehensive Hernia Center
Associate Professor
Department of Surgery
Johns Hopkins Medical Institutions
Baltimore, Maryland
Incisional, Epigastric, and Umbilical Hernias

Jake A. Nicholson, DO
Resident Physician
Vascular Surgery
Spectrum Health
Michigan State University
Grand Rapids, Michigan
Gangrene of the Foot

Management of Cystic Disorders of the Bile Ducts

Preface

The first edition of *Current Surgical Therapy* was published in 1984. The textbook has thus been in existence for almost 40 years, and this is the fourteenth edition. In each edition, we have updated the material to reflect the continuing evolution of the field of general surgery. The textbook continues to be perhaps the most popular surgical book in the field, and as long as it fulfills a need, we plan to continue the publication every 3 years. It has been a special privilege and honor for the two editors to be able to review contributions from surgeons around the country and, indeed, from around the world, on what they believe is the current surgical therapy for essentially all common general surgical topics. It is an enjoyable task and keeps two surgeons who care for surgical patients current on all general surgical topics.

As with prior editions, nearly every chapter has been written by a new author. All authors have contributed their specific and personal thoughts on the current surgical therapy of the disease about which they are experts. Therefore, to obtain a broad view of the topic, the reader may want to review the contributions of the other experts in the past two or three editions of *Current Surgical Therapy.*

As with the past editions, disease presentation, pathophysiology, and diagnosis are discussed only briefly, with the emphasis on current surgical therapy. When an operative procedure is discussed, an effort has been made to include brief and concise descriptions with figures and diagrams when possible. *Current Surgical Therapy* is written for surgical residents, fellows, and fully trained surgeons in private practice or in an academic setting. Many have told us that it is an excellent textbook to review before taking the general surgical boards or recertifying. Medical students have also given us feedback that they believe the text is of value to them. However, *Current Surgical Therapy* is not written principally for medical students. We believe a more classic surgical textbook with substantial sections on disease presentation, diagnosis, and pathophysiology is more appropriate for medical students.

We remain grateful to the many surgeons throughout the country, as well as to the international surgeons, who participated in creating this textbook. Most of the potential authors whom we solicit respond enthusiastically to the opportunity to present their expert views. Their efforts obviously are what make this textbook a success. In addition, we could not have compiled this textbook without the herculean efforts of Ms. Irma Silkworth, who has been involved with virtually all of these editions. Ms. Katie DeFrancesco at Elsevier has also has been a terrific help and stands out in the publishing industry.

Both editors continue to enjoy and thrive in our chosen profession of general surgery. In recruiting medical students into our specialty over the past 40 years, we have used the statement, "If you pick a profession you love, you never have to work the rest of your life." In our view, that profession is surgery.

Finally, we would like to dedicate this edition, as with the others, to the surgical house staff and fellows at Johns Hopkins Hospital, who are "the best of best."

The American Board of Surgery Certifying (Oral) Examination

The American Board of Surgery Certifying (Oral) Examination

Jo Buyske, MD, and Daniel L. Dent, MD

PRINCIPLE

The American Board of Surgery (ABS) was founded in 1937, with a mission to protect the public and enhance the profession. At the time, the standards for becoming a surgeon were vague and inconsistent. Some people did a Halstedian residency. Some apprenticed themselves to surgeons. Others did internships and then were self-taught, or they skipped formal training altogether. The public had no way to distinguish the training or skill of these practitioners. The ABS and the certification process was a way to set standards for the profession and to provide a testimonial to patients that their surgeon was qualified.

Certification by the ABS is the culmination of surgical training. It is a testimonial to quality, knowledge, and judgment based on several distinct components. First, training in an Accreditation Council for Graduate Medical Education (ACGME)-accredited training program is a prerequisite for certification in nearly all cases. Second, candidates must meet the standards of training as set by the ABS, including things like passing knowledge and skills tests in laparoscopy (FLS), endoscopy (FES), trauma (ATLS), and cardiovascular events (ACLS). Candidates must meet case minimums both in the early years of training to "prepare the soil" and also during the chief year to demonstrate maturation. There are time requirements, and required observations of both clinical and operative skills. Third is a knowledge exam, the Qualifying Examination. The Qualifying or written examination is a 300-plus question, computer-based multiple choice exam designed to test foundational knowledge.[1] Finally, after all of these other qualifications have been met, the Certifying, or oral examination, is a test of judgment and applied knowledge. The two tests measure different assets, and candidates' performance is not predictable across the two exams. That is to say, doing well on one exam does not predict doing well on the other exam. They measure different attributes, and each one is important to fulfill the ABS mission of serving the public and the profession.[2]

The Certifying Examination consists of a series of carefully created scenarios. The scenarios are the tool that supports the examiners in their charge, which is to "evaluate a candidate's clinical skills in organizing the diagnostic evaluation of common surgical problems and determining appropriate therapy. Emphasis is placed on candidates' ability to use their knowledge and training to "safely, effectively and promptly manage a broad range of clinical problems." Additionally, "Technical details of operations may also be evaluated, as well as issues related to a candidate's ethical and humanistic qualities."[3]

CONTENT

The content of the Certifying Examination is generally aligned with the ABS SCORE Curriculum Outline. The majority of the exam will focus on topics that are listed among the core content of the curriculum. The remainder of the exam will be on complications of these basic scenarios or may be taken from the advanced portion of the curriculum.[4] While each exam roster contains 12 cases, the content for the exam comes from 13 question-writing committees. There is some overlap of the content between committees. For example, a case of septic shock secondary to a colonic perforation from an incarcerated hernia could have been put forward as content from the colorectal, hernia, or critical care committees. Each roster of cases is reviewed for breadth of content and consistency of difficulty relative to historical performance of the individual questions so exam difficulty is consistent across all rosters. Because the candidate will also be tested as to baseline surgical knowledge on the qualifying (written) exam, it is not generally expected that the candidate will be asked to regurgitate basic surgical facts. With that said, the candidate can expect that some questions may include a list of questions asking how the candidate's management plan might change in the face of variations of patient presentation or pathologic findings, or in the setting of intraoperative or postoperative complications. This should not necessarily be interpreted as meaning that the candidate is off track, but rather is a way of probing the candidate's skill and judgment in managing a variety of situations.

PROCESS

The Certifying Examination consists of three exam sessions that each last 30 minutes. In each session, the candidate will be presented with four case scenarios. Two examiners are used in each session to help ensure the validity of the exam. All examiners are in active practice, currently certified by the ABS, and participating in the ABS Continuous Certification Program. All of the examiners have taken the certifying exam themselves, some of them more than once. Examiners are all volunteers, and they do not receive any financial compensation for their service.[5–7]

The examiners will typically alternate in presenting the case information to the candidate. In presenting the case scenarios, the goal of the examiners is to provide a clear description of each case. It is the intent of the examiners to provide sufficient information at each step in the case so the candidate may make pertinent decisions on how to progress in the workup and treatment of the patient.

The COVID-19 pandemic presented a new challenge for the administration of the Certifying Examination. The inability to administer the exam in person created a need to administer the exam in a virtual format. In the 2020–2021 academic year, the exam was administered with all candidates and examiners participating virtually. This necessitated some modifications to the timing of the exam, specifically that each room was given an extra 5 minutes in case of

technical difficulties. The time allotted to answering questions did not change; if the extra time was not needed, then there was simply a short break between sessions. The candidates found the experience to be fair and the vast majority support keeping the exam in a virtual format going forward.[8]

PREPARATION

The ideal preparation for the Certifying Examination is to have successfully provided evidence-based care for each condition that will be covered during the exam. Surgical residency, as currently structured by the parameters of the ACGME, Residency Review Committee (RRC), and ABS, provides strong foundation for the exam. Given the breadth of general surgery, however, it is likely that candidates will encounter scenarios they have not seen in training. Before taking the exam, candidates are encouraged to practice taking oral exams with colleagues who have successfully completed the examination process as the concise oral presentation of decision making benefits from repetition and practice. In doing so, the candidate should practice case scenarios over a wide range of pathologic conditions. Specific recommendations for preparing for the exam include the following:

- Practice clarity of communication with regard to explaining the decision-making process.
- Practice anatomic descriptions of common procedures (e.g., inguinal herniorrhaphy) as verbalizing operative anatomy can be challenging in a high-stakes setting.
- Recognize that the goal of the exam is to convey how one would actually safely manage a patient, not to try to guess what the examiners want to hear.
- Plan for management of complications and consequences of treatment decisions. For example, in appropriately selected patients with colon pathology, it may be appropriate to perform primary anastomosis. However, the candidate should also know how to handle the potential consequence of an anastomotic leak. Conversely, if the candidate initially chooses to manage the patient with a colostomy, it is reasonable to expect that the candidate can also manage ostomy ischemia and parastomal hernia.
- Recognize that the exam is not a multiple-choice exam and that each case discussion is an ongoing conversation. As the case evolves, the optimal management evolves with it. For example, it may be appropriate to initially manage a patient nonoperatively but then convert to operative management if the patient's condition changes.

ASSESSMENT

Examiners receive standardized training before giving an exam. This includes practice scoring, implicit bias training, and team review of the scenarios. In addition, examiners routinely get formative feedback from observers and their co-examiners. Finally, examiner scoring patterns are evaluated from a psychometric perspective, looking at patterns of consistency and severity as well as any evidence of bias.[9]

- Each examiner records a score for each case to maximize the number of independent observations that contribute to the candidate's total score. A total score that reflects the ability to safely care for the broad array of cases that are presented over the course of the exam is considered a passing grade. There is no preset pass or fail rate for the exam. On each scenario, candidates may be given a passing grade, a failing grade, or an equivocal grade. The equivocal grade is given when the examiners do not have enough information to give a passing grade, such as when the candidate spends more time asking questions than answering them, or when the candidate makes multiple noncritical errors while also making a number of correct management choices. The examiners are charged with assessing the following characteristics of the candidate's performance:

- Demonstrates an organized approach and solid rationale for planned actions.
- Rapidly determines and interprets key findings in a clinical presentation.
- Effectively and efficiently uses clinical knowledge to solve clinical problems; effectively addresses key management points.
- Avoids errors and critical fails (omission and commission) associated with the case.
- Recognizes personal limitations in knowledge and expertise when diagnosing and treating clinical problems.
- Reacts in a prompt but flexible manner to alterations in the patient's course (e.g., disease or treatment complications).
- Overall, demonstrates appropriate surgical judgment, clinical reasoning skills, and problem-solving ability.[2,3]

In answering the examiners' questions, candidates should be able to not only state what they would do, but also concisely explain how and why they would provide the stated care.[5]

SUMMARY

The ABS Certifying Examination is an assessment of a surgeon's thought processes in managing surgical conditions. Board certification is the culmination of targeted training in accredited programs, meeting specific training requirements in order to be eligible for the exam process, and then passing a written foundational knowledge exam and an oral exam of judgment delivered by trained surgical examiners. The process serves as a testimonial that board-certified surgeons have met the standards established by the profession.

Esophageal Function Tests

Wasay Nizam, MBBS, Hamza Khan, MD, and Malcolm V. Brock, MD

The esophagus is a muscular, tubelike structure located in the posterior mediastinum. It spans from the posterior oropharynx to the cardia of the stomach with three functional regions: the upper esophageal sphincter (UES), esophageal body, and lower esophageal sphincter (LES). With the aid of peristalsis and coordinated relaxation/contraction of sphincters, the esophagus allows the transport of food boluses to the stomach and prevents the reflux of corrosive stomach contents. Assessment of esophageal motility requires evaluating its structural integrity, peristalsis, and synchronized pressure changes of the sphincters. The diagnostic tools assessing these functions are termed *esophageal function tests.* Utilizing pressure sensors, these tests provide a dynamic demonstration of esophageal motility and an assessment of alternating pressures within the LES.

Patients presenting with dysphagia, reflux, or non-cardiac chest pain should undergo endoscopic or radiologic examination first to rule out structural lesions such as malignancy. Once these are ruled out, functional disorders secondary to esophageal dysmotility are considered (Box 1). This chapter will review commonly used tests, such as manometry and esophageal pH monitoring. Esophageal integrity may be evaluated both directly and indirectly by endoscopy or radiologic tools, respectively. These modalities will also be discussed in depth in subsequent chapters along with details on management of esophageal dysmotility disorders such as achalasia.

ESOPHAGEAL MANOMETRY

Esophageal manometry remains the gold standard for assessing esophageal motility. This test permits evaluation of the contractility and coordination of esophageal muscles. It measures a series of pressure events along the esophageal length and presents them as curves of amplitude over time. Originally developed in the 1950s, esophageal manometry underwent numerous modifications before becoming the state-of-the-art diagnostic tool it is today. Briefly, all versions of the manometer contain a series of sensors placed on a thin catheter that transduce intraluminal esophageal pressure into electrical signals that are then displayed as pressure waves. The original version was based on a pneumo-hydraulic system that has since been replaced by a solid-state catheter that provides a faster response and requires less technical expertise.

Conventional manometry utilizes information from sensors placed at fixed locations (~5 cm) along the length of the catheter. This catheter is placed transnasally into the esophagus with its distal tip in the stomach. Characteristics of the pressure waveform after a swallowing event allow for the recognition of the UES, the esophageal body, the LES, and the gastric cardia (Fig. 1). However, conventional manometry has several limitations including: (1) widely spaced sensors that preclude information on motor activity less than 5 cm apart, (2) unidirectional sensors unable to record pressures accurately in an asymmetrical lumen, and (3) false pressure readings during swallowing because of the tendency of the sphincters to move cephalad, dislodging the catheter.

To overcome these challenges, manometry systems have evolved to utilize more sensors (20–36) placed 1 cm apart that also record circumferentially. As a result, data on various pressure points are gathered and plotted using computer software as a smooth contour plot giving a high-resolution manometry (HRM) image. Readings are presented in color-coded spatiotemporal pressure graphs called *esophageal pressure topography* (EPT) or *Clouse plots,* named after Ray Clouse, who established the technique. These topographical plots represent time on the *x*-axis, location of the pressure wave on the *y*-axis, and color denoting pressure (Fig. 2). With the advent of HRM, a smooth continuous pressure wave along the esophagus in real-time is now available. This led to advances in our understanding of many esophageal motor diseases that were previously puzzling, such as achalasia.

A standard protocol for esophageal manometry conduction has been outlined in version 4.0 of the Chicago Classification. The original classification scheme, proposed in 2009 by the International HRM Working Group, was in response to rapid advances in HRM technology. But the scheme became so clinically useful that

BOX 1 Indications and Contraindications for Esophageal Function Tests

Indications

- Noncardiac chest pain or heartburn with no improvement from acid suppression and no explanation on radiologic or endoscopic examination
- Nonobstructive dysphagia or odynophagia that is unexplained
- Evaluating esophageal peristalsis before foregut surgery
- Localizing LES to place impendence probe in preparation of pH monitoring study
- Evaluating dysphagia after foregut surgery
- Workup of scleroderma

Contraindications

- Esophageal mass causing obstruction
- Abnormal nasal-oropharyngeal anatomy precluding catheter placement
- Nonresponsive patients unable to follow commands
- Patients on anticoagulation with high risk of bleeding

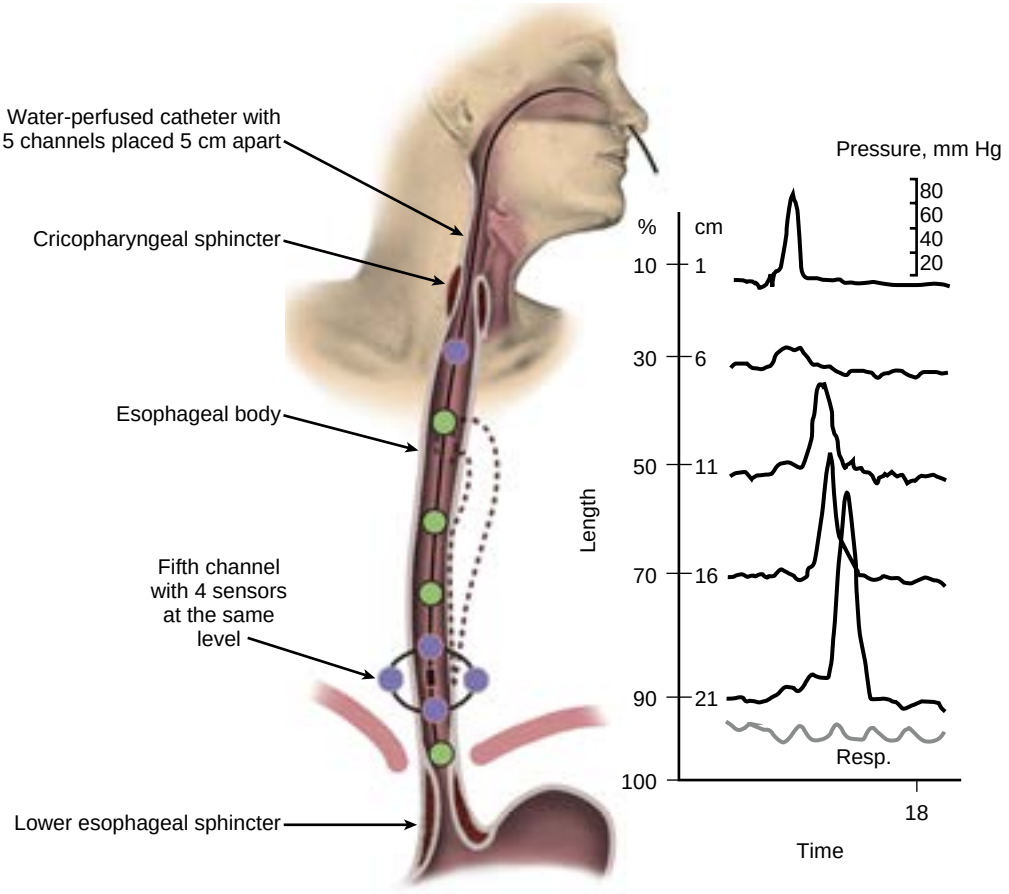

FIG. 1 Esophageal manometry showing a transnasally placed catheter that records a normal waveform progression. Newer solid-state catheters have sensors placed 1 cm apart.

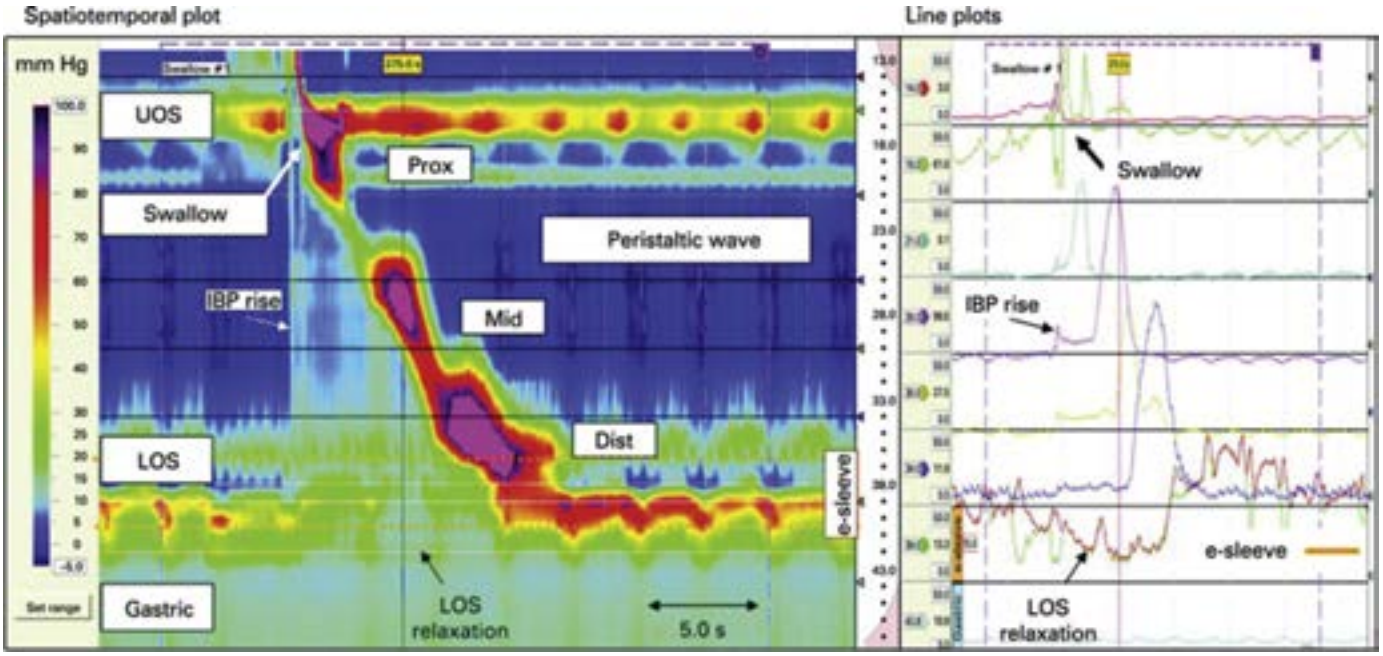

FIG. 2 Clouse plot showing a peristaltic wave after swallowing in a healthy individual. *(From Baldwin D, Puckett Y. Esophageal manometry. Updated Sep 28, 2021. In: StatPearls. Treasure Island, FL: StatPearls Publishing; 2021. https://www.ncbi.nlm.nih.gov/books/NBK559237/.)*

it helped accelerate esophageal HRM's current position as the state-of-the-art diagnostic tool that has thoroughly replaced conventional line tracing. Before the procedure, patients are obliged to fast for a minimum of 4 hours, and then the procedure begins with patients in the supine position for 10 wet (5-mL) swallows spaced 30 seconds apart. This is followed by a single multiple rapid swallow sequence (five 2-mL swallows, 2–3 seconds apart) that can be repeated up to three times. Following this, the patient is placed upright and given

five additional wet swallows and one rapid drink challenge (200 mL of water ingested as fast as possible). More provocative testing may include the utilization of a solid swallow test, a solid test meal, or even pharmacologic provocation. Pressure sensors within the body of the catheter then record intraluminal pressure that is transmitted to an external recording device. Clouse plots generated from HRM are interpreted with consideration of the following five metrics:

1. Integrated relaxation pressure (IRP): the average deglutitive relaxation pressure in a 4-second window beginning at UES relaxation
2. Distal contractile integral: the product of amplitude, duration, and length of the distal esophageal contraction
3. Distal latency: the interval between UES relaxation and the contractile deceleration point
4. Peristaltic breaks
5. Pressurization patterns

Information from these indices may be applied toward the diagnoses of esophageal motility disorders. The Chicago Classification broadly divides these disorders into disorders of esophagogastric junction (EGJ) outflow or of peristalsis. A useful algorithm presented in the classification then allows for the delineation of specific disorders, based on manometry findings (Fig. 3).

HRM is the preferred diagnostic tool when evaluating esophageal motor function, especially when radiologic or endoscopic studies are unable to explain the patient's symptoms. It is safe, with a low-risk profile of complications that is similar to those of nasogastric tube placement, namely, gagging, oropharyngeal discomfort, epistaxis, and rarely aspiration or perforation. Diet can be resumed immediately following removal of the catheter because only topical nasal anesthesia is used. It is an outpatient procedure requiring no sedation, and patients can drive home afterward. It is important, however, that patients stop H_2-blockers, proton pump inhibitors, opioids, nitrates, and calcium channel blockers before the study to avoid any interference with testing. Furthermore, it must be remembered that patients with a history of esophageal surgery, peptic stricture, or those with a current hiatal hernia are prone to false readings.

ESOPHAGEAL pH MONITORING

Acid reflux into the esophagus may be assessed with intraluminal pH monitoring. This can be performed with catheter-based devices or a wireless device (Bravo probe, Medtronic, Minneapolis, MN). Catheter-based devices are inserted transnasally, with the distal pH probe located approximately 5 cm above the LES. This device is then left in situ for 24 hours with patients instructed to record meals, symptoms, and periods of sleep by pressing buttons on a recorder. A wireless device is placed endoscopically in the distal esophagus and attached to the esophageal mucosa with a clip. This device then transmits information to a recorder. As there is no external component to this method, patient activities, dietary patterns, and comfort levels are more natural. Furthermore, because this is a single device, pH levels are only assessed at a single level, rather than across the length of the esophagus.

pH monitoring is used to determine whether or not acid exposure to the esophagus is physiologic. Data gathered from the probe are correlated with symptoms, patient positioning, and relation to meals. The information from the device is then used to calculate a composite pH or DeMeester score. Scores of 14.72 (95th percentile of normal) or greater are considered abnormal. The components of the DeMeester score include the following:

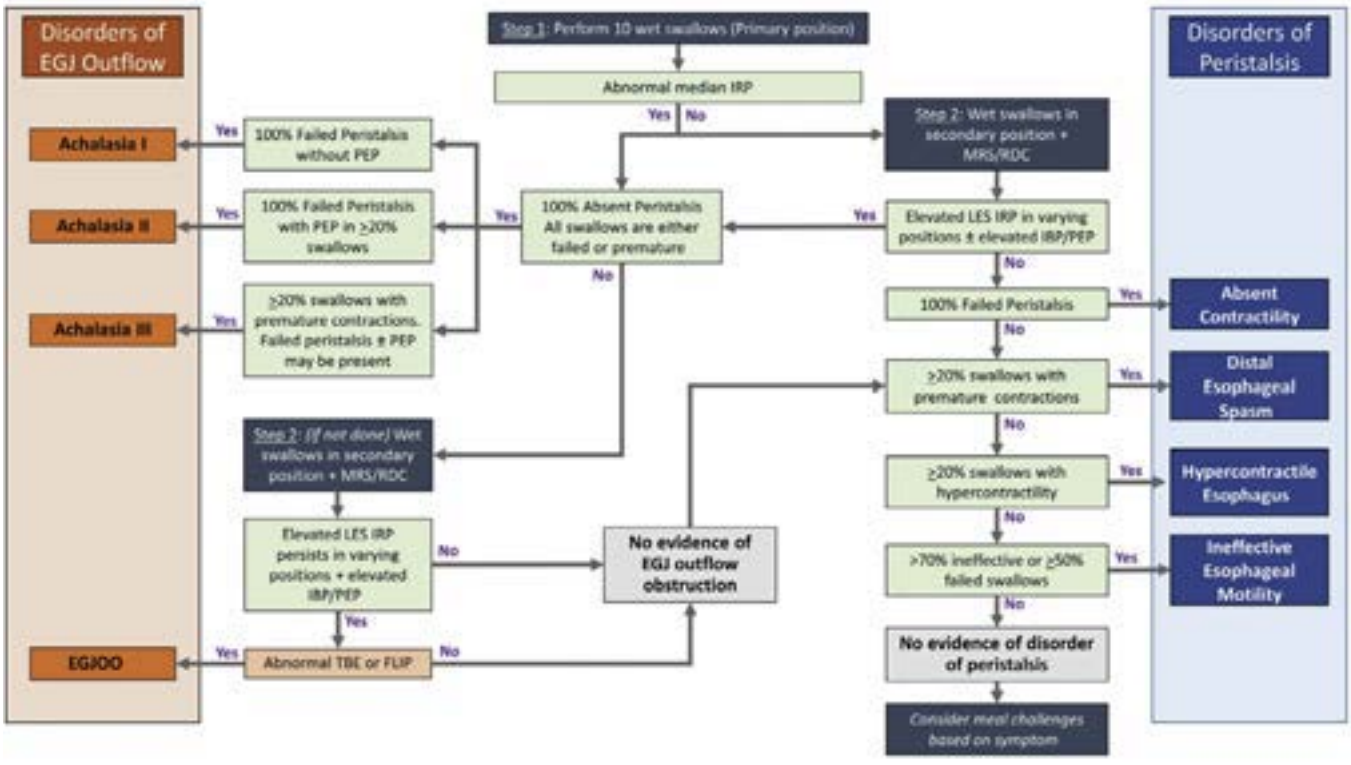

FIG. 3 Esophageal motility disorders on high-resolution manometry: Chicago classification version 4.0 Hierarchical Classification Scheme. *EGJOO*, Esophagogastric junction outflow obstruction; *FLIP*, functional lumen imaging probe; *IBP*, intrabolus pressurization; *IRP*, integrated relaxation pressure; *LES*, lower esophageal sphincter; *MRS*, multiple rapid swallows; *PEP*, pan-esophageal pressurization; *RDC*, rapid drink challenge; *TBE*, timed barium esophagram. *(From Yadlapati R, Kahrilas PJ, Fox MR, et al. 2. Percent upright time pH <4
3. Percent supine time pH <4
4. Number of reflux episodes
5. Number of reflux episodes ≥5 minutes
6. Longest reflux episode (in minutes)

IMPEDANCE TESTING

Impedance testing utilizes the principles of current resistance. A long flexible catheter with 6 to 8 sensors is placed transnasally for 24 hours, with patients instructed to proceed with normal activity. The tube is connected to a small receiver for data recording. A small voltage is applied between two electrodes. In principle, at resting state, an electrical charge within the esophageal mucosa carries current between the catheter sensors. Because liquids permit faster ion conductivity, a liquid bolus will be sensed as a rapid decrease in impedance (resistance) between the sensors. In contrast, air is a poor conductor, and swallowed air boluses will be detected as increased impedance. Based on the direction of change, this can assess both antegrade and retrograde movement (normal peristalsis or gastroesophageal reflux). Data on change in impedance gathered from multiple electrodes along the catheter is then used to determine the position of a bolus after swallowing and whether there is reflux back into the esophagus after it has entered the stomach (Fig. 4). Special impedance catheters are also available that combine impedance testing with assessment of esophageal pH sensors and manometry testing (high-resolution impedance manometry [HRIM]), allowing for improved diagnosis.

FUNCTIONAL LUMINAL IMAGING PROBE PANOMETRY

Functional luminal imaging probe (FLIP) panometry is an emerging technology in esophageal function testing used in concert with endoscopy. It is performed with a catheter possessing a distal overlying balloon. The tip of the catheter functions as an imaging probe, and within the balloon, electrodes are present, enabling the detection of impedance. The balloon may be inflated with saline in 10-mL increments up to 70 mL. The data from the sensors are then converted in real time to allow for assessment of the various metrics such as wall stiffness, pressure changes, diameter, volume, and EGJ dynamics. FLIP panometry may be used as a complementary tool in diagnosing esophageal motility disorders as well as intraoperatively during antireflux procedures to assess the adequacy of esophageal wraps.

CONCLUSION

Esophageal function testing can provide valuable information regarding the biomechanics of esophageal motility. The practicing surgeon must be well aware of the utility of these tests and be able to interpret them in light of the patient's symptoms. Optimal outcomes require close collaboration between the radiologist, gastroenterologist, and surgeon within the clinical realm to treat these complex patients. As technology evolves, newer testing techniques may improve our understanding of complicated esophageal disease and assist with intervention.

Surgical Management of Gastroesophageal Reflux Disease

Jay Zhu, MD, and Brant K. Oelschlager, MD

Gastroesophageal reflux occurs when the contents and secretions of the stomach flow retrograde into the esophagus across an inappropriately relaxed or compromised lower esophageal sphincter. Although nearly everyone experiences symptomatic episodes of reflux to some degree in their lifetime, gastroesophageal reflux disease (GERD) is a condition characterized by chronic symptoms or complications related to gastroesophageal reflux. GERD is a common diagnosis, affecting up to 20% to 30% of the US population and costing an estimated $12 billion to $20 billion in direct healthcare expenditure annually. The high incidence of GERD in the United States and other Western countries is also thought to be the primary reason behind the rising incidence of esophageal adenocarcinoma over the past four decades. In this chapter, we discuss the surgical evaluation and technical approach to gastroesophageal reflux disease.

PRESENTATIONS OF GERD

Symptoms related to GERD can be divided into typical, atypical, and alarm symptoms (Box 1). Typical symptoms of GERD are the classic esophageal manifestations of gastroesophageal reflux, which include heartburn and regurgitation. Atypical symptoms encompass the extraesophageal manifestations of reflux such as cough, dysphonia, sore throat, globus sensation, and noncardiac chest pain. Although GERD can be clinically diagnosed in patients presenting with typical symptoms, patients presenting primarily with atypical symptoms require further investigation to rule out other causes. For surgeons, distinguishing typical from atypical symptoms is useful in assessing the likelihood that a patient's symptoms are attributable to GERD and thus will respond to surgical intervention. Patients with heartburn and regurgitation tend to be more responsive to acid suppression therapy and experience higher rates of symptom resolution after antireflux surgery (ARS) when compared with those presenting with atypical symptoms.

Alarm symptoms are ones that raise suspicion for malignancy and other complications of GERD. These include weight loss, early satiety, dysphagia, odynophagia, and signs of gastrointestinal bleeding. Alarm symptoms should never be attributed solely to uncomplicated GERD, and patients presenting with these symptoms require further workup. The chronic inflammation and irritation associated with reflux can lead to intraesophageal complications such as peptic stricture, Barrett's metaplasia, and esophageal adenocarcinoma. Less commonly, reflux can also lead to extraesophageal complications such as laryngopharyngeal reflux and lung injury from aspiration. Exacerbations of asthma or interstitial lung diseases are unusual manifestations of GERD but clear reasons to consider surgical intervention. It is important to mention that decisions regarding ARS in patients with complications of GERD are often shared across disciplines. When treating patients with GERD-related complications, we often work closely with colleagues in gastroenterology, otolaryngology, or pulmonology depending on the specific complication.

BOX 1 Presenting Symptoms of Gastroesophageal Reflux

Typical Symptoms

Heartburn (also known as *pyrosis*)
Regurgitation
Acid brash

Atypical Symptoms

Cough
Wheezing
Dyspnea/shortness of breath
Voice changes
Sore throat
Globus sensation

Alarm Symptoms

Dysphagia
Odynophagia
Anorexia/early satiety
Weight loss
Gastrointestinal bleeding

DIAGNOSIS AND PREOPERATIVE EVALUATION

The primary purpose of preoperative of testing in the surgical evaluation of GERD is to (1) confirm the correct diagnosis, (2) evaluate the anatomy (e.g., the presence of a hiatal hernia), and (3) rule out concurrent esophageal or gastric pathology before surgery. We routinely obtain the following tests before surgical consultation for GERD.

- **pH testing:** Ambulatory pH monitoring in patients off acid suppression therapy is the gold standard for diagnosing GERD. This is accomplished using either a 24-hour dual-probe catheter system placed transnasally or a 48-hour wireless capsule placed endoscopically. Both tests rely on correct spacing above the lower esophageal sphincter and generate a composite score based on the frequency and duration of distal esophageal acid exposure (i.e., pH below 4). A DeMeester composite score above 14.72 or total distal esophageal acid exposure time greater than 5% to 6% are commonly used thresholds indicative of pathologic reflux.
- **Upper endoscopy:** The presence of LA Grade C or D esophagitis (Table 1; Fig. 1), Barrett's metaplasia, or a peptic stricture on

TABLE 1 The Los Angeles Classification of Esophagitis

Grade	Lesion
A	One (or more) mucosal break <5 mm long that does not extend between the tops of two mucosal folds
B	One (or more) mucosal break >5 mm long that does not extend between the tops of two mucosal folds
C	One (or more) mucosal break that is continuous between the tops of two or more mucosal folds but that involves <75% of the circumference
D	One (or more) mucosal break that involves at least 75% of the esophageal circumference

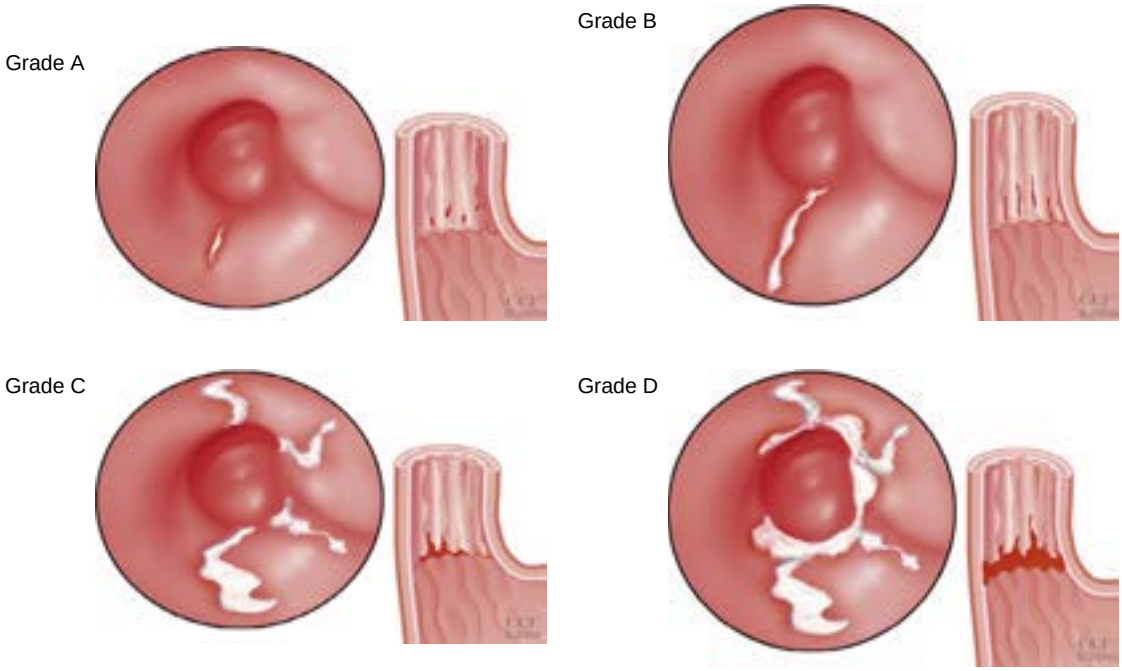

FIG. 1 The Los Angeles classification of esophagitis. Grades A to D are illustrated as described in Table 1. *(From Nayar DS, Vaezi MF. Classifications of esophagitis: Who needs them?* Gastrointest Endosc. *2004;60[2]:253–257.)*

endoscopy are all findings that confirm the diagnosis of GERD. In the case of peptic strictures, serial endoscopic dilations can provide therapy before ARS. Furthermore, endoscopic examinations are useful in identifying hiatal hernias, retained food suggestive of delayed gastric emptying, and other gross pathology involving the esophagus and stomach.

- **Manometry:** We use esophageal manometry in the setting of GERD primarily to help determine the type of fundoplication to perform. Our preference is to perform a complete 360-degree posterior (Nissen) fundoplication for patients who exhibit normal esophageal motility as this is likely the most durable treatment for reflux. For patients who have ineffective esophageal motility according to Chicago Classification version 4.0 (updated in 2020), we consider performing a partial 270-degree posterior (Toupet) fundoplication to avoid issues with postoperative dysphagia. Obtaining a manometry study also serves to rule out achalasia and other named esophageal motility disorders, which can sometimes present with symptoms that overlap with GERD.
- **Barium Esophagram:** Combined with the aforementioned studies, an upper GI barium esophagram increases the sensitivity of diagnosing a hiatal hernia or identifying other anatomic abnormalities such as an esophageal diverticulum. This is especially relevant when the treating surgeon is not the one performing the preoperative endoscopy. Furthermore, a high-quality barium esophagram is particularly useful in understanding the anatomy and geometry of a previously constructed wrap in patients with postoperative concerns or complications.

INITIAL MANAGEMENT AND INDICATIONS FOR SURGERY

With rare exception, all patients should be on acid suppression therapy with a proton pump inhibitor (PPI) before being considered for ARS. It is important to ensure that patients are taking PPIs consistently and correctly (usually 40 mg daily) to maximize the drug's efficacy and assess for a clinical response in symptoms. In general, PPIs are well-tolerated, and adverse reactions or side effects such as nausea, diarrhea, constipation, and abdominal discomfort are rare. Patients who report preoperative issues with bloating may be evaluated for delayed gastric emptying and should be counseled on the risk of worsening gas bloat when weighing the risks and benefits of ARS.

Indications for Surgical Management of GERD

The primary reason to perform ARS is for symptomatic control to reduce suffering and improve patients' quality of life. Fundoplication has not been shown to reduce rates of esophageal adenocarcinoma or improve survival outcomes. Accordingly, the most common indication for ARS is the presence of persistent symptoms that affect quality of life despite maximal medical therapy. As previously discussed, patients who exhibit atypical or alarm symptoms should undergo appropriate workup and/or interdisciplinary consultation as indicated. In patients with atypical symptoms and objectively confirmed reflux, we estimate that approximately one-third of these patients may not see improvement in their symptoms following ARS. Thus, it is important to counsel such patients carefully when weighing the risks and benefits of an operation. In general, patients presenting with typical GERD symptoms that are partially mitigated with acid suppression (or worsen when stopping acid suppression) are most likely to experience significant improvement following ARS.

Although the inability to tolerate acid suppression therapy is an indication for surgical management, true medication intolerance in the treatment of GERD should be rare. More commonly, patients will present with hesitancy or concerns surrounding long-term acid suppression therapy, with many seeking a definitive solution to their reflux. In patients who have well-controlled symptoms on a PPI, we typically advise against surgical intervention because the risks and side effects of ARS outweigh the risks of regular acid suppression therapy. Stated differently, it is very difficult to improve upon medically well-managed symptoms through an operation.

Finally, some patients with interstitial lung disease and objective findings of GERD may benefit from ARS. Data suggest that ARS can slow the deterioration of pulmonary function in these patients,

which can be particularly relevant for patients who are either being considered for lung transplantation or have already undergone transplantation. The decision and timing of ARS in this setting should be made in discussion with the patient's pulmonologist.

Contraindications to Antireflux Surgery

Patients with a normal DeMeester score and normal distal acid exposure on ambulatory pH testing should not be considered for ARS. Symptomatic patients who do not demonstrate objective findings of abnormal reflux should undergo further workup to identify an alternative diagnosis. The use of impedance or pharyngeal pH monitoring to confirm pathologic GERD is controversial and should be evaluated with caution. On the other hand, patients may have abnormal ambulatory pH monitoring, but complete preoperative workup demonstrates another diagnosis altogether such as achalasia, esophageal cancer, or a large paraesophageal hernia. In these cases, the primary diagnosis is not GERD, and patients should be treated appropriately for these other disorders. Finally, obesity is a relative contraindication for ARS. Patients with a BMI >40 should be referred for bariatric surgery evaluation to be considered for Roux-en-Y gastric bypass, as this procedure addresses the broader spectrum of obesity-related health problems, which includes GERD.

SURGICAL TECHNIQUE

In 1937, Rudolf Nissen performed the first known fundoplication in which he wrapped the stomach to buttress an esophagogastric anastomosis as part of the repair for a penetrating esophageal ulcer. Later in the 1950s, he utilized this technique for the first time as a treatment for reflux. Since then, the eponymous 360-degree wrap has become the gold standard in ARS. Although advances in technology have introduced laparoscopic and robotic-assisted approaches to ARS, the surgical principles remain the same with the goal of restoring intraabdominal esophageal length, closing the hiatal defect, and creating a one-way flap valve. Newer endoscopic approaches such as the transoral incisionless fundoplication only accomplishes one of these three goals, and long-term outcomes are still unknown. Here, we describe a laparoscopic Nissen fundoplication, which continues to be our favored procedure for GERD, and a laparoscopic Toupet fundoplication, which we perform in patients with ineffective esophageal motility (Fig. 2).

Steps of the Procedure: Initial Setup, Hiatal Dissection, and Closure of the Crura

The initial steps in performing a laparoscopic fundoplication are similar, regardless of whether a partial or complete fundoplication is being constructed. We use the same instruments (Box 2), patient positioning, and port placement (Fig. 3) for both a Nissen and a Toupet fundoplication. Although the hiatal dissection can begin on either side of the gastroesophageal junction, we prefer to first expose the left crus and then enter the mediastinum starting on the left, as follows.

1. Patient positioning and port placement
   a. The patient is positioned supine in the split leg position with padded straps secured around both thighs (some prefer lithotomy). The surgeon stands between the patient's legs while the assistant stands on the left side of the patient. Before draping, the operating table should be tested in the steep reverse Trendelenburg position in which the procedure is performed to ensure that the patient is secure and not at risk of shifting or sliding during the operation.
   b. A Veress needle is used to access and insufflate the abdomen, and the ports are placed as shown in Figure 3. The patient is then placed in steep reverse Trendelenburg before elevating the left lateral segment of the liver using a liver retractor (we use a Nathanson retractor). We typically use a 5-mm 30-degree scope.
2. Exposing and opening the hiatus on the left side (note that some prefer to start on the right)
   a. The fundus is retracted caudally to expose the membranous avascular phrenogastric attachments between the fundus and the diaphragm. These attachments are divided to begin exposure of the left crus.
   b. The gastrosplenic ligament is divided near the inferior pole of the spleen to enter the lesser sac. The gastrosplenic ligament and the associated short gastric vessels are then divided with a vessel-sealing energy device to mobilize the fundus. The posterior attachments of the stomach are divided to ensure that the fundus is completely mobilized.
   c. With the fundus retracted medially, the left crus should be clearly exposed. Additional medial traction on the gastroesophageal junction places the phrenogastric ligament on tension, exposing this white membranous connection between the medial border of the left crus and the intraabdominal esophagus. This membrane is carefully divided at the posterior base of the left crus, opening a space to the left of the esophagus. The correct mediastinal plane contains thin areolar connective tissue that can typically be easily developed with blunt dissection using the tip of a suction device or other instrument. Once the correct plane is identified, the left phrenoesophageal membrane is continually placed on stretch as it is divided, progressing anteriorly and sweeping tissue away from the membrane toward the esophagus to avoid injury to the anterior vagus nerve. Care is taken not to denude the peritoneum off the crus, as this can weaken the crural closure.
   d. A blunt instrument can then be inserted behind the esophagus to create a retroesophageal window from the left side.
3. Exposing and opening the hiatus on the right side
   a. The gastrohepatic ligament is divided starting at the pars flaccida and continuing cephalad toward the anterior aspect of the esophageal hiatus to expose the right crus. If a sizeable accessory or replaced left hepatic artery is encountered, this should be preserved.
   b. The retroperitoneal fat attached to the right crus above the left gastric artery can be retracted toward the patient's left to expose the right phrenoesophageal membrane. This should be divided to enter the same mediastinal plane that was developed on the left. The dissection can then be carried out circumferentially in similar fashion as on the left side, following the same principles of preserving the peritoneal covering over the right crus while bluntly sweeping tissue toward the esophagus to identify and preserve both anterior and posterior vagal nerves (Fig. 4).
   c. Once the phrenoesophageal membrane has been circumferentially opened around the esophagus, a ½-inch Penrose drain is inserted and encircled around the gastroesophageal junction, and then secured to itself using either suture or clips. This provides the assistant a handle to retract the esophagus during mobilization of the distal esophagus.
4. Distal esophageal mobilization
   a. The dissection is carried circumferentially around the esophagus, identifying and preserving both vagal nerves as the dissection progresses up into the mediastinum. Direct arterial branches from the aorta to the esophagus can be ligated using a vessel-sealing energy device. Care should be taken to avoid dissecting into the retroperitoneal fat overlying the aorta, as this is where the thoracic duct resides.
   b. The parietal pleura when identified should be swept laterally to avoid injury and creation of a capnothorax. If the pleura is entered inadvertently, it is important to communicate this finding with the anesthesia provider. If the opening in the pleura is easily identified, we typically choose to close this defect in an effort to limit the temporary physiologic

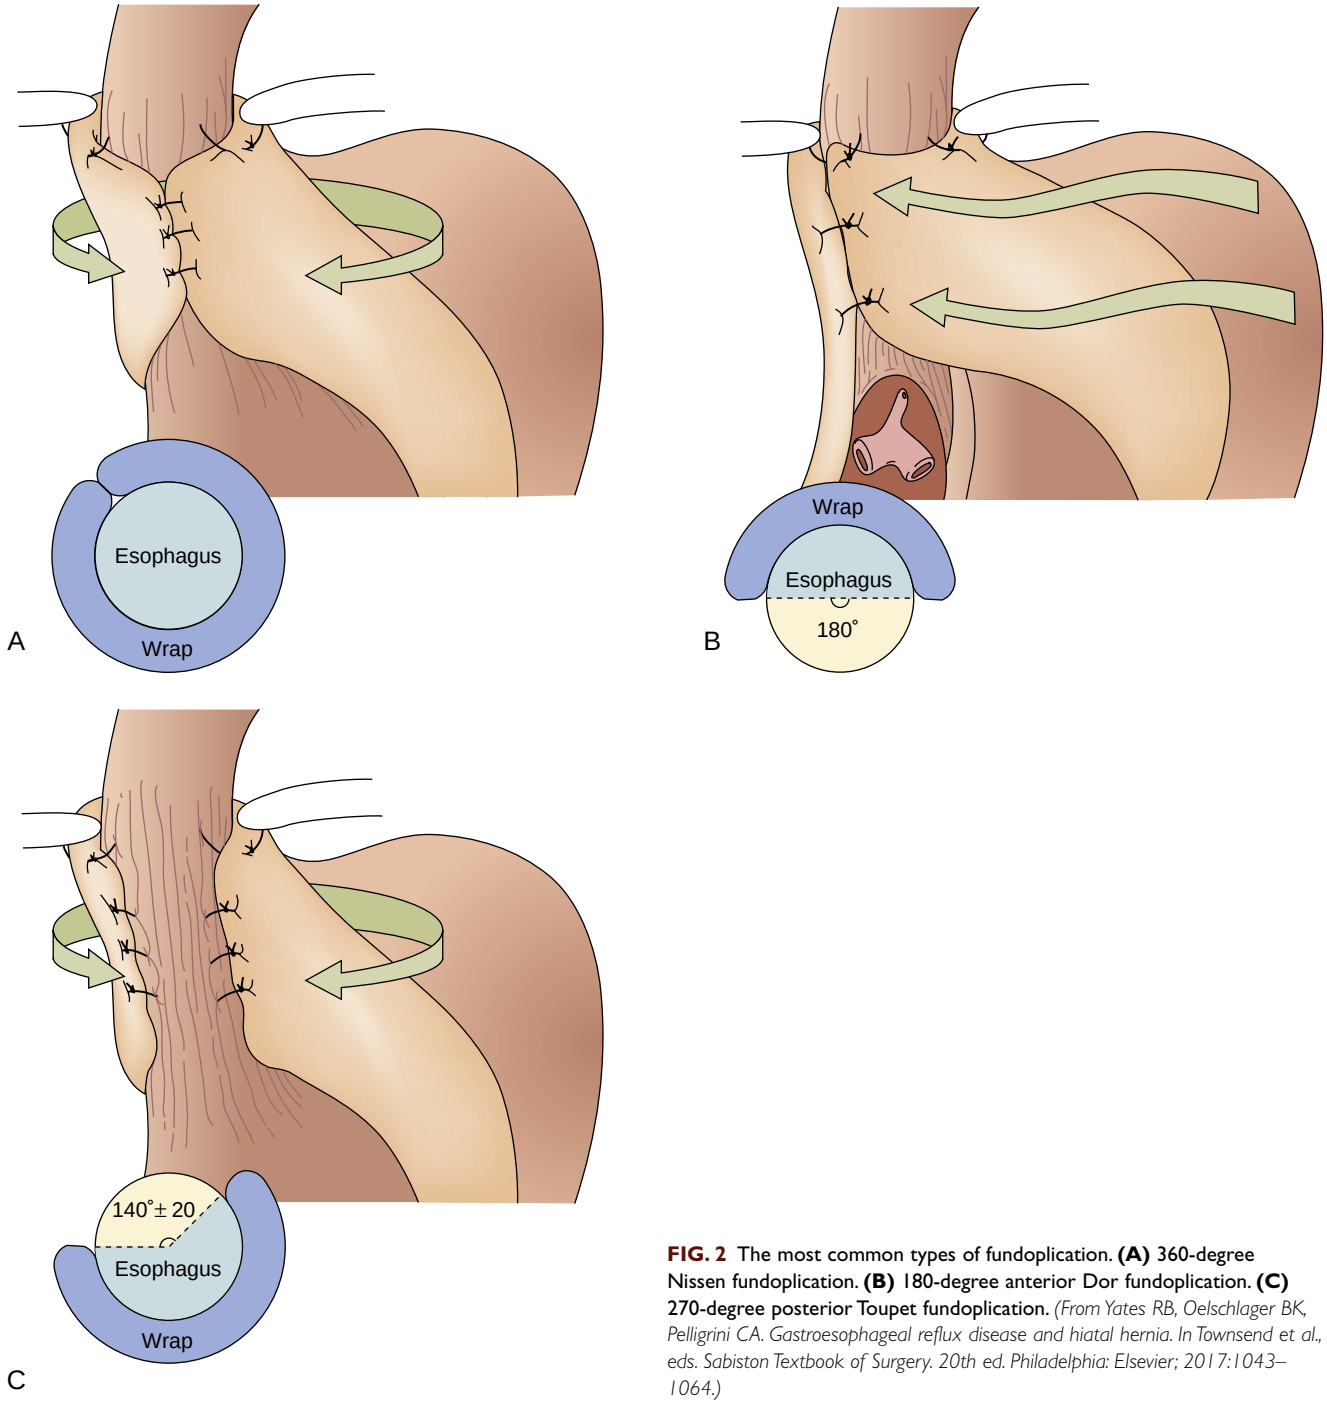

FIG. 2 The most common types of fundoplication. **(A)** 360-degree Nissen fundoplication. **(B)** 180-degree anterior Dor fundoplication. **(C)** 270-degree posterior Toupet fundoplication. *(From Yates RB, Oelschlager BK, Pelligrini CA. Gastroesophageal reflux disease and hiatal hernia. In Townsend et al., eds. Sabiston Textbook of Surgery. 20th ed. Philadelphia: Elsevier; 2017:1043–1064.)*

derangements associated with a capnothorax. However, when closure of a pleural defect is not easily achievable, expectant management and lowering of the intraabdominal insufflation pressure will typically suffice as this allows the patient to compensate physiologically for the carbon dioxide introduced into the hemithorax. Usually after a few minutes, parameters such as decreased blood pressure, increased ventilatory pressure, and increased end-tidal CO_2 will stabilize, allowing the surgeon to proceed with the operation.

c. The lower esophagus should be mobilized to achieve 3 to 5 cm of intraabdominal length without tension.

5. Closure of the crura
   a. Nonabsorbable suture is used to reapproximate the crura posterior to the esophagus. We prefer to use interrupted 2-0 silk without pledgets. This closure is performed until the esophageal hiatus approximates the diameter of the esophagus without any notable gaps. At the same time, the hiatal closure should not apply any external compression on the esophagus.
   b. On rare occasion, we will place a single anterior suture to close the anterior hiatus if there is concern that the posterior closure is bringing the esophagus so far anterior that it may be creating an angle as the esophagus exits the chest.

BOX 2 Equipment for Laparoscopic Antireflux Surgery

Basic Laparoscopic Supplies

0- and 30-degree laparoscope, camera, and video equipment
5- and 12-mm ports
Veress needle
Suction-irrigation device

Laparoscopic Energy Devices

Hook electrocautery
Bipolar or ultrasonic vessel-sealing device

Specialized Equipment

Liver retractor (e.g., Nathanson)
52-Fr Bougie (optional for partial fundoplication)
Laparoscopic suturing supplies
½-inch Penrose drain
Equipment for upper endoscopy

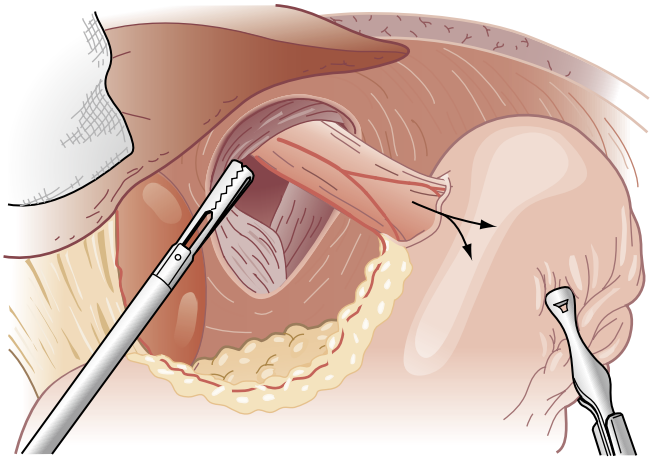

FIG. 4 Completion of the circumferential crural dissection. This illustration depicts the view immediately before insertion of the Penrose drain. *(From Yates RB, Oelschlager BK, Pelligrini CA. Gastroesophageal reflux disease and hiatal hernia. In: Townsend et al., eds. Sabiston Textbook of Surgery. 20th ed. Philadelphia: Elsevier; 2017:1043–1064.)*

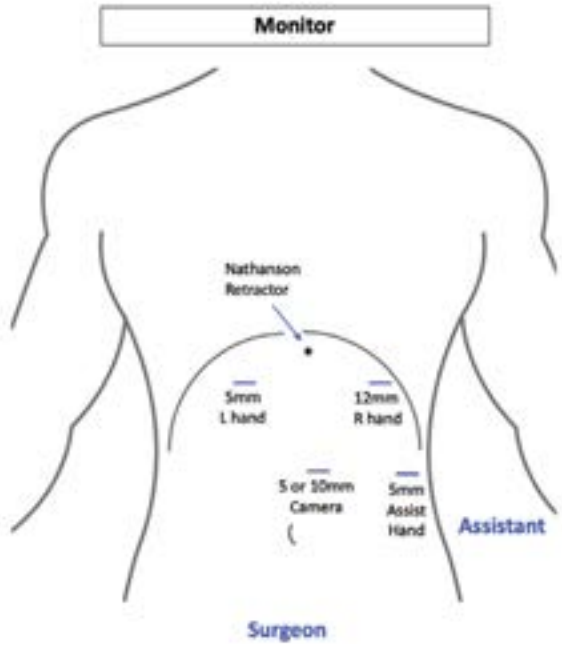

FIG. 3 Port placement for laparoscopic antireflux surgery. The camera port is positioned approximately 15 cm below the left costal margin, 2 cm to the left of midline. The Nathanson liver retractor is inserted through a stab incision in the epigastrium to the left of midline.

Steps of the Procedure: Creating a 360-Degree Nissen Fundoplication

As previously discussed, we prefer to perform a complete fundoplication in patients with normal esophageal motility. We believe this provides a more durable repair, and we find that the geometry of a complete fundoplication lends itself to greater reproducibility from a technical standpoint.

1. Orientation of the wrap
   a. The fundus and greater curve of the stomach is retracted medially, and a marking stitch is placed on the posterior fundus approximately 3 cm below the angle of His and 2 cm inside the greater curve.
   b. The posterior fundus is passed behind the esophagus, and the point on the stomach where the marking stitch was placed is lifted anteriorly against the right side of the esophagus.
   c. A point on the anterior fundus is identified that mirrors the location where the marking stitch was placed posteriorly (approximately 3 cm away from the angle of His and 2 cm from the greater curvature of the stomach). This point on the stomach is pulled up along the left side of the esophagus.
   d. A "shoe-shine" maneuver is performed to assess the symmetry of the fundoplication before bringing the two sides of the fundus together anterior to the esophagus (Fig. 5). With this construction, the greater curve of the fundus should run longitudinally posterior and to the left of the esophagus (and thus is no longer visible when suturing the fundoplication).
2. Suturing the fundoplication
   a. The first stitch is placed, bringing the anterior and posterior fundus together at the points identified in the previous steps. The marking stitch and Penrose drain are then removed. A 52F bougie is then passed down the esophagus and into the stomach.
   b. The remaining two or three sutures are placed with the bougie in place to complete the fundoplication. The bougie is then removed (see Fig. 5).
   c. We place a coronal suture on each side of the wrap that incorporates the top of the fundus/wrap, a partial thickness bite of the esophagus, and the ipsilateral crus. This helps fix the orientation of the fundoplication in the abdomen (see Figs. 2A and 5).
   d. We also typically place a suture between the posterior aspect of the fundoplication and where it naturally rests against the crural closure as an additional fixation point.
   e. We perform routine upper endoscopy upon completion of the fundoplication to evaluate and document the appropriate appearance of the newly augmented flap valve.

Steps of the Procedure: Creating a 270-Degree Posterior Toupet Fundoplication

In patients with manometric evidence of ineffective esophageal motility, we typically recommend a partial fundoplication. When

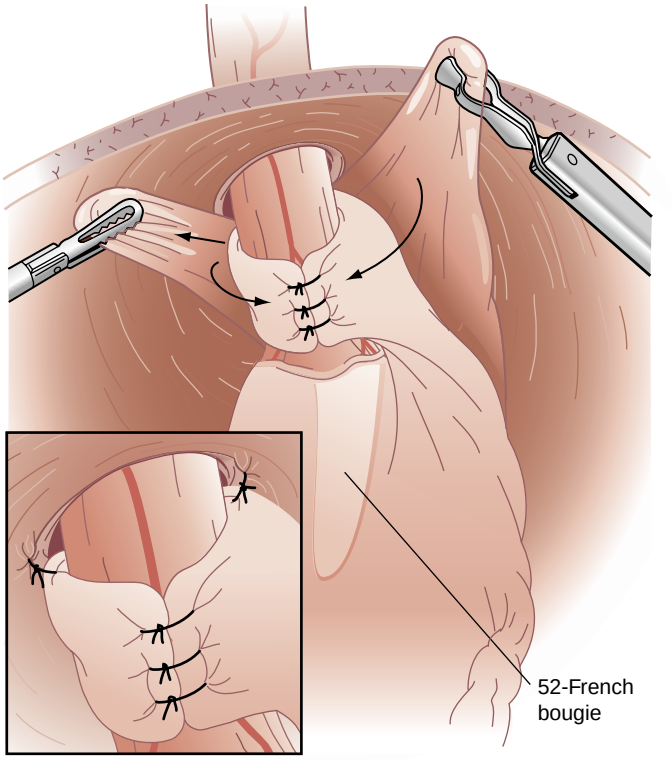

FIG. 5 Creating a 360-degree Nissen fundoplication. The "shoe-shine" maneuver is performed by grasping the posterior and anterior fundus with the left and right hand, respectively, 3 cm from the angle of His, and 2 cm from the greater curvature of the stomach. *(From Oelschlager BK, Eubanks TR, Pellegrini CA. Hiatal hernias and gastroesophageal reflux disease. In: Townsend CM, Beauchamp RD, Evers MB, et al., eds. Sabiston Textbook of Surgery. 19th ed. Philadelphia: Elsevier; 2012.)*

considering the geometry of a 270-degree (Toupet) fundoplication, the inner circumference of the fundoplication should approximate that of the esophagus, while the outer circumference should be appropriately redundant, resembling a crescent with rounded corners in cross-section. This geometry provides volume to the fundoplication, which supports the intended flap-valve effect. The constructed geometry should be very similar to that of a Nissen, just without bringing the stomach together, thus the following description is very similar. Of note, we do not routinely use an esophageal bougie when performing a partial fundoplication.

1. Orienting and creating the right half of the wrap.
   a. The fundus and greater curve of the stomach is retracted medially, and a marking stitch is placed on the posterior fundus approximately 3 cm below the angle of His and 2 cm inside the greater curve.
   b. The posterior fundus is passed behind the esophagus, and the point on the stomach where the marking stitch was placed is lifted anteriorly against the right side of the esophagus.
   c. A coronal suture is placed on the right side, incorporating the posterior fundus, a partial thickness bite of the esophagus, and the right crus (just like in a Nissen).
   d. A posterior stitch is placed to fixate the wrap to where it naturally lies against the crural closure.
   e. Two additional sutures are placed between the esophagus (to the right of the anterior vagus nerve) and posterior fundus, completing the right side of the fundoplication (see Fig. 2C).
2. Completing left side of the fundoplication
   a. The anterior fundus is pulled laterally to remove the redundant stomach from behind the esophagus.
   b. A left coronal suture is placed, incorporating the anterior fundus, a partial bite of the esophagus, and the left crus (again, just like the Nissen orientation).
   c. Two additional sutures are placed between the esophagus (to the left of the anterior vagus nerve) and posterior fundus, completing the left side of the fundoplication (see Fig. 2C).
   d. We routinely perform an upper endoscopy upon completion of the fundoplication to evaluate and document the appropriate appearance of the newly augmented flap valve.

POSTOPERATIVE CARE, SURGICAL COMPLICATIONS, AND OUTCOMES

Postoperatively, acid suppression therapy is routinely discontinued, and all medications are administered in either crushed or liquid form for 4 weeks. We typically admit patients to the hospital on a liquid diet and monitor for appropriate pain control and PO intake before discharge the following day. Although some surgeons routinely obtain a barium esophagram on the first postoperative day, we have not adopted this practice. Instead, patients who are able to tolerate a liquid diet without issue are advanced to a soft esophageal diet upon discharge on the first postoperative day, and this diet is maintained for 4 weeks.

Mild dysphagia is very common following ARS, and patients should be counseled to expect this during their preoperative and postoperative diet education. Similarly, patients are typically unable to belch or vomit following ARS, and many patients may experience mild bloating discomfort, abdominal distention, or epigastric pain. For most patients, both dysphagia and gas bloat should improve after 6 to 8 weeks. If these symptoms persist beyond this timeframe, endoscopic dilation of the wrap may be considered.

Long-term outcomes associated with laparoscopic ARS can be measured by examining patient-reported symptoms, objective measures of distal esophageal acid exposure, resumption of PPI use, complications of GERD, or rates of reoperation. Thus, depending on the primary outcome examined, definitions of success and failure vary across studies. In general, available studies demonstrate a 15% to 30% recurrence rate for GERD at 10 years in patients following laparoscopic ARS. Most patients with recurrent GERD are medically managed with acid suppression therapy, while a minority (less than 5%–10%) undergo reoperation. As mentioned previously, ARS is associated with higher complication rates compared with acid suppression therapy. In studies that focus on patient-reported outcomes, ARS generally outperforms medical therapy when patients are surveyed on GERD-related symptoms and quality of life. Patient-reported satisfaction following ARS consistently approaches 90% or higher.

SPECIAL CONSIDERATIONS

It is important to distinguish ARS from paraesophageal hernia repairs as the surgical evaluation and approach to GERD differs from that of paraesophageal hernias. This can be confusing because fundoplications are often performed in conjunction with paraesophageal hernia repairs, thus the anatomic result following completion of both procedures is essentially identical. However, in the absence of a paraesophageal hernia, adequate circumferential mobilization of the distal esophagus should almost always provide enough intraabdominal length to obviate the need for an esophageal lengthening procedure. When performing ARS in patients with a small- to moderate-sized sliding hiatal hernia, the lower esophageal sphincter should (by definition) reach the intraabdominal cavity. Thus, we reserve the discussion of Collis gastroplasty and esophageal lengthening procedures for chapters focused on paraesophageal hernia repair. In the same vein, although the use of absorbable mesh has

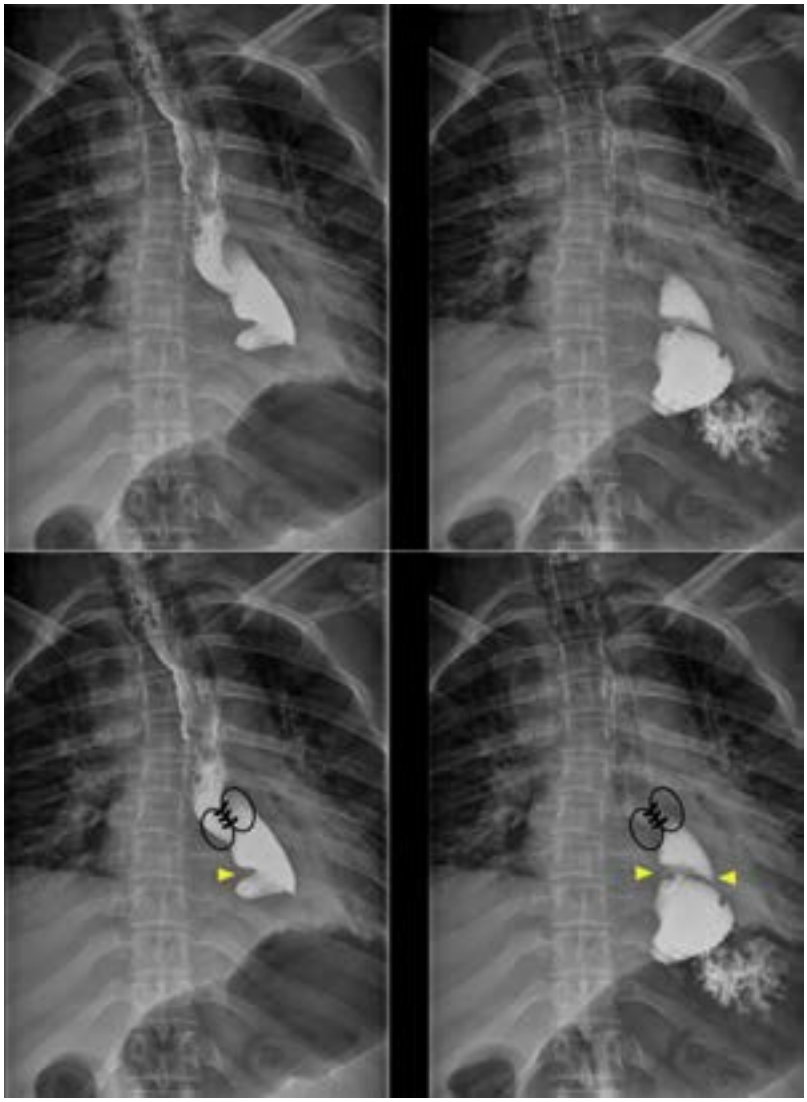

FIG. 6 Upper gastrointestinal barium esophagram depicting herniated fundoplication. Original radiographs *(top)*. Herniated position of fundoplication is outlined in *black (bottom)*. *Yellow arrowheads* depict diaphragmatic impression.

been studied and debated in the context of paraesophageal hernia repairs, there is no real indication for mesh use in laparoscopic ARS for GERD.

In patients who develop recurrent GERD symptoms following ARS, it is important to review the prior operative records and obtain a complete workup as described earlier in this chapter. Herniation of the wrap cephalad into the mediastinum is the most common cause of anatomic failure in patients with a previous fundoplication (Fig. 6). Failure can also result from an inappropriately constructed fundoplication that incorporates the body of the stomach (Fig. 7) or simply from loosening of the wrap over time. Anatomic failures can lead to recurrent GERD and new symptoms of dysphagia, odynophagia, or epigastric pain. Just as in the initial management of GERD, patients presenting with typical reflux symptoms following ARS can often be managed medically. In patients with persistent dysphagia, epigastric pain, or poorly controlled reflux symptoms despite medical therapy, surgical revision may be considered after careful evaluation to identify anatomic causes of failure while ruling out other possible etiologies. In general, caution should be exercised when considering a surgical revision as the complication rates associated with revisional surgery are higher than for first-time ARS.

When approaching a revisional operation, the surgeon should always plan to take down the prior fundoplication as this is the only way to evaluate the construction of the prior wrap and ensure the correct construction of a new fundoplication. After both halves of the fundoplication have been dissected free, the right half should be passed behind the esophagus to restore the normal orientation of the stomach and confirm that the wrap has been completely taken down before creating a new fundoplication. Importantly, we have encountered many barium esophagrams with radiology reports suggesting complete dehiscence of a previous fundoplication. In our institution's collective experience performing revisions, we have never encountered a complete dehiscence in the operating room. There is always a wrap that needs to be properly identified and taken down. Finally, when evaluating patients who have failed two prior antireflux procedures, we generally do not consider a third attempt to redo the wrap. If indications arise to consider another revision after multiple prior failures, a revision may be considered, but the surgeon and patient should be prepared for the possibility of a partial gastrectomy and Roux-en-Y reconstruction with either a gastrojejunostomy or potentially an esophagojejunostomy. This is, of course, is a major operation, and the associated risks and lifelong dietary modifications

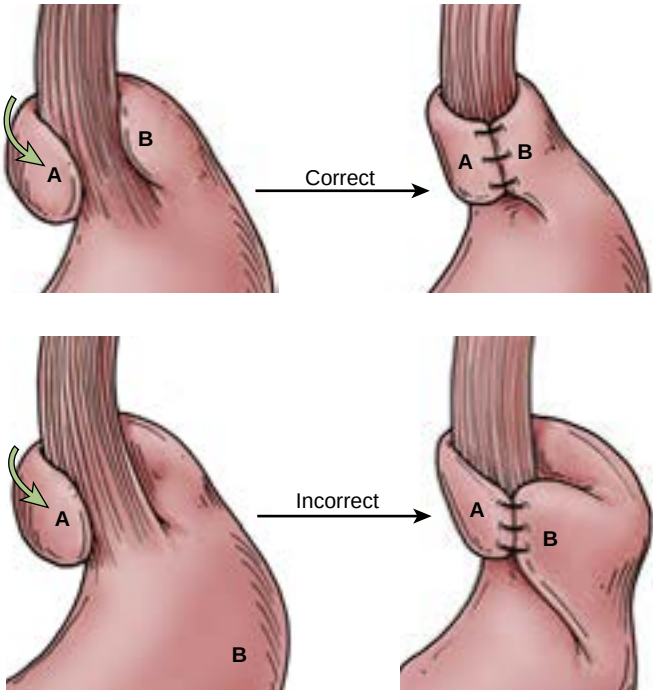

FIG. 7 A wrap can be incorrectly constructed by suturing the fundus to the body of the stomach. *(From Smith CD, McClusky DA, Rajad MA, Lederman AB, Hunter JG. When fundoplication fails: redo? Ann Surg. 2005;241[6]:861–869.)*

should be weighed against the severity of the patient's symptoms when counseling patients who have failed multiple attempts at ARS.

New Approaches to Gastroesophageal Reflux Disease (LINX)

Tom R. DeMeester, MD

Between the early 1960s and early 1970s, Drs. Rudolf Nissen, Ronald Belsey, and Lucius Hill introduced the golden era of antireflux surgery. These physicians designed procedures that took down a hiatal hernia, altered the anatomy of the gastroesophageal junction with a fundoplication of various degrees, and stopped reflux of gastric juice into the esophagus. In 1975, the first randomized controlled study confirmed the superiority of surgical over medical therapy with antacids. Surgery was off and running.

All came to a dramatic halt when the Nobel Prize was awarded to Sir James W. Black in 1988. He discovered an approach to drug development called *rational drug design structure*. Simply stated, if the pathophysiology of a disease is properly understood, a specific drug could be synthesized to interrupt key points in the pathogenesis and cure the disease. He used this concept to discover the beta and H_2 receptor antagonists, propranolol and cimetidine. Cimetidine became the first drug ever to exceed $1 billion per year in sales. The methodology eventually led to the development of proton pump inhibitors (PPIs), which block the secretion of acid by the parietal cells. The aim of these drugs is to increase the pH of the gastric juice, which, along with the lower esophageal sphincter, contribute to gastroesophageal reflux disease (GERD). By the 1980s, the clinical benefits of PPIs were demonstrated dramatically by the abolishment of GERD symptoms and the virtual elimination of acid-induced reflux esophagitis, strictures, and giant Barrett's ulcers. Now medicine was off and running.

WHY A NEW SURGICAL ANTIREFLUX PROCEDURE?

After 35 years of experience with more than 20 million GERD patients on prescribed PPIs, physicians have developed some concerns. Despite the introduction and use of the new powerful acid-suppression drugs over this period, the incidence of GERD continues to increase by 30% every 10 years, and 30% to 40% of patients on PPI therapy have only partial relief of their symptoms. Between 2% and 3.5% of the 20 million patients with GERD receiving PPI therapy develop Barrett's esophagus every year, of which 0.5% to 1% progress to esophageal adenocarcinoma. Despite this high percentage of patients with a partial response and disease progression on PPI therapy, less than 1% seek surgical therapy. These concerns have given rise to the thought that the time has come for a change in the treatment strategy of GERD. The current treatment strategy focuses only on one of the two determinants of the disease, the acid composition of the gastric juice, whereas the other determinant, failure of the lower esophageal sphincter (LES), is ignored. This focus on PPIs and disregard for the LES is likely the result of a historical misunderstanding that GERD is primarily an acid peptic disease. The primary abnormality in GERD is the loss of an effective LES to keep the gastric juice in the stomach. This was pointed out in 2003 in a publication by Dr. G. Wetscher and colleagues

from Innsbruck, Austria. They showed that the recurrence of reflux symptoms and/or endoscopic esophagitis in patients on PPIs was related to the functional status of the LES and esophageal body. Patients with both a defective LES and esophageal contractions had an 80% recurrence rate compared with 39% in those patients with a defective LES and normal esophageal body contractions, or 8% in those with both a normal LES and normal esophageal contractions. They concluded that the status of the LES is a critical factor in the effectiveness of PPI therapy. The medication works well in patients with a normal LES and not so well in patients who have a defective LES. In the latter situation, reflux episodes continue at the same frequency whether the patient is off or on the medication. The only difference is a change in the pH of the refluxed gastric juice. As a consequence, 85% of patients on PPIs still experience GERD-related symptoms, and in 35% the symptoms have reached the level to cause dissatisfaction with PPI therapy. In an effort to improve symptom control, the prescriptions for double-dose PPIs have increased by 50% in the past 7 years, and 42% of patients supplement their prescription with other acid-suppression medication in an effort to gain relief. Of greatest concern is that 10% to 15% of patients have disease progression while on PPI therapy, and the longer the disease persists, the greater the number of patients who progress.

Over the past 35 years, antireflux surgery has not fared much better. Even though the surgery can be performed through a laparoscope and achieve effective control of reflux symptoms and heal esophagitis, the outcomes vary in their effectiveness and durability, and the early surgical revision rate is too high. The procedures have significant side effects in that patients are unable to belch or vomit, risk having increased flatulence and postprandial bloating, and have a small possibility of bothersome dysphagia. When performed by the occasional surgeon, only 61% of patients are completely satisfied with their operation. These results discourage patients against antireflux surgery, and at present less than 1% of GERD patients have surgical therapy. Unless there are some fundamental improvements in surgical therapy, it appears that the use of surgery for the treatment of GERD will reach a standstill.

NEW SURGICAL APPROACH TO GERD

The ideal surgical procedure to improve the function of the LES in a patient with GERD would be a minimally invasive, short, outpatient procedure that augments the LES function without causing anatomic alterations. Based on the effectiveness of the Nissen fundoplication, it should have a greater than 80% probability of normalizing esophageal acid exposure and a 90% probability of eliminating GERD-related symptoms. It should allow an unrestricted diet and cause no long-term side effects such as persistent dysphagia, symptomatic bloating, increased flatus, or the inability to belch or vomit. Further, it must be reversible without sequelae.

Over the past 10 years, studies on the pathophysiology of the LES have opened the door for technology to design a new device that meets the ideal requirement for a new surgical procedure for the treatment of GERD. These studies have shown that gastric distension or dilation after meals can cause effacement of the LES, resulting in progressive shortening of its length and, as a consequence, loss of its competency (Fig. 1). This process exposes the effaced squamous mucosa of the distal esophagus and the underlying muscle of the LES to gastric juice. The inflammatory injury that occurs destroys the squamous mucosa, heals by the induction of metaplastic cardiac mucosa, and induces permanent damage to the muscle of the LES, resulting in a loss of its abdominal length, overall length, and pressure. The resulting structurally defective LES allows repetitive LES effacement to occur with ease, resulting in escalation of the degrees of esophageal exposure to acidic bile containing gastric juice. Placing a loose ligature or ring around the inferior border of the LES can stop the effacement and has formed the basis for the design of new devices to augment LES function.

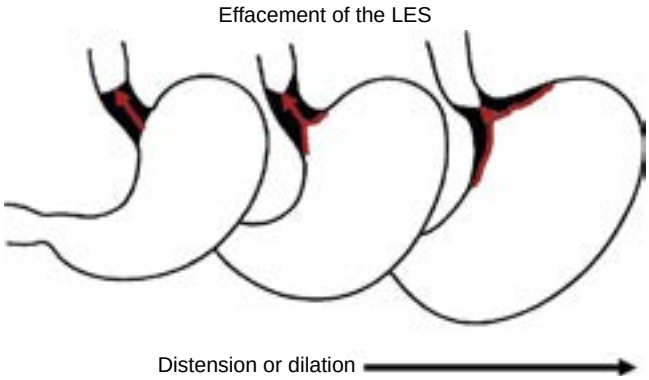

FIG. 1 Effacement and shortening of the length of the lower esophageal sphincter *(LES)* that occurs with gastric distension or dilation after meals and, as a consequence, loss of its competency. The process exposes the effaced squamous mucosa of the distal esophagus *(red line)* and the underlying muscle of the LES *(black area below the red line)* to gastric juice.

LINX ANTIREFLUX DEVICE

One of the new devices is the LINX Reflux Management System (Torax Medical, St. Paul, MN). It is a simple procedure, performed laparoscopically, that does not alter gastric or gastroesophageal junctional anatomy, augments the LES as a functional barrier to reflux, and can be reversed easily if necessary, thereby preserving the option for fundoplication or other therapies in the future. The LINX procedure is designed to limit technical variability, which will result in more standardization of antireflux surgery and more consistent clinical outcomes. The LINX device consists of a series of titanium beads with magnetic cores hermetically sealed inside (Fig. 2). The beads are interlinked with independent titanium wires to form a dynamic ring designed to conform to the changing physiologic movements of the esophagus during swallowing. The device was designed to use the magnetic attraction between adjacent beads to prevent the opening of the LES by distal to proximal effacement and shortening of its length caused by episodes of gastric distension or postprandial gastric dilation secondary to adaptive relaxation. The device is sized to fit around the external circumference of the esophagus at the distal end of the LES without compressing the esophageal musculature. The beads separate to allow the transport of a food bolus into the stomach, to relieve gastric distension by belching or nausea by vomiting (Fig. 3).

The LINX device was not designed to deter reflux episodes caused by pressure challenges that affect the whole abdominal environment. To deter these challenges requires sufficient esophageal length in the abdominal domain to allow the LES to be compressed by changes in the abdominal environmental pressure that occur with daily living and working. For this reason, it is recommended that, if possible, the LINX device be implanted with minimal disruption of the phrenoesophageal ligament to preserve sufficient length of esophagus in the abdominal domain.

LINX IMPLANTATION PROCEDURE

The LINX magnetic sphincter augmentation device is implanted laparoscopically under general anesthesia. Surgical ports are placed similar to the pattern used for the laparoscopic Nissen fundoplication with one exception. The dissection port in the patient's right upper quadrant is placed far laterally to optimize the visualization and sizing of the esophagus at the gastroesophageal junction. A limited focus dissection is ideal for implantation of the LINX device in a patient without a hiatal hernia. When performing a limited focus

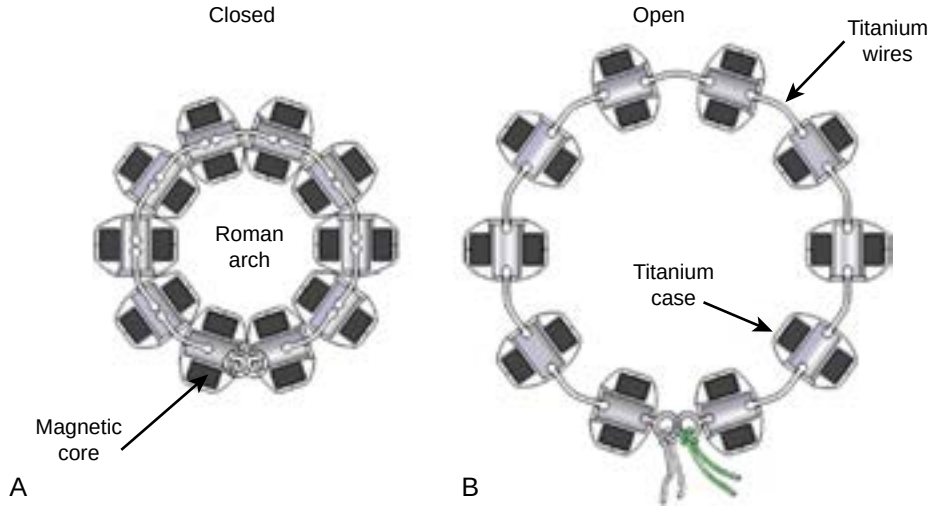

FIG. 2 Engineering schematic of the magnetic sphincter augmentation device. The device consists of an expansible bracelet of magnetic beads designed to be placed surgically around the exterior surface of the distal end of the lower esophageal sphincter *(LES)*. Each bead is composed of a titanium case containing a magnetic core of small disk-shaped magnets. The beads are connected by titanium wires of specific lengths that limit the distance any two individual beads can move apart. When the device is closed **(A)**, the magnetic force is sufficient to prevent effacement and opening of the LES yet is weak enough to allow the device to open **(B)** with esophageal peristalsis. When the device is closed, the Roman arch construction prevents compression of the esophageal tissues.

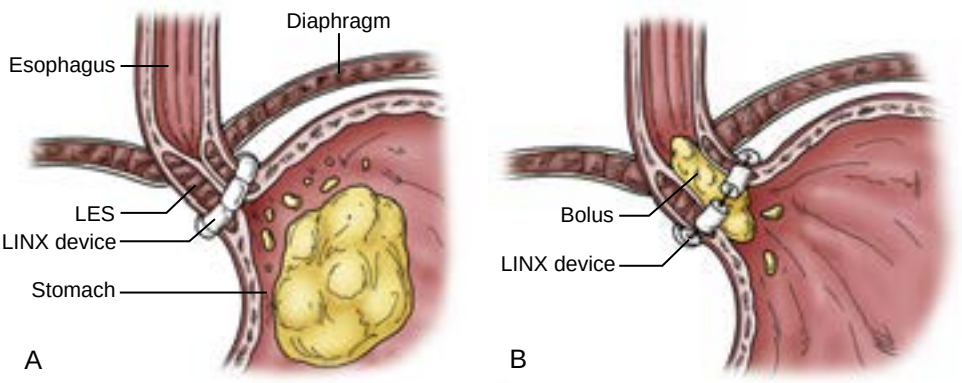

FIG. 3 The LINX magnetic sphincter augmentation device is implanted around the inferior border of the lower esophageal sphincter *(LES)*, as shown. **(A)** The magnetic device is shown in the closed position, which prevents effacement and opening of the LES and subsequent reflux. Each magnetic bead rests on the adjacent beads to prevent compression of the esophageal tissues. **(B)** The device is shown in the open position, which allows transport of food by esophageal peristalsis, belching of an overdistended stomach, and vomiting when necessary.

dissection, the surgeon must preserve and not dissect the phrenoesophageal ligament.

The surgical dissection begins by mobilizing the posterior gastric fundic wall off the lateral surface of the left crus to expose the caudal anterior edge of the left crus. In doing so, as few short gastric vessels as possible are divided. A 1-cm segment along the anterior margin of the left crus just above the crural decussation is identified. At this location, a medial dissection is performed just beneath the esophagus to form a pocket target for the right-sided tunnel dissection. In performing this dissection, care is taken not to enter the mediastinum. After the pocket target is made, the dissection is switched to the right side of the esophagus. The gastrohepatic ligament is opened by making two windows, a small one just superior to the hepatic branch of the anterior vagal nerve and a larger one inferior to the hepatic branch. The inferior window allows access to construct a retroesophageal tunnel through a 1- to 2-cm incision in the peritoneum along the anterior edge of the right crus just above the crural decussation. Using a dissector placed through the far lateral right upper quadrant port and the inferior window in the gastrohepatic ligament, a gentle dissection is made toward the left crus just to identify the posterior vagal nerve as it leaves the esophagus and drops posterior to the celiac plexus (Fig. 4A). Bleeding from the small vessels can obscure the dissection and is controlled with judicial use of cautery. Delicately, a tunnel is dissected in a right-to-left direction, between the posterior vagal nerve and the posterior esophageal wall, to connect with the previously constructed pocket target on the anterior margin of the left crus. Entering the mediastinum during the tunnel dissection should be avoided. The dissector is passed through the pocket target and into the left upper quadrant. The dissector is removed from the left upper quadrant, drawing a ¼-inch Penrose drain through the tunnel and securing its right and left ends for retraction. In line with the expected position of the device, the fibroareolar tissue from the right and left lateral esophageal surfaces is removed, and a trench is constructed through existing fat on the anterior surface of the esophagus below the inferior leaf of the phrenoesophageal ligament. The circumference of the esophagus then is measured to choose the proper size of the LINX device to be implanted. The sizing tool is a laparoscopic instrument with a soft, circular curved tip that is actuated by coaxial tubes through a handset. The handset contains a numerical indicator that corresponds to the size range of the LINX

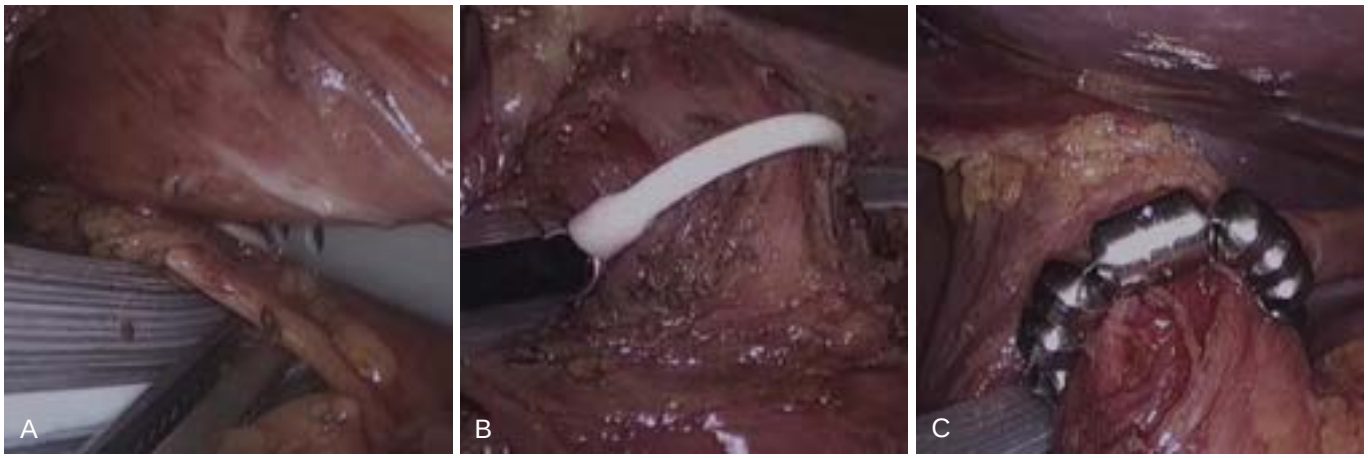

FIG. 4 Intraoperative images. **(A)** Dissection of the tunnel between the posterior vagal nerve and the posterior esophageal wall at the inferior border of the lower esophageal sphincter *(LES)*. **(B)** The position of the sizing tool to measure the circumference of the esophagus at the lower border of the LES. **(C)** Completed implantation of the LINX device around the lower border of the LES with the clasps connected.

device. The sizing tool is inserted through the far-lateral placed right upper quadrant port and then passed through the dissected tunnel between the posterior vagal nerve and esophageal wall and around the esophagus (see Fig. 4B). Anterior retraction on the previously placed Penrose drain simplifies this maneuver. When making the measurement, the surgeon must not intubate the esophagus or compress its muscular wall by the measuring device. Two measurements should be taken. If the measurement is between two sizes, the larger size is selected. The most common size is 14, and smaller sizes should be used sparingly and with caution. The appropriate size of device is selected and pulled through the tunnel in a left to right direction. Again, anterior retraction of the Penrose drain simplifies this maneuver. The ends of the device are brought anteriorly around the esophagus, the left end around the Angle of His and the right end over the gastrohepatic branch of the anterior vagal nerve. The clasps are connected, and the anterior portion of the device is placed in the trench if present (see Fig. 4C). If the right and left crura appear to diverge from one another above the crural decussation, one or two figure-of-8 sutures can be placed to approximate them, provided no further dissection is required. A small hiatal hernia less than 3 cm in size can be effectively repaired by this maneuver. The surgical time is usually less than 1 hour. The patient is discharged the same day or, if an afternoon procedure, the next morning. The patient is instructed to slowly return to a normal diet over the next week and discontinue the use of acid-suppression medication.

For patients with a hiatal hernia greater than 3 cm, a more extended and less focused dissection can be done to allow dissection and reduction of the hernia into the abdomen, approximation of the crura around a 2- to 3-cm length of abdominal esophagus, and implantation of the LINX device. An extended dissection also provides a fallback solution when greater exposure is necessary to implant the LINX device for reasons other than a hiatal hernia. Normalization of esophageal acid exposure is similar in patients after a limited focus or extended dissection (Fig. 5). Again, when doing an extended dissection, it is important to approximate the crura around the esophagus in a manner that maintains 2 to 3 cm of esophagus in the abdominal environment. When this is not done, the ability to deter the reflux of gastric juice into the esophagus caused by episodes of increased abdominal environmental pressure is compromised.

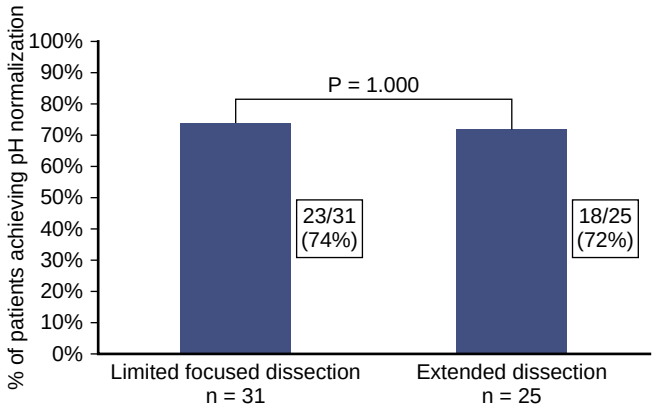

FIG. 5 The degree of dissection necessary to implant the LINX antireflux device and normalization of esophageal acid exposure. With either dissection (limited focus or extended), the esophageal acid exposure was normalized in more than 70% of patients. The durability of competency with a limited focus dissection is beyond 5 years. The durability of competency with an extended dissection is unknown.

LONG-TERM CLINICAL OUTCOMES OF THE LINX MAGNETIC SPHINCTER AUGMENTATION DEVICE

Long-term outcomes of patients who had the LINX magnetic sphincter augmentation device implanted for GERD have been reported recently. The final 5-year results of the US Food and Drug Administration's approved trial provides a careful analysis of the safety and effectiveness of the LINX device. The studied population consisted of 100 adults who had GERD for at least 6 months or longer, were partially responsive to daily PPIs, and had abnormal esophageal acid exposure on 24-hour pH testing. The LINX device was placed using standard laparoscopic techniques. In this study, 85 subjects were followed for 5 years and evaluated for quality of life (GERD-HRQL score), reflux control (postoperative 24-hour pH testing at 1 year), use of PPIs, and side effects. A quality of life questionnaire was administered at baseline to patients on and off PPIs and after placement of the LINX device yearly for 5 years. Over the follow-up period, no device erosions, migrations, or malfunctions occurred. At baseline, the median GERD-HRQL scores were 27 when patients were not taking PPIs, 11 when taking PPIs, and decreased to 4 at 5 years after LINX placement (Fig. 6). All patients were taking daily PPIs at baseline, and this decreased to 15.3% at 5 years (Figs. 7 and 8). Moderate to severe heartburn occurred in 89% of patients at baseline but only 11.9% at 5 years (see Fig. 7). Moderate to severe regurgitation occurred in 57% of patients at baseline, but only 1.2% at 5 years

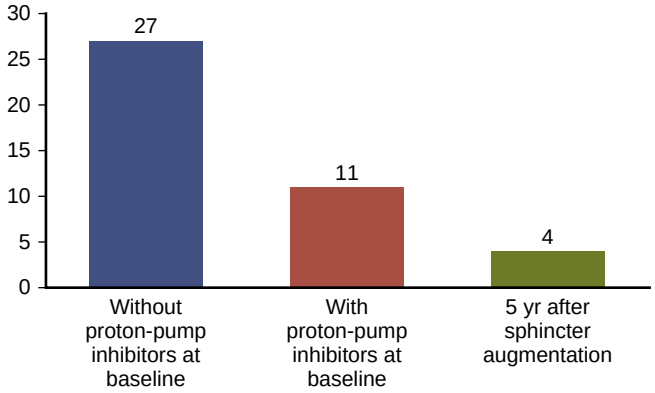

FIG. 6 Median total GERD-HRQL scores measured at baseline without and with proton pump inhibitors, as compared with 5 years after implantation of the LINX sphincter augmentation device. Higher scores indicate worse symptoms. $P < 0.001$ for all comparisons with baseline.

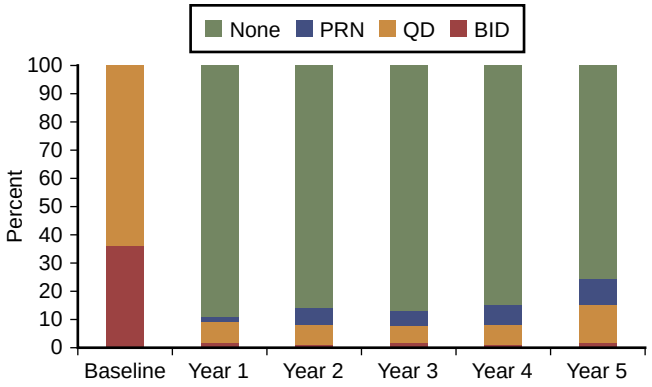

FIG. 8 The use of PPIs at baseline and yearly throughout the 5 years. PPI use was categorized as none, as needed *(PRN)*, once a day *(QD)*, and twice a day *(BID)* at each yearly visit based on the prior 30 days. Patients who required BID PPIs decreased from 36% at baseline to 2.4% at 5 years.

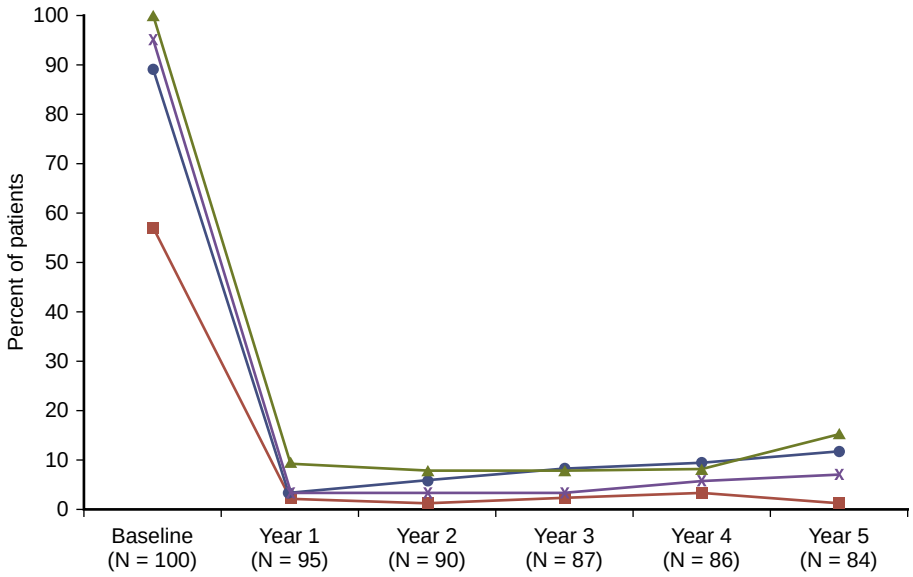

FIG. 7 Reflux control of moderate-severe heartburn, moderate-severe regurgitation, PPI dependency, and dissatisfaction with therapy. P < 0.001 between baseline and yearly follow-up evaluation out to 5 years for all comparisons. Of the six patients who were dissatisfied at 5 years, five reported daily use of PPIs.

(see Fig. 7). All patients reported the ability to belch and vomit if needed. Bothersome dysphagia was present in 5% at baseline and in 6% at 5 years (Fig. 9). Bothersome gas bloat was present in 52% at baseline and decreased to 8.3% at 5 years (see Fig. 9). No significant complications occurred. No new safety risks emerged over the 5 years of follow-up. On the basis of this and other reported studies, LINX is an effective fundic-sparing, antireflux procedure with minimal side effects. It is applicable to patients who have a partial response to PPIs, a desire to be off PPIs, or endoscopic/histologic signs of progression while on PPI therapy. A hiatal hernia is likely not a contraindication to the use of the LINX device, but long-term results regarding the recurrence rate of the hiatal hernia are needed.

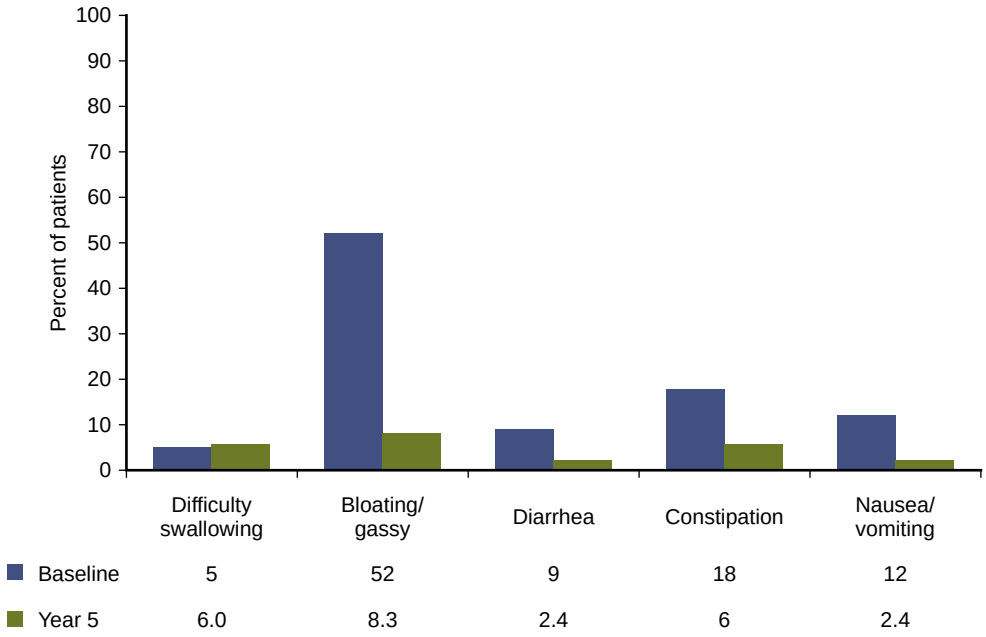

FIG. 9 Potential side effects of LINX magnetic sphincter augmentation at 5 years when compared with the same symptoms at baseline. $P = 0.739$ for difficulty swallowing, $P < 0.001$ for bloating/gassy feeling, $P = 0.103$ for diarrhea, $P = 0.008$ for constipation, and $P = 0.003$ for nausea and vomiting.

Management of Barrett's Esophagus

Stephen R. Broderick, MD, MPHS

DEFINITION OF BARRETT'S ESOPHAGUS AND TREATMENT OBJECTIVES

Barrett's esophagus (BE) is defined as metaplastic change of the epithelial lining of the distal esophagus from normal stratified squamous epithelium to intestinal columnar epithelium containing goblet cells. The diagnosis of BE must be made endoscopically with a visible change in the lining of the distal esophagus and biopsy demonstrating columnar epithelium with goblet cells (Fig. 1). BE results from chronic injury to the esophageal mucosa secondary to long-standing gastroesophageal reflux disease (GERD). Population-based estimates of the prevalence of BE range from 0.4% to 2%, with higher rates (5%–15%) among patients with GERD. BE is the major risk factor

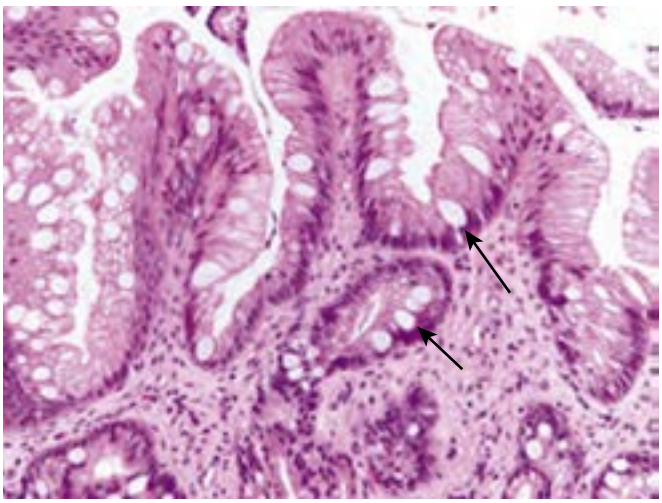

FIG. 1 Intestinal metaplasia with goblet cells *(arrows)*.

for esophageal adenocarcinoma (EAC). Therefore, the objectives of treatment are to treat the underlying reflux disease, prevent progression of BE, and treat BE with dysplasia before progression to EAC.

CLINICAL EFFECT AND FEATURES OF BARRETT'S ESOPHAGUS

The primary clinical implication of BE is the risk of progression to EAC. Rates of EAC in Western populations have been increasing over recent decades, and overall survival remains poor despite improvements in early diagnosis and treatment. Estimates of risk of EAC in patients with BE range from 30 to 125 times that of the general population. Progression from BE to EAC generally takes place in a stepwise manner over time from normal squamous epithelium to non-dysplastic BE, low-grade dysplasia (LGD), high-grade dysplasia (HGD), and finally EAC. LGD and HGD are determined by the degree of distortion in the architecture of dysplastic cells. This distinction can be subtle with a high degree of interobserver variability.

In addition to GERD, a number of other risk factors have been associated with the development of BE and subsequent EAC. These include family history, age older than 50 years, male sex, central obesity, white race, presence of hiatal hernia, and tobacco use.

SCREENING AND EVALUATION OF BARRETT'S ESOPHAGUS

Screening

Given the low background prevalence of BE, routine endoscopic screening is not recommended. Various society guidelines exist supporting screening in patients with risk factors. The American College of Gastroenterology (ACG) Clinical Guidelines support screening for males with chronic GERD, defined as symptoms for 5 or more years with at least weekly symptoms and two or more additional risk factors (age >50, white race, central obesity, current or past smoking, family history in a first-degree relative). Screening is not recommended in women but may be considered on an individual basis if risk factors are present.

Evaluation

The initial evaluation for BE consists of white light endoscopy. BE should be suspected when salmon pink mucosa is identified proximal to the gastroesophageal junction (GEJ). The endoscopist should inspect for areas of columnar metaplasia as well as irregularities in the mucosal surface. These may signify areas of dysplasia or invasive adenocarcinoma. The Prague classification is the most commonly used standardized reporting mechanism which identifies the proximal extent of circumferential BE as well as the maximal extent of any tongues of BE. The presence and size of any hiatal hernia should also be noted.

Biopsies should be taken of the distal esophagus in four quadrants from the GEJ at 1- to 2-cm intervals through the proximal extent of suspected BE (the Seattle protocol). Biopsies of the gastric mucosa for comparison purposes and of any areas with mucosal irregularity should also be taken. Narrow band imaging (or another form of chromoendoscopy) should be employed to enhance visualization of mucosal surface vascular patterns and irregularities (Fig. 2). The finding of BE with dysplasia requires confirmation by a second pathologist with gastrointestinal (GI) expertise.

SURVEILLANCE

Current practice guidelines from both medical and surgical societies universally recommend endoscopic surveillance once BE is identified. The goal of surveillance is to identify progression to dysplasia or EAC at an early, treatable stage. There is some degree of variation in the details of surveillance protocols. Areas of consensus and debate include the following:

1. White light endoscopy is the preferred method of surveillance with or without the addition of narrow band imaging.
2. There is near consensus that the Seattle protocol consisting of four-quadrant biopsies is the optimal biopsy strategy, with some debate over a 1-cm versus 2-cm interval between biopsies. All nodular lesions should be biopsied and sent separately for pathologic evaluation. Some guidelines recommend against biopsies in areas of active esophagitis, favoring repeat endoscopy after a period of suppressive therapy.
3. There is unanimity that dysplasia should be confirmed by a second pathologist with expertise in GI pathology.
4. Guidelines are consistent regarding a surveillance interval of 3 to 5 years for nondysplastic BE. There is variation in the impact of the length of the BE segment on the recommended surveillance interval, with some guidelines suggesting shorter intervals for patients with longer-segment BE.

FIG. 2 Barrett's esophagus seen on endoscopy under both white light endoscopy **(A)** and narrow band imaging **(B)**.

5. There is no consensus regarding when to stop surveillance. Cessation is recommended when patients are no longer candidates for endoscopic or surgical therapy or cannot tolerate repeat endoscopic procedures.

MANAGEMENT OF BARRETT'S ESOPHAGUS WITHOUT DYSPLASIA

The overriding principle in managing a patient with non-dysplastic BE is treatment of underlying GERD. This will accomplish not only symptom control but also protect the esophageal mucosa from repetitive reflux injury. Medical therapy with once-daily dosing of proton pump inhibitors (PPIs) is the recommended first-line therapy in addition to diet and lifestyle modifications. Escalation to twice-daily dosing is recommended only when symptom control on daily dosing is inadequate.

Antireflux surgery is an adjunct to medical therapy for GERD. Data supporting the role of surgery in preventing progression to EAC are weak. Therefore, surgery is recommended for failure of medical therapy to control symptoms or impaired quality of life. The role or benefit of mucosal ablation with radiofrequency or other modalities is unproven in patients with non-dysplastic BE. There may be a role for ablation in patients with ultralong segment (>8 cm) BE to reduce the complexity of biopsy procedures.

Regardless of the approach to treat GERD (medical therapy or surgery), surveillance endoscopy is necessary to evaluate for progression to dysplasia.

MANAGEMENT OF BARRETT'S ESOPHAGUS WITH LOW-GRADE DYSPLASIA

LGD is associated with an increased risk of progression to adenocarcinoma compared with nondysplastic BE. The presence of LGD on any biopsy necessitates thorough evaluation with four-quadrant biopsies every 1 to 2 cm over the entire area of BE if not already performed. The presence of dysplasia should be confirmed by an expert GI pathologist, as the distinction of LGD from inflammatory atypia can be subtle. Patients with LGD should then be initiated on PPI therapy with repeat endoscopic evaluation in 6 months. LGD will often regress to nondysplastic BE with PPI therapy. Antireflux surgery should be considered at the identification of LGD or if LGD persists despite initiation of PPIs. Nissen fundoplication has demonstrated superior rates of regression of LGD compared with PPI therapy alone.

Persistent dysplasia despite control of GERD with PPI and/or antireflux surgery is an indication for mucosal ablation. Radiofrequency ablation has been shown to reduce the risk of progression to adenocarcinoma compared with surveillance alone.

MANAGEMENT OF BARRETT'S ESOPHAGUS WITH HIGH-GRADE DYSPLASIA

Given the proven high risk for progression to EAD, the presence of BE with HGD is an indication for intervention in most patients. If initial endoscopic evaluation identifies HGD, a careful repeat endoscopy is performed to thoroughly map areas of HGD and identify any areas of nodularity or ulceration in the metaplastic columnar mucosa. Both white light and narrow band imaging (or another form of chromoendoscopy) should be employed to aid in identification of mucosal lesions.

Endoscopic mucosal resection (EMR) should be used to remove any small, discrete nodules. In EMR, a cap is attached to the tip of the endoscope, the target lesion is suctioned into the cap, and a band is applied to the base, creating a "pseudopolyp." This is then snared and sent for pathologic evaluation. In lesions 1 cm or larger, endoscopic ultrasound (EUS) is employed to assess for invasion into the esophageal wall and presence of periesophageal lymphadenopathy. EUS is not useful for very small lesions or HGD in which no mucosal abnormality is identified. In the event that an EMR specimen demonstrates adenocarcinoma, the depth of invasion (Tis vs. T1a vs. T1b) is critical in determining the next steps in evaluation and treatment. Thus, a good EMR specimen will contain mucosa and submucosa, leaving muscularis at the base of the resection site. The ER specimen can also be evaluated for other high-risk features including degree of differentiation or lymphovascular invasion, which may prompt more aggressive management. Invasion into the submucosa (T1b), a poorly differentiated lesion, and lymphovascular invasion increase the likelihood of occult lymph node metastases. Thus, these features should prompt further staging investigations and consideration of esophagectomy in appropriate surgical candidates.

Patients found to have HGD alone or adenocarcinoma confined to the mucosa (T1a) without high-risk features are candidates for endoscopic interventions to ablate the lesion(s) and preserve the esophagus. The goal of endoscopic therapy should be resection of all raised or suspicious mucosal lesions. This can be accomplished with in one or multiple sessions over a 6- to 8-week period until all documented areas of dysplasia are removed. Oftentimes ablation of the residual metaplastic mucosa is then performed to reduce the risk of progression to further areas of dysplasia.

After complete eradication of both dysplasia and intestinal metaplasia, ongoing surveillance is essential. Surveillance endoscopy after ablation of HGD should be performed every 3 months for the first year, every 6 months for the second year, and annually thereafter if no recurrent areas of dysplasia are identified. It is also critical that patients with documented HGD achieve long-term control of underlying GERD with medical therapy or antireflux surgery.

Esophagectomy in High-Grade Dysplasia

Although endoscopic therapies are now the standard of care, there remains a role for esophagectomy in select patients in whom BE with HDG is identified. Esophagectomy provides the most thorough eradication of the diseased esophagus but carries the significant potential morbidity and mortality of surgery. Operative mortality associated with esophagectomy for HGD is less than 1% at experienced centers. Esophagectomy is considered in patients with the following characteristics:

- High-risk features: length > 2 to 3 cm, lymphovascular invasion, multifocality, poorly differentiated lesion
- Patient with preference for surgery or inability to attend repeat surveillance or procedural endoscopies
- Inability to eradicate areas of HGD with endoscopic therapies
- Evidence of progression despite endoscopic ablation
- Technically insufficient endoscopic ablation
- End-stage esophageal function (secondary to motility disorder, stricture, hernia)

CONSIDERATIONS REGARDING ANTIREFLUX SURGERY IN BARRETT'S ESOPHAGUS

GERD that leads to BE is associated with a higher degree of reflux, incompetent lower esophageal sphincter (LES), esophageal dysmotility, and hiatal hernia. These factors lead to lower likelihood of control of GERD with medical therapy alone. Antireflux surgery has several theoretical benefits in the management of GERD, including the control of both acid and biliopancreatic substrates that are contributing to mucosal injury and restoration of the hiatus and incompetent LES. More complete control of reflux into the distal esophagus has been

associated with more frequent regression of BE and reduced rates of progression to EAC.

Antireflux surgery in the setting of esophageal dysmotility or hiatal hernia can be more challenging than routine fundoplication. Fundoplication is more likely to fail in patients with BE, and failure is associated with progression of BE. Thus, patients who undergo antireflux procedures still require frequent surveillance endoscopy.

In addition to endoscopy, evaluation of the patient with BE for consideration of antireflux surgery consists of contrast esophagram and high-resolution manometry. Preoperative and postoperative pH testing can assist in determining which patients can discontinue PPI therapy following fundoplication. Consideration to the type of fundoplication (complete vs. partial) should be given based on the patient's esophageal motility.

CONCLUSION

Management of the patient with BE is closely associated with management of the patient's underlying GERD. There are two intertwined objectives of therapy: (1) identification, treatment, and surveillance of intestinal metaplasia and (2) treatment of the underlying GERD. Combined, these strategies serve to reduce the risk of progression from nondysplastic BE to dysplasia or adenocarcinoma. In addition, treatment of GERD reduces symptomatology and improves dietary quality of life. Antireflux surgery can be beneficial to eradicate GERD symptoms, induce regression of dysplasia, and reduce the chance of progression. Patients should be carefully selected for surgery as those with BE are commonly associated with hiatal hernia and esophageal dysmotility, putting them at higher risk for failure of fundoplication. Endoscopic therapies are now the standard of care for patients with dysplasia and

allow for preservation of the esophagus. However, there remains a role for esophagectomy in select patients with BE (Figs. 3 and 4).

Endoscopic Treatment of Barrett's Esophagus

Anne P. Ehlers, MD, MPH, and Brant K. Oelschlager, MD

Barrett's esophagus (BE) is a disease characterized by the gradual replacement of the normal stratified squamous epithelium of the esophagus with columnar, intestinal metaplasia (Figs. 1 and 2). This transformation is due to chronic exposure to gastric contents, often within the context of gastroesophageal reflux disease (GERD). Patients at risk for BE are screened with endoscopy and biopsy. The major concern with BE is that it is a precursor lesion for esophageal adenocarcinoma (EAC), a disease with poor prognosis and poor long-term survival. In addition, EAC is a disease that continues to increase in incidence. Given this, identifying and eradicating BE before progression to adenocarcinoma is a top priority. In the past, patients with BE often were recommended for esophagectomy. More recently, evolving endoscopic techniques have replaced esophagectomy for many of these patients, allowing for eradication of BE with less morbidity and fewer complications.

SURVEILLANCE AND MANAGEMENT ALGORITHM

Screening

The primary risk factor for BE is longstanding GERD, along with male sex, age older than 50 years, and central obesity. Patients with GERD have a 10% to 15% risk of BE; increasing age and long-segment BE (>3 cm) are risk factors for progression to dysplasia. Overall, the rate of progression from BE to esophageal adenocarcinoma is low, perhaps as low as 0.12% per year. Other evidence suggests that for patients with nondysplastic BE, the annual risk of progression to EAC is 0.33% per year among all patients with BE and 0.19% per year among patients with short-segment BE (<3 cm). For patients with low-grade dysplasia (LGD), this risk increases to 0.5% per year. The risk increases substantially among those with high-grade dysplasia (HGD), up to 19% in some studies. Early detection of invasive cancer is important because patients detected at an early stage have a much higher 5-year survival rate (83%–90%) compared with patients who present symptomatically with more advanced disease (10%–30%).

Identifying the most appropriate pool of patients for screening is an area of active debate, especially with the large number of adults who have GERD. Because only a minority of patients with GERD will ever develop BE, screening every patient with GERD is neither feasible nor efficient. However, evidence suggests that surveillance of BE is associated with diagnosis of EAC at an earlier stage, which may be associated with improved outcomes. For these reasons, accurately identifying the population of patients with BE is critical. Current guidelines from the American College of Gastroenterology (ACG) recommend screening male patients with 5 or more years of GERD symptoms AND two or more risk factors for BE or EAC (age >50 years, white race, central obesity, history of smoking, family history of BE or EAC). Screening for female patients is generally not recommended, except for patients with multiple risk factors, as outlined previously.

Screening is generally undertaken using high-resolution endoscopy with liberal use of narrow band imaging and biopsy, but as previously stated this can be very labor and time intensive. Several novel screening modalities have been proposed to reduce this burden. One alternative is transnasal esophagoscopy, which is an office-based procedure that uses topical anesthetic to pass an endoscope through the nares and into the esophagus. Compared with traditional high-resolution endoscopy, the image quality is reduced and the biopsies are smaller but often are sufficient for histologic analysis to allow a diagnosis of BE to be made without a formal endoscopy. A second option for screening is the Cytosponge, which is a gelatin-coated capsule attached to a string that is then swallowed by the patient. Once in the stomach, the gelatin coating dissolves leaving behind a sponge that is then retrieved by pulling on the string. As the sponge comes back through the esophagus, it picks up cells that can then be examined for abnormalities. It currently holds promise as a screening tool for BE but is not adequate to screen for EAC. Because transnasal esophagoscopy and Cytosponge are still relatively new, high-resolution endoscopy is still the gold standard for diagnosis of BE.

Surveillance

Patients with confirmed BE in the absence of dysplasia or EAC should be regularly surveilled to detect disease progression. A challenge in the past has been lack of universal criteria for describing the extent of disease. To address this challenge, the Prague Criteria are a set of endoscopic data developed and validated by a working group specifically focused on esophagitis using standardized videos of endoscopies. The purpose was to improve on the previously used vague descriptions of "long" versus "short" segment disease and to facilitate communication between providers. The Prague Criteria measures the extent of disease based on circumference and maximum extent (C&M) criteria, with C being the maximum circumferential extent of disease and M the maximum length, including any isolated tongues of disease.

Once a patient has been diagnosed with BE, the next step is to evaluate for any dysplasia or invasive cancer. The current recommendation is to evaluate the patient with high-resolution or high-definition white light endoscopy followed by meticulous inspection of the esophageal lumen, after both insufflation and desufflation, including inspection of the gastroesophageal junction in the retroflexed view. Some data suggest that longer inspection time is associated with better detection of dysplasia or EAC. Suspicious lesions such as erosions, ulcerations, nodules, plaques, and other mucosal or luminal abnormalities should be selectively sampled. Random biopsies are not recommended. Suspicious lesions in patients with known dysplasia are best removed via endoscopic mucosal resection (EMR), which will be described later in the chapter. Additionally, the ACG recommends against taking biopsies in areas of active, erosive esophagitis and instead suggests waiting until the patient has been treated with antisecretory agents to allow the inflammation to subside.

Ongoing surveillance is dependent on the pathology determined at the time of biopsy. For patients who have BE without evidence of dysplasia, the recommendation is that they undergo repeat endoscopic surveillance every 3 to 5 years, as described previously. In cases in which biopsies are inconclusive for dysplasia, patients should be placed on an acid suppression regimen for 3 to 6 months, after which repeat endoscopy should be performed. If the biopsies are still inconclusive at that time, repeat endoscopy should be performed 12 months later. If dysplasia is diagnosed (LGD or HGD), the biopsies should be reviewed by two separate pathologists, one of whom is an expert in gastrointestinal pathology because there is a high level of interobserver variability when it comes to dysplasia.

Once dysplasia is confirmed, the next steps depend on the degree of dysplasia. For LGD, endoscopic therapy is preferred for patients without significant comorbidity; however, repeat endoscopy in 12 months is acceptable in these cases. For HGD, endoscopic therapy is recommended except in the case of life-limiting comorbid conditions. Patients with a diagnosed cancer should undergo further staging workup to determine whether the cancer is resectable, and some early adenocarcinomas can be managed endoscopically. For certain young patients with long-segment multifocal HGD, recurrent HGD, or

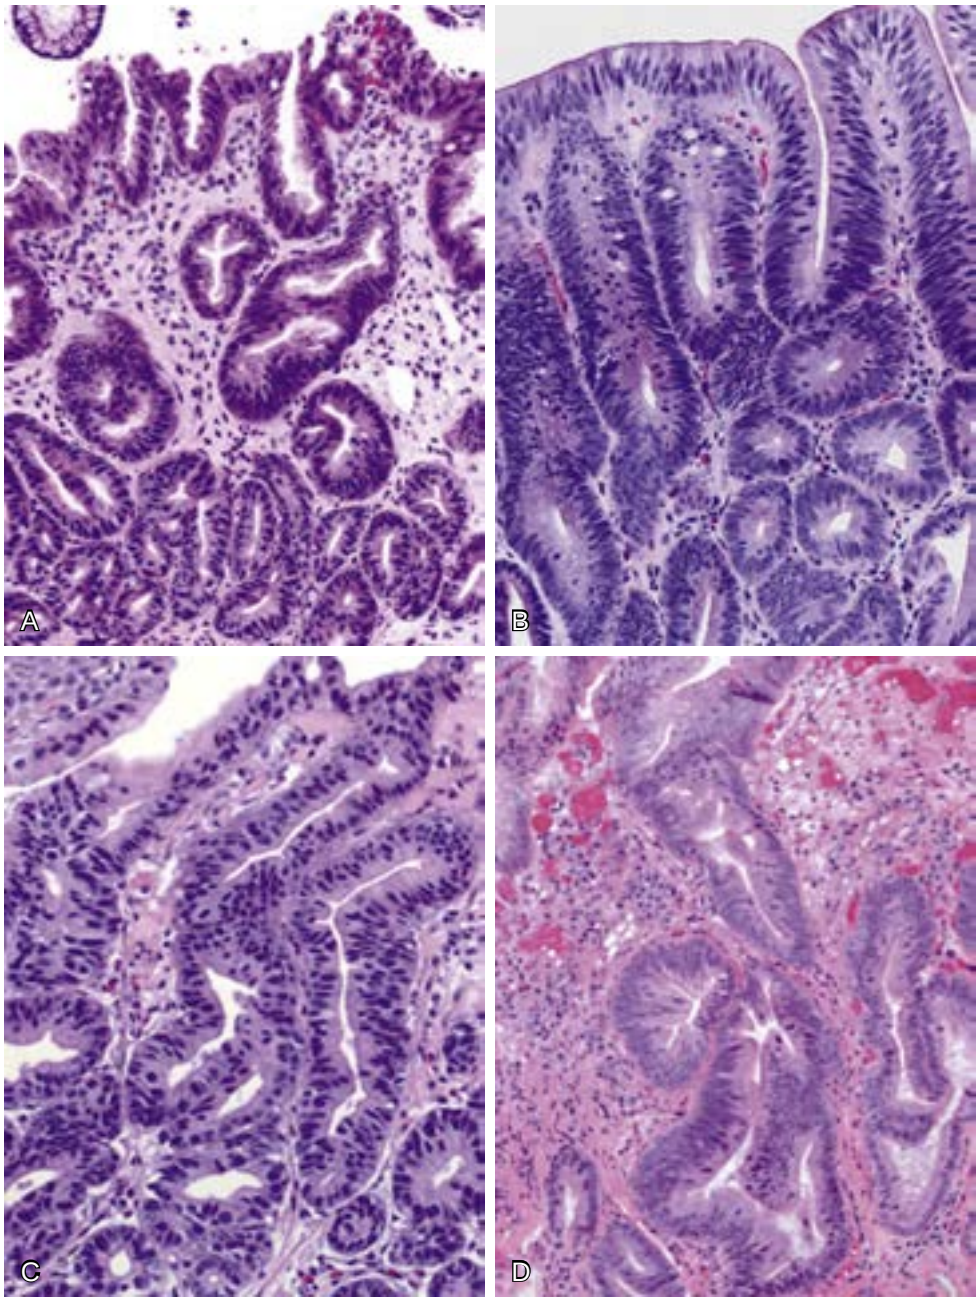

FIG. 1 Spectrum of dysplasia grading. **(A)** Negative for dysplasia. Although some nuclear hyperchromasia is noted, it is limited to the normal proliferative zone with evidence of surface maturation. **(B)** Low-grade dysplasia shows basally oriented, hyperchromatic nuclei with pseudostratification. Crypt architecture is preserved. **(C)** High-grade dysplasia demonstrates prominent mitotic activity, enlarged nuclei, and loss of nuclear polarity with evidence of glandular crowding. **(D)** This lesion shows cytoarchitectural atypia, equivalent to that of low-grade dysplasia, in the deep glands. However, given the presence of surface maturation and the stromal changes suggestive of a reparative process, it is best classified as indefinite for dysplasia. *(From Hagen CE, Lauwers GY, Mino-Kenudson M. Barrett esophagus: diagnostic challenges. Semin Diagn Pathol. 2014;32:100–113.)*

intramucosal cancer, surgery should be considered. A summary of the surveillance and treatment algorithm is provided in Figures 3 and 4.

PRINCIPLES OF ENDOSCOPIC THERAPIES

The current evidence suggests that endoscopic therapy should be used for patients with BE who have LGD, HGD, and for some patients with early intramucosal (T1a) EAC because the risk of lymph node metastasis is nonexistent for LGD and HGD and is low for intramucosal EAC. Endoscopic techniques work by either removing it before development of invasive disease or destroying abnormal tissue (ablative techniques). The intestinal metaplasia is then replaced with normal appearing squamous epithelium (Fig. 5).

ENDOSCOPIC RESECTION TECHNIQUES

Endoscopic Mucosal Resection

EMR is a technique that allows removal of lesions within segments of BE for complete histologic analysis, including dysplasia and superficial T1a adenocarcinoma. It offers an advantage over ablative techniques because it allows for examination of tissue specimens, rather than just destroying them. The ACG recommends EMR as the initial treatment modality for patients with nodular BE. For patients

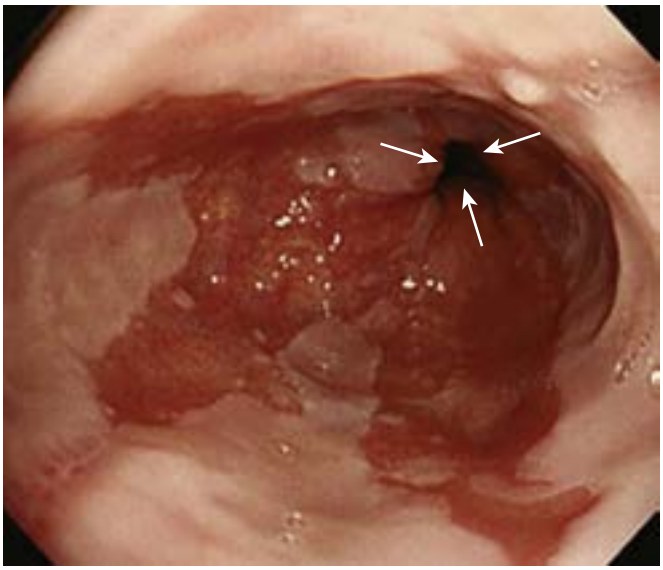

FIG. 2 Endoscopic image of Barrett's esophagus. The arrows mark the esophagogastric junction, which is identified endoscopically as the most proximal extent of the gastric folds. The reddish color and velvet-like texture of the Barrett's epithelium contrast sharply with the pale and glossy appearance of the esophageal squamous epithelium. Note that the Barrett's columnar epithelium extends well above the esophagogastric junction to line the distal esophagus. *(From Spechler SJ, Souza RF. Barrett's esophagus. In: Sleisenger and Fordtran's gastrointestinal and liver disease. Philadelphia: Elsevier; 2016.)*

without high-risk features (submucosal invasion, poor differentiation, or lymphatic vascular invasion), EMR has 98.8% eradication rate of BE; in patients with high-risk features, the rate is 80.6%. For T1a tumors, EMR has a 91% to 98% eradication rate.

There are several methods used for EMR. In the cap-assisted method, the endoscope is fitted with a transparent cap. Once located, the target lesion is sucked into the cap and a specialized electrocautery snare is used to resect the lesion. A submucosal injection can be performed to facilitate this. In the ligation-assisted method, lesions are removed using a band-ligation device attached to the tip of the endoscope. Once identified, the target lesion is again sucked into the endoscope and the band is applied around the lesion to create a pseudopolyp. Electrocautery is then used to remove the pseudopolyp. In the injection-assisted technique, the submucosal space is injected to lift the lesion and allow it to be snared and cut.

One of the primary side effects of EMR is esophageal stricture, which occurs in up to 40% of patients. Typically, these lesions can be managed with endoscopic dilation or stents. EMR is often used in conjunction with radiofrequency ablation (RFA) with good effect. In a recent systematic review, EMR alone had a 33.5% risk of stricture, 7.5% risk of bleeding, and 1.3% risk of perforation compared with 10.2%, 1.1%, and 0.2%, respectively, in patients undergoing EMR in conjunction with RFA.

Endoscopic Submucosal Dissection

Endoscopic submucosal dissection (ESD) is a technique that allows for complete, en bloc resection of suspicious lesions to allow for thorough histologic evaluation. When compared with EMR, it also

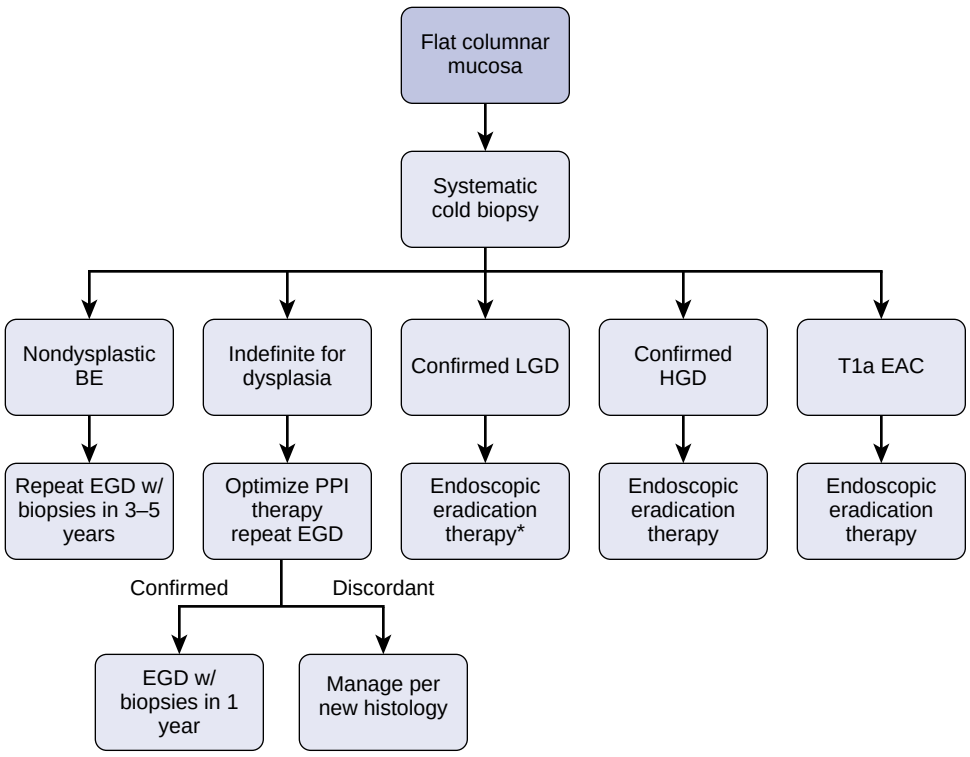

FIG. 3 Management of nonnodular Barrett's esophagus (BE). *Although endoscopic eradication therapy is associated with a decreased rate of progression, surveillance upper endoscopy at 1-year intervals is an acceptable alternative. This algorithm assumes that the T1a esophageal adenocarcinoma (EAC) displays favorable characteristics for endoscopic therapy, including well-differentiated histology and lack of lymphovascular invasion. *HGD,* High-grade dysplasia; *LGD,* low-grade dysplasia; *PPI,* proton pump inhibitor. *(From Shaheen NJ, Falk GW, Iyer PG, et al. FIG. 4 Management of nodular Barrett's esophagus (BE). *Little data exist on the clinical course of patients with low-grade dysplasia (LGD) managed by endoscopic surveillance following endoscopic mucosal resection (EMR), although this is an alternative treatment strategy. Endoscopic submucosal dissection is an alternative to EMR. Favorable histology consists of no lymphatic or vascular invasion and moderate to well-differentiated disease. *EAC*, Esophageal adenocarcinoma. *(From Shaheen NJ, Falk GW, Iyer PG, et al. ACG Clinical Guideline: Diagnosis and Management of Barrett's Esophagus.* Am J Gastroenterol. *2016;111:30–51.)*

allows for complete resection of lesions, rather than having to resect lesions in a piecemeal fashion, especially for larger lesions (>1.5–2 cm). The primary indication for ESD is resection of nodular lesions within a segment of BE to allow for complete histologic evaluation. Given the relative technical difficulty of this procedure, as well as the concern for significant adverse events, it is not as widely used. The ACG recommends that ESD only be performed in centers of clinical expertise.

The technique of ESD involves first marking the area of resection with coagulation. The submucosal space of the marked area is then injected with a saline solution to lift the area, and finally ESD resection knives are used to incise the mucosa and perform the submucosal dissection.

Most of the available data on ESD is from Europe or Asia, but a recent multicenter study performed in the United States showed that en bloc resection occurred in 95.7% of patients with a median resection size of 45 mm. Nearly half of patients required admission after the procedure, either for routine observation or for pain control. An R0 resection was achieved in 76.1%, and the overall cure rate was 69.6%. More than two-thirds of patients in this study were found to harbor EAC in the resected specimen, resulting in histologic upstaging in more than half of all patients. Adverse events occurred in 23.9% of patients, including bleeding (6.5%), perforation (2.2%), and esophageal stricture (15.2%). All adverse events were managed endoscopically.

These results were confirmed by a recent meta-analysis demonstrating that ESD has a 92.9% success rate of achieving en bloc resection, a 74.5% rate of achieving an R0 resection, and a 64.9% rate of achieving curative resection. Bleeding occurred in 1.8% of patients, and 1.5% of patients sustained esophageal perforation. Both the bleeding and perforation events were managed endoscopically. Overall esophageal stricture rate was 11.6%; these were managed with endoscopic dilation. The total rate of immediate and delayed adverse events was 4.95%.

ENDOSCOPIC ABLATION TECHNIQUE

Photodynamic Therapy

Photodynamic therapy (PDT) involves administration of a systemic photosensitizing agent that is taken up preferentially by neoplastic tissues. The photosensitizing agent then produces cytotoxicity after exposure to an appropriate wavelength and power of light, specific to the photosensitizing agent. The two most widely available photosensitizing agents are Photofrin and 5-aminolevulinic acid. Randomized trial data indicate that complete ablation of HGD can be achieved in 77% of patients with PDT, and 52% of patients had complete replacement of all BE tissue with normal squamous epithelium.

There is a relatively high complication rate associated with PDT. Because of its systemic administration, the photosensitizing agents can predispose to cutaneous photosensitivity similar to a sunburn in more than two-thirds of patients. Other complications include odynophagia, constipation, vomiting, noncardiac chest pain, dehydration, dysphagia, and stricture formation (up to 36% in some studies). This was the first effective ablation technique, but because of the relatively high complication rate, PDT is no longer widely used.

Argon Plasma Coagulation

Argon plasma coagulation (APC) uses a beam of argon gas to conduct an electrical current, resulting in a noncontact form of thermal electrocoagulation. The depth of necrosis is relatively shallow (2–3 mm) and can be useful in conditions such as BE that involve the mucosa. In the initial randomized controlled trial (RCT) conducted by Ackroyd et al., after a median of three treatments, patients treated

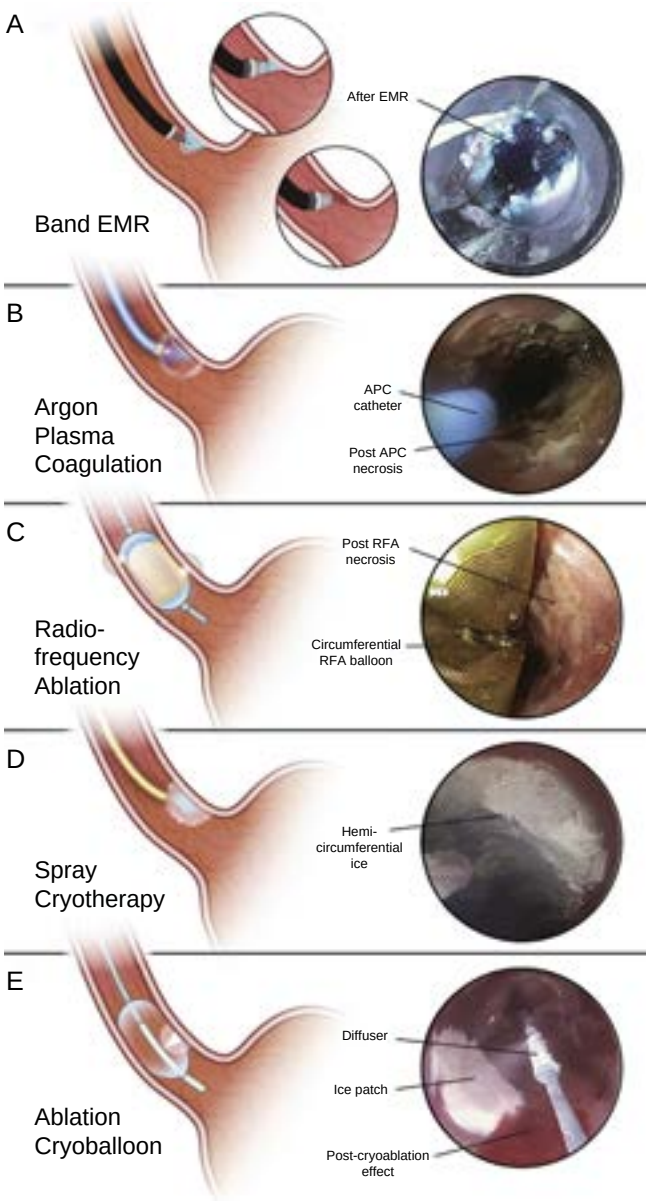

FIG. 5 Endoscopic techniques for eradication of esophageal early neoplasia. **(A)** Band endoscopic mucosal resection involves suction and ligation (banding) of a target lesion, with or without prior submucosal injection, followed by resection using snare polypectomy technique. Endoscopic photo shows the endoscopic view of the submucosa through the banding device after complete resection of well-differentiated adenocarcinoma. **(B)** Argon plasma coagulation (APC) involves conduction of heat energy with argon gas to the mucosa. Endoscopic image shows the APC catheter and white coagulation necrosis of treated BE mucosa. **(C)** Radiofrequency ablation (RFA) involves the application of a preset amount of heat energy (12 J) through electrodes on a circumferential (Halo 360) ablation catheter inflated to make contact with the esophageal mucosa. Endoscopic image of post-RFA necrosis. **(D)** Liquid nitrogen spray cryotherapy involves release of liquid nitrogen that expands to gas and freezes large areas of tissue to −196°C. The dosing of liquid nitrogen cryogen has varied from 15 to 20 seconds of ice, followed by a timed minimum 45 seconds of thaw, and repeated for three cycles. Endoscopic image of a hemicircumferential patch of ice on the esophageal mucosa. **(E)** The cryoballoon ablation system includes a portable handheld reusable controller that delivers nitrous oxide gas into a low-pressure compliant, 30 mm, oval-shaped balloon at the end of a disposable balloon catheter passed through the endoscope channel. The balloon at the end of the catheter is inflated and simultaneously cooled by the gas expansion. The cryogen is directed toward a specific location by rotation of the diffuser. Endoscopic image shows the endoscopic view through the cryoballoon with a focal ice patch and thawed treated mucosa with post cryotherapy red color change. *EMR,* endoscopic mucosal resection. *(From di Pietro M, Canto MI, Fitzgerald RC. Endoscopic management of early adenocarcinoma and squamous cell carcinoma of the esophagus: screening, diagnosis, and therapy.* Gastroenterology. *2018;154:421–436.)*

with APC achieved complete macroscopic ablation 60% of the time, with the remaining patients achieving a significant decrease in the size of their BE. At the 1-year follow-up, 58% of patients had no macroscopic evidence of disease compared with only 15% in the surveillance group. At 5-year follow-up, 70% of patients in the APC group had sustained at least a 95% reduction in the surface area of BE, and 40% had no histologic or macroscopic disease compared with only 25% and 15%, respectively, in the surveillance group.

There were no early complications, and long-term complications included strictures that were managed with endoscopic dilation.

Other reported complications include chest pain, odynophagia, ulceration, bleeding, perforation, and death. One advantage of APC is that the equipment is widely available and is relatively inexpensive. However, as noted in the RCTs, it often requires multiple treatments over time to achieve regression of disease.

Cryotherapy

Cryotherapy directly destroys tissue by freezing it, resulting in both immediate and delayed tissue destruction. There are several cryotherapy systems available, but the most widely studied is liquid nitrogen. In a retrospective study of patients treated with liquid nitrogen, Shaheen et al. found that after an average of four treatments, 97% of patients had resolution of HGD, 87% had resolution of intestinal dysplasia, and 57% had resolution of intestinal metaplasia. There were no serious complications, but 3% of patients developed strictures that were managed with endoscopic dilation.

At the 5-year follow-up, 93% of patients had complete resolution of high-grade dysplasia, 88% had resolution of dysplasia, and 75% had resolution of intestinal metaplasia, although some of these patients underwent "touch-up" therapy after the initial round of treatment. As with other endoscopic methods of treatment, ongoing endoscopic surveillance is required.

One advantage of cryotherapy is that it can be used both as a first-line treatment for BE with dysplasia and as a second-line treatment in patients who have failed other treatments. As with other therapies, however, it often requires multiple treatments to completely eradicate disease. In a recent review of liquid nitrogen cryotherapy, the complication rate ranged from 0% to 3% with the most frequent complication being pain requiring narcotics (10% of patients), followed by stricture requiring dilation (up to 9%), then bleeding and perforation.

Radiofrequency Ablation

The most commonly used ablative technique is RFA. Using either a balloon catheter or a focal catheter, a generator and a bipolar electrode array deliver a fixed amount of thermal energy, resulting in a uniform burn to a depth of 0.5 mm. RFA can be performed in the outpatient setting and is targeted as either a circumferential ablation (using the balloon catheter) or a focal ablation (using the focal catheter). Circumferential ablation is for circumferential segments of BE that are longer than 2 cm, whereas focal ablation is for shorter segments, or tongues, of BE. After treatment, follow-up is recommended in approximately 2 months, and often multiple sessions of RFA are required to achieve complete eradication of dysplasia, with close follow-up following eradication.

In an RCT comparing RFA with sham endoscopy, complete eradication of LGD occurred in 90.5% of patients and complete eradication of HGD occurred in 81% of patients following RFA, compared with only 22% and 19% in the sham group, respectively. Among all patients, RFA completely eradicated evidence of intestinal metaplasia in 77.4%, compared with only 2.3% in the control group. All these results were statistically significant. There is a known rate of progression to esophageal cancer, and in this study 19% of patients with HGD progressed to cancer over a 1-year timeframe. At 2-year follow-up, these results were found to be durable: complete eradication of dysplasia occurred in 95% of patients, and complete eradication of intestinal metaplasia occurred in 93% of patients; results were similar at 3-year follow-up.

The primary side effects of RFA are chest pain and dysphagia lasting up to 4 days, and strictures occur in up to 8% of patients. Bleeding is rare. No deaths have been reported following RFA. RFA is the preferred therapy for nonnodular BE.

CONCLUSION

The management of BE continues to evolve as new technology and more effective treatments become available. Compared with esophagectomy, endoscopic techniques have the advantage of being less invasive with fewer complications; however, in all cases, it is important to ensure that the correct technique is being used, which requires a baseline understanding of each technique. In general, patients with nodular disease should have this resected, and patients with early esophageal cancer should be referred for discussion at a multidisciplinary cancer group or tumor board to discuss alternative therapies to endoscopic ones.

Management of Paraesophageal Hernia Repair

Richard J. Battafarano, MD, PhD

The most common acquired diaphragmatic hernia is the hiatal hernia. Widening of the esophageal hiatus and weakening of the phrenoesophageal ligament is associated with herniation of the stomach and other intraabdominal organs through the hiatus and into the mediastinum. Many patients are noted to have hiatal hernias with minimal symptoms. However, the most common symptoms associated with hiatal hernia are gastroesophageal reflux disease (GERD) and early satiety. Patients who develop abdominal pain after eating or who present with anemia in the setting of a hiatal hernia often have larger paraesophageal hernias with at least partial organo-axial volvulus of the stomach. Patients with these symptoms are at greater risk for the potentially lethal consequences of complete volvulus, strangulation, incarceration, and perforation. Paraesophageal hernias are classified into four types (Box 1) based on the location of the esophagogastric junction (EGJ) and the herniated abdominal contents. Type I hiatal hernias are the most common; they account for 90% to 95% of all hernias and most frequently present with GERD. Patients with type II, type III, and type IV paraesophageal hernias often present with the additional symptoms of early satiety, anemia, and postprandial abdominal or chest pain, vomiting, dysphagia, and weight loss.

BOX 1 Classification of Paraesophageal Hernias

Type I: The esophagogastric junction (EGJ) herniates above the diaphragm into the mediastinum ("sliding hernia").
Type II: A portion of the stomach is herniated into the mediastinum alongside a normally positioned (i.e., intraabdominal) EGJ.
Type III: The EGJ is above the hiatus, and a portion of the stomach is folded alongside the esophagus.
Type IV: An intraabdominal organ other than the stomach also is herniated through the hiatus.

SURGICAL INDICATIONS AND PREOPERATIVE EVALUATION

The indications for surgery in patients with paraesophageal hernia depend on the severity of the patient's symptoms and the patient's other comorbid medical conditions. Patients with paraesophageal hernias whose symptoms are well controlled on acid suppression medications and who do not have dysphagia, weight loss, or pain may be followed closely and do not require immediate repair of the paraesophageal hernia. However, patients with other symptoms should be thoroughly evaluated before proceeding with paraesophageal hernia repair. As part of the evaluation for patient's symptoms, many will have either a contrast esophagram (Fig. 1) or a computed tomography (CT) scan (Fig. 2) at the time of presentation. Although these two radiographic studies often complement one another, the current thin-cut CT scans, with coronal and sagittal reconstructions, are quite helpful for delineating the anatomy of the paraesophageal hernia and for determining if additional organs have also herniated into the mediastinum (type IV paraesophageal hernia). An upper endoscopy is important to determine the presence of esophagitis, gastritis, Cameron ulcers, and peptic ulcer disease and to rule out malignancy. Esophageal manometry is very important in patients with type I and type II paraesophageal hernias to assess esophageal motility, which will guide the decision for the appropriate fundoplication at the time of the paraesophageal hernia repair. The use of esophageal manometry in patients with large type III or type IV paraesophageal hernias is often quite difficult to accurately perform because the catheters often curl in the esophagus or herniated stomach, limiting the data that can be obtained. In these patients, a partial fundoplication should be performed. The use of pH testing in patients with paraesophageal hernia does not usually add significant information in patients whose EGJ is above the diaphragm. However, pH monitoring is critically important in patients who have significant symptoms of gastroesophageal reflux disease without the presence of a paraesophageal hernia.

SURGICAL TECHNIQUE

Type I and type II paraesophageal hernias can almost always be successfully repaired using the laparoscopic technique. Laparoscopic repair of these hernias has been associated with decreased operative morbidity, especially when compared with thoracotomy. However, the choice of operation for large type III and type IV paraesophageal hernias is somewhat more controversial. Patients with more advanced type III and type IV paraesophageal hernias often develop dense adhesions between the hernia sac and the pericardium, lung, and even the airway itself. Dissecting the sac and its contents away from these structures often results in pneumothorax with subsequent loss of pneumoperitoneum and subsequent visualization. In addition, visualizing the structures above the level of the inferior pulmonary veins becomes much more difficult using a laparoscopic approach. In these large paraesophageal hernias, open repair using either an upper midline laparotomy or a left thoracotomy may be more efficacious. Other relative indications for open repair rather than laparoscopic repair of paraesophageal hernias include a previous paraesophageal hernia repair (especially if mesh was used at the hiatus), extension of the paraesophageal hernia into one or both pleural spaces, and proximal extension of the paraesophageal hernia to the level of the carina.

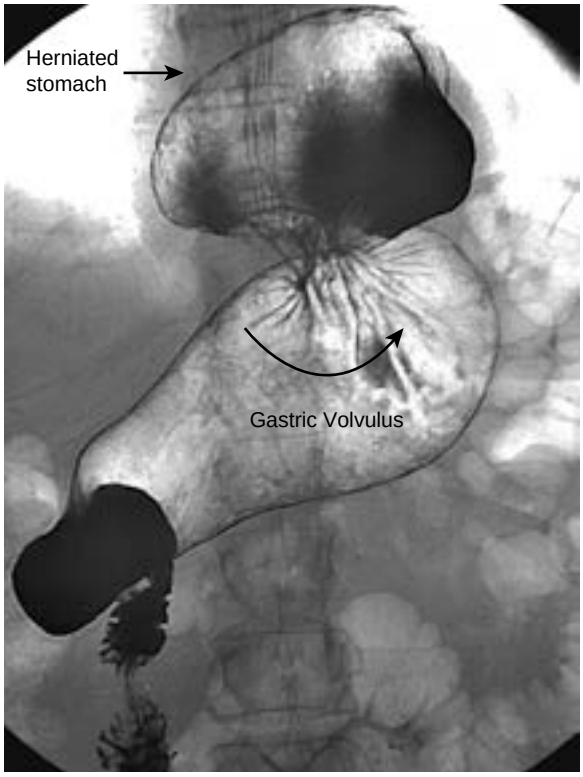

FIG. 1 Barium esophagram showing a large paraesophageal hernia with a gastric volvulus.

Laparoscopic Repair of Paraesophageal Hernias

Positioning of the Patient and Placement of Ports

After adequate general anesthesia has been performed, a nasogastric tube is placed to decompress the stomach. Although many surgeons utilize the low lithotomy position for this procedure, we have chosen to keep the patient in the supine position with a footboard to allow the steep reverse Trendelenburg position. A total of five ports are used for the procedure: one for the camera (port 1, 10 mm); two for the operating surgeon (port 4, 10 mm; port 5, 5 mm); one for the assistant (port 2, 5 mm); and one for the liver retractor (port 3, 5 mm). The first port is usually placed in the midline approximately 14 cm below the xiphoid process and is utilized for the camera. We prefer to place this port via an open technique to minimize the risk of injuring any intraabdominal contents upon entry. The remaining ports are all carefully placed under direct vision (Fig. 3). At the completion of the procedure, the fascia around each of the two 10-mm ports is closed with absorbable suture to decrease the risk of port site hernias.

Dissection and Reduction of the Hernia Sac

We begin by opening the gastrohepatic ligament up to the level of the right crus of the diaphragm. Great care is taken to identify the presence of a replaced or accessory left hepatic artery. If one of these is identified during this portion of the dissection, they are encircled

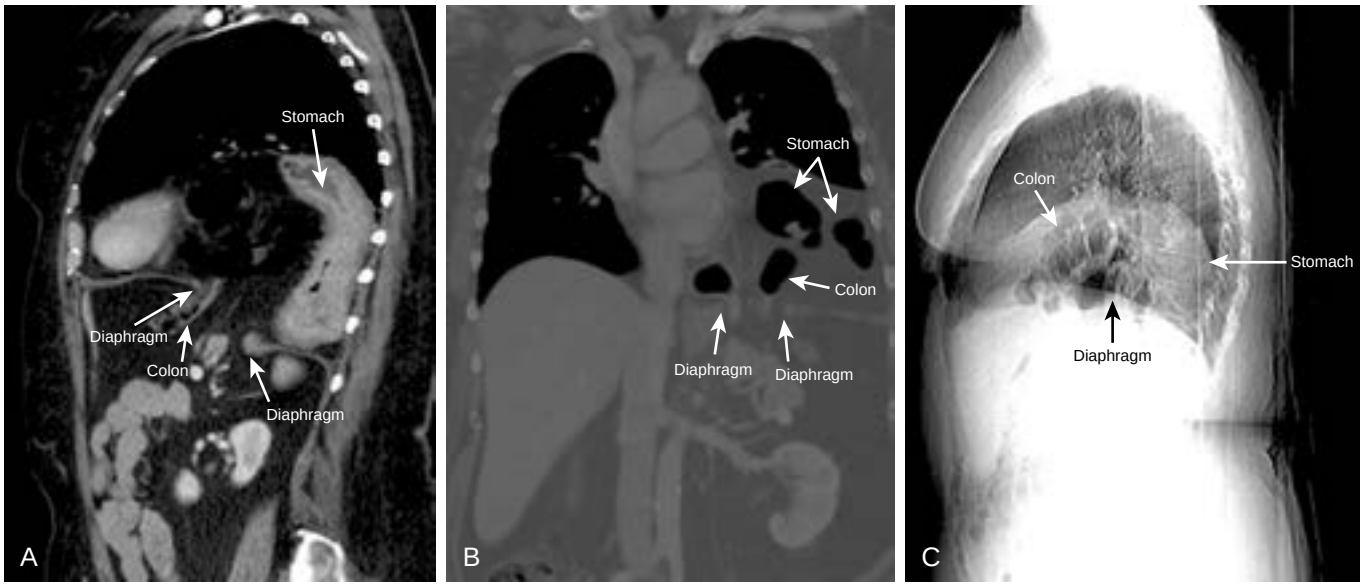

FIG. 2 CT scans showing a type IV paraesophageal hernia.

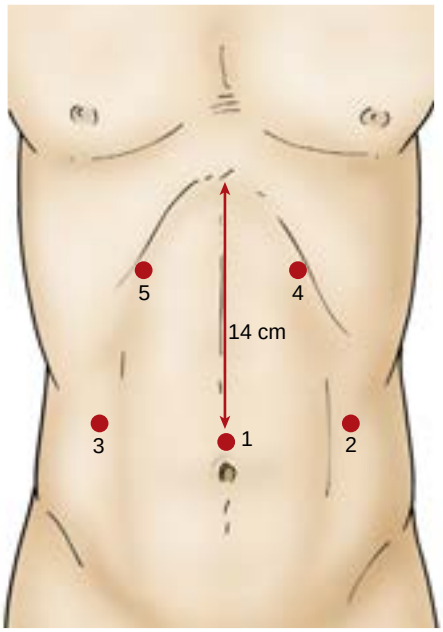

FIG. 3 Port placement for laparoscopic paraesophageal hernia repair. *(From Patti MG, Fisichella PM. Laparoscopic paraesophageal hernia repair. How I do it.* J Gastrointest Surg. *2009;13:1728-1732.)*

with a vessel loop and gently retracted during the remainder of the dissection and creation of the fundoplication. The periesophageal tissues are then dissected away from the right crus, and the anterior and posterior vagus nerves are identified. This dissection is then continued anteriorly to dissect the sac away from the pericardium and extended to the left crus of the diaphragm. The hernia sac is then dissected away from the left crus of the diaphragm exposing the posterior aspects of both the right and left crura just above the aorta. The posterior dissection is completed allowing the herniated stomach and the hernia sac to be reduced into the abdomen, and the esophagus is encircled in the lower mediastinum with a Penrose drain. Mobilization of the hernia sac and its contents in this manner decreases the amount of force applied to the stomach during this step of the procedure and greatly reduces the risk for gastric injury or perforation. With the stomach reduced into the abdomen, we mobilize the greater curvature of the stomach, dividing all of the short gastric vessels using a harmonic scalpel. Our focus on removing the entire hernia sac during the procedure often results in small tears in the pleura, creating capnothorax with associated hypotension or increased airway pressure. Reduction of the insufflation pressure and close cooperation between the surgical and anesthesia teams almost always allows completion of these procedures laparoscopically without conversion to laparotomy.

Esophageal Mobilization and Lengthening

The hernia sac is then resected taking great care to preserve both vagus nerves, and the EGJ is identified. The mediastinal dissection is extended proximally by dividing the small esophageal arterial branches using the harmonic scalpel. The dissection is continued up into the mediastinum to achieve at least 3 cm of intraabdominal esophagus. It is quite helpful to decrease the insufflation from 15 mm Hg to 8 mm Hg and to not utilize any caudal traction of the stomach at this time so an accurate measurement of intra-abdominal esophagus can be achieved. Once an accurate measurement of intra-abdominal esophagus has been made, the insufflation is returned to 15 mm Hg, and attention is directed toward posterior approximation of the right and left crura.

Closure of the Esophageal Hiatus

Retraction of the esophagus upward and toward the patient's left with the Penrose drain optimizes visualization of the posterior right and left crura. Interrupted 0 Ethibond sutures are placed to reapproximate the posterior right and left crura just above the aorta using a laparoscopic needle driver through the left upper quadrant 10-mm port. Although many surgeons perform intracorporeal knot tying, we prefer to utilize the Ti-KNOT. It is important to accurately space these posterior crural sutures on each crus because the left crus is often much longer than the right crus. In addition, it is important for the surgeon to carefully place these sutures, being mindful that both the aorta and inferior vena cava are in close proximity to the posterior crura. Before the last crural sutures are tied, a 52F or 56F bougie is carefully inserted down the esophagus, and there should be room for a closed grasper to easily slide between the esophagus and crura. Although there was initial enthusiasm for the use of biologic mesh for reinforcement of the crural closure, more recent studies have demonstrated that the long-term recurrence rates are

similar between cruroplasty alone versus cruroplasty with biologic mesh. However, the overall morbidity seems to be higher in patients repaired with nonabsorbable mesh.

Creation of the Fundoplication

For a Nissen (360-degree) fundoplication, the 56F bougie remains in the lumen of the esophagus, and the fundus of the stomach is passed behind the esophagus, taking great care to ensure sufficient mobilization to avoid having part of the gastric fundus above the wrap. A total of three 2-0 Ethibond sutures are used to create the Nissen fundoplication. Each stitch is placed through the seromuscular wall of the stomach on the left side of the fundus, the muscular wall of the esophagus, and the right side of the fundus at 1-cm intervals. At the completion of the fundoplication, the anterior portion of the fundoplication should be approximately 2 cm in length and should sit comfortably below the hiatus. Many surgeons place sutures between the superior aspect of the wrap and the right and left sides of the crural closure, creating a gastropexy to anchor the wrap below the hiatus (Fig. 4). It is critical that the wrap is not created under tension.

When the patient's esophageal motility will not allow a Nissen fundoplication, a Toupet fundoplication (posterior 240-degree fundoplication) is created by placing a total of six 2-0 Ethibond sutures. Three are placed through the seromuscular right and left sides of the fundus and are separately sutured to the right and left sides of the muscular wall of the esophagus, leaving 120 degrees of the anterior esophageal wall uncovered (Fig. 5).

Open Repair of Large Paraesophageal Hernias

Repair through an Upper Midline Laparotomy

Although a number of surgeons will repair large paraesophageal hernias (type III and type IV) and reoperative paraesophageal hernias using laparoscopic and/or a combination of laparoscopic and thoracoscopic techniques, operative times are longer, and the risk for complications such as gastric or esophageal perforation is higher. For this reason, we often repair large paraesophageal hernias and reoperative paraesophageal hernias through a limited upper midline laparotomy. The postoperative morbidity of an upper midline laparotomy is minimal and offers a number of advantages over a difficult laparoscopic dissection. First, without utilizing insufflation, entrance into either the left or right pleural space as part of resection of the sac does not negatively affect or limit the ability to complete the procedure. Reduction of the sac and its contents from the mediastinum or the pleural space can often be performed more gently with one's hands in comparison with using Babcock or other laparoscopic clamps, and complete resection of the sac can be accomplished in all cases. Because large paraesophageal hernias are more likely to be associated with an EGJ that does not comfortably sit 3 cm below the hiatus despite extensive proximal mobilization of the hiatus, accurate assessment of esophageal length and the creation of esophageal lengthening procedures such as a Collis gastroplasty or a fundic wedge gastroplasty are more easily performed. In reoperative cases, takedown of the adhesions from the previous repair can be more safely achieved, especially when mesh was utilized at the time of the primary repair. CT images of a representative large type III paraesophageal hernia performed through an upper midline laparotomy are shown (Fig. 6).

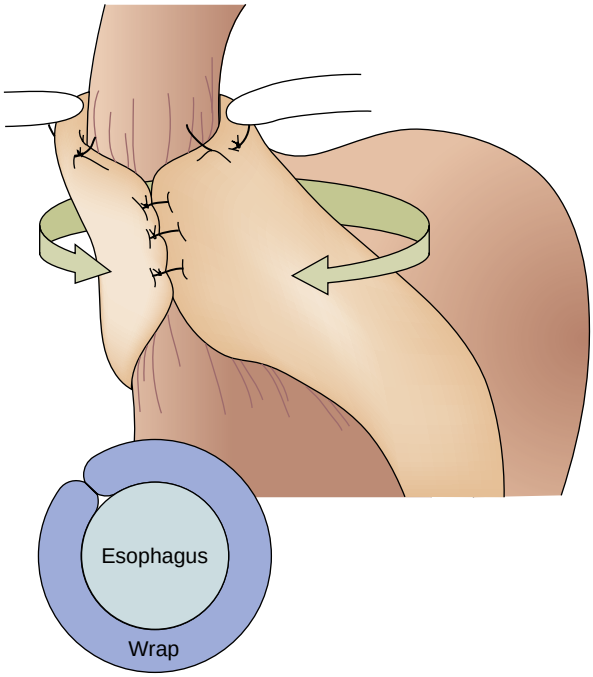

FIG. 4 Crural repair and total 360-degree fundoplication. *(From Townsend CM, Beauchamp RD, Evers BM, Mattox KL.* Sabiston Textbook of Surgery. *20th ed. Philadelphia: Elsevier; 2017.)*

Upper abdominal exposure is achieved using a standard bookwalter retractor system, and the steps of the operation are performed exactly as described earlier. When an esophageal lengthening procedure is necessary, it is performed over a 56F bougie using an endoscopic stapler with a closed staple height of 2 mm. A Toupet fundoplication is performed (instead of a Nissen fundoplication) to prevent postoperative dysphagia.

Repair through a Left Thoracotomy

Historically, the transthoracic repair of paraesophageal hernias was the standard approach for patients with this disease led by Dr. David Skinner and Dr. Ronald Belsey. Because of the increased postoperative pain associated with a thoracotomy, procedures performed using laparoscopy or through an upper midline laparotomy are currently preferred. However, transthoracic repair of large paraesophageal hernias still has a role in the care of patients with this disease (Fig. 7).

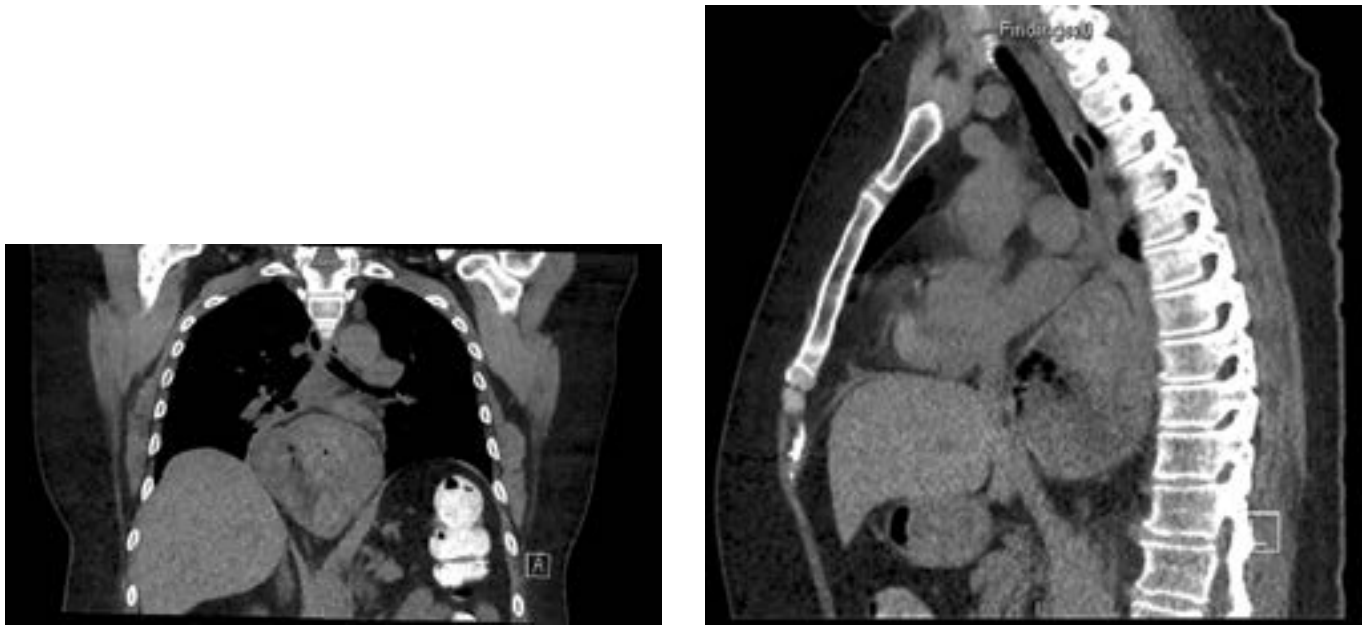

FIG. 6 Coronal and sagittal images of a large type III paraesophageal hernia extending up proximally in the mediastinum up to the level of the pulmonary veins.

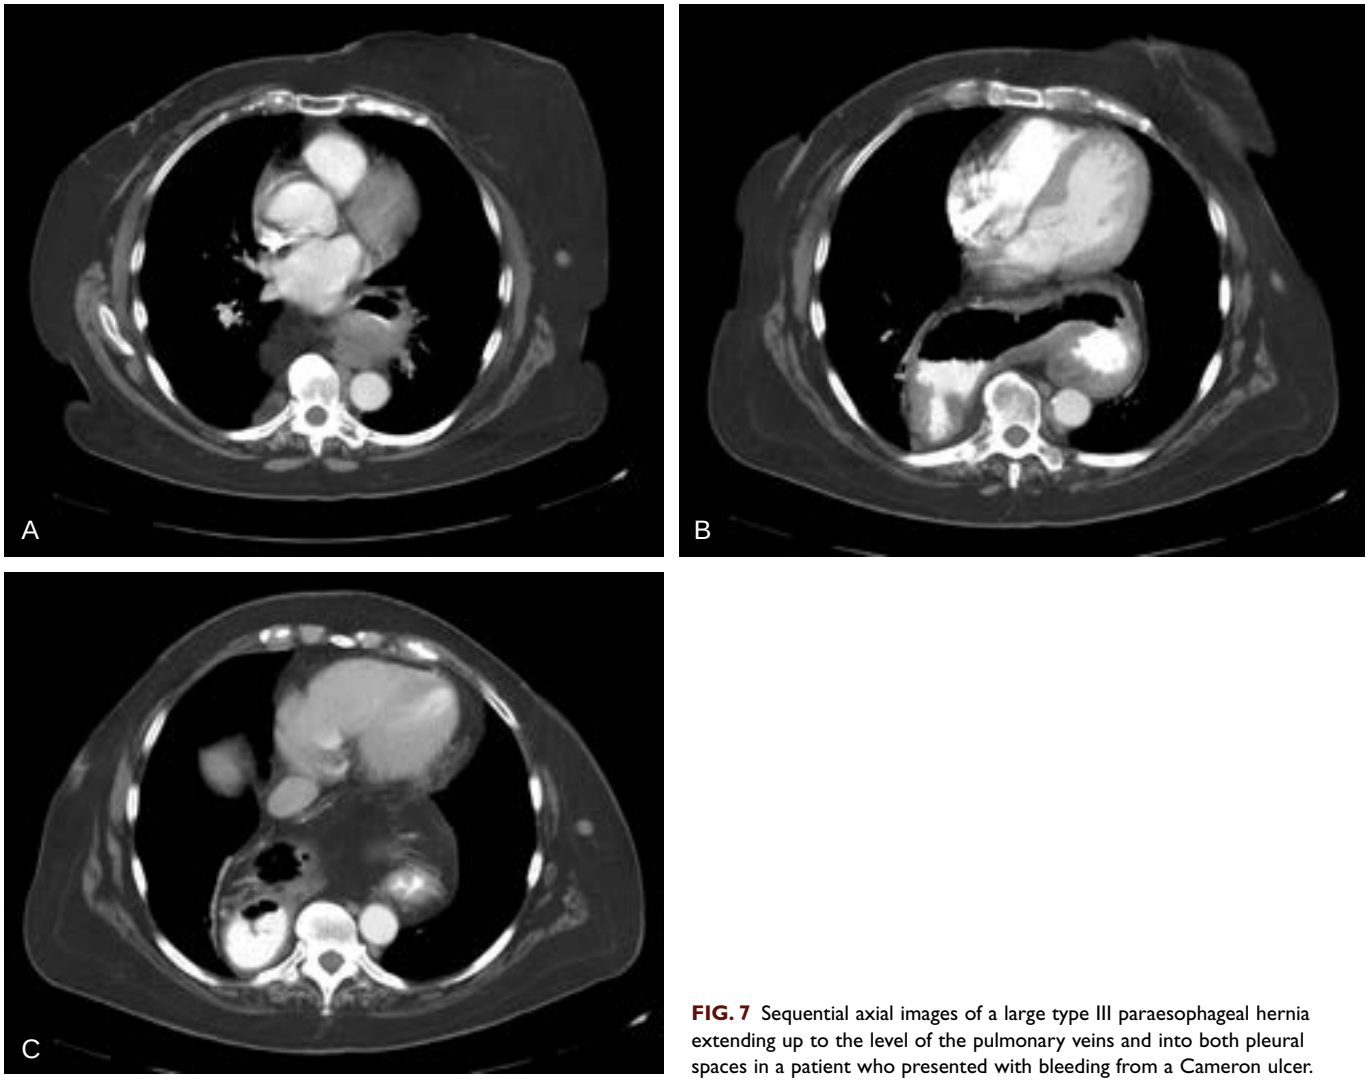

FIG. 7 Sequential axial images of a large type III paraesophageal hernia extending up to the level of the pulmonary veins and into both pleural spaces in a patient who presented with bleeding from a Cameron ulcer.

Transthoracic repair allows the surgeon to more easily divide dense adhesions between the hernia sac and its contents from the lungs and pericardium. It also allows the esophagus to be mobilized up to the level of the aortic arch behind the carina, generating maximal tension-free esophageal length. In the rare cases in which this degree of esophageal mobilization does not achieve enough length to allow the EGJ to sit comfortably below the hiatus, a Collis gastroplasty can be easily performed. Although the traditional fundoplication utilized by Skinner and Belsey was the Belsey Mark IV repair (270-degree fundoplication), this procedure can be conceptually more difficult to understand and to teach to others. Therefore, a standard Toupet fundoplication can be created in the left chest and then returned to the abdomen before tying the final two posterior crural approximation stitches to complete the repair.

POSTOPERATIVE CARE

No matter which surgical approach is utilized, patients are extubated immediately after the completion of the procedure. Nasogastric tubes are not necessary for patients with type I or type II paraesophageal hernias. However, patients with type III and type IV paraesophageal hernias often have significant gastric distension and benefit from tube decompression. I obtain a contrast esophagram on the first postoperative day to ensure flow of contrast through the fundoplication and to ensure gastric emptying. Patients are discharged on full liquids and a limited soft diet until they are seen at follow-up in approximately 2 weeks. Although patients whose repair was performed through a midline laparotomy or a left thoracotomy initially have more incisional pain, complete recovery and return to work is achieved in approximately 4 weeks.

OUTCOMES

Laparoscopic and open repair of paraesophageal hernias is associated with excellent recovery and long-term symptom relief. The choice between laparoscopic and open repair depends on the paraesophageal type and the patient's previous surgical history. Many series have demonstrated a relatively high radiographic recurrence rate. However, the need for reoperation remains quite low, especially in patients initially treated for type I and type II paraesophageal hernias.

ACKNOWLEDGMENTS

I recognize the authors of this chapter in the previous editions, as I have revised and updated their excellent work.

MANAGEMENT OF ZENKER'S DIVERTICULUM

Fernando A.M. Herbella, MD, Riccardo Rosati, MD, and Marco G. Patti, MD

GENERAL CONSIDERATIONS

Zenker's diverticulum is a rare disease that occurs in the pharyngoesophageal area. It is a pulsion pseudodiverticulum because it is composed of mucosa only and not all wall layers. A large proportion of patients with esophageal diverticula are asymptomatic. Dysphagia is the most common symptom, but regurgitation, weight loss, chest pain, halitosis, and aspiration are also common complaints.

PATHOPHYSIOLOGY

Pharyngoesophageal diverticulum occurs in areas of muscular gap at the transition of the cricopharyngeal, inferior constrictor of the pharynx and esophageal intrinsic muscles. Three separate weak areas have been described (Laimer's, Killian's, and Killian-Jamieson's triangles); however, even though there are different eponyms for the diverticula in each area, they are usually collectively called *Zenker's diverticulum* and are similarly treated because of their proximity and pathophysiology (Fig. 1).

An altered motility of the upper esophageal sphincter is necessary to create a high-pressure zone and force the mucosa through these areas of weakness. Gastroesophageal reflux disease (GERD) is associated in up to 95% of patients, and this association may be related to esophageal longitudinal muscles reflex contraction and consequent widening of the gap between pharyngeal constrictors and cricopharyngeal muscles, or upper esophageal sphincter spasm. The incidence of cancer in a diverticulum is almost negligible.

DIAGNOSIS

Upper digestive endoscopy is usually performed to diagnose the diverticulum and to rule out malignancy and associated diseases. Endoscopists should be aware of the possibility of this diagnosis to prevent missing small diverticula or causing perforation of large diverticula misdiagnosed as the esophageal lumen (Fig. 2).

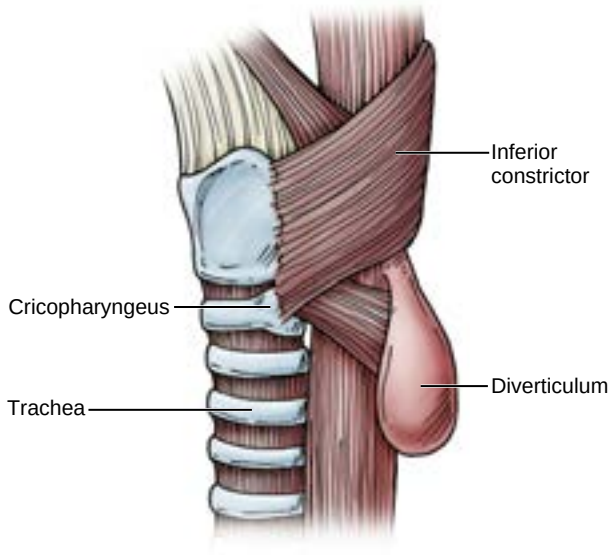

FIG. 1 Zenker's diverticulum at the pharyngoesophageal area.

FIG. 2 Zenker's diverticulum at upper digestive endoscopy.

FIG. 3 Barium swallow disclosing a Zenker's diverticulum *(arrow)*.

Barium swallow allows estimation of the size and location better than the endoscopy because the contrast distends the diverticulum (Fig. 3). Esophageal manometry may be used to diagnose the upper sphincter dysfunction, even though most experts believe that a motor disorder is always present and esophageal manometry is no more than an academic curiosity. Ambulatory pH monitoring may be indicated in patients with suspected GERD to allow planning of a combined procedure or guide medical therapy.

TREATMENT

Some propose treating only symptomatic diverticula, while others advise treatment to prevent complications such as aspiration, even in the absence of symptoms. The diverticulum may be treated by: (1) myotomy of the cricopharyngeal muscle alone; (2) myotomy plus diverticulectomy; (3) myotomy plus diverticulopexy; or (4) endoscopically by division of the septum between the diverticulum and the esophagus (diverticulo-esophagostomy [Dohlman's procedure]) (Fig. 4).

SURGICAL MANAGEMENT

Surgical Anatomy and Access

Most surgeons prefer a left cervical incision following the medial border of the sternocleidomastoid muscle, while others opt for a bilateral arciform incision. The layers to be dissected are: (1) skin; (2) subcutaneous tissue that is conjoined with the platysma muscle; and (3) superficial cervical fascia. After these planes are dissected, the infrahyoid muscles will be exposed. Usually there is no need to divide muscles. The sternohyoid muscle can be retracted medially and the omohyoid superiorly. The diverticulum is usually located below the omohyoid muscle. After the muscles are retracted, the esophagus is exposed. There is no need for circumferential dissection of the esophagus as it increases the risk of damage to the left recurrent laryngeal nerve located in the groove between the esophagus and the trachea. If the diverticulum is not yet identified, the esophagus should be rotated to expose the posterior side. Sometimes esophageal intubation by the anesthesiologist or intraoperative endoscopy is necessary to identify the diverticulum.

Dysmotility Treatment

The myotomy of the cricopharyngeal muscle must always be performed based on the assumption that an upper esophageal sphincter dysfunction is part of the pathophysiology of the disease. If the neck of the diverticulum is properly dissected, the myotomy is easily performed because the diverticulum is composed entirely of mucosa,

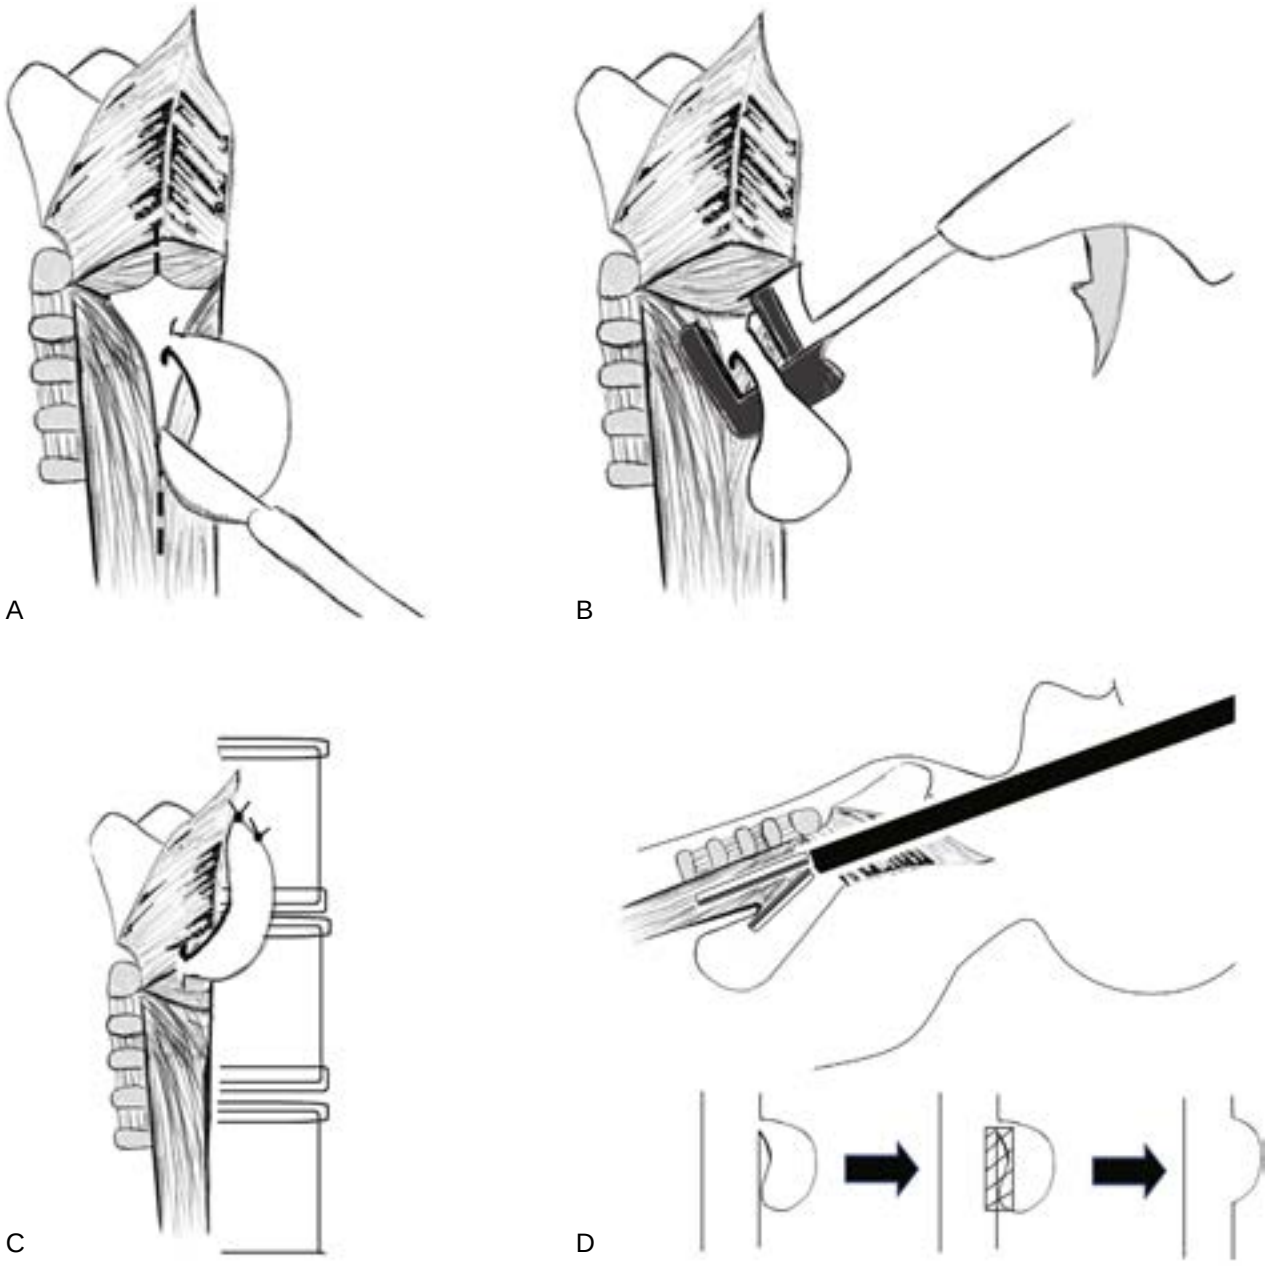

FIG. 4 Treatment options for Zenker's diverticulum. (A) Myotomy of the cricopharyngeal muscle. (B) Stapled diverticulectomy. (C) Diverticulopexy. (D) Endoscopic diverticulo-esophagostomy. *(From Herbella FA, Patti MG. Modern pathophysiology and treatment of esophageal diverticula.* Langenbecks Arch Surg. *2012;397:29–35.)*

and the interface between the muscular and mucosa layers can be effortlessly found. The myotomy must be extended about 3 cm downward onto the esophageal wall.

Diverticulum Treatment

There is no need to resect small diverticula (<2 cm) because of the low risk of complications and cancer. Larger diverticula may be resected or fixed upward to the prevertebral fascia (diverticulopexy). Resection may be performed with manual sutures or staplers. Before transecting the neck of the diverticulum, it is important to place a bougie (36Fr–40Fr) inside the esophagus to avoid pulling too much mucosa and causing narrowing of the esophageal lumen.

Some authors adopt a tailored approach choosing among the previous modalities based on the size of the diverticulum.

Outcome

Symptomatic relief is obtained in over 90% of patients. Complications may occur in up to 15% of cases and usually present as leakage and vocal cord paralysis.

ENDOSCOPIC TREATMENT OF ZENKER'S DIVERTICULUM

The treatment of Zenker's diverticulum has evolved over the past two decades from an invasive surgical procedure to an endoscopic approach that achieves favorable results in terms of symptom relief with a low complication rate, short hospital stay, and prompt return to an oral diet. Another factor in favor of the endoscopic approach is the possibility of a second attempt in cases of failure of primary treatment or recurrence of symptoms, without increasing the risk of complications such as nerve palsy.

Two different approaches can be used: rigid endoscopy or flexible endoscopy. To date, no controlled trials have been performed to demonstrate the superiority of one technique over the other, and consequently there are no accepted guidelines for patient management. The ability to access the diverticular common wall endoscopically may be limited by the patient's anatomy; therefore, a careful evaluation of the dimension of the diverticulum and its septum, clinical examination with evaluation of the anatomy of the oral cavity, and head hyperextensibility at the cervical spine level are mandatory to decide which technique is best.

Rigid Endoscopic Technique

Endoscopic diverticulostomy was first described by Mosher in 1917 using a cold knife. After initial success, the technique was abandoned and did not gain popularity until the 1960s, when Dohlman and Mattson described with success the endoscopic use of electrocautery to divide the common wall in a series of 100 patients. Since the 1990s, the endoscopic stapled-assisted diverticulostomy has become the standard approach to Zenker's diverticulum because of its low morbidity rate and excellent outcomes.

The procedure is performed with the patient under general anesthesia, lying supine with a fully extended neck. Under direct view, the Weerda diverticuloscope (Karl Storz, Tuttlingen, Germany) is carefully introduced through the mouth with the inferior blade into the pouch and the superior blade into the esophageal lumen (Fig. 5A). When a good view of the septum is achieved, the diverticuloscope is secured. To expose the diverticular septum and pouch and allow the insertion of the stapler, the two blades are gently opened. Any undigested food, saliva, or pills are aspirated. Two stay sutures (Endo Stitch 10-mm suturing device) are positioned on each side of the septum to maximize exposure and obtain traction (see Fig. 5B), therefore allowing insertion of the stapler deeper in the diverticular pouch. A modified linear stapler (AutoSuture Endo GIA 3.5, 30 mm) is introduced through the diverticuloscope with the jaws across the septum (see Fig. 5C) that is sealed and cut by firing the stapler, thus creating a common cavity between the esophagus and the diverticular sac (see Fig. 5D). A modification of the anvil by cutting the edge of the jaw (Fig. 6) introduced in the diverticular sac is mandatory to obtain the full-length division of the septum. In cases of big diverticula, more than a cartridge can be used to complete the section (see Fig. 5E, F). The residual millimeters of uncut staple line are sectioned with scissors or a coagulating hook;

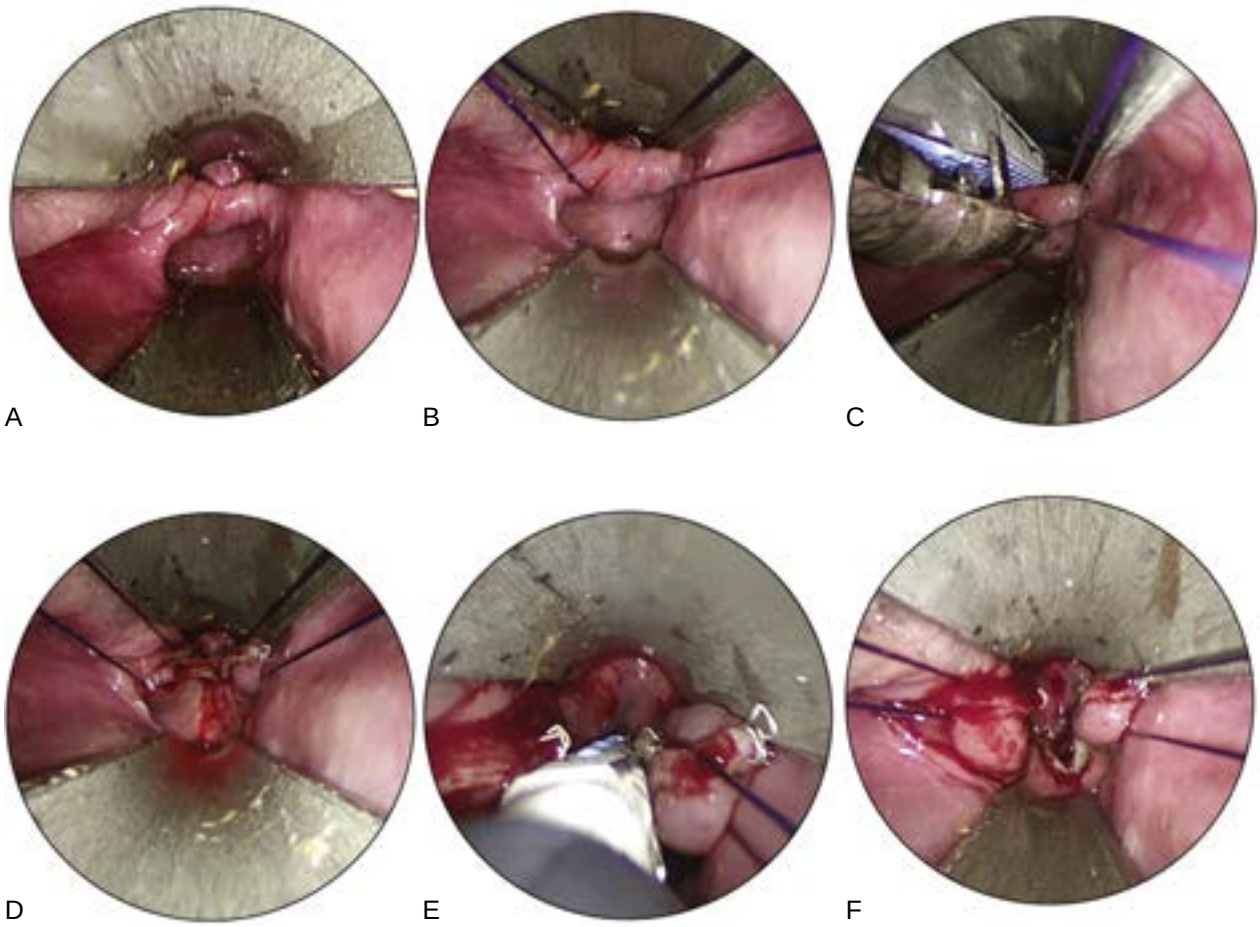

FIG. 5 Endoscopic therapy for Zenker's diverticulum. (A) Exposure of septum by the Weerda diverticuloscope. (B) Positioning of two anchoring stitches (Medtronic Endo Stitch 10-mm suturing device) at both septum sides. (C) Introduction of the linear stapler (AutoSuture Endo GIA 3.5, 30 mm) with the modified jaw into the diverticulum pouch. (D) Partial dissection of the septum after one stapler suture. (E) Further introduction of the linear stapler to obtain the full-length dissection of the septum. (F) Final appearance of the complete dissection of the septum and pouch obliteration.

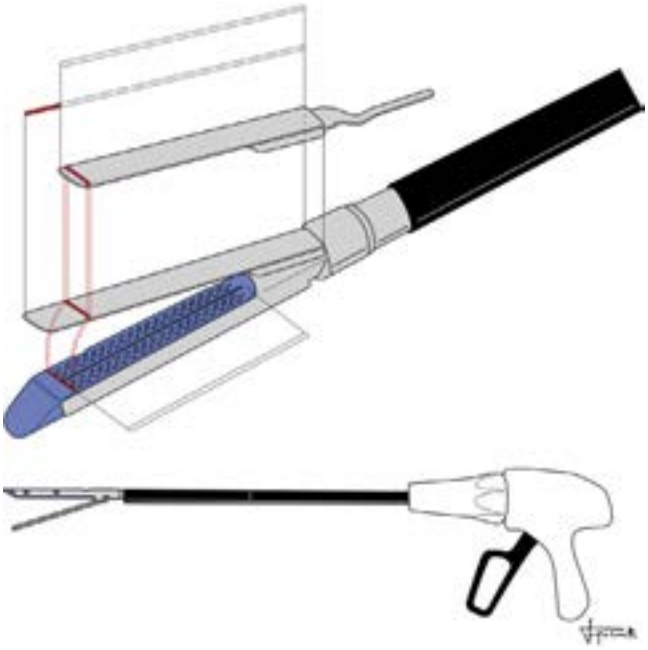

FIG. 6 Design of the modified anvil of the AutoSuture Endo GIA linear stapler, by Riccardo Rosati, and comparison with the traditional one.

any bleeding is controlled by electrocautery. In some series, division of the septum was performed using CO_2 laser, a Harmonic scalpel, or other devices as alternatives to the stapler (see Fig. 6).

This procedure is very effective, with an overall success rate of more than 90% in all large published series and a complication rate around 7.0%. The most common complications were dental injuries (2%) and esophageal mucosal perforation (1.6%).

Inability to access and fully divide the diverticular septum is a concern of this procedure. Data in the literature have shown a rate of procedure abandonment resulting from incomplete visualization that ranges between 3% and 26%. The reasons for this problem are a small oral inlet, limited neck extension, presence of osteophytes, a very small diverticular pouch, or concern regarding dental injuries. In addition, limited experience in the insertion of the diverticuloscope plays a major role.

Historically, diverticula smaller than 2 to 3 cm have not been amenable to the endoscopic technique because of the risk of a too-short myotomy length, but use of the stay sutures facilitates anchoring of the stapler in the diverticular pouch. Furthermore, a higher success rate using sutures with a single session has been achieved than without stay sutures (87.3% vs. 65.3%, respectively).

Flexible Endoscopic Technique

The rigid endoscopic approach has some limitations such as the need for general anesthesia, the inability of neck hyperextension, and anatomic problems such as a diverticulum less than 3 cm (not suitable for correct positioning of the stapler). Flexible endoscopic techniques have been proposed to overcome such difficulties. They vary from the "classic" flexible endoscopic septum division to the most cutting-edge third-space approaches. In every case, the procedure is done under direct vision of the cricopharyngeal muscle fibers. All of the procedures are performed with the patient in the left decubitus, with the patient either under conscious sedation or under narcosis.

Endoscopic Septum Division

The first technique proposed in the mid-1990s was endoscopic septum division, which shares the same principles of rigid endoscopy and involves a full-thickness incision of the mucosa, submucosa, and muscular fibers of the septum to obtain a common cavity with the esophageal lumen.

Before performing the procedure, a nasogastric tube is inserted into the esophagus as a guide to recognize the lumen. Since its introduction, many tools have been proposed, and the technique has improved: some endoscopists use a soft rubber diverticuloscope as overtube (Zenker's Diverticulum Overtube, Cook Endoscopy, Winston-Salem, NC) to obtain a better view and set the surgical field, or a short cap on the tip that also improves visibility and stabilizes the endoscope. Septotomy is performed with no need of submucosal injection. The most common devices used are the needle-knife and the hook-knife, but others can be used such as monopolar forceps or argon plasma coagulation, depending on the endoscopist's preference and personal experience. After the septotomy is completed, one or more endoclips are placed to close the incision to reduce the likelihood of a leak or bleeding. Outcomes of the septotomy are similar to the previous technique, with nearly 90% symptom relief and a recurrence rate of 11%. A retrospective comparative review showed that both rigid endoscopy septotomy and the flexible endoscopic technique have similar results and provide symptom control comparable with open surgery, with a decreased risk of serious complications.

Z-POEM

Recent advances in natural orifice transluminal endoscopic surgery (NOTES), especially for treatment of achalasia, have given rise to novel myotomy techniques for the treatment of Zenker's diverticulum. In 2016, the first septum division via a submucosal tunneling approach was reported, later called *Z-POEM*.

The advantage of this approach is that it is easier to perform a complete transection of the entire muscular septum by operating within a submucosal tunnel, thus maintaining mucosal integrity and lowering recurrence of symptoms because of incomplete transection of the muscle.

The procedure starts with submucosal injection and mucosotomy nearly 3 cm proximal to the septum. This is very difficult because the area involved as muscular spasm and anatomic limitations of the upper esophageal sphincter may reduce the ability to properly manage the mucosal incision. Then a submucosal tunnel is created along both sides of the septum, ending in the normal esophagus, 1 to 2 cm distally to the end of the septum. The muscular fibers are at this point clearly visible and can be safely transected. After removal of the endoscope, the mucosotomy site is closed with clips. It is a technically challenging procedure, but the success rate is comparable with other endoscopic approaches, with 92% achieving favorable results and 6.7% experiencing complications such as bleeding or perforation. As it is a new procedure, long-term results and comparative studies are lacking as well as the rate of recurrence.

Achalasia of the Esophagus

T. Robert Qaqish, MD, and Mark Katlic, MD

Achalasia is a rare (US prevalence: 10 per 100, 000) neurodegenerative disorder that results in the inability of the lower esophageal sphincter (LES) to relax in combination with an aperistaltic esophagus. All age groups are affected without predilection to race or sex. There is a peak incidence of those manifesting the disease between 30 and 60 years of age. Although not completely understood, there may be a genetic predisposition to individuals with achalasia. Moreover, environmental factors may play a role, and lastly, autoimmune destruction of the underlying myenteric plexus of the esophagus may also serve as an explanation with a viral infection as the inciting agent.

The spectrum of manifestations of the disease includes regurgitation of food, retrosternal chest pain, and dysphagia. Advanced forms of disease may manifest with recurrent aspiration pneumonia, weight loss, and failure to thrive. The Eckardt score (Table 1) can be used to evaluate the severity of symptoms associated with achalasia.

TABLE 1 The Eckardt Scoring System*

Score	Weight Loss (kg)	Dysphagia	Retrosternal Chest Pain	Regurgitation
0	None	None	None	None
1	<5	Occasional	Occasional	Occasional
2	5–10	Daily	Daily	Daily
3	>10	With each meal	With each meal	With each meal

*The Eckardt scoring system allows clinicians to assess the severity of symptoms associated with achalasia and the effectiveness of any therapeutic intervention.

Moreover, the adequacy and effectiveness of treatment can also be assessed with application of the Eckardt scoring system.

Evaluation of the patient with an esophageal complaint suspected to be achalasia involves a thorough history and physical examination along with radiographic, endoscopic, and functional esophageal testing. A barium swallow may reveal the classic "bird's beak" appearance (Fig. 1). Endoscopy is recommended to rule out a mechanical obstruction such as malignancy, a benign stricture, or pseudoachalasia. In cases of long-standing disease, the esophagus may appear markedly dilated, and there may be retained food within the esophageal lumen. Functional esophageal testing in the form of high-resolution manometry (HRM) (Fig. 2) is the mainstay for the diagnosis of patients with achalasia. In type I achalasia, there is no esophageal contraction or esophageal pressurization with an integrated relaxation pressure (IRP, the mean of the 4 seconds of maximal deglutitive relaxation in the 10-second window beginning at upper esophageal sphincter [UES] relaxation on HRM) greater than 15 mm Hg. In type II achalasia, there is panesophageal pressurization and no peristaltic contraction. In type III achalasia, there are at least 20% premature (spastic) contractions. Depending on the HRM findings, achalasia and the subclassification of types can be further classified based on the Chicago Classification 3.0 (Fig. 3).

TREATMENT

There is no cure for achalasia. Available therapeutic interventions are aimed at relieving the functional obstruction at the LES. Intrasphincteric injection of botulinum toxin, pneumatic dilation of the LES, and myotomy via endoscopic and surgical means all achieve this goal with varying efficacy and duration of success. In cases of end-stage achalasia from long-standing disease or in the setting of previous myotomy, esophagectomy may be an option for medically fit patients.

Botulinum Toxin

In patients who have contraindications to general anesthesia and frail elderly patients, intrasphincteric injection of botulinum toxin may be a useful temporary measure. Injection is performed endoscopically

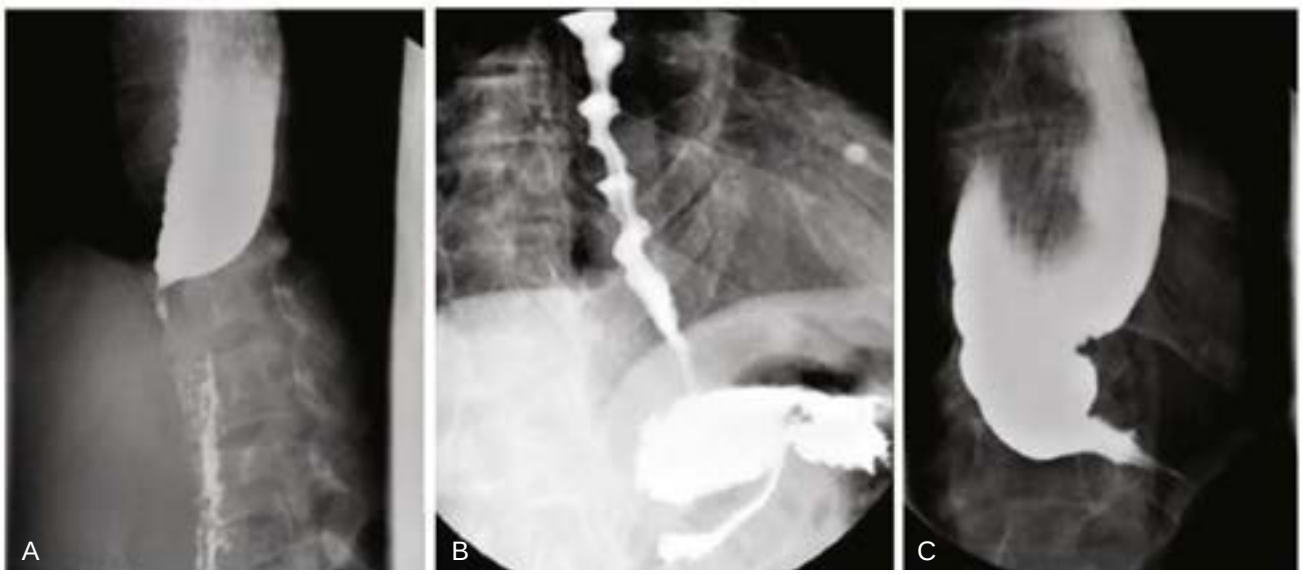

FIG. 1 Achalasia types shown on barium esophagography. **(A)** Classical barium esophagram showing tapering of the distal esophagus in (type I) achalasia, commonly referred to as a "bird's beak." **(B)** Spastic (type III) achalasia with a "corkscrew" type appearance. **(C)** Sigmoid-shaped esophagus from advanced achalasia. *(From Petrov RV, Fajardo RA, Bakhos CT, Abbas AE. Peroral endoscopic myotomy: techniques and outcomes.* Shanghai Chest. *2021;5:14).*

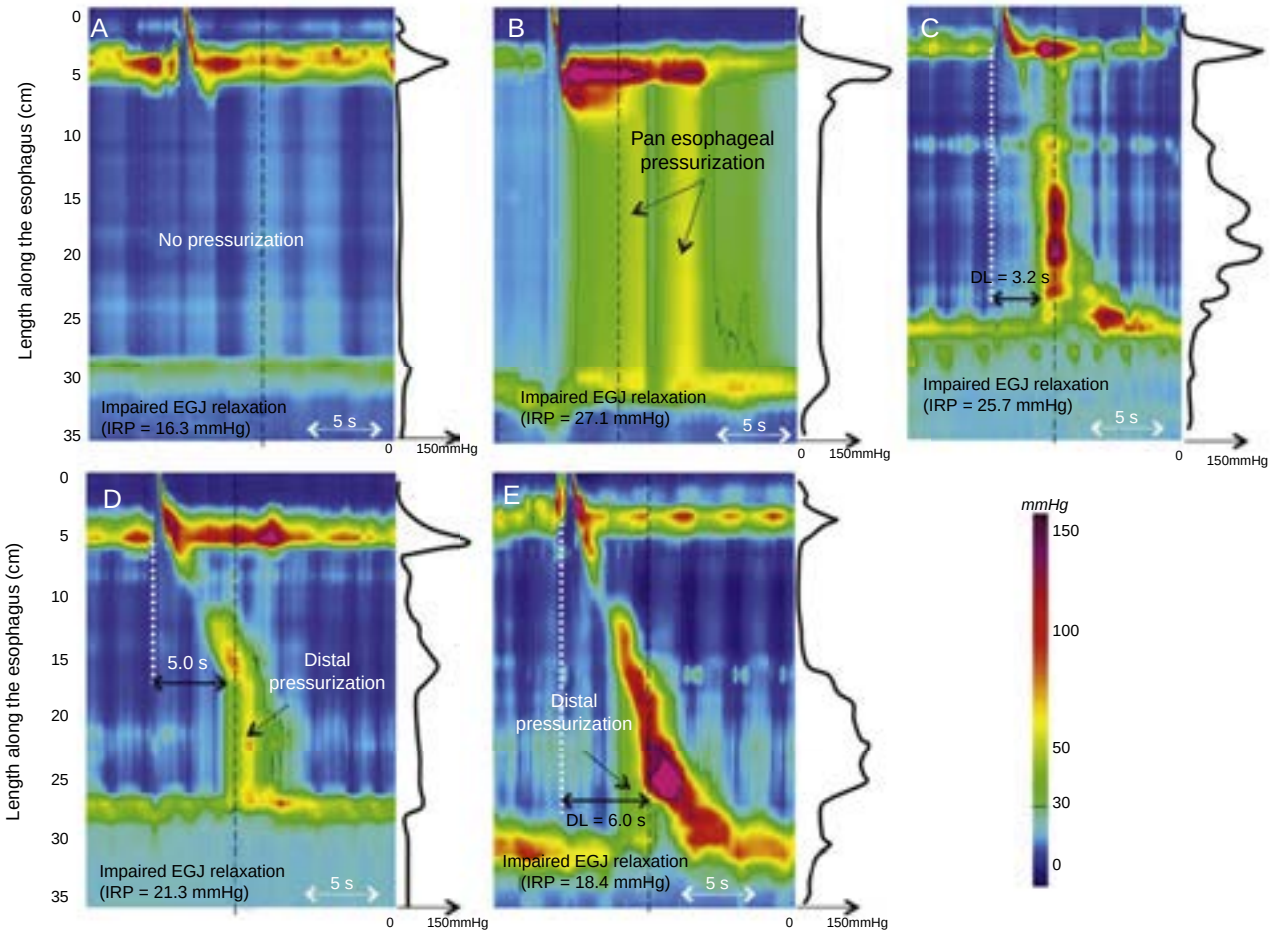

FIG. 2 High-resolution manometric images illustrating disorders associated with esophagogastric junction *(EGJ)* outflow obstruction. Impaired EGJ relaxation is evident by an integrated relaxation pressure (IRP, defined as the mean of the 4 seconds of maximal deglutitive relaxation in the 10-second window beginning at upper esophageal sphincter [UES] relaxation) >15 mm Hg. Instantaneous pressure along the *black dashed line* is represented by the *black line* on the *right* side of each panel. **(A)** Type I achalasia: characterized by no esophageal contraction or esophageal pressurization. **(B)** Type II achalasia: characterized by panesophageal pressurization and no peristaltic contraction. Note that pressurization corresponds to homogeneous pressure along the spatial pressure variation plot. **(C)** Type III achalasia: characterized by at least 20% premature contractions, defined as distal latency *(DL)* less than 4.5 seconds. DL is defined as the interval between UES relaxation and the contractile deflection point (CDP), which is a pressure topographic metric that demarcates peristalsis from ampullary emptying, localized within 3 cm of the proximal LES. Note the multiple peaks corresponding to contractions along the spatial pressure variation plot. EGJ outflow obstruction may represent achalasia **(D)** It might also be the consequence of a mechanical obstruction **(E),** such as a distal esophageal stenosis. *(From Kahrilas PJ, Bredenoord AJ, Gyawali CP, et al.; International High Resolution Manometry Working Group. The Chicago Classification of Esophageal Motility Disorders, v3.0.* Neurogastroenterol Motil. *2015;27[2]:160–174).*

and involves injecting the toxin into four quadrants of the LES. Typically, 80 to 100 units are injected (20–25 units/quadrant). Its mechanism of action involves irreversible inhibition of acetylcholine release from presynaptic terminals that eliminates the neurogenic component of the LES pressure. Therapeutic relief is short-lived, however, as new axonal growth will eventually occur, and the patient's symptoms will recur. Patients typically report an improvement in their symptoms for up to 1 year but often require repeat endoscopic injection. Repeat injection may be associated with local inflammatory reactions and fibrosis, which limit its repetition. Chest discomfort and rash are also known side effects of the therapy.

Pharmacologic therapies administered via the sublingual route before eating have also been employed in patients who are unfit for general anesthesia. These have included smooth muscle cell relaxants such as nitrates and calcium channel blockers that can lower the LES pressure. Side effects such as headaches limit the use of nitrates. Nifedipine administered via the sublingual route (30 mg/day) is also associated with headache, orthostasis, and dizziness and has limited efficacy. Sildenafil has also been trialed and has short-lived efficacy. Its use is limited by cost and potential side effects.

Pneumatic Dilation

Endoscopic dilation is the most effective nonsurgical option for achalasia. The principles of this therapy involve disruption of the circular muscle fibers of the LES as a result of dilation. Pneumatic dilators are more effective in achieving physical disruption of the muscle fibers in comparison with rigid dilators. These endoscopic procedures are performed under conscious sedation, and aspiration risk is not insignificant in this patient population because there may be retained food within the esophageal lumen. Implementation of a clear liquid diet for longer than 1 day may be advisable.

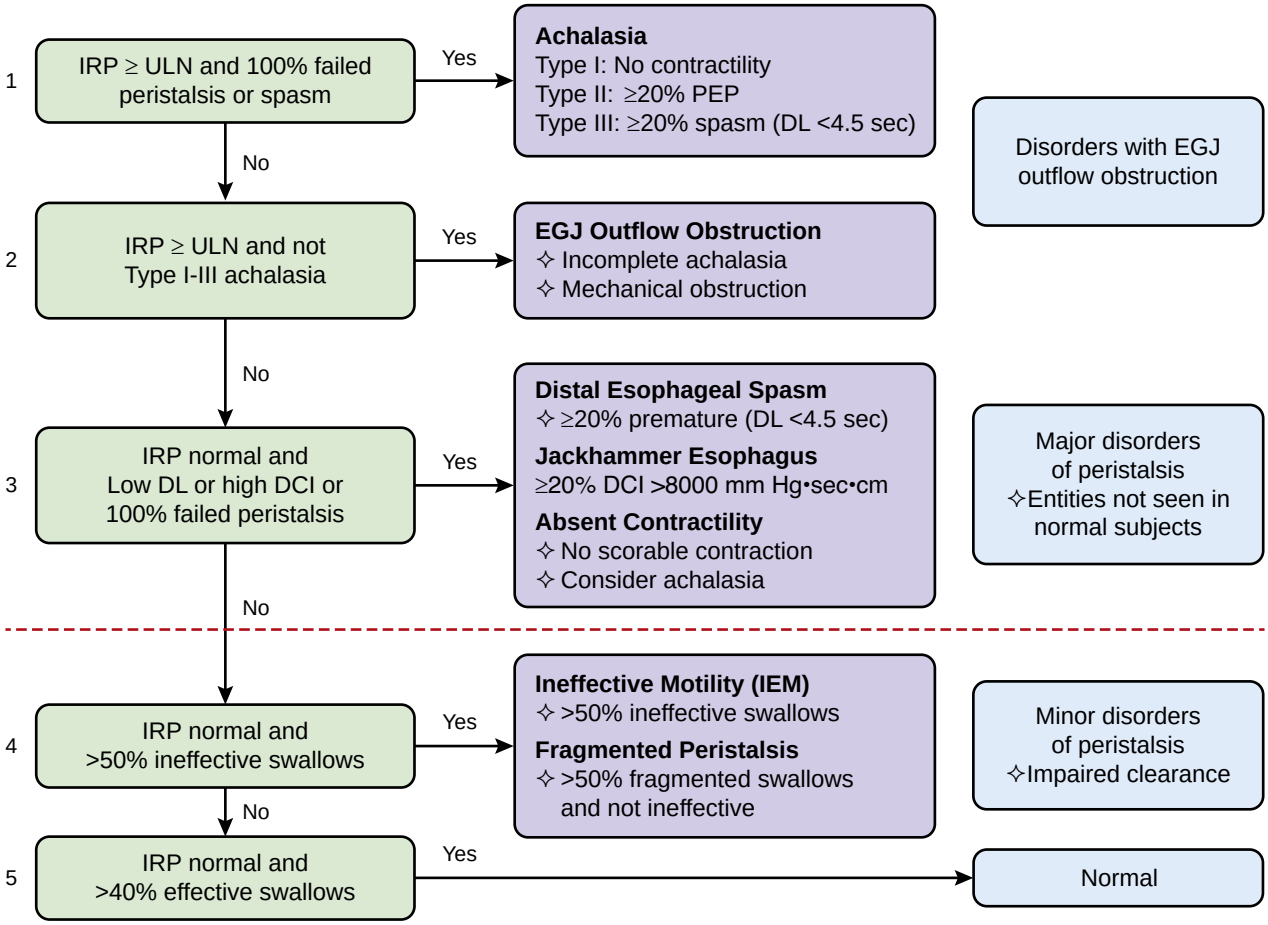

FIG. 3 The Chicago Classification version 3.0, a hierarchical analysis. The initial step involves evaluating the relaxation of the esophagogastric junction *(EGJ)* upon swallowing by using the integrated relaxation pressure (IRP, defined as the mean of the 4 seconds of maximal deglutitive relaxation in the 10-second window beginning at upper esophageal sphincter (UES) relaxation. If elevated (greater than upper limit of normal [ULN] of 15 mm Hg), patients should be classified as having achalasia or EGJ outflow obstruction, depending on the peristalsis. In the case of a normal IRP, peristalsis is classified based on its absence, distal latency (DL, defined as the interval between UES relaxation and the contractile deflection point, CDP, which is a pressure topographic metric that demarcates peristalsis from ampullary emptying, localized within 3 cm of the proximal lower esophageal sphincter, LES), distal contractile integral (DCI, defined as: amplitude × duration × length (mm Hg • s • cm) of the distal esophageal contraction exceeding 20 mmHg from the transition zone to the proximal margin of the LES) and fragmentation. If there are abnormalities, patients are classified as having a major or minor disorder of peristalsis. Major disorders are never observed in controls, in contrast with minor disorders. If a patient has a normal IRP and more than 50% of swallows are effective, esophageal motility is normal. *(From Pandolfino JE, Kahrilas PJ. Esophageal neuromuscular function and motility disorders. In: Feldman M, Friedman LS, Brandt LJ, eds. Sleisenger and Fordtran's Gastrointestinal and Liver Disease. 11th ed. Philadelphia: Elsevier; 2021:chap 44; Rohof WOA, Bredenoord AJ. Chicago Classification of Esophageal Motility Disorders: Lessons Learned.* Curr Gastroenterol Rep. *2017;19[8]:37.)*

Gastroscopy and fluoroscopy are used to guide inflation of the dilating balloon. Balloon sizes can range from 3.0 to 4.0 cm in 0.5 cm increments. A handheld manometer is used as the balloon is passed over a wire fluoroscopically. The "waist" of the balloon is created as a result of the LES and should essentially be carefully effaced during inflation. Long-lasting reduction in LES pressure typically involves dilation of the LES to 3 cm. A cautious approach should always be employed starting with the smallest balloon first. If the patient does not have symptomatic relief or there is an unsatisfactory result with dilation, it may be useful to repeat the dilation at a short interval (2–3 weeks).

Esophageal perforation is the most worrisome complication of pneumatic dilation and can occur at an incidence of 1%. Some practitioners perform a water-soluble followed by barium esophagram to follow each of their dilations routinely. Most perforations are apparent within the first hour after the procedure as fever, chest pain, and subcutaneous emphysema may be indicative of an esophageal leak. If the perforation is small, conservative measures including NPO, intravenous antibiotics and antifungals, and inpatient observation can be employed. If there is worsening fever, chest pain, or an uncontrolled leak, surgical therapy is recommended as early as possible (<6–8 hours). Computed tomography (CT) should also be employed, and a CT esophagram can be useful if available. Placement of a temporary esophageal stent for perforation after pneumatic dilation for achalasia is a more common intervention employed at institutions where the resources are available and should be employed if the esophageal leak is small.

The clinical efficacy of pneumatic dilation is variable and ranges from 30% to greater than 90%. This is believed to be a reflection in the variability in technique, practitioner-related variability in assessing outcomes, and variable approaches and timing for repeat dilation. Most patients will eventually require repeat dilation. Furthermore, future response to surgical myotomy is not influenced by the number of previous dilations.

Myotomy: Laparoscopic Heller Myotomy and Peroral Endoscopic Myotomy

Laparoscopic Heller Myotomy

In patients who can tolerate general anesthesia, laparoscopic Heller (or Heller's) myotomy (LHM) is effective and to date is the most durable surgical intervention for long-term control of achalasia. The procedure (myotomy) was first performed by the late German surgeon, Dr. Ernst Heller (Fig. 4). LHM is performed with the patient in the low-lying lithotomy position with bilateral arms tucked and padded. Before placing the patient in the lithotomy position, we carefully perform an esophagoscopy. Minimal insufflation is used, and the gastroscope is kept in the stomach after it is decompressed. The patient is then positioned. Precautions are taken to ensure that bony prominences on the upper and lower extremities are protected and cushioned in stirrups. A beanbag is used to create a bulky fold underneath the patient's gluteus and upper posterior thighs. This creates a "seat" and protects the patient's position from shifting during steep reverse Trendelenburg positioning. A test of steep reverse Trendelenburg positioning is always performed before prepping to ensure that the patient does not slip.

Ports are placed with the camera port 13 cm caudal to the base of the xiphoid in the midline. A pretzel liver retractor is placed in the right lower quadrant, curved around the left hepatic lobe, and then retracted to reveal the hiatus. The patient is then placed in the reverse Trendelenburg position, and the hiatus is better visualized. A 5-mm port is placed in the right mid-epigastric region, and a 12 mm port is placed in the left paramedian plane for the surgeon's working right hand. Lastly, a 5 mm assistant port is placed in the left lower quadrant.

The procedure is begun by identifying both the left and right crus and delineating the hiatal anatomy. The right crus is dissected from its medial portion and traced up anteriorly over the esophagus over toward the left crus. The esophagus is not circumferentially dissected. The gastric fat pad is then dissected off the lower esophagus exposing the anterior portion of the gastroesophageal junction (GEJ). The anterior vagus nerve and phrenoesophageal ligament are identified, and the contours of the fibers should be carefully noted. The cranial myotomy must extend across the GEJ in a manner that follows a straight line in the middle of the esophagus, and the caudal myotomy onto the stomach should remain as much as possible in an imaginary line that bisects the lesser and greater curvature.

A clear plane and potential trajectory for the myotomy should be kept in mind during the process (Fig. 5). We use two Maryland graspers to grab the esophageal muscle (starting with the outer, longitudinal layer) and apply equal pressure orthogonal to the long axis of the esophagus. Minimal cautery is used. This tedious teasing of fibers is continued until the mucosa is visualized. Oftentimes, strands of the circular muscle fibers remain, and these are individually peeled off and divided. Once the appropriate plane is established, the myotomy is extended 4 to 6 cm cranially into the mediastinum and 2 to 3 cm on to the stomach. At the end of the myotomy aspect of the procedure and before fundoplication, the mucosa is visualized endoscopically, and an insufflation test into the esophageal lumen is performed under saline.

Aus der Chirurgischen Klinik zu Leipzig (Direktor: Prof. Dr. E. Payr).

IV.

Extramuköse Cardiaplastik beim chronischen Cardiospasmus mit Dilatation des Oesophagus.

Von

Privatdocent Dr. E. Heller,
Oberarzt der Klinik.

(Hierzu 3 Abbildungen im Texte.)

Im ersten Heft des Archivs für klinische Chirurgie 1913 hat Heyrovsky eine subdiaphragmatische Oesophagusgastroanastomose beschrieben, die er bei zwei Fällen der sogenannten „idiopathischen Dilatation der Speiseröhre" mit Erfolg ausgeführt hat. Kurz nach dem Erscheinen dieser Mitteilung kam ein Patient mit chronischem Cardiospasmus und starker sackförmiger Dilatation des Oesophagus in die Behandlung der Leipziger chirurgischen Klinik, bei dem mir nach Lage des Falles chirurgische Hilfe zur Beseitigung des Leidens geboten erschien. Unter dem Eindruck der Heyrovskyschen Erfolge beabsichtigte ich den operativen Eingriff in der gleichen Weise vorzunehmen. Im Verlauf der Operation kam ich jedoch, bestimmt durch gewisse Schwierigkeiten der operativen Technik und später ausführende theoretische Ueberlegungen, zu einer vom ursprünglichen Plane abweichenden Durchführung der Operation, nämlich zur Ausführung einer extramukösen Cardiaplastik. Da der Erfolg, wie ich vorgreifend bemerken will, im funktionellen Sinne sehr befriedigend ausgefallen ist, und diese Aenderung des operativen Vorgehens meines Erachtens nicht unerhebliche praktische Vorteile gegenüber den für die Behandlung des Cardiospasmus mit Oesophagusdilatation vorgeschlagenen und ausgeführten operativen Maßnahmen besitzt, möchte ich mir erlauben, den Fall kurz mitzuteilen.

FIG. 4 Dr. Ernst Heller (1867 to 1964) and his publication from 1913 on extramucosal esophagomyotomy.

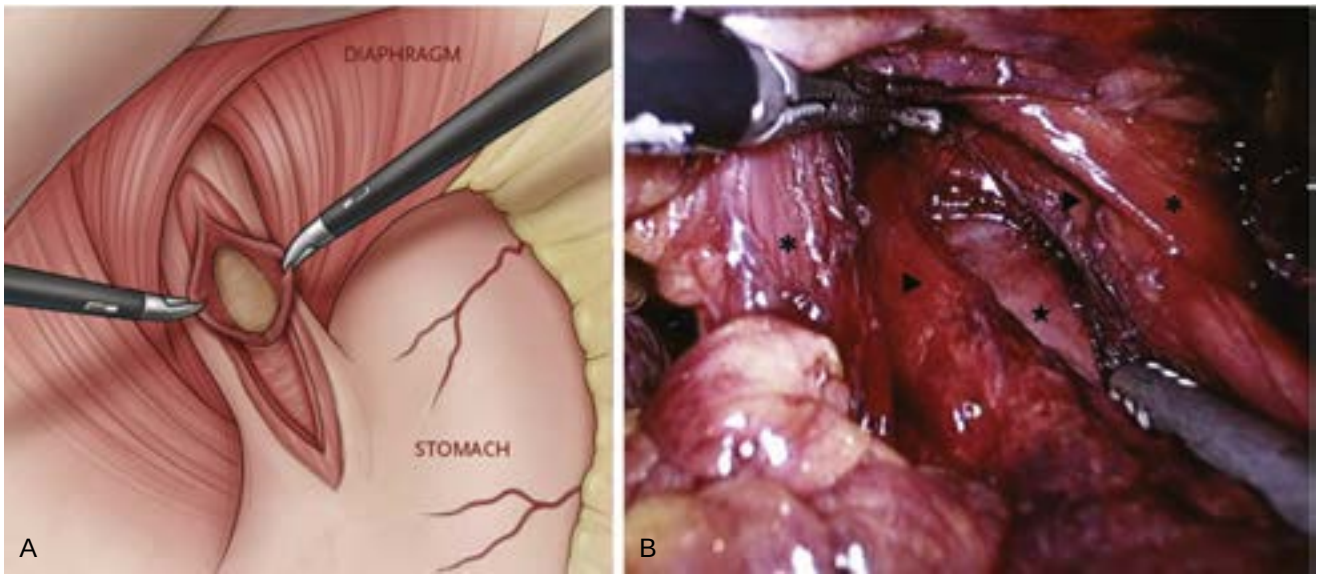

FIG. 5 Laparoscopic point of view during Heller myotomy. **(A)** Schematic showing left and right myotomy edges being elevated using the laparoscopic graspers with the mucosal layer in between. **(B)** Intraoperative photograph from a laparoscopic Heller myotomy showing the left and right crura *(asterisk)*, the left and right myotomy edges *(arrowheads)*, and the underlying exposed mucosa *(star)*. *(A, From Werner YB, Hakanson B, Martinek J, et al. Endoscopic or surgical myotomy in patients with idiopathic achalasia.* N Engl J Med. *2019;381[23]:2219–2229.)*

We invariably perform a Dor fundoplication and only take down some of the short gastric vessels if there is tension. Four intracorporeal sutures are used for the partial fundoplication. If the Dor fundoplication can be imaged as if it were a "door" covering the myotomized LES, the left myotomy edge is sutured to the inner aspect of the door, where the hinges would be. This is performed in two areas: one cranial and one caudal. The remaining tacking sutures to complete the Dor involve suturing the right myotomy edge to the free edge of the door, the side of which the doorknob is placed. 2-0 Ethibond (Ethicon) is used, and sutures are placed using the Endo Stitch suturing device (Medtronic, Minneapolis). The most cranial aspect of the fundoplication is also sutured to the right crus. A nasogastric tube is not routinely placed.

A barium swallow on postoperative day 1 is performed to evaluate for an esophageal leak. If negative, the patient is discharged on clear liquids for 3 days and full liquids for another 3 days, with soft food until the first postoperative visit at 2 weeks. The patient's diet is advanced as tolerated thereafter.

Peroral Endoscopic Myotomy

POEM is the newest surgical therapy to emerge in treating patients with achalasia. The procedure is performed in the operating room under general anesthesia with the patient supine. The procedure has four main components (Fig. 6). The mucosotomy is created approximately 10 to 15 cm proximal to the GEJ. The muscularis mucosa must be disrupted to expand the submucosal space with the injection of water. After mucosotomy, the submucosal fibers are dissected. To assist with separation and further creation of the tunnel, a methylene blue dye and water mixture is injected in this plane to delineate the underlying circular muscle fibers. The tunnel is created and must remain perpendicular to the circular muscle fibers of the esophagus. The tunnel takes a slight leftward turn at the GEJ and is extended a few centimeters past the GEJ. Commencement of the myotomy begins at the proximal extent of the tunnel posteriorly. A selective myotomy is performed proximally (circular muscle fibers only), and a full thickness (circular and longitudinal) myotomy is performed distally. The mucosa should be closely examined for inadvertent disruption in other areas remote from the mucosotomy. The mucosotomy is then closed using clips or an endoluminal suturing device.

The postoperative course after POEM is not dissimilar to that after LHM. A barium esophagram is obtained on postoperative day 1, and the patient may be discharged on clear liquids and proton pump inhibitor (PPI) therapy as long as there is no evidence of leak. Ambulatory pH testing and esophagogastroduodenoscopy should be performed between 3 and 6 months to evaluate for objective evidence of gastroesophageal reflux (GER).

Complications related to the procedure include inadvertent mucosal disruption, pneumothorax, pneumomediastinum, pneumoperitoneum, submucosal hematoma, and esophageal leak. Generally most complications are minor, and very few are severe.

Perioperative outcomes of patients who undergo LHM versus POEM are similar. The literature describing the long-term durability of POEM is scant and not yet precisely known. The longest follow-up report was recently published in 2021 by Campagna et al. and followed patients up to 55 months (4.5 years) after POEM. Clinical success (defined by an Eckardt score less than or equal to 3) was reported in 88/100 patients, with the remaining 12 noting a score greater than 3 at some point during the follow-up period. As there is no antireflux procedure that is performed alongside POEM, the risk of GER remains a significant postprocedural sequela that the patient must manage pharmacologically. In the above-mentioned study, approximately one-third of patients had evidence of GER on endoscopy. The durability of the LHM is well established in experienced hands and may be between 5 and 10 years.

As the data continue to accumulate, the approach to treat patients via endoscopic versus laparoscopic myotomy should be an individualized one. A patient-centric decision should be guided by the surgeon as to the best approach considering patient factors (e.g., BMI, previous operations, and overall preference) and institutional factors (e.g., clinician experience performing surgical vs. endoscopic myotomy vs. both and the institution's resources to manage complications). In July 2020, the Board of Governors from the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) recommended (conditionally, low certainty of evidence) either POEM or LHM in the treatment of type I or type II achalasia in adults and children and POEM over LHM (based on expert opinion) in adults and children with type III achalasia (Fig. 7).

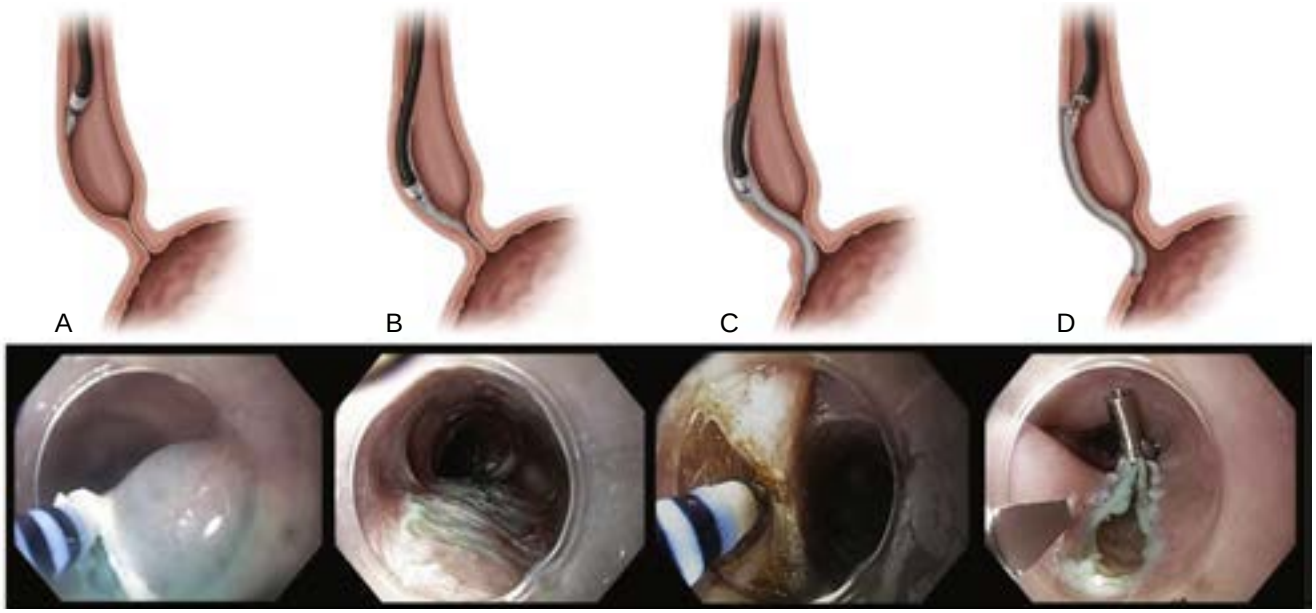

FIG. 6 Key elements of the peroral endoscopic myotomy procedure. **(A)** A mucosotomy is created with the corresponding endoscopic image beneath. **(B)** An endoscopic view of the completed submucosal tunnel after creation and completion. **(C)** Myotomy schematic and corresponding endoscopic image captured of the myotomy. **(D)** Closure of mucosotomy is performed with endoscopic placement of clips. *(From Petrov RV, Fajardo RA, Bakhos CT, Abbas AE. Peroral endoscopic myotomy: techniques and outcomes.* Shanghai Chest. *2021;5:14; corresponding endoscopic images provided courtesy Dr Henning Gerke, Clinical Professor from the University of Iowa Hospitals and Clinics.)*

TREATMENT FAILURE, ADVANCED DISEASE, AND FOLLOW-UP

Dysphagia in the postoperative course is likely an indication of treatment failure. The diagnostic workup should proceed with endoscopy, fluoroscopy with timed barium swallow, high-resolution impedance manometry, and, if available, functional lumen imaging probe (FLIP). Depending on the findings, pneumatic dilation versus repeat myotomy may be warranted. The patient should be evaluated for other factors that could be contributing to the esophageal complaints such as paraesophageal hernia or stricture. POEM may provide an avenue for patients who have had failed laparoscopic myotomy. POEM allows a dissection plane to be created endoscopically remote from a previously created dissection plane that was performed laparoscopically. In advanced cases in which the patient's disease process is refractory to multiple therapeutic interventions and there is severe esophageal dysfunction, esophagectomy may be warranted.

In patients with advanced disease, as evidenced by severe esophageal dysfunction and a dilated (sigmoid) esophagus, esophagectomy may be warranted if they are medically fit, especially in the setting of failed myotomy. Esophagectomy is both safe and effective. Both the transthoracic and transhiatal routes have been described with similar outcomes in experienced hands from tertiary referral centers. There are unique technical challenges that are important to consider when performing esophageal resection for end-stage achalasia. Prior myotomy may have created scarring between the esophageal submucosa and the aorta, and there may be large aortic esophageal arterial branches that must be carefully controlled during the dissection. Moreover, the dilated esophagus may be deviated into the right chest. We prefer a transhiatal approach for end-stage achalasia and start the procedure thoracoscopically to mobilize the esophagus under direct vision, control the large esophageal arterial branches, and ligate the azygous vein. Lastly, encircling the cervical esophagus may prove difficult in the neck.

There are no society-driven guidelines for surveillance endoscopy in patients with achalasia after myotomy. Chronic mucosal irritation from stasis esophagitis, long-standing GER, and Barrett's esophagus are risk factors for carcinoma. If surveillance is pursued, it is reasonable to perform surveillance upper endoscopy 15 years after the onset of symptoms.

Robotic Heller Myotomy with Dor Fundoplication

Robotic-assisted LHM with Dor fundoplication is well established, and the current literature shows nearly equal efficacy and outcomes in treating patients with achalasia. Surgeon experience with both the robotic or purely laparoscopic approach is probably the most important factor that determines a successful operation. The robotic platform offers improved visualization and may offer finer motor control with more comprehensive and robust instrument movement. Safe and careful patient positioning and port placement can be in similar positions to the laparoscopic approach or can also be placed in a horizontal line on either side of the umbilicus. The camera port is in the periumbilical region with two subsequent 8-mm ports on each side, each 8 cm lateral to the umbilical port and 8 cm away from each other. Retraction of the liver can be facilitated with a tip-up fenestrated grasper from the most lateral left-sided port. The robot is typically docked *after* the patient is placed in the steep reverse Trendelenburg position. The case proceeds in a similar fashion to the laparoscopic approach. Some surgeons use an endoscopically placed inflated balloon across the LES to better delineate the muscle fibers from the submucosal layers during dissection.

SUMMARY

Achalasia is a rare esophageal disease but represents the most common esophageal motility disorder. Based on the current status of evidence in the literature, a treatment algorithm is outlined in Figure 7. With the rapid and successful adoption of POEM in treating patients with achalasia and those who have failed laparoscopic (or robotic) myotomy, it is advisable that trainees and seasoned surgeons become more facile with advanced endoscopic interventions.

Management of Disorders of Esophageal Motility

Melissa Louise DeSouza, MD, and Lee L. Swanstrom, MD

Disorders of esophageal motility present a diagnostic and therapeutic challenge to gastroenterologists and surgeons. Achalasia, the most prevalent and best understood of these disorders, is addressed under "Management of Achalasia of the Esophagus" elsewhere in this textbook. Nonachalasia esophageal motility disorders are less prevalent, incompletely understood, and often difficult to treat. The optimal classification scheme for this group of disorders is a work in progress. Management strategies are also controversial, and there is no universally accepted standard of care. In this chapter, we attempt to guide the surgeon in a review of nonachalasia esophageal motility disorders and the application of their most current classification, with recommendations for management based on recent data.

PRESENTATION

Patients with disorders of esophageal motility may present with chest pain, dysphagia, regurgitation, heartburn, globus sensation, upper respiratory complaints, or some combination of these. Because

these symptoms are nonspecific and esophageal motility disorders are rare, workup for other life-threatening conditions is necessary. Cardiovascular and pulmonary causes usually have been ruled out already in the patient with chest pain before referral to the surgeon. A negative cardiac workup is reassurance enough for some patients who may be able to conservatively manage mild symptoms. Anxiety, depression, somatoform disorders, and other psychiatric diagnoses are more common in the population of patients with esophageal motility disorders; thus a psychiatric history is an important part of the evaluation. Gastroesophageal reflux disease (GERD) is another common cause of noncardiac chest pain. A trial of a proton pump inhibitor (PPI) is warranted, and further diagnostic testing should be carried out if troublesome symptoms persist. Concerning associated symptoms, such as dysphagia with weight loss, should heighten the suspicion for a mechanical or malignant process and prompt, expedient, and careful evaluation.

Diagnostic Testing

All patients evaluated for esophageal motility disorders must undergo a comprehensive diagnostic workup. This includes a contrast esophagram to help visualize anatomy, esophageal length, and the presence of a diaphragmatic hernia or esophageal diverticulum. A pH study with or without impedance is important to identify GERD, which may be the primary or contributing cause of symptoms. Endoscopic evaluation with biopsy is also mandatory to identify Barrett's esophagus, malignancy, peptic stricture or esophagitis related to acid exposure, eosinophilia, or infection. In the absence of mechanical obstruction or mucosal abnormalities, esophageal motility is evaluated next by manometry.

High-resolution manometry (HRM) with esophageal pressure topography (EPT) is the preferred method to evaluate for esophageal motility. HRM precisely defines esophageal contractile function, peristalsis, and bolus transit when impedance evaluation is included. Compared with conventional manometry, study acquisition is faster, more comfortable, and better tolerated by patients. For technicians and physicians, the topography contour plots increase diagnostic yield and provide an intuitive visual permutation of anatomic and physiologic characteristics.

Classification of Disease

Classifying esophageal motility disorders is an evolving process. Definitions of disease phenotype have changed over time, with improvements in diagnostic technology and better understanding of the clinical importance of various manometric patterns. In 2001, Richter systematically classified esophageal motility disorders using conventional manometric criteria. Using HRM, Kahrilas and colleagues redefined this scheme in 2008 with the first edition of the Chicago Classification of esophageal motility disorders. The Chicago Classification is currently in its fourth edition (CC v4.0), which is intended to simplify and clarify recognition of EPT patterns and physiologic metrics to better define clinically relevant phenotypes of esophageal dysmotility. CC v4.0 classifies the various manometric entities as *disorders of esophagogastric outflow obstruction* and *disorders of peristalsis* (Fig. 1). Manometric findings that do not meet criteria for these categories may be considered normal; however, when compared with CC v3.0, the most recent classification schema recognizes that manometry findings alone may be insufficient to provide a patient diagnosis or guide treatment. In particular, the

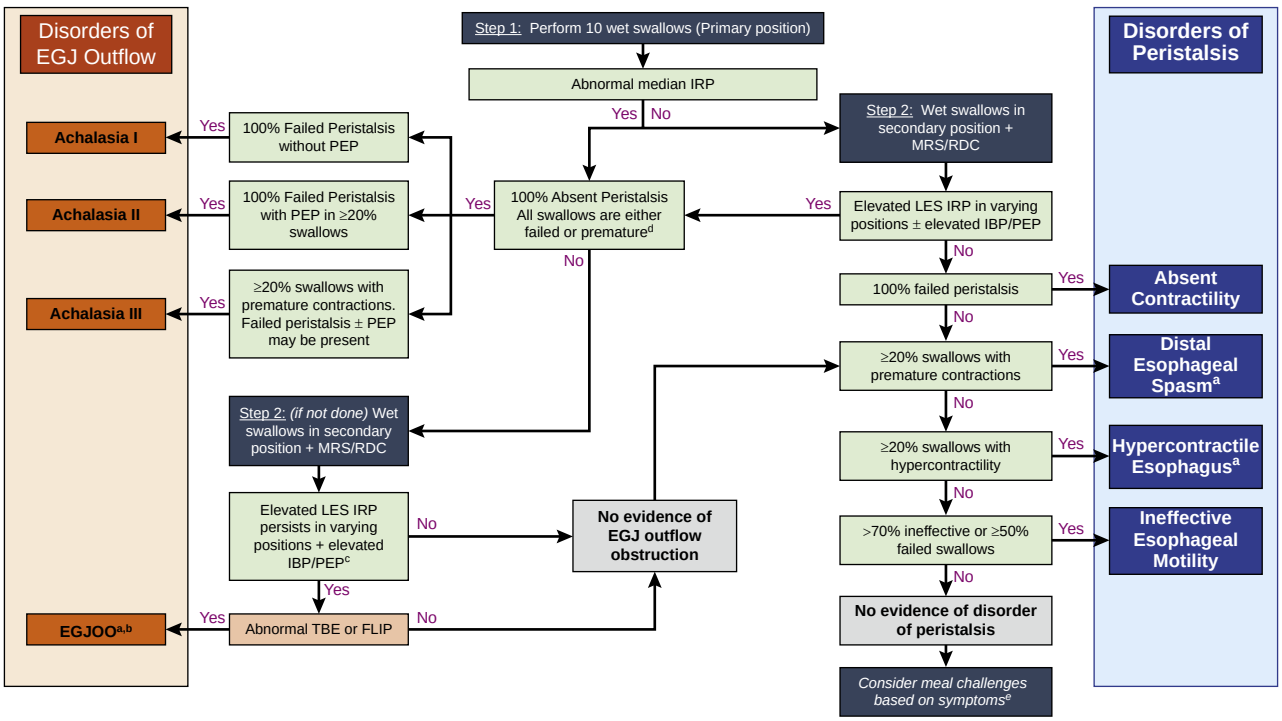

FIG. 1 Chicago Classification v4.0. *EGJ,* Esophagogastric junction; *EGJOO,* esophagogastric junction outflow obstruction; *IBP,* intrabolus pressure; *FLIP;* functional lumen imaging probe; *IRP,* integrated relaxation pressure; *LES,* lower esophageal sphincter; *MRS,* multiple rapid swallow; *PEP,* pan-esophageal pressurization; *RDC,* rapid drink challenge; *TBE,* timed barium esophagram. [a]Manometric patterns of unclear clinical relevance. [b]Patients with EGJOO may have features suggestive of achalasia or disorders of peristalsis. [c]RDC, solid test swallows, and/or pharmacologic provocation with amyl nitrite or cholecystokinin can be used to assess for obstruction. [d]Patients with previously defined absent contractility based on 10 swallows in the primary position may have achalasia if IRP is elevated in alternate position, with RDC, and/or with MRS. [e]A solid test meal can be added to rule out an obstructive pattern. *(From Yadlapati R, Kahrilas PJ, Fox MR, et al. Esophageal motility disorders on high-resolution manometry: Chicago classification version 4.0.* Neurogastroenterol Motil. *2021;33:e14058.)*

clinical relevance of esophagogastric junction outflow obstruction (EGJOO), hypercontractile esophagus, and distal esophageal spasm (DES) require corroboration by additional diagnostic testing or presence of associated symptoms. This chapter reviews nonachalasia disorders of esophageal motility according to the hierarchic analysis of the most current version of the Chicago Classification.

Esophagogastric Outflow Obstruction

EGJOO may be the result of intrinsic or extrinsic pathology, which highlights the importance of the comprehensive esophageal workup. Hiatal hernia, peptic stricture, a stiff esophageal body resulting from scarring or radiation, prior surgical interventions, pseudoachalasia resulting from malignancy, or vascular obstruction from a diseased aortic arch are potential sources of mechanical outflow obstruction (Fig. 2A). Prominent vascular artifact on manometry or a history suggestive of malignancy should prompt adjunct evaluation with endoscopic ultrasonography (EUS) or computed tomography. In a retrospective study, findings on selective EUS altered clinical management in as many as 15% of concerning cases. When other mechanical causes of esophagogastric outflow obstruction and achalasia have been ruled out, idiopathic cases remain. This is identified by incomplete relaxation of the EGJ, currently defined by HRM as elevated integrated relaxation pressure and elevated intrabolus pressure in the setting of preserved peristalsis (Fig. 2B), differentiating EGJOO from achalasia.

EGJOO was first introduced as a distinct entity in CC v3.0, and since that time nearly 10% of patients undergoing HRM have been found to have morphology that fits this description. It is hypothesized that EGJOO may represent an incompletely expressed or precursor variant of achalasia, but this has not been verified in large numbers of patients. Furthermore, findings on HRM may be related to artifact, mechanical effects, viral etiology, or opiate use without clinical significance. A notable update to CC v4.0 recommends that in addition to manometric findings of EGJOO, the diagnosis should be supported by both the presence of symptoms such as dysphagia or noncardiac chest pain, and evidence of obstruction on either timed barium esophagram, or real-time impedance evidence of obstruction with the use of a functional lumen imaging probe (FLIP). As opiate medications have been demonstrated to be associated with type III achalasia and EGJOO, it is also recommended that patients be off of these medications before HRM testing. There is controversy over surgical treatment of EGJOO, and the definition of obstruction continues to evolve with subsequent versions of the Chicago Classification. Cases previously classified as hypertensive lower esophageal sphincter (HTLES) by older versions of the Chicago Classification would now likely meet criteria for EGJOO. Interestingly, patients diagnosed with HTLES were found to have paradoxically elevated esophageal acid exposure about 25% of the time, despite relative EGJ obstruction. Therefore, treatment of patients in this group should be tailored based on symptoms. PPIs should be considered if GERD is the major complaint. If dysphagia without abnormal esophageal acid exposure is identified, then medications directed to esophageal smooth muscle relaxation can be attempted. Endoscopic pneumatic dilation (PD) or botulinum toxin (Botox) injections are moderately effective options for relief of obstructive symptoms. Surgical therapy may be indicated in cases of severe or refractory symptoms. Esophageal myotomy, fundoplication, or a combination of the two may be tailored to the patient's symptoms and objective pathophysiology. Antireflux surgery without myotomy has been found to achieve good long-term results for patients with reflux and mild EGJOO caused by acid-induced spasm and inflammation, although preoperative dysphagia was found to predict a higher rate of failure. With dysphagia as the primary symptom, and either treated or normal esophageal acid exposure, laparoscopic Heller myotomy with partial fundoplication and peroral endoscopic myotomy (POEM) have been used successfully. In disorders such as EGJOO that do not affect the

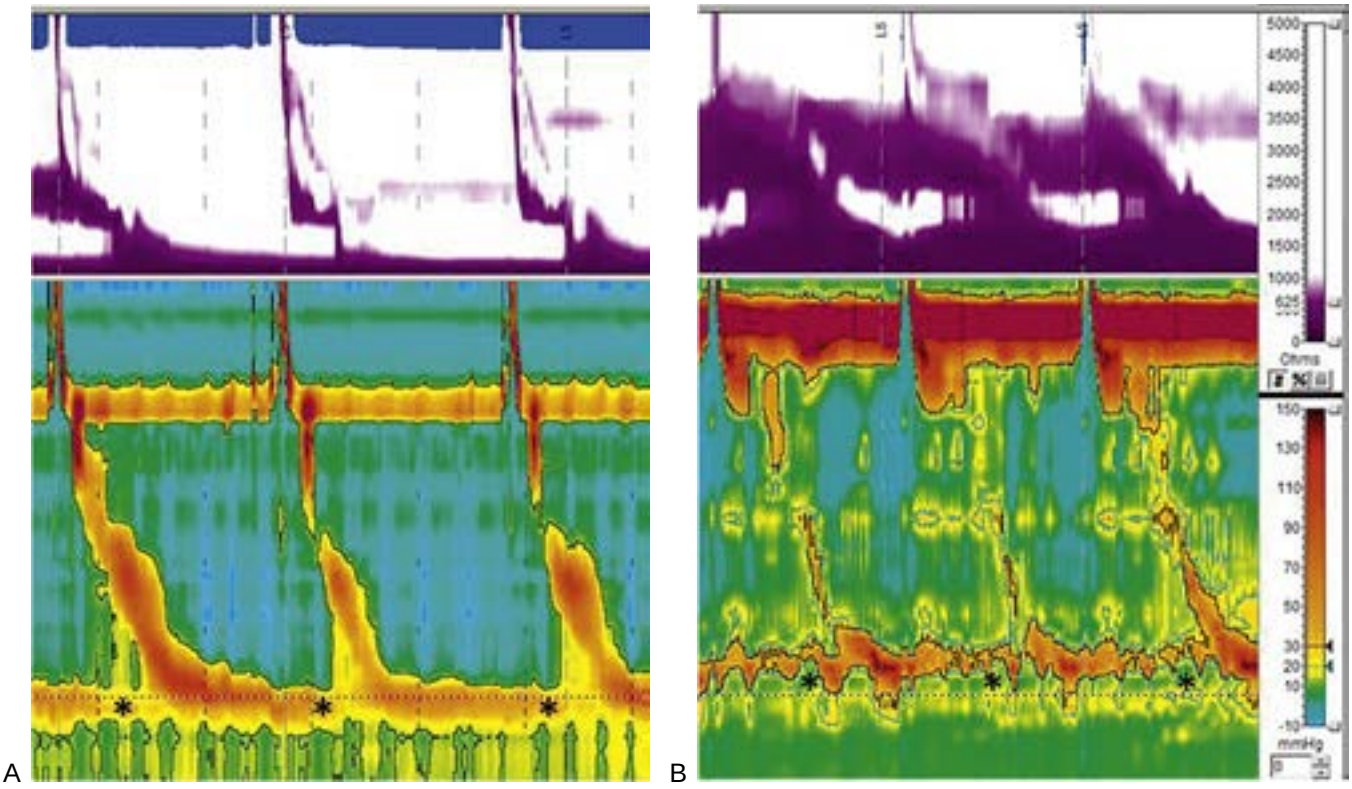

FIG. 2 Esophagogastric junction (EGJ) outflow obstruction. Note the high-pressure, nonrelaxing EGJ *(asterisks)*. **(A)** In this case caused by a hiatal hernia. **(B)** Idiopathic, in the setting of ineffective motility and incomplete bolus clearance. *(Courtesy The Oregon Clinic.)*

esophageal body, abdominal approaches for surgery are favored over thoracic approaches because adequate proximal dissection is possible without accessing the thoracic cavity. Abdominal fundoplication options also offer greater symptom relief and generally are considered less technically challenging.

Disorders of Peristalsis

This group of disorders was previously defined as major and minor esophageal motility disorders in older versions of the Chicago Classification. These disorders are considered when a disorder of esophagogastric outflow obstruction has been ruled out. This group of disorders includes manometric patterns of both hypercontractility and hypocontractility on HRM. Manometric findings may be present in the absence of clinical symptoms, and further supportive testing may be necessary before treatment.

Distal esophageal spasm (DES), also frequently referred to as *diffuse esophageal spasm,* is sometimes grouped with jackhammer esophagus or nutcracker esophagus and achalasia type III as hypercontractile or "spastic" motility disorders. The presence of clinical symptoms of chest pain, dysphagia, or regurgitation resulting from spastic contractions is required for the definition of DES as manometric findings of premature and spastic distal contractions may be seen in the absence of the disorder. The cause of DES is believed to be an impaired neurologic inhibitory pathway, allowing premature esophageal smooth muscle contractions. This disorder may overlap with or progress to achalasia. DES currently is defined by premature contractions in more than 20% of swallows with associated clinical symptoms including dysphagia and noncardiac chest pain. Premature contractions are indicated on HRM as a low distal latency, which is a truncated interval between initiation and deceleration of peristalsis (Fig. 3A). Barium esophagram classically shows a corkscrew pattern of simultaneous contractions, although this pattern is actually uncommon and not required for diagnosis (see Fig. 3B). Treatment options for DES vary. Patients initially may benefit from reassurance with dietary and behavioral modifications or pharmacologic therapy. Persistent cases may require endoscopic intervention with PD or Botox, or surgical myotomy of variable length, though these interventions are more successful in managing symptomatic dysphagia and less effective if the primary symptom is chest pain. Surgical approaches are discussed in more detail in the treatment section of the chapter.

Jackhammer esophagus was named to describe extreme hypercontractility and avoid confusion with DES. This cause of this disorder is believed to be excessive cholinergic drive, causing asynchronous contractions of circular and longitudinal muscle. *Jackhammer* is defined manometrically by at least two swallows with significant hypercontractile vigor as measured by a distal contractile integral (DCI) exceeding 8000 mm Hg • s • cm (Fig. 4A). The hypercontractile segment may involve the esophageal body or may be limited to the esophagogastric junction (EGJ), with EGJ relaxation pressure usually in the upper limit of normal.

Patients with jackhammer esophagus are consistently symptomatic with chest pain, dysphagia, or regurgitation. Nutcracker esophagus was first differentiated from jackhammer esophagus in the CC v3.0 as hypertensive peristalsis with DCI between 5000 to 8000 mm Hg • s • cm (Fig. 4B). Although some patients with DCI in this range are symptomatic, some symptom-free control patients also fall into this range. For this reason, the clinical relevance of nutcracker esophagus has been questioned. Further study of outcomes for these hypercontractile groups will be required with time. Treatment is aimed at controlling spasm and can include dietary and behavioral modifications, pharmacologic therapy, or endoscopic or surgical treatments, which are subsequently discussed.

Peristaltic, vigorous contractions with DCI 5000 to 8000. DCI, Distal contractile integral. *(Courtesy The Oregon Clinic.)*

The Chicago Classification additionally addresses clinical entities of absent contractility and ineffective esophageal motility. Absent contractility is defined as HRM with hypocontractility and failed peristalsis in 100% of swallows in the setting of an EGJ with normal relaxation pressure. Premature hypocontractile swallows with failed peristalsis are grouped here. In cases with borderline EGJ relaxation and evidence of esophageal pressurization, achalasia should be considered and the patient managed accordingly.

Systemic sclerosis (scleroderma) falls into the *absent contractility* category (Fig. 5). This figure demonstrates complete hypocontraction of esophageal smooth muscle, with preserved skeletal muscle contraction in the upper esophageal sphincter and diaphragm. Therapeutic options specific to diminished esophageal motility are limited, so treatment is directed primarily at the underlying systemic disorder as well as relief of symptoms. Unfortunately, no specific pharmacologic therapy improves contractility and function of esophageal smooth muscle. Prokinetic agents are fraught with side effects and are primarily avoided. GERD has been identified frequently in these patients and should be treated aggressively with PPIs. Antireflux surgery can be considered carefully for refractory GERD cases in this setting, but it should be approached with caution at the risk of exacerbating dysphagia. Because connective tissue disorders such as scleroderma also can affect gastric motility, one should be aware that GERD symptoms may be a result of overflow reflux and should not be treated by fundoplication alone. A small retrospective review of scleroderma patients treated with fundoplication or Roux-en-Y gastric bypass (RYGBP) revealed improvement in control of reflux and dysphagia in the RYGBP group compared with fundoplication. In very carefully selected cases, RYGBP may be considered for primary management of refractory GERD in scleroderma. Less-invasive endoscopic procedures such as suture plication or radiofrequency ablation may be more appealing for GERD in such fragile patients but are less effective at reducing reflux.

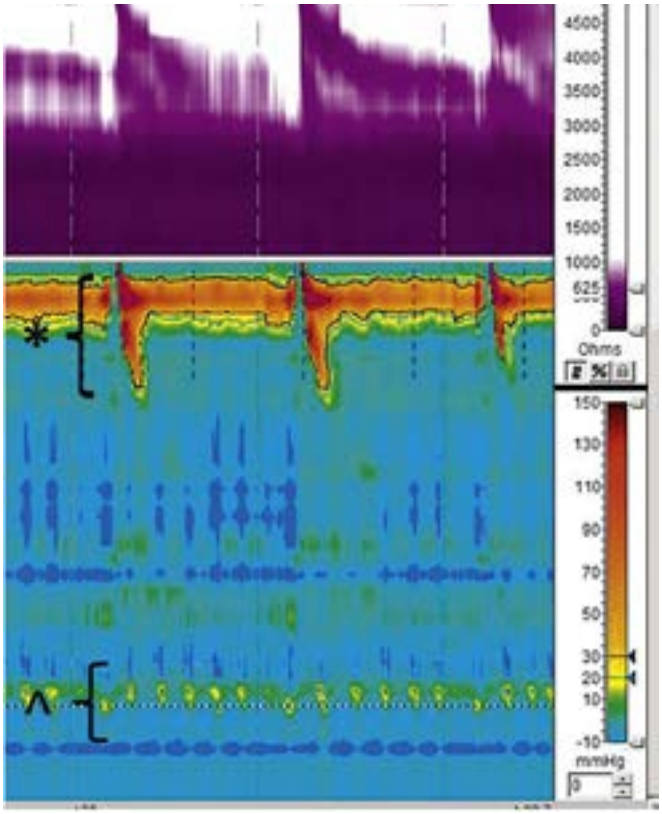

FIG. 5 Absent contractility. This is a case of scleroderma with complete hypomotility of esophageal smooth muscle; note preserved function of skeletal muscle of the upper esophageal sphincter *(asterisk)* and diaphragm *(circumflex)*. *(Courtesy The Oregon Clinic.)*

Ineffective esophageal motility (IEM) is a minor esophageal motility disorder defined by a significant number of weak or failed swallows. Presentation may include heartburn and regurgitation with or without dysphagia, and symptoms tend to be mild. GERD often plays a significant role in the underlying cause of IEM because many of these patients are found to have underlying abnormal esophageal acid exposure. IEM is redefined by HRM criteria in CC v4.0 as at least 50% failed peristalsis, or more than 70% ineffective swallows. Ineffective swallows are indicated by DCI less than 450 mm Hg • s • cm, failed peristalsis indicated by DCI less than 450 mm Hg • s • cm, or fragmented peristalsis (Fig. 6). Interestingly, symptom-free healthy patients may also exhibit a manometric pattern consistent with IEM. In the patient with IEM, the manometry technician may elect to perform additional provocative testing with multiple repetitive swallow (MRS) assessment. Deglutitive inhibition of the esophageal body and EGJ occurs during MRS, usually followed by augmented esophageal contraction vigor and improved bolus transit. Augmented contraction with MRS may be reassuring to the physician who is considering an antireflux procedure to treat underlying GERD while avoiding iatrogenic postoperative dysphagia. When MRS does not augment subsequent contraction, it is predictive of late dysphagia after fundoplication. Although evidence would indicate that there is a relatively low risk of postoperative dysphagia with Nissen fundoplication for patients with IEM, many surgeons choose to carefully tailor a partial fundoplication to avoid the risk of postoperative dysphagia. Clinical implications of MRS findings in this setting have yet to be defined clearly and require further study because these provocative maneuvers are used more frequently with HRM.

Therapeutic options are limited for IEM patients. Because many, if not most, IEM cases are related to chronic reflux disease, correction of GERD may result in correction of the motility disorder. Reassurance and antacid medications along with dietary and behavioral modifications may be helpful. As in other motility disorders, prokinetic drugs generally are not recommended. Low-dose antidepressants, especially tricyclic antidepressants or trazodone, may reduce functional chest discomfort, heartburn, and globus sensation but may not be effective for dysphagia.

Nonoperative Management

The main goals of any treatment for patients with esophageal motility disorders include reduction of chest pain and dysphagia. Treatment is focused on reducing spasm, GERD, and outflow obstruction to facilitate esophageal emptying. Reassurance alone can be beneficial. Reassurance not only helps relieve anxiety but also has been shown to reduce the severity of chest pain and the frequency of healthcare use.

Dietary and Behavioral Modifications

Dietary and behavioral modifications can be very helpful for avoiding chest pain or dysphagia. These modifications include sitting upright and allowing plenty of time for meals, taking small bites, chewing thoroughly, and taking sips of liquid between bites. Foods such as bread, meat, and rice are notorious for worsening dysphagia and should be ingested with caution or minimized. Extremely hot or cold foods can exacerbate esophageal spasm. Choosing soft or liquefied foods can be helpful during symptom flares.

Pharmacologic Therapy

Before pharmacologic therapy is initiated, it is important to carefully review the patient's home medications and minimize those that affect esophageal motility. DES in particular is associated with chronic opioid use and has been shown to improve with opioid cessation. A few classes of drugs have been used with some success in providing symptomatic relief of esophageal spasm. Smooth muscle–relaxing agents (nitrates or calcium channel blockers) taken 15 minutes before meals may provide some symptomatic relief in spastic or hypercontractile disorders, including DES, some cases of EGJOO,

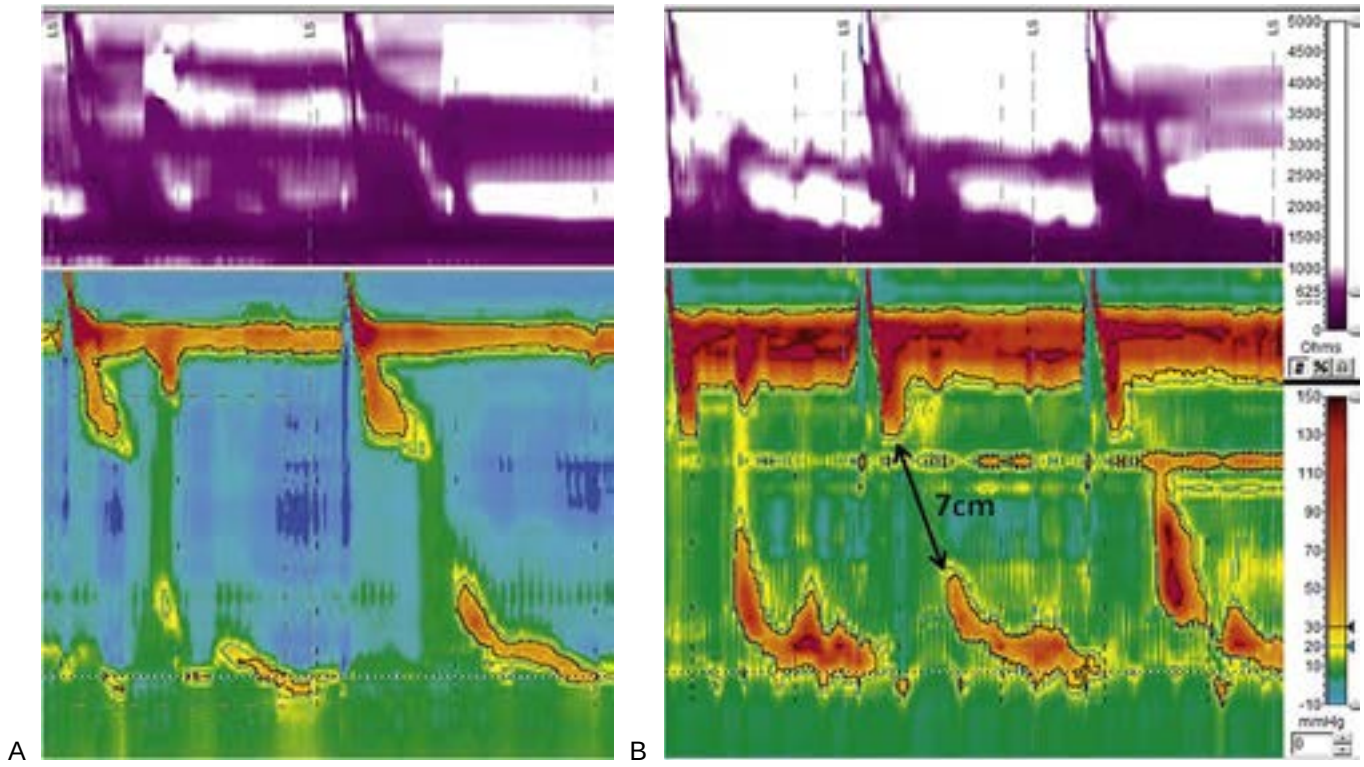

FIG. 6 Minor disorders of peristalsis. **(A)** Ineffective esophageal motility, weak peristalsis (DCI <450). **(B)** Fragmented peristalsis. Large breaks (>5 cm) with preserved contractile vigor (DCI >450). *DCI,* Distal contractile integral. *(Courtesy The Oregon Clinic.)*

and jackhammer esophagus. Phosphodiesterase-5 inhibitors such as sildenafil, which acts by blocking degradation of nitric oxide, also can be effective. These drugs may be tolerated poorly because of lightheadedness, headache, or other side effects, and tachyphylaxis has been noted. The cost of sildenafil may be prohibitive, and effects of daily long-term use of this agent in various populations of patients are unknown. Low-dose antidepressants, including tricyclic agents and trazodone, may provide pain modulation and anxiety relief for noncardiac chest pain. As previously discussed, GERD is frequently part of the clinical syndrome of esophageal dysmotility, although its role in pathogenesis is not understood completely. A trial of PPIs is warranted and may help reduce inflammation, pain, and spasm related to abnormal esophageal acid exposure.

Endoscopic Therapy

PD has been used to treat spastic esophageal motility disorders affecting the EGJ, including EGJOO, DES, and nutcracker esophagus, with variable success. In small studies, 26% to 70% of DES and nutcracker patients had a favorable response with PD, although there is concern that some of these cases may have been classified more accurately as achalasia. From the achalasia literature, there is a known risk of perforation with pneumatic dilation in the range of about 2% to 5% of cases performed by expert endoscopists. This rate of perforation is unacceptable to many endoscopists, who no longer use PD as first-line therapy.

Endoscopic injection of botulinum toxin (Botox) may be temporarily effective in relief of spasm in EGJOO, DES, or jackhammer disorders. The technique for administration of botulinum toxin has not been standardized; some report injection of the EGJ alone, and others include the esophageal body. Botox to the esophageal body may be helpful in cases such as DES or jackhammer, although it is uncertain exactly where and how much drug should be injected. Infection is an uncommon but serious risk of Botox injections. One death resulting from mediastinitis has been reported in a DES case treated with Botox, although other serious adverse events have been rare. Endoscopists may elect to use EUS to guide positioning and depth of injections into the thinner-walled esophageal body. In small studies of patients with EGJOO and DES, successful relief of symptoms with botulinum toxin injections was achieved in more than 50% of patients at 6 months, with further improvement from serial on-demand treatments thereafter. This was comparable to efficacy in achalasia. Fall-off of symptom relief is present in each of these disorders with time, which may require repeat treatments or escalation to surgical intervention. Prominent symptoms and spastic features may predict early recurrence of symptoms. Botulinum toxin before surgical myotomy has been noted to cause submucosal fibrosis and increase difficulty in identifying and maintaining the proper dissection plane. Prior Botox is not an absolute contraindication to surgery, however, and may be useful as a trial to determine if a patient may respond well to surgical myotomy. Long-term studies are not available evaluating the efficacy of repeated botulinum toxin injection for spasm.

Surgical Management

Surgical therapy is an option for nonachalasia esophageal motility disorders, but optimal timing and approach are controversial. Surgery generally has been reserved for medically refractory cases because outcomes are variable, somewhat unpredictable, and may be associated with surgical morbidity. As mentioned earlier, IEM patients with GERD, whether they also have dysphagia, tolerate antireflux surgery with a tailored fundoplication well, and treatment of the reflux often corrects the motility disorder as well. Classically, these patients have a partial fundoplication, most commonly a 270-degree posterior wrap (Fig. 7). Nissen fundoplication also has been shown to be well tolerated in select patients; a full wrap should be reserved for IEM patients with minimal symptoms of dysphagia before surgery and significant reflux disease. Endoluminal antireflux procedures such as Stretta (radiofrequency) and transoral incisionless fundoplication, which provide less-aggressive valve reconstructions, also may be good options for these patients.

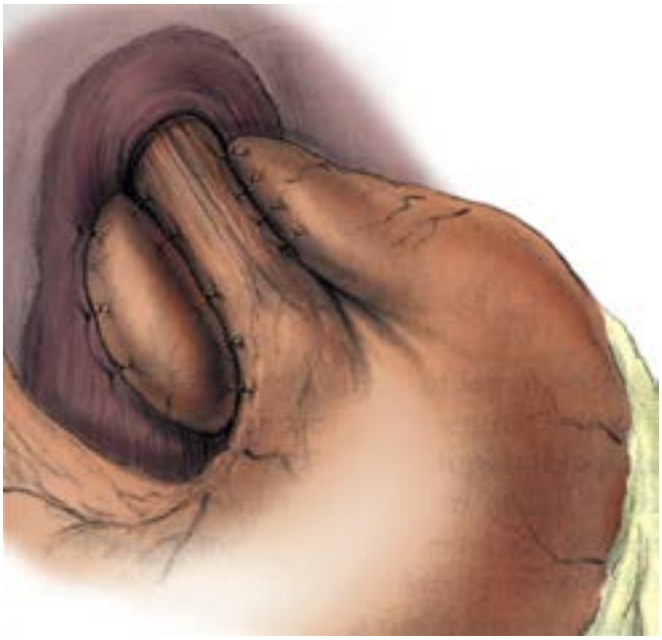

FIG. 7 Completed laparoscopic 270-degree posterior Toupet fundoplication.

Data on surgical outcomes for EGJOO, DES, and other hypercontractile disorders are limited to a few series, mostly small and nonrandomized over the past 50 years. As diagnostic modalities have improved and disease classifications have evolved, these data become even more difficult to interpret. In general, outcomes for surgery are better for relief of chest pain and dysphagia compared with medical or endoscopic therapies. In DES, which is the most frequently studied esophageal motility disorder aside from achalasia, favorable symptomatic outcomes are reported in about 70% of cases treated with surgical myotomy via an abdominal or thoracic approach at highly skilled centers. These outcomes are notably less successful than those for surgical myotomy for achalasia, so surgery often is reserved as a last resort for patients with nonachalasia motility disorders. Symptoms of chest pain are less reliably improved than dysphagia in these patients, and prior series have reported only 50% reduction in chest pain for patients with nutcracker esophagus. Therefore, many of these patients endure long courses of medical or endoscopic therapy because there is no clear definition of "medical failure."

Surgical techniques for esophageal myotomy are varied. Traditional open surgery largely has been replaced by minimally invasive techniques, and new endoscopic options are available. Length of the esophageal body myotomy, inclusion of the EGJ in the myotomy, and addition of a concomitant antireflux procedure are variable from surgeon to surgeon. Previous authors in this text have recommended a long thoracic myotomy for the treatment of DES or other esophageal body motility disorders and have described the technique in detail (Fig. 8). Thoracic access allows myotomy extension for the full length of the esophageal body, which is not possible with laparoscopic Heller myotomy. However, thoracic myotomy has the disadvantage of requiring single lung ventilation, chest tube placement, and typically a longer length of stay. The thoracic approach is complicated further if the surgeon desires a fundoplication or extended gastric myotomy.

POEM offers several advantages for esophageal myotomy and is preferred as a less invasive technique for patients with hypercontractile/spastic esophageal motility disorders. This natural orifice transluminal endoscopic surgery procedure is completely endoscopic

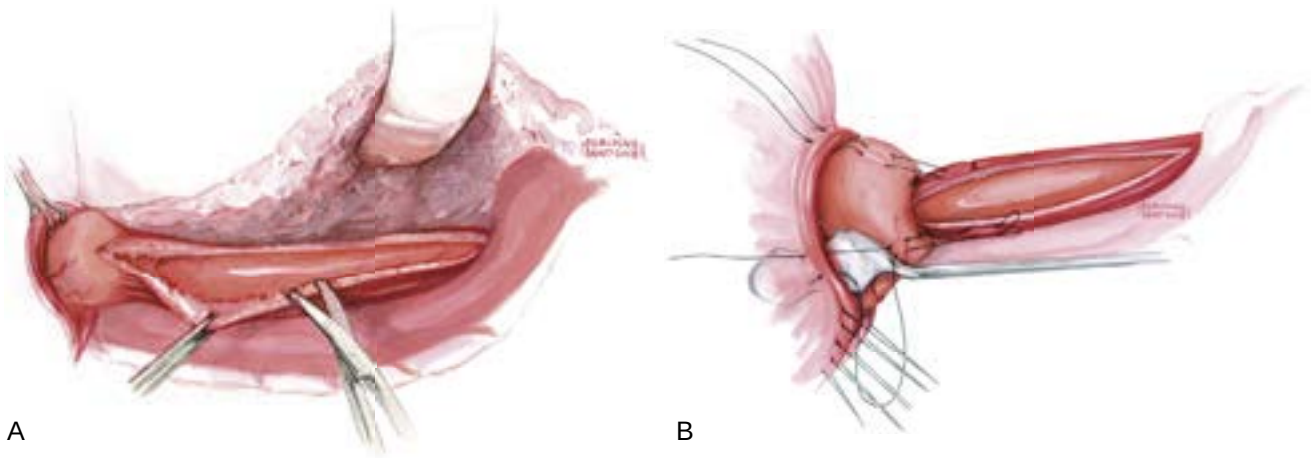

FIG. 8 (A) Thoracic myotomy and **(B)** Belsey fundoplication. Courtesy Corinne Sandone. *(From Cameron JL, Sandone C.* Atlas of Gastrointestinal Surgery, *vol 1. 2nd ed. Shelton, CT: People's Medical Publishing; 2007.)*

and incisionless. It provides the ability to tailor the length and location of the myotomy with ease because the entire affected esophageal body and EGJ are accessible. POEM allows the surgeon to produce a selective circular myotomy and avoids the risk of vagus nerve injury or disruption of the diaphragmatic crural component of the EGJ. Single lung ventilation, lateral or prone positioning, and chest tubes are not required. Moreover, postoperative pain is usually minimal.

POEM was first applied clinically for achalasia by Inoue in 2008, and since then more than 4000 cases have been performed worldwide with an excellent safety profile and good clinical results, mostly for patients with achalasia. Until recently, studies of POEM for nonachalasia esophageal motility disorders included only a few such cases and have not always been stratified by subtype. POEM is also used for spastic esophageal disorders such as DES, jackhammer esophagus, and EGJOO (including cases of nutcracker esophagus and HTLES as classified before CC v3.0) with favorable results. POEM has reported success rates of more than 80% for these disorders with relatively low morbidity at expert centers. In a meta-analysis by Khan et al. examining the clinical success of POEM in spastic esophageal disorders including type III spastic achalasia, DES, and nutcracker esophagus, 179 patients were pooled for analysis from 8 observational studies. Clinical success for all types of spastic esophageal disorders was 87%. Although these studies are small, they suggest comparable outcomes for extended POEM with low morbidity compared with traditional open or laparoscopic/thoracoscopic approaches for extended esophageal myotomy.

Given the subsequent weakening of peristalsis after esophageal body myotomy, it is recommended to extend the myotomy through the EGJ onto the stomach to prevent relative outflow obstruction and postoperative dysphagia, even in the setting of a normally relaxing EGJ. POEM myotomy length should be tailored based on HRM topography and endoscopic measurement of the high-pressure zone and has been extended proximally anywhere between 6 and 23 cm above the gastric cardia in such cases. POEM with variable length of myotomy was comparable to other surgical techniques for relief of dysphagia and chest pain and had less morbidity.

A disadvantage of POEM is the requisite learning curve, which is about 20 cases for experienced endoscopists as demonstrated by Kurian and colleagues. GERD is also a long-term risk of POEM, currently with a 20% to 46% risk based on cumulative data. This is in fact comparable to Heller myotomy with partial fundoplication, which has a postoperative rate of GERD between 21% and 42%, depending on the fundoplication technique. Postoperative GERD is asymptomatic in one-half of patients, so routine follow-up pH testing or endoscopy is prudent. Patients identified with GERD have been treated successfully with PPIs with avoidance of long-term sequelae of reflux thus far. POEM results in a low rate of clinically significant leak or stricture and has been shown to be safe and effective in revision after Heller myotomy, Botox, and PD. POEM does not preclude subsequent endoscopic, laparoscopic, or thoracoscopic procedures should they be required. Because of these benefits, extended myotomy by POEM should be the preferred approach for primary spastic motility disorders requiring intervention.

Peroral Endoscopic Myotomy Operative Technique

Previous chapters in this and other texts have described esophageal myotomy with or without fundoplication via abdominal and thoracic approaches, so these are not repeated in detail here.

POEM is performed in the operating room under general anesthesia. The procedure requires a high-definition endoscope for optimal visualization and CO_2 insufflation because it has a better safety profile than room air. The patient is placed in the supine position to allow access to the abdomen or chest. For a few days before the procedure, patients are given a Nystatin rinse prophylactically to clear any *Candida* esophagitis related to esophageal stasis and allowed only a liquid diet for 1 day to allow clearance of retained food. A preoperative antibiotic and a single preoperative dose of intravenous steroid are administered to prevent development of mucosal edema.

Upper endoscopy is performed to evaluate the anatomy, rule out *Candida* spp., and clear any fluid or food debris within the esophagus before proceeding. An endoscopic functional lumen imaging probe (EndoFLIP) is used to measure baseline esophageal diameter, pressure, cross-sectional area, distensibility, and compliance. An overtube is used for distal myotomy to stabilize the scope from overtorquing. No overtube is used for extended myotomy. The gastric wall is tattooed with indigo carmine 2 cm distal to the EGJ in the anterior position along the lesser curvature, marking the target for the distal extent of the myotomy. The location and extent of the myotomy and mucosotomy are calculated based on careful evaluation of the preoperative manometry and intraoperative evaluation of the high-pressure zone. An angled dissecting cap is attached to the high-definition endoscope to facilitate dissection and visualization. A mucosal lift is created with injectable saline with dilute indigo carmine in the anterior esophagus 2 to 4 cm proximal to the proximal extent of the planned myotomy (Fig. 9).

An endoscopic cautery knife is used to create a 1.5-cm longitudinal mucosal incision to expose the submucosa. Using the dissecting cap, the surgeon advances the endoscope through the mucosotomy and into the submucosal plane. Once inside, spray cautery and serial injections of lifting solution are used to create a submucosal tunnel, separating the mucosa from the circular muscle. Visible vessels are coagulated with the dissecting knife or grasped with hot biopsy

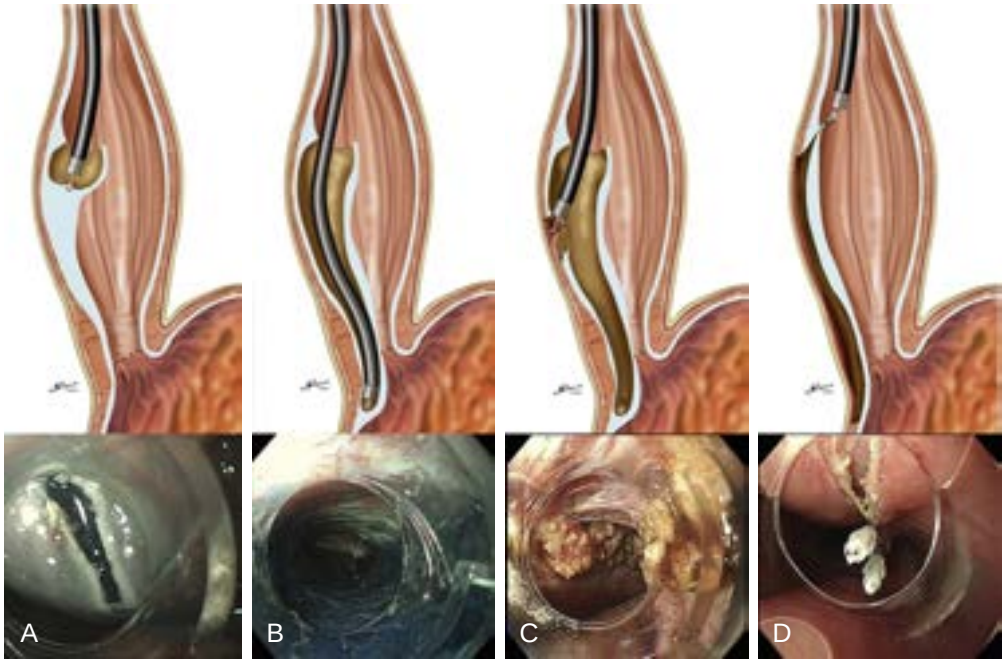

FIG. 9 Peroral endoscopic myotomy. **(A)** Entry into submucosal plane. **(B)** Creation of submucosal tunnel (mucosa is inferior, circular muscle is superior). **(C)** Myotomy of circular muscle. **(D)** Closure of mucosal entry site with clips. *(From Inoue H, Sato H, Ikeda H, et al. Per-oral endoscopic myotomy: a series of 500 patients.* J Am Coll Surg. *2015;221:256–264).*

forceps. The submucosal tunnel is extended distally across the GEJ and onto the gastric wall until the distal darker blue tattoo is reached.

Once satisfied with the extent of the tunnel, the endoscope is brought back, and the myotomy is created by selectively dividing the circular muscle layers. The thin longitudinal muscle layer is left intact whenever possible. Full-thickness breaches of the muscle are usually not critical as the mediastinal adventitial tissue is left intact. The myotomy is extended across the EGJ and onto the proximal gastric wall. During the procedure, exiting the tunnel to deflate insufflated gas from the stomach may be required to relieve gastric distension. Capnoperitoneum may develop in up to 30% of cases; it is often minor and self-limited but is evacuated easily with a Veress needle if abdominal overdistension or respiratory compromise develops.

After the myotomy is completed, the surgeon withdraws the endoscope, checking for hemostasis. Completion endoscopy identifies any inadvertent mucosal injuries, which are treated with endoscopic clips. The EndoFLIP catheter is replaced, and measurements are compared with those obtained before surgery to ensure adequacy of the myotomy before closure. Endoscopic clips then are used to close the proximal mucosotomy in a longitudinal fashion from distal to proximal.

Postoperative Care

The patient is kept NPO overnight, and a routine contrast esophagram is obtained on the first postoperative day. If no leaks or obstruction are identified, the patient is allowed clear liquids and crushed medications. The patient may be discharged on postoperative day 1 if liquids are tolerated and should maintain a puree-consistency diet for 1 week to avoid disruption of the mucosal closure clips. In most cases, postoperative pain is minimal and usually does not require narcotics.

Complications

Acute postoperative complications can include intratunnel bleeding, mucosal leak or dehiscence, or mediastinitis. No deaths have been reported. Bleeding may require transfusion and repeat endoscopy to achieve hemostasis. Mucosal leaks or dehiscence may seal with conservative management but often require repeat endoscopy and repair with additional clips or suturing. Mediastinitis is treated with antibiotics and may require percutaneous or surgical drainage. Postprocedure adverse events in the meta-analysis reported by Khan et al. for all types of spastic esophageal disorders were 14%. Most of the adverse events (74%) were managed conservatively. Five patients required prolonged hospitalization and/or an intervention for pneumothorax, pulmonary embolism, capnoperitoneum, or bleeding.

CONCLUSION

There is work to be done in the realm of nonachalasia esophageal motility disorders as HRM diagnostics and treatment options evolve. To achieve the best possible outcome, therapeutic options should be considered carefully and individually tailored. Patients should be advised on expectations because treatment outcomes are somewhat unpredictable and may be disappointing in some cases. POEM is a promising, minimally invasive treatment option for hypercontractile and spastic disorders and perhaps will be considered as an early surgical intervention rather than salvage therapy, given its relative success and safety profile. For hypomotility disorders associated with GERD, partial fundoplications remain the gold standard, although Nissen fundoplication also has been shown to be well tolerated in many cases of at least partially preserved peristalsis. There also may be a role for newer endoscopic antireflux procedures, although there are insufficient data at this time to define their application for these relatively rare disorders.

Management of Esophageal Cancer

Fatima G. Wilder, MD, and Stephen C. Yang, MD

EPIDEMIOLOGY

Esophageal cancer is the eighth deadliest cancer in the world as reported by the World Health Organization in 2020. The two predominant histologic types are adenocarcinoma (most common in the United States) and squamous cell carcinoma (most common worldwide). Notable risk factors include gastroesophageal reflux, smoking, alcohol consumption, nutritional deficiencies, environmental carcinogens, long-standing achalasia, and caustic injury.

CLINICAL PRESENTATION

Commonly reported symptoms at the time of presentation include regurgitation, odynophagia, weight loss, and hematemesis. Dysphagia is the most common presenting symptom in patients with esophageal cancer. In the early phases of obstruction, patients typically compensate for their symptoms by adjusting their diet and consuming semisolid and liquid nutrition as tolerated. Dysphagia does not typically present until the tumor occludes two-thirds of the lumen. A notable component of the patient's past medical history is often a long-standing history of gastroesophageal reflux disease with or without a hiatal hernia. Due to the fact that symptoms often present late, patients are typically at an advanced stage at the time of diagnosis. However, those with a history of reflux disease may be diagnosed earlier on surveillance endoscopy.

DIAGNOSIS/STAGING

Diagnosis and staging should be carried out in an expeditious manner to avoid delay in therapy, potentially compromising outcome. The eighth edition of the American Joint Committee on Cancer (AJCC) staging of epithelial cancers of the esophagus and esophagogastric junction (EGJ) presents separate classifications for clinical (cTNM), pathologic (pTNM), and postneoadjuvant (ypTNM) stage groups, and differs slightly between adenocarcinoma and squamous cell histologies (Fig. 1).

Barium swallow should be the first study in the diagnostic workup of esophageal cancer, as it will provide critical information regarding the source of obstruction. However, esophagogastroduodenoscopy (EGD) remains the gold standard for evaluation and tissue diagnosis when there is a concern for malignancy. It allows for identification of anatomical location of the mass, tumor characteristics, relation to surrounding structures, and tumor grade. Evidence of Barrett's esophagus should be characterized according to the Prague criteria.

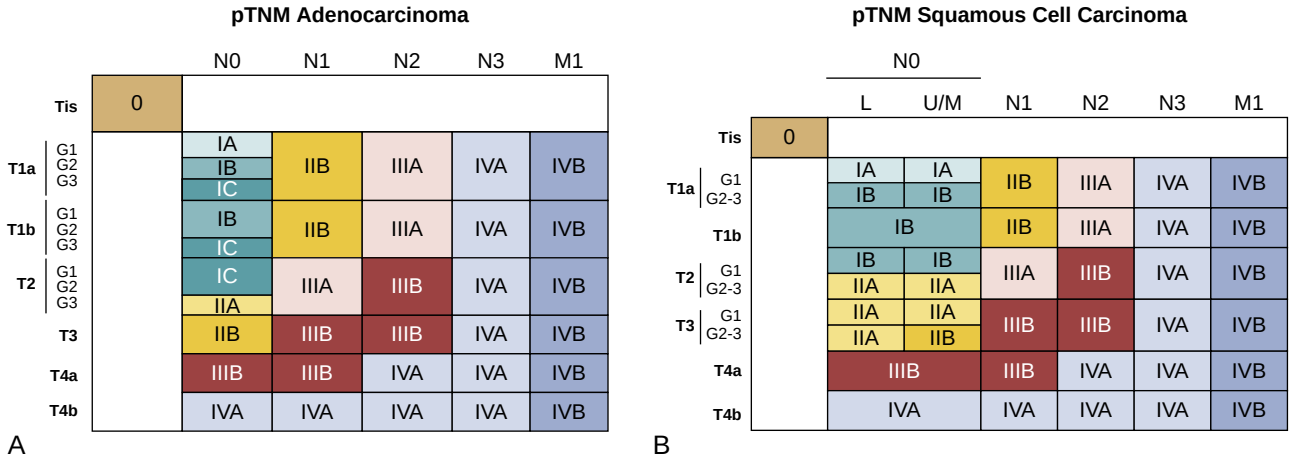

FIG. 1 Staging of esophageal cancer, American Joint Committee on Cancer Manual, eighth edition. Pathologic stage groups (pTNM) for **(A)** adenocarcinoma and **(B)** squamous cell carcinoma. *(From Rice TW, Ishwaron H, Ferguson MK, Blackstone EH, Goldstraw P. Cancer of the esophagus and esophagogastric junction: an eighth edition staging primer. J Thoracic Oncol. 2017;12[1]:36–42.)*

TABLE 1 Siewert Classification

Siewert Type	Description
I	Adenocarcinoma of the lower esophagus with the epicenter located within 1 to 5 cm above the anatomic GEJ
II	True carcinoma of the cardia with the tumor epicenter within 1 cm above and 2 cm below the EGJ
III [Considered gastric cancer; utilize gastric cancer algorithm for management guidelines]	Subcardial carcinoma with the tumor epicenter between 2 and 5 cm below the EGJ, which infiltrates the EGJ and lower esophagus from below

All suspicious lesions should be biopsied simultaneously. Based on the Seattle protocol, six to eight four-quadrant biopsies of the mass utilizing standard size endoscopy forceps should be obtained along every centimeter of gross disease.

If available at the time of EGD, endoscopic ultrasound (EUS) is important as an early staging modality and to determine the Siewert classification (Table 1), as location will determine optimal treatment pathways. EUS will also assess tumor invasion (T stage), presence of suspicious lymph nodes (N stage), and, at times, presence of regional metastases (M stage). The addition of fine-needle aspiration (FNA) aids in the accuracy of diagnosis.

Endoscopic mucosal resection (EMR) can be considered therapeutic especially in patients with early-stage disease (T1a or T1b). This typically correlates with small, nodular lesions ≤2 cm. Focal nodules should be completely excised and sent for pathology. Tumor samples should be assessed for depth of invasion, degree of differentiation, and presence of vascular and/or lymphatic invasion. Presence of poor differentiation, deep submucosal invasion, and/or lymphovascular invasion (LVI) are associated with greater risk of lymph node involvement.

Additional workup including computed tomography (CT) of the chest, abdomen, and pelvis with oral and IV contrast is indicated to evaluate for metastatic disease, assess the locoregional extent of the disease, and evaluate for issues of unresectability. CT is poorly sensitive for early-stage disease, type of Siewert location, and limited in its ability to distinguish T3 from T4 lesions. However, esophageal thickening of more than 5 mm clearly is considered abnormal. Whole body ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET)/CT is done to assess for metastatic disease. In patients with tumor that is at or above the carina, with no evidence of M1 disease, bronchoscopy should be performed.

Symptom management in the preoperative settings includes esophageal dilation for those with obstructive symptoms. Tumor ablation with Nd:YAG laser, photodynamic therapy (PDT), and cryoablation can be utilized for long-term ablation. Expandable metal or plastic stents can also be utilized to relieve obstructive disease but should not be placed if radiation therapy is offered for local control.

STAGE-BASED TREATMENT STRATEGIES/ ALGORITHMS

There are subtle differences in the treatment of esophageal cancer based on stage depending on the histology; these are briefly listed in Table 2.

T1 tumors involving the mucosa and superficial submucosa may be addressed with EMR or endoscopic submucosal dissection; deeper submucosal lesions may be treated with esophagectomy. Data regarding treatment of squamous cell carcinoma with EMR are limited.

Optimal management of T2N0M0 disease is somewhat controversial. Due to unreliable clinical staging modalities, a significant percentage of patients are under- and overstaged. Although historical evidence supports induction therapy for this group, there are a growing number of studies that suggest induction therapy is not beneficial in those with node-negative disease. Current NCCN guidelines suggest that, for patients who are medically fit, there are a variety of treatment possibilities including definitive chemoradiation and esophagectomy with or without induction or adjuvant therapy.

Treatment selections also take into consideration low- versus high-risk lesions. cT1b-cT2, N0 low-risk lesions that are <3 cm in size and well-differentiated should be resected with esophagectomy (including for noncervical squamous cell cancer). Generally, higher risk lesions (LVI, ≥3 cm, poorly differentiated), cT1b-cT2N+, or cT3-cT4aN+ should undergo preoperative chemoradiation (for noncervical squamous cell) or definitive chemoradiation (for cervical squamous cell). In patients with adenocarcinoma, preoperative

TABLE 2 Treatment Strategies for Adenocarcinoma and Squamous Cell Carcinoma in Medically Fit Patients

Adapted from National Comprehensive Cancer Network treatment guidelines, August 3, 2021.

chemoradiation is preferred. Definitive chemoradiation should be reserved for patients who decline surgery, have poor performance status, and those with bulky, multistation nodal involvement.

Approximately 32% of patients with esophageal cancer are found to have regional disease at the time of diagnosis. Survival is found to only be in the 10% to 30% range. Management of patients with T3-4aN0, T1-4aN1M0 is highly variable. NCCN guidelines suggest a variety of combinations of esophagectomy and chemoradiation as opposed to definitive chemoradiation. Recent studies suggest that induction chemoradiation followed by surgery is the optimal treatment for patients with T3-4a tumors or nodal disease. Additionally, a recently published randomized trial demonstrated a survival benefit to induction chemoradiation after surgery compared with surgery alone for esophageal or EGJ cancer.

OPERATIVE APPROACHES TO ESOPHAGEAL CANCER

Surgical Resection

Before any operative planning, patients should be assessed for their ability to undergo general anesthesia and major surgery. One must take into account a patient's age and performance status in making this decision. Although no defined number of lymph nodes has been definitively established, NCCN guidelines suggest that patients who have not received induction chemoradiation should have at least 15 lymph nodes resected and assessed for adequate staging. Cervical or cervicothoracic esophageal carcinomas located less than 5 cm from the cricopharyngeus should be treated with definitive chemoradiation. Consideration should be given to placement of a feeding tube (jejunostomy tube preferred) before induction therapy if the patient is near totally obstructed and cannot tolerate any oral liquids.

Approaches to resection of esophageal cancer include (open versus minimally invasive) Ivor Lewis, McKeown, transhiatal, or left transthoracic/thoracoabdominal approach with the anastomosis in the chest or neck. Selection of the operative approach depends on tumor location and surgeon expertise. Options for a conduit are the stomach (preferred), colon, or jejunum. NCCN guidelines recommend definitive chemoradiotherapy for patients with cervical esophageal squamous cell carcinoma. Minimally invasive techniques include laparoscopy, thoracoscopy, and robotic approaches; there are hybrid approaches that combine open/minimally invasive, but available data show no superiority for any specific technique.

Ivor Lewis Esophagectomy

Ivor Lewis esophagectomy is the most commonly performed method of esophageal resection worldwide in patients with esophageal cancer. Although open resection is still utilized by some, minimally invasive esophagectomy (MIE) has rapidly become the more common approach. Data have suggested decreased morbidity and faster recovery times with this approach when compared with open resection. Ivor Lewis esophagectomy is ideal for intraabdominal and intrathoracic exposure in patients with cancer in the mid- and distal esophagus. With either the open or minimally invasive approach, resection begins with the patient in the supine position. In MIE, the patient is placed in a split-leg position with moderate reverse Trendelenburg. Intraperitoneal access is obtained by standard upper midline laparotomy for open resection. In the MIE approach, five intraabdominal ports and an atraumatic liver retractor for the left hepatic lobe are positioned to expose the hiatus. The intraperitoneal space should be carefully inspected to rule out any metastatic disease. Once this is confirmed, dissection is started at the gastrohepatic ligament, exposing the right crus. Care is taken to preserve a large accessory or replaced left hepatic artery. A complete D2 lymph node dissection is performed starting at the celiac trunk and following the hepatic and left gastric artery, the superior margin of the portal vein, and the peripancreatic tissue. The left gastric vascular pedicle is divided with a stapling device or suture ligation. A thorough node dissection is particularly important for adenocarcinoma of the cardia, which has higher propensity to metastasize to these lymph nodes. Equally important is an en bloc dissection of the distal mediastinum, which is easily done from the laparoscopic approach. The gastrocolic ligament is then divided just distal to the gastroepiploic arcade taking care not to injure the perigastric vascular structures, which might compromise the blood flow to the newly formed gastric conduit (Fig. 2). In situations where there is difficulty with identification of the right gastroepiploic artery, fluorescence imaging and Doppler at this stage can facilitate identification and determine the adequacy of perfusion at the distal conduit.

The dissection is carried out medially to the level of the duodenum and then extended to the fundus by dividing the short gastric vessels and the lateral phrenoesophageal ligament. The stomach is then lifted anteriorly, and the retroperitoneal attachments are divided. Pyloroplasty or botulinum toxin injection of the pylorus is performed at this stage to aid the emptying of the conduit. Transhiatal dissection of the esophagus is then performed dividing the phrenoesophageal ligament and dissecting the paracardial and lower paraesophageal nodes and dividing the peritoneum from the crurae bilaterally. A Penrose drain is used to encircle the distal esophagus for retraction during both the abdominal and thoracic phase. A 3 to 5 cm-wide gastric conduit is then created by dividing the stomach with multiple findings of a linear stapler, starting at the level of the incisura on the medial side all the way proximal to the fundus leaving the last 5 cm of stomach undivided to allow retrieval during the thoracic phase (Figs. 3 and 4). The staple line can be reinforced either with a running or interrupted Lembert suture. As a final step, a feeding jejunostomy tube is inserted in the small bowel.

After the abdominal portion is complete and the incisions are closed, the patient is re-positioned in the left lateral decubitus position. While this is the traditional approach, there are centers that complete the thoracic portion with the patient in the prone position. Anesthesia is asked to collapse the right lung either by use of a double lumen endotracheal tube or capnothorax with minimally invasive ports. A posterolateral thoracotomy incision is made in the fifth intercostal space and access is gained to the thorax. In the MIE approach, four trocars are placed in the thoracic wall in a diamond pattern. The pulmonary ligament is divided to the level of the inferior pulmonary vein. A retractor (fan retractor if MIE) is placed to improve visualization of the posterior mediastinal pleura at the level of the azygos vein. The azygos vein is divided with a vascular stapler to allow exposure of the entire esophagus (Fig. 5).

The Penrose drain left around the esophagus is retrieved and used to retract the esophagus and facilitate dissection. The esophagus is dissected out of the mediastinum, being extremely careful using energy devices in the subcarinal and paratracheal areas to avoid injury to the airway. Proximal dissection should be carried out to provide a margin of 5 cm from the tumor's edge. The esophagus is then divided and the proximal margin is sent for frozen section to assess for the presence of Barrett's esophagus and tumor.

With the esophagus mobilized from the mediastinum, lymph node dissection is performed in the paratracheal, subcarinal, and inferior pulmonary ligament regions. Some surgeons also prophylactically ligate the thoracic duct by passing sutures at the T9 and/or T10 level in the prevertebral tissues.

The gastric conduit is then gently pulled up into the chest up to the level of the staple line that was previously created, making sure no twists are present. A transoral circular end-to-end anastomotic (EEA) stapler is then inserted through the patient's mouth into the esophageal stump. The nasogastric tube connected to the anvil is passed through a small opening next to the staple line and removed through one of the trocars. At this point, fluorescence imaging can be used again to determine appropriate perfusion of the conduit. This can be trimmed to a point of maximal perfusion, making sure that excessive tension is avoided. The EEA stapler is introduced

through an opening made in the proximal gastric conduit. The conduit is pulled over the stapler to allow the piston to come out next to the greater curvature of the stomach in the area chosen for the anastomosis (Fig. 6). The anvil and the stapler are engaged, and the stapler is fired to complete the anastomosis. Using a linear stapler, the specimen is trimmed from the conduit (Fig. 7). The specimen is then extracted with the help of a wound protector and the gastric margin is checked. If excess perigastric fat is available from the conduit, this is placed around the anastomosis to decrease the chance of an anastomotic leak.

McKeown

The McKeown (three-field) esophagectomy is utilized for patients with a proximal thoracic tumor located near the airways, with extensive Barrett's esophagus, or if there is a concern for attaining an adequate proximal margin that is tumor free. A McKeown esophagectomy has a cervical anastomosis that may represent a better option for proximal esophageal disease. The steps of the operation are the same as for an Ivor Lewis esophagectomy except that the thoracic portion is performed first. After the abdominal portion is complete, through an oblique incision anterior to the sternocleidomastoid muscle, the thoracic inlet is then dissected and the specimen is extracted through this incision. A single-layer esophagogastric anastomosis is constructed using interrupted 3-0 silk sutures. Alternatively, if there is enough overlap of the esophagus and gastric conduit, the posterior row can be made with a GIA 30 stapler, and the remaining closed with interrupted sutures in two layers, as originally described by Orringer.

Transhiatal

A transhiatal esophagectomy should be the procedure of choice for lower esophageal early-stage disease. With this approach, a right thoracotomy is avoided. The transhiatal approach includes an initial abdominal approach, similar to the Ivor Lewis esophagectomy, with preparation of the gastric conduit. Following this, the patient remains in the supine position and a cervical anastomosis is created, after the blunt transhiatal dissection. Transhiatal MIE uses laparoscopic abdominal dissection and preparation of the gastric conduit followed by a cervical anastomosis in the left neck as previously described. Mediastinal dissection of periesophageal lymph nodes, including those in the subcarinal station, can be accessed through the hiatus, using the lighting and magnification afforded by the laparoscope. The esophageal specimen is removed through the neck. The transhiatal operation is the least invasive esophagectomy, requires less operative time, and has excellent functional outcomes. The chest need not be violated for early-stage disease, unless there is concern for an inadequate gastric conduit length to perform a safe cervical anastomosis. Although long-term survival differences have not been demonstrated, many experts believe this operation has a lower oncologic yield, although this has not been analyzed for the minimally invasive approach where en bloc dissection of the distal mediastinum is possible.

COMPLICATIONS

Some of the most common postesophagectomy complications can be related to respiratory events, chyle leak, anastomotic/conduit complications, and atrial fibrillation.

Atrial fibrillation is a common complication after esophageal resection. It is reportedly more common in older patients and those who have undergone neoadjuvant therapy. The occurrence of atrial fibrillation should prompt a workup for possible anastomotic leak. Standard atrial fibrillation management includes electrolyte correction, medical management with antiarrhythmics, and defibrillation if needed.

Respiratory complications are additionally a common event after esophagectomy. Aspiration and subsequent pneumonia increases a patient's risk for worse outcome, including an increased mortality risk. Aspiration precautions should be strictly followed in the postoperative period.

Chyle leak is another well-documented complication. Low-volume chyle leaks can be managed by making the patient nil per os (NPO), initiating parenteral nutrition and conservative management until chest tube output declines. If output remains high despite these changes, one can consider invasive management, either with thoracic duct embolization by interventional radiology or by surgical ligation.

Anastomotic complications include anastomotic leak and stricture. In the setting of anastomotic leak, management depends on the approach to the primary surgery. If the patient has undergone Ivor

Lewis esophagectomy, an anastomotic leak can be handled by placement of a metallic or plastic stent (if small and contained), or reoperation. In the setting of a cervical anastomosis with a McKeown or transhiatal esophagectomy, an anastomotic leak is more easily managed with a bedside neck washout and negative pressure therapy, if needed. Patients should be treated with antibiotics if systemic signs of illness appear and repeat assessment of the leak should be completed at an interval time.

Recurrent laryngeal nerve injury has been reported more commonly in patients with cervical anastomoses and three-field lymph node dissections. There is an increased risk of pulmonary complications in the postoperative period in patients with recurrent laryngeal nerve injury. Swallow evaluation should be carried out and, if necessary, vocal cord medialization can be performed.

CONCLUSION

The management of esophageal cancer continues to evolve. Minimally invasive interventions such as ablation, EMR, and ESD are increasingly common as improved screening tools have led to earlier diagnosis. With these less invasive techniques, up to 90% cure rates have been seen. Detailed preoperative workup and staging remains paramount to appropriate management. Minimally invasive surgical approaches are quickly becoming the gold standard for surgical treatment in most centers, as the data are trending toward better functional outcomes and quality of life compared with totally open procedures.

Perhaps one of the most impactful recent advances that has been instituted as standard of care is the addition of nivolumab as adjuvant therapy for patients with resected esophageal (or gastroesophageal junction) cancers with residual pathologic disease if they had received induction chemoradiation therapy. In the recently completed CheckMate-577 trial, nivolumab given postoperatively doubled the median disease-free survival versus placebo (22 vs. 11 months, respectively), translating to a 31% reduction in the risk of disease recurrence. Better understanding of the patient-specific risk factors for treatment failures as well as patient-specific tumor profiling and treatments has ushered in an era of minimally invasive and precision therapeutics that holds a promise of improved outcomes for this highly lethal disease.

Multimodality Therapy in Esophageal Cancer

Brooks V. Udelsman, MD, MHS, and Uma M. Sachdeva, MD, PhD

OVERVIEW

In patients with locally advanced esophageal adenocarcinoma and esophageal squamous cell carcinoma, optimal treatment involves multimodal therapy. This rapidly evolving field includes surgery, chemotherapy, radiotherapy, and more recently immunotherapy. The goal of this multimodal approach is to increase R0 resection rates, decrease local and systemic recurrence, and improve disease-specific and overall survival. With current treatment regimens, 5-year survival has increased to nearly 50% in patients with resectable disease; however, risk of recurrence remains high in individuals without a complete pathologic response to neoadjuvant therapy. In this chapter, we review the current status of multimodal therapy in treatment of locally advanced esophageal cancer, with special focus on the emerging role of immunotherapy in resectable disease and new approaches to oligometastatic disease. This chapter is intended to provide an overview of the key studies driving current practice rather than serve as an exhaustive review of all multimodal combinations currently in trials for esophageal cancer.

DEFINITIONS OF MULTIMODAL THERAPY AND INDICATIONS IN ESOPHAGEAL CANCER

Multimodal therapy refers to the use of surgery in combination with chemotherapy, radiotherapy, and immunotherapy in the oncologic treatment of malignant disease. Surgery involves esophagectomy with reconstruction, which can be performed using open, minimally invasive, or robotic-assisted techniques. The procedural conduct of esophagectomy is discussed in detail in the chapter entitled "Management of Esophageal Cancer" and therefore will not be reviewed here. Oncologic treatment occurring before surgery is termed *neoadjuvant therapy,* while treatment occurring after surgery is termed *adjuvant therapy*. Both neoadjuvant and adjuvant therapy may include chemotherapy alone or chemotherapy combined with radiotherapy (i.e., chemoradiotherapy). Similarly, immunotherapy may be delivered in the neoadjuvant or adjuvant setting, alone or in combination with chemotherapy or chemoradiotherapy. In some publications, the term *induction therapy* is used interchangeably with *neoadjuvant therapy;* however, *induction* specifically refers to the delivery of chemotherapy before radiation therapy, in contrast with concurrent chemoradiotherapy. In this chapter, we will refer to all treatment before surgical resection simply as *neoadjuvant therapy.*

The success of multimodal therapy regimens is determined through quantified improvements in overall survival and disease-specific survival. Surrogate markers of successful response include increased R0 resection rate, decreased time to recurrence, and increased likelihood of obtaining a complete pathologic response, meaning the absence of residual disease identified in the resection specimen following neoadjuvant treatment. These surrogates are highly correlated with improved survival and are often reported after a shorter follow-up time, allowing for clinical practice to be influenced by interim trial results while awaiting results of the primary survival endpoints.

The two main histologic subtypes of esophageal cancer are esophageal adenocarcinoma and esophageal squamous cell carcinoma. Together they represent 19,000 new cases per year in the United States alone and are associated with 15,000 deaths annually. Worldwide, squamous cell carcinoma is the more common subtype, with high prevalence in Asia and Africa. Esophageal squamous cell carcinoma has well-defined and strongly associated risk factors, including use of tobacco, alcohol, and betel quid and ingestion of very hot

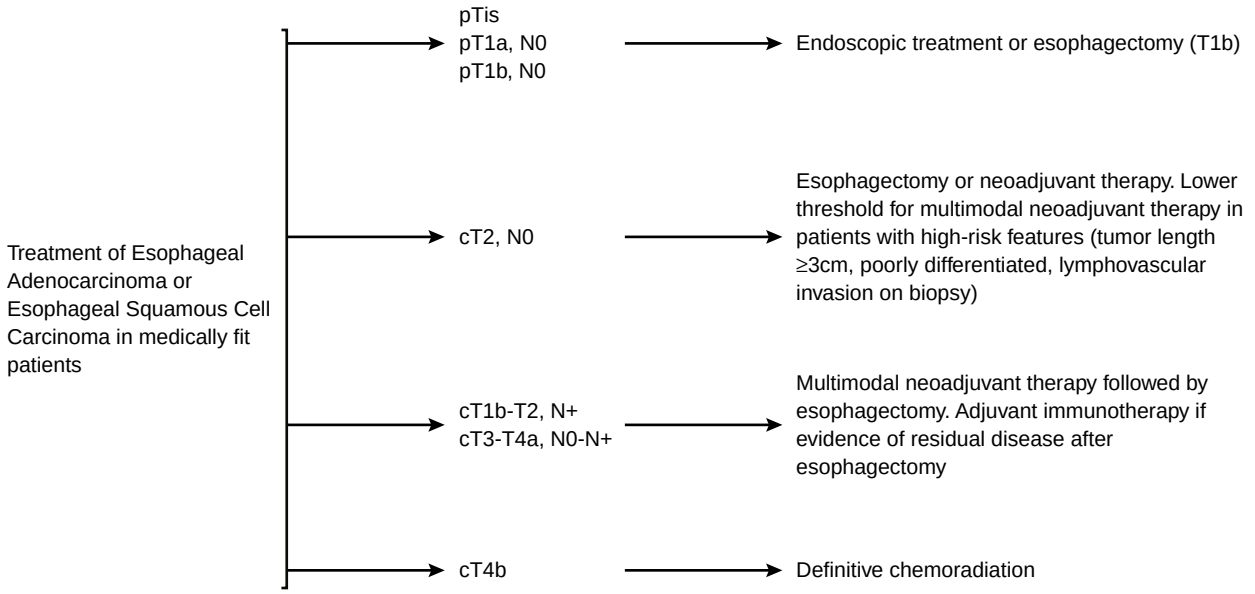

FIG. 1 Treatment algorithm for adenocarcinoma and squamous cell carcinoma in medically fit patients. *(Data from National Comprehensive Cancer Network.)*

temperature liquids, as well as some genetic predisposition. In contrast, adenocarcinoma is the dominant histology in Western Europe and the United States, with risk factors including gastroesophageal reflux disease, Barrett's esophagus, and obesity, without clearly defined genetic predisposition. Both types of esophageal cancer are significantly more common in men than in women.

In both histologic subtypes, multimodal therapy in the neoadjuvant setting has demonstrated survival benefits and is now standard-of-care for patients with locally advanced disease (Fig. 1). This includes patients with at least clinical T3 disease or clinical N1 disease. Neoadjuvant multimodal treatment for patients with clinical T2N0 esophageal cancer is controversial and nuanced. Up to 50% of patients with clinical T2 disease will have occult nodal disease not identified on staging computed tomography–positron emission tomography. These patients with occult nodal disease stand to benefit from neoadjuvant treatment, while those without nodal disease may not. Factors supporting the upstaging of T2N0 disease and use of neoadjuvant therapy in this setting include tumor length ≥3cm, poorly differentiated histology, and evidence of lymphovascular invasion on biopsy. Consideration for neoadjuvant multimodal therapy in patients with T2N0 disease should be discussed in a multidisciplinary tumor board within the context of the patient's unique risk factors and tolerance for multimodal therapy before surgery.

Traditional Multimodal Treatment

Esophageal Adenocarcinoma and Gastroesophageal Junction Adenocarcinoma

Current multimodal treatment of esophageal adenocarcinoma and gastroesophageal junction adenocarcinoma involves concurrent perioperative chemotherapy and radiotherapy. The benefit of perioperative chemotherapy as a single modality was definitively demonstrated through the randomized controlled MAGIC trial in 2006 (Table 1). A regimen of three preoperative cycles of epirubicin, cisplatin, and fluorouracil (5-FU) (ECF) followed by three postoperative cycles of the same was compared with surgery alone in patients with resectable adenocarcinoma of the stomach, gastroesophageal junction, and lower esophagus, and demonstrated substantial improvements in both R0 resection rate and 5-year survival (36% vs. 29%) with neoadjuvant chemotherapy. Ychou et al. reported similar results in 2011 comparing a regimen of three cycles each of preoperative and postoperative cisplatin with 5-FU with surgery alone. More recently, the FLOT4 trial demonstrated the superiority of four preoperative and postoperative cycles of docetaxel, oxaliplatin, leucovorin, and 5-FU (FLOT) compared with ECF dosed according to the MAGIC protocol, with an increase in median survival from 35 months to 50 months with FLOT4. The major downside to these regimens has been the number of patients (almost 50% in some series) who are unable to complete the postoperative chemotherapy because of operative complications, patient deconditioning, or intolerance. Given this limitation, there has been a push toward total neoadjuvant treatment, with active studies using FLOT4 and FOLFOX (folinic acid, 5-FU, oxaliplatin) regimens in the preoperative setting. The use of chemotherapy alone in the neoadjuvant setting tends to be more common in European and Asian centers, while North American centers tend to favor delivery of chemotherapy with concurrent radiation, with or without an initial induction phase of chemotherapy in a total neoadjuvant approach, before surgical resection for locally advanced disease. The use of concurrent chemoradiation in the neoadjuvant setting for gastroesophageal adenocarcinoma dates to the 1990s, when Bass et al. performed a randomized controlled trial comparing surgery alone against a treatment regimen of two cycles of neoadjuvant 5-FU and cisplatin along with external beam radiation on days 1 to 5, 8 to 12, and 15 to 19. Patients with adenocarcinoma who received this regimen demonstrated an increase in overall survival to 76 months compared with 23 months for patients treated with surgery alone. Tepper et al. replicated these results using a similar regimen of neoadjuvant cisplatin, 5-FU, and radiotherapy, demonstrating a 5-year survival of 39% in the multimodal treatment arm versus 16% in the surgical monotherapy arm ($P = 0.002$). Unfortunately, this study was closed early because of poor patient accrual.

In a direct comparison of neoadjuvant chemoradiotherapy to neoadjuvant chemotherapy alone, Stahl et al. demonstrated significantly higher rates of pathologic complete response and negative lymph nodes at time of resection in patients who received two cycles of cisplatin, 5-FU, and folinic acid in conjunction with 30 Gray of radiation as compared with patients who received 2.5 cycles of neoadjuvant chemotherapy alone. However, this study was also closed early because of poor patient accrual, and no significant survival benefit was demonstrated. Using a similar regimen, Burmeister et al.

TABLE 1 Summary of Landmark Randomized Controlled Trials Using Traditional Multimodal Treatment of Esophageal Adenocarcinoma/Gastroesophageal Junctional Adenocarcinoma and Squamous Cell Carcinoma

Study	Publication Year	N	Histology	Control Regimen	Experimental Regimen	Overall Survival (Control vs. Experimental)
Ancona et al.[1]	2001	94	ESCC	Surgery alone	2–3 preoperative cycles of cisplatin and 5-FU	5 year: 22% vs. 34%
MRC Oesophageal Cancer Working Party[2]	2002	802	ESCC	Surgery alone	2 preoperative cycles of cisplatin and 5-FU	Median: 13.3 months vs. 16.8 months
Cunningham et al. (MAGIC)[3]	2006	503	EAC	Surgery alone	3 preoperative and 3 postoperative cycles of epirubicin, cisplatin, and 5-FU	5 year: 29% vs. 36%
Lv et al.[4]	2010	238	ESCC	Surgery alone	2 preoperative cycles of paclitaxel and cisplatin with concurrent radiotherapy OR 2 postoperative cycles of paclitaxel and cisplatin with concurrent radiotherapy	5 year: 33.8% (control) vs. 43.5% (preoperative) vs. 42.3% (postoperative)
Boonstra et al.[5]	2011	169	ESCC	Surgery alone	2–4 preoperative cycles of cisplatin and etoposide	5 year: 17% vs. 26%
Ychou et al.[6]	2011	224	EAC	Surgery alone	3 preoperative and 3 postoperative cycles of cisplatin and 5-FU	5 year: 24% vs. 38%
Alderson et al. (0E05)[7]	2017	897	EAC	2 preoperative cycles of cisplatin and 5-FU	4 preoperative cycles of epirubicin, cisplatin, and capecitabine	Median: 23.4 months vs. 26.1 months
Yang et al. (NEOCRTEC5010)[8]	2018	451	ESCC	Surgery alone	2 preoperative cycles of vinorelbine and cisplatin with concurrent radiotherapy	Median: 66.5 months vs. 100.1 months
Al-Batran (FLOT4)[9]	2016, 2019	716	EAC	3 preoperative and 3 postoperative cycles of ECF/ECX	4 preoperative and 4 postoperative cycles of FLOT	5 year: 36% vs. 45%
van Hagen (CROSS)[10,11]	2012, 2015, 2021	368	EAC/ESSC	Surgery alone	5 preoperative cycles of carboplatin, paclitaxel, and concurrent radiotherapy	5 year: 33% vs. 47%

showed an improvement in histopathologic response in patients who received neoadjuvant chemoradiotherapy over patients who received neoadjuvant chemotherapy alone.

More recently, the CROSS trial demonstrated significantly improved overall and progression-free survival with neoadjuvant chemoradiotherapy as compared with surgery alone using a regimen of six cycles of carboplatin and paclitaxel in combination with 41.4 Gray of radiation given in 23 fractions. This survival benefit was seen in both adenocarcinoma and squamous cell carcinoma, but it was more pronounced in the latter group, which also demonstrated a higher rate of pathologic complete response following neoadjuvant therapy. In long-term follow-up of the CROSS trial, 5-year and 10-year survival have been 47% and 38%, respectively. Given the durable success of this neoadjuvant chemoradiotherapy regimen, it has become standard-of-care at many centers. Ongoing trials of additional regimens, including neoadjuvant FOLFOX, neoadjuvant FLOT, induction chemotherapy before the CROSS regimen, use of Herceptin for Her2-positive tumors, and proton beam therapy rather than traditional radiation, are currently underway.

Esophageal Squamous Cell Carcinoma

Treatment of esophageal squamous cell carcinoma with chemotherapy and chemoradiotherapy in conjunction with surgical resection has been studied for the past several decades. In 2001, a randomized controlled trial published by Ancona et al. failed to demonstrate an overall survival benefit with neoadjuvant chemotherapy using two to three cycles of cisplatin and 5-FU, but did report a significant survival advantage in subgroup analysis among patients whose tumors responded to preoperative chemotherapy. The overall survival benefit for preoperative chemotherapy in squamous cell carcinoma was subsequently demonstrated in two separate randomized controlled trials conducted by the medical research council on esophageal cancer working party and Boonstra et al. using regimens of cisplatin and 5-FU and cisplatin and etoposide, respectively.

Over the past decade, several randomized controlled trials have demonstrated a survival benefit to preoperative chemoradiotherapy compared with surgery alone. These studies include the CROSS trial, the NEOCRTEC5010, and a separate analysis by Lv et al. In the NEOCRTEC5010 trial, 2 cycles of neoadjuvant vinorelbine and cisplatin delivered concurrently with 40 Gray of radiation in 20 fractions was compared with surgery alone. In contrast, Lv et al. randomized patients to either neoadjuvant or adjuvant delivery of two cycles of cisplatin/paclitaxel concurrently with 40 Gray of radiation in 20 fractions. Meanwhile, the CROSS trial, as described earlier, demonstrated the greatest relative benefit for the subgroup of patients with squamous cell carcinoma, with median survival of 81.6 months in the neoadjuvant group versus 21.1 months in the surgery alone group. Despite the differences in neoadjuvant regimens used, all three studies demonstrated a significant benefit to neoadjuvant chemoradiation in both overall and disease-free survival in patients with locally advanced squamous cell carcinoma (Table 1).

There have been few published studies directly comparing neoadjuvant chemoradiotherapy to neoadjuvant chemotherapy, though this is an ongoing area of study. Early results from Wang et al. directly comparing a regimen of cisplatin and paclitaxel with or without 40 Gray of concurrent radiation have shown an improvement in complete pathologic response among those receiving chemoradiotherapy, although it remains to be seen whether this will translate into an overall or disease-specific survival benefit.

Immunotherapy in Neoadjuvant and Adjuvant Settings

Immunotherapy is an increasingly important tool in medical oncology that utilizes the body's natural defense mechanisms to fight cancer cells. Common targets of immunotherapy agents include the programmed cell death protein (PD-1) and the associated programmed cell death ligand 1 (PD-L1). PD-1 is a cell surface receptor expressed on activated immune cells, including T cells, B cells, and myeloid cells, while PD-L1 is expressed on the surface of some cancer cells to trigger immune evasion. When PD-1 is bound to PD-L1, an immune checkpoint is activated, preventing the T cells from targeting cancer cells for death. Novel immunotherapeutic medications include monoclonal antibodies that bind either PD-1 on the surface of T cells (nivolumab, pembrolizumab, and toripalimab) or PD-L1 on the surface of tumor cells (atezolizumab, avelumab, and durvalumab) to block this immune checkpoint and thus reactivate the T-cell–mediated antitumor immune response. This targeted approach can lead to more effective tumor targeting and cytotoxic response with less systemic side effects than traditional chemotherapeutic agents.

Although better tolerated than traditional chemotherapy, immunotherapy-related toxicities can occur. Most commonly this involves an autoimmune response that can affect the gastrointestinal tract, skin, endocrine glands, and liver. More serious, but less common, adverse immune responses can include myocarditis, pneumonitis, and disorders of the central nervous system. These events may require cessation of immunotherapy and treatment with glucocorticoids.

The benefits of immunotherapy regimens utilizing checkpoint inhibitors have been demonstrated in several cancers, including malignant melanoma and non–small cell lung cancer. The efficacy of these agents as first-line therapy in esophageal adenocarcinoma has been shown in advanced unresectable disease and in recurrent or metastatic disease.

Recently, the CheckMate 577 trial demonstrated the efficacy of immunotherapy in multimodal treatment through use of adjuvant nivolumab in patients with locally advanced esophageal adenocarcinoma and esophageal squamous cell carcinoma. Patients treated with total neoadjuvant chemoradiotherapy with residual pathologic disease after resection were randomized to treatment with nivolumab versus placebo. Patients in the treatment arm demonstrated a significant improvement in median disease-free survival compared with placebo (22.4 months vs. 11.0 months). The success of this trial has led to additional studies exploring the potential benefits of immunotherapy in the neoadjuvant setting (Table 2). As the results of these trials are reported, the multimodal treatment of esophageal cancer, both adenocarcinoma and squamous cell carcinoma, may change rapidly in the next several years.

Multimodal Therapy for Recurrent and Oligometastatic Disease: A New Frontier for Surgery?

Despite improvements in the treatment of resectable locally advanced esophageal cancer, patients who present with recurrent or oligometastatic disease continue to have an extremely poor prognosis. In patients with distant organ metastasis, 5-year survival is less than 5%, even in the setting of aggressive chemotherapy regimens. In an effort to improve these outcomes, several groups have evaluated the potential benefit of multimodal therapy in patients with recurrent and/or oligometastatic disease. For these patients, there is potential benefit to definitive local therapy (e.g., resection or radiation) to the oligometastatic site in conjunction with systemic therapy.

Data supporting the local treatment of oligometastatic disease have been reported by Li et al. In their retrospective analysis of 576 patients with oligometastatic disease, radiotherapy or chemoembolization to the metastatic site were independent factors associated with improved progression-free and overall survival. Similarly, Port et al. demonstrated prolonged survival in patients who underwent surgical resection followed by adjuvant chemoradiation for recurrent nodal disease or oligometastatic solid organ metastasis as compared with definitive chemoradiation alone. These results have been replicated in several other publications demonstrating improved survival in patients treated with chemoradiotherapy or surgical resection for recurrent oligometastatic disease in individuals who had previously undergone esophagectomy. Moreover, the site of oligometastatic

TABLE 2 Summary of Completed and Active Trials Utilizing Adjuvant and Neoadjuvant Immunotherapy Regimens

Study	Histology	Inclusion Criteria	Control Regimen	Experimental Regimen	Primary Outcome*	Status
CheckMate 577[1]	EAC/ESSC	Neoadjuvant chemotherapy with incomplete pathologic response in esophagectomy specimen	Placebo	Adjuvant nivolumab	Disease-free survival (11.0 vs. 22.4 months; $P < 0.001$)	Completed

disease plays a role, with improved survival associated with lung metastasis as compared with brain or liver metastasis.

Although promising, all of these studies are limited by retrospective study design and/or a lack of randomization. For patients who present with limited metastatic gastroesophageal junction adenocarcinoma, a survival benefit to neoadjuvant therapy followed by surgical resection of the primary tumor and all metastatic sites has been shown in the FLOT3 trial. Although there is much still unknown, these studies indicate a potential benefit to aggressive systemic and local treatment of limited metastatic and recurrent disease.

Additional Considerations to Multimodal Therapy

The success of a multimodal approach for the treatment of locally advanced esophageal cancers, both adenocarcinoma and squamous cell carcinoma, is dependent on the patient's ability to tolerate the effects of chemotherapy and radiotherapy and to recover from major surgery. Although minimally invasive approaches can decrease surgical morbidity, aggressive neoadjuvant protocols can also increase the complexity of surgery, and many surgeons may feel more comfortable with open surgical approaches in this setting. Frailty, sarcopenia, and malnutrition limit the ability of patients to complete multimodal treatment and increase the risk for postoperative complications and postdischarge institutionalization. This is exacerbated by symptomatic dysphagia, which often accompanies locally advanced esophageal cancers.

To improve the likelihood of successful completion of multimodal therapy, several adjunctive measures have been utilized. First, there has been a shift toward total neoadjuvant therapy. By giving all chemoradiotherapy during the preoperative period, delays in treatment that may occur as a result of postoperative complications or deconditioning are eliminated. Moreover, total neoadjuvant treatment increases the likelihood of obtaining a complete pathologic response and can give a better indication of expected prognosis at the time of surgery. A summary of current neoadjuvant and total neoadjuvant treatment regimens is included in Table 3.

To improve patient fitness for major surgery, the concept of prehabilitation has gained traction. Prehabilitation has shown early

TABLE 3 Summary of Current Neoadjuvant and Total Neoadjuvant Treatment Regimens

Neoadjuvant with Adjuvant

promise in patients with esophageal cancer and other malignancies that require major operations and prolonged multimodal treatment in either the neoadjuvant or adjuvant setting. Often, these multimodal treatments are described as a *marathon,* with the idea that pretreatment "training" may improve outcomes and reduce associated morbidity and mortality. Prehabilitation regimens include aerobic exercise, strength-based exercise, and inspiratory muscle training. Unfortunately, well-designed studies evaluating the effectiveness of these interventions are limited at present. The strongest evidence for use of preoperative training regimens has been reported by Minella et al. In a randomized controlled trial of patients undergoing multimodal treatment for esophageal cancer, they demonstrated a significant improvement in functional capacity both before and after surgery in the treatment group that underwent preoperative home-based aerobic and strength training as compared with a control group without prehabilitation. Although prehabilitation seems instinctively beneficial, additional trials are needed to optimize training programs and resource allocation.

An additional challenge in the multimodal treatment of esophageal cancer is the associated difficulty in maintaining adequate nutrition. Because the stomach is most often used as the conduit for reconstruction after esophagectomy, gastric feeding tubes are generally avoided in the preoperative setting. Patients who need additional preoperative or postoperative nutritional supplementation often undergo jejunal feeding tube placement, either before neoadjuvant therapy, during neoadjuvant treatment, or at the time of esophagectomy. Less desirable alternatives include total parenteral nutrition (TPN) or nasoenteral feeding tubes. The optimal feeding strategy for patients undergoing esophagectomy for esophageal cancer has been explored in multiple studies. In several randomized controlled trials, jejunostomy tube feeding demonstrated superiority both to TPN and long-term nasoenteric tube feeding. Studies comparing enteral feeding without a jejunostomy tube to jejunostomy tube feeding have had more mixed results, and the optimal strategy remains unclear. Although jejunal feeding tube placement certainly benefits a subset of the population, they are also associated with an up to 30% complication rate. Determining which patients may benefit from a jejunal feeding tube and the optimal timing of placement is an area of active investigation. For now, the decision regarding placement of a jejunal feeding tube remains dependent on specific patient, operative, and institutional factors.

CONCLUSIONS

The past two decades have brought major advances in the treatment of locally advanced esophageal cancer, including both adenocarcinoma and squamous cell carcinoma. Multimodal therapy involving neoadjuvant chemotherapy or chemoradiotherapy has become standard-of-care for locally advanced disease and has led to major improvements in the prognosis of patients with this disease. Outcomes have dramatically improved, and patients and clinicians can expect a 5-year survival approaching 50% with current regimens. The role of surgery and localized radiation or radiofrequency ablation in patients with recurrent disease or oligometastatic disease is an area of active investigation, and there is evidence that multimodal therapy can benefit well-selected patients within this high-risk patient subgroup that was previously considered unresectable.

In the next 5 to 10 years, the field is expected to undergo a second revolution with the addition of immunotherapy to current treatment regimens in both the adjuvant and neoadjuvant settings. This will come along with continued refinement and direct comparison of current in-trial neoadjuvant chemotherapy and chemoradiotherapy regimens.

Finally, as the arsenal of the surgical oncologist has grown, there is even greater need for patient optimization before surgery, as patients must now endure major surgery involving esophageal resection and reconstruction after completing often-grueling neoadjuvant regimens, with the potential for additional adjuvant treatments after recovery from surgery. To reap the maximal benefit from these ongoing advances in multimodal therapy, concomitant work will be needed to combat frailty and malnutrition and to maintain patient quality of life along with enhanced survival.

Use of Esophageal Stents

Matthew D. Grunwald, MD, Anthony N. Kalloo, MD, and Dmitriy O. Khodorskiy, MD

First described by French surgeon Leroy D'Etiolles in 1845, esophageal stenting (ES) was, at its inception, reserved mainly for the palliation of severe dysphagia in advanced esophageal cancer (EC). Over the years, the use of esophageal stent has steadily increased with an expansion of its indications to include benign disease. Improvement in stent design, endoscopic techniques, and complication rates have made it an attractive therapeutic option for patients with either mechanical or functional dysphagia, perforations, leaks, or fistulas. ES generally has one of two main goals: (1) to maintain luminal patency and relieve severe dysphagia in the setting of benign or malignant strictures and (2) to stave off potentially fatal luminal contamination of the mediastinum. For patients with debilitating disease, ES offers the prospect of improved oral intake, symptomatic relief of dysphagia or aspiration, and the avoidance of morbid surgical interventions.

This chapter reviews the evolution of ES, currently available stents, most current indications for ES, stent placement techniques, and complications.

STENTS THROUGH THE AGES

D'Etiolles' stents, which were made of decalcified ivory, were unfortunately unsuccessful. Over the next 4 decades, several attempts by the likes of Sir Morrell Mackenzie in England yielded similarly disappointing results. The first successful esophageal stent was designed by Sir Charters Symonds in 1885. Symonds' stent, which was blindly inserted, featured an esophageal tube affixed to a boxwood funnel by a silver wire and was secured to the ear by a silk thread passing through the mouth or nose. Over the next decades, as interest in plastic polymers grew, stent design evolved. The first stents widely used in the esophagus were constructed from silicon rubber. These early stents were inserted with the assistance of a rigid esophagoscope but had a high rate of stent misplacement and migration. In the late 1950s, Celestin successfully palliated a malignant esophageal stricture using a plastic stent inserted via an open gastrostomy. The next few years would see an evolution in stent placement technique as endoscopic tools evolved. In the 1970s, Atkinson introduced an endoscopically inserted plastic prosthesis. Unfortunately, a significant drawback of the Atkinson stent was its small internal diameter, which proved rate limiting when patients resumed a regular diet. High complication rates plagued many of these early plastic endoprostheses. Because of their rigidity and fixed internal as well as external diameters, most stents required endoscopic dilation, which invariably led to perforations. Additionally, their inability to conform intimately to the strictural morphology caused frequent stent migrations requiring intervention. In 1983, the modern era of esophageal stent innovation was ushered in when Frimberger published the first description of the endoscopic placement of a self-expanding metal stent (SEMS) for a patient with a malignant esophageal stricture. In the 1990s, SEMS grew in popularity, in part fueled by the results of a series of trials conducted by Knyrim et al., which demonstrated that SEMS had higher patency rates, successful placement rates, and a better safety profile than available rigid plastic endoprostheses. Over the next few years, stent design and materials would continue to evolve. The modern esophageal stent is self-expanding and made of either plastic, Nitinol (a metal alloy), or biodegradable material. It may also come fully or partially covered. Table 1 reviews currently available stents and their characteristics.

STENT SELECTION

Selecting the appropriate stent for a given lesion—a critical step in preprocedural planning and a significant determinant of outcome—requires an understanding of the mechanical and physical properties of the various stents models (Fig. 1).

The majority of SEMS are made of Nitinol, a nickel-titanium alloy, that has superelasticity and shape memory. This property allows a metal's shape to be easily modulated by small temperature variations, but there is also a spontaneous return to the original shape when the temperature is outside of the transformative range. These unique characteristics are exploited in SEMS as they expand at body temperature to fit the morphology of a given lesion. Nitinol is also resistant to corrosion and hypoallergenic. Although biologically inert, it triggers a mild inflammatory response with resulting fibrosis that is useful in reducing stent migration. Unfortunately, this same property can be a major drawback of uncovered SEMS (uc-SEMS), fostering stent stenosis by allowing fibrotic tissue ingrowth through the openings in the mesh material. To counter this phenomenon, fully covered and partially covered stents were developed. These stents feature proximal and distal ends that remain bare and uncovered to provide additional luminal anchorage. Covered stents are believed to have less tumor ingrowth but can potentially be more

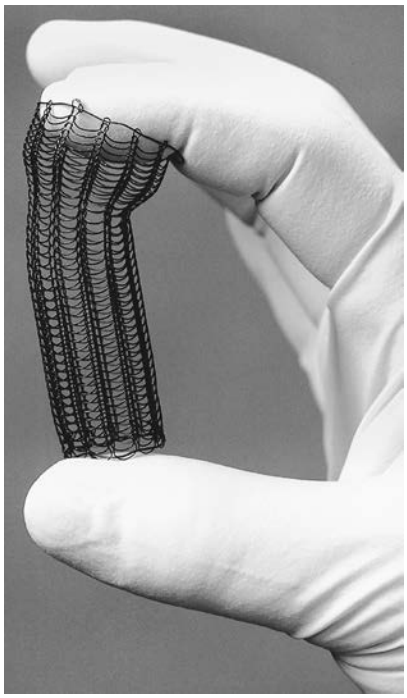

FIG. 1 Self-expanding metal stent.

susceptible to stent migration, especially in high-risk areas such as at the distal esophagus.

Self-expandable plastic stents (SEPS) are double-layered, featuring polyester mesh on their external surface with an embedded silicon layer forming a smooth inner surface. To prevent migration, flared distal and proximal ends facilitate luminal anchorage. Considering that their internal diameter tends to decrease under tension, SEPS are easily retrieved endoscopically, making them ideal for short-term stenting.

Introduced in the mid-2000s, biodegradable stents (BDS) are mainly used in the setting of benign strictures, as they negate the need for retrieval. These are made of plaited polydioxanone, a monofilament that undergoes hydrolytic degradation over 8 to 12 weeks. These maintain their mechanical strength for 4 to 6 weeks.

PATIENT SELECTION

Careful clinical evaluation and characterization of the lesion of interest are necessary to optimize clinical outcome in patients receiving ES. Baseline assessment of dysphagia, nutritional status, and quality of life (QOL) will provide a reference point from which the efficacy of the intervention can be measured. The Dysphagia Scoring Scale by Ogilvie et al. (Table 2) is a simple and effective tool to assess dysphagia in patients with strictures. Combining radiographic modalities such as esophagram, positron emission tomography, computed tomography (CT), and endoscopy can provide invaluable information about the lesion's location, size, morphology, and relationship to adjacent extrinsic structures and thus inform stent selection.

INDICATIONS

The Food and Drug Administration (FDA) has approved ES for the preservation of luminal patency in the setting of intrinsic or extrinsic malignant strictures, and the occlusion of concurrent esophageal fistula. In practice, however, the list of lesions amenable to ES has increased, owing to better stent design, improved safety profile, and sophisticated endoscopic techniques. In the United States and other developed nations, stenting for malignant esophageal strictures has decreased because of improved outcomes with single-dose brachytherapy. Conversely, ES for the management of various benign conditions, such as refractory benign esophageal strictures (RBES),

TABLE 2 Dysphagia Scoring Scale

Class	Dysphagia Scoring Scale
0	Able to consume normal diet
1	Dysphagia with certain solid foods
2	Able to swallow semisolid foods
3	Able to swallow liquids only
4	Unable to swallow saliva (complete dysphagia)

Data from Ogilvie AL, Dronfield MW, Ferguson R, Atkinson M. Palliative intubation of oesophagogastric neoplasms at fiberoptic endoscopy. *Gut*. 1982;23:1060–1067.

esophageal perforations, variceal bleeding, postsurgical anastomotic leaks, and achalasia has increased by more than 50% in the past decade.

Malignant Esophageal Disease

Malignant Esophageal Strictures

Malignant esophageal dysphagia results from luminal narrowing either by intramural growth of primary esophageal tumors or extrinsic compression from mediastinal and airway tract neoplasms. Primary EC remains one of the most lethal cancers of the alimentary tract. Because of its insidious course, clinically apparent disease is typically synonymous with advanced stage. In these patients, relief of dysphagia and resumption of oral intake provides an invaluable improvement in QOL and, in some cases, survival prospects. Since its inception, ES has been regarded as the first-line therapy for the palliation of malignant dysphagia. SEMS provides prompt relief and the opportunity to optimize patients' nutritional status. Interest in regionally targeted radiation modalities such as brachytherapy has transformed the clinical approach to malignant dysphagia. A randomized controlled trial (RCT) comparing SEMS to single-dose brachytherapy demonstrated that, although stenting resulted in earlier relief of dysphagia, brachytherapy provided longer-lasting relief, higher QOL scores, and significantly less morbidity as evidenced by a rate of major complication of 13% compared with 25% for SEMS. Despite these findings, the initial enthusiasm for brachytherapy is fading due to the frequently noted need to insert rescue stents. Brachytherapy may be considered for carefully selected patients with mild to moderate dysphagia who have a longer life expectancy. ES thus remains the first line of intervention for patients with moderate to severe dysphagia who are not candidates for other modalities or patients with recurrent dysphagia after brachytherapy. Fully covered SEMS (fc-SEMS) are the stents of choice for the management of malignant strictures. Recent studies have demonstrated a lower rate of tumor ingrowth compared with uc-SEMS and a lesser risk of stent migration when compared with SEPS. Although there is no difference in outcomes between fc-SEMS and partially covered SEMS (pc-SEMS), the latter is often subject to tumor ingrowth at its uncovered distal and proximal ends, thus making for challenging endoscopic retrieval.

Malignant Esophageal Fistulas

Malignant esophageal fistulas result primarily from esophageal tumor infiltration into surrounding structures, such as the trachea, mediastinum, pleura, and proximal abdominal cavity, and less commonly from extrinsic infiltration of respiratory tract tumors or chemoradiation-induced tumor necrosis. Regardless of the mechanism, temporary suspension of oral intake, drainage of involved spaces, and endoscopic insertion of a fc-SEMS are frequently recommended. The Amplatzer atrial septal defect (ASD) occluder has also been used off-label for closure of trachea-esophageal fistulas in limited studies. Currently, successful fistula closure rates are more than 70%, and recent evidence suggests a modest survival advantage once closure is achieved. The early appeal of concurrent stenting of the tracheobronchial tract (Fig. 2), or "dual stenting," has been largely overshadowed by a higher risk of highly lethal intermural and vascular erosions due to synergistic pressure necrosis. Despite the scarcity of data available regarding the most appropriate stent for malignant fistulas, fc-SEMS are the modality of choice by consensus.

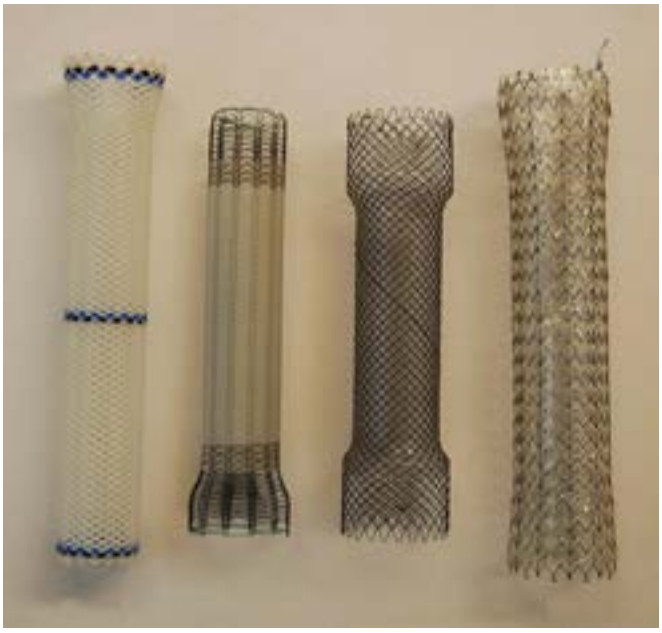

FIG. 2 Left to right, Self-expandable plastic stent, partially covered self-expanding metal stent (pc-SEMS), double-layer fully covered SEMS (fc-SEMS).

Gastroesophageal Junction Tumors

Palliation of gastroesophageal junction (GEJ) strictures by endoscopic means is technically challenging, owing to intrinsic anatomic peculiarities. Unlike the upper and middle esophagus, the GEJ features an acute angle and varying luminal diameters, which may interfere with satisfactory stent fixation. ES at this location is frequently associated with an increased risk of acid reflux, distal migration, and ineffective palliation. The higher rate of complications is often compounded by the overall poorer survival ascribed to GEJ tumors and has long been a basis for the argument against stenting of these lesions. In clinical practice, pc-SEMS are considered the stent of choice for GEJ strictures, as their bare ends allow for better anchorage. The introduction of modified fc-SEMS featuring progressive step flaring of the distal end (conforms better to the gastric opening) and one-way reflux valves at the distal end theoretically favors improved treatment of GEJ lesions. A recent RCT by Persson et al. comparing modified fc-SEMS with pc-SEMS in 95 patients with malignant GEJ strictures showed no difference in stent migrations, although there was a trend toward better relief of dysphagia with fc-SEMS.

Bridge to Surgery

Preoperative ES in patients with locally advanced EC undergoing neoadjuvant therapy may allow for nutritional optimization before surgical resection. Although several small studies have demonstrated improved oral intake, weight stabilization, and QOL when SEMS, SEPS, or BDS were used as a bridge-to-surgery in a neoadjuvant setting, a retrospective study by Mariette et al. reported worse oncologic outcomes with SEMS. A lower rate of complete resection

(71.0% vs. 85.5%; $P = 0.041$), shorter disease-free interval (6.5 vs. 9.0 months; $P = 0.040$), and worse 3-year overall survival (25% vs. 44%; $P = 0.023$) were noted in the preoperative SEMS group. One possible explanation resides in the fact that SEMS-induced mural inflammation may distort the tissue planes and interfere with the completeness of resection. There is currently no evidence regarding oncologic outcomes with preoperative stenting during neoadjuvant therapy for SEPS and BDS. Of note, although stent migration rates in this setting are upward to 50%, they may represent a favorable response to neoadjuvant therapy.

Benign Esophageal Disease

Benign Refractory Esophageal Strictures

The mainstay in the treatment of benign esophageal stricture is periodic endoscopic balloon dilation. However, for a subset of patients, dysphagia will persist despite repeated dilation, thus requiring more aggressive interventions. RBES are most commonly encountered after caustic injuries, radiation to the chest or mediastinum, postsurgically after esophagodigestive anastomoses, or after endoscopic interventions such as per-oral endoscopic myotomy (POEM) and endoscopic mucosal resection. Although no study has, to date, evaluated the impact of dilation time on outcomes, proponents of temporary stenting for RBES purport that continued radial pressure on the esophageal lumen may result in sustained luminal patency. The challenge in selecting a stenting modality for RBES resides in the transient nature of the intervention. The ideal stent needs to be easily retrievable and yet resistant to migration. To this end, fc-SEMS are the most commonly used. Although initially showing great efficacy, Polyflex, the only FDA-approved SEPS for RBES, was discontinued in the United States owing to a disappointing safety profile. Its insertion resulted in migration rates up to 50% and a rate of severe stent-related complication nearing 25%. There are currently no RCTs evaluating outcomes for various stent designs in the management of RBES. A recent meta-analysis by Thomas et al. examined the performance of fc-SEMS in 199 patients with RBES. The efficacy of fc-SEMS for palliation was 46.2% with a migration rate of 26.4% and a successful retrieval rate of 87%. BDS has shown similar efficacy to fc-SEMS and has the added advantage of not requiring retrieval. However, BDS has a higher rate of stent-related complications such a retrosternal pain and bleeding. In brief, ES with either fc-SEMS or BDS is an intervention of last resort in benign esophageal strictures, reserved for carefully selected patients with RBES.

Benign Perforations, Anastomotic Leaks, and Fistulas

Benign esophageal perforations (BEP) can be classified as spontaneous, such as in Boerhaave's syndrome, iatrogenic, or traumatic. As for fistulas, contamination of surrounding mediastinal or pleural spaces by esophageal luminal contents can have dire consequences, triggering highly lethal inflammation and infection. Early determination of the etiology and severity of the leakage is crucial, as these considerations will guide therapeutic management and determine outcomes. A contained perforation or anastomotic leak in an otherwise clinically stable patient may be successfully treated with conservative measures. In these patients, nil per os, intravenous hydration, nasogastric drainage, and broad-spectrum antibiotics are the mainstays of therapy. In patients with noncontained leaks, ES may allay the potential morbidity of surgical intervention and is now increasingly used (Figs. 3 and 4). As with traditional surgical approaches, the goal of therapy in using stents in these patients remains complete drainage of the contaminated spaces, successful sealing of the leak, diversion of oral secretions, and prevention of widespread infection. In a recent meta-analysis comparing SEMS to surgical intervention in patients with esophageal leakage, Persson et al. reported a higher success rate (88% vs. 83%) and a lower mortality rate (7.5% vs. 17%) when SEMS were used. We recommend the use of covered stents—either fc-SEMS or pc-SEMS—for the management of hemodynamically stable patients with BEP. Concurrent drainage of the involved space, broad systemic antibiotic therapy, intravenous fluid administration, and temporary diversion of oral secretions are often employed to optimize clinical outcomes.

FIG. 3 Acquired tracheoesophageal fistula. *(Courtesy Dr. Richard K. Freeman, MD.)*

Achalasia

The role of ES in the treatment of achalasia is evolving. Over the last 3 decades, the introduction of temporary stenting using retrievable SEMS has renewed interest in this modality. In 2010, a long-term follow-up of a prospective comparison of pneumatic dilation and SEMS of various diameters in 120 patients with achalasia showed a higher clinical remission rate at 13 years (83.3% vs. 0) when 30-mm SEMS were used compared with pneumatic dilation. Although surgical and endoscopic interventions such as Heller myotomy and POEM are the mainstays of definitive therapy for achalasia, temporary retrievable stenting with SEMS may be an option for patients who are not surgical candidates (Fig. 5).

Refractory Esophageal Variceal Bleeding

Fully covered SEMS may be used for refractory esophageal variceal bleeding. There are specially designed SEMS with a wide diameter (at least 25 mm) for this indication. There are multiple small studies that have been published with encouraging results. In a recent meta-analysis, technical success was achieved in 97% of cases and bleeding was controlled in 96%. However, one small trial comparing SEMS to balloon tamponade showed no difference in survival. All studies performed for this indication have reported adverse events that include stent migration and ulceration.

PROCEDURE

Meticulous planning is necessary when considering ES. Although both conscious sedation and general anesthesia are comparable, the latter would best serve a patient at high risk for aspiration. Preprocedural endoscopic evaluation of the lesion should be comprehensive. The luminal diameter, location, and size of the lesion of interest must be carefully assessed and documented. Evaluating the friability of the luminal tissue is equally important, as it could portend a greater risk than usual of bleeding, pressure necrosis, or mural erosion after the procedure. Endoscopic predilation of the lesion is no longer routinely performed but could be considered for the small subset of patients in whom the severity of the stenosis might

FIG. 4 **(A)** Upper gastrointestinal (GI) series with water-soluble oral contrast medium demonstrating extraluminal extravasation of contrast medium from the left side of the esophagus approximately 2 cm below the level of the carina, consistent with esophageal perforation. **(B)** Repeat upper GI series with water-soluble oral contrast medium in the same patient as in **(A)** demonstrates a distal esophageal stent in good position. There is no evidence of contrast medium extravasation to suggest a persistent leak.

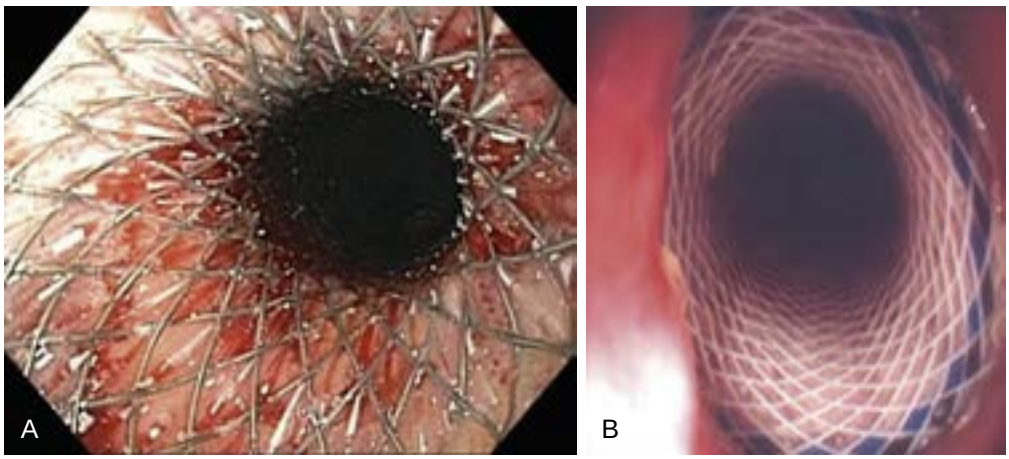

FIG. 5 Endoscopic view of deployed and expanded self-expanding metal stent **(A)** and self-expandable plastic stent **(B).**

prevent stent insertion. Particular attention should be paid to stent size. The internal diameter of the stent should be slightly larger than the lesion of interest, thus allowing for adequate radial force to be applied. An inadequately small stent diameter may increase the risk of migration, whereas an oversized stent may lead to perforation and excessive pressure necrosis. The length of a stent should be at least 4 cm longer than that of the lesion, overlapping it both proximally and distally by at least 2 cm. However, the location of an esophageal obstruction may necessitate modification to the general technique for stent deployment. Most notably, stent placement in the proximal esophagus is known to be challenging. In patients with esophageal strictures near the upper esophageal sphincter (UES), the placement is adjusted so that the proximal margin of the stent is below the UES (i.e., the proximal stent margin may be <2 cm). Stent placement in the distal esophagus or across the GEJ may also be challenging. In these instances, it is important to avoid an excessively long stent so that the distal margin of the stent does not result in contact with the contralateral gastric wall and lead to ulceration or perforation.

ES can be achieved using either fluoroscopic guidance, endoscopic guidance, or both. One technique is the Seldinger technique, in which a guidewire is endoscopically advanced into the esophagus 2 to 3 cm past the distal end of the lesion, the endoscope is removed,

and the stent delivery system is advanced over the guidewire. The endoscope is then reinserted, and the stent positioned and deployed under direct visualization. Caution should be used to ensure that the stent is not fully deployed until satisfactory positioning has been achieved. Using fluoroscopy, the guidewire is inserted using a catheter. Once a satisfactory position has been secured, a small amount of water-soluble contrast medium is injected through the catheter to delineate the stricture. Radiopaque markers are then used to delineate the location and length of the stricture on the patient's skin. Next, after the catheter is removed, the delivery system is advanced over the guidewire, and the stent is deployed under continuous fluoroscopic monitoring.

The development and increased availability of through-the-scope (TTS) SEMS has allowed for this technique to be performed by advancing the stent catheter under direct visualization through the accessory channel of a therapeutic double channel upper endoscope.

After deployment, the stent expands against the stricture and the mucosa at the margins of the stricture. This anchors the stent in place and helps prevent stent migration. Repeat endoscopy or an upper gastrointestinal series 24 to 36 hours postdeployment is often performed before resumption of oral intake. The stent is expected to completely expand within 48 to 72 hours. When oral intake is resumed, patients are discharged with written diet instructions based on results of stent placement and the expected gradual expansion of the stent. Patients are typically advised to consume liquids only for 24 to 48 hours and then to advance to a soft solid diet as tolerated, as well as to adhere to long-term avoidance of fibrous foods such as raw vegetables and large pieces of meat.

COMPLICATIONS

Close to 30% of patients undergoing an esophageal stent placement experience complications (Table 3). These events are often classified as early or late (Table 4). Events of mild to moderate severity such as retrosternal pain or reflux symptoms typically resolve within 1 or 2 weeks postprocedure. Persistence of retrosternal pain beyond 2 weeks may indicate the need for endoscopic removal of the stent. Recent studies have shown improvement of reflux symptoms with the use of stents equipped with a distal reflux valve, especially in patients with GEJ lesions. Other measures to prevent acid reflux and aspiration of gastric contents include maintaining an upright (or semi-upright) position at all times and a daily proton pump inhibitor.

Stent occlusion secondary to tumor in-growth is most commonly seen with uncovered or partially covered stents but can now be successfully managed with a stent-in-stent technique (Fig. 6). This chapter focuses on the major complications of stent migration and vascular and aerodigestive erosions.

TABLE 3 Overview of Adverse Events Related to Esophageal Stent Placement for Different Indications

Complications	Malignant Dysphagia (n = 1017)	Benign Dysphagia (n = 232)	Esophageal Leakage (n = 599)
SERIOUS ADVERSE EVENT (%)			
Major bleeding	8.0	3.0	1.3
Aspiration pneumonia	5.0	1.3	0.7
Perforation	2.0	1.3	1.0
ADVERSE EVENTS (%)			
Retrosternal pain	30.0	4.3	0.5
Reflux symptoms	7.0	2.6	0.5
Recurrent dysphagia	31.0	29.0	20.0
Stent migration	11.0	24.5	16.5
Tissue ingrowth/overgrowth	14.0	2.2	2.7
Food obstruction	7.0	2.2	1.1

TABLE 4 Common Early and Late Complications After Esophageal Stent Placement

Early Complications (<2 weeks), 10%–20%	Late Complications (>2 weeks), 15%–37%
Retrosternal pain	Migration
Minor hemorrhage	Stent fracture
Aspiration	Obstruction/tumor ingrowth
Gastroesophageal reflux disease	Erosion
Migration	Airway erosion/compression
Occlusion	Vascular erosion
Airway erosion/compression	
Vascular erosion	

Modified from Vermeulen BD, Siersema PD. Esophageal stenting in clinical practice: an overview. *Curr Treat Options Gastroenterol*. 2018;16:260–273.

Tissue Erosion

Stent erosion into neighboring mediastinal structures such as the big vessels and airway is rare but highly lethal when it occurs. Tissue necrosis resulting from high radial pressure exerted on the esophageal wall is often compounded by poor tissue perfusion and impaired wound healing secondary to malnutrition or radiation exposure. Some studies have shown that a history of radiation to the chest or mediastinum increases the risk of tissue erosion from ES. Similarly, dual stenting of the esophagus and trachea is also associated with an increased risk of tissue erosion.

Vascular Erosion

Vascular erosion is rare but highly lethal. Although aortoesophageal fistula is perhaps the most common, vascular erosion involving the retroesophageal subclavian and common carotid arteries have been reported. One must always have a high degree of suspicion as to its possibility. For example, an abrupt sentinel hematemesis associated with retrosternal chest pain in a patient with a history of esophageal stent placement should prompt immediate evaluation and intervention before a potential catastrophic exsanguination. Emergent management of an aortoesophageal fistula involves prompt control of the potentially fatal hemorrhage, followed by timely vascular repair (Fig. 7). Concurrent activation of the massive transfusion protocol and airway protection may be necessary. In such an emergent setting, endoscopic balloons can often be used to control the bleed, and some surgeons have even successfully used Sengstaken-Blakemore tubes for this purpose. Temporary intravascular occlusion and emergent surgery are also options. Once control is obtained, it can be followed with endovascular repair of the aortic defect. After the patient is stabilized, attention can then be turned to the esophageal defect. After removal of the offending stent, a small defect may be primarily repaired with muscle interposition. An esophagectomy may be necessary for larger defects. Alternatively, in moribund patients, a conservative approach involving diversion of esophageal contents and palliative care may be more appropriate.

Definitive treatment for aortoesophageal fistula by endovascular stent graft.* Indian J Surg. *2016;78:151–154.)*

Aerodigestive Erosion

Tracheoesophageal erosions have been reported in 4% to 8% of patients after ES (see Fig. 4). Unlike the dramatic presentation seen with vascular erosion, patients often present with nonspecific symptoms such as dyspnea and frequent pulmonary infections. Although a chest CT scan may help identify the lesion of interest, bronchoscopic and endoscopic evaluations are often necessary to characterize the extent and size of the defect. The management of tracheoesophageal fistulas depends on the patient's hemodynamic status and on the underlying pathology that led to esophageal stricture. In a patient who presents in extremis, securing the airway must be the priority. One should maintain spontaneous ventilation if possible, but the patient should be promptly intubated if there is an inability to ventilate. A variety of intubation methods can be used if ventilation is difficult including contralateral mainstem intubation, use of a double

lumen tube, employing a bronchial blocker, or sedating the patient to ventilate. In some cases, tracheal stenting and esophageal diversion may be needed, and definitive management may be delayed. Stable patients with good functional status and with good esophageal tissue integrity can undergo either a primary repair with muscle interposition or an esophagectomy. Otherwise, tracheal stenting, esophageal diversion, and palliative care should be considered.

Stent Migration

Stent migration is perhaps the most common complication of esophageal stricture, occurring in 11% to 33% of cases. Over the past 2 decades, various interventions aimed at reducing the frequency of migrations, such as anchoring the stent to the esophageal wall, have been introduced. Endoclips are used to secure the proximal stent end to the esophageal wall, but a high migration rate persists (Fig. 8). Endoscopic suturing using Apollo OverStitch and Apollo OverStitch Sx devices (Figs. 9 and 10) has also shown some benefit in small studies; however, high-quality evidence is not available. More recently, a specialized over-the-scope clip (OTSC) has become available for stent fixation with promising results. Small studies indicate reduced migration rates that, however, still exceed 15%. Additionally, off-label use of lumen-apposing metal stent (LAMS) has been studied for management of short-segment benign gastrointestinal strictures. Their unique dumbbell-shaped design helps to fix the stent in place (Fig. 11). LAMS is an alternative to traditional options; however, data are limited and future studies are needed to measure their efficacy. The best treatment of migration is probably prevention. A study

Data from Freeman RK, Ascioti AJ, Dake M, Mahidhara RS. An assessment of the optimal time for removal of esophageal stents used in the treatment of an esophageal anastomotic leak or perforation. *Ann Thorac Surg*. 2015;100:422–428.

by Freeman et al. evaluating the impact of stent indwelling time in 162 patients treated with ES showed a significant reduction in stent-related complications in patients who had a shorter indwelling time (Table 5). In patients with anastomotic leaks, a 30% ($P = 0.04$) reduction in stent migration rates was noted with a stent duration of fewer than 14 days. Patients with acute perforation experienced a 34% reduction in stent migration when the indwelling time was fewer than 28 days.

CONCLUSION

ES remains a mainstay in the palliation of advanced malignant strictures. Although its indications have greatly expanded to include various benign esophageal diseases, complications associated with this procedure mandate thorough preprocedural evaluation of the patients as well as an individualized therapeutic approach.

MANAGEMENT OF ESOPHAGEAL PERFORATION

Juan A. Muñoz-Largacha, MD, and James M. Donahue, MD

INTRODUCTION

Despite advances in diagnostic imaging and early recognition, esophageal perforation continues to be a life-threatening condition with high morbidity and mortality rates. Reported mortality ranges between 10% and 25% when diagnosis and treatment are initiated within 24 hours and can be as high as 40% to 60% when diagnosis and treatment are delayed. Other patient-related factors such as comorbidities, functional condition, presence of sepsis and multiorgan failure, and location and cause of perforation can also influence mortality in this group of patients.

Iatrogenic injuries resulting from endoscopic procedures (diagnostic, biopsy, dilation, sclerotherapy, laser therapy, photodynamic therapy, stent placement, transesophageal echocardiogram, esophageal ultrasound) are the most common cause of esophageal perforation, accounting for 60% to 70% of cases. Spontaneous rupture, or *Boerhaave's esophagus,* is the second most common cause of esophageal perforation (15%–30%). Other, less frequent causes include trauma (penetrating or blunt), foreign body or caustic ingestion, cervical, nonesophageal surgery (thyroidectomy, mediastinoscopy, spine surgery), and malignancy of the esophagus, lung, or other mediastinal structures. Esophageal perforation has also been described in association with infectious processes in immunocompromised patients (candida, herpes, syphilis, and tuberculosis), in the setting of severe gastroesophageal reflux, and following Mallory-Weiss tears (Table 1).

DIAGNOSIS

A prompt diagnosis of esophageal perforation is crucial to improve outcomes and survival, and a high level of suspicion should be

TABLE 1 Causes of Esophageal Perforation

Iatrogenic	Endoscopic procedures (diagnostic, biopsy, dilation, stent placement) Transesophageal echocardiography Esophageal ultrasonography
Spontaneous	Barogenic-Boerhaave syndrome
Traumatic	Blunt Penetrating Surgical intervention: cervical intervention or mediastinal surgery (i.e., thyroidectomy)
Ingestion	Caustic Foreign body
Neoplastic	Primary esophageal malignancy Mediastinal malignancy with esophageal involvement and erosion
Infectious	Candida, herpes, syphilis, tuberculosis

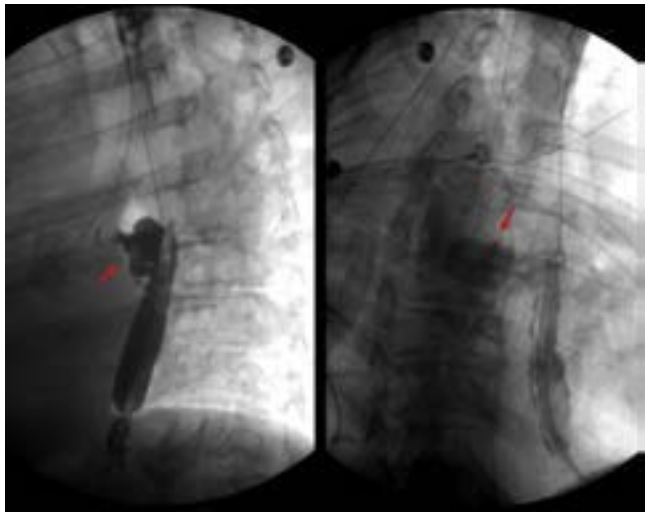

FIG. 1 Esophagram with water-soluble contrast. Evidence of esophageal perforation and contrast extravasation in the right posterolateral aspect of the mid-esophagus (red arrows).

maintained to achieve this goal. A detailed history and physical examination are of utmost importance and will help determine the most likely cause of perforation. Commonly, patients will report recent esophageal instrumentation or forceful vomiting. Initial complaints often involve a vague description of pain localized to the neck, chest, shoulder, or epigastrium. As the process progresses, patients may experience dyspnea, dysphagia, or odynophagia. On physical examination, patients may remain hemodynamically stable or present with signs of septic shock or mediastinitis such as tachycardia or hypotension. Laboratory values generally reveal a leukocytosis. Commonly, a chest x-ray is performed as part of the initial assessment of these patients, which may reveal presence of pneumomediastinum, pleural effusion, pneumothorax, subcutaneous emphysema, or an abnormal cardiomediastinal contour. When esophageal perforation is on the differential diagnosis, further imaging studies such as contrast esophagram and computed tomography (CT) are performed for better evaluation of the extent of the injury, location, and degree of mediastinal and pleural contamination.

Esophagram

An esophagram is a noninvasive diagnostic tool that can help determine the presence and location of a perforation. Either water-soluble contrast (Gastrografin) or diluted barium can be used. Gastrografin is generally preferred over barium because of the lower risk of mediastinitis. However, the sensitivity of Gastrografin has been reported between 60% and 70%, so negative results do not completely exclude perforation, especially in the cervical esophagus, because of the rapid transit of the contrast. In addition, barium has been shown to have better resolution for differentiating between contained and noncontained perforations. In practice, a Gastrografin esophagram is often obtained first, and if inconclusive, repeat images with diluted barium can be obtained as necessary for improved sensitivity and specificity. If Gastrografin demonstrates free perforation into the pleural space or abdominal cavity, the procedure is terminated. Figure 1 shows evidence of esophageal perforation on a Gastrografin esophagram.

Computed Tomography

CT is readily available and provides important supportive information related to an esophageal perforation, such as differentiating between a contained versus noncontained perforation. A contained perforation is characterized by no or minimal extravasation of contrast at the site of perforation without evidence of pleural or peritoneal contamination, or by contrast drainage back into the esophagus. In addition, CT allows for evaluation of the location of injury as well as the severity of mediastinal, pleural, or peritoneal contamination if present. Figure 2 shows evidence of esophageal perforation on chest CT.

Computed Tomography Esophagography

CT esophagography is a more recently available option with the potential to improve workflow and expedite the diagnosis of esophageal perforations by reducing the need for two radiologic examinations. Multiple reports over the past decade have shown its utility for the evaluation of postoperative leaks after esophagectomy; however, its use in the setting of acute esophageal perforations must be clarified. This technique is generally readily available, is less cumbersome for the patient, and does not require a fluoroscopy suite, an additional technician, and a supervising radiologist. One of the main limitations of a fluoroscopic esophagram is that critically ill patients may not be able to swallow the contrast or stand and change positions, which are requisite parts of the examination. In CT esophagography, noncontrast images are obtained first. For patients who cannot swallow, this allows for repositioning of a nasogastric tube (NGT) into the proximal esophagus to allow for contrast administration. These precontrast images are also useful to identify any radiopaque structures (i.e., staples, calcifications) that could be confounded with the contrast in subsequent images. Then, oral contrast is either ingested or administered via the NGT, and supine images are obtained. The reported sensitivity and specificity of this technique are comparable to those for fluoroscopic esophagography, with an equal, if not superior, accuracy for the diagnosis of acute esophageal perforations. In practice, a fluoroscopic esophagram is often obtained following a negative CT esophagram before enteral nutrition is implemented.

Endoscopy

Endoscopy is another helpful diagnostic and potentially therapeutic tool for management of esophageal perforations. Its use should be considered in patients with high suspicion for perforation who could not undergo a swallow examination or underwent a nondiagnostic study. It allows for direct visualization and careful inspection of mucosal integrity and viability as well as characterization of the

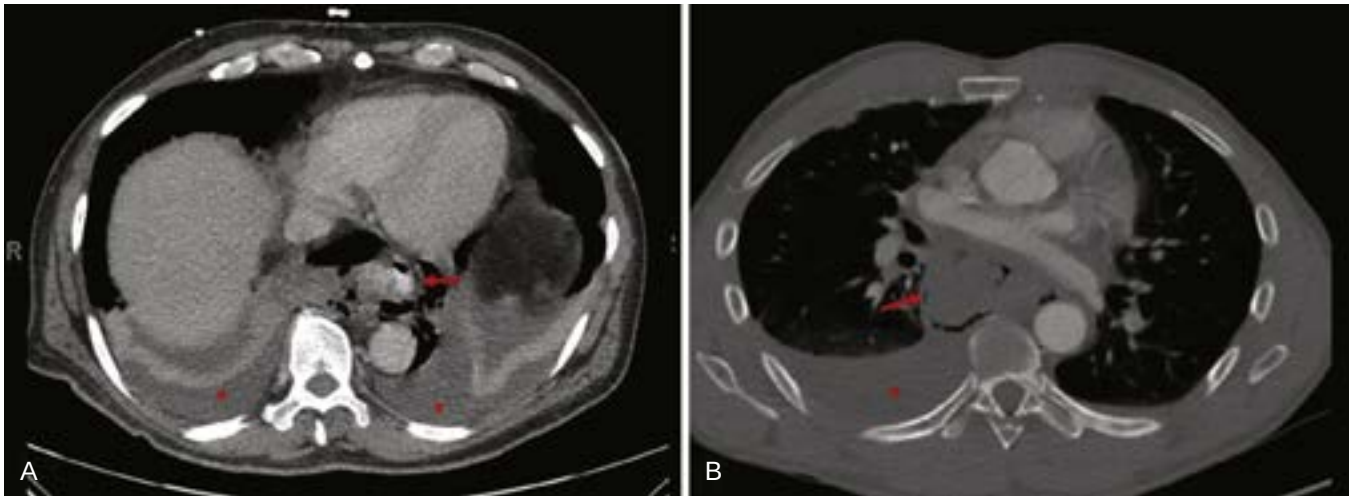

FIG. 2 Chest CT with contrast. **(A)** Patient with spontaneous distal esophageal perforation with pneumomediastinum and periesophageal fluid with contrast extravasation *(red arrow)* and bilateral small pleural effusions *(asterisks)*. **(B)** Large periesophageal fluid collection *(red arrow)* with associated pneumomediastinum and small right pleural effusion *(asterisk)*.

anatomic location of the injury and identification of other pathologic changes or underlying diseases of the esophagus such as strictures or neoplasms. Careful inspection with minimal air insufflation should be performed because this could potentially increase the size of the perforation or cause a tension pneumothorax through a free perforation into the pleural space. As discussed later, endoscopy can also be used for therapeutic purposes, as a stent may be placed in the same setting as the diagnostic procedure.

Assessing Severity of Illness and Prognosis

Several illness severity scoring systems, such as the APACHE system, have been applied to patients with esophageal perforation with various degrees of accuracy. The Pittsburgh Severity Score (PSS) is a scoring system specially devised for esophageal perforation patients that was first described by Abbas et al. in 2009. The authors attempted to identify clinical factors that could predict survival and potentially identify those patients amenable to nonoperative management. The score includes 10 clinical variables that were considered by the authors to be potentially important indicators of injury severity and patient outcomes, which are assigned a value from 1 to 3 (Table 2). In their report, all survivors had PSS ≤3.3, and all patients who died had a PSS ≥6.5. Lower PSS scores were also associated with successful nonoperative management, shorter length of stay, and decreased morbidity. Similar findings have been found in other, independent cohorts. The PSS is a useful tool in terms of estimating prognosis for patients with esophageal perforation, but its validation with the use of prospective studies and potential improvement with more rigorous analysis of clinical data are still needed to definitively guide management.

TABLE 2 Pittsburgh Severity Score

MANAGEMENT

The management of patients with confirmed esophageal perforation after appropriate diagnostic workup can be determined by clinical and imaging characteristics. In a select group of patients with contained perforations, a nonoperative approach may be appropriate. For patients with free perforations, operative management with open primary repair of the perforation has been the traditionally preferred approach, particularly when the repair can be undertaken within 24 hours of the perforation. Recent evidence has shown that a less invasive approach consisting of endoscopic stenting and thoracoscopic mediastinal and pleural drainage produces encouraging results. In the most dire situations, esophageal resection and exclusion may be necessary. Regardless of the therapeutic approach chosen, initial management of patients with esophageal perforation should include close monitoring in a surgical critical care unit. Patients should be maintained *nil per os* (NPO), appropriately resuscitated with intravenous fluid, and started on broad-spectrum antibiotics to include fungal coverage. Adequate intravenous analgesia and a proton pump inhibitor (PPI) should be started, and early total parenteral nutritional support can be considered if a prolonged course is expected.

Nonoperative Management

Criteria for nonoperative management were initially described by Cameron et al. in 1979 and further modified by Altorjay. These included early diagnosis, contained perforations or perforations draining back into the esophagus, no significant mediastinal contamination, absence of sepsis or multiorgan failure, and perforation not associated with malignancy or obstruction of the esophagus. If

hemodynamically stable without signs of sepsis or multiorgan failure, the patient is admitted to the surgical critical care unit for 48 to 72 hours of observation. Patients should be maintained NPO with the head of the bed elevated, started on 72 hours of broad-spectrum antibiotics and a PPI, and, dependent on premorbid nutritional status, considered for parenteral nutritional support. Repeat imaging is obtained in 72 to 96 hours. If this demonstrates no evidence of free perforation, a liquid diet may be initiated. It is important to remember that these patients require close observation to ensure that they continue to meet nonoperative criteria. Should the patient's clinical condition deteriorate as evidenced by the development of fever, leukocytosis, tachypnea, tachycardia, or mental status changes, repeat imaging and possible endoscopy are indicated.

Endoscopic Stenting with Thoracoscopic Mediastinal and Pleural Drainage

For patients with evidence of free contrast extravasation into the mediastinum, endoscopic covered stent placement or endoluminal clipping to attempt to seal the perforation can be performed as an alternative to open surgical repair. It is vital to remember that this approach does not address the associated mediastinal and possible pleural contamination. For this reason, early video-assisted thoracoscopic surgery (VATS), performed either immediately after stent placement or within 1 to 2 days following the procedure, is generally required for debridement and drainage of the mediastinum and pleural cavity. At the conclusion of the VATS procedure, depending on the degree of contamination, at least one chest tube is left in the pleural space, and another (often a Blake drain) is left adjacent to the esophagus. Typically, a contrast esophagram is performed 48 hours after stent placement to determine if sealing of the esophageal perforation has occurred. If there is no evidence of extravasation, a clear liquid diet can be started and advanced to full liquids. It is advisable to leave the tube in place adjacent to the esophagus while the liquid diet is being initiated to monitor the character of the output as well as the patient's clinical condition. On the other hand, if the esophagram shows extravasation of contrast around the stent into the mediastinum or the drainage character changes after liquids are begun, the patient should be returned to NPO status and will require placement of a jejunostomy tube.

In their study, Ben-David et al. showed encouraging results in 76 patients with esophageal perforation (majority iatrogenic or spontaneous) managed with endoscopically placed metallic covered stents in addition to laparoscopic or VATS drainage and enteral feeding access placement. All patients were treated within 24 hours of initial presentation, and perforation occlusion was confirmed within 48 hours after stent placement in 68 patients (89.5%). Additionally, no need for an open esophageal procedure was required, avoiding the morbidity of a more invasive operation. However, stent placement was not without complications, with an almost 40% migration rate requiring additional intervention within the first week of placement.

The ideal time for esophageal stent removal remains controversial and may depend on the size of the perforation. Some studies have shown adequate healing within 10 days for small perforations, while this process may take up to 8 weeks for larger defects. Ben-David et al. showed a mean length of 36 days from initial placement to final stent removal. In practice, waiting between 4 and 6 weeks, depending on the size of the perforation, is reasonable. Imaging confirmation of perforation healing with an esophagram should be obtained following stent removal before a liquid diet is initiated. If the perforation has not healed at the time of stent removal, the stent can be replaced for another 4 to 6 weeks.

Endoscopic Techniques

The use of endoluminal stents for the management of esophageal perforations is not a new concept, and in fact the most used self-expanding metal stents (SEMS) have been available since the 1990s. Technology improvement with better deployment mechanisms have also increased their use. The development of covered stents with different polymers has increased the technical and clinical success of the management of esophageal perforations and, at the same time, has decreased the rate of stent-related complications. Esophagogastroduodenoscopy (EGD) is performed to localize the defect, determine the extent of the perforation, and identify anatomic landmarks and other esophageal abnormalities. Under direct vision and with the concomitant use of fluoroscopy, a careful assessment of the landing zones and the desired diameter and length of the stent is conducted. Once this assessment is completed, the landmarks for the proximal and distal extent of the stent are marked with radio-opaque markers under fluoroscopy. A guidewire is then introduced under fluoroscopy. Figure 3 shows an endoscopic view of a perforation and subsequent stent placement. Ideally, the stent deployment will successfully cover the perforation on the first attempt, however the stent can be endoscopically repositioned to achieve complete coverage of perforation if needed. If there is evidence of incomplete radial deployment, a balloon dilation may be performed to attain complete contact between the stent and esophageal mucosa. An NGT can be placed under direct vision for gastric decompression in the acute setting. An anteroposterior and lateral chest x-ray should be obtained after stent placement to have a baseline for its location and facilitate further assessment of adequate positioning. As noted, a contrast esophagram should be obtained 48 hours after stent placement before liquids are begun. Figure 4 shows a SEMS in adequate position without evidence of contrast extravasation.

Stent complications include migration, bleeding, erosion, and tissue overgrowth, among others. Migration is the most common complication reported in about 8% to 40% of cases, with less migration rates reported with the use of metallic stents compared with plastic stents. Some studies have reported endoscopic suturing or clipping to secure the stent and prevent migration with favorable results.

Endoscopic suturing or clip placement may also be used to attempt to primarily repair small, early perforations. Previous reports demonstrate higher rates of closure, with an average defect size of 8 mm and higher failure rates when the lesion is greater than 13 mm. EGD is performed, and the esophageal defect is identified to confirm healthy mucosal edges for adequate clip placement. Through-the-scope clips can be used for defects less than 1 cm, and an over-the-scope clip system can be used for larger lesions. Suction can be used to help approximate the lesion edges and aid with better clip deployment. Even though acceptable results have been reported in the literature, this technique is not commonly used given that patients usually present with a more advanced disease process requiring more aggressive interventions.

Open Repair

Currently, little data exist to guide surgeons as to whether to proceed with an open repair or choose stent placement with pleural/mediastinal drainage. Elderly patients and those with multiple medical comorbidities are likely better served with the endoscopic/thoracoscopic approach. Although the likelihood of success of an open repair diminishes over 24 hours from the perforation event, several reports describe successful repairs being performed for perforations beyond the 24-hour mark. Following initial resuscitation efforts, patients who remain hemodynamically labile may still undergo successful repair, although a less invasive approach has obvious advantages in these patients. Ultimately, the decision is left to surgeon judgment and experience of the surgeon and his or her team with each approach. If open repair is chosen, it is critical to identify the location of the perforation to guide the surgical approach. This may require performance of endoscopy in the operating room before incision. Whenever feasible, two-layer closure should be performed and reinforced with a pedicled buttress. In cases of delayed perforation, single-layer closure may be all that is possible.

(**B**) Endoscopic view of the stent in place. *(From Chirica M, Champault A, Dray X, et al. Esophageal perforations. J Visc Surg. 2010;147[3]:e117–e128.)*

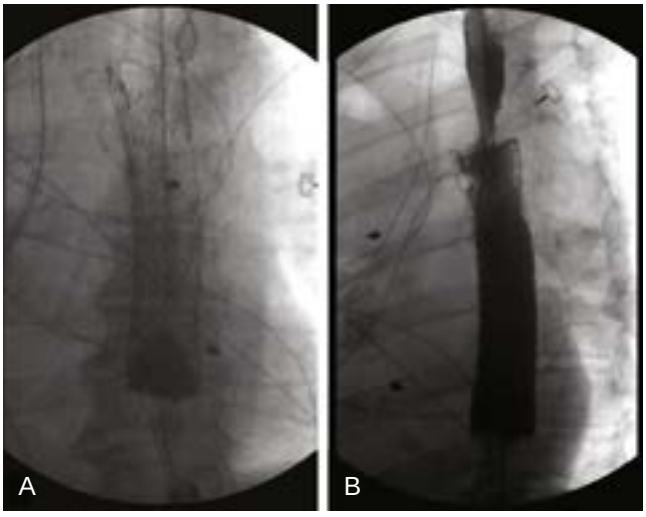

FIG. 4 Esophagram. (**A**) Esophageal stent in adequate position covering a prior perforation. (**B**) Stent in place without evidence of contrast extravasation.

Thoracic Perforations

Perforations of the upper and middle thirds of the esophagus are best approached through a right posterolateral thoracotomy via the fourth or fifth intercostal space. The intercostal muscle (ICM) within the interspace is harvested at this time using electrocautery to ultimately buttress the repair. The cautery tip is positioned near parallel with the surface of the superior rib to avoid injury to the neurovascular bundle. The ICM is freed from the rib to the level of the lumbar-dorsal fascia. Care must be taken to identify this landmark because further dissection risks injury to the intercostal vessels. The ICM flap is transected anteriorly after ligating or clipping the anterior aspect of the muscle to prevent bleeding. Next, the pleura is opened in the area of the perforation, and the esophagus is dissected enough to obtain clear visualization of the perforation. The edges of the perforation should be debrided to determine the full extent of the injury. Of note, the mucosal injury may extend a greater distance than the visualized muscular injury. The esophageal mucosa is closed with running or interrupted absorbable suture (4-0 Vicryl or PDS), and the muscularis is closed with interrupted 3-0 silk sutures. The pleural side of the ICM flap is then placed in contact with the repair and secured to the muscle layer of the esophagus with multiple interrupted silk sutures. Pleural and mediastinal drainage tubes are placed at the conclusion of the operation.

Perforations of the lower third of the esophagus should be approached through a left posterolateral thoracotomy in the seventh or eighth intercostal space. Although an ICM flap is generally used as a buttress, a diaphragmatic flap is also an option. A posteriorly based full-thickness diaphragmatic flap of adequate length and width can be mobilized to reach the area of primary repair. The flap is secured to the esophageal muscle with interrupted silk sutures to cover the repair. The diaphragm then is closed primarily with nonabsorbable suture. Advantages of diaphragmatic flap use include its, thickness, ease, and extent of mobility.

Cervical Perforations

The preferred method of exposure for cervical esophageal perforation is a left-sided neck incision along the anterior border of the sternocleidomastoid muscle (SCM). It may be necessary to ligate the middle thyroid vein for improved exposure. The trachea and thyroid gland are retracted medially for exposure of the esophagus (Fig. 5). The retroesophageal space is entered bluntly along the prevertebral fascia, with care taken to preserve the recurrent laryngeal nerve. Blunt dissection should be continued down to the posterior mediastinum to drain all fluid collections. If the perforation is identified, the defect is repaired primarily as described earlier. A strap muscle can be used to buttress the repair. If the defect is not clearly identified, closed drainage of the area is performed.

Abdominal Perforations

Patients with abdominal esophageal perforation and uncontained leak should be taken to the operating room for primary repair.

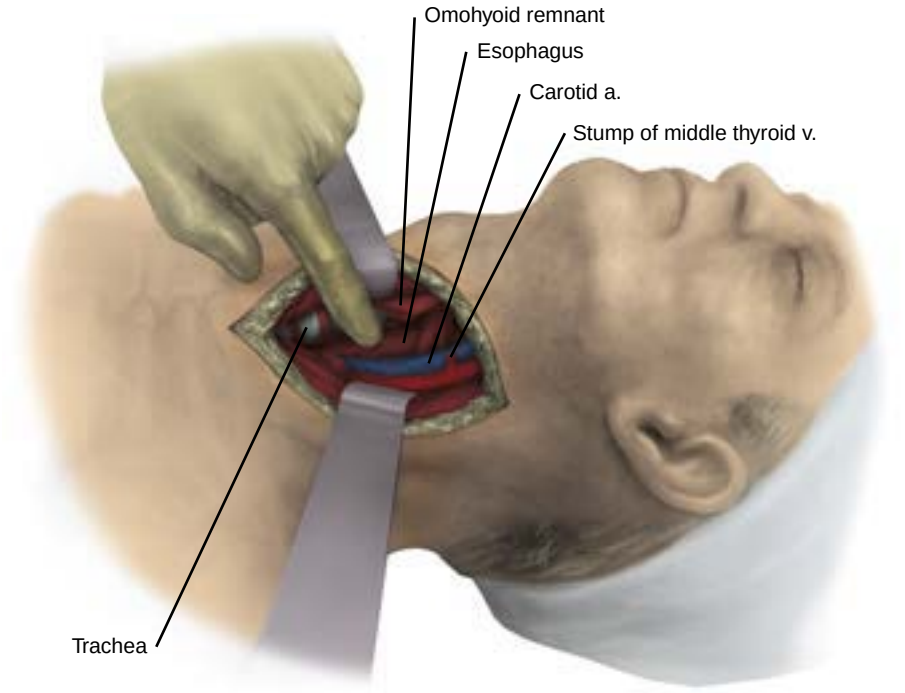

FIG. 5 Cervical esophagus exposure. Incision is made over the anterior border of the sternocleidomastoid muscle. If necessary, the middle thyroid vein and inferior thyroid artery can be ligated. Medial retraction of the trachea and thyroid gland is performed to help expose the esophagus. *(From Cooke DT, Lau CL. Primary repair of esophageal perforation.* Op Tech Thor Cardiovasc Surg. *2008;13[2]:126–137.)*

Perforations of the abdominal esophagus can be approached via an upper midline incision. Once debrided, the perforation should be closed primarily and buttressed with omentum or, more commonly, a fundoplication.

Nutritional Management Following Repair

Traditionally, following transthoracic repair, patients were immediately repositioned for a laparotomy and underwent placement of a gastrostomy tube for gastric decompression and a jejunostomy tube for nutritional access. This has become less commonly performed over time. If patients are requiring inotropic support following the repair, spending extra time in the operating room to place these tubes is not warranted. Furthermore, if the repair is successful, oral nutrition may be able to be started within 1 week, obviating the need for the feeding tube. To promptly begin nutritional support, as an alternative to a surgical feeding tube, a Dobhoff tube may be placed at the time of the repair under direct vision before the repair has been completed. The tube can then be advanced to a post-pyloric position postoperatively to allow early initiation of enteral feeding. An NGT could also be placed at this same time to allow for gastric decompression if the surgeon feels this is necessary. Early initiation of total parenteral nutrition is another option. Regardless of the initial nutritional strategy, an esophagram is obtained approximately 5 to 7 days after surgery depending on the patient's condition. If no leak is identified, liquids may be started and slowly advanced to a soft diet. If there is a persistent leak, this may be managed with subsequent stent placement, which may seal the leak. If the leak persists following stent placement, the patient will require jejunostomy tube placement as several weeks or more will likely be required for healing of the perforation. Although it can be difficult to maintain patience, ultimate healing is still very likely to occur following adequate mediastinal debridement, appropriate antibiotic therapy, and good nutritional support.

Resection with Diversion

Although every attempt should be made to preserve the patient's esophagus, there are rare instances in which this is not possible. These include long (generally >6 cm) perforations that are not amenable to stenting, a large segment of devitalized esophagus, which generally is seen with long delays in diagnosis, or perforated cancers that cannot be stented because of the size of the perforation or tumor. In stable patients, when large defects are encountered, options like stenting followed by operative coverage of the defect with biodegradable mesh and a muscle flap, such as the serratus anterior or latissimus dorsi, can be considered. Although the healing process will take months, an intact, functional esophagus is still possible. Previous reports have described use of a T-tube to create a controlled esophageal fistula for management of very large defects. This is often cumbersome to care for postoperatively and has generally been abandoned. When repair is deemed not to be possible, esophageal exclusion is recommended over resection and immediate reconstruction. The risk of anastomotic failure in patients who are hemodynamically unstable and/or have significant mediastinal contamination is very high.

Once the decision has been made to perform an esophageal exclusion procedure, the esophagus should be mobilized as much as possible in the chest. The esophagus is dived as far distally as possible near the gastroesophageal junction with a 45-mm stapler. After the chest is closed, the patient is then turned to the supine position. A left-sided neck incision is made along the anterior border of the SCM, as described for cervical esophageal perforations. The esophagus should be dissected circumferentially with care taken to avoid injury to the recurrent laryngeal and vagus nerves. Once mobilized from the prevertebral fascia and posterior mediastinum, the esophagus is elevated into the wound. It is vital to preserve as much viable esophagus as possible to aid in future reconstruction. After the esophagus has been transected, it is tunneled subcutaneously onto the left chest, and an end esophagostomy is created. A jejunostomy tube is then placed. If the surgeon wishes to place a gastrostomy tube for gastric decompression, care must be taken not to compromise the use of the stomach as a conduit for later reconstruction.

Special Situations

Malignancy

When esophageal perforation involves a malignancy, consideration must be given to the treatment of both problems. If drainage is adequate, placement of an esophageal stent to control contamination is favored, reserving resection and anastomosis for a later time. If the

patient is found to have massive contamination with hemodynamic instability not amenable to stent placement, resection, cervical esophagostomy, tube placement, and gastrostomy should be considered as described earlier.

Achalasia

Patients with a known diagnosis of achalasia with perforation require special consideration. These patients may experience esophageal perforation during pneumatic dilation, at the time of myotomy, or with other previously mentioned mechanisms. Because of the elevated intraluminal pressure proximal to the esophageal sphincter, healing of the repair often is precluded. Following repair of the perforation, these patients require myotomy for adequate healing. The myotomy should be performed on the opposite side of the esophagus from the perforation.

Benign Gastric Ulcer

Daniel T. Dempsey, MD, MBA

Benign gastric ulcer is a discrete macroscopic wound in the luminal surface of the stomach, extending into the submucosa or muscularis propria and rarely to the serosa of the organ. It is generally believed to start as a mucosal defect that remains unrepaired and deepens because of an imbalance between gastric mucosal defenses and aggressive luminal forces, primarily acid and pepsin. The early natural history of benign gastric ulcer is poorly understood, but most patients presenting to a surgeon with this problem are believed to have had the ulcer for weeks or months or even years. However, gastric ulcers related to drugs (nonsteroidal antiinflammatory drugs [NSAIDs] or cocaine) or stress may form and create clinical problems more rapidly. Most gastric ulcers are caused by (or strongly associated with) *Helicobacter pylori* infection, NSAID use (including aspirin), smoking, or physiologic or psychological stress. There are undoubtedly other factors that play a role in ulcer formation and healing, such as abnormalities in locoregional gastric blood flow, gastroduodenal motility, or duodenogastric reflux.

It is likely that microscopic defects occur commonly in the surface epithelial layer of the gastric mucosa. These are repaired by a process of rapid restitution, restoring an intact layer of surface epithelial cells (SECs). Numerous mucosal defenses are necessary for this local healing process to occur, lest luminal acid and pepsin enter the lamina propria, causing further tissue damage. The mucus secreted by the SECs forms a physiologic bandage over the denuded mucosa, while healthy SECs move in from the periphery to reconstitute an intact epithelial layer. Mucosal blood flow is augmented during this process. Prostaglandins are important mediators. The causes of gastric ulcer described above interfere with these mucosal defenses. NSAIDs and aspirin block prostaglandin production. Smoking decreases mucosal blood flow. Helicobacter causes chronic mucosal inflammation, priming the lamina propria with inflammatory cells and mediators, which interfere with local defenses. These inflammatory cells are probably upregulated when the mucosal layer breaks, exposing them to acid and pepsin. Helicobacter infection also interferes with acid and gastrin secretion. Severe physiologic or psychologic stress can interfere with mucosal blood flow, gastric motility, and acid secretion.

TYPES OF BENIGN GASTRIC ULCER

Johnson initially defined three types of gastric ulcer (Fig. 1). Type 1 ulcers are the most common benign gastric ulcer. They typically occur at or near the angularis incisura on the lesser curvature of the stomach where the parietal cell containing body transitions to the gastric antrum (locus minoris resistentiae). Type 1 gastric ulcers are not associated with gastric acid hypersecretion, and thus vagotomy has not traditionally been part of the surgical treatment. Type 2 ulcers usually occur in the distal stomach and are associated with duodenal ulcer disease, either active or chronic. Type 3 ulcers occur in the prepyloric region. Pathophysiologically, type 2 and 3 gastric ulcers are believed to resemble duodenal ulcers, and thus truncal vagotomy to ameliorate acid hypersecretion has been part of the surgical treatment. Recently two additional types of gastric ulcer have been described, resulting in a "modified Johnson classification" (Table 1). Type 4 gastric ulcer occurs high on the lesser curvature near the gastroesophageal (GE) junction. Excision of type 4 ulcers may get close to the esophagus, requiring Roux reconstruction (Csendes operation). Type 5 gastric ulcers are believed to be drug induced and typically occur toward the greater curvature, making them amenable to simple wedge resection. Neither type 4 nor 5 gastric ulcers are believed to be associated with acid hypersecretion, so vagotomy is probably unnecessary.

SURGICAL OPTIONS FOR GASTRIC ULCER

When operating on a patient with gastric ulcer, the choice of operation depends on a variety of technical and clinical factors, which will be discussed further below. Fundamentally, operations for gastric ulcer fall into two categories: those that excise the ulcer and those that do not (Table 2). If the ulcer is not excised, it must be biopsied to rule out cancer. Formal gastric resection with anastomosis is avoided in unstable patients. Before embarking on resection, it is prudent to assess during surgery whether the ulcer involves the pancreas, portal triad, or celiac artery or branches. For low-risk patients with distal gastric ulcers, distal gastrectomy with (type 2 and 3 ulcers) or without (type 1 ulcers) truncal vagotomy is the treatment of choice. Reconstruction consists of Billroth 1 gastroduodenostomy or Billroth 2 gastrojejunostomy (Fig. 2). The latter may be preferred when there is concomitant duodenal ulcer disease (type 2 gastric ulcer). With both types of reconstruction, we prefer to do the anastomosis to the greater curvature side of the gastric remnant. Roux reconstruction is much preferred with small gastric remnants when the gastrojejunostomy is close to the GE junction, but it should be avoided with large gastric remnants. For low-risk patients with high gastric ulcers (type 4), distal subtotal gastrectomy and in-continuity excision of the high lesser curvature ulcer can be considered, with reconstruction via Roux-en-Y esophagogastrojejunostomy (Csendes procedure) if resection encroaches on the gastric cardia (Fig. 3). For type 4 ulcers that are more distally located (or type 1 ulcers that are unusually proximal), a more limited distal gastric resection and lesser curvature extension can be performed, with reconstruction by gastrojejunostomy (Billroth 2 or Roux) (Pauchet procedure). Simple wedge resection is a good option for type 5 gastric ulcers, but it is difficult to perform for prepyloric ulcers (type 2 and 3), juxtacardial

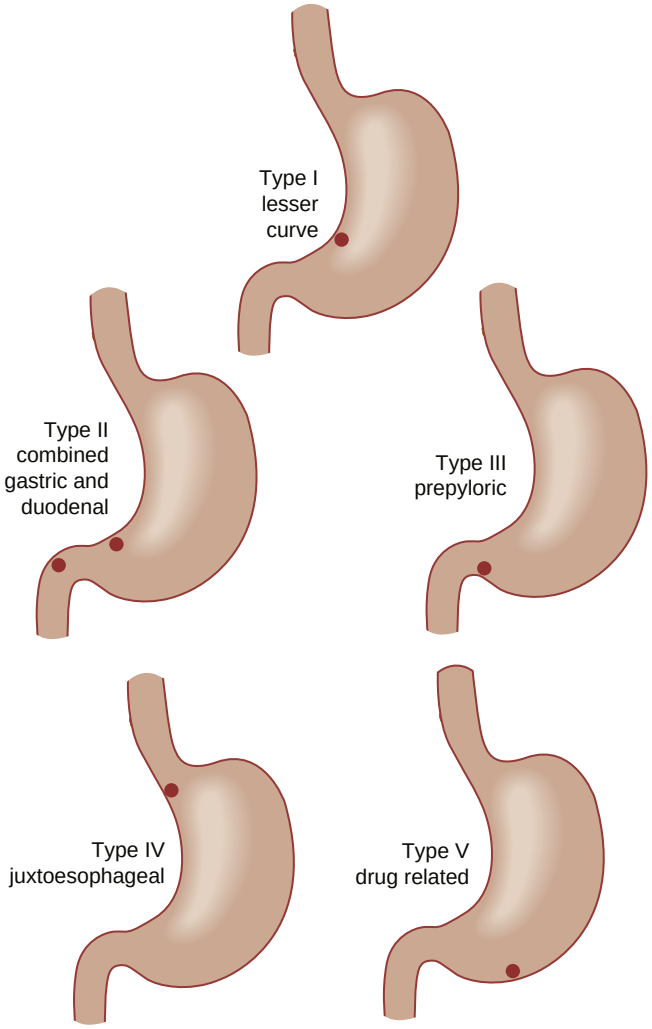

FIG. 1 Types of gastric ulcer. *(From Matthews JB, Silen W. Operations for peptic ulcer disease and early operative complications. In: Sleisenger MH, Fordtran JS, eds. Gastrointestinal disease. Philadelphia: Saunders; 1993.)*

TABLE 1 Modified Johnson Classification

Type	Location	Acid Hypersecretion
I	Lesser curvature, incisura	No
II	Body of stomach, incisura, and duodenal ulcer (active or healed)	Yes
III	Prepyloric	Yes
IV	High on lesser curve, near gastroesophageal junction	No
V	Anywhere (medication induced)	No

ulcers (type 4), and ulcers on the lesser curvature. For type 2 and 3 gastric ulcers that are left in situ, truncal vagotomy and gastrojejunostomy (with ulcer biopsy) may be a reasonable alternative to distal gastric resection. Similarly, for type 4 gastric ulcers, distal gastrectomy without ulcer excision (but with ulcer biopsy) can be considered (Kelling-Madlener operation).

TABLE 2 Choice of Operation for Gastric Ulcer by Type*

Gastric Ulcer Type	Option 1 (Resect Ulcer)	Option 2 (Biopsy Ulcer)
1	Distal gastrectomy	Vagotomy and drainage (with or without wedge excision)
2	Distal gastrectomy and vagotomy	Vagotomy and drainage
3	Distal gastrectomy and vagotomy	Vagotomy and drainage
4	Csendes or Pauchet procedure	Kelling-Madlener procedure, or vagotomy and drainage
5	Wedge resection	Patch/oversew

*Simple patch or oversew with biopsy is a reasonable option for all types of gastric ulcer in unstable patients.

INDICATIONS FOR OPERATION

Most patients with benign gastric ulcer never see a surgeon. They present to primary care or gastrointestinal (GI) practices or emergency departments, with complaints of upper abdominal pain, nausea, vomiting, or iron deficiency anemia. These complaints are evaluated with upper endoscopy with or without upper GI radiology. If a gastric ulcer is diagnosed, it is aggressively biopsied to rule out gastric cancer. If biopsy and cytology specimens are benign, the patient is treated with acid suppression, and the causative factors discussed above (*H. pylori,* NSAIDs, smoking) are eliminated if possible. Then the upper endoscopy is repeated in 2 to 3 months to document ulcer healing and to perform repeat biopsy. With this approach, the likelihood of misdiagnosing a gastric adenocarcinoma or lymphoma as a benign gastric ulcer is 1%.

If helicobacter is eradicated, NSAID and aspirin use is stopped, and smoking is eliminated, almost all gastric ulcers will heal with a 2- to 3-month course of proton pump inhibitor therapy, and recurrence or nonhealing is unusual. But, if helicobacter infection, NSAID or aspirin use, or smoking persists, recurrent gastric ulcer is the rule after the cessation of acid suppression. It is doubtful that definitive operation can completely nullify this fact, although recurrence of peptic ulceration (gastric or marginal ulcer or both) may be delayed after operation. For optimal results after operation for gastric ulcer, it is very important to strive for and document after surgery the absence of helicobacter infection, NSAID use, and smoking. Vagotomy or long-term acid suppressive medication may prevent recurrent peptic ulcer in some patients, and clearly patients having operation for gastric ulcer who require long-term NSAIDs or aspirin should receive long-term acid-suppressive medication. Selective COX-2 inhibitors should be considered in patients with ulcers requiring NSAIDs because these may have a lower risk of peptic ulceration.

PERFORATED GASTRIC ULCER

The most common indication for operation in benign gastric ulcer is perforation. Patients with gastric ulcer perforation present with acute abdominal pain and tenderness, usually with signs of peritoneal irritation (i.e., rebound tenderness and referred rebound tenderness). Because of the severity and acuteness of the symptoms, these patients most commonly present to the emergency department

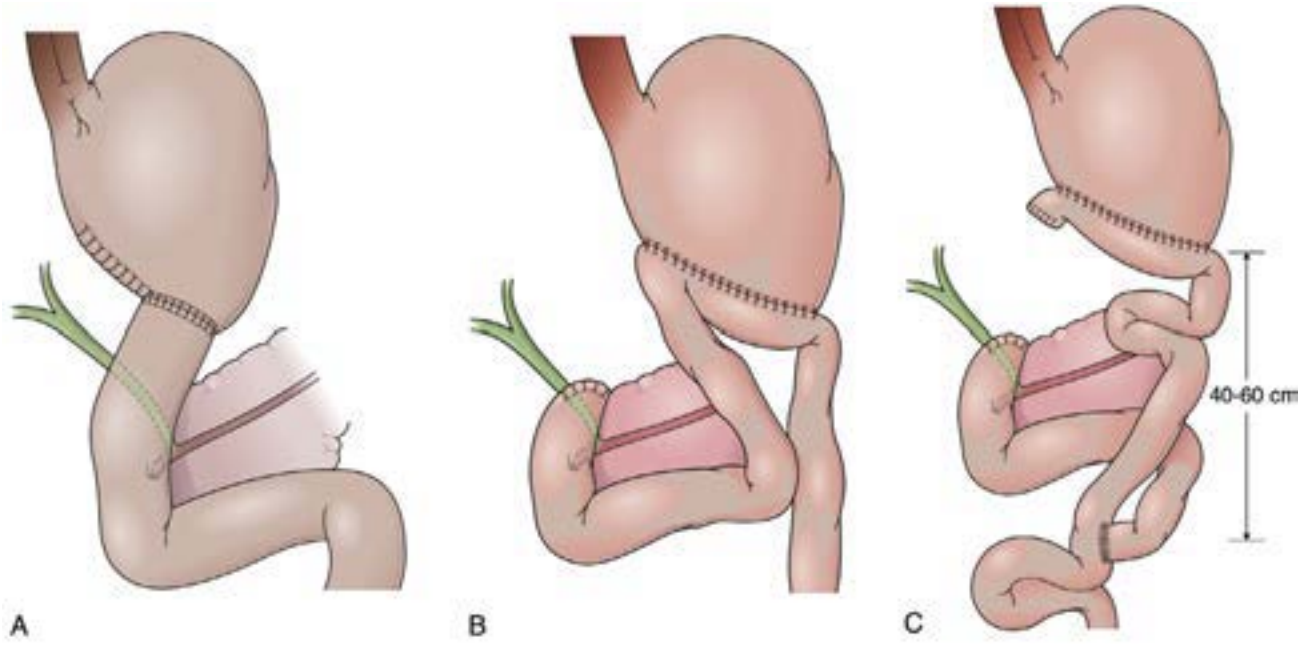

FIG. 2 Three types of reconstruction after distal gastrectomy. **(A)** Billroth I: A gastroduodenostomy is performed toward the greater curvature. **(B)** Billroth II: A gastrojejunostomy is created to reestablish the alimentary transit. Several variations may be observed in this type of reconstruction. **(C)** Roux-en-Y: To prevent biliopancreatic reflux into the stomach, a 50-cm to 60-cm Roux limb is anastomosed to the stomach with the biliopancreatic limb brought in 50 to 60 cm distal to the gastrojejunostomy. *(Modified from Ginsburg GG, Kochman ML, Norton ID, Gostout CJ.* Clinical gastrointestinal endoscopy. *2nd ed. Philadelphia: Elsevier, 2011.)*

Operations for peptic ulcer and their complications. In: Feldman M, Scharschmidt BF, Sleisenger MH, eds.* Gastrointestinal disease. *Philadelphia: Saunders; 1998.)*

where computed tomography (CT) scanning reveals free intraperitoneal air, usually with free fluid as well. If water-soluble oral contrast has been administered, the scan often reveals extravasation from the stomach. Gastric wall thickening is difficult to evaluate on CT if the stomach is collapsed. Simple upright chest radiography usually shows free air under the diaphragm, but this classic radiologic finding may be absent in 20% of patients with perforated gastric ulcer.

Intravascular volume depletion is the rule, so fluid resuscitation begins with 1 to 2 L of isotonic fluid. Induction of general anesthesia in the patient with severe hypovolemia may result in cardiovascular collapse and cardiac arrest. Intravenous antibiotics (cefazolin and fluconazole) are administered. Careful insertion of a nasogastric (NG) tube before surgery for gastric decompression is prudent, especially if water-soluble oral contrast has recently been administered or if imaging shows gastric distention. Operation is planned to occur usually within 2 hours of presentation. Rarely, nonoperative treatment is indicated if the patient is clinically stable, without signs and symptoms of sepsis, and with good radiologic evidence that the perforation has sealed.

Operation may be done open or laparoscopically. Copious irrigation of the soiled peritoneal cavity is performed with 5 to 10 L of warm saline. The entire anterior surface of the stomach is inspected. If no perforation is seen, the lesser sac is entered through the gastrocolic omentum and irrigated and the posterior stomach inspected. If still no perforation is found, it may be along the greater or lesser curvatures. If the patient is hemodynamically unstable or a poor operative risk, the perforated gastric ulcer should be biopsied and closed, either with a Graham (omental) patch or with a wedge resection of

TABLE 3 Choice of Operation for Gastric Ulcer by Indication

Indication	Option 1	Option 2	Option 3
Perforation	Patch or wedge excision	Patch or wedge excision with vagotomy and drainage	Distal gastrectomy*
Bleeding	Oversew or wedge excision	Oversew with vagotomy and drainage	Distal gastrectomy*
Obstruction	Vagotomy and distal gastrectomy	Vagotomy and gastrojejunostomy	
Nonhealing/Intractability	Distal gastrectomy (with vagotomy for type 2 and 3)	Wedge excision with vagotomy and drainage	

*Consider addition of vagotomy for type 2 and 3 gastric ulcer.

ASCVD, Atherosclerotic cardiovascular disease; *BP,* blood pressure; *CHF,* congestive heart failure; *COPD,* chronic obstructive pulmonary disease; *GI,* gastrointestinal; *P,* pulse.

the ulcer (Table 3). The latter is appropriate for perforations that occur along the greater curvature, or on the anterior or posterior surface of the proximal stomach. In the low-risk patient who is hemodynamically stable, definitive operation can be considered, either distal gastrectomy, including the ulcer in the specimen (vagotomy should be considered for type 2 and type 3 ulcers), or vagotomy and drainage with ulcer biopsy and closure for inconveniently located ulcers (high juxtacardiac ulcers, peripyloric ulcers with scarred duodenum or inflammatory mass). Giant (>2 cm) perforated gastric ulcers may be too big to securely patch with omentum and thus may require resection. If resection is deemed hazardous, it may be possible to achieve closure by anastomosing the perforation to a Roux limb (mucosa to mucosa). Before closure of the abdomen, the NG tube is positioned appropriately in the stomach and secured to the nose. We test the repair with both air insufflation and methylene blue via the NG tube. If postoperative reinsertion of the prematurely pulled NG is deemed a risk to the ulcer repair or suture line, it should be sutured or "bridled" to the nose before leaving the operating room. After surgery antibiotics are continued until the patient is fever free with a normal white blood cell count. Once GI function has returned, gastrografin swallow is performed before the initiation of a liquid diet. Leakage at the repair site is managed without surgery, if adequately drained and the patient is doing well. Otherwise, early reoperation is necessary, the primary goal of which is to achieve adequate drainage of the leak, and enteral access for proximal decompression (e.g., gastrostomy) and feeding distally (e.g., jejunostomy).

BLEEDING GASTRIC ULCER

Although still a common reason for hospitalization, bleeding gastric ulcer is increasingly less common as an indication for operation. This is likely due to the increasing effectiveness of medical and endoscopic treatment for bleeding gastric ulcer. The most common cause of GI bleeding in hospitalized patients is peptic ulcer, and annually in the United States a few thousand patients die of peptic ulcer bleeding. About half of these patients succumb to bleeding gastric ulcer. Essentially all the deaths from bleeding ulcer occur in patients with risk factors for persistent or recurrent bleeding. Thus, it is important to identify this high-risk group, which represents about one-quarter of patients admitted to the hospital with bleeding peptic ulcer. Risk assessment tools have been developed for this, such as the Rockall score (Table 4). None of these tools can predict with 100% accuracy who does and does not have a life-threatening ulcer bleed, but they are useful as guides. Patients with a Rockall score of 0 to 1 are very unlikely to have a life-threatening GI hemorrhage, whereas patients with a score from 9 to 11 may very well succumb to the bleed. In general, patients at high risk present with hematemesis, hypotension, or the requirement for multiple units of blood transfusion. These patients require early surgical consultation. Urgent upper endoscopy often shows high-risk endoscopic features, such as active bleeding or visible vessel in the ulcer base. Such patients should have endoscopic hemotherapy consisting of cautery, injection of epinephrine, and application of clips. Intravenous acid suppression and fluid resuscitation are important. Rebleeding can usually be managed with repeat endoscopic therapy, but angiography with possible embolization should also be considered. In the occasional patient in whom these modalities fail, operation should be considered. In general, candidates for operation for bleeding gastric ulcer have been transfused more than a few units of blood, have recurrent or refractory hemorrhagic shock, or have ulcer erosion into a large artery such as the left gastric or splenic artery. The operative mortality rate is around 25%.

Biopsy and oversewing of the bleeding ulcer is the appropriate operation for high risk or hemodynamically unstable patients. Wedge resection should be considered for bleeding ulcers on the greater curvature or free wall of the proximal stomach. Formal resection should be reserved for good risk and hemodynamically stable patients. Rebleeding is more common when the ulcer is not resected, but ultimate hospital mortality is similarly high in patients who are initially managed with oversewing and those initially managed with

resection. Postoperative bleeding might respond to angiographic embolization.

OBSTRUCTING GASTRIC ULCER

The most common cause of gastric outlet obstruction in the adult patient is cancer (pancreatic, duodenal, or gastric). So, when considering operation for obstructing distal gastric ulcer, the surgeon must ask whether the patient might have malignant obstruction. Whereas upper endoscopy, biopsy, contrast radiography, endoscopic ultrasound, CT, or magnetic resonance imaging may all be reassuring that the obstruction is benign, misdiagnosis, although rare, remains a real possibility. The classic operation for obstructing gastric ulcer is vagotomy and distal gastrectomy, but vagotomy and gastrojejunostomy may be an acceptable alternative. The latter procedure has a lower operative mortality risk, and, in the event of severe dumping, the gastrojejunostomy is potentially reversible if gastric outlet patency can be maintained. However, distal gastrectomy confirms the absence of cancer. Vagotomy should be performed because obstructing gastric ulcers are likely to be Johnson type 2 or 3 lesions.

NONHEALING GASTRIC ULCER (INTRACTABILITY)

Operation for nonhealing gastric ulcer should be unusual today because our understanding of ulcer pathophysiology is more complete than ever. Acid suppression, eradication of helicobacter, elimination of NSAIDs, and smoking cessation should heal the ulcer. So why would the gastric ulcer persist? Could it be cancer? Is the patient noncompliant? Is there unrecognized gastric stasis or enterogastric reflux? Are there important factors in ulcer pathogenesis that we have not discovered yet? These are all important questions for the surgeon to consider before operating on a patient for nonhealing gastric ulcer. Furthermore, it must be recognized that patient noncompliance and unknown pathophysiologic factors may predispose to ulcer recurrence or poor functional results after gastrectomy for nonhealing ulcer. This may be particularly problematic in thin patients who are easy to operate on but who have insufficient nutritional reserves in the event of a poor functional outcome.

In the event that operation for nonhealing ulcer is necessary, the ulcer should be excised either with distal gastrectomy or wedge resection. This both excludes cancer and resects the vulnerable part of the stomach. If distal gastrectomy, the classic operation, is performed, then vagotomy should be added for type 2 and 3 gastric ulcers. If the ulcer is wedged out, then vagotomy and drainage should be added.

MARGINAL AND RECURRENT ULCER

Ulcers that occur at or near the gastroenterostomy are termed *marginal ulcers*. They may occur on either side of the anastomosis. When on the distal side, they are generally believed to be due to acid/peptic injury to small bowel mucosa, which is ill equipped to defend itself against unbuffered gastric juice. This occurs more commonly in Roux gastrojejunostomy because the anastomosis is devoid of the buffering effects of duodenal contents, which help protect a Billroth 2 anastomosis. When on the proximal side of the anastomosis, the ulcer is generally thought to be due to ischemia, stasis, foreign body (suture), bile reflux, or the circumstances that led to the gastric ulcer in the first place (recurrent ulcer). Marginal ulcer complicates Roux-en-Y gastric bypass in about 8% of patients, and presently this is the most common cause of marginal ulcer, which may also complicate gastrojejunostomy for cancer or ulcer.

The medical treatment of marginal ulcer is identical to gastric ulcer: acid suppression, eradication of helicobacter, elimination of NSAIDs, and smoking cessation. Indications for operation are also identical to those for gastric ulcer: perforation, bleeding, obstruction, and intractability. The realization that reoperation for recurrent or marginal ulcer puts the patient at increased risk (and closer to total gastrectomy) underscores the importance of patient education and good management after the first ulcer operation, which includes minimizing the risk factors for ulcer recurrence. In addition to elimination of helicobacter, NSAIDs, and smoking, we consider every patient who has had an operation for gastric ulcer a candidate for lifelong acid suppression, unless the patient has had a vagotomy.

Perforated marginal ulcer may be treated with simple patch closure, which is certainly appropriate in high-risk and unstable patients. It may also be the preferred treatment in patients with Roux-en-Y gastric bypass because resection may necessitate esophagojejunostomy. In stable low-risk patients with perforated gastrojejunostomy after distal gastric resection, resection of the anastomotic region (segmental jejunal resection with additional gastrectomy) is preferred. The addition of truncal vagotomy may be considered. If the remaining gastric remnant is 30% or less, reconstruction should be Roux gastrojejunostomy to avoid bile reflux esophagitis. If the remaining remnant is larger than 30%, reconstruction should be via Billroth 1 or 2 technique to minimize recurrence of marginal ulceration. If the original operation was a simple loop gastrojejunostomy, consideration may be given to reversal (if the gastric outlet is patent) or distal gastrectomy with Billroth 1 or 2 reconstruction.

Bleeding marginal ulcer can usually be managed without surgery with the help of endoscopic hemostatic techniques or angiographic embolization, unless the ulcer has eroded into a named visceral vessel such as the splenic, left gastric, or middle colic artery. Those patients requiring emergency operation may have torrential bleeding and often present with a less impressive "herald bleed." Whereas gastroenterotomy and transluminal oversewing of the bleeding vessel may prove adequate, resection of the anastomotic region may be expeditious and safer. Postoperative angiographic embolization might complement the operation. Marginal ulcers associated with obstruction or intractability should be treated with elective resection of the anastomosis, followed by Roux or Billroth reconstruction, depending on how close the anastomosis is to the GE junction.

Management of Duodenal Ulcers

Daniel T. Dempsey, MD

INTRODUCTION

Duodenal ulcer is an acute or chronic localized wound of the duodenal mucosa caused by acid/peptic injury. Superficial ulcers involve the submucosa; deeper ulcers involve the muscularis propria or the serosa and may penetrate posteriorly or perforate anteriorly. Common predisposing factors are *Helicobacter pylori* infection, use of nonsteroidal antiinflammatory drugs (NSAIDs) or aspirin, smoking, and stress. Less common causative factors include gastrinoma (Zollinger-Ellison syndrome), radiation, Crohn's disease, cocaine, and gastroduodenal dysmotility. The most common symptoms of duodenal ulcer are abdominal pain, nausea, vomiting, and anemia.

The reasons for hospitalization resulting from duodenal ulcer are (in decreasing order) upper gastrointestinal (GI) bleeding, perforation, obstruction, and intractability. Peptic ulcer is the most common cause of clinically significant upper GI bleeding requiring hospitalization, but nowadays very few of these patients require operation. Currently the most common indication for operation in duodenal ulcer patients is perforation. Surgery for bleeding and obstruction is less common, and surgery for medically intractable duodenal ulcer is very uncommon. The operative (90-day) mortality rate for emergency peptic ulcer surgery is about 30%. After surgery for duodenal ulcer, recurrent ulcer can be minimized if all of the following conditions are met: eradication of *H. pylori* infection, diligent and permanent avoidance of NSAIDs and aspirin, and long-lasting abstention from smoking. If compliance with these management principles cannot be followed, eventual ulcer recurrence is likely. Testing for *H. pylori* infection should be performed in all patients with active peptic ulcer disease or a history of peptic ulcer disease unless previous cure of *H. pylori* infection has been documented. Testing should also be strongly considered if long-term aspirin or NSAIDs are required. All patients who test positive should be treated. Testing for *H. pylori* infection should be performed in all patients with peptic ulcer, mucosa-associated lymphoid tissue (MALT), early gastric cancer, and those on long-term aspirin or NSAID regimens (Box 1). With the appropriate 10- to 14-day multidrug regimen (which takes into account local antibiotic resistance and recent antibiotic usage) and patient compliance, *H. pylori* eradication will be confirmed in about 85% of patients who undergo a urea breath test, fecal antigen test, or endoscopic biopsy (*H. pylori* serology should not be used to test for cure of *H. pylori* infection). Consultation with a gastroenterologist or infectious diseases specialist with an interest and expertise in *H. pylori* treatment and cure should be considered.

If medically indicated, daily aspirin for cardiovascular prophylaxis may be taken safely, provided a daily proton pump inhibitor (PPI) is also taken. It is not unreasonable to consider long-term PPI treatment (e.g., omeprazole 20 mg before breakfast) for all patients who have required hospitalization for duodenal ulcer unless a vagotomy has been performed, particularly in patients for whom the above conditions cannot be assured. It is unclear whether definitive duodenal ulcer surgery (e.g., vagotomy and drainage; vagotomy and antrectomy [V/A]) is as effective in preventing ulcer recurrence as it was in the past. The acid suppressive effect of vagotomy may be no more profound than a properly taken PPI, but admittedly the former does not depend on patient compliance. Clearly, the concept that a more complex surgery is better should be used carefully and sparingly today in ulcer surgery, particularly during emergency surgery, which now is far more common than elective surgery. Gastrectomy for duodenal ulcer should be avoided in thin or chronically malnourished patients.

MEDICAL MANAGEMENT OF DUODENAL ULCER

Most patients with duodenal ulcer are treated medically as outpatients and never seen by a surgeon. Typically, the diagnosis is made with esophagogastroduodenoscopy (EGD). Biopsy of duodenal ulcer is unnecessary, but gastric biopsies should be taken to rule out *H. pylori* infection. Medical management includes acid suppression with a PPI, diagnosis and treatment of *H. pylori* infection (present in up to 90% of duodenal ulcer patients), elimination of NSAIDs, smoking cessation, and (in the appropriate clinical setting) evaluation for gastrinoma. Unless the patient has required hospitalization for an ulcer complication, long-term PPIs are not indicated. The obvious exceptions are duodenal ulcer patients who require long-term NSAIDs, aspirin, or anticoagulants, all of whom require PPI ulcer prophylaxis.

Perforated Duodenal Ulcer

Duodenal ulcer perforation (Fig. 1), the most common indication for surgery, presents as an acute abdomen. The patient usually can pinpoint the onset of severe abdominal pain. There may or may not be a history suggestive of chronic duodenal ulcer. The longer surgery is delayed from the onset of perforation, the higher the mortality risk. On examination, the patient is very uncomfortable and loath to move. Tachycardia may be the only early vital sign abnormality. Fever and tachypnea then ensue, and hypotension is a late finding. The abdomen is rigid, and there is obvious peritonitis. Leukocytosis is common. Anemia suggests the possibility of a second, usually posterior, bleeding ulcer ("kissing ulcers"), which can be evaluated intraoperatively with direct inspection or EGD. An upright chest x-ray usually shows pneumoperitoneum (absent in 10% to 15% of cases). Computed tomography (CT) nearly always reveals extraluminal air in the upper abdomen, often with free peritoneal fluid. The mortality risk of perforated duodenal ulcer in the modern era is high, up to 30% in some series. Although this may be caused in part by the frailty of the patient population affected, there is no doubt that delayed treatment increases mortality risk. Prompt fluid

BOX 1 *Helicobacter pylori* Tests

Tests for *H. pylori* (All Positive Patients Should Be Treated)

- Fecal antigen test
- Urea breath test
- Esophagogastroduodenoscopy and biopsy
- Rapid urease test
- Histology
- Culture
- Molecular real-time polymerase chain reaction (RT-PCR)

Some Common *Helicobacter* Treatment Regimens (10–14 Days)

- Clarithromycin triple therapy (PPI, clarithromycin, amoxicillin, or metronidazole)
- Bismuth quadruple therapy (PPI, bismuth, tetracycline, nitroimidazole)
- Sequential therapy (PPI and amoxicillin for 5–7 days, and then a PPI, clarithromycin, and nitroimidazole for 5–7 days)
- Hybrid therapy (a PPI and amoxicillin for 7 days, and then a PPI, amoxicillin, clarithromycin, and nitroimidazole for 7 days)

PPI, Proton pump inhibitor.

resuscitation and intravenous (IV) antibiotics are important, but so is prompt surgery. Medical optimization, although necessary, should not be an excuse for prolonged delay in surgical treatment. In addition to routine empiric broad-spectrum perioperative antibiotics, selective antifungal treatment may be considered in frail, immunosuppressed, or hospitalized patients. Routine use of antifungal agents is not indicated. Rarely, a stable patient without peritonitis and with a radiologically documented sealed perforation may be cautiously managed nonoperatively. Laparotomy or laparoscopy with peritoneal washout (5 to 10 L) and omental patch closure of the perforation is the treatment of choice for most patients with a perforated duodenal ulcer. Peritoneal fluid should be sent for culture and sensitivity (including fungal studies). Routine ulcer biopsy is not necessary but should be performed if there is any suspicion of malignancy. At least one closed-suction peritoneal drain is placed. Leakage at the repair site is not uncommon.

Omental Patching

Omental patching (Graham patching), a technique attributed to Dr. Roscoe Graham, is the most common method of perforated duodenal ulcer repair (Fig. 2). Typically, the hole in the duodenum is small (<1 cm) and is not repaired primarily before application of a well-vascularized tension-free piece of omentum. The duodenal tissue immediately adjacent to the perforation is friable, and attempts at primary closure often result in the sutures pulling through, enlarging the hole considerably. Primary closure may also further narrow an already scarred gastric outlet. The omental patch is held in place by interrupted seromuscular Lembert sutures placed into healthy duodenum on either side of the perforation. We usually place two or three interrupted bridging sutures, lay the patch on, and then tie the sutures gently but snugly over the omental patch. This technique creates better apposition between the duodenum and the omentum than the technique of using the suture "tails" from a primary closure to secure the omentum (Fig. 3). If necessary, additional sutures may be placed circumferentially between the healthy duodenum and the omental patch. Once the patch is secure, the adequacy of the seal can be tested by submerging the site under irrigation fluid while injecting air and/or methylene blue into the nasogastric (NG) tube (which remains in place postoperatively), and a closed-suction peritoneal drain is placed.

Special Considerations for Large Ulcer Perforations

Large ulcer perforations (>2 cm) merit special considerations. They are difficult to securely close with the Graham patch technique described earlier, but primary repair of a large perforated chronic duodenal ulcer is more prone to break down than primary repair of a similar-size acute duodenal laceration. And in the high-risk patient, an expeditious surgery is important. After peritoneal irrigation, the perforation is closed if possible with sutures or stapling, and the closure is buttressed with omentum or a falciform ligament. If it can be done safely, a Kocher maneuver facilitates primary closure. Multiple drains are placed. If the large perforation cannot be closed primarily, it can be plugged with omentum or falciform, which is pulled into the perforation using double-armed sutures placed first in the plug and then "inside out" into the duodenum surrounding the perforation (Fig. 4). Alternatively a loop of jejunum can be used as a serosal patch. Treatment of large perforations by direct intubation with or without an omental buttress is prone to ongoing leakage, but it can be used as a last resort or bailout procedure (Fig. 5). Multiple peritoneal drains are placed. In unstable patients, a damage control approach might be considered.

The fact that large perforated duodenal ulcers are hard to fix is indicated by the wide variety of (sometimes anecdotal) repair techniques. One useful ancillary procedure that has been evaluated with a retrospective controlled study is the *triple-tube technique*, which

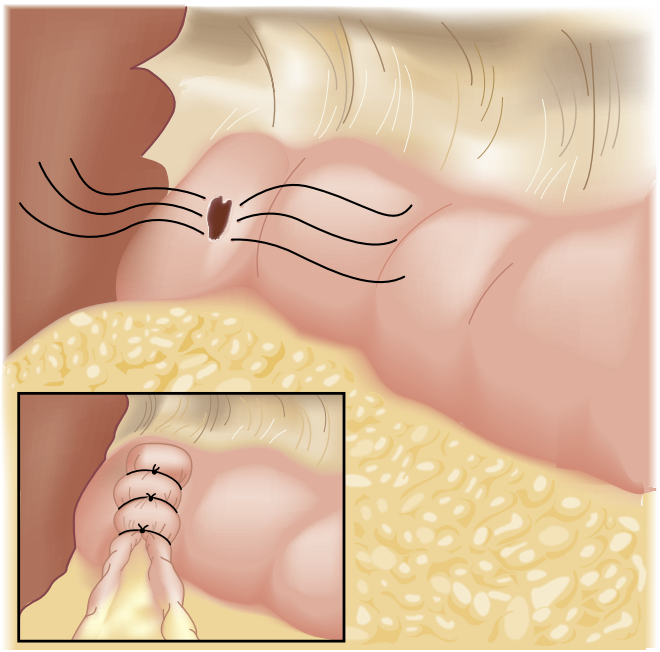

FIG. 4 Technique to "pull" an omental patch into a large perforated duodenal ulcer. *(From Townsend C. Sabiston Textbook of Surgery. 21st ed. Philadelphia: Elsevier, 2021).*

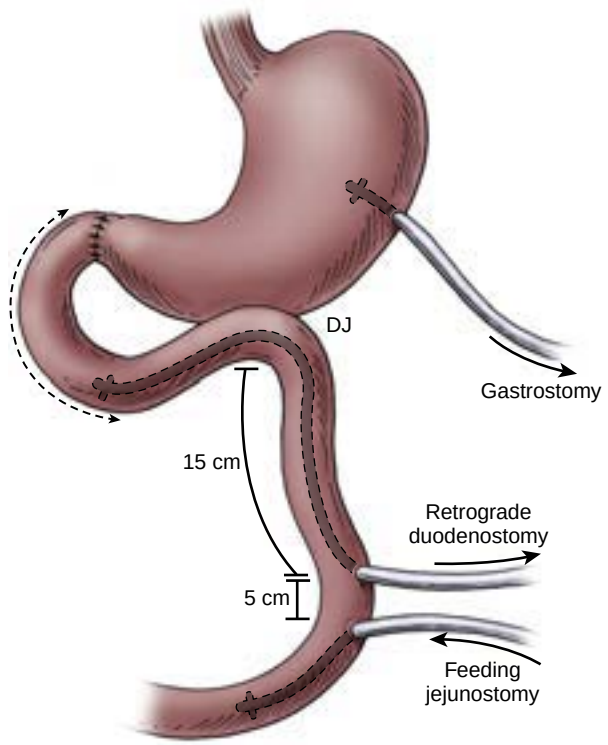

FIG. 5 Triple tube technique for high-risk perforated duodenal ulcer.

should be considered in high-risk perforations, whether repaired as described earlier or with one of the more complex surgeries described later. This involves placement of a gastrostomy, antegrade feeding jejunostomy, and a retrograde jejunostomy tube that is passed into the duodenum for decompression. This technique is safe and quick, and we have never regretted using it in the setting of high-risk duodenal perforation. We much prefer this to lateral duodenostomy or transpyloric intubation. For the most tenuous duodenal closures, we consider pyloric exclusion (pyloric closure with heavy absorbable suture and dependent loop gastrojejunostomy). One other option for repair of a large chronic duodenal perforation in a stable low-risk patient is a Roux-en Y duodenojejunostomy in which a tension-free two-layer anastomosis is created between the debrided duodenal opening and a Roux limb.

Definitive Ulcer Surgery

Definitive ulcer surgery can be considered in stable patients of low to medium risk (ASA 1 or 2) requiring emergency surgery for a perforated duodenal ulcer if there is a clinical history of duodenal ulcer, or if the perforation is large (>2 cm). Definitive surgery should not be performed if peritonitis is severe or well established (exudative). All of these contingencies (low-risk patient with a positive history or large perforation and without serious peritonitis) mean that the majority of patients with a perforated duodenal ulcer are *not* candidates for definitive ulcer surgery. Parietal cell vagotomy as a definitive ulcer surgery in this setting is largely of historical interest. Currently the two options for definitive surgery are (1) truncal vagotomy and gastrojejunostomy ([V/GJ] with or without temporary pyloric closure) after repair of perforation as described earlier; or (2) truncal V/A if the perforated duodenum can safely be resected with the antrum and a secure duodenal stump fashioned. If the ampulla is deemed to be at risk, a biliary Fogarty catheter can be advanced from above via the cystic duct or common bile duct. Resection should not be contemplated if a tenuous duodenal stump is likely or if injury to the ampulla or bile duct is an obvious possibility.

Minimally Invasive Surgery

Minimally invasive surgery for perforated duodenal ulcer is now commonplace, and some studies suggest that the laparoscopic approach is superior to open operation. Laparoscopy confirms the diagnosis, including the size and location of the perforation and the severity of peritonitis. Thorough irrigation of the peritoneal cavity can readily be accomplished laparoscopically. Laparoscopic omental patch closure of the perforation is usually straightforward for the typical small perforation. Even when conversion to open surgery is necessary, the laparotomy incision is smaller and optimally placed after laparoscopic evaluation. In the unlikely event that a definitive surgery is indicated, it can be performed either open or laparoscopically. Even a modest size perforation can be repaired laparoscopically, and vagotomy is straightforward for the minimally invasive surgeon with some foregut experience. A dependent loop gastrojejunostomy completes the ulcer surgery. Two types of vagotomy may be considered: (1) the more traditional bilateral truncal vagotomy or (2) a modified Taylor procedure. The latter consists of posterior truncal vagotomy and division of the segmental vagal branches to the anterior stomach with preservation of the anterior innervation to the antropyloric region. This technique may facilitate gastric emptying.

Postoperative Management

Postoperative management for many perforated ulcer patients starts in the ICU with continued optimization of critical organ function, fluid management, and treatment of sepsis. The decision to remove the NG tube and initiate oral liquids is made on clinical grounds. Postoperative contrast study (fluoroscopy or CT) is usually performed to rule out ongoing leak and to demonstrate gastric emptying. Antibiotics are discontinued on postoperative day 5 unless there is obvious ongoing infection. Peritoneal drains are removed 24 hours after the initiation of oral liquids if drainage is benign and the patient is doing well. Reoperation is sometimes required for persistent leakage from the perforation site or from abdominal wound dehiscence. Percutaneous drainage can be performed for localized infected fluid collections, but multiple fluid collections or extensive peritoneal fluid in the setting of sepsis may be a manifestation of uncontrolled

leakage and is best treated with reoperation and washout. Some sort of abdominal reintervention is necessary in about 25% of patients after repair of a perforated duodenal ulcer. We think emergency surgery for duodenal ulcer is an indication for chronic PPI therapy and empiric treatment of *H. pylori* infection. Patients are strongly advised to avoid NSAIDs, aspirin, and smoking. Low-dose aspirin is permissible provided chronic PPI treatment is continued.

BLEEDING DUODENAL ULCER

The most common reason for hospitalization and death in the duodenal ulcer patient is bleeding. However, bleeding has become an infrequent indication for surgery in duodenal ulcer largely because of the effectiveness of medical and endoscopic treatment. There also has been an increased appreciation of the risks associated with surgery for bleeding duodenal ulcer, including rebleeding, postoperative complications, and a postoperative in-hospital mortality rate as high as 40%. Endoscopic hemostatic therapy with cautery, topical agents, epinephrine injection, and/or clips has clearly decreased the need for surgery; selective angiography with embolization probably has too.

Risk Stratification

Three-fourths of patients with bleeding duodenal ulcer (Fig. 6) will stop bleeding with only IV fluid and IV PPIs. These are administered to all patients admitted to the hospital with upper GI bleeding. The other 25% will continue to bleed or rebleed, and essentially all deaths related to bleeding duodenal ulcer occur in this group. Therefore it is important to identify patients in this group. Not surprising, these are the patients with the bigger bleeds. They are more likely to have hematemesis, hypotension, a multiunit transfusion requirement, and/or endoscopic stigmata (visible vessel and/or active bleeding). Two commonly used prognostic systems for risk-stratifying patients with upper GI bleeding are the Glasgow-Blatchford score (GBS) and the Rockall score (Box 2). The former is designed to identify low-risk patients who do not require hospitalization (GBS 0–1) versus high-risk patients who require treatment (usually endoscopic) to stop the bleeding (GBS ≥6 indicates a 50% likelihood of requiring treatment). The Rockall score predicts mortality risk. High-risk bleeding duodenal ulcer patients should be seen in consultation by an endoscopist and surgeon, and they should be watched carefully in the hospital, perhaps initially in the ICU. Endoscopic findings and the treatment plan should be understood by the surgeon if the surgeon is not the endoscopist. Deep posterior bleeding ulcers in the proximal duodenum are particularly worrisome because they may involve the gastroduodenal artery, which can cause exsanguinating hemorrhage. Hemostasis usually can be achieved with PPI infusion and endoscopic treatment. Rebleeding should prompt repeat endoscopic treatment and consideration of arteriography and possible angioembolization. Surgery should be considered for persistent or recurrent bleeding in patients with hemodynamic instability or a transfusion requirement in excess of 6 units of red blood cells, but recognizing (for example) that predicted postoperative mortality in an older adult patient with a bleeding duodenal ulcer, hypotension, chronic obstructive pulmonary disease (COPD), and a visible vessel on EGD is 40% by the Rockall score.

FIG. 6 Bleeding duodenal ulcer. *(Courtesy Dr. Gregory Ginsberg.)*

BOX 2 Risk Stratification for Upper Gastrointestinal Bleeding

Glasgow-Blatchford Score*

• Elevated BUN	2–6 points
• Low Hgb	1–6 points
• Low BP	1–3 points
• Elevated HR	1 point
• Melena	1 point
• Syncope	2 points
• Liver disease	2 points
• Heart failure	2 points

Rockall Score**

• Age	0–2 points
• Shock	0–2 points
• Comorbidity	0–3 points
• EGD stigmata	0–2 points
• EGD diagnosis	0–2 points

*0 points = outpatient management.; 6+ points = 50% need endoscopic hemostatic Rx

**0–1 points = 0% mortality; 5 points = 10% mortality; 8+ points = 40% mortality

BP, Blood pressure; *BUN,* blood urea nitrogen; *Hgb,* hemoglobin; *HR,* heart rate.

Surgery for Bleeding Duodenal Ulcer

There are three surgical options for bleeding duodenal ulcer: (1) oversewing alone, (2) oversewing with vagotomy and drainage, and (3) V/A. Clinical trials from a previous era suggest that the ultimate result (i.e., survival) is similar with either of the two latter surgical options, but reoperation for rebleeding is less common after V/A. However, resection for bleeding duodenal ulcer is rarely done nowadays because most surgical patients are at high risk. Furthermore, fashioning a secure duodenal stump can be difficult because the bleeding ulcer either must be resected, or, if not resected, it must be oversewn. Review of National Surgical Quality Improvement Program data suggests that vagotomy and drainage for a bleeding peptic ulcer may result in a significantly lower 30-day postoperative mortality rate (12%) than vagotomy and resection (23%) or oversewing alone (27%).

Oversewing of a Bleeding Duodenal Ulcer

Oversewing of a bleeding duodenal ulcer starts with exposure of the lesion, usually through a longitudinal duodenotomy or pyloroduodenotomy. The Kocher maneuver is done first because this not only decreases tension on the closure, but facilitates manual control of a bleeding gastroduodenal artery with the left hand of the surgeon standing on the patient's left side (long fingers behind the head of the pancreas, thumb in front). Deep posterior ulcers usually require placement of two or three heavy suture ligatures placed in figure-of-8 or over-and-over fashion in the ulcer bed. The U-stitch has been well described. Surgeons with advanced hepato-pancreato-biliary experience might be tempted to ligate the gastroduodenal artery extralumenally above and below the duodenum, but this is usually hazardous and inadvisable, and it misses the pancreatic branch for which the U-stitch was conceived. Once hemostasis is achieved, the ulcer bed should be abraded with the sucker tip to ensure that rebleeding does not occur. The anterior incision can then be closed either longitudinally, or transversely as a pyloroplasty.

Definitive Ulcer Surgery

Definitive ulcer surgery may be appropriate for some patients with a history of ulcer chronicity or for those with a large (>2 cm) deep posterior ulcer, but this is clearly contraindicated in ASA 4 and 5 patients and should be done quite selectively in ASA 3 patients. If the patient is stable and exposure straightforward, truncal vagotomy and drainage (pyloroplasty or gastrojejunostomy) is the preferred definitive surgery. In the setting of bleeding ulcer, parietal cell vagotomy, probably comparable to PPI therapy, is not indicated, and gastric resection is quite likely to be problematic, as discussed earlier.

Postoperative Management

Postoperative management is similar to that after repair of a perforated duodenal ulcer. High-dose PPIs in the early postoperative period may decrease rebleeding risk. There is no evidence that transfusion triggers must be increased after surgery for a bleeding ulcer. Early rebleeding should be evaluated with upper endoscopy and arteriography (CT angiography or standard arteriography). Long-term smoking cessation is imperative. If NSAIDs are medically necessary, a selective COX-2 inhibitor should be considered, and long-term PPI therapy is necessary. Similarly, long-term PPIs are definitely prescribed if chronic aspirin or anticoagulants are necessary, and this treatment may not be unreasonable for all patients admitted for duodenal ulcer complications unless definitive surgery has been performed.

GASTRIC OUTLET OBSTRUCTION

Chronic gastric outlet obstruction secondary to chronic inflammation and scarring is now the second most common indication for duodenal ulcer surgery in some hospitals. Patient history and endoscopic findings can usually differentiate between an acute potentially reversible obstruction and chronic obstruction. Patients usually experience nausea, nonbilious vomiting, epigastric distension, and weight loss. A succussion splash may be present on abdominal auscultation, and in the setting of high-grade obstruction and dehydration, hypokalemic hypochloremic metabolic alkalosis is often present. The differential diagnosis obviously includes cancer because most patients with these symptoms have malignant gastric outlet obstruction (pancreatic, duodenal, or gastric cancer). Evaluation includes EGD and biopsy, upper gastrointestinal fluoroscopy with oral barium, and CT. Endoscopic dilation and medical ulcer treatment may delay surgery for 1 to 2 years in one-half of patients with benign gastric outlet obstruction from duodenal ulcer, but most patients requiring hospitalization or dilation will ultimately undergo surgery.

Surgery for Obstructing Duodenal Ulcer

Vagotomy and Antrectomy

V/A is the gold standard surgery for obstructing duodenal ulcer, but V/GJ is a good alternative in some patients. The advantage of V/A is lower recurrence rate and reassurance that the cause of the obstruction is benign. The disadvantage is higher operative mortality risk (2%). The advantage of V/GJ is a lower operative mortality and the potential for reversal of the GJ in the unlikely event that dumping becomes intolerable. Another advantage is that V/GJ is readily accomplished laparoscopically. A disadvantage of V/GJ is that obstructing cancer may be missed, and marginal ulcer may occur. The remote possibility of pyloric channel or proximal duodenal cancer must be considered in the operative planning for obstructing ulcer because optimal surgical treatment may involve pancreaticoduodenectomy.

V/A can be done through an upper midline or transverse incision. A mechanical retractor is helpful. Exploration of the gastroduodenal area for any evidence of malignancy is done. Truncal vagotomy is accomplished first. The peritoneum over the abdominal esophagus is incised, and the gastrohepatic ligament is opened above the hepatic vagal branches. Pulling down on these branches makes the anterior vagal trunk stand out, and it is clipped and severed easily; a short segment is sent to pathology. The phrenoesophageal ligament then is opened along the right crus, and the retroesophageal space is entered where the posterior vagus is reliably located, clipped, severed, and sent for biopsy. Unless it appears that duodenal stump closure would be difficult, we then proceed with antrectomy. The lesser curvature neurovascular bundle is divided at the angularis incisura, and the right gastroepiploic arcade is divided on the greater curvature at a point directly opposite. This is where the stomach is transected with a green handheld GIA or a purple or black laparoscopic GIA cartridge. The chronically obstructed stomach may be unusually thick walled, and it is important that adequately large staples be used lest the gastric closure dehisce. The gastrocolic ligament attached to the antrum (i.e., the specimen) is taken usually outside the gastroepiploic arcade, progressing distally to the right gastroepiploic pedicle, which is ligated and divided. The right gastric is also ligated and divided. The pylorus and duodenal bulb are carefully separated from the pancreas, and then the postpyloric duodenum is transected with a GIA or TA stapler. The outlet obstruction should be resected. If the obstruction is prepyloric, it is important that the surgeon ensure that the distal staple line is in fact distal to the pylorus to avoid retained antrum. Rarely, resection of the obstruction is difficult or hazardous because it is in the second portion of the duodenum. The surgeon should try hard to rule out cancer if the site of outlet obstruction is left behind, and intraoperative consultation with an hepato-pancreato-biliary colleague may be helpful.

Antecolic isoperistaltic Billroth II gastrojejunostomy is performed on the greater curvature side of the gastric remnant, with the afferent loop on the greater curvature side and the efferent limb on the lesser curvature side. We avoid Roux-en Y reconstruction with a large gastric remnant because of the possibility of marginal ulceration and/or delayed gastric emptying. We usually do not oversew the duodenal staple line but after allowing some time to ensure complete hemostasis and no bile staining on the stump, just before abdominal closure we irrigate the staple line and cover it with well-vascularized omentum held in place by two or three strategically placed sutures. A closed-suction right upper quadrant drain is placed, although admittedly routine peritoneal drainage after gastrectomy is not supported by clinical evidence.

V/GJ can be performed with an open or minimally invasive technique. After evaluation of the stomach and proximal duodenum, vagotomy is performed. Either a bilateral truncal or posterior truncal with anterior highly selective technique is acceptable. Loop gastrojejunostomy is then constructed to the dependent greater gastric

curvature. We divide the little branches from the gastroepiploic to the stomach for a length of 6 to 8 cm, creating a target for the hand-sewn or stapled antecolic isoperistaltic gastrojejunostomy. Patients with obstructing chronic duodenal ulcer disease who are treated with V/GJ should be followed closely for 2 years to ensure that an obstructing cancer was not missed. If the patient is not doing well clinically, reevaluation and open exploration should be considered with conversion of the loop GJ to distal gastrectomy, which should include the area of obstruction.

INTRACTABLE DUODENAL ULCER

The endoscopically documented persistence of a benign symptomatic duodenal ulcer despite adequate medical treatment should be a very unusual indication for surgery nowadays. The 50+-year-old literature describing the salutary effect of ulcer surgery for intractability is largely irrelevant to this situation nowadays. Assuming gastrinoma and cancer have been ruled out, a duodenal ulcer will heal if *H. pylori* infection has been cleared (best documented with a urea breath test, fecal antigen test, or endoscopic biopsy), the patient diligently takes PPIs as prescribed, diligently avoids NSAIDs and aspirin, and does not smoke. Surgery should not be considered for intractability unless the surgeon is certain that all of these conditions have been fulfilled. Though it may take a while, ulcer recurrence is almost inevitable after definitive ulcer surgery for intractability in patients who cannot give up NSAIDs or smoking. It is also important to keep in mind that *if* the patient has persistent peptic ulceration despite all the aforementioned conditions being fulfilled, perhaps the patient has some other unusual poorly understood factors predisposing to duodenal ulcer (e.g., stress or dysmotility). This may contribute to the high incidence of debilitating postoperative symptoms in patients undergoing vagotomy and drainage or V/A for intractable duodenal ulcer in the modern era.

MANAGEMENT OF THE DIFFICULT DUODENAL STUMP

The routine closure of the proximal duodenum during Billroth II distal gastrectomy is accomplished most easily with a GIA- or TA-type stapler (blue cartridge). A two-layer suture closure is also straightforward in routine cases, but excessive suturing and imbrication should be avoided because it may predispose to stump leakage. Occasionally ulcer location or size or the extensiveness of the inflammation and/or scar may render secure duodenal closure difficult. In this situation, difficult duodenal stump closure is best avoided by not performing a distal gastrectomy because operative mortality skyrockets with postoperative duodenal leakage. However, a difficult duodenal stump is occasionally unavoidable. If the ulcer has destroyed the posterior duodenal wall, the anterior edge of the open duodenum can be sewn to the proximal or distal "lip" of the ulcer on the pancreas with interrupted suture. Secure hemostasis in the ulcer bed must be accomplished. The integrity of the closure is tested by placing the tip of the NG tube at the ligament of Treitz (through the gastrojejunostomy) and distending the duodenum with air. Additional sutures may be necessary to render the duodenal closure air tight. Then healthy omentum is sewn over the closure, and multiple closed-suction drains are placed. Duodenal decompression should be performed, ideally with a retrograde tube via the proximal jejunum; other options include lateral duodenostomy or NG decompression by threading the NG tube through the gastrojejunostomy into the afferent limb and duodenum. The latter option requires suturing or bridling the NG to the nose, and it soon becomes uncomfortable unless it can be converted to a percutaneous transgastric arrangement. As discussed earlier, placement of a large tube into the end of the duodenal stump inevitably leaks around the tube and should only be performed if no other primary duodenal closure options are available. Postoperative duodenal stump leakage is usually managed nonoperatively unless the patient develops diffuse peritonitis or worsening sepsis. At reoperation, wide drainage and source control are paramount. Suture closure of a leaking stump is destined for failure. Generally an appropriately sized tube is brought through the abdominal wall and placed into the leak, and the duodenum is gently snugged up around this tube, which is buttressed with omentum or falciform or peritoneum/skeletal muscle. Multiple closed-suction drains are placed. If a chronic fistula persists, a definitive repair can be attempted much later with Roux-en-Y duodenojejunostomy or resection.

CONCLUSION

Duodenal ulcer is no longer considered a surgical disease. The effectiveness of modern medical management means that only a very small percentage of patients with this diagnosis will ever see a surgeon. However, general and acute care surgeons still have an important role in the management of hospitalized patients with duodenal ulcer. About 25% of this group have a perforated duodenal ulcer, and essentially all require emergency surgery. Prompt resuscitation and surgery in this group will save lives because even a delay of a few hours substantially increases mortality risk. The appropriate surgery for most of these patients is patch of the ulcer with peritoneal irrigation and drainage. About 75% of hospitalized duodenal ulcer patients experience bleeding, and only a small number require surgery, but the right surgery at the right time can rescue these patients. For the highest-risk patients (ASA 4 and ASA 5), probably the best surgery is secure oversewing of the bleeding ulcer and high-dose acid suppression. For patients with lower operative risk (ASA 1–3), probably the best surgery is secure oversewing of the ulcer, truncal vagotomy, and drainage. Duodenal ulcer patients requiring surgery for perforation or bleeding are a small, high-risk subgroup of hospitalized patients that largely accounts for the high postoperative mortality rate (up to 30%). Finally, most patients with ulcer-related chronic gastric outlet obstruction will be seen in the surgical clinic instead of the hospital, and the majority will eventually come to surgery. V/A remains the surgery of choice in this group. Other important but less common issues related to ulcer surgery are also discussed.

Management of Zollinger-Ellison Syndrome

David W. McFadden, MD, MBA, and Brian D. Shames, MD

Zollinger-Ellison syndrome (ZES) is a constellation of symptoms comprising severe peptic ulcer disease, chronic diarrhea, and gastroesophageal reflux disease (GERD). It is caused by gastrin-secreting tumors of the pancreas or duodenum that result in increased stimulation of the acid-secreting parietal cells of the stomach. Patients with ZES have two problems that must be addressed: control of the acid hypersecretion that causes refractory peptic disease (and its complications) and control of the gastrinoma, which is malignant in the majority of cases. The terms *gastrinoma* and *ZES* are often used synonymously. However, *gastrinoma* refers to the neuroendocrine tumor (NET) that secretes gastrin, and ZES refers to the clinical manifestations of the disease. Many tumors, including some non-NET neoplasms, synthesize gastrin, but in most it is not fully processed to biologically active gastrin. Consequently these tumors do not cause ZES as they do not secrete sufficient amounts of fully processed gastrin. Therefore, they are not referred to as *gastrinomas* by most clinicians and in the classification of pancreatic NETs (pNETs). The syndrome was first described in 1955 by Zollinger and Ellison, who reported two patients with severe ulcer diathesis associated with jejunal ulcerations who ultimately required total gastrectomy after undergoing several failed ulcer operations. In both of the initial patients, non–beta islet cell tumors were identified in the pancreas. Zollinger and Ellison postulated that these tumors were potentially secreting a hormone that caused acid secretion with resultant peptic ulcer disease. The paper was presented at the American Surgical Association in 1955, and in discussion, Dr. Lester Dragstedt, the father of vagotomy, opined that these tumor cells may be similar to the antral cells that produce gastrin. Interestingly, six additional cases were disclosed by discussants of the paper. The syndrome's name was subsequently suggested by Dr. Ben Eiseman in 1956. In 1960, researchers using a tumor extract bioassay at the University of Liverpool discovered that tumors from ZES patients contained large amounts of a gastrin-like substance. Before the 1970s, ZES diagnosis required incisive clinical review and a high index of suspicion as there was an absence of blood or imaging tests to confirm the diagnosis.

In 1966, a radioimmunoassay (RIA) for gastrin was described by James D. McGuigan and now serves as the linchpin of diagnosis. Before the development of gastrin RIA, patients usually underwent multiple gastric operations before diagnosis. Recommended treatment at that time became total gastrectomy as it reduced the mortality of the syndrome, which was generally related to ulcer diathesis complications, such as perforation or bleeding. Later advances in pharmacologic control of acid secretion with histamine-2 (H_2) antagonists and proton pump inhibitors (PPIs) have essentially eliminated the need for total gastrectomy. Presently, it is recognized that ZES is caused by gastrin secretion from neuroendocrine tumors that arise from the pancreas, duodenum, or rarely ectopic sites. These tumors are called *gastrinomas.*

In 20% to 25% of cases, ZES is associated with multiple endocrine neoplasia type 1 (MEN-1), an autosomal dominant disorder, whereas nearly 50% of patients with MEN-1 will have gastrinomas. An average of 8 years is reported from the start of symptoms to diagnosis secondary to the widespread use of PPIs. Current surgical treatment is predicated upon gastrinoma resection. It also relies on long-term pharmacologic suppression of acid secretion for control of the peptic ulcer disease and management of the hyperparathyroidism and other endocrine disorders associated with MEN-1.

CLINICAL PRESENTATION

Behind insulinoma, gastrinoma is the second most common functional neuroendocrine tumor, with an annual incidence of 1 to 3 cases per 1 million people. Gastrinoma is the underlying cause of peptic ulcer disease in only 0.1% to 1% of patients and is one of the rarest of all causes of ulcer disease.

ZES is usually diagnosed in the fifth decade of life, and it is diagnosed between 20 and 60 years of age in 90% of patients. It is more common in men. ZES most commonly occurs as a noninherited disease; however, it is associated with MEN-1 in 20% to 25% of cases. Gastrinoma is the most common functional neuroendocrine tumor in MEN-1, occurring in 50% of patients with the syndrome. Hence, MEN-1 must be excluded in the workup of patients with suspected gastrinoma, and patients with MEN-1 should also be screened for gastrinoma. Patients with MEN-1 have their disease onset almost a decade earlier; the average age of onset of ZES is 33.2 years for patients with MEN-1 compared with 43.5 years for sporadic gastrinoma patients. Gastrinoma is also seen in association with von Hippel-Lindau syndrome and von Recklinghausen's disease.

Gastric acid secretion is usually controlled by negative feedback mechanisms from the release of somatostatin by gastric D cells. This normally maintains gastric acid homeostasis and pH. Because of the unopposed gastrin release by the gastrinoma, severe peptic ulcer disease results from the excess gastric acid secretion via the trophic effect of gastrin on parietal cells. Significantly, ZES is not the initial diagnosis in 97% of affected patients. Presenting symptoms for this disease have altered little despite successful pharmacologic treatment of gastric hypersecretion and the pervasive use of these drugs for symptoms of dyspepsia and other digestive ailments. The clinical presentation of gastrinoma is often not specific. There is often overlap of the symptoms associated with this illness and other more common gastrointestinal conditions that result in a high frequency of misdiagnosis and diagnostic delays. In most series, abdominal pain and diarrhea were the most common symptoms, reported in more than 70%, followed by heartburn (44%), nausea (33%), vomiting (25%), and weight loss (17%).

Despite an increased awareness of ZES, multiple experts have remarked that the diagnosis is more difficult today given the nearly ubiquitous use of PPIs. Diagnosis can normally be confirmed by measurement of fasting serum gastrin levels when the patient is off of PPIs, however the average time from symptom onset to diagnosis remains between 6 and 8 years. Another reason for the delay in diagnosis is that many patients with ulcer disease are symptomatically improved by H2 antagonists or PPIs without excluding the possibility of ZES. This treatment controls the acid secretion and related symptoms but may delay diagnosis if gastrinoma is not initially considered in the differential diagnosis.

CLINICAL PATHOLOGIC CORRELATION

In nearly 70% of patients, gastrinomas are found in the pancreas or duodenum within the region known as the *gastrinoma triangle.* This devised triangle is bounded by the cystic duct, the second and third portion of the duodenum, and the neck and body of the pancreas. Rarely, gastrinomas may occur in ectopic locations, including the stomach, bile duct, periportal lymph nodes, lungs, heart, and ovaries. Most gastrinomas (50%–70%) are located in the duodenum rather than the pancreas. They are most common in the first portion of the duodenum with a diminishing incidence as one progresses distally. Duodenal gastrinomas may be very small and hence difficult to identify preoperatively and intraoperatively. Both pancreatic and duodenal gastrinomas occur in MEN-1 patients, however these patients are more likely to have multiple tumors in the pancreas or duodenum. Initially, it was thought that, similar to insulinomas,

almost all sporadic gastrinomas occurred in the pancreas. However, it is now established that most (60%–95%) occur in the duodenum; in a recent series, they were 3- to 9-fold more frequent than pancreatic gastrinomas. Duodenal and pancreatic gastrinomas differ in their biologic behavior. Although both are associated with frequent lymph node metastases (30%–70%), pancreatic tumors have a much higher rate of liver metastases, which is the primary determinant of long-term survival. Hence, patients with pancreatic gastrinomas have a poorer prognosis. Sporadic gastrinomas are malignant in 60% to 90% of cases; approximately 13% to 53% (mean 34%) of patients have liver metastases at presentation, with most being diffuse liver involvement.

Gastrinomas are generally well differentiated and slow growing. They have a low proliferative rate with a Ki-67 of 1% to 2%. The tumors are usually more indolent and slower growing than other gastrointestinal malignancies. Duodenal gastrinomas have a greater incidence of lymph node metastases than pancreatic gastrinomas, 70% versus 40%, respectively. Liver metastases occur in approximately 25% of patients and are more common with pancreatic primary tumors (50% vs. 10%), particularly those occurring to the left of the superior mesenteric vessels. Unlike lymph node metastases, liver metastases herald a poor prognosis, with the extent of liver involvement an important predictor of survival. In patients with diffuse liver metastases, the 10-year survival is 10% to 15% compared with 95% in the absence of liver metastasis. The prognosis is also more favorable in patients with single-lobe liver metastasis, with a 10-year survival of nearly 60%. Regardless of location, primary tumor size is predictive of distant metastasis (Table 1).

TABLE 1 Primary Tumor Size and Frequency of Distant Metastases

Tumor Class	Diameter Range (cm)	Patients (No.)	Distant Metastases (%)
T0 (no tumor)	0	18	0
T1	0.4–1.0	21	10
T2	1.2–2.0	22	14
T3	2.2–2.6	16	12
T4	3.0–8.5	29	59

Modified from Ellison EC, Johnson JA. The Zollinger-Ellison syndrome: a comprehensive review of historical, scientific, and clinical considerations. *Curr Probl Surg.* 2009;46:13-106.

DIAGNOSIS

Although rare, a patient should be referred for prompt ZES workup in the presence of refractory peptic ulcer disease, long-standing diarrhea, ulcer disease in the absence of *Helicobacter pylori* infection, or failure to improve after treatment for established *H. pylori* and acid suppression therapy. In addition, the presence of hypercalcemia or nephrolithiasis should raise suspicion of possible MEN-1, and such patients should be screened for gastrinoma and MEN-1. The algorithm for the diagnosis of gastrinoma is shown in Figure 1. The diagnostic steps include measurement of gastric acid, baseline fasting gastrin levels, and secretin-stimulated serum gastrin levels as well as cross-sectional imaging.

Fasting serum gastrin is the appropriate initial diagnostic test, but it is insufficient alone to prove the diagnosis. Several medical conditions may cause hypergastrinemia, including pernicious anemia and atrophic gastritis, which are the two most common causes of hypergastrinemia. In affected patients, it is common for the fasting gastrin level to exceed 1000 pg/mL. Therefore, a fasting serum gastrin level greater than 1000 pg/mL is not diagnostic for ZES unless it occurs in association with increased gastric acid secretion (gastric pH <2). Other conditions that may cause fasting hypergastrinemia associated with increased acid hypersecretion include *H. pylori* infection, peptic ulcer associated gastric outlet obstruction, antral G-cell hyperplasia, retained antrum, renal failure, and short bowel syndrome. However, it is pharmacologic acid suppression that often confounds diagnosis, as such agents may cause achlorhydria. This can produce hypergastrinemia as a consequence of the absence of acid suppression of gastrin secretion from the G cells in the gastric antrum. It is important to emphasize that determination of gastric pH and verification of acid production is mandatory to confirm the diagnosis of ZES. A patient who is not being treated with PPIs is unlikely to have ZES in the absence of gastric acid. Basal acid output tests have 98% sensitivity if levels greater than 15 mEq per hour are seen in an unoperated patient or greater than 5 mEq per hour for those who had a previous resection.

Serum gastrin is measured by RIA. The patient should discontinue pharmacologic acid suppression with PPI for a minimum of 72 hours (ideally, 7 days) before testing. H2 receptor antagonists may be taken during this time to control acid secretion and symptoms. In ZES, a normal fasting gastrin is very rare, occurring in less than 3% of patients. This makes serum gastrin measurement an excellent screening test for ZES, with a sensitivity that approaches 99%. Patients with suspected ZES who have fasting hypergastrinemia and gastric pH measurement revealing the presence of gastric acid should undergo confirmation with provocative stimulation of gastrin with

secretin. Following an overnight fast, patients are given an intravenous bolus injection of secretin of 0.4 μg/kg of body weight. Blood samples are collected for determination of gastrin levels at 0, 2, 5, 10, 20, and 30 minutes following secretin administration. It is not necessary to discontinue PPIs or H2 antagonists for this test. Side effects of intravenous secretin administration are minimal and include nausea and flushing. The accepted threshold for a positive secretin test is an increase in gastrin of 110 pg/mL over baseline. This threshold has been found to be accurate in nearly 100% of patients. Rarely, false-negative or false-positive tests occur. The false-positive rate is 0% in patients without achlorhydria when an increase over baseline of more than 110 pg/mL is used. Once the biochemical diagnosis of gastrinoma is confirmed, the patients should be screened for MEN-1 with measurement of ionized calcium, parathyroid hormone, prolactin, and pancreatic polypeptide. MEN-1 is strongly suspected if patients have primary hyperparathyroidism, and parathyroidectomy is recommended initially.

TUMOR LOCALIZATION

Imaging is obligatory to localize the tumor before surgical intervention. Initial localization should be attempted with computed tomography (CT) of the abdomen and pelvis, with fine cuts through the pancreas (pancreas protocol CT). Magnetic resonance imaging (MRI) may also be used and may be more sensitive for detecting metastatic disease. Neuroendocrine tumors are hypervascular and demonstrate a greater degree of enhancement than the normal pancreas during the arterial and capillary phases of the contrast bolus. This is useful in identification and differentiation of pancreatic neuroendocrine tumors (PNETs) from pancreatic adenocarcinoma. Dual-phase MRI of the abdomen, with delayed images, may be useful to delineate the primary tumor or metastases to the liver. Somatostatin receptor scintigraphy (SRS) can also be helpful in the preoperative localization of gastrinoma. SRS is sometimes called an *OctreoScan* and employs indium-labeled octreotide with a strong affinity for type 2 somatostatin receptors, which are expressed on gastrinoma cells. SRS has been reported to be significantly better than all of the conventional imaging methods in the identification of gastrinomas subsequently found at surgery, but SRS will not detect 20% of gastrinomas. 68Ga-Dotatate positron emission tomography (PET) CT is replacing SRS for localization of neuroendocrine tumors, including those causing ZES (Fig. 2). 68Ga-Dotatate PET/CT is more accurate for staging and superior to OctreoScan in the detection of overall number of lesions in the body, bones, and viscera. 68Ga-Dotatate PET/CT also allows for calculation of standardized uptake value, has less whole-body radiation, and is quicker than OctreoScan. In contrast with fluorodeoxyglucose (FDG) PET/CT, 68Ga-Dotatate PET demonstrates a high uptake because neuroendocrine tumors express extensive somatostatin 2 receptors. Standard 18F-fluorodeoxyglucose PET/CT is not recommended for evaluation because the slow metabolic activity of gastrinomas renders them typically indemonstrable. The National Comprehensive Cancer Network guideline has added 68Ga-Dotatate PET/CT as an appropriate test in the diagnosis and management of neuroendocrine tumors. Endoscopic ultrasound (EUS) is an invasive alternative to be considered if cross-sectional imaging and 68Ga-Dotatate PET have not identified the location of a gastrinoma. In addition, a biopsy can be accomplished at the time of EUS. The sensitivity of EUS to localize small PNETs approaches 97% compared with CT (85%) or MRI (70%).

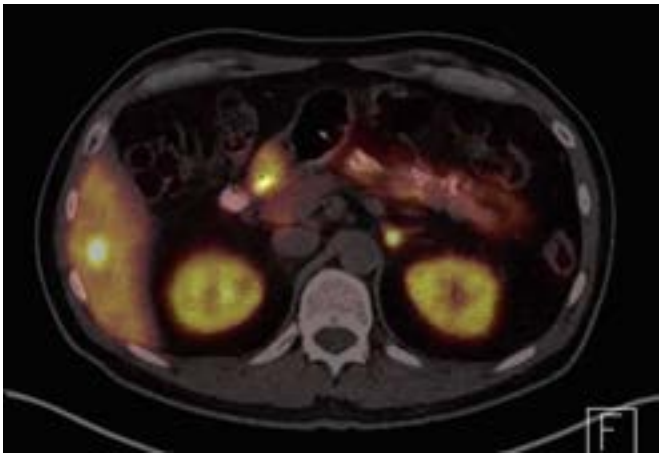

FIG. 2 ^{68}Ga-Dotatate positron emission tomography showing duodenal gastrinoma and liver metastasis.

Although rarely used currently, a selective secretin stimulation test may be performed with direct secretin injection into the hepatic, splenic, gastroduodenal, and superior mesenteric artery with sampling from the right hepatic vein for measurement of serum for gastrin. Secretin is selectively administered intraarterially with sampling at 0, 20, 40, and 60 seconds. A "step-up" in hepatic vein gastrin will indicate the dominant blood supply of the tumor and therefore its likely location. Small case series report sensitivities ranging from 77% to 100% for the combination of selective angiography and selective stimulation. This technique is an option for patients in whom conventional imaging fails to localize a tumor.

For cost-effectiveness, consider the following sequence in imaging: Cross-sectional imaging with CT or MRI followed by 68Ga-Dotatate PET. If these studies are negative, then EUS should be considered. If that is negative, consider selective secretin testing.

SURGICAL MANAGEMENT OF GASTRINOMA

The surgeon should consider whether an operation is indicated only after a diagnosis of gastrinoma is confirmed. It is recommended that in sporadic ZES surgical resection should be carried out if a complete tumor resection can be performed and there are no comorbidities limiting life expectancy or increasing surgical risks to unacceptable levels. The surgical approach to the sporadic gastrinoma, whenever possible, is recommended for several reasons. Imaging modalities have markedly improved in sensitivity, making it possible to better localize the primary tumor and stage the disease, decreasing unsuccessful surgery. More recent surgical studies have demonstrated increased disease-free rates approaching 40% to 63% of patients operated upon without Whipple resections and higher in patients with Whipple resections, although the latter finding may represent a selection bias. Importantly, two studies have provided evidence that surgical resection in sporadic ZES leads to a decreased rate of the development of liver metastases. Finally, the surgical approach to locate duodenal gastrinomas has been evaluated and demonstrates that certain specific techniques are needed to find the tumor (duodenotomy, mobilization of duodenum, intraoperative transillumination of duodenum in some cases).

The importance of routine lymphadenectomy in sporadic ZES has recently been studied in a number of studies. Although controversial, it is now recommended by some authors. One larger study showed that in 41 patients who underwent potentially curative surgery, systematic lymphadenectomy with excision of more than 10 lymph nodes resulted in a higher rate of biochemical cure after surgery than no or selective lymphadenectomy (13 of 13 vs. 18 of 28 patients; $P = 0.017$). There was also a trend toward prolonged disease-specific survival and a reduced risk of death. The presence of primary lymph node gastrinomas is controversial, even though several studies have reported long-term (up to 20 years) disease-free survival after resection if only a gastrinoma-containing lymph node was resected. Therefore, routine lymphadenectomy may increase the

disease-free survival rate. The number of positive lymph nodes or the lymph node ratio may also have important prognostic significance in gastrinomas and other pNETs. Other reported negative prognostic factors for disease-specific survival include tumor size larger than 25 mm, Ki-67 index more than 5%, preoperative gastrin level greater than 3000 pg/mL, and liver metastases. Sex, age, type of surgery, and presence of lymph node metastases had no influence on disease-free or disease-specific survival.

In sporadic gastrinoma patients, exploration is warranted in the presence of confirmatory imaging studies. Sporadic gastrinoma patients with negative imaging merit exploration as tumors in the duodenum, pancreas, or lymph node primaries may be very small and undetectable by imaging. One study demonstrated that in patients with sporadic ZES with negative preoperative imaging studies, an experienced surgeon will find a gastrinoma in 98% of the patients, with 50% of patients made disease free. This is not different from the results in patients with positive preoperative imaging. Interestingly, survival in patients who have negative imaging studies or no tumors identified at operation is very high, approaching 90% 20-year disease-free survival without later-stage progression.

In the MEN-1 patient, surgical treatment of the associated parathyroid hyperplasia is fundamental. This requires a 3½ gland parathyroidectomy or a total parathyroidectomy, followed by autotransplantation of parathyroid tissue. Control of hyperparathyroidism with normalization of serum calcium will reduce baseline gastrin levels and may reduce the medication requirements to control gastric acid secretion. Although reports of simultaneous parathyroidectomy and abdominal exploration exist, most surgeons prefer to perform parathyroidectomy as the first procedure and exploration for gastrinoma subsequently.

The role of resection of gastrinoma in MEN-1 patients is still evolving. Although some advocate pancreaticoduodenectomy or total pancreatectomy for gastrinoma with MEN-1, most experts do not. Guidelines from the National Institutes of Health, the European Neuroendocrine Tumor Society, and the North American Neuroendocrine Tumor Society do not recommend such aggressive resections. Reasons include that these patients may survive up to 30 years without aggressive resection and the metabolic sequelae, including diabetes and pancreatic insufficiency, may worsen the quality of life for these patients. One algorithm is that the decision to resect the gastrinoma in a patient with MEN-1 is determined by imaging. Image-negative patients are carefully observed and do not undergo exploration given the low cure rates with surgery. Image-positive patients without distant metastases undergo exploration for local surgical resection as resection has been shown to improve survival independent of a biochemical cure.

SURGERY FOR ZOLLINGER-ELLISON SYNDROME

As Ellison emphasizes, the primary goal of surgery in ZES is tumor control. First, removal of the primary tumor or tumors is accomplished to reduce the possibility of metastatic disease at a later date. Second, removal of all tumors can potentially correct the hypergastrinemia that causes ZES and reduce the need for long-term PPI use. Size is clearly related to the presence of distant metastases, and pancreatic gastrinomas are more likely to metastasize to the liver, even when they are small (<2 cm). Norton and colleagues showed that ZES patients who have surgical resection have improved long-term survival and are less likely to develop metastases. Currently, the preferred approaches, if possible, are enucleation, local resection for pancreatic head lesions, or distal pancreatectomy when necessary for distal pancreatic lesions. Whipple resections are generally reserved for large pancreatic head or duodenal lesions that are unamenable to enucleation. One of the main problems with rendering patients disease free is that lymph node metastases are found in 30% to 70% of cases and therefore are often missed without more extensive surgery, such as a Whipple resection. Some studies support an increased disease-free rate with Whipple resection. Because of possible long-term complications, coupled with the excellent prognosis of patients who are not cured but with minimal residual disease, more aggressive general use of Whipple resections is currently not recommended. Ellison showed a long-term survival advantage in both sporadic and MEN-1 patients having an R0 or R1 resection compared with those having an R2 resection. R0 is defined as complete surgical excision with normal postoperative serum gastrin levels, R1 is defined as residual microscopic disease or complete tumor excision and persistent hypergastrinemia, and R2 is defined as gross residual disease with persistent hypergastrinemia.

SURGICAL EXPLORATION AND RESECTION TECHNIQUES

Preoperatively, the serum gastrin levels, secretin test, and imaging should be reviewed and confirmed. The surgeon should consider the special equipment that may be necessary including intraoperative ultrasound and an endoscope. The morning of surgery, the patient should receive an intravenous administration of a PPI. General endotracheal anesthesia is preferred. A nasogastric tube is inserted. The anesthesiologist should monitor the nasogastric tube output as large volumes of gastric secretion may occur. Laparotomy is performed through a midline or bilateral subcostal incision. Although reports of laparoscopic and robotic exploration exist, an open approach still provides the surgeon with the best exposure and tactile feedback to help identify very small tumors, especially in the duodenum. Our exception for minimally invasive surgery is for clearly localized PNETs that appear amenable to enucleation on preoperative cross-sectional imaging or EUS. Concomitant gastroduodenal procedures are only performed if there are specific complications of ZES that may require surgical treatment, such as gastric outlet obstruction or bleeding ulcer.

Upon opening the abdomen, palpation of the intraabdominal organs, including "running" the small intestine, is necessary to exclude secondary tumors or ectopic tumors. Masses in the liver may be further examined by ultrasound, and an excision or needle biopsy should be performed depending on the size and location. Given the extensive preoperative imaging in gastrinoma, the surgeon will rarely be surprised by unsuspected metastatic disease, observed in only 2% of patients. Therefore, diagnostic laparoscopy is rarely indicated before laparotomy. Exposure requires a wide Kocher maneuver to facilitate bimanual palpation of the head of the pancreas and possible use of intraoperative ultrasound. Division of the gastrocolic omentum is then performed to widely open the lesser sac for exposure of the body and tail of the pancreas.

Pancreatic evaluation is performed by bimanual palpation of the head of the pancreas after a thorough Kocher maneuver, taking note of any masses for later excision. Bimanual palpation of the body and tail of the pancreas is facilitated by incising the peritoneum overlying the inferior edge of the body and tail of the pancreas. Intraoperative ultrasound may be used to assess the head, uncinate process, body, and tail of the pancreas, noting any hypoechoic masses for later excision. Palpation of the hepatoduodenal ligament and removal of any enlarged lymph nodes is then performed. These are sent for standard histology unless no primary gastrinoma is identified in the typical locations, in which case they are sent for frozen section as they may represent the rare ectopic lymph node primary tumor.

Local excision of tumors smaller than 2 cm in diameter may be performed in the head of the pancreas and uncinate process if the pancreatic duct is not involved as determined by intraoperative ultrasound. These tumors are hypervascular, and use of bipolar coagulation aids in the dissection. We have also found the ultrasound coagulating device (harmonic scalpel) to be very useful. As mentioned, larger tumors may require a pancreaticoduodenectomy.

In the body and tail of the pancreas, the tumors usually are adjacent to the pancreatic duct and, as such, distal pancreatectomy and splenectomy are preferred to avoid injury to the pancreatic duct. Because the majority of gastrinomas are malignant, splenectomy is currently recommended, as is distal pancreatectomy to remove lymph nodes in the splenic hilum.

The next step is examination of the duodenum and removal of duodenal nodules. This requires a longitudinal duodenotomy and internal palpation of the duodenum. Most gastrinomas are in the first portion of the duodenum. Use of external palpation or ultrasound only identifies 20% to 30% of these tumors. Intraoperative endoscopy and transillumination of the duodenum may also be helpful in some cases for identification. Suspected duodenal gastrinomas may be locally excised and do not require duodenal resection. The tumors are submucosal, and closure of the mucosal defect created by the excision is recommended. For lesions on the anterior or lateral wall of the duodenum, full-thickness excision is possible. The duodenum is closed longitudinally or transversely with a single layer closure based on the surgeon's preference. A closed suction drain is placed near any sites in the pancreas in which a tumor was locally excised or the transected pancreas if a pancreatectomy was performed.

If a laparoscopic approach is performed, we place the patient in the lithotomy position and use the standard five-port technique for minimally invasive foregut or pancreatic procedures. For proximal lesions, the lesser sac is entered and a Kocher maneuver is performed as noted earlier for open procedures. Enucleatable lesions may be removed using an ultrasonic dissector or a hook electrocautery device. I place a traction suture through the lesion to facilitate dissection. Formal resections may be performed using well-described techniques. Liberal use of intraoperative endoscopy and ultrasound are recommended.

Postoperative Management

The nasogastric tube is removed at the discretion of the attending surgeon. PPI treatment is continued by intravenous administration and then switched to an oral form when the patient is taking liquids orally. Hypergastrinemia induces parietal cell hyperplasia that may take 3 months to resolve; as such, PPI treatment should be continued for 3 months in a patient with normal postoperative fasting gastrin. A fasting gastrin level is drawn on day 3 and repeated at the first postoperative visit. In a patient with established ZES, postoperative false-positive elevations of gastrin caused by continued PPI therapy are rarely seen. If postoperative fasting gastrin levels are elevated, then PPI therapy should be continued and repeat imaging completed at 6 months after surgery. If there is positive imaging, reexploration should be considered.

Results of Treatment

Biochemical cure of sporadic gastrinoma is reported in 30% to 50% of patients with recurrence documented in almost one-third of patients. The usual time to recurrence is 5 to 10 years. Regardless of achieving biochemical cure, complete resection of all gross tumor is associated with improved survival. The 10-year disease-specific survival in patients having R0/R1 resection of sporadic gastrinoma is 85% compared with 40% for patients having R2 resection and 25% for those having no resection. Pancreatic gastrinoma survival favorably compares well with other PNETs (Table 2). In large experiences of MEN-1 patients operated for curative intent, cure was achieved in only 6% of patients. The 10-year survival with gastrinoma in MEN-1 with R0/R1 resection was 90% compared with only 45% for patients having an R2 resection or no resection. Because R2 resections do not increase survival, MEN -1 patients with extensive metastatic disease or locoregional spread that proscribes complete resection benefit little from surgical resection, and these patients are typically not offered surgery.

TABLE 2 Median Survival of Pancreatic Gastrinoma Compared with Other Pancreatic Neuroendocrine Tumors

Tumor Type	Median Survival (Yr)
Insulinoma	12.7
Gastrinoma	10.2
VIPoma	7.7
Mixed tumors	3.4

Modified from Keutgen XM, Nilubol N, Kebebew E. Malignant-functioning neuroendocrine tumors of the pancreas: a survival analysis. *Surgery*. 2016;159:1382-1389.

Recurrent Gastrinoma

Norton et al. reported 223 patients who had an initial operation for ZES in a prospective database. They reported that 52 patients (23%) underwent reoperation a mean of 6 years for recurrent ZES with gastrinoma on imaging after the initial surgery. Of the 53 reoperated patients, 12 had ZES with MEN-1. After reoperation, 18 of 52 patients were initially free from disease (35%); after a mean follow-up of 8 years, 13 of 52 remained disease free (25%). During follow-up, 9 of 52 (17%) of the reoperated patients died, of whom 7 died of disease (13%). The overall survival from initial surgery was 84% at 20 years and 68% at 30 years. These findings suggest that ZES patients should have systematic imaging after excisional surgery, and if gastrinoma recurs or is persistent, they should be given the option for reoperation. Patients with persistent or recurrent gastrinoma with negative imaging are unlikely to benefit from reexploration. Data concerning reoperation for recurrent image-positive gastrinoma in MEN-1 are less clear; most experts are unlikely to recommend reoperation in this scenario.

Management of Metastatic or Locally Advanced Disease

Similar to other advanced NETs, the role of surgical resection in patients with ZES with advanced metastatic disease or even with extensive invasive localized disease is not well defined. Unfortunately, most patients presenting with hepatic metastases with gastrinomas have metastases in both hepatic lobes, with only 5% to 15% having localized hepatic metastases. If imaging studies support the resectability of the metastases, then surgical resection is generally recommended if patients are operative candidates without other medical conditions precluding surgery. Similarly, if most or all disease is thought surgically resectable, surgery is generally recommended. Patients with gastrinomas may present with local invasion and/or vessel encasement or possible involvement, which has led them to not being considered surgical candidates. One recent study demonstrated that 17% of all gastrinomas fall into the category demonstrating possible major vascular involvement; in fact, 42 patients had a pNET that could be resected, with only 9 patients requiring vascular reconstruction; 30% showed long-term disease-free status, and after resection, the patients had a 10-year survival of 60%. This result led the investigators to conclude that surgical resection of pNETs with vascular abutment/invasion is indicated and generally successful without requiring vascular reconstruction and should not be a contraindication to surgery.

TABLE 3 Treatment Options for Metastatic Disease

Liver Resection	Metastases Resection	Effective if Unilobar
Liver transplant	Liver replacement	30% 5-year survival
Targeted liver therapy (TACE, RFA)	Direct liver metastasis damage	For nonsurgical candidates, paucity of published data
Chemotherapy (doxorubicin, streptozocin, 5-Fluorouracil)	Historical treatment	Limited efficacy, limiting toxicity
Everolimus	mTOR inhibitor	Considered second-line therapy after somatostatin analogues or liver-directed therapy
Sunitinib, sorafenib	Tyrosine kinase inhibitors	Limited response, clinical trials ongoing
Somatostatin analogues	Activate somatostatin	First-line therapy, acid reduction largely replaced by PPI, 50% short-term response in tumor growth effects
Lutetium 177, peptide receptor radionuclide therapy	Targeted radiolabeled somatostatin analogue	Partial response in 70%

PPI, Proton pump inhibitor; *RFA*, radiofrequency ablation; *TACE*, trans-arterial chemoembolization.

Patients with malignant gastrinoma often present with liver metastases. In these situations, it is essential for the surgeon to work collaboratively with a multidisciplinary team. The extent of disease burden in the liver often dictates the quality and length of survival. Surgical excision of both the primary tumor and liver metastases has been reported in the literature; however, its use should be considered cautiously. Some authors suggest that select patients may see a survival benefit if a complete or near-complete (90% or more) resection of hepatic metastases can be achieved. Orthotopic liver transplantation has been considered an exploratory option for patients who are unamenable to limited hepatic resection. The 5-year disease-free survival rate was similar (approximately 30%) to that of hepatic resection in the two largest series. Considering the risks and resources involved, transplantation was considered to be an investigational method in the treatment of ZES. Prospective clinical trials are needed to determine the true benefits of orthotopic liver transplantation.

Those with advanced disease need to have multidisciplinary input for more nonsurgical options including chemotherapy with everolimus, sunitinib, and somatostatin analogs, chemoembolization, radioembolization, and radiofrequency ablation. A variety of options for the treatment of metastatic disease is shown in Table 3. The decision to proceed with treatment depends on the rate of disease progression and the patient's symptoms. Because gastrinoma is a rare condition, clinical trials should be considered to define the best treatments in the future.

SUMMARY

ZES is a syndrome caused by gastrinoma. Two-thirds of cases are located within the gastrinoma triangle and associated with symptoms of peptic ulcer disease and diarrhea. The diagnosis of ZES is established by measuring fasting levels of serum gastrin, gastric pH, and secretin provocative gastrin stimulation. ZES is frequently associated with MEN-1; therefore this must be excluded in all patients. Treatment of ZES consists of medical control of symptoms with PPIs and evaluation for potentially curative surgery. Preferred preoperative imaging studies include cross-section MRI or CT and 68Ga-Dotatate PET/CT scans. EUS may be performed to further evaluate primary tumors if other testing is negative. All patients with resectable sporadic gastrinoma should undergo surgical exploration. The goal of surgery is tumor control. Intraoperative tumor localization requires methodical exposure of the pancreas and duodenotomy for possible duodenal gastrinoma. In patients with MEN-1, surgical resection should be pursued only if there is a tumor localized on imaging in the absence of metastatic disease. Patients with sporadic ZES and negative imaging should also undergo surgery. In patients who have synchronous or metachronous liver metastases, surgery should be performed if all visible tumor can be removed safely. Patients with recurrent ZES should be restaged and operation considered if localized tumor is identified. Patients with liver metastases benefit from multidisciplinary care and not infrequently will have survival prolonged by surgical resection.

Management of Mallory-Weiss Syndrome

Michael G. House, MD

Mallory-Weiss syndrome was first described by G. Kenneth Mallory and Soma Weiss in 1929, with an initial description of 15 patients who developed violent vomiting leading to massive hematemesis. Mortality resulted in four patients, and autopsy revealed vertical gastric mucosal lacerations at the gastroesophageal junction (GEJ). Mallory-Weiss tears (MWTs) of the GEJ are most commonly due to forceful retching and vomiting, but other precipitating factors have been described including injury during rigid and flexible endoscopy, blunt abdominal trauma, prolonged coughing, persistent hiccups, and tonic-clonic seizures. Large case series of flexible esophagogastroduodenoscopy (EGD) indicated for new onset acute upper gastrointestinal bleeding (UGIB) have reported MWT as the source of bleeding in up to 10% of patients.

PATHOPHYSIOLOGY AND RISK FACTORS FOR MWT

Forceful vomiting causes a sudden increase in the resting pressure gradient between the abdominal and thoracic cavities. The pyloric channel tightens while the lower esophageal sphincter, gastric cardia, and diaphragmatic hiatus relax. Simultaneously, the abdominal wall, diaphragm, and stomach contract to propel gastric contents retrograde. This action leads to retrograde prolapse of the proximal stomach mucosa into the esophageal lumen and results in tearing of the gastric and occasionally esophageal mucosa. Alternatively, the sudden increase in intragastric pressure and relaxation of gastric cardia leads to sudden dilation of gastric cardia and distal esophagus that causes tension-related linear lacerations of the GEJ mucosa. For patients without paraesophageal hernia, MWTs tend to be located at the GEJ, most commonly along the lesser curvature (Fig. 1). Regardless of size, an existing paraesophageal hernia may be associated with MWTs involving the gastric cardia alone. Isolated esophageal mucosal tears are unusual for Mallory-Weiss syndrome. Multiple small case series have observed a paraesophageal hernia in 20% to 30% of patients with MWT.

MWTs account for about 7% to 10% of all cases of acute UGIB. Approximately one-half of patients with MWT-associated bleeding have either a recent or active history of alcohol use, whereas alcohol use is present in only 20% of patients with bleeding peptic ulcers. Patients with underlying liver disease or cirrhosis tend to have more severe MWT-associated bleeding. The prevalence of MWT in patients with hepatic cirrhosis is similar to the prevalence of MWT in the general population. Bleeding from MWT is less likely to result in hemorrhagic shock; 1.4% risk compared with 6.7% for peptic ulcer bleeding. Also, patients with MWT bleeding carry higher American Society of Anesthesiologists risk scores compared with patients with bleeding peptic ulcers. Distinct differences exist between the characteristics of patients bleeding from MWT and patients bleeding from peptic ulcers.

DIAGNOSIS

A typical patient with bleeding from MWT presents with an acute history of forceful nonbloody emesis followed by hematemesis. Less than 10% of patients with MWT report a history of recent melena, and abdominal pain is uncommon. Recent alcohol consumption is variable but may be the causative factor for otherwise unexplained emesis. Definitive diagnosis of MWT is established with direct visualization by flexible endoscopy. Flexible endoscopy has become the standard diagnostic tool for evaluating UGIB. Esophagogastroscopy with retroflexed views of the GEJ permits visualization of MWTs at the cardia mucosa; however, 75% of tears will have no active bleeding at the time of endoscopy. Most MWTs are 0.5 to 2.5 cm in length, but some can measure up to 5 cm. Complete evaluation of the esophagus, stomach, and duodenum is necessary to evaluate for other concomitant sources of UGIB. Bleeding from esophageal or gastric varices, gastritis, duodenitis, or peptic ulcers is often present in patients with MWT.

Other less common diagnostic tests for UGIB include tagged red blood cell scan, direct angiography, and multidetector computed tomography (CT) angiography. For patients actively bleeding from MWT, direct angiography of the left gastric or inferior phrenic artery may show a linear contrast collection at the GEJ. CT angiography has largely replaced direct angiography and is a sensitive modality for diagnosing any source for gastrointestinal bleeding.

TREATMENTS FOR MWT: ENDOSCOPY, ANGIOGRAPHY, AND SURGERY

All patients with UGIB need to be evaluated emergently for hemodynamic instability before considering diagnostic studies or interventions. The treatment outline is summarized in Figure 2. Like any critical care situation, shock protocols should be implemented for patients with active UGIB. Assessment of airway, respiratory, and circulatory status is part of the primary survey. Initial laboratory studies should include blood typing and adequate blood supply cross-matching for the potential of a massive transfusion requirement. Other immediate lab testing should include a complete blood count for hemoglobin level and platelet count, coagulation parameters, and comprehensive metabolic panel with hepatic function. Patients with thrombocytopenia or receiving antiplatelet therapy may require platelet transfusion. Coagulopathy due to liver disease or anticoagulation therapy should be corrected promptly with proper agents.

Large bore (e.g., 14- or 16-gauge catheter) peripheral venous access should be obtained immediately in patients with active UGIB. If peripheral venous access cannot be established for a patient in hemorrhagic shock, a central venous catheter (e.g., 8.5 French) should be placed for resuscitation with blood products. Organ perfusion status should be monitored invasively in a critical care unit.

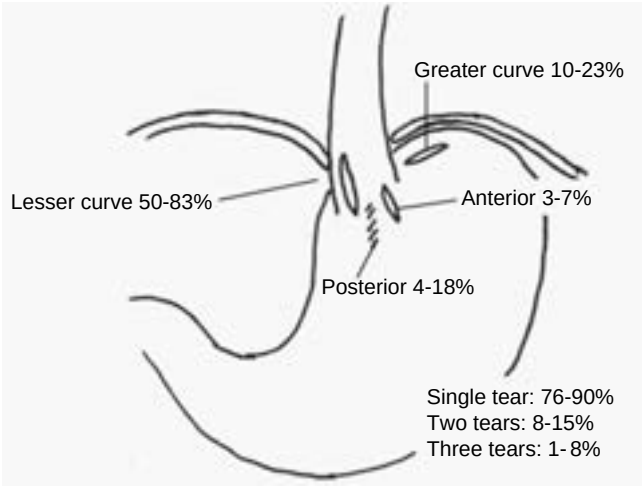

FIG. 1 Distribution of tear(s) in Mallory-Weiss syndrome.

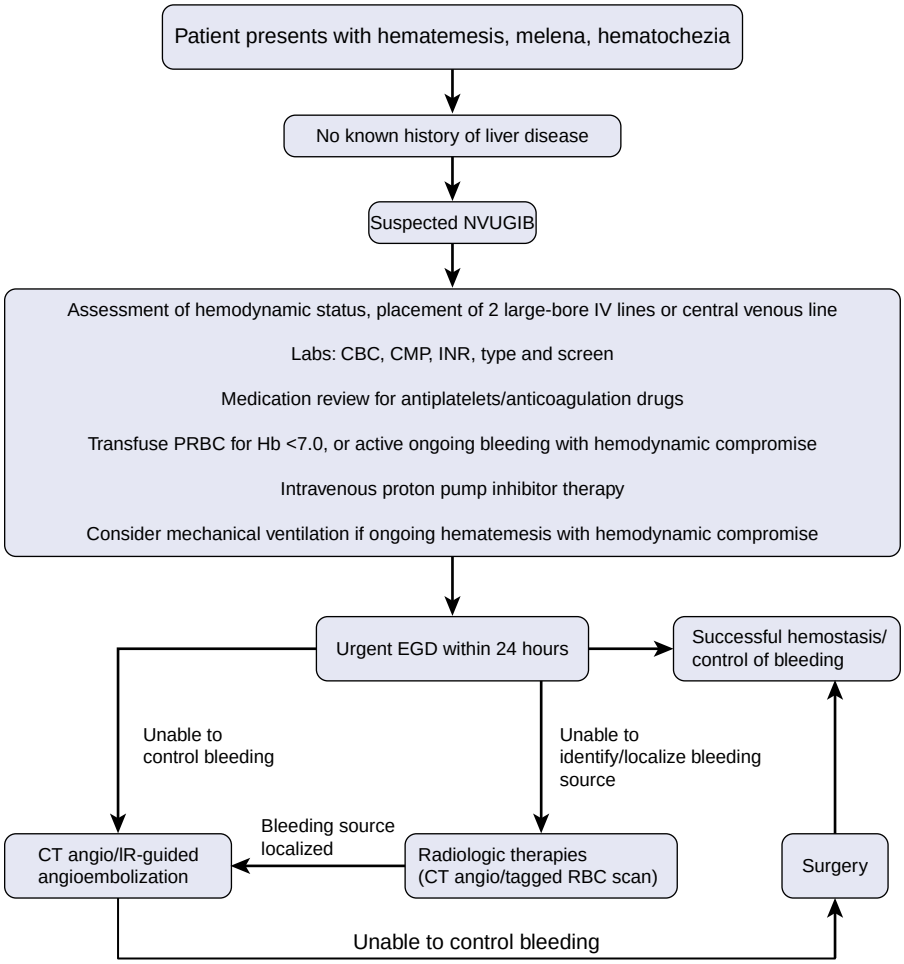

FIG. 2 Initial evaluation and management of nonvariceal gastrointestinal bleeding. *CBC*, Complete blood count; *CMP*, comprehensive metabolic panel; *CT*, computed tomography; *EGD*, esophagogastroduodenoscopy; *Hb*, hemoglobin; *INR*, international normalized ratio; *IR*, interventional radiology; *IV*, intravenous; *NVUGIB*, nonvariceal upper gastrointestinal bleeding; *PRBC*, packed red blood cells. *(Modified from Samuel R, Bilal M, Tayyem O, Guturu P. Evaluation and management of nonvariceal upper gastrointestinal bleeding. Dis Mon. 2018;64:333–343.)*

Antinausea medication should be started for patients with nausea and vomiting, and a dual or triple lumen 18 French nasogastric tube should be placed to decompress the stomach. Gastric lavage through the nasogastric tube will confirm UGIB and helps clear blood from the stomach before upper endoscopy. Gastric acid suppression with high-dose proton pump inhibitors decreases the need for endoscopic intervention and transfusion for patients with any source of UGIB and facilitates early healing of mucosal disruptions of the stomach.

Endoscopic Treatment

Endoscopic treatment is successful in 99% of patients with MWT-associated bleeding and in 95% of patients with low-risk bleeding from peptic ulcer disease. Gastroscopy with retroflex visualization of the GEJ is essential for the diagnosis and treatment of MWT. At the time of endoscopy, 50% to 70% of MWTs will have no bleeding. These tears can be treated with antiacid therapy alone for 2 weeks and do not require repeat endoscopy for proof of healing. Modalities for treating active bleeding during endoscopy include hemoclip, ligation banding, thermal coagulation, and injection of sclerosing or vasoconstricting agents. Each modality has its own advantages, but no comparative outcomes data exist to support one treatment over another. Injection of 15 to 30 mL of dilute epinephrine (1:10,000) causes local vasoconstriction to stop bleeding. Sclerosing agents, such as cyanoacrylate, can be injected into the bleeding site to cause vascular thrombosis; however, incidents of sclerosing agents causing extensive tissue necrosis leading to perforation have been reported. Hemoclip placement in addition to epinephrine or sclerosant injection decreases the risk for rebleeding even further. Thermal coagulation with monopolar or bipolar electrical energy or argon plasma coagulation (APC) is highly effective in stopping bleeding from MWT. Endoscopic techniques that use an over-the-scope clip application are also remarkably effective to address MWT bleeding. This device allows clip placement in a tangential rather than head-on approach. Topical hemostatic agents that concentrate coagulants at the site of mucosal tear or ulceration are typically not necessary for MWT. Endoscopic suturing devices have been described for controlling sources of bleeding at the GEJ but are rarely needed for MWT.

Angiography

Transcatheter arterial embolization or infusion of vasopressin is a treatment option for patients who are poor surgical candidates and who have failed endoscopic treatment to control bleeding from MWT. Targeted vasopressin infusion has been replaced by angioembolization because of a higher risk of recurrent bleeding with the former. Selective angioembolization involves direct injection of microspheres, small coils, or glue into the bleeding damaged vessel. Even during hemodynamic instability, angiography will demonstrate active vessel extravasation in less than half of patients with MWT due to generalized vasoconstriction from hypovolemia or temporary thrombus formation. Provocative angiography with injection of vasodilators or anticoagulants such as heparin can induce bleeding and reveal the

culprit bleeding vessel. Bleeding from an MWT usually involves either the left gastric artery or inferior phrenic artery. Empiric embolization of these arteries based on endoscopic localization may be necessary if angiography is unable to identify active extravasation. Compared with surgical treatment, angioembolization has a higher rebleeding rate. However, even nonselective angioembolization may be indicated for patients who are otherwise poor operative candidates.

Surgical Treatment

Endoscopic therapy is successful in 99% of UGIB caused by MWT. Unlike endoscopy, few advancements have been applied to the surgical treatment of MWT. As a result of the introduction of advanced endoscopy, less than 1% of patients with MWT will require surgical intervention. Patients who fail initial endoscopic therapy should undergo a second procedure with an experienced endoscopist before proceeding to surgery. Before operation, the bleeding site location must be identified by endoscopy. A high anterior longitudinal gastrotomy allows visualization of the mucosal tear at the GEJ. The MWT is oversewn within the gastric lumen using absorbable sutures. If the lesion cannot be visualized because of massive hemorrhage, direct tamponade with a sponge stick will stop active bleeding and allow time for resuscitation. The surgeon should look for other lesions after repair of MWT because most cases of MWT requiring operation will harbor other lesions. The anterior gastrotomy should be closed in two layers. Placing a large transoral bougie at the time of the gastric closure will prevent narrowing at the GEJ leading to gastric inlet obstruction. A coexisting paraesophageal hernia should not create challenges if proper caudal traction in placed on the stomach during the gastrotomy, MWT oversewing, and gastric closure. Laparoscopic-assisted oversewing of MWT with endoscopic guidance has been described through an anterior gastrotomy. However, almost all cases of MWT requiring operation are complicated by brisk bleeding that impairs visualization with endoscopy and laparoscopy.

SUMMARY

MWT is a linear laceration of the mucosa at the GEJ that is most associated with repeated retching or violent emesis. Acute UGIB caused by MWT is self-limited in 80% to 90% of cases. Initial management of patients with upper gastrointestinal bleeding associated with hemodynamic instability requires rapid resuscitation, often with blood products. Urgent endoscopy should be the first intervention for diagnosis and definitive treatment. Less than 1% of patients with bleeding from MWT will require surgical treatment.

Management of Gastric Adenocarcinoma

Alex B. Blair, MD, and Mark D. Duncan, MD

INTRODUCTION

Gastric cancer represents the 14th highest cancer incidence and 13th highest cause of cancer death in the United States. Worldwide, however, the prevalence is even more pronounced serving as the 5th most common cancer and third leading cause of cancer death with highest rates of disease in East Asia and Central and South America. Gastric cancer disproportionately affects men representing 60% of new cases, with higher associated mortality in African Americans, Asian Americans, and Hispanics as compared with Caucasians. It is more frequently seen in older individuals with peak incidence in the seventh decade of life. Late-stage diagnoses and limited effective therapeutic options are two prominent causes for its associated mortality risks. Due to its rampant prevalence, Japan (and in limited fashion Korea) has initiated gastric cancer screening protocols allowing earlier disease detection with associated improvements in mortality.

RISK FACTORS

Although most commonly observed as a sporadic disease with multifactorial etiology, there are multiple established risk factors for gastric cancer. Risk factors include both environmental and genetic factors, many of which end in a similar common thread of chronic inflammation leading to dysplasia. Environmental risk factors include long-term infection with *Helicobacter pylori (H. pylori)*, atrophic gastritis, gastroesophageal reflux disease, pernicious anemia, tobacco use, high-salt foods, and smoked meats with high levels of nitrates. Low intake of fruits and vegetables is also associated with increased risk of gastric cancer. Nitrogen compounds found in tobacco smoke or generated after nitrate ingestion can be damaging to the stomach mucosa. Ascorbic acid contained in fresh fruits and vegetables can bind to and remove the carcinogenic inflammatory nitrogen compounds and oxygen free radicals mitigating some of this risk. The overall mortality rate and incidence of gastric cancer have been slowly declining, perhaps related to decreased rates of smoking, changes in diet, and improved refrigeration.

In addition to extrinsic environmental factors, emerging evidence support a growing impact of genetic risk factors including overexpression of COX2, cyclin D2, p53 mutations, or microsatellite instability (MSI). Furthermore, a subset of "familial gastric cancers" is associated with inherited genetic syndromes including hereditary diffuse gastric cancer, hereditary nonpolyposis colorectal

cancer, Li-Fraumeni syndrome, and polyp-associated gastric cancer syndromes.

PATHOLOGY

More proximal gastric cancer has been seen in the past few decades. The proximal lesser curvature, cardia, and esophagogastric junction represent the most common sites of gastric cancer in the United States. Adenocarcinomas comprise most primary gastric malignancies at 95% with the remaining made up of lymphoma (4%) and gastrointestinal stromal tumor (<1%). This chapter will focus on adenocarcinoma.

The Borrmann classification of gastric cancer in 1926 was developed based on the gross appearance of endoscopic findings: *Type I* for polypoid; *Type II* for a fungating lesion; *Type III* for presence of ulceration; and *Type IV* for diffusely infiltrating growths classically termed linitis plastica. The Lauren classification proposed in 1965 is the most useful and widely used classification system dividing adenocarcinoma into two broad histologic subtypes: intestinal and diffuse. The intestinal type has increasing incidence with age and is often associated with extrinsic environmental risk factors or precancerous conditions such as atrophy and metaplasia. The diffuse type of gastric cancer presents as tiny clusters of small, uniform, signet ring cells and is more likely to be poorly differentiated with high rates of early metastasis via submucosal lymphatic spread and transmural extension.

DIAGNOSIS AND STAGING

Symptoms related to gastric cancer are typically vague and nonspecific, often leading to delayed disease diagnosis due to the assumption of dyspepsia, peptic ulcer disease, or gastritis. Most frequently these symptoms include early satiety and weight loss with more advanced lesions associated with obstruction and dysphagia depending on the location of the tumor. Bleeding may occur with 40% of patients having some form of anemia at the time of diagnosis. Physical examination is often limited to identification of distant metastatic nodal disease including the Sister Mary Joseph, or periumbilical, node. Of historical note, Sister Mary Joseph was surgical assistant to Dr. William Mayo. When preparing patients for surgery, she observed that the presence of a palpable periumbilical mass was predictive of patients with advanced intraabdominal disease on laparotomy (Fig. 1). Other eponymous signs of distant metastatic disease of interest include Virchow's node (supraclavicular adenopathy), Krukenberg tumor (drop metastases to the ovary), or Blumer's shelf (peritoneal metastases palpated in the pouch of Douglas on rectal examination).

The American Joint Committee on Cancer (AJCC) and Union for International Cancer Control (UICC) have jointly developed the TNM staging system utilized in the Western Hemisphere. This includes the depth of tumor invasion (T), number of involved lymph nodes (N), and presence or absence of metastatic disease (M). Baseline clinical staging guides the development of appropriate initial treatment. The stage of disease at the time of diagnosis is of utmost importance for outcome measures with approximately 50% of people presenting with advanced disease; of those with locoregional disease, 70% to 80% have regional lymph node involvement. Multiple modalities have improved the ability to obtain accurate initial clinical staging including endoscopy, endoscopic ultrasound (EUS), computed tomography scan (CT), positron emitted tomography (PET), magnetic resonance imaging (MRI), and diagnostic laparoscopy with peritoneal washings.

Endoscopy is the primary tool for the diagnosis of gastric adenocarcinoma. While Japan and Korea have implemented initial broad screening strategies with upper endoscopy and barium radiography, upper endoscopic screening is not done in the United States apart from selective screening for patients with specific risk factors including the presence of gastric polyps, pernicious anemia, or genetic disorders. The usual indications for diagnostic endoscopy are anemia with or without weight loss or dysphagia. Biopsy of suspicious lesions provides tissue for a confirmatory pathologic diagnosis. The NCCN currently recommends multiple biopsy specimens from different areas of the lesion. Endoscopy also localizes the disease for surgical planning with special attention to the relation of proximal tumors to the gastroesophageal junction (GEJ). The Siewert-Stein classification proposed in 1996 describes the relationship of a proximal gastric tumor to anatomic landmarks:

Type I: distal esophagus 1 to 5 cm above the GEJ
Type II: cardia up to 1 cm above and 2 cm below GEJ
Type III: subcardial 2 to 5 cm below GEJ

Siewert type III lesions are considered gastric cancers and thus should be treated as described by this chapter, ensuring adequate esophageal resection to obtain negative margins. For a small number of select patients with gastric adenocarcinoma, endoscopic mucosal resection (EMR) or endoscopic submucosal dissection (ESD) can be performed for small lesions <2 cm with the potential to be definitive treatment for Tis or T1a tumors limited to the mucosa.

CT imaging of the chest, abdomen, and pelvis with oral and IV contrast is routinely used in preoperative staging. CT readily detects most primary tumors and any gross adenopathy, and particularly looks for metastatic disease in the liver or elsewhere. Ascites on CT is a bad prognostic sign usually indicating peritoneal carcinomatosis. PET can be utilized as an adjunct to CT either to identify occult metastatic disease with a negative CT or to further evaluate suspicious lesions identified by CT. PET may also have a role when evaluating the response to neoadjuvant therapy. When metastatic disease is detected, biopsy may be recommended when confirmatory diagnosis is required.

EUS is frequently performed as a vital component of initial staging workup for gastric adenocarcinoma. This provides the most accurate evaluation of the depth of tumor invasion and assessment of perigastric lymph node involvement. Fine-needle aspiration (FNA) should be implemented in the case of identification of suspicious lymph nodes identified on EUS. EUS is particularly useful for smaller tumors with no gross adenopathy on CT; those patients may be candidates for upfront surgery instead of neoadjuvant therapy.

Laparoscopic staging can detect occult metastases and is routinely implemented due to the relatively low sensitivity of CT and PET/CT. In a study conducted over a period of 10 years, 657 patients with potentially resectable gastric adenocarcinoma underwent laparoscopic staging with metastatic disease detected in 31% of patients. The NCCN thus recommends staging laparoscopy for *all patients with T2 or greater gastric cancer and no prior evidence of metastatic disease on imaging*. Cytologic assessment of peritoneal fluid offers additional improvement in laparoscopic staging through identification of occult carcinomatosis, a poor prognostic factor associated with a lower disease-free survival following resection. Positive peritoneal cytology in the absence of visible peritoneal implants offers a challenging paradigm. Clearing of cytology-positive disease by induction chemotherapy is associated with improved disease-specific survival; however, cures remain uncommon. The role of repeat staging laparoscopy following neoadjuvant treatment for advanced disease remains a question with no definitive answer; however, occult metastatic disease may still be detected following induction even with a negative staging laparoscopy.

As noted, the point of staging workup is to determine the best course of therapy. Generally, patients with early T1 tumors with no evident adenopathy (N0) and no distal disease (M0) are offered upfront surgery, whereas patients with T2 or T3 depth of invasion or with any evident adenopathy are counseled for neoadjuvant chemotherapy followed by surgery. Patients with significant bleeding or obstruction are usually treated by surgery first with adjuvant chemotherapy following. Often, however, patients present with advanced metastatic disease and resection for cure is not an option. This includes those with distant

FIG. 1 **(A)** Sister Mary Joseph (birth name Julia Dempsey) was a nurse and administrator at the St. Mary's Hospital in Rochester, MN. In addition to her role as William Mayo's surgical assistant, she was the head nurse and superintendent of the hospital for almost 50 years. **(B)** Sister Mary Joseph's nodule in a patient with stage IV gastric adenocarcinoma. **(C)** CT scan of patient above demonstrating subcutaneous umbilical mass. *(Used with permission of Mayo Foundation for Medical Education and Research. metastasis, including N3 (root of mesentery nodal involvement) and N4 (paraaortic nodal involvement) disease or encasement of major vascular structures (excluding the splenic vessels). For the small subset of patients with low burden peritoneal disease or occult peritoneal disease found on washings in the absence of visible lesions, we offer hyperthermic intraperitoneal chemotherapy (HIPEC) in addition to gastrectomy after neoadjuvant therapy.

Increasingly, molecular profiling is used to both understand the biologic behavior of the tumor and identify targets for biologic immune therapy. Human epidermal growth factor receptor 2 (HER2) gene expression has been implicated in the development of gastric adenocarcinoma with reported rates of overexpression in 9% to 23% of patients with gastric cancer. While the prognostic significance of HER2 status in patients with gastric adenocarcinoma remain debated, HER2 testing is now recommended by the NCCN for all patients with metastatic disease at the time of diagnosis. The expression of programmed cell death ligand-1 (PD-L1) represents another pathologic feature that may influence treatment decisions in gastric cancer. The PD-L1 pathway inhibits the differentiation and proliferation of T cells, and its inhibition through immunotherapy is an area of ongoing research. MSI is caused by mutations in DNA mismatch repair and is found in ~10% of gastric cancers. This is a subgroup associated with older age, female sex, lower number of lymph node metastases, and a distal stomach location. The presence of MSI is thought to be predictive of superior survival outcomes compared with patients with microsatellite stable (MSS) gastric tumors. Interestingly, unlike MSS counterparts, MSI tumors do not show benefit of chemotherapy added to surgery; in fact, in some studies, it results in worse survival. Thus, chemotherapy is typically not recommended for this subset of patients. Emerging data report strong immunogenicity and increased expression of checkpoint ligands like PD-L1 in MSI subtype, and these patients may be more suitable for immunotherapeutic treatment approaches.

SURGERY

Surgery remains the standard of care for patients with potentially resectable locoregional disease who are medically able to tolerate major surgery. The goal of surgery is for complete extirpation of disease with wide margins and an adequate regional lymphadenectomy. The stomach has a rich supply of lymphatics with each nodal station described by the location relative to the stomach. The number of metastatic lymph nodes does correlate with survival, and the extent of lymphadenectomy remains an area of ongoing debate. A D1 nodal dissection comprises a gastrectomy and resection of both the greater and lesser omenta including the perigastric lymph nodes along the lesser and greater curvature, suprapyloric nodes along the right gastric artery, and infrapyloric nodes: stations 1 to 7. A D2 nodal dissection includes D1 as well as those along the named vessels of the celiac axis: left gastric, common hepatic, celiac, splenic artery, and splenic hilum: stations 1 to 12. A D3 includes additional clearance of periaortic nodes: stations 1 to 16. While early randomized controlled trials showed no survival benefit for D2 lymphadenectomy, later trials including follow-up from The Dutch Gastric Cancer Trial noted improved disease-specific survival for D2 dissection over D1. D3 dissections have not shown to offer survival benefit but do increase morbidity and thus are not recommended or routinely employed. NCCN guidelines recommend a D2 dissection without splenectomy. Of note, in many Western populations, surgeons often will forgo complete dissection of the splenic artery and hilum and employ "cherry-picking" of any evident station 10 or 11 nodes, thus complete removal of 1 to 9 and 12 has been termed "D1 over" by some and is a common substitute for D2 lymphadenectomy.

Open surgery utilizing an upper midline abdominal incision is a common approach in the United States, but minimally invasive techniques, both laparoscopic and robotic, are being increasingly used. In experienced hands, the short-term outcomes are comparable to the open approach. Prospective trials are ongoing to address any potential differences in durable oncologic outcomes between an open and minimally invasive approach; initial observational retrospective data suggest relative equivalency.

The technique of total versus partial gastrectomy is determined based on the location of the tumor. Cancers of the distal stomach including the body and antrum can be approached via a distal or subtotal gastrectomy with the proximal stomach transection point depending on the proximal extent of tumor, typically with a 4- to 5-cm gross margin. The distal transection is across the first portion

of the duodenum just distal to the pylorus. For practical purposes, the surgeon can mobilize the first portion of the duodenum until the gastroduodenal artery is completely exposed and then divide the duodenum to the right of this vessel after having first divided the right gastroepiploic artery. For all gastrectomies, dissection and high ligation of the left gastric artery with associated station 7 lymph nodes is best accomplished by elevating the stomach and putting this vessel on stretch, facilitated by partially using the resected gastroepiploic vessels as a partial handle (Fig. 2). Reconstruction following distal or subtotal gastrectomy is most commonly performed with a Roux-en-Y. A Billroth II gastrojejunostomy, which can lead to more alkaline reflux gastritis, is usually only done for patients with stage IV disease. Assessment of margins by frozen section is recommended routinely before reconstruction is performed. For any distal gastrectomy, a positive margin mandates further resection. With a total gastrectomy, a positive margin is not desirable, but a multiinstitutional series suggests that further resection of esophagus in the event of a microscopic frozen section positive margin may afford little survival advantage, even though it satisfies the oncologic desire of the surgeon. A total gastrectomy is employed for most midbody and proximal tumors. When performing a total gastrectomy, the authors favor the formation of an intestinal pouch to serve as an increased reservoir (Fig. 3). This is believed to lead to improved functioning in the short and long term, allowing many patients improved ability to eat.

Proximal Gastrectomy

Although uncommonly utilized in the United States, a proximal gastrectomy can be performed in appropriately selected patients with smaller gastric tumors near the GEJ (Fig. 4). Oncologic outcomes are believed to be equivalent, although the total lymph node harvest may be less with proximal gastrectomy. Earlier retrospective studies reported higher rates of anastomotic stenosis and reflux esophagitis following proximal gastrectomy; however, these operations usually resect the majority of the stomach whereas a contemporary proximal gastrectomy does not. Further, a larger remnant pouch may offer improved postoperative nutrition. Japanese studies have demonstrated better functional results with proximal gastrectomy than total gastrectomy with Roux-en-Y reconstruction if more than 50% of the stomach remains. If oncologic resection mandates removal of greater than 50% of stomach tissue, then proximal gastrectomy no longer offers benefit over the total gastrectomy counterpart secondary to bile reflux. Proximal gastrectomy may also be appropriate for patients with less physiologic reserve to tolerate a more aggressive total gastrectomy. Exposure for both dissection and reconstruction is facilitated by dividing the diaphragm by electrocautery in the midline after ligating the crossing phrenic vein. The crura are distracted laterally with stay sutures, and a self-retaining retractor is placed in the opened diaphragmatic hiatus. This allows mobilization of the distal mediastinal esophagus. A primary esophagogastrostomy is performed in an end-to-side manner over a nasogastric (NG) tube, which is left overnight (Fig. 5). The anastomosis comes to lie in the low mediastinum after reapproximation of the diaphragm (Fig. 6).

A pylorus-preserving gastrectomy has been offered in Korea and Japan for patients with early gastric cancer (T1N0M0) located in the middle-third of the stomach at least 4.0 cm away from the pylorus. Ongoing studies are attempting to find the ideal balance between optimizing postoperative quality of life while still achieving a complete, appropriate oncologic resection and lymphadenectomy.

Surgery can still be considered in carefully selected patients with advanced disease. Locally advanced gastric adenocarcinoma with extension into nearby organs requires a multivisceral en bloc resection of involved structures. While multivisceral resection increases morbidity and perioperative mortality compared with total gastrectomy alone, the achievement of an R0 resection in these patients leads to clinically and statistically significant survival benefit compared with palliative resection or chemotherapy alone. This is particularly in reference to distal pancreatectomy splenectomy or pancreaticoduodenectomy in the case of adherence or direct pancreatic invasion. Highly selected individuals with limited peritoneal disease equating to a peritoneal cancer index score of ≤7 may benefit from cytoreductive surgery (CRS) and HIPEC in addition to systemic chemotherapy and gastrectomy. Use of preoperative diagnostic or staging laparoscopy as described earlier is imperative to identify this subgroup of patients who may see benefit from the aggressive CRS and HIPEC approach. A complete cytoreduction and HIPEC with mitomycin C, in addition to complete gastrectomy and lymphadenectomy, have been associated with encouraging overall survival. A phase II trial of cytoreduction, gastrectomy, and HIPEC for 20 patients with gastric cancer and metastatic peritoneal disease resulted in an encouraging median overall survival of 2.1 years from the time of diagnosis. Guidelines will evolve as clinical trials for individuals with low volume peritoneal carcinomatosis continue and mature. These complex patients should be referred to experienced centers with established multidisciplinary gastric cancer teams to ensure optimal outcomes.

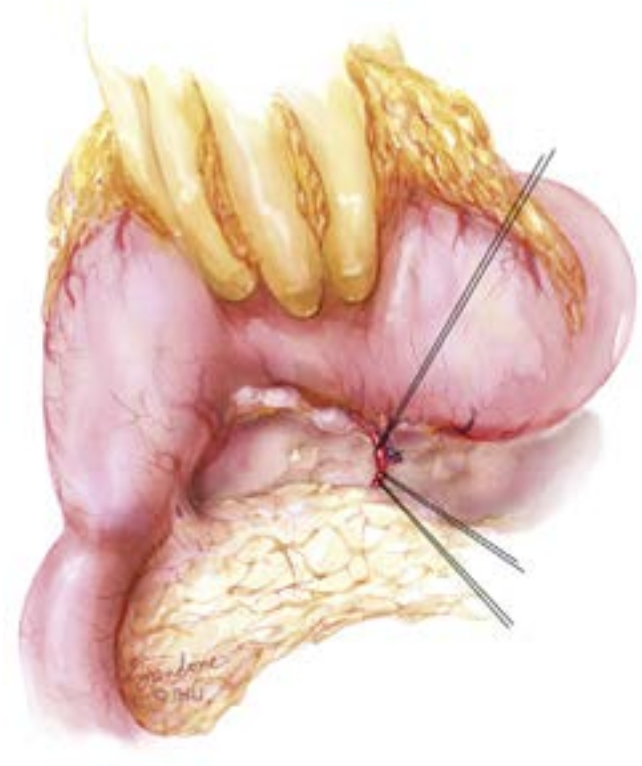

FIG. 2 Illustration of identification, dissection, and high ligation of left gastric artery at its takeoff from the celiac trunk just cephalad to the pancreas.

POSTOPERATIVE RECOVERY

Distal gastrectomy is associated with a low leak rate of 1% to 2%, and thus the authors' practice is to pull the NG tube in the operating room and initiate a clear liquid diet the night of surgery or the following day. This is advanced to a regular diet on enhanced recovery after surgery (ERAS) pathway with typical discharge on postoperative day 3 to 5.

Total gastrectomy requires a longer stay and slower transition in diet. Typically with an esophageal anastomosis that carries a much higher risk of leak, a fluoroscopic swallow study is obtained on postoperative day 3 followed by progression from liquids to soft foods. Total gastrectomy patients may be discharged on either soft or

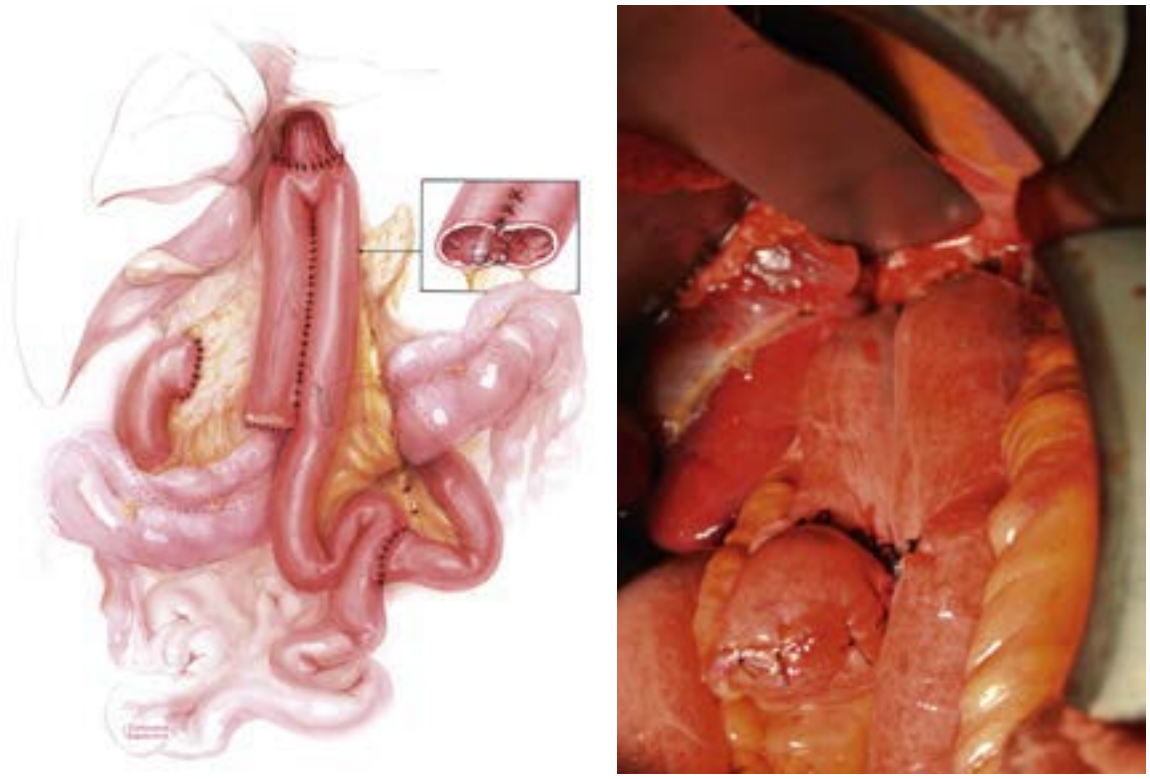

FIG. 3 Reconstruction and formation of jejunal pouch following total gastrectomy. *(From Cameron JL, Sandone C.* Atlas of Gastrointestinal Surgery, *Vol II, 2nd ed. Shelton, CT: People's Medical Publishing; 2014.)*

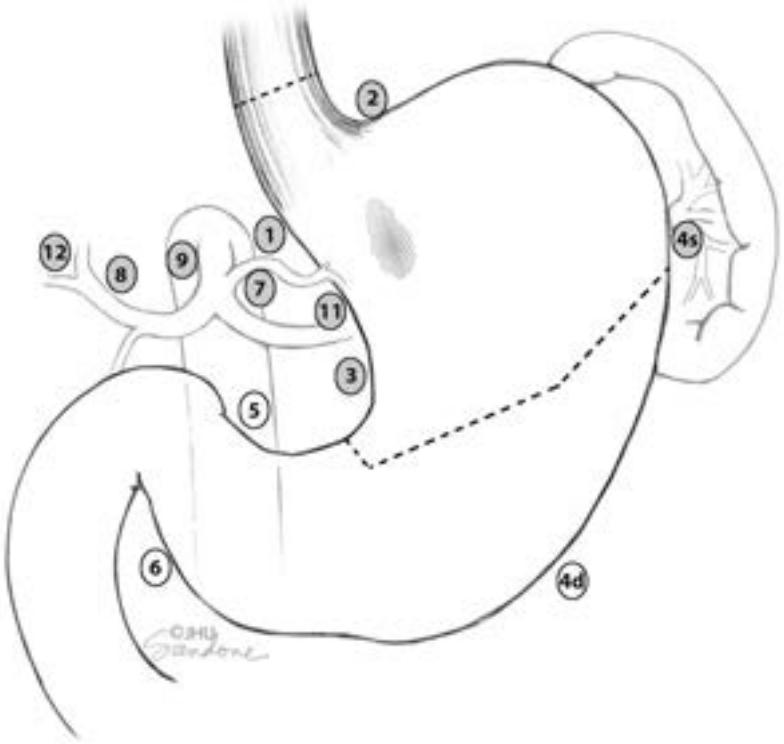

FIG. 4 Proximal gastrectomy for select smaller tumors near the gastroesophageal junction. The dashed lines show the transection of the esophagus proximally and the oblique transection of the stomach 4 to 5 cm distally. At least 50% of the stomach should be preserved in which case the functional results are better than with total gastrectomy. The shaded lymph nodes (1-4s,6-10,12) are included with the resection, while the suprapyloric and infrapyloric nodes that are extremely rarely involved by proximal tumors are left behind.

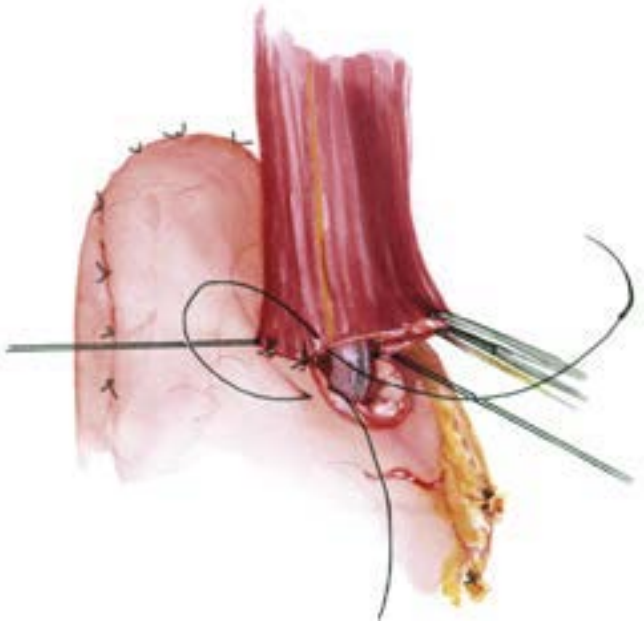

FIG. 5 A primary esophagogastrostomy performed as reconstruction after proximal gastrectomy. In this case, a two-layered handsewn anastomosis is employed with an outer layer of interrupted 3-0 silk and an inner layer of interrupted 3-0 Vicryl. A nasogastric tube is passed across the anastomosis after completing the posterior inner layer.

FIG. 6 The esophagogastrostomy comes to lie at or above the diaphragm in the low mediastinum after proximal gastrectomy. The diaphragm has been divided after ligating the crossing phrenic vein to facilitate exposure. It will be reapproximated with interrupted 0-PDS.

regular diet. All gastrectomy patients are seen by a dietician on the nutrition team. The authors do not routinely utilize a jejunal tube for feeding with only select use in older patients with significant preoperative weight loss, malnutrition, or frailty.

SYSTEMIC THERAPY

Gastric adenocarcinoma is a biologically aggressive cancer with high recurrence and mortality, thus multimodal systemic therapy is utilized to maximize survival for surgical candidates. Multiple clinical trials and meta-analyses support survival advantage of systemic chemotherapy in combination with complete oncologic resection for patients with greater than T2N0 disease. First-line regimens include 5-fluorouracil (5FU), leucovorin, oxaliplatin, and docetaxel (FLOT); capecitabine and oxaliplatin (CAPOX); 5FU, leucovorin, and oxaliplatin (FOLFOX); and epirubicin, cisplatin, and 5FU (ECF). The CLASSIC trial was a phase III, randomized controlled trial in Asia that enrolled 1035 patients with stage II-IIIB gastric cancer who underwent gastrectomy with D2 lymphadenectomy. They were assigned to receive adjuvant capecitabine and oxaliplatin or surgery alone. The trial was stopped early due to a clear survival advantage of the chemotherapy plus surgery group with a 3-year disease-free survival of 74% compared with 59% in the surgery only group.

Despite the clear data supported advantage of adjuvant chemotherapy, there is a high rate of failure to complete adjuvant treatment secondary to multiple issues including surgical complications and patient performance status, thus there has been a recent focus on neoadjuvant rather than postoperative adjuvant therapy. The MAGIC trial enrolled 503 patients with stage II or higher gastroesophageal cancer to either surgery alone or perioperative chemotherapy with a 3-week cycle of ECF preoperatively and three additional cycles postoperatively. The systemic therapy plus surgery group had better pathologic results with lower T stage in the final specimen and a higher proportion of limited nodal disease (N0 or N1) compared with surgery alone. Local recurrence, distant metastases, and 5-year overall survival were all improved in the chemotherapy plus surgery group compared with surgery only.

A phase II trial treated 49 patients with locally advanced gastric cancer with cisplatin, docetaxel, and capecitabine, finding an overall R0 resection rate of 63%, much higher than historical rates of as low as 30%. At a median follow-up of 51 months, median progression-free survival was not reached with predicted 5-year overall survival of 54% for patients in this study without peritoneal disease but classified as locally advanced due to adjacent organ involvement. A separate Japanese phase II study of 55 patients with locoregionally advanced disease studied neoadjuvant irinotecan and cisplatin followed by gastrectomy and D3 lymphadenectomy. R0 resection rate was 65% with a 3-year survival rate of 27%.

The FLOT4-AIO phase III trial compared the MAGIC regimen to four preoperative and four postoperative cycles of FLOT. In the study, 716 patients were randomized with significant improvement in median overall survival with the FLOT regimens (50 vs. 35 months).

The benefit of adjuvant radiation therapy is less clear. The Intergroup 0116 trial enrolled 556 patients for curative gastrectomy alone or surgery in combination with adjuvant 5FU and radiotherapy. This study revealed a significant benefit for adjuvant therapy for overall survival of 50% vs. 41% and recurrence-free survival of 64% versus 41%. Nevertheless, this study is often criticized for the high rates of inadequate lymphadenectomy potentially influencing the observed locoregional benefit. The ARTIST trial randomized patients with gastrectomy and D2 lymphadenectomy to adjuvant chemotherapy with capecitabine and cisplatin alone or with radiotherapy. There was no difference in disease-specific outcomes; however, in a subgroup analysis, radiotherapy did appear to improve disease-free survival in patients with any nodal metastases.

TARGETED THERAPY

Although surgery remains the only potentially curative treatment, the last decade has seen an evolution of cancer care with an increased focus in targeted therapy in an attempt to optimize and personalize care.

The CheckMate-649 phase III randomized trial showed that treatment with the PD-1 inhibitor nivolumab in combination with chemotherapy resulted in an improvement of survival in patients who had PD-L1 positive advanced gastric cancer, GEJ cancer, and esophageal cancer compared with patients receiving chemotherapy alone (13.8- vs. 11.6-month median survival). The results of this study lead to FDA approval of nivolumab for the initial treatment of patients with advanced disease in 2021. Additional targeted therapies under ongoing investigation include the tyrosine kinase inhibitors ramucirumab and bevacizumab that target the vascular endothelial growth factor (VEGF) receptors induced by tumor angiogenesis. Phase II studies have suggested these anti-VEGF antibodies may enhance efficacy of chemotherapy for advanced gastric cancer, although phase III trials remain conflicted. The human epidermal growth factor receptor (ErbB) family has been extensively investigated in gastric cancer. This includes ErbB-2 (HER2), which plays a critical role in regulating cell growth and proliferation and may be overexpressed in gastric cancer. A phase III trial evaluated 594 patients with HER2 overexpressing advanced gastric cancer comparing chemotherapy with or without the addition of trastuzumab and identified a better median survival in the group that included combination with the HER2 targeted monoclonal antibody. The armamentarium for advanced gastric cancer will likely continue to grow with the maturation of multiple ongoing clinical trials investigating different targets and combinations of chemotherapy and immunotherapy.

SURVEILLANCE

All patients with gastric cancer are recommended for systematic postoperative surveillance. This typically entails a complete history and physical examination, basic laboratory testing, and imaging with a CT scan every 3 to 6 months for 1 to 2 years, and then every 6 to 12 months until 5 years out from treatment. This recommendation is despite data that shows no survival benefit to routine CT surveillance. Unfortunately, recurrent gastric cancer is almost never curable. Most all cases of recurrent gastric cancer present within the first 4 to 5 years of initial treatment, and thus 5-year disease-free survival from gastric cancer is considered a cure. For those with recurrent disease, first-line therapy with two drug chemotherapy regimens is the preferred approach for patients, with three drug regimens offered to patients with good performance status. Second-line therapy regimens are recommended based on prior therapy and patient performance status. Although not supported by robust prospective data, surgery can be considered as an option for resectable locoregional recurrence in patients who are medically fit. Some clinical trials are open for recurrent and stage IV disease.

PALLIATION

Approximately 50% of gastric cancer patients initially present with locally advanced unresectable or widespread metastatic disease. With best supportive care, the median survival of these patients without the option for curative resection is only 5 months. Nevertheless, palliative care aims to prevent, reduce, and relieve suffering while maximizing quality of life. The goal can be described as helping patients live as strong as possible for as long as possible emphasizing quality of life in addition to longevity alone. Symptoms of progressive gastric cancer can include bleeding, obstruction, nausea, and pain. Endoscopic coagulation can assist with control of bleeding with adjuncts of external beam radiation or angiographic embolization for recurrent bleeding that is not controlled. The primary goals for patients with obstruction are to reduce nausea and, when possible, resume an oral diet. To accomplish this, a multidisciplinary approach is encouraged, and individual management strategies may include external beam radiation therapy, chemotherapy, placement of an endoscopic stent, surgical gastrojejunostomy, venting gastrostomy, or even palliative gastrectomy in selective patients. Indeed, a distal gastrectomy is a much simpler operation with less physiologic insult that is much better tolerated, which may be offered to some patients with distal tumors aiming to improve their quality of life. A total gastrectomy, however, is a much bigger operation with higher complication rates, including anastomotic leak, of up to 10%, even at high volume centers. Thus, it must be very carefully considered before being offered as a palliative procedure. One must weigh the expected recovery time of the potential procedure against the anticipated survival. A gastrostomy or jejunal feeding tube may be required to provide adequate hydration and nutritional support for patients who cannot tolerate an oral diet.

CONCLUSION

Complete surgical extirpation with appropriate lymphadenectomy remains the foundation of curative therapy for patients with operable gastric adenocarcinoma. The extent of gastric resection and selection of surgical technique depends on the location and extent of the tumor as well as the experience of the surgical team. Addition of neoadjuvant or adjuvant systemic chemotherapy improves survival over surgery alone. Newer biologic therapies target the molecular profile of the tumor allowing for personalized and biology-based therapy. The treatment armamentarium continues to grow as trials investigating HIPEC, immunotherapy, and targeted therapy begin to mature.

Familial Gastric Cancer

Hamza Khan, MD, Juliet Siena Lumati, MD, and Fabian M. Johnston, MD

The World Health Organization (WHO) estimates that gastric cancer is the sixth most common cause of malignancy worldwide and is responsible for more than 1 million new cases and more than 750,000 annual deaths as of 2020. Unfortunately, late diagnoses with concomitant advanced disease and limited effective therapeutic options ultimately lead to high mortality. As with most cancers, gastric adenocarcinoma is most commonly sporadic in nature with a multifactorial etiology. Multiple risk factors have been extensively studied including *Heliobacter pylori* infection, smoked/processed foods, obesity, alcohol/tobacco consumption, long-term inflammation, and gastroesophageal reflux disease. However, up to 10% of these cases have a familial predisposition. The term *familial* is attributed to families who have two first- or second-degree relatives with gastric cancer diagnosed before 50 years of age or three first- or second-degree relatives diagnosed at any age.

Although there are multiple subtypes of gastric cancer, gastric adenocarcinoma is the most common subtype (90%–95%), followed by primary gastric lymphoma (2%–8%), gastrointestinal stromal tumor (<1%), and neuroendocrine tumor (<1%). For the purpose of clarity, we will focus on gastric adenocarcinoma in this chapter. Familial gastric cancer is most commonly associated as being identified in 1998 when Guilford et al. reported a high incidence of multigenerational diffuse gastric cancer affecting individuals at a young age within the indigenous Māori people of New Zealand. This family was found to have germline mutations within the gene coding for the calcium-dependent E-cadherin cell-cell adhesion molecule *(CDH1),* which was identified as a seminal mutation leading to the development of gastric cancer. This finding identified the need for physicians to have an understanding of the molecular profiles specific to familial gastric cancer, allowing them to identify individuals and family members at high risk who may benefit from early surveillance, prevention, or intervention.

PATHOLOGY OF GASTRIC CANCER

Per the Lauren classification, gastric adenocarcinoma is histologically divided into intestinal and diffuse subtypes. The intestinal subtype is composed of tumor cells that are arranged in a glandular formation, is commonly associated with environmental risk factors, and offers a more favorable prognosis. In contrast, the diffuse subtype lacks adhesion molecules and has poorly cohesive cells that are highly metastatic. It is associated with lesions that are transmural, poorly differentiated, and common in younger patients, overall offering a poor prognosis. Genetic mutations by random error at the cellular level accumulate to transform normal cells into a malignant state. Patients with familial gastric cancer syndromes are at increased risk of developing malignancy because they inherit the initial hit to the genome that allows development of the subsequent neoplastic phenotype more easily.

Hereditary Diffuse Gastric Cancer

Hereditary diffuse gastric cancer (HDGC) is an autosomal dominant malignancy that composes about 1% to 3% of all gastric cancers. This syndrome was first identified in the Māori families of New Zealand. HDGC is associated with a loss-of-function mutation in the calcium-dependent adhesion protein *(CDH1)* gene on chromosome 16q. *CDH1* has an important role in cell-cell adhesion, thus the loss of function increases invasiveness and epithelial-to-mesenchymal transition. Families with a *CDH1* mutation are at an increased risk of developing diffuse, aggressive, signet ring gastric adenocarcinoma, lobular breast carcinoma, or cleft lip and palate.

The *CDH1* pathogenic variant lends a lifetime risk of 37% to 42% for men and 25% to 33% for women of developing gastric adenocarcinoma in carriers. Up to 60% of female patients are also at risk of developing lobular breast cancer along with 14% of the families reporting cleft lip and palate. Given the high degree of penetrance with this mutation, mapping out familial pedigree is imperative. Testing guidelines for *CDH1* are based on recommendations from the International Gastric Center Linkage Consortium (IGCLC) (Box 1). These guidelines suggest that testing begin at 18 years of age because the IGCLC recommends against testing in children. Typically, asymptomatic family members undergo testing 5 years before the earliest age of the family member with diagnosed invasive cancer or in their second decade of life.

Patients with HDGC can develop poorly differentiated diffuse gastric cancer on average by 38 years of age. Carriers are offered prophylactic total gastrectomy (PTG) as a risk-reducing procedure because it offers excellent outcomes in primary prevention of gastric cancer, even if carriers are asymptomatic. Before undergoing PTG, a preoperative workup including nutritional assessment, risks of intervention, and discussion about long-term sequalae such as dietary changes is of utmost importance. For individuals who decline surgery, annual endoscopic surveillance is offered starting at 20 years of age and includes multiple biopsies of any identifiable lesion and at least 30 random biopsies from all five anatomic zones of the stomach. However, endoscopy is a poor screening tool because early disease of the diffuse gastric cancer subtype can infiltrate the submucosa without endoscopically visible lesions, leading to a high false-negative rate. Following prophylactic gastrectomy, close pathologic inspection reveals multiple foci of intramucosal (T1a) diffuse signet ring cell carcinoma ranging from 0.1 to 10 mm in the overwhelming majority of cases. In a study on prophylactic total gastrectomy in patients with a *CDH1* mutation, 92% of patients were found to have T1N0

BOX 1 2020 Hereditary Diffuse Gastric Cancer Genetic Testing Criteria

Family Criteria (First- or Second-Degree Blood Relatives)

- ≥2 cases of gastric cancer in family regardless of age, with at least one DGC
- ≥1 case of DGC at any age and ≥1 case of lobular breast cancer at <70 years of age in different family members
- ≥2 cases of lobular breast cancer in family members before 50 years of age

Individual Criteria

- DGC before 50 years of age
- DGC at any age in individuals of Māori ethnicity
- DGC at any age in individuals with a personal or family history (first-degree relative) of cleft lip or cleft palate
- History of DGC and lobular breast cancer, both diagnosed before 70 years of age
- Bilateral lobular breast cancer, diagnosed before 70 years of age
- Gastric in situ signet ring cells or pagetoid spread of signet ring cells diagnosed before 50 years of age

DGC, Diffuse gastric cancer.

Modified from Blair VR, McLeod M, Carneiro F, et al. Hereditary diffuse gastric cancer: Updated clinical practice guidelines. *Lancet Oncol.* 2020;21(8):e386–e397.

malignancy on histopathologic examination, whereas only 16% had a tumor diagnosed on endoscopic surveillance.

Given the high lifetime risk of developing lobular breast cancer, women carriers of *CDH1* are also offered annual surveillance with mammography or breast MRI starting at 30 years of age. Although data are insufficient, bilateral prophylactic mastectomy can be considered between 30 and 60 years of age. In patients with a family history of two or more individuals with lobular breast cancer or individuals with bilateral disease, *CDH1* genetic testing should be offered. Studies have shown that 3% to 6% of patients with lobular breast cancer have *CDH1* mutations, therefore it is necessary that physicians caring for patients with breast diseases are also familiar with familial gastric cancer syndromes so appropriate counseling can be performed.

Ideally, care for these patients is undertaken by a multidisciplinary team consisting of a surgical oncologist, gastroenterologist, dietician, pathologist, and genetic counselor who can provide the patient with the most up-to-date guidelines regarding surveillance, intervention, and long-term care. High-volume centers are better equipped with the resources that are necessary to provide longitudinal care for HDGC patients and their families.

Hereditary Nonpolyposis Colorectal Cancer

Henry T. Lynch initially discovered two families predisposed to develop colorectal cancer (CRC) in the 1960s and deemed it *hereditary nonpolyposis colorectal cancer* (HNPCC). The development of cancers other than CRC, including gastric cancer, has been identified and thus the term *Lynch syndrome* has gained popularity. HNPCC is a highly penetrant, dominantly inherited familial cancer syndrome with a molecular phenotype of DNA microsatellite instability. Accumulated germline mutations in mismatch repair (MMR) genes *MLH1, MSH2, MSH6,* or *PMS2* result in carcinogenesis in several organs including the colon, rectum, uterus, ovaries, stomach, and hepatobiliary systems. These mutations account for up to 3% of all newly diagnosed CRC cases, making it the most commonly inherited CRC disease. Mutations in the *hMSH2* gene on chromosome 2p and the *hMLH1* gene on chromosome 3p cause 90% of the microsatellite instability observed in CRC from HNPCC families and are believed to play a role in inherited gastric cancers.

The Bethesda criteria (Box 2) are used to identify patients with HNPCC but do not include gastric adenocarcinoma as a defining criterion. The criteria include (1) CRC diagnosed in an individual younger than 50 years of age; (2) presence of synchronous or metachronous CRC or other HNPCC-related tumors, irrespective of age; (3) CRC with high microsatellite instability histology diagnosed before 60 years of age; (4) individuals with CRC with at least one first-degree relative with CRC or HNPCC-related tumor diagnosed before 50 years of age; and (5) individuals with CRC with at least two first- or second-degree relatives with CRC or an HNPCC-related tumor, irrespective of age. Individuals who meet these criteria are referred for molecular and immunohistochemical testing for microsatellite instability because some individuals may meet the clinical criteria but are microsatellite stable on testing, which is an exclusionary characteristic.

Gastric malignancy is found in approximately 4% to 8% of patients with Lynch syndrome. Patients typically present before 50 years of age with gastric carcinoma, which is more commonly the intestinal phenotype. Endoscopic surveillance is recommended for patients with HNPCC and a family history of gastric cancer or carriers of *MLH1/MSH2* mutations. This surveillance is important given the rate of gastric cancer development and the importance of understanding that there is no role for prophylactic gastrectomy, and surgery is limited to cases with confirmed malignancy.

Li Fraumeni Syndrome

Li Fraumeni syndrome (LFS) is characterized by germline mutations in the *TP53* gene on chromosome 17. *TP53* encodes the tumor suppressor protein p53 that regulates apoptosis in cells with damaged DNA and is termed *guardian of the genome. TP53* mutations prevent cell cycle arrest and permit unregulated division of cells, with mutated DNA leading to an autosomal dominant cancer syndrome composed of various malignancies. Suppression or deletion of *TP53* are common mutations found in the majority of familial or sporadic gastric cancer cases. LFS is associated with *TP53* mutation, thus encompassing several tumor types such as sarcoma, breast tumors, or leukemia that generally develop before 45 years of age (Box 3). Gastric carcinoma is diagnosed in up to 4.9% of LFS carriers, and up to 40% of families with *TP53* mutations report gastric tumor in the pedigree. The median age of diagnosis for gastric malignancy is 36 years, but it has been seen as early as 12 years of age, with the majority of tumors in the proximal stomach and displaying the intestinal phenotype. Screening is focused on breast and CRC, however the phenotypic diversity of LFS complicates effective screening. Therefore periodic screening gastroscopy should be considered at an early

BOX 2 Clinical Criteria to Identify Individuals at Risk for Lynch Syndrome: Bethesda Guidelines

Revised Bethesda Guidelines

Tumors from individuals should be tested for MSI in the following situations:

1. CRC diagnosed in a patient who is younger than 50 years of age.
2. Presence of synchronous, metachronous colorectal or other HNPCC-associated tumors, regardless of age.
3. CRC with the MSI-H† histology diagnosed in a patient who is younger than 60 years of age.
4. CRC diagnosed in one or more first-degree relatives with an HNPCC-related tumor, with one of the cancers being diagnosed before 50 years of age.
5. CRC diagnosed in two or more first- or second-degree relatives with HNPCC-related tumors, regardless of age.

Amsterdam Criteria II

1. There should be at least three relatives with an HNPCC-associated cancer (CRC, cancer of the endometrium, small bowel, ureter, or renal pelvis).
2. One should be a first-degree relative of the other two.
3. At least two successive generations should be affected.
4. At least one should be diagnosed before 50 years of age.
5. Familial adenomatous polyposis should be excluded in the CRC case(s) if any.
6. Tumors should be verified by pathologic examination.

CRC, Colorectal cancer; *HNPCC,* hereditary nonpolyposis colorectal cancer; *MSI,* microsatellite instability.

Revised Bethesda Guidelines for hereditary nonpolyposis colorectal cancer (Lynch syndrome) and microsatellite instability. *J Natl Cancer Inst.* 2004;96(4):261–268; Amsterdam Criteria II: Vasen, Hans FA, et al. New clinical criteria for hereditary nonpolyposis colorectal cancer (HNPCC, Lynch syndrome) proposed by the International Collaborative group on HNPCC. *Gastroenterology* 1999;116(6):1453–1456.

BOX 3 Diagnostic Criteria for Li Fraumeni Syndrome

Classic LFS criteria (must meet all three)
1. A proband with a sarcoma diagnosed before 45 years of age
2. A first-degree relative with any cancer diagnosed before 45 years of age
3. A first- or second-degree relative with any cancer diagnosed before 45 years of age or a sarcoma diagnosed at any age

Modified from Schneider K, Zelley K, Nichols KE, Garber J. Li-Fraumeni Syndrome. 1999 Jan 19 [updated 2019 Nov 21]. In: Adam MP, Ardinger HH, Pagon RA, Wallace SE, Bean LJH, Gripp KW, Mirzaa GM, Amemiya A, editors. GeneReviews [Internet]. Seattle (WA): University of Washington, Seattle; 1993–2022. PMID: 20301488.

age for LFS carriers who have at least one family member affected by gastric cancer.

Polyp-Associated Gastric Cancer Syndromes

Familial gastric cancer syndromes can be subclassified broadly into those prominently associated with polyps and those that are not. Benign neoplasms and polyps of the gastric mucosa are made up of multiple taxonomies including adenomatous, fundic gland, hyperplastic, inflammatory, and hamartomatous polyps. In general, the inflammatory, hyperplastic, and hamartomatous polyps are considered benign, although occasionally malignant potential is appreciated. Gastric adenomatous polyps and fundic gland polyps are uncommon outside of familial syndromes and are more likely to behave as premalignant lesions. Despite displaying relatively indolent rates of neoplastic development, these subsets of polyps are associated with a significantly increased lifetime risk of developing gastric adenocarcinoma and are thus approached with greater caution. A number of inherited cancer syndromes are characterized by a higher frequency of these polypoid lesions yielding an increased risk of gastric cancer.

Familial Adenomatosis Polyposis and *MUTYH*-Associated Polyposis Syndromes

Familial adenomatous polyposis (FAP) is an autosomal dominant syndrome characterized by a loss-of-function mutation in the adenomatous polyposis coli *(APC)* tumor suppressor gene on chromosome 5q. Classic FAP is known for the presence of hundreds of colorectal polyps leading to 100% of affected individuals developing CRC. In contrast, attenuated FAP is characterized by fewer polyps, a later age of diagnosis for adenomas or cancer, and a lower risk of CRC (80%) compared with classic FAP. Adenomatous polyps are also manifested in the upper gastrointestinal tract in 50% to 88% of FAP cases. Gastric polyposis (>20 gastric polyps) may also be identified. In cases of gastric polyposis, the polyps are predominately located in the body/fundus, with adenomatous change most frequently identified near the body/antrum junction. The risk of developing dysplasia is proportional to the polyp size. Furthermore, although the overall risk of carcinoma is low (2%), polyps are more likely to harbor dysplasia in patients with familial polyposis compared with sporadic gastric polyps. In the West, up to 4% of patients with FAP are at risk of developing gastric carcinoma, which is mostly of the intestinal subtype.

FAP patients are recommended to undergo prophylactic total proctocolectomy with ileal pouch anal anastomosis because of the high penetrance of early CRC cancer. No standard guidelines, however, currently exist for gastric surveillance. The age of gastric manifestations is variable in FAP patients, although gastric adenocarcinoma is typically developed long after their colectomy. Current data suggest upper endoscopy initiated at 21 to 30 years of age and performed at intervals of 3 to 5 years with a decreased interval following finding of adenomatous polyps or dysplasia. Polyps larger than 1 cm should be removed to confirm the diagnosis and diminish the risk of malignant degeneration. If dysplasia is identified, low-grade dysplasia is most common, and the overall risk of carcinoma is low. Surgical intervention is typically reserved for patients with severe polyposis causing symptoms (i.e., bleeding) or in the case of confirmed malignancy on endoscopic biopsy. Prophylactic gastrectomy can be discussed for patients who have FAP or attenuated FAP and display diffuse fundic gland polyps, large polyps, or high-grade dysplasia polyps.

The *MUTYH* gene on chromosome 1p regulates DNA damage, and a loss-of-function mutation can lead to *MUTYH*-associated polyposis (MAP) syndrome. This is an autosomal recessive disease, and diagnosis requires evidence of a wild-type *APC* gene to rule out FAP. Clinical presentation, however, is similar to attenuated FAP, with the colon primarily affected along with multiple extracolonic manifestations, such as the development of breast, ovary, or skin cancers. In contrast, patients with MAP have gastric polyps in 11% of the cases compared with up to 90% in FAP. These polyps include both fundic polyps and adenomas with an overall lower risk (2%) of developing gastric cancer compared with patients with FAP.

For both FAP and MAP, surveillance is the mainstay of treatment. Surgical intervention is considered only when gastric carcinoma is established or in the presence of symptomatic polyps that typically present with bleeding or obstruction. For screening, current data suggest endoscopy starting after 25 to 30 years of age in 3- to 5-year intervals. Other therapies such as acid-suppression or nonsteroidal antiinflammatory drugs (NSAIDs) have been shown to reduce polyps, although the effect on overall survival is unknown. Minors have low risk for conversion to malignancy, hence screening is not recommended in this age group. Patients are also at significant risk of duodenal polyps with conversion to malignancy, hence continued endoscopic surveillance after gastric resection is prudent. Thus, surgeons should consider a wider Roux-en-Y anastomosis with a deliberately shorter biliary pancreatic limb to facilitate subsequent endoscopic surveillance of the duodenal stump. Surgeons also should recognize that this may lead to an increased risk of bile reflux.

Peutz-Jeghers Syndrome

Genetic mutation in the tumor suppressor gene *STK11* can lead to the development of Peutz-Jeghers syndrome (PJS). PJS is an autosomal dominant disease classically known for mucocutaneous pigmentation, multiple hamartomatous polyps along the entire gastrointestinal tract, and a high risk of developing various cancers, particularly gastrointestinal and breast tumors. Polyps are found throughout the gastrointestinal tract, more commonly in the small bowel, colon, and stomach (70%–90%, 50%, and 25%, respectively). Gastric polyps can involve the antrum and pylorus and can grow to large sizes, mimicking carcinoma. Because of their size, these polyps are occasionally associated with symptoms including bleeding, abdominal pain, intussusception, and even obstruction.

PJS is associated with the *PJS1* gene on chromosome 19p. Seventy percent of individuals with PJS also have germline mutations of *STK11* on chromosome 19p. The role of these genes as initiators of gastric cancer is poorly defined, but the association of gastric polyps and cancers implicates a potential role. Individuals with *STK11* mutations are more likely to develop gastric polyps and malignancies than their wild-type counterparts. Gastric polyps can present as early as 2 years of age, with a median age of onset of 16 years. Despite the early onset of disease, progression to carcinoma is rare and has a long latency period of greater than 20 years. The lifetime risk of developing gastric cancer in individuals is up to 30% along with an increased risk of malignancy in the pancreas, lung, breast, ovary, or cervix. Given the young age of disease onset, screening with upper and lower endoscopy is recommended to start by 8 years of age with subsequent surveillance based on endoscopic findings. In patients with

no evidence of polyps, surveillance is reinitiated by 18 years of age. Surgical intervention is reserved for histologically confirmed malignancy or symptomatic polyps. Annual CBC is also recommended to screen for anemia from chronic slow bleeding polyps. Select studies have shown some benefits of COX-2 or mTOR inhibitors (rapamycin) in controlling the polyp burden.

Gastric Adenocarcinoma and Proximal Polyposis of the Stomach

Extensive gastric polyposis limited to the body and fundus in the absence of duodenal or colorectal polyposis is termed *gastric adenocarcinoma and proximal polyposis syndrome* (GAPPS). It is a relatively new, autosomal dominant disorder with incomplete penetrance. Diagnosis requires exclusion of other polyposis syndromes by ruling out mutations in *CDH1, MUTYH*, and *APC*, among other genes. The precise genetic mutation leading to this syndrome is yet to be identified. Affected individuals have greater than 100 gastric polyps if they are the index case or greater than 30 polyps if they are a first-degree relative of the index case (Fig. 1). Polyps are typically smaller than 1 cm in size and can harbor dysplasia with progression to intestinal-type adenocarcinoma. The syndrome can present as early as the first decade of life, and up to 13% of patients can develop gastric malignancy. GAPPS appears to have an inverse association with *H. pylori* infection, and it is unclear whether it is because *H. pylori* is protective against the syndrome or because infection is rare given the altered gastric morphology from polyposis. Patients who are on proton pump inhibitors (PPIs) are recommended to stop the medication and repeat endoscopy because PPIs can increase the risk of gastric fundic polyps. Endoscopic surveillance is difficult in the presence of extensive polyposis, and total gastrectomy can be considered based on the individual patient's risk versus the morbidity of the surgery.

PREOPERATIVE WORKUP AND SURGICAL INTERVENTION

Although rare, familial gastric cancer syndromes have major implications for patients and their families. Better understanding of the biology of these hereditary syndromes will allow improved outcomes and quality of life. Among the many syndromes discussed (Table 1), once any of them is suspected, care is entailed by a multidisciplinary team. Family counseling is initiated to identify members at increased risk of disease so surveillance can be offered. Methods of surveillance, their frequency, and surgical intervention are discussed on a case-by-case basis depending on the individual's age, their relative's age at the time of diagnosis of cancer, family history, genetic mutation, and most importantly, personal preference. Large institutions can develop a specialized program that is equipped to deal with the complexity that is required for these patients.

Patients who are diagnosed with gastric carcinoma and require gastrectomy are preoperatively referred to a dietician for nutritional evaluation. Preoperative radiologic, endoscopic, and positron emission tomographic (PET) imaging allow adequate staging of the disease. In patients with a hereditary gastric cancer syndrome with a biopsy-proven gastric malignancy, care is similar to any patient with sporadic gastric cancer. Operative intervention with a goal for complete resection offers the only curative treatment option. Surgical margins of 5 cm from gross tumor along with frozen sections are recommended, particularly in cases of diffuse-type gastric cancer because the cells are highly infiltrative. Lymph node involvement and depth of tumor invasion are the most important prognostic indicators. For adequate staging, more than 15 resected lymph nodes are necessary, and a D2 lymphadenectomy is performed.

For patients undergoing a prophylactic total gastrectomy, an upper endoscopy is performed for evaluation of any visibly abnormal sections of the stomach along with random biopsies taken from visibly normal-appearing areas. In patients with no apparent pathology, a conservative approach to harvesting perigastric lymph nodes is taken because it is rare for the tumor to metastasize to the nodes in the setting of visibly unremarkable mucosa. In this scenario, minimally invasive techniques can also be employed, offering shorter hospital stays and possibly improved pain.

FIG. 1 Retroflexed view of gastric endoscopy showing diffuse polyposis covering the body and fundus. *(From Tacheci I, Repak R, Podhola M, et al. Gastric adenocarcinoma and proximal polyposis of the stomach (GAPPS)—A Helicobacter-opposite point. Best Pract Res Clin Gastroenterol. 2021;50–51:101728.)*

POSTSURGICAL CARE

Because patients with familial gastric syndrome may undergo prophylactic gastrectomy at a time when they feel completely healthy, it is important to discuss expectations about postoperative recovery beforehand. Postsurgical recovery can be complicated by potential operative complications or infections. Within the first few weeks after surgery, it is common to have difficulty eating, and patients are also counseled to expect a 10% to 20% weight loss in the beginning as they adapt to a new lifestyle for meals. Derangement in intestinal motility occurs in about 20% of patients and can lead to early satiety, bloating, epigastric pain, and nausea. Dietary modifications like consuming multiple small meals throughout the day in most cases improves symptoms of dumping syndrome, and patients rarely need medical or surgical intervention. In the early recovery phase, well-cooked and soft meals that are high in protein are recommended. As patients improve, a return to their own regular diet in smaller amounts multiple times a day works well. A nutritionist is often an integral part of the team at this stage and can help patients with dietary modifications. Other known risks after total gastrectomy are vitamin B_{12} deficiency from loss of intrinsic factor and calcium, folic acid, iron, thiamine, or other trace mineral deficiencies from malabsorption. Additional supplementation by multivitamin pills or capsules is advised to meet daily requirements.

Long-term, large-scale studies on patient outcomes are lacking because familial gastric cancer syndromes are rare; however, quality of life indicators assessing psychological health and body image generally return to baseline by 12 months after surgery. In a survey conducted on 53 patients, 6% were dissatisfied with their decision to undergo surgical intervention. Because patients are asymptomatic at the time of operative intervention, it is normal that they experience remorse or regret for their choices, particularly in the face of a difficult postoperative recovery. In our experience, a support group composed of patients with a similar background is very helpful as it

TABLE 1 Familial Gastric Cancer Syndromes with Characteristic Molecular and Clinicopathological Features Along with Management

Syndrome	Gene Affected	Autosomal Inheritance	Risk of Gastric Cancer %	Age of Onset for Gastric Polyps	Endoscopic Surveillance, Initiation (Years)	Treatment

Management of Gastrointestinal Stromal Tumors

Laurence P. Diggs, MD, and Miral Sadaria Grandhi, MD

Gastrointestinal stromal tumor (GIST) is the most common sarcoma of the gastrointestinal (GI) tract and the most common subtype of sarcoma overall; thus, a general surgeon should be familiar with the unique principles of management for this disease. Derived from mesenchymal cells of the GI tract known as interstitial cells of Cajal, GISTs generally present in the stomach followed by the small bowel, rectum, and colon. Over the last several decades, knowledge of the pathophysiology of GISTs has led to improved management and treatment of this disease process. In most cases, development of GISTs is a result of a gain of function mutation and subsequent activation of tyrosine kinase proteins. Mutations activating the KIT proto-oncogene are the most common, accounting for approximately 75% of these tumors. Platelet-derived growth factor receptor (PDGFR) α mutations account for another 10% of these tumors and is mutated in approximately 80% of KIT-wild type (WT) tumors. BRAF mutations have been reported in 13% of KIT-WT tumors. Certain familial syndromes associated with GIST, such as neurofibromatosis type 1 (NF1) and mutations to succinate dehydrogenase (SDH), also make up a percentage of the KIT-WT tumors. WT or sporadic GISTs, whereby a driver mutation has not been identified, are currently thought to account for no more than 5% of all cases.

Since the description of a gain of function mutation in the KIT proto-oncogene in 1998, targeted therapy against GIST has been

studied extensively. Imatinib mesylate (Gleevec), a tyrosine kinase inhibitor (TKI) of ABL, BCR-ABL, KIT, and PDGFR, has become a major component in the multidisciplinary management of patients with GIST. In patients with metastatic disease, imatinib prolongs median survival to more than 5 years from a historical median of 18 months. In the adjuvant setting, imatinib prolongs recurrence-free survival (RFS). Neoadjuvant imatinib therapy may improve resectability for tumors that are locally advanced or located in anatomically difficult areas and, in some instances, may allow organ-preserving resection. Imatinib therapy has also expanded the role of surgical therapy for metastatic GIST. The ability to estimate the risk of recurrence in GIST patients is increasingly refined. In addition to traditional stratification using tumor size, mitotic index, and organ site, specific mutations in KIT have a significant bearing on tumor behavior and sensitivity to TKIs. Although targeted therapy plays a major role in the management of patients with GIST, surgery remains the only potentially curative therapy for GIST.

CLINICAL PRESENTATION

GIST is typically a disease of adults, with a median presenting age of approximately 60 years and a slight male predominance. The incidence of GIST is estimated to be approximately 6000 new cases per year in the United States. According to autopsy studies, the incidence of micro-GISTs, smaller than 1 cm, is much higher. Although GISTs have been reported throughout the GI tract from esophagus to rectum, the majority are found within the stomach (>50%) followed by the small bowel (25%–35%). Within the small bowel, the majority are found in the ileum and jejunum with only 5% arising in the duodenum. Although other sites of GIST are rare, including rectum, colon, esophagus, and extraintestinal/indeterminate locations, an increasing number of GISTs have been discovered in the colon and the rectum due to the widespread use of screening colonoscopy. The median size of GIST at presentation is 5 to 7 cm but can grow to be larger than 30 cm in size. Often, GISTs are discovered incidentally by endoscopy or imaging during workup for other conditions or at time of unrelated surgery. Patients may have symptoms at the time of diagnosis, particularly with large GISTs, including pain, fullness, early satiety, nausea, vomiting, weight loss, or noticeable mass. Although GISTs are not mucosal-based lesions and grow from the muscle layer of the bowel wall, roughly one-quarter of patients present with GI bleeding secondary to erosion and ulceration of the underlying mucosa. Bleeding from tumor rupture into the peritoneal cavity is a rare but negative prognostic factor and may lead to life-threatening hemorrhage. Metastasis typically involves the liver or peritoneal cavity. Lymph node involvement, occurring in less than 5% of patients, is rare in adult GIST and usually reflects direct tumor extension.

Two subsets of GIST are worth noting. Pediatric GISTs, often associated with SDH deficiency, exhibit different biology compared with adult GIST. This disease is indolent with female predominance, multifocal disease, frequent lymph node metastasis, and universal imatinib resistance. Familial GISTs involving germline mutations in KIT or PDGFRα are rare. Typically, tumors are multifocal and indolent. For patients with an SDH mutation, certain constellations may be observed including Carney's triad (GIST, paraganglioma, and pulmonary chondroma) or Carney-Stratakis syndrome (GIST and paraganglioma). More rarely, patients with mutations in NF1 may develop GISTs and present with additional tumors including gliomas, malignant peripheral nerve sheath tumors, and the typical neurofibroma.

WORKUP

Cross-sectional imaging consisting of a computed tomography (CT) scan of the abdomen and pelvis with IV and oral contrast is the imaging modality of choice for initial evaluation of a GIST tumor. Typical features of a GIST include an enhancing mass arising in the wall of the stomach or small intestine. GISTs may be grossly categorized as exophytic, endophytic, or mixed/dumbbell shape (Fig. 1). Tumor heterogeneity is common in larger tumors due to tumor necrosis. Small masses may not be evident on CT scan depending on the level of distention of the bowel or stomach and if oral contrast was given or not. Alternatively, a large hypervascular mass arising from the lesser curvature of the stomach may be misinterpreted as a primary liver tumor. Determining whether adjacent structures are involved by large tumors can be difficult because of loss of plane interfaces on CT; however, most GISTs are found to be mobile at the time of operation and do not require multivisceral resection. For periampullary and rectal tumors, MRI can help further delineate anatomy. Although GISTs are typically glucose avid on [^{18}F] fluoro-2-deoxy-D-glucose positron emission (PET)/CT, this test is not necessary for initial assessment. PET/CT may be considered to assess for occult metastatic disease and to test for tumor response to TKIs. In addition, it may be useful in determining neurofibromas from GIST tumors in NF1 patients.

CT scan may be sufficient during workup of gastric or small bowel masses that exhibit classic features of GIST. However, many tumors require further evaluation to obtain a definitive diagnosis. Endoscopic evaluation including endoscopic ultrasound (EUS) and fine-needle aspirate (FNA) is the next step in evaluation. It is important to note that biopsies should be obtained endoscopically and that percutaneous biopsies of small bowel GISTs are never recommended due to the risk of peritoneal dissemination. Tissue analysis remains the gold standard to confirm the diagnosis and rule out other potential gastric and intestinal tumors, including adenocarcinoma, lymphoma, and leiomyoma. Pathology consistent with GIST will reveal a population of spindle cells that stains positive for CD117 (KIT) on immunohistochemistry. In addition, tissue analysis is essential to detect additional genetic mutations, including PDGFRα, BRAF, SDH, and NF1, and to help guide effective targeted therapy. In tumors that would require a potentially morbid operation, such as gastroesophageal junction (GEJ) tumors, periampullary duodenum, or rectum, tissue diagnosis is necessary to further determine the sequence of intended treatments with targeted therapy and surgical resection.

RISK STRATIFICATION

Three clinicopathologic parameters have been shown to independently predict risk of recurrence after complete resection of primary GIST: tumor size, mitotic rate, and tumor site. Size greater than 5 cm, mitoses larger than 5/50 high-powered field (HPF), and nongastric site are poor prognostic variables. Several different risk stratification systems have been developed based on these variables (Table 1). A nomogram that incorporates all three criteria (Fig. 2) provides an individualized estimate of 2- and 5-year RFS after complete resection of a primary GIST and can provide selection criteria for adjuvant imatinib.

Identification of the specific *KIT* or other gene (e.g., *PDGFR*, *SDH*) mutation in GIST, either after resection or even preoperatively, provides useful information regarding responsiveness to targeted therapy and progression-free survival (PFS) after resection. Specific mutations are associated with tumor biology and, most importantly, tumor response to imatinib therapy. Three-quarters of tumors harbor a KIT mutation, varying substantially in aggressiveness. Mutations of exon 11 are the most common, representing 65% of all GISTs. Among exon 11 mutations, codons 557 and 558 are hot spots for mutation, and tumors with deletions of this part of the gene are more likely to metastasize or recur compared with point mutations or insertions in this area. Of note, patients with KIT exon 11 deletions in the ACOSOG Z9001 study were responsible for nearly all the improvement in RFS achieved with 1 year of adjuvant imatinib, whereas other KIT mutations demonstrated little difference. KIT exon 9 mutations (about 10% of all GISTs) typically arise in nongastric tumors and carry unfavorable biology. Meta-analysis of two large trials of imatinib in metastatic unresectable GIST demonstrated that patients with exon 9 mutations require higher dose imatinib for

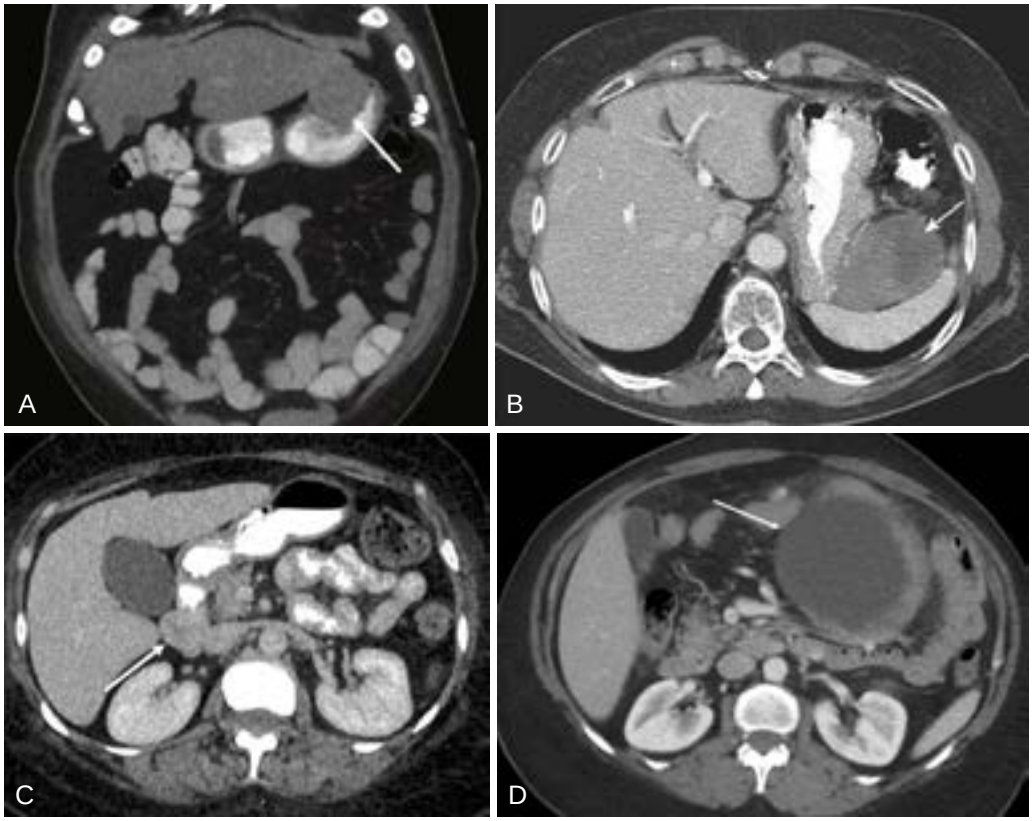

FIG. 1 Contrast-enhanced CT scan of a typical gastric and small bowel gastrointestinal stromal tumor (GIST). Gastric GIST may be **(A)** endophytic, **(B)** exophytic, or intramural (not shown). Small bowel GISTs can occur anywhere along the small bowel, such as the **(C)** duodenum or **(D)** jejunum.

TABLE 1 Risk Classification for Primary Gastrointestinal Stromal Tumor According to Mitotic Index, Tumor Size, and Tumor Site

Tumor Parameters		Risk of Disease Progression (% of Patients)			
Mitotic Index	**Size (cm)**	**Stomach**	**Duodenum**	**Jejunum or Ileum**	**Rectum**
≤5 per 50 HPF	≤2	None	None	None	None
	>2 to ≤5	Very low (1.9)	Low (8.3)	Low (4.3)	Low (8.5)
	>5 to ≤10	Low (3.6)	Insufficient data	Moderate (24)	Insufficient data
	>10	Moderate (10)	High (34)	High (52)	High (57)
>5 per 50 HPF	≤2	None	Insufficient data	High	High (54)
	>2 to ≤5	Moderate (16)	High (50)	High (73)	High (52)
	>5 to ≤10	High (55)	Insufficient data	High (85)	Insufficient data
	>10	High (86)	High (86)	High (90)	High (71)

Data based on long-term follow-up of 1055 gastric, 629 small intestinal, 144 duodenal, and 111 rectal GISTs.
GIST, Gastrointestinal stromal tumor; *HPF*, high-powered field.
Modified from Miettinen M, Lasota J. Gastrointestinal stromal tumor: pathology and prognosis at different sites. *Semin Diagn Pathol.* 2006;23(2):70–83.

response (800 mg vs. 400 mg daily). PDGFRα-mutant tumors, representing 10% of GISTs, are almost always gastric and demonstrate comparably indolent biology. However, the most common *PDGFRα* mutation is exon 18 (D842V), which imparts imatinib resistance but does respond to avapritinib therapy, recently FDA-approved as first-line therapy for these patients. Thus, understanding the biology associated with a specific mutation and the expected response to imatinib can help plan treatment and follow-up.

SURGERY FOR PRIMARY DISEASE

Indications

Surgical resection remains the mainstay of treatment for most patients with GISTs. According to the National Comprehensive Cancer Network (NCCN), resection is indicated for all GISTs greater than 2 cm in size in patients who are otherwise acceptable candidates for surgery. Tumors less than 2 cm in size that

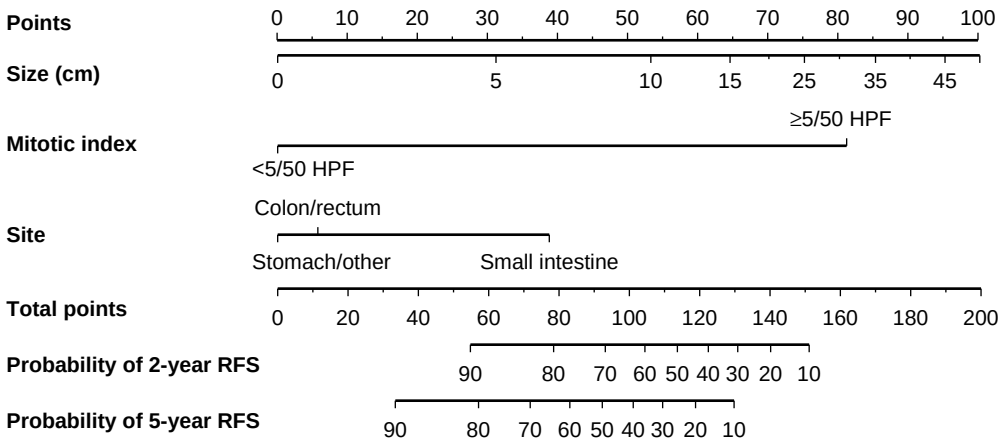

FIG. 2 Nomogram for predicting 2- and 5-year recurrence-free survival (RFS) after resection of primary gastrointestinal stromal tumor. Points are assigned on tumor size, mitotic index, and site by drawing a vertical line from each row to the "points" row. The sum is then located in the "total points" row, and a vertical line is drawn to the "probability" rows to estimate RFS. *HPF*, High-powered field. *(Modified from Gold JS, Gönen M, Gutiérrez A, et al. Development and validation of a prognostic nomogram for recurrence-free survival after complete surgical resection of localised primary gastrointestinal stromal tumour: a retrospective analysis. Lancet Oncol. 2009;10:1045–1052.)*

are asymptomatic, uncomplicated, and indolent in nature can be observed with surveillance imaging. In selected cases of tumors with locally advanced or low volume metastatic disease, surgical resection may also be considered as well as the role for neoadjuvant therapy. For those on neoadjuvant imatinib therapy, imatinib can be stopped right before surgery and restarted as soon as the patient tolerates oral medications. For all other TKIs, therapy should be stopped at least 1 week before surgery and restarted based on clinical judgment or recovery from surgery.

General Technical Principles

Upon entry into the abdominal cavity, whether open or minimally invasive, special attention should be given to the peritoneum, omentum, and liver to assess for metastatic disease. Exophytic anterior and greater curvature gastric tumors are immediately apparent. Posterior gastric tumors require mobilization of the stomach, which is facilitated by retracting the left lobe of the liver to the right and entering the lesser sac through the greater omentum or gastrocolic ligament. Small intramural, intraluminal, or endophytic tumors that are difficult to identify externally can be localized by intraoperative endoscopy with a gastroscope. Duodenal tumors beyond the first portion require extensive Kocher maneuver and possibly mobilization of the ligament of Treitz. Ileal and jejunal tumors are identified best by carefully running the small bowel from the ligament of Treitz to the terminal ileum. After the primary tumor is identified, all tumor manipulation should be done with great care because these tumors are friable and can rupture, especially after neoadjuvant therapy. Tumor rupture, whether spontaneous or iatrogenic, is associated with almost inevitable peritoneal recurrence. GISTs commonly have large arterial and venous collateral blood vessels, and care must be given to avoid potential significant blood loss. Although GISTs typically displace and do not invade adjacent organs, any tissue surface that is densely adherent to the tumor should be at least partially resected en bloc.

Although gastric adenocarcinoma requires a formal anatomic gastrectomy with wide margins, resection of GIST does not require wide margins or lymphadenectomy because they do not typically spread via lymphatics. The goal of surgery is to resect the entire tumor with microscopically negative margins (R0 resection). However, data from 819 primary GISTs 3 cm or larger resected in the American College of Surgeons Oncology Group Z900 and Z9001 trials demonstrated no difference in the RFS in the 72 (8.8%) patients who had microscopically positive margins (R1 resection) on final pathology compared with those who underwent R0 resection, irrespective of imatinib treatment. Gross circumferential resection margins of 1 cm will ensure an R0 resection.

Minimally Invasive Approach

In several studies, a minimally invasive approach, including both laparoscopic and robotic approaches, for the resection of gastric GISTs has been demonstrated to be safe and efficacious with equivalent oncologic outcomes in terms of R0 resection, tumor rupture rates, and recurrence rates. In addition, a minimally invasive approach offers the advantage of decreased length of stay and low morbidity. However, operative times for robotic resection tended to be longer. During a minimally invasive approach, surrounding tissue should be grasped, and a no-touch technique should be employed. If excessive tumor manipulation cannot be avoided during a minimally invasive approach, conversion to an open approach should strongly be considered. In addition to careful manipulation of the tumor during a minimally invasive technique, retrieval of the specimen in a securely fashioned retrieval bag is essential to mitigating the risk of rupture and peritoneal dissemination. For large gastric tumors, a minimally invasive approach is not well described. In addition, there is currently little data comparing minimally invasive approaches to open approaches for nongastric GISTs. Ultimately, surgeon expertise and comfort level should guide the surgeon's decision on the approach to surgical resection of both gastric and nongastric GISTs.

Site-Specific Considerations

The surgical approach to GISTs varies greatly depending on the location of the tumor. Although many exophytic gastric tumors with a narrow stalk or those on the greater curvature or fundus of the stomach can be removed easily with a wedge partial gastrectomy using surgical staples without compromising the lumen, direct visualization facilitates safe resection while minimizing luminal narrowing in more difficult areas, such as the antrum, incisura, lesser curvature, or GEJ. A unique technique of tumor excision with a small negative margin (usually 1 cm) under direct visualization using cautery is useful for gastric GISTs (Fig. 3). Direct visualization and excision facilitate safe resection while preserving gastric capacity and minimizing luminal narrowing in these more difficult areas. GISTs involving the GEJ should attract attention for neoadjuvant imatinib for tumor downsizing before

resection. Although open surgery is preferred by most surgeons for tumors along the posterior aspect of the GEJ (Fig. 4), these tumors can be approached minimally invasively. Once open, a gastrotomy is performed to resect the tumor with a 1-cm margin, and a hand-sewn closure is performed in the direction providing the widest lumen (see Fig. 3). A bougie (usually 50Fr) should be placed in the esophagus during reconstruction to avoid narrowing the GEJ. Minimally invasive, an anterior gastrotomy is created to visualize the posterior tumor and excise the tumor with small negative margin under direct visualization. The posterior gastrotomy is closed in the direction providing the widest lumen. A bougie (usually 50Fr) is placed in the esophagus, and then the anterior gastrotomy is closed primarily. This minimally invasive approach to a GEJ GIST again requires surgeon experience and expertise to minimally invasive surgery. Tumor excisions from the lesser curvature of the stomach will require careful dissection to preserve vagal nerve integrity. When the vagal trunks cannot be preserved, pyloroplasty or pyloromyotomy should be performed.

Total gastrectomy or esophagogastrectomy is rarely necessary but may be required for sizable tumors involving a large area of the lesser gastric curvature or GEJ, respectively. Massive tumors may be adherent to the spleen, distal pancreas, or colon, necessitating en bloc resection. When recognized preoperatively, preference lies with neoadjuvant imatinib to accomplish tumor downsizing and devascularization before an attempt at organ-preserving resection.

The next most common site of GIST is the small bowel. Jejunal and ileal tumors can be removed easily with either open or minimally invasive techniques. If employing a minimally invasive technique, the small bowel anastomosis can be performed intracorporeally or extracorporeally using a wound protector. Management of duodenal GISTs is complicated because of the relationship with the pancreas and bile duct. Consideration for neoadjuvant imatinib should occur for any duodenal GIST when pancreatoduodenectomy is deemed necessary for complete resection. When the tumor is near the ampulla, a cholecystectomy can be performed to cannulate the cystic

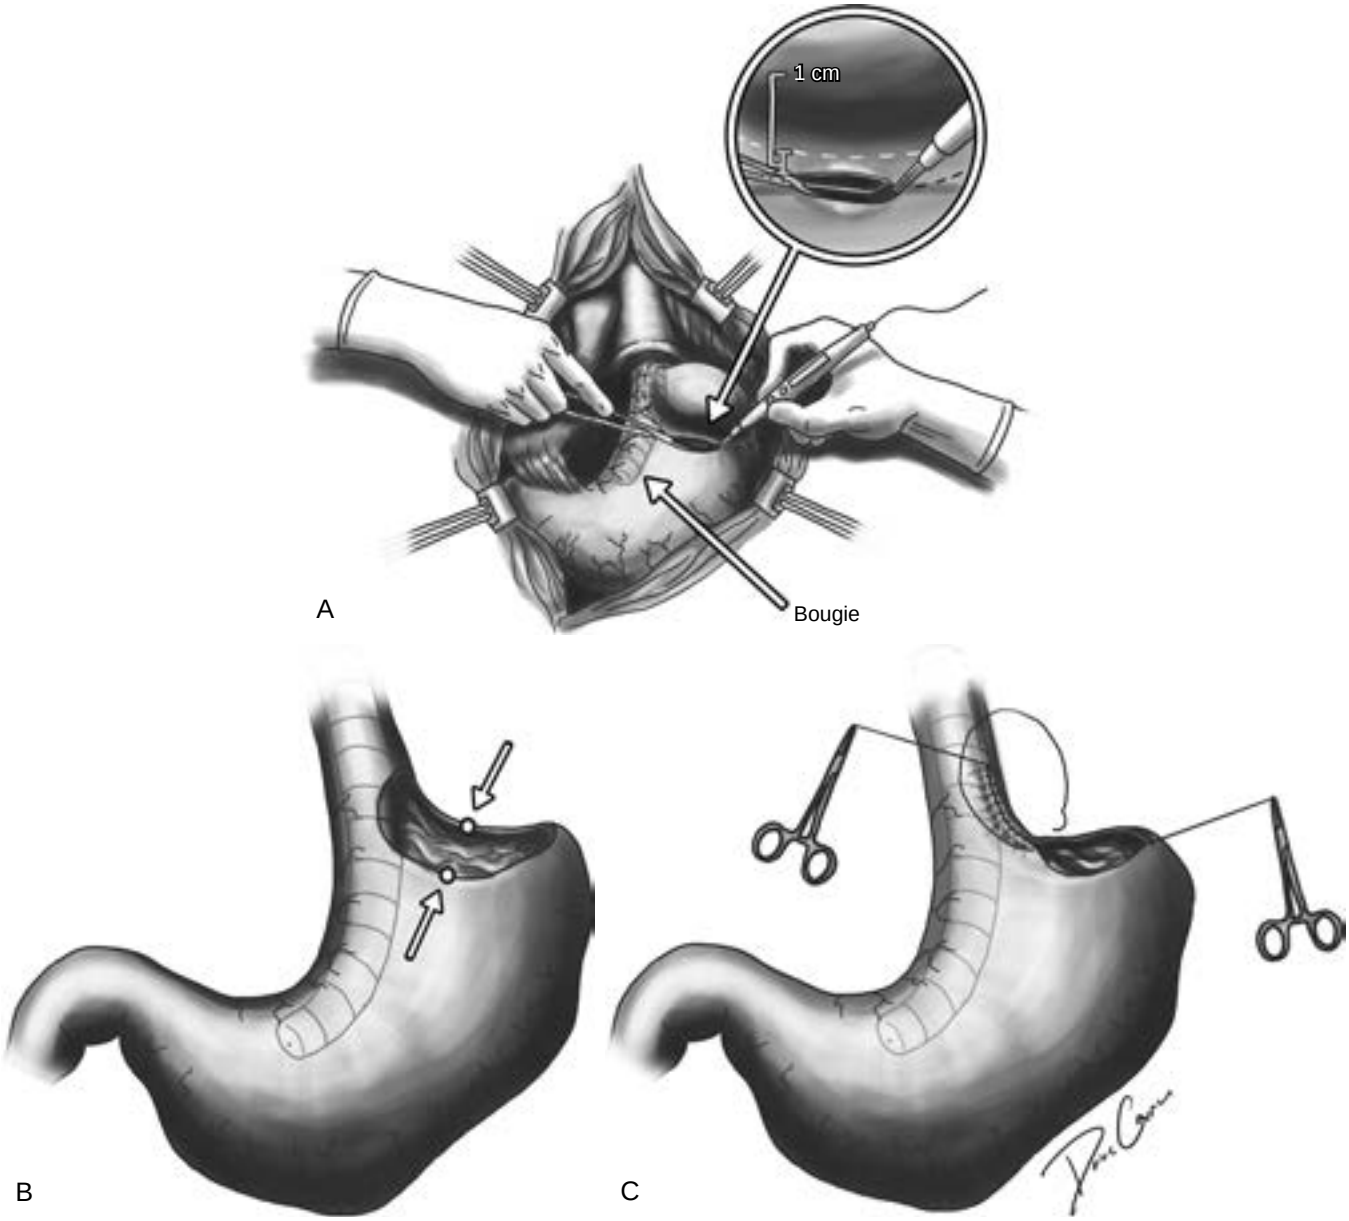

FIG. 3 Resection of a large gastrointestinal stromal tumor at the gastroesophageal junction. **(A)** After making a gastrostomy with cautery, the tumor is resected with a 1-cm margin. **(B)** The defect **(C)** is then sewn closed over a large bougie placed in the esophagus to prevent narrowing. *(Courtesy Dave Cavnar.)*

duct with a 4Fr Fogarty catheter and enter the duodenum through the ampulla, facilitating localization of the ampulla. Small GISTs not involving the periampullary duodenum can be resected without pancreatectomy. Periampullary GISTs involving the medial duodenal wall generally require pancreatoduodenectomy even after neoadjuvant imatinib. Small GISTs arising from the lateral wall of the second portion of duodenum can usually be excised. The duodenal defect can be closed with suture duodenorrhaphy without compromising luminal caliber. Alternatively, the duodenal defect can be reconstructed with a Roux-en-Y duodenojejunostomy. Tumors in the third or fourth portion of the duodenum can be managed with segmental duodenectomy followed by primary duodenojejunostomy.

Rectal GISTs are rare but are much more common than colonic GISTs. Neoadjuvant imatinib treatment should be offered to patients with large rectal GISTs to accomplish tumor downsizing and sphincter preservation. Small GISTs involving the lower rectum can be excised transanally with possible need for transanal endoscopic mucosal surgery.

ENDOSCOPIC MANAGEMENT OF GIST

Although endoscopic management of GIST has not been incorporated as standard of care into the NCCN guidelines at this time, a body of literature focused on the endoscopic management of GISTs exists. Currently, guidelines advocate for gastric GISTs under 2 cm with no concerning risk factors undergo active surveillance. However, GIST can still have malignant potential, initially leading to the development of endoscopic treatment strategies for small GISTs <2 cm. At present day, endoscopic management of upper gastrointestinal tract GIST has been described as feasible and safe for lesions <5 cm in size after exclusion of high-risk features, such as high mitotic rate, enlarged lymph nodes, irregular margins, internal heterogeneity, and presence of cystic spaces within the mass on EUS. These procedures include endoscopic band ligation (EBL), endoscopic submucosal excavation (ESE), endoscopic submucosal dissection (ESD), endoscopic mucosal dissection (EMD), endoscopic submucosal tunnel dissection (ESTD), submucosal tunneling endoscopic resection (STER), endoscopic full thickness resection (EFTR), laparoscopic endoscopic cooperative surgery (LECS), nonexposed endoscopic wall-inversion surgery (NEWS), and a combination of laparoscopic and endoscopic approaches to neoplasia with a nonexposed technique (CLEAN-NET). When considering endoscopic enucleation, GISTs must be classified into four types based on their location in the gastric wall (Fig. 5). Endoscopic enucleation, including EBL, ESD, EMD, ESTD, and STER, is most suitable for types 1 and 2. Types 3 and 4 are not amenable to endoscopic enucleation, and EFTR, LECS, NEWS, and CLEAN-NET should be considered.

NEOADJUVANT THERAPY

For nonmetastatic GISTs, neoadjuvant imatinib treatment should be considered for tumors that are locally advanced, require multivisceral resections, and are in difficult anatomic locations where tumor downsizing may allow for a less morbid operation. For those with D842V mutation of exon 18 of the *PDGFRα* gene, avapritinib therapy should be used due to imatinib resistance in these patients. Although change in metabolic activity is evident on PET/CT within days of imatinib exposure, objective tumor downsizing may take many weeks or even several months on imatinib treatment. In addition, responding tumors may even swell temporarily. Treatment response is more reliably assessed by comparing tumor density and dimensions, particularly when evaluating early tumor response (Fig. 6). After initiation of neoadjuvant imatinib, a follow-up contrast-enhanced CT should be obtained within 6 to 8 weeks. Surveillance imaging is typically obtained at 3-month intervals thereafter. Beyond 6 months of neoadjuvant imatinib therapy, further tumor downsizing is unlikely to be observed. Unlike most cytotoxic chemotherapy regimens used in a neoadjuvant setting, neoadjuvant imatinib can be continued up until the time of surgery without compromising wound healing or causing immunosuppression. Likewise, it may be resumed when the patient is eating normally and has regained bowel function. Avapritinib or other TKI should be stopped at least 1 week before surgery and restarted based on clinical judgment or recovery from surgery.

ADJUVANT THERAPY

The initial large-scale studies of imatinib in metastatic unresectable GIST were highly successful, resulting in a dramatic improvement in survival from a historical median of 18 months to beyond 5 years. However, demonstrating similar improvement in survival from adjuvant imatinib after complete surgical resection has proven more difficult. Randomized adjuvant trials designed with cross-over treatment arms have demonstrated that placebo-treated patients who develop recurrence are usually salvaged with imatinib therapy followed by surgery and survive for extended periods of time. The benefits of adjuvant imatinib were first demonstrated in the American College of Surgeons Oncology Group Z9001 study, which was a phase III multicenter prospective randomized clinical trial of imatinib compared with placebo for 1 year after resection of primary GISTs of at least 3 cm size regardless of mitotic index. The study was stopped early at interim analysis when the imatinib group was noted to have significantly improved RFS over the placebo group (98% vs. 83% at a median follow-up of 19.7 months), resulting in approval by US and European regulatory agencies for imatinib treatment in GIST. Long-term follow-up of these patients revealed that relapse occurred within 5 years after completing 1 year of prescribed imatinib (Fig. 7). After 74 months of follow-up, the RFS curves of the placebo and imatinib treatment arms converged, demonstrating that imatinib controlled but did not eradicate residual disease. Most of the improvement in RFS from imatinib was primarily observed in the patients with exon 11 deletion but not other mutations.

The follow-up SSG XVIII phase III randomized study compared the benefits of 1 year versus 3 years of adjuvant imatinib. This study demonstrated improved 5-year RFS (66% vs. 48%) with a slight improvement in overall survival (92% vs. 82%) for 3 years of adjuvant imatinib over 1 year of adjuvant imatinib. The PERSIST-5 (Pacritinib versus Best Available Therapy for the Treatment of Myelofibrosis Irrespective of Baseline Cytopenias-5) trial was a phase II single-arm study of 5 years of adjuvant imatinib after resection of primary GISTs at high risk for recurrence (any site ≥ 2 cm with ≥ 5 mitoses/50 HPF or any nongastric GIST ≥ 5 cm). Five years of imatinib treatment for this group of GIST patients was effective in preventing recurrence in those with sensitive *KIT* gene mutations.

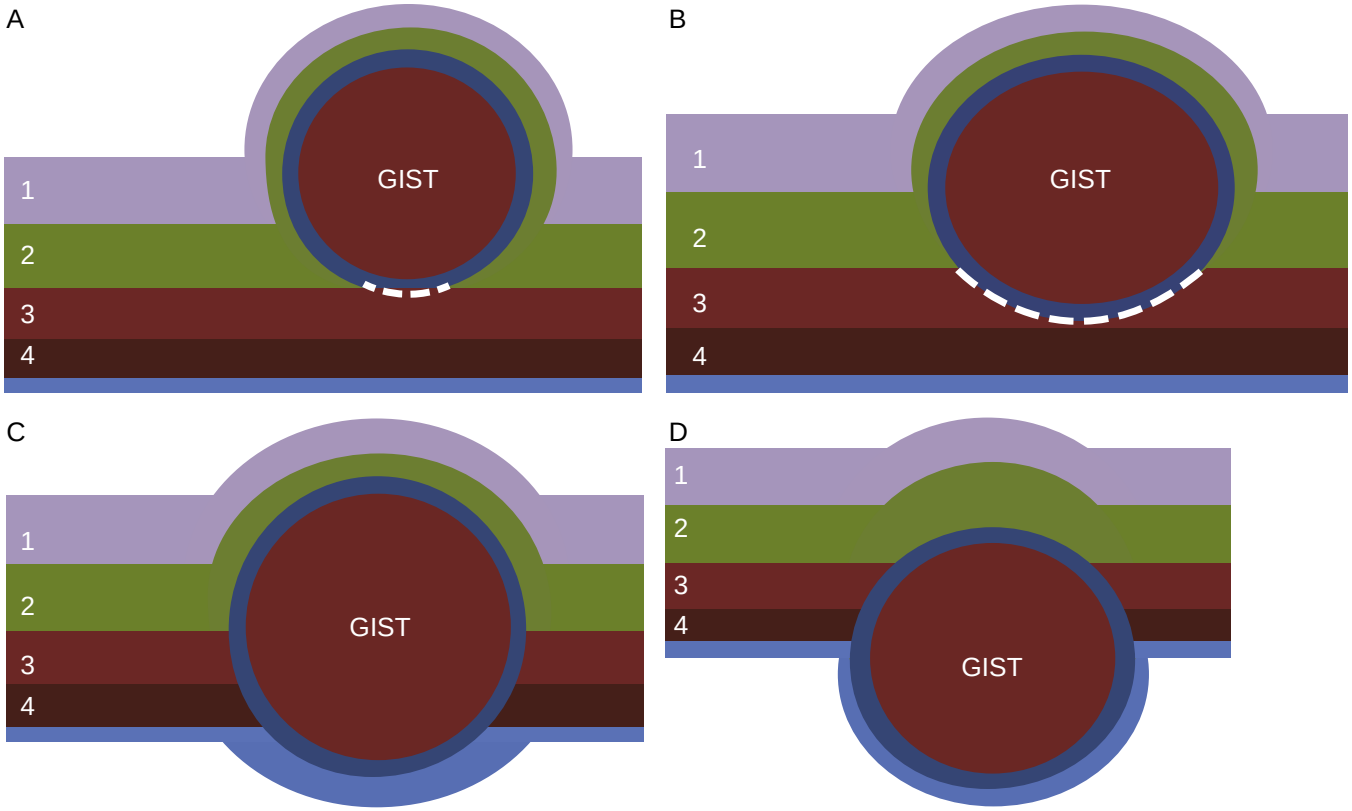

FIG. 5 Classification of gastrointestinal stromal tumor (GIST) according to the location in the gastric wall. **(A)** Type I is a GIST that has a very narrow connection with the proper muscle layer and protrudes into the luminal side like a polyp. **(B)** Type II has a wider connection with the proper muscle layer and protrudes into the luminal side at an obtuse angle. **(C)** Type III is located in the middle of the gastric wall. **(D)** Type IV protrudes mainly into the serosal side of the gastric wall. White dotted lines indicate the area dissected from the proper muscle layer. *1:* Mucosa; *2:* Submucosa; *3:* Circular layer of proper muscle; *4:* Longitudinal layer of proper muscle. *(From Kim HH. Endoscopic treatment for gastrointestinal stromal tumor: Advantages and hurdles. World J Gastrointest Endosc. 2015;7:192–205.)*

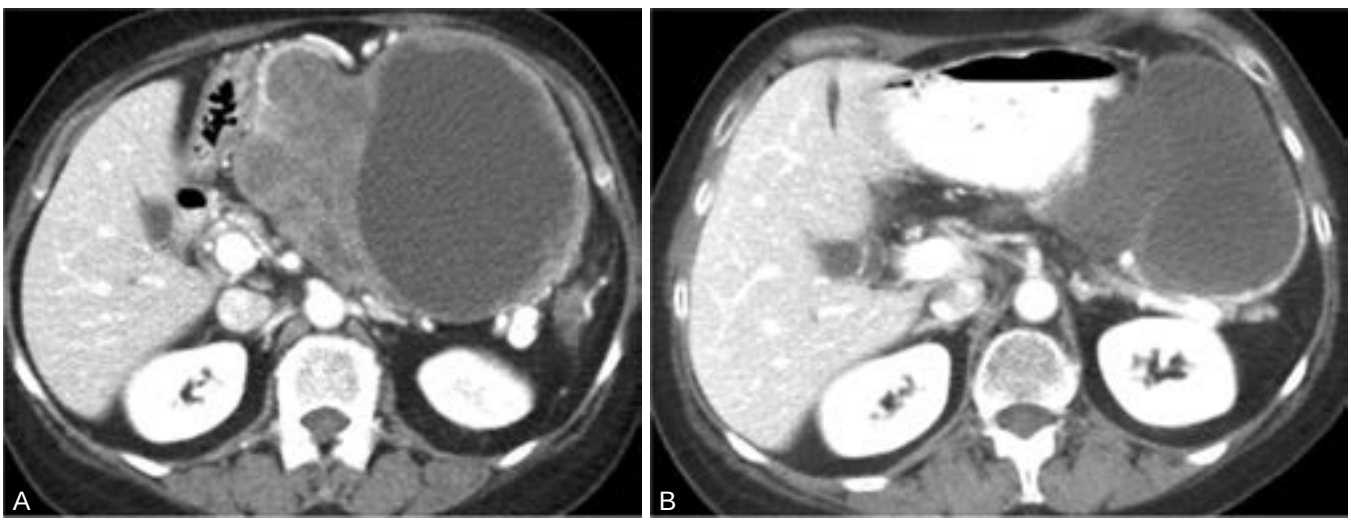

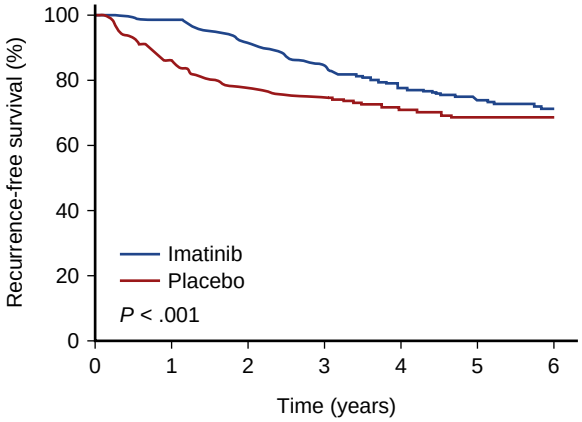

FIG. 6 Initial treatment response to neoadjuvant imatinib is best assessed by changes in tumor density. **(A)** A large gastric gastrointestinal stromal tumor at the time of diagnosis. **(B)** After treatment with 9 months of imatinib therapy, computed tomography scan demonstrated significantly decreased size with decreased density, demonstrating primarily cystic, necrotic tumor.

RECURRENT, METASTATIC, AND RESISTANT DISEASE

In patients with disease recurrence after primary resection without adjuvant therapy and those with metastatic disease, imatinib is highly effective with partial response or stable disease in the majority of patients. However, the median time to disease progression with imatinib therapy alone is on the order of 24 months, generally reflecting the development of secondary mutations in *KIT*, most commonly in exons 13, 14, or 17. Resistance to imatinib may be detected during radiographic surveillance with the appearance of enhancing nodules within a nonviable, necrotic, responding tumor (Fig. 8). These imatinib resistant tumors often demonstrate a partial response to second-line TKIs, with each further line of therapy providing sequentially diminishing returns. For example, second-line sunitinib improved PFS from 6 weeks to 27 weeks, whereas third-line regorafenib only improved PFS from 0.9 to 4.8 months. Of note, avapritinib should be used as first-line therapy for GISTs with the D842V mutation of exon 18 of the *PDGFRα* gene.

Patients with recurrent or metastatic GIST should be imaged on a 3-month basis. Operative resection can be considered when tumor resistance becomes apparent. Survival benefit from surgical therapy in these two situations is realized only in carefully selected patients with limited burdens of disease. Patients with partially responsive GISTs after TKI therapy will experience improved survival after surgery compared with patients who develop either rapid or multifocal tumor resistance patterns. Patients with multifocal sites of tumor resistance during TKI therapy should be referred for clinical trials.

Resection or ablation of hepatic GIST metastases should be planned to clear all detectable sites of tumor with attention to parenchymal preservation of the liver remnant. Resection of peritoneal GIST metastases may require removal of adjacent organs. After resection of hepatic or peritoneal metastases, adjuvant TKI therapy should be continued indefinitely or until tumor recurrence develops.

FIG. 8 Development of resistant tumor subclone growing on imatinib therapy within necrotic tumor in the setting of responding hepatic and peritoneal metastases.

CONCLUSION

GIST is a relatively rare sarcoma arising throughout the GI tract, most commonly in the stomach or small intestine, with activating mutations in the *KIT* or *PDGFRα* genes. GIST is a heterogeneous disease process that may present as a clinically irrelevant microtumor or a rapidly progressive malignancy with widespread metastatic disease. Surgery for GIST requires a no-touch technique to avoid tumor rupture and spillage. Tumor locations along the alimentary tract dictate the specific aspect of surgical therapy that will provide complete tumor clearance. Operative resection of larger tumors and tumors located at difficult anatomic locations, such as the GEJ, rectum, or duodenum, may be facilitated by neoadjuvant imatinib therapy. Risk for tumor recurrence is independently predicted by tumor size, mitotic rate, and site of disease. Specific mutations of KIT help to predict responsiveness to TKI therapy. Adjuvant imatinib should be used for at least 3 years in patients at high risk for disease recurrence predicted by individualized nomograms. Resection of recurrent or metastatic GIST should be considered for patients with limited burden of disease who are responding to TKI therapy or demonstrate only focal tumor resistance. An algorithm for multimodality therapy of GIST is shown in Figure 9.

Gastrointestinal Tubes for Feeding and Decompression

Lawrence B. Brown, MD, MPH, MHS, and Susan L. Gearhart, MD

INTRODUCTION

The primary purposes for placement of upper gastrointestinal access tubes are gastric decompression, prevention of aspiration, and administration of medications or nutrition. Over the past decade, the importance of gastrointestinal access in the management of several conditions has been redefined. This chapter highlights the current indications and contraindications to the use of gastrointestinal access and outlines current knowledge regarding their safe placement and usage.

NASOGASTRIC TUBE

A nasogastric (NG) tube is a flexible tube with a single or double lumen that is passed through the nose, down the nasopharynx, and into the stomach. NG tubes are made of polyurethane, polyvinyl chloride (PVC), or silicone. They come in several sizes and vary based on patient size (pediatric or adult). The most common type of NG tube is the Salem-sump, and its primary function is gastrointestinal decompression (Fig. 1). This tube has two lumens; the larger lumen connects to wall suction to provide aspiration of gastric contents. When not connected to suction, this port can be used for medication delivery or enteral feeding. The smaller lumen is used to vent to the atmosphere to prevent the distal tip of the tube from adhering to the stomach wall. This equalization takes place in the stomach once the gastric contents have been emptied.

Unlike the Salem-sump tube, the Levin tube (Fig. 2) has a single lumen with multiple distal holes. Its advantage lies in its relatively large single internal diameter. However, because of its inability to vent, there is a high likelihood that without venting, the suction would cause the mucosa of the stomach to adhere to the tube, leading not only to poor decompression but also to potential mucosal ischemia. Because of this likelihood, the Levin tube is uncommonly used in practice. Finally, a tri-lumen long tube with the ability to intubate into the mid-jejunum has been described and found to have a reduced failure rate for conservative management of an acute small bowel obstruction (ASBO) in one study. However, the long tube can only be placed endoscopically and for this reason is rarely used.

FIG. 1 Salem-sump tube. In addition to a suction lumen for decompression, this tube has a second lumen that allows venting during continuous suction. Insertion depth markers are placed on the tube *(black dots)*.

FIG. 2 The Levin tube has a single lumen and multiple distal holes.

Indications for Nasogastric Tube Placement

Indications for NG tube decompression include management of acute gastrointestinal obstruction, management of prolonged ileus with vomiting, and prevention or treatment of intestinal perforation (Table 1). The successful removal of gastrointestinal contents decreases emesis and the chance of possible aspiration pneumonia. The NG tube is essential in the nonoperative management of an ASBO and is generally placed early in the treatment algorithm. In consensus statements regarding the management of ASBO, most societies agree that

TABLE 1 Indications and Types of Commonly Used Gastrointestinal Tubes

Indications	Type of Tube
Acute intestinal obstruction	NG tube, long enteric tube
Prolonged ileus with vomiting	NG tube
Decompression during minimally invasive surgery	NG tube, Levin tube
Long-term nutritional supplementation, medication delivery, decompression using gastric access	PEG
Long-term nutritional supplementation without gastric access	DPEJ

DPEJ, Direct percutaneous endoscopic jejunostomy; *NG,* nasogastric *PEG*, percutaneous endoscopic gastrostomy.

NG tube decompression is effective for up to 72 hours, after which the risks outweigh the benefits. Routine use of an NG tube for prevention of postoperative ileus in no longer recommended in adult or pediatric patients. In addition, a recent Cochrane review suggests that NG tube placement for postoperative ileus is associated with a slower return to bowel function and higher likelihood of pulmonary complications. The review found that use of an NG tube was only beneficial in patients who were experiencing vomiting.

During both minimally invasive and open abdominal surgery, an NG tube is often placed postintubation to decompress the stomach for safe port placement and to prevent emesis/aspiration caused by increased gastric distention following positive pressure/bag-mask-valve ventilation. The risk of gastric injury during port placement for minimally invasive surgery is reportedly 7%, although these data are from a study performed before the development of newer access ports with more safety features. Esophageal and gastric trauma is managed with NG tube decompression until healing of the injury is confirmed. For patients unable to swallow, an NG tube may be placed to administer medications or oral contrast for a computed tomography (CT) scan.

Contraindications

NG tube placement is contraindicated in patients with basilar skull fracture or facial fractures because of the risk of intracranial penetration and misplacement. Additionally, their blind placement should be avoided in patients with esophageal stricture or a history of alkali ingestion because of the risk of esophageal perforation. Because of the increased risk of bleeding, esophageal varices and coagulation abnormalities are relative contraindications to NG tube placement.

Placement of Nasogastric Tubes

NG tubes are often placed at the bedside in an awake patient, and the benefits and risks should be discussed. The head of the bed is raised so the patient is upright. An absorbent pad or emesis basin is placed on the patient's lap in case vomiting is induced by the procedure. The insertion distance should be estimated by measuring the distance between the tip of the nose to the earlobe and then to the xiphoid; 15 cm should be added to this number and noted on the tubing. One should visualize the nares for obstruction and ask the patient to sniff while occluding one nostril to determine the most patent nostril for placement. To reduce gagging and discomfort with insertion, the nares, nasopharynx, and oropharynx are anesthetized before NG tube placement. Typically, this is performed with lidocaine gels, Cetacaine (a combination of tetracaine, butyl aminobenzoate, and benzocaine), or nebulized or atomized lidocaine. Additionally, some

have administered antinausea medications before NG placement to reduce nausea and gagging. Gentle pressure should be applied if mild resistance is encountered in the posterior nasopharynx. Asking the patient to sip water through a straw will take advantage of the swallowing mechanism to facilitate the passage of the tube into the stomach. Additionally, flexing the patient's neck once the tube is in the nasopharynx aids in allowing it to traverse into the esophagus rather than the trachea. If too much resistance or bleeding is met upon initial passage into the nasopharynx, then one should attempt passage down the other naris. Gagging is a common occurrence during NG tube placement and should not be an indication to halt the procedure. However, excessive choking, coughing, voice changes, or condensation within the NG tube indicates tracheal placement, and the tube should be removed.

NG tube placement in patients who are incapacitated as a result of cognitive disorders or sedation and in patients on a ventilator can be challenging and is reportedly only successful 50% of the time. Airway protection is of primary importance, and securing the airway before NG tube placement may be required. Once secured, NG tube passage can be assisted with the use of a laryngoscope or a nasopharyngeal airway. One randomized study demonstrated that placement of a right nasopharyngeal airway in intubated patients increased first-time success rates to 80%. Furthermore, icing a PVC or silicone tube increases its stiffness, which may prevent coiling and assist in placement.

The NG tube should be secured with a commercial adhesive holder applied to the nose. Guidelines exist for proper securing and repeat assessment of the NG tube fixation method. For long-term insertion, bridling of the NG tube is a method that has been shown to significantly decrease inadvertent removal and pressure injury. NG tube bridle kits are available and assist in the safe passage of a bridle loop through the posterior nasopharynx from one nostril to the other.

Confirmation of Nasogastric Tube Placement

Before using an NG tube, one should confirm placement. Bedside confirmation can be accomplished by auscultation over the stomach for a rushing noise while one insufflates the stomach with air through the NG tube. Unfortunately, this method is unreliable. Literature also describes confirmation with ultrasound, litmus paper testing, pH paper testing, capnography/colorimetric capnometry, manometric techniques, and electromagnetic tracing; however, these tests are impractical. The goal standard method for confirming NG tube placement is performing a lower-chest/upper-abdominal x-ray. Based on imaging, the NG tube should be advanced or retracted so it is properly positioned in the middle of the stomach for best function. NG tube placement should be reassessed every 4 hours and before using for administration of medications or feeding.

Complications

The most common complication from NG tube placement is aspiration pneumonia. This may result from insertion of the NG tube directly into the airway during insertion or from occlusion of the tube during use, allowing for reflux and aspiration of gastric contents. Pressure injuries to the nares from prolonged NG tube insertion are most common among ICU patients, and the reported incidence is 0.13/1000 patient days. Gastric mucosa trauma has been shown to be reduced if continuous low-pressure wall suction is utilized compared with intermittent suction.

FEEDING TUBES

Current literature demonstrates that enteral nutrition is superior to parenteral nutrition. Indications for nutritional support are as follows: critical illness, poor caloric intake, oropharyngeal dysfunction, neurologic disorders, acute and chronic pancreatitis, short bowel syndrome, serious trauma and burns, and malnutrition before elective major surgery. Enteral feeding tubes are classified by the location of the tip of the tube, with termination in the stomach, proximal intestine, or both. Post-pyloric feeding has been shown to prevent aspiration of feeds and is largely recommended. Patients with diseases or who have had procedures associated with gastric atony (Box 1) may require enteral feeds that are beyond the ligament of Treitz. ICU patients have been found to have abnormal small bowel motility leading to retroperistalsis and increasing the risk of aspiration when fed directly into the stomach.

Nasoenteric Tubes

Nasoenteric tubes (NETs) are best suited for short-term (<6 weeks) use for nutritional assistance. NETs can be placed unassisted at the bedside or with endoscopic or fluoroscopic guidance. NETs are made of silicone or polyurethane and are commonly 12 or 14F in diameter (Fig. 3). If performed at the bedside, informed consent should be obtained before insertion. Like NG tube placement, the NET should be measured from the patient's nose to the xiphoid process. After lubrication, the NET should be inserted to the distance previously measured to the xiphoid process. Once secured, one should obtain a chest x-ray to confirm placement in the esophagus. If confirmed, the tube should be advanced slowly to 75 cm. Placing the patient and right lateral decubitus and insufflating the stomach can assist with tube advancement. If the stylet moves freely (slides back and forth by 5–10 cm), the tube is likely not coiled in the stomach, and the NET can be advanced to its furthest point (approximately 110 cm). NETs may also be placed via endoscopic means into the small intestine. Once an endoscope has traversed through the stomach into the small bowel, a guidewire is advanced through the accessory channel. The endoscope is then removed while the guidewire remains in place. The NET is placed over this guidewire. One should obtain an abdominal x-ray while the patient is lying in the supine position to confirm placement. Once post-pyloric placement is confirmed, the stylet or guidewire is removed, and the tube is used for enteral feeding.

Percutaneous Endoscopic Gastrostomy or Jejunostomy Tubes

Percutaneous endoscopic gastrostomy or jejunostomy (PEG or PEG/J) tubes are widely used for enteral nutrition. Common indications for PEG placement include disease processes that interfere with normal oral intake and swallowing, such as severe neurologic impairment, facial trauma, and oropharyngeal tumors. Jejunostomy tubes are required if the stomach is absent or nonfunctioning as a result of gastroparesis or tumor. Patients who are unable to maintain sufficient nutritional intake for more than 1 month, despite a functioning gastrointestinal tract, are candidates for a feeding tube placement.

Placement of PEG, PEG/J, or direct percutaneous endoscopic jejunostomy (DPEJ) tubes can be performed endoscopically (PEG, PEG/J, DPEJ), radiographically (PEG), and surgically (PEG, jejunostomy). For

the purpose of this chapter, the endoscopic technique will be discussed as surgical placement usually occurs when the patient is going to the operating room for a separate procedure. On occasion, laparoscopy is used to guide placement when endoscopic placement alone is challenging; however, the technique does not differ greatly as endoscopic insertion techniques are used while laparoscopy is performed. Laparoscopic or endoscopic jejunostomy is rarely performed as there is a significant risk for tube leakage and failure. There are three main techniques: (1) Sachs-Vine push technique, (2) Ponsky pull technique, and (3) Russell external dilation. Antibiotics should be given before the procedure.

Contraindications to feeding tube placement are esophageal or oropharyngeal obstruction (i.e., unable to perform endoscopy), aspiration risk, gastric varices, severe coagulopathy, massive ascites, gastroparesis, gastric outlet obstruction, gastric resection, and hemodynamic instability.

Endoscopic Placement Technique

Once sedated, the left upper quadrant and mid-abdomen are prepped and draped in a sterile fashion. An endoscope is passed into the patient's mouth, down the esophagus, and into the stomach. For a jejunostomy, the endoscope must be passed to the jejunum. After inspection of the gastrointestinal tract, the antrum of the stomach or a dilated loop of proximal jejunum will be viewed through the endoscope. A double-balloon endoscopic technique may assist in performing DPEJ. An antiperistaltic medication can be given to reduce peristalsis of the small bowel. Transillumination must occur. The surgeon will use a finger to indent the external abdominal wall to determine the optimal puncture site where the abdominal wall and the stomach or jejunum are closest; this should be noted via the endoscope. If transillumination is possible, an introducer or seeker needle with a syringe attached is passed through the abdominal wall. This syringe is advanced until the needle tip is seen entering the gastric or jejunal lumen on endoscopic views. Upon aspiration, if air is seen and the needle tip is not visualized, then the needle is likely in another section of the gastrointestinal tract and not the stomach. Once correct intraluminal location has been confirmed, a guidewire is placed into the lumen and grasped by a snare via the endoscope. The needle is removed from the skin once the wire has been grasped. For PEG tube insertion using the pull technique, the endoscope is removed over the guidewire. The wire is then attached to the gastrostomy tube, and a small skin incision is made around the wire in the abdominal wall. The gastrostomy tube is then pulled through the mouth, into the stomach, and out of the incision created in the abdominal wall. The dilation technique and push technique are used for jejunostomy placement. A smaller jejunal tube can also be passed through one port of the PEG tube and endoscopically placed in the jejunum. However, one randomized trial suggested that the DPEJ tube as compared to the PEG/J clogged less due to the larger caliber.

It is important to note that the internal bolster of the feeding tube should contact the mucosa, and the external bolster (or crossbar) should be placed snugly against the abdominal wall. Endoscopic and radiologically placed tubes have a soft cupped bolster internally and a second bolster that is placed over the tube near the abdominal wall. This design allows for the internal bolster to deform and the tube to be removed by applying traction on the tube when necessary. It also avoids common issues such as inadvertent deflation of the balloon, which can happen with balloon-tipped gastrostomy tubes (Fig. 4). Immediately after placement, the tube can be placed to gravity drainage. After 4 to 6 hours, the tube can be used for medication delivery. Historically, enteral feeds start 12 to 24 hours following the procedure.

Routine Care

Routine care involves three considerations: positioning of the external bolster to avoid compression of the abdominal wall between the bolsters, flushing the tube to prevent clogging, and maintaining a clean feeding tube site. Compression of the tissues between the internal and external bolsters of a feeding tube can lead to pressure necrosis, breakdown of the gastrostomy tract, and buried bumper syndrome (where the internal bumper migrates alongside the tract of the stoma and lodges between the intestinal wall and the skin). The external bolster should be situated in such a manner as to allow 1 to 2 cm of in-and-out movement of the tube in the abdominal wall. Additionally, gauze pads

FIG. 4 Gastrostomy tube with balloon.

should not be placed underneath the feeding tube as this may allow for pressure on the tract. During daily care, the feeding tube should be pushed forward into the wound slightly and rotated to ensure that the internal bumper does not become buried in the mucosa.

Feeding tubes tend to clog as a result of the interaction of protein-based formulas with an acidic environment and medications. Tubes with a smaller diameter clog more frequently, and all feeding tubes should be flushed with 20 mL of water every 4 to 6 hours and after administration of medications or enteral feeds. If the tube becomes clogged, and water flushing does not open the tube, the installation of pancreatic enzymes is efficacious in relieving more than 50% of occluded tubes. Mechanical devices, such as a Fogarty balloon, biopsy brush, or commercially available tube decloggers, may be used if prior measures fail. Tube replacement is reserved as a last resort to tube clogging. Bulking agents (e.g., psyllium) and resins (e.g., cholestyramine) should not be placed through feeding tubes as they are prone to clogging.

Complications

Immediate complications of enteral access include aspiration, hemorrhage, perforation, and the risk of sedation/anesthesia. Aspiration risks can be minimized by avoiding excessive sedation, aspiration of gastric contents preprocedure, suctioning insufflated air from the stomach postprocedure, and reducing the procedure time. A particularly morbid complication is inadvertent perforation of the stomach, small bowel, or colon during percutaneous insertion leading to peritonitis. This harm may be reduced by maximizing endoscopic transillumination and using discrete finger palpation on the abdominal wall to identify a safe entry site. In addition, laparoscopic assistance can be used. Delayed complications of feeding tube insertion include peristomal leakage or irritation, site infection, intraabdominal leakage, herniation of omentum, jejunal volvulus, gastric ulceration or hemorrhage, fistulous tracts, inadvertent tube removal, fungal tube infection, "buried bumper syndrome," and tumor tract seeding.

Tube Deterioration and Replacement

Deterioration of the feeding tube is a common problem that is recognized by the presence of discoloration, irregular beading of the tube, and foul odor. Though deterioration presents no direct risk to the patient, a leak or break in the tube would disallow tube feeding. Replacement tubes have a balloon at the distal tip. These should only be placed in the tract once the site has matured (approximately 4 weeks). A Foley catheter may serve as a temporary replacement tube, particularly in situations in which a tube has been inadvertently removed and a replacement tube is unavailable.

Gastrostomy or Jejunostomy Tube Removal

Methods for removing a feeding tube vary by the type of tube (i.e., removal with traction on the tube, removal after deflating a balloon at the distal tip, and tubes that required endoscopic visualization before removal). One should know the type of tube and how it was placed before an attempt to remove a tube. Endoscopic and radiologically placed tubes have a soft cupped bolster within the lumen. This design allows for the tube's internal bolster to deform and the tube to be removed by applying traction on the tube when necessary. Endoscopic visualization should be performed if the type of tube cannot be confirmed with the patient's medical record. Once removed, the feeding tube site should be covered with a dressing until the tract closes. Generally, the tract closes within 24 to 72 hours following removal.

Management of Morbid Obesity

Michael A. Schweitzer, MD, and Vivek Kumbhari, MD

The prevalence of morbid obesity has continued to increase in the United States and throughout the world. The Centers for Disease Control and Prevention (CDC) estimates that 42.4% of US adults are classified as obese with a body mass index (BMI) greater than 30 kg/m^2, with more than 9.2% being severely obese (BMI >40 kg/m^2). Bariatric surgery continues to be the only durable method to obtain sustained weight loss and improvement of obesity-related medical disease for most patients. New flexible endoscopic (intragastric balloon [IGB], endoscopic sleeve gastroplasty [ESG]) and pharmaceutical therapies (e.g., GLP-1 analogs) have recently shown better weight loss than any previous medical therapy; however, there is a lack of long-term follow-up studies.

Weight loss surgery first came into prominence in the 1970s, but early procedures were abandoned largely because of unacceptable complications and poor long-term results. In the late 1990s, weight loss surgery saw a resurgence, largely because of the development of improved bariatric procedures and application of minimally invasive surgical techniques. Currently, more than 250,000 bariatric procedures are performed in the United States annually. Over the last decade, numerous well-designed clinical trials have demonstrated the safety, efficacy, and durability of weight loss surgery. The most common bariatric operations performed in the United States include vertical sleeve gastrectomy, Roux-en-Y gastric bypass, and duodenal switch with biliopancreatic diversion. The American Society of Metabolic and Bariatric Surgery (ASMBS) estimates that laparoscopic adjustable gastric band represents less than 1% of bariatric surgeries in the United States in 2019. Weight loss surgery also has been demonstrated to have significant metabolic and neurohormonal effects (independent of restriction and malabsorption), which play an important role in the long-term success of these procedures.

PATIENT SELECTION

The National Institutes of Health issued a consensus statement in 1991 regarding the effectiveness of bariatric surgery and outlined patient selection criteria that are still being used today by most insurers. Patients are considered candidates for bariatric surgery if they have a BMI of 40 kg/m^2 or greater or a BMI between 35 and 40 kg/m^2 if an obesity-related comorbidity such as diabetes or hypertension is present. The ASMBS position statement on class one obesity (30–35 kg/m^2) patients with obesity-related comorbidities states, "bariatric surgery should be considered after a patient fails nonsurgical treatment methods and should be strongly considered for patients with type 2 diabetes." An alternative to bariatric surgery for patients with a BMI of 30 to 40 kg/m^2 could be IGB or ESG. These flexible endoscopic therapies are especially worthy of consideration in patients who have a contraindication to bariatric surgery (e.g., hostile abdomen, large incisional ventral hernia, etc.) or are simply unwilling to undergo bariatric surgery despite being aware of its effectiveness. In general, appropriate candidates for surgery should demonstrate prior attempts at nonsurgical weight loss options that may include dietary intervention, pharmacologic therapy, or behavioral modification. Patients should also have realistic expectations regarding the long-term outcomes achieved with surgery (Box 1). Relative contraindications include inability to comply with postoperative requirements, active alcohol or substance abuse, and uncontrolled psychiatric disease.

The evaluation of potential patients for bariatric surgery should involve a multidisciplinary team approach. This team should include a dietician and a mental health professional familiar with bariatric surgery. Their purpose is to obtain a complete past dietary and behavioral eating history, educate the patient on postoperative dietary expectations, examine social support structure, and ensure that any psychiatric or behavioral disorders are optimally controlled. At the Johns Hopkins Center for Bariatric Surgery, all patients are asked to attend an online preoperative education seminar. Participation in postoperative support group meetings also is encouraged.

The age limits for surgery have expanded considerably over the last two decades. Select centers now offer surgery to adolescent patients and to patients over the age of 70 years, with overall good results.

OPERATIVE PROCEDURES

Most bariatric surgical procedures are performed laparoscopically, or robot-assisted, with a hospital length of stay of 1 day or less. Staged operations may be used in select cases for high BMI patients where a laparoscopic sleeve gastrectomy is performed first followed by a Roux-en-Y gastric bypass or duodenal switch with biliopancreatic diversion at a later time, usually over a year out, if further weight loss is desired. An alternative approach for patients with a relatively lower BMI could be to commence with a flexible endoscopic approach and then proceed to bariatric surgery, though data on this are limited.

BOX 1 Indications for Bariatric Surgery for Morbid Obesity

1. BMI of 40 kg/m^2 or greater
2. BMI 35 to 39 kg/m^2 with significant obesity-related comorbidities (diabetes, hypertension)
3. BMI 30 to 35 kg/m^2 and obesity-related comorbidities who have failed nonsurgical treatments
4. Clearance by a dietitian and mental health professional
5. No medical contraindications to surgery

On the morning of surgery, all patients should receive appropriate antibiotics as well as subcutaneous unfractionated or low-molecular-weight heparin to help minimize venous thromboembolic complications. Laparoscopic surgery involves the use of reverse Trendelenburg position, and the patient must be placed appropriately on the operating room table with use of a footboard and arms and legs secured. Initial laparoscopic entry in a morbidly obese patient can be difficult. We have found that the safest way to enter the peritoneal cavity is in the left upper quadrant with direct vision, while using a device that allows visualization of the abdominal wall layers during entry with a zero-degree laparoscope. Alternatively, we may use a Veress needle, placed in the left upper quadrant, to insufflate the peritoneal cavity and then place our midline optical trocar first, followed by the remaining trocars under direct view with the laparoscope inside the peritoneal cavity.

Laparoscopic Roux-en-Y Gastric Bypass

Roux-en-Y gastric bypass (Fig. 1) is the second most common bariatric procedure performed in the United States (~20% of all bariatric surgery cases). Numerous articles have shown that gastric bypass results in durable long-term weight loss and remission of metabolic disease with a reasonably low complication rate.

A 45-degree angled laparoscope is inserted into the peritoneal cavity through the midline trocar, and the operation is performed using a total of five laparoscopic trocars. The omentum and transverse colon are retracted cephalad until the ligament of Treitz is visualized. The jejunum is then transected approximately 40 to 75 cm distal to the ligament of Treitz with a 60-mm white stapler cartridge. The mesentery is then divided with a gray stapler cartridge or ultrasonic shears. The proximal biliopancreatic limb of jejunum is then anastomosed to the distal segment of jejunum 75 to 100 cm distal from the point of division. We perform this anastomosis in a side-to-side fashion using a white 60-mm-length laparoscopic stapler cartridge. The common enterotomy is then closed with a white 60-mm-length laparoscopic stapler cartridge. The resulting mesenteric defect is closed with a running suture to help minimize the risk of internal hernia.

Next the patient is placed in reverse Trendelenburg position, and the gastric pouch is created. The left lateral segment of the liver is retracted using a Nathanson retractor (Cook Medical, Bloomington, IN) through a subxiphoid 4-mm puncture and is held in position with a movable arm that attaches to the bed. We next dissect the peritoneal attachments at the angle of His to expose the left crus, which is then followed by opening the bare area of the gastrohepatic ligament with the ultrasonic shears to enter the lesser sac. Division of the neurovascular bundle on the lesser-curve side of the stomach just distal to the left gastric artery and vein is accomplished using a gray vascular cartridge or ultrasonic shears. Multiple 60-mm blue staple cartridges are then used to transect the stomach up to the angle of His, creating a vertically oriented, 20-mL proximal gastric pouch. A 40 French bougie can be placed down into the stomach along the

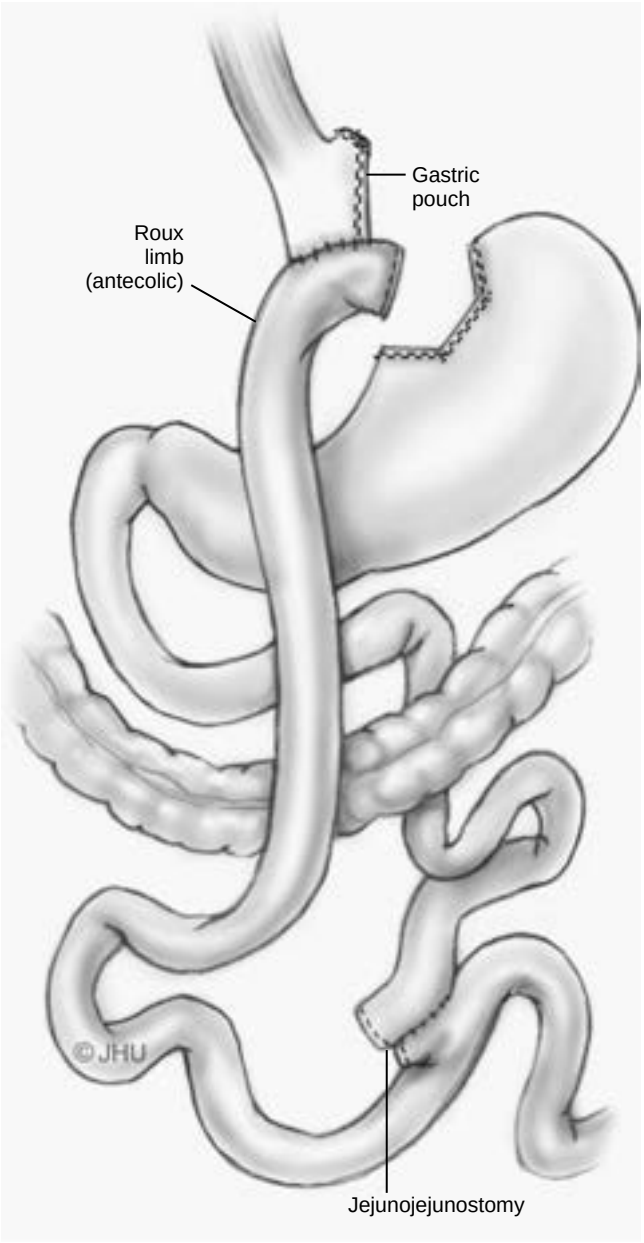

FIG. 1 Antecolic-antegastric Roux-en-Y gastric bypass. *(Courtesy Corinne Sandone, Johns Hopkins University.)*

lesser curve after the first firing of the stapler to assist in transecting the stomach where the bougie is used as a guide to the angle of His. The 40 French bougie is then removed. Any bleeding from the staple lines is controlled with clips or suture ligation.

We routinely bring the Roux limb up to the gastric pouch in an antecolic-antegastric orientation. This seems to reduce the incidence of internal hernias, gives excellent exposure, and is simpler to perform than a retrocolic retrogastric approach. The side of the Roux limb is sutured to the gastric pouch staple line. A small enterotomy is made just proximal to the end of the Roux limb, and a similarly sized gastrotomy is made in the gastric pouch for the placement of the stapler. The stapler is loaded with a 60-mm blue cartridge to create the gastrojejunostomy, using only the first 40 mm of the staple cartridge. After the stapler is fired, a stay suture is placed on the lesser curve (right) side of the opening. A 32F, blunt, round-end bougie then is passed from the mouth and through the gastrojejunal anastomosis and into the Roux limb. The bougie can then be seen through the opening that was formed after the stapler was removed. This stay suture and the stay suture on the left (angle of His side) are used to elevate the tissue so that the 60-mm length blue load cartridge can be used to close the opening. The stapler is brought down on top of the bougie while the tissue to be transected is retracted and then fired. The gastrojejunostomy is completed by running a 2-0 absorbable suture as a second layer. The resultant anastomosis is approximately 12 mm in diameter. A leak test may be performed if the surgeon desires by clamping the Roux limb just distal to the anastomosis and insufflating air (via endoscope or orogastric tube), whereas the gastric pouch and anastomosis are submerged in saline. The mesenteric defect then is closed between the Roux limb mesentery and the transverse mesocolon, up to the transverse colon.

Laparoscopic Vertical Sleeve Gastrectomy

Laparoscopic vertical sleeve gastrectomy (LVSG) (Fig. 2) is currently the most performed weight loss operation in the United States (~60% of all bariatric surgery cases).

The LVSG is primarily restrictive, as the lateral aspect of the stomach is removed to create a sleevelike tube or reservoir. The gastric resection also may assist with weight loss by causing hormonally assisted satiety. The fundus produces the proappetite hormone ghrelin, and because the fundus is removed, these hormone levels are reduced after LVSG. Although this bariatric procedure is not reversible, it can be converted into a Roux-en-Y gastric bypass or duodenal switch if greater weight loss is desired. It may also need to be revised to a Roux-en-Y gastric bypass if postop complications were to occur, for example, gastric stricture or severe gastroesophageal reflux disease.

The VSG typically is performed with one 5-mm, two 12-mm, and one 15-mm trocar. With the liver retracted with the Nathanson, the short gastric vessels are divided along the greater curve of the stomach. A LigaSure device (Covidien, Norwalk, CT) typically is used to accomplish this. A 40F blunt-tip bougie is placed in the

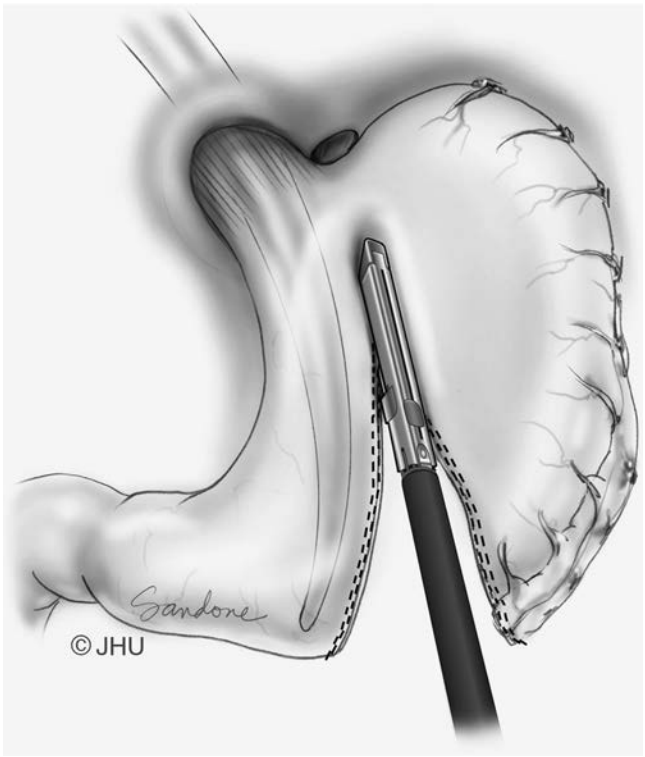

FIG. 2 Creation of the gastric sleeve. *(Courtesy Corinne Sandone, Johns Hopkins University.)*

stomach and directed along the lesser curve. The stomach is divided at the greater curvature, beginning 4 to 6 cm proximal to the pylorus. Green and blue staple loads are used adjacent to the 40Fr bougie and extending to the angle of His. When stapling, it is important to avoid stapling too close to the incisura angularis of the stomach since this may lead to a gastric stricture. The staple line can be oversewn or an absorbable buttress material can be used with the clips to assist with hemostasis of the gastric staple line.

The partial gastrectomy specimen is removed through the 15-mm trocar site. Care should be taken to suture close the fascial opening of this enlarged trocar site to prevent postoperative herniation. As with Roux-en-Y gastric bypass, a limited upper gastrointestinal study is performed only if clinically indicated.

Laparoscopic Duodenal Switch with Biliopancreatic Diversion

The laparoscopic duodenal switch with biliopancreatic diversion (DS-BPD) is primarily a malabsorptive operation that involves preservation of the pylorus and creation of a short, 100-cm ileal "common channel" (Fig. 3). The DS-BPD is the least common bariatric procedure performed because of its surgical complexity, potential for severe malabsorptive nutritional deficiencies, and possible diarrhea.

This procedure can be performed in a single operation or in two stages if the patient has a high BMI (>70). The first stage is similar to a VSG operation with the creation of a gastric sleeve. After approximately 1 to 2 years, patients can be revised to DS-BPD and the malabsorptive second stage performed. This is performed by dividing the small bowel 250 cm from the ileocecal valve. The proximal end of bowel then is anastomosed to the distal ileum 100 cm from the cecum.

The patient is placed in steep reverse Trendelenburg position, and the liver is retracted. If the sleeve gastrectomy portion has not been performed previously, then partial gastrectomy proceeds as previously described. The duodenum is then divided approximately 3 cm distal to the pylorus with a blue Endo GIA 60-mm stapler.

The Roux limb is directed in an antecolic fashion, and a side-to side anastomosis is performed with the first part of the duodenum. Finally, the mesenteric defect is then closed between the Roux limb mesentery and the transverse mesocolon.

Laparoscopic Single Anastomosis Duodenal Switch

The laparoscopic single anastomosis duodenal switch (Fig. 4), also referred to as loop duodenal switch or single-anastomosis duodenoileal bypass with sleeve gastrectomy (SADI-S), was recently approved by the American Society of Metabolic and Bariatric Surgeons (ASMBS). When compared with duodenal switch with biliopancreatic diversion, SADI-S is easier to perform with possibly a lower rate of internal herniation than DS-BPD. However, it does not divert the biliopancreatic fluid since there is no Roux limb but instead there is a loop anastomosis that, if there is a leak, may potentially be more difficult to treat since biliopancreatic fluid is flowing through where the small bowel is anastomosed with the duodenum. Controversy exists with the size of the bougie for creating the sleeve

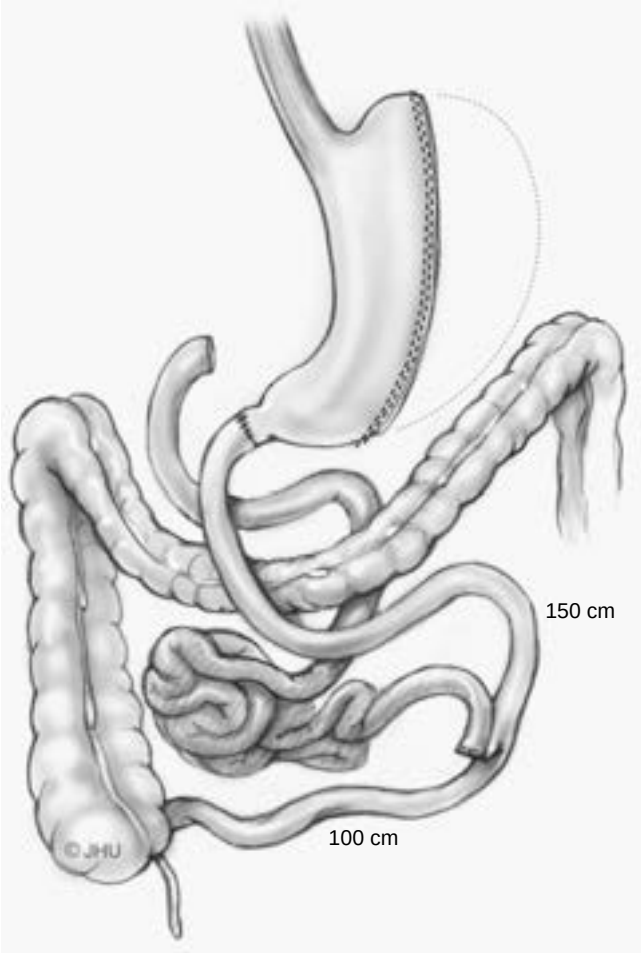

FIG. 3 Antecolic duodenal switch with biliopancreatic diversion. *(Courtesy Corinne Sandone, Johns Hopkins University.)*

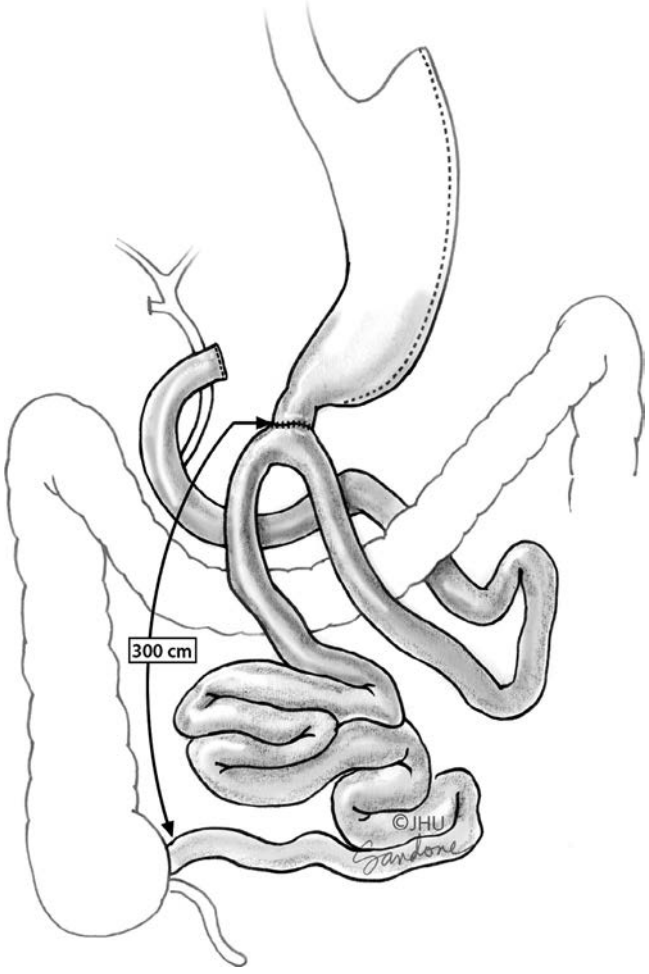

FIG. 4 Laparoscopic single anastomosis duodenoileal bypass with sleeve gastrectomy (SADI-S). *(Courtesy Corinne Sandone, Johns Hopkins University.)*

gastrectomy and length of the efferent or absorptive limb. Bougie size has decreased down to a size of 40 French by many surgeons, and the absorptive channel has increased from 200 to 300 cm to decrease protein and vitamin deficiencies while maintaining excellent weight loss. Diarrhea can be troublesome after DS-BPD and SADI-S, but by increasing the length of the absorptive channel, this may become less of a problem for most patients.

The sleeve gastrectomy is performed as previously described. The dissection is then continued a few centimeters past the pylorus where the duodenum is divided with the endoscopic linear stapler. The omentum is then divided with the energy device at a point where the path of the small bowel is unobstructed as it travels to be anastomosed to the first part of the duodenum.

The surgeon then measures the absorptive limb by starting at the ileocecal valve and walking back the bowel 300 cm. This point on the bowel is then carefully brought up to the duodenum and stay sutures are then placed while making sure there is no twisting nor tension present before creating the anastomosis.

The anastomosis may be formed using a stapler technique, in which an endoscopic stapler is used to join the small bowel to the duodenum and then the common enterotomy opening is closed with either a suture or another stapler firing, taking care not to make the open channel too tight. The anastomosis can also be formed by using handsewn two-layer suturing technique.

It is recommended to place a stitch from the afferent limb, just before the anastomosis, to the gastric antrum to prevent an obstruction from the limb rotating. The mesenteric defect between the small bowel mesentery and transverse colon mesentery can be sutured closed to prevent possible internal herniation, but in the SADI-S operation this is still controversial when it is discussed, with many surgeons finding that it is unnecessary. Hopefully, future analysis of long-term outcomes data will help resolve the need for this step.

Intragastric Balloon

IGBs are gas- or fluid-filled devices that are deployed in the stomach for a period of 6 to 12 months. As a result of being a temporary implant, they require two endoscopic procedures (one for insertion and another for removal of the IGB). Though initially appealing to patients, IGBs have been plagued by poor tolerability and concerns regarding safety. Furthermore, as a result of the device needing to be removed, weight regain is somewhat expected. The mechanism of action is unclear with theories ranging from that of effective volume reduction due to space occupation to alterations in gastric emptying; some believe there are even neurohormonal benefits. Notably, regardless of the IGB type, weight loss seems to taper at 3 months, and this appears to be the result of an accommodation phenomenon. Therefore, newer space-occupying devices attempt to circumnavigate this by being adjustable. There is even a capsule that is taken twice a day before meals that dissolves, releasing hundreds of hydrogel beads that result in temporary space occupation.

Endoscopic Sleeve Gastroplasty

ESG was first reported in 2013 and, since then, has disseminated globally, being performed by gastroenterologists and surgeons alike. It attempts to recapitulate laparoscopic greater curvature plication through an over-the-scope attachment of the OverStitch (Apollo Endosurgery, Austin, TX) and 2-0 nonabsorbable monofilament sutures. A running suture pattern is performed using a tissue helix such that plications are made to the distal gastric fundus (a small residual fundal pouch is inevitable). The procedure is performed on an outpatient basis with 5 to 9 running full-thickness sutures being placed with a total procedure duration of 1 hour. The current technique results in a stomach with decreased gastric volume and reduced compliance. Published data demonstrate outcomes that it is more effective than even high intensity diet and lifestyle program, but it is less effective than laparoscopic sleeve gastrectomy. ESG has been used not only as a primary weight loss therapy but in patients who have had weight regain and dilation of the stomach after surgical sleeve gastrectomy.

ENHANCED RECOVERY AFTER SURGERY

We implemented an Enhanced Recovery After Surgery (ERAS) program for bariatric surgery at our center in 2017 and published a decrease in length of stay from 2.77 days to 1.77 days (P <0.001) with a reduced 30-day readmission rate from 7.94% to 2.86% (P = 0.011). On the day of surgery, patients have a scopolamine patch placed if there is no contraindication. During the operation, opioids are minimized, acetaminophen 1000 mg IV is given, no Foley is placed, and no drains are used for routine bariatric surgery operations. Dexamethasone 4 to 8 mg IV is given after induction, and postoperatively, we give our sleeve gastrectomy patients a second dose of dexamethasone IV 8 hours after leaving the operating room. Ondansetron is used intraoperatively and postoperatively to prevent nausea as well as treat it. Metoclopramide is used if ondansetron is not enough to treat a patient's postoperative nausea complaints. Patients are instructed to walk soon after surgery. Clear liquids are started that evening and increased the following morning, with discharge on postoperative day number one. Oral acetaminophen is used for pain control as well as oral narcotics for breakthrough pain, but it is stressed to the patient to try and avoid narcotics if possible. IV narcotics are discouraged and avoided if possible. The patient is discharged once they are drinking enough to maintain hydration at home.

OUTCOMES AND COMPLICATIONS

After any of the bariatric procedures, patients are seen in follow-up at 2 weeks to ensure that they are well-hydrated, tolerating oral intake, and without wound complications. They are then seen at 3, 6, 12, 18, and 24 months and then annually thereafter to follow weight loss and nutritional issues. For patients who undergo flexible endoscopic techniques, more rigorous surveillance in the first 24 months is necessary as there is a greater propensity for weight regain. Regardless of the procedural technique, patients are encouraged to meet with dieticians and remain with their support groups indefinitely.

For 1 month after surgery, patients are all maintained on a high-protein puree consistency diet; after that they gradually are advanced to solid food. They also receive multivitamins, calcium, and vitamin B_{12} supplements. This is especially important for patients with gastric bypass and DS-BPD who are at higher risk for malabsorption and possible malnutrition. Supplemental iron should be considered for menstruating women.

Weight loss after gastric bypass and DS-BPD occurs primarily in the first 12 to 18 months after surgery and averages approximately 70% and 80% excess weight loss (EWL), respectively. Sleeve gastrectomy patients typically have less EWL, on average 50% to 60% over a 2-year period.

One of the most important outcome measures after bariatric surgery is remission of obesity-related metabolic diseases, such as type 2 diabetes. More than 70% to 80% of patients with diabetes experience complete remission after undergoing gastric bypass or DS-BPD. The restrictive operations have a 50% remission rate of diabetes. Hypertension, sleep apnea, hyperlipidemia, and fatty liver disease have similar remission rates after surgery. Flexible endoscopic approaches confer less weight loss than their surgical counterparts and do not appear to induce the weight-independent metabolic benefits seen with bariatric surgery.

Overall complication rates after bariatric surgery are less than 15% in most reports. Like most surgeries, there are early and late complications for bariatric surgery. Early or perioperative complications include bleeding, anastomotic leakage, and deep venous thrombosis. The mortality rate is less than 0.5% and is usually attributable to a pulmonary embolus or sepsis from anastomotic leak. Persistent

unexplained tachycardia higher than 120 beats/min may be an early sign of sepsis, and an appropriate workup should be considered.

Vitamin B_{12}, calcium, iron, vitamin D, and protein deficiencies are long-term complications that can occur within the first year after surgery. Rigorous monitoring of nutrition status is necessary. Vitamin B_1 deficiency also can occur in patients with protracted vomiting after surgery, and they may experience extremity paresthesias, confusion, and nystagmus. Lower extremity weakness and paresthesias also can be seen with vitamin B_{12} deficiency. Anastomotic stenosis and obstruction at the gastrojejunostomy in the first few months after surgery occur in less than 5% of patients after gastric bypass and usually can be managed with endoscopic dilation.

Internal hernias are also a possible complication and can occur at any time after surgery. The symptoms of internal hernia can be similar to an acute bowel obstruction or become chronic and described as postprandial periumbilical cramping pain. If internal hernia is suspected, operative intervention may be required to avoid possible bowel ischemia.

In general, the results of weight loss surgery are excellent, with most patients losing more than 50% of their excess weight with dramatic improvement or remission of metabolic disease. Approximately 10% to 15% of patients either do not achieve significant weight loss or partially regain their weight after 2 to 3 years. Ideally, these patients respond to dietary counseling, although some may need operative revision or conversion to a more malabsorptive procedure, such as the DS-BPD.

Unfortunately, no perfect method exists for choosing the best operation for each individual patient. Certainly, a multidisciplinary team approach is helpful in providing patient support throughout the preoperative and postoperative course. Reducing obesity-related diseases should be the major goal, not merely cosmetic improvement. Patients must understand that bariatric procedures are a tool to assist with weight loss, and it must be combined with lifelong changes in dietary, exercise, and lifestyle habits.

Management of Small Bowel Obstruction

Charudutt Paranjape, MD, and George Velmahos, MD

INTRODUCTION

Small bowel obstruction (SBO) accounts for 2% to 4% of emergency department (ED) visits for abdominal pain and accounts for as many as 16% of surgical admissions and more than 300,000 operations annually in the United States. The associated cost is over $2 billion in inpatient costs annually. Although some obstructions occur in the large intestine, close to 80% of bowel obstructions occur in the small intestine. Unfortunately, patients may experience a high complication rate including strangulation. The overall mortality rate associated with SBO is less than 3%, but the rates escalate to 7% to 14% in the elderly.

CAUSES

Postoperative adhesions account for 75% to 80% of all cases of SBO. Adhesive small bowel obstruction (ASBO) represents a common entity among emergency surgical diseases, accounting for 4.6% for all types of operations. Among patients operated on for prior ASBO, the incidence of operative intervention increases to 15.6%. Other causes of SBO include congenital anatomic abnormalities (e.g., midgut volvulus, ileal atresia, de novo adhesions), disorders of the bowel wall (e.g., intussusception, stricture, tumor), extrinsic compression (e.g., compression from mass), intraluminal disorders (e.g., meconium ileus, gallstones, foreign body, bezoar), strangulated hernias (most common cause of SBO in undeveloped countries), foreign bodies (e.g., bezoars, swallowed objects, gallstones), radiation, endometriosis, and infection (a common cause in undeveloped countries, such as tuberculosis). In the absence of previous intraabdominal surgery, abdominal wall hernia with small bowel incarceration is the most common cause of bowel obstruction. Older patients with suspected SBO but no prior abdominal surgery and the absence of a hernia on examination should be evaluated for malignancy.

CLINICAL PRESENTATION

The diagnosis of SBO is not always straightforward, as many patients have variable symptoms at onset, and some cases may initially be misdiagnosed. Patients may describe nausea and vomiting, intermittent abdominal pain, abdominal distension, hyperactive bowel sounds, and inability to keep food and fluids down. Symptoms may then progress to continuous pain, hypoactive bowel sounds, and worsening vomiting. However, these signs and symptoms are not specific for diagnosis, and patients with SBO may continue to pass stool and flatus. Specific historical elements that should be discerned include previous bowel obstructions and their management, abdominal operations, radiation, and other abdominal disorders (e.g., inflammatory bowel disease [IBD], neoplasm).

The physical examination should begin with evaluating for systemic toxicity necessitating resuscitation, followed by abdominal examination and evaluation for the presence of any hernia causing the obstruction. Peritonitis, localized tenderness, hypotension, or tachycardia suggest strangulation and bowel ischemia. Fever, leukocytosis, decreased urine output, altered mental status, and metabolic acidosis are also concerning for systemic toxicity and bowel ischemia. Persistent pain that continues to worsen or pain out of proportion to examination is suggestive of ischemia or closed-loop obstruction and should be evaluated without delay. Palpation of the abdomen of patients with SBO is critical and a learned art. Significant pain to light percussion, focal tap tenderness, and guarding are potential signs of peritonitis and merit close attention and possible surgical exploration. Rectal examination is mandatory because it can identify fecal impaction, rectal masses, blood, or the rare obturator hernia, all of which would critically alter management.

DIAGNOSIS

Although the history and physical examination can guide the clinician toward a diagnosis of SBO, they are not sufficiently sensitive or specific for the diagnosis of SBO and its potential complications; thus, imaging has become essential for a diagnosis.

Laboratory Testing

There are no laboratory tests that are sensitive or specific for the diagnosis of SBO or that can reliably predict ischemic bowel. Recommended tests in patients with abdominal pain, nausea, and vomiting include a basic metabolic panel with magnesium and phosphate, a complete blood count with differential, and if bowel ischemia is suspected, a lactic acid level. A basic metabolic panel can identify electrolyte imbalances and renal dysfunction caused by hypovolemia. Patients with SBO may have hypokalemia, contraction alkalosis, or metabolic acidosis. A CBC (with differential) can assess leukocytosis. Leukocytosis with a left shift is a nonspecific indicator of inflammation and/or infection; it does not correlate with disease severity. An elevated lactic acid level can be seen with bowel ischemia, but notably, a normal lactate level does not rule it out. An elevated lactic acid level can also be a nonspecific indicator of inadequate perfusion of any number of organs.

Imaging

Plain Radiography

Plain radiographs may have a role in the initial diagnostic evaluation because of their widespread availability, low cost, and ability to follow

disease progression serially; however, the sensitivity of plain films is 66% to 85%. In addition, over 20% of abdominal radiographs in patients with SBO are nonspecific or normal. The typical gas pattern for SBO on plain film demonstrates dilated gas- or fluid-filled loops of small bowel in the setting of a gasless or nondistended colon (Fig. 1). However, a patient with SBO may demonstrate more subtle findings on x-ray study, and a plain film can simply show air-fluid levels with a normal or slightly distended colon. Small bowel perforation may be diagnosed with upright radiography, although not with an optimal level of accuracy. The severity of SBO can be underestimated on abdominal radiography if the dilated bowel loops are predominantly fluid-filled. If a strong suspicion for SBO is present, other testing is recommended as a negative radiograph cannot exclude the diagnosis.

Computed Tomography

CT is the imaging modality of choice and currently considered the standard of care for imaging SBO in most cases. Per the Eastern Association for the Surgery of Trauma (EAST) guidelines, level 1 evidence recommends the use of CT for diagnosing SBO. Intravenous contrast is desirable in the absence of contraindications. Although oral contrast may not be used in the initial CT scan as it causes delays and possible aspiration, Gastrografin may be given in partial adhesive SBO at a later point to expedite resolution of the obstruction. CT identifies the site of obstruction (transition point between distended and collapsed bowel) with a 93% sensitivity and 67% specificity and can detect bowel ischemia or closed-loop obstruction. Findings concerning for bowel wall compromise include bowel wall edema or hemorrhage, altered bowel wall enhancement, interloop ascites, mesenteric edema/fat stranding, vascular engorgement, and/or vessel occlusion. As in abdominal radiographs, pneumatosis of the bowel wall, mesenteric and/or portal venous gas, and extraluminal free air are late signs of bowel wall compromise and indicate bowel wall necrosis in the setting of SBO. Despite the sensitivity of CT in detecting direct and indirect signs of bowel compromise, it cannot be used alone for the decision to operate. Such a decision is always based on a combination of clinical, laboratory, and imaging findings.

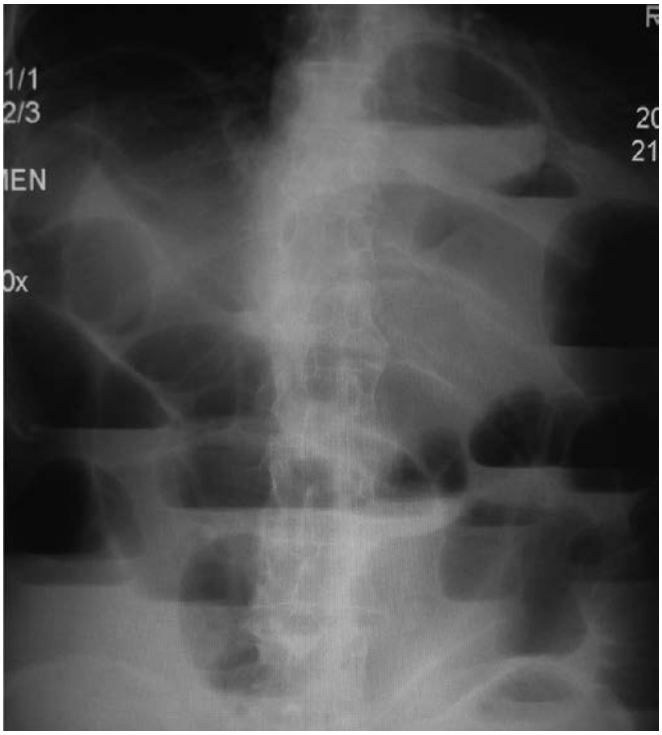

FIG. 1 Plain x-ray of the abdomen showing many distended small bowel loops caused by a distal obstruction.

Magnetic Resonance Imaging

Advantages of MRI over CT include lack of ionizing radiation, improved soft tissue contrast, the ability to provide dynamic information regarding bowel distention and motility, and relatively safe intravenous contrast agents. MRI possesses high sensitivity and specificity for diagnosis. MRI possesses limitations, including limited availability, long scan times, high cost, variability in examination quality, and lower spatial and temporal resolution compared with CT. At this time, except for pregnant women and children, CT is preferred over MRI.

CLASSIFICATION

The aforementioned diagnostic process will allow the patient to be categorized into one of three groups (Fig. 2).

Partial Small Bowel Obstruction

Patients with partial small bowel obstruction (pSBO) have incomplete obstruction with luminal narrowing, but some contents continue to pass through the intestine. Clinically, this is recognized when patients exhibit the signs, symptoms, and radiographic findings consistent with SBO, but exhibit a benign abdominal examination and continue to pass bowel movements and flatus.

Complete Small Bowel Obstruction

These patients have obstruction with no passage of luminal contents beyond the point of obstruction. Clinically, this is recognized when patients exhibit the signs, symptoms, and radiographic findings consistent with SBO and are not passing bowel movements or flatus.

Complete Small Bowel Obstruction with Bowel Compromise

The bowel is considered compromised when there is ischemia or injury that has led or may lead to necrosis and/or perforation of the bowel wall. There is a high risk of morbidity and mortality if compromised bowel is not treated in an expedient manner. Signs, symptoms, and imaging findings of bowel compromise are shown in Table 1.

MANAGEMENT

The initial goal of evaluating a patient with SBO is to immediately identify hemodynamic instability, the presence of strangulation or bowel ischemia, and the need for urgent operative intervention. These decisions should be made concurrently with resuscitation. Patients with SBO should be provided intravenous fluid resuscitation and electrolyte replacement, symptomatic control with antiemetics and analgesics, and bowel rest by nil per os. Decompression via nasogastric tube (NGT) is necessary in most but not all cases. Early evaluation by a surgical service is desirable.

Nonoperative Management

Expectant therapy and symptomatic management are typically recommended for patients without peritonitis or hemodynamic instability, with high success rates.

The use of NGT decompression is based on old and often debated evidence. Supposedly, proximal decompression facilitates relief of the obstruction, but the pain and discomfort to the patient is not negligible. The exact population that can be managed safely without it has not been accurately determined, although it exists.

Patients with partial adhesive SBO without strangulation are good candidates for water-soluble contrast medium such as Gastrografin

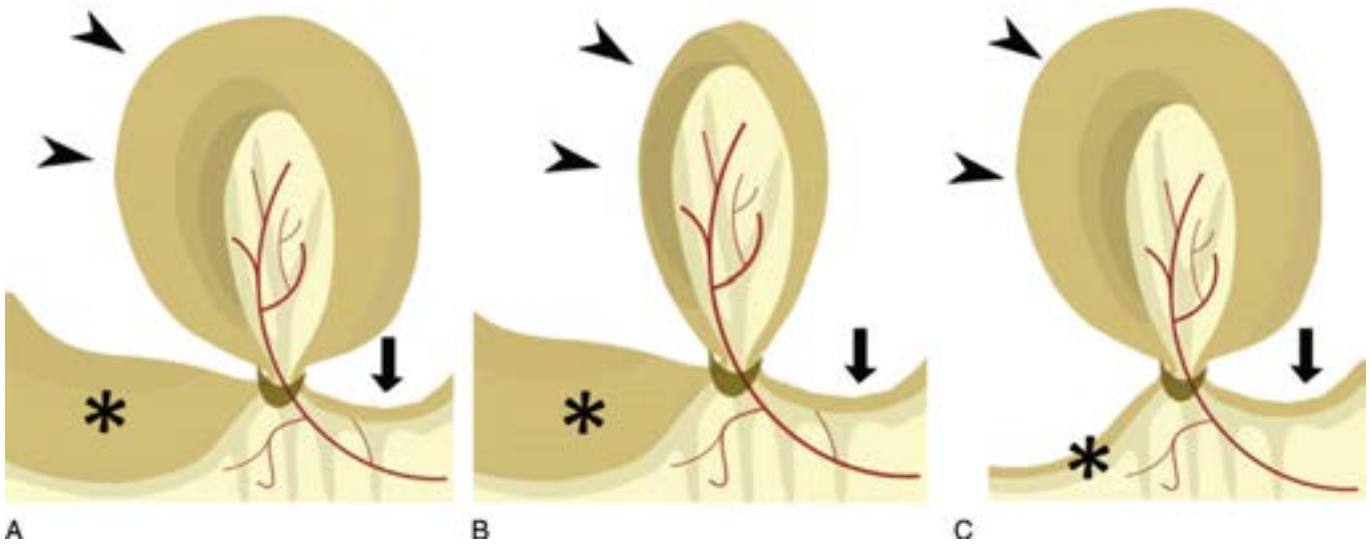

FIG. 2 Diagram of the three CT patterns of closed-loop small bowel obstruction, which is defined as obstruction of the bowel lumen at two sites located next to each other, creating a closed loop. **(A)** In typical closed-loop obstruction, the afferent loop *(asterisk)* and closed loop *(arrowheads)* are dilated and the efferent loop *(arrow)* is collapsed. **(B)** In collapsed closed-loop obstruction, the closed loop *(arrowheads)* is collapsed, the afferent loop *(asterisk)* is dilated, and the efferent loop *(arrow)* is collapsed. **(C)** In flat-belly closed-loop obstruction, the closed loop is dilated *(arrowheads)* and the afferent *(asterisk)* and efferent *(arrow)* loops are collapsed. *(From Rondenet C, Millet I, Corno, L., et al. CT diagnosis of closed loop bowel obstruction mechanism is not sufficient to indicate emergent surgery. Eur Radiol. 2020;30:1105–1112.)*

TABLE 1 Findings Consistent with Small Bowel Compromise

Clinical Presentation of SBO	Concerning Radiographic Signs
• Severe abdominal pain • Fever • Hypotension • Tachypnea • Tachycardia • Mental status changes • Peritoneal signs (guarding on examination, rebound tenderness) • Nonreducible hernia with severe pain and overlying skin changes (erythema and/or dark discoloration) • Decreased urine output • Leukocytosis • Elevated lactate	**Abdominal x-ray or CT abdomen/pelvis:** • Pneumatosis, mesenteric and/or portal venous gas, and extraluminal free intraperitoneal air are late signs and indicate bowel necrosis in the setting of SBO. **Other signs:** • Bowel wall edema or hemorrhage • Altered bowel wall enhancement (decreased, absent, or delayed hyperenhancement) • Interloop ascites • Mesenteric edema/fat stranding, ascites, vascular engorgement or occlusion • Multiple transition zones: Closed-loop obstruction demonstrates radial small bowel arrangement with a U- or C-shaped configuration, converging at the site of obstruction. • Swirling of mesenteric vessels (also known as the *swirl sign* or *whirl sign*) may indicate volvulus and/or closed-loop obstruction.

SBO, Small bowel obstruction.

for both diagnostic and therapeutic purposes. Gastrografin is administered orally or most commonly by NG tube in doses of 100 mL in 50 mL of water, either immediately at admission, or if conservative therapy with decompression fails, after 48 hours. After administration, Gastrografin appearing in the colon within 24 hours on x-ray study predicts resolution without surgical intervention. The radiograph can be repeated every 8 to 12 hours as long as the patient's examination, symptoms, laboratory tests, and vital signs improve or remain stable. Literature suggests that this intervention is safe and can reduce the need for surgery, SBO time to resolution, and hospital stay. Nonoperative techniques can be utilized for 2 to 3 days, but if the patient demonstrates no improvement or no passage of Gastrografin into the colon, operative therapy should be strongly considered.

Operative Management

Patients with signs of strangulation or generalized peritonitis, evidence of clinical deterioration (continuous or worsening pain, fever, hypotension, tachycardia, metabolic acidosis), or concern for bowel compromise based on imaging should undergo surgical exploration (level 1 recommendation per EAST guidelines). Nearly all other patients can be offered a trial of nonoperative management. Close monitoring during nonoperative management allows identification of patients with worsening symptoms who should be explored. A greater point of debate presents the time of surgery for those who have a benign abdominal examination but remain with a persistent obstruction. From the old dictum of "never let the sun rise or set on a small bowel obstruction," we now accept that nonoperative treatment can continue for days. The likelihood for spontaneous resolution

TABLE 2 Eastern Association for the Surgery of Trauma Practice Management Guideline for Managing SBO

Management	Recommendation Level
Patients with generalized peritonitis or other evidence of clinical deterioration (fever, leukocytosis, tachycardia, acidosis, continuous pain) should undergo timely surgical exploration.	1
Patients with no evidence of clinical deterioration can safely undergo nonoperative management initially.	1
CT findings consistent with bowel ischemia require a low threshold for operative intervention.	2
Laparoscopic treatment of SBO is a viable option compared with laparotomy in selected cases.	2
Water-soluble contrast should be considered for patients with partial SBO that has not resolved in 48 hours.	2

SBO, Small bowel obstruction.

decreases after the third day, and a number of studies suggest that the likelihood of complications increases. However, the evidence is poor and controversial. The EAST guidelines for general operative management are shown in Table 2.

Laparoscopic Management

Historically, abdominal exploration through laparotomy was the standard treatment for SBO, but laparoscopy has been used with a higher frequency over recent years. In a systematic review and meta-analysis of 14 nonrandomized studies, laparoscopic adhesiolysis reduced the risk of morbidity, in-hospital mortality, and surgical infections. Predictors for successful laparoscopic treatment of SBO are the following: a history of ≤2 laparotomies, appendectomy as the sole previous operation and cause of the obstruction, no previous median laparotomy incision, and a single adhesive band.

SBO WITH CONFOUNDING CONDITIONS

Closed-Loop SBO

Patients with closed-loop SBO are at increased risk for both strangulation and failure of nonoperative treatment (Fig. 3). The threshold for surgical exploration lowers significantly, and vigilance increases. However, it must be emphasized that not all closed-loop obstructions automatically need an operation. As stated earlier, the decision to operate is a combination of various factors, including clinical presentation and imaging findings, and not just a picture on CT.

SBO with a Transition Point at the Site of a Hernia

Patients presenting with a transition zone at the site of an abdominal wall hernia require special attention. These obstructions should only be reduced by the surgical team. Assessment for ischemic bowel is required to be performed by a member of a surgical team. If ischemic bowel is suspected (severe pain, tense hernia, overlying skin changes), urgent surgical exploration should be performed. The surgical team admitting the patient may decide to reduce the bowel and monitor post–hernia reduction (typically at least 24 hours) if there are no concerns for bowel compromise.

FIG. 3 Closed loop small bowel obstruction.

Geriatric Patients

Because of medical comorbidities, especially in the emergency setting, patients older than 60 years and 80 years have twice and thrice the risk of adverse outcomes after surgery, respectively, relative to younger adults. Preoperative cardiac risk stratification and physiologic optimization is desirable when not leading to undue delays. Overall, the decision to operate in geriatric patients should balance the desire to intervene early and before fragile physiologic reserves are exhausted, while not liberalizing major abdominal surgery on frail individuals. Goals of care, code status, and discharge disposition should ideally be discussed at the time of admission.

Pregnancy

SBO in pregnancy is rare; it is estimated that a practicing surgeon may manage 1 to 2 cases in a career. One-half of reported SBO cases during pregnancy are caused by adhesions. Fetal mortality averages 21% and is more likely with surgery in the first trimester. An urgent MRI is advised absent immediate indications for surgery. Pregnancy is not an absolute contraindication to ionizing radiation from radiographs or CT scans; however, the risks and benefits of fetal exposure to radiation must be carefully weighed. Overall, the same rules of operative versus nonoperative management that are used in the general population apply also to pregnancy.

Obstruction Due to Inflammatory Bowel Disease

Although most IBD patients are admitted to a medical service, early surgical consultation is recommended in the presence of an acute SBO. Evidence of intestinal obstruction represents one of the defining characteristics for severe/fulminant IBD. Although there is no strong evidence in support of specific treatment algorithms on the acute management of intestinal obstruction associated with IBD, a number of evidence-based recommendations have been made. It has

been recommended that the treatment plan be based on factors such as the location and length of the stricture, degree of concomitant inflammation, degree of upstream bowel dilation, and other accompanying features, such as abscess or phlegmon. Early cross-sectional imaging with a CT enterography (CTE) protocol is essential as is the early involvement of both gastroenterology and colorectal surgery in the treatment team. The team should determine early surgery versus neoadjuvant antiinflammatory therapy and the need for antibiotics and/or abscess drainage.

Malignancy

Unlike nonmalignant etiologies, these patients tend to have a subacute clinical picture with a slow insidious onset that is typical of partial SBO. For patients who present with SBO caused by a nonmetastatic or locally advanced primary small bowel tumor, an operative intervention with curative intent remains the principal tenet of management. The differential for these tumors typically includes small bowel neuroendocrine tumors, adenocarcinomas, lymphomas, and gastrointestinal stromal tumors. For such patients, oncologic principles should include a resection of the involved segment of bowel along with a 5- to 10-cm margin proximally and distally as well as removal of all associated mesentery. Small bowel resection is a preferable approach when the site of obstruction is isolated, the tumor causing the obstruction is intrinsic to bowel, negative margins are a possibility, and the postoperative outcome is potentially curative. A small bowel bypass is preferable if the tumor causing the obstruction cannot be completely resected and multiple sites of bowel obstruction exist. The goal with bypass is palliation. For patients who present with obstruction from incurable advanced disease, the factors affecting the final treatment plan include established goals of care set forth by the patient with the guidance of the surgeon and the medical oncologist. It is beneficial to involve a palliative care specialist at this juncture as well.

Virgin Abdomen

Based on findings in recent reviews, SBO in virgin abdomen (VA) has a mostly benign cause; this is in contrast with older literature and surgical textbooks that suggest malignancy as the main cause of obstruction in VA patients. Etiology and treatment results for patients with SBO in VA are largely comparable to the results in patients with SBO after previous abdominal surgery. CT has a pivotal role in the assessment of SBO in VA to assess the etiology and to evaluate if the bowel is compromised, demanding early surgery. Moreover, modern high-resolution CT is also useful in minimizing the risk of failure to detect a malignant cause. As with ASBO in general, the majority of cases with SBO in VA can be treated by nonoperative trial initially. Nevertheless, a laparotomy remains indicated in case of a nonresolving obstruction. The need to perform surgical exploration in every patient with SBO in VA can be waived. Noninvasive diagnostics with high accuracy for detection of malignancy and a close follow-up are mandatory.

Bariatric Surgery

Bariatric patients can present with obstruction from the same causes as all other patients, but also carry a greater risk of internal hernia, intussusception, and closed-loop obstructions resulting from surgical creation of mesenteric defects. CT results for patients with a history of laparoscopic Roux-en-Y gastric bypass may be subtle. A significantly dilated small bowel with a transition point is often a late finding. Elevated amylase and/or lipase may be a significant finding in this patient population, especially with acute obstruction of the biliopancreatic limb. Reviewing the CT scan with the radiologist to discuss any subtle findings and having a lower threshold to proceed to the operating room for any suspicious findings is recommended. Early intervention is necessary to prevent the loss of significant portions of bowel to ischemia with resulting increased morbidity and mortality. Laparoscopic enterolysis is feasible and safe. Careful bowel handling and clearly identifying all three limbs is essential because mesenteric or internal hernia can occur at multiple sites.

Early Postoperative Small Bowel Obstruction

Pivotal problems in the management of obstruction in the early postoperative period (3–4 weeks after surgery) are differentiation of ileus from mechanical obstruction and distinction between simple and strangulating obstruction if mechanical obstruction is present. Early postoperative small bowel obstruction (ESBO) poses an interesting dilemma for the surgeon. Although some ESBOs will resolve with nonoperative/conservative treatment, waiting beyond the 2-week period after the index surgery can result in forcing the surgeon to operate in a "hostile abdomen" because of significant inflammatory/postoperative adhesions. The decision to reoperate should account for clinical and radiographic signs suggesting impending strangulation or closed-loop obstruction, elapsed length of time of nonoperative management, and the nature of the index operation. Early reoperation should be considered after certain laparoscopic procedures. Surgeons managing SBO can benefit from understanding the unique features of ESBO after Roux-en-Y gastric bypass.

CONCLUSION

Small bowel obstructions remain an exceedingly common reason for emergency/unplanned admissions. SBO is a significant burden to the healthcare system, accounting for over 300,000 admissions per year and $1.3 billion per year in US healthcare costs. They present a management dilemma for clinicians and, most importantly, are a significant burden to patients because of the use of nasogastric tubes, need for operative intervention, and the often recurrent nature of the disease process. Unique variations of SBO pose challenging clinical decision dilemmas. The management of SBO is based on clinical evaluation, biological tests, and CT imaging. The goal of the initial assessment of a patient with SBO is to quickly identify signs of bowel ischemia that would necessitate urgent surgical intervention with concurrent resuscitation. The challenge for the emergency general surgeon is identifying as quickly as possible the minority of patients presenting with SBO who will not resolve without surgery. In the absence of any "alarming" signs, the patient can be managed with a trial of nonoperative management. Incorporation of a water-soluble contrast agent challenge early in the treatment algorithm can efficiently predict the success of nonoperative management and potentially hasten the return of bowel function, reducing hospital length of stay. Absence of passage of contrast into the cecum or interval deterioration of clinical examination suggests the need for operative intervention. Adhesive SBO can lead to small bowel strangulation, which is considered a major cause of morbidity and mortality. Therefore, surgery is indicated in patients with clinical deterioration or with radiologic evidence of strangulation and/or persistent obstruction. Laparoscopic surgery is becoming more common in the management of SBO and has distinct advantages in selected patients.

Management of Crohn's Disease of the Small Bowel

John Peter Ricci, MD, and Mark A. Talamini, MD

Crohn's disease is a chronic inflammatory transmural disease that can affect the entire gastrointestinal (GI) tract. As often is stated in medical school lectures, it can present anywhere from "the mouth to the anus." Most commonly, it occurs in the small intestine with the terminal ileum being the most common location. Its incidence is increasing worldwide and now is noted to be present in 201 of 100,000 adults in the United States. Its exact cause is unclear and continues to be an enigma despite intense investigation. A complex interaction of genetics, environment, and the microbiome with the host's immune system appears central in understanding the origin of Crohn's disease. Clinically, it tends to be a cyclical disease in symptoms and pathophysiology. There are episodes of alternating active inflammation and relative dormancy that contribute to the overall difficulty in management. There is a large spectrum of severity in presentation ranging from mild inflammation to significant complications including strictures, perforations, hemorrhage, abscess formation, and malignant degeneration.

The clinical hallmark of Crohn's disease is abdominal pain and diarrhea. The broader spectrum of associated symptoms may include hematochezia, fever, anorexia, weight loss, fatigue, nausea, emesis, malnutrition, vitamin deficiency, and stunted growth in younger patients. Most patients are diagnosed between 15 and 30 years of age, but a second spike in diagnosis has been noted in the sixth decade of life, largely in females. In its early presentation, Crohn's disease must be differentiated clinically from acute GI conditions such as appendicitis and bowel obstruction. Definitive diagnosis is not always easily obtained and depends on a detailed family history, environmental history, and physical examination. CT enterography and MRI enterography have become essential in the initial evaluation of these patients as have blood tests to monitor and follow inflammatory markers. Endoscopy and colonoscopy are performed for direct visualization of bowel mucosa and to obtain tissue diagnosis. Capsule endoscopy can be employed for further direct evaluation of the small bowel mucosa. At initial presentation, 40% of patients will have terminal ileal disease, 20% colonic disease, 10% proximal small bowel disease, 10% perianal disease, and 20% will have involvement of more than one anatomic location.

Over the past 20 years, medical management of inflammatory bowel disease has improved significantly with the development of tumor necrosis factor (TNF) inhibitors and other biologic therapies. Despite this fact, surgery remains a significant treatment option in the management of a large cohort of patients, and approximately one-half of Crohn's patients will require some surgical intervention within 10 years of diagnosis. Surgery for Crohn's disease is not curative; therefore its application in patient management can be challenging. Overall, the goals of surgical treatment are alleviating symptoms, improving quality of life, and preserving bowel length. Surgery can provide remission of active inflammation that cannot be obtained with medical therapy alone. It can also be used to treat strictures, abscesses, and fistulas that also will not respond to medicine.

MULTIDISCIPLINARY MANAGEMENT

The optimal management of the Crohn's disease patient requires a team approach. This team is anchored by the surgeon and gastroenterologist. A multidisciplinary group will also require input from radiology, pathology, social work, nutrition, enterostomal therapy, and associated specialties. Complex cases often are reviewed in a formal organized setting in which a member from each specialty is represented so the best treatment plan can be formulated.

MEDICAL TREATMENT

Mild to moderate disease is noted in the majority of patients at initial presentation. Standard initial management, in these cases, will usually include 5-aminocalycylates or budesonide depending on the location of disease. Acute flares can be treated with short courses of corticosteroids with transition to maintenance therapy once an adequate remission has been achieved. TNF inhibitors have drastically changed the approach to patients with moderate to severe disease. Studies have shown fistula resolution and combination therapy with methotrexate has demonstrated high mucosal healing rates. Newer biologic agents including anti-interleukin12/23 antibody (ustekinumab), anti–alpha-4 beta-7 integrin antibody (vedolizumab), and JAKs-based therapies (tofacitinib) continue to be developed with new molecular targets to decrease inflammation.

These new medications have been shown to decrease the need for surgical intervention in milder forms of the disease. They also provide the gastroenterologist a means of delaying surgery for prolonged periods. However, surgery remains an important treatment option for severe disease and disease that is otherwise refractory to medical management.

INDICATIONS FOR SURGERY

The main indications for surgery in Crohn's disease are obstruction, perforation, and failure of medical management. Emergency surgery is infrequently required as free perforation and massive bleeding are rare and obstruction is usually gradual in presentation. Acute appendicitis can occur, but this often is treated with antibiotics as associated small bowel and colonic inflammation are usually noted before intervention on CT imaging. Patients with long-standing Crohn's disease are at increased risk of developing adenocarcinoma. Principles of surgical management would be the same as a patient with de novo adenocarcinoma of the small bowel. However, diagnosis is commonly an incidental finding after standard Crohn's disease surgery.

Obstruction

Obstruction is the most common indication for surgery in Crohn's disease. The natural history is that of gradual onset in the setting of

chronic relapsing disease. The cycling of inflammation and repair over time in an affected segment eventually converts soft pliable bowel into a constricted "stovepipe." Clinically as this process progresses, the symptomatology evolves from intermittent partial obstruction experienced during episodes of transmural inflammation to chronic partial obstruction that exists between episodes of acute inflammation. The latter situation is commonly referred to as a *fibrostenotic stricture*. Once this stricture has developed, minimal acute inflammation can lead to obstructive symptoms and an acute flare. On imaging, proximal bowel to the stricture is noted to be dilated, prompting treatment frequently with corticosteroids and antibiotics. All strictures have some component of chronic scarring, and it can be difficult to differentiate a stricture that is largely inflammatory versus one that is largely fibrostenotic. Both MRI and CT enterography have improved significantly over the past decade, making this differentiation somewhat clearer. In the authors' practice, once the patient is treated acutely with anti-inflammatory medication and is noted to be asymptomatic, imaging is repeated. If persistent dilation of the bowel proximal to the stricture is appreciated, predominant fibrostenotic disease is assumed to be present. This is a clear indication for surgical intervention as medication will not be effective in the treatment of chronic scar tissue. If the bowel is noted to be decompressed, medical therapy should be optimized.

Perforation

Perforation is the next most common indication for surgery. As a transmural inflammatory process, Crohn's disease can cause localized perforation with abscess formation leading to fistulization. The pathophysiology is that of the inflammatory process in the affected bowel perforated into the peritoneal cavity, usually forming a walled off abscess. This abscess can become chronic requiring long-term antibiotics or percutaneous drainage. If an abscess persists, it ultimately will require surgical intervention. If the abscess can be treated nonoperatively, a multidisciplinary approach should be used to determine ongoing treatment on an individual basis. A small resolved abscess on a patient on minimal medical therapy would likely benefit from medical escalation and optimization, whereas a resolved abscess in a patient who has failed three biological medications would likely be offered surgery.

Frequently, these abscesses can "burrow" to adjacent "innocent" structures, creating a fistula. The structures most commonly involved are pieces of bowel (enteroenteric/enterocolonic fistula), the bladder (enterovesical fistula), or the skin (enterocutaneous fistula). When the process creates a clean fistula into another portion of the GI tract without an associated abscess, the decision regarding surgery depends on the impact of this connection. Thus, enteroenteric or enterocolonic fistula are not in themselves a definite indication for surgery. Only when the fistula causes worsening clinical symptoms or nutritional deficiencies should surgery be performed. In addition, studies have shown that TNF inhibitors have some effect in treating GI tract fistula. Enterovesical fistulas are usually not life-threatening, but they lead to recurrent urinary tract infections, pyelonephritis, and, in rare cases, urosepsis. In addition, the symptoms of pneumaturia and fecaluria are generally intolerable to most patients. Surgical repair should be pursued in this situation. Similarly, enterocutaneous fistulas require surgical intervention because of chronic drainage from the abdominal wall, chronic abdominal wall wounds, dehydration, and frequent nutritional deficiencies.

Failure of Medical Management

Failure of medical management is probably the most difficult indication to determine as it is largely patient dependent. The surgeon, gastroenterologist, and patient must work closely together to determine when during the treatment process surgical intervention is most appropriate for "medical refractory" disease. As medical therapies have advanced, new treatments continually become available that have allowed some patients to avoid surgery while only delaying it for others. Clearly, given their long-term consequences, inability to wean steroids after an acute flare and transition to maintenance therapy is an absolute indication for surgery. It is less clear how to proceed when a patient remains symptomatic and has tried multiple medications, but additional options exist. In these instances, attempting additional second- and third-line therapies can take several months to determine success and possibly delay the inevitable need for surgery. It should also be noted that eliminating the burden of active disease and inducing remission surgically can provide patients with a "fresh start" off all agents and allows previously failed medications to be reattempted.

PREOPERATIVE CONSIDERATIONS

Timing

The timing of surgery is important in maximizing the clinical outcome. The patient's willingness or resistance to surgery affects decision making. The input of the surgeon and gastroenterologist regarding recommendations is imperative. Operating too soon when the bowel is intensely inflamed is technically challenging and puts non-diseased bowel at risk. Allowing an acute flare time to resolve, at least partially, can greatly affect outcome. Every effort should be made to convert more emergent situations to urgent and elective scenarios. Active abscesses should be drained percutaneously. Conversely, these patients frequently have some aspect of malnutrition, and waiting too long for intervention can worsen this situation. In rare instances when a significant length of bowel is at risk, bowel rest and total parenteral nutrition may be required.

Once a decision regarding elective surgery has been made, the patient's current disease state must be assessed to inform preoperative planning. The patient's general medical condition must be assessed and optimized. If nutritional deficits exist and time allows, nutritional improvement should be pursued. The authors follow a strict enhanced recovery protocol and surgical site infection bundle. A standard mechanical bowel preparation with oral antibiotics is given unless a prolonged high-grade bowel obstruction is present. In this case, an extended period of clear liquid diet is employed. Patients are maintained on a clear liquid diet until 2 hours before surgery and are given a carbohydrate-rich beverage preoperatively. If bowel diversion is anticipated, the patient is evaluated by an enterostomal therapist for preoperative stoma siting.

Medications

Prolonged and chronic use of corticosteroids has clearly been shown to adversely affect wound healing and to increase the risk of surgical site infection. This is especially an issue as dosages increase from lower to higher daily prednisone equivalents. All efforts should be made to wean or discontinue steroids before surgery, but this is frequently not an option in the actively inflamed patient. In addition, patients may require perioperative steroid supplementation depending on duration of use and dosage to prevent acute adrenal insufficiency. More recently, the question of TNF inhibitor impact on wound healing has come into question. Unfortunately, the literature provides no definitive guidance on this matter. Some studies have shown no effect, with others showing a significantly increased incidence of infectious complications when patients have taken the medications within 6 to 8 weeks before surgery.

Consideration of bowel diversion with stoma creation must be entertained when patients are on long-term steroid treatment. This is likely true to a lesser extent when a patient has taken a TNF inhibitor in the perioperative period. Malnutrition and bowel quality also must be taken into account when considering stoma creation. This ideally will be discussed with the patient preoperatively and the patient will be referred to enterostomal therapy for evaluation.

TECHNICAL CONSIDERATIONS FOR SURGICAL INTERVENTION

Once it has been determined that surgery is the next step in treatment for a patient, meticulous preparation is required. This is necessary to plan the possible extent of resection and identify all areas of active disease. The entire small bowel should be evaluated, and the exact state of the disease should be elucidated. Usually this involves a current axial imaging study (CT or MRI enterography). If questions remain regarding the small bowel anatomy or disease state, capsule endoscopy or small bowel push enteroscopy can be pursued. The colon should be evaluated via colonoscopy. The cecum and the terminal ileum in particular merit examination because the state of colonic disease can be more difficult to evaluate intraoperatively than small bowel disease. Endoscopy should be performed for disease in the duodenum and proximal jejunum. Despite extensive workup, intraoperative assessment can sometimes alter the surgical plan.

Preoperatively, findings of the workup and contingencies must be reviewed with the patient. The possible nutritional effects of surgery and the possible role of a stoma should be discussed, as previously noted. The more information the patient and family understand regarding the plan, the better.

Resection

The mainstay of surgical therapy for Crohn's disease of the small intestine is resection. The most commonly faced initial operative scenario is a tight, but reasonably short segment of chronically obstructed and scarred terminal ileum. The most common operation, therefore, is an ileocecectomy. This accounts for approximately half of the surgery for Crohn's disease on the small intestine. Additional ascending colon may need to be included with the resection specimen depending on the disease activity noted on colonoscopy. Consideration of isolated terminal ileal resection should be considered only if 15 centimeters or more of normal small intestine is present just proximal to the ileocecal valve. A short, isolated segment of terminal ileum is extremely susceptible to recurrent inflammation.

In virtually all cases, the authors attempt laparoscopic access, dissection, and mobilization of the targeted diseased tissue. The laparoscope is placed in a periumbilical or umbilical position with a Hassan port via a direct cut-down technique. A 10-mm 30-degree scope is used to maximize visualization from a variety of angles. Generally, three 5-mm ports are employed on the left side of the abdomen as working ports. Upon entrance into the abdomen, full evaluation of the GI tract should be performed. This should be correlated with the visual information from the preoperative evaluation. If isolated mid small bowel disease is noted, this can be identified and easily externalized through extension of the umbilical port for resection and re-anastomosis. If a fistula exists, it must be identified. Enteroenteric fistula of the terminal ileum to itself can usually be preserved as the entire segment of bowel usually requires en bloc resection as an inflammatory mass. If the terminal ileum is fistulizing to otherwise "innocent" portions of the GI tract, the fistula must be transected and the healthy bowel must be assessed. This situation typically occurs with a small bowel to sigmoid colon fistula. In this scenario, the fistula opening in the sigmoid colon must be debrided to healthy tissue and can be closed primarily. The author prefers a handsewn two-layer approach in this situation, but a stapled repair can also be performed. In some instances, colonic resection will be required given associated inflammation in the area. A similar approach to fistulas must be employed for "innocent" small bowel involvement. A fistula to the bladder is usually taken down with primary repair of the bladder if a definite opening is noted, and prolonged Foley catheter drainage is performed. The catheter is removed after CT cystogram confirms healing of the bladder.

Sufficient mobilization of tissue for resection must be performed. This almost always involves some mobilization of the cecum, right colon, and terminal ileal mesentery from the retroperitoneum. This can be performed in a lateral-to-medial or medial-to-lateral approach. However, the medial-to-lateral technique cannot always be performed because of significantly thickened mesentery. Care must be taken in this dissection to ensure that the proper plane is identified and retroperitoneal tissue is preserved. The ureter should be identified clearly. In rare cases of extreme inflammation, this is not possible. In this situation, dissection of the ureter should be performed in the pelvis to better evaluate its course. In addition, if this inflammation is noted and expected, preoperative ureteral catheter placement should be performed.

As stated earlier, the specimen is generally extracted through an extended umbilical incision. If extensive pelvic inflammation is noted, the incision may need to be extended inferiorly. Vascular transection can be performed intracorporeally, however frequently the bowel mesentery is significantly foreshortened and thickened from chronic inflammation. Transecting this mesentery can be tortuous and may require proximal vascular control to prevent extensive blood loss. Attempt at laparoscopic transection should be considered carefully.

The basic principle of small bowel resection for Crohn's disease is to remove all of the grossly involved disease while preserving as much bowel length as possible. The authors attempt to measure pre-resection and post-resection bowel length so it will be notated if additional surgery is performed in the future. Grossly involved bowel is best determined by visual and tactile evaluation. Fat creeping should not be present, and the mesenteric margin should be palpable in unaffected intestine. Division of the mesentery, as previously noted, can be difficult. The authors generally use a combination of approaches including a vessel-sealing energy device, vascular staplers, and sutures to control bleeding from exceptionally thickened mesentery. When at all possible, transection of mesentery distally should be attempted so as not to compromise the vascular supply of otherwise healthy bowel.

The worst complication in any bowel surgery is anastomotic dehiscence, and this is no different for the Crohn's disease patient. Anastomotic techniques have been studied at length with no definitive determination on the superiority of stapled or handsewn anastomosis. It is the authors' opinion, however, that the technique employed should be that which is most comfortable for the primary surgeon. This should hopefully maximize reproducibility and quality. The mesenteric defect is closed, when possible, to prevent internal herniation but is left fully open for large defects that cannot be reapproximated.

Ileostomy

As previously noted, sometimes patients will require temporary bowel diversion after surgery for Crohn's disease of the small intestine. This usually is required when the bowel or the patient is not healthy enough to undergo primary anastomosis. This can occur with extensive contamination from a drained abscess or if the bowel is noted to be significantly dilated precluding healthy anastomosis. High-dose steroid use and severe malnutrition can also create such an environment. Rarely, a proximal diversion is required when significant inflammation of long segments of small intestine are noted. In this situation, too much bowel is involved to resect, and proximal diversion is performed as a last-ditch effort to induce remission. Unfortunately, this diversion will undoubtedly be accompanied by a high-output stoma requiring parenteral nutrition.

Disease of the Duodenum

Crohn's disease of the duodenum frequently presents with nausea, epigastric fullness, and emesis. It is easily diagnosed with imaging

and upper endoscopy. Initial attempts at management can be performed with endoscopic balloon dilation. However, recurrence is common. When surgery is indicated, strictureplasty is the procedure of choice. Frequently, the disease is too diffuse, making a bypass procedure necessary. Gastrojejunostomy is most commonly employed. It is recommended that the patient undergo a pH study before the procedure to determine the need for associated vagotomy. In addition, when possible, gastroduodenal bypass is recommended for proximal disease of the duodenum to prevent marginal ulceration in the future.

Strictureplasty

Bowel-sparing procedures and strictureplasty are discussed directly in a separate chapter in this text, but we will discuss them briefly as they are a critical tool in the inflammatory bowel disease surgeon's armamentarium. In patients with small bowel Crohn's disease, 20% to 30% can be managed with some form of strictureplasty. Technically, a strictureplasty can be performed laparoscopically, but because of the extensive suturing required, it is often performed through a small laparotomy after identification of strictures laparoscopically. The most challenging operative situation involving structuring disease is the case of diffuse jejunoileitis. In this situation, multiple strictures separated by inches throughout the small intestine are encountered. Deciding what requires resection, what will resolve with strictureplasty, and what can be left alone requires careful consideration and judgment. It has been described that inflating a Foley catheter with 3 mL to 10 mL of saline and inserting it into the bowel through an enterotomy can be used to determine clinically significant strictures. Once it has been determined that a strictureplasty is to be performed, the mucosa of the affected bowel must be examined once opened to evaluate for underlying pathology. Biopsies with possible frozen section must be performed if malignancy is suspected.

Heineke-Mikulicz Strictureplasty

The Heineke-Mikulicz strictureplasty is the most commonly employed technique and the simplest to perform. It is generally used for strictures less than 7 cm in length. An incision is made parallel to the bowel on the antimesenteric border. It should extend approximately 2 cm past the active inflammation on either side. The incision is then reapproximated transversely. This can be performed with a running or interrupted suturing technique in one or two layers.

Finney Strictureplasty

The Finney strictureplasty is generally used for medium-length strictures between 8 and 15 cm. Once again, a longitudinal incision is made on the antimesenteric border of the actively inflamed bowel. The defect is then closed as a U-shaped enterotomy with the bowel folded on itself at the midpoint of the enterotomy. This is usually performed in two layers with interrupted sutures on the outside and running or interrupted sutures on the inside.

Side-to-Side Isoperistaltic Strictureplasty (Michelassi Strictureplasty)

The Michelassi strictureplasty is a specialized technique that should only be employed by the most experienced Crohn's disease surgeons. It allows for preservation of long segments of diseased small intestine. It entails transection of actively inflamed portions of small intestine and aligning them in isoperistaltic side-to-side fashion. The bowel is usually anastomosed by a two-layer handsewn technique while spatulating the ends for full closure.

POSTOPERATIVE CARE

Postoperatively, patients continue on the hospital's enhanced recovery pathway. Preoperative blocks and spinal anesthesia are used to initiate postoperative pain control. Nasogastric tubes are not employed. Narcotics are minimized, mobilization is initiated as early as possible, and diet is started immediately. Patients are discharged once there is clear evidence of sufficient bowel function to maintain hydration and nutrition independent of the hospital. Once home, patients are provided with information regarding warning signs of complications and given a quick and clear pathway back to the team should concerns arise. They are contacted by the team directly for the first three days post-discharge.

It is well known and even assumed that Crohn's disease will recur and that it will do so at a microscopic level early at the anastomotic site. How to address and survey these patients is imperative to their long-term success and prevention of additional surgical interventions. A recent and important advance in the team management of surgical Crohn's patients is early postoperative medical therapy, according to logical protocols. This is an active area of investigation worthy of monitoring.

Use of Strictureplasty in Crohn's Disease

Lea Lowenfeld, MD, and Fabrizio Michelassi, MD

Crohn's disease (CD) is a chronic, full-thickness, inflammatory bowel disease. It can affect any site along the gastrointestinal tract and may present with one of three phenotypes: (1) nonpenetrating/nonstricturing disease characterized by inflammatory masses, (2) penetrating disease characterized by fistulae and abscesses, or (3) fibrostenotic disease characterized by fibrotic strictures. Strictures are defined as "a constant luminal narrowing with prestenotic dilation or obstructive signs without penetrating disease" (Satsangi et al., 2006). Fibrostenotic Crohn's strictures most commonly affect the small bowel, leading to small bowel obstruction. To date, there is no medical therapy that prevents or reverses stricturing disease; therefore, endoscopic and surgical treatments are the mainstays of treatment to palliate symptoms and treat complications. Endoscopic approaches include dilation, stricturotomy, and endoscopic stenting. Surgical options include proximal diverting stoma, resection, intestinal bypass, and strictureplasty. This chapter focuses on strictureplasties, specifically on indications, technical aspects of different strictureplasty techniques, and outcomes.

CLINICAL PRESENTATION

Patients with strictures may develop progressive luminal narrowing over time and only become symptomatic when a critical degree of narrowing has been reached. Patients with gastroduodenal strictures typically present with early satiety, postprandial fullness, burping, and vomiting. Patients with strictures of the small intestine initially notice postprandial bloating, crampy abdominal pain, obstipation, and constipation and may progress to nausea, vomiting, and high-grade intestinal obstruction. Patients with colonic strictures present with bloating, distension, obstipation, constipation, and abdominal pain. Patients with stricturing disease may develop a single stricture or a series of strictures with intervening healthy intestine. In the presence of multiple strictures, symptoms originate from the most proximal critical stricture.

Noninvasive imaging modalities, including computed tomography enterography (CTE) and magnetic resonance enterography (MRE), are useful in showing luminal narrowing, intestinal wall thickening, and prestenotic bowel dilation to map the number, degree, length, and location of strictures and also to estimate overall small-bowel length in preoperative planning. Endoscopic evaluation with or without biopsy is important to evaluate for extension and severity of luminal disease and presence of malignancy, but it may be limited by tight strictures or luminal narrowing secondary to angulations caused by adhesions from previous surgical procedures or localized sepsis.

Resection remains the most common approach for patients undergoing operative treatment for obstruction caused by stricturing CD. The initial presentation of a patient with a single stricture or a series of strictures in a relatively short segment of intestine is most often best managed with surgical resection. However, patients with multifocal, extensive, and recurrent disease are at risk of short gut syndrome, especially following prior extensive bowel resections. In these cases, bowel-sparing procedures offer an alternative to resections by enlarging the lumen of the bowel while maintaining the overall absorptive surface area of the intestine.

INDICATIONS AND CONTRAINDICATIONS FOR STRICTUREPLASTY (BOXES 1 AND 2)

Strictureplasty is indicated for fibrotic strictures in the duodenum and small bowel, particularly if multiple strictures are present over an extensive length of intestine or when recurrent strictures develop in a patient with previous bowel resections at risk for short bowel syndrome. Relative contraindications include malnutrition; the presence of a fistula, unless the fistulous opening is devoid of acute inflammation and located on the antimesenteric side of the bowel, where it can be debrided as part of the strictureplasty; a stricture close to an area of resection, which is usually included in the resection unless the patient is affected by or at risk for short bowel syndrome; or a long stricture with thick, unyielding intestinal wall. Absolute contraindications include acute or chronic hemorrhage; a stricture within an inflammatory mass or in proximity to a perforation or abscess; or the presence of dysplasia or malignancy. If there is concern for malignancy, the intestinal segment must be resected according to standard oncologic principles.

Asymptomatic strictures should not be resected, but they can be strictureplastied or included in a strictureplasty for an adjacent symptomatic stricture to prevent progression of the stricture to a critical narrowing. If left untouched, disease progression requiring subsequent surgical treatment occurs in one-fourth of cases over the ensuing 3 to 4 years.

Patients requiring surgical intervention for obstructive symptoms are frequently malnourished. Patients who are nutritionally compromised should undergo nutritional repletion with a liquid enteral diet or parenteral diet supplementation, if needed, to reverse their catabolic state before surgery.

OPERATIVE PLANNING

Careful preoperative patient evaluation is critical to operative planning. The nature of the patient's past and current disease activity (obstructive, septic, hemorrhagic, or neoplastic) should be evaluated and documented. Obtaining a thorough history of prior operations

BOX 1 Indications for Strictureplasty

- Fibrotic small bowel stricture without associated inflammation
- Multiple strictures throughout the small bowel
- Recurrent small bowel stricture(s) following previous resection

BOX 2 Contraindications for Strictureplasty

Absolute Contraindications
- Hemorrhage
- Evidence of dysplasia or malignancy
- Stricture at a site of uncontrolled sepsis (perforation, abscess, or inflammatory mass)

Relative Contraindications
- Malnutrition, albumin level <2
- Fistula involving the stricture
- Stricture in close proximity to a segment planned for resection
- A long stricture with a thick, unyielding intestinal wall
- Multiple strictures within a short segment of small bowel in a patient who has not had a prior resection

and operative reports is helpful to understand the patient's current gastrointestinal anatomy. Imaging with CTE or MRE and endoscopic evaluation provide a preliminary "road map" of the distribution of disease activity as well as any unsuspected entero-enteral fistulae, contained perforations, and an overall estimate of small bowel length. The optimal stoma site should be marked preoperatively when a temporary or permanent stoma is likely.

The first step in any CD abdominal procedure is to thoroughly examine the entire bowel. The bowel can be examined laparoscopically or via laparotomy, with the preoperative imaging and endoscopic evaluation in mind, matching the preoperative findings to the visual appearance of the bowel. The bowel must be visually inspected, palpated digitally or through laparoscopic instruments, and, if necessary, the lumen can be evaluated by passing a well-lubricated Foley or Fogarty balloon through the bowel and then retracting the partially inflated balloon to identify more subtle luminal narrowings. Areas of small bowel disease usually display creeping fat, wall thickening, and mesenteric thickening. Disease in the colon may manifest more subtle external changes: mucosal disease can be present with the external wall looking normal, hence preoperative endoscopic evaluation is useful.

At the end of the examination, the surgeon should have a mental road map of the gastrointestinal tract, with the total length of the small bowel, the length and location of the diseased bowel, the phenotypic appearance of the disease, and the presence of previous resections and strictureplasties. Each diseased segment should be evaluated to determine whether it is a candidate for strictureplasty, resection, or no intervention in the case of a noncritical narrowing. The relationship of multiple fibrostenotic strictures to one another must also be noted to see whether they would need multiple simple strictureplasties, a single intermediate or complex strictureplasty, a resection, or a combination of strictureplasties and resections. If abscesses or fistulae are present, they must be computed in the surgical plan.

Gastroduodenal strictures are most often endoscopically accessible and can be treated with endoscopic dilation. When surgery is indicated, short strictures throughout the first three portions of the duodenum may be treated with the Heineke-Mikulicz strictureplasty, and strictures of the fourth portion of the duodenum may be treated with the Finney strictureplasty by recruiting the first loop of jejunum. These procedures are discussed later in this chapter. To treat a duodenal stricture, the duodenum must be fully mobilized to allow for a strictureplasty without tension. If a strictureplasty is not feasible, a gastrojejunal bypass is a viable alternative.

Jejunal-ileal strictures may be addressed with a combination of resection and strictureplasty techniques. Heineke-Mikulicz strictureplasty is the procedure of choice for short-segment strictures. Finney strictureplasty is performed for longer-segment strictures. The Michelassi strictureplasty is used for multiple sequential strictures. These procedures are discussed later in this chapter.

Terminal ileum and colon strictures are usually the result of inflammatory, nonpenetrating/nonstricturing or penetrating disease. Therefore, a segmental resection is usually preferred. Occasionally, Crohn's terminal ileitis can be addressed with a modified Michelassi strictureplasty.

Anastomotic strictures may be addressed with endoscopic dilation if endoscopically accessible. Anastomotic strictures that are not amenable to endoscopic treatment can be addressed with resection or strictureplasty. To perform a tension-free strictureplasty at the site of a prior anastomosis, adequate mobilization of the intestinal loop and lysis of adhesions must be performed. Anastomotic strictureplasty is safe and efficacious, but it is associated with a high rate of recurrence (57%) when followed long term.

STRICTUREPLASTY TECHNIQUES (BOX 3)

The technical difficulty of strictureplasty varies from simple (Heineke-Mikulicz) and intermediate (Finney) to complex (Michelassi). Certain overarching principles are shared by all strictureplasty techniques:

BOX 3 Strictureplasty Operative Strategy

- An incision is made along the length of the stricture.
- Examine the mucosa, and perform a biopsy on any areas suspicious for dysplasia or carcinoma.
- Obtain excellent hemostasis.
- Close the enterotomy with absorbable or nonabsorbable suture in one or two layers.

- After opening the bowel during the performance of a strictureplasty, the mucosal surface of the affected and neighboring bowel must be evaluated for disease severity and presence of dysplasia/carcinoma. Suspicious areas must be biopsied for frozen-section analysis. If dysplasia or malignancy is confirmed, the strictureplasty is aborted in favor of an oncologic resection.
- Excellent hemostasis is critical. Bleeding from a strictureplasty site is one of the most common and troubling postoperative complications. Bleeding is usually self-limited, but occasionally requires blood transfusions. For persistent bleeding originating from a strictureplasty within reach of an endoscope, endoscopic techniques can be employed to achieve hemostasis. Selective mesenteric angiography with intraarterial vasopressin infusion effectively controls most episodes of bleeding originating from strictureplasties that are not accessible with endoscopic techniques. In the presence of multiple suture lines (strictureplasties, anastomoses), India ink blue dye can be injected at the time of selective mesenteric angiography for subsequent intraoperative localization of the bleeding.
- Minimally invasive approaches to surgery can be utilized during the performance of a strictureplasty either completely intracorporeally with effective laparoscopic or robotic suturing skills or in a hybrid fashion by mobilizing and exteriorizing the affected segment through a small incision in the abdominal wall.

Heineke-Mikulicz Strictureplasty (Fig. 1)

Short strictures are best treated with a Heineke-Mikulicz strictureplasty, a technique derived from the Heineke-Mikulicz pyloroplasty performed for pyloric stenosis. The Heineke-Mikulicz strictureplasty is appropriate for strictures up to 5 cm in length.

First, two 3-0 sutures, either nonabsorbable or absorbable, are placed on each side of the bowel at the midportion of the stricture to act as stay sutures. A longitudinal enterotomy is made over the stricture on the antimesenteric side of the bowel, extending 1 to 2 cm beyond the length of the stricture proximally and distally into

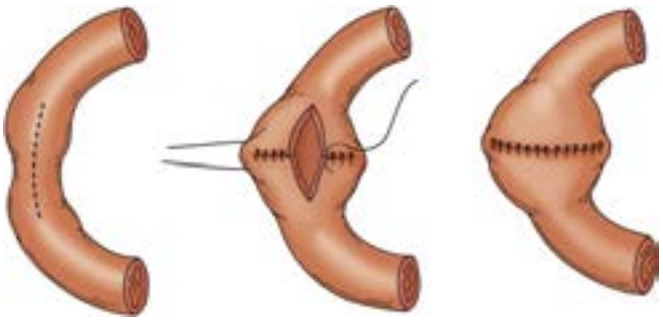

FIG. 1 Heineke-Mikulicz strictureplasty. The longitudinal enterotomy is closed transversely to reconstruct a more widely patent lumen.

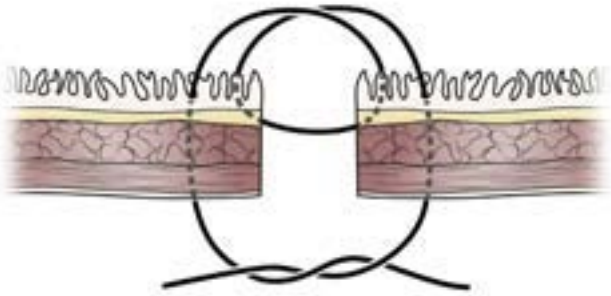

FIG. 2 Modified Gambee stitch. First the stitch penetrates all layers of the bowel wall from the serosa to the luminal mucosa approximately 0.5 cm from the cut edge. The mucosa of the other limb is traversed out of the bowel lumen, and then the mucosa of the first side is traversed back into the bowel lumen. Finally, on the other limb, the stitch penetrates all layers of the bowel wall from the luminal mucosa to the serosa approximately 0.5 cm from the cut edge. *(From Shureih SF, Wilson TH Jr, Howard WH. Modified Gambee stitch. Safe, easy and fast modification. Am J Surg. 1981;141:304.)*

nondiseased bowel. The stay sutures are then pulled perpendicular to the long axis of the bowel, lining up the enterotomy to be closed transversely. The closure may be performed in one or two layers. For a one-layer closure, the Gambee stitch (Fig. 2), using an absorbable suture, ensures appropriate approximation of the mucosa and serosa while leaving the blood supply intact between sutures and is particularly well-suited to strictureplasty. For a two-layer closure, a running absorbable inner layer is followed by an interrupted Lembert nonabsorbable suture outer layer.

A Sasaki modification of the Heineke-Mikulicz strictureplasty technique (Fig. 3) can be applied to two short-segment strictures in very close proximity. The enterotomy is created along the antimesenteric border through both strictures and the intervening healthy segment of intestine. The resulting longer enterotomy is then closed transversely after tailoring the end of each transected stricture.

The Moskel-Walske-Neumayer strictureplasty (Fig. 4) is another modification of the Heineke-Mikulicz strictureplasty that applies a V-Y advancement flap closure to address the disparity in size between a very dilated proximal bowel and a nondilated distal bowel. The enterotomy is created along the antimesenteric border of the stricture extending into a *Y* shape on the antimesenteric border of the dilated bowel just proximal to the stricture. The *Y*-flap of the proximal dilated bowel is advanced into the strictured area and closed in a transverse fashion.

The Judd strictureplasty is a variation of the Heineke-Mikulicz strictureplasty used when the strictured segment also includes a fistula opening. This technique can be used when the fistula opening is located on the antimesenteric side of the bowel. The anti-mesenteric longitudinal incision is made to include the fistula opening. The fistula opening is debrided, leaving healthy tissue, and the enterotomy is closed transversely using the described Heineke-Mikulicz technique.

Finney Strictureplasty (Fig. 5)

The Finney strictureplasty is also derived from the homonymous pyloroplasty technique. The Finney strictureplasty is appropriate for strictures 5 to 12 cm in length or for a similar-length segment with multiple short strictures closely grouped together with intervening short segments of dilated bowel.

The strictured segment is folded creating a U-shape loop. A rigid stricture that lacks the pliability to fold onto itself may require folding normal bowel onto diseased bowel. The two limbs of the *U* are sutured together in a side-to-side fashion. Interrupted Lambert

sutures are placed close to the facing mesenteric borders forming the posterior outer layer, extending 1 to 2 cm beyond the length of the stricture proximally and distally. A longitudinal enterotomy is created just above the stitches. The side-to-side anastomosis is

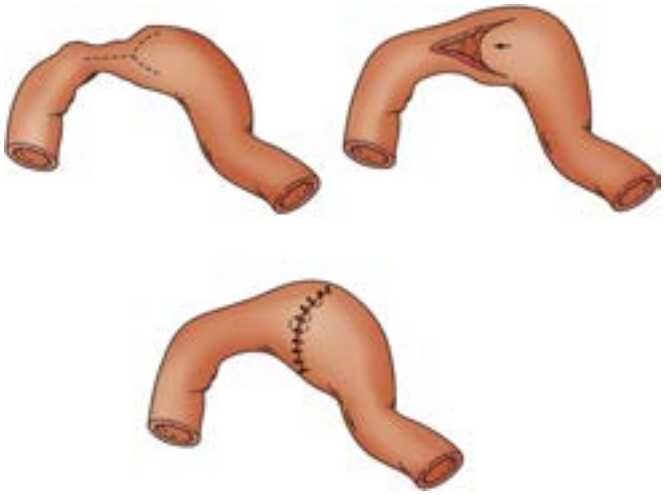

FIG. 4 Moskel-Walske-Neumayer strictureplasty is a modification of the Heineke-Mikulicz strictureplasty that can be used to address a size mismatch of the dilated proximal segment of small bowel and the strictured segment of small bowel. The longitudinal enterotomy along the stricture is extended into a Y-shaped enterotomy on the dilated proximal bowel and closed transversely by advancing the apex of the *Y* into the most distal point of the enterotomy. *(From Tichansky D, Cagir B, Yoo E, et al. Strictureplasty for Crohn's disease: meta-analysis. Dis Colon Rectum. 2000;43:911–919.)*

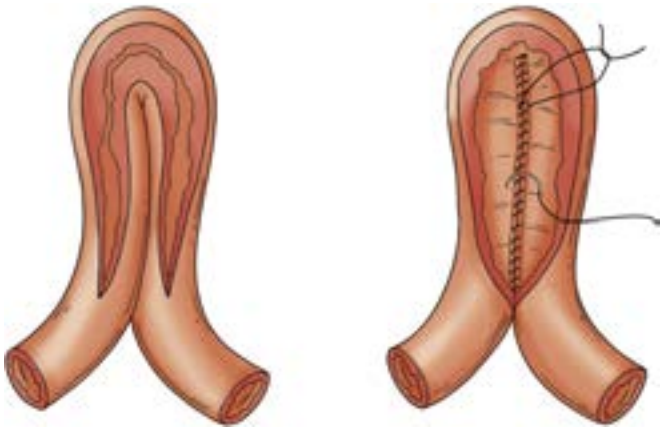

FIG. 5 Finney strictureplasty. The stricture is folded into a U-shape, and a side-to-side anastomosis is created between the proximal and distal portions of the stricture.

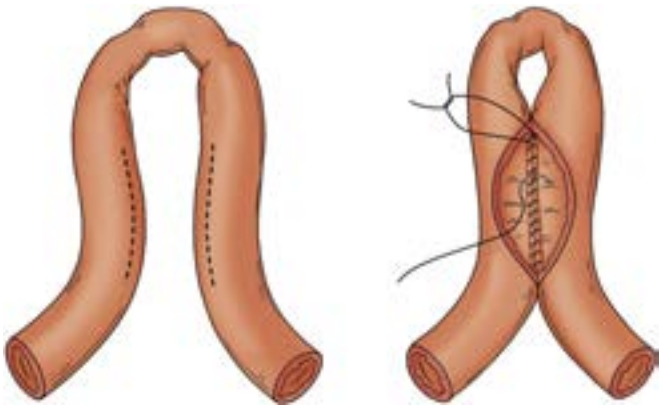

FIG. 6 The Jaboulay strictureplasty is a modification of the Finney strictureplasty that excludes the segment of the stricture that is not amenable to suturing.

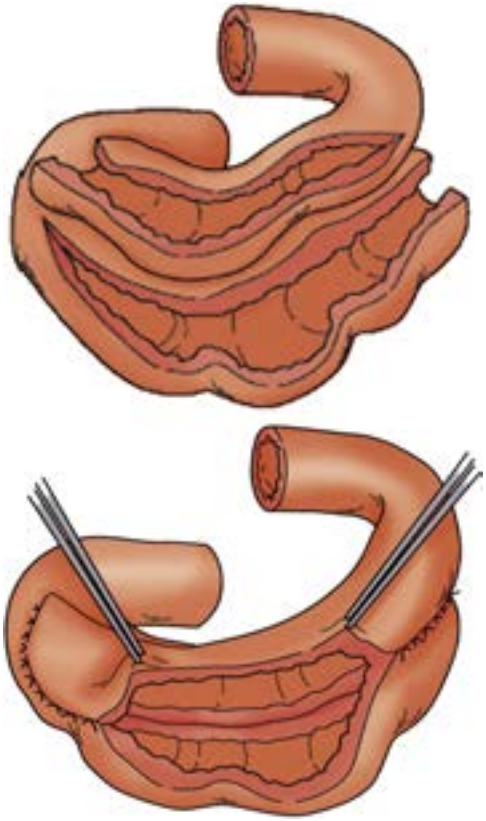

FIG. 7 Michelassi strictureplasty (side-to-side isoperistaltic strictureplasty). Long strictures or multiple consecutive strictures can be treated with side-to-side isoperistaltic strictureplasty. The involved segment and associated mesentery are divided to allow for the two segments to align alongside one another and create an isoperistaltic side-to-side anastomosis. *(From Tichansky D, Cagir B, Yoo E, et al. Strictureplasty for Crohn's disease: meta-analysis. Dis Colon Rectum. 2000;43:911–919.)*

constructed with an inner layer of running absorbable suture, reinforced by an anterior outer layer of interrupted Lambert sutures.

If the bowel quality of the stricture is not suitable for suturing, a Jaboulay strictureplasty (Fig. 6) is a modification of the Finney strictureplasty in which a side-to-side anastomosis is created between the uninvolved healthy bowel proximal and distal to the stricture, leaving the strictured segment in place as a short bypassed segment. This side-to-side anastomosis can also be created using a stapler device. One concern specific to the Jaboulay strictureplasty is that the short-bypassed segment may lead to long-term issues of bacterial overgrowth, septic complications, and malignant degeneration.

Michelassi Strictureplasty or Side-to-Side Isoperistaltic Strictureplasty (Fig. 7)

The side-to-side isoperistaltic strictureplasty (SSIS) preserves long segments of bowel that otherwise would be resected leading to major loss of intestinal absorptive capacity. Segments of bowel greater than 12 cm containing a single long stricture or a series of shorter strictures in close proximity to one another over a long intestinal segment may be addressed with SSIS.

The bowel and the mesentery are divided at the midpoint of the segment of bowel intended for the strictureplasty. The proximal and

distal loops of the diseased bowel are brought alongside each other to overlap in a side-to-side isoperistaltic fashion, lining up the stenotic areas of one loop against the dilated areas of the other loop as much as possible. The two limbs are approximated with interrupted non-absorbable Lambert sutures, forming the posterior outer layer of the ultimate closure. A longitudinal enterotomy is then made just above the sutures along the length of each of the two intestinal loops. The ends of the bowel are spatulated to avoid creating blind ends. Luminal hemostasis is obtained with suture ligation and electrocautery. The inner layer of running full-thickness absorbable sutures starts with two sutures at the middle of the posterior suture line and each progresses anteriorly as a continuous Connell stitch. An anterior outer layer of interrupted seromuscular sutures completes the two-layer closure. Thick and friable mesentery may restrict the mobility of the small bowel and thereby limit the ability to transect and slide the proximal intestinal loop alongside the distal intestinal loop, precluding creation of an SSIS.

If the transection of the intestine and the mesentery cannot be performed at the midpoint of the diseased loop and one resulting loop is shorter than the other, normal bowel can be recruited into the anastomosis when aligning the two limbs. The Michelassi strictureplasty can also be combined with resection of very severely diseased segments. If the middle of the diseased loop of intestine is severely affected by a long, rigid stricture that is not amenable to creating a safe anastomosis, that segment can be resected before sliding the proximal and distal loop alongside each other and creating the SSIS (Fig. 8A). Similarly, if one end of the diseased loop of intestine is severely affected, that segment can be resected, and

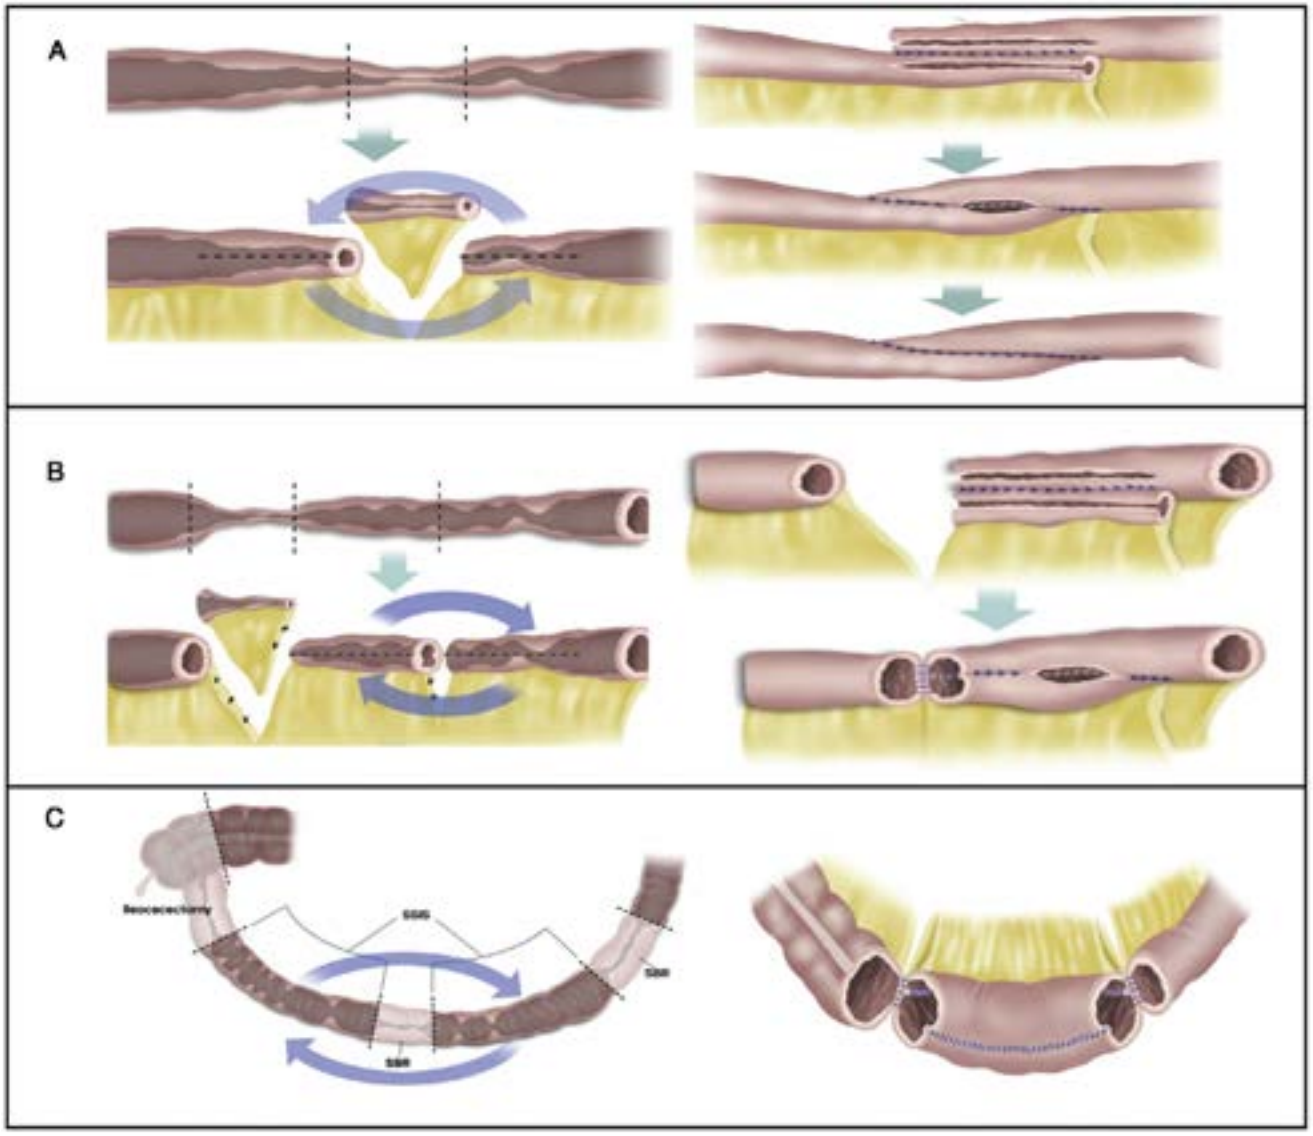

FIG. 8 **(A)** Resection side-to-side isoperistaltic strictureplasty (SSIS). The severe stricture located in the middle of the diseased loop can be resected before sliding the proximal and distal loops alongside each other and performing the SSIS. (**B**) Side-to-side-to-end SSIS. The severe stricture located at one end of the diseased loop can be resected, and the SSIS can be anastomosed to the uninvolved bowel in an end-to-end fashion. (**C**) End-to-side-to-side-to-end SSIS (SSIS with two discontinuous bowel loops). Severe strictures located in the middle and at either end of the diseased loop can be resected before performing the SSIS using the discontinuous diseased loops and then creating an end-end anastomosis at each end of the SSIS (Michelassi II). *SBR*, small bowel resection. *(From Lowenfeld L, Michelassi F. Managing stricturing Crohn's disease: Resect? Strictureplasty? Dilate? J Laparoendosc Adv Surg Tech A. 2021;31[8]:881–889.)*

the side-to-side strictureplasty can be anastomosed to the distal or proximal uninvolved bowel (Fig. 8B). When three severely fibrotic and deformed bowel segments are separated by two strictured segments, the Michelassi II strictureplasty can be employed (Fig. 8C). After resection of the three severely diseased segments located in the middle and at either end of the diseased loop, the remaining two discontinuous segments are used to perform an SSIS, according to the original description. Finally, each of the two ends of the SSIS is then anastomosed with the proximal and the distal bowel fashioning an end-to-side-to-side-to-end strictureplasty.

Results

In one of the largest systemic reviews and meta-analysis of 23 series on strictureplasty, including 1112 patients and 3259 strictureplasties, Yamamoto et al. reported that the most commonly performed strictureplasty was the Heineke-Mikulicz strictureplasty (81%), and strictureplasties are most often performed in the jejunoileal region (94%). The mean number of strictureplasties performed during one operation was 3 (range 1–21). The majority of patients underwent simultaneous resection and strictureplasty (61%). These observations have remained constant despite the widespread use of biologics and the development of complex strictureplasty techniques to address extensive CD in the past two decades (Heineke-Mikulicz 82.6%, jejunoileal 99.7%, simultaneous resection 73.7%). In a paper reviewing the 25-year experience with SSIS, Michelassi et al. found that 24% of patients who underwent strictureplasty for jejunoileitis underwent one or more SSIS procedures, and of the patients who underwent SSIS, 47% required additional small bowel resection away from the site of strictureplasty, and 45% required at least one synchronous conventional strictureplasty.

Yamamoto et al. reported a 13% overall complication rate following jejunoileal strictureplasty.[6] Septic complications occurred in 4% of cases, with 78% of septic complications related to the strictureplasty site and 44% of patients experiencing postoperative sepsis requiring laparotomy. The risk of postoperative hemorrhage requiring at least 2 units of packed red blood cells was 3%, probably as a result of creating a suture line in thick, diseased bowel. Most were successfully managed nonoperatively, only 6% requiring laparotomy. Only 2% of patients developed postoperative ileus, and 1% developed postoperative bowel obstruction. Of the patients who developed bowel obstruction, 27% required laparotomy. Emergency surgery, intraabdominal abscess, low hemoglobin, hypoalbuminemia, preoperative weight loss, and older age were significant risk factors for postoperative complications. In a meta-analysis including 32 studies with a total of 1616 patients and 4538 strictureplasties, Campbell et al. found that the incidence of early or late complications after a conventional (Heineke-Mikulicz, Finney) or nonconventional (SSIS) strictureplasty was similar (early complications 15% vs. 8% and late complications 29% vs. 17%, respectively).

Large studies and meta-analyses support strictureplasty as at least an equivalent alternative to resection in the treatment of CD. For extensive CD, use of the Michelassi strictureplasty may help avoid postoperative short gut syndrome. In the paper reviewing the 25-year experience with SSIS, Michelassi et al. showed that the median length of spared bowel was 52.5 cm (range: 20–280), equal to 17% of bowel length (range, 4.3%–40%).

In terms of disease recurrence following strictureplasty, Yamamoto reported a 5-year recurrence rate following strictureplasty of 28%, with only a 3% site-specific recurrence rate. Comparing recurrence rates after strictureplasty and resection is challenging because these operations are usually performed in two different groups of patients who may have a different risk for recurrence: strictureplasties are performed in fibrostenotic CD, while resections are performed in all types of CD (fibrostenotic, inflammatory, and penetrating). How much the phenotype of the disease influences the recurrence rate is poorly understood. Yet, from available data, it seems that the site-specific operation-free interval is similar for patients who undergo resection or strictureplasty.

SUMMARY

No treatment is curative in CD, and there is no medical therapy to prevent or reverse stricturing disease. Stricturing CD most commonly occurs in the small intestine and, over time, can lead to small bowel obstruction. While small bowel resection appropriately addresses a first incidence of obstruction at a single site, bowel preservation must be prioritized in the treatment of recurrent, extensive, and multifocal CD to avoid or delay the occurrence of short gut syndrome. Strictureplasty techniques alleviate strictures and preserve small bowel absorptive surface. Different strictureplasty techniques have been developed to address the variety of disease presentations. The safety profile of strictureplasty is good, making the technique safe. In terms of disease recurrence, the site-specific operation-free interval is similar for patients who undergo resection or strictureplasty. Strictureplasty can be used as a complement to medical therapy, endoscopic treatments, and surgical resection. These treatments may be used simultaneously, sequentially, and repeatedly.

Management of Small Bowel Tumors

Ramy El-Diwany, MD, PhD, and John W. Harmon, MD

Small bowel malignancies are rare, difficult to diagnose, and have few treatment guidelines. Because small bowel tumors present with vague and common symptoms, it is imperative that the surgeon keep them on the differential for abdominal pain, obstruction, and gastrointestinal (GI) bleed. However, the majority of patients referred to surgeons for small bowel tumors have a suspicious mass on imaging. Evidence-based guidelines on management of small bowel malignancy are difficult to find, and given the rarity of these lesions, there is little information in the literature to provide reference for clinical decision making.

PRESENTATION

The typical presenting symptoms of small bowel tumors are vague and highly variable. Many patients with a known mass, discovered following workup for GI bleeding or encountered incidentally on imaging, present to surgeons as a referral from a primary care provider or a gastroenterologist. Others will present with colicky pain from obstruction, either partial or complete, and will be found to have a small bowel tumor during surgery. The mass itself can be intraluminal or circumferential, directly responsible for obstruction, or can have surrounding fibrosis that results in stricture and adhesion to the mesentery or retroperitoneum. GI stromal tumors (GIST) are frequently asymptomatic but can present with bleeding or obstruction.

Paraneoplastic symptoms such as weight loss and vague abdominal pain are concerning for malignant neoplasms like adenocarcinoma and lymphoma, particularly in the context of a known small bowel mass; however, these nonspecific symptoms should prompt broad investigations, as small bowel tumors are one of the rarer malignancies. Neuroendocrine tumors (NETs) that are productive of vasoactive amines can present with a wide range of symptoms, from epigastric pain and ulcerations to flushing, sweating, and diarrhea. However, most are asymptomatic and are found incidentally on imaging workup for other conditions.

Predisposing Conditions

Familial adenomatous polyposis (FAP), hereditary nonpolyposis colon cancer (HNPCC) and Peutz-Jeghers syndrome (PJS) are genetic cancer syndromes that predispose to small bowel malignancy. Crohn's disease and celiac sprue, chronic inflammatory conditions involving the small bowel, also predispose to small bowel malignancy, and risk increases with increased severity and longer duration of disease. Patients with cystic fibrosis have 19-times higher incidence than the general population, with an additional 2- to 5-fold higher risk following lung transplantation. Obesity, tobacco use, and high dietary intake of red meat, smoked foods, alcohol, and refined sugar have all been shown to have an association with small bowel tumors, but the links between these risk factors and tumorigenesis are not clear. In fact, the etiology of small bowel tumors that are not associated with either chronic inflammatory diseases or genetic cancer syndromes is poorly understood.

Examination and Diagnostics for Patients Found to Have Small Bowel Tumors

On physical examination, it is only rarely possible to palpate an abdominal mass. Laboratory workup should include the standard complete blood count to look for anemia or elevated white blood cell count in the acute setting if signs of perforation are present. Elevated liver enzymes or amylase suggest possible duodenal mass or obstruction. Carcinoembryonic antigen (CEA) is often elevated in small bowel adenocarcinoma but is not sensitive or specific. Serum 5-HIAA and chromogranin A should not be routinely tested unless there is a strong clinical suspicion of NET based on symptoms or imaging features.

Imaging

Upon presentation with obstructive symptoms, a computed tomography (CT) scan with IV contrast allows clinicians to visualize the location of obstruction and possibly even the mass itself (Fig. 1). Masses can be constricting, occasionally demonstrating an "apple core" appearance with a circumferential constriction of the lumen. Some masses are polypoid, projecting intraluminally, and are better visualized with oral contrast. Close evaluation of the contour of the bowel is necessary to find submucosal lesions, and the keen surgeon should also thoroughly evaluate the mesentery for associated enlarged nodes or a mesenteric-based mass. Occasionally, enlarged nodes are the only sign of a nearby small tumor. A negative CT should not rule out small bowel tumor, as they are not particularly sensitive in this condition. However, CT does detect abnormalities in up to 80% of patients who do have a small bowel tumor. CTs are also valuable for staging nodes and metastatic lesions. Additional specialized imaging modalities such as octreotide or PET/DOTATATE scans are helpful in localization of NETs and identification of multifocal and metastatic disease (Fig. 2). In some institutions, these scans are routine before operative intervention.

Endoscopy

Esophagogastroduodenoscopy (EGD) can detect tumors into the third portion of the duodenum and is an excellent tool to begin the workup for GI bleed or other symptoms that are suspicious for GI masses. Endoscopic ultrasound is a useful adjunct to standard EGD

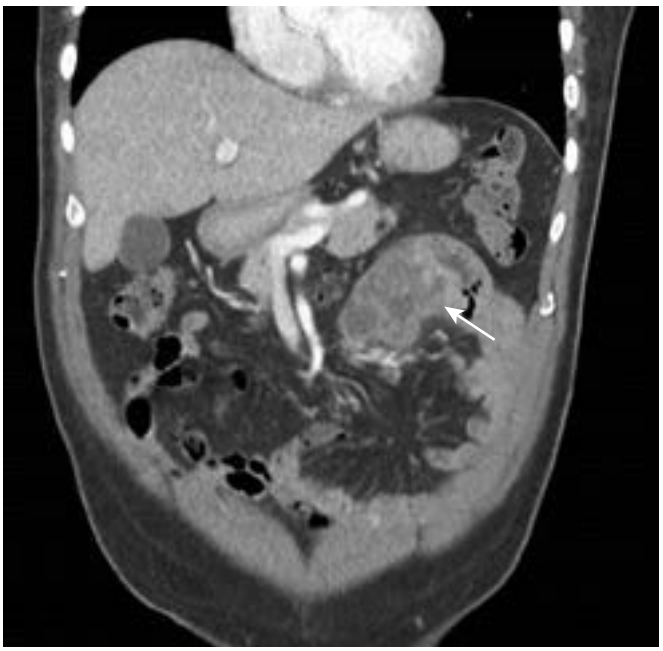

FIG. 1 Adenocarcinoma in the fourth portion of duodenum *(arrow)*.

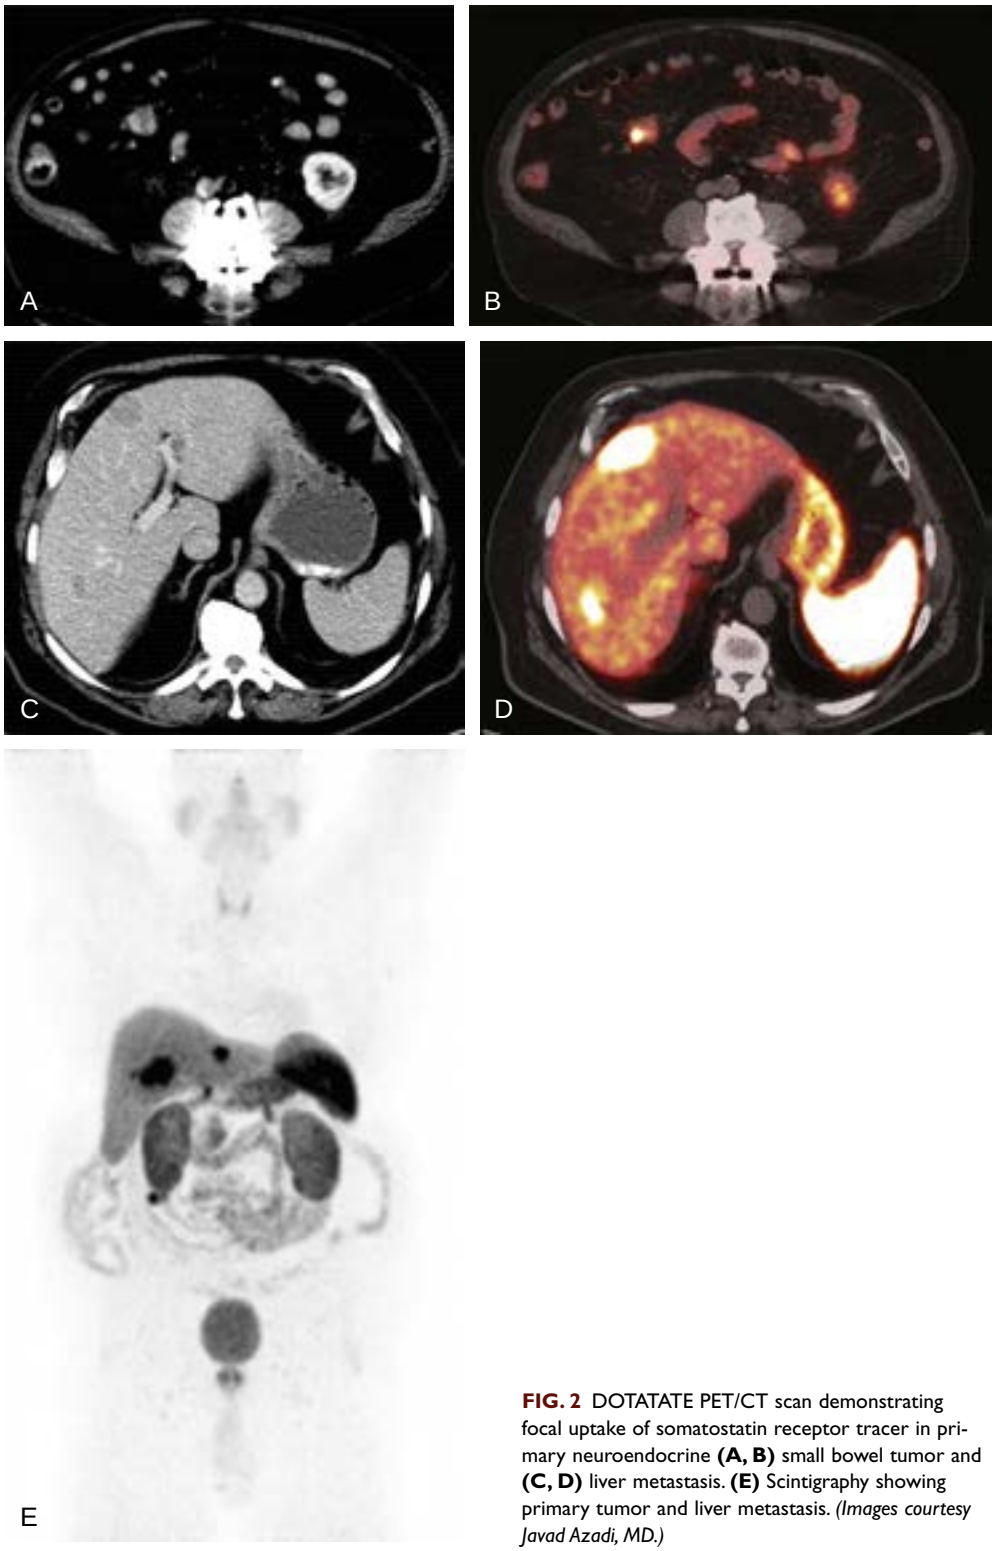

FIG. 2 DOTATATE PET/CT scan demonstrating focal uptake of somatostatin receptor tracer in primary neuroendocrine **(A, B)** small bowel tumor and **(C, D)** liver metastasis. **(E)** Scintigraphy showing primary tumor and liver metastasis. *(Images courtesy Javad Azadi, MD.)*

but in the discussion of small bowel tumors is limited to evaluation of duodenal lesions. For more distal evaluation, balloon-assisted deep enteroscopy or push endoscopy techniques can be performed by expert gastroenterologists and allow for visualization of most or even all of the small bowel lumen. This, however, is only rarely employed and only available in specialized centers. Video capsule endoscopy (VCE) also affords the ability to evaluate the mucosal surface of the entire small bowel, with an average of 30,000 images captured in the small bowel alone during an examination. With the assistance of neural networks and machine learning, the interpretation of these studies is becoming more sensitive and specific, making them an increasingly helpful tool for the investigation of small bowel tumors. VCE does not allow for tissue diagnosis and is contraindicated in patients with obstructive symptoms.

MANAGEMENT

Benign

Several types of benign small bowel neoplasms exist, and all are quite rare. Adenomas can be categorized as either villous, tubular, or Brunner's gland associated. As in colorectal cancer, some adenomas have malignant potential. There are no firm guidelines regarding management of these masses, but conventionally, the colorectal cancer pathway is followed with endoscopic resection if possible. Adenomas have increased malignant potential when associated with FAP. The number, size, histology, and dysplastic characteristics of the polyps should guide management using the Spigelman classification.

Surgical resection is warranted for large adenomas that are not amenable to endoscopic resection, particularly if biopsy reveals villous features. Additionally, patients should be screened for synchronous colorectal lesions with colonoscopy.

Leiomyomas are small tumors that are present in the submucosa of the small bowel. They are routinely small, firm, and well circumscribed. While they may cause obstruction and require resection for this reason, their presence alone is not an indication for surgery. Differentiating between leiomyosarcoma and leiomyoma can be difficult, and often these lesions are surgically resected to rule out malignant disease.

Lipomas are diagnosed relatively easily on CT due to their characteristic fatty density. Hamartomas associated with PJS should be resected only if causing bleeding or obstructive symptoms. In addition to lipomas and hamartomas, fibromyxomas and ganglioneuromas do not require resection, although biopsy may be necessary for diagnostic confirmation. Hemangiomas can be present along the length of the small bowel. Fortunately, these are easily differentiated on CT with IV contrast or magnetic resonance (MR) enterography obviating the need for biopsy.

Malignant

Malignant tumors of the small bowel are rare, with an estimated 10,470 cases and an estimated 1450 mortalities in the United States in 2018. Small bowel cancer comprises only 1% to 2% of GI malignancies. Because of the rarity of these cases and available retrospective data, there are very few guidelines available even worldwide for treatment of small bowel malignancy, and those are routinely derived from expert opinion based on analogous management of colon cancer. For this reason, each case should be evaluated on an individual basis and overseen by a multidisciplinary oncology team including a surgical oncologist.

Neuroendocrine Tumors

Derived from enterochromaffin cells, known as Kulchitsky cells, NETs are found throughout the crypts of Lieberkühn and are the most common small bowel tumor. They are histologically characterized by cytoplasmic core granules most commonly containing chromogranin A, synaptophysin, and neuron-specific enolase (Fig. 3). They often have the capacity to secrete clinically relevant vasoactive monoamines, peptides, and hormones. Neuroendocrine tumors are commonly referred to as carcinoid tumors and are the most common tumors of small bowel, accounting for more than 20% of the malignant tumors in the small bowel. Although small bowel NETs are often incidentally identified, many individuals present with advanced disease. At presentation, 40% of individuals will have multifocal tumors >2 cm, 70% will have invasion into the muscularis propria and regional lymph nodes, and 50% will have liver metastasis. Five-year cancer-specific survival in local staged small bowel NETs is 95%; however, with nodal and distant disease, this falls to 84% and 51%, respectively, with an overall survival of 32% in individuals with distant disease. Well-differentiated NETs are characterized as grade 1 to 3 based on Ki-67 index (%) and mitotic index/10 high-powered field (Table 1). GI NETs can occur anywhere in the GI tracts; however, 35% to 45% of them occur in the small intestine, and most are found within 60 cm of the ileocecal valve. On CT scan, carcinoid lesions are hyperenhancing in contrast to adenocarcinomas that are only moderately enhancing. They tend to extend through the serosa and can cause foreshortening of the mesentery secondary to a desmoplastic reaction. Frequently, the primary small bowel lesion is not visualized on imaging, and the presenting finding is bulky mesenteric adenopathy.

The regional spread of carcinoid tumors necessitates en bloc resection of the mass and mesentery, including an extensive lymphadenectomy, which is often more amenable to an open exploration (Fig. 4). During the operation, it is important to inspect for multicentric disease and liver metastases. However, even if these are present, it is still recommended to resect the primary lesion both for local control and longevity. Evidence indicates that 90% of the disease burden should be removed to yield the most durable symptomatic improvement, so any disease that seems resectable should be targeted at the time of surgery. In patients with liver metastasis, occasionally a staged approach to resection is implemented. Operative manipulation of carcinoid tumors has been associated with hemodynamically significant surges in vasoactive peptides known as carcinoid crisis, which is generally managed with high-dose somatostatin analogues in addition to hemodynamic stabilization. There is mixed evidence supporting the use of prophylactic somatostatin analogues for the prevention of carcinoid somatostatin crisis, and the practice varies substantially among surgeons and institutions. For duodenal carcinoid, endoscopic resection may be possible for small lesions. Anterior wall duodenal lesions may be directly excised with laparoscopic or open surgery. For select posterior lesions, local excision through an anterior duodenotomy to expose the posterior wall is an excellent approach. When both an anterior and posterior duodenotomy are performed, a gastrojejunostomy is recommended to avoid obstruction from narrowing of the duodenum. A Fogarty balloon, introduced through the gallbladder or cystic duct and passed proximally through the ampulla, can provide guidance during resection of tumors in the second portion of the duodenum. A cholecystectomy is then performed. This avoids opening the common bile duct. If the tumor is too close to the ampulla to be safely resected, a pancreaticoduodenectomy may be the only recourse.

Typical small bowel carcinoid resection removes 1 to 2 feet of small bowel, with wide lymphatic mesenteric clearance. The mesenteric involvement of this disease is often underestimated and can be misleading, necessitating more bowel resection than originally anticipated in some cases. It is imperative that patients are counseled about the risks of extensive resection preoperatively. Cases in which there is extensive involvement of small bowel mesentery require careful deliberation, and in some cases, leaving mesenteric disease behind is a disconcerting but necessary consideration to avoid short-gut syndrome. The authors would like to emphasize that while extensive resection should be considered for debulking symptomatic, multifocal, or metastatic disease, the consequences of a near-complete enterectomy, if less than 120 cm of small bowel remained, certainly outweigh the benefits of resection for these cases. Similarly, if the disease is extensive but relatively asymptomatic, with heavy mesenteric involvement to the root, the OR may best be left out of the treatment plan and systemic medical treatment with a somatostatin analogue is warranted.

Both multiple endocrine neoplasia type I (MEN1) and neurofibromatosis predispose patients to small bowel NETs; however, these occur primarily in the foregut, presenting as gastrinomas or somatostatinomas. The diagnosis and management of individual NETs is discussed elsewhere in this textbook.

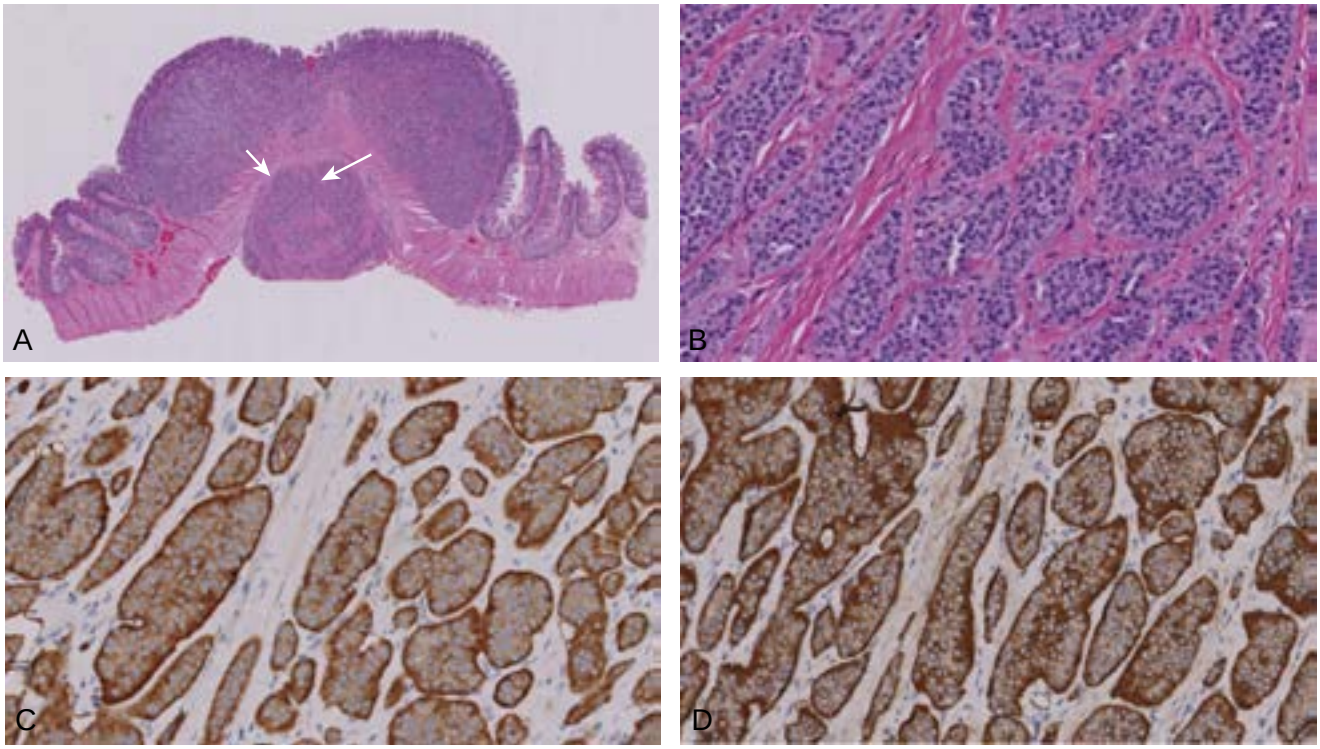

FIG. 3 Histology of NET. **(A, B)** Small bowel serosal invasion with surrounding normal small bowel mucosa (H&E, 2× and 20× magnification). **(C)** Synaptophysin (20× magnification). **(D)** Chromogranin (20× magnification). *(Images courtesy Neil Neumann, MD, PhD, and Sarah Umetsi, MD, PhD.)*

Adenocarcinoma

More than a third of small bowel cancers are adenocarcinoma and occur primarily in the duodenum. Unfortunately, because they are relatively asymptomatic until they are large enough to be obstructive or cause clinically evident bleeding, more than half of these tumors present at advanced stages, a third with nodal spread, and a quarter with distant metastases. Because of this, the 5-year survival following diagnosis is only 20% to 40% in most cases. Surgical resection is the mainstay of therapy, with a segmental resection and accompanying wide local excision of the mesentery to collect the nodal basin (Fig. 5). For those at the terminal ileum, an ileocolectomy should be performed. For duodenal lesions at the ampulla, a pancreaticoduodenectomy is necessary.

For unresectable primary disease, it is reasonable to perform a palliative surgical bypass of the obstructive lesion. Palliative radiation for unresectable disease is usually not beneficial. Clinical trials are ongoing to improve local and systemic control of unresectable disease, and surgeons are encouraged to help patients seek out these resources if possible.

GIST

Mesenchymal tumors such as GISTs are most often found in the stomach (>50%) but also develop in the small bowel, with 25% in the jejunum. Derived from the interstitial cells of Cajal, they comprise approximately 10% of small bowel tumors. About 20% to 30% of GISTs are malignant at presentation, more often malignant when involving the small bowel. On CT scan, they appear as smooth, well-defined masses arising from the small bowel wall demonstrating exophytic growth patterns and internal heterogeneity. They may have areas of central hemorrhage or necrosis (Fig. 6). GIST rarely metastasize to nodes or spread outside of the abdominal cavity but can be aggressive. Metastases to the liver can present with multiple serosal-based nodules. The primary lesions are known for causing ulceration through the mucosa, presenting with bleeding. GIST can be differentiated from other sarcomas of smooth muscle by immunostaining for c-KIT. Activating mutations of the KIT oncogene can be seen in over 80% of GISTs. CT-guided biopsy is usually not necessary as radiographic appearance is distinctive and resection is indicated.

A laparoscopic approach for resection of GIST is often ideal. These tumors are exophytic, making them easier to locate than other small bowel tumors during laparoscopic exploration, and as they do not spread via lymphatics, lymphadenectomy is not required. A short segmental enterectomy with only 2 cm margins is recommended. If the tumor is bulky or adjacent organ involvement is suspected, preoperative imatinib can aid in shrinking the mass to facilitate resection. Unfortunately, more than 50% of these masses recur within 5 years. To prolong disease-free survival, high-risk patients should be treated postoperatively with a minimum of 12 to 24 months of imatinib, and studies are ongoing regarding longer or even indefinite treatment to prevent recurrence. High-risk features include tumor size >2 cm, high mitotic index, poorly differentiated cell type, presence of metastasis, and positive margin.

Sarcoma

Sarcoma, typically leiomyosarcoma, is rare, occurring most often in the ileum. Five-year survival is approximately 50%. Radical surgical excision is recommended if the primary disease is resectable. Similar to adenocarcinoma, if the disease is deemed unresectable, surgical bypass should be considered. Palliative radiation has a greater role in sarcoma management compared with other small bowel tumors.

Lymphoma

The small bowel is the most frequently encountered extranodal site for lymphoma. This tumor is usually non–Hodgkin-type lymphoma and involves the small bowel mesentery more commonly than the luminal surface. It is most common in the ileum, the most lymphoid-rich region of the small bowel. Clinicians should maintain a high suspicion for other sites of involvement, as a solitary small

FIG. 7 Small bowel lymphoma.

intestinal lesion is a rare presentation for lymphoma. Patients with Celiac disease have a 20-fold higher risk of GI lymphoma, and patients with chronic immunosuppression including transplant recipients and those with HIV are also at an increased risk. On CT with IV contrast, the mass often appears well circumscribed and homogeneous (Fig. 7).

A tissue diagnosis is required for lymphoma, and as there are a variety of non-Hodgkin subtypes, it is imperative that enough tissue is harvested to perform the full battery of cytopathology and flow cytometry. The subtype dictates the tumor behavior, treatment, and prognosis. Most small bowel lymphomas do not require resection and rather are best treated with multidrug chemotherapy. The 5-year survival is 50%, with poorer prognosis in males and the elderly. Surgery may be necessary for obstruction, or the diagnosis of lymphoma may be made postoperatively after surgical intervention for small bowel obstruction (SBO) has already taken place. In patients without signs and symptoms of SBO, CT-guided or endoscopic biopsy is appropriate to guide therapy. Indeed, the main role of biopsy in small bowel tumors is to distinguish lymphoma, as most other small bowel masses require resection as the primary management.

Metastatic Disease

Secondary involvement of the small bowel from other metastatic lesions presents as multifocal advanced cancer and not as an isolated small bowel lesion. Lung, melanoma, breast, colon, and cervical cancers can all spread to the small bowel. Sarcomas and adenocarcinomas can also impact the small bowel, either through direct erosion or carcinomatosis of overlying peritoneum. As an innocent bystander, the small bowel may need to be resected or bypassed depending on the type and stage of primary tumor.

SUMMARY

Small bowel tumors are rare and present with a constellation of common symptoms. Late diagnosis makes the prognosis of small bowel malignancy particularly poor, and a thorough workup to rule out small bowel tumors should be undertaken in anyone with vague abdominal pain and paraneoplastic symptoms with no other apparent source. Aside from small bowel lymphoma, most other suspicious small bowel masses do not require biopsy and should be resected. Nuanced management of these malignant lesions has room for investigation, and surgeons should feel compelled to lead efforts to discover optimal treatment paradigms and create guidelines.

Small Bowel Diverticulosis

Jonathan B. Greer, MD

INTRODUCTION

Although small bowel diverticulosis is a rare clinical entity, all general surgeons should be comfortable with its diagnosis and management. The true prevalence is unknown, but a busy practitioner will frequently encounter these in clinical practice. Less than 4% of all small bowel diverticula will become overtly symptomatic. The duodenum is the most common site, while Meckel's diverticula are the most well-known. Small bowel diverticula can be congenital or acquired. These can be classified as either true or false, based on whether all three walls of the bowel are involved. Meckel's diverticula are the most well-known true diverticula of the small bowel. They are further classified by location (duodenal or jejunoileal), but they are best delineated by those that are asymptomatic and therefore incidentally detected versus those that present with clinical symptoms (usually bleeding or diverticulitis) and rarely as a cause of obstruction or perforation. Many manuscripts have been published on this topic, mostly single-center studies or case reports. There is a paucity of high-level evidence, however. Nonetheless, improvements in both axial imaging and advanced endoscopic techniques will likely lead to the increased detection of small bowel diverticulosis over time. This chapter will review the diagnosis and management of this clinical entity.

DETECTION AND MANAGEMENT OF ASYMPTOMATIC (INCIDENTALLY DISCOVERED) SMALL BOWEL DIVERTICULOSIS

The increasing frequency of high-quality cross-sectional imaging and endoscopic procedures has led to an increase in the detection of asymptomatic small bowel diverticulosis. However, this has not led to an increase in symptomatic cases. There are three principal groups of asymptomatic small bowel diverticula: duodenal, jejunoileal, and Meckel's diverticula, a subset of jejunoileal diverticula that are always congenital and true diverticula.

Duodenal Diverticula

The most common diverticula of the small bowel are duodenal diverticula, comprising 45% to 79% of cases. In terms of prevalence, a true number is difficult to ascertain, but these have been reported in 2% to 5% of upper gastrointestinal contrast studies, 7% of endoscopic retrograde cholangiopancreatography, and as high as 20% in one autopsy series. The only known risk factor is age. Duodenal diverticula are most commonly located in the second portion of the duodenum (60% to 95% of cases). They are much more commonly asymptomatic. These can be congenital or acquired, and extraluminal or intraluminal. The vast majority are acquired and extraluminal. The mechanism is thought to relate to weakness of the bowel wall where perforating vessels are found. There are rare congenital duodenal diverticula that are intraluminal, called *windsock diverticula,* and are lined with duodenal mucosa on the entirety of the diverticulum, both inside and outside, from a failure of canalization of the embryonal foregut.

Diagnosis is made by the discovery of an outpouching of the duodenum on cross-sectional imaging, fluoroscopic contrast studies, endoscopy, or at the time of an abdominal operation. Though duodenal diverticula can be quite large, asymptomatic diverticula are, by definition, asymptomatic; therefore, no treatment is required. Particularly in cases that would require a pancreaticoduodenectomy, surgical resection is associated with significant morbidity and therefore is not recommended for an incidentally discovered diverticulum.

Jejunoileal Diverticula

Jejunoileal diverticula are less common than duodenal diverticula, comprising less than 20% of small bowel diverticulosis in most series, although they are more likely to cause complications than their duodenal counterparts. The actual prevalence is unknown, but autopsy series have reported a prevalence as high as 7%. The vast majority are asymptomatic. These can be single or multiple, with 80% in the jejunum, 15% in the ileum, and 5% found in both. False diverticula are the most common. These are likely caused by the gradual weakening of the wall of the intestine from increased intraluminal pressure that can be generated by dysfunction of the migrating motor complexes. As such, age is the most widely reported risk factor. Other risk factors include intestinal dysmotility disorders. The most common location is the proximal jejunum, and these are frequently multiple.

Jejunoileal diverticula can be discovered on laparotomy, although they are commonly also diagnosed on radiographic or endoscopic studies. Enteroclysis is the best radiographic study to evaluate jejunoileal diverticula, though CT and MR enterography are increasingly used as techniques improve. Capsule endoscopy may be useful as well. There is no role for the surgical management of incidentally discovered jejunoileal diverticula.

Meckel's Diverticulum

Meckel's diverticula are the most common congenital diverticula of the small bowel and account for 25% of small bowel diverticula (Fig. 1). A prevalence estimate in an autopsy study was 1.23%.

FIG. 1 Common presentation of a Meckel's diverticulum projecting from the antimesenteric border of the ileum. *(From McKenzie S, Evers BM. Small intestine. In: Townsend CM Jr, ed. Sabiston Textbook of Surgery. 19th ed. Philadelphia: Elsevier; 2012.)*

They are, by definition, true diverticula of the ileum and represent a remnant vitelline (omphalomesenteric) duct that connects the embryonic midgut to the yolk sac. This duct is normally obliterated during embryologic development. As a true diverticulum, it involves all three layers of the bowel wall and is always antimesenteric. The classic "rule of two" for Meckel's diverticula is thus: They are located approximately 2 feet from the ileocecal valve, contain two types of heterotopic tissue (gastric or pancreatic), occur twice as commonly in males, in 2% of the population, are symptomatic in about 2% of cases, tend to be diagnosed within the first 2 years of life, and can extend over 2 inches in length. Additionally, there are two types of symptoms that can arise: bleeding and obstruction.

Given their small size, most asymptomatic Meckel's diverticula are discovered during surgery for another indication. They are less frequently found on axial imaging. Meckel's diverticula have a low lifetime risk of complications related to the diverticula itself, and mortality is extremely rare. Therefore, in most cases, there is no compelling indication for surgical resection of an incidentally discovered Meckel's diverticulum in an adult. Some authors advocate for prophylactic resection in children, and in adults in cases of palpable ectopic tissue, prior history of diverticulitis, hemorrhage, intussusception, or the presence of a mesodiverticular band. This is in contradistinction to the management of clinically significant Meckel's diverticula, which will be discussed later in this chapter.

DETECTION AND MANAGEMENT OF SYMPTOMATIC SMALL BOWEL DIVERTICULOSIS

The minority of small bowel diverticula present with clinical manifestations, which can be infection (diverticulitis), bleeding, or obstruction. Unlike the incidentally discovered and therefore asymptomatic versions, symptomatic small bowel diverticula require treatment.

Duodenal Diverticula

Only about 5% of patients with duodenal diverticula present with complications. The most commonly reported symptom is postprandial epigastric abdominal pain, which can be associated with nausea and vomiting. Obstruction from a duodenal diverticula is quite rare but can occur, particularly in cases in which the diverticula is large. This can result in extraluminal compression of the duodenum. There can also be extrinsic compression of the biliary tree or pancreatic duct, thus resulting in a rare cause of obstructive jaundice or recurrent pancreatitis. More commonly, infectious complications may develop, such as diverticulitis +/– abscess, perforation, and rarely, fistula. Bleeding may also occur secondary to diverticulitis as inflammatory erosion into a neighboring vessel may result in fairly significant bleeding, with hematemesis and melena as the presenting signs.

After initial nasogastric tube decompression for duodenal obstruction, diagnosis of a duodenal diverticula as the underlying cause is usually one of exclusion, as a malignancy would be far more common. This diagnosis can be made by axial imaging, usually CT, although an upper gastrointestinal contrast study may also be helpful. These can be challenging in an obstructed patient. In conjunction with these radiographic studies, endoscopy is necessary to rule out mucosal-based lesions as the etiology. In cases of biliary tree or pancreatic duct obstruction from duodenal diverticula, axial imaging (CT or MRI) in concert with endoscopy, including ERCP, are essential to make the diagnosis. Duodenal diverticulitis will usually be diagnosed on CT with characteristic findings similar to the vastly more common colonic diverticulitis. CT angiography may be necessary to identify a bleeding vessel related to a duodenal diverticula, although endoscopy may also be helpful. The patient's clinical condition should dictate whether purely diagnostic studies (e.g., CT angiography or endoscopy) can be safely done, rather than diagnostic and therapeutic modalities, such as mesenteric angiography in interventional radiology.

Management of duodenal diverticulosis in the asymptomatic patient is straightforward (nothing to do) but can be more nuanced in symptomatic patients and varies greatly with the clinical scenario. The rare case of duodenal obstruction secondary to a duodenal diverticula may require surgical intervention. This may include resection of the diverticula alone with transverse closure of the duodenum, use of a serosal small bowel (Thal) patch, a Roux-en-Y duodenojejunostomy, or potentially a segmental duodenal resection. Assessment of the anatomic relationship between the ampulla of Vater and the line of transection is crucial for segmental resection of the duodenum. Involvement of the medial side of the duodenum that results in obstruction will require a pancreaticoduodenectomy. The more common case involving biliary or pancreatic obstruction should be temporized first via endoscopic means, usually with stenting. Surgical resection, which would be a pancreaticoduodenectomy, should be reserved for patients who fail endoscopic management. As with all complex hepatobiliary procedures, surgeon familiarity and comfort with these techniques along with well-delineated anatomic relationships between the duodenal diverticula and important neighboring structures is critical. Most cases of duodenal diverticulitis, even with contained perforation, can be managed conservatively with nil per os, placement of a nasogastric tube, antibiotics, and occasionally percutaneous drainage. Surgical management in the acute setting is almost never indicated and can be quite challenging. Bleeding duodenal diverticula are managed similar to other causes of upper gastrointestinal bleeding, either via endoscopy or interventional radiology. Surgical management is rarely indicated.

Jejunoileal Diverticula

Symptomatic false jejunoileal diverticula are rare, but about 10% of all jejunoileal diverticula will become symptomatic. Patients can present with nonspecific symptoms such as abdominal pain, early satiety, bloating, and malabsorption (diarrhea and/or steatorrhea) secondary to small intestinal bacterial overgrowth (SIBO). The complications that can arise and therefore lead to detection are diverticulitis, bleeding, obstruction, or perforation. The clinical presentations associated with each of these complications are similar to their large bowel counterparts, although the pain is typically epigastric or periumbilical in location. Cross-sectional imaging is the most common means of detection as these patients will usually present with abdominal pain or melena.

SIBO is treated with antibiotics. The treatment of jejunoileal diverticulitis is identical to that of colonic diverticulitis: bowel rest, intravenous fluids, and antibiotics. Surgical intervention is not always needed, particularly in isolated cases. Recurrent or complicated episodes may mandate segmental resection, although rare. Management of perforated jejunoileal diverticula depends greatly on the condition of the patient. Conservative management may be appropriate in cases in which the perforation has walled off and the patient is minimally symptomatic. Conversely, critically ill patients warrant urgent exploration and segmental resection. Enterocutaneous fistulae secondary to jejunoileal diverticulitis have been reported. A bleeding jejunoileal diverticulum can be found on push or double-balloon enteroscopy or on capsule endoscopy, and it should be considered in cases of gastrointestinal bleeding in which both esophagogastroduodenoscopy and colonoscopy are negative. Endoscopic management of bleeding can be difficult, and interventional radiology angioembolization is not typically attempted. After a trial of conservative management, surgical intervention is warranted. Small bowel obstructions secondary to jejunoileal diverticula are managed like adhesive small bowel obstructions. Resection of the diverticula would be warranted in cases of failure of conservative management. An uncommon clinical scenario is bowel obstruction secondary to an impacted fecalith. These can be treated surgical by enterotomy and stone extraction.

Meckel's Diverticula

The risk of a complication that leads to discovery of a Meckel's diverticulum is estimated to be in the 2% to 6% range. The most common mechanism of a symptomatic Meckel's diverticulum is thought to relate to acid production by heterotopic gastric mucosa within the diverticulum leading to ulceration. The symptoms/complications that can arise are bleeding, obstruction, or abdominal pain. These usually occur in the pediatric population. The relative proportion of each of these findings is not fixed, but one single-center series of known Meckel's diverticula in pediatric patients had 19% discovered incidentally, whereas the remaining patients presented with the following: 35% gastrointestinal bleeding, 20% diverticulitis or perforation, 14% obstruction, and 12% intussusception.

Gastrointestinal bleeding that is caused by a Meckel's diverticulum may be acute or chronic. It is frequently associated with heterotopic gastric mucosa, much more so than an asymptomatic Meckel's diverticulum. The suspicion of a bleeding Meckel's diverticulum should be higher in young patients with no evidence of an inflammatory explanation for the bleeding, such as infectious illnesses or inflammatory bowel disease, or in adults <30 years of age in whom an exhaustive workup for gastrointestinal bleeding is otherwise negative. Algorithms for gastrointestinal bleeding should be followed in the appropriate clinical setting. A Meckel's scan, which is a scintigraphic study, or mesenteric angiography may localize the Meckel's diverticulum as the source of the bleed, as can advanced endoscopic techniques such as double-balloon or capsule endoscopy (Fig. 2). CT angiography has been shown to play an increasing role as a sensitive test, but in a young, hemodynamically stable patient, the Meckel's scan is the test of choice as it will detect heterotopic gastric mucosa in 85% to 97% of cases. Rarely, if all other studies are negative, in the setting of ongoing bleeding leading to hemodynamic compromise, surgical exploration may be warranted to exclude a bleeding Meckel's diverticulum.

There are multiple mechanisms by which a Meckel's diverticulum can lead to a small bowel obstruction, including hernia formation. In

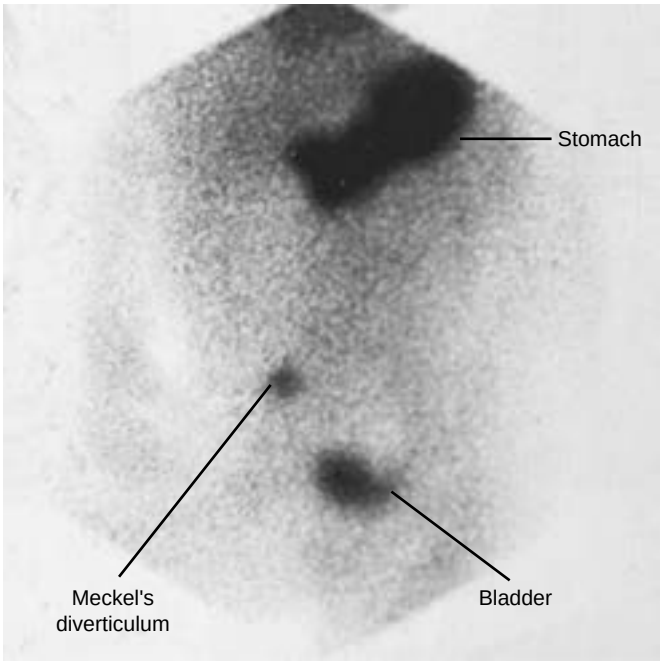

FIG. 2 Technetium-99m pertechnetate scintigram from a child with a Meckel's diverticulum clearly differentiated from the stomach and bladder. *(From McKenzie S, Evers BM. Small intestine. In: Townsend Jr CM, ed. Sabiston Textbook of Surgery. 19th ed. Philadelphia: Elsevier; 2012.)*

children, volvulus and intussusception can occur, whereas these are rare in adults. Symptoms are similar to non–Meckel's-related small bowel obstruction. Diagnosis can be made by CT scan, but often it is made at exploration.

Diverticulitis or perforation secondary to a Meckel's diverticulum will lead to abdominal pain and tenderness on physical examination. Although the location of tenderness secondary to Meckel's diverticulitis may be variable, perforation will lead to lower abdominal tenderness.

The treatment of a clinically significant Meckel's diverticulum is first to address the clinical scenario in a standard fashion. For example, in the case of a bowel obstruction secondary to a Meckel's diverticulum, nasogastric tube decompression and volume resuscitation are the first steps. Following this, surgical resection should be undertaken. Surgical resection can be either via a diverticulectomy or segmental bowel resection and reconstruction. A segmental resection is recommended in cases in which the base of the diverticulum is broad or there is a palpable abnormality. Furthermore, in bleeding secondary to a Meckel's diverticulum, segmental resection is recommended because the ulcer is commonly on the mesenteric side of the ileum, sometimes downstream of the diverticulum. Some authors advocate for appendectomy at the time of operation for a symptomatic Meckel's diverticulum so as to avoid diagnostic dilemmas in the future.

Diagnosis and Management of Motility Disorders of the Stomach and Small Bowel in the Current Era

Omar M. Ghanem, MD, and Michael G. Sarr, MD

INTRODUCTION

Unlike in the duodenal ulcer/vagotomy era of the 1950s–1980s, motility disorders of the upper gut are currently quite uncommon. When present, this spectrum of disorders is difficult to both diagnose and treat effectively. To suspect these disorders, it is necessary to understand the overall control of motility of the stomach and small bowel; thus, we will present a very brief review of the physiology of motility.

In brief, the contractile activities of the stomach and small intestine are controlled by the enteric (autonomic) neuromuscular system in the wall of the gut. This is important to remember, because the extrinsic innervation to the gut (parasympathetic/vagal nerves and sympathetic/paravertebral nerves) do not control or initiate motility; but rather, they can only influence motor patterns as can some hormones. Basically, contractile activity is generated by spontaneously active neuromotor cells within the wall of the gut. When the stomach and small intestine are completely separated from the central nervous system (as after a small intestinal transplantation), relatively normal motility still occurs.

Contractile activity has two basic patterns, one during fasting (the so-called interdigestive period) and another after feeding (the postprandial period). Also, all contractile activity is oriented in a distal, downstream direction of propagation that leads to distal transit of ingested foods.

The stomach and small intestine, however, do differ in their contractile patterns. During the interdigestive period when there is no food ingested, the stomach and small intestine cycle through a recurrent pattern of intense contractions that travel peristaltically but only up to about 30 cm; this band of contractions begins in the stomach and then moves slowly down the small intestine over about 90 minutes. These contractions are of very high amplitude to clear the lumen of undigested food and debris. In contrast, during the postprandial period after ingestion of food, the contractile patterns

maximize contact of ingested foodstuffs with the mucosa. In the stomach, the contractile pattern mixes and mechanically breaks down (triturates) the bigger food particles to maximize digestion (indeed, larger food particles do not leave the stomach during this period, because the so-called antropyloric pump controls the size of the pylorus to only allow food particles <1 cm to leave the stomach), while the small intestine slows transit through the gut to maximize absorption.

Although we talk about "peristalsis" of the gut, the contractions of the stomach and small intestine do NOT peristalse as does the esophagus, where a contraction that starts in the proximal esophagus propagates down the entire length of the esophagus in a very orderly, peristaltic fashion (indeed the motor activity of the esophagus is designed only to transport food into the stomach). In contrast, the stomach and the small intestine are designed to move content distally but in doing so to maximize digestion and absorption.

Contractile activity of the stomach differs considerably from the esophagus, and understanding these differences is absolutely crucial to diagnose gastric motility disorders. The proximal and distal stomach have different contractile activity with the proximal stomach controlling emptying of liquids and the distal stomach the emptying of solids. The proximal stomach has a nonphasic, slow continuous tonic activity that gradually relaxes the proximal stomach increasing its volume for the ingestion of food, the so-called vagally mediated "receptive relaxation" that allows that full plate of spaghetti we eat to enter the large volume reservoir of the proximal stomach. Later, the proximal stomach slowly contracts tonically, thereby decreasing the volume reservoir, increasing intraluminal pressure, and leading to gastric emptying of liquids. In contrast, the mid to distal stomach has definite physic contractions (2–4 per minute) that arise from a pacemaker region in the mid stomach (similar in principle to the pacemaker in the heart). These contractions then propagate in a peristaltic manner distally from the distal mid stomach to the antrum and down to the pylorus. Why is this important to understand? Nearly all current motility disorders of the stomach are related to injuries of the vagus nerves that control both the relaxation of the proximal stomach (emptying of liquids) as well as modifying the coordination of contractions of the distal stomach with the pylorus (emptying of solids).

The small bowel also has a pacemaker region in the proximal duodenum that drives the rate and distal direction of contractions in the small bowel. But peristalsis as we know it in the esophagus is NOT present in the small bowel despite our use of the term "peristalsis" of the small bowel. Although contractile activity is phasic (6–12 per minute) and always oriented distally, the length over which a true peristaltic contraction migrates after a meal is only 5 to 10 cm, leading to the small areas that tend to move content distally but only for a short distance; this pattern of contractions leads to a segmenting appearance that we readily see on contrast fluoroscopy. This pattern increases contact of luminal content with the mucosa, slows transit, and increases absorption. Control of this activity is not vagally dependent, but the sympathetic system does have modulatory effects (primarily inhibitory) on small intestinal contractions as evidenced both by postoperative ileus (POI) and especially by the condition of adynamic ileus that can occur with retroperitoneal trauma, infection, or "irritation." (We will expand on this later.)

In summary, most true gastric motility disorders that currently occur are related to inadvertent operative injury to the vagus nerves or vagal neuropathies, whereas small intestinal motility disorders are much less common and are related either to congenital/hereditary abnormalities in the enteric nervous system or to sympathetic neural effects.

MOTILITY DISORDERS OF THE STOMACH

In our current era, objective dysmotility of the stomach (with either documented delayed gastric emptying or dumping with accelerated gastric emptying) occurs more typically after upper gut operations that purposely or inadvertently cut or injure the vagus nerves or occur as a result of damage to the vagus nerves (neuropathy) from chronic illness, such as poorly controlled diabetes. Surgeons see gastric dysmotility most often after operative interventions that disrupt vagal nerve function, such as after a gastrectomy, after an esophagectomy that necessitates transection of the vagus nerves, or after a hiatal herniorrhaphy that injures the branches of the vagus nerves at the esophageal hiatus. In the past when duodenal ulcer operations centered around a truncal vagotomy, the loss of vagally mediated receptive relaxation of the proximal stomach leads to rapid emptying of liquids leading to dumping syndrome and/or disruption of emptying of solids. Less commonly, after creating a Roux-en-Y limb to drain the gastric remnant or the esophagus, gastric emptying can be delayed. The obligate transection of the jejunum disrupts myoelectric continuity (which controls orderly coordination of contractions) of the Roux limb with the duodenal pacemaker; this leads to erratic, noncoordinated contractions in the Roux limb with some contractions actually going upstream, thereby delaying gastric emptying (the so-called Roux stasis syndrome). There is also a spectrum of idiopathic gastroparesis syndrome that usually occurs in young females that is poorly understood and is often not associated with any objective delay in gastric emptying; yet because of the symptoms, this has been termed "gastroparesis-like syndrome." Overall, true gastric motility disorders involve either delayed emptying (mild or severe gastroparesis) or too rapid emptying (dumping).

When functioning normally, the proximal stomach is responsible for vagally mediated relaxation (receptive relaxation) to accommodate the entry of solids and liquids by providing a reservoir necessary for temporary storage and the start of enzymatic and mechanical breakdown of the ingested content. This relaxation is mediated by the vagus nerves. In addition, some protein and fat digestion in the stomach begins by way of pepsin and hydrochloric acid; the presence of amino acids in the duodenum will lead to hormonal signaling that causes a slow tonic contraction of the proximal stomach. This tonic contraction increases the intraluminal pressure in the proximal stomach, thereby leading to emptying of chyme into the duodenum. In contrast, fats in the duodenum can slow gastric emptying by prolonging the relaxation of the proximal stomach. Gastric emptying mediated by the enteric nervous system can be disrupted by surgical procedures as previously listed. Little is known about specific causes that lead to altered gastric emptying after gastroesophageal surgery, but it appears to be multifactorial. The surgical process itself, in addition to patient-related factors, such as the presence of diabetes, hypothyroidism, chronic narcotic use, or cancer, can contribute to this process. As aging occurs, the rate of gastric emptying decreases, so older patients are more susceptible to this syndrome. This section focuses on motility disorders after surgical interventions, postsurgical gastroparesis syndrome, and rapid gastric emptying. There is also a separate section on gastroparesis-like syndrome.

Delayed Gastric Emptying/True Gastroparesis

Although uncommon, delayed gastric emptying can occur after operations on the distal esophagus or stomach that include a known or inadvertent vagotomy, Roux-en-Y gastrojejunostomy, or even after an antireflux procedure. The risk of delayed gastric emptying after a gastrectomy that includes a truncal vagotomy increases twofold and can plague patients undergoing a classic pancreatoduodenectomy (which includes an antrectomy) with the Roux-en-Y reconstruction with a rate of up to 30%. The exact causes are unknown, but certainly vagus nerve dysfunction is a key contributor as is the disruption of the continuity of the proximal jejunum with the duodenal pacemaker after duodenal resection leading to incomplete emptying or gastric stasis. Truncal vagotomy causing the disruption of afferent vagal signaling to the brain also may lead to stasis or even gastric atony.

Clinical Presentation and Diagnosis

Symptomatically, patients found eventually to have an objective delay in gastric emptying (i.e., true gastroparesis) and not the

gastroparesis-like syndromes (see later, Gastroparesis-Like Syndromes) often describe epigastric fullness or pain and complain of early satiety that may or may not be accompanied by nausea and vomiting, usually of solids more than liquids. Look for delayed vomiting of undigested food, hours or even the day after ingestion of the solid food; this delayed vomiting of undigested food is virtually pathognomonic of gastroparesis provided there is no mechanical gastric outlet obstruction. Liquid intake will be better tolerated than solids but may be limited by early satiety, anorexia, or the inability to ingest enough calories because of symptoms of gastric fullness; this situation can be severe enough that patients may develop dehydration, weight loss, or malnutrition.

A detailed history is necessary to evaluate risk factors, such as prior upper abdominal surgery (esophageal, gastric, or duodenal), or metabolic disturbances, such as diabetes or rarely hypothyroidism. The physical examination is often not helpful, but a succussion splash will be evidence of delayed emptying of the stomach but most probably from a mechanical obstruction. During the diagnostic phase, it will be necessary to exclude any type of mechanical obstruction, such as an efferent limb syndrome, anastomotic stricture, or rarely an intussusception after a gastroenterostomy. Once mechanical obstruction is excluded, clinicians must exclude metabolic derangements that can be observed from persistent vomiting or contributing causes, such as diabetes and hypothyroidism. It is important to evaluate the nutritional state with nutritional parameters such as serum albumin levels. Because albumin levels may be normal (they take a week or more to decrease substantially), ordering a prealbumin that has a shorter half-life may help determine a more acute or subacute process. If patients have a mechanical obstruction at the gastroenteric anastomosis identified as an anastomotic stricture or a stricture immediately downstream from the anastomosis, ensure that they are not abusing aspirin or nonsteroidal antiinflammatory drugs (NSAIDs) and thereby contributing to ulceration and anastomotic inflammation. Unfortunately, patients will not always admit this, so if you suspect it, check a urinary level of aspirin, not a serum level that is more transient.

Imaging can begin with abdominal x-rays with contrast to rule out a mechanical obstruction. One caveat to remember: most cases of a gastric motility disorder leading to gastroparesis do NOT have gastric distension, because as stated earlier, most cases are related to vagal dysfunction and the loss of proximal gastric relaxation; there may, however, be solid matter retained in the remnant. In contrast, if there is a markedly dilated gastric pouch of stomach, it is much more likely due to a mechanical obstruction. One exception is the transient POI or a generalized adynamic ileus in which the stomach may very well be distended.

Upper endoscopy will allow visualization of undigested food in the stomach (always an abnormal sign if present more than 2 or at most 3 hours after ingestion), elimination of the possibility of anastomotic stricture, and the means by which to obtain biopsies if necessary. Remember, postvagotomy gastroparesis and most other forms of gastroparesis are NOT associated with a dilated, distended stomach.

Currently, there are three potential tests to demonstrate delayed gastric emptying objectively: scintigraphy, wireless motility capsule (WMC), and carbon breath testing. The gold standard for evaluation of delayed gastric emptying, and thus the diagnosis of gastroparesis, is the 4-hour scintigraphic gastric emptying of solids. The most reliable parameter for the diagnosis is gastric retention of solids is based on the percent retention at 4 hours, graded as mild (<15%), moderate (16%–35%), and severe (>35%) gastroparesis. The WMC, though new and a technique that avoids the (minimal) radiation exposure of a scintigraphic technique, is not well standardized and relies on the emptying of just this one capsule; this test is used primarily under experimental studies. Carbon breath testing has been used in Japan and elsewhere but is still experimental in the United States and is not used except in selected centers. Barium swallow is not a good measure of gastric emptying, and gastric manometry, when available, has not really become a go-to diagnostic test. With the presence of retained solid food in the gastric reservoir, these studies attempting to quantify the rapidity of gastric emptying are usually not necessary.

Nonoperative Treatment

Treatment begins with the management of contributing factors, such as obtaining tighter glucose control or treatment of hypothyroidism. The mainstay of treatment is directed at modifying the diet. One should focus on encouraging the ingestion of liquids more than solids and adapting to smaller and more frequent meals (ideally six or even more if necessary while awake). If well-tolerated, some of the high-calorie, high-protein, low-fat, so-called small particle liquid formulations, though often not as palatable, can provide the necessary calories for patients with nutritional challenges; if associated dumping (see later) is problematic, the high-calorie liquids may not be a good option, but the high-protein formulations may help. The authors recommend a low-residue diet (i.e., lower fiber content) and softer foods that do not require mechanical breakdown. Remember, this will be the mainstay of treatment. Having the patient develop a relationship with an informed dietician can be extremely beneficial.

Pharmacologic agents: If dietary modification does not manage symptoms, a trial of a prokinetic drug, such as metoclopramide, domperidone (if the patient still has an antrum, which is where domperidone takes effect), or low-dose erythromycin (125 mg) that activates the prokinetic motilin receptor, may help stimulate emptying, but NOTE not the usual antibacterial doses of 250 or 500 mg (Table 1). Be aware that these medications do not work in most patients, and if after a short trial no results occur, there is no benefit of continuing their use. The medications used most commonly are metoclopramide and domperidone. As with any D2 receptor antagonist that penetrates the blood-brain barrier, extrapyramidal side effects can occur. Metoclopramide should be started at 5 to 10 mg three times daily but needs to be administered 30 minutes before each meal; the use of >40 mg per day is associated with a not-insignificant risk of extrapyramidal effects, both acute (spasmodic dystonias) and chronic (tardive dyskinesia), especially in the elderly. As the prescribing physician, you will need to explain and warn patients of this very alarming side effect and stop the medication if any such symptoms occur. The latter risk has led to the US Food and Drug Administration (FDA) to issue a black box warning that has effectively decreased its use as an antinausea medication as well as a prokinetic agent. Domperidone, although not approved in the United States, is a closely related D2 receptor antagonist that does not cross the blood-brain barrier. This agent is used widely outside the United States and still is recommended frequently by US physicians (with patients obtaining this medication from other countries such as Canada). Recently, however, concerns about cardiovascular proarrhythmic risks (QT prolongation and tachyphylaxis) are the most concerning adverse effects from domperidone that has led to warnings in Europe and has had some feedback in the United States. Erythromycin is useful for improving gastric emptying in the short term (e.g., in hospitalized patients) but has never been rigorously evaluated for symptomatic relief with its long-term use; its tachyphylaxis requires "drug holidays."

Several newer, highly selective 5HT3 antagonists and 5HT4 receptor agonist medications may help selected patients with the nausea and vomiting, but do not expect these agents to increase effective gastric emptying. Total parental nutrition (TPN) or, if tolerated, enteral nutrition may be required in severe and life-threatening cases of malnutrition; indeed, enteral delivery of nutrition should always be tried before TPN. Finally, tricyclic antidepressants have been suggested and may be considered for especially refractory nausea and vomiting, but the data are quite controversial, because the anticholinergic component of it could potentially worsen symptoms and it might actually retard gastric emptying. Therefore, these agents should be considered only with close monitoring and only after failure of prokinetic agents.

TABLE 1 Medications for Gastroparesis

Drug	Indication	Mechanism	Dose	Side Effects
Metoclopramide	Gastroparesis (FDA-approved for this indication)	Central/peripheral dopamine receptor antagonist, 5HT3 receptor antagonist, 5HT4 receptor agonist (prokinetic and antiemetic)	5–10 mg 3 times daily 30 min before meals	Up to 30% CNS symptoms to some extent: most serious is Parkinsonian, tardive dyskinesia (FDA black box warning)
Domperidone	Gastroparesis (not available in the United States except under FDA IND); often can be bought in Canada	Peripheral dopamine receptor antagonist (prokinetic and antiemetic)	10–20 mg 4 times daily	Rarely can cause QTc prolongation, with risk of arrhythmia; hyperprolactinemia
Erythromycin	Gastroparesis (off-label)	Motilin receptor agonist (prokinetic)	50–125 mg given 30 minutes before a meal; note the dose is considerably less than that used for an infection	May worsen nausea, vomiting, abdominal pain; tachyphylaxis with long-term use requires drug holidays; can cause QTc prolongation with risk of arrhythmia, greater doses can cause vomiting and nausea
Mirtazapine	Gastroparesis (off-label)	Alpha adrenergic, 5HT2, 5HT3, and H1 receptor antagonist (prokinetic, antiemetic)	15–30 mg every day at bedtime	This is an antidepressant, can cause somnolence, increased appetite, and weight gain
Prucalopride	Gastroparesis POI, CIIPO (off-label)	Highly selective 5HT4 receptor agonist (prokinetic, secretagogue)	1–2 mg daily	Headache, nausea, abdominal pain, diarrhea

CIIPO, Chronic idiopathic intestinal pseudo-obstruction; *CNS*, central nervous system; *FDA*, US Food and Drug Administration; *GI*, gastrointestinal; *IND*, investigational new drug; *POI*, postoperative ileus.

Operative Treatment of Delayed Gastric Emptying

Operative intervention should be limited to patients with severe, medically refractory symptoms affecting quality of life and challenging the patient's nutritional health. First, we will discuss those patients with objective evidence of delayed gastric emptying (true gastroparesis). A jejunal feeding tube (percutaneous or open or as one of the authors prefers a duodenostomy) may be indicated, but only after a trial of nasoenteric feeding to evaluate for tolerance of such feedings; NOTE: such a trial is absolutely essential, because some patients have a poorly understood postvagotomy small bowel dysmotility and cannot tolerate these feedings. This is especially true for patients who also complain of substantial abdominal pain, which is another indication that a trial of feedings is absolutely crucial before placing a J tube. The inability to tolerate enteric feedings, either because they cannot tolerate the volume related to severe bloating or the feedings exacerbate the abdominal pain, is a very bad sign for the optimistic hope of a good response to enteric feedings. In some situations of severe refractory gastroparesis, TPN may be the only viable option. A venting gastrostomy tube may assist with the feeling of gastric fullness or persistent vomiting; one just needs to be careful to monitor how much volume is lost via such a gastrostomy tube, because the volume will have to be replaced. Also, if the gastric drainage is voluminous and bilious, loss of bile salts will be a distinct possibility and may even require reinfusing the gastric drainage; as might be expected, this is quite cumbersome and not at all appealing, and thus placement of a gastrostomy tube alone may not be the best option. If the enteric feeding trial is successful, then some form of direct, enteric placement of a feeding tube is best. Placement can be done either via a laparoscopic, open, or direct percutaneous placement (PEJ) rather than a PEG tube with a jejunostomy extension, the latter of which all too often flips back up into the stomach and requires replacement via gastroscopy.

In a small subset of patients with objective gastroparesis and who had undergone an operation with a postoperative total vagotomy or a defined vagal injury, a near total (>95%) gastrectomy (with a cardiojejunostomy leaving no effective volume reservoir) or even a completion gastrectomy may be an option. A multidisciplinary discussion is mandatory before recommending this controversial strategy. An examination of 20 years of Mayo Clinic's experience of providing near total or completion gastrectomy in patients with severe postsurgical gastroparesis after a prior partial gastrectomy with truncal vagotomy showed that only about half the patients were able to maintain their nutrition orally. A similar trial of near total gastrectomy after a prior Nissen fundoplication in patients with postsurgical gastroparesis who had also had a pyloroplasty (remember the vagus nerves also help to coordinate antropyloric function presumed to be related to vagal nerve injury) found no benefit; the majority of this unusual subset of patients had persistent symptoms and required supplemental nutrition (enteral or parenteral) after the gastric resection. *Please Note!* We learned early on that a trial of enteric feedings was absolutely necessary with any type of operative intervention designed to deliver food by mouth, because as stated before, if the patient cannot tolerate enteric feedings, then the delivery of ingested foods into the jejunum via the esophagus will also not be tolerated. Therefore, the authors do not recommend near or total gastrectomy as a routine strategy for postsurgical gastroparesis, except in selected patients who are demonstrated to tolerate enteric feedings.

In recent years, there has been a new interest in various stomach-specific treatments that might appear to help with gastric emptying, including pyloroplasty, either done as a formal operation (laparoscopic or open) or via an endoscopic approach titled per-oral pyloromyotomy (POP) or gastric per-oral endoscopic myotomy (G-POEM; also known as POEM or endoscopic POP) based on the rationale that pyloric dysfunction could result in gastric outlet obstruction. If any of these procedures are to be considered, a preoperative trial of injection of botulinum toxin into the pylorus should be considered strongly. This temporizing approach relaxes the pylorus similar to a pyloroplasty; if no symptomatic relief occurs, then an operative procedure on the pylorus is probably not indicated. Sleeve gastrectomy (with or without pyloroplasty) has received quite a bit of interest recently. This operation decreases the reservoir capacity of the stomach because it resects all the fundus and the lesser curvature tube has no substantial reservoir capacity; when combined with a pyloroplasty, there should be no resistance at the pylorus, and thus there is some theoretic interest in its potential efficacy. The operation might increase gastric emptying and thus have an emerging role in the treatment of gastroparesis, especially in patients suffering from obesity and/or diabetes. The data are still scarce and not yet well accepted, and gastroesophageal reflux disease in the setting of a sleeve anatomy and nonresolving gastroparesis remain of concern without even midterm postoperative data. Acupuncture has been shown anecdotally to have some symptomatic benefit in the management of selected patients with gastroparesis.

Finally, implantation of an electrical gastric stimulator (Fig. 1) into the stomach wall has been suggested with increasing frequency by some groups; this approach of gastric electrical stimulation (GES) may be an option for patients with severe and refractory gastroparesis and who have diabetes or with predominant symptoms of nausea or vomiting. Although these nerve stimulators might help with nausea and vomiting, they are very controversial, with quite radically different success reported by various groups. Because GES does not reliably increase effective gastric emptying (see later, Gastroparesis-Like Syndromes), be aware that patients may consider these like a cardiac pacemaker that will "pace" the stomach and increase the rate of contractions, but no one has been able to show that gastric stimulation can actually "pace" the stomach.

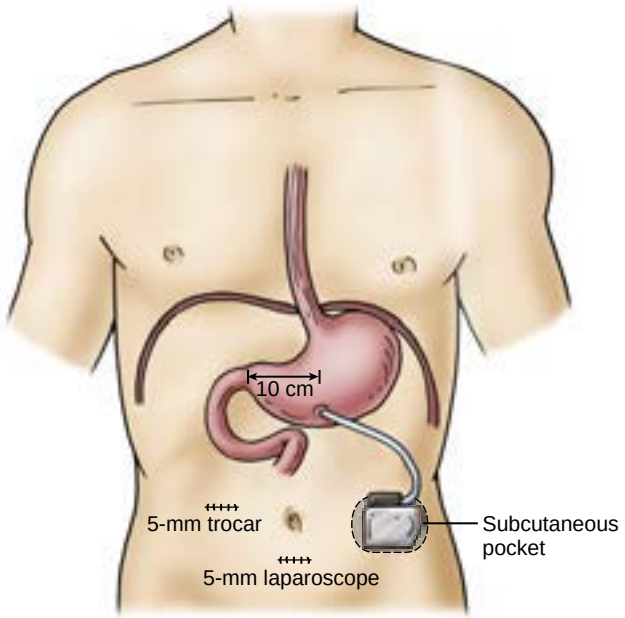

FIG. 1 Laparoscopic approach for gastric electrical stimulator: placement of gastric wall electrodes and subcutaneous battery.
(Modified from Ginsburg GG, et al. Clinical Gastrointestinal Endoscopy. 2nd ed. Philadelphia: Saunders; 2012.)

GASTROPARESIS-LIKE SYNDROMES

In recent times, symptoms suggestive of gastroparesis but often without any objective delay in gastric emptying have received considerable attention in the literature. It remains unknown whether these syndromes have always been present or whether this spectrum of disorders are related to a more focused, increased interest in symptomatic functional disorders without objective evidence of delayed gastric emptying. These syndromic conditions present with early satiety, nausea, and often vomiting, mimicking true gastroparesis and are most often seen in young females in their 20s or 30s. Although gastroparesis by definition implies a delay in gastric emptying, it has become clear that there is poor correlation between the severity of delay and symptoms in these patients. A substantial percentage of these patients have normal emptying, although their symptoms are indistinguishable from those in patients with overt delay; this syndromic presentation is likely part of a clinical spectrum that has been termed *chronic unexplained nausea and vomiting* or *gastroparesis-like syndrome*. In these patients, other mechanisms (e.g., impaired gastric accommodation with increased tension in the proximal stomach wall, sensitization of vagal afferent pathways, etc.) may account for the symptomatology.

Symptomatic treatment for this spectrum of complaints first revolves around excluding true gastroparesis, often requiring a formal radionuclide gastric emptying study. Because there is little association of symptoms with the rate of gastric emptying, the focus on these patients is to treat the symptoms of nausea and vomiting. Some modification of diet as for true gastroparesis can help, but treatment begins with antiemetics and antinausea medications. The usual approach is to start with the classic antinausea medications, like metoclopramide or the 5HT3 receptor antagonists, typically beginning with ondansetron (which is also available in an orally disintegrating tablet form) or granisetron, which is available as a subcutaneous delivery patch. A more general approach to nausea has been in the form of neuromodulators (e.g., tricyclic antidepressants such as nortriptyline). Although most of these agents have prominent anticholinergic activity, these drugs generally do not affect motility when used in low doses. Several anecdotal reports suggested substantial relief, but a randomized controlled study showed no improvement in nausea. A more promising agent is mirtazapine, which is being used increasingly to treat nausea (due to its 5HT3 receptor antagonism), improve appetite, and to a lesser extent modulate functional pain. Buspirone is an anxiolytic that is an agonist of the 5HT1A receptor, which may also be responsible for its ability to improve gastric accommodation. It may prove useful in patients with prominent early satiety.

Over the past 15 to 20 years, the still not fully accepted treatment of neuromodulation by various forms of GES has been recommended with increasing frequency. GES is a technique in which serosal electrodes are implanted onto the gastric antrum via an open or laparoscopic approach (see Fig. 1). The accepted use for GES includes the indication approved by the US FDA of "drug refractory disease," but there are no defined criteria for the diagnosis of this condition. Because under the FDA statute for the Practice of Medicine, any FDA-approved device can be used off-label with an adequate justification, GES can be used in the "off-label" setting. Because the current devices for GES require a Humanitarian Use Device (HUD) approval, any centers employing these devices should have some form of Institutional Review Board (IRB) oversight. Some investigators have advocated that multiple uses of GES are allowed under certain conditions. Randomized crossover trials have shown no or only modest symptom relief with the device when on versus off, although many prospective, open label trials have rather aggressively suggested impressive benefit, particularly in patients with diabetic gastroparesis. Putative mechanisms of action are presumed

to be via modulation of vagal signaling and not via improved gastric emptying. The bottom line is that the role of GES in gastroparesis, despite its now relatively frequent use, remains unclear.

The problems with this spectrum of gastroparesis-like syndromes are that we do not understand their etiology, it appears to be in the spectrum of functional disorders of the gut, and the response to different medications varies considerably. These patients are best managed by a thoughtful, considerate, and understanding gastroenterologist.

DIABETIC GASTROPARESIS

Diabetic gastroparesis should be discussed as a separate entity. Most investigators agree that this disorder is related primarily to poor glucose control and its effects on vagal nerve function. One important aspect of this disorder is that although it is associated with a true delay in gastric emptying, the clinical symptomatology waxes and wanes in severity, and thus any attempt to intervene in an irreversible way is usually to be avoided. Many times, the symptoms are more cumbersome than any problems with caloric intake or nutrition aside from the underlying diabetes mellitus.

This intermittent nature of diabetic gastroparesis should weigh into any therapeutic considerations. Attempts to obtain better control of glucose intolerance are definitely appropriate. Some reports suggest that the use of insulin pumps in patients with type 1 diabetes can lead to fewer hyperglycemic events, a decrease in HbA1c, and considerable improvement in the symptoms of gastroparesis. Of course, the initial therapeutic suggestions should concentrate on dietary modifications as discussed earlier and trying the various pharmacologic agents as for other forms of gastroparesis. A true venting gastrostomy may be advantageous in these patients for relief from bloating symptoms, but as with any gastrostomy, it should not be open to continuous drainage for fear of dehydration, bile salt wasting, and so on. Specific counseling of patients with such a venting gastrostomy is imperative. Also, this may be a potential avenue for a somewhat safer jejunal extension tube to allow intrajejunal feedings if the patient can tolerate them. In terms of a gastric resection, the senior author of this chapter performed a near total gastrectomy in one highly unusual patient with chronic, unrelenting diabetic gastroparesis of 5 years' duration who could also tolerate jejunal feedings. Although this patient did well for 8 years after which follow-up was lost, we want to stress that this approach (tailored after treatment of vagal dysfunction in selected patients as described before) should not be considered in the overwhelming majority of patients with diabetic gastropareses.

Because diabetic gastroparesis can lead to considerable symptomatology of vomiting and nausea, GES might have benefit in this population and should be entertained in the highly symptomatic patient. Whether it will augment gastric emptying is not necessarily to be expected, but it may help with symptoms.

RAPID GASTRIC EMPTYING

The overly rapid early emptying of gastric contents from the stomach into the duodenum or the jejunum, also known as *dumping,* can result from gastric operations that almost universally involve a vagotomy; this condition leads to the dumping of a bolus of liquid or hyperosmolar chyme into the proximal gut. Approximately 10% to 15% of patients experience some extent of dumping after gastric surgery. If the contents are of high osmolarity, such as a carbohydrate-rich bolus, then the resultant symptoms can be very unpleasant for the patient. Because of increased osmolality, some have suggested that the rapid shift of fluid into the lumen of the small bowel can lead to feelings of bloating. The old theory that dumping may result in a relative hypovolemia from the fluid shift into the gut has been disproven and is not the primary cause of the symptoms; indeed, the majority of the symptoms arise from the release of vasoactive substances related to the high osmolality of the intraluminal content. Also important to remember is that many physicians relate dumping to diarrhea; this is neither appropriate nor accurate, because many patients with dumping have no diarrhea. The symptoms of dumping are abdominal bloating, nausea, and the feeling of a need to lie down early after eating; diarrhea may occur but not always.

Dumping can be seen after virtually any operation on the distal stomach but usually those involving a vagotomy; the greatest frequency is after subtotal gastrectomy with vagotomy and the least frequent is after pyloroplasty alone. Patients who have undergone a truncal vagotomy (or an inadvertent or necessary vagotomy) and pyloroplasty will experience dumping at greater rates than those who had pyloroplasty alone. The symptoms occur early, usually within 30 minutes of eating. Symptoms are likely to be elicited after a large, rapidly ingested meal and are much worse with liquid meals of high osmolarity. In the past, dumping was a very common feature after truncal vagotomy and pyloroplasty, but in the current era, dumping is observed primarily after Roux-en-Y gastric bypass surgery. Thankfully, dumping rarely is a permanent state, especially after gastric bypass, in which the majority of patients will not have prominent or persistent symptoms after the first 3 months. Predicting who will develop dumping is challenging.

There is also a form of dumping called *late dumping*, in which the symptoms occur 90 minutes to 3 hours after eating. This symptomatology is believed to be related to the delivery of high-calorie meals to the more distal intestine, whereby a different neurohormonal milieu occurs. The initial symptoms are quite similar to early dumping, but also often involve diarrhea, which is not a part of early dumping. Some of the symptomatology of this late dumping appear to be related to the entry of high caloric value into the duodenum or jejunum overwhelming the regulatory mechanisms for insulin release, resulting in a delayed continuous increase in the levels of serum insulin leading to the rapid "reactive" development of hypoglycemia; this rapid onset of hypoglycemia then causes symptoms very similar to early dumping along with the symptoms of hypoglycemia. Indeed, the hypoglycemia can be quite severe (<20 mg/dL) and can even lead to disturbed thinking, seizures, and even coma. Although some have described this late hypoglycemia as a new postbariatric syndrome called noninsulinoma postprandial pancreatogenous hypoglycemia syndrome (NIPPS) that can occur after a Roux-en-Y gastric bypass, quite frankly, this syndromic complex was well-recognized in the past era of duodenal ulcer operations as "late dumping" after gastric resections.

Clinical Presentation and Diagnosis

The majority of patients, about 75%, will present with early rather than late symptoms of dumping. The differential diagnosis must exclude the afferent loop syndrome, pancreatic insufficiency, and bowel obstruction after prior gastric surgery. A detailed history will help to differentiate between dumping and these other potential complications. With *early dumping,* patients will complain of early satiety, abdominal pain, nausea, and evidence of autonomic dysfunction, such as a racing heartbeat, sweating, dizziness, and tremors. Unlike with late dumping, diarrhea is not common with early dumping symptoms. The symptoms may last for about an hour, because the high osmolarity causes release of vasoactive substances. Patients often are self-immobilized and want to lie down because of the severity of the ill feeling they experience. *Late dumping* has similar symptoms but generally occurs approximately 90 minutes to 3 hours after a meal. Additional features include fatigue, mental changes, or even fainting associated with reactive hypoglycemia. Recognition of this unfortunate sequela is important for patients to understand so that they can seek appropriate care if needed.

Provocative testing to help confirm the diagnosis of late dumping involves giving 50 g of orally administered glucose followed by serial measurements of glucose and plasma insulin levels as well as heart rate and determining any symptoms of dumping experienced by the patient. Some suggest a concomitant, hydrogen breath test; an

increase in the heart rate greater than 12 beats per minute and an increase in hydrogen breath excretion allegedly has a sensitivity of 94% and a specificity of 92%. An upper gastrointestinal (GI) series may help to define anatomy but is often not necessary. Usually, however, the diagnosis is evident by the patient's symptoms and the clinical setting.

Treatment

The primary treatment of dumping syndrome is dietary modification. Avoiding simple sugars (which includes alcohol and most dessert-type food items) and the intake of calorie-dense carbohydrates helps minimize symptoms. Simple measures, such as avoiding drinking 30 minutes before, during, and after a meal also may help. Adding fiber supplements and complex carbohydrates may help to slow transit; in addition, drinking plenty of water at other times during the day, especially if concomitant diarrhea is present, serves to avoid dehydration as a result of the dumping. Patients should avoid an upright posture while eating and instead recline if possible after eating, because upright posture may accelerate gastric emptying in some patients. Although diarrhea is not the main presenting symptom of dumping, patients may have a late onset of diarrhea. As before, eating small, frequent meals and having proteins and fats with meals may help to slow gastric emptying.

Dietary modifications alone may not relieve the dumping symptoms; 3% to 5% of patients will have refractory symptoms. A trial of octreotide in these patients may offer great relief of the dumping symptoms but in only about 20% of patients. In several randomized, controlled trials, octreotide improved symptoms in some patients when compared with controls. If octreotide is effective, then a longer-acting formulation of octreotide should be used. The timing of administration of subcutaneous octreotide is important and should be given 30 minutes before a meal. For patients on long-acting octreotide, steatorrhea can be a problem, because octreotide inhibits pancreatic enzyme secretion, but the resulting steatorrhea can be ameliorated with pancreatic enzyme replacement. Increasing the viscosity of the intraluminal contents by adding pectin and guar may slow the emptying process and alleviate symptoms.

The role of any operative interventions to manage dumping is limited. Distant literature describes the use of a 10-cm, reversed jejunal limb at 100 cm distal to the ligament of Treitz in patients who have severe diarrhea associated with rapid gastric emptying. There are, however, many complications with these reversed limbs, and studies have not shown any substantial benefit; this often quoted but outdated procedure should be relegated to history and no longer used currently. For the late form of dumping and the hypoglycemia associated with Roux-en-Y gastric bypass (NIPPS), endoscopic transoral outlet reduction (TORe) might be of benefit in some patients. With this procedure, the diameter of the gastrojejunostomy is decreased via endoscopic suturing, but consistently good results across different practices are lacking. Operatively reversing the gastric bypass or redirecting the Roux limb into the duodenum may be the only option. A prior high visibility suggestion of subtotal pancreatectomy to treat any associated hypoglycemia has proven to be ineffective in long-term outcomes.

MOTILITY DISORDERS OF THE SMALL INTESTINE

True motility disorders of the small intestine are actually quite unusual and represent a spectrum from transient, reversible problems of motility, such as generalized adynamic ileus to the rare and progressive familial disorders of chronic idiopathic intestinal pseudo-obstruction and the acquired disorder of scleroderma. There are also several unique, albeit rare, clinical scenarios that involve motor abnormalities, such as the bypass enteropathy of the defunctionalized jejunoileum in patients after the original bariatric operation of the jejunoileal or "small bowel" bypass, small intestinal intussusception, and the dysmotility that can complicate small bowel function in patients who were born with intestinal atresia. This section, however, will focus on the two forms of adynamic ileus and the pseudo-obstructions of the small bowel.

Adynamic Ileus

A true small intestinal "ileus" after intraabdominal operations actually is very unusual. In contrast, the "physiologic ileus" that occurs in the early postoperative period (first 1 to 4 days) after a laparotomy is often talked about and called "postoperative ileus." This form of transient ileus, or the inability to eat and have bowel movements, is primarily a gastric and colonic response to the abdominal wall trauma of a laparotomy. Interestingly, it is not a small bowel ileus or even a dysmotility of the small bowel; indeed, small intestinal contractile activity is present during the operation as can be seen and demonstrated by "tweaking" the small bowel and observing it contract (in contrast to the stomach and colon, which have no spontaneous or stimulated contractile activity intraoperatively). Also, intraintestinal feeding can be administered immediately postoperatively. In essence, the small intestine works relatively normally, whereas the motor activity leading to gastric emptying and colonic emptying is delayed for 2 to 4 days. Thus, POI is not a small bowel dysmotility. The absence of "bowel sounds" early postoperatively is due to the loss of gastric emptying of swallowed gas; it is the gas/liquid interface that leads to bowel sounds.

Adynamic ileus, however, is a rare, generalized motor disorder of the entire gut, involving the small intestine as well as the stomach and colon. Adynamic (generalized) ileus involves a secondary, neurally mediated blockade of effective contractile activity in response most commonly to a systemic inflammatory disorder (such as sepsis), after retroperitoneal operations (e.g., kidney transplantation), or with retroperitoneal conditions (e.g., trauma, hematoma), all believed to interfere with the autonomic nervous innervation to the gut. True adynamic ileus should not be confused with isolated colonic ileus (colonic pseudo-obstruction) that can complicate a total hip arthroplasty or retroperitoneal operations; this form of localized ileus involves only the colon but not the stomach or small bowel.

Clinical Presentation and Diagnosis

Diagnosis is based on the presence of symptoms similar to those of a small bowel obstruction that occur in the appropriate clinical setting: vomiting, bloating, abdominal distention, obstipation of stool and gas, and the physical findings of tinkling bowel sounds and generalized bowel distention (small and large bowel) on diagnostic imaging. Crampy abdominal pain as occurs with a mechanical small bowel obstruction, however, is distinctly unusual. With a heightened clinical suspicion, a simple abdominal radiograph will suffice showing the dilation of the stomach, small intestine, and entire colon. The differential diagnosis includes the exclusion of an obstructing rectal lesion, which may require proctoscopy or a transrectal contrast radiograph.

Treatment

Treatment should be directed at the cause of the ileus, most commonly sepsis. Specific pharmacologic or operative intervention is neither needed nor effective in an attempt to treat or reverse the ileus. Management is otherwise conservative, often including a nasogastric tube. Prokinetic agents are not effective. Adynamic ileus is transient and resolves when the systemic cause of the ileus has been controlled.

Postoperative Ileus

We want to differentiate POI from adynamic ileus; these represent two distinct and different entities. The former is a physiologic response to abdominal wall trauma, while the second is a pathologic response to infection, etc. Also, to be clear, POI involves the stomach and colon but not the small intestine as stated earlier, whereas

adynamic ileus involves the entire gut: stomach, small intestine, and colon.

A far too great emphasis has been devoted to POI when it is a transient condition that resolves spontaneously; the term itself has been magnified out of proportion to its importance. Although speeding discharge by at most 1 day is important after an open, full laparotomy for colonic or other operations that can delay early discharge within the first 3 days or so, laparoscopic operations are much less susceptible to POI as shown numerous times recently after laparoscopic colectomy. Much of this misunderstanding of POI stems from the inaccurate belief that POI is related to the extent of handling of the intestine; indeed, an excellent study in dogs showed that extensive handling of the small bowel was not associated with more POI than a simple laparotomy. This and other studies show that POI is related to the abdominal wall trauma of the laparotomy in combination with other factors such as opioid medications. Remember, POI does not affect small bowel motility, rather just the stomach and colon.

Thus, with so many operations now being performed laparoscopically, POI is no longer that relevant or problematic. Moreover, recent work with enhanced recovery after surgery (ERAS) has improved our understanding of early postoperatively feeding of either the stomach directly, even after major resections (e.g., pancreatoduodenectomy), or the small intestine such as after a Roux-en-Y gastric bypass where essentially all oral intake bypasses the stomach and enters the jejunum directly; this experience reinforces the lesser importance of POI currently.

There is one exception to these observations. On occasion after a distal gastrectomy when there has been mechanical obstruction of the gastric outlet and the stomach is dilated, recovery of gastric emptying can be delayed markedly, the exact cause of which remains poorly understood. With this quite rare condition, most so-called prokinetic medications, such as erythromycin, domperidone, prucalopride, acetylcholinesterase inhibitors, and alvimopan (a peripheral mu opioid receptor antagonist shown to speed discharge somewhat after open colonic operations), have been of minimal or no benefit, and watchful waiting without reoperation to "redo" the gastroenteric anastomosis because of concerns of its anatomic lie should be avoided at all costs.

Chronic Idiopathic Intestinal Pseudo-Obstruction

This family of heritable disorders is quite uncommon, and the diagnosis, which closely mimics a mechanical small bowel obstruction, can be confusing and difficult to recognize preoperatively, especially if there is no prior family history and if the patient has had no prior intraabdominal operation. The three most common forms of chronic idiopathic pseudo-obstruction, all of which are progressive, are the following: a histopathologic myopathy of smooth muscle, a histopathologic neuropathy, and a less well-characterized form of neuromotor dysmotility that lacks any definitive histopathologic findings. Another extremely rare genetic cause of GI pseudo-obstruction includes mitochondrial neurogastrointestinal encephalopathy disease, a multisystem disorder with peripheral as well as prominent GI dysfunction and an associated neurologic phenotype (ptosis/ophthalmoplegia, peripheral neuropathy, leukoencephalopathy); this disorder affects teens and young adults and is caused by a mutation in the gene encoding for thymidine phosphorylase. All these disorders lead to disorganized patterns of motility with ineffective, uncoordinated contractile activity resulting in intestinal distention and stasis of intestinal content.

Familial Visceral Myopathy

With this disorder of visceral smooth muscle, the amplitude of contractions is markedly abnormal, as is the coordination of propulsive contractile activity along the gut. This myopathy eventually affects the esophagus, stomach, small intestine, and colon, as well as the genitourinary system. The most common organs affected first (and often isolated) by this myopathy can be the esophagus (megaesophagus), the duodenum (megaduodenum), the colon (megacolon), or the urinary system (megaureter). With time, however, all smooth muscle of the gut and genitourinary system becomes involved to some varied extent.

Familial Visceral Neuropathy

This disorder involves the autonomic nervous system of the gut, leading to discoordinated contractile activity with ineffective transit. Histologic findings are subtle and require special expertise not only in the reading of the slides (which require a full thickness biopsy, not just an endoscopic biopsy) but also in the staining of the tissue. Currently there are very few histopathologists who have access to the appropriate staining techniques or experience in reading the biopsy slides, making the need for a transmural biopsy less important.

As Yet Undefined Neuromotor Dysmotility

This form of chronic, truly "idiopathic" pseudo-obstruction mimics the primary visceral neuropathy form but lacks any discernible histopathologic findings. It is rare but possible for a patient to develop a form of this dysmotility as a paraneoplastic phenomenon mediated by an as yet noncharacterized humoral agent released by the neoplasm.

Clinical Presentation

Many times, the symptoms of the hereditary dysmotility syndromes begin initially in one organ. A common presentation is severe constipation, which then progresses over a variable time (months to years) to also involve the small intestine. Some of these patients have been treated (inappropriately) by colectomy for a diagnosis of colonic inertia. Others present with initially isolated megaesophagus, mimicking achalasia in some respects; but over a variable time interval, the disease eventually involves the distal gut as well. In teenagers, one of the more common presentations of pseudo-obstruction is that of megaduodenum of the first and second portion of the duodenum, often confused with superior mesenteric artery (SMA); the latter itself is very rare and virtually always follows a marked weight loss rather than preceding or causing the weight loss as with pseudo-obstruction. Because these disorders are a familial, heritable disorder, for patients other than the proband, there should be a family history of esophageal, colonic, or genitourinary problems unless, of course, it is a new mutation.

The age of onset varies with the site of intestinal pseudo-obstruction. Often the symptoms begin insidiously during late childhood/early teenage years with vague, chronic GI complaints. Other forms of onset appear in the 20s and 30s in patients with a prior history of complaints, such as substantial constipation, dysphagia, gastroesophageal reflux, or intermittent abdominal distention/cramping. A clue to the clinical presentation/diagnosis is that, all too frequently, these patients have been operated on for a prior, presumed, mechanical "small bowel obstruction" secondary to a presentation of abdominal pain, distention, and markedly dilated small intestine, usually with no really objective or convincing site of mechanical obstruction found at the time of exploration. The disease and symptoms often wax and wane, which raises the question if the current symptoms are secondary to adhesions from prior abdominal operation(s) rather than to the dysmotility itself.

Diagnosis

The diagnosis of these forms of chronic idiopathic intestinal pseudo-obstruction is most often one of exclusion (unless, of course, there is a strong family history). Because of their rarity, the diagnosis often is not even considered initially, and patients are treated operatively as if they have a mechanical small bowel obstruction, a colonic obstruction, or colonic inertia. Even when there is no definitive site

of obstruction, all too often the assumption by the operating surgeon is that the obstruction was related to a transient kinking or twist that resolved; interestingly, this "obstruction" in the postoperative course may resolve without a protracted postoperative "ileus." A key here is that the small intestinal dilation occurs right down to the cecum, making a transient obstruction unlikely. Because the disease is intermittent at first, when the patient presents again with abdominal distention after a prior negative laparotomy and a clinical picture of a mechanical small bowel obstruction, the concern of an adhesive obstruction is always present, even in patients in whom a concern of pseudo-obstruction remains from the prior operation. This presentation makes the diagnosis and treatment very difficult.

Marked small intestinal distention (and often gastric as well) is the hallmark of diagnosis on radiographic imaging, and the distention of the small bowel extends all the way to the cecum without a transition point. Early in the course of the disease, megaesophagus or megaduodenum may be the first sign, but later in the course, the entire small bowel is dilated, mimicking a very distal mechanical small bowel obstruction. A prior history of a negative exploration in the past, a history of multiple recurrent complaints as a child with abdominal distention or constipation, or a presentation without any history of a potential cause of a mechanical obstruction, such as a prior intraabdominal operation or hernia, should at least raise suspicion of the diagnosis, especially in the younger patient; however, no one wants to mismanage or delay definitive treatment of a mechanical obstruction by delaying necessary definitive operative intervention, which makes the diagnosis difficult.

There is no definitive or objective means of preoperative diagnosis other than a well-defined family history or a known problem with genitourinary problems related to megaureter. A prior operation(s) without a defined site of obstruction (and often it is necessary to read between the lines of the previous operative note by the surgeon trying to convince themselves that there was a site of obstruction) should raise suspicion of pseudo-obstruction, but nevertheless, there is always the worry of a mechanical cause being present.

Multiple attempts at diagnosis by characterizing the motor (contractile) pattern have been largely unsuccessful. Although the amplitude of contractions is decreased markedly in the visceral myopathic form, measuring true amplitude in the presence of gastric and/or intestinal distension is not reliable whatever the cause. The most reliable method of diagnosis in those highly suspected of idiopathic pseudo-obstruction is best carried out by a "diagnostic" laparoscopic exploration, which allows for a less-invasive visualization of the distended bowel with the least risk of subsequent adhesion formation. The finding of intestinal distention of the entire small intestine all the way down to the cecum without any convincing site of concurrent or prior obstruction (adhesions, hernia, localized thickening of the bowel, or intraluminal mass that may have caused a transient intussusception) should confirm the suspicion of this motility disorder.

Treatment

Treatment of intestinal pseudo-obstruction is only symptomatic and supportive. Being a progressive disorder that eventually involves the entire small intestine, any resections or internal bypasses should be avoided. Similarly, repeated laparotomies should be avoided, if at all possible, because of the subsequent development of more adhesions, which only confuses the clinical picture concerning the etiology of the intestinal distension and complicates future decision making, especially by another surgeon. When the diagnosis is suspected, laparoscopic exploration rather than laparotomy should be used to confirm the diagnosis. Yes, these patients can develop a true mechanical obstruction from adhesions related to prior laparotomies, so the differentiation of mechanical from functional obstruction is a consideration. Whether a full-thickness biopsy is indicated or not is debatable, because there usually is no definite recognizable pathology evident, and most centers do not have the expertise to really identify abnormalities of the autonomic nervous system with the specialized neuromuscular staining needed; moreover, it requires an enterotomy because a full thickness biopsy is needed. Similarly, for patients operated on previously, a laparoscopic exploration may allow the least invasive confirmatory approach as opposed to open laparotomy.

Because the symptoms and severity tend to wax and wane early in the course of the disease, any nonreversible treatment should be avoided. As the disease progresses, if the primary area is the esophagus, stomach, and/or duodenum, intrajejunal feedings may be possible initially and will put off the need for chronic parenteral feeding, but chronic parenteral nutrition eventually becomes the mainstay of treatment. In the latter stages of the disease, when the abdominal distention becomes chronic and symptomatic, a decompressive tube enterostomy (not a formal enterostoma because of the inordinate risk of stomal prolapse) may provide some benefit for the small intestinal distention. These venting tubes should be considered cautiously because of the known complications of any enterostomy tube, such as discomfort, fluid loss, or infection. Similarly, if vomiting is problematic, a venting tube gastrostomy also can be entertained, but again, all fluid loss from these decompressive tubes will need to be replaced, making intravenous support more difficult. In the authors' opinion, chimney stomas are not indicated as a decompressive procedure, because they can serve as a large drain of enteral fluids and can lead to retrograde prolapses.

Intestinal transplantation is a therapeutic possibility in highly selected individuals. This approach obligates its own problems, such as immunosuppression and infections. Whether intestinal transplantation is state-of-the-art currently is a quality judgment for each individual patient. With improvements in immunosuppression, transplantation represents the best potential alternative for this progressive and otherwise untreatable disease.

Scleroderma

Scleroderma can involve the small bowel and colon with severe symptoms in about 10% of patients. The onset of small bowel involvement is usually later in the course of the disease. Involvement of the esophagus with gastroesophageal reflux is much more common, but the small bowel dysmotility when present is difficult to treat. Although most assume that involvement of the small bowel wall involves a fibrosis, usually the most prevalent finding is a myopathy with hypoplasia of the muscles of the intestinal wall. This myopathy leads to poor amplitude contractions as well as an overall dyscoordination of contractile patterns leading to poor propulsion of luminal content. While the presentation and findings are very similar to chronic idiopathic pseudo-obstruction, the underlying cause is a bit different. Most treatment is symptomatic, but while some have tried pyridostigmine (an acetylcholinesterase inhibitor), octreotide, and even oral antibiotics for bacterial overgrowth due to luminal stasis, most of these treatments are only marginally helpful at best.

Postvagotomy Diarrhea

Postvagotomy diarrhea is a very rare form of dysmotility that is poorly understood and has no known effective treatment. Now that the era of vagotomy for duodenal ulcer disease is over, this rare disorder should be even rarer.

Clinical Presentation

Although presenting as diarrhea, the underlying pathophysiology is believed to be a dysmotility, causing a rapid transit through the small intestine and not a malabsorption as such. The symptoms are diarrhea and cramping after eating, but specifically and importantly in the differential diagnosis, there is no diarrhea or cramping between meals. There is no real malabsorption as such in terms of fat (steatorrhea), protein (azotorrhea), or vitamins or minerals, but instead pain and fluid and electrolyte balance predominate. When analyzed, the diarrhea is a watery form, but the presence of undigested foodstuffs is evidence of rapid transit.

Diagnosis and Treatment

The diagnosis is rare, often not thought of, and is one of exclusion. Most physicians and currently most surgeons will never see such a patient in their career. Endoscopies show normal mucosa confirmed on biopsy. Every form of diarrhea should be excluded before this diagnosis is made. A detailed evaluation by an insightful gastroenterologist or surgeon is very important because there is no effective treatment. Pharmacologic attempts at slowing transit with opiates and even octreotide have been uniformly unsuccessful. Prior attempts to slow transit by operative means such as reversed segments of small intestine are also not indicated, because they just do not work. Once all other forms of diarrhea have been excluded, the treatment is supportive. The senior surgeon working in a major referral center for motility disorders has seen three such patients in his 30-year career; these patients are miserable and very unsettling to manage.

Management of Short Bowel Syndrome

Jon S. Thompson, MD

Short bowel syndrome (SBS) is characterized by malabsorption and malnutrition, which generally occur when less than 180 cm of functional intestine remains in adults. The severity of the clinical features of SBS depends on several factors, including not only the extent of resection but also the site of resection, the underlying intestinal disease, the presence or absence of the terminal ileum and ileocecal valve, the functional status of the remaining digestive organs, and the adaptive capacity of the intestinal remnant. Three-fourths of these instances result from massive intestinal resection, and one-fourth result from multiple sequential resections of the small intestine. Approximately two-thirds of patients who develop SBS survive from that hospitalization, and a similar percent are alive 1 year later. Long-term outcome is primarily determined by the patient's age and underlying disease. However, a number of deaths are caused by complications directly related to the management of SBS.

The pathophysiologic changes that occur in SBS relate to the loss of intestinal absorptive surface and more rapid intestinal transit. Malabsorption of nutrients results in malnutrition and weight loss, diarrhea and steatorrhea, vitamin deficiency, and electrolyte imbalance. Other specific complications include an increased incidence of nephrolithiasis from hyperoxaluria, cholelithiasis secondary to altered bile salt and bilirubin metabolism, and transient gastric hypersecretion. Bacterial overgrowth can also occur secondary to mechanical obstruction or primary motor abnormalities. In patients dependent primarily on parenteral nutrition (PN), liver disease remains an important factor in mortality. Functional and structural adaptation of the remaining intestine occurs after massive intestinal resection, resulting in improved absorption of nutrients and a decrease in diarrhea within the first few months after resection. The degree of adaptation that occurs depends on the extent and site of resection, the provision of enteral nutrients, and the response to gastrointestinal hormones and other regulatory polypeptides.

Early management of the patient with SBS is that of the critically ill surgical patient having recently undergone intestinal resection and other concomitant procedures. Thus, controlling sepsis, maintaining fluid and electrolyte balance, and initiating nutritional support are important in the early management of these patients. Beyond this phase, the primary goals of management of SBS are to maintain adequate nutritional status, maximize the absorptive capacity of the remaining intestine, and prevent the development of complications related to both the underlying pathophysiology and the nutritional therapy itself. Surgical approaches have become increasingly important and generally include preserving the intestinal remnant, maximizing or improving the function of the intestinal remnant, and augmenting intestinal length via transplantation.

THERAPEUTIC GOALS

Maintain Nutritional Status

The most important therapeutic objective in the management of SBS is to maintain the patient's nutritional status. By necessity, this is achieved primarily by PN support in the early postoperative period. Enteral nutrition support can be started early after operation when the ileus has resolved. With time, an increasing amount of nutrients will be absorbed via the enteral route; this is important for maximizing intestinal adaptation and for preventing complications related to PN. As their conditions improve and intestinal adaptation occurs, many patients are able to absorb the necessary nutrients entirely via the enteral route. Intestinal remnant length has important prognostic implications in this regard. Patients with more than 180 cm of small intestine remaining generally require no PN, those with more than 90 cm of small intestine and particularly with colon will generally require PN for less than 1 year, and those with less than 60 cm of small intestine will likely require permanent PN.

During the transition from parenteral to enteral nutritional support, the primary objectives are to maintain a stable body weight and prevent large fluctuations in fluid balance. Metabolic monitoring is necessary to detect and correct any metabolic abnormalities and micronutrient deficiency. A marked increase in gastrointestinal fluid loss is a sign that further increases in enteral feeding will not be tolerated. As parenteral requirements diminish, intermittent PN can be instituted, reducing hours of therapy during the day and eventually alternating days. Some patients will require ongoing fluid supplementation.

Maximize Enteral Nutrient Absorption

Dietary management for an individual patient with SBS is determined by a variety of factors, including intestinal remnant length and location, any underlying intestinal disease, and the status of

the remaining digestive organs. The existence of a stoma is also an important consideration because diarrhea and perianal complications may markedly diminish oral intake. Thus, patients with stomas may be more likely to take a greater percentage of their calories enterally. Patients with SBS, in fact, may develop hyperphagia to overcome their inefficient absorption. Continuous rather than intermittent enteral feeding may permit greater absorption of nutrients in patients with remnants less than 90 cm.

The optimal diet for patients with SBS is determined primarily by whether or not the colon is in continuity. Initially a high-carbohydrate, high-protein diet is appropriate to maximize absorption. Fat absorption requires more digestion unless the fat is supplied in the form of medium-chain triglycerides. Stool fat increases markedly, however, with remnants less than 60 cm. The ability to absorb these nutrients does improve with time; thus, the diet should be continually modified. Other problems, such as lactase deficiency, may also be present. Patients with colon in continuity should have fat restricted to 20% to 30% of caloric intake and should have oxalate restricted to prevent nephrolithiasis. Because jejunal mucosa is relatively permeable, isotonic feedings are particularly important with jejunal remnants. Ingestion of a glucose-electrolyte oral rehydration solution with a sodium concentration of at least 90 mmol/L optimizes water and sodium absorption in the proximal jejunum and prevents secretion into the lumen. The role of specific nutrients (e.g., glutamine) remains controversial.

Another important aspect of the dietary management is to provide a diet that will maximize the intestinal adaptive response. Provision of fat, particularly long-chain triglycerides, and dietary fiber may be particularly important in this regard. Glutamine may be trophic to the gut. Although these nutrients may act directly to stimulate intestinal adaptation, the meal may also stimulate intestinal adaptation via endocrine or paracrine effects. Growth factors (e.g., growth hormone and glucagon-like peptide 2 [GLP-2]) may also stimulate intestinal adaptation.

Minimizing gastrointestinal secretion and controlling diarrhea are also important goals for maximizing absorption (Table 1). The addition of dietary fiber is useful in patients who are not fluid secretors. Several agents are useful for improving absorption via their antisecretory and antimotility effects, including narcotics such as codeine and diphenoxylate-atropine (Lomotil) and the peripherally acting narcotic loperamide. The long-acting somatostatin analogue octreotide improves diarrhea by increasing small intestinal transit time, reducing salt and water excretion, and reducing gastric hypersecretion. However, it may not remain effective long term and has potentially deleterious effects, including steatorrhea, inhibition of intestinal adaptation, and increased incidence of cholelithiasis. Thus, octreotide should not be used routinely for the management of chronic diarrhea. Both H_2 receptor antagonists and proton pump inhibitors have been shown to be effective in controlling gastric hypersecretion. Cholestyramine may also be beneficial when the diarrhea is related to the cathartic effect of unabsorbed bile salts in the colon and less than 100 cm of ileum has been resected.

Pharmacologic therapy for SBS is a rapidly expanding area of investigation. A variety of growth factors and hormones have been identified that promote intestinal growth or enhance absorptive function. Growth hormone has trophic and pro-absorptive effects on the gut as well as other metabolic effects. However, growth hormone alone has not had a consistent beneficial effect in clinical trials. Teduglutide, a GLP-2 analogue, is approved for use in SBS and promotes intestinal absorption and adaptation. Studies suggest that this therapy reduces the need for supplemental fluids and nutrients. Liraglutide and other GLP-1 analogues are currently being used off-label to slow gastric emptying and intestinal motility.

*Off-label use.

Prevent Complications

Metabolic complications are common in SBS patients (Table 2). Patients are at risk for dehydration and renal dysfunction. Hypocalcemia is a common problem related to poor absorption and binding by intraluminal fat. Maintaining adequate levels of calcium, magnesium, and vitamin D supplementation are important to minimize bone disease. Hyperglycemia and hypoglycemia are frequent complications of patients receiving a large amount of their calories parenterally. Both metabolic acidosis and alkalosis can occur.

Specific nutrient deficiencies must be prevented and monitored closely. These include iron and vitamin deficiencies as well as micronutrients such as selenium, zinc, and copper. Because fat is poorly absorbed, fatty acid deficiency can also occur. Serum free fatty acid levels and triene-to-tetraene ratios may need to be monitored periodically to determine the need for supplementation and response to treatment. In general, the enteral intake must greatly exceed the absorptive needs to ensure that these needs are being met.

Catheter-related sepsis is an important problem that often necessitates rehospitalization and replacement of catheters. Attention to technique and meticulous patient education are important to prevent this complication. Ethanol and antibiotic lock therapy may also be preventative. Catheter thrombosis is another frequent problem. In patients who require total parenteral nutrition permanently, this may become an important factor in the patient's survival because vascular access may not be achievable indefinitely.

PN-induced liver disease is another potential long-term problem. This appears to be a multifactorial process that is often reversible but may lead to severe steatosis, cholestasis, and eventually cirrhosis. It occurs more frequently in children and accounts for one-third of deaths in patients on long-term PN. It can be minimized by providing as large a portion of the calories as possible enterally, avoiding overfeeding, using mixed fuels (<30% fat), minimizing lipids (especially soy based), and preventing specific nutrient deficiencies. Treating bacterial overgrowth and preventing recurrent sepsis are also important.

Bacterial overgrowth may result from impaired motility or stasis caused by obstructive lesions. Depending on the bacterial species present, secretory diarrhea may also occur. Bacterial overgrowth requires a high degree of suspicion for diagnosis. This complication

TABLE 2 Complications in Short Bowel Syndrome

Therapy Related	Physiologic
Metabolic	Bacterial overgrowth
Nutritional	Cholelithiasis
Infectious	Nephrolithiasis
Liver disease	Gastric hypersecretion

should be suspected when a patient's absorptive capacity and stool habits change acutely. This may result from a mechanical obstruction or a blind loop, which can be relieved by operation. However, it is often a primary motor abnormality, which requires intermittent therapy with antibiotics. Colonization of the lumen with probiotics is another potential therapy.

Cholelithiasis occurs in 30% to 40% of SBS patients. Long-term PN causes both altered hepatic bile metabolism and gallbladder stasis. Biliary sludge forms within a few weeks of initiating PN if there is no enteral intake but rapidly disappears when enteral nutrition is resumed. Patients receiving PN are at risk for both cholelithiasis and hepatocellular dysfunction and thus require careful clinical evaluation. Intestinal mucosal disease and resection, particularly of the ileum, cause bile acid malabsorption, leading to lithogenic bile and the formation of cholesterol stones. The risk for cholelithiasis is significantly increased if less than 120 cm of intestine remains after resection, the terminal ileum has been resected, and PN is required. The incidence of cholelithiasis can be minimized by providing nutrients enterally whenever possible and using therapies to intermittently stimulate gallbladder emptying. Cholelithiasis is more likely to be complicated in patients with SBS and requires more extensive surgical treatment. Prophylactic cholecystectomy should be considered when laparotomy is being undertaken for other reasons.

Nephrolithiasis, primarily calcium oxalate stones, also occurs with some frequency. Oxalate is normally bound to calcium in the intestinal lumen and is not absorbed. Decreased availability of calcium secondary to reduced intake or binding by intraluminal fat leaves free oxalate in the lumen. Thus, the oxalate is absorbed in the colon and forms calcium oxalate in the urine. Nephrolithiasis is unusual in patients with intestinal resection and jejunostomy but occurs in one-fourth of such patients with an intact colon within 2 years of resection. Nephrolithiasis can be prevented by maintaining a diet low in oxalate, minimizing intraluminal fat, supplementing calcium orally, and maintaining a high urinary volume. Cholestyramine, which binds oxalic acid in the colon, is another potential treatment.

Gastric hypersecretion is a potential problem in patients with SBS. Massive intestinal resection can cause gastric hypersecretion as a result of parietal cell hyperplasia and hypergastrinemia. This phenomenon is usually transient, lasting several months, and presumably involves loss of an inhibitor from the resected intestine. The associated hyperacidity exacerbates malabsorption and diarrhea. About one-fourth of patients undergoing massive resection develop peptic ulcer disease. Treatment of gastric acid secretion may improve absorption but also prevents peptic ulcer disease. Control of acid secretion by H_2 receptor antagonists or proton pump inhibitors should be initiated in the perioperative period after resection and maintained until the increased acid production resolves. A few patients eventually require surgical intervention, but gastric resection should be avoided when possible.

SURGICAL STRATEGIES

Preserve the Intestinal Remnant

Abdominal reoperation is required in approximately 50% of patients with SBS after discharge from the hospital. Intestinal problems are the most frequent indication. An important goal in any reoperation in patients with SBS is to preserve the intestinal remnant length. Resection can often be avoided by using intestinal tapering to improve the function of dilated segments, employing strictureplasty for benign strictures, and using serosal patching for certain strictures and chronic perforations. Resection should be limited in extent when it cannot be avoided. Depending on the previous operations performed, patients will occasionally have intestinal segments that can be recruited into continuity at the time of reoperation. Often reconstruction of the proximal gastrointestinal tract is beneficial (e.g., previous Roux-en-Y gastric bypass). It is always important to document the length of intestine remaining during any operation on a patient with SBS.

An important clinical issue is whether to establish intestinal continuity in patients who have a colonic remnant. There are both advantages and disadvantages to restoring continuity. The colon may in fact improve intestinal absorption by increasing the absorptive surface area, deriving energy from short-chain fatty acids and prolonging transit time. It also improves quality of life by avoiding the stoma. However, the response of the colon to luminal contents is somewhat unpredictable. Bile acids may in fact cause a secretory diarrhea. Perianal problems can be disabling and decrease the patient's oral intake. Oxalate is absorbed primarily in the colon, and patients are thus at increased risk for the formation of calcium oxalate stones. Historically, only one-fourth of patients who initially had a stoma formed ultimately had continuity restored with a satisfactory outcome. However, we have become more aggressive about restoring continuity. This decision should be considered on an individual basis, depending on the length of the intestinal remnant and other anatomy and the patient's overall condition. Generally, at least 60 cm of small intestine are required to prevent severe diarrhea and perianal complications.

Surgical Therapy for Short Bowel Syndrome

There are several goals of surgical therapy for short bowel syndrome (Fig. 1). One has been to slow intestinal transit by reversing intestinal segments, interposing colonic segments into the small intestine, and other innovative approaches. Another goal has been to improve the function of existing intestine. For example, stenotic segments cause partial obstruction, which could lead to malabsorption. This can be managed by relieving the obstruction, often with a simple approach such as a strictureplasty. Furthermore, dilated dysfunctional segments aggravate malabsorption. These can be treated by tapering enteroplasty. For patients with particularly short remnants, increasing intestinal surface area is the best option for improving nutrient absorption. Intestinal lengthening procedures combine tapering with lengthening and are applicable in some patients. However, intestinal transplantation may be the final solution to this problem.

The surgical approach to the patient with SBS depends on several factors. The nature of nutritional support is obviously the primary determinant as to whether operation should be considered. In our experience, one-half of patients with SBS are able to sustain themselves on enteral nutrition alone. Operation should be considered cautiously and generally performed in these patients only if they demonstrate worsening malabsorption, are at risk for requiring PN, or have other symptoms related to malabsorption. Almost one-half of patients who are stable on long-term PN are candidates for operation, with the goal in this group being primarily to get the patient off PN. Patients who develop significant complications while dependent on PN have more compelling reasons to undergo operation. Most of these patients should undergo intestinal transplantation because many will die. Although liver disease is a frequent indication for transplantation, difficult vascular access and recurrent sepsis are also considerations. Patient age and underlying disease are also important factors. Children are much more likely to adapt to enteral nutrition but are also more likely to be candidates for operative treatment. In our experience, adult patients with mesenteric vascular disease and malignancy undergo operation less frequently.

The choice of operation for SBS is influenced by intestinal remnant length, intestinal function, and the caliber of the intestinal remnant (Fig. 2). These factors allow identification of several patient groups that might be treated by specific surgical procedures.

Adequate Remnant Length with Dilated Bowel

Adult patients with intestinal remnants greater than 120 cm are likely to be sustained on enteral nutrition alone, particularly if the ileocolonic junction is intact. However, these patients may develop

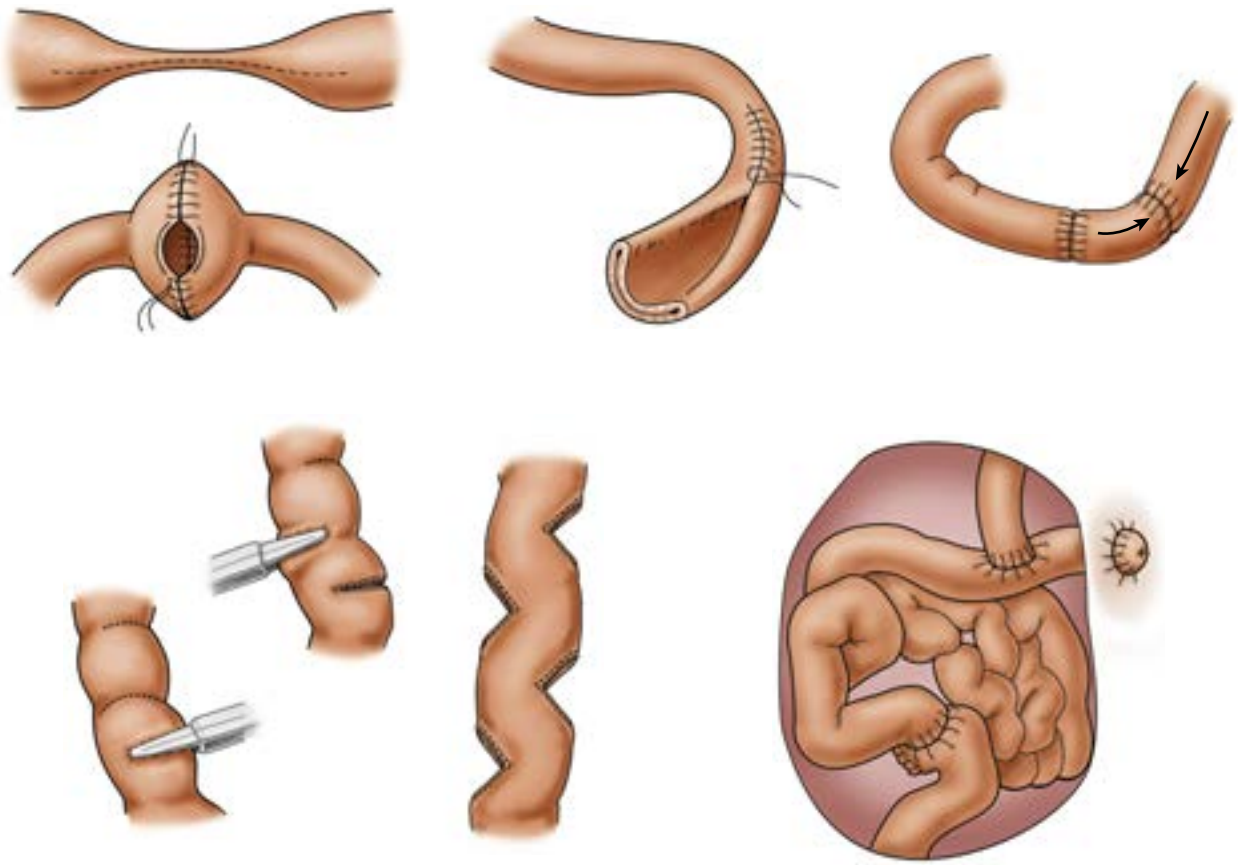

FIG. 1 Surgical procedures for improvement of intestinal function in short bowel syndrome. *(Modified from Thompson JS, Langnas AN, Pinch LW, et al. Surgical approach to short-bowel syndrome. Experience in a population of 160 patients. Ann Surg. 1995;222:605–607; Kim HB, Fauza D, Garza J, et al. Serial transverse Enteroplasty [STEP]: a novel bowel lengthening procedure. J Pediatr Surg. 2003;38:425–429.)*

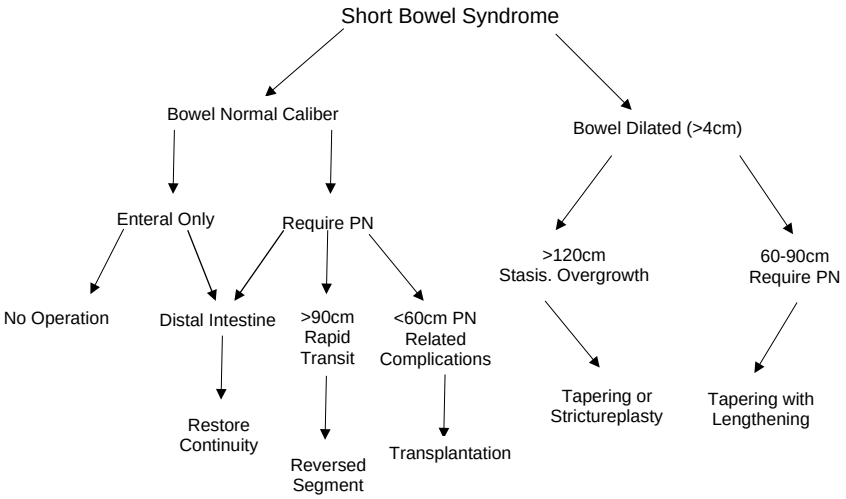

FIG. 2 Surgical management of short bowel syndrome. *PN,* Parenteral nutrition.

dilated bowel secondary to obstruction, often at the site of a previous anastomosis. A useful approach to these patients is to relieve the intestinal obstruction, often with a strictureplasty, although other procedures may be necessary. Children with remnants greater than 60 cm usually are sustained on enteral nutrition alone. Dilation of the intestinal remnant occurs more frequently in children and appears to have a different pathophysiologic basis. This may be a variant of intestinal pseudo-obstruction. Only one-fourth of children with a significantly dilated bowel have mechanical obstruction, but they routinely have bacterial overgrowth. Thus, for children, a tapering enteroplasty is often the appropriate therapy and also deals with any obstructive component present. This can be accomplished either by excising the redundant bowel along the antimesenteric border or simply imbricating it; the latter is our preferred approach. Motility is

generally slow to return. Recurrent dilation is a concern, but repeat tapering may be feasible.

Moderate Remnant Length with Rapid Transit

A challenging group of patients are those who have a shorter remnant (90–120 cm in adults) and signs of rapid transit. Slowing the rapid intestinal transit may permit these patients to be supported by enteral means alone. There are several possible approaches to this problem. Reversing 10- to 15-cm intestinal segments has been used most frequently in SBS. Longer reversed segments are more likely to be associated with chronic obstruction, whereas the shorter segments have less influence on intestinal transit and function. Almost 100 patients have been reported in the literature, and although documentation is usually not extensive, clinical improvement has been reported in at least one-half of patients. Some concerns have been raised about long-term function with the procedure. Both isoperistaltic and antiperistaltic colon interposition have been attempted. Although it appears that transit time may be prolonged because of the intrinsic differences in motility between the colon and small intestine, actual benefit has been difficult to show in a few anecdotal reports. Creation of various artificial valves to replace the ileocecal valve has been attempted. We have performed the valve procedure by creating a sphincter similar to that used in the continent ileostomy procedure but of shorter length (2 cm). We have had a favorable result in one adult and one child with this valve, but outcomes have not been as successful in the few other reports.

Patients with a Short Remnant and Dilated Bowel

Patients with short remnant length (<90 cm in adults and <30 cm in children) and dilated intestinal segments represent a more difficult problem. Even though the dilated segment could be tapered, this still does not result in enough functional bowel to avoid PN. In this situation, we and others have found intestinal lengthening to be the optimal treatment. The initial technique involved longitudinal intestinal tapering and lengthening, the Bianchi procedure. This involves dissection along the mesenteric edge of the bowel to allocate terminal blood vessels to either side of the bowel wall. Longitudinal transection of the bowel is then performed, usually with a stapling device that creates two parallel limbs of a smaller caliber. These can then be anastomosed to lengthen the intestinal remnant. More than 100 cases have been reported, mostly in children. Segments have been lengthened up to 55 cm, and overall improved nutrition resulted in approximately 90% of patients. This is a technically challenging procedure. Complications have been reported in 20% of procedures, which not surprisingly include ischemia and anastomotic leaks. Recurrent dilation has been a concern. However, follow-up for longer than 10 years suggests that this procedure has long-term benefit.

More recently, longitudinal lengthening has been supplanted by the *serial transverse enteroplasty procedure* (STEP) (see Fig. 1). This involves serial transverse applications of a linear stapler from opposite directions, dividing the bowel from either the mesenteric and antimesenteric sides or transversely. The length of the transverse division is determined by the intestinal diameter. This procedure avoids the difficult dissection along the mesenteric border of the Bianchi procedure and the end-to-end anastomosis. The bowel may have to be more dilated to use this technique. lt is more feasible in challenging areas such as near the ligament of Treitz. There are fewer complications with this technique. This procedure can be repeated if recurrent dilation occurs. Thus, the technique has become the procedure of choice for intestinal lengthening.

One of the limitations of intestinal lengthening procedures is that they can be applied only to a fairly select group of patients who have both a short intestinal remnant and an intestinal diameter greater than 3 to 4 cm. To improve the applicability of this technique, surgeons have used sequential operations employing first a procedure such as inserting an artificial valve to produce intestinal dilation and then performing the lengthening at a later time.

Short Remnant Length and Parenteral Nutrition–Related Complications

Patients with short intestinal remnants (<60 cm in adults and <30 cm in children) who develop complications related to PN represent a challenging group. For these patients, intestinal transplantation is the ideal solution. Patients with liver failure and SBS have been candidates for combined liver and small intestine transplantation. Patients who have reversible liver dysfunction or who have adequate liver function but other complications such as difficult vascular access and recurrent infection are candidates for solitary intestinal transplantation. More recently, isolated liver transplantation has been advocated for patients with irreversible liver failure and SBS that can be rehabilitated. The significant mortality rate among patients developing PN-induced complications justifies what continues to be a formidable operative approach.

More than 3000 intestinal transplantations have been performed worldwide. These have included primarily isolated small intestinal grafts (50%), combined liver and small intestinal grafts (25%), and multivisceral grafts (25%). The majority of transplant recipients are children. Although the morbidity and mortality rates remain significant, 80% of patients who survive the procedure long term have been able discontinue PN and return to more normal function. Long-term graft loss remains an important issue. Reported patient survival is 76% at 1 year, 56% at 5 years, and 43% at 10 years.

It is hoped that with greater experience and improved results, this therapy can be extended to other patients with SBS. The more successful recent outcome has been related, in part, to the use of new immunosuppressive agents and other innovative approaches to modifying the immune response. Of all of the surgical approaches, intestinal transplantation has the greatest potential for treating these patients, both in terms of the number of patients who would benefit and the functional improvement derived. Transplantation is clearly appropriate for individuals with anticipated survival of less than 12 months related to PN-induced complications. A more aggressive approach to the use of intestinal transplantation, particularly solitary transplantation, is justified in patients with signs of early liver dysfunction and other severe complications of nutritional therapy.

MULTIDISCIPLINARY APPROACH

Comprehensive care of intestinal failure patients requires a multidisciplinary approach. A physician leader with expertise in gastrointestinal disease should coordinate the efforts. Gastrointestinal surgical expertise in both adult and pediatric patients is required, and the presence of a transplant surgeon broadens the therapeutic options. Administrative support to coordinate the process and database is essential. A nurse coordinator is indispensable in day-to-day management. A nutritionist is essential. Psychologists and social workers are important for addressing psychosocial issues. This multidisciplinary effort can optimize patient outcome.

Management of Enterocutaneous Fistulas

Grace C. Lee, MD, and Richard A. Hodin, MD

OVERVIEW

Enterocutaneous (EC) fistulas are among the most challenging, morbid conditions that general, gastrointestinal, and colorectal surgeons face. EC fistulas are abnormal connections between the lumen of the gastrointestinal tract and the skin. This term also includes enteroatmospheric (EA) fistulas, which are direct communications between the bowel and a nonepithelialized granulating wound that occur after nearly 10% of temporary abdominal closures. The majority of EC fistulas (75%–85%) are iatrogenic or postoperative in etiology, caused by anastomotic leaks (50%), missed enterotomies (45%), missed traumatic injuries, puncturing of bowel by percutaneous catheters, and/or erosion of foreign material such as mesh into adjacent bowel. The 15% to 25% of EC fistulas that develop spontaneously are often due to inflammatory bowel disease, malignancy, or prior radiation (Box 1).

Patients with EC fistulas can have severely impaired quality of life with malnutrition and chronic wounds that can be difficult to manage. Despite significant improvements in our knowledge of how to care for patients with EC fistulas, the overall mortality rate remains 15% to 25%, usually due to sepsis, malnutrition, and electrolyte imbalances.

This chapter focuses on the management of EC fistulas, which involves the multidisciplinary care by surgeons, wound and ostomy nurses, nutritionists, pharmacists, radiologists, and occasionally gastroenterologists. Through a stepwise approach that includes sepsis control, fluid and electrolyte repletion, nutritional optimization, control of effluent, wound care, and potential delayed operative intervention, outcomes have improved, though patients must be counseled that the process is resource-intensive and can take months to years.

PRESENTATION

The classic presentation of an EC fistula is in a patient anywhere from several days to several weeks out from surgery who develops fever, leukocytosis, and erythema around their incision. Opening the infected part of the incision generally releases purulent fluid, which then continues to drain and becomes a bilious green or brown color in appearance. EC fistulas can also be found in postoperative patients who develop abdominal pain, fever, and leukocytosis, and are found to have intraabdominal fluid collections on CT scans. An image-guided percutaneous drain initially produces purulent output, which then turns bilious or feculent.

Patients who develop EC fistulas can range from floridly septic with localized or diffuse peritonitis, which is less common, to having more mild symptoms of abdominal discomfort and leukocytosis. Surgeons must have a high index of suspicion for EC fistulas, as early recognition is key to starting appropriate treatment and preventing the development of sepsis.

BOX 1 Causes of Enterocutaneous Fistula Formation

Postoperative or iatrogenic (75%–85%)
- Anastomotic leak
- Missed enterotomy
- Missed traumatic injury
- Bowel injury from percutaneous catheter placement
- Erosion of foreign material (i.e., mesh) into adjacent bowel

Spontaneous (15%–25%)
- Inflammatory bowel disease
- Malignancy
- Prior radiation

CLASSIFICATION

EC fistulas are primarily classified based on daily output (Table 1). After recognition of an EC fistula, patients should be made nil per os (NPO) so that baseline fistula output, without any oral or enteral stimulation, can be ascertained. Low-output fistulas drain <200 mL per day, moderate-output fistulas drain 200 to 500 mL per day, and high-output fistulas drain >500 mL per day. This classification influences how fistulas are managed because low-output fistulas are much more likely to spontaneously close, whereas high-output fistulas are associated with dehydration, electrolyte disturbances, and malnutrition.

Fistulas are also classified based on location of the origin of the gastrointestinal leak. These include gastric, duodenal, enteric (small intestine), and colonic, the latter of which is called a *colocutaneous fistula.*

STABILIZATION AND SEPSIS CONTROL

The first step in management of EC fistulas is stabilization and sepsis control. Septic patients must be treated as per the Surviving Sepsis Guidelines, with fluid resuscitation, hemodynamic assessment, transfer to an intensive care unit if necessary, and initiation of broad-spectrum antibiotics. This step is critical because more than 70% of the mortality associated with EC fistulas is due to sepsis and uncontrolled infection.

Once the patient has been stabilized, the next step is to obtain source control by draining any intraabdominal abscesses. Abdominal axial imaging should be obtained to identify and characterize any abscesses (Fig. 1). For superficial abscesses that are already draining spontaneously, a small incision and debridement bedside procedure can be done to ensure continued egress of the effluent. Deeper intraabdominal or pelvic abscesses can be drained with image-guided percutaneous catheter placement by interventional radiology. These drains should be upsized and replaced as needed, with the goal of converting an uncontrolled enteric leak into a controlled EC fistula.

Operative intervention at this stage is rarely indicated; however, the occasional patient with peritonitis or evidence of free perforation on imaging should be taken urgently to the operating room for exploration. Abscesses and enteric contamination should be washed out. Oftentimes, the degree of inflammation and friability of tissues

TABLE 1 Classification of Enterocutaneous Fistulas Based on Daily Output

Classification	Daily output (mL/day)
Low output	<200
Moderate output	200–500
High output	>500

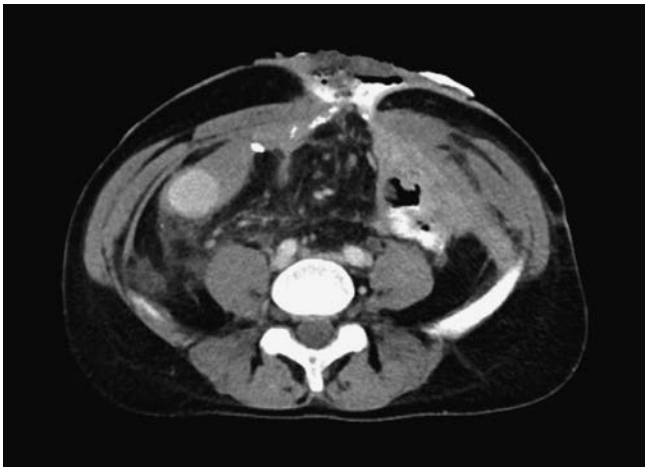

FIG. 1 CT scan shows enterocutaneous fistula with no drainable abscesses.

precludes safely running the bowel and identifying the leak. Performing an extensive lysis of adhesions in this state is fraught with danger, as healthy loops of bowel can be injured, leading to unnecessary bowel resections or missed enterotomies. If the source of the leak is identified, bowel resection can be performed; however, an anastomosis should not be created, as the risk of a recurrent leak is substantial. Similarly, primary repairs tend to not be durable solutions. Surgeons should have a low threshold to perform fecal diversions and/or leave drains to create a controlled fistula. It is important to remember that these are damage-control operations to address intraabdominal sepsis, not to definitively repair the enteric leak.

Once a patient has been stabilized and abscesses have been drained, antibiotics can be stopped in 4 to 7 days, pending clinical improvement. Longer courses of antibiotics are unnecessary for controlled EC fistulas and could lead to multiresistant organisms, which could make further antimicrobial management difficult. If a patient develops recurrent fevers, leukocytosis, or abdominal pain, clinicians should have a low threshold to reimage, as new abscesses could develop even after initial source control has been obtained.

LONG-TERM MANAGEMENT

As soon as the patient is stabilized and sepsis is controlled, then long-term management begins, usually starting within 2 days of diagnosis and lasting months to years. This chronic management consists of fluid and electrolyte repletion, nutritional optimization, pharmacologic control of effluent volume, and wound care, all of which are performed in parallel, using multidisciplinary expertise (Fig. 2). With this treatment, approximately 30% to 35% of EC fistulas will heal spontaneously within 5 to 6 weeks of diagnosis. Therefore, long-term management aims to increase the likelihood of spontaneous closure while also optimizing the patient for possible operative intervention.

Fluid and Electrolyte Repletion

Patients with EC fistulas, particularly high-output EC fistulas, can develop severe dehydration and electrolyte derangements. Quantifying fistula output and resuscitating adequately are crucial for the acute and long-term management of these patients. Many patients with high-output EC fistulas utilize total parenteral nutrition (TPN) for not only nutrition but also volume resuscitation. These patients often have long-term central access (such as peripherally inserted central catheters) for TPN, which enables them to also administer extra intravenous fluid infusions at home if needed based on fistula output.

The most common electrolyte abnormalities are hyponatremia, hypokalemia, and hypomagnesemia. Hyponatremia often normalizes with fluid resuscitation, and potassium and magnesium should be aggressively repleted. Patients with duodenal fistulas can develop metabolic acidosis requiring sodium bicarbonate replacements. After starting parenteral nutrition or resuming enteral nutrition, patients must be closely monitored for refeeding syndrome, with frequent serum phosphorus checks and phosphorus repletion.

Nutritional Optimization

Patients with EC fistulas can develop profound malnutrition, as they can lose up to 500 g of protein daily. Markers of nutritional status such as prealbumin, albumin, and transferrin should be monitored closely. Patients with low-output fistulas require 20 kcal/kg per day of carbohydrates and fat and 1 g/kg per day of protein, which can increase to 30 kcal/kg per day and 1.5 to 2.5 g/kg per day for patients with high-output fistulas.

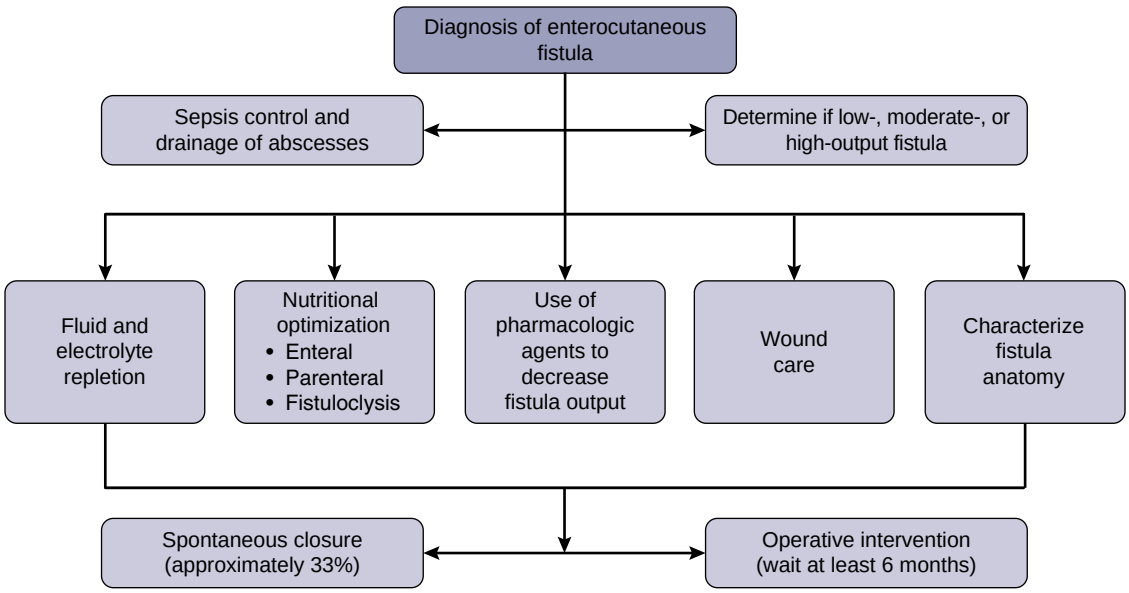

FIG. 2 Algorithm for the management of enterocutaneous fistulas.

Enteral feeding is preferred to parenteral nutrition because it promotes mucosal integrity, maintains intestinal function, and supports immune function. However, oral intake can often increase fistula output substantially, which can be a problem for wound care in some patients. TPN is usually needed as a bridge to enteral feeding or for longer-term nutrition in patients who cannot tolerate oral intake.

A common approach for patients with newly diagnosed fistulas is to attempt a few days of bowel rest, with or without TPN depending on the patient's nutritional status, to see if the fistula spontaneously closes or if the output decreases. If the output persists, then an oral diet is gradually introduced. If the fistula output increases significantly and there are concerns for malabsorption, then TPN is started. Pharmacologic measures, as discussed later, should be used to slow fistula output. As long as fistula output is controlled and wound care is manageable, most patients are able to continue an oral diet, with or without TPN for nutritional support. This holds true even for high-output fistulas, assuming that ostomy appliances are well seated and capture the output, and assuming that patients can provide themselves with additional IV fluids as needed.

Fistuloclysis

Fistuloclysis has become a popular method of enteral feeding distal to the EC fistula. With this technique, the distal limb of the EC fistula is identified using a fistulogram, which can be performed by interventional radiology or in the operating room using fluoroscopy (Fig. 3). The interventional radiologist or surgeon cannulates the distal limb with a catheter, which can then be used to instill tube feeds. Ideally, the surgeon tunnels the catheter under the skin, which enables securing of the catheter more firmly in place and facilitates easier wound care. For patients with high-volume liquid output, their effluent can be collected, strained, and then refed into the distal feeding tube. This method should only be used in patients who have fistulas that are not expected to close spontaneously, as cannulating the distal limb of the fistula will prevent it from closing.

FIG. 3 Example of a fistulogram, in which a catheter is inserted into the fistula, enteric contrast is injected, and the bowel is opacified.

Fistuloclysis enables maintenance of mucosal integrity and promotes intestinal adaptation and lengthening, which is beneficial for patients who will likely require operative intervention. It also enables patients to wean off parenteral nutrition. Furthermore, fistuloclysis has been shown to activate an "ileal brake," in which refeeding of succus leads to decreases in gastric acid secretion, pancreatic enzyme secretion, and peristalsis, thereby decreasing EC fistula output.

The careful balance between oral intake, distal tube feeds, succus refeeding, and parenteral nutrition requires collaboration with nutritionists who follow these patients closely as inpatients and outpatients and whose expertise is key to the long-term optimization of these patients.

Pharmacologic Management of Fistula Output

Another key component to the long-term management of EC fistulas is controlling effluent volume. First-line pharmacologic agents include opiate receptor agonists such as loperamide, diphenoxylate/atropine, codeine, and distilled tincture of opium, which act on the circular and longitudinal intestinal muscles to decrease peristalsis. These medications can be titrated up as needed to slow fistula output. Proton pump inhibitors and histamine-2 receptor antagonists are also part of the first-line treatment of high-output EC fistulas, as they lower the acidity of fistula output, while also decreasing volume due to their antisecretory effects.

Other agents can be added to the first-line pharmacologic therapies. Amitriptyline is a tricyclic antidepressant that causes constipation via anticholinergic pathways. Clonidine, an alpha 2-adrenergic agonist, increases mucosal absorption of fluids and electrolytes. Bulking agents such as psyllium or banana flakes can also be helpful to thicken enteric contents. Cholestyramine, a bile acid sequestrant, is useful in decreasing the output of more proximal EC fistulas, such as those originating from the duodenum or proximal jejunum. Octreotide, a somatostatin analog, has been recommended for use in high-output fistulas. It acts by reducing gastric acid and pancreatic enzyme secretions, as well as enhancing fluid and electrolyte absorption by prolonging intestinal transit time. Numerous studies have demonstrated that octreotide does not increase the likelihood of spontaneous fistula closure; however, it does decrease fistula output and the time it takes for fistulas to close.

With these pharmacologic agents, even high-output EC fistulas can be slowed to the point that many patients resume oral intake while keeping fistula output within a goal of <1 to 1.5 L per day.

Wound Care

The skin surrounding EC fistulas often becomes excoriated due to spillage of acidic succus, similar to ileostomies that are difficult to pouch (Fig. 4A). Patients with EC fistulas benefit from the expertise of wound and ostomy nurses who develop plans for isolating the fistulas and protecting the surrounding skin. These complex wounds usually require a combination of stoma paste and powders, barrier rings, and hydrocolloid dressings, as well as specialty ostomy appliances that can be cut to fit the fistulas (Fig. 4B and 4C). Pouches need to accommodate fistuloclysis catheters that directly enter the wound, which is why catheters that tunnel under the skin and come out away from the wound are preferred. EA fistulas sometimes require sump drains to collect the effluent and divert it away from the surrounding skin.

Vacuum dressings can be used to promote granulation of the surrounding tissues and protect those tissues from effluent. However, they must be used with caution. If vacuum dressings are placed

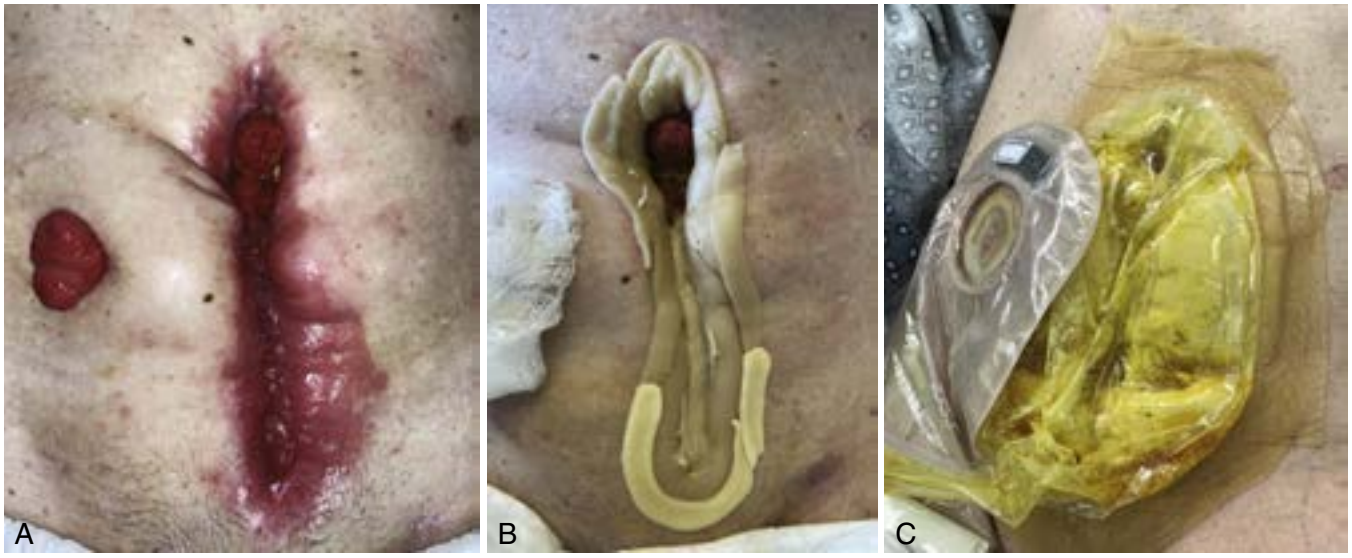

FIG. 4 A patient with multiple enterocutaneous (EC) and enteroatmospheric (EA) fistulas along a prior midline incision. **(A)** Note the skin excoriation around the fistulas. There is an ileostomy in the right lower quadrant that was distal to the fistulas. **(B)** The wound care plan included protecting the surrounding skin with stoma paste and barrier rings molded to the shape of the wound, thus also isolating the main fistulas. **(C)** Stoma appliances were then placed over the fistulas and the ileostomy to catch the effluent. Note that the main stoma appliance is further secured by adhesive dressings.

on granulation tissue directly over bowel or on a skin graft directly over bowel, the suction force could promote the development of new fistulas. Nevertheless, numerous small studies have demonstrated that, when used appropriately, vacuum dressings can promote wound healing and may even accelerate spontaneous closure.

Wound care plans often change over time as the wounds ideally heal and contract. Wound and ostomy nurses work very closely with patients and their families, teaching them tips and tricks to care for their wounds during the months- to years-long process.

Define the Fistula Anatomy

Next, it is critical to characterize the anatomy of the EC fistula, utilizing imaging studies such as CT scans with oral contrast, upper gastrointestinal swallow studies with small bowel follow through, contrast enemas, and fistulograms in which the proximal and distal limbs of the fistula are cannulated and injected with oral contrast under fluoroscopy (see Fig. 3). The goal of these studies is to delineate the location of the fistula, how much bowel is proximal and distal to the fistula, and assess if there are multiple fistulas. They can also determine if fistuloclysis will be possible. Furthermore, these studies can assess for distal obstructions, which would make spontaneous closure unlikely, and can help with operative planning.

SPONTANEOUS CLOSURE

Approximately 30% to 35% of EC fistulas will close within 2 months of diagnosis without operative intervention (Box 2). Fistulas with tracts longer than 2 cm, defect sizes of <1 cm^2, and decreasing output are more likely to heal spontaneously. Distal obstructions, ongoing sepsis or abscess, and malnutrition are all predictors of requiring operative intervention. EC fistulas caused by Crohn's disease, malignancy, radiation, or a foreign body are also less likely to close spontaneously.

OPERATIVE INTERVENTION

EC fistulas that have not spontaneously closed within 2 months will likely require operative management. Most surgeons recommend waiting at least 6 months after the diagnosis of the fistula before considering an operation. Over this period of time, intraabdominal adhesions soften and become more filmy, thus making the operation easier and less prone to causing enterotomies. The "pinch test" for EA fistulas, in which tissue or skin graft overlying bowel is pinched to see if the underlying bowel separates easily, can also be used to determine readiness for surgery. Surgeons should wait until the patient is nutritionally optimized, sepsis is controlled, and the patient is at or close to their baseline functional status.

In the operating room, surgeons should prepare for a difficult, lengthy procedure. Ideally, the case should start in the morning, and, for complex fistulas, no other operations should be planned for the same day. Anesthesiologists should be prepared for high insensible losses and should resuscitate accordingly, using a urinary catheter for

BOX 2 Characteristics Predictive of Spontaneous Closure of Enterocutaneous Fistulas

Increased Likelihood of Spontaneous Closure
- Postoperative etiology
- Fistula tract longer than 2 cm
- Fistula defect <1 cm^2
- Healthy surrounding bowel
- Good nutritional status
- Low fistula output

Decreased Likelihood of Spontaneous Closure
- Non-postoperative etiology (inflammatory bowel disease, cancer, radiation)
- Distal obstruction
- Presence of a foreign body
- Continued sepsis or abscess present
- Epithelialized fistula tract
- Steroid use
- Malnourished
- High fistula output

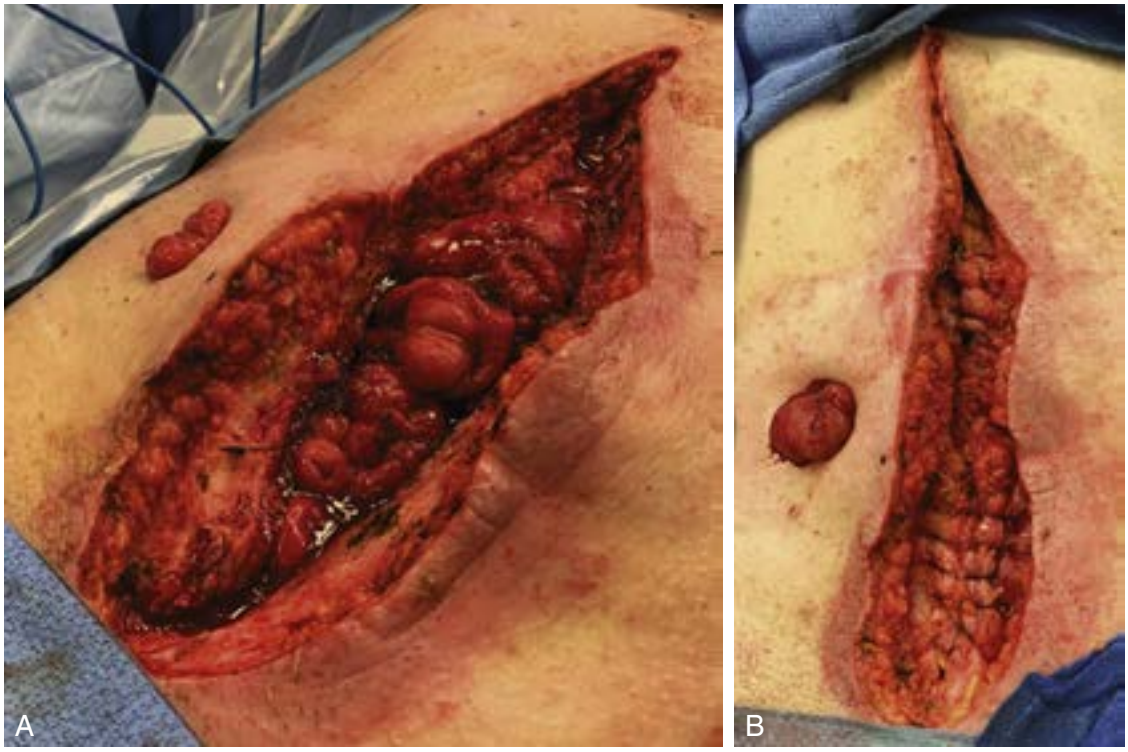

FIG. 5 The same patient from Figure 4 was taken to the operating room for an enterocutaneous (EC) fistula takedown. **(A)** Opening the wound revealed multiple loops of small bowel densely adhered to the prior incision, which were the sources of the numerous EC and enteroatmospheric (EA) fistulas. **(B)** At the conclusion of the case, a unilateral anterior component separation was used to close the fascia primarily. The loop ileostomy was converted to an end ileostomy.

accurate recording of urine output. Epidural catheters or transversus abdominis blocks should be considered for postoperative pain management. The incision should be made away from prior incisions, if possible, usually subxiphoid, and dissection should be started away from the EC fistula. An extensive lysis of adhesions with sharp dissection should be performed and the bowel should be fully mobilized, such that the exact location of the fistula, the amount of bowel involved in the fistula, and the presence of any other enterotomies can be identified. It is not uncommon for multiple loops of bowel to be involved in the inflammatory mass surrounding EC fistulas (Fig. 5A). Any foreign material such as previous mesh should be removed. The surgeon should look for any distal obstruction so that it can be fully addressed. At this point, the amount of bowel to resect can be determined with the goal of preserving as much small bowel as possible to prevent future short-gut syndrome. Fistula defects should not be repaired primarily, as it will likely lead to recurrent leaks. The amount of remaining bowel should be documented.

Most of these operations require closure of a large abdominal wall defect. Due to the contamination of the wound, many surgeons would not recommend placing synthetic mesh to aid in abdominal closure. Instead, component separations should be used to close the fascia if simple primary closure is not possible (Fig. 5B). Biologic mesh can be placed in an underlay fashion if needed. Involving general surgeons or plastic surgeons who specialize in abdominal wall reconstruction can be beneficial, particularly for large and complex abdominal wall defects.

Surgeons and patients must be prepared for the possibility of a frozen abdomen. If it becomes clear that the EC fistula itself cannot be resected safely, other options include creating a diverting stoma, if one is not already present, or placing a venting gastrostomy tube and/or a distal feeding jejunostomy tube.

Though the morbidity and mortality rates of EC fistula takedowns have been improving over time, patients must still be counseled preoperatively on the risks of the procedure and the long postoperative recovery. Approximately 16% to 36% of EC fistulas will recur after surgery, though some recent studies quote operative success rates as high as 92%. Mortality has decreased from approximately 40% in the 1970s to approximately 20% currently, with some studies citing mortality rates as low as 2%. Nevertheless, 30-day morbidity rates have been reported to be nearly 50% based on analysis of the American College of Surgeons National Surgical Quality Improvement dataset. Although significant improvements have been made over the years, EC fistula takedowns remain complex, morbid operations, and patient expectations should be set preoperatively.

The postoperative recovery period typically lasts for several months. Parenteral nutrition can be weaned off as enteral nutrition improves. Many patients benefit from postoperative physical therapy, and some require stays in rehabilitation facilities.

SUMMARY

EC fistulas are complex, debilitating conditions that require multidisciplinary, long-term management. By using the algorithm of sepsis control followed by simultaneous fluid and electrolyte management, nutritional optimization, decreasing the volume of effluent, and wound care, approximately one-third of EC fistulas will close on their own. For patients who require operative intervention, waiting at least 6 months to allow for preoperative optimization and softening of adhesions has led to decreasing mortality rates and increasing rates of operative success.

Management of Radiation-Induced Injury to the Small and Large Bowel

Sophia Y. Chen, MD, MPH, and Chady Atallah, MD

INTRODUCTION

Radiation therapy plays an important role in the multimodal management of anorectal, gynecologic, and urogenital pelvic malignancies. Approximately 70% of cancer patients undergo radiation therapy for the treatment of these malignancies to prolong their disease-free survival and reduce local recurrence. Although radiation delivery is directed at the target tissue for maximum benefit, radiation fields required to treat these malignancies may nevertheless include normal small intestine, colon, and/or rectum, leading to potential injury of otherwise healthy tissue. Radiation-induced injury to the bowel therefore remains a critical issue requiring careful management considerations and preventative strategies.

PATHOPHYSIOLOGY AND HISTOPATHOLOGY

Radiation therapy is most commonly delivered via external beam radiation therapy (EBRT), which uses a linear accelerator to produce ionizing radiation. EBRT can directly or indirectly damage DNA within malignant and normal cells through its interaction with water and the release of free radicals. Depending on the extent of DNA damage, EBRT can result in mitotic inhibition or cellular apoptosis. Brachytherapy is another method of radiation delivery and involves the placement of a radiation source within the body, often in the form of pellets or beads.

The pathophysiology of radiation damage to the bowel has been described in the literature via the "target cell" theory, in which acute effects of radiation-induced injury target cells of the bowel epithelium, whereas chronic effects of radiation-induced injury target cells with slower turnover, such as endothelial cells and fibroblasts. Rapidly dividing cells like those in the gastrointestinal (GI) tract are most susceptible to radiation injury; as such, radiation affects the cells of the mucosa first, followed by the submucosa, muscularis, and serosa. Chronic radiation injury to the bowel is often associated with ischemic injury. Reaction of fibroblasts to cytokines, growth factors, and chemokines leads to fibrosis. Cellular death leads to intestinal atrophy and subsequent malabsorption and stricture formation. Radiation can also result in vascular damage, leading to dilatation of small blood vessels presenting as telangiectasias. Furthermore, arteriolar constriction can result in bowel ischemia and necrosis.

Histopathologically, acute radiation injury to the bowel is often characterized by extensive mucosal inflammation, crypt atrophy/abscesses, nuclear atypia with bizarre mitoses, and eosinophilic submucosal infiltration. Chronic radiation injury to the bowel is often characterized by obliterative enteritis (irregularly shaped endothelial cells, fibroblasts, myofibroblasts, and foamy cells within arteries), small-vessel vasculopathy (dilated, thickened, hyalinized blood vessels), ulceration, fibrous induration, and superimposed episodes of ischemic changes (Fig. 1).

RISK FACTORS

Risk factors associated with radiation-induced bowel injury include both patient factors and radiation treatment-related factors. Patient comorbidities associated with an increased risk for radiation-induced injury include smoking, diabetes mellitus, hypertension, vascular and collagen disorders, atherosclerosis, coronary artery disease, inflammatory bowel disease, and prior intestinal surgery. Chemotherapy such as fluoropyrimidines, taxanes, platinum agents, mitomycin C, gemcitabine, methotrexate, actinomycin D, topotecan, and doxorubicin can act as radiosensitizers and potentiate the effects of radiation. Low body mass index (BMI) has also been associated with increased risk for radiation injury due to higher rate of radiation toxicity.

Radiation treatment-related factors associated with increased risk for radiation-induced injury include higher radiation dose, longer length of bowel irradiated, fewer dose fractionation, and larger radiation field size.

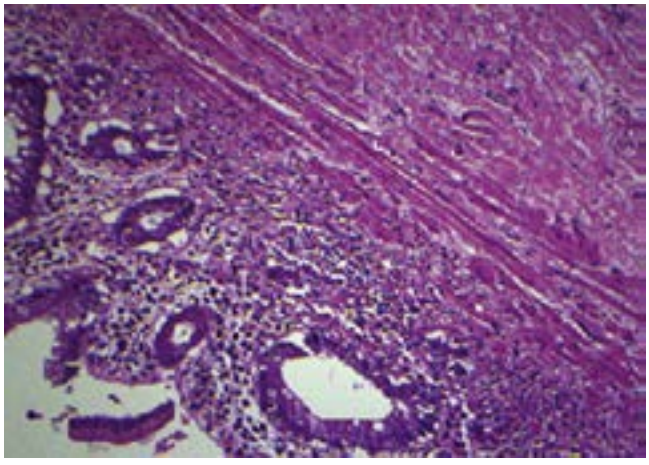

FIG. 1 Histopathology (magnification ×20) showing submucosal fibrosis with atypical fibroblasts, endothelial cells, and increased inflammatory cell infiltrate. *(From Theis VS, Sripadam R, Ramani V, Lal S. Chronic radiation enteritis. Clin Oncol. 2010; 22[1]:70–83.)*

RADIATION THERAPY TOXICITY GRADING SYSTEMS

Although various radiation toxicity grading systems exist in the literature, the Radiation Therapy Oncology Group (RTOC) and the European Organization for Research and Treatment of Cancer (EORTC) grading system is one of the most commonly used (Table 1). The RTOC/EORTC grading system differentiates acute radiation morbidity (day 1 through 90) from chronic radiation morbidity (after day 90) on a scale from 0 to 5 based on presenting symptoms. Although these grading systems provide a standardized assessment based on patient symptoms, they do not include endoscopic and histopathologic information. Other available grading systems include the Late Effects Normal Tissue (LENT) system; the Subjective, Objective, Management, and Analytic (SOMA) grading system for chronic radiation injury; and the National Cancer Institute Common Terminology Criteria for Adverse Events (CTCAE).

CLINICAL FEATURES

Acute radiation-induced bowel injury can occur from the time of radiation treatment up to 6 months after treatment completion. Because acute radiation damage leads to mucosal inflammation and damaged mucosal surface, diarrhea is one of the most common symptoms. Injury to the mucosal barrier also increases the risk for bacterial translocation and subsequent bacteremia and sepsis. Other symptoms of acute radiation-induced bowel injury include nausea, bloating, cramping, abdominal pain, and GI dysmotility. Acute radiation colitis and proctitis can present with additional symptoms of bleeding, mucus discharge, urgency, and tenesmus.

Chronic radiation-induced bowel injury can continue from the acute phase or present after a latent period. Chronic radiation injury symptoms typically present 8 to 12 months after treatment completion; however, symptoms have been reported up to 30 years after a latent period. Like acute radiation-induced injury, diarrhea is one of the most common symptoms. Chronic radiation proctitis can also commonly present with rectal bleeding due to telangiectasias. Patients with chronic radiation-induced bowel injury can also have ulcerations from ischemia, abscesses, and fistula formation. Chronic ischemic changes can lead to stricture formation and subsequent bowel obstruction. Full thickness necrosis of the bowel can result in fistulae or free perforation.

DIAGNOSIS

Acute radiation-induced injury to the small intestine, colon, and rectum is generally diagnosed based on the patient's presenting symptoms and history. Chronic radiation-induced bowel injury is diagnosed not only by symptoms but also may require additional imaging such as a CT scan or MR enterography to evaluate the anatomy and assess for strictures, fistulae, or bowel wall thickness abnormalities. Patients with suspicion for radiation colitis or proctitis may occasionally undergo barium and water-soluble contrast enemas, which can reveal shortening, narrowing, lack of distensibility, and absent haustral/mucosal folds of the bowel. Fistulae may need to be further evaluated with MRI, fistulograms, cystograms, and pelvic examinations.

Definitive diagnosis can be made endoscopically with biopsies demonstrating histologic features pertaining to radiation injury, as described previously. Upper endoscopy may be considered for suspected radiation injury to the duodenum; however, lower endoscopy may not be effective in reaching more distal areas of radiation enteritis. Capsule endoscopy should only be considered if intestinal strictures have been excluded. Lower endoscopy via colonoscopy or sigmoidoscopy is beneficial in diagnosing radiation colitis and proctitis. These are characterized by neovascularization with fragile vessels on lower endoscopy (Fig. 2). Other features of radiation-induced bowel injury include pallor and friability. Rectal biopsies should be performed judiciously, as they have been associated with increased risk of rectal fistula formation.

MANAGEMENT STRATEGIES

Medical Management

Between 50% and 75% of patients with acute radiation-induced bowel injury present with symptoms. Fortunately, these symptoms are often self-limited and can be managed medically. Diarrhea can be managed with antidiarrheal medications such as loperamide and fiber supplements, and with dietary modifications (e.g., lactose-free diet, low-fat diet, low-residue diet, or elemental diet). Patients with severe diarrhea, dehydration, and nutritional deficits may need to be admitted to the hospital for intravenous fluids and/or parenteral nutrition. If first-line antidiarrheals are ineffective, octreotide may be given. Nausea can be managed with antiemetics. Anticholinergics,

TABLE 1 RTOG/EORTC Radiation Toxicity Grading System

Grade	1	2	3	4	5
Acute radiation morbidity (Days 1–90)	• Increased frequency or change in bowel habits • Rectal discomfort • No medication	• Diarrhea requiring parasympatholytic drugs • Mucus discharge not requiring sanitary pads • Rectal or abdominal pain requiring analgesics	• Diarrhea requiring parenteral support • Severe mucus or blood discharge requiring sanitary pads • Abdominal distension	• Acute/subacute obstruction, fistula, or perforation • GI bleed requiring transfusion • Abdominal pain or tenesmus requiring tube decompression or bowel diversion	• N/A
Late radiation morbidity (Days >90)	• Mild diarrhea and cramping • Bowel movement ≤5 times daily • Slight rectal discharge or bleeding	• Moderate diarrhea and cramping • Bowel movement >5 times daily • Excessive rectal mucus or intermittent bleeding	• Obstruction or bleeding requiring surgery	• Necrosis, perforation, or fistula	• Death

RTOG/EORTC, Radiation Therapy Oncology Group/European Organization for Research and Treatment of Cancer

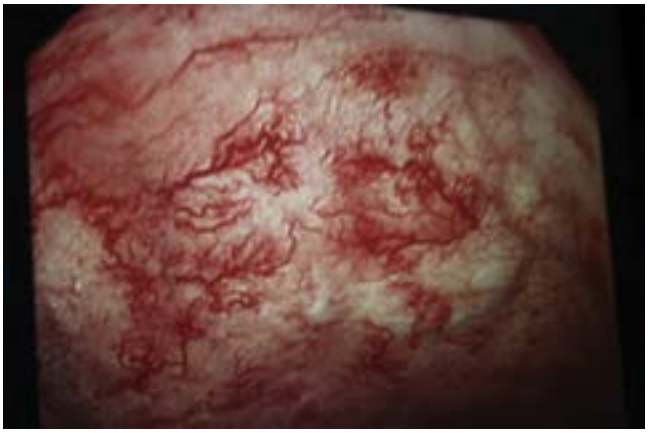

FIG. 2 Endoscopic appearance of radiation proctitis showing telangiectasias. *(From Hogan NM, Kerin MJ, Joyce MR. Gastrointestinal complications of pelvic radiotherapy: medical and surgical management strategies. Curr Probl Surg. 2013; 50[9]:395–407.)*

antispasmodics, bile acid–binding agents like cholestyramine, and antisecretory agents can also be considered.

Butyrate enemas have been shown to provide some benefit for the management of acute radiation proctitis due to the provision of short chain fatty acids as nutrient for colonocytes; however, they have had mixed results for the management of chronic radiation proctitis. Recent Multinational Association of Supportive Care in Cancer (MASCC) guidelines for patients with chronic proctitis in patients with rectal bleeding recommend the use of sucralfate enemas, given sucralfate's ability to evoke a protective barrier and promote epithelial healing. Other enemas such as mesalamine (5-ASA) enemas, short-chain fatty acid enemas, and steroid enemas have had mixed findings and require further investigation.

Formalin therapy has been found to be an effective form of topical treatment for bleeding from chronic radiation proctitis by chemically cauterizing telangiectasias and ulcers. Formalin (4%–10% concentration) can be delivered via irrigation with aliquots of 20 to 50 mL for a total volume of 400 to 500 mL or via direct application of formalin-soaked gauze onto mucosa via rigid proctoscopy. Washout with formaldehyde is typically recommended after application of formalin. Although formalin therapy is effective, multiple application sessions may be required. It is important to avoid direct contact of formalin to the anoderm because this may cause irritation and pain. Potential complications of formalin therapy include anal/pelvic pain, stricture, rectal wall necrosis, and fistula formation.

Other medical treatments that can be considered for radiation-induced bowel injury include antioxidants (vitamins E and C), probiotics, and hyperbaric oxygen to facilitate angiogenesis. A few studies have suggested that a 4-week course of oral metronidazole may be associated with decreased bleeding, ulceration, and diarrhea in radiation proctitis.

Endoscopic Management

Endoscopic therapy can play an important role in the treatment of chronic radiation-induced bowel injury. Argon plasma coagulation (APC) is currently the treatment of choice for bleeding, before considering the use of formalin therapy. APC has been found to stop bleeding in 80% to 90% of cases and is a safe approach because it coagulates at a superficial depth (Fig. 3). Some studies also demonstrate improvement of bowel function after APC. However, like formalin therapy, patients may require multiple APC treatments. It is important when performing APC to avoid the dentate line because contact may result in anorectal pain. Potential complications for APC include anorectal pain and abdominal cramping. Although

FIG. 3 Argon plasma coagulation of rectal ulcer. *(From Araujo IK, Muñoz-Guglielmetti D, Mollà M. Radiation-induced damage in the lower gastrointestinal tract: Clinical presentation, diagnostic tests and treatment options. Best Pract Res Clin Gastroenterol. 2020; 48–49:101707.)*

neodymium-doped yttrium aluminum garnet (Nd:YAG) laser therapy, radiofrequency ablation, and cryotherapy are alternative endoscopic treatments that can be performed to treat bleeding, they are now rarely performed due to the effectiveness of APC.

Surgical Management

More than 30% of patients with chronic radiation-induced bowel injury will require surgical intervention. Surgery is indicated for patients whose symptoms are unable to be managed medically or endoscopically, as well as for patients with complications including perforations, fistulae, strictures, obstruction, intractable pain, and incontinence. Surgery for patients with radiation-induced bowel injury is fraught with technical challenges and a high potential for complications. Morbidity and mortality rates after surgical intervention can range from 30% to 65% and 6.7% to 25%, respectively. The irradiated abdomen can contribute to a hostile operative environment with friable tissue, extensive adhesions, and high risk for bowel injury and poor healing. Careful preoperative planning based on individual patient factors in a multidisciplinary/specialized setting and a structured approach to operative intervention is therefore critical to achieving safe and effective surgery. It is important to also appreciate the risk of recurrence or de novo malignancy in the irradiated bowel segment during preoperative planning. Once the decision to proceed with surgery is made, effort must be made to correct modifiable factors and optimize the patient preoperatively. This may entail correcting electrolyte derangements and providing enteral nutrition for severely malnourished patients. Surgical options for radiation-induced bowel injury include limited bowel resection, bypass/exclusion procedures, stricturoplasty, and fecal diversion.

The choice of surgical incision for patients with chronic radiation injury should be carefully considered because patients who undergo radiation therapy have impaired wound healing. Some surgeons may prefer a low transverse incision inferior to the umbilicus to avoid the irradiated area. Others may prefer a lower midline incision to allow for adequate exposure and in case further interventions are needed

in the future. A Pfannenstiel incision may be considered for thin female patients. The role of minimally invasive surgery for radiation-induced bowel injury is controversial. A diagnostic laparoscopy with abdominal entry via open Hasson technique would determine whether a minimally invasive approach is feasible, with dense adhesions or pelvic fibrosis serving as contraindications. Once the abdomen is entered and the severity of disease is assessed, dissection should begin proximally, where radiation-induced damage is less severe, and move distally. Gentle handling and extreme care of tissue via sharp dissection using Metzenbaum scissors is recommended to prevent bowel injury. Blunt dissection can be associated with a high risk of enterotomy and should be avoided.

For patients with extensive, dense adhesions, limited adhesiolysis should be performed only in the area of interest and only if the bowel is resectable because there is increased risk for fistula formation and bowel injury. Patients with pelvic adhesions generally have small bowel segments adherent in the pelvis; bowel adherent to the sacrum may be extracted from the pelvis with careful dissection, although it is important to avoid damage to the presacral veins and to be able to deal with any ensuing hemorrhage that could occur. Enterotomies would commit the surgeon to extracting the bowel from the pelvis. If a bowel segment were fibrosed to the sacrum, it may be safer to leave this segment attached while applying diathermy to the mucosal surface. Hydrodissection via saline injection into dense interloop adhesions can prevent serosal injuries.

Limited bowel resection of the involved segment is generally preferred over other surgical alternatives such as bypass/exclusion because it is associated with decreased rates of reoperation and increased survival. During bowel resection, careful consideration is necessary when selecting the two pieces of bowel to be used for bowel anastomosis. Grossly irradiated bowel can appear pale, mottled, yellowish/gray, or telangiectatic with features of vascular insufficiency (Fig. 4). However, irradiated bowel can also appear indistinguishable from normal bowel. Anastomotic leak rates between two pieces of irradiated bowel can be as high as 50%; as such, anastomosis between nonirradiated bowel is recommended when possible. If an anastomosis is necessary, the cecum and terminal ileum should be avoided as these segments often experience severe radiation injury. Hand-sewn anastomosis is favored when possible to avoid staple-line ischemia. Because radiation can lead to friable, thickened, and foreshortened mesentery, it is also recommended to over-sew the mesentery with an interlocking heavy #1 chromic suture between clamps rather than simply ligating the mesentery with vessel sealers or a clamp, cut, tie technique.

FIG. 4 Intraoperative comparison of radiation-damaged small bowel *(left)* with healthy bowel *(right)*. *(From Hogan NM, Kerin MJ, Joyce MR. Gastrointestinal complications of pelvic radiotherapy: medical and surgical management strategies. Curr Probl Surg. 2013; 50[9]:395–407.)*

Although bowel resection is preferred, bypass/exclusion can be considered in patients with extensive adhesions and/or pelvic fixation in which resection is not possible. Bypass is associated with a decreased risk of bowel or mesenteric injury and lower anastomotic leak rate compared with bowel resection; however, it increases the risk of blind loop syndrome and fistula formation from the affected segment left behind, which can contribute to further complications. In select cases, stricturoplasty may be considered as an intestine-preserving alternative to more extensive bowel resection or bypass techniques to reduce risk of short gut syndrome and avoid total parenteral nutrition (TPN) dependence.

The management of postradiation enteric and pelvic fistulae are similar to those employed for other types of fistulae, including sepsis management, nutritional optimization, and fistula maturation/output optimization. Higher pelvic fistulae (rectovaginal, rectourethral) can be treated with proctectomy and anastomosis of colon to distal nonradiated rectum or anus. Hand-sewn coloanal anastomosis should only be considered in younger patients with intact sensation, function, and control. Interposition of well-vascularized tissue (omentum or rectus pedicle flap) between the affected organ and anastomosis is highly recommended. Lower pelvic fistulae can be managed similarly or via a perineal (Kraske) or transsphincteric (York-Mason) approach. Flap reconstruction (gracilis, omentum, rectus, bulbocavernosus, or Martius) should be considered for better healing. In severe circumstances, it may be necessary to perform a pelvic exenteration.

Fecal diversion has been found to be effective in the management of pain, tenesmus, incontinence, obstruction, and sepsis and for patients who are not optimal surgical candidates. Because dissection can be difficult in an irradiated pelvis with greater risk for bowel injury, loop ileostomies and transverse/descending colostomies may be safer to perform than sigmoid colostomies.

PREVENTION

The risk of radiation-induced bowel injury can be minimized with careful attention to radiotherapy planning and radiation delivery methods. Recent advances in radiation therapy techniques have sought to maximize radiation dose to the tumor while minimizing radiation to adjacent normal tissues. One method for doing so is 3D conformal radiation therapy (3DCRT), which utilizes 3D planning via CT and computer technology to plan and deliver radiation treatment that matches the shape of the tumor, thereby allowing for higher dose of radiation delivery to the tumor with less effect on normal tissue. Intensity-modulated radiation therapy (IMRT) is another technology in which varying intensities of radiation are delivered in a planned field with clear identification of malignant vs. normal tissue. Brachytherapy is another method that can be used alone or in conjunction with EBRT to reduce normal tissue injury. Proton therapy is also a new technology being used by certain tertiary centers as an option to minimize the amount of radiation to structures and organs surrounding the target anatomy.

Other strategies to reduce radiation injury include prone positioning, protective belly boards, and ensuring that the bladder is full during radiation delivery. Amifostine, a prodrug that metabolizes into a thiol metabolite that functions as a free radical scavenger, has demonstrated benefit in some studies to prevent symptoms of acute radiation proctitis, though these findings have largely been reported in small, single center studies. Operative maneuvers including the use of omental slings and tissue expanders to fill the pelvis can be considered if radiation were to be administered postoperatively.

Preoperative Bowel Preparation: Is It Necessary?

Anna Chudnovets, MD, and Sandy Hwang Fang, MD

Patients who undergo colorectal surgery for cancer and inflammatory bowel disease often have associated risk factors that impair wound healing, such as chemoradiation therapy, steroid therapy, and malnutrition. Additional complicating factors include case complexity, perineal wounds, and combined multispecialty cases. Due to the nature of the colon and rectum yielding high bacterial inoculum and these contributing factors, the risk of postoperative infections after surgery is significant, with an incidence approaching 40%.

The overall objective for the use of bowel preparation in colorectal surgery is to reduce postoperative complications:

1. Decrease the rate of surgical site infections (SSIs)
2. Decrease anastomotic leak rates
3. Alter gut microbiome

A bowel preparation accomplishes these goals via two mechanisms: the evacuation of fecal material from the colon and the eradication of stool bacterial load. In addition, a bowel preparation should not alter the histologic appearance of the mucosa.

Historically, bowel preparations have created a harsh physiologic response to the human body. Newer bowel preparation formulations are smaller in volume, ingested in a short period of time with effective evacuation of stool, while also decreasing gastrointestinal discomfort and side effects, such as nausea and emesis. In addition, these newer drugs produce no fluid shifts, electrolyte imbalances, or dehydration, which optimizes the patient, leading into the operative stage of colorectal surgery with goal-directed fluid therapy (GDFT) as part of the enhanced recovery pathway or enhanced recovery after surgery (ERP or ERAS).

This chapter discusses the bowel preparation types, the efficacy of mechanical bowel preparations (MBP) versus oral antibiotics (OA) versus no bowel preparation, colorectal disease pathology and indications for bowel preparation, and its role in ERAS.

TYPES OF BOWEL PREPARATION

There are two types of bowel preparation: mechanical bowel preparation and oral antibiotics. MBPs are oral cathartics that clear feculent material from the colon. OA decrease intraluminal bacterial load.

Mechanical Bowel Preparation

Two types of MBPs exist: hyperosmotic versus isosmotic (Table 1). Hyperosmotic MBPs (e.g., magnesium citrate, sodium phosphate) exert an osmotic effect, drawing fluid into the bowel lumen, as a mechanism of flushing out colonic contents. Although patients are able to tolerate ingestion of these lower volume formulations, they cause electrolyte and fluid imbalances and dehydration. Patients subsequently become orthostatic and may develop acute kidney injury. Contraindications to hyperosmotic solutions include renal failure, acute coronary syndrome, congestive heart failure, bowel obstruction, ileus, intestinal malabsorption, and ascites. The use of hyperosmotic MBP solutions is not recommended in current consensus guidelines for ERPs.

ERAS consensus guidelines recommend the utilization of isosmotic MBPs, which consist of osmotically balanced, nonabsorbable solutions that do not produce significant fluid or electrolyte shifts. Isosmotic bowel preparations are deemed safe in patients with the comorbidities of hepatic disease, congestive heart failure, and renal failure.

Large volume polyethylene glycol (PEG) preparations include GoLYTELY, Colyte, NuLytely, and TriLyte. Patients have difficulty tolerating these large-volume solutions as they are not palatable and cause nausea and emesis in 4% to 17% of patients. New low-volume PEG (1–2 L) preparations combined with other agents have been developed and include MiraLAX, HalfLytely, MoviPrep, and BiPeglyte.

There are multiple studies/clinical trials and meta-analyses that show conflicting results for the effectiveness of MBPs in regard to surgical outcomes. In a Cochrane review in 2011, 18 randomized controlled trials were reviewed that included 5805 participants; 2906 patients were administered MBP while 2899 received no bowel preparation before elective colorectal surgery. There was no statistically significant difference between the MBP and non-MBP groups in regard to anastomotic leak for colonic resections and low anterior resection. These results are similar to a recent meta-analysis, published in 2018, evaluating eight studies with 1065 patients. However, both studies have reported that evidence quality is low due to the variation in bowel preparations. Because of this, MBP alone is generally not recommended for elective colorectal surgery.

Oral Antibiotics

First-line antibiotics include a combination of oral neomycin sulfate plus oral erythromycin base or oral neomycin sulfate plus oral metronidazole (Table 2). The most common side effects are nausea and emesis. Multiple randomized controlled trials have reported a significant improvement in SSIs with the use of OA. Two large studies from American College of Surgeons National Surgical Quality Improvement Program (NSQIP) (>300,000 patients) and one large meta-analysis of prospective studies (69,000 patients) have confirmed that many medical centers are using OA alone for their bowel preparations before colorectal surgery. These studies suggest that OA alone is associated with similar SSI rates to OA plus MBP and lower SSI rates as compared with both MBP alone and no bowel preparation.

TABLE 1 Mechanical Bowel Preparations

Adjuncts to Mechanical Preparation	Agent	Volume/Dose	Mechanism	Use
PEG (electrolyte lavage)	Colyte* GoLYTELY*	3785 mL 4000 mL	No solid food for at least 2 hours before ingestion of the solution; 240 mL (8 oz) every 10 minutes until rectal output is clear or 4 L are consumed	Divided dose regimens (3 L the night before procedure, 1 L morning of procedure) may improve patient tolerance. PEG is considered safer than osmotic laxatives/NaP for patients with electrolyte/fluid imbalances, renal or liver insufficiency, CHF, or renal or liver failure.
Sulfate-free PEG (improved smell/taste, more palatable for patients)	NuLYTELY* TriLyte*	4000 mL 4000 mL	No solid food for at least 2 hours before taking the solution; 240 mL (8 oz) every 10 minutes until rectal output is clear or 4 L are consumed	Similar efficacy to PEG
Low-volume PEG and bisacodyl tablets (decrease volume-related discomfort [e.g., bloating, cramping])	HalfLytely and bisacodyl tablet bowel prep MiraLAX	2000 mL 255 g in 2000 mL	Only clear liquids on the day of the preparation. Dosage is four bisacodyl delayed-release tablets (5 mg) at noon. Wait for bowel movement or maximum of 6 hours; 240 mL (8 oz) low-volume PEG (i.e., HalfLytely) or 240 mL (8 oz) of clear liquid containing one capful of MiraLAX or other PEG-3350 regimen every 10 minutes until 2 L are consumed.	Equally effective as 4 L solutions; additional studies needed regarding safety
Aqueous NaP solutions	Fleet	90 mL with 48 oz additional liquid	Only clear liquids can be consumed on the day of preparation. Two doses of 30–45 mL (2–3 tbsp.) of oral solution are given at least 10–12 hours apart. Each dose is taken with at least 8 oz of liquid followed by an additional minimum of at least 16 oz of liquid. The second dose must be taken at least 3 hours before the procedure.	May cause significant fluid shifts. Not for use in pediatric or elderly patients or those with bowel obstruction, gut dysmotility, other structural intestinal disorders, renal or liver failure, or congestive heart failure. NaP may cause ulceration or mucosal abnormalities; do not use in patients with inflammatory bowel disease. Patients with compromised renal function or those taking ACE inhibitors or ARBs are at risk for phosphate nephropathy. In 2006, the FDA issued an alert regarding the risk for acute phosphate nephropathy, a type of acute renal failure, with use of oral sodium phosphate solution or tablets.
Oral sodium phosphate (tablet)	Visicol (discontinued)	32–40 tablets with 48 oz clear liquid	Dosage is 32–40 tablets: 20 tablets on the evening before the procedure and 12–20 tablets the day of the procedure (3–5 hours before). The 20 tablets are taken as 4 tablets every 15 minutes with 8 oz of clear liquid. Bisacodyl is prescribed by some physicians as an adjunct.	Early tablet composition included higher concentration of microcrystalline cellulose per tablet, which left residue obscuring the mucosal surface. Later tablet composition decreased microcrystalline cellulose concentration. Overall, tablet NaP is not associated with significantly improved patient tolerance when compared with aqueous NaP.

TABLE 1 Mechanical Bowel Preparations—cont'd

Adjuncts to Mechanical Preparation	Agent	Volume/Dose	Mechanism	Use
Enemas	Tap water Soap suds Fleet enema Fleet bisacodyl Enema Fleet mineral oil	500–1000 mL 500–1000 mL 135 mL 10 mg 1.25 oz 37.5 mL 480 mL	Distention and lavage of rectum and distal colon	Routine addition of enemas to oral preparation does not improve the quality of bowel cleansing but does increase patient discomfort. Use enemas in patients presenting for endoscopy with poor distal colon preparation and in patients with defunctionalized distal colon (e.g., Hartmann's).
Bisacodyl	Bisacodyl	5-mg tablet	Poorly absorbed diphenylmethane that stimulates colonic peristalsis, used as adjunct for NaP or PEG preparations	Has been found to decrease the volume of PEG preparation required
Saline laxatives	Magnesium citrate (liquid) Picolax (sodium picosulfate/ magnesium citrate)	250–300 mL	Hyperosmotic saline laxatives that increase motility by increased intraluminal volume	Addition of magnesium citrate to PEG allows for lower volume preparation. Use with extreme caution in patients with renal insufficiency or renal failure because of exclusive renal excretion of magnesium.
Senna	Senna Senokot X-Prep Syrup (8 mg/5 mL)		Anthraquinone derivatives (glycosides and sennosides) are activated by colonic bacteria and directly increase the rate of colonic motility, with a subsequent increase in colonic transit and reduced water and electrolyte secretion.	Senna with PEG may improve the quality of preparation and reduce volume required.
Simethicone	Gas-X Mylicon Mylanta Generic formulations (80 mg)		Antiflatulent, often used to prevent foam formation after PEG preparation. Mechanism of action is unclear.	May improve lumen visualization and patient toleration of bowel prep
Metoclopramide	Reglan Generic formulations also available	5 mg	Dopamine antagonist gastro-prokinetic, increasing the amplitude of gastric contraction, with increased peristalsis in duodenum and jejunum but without change in colonic motility	May reduce nausea, bloating; does not improve colonic cleansing
Carbohydrate-electrolyte solutions	Gatorade E-Lyte Generic formulations	20 oz	Used with PEG and/or NaP solution to improve flavor and prevent NaP-related fluid and electrolyte shifts	Carbohydrate-based solutions more palatable for patients; however, associates with a theoretical risk of cautery-induced explosion if these carbohydrates are metabolized by colonic bacteria into explosive gases.

*Flavored options are available.

ACE, Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *CHF,* congestive heart failure; *FDA,* US Food and Drug Administration; *NaP,* sodium phosphate; *PEG,* polyethylene glycol.

Modified from Wexner SD, Beck DE, Baron TH, et al. A consensus document on bowel preparation before colonoscopy: prepared by a task force from the American Society of Colon and Rectal Surgeons (ASCRS), the American Society for Gastrointestinal Endoscopy (ASGE), and the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES). *Dis Colon Rectum.* 2006;49:792–809.

Currently, there is a prospective randomized controlled trial using the Rethinking Clinical Trials (REaCT) platform and NSQIP to compare no bowel preparation versus preoperative OA alone to evaluate SSI rate in elective colorectal surgery. Results are pending at this time. A similar multicenter randomized controlled trial was performed in Spain (ORALEV) in which 536 patients were randomized to no OA versus OA. The incidence of SSI in the no OA group (30/269, 11%) was significantly higher than in the OA

TABLE 2 Oral Antibiotic Regimens

Oral Antibiotic Prophylactic Regimen*	Use in Prior Literature
Neomycin + erythromycin	Coppa, 1988; Kaiser, 1983; Khubchandani, 1989; Lau, 1988; Nichols, 1973; Stellato, 1983
Metronidazole + neomycin	Epsin-Basany, 005; Hanel, 1980; Lewis, 2002; Nohr, 1990 (included bacitracin); Reynolds, 1989
Metronidazole + kanamycin	Lazorthes, 1982; Monrozies, 1983; Takesue, 2000
Tinidazole + neomycin	Peruzzo, 1987
Kanamycin + erythromycin	Ishida, 2001; Kobayashi, 2007

*Each of these oral antibiotics was combined with a range of intravenous antibiotics in the studies listed.
Modified from Bellows CF, Mills KT, Kelly TN, Gagliardi G. Combination of oral non-absorbable and intravenous antibiotics versus intravenous antibiotics alone in the prevention of surgical site infections after colorectal surgery: a meta-analysis of randomized controlled trials. *Tech Coloproctol.*2011;15:385–395.

group (13/267, 5%) (χ^2 test, p = 0.013). The no OA group had more complications (76/269, 28%) compared with the OA group (51/267) (P = 0.017).

MECHANICAL BOWEL PREP VS ORAL ANTIBIOTICS VS NO BOWEL PREPARATION

The combination of MBP and OA was described as early as 1973 when the Nichols-Condon bowel prep (a combination of MBP and OA) reported a decrease in the SSI rate from 43% to 9%. In 2012, a retrospective study utilizing the Veterans Affairs Surgical Quality Improvement Program preoperative risk and SSI outcome data evaluated no bowel preparation versus MBP alone versus OA alone versus MBP + OA. Those receiving no bowel preparation had similar SSI rates to those who had MBP only (18.1% vs 20%). Patients receiving OA alone had a SSI rate of 8.3%, and those receiving OA + MBP had an SSI rate of 9.2%. In adjusted analysis, the use of OA alone was associated with a 67% decrease in SSI rate (OR = 0.33, 95% CI 0.21–0.50). OA + MBP was associated with a 57% decrease in SSI rate (OR = 0.43, 95% CI 0.34–0.55). A retrospective analysis of the NSQIP colectomy cohort from 2011 to 2012 subsequently showed that the use of OA alone decreased SSI rates, consequently decreasing postoperative length of stay (LOS) and readmission rates.

The rate of antibiotic resistance or *Clostridium difficile* infection is similar in the OA alone, no bowel preparation, and OA + MBP groups.

OUTCOMES OF SURGERY DEPENDENT ON TYPE OF SURGERY

Studies have demonstrated that right colon bacterial concentrations range from 10^6 to 10^7 bacteria/g of stool content, whereas these numbers rise to 10^{11} to 10^{12} bacteria/g in the rectosigmoid. Several studies have demonstrated a lower risk of SSIs after right colectomies versus left colectomies or rectal resections. Studies evaluating patients undergoing right-sided versus left-sided colectomies/proctectomies show a preventative function of OAs in left-sided colectomies/proctectomies with an overall incidence SSIs as 7.01% vs 15.89% (p= 0.004) and superficial SSIs as 2.34% vs 7.01% (p= 0.03).

TABLE 3 Our Protocol at Johns Hopkins Hospital

	Medication	Comments
Mechanical bowel preparation	MiraLAX (238 g) Bisacodyl (four 5-mg tablets)	MiraLAX (238 g) mixed in a clear liquid and started at noon the day before surgery and completed after hourly administrations. Bisacodyl tablets taken as an adjunct to MiraLAX.
Oral antibiotics	Neomycin (six 500-mg tablets) Metronidazole (six 500-mg tablets)	Taken in three doses the day before surgery

Clear liquid diet initiated the day before surgery up until 2 hours before surgery.

BOWEL PREPARATION IN ERAS

ERAS guidelines recommend the routine use of combined isosmotic MBP with OA before elective colorectal surgery (Table 3). With the addition of oral carbohydrate loading to MBP, in addition to the emphasis on intake of clear liquids up to 2 hours before surgery as denoted by American Society of Anesthesiologists (ASA) Fasting Guidelines, patients undergoing elective colorectal surgery better tolerate adverse side effects of MBP while also requiring less fluid administration intraoperatively.

CONCLUSION

The use of isosmotic MBP + OA as part of the ERAS pathway prevents postoperative complications, such as SSIs, and reduces hospital LOS, costs, and readmission rates. Although evidence shows that MBP alone has not shown benefit, evidence is lacking for the use of OA alone. Future studies, such as an ongoing prospective randomized controlled trial using the REaCT platform and NSQIP will help to inform the perioperative benefits of OA alone.

Management of Diverticular Disease of the Colon

Katharina M. Scheurlen, MD, and Susan Galandiuk, MD

INTRODUCTION

Diverticular disease of the colon is common and a progressively increasing burden on both patients and the healthcare system. This term includes both asymptomatic diverticulosis as well as complications arising from diverticulosis that require further medical evaluation and treatment. Approximately 50% of Americans older than 60 years of age are diagnosed with diverticulosis; however, hospital admission rates resulting from complications of the disease, such as diverticulitis and diverticular bleeding, are specifically increasing in patients younger than 45 years of age. Underestimation of the prevalence of this disease in the young often leads to misdiagnosis of diseases causing similar symptoms, such as appendicitis. Inpatient treatment rates for diverticulitis have risen in young adults and show geographic variation caused by dietary habits and environmental factors.

Colonic diverticula are typically not true diverticula as they do not involve all layers of the bowel wall, but only consist of mucosa and submucosa protruding through the muscularis propria. Intraluminal pressure is thought to cause this herniation of mucosa through weak points of the muscle layer, where intramural branches of the vasa recta penetrate to deliver blood to the luminal layers of the colonic wall. Contributing factors that cause increased intraluminal pressure include a low-fiber diet with small-caliber stools and constipation as well as consumption of red meat. Other risk factors for developing diverticular disease are overweight and obesity, physical inactivity, smoking, use of nonsteroidal antiinflammatory drugs (NSAIDs), and a positive family history. In Western countries, diverticula usually occur in the sigmoid colon, whereas in Asia, right-sided location is common.

Diverticular disease usually remains asymptomatic, but 4% to 15% of affected individuals may develop diverticulitis during their lifetime, and another 5% to 15% develop diverticular bleeding. Diverticulitis refers to inflammation of the diverticulum resulting from a combination of poorly understood factors including bacterial stasis, the presence of a fecalith, an altered microbiome, impaired mucosal barrier function, and a subsequent inflammatory cascade. Although its pathogenesis is not completely understood, clinical and histopathologic findings in patients with diverticulitis show some similarities to those found in ulcerative colitis. Certain types of diverticulitis, such as segmental colitis associated with diverticulosis (SCAD), is considered to be an inflammatory bowel disease, suggesting an autoimmune etiology. Recent studies suggest that genetic predispositions involving immunomodulatory genes may also play a role.

Diverticular bleeding is typically painless and usually occurs in the absence of colonic inflammation. It originates from ruptured vasa recta at either the dome or neck of the diverticulum and is arterial. Repeated microtrauma involving mechanical and chemical stress within the diverticular lumen leads to thinning of the mucosal layer and subsequent rupture of arterial branches. Diverticular bleeding is more likely to occur in right-sided diverticular disease. This is because diverticula of the right colon typically have a wider lumen, exposing a larger mucosal surface area to luminal stress, along with a thinner colonic wall.

This chapter will focus on evaluation and management of patients with diverticulitis. A brief section about the evaluation and treatment of patients with diverticular bleeding is included as this topic will also be covered in the chapter devoted to gastrointestinal bleeding.

MANAGEMENT OF DIVERTICULITIS

Clinical Presentation and Diagnosis

Uncomplicated acute diverticulitis is typically located in the sigmoid colon and characterized by the symptom triad of left lower quadrant pain, fever, and leukocytosis. A mobile sigmoid colon or atypical manifestation in other segments of the colon can lead to abdominal pain in locations other than the left lower quadrant, such as the suprapubic region or even the right-side of the abdomen.

Severe complications occur in approximately 25% of cases and can complicate the diagnosis of underlying diverticulitis. Complications involve abscesses that occur in 30% of cases, fistula in 14%, and free perforation with peritonitis in 1% to 2% of patients. Colonic stricture with subsequent bowel obstruction is uncommon. For patients with complicated diverticulitis, medical treatment may be ineffective, and the majority require surgical intervention. Complications can be highly variable, and differential diagnoses must be excluded; therefore findings on physical examination and on blood and urine analyses should be further evaluated with diagnostic imaging. Computed tomography (CT) is the mainstay imaging modality in the assessment of acute diverticulitis and accompanying complications. A CT of the abdomen and pelvis with intravenous and oral contrast is used to evaluate the severity of inflammation and the presence of bowel strictures, obstruction, and local or distant complications such as abscesses and fistulas. In patients with contrast allergy, a noncontrast study or an alternative approach may be performed (e.g., magnetic resonance imaging or ultrasonography), particularly in the pregnant patient. Ultrasonography may identify a hypoechoic colonic wall with a fecalith obstructing the diverticulum, an adjacent bowel wall, and mesenteric edema, which may indicate abscess formation. The diagnostic accuracy of ultrasound is, however, dependent on the examiner's skill and experience.

Classification of diverticulitis is essential to follow a standardized treatment algorithm that provides the highest success rates for disease management. The Hinchey classification, originally published in 1978, is used as a basis to provide evidence-based management strategies for patients with diverticular disease. The modification by Wasvary et al. is widely used and is based on CT findings concerning abscess formation and peritonitis (Table 1). Both imaging and clinical evaluation are required for a complete patient assessment.

Management of the Patient with Acute Diverticular Disease

Uncomplicated Diverticular Disease

The inflammatory processes in uncomplicated diverticulitis (Stage 0 or Ia) are restricted to the colon only, while complicated diverticulitis shows signs of inflammation beyond the colon, involving the peritoneum and pericolic structures. Although antibiotic therapy for acute uncomplicated diverticulitis has been the traditional treatment recommendation for many years, there have now been several large prospective randomized clinical trials showing that uncomplicated diverticulitis can be treated *without* antibiotics (Table 2). It will take clinical practice a long time to follow this evidence. Much of this is the result of established practice patterns and patient expectations. In the event that symptoms limit oral intake or are severe enough to warrant hospital admission, fluid resuscitation and bowel rest will result in improvement while gradually advancing to a low-residue diet. If antibiotics are used for diverticulitis, they should cover both gram-negative and anaerobic bacteria, which is provided by either ciprofloxacin plus metronidazole or levofloxacin plus metronidazole.

TABLE 1 "Staging" or Grading of Diverticulitis Severity*

Hinchey Classification		Modified Hinchey Classification by Wasvary	
		0	Mild clinical diverticulitis
I	Pericolic abscess/phlegmon	Ia Ib	Colonic wall thickening/confined pericolic inflammation Confined pericolic or mesocolic abscess (<5 cm)
II	Pelvic, distant intraabdominal or retroperitoneal abscess	II	Pelvic, distant intraabdominal or retroperitoneal abscess
III	Generalized purulent peritonitis	III	Generalized purulent peritonitis
IV	Generalized fecal peritonitis	IV	Generalized fecal peritonitis

*Based on the Hinchey classification and modified Hinchey classification by Wasvary to reflect computed tomographic findings.

TABLE 2 Overview of Selected Multicenter Randomized Controlled Trials

Study	Acronym	Investigation	Main Findings
DIverticulitis: **A**nti**B**iotics **O**r c**L**ose **O**bservation?)	DIAB-OLO	Cost-effectiveness of conservative treatment (hospital admission plus antibiotics) versus liberal treatment (no antibiotics and no strict need for hospital admission); primary endpoint: time-to-full recovery	In patients with uncomplicated diverticulitis, observational treatment without antibiotics shortens hospital stay and does not prolong recovery
Antibiotika **V**id **O**komplicerad **D**ivertikulit (Swedish for "antibiotics in uncomplicated diverticulitis")	AVOD	Treatment of uncomplicated diverticulitis with antibiotics versus without antibiotics; primary endpoint: complications and emergency surgery during hospital stay	No differences in diverticulitis recurrence, diverticulitis complications, or emergency surgery rates (sigmoid resection) in the long-term; antibiotic treatment had no favorable outcome
Outpatient versus Hospitalization Management for Uncomplicated Diverticulitis	DIVER	Hospitalization versus outpatient treatment in patients with uncomplicated diverticulitis; primary endpoint: treatment failure rate of outpatient protocol, need for hospital admission	Outpatient antibiotic treatment and diet is effective and safe, cost-saving, and associated with a similar quality of life compared with hospitalization with intravenous antibiotic treatment
Perforated **DIV**erticulitis: sigmoid resection with or without **A**nastomosis	DIVA (LADIES trial)	Sigmoidectomy with primary anastomosis versus Hartmann's procedure in purulent perforated diverticulitis; primary endpoint: 12-month stoma-free survival rate	Primary anastomosis leads to increased stoma-free survival and is more cost-effective compared with the Hartmann's procedure
Lapar**O**scopic **LA**vage trial	LOLA (LADIES trial)	Laparoscopic lavage and drainage versus Hartmann's procedure versus sigmoidectomy with primary anastomosis; primary endpoint: major morbidity and mortality	Premature end of the LOLA group: higher rate of in-hospital major morbidity, mortality, and reintervention rate in the laparoscopic lavage arm
SCANdinavian **DIV**erticulitis trial	SCANDIV	Laparoscopic lavage versus primary resection in patients with perforated diverticulitis; primary endpoint: severe postoperative complications within 90 days	Laparoscopic lavage does not reduce severe postoperative complications, increases the reoperation rate, and leads to a higher risk of missing associated colon carcinomas
DIverticulitis–**LA**paroscopic **La**vage trial	DILALA	Laparoscopic lavage versus Hartmann's procedure in patients with purulent perforated diverticulitis; primary endpoint: number of reoperations within 12 months	Patients undergoing lavage have fewer reoperations and equal hospital readmission and mortality rates.

Because of an increasing prevalence of *Escherichia coli* resistance to fluoroquinolones worldwide, amoxicillin-clavulanate monotherapy or trimethoprim-sulfamethoxazole plus metronidazole can be used as an alternative.

Two randomized controlled trials showed no difference in patient outcome comparing treatment with antibiotics versus fluid resuscitation only. The most recent trial from the Dutch Diverticular Disease Collaborative Study Group (DIAB-OLO) demonstrated that no difference concerning mild or serious adverse events could be found between groups, but a significantly higher rate of adverse events were associated with antibiotic treatment. Long-term follow-up data, 11 years after The Swedish Antibiotic Therapy of Acute Uncomplicated Colonic Diverticulitis (AVOD) trial, showed no difference in recurrence rates, complications, surgical treatment rates for the disease, and quality of life between the patient groups. Based on these data, otherwise healthy patients with uncomplicated diverticulitis can be treated without antibiotics. Evidence from randomized controlled trials has also shown that a 4-day course of intravenous

antibiotics was as effective as a 7-day course, while clinical outcomes of inpatient and outpatient antibiotic treatment in otherwise healthy patients tolerating oral intake did not differ (DIVER trial). If a patient's clinical status does not improve after 5 days of treatment with persistent fever, leukocytosis, and elevated acute-phase proteins (C-reactive protein), further CT evaluation for an abscess should be considered.

Patients who present with uncomplicated diverticulitis have a low incidence (<2%) of occult colonic malignancy in contrast with those with complicated diverticulitis, in whom the incidence is 8% to 11 %. Colonoscopy is typically performed 6 weeks *after* symptom resolution, especially in those of screening age and family history. In case of recurrent episodes affecting quality of life, smoldering disease, or immunocompromise, elective colon resection may be indicated.

Diverticular Disease with Pericolic Abscess

Complicated diverticulitis that is accompanied by either a mesocolonic (stage Ib) or more distant abscess formation (stage II) occurs in 15% to 40% of acute diverticulitis patients. It can be treated nonoperatively with antibiotics in an outpatient setting in stable patients with abscesses ≤3 cm in size. Abscesses >3 cm or patients who do not respond to antibiotic treatment alone require percutaneous drainage, typically via a transabdominal approach (Fig. 1). Alternative approaches are transgluteal for pelvic abscesses (even though they are associated with greater patient discomfort and a higher risk of drain dislocation) and transvaginal or transrectal approaches. Conservative treatment strategies are typically effective with small abscesses, with an overall success rate in 80% of patients presenting such abscesses. There is a failure rate of up to 34% with nonoperative treatment of abscesses >3 cm in size.

If the patient is in stable condition with nonoperative treatment, the diet is gradually advanced to a low-residue diet. If a CT-guided drain is placed, decreasing white blood cell and drain output to <30 mL/day indicate when the drain can be considered for removal. In many cases, a drain contrast study will show the size of the residual abscess cavity and whether there is a communication to the colon. The rate of recurrent abscesses after conservative treatment is high, although it is considerably lower after percutaneous drainage (25%–60% vs. 15%–25%). The overall failure rate of these nonoperative approaches is 15% to 32%. In case of failure, surgery is indicated, with urgent abscess drainage and colectomy, typically with primary anastomosis and proximal diversion.

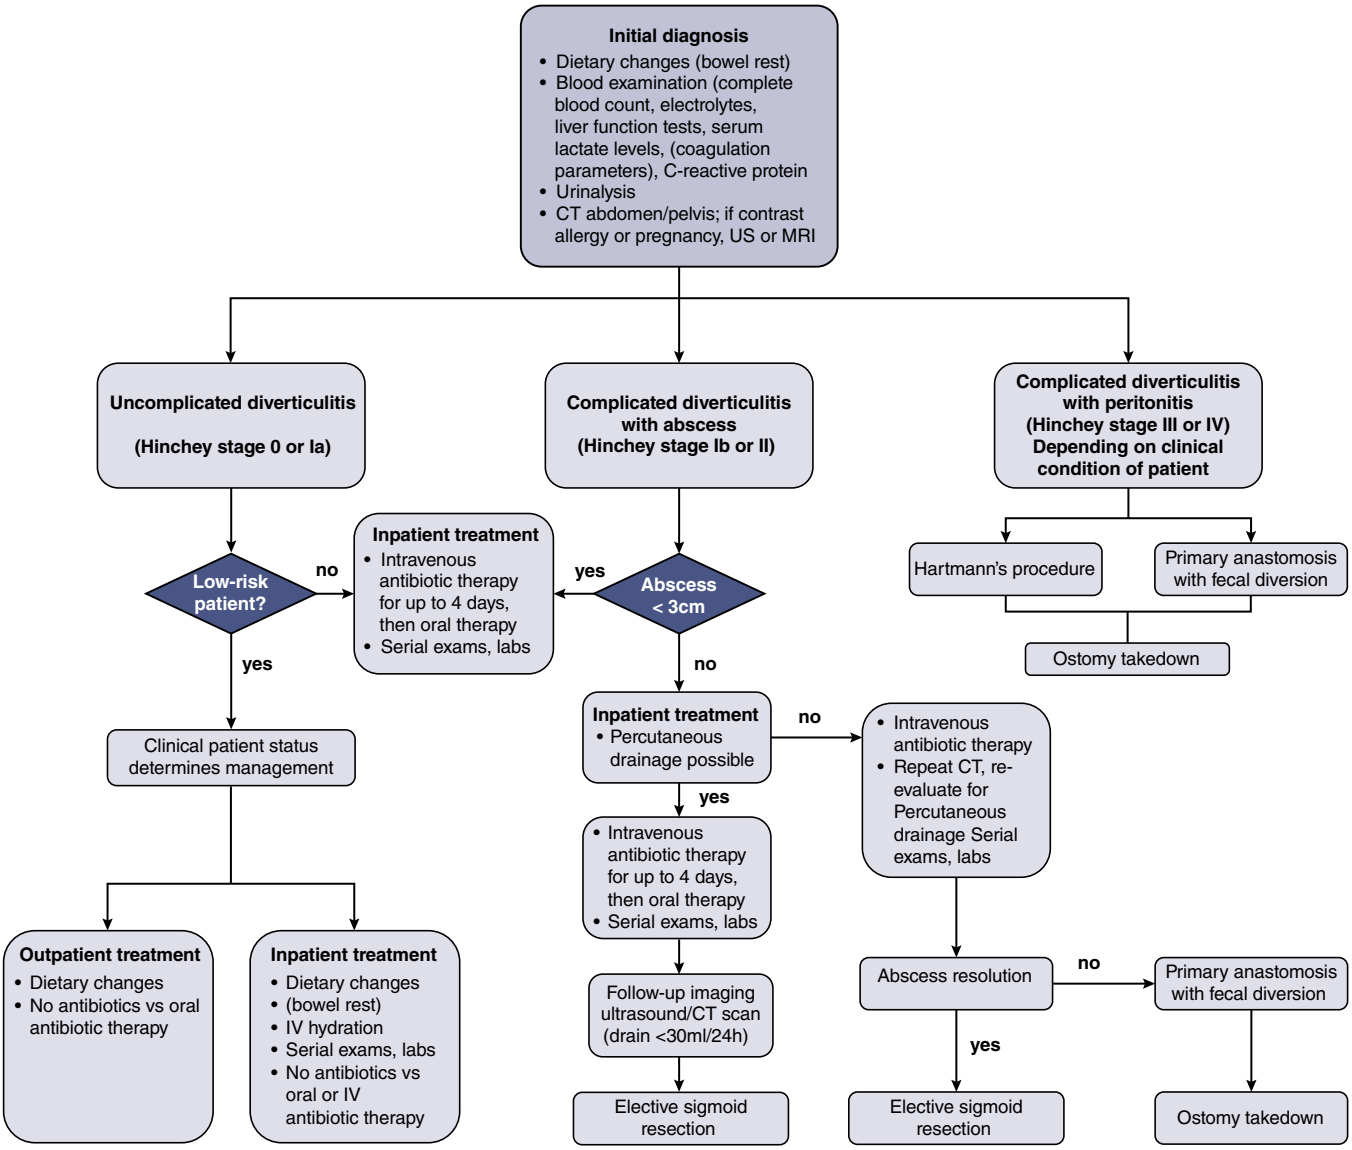

FIG. 1 Management of acute diverticulitis. This evidence-based algorithm should be individualized and modified based on the patient's clinical course.

Diverticular Disease with Perforation/Peritonitis

Purulent peritonitis (Hinchey III) and feculent peritonitis (Hinchey IV) cannot be distinguished from one another clinically. Emergency surgery with abdominal exploration is necessary for diagnosis. Hinchey III is defined by an occult colonic diverticular perforation with abscess formation and subsequent abscess rupture. Hinchey IV denotes a free perforation of a diverticulum with peritoneal fecal contamination.

Emergency surgery is required in 15% to 32% of patients who are hospitalized for acute diverticulitis. Acutely ill patients with diverticulitis and peritonitis should undergo expedited intravenous antibiotic therapy, fluid resuscitation, and emergency surgery. Abdominal exploration, resection of the acutely inflamed colon containing the area of perforation, and thorough peritoneal lavage should be performed. Overall, 30-day hospital mortality after emergency colectomy as reported by a retrospective National Surgical Quality Improvement Program (NSQIP) study in 2013 was 5.1%. Significantly higher mortality rates up to 53% were found in patients with two or more of the following risk factors: age >80 years, ASA class 4 or 5, elevated serum creatinine (>1.2 mg/dL), and hypoalbuminemia (<2.5 g/dL).

Two types of colectomy can be performed: (1) resection with primary anastomosis with or without proximal diversion (loop-ileostomy) or (2) resection with discontinuity and a Hartmann rectal stump and proximal end colostomy. Although discontinuity with a Hartmann stump was once the standard in an emergency setting, several randomized controlled trials and meta-analyses have demonstrated that primary anastomosis with or without proximal diversion yields favorable outcomes. In 2019, the DIVA arm of the LADIES trial showed a significantly higher 12-month stoma-free survival rate in patients receiving primary anastomosis with or without a defunctioning ileostomy compared with patients undergoing Hartmann procedures in perforated diverticulitis (95% vs. 72%). There were no significant differences in terms of morbidity and mortality between groups (see Table 2).

Bowel reconstruction with closure of an end colostomy after a Hartmann procedure is associated with higher morbidity compared with closure of a loop ileostomy after primary anastomosis with proximal diversion because of the extent of the actual disease and procedure. For this reason, high-risk patients who are at substantial risk of anastomotic leakage and major complications often never undergo the second operation of colostomy closure and Hartmann takedown. It is estimated that there are more than 5-fold the number of Hartmann procedures performed than the number of Hartmann reversals, and most of these colostomies can be considered permanent. The decision on whether bowel continuity should be restored after resection in patients with Hinchey III or IV diverticulitis should consider patient factors (presence of shock, hemodynamic stability, immunosuppression, age) and intraoperative findings (quality of tissue, presence of pan-abdominal inflammatory changes). The experience of the respective surgeon should determine the most appropriate procedure in these high-risk settings.

An alternative to bowel resection in case of perforated diverticulitis is laparoscopic lavage with drain placement. This procedure is not recommended with feculent perforation (Hinchey IV). It can be considered in select patients with purulent peritonitis (Hinchey III); however, colectomy is generally preferred as the need for secondary interventions is higher with laparoscopic lavage. Three randomized controlled trials investigated laparoscopic lavage in Hinchey III disease: the LOLA trial, SCANDIV trial, and DILALA trial (see Table 2). These studies were heterogeneously designed and focused on different techniques and endpoints. Several meta-analyses have tried to make sense of this heterogeneity. Overall, laparoscopic lavage was associated with a higher rate of surgical reintervention (20% vs. 7%, LALA trial) and a high rate of subsequent abscess formation requiring drainage (20% vs. 0%, LALA trial). An acute or elective surgical intervention was necessary in 48% of cases following laparoscopic lavage (LALA trial). Deep surgical site infection (32% vs. 13%) and unplanned reoperation rates (27% vs. 10%) were also higher in the lavage group (SCANDIV trial). The DILALA trial, however, showed that the lavage group had a 45% reduced risk of undergoing reoperations 2 years after the initial procedure.

Laparoscopic lavage is, however, an appealing approach because of its shorter operative time and lower risk for cardiac complications, wound infection, and stoma formation. This procedure may have a limited role in select young patients with a low ASA score and high BMI to reduce the risk of a stoma in the acute setting, allowing for a future elective resection. The lack of homogenous supporting evidence does not, however, allow for a general recommendation for this procedure.

Treatment of Sequelae of Complicated Diverticulitis

Diverticular Stricture

Strictures of the colon can result from chronic inflammation in patients with smoldering or recurrent diverticular disease. In the case of a diverticular stricture, underlying malignancy must always be suspected, and an oncologic resection of the diseased colonic segment with lymph node clearance should be performed if colonoscopy cannot be performed preoperatively to confirm the diagnosis.

Diverticular Fistula

Fistulas can develop in up to 2% of patients with diverticular disease, with colovesical fistulas representing half of all fistulas. Other types of fistulas include colocutaneous fistulae following interventional drain placement for abscess drainage, colovaginal fistulas, which almost always occur in women who have undergone prior hysterectomy, or rarely coloenteric or colouterine fistulas. Fistulas can also occur in the presence of Crohn's disease or cancer, and colonoscopy should be performed to clarify their etiology. In patients with fistulas, sepsis and clinical instability are uncommon. Patients can often be evaluated and monitored in the outpatient setting until the time of elective surgery.

Surgical Treatment

Route of Access

Surgical approaches for colectomy in patients with diverticular disease include open surgery with laparotomy or minimally invasive surgery with either a laparoscopic or robotic approach. Regardless of route of access, surgical management of diverticular disease follows the same principles. A minimally invasive approach is preferred if expertise is available, as this has been associated with superior outcomes in terms of reduced postoperative morbidity and reduced hospital stay. The robotic approach has been associated with decreased conversion rates because of improved optics and instrument maneuverability and is especially useful when dealing with inflammatory disease adherent to the pelvic side wall. Compared with the laparoscopic approach, robotic access has been associated with reduced rates of ileus and postoperative complications and a shorter length of hospital stay, but significantly increased hospital charges and longer operative times.

Clinical factors, such as hemodynamic stability, patient comorbidities, the presence of coexisting bowel obstruction, and prior abdominal procedures causing adhesions determine whether minimally invasive surgery is feasible or open surgery should be performed. Several studies have shown that a minimally invasive approach can be performed in the emergency setting with improved morbidity. Clinical factors in the high-risk patient and longer operative times of laparoscopic procedures can, however, influence the decision regarding choice of approach.

In the acute situation, it is important to mark the patient for a possible stoma site in the sitting position and to avoid skin folds and creases. In obese individuals, the upper abdomen may provide a thinner abdominal wall, with easier stoma creation. Marking several possible stoma sites is never wrong. Remember, the patient may have the stoma a long time, and a well-placed stoma is essential.

Open access is performed via midline laparotomy. For laparoscopic access, four port incisions are required, followed by a subsequent suprapubic incision to remove the resected specimen. A large periumbilical camera port and two 5-mm ports in the right upper quadrant

and left lower quadrant are placed. The port in the right lower quadrant should be of larger size because access to an endoscopic stapler should be provided. Robotic access incisions are dependent on the robotic system used. The Si robot incisions are similar to those of laparoscopic access, with modified placement of the large camera port to the right of the umbilicus. The Xi robot requires ports oriented along a straight diagonal line from the lower right abdomen medial to the anterior superior iliac spine upward toward the patient's left, with an additional 5-mm assistant port in the right lower quadrant.

Common Surgical Themes Among All Routes of Access

1. **Work from normal to abnormal.** Beginning to work in a phlegmon can be challenging.
   Open: Begin dissection proximally, freeing up retroperitoneal structures superiorly and slowly working toward the area of inflammation
   Minimally invasive: Lateral-to-medial: same as for open
   Minimally invasive: Medial-to-lateral: essentially begins in "normal" retroperitoneal plane proceeding laterally toward inflammation
2. **Visualize the left ureter.** If technical difficulties are anticipated, ureteral stents are useful. See https://youtu.be/pVaFId9UuC4 for use of indocyanine green in ureteral stents for easy intraoperative visualization.
3. If not performing an anastomosis, resect the area of perforation. There is **no need to go down lower to the rectum itself** because this will make the subsequent surgery more difficult.
4. If performing an anastomosis, **the distal part of the colorectal anastomosis should lie within the upper rectum.** This is most easily located as the area where the colonic tenia confluence. If an anastomosis is made in the sigmoid colon, there is an up to 25% recurrence rate.
5. If extra colonic length is needed, **the splenic flexure may need to be mobilized and the inferior mesenteric vein and/or artery may need to be divided.**
6. The **proximal line of transection should be in soft pliable bowel.** All of the diverticula-bearing colon does not need to be removed.
7. If there is a **dense inflammatory scar around the rectum, the rectum may need to be mobilized to allow a circular stapler to pass.**

In case of bowel reconstruction with primary anastomosis, an end-to-end circular stapler is used to create a double-stapled or triple-stapled anastomosis. If there is a lot of edema or an inability to pass a stapler transanally, a hand-sewn colorectal anastomosis is an option. In cases in which fecal diversion is appropriate, either a protective loop-ileostomy (primary anastomosis and proximal diversion) or an end colostomy (Hartmann procedure with rectal stump and discontinuity) is created. Placement of a drain is generally not required if the dissection is above the level of the peritoneal reflection. In the case of a colovesical fistula, a drain is typically placed near the bladder repair.

Most Common Surgical Errors

1. No preoperative stoma marking
2. Anastomosis performed in the distal sigmoid colon
3. Attempt to resect all colonic diverticula
4. Very low Hartmann procedure performed, making subsequent closure more difficult

MANAGEMENT OF DIVERTICULAR BLEEDING

Clinical Presentation and Diagnosis

Three to five percent of patients with diverticular disease develop diverticular bleeding, presenting as either bright red blood per rectum, hematochezia, or melena. Risk factors include the use of NSAIDs, thrombocyte aggregation inhibitors, and anticoagulants, which is common among the elderly. Although diverticular bleeding can cause severe blood loss, it will stop spontaneously in approximately 80% of cases. The overall mortality rate is 2% to 4%. Recurrent bleeding is common and occurs in up to 38% of patients.

Diverticular disease is the underlying cause of more than 40% of cases of lower gastrointestinal bleeding. Typically, patients present with painless hematochezia. Initial standard management includes establishing large-gauge peripheral intravenous access at two different sites, cardiopulmonary monitoring, and supplemental oxygen. Initial laboratory analyses should include complete blood count, electrolytes, liver parameters, lactate levels, and coagulation parameters if the patient is on anticoagulant therapy. Hemoglobin levels are serially reevaluated, and blood transfusion is considered according to the patient's clinical status and the dynamics of changing hemoglobin levels. A hemoglobin level of 6 g/dL absolutely indicates the need for a blood transfusion in the acute setting. Patients with a history of cardiovascular disease should receive blood at an Hb level of 8 g/dL, and a level of 10 g/dL should be maintained.

Recommendations for withholding anticoagulants or antiplatelet drugs in patients with acute diverticular bleeding are based on moderate to low quality evidence. The type of drug, the history of the patient determining their individual thrombotic risk, and their clinical status should all be considered. Aspirin as a primary prophylaxis for cardiovascular events generally can be continued, even perioperatively in the case of emergent surgical treatment. In patients with a low thrombotic risk and unstable gastrointestinal hemorrhage under warfarin therapy, anticoagulation can be immediately reversed using prothrombin complex and vitamin K. Once the bleeding has stopped, warfarin therapy should be restarted after an interval of 7 days. In case of high thrombotic risk (mechanical heart valve, atrial fibrillation with a prosthetic heart valve or mitral stenosis, recent venous thromboembolic event [within prior 3 months]), however, the pausing of warfarin therapy has to be evaluated carefully. Anticoagulant therapy with heparin can be considered as a transitional solution in an emergency setting. With heparin therapy, monitoring the partial thromboplastin time (PTT) every 6 hours is essential. Dosing should be carefully adjusted according to PTT levels and body weight.

The two main diagnostic approaches to distinguish diverticular bleeding from other etiologies of lower gastrointestinal bleeding are colonoscopy and computed tomography angiography (CT-A).

Endoscopic Strategies for Diverticular Bleeding

Colonoscopy is performed to identify the endoluminal source of bleeding, while also providing an opportunity for hemostatic intervention. Ideally, the clinically stable patient with lower gastrointestinal bleeding receives colonoscopy within 24 hours of hospital admission, following a bowel preparation. Endoscopic treatment includes epinephrine injection (1:10,000, 1–2 mL aliquots), bipolar cautery, endoclipping, band ligation, or application of topical hemostatic agents (e.g., Hemospray).

Radiologic Strategies for Diverticular Bleeding

Following unsuccessful endoscopic evaluation, recurrent bleeding, or clinical instability of a patient that does not allow for colonoscopy, CT-A of the abdomen and pelvis is considered. CT-A sensitivity is relatively low (85%), but the technique is sensitive enough to detect bleeding rates of 0.3 to 0.5 mL/min. Only active bleeding sources can be detected, which can be critical because of the intermittent dynamic of diverticular bleeding. Minimally invasive interventional treatment using selective angioembolization can be performed via vasopressin infusion or coil embolization. Once the bleeding source is identified, success rates of embolization are up to 85%.

Surgical Strategies for Diverticular Bleeding

Surgery in patients with diverticular bleeding is indicated in emergency settings with persistent or recurrent bleeding that cannot be

managed via either endoscopic or angiographic approaches. Indications are transfusion of 6 units of blood within 24 hours to maintain a hemoglobin level, persistent bleeding for 72 hours, or bleeding recurrence after initial treatment.

If the source of bleeding cannot be identified preoperatively, a subtotal colectomy with end ileostomy should be considered. Even in cases of successful preoperative localization, a targeted segmental colectomy is associated with a rebleeding rate in 14% of cases. The mortality rate for colectomy for diverticular bleeding in an emergency setting is 25%. Overall rebleeding rates 1 year after hospital discharge range from 4% to 42%. Therefore, a prophylactic elective resection after initial bleeding in patients at high-risk for rebleeding episodes can be considered.

Clinically stable patients who tolerate longer operative times should receive colectomy via a laparoscopic approach. Hemodynamic instability and cardiovascular comorbidities indicate an open approach.

In case of subtotal colectomy, after mobilization of the distal ileum beyond the ligament of Treves, the entire colonic mesentery is taken down. An end ileostomy with a rectal stump is created in the event of hemodynamic instability. In select stable patients undergoing elective surgery for diverticular bleeding, an ileorectal anastomosis can be considered.

CONCLUSION

In summary, management of diverticular disease has a significant role in everyday clinical practice, and the therapeutic algorithm is largely based on the patient's clinical status and on diagnostic imaging and endoscopy to exclude the presence of complications such as abscesses/fistula or cancer. Antibiotic therapy is a therapeutic standard in complicated diverticulitis; however, several randomized prospective studies have shown that they are not necessary in the treatment of uncomplicated diverticulitis. Although patients with recurrent disease generally benefit from clinical improvement and elective surgery in a symptom-free interval, patients with perforated diverticulitis require emergency surgical treatment. Once a Hartmann procedure is performed, reconstruction of fecal continuity is challenging and, in the end, often not successful. Recent studies show that primary anastomosis with or without a protective ileostomy can prevent many patients from having a lifelong stoma without excess morbidity. Stronger evidence, however, is required before including these strategies in the treatment algorithm.

Bleeding of the lower gastrointestinal tract often originates from diverticula, and treatment can be challenging in the acute setting because of the use of anticoagulants or antiplatelet medication, particularly in the elderly. Endoscopic control of bleeding and interventional angioembolization show high success rates. A laparoscopic approach is an option in hemodynamically stable patients with recurrent bleeding undergoing resection. In case of hemodynamic instability, a laparotomy with resection of the respective bowel segment up to a subtotal colectomy in cases of an unknown bleeding source must be considered.

Careful clinical examination of the patient accompanied by established diagnostic algorithms lead the way in treating the complications associated with diverticular disease.

MANAGEMENT OF CHRONIC ULCERATIVE COLITIS

Kirkpatrick Beekman Fergus, MD, Michael G. Kattah, MD, PhD, and Elizabeth C. Wick, MD

INTRODUCTION

Ulcerative colitis (UC) is a chronic inflammatory bowel disorder (IBD) characterized by inflammation in the rectum (proctitis) that may extend proximally to include the colon (proctocolitis). Unlike Crohn's disease, which can affect anywhere in the gastrointestinal (GI) tract from the mouth to the anus, UC only affects the mucosa and submucosa of the colon and rectum. In general, UC is continuous, starting in the rectum (proctitis) and, in many patients, extending more proximally into the colon, first the sigmoid or descending colon (left-sided or distal colitis) and, in more severe cases, proximal to the splenic flexure (extensive or pancolitis). Patients exhibit a range of symptoms including frequent, small-volume, bloody diarrhea, urgency, hematochezia, proctalgia, and colicky abdominal pain. Associated hematochezia varies in frequency but is usually small volume and typically does not cause rapid drops in hemoglobin. In severe cases, patients can have significant weight loss, anorexia, and fatigue. With rectal inflammation, patients can develop rectal pain,

spasm, and difficulty evacuating. In general, UC is a chronic disease, but patients may experience acute exacerbations or periods of remission, particularly those undergoing medical therapy.

EXTRACOLONIC MANIFESTATIONS OF UC

Extracolonic manifestations of UC include arthritis, eye disease (uveitis, episcleritis, iritis, conjunctivitis), oral aphthous ulcers, hepatobiliary disorders (asymptomatic transaminitis and primary sclerosing cholangitis [PSC]), erythema nodosum, and pyoderma gangrenosum (pretibial area and peristomal). Many extracolonic manifestations improve after proctocolectomy, but surgery does not improve outcomes in PSC, ankylosing spondylitis, or sacroiliitis.

In patients with UC and PSC, the liver symptoms usually occur in the setting of significant colonic symptoms and, in general, persist even after proctocolectomy. Therefore, it is important that management be collaborative with gastroenterology, hepatology and/or liver transplant surgery, and colorectal surgery. Patients with UC and PSC are at higher risk for dysplasia and colorectal cancer and should undergo annual colonoscopic surveillance beginning when PSC is diagnosed.

RISK FACTORS

The etiology of UC is poorly understood, but it is multifactorial with genetic, microbial, and environmental contributing factors. The microbiome, GI infections (bacterial, viral, and parasitic), food allergies, antibiotic exposure, dietary habits such as high sugar intake, or toxins have all been implicated in animal models and/or population-based studies. Cigarette smoking, of note, has been shown to be protective against UC, even though it is a risk factor for Crohn's disease. The relationship and data regarding cigarette smoking are complex, and the overall health benefits of smoking cessation outweigh the theoretical disease control benefits in UC, therefore all patients should be encouraged to cease smoking.

DIAGNOSIS

Patients are usually evaluated by a gastroenterologist in the outpatient setting or, in the case of acute severe ulcerative colitis (ASUC), the inpatient setting. By the time of surgical evaluation, the diagnosis has generally been made. Endoscopy (sigmoidoscopy and/or colonoscopy) with biopsy is the gold standard for making the diagnosis of UC. Examination of the terminal ileum can help avoid misdiagnosis of Crohn's disease, and a complete examination can help rule out malignancy. The endoscopist should grade the mucosa using the Mayo endoscopic subscore (Table 1) and include photographs in the report. The mucosa in UC is erythematous, friable, edematous, and in severe cases can present with large ulcerations. Although pseudopolyps or even strictures can be seen in a UC postinflammatory state, the presence of strictures or fibrotic disease should raise suspicion for Crohn's colitis or malignancy. Biopsies should be taken from inflamed areas to confirm both chronic and active colitis, and to rule out viropathic effects seen with cytomegalovirus (CMV).

TABLE 1 Mayo Endoscopic Subscore

Score	Disease Activity	Endoscopic Feature
0	Normal or inactive	None
1	Mild	Decreased vascular pattern, erythema, mild friability
2	Moderate	Absent vascular pattern, marked erythema, friability, erosions
3	Severe	Spontaneous bleeding, ulceration

Supplemental tests include laboratory testing, stool testing, and imaging. In addition to complete blood count and complete metabolic panel, the inflammatory markers erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are often associated with disease activity. Stool testing should be obtained to rule out *Clostridioides difficile (C. diff)* and other common bacterial, viral, and parasitic pathogens. Fecal calprotectin is a noninvasive fecal marker commonly used to differentiate between inflammatory versus noninflammatory diarrhea in the outpatient setting and correlates well with disease activity in many patients. CT scan is frequently used in the acute setting to rule out toxic megacolon or perforation but has limited utility for evaluating the small intestine. CT enterography and MR enterography delineate the bowel better and, importantly, can identify any small bowel disease that might suggest the patient's diagnosis is in fact Crohn's disease and not UC.

MEDICAL THERAPY

Medical therapy for UC aims to both improve symptoms and heal the colon mucosa. Treatment is tailored for *induction* of remission followed by *maintenance* of remission. Agents for induction and maintenance for mild to moderate UC include aminosalicylates (mesalamine or diazo-bonded 5-ASA) given orally and/or topically by suppository or enema. Oral prednisone, rectal steroids, or oral or rectal budesonide multimatrix (MMX) can also be used to aid in achieving remission.

Medical therapy for moderate to severe disease requires biologics (monoclonal antibodies) with or without an immunomodulator (e.g., azathioprine) or small molecules. Except for steroids, medications used for induction of remission for moderate to severe UC are continued for maintenance. Nonresponse or loss of response among individuals on biologic agents is managed by dose-intensification or switching to a different biologic agent or small molecule.

For patients with ASUC requiring hospitalization, management includes bowel rest, intravenous hydration, venous thromboembolism prophylaxis, minimizing narcotics, and cessation of antidiarrheal agents to avoid toxic megacolon. *C. diff* should be ruled out, and flexible sigmoidoscopy aids in both risk-stratification and to rule out superimposed CMV colitis. Medical management involves intravenous steroids and biologic agents. Surgical consultation for patients with acute colitis can be helpful to discuss possible surgery earlier in the hospital course. As described later, in the setting of ASUC, surgery results in an end ileostomy. Allowing patients to be partners in this decision and, if time permits, affording them the opportunity to talk to an enterostomal nurse and to patients who have previously undergone surgery for UC can improve the experience.

SURGERY AND ULCERATIVE COLITIS

Overview

The 10-year cumulative risk of colectomy for patients with UC is 10% to 15%, and the rate appears to be decreasing in the era of biologics. Despite evolving medical therapies, patients come to surgery for three main reasons: (1) failure of medical management to control either the intestinal or extraintestinal manifestations of UC, (2) dysplasia and colorectal cancer, or (3) toxic megacolon.

The first is far and away the most common indication for surgery. A patient with UC is cured of colitis by removing the entire colon and rectum (from the terminal ileum to the anorectal junction). This stands in contrast to Crohn's disease where surgery is used to address immediate symptoms, but there is always the risk of the disease returning in a new area.

Patients with UC are at higher risk of colorectal cancer and require routine endoscopic surveillance beginning 8 to 10 years after disease onset or sometimes sooner. Colonoscopy should occur every 1 to 3 years depending on risk factors such as PSC, a family history of colorectal cancer, and whether active inflammation is present. In the past, patients with dysplasia were encouraged to undergo surgery due a high rate of colorectal cancer even with immediate colectomy. Now with

improved endoscopic techniques, patients with visible and resectable dysplasia can be safely followed with close colonoscopic surveillance by experienced gastroenterologists using dye spray or virtual chromoendoscopy and high-definition endoscopes. In the event of persistent invisible multifocal or high-grade dysplasia, unresectable dysplasia, or colorectal cancer on biopsy, patients should undergo proctocolectomy.

Patients with advanced disease despite maximal medical therapy may also progress to toxic megacolon, characterized by colonic dilation, fevers, tachycardia, leukocytosis, and abdominal distension. This requires urgent surgical intervention to prevent perforation.

While the surgical concepts are the same for all UC patients, the approach should be tailored to each patient's indications, urgency, comorbidities, and severity (corticosteroids, biologics, nutritional status) as well as long-term goals of care with regards to life with an ostomy versus bowel frequency. Shared decision making and a team-based approach with the patient, family, gastroenterologist, and surgeon should be embraced to ensure that the patient is knowledgeable and prepared for the operation(s) and long-term impact on lifestyle.

Total Abdominal Colectomy with End Ileostomy

For urgent indications (toxic megacolon, severe medically refractory disease, refractory ASUC, perforation), total abdominal colectomy with end ileostomy is the best course of action. It is a relatively short operation (2–3 hours) that removes a good amount of diseased bowel (colon) and diverts the fecal stream away from the rectum, allowing the mucosa to partially heal. The rectum is left in place during this operation to reduce the risk of complications associated with pelvic dissection in the setting of severe inflammation and to allow for restoration of fecal continence via an ileal pouch later. Before surgery, if time allows, the patient should have a visit with an enterostomal therapist and the site for the end ileostomy should be selected. It is usually in the right lower quadrant, but it is important that it is tailored to the patient's body habitus. A poorly placed ileostomy (in a skin fold or scar, belt line, etc.) can be very challenging to manage, time consuming, and lifestyle limiting for the patient and family.

The approach should be laparoscopic if the surgeon has experience and the patient is hemodynamically stable. A fully laparoscopic, hand-assisted laparoscopic, or robotic approach have all been described. In general, after the pneumoperitoneum is established, the colon is mobilized, either with a medial to lateral approach with ligation of the vessels first (ileocolic, middle colic, and inferior mesenteric) or lateral to medial approach with ligation of the vessels second. High ligation is not needed unless there is concern for dysplasia or malignancy, and it is generally safest to stay close to the colon when dividing the mesentery.

In a medial to lateral approach, the dissection begins on the left by the sigmoid colon, which is retracted anteriorly to identify the inferior mesenteric artery pedicle. A window is created to isolate the pedicle, and before ligation it is important to identify and preserve the left ureter and gonadal vessels. After ligation, the dissection then proceeds superiorly separating the colon from Gerota's fascia up to the splenic flexure. The lateral attachments are taken next, following the white line of Toldt to free the descending colon from the retroperitoneum. Division of the rectosigmoid junction with a stapler is performed next, followed by ligation of mesenteric vessels. Attention is then turned to the right colon with identification and ligation of the ileocolic artery. The medial dissection proceeds superiorly toward the hepatic flexure, followed by a lateral dissection releasing the peritoneal attachments. After dividing the hepatic flexure, all remaining attachments along the transverse colon are divided. The colectomy is completed with division of the terminal ileum. Of note, based on surgeon preference, the dissection either proceeds from left to right (as described) or right to left.

There are a few key considerations when selecting the proximal and distal resection sites. The rectosigmoid junction should be divided either intracorporeally or extracorporeally (via Pfannenstiel or lower midline incision). If the rectosigmoid bowel is thick and edematous, it is possible that the staples will not hold. If there is concern, the selected division point should allow for the rectosigmoid area to be matured to the skin as a mucous fistula. Other strategies for managing a challenging rectal stump include oversewing the staple line and decompressing the rectum with a rectal tube. Delayed intraabdominal breakdown of the rectal stump results in sepsis and usually needs to be managed with reoperation. The proximal division should be in the very distal terminal ileum so that sufficient small bowel remains for an ileal pouch if the patient desires.

After the colectomy specimen is removed, the ileostomy should be brought out through the previously marked area and everted or "Brooked." By having the ileostomy above the skin, it will allow for a well-fitting ileostomy appliance and reduce risk of skin breakdown, pain, and discomfort. When bringing the ileostomy through the abdominal wall, it is also important to ensure that the mesentery of the small bowel is not twisted as this can lead to obstruction and/or ischemia requiring reoperation.

For most patients, the total abdominal colectomy will restore appetite, weight, energy, and overall quality of life. There will be some bloody mucus drainage from the rectum, but if patients are warned to expect this it is usually quite manageable.

Completion Proctectomy/Total Proctocolectomy

For patients undergoing surgery for dysplasia, cancer, or chronic medically refractory disease (not hospitalized, not on high dose steroids, and without signs of malnutrition), the best approach is to remove the colon and rectum (total proctocolectomy) in one operation. In this case, the patient and surgeon should plan to either proceed with ileal pouch anal anastomosis (IPAA) with a temporary diverting loop ileostomy or simply remove the rectum and remain with a permanent end ileostomy. If the plan is to complete the proctocolectomy in one operation, the colectomy is completed as described before and the rectum is removed as described later.

Proctectomy can be completed laparoscopic, hand-assisted laparoscopic, robotic, or open. The rectum is identified, and the inferior mesenteric artery is noted coursing along the retroperitoneum. The peritoneum is incised, and the left ureter is identified. The inferior mesenteric artery and vein are ligated. The dissection is then carried into the pelvis posteriorly by developing the plane between the mesorectum and the fascia propria of the rectum. The superior hypogastric plexus should be identified and preserved. Once the pelvic floor is reached, the anterior dissection should be initiated by developing the plane between the rectum and prostate or vagina. Care should be taken to err on the side of the rectum and, in men, avoid entering Denonvilliers' fascia as nerves controlling sexual function course around the pelvic brim and are at risk of injury. The lateral stalks of the rectum should be divided on the right and left, and the rectum should now be free circumferentially to the pelvic floor. This can be confirmed by placing a finger in the anus. If the patient is not to have an ileal pouch constructed, the rectum and anus will be completely removed by completing the dissection from the anus. This dissection is initiated with a self-retaining retractor effacing the anus. It is generally a simple dissection conducted from the perineum in the intersphincteric (between the internal and external anal sphincter) groove. This is usually bloodless and leaves the external sphincter in place to help with perineal wound healing and prevent herniation later.

The perineum is closed in multiple layers approximating the muscle layers using Vicryl or other absorbable suture, followed by skin closure. Surgical closed suction drains are typically left in the presacral space to protect the perineal wound from seroma formation and reduce the risk of infection and dehiscence.

Creation of Ileal Pouch Anal Anastomosis

Most patients will desire ileal pouch creation; IPAA is the most common operation done for UC in the United States. Although it is associated with more risks (short and long term) than end ileostomy, for many patients restoring intestinal continuity is important to their

quality of life. For most patients with an IPAA, it is reasonable to expect 6 to 10 bowel movements per day. The stool will be looser, although consistency may improve with time as the small bowel adapts to absorb some water. A significant number of patients will experience urgency and even some fecal incontinence, but for the most part the pain associated with bowel movements is gone.

It is important to recognize scenarios where IPAA is not appropriate. These include patients with a history of fecal incontinence or sphincter injury, history of anorectal disease (anal fistula), uncertainty related to the diagnosis of UC versus Crohn's disease (indeterminate colitis or IBD unclassified), and those who are frail and would not be able to tolerate the complications associated with IPAA (pelvic sepsis). IPAA should not be undertaken in patients with Crohn's disease except by expert surgeons in specific situations as it is associated with a much higher rate of postoperative complications and pouch failure.

If the plan is to create an ileal pouch, when the rectal dissection is at the level of the pelvic floor, the rectum is transected with a stapler, approximately 1 cm above the anal sphincters. After the rectum is removed, the ileal pouch is created. If the colectomy was done in a prior operation, the terminal ileum is freed up from the ileostomy site. The distal terminal ileum is identified as is the superior mesenteric artery. The "tip" of the small bowel is located—the area of the small bowel that will reach the furthest into the pelvis. This is usually 10 to 15 cm proximal from the distal end. If this "tip" can touch the pubic bone, it will likely reach the anus. The two limbs of the ileal pouch are aligned, and a linear stapler is used to fashion the pouch (Fig. 1). Usually, two loads of the linear stapler are needed as the goal is to have the pouch 10 to 12 cm in length. The pouch to anus anastomosis is created with a circular stapler (Fig. 2). The anvil is placed in the pouch, secured with purse-string suture, and the handle is placed in the anus. The anastomosis is fashioned by firing the stapler. It is essential that there is excellent visibility in the pelvis when creating the anastomosis to ensure that the small bowel, bladder, vagina, etc. do not fall into the staple lines. There should be two complete "donuts" on the stapler, and the pouch should be inspected for bleeding by sigmoidoscopy and for air tightness by inflating air into the

pouch and looking for air bubbles in the pelvis (saline irrigation is used to submerge the pouch from the abdominal side).

Most surgeons, when creating an IPAA, protect the pouch with a diverting loop ileostomy, created using more proximal small bowel brought up as a loop in the right lower quadrant. Although this does not prevent postoperative pelvic sepsis, it mitigates the severity as the fecal stream is diverted. The diverting loop ileostomy is closed in a separate operation about 3 months later. In most cases, this can simply be done with an incision around the ileostomy site, and the hospital stay is 1 to 2 nights. Rarely, more extensive dissection is needed, and a laparotomy is required. Before the ileostomy closure operation, the ileal pouch is interrogated with a Gastrografin enema to check for leaks at the staple lines and sometimes a flexible sigmoidoscopy to dilate the anus and inspect the mucosa.

PERIOPERATIVE AND POSTOPERATIVE CONSIDERATIONS

Perioperative Management

Enhanced recovery protocols beginning in the days leading up to surgery and continuing through postoperative management should be used. Pain medication regimens should limit opioids and maximize nonopioid analgesia including regional analgesia as appropriate. For patients on high-dose, long-term steroids, a short course of steroid taper should be used to avoid manifestations of adrenal insufficiency. Surgical site infection prevention bundles including presurgery bathing with chlorhexidine, mechanical bowel preparation with oral antibiotics (elective surgery), preincisional prophylactic antibiotics (cefazolin and Flagyl, or as determined by the hospital), alcohol-based skin preparation in the operating room, and appropriate attention to sterile technique using a closing set when suturing on the fascia and skin should be employed. Early ambulation with deep venous thrombosis prophylaxis is essential to reduce the risk of clot formation as this patient population is at significantly increased risk. Catheter-associated urinary tract infection bundles should also be employed comprising of careful insertion by a trained provider and prewash with antiseptic soap; early removal either at the end of the surgical case or the following morning should also be integrated into the care.

Ileal Pouch Complications

Complications can be divided into immediate perioperative complications associated with pelvic surgery and longer-term complications more specific to the ileal pouch. Surgical risks include injury to surrounding structures, especially nerves associated with sexual and urinary function, infection related to leaking at staple lines leading to pelvic abscess and sepsis, bleeding and ileus, or early postoperative small bowel obstruction. Overall, the short-term complication rates are in the range of 10% to 15%. Postoperative management should also include monitoring for persistent frank blood in the stool consistent with intraluminal bleeding (although some bleeding is expected in the first few days), which may require endoscopy with inspection of the staple line. Hemodynamically unstable patients should be taken to the operating room. Early anastomotic leak will present with fever, tachycardia, leukocytosis, and pelvic abscess on cross-sectional imaging and is usually treated with a percutaneous drain, but sometimes it is very low in the pelvis and needs to be drained transanally in the operating room.

Pouch-specific issues include acute, recurrent, or chronic inflammation in the ileal pouch, termed pouchitis. This can occur in about half of patients and is generally treated with antibiotics, mesalamine, topical steroids, budesonide, or biologic agents. A small subset of patients may develop de novo Crohn's disease after IPAA. Medically refractory pouchitis, especially secondary to de novo Crohn's disease, may lead to pouch failure and necessitate end ileostomy and/or pouchectomy. Patients with inactive UC and no prior pelvic surgery have similar infertility rates to the general population. However, women should be counseled that IPAA has been reported to increase the infertility rate compared with medically managed patients, although laparoscopic approaches may preserve fertility.

SUMMARY

Patients with UC are best cared for by a patient-centered transdisciplinary team that includes an experienced surgeon, gastroenterologist, enterostomal therapist, and, if needed, hepatologist and dermatologist. Surgical approaches should be tailored to the patient's goals of care, and patients who have previously undergone surgery for UC can serve as an important resource for future patients.

Management of Toxic Megacolon

Jonathan E. Efron, MD

Toxic megacolon was first described in 1933 at Massachusetts General Hospital as a case report but became more widely known in the 1950s. It is an infrequent, potentially life-threatening condition that results from any inflammatory condition of the colon. It is most commonly seen as a complication of inflammatory bowel disease (IBD), more commonly ulcerative colitis (UC) than Crohn's disease (CD) and some infectious colitides, most commonly with *Clostridium difficile*–associated (pseudomembranous) disease (CDAD). In cases of IBD, toxic megacolon results as a progression from fulminant colitis. Although fulminant colitis is not precisely defined, this term generally refers to severe inflammation of the colon with associated systemic toxicity with or without colonic dilatation. According to the diagnostic criteria of Truelove and Witts for the disease activity in UC, fulminant colitis is diagnosed by the presence of bloody diarrhea more than 10 times, heart rate

higher than 90 beats/min, temperature above 37.5°C, requirement of blood transfusion, erythrocyte sedimentation rate (ESR) more than 30 mm/hr, with the presence of abdominal distension and tenderness on clinical examination, and dilated colon on x-ray. In the context of CDAD, according to the Dallal classification of CDAD severity, fulminant colitis is diagnosed by the presence of a heart rate above 120 beats/min, leukocytosis with more than 30% bands, severe oliguria, and requirement of mechanical ventilator and vasopressors. Toxic megacolon is defined as segmental or total colonic distension of 6 cm or more in the presence of acute colitis with systemic toxicity. Radiologically, it typically exhibits dilatation of the proximal colon with thickened inflamed distal colon and associated pneumatosis. Unlike colonic obstruction, in which cecal dilation with perforation is a concern, the transverse colon is the most common area of dilatation in toxic megacolon.

Given the other conditions that cause colonic distention, such as colonic pseudo-obstruction and Hirschsprung's disease, toxic megacolon is distinguished from these conditions by its systemic manifestations of toxicity. Early diagnosis and aggressive medical management are pivotal to prevent progression to the associated high morbidity and mortality. Moreover, prompt recognition of disease progression and severity and timely surgical intervention may be lifesaving. The mortality rate for patients with toxic colitis significantly increases when the disease progresses to perforation—2% for those patients without perforation or 40% to 50% for those patients with perforation; therefore, close observation and surgical intervention before perforation is essential.

CAUSE, INCIDENCE, AND PATHOGENESIS

Any inflammatory condition of the colon can result in toxic megacolon. These include IBD, infectious causes including pseudomembranous colitis caused by *C. difficile* or other bacteria, such as *Salmonella, Shigella, Campylobacter,* or *Entamoeba,* and ischemic colitis (Box 1).

The incidence of toxic megacolon varies by the underlying cause. In patients with UC, it is estimated to be 5%, and the risk is higher early on in the disease. Historically, the reported incidence of CDAD ranged between 0.4% and 3%. However, with the changes in the epidemiology of *C. difficile* infections and emergence of new strains, there has been a 23% annual increase in the rate of hospitalizations resulting from CDAD in the United States.

The pathogenesis of the toxic dilatation of the colon is not fully understood. However, it is thought to be a result of severe inflammation of the colon associated with release of inflammatory mediators that induce colonic smooth muscle relaxation and inhibit colon motility. The acute severe mucosal inflammation becomes transmural and extends into the smooth muscle layer, resulting in loss of motor tone and paralysis. The severely inflamed smooth muscle produces nitric oxide, which is released into the colonic wall and further inhibits smooth muscle tone and causes dysmotility and atony. This generally causes dilatation of the colon proximal to the colonic segment that is severely inflamed. The toxic systemic response results from bacterial translocation and subsequent bacteremia.

Several other factors such as hypokalemia, hypomagnesemia, opiates, anticholinergic or antimotility agents, antidepressants, barium enemas, and colonoscopy may affect adversely colonic motility and exacerbate colon dilatation.

BOX 1 Causes of Toxic Megacolon

Most Common

Ulcerative colitis
Clostridium difficile–associated colitis

Less Common

Crohn's disease
Salmonella
Shigella
Campylobacter
Yersinia
Cytomegalovirus
Entamoeba histolytica
Cryptosporidium
Ischemia colitis
Chemotherapy
Colonoscopy
Barium enema
Drugs that slow colonic motility (narcotics, antidiarrheal drugs, anticholinergic drugs)

DIAGNOSIS

The diagnosis of toxic megacolon is based on both clinical and radiologic findings. Therefore, a thorough history and physical examination are crucial. The diagnosis must be suspected in patients who have diarrhea, abdominal distension, and signs of systemic toxicity.

The patient's history typically reveals symptoms of severe colitis that preceded the acute onset of colonic dilatation. These include severe diarrhea (usually bloody), abdominal pain, fever, chills, and tachycardia. Obtaining a history about a previous diagnosis of IBD with the extent of colonic involvement and medical therapy and recent use of antibiotic or other medications such as steroid, antimotility, and chemotherapeutic agents will help in determining the underlying cause.

Physical examination reveals significant localized or generalized abdominal tenderness and reduced bowel sounds accompanied with signs of systemic toxicity, such as fever, tachycardia, and hypotension. Presence of signs of peritonitis may indicate colonic perforation. However, it is not uncommon that peritoneal signs maybe masked by high dose steroid treatment typically used in IBD patients with fulminant colitis.

The best acceptable clinical criteria for the diagnosis of toxic megacolon were described by Jalan et al. in 1969. The presence of three of the following criteria is required for the clinical diagnosis: fever higher than 101.5°F (38.6°C), heart rate higher than 120 beats/min, white blood cell count above 10.5 ($\times 10^9$/L), or anemia. In addition, patients should have one of the following criteria: dehydration, mental changes, electrolyte disturbances, or hypotension.

A plain abdominal x-ray is useful in confirming the diagnosis of toxic megacolon as it identifies the proximal colonic distention and may be used to follow the disease course and the rate of colon expansion. It typically shows dilatation of the ascending and transverse colon that varies from 6 cm up to 15 cm. Once the transverse colon is dilated past 8 cm, there should be great concern for pending perforation. Other radiologic features include presence of air fluid levels and the loss of normal haustral pattern in the colon with thickening and edema of colonic wall. Small bowel and gastric distension may be seen as well, and they have been shown to be significant predictors of toxic megacolon and progression to multisystem organ dysfunction in UC.

Computed tomography (CT) scan of the abdomen and pelvis is useful in confirming the diagnosis, excluding other causes of colonic dilatation, such as obstructing colonic cancer or diverticular stricture, and helping to exclude other abdominal complications, such as colonic perforation and ascending pyelophlebitis. Presence of colonic wall thickening, submucosal edema, pericolic stranding, and thickened haustra are indicative of severe colitis. As with plain abdominal x-rays, the presence of dilatation of the transverse colon (greater than 6–8 cm) confirms the diagnosis of toxic megacolon (Fig. 1).

Laboratory tests are not specific and show the findings of systemic inflammatory response with leukocytosis, anemia, elevated ESR or serum C-reactive protein, and electrolyte abnormalities with hypokalemia, hypomagnesemia, and hypoalbuminemia. These findings, if not corrected, may exacerbate the condition.

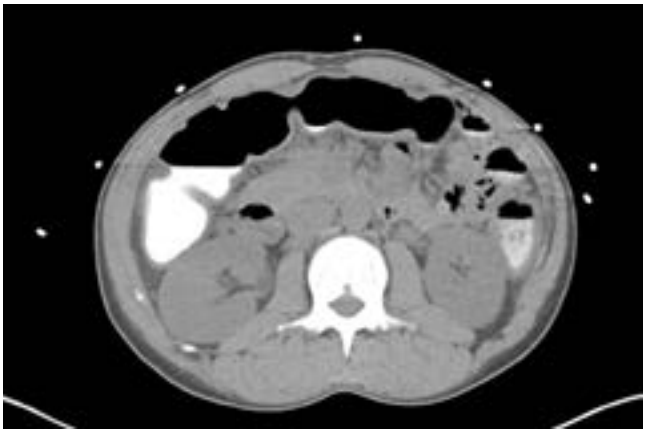

FIG. 1 Computed tomography scan of the abdomen showing dilated and thickened wall of the colon.

TABLE 1 Laboratory Tests for the Diagnosis of *Clostridium difficile* Infection

Test	Sensitivity	Specificity
Cell cytotoxicity assays	60%–100%	96%–99%
Cell culture neutralization assay	67%–86%	97%–100%
Enzymatic detection of glutamate dehydrogenase	71%–91%	76%–98%
Enzyme immunoassay tests for toxins A and B	39%–76%	84%–100%
Nucleic acid amplification test for toxins A and B	84%–100%	94%–100%

Stool sample for culture, sensitivity, and *C. difficile* toxin assay should be sent as well as blood culture because bacteremia occurs in up to 25% of patients with toxic megacolon. Several tests to detect *C. difficile* are available. Sensitivity and specificity of each test vary; therefore, it is recommended to perform a two-stage test approach to improve the diagnosis accuracy. Stool culture is highly sensitive; however, it does not differentiate between the presence of *Clostridium* bacteria and active infection. It generally is used in conjunction with other diagnostic tests (Table 1). The commonly used two-stage test approach includes initial screening with glutamate dehydrogenase assay followed by confirmation of a positive test with cell cytotoxicity assay. Some centers use toxin B gene PCR testing with nucleic acid amplification test as a single test to diagnose *C. difficile*.

Limited endoscopy, proctoscopy, or sigmoidoscopy may be considered to determine the cause of toxic megacolon in patients who are not known to have IBD. It can differentiate between the infectious causes of toxic megacolon because the finding of pseudomembranes is suggestive of CDAD, whereas the presence of inclusion bodies in the biopsies indicates cytomegalovirus (CMV) colitis as an underlying cause, which may occur in patients with IBD. It should be performed with extreme caution, without bowel preparation, and with minimal air insufflation; the endoscope should be advanced only as far as necessary to make a diagnosis. Complete colonoscopy should not be performed because of the high risk of perforation.

THERAPY

Management of toxic megacolon requires coordination between medical and surgical services with aggressive attempts of medical therapy and early surgical intervention in the absence of improvement, development of complications, or deterioration.

Medical Therapy

Regardless of the underlying cause of toxic megacolon, immediate aggressive supportive management in an intensive care unit must be initiated.

There is no evidence to support the use of nasogastric tube decompression because it does not decompress the colon. Frequent patient repositioning has been described as a method of colon decompression based on the observation that gas tends to accumulate in the transverse colon if the patient remains in the prone position and may be redistributed to the distal colon and rectum with frequent repositioning. There is no strong evidence to support use of this technique; however, it is simple and may be attempted.

Complete bowel rest with adequate intravenous fluid replacement is required. Electrolyte abnormalities, especially hypokalemia, dehydration, and anemia can exacerbate colonic dysmotility and must be corrected aggressively. Any medications that affect colonic motility such as opiates, antimotility agents, and anticholinergics should be discontinued immediately. Prophylaxis for deep venous thrombosis and gastric ulcer should be administered. Broad-spectrum antibiotics were found to reduce the mortality from septic complications that result from associated bacteremia or colonic perforation and should be initiated, whereas any agent that may have led to *C. difficile* overgrowth should be discontinued. Frequent clinical assessment and close monitoring with physical examination, serial complete blood counts, electrolyte monitoring, and abdominal x-rays must be performed (Fig. 2).

Management of Patients with Inflammatory Bowel Disease

High-dose intravenous steroid (hydrocortisone 100 mg every 6 hours) should be administered immediately to patients known to have IBD who have symptoms of fulminant colitis to prevent progression to toxic megacolon. There is no evidence that steroid therapy increases the risk of perforation; however, it may mask the signs of colonic perforation, so again close surveillance is required.

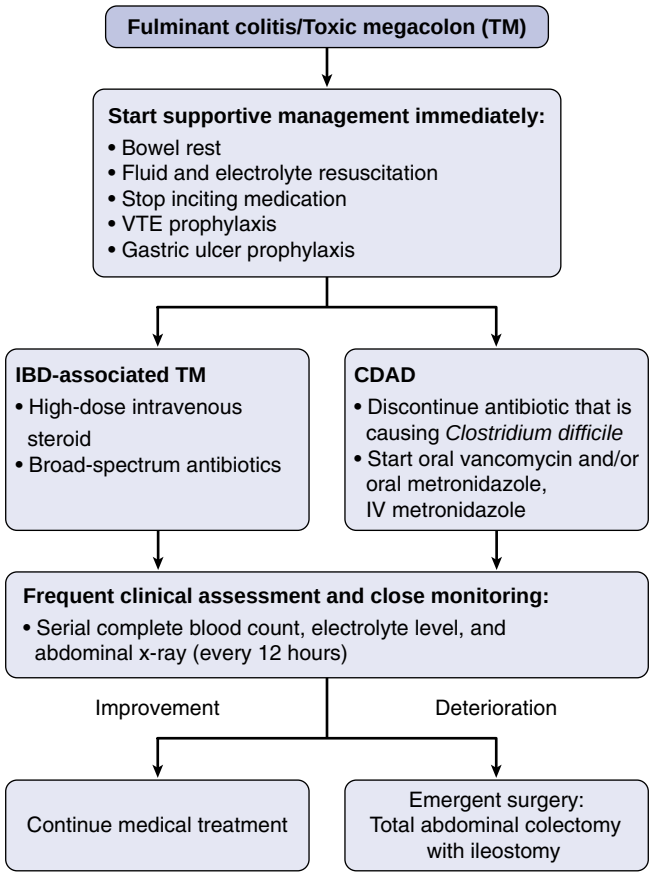

FIG. 2 Management algorithm for toxic megacolon.

Aminosalicylic acid products are used in mild to moderate cases of UC; however, there are no data to support their benefit in treating toxic megacolon. Similarly, cyclosporine and antitumor necrosis factor-alpha (TNF-α) are immunosuppressant medications used in severe cases of UC. Both medications are initiated if there is no response to high-dose intravenous steroids within 3 days. Although generally not started for patients with acute toxic megacolon, as mentioned these drugs are often given to patients with fulminant colitis who are not responding to steroid therapy and so are often seen in patients who progress to surgery. Some data suggests that cyclosporin may have an initial effect in 80% of patients with severe fulminant colitis bordering on toxic megacolon and therefore may reduce the need for emergent surgery. The medical management is the same regardless of the defined IBD: UC, CD, or indeterminant colitis.

Management of Patients with Clostridium difficile*–Associated Disease*

If toxic megacolon is thought to be caused by CDAD, the antibiotics thought to have initiated the *C. difficile* infection should be withdrawn immediately, and treatment with oral vancomycin (125–500 mg four times a day) and/or oral metronidazole (200–500 mg four times a day, or 500 –750 mg three times a day) is initiated. Intravenous metronidazole is also acceptable. If a patient cannot tolerate oral vancomycin because of severe ileus, it may be administered via an enema or nasogastric tube. There have been reports of successful treatment of severe *C. difficile* colitis with colonoscopy and intracolonic vancomycin lavage. We would advise against this in patients suspected of having toxic megacolon due to the risk of perforation, which significantly increases the mortality rate of the patient.

Surgical Therapy

Timing of surgical intervention is paramount in decreasing the morbidity and mortality of toxic megacolon and improving the patient's overall outcome. Medical management has been reported to be effective and successful in 50% to 70% of patients with toxic megacolon. However, delay in surgical intervention carries a risk of developing abdominal complications such as colonic perforation and abdominal compartment syndrome, which increases the mortality rate from 2% to 50%.

The possible need for surgical intervention and the nature of surgery must be discussed with patients and their families on admission. All patients must be evaluated and marked by an enterostomal therapist who should mark the best site for an end ileostomy.

Surgery is absolutely indicated in the presence of progressive colonic dilatation, uncontrolled hemorrhage, development of complications such as free perforation, and with general clinical deterioration. This includes progressive sepsis with continued tachycardia, hypotension, or the need for presser agents to maintain blood pressure. Lack of improvement within 48 hours is also a relative indication for surgical intervention. It is better to proceed to the operating room sooner as opposed to later, and any of the previously mentioned findings should push the surgeon to operate.

Mechanical bowel preparation is contraindicated, and the surgery typically is performed through an open approach for two reasons. The significant colon dilatation and friability of the colonic wall do not allow for a workable space or graspable tissue and therefore preclude a laparoscopic approach. The patient is often unstable and needs significant resuscitation from sepsis, requiring a quick efficient operation. Patients with fulminant colitis who have not progressed to toxic megacolon are often managed with a laparoscopic total colectomy and end ileostomy. If the surgeon feels the colonic distention will not interfere with laparoscopic visibility, the patient is hemodynamically stable and not on any pressor medications, and colonic wall does not appear significantly thinned or necrotic, an attempt at a laparoscopic total colectomy is feasible.

The current surgical standard of care for patients with toxic megacolon who require surgery is total colectomy with end ileostomy. This removes the diseased colon and allows restoration of intestinal continuity after the patient has recovered. The rectum should not be resected at the time of this emergent operation despite how inflamed it may appear. The bowel is often fragile with a high likelihood of intraoperative perforation with manipulation resulting from the significant dilatation and inflammatory process, and thus it should be handled with extra care. During hepatic and splenic flexures mobilization, the colonic mesentery is divided close to the bowel wall to avoid damage to retroperitoneal structures.

The rectal stump is often just as severely inflamed and, therefore, difficult to manage. If the rectosigmoid junction appears too inflamed to hold staples or sutures, then the surgeon should leave a short segment of sigmoid colon to form a mucous fistula to decompress the remaining colon and rectum. In obese patients, the rectal stump may be brought through the inferior aspect of the midline fascial incision and left buried in the subcutaneous space. This will be removed at time of stoma reversal, and if the stump blows out, it allows for decompression through the wound as opposed to in the peritoneal cavity. If a rectal stump is left in the peritoneal cavity, it should be decompressed in the operating room with a rectal tube that is left in place to allow for further postoperative decompression and possible vancomycin enemas. Drains should be left on top of the stump. A rectal stump leak typically occurs 5 to 10 days after surgery; therefore, if a patient manifests signs of peritonitis 5 to 7 days after surgery after initially recovering well, the surgeon should have a high suspicion for rectal leak. Emergent return to the operating room with washout and drainage is necessary.

Postoperative care requires transferring the patient to an intensive care unit where all supportive measures are continued as needed. Preoperative antibiotics are discontinued within 24 hours, and intravenous steroids are tapered to a maintenance dose (equivalent of 10–20 mg of prednisone per day). On restoration of gastrointestinal motility, enteral feeding is given. The rectal tube is removed on the fifth to seventh postoperative day.

An alternative, less invasive, colon-preserving surgical approach for the treatment of CDAD is the formation of a loop ileostomy with antegrade vancomycin irrigation of the colon. In a case-controlled study, Neal et al. treated 42 patients with creation of a loop ileostomy after visual assessment of colon viability. Intraoperatively, colonic lavage with 8 L of warmed polyethylene glycol 3350/electrolyte solution was performed via the ileostomy and drained via rectal tube. Postoperatively, patients received antegrade vancomycin enema (500 mg in 500 mL of lactated Ringer's every 8 hours for 10 days) via the efferent limb of the ileostomy. All patients received intravenous metronidazole (500 mg every 8 hour for 10 days). These patients were compared with matching historical controls treated with total colectomy and end ileostomy. In the study cohort, 35 (83%) cases were performed laparoscopically. The colon was preserved in 39 (93%) patients, and subsequent colectomy was required for continued sepsis in one patient and for abdominal compartment syndrome in two patients. When compared with a historical population, mortality was reduced from 50% to 19%.

Although this novel surgical approach may represent a less-invasive surgical treatment with promising outcomes, the results of this study are limited by the retrospective nature and lack of randomization that introduce a selection bias. Furthermore, there are no clear criteria to suggest which patient may benefit from this approach. Finally, the results were never reproduced by other investigators. There has been little written recently, but the technique may still be considered for those patients who are less severe. The 2015 practice parameters of the American Society of Colon and Rectal Surgeons for the management of *C. difficile* infection considered that the evidence for loop ileostomy formation in the management of toxic megacolon from *C. difficile* to be weak and strongly recommend the standard surgical approach in managing these patients, which is subtotal colectomy with end ileostomy. Loop ileostomy with antegrade colonic vancomycin lavage should not be considered in the severely septic patient requiring significant (presser or ventilatory) support.

OUTCOMES

The mortality rates from IBD-associated toxic megacolon have changed dramatically over the years. In an early review (1976) of 604 patients, the overall mortality was 19%, and it was higher in medically managed patients when compared with patients who were treated with early surgery (27% vs. 19.5%). The presence of perforation increased the mortality to 41.5% compared with 8.8% in the absence of perforation. In more recent reports, mortality rate after colectomy is 2% to 5%. Older age and multiple comorbidities are associated with a higher mortality rate. The mortality rate after colectomy for CDAD remains high. In a systematic review (2009) of 1433 patients, it was found to be 41.3%. Preoperative intubation, acute renal failure, multiorgan failure, and requirement of vasopressors were found to be predictors of postoperative mortality.

SUMMARY

Toxic megacolon can complicate inflammatory or infectious colitis. It is a life-threatening emergency characterized by severe colonic distension and systemic toxicity. Early recognition, a multidisciplinary management approach, and the time of surgical intervention are crucial to improving outcomes.

Surgical Management of Crohn's Colitis

Hanjoo Lee, MD, Alessandro Fichera, MD, and James W. Fleshman Jr., MD

INTRODUCTION

Crohn's disease (CD) is a chronic inflammatory disorder of the gastrointestinal tract first described by Burrill Crohn, Leon Ginzburg, and Gordon Oppenheimer in 1932. The disease was thought to be limited to the small intestine and was referred to as "regional enteritis." Subsequent observations confirmed that CD may not only affect any segment of the gastrointestinal tract but also involve a slew of extraintestinal organs including the bronchopulmonary, integumentary, ocular, and joint systems. Currently, 3 million patients are affected by the disease in the United States with an incidence of 3 to 20 cases per 100,000 people. Interestingly, the past five decades have seen a gradual increase in incidence. Populations with Northern European and Jewish heritage exhibit the highest incidence of CD. However, an increasing trend amongst Asian and Hispanic populations has also been noted in recent years. The disease onset shows bimodal peaks around ages 20 and 50, although diagnosis in children is not uncommon. Few pathologies involving the gastrointestinal tract have puzzled the medical community as much as CD. The pathophysiology of the disease is exceedingly difficult to characterize due to the complex interplay between multiple environmental and genetic factors involved. The environmental factors include gastrointestinal infection, chronic use of nonsteroidal antiinflammatory medications, and exposure to antibiotics to name a few. Generally, a disruption in the integrity of the intestinal mucosa and natural gut flora are thought to be involved. Perhaps the most remarkable known risk factor is smoking. Active and passive smoking as well as previous history of smoking are all shown to increase the risk of development and worsening disease severity. Several genetic risk factors have been identified including mutations in *MLH1,* a DNA mismatch repair gene, and in *CARD15*, a nuclear factor-kappa B transcription factor. Increased incidence in identical twins and first-degree members of Crohn's patients also points to hereditary contribution of disease development. Clinical presentation of CD is multifaceted. It may range from minimal symptoms to fulminant colitis or debilitating perianal disease. As mentioned before, CD can affect the entire gastrointestinal tract. In 20% to 30% of cases, the disease presents as isolated Crohn's colitis (CC). When CC is suspected, it is extremely important to differentiate this diagnosis from ulcerative colitis (UC). Although there is a symptom overlap between CC and UC, the goal of surgical treatment is different. A prudent practitioner must be aware of several key differences between these two entities. Skip lesions, rectal sparing, longitudinal ulcers, intestinal and perianal fistulizing disease, and mucosal cobblestoning are all notable characteristics pointing toward CC rather than UC (Fig. 1). Abdominal pain, fever, and diarrhea are common initial symptoms of CC, and occasionally a palpable abdominal mass can be present. Unlike UC, rectal bleeding is uncommon in CC. Development of carcinoma of the colon is well described in patients with CC based on the extent of involvement and duration of the disease, and it is not dissimilar to the risk in UC.

The presentation of CC as a solely perianal disease is rare (<6%), but almost 20% of patients with CC will develop perianal disease over their lifetime. History and physical exam alone can be useful in establishing the diagnosis of CC. Laboratory workup should include C-reactive protein, erythrocyte sedimentation rate, fecal calprotectin, and albumin levels in addition to the standard complete blood count and basic metabolic panel. These values can also be used to assess disease progression. Plain x-rays of the abdomen are helpful initial radiographic tools to identify free perforation and evaluate severity of colonic dilation. Barium enema can show several characteristic findings of CC including longitudinal or transverse ulcers, deep fissuring of the bowel wall, coarse mucosa cobblestoning, or longitudinal intramural fistulas. Single or double contrast barium enemas are rarely used due to the excellent tomographic techniques available that can provide enterography with no heavy contrast or risk of perforation. Computed tomography (CT) with enterography is useful in evaluating bowel wall thickness, stricturing, intraabdominal abscess, internal hernias, and/or extraintestinal involvement. If previous surgical history is unclear, CT can help clarify the anatomy. Endoscopic examination of the colon with biopsy is crucial for diagnosis and grading of disease intensity. Proctosigmoidoscopy may be sufficient in diagnosing

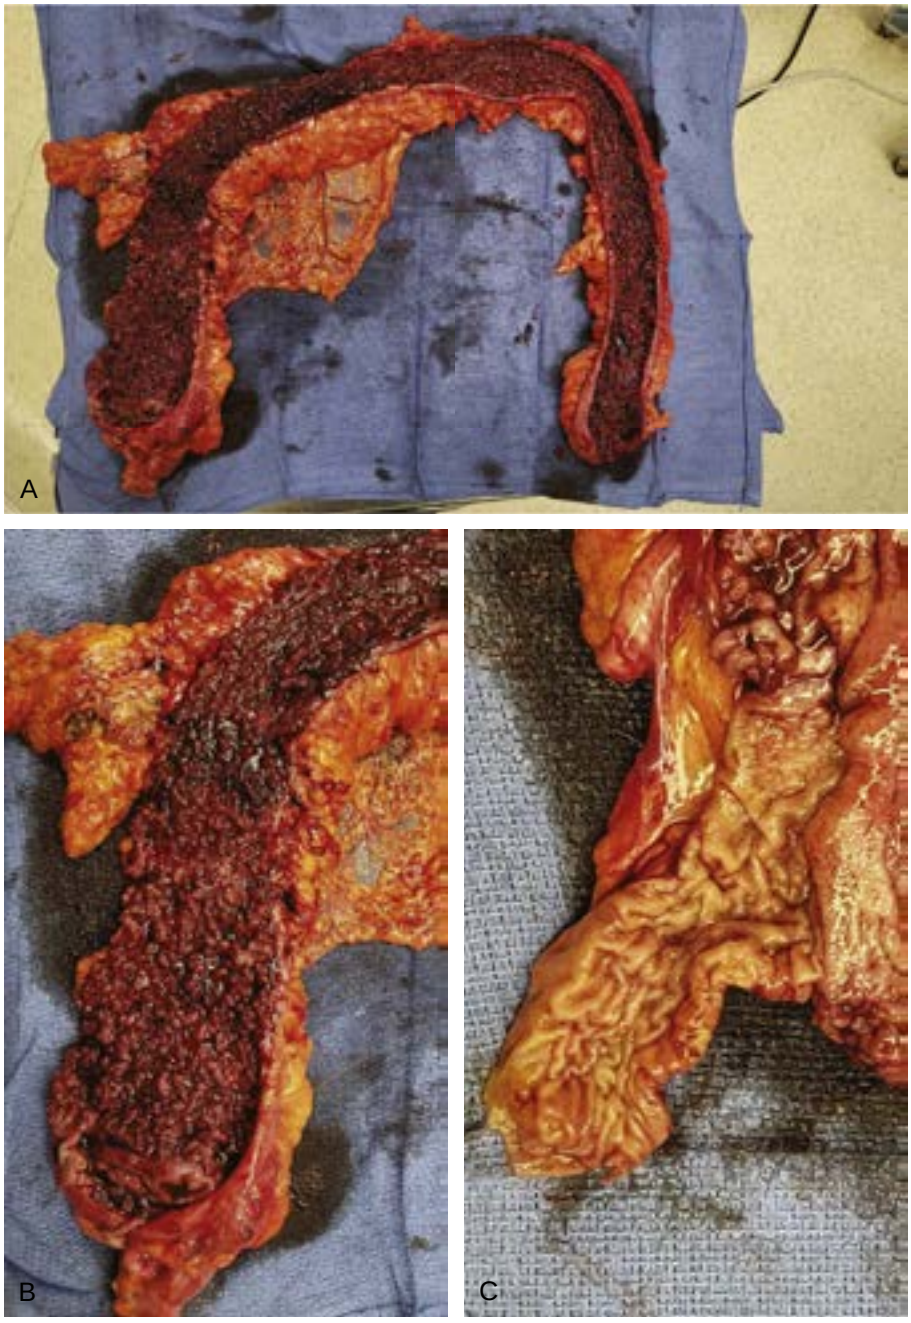

FIG. 1 Mucosal appearance of CC. **(A)** Entire colon is involved on a TAC specimen. **(B)** Extensive mucosal cobblestoning is present. **(C)** Normal-appearing terminal ileum.

CC, but most practitioners prefer full colonoscopy, especially in the preoperative setting. This is because 40% of CD spares the rectum regardless of perianal involvement. If UC is suspected, biopsy of the rectum, even if normal appearing on visual inspection, is helpful to rule out pathologic inflammatory changes. In 10% to 15% of cases, differentiation between UC and CC may truly not be possible even under pathologic examination. These cases are categorized as inflammatory bowel disease unclassified (IBDU) and called indeterminate colitis. In the absence of definitive microscopic findings (i.e., noncaseating granulomas), pathologists often refer to clinical information to arrive at their definitive diagnosis.

MEDICAL MANAGEMENT

Similar to UC, initial management of CC should be supportive care with bowel rest, intravenous hydration, and antibiotics. Placement of a nasogastric tube may alleviate symptoms if the stomach and small bowel are dilated. Intravenous glucocorticoids should be initiated early in the course of management. Serial abdominal exam, plain radiographic films, and serologic markers described previously can be used to monitor disease progression. If symptoms do not improve in 72 hours, use of an anti-TNF antibody (infliximab) should be considered. Generally, response to anti-TNF should occur within 5 to 7 days.

INDICATION FOR SURGICAL INTERVENTION

Despite the remarkable advances in medical therapies in the past two decades, surgery still plays an important role in the management of CD. In fact, lifetime risk of needing a resection ranges between 50% to 80%, and this rate remained relatively stable in the postbiologics era. Therefore, discussion with patients about indication for surgery should occur early in the disease process so that a fully informed decision can be made when the need for surgery arises. The indications for surgical intervention can be categorized into emergent, urgent, and elective (Table 1). Acute abdomen with diffuse peritonitis, severe bleeding, and hemodynamic instability undoubtedly warrant emergent exploration. Toxic megacolon, acute large bowel obstruction unresponsive to medical management, and intraabdominal abscess without successful control of sepsis by percutaneous drainage often require urgent exploration within the same hospitalization. Elective surgery is appropriate in cases where disease continues to progress despite extensive medical therapy, partial obstruction with fecalization of the small bowel, persistent intraabdominal abscess despite percutaneous drainage and antibiotics, presence of high-grade dysplasia or malignancy, and failure to thrive in children. Every effort should be made to transition urgent surgery to an elective surgery setting to gain invaluable time needed to optimize the patient and reduce the risk of postoperative complications.

PREOPERATIVE OPTIMIZATION

Colonic resection for CC, regardless of the specific indication, is associated with significant morbidity. Postoperative outcomes are intimately associated with preoperative optimization. Multidisciplinary management including gastroenterology, infectious disease, enterostomal nursing, nutrition, surgery, and interventional radiology is critical. Since inflammatory bowel disease management has numerous nuances, it is best managed in a facility that cares for tertiary and quaternary level patients and provides optimal resources for the high-risk complex gastrointestinal procedures. Patients referred for surgery are typically immunocompromised and malnourished. Dose-dependent operative morbidity with steroid therapy is well documented. In contrast, no clear association has been established between use of immunomodulators such as azathioprine, 6-mercaptutopurine, and methotrexate and postoperative morbidity. Safety of preoperative exposure to biologic agents is a highly controversial subject due to a number of large-scale studies that showed conflicting results. Given the lack of conclusive data, urgent surgery generally should not be delayed based on recent exposure to biologic agents alone, and fecal diversion should be individualized based on the overall clinical picture.

Nutritional status is a significant preoperative factor to consider not only in CD but in any complex surgical case. Malabsorption of nutrients and change in dietary habits are inherently associated with CD before resection. Therefore, nutritional optimization is of critical importance. Notably, weight loss >10% is associated with postoperative intraabdominal septic complication. Nutritional supplementation can be administered via either elemental enteral alimentation (EEA) or total parenteral nutrition (TPN). EEA is preferred over TPN due to maintenance of the physiologic route of nutrient absorption and avoidance of complications associated with TPN and central line placement. Preoperative EEA supplementation, for 3 months when feasible, has been shown to reduce the rate of postoperative septic complications. If intraabdominal sepsis is present, medical management should be initiated immediately, and it should include intravenous hydration and initiation of antibiotics to cover enteric flora. The antibiotic regiment can then be tailored according to culture results. Any intraabdominal collection >3 cm should be managed with percutaneous drainage with interventional radiology whenever possible. These measures may lead to a definitive resolution with medical therapy or serve as a bridge to surgery. If an enterocutaneous fistula is present, early involvement of a wound and ostomy nurse is critical. The reduction of the surrounding secondary inflammatory response to an area of severe disease or local perforation should be a primary goal of preoperative optimization.

The tissue handling characteristics of a "phlegmon" will often result in secondary injury of secondarily involved normal intestine and a wider resection of intestine than actually required to manage the disease. The risk of short bowel syndrome is thus increased. Patience on the part of the surgeon and patient will soften the tissue to allow sharp, atraumatic dissection in normal tissue planes. Patients with CD are at increased risk of developing venous thromboembolism (VTE) due to several associated factors including hypercoagulability in a proinflammatory state, malnutrition, anemia, thrombocytosis, prolonged hospital stay with limited mobility, and use of steroids. Venous thromboprophylaxis should be initiated during the optimization period and carried through the operation unless significant bleeding risk is present. The risk of VTE continues to be elevated at least 30 days after an operation, and VTE prophylaxis should be continued postoperatively. Judicious use of postdischarge VTE prophylaxis should be considered, especially if other risk factors are involved such as smoking, obesity, prolonged pelvic surgery, immobilization, and malignancy.

TABLE 1 Indications for Surgical Intervention for Colonic Crohn's Disease

Emergent	• Acute abdomen with diffuse peritonitis • Severe bleeding • Hemodynamic instability
Urgent	• Toxic megacolon • Acute large bowel obstruction unresponsive to medical management • Intraabdominal abscess without successful control of sepsis by percutaneous drainage
Elective	• Continued disease progression despite extensive medical therapy • Partial large bowel obstruction with fecalization of the small bowel • Persistent intraabdominal abscess despite percutaneous drainage and antibiotics • Presence of high-grade dysplasia or malignancy • Failure to thrive in children

SURGICAL MANAGEMENT

Surgical options for CC are segmental colectomy, total abdominal colectomy (TAC) with or without ileorectal anastomosis, total proctocolectomy (TPC) with a permanent end ileostomy, and restorative proctocolectomy with ilea-anal pouch anastomosis in a selected patient population (Table 2). While minimally invasive surgery for CD disease has been found to be associated with better short-term outcomes, the approach should be tailored to the clinical presentation and surgeon's skills and expertise. The critical principles of small bowel preservation apply to CC. This is especially important if the patient has already lost a significant amount of small bowel. The absorptive capacity of the colon that is not diseased can reduce diarrhea and possible "short bowel syndrome" secondary to operative treatment of ileocolonic CD. If <20 cm colon is affected, especially in the proximal colon, segmental resection with primary anastomosis should be considered. Leaving behind a segment of colon does put the patient at increased risk of recurrence, up to 62% at 5.5 years. This risk should be clearly discussed with the patient before surgery. Typical surgical considerations and principles apply to segmental colectomies for CC.

TABLE 2 Surgical Options for Colonic Crohn's Disease

Segmental colectomy	• Previous multiple small bowel resections • <20 cm involved segment in the proximal colon, segmental resection with or without primary anastomosis should be considered
Total abdominal colectomy (TAC)	• More than two segments of colon are involved with rectal sparing and anastomosis is deemed unsafe • Patient is in extremis with pancolitis and a total proctocolectomy is not indicated • Definitive diagnosis is not established, and indeterminate colitis is considered
Total proctocolectomy (TPC)	• Involvement of two or more segments of colon especially with perianal fistulizing disease • Visible dysplasia not amenable for complete endoscopic removal • Multifocal dysplasia, dysplasia in the surrounding flat mucosa • Carcinoma in the setting of pancolitis
Ileal pouch-anal anastomosis (IPAA)	• Absence of small bowel or perianal involvement with a definitive preoperative diagnosis of CC

Total Abdominal Colectomy

In a patient without free perforation, the preferred methods for TAC are laparoscopic mobilization of the abdominal colon and transection of the terminal ileum and rectosigmoid junction through a Pfannenstiel incision or intracorporeal transection at the rectosigmoid junction and extraction through the ileostomy site incision. There are several indications for TAC: (1) when more than two segments of colon are involved, with rectal sparing, and anastomosis is deemed unsafe; (2) when a patient presents in extremis with pancolitis, but a TPC is not indicated; and (3) when definitive diagnosis is not established, and indeterminate colitis is considered. The dissection for laparoscopic TAC begins with transection of the ileocolic pedicle and mobilizing the cecum away from the right iliac vessels at the right pelvic brim in a medial to lateral fashion and continues in a clockwise rotation to the hepatic flexure taking care to avoid injuring the duodenum. The gastrocolic ligament and any ligamentous attachments to the liver, spleen, and pancreas are divided to mobilize the transverse colon. The lateral attachments of the right colon to the lateral abdominal sidewall are divided last to finally release the right colon to the midline. The authors prefer to divide the omentum distal to the gastroepiploic arcade and remove it with the specimen. Many surgeons would try to preserve the omentum, but the difficulty in releasing the omentum from an inflamed transverse colon is likely to result in a colotomy and fecal spillage.

The splenic flexure is mobilized in an antegrade fashion from the right to the left, when feasible. When severely inflamed or in obese patients, it may be necessary to return to the splenic flexure in the retrograde fashion after partial mobilization of the left colon. Care must be taken to divide the base of the mesentery of the splenic flexure with sealing energy in case the arc of Riolan is a significant vessel and the branches of the inferior mesenteric vein (IMV) persist. All ligamentous attachments of the splenic flexure should then be dissected close to the colon to avoid injury to the splenic capsule. The left colon is mobilized by dividing the lateral attachments and freeing it off of the retroperitoneum starting at the left pelvic brim and dissecting medially, taking care to avoid injury to the left ureter. Ureteral stents placed at the induction of anesthesia can facilitate identification and protection of the ureters in a patient with severe inflammation in the descending colon and sigmoid regions. A medial approach to releasing the left colon and rectosigmoid junction allows avoidance of inflammatory attachments of the sigmoid and left colon to the critical structures at the pelvic brim. Working from soft normal dissection planes toward the diseased areas gives a better chance to complete the dissection and avoid injury to diseased and normal structures. Unlike TAC for malignancy, ligation of the vascular supply to the colon does not need to occur close to its origin in CC, and the mesentery can be ligated closer to the colon.

To date, the benefit of extended mesenteric resection for CD in reducing recurrence rate is not clearly established. However, the mesentery near the diseased bowel is often inflamed and thickened, so the soft, normal embryologic plane at the base of the mesentery may be the preferred dissection plane. Care must be taken to avoid significant bleeding from the thickened, friable mesentery during the transection of the vessels and at the point of transection of the colon. The rectum is identified at the distal sigmoid colon where the tenia coli "splay" out onto the anterior surface of the rectum. The peritoneal reflection is incised around the pelvic sidewalls and the proximal rectum is mobilized using the areolar tissue plane posterior to the rectum at the sacral promontory. The terminal ileum and the rectosigmoid junction are transected with a linear cutter stapler to control spillage after dividing the mesentery up to the bowel wall, either intracorporeally or through a small Pfannenstiel incision. The rectosigmoid junction is the preferred level of distal transection. This provides adequate rectal length for ileorectal anastomosis or creation of a mucus fistula and removes all colonic mucosa. Depending on the clinical scenario either an end ileostomy or ileorectal anastomosis is performed using either hand-sewn or stapled technique.

Patients who are restored to intestinal continuity with an ileorectal anastomosis often experience a period of rapid return of bowel function followed by a sudden decrease in bowel function, marked abdominal distension, and vomiting. This phenomenon, sometimes described as "ileorectal syndrome", is caused by exposure of the terminal ileum to a high back pressure from the rectal vault. Drainage of rectal contents and relief of build-up of pressure in the ileum using an in-dwelling large catheter (24–34F) in the rectum can alleviate this ileal response to perceived obstruction caused by normal rectal pressures withholding stool from evacuations until a steady bowel function returns.

There are certain factors that need to be considered when deciding between ileorectal anastomosis and end ileostomy. The rectum and the perianal region must be examined carefully to make sure they are free of stricturing or fistulizing disease before committing to ileorectal anastomosis. Adequate sphincter resting tone and maximal squeeze pressures are required to prevent incontinence of liquid stool. The presence of fistulotomy or episiotomy scars should raise concern for postoperative inadequate control of liquid stool. The patient's general condition such as nutritional status, weight loss, usage and dosage of steroidal agents, and smoking status should be reviewed to determine the feasibility of anastomosis. Opting for an end ileostomy confers a lower rate of recurrence of CD, especially in active smokers and patients with penetrating disease. The ileostomy and Hartmann stump of the rectum allows the surgeon to appreciate the natural history of the patient's disease to determine whether an ileorectal anastomosis is possible in the future. A Brook ileostomy should be performed in the acute setting, in cases of indeterminate colitis, and when the rectum is involved. Management of the rectal stump remains controversial. It is the authors' preferences to drain the stump with a rectal tube and leave a drain by the staple line for the duration of the hospital stay. The transected Hartmann rectal stump of an inflamed rectum is at risk for dehiscence of the upper staple line due to active disease and tissue friability. Other surgeons bring the stump to the incision and either suture it to the fascia or

open it as a formal mucus fistula. These two options require a longer stump that may not be feasible with sigmoid involvement or in the obese patient.

Total Proctocolectomy

If two or more segments of colon are involved, and if associated perianal fistulizing disease is present, TPC with end ileostomy should be performed. Any presence of visible dysplasia not amenable for complete endoscopic removal, multifocal dysplasia, dysplasia in the surrounding flat mucosa, or carcinoma in the setting of pancolitis should also warrant TPC and end ileostomy. This is based on the observation that more than a third of patients who undergo colectomy for dysplasia are found to have multifocal dysplasia. In addition, 14% to 40% of patients who undergo colectomy for carcinoma in CC eventually develop metachronous cancer. The proctectomy portion of TPC proceeds after the abdominal portion as described earlier. Typically, the pelvic dissection follows the total mesorectal excision (TME) plane performed for rectal cancer surgery. This plane allows for decreased blood loss especially in the presence of inflamed mesorectum. Using electrocautery, the loose avascular areolar tissue of the retrorectal space is dissected to mobilize the rectum with the mesorectum intact. Once the posterior dissection is complete to the levator ani, the lateral attachments and the anterior Denonvilliers' fascia/rectovaginal septum are dissected to the levator ani to completely mobilize the mesorectum. Extra care must be taken not to mistake the pelvic parietal fascia for the fascia propria of the rectum because the loose avascular areolar tissue between presacral fascia and pelvic parietal fascia can look identical to the one present in the retrorectal space. Surgeons often realize this mistake mid-dissection and, in an attempt to return to the correct retrorectal space, transect the hypogastric nerve embedded within the pelvic parietal fascia. A helpful hint is that if median sacral vessels running on the sacral periosteum are visualized, the dissection plane is already in a posterior plane deep to the desired plane anterior to the pelvic parietal fascia. One technique to reduce potential pelvic nerve injuries is to perform close rectal dissection (CRD). In this technique, the dissection is performed close to the rectal muscle wall within the mesorectum. This minimizes the risk of injury to the hypogastric nerves, the pelvic splanchnic nerves, and the inferior hypogastric plexus.

When ileal pouch-anal anastomosis (IPAA) for benign disease was randomized to CRD and TME, the CRD group suffered significantly fewer severe complications and improved quality of life. However, dissection through the mesorectal tissue often results in bleeding and is understandably associated with longer operating time (approximately 30 minutes). Once the rectum is completely mobilized intraabdominally as close to the anal canal as possible, the transperineal portion of the procedure is begun. Intersphincteric dissection for the completion proctectomy is preferred, whenever possible. The dissection is begun at the anal verge in the palpable intersphincteric groove with a circumferential incision into the space between the internal and external sphincters. The autonomic internal sphincter circular fibers do not twitch when touched with electrocautery. The somatic external sphincter fibers that encircle the internal sphincter fibers do twitch. The longitudinal rectal muscle fibers run at right angles to the circular fibers in the intersphincteric space and guide the dissection cephalad to the level of the puborectalis muscle. Preserving the well-vascularized external sphincter reduces the size of the perineal wound, allows better pelvic closure and healing, and reduces the risk of injury to the vagina/prostate and neurovascular bundle. Notwithstanding, extra care must be taken during anterior dissection to avoid injury to the vagina or the prostatic capsule. Frequent palpation of the posterior vaginal wall or the bladder catheter in the perineal and prostatic urethra helps to maintain orientation in the correct dissection plane. The dissection progresses circumferentially in a cephalad direction, and the levator ani muscles are finally separated from the rectum at the puborectalis sling to join with the dissection plane from the intraabdominal portion of the procedure. Once the rectum is removed, a drain is left in place in the pelvis through the abdominal wall or perineum. The levator ani, the external sphincter, and the ischiorectal fat are approximated in layers across the midline, but the subcutaneous tissue and skin are left open. This serves the purpose of draining the wound as well as leaving an opening that cosmetically resembles an anal orifice. The drain is typically removed in two weeks if drainage is minimal.

Restorative Proctocolectomy with Ileal Pouch Anal Anastomosis

There is a rare, select patient group with isolated CC without small bowel or perianal involvement who may be candidates for IPAA. If the diagnosis of CD is made before IPAA, pouch failure rate is 15%. If the patient is able to keep the pouch, functional outcomes and quality of life are similar between IPAA for CD and UC.

Minimally Invasive Surgery

Adaptation of laparoscopic surgery for CD has been rather unhurried in the surgical community compared with other arenas of abdominopelvic surgery. This is because the disease involves chronically inflamed bowel with friable and thickened mesentery that makes laparoscopic surgery particularly challenging. The initial randomized and observational studies comparing the outcomes of laparoscopic colectomy to open surgery have been promising. Similar to comparative studies for other colorectal disorders, laparoscopic colectomy showed decreased morbidity, decreased blood loss, faster return of bowel function, shorter hospital stays, and, in some cases, decreased costs. Furthermore, laparoscopic surgery allows specimen extraction through a Pfannenstiel incision, which affords decreased incisional hernia rate and pain (Fig. 2). Fistulizing disease warrants a special mention as it adds another layer of complexity. So far, comparative observational studies have shown that although operating time, conversion rate to open surgery, and rate of stoma creation are all increased, overall morbidity rate remains the same between laparoscopic surgeries for fistulizing and nonfistulizing disease. Individual surgeon's skill and comfort level should dictate if laparoscopic surgery is feasible in these cases. The use of hand-assisted laparoscopic surgery is an intermediate step between open operation and totally laparoscopic operations. The experienced hand, inserted through an airtight seal in the Pfannenstiel incision, can facilitate dissection by finding planes, identifying structures, encircling vessels bluntly, and guiding the incision by feel to speed the operation, thus reducing stress and risk and achieving the same outcomes as a pure laparoscopic procedure.

Robotic Surgery

Advantages of robotic surgery including intracorporeal anastomosis, smaller incision, and minimal manipulation of the bowel generally apply to CD. Robotic surgery is associated with a median of 2-day shorter length of stay and lower 30-day complication rate compared with open surgery. When robotic TAC for CC was compared with laparoscopy, no differences were noted including complications. Evidence in favor of robotic surgery in the management of CD is still in development.

SURGICAL PEARLS

- Utilize transversus abdominis plane (TAP) block and enhanced recovery after surgery (ERAS) pathway to improve outcomes.
- If proceeding with laparoscopy, have predetermined criteria for conversion to open operation. This can be based on operative findings, inability to make progress, or hemodynamic instability.
- Position with memory foams and chest straps in obese patients to avoid brachial plexus injury caused by shoulder brace and sliding of the patient on the table.

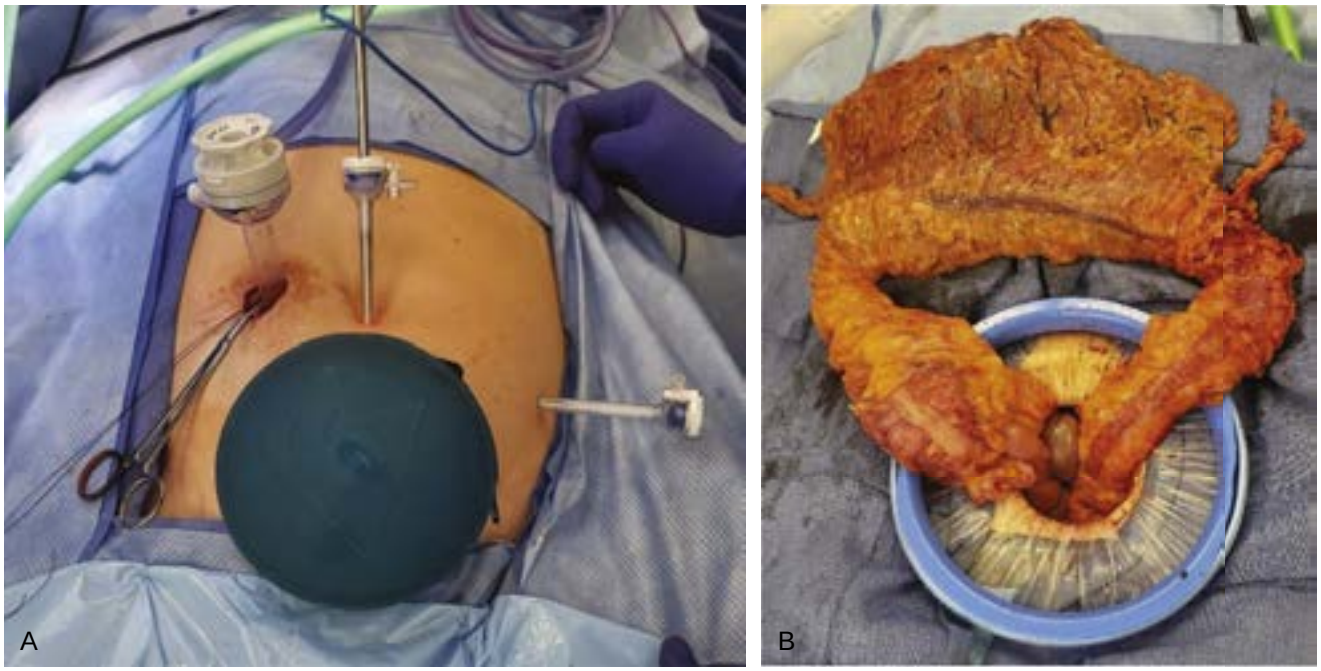

FIG. 2 Hand-assisted laparoscopic TAC. **(A)** 5-mm umbilical laparoscope port for the camera, 12-mm right working port at the site of the future stoma (this is also the entry site), 5-mm left lateral assistant port, Pfannenstiel incision for hand assist and specimen extraction. **(B)** The entire colon is externalized through the Pfannenstiel incision.

- Tilt operating table at appropriate angles to improve visualization with gravity movement of abdominal contents.
- Set up stirrups to keep legs no more than 10 degrees flexed at hips to allow adequate motion of instruments.
- Foley catheter should be in place before trocars are inserted.
- Keep insufflation pressure below 15 mm Hg if possible.
- Insert trocars under direct vision with camera.
- Insert instruments with camera guidance if at all possible.
- Lift tissue without grasping whenever possible.
- Start dissection at the base of the mesentery at the vascular bundle to make bloodless dissection possible.
- Ensure no twist in the mesentery of the small bowel for ileostomy. This may require reinsufflation of abdomen for laparoscopic view of cut edge of mesentery without twist.
- Know the protocol for air embolism: Trendelenburg and left lateral decubitus positioning to move the air into the right atrium to be aspirated.

POSTOPERATIVE MANAGEMENT

To date, there is no validated scoring system to stratify risk factors for postoperative recurrences. However, some of the known risk factors include penetrating disease, two or more previous CD surgeries, history of extensive small bowel resection of >10 cm, age <30 at diagnosis, an interval <10 years between diagnosis and surgery, and presence of perianal disease. Finally, smoking is an important modifiable risk factor that portends higher risk of recurrence. The number of risk factors involved can help categorize patients into low, moderate, and high risk of recurrence. Patients with no risk factor are considered low risk. These patients may stay off of medical therapy after surgery unless recurrence is noted at 6-month surveillance colonoscopy. Presence of several risk factors put the patient at moderate risk of recurrence. These patients should be aggressively managed with medical therapies including anti-TNF therapy in combination with immunomodulator. Alternatively fecal calprotectin monitoring 3 months after surgery can serve as an early indication for endoscopic examination.

CONCLUSION

Despite a century of advances in medical and surgical therapy, CD remains a clinical challenge for the treatment team and a chronic malady for patients. The complexity of the disease process and multifaceted phenotypic presentations demand multidisciplinary management. To date, the majority of patients suffering from CD ultimately will require surgery, and therefore surgeons are an integral part of this multidisciplinary team. A thorough preoperative workup is imperative to establish a clear diagnosis of CC and to adequately optimize nutritional status. A number of surgical techniques are available as minimally invasive options enter the fray. Each technique should be tailored to the patient's condition and the surgeon's skill and clinical judgment.

Ischemic Colitis

Ranim Alsaad, MD, and Pamela A. Lipsett, MD, MHPE

DEFINITION AND EPIDEMIOLOGY

Ischemic colitis (IC) is a condition that occurs when the blood supply to colonocytes does not meet metabolic demands. It is the most common cause of gastrointestinal (GI) ischemia. Injury can occur in one of two ways: at the initial incident of decrease in blood flow phase and/or after reperfusion. If the injury occurred only at the mucosa, it can be reversible. However, a transmural injury can present as a life-threatening condition that can lead to stricture formation, perforation, sepsis, and death. The incidence of IC ranges from 4.5 to 44 cases per 100,000 persons per year. Patients generally present after the age of 60, and there is a higher prevalence in women. The incidence of IC is expected to rise given the growing proportion of elderly patients. It most commonly occurs after aortic or cardiac surgeries. The severity of the disease dictates specific management strategies. About 20% of patients diagnosed with IC will require operative intervention, typically in an emergent setting.

ETIOLOGY

To understand the pathophysiology behind IC, we must consider the arterial anatomy of the colon. As shown in Figure 1, the colon is supplied by the superior mesenteric artery (SMA), inferior mesenteric artery (IMA), and branches of the superior rectal artery. In addition to these primary arterial branches, there is a rich collateral circulation. Griffith's point, at the splenic flexure, and Sudek's point, at the rectosigmoid junction, are particularly prone to ischemia, cumulatively compromising 80% of IC cases. These high-risk, or "watershed," areas identify the regions in the colon between two major arteries; the splenic flexure is the area between the SMA and the IMA arterial supply, and the rectosigmoid junction is the region between the IMA and the superior rectal artery supply. The former area is mostly supplied by the marginal artery; however, in 50% of the population, this artery is poorly developed. During aortic surgery, when intraperitoneal, efforts should be made to ensure that the left colon has adequate blood supply if the IMA is acutely sacrificed.

IC is classified according to the mechanism of decreased blood flow to the colon. This is most commonly nonocclusive, as in cases of shock, drugs, and colon obstruction. Less commonly, IC occurs after a vascular insult, which could be due to an arterial thrombosis, embolism, or even a venous occlusion. A special entity is the postoperative IC that can occur after cardiac and vascular surgeries, in which there is an intraoperative temporary cessation of blood flow to the colon. For example, following abdominal aortic aneurysm repair or bypass, if the IMA was sacrificed or if there was prolonged cross clamp time, IC can occur.

During periods of hypotension, blood flow is redirected to the brain at the expense of the splanchnic circulation. At a histologic level, the initial ischemic changes are always in the mucosa on the antimesenteric side. These changes will eventually spread through the colon wall to the serosa if the insult continues. Mucosal injury will develop in 20 minutes to 1 hour of decreased blood flow, whereas transmural infarction occurs within 8 to 16 hours. Additional insult occurs when blood flow is reestablished, causing reperfusion injury. Reperfusion injury is associated with the release of reactive oxygen species, which causes lipid peroxidation within cell membranes and leads to cell necrosis.

Risk factors for IC include advanced age, female gender, peripheral artery occlusive disease, coronary artery disease, heart failure, chronic obstructive pulmonary disease, and inflammatory bowel disease (IBD). Postoperative IC occurs most commonly after aortic surgery or after cardiac surgery with temporary GI vascular

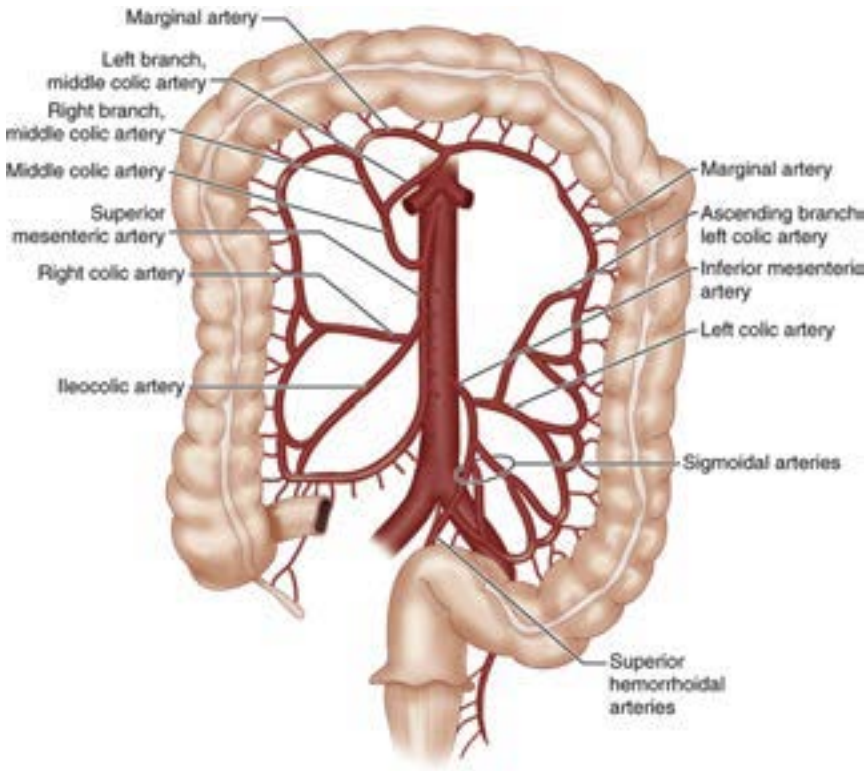

FIG. 1 Colon blood supply. *(From Araghizadeh F, Abdelnaby A, Colorectal surgery. In Anatomy and Physiology. Elsevier; 2013.)*

exclusion. In addition, the odds of developing IC are higher in cigarette smokers, both current and former (relative to never smokers). The use of cardiovascular medications such as diuretics or digoxin and psychotropic medications within the past month of presentation is also significantly associated with IC.

CLASSIFICATION

One can classify IC into mucosal vs. transmural types with further classification by severity as mild, moderate, and severe IC. Severe IC often involves transmural infarcts of the colon wall, which leads to peritonitis, sepsis, perforation, and death. Another way to look at different types of IC is by anatomic location or distribution: segmental colitis or sidedness. A special entity is isolated right-sided colon ischemia (IRCI) as it is associated with poor outcomes. IRCI has 30-day mortality rate of 20.3% compared with 9.0% in those with non-IRCI, higher frequency of severe cases requiring surgical intervention (40.9% of patients compared with 10.3% in those with non-IRCI), and is associated with acute mesenteric ischemia. Pancolitis and IRCI may be seen frequently in patients with sepsis, and IRCI is associated more frequently in patients with coronary artery disease and chronic kidney disease on hemodialysis. 61% of episodes of IC that required surgical intervention had either IRCI or bilateral (pancolonic) patterns of ischemia.

PRESENTATION

The presentation of IC is often vague, and the diagnosis is often delayed while other differential diagnoses are ruled out. The most common symptoms of IC are acute onset abdominal pain, hematochezia, and an urgent desire to defecate. Gangrenous colitis is characterized by increasing abdominal tenderness, guarding, rebound tenderness, rising temperature, and paralytic ileus. The sudden onset of a toxic colitis with signs of peritonitis and a rapidly progressive course are typical of universal fulminant colitis, a rare variant of IC. Rectal bleeding is found more frequently in non-IRCI (69.9%) compared with IRCI (39.4%). One must have a high index of suspicion when patients present with severe acute abdominal pain without bleeding, especially if they have the common risk factors associated with IRCI. A timely diagnosis of IRCI is important for patient survival.

DIAGNOSIS

After a thorough history and physical examination looking for specific risk factors for IC, laboratory studies, imaging, and endoscopy might be used to reach the correct diagnosis.

Routine laboratory studies are unhelpful in reaching a diagnosis of IC but are important for prognostication and assessing severity. Leukocytosis is a frequent finding. Elevated lactate, urea, and creatinine are sometimes found. Some patients may present with metabolic acidosis and a base deficit in cases of severe ischemia, gangrene, and sepsis. Decreased hemoglobin levels, low serum albumin, and the presence of metabolic acidosis can be used to predict severity of IC.

Imaging usually involves a CT scan, but sometimes in entertaining other differential diagnoses, an abdominal x-ray is ordered. Classic findings on an x-ray include thumbprinting, which indicates mucosal edema. In cases of bowel perforation, an x-ray is a quick way to see free air under the diaphragm. The use of contrast enemas had previously been the diagnostic modality of choice, but has been replaced, for the most part, by CT imaging and colonoscopy.

CT is the most helpful modality in the initial assessment of the patient with abdominal pain. It can exclude other causes of abdominal pain, suggest a location and source of ischemia, and identify complications associated with more advanced disease (Figs. 2 and 3). CT will frequently show bowel wall thickening, thumbprinting, and pericolonic stranding with or without ascites. After reperfusion, there may be evidence of submucosal edema or hemorrhage. Emboli or thrombi causing complete arterial occlusion are occasionally seen with corresponding thin, unenhancing colonic wall due to complete lack of reperfusion. CT findings of colonic pneumatosis and

FIG. 2 Contrast enhanced axial CT image demonstrating foci of gas in the portal veins *(arrow)*. Peripherally branching air on CT helps differentiating portal venous gas from pneumobilia, which typically is more central. Significant bowel distention is also noted.

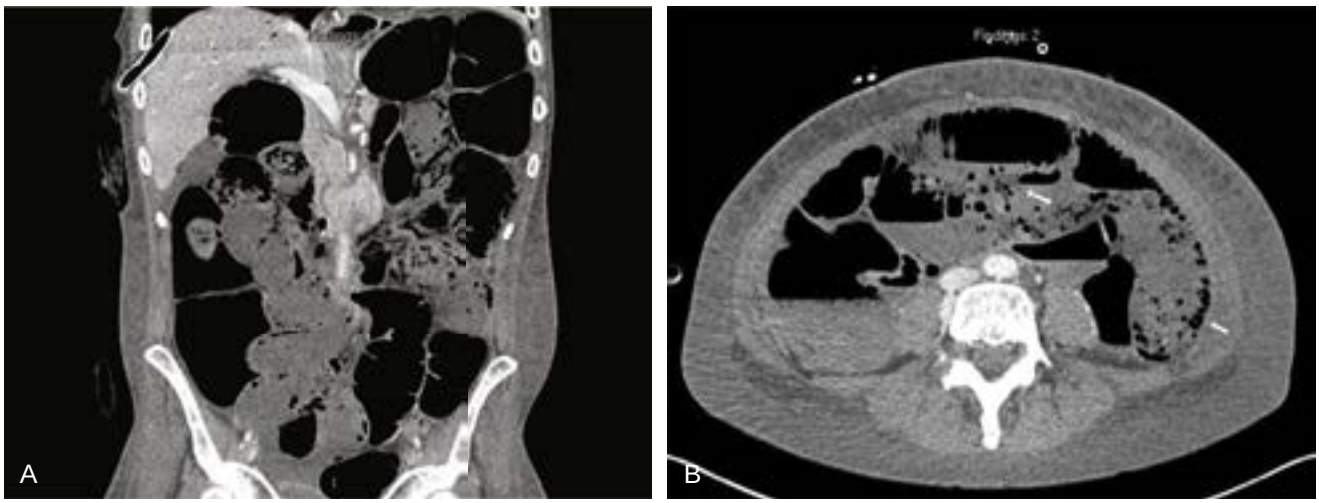

FIG. 3 **A** and **B**, Contrast enhanced axial CT image showing extensive dilatation and pneumatosis *(arrow)* of the small bowel. Pneumatosis was also seen in the cecum, corresponding to the superior mesenteric artery vascular tract. Mesenteric venous gas is noted as well *(arrow with *)*.

portomesenteric venous gas can be used to predict the presence of transmural colonic infarction but can also be present with other conditions like chronic obstructive pulmonary disease and infectious colitis. CT can also be diagnostic in severe cases, showing bowel perforation and free air in the peritoneal cavity. Of course this should be suspected on physical examination. In a patient in whom the presentation of IC may be a heralding sign of acute mesenteric ischemia (e.g., IRCI, severe pain without bleeding, and atrial fibrillation) and the multiphasic CT is negative for vascular occlusive disease, traditional splanchnic angiography should be considered for further assessment. Angiography is otherwise rarely helpful in diagnosing IC as most cases are caused by transient hypoperfusion.

The gold standard for confirming diagnosis of IC is endoscopy, where ischemic mucosa can be identified and biopsied for confirmation. Thus, early colonoscopy (within 48 h of presentation) should be performed in suspected IC cases to confirm the diagnosis. Typical findings of IC include segmental erythema, edema, mucosal ulceration, submucosal hemorrhagic nodules, and involvement of watershed areas. Occasionally, pseudomembranes related to mucosal sloughing are observed. The colonic single stripe sign, a single linear ulcer running longitudinally along the antimesenteric colonic wall, is associated with IC (Fig. 4). After 48 hours, sloughing occurs, the purple submucosal hemorrhages dissipate, and ulcerations develop. In more severe ischemia with transmural infarction, the mucosa may appear gray-green or even black (Fig. 5).

Endoscopy will also allow biopsies to be taken to further confirm diagnosis. On histologic examination, signs of IC include mucosa of normal architecture with necrosis and sloughing of the surface epithelium, loss of epithelium in the superficial aspects of the crypts (with or without ghosts of crypts), mucin depletion and reactive changes in the residual crypt epithelium with nuclear hyperchromasia and increased mitoses, paucity or complete absence of acute inflammatory cells, and the presence of hyalinosis in the lamina propria (Fig. 6).

SEVERITY

IC is classified into three categories: mild, moderate, and severe. Most cases of IC are mild or moderate, and about 20% are severe at initial presentation.

The classification is based on clinical, laboratory, imaging, and endoscopic criteria. Management is driven accordingly. For mild and moderate disease, treatment is supportive care, which includes bowel rest, intravenous fluids, optimizing cardiac output, avoiding medications that could worsen colonic ischemia like vasopressors, correction of electrolytes and nasogastric tube decompression for ileus. For confirmed IC, intravenous antibiotics are used to treat bacterial translocation that occurs when the mucosal barrier is damaged. The antibiotic(s) selected should include both aerobic and anaerobic pathogens. You should not expect to cover highly resistant pathogens. The duration of antibiotic therapy needed has yet to be studied and determined, although some authors have recommended 2 weeks. However, a period covering the time of mucosal injury when translocation is theoretically occurring seems reasonable.

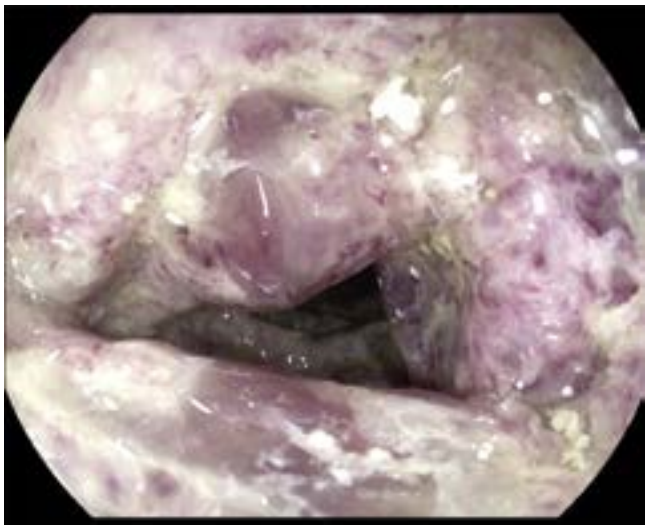

FIG. 5 Colonoscopic image showing cyanotic/black mucosal nodules with deep ulcerations until mucosal necrosis. *(From Maimone A, De Ceglie A, Siersema PD, et al. Colon ischemia: A comprehensive review. Clin Res Hepatol Gastroenterol. 2021;45(6):101592.)*

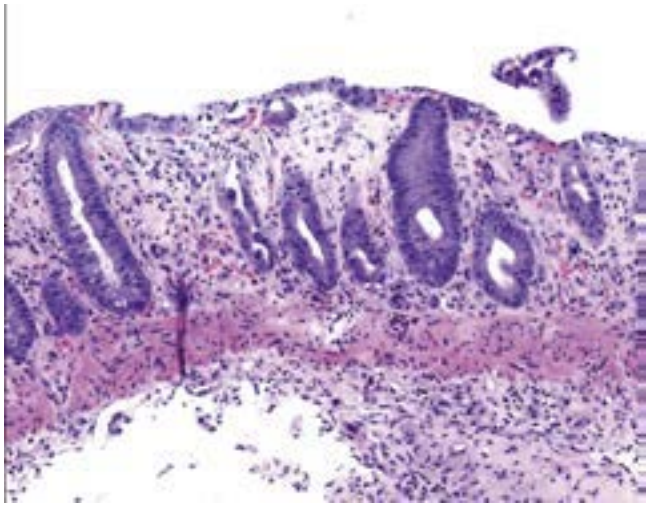

FIG. 6 Ischemic colitis, H&E, 100×. This image shows characteristic features of ischemic colitis, including superficial epithelial injury, crypts with atypia including nuclear hyperchromasia, and hyalinized lamina propria. The crypts appear closer together due to lamina propria collapse. *(Image courtesy Jacqueline Birkness-Gartman, MD.)*

A heart rate of >100 beats per min and systolic blood pressure of <90 mm Hg at the time of diagnosis are associated with the need for surgical intervention and/or mortality as are Hgb <12 mg/dL, hyponatremia (Na <136 mEq/L), LDH >450 U/L, and blood urea nitrogen (>28 mg/dL). A pancolonic distribution of disease and IRCI also portend a poor outcome.

Patients who meet criteria for severe disease need a surgical evaluation and most often will require operative intervention. This was the initial management in 53.6% of those with IRCI versus 14.5% in those with non-IRCI.

Surgical intervention should be considered in the presence of IC accompanied by hypotension, tachycardia, and abdominal pain without rectal bleeding; for IRCI and pancolonic IC; and in the presence of gangrene.

SURGICAL APPROACH

Operative management of patients with IC is either in the acute setting or for treatment of the sequelae of colon ischemia. In the acute setting, operative indications include peritonitis on examination, massive bleeding, fulminant colitis, portal venous gas or pneumatosis on imaging with clinical picture of IC, or worsening clinical condition on medical management alone.

The general principle of surgery is to remove all segments of the colon that are grossly ischemic (Fig. 7). Surgery is usually approached with a midline laparotomy; however, in certain circumstances, a diagnostic laparoscopy may be warranted. However, it can be difficult to determine the extent of resection as the serosa can be misleading as it will appear normal until transmural necrosis occurs. Therefore, a preoperative CT scan or endoscopic evaluation of the colon is important to establish the extent of bowel involvement. Intraoperatively, one may use Doppler ultrasonography, endoscopy, or photoplethysmography to assess mucosal viability or colonic blood flow. After adequate resection has occurred, in patients where there is concern for ongoing ischemia, it is not uncommon to leave the fascia open and bowel in discontinuity and take the patient to the intensive care unit for continued resuscitation for a planned second-look laparotomy and closure in 12 to 48 hours to make sure all necrotic tissue has been removed.

The decision to construct an anastomosis versus an ostomy depends on many factors. The main concern is anastomotic leak or nonhealing anastomosis. A primary anastomosis can be done safely in uncomplicated isolated right colon ischemia when the rest of the bowel appears very well perfused. However, for left-sided IC, published opinion advocates for an end colostomy and rectal stump (Hartmann procedure), which can be reversed later (i.e., no sooner than 6–8 weeks postsurgery). In selected cases, it may be reasonable even with left-sided disease to perform a primary anastomosis with or without a protective diverting loop ileostomy. With additional experience with preoperative localization of the extent of ischemia, less invasive surgical approaches may become more attractive.

POSTOPERATIVE COURSE

Overall, the postoperative course of patients undergoing surgery for acute IC is associated with high rates of morbidity and mortality. Two-thirds of patients with severe IC requiring surgery develop medical complications such as pneumonia, urinary tract infections, atrial fibrillation, postoperative myocardial infarction, acute renal failure, or the need for hemodialysis. There is a 37% in-hospital mortality rate for severe IC.

Independent risk factors of mortality after emergent colectomy for IC include elderly age, poor functional status, multiple comorbidities, low output heart failure (e.g., cardiac ejection fraction <20% on echocardiogram), preoperative septic shock, preoperative blood transfusions, preoperative acute renal failure, and delay from hospital admission to surgery. Postoperative death is associated with the peak preoperative lactate level (if above 2.5 mmol/L), amount of intraoperative blood loss, pre- and intraoperative catecholamine administration, subtotal or total colectomy, need for dialysis postoperatively, and an American Society of Anesthesiologists (ASA) class 4.

Operative intervention is sometimes required for sequelae of IC such as symptomatic colonic strictures or for ostomy reversal. Studies showed high rates of complications after ostomy reversal (i.e., longer length of stay, anastomotic leaks, and mortality). Other indications for a second operation include facial dehiscence and wound complications. Patients with nongangrenous IC sometimes present with abdominal pain, bloating, and obstructive symptoms weeks after their initial episode. If a stricture is suspected, either a colonoscopy or a contrast enema can identify it; the latter is helpful to describe the length and location of the stricture. In 10% of the cases, strictures develop as the colon heals. If clinically significant, causing obstruction or severe abdominal pain, strictures need operative intervention by elective resection and primary anastomosis. Alternatively, there are nonoperative methods to temporize symptoms when surgery is not feasible, such as balloon dilation, and in some instances, stenting.

CONCLUSION

The incidence of IC has increased during the last few decades. Acute IC continues to represent a very deadly disease associated with high rates of morbidity and mortality. IC in the community typically presents in older patients with multiple comorbidities. Patients who survive their initial episode may require additional intervention, and around 7% of patients will have another episode within 5 years. IC is challenging to diagnose due to its nonspecific presentation, but efforts should be directed to early consideration of this diagnosis when risk factors and clinical conditions warrant.

Management of Clostridioides Difficile Colitis

Marylise Boutros, MD, Maria Abou Khalil, MD, and Steven D. Wexner, MD, PhD (Hon)

Clostridioides (formerly *Clostridium*) *difficile* infection (CDI) is an important cause of community and nosocomial acquired diarrhea. It is associated with significant morbidity and mortality, especially amongst the immunosuppressed and elderly. This chapter will review the clinical presentation and treatment options for patients with CDI.

BACKGROUND

While *C. difficile* was first described as an important cause of antibiotic-associated colitis in 1978, it was not until the early 2000s that CDI was experienced as a threatening nosocomial problem due to an increase in disease frequency, severity, and mortality. This change was attributed in part to the emergence of hypervirulent strains, including NAP1/BI/027. Antibiotic stewardship programs and strict infection control measures allowed for early case identification and treatment, leading to a dampening of CDI incidence. Nonetheless, CDI remains an important cause of nosocomial acquired infection and an increasingly recognized cause of community acquired disease and transmission.

C. difficile is an anaerobic toxin-producing gram-positive bacillus that can exist in spore form (outside the colon) or vegetative forms. The bacteria produce two exotoxins (toxin A and toxin B) responsible for the colitis and diarrhea. Hypervirulent strains have been associated with significantly increased toxin production and subsequently a more severe clinical course. Ingestion of spores of *C. difficile* via a fecal-oral route is a common cause of transmissibility, and transmission is higher in patients with active disease compared with asymptomatic carriers.

Clinical Risk Factors for CDI

Several risk factors for contracting CDI have been identified. The most widely recognized and modifiable risk factor for CDI is antibiotic use; CDI can occur up to 3 months after antibiotic discontinuation. Antibiotics result in a disruption of the balanced normal colonic microbiota allowing pathogenic *C. difficile* bacteria to multiply and cause disease. While clindamycin was the first antibiotic to be associated with CDI, many other antibiotics have since been implicated. Antibiotic resistance patterns of *C. difficile* have also been found to be correlated to virulence. Another important risk factor for CDI is advanced age. Furthermore, immunosuppression, inflammatory bowel disease (IBD), gastrointestinal surgery, and length of hospitalization have all been associated with increased risk of CDI. Special attention needs to be paid to patients with IBD, as disease exacerbation can mimic *C. difficile* colitis. Although some epidemiologic studies have implicated gastric acid suppression as a risk factor, this association was not consistently found after adjusting for confounding factors and is most likely to be the result of patient illness and hospital length of stay.

CLINICAL PRESENTATION

Although some patients can be asymptomatic carriers of *C. difficile*, CDI usually has clinical manifestations that can range from mild colitis to fulminant severe disease with toxic megacolon. Patient factors and pathogen characteristics have been implicated in the severity of the clinical course. Increasing age, immunosuppression, and comorbidities are amongst the most reported predictors of severe disease presentation.

Different CDI severity classification systems exist; however, there is no universally accepted system. This limitation is likely because of the inability of one scoring system to accurately predict the clinical course, be simple enough to allow widespread point-of-care use, and allow for time-dependent variables to be adjusted as the patient's clinical course evolves. In general, the existing CDI severity classifications include a combination of factors associated with increased morbidity and mortality. These factors include physical examination findings, signs of shock, and laboratory data. A useful disease classification system was published in 2017 by the Infectious Disease Society of America and Society for Healthcare Epidemiology of America (IDSA/SHEA) and is summarized in Table 1. Thus, the evaluation of patients with CDI should include a history, physical examination including vitals, urine output, fluid requirements, as well as laboratory tests including complete blood count (with significant leukocytosis being a hallmark, but not a pathognomonic feature, of CDI), renal function tests, albumin, and lactate as a marker of end-organ perfusion.

DIAGNOSIS

Testing is recommended for patients with unexplained new onset diarrhea (3 stools/day) especially in the presence of risk factors for CDI. Patients should be placed on preemptive isolation while awaiting results. Hand hygiene with soap and water is superior to alcohol-based hand-hygiene products for elimination of *C. difficile* spores and is recommended in addition to contact precautions including gloves and gowns.

TABLE 1 Disease Severity and Recommended Treatment

Disease Severity	Clinical Characteristics	Recommended Treatment
Nonsevere disease	Leukocytosis, WBC ≤15,000 or serum creatinine <1.5 mg/dL	Vancomycin 125 mg PO QID × 10d OR fidaxomicin 200 mg PO BID × 10d Use metronidazole 500 mg PO TID if none of the above available
Severe disease	Leukocytosis WBC ≥15,000 or serum creatinine >1.5 mg/dL	Vancomycin 125 mg PO QID × 10d OR fidaxomicin 200 mg PO BID × 10d
Fulminant disease	Hypotension/shock, ileus, or megacolon	Vancomycin 500 mg QID PO/PT (consider adding rectal vancomycin if ileus) + IV metronidazole (500 mg q8h)
Recurrent disease		Pulse-tapered vancomycin regimen or fidaxomicin regimen is recommended. Fidaxomicin, vancomycin with or without rifaximin, and fecal microbiota transplant (FMT) are used for second or subsequent recurrences. With recurrences presenting with fulminant disease, in addition to the antibiotic regimen administered, some advocate for the addition of FMT.

TABLE 2 Diagnostic Tests for *C. difficile*

Test	Details	Sensitivity	Specificity	Substance Detected
Selective anaerobic culture	Rarely used Takes a long time to finalize Can be useful in patient with ileus (rectal swab)	High	Low	*C. difficile* vegetative cells or spores
Cell culture cytotoxicity assay	Resource intensive and time consuming, not routinely done Has been used as a gold standard test	High	High	Free toxins
Nucleic acid amplification tests (NAAT)	Detects one or more genes specific to toxigenic strains Capable of detecting asymptomatic carriers	High	Low/ Moderate	*C. difficile* nucleic acid (toxic genes)
Enzyme immunoassay *C. difficile* glutamate dehydrogenase (GDH)	GDH antigen is an essential enzyme produced by all *C. difficile* isolates, but cannot differentiate between toxigenic and nontoxigenic strains	High	Low	*C. difficile* common antigen
Enzyme immunoassay for *C. difficile* toxins A and B	Most strains produce toxins A and B although some strains produce toxin B only, but CDI due to strains producing toxin A alone has not been reported	Low	Moderate	Free toxins

A variety of laboratory tests for *C. difficile* exist. They can detect either the organism itself or the toxins in the stools. To avoid false positive results, laboratory protocols recommend that only liquid or loose stool samples be tested. Stool toxin tests are often used as a multistep algorithm either with glutamate dehydrogenase (GDH) assay or nucleic acid amplification tests (NAAT) assay followed by toxin-recognition to help differentiate between asymptomatic carriers and patients with the disease. A summary of the commonly used tests is presented in Table 2.

Endoscopy

Pseudomembranes are a characteristic endoscopic feature of CDI that appear as raised white and yellow plaques and consist of toxin-induced ulcers with inflammatory cells and mucous (Fig. 1). Confirmatory endoscopy with flexible or rigid sigmoidoscopy is not necessary; however, it is often performed to exclude other causes of colitis such as cytomegalovirus infection, graft-versus-host disease, IBD exacerbation, or ischemic colitis. Endoscopic confirmation has also been used in cases where a decision on surgical management needs to be expediently made and the situation does not allow waiting for confirmatory laboratory testing.

Imaging

Abdominal imaging can aid in the diagnosis of colitis and identify complications requiring operative intervention. Rarely, complications such as free air may also be seen. Classically, plain films were used to assess for "thumb printing" secondary to submucosal edema or toxic megacolon with colonic distention. Nowadays, an infused computed tomography (CT) scan of the abdomen and pelvis is the preferred imaging modality to assess the degree, extent, and complications of the colitis. Typical findings in severe or fulminant disease include pancolitis with significant colonic thickening and ascites (Fig. 2A). If gastrointestinal contrast is given, it can be seen trapped between the edematous haustral folds (accordion sign) (Fig. 2B). Evidence of complications such as bowel perforation, toxic megacolon, and ischemia can also be seen on CT.

MEDICAL TREATMENT

Given the role of antibiotics in the development of CDI and its potential recurrence, it is recommended to stop the inciting antibiotics as soon as possible. Early treatment for CDI while awaiting confirmatory tests should be initiated, especially in patients with severe or fulminant disease. Although probiotics can decrease the occurrence of

FIG. 1 Endoscopic appearance of pseudomembranes. *(From Iseman DT, Hamza SH, Eloubeidi MA. Pseudomembranous [Clostridium difficile] colitis. Gastrointest Endosc. 2002;56[6]:907.)*

CDI, they have no role in the treatment of the disease. Metronidazole was commonly used for treatment; however, vancomycin or fidaxomicin have been found to be superior to metronidazole and have largely replaced it. The recommended treatment regimen with these agents is based on disease severity and is outlined in Table 2. For the first recurrence, a pulse-tapered vancomycin regimen or fidaxomicin regimen is recommended. Fidaxomicin, vancomycin with or without rifaximin, and fecal microbiota transplant (FMT) are used for second or subsequent recurrences.

With recurrences presenting with fulminant disease, in addition to the antibiotic regimen administered as outlined in Table 2, some advocate for the addition of FMT.

Patients with severe colitis require special attention. They should have large bore intravenous access and accurate measurements of intake and output to guide aggressive fluid resuscitation

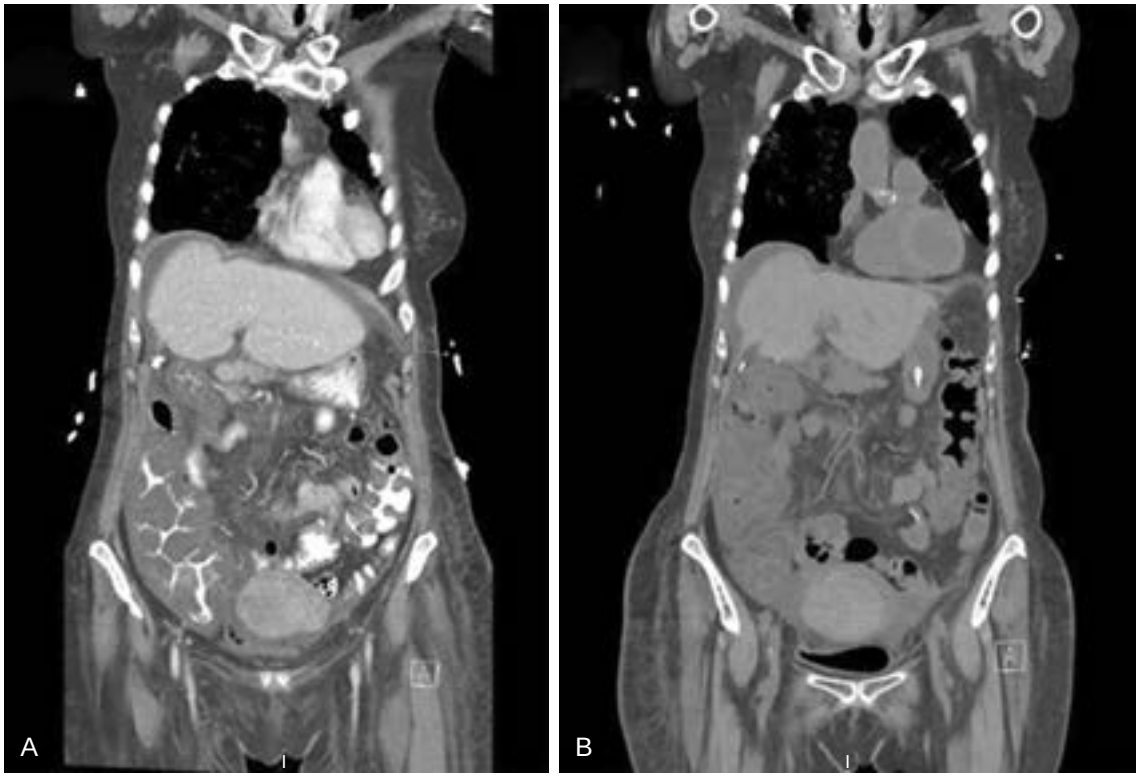

FIG. 2 Computed tomography scan showing fulminant *Clostridioides difficile infection,* with (**A**) and without (**B**) contrast.

with crystalloids. Acute kidney injury is a common complication of severe colitis and resuscitation is generally the initial approach. Patients should be kept fasting with complete bowel rest until their symptoms improve. We recommend serial clinical examinations of patients with severe disease including vital signs, abdominal examination, and laboratory investigations as the clinical course can evolve rapidly. Prompt recognition of complications associated with the colitis will allow early management and improve outcomes. A multidisciplinary approach including surgeons, intensive care and infectious disease specialists, may aid in the care of these patients.

SURGICAL MANAGEMENT

Although rare (0.3%–6.2% depending on the epidemic status), surgical management is reserved for patients with fulminant disease who fail to respond to medical management, worsen on treatment, or in whom complications related to the colitis arise including hemodynamic compromise, abdominal compartment syndrome, or colonic perforation (Box 1).

BOX 1 Indications for Surgical Management

- Colonic perforation
- Full-thickness ischemia
- Peritonitis, worsening abdominal exam despite adequate medical treatment
- Abdominal compartment syndrome
- Hemodynamic instability with ongoing or increasing need for vasopressor support
- Need for intubation and mechanical ventilation
- Worsening end-organ failure (especially renal failure)

In the absence of absolute indications for surgery, no clear guidelines exist to define failure of medical management or the optimal timing to intervene with surgery. Despite the morbidity associated with emergency surgery in critically ill patients, evidence from retrospective studies suggests that earlier time to surgical intervention with fulminant disease improves survival compared with continued medical management alone.

Total Abdominal Colectomy with End Ileostomy

An open total abdominal colectomy (TAC) with an end ileostomy remains the gold standard operation for patients with fulminant *C. difficile* colitis (FCDC) requiring surgery and is the operation to which all others are compared. Outcomes after segmental colectomies for the treatment of FCDC have been shown to be inferior to TAC, and thus segmental colectomy is not recommended even if the colitis appears to be limited to a part of the colon on CT imaging. Upon entry into the abdominal cavity, usually profuse ascites is encountered. The colon usually appears dilated and edematous but otherwise has a normal serosal surface, as this is a mucosal disease. The distal extent of the resection is at the rectosigmoid junction, where the rectum is transected and stapled; however, if the rectosigmoid appears too friable and there is heightened concern for rectal stump blowout, the surgeon can consider a more proximal transection to allow delivery of a distal stapled end of more proximal sigmoid as a mucous fistula. It is our preference to place a Malecot rectal catheter in the rectal stump for the first few postoperative days to allow decompression while healing. Postoperatively, patients should remain in a monitored setting until their vital functions are stable without the supportive measures offered in the intensive care unit and until their systemic inflammatory response syndrome (SIRS) starts improving. Postoperative length of stay is often prolonged by the patient's comorbidities, and rapid recovery is limited by the severity of the multiorgan system involvement. After recovery, ileorectal anastomosis can be

performed if the patient has returned to a functional baseline. This usually occurs starting at 3 to 6 months postoperatively. Given the significant postoperative morbidity associated with a colectomy for severe CDI, many patients do not reach a level of fitness suitable to endure another extensive operation for restoration of gastrointestinal continuity with an ileorectal anastomosis. In the literature, most patients who undergo a TAC do not eventually have restoration of gastrointestinal continuity.

Colonic Lavage and Diverting Loop Ileostomy

The creation of a diverting loop ileostomy (DLI) with colonic lavage has been advocated as a less-invasive alternative to TAC in this critically ill-patient population. In 2011, Neil et al. described this approach, which consists of the creation of a DLI with colonic lavage with warm polyethylene glycol solution and postoperative antegrade installation of vancomycin flashes by the ileostomy (Fig. 3). In their single-institution, single-surgeon series, the authors compared 42 patients who underwent surgery for FCDC with 42 historical patients who had undergone TAC. The authors observed a decreased 30-day postoperative mortality for patients who underwent a DLI compared with TAC. In addition to the survival benefit, the authors demonstrated increased ileostomy closure rates at six months. A minority of patients in the DLI group required conversion to a TAC either due to the development of abdominal compartment syndrome or for failure of improvement. Since the first description of this novel procedure, few studies have compared it to TAC. There remains a lack of high-quality prospective data comparing these two operations given the difficulty in conducting such studies in the setting of a disease associated with high mortality in the emergency setting. A recent meta-analysis of 733 patients with DLI and 2950 patients with TAC found no difference in postoperative morbidity or mortality but found higher gastrointestinal restoration rates for patients with DLI.

Thus, while no recommendations can be made on which patients would best benefit from DLI vs. TAC, we believe patients with severe disease early in their disease course, who do not have any complications associated with their colitis necessitating a TAC (perforation, ischemia, or toxic megacolon), can be offered a DLI with colonic lavage. However, one must be cautious that patients need close follow-up as the diseased colon is still in situ, and thus there is a longer time to resolution of SIRS. Typically, patients may take up to a few days to a week in this SIRS state before improving. Tables 3 and 4 summarize the current evidence and the advantages and disadvantages of each operation.

Theoretically, the creation of a DLI is relatively simple; however, there are a few technical challenges associated with fulminant disease state and with performing the colonic lavage. We summarized the steps of the operation in Box 2 and at the following link https://www.youtube.com/watch?v=1VMQrEI6jro&t=26s. Furthermore, comorbidities such as elevated BMI may be challenging and may be overcome with the creation of an end loop ileostomy.

SPECIAL POPULATION: PATIENTS WITH INFLAMMATORY BOWEL DISEASE

IBD, particularly ulcerative colitis, is a risk factor for the development of CDI. Patients with IBD are also more likely to need surgical intervention and have longer length of stay and increased mortality with CDI.

TABLE 3 Comparison Between Total Abdominal Colectomy and Diverting Loop Ileostomy and Colonic Lavage

	Pros	Cons
Diverting loop ileostomy	Less invasive operation and minimally invasive option Higher gastrointestinal restoration rates Improved postoperative morbidity compared with total abdominal colectomy (TAC)	Limited data supporting its use Optimal patient population not defined Patients may require reoperation in the event of failure Slower resolve of systemic inflammatory response
Total abdominal colectomy	Definitive management Faster resolution of the systemic inflammatory response	High morbidity and mortality Low gastrointestinal restoration rates

TABLE 4 Summary of Published Papers Mortality Following Total Abdominal Colectomy and Diverting Loop Ileostomy

	Study Design and Location	Study Interval	Patient Population (n)	30-Day Postoperative Mortality
Neal et al. (2011)	Prospective cohort, single center	2009–2011	DLI: 42 TAC: 42	DLI 19% vs. TAC 50% ($P = 0.006$)
Fashandi et al. (2017)	Retrospective, single center	2011–2015	DLI: 10 TAC: 13	DLI 30% vs. 23% 50%, ($P = 1$)
Ferrada et al. (2017)	Retrospective, multicentric	2010–2014	DLI: 21 TAC: 77	DLI 17.2% vs. TAC 39.7% ($P = 0.002$)
Hall et al. (2018)	Retrospective review of prospectively maintained database (ACS-NSQIP)	2011–2016	DLI: 47 TAC: 410	DLI 36% vs. TAC 31% ($P = 0.451$)
Juo et al. (2019)	Retrospective review of administrative database (NIS database)	2011–2015	DLI: 613 TAC: 2408	DLI 26.0% vs. TAC 31.1% ($P = 0.28$) *In-hospital mortality

BOX 2 Technical Details and Tips

- Exploratory laparotomy or diagnostic laparoscopy confirming diagnosis and ruling out contraindications to DLI (laparoscopy is preferable if patient is a candidate and the surgeon is comfortable with this approach).
- Creation of a diverting loop ileostomy 20 cm from the ileocecal valve in a typical fashion (Brooke proximal limb, flush distal limb; Fig. 3A).
- Inserting a catheter, typically 18F Foley urinary catheter into the distal limb of the ileostomy, ideally positioned in the cecum (Fig. 3B).
- Lavage of the colon is performed with 8L of polyethylene glycol (PEG) solution warmed to 37°C.
- Foley catheter connected to the bag containing the PEG solution using urologic connection tubing (used in cystoscopy), allowing flow control of the PEG solution to the diseased colon.
- PEG solution administered in increments, ensuring that effluent drainage is collected in the rectal tube.
- If the procedure is performed laparoscopically, pneumoperitoneum can be maintained at 7–10 mm Hg during lavage. Laparoscopic bowel graspers may be used to aid in pushing the fluid along the colon.
- If performed by a laparotomy, the abdomen is kept open, and the surgeon can manually aid the movement of the fluid through the colon.
- If trouble is encountered getting fluid through the colon, the patient may be moved into the Trendelenburg/reverse Trendelenburg positions as well as left side up/down and right side up/down to move the fluid along the colon.
- Rarely, flexure mobilization may be necessary.
- Due to fluid sequestration in the diseased and atonic colon, an abdominal compartment syndrome (ACS) may occur during or after the operation and the surgeon should be aware of this possibility.
- Abdominal drain can be left to remove excess ascites and potentially reduce the risk of ACS
- Postoperatively, vancomycin flushes (500 mg in 500 mL of lactated Ringer's) are delivered to the diseased colon through the Foley catheter that was left in the efferent limb of the ileostomy. The first vancomycin flush is given after completion of the PEG flushes, and administration should be continued every 8 h for 10 days or until the patient has clinically recovered (Fig. 3A and B).

Given that CDI can mimic IBD flares, it should be considered in patients with worsening, smoldering, or relapsing IBD. While the treatment for CDI in patients with IBD is identical to patients without IBD, given the increased morbidity and mortality in this population, they should be monitored closely and have a lower threshold for early surgical intervention. It remains important to note that while CDI enteritis is a very rare event, it can occur after TAC with end ileostomy or following ileal pouch anal anastomosis, as a rare cause of pouchitis, and should be excluded in the event of a high-output ileostomy with SIRS.

CONCLUSION

CDI is a common cause of colitis especially in the surgical population. Most patients respond well to treatment with medical management alone. A small proportion of patients need intensive care unit admission to support the multisystem organ failure that can arise. Surgery may be required for the treatment of fulminant disease or to treat complications of the colitis needing urgent surgical attention. Although TAC is the standard operation, DLI and lavage has recently emerged as an alternative in select patients early in their disease.

Acknowledgments

The authors would like to acknowledge Dr. Rachel L. Choron and Dr. Pamela A. Lipsett for the previous version of this chapter.

Management of Large Bowel Obstruction

Anthony J. Senagore, MD, MS, MBA, and Yesenia Rojas-Khalil, MD

Large bowel obstruction has traditionally been managed with urgent if not emergent surgery resulting inevitably in a laparotomy and stoma. However, in the past two decades with increasing use of endoscopy and experience with minimally invasive techniques, management can be more specifically tailored to the severity of obstruction and etiology. Nonetheless the management of large bowel obstruction requires prompt evaluation and diagnosis.

ETIOLOGY

The cause of large bowel obstruction can be categorized broadly as either mechanical or functional. Mechanical obstruction is more common than functional and often results from a neoplastic process. Mechanical obstructions can result from intrinsic or extrinsic processes, such as colorectal and ovarian cancer, respectively. Colorectal carcinoma is the most common etiology and accounts for nearly half of mechanical large bowel obstructions. Up to one-third of patients with colorectal cancer have a near or complete mechanical obstruction because of tumor burden, often representing an advanced stage.

Diverticular disease is the second most common cause of mechanical large bowel obstruction. Chronic inflammation in the sigmoid can cause a stricture in up to 17% of patients. This often results in a more chronic presentation of a large bowel obstruction. However, complicated diverticulitis with significant inflammation can also present as a large bowel obstruction due to the inflammatory stricture, phlegmon, or abscess. The third most common cause of large bowel obstruction is volvulus, and this occurs in 5% to 10% of all large bowel obstructions. Volvulus is a result of a long redundant segment of colon that has developed an axial rotation about its colonic mesentery. Because the blockage is not only of the colon lumen but also involves the mesentery, the risk of strangulation and ischemia is significantly higher that other causes of large bowel obstruction. The most common location for volvulus is the sigmoid colon (60%–70%), followed by the cecum (25%–40%), and very rarely the transverse colon (1%–4%).

Functional causes of large bowel obstruction are less common than mechanical obstructions. These include colonic pseudo-obstruction (Ogilvie's syndrome), narcotic-induced adynamic ileus, and adynamic ileus due to systemic illness such as toxic megacolon from *Clostridium difficile* infection. Treating the underlying cause in functional large bowel obstruction often improves the symptoms.

CLINICAL PRESENTATION

Large bowel obstruction symptoms vary based on the acuity of the obstruction, resulting in a wide range of symptoms. Typically, patients will present with crampy abdominal pain, distension, and obstipation. Patients with an incompetent ileocecal valve will eventually present with nausea and emesis. Often, acute large bowel obstruction is associated with signs of hypovolemia and electrolyte imbalances secondary to fluid sequestration in the intestines as well as oral intolerance. Symptoms from chronic obstruction are typically mild and often associated with change in bowel habits, bloating, narrow caliber stools, and unintentional weight loss. This constellation of findings should raise suspicion for malignancy.

DIAGNOSIS

History and Physical Examination

Prompt evaluation and diagnosis beginning with a focused history and physical examination should occur in patients presenting with signs and symptoms of a large bowel obstruction. Obtaining a careful history of the development of symptoms can often cue surgeons to the most likely diagnosis. Patients may report a rapid or slow progression of their symptoms depending on the etiology. Recent orthopedic or gynecologic procedures are commonly associated with the development of colonic pseudo-obstruction. A family or personal history of colonic neoplasms, diverticular disease, or inflammatory bowel disease, as well as findings on previous colonoscopy (if performed) should be ascertained as this helps narrow the diagnosis. A review of current medications may indicate prescription medication-induced constipation but equally importantly can provide an overview of the patient's overall underlying health status and comorbid conditions.

The physical examination classically reveals a tympanitic and distended abdomen. On occasion, a mass can be palpated through the abdominal wall in thin patients. Focal tenderness on examination may suggest ischemia or localized perforation, whereas diffuse tenderness is concerning for peritonitis. A digital rectal examination is an important part of the exam and should be performed on all patients to rule out fecal impaction, foreign body, or anorectal malignancy as the cause. In elderly patients and/or those with severe comorbid medical problems, it is important to ascertain goals of care, especially when advanced malignancy is suspected.

Imaging

Because of ease in accessibility, upright and supine abdominal radiographs are often the first images obtained. For the diagnosis of large bowel obstruction, plain films have a sensitivity and specificity of 84% and 72%, respectively. Importantly, they can help rule out an abdominal disaster such as pneumatosis coli or pneumoperitoneum, which in the right clinical context may obviate additional imaging. Cecal distension of 9 to 12 cm on plain abdominal film is concerning for impending perforation. In the setting of an incompetent ileocecal valve, reflux of contents back into the small intestine may reflect as air-fluid levels of the small bowel with distension. When colonic volvulus is the cause of large bowel obstruction, plain films can confirm the diagnosis. The classic findings of a sigmoid volvulus are seen in about two-thirds of patients and are commonly described as the "bent inner tube" sign or an "omega loop." In the case of cecal volvulus, this classically presents as the "coffee bean" sign; however, it is only seen radiographically in less than 20% of the patients.

Contrast enemas (CEs) were once the gold standard in the diagnosis of large bowel obstruction. However, because these tests are labor intensive and require additional time, CEs are not readily accessible and are underutilized. CEs have a 96% sensitivity and a 98% specificity for diagnosing large bowel obstruction, compared to the 84% and 72%, respectively, of plain abdominal films. Classic finding is a "bird's beak" deformity at the site of a volvulus or an "apple core lesion" at the site of an obstructing cancer. CE can also provide additional details such as the length, width, and tortuosity of the narrowing that may be helpful when intraluminal stents are being considered. In cases of colonic pseudo-obstruction, contrast will freely flow without evidence of transition point. Additionally, in the setting of fecal impaction, contrast may be therapeutic.

Computed tomography (CT) has become the preferred imaging modality in the evaluation of a patient with signs and symptoms of a large bowel obstruction. CT is much more readily accessible than CE and has largely supplanted CE as the diagnostic modality of choice. CT confirms the diagnosis of large bowel obstruction with almost 100% sensitivity and 90% specificity; it also allows multiplanar reconstruction that further facilitates the definitive etiology of large bowel obstruction. Finally, CT may have a substantial impact on the clinical management of a large bowel obstruction by demonstrating signs of intestinal ischemia, early pneumatosis, or pneumoperitoneum leading to earlier interventions.

TREATMENT

Initial Management

In concert with the initial history and physical, laboratory assessment should include serum chemistry and electrolytes, complete blood count, and lactate level. Hypovolemia and electrolyte imbalances are common and should prompt aggressive resuscitation with accurate monitoring of intake and output with a urinary catheter. Decompression with a nasogastric tube should be performed early. If surgery is a consideration, preoperative antibiotics and stoma marking should occur as an ostomy is frequently required.

Surgical Management

The optimal surgical management and approach, either laparoscopic or open, will vary according to the degree of obstruction, the underlying etiology of large bowel obstruction, as well as the clinical condition of the patient. Broadly, the surgical management of large bowel obstructions can be guided by the urgency of decompression, emergent or nonemergent.

Emergent Surgical Management

Patients who present with impending perforation on imaging, pneumoperitoneum (evidence of existing perforation), peritonitis, and/or with clinical signs of sepsis require emergent intervention. The best approach in this setting is a midline laparotomy that allows for decompression of the bowel, prompt identification of the lesion, and adequate exposure for a variety of procedures. Laparoscopic intervention may be difficult secondary to colonic distension and/or clinical instability. The primary goal of surgery in this setting is to decompress the large bowel as expeditiously as possible to prevent ischemia or perforation, if it has not already occurred. Ideally, this would entail treating the underlying etiology of the obstruction. When the obstructing lesion is resectable, the next decision is whether to restore intestinal continuity following resection. In general, under emergent setting where the patient is unstable or with gross intraabdominal contamination, primary anastomosis is contraindicated. For these patients, segmental resection with an end stoma is the safest choice.

For lesions on the right side, proximal to the splenic flexure, a *right hemicolectomy with end ileostomy* is recommended. For left-sided lesions, a *Hartmann procedure* should be performed. Introduced in 1923 by Henri Hartmann specifically for the management of large bowel obstruction, the Hartmann procedure involves resection of the distal obstruction and the formation of an end colostomy. To perform a Hartmann procedure, the patient should be placed in the lithotomy position, which greatly enhances pelvic dissection and allows for access to the rectum if necessary. After resection of the lesion, decompression of the colon is best achieved with an end colostomy. In a review of 35 studies by van de Wall and colleagues, of the 6249 patients who underwent a Hartmann procedure, only 44% underwent reversal with a mean time to reversal of 7.5 months. Morbidity rate was 3% to 50% (mean, 16.3%) and mortality rate from 0% to 7.1% (mean, 1%).

It is important to inspect the entire colon proximally to rule out any injury due to distension or synchronous pathology and, when feasible, to exteriorize the distal colon conduit as a mucus fistula or in the subcutaneous tissue at the inferior midline incision or the stoma site to facilitate reversal in the future. Given the emergent nature of the procedure, distinguishing between malignancy and inflammation can be difficult; however, attempts should be made to provide an oncologic resection when feasible.

Conversion from segmental resection to *subtotal colectomy* is rarely needed and determined by the integrity of the colon proximal to the obstruction. A subtotal colectomy is indicated when perforation, large serosal injuries, or synchronous lesions are found at the time of exploration. When performing a subtotal colectomy in the emergent setting, creation of an end ileostomy is often necessary.

Less commonly, there are circumstances in which addressing the underlying cause is not feasible. In instances of unresectable malignancy, diffuse carcinomatosis, severe inflammation, or in patients who are extremely unstable, a *diverting loop colostomy* proximal to the obstruction is indicated. A loop colostomy is preferred over an end colostomy as the blind end that is left in the abdomen may perforate. A colostomy relieves patients of their symptoms and limits subsequent concerns for an anastomotic leak.

However, colostomies can be associated with significant morbidity, including high rates of parastomal hernia (50%), decreased quality of life, and low rates of stoma closure.

Nonemergent Surgical Management

In the absence of generalized peritonitis, perforation, or sepsis, the nonemergent management of a stable patient allows for more surgical treatment options. The surgical technique will depend on the skill of the surgeon as well as available hospital resources.

In patients with a right-sided obstruction and the point of obstruction is proximal to the splenic flexure, urgent *right hemicolectomy with primary anastomosis* should be considered and can often be performed laparoscopically in a stable patient with limited bowel distension. This procedure is associated with low anastomotic leak rates (<5%) in a hemodynamically stable patient who has not undergone a bowel preparation. An alternative is performing a *right hemicolectomy with primary anastomosis and proximal diverting loop ileostomy*. This can be considered in patients who may have associated small bowel dilation or who are immunosuppressed, on steroids, or malnourished from chronic obstruction where concern for anastomotic leak is higher or where a leak would preclude or delay further treatment such as chemotherapy in the setting of cancer. Additionally, reversal of a loop ileostomy is a less morbid surgery than reversal of an end ileostomy.

There is more debate regarding the preferred surgical procedure for an obstructing lesion arising in the descending sigmoid colon, rectum, or anus. Traditionally, primary anastomosis at the initial procedure was avoided because of the higher rates of anastomotic leak (20%). Currently, *segmental resection with primary anastomosis* is a good option for carefully selected patients if the proximal colon is not dilated significantly. Retrospective reviews have shown similar rates of operative mortality and anastomotic leak in carefully selected patients undergoing left-sided colectomy compared with right-sided colectomy. Furthermore, quality of life is improved. A good option for a high-risk patient is *segmental colectomy, anastomosis, and a diverting loop ileostomy*. This still allows for diversion of the fecal stream, and in the event of an anastomotic leak, intraabdominal sepsis is contained and can usually be managed nonoperatively with percutaneous drainage and antibiotics. Loop ileostomy reversal is a less invasive operation and patients will more likely undergo this procedure to have their intestinal continuity restored as compared to reversing a Hartmann's procedure. The disadvantage is that ileostomy management in some patients (particularly the elderly) may be challenging with fluid and electrolyte shifts.

Colonic Lavage

In select patients, the use of an on-table colonic lavage may permit a single-stage surgery in the setting of a left-sided large bowel obstruction. Following resection of the lesion, the colon should be fully mobilized at both hepatic and splenic flexures to facilitate irrigation and allow descending colon to extend beyond the abdominal cavity. Next, an appendectomy is performed, and a catheter is passed into the cecum and secured with a purse-string suture. This catheter is attached to a large bag of warmed saline and elevated on a pole. If the cecum is thinned, an alternative is to insert the catheter into the terminal ileum and secure with a purse-string suture. The staple line at the distal segment of colon is opened and a generous length of sterile corrugated tubing is placed into the lumen of the descending colon. The tubing is secured in place with umbilical tape or a purse string and then draped off the table into a basin. Three to six liters of warmed saline is then flushed through the colon. This is continued until the effluent clears (Fig. 1). The catheter and tubing are removed, and the site of the appendectomy is closed. Before the anastomosis, the colon is inspected for injuries that may have occurred during the lavage. The anastomosis is then performed in the standard fashion, either end-to-end or side-to-side if there is a large bowel size discrepancy. A modified version of this method uses a Y-shaped connector (Fig. 2). One limb allows for retrograde infusion of saline through the descending colon and the other is attached to drainage tubing. This modification is appealing as it obviates the need for the appendectomy or cecostomy. In a study by Jung and colleagues, 171 patients with an obstructing left-sided lesion received intraoperative colonic lavage with primary anastomosis. Compared with elective, nonobstructed patients during the same interval, anastomotic leakage and wound infection were not significantly different.

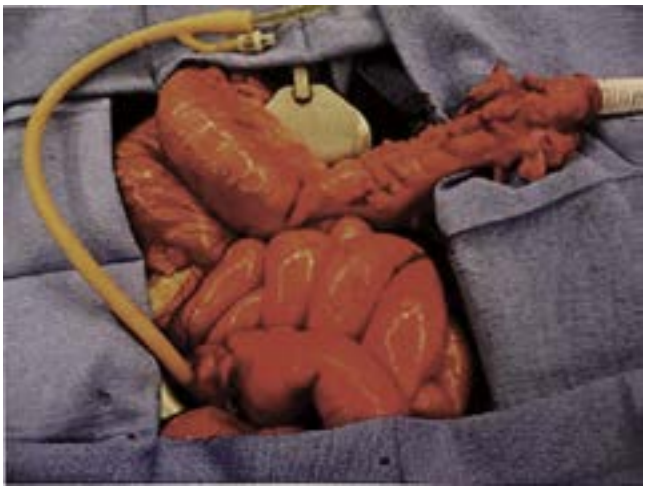

FIG. 1 On-table colonic lavage.

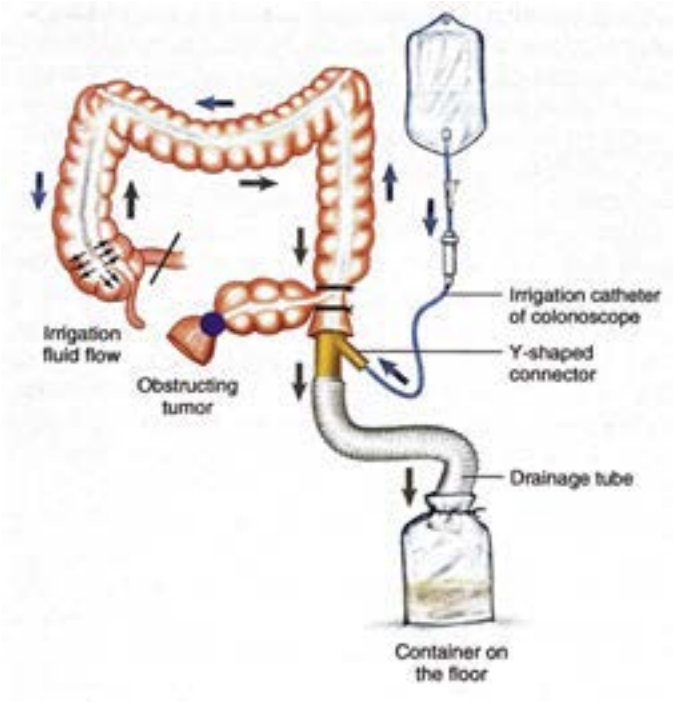

FIG. 2 Alternative colonic lavage using a Y-shaped connector.

Endoscopic Stenting

In the past decade, endoscopic management of obstructing large bowel lesions has gained significant attention. Much of the literature is on stenting of obstructing left-side lesions, and although reports of right-sided lesions exist, the indication is less clear. In the appropriately selected patient, endoscopic stents can be tremendously beneficial. Indications for stent placement include palliation of an

inoperable obstructing lesion (e.g., stage IV colorectal cancer) and as a temporizing "bridge" to definitive therapy in a patient with a curable or potentially curable lesion. The ability to stent a curable or potentially curable lesion affords time for colonic decompression, medical optimization, endoscopic evaluation for synchronous lesions, and increases the likelihood of a single-stage operation. Contraindications to stent placement include any of the previously discussed indications for emergent surgery, an abscess/infection closely associated with the lesion, short and tethered colon, and a lesion less than 5 cm from the anal verge.

Perioperative antibiotic coverage is unnecessary for stent placement. Gentle tap water enemas should be used to evacuate stool distal to the lesion. If an oral bowel preparation is desired, it may be attempted only if the obstruction is partial and the patient is closely monitored for the development of new or worsening symptoms. Colonoscopic evaluation of the lesion must be done with the utmost care; forceful attempts to traverse beyond the lesion are strictly avoided. Perforation is the most feared complication of stent placement. To mitigate the procedural risk of perforation, insufflation with carbon dioxide is preferred over room air because of the dramatically faster clearance time. The most common stents used in the United States are uncovered, self-expanding metal stents (SEM). Through-the-scope (TTS) and over-the-wire, also referred to as non-TTS, are the two conventional approaches to stent placement. TTS is usually the first-line approach (Fig. 3). The TTS system requires a colonoscope equipped with a working channel to pass the guidewire and stent. The scope is advanced and parked in an area immediately distal to the lesion. Contrast is administered and the lesion assessed with fluoroscopy. The guidewire is then advanced safely beyond the lesion followed by the stent (Seldinger's technique). Endoscopy and fluoroscopy confirm the correct location of the wire and the stent. Most TTS systems encourage a proximal and distal stent overlap of 2 cm. For longer lesions, additional stents can be placed in series. If assessment of the lesion shows anatomy unfavorable for TTS (e.g., available size of the stents), the procedure is converted to over-the-wire.

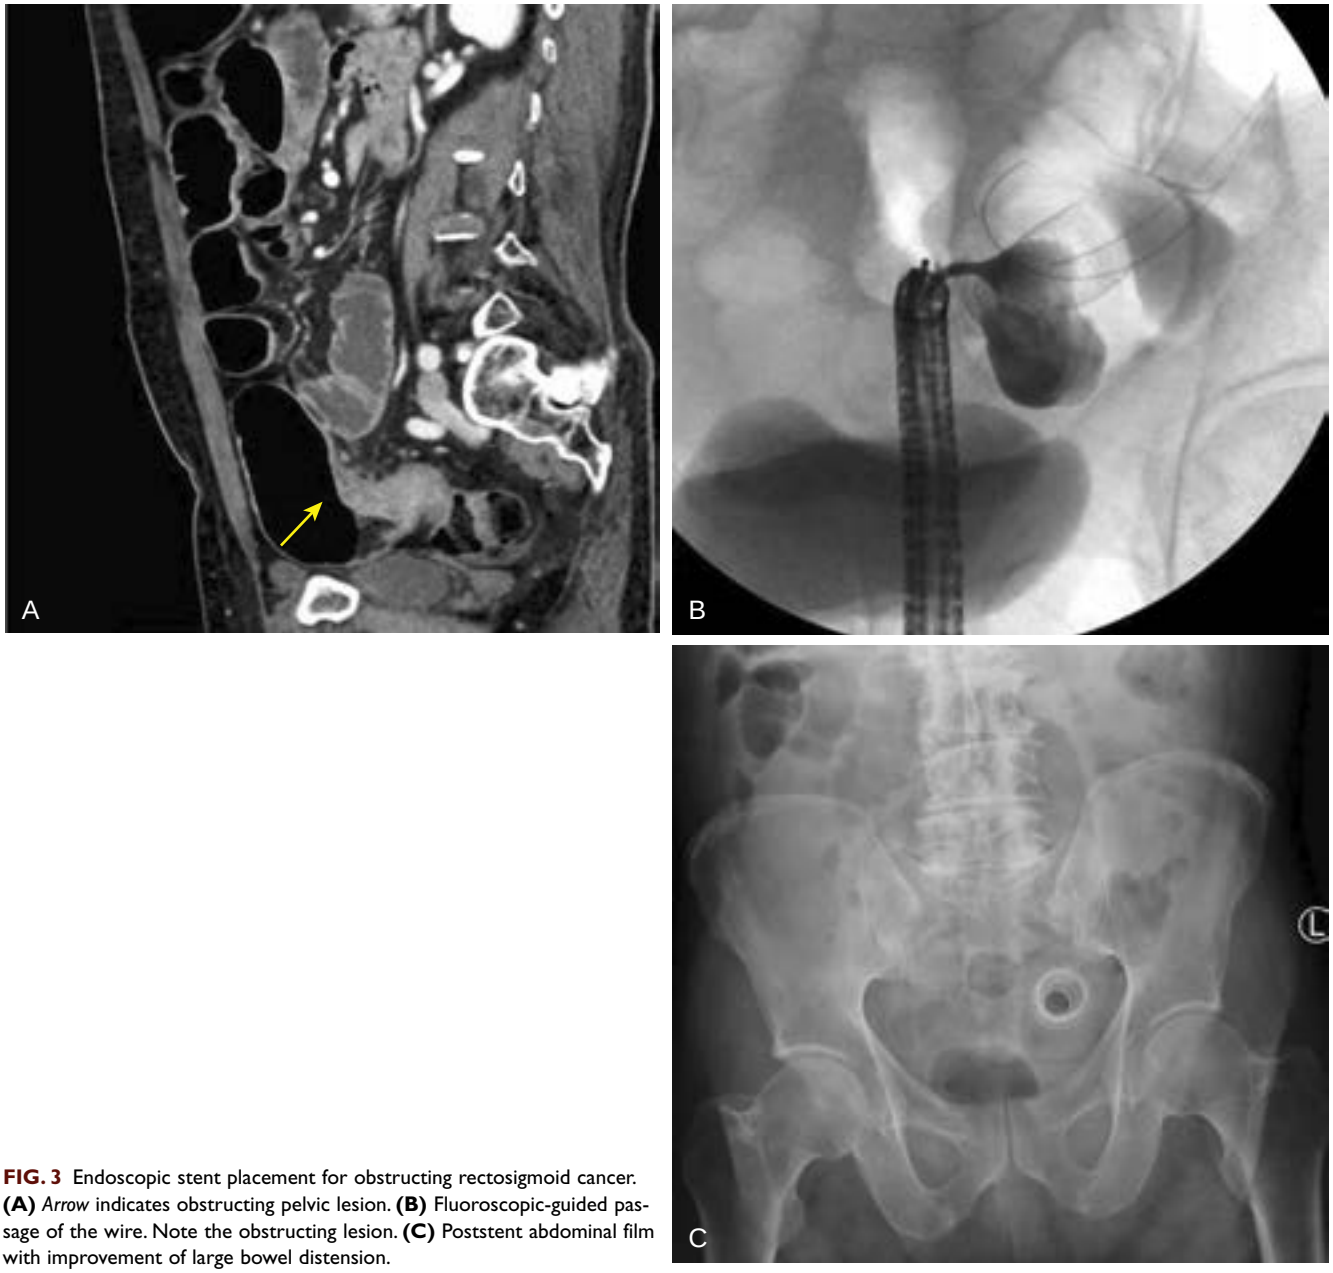

FIG. 3 Endoscopic stent placement for obstructing rectosigmoid cancer. **(A)** *Arrow* indicates obstructing pelvic lesion. **(B)** Fluoroscopic-guided passage of the wire. Note the obstructing lesion. **(C)** Poststent abdominal film with improvement of large bowel distension.

With the guidewire fixed, the colonoscope is withdrawn entirely. The appropriate stent is selected and passed directly over the wire into position using fluoroscopy. Fluoroscopic or postprocedural abdominal films are obtained to confirm the typical stent appearance of a narrowed or waisted midportion with proximal and distal flaring. The flaring represents adequate overlap into normal, low-resistance lumen. To reduce development of rapid restenosis, the intraluminal diameter at the midportion of the stent should be at least 24 mm. Balloon dilation should not be attempted because of significant risk of perforation. If imaging does not demonstrate flaring at one or both ends of the stent, additional stenting is likely necessary and typically done in an end-to-end fashion. Patients should expect gradual improvement of symptoms over 3 to 5 days as the stents reach maximal expansion and the colon decompresses. For descending colon and beyond, patients are advised to consume a low-residue, low-fiber diet along with daily laxatives (e.g., polyethylene glycol) to promote soft stools that are unlikely to become impacted at the stent. It is important that if definitive therapy is planned, it should be done within 7 to 14 days following placement of the stent. Patients who receive stenting for palliation and the anticipated duration greater than 2 weeks have a significantly increased risk of stent complications, primarily perforation. Multidisciplinary discussion should weigh the possibility of surgical palliation in this high-risk population. Current literature reports successful stent placement for acute large bowel obstruction between 70% and 90%. In a pooled analysis by Sebastian et al., 25% of the 1198 patients who underwent stent placement for obstruction developed a complication. Most common complications include stent migration, reobstruction, and perforation. The most serious complication is perforation and occurs in 4% to 5% of patients. Intrinsic factors that may increase the risk of stent-related perforation include longer segment of obstruction (median length of 64 mm), benign etiology, and extraluminal origin.

SPECIFIC SITUATIONS

Sigmoid Volvulus

Volvulus, from the Latin, *volvere*, means to roll. The classic patient with a sigmoid volvulus presents with colicky lower abdominal pain and obstipation. The demographic profile most affected by sigmoid volvulus is a black male older than 70 years with significant comorbidities. The two primary goals for management of sigmoid volvulus are to relieve the obstruction and prevent recurrence. The gold standard in the management of uncomplicated sigmoid volvulus is endoscopic detorsion, gross inspection to ensure viability of the colon, and placement of a drainage catheter (successful in up to 70%–90% of patients). Endoscopic reduction converts an emergency situation into an elective one and allows preparation of bowel and patient prior to definitive surgery. Failure of endoscopic reduction and/or presence of bowel ischemia is an indication for emergent resection. Primary anastomosis in this setting is an ongoing controversy and dependent of clinical picture of the patient. When endoscopic reduction is successful, definitive elective operation is recommended based on the high rate of recurrence; most studies cite a rate in the 50% to 80% range. Atamanalp and colleagues published data from a single-center review of 686 patients. They found morbidity and mortality of 35% and 16% for emergent surgery for recurrent sigmoid volvulus and 12.5% and 0% for elective surgery, respectively. Some suggest performing the definitive surgery as early as the index admission. Regardless of timing, the approach can be either open or minimally invasive. The redundant colon and narrowed mesentery leading to sigmoid volvulus results in an anatomical configuration that facilitates sigmoid resection with minimal difficulty. The gold standard is resection with primary anastomosis. For isolated sigmoid volvulus and the elective sigmoid colectomy, the recurrence rates are very low.

Cecal Volvulus or Bascule

The second most common site of colonic volvulus is the cecum (Fig. 4). In patients with cecal volvulus, there is a female predominance, and typically patients are in the second and third decade of life, younger than those presenting with sigmoid volvulus. Presentation is similar to small bowel obstruction with abdominal distension, nausea, and vomiting; however, this can vary. There are three types of cecal volvulus:

1. Axial cecal volvulus: A twist of the intestines in which the affected cecum remains in the right lower quadrant.
2. Loop cecal volvulus: The cecum and terminal ileum are twisted in the axial plane and the affected cecum typically lies in the left upper quadrant.
3. Cecal bascule: A redundant cecum folds in the sagittal plane onto itself and the proximal ascending colon leaving the affected cecum within the right upper quadrant.

All three types necessitate either an acquired or congenital hypermobile cecum and ascending colon. Types 1 and 2 are the most common, accounting for roughly 80% of cecal volvuli. Unlike types 1 and 2, type 3 does not exhibit torsion. Patients who present

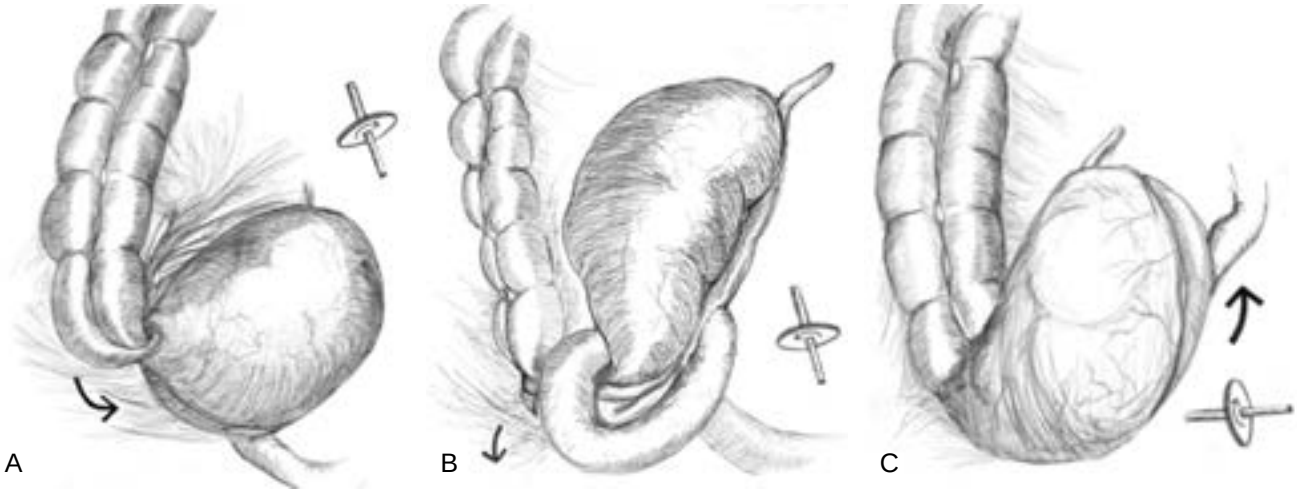

FIG. 4 Types of cecal volvulus. **(A)** Type 1, axial cecal volvulus. **(B)** Type 2, loop cecal volvulus. **(C)** Type 3, cecal bascule. *(Courtesy Matthew P. Kelley, MD.)*

with type 3 typically have a much more insidious presentation. Endoscopic management is not recommended for cecal volvulus or bascule because of a low rate of successful detorsion, and colonic ischemia can be missed in up to 25% of patients. For the patient presenting with a high probability of cecal volvulus, the operation of choice is an exploratory laparotomy. Severe ischemia, necrosis, or perforation occurs in up to 44% of patients with cecal volvulus; if present, mortality rates are equally as high. Management of the patient with nonviable cecum is resection and creation of end ileostomy, with consideration for mucous fistula. If the cecum is viable or with patchy ischemia, there is less consensus on the appropriate management. Nonresectional options include detorsion with cecopexy and cecostomy. Widely variable rates of recurrence, morbidity, and mortality have been demonstrated, although there is a paucity of recent data that compares these options and with respect to viable versus nonviable bowel. Distillation of the current data favors ileocecectomy with primary anastomosis for patients with acute cecal volvulus, even when bowel appears viable. Laparoscopic approach is an acceptable option in stable patients with limited bowel distension if performed by an experienced surgeon.

Acute Colonic Pseudo-Obstruction

Acute colonic pseudo-obstruction (ACPO) is also referred to as Ogilvie's syndrome in homage to British surgeon Sir Heneage Ogilvie who in 1948 identified two patients who presented with large bowel distension without an identifiable lesion. This syndrome is most encountered in the hospitalized, elderly male patient. Hospitalization is notably unrelated to the presenting symptoms rather for unrelated surgical procedure (most commonly involving pelvic dissection) or traumatic bony injury. Additional predisposing factors include severe electrolyte disturbances, certain medications, and acute deconditioning. Presentation is consistent with other etiologies of large bowel obstruction, including nausea, vomiting, and persistent abdominal pain. A significant portion of these patients will continue to pass loose stool. Focal peritonitis confined to the right lower quadrant may be a warning sign of impending perforation because of the profound cecal distension. These findings should encourage expeditious intervention. Perforation at the time of presentation occurs in about 15% of patients and often is associated with abdominal tenderness, cecal diameter greater than 12 cm, fever, and leukocytosis. Abdominal plain films are the best initial imaging study, although findings are nonspecific. Second-line imaging has traditionally been with water-soluble CE. Unfamiliarity with the technique coupled with the risk of perforation makes this option less favorable. The gold standard imaging modality is CT; findings include diffuse colonic distension, possible transition point near splenic flexure, and, importantly, no evidence of a mechanical obstruction. Nonoperative management of ACPO is successful in more than two-thirds of patients. This consists of aggressive fluid resuscitation, repletion of serum electrolytes as necessary, cessation of possible offending medications (e.g., opioids, anticholinergics), and bowel rest. The use of nasogastric and rectal tubes for decompression may also encourage the passage of flatus. These principles of nonoperative management are continued for up to 72 hours. During this period, it is essential to monitor the patient with the use of serial imaging and physical examination.

Failure to improve over this period necessitates the next step in the algorithm, neostigmine. Neostigmine increases the availability of acetylcholine through its antiacetylcholinesterase mechanism. In the colon, additional acetylcholine results in improved contractility and generalized motility. Before administration, the patient should be transferred to a unit with continuous cardiopulmonary monitoring and the ability to administer atropine, glycopyrrolate, or both. Neostigmine is contraindicated in patients in whom there is suspicion for ischemia or perforation, severe acute bronchospasm, poorly controlled cardiac dysrhythmia, or pregnancy. With the patient connected to continuous monitoring, the first dose of neostigmine of 2 to 5 mg is given intravenously over 1 to 5 minutes. Success is achieved with passage of flatus, stool, or decreased abdominal distension. Patients are observed over the next 80 minutes. Atropine and glycopyrrolate should be readily available if there is development of bradycardia or bronchospasm, respectively. Neostigmine is successful at treating ACPO in more than 90% of cases. For patients who are partial responders or nonresponders after one dose, a second can be administered with high rates of success. For those who fail to respond to neostigmine, the next step in management is endoscopic decompression. Geller et al. reviewed 50 patients with ACPO treated with colonoscopic decompression and found clinical success in 95% following a single intervention, 18% needed at least one additional colonoscopy; for patients who did not receive a decompression tube at the time of the procedure, clinical success was only achieved in 25%. Regarding technical considerations, insufflation should be minimized and preferably with carbon dioxide. The scope should be advanced into the right colon. A decompression tube is strongly recommended and should originate from the right colon; however, randomized controlled trial data are lacking to support the use of decompression tubes. Evidence does, however, support the use of polyethylene glycol solution after endoscopy and neostigmine to lower recurrence rate. The endoscopist should remove as much gas as possible during withdrawal of the scope. If endoscopic decompression is not possible or unsuccessful, percutaneous cecostomy can be used with variable success. When all these interventions have been unsuccessful, operative management is indicated. The surgery is dictated by the intraoperative findings. A minilaparotomy may be enough to assess the viability of the colon. If there is no evidence of perforation or ischemia, a tube cecostomy or surgical cecostomy may be sufficient. When ischemia is identified, the affected region should be resected, including subtotal colectomy if indicated. Primary anastomosis is not recommended but rather the creation of end colostomy with or without mucous fistula.

SUMMARY

Large bowel obstruction is a serious disorder that often necessitates surgical intervention. Rapid evaluation is essential to providing appropriate management. The approach and type of surgery will be largely dependent on the clinical condition of the patient and surgeon comfort. Emergent laparotomy should be performed in unstable patients with peritonitis and/or signs of symptoms of ischemia. Segmental resection with primary anastomosis should be considered in patients who are stable and have minimal barriers to healing. Endoscopic stenting can be considered as a bridge to surgery or as palliation in select patients.

Enteral Stents in the Treatment of Colonic Obstruction

Shruti Mony, MBBS, Clement Wu, MBBS, and Mouen Khashab, MD

INTRODUCTION

Large bowel obstruction is frequently encountered by surgeons and gastroenterologists. Although up to 30% of cases are caused by malignant obstruction from colon cancer, benign causes such as ischemia, radiation injury, volvulus, and diverticular or inflammatory bowel disease are other etiologies. Malignant large bowel obstruction is a surgical emergency, with operative management carrying a high morbidity and mortality of 15% to 34% and 32% to 54%, respectively.

Since the experimental use of uncovered self-expandable metal stents (SEMS) by Spinelli et al. in the early 1990s, colonic stents have significantly evolved. In the past, their primary indication was for palliation of inoperable colorectal malignancy avoiding the need for surgical diversion and stoma formation. The indications of colonic stenting have now expanded beyond palliation to include treatment of benign and malignant colonic obstructive disease as well as a bridge to surgery (BTS) for malignant disease.

The advantages of colonic stenting include converting emergency surgery to elective surgery and minimizing the risks associated with emergency surgery. Elective surgery is preferred as it is cost-effective and allows time to optimize the patient's nutritional status, restore bowel function, and increase the chance of primary anastomosis. From an oncologic perspective, it enables completion of cancer staging and administration of neoadjuvant therapy. However, concerns regarding complications and long-term oncologic outcomes necessitate multidisciplinary discussion in certain instances. This chapter focuses on the indications, contraindications, techniques, and outcomes of colonic stenting.

INITIAL EVALUATION

It is imperative to understand the underlying etiology of a colonic obstruction as well as accurately define the stricture location before any intervention. A thorough physical examination and radiographic imaging should be performed to exclude a surgical abdomen and luminal perforation. The therapeutic approach differs for benign disease versus malignancy. Inflammatory, ischemic, or anastomotic colon strictures can often be managed with endoscopic balloon dilation. Malignant colonic strictures will not respond to endoscopic balloon dilation, which also carries a non-trivial risk of perforation in these patients. Alternative management strategies such as placement of a SEMS or surgical intervention is often required.

INDICATIONS FOR STENT PLACEMENT

Malignant Colonic Obstruction

Malignant colonic obstruction (MCO) is primarily caused by left-sided colorectal cancer (Fig. 1). Right-sided (proximal) colon cancer presents less frequently with colonic obstruction and is often managed with one-stage surgery without the need for bowel preparation or permanent stoma formation. The outcomes of SEMS deployment in this group are conflicting, and prospective trials are warranted. On the contrary, left-sided MCO benefits from SEMS and surgical decompression. There are three main indications for SEMS placement in patients with MCO: (1) bridging to elective surgery, (2) palliation in nonoperative candidates, and (3) overcoming extrinsic compression from extracolonic tumors.

International guidelines provide limited and contrasting information on the management of MCO and lack standardization, specifically for surgically resectable colorectal cancer presenting with frank obstruction. A recent review of the international guidelines by Webster et al. showed that there is a lack of high-quality evidence to define the best management strategy in terms of morbidity, mortality, and long-term oncologic outcomes. Clinical practice guidelines are more consistent in the setting of disease palliation. Colonic stenting is recommended as the treatment of choice in such cases.

Bridge to Elective Surgery

The advantages of preoperative colonic SEMS placement as a bridge to future definitive surgical intervention include the following:

1. Restoration of bowel function with a one-stage operation and avoiding the need for an ostomy, thus also improving quality of life (QoL)
2. Conversion of an emergency surgery to an elective surgery

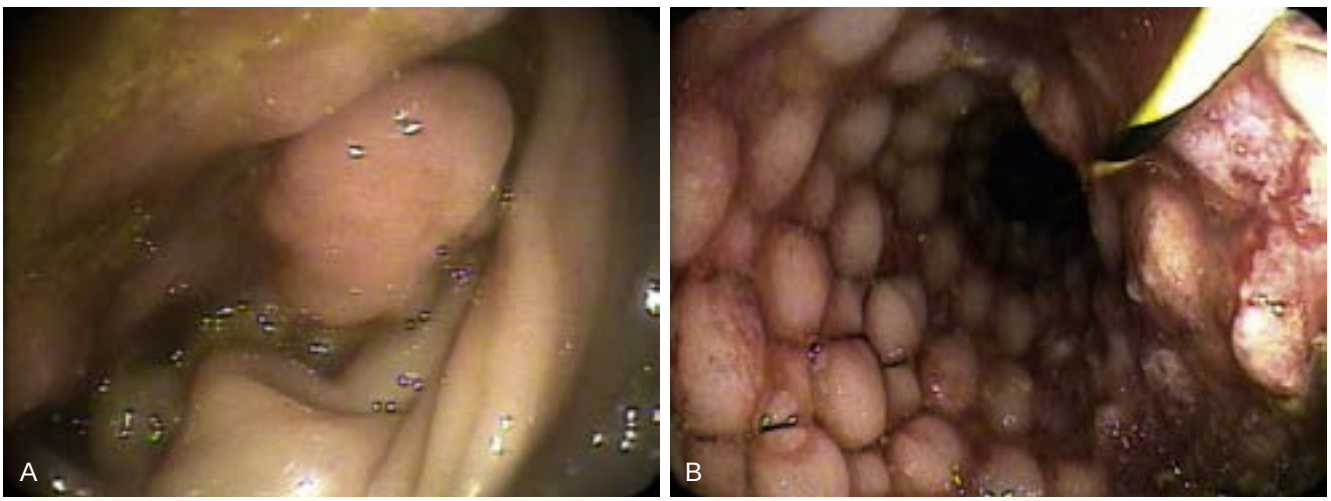

FIG. 1 **(A)** Endoscopic view of obstructing proximal rectosigmoid adenocarcinoma. (**B**) Endoscopic view of obstructing rectosigmoid adenocarcinoma followed by immediate poststent deployment. Endoscopic view with decompression of the luminal obstruction.

3. Nutritional optimization
4. Improvement of surgical outcomes, including reduction of complication rates, shortening hospital stays, and increasing rates of primary anastomosis
5. Assessment and optimization of underlying comorbid medical illnesses
6. Reduction of morbidity and mortality associated with surgery
7. Increasing time for optimal staging workup and administration of neoadjuvant therapy

Initial results for the use of SEMS as a BTS for left-sided MCO were promising. Prior meta-analyses showed that BTS stenting was associated with lower complication rates, higher primary anastomosis rate, and lower permanent stoma rates compared with emergency surgery. However, subsequent randomized clinical trials (RCTs) comparing preoperative SEMS to emergency surgery showed conflicting results in terms of adverse events and oncologic safety. The hypothesis was that placement of SEMS may cause microperforations that result in peritoneal seeding and increase the risk of metastatic spread.

Despite superior short-term outcomes, data from nonrandomized and retrospective studies raised concerns of long-term oncologic outcomes in patients with potentially curable disease who underwent BTS stenting. There was thus a shift in the guideline recommendations, with many advising against stenting between 2014 and 2016 including the European Society of Gastrointestinal Endoscopy (ESGE). However, several more recent studies have reported that stenting does not compromise oncologic outcomes. The results from the recent multicenter randomized controlled trial by Arezzo et al. (ESCO trial, 2020) allowed better analysis of the long-term outcomes from BTS stenting. This was a multicenter RCT in which patients with left-sided malignant large bowel obstruction were randomized to receive either BTS stenting or emergency surgery. The median follow-up was approximately 3 years, and no significant differences were observed in the BTS stenting group compared with the emergency surgery group in terms of overall survival, time to progression, and disease-free survival. The authors postulated that previously reported high rates of stent-associated perforation were caused by variation in operator experience.

A more robust meta-analysis by Foo et al. (2019) included seven RCTs comparing the safety of preoperative colonic stents versus emergency surgery among 448 patients with acute left-sided MCO. Notably, three of the seven RCTs were prematurely terminated. Two RCTs were terminated because of a high perforation rate in the BTS stenting arm, and one RCT was terminated because of a high anastomotic leakage rate in the emergency surgery arm. The overall complications were significantly lower in the SEMS group (RR = 0.605; $P = 0.032$). The overall 30-day mortality rate was similar in both groups (RR = 0.963; $P = 0.918$); however, the overall recurrence rate was significantly higher in the SEMS group (37.0% vs. 25.9%; RR = 1.425; $P = 0.049$). Specifically, the systemic recurrence in the SEMS group was 25.3% versus 15%, while the locoregional recurrence was not statistically significant between the groups. There was also no difference in 3-year disease-free survival or 3-year overall survival between the groups. The findings by Foo et al. were in line with the results of a meta-analysis by Spannenburg et al (2020), which showed that SEMS as a BTS had significant advantages in terms of short-term surgical outcomes but no significant difference in long-term outcomes in 3- and 5-year disease-free survival and overall survival. Additionally, SEMS placement was found to have a lower 30-day mortality rate, lower overall complication rate, less cumulative blood loss, and a higher chance of receiving a primary anastomosis, avoiding the need for a stoma with a shorter length of hospital stay.

The previous lack of high-quality evidence has limited the ability of clinicians to elucidate the best management strategy in terms of morbidity, mortality, and long-term oncologic outcomes. Recent guidelines have again begun advocating stenting as a BTS including the updated 2020 ESGE guidelines that now recommend colonic stenting as a BTS to be discussed, within a shared decision-making process, as a treatment option in patients with potentially curable left-sided obstructing colon cancer as an alternative to emergency resection. This is also supported by the American Society of Gastrointestinal Endoscopy (ASGE) guidelines. Among the surgical societal guidelines, the National Institute for Health and Clinical Excellence (NICE) and the World Society of Emergency Surgery (WSES) have advocated the use of SEMS in acute left-sided MCO, especially in centers with considerable expertise. The Eastern Association for the Surgery of Trauma (EAST) conditionally recommends SEMS in comparison with open surgery, when available, as it has shown to decrease mortality and decrease emergency procedures.

Although more long-term data are necessary to confirm the safety of SEMS as a BTS, it is important to understand that stenting should only be considered at specialized centers after multidisciplinary discussions among the endoscopy, surgical, and oncology teams.

Palliative Stenting

Patients with unresectable neoplasia carry a poor prognosis and are considered high risk for surgery given their comorbidities and poor functional status. Thus, the goal for treating these patients is to prolong survival and improve QoL by avoiding the need for permanent colostomy. SEMS placement helps achieve this goal. In the palliative setting, the surgical and gastroenterology guidelines are more consistent, recommending stenting as the preferred alternative to decompressive surgery.

Abelson et al (2017) conducted a large database cohort study among 345 patients and found no differences in the rates of post-procedure complications between patients with palliative stenting and those with a stoma. Palliative stenting was associated with a shorter length of stay, lower rates of discharge to a rehabilitation or nursing facility, and reduced hospital costs. A recent systematic review and meta-analysis of RCTs by Ribeiro et al. (2018) comparing the use of SEMS to emergency surgery solely for palliative intent reported similar 30-day mortality, mean survival, length of ICU stay, and rate of early complications between both groups. Although surgery was associated with a higher clinical success, SEMS resulted in a shorter hospital stay and lower rates of permanent colostomy (14.3% vs. 86.1%). Early complications of SEMS (perforation, migration, and obstruction) were observed in 36.5% of patients, while surgical complications (nonfunctioning ostomy, suture dehiscence, and intestinal volvulus) were observed in 24.1% of patients.

A multidisciplinary approach regarding the risks and benefits of palliative SEMS placement is paramount and should be undertaken in the context of a patient's overall outlook, goals of care, and expected subsequent oncologic therapy. Patient selection should be dictated by a multidisciplinary consultation or tumor board meeting. Palliative SEMS placement can complement new chemotherapies to improve survival and QoL of patients with unresectable colorectal neoplasia. Lastly, prophylactic colonic stent placement is not recommended in patients who are not yet symptomatic.

Extrinsic Malignancy

The majority of colonic obstructions are caused by intraluminal cancer. Rarely, extracolonic malignancy may result in extrinsic compression of the colonic lumen and result in obstruction. The most common causes include gynecologic (ovarian and uterine) malignancies, bladder cancer, advanced gastric cancer, or metastatic lesions to the pelvis.

Most often, these patients have limited surgical options because of their advanced disease with reduced life expectancy. Management is challenging as a result of several factors: (1) Tumors are multifocal, compressing a long segment of large bowel, and often associated with peritoneal carcinomatosis, and (2) most patients have an extensive surgical history with dense pelvic adhesions or have had prior

exposure to radiotherapy. The technical and clinical successes of stenting are lower when compared with primary colorectal tumors. Proper patient and family counseling is key in setting a realistic expectation and preparing the patient for the potential need for surgical intervention in case of an immediate technical failure or long-term clinical failure.

Benign Colonic Disease

Benign colonic strictures resulting in clinically significant obstruction can be caused by factors related to diverticulitis, inflammatory bowel disease, ischemia, radiation, postoperative anastomotic strictures, or complex colorectal fistulas including colovesical and colovaginal fistulas. Anastomotic strictures are known to be the most common complication following colonic surgery, seen in up to 30% of cases. The bulk of scientific literature on the management of benign colonic strictures stems from Crohn's disease strictures, which are usually found at the ileocecal valve or at the surgical anastomoses. The available data on management of strictures from other etiologies, such as diverticular disease, colonic ischemia, and radiation injury, are limited.

The morphology of benign strictures differs from malignant ones in that they are associated with increased fibrosis and scarring; thus, therapy is more challenging. Some of the endoscopic therapies include endoscopic balloon dilation (EBD), intralesional steroid injections, SEMS placement, endoscopic incisional therapies, and more recently, placement of a lumen-apposing metal stent (LAMS). Graded EBD is the recommended initial treatment for benign strictures and should be considered before alternative endoscopic or surgical therapies. On one hand, balloon dilation has a high clinical success exceeding 88% (Fig. 2), but on the other hand it has a high recurrence rate of 30% to 88%, often requiring redilations. Strictures remain refractory in >20% of cases and may eventually require surgical revision. Patients with complex anastomoses or multiple strictures are less likely to have favorable treatment outcomes compared with those with a short (<4 cm) focal stricture in a straight colonic segment. In patients with Crohn's disease, it is preferable to avoid dilation in the setting of poor prognostic factors for response to dilation, such as active inflammation, presence of large ulcers within a stricture, or smoking. Intralesional steroid injection is a known adjunct that can enhance the effectiveness of balloon dilation, reducing the time to redilation, and should be considered, especially in cases of acute inflammatory strictures.

On the basis of paucity of data and heterogeneous studies, SEMS should not be used as first-line therapy for benign strictures. Uncovered colonic SEMS are typically not removable and may predispose patients to long-term complications. The use of fully covered self-expandable metal stents (FCSEMS) in benign colonic strictures is not FDA approved; however, off-label use of FCSEMS could be considered in refractory or recurrent benign colonic strictures. Some of their drawbacks include patient intolerance, iatrogenic stricture formation, and a high rate of early stent migration of up to 40%, which may reduce long-term clinical success. Recently, endoscopic suturing of FCSEMS to overcome migration has been used, but

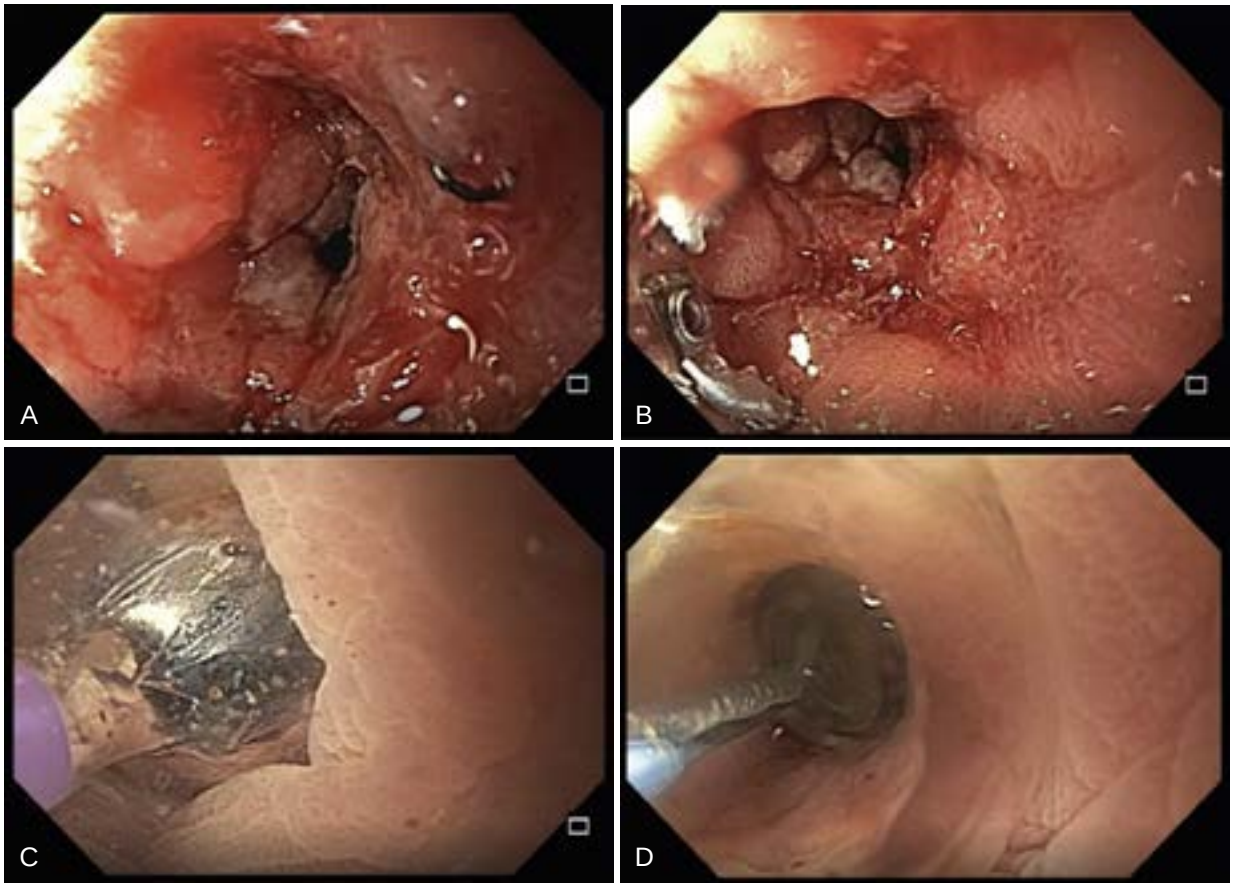

FIG. 2 Endoscopic balloon therapy for benign strictures. **(A)** History of colonic diverticulitis status after sigmoid colectomy and colostomy followed by takedown complicated by stricture at left-sided colorectal anastomosis with erythema and edema. **(B)** The stricture was approximately 3 mm in width (compared with opened biopsy forceps). **(C)** A long 0.035-inch guidewire was passed across the stricture, and a through-the-scope dilating balloon was used to dilate the stricture to 11 mm. **(D)** Water was infused, and the balloon was pulled close to the scope lens to enable visualization of the lumen of the stricture during dilation. *(From Copland AP, Wang AW. Clinical Gastrointestinal Endoscopy (3rd ed.). Chapter 40: Colonic Strictures.)*

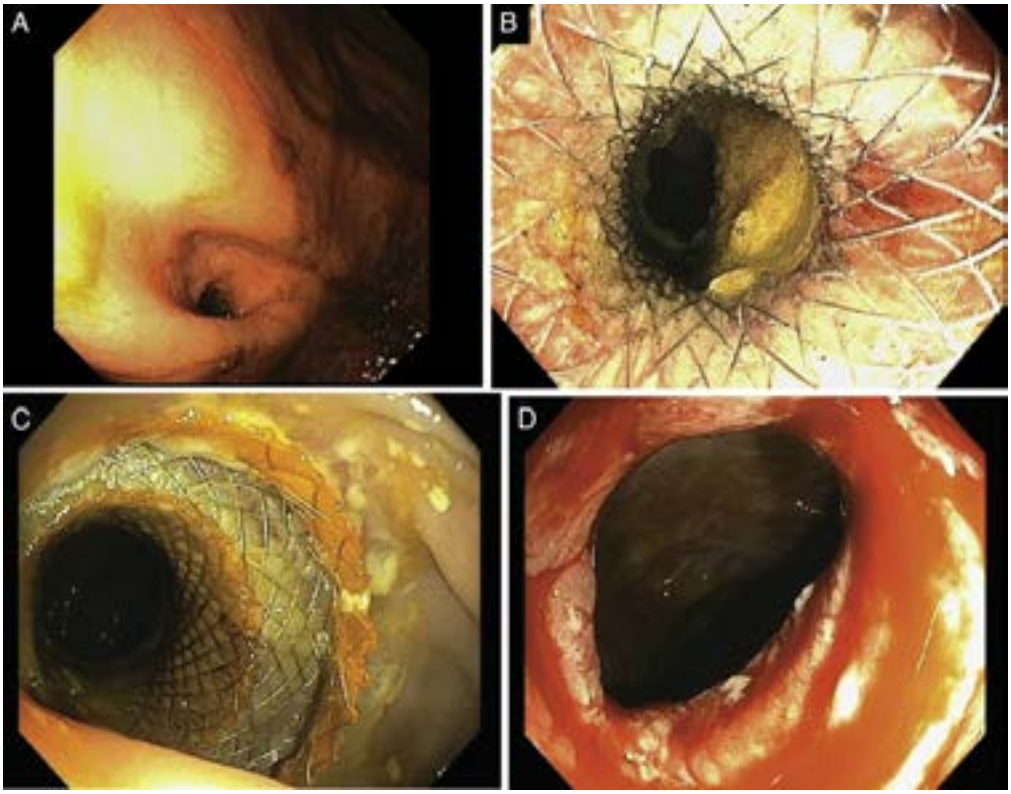

FIG. 3 Lumen-apposing metal stent for benign colonic stricture from Crohn's disease. **(A)** Crohn's disease–related high-grade stricture. (**B** and **C**) Endoscopic view of fully covered lumen-apposing, self-expanding metal stent (AXIOS; Boston Scientific). **(D)** Stricture following removal of lumen-apposing metal stent showing significant improvement. *(From Clinical Gastroenterology and Hepatology Image of the Month: Treatment of Crohn's Disease Anastomotic Stricture with a Lumen-Apposing Metal Stent. Jordan E. Axelrad, Simon Lichtiger, Amrita Sethi. Published May 18, 2017. Figures A, B, and D: doi.org/10.1016/j.cgh.2017.05.016.)*

this procedure is expensive and technically difficult and should be performed by experienced endoscopists. Caruso et al. (2015) performed a retrospective analysis of 16 patients who had postsurgical anastomotic colorectal strictures that were refractory to endoscopic dilation and underwent stent therapy, and they reported a 100% technical and early clinical success with median follow-up of 21 months. Prolonged clinical success was achieved in 9/16 (56%) cases. There were no major complications, including perforation and bleeding. Stent migration occurred in 3 (19%) cases, and a larger median stent diameter was significantly associated with a more successful clinical outcome (26 mm vs. 20 mm, $P = 0.006$). In certain clinical situations, covered esophageal stents have also been used in an off-label manner to treat benign colonic strictures. Unfortunately, most covered esophageal stents come on a stiff introducer (ranging from 16Fr to 24Fr in size) and within short catheters and must be passed over a guidewire, not through the scope channel (TTS), thus limiting their use to left-sided colonic strictures. However, one commercially available covered esophageal stent in the United States made by Taewoong Medical (Niti-S Esophageal TTS, Gyeonggi-do, South Korea) comes on a 10.5Fr flexible catheter that can be deployed through the channel of a therapeutic gastroscope, which might enable successful covered metal stenting of difficult to reach or angulated colonic strictures.

Endoscopic incisional therapies using a sphincterotome or a needle-knife to perform strictureplasty allows for controlled radial mucosal incisions along the circumference of the stricture. Whereas there is evidence that this may be a viable approach in select cases, such procedures should only be performed by interventional endoscopists with considerable expertise and in settings with the appropriate radiologic and surgical backup.

Lastly, the use of a LAMS for benign gastrointestinal strictures has emerged as an alternative to other traditional endoscopic therapies. The unique design, short length, saddle shape, and wide flange at each end are design features that facilitate stent retention, which improves patient tolerance and makes them less prone to migration (Fig. 3). Their safety and long-term efficacy data are lacking; however, they might be an alluring prospect for benign strictures. With an increasing interest in endoscopic intraluminal surgery, newer technologies will undoubtedly become available in the future. The management of colonic obstruction is summarized in Figure 4.

CONTRAINDICATIONS TO COLONIC STENTS

The absolute contraindications to stent placement include the presence of colonic perforation or severe colonic ischemia with impending necrosis, which can be assessed with a thorough physical examination and radiologic imaging. Other contraindications are summarized in Table 1.

Technical Considerations

Types of Colonic Stents

Currently all commercially available SEMS for MCO are uncovered because of the high rate of migration associated with covered SEMS. Most commercially available SEMS work with the same mechanism; the main features to consider include stent dimensions, material, design, and delivery system. The various types of colonic stents are summarized in Table 2.

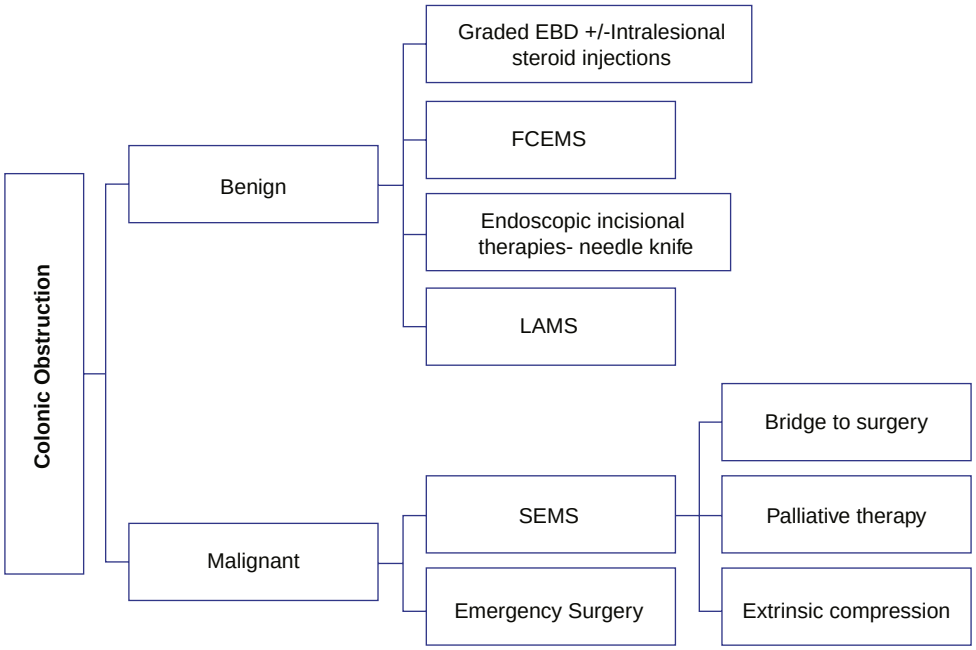

FIG. 4 Summary of management of colonic obstruction/stricture.

TABLE 1 Contraindications to SEMS Placement

Contraindication	
Absolute	• Colonic perforation or severe colonic ischemia with impending necrosis
Relative	• Distal rectal lesions with 5 cm from the dentate line (stents crossing the anal verge can induce severe pain, tenesmus, bleeding, and risk of migration) • Presence of diffuse peritoneal carcinomatosis (higher failure rate) • Persistent severe coagulopathy (risk of bleeding) • Patients on chemotherapy with antiangiogenic drugs (such as bevacizumab) • Tumors close to the anal verge (<5 cm)
Special considerations	• Lesions in tortuous or angulated portions of the colon, such as the splenic flexure (technically challenging and may have a higher failure rate) • The use of prophylactic stents in patients with metastatic disease to prevent potential obstruction is not recommended. • Right-sided or proximal colonic lesions are better managed with surgical resection with primary anastomosis or stoma creation. Although SEMS placement is performed in some palliative cases, it is not recommended given the technical challenges and non-inferiority to surgery.

Stent Dimensions

The uncovered stents in the United States come in sizes that fall between 5.7 and 12 cm in length and mid-body diameters of 20 to 30 mm (with variably flanged ends that are wider than the width of the stent body) after deployment. They come within a 10Fr catheter that fits through the accessory channel of an adult colonoscope or a therapeutic gastroscope (with a channel diameter of at least 3.7 mm), which allows for the stent to be placed using both endoscopic and fluoroscopic visualization.

Stent Material

SEMS are composed of a radiopaque, woven, metal mesh with a cylindrical shape that exerts self-expansion forces. In their unexpanded form, they fit through the channel of an endoscope. Following deployment to the desired location, they expand to oppose the luminal surface of interest. Although the basic delivery system and deployment mechanism are identical, stents are classified based on their coating and manufacture material.

Stents are made from stainless steel or other alloys such as Nitinol (comprising nickel and titanium) or Elgiloy (comprising cobalt, chromium, and nickel). Nitinol is the most widely used metal alloy. Its main advantage over other stent materials is its malleability at low temperatures and strong radial forces at body temperature without losing its flexibility (Fig. 5). Stainless steel stents are relatively stiff and may affect the quality of imaging studies such as MRI. Stents made of Elgiloy are thinner, more elastic, and more flexible, and they are MRI-compatible with less imaging artifact.

Covered versus Uncovered Stents

Uncovered stents have bare wires, while covered stents have a silicone membrane over the bare wires. Covered stents can be subdivided into fully and partially covered stents. Although covered stents reduce the risk of tumor ingrowth and can be used to seal fistulas, fully covered stents have less anchoring power and an increased risk of migration compared with uncovered stents. Partially covered stents with flared uncovered segments at both ends were developed to overcome migration risk. Patency rates between uncovered and covered SEMS are thought to be similar, however more data are required to validate these findings. In a systemic review and meta-analysis by Mashar et al. (1 RCT and 9 observational studies including 753 patients) comparing covered and uncovered stents in management of MBO, uncovered stents were associated with a lower risk of complications (RR 0.57, 95% CI 0.44–0.74, $P < 0.0001$), tumor overgrowth (RR 0.29, 95% CI 0.09–0.93, $P = 0.04$), and stent migration (RR 0.29, 95% CI 0.17–0.48, $P < 0.00001$); longer duration of patency (MD 18.47, 95% CI 10.46–26.48, $P < 0.00001$); lower need for stent reinsertion (RR 0.38, 95% CI 0.17–0.86, $P = 0.02$); and higher risk of tumor ingrowth (RR 4.53, 95% CI 1.92–10.69, $P = 0.0008$). Rates of technical success (RR 1.02, 95% CI 0.99–1.04, $P = 0.21$), clinical success (RR 1.03, 95% CI 0.98–1.08, $P = 0.32$), perforation (RD 0.01, 95% CI 0.03–0.02, $p = 0.65$), bleeding (RD 0.00, 95% CI 0.03–0.03, $P = 0.98$), stool impaction (RR 0.56, 95% CI 0.12–2.04, $P = 0.38$), and stent obstruction (RR 2.23, 95% CI 0.94–5.34, $P = 0.97$) were similar. These results concluded that uncovered stents were superior in the management of MBO. It is worth mentioning that only uncovered colonic SEMS are available in the United States.

Technical Aspects of Stent Deployment (Box 1)

Pre-stent placement

Before performing colonic SEMS placement, one should assess the location and morphology of the stricture (Fig. 6). The imaging modalities commonly used include a retrograde water-soluble contrast enema (barium enema or Gastrografin) (Bracco Diagnostics Inc., Monroe

FIG. 5 Various types of self-expandable uncovered metal colonic stents. *(From Baron TH, Wong Kee Song LM, Repici A. Role of self-expandable stents for patients with colon cancer (with videos). Gastrointest Endosc. 2012;75:653–662.)*

Township, NJ) or cross-sectional imaging (CT scan). These imaging modalities can help delineate the anatomy (number, length, location, and degree of stricturing) and in some cases reveal synchronous proximal lesions and rule out the presence of a leak or perforation. CT scans can also assist with defining the surrounding soft tissue, lymph nodes, and more distant organs, which can be critical in cases of mass lesions, as well as in inflammatory bowel disease, which can be further complicated by fistulas or abscesses. Patients are usually given one or two cleansing enemas to prepare the distal colon. Oral bowel prep should be avoided as it may worsen the symptoms of obstruction. In some cases, a diagnostic colonoscopy is warranted in determining the etiology of a stricture as it can help obtain sampling for pathologic diagnosis.

In patients with complete obstruction and dilated colon proximally, prophylactic intravenous antibiotic therapy is recommended by the surgical societies. It is postulated that during insufflation for stent deployment, the increase of wall tension and intestinal barrier damage may cause microperforations resulting in bacterial translocation. However, several studies report a negligible risk of infection within 48 hours post-stenting. Likewise, Kim et al. performed a propensity score-matched analysis of prophylactic antibiotics for colonic stenting that did not show significant differences in infectious complications (such as fever, bacteremia, and systemic inflammatory response syndrome) between patients who received antibiotic prophylaxis and those who did not. The ESGE and ASGE do not recommend the routine use of antibiotic prophylaxis.

Stent Deployment Process

The procedure is usually carried out in the endoscopy suite or operating room depending on the physician performing the procedure.

BOX 1 Technical Aspects of Stent Placement

Prerequisites

Thorough history and physical examination; rule out perforation
Assess location and morphology of stricture with contrasted imaging:
Retrograde barium/Gastrografin enema or CT with contrast
Avoid oral mechanical bowel prep; consider enemas
Diagnostic colonoscopy (some cases)

Intraprocedural

Endoscopy suite or operating room
General anesthesia preferred
Left lateral position
Therapeutic gastroscope or colonoscope (depending on location)
CO_2 insufflation

Stent Deployment

Combined endoscopy and fluoroscopy technique
TTS stent deployment with guidewire

Post-stent care

Confirm large bowel decompression on endoscopy
Post-procedure imaging (x-ray or CT)
Repeat x-ray in 2 days to confirm stent expansion and position

TTS, Through the scope.

FIG. 6 Morphology of colonic stricture with apple core lesion, pathognomic for colonic adenocarcinoma. **(A)** Barium enema showing morphology of colonic stricture. **(B)** CT abdomen and pelvis (sagittal view) with intravenous and intraluminal contrast showing a colonic stricture *(arrow).* *(From Copland AP, Wang AW.* Clinical Gastrointestinal Endoscopy *3rd ed. Chapter 40: Colonic Strictures.)*

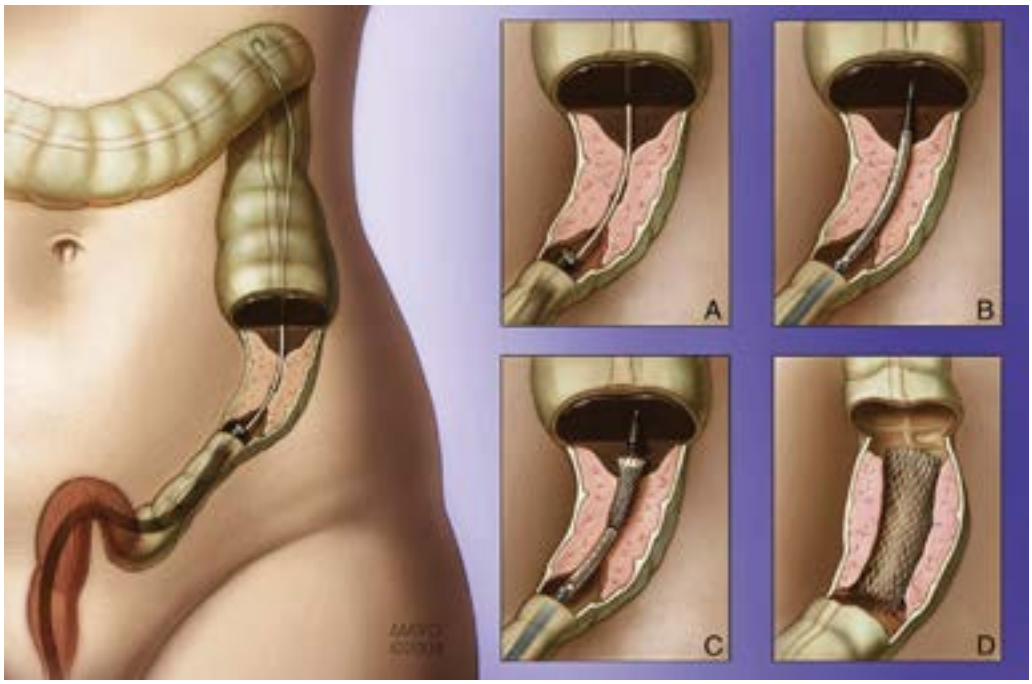

FIG. 7 Through-the-scope (TTS) colonic self-expandable metal stent placement process. The endoscope is passed to the lesion, and a guidewire is advanced across the obstruction *(far left).* **(A)** The catheter is advanced across the lesion. **(B)** The predeployed stent is advanced through the endoscope channel and across the lesion. **(C)** The restraining sheath is withdrawn. **(D)** The stent is fully deployed. *(From Baron TH, Wong Kee Song LM, Repici A. Role of self-expandable stents for patients with colon cancer (with videos). Gastrointest Endosc. 2012;75:653–662.)*

Anesthesia choice is based on physician preference, but intubation is recommended in cases of acute colonic obstruction given the risk of aspiration during the procedure. Patients are placed in the left lateral position to facilitate passage of the endoscope. For left-sided colonic strictures, a therapeutic gastroscope is often the instrument of choice, but for more proximal or right-sided strictures, an adult colonoscope may be required. CO_2 insufflation is preferred over air as CO_2 is more rapidly absorbed and leads to reduced abdominal discomfort and may decrease the risk of perforation.

A SEMS can be loaded using two different delivery systems: through-the-scope (TTS) stents or over-the-wire (OTW) stents. TTS stents are traditionally loaded into 10Fr catheters, introduced over the guidewire, and placed across the stricture under endoscopic and fluoroscopic guidance. OTW stents are passed over the guidewire and placed under fluoroscopic visualization. The use of simultaneous side-by-side endoscopy with a small-caliber endoscope is recommended in some cases but not mandatory. This technique is preferred in case of rectal or sigmoid strictures, acute angulations, or other conditions with poor endoscopic visualization. Both fluoroscopic and endoscopic guidance is preferred as fluoroscopy not only assists in defining the stricture but also adjunctively guides stent placement. TTS colonic SEMS placement is illustrated in Figure 7 and Video 1.

TABLE 3 Technical Tips for Stent Deployment and Guidewire Passage

Instrument	Technical Tip
Triple-lumen biliary occlusion (stone retrieval) catheter	Method 1: Catheter with the balloon inflated to 12–15 mm and positioned just distal to or impacted at the obstruction site followed by stricturogram Method 2: Biliary stone retrieval balloon passed beyond the stricture and then inflated to a large-diameter 12–15 mm, and balloon is withdrawn until it abuts the proximal shelf of the stricture meeting resistance. The endoscopist then holds the catheter at the biopsy port. The balloon is deflated and withdrawn while keeping the finger position on the catheter. When the balloon is seen endoscopically on the distal aspect of the stricture, the distance from the endoscopist's fingers to the biopsy port corresponds to the length of the stricture.
Guidewires	Using hydrophilic biliary guidewires (e.g., Glidewire; Boston Scientific)
Cap, sphincterotome	For lesions at flexures or corners, a clear cap to obtain a more en face view and a sphincterotome, preferably a rotatable sphincterotome (e.g., Autotome RX; Boston Scientific), are used to orient the catheter in the direction of the lumen.
Stent deployment	SEMS should be of suitable length to bridge the stricture and extend at least 2 cm on each side of the obstruction. Keep in mind the degree of SEMS shortening during deployment and stent migration away from the endoscope.

On reaching the stricture, a guidewire with a hydrophilic soft/floppy tip (typically a 0.035-inch-diameter guidewire for added stiffness) is passed across the stricture. Careful guidewire passage and measuring the appropriate stricture length are key steps to technical success of the stent deployment process. A few additional technical tips are described in Table 3.

Deployment of TTS uncovered or covered metal stents follows similar principles and involves an assistant deploying the stent while the endoscopist pulls back on the restraining catheter until the stent is released. The stent is then deployed by withdrawing the constraining sheath or unraveling string (depending on the device). Most colonic SEMSs deploy from a proximal (oral) to distal (rectal) fashion. Although there is no validated rule for stent deployment, it is recommended that the SEMS should be of suitable length to bridge the stricture and extend at least 2 cm on each side of the obstruction once the stent is deployed. One must also account for the degree of shortening that occurs during deployment and stent migration away from the endoscope. If stent coverage is inadequate, an additional stent can be deployed overlapping the existing stent. It is important to keep the wire in place across the lesion until the final position of the stent is assessed radiographically because passing a wire through a newly deployed stent can be technically challenging. In patients who present with complete colonic obstruction, consideration should be given to leaving the guidewire in place after stent deployment to pass a colonic decompression tube through the stent and into the proximal bowel if immediate passage of stool does not occur after stent placement. For right-sided colonic obstruction, stents can also be successfully placed proximally, although the lesions typically require a TTS SEMS placed via an adult colonoscope.

After stent deployment, additional balloon dilation is not recommended because it is associated with a high risk of perforation. Because of the nature of the self-expansion, stents are allowed to slowly expand over time. The peristaltic movements of the colon after decompression may facilitate full expansion. Immediately after stent placement, the enema examination can be repeated to document post-stenting patency and correct positioning, although this is not always needed.

FOLLOW-UP CARE

Immediately following stent placement, large bowel decompression, confirmed on endoscopy, is suggestive of successful deployment of a stent. If a nasogastric tube is present, it can often be removed the following day. A postprocedural abdominal radiograph or CT is obtained immediately after stent placement to confirm position and exclude free air (Fig. 8). An abdominal x-ray is repeated within 24 to 48 hours when full expansion of the stent is expected. A liquid diet can typically be initiated within 24 to 48 hours of stent placement in most patients. Several days are needed for complete decompression to a normal-sized colon.

FIG. 8 Postprocedural abdominal radiograph demonstrating a well-positioned transverse colon stent across a malignant stricture.

OUTCOMES AND ADVERSE EVENTS

The mortality rate of colonic stenting is roughly 1.5% to 3%. Technical success (immediate or short-term success) is defined

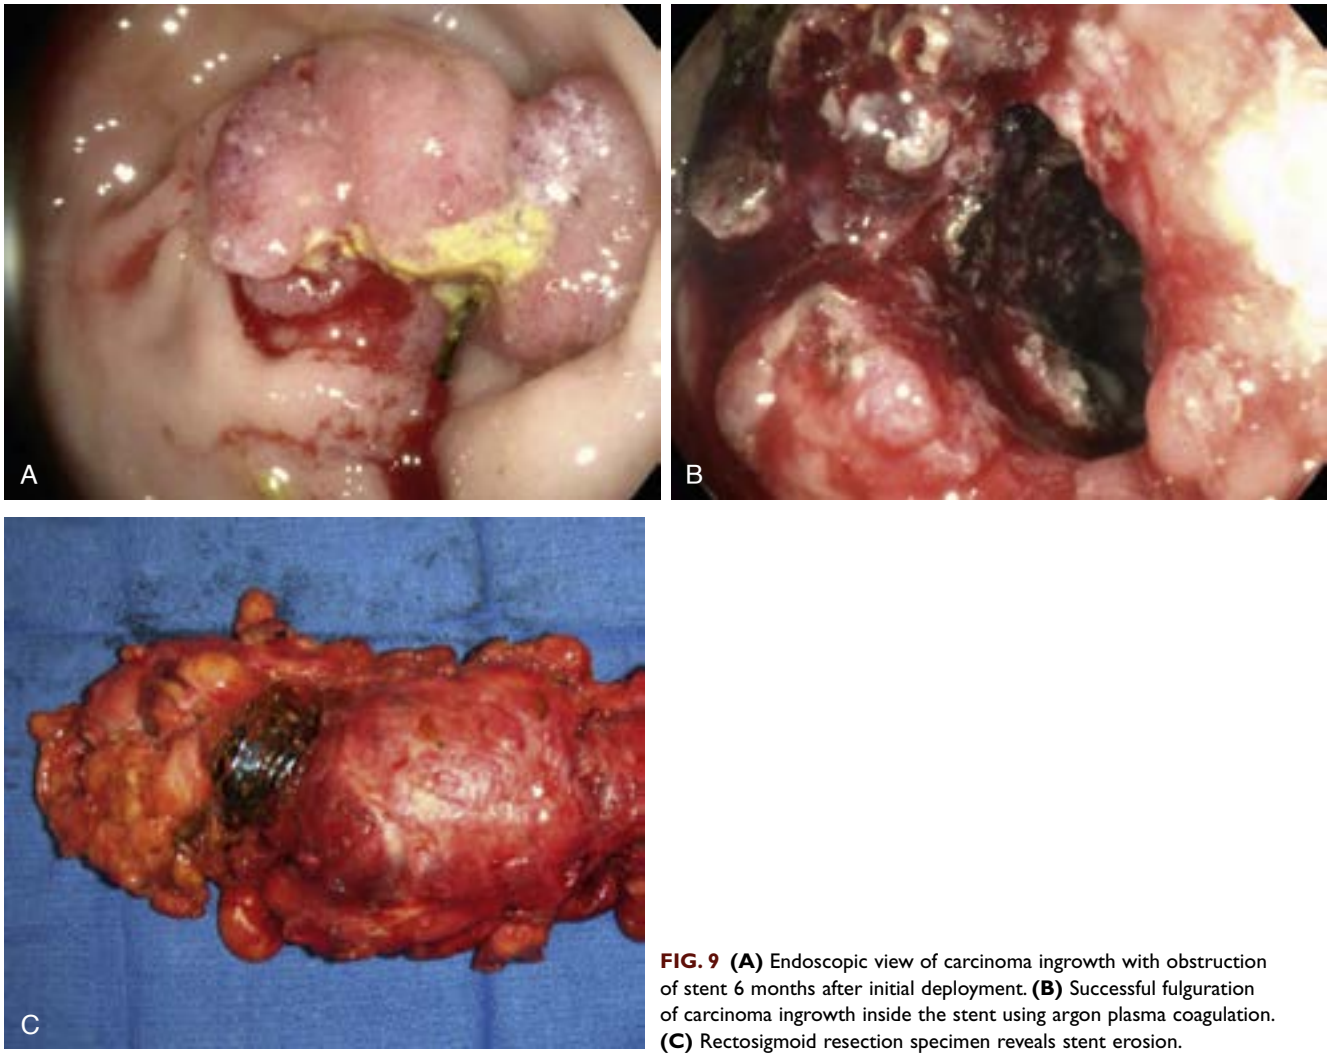

FIG. 9 **(A)** Endoscopic view of carcinoma ingrowth with obstruction of stent 6 months after initial deployment. **(B)** Successful fulguration of carcinoma ingrowth inside the stent using argon plasma coagulation. **(C)** Rectosigmoid resection specimen reveals stent erosion.

as the ability to safely deploy and properly position the stent across the stricture without any immediate complication. Clinical success (long-term success) is defined as the ability to achieve long-term decompression without the need for operative intervention to treat long-term failure of the stent or related complications. Colonic stenting has a high technical success of 80% to 100% and clinical success of 70% to 100%. The rates of complications are variable across studies but can be broadly divided into early (<2 weeks) and late (>2 weeks) complications, with an overall complication rate of 10% to 15%.

Early Complications

Perforation

The most feared complication is perforation. The rate of perforation in malignant obstruction is 6% across various studies, while that of silent or microperforations is up to 14%. Angiogenesis inhibitors (e.g., bevacizumab) are independent risk factors of perforation, even in the absence of stenting, and are known to increase the rate of perforation to 12.8%. The ESGE does not recommend the combination therapy of stent with antiangiogenic drugs (Fig. 9). Perforation rates are highest in colonic SEMS deployment for benign strictures (18%). When large perforations occur, they are best managed operatively. Microperforations may be managed with bowel rest and intravenous antibiotics.

Stent Migration and Failure

Failure of the stent to resolve the obstruction and early stent migration (seen in 4%–11.7%) should raise suspicion for stent malposition (inadequate stricture coverage), incomplete expansion, or undetected synchronous tumors. Stent migration rates are determined by the type of stent deployed, the degree of stenosis, the proximal and distal clearance, and the flare diameter. Short stents, smaller-diameter stents (<25 mm), and covered stents have higher rates of migration. SEMS migration can typically be managed endoscopically by removing the migrated stent with the goal of either placing a larger stent or a different type of stent that might be less prone to migration. Other alternatives to replacing a migrated SEMS include observation (particularly if the stricture has become more patent following stenting) or more definitive surgical intervention.

Abdominal/Rectal Pain and Incontinence

Abdominal/rectal pain and incontinence may occur if stents are placed within 5 cm of the anal verge. Pain is also commonly caused by mucosal irritation from the stent itself. Bleeding may occur in up to 5% of patients. This is usually mild to moderate in severity, however endoscopic interventions are recommended before surgery.

Late Complications

Late stent migration can be seen in cases following chemotherapy or radiotherapy with subsequent tumor shrinkage.

Occlusion by Fecal Impaction and/or Tumor Ingrowth

Tumor ingrowth has been reported in 15% of patients. Although most patients currently treated with palliative stents succumb to their

disease before obstructing, the impact of newer chemotherapeutic agents on long-term survival may affect the rate of this long-term complication. Tumor ingrowth and fecal impaction of the stent can be managed endoscopically by placing another stent through the occluded stent.

CONCLUSION

Colonic SEMS are an important part of the treatment armamentarium of managing obstructing colorectal cancer. It is a relatively safe and effective procedure that is used for palliation of obstruction and as a bridge to a safer, less morbid surgery. As newer technologies and medical therapies continue to evolve, surgeons and gastroenterologists must work in close collaboration to appropriately select patients who would most benefit from these interventions.

Management of Acute Colonic Pseudo-Obstruction (Ogilvie's Syndrome)

Marshall S. Bedine, MD

Acute colonic pseudo-obstruction (ACPO), often known as Ogilvie's syndrome, is a condition of sudden onset associated with an acute dilation of the colon with no evidence of mechanical obstruction. The syndrome was first reported by William Ogilvie in 1948.

Pathogenesis of ACPO has been thought to be related to impairment of the autonomic nervous system leading to an atonic distal colon and functional obstruction. When this occurs, colonic diameter increases with a rise in tension on the colonic wall. This, in turn, increases the risk of colonic ischemia and perforation as the colon dilates and cecal diameter exceeds 10 to 12 cm. Ischemia with or without perforation increases rapidly as the colon dilates, particularly if the duration of distention exceeds 6 days.

ACPO most often occurs in hospitalized or institutionalized patients usually with severe comorbid illness. Associated conditions include infection, cardiac disease, and inoperative trauma as well as orthopedic procedures including hip and spine surgery or after pelvic surgery. In one study, 92% of postpartum cases of ACPO were in patients following cesarean section after complicated pregnancies. The incidence of ACPO is approximately 1:1000 of hospitalized patients. If colonic ischemic or perforation occur, the mortality may be as high as 50%.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Clinical manifestations of ACPO may occur gradually or rapidly with abdominal pain occurring in 80% of patients associated with distention. Nausea and vomiting are frequent, and constipation or even diarrhea has been reported in 40% to 50%.

Physical examination reveals a protuberant abdomen that is tympanic to percussion and associated with bowel sounds in up to 90% of patients. Fever, abdominal tenderness, and peritoneal signs are worrisome and suggest colonic ischemia or impending perforation.

The diagnosis of ACPO is made on imaging studies. CT of the abdomen and pelvis typically demonstrate proximal colon dilation with an intermediate transition zone near the splenic flexure (Fig. 1). Occasional dilation may extend to the rectum. This will exclude a mechanical obstruction. Plain abdominal films can be used to monitor interval changes of colonic dilation (Fig. 2). Contrast enemas can be hazardous and may increase the risk of perforation. Stool cultures and stool evaluation for *Clostridioides difficile* toxin should be obtained. Hypokalemia, hypocalcemia, and hypomagnesemia are common and should be corrected. The differential diagnoses include acute mechanical obstruction, toxic megacolon, and chronic intestinal pseudo-obstruction.

MANAGEMENT

Initial management of ACPO should include keeping the patient NPO, attempting decompression with nasogastric and rectal tube suction, and avoiding inciting medications such as opioids, anticholinergics, antipsychotics, cytotoxic drugs, calcium channel blockers, and clonidine (Fig. 3). Fluid and electrolyte imbalance should be corrected. Mobilizing the patient, if possible, should be considered. Positioning the patient in a prone position with hips elevated can be helpful in allowing the patient to pass gas for relief of distention. These maneuvers should be considered for 24 to 48 hours as long as the patient is undergoing frequent physical examinations and abdominal films at 12-hour intervals. The response to conservative management may vary between 20% and 92%. A surgical consultation should be obtained as soon as a diagnosis has been made to guarantee optimal care (Box 1).

When conservative management is ineffective, pharmacologic agents should be considered. The primary pharmacologic treatment of ACPO

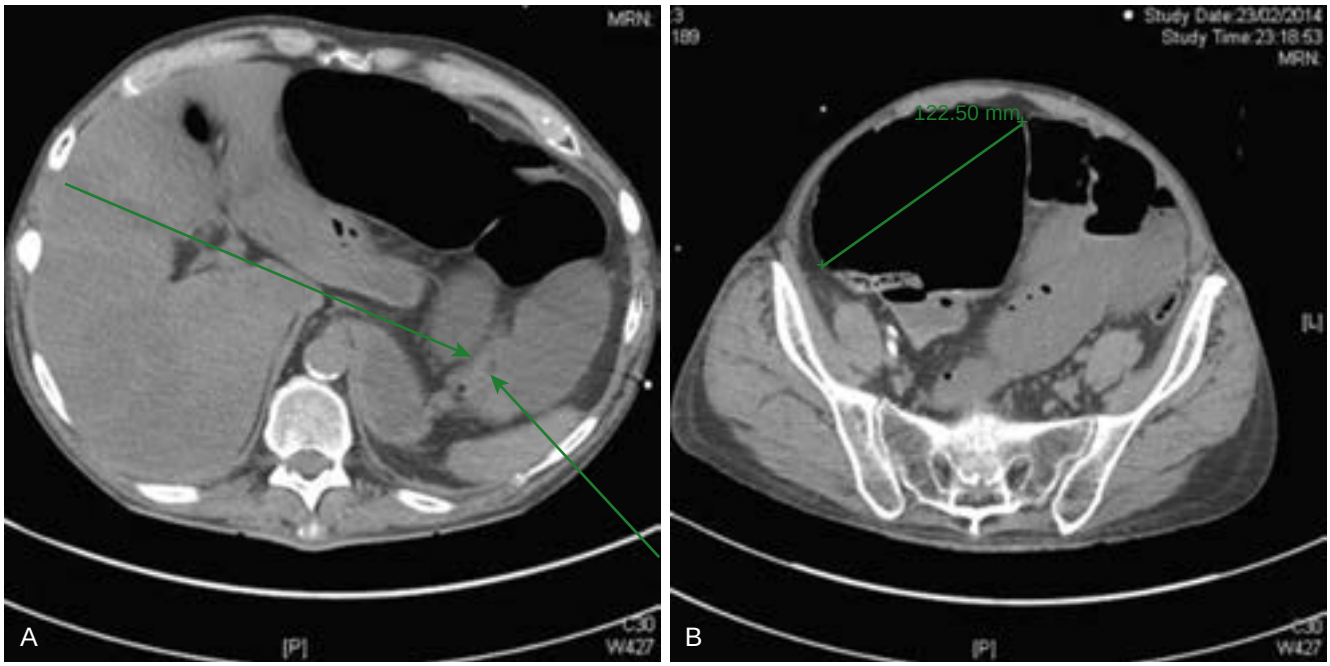

FIG. 1 CT images of colonic dilation, with arrows denoting transition point in the absence of mechanical obstruction **(A)**, consistent with Ogilvie's syndrome, and a ruler demonstrating cecal diameter at the typical threshold of concern for perforation (12 cm) **(B)**. *(From Pereira et al. Ogilvie's syndrome—acute colonic pseudo-obstruction.* J Visceral Surg. *2015;152:99–105.)*

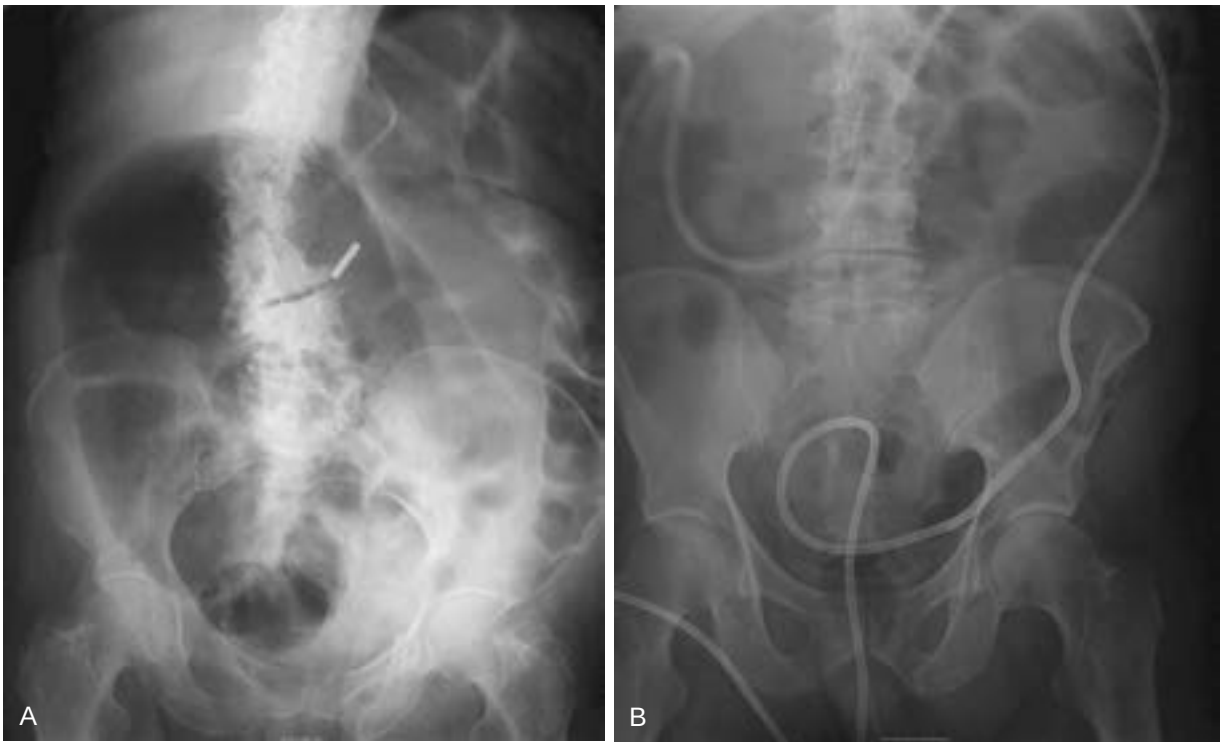

FIG. 2 Upright abdominal plain films demonstrating acute colonic pseudo-obstruction before **(A)** and after **(B)** placement of a decompression tube. *(From Saunders MD. Acute colonic pseudo-obstruction.* Best Pract Res Clin Gastroenterol. *2007;21:671–687.)*

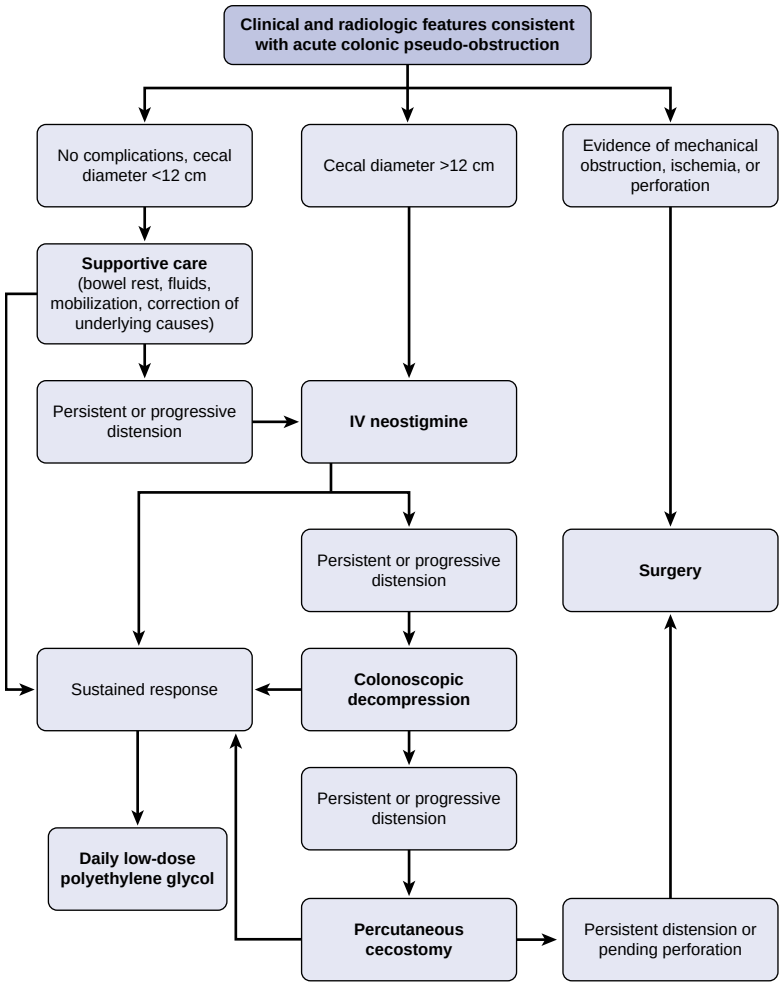

FIG. 3 Algorithmic approach to stepwise therapy in acute colonic pseudo-obstruction.

BOX 1 Conservative Management

1. Correct metabolic abnormalities
2. Follow CBC, electrolytes, serum lactate
3. Check stool for *Clostridioides difficile*
4. Decompression with nasogastric and rectal tubes
5. NPO with intravenous hydration
6. Serial imaging and physical examinations
7. Avoid opiates, anticholinergics, calcium channel blockers, and antipsychotics

is the use of neostigmine, an anticholinesterase parasympathomimetic agent. This is indicated in patients with ACPO with a cecal diameter of 12 cm who have failed conservative management. Neostigmine (2 mg) is given intravenously over a 5-minute period with constant monitoring of vital signs and electrocardiography. Patients should be supine on a bedpan as they may respond quickly with passage of gas and stool. A response will generally occur within 30 minutes. Glycopyrrolate should be available to treat bradycardia. Response to neostigmine will occur in up to 94% with the initial dose. There is a recurrence rate of about 31%. A second dose can be given no sooner than 8 hours but up to 24 hours later, which may lead to a further response of 40% to 100%. Three placebo-controlled, double-blind, randomized trials have demonstrated the effectiveness of neostigmine (Box 2).

Risk factors for neostigmine failure include male gender, younger age, electrolyte imbalance, and postsurgical status. It is recommended that regular administration of polyethylene glycol via nasogastric tube may also increase the effectiveness of treatment with neostigmine.

Neostigmine has most often been administered intravenously in a bolus, but studies have shown success with subcutaneous neostigmine or continuous infusion of 0.4 mg/h in saline over 24 hours. Subcutaneous neostigmine has been shown to result in passage of stool within a median of 29 hours. Continuous infusion of neostigmine was associated with greater bowel diameter reduction in 24 hours, and adverse events may also be diminished by continuous infusion. In one study, subcutaneous neostigmine was found to be safe and effective. Response to a bolus infusion is more rapid.

Bradyarrhythmias may occur in 5% to 10% of patients with other potential side effects being bronchoconstriction, hypotension, agitation, abdominal cramps, nausea and vomiting, salivation, and diaphoresis. Glycopyrrolate 0.4 mg may attenuate some of these side effects. Mechanical intestinal obstruction, urinary tract obstruction, or peritonitis are absolute contraindications. Particular care must be taken in patients with heart rates of <60 beats per minute, systolic blood pressure of <90 mm Hg, reactive airway disease, recent myocardial infarction, and concomitant β-blocker use. The usage of neostigmine in the setting of pregnancy has not been studied.

BOX 2 Neostigmine Therapy

1. 2 mg intravenously over 5 minutes with available glycopyrrolate or atropine
2. Consider 0.4 mg/h IV continuous infusion
3. Monitor EKG, oxygen saturation, and blood pressure
4. Adjust for renal failure if:
   - Creatinine clearance less than 50 mL/min 50%
   - Creatinine clearance of less than 10 mL/hr 75%
5. Avoid if:
   - Mechanical, intestinal, or urinary tract obstruction
   - Bradycardia less than 60 bpm or systolic blood pressure less than 90 mm Hg
   - Recent myocardial infarction
   - Peritonitis
   - β-Blocker use

Other pharmacologic agents have been used with varied response. Anecdotal reports have recommended the use of erythromycin, metoclopramide, and cisapride (not available in the United States). These drugs have yielded inconsistent results. Oral pyridostigmine, a long-acting acetylcholinesterase inhibitor, has been successful in treating some patients refractory to neostigmine. In one report, a patient was treated with methylnaltrexone, a μ-opioid-receptor antagonist. This is an option for treatment of patients who have been on opioid treatment. Prucalopride has also been reported to be successful. These drugs will require further studies before routine use can be considered.

COLONOSCOPIC DECOMPRESSION

When patients do not improve with either conservative management or infusion of neostigmine, endoscopic colonic decompression should be considered. The procedure should be done without prior preparation to decrease the risk of perforation. The risks of colonoscopic decompression include a perforation rate of 2% and mortality of 1%. The procedure can be performed without air insufflation preferably using small amounts of CO_2. Air and liquid stool can be aspirated through a large-bore suction channel. The ascending colon and cecum may not be well perfused and appear ischemic. Adequate decompression can be obtained when the colonoscope is passed to the proximal transverse colon under fluoroscopic guidance. Decompression may be effective in 50% by suction of air and liquid. Most endoscopists will pass a guidewire through the accessory channel of the colonoscope and slowly withdraw the scope under fluoroscopic guidance. A decompression tube can then be passed over the guidewire followed by low intermittent suction with saline flushes every 4 to 6 hours to decrease obstruction of the decompression tube. Repeat colonoscopy is often required due to a recurrence rate of 40%. Randomized controlled trials are not available supporting the use of decompression tubes. The use of polyethylene glycol after endoscopic decompression is recommended. There is limited data suggesting that colonoscopic decompression is superior to neostigmine infusion. Other studies suggest that both modalities are equivalent (Box 3).

PERCUTANEOUS CECOSTOMY

Among patients who are at high perioperative risk and have failed conservative, pharmacologic, and endoscopic decompression, percutaneous cecostomy (PECcecum) may be considered for colon decompression. PEC-cecum tubes can be placed endoscopically or through interventional radiology techniques with an excellent response rate. However, this is an invasive procedure with serious adverse events that include wound infection, bleeding, perforation, granuloma, and buried bumper necrosis. Such procedures should be managed by experts in interventional radiology and therapeutic endoscopy. Adequate studies of these procedures are lacking.

BOX 3 Endoscopic Decompression

1. Failure to respond to conservative management and trial of neostigmine
2. Persistent ACPO
3. Colonoscope passed to hepatic flexure or cecum
   - Avoid air-limited CO_2 infusion
   - Large bore suction of air in stool
   - Guidewire placement through accessory channel under fluoroscopy
   - Decompression tube placed over guidewire
4. Low intermittent suction
5. Flush tube with saline every 4–6 hours
6. 72-hour limit then remove tube
7. Avoid with ischemic mucosa, perforation, or peritonitis

SURGICAL THERAPY

When the previous management options are unsuccessful, surgery should be considered. These patients have a high morbidity and mortality rate with mortality in the range of 30% to 60%. Surgery may include the placement of a cecostomy tube or subtotal colectomy and stoma formation. High mortality rates are associated with those patients with ischemic disease or perforation.

SUMMARY

ACPO presents with signs and symptoms of mechanical colonic obstruction without evidence of structural lesions. It is a motility disorder that occurs primarily in hospitalized patients with comorbid medical illness or recent surgery or trauma. Diagnosis is made by performance of cross-sectional imaging. There is a high rate of complications from ischemia and perforation. Close monitoring should be done with serial imaging, bowel rest, intravenous fluids, and frequent imaging studies. If colonic distention persists or progresses, pharmacologic treatment with neostigmine should be considered followed by endoscopic colonic decompression with guided intraluminal tube placement. Further treatment may necessitate percutaneous cecostomy by experienced experts followed by either laparoscopic or open surgery. Surgery for refractory ACPO carries a high mortality rate.

Management of Colonic Volvulus

Jose G. Guillem, MD, and Jonathan M. Stem, MD

INTRODUCTION

Colonic volvulus, or a twisting of the colon on its tethered mesenteric axis, is a rare condition that accounts for less than 5% of bowel obstructions in the United States. In other regions of the world, colonic volvulus is more prevalent, accounting for up to 50% of intestinal obstructions. It most commonly occurs in the sigmoid colon, followed by the cecum. The transverse colon and splenic flexure are additional rare sites of occurrence.

SIGMOID VOLVULUS

Sigmoid volvulus is the most common form of colonic volvulus accounting for 50% to 90% of all cases. It is associated with significant morbidity and mortality, with mortality rates approaching 10%. There is a 2:1 male predominance as well as an association with increasing age. Patients typically present in the seventh decade of life or beyond. In addition to advancing age, many factors including diet, race, diabetes, pregnancy, and constipation/dysmotility increase one's risk for sigmoid volvulus. Institutionalized patients as well as those with psychiatric and neurologic disorders are at a greater risk secondary to gastrointestinal dysmotility resulting from behavioral and pharmacologic factors.

Presentation is analogous to that of any large bowel obstruction: obstipation, abdominal distention, pain, and cramping. Early in the patient's course, there is often a lack of systemic manifestations. Tachycardia, hypotension, and oliguria occur with progressive disease. In more advanced cases, characterized by ischemia and perforation, patients may present with peritonitis and sepsis. Diagnosis relies upon radiographic findings such as a "bent inner tube" or "omega loop," which are noted on plain films in 60% to 75% of patients (Fig. 1). If plain films are nondiagnostic, computed tomography (CT) will provide additional diagnostic information by demonstrating a mesenteric whirl and paucity of rectal gas (see Fig. 1). CT provides a near 100% accuracy in the diagnosis of sigmoid volvulus.

Once the diagnosis of sigmoid volvulus has been made, initial treatment may be operative or nonoperative depending upon the stability and examination of the patient. Initial management strategies aim to relieve the large bowel obstruction with either reduction of the volvulus or resection of the affected colon. Further definitive treatment is directed at the prevention of recurrence.

The initial decision point in the management of the patient with sigmoid volvulus is dictated by hemodynamic stability and physical findings. Patients who are stable, with no evidence of colonic ischemia, including fever or peritonitis, should proceed with an attempt at endoscopic detorsion. This can be accomplished by the use of a rigid proctoscope or a flexible endoscope. Rigid proctoscopy should be performed only in the setting of a lack of access to standard flexible endoscopy, as it carries a higher risk of perforation and does not afford the ability to visually inspect colonic mucosa. Upon insertion of the endoscope, a classic "pinwheel" appearance is noted at the point of torsion of the colonic mucosa (Fig. 2). With gentle pressure and insufflation, the scope should be passed through the torsed segment. The remaining colon should be endoscopically decompressed, ultimately allowing for detorsion of the colon. Rates of successful endoscopic detorsion are variable, ranging from 55% to 94%. After detorsion, we prefer to leave a soft red-rubber catheter in the colon to allow for continued decompression and prevention of a short-term recurrence of the volvulus.

After successful detorsion of the sigmoid volvulus, the focus moves to prevention of recurrence, which can occur in up to 85% to 90% of cases. Measures aimed to prevent recurrence of sigmoid volvuli historically consisted of two main strategies: colonic fixation and resection. There have been numerous methods of colonic fixation described; however, these are typically not recommended as many carry a significant risk of recurrence. In spite of this, there may be a role for their use in highly selected cases.

The current gold standard approach for the prevention of recurrent sigmoid volvulus is sigmoid colon resection with primary anastomosis. Because morality rates are as high as one in three with recurrent volvulus, it is recommended that elective resection be

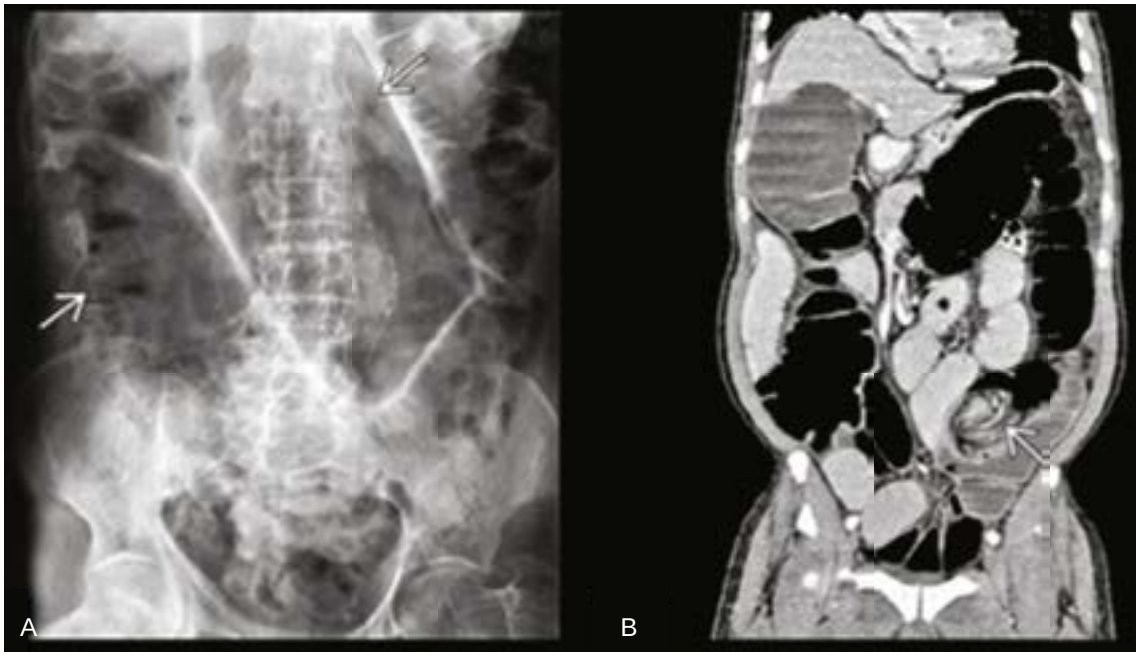

FIG. 1 (A) Plain film abdominal radiograph demonstrating the classic "bent inner tube" sign of sigmoid volvulus directed towards the right upper quadrant. **(B)** Coronal CT image displaying a mesenteric whirl characteristic of sigmoid volvulus. *(From Federle M, Lau, J. Sigmoid Volvulus. In:* Imaging in Abdominal Surgery. *Elsevier; 2018, 282.)*

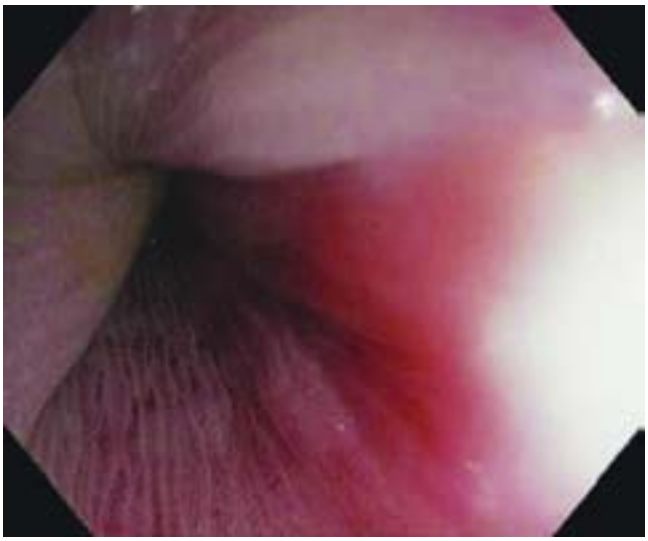

FIG. 2 Classic pinwheel appearance of colonic mucosa visualized during endoscopic decompression of sigmoid volvulus. *(From Tang S-J, Wu R. Endoscopic decompression, detorsion, and reduction of sigmoid volvulus. Video J Encyclopedia GI Endos. 2014;2:22.)*

performed during the index hospitalization. Both open and minimally invasive laparoscopic or robotic techniques are acceptable. When performing an open resection, a lower midline laparotomy or Pfannenstiel incision will typically suffice. Resection with end colostomy and Hartmann's pouch, as well as primary anastomosis with diverting loop ileostomy, are additional acceptable options that may be used when severe colonic edema is encountered. In all cases of sigmoid resection, a nononcologic resection is performed, ligating the sigmoid mesentery close to the bowel. Recurrence after sigmoidectomy for volvulus is extremely rare. One specific setting in which recurrence rates remain high after sigmoidectomy, however, is in patients presenting with megacolon. Recurrence rates after sigmoidectomy in megacolon are greater than 80%. In this circumstance, consideration may be given to subtotal colectomy. One caveat is that the patient's ability to tolerate such an operation must be thoroughly considered.

In contrast to clinically stable patients, those presenting with signs of ischemia, perforation, sepsis, or evidence of shock should proceed with emergent surgical intervention as should those that fail attempted endoscopic detorsion. After initial resuscitation and administration of broad-spectrum antibiotics, a midline laparotomy should be performed with resection of the ischemic or perforated segment of bowel. Compromised bowel should not undergo detorsion before resection. In the setting of perforation, copious irrigation of the abdomen with saline is performed. After resection of the specimen, two options may be considered at the time of initial operation: primary anastomosis versus end colostomy with a Hartmann's pouch. The decision to restore gastrointestinal continuity is dependent upon intraoperative findings and patient-specific factors. Proximal bowel dilatation, fecal contamination, and the presence of ongoing hemodynamic abnormalities must be weighed when deciding upon restoration of continuity. Additional patient factors such as nutritional, functional, and frailty status must be taken into account. Surgical resection in the emergent setting is associated with higher rates of mortality. This should be addressed with patients and family at the time of initial presentation.

CECAL VOLVULUS

The second most frequent type of colonic volvulus is the cecal volvulus, which accounts for 10% to 40% of colonic volvulus cases. In general there are two types of volvuli that can occur in the cecum. The most common is characterized by an axial twisting of the cecum and accounts for up to 90% of cases. In this type, the cecum rotates around its long axis forming a clockwise twist, leaving the cecum in the right lower quadrant. The less common type is not a true volvulus but rather a folding of the cecum upon itself directed toward the hepatic flexure, known as a *bascule.* Overall this accounts for only 10% of reported cases.

Although a mobile cecum predisposes one to volvulus, factors and conditions often noted in patients presenting with cecal volvulus include chronic constipation, psychiatric illness, high fiber

FIG. 3 **(A)** Plain film abdominal radiograph demonstrating the classic "coffee bean" sign of cecal volvulus, with the axis directed toward the left upper quadrant. **(B)** Coronal CT image revealing distended, upside-down, backward cecum with the ileocecal valve pointed lateral. *(From Federle M, Lau J. Cecal Volvulus. In:* Imaging in Abdominal Surgery. *Elsevier; 2018, 283.)*

diet, chronic laxative use, pregnancy, and prior abdominal surgeries. Cecal volvulus has a slight female predominance of 1.4:1.

The presentation of cecal volvulus is variable and nonspecific. Patients may present in a chronic or acute manner. Symptoms may be mild and intermittent including dull, crampy abdominal pain and constipation. Other common signs and symptoms are obstipation, severe pain, and nausea/vomiting. Radiographic workup is essential in all suspected volvulus patients. In very few cases, plain film abdominal x-rays will be diagnostic. Plain film radiographs diagnostic of cecal volvulus will reveal a large, dilated loop of colon with a classic "coffee bean" sign pointing to the left upper quadrant (Fig. 3). Most often there will be an associated paucity of rectal gas. CT scan provides the added benefit of assessing bowel for ischemia or signs of impending ischemia. Intestinal thickening, hypoenhancement of the bowel wall, pneumatosis, and abdominal free fluid should prompt more urgent operative intervention.

Similar to sigmoid volvulus, patients presenting with signs of cecal ischemia, perforation, or shock should immediately undergo aggressive fluid resuscitation, administration of broad-spectrum antibiotics, and proceed to the operating room for emergent intervention. Surgical intervention in the emergent setting consists of an ileocolic resection or right hemicolectomy, ensuring resection of the compromised segment. Primary anastomosis at the time of the initial operation will be dependent on many patient-specific factors including hemodynamics, comorbidities, fecal contamination, and local inflammatory changes.

For patients who present without signs of acute shock or perforation, surgical intervention, although not emergent, remains urgent in nature. Unlike sigmoid volvulus, endoscopic reduction is not recommend because attempts are unlikely to be successful (approximately 30% success rate) and may lead to perforation. Initial operative management consists of assessment of bowel viability. This should be done via laparotomy. Minimally invasive techniques are hindered by the gross distension of the cecum and proximal small bowel. Upon laparotomy and inspection of the abdomen, necrosis of the cecum is a common finding necessitating resection with consideration of primary anastomosis. If no necrosis is detected, a right hemicolectomy or ileocolic resection with a side-to-side stapled anastomosis is typically performed.

In the absence of necrosis, nonresection techniques such as detorsion with or without cecostomy and cecopexy have been described in the literature. These techniques are not recommended, however, due to their high recurrence rates as well as high morbidity and mortality. Both cecostomy and cecopexy are reserved for patients who are poor resection candidates due to their underlying comorbid conditions or physiologic status. It is important to assess the quality of the bowel wall when considering these strategies. The fragile or edematous tissue typically associated with cecal volvulus is a poor candidate for holding suture. This can ultimately lead to complications such as leak and failure of apposition to the abdominal wall or retroperitoneum.

Rare Types of Volvulus

Sigmoid and cecal volvuli account for the majority of colonic volvulus with other types of volvuli occurring in rare instances. Transverse colon and splenic flexure volvuli account for 2% to 5% of all colonic volvulus cases. Typically, these occur in a younger patient population with an increased incidence in women. Similar to other forms of volvulus, predisposition to transverse colon and splenic flexure volvuli is due to conditions that elongate the colon and its mesentery. These include high fiber diet, chronic constipation, and colonic obstruction. Additionally, the loss of the traditional attachments of the colon due to abdominal surgery is associated with increased rates of splenic flexure volvulus.

Patients will present in a similar manner to other types of volvulus, with either acute symptoms of large bowel obstruction or more chronic and intermittent symptoms. Diagnosis is rarely made by using plain films alone. Splenic flexure volvulus is characterized by a "coffee bean" sign in the left upper quadrant on abdominal x-ray. Conversely, volvulus of the transverse colon can be characterized by an "inverted coffee bean" sign. Additionally, two distended loops of colon and a paucity of rectal gas may be visualized. CT imaging provides improved diagnostic capability and will reveal a mesenteric whirl. Oftentimes, laparotomy is required to determine the location of the whirl and volvulus. Due to the rarity of the condition, diagnosis is delayed in many instances, leading to high mortality rates.

Treatment of these rare types of volvulus is similar to that of cecal volvulus. Endoscopic decompression should not be attempted because recurrence rates are high. The initial step in treatment is laparotomy with assessment of bowel viability. Noncompromised bowel may be detorsed before resection. The extent of the resection depends upon the location of the volvulus. Options for resection consist of extended right hemicolectomy or a segmental resection.

Determination of primary anastomosis versus end colostomy will depend upon patient-specific factors and operative findings.

One other form of volvulus is ileosigmoid knotting, which is exceedingly rare in Western society. This occurs when a loop of ileum becomes entangled with the sigmoid colon leading to obstruction. There are three major types of ileosigmoid knotting. Type 1, accounting for approximately 50% to 60% of cases, occurs when a portion of ileum encircles the sigmoid colon. Type 2 accounts for approximately 20% of cases and is characterized by wrapping of the sigmoid colon around a loop of ileum. In both type 1 and type 2, wrapping can occur in a clockwise or counterclockwise fashion. Type 3, a rare entity, consists of the ileocecal segment wrapping around the sigmoid colon. The remaining cases are of indeterminate anatomy.

Most commonly, ileosigmoid knotting occurs in males (approximately 80%) in the late third or fourth decade of life. The true incidence is unknown, and the majority of case reports are from Asia, Africa, and the Middle East. Clinical presentation consists of abdominal pain and tenderness with associated symptoms of small bowel obstruction such as distention, nausea, and emesis.

Diagnosis can be challenging as radiographic imaging will reveal dilated loops of small bowel accompanied by a distended sigmoid loop. Abdominal plain films alone are rarely diagnostic. In addition to bowel dilatation, CT imaging will reveal whirling of the ileal and sigmoid mesentery with associated medial deviation of the cecum and left colon. Ileosigmoid knotting may be confused for sigmoid volvulus on imaging prompting attempted endoscopic decompression. In these cases, endoscopic decompression will fail due to the wrapping of the mesentery, further raising the suspicion for ileosigmoid knotting.

After initial resuscitation, emergent laparotomy is indicated because clinical deterioration is often rapid due to the quick progression of knotted bowel segments to ischemia. In fact, upon operative exploration, gangrenous bowel is discovered in more than 70% of cases. Operative management will vary depending on the nature of the ileosigmoid knot as well as the stability and condition of the patient. As the majority of cases present with gangrene, resection is typically performed. In many cases, multiple resections are necessary. In the event that a viable sigmoid colon is encountered, resection is recommended to prevent further recurrence. The decision to perform primary anastomosis versus enteric diversion will depend upon many factors.

SUMMARY

Colonic volvulus is a rare entity in the United States, accounting for <5% of all intestinal obstructions. In spite of this, a high index of suspicion must be present as prompt surgical evaluation is a necessity. Clinical presentation is quite variable, ranging from chronic mild symptomatology to acute obstruction and shock. Only in the case of sigmoid volvulus is initial endoscopic decompression appropriate. Definitive treatment consists of operative intervention. Although techniques without resection are described in rare specific circumstances, colonic resection is considered the gold standard to alleviate obstruction and prevent future recurrence. Operative decision making regarding performance of primary anastomosis must be decided on an individualized basis and is impacted by many patient-specific factors as well as surgeon experience and comfort.

Management of Rectal Prolapse

Shannon N. Radomski, MD, and Alodia Gabre-Kidan, MD, MPH

ETIOLOGY

Rectal prolapse is defined as a prolapse of either the full or partial thickness rectal wall through the anus beyond the anal verge. Prolapse that does not go beyond the anal verge—internal prolapse or intussusception—is managed differently and will not be discussed in this chapter.

Rectal prolapse is far more common in women than in men and has a peak incidence in the sixth or seventh decade of life. In these patients, rectal prolapse can coincide with prolapse or dysfunction of other pelvic floor organs indicating an underlying etiology of pelvic floor weakness, which in women is often from multiparity. However, rectal prolapse can also occur in men and nulliparous women suggesting a different etiology related to constipation and/or straining due to disordered defecation.

Although rectal prolapse relies on surgical correction as the mainstay of treatment, it is important to recognize that the causative factors for each patient may differ, and adjunctive treatments such as pelvic floor physical therapy, consultation with urogynecologists, and bowel modifications should be employed to optimize the success of any surgical repair.

PRESENTATION

Patients with rectal prolapse can present with a number of different symptoms. Most commonly patients describe prolapse of tissue that spontaneously reduces or has to be manually reduced, rectal pressure or discomfort, bleeding, mucus drainage, constipation or inability to fully evacuate, fecal urgency, or fecal incontinence. Prolapse can be a significant source of stress for patients, and many describe limiting their activities to be near a bathroom or planning their days to accommodate for bowel habits.

Constipation can be both a cause of the rectal prolapse and a result of it. Disordered defecation/pelvic floor dyssynergia leads to increased straining, which can result in a prolapse, especially in patients who do not have risk factors for pelvic floor weakness. Once the prolapse becomes recurrent, it can act as a mechanical obstruction making evacuation even more difficult and lead to an increase in the behaviors (straining, increased toilet time) that will worsen the prolapse. This is a point of debate as many feel that it is not the mechanical obstruction of the prolapse but the ongoing, unaddressed

pelvic floor issues that worsen the prolapse. With chronic prolapse, fecal incontinence can also occur from the rectal prolapse stenting open the sphincter complex and allowing feces to leak. Over time, however, chronic stretch of the sphincter complex by the prolapsed segment of rectum can lead to irreversible impairment in continence. It is important to discuss this with patients before repair in order to appropriately set expectations. Surgical repair of the prolapse will address the mechanical issue but may not result in a return to their functional baseline.

EVALUATION

Any patients presenting with rectal prolapse should have a thorough pelvic floor history and physical examination. It is important to obtain a detailed history including onset of symptoms, bowel habits, prior obstetrical history, prior anorectal surgery, associated pelvic organ symptoms (urinary incontinence, frequency, prolapse, rectocele, etc.), and colonoscopy history. Physical examination for rectal prolapse can occur in the left lateral or prone jack-knife position. External visual examination can yield important information such as presence of fecal smearing, mucus drainage, skin irritation or breakdown from moisture, a patulous anus, and presence of any prolapsed tissue at rest. The patient is then asked to bear down. If the prolapse cannot be elicited with Valsalva in the left lateral or prone jack-knife positions, the patients should be asked to Valsalva in a seated position on the commode. If the prolapse still cannot be elicited, photographs of the prolapse as it occurs at home can be helpful and/or further testing such as defecography can be pursued. Hemorrhoidal prolapse is far more common than true rectal prolapse and patients often cannot distinguish between the two; thus it is important for the surgeon to visualize the prolapsed tissue themselves. Full thickness rectal prolapse appears as concentric rings/circles as the rectum telescopes out of the anus while hemorrhoidal prolapse creates radial lines from the center of the anus as the hemorrhoidal columns prolapse out. Partial thickness, or mucosal, prolapse can also occur and appears as a shorter segment of prolapsed rectum lacking the radial lines of hemorrhoidal prolapse. The treatment of mucosal prolapse differs from full thickness prolapse, thus distinguishing between the two is important to guide future interventions. It is also important to document anal sphincter tone during the examination as well as presence or absence of any associated vaginal prolapse. For patients with multicompartmental prolapse, a combined approach with a urogynecologist is favored to address all potential issues during one surgery as opposed to requiring the patient to undergo multiple surgeries.

MANAGEMENT/SURGICAL APPROACH

When considering repair of a rectal prolapse, there are several decision points that can aid in the ultimate choice of approach. First and foremost, acutely incarcerated prolapse must be recognized because this constitutes a surgical emergency. Similar to an incarcerated hernia, the prolapsed bowel can become ischemic if not reduced in a timely fashion. Temporizing measures such as applying sugar to the mucosa of the prolapsed segment of rectum can be used in cases where the bowel is edematous but not ischemic. If the bowel still will not reduce after application of sugar, then urgent surgical repair must be considered. In the setting of acute incarceration that cannot be reduced, a perineal rectosigmoidectomy is most prudent as it ensures that all compromised rectum is excised. Abdominal approaches can be used if ischemia is not present and the rectum reduces with induction of anesthesia and relaxation of the sphincter complex. Fortunately, acute incarceration is relatively rare owing to the stretch of the sphincter over time. As the sphincter is stretched by chronic prolapse, the likelihood that it will be constricting and not allow the rectum to be reduced is lowered.

Putting emergent indications aside, the majority of rectal prolapse repairs will occur in the elective setting. The approach to repair will need to take the degree of prolapse (full thickness vs. partial thickness), patient factors (comorbidities, prior surgery), and associated pelvic floor pathology into account. There are six widely used approaches to prolapse outlined in Figure 1, not taking into account the choice of open, laparoscopic, or robotic approaches to abdominal procedures. Thiersch wire procedures will not be discussed as they are largely of historical interest with high rates of complications.

PARTIAL THICKNESS PROLAPSE

Mucosal Sleeve Resection

The first decision point is whether the patient is experiencing a partial or full thickness prolapse. Partial thickness prolapse is repaired with a perineal approach using a Delorme procedure. This is a mucosal sleeve resection, which excises the redundant mucosa and sutures it back to the anal transition zone just proximal to the dentate line (Fig. 2). Of note, this procedure can also be used in short segment (<5 cm) full thickness prolapse. After the patient is positioned, the rectum is retracted out to reproduce the maximum amount of prolapse. A solution of saline mixed with epinephrine is injected into the submucosal layer both to lift it off of the underlying muscular layers but also to aid with hemostasis. A circular incision is created just proximal to the dentate line with electrocautery and carried down to this submucosal layer. In a patient with full thickness prolapse, plicating sutures would then be placed through the muscularis to accordion the rectum back to the anal canal. These are typically placed in four quadrants to offset the sutures to account for the mesorectum. The redundant mucosa is then amputated, and the remaining mucosa is sutured back to the proximal resection point.

FULL THICKNESS PROLAPSE

The options for repair of full thickness prolapse are separated into abdominal or perineal approaches (see Fig. 1). Traditionally we recommend a perineal approach to elderly or frail individuals as it avoids the physiologic stress associated with a major abdominal surgery and, in patients who are unfit for general anesthesia, can be done under regional anesthesia. In fact, Altemeier was not the first person to describe this technique, but his paper in 1952 described his experience using this approach in elderly, high-risk patients and was the beginning of the association of age and comorbidities with a perineal approach. However, this dogma is challenged by the evolution of better anesthetic techniques and the use of minimally invasive surgical techniques with relatively low rates of complications and faster recovery. Still, however, for some patients with full thickness prolapse who may be unacceptably high risk for an abdominal approach or have had multiple prior abdominal surgeries, a perineal approach is a good option.

Perineal Rectosigmoidectomy

Unlike a Delorme procedure, a perineal rectosigmoidectomy, or Altemeier procedure, is a full thickness resection and coloanal anastomosis. Once the patient is in position, the rectum is again prolapsed out to its maximum amount and a full thickness incision is made through the rectal wall about 1 to 2 cm proximal to the dentate line. This is carried around circumferentially and the pelvis is typically entered anteriorly between the rectum and vagina/prostate by dividing the peritoneal attachments to enter the pouch of Douglas. The lateral ligaments are similarly divided using an energy device to ensure hemostasis. The rectum and sigmoid colon are then prolapsed out by taking posterior attachments and vessels of the mesorectum and mesocolon until the colon cannot be prolapsed any further. The full thickness colon wall is then divided making sure to take the mesocolon at this level so as to not devascularize the segment that will become part of the anastomosis. It is important to place anchoring, full thickness sutures through the colon wall as it is circumferentially divided as it can retract back into the abdomen without

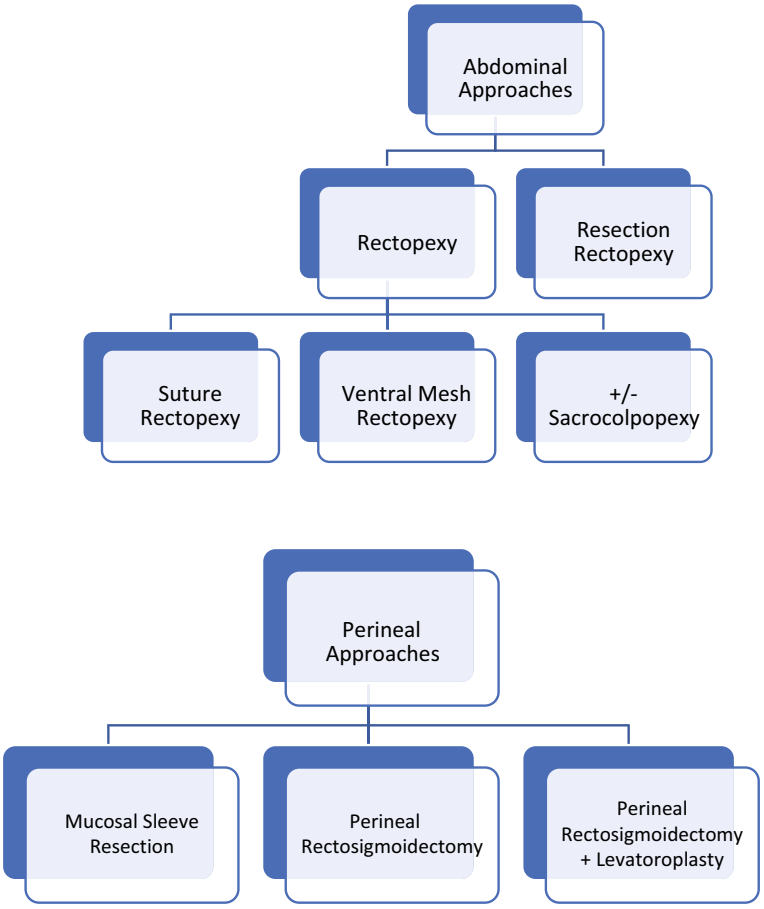

FIG. 1 Approaches to rectal prolapse.

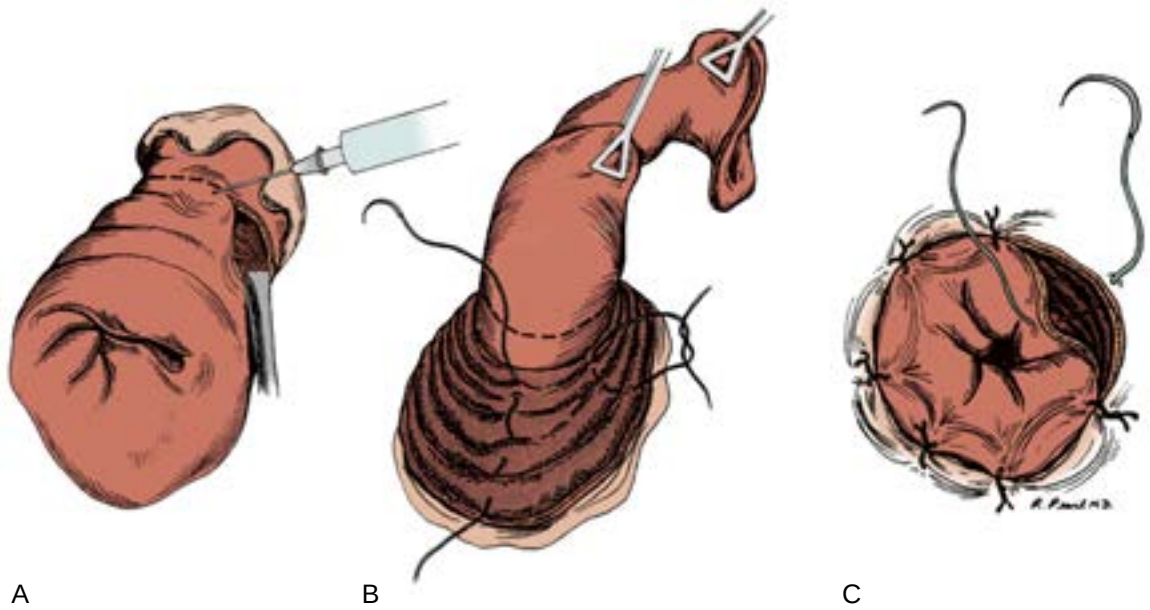

FIG. 2 Mucosal sleeve resection. **(A)** Injection of saline mixed with epinephrine to life submucosal layer. **(B)** Plication of muscularis and division of redundant mucosa. **(C)** Handsewn anastomosis. *(From Doane S, Yeo C. Shackelford's* Surgery of the Alimentary Tract, *Vol. 2. 2019:1097–1112.)*

them. At this point, if the patient had preoperative incontinence and has a wide levator hiatus, a posterior levatorplasty can be performed with interrupted sutures to narrow the levators. This can also be performed anteriorly for very wide defects, but care must be taken not to incorporate the anterior structures or make the opening too narrow. The coloanal anastomosis can be performed in a handsewn or stapled fashion depending on preference. For a stapled approach, the anvil of the stapler is placed in the proximal colon and a purse

string is sewn around the anal canal through which the stapler would be placed. Some surgeons advocate for the creation of a small colonic J-pouch to act as a reservoir, but a straight coloanal anastomosis with levatorplasty is an option as well to help with incontinence as a result of chronic stretch of the sphincter complex.

Abdominal Approaches

There are two main abdominal procedures for rectal prolapse: rectopexy or resection rectopexy. These can be accomplished via open, laparoscopic, or robotic approaches, and in a resection rectopexy the surgeon would perform a sigmoid colectomy in conjunction with their chosen rectopexy technique. Centered around this decision point is the debate as to whether resection rectopexy offers an advantage over rectopexy alone. Advocates of resection rectopexy argue that a redundant sigmoid colon contributes to constipation, which then leads to the prolapse. Advocates of a rectopexy alone argue that segmental resection is not an adequate operation for constipation and adding a resection increases the potential for complications, especially in frail patients. This was studied as one arm of the PROlapse Surgery PErineal or Rectopexy (PROSPER) trial that is still, to date, the largest randomized trial comparing approaches to rectal prolapse. In this study, there was no significant difference in recurrence between patients undergoing a resection rectopexy versus suture rectopexy alone, although the main limitation was inadequate sample size to power all comparisons.

The next decision point is in the technique used for the rectopexy. The most common technique is a suture rectopexy, but ventral mesh rectopexy is gaining in popularity for a number of reasons that will be discussed.

Suture Rectopexy

The goal of suture rectopexy is to fully mobilize the rectum down to the levator muscles and restore its anatomic position by suturing it to the sacral promontory to allow further scarring and fibrosis to occur to fix the rectum back in place. Whether this is accomplished in an open, laparoscopic, or robotic approach depends on surgeon experience. The rectum is fully mobilized by incising the peritoneum at the sacral promontory, and this dissection is carried down to the levator muscles posteriorly. It is important to note that the surgeon should not divide lateral stalks of the rectum close to the rectal wall but rather leave peritoneal "wings" to suture back to the sacral promontory. Care must be taken to avoid injury to the hypogastric nerves when performing this posterior dissection. Once the rectum is fully mobilized, the lateral stalks are placed on tension to bring the rectum back to its anatomic position and suture it to the sacral promontory on both sides with nonabsorbable suture or tacks if using a minimally invasive approach. The sutures should be placed lateral to the hypogastric nerves and medial to the ureter and, once they are tied down, should not narrow the rectum or place it at a sharp angle, which will make evacuation difficult postoperatively. Potential areas for concern postoperatively include increased constipation due to division of lateral stalks and compromise of nervous innervation running within them as well as potential for sexual dysfunction in men due to the extensive posterior mobilization with increased risk of nerve damage. Many surgeons advocate for a perineal approach to full thickness prolapse in men to avoid these areas of potential nerve damage altogether.

Ventral Mesh Rectopexy

There have been many approaches to rectal prolapse that involve the use of mesh either as a material to fix the rectum to or as a sling/wrap to return the rectum to its usual position in the pelvis. A ventral mesh rectopexy avoids the posterior dissection and division of the lateral stalks that are worrisome in a suture rectopexy and relies on an anterior fixation. Similar to a suture rectopexy, the peritoneum is incised over the sacral promontory taking care to avoid the hypogastric nerves and iliac bifurcation. This is only performed on one side of the rectum, typically the right side. This dissection is carried down laterally and into the rectovaginal septum with a complete dissection anteriorly to the pelvic floor (Fig. 3). A strip of mesh is cut and placed into the space between the rectum and

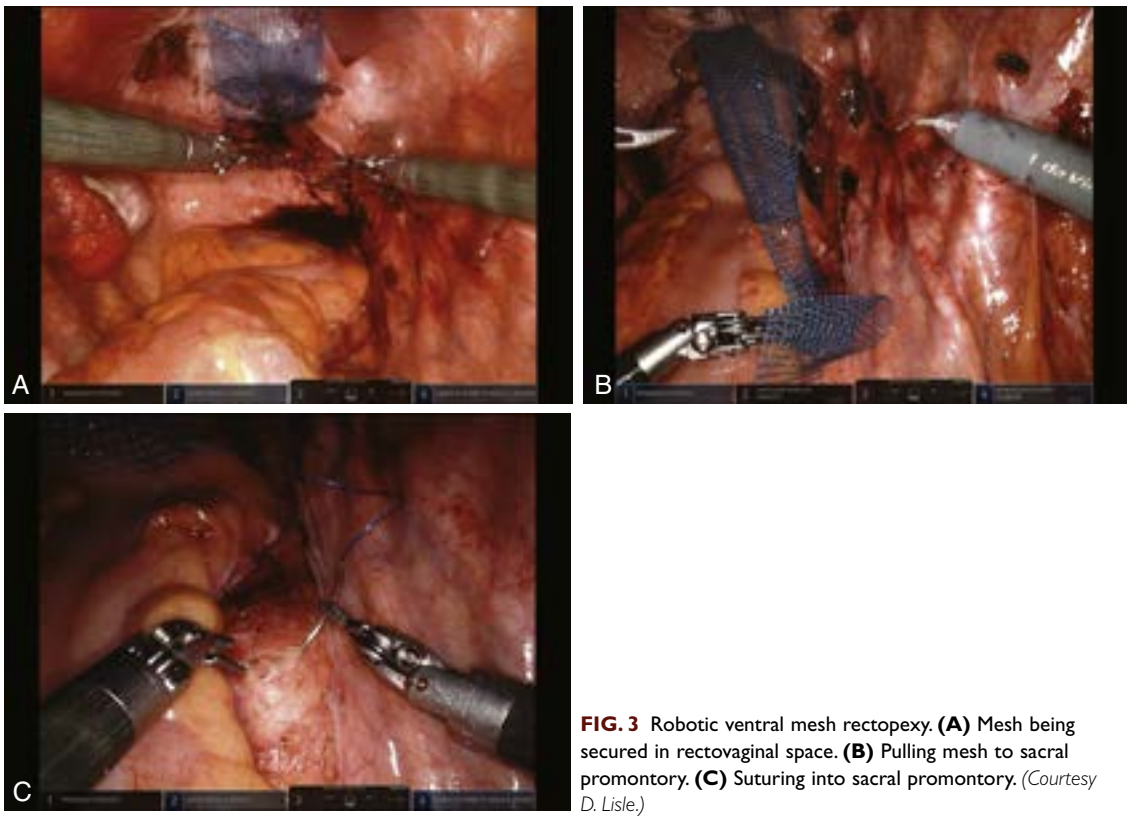

FIG. 3 Robotic ventral mesh rectopexy. **(A)** Mesh being secured in rectovaginal space. **(B)** Pulling mesh to sacral promontory. **(C)** Suturing into sacral promontory. *(Courtesy D. Lisle.)*

vagina and sutured to the anterolateral rectal wall on either side of the rectum also incorporating a small amount of pelvic floor musculature into sutures. The mesh is then stretched to the sacral promontory and tacked or sutured to the right side of the promontory after it has been adequately cleared. The peritoneum that has been incised laterally is usually then sutured back to itself to cover the mesh if possible.

Advantages to ventral mesh rectopexy include lack of a posterior mobilization and potential autonomic nerve injury, as well as the ability to address multicompartmental prolapse in a combined approach with our female pelvic medicine and reconstructive surgery (FPMRS) colleagues. Potential complications include mesh erosion and/or infection, which has motivated some surgeons to use biologic mesh instead of synthetic mesh. Regardless, rates of erosion even with synthetic mesh are quite low and reported to be anywhere between 2% to 4%. There have not been many studies to determine if there is a difference between recurrence rates using biologic versus synthetic mesh, but in a recent meta-analysis by Lobb et al. of suture rectopexy versus ventral mesh rectopexy, there was no statistically significant difference in recurrence between the two groups.

Recurrent Prolapse

The complication that is an inherent risk of any rectal prolapse repair is recurrence. Data in the literature vary widely depending on the degree of prolapse present preoperatively, the approach, and patient factors. The widely accepted dogma that perineal approaches lead to higher rates of recurrence has been challenged with the results of the PROSPER trial showing that there was no statistically significant difference in recurrence between perineal and abdominal approaches. However, this trial also showed recurrence rates between 13% and 31%. This is much higher than the averages reported in the literature, which are typically below 10% to 15% and are likely a reflection of specialization of surgeons and a multidisciplinary approach to pelvic floor dysfunction.

The most important factor to consider in the approach to a recurrent rectal prolapse is the type of repair the patient underwent previously. Every effort should be made to obtain previous operative records. The biggest mistake that can be made is to inadvertently leave behind a segment of devascularized colon. This can only happen in patients who had a previous resection via a resection rectopexy or perineal rectosigmoidectomy. In these patients, the safest approach is a rectopexy as it does not involve any further resection and potential for vascular compromise. In patients who had a previous perineal rectosigmoidectomy, a repeat perineal rectosigmoidectomy can be performed provided that their previous anastomosis is fully resected.

CONCLUSION

Rectal prolapse is a debilitating disease that can be successfully treated with a thoughtful surgical approach. Many factors including presenting symptoms, patient comorbidities, bowel function, and degree of prolapse must be considered as there is no single superior approach that will be successful for every patient. However, with the right surgical approach and technique, patients can experience a drastic improvement in their quality of life and often even a return to their preoperative functional baseline.

Surgical Management of Constipation

Nathalie Mantilla, MD, and Jose R. Cintron, MD

Healthy bowel habits are those considered regular, soft formed consistency, and without the need for excessive straining. However, they may vary in frequency and consistency from one person to another and still be considered normal. Constipation is a common condition defined by fewer than three bowel movements per week, hard stools requiring excessive straining to pass, and/or sensation of incomplete emptying after defecation. Chronic constipation is classified as functional (primary) or secondary. Functional constipation subtypes are based on the etiology: slow-transit constipation (colonic dysmotility), normal transit constipation, and/or obstructed defecation syndrome (pelvic floor dysfunction, rectal hyposensitivity, organ prolapse, internal intussusception). Secondary chronic constipation may be related to medications and/or medical conditions (neurologic or endocrine problems, irritable bowel syndrome, etc.).

Constipation affects approximately 15% of the population worldwide and is a common cause of visits to gastroenterologists and colorectal surgeons. Despite its benign nature, it can be quite debilitating and can significantly impact the quality of life of those who suffer from it.

ANATOMY AND PHYSIOLOGY

Normal defecation is a multistep physiologic process that involves various organs. Colonic mucosa and musculature play an important role in stool formation through a proper balance between water absorption and bowel motility. Coordination of the pelvic floor and abdominal muscles is required in the final steps of stool elimination. Colonic peristalsis helps advance the stool bolus distally as it thickens inside the bowel lumen. Once feces reach the rectum, distention of the rectal wall and feedback from specialized cells in the proximal anal canal will aid distinguishing between gas, solid or liquid stools, and facilitates evacuation when socially acceptable. This process requires coordination between autonomic and somatic nervous system functions.

DIAGNOSIS

Clinical Assessment

A thorough evaluation is required for patients with suspected constipation, including an in-depth interview discussing associated symptoms (such as rectal bleeding, weight loss, changes in stool caliber, etc.) medical, surgical, and family history medications, diet, toilet habits, and so on. Characteristics of the stools should be discussed, including consistency (Bristol stool form scale, Fig. 1), caliber, and frequency. It is also crucial to know the onset and duration of symptoms. Reported symptoms are useful to distinguish the type of constipation. Infrequent hard stools refer more to cases of colonic dysmotility, whereas patients with pelvic floor dysfunction and obstructed defecation syndrome complain more of incomplete evacuation and straining. Abdominal pain that alleviates after defecations may indicate irritable bowel syndrome (Box 1). Evaluation of events occurring at the onset of symptoms may identify causes or contributing factors such as new diagnoses or medications. For example, hypercalcemia, hypothyroidism, neurologic problems, psychosocial issues, the use of opioids, antidepressants, anticholinergics, calcium channel blockers, and calcium supplements are among some common conditions and medications to look for when taking the history. Unfortunately, in many cases of constipation, no cause is identified. A focused abdominal and pelvic physical examination is critical, which should include external inspection followed by digital rectal examination, including evaluation of anal tone, presence of stools, and puborectalis muscle. In women, vaginal examination may be necessary when rectocele is being ruled out. Rome criteria are used to identify constipation and its subtypes but do not assess severity of the condition (Box 2). Complementing the clinical evaluation with validated instruments may help to distinguish the type of constipation, impact on quality of life, and the need to pursue additional diagnostic testing. Multiple questionnaires have been made available to assess the severity of constipation and to follow up on the response to treatment.

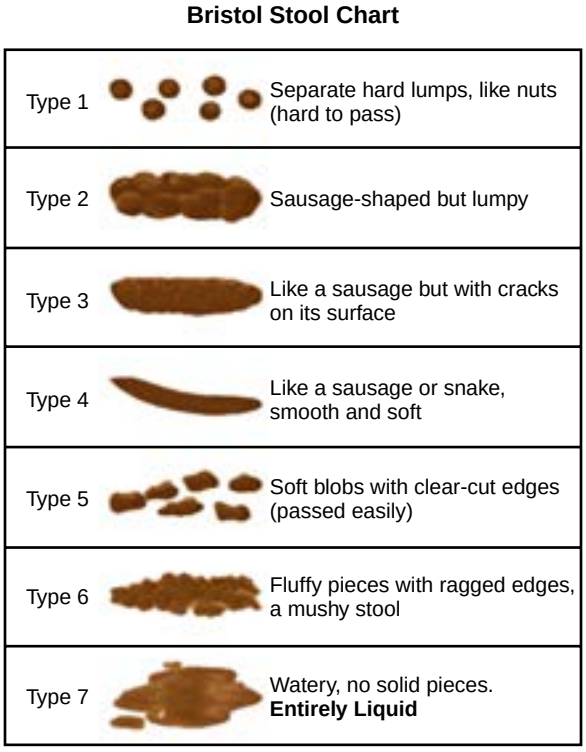

FIG. 1 Bristol stool form scale. *(From Lewis SJ, Heaton KW. Stool Form Scale as a Useful Guide to Intestinal Transit Time. Scand J Gastroenterol. 1997;32[9]:920–924.)*

BOX 1 Rome IV Criteria for IBS-C

Recurrent abdominal pain, on average, at least 1 day per week in the past 3 months, associated with two or more of the following criteria:

- Related to defecation
- Associated with a change in frequency of stool
- Associated with a change in form (appearance) of stool
- Criteria fulfilled for the last 3 months with symptom onset at least 6 months before diagnosis
- Patient reports that abnormal bowel movements are usually constipation (such as type 1 or 2 Bristol stool form scale)

IBS-C, Irritable bowel syndrome with predominant constipation.
From Lacy BE, Mearin F, Chang L, et al. Bowel disorders. *Gastroenterology.* 2016;150(6):1393–1407.

BOX 2 Rome IV Criteria for Functional Constipation

Requires two or more of the following:

- Straining with more than 25% of defecations
- Lumpy or hard stools (Bristol stool form scale 1 or 2) more than 25% of defecations
- Sensation of incomplete evacuation more than 25% of defecations
- Sensation of anorectal obstruction/blockage more than 25% of defecations
- Manual maneuvers to facilitate more than 25% of defecations (such as digital evacuation or support of the pelvic floor)
- Fewer than three spontaneous bowel movements per week

Plus:

- Loose stools are rarely present without the use of laxatives
- Insufficient criteria for irritable bowel syndrome
- Criteria fulfilled for the last 3 months with symptom onset at least 6 months before diagnosis

From Lacy BE, Mearin F, Chang L, et al. Bowel disorders. *Gastroenterology.* 2016;150(6):1393–1407.

Following screening recommendations or the presence of alarming symptoms, a colonoscopic evaluation should be included to rule out intraluminal lesions, strictures, or any other underlying conditions. Adjunct blood tests to rule out endocrine disorders should be included when clinically indicated (thyroid and parathyroid function, diabetes, etc.).

Radiologic Testing

Sitz Marker Study (Radiopaque Marker Study)

In cases where colonic transit requires further investigation, radiopaque markers, scintigraphy, or wireless motility capsules can be used. The sitz marker study is simple, inexpensive, and easily available because it only requires swallowing the capsule containing the ring-shaped markers and abdominal plain films on the day of ingestion of radiopaque markers by the patient and on day 5 after the ingestion. A normal test is considered if, on day 5, at least 80% of the markers have passed. In cases when more than 20% of the markers are still observed in the colon, the study is considered abnormal. Slow-transit constipation is suggested in cases when the markers are distributed throughout the colon (Fig. 2), whereas retained markers in the rectosigmoid colon are suggestive of obstructed defecation.

Defecography

Defecography is a dynamic test that can be performed using fluoroscopy (cinedefecography), magnetic resonance (MRI

defecography), or ultrasound equipment (ecodefecography) and uses radiologic contrast or ultrasound gel to opacify the rectum and capture images during the evacuation process for further analysis (Fig. 3). It is used to rule out associated pathologies such as rectoceles or intussusceptions and nonrelaxing puborectalis as the cause of obstructive defecation. Each technique offers valuable information, but they all have advantages and limitations.

Anorectal Physiology Testing

In selected cases when pelvic floor dysfunction is suspected, anorectal physiology testing might be useful, such as anorectal manometry (ARM) measuring resting and squeeze pressures, rectal volume sensation, rectoanal inhibitory reflex, and balloon expulsion (Fig. 4). Additionally, electromyography (EMG) is useful in evaluating proper puborectalis contraction and relaxation.

FIG. 2 Sitz marker study. Radiopaque marker study 5 days after ingestion of the Sitz marker capsule. Retention of markers present throughout the colon, suggesting colonic dysmotility. *(From Kapadia M, Varma M. Evaluation of Constipation and Treatment of Abdominal Constipation. In Steele S, et al.* The ASCRS Textbook of Colon and Rectal Surgery. *Springer; 2016.)*

MANAGEMENT

Medical Management

The first line of treatment for constipation is usually nonoperative and includes patient education about diet modifications to increase fiber and water intake. Fiber-rich foods and fiber supplements are both acceptable options and are recommended before beginning laxatives and/or enemas. Behavioral education regarding toilet habits is a critical part of the education and treatment (straining, time spent sitting on the toilet, etc.).

Osmotic laxatives (polyethylene glycol, magnesium hydroxide, and lactulose) are safe options that have been demonstrated to be very effective in most cases of constipation. Short-term use of stimulant laxatives (bisacodyl) is recommended. Newer alternatives such as lubiprostone and linaclotide should be reserved for cases when fiber and water intake is adequate and osmotic and stimulant laxatives have failed.

Noninvasive Techniques

Biofeedback therapy is a useful therapy in cases of constipation due to pelvic floor dyssynergia. It has shown to improve the number of spontaneous bowel movements by correcting pelvic muscle dysfunction, mirrored by improved quality of life.

Surgical Management

Refractory cases are those that fail to improve symptoms consistently after appropriate medical treatment and in which surgery provides the only option to restore quality of life. Figure 5 shows the algorithm for management of constipation.

Colonic Slow-Transit Constipation

For patients with confirmed colonic dysmotility as the cause of constipation in whom nonoperative measures have failed, total abdominal colectomy with creation of an ileorectal anastomosis (TAC-IRA) has shown excellent results and is the procedure of choice (overall success rates are approximately 86%). Segmental colectomies are not recommended in these cases because failure rates are as high as 100%. Upper gastrointestinal dysmotility problems must be ruled out before proceeding to perform a colectomy to decrease chances of recurrent constipation. It is imperative to have a thorough conversation with the patient, setting clear expectations about outcomes and possible complications. TAC-IRA can be performed open or

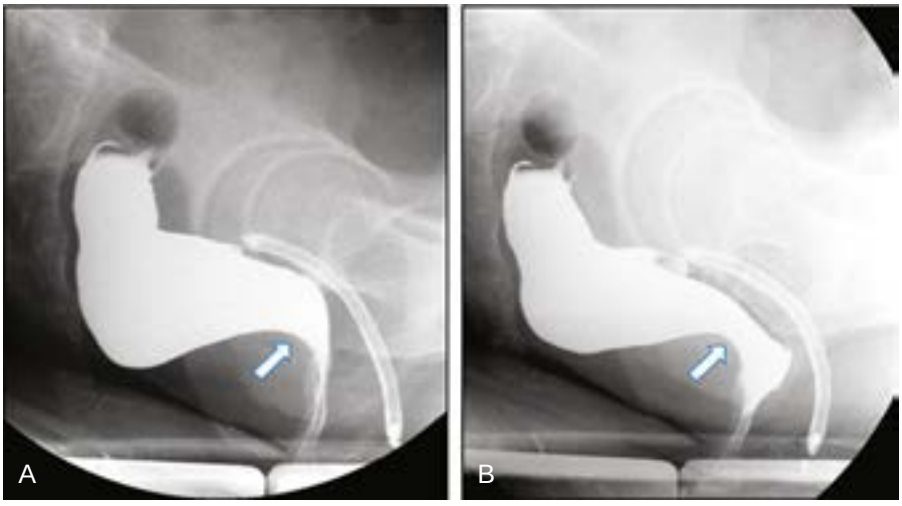

FIG. 3 Defecography. Dyskinetic puborectalis muscle syndrome. Note abnormally deep puborectalis impression *(arrow)* at rest **(A)** and at evacuation phase **(B)**. During the evacuation phase, there is lack of pelvic floor descent. *(From Ah Young Kim. FIG. 4 Anorectal manometry. **(A)** Normal manometry. Green = 20 mm Hg pressure. **(B)** Dyssynergic defecation. Red = 100 mm Hg pressure. *(From Rao SS, Meduri K. What is necessary to diagnose constipation?* Best Pract Res Clin Gastroenterol. *2011;25[1]:127–140.)*

using a minimally invasive approach (laparoscopic or robotic) with good outcomes and low morbidity. The approach will depend on the surgeon's preference and patients' preexisting conditions (e.g., prior abdominal surgeries). Anastomotic leak has been reported between 1% to 11%, bowel obstruction up to 33%, and postoperative ileus up to 24%. Special attention must be paid to proper orientation of the small bowel to avoid torsion of the mesentery, which could carry devastating consequences. Evaluation of the anal sphincter is imperative, including ARM testing when physical exam triggers concern such as low sphincter tone or poor squeeze effort. The rationale behind this is the incidence of diarrhea and fecal incontinence after this type of surgical procedure, which can be as high as 46% and 47%, respectively.

In some patients with colonic slow-transit constipation, ARM testing may identify an additional component of pelvic floor dysfunction. This group should be treated with biofeedback before subtotal colectomy (TAC-IRA), because higher rates of recurrent constipation are common. Similarly, if rectal intussusception or a rectocele/enterocele is identified on defecography, repair of the outlet obstruction may be necessary before or at the same time of TAC-IRA. Details about surgical repair of rectoceles are described in the outlet obstruction constipation section.

Total Abdominal Colectomy with Ileorectal Anastomosis

The approach (open, laparoscopic, or robotic) will depend on the patient's preexisting conditions, abdominal surgical history, and surgeon's preference and expertise. The authors prefer and recommend a minimally invasive approach whenever feasible due to the benefits of less postoperative pain, fewer wound infections (particularly in obese patients), and faster bowel recovery. A detailed description of the laparoscopic technique will be discussed in the following sections.

Preoperative. A mechanical bowel preparation with polyethylene glycol or sodium phosphate in addition to a Nichols and Condon prep is used preoperatively. Patients should undergo education and marking of potential stoma sites in case it is necessary, as well as become enrolled in the enhanced recovery after surgery (ERAS) protocol per each institution.

Intraoperative. The procedure is performed under general anesthesia, and patients should be placed on an antislip pad and well secured to the operating table to eliminate unwanted sliding during intraoperative changes in position, while also protecting the skin and nerves at pressure points. A modified lithotomy position with the legs slightly abducted and arms tucked to the sides provides access to the anorectal area. Sequential compression devices (SCD) should be placed on both legs unless otherwise contraindicated before anesthetic induction. Surgical prophylactic antibiotics should be administered within one hour of the skin incision to reduce surgical site infections. Antibiotic selection will vary based on institutional resistance patterns and availability, as well as the patient's allergies. The authors prefer ceftriaxone and metronidazole in the absence of contraindications. All patients should undergo a venous thromboembolism (VTE) risk assessment perioperatively and be managed accordingly. A Foley catheter should be inserted under sterile conditions and the rectum irrigated with a mixture of Betadine and warm sterile water solution. An orogastric tube should be inserted to decompress the stomach but removed postoperatively. Pneumoperitoneum can be established using a Veress needle or a Hasson's technique depending on the patient's body habitus and prior surgeries, as well as the surgeon's preference. Traditionally, a 12-mm trocar is placed in the umbilical region to introduce a 10-mm 30-degree laparoscope. An abdominal pressure of 15 mm Hg is achieved, and upon entering the abdominal cavity, visceral injuries caused by the entry instrument should be ruled out. Initially, four additional ports are placed under direct laparoscopic vision: we use 5-mm ports, one on each flank, one in the suprapubic position, and one in the subxiphoid region. Eventually, one of the 5-mm ports will be replaced by a 12-mm trocar to introduce the laparoscopic linear stapler. Depending on the body habitus of the patient, a 12-mm trocar can be placed in the right lower quadrant at the beginning of the surgery. When using a hand-assisted technique, a Gelport (Applied Medical; Rancho Santa Margarita, CA) is placed in the lower abdomen through a Pfannenstiel incision. Figure 6 shows a suggested port placement for laparoscopic cases. Dissection of the colon can be performed using different approaches (top-down, bottom-up, medial to lateral, or lateral to medial). The authors prefer the medial to lateral approach, therefore this will be the technique described next.

Colonic mobilization can be initiated on the left or right side instinctively, keeping in mind that leaving the dissection of the flexures for later facilitates self-retraction of the colon, otherwise it will be floppy, compromising the exposure. Depending on which side of the colon is being mobilized, adjustment of the patient's position will improve exposure. Retraction of the omentum

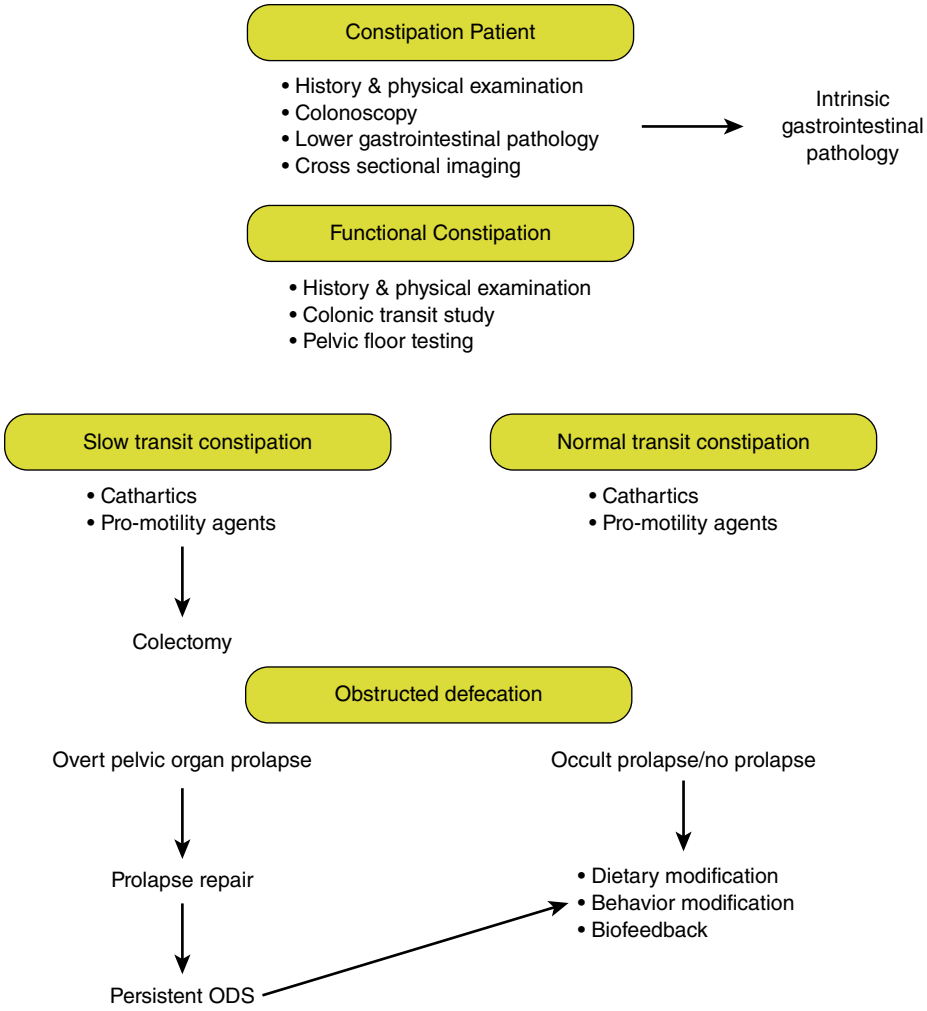

FIG. 5 Algorithm of the management of constipation. *(From McNevin MS. Obstructed Defecation. In Steele S, et al.* The ASCRS Textbook of Colon and Rectal Surgery. *Springer; 2016.)*

and transverse colon into a cephalad position over the liver and stomach is one of the first steps in either right or left colectomies. Ligation of named vessels does not need to be at their origin, but rather an intramesenteric dissection is acceptable. Energy devices, clips, and staplers are some of the available options to ligate vessels depending on the anatomy and diameter of the vessel and surgeons' preferences. During right colectomies, dissection and identification of the ileocolic vessels is a main step, in addition to identification and preservation of critical structures such as the duodenum and right ureter. During left colectomies, identification of the inferior mesenteric artery (IMA) is aided by palpation of the promontory either by hand during hand-assisted procedures or using a grasper during straight laparoscopy. The inferior mesenteric vein (IMV) is identified lateral to the duodenum at the ligament of Treitz, caudal to the inferior border of the pancreas. Its ligation usually facilitates the identification of the plane of dissection between the left mesocolon and the retroperitoneal structures. Careful manipulation of the IMV is crucial, as an inadvertent tear or avulsion can result in retraction of the proximal end underneath the pancreas, producing significant bleeding that can be hard to control. Mobilization of the flexures requires preservation of the spleen and tail of the pancreas on the left side and gallbladder, duodenum, and portal pedicle on the right. It is important to avoid dissection of both flexures before proceeding to perform the transverse colectomy, because all the tension will fall on the middle colic vessels. Therefore, the surgeon would decide which flexure to dissect first, then proceed to transect the middle colic vessels, and lastly take down the other flexure. The middle colic vessels are short, hence meticulous dissection is pivotal. Another approach is to dissect the right side of the colon and continue the dissection through the transverse colectomy followed by the left colectomy. The best approach is usually the one the surgeon is most comfortable with.

Division of the bowel is performed with a laparoscopic linear stapler at the level of the terminal ileum proximally and at the conversion of the taenia at the rectosigmoid junction. The specimen is removed through a small Pfannenstiel incision in straight laparoscopy or by opening the Gelport (Applied Medical; Rancho Santa Margarita, CA) during hand-assisted cases. The ileorectal anastomosis is then created and either handsewn or stapled side to side, end to end, side to end, or end to side (Fig. 7). At the same time, stapled anastomosis can be performed using circular or linear surgical staplers. Lastly, after reestablishment of the pneumoperitoneum, a leak test must be performed using warm saline irrigation of the pelvis and a flexible sigmoidoscope. The anastomosis should satisfy the principles of being free of tension, well vascularized, and with a confirmed negative leak test. In patients in whom an IRA anastomosis is not possible or wanted (e.g., poor

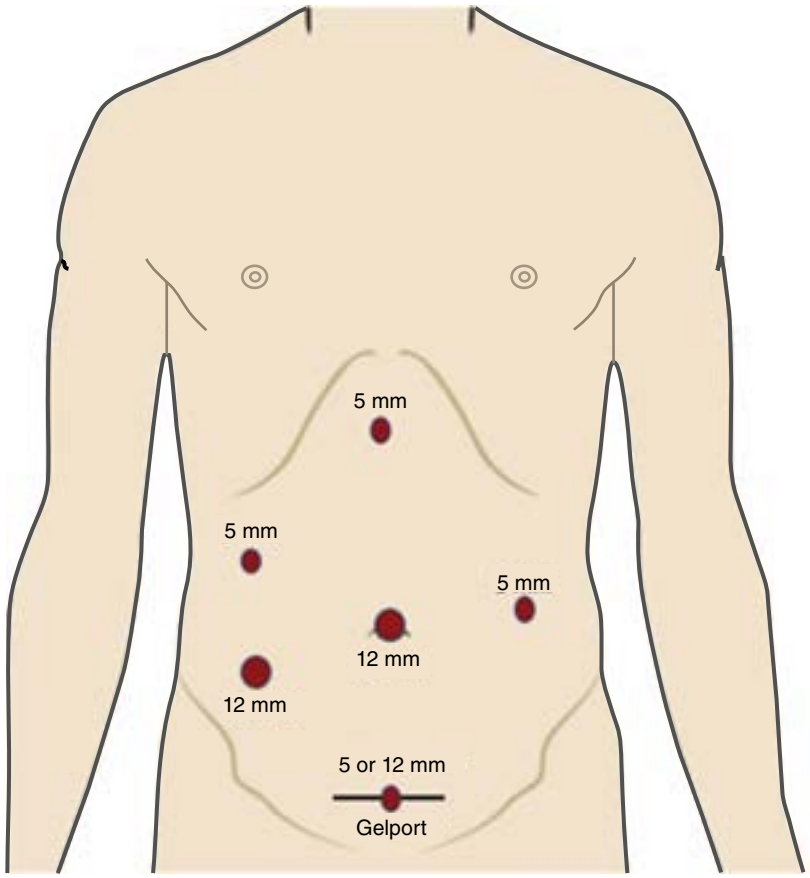

FIG. 6 Laparoscopic port placement.

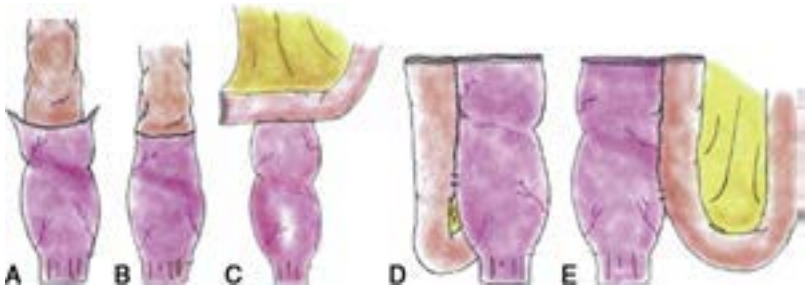

FIG. 7 Variations of ileorectal anastomosis. **(A)** End-to-end (EE) anastomosis with a double-stapled anastomosis. **(B)** EE anastomosis with a double purse-string anastomosis. **(C)** Side-to-end anastomosis. **(D)** Side-to-side anastomosis with the small bowel on the right side. **(E)** Side-to-side anastomosis with the small bowel on the left side. *(From Jolly S, Dudi-Venkata NN, Hanna-Rivero N, et al. Four different ileorectal anastomotic configurations following total colectomy.* ANZ J Surg. *2020;90[9]:1588–1591.)*

sphincter function with fecal incontinence), an alternative is the creation of an end ileostomy.

Robotic port placement will depend on the robotic platform used. However, the technical aspects of the surgery are essentially the same.

Cecorectal Anastomosis

Alternatively, other surgical options are a side-to-side cecorectal anastomosis and antiperistaltic cecorectal anastomosis with subtotal colectomy. The benefit of a subtotal total colectomy with cecorectal anastomosis (Jinling procedure) is the resolution of the obstructive defecation symptoms with less likelihood of consequence diarrhea due to preservation of the ileocecal valve (Fig. 8).

Completion Proctectomy with Ileal Pouch–Anal Anastomosis (IPAA)

Completion proctectomy with ileal pouch–anal anastomosis (IPAA) is typically not recommended as first-line treatment but instead is reserved for patients who have failed all other available options. Usually, IPAA is offered before committing to a permanent stoma. Most patients undergoing IPAA have undergone an abdominal TAC-IRA and present recurrent symptoms of constipation. Pouch

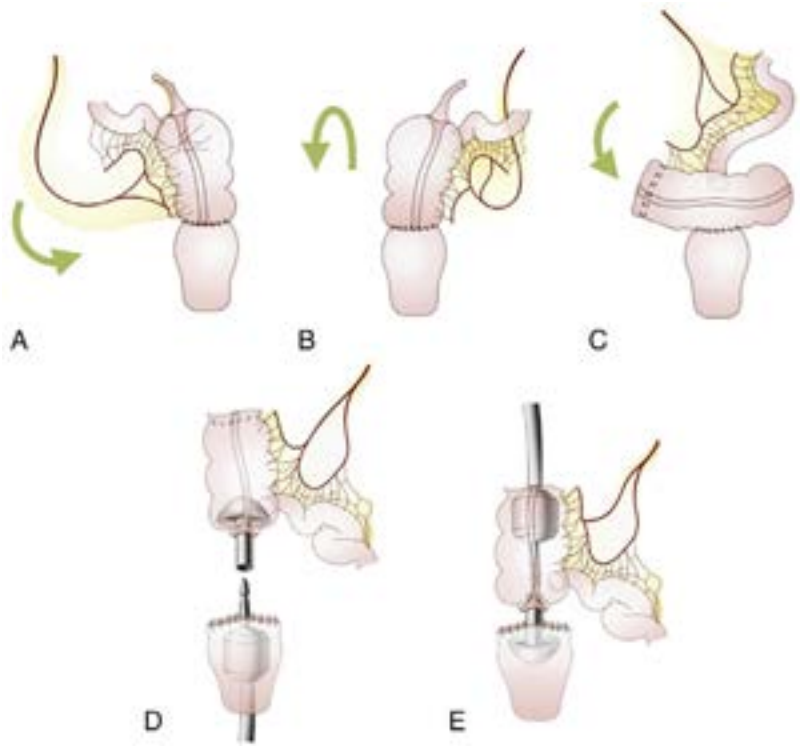

FIG. 8 Types of reconstructive surgery after subtotal colectomy with ileocecal junction preservation. **(A)** Isoperistaltic ascendo- or cecorectal anastomosis, proposed by Lillehei and Wangensteen. **(B)** Counterclockwise rotation of the cecum and ascending colon (Deloyers procedure). **(C)** Ascendo- or cecorectal anastomosis, side-to-end. **(D, E)** Cecorectal anastomosis. *(From Efetov SK, Zubayraeva AA, Nekoval VM, et al. Extended colectomy followed by cecorectal anastomosis as a surgical treatment modality in synchronous colorectal cancer. Case Rep Oncol. 2020;13(2):813–821.)*

excision and poor functional outcomes are some of the complications associated with an IPAA; therefore, the authors recommend a full workup (including ruling out Hirschsprung's disease) and comprehensive discussion and counseling of possible risks and benefits with the patient before committing to the procedure. Careful patient selection is key.

Diverting Ileostomy

Creation of a stoma is usually reserved as a last resort in patients in whom all other alternatives have failed (up to 25% of cases), those with associated fecal incontinence, or those deemed poor surgical candidates unfit to undergo major surgery. The type of stoma will depend on the etiology of the constipation. A diverting loop ileostomy is preferred for patients suffering from colonic slow-transit constipation. It allows symptomatic relief while offering information about the function of the upper gastrointestinal tract. This can be extremely helpful in cases such as global gastrointestinal dysmotility disorders.

Outlet Obstruction Constipation. Obstructed defecation is generally a complex problem due to the presence of concurrent conditions that may engender frustration in patients and treating physicians. This occurs because of slow treatment response, poor resolution of debilitating symptoms, and consequent negative impact on the quality of life. The primary treatment of obstructive defecation constipation is nonoperative. However, in cases of rectal intussusception or large rectoceles refractory to nonoperative management, surgery may be considered. Although it may resolve associated anatomic problems (e.g., rectal ulcers), it may not improve or, in some cases, may potentially worsen functional outcomes.

Rectocele Repair

Rectoceles are the result of an abnormal rectovaginal fascia, typically caused by obstetric trauma. Most symptomatic rectoceles are successfully managed with conservative treatment such as an adequate bowel regimen, changing toilet habits, and biofeedback therapy. Conventionally, only large (>4 cm) symptomatic rectoceles or those in which nonoperative treatments have failed are offered surgical repair. Nonetheless, the decision should be individualized after a thorough discussion with the patient, understanding the symptoms and setting clear postoperative expectations. Transvaginal, transrectal, or transperineal approaches have shown similar outcomes. The selection will be based on the surgeon's experience and preference. The authors prefer transvaginal repair since it is a rather simple technique that allows better access to the endopelvic fascia and levator muscle, and it is associated with fewer complications such as infection and fistula formation because it does not violate the rectal mucosa. Transvaginal repairs include the midline plication (traditional technique) and the site-specific repair.

Preoperative. A mechanical bowel preparation with polyethylene glycol or sodium phosphate in addition to a Nichols and Condon prep is used preoperatively in case the rectal wall is injured inadvertently during the dissection.

Intraoperative. The procedure can be performed under spinal or general anesthesia; the authors prefer the latter. Patients are placed in a modified lithotomy position. The rectum should be irrigated, and extra gloves should be available on the instrument table in anticipation of digital rectal examinations during the procedure. SCD should be placed on both legs unless otherwise

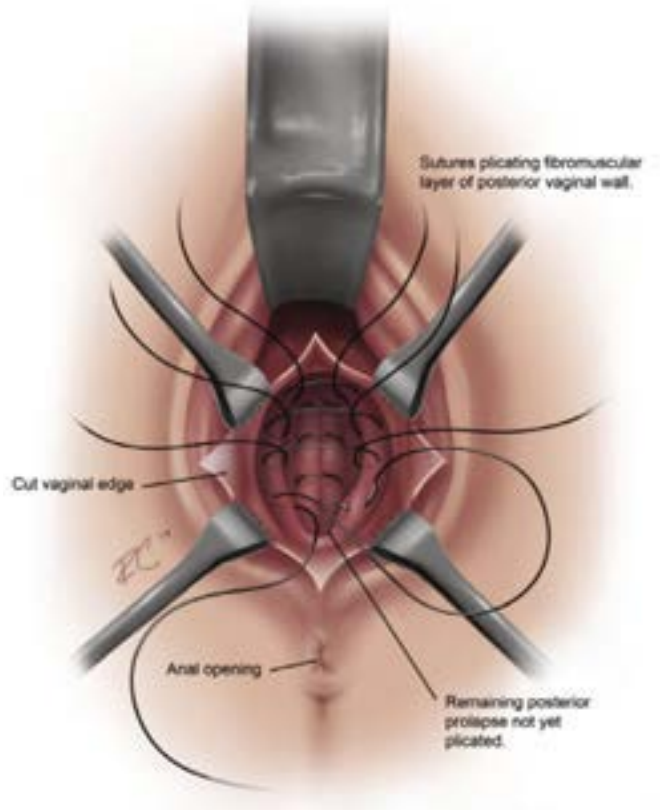

FIG. 9 Posterior vaginal repair of rectocele. *(From Joint Report on Terminology for Surgical Procedures to Treat Pelvic Organ Prolapse [published correction appears in* Female Pelvic Med Reconstr Surg. *2020;26(6):407].* Female Pelvic Med Reconstr Surg. *2020;26[3]:173–201.)*

contraindicated before anesthetic induction. Surgical prophylactic antibiotics should be administered within one hour of the skin incision to reduce surgical site infections. Antibiotics selection will depend on each institution, as well as the patient's allergies. The authors prefer ceftriaxone and metronidazole in the absence of contraindications. All patients should undergo a VTE risk assessment perioperatively and be managed accordingly. A Foley catheter should be inserted under sterile conditions and placed over one of the legs. Using a marking pen, a longitudinal mark is made over the longest axis of the rectocele in the center of the posterior vaginal wall. Then, a local anesthetic with dilute epinephrine (lidocaine 1% with 1:200,000 units of epinephrine) is injected to aid with hemostasis. With the use of a 15-blade scalpel, a midline incision is made over the vaginal mucosa, which is deepened using electrocautery, and the fibromuscular layer of the vagina is dissected. Upon creation of vaginal wall flaps on each side, clamps are placed to facilitate gentle traction. In cases of associated enteroceles, the sac should be opened, the content reduced, and then the sac is closed with a purse-string, delayed-absorbable suture. Once the dissection reaches the extent of the rectocele on both sides and the rectal wall has been examined and confirmed intact, the surgeon proceeds to plicate the vaginal muscularis and rectovaginal tissues in the midline using 2-0 or 0 absorbable or delayed-absorbable interrupted sutures. In the event of a rectal wall injury, it should be immediately repaired using delayed-absorbable suture. If deemed necessary by digital rectal examination, the levator muscles are plicated in the midline, avoiding overcorrection. Lastly, after verifying hemostasis, the redundant vaginal mucosal edges are trimmed on both sides and reapproximated using a 2-0 absorbable suture. A vaginal packing is placed and removed 24 hours postoperatively.

Patients can be placed in 24-hour observation and should be offered laxatives to avoid straining. Figure 9 shows a transvaginal rectocele repair.

There is supporting data on the use of reinforcement of rectocele repairs using synthetic or biological mesh products, particularly for rectocele repairs performed with a transvaginal or transperineal approach. Similar postoperative results have been described.

Transrectal stapled repair of rectoceles and rectal intussusception lost popularity over the years due to the high rate of complications.

Reporting of short-term results shows improvement of constipation symptoms in greater than 80% of patients, with low complication and recurrence rates.

Colostomy Creation

In patients with outlet obstruction constipation who are not compliant or have failed nonoperative therapy, or those who are not candidates for other available treatment options, a colostomy can be considered. If workup reveals a normal colonic transit, a descending colostomy is generally a good alternative with much less morbidity than ileostomies.

Other Surgical Options

Colonic Disimpaction

Not all patients tolerate bedside enemas or disimpaction, in which cases disimpaction under anesthesia may be necessary. These are relatively simple procedures that commonly require only sedation and irrigation. It also allows an opportunity to perform endoscopic procedures and biopsies when deemed necessary.

Malone Antegrade Colonic Enema

Originally described to treat fecal incontinence in children, the antegrade colonic enema uses an appendicostomy or cecostomy to manage constipation symptoms in carefully selected and highly motivated patients who are not interested in or are not candidates for colectomy. Although this technique has been abandoned by many surgeons due to the high rates of malfunction due to stenosis (almost 100%) or leakage, it continues to be an alternative treatment option.

Sacral Nerve Stimulation

This therapy is not currently approved by the Food and Drug Administration (FDA) for the management of constipation; however, it is widely used in the treatment of urinary and fecal incontinence. However, sacral neuromodulation (SNM) or acral nerve stimulation (SNS) has been used for the treatment of slow-transit or outlet obstruction constipation outside of the United States. Success rates are widely variable, ranging between 42% and 100%.

ADULT HIRSCHSPRUNG'S DISEASE

In adult patients with constipation symptoms since childhood and poor or no response to treatment, Hirschsprung's disease should be suspected and ruled out. A disease known to be caused by the congenital absence of submucosal and myenteric ganglion cells, it is confirmed by biopsy of the affected bowel segment. Frequently unrecognized among the adult population because it is considered a children's disease, an absent rectoanal inhibitory reflex during ARM is pathognomonic. It can be surgically managed with the following procedures: Duhamel's, Swenson's, myectomy, Soave's, and low

anterior resection. There is a paucity of data comparing success rates between these techniques in adults.

CONCLUSION

Constipation is a chronic disease with a significant impact on the quality of life of those who suffer from it. Most cases respond successfully to conservative management. However, those who are refractory to medical treatment may benefit from surgical procedures. Individualized workup and treatment are key to achieving resolution of symptoms and improving quality of life.

Surgical Management of the Polyposis Syndromes

Scott R. Kelley, MD, and Sacha P. Broccard, MD

INTRODUCTION

Colorectal polyps can be classified as adenomatous, hamartomatous, hyperplastic, neoplastic, and inflammatory. The development of multiple polyps is considered a polyposis syndrome, and several have been described. Each syndrome has different characteristics including presentation, genetic basis, extracolonic manifestations, and malignancy risk (Table 1). Management options include strict surveillance for the early detection of cancer, chemopreventive medications, and surgery. A detailed family history and genetic evaluation are imperative, and siblings and offspring should be offered genetic counseling and testing. Multidisciplinary care (clinical services, support, counseling) and referral to a polyposis registry is recommended. This chapter focuses on the most common polyposis syndromes.

ADENOMATOUS POLYPOSIS SYNDROMES

Familial Adenomatous Polyposis

Familial adenomatous polyposis (FAP) is an autosomal dominant inherited disease resulting from a mutation in the adenomatous polyposis coli (APC) tumor suppressor gene located on chromosome 5q21. Most mutations are found between codons 168 and 1640, with two of the most significant being 1061 and 1309. FAP is defined as greater than 100 synchronous adenomas or fewer than 100 with a positive family history. Polyps, predominately found in the rectum and left colon, develop in adolescence and are present in up to 15% of patients by 10 years of age and 75% by 20. If untreated, the risk of colorectal malignancy is nearly 100% by 35 to 40 years of age. Approximately 25% to 30% do not have a family history and will develop FAP de novo. The most common presenting symptoms are bleeding, diarrhea, abdominal pain, and mucous discharge.

For those with a family history or identified APC mutation, a screening colonoscopy should be performed at 10 to 12 years of age and continue annually. With the predilection for polyp development in the left colon and rectum, a yearly flexible proctosigmoidoscopy can be completed instead of a formal colonoscopy. If adenomatous polyps are appreciated on sigmoidoscopy, a formal colonoscopy should ensue.

Extracolonic Intestinal Disease

Extracolonic intestinal disease is a common manifestation of FAP. Hyperplastic gastric fundic glad polyps (FGPs), which have low malignant potential, will develop in 30% to 90% of patients. They affect women and men equally and commonly present in the third or fourth decade of life. In contrast to FGPs, gastric adenomas have the potential for malignant progression, are rare (10%–30%), and typically occur in the antrum. They are more commonly associated with the Japanese and Korean population where the risk of gastric cancer is three to four times higher than western FAP patients.

Duodenal adenomas, most commonly found around the ampulla of Vater and macroscopically different than colonic adenomas, are found in more than 95% of patients with FAP and develop approximately 15 years later than colonic polyps. Duodenal cancer, typically diagnosed around 50 years of age, occurs in 5% to 10% and is the second leading cause of death associated with FAP. A screening esophagogastroduodenoscopy (EGD) is typically performed around 20 years of age, and the Spigelman severity score and staging system (Table 2) is used to determine surveillance intervals (Table 3). The risk of developing cancer after 10 years of follow-up for stage I is 0, stage II and III 2%, and 36% for stage IV. Small tubular adenomas, as well as those with low-grade dysplasia, can be biopsied and observed. High-risk adenomas (villous, >1 cm), severe duodenal

TABLE 1 Summary of Colorectal Polyposis Syndromes

Syndrome	Gene	Inheritance Pattern	Clinical Presentation	Extraintestinal Manifestations	CRC Risk (%)
FAP	*APC*	AD	Left colon and rectum >100 adenomas Duodenal adenomas (95%) Fundic gland hyperplasia (90%) Gastric adenomas (10%)	Benign osteomas (80%) CHRPE (75%) Epidermoid cysts (50%) Dermoid tumors (30%) Supernumerary teeth Cerebellar medulloblastoma	100

Serrated Polyposis	Unknown	Unknown	Colon and rectum At least 5 serrated polyps, all greater than 5 mm in size and proximal to the rectum, 2 of which are greater than 10 mm in diameter -OR- More than 20 serrated polyps of any size distributed throughout the large intestine with 5 being proximal to the rectum	None	30-50

AD, Autosomal dominant; *AR*, autosomal recessive; *AVMs*, arteriovenous malformations; *CHRPE*, congenital hypertrophy of the retinal pigment epithelium; *CRC*, colorectal cancer; *aFAP*, attenuated FAP; *FAP*, familial adenomatous polyposis; *GI*, gastrointestinal; *GU*, genitourinary; *MUTYH*, mutation-Y-homologue associated polyposis; *NG*, no greater than general population.

polyposis, high-grade dysplasia, or stage IV disease should be offered a pancreas-preserving duodenectomy, and those with cancer a pancreaticoduodenectomy. Chemoprevention with nonsteroidal antiinflammatory agents (sulindac, celecoxib) can result in polyp regression in those with a lesser polyp burden, though overall the effect is minimal at best.

Extraintestinal Manifestations

Common extraintestinal manifestations of FAP include osteomas, congenital hypertrophy of the retinal pigmented epithelium (CHRPE), epidermoid cyst, and dermoids. Benign osteomas of the mandible, skull, and tibia are the most common extraintestinal finding occurring in upward of 80% of patients. Although CHRPE

Histology	Tubular	Tubulovillous	Villous
Dysplasia	Mild	Moderate	Severe

*Spigelman stage I, score 1–4; stage II, score 5–6; stage III, score 7–8; stage IV, score 9–12.

TABLE 3 Derivation of Spigelman Stage from Scores

Total Points	Spigelman Stage	Suggested Interval to Next Duodenoscopy (Years)
0	0	5
1–4	I	3–5
5–6	II	3
7–8	III	1
9–12	IV	Duodenectomy; if not, rescope in 6 months

is not specific to FAP, four or more areas of large patchy fundic discoloration is pathognomonic and will be present in around 75% of individuals. Epidermoid cysts occur approximately 50% of the time.

Other extraintestinal manifestations, though rare, include supernumerary teeth, cerebellar medulloblastoma, and cancers of the liver, biliary tree, adrenal glands, and thyroid.

Desmoid Tumors

Desmoids develop in 15% to 30% of patients and are locally invasive abdominal wall and intraabdominal/retroperitoneal myofibroblastic tumors that typically develop 2 to 3 years after surgery and occur around 30 years of age. They can develop spontaneously, are the third most common cause of death associated with FAP, and have been noted to be associated with trauma. Risk factors associated with the development of desmoids are mutations in the 3′ end of the APC gene, female gender, extraintestinal manifestations, and a family history of desmoid disease. Ten percent of desmoids grow rapidly, 10% resolve spontaneously, 30% vacillate between cycles of growth and regression, and 50% remain stable or grow very slowly.

Extraabdominal desmoids are best treated with surgical extirpation with a 1-cm margin, though recurrence is high with documented rates of 20% to 50%. Early excision is recommended to decrease the size of the resultant abdominal wall defect.

Intraabdominal/retroperitoneal desmoids can invade the mesentery and surrounding structures resulting in obstruction, hemorrhage, fistulization, ischemia, and perforation. The primary treatment is medical and includes nonsteroidal antiinflammatory agents (sulindac, celecoxib), estrogen antagonists (tamoxifen, toremifene, raloxifene), and chemotherapy (vinblastine, methotrexate, doxorubicin, Adriamycin, dacarbazine). Radiotherapy can be used for palliative measures but is associated with small bowel necrosis and fistulas. Surgical removal is difficult and often impossible if the root of the mesentery is involved. Resection with completely uninvolved margins (R0) will result in recurrence 50% of the time. FAP-associated desmoid tumors are more likely to recur than their sporadic or pregnancy-associated counterparts. If possible, nonresective procedures such as diversion and bypass can be pursued for palliation. Ureteral obstruction is best treated with stenting.

There is not a defined screening regimen for desmoid tumors, although computed tomography (CT) and magnetic resonance imaging (MRI) can be utilized, especially for those with an increased risk of developing desmoids.

Attenuated Familial Adenomatous Polyposis

In contrast to classic FAP, attenuated FAP (aFAP) presents at a later age (30s–40s) with fewer than 100 polyps predominantly found in the right colon. If untreated, the risk of colorectal malignancy is nearly 100% by 59 years of age. Extracolonic and intestinal manifestations including gastric adenomas, desmoids, and CHRPE are typically not seen in aFAP. Gastrointestinal (GI) malignancy from duodenal polyps has been described in patients with aFAP.

For those with a family history or identified APC mutation suggestive of aFAP, screening colonoscopy should begin between 18 to 20 years of age and repeated every 1 to 2 years. With the predilection for polyp development in the right colon, a formal colonoscopy is recommended. Screening EGD should begin between the ages of 20 to 25, or before colectomy, with repeat interval based on Spigelman stage.

Mutation Y-Homolog Associated Polyposis

Mutation Y-homolog (MYH)-associated polyposis (MAP) is an autosomal recessive inherited form of FAP resulting from a biallelic mutation in the *MYH* gene located on chromosome 1p34. The number of polyps associated with MAP is variable (tens to hundreds) with a median around 50. Polyps are most commonly found in the left colon and present at a median age of 48. If untreated, the risk of colorectal malignancy is around 80% by 70 years of age. Extraintestinal manifestations are associated with MAP, though exceedingly rare.

Due to the phenotypic overlap with FAP, genetic testing for the MYH is typically performed when no APC mutation is detected, there are fewer than 100 adenomatous polyps, and the family history is irrelevant or does not reveal a dominant mode of inheritance.

Screening colonoscopy should begin between ages 18 to 20 and repeated every 1 to 2 years. Screening EGD should begin between ages 30 to 35, or before colectomy, with repeat interval based on Spigelman stage.

CHEMOPREVENTION

Although clinical trials have shown that nonsteroidal antiinflammatory drugs (sulindac, exisulind, celecoxib) and aspirin can reduce the size and number of adenomas in the colon and rectum, there was not an appreciable reduction in cancer. Chemoprevention is not recommended as a primary therapy for polyposis syndromes and is not an appropriate alternative to prophylactic surgery. Situations where chemoprevention can be entertained include treating ileal pouch anal anastomosis (IPAA) polyps, a high family risk of desmoid tumors, delayed surgery, and unwillingness or inability to tolerate polypectomy or completion proctectomy.

SURGERY

The primary goal of surgery is to prevent colorectal cancer. The timing and type of surgery offered depends on a multitude of factors including clinical presentation, family history, and, if known, the site of the chromosomal mutation. Severe polyposis (>1000 colonic or 20 rectal polyps) and *APC* mutations between codons 1250–1464 carry a higher risk of cancer, and surgery should be offered as early as possible. Surgery should also be pursued early for symptomatic disease. For those with a high risk of desmoid disease (family history, mutation in the 3′ end of the *APC* gene, female gender, extracolonic manifestations), surgery should be delayed as long as possible to decrease the chance of desmoid tumors developing. Young patients

should have surgery delayed, if possible, to allow for adequate physical, social, and intellectual maturity. For patients with classic FAP, surgery should be pursued well before cancer develops and typically occurs around 16 to 20 years of age.

Surgical options include an open or minimally invasive total proctocolectomy (TPC) with creation of an end or continent ileostomy, total abdominal colectomy (TAC) with creation of an ileorectal anastomosis (IRA), and a TPC with creation of an IPAA.

Proctocolectomy with End Ileostomy

A proctocolectomy with end Brooke ileostomy has a low rate of complications but leaves the patient with an incontinent stoma. Indications for this approach are patient preference, low rectal cancer requiring an abdominoperineal resection, rectal cancer requiring postoperative pelvic radiation, inability to create an IPAA (inadequate mesenteric length), and poor sphincter function.

The procedure is carried out in an oncologic approach secondary to the risk of a preoperatively unrecognized cancer. A perineal intersphincteric dissection is carried out preserving the external sphincter and levator ani muscles. The perineum is closed in layers, and the greater omentum, if present, is mobilized and placed in the pelvis to prevent future bowel obstructions. After closure of the abdomen, the ileostomy is matured in a standard evaginated Brooke fashion, with an attempted ideal projection of 2.5 cm.

Proctocolectomy with Continent Ileostomy

Initially described by Nils Kock in 1969, the continent ileostomy still remains a viable alternative for motivated patients who are not candidates for an IPAA. Modifications and revisions to the original Kock continent ileostomy have been described (Barnett continent ileostomy reservoir and T-pouch) though without evidence to suggest they are better than the Kock pouch. Contraindications to construction of a continent ileostomy include Crohn's disease, obesity, marginal small bowel length, and anyone with a psychological or physical disability that would preclude understanding or being able to perform daily stomal intubation.

Total Abdominal Colectomy with Ileorectal Anastomosis

Colectomy with ileorectostomy should only be considered in cases of attenuated or mild polyposis (<20 rectal, <1000 colonic adenomas), rectal polyps less than 3 cm in size, no colorectal dysplasia or cancer, a distensible and compliant rectum, and in patients with an intact sphincter mechanism who are willing to adhere to strict follow-up. Ileoproctostomy is an appealing alternative in younger patients of reproductive age to decrease the risk of impotence and reduced fecundity. Strict rectal surveillance (every 6–12 months) must be adhered to due to the increased risk of future neoplastic changes. The risk of rectal carcinoma can reach up to 40% by 30 years, though this is based on literature from the pre-IPAA era. In patients who require a completion proctectomy, an end ileostomy, restorative IPAA, or continent ileostomy are all options.

Restorative Proctocolectomy/Ileal Pouch Anal Anastomosis

Initially described in 1978 by Parks and Nicholls, the restorative proctocolectomy has become the most common continence-preserving procedure performed in patients who are appropriate candidates. Indications include severe polyposis (>20 rectal, >1000 colonic adenomas), rectal polyps larger than 3 cm in size, colonic dysplasia or cancer, dysplastic rectal polyps, and patients with an intact sphincter mechanism willing to adhere to strict follow-up. The restorative pouch can be fashioned in two limbs (J), three limbs (S), four limbs (W), or isoperistaltic (H) configurations. The J-pouch, due to its ease of construction and excellent functional outcomes, has become the most common choice for surgeons.

A total colectomy is performed in an oncologic fashion, and the ileum is transected flush with the cecum (Fig. 1). To provide adequate perfusion to the pouch, it is imperative to preserve the ileal branches of the ileocolic and distal mesenteric arteries. Evaluation for adequacy of reach of the small bowel to the deep pelvis should be undertaken before creation of the pouch. The proposed point of the pouch-anal anastomosis can be pulled down to the pubis, and if this point can be easily advanced 3 to 4 cm below the inferior edge of the pubis, one can feel confident of successful reach for anastomosis. Strategies to decrease tension at the anastomosis include complete mobilization of the small bowel mesentery to the root of the superior mesenteric artery cephalad to the head of the pancreas (Fig. 2), proximal division of the ileocolic artery (Fig. 3), and relaxing incisions of the mesentery over tension points along the superior mesenteric artery (Fig. 4). Rectal dissection is completed in the TME plane, and transection of the rectum with a 30- to 40-mm transverse stapler

should occur 2 to 3 cm above the dentate line in the anal transition zone (ATZ) (Fig. 5). After reach has been verified, a J-configuration is fashioned with each limb measuring between 12 to 15 cm in length. The limbs are paired in an antimesenteric fashion and held in orientation with interrupted stay sutures. For those without evidence of adenomas in the ATZ or dysplasia in the lower rectum, a double-stapled IPAA can be fashioned, otherwise an anal mucosectomy and handsewn IPAA is recommended. Following creation of the IPAA, an air insufflation leak test is performed and, if necessary, a protective loop ileostomy fashioned, which should be created as close

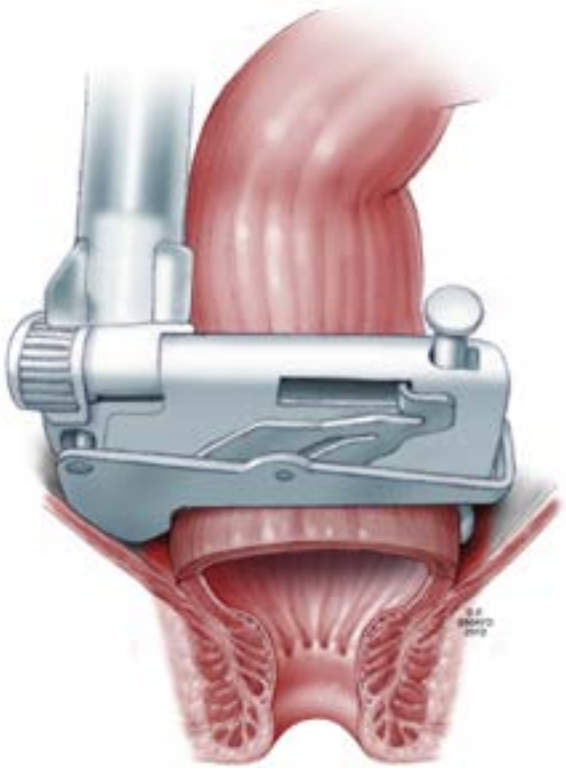

FIG. 5 Rectal transection. *(From Kelley SR, Dozois EJ. Ulcerative Colitis. In* A Companion to Specialist Surgical Practice: Colorectal Surgery. *5th ed. Edinburgh: Elsevier; 2014:132.)*

to the pouch as possible to decrease issues with high output and in the unlikely case that a redo-IPAA would need to be performed. In selected patients, the operation can be completed with good results without the creation of a diverting loop ileostomy.

Double-Stapled Technique

An enterotomy is made in the antimesenteric apex of the pouch, and a linear cutting stapler is used to divide the walls of the two limbs creating a common channel (Fig. 6). A purse-string suture is then fashioned around the enterotomy, and the anvil from a circular stapler is placed inside the pouch where it is held in place by tightening the purse string (Fig. 7). The circular stapler is then placed transanally. After appropriate orientation, the circular stapler cartridge spike is advanced either above or below the transverse rectal staple line and attached to the anvil. The stapler is then closed, approximating the pouch and anus (Fig. 8).

Handsewn Technique

An anal canal mucosectomy is performed starting at the dentate line. Raising the mucosa with a submucosal injection (Fig. 9) of dilute saline and epinephrine (1:200,000) facilitates dissection of the mucosa away from the internal sphincter muscle (Fig. 10), which can be completed sharply or with electrocautery. After the mucosa and proximal rectum have been removed circumferentially, the pouch is gently brought down to the level of the dentate line. An enterotomy is made in the apex of the pouch, if not already created, and it is anchored in position by placing a suture in each of the four quadrants incorporating a full thickness bite of the pouch, internal sphincter muscle, and mucosa. Sutures are placed between the anchoring stitches to complete the anastomosis (Fig. 11).

Postoperative Surveillance

After the creation of an IPAA or IRA, lifelong interval lower endoscopic surveillance is required for adenomas, dysplasia, and

FIG. 6 J-pouch creation. *(From Mayo Foundation for Medical Education and Research.)*

FIG. 7 Anvil in J-pouch. *(From Mayo Foundation for Medical Education and Research.)*

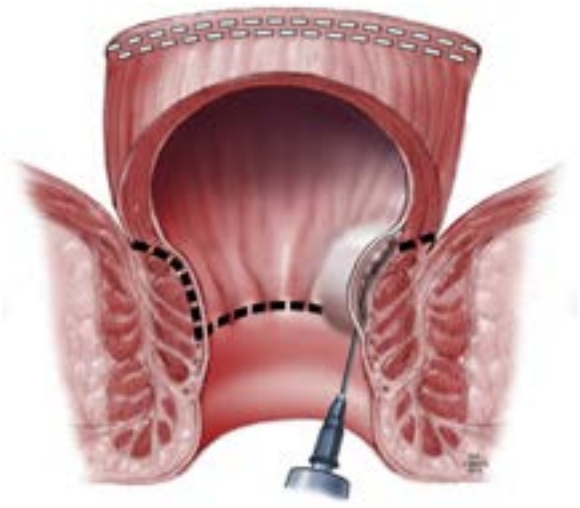

FIG. 9 Submucosal injection. *(From Mayo Foundation for Medical Education and Research.)*

carcinomas at 1- to 2-year or 6-month to 1-year intervals, respectively. Histologic evaluation of random biopsies and polyps should be performed to exclude dysplasia and cancer. More frequent surveillance is performed for increased numbers or size of polyps. Severe dysplasia and villous adenomas >1 cm in size should prompt a completion proctectomy in those with an IRA. Following TPC with end ileostomy, yearly stoma site surveillance by a stoma nurse or experienced practitioner is recommended due to the rare development of ileal adenocarcinoma, most commonly near the mucocutaneous junction in the setting of long-standing ileostomies.

OTHER POLYPOSIS SYNDROMES

Peutz-Jeghers Syndrome

Peutz-Jeghers syndrome (PJS) is an autosomal dominant inherited disease resulting most commonly from a mutation in the *LKB1* (*STK11*) tumor suppressor gene located on chromosome 19p13. Anywhere from 30% to 40% will occur de novo. Hamartomatous polyps are found throughout the GI tract, though most commonly in the small intestine. Extraintestinal manifestations are common

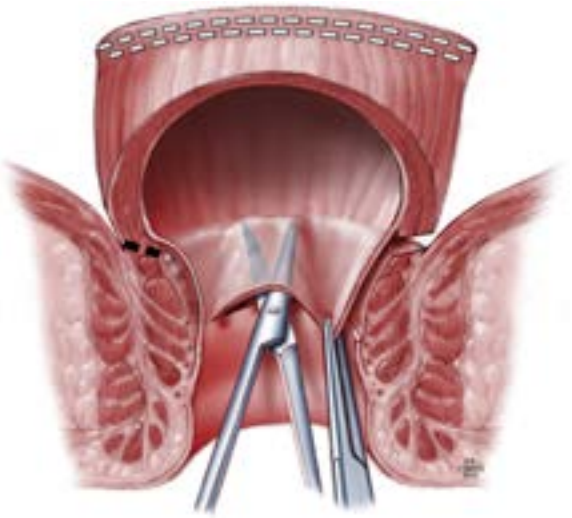

FIG. 10 Anal mucosectomy. *(From Kelley SR, Dozois EJ. Ulcerative Colitis. In* A Companion to Specialist Surgical Practice: Colorectal Surgery. *5th ed. Edinburgh: Elsevier; 2014:134.)*

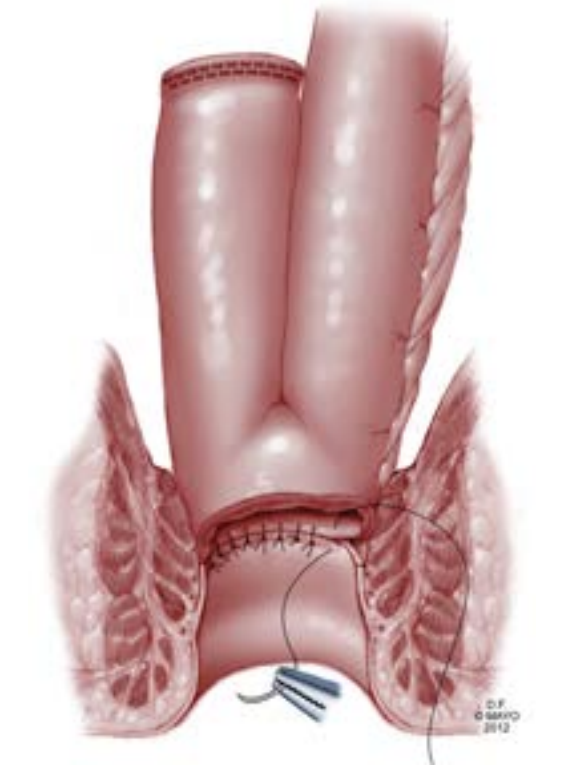

FIG. 11 Hand sewn ileal pouch anal anastomosis. *(From Mayo Foundation for Medical Education and Research.)*

with the hallmark phenotypic feature in adolescence being mucocutaneous hyperpigmentation that can affect the perioral and buccal region, eyes, nostrils, perianal region, fingers and toes, and hands and feet. Hyperpigmentation dissipates as one ages. Hamartomatous polyps and mucocutaneous pigmentation confirms a diagnosis of PJS. Presenting symptoms can include abdominal pain, alteration in bowel habits, weight loss, bowel intussusception, anemia, hematochezia and melanotic stools, and small bowel obstruction. The risk of malignancy increases with age (13-fold higher than the general population) with the most common cancers being colorectal, breast, pancreatic, and genitourinary.

Colonoscopy and EGD should be initiated at 8 years of age. If polyps are detected, endoscopic evaluation should continue every 2 to 3 years. If no polyps are found, repeat endoscopy and small bowel follow-through or capsule enteroscopy should be initiated by 20 years of age and repeated every 2 to 3 years. Other surveillance recommendations with low levels of evidence include an annual clinical exam, annual testicular ultrasound starting at age 10, monthly breast exam and annual breast MRI starting at 18 years of age, cervical smear starting at age 25, and magnetic resonance cholangiopancreatography (MRCP) of the pancreas starting at 25 years of age.

GI surgery is reserved for symptomatic disease or cancer. Any polyp larger than 1.5 cm should be removed, if possible, at the time of surgery. Intraoperative on-table endoscopy can be utilized to evaluate the entire GI tract.

Juvenile Polyposis Syndrome

Juvenile polyposis syndrome (JPS) is an autosomal dominant inherited disease resulting most commonly from mutations in the *SMAD4* and *BMPR1A* genes, which are respectively located on chromosomes 18q21 and 10q22. Polyps can be found throughout the GI system with the colon being affected 100% of the time. Extraintestinal manifestations occur around 15% of the time and can include cleft lip and palate, polydactyly, genitourinary anomalies, intestinal malrotation, hydrocephalus, and congenital heart disease. Hereditary hemorrhagic telangiectasia and bleeding arteriovenous malformations (AVMs) are associated with some *SMAD4* mutations and are found in the GI tract, lungs, brain, and mediastinum. Diagnosis of JPS is confirmed when five or more juvenile polyps are found in the colon or rectum, multiple polyps are appreciated in other regions of the GI tract, or after identification of polyps with a positive family history. Presenting symptoms can include hematochezia and melanotic stools, anemia, intussusception, obstruction, and passage of autoamputated or prolapsed polyps. Colorectal cancer is the most common associated malignancy with lifetime rates as high as 39%. Other malignancies include gastric, duodenal, and pancreatic.

Asymptomatic patients should begin with screening colonoscopy by 12 to 15 years of age and earlier for those with symptoms. If no polyps are detected, evaluation can be repeated every 2 to 3 years, otherwise annually. EGD is recommended by age 15. Those with a *SMAD4* mutation should have periodic screening for AVMs.

Colorectal surgery is reserved for symptomatic disease, dysplasia, cancer, or significant polyp burden (>100 polyps). For those with a relatively spared rectum, a TAC with IRA can be pursued, and if the rectum is significantly involved, a TPC with IPAA is advisable. Surgeries in the remaining GI tract may also be warranted.

Cowden's Syndrome

Cowden's syndrome (CS) is an autosomal dominant disorder resulting from a mutation in the *PTEN* tumor suppressor gene located on chromosome 10q23. Polyps typically occur in the colon and stomach, and colonic polyps can include hamartomas, fibromas, adenomas, lipomas, and neurofibromas. Extraintestinal manifestations include pathognomonic trichilemmomas, macrocephaly, and a wide variety of tumors and hamartomas of various organ systems (breast, thyroid, uterus).

The increased risk of colorectal cancer is estimated to be two or three times the general population (9%–16%). National Comprehensive Cancer Network (NCCN) guidelines recommend a screening colonoscopy starting at the age of 35. Thyroid screening with physical exam and ultrasound should be performed annually and begin at age 15. Annual mammography, with MRI for suspicious findings, should begin at the age of 30. Treatment is based on symptoms and pathology.

Bannayan-Riley-Ruvalcaba Syndrome

Bannayan-Riley-Ruvalcaba syndrome (BRRS) is an autosomal dominant disorder resulting from a mutation in the *PTEN* tumor

suppressor gene located on chromosome 10q23. Common findings associated with BRRS include pigmented penile macules, macrocephaly, hamartomas, hemangiomas, and mental retardation in upward of 50%.

The risk of developing colon and rectal cancer is thought to be no greater than the general population. Treatment is based on symptoms.

Cronkhite-Canada Syndrome

Cronkhite-Canada syndrome (CCS) is a noninherited disorder resulting from a mutation in the *PTEN* tumor suppressor gene located on chromosome 10q23. Hamartomatous GI polyps in addition to alopecia, macrocephaly, onycholysis, and cutaneous pigmentation are common findings. Diffuse GI inflammation resulting in malabsorption, diarrhea, and protein-losing enteropathy can occur.

The risk of developing colon and rectal cancer is thought to be greater than the general population. Treatment is based on symptoms and pathology.

Hereditary Mixed Polyposis Syndrome

Hereditary mixed polyposis syndrome (HMPS) is thought to be an autosomal dominant inherited syndrome, though a specific mutation has yet to be identified. HMPS presents with multiple different colon and rectal polyps (adenomatous, hamartomatous, and hyperplastic).

The risk of developing colon and rectal cancer is thought to be greater than the general population, although this is unsubstantiated at this time. Screening colonoscopy should begin between the ages of 25 to 30. Treatment is based on symptoms and pathology.

Serrated Polyposis Syndrome

Serrated polyposis syndrome (SPS) is a disorder characterized by multiple polyps (hyperplastic or serrated) throughout the colon. A heritable pattern and genetic cause has not been identified. The World Health Organization has proposed two criteria for diagnosing SPS, of which diagnosis is made upon fulfillment of either of the criteria. The criteria include (1) at least five serrated polyps, all greater than 5 mm in size and proximal to the rectum, two of which are greater than 10 mm in diameter, or (2) more than 20 serrated polyps of any size distributed throughout the large intestine with five being proximal to the rectum. These criteria distinguish the two SPS phenotypes; large serrated polyp proximal disease and distal small serrated polyp distal disease.

The risk of developing colon and rectal cancer is increased with rates of up to 25% to 70% documented in those with multiple polyps. The average age for developing colon and rectal cancer is 50 to 60. Treatment is based on polyp burden and dysplastic or neoplastic changes.

Strict surveillance with colonoscopy every 1 to 2 years is advisable. First-degree relatives are at an increased risk of SPS and developing colon and rectal cancer (5-fold), and should be offered the same surveillance starting at 40 years of age or 10 years younger than the index case.

Surgical Management of Colon Cancer

Mohamad A. Abdulhai, MD, and Michael A. Choti, MD

Colon cancer is the third most common cancer and cause of cancer death in the United States. An estimated 4.5% of the US population will be diagnosed with colon cancer in their lifetime. Fortunately, the mortality from colon cancer has been declining in recent decades, in part as a result of improvements in screening, surgical management, and chemotherapeutic options. The incidence of colon cancer in older adult patients has been steadily declining; however, we have been seeing an increase in frequency in patients younger than 50 years of age. More than two-thirds of colorectal cancers arise in the colon, defined as the intraabdominal portion of the large bowel that extends from the cecum to the peritoneal reflection. Although the biologic distinction between the colon and rectum is somewhat arbitrary, the oncologic behavior and cancer management differs considerably. Yet, similar to rectal malignancies, colon cancer is also best managed using a multidisciplinary team approach to optimize outcome. This chapter reviews the preoperative evaluation, clinical staging, and management of patients with colon cancer, highlighting the importance of a multidisciplinary approach.

CLINICAL PRESENTATION AND SCREENING

Colon cancer patients can present with a variety of gastrointestinal symptoms, depending on the size and location of the tumor. This can include abdominal pain, hematochezia, weight loss, anemia, constipation, diarrhea, or change in the caliber of stools. Classically, right-sided tumors tend to present with anemia, whereas, left-sided cancers are more likely to present with obstructive symptoms. However, many patients with colon cancer are asymptomatic at the time of diagnosis and identified by screening. This highlights the importance of screening to detect colon cancer before it becomes symptomatic. Implementation of increased screening, including colonoscopy, has contributed to the decline in colon cancer-related mortality seen in the past 20 years.

Screening for average-risk adults is now recommended to begin at age 45. There are several options for screening, including colonoscopy every 10 years, multitarget stool DNA testing every 3 years, annual fecal immunochemical testing, annual fecal occult blood testing with flexible sigmoidoscopy every 5 years, or double-contrast enema and CT colonography every 5 years. Those at higher risk for the development of colorectal cancer may require more frequent screening. In some conditions such as familial polyposis syndromes or hereditary nonpolyposis (Lynch syndrome), prophylactic colectomy may be indicated. Options for screening for colorectal cancer may be changing in the future, particularly with the application of newer technologies for the detection of minute fragments of circulating tumor DNA (ctDNA) in the bloodstream. Studies are underway evaluating the role of ctDNA for cancer screening.

PREOPERATIVE EVALUATION AND STAGING

The initial evaluation may depend on the type and severity of symptoms the patient is experiencing, in some cases necessitating more urgent intervention. In most cases, colon cancer presents more electively, affording the opportunity for careful evaluation and staging. Adequate preoperative colonoscopy is important to assess the details of the colon tumor, including the size, location, and extent. Biopsy provides histologic confirmation and characterization of pathologic features such as tumor grade, microsatellite status, and in some cases molecular sequencing. However, in some cases of invasive cancer, the biopsy may miss the invasive component. In such cases, one must be careful not to assume no malignancy if the biopsy is negative, particularly with a presentation or appearance consistent with cancer. During colonoscopy, it is important to ensure that the entire colon is examined when possible as ~5% of patients have a synchronous cancer and ~10% to 20% have a synchronous advanced polyp, which might alter the surgical plan. In some cases, an endoscopically obstructing distal tumor may prevent the ability to evaluate the proximal colon. In such cases, one can evaluate the proximal colon intraoperatively or with a colonoscopy 3 to 6 months after resection. During colonoscopy, tattooing should be considered in some cases to facilitate intraoperative detection.

Routine blood analysis should be obtained, including a complete blood count and metabolic profile. In addition, a preoperative carcinoembryonic antigen (CEA) level should be measured. It is important to obtain a baseline CEA level to compare with postoperative levels on surveillance and to alert to the increased probability of advanced disease. Cross-sectional imaging, most commonly CT, is also important before surgical intervention to determine the extent of local disease and assess for metastatic disease. Fluorodeoxyglucose positron emission tomography (FDG-PET) is not routinely recommended for the initial evaluation and should be used only selectively when the imaging is inconclusive or preoperative CEA is high (>20 ng/mL).

SURGICAL MANAGEMENT

Preoperative Preparation

The management of colon cancer depends on the stage at presentation. The majority of patients with stage I to III colon cancer can be managed with initial surgical resection with curative intent. The goal of surgical resection is removal of the primary tumor in its entirety with negative margins in addition to performing a complete lymphadenectomy of the draining lymph nodes. In cases in which the tumor involves adjacent organs, en bloc resection of those structures should also be considered. In cases of more advanced disease (stage IV), surgical resection of the primary tumor is done selectively, either palliatively for those with significant symptoms or as part of a curative-intent approach combined with metastatectomy.

The patient should undergo medical optimization before surgery to ensure safety of proceeding with an abdominal operation under general anesthesia. Both mechanical and oral antibiotic bowel preparations should be performed to decrease the risk of infectious complications. This includes a clear liquid diet the day before surgery and consumption of a purging solution such as polyethylene glycol (GoLYTELY or MiraLAX). In addition, patients are given oral antibiotics (e.g., neomycin and metronidazole) concurrently with the mechanical bowel preparation.

As with other complex operative procedures, the perioperative management of patients undergoing elective colorectal surgery should be guided by enhanced recovery protocols to improve outcomes, standardize care, and lower healthcare costs. Such pathways focus on improved pain management and minimizing narcotics by using a multimodal pain regimen. In addition, early mobilization, early feeding, and limiting fluid administration is important to hasten the return of bowel function and improve recovery.

The patient should receive prophylactic intravenous antibiotics before skin incision to reduce the risk of surgical site infection. In addition, patients should receive subcutaneous heparin and a sequential compression device placed before induction of anesthesia for venous thromboembolism prophylaxis. An indwelling urinary catheter is typically used. The patient is positioned supine for right-sided lesions and in the modified lithotomy position for left-sided lesions to allow access to the perineum for use of the end-to-end stapler and intraoperative endoscopy.

Operative Approach

The choice of operative method for colon resection can vary based on surgeon experience and patient/tumor factors. Several large multicenter randomized controlled trials have shown equivalent oncologic outcomes (e.g., nodal harvest, recurrence, survival) between open and laparoscopic colectomy. In most cases, a minimally invasive approach results in less pain, shorter hospital stay, and faster recovery, and it is recommended whenever the appropriate expertise is available. More recently, the use of robot-assisted surgery has been advocated as an alternative minimally invasive approach. Although few randomized trials have been conducted comparing robotic versus laparoscopic colectomy, improved visualization, facilitated intracorporeal anastomosis, and lower conversion rates may promote the robotic technique, albeit at a higher cost. In cases of large and locally advanced tumors requiring multivisceral resection, an open colectomy remains the preferred approach in most cases.

Colon Resection

Regardless of whether a minimally invasive or open approach is used, the technical and oncologic principles during surgery are the same. A thorough exploration of the abdomen should be initially performed to assess for metastatic disease. This includes visual inspection and, when possible, palpation of the peritoneal cavity along with the abdominal and pelvic organs, including the liver, omentum, and peritoneal surfaces. A curative resection of colon cancer entails removal of the involved segment of colon along with its mesentery at the origin of the feeding vessel. A 5- to 7-cm proximal and distal margin is typically recommended to ensure adequate removal of the pericolic lymph nodes. Histologic evaluation of a minimum of 12 lymph nodes is recommended to accurately determine nodal stage. Following extirpation, bowel continuity is restored using a tension-free, well-vascularized anastomosis. The alignment of the mesentery should be verified to avoid any torsion or internal hernia. Anastomotic technique can differ based on surgeon preference. Randomized studies have shown no difference in outcomes between stapled and handsewn techniques. Ileocolonic anastomoses are usually performed in a side-to-side functional end-to-end fashion. Colocolonic and colorectal anastomoses can be performed using either an end-to-end or side-to-end technique.

The extent of colonic resection depends on the location of the primary tumor and its draining lymphatic basin (Fig. 1). Tumors of the cecum, ascending colon, and hepatic flexure are managed with

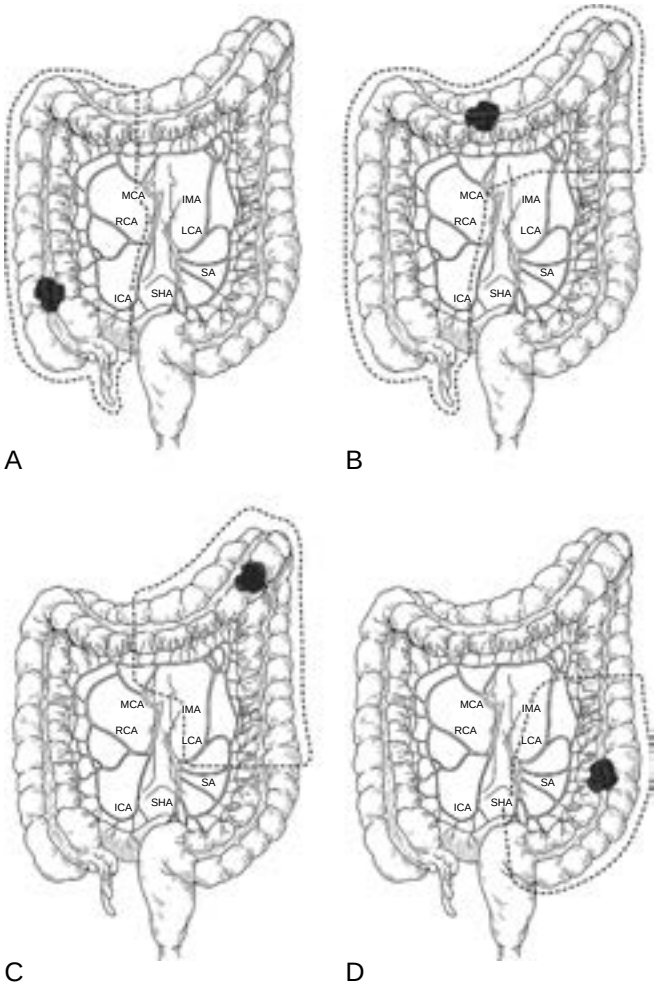

FIG. 1 Extent of resection for colon carcinoma. **(A)** Cecal or ascending colon cancer. **(B)** Transverse colon cancer. **(C)** Splenic flexure colon cancer. **(D)** Sigmoid colon cancer. *ICA*, Ileocolic artery; *IMA*, inferior mesenteric artery; *LCA*, left colic artery; *MCA*, middle colic artery; *RCA*, right colic artery; *SA*, sigmoidal arteries; *SHA*, superior hemorrhoidal artery. *(From Ruo L, Guillem JG. Cancer of the colon. In: Bland KI, Daly JM, Karakousis CP, eds. Surgical Oncology: Contemporary Principles and Practice. New York: McGraw-Hill; 2001.)*

a right hemicolectomy. This entails high ligation of the ileocolic and right colic vascular pedicles and preservation of the middle colic vessels. This is followed by removal of the terminal ileum, cecum, ascending colon, and hepatic flexure and construction of an ileotransverse anastomosis. Transverse colon cancers are managed depending on their location. Tumors of the mid or distal transverse colon are managed with an extended right hemicolectomy, which involves ligation of the ileocolic, right colic, and middle colic pedicles and removal of the cecum, ascending colon, transverse colon, and construction with an ileodescending anastomosis. Tumors of the splenic flexure or descending colon can be managed with either a left hemicolectomy or an extended left hemicolectomy. The former entails takedown of the splenic flexure with ligation of the left colic artery along with the left branch of the middle colic artery and construction of a transverse-to-sigmoid anastomosis. The latter involves ligation of the inferior mesenteric artery with anastomosis of the distal transverse colon to the upper rectum. The oncologic outcomes for either approach are considered equivalent. Sigmoid tumors are managed with anterior resection of the sigmoid colon performed by high ligation of the inferior mesenteric pedicle with anastomosis of the descending colon to the upper rectum.

SPECIAL SCENARIOS

Malignant Polyp

A malignant polyp is defined as an adenoma containing a focus of adenocarcinoma invading the muscularis mucosa into the submucosa (T1). About 5% of all endoscopically resected adenomas will contain invasive adenocarcinoma. Management of these polyps relies on detailed histopathologic examination of the specimen to estimate the risk of residual luminal cancer and the risk of lymph node metastasis. This in turn will determine whether endoscopic resection is sufficient or an oncologic segmental resection is warranted. If a negative histologic margin cannot be assessed, repeat endoscopy or segmental resection may be required. High-risk features for lymph node involvement include poor differentiation, deep submucosal invasion, presence of lymphovascular or perineural invasion, high tumor budding score, and positive endoscopic resection margin. Sessile polyps in general confer a higher risk of lymph node metastasis compared with pedunculated polyps. A 2-mm negative resection margin is considered adequate. The depth of invasion into the submucosa is also predictive of occult lymph node metastasis, and several classification systems have been developed to estimate the risk. The first is the Haggit classification for pedunculated polyps. In the absence of other high-risk features, the risk of lymph node metastasis in Haggit level 1, 2, and 3 lesions is less than 1%, but it can be up to 30% in Haggit level 4 polyps. The other commonly used classification system is the Kikuchi system, which evaluates the depth of invasion into the submucosa. The submucosa is divided into thirds: upper (Sm1), middle (Sm2), and lower (Sm3). The risk of lymph node metastasis for Sm1 tumors is 1% to 2%, Sm2 is <10%, and Sm3 is 20% to 25%. The application of the Kikuchi classification following endoscopic resection can be problematic as the muscularis propria layer is usually not included in the specimen. Therefore, alternatively the absolute depth of invasion into the submucosa is used with depth of invasion less than or equal to 1 mm conferring a low risk of lymph node metastasis.

Patients who undergo complete adequate endoscopic resection and are considered to have a very low risk of occult lymph node metastasis must be closely monitored for recurrence. There is currently no established standard for surveillance after endoscopic resection of malignant polyps in patients who do not undergo surgery. However, most experts recommend surveillance colonoscopy in 3 to 6 months. It is crucial to ensure that the site of the polypectomy is marked with a tattoo at the time of polypectomy or soon after (within 2 weeks) to allow for identification of the polypectomy scar on subsequent surveillance colonoscopies.

Locally Advanced Cancer

Locally advanced colon cancers with invasion of surrounding structures (T4) are seen in 5% to 10% of cases. Some of the most commonly involved organs include the small bowel, bladder, spleen, duodenum, and stomach. Detailed evaluation using cross-sectional imaging (CT scan or MRI) is important preoperatively to recognize multivisceral involvement. When possible, an en bloc multivisceral resection should be done to achieve an R0 resection and offer the best chance for cure. In such cases, neoadjuvant chemotherapy and sometimes radiation therapy can be used to improve the ability to achieve complete resection. This is reported in the FOxTROT international randomized controlled trial, which showed a 59% evidence of histologic downstaging and halving the rate of incomplete resections when using neoadjuvant chemotherapy. In addition, neoadjuvant chemotherapy was well tolerated and did not increase perioperative morbidity. The long-term oncologic outcomes using this approach are yet to be determined.

Stage IV Cancer

About 20% to 25% of patients will present with synchronous metastatic disease. Colon cancer most commonly metastasizes to the liver,

followed by the lung and peritoneal cavity. The management of stage IV colon cancer can be complex. First, it is important to identify if the metastatic disease burden is considered resectable to determine if the patient falls under a curative intent paradigm of treatment. Second, one should evaluate if the primary tumor is symptomatic, resulting in significant bleeding or obstruction. Recent evidence suggests less need for early palliative colectomy than in the past. Only if the primary cancer is appreciably symptomatic should the patient have this addressed with resection, diversion, or stenting before considering systemic therapy. Otherwise, early surgery is not indicated, and systemic chemotherapy is initiated. Even in symptomatic patients, it is not uncommon for the symptoms to improve following response to chemotherapy. The choice of first-line chemotherapy for advanced colon cancer typically includes a combination regimen of fluoropyrimidine, oxaliplatin, and/or irinotecan. In some cases, a biologic therapy such as bevacizumab may be included. Caution must be used, however, when administering bevacizumab with a bleeding or partially obstructing colon cancer in situ as this agent may increase the risk of wound complications or bleeding.

If curative resection of the oligometastatic disease is being considered, surgical resection both of the primary tumor and metastases should be done, either in a staged or synchronous approach. The decision to proceed with which approach should be tailored to the individual patient and surgical availability, considering the patient's physical condition and the extent and magnitude of the primary resection and proposed metastatectomy. In general, one can perform a limited metastatectomy (e.g., minor hepatectomy) with primary resection in a single stage. More complex surgery such as a major hepatectomy can be combined with a simple primary resection, but extensive metastatectomy along with complex primary resection is best managed with a staged approach.

TUMOR-RELATED EMERGENCIES

Perforation

The management of perforated colon cancers can be quite challenging as the surgeon must address both the sepsis and contamination associated with the perforated colon while adhering to the oncologic principles of complete cancer resection when possible. Moreover, perforated tumors are associated with a higher risk of recurrence. Because emergent colectomy for perforation with primary anastomosis is associated with a higher risk of anastomotic leak, consideration of a proximal diversion (loop ileostomy) or resection with end colostomy/ileostomy with a Hartmann pouch may be prudent. When making this decision, one must consider the clinical condition and stability of the patient along with the quality of the bowel and degree of abdominal contamination.

Bowel Obstruction

Large bowel obstruction can be seen in up to one-third of newly diagnosed colon cancers. Left-sided tumors are more likely to cause obstruction compared with right-sided lesions. The management of obstructing colon cancer varies by location, degree of obstruction, and the clinical condition of the patient. The first step is to assess the acuity and degree of obstruction, determined by clinical examination and imaging. It is important to assess the degree of proximal colonic dilation on imaging and look for signs of impending perforation (significant dilation of the cecum to >10 cm or evidence of pneumatosis). One must also evaluate whether the ileocecal valve is competent as this can result in a closed-loop large bowel obstruction and a higher risk of perforation.

In general, obstructing right-sided lesions can be managed with a right or extended right hemicolectomy, often with primary anastomosis. In patients who are hemodynamically unstable, frail, or malnourished, end ileostomy or proximal diversion should be considered. The management of left-sided obstructing lesions can be more challenging. One must consider whether the tumor is resectable as well as the presence and extent of metastatic disease. When performing urgent surgery for an obstructing left-sided cancer, options for resection with anastomosis and diverting ileostomy, resection and end colostomy, simply diverting proximal colostomy without resection should be entertained.

Endoscopic stenting can also have a role in the management of obstructing left-sided tumors. In selected cases, stenting can allow for temporary decompression and bowel preparation and is followed by elective single-stage colectomy. In situations with more advanced disease, palliative stenting followed by systemic chemotherapy can be considered. Stenting should only be performed by experienced endoscopists to mitigate the risks of perforation, occlusion, and migration. Stenting therefore can be considered either as a bridge to curative intent surgical resection or in palliative cases in which patients have incurable disease, limited life expectancy, and poor surgical candidacy.

ADJUVANT THERAPY

The goal of adjuvant systemic chemotherapy following curative-intent resection of colon cancer is eradicating micrometastatic disease and increasing the probability for cure. The decision to offer adjuvant chemotherapy is largely based on nodal status. However, the final shared decision should be individualized, considering other risk factors for recurrence and the patient's general physical condition. In general, systemic adjuvant chemotherapy is indicated in stage III disease. Several large randomized clinical trials have demonstrated improvement in survival, with a 30% reduction in recurrence risk and mortality. In some cases, adjuvant chemotherapy can also be considered for patients with high-risk stage II colon cancer as their recurrence risk is similar to that of stage IIIA disease. The high-risk features include T4 tumors, poorly differentiated histology, <12 lymph node harvest, presence of lymphovascular or perineural invasion, obstructed or perforated tumors, and positive margins. A regimen including a fluoropyrimidine and oxaliplatin (FOLFOX or CapeOX) is typically recommended for adjuvant therapy following colectomy, most commonly for a 6-month duration. Recent randomized trials have found comparable benefit with shorter duration (3 months) in select cases. Studies are ongoing to evaluate the emerging role of ctDNA to detect minimal residual disease following resection of colon cancer. This technology may help more clearly identify which patients will derive benefit from chemotherapy and can reduce its use in those with a higher probability of surgical cure.

SURVEILLANCE

Postoperative surveillance is important to allow for early identification of recurrent disease. Based on guidelines from the National Comprehensive Cancer Network, patients with stage II or III colon cancer should undergo serial serum CEA testing every 3 to 6 months for the first 2 years, then every 6 months up to 5 years. CT scanning is recommended every 6 to 12 months for 5 years. Surveillance colonoscopy is recommended 1 year after resection and again in 3 years if no polyps are found.

CONCLUSION

Improvement in early detection, surgical techniques, and multidisciplinary management have led to improved outcomes for patients with colon cancer. Although operative approaches to colon resection can vary, the principles of oncologically adequate surgery remain standard. Importantly, adherence to evidence-based perioperative management can contribute to safer surgery, more rapid postoperative recovery, and improved long-term outcome. Beyond surgical technique, future discoveries in molecular genetics, screening, improved detection, risk determination, and systemic therapies will likely continue to improve outcomes in the next decade.

PET Scanning in the Management of Colorectal Cancer

Joy Zhou Done, MD, and Sandy Hwang Fang, MD

INTRODUCTION

Accurate staging of disease is crucial to the management of colorectal cancers. Widely disseminated disease is a contraindication to surgical resection of a primary tumor, and thus the detection of metastatic disease provides important information to guide therapeutic goals. According to National Comprehensive Cancer Network (NCCN) guidelines, computed tomography (CT) and magnetic resonance imaging (MRI) play a significant role in the initial diagnosis, staging, and management of colorectal cancer (CRC); however, these imaging techniques provide only anatomic information about the tumor. The use of positron emission tomography (PET) as a hybrid to tomographic imaging, such as CT and MRI, adds functional data to these imaging modalities (Figs. 1 to 3; Table 1). The combined acquisition of PET CT provides more accurate information than either study alone by capturing quantitative data from regions of interest (ROI) to provide information about the entire cancer phenotype or microenvironment. Parametric analysis (PA) allows the extraction of numerical data contained in the voxels of each image to determine tumor biology of a specified ROI. PA can characterize tumor perfusion, heterogeneity, cellularity and fibrosis, oxygenation, and glucose consumption within an ROI using quantitative data on spatial complexity, density, signal intensity, activity, and distributions. This chapter describes the functional utility of PET scanning in the management of CRC, which gives information beyond what is delineated through visual inspection by CT or MRI alone.

POSITRON EMISSION TOMOGRAPHY CONCEPTS AND DEFINITIONS

PET is a diagnostic nuclear imaging study that measures uptake of 2-deoxy-2-[fluorine-18]fluoro-D-glucose (18F-FDG), an analogue of glucose, to detect metabolic abnormalities based on increased glucose uptake and glycolysis in cells of the body. Cancer cells have increased glucose metabolism compared with normal cells and thus higher FDG uptake in viable cancer cells. Standardized uptake value (SUV) evaluates the metabolic uptake of FDG in tumor cells. SUV may be quantified as the standardized maximum (SUV_{max}) or mean (SUV_{mean}) uptake. SUV_{max} is defined as the highest uptake value of the most intense pixel inside an ROI divided by the injected dose (corrected for decay and normalized for the patient's body weight or body surface area). SUV_{max} does not reflect overall tumor behavior because several confounding factors might affect SUV measurement: tumor heterogeneity, body size, image acquisition time, and partial volume effects. The SUV_{mean} is the average of all the pixel uptake values within an ROI. Increased SUV_{mean} values represent higher metabolic rates, which correlate with more aggressive tumor histology and worse overall survival (OS). Volumetric parameters of PET CT studies reflect the burden of the metabolically active tumor. The metabolic tumor volume (MTV) is the volume of tumor tissue with pathologic FDG uptake within a three-dimensional ROI. Total lesion glycolysis (TLG) is calculated by multiplying the SUV_{mean} by MTV.

INITIAL DIAGNOSIS, WORKUP, AND STAGING OF COLORECTAL CANCER

In the most current NCCN guidelines, initial staging of CRC involves a CT of the chest, abdomen, and pelvis to evaluate for the presence of distant metastasis. In rectal cancer, MRI is used for initial tumor and nodal staging. PET CT is not indicated in the initial workup of a pedunculated or sessile polyp with invasive cancer or resectable CRC (nonmetastatic) (stages I–III). Of note, mucinous tumors have no FDG uptake and account for ~17% of CRCs. PET CT also has limited sensitivity in detecting metastatic tumors less than 10 mm. Special consideration may be given to patients with a significant allergy to iodinated or gadolinium contrast or renal failure. In these circumstances, MRI without contrast or FDG-PET CT is recommended. FDG-PET CT may also be considered in cases where CT or MRI yields equivocal or nondiagnostic information to assist in percutaneous or surgical biopsy for a tissue diagnosis.

There is no established consensus regarding criteria to differentiate between benign, premalignant, or malignant lesions based on standard CT or MRI imaging. A small series evaluating 76 rectal cancer patients with preoperative FDG-PET CT determined that an MTV threshold of 2.5 predicted pathologic T3 and T4 staging as opposed to T1 and T2 staging (odds ratio, 1.81; 95% confidence interval, 1.26-2.60; $P = 0.001$).

Preoperative nodal staging (N-staging) with FDG-PET CT requires accurate identification of pericolorectal and mesenteric lymph nodes with metastatic disease. Studies have evaluated the cut-off value of SUV_{max} of 1.5 or 2.0, both values significantly increasing the identification of malignant lymph nodes. FDG-PET CT has been found to increase the accuracy of N-staging from 48% to 66% when compared to CT, with a potential change in rectal cancer management by 26%. False-negative FDG-PET CT results can be due to intense FDG uptake by the primary tumor, which can obscure adjacent structures, as well as low FDG uptake in microscopically positive nodes. For this reason, FDG-PET CT has been found to have low sensitivity for regional lymph node metastases. In two small, prospective studies comparing contrast enhanced CT with FDG-PET CT in patients with rectal cancer, PET CT altered the staging in nearly one-third of cases, and altered staging (primarily due to revised nodal status). This changed the management strategy and/or surgical plan in up to 14% of the cases. Despite a handful of positive studies, others have found that the routine use of PET CT for preoperative staging in colon and rectal cancers did not impact disease management in more than 96% of patients.

The major advantage of FDG-PET CT compared with contrast-enhanced CT is its superiority in identifying extrahepatic metastatic lesions with a high accuracy of up to 97%. Regarding lung metastases, some studies demonstrate high positive predictive value (PPV) and negative predictive value (NPV) for FDG-PET CT (90% and 94%, respectively), whereas other studies show similar low accuracy both for FDG-PET CT and CT. For liver metastases, a meta-analysis reported the sensitivity and specificity of FDG-PET CT to be 74.1% and 93.9%, respectively. The role of FDG-PET CT in the diagnosis, workup, and preoperative management of liver metastases will be discussed further in this chapter.

THE ROLE OF PREOPERATIVE FDG-PET CT IN COLORECTAL MALIGNANCY

The panel for NCCN strongly discourages the routine use of FDG-PET CT scanning for staging, baseline imaging, or routine follow-up. However, the panel recommends consideration of a preoperative FDG-PET CT at baseline if prior anatomic imaging indicates the presence of potentially surgically curable metastatic disease (M1). Two different meta-analyses studying more than 3000 study participants have demonstrated that FDG-PET CT may identify unrecognized metastatic disease that would preclude the possibility of surgical management, such as hepatic resection or radiofrequency ablation.

POSTTREATMENT EVALUATION OF COLORECTAL MALIGNANCY

In the past decade, overall survival has improved as a result of the introduction of treatment options, such as new chemoradiation therapy techniques (e.g., total neoadjuvant therapy [TNT]) and immunotherapy. However, it remains a challenge to determine which patients are optimal candidates for what type of therapy. Currently, we rely on response evaluation after treatment. It is difficult to predict response to treatment at treatment outset and long-term outcomes. Imaging is routinely used during diagnosis and follow-up and may aid in identifying noninvasive biomarkers that could determine response and long-term outcomes and ultimately tailor treatment regimens for CRC.

Standard assessment of the response to chemotherapy utilizes Response Evaluation Criteria in Solid Tumor (RECIST) to measure the change in size of the posttreatment tumor. However, these criteria do not take into account information about intralesional features, such as tumor necrosis.

In the posttreatment setting, a decrease in SUV on FDG-PET CT following treatment correlates to a greater chance of a complete response and improved long-term survival. A preliminary case series evaluated response to neoadjuvant chemoradiation therapy (nCRT) for rectal cancer 12 days after beginning nCRT identified a ≥52% decrease in SUV_{mean} for responders, of whom responders had a 5-year recurrence-free survival that was significantly higher than that of nonresponders.

On a cautionary note, PET CT may be transiently negative after chemotherapy, despite the presence of residual microscopic cancer cells that may not allow for sufficient FDG uptake. In addition, false-positive PET CT results can occur in the presence of tissue inflammation after surgery or infection.

COLORECTAL CANCER SURVEILLANCE

NCCN guidelines recommend that serial carcinoembryonic antigen (CEA) levels, colonoscopies, and CT scans are obtained for

CRC surveillance. FDG-PET CT is not indicated in standard CRC surveillance.

As per NCCN guidelines, circumstances that may warrant FDG-PET CT are reserved for select patients, in which distant recurrence workup with metachronous metastases is documented by CT, MRI, or biopsy. In this situation, FDG-PET CT determines whether there are other distant metastases that would disqualify the patient from surgery and thus make the patient a candidate for systemic chemotherapy. FDG-PET CT plays an important role in the detection of recurrence in patients who have an unexplained rise in their CEA levels. Residual soft tissue abnormalities are frequently seen in the tumor bed after treatment, which can complicate the interpretation of follow-up scans using conventional imaging techniques; therefore, FDG-PET CT may be considered as the next step in the workup of cancer recurrence. A soft tissue lesion identified using FDG-PET CT 6 months after completion of therapy likely represents recurrence, and the PPV of such a finding increases if it has been more than 12 months since the completion of therapy. The sensitivity and specificity of detection varies by anatomic location, with the highest sensitivity, specificity, and accuracy for the detection of extraabdominal and hepatic recurrence (sensitivity 95%, specificity 100%, and accuracy 99%). For intraabdominal but extrahepatic recurrence, the sensitivity is 88%, specificity 94%, and accuracy 92%. After image-guided liver-directed therapies (i.e., ablation, radioembolization), FDG-PET CT can be considered for assessment of treatment response and liver recurrence.

FDG-PET CT may also be helpful in determining local recurrence of rectal cancer. In a meta-analysis, detection of local recurrence (i.e., recurrence at the anastomosis or in the presacral region for rectal cancers) or distant metastasis, sensitivity of detection by PET CT was 94%, with a specificity of 93%. Postchemoradiation therapy and surgery yields presacral soft tissue findings on surveillance imaging in up to half of rectal cancer patients. FDG-PET CT may be useful in determining whether this presacral or anastomotic thickening represents fibrosis that is metabolically inactive versus recurrent cancer. However, FDG avidity in the pelvis may also be due to benign inflammatory changes from previous postoperative complications such as abscess or anastomotic leak or fistula. Thus, FDG-PET CT false-positive results of local recurrence may require further investigation via endoscopic, percutaneous, or image-guided biopsy.

THE ROLE OF PET CT IN COLORECTAL LIVER METASTASES

There is evolving evidence in the literature to support the utilization of FDG-PET CT in the preoperative evaluation of colorectal liver metastases (CRLM) and surveillance in a select population of patients. A randomized controlled trial evaluating preoperative CRLM, FDG-PET CT on surgical management for metastatic Colorectal Adenocarcinoma to liver Metastases ("PET-CAM"), was a multicenter study that aimed to identify the effect of preoperative PET CT vs. no PET CT on the surgical management of patients with resectable CRC liver metastases as determined by CT scan and/or MRI. Of the 263 participants who underwent FDG-PET CT in the trial, 21 (8%) had a change in surgical management with 7 (2.7%) avoiding futile laparotomy after the discovery of additional loci of metastatic disease (i.e., within the bone, peritoneum/omentum, and lymph nodes). In addition, 1.5% of patients underwent more extensive hepatic resections and 3.4% underwent extrahepatic surgery for distant metastases. A meta-analysis of 18 studies including 1059 patients with hepatic colorectal metastases found that PET or PET CT results changed management in 24% of patients. Controlling for similar baseline patient characteristics, the proportion of major liver resection (defined as greater than two liver segments) performed was higher in the PET-CT arm compared with the no PET-CT arm (76% vs. 67%, respectively). Preoperative staging PET CT improves survival in patients with resectable liver metastases primarily by demonstrating the presence of extrahepatic metastases, thereby identifying patients with inoperable disease who would not benefit from undergoing surgical resection and may instead benefit from neoadjuvant chemotherapy. Thus, these data support the use of FDG-PET CT before hepatic surgery among patients with otherwise resectable CRC liver metastases, as identified on CT scan or MRI. FDG-PET CT is highly accurate for detection of liver metastases on a per-patient basis but less accurate on a per-lesion basis. Notably, PET CT is limited in its ability to demonstrate lesions smaller than 1 cm; these lesions are best detected with MRI. PET CT may be especially useful in guiding liver biopsies, ablations, or hepatic resections in patients with indeterminate or suspicious findings on CT. PET CT is also used to detect occult recurrence and liver metastases in patients with a history of CRC, rising or abnormal CEA level, and otherwise negative imaging studies.

The Ontario Clinical Oncology Group (OCOG) performed a follow-up study evaluating long-term oncologic data (cancer recurrence events and death) for 7 years after the last day of follow-up of the original PET-CAM trial. However, they found no difference in median disease-free survival or OS between both trial arms among those patients who underwent liver resection. Most first recurrences were isolated to one organ site, primarily the lung or the liver, and the majority of recurrences happened more than 1 year following liver resection. These results are similar to prior published literature.

FDG-PET MRI

The use of FDG-PET combined with MRI has recently been introduced as a diagnostic method of detecting CRC metastasis. One retrospective study demonstrated the added value of PET MRI to CT to detect extrahepatic CRC metastasis, whereas another study reported that PET MRI can improve the limited sensitivity of PET CT to detect small lesions. In general, the combination of PET and MRI can improve the detection of both intra- and extrahepatic lesions over PET CT alone.

CONCLUSION

The imaging modalities of CT and MRI remain mainstays of the initial diagnosis, workup, and preoperative planning in management of CRC. Hybrid imaging modalities combining PET and either CT or MRI continue to evolve and has proven utility in a select population of CRC patients. Although CT and MRI are the preferred modalities in detecting extrahepatic and hepatic metastasis, the combination of functional and anatomical imaging modalities such as FDG-PET CT and/or FDG-PET MRI can improve the diagnostic detection of intrahepatic and extrahepatic CRC metastases and aid in the preoperative evaluation of CRC.

Neoadjuvant and Adjuvant Therapy for Colorectal Cancer

Yilin (Linda) Cao, MD, and Nilofer Azad, MD

Colon and rectal cancer, or colorectal cancer (CRC), is a common disease in the United States with an estimated 104,610 new cases of colon cancer and 43,340 new cases of rectal cancer in 2020. The lifetime risk of developing CRC is approximately 1 in 23 (4.4%) for men and 1 in 25 (4.1%) for women. Although the mortality and incidence rates have been declining over the last few decades, CRC remains the second leading cause of cancer-related deaths in the United States, expected to cause nearly 53,000 deaths during 2021. Moreover, deaths from CRC among individuals under the age of 55 have actually increased 1% annually from 2008 to 2017.

For early-stage CRC (stages I–III), surgical resection remains the basis of curative treatment. Distant recurrence, despite appropriate surgical resection, increases based on stage and is thought to be due to micrometastatic disease that is not readily detectable by current methods. For this reason, neoadjuvant and adjuvant therapies are often utilized to target micrometastases with the goal of complete eradication and prolonged survival. The challenge lies in determining which patients will benefit from additional therapy beyond surgical resection. The decision to add neoadjuvant or adjuvant therapy is based in large part on evaluating risk factors, which take into consideration not only clinical tumor stage but also patient-specific data like clinicopathologic features, such as lymphovascular invasion, and molecular profiling, such as microsatellite instability (MSI) status. Adjuvant and neoadjuvant therapeutic approaches to CRC are different for colon versus rectal cancer and are discussed separately in this chapter.

STAGING

Formal CRC staging is essential to risk stratification for guiding clinician treatment decisions for individual patients. Guidelines from the National Comprehensive Cancer Network (NCCN) for preoperative workup of newly diagnosed CRC should include the following: colonoscopy (plus consideration of rigid proctoscopy for rectal cancer) with biopsy and pathology review; complete blood counts, chemistry profile, and carcinoembryonic antigen (CEA) serum level; and computed tomographic (CT) scan of chest, abdomen, and pelvis for colon cancer versus CT chest with magnetic resonance imaging (MRI) of the abdomen and pelvis with contrast for rectal cancer. Endorectal ultrasound for rectal cancer is no longer indicated unless a patient has contraindications to MRI, such as an incompatible pacemaker. Preoperative staging is particularly important in rectal cancer because it determines whether patients receive neoadjuvant radiation therapy (RT), with the goal of both improved long-term local control as well as down-staging, allowing for less morbidity from curative surgical resection. Per the 2021 NCCN Guidelines, positron emission tomography is not recommended. CRC is staged based on the TNM staging system (T, primary tumor; N, regional lymph nodes; M, distant metastasis) adopted by the American Joint Committee on Cancer (AJCC). In the most recent version of the AJCC Cancer Staging Manual (eighth edition, 2017), several modifications were made to assist clinicians with prognostication, including the additional subdivision of M1c, which qualifies peritoneal carcinomatosis as a poor prognostic factor; clarification as to how tumor deposits in lymph nodes are defined; reintroduction of the "L" and "V" elements to better identify lymphatic and vessel invasion; and the identification of MSI status, KRAS, NRAS, and BRAF mutations as additional prognostic and predictive factors. The importance of accurate staging is reflected in Figure 1, which outlines the predicted 2-year overall survival rates by stage.

Colon Cancer

Stage II Colon Cancer

Adjuvant chemotherapy in stage II disease remains controversial due to a lack of demonstrated survival benefit in subset analyses of large clinical trials encompassing stage II–III colon cancer patients. However, stage II colon cancer is a highly heterogeneous group, and accordingly, stratification into a low-risk and high-risk group has been established. Based on NCCN 2021, high-risk factors for recurrence include poorly differentiated/undifferentiated histology, lymphovascular invasion, perineural invasion, emergency presentation such as bowel obstruction or perforation, inadequate lymph node sampling (<12 nodes in the surgical specimen), tumor budding, and indeterminate/close/positive margins. Tumor budding is the presence of single tumor cells or small clusters of tumor cells in the stroma at the invasive front of the tumor (i.e., "buds" that have detached from the main mass) and is thought to reflect epithelial-mesenchymal transition.

Unfortunately, there is currently no consensus for interpreting the relative importance of these diverse factors and how each should impact adjuvant chemotherapy selection in stage II disease. Studies do suggest that pT4 staging may be one of the most prognostic of these factors, with T4 accounting for a loss of 10% to 15% in 5-year overall survival (OS) compared with T3. A particularly pertinent risk factor within the surgeon's purview is that of lymph node sample size. The minimum number of 12 noted in NCCN stems from a 1989 publication reporting that this was an adequate number to determine node positivity in 94% of specimens. Furthermore, the importance

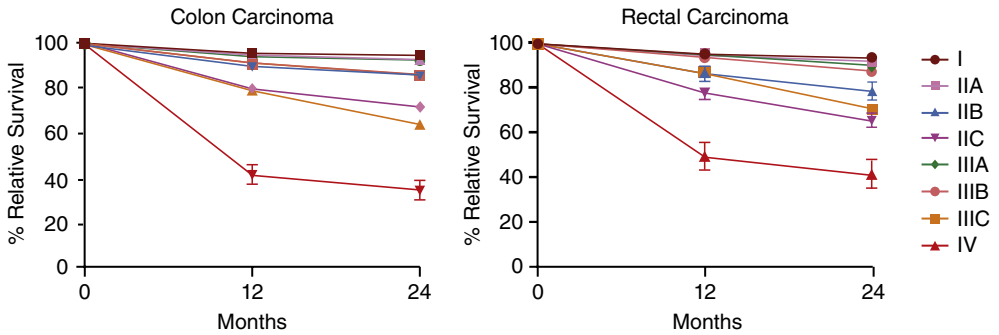

FIG. 1 Survival by stage for colon and rectal cancer patients in the SEER database since 2010. *(Data from* AJCC Cancer Staging Manual. *8th ed. New York: Springer; 2017.)*

of adequate lymph node sampling was demonstrated clinically by the Intergroup 0089 study, which found an absolute 5-year OS difference of 14% in stage II patients who had <10 negative lymph nodes examined compared with those with >20. These data and similar patterns demonstrated by other studies may be enough to warrant surgical reassessment in cases of particularly low-yielding lymph node dissection.

Generally, the presence of any of these high-risk features supports at least the consideration of adjuvant chemotherapy in stage II patients. The most common regimens are 6 months of FOLFOX (folinic acid, 5-FU, and oxaliplatin) or 3 months of XELOX (also known as CAPOX, capecitabine and oxaliplatin). An analysis of high-risk stage II patients from four of the six studies in the International Duration Evaluation of Adjuvant Chemotherapy (IDEA) collaboration published in 2021 found that, while noninferiority of 3 vs. 6 months of therapy could not be demonstrated, the decreased cost and toxicity of 3 months of adjuvant therapy made it a reasonable choice in this population given the small relative difference in outcomes. DNA mismatch repair status is another emerging prognostic factor, where MSI-high (i.e., mismatch repair deficient or *dMMR*) tumors portend a survival advantage, favoring observation over adjuvant therapy due to high rates of resistance.

There are also molecular assays that predict recurrence of CRC in the stage II setting. Five assays are commercially available, with the most data available for Oncotype-DX colon, a 12-gene recurrence score that has been validated to predict recurrence in mismatch repair proficient stage II disease. However, the assay has not been validated to show which patients benefit from adjuvant therapy. Multiple assays are in development and will require prospective studies to show that they have both a prognostic and predictive benefit, the latter of which could help in clinical decision making regarding adjuvant therapy.

Stage III Colon Cancer

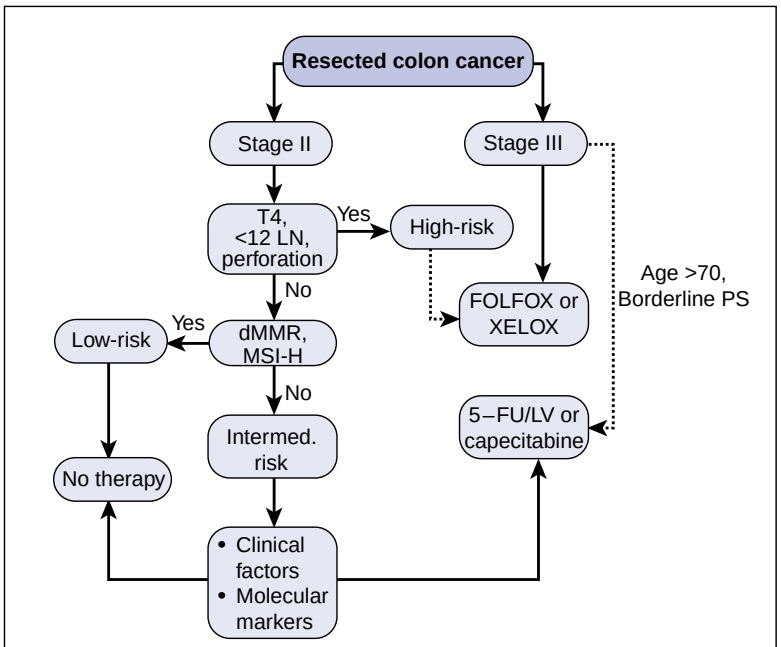
In stage III colon cancer, adjuvant chemotherapy has been the standard of care since 1990, with several large randomized clinical trials showing benefits in both OS and disease-free survival (DFS). The addition of adjuvant chemotherapy to surgical resection in patients with stage III colon cancer leads to an approximately 40% to 50% reduction in recurrence and 22% to 32% reduction in mortality. The National Surgical Adjuvant Breast and Bowel Project (NSABP) C-01, conducted from 1977 to 1983, was the first trial to demonstrate 5-year OS benefit for adjuvant therapy in colon cancer, specifically with the regimen of semustine, vincristine, and 5-FU (MOF). The NSABP C-03 trial, along with other similar studies, later demonstrated inferiority of MOF to intravenous 5-FU/LV regimens.

The benefit of the addition of oxaliplatin to 5-FU/LV (i.e., to become modern-day FOLFOX) was demonstrated by the MOSAIC trial. The primary endpoint of 5-year DFS was significantly higher with FOLFOX (73% vs. 67%, hazard ratio [HR]: 0.8). However, this came at the cost of increased rates of febrile neutropenia, peripheral neuropathy, and grade 3 to 4 diarrhea. OS rates were significantly higher for stage III disease (60% of the cohort) with FOLFOX but not in stage II disease. Subsequently, when capecitabine was combined with oxaliplatin (i.e., XELOX or CAPOX) in the NO16968 trial and compared with bolus 5-FU/LV, this demonstrated significantly improved 7-year DFS (63% vs. 56%, HR: 0.8), which translated to a 7-year OS benefit.

The current recommendation for adjuvant therapy for stage III colon cancer is 3 to 6 months of an oxaliplatin-containing regimen such as FOLFOX or XELOX. The IDEA collaboration analyzed six randomized trials of 3 versus 6 months of oxaliplatin-based adjuvant therapy. Results suggested that 6 months of therapy remains the standard of care for high-risk stage III colon cancer (T4N1-2; or any N2 disease). However, in low-risk disease (T1-3N1), 3 months of XELOX is considered noninferior to 6 months while conferring significantly less neuropathy. For patients with significant comorbidities, peripheral neuropathy, or age greater than 70 years, 3 to 6 months of infusional 5-FU/LV or capecitabine without oxaliplatin can be considered.

As new biomarkers and predictors of recurrence/prognosis are discovered and more antineoplastic agents are developed, recommendations will continue to be updated. A promising tool in its infancy is the use of cell-free DNA (cfDNA) for minimal residual disease detection after surgery to guide adjuvant therapy. One biomarker study by Tie et al. in 100 stage III colon cancer patients found that detectable cfDNA in postoperative plasma samples was significantly associated with inferior recurrence-free survival (HR 3.8), which remained independently predictive after adjusting for known clinicopathologic risk factors. Tools such as this will likely lead to more highly individualized cancer therapy algorithms in the coming years, but a graphical summary of current clinical decision making can be found in Figure 2.

RECTAL CANCER



Although rectal cancer has similar pathogenesis and molecular phenotypes to colon cancer, local recurrence rates in rectal cancer are significantly higher than in colon cancer. This discrepancy may be secondary to differences in both tumor factors, such as vasculature and lymphatic drainage patterns associated with the anatomic location, and surgical factors, such as completeness of mesorectal excision and extent of lymphadenectomy. As many as 10% of patients with T1 or T2 rectal cancer, 15% to 35% of patients with T3N0 rectal cancer, and 45% to 65% of patients with node positive T3 or T4 rectal cancer will experience local recurrence with standard resection, which can be significantly decreased with total mesorectal excision (TME) and neoadjuvant or adjuvant radiation.

In terms of the adjuvant/neoadjuvant therapy approach, two significant factors distinguish the management of rectal cancer from colon cancer. The first is that, in rectal cancer, there has been increasing emphasis of neoadjuvant as opposed to adjuvant therapy, termed "total neoadjuvant therapy" or TNT. The second is that RT and radiation therapy with concurrent chemotherapy (chemoRT) play a significant role in rectal cancer, whereas it is not standardly indicated in colon cancer. Concurrent chemotherapy refers to chemotherapy that overlaps the RT course (altogether termed chemoRT), which is delivered at lower than standard doses to help potentiate the ability of RT to kill tumor cells, or "radiosensitization".

Adjuvant Therapy for Rectal Cancer

Although neoadjuvant therapy is now the standard of care, historically, adjuvant therapy was intended to address the high rates of local recurrence and low rates of survival in rectal cancer. In 1985, the Gastrointestinal Tumor Study Group (GITSG) published a prospective randomized control trial of 227 patients with T3-4 or node-positive disease and negative margins on resection who were randomized to (1) surgery alone, (2) post-op bolus 5-FU/lomustine, (3) post-op RT alone, or (4) post-op chemoRT with 5-FU followed by 5-FU/lomustine. In this trial, recurrence rates were significantly reduced with combined chemoRT (33%) versus observation (55%), and OS was longer for chemoRT as well, although it did not reach statistical significance.

It was not until the mid-2000s and the era of TME that the German Rectal Study established the role of neoadjuvant chemoRT in cT3-4 or node-positive disease. It compared 50.4 Gy in 28 fractions (~5.5 weeks of RT) with concurrent infusional 5-FU *preoperatively* 6 weeks before TME to *postoperatively* 4 weeks after TME. All patients had four cycles of IV bolus 5-FU after completion of trial arm therapy. Although the study did not show any benefit in the primary endpoint of OS (~60% at 10 years for both arms), several advantages of the neoadjuvant setting led to this becoming the prevailing paradigm for chemoradiation therapy. Specifically, the study found that the neoadjuvant arm had much higher compliance (90% vs. 50%), decreased nodal involvement rate (25% vs. 40%), significantly improved acute and late grade ≧3 toxicity rates, 3% absolute reduction in 10-year local recurrence rate (7% vs. 10%), and improved likelihood of sphincter-preservation surgery in those initially felt to require abdominal perineal resection (39% vs. 19%).

FOLFOX	FOL = Folinic acid (Leucovorin) F = Fluorouracil OX = Oxaliplatin
CAPOX or XELOX	CAP = Capecitabine OX = Oxaliplatin
FOLFIRI	FOL = Folinic acid (Leucovorin) F = Fluorouracil IRI = Irinotecan
5FU/LV	FU = Fluorouracil LV = Leucovorin (Folinic acid)

Neoadjuvant Therapy for Rectal Cancer

Currently, the majority of United States cancer centers utilize a combined modality approach to neoadjuvant therapy with radiotherapy (50.4 Gy total radiation dose over the course of ~5.5 weeks) and concurrent chemotherapy (5-FU/LV or capecitabine), followed by surgical resection 4 to 6 weeks after completion of chemoRT. An emerging alternative strategy that is quickly gaining increasing utilization is short-course (or hypofractionated) radiotherapy of 5 Gy × 5 fractions (25 Gy total dose), which is not delivered with concurrent chemotherapy but is generally followed by a variable number of cycles of neoadjuvant chemotherapy. The need for adjuvant chemotherapy after TNT is still being assessed, with recent trials described in the following sections suggesting that it may not be necessary.

RT is most clearly indicated in stage II–III rectal cancers (i.e., T3-4 disease or node-positive disease). The goal of RT is two fold: to shrink the primary disease and to sterilize the draining lymph nodes. The typical radiation field will cover the perirectal, presacral, and internal iliac lymph nodes to a dose of 45 Gy followed by a more focused field on the primary tumor and mesorectum to 50.4 Gy when using standard chemoRT. For the short-course RT approach, the entire volume receives 25 Gy over 5 fractions (Fig. 3). If there is tumor extension to the prostate or vagina, one would consider adding the external iliac nodal region to the RT treatment volume as well. The Polish II trial established oncologic equivalence of neoadjuvant short-course RT and standard chemoRT in patients with cT3-4 disease, with no difference in sphincter preservation, local recurrence, and disease-free or overall survival. Short-course RT was associated with significantly lower grade ≧3 acute toxicity, but both regimens are considered to be acceptable and largely dependent on institutional practice preferences.

Preoperative therapy offers the opportunity to achieve pathologic complete response, with rates as high as 12% to 16% in the aforementioned Polish II trial. There has been increasing interest in modifying perioperative therapy to optimize pathologic complete response (pCR) rates and oncologic outcomes, potentially even opening a window for patients who may qualify for nonoperative treatment strategies aimed at organ preservation. The Timing of Rectal Cancer Response to Chemoradiation Consortium designed a phase II trial to investigate the effect of extending the interval between neoadjuvant chemoRT and surgery while administering additional chemotherapy (modified-FOLFOX) during the waiting period. Nearly 300 patients with stage II–III locally advanced rectal cancer were assigned to four treatment groups ranging from standard therapy (chemoRT followed by TME in 6–8 weeks), to groups receiving two, four, or six cycles of mFOLFOX6 following chemoRT. The pCR rate increased linearly by number of chemotherapy cycles, ranging from 18% in standard

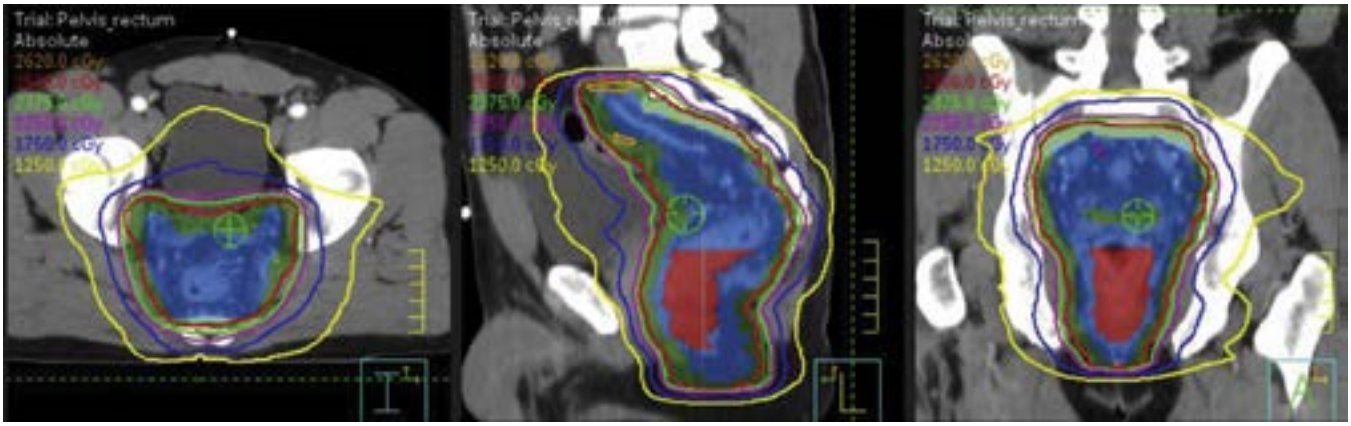

FIG. 3 An example of a preoperative short-course radiation therapy field for rectal cancer, including the perirectal, presacral, and internal iliac nodes *(blue colorwash)* and gross disease *(red colorwash)*.

chemoRT alone to 38% in the group receiving six additional cycles of neoadjuvant mFOLFOX. This promising data encouraged further studies in TNT. The RADIPO trial enrolled 920 patients with high-risk, locally advanced rectal cancer based on pelvic MRI features. Patients received 50 to 50.4 Gy of chemoRT with concurrent oral capecitabine and postoperative chemotherapy (XELOX or FOLFOX) vs. the experimental arm of short-course RT followed by preoperative chemotherapy. The 3-year treatment failure rate was significantly lower in the experimental arm (23.7% vs. 30.4%). The PRODIGE 23 trial corroborated the improvement in oncologic results with TNT, although it utilized a more rigorous chemotherapy regimen (FOLFIRINOX), and chemoRT therapy in both arms and allowed both low- and high-risk rectal cancer, with a 7% absolute benefit in 3-year DFS for the neoadjuvant group. These key trials for TNT are summarized in Table 1.

Treatment deescalation is also being actively investigated. Currently, a large phase III randomized prospective trial (PROSPECT-N1048) is ongoing to assess R0 resection rate and DFS for neoadjuvant chemotherapy alone vs. chemotherapy plus RT in patients with locally advanced rectal cancer (T2N1, T3N0, T3N1). The "watch and wait" strategy for organ preservation has also gained increasing academic interest. A case series of 113 patients at Memorial Sloan Kettering who elected for a watchful waiting approach after clinical complete response to neoadjuvant therapy demonstrated excellent rectal preservation and pelvic tumor control rates (82% and 91%, respectively). However, when compared with a surgical group that achieved pCR, the watchful waiting group had worse overall survival (73% vs. 94%), potentially owing to a high rate of distant metastasis in patients who had local recurrence (36%). These data suggest that better tools for risk stratification are necessary to identify optimal candidates for organ preservation strategies.

SURVEILLANCE

Despite the ever-evolving therapies for CRC, distant and local recurrence rates can be as high as 40%, with the majority of recurrences occurring in the first 2 years after completion of initial definitive therapy. Early identification of recurrence or new primary tumors may allow for potentially curative therapy (surgical resection or systemic therapy) and improved outcomes. For this reason, appropriate

TABLE 1 Key Trials Investigating Total Neoadjuvant Therapy in Rectal Cancer

Trial	Patient Population	Neoadjuvant Treatment Regimen	Time to Surgery	pCR Rate	Result
RAPIDO	920 high-risk patients*	Short course RT → CAPOX 6c or FOLFOX 9c → surgery vs. ChemoRT → surgery → optional adjuvant chemo	4–6 weeks	28% vs. 14%	No differences in complication rates, TNT improved pCR and 3-yr disease-related failure rates
TIMING	259 patients w/ T3-4, N1-2 disease <12 cm from anal verge	Concurrent chemoRT with 5-FU → FOLFOX for 0c, 2c, 4c, or 6c → surgery	6–8 weeks	0c = 18% 2c = 25% 4c = 30% 6c = 38%	No significant differences in surgical complications when bridging with FOLFOX during increasing interval to surgery
PRODIGE 23	461 patients w/ cT3-4 disease <15 cm from anal verge	FOLFIRINOX × 6c → concurrent chemoRT with capecitabine → surgery → adjuvant FOLFOX × 3c vs. Concurrent chemoRT → surgery → adjuvant chemo × 6 months	6–8 weeks	28% vs. 12%	Significant improvement in 3-yr disease-free survival and increased pCR rate with neoadjuvant FOLFIRINOX

*High risk was defined as at least one of the following MRI features: cT4, cN2, enlarged lateral lymph nodes, extramural vascular invasion, or mesorectal fascia involvement.*c,* Cycles; *CAPOX,* capecitabine and oxaliplatin; *FOLFOX,* folinic acid, fluorouracil, oxaliplatin; *FOLFIRINOX,* folinic acid, fluorouracil, irinotecan, oxaliplatin; *pCR*, pathologic complete response; *TNT,* total neoadjuvant therapy.

aggressive surveillance is imperative. Although there are subtle differences among professional organizations, most guidelines are generally in line with those published by NCCN.

For patients with stage I–III colon or rectal cancer, recommended surveillance is colonoscopy 1 year after resection, with subsequent colonoscopy in 3 years, then followed by every 5 years assuming no advanced adenomas are detected. For patients with rectal cancer who underwent transanal local excision only, the addition of proctoscopy with endoscopic ultrasound scan or MRI with contrast is recommended every 3 to 6 months for the first 2 years, then every 6 months through year 5.

For patients with stages II–III colon or rectal cancer, serum CEA is recommended every 3 to 6 months for 2 years, then every 6 months until year 5. CT chest, abdomen, and pelvis should be performed every 6 to 12 months for 5 years. Positron emission tomography/CT is not indicated for routine surveillance.

Management of Colorectal Polyps

Gifty Kwakye, MD, MPH, and Genevieve B. Melton-Meaux, MD, PhD

OVERVIEW

Colorectal cancer (CRC) remains the second leading cause of cancer deaths in the United States for men and women combined. Rates of early-onset CRC have also increased steadily over the past several decades, with 1 in 10 CRC patients diagnosed under the age of 50 years associated with a 58% greater risk of presenting with late-stage disease than their older counterparts. Identifying and removing premalignant colorectal polyps forms the basis of CRC screening programs using a variety of approaches. Of those approved by governing bodies, colonoscopy is the only one that allows for both detection and simultaneous removal of polyps, facilitating CRC prevention.

A colorectal polyp is a macroscopically visible lesion or mass that results from pathologic epithelial elevation of the colonic mucosa. Several other lesions can present as luminal masses, such as lipomas, carcinoid tumors, and leiomyomas. These lesions are covered by normal mucosa and, by definition, are not polyps. Most colonic polyps are asymptomatic; however, they are of clinical concern because of their malignant potential. The term *polyp* is nonspecific, and the importance of any one colorectal polyp is based on its histopathology, which determines the patient's risk of malignancy and, therefore, further treatment and follow-up. Colorectal polyps can be classified as either *sporadic* (approximately 60%) or *hereditary,* with the latter comprising a variety of familial syndromes that are potentially malignant conditions. A variety of approaches are used to address polyps, as outlined.

HISTOPATHOLOGY OF POLYPS

Adenomas

Adenomas are the most common neoplastic polyp identified in patients undergoing colonoscopy, representing 50% to 65% of all colonic polyps. Of sporadic CRC, approximately 80% develop from adenomas. The adenoma-carcinoma sequence, also known as the *loss of heterozygosity* or *chromosomal instability pathway,* is a cascade of sequentially accumulated genetic mutations (Fig. 1). Approximately 10% to 25% of asymptomatic patients at average risk and older than 50 years of age have an adenomatous polyp. The histology of these adenomas is most commonly tubular (65% to 85%), but they may also be tubulovillous (10%–25%) or villous (10%). Advanced adenomas are those that are greater than 1 cm or having a villous architecture, severe dysplasia, or carcinoma. The prevalence rate of advanced adenomas ranges from 3.5% to 9.5%, depending on gender and age. Identification of an adenoma should prompt a complete colonoscopy because of the 20% to 40% risk of proximal neoplastic lesions. Recommendations for follow-up colonoscopy are made based on the number, size, and histopathology of the adenomas and other clinical factors such as personal risk factors and family history. Removal of adenomas reduces future CRC and the development of advanced adenomas.

Serrated Polyps

In addition to the adenoma-carcinoma sequence, an increasingly recognized CRC carcinogenesis process is the serrated pathway (see Fig. 1). In fact, recent studies show that prevalence of serrated polyps in average-risk individuals is as high as 20% to 40%, accounting for almost 25% of sporadic CRCs. As outlined by the updated World Health Organization (WHO) classification system, serrated polyps include hyperplastic polyps (HPs), sessile serrated lesions (SSLs) and traditional serrated adenomas (TSAs). HPs are small, diminutive polyps, typically located in the left side of the colon and are identified by the absence of SSL architectural features on pathology. They have traditionally been thought of as benign but in special situations can have an increased malignant potential. These include large size (>1 cm diameter), location in the right colon, mixed adenoma/hyperplastic histology, more than 20 hyperplastic colonic polyps, familial hyperplastic polyposis, and a family history of CRC.

SSL is the recommended terminology for polyps previously called *sessile serrated adenoma, sessile serrated polyp,* or *sessile serrated adenoma/polyp.* Unlike HPs, SSLs have crypt distortion, presence of mucosal prolapse, or stromal proliferations. TSAs have distinct features that include ectopic crypts with narrow slits, prominent eosinophilic cytoplasm, and penicillate nuclei. Serrated polyposis syndrome can occur, characterized by the presence of either (1) ≥5 serrated lesions/polyps proximal to the rectum, all being ≥5 mm in size, with ≥2 being ≥10 mm in size or (2) >20 serrated lesions/polyps of any size distributed throughout the large bowel, with ≥5 being proximal to the rectum.

Hamartomas

A hamartoma is an outgrowth composed of normal mature cells that originate from below the mucosa. When sporadic, hamartomas

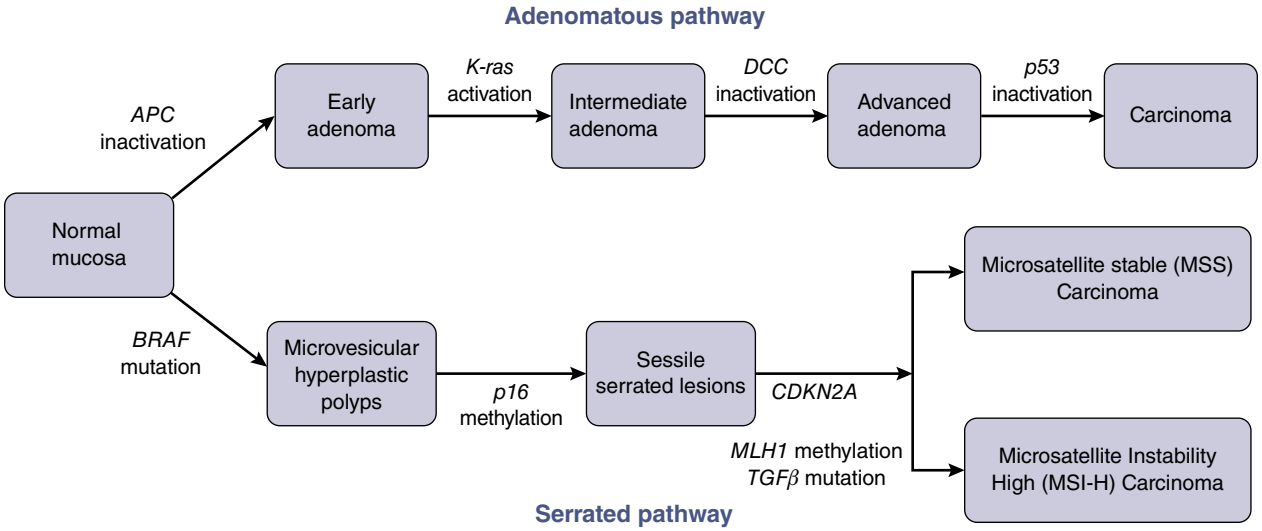

FIG. 1 Colorectal carcinogenesis pathways.

are frequently called *juvenile polyps* because they are relatively common in children. This second histologic category of colorectal polyps is mostly associated with one of three autosomal-dominant familial syndromes: Peutz-Jeghers syndrome, juvenile polyposis, and Cowden's syndrome. Although sporadic hamartomatous polyps are not considered premalignant, the familial syndromes have a significant rate of cancer development; therefore patients with these syndromes should undergo regular colonoscopic surveillance.

The typical phenotype of patients with Peutz-Jeghers syndrome includes perioral hyperpigmentation and multiple hamartomatous polyps located in the small or large bowel. These polyps may cause intussusception, bleeding, or obstruction at a young age. After the third decade, patients with Peutz-Jeghers syndrome have a 2% to 13% risk of gastrointestinal (GI) cancer and therefore should undergo regular endoscopic surveillance.

Juvenile polyposis is diagnosed when a young patient has 10 or more hamartomatous GI polyps. Lesions may occur anywhere within the GI tract, although they are frequently in the colon. These polyps may twist and auto-amputate, causing bleeding. Colon cancer affects up to 50% of those afflicted with juvenile polyposis and may occur in the fourth decade of life.

Cowden's disease, also known as *multiple hamartoma syndrome,* is characterized by hamartomatous neoplasms of the skin and mucosa, GI tract, bones, central nervous system, eyes, and genitourinary tract. A significant risk exists for skin, thyroid, endometrial, and breast cancer in Cowden's syndrome. Emerging evidence suggests an increased incidence of CRC as well.

TECHNIQUES FOR EXCISING POLYPS

Colonoscopic Approach

Polypectomy has proven to be an effective means of CRC prevention, allowing for identification, removal, and histopathologic evaluation of polyps. Most colorectal polyps are treated with endoscopic polypectomy, either with biopsy forceps or snare polypectomy, both of which can be either hot with electrocautery or cold. Snare excision typically provides a larger specimen, and the stalk (or base) can be evaluated histopathologically to better define the level of superficial malignancy if present. Large lesions may be removed with a piecemeal excisional technique, which allows for sequential excision of the entire lesion or en bloc with more advanced endoscopic techniques described in the next section.

Relative contraindications to colonoscopic polypectomy include anticoagulation therapy, bleeding diathesis, acute colitis, and evidence of invasive malignancy, such as central ulceration, a hard or fixed lesion, necrosis, or inability to raise the lesion with submucosal injection.

Complications related to colonoscopic polypectomy are uncommon and typically minor. The risk of death is 1 in 14,000. The most common serious complications are bleeding and perforation. Bleeding occurs in 4.8 in 1000 patients after colonoscopic polypectomy and may occur immediately or days later when clot dissolution occurs. Most post-polypectomy bleeds stop spontaneously and, when persistent, can usually be controlled with endoscopic clipping or cauterization. Rarely, interventional angiography or colectomy is necessary. Bleeding risk should be minimized by stopping warfarin and aspirin 5 days before polypectomy and clopidogrel 7 days before and possibly holding these agents for several days after polypectomy, although stopping any of these agents must be tailored to the patient's risk profile (e.g., patient with a mechanical mitral valve with a high risk of stroke off anticoagulation therapy).

Colonic perforation after conventional polypectomy occurs in 0.1% of patients, most of whom undergo successful treatment with conservative therapy that includes inpatient observation, bowel rest, and intravenous antibiotics. These patients must be followed closely as inpatients for any sign of clinical deterioration warranting laparotomy. One alternative approach is early laparoscopic primary repair of the defect, with colonoscopic assistance if the perforation is not easily identified on laparoscopy. The patient should be in the lithotomy position, and if colonoscopy is necessary, minimal insufflation with carbon dioxide should be used. Contraindications to this approach include peritonitis, malignancy, and the presence of significant fecal soilage.

Post-polypectomy syndrome has been reported to occur in up to 0.3% of patients after polypectomy, most often when cauterization has been used. The etiology is believed to be that the cautery causes a microperforation in the colonic wall and results in bacterial translocation. Patients typically present anywhere from 0 to 3 days after the polypectomy with abdominal pain and tenderness, fever, and leukocytosis. On computerized tomographic scan, fat stranding is typically seen in the mesentery, and the colonic wall of the polypectomy site is thickened; however, unlike with colonic perforation, pneumoperitoneum is not present. Patients should be treated with bowel rest, intravenous antibiotics, and close observation until symptoms resolve. Recognition of post-polypectomy syndrome is important to avoid unnecessary laparotomy in these patients, who may present with localized peritonitis.

FIG. 2 Endoscopic mucosal resection (EMR) of a large multilobar colonic polyp. **(A)** Polyp. **(B)** Injection of a lifting agent. **(C)** Resection bed after polyp removal. *(Photographs courtesy Dr. Allison Schulman, Advanced Gastrointestinal Endoscopist, University of Michigan).*

Endoscopic Mucosal Resection

Initially described in Japan, endoscopic mucosal resection (EMR) is one of two advanced endoscopy techniques gaining traction that allows for removal of large superficial polyps within the GI tract. A solution is injected into the submucosa, right underneath the polyp (Fig. 2). This raises the mucosal layer, facilitating better encirclement with the snare device. Solutions typically used include saline (normal or hypertonic), glycerol, hyaluronic acid, and diluted epinephrine. EMR improves the safety of polypectomy by increasing the distance between the mucosa and the muscularis propria. It is critical to tattoo the area with India ink when large or suspicious polyps are removed because typically further endoscopic evaluation or resection is indicated. For larger lesions, a piecemeal polypectomy typically still occurs because of the limitations of the procedure. This affects the ability to perform accurate pathologic staging, resulting in the need for a segmental colectomy that could potentially have been avoided.

Endoscopic Submucosal Dissection

Compared with EMR, endoscopic submucosal dissection (ESD) better allows for en bloc resection of even large polyps. The border of the polyp is typically marked by injecting indigo carmine. The polyp is then lifted with introduction of solution into the submucosal layer, like in EMR. Using special endoscopic knives and electrocautery, the lesion is excised in one piece. Because of violation of the submucosal layer, bleeding is quite common and can be easily controlled with electrocautery or placement of endoscopic hemoclips. Caution should however be used when applying any heat device in the thin-walled colon because this could lead to perforation. Although ESD allows for en bloc polyp excision consistent with oncologic principles, it has a higher perforation rate, takes longer to complete, and has a steeper learning curve, which have affected widespread adoption.

Combined Endo-Laparoscopic Surgery

Even with advanced endoscopic techniques described earlier, removal of large colonic polyps is not always feasible. Traditionally, these cases have been referred for segmental colectomy, which has an associated increased risk for morbidity and, in select patients, even mortality. In combined endo-laparoscopic surgery (CELS), endoscopic resection of the polyp is performed while manipulating the bowel laparoscopically by either invaginating the bowel wall to allow for easier polyp snaring or mobilizing the bowel to improve reach endoscopically. One of its advantages is immediate detection of full-thickness bowel injury, which can be repaired laparoscopically in experienced hands. However, it is limited by the challenges presented by combining two very different techniques. For instance, insufflation of the bowel lumen endoscopically might limit the ability to visualize and maneuver laparoscopic instruments, increasing the risk for injury to underlying intraabdominal structures. Clamping the terminal ileum during endoscopic insufflation could limit distension of the small bowel but fails to address colonic distension. At the end of the case, an air leak test can be performed to identify any injury not detected previously. With careful patient selection, CELS has been shown to be successful in 70% to 97% of cases.

Surgical Approach

Large polyps or early rectal cancers not amendable to endoscopic excision can be addressed using surgical techniques performed transanally. These allow for complete en bloc excision of the lesion, which is important for pathologic evaluation. This also potentially avoids the morbidity and mortality of a more invasive low anterior resection or abdominoperineal resection in patients with benign disease or early cancers. The surgical approach used is determined by location of the polyp relative to the anal verge. In addition to routine history and physical examination, patients should have a proctoscopy completed to assess the location of the polyp and its size to assist with both patient positioning intraoperatively but also choice of surgical technique to use. Placement of the patient in the lithotomy position, prone with split legs or lateral decubitus should be performed aiming to have the lesion located inferiorly in the 5 to 7 o'clock position. Orientation of the specimen once removed needs to be always maintained in case additional margin(s) must be resected after pathology review. An easy strategy to accomplish this involves pinning the specimen to the white pad found in most surgical needle boxes and labeling the cardinal points with permanent ink. Complications related to surgical polypectomy include urinary retention, bleeding, infections, and bowel perforation. There is also a chance for incomplete resection or need to convert to a different more invasive approach. Both can be avoided with proper patient selection following careful review of perioperative workup. The surgery can be done as an outpatient or with a short period of inpatient observation depending on practice preferences.

Conventional Transanal Excision

For large polyps in the distal rectum, local excision has been shown to be effective at complete removal, where lymph node sampling is not required. Polyps amendable to standard conventional transanal excision (TAE) must be located within 6 to 8 cm from the anal verge, be <3 cm in size, and occupy less than 30% of the rectal circumference. For known malignant polyps, recommendation is to proceed with TAE in tumors with T1 depth of invasion only. Because of the tendency for suboptimal visualization, higher rates of positive margins and recurrence following conventional TAE resections have been reported.

Transanal Endoscopic Microsurgery

Transanal endoscopic microsurgery (TEM) allows for excision of lesions higher up in the rectum than conventional TAE, including up to the distal sigmoid colon per published reports. It requires a reusable, rigid 4-cm-diameter proctoscope, which comes in either a 12-cm or 20-cm length; a laparoscopic camera; and modified angled laparoscopic instruments. The rigid platform has three additional 5- to 9-mm ports through which instruments and a suction device can be passed. CO_2 pneumorectum is established through a port on the proctoscope to help maintain distension of the bowel wall while operating. Electrocautery is used to demarcate a 5- to 10-mm margin around the lesion. Then, using an instrument to grasp and adjust the distal edge, an energy device is used to perform submucosal or full-thickness dissection of the outlined area. For mainly posterior tumors, a partial resection of the mesorectum can be performed en bloc with the polyp. Care must be taken to avoid grasping the lesion directly because this could result in tissue breakage. Also, it is important to remain perpendicular to the lesion during dissection to avoid early tunneling, which could compromise the deep margin. Once the specimen is removed, hemostasis is achieved.

If a full-thickness excision was performed, it is recommended that the defect be closed transversely using a running or interrupted figure-of-8 absorbable suture. This tends to be a more time-consuming aspect of the procedure and requires some comfort with laparoscopic suturing to complete successfully. One could consider using barbed suture (e.g., V-lock), a knot pusher, or laparoscopic suture clips to eliminate the need to tie intracorporal knots, which can be challenging. Studies show that lesions located anteriorly in the upper or middle rectum tend to have a higher rate of intraperitoneal entry during dissection. In experienced hands, this can be sutured closed using the TEM platform with the patient placed in the steep Trendelenburg position to shift the bowel out from the pelvis. If unable, a transabdominal approach might be required.

The main limitation of TEM is the cost of the equipment. In addition, the rigid proctoscope can make it difficult to manipulate instruments when operating, requiring a steep learning curve to troubleshoot. Patients should complete a full bowel prep before the procedure to avoid stool interfering with visualization during the intraluminal portion of the case. This is also important if one anticipates a higher risk for intraperitoneal entry, with the potential need for transabdominal surgery based on lesion location.

Transanal Minimally Invasive Surgery

Because of the limitations associated with TEM, transanal minimally invasive surgery (TAMIS) was introduced as an alternative. It combines TEM principles with single-site laparoscopy, without the need for expensive specialized equipment or complex learning curves. The setup includes a flexible disposable single-site laparoscopic platform along with standard laparoscopic cameras, insufflators, and instruments. The more commonly used GelPOINT Path access channel comes in three lengths: 4 cm, 5.5 cm, and 9 cm. Channel length selection again is based on lesion location from the anal verge. The kit comes with self-retaining sleeves that are inserted into the gel cap, which can accommodate 5- to 10-mm standard instruments, in addition to frequently used needle sizes. Pneumorectum is established through a side port using standard insufflation equipment. If available, the AirSeal device can be used instead with the added advantage of providing stable bowel distension, even during suctioning activities. Dissection is performed in a similar fashion as in TEM.

Although the flexible platform allows easier maneuvering of instruments, the most challenging part of the procedure remains suturing the defect close at the end of the case because of the confined intraluminal space. To navigate this issue, many have turned to using the robotic platform with the TAMIS setup, capitalizing on the increased degree of articulation at the wrist of the robotic instruments.

Even though most vendors offer a shorter channel length, lesions in the distal rectum just above the dentate line might still be difficult to resect completely because of the platform. A hybrid approach using TAMIS for the proximal margin and then removing the platform to facilitate a conventional TAE can allow for complete excision and closure of the defect.

APPROACH TO THE MALIGNANT POLYP

Up to 5% of polyps that appear benign contain invasive cancer. This risk of cancer correlates with increasing polyp size such that polyps greater than 2 cm have an approximately 30% risk of cancer. For this reason, as mentioned previously, the colon should be tattooed at the site of any large polyp or any suspicious polyp if further treatment and evaluation are necessary.

Malignant polyps with deeper depth of invasion (i.e., >T1) have increased risk for lymph node metastases and should proceed to formal segmental resection. Even superficial or T1 early cancers can have higher risk for lymph node involvement based on the location within the polyp. To assist with risk prediction in this setting, the Haggitt level and Kikuchi submucosal (Sm) classification systems are used (Table 1). Haggitt levels 1 to 3 correspond with Sm1, but Haggitt level 4 can be Sm1, Sm2, or Sm3. A malignant polyp with an Sm3 classification is an indication for formal resection. Other factors predictive of lymph node metastases or recurrence are high tumor grade, extensive tumor budding, and lymphovascular invasion. In the absence of any of these features, the risk of adverse outcome is less than 1%; however, if a malignant polyp has one of these features, the risk increases to 20%. If two or more of these adverse features are present, the risk of adverse outcomes increases to 36%. Further evaluation of these features may better define patients who can be spared major surgery.

TABLE 1 Classification of Invasion Level

Haggitt Classification (Pedunculated Polyps)	Definition	Kikuchi Classification (Sessile Polyps)	Definition	Risk of Lymph Node Metastasis
1	Invades submucosa but limited to the head of the polyp	Sm1	Invades into the upper third of the submucosa	3%
2	Invades the neck of the polyp	Sm2	Invades into the middle third of the submucosa	8%
3	Invades the stalk of the polyp	Sm3	Invades into the lower third of the submucosa	23%
4	Invades the submucosa of the bowel wall below the stalk			

Haggit 1-3 corresponds to Sm1. Haggit 4 corresponds to Sm1, Sm2, or Sm3 levels.

Criteria for close surveillance after endoscopic removal of a malignant polyp include complete excision, a microscopic margin greater than 2 mm, no lymphatic or vascular invasion, moderate to well differentiation, Haggitt level 1 to 3, or Sm level 1 to 2.

All other malignant polyps that do not meet the aforementioned criteria should be considered for surgical resection. However, even with some high-risk features, patients with serious medical comorbidities may be best managed with close surveillance and nonsurgical treatment. An alternative to patients at high risk with a malignant rectal polyp may be full-thickness surgical excision (TAE, TEM, or TAMIS) with adjuvant chemoradiation.

Management of Peritoneal Surface Malignancies

Fabian M. Johnston, MD, and Juliet Siena Lumati, MD

Peritoneal surface malignancies represent a heterogenous group of intraperitoneal malignancies arising from the lining of the abdominal and pelvic cavity. They include primary malignancies of the peritoneum such as diffuse malignant peritoneal mesothelioma, peritoneal serous papillary carcinoma, desmoplastic small round cell tumors, and metastases from other primary tumors typically involving the colon, stomach, and ovaries. Cytoreductive surgery (CRS) and hyperthermic intraperitoneal chemotherapy (HIPEC) have evolved over the past decade to provide a therapeutic advantage to patients who otherwise have limited options beyond systemic chemoradiation for locoregional control or palliation. The purpose of this chapter is to review the epidemiology of peritoneal surface malignancies as well as current treatment guidelines.

EPIDEMIOLOGY AND CLASSIFICATION

Appendiceal Neoplasm

The true incidence of appendiceal neoplasms is unknown but is thought to be about 0.12 cases per 100,000 people per year in the United States. They are more commonly diagnosed incidentally on pathology in about 1% to 2% of appendectomy specimens. These tumors can be of mucinous or non-mucinous histology and may contain a signet ring cell component. Signet ring cell carcinomas are very aggressive, with up to 60% of cases already showing distant metastasis at the time of diagnosis. Patients with mucinous tumors may clinically present with *pseudomyxoma peritonei* (PMP), which is a condition characterized by mucinous ascites and peritoneal implants. Because of the rarity of these neoplasms, histologic classification had been challenging until 2010, when the World Health Organization recognized three categories of primary appendiceal neoplasms: *mucinous adenoma, low-grade appendiceal mucinous neoplasm* (LAMN), and *mucinous adenocarcinoma*. Subsequently in 2016, The Peritoneal Surface Oncology Group International Consensus developed a classification system to describe both the primary lesion and peritoneal disease. It also classified noncarcinoid epithelial neoplasms of the appendix itself and added a new term, *high-grade appendiceal mucinous neoplasm* (HAMN) for lesions with the low-grade architectural features of low-grade appendiceal mucinous neoplasm but with high-grade cytologic features (Box 1).

CLINICAL MANIFESTATION

Clinical symptoms on presentation can be quite nonspecific. Common presentations include increasing abdominal girth, weight loss, fatigue, bloating, constipation, and pain. Not uncommonly the diagnosis is made on presentation with acute appendicitis obstruction of the appendiceal lumen by malignant cells, which may lead to inflammation and infection of the appendix. Similarly, mucinous tumors may present with cystic dilation of the appendix, which could also mimic symptoms of appendicitis or be found incidentally on imaging for a different etiology. Men may also present with hernias and women with a bulky pelvic mass. Anorexia, early satiety, and massive ascites are also common manifestations, and in some ways, likely underestimate the true incidence of the disease given the late clinical presentation of these neoplasms.

PREOPERATIVE WORKUP

Preoperative workup should include staging CT of the chest, abdomen, and pelvis. Routine CBC, basic metabolic panel, and nutritional markers are often helpful. Other parameters include serum tumor markers including CEA, CA 19-9, CA125, and chromogranin A as well as obtaining a preoperative colonoscopy to evaluate for synchronous or metachronous colonic lesions, which at times may be negative. A diagnostic laparoscopy may be useful in determining eligibility for cytoreductive surgery in addition to obtaining histologic assessment, which may help guide treatment plans.

PATIENT SELECTION

Patient selection is extremely important in deciding who will most benefit from CRS and HIPEC and to avoid significant morbidity and mortality in patients who are not expected to benefit. Surgeons

BOX 1 PSOGI 2016 Classification of Noncarcinoid Appendiceal Epithelial Neoplasms

- Tubular, tubulovillous or villous adenoma, low- or high-grade dysplasia
- Serrated polyp with or without dysplasia (low or high grade)
- Low-grade appendiceal mucinous neoplasm
- High-grade appendiceal mucinous neoplasm
- Mucinous adenocarcinoma: well, moderately, or poorly differentiated
- Poorly differentiated (mucinous) adenocarcinoma with signet ring cells
- (Mucinous) signet ring cell carcinoma
- Adenocarcinoma: well, moderately, or poorly differentiated

should consider the extent of disease, tumor biology, physiologic age, comorbidities, and the ECOG/WHO functional and frailty status when selecting patients. Scoring systems such as the peritoneal disease severity score (PDSC), which was devised to stage patients with colon cancer based on clinical symptoms, extent of carcinomatosis based on radiographic evidence, and tumor histopathology may be useful to facilitate appropriate patient selection. For patients with LAMN (grade 1) CRS + HIPEC is the treatment of choice if complete cytoreduction can be achieved. Patients with adenocarcinoma and peritoneal metastasis are less likely to have complete cytoreduction and overall have poorer survival than those with LAMN. It is important to note that not all LAMNs or well-differentiated mucinous adenocarcinomas require a right hemicolectomy unless there is clear involvement of the colon serosa, which would necessitate colectomy. Furthermore, The American College of Surgeons' NSQIP surgical risk calculator may also be used to estimate perioperative risk, especially in patients with significant cardiopulmonary comorbidities not captured by the PDSC. It is important to note that no risk calculator is absolute; therefore, it is the combination of risk factors and expected net benefit that guides preoperative discussions with patients to set appropriate expectations. Furthermore, all patients should be presented at multidisciplinary team with considerations given to probability of extensive organ resection, morbidity, quality of life, and recurrence risk. The Chicago Consensus Guidelines on the management of appendiceal neoplasms are highlighted in Figures 1 and 2.

COLORECTAL CANCERS

The care of patients with advanced colorectal cancer has evolved over the past several decades, with overall improvement in the median survival for patients with stage IV disease. This has been largely attributed to improvements in the use of multimodal targeted therapy (i.e., neoadjuvant chemotherapy [NACT] and chemoradiation for rectal tumors), surgical technique, adjuvant chemotherapy for colon cancer, and improved patient selection. This is in addition to improving evidence that metastasectomy of liver and lung metastases improves 5-year survivorship.

In 2003, Verwall et al. randomized 105 patients with metastatic colon cancer with peritoneal carcinomatosis to receive CRS + HIPEC or systemic therapy alone that consisted of monotherapy 5FU/leucovorin. Results from this clinical trial showed an improvement in median survival in the HIPEC arm at 22.3 months compared with 12 months in the standard group at the median follow-up of 22 months. However, a subsequent follow-up study published in 2008 found no difference at the 8-year follow-up. Similarly, the COLOPEC trial, which was a multicenter randomized controlled trial (RCT) of 204 patients compared adjuvant HIPEC + systemic chemotherapy to systemic chemotherapy alone. The authors found no difference in metastasis-free survival at 18 months and a slight increase in postoperative complications in the HIPEC + chemotherapy group. Given that HIPEC is typically performed concurrently with CRS, the first study to evaluate HIPEC + CRS versus CRS alone was the PRODIGE trial with results recently published as of February 2021. This was an RCT comparing HIPEC + CRS versus CRS alone and recruited 265 patients across 7 centers. The authors found no significant difference in the median survival in the HIPEC + CRS group versus the CRS group (41 months vs. 40 months, respectively) at a median follow-up of 63 months. In a subgroup analysis, patients with a moderate burden of peritoneal disease (peritoneal cancer index [PCI] 11–15) who received HIPEC had a significant improvement in overall survival at 41 months compared with 32 months in CRS, though outpatient complication rates were higher in the HIPEC + CRS group versus

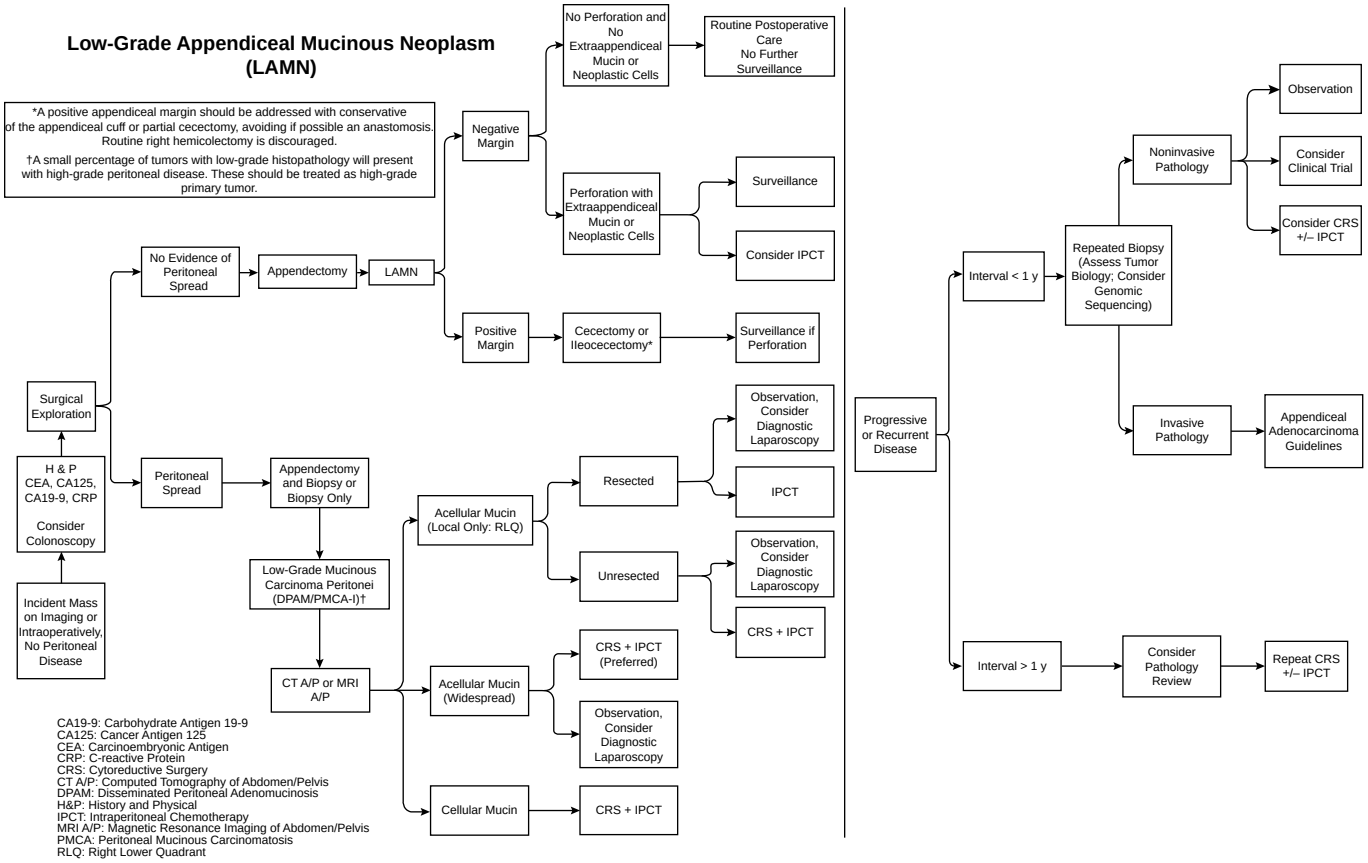

FIG. 1 The 2018 Chicago Consensus Guidelines on the Management of Low-Grade Appendiceal Mucinous Neoplasm (LAMN). *(From Chicago Consensus Working Group. The Chicago consensus on peritoneal surface malignancies: standards. Cancer. 2020;126:2516–2524.)*

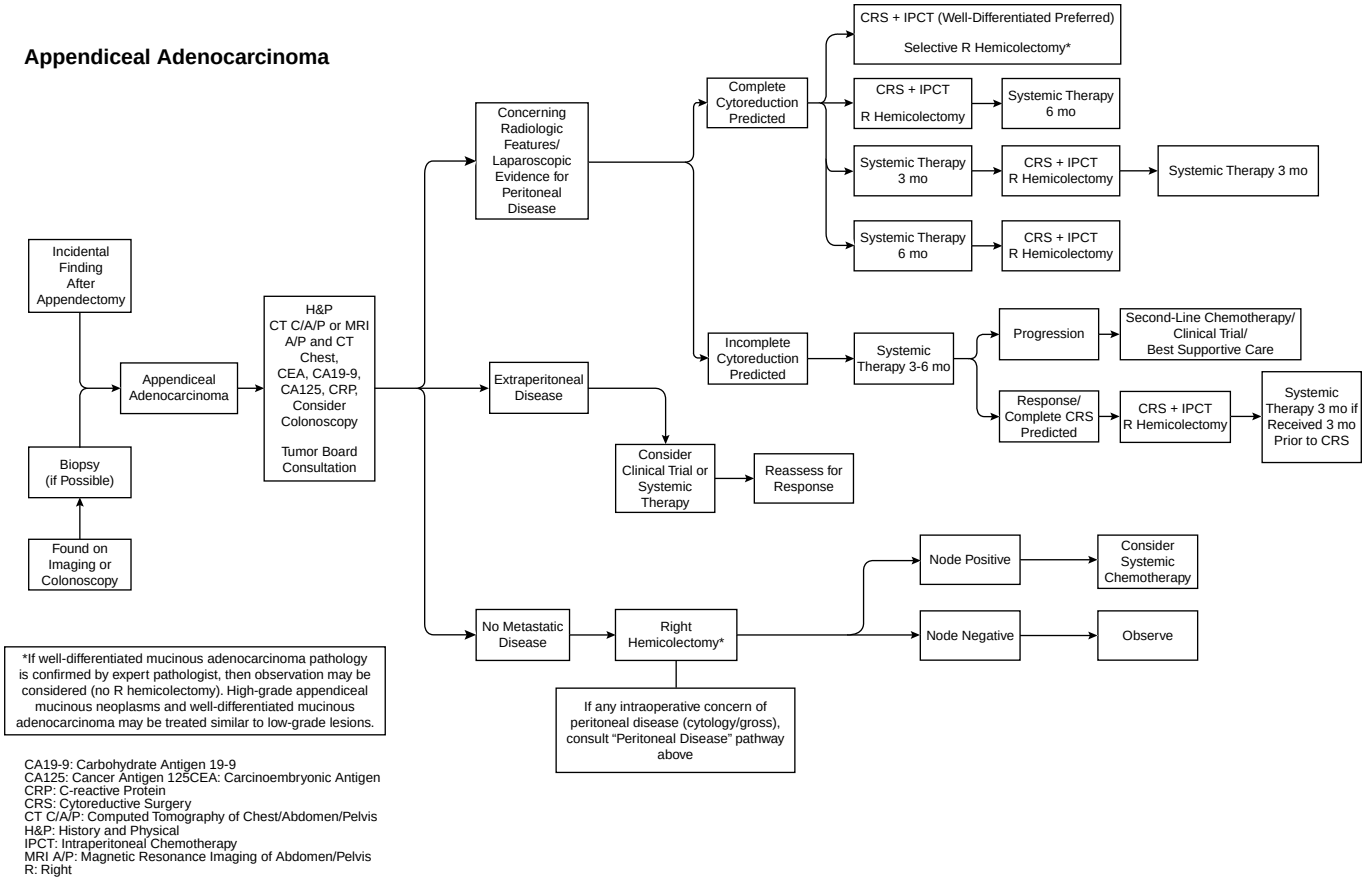

FIG. 2 The 2018 Chicago Consensus Guidelines on the Management of Appendiceal Adenocarcinomas. *(From Chicago Consensus Working Group. The Chicago consensus on peritoneal surface malignancies: standards.* Cancer. *2020;126:2516–2524.)*

the CRS group (24% vs. 13%, respectively). The results of these studies on prospective clinical trials highlight the need for a multidisciplinary approach to selecting patients who will maximally benefit from CRS versus HIPEC+ CRS. It also highlights the benefit of cytoreduction in combination with NACT.

Epidemiology

Peritoneal disease is present in about 8% of CRC patients at the time of primary resection, and up to 25% of patients with recurrent CRS will develop metastatic disease confined to the peritoneal surface. Risk factors for peritoneal metastases include mucinous histology, T4 cancers, vascular invasion, spontaneous or iatrogenic perforation, and right-sided tumors, which overall confer a worse prognosis. The presence of untreated visceral solid organ metastasis is a relative contraindication to HIPEC and CRS.

Clinical Manifestations

Peritoneal metastases secondary to CRC may present with ascites manifesting as increasing intraabdominal girth, pain, or small bowel obstruction. However, just as often, synchronous peritoneal disease may be asymptomatic and detected at the time of primary surgery or on staging imaging. For patients with metachronous disease, it is most common to identify peritoneal metastases during surveillance given the intensity of imaging use in current practice.

Preoperative Workup

Patient selection is very important in determining the appropriateness of cytoreductive surgery and HIPEC. Preoperative evaluation should include a thorough history and physical examination along with axial imaging including CT of the chest, abdomen, and pelvis. PET/CT may be useful in patients with non-mucinous tumors. Laboratory workup includes CEA, CA-19, and CA-125 levels and nutritional markers. A complete colonoscopy is also recommended if not already completed. Diagnostic laparoscopy may be helpful for staging and assessment of surgical eligibility given the poor sensitivity of axial imaging for detecting peritoneal metastasis. In addition, small tumors in specific locations such as the root of the mesentery and serosal surface of the small bowel are harder to detect on CT scan. PET/CT has a sensitivity of 78% to 100% and is not uncommonly ordered before surgery. It is however associated with false-negative results for tumors that are not PET/CT avid (mucinous tumors) or false-positive results for inflammatory processes. There have been limited studies evaluating the role of diffusion weight MRI in detecting subcentimeter deposits in difficult anatomic locations, though it is not widely adopted given the contraindications, costs, and availability.

Patient Selection for Surgery

Patient selection is critical in determining who would most benefit from CRS + HIPEC. Generally, good candidates for CRS + HIPEC are patients with good performance status who have an ECOG/WHO status of 1 or less, have adequate physiologic and organ function, have a low/moderate PCI, and can receive systemic chemotherapy. In fact, response to initial chemotherapy is often used as prognostic marker to screen patients with rapidly evolving tumor biology. PCI scores range from 0 to 39, with a score less than 12 considered most favorable for resection. A PCI greater than 20 is typically considered a contraindication to resection. Patients with a PCI between 12 and 20 may be determined on a case-by-case basis depending on

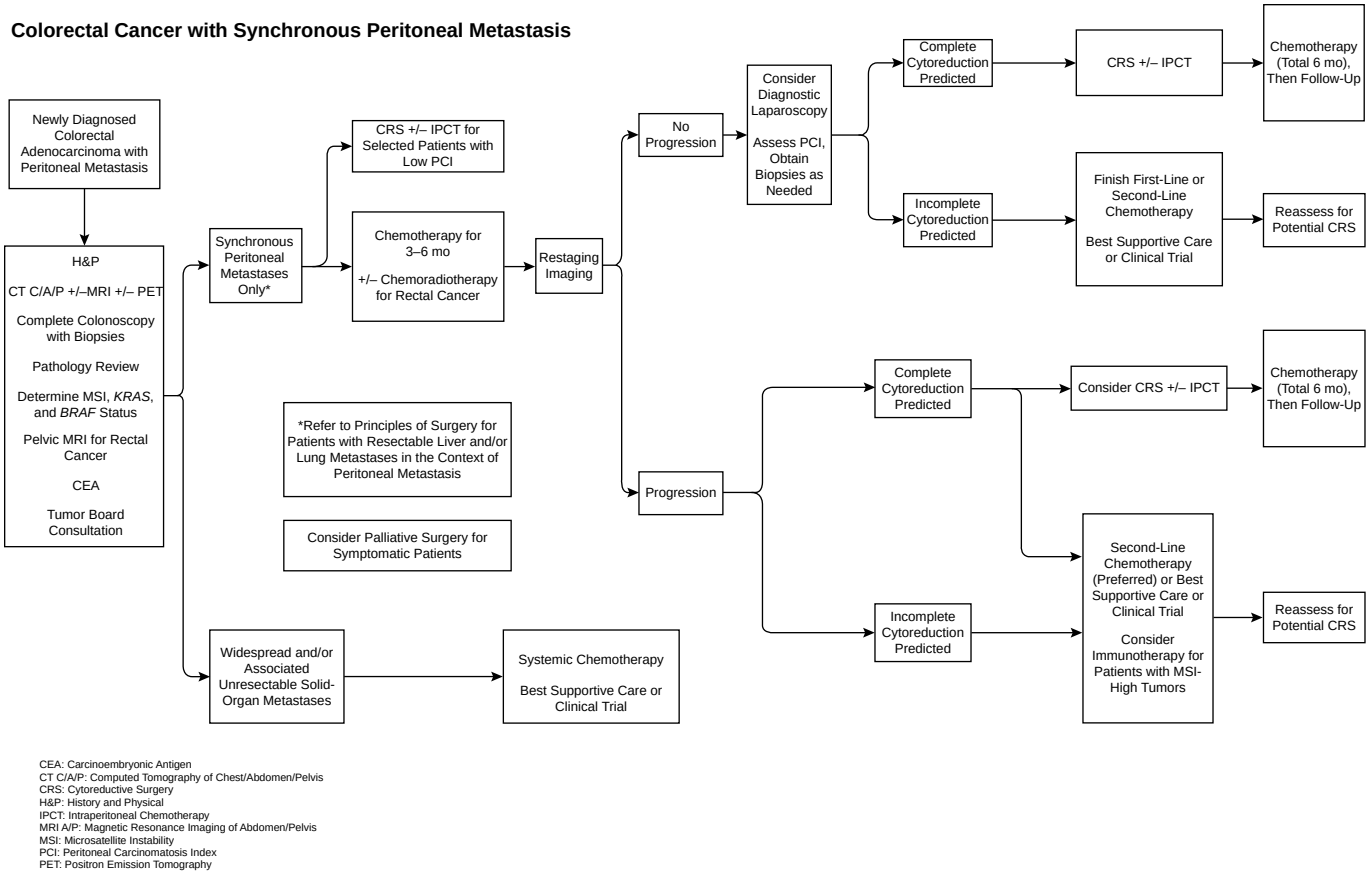

FIG. 3 The 2018 Chicago Consensus Guidelines on the Management of Colorectal Cancers with Synchronous Peritoneal Metastasis. *(From Chicago Consensus Working Group. The Chicago consensus on peritoneal surface malignancies: standards. Cancer. 2020;126:2516–2524.)*

additional clinical parameters, such as extent of extraperitoneal metastasis and tumor biology. A more conservative PCI cutoff of 17 has been proposed based on results of a prospective study by Goere et al., which showed no benefit of HIPEC + CRS in patients with a PCI greater than 17. It is important to note that a preoperative radiologic PCI score may not always correlate with an intraoperative PCI score, hence staging laparoscopy can be used as an adjunct to assess borderline cases. The presence of malignant ascites, large tumor burden, or multifocal bowel obstructions are relative contraindications to curative intent surgery in addition to the presence of liver or lung metastasis that are untreated. Visceral metastases should be considered for therapy on an individualized basis. Lastly, the treatment options and timing for patients with synchronous or metachronous lesions similar to appendiceal neoplasms should be discussed among a multidisciplinary team. Figure 3 summarizes the Chicago Consensus Guidelines on CRS and HIPEC in colorectal cancers.

GASTRIC CANCER

Epidemiology and Clinical Manifestation

Gastric cancer is a leading cause of cancer-related deaths, with a mortality rate of 8.9% after lung cancer (19.7%) and breast cancer (12.9%), respectively. Overall 5-year survival approaches 90% in countries like Japan and varies between 10% and 30% in Western countries. Peritoneal carcinomatosis occurs synchronously with primary tumors in 14%% to 43% of patients with gastric cancer and accounts for 35% of synchronous metastasis. Risk factors for peritoneal metastasis include extranodal involvement, diffuse infiltrated type, signet cell histology, higher CEA levels, liver involvement, young age, and female gender. Prognosis of untreated gastric cancer with peritoneal carcinomatous is quite poor, with a median 5-year survival that approaches 0%.

Preoperative Workup

Preoperative workup includes history and physical examination, upper endoscopic ultrasound, and endoscopic ultrasound with biopsy for local regional staging. Imaging includes CT of the chest, abdomen, and pelvis with contrast and PET/CT if there is no evidence of M1 disease. HER2/NEU testing should be obtained if metastatic disease is suspected. Molecular profiling to assess for microsatellite stability and PDL1 positivity maybe helpful for patients with unresectable disease. Genetic counseling is recommended in young patients to evaluate for *CDH1* mutations given their high penetrance. Nutritional markers should be considered in addition to smoking cessation and counseling. Patients typically receive the most commonly used perioperative chemotherapy, which includes FOLFOX, XELOX, FLOT, ECF, +/– radiation for 3 to 6 months followed by restaging and diagnostic laparoscopy with peritoneal washings. Patients with advanced tumors, clinical T3 or greater, or node-positive disease should undergo laparoscopic staging with peritoneal washings to evaluate for extent of peritoneal disease.

Patient Selection for Surgery

All patients with biopsy-proven gastric cancer should be presented to a multidisciplinary tumor board to discuss a tailored treatment plan, which is largely dependent on the patient's functional status and

tumor biology. Generally, patients with low peritoneal disease burden and lack of progression of disease after systemic therapy should be restaged and considered for HIPEC + CRS. Various options include early postoperative chemotherapy (EPIC) or bidirectional intraperitoneal and systemic induction chemotherapy before CRS + HIPEC. Ideal candidates should be young (<70 years of age) and have a good performance status, a PCI score <10, small nodules, a resectable primary tumor, no evidence of paraaortic lymphadenopathy, no liver or extraperitoneal metastasis, and have responded well to NACT.

Hoptopp et al. found an overall increase in survival in patients with gastric cancer and confirmed peritoneal metastasis who underwent NACT with FLOT followed by CRS + HIPEC versus chemotherapy alone (17 months vs. 6 months) in a single-center study. A more recent advancement is the use of neoadjuvant intraperitoneal and systemic chemotherapy protocol/bidirectional intraperitoneal and systemic induction chemotherapy (NIPS/BISIC), which aims to reduce the stage and increase the incidence of complete cytoreduction. By simultaneously administering intravenous and intraperitoneal chemotherapy, the cancer cells are targeted both from the peritoneal cavity and subperitoneal blood vessels. Several studies have examined the effectiveness of this therapy in complete cytoreduction and improving survivorship. Yonemura et al published a prospective study of 194 patients who had BIPSC followed by CRS + HIPEC. Patients had (1) biopsy-proven peritoneal carcinomatosis, (2) no evidence of liver or lung metastasis, and (3) good performance scores. In this study, 152 patients responded to BIPSC and subsequently underwent CRS + HIPEC. Complete cytoreduction was achieved in about 70% of these patients. Median survival was 15.8 months in patients who had CRS + HIPEC after BIPSC versus patients who did not (7 months). Completeness of cytoreduction, pathologic response to NIPS, and PCI on multivariate analysis overall predicted survivorship. It is important to note that the complication rate was 24%, which is similar to that found in a study by Hultman et al., which also showed an improvement in median survivorship (19 months vs. 14 months) but reported a higher complication rate of 63%. This is most commonly caused by anastomotic leak, sepsis, wound infections, and organ failure. These studies show that appropriate patient selection and identification of patients with unresectable or disseminated disease who are eligible for complete cytoreduction is paramount.

PERITONEAL MESOTHELIOMA

Epidemiology and Clinical Manifestation

Mesothelioma is a rare malignancy of serosal membranes. This includes the pleura, peritoneum, pericardium, and the tunica vaginalis testes. The peritoneum is the second most common location and is estimated to represent about 10% to 15% of all mesotheliomas. The highest incidence is reported in countries such as New Zealand, the United Kingdom, and Australia, and the lowest incidence is reported in countries such as Japan, Slovenia, and Central Europe. The estimated incidence is 1.94 per 100,0000 and 0.41 per 100,000 for men and women, respectively, in the United States. Mesothelioma is commonly associated with exposure to asbestos, but 33% to 50% of patients diagnosed with malignant pleural mesothelioma (MPM) have no prior asbestos exposures. Other risk factors include exposure to radiation minerals such as thorium, chronic peritonitis, and germline BRCA-1–associated protein *(BAP-1)* gene mutation. Histologic classifications include epithelioid, sarcomatous, and biphasic/mixed. About 75% of all mesotheliomas are epithelioid in origin, which overall have the most favorable prognosis.

Perioperative Workup

Making the diagnosis is often challenging as patients present with mostly vague abdominal symptoms. On imaging, patients may have ascites, evidence of omental caking, or mesenteric fatty infiltration. Definitive diagnosis is based on histology and pathologic assessment, which could be obtained on percutaneous biopsy or diagnostic laparoscopy. Diagnostic laparoscopy is indicated to evaluate the extent of disease amenable to surgery. Pathologic assessment is essential to differentiating subtypes of mesothelioma that may be more amenable to surgery versus chemotherapy alone. Epithelioid histology has overall the most favorable response to HIPEC + CRS in contrast with sarcomatoid, biphasic subtypes, which overall have a poorer prognosis and for which surgery is less likely to offer a survival benefit. Furthermore, the CA-125 and Ki-67 index are often obtained in addition to germline testing for a *BAP-1* gene mutation.

Patient Selection for Surgery

The natural history of MPM is aggressive; without treatment, median survival is approximately 6 months. Median survival with systemic chemotherapy alone is approximately 16 months; however, it improves to approximately 40 months with HIPEC + CRS. Patients with MPM are considered for surgical therapy with CRS/HIPEC if their disease burden is amenable to resection of all or nearly all (CC-0 or CC-1) visible disease and are suitably fit for such extensive resection.

OVARIAN CANCER

Epidemiology and Clinical Manifestation

Ovarian cancer is associated with one of the highest mortalities from gynecologic cancers in the world, with an estimated 5-year survival rate of 39%. Despite efforts to screen for ovarian cancer, 35% to 43% of patients still present with advanced disease involving the peritoneum at the time of diagnosis. Risk factors for peritoneal disease include germline mutations, incomplete resection at initial cytoreductive surgery, shorter treatment-free survival, higher FIGO (International Federation of Gynecology and Obstetrics) stage, and the present of malignant ascites. The most common type of ovarian cancer is epithelial in origin; less common types include clear cell, mucinous, carcinosarcoma, endometroid carcinoma, and malignant germ cell tumors. Symptoms include early satiety, bloating, nonspecific abdominal pain, and urinary symptoms. Others may present with massive ascites, which is typically associated with mucinous neoplasms.

Preoperative Workup

The diagnosis is made based on clinical suspicion, imaging, and tumor markers, with elevation of CA-125, inhibin, B-HCG, LDH, and CEA levels being pathognomonic. Nutritional parameters, CBC, and liver function tests and chemistries are routinely ordered. A complete colonoscopy is recommended to evaluate for synchronous gastrointestinal malignancies that can present similarly. Genetic counseling is recommended for all patients given the incidence of *BRCA* mutation, which may help guide adjuvant systemic therapy. Surgery is the mainstay therapy and typically includes extensive debulking and cytoreduction with a total abdominal hysterectomy and bilateral salpingo-oophorectomy (TAH + BSO) but can include appendectomy, colon or small bowel resection, cholecystectomy, and omentectomy. Diagnostic laparoscopy is essential to quantify tumor burden and identify patients whose disease is amenable to adequate cytoreduction. The presence of omental caking, peritoneal and diaphragmatic extensive carcinomatosis, mesenteric retraction, bowel and stomach infiltration, and spleen and/or liver superficial metastasis are typically assessed on laparoscopy. Importantly, these operations are typically conducted using a multidisciplinary approach involving gynecology oncology and surgical oncology to improve the chances of complete cytoreduction.

Patient Selection for Surgery

HIPEC is typically considered in patients with stage III disease of epithelial origin as the other cell types are less chemosensitive. Furthermore, NACT with interval CRS is considered in patients with advanced-stage ovarian cancer who are not good candidates for upfront primary debulking surgery (PDS) because of advanced age, frailty, poor performance status, or for those in whom the disease is unlikely to be optimally cytoreduced. This has the potential to facilitate medical optimization and to downstage the disease. The addition of HIPEC to CRS has been evaluated in several studies in the recurrent setting. In a 2015 RCT, Spilotis found a 13-month improvement in survival with HIPEC + CRS versus CRS alone. In a retrospective cohort study of 584 patients with stage III epithelial ovarian cancer, Lei et al. found an overall 15-month improvement in survival in patients undergoing CRS + HIPEC versus CRS alone, and patients with complete CRS had the most favorable survival outcomes. In an RCT of 245 patients randomized to HIPEC + CRS versus CRS alone, Van Driel et al. found an increase in overall median survival in the HIPEC + CRS group at 45.7 months versus 33.9 months in the CRS group alone. The CHIPPI-1808 trial comparing HIPEC + NACT + CRS versus NACT + CRS should have results by 2026 and perhaps may help improve patient selection and justify the use of upfront HIPEC in the primary setting versus the current standard of care, which is typically in the recurrent setting with interval CRS.

Intraoperative Management and Technique

The Chicago Consensus Working group publishes a consensus on peritoneal surface malignancies that includes guidelines for standard operations and metrics. Generally speaking, a fellowship experience with CRS + HIPEC, documentation of number of cases, and availability of two surgeons are necessary in addition to established criteria for institutional credentials. Process standards include confirmed tissue diagnosis, relevant tumor markers depending on the cancer type, cross-sectional imaging, and ideally registry of all patients in a data repository. Quality standards also exist for reporting of pathology, intraoperative monitoring, perfusion equipment used, and rating of the completeness of intraoperative cytoreduction. A complete list of standards, quality, and process measures is available online.

Preoperatively patients undergo mechanical bowel preparation with oral antibiotics before surgery. Patients are positioned supine for lithotomy if any concern of needing lower pelvic work; DVT prophylaxis with SCDs and subcutaneous heparin in addition to perioperative IV antibiotics are administered. It is important to maintain good communication with anesthesia and the intraoperative room staff to ensure that the patient's core body temperature is maintained and that the patient is adequately being resuscitated to maintain good urine output given insensible losses that can occur during the operation. Adequate monitoring of cardiovascular and fluid resuscitation is crucial in the intraoperative and postoperative period. If not closely monitored and managed, patients are at risk for abdominal hypertension, coagulopathy, decreased systemic vascular resistance, and high-output cardiac failure in addition to toxicities directly related to the chemotherapy agent being used. Therefore, early determination of the need for recovery in the intensive care unit (ICU) should be determined intraoperatively. Increasingly, intraoperative goal-directed fluid therapy and enhanced recovery pathways have been implemented in various institutions with the goal to improve postoperative outcomes. For example, tools such as stroke volume variation are used to guide fluid management and maintain urine output. This strategy overall leads to less overall fluid administration and is associated with less postoperative morbidity.

The procedure begins with an exploratory laparotomy with complete evaluation of the extent of peritoneal metastasizes and probability of complete cytoreduction through a midline incision. Diagnostic laparoscopy may be undertaken before laparotomy if there is concern that the extent of disease may preclude cytoreduction. Lysis of adhesions may be required if the patient already had prior surgeries or malignant adhesions that may preclude safe entry. A pre-cytoreduction PCI is assessed followed by complete cytoreductive surgery with the intent of removing all tumors greater than 0.25 cm. (CC-0 or CC-1). We generally inspect systematically the bilateral diaphragm surfaces, lesser sac, small bowel and its mesentery, porta hepatis, aortocaval groove (IVC bursa) near the caudate and pelvis, and all solid organs. Once all sites have been inspected, we recommend running the small bowel in its entirety from the ligament of Treitz to the ileocecal valve as well as inspecting the right and left colon and its mesentery to the level of the sacral promontory. All prior anastomoses should also be inspected in addition to incising the nodal tissue at the ligament of Treitz, falciform ligament, and triangular ligament for liver mobilization. Small lesions can be removed sharply, but larger lesions that are infiltrative or cannot be separated easily require formal resection. Generally, extensive small bowel disease or nodal disease involving the root of the mesentery are contraindications to complete cytoreduction. Complete cytoreduction typically requires an omentectomy, selective peritonectomy, and visceral resection.

For HIPEC, most units prefer a closed technique, which overall reduces exposure of the operative room team and decreases heat dissipation. Other institutions utilize an open technique for delivery. Mitomycin C, oxaliplatin, or doxorubicin is typically used. Selection of the type of chemotherapy agent is typically based on tumor histology and institutional protocol. Several studies have shown no difference in progression-free survival comparing HIPEC with mitomycin C versus oxaliplatin, the two most used chemotherapy agents. These studies also suggest differences in side-effect profiles, suggesting that more studies are needed.

The inflow and outflow cannulas as well as a temperature probe are placed into the abdomen, and the incision is temporary closed. Using a hyperthermia perfusion pump, 3 to 6 L of warm fluid is instilled until abdominal distension based on intraoperative determination of peritoneal volume. The fluid is heated to about 40° to 43°C. Once the target temperature is achieved, the chemotherapy agent is infused over 30 to 120 minutes. Once this is complete, the abdomen is opened and reinspected. There is no known difference in outcomes based on anastomosis pre- or post-HIPEC. The fascia is closed, and a completeness cytoreduction score is assigned at the end of the case. In early postoperative intraperitoneal chemotherapy (EPIC), the abdomen is filled with 1 L of lactated Ringer solution, then mitomycin +/– cisplatin is given continuously or on postoperative day 1 and 2 at varying doses. In NIPs + HIPEC + CRS, patients are given intravenous chemotherapy preoperatively and administered docetaxel and/or cisplatin intraperitoneally on day 1 and day 8. This is repeated three times, and laparotomy with cytoreduction is performed 2 weeks after the last administration of intravenous chemotherapy. These alternatives have shown some promising results in select populations.

Postoperative Management

Depending on institutional support (e.g., nursing levels, telemetry) patients are admitted to the floor, step-down unit, or ICU. Patients with larger cytoreductions or significant comorbidities benefit from ICU management. Patients are generally at risk of postoperative ileus. Commonly, a nasogastric tube is placed at the time of surgery. Early ambulation and incentive spirometry are strongly encouraged. If extensive diaphragm stripping or resection is performed, some patients with respiratory comorbidities may benefit from chest tubes. Patients are typically managed with fluid restriction after the initial resuscitative phase, which typically is in the first 72 hours. Early discontinuation of intravenous fluids when

tolerating a regular diet and/or adequately resuscitated is encouraged. Though ERAS protocols for HIPEC + CRS have not been widely adopted, they do show some promising results in reducing length of stay for patients undergoing HIPEC + CRS, though no RCT has been conducted to date. In general, patients remain in the hospital until they have adequate return of bowel function and pain control. Initially some patients may have electrolyte and metabolic derangement caused by fluid shifts and should be monitored closely. Risk factors associated with increased risk of complications include number of anastomosis performed, diaphragm resection, number of blood transfusions required, and thermal bowel injuries. Overall postcomplication rates are described between 10% and 40%, depending on the series. Average length of stay is approximately 7 to 10 days. Advanced age, malnutrition, and multiple visceral resections are associated with an increased length of stay, hence early intervention to identify patients at most risk is crucial to obtaining quality long-term outcomes for HIPEC and CRS.

Management of Lower Gastrointestinal Bleeding

Anna Liveris, MD, and Peter Muscarella II, MD

INTRODUCTION

Lower gastrointestinal bleeding (LGIB) is a frequently encountered and complex clinical problem for surgeons. Classically defined as gastrointestinal (GI) bleeding emanating from any point distal to the ligament of Treitz, LGIB can originate anywhere from the small bowel to the anus and accounts for an estimated 30% of all GI bleeding. Nearly all LGIB can be isolated to the colon and rectum, with diverticular bleeding being the most common cause. Less than 10% of LGIB originates from the small bowel or anus. Aggressive resuscitation, accurate localization, and control of bleeding are the primary goals of treatment for patients who present with hemorrhagic shock. A systematic approach to diagnosis and management is pivotal in reducing morbidity and mortality.

Etiology

LGIB can be further categorized as massive, moderate, or occult. Massive bleeds are the most life-threatening, with mortality rates approaching 20%. Despite this, more than 80% of all LGIB will resolve spontaneously, and the overall mortality rate is about 4%. Patients presenting with massive LGIB are usually >65 years and present with hematochezia or bright red blood per rectum in the setting of hemodynamic instability. The most common causes are diverticulosis and angiodysplasia. Interestingly, one-third of patients with presumed massive LGIB will have an upper GI source, so assessing for risk factors of peptic ulcer disease is important.

Moderate and occult bleeding can occur at any age. Moderate LGIB presents as hematochezia or melena in a hemodynamically stable patient. The differential diagnosis is broad (Table 1). Occult LGIB is otherwise asymptomatic, except for microcytic anemia resulting from chronic blood loss. The differential diagnosis of these patients includes malignancy, inflammatory conditions, ischemia, and congenital causes such as bleeding Meckel's diverticula.

Epidemiology

Approximately 30% of all patients presenting with major GI bleeding are found to have bleeding distal to the ligament of Treitz. Among patients with presumed LGIB, 80% originate distal to the ileocecal valve, with only 10% originating from the small bowel. The remaining cases usually arise in the upper GI tract. The overall incidence of LGIB is notably higher in older adult patients, particularly those who are on multiple medications.

Diverticulosis accounts for over 40% cases of LGIB and often presents as painless hematochezia. Diverticular bleeding frequently recurs, and the prevalence increases in patients older than 80 years of age or in those with chronic constipation. Ischemic colitis accounts for 20% of LGIB and is also more prevalent in the elderly. This may occur in response to reduced mesenteric flow to the colon caused by decreased cardiac output, vasospasm, or atherosclerotic disease. Treatment is generally supportive and conservative unless there is evidence of full-thickness necrosis and/or peritonitis. The watershed area of the splenic flexure is a common location for ischemic colitis, and involvement of this area on imaging should alert the clinician to the possibility of this diagnosis. The most common cause of LGIB in patients younger than 50 years of age is benign anorectal disease, usually hemorrhoids or anal fissures. The possibility of inflammatory bowel disease (IBD) or NSAID-induced mucosal ulceration should also be considered in these patients. Post-polypectomy bleeding can result in brisk bleeding following colonoscopy and polypectomy. Risk factors include age greater than 65 years and polyp size larger than 1 cm. Though the bleeding is usually self-limited, presentation can be delayed for up to 1 week after the procedure; therefore ascertaining the history of colonoscopy with polypectomy is crucial.

TABLE 1 Differential Diagnosis of Lower Gastrointestinal Bleeding

Anatomic Source of Bleeding	Etiologies
Small intestine	Angiodysplasia Crohn's disease Mesenteric ischemia Recent surgery/trauma Meckel's diverticulum Dieulafoy's lesion Aortoenteric fistula Intussusception
Colon	Diverticulosis Neoplasm Angiodysplasia Inflammatory bowel disease Recent colorectal surgery/trauma Recent colonoscopy/ polypectomy Ischemic colitis Infectious colitis Enterohemorrhagic *Escherichia coli* (EHEC) *Salmonella* *Campylobacter* *Shigella* *Cytomegalovirus* *Entamoeba histolytica* Fecal impaction Aortoenteric fistula
Rectum	Radiation proctitis Neoplasm Angiodysplasia Rectal varices Fecal impaction Inflammatory bowel disease Solitary rectal ulcer Rectal prolapse Recent colorectal surgery/trauma
Anus	Hemorrhoids Anal fissure Inflammatory bowel disease Local trauma Perianal variceal disease

History and Physical Examination

The differential diagnosis for LGIB is broad, so a thorough history and physical examination is necessary. The history may suggest a cause of LGIB and can inform decision-making regarding

diagnostic evaluation and management. Key details in the history should include the quantity, quality, and frequency of the bleeding, specifically whether the bleeding is recurrent or sporadic. Inquiry into other associated symptoms such as presence of abdominal pain, nausea, vomiting, or a recent change in bowel habits is also warranted. The clinician should specifically inquire about prior episodes of LGIB, history of abdominopelvic radiation, trauma, symptomatic arrhythmias, liver disease or cirrhosis, HIV status, and recent endoscopic or surgical procedures. A detailed review of the patient's medications including antiplatelet agents, anticoagulants, and NSAIDs as well as a family history of colon cancer or inflammatory bowel disease should also be noted.

Abdominal examination and digital rectal examination should be completed in all patients presenting with LGIB. Abdominal examination may reveal tenderness, distension, or a mass. Digital rectal examination is important to inspect for anorectal pathology such as hemorrhoids or fissures. Additionally, the quality of the stool in the rectal vault, whether it is impacted, dark melena, maroon-colored, or frank blood, should be documented. Importantly, the clinician should pay close attention to the patient's vital signs at all points during the history and physical examination as any hemodynamic instability warrants a rapid resuscitation and aggressive diagnostic effort.

MANAGEMENT

All patients presenting with LGIB should be triaged and evaluated immediately as decompensation can be rapid. Administration of supplemental oxygen, the establishment of intravenous lines access with two large-bore peripheral venous catheters, and placement on a cardiopulmonary monitor should be performed initially. Infusion of crystalloid solutions should be started immediately to resuscitate the patient. Laboratory examination should include a complete blood count, metabolic panel, liver function tests, lactate, coagulation studies, and a type and screen.

Resuscitation and Transfusion

Appropriate resuscitation of a patient with LGIB is crucial to minimize morbidity. The process should begin as described earlier as soon as it is recognized that the patient is actively bleeding. For patients with evidence of multiple comorbidities or massive LGIB, a critical care consultation and monitoring in a critical care setting is warranted.

Most patients with moderate or occult LGIB present without signs of instability. These patients may warrant less aggressive resuscitation with crystalloid during their initial workup and evaluation. Transfusion should be initiated to correct any overt coagulopathy and to maintain a hemoglobin >7 g/dL for most patients. Some patients, particularly those with other comorbidities, may require a higher goal hemoglobin and should be treated on an individual basis. International normalized ratio (INR) should be corrected to <1.5, and platelets should be transfused to >50,000/μL.

The massive LGIB patient who presents in hemorrhagic shock is similar to a trauma patient. Therefore, activation of a massive transfusion protocol and the use of empiric blood product ratios of 1:1:1 of packed red blood cells to fresh-frozen plasma to platelets in order to correct coagulopathy is effective. Early use of fresh-frozen plasma and platelets should be considered. The end goals of resuscitation are correction of coagulopathy and hemodynamic support. A policy of permissive hypotension with systolic blood pressure >90 mm Hg is sufficient for most patients. Although crystalloid solutions may be indicated in other cases of LGIB, care should be taken to avoid the overuse of crystalloids in this subset of patients because this may contribute to bowel edema and other complications such as abdominal compartment syndrome or respiratory failure. The use of thromboelastography (TEG) may also be a useful adjunct for the care of the hemodynamically unstable LGIB patient in centers where this technology is available. Prompt progression to the next phases of management, bleeding localization and hemorrhagic control, is important to minimize mortality. Aggressive efforts to correct coagulopathy and metabolic derangements before surgical intervention should be undertaken, although salvage procedures may be required in rare cases. This will be discussed further in later sections.

Special Hematologic Considerations

Early identification of hematologic disorders or medications is mandatory during the resuscitative process. Laboratory studies, including traditional coagulation studies and possibly TEG, should be obtained during the initial workup. Anticoagulants and antiplatelet agents should be discontinued, and reversal should be considered in patients with hemodynamic instability or ongoing bleeding. For patients who are therapeutic or supratherapeutic on warfarin, a prothrombin concentrate complex should be considered. Vitamin K and fresh-frozen plasma can also be utilized for this purpose, but prothrombin complex concentrate has the advantage of rapid reversal with lower fluid volumes. In recent years, idarucizumab has become more readily available to reverse dabigatran. Although not widely available yet, andexanet alfa has also been approved by the US Food and Drug Administration (FDA) for the reversal of apixaban and rivaroxaban. Currently, there is no specific reversal agent for antiplatelet agents such as aspirin and clopidogrel. Most clinicians favor early platelet transfusion and/or desmopressin administration in the setting of active hemorrhage. Cardiology consultation should be considered for patients who have had drug-eluting cardiac stents placed within the past year because they are at risk for stent thrombosis if dual antiplatelet agents are discontinued, and this can contribute to mortality. It may be reasonable to continue aspirin therapy in some of these patients. Desmopressin administration can be particularly useful to reverse coagulopathy in the uremic patient. For patients with inherited or acquired coagulation disorders, specific reversal agents and therapies should be guided in consultation with the hematology service. More specialized laboratory studies may be indicated in some patients.

Localization

The first step in management and hemorrhage control is localization of the bleeding site. As previously discussed, LGIB has a broad differential, and identifying the source of bleeding is tantamount to further management.

Nasogastric Lavage

An upper GI source should always be considered in patients with suspected LGIB, particularly in patients with hemodynamic instability, brisk bleeding, or unrevealing evaluation of the lower GI tract. Bleeding peptic ulcers, angiodysplasia, or esophageal varices can often manifest as visible blood in the stool. Clearly, management diverges drastically if the source of bleeding is in the upper GI tract. Nasogastric lavage has classically been recommended as the first step in determining an upper versus lower GI source, particularly in the unstable patient. A nasogastric tube is inserted bedside, and then the contents of the stomach are suctioned. Alternatively, 200 to 300 mL saline is instilled into the tube and then suctioned back to look for blood or coffee grounds in the stomach. Fluid with bile present but without blood is considered to be a negative lavage. The lack of bilious fluid suggests inadequate evaluation of the post-pyloric region. A clear effluent is considered nondiagnostic and is not uncommon. Disadvantages of nasogastric lavage include patient discomfort and lack of therapeutic benefit. Nasogastric lavage has fallen out of favor in recent years and should be reserved for cases of suspected upper GI hemorrhage to improve visualization at the time of endoscopy. The authors liberally employ the use of upper endoscopy for the evaluation and management of GI bleeding because of its numerous advantages.

Anoscopy/Rigid Sigmoidoscopy

In patients with a strong suspicion for GI bleeding from the anorectum or distal sigmoid, anoscopy or rigid sigmoidoscopy should

be considered. Anoscopy can be quickly performed with little to no sedation at the bedside by inserting a tubular instrument into the patient's anus to visualize hemorrhoids, anal fissures, fecal impaction, or local trauma to the anus. Anoscopy can also be therapeutic as it can be used to assist with banding or other treatment of bleeding hemorrhoids. Rigid sigmoidoscopy is also a technically simple bedside procedure but generally requires additional sedation. The instrument is longer and allows for insufflation, which can facilitate visualization of the rectal and distal sigmoid mucosa. Both procedures can be uncomfortable for the patient and provide limited visualization of the most distal GI tract. When possible, flexible sigmoidoscopy or colonoscopy is preferred.

Colonoscopy

When there is a high degree of suspicion for a colorectal source of LGIB, colonoscopy is the modality of choice to localize the source if possible. It has been shown to correctly identify the location of LGIB in more than 75% of patients. Colonoscopy is performed using a flexible scope guided from the anus through the entirety of the rectum and colon until the ileocecal valve is reached. Colonoscopy can detect discrete sources of bleeding, such diverticula, angiodysplasia, and tumors, as well as more diffuse sources of bleeding, such as inflammatory bowel disease, ischemic colitis, and radiation proctitis.

An important benefit of the procedure is the ability to perform therapeutic intervention. Bleeding should only be ascribed to lesions with stigmata of recent hemorrhage, including visualized bleeding, exposed blood vessels, or adherent clots. Colonoscopic hemostasis can be achieved with dilute epinephrine injections (1:10,000) in 1 to 2 mL aliquots up to 30 mL total. This result is usually temporary, and a second hemostatic method is recommended. Epinephrine injections are best suited to facilitate site identification in cases of active or copious bleeding. Endoclip placement results in hemostasis for nearly all diverticular bleeds with stigmata of recent hemorrhage and in nearly 70% with other forms of LGIB (Fig. 1). Other endoscopic techniques for hemostasis include bipolar electrocoagulation, heater probe cautery, argon plasma coagulation, and rubber band ligation. Angiodysplasia is particularly amenable to argon plasma coagulation (Fig. 2). Rubber band ligation has the highest rates of rebleeding and can add significant procedure time depending on the site. Tattooing is recommended to expedite site identification in the event of recurrent bleeding, particularly if surgical intervention is determined to be necessary.

The timing of colonoscopy in the evaluation of LGIB remains controversial. Ideally, a bowel prep should be attempted to maximize visualization during the procedure. Notably, early colonoscopy performed while the patient is actively bleeding has been shown to improve diagnostic yield. Colonoscopic evaluation following bowel

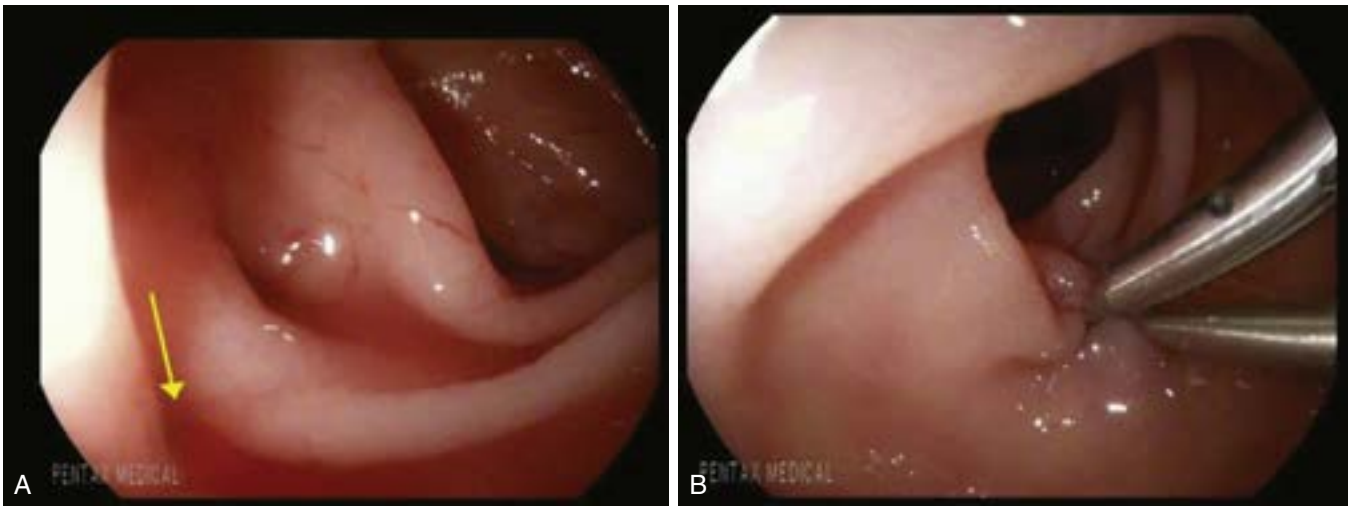

FIG. 1 **(A)** Colonic diverticulum with stigmata of recent hemorrhage. **(B)** Successful endoscopic clipping of bleeding diverticulum. *(Courtesy Daniel S. Behin, MD, Montefiore Medical Center/Albert Einstein College of Medicine, New York.)*

preparation is generally recommended within the first 24 hours of admission for patients with LGIB.

If the patient is not stable enough for endoscopic evaluation, radiologic evaluation or surgical intervention should be considered as an alternative. Colonoscopy should also be deferred if there is suspicion for active diverticulitis as this reportedly increases the risk of perforation. Other procedural risks include mucosal injury and the general risks of anesthesia/sedation.

Computed Tomographic Angiography

Computed tomographic angiography (CTA) is an important diagnostic tool for the evaluation of active LGIB. The study is performed using intravenous contrast timed such that active arterial extravasation from a vessel into the lumen of the small bowel can be visualized on a multidetector helical CT scanner. Extravasation of intravenous contrast into the lumen of the bowel, or an active "blush," constitutes a positive finding (Fig. 3). This study has a sensitivity close to 90% and can detect bleeding rates as low as 0.3 mL/min to 0.5 mL/min. Localization accuracy is as high as 97% in patients with high transfusion requirements and/or hemodynamic instability. Unfortunately, CTA has a relatively low specificity of 85%.

CTA is widely available, fast, minimally invasive, and does not require any bowel preparation or oral contrast administration. As a result, it is very useful in hemodynamically unstable patients who do not have time to undergo bowel preparation before intervention and are transiently responding to resuscitation. CTA is also useful in identifying other causes of LGIB such as ischemic colitis and can be used to evaluate the small bowel. Disadvantages include the requisite for active hemorrhage at the time of the study, possible allergic reaction to intravenous contrast, radiation exposure, difficulty with precise localization of a small-intestinal source, and lack of direct therapeutic application.

Nuclear Scintigraphy with Technetium-99m

Like CTA, nuclear scintigraphy allows for radiographic location of LGIB and is purely a diagnostic test. The patient's red blood cells are tagged with the radiotracer Technetium-99m (^{99m}Tc) and re-injected into the patient followed by sequential imaging. Nuclear scintigraphy is a far more sensitive test than CTA as it can detect bleeding rates as low as 0.1 mL/min. An important advantage of this study is its ability to detect bleeding occurring up to 24 hours after tracer injection as the radio-labeled red blood cells remain detectable. The half-life of ^{99m}Tc allows for sequential imaging several times in a 24-hour period.

Despite the high sensitivity rates, nuclear scintigraphy results in false localization rates approaching 25% have been reported, making it less accurate than CTA. This study is best suited as a screening tool for hemodynamically stable patients with scant, intermittent bleeding and not for definitive localization. Arteriography is generally warranted in the event of a positive study for localization and possible therapeutic intervention. Surgical intervention, particularly segmental resection, should not be guided by the results of nuclear scintigraphy.

Angiography

Angiography offers the advantages of accurate localization and the opportunity for therapeutic intervention, and it is a particularly useful option in patients with unstable vital signs requiring ongoing blood transfusions. Appropriate indications include copious bleeding precluding colonoscopic evaluation and positive extravasation on CTA or nuclear scintigraphy. For the latter, angiography further localizes the source of bleeding and potentially allows for hemorrhage control. These patients require little to no sedation, and access is usually obtained through the femoral artery. Fluoroscopic visualization is used to identify extravasation following selective mesenteric arterial cannulation and injection of contrast material. Angiography can detect bleeding at rates as low as 0.5 mL/min and has a high sensitivity for LGIB. Overall, it is a better test for patients with profuse, active bleeding than for those with scant, intermittent bleeding.

Embolization can be attempted for patients with positive localization during angiography. Super subselection with microcatheters and microcoil embolization are preferred when possible. Embolization, including highly selective embolization, is clinically successful in the majority of cases, with demonstrated bleeding resolution rates of 75% to 90%, depending on the location (Fig. 4). Other therapeutic options include intraarterial infusion with vasopressin, a potent vasoconstrictor, which is effective in substantially decreasing bleeding. These maneuvers may eliminate the need for emergent operation and facilitate continued resuscitation followed by surgical intervention under more controlled circumstances. For cases of venous bleeding, embolization of the venous system is possible, though not frequently undertaken.

Many have advocated for the preferential use of angiography in frail patients with severe comorbidities for whom an emergent operation would carry a prohibitively high mortality. Angiography is usually reserved for hemodynamically unstable patients or patients with a continued transfusion requirement. Unfortunately, the rebleeding rate is not insignificant and approaches 20% in some studies. Potential risks of angiography include bowel ischemia, contrast allergy or nephropathy, the risks of sedation, pseudoaneurysm, hematoma, and other vascular complications at the access site. Table 2 outlines and compares salient characteristic features of the various radiologic diagnostic and treatment options.

For patients with intermittent, obscure LGIB that has not been identified via other methods, provocative angiography is a technique that can be utilized. During this procedure, a therapeutic dose of anticoagulant is administered with the goal of provoking the bleeding lesion into an active hemorrhage so it can be captured on angiography. The lesion is then embolized in the same fashion as described previously. Systemic anticoagulation is usually achieved with heparin and followed by incremental and selective transcatheter injection of urokinase and a vasodilator, such as nicardipine. Multiple studies have shown that this procedure has an acceptable risk profile, including minimal risk of bleeding complications from the anticoagulant.

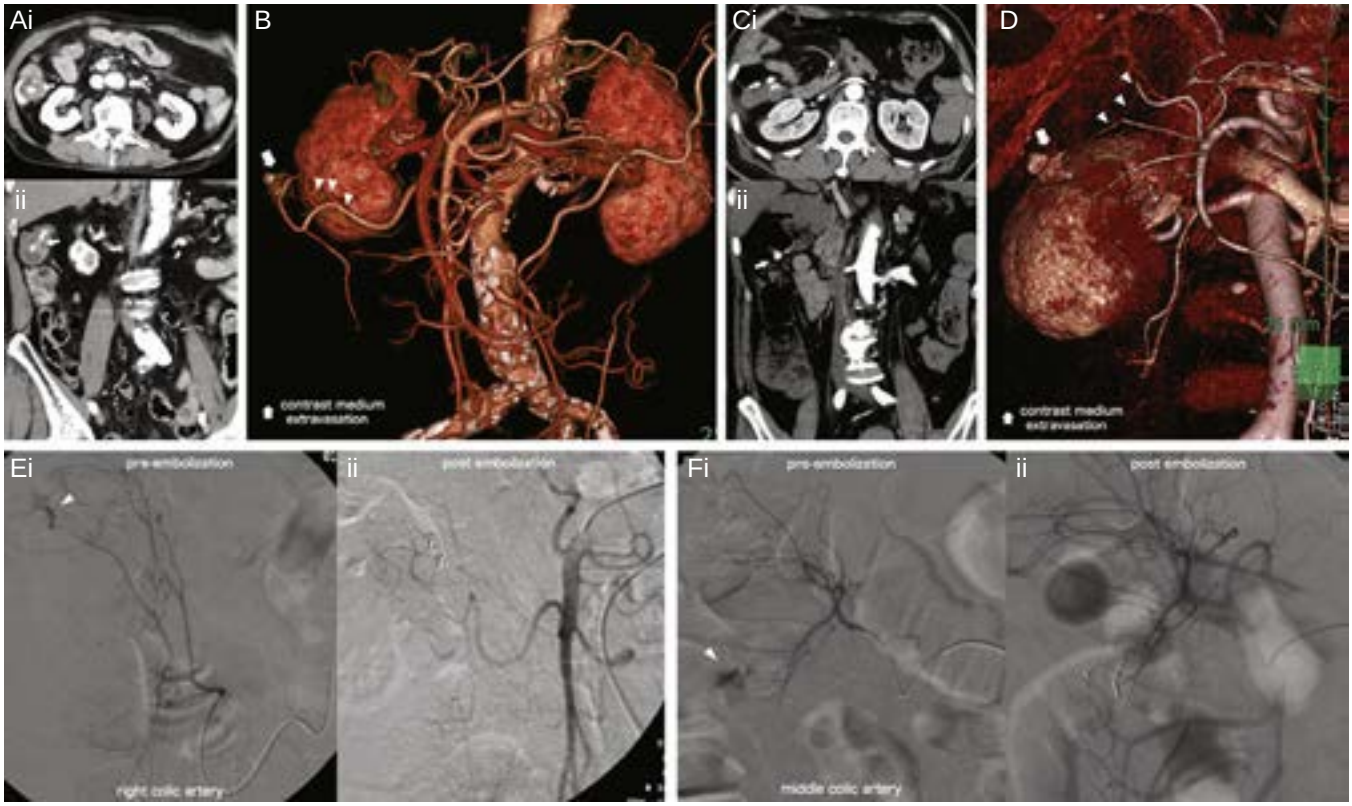

FIG. 4 Bleeding at the hepatic flexure of the colon secondary to diverticulosis in two patients. Multiplanar reconstruction (MPR) and volume-rendered 3D reconstruction of arterial-phase CT images reveal arterial bleeding from the peripheral branch of the right colic artery **(A** and **B)** and the middle colic artery **(C** and **D).** Pre- and postembolization images demonstrate extravasation of contrast from the involved vessels and resolution of bleeding, respectively **(E** and **F).** *(From Tsurukiri J, Ueno M, Kaneko N. Bleeding at the hepatic flexure of the colon secondary to diverticulosis.* Clin Gastroenterol Hepatol. *2012;10:e11–e12.)*

NS	–	0.1	–	–
Angiography	+	0.5	+	+

CTA, Computed tomographic angiography; *NS,* nuclear scintigraphy.

Nearly one-third of patients with a previously unidentified source of LGIB have a source identified with provocative angiography. Bleeding lesions can be treated by embolization or surgical resection. Resection is the preferred treatment for hypervascular neoplasms and can be useful for selected patients with angiodysplasia. If surgical resection is being considered and no mass lesion is identified at the time of selective arteriography, a microcatheter should be left in the feeding artery. The patient should be brought to the operating room in an expeditious fashion for surgical exploration. Injection of the catheter with blue dye will allow for visualization of the involved segment and can be used to guide the extent of resection.

Capsule Endoscopy

Although the majority of LGIB is colonic in origin, some cases of obscure bleeding originate from the small bowel. Capsule endoscopy is a useful modality for the subset of patients who have persistent bleeding and negative endoscopic evaluations of the colon and foregut. The patient swallows a pill-sized capsule that contains a small camera. The camera takes intermittent photographs as it travels through the patient's GI tract, and the photos are retrieved after the capsule is returned. The images are reviewed carefully to determine the source of bleeding. Capsule endoscopy is therefore best suited for hemodynamically normal patients who have chronic GI bleeding with a suspected small intestinal source. Diagnostic accuracy is good with sensitivities and specificities of approximately 90% and 95%, respectively. Diagnostic yield is improved in patients with acute bleeding and in those taking anticoagulants. The procedure is noninvasive and has an overall low complication rate; however, complications may include battery failure, capsule retention, and bowel perforation. Other disadvantages include the lack of potential for localization or therapeutic intervention. Patients may be administered a test capsule made of absorbable material before the

actual pill camera if the patient is at high risk for a retained capsule. Surgical intervention is required for retained capsules but may result in accurate identification and treatment of the bleeding pathology in rare circumstances.

Double Balloon Enteroscopy

Similar to capsule endoscopy, double balloon enteroscopy allows for visualization of the small bowel. The study is performed under anesthesia/sedation. An endoscope is utilized with the addition of an overtube. Both the endoscope and overtube have balloons at their distal aspects. The procedure begins like any other endoscopy, and the endoscope is advanced into the proximal small bowel. The overtube balloon is then inflated and the overtube retracted, thus pulling the small bowel toward the endoscope and allowing the latter to advance further into the small bowel. To pass further, the endoscope's balloon is inflated, and the overtube's balloon deflated advancing it forward to meet the endoscope. This tedious process allows the endoscope to advance though the small bowel as a result of retraction of the overtube.

Frequently, patients have already undergone CTA or capsule endoscopy to identify an area of interest. The major advantages over capsule endoscopy include the potential for therapeutic intervention and tissue sampling. In addition, double balloon endoscopy can be performed via the transoral or transanal routes. Disadvantages include the risk of bowel perforation and the risks associated with anesthesia as well as prolonged duration of the procedures, often lasting 60 to 90 minutes.

Management Algorithm for LGIB

Further management of the patient presenting with LGIB depends on the results of the aforementioned localization studies. A treatment algorithm is proposed to guide management for these complex patients (Fig. 5). We recommend colonoscopy as a first-line test for stable patients with mild or moderate LGIB. Many of these patients will have diverticular bleeding, and this has been shown to resolve spontaneously in 80% of cases, with most patients receiving fewer than 4 units of blood. This is irrespective of colonoscopic intervention. Up to one-third of spontaneously resolving diverticular bleeds

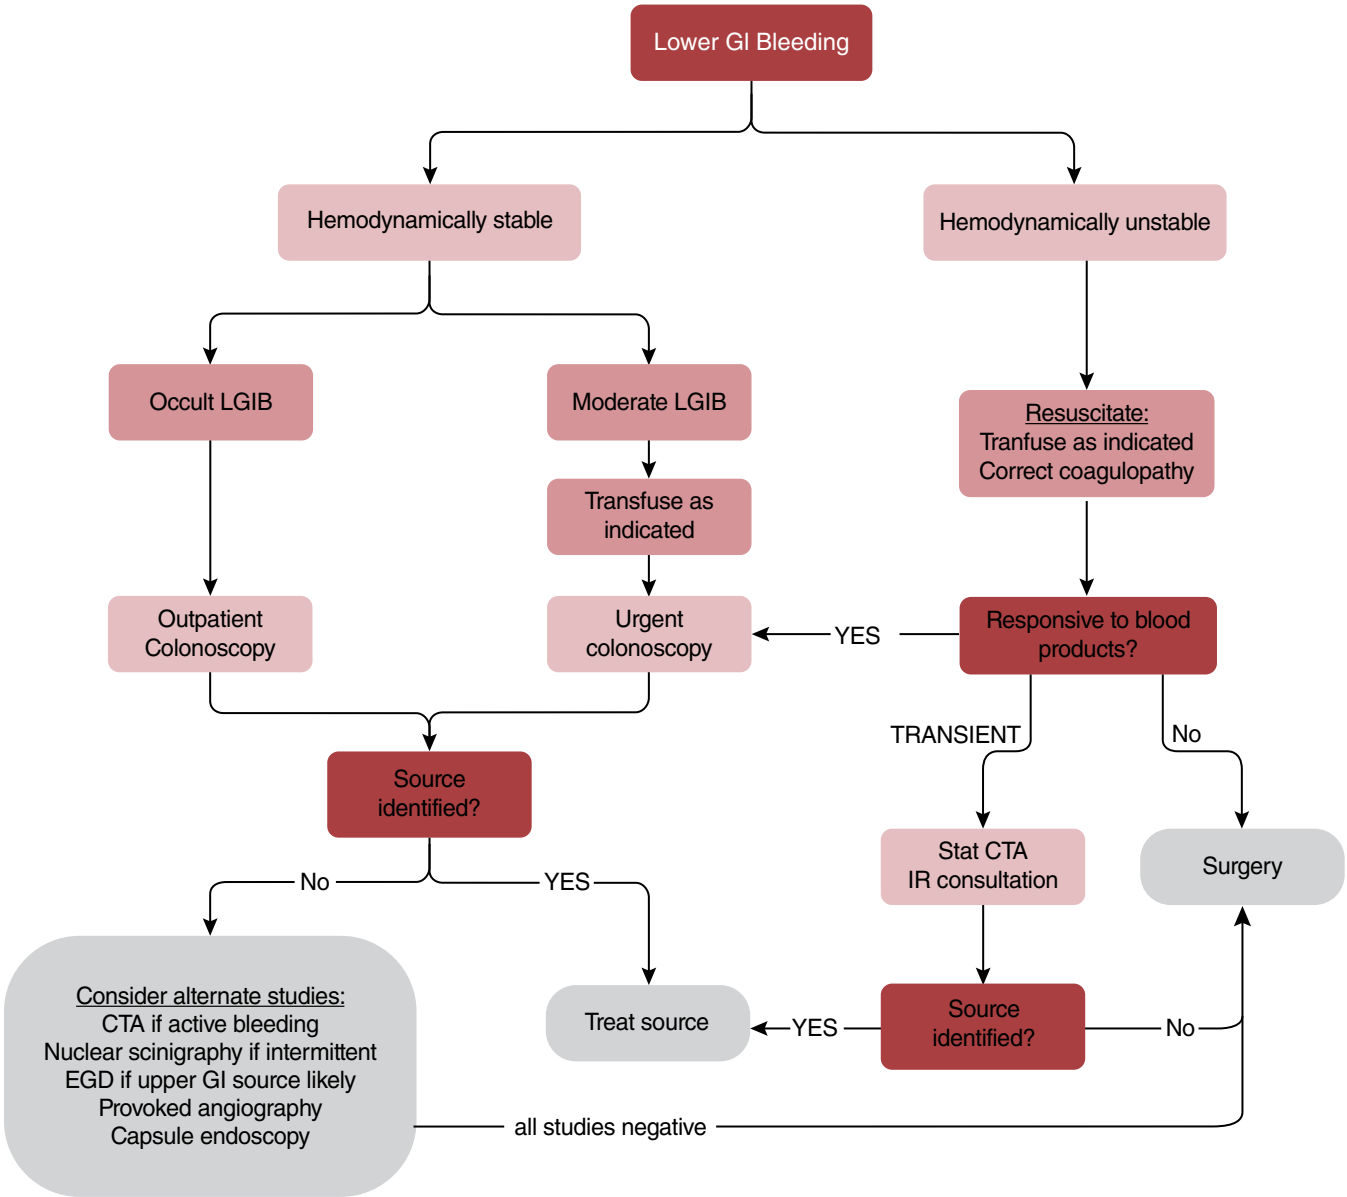

FIG. 5 Algorithm for the management of lower gastrointestinal bleeding. *CTA,* Computed tomography angiography; *EGD,* endoscopy; *GI,* gastrointestinal; *IR,* interventional radiology *LGIB,* lower gastrointestinal bleeding.

will recur within 6 to 12 months. Other forms of LGIB will also spontaneously resolve at high rates, including angiodysplasias, the most common cause of obscure LGIB. These may also recur at rates nearing 50% within 1 year. Although observation and serial hemoglobin monitoring may be an acceptable monitoring plan in some patients, therapeutic intervention with endoscopic or interventional techniques is preferred by surgeons whenever possible.

In patients with massive LGIB or moderate LGIB with instability, emergent CTA should be performed if the patient transiently responds to blood transfusion. Early notification of the interventional radiology team for possible angiography with embolization is crucial in the critically ill patient, and CTA can be bypassed altogether if the patient is increasingly unstable with minimal response to blood transfusion. Emergent esophagogastroduodenoscopy (EGD) should be considered if an upper GI source is suspected based on the history and physical examination. Aggressive resuscitation in a critical care setting along with reversal of coagulopathy and appropriate transfusion should be performed concurrently.

Emergent surgical intervention is a last resort in the management of LGIB because of high mortality rates but can be necessary and life-saving for some patients. Consequently, it is important for surgeons to be involved in the management of these patients early in their treatment as patients can decompensate quickly, leaving only a small window of opportunity for optimization. In general, emergent surgery is reserved for hemodynamically unstable patients or for those who have undergone failed interventions.

SURGICAL CONSIDERATIONS

Indications

Improvements in endoscopic and interventional radiology hemostatic techniques during recent years has resulted in a decreased role for emergent surgical intervention in patients with LGIB. Current indications for emergency surgical management are limited to failure of nonoperative intervention with a confirmed or presumed source and ongoing bleeding or hemodynamic instability, particularly in patients who have received transfusion of more than 6 units of blood products. In a hemodynamically stable patient, nonurgent surgical intervention may also be warranted in select cases, such as malignancy, bleeding hemorrhoids, or Meckel's diverticulum.

Operative Technique

Operative planning relies heavily on localization of the bleeding source and stability of the patient. For most patients with a presumed colonic source, surgical options include either a segmental resection or a subtotal colectomy. For patients with bleeding that cannot be controlled endoscopically, one consideration is to have the endoscopist tattoo the segment to facilitate intraoperative identification, which is an otherwise a difficult task.

Localization of the bleeding lesion before surgery is helpful to prevent excess mortality from a subtotal colectomy. In most studies, the mortality from this procedure approaches 40%, whereas segmental resection carries only a 20% mortality risk. Additionally, localization ensures that rebleeding from an unresected lesion is prevented. In contrast with the mortality risk, subtotal colectomy carries only a 4% risk of rebleeding, whereas segmental resection has a close to 20% risk. These risks and benefits should be considered on an individual basis with the understanding that the primary goal of surgery is to provide immediate control of the bleeding. If there is any question at all about localization, the surgeon should strongly consider performing a subtotal colectomy.

Patients requiring emergent colectomy for acute LGIB are at high risk for morbidity and mortality, with close to 60% suffering complications such as respiratory or renal failure. The surgeon should have a low threshold to perform a damage-control operation and delay formal closure of the abdomen. This will allow for ongoing resuscitation of the patient and monitoring for ongoing bleeding in a critical care setting. Temporarily packing the abdomen with laparotomy sponges can be considered for coagulopathic patients with diffuse hemorrhage from surgical surfaces to minimize time in the operating room. The patient can be returned to the operating room in 24 to 48 hours for reexploration and formal closure. The decision whether to create an ostomy or reconstruct the GI tract with an anastomosis can be made at that time. Since an anastomotic leak can be catastrophic, the creation of an anastomosis at the time of initial emergent surgery in the setting of coagulopathy and hemodynamic instability should be discouraged.

CONCLUSION

LGIB is a heterogeneous disease state consisting of a broad differential diagnosis with a range of severity. Owing to this complexity, a thorough history and physical examination is most important to narrow the differential diagnosis and proceed through a thoughtful diagnostic algorithm. Resuscitation, correction of coagulopathy, and blood transfusion are the cornerstones of management of LGIB and are often the only therapeutic maneuvers necessary given that most patients presenting with LGIB will spontaneously resolve. Endoscopic and interventional radiology procedures should be the initial localization and therapeutic modalities for most patients with LGIB depending on the clinical status of the patient. Surgery is reserved for a small subset of patients with continued hemodynamic instability or failure of less-invasive techniques, but it can be life-saving. Surgeons should be actively engaged in the management of patients with LGIB and should be prepared to intervene in the rare circumstance that this becomes necessary.

Appendicitis: Diagnosis and Management

Elaa Mahdi, MD, MPH, and Walter Pegoli Jr., MD

Appendicitis continues to be one of the most common causes of the acute surgical abdomen treated by general surgeons. The global incidence of appendicitis ranges from 100 to 150 per 100,000 persons per year, with a lifetime risk of 7% to 10%. In the United States, there are about 400,000 cases diagnosed each year, of which 16% to 40% are perforated. The pathogenesis of appendicitis remains unclear, with the thought being that obstruction of the appendiceal lumen results in inflammation and bacterial infection. The diagnosis is made on patient history, physical examination, laboratory tests, and various imaging modalities. Traditionally, treatment has included the initiation of antibiotics followed by surgical resection of the appendix. However, recent studies have demonstrated efficacy for the treatment of uncomplicated appendicitis using antibiotics alone. In this chapter, we discuss the pathophysiology, diagnostic workup, and most recent recommendations regarding management of patients with appendicitis.

ANATOMY OF THE APPENDIX

The appendix is an approximately 9 cm long and 0.6 cm wide vermiform or "worm-shaped" hollow viscus structure originating from the terminal cecum, where the three taenia coli converge. Upon completion of normal antenatal rotation of the intestine, the cecum and appendix are typically found in the right lower quadrant (RLQ). However, their location can be varied in patients with nonrotation or malrotation of their intestines. Although the base of the appendix always emanates from the cecum, the location of the tip of the appendix is often more variable (Fig. 1). It can be found retrocecal, subcecal, pelvic, preileal, or postileal, accounting for the diversity of presenting signs and symptoms. The blood supply to the appendix and mesoappendix is from the appendiceal artery, a branch off the ileocolic artery.

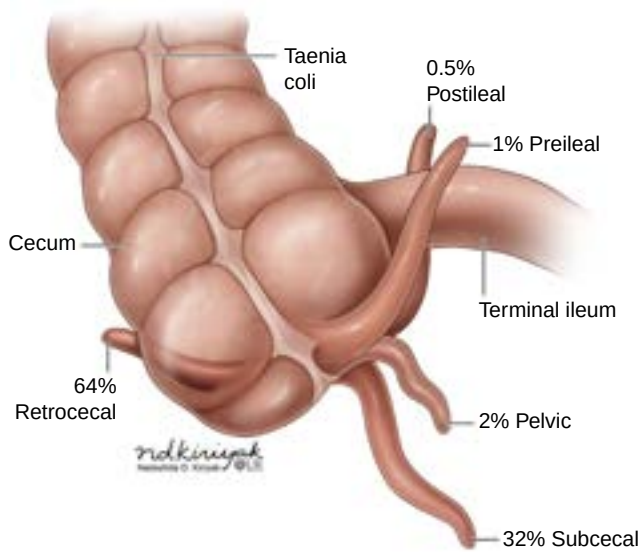

FIG. 1 Variations in the positions of the vermiform appendix.

PATHOLOGY OF ACUTE APPENDICITIS

The etiology of acute appendicitis is thought to be caused by obstruction of the appendiceal lumen. The most common cause of luminal obstruction is mechanical obstruction from a fecalith or appendicolith. Other causes include lymphoid hyperplasia, parasitic infections, neoplasm, or a foreign body. If left untreated, the ongoing obstruction results in a cycle of increased bacterial overgrowth, mucus production, inflammation, and venous congestion. The subsequent distension of the normally narrow-caliber appendix causes stretching of the visceral afferent nerve fibers, resulting in the vague periumbilical abdominal pain that is often described as one of the first symptoms. Similarly, distension of the appendix can result in nausea and vomiting early in the course of the disease. The increasing congestion eventually leads to obstruction of arterial inflow, resulting in ischemia, with progression to necrosis, gangrene, and eventually perforation with or without abscess formation. Organisms isolated in patients with acute appendicitis include *Escherichia coli, Bacteroides fragilis, Klebsiella pneumoniae, Streptococcus, Enterococcus,* and *Pseudomonas aeruginosa*. In cases of gangrenous or perforated appendicitis, *E. coli* and *Bacteroides* spp. are found in a majority of patients. Knowing the most common bacterial culprits helps guide antibiotic management in the treatment of appendicitis, especially if a nonoperative approach is chosen or postoperative antibiotics are required.

CLINICAL PRESENTATION AND DIAGNOSTIC WORKUP

History and Physical Examination

The diagnosis of appendicitis has typically been a clinical diagnosis based on history and physical examination. Patients will often complain of a vague onset of symptoms including anorexia, malaise, and epigastric or periumbilical abdominal pain/discomfort. This will typically progress to nausea and/or vomiting associated with abdominal pain that migrates to the RLQ. Findings on physical examination include fever, tachycardia, RLQ tenderness, guarding, and percussion tenderness. The tenderness usually is most intense at McBurney's point, which is located one-third of the distance between the right anterior superior iliac spine and the umbilicus. The patient may exhibit a positive Rovsing's sign, which is defined as palpation of the left lower quadrant (LLQ) resulting in RLQ pain. Additionally, physical examination findings will differ based on the location of the appendiceal tip and the degree of inflammation. A patient with a retrocecal appendix may not present with RLQ pain, but will have a positive psoas sign when extension of the right hip produces pain. A patient with a pelvic appendix may have an obturator sign, when internal rotation of the right hip causes pain. However, recent data suggest that although these signs are specific, they are not very sensitive for diagnosing acute appendicitis (Tables 1 and 2). Multiple

TABLE 1 Clinical Signs and Symptoms of Acute Appendicitis

History	**Onset of vague abdominal discomfort, cramping, nausea, progressing to right lower quadrant pain, with associated anorexia, vomiting, and general malaise**
Physical examination	Right lower quadrant tenderness, voluntary and involuntary guarding, fever, tachycardia, occasionally palpable mass
Laboratory examination	Leukocytosis, No bacteria on urinalysis, negative pregnancy testing
Diagnostic imaging	Distended fluid-filled appendix with surrounding inflammation, perforation, abscess, fecalith

clinical scoring systems have been developed to aid in the diagnosis of appendicitis. The Appendicitis Inflammatory Response (AIR) and the Alvarado score are used in adults, with the AIR found to have the superior performance. In children, the Pediatric Appendicitis Score (PAS) was developed to help identify patients with appendicitis using eight signs, symptoms, and laboratory values often associated with appendicitis (Table 3).

However, even when a patient presents with the "classic" signs and symptoms of appendicitis, a broad differential diagnosis including inflammatory bowel disease, urinary stones, Meckel's diverticulitis, and other potential etiologies should also be considered.

Laboratory Examination

On laboratory examination, patients are typically found to have a leukocytosis (>10,000 cells/mm^3), a left shift (>75% neutrophilia), and elevated markers of inflammation such as C-reactive protein (CRP). Although these are nonspecific findings of appendicitis, a normal laboratory value for them is less likely to be indicative of appendicitis. A urinalysis should be obtained to evaluate for a possible urologic source. Of note, sterile pyuria can result from the proximity of an inflamed appendix to the bladder.

Diagnostic Imaging

Different imaging modalities can be used to assist in the diagnosis of acute appendicitis, depending on patient age, body habitus, and risk of radiation exposure. In the pediatric patient, ultrasound (US) remains the initial imaging study of choice. It is easy to perform, inexpensive, and does not expose patients to harmful radiation. However, it is user-dependent and has limited visualization in obese patients. The overall specificity is 83% and sensitivity is 78%. Ultrasound findings typically include a distended, noncompressible appendix >6 mm in diameter with hypervascularity on Doppler studies (Fig. 2). Computed tomography (CT) is the most widely used study in the adult population. It is quick, not user-dependent, and has a specificity of 90% and sensitivity of 94%. However, it is more expensive than US and exposes patients to ionizing radiation. Of note, when used in children, low-dose radiation techniques should be utilized. Findings typically include a distended, fluid-filled appendix, periappendiceal fat stranding, and appendicoliths when present (Fig. 3). It can also demonstrate free fluid, abscess, phlegmon, and other findings associated with complicated appendicitis. In addition, colitis, diverticulitis, inflammatory bowel disease, gynecologic pathology, and other maladies in the differential diagnoses can be elucidated by CT. Magnetic resonance imaging (MRI) is gaining popularity as an imaging modality in children and in pregnant women. The diagnostic accuracy is similar to CT, without the exposure to ionizing radiation. However, it is associated with increased cost compared with CT. In their meta-analysis of second-line imaging after equivocal initial US, Eng et al. reported pooled MRI sensitivities and specificities of 97.4% and 97.1% in children, and 89.9% and 93.6% in adults, respectively. MRI is a viable alternative to CT in children or pregnant women with inconclusive findings on US.

MANAGEMENT OF ACUTE APPENDICITIS

The management of acute appendicitis has continued to evolve over time. Whereas the diagnosis of acute appendicitis would have traditionally meant the initiation of antibiotics and an emergent trip to the operating room, more recently the trend has been to delay surgical intervention until convenient for up to 24 hours. Some practitioners are now even managing patients with uncomplicated appendicitis nonoperatively using antibiotics alone.

Once the diagnosis of appendicitis has been made, patients should be resuscitated with intravenous crystalloid fluids (if necessary) and started on broad-spectrum intravenous antibiotics with gram-negative and anaerobic coverage as some of the most common organisms associated with acute appendicitis are *E. coli*, *B. fragilis,* and *K. pneumoniae.* Popular broad-spectrum antibiotics include piperacillin-tazobactam, ampicillin-sulbactam, and imipenem-cilastatin. Alternative antibiotics include ceftriaxone-metronidazole or cefoxitin. Cameron et al. compared the effectiveness of extended-spectrum antibiotics (piperacillin-tazobactam) versus narrow-spectrum antibiotics (cefoxitin or ceftriaxone-metronidazole) on rate of surgical site infections and hospital readmission rates in children with uncomplicated appendicitis. They found no difference in the outcomes, supporting the use of narrow-spectrum antibiotics in an era of increasing incidence of antibiotic-resistant bacteria. The duration of antibiotic therapy should be dependent on the severity of disease and whether the patient undergoes an appendectomy. For those with uncomplicated appendicitis who undergo appendectomy, antibiotics need not be continued postoperatively. Patients with complicated appendicitis will require a longer course of antibiotic therapy predicated upon extent of disease and clinical condition.

Timing of Surgery

The diagnosis of uncomplicated appendicitis is no longer considered an acute surgical emergency. Van Dijk et al. found no significantly higher risk for developing complicated appendicitis when surgery was delayed for up to 24 hours from hospital presentation. Data from the National Surgical Quality Improvement Program (NSQIP) reported similar outcomes, even when appendectomy was delayed until hospital day 2. However, those who underwent appendectomy on hospital day 3 had increased 30-day mortality and major postoperative complications. The WSES Jerusalem 2020 guidelines recommend operating within 24 hours of presentation in children and adults with uncomplicated acute appendicitis. In addition, they state that in pregnant patients with equivocal findings, a short in-hospital delay with repeat abdominal US is acceptable without a significant increased risk of adverse maternal or fetal outcomes.

Laparoscopic Appendectomy

The patient is placed in the supine position on the operating table with the left arm or both arms tucked. A Foley catheter should be considered if the patient was not confirmed to have voided before the case. The patient is prepped from the xiphoid process to the pubis. The abdomen is accessed through the umbilicus either with an open technique using a Hasson trocar or closed technique with a Veress needle. For placement of the Veress needle, the umbilicus is elevated with two towel clips, and an incision is made through the skin. The Veress needle is inserted perpendicular to the skin and advanced until two audible clicks as the spring-loaded needle retracts are appreciated. The first click occurs as the needle transverses the fascia, and the second click occurs as the needle transverses the peritoneum. A saline drop test is then performed to confirm entry into the peritoneal cavity. The abdomen is insufflated with carbon dioxide until intraabdominal pressure is 12 to 15 mm Hg. The Veress needle is retracted, followed by either a blind entry with a 12-mm closed conventional trocar or radially expanding trocar versus visual entry with an optical trocar (Optiview, Visiport). For the Hasson open technique, an incision is made into the infraumbilical or supraumbilical fold and carried through the subcutaneous tissue. Dissection is then performed through the subcutaneous tissue with S-retractors or a Kelly clamp until the rectus fascia is visualized. Two retention sutures are placed into the fascia on either side of the midline. With a knife, scissors, or electrocautery, a vertical incision is made through the fascia elevated with the retention sutures. The peritoneal cavity is entered bluntly with a Kelly clamp. The Hasson port is inserted under direct visualization and anchored in place with the stay sutures. The abdomen is insufflated and inspected to ensure that no injury occurred during entrance. The placement of subsequent trocars can be variable, depending on patient size, age, and pregnancy (Fig. 4). However, our preference is the use of an umbilical camera port and the working 5-mm ports at the right upper quadrant and LLQ (see Fig. 4A). A four-quadrant exploration is first done to quickly rule out other intraabdominal abnormalities before the patient is placed in reverse Trendelenburg with the right side up. Atraumatic graspers are used to follow the cecum to the convergence of the taenia coli. The cecum is lifted toward the left upper quadrant to better expose the base of the appendix. The mesoappendix is grasped/elevated, and peritoneal and/or omental attachments are lysed to expose the entirety of the appendix. For the retrocecal appendix, the white line of Toldt must be divided to mobilize the cecum and expose the appendix. A window is created through the mesoappendix. A linear gastrointestinal endoscopic stapler with a white load or an electrosurgical device (cautery or LigaSure) is introduced through the umbilical port, and the mesoappendix is divided, leaving the base of the appendix exposed (Fig. 5A). A blue load on the stapler is then used to divide the appendix (Fig. 5B; Fig. 6). Of note, an Endoloop may also be used to control the appendiceal base. The appendix is placed in a retrieval bag and withdrawn through the umbilical port. The staple line is then inspected, and hemostasis is achieved, as necessary. If murky, turbid fluid is observed in the pelvis, consideration should be given to obtaining a sample for Gram stain, culture, and sensitivities. Information gained may influence the choice of postoperative antibiotics. Recent data discourage peritoneal irrigation as it shows no benefit and may lead to an increased incidence of postoperative abscess formation. The working ports are removed under direct visualization, followed by desufflation through the umbilical port and closure of the trocar sites.

Open Appendectomy

Although the laparoscopic approach to appendectomy is most commonly used, the ability to perform an open appendectomy is essential. The patient is placed in the supine position and prepped in the usual sterile fashion. An imaginary line is drawn between the anterior superior iliac spine (ASIS) and the umbilicus. McBurney's point is identified and marked (see Fig. 4D). A skin incision is made within a natural crease. The dissection is carried down to the external oblique aponeurosis. The muscle is incised in the direction of its fibers and spread bluntly to expose the underlying internal oblique muscle. It too is dissected similarly to expose the transversus abdominis, which is split to expose the peritoneum. The peritoneum is elevated and sharply incised with care taken to avoid injury to the underlying bowel.

Once inside the abdomen, the cecum is identified and elevated into the wound. The appendiceal base is located at the confluence of the tenia. The appendix is dissected free from surrounding structures. A stapling device can be used to ligate/divide the mesoappendix and the appendiceal base. The "classic" technique divides the mesoappendix between Kelly clamps and ligating the ends using 3-0 silk. The base of the appendix is crushed with a Kelly clamp. The clamp is then relocated on the appendix 1 cm distal to the crushed zone (CZ). The appendix is ligated at the CZ with an 0 Chromic suture. The appendix is divided just proximal to the clamp. The stump may be cauterized or invaginated with a purse-string suture or a *Z*-stitch.

The incision is closed in layers. First, the peritoneum and transversus abdominis are closed with a running absorbable suture. Next, the internal and external oblique muscles are anatomically approximated with interrupted absorbable sutures. Finally, the skin is closed with a running absorbable subcuticular suture. In the case of perforation, the skin may be left open or loosely approximated.

Management of Perforated (Complicated) Appendicitis

Perforated appendicitis occurs in up to 40% of cases of appendicitis. Such patients will usually have had a longer duration of symptoms before presentation. The findings on abdominal examination may range from a tender RLQ abdominal mass to a rigid distended abdomen with diffuse peritonitis. Imaging findings may range from pneumoperitoneum and free fluid to an RLQ phlegmon or abscess. Patients diagnosed with complicated appendicitis should be resuscitated with intravenous fluids and immediately started on intravenous antibiotics such as piperacillin-tazobactam alone or a ceftriaxone with metronidazole. The decision to proceed with surgical intervention will depend on their clinical picture. Patients who are diffusely peritonitic and hemodynamically unstable should be aggressively resuscitated and taken to the operating room when adequately resuscitated. Patients who are found to have phlegmon or abscess formation can be considered for nonoperative management, which consists of intravenous antibiotics, percutaneous drainage (for patients with a drainable collection), and nutritional support for those who are unable to aliment orally. Appendectomy in the setting of an abscess or phlegmon is technically challenging and has been associated with a higher incidence of intraoperative and postoperative complications. Antibiotic therapy should be dictated by culture results, if available. Once patients are tolerating a regular diet, they can be transitioned to oral amoxicillin/clavulanate (Augmentin) for a total 5-day course, which has been shown to be as efficacious as 7 days of antibiotics, with no increase in the risk of abscess formation.

CURRENT CONTROVERIES

Nonoperative Management of Nonperforated Appendicitis

Although appendectomy remains the treatment of choice in patients with uncomplicated acute appendicitis, nonoperative management with antibiotics has become a viable alternative. O'Leary et al. performed a randomized clinical trial comparing the efficacy of antibiotic only versus appendectomy in uncomplicated acute appendicitis. They found that 25% of their antibiotic-only group experienced recurrence within 1 year. Of note, the antibiotic-only group also reported a decreased quality of life when compared with the surgical cohort. They concluded that surgery remains the mainstay of treatment. In their randomized clinical trial, the CODA Collaborative

compared a 10-day antibiotic course verses appendectomy at 25 centers in the United States. They found that although antibiotics were not inferior to appendectomy for the 30-day health status, the antibiotic-only group had higher failure rates, with 29% undergoing appendectomy by 90 days (41% of those with appendicolith and 25% of without appendicolith). Of note, most recent studies have shown a 5-year recurrence rate approaching 50% in both children and adults who were treated with antibiotics alone. Careful patient selection must be utilized in selecting which patient is an appropriate candidate for nonoperative management. Appropriate candidates should have a small appendix that does not contain an appendicolith on diagnostic imaging, CRP < 60 g/L, WBC < 12, and age < 60 years to

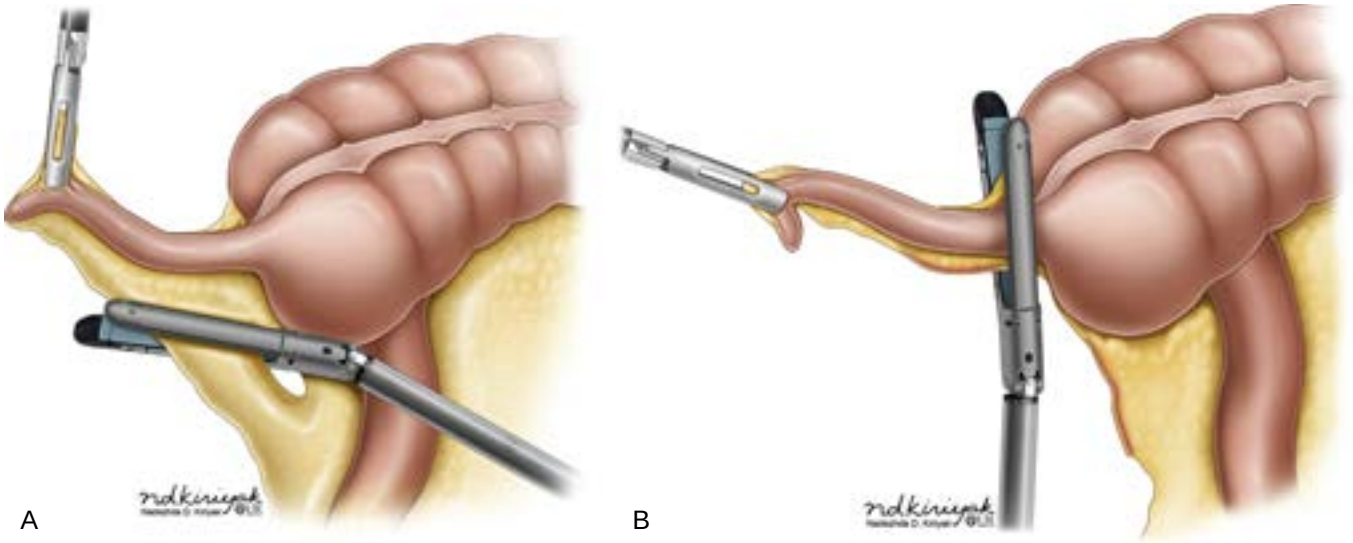

FIG. 5 **(A)** A window is created in the mesoappendix between the base of the appendix and the cecum, and the mesoappendix is divided with a white, vascular load. **(B)** The base of the appendix is stapled and divided with a blue gastrointestinal staple load.

have a chance of successful recovery based on studies by Hansson et al. and Loftus et al. Antibiotic duration for these patients ranges from 7 to 10 total days, with transition from intravenous to oral antibiotics following clinical improvement.

Interval Appendectomy

Interval appendectomy in patients who underwent initial nonoperative management of complicated appendicitis remains a controversial subject. It is typically considered safe to perform 6 weeks after successful treatment, as the acute inflammatory process has resolved by that time. Some argue that such patients have a very low rate of recurrence after their initial presentation and that surgery, with its 11% complication rate, is unnecessary. Proponents of interval appendectomy argue that there is a significant rate of recurrence and stress the importance of excluding an underlying appendiceal malignancy. At present, there is still no strong evidence to recommend for or against it in adults. However, it is recommended that adults 40 years of age and older undergo interval CT and colonoscopy to rule out malignancy. In children, several studies have shown that interval appendectomy is indicated. A 2017 multicenter randomized study found that 23% of children initially treated nonoperatively recurred and required appendectomy within 1 year, with a morbidity rate of 6%. Of note, the performance of interval appendectomy is often driven by parental concerns.

SUMMARY

Acute appendicitis continues to be a common, but complex, diagnostic and management challenge to surgeons. The variability in clinical presentation across ages and the broad differentials can cloud the diagnosis. No one clinical finding, laboratory study, or imaging finding can reliably make the diagnosis 100% of the time. Surgeons must combine these findings and resources to discern the diagnosis. Even then, the management can be complex and is ever evolving. Preoperative antibiotics and appendectomy remain the gold standard in the management of uncomplicated cases. In complicated cases, those patients with uncontrolled intraabdominal sepsis should be resuscitated, given broad-spectrum antibiotics, and taken to the operating room as soon as possible. Controversy exists on how to best treat those patients with complicated appendicitis who are clinically stable. Some clinicians advocate the use of antibiotics with or without percutaneous drainage in those with abscess formation, while others advocate for early surgical intervention. Further studies are needed to delineate which approach is truly superior. For now, all agree that appendicitis still remains a surgical disease.

Management of Hemorrhoids

Ariane M. Abcarian, MD, and Herand Abcarian, MD

INTRODUCTION

Hemorrhoids are specialized vascular cushions in the anal canal or at the anal verge. These cushions are composed of blood vessels, connective tissue, and smooth muscle fibers. Hemorrhoids are a normal part of human anatomy and are responsible for 15% to 20% of anal resting pressure. Hemorrhoids are typically paired and located in the right posterior, right anterior, and left lateral locations. Internal hemorrhoids are positioned cephalad to the dentate line and are covered with mucosa, and external hemorrhoids are located caudal to the dentate line and are covered with anoderm, and most distally, skin. (Fig. 1). Internal hemorrhoids are classified based on their degree of prolapse (Table 1).

ETIOLOGY AND SYMPTOMS

Hemorrhoids are a normal part of human anatomy. Pathologic hemorrhoids occur as such through increased abdominal pressure, usually caused by constipation, straining, and poor toileting hygiene. Other causes for hemorrhoid enlargement and complications are diarrhea, pregnancy, chronic obstructive pulmonary disease (COPD), and portal hypertension (PH). Approximately 10 million Americans are affected by symptomatic hemorrhoids, making it roughly 4.4% of the population affected. The majority of these patients are over the age of 50.

Most patients with anorectal complaints will be labeled as having "hemorrhoids." It is imperative that the practitioner differentiate hemorrhoidal symptoms from other benign or malignant anorectal conditions. Patients with rectal bleeding from hemorrhoids will describe bright red bleeding, usually with defecation. The blood can be minor and seen on the paper with wiping, or can fill the toilet bowl and include clots. Symptoms of constipation and straining or diarrhea should be elicited, and documenting bowel and toileting habits is a good place to start when evaluating these patients. Time spent on the toilet should be noted, and it should be discerned if this time is spent defecating, engaging in reading, and so on. It should be documented if the patient feels a prolapse of tissue and whether they need to manually reduce this. Hemorrhoidal prolapse should be easily differentiated from true rectal prolapse by the absence of circumferential folds and the presence of radial folds (Fig. 2). A family history of colon cancer, polyps, or inflammatory bowel disease should be documented. Thorough examination of the anorectum (externally, digitally, and with anoscopy) should be performed. All patients with bleeding should have a discussion regarding colonoscopy. Patients with symptomatic external hemorrhoids are almost always suffering from thrombosis, and this may be solitary or in conjunction with strangulated internal hemorrhoids (Fig. 3). It may be difficult to examine these patients because of discomfort and fear, and examination under anesthesia may be warranted. Skin tags are common and asymptomatic but may contribute to hygiene problems and pruritus ani.

TREATMENT

Dietary and Lifestyle Modifications

Once the patient has been diagnosed with symptomatic hemorrhoids and other conditions fully ruled out, first-line treatment with conservative, nonoperative therapy should commence. The vast majority of patients are started on a fiber supplement such as psyllium or methylcellulose and a stool softener such as docusate. Patients are encouraged to drink eight or more glasses of water per day, cut back on caffeinated beverages, and increase dietary fiber. Patients should also be advised on proper toileting hygiene as reducing pressure to the pelvic floor by avoiding straining is imperative. Patients are encouraged to reduce time on the toilet to less than 3 minutes and not to sit longer than necessary (no reading, cell phone, crossword puzzles). In a large systematic review, these simple measures were sufficient to decrease symptoms in the majority of patients with grade I and II hemorrhoids. Warm sitz baths two to three times daily may also help with symptom relief, as may application of cotton soaked with witch hazel to reduce edema. Over-the-counter topical remedies usually contain hydrocortisone or *-caine* analgesics and may provide temporary relief, but they do not help reduce symptoms in the long run.

The use of phlebotonics including the natural plant extract flavonoids are thought to improve hemorrhoids through an unknown mechanism of action. Studies report increased venous drainage and decreased hemorrhoidal inflammation. Patients report less bleeding, less pruritus, and overall symptom improvement. Long-term data do not exist to support durability at this time.

Some patients will fail conservative treatment and require procedural intervention. Office-based procedures include rubber band ligation (RBL), sclerotherapy, infrared coagulation (IRC), and use of the HET bipolar system. Operative procedures are also included in the algorithm of treatment and may be employed as more conservative treatments fail.

Office-Based Procedures

Rubber Band Ligation

RBL is the most common office-based procedure for symptomatic hemorrhoids. It is appropriate for use on grade I, II, or III hemorrhoids and requires no anesthetic or bowel preparation. Patients who are on anticoagulation, on antiplatelet therapy, or are allergic to latex are not eligible for this procedure. With the former, there is a risk of

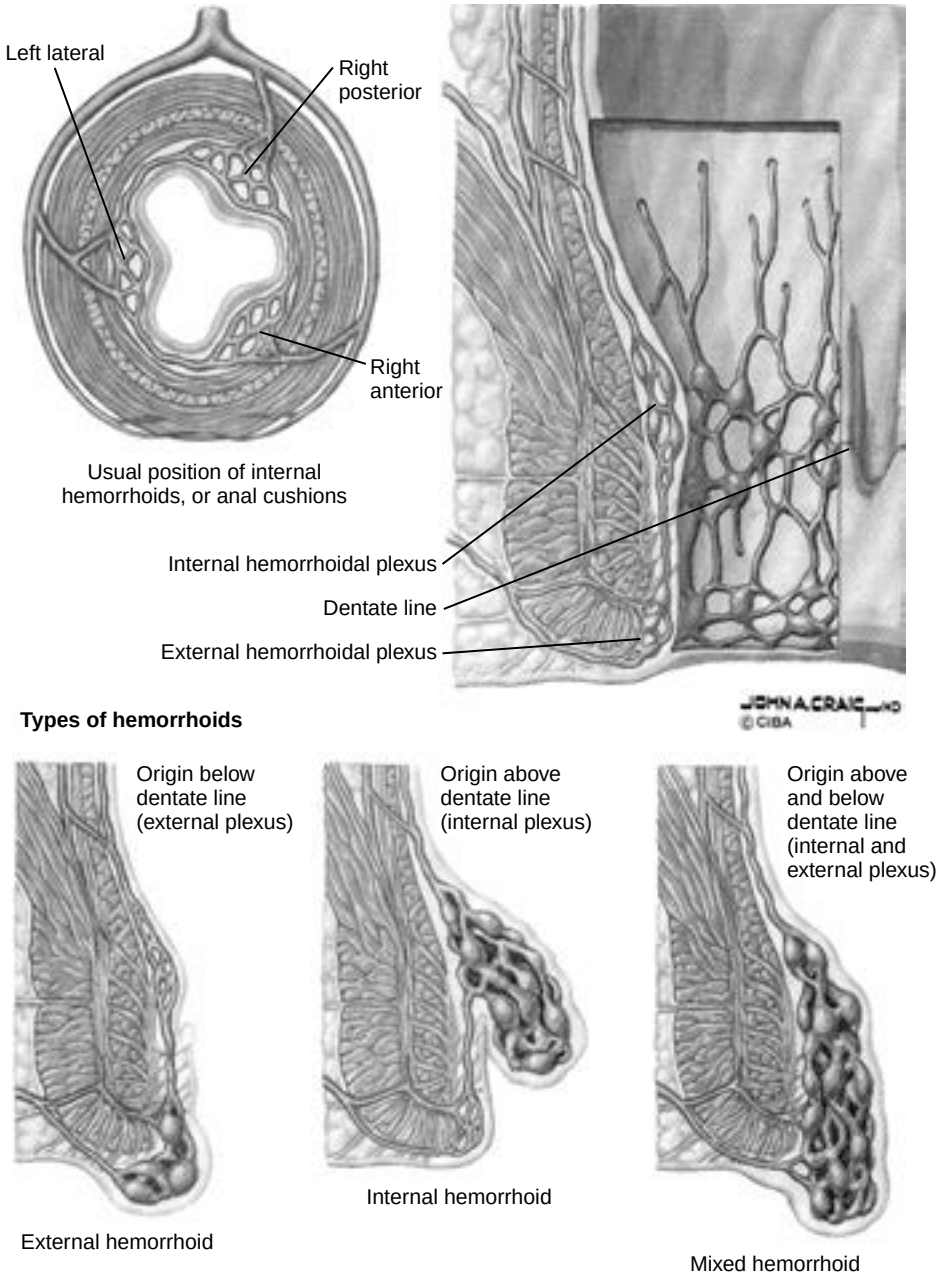

FIG. 1 Location and types of hemorrhoids.

TABLE 1 Classification of Internal Hemorrhoids

Grade	Location	Symptoms
1	Bulge into anal canal	Painless bleeding
2	Prolapse, reduce spontaneously	Bleeding, pressure, itching
3	Prolapse, require manual reduction	Bleeding, pressure, mucoid drainage
4	Prolapse, cannot be reduced	Pain, bleeding, pressure, mucoid drainage

delayed bleeding. Patients are asked to abstain from aspirin-containing products at home for 7 days before the procedure. They are placed in the left lateral decubitus or prone jack-knife (preferred) position on a procto table. Anoscopy is performed, and the hemorrhoids are visualized. The largest or most excoriated hemorrhoid is addressed at the first session. The rubber band is placed approximately 2 cm above the dentate line at the apex of the hemorrhoid (Fig. 4). There is no somatic pain sensation at this level, and many patients report dull pelvic pressure.

There are several types of rubber band ligators available; our preference is shown. Suction ligators have the benefit of not needing an assistant. RBL helps reduce hemorrhoid size by reducing blood flow to the hemorrhoidal cushion and by removing a small portion of rectal mucosa. Over time, fibrosis and scarring occur, which help pull the hemorrhoid cephalad and further reduce size and prolapse symptoms. Hemorrhoid banding has a high success rate of over 90%. Many patients may need a series of bandings to fully address symptoms; these should be scheduled roughly 3 to 4 weeks apart. Our preference is to band one hemorrhoid at the first occasion and up to two thereafter. We avoid banding all three hemorrhoidal columns to reduce pelvic pressure and pain. The band will slough in approximately 1 week, causing some minor bleeding. Again, it is this part

of the procedure that makes it unsuitable for those on anticoagulants or aspirin. For those who can stop anticoagulation 1 week before and after, banding is a good option. For those who cannot, sclerotherapy can be offered.

RBL is safe, and its most common complications are pain, bleeding, vasovagal symptoms, or thrombosis of the contiguous external hemorrhoid. Severe pain immediately after banding indicates the band was placed too low, and band removal is required either in the operating room or with a band-removing tool in the office. Rarely, pelvic sepsis can occur with fever, increasing and severe pain, and urinary retention. It is a rare but serious complication and requires immediate operative intervention to control sepsis with wide debridement of necrotic tissue.

FIG. 2 Prolapsed external and internal hemorrhoids.

Sclerotherapy

Sclerotherapy is an office-based procedure used for grade I and II hemorrhoids and is a viable option for patients on anticoagulants and antiplatelet agents. A sclerosant is injected into the hemorrhoid, resulting in shrinkage, fibrosis, scarring, and fixation. Sclerosing agents include 5% phenol (suspended in almond oil), hypertonic saline, or ethanolamine. Anoscopy is performed and, using a 25-gauge needle, the surgeon injects the sclerosant 1 cm above the dentate line in the submucosa of the hemorrhoid. The volume injected varies based on the sclerosant but is typically 2 to 3 mL when using phenol and 1 mL when using ethanolamine, and all three hemorrhoids can be treated in one session. Digital pressure is used to control needle site bleeding in patients who are anticoagulated. Sclerotherapy, like RBL, can be repeated to achieve the desired effect. Complications are similar to RBL and arise usually from injecting the sclerosant into the muscle or mucosa, which leads to pain, ulceration, and eventual sloughing of the mucosa.

Other Office-Based Procedures

IRC and bipolar diathermy are also utilized for grade I and II hemorrhoids. Like sclerotherapy, both can treat all hemorrhoid columns in one setting. In IRC, the tip of the infrared coagulator (IRC 2100, Redfield Corporation) is placed at the apex of the hemorrhoid. A 1- to 1.5-second pulse is applied, resulting in a 4-mm^2 focus of coagulation. This creates a 2.5-mm-deep ulcer. Typically three to four applications are made on each hemorrhoid. The overall effect is thrombosis and tissue destruction, which leads to shrinkage, scarring, and fixation of the hemorrhoid. IRC is well tolerated and has similar side effects to RBL and sclerotherapy (Fig. 5).

The HET system (HET bipolar system, Covidien) is also used in the office setting. Using specialized forceps, the hemorrhoid is grasped, and bipolar energy is applied. HET is well tolerated and has similar side effects to RBL and sclerotherapy.

Operative Treatment

Operative treatment is indicated for patients with grade III and grade IV hemorrhoids and for those who have persistent symptoms

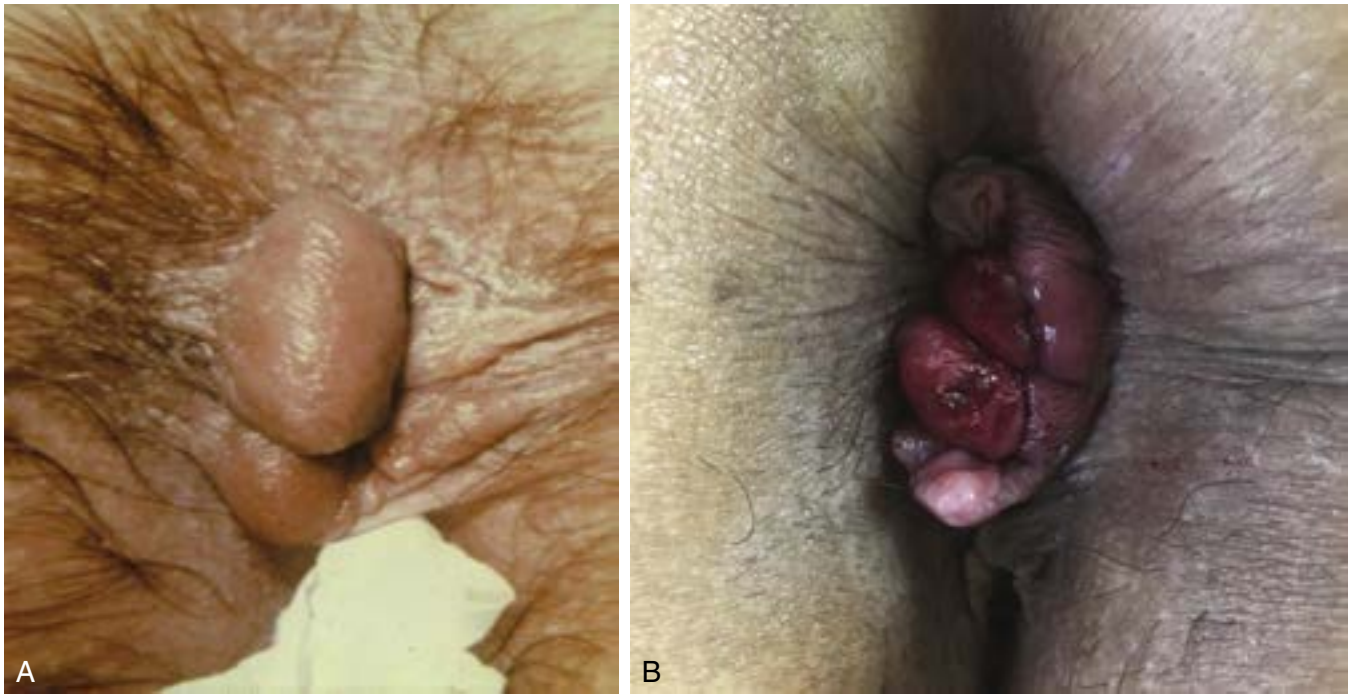

FIG. 3 (A) An acute, thrombosed external hemorrhoid. **(B)** Prolapsed and strangulated internal hemorrhoids with an external component.

despite conservative and office-based procedures. Some patients are suitable to go directly to an operation in the nonurgent setting. Only about 5% to 10% of patients with symptomatic hemorrhoids will require an operation. Surgery is superior to office-based procedures in terms of durability but has more potential complications including pain, urinary retention, bleeding, anal stenosis, infection, and changes in continence. Use of long-acting injectable anesthetics is helpful. Detailed postoperative instructions including pain management, local wound care, controlling constipation, and return precautions are important for patient satisfaction and comfort in the postoperative period.

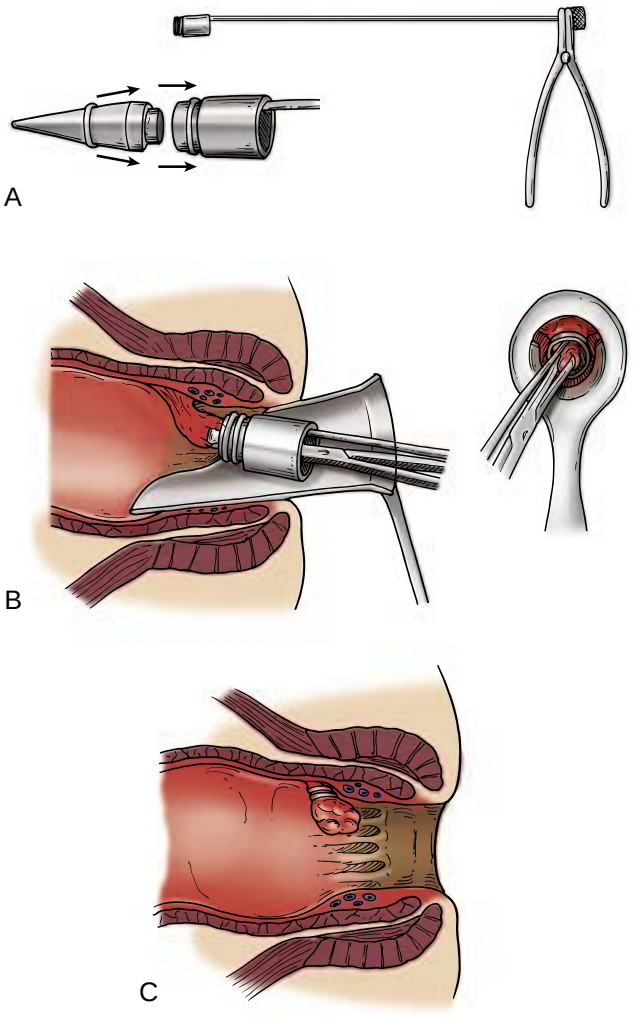

FIG. 4 Rubber band ligation of internal hemorrhoids. (A) A rubber band is placed onto a banding gun. **(B)** The hemorrhoid is grasped 2 cm above the dentate line, and the band is advanced over the hemorrhoid. **(C)** The band is shown in the correct position after ligation.

Acute Hemorrhoidal Crisis

The term *acute hemorrhoidal crisis* is attributed to Dr. Eugene Salvati, whose robust practice of over 50 years focused heavily on proctology. Acute hemorrhoidal crisis refers to circumferential prolapsed, thrombosed, and incarcerated internal and external hemorrhoids, with or without necrosis. In the absence of necrosis, the patient can be treated definitively or temporized with the use of an injected mixture of 1% lidocaine with epinephrine, normal saline, and hyaluronidase. The mixture is injected into all edematous tissues. The area is massaged, and a pressure dressing is applied. We typically have the patient sit on a roll of kerlix. The procedure can be repeated (Fig. 6). With necrosis present, this should be managed operatively with hemorrhoidectomy. Before incision, the hyaluronidase mixture can be injected and the hemorrhoids reduced to better delineate the tissues that are necessary for excision and reduce the chances for overexcision of anoderm. Single-column thrombosis can be excised and the wound left open to granulate. This is best done within the first 72 hours of thrombosis, and patients should be counseled that pain and drainage will be present after the procedure (Fig. 7).

Ferguson Hemorrhoidectomy

The Ferguson or "closed" hemorrhoidectomy is the most common hemorrhoid operation performed in the United States and offers a durable solution to hemorrhoidal symptoms. It involves excision of the hemorrhoidal tissue (internal and external) with ligation of the hemorrhoid pedicle and closure of the mucosal defect and skin. Our preference is to perform this operation under spinal anesthesia with the patient in the prone jack-knife position. The hemorrhoid is marked for excision at the anoderm. It is injected with an equal mixture of lidocaine with epinephrine and bupivacaine. A V-shaped incision is made in the perianal skin, and the hemorrhoid is elevated off the external and internal sphincter as the dissection is carried cephalad. The sphincter muscles should be clearly identified in situ as the incision is continued onto the mucosa. The apex of the hemorrhoid is identified, and the vascular pedicle is clamped before excision of the hemorrhoid. The pedicle is suture ligated (we use 2-0 Vicryl on a tapered needle), and the defect is then closed using a locking running suture until reaching the skin, where simple running sutures complete the closure. The last few millimeters are left open to drain (Fig. 8). The procedure can also be performed using a bipolar

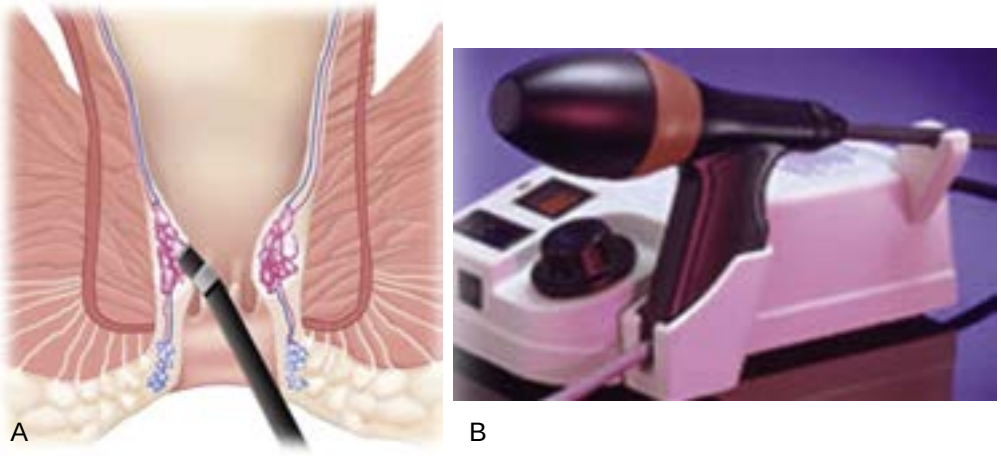

FIG. 5 Infrared coagulation of internal hemorrhoids. (A) The applicator is applied to the apex of the hemorrhoid. **(B)** The IRC 2100 device (Redfield Corporation).

FIG. 6 Acute hemorrhoidal crisis. (A) Thrombosed internal and external hemorrhoids with severe edema before injection. **(B)** After hyaluronidase mixture injection and massage. Note the absence of edema.

sealing device (LigaSure or Harmonic). Careful identification of the internal sphincter is mandatory to proceed safely with this technology, and caution must be used to prevent overexcision of anoderm with resultant anal stenosis. Using an energy device will also significantly increase cost.

Milligan-Morgan Hemorrhoidectomy

The Milligan-Morgan, or "open" hemorrhoidectomy, is performed most commonly in Europe and the United Kingdom. The procedure is identical to the Ferguson hemorrhoidectomy, but after excision the wound is left open to heal by secondary intention.

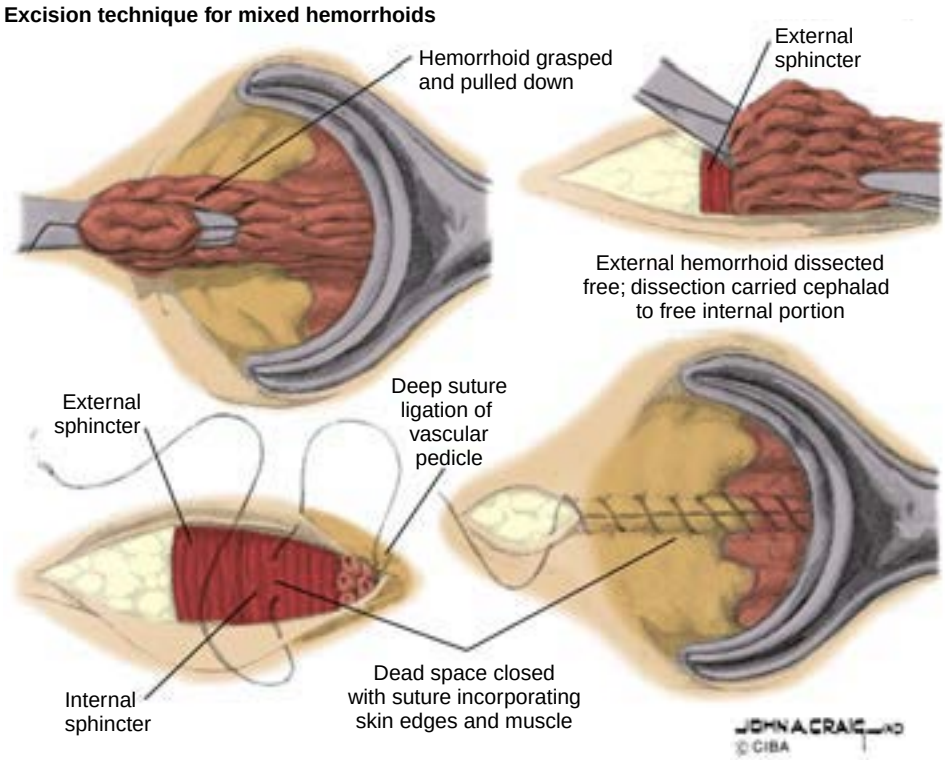

FIG. 8 **Ferguson hemorrhoidectomy.**

Outcomes and overall durability are similar, but wound healing is much longer.

Stapled Hemorrhoidopexy

Stapled hemorrhoidopexy (or procedure for prolapsed hemorrhoids [PPH]) is usually offered to patients with grades I to III circumferential internal hemorrhoids without a bulky external component. It was developed as an alternative to excisional hemorrhoidectomy because of the associated postoperative pain. The technique uses a specialized circular end-to-end anastomosis (EEA) stapler that removes a circumferential band of mucosa and submucosa proximal to the hemorrhoids. It does not remove the hemorrhoids, but flattens them with tension and disruption of the vascular pedicle and helps reposition them back to their normal anatomic position in the anal canal. There are no external wounds, and the staple line is cephalad to the dentate line, thus reducing pain compared with traditional excisional hemorrhoidectomy. PPH can help flatten external disease, but it will not completely address large external hemorrhoids.

Stapled hemorrhoidopexy is also performed under spinal anesthesia in the prone jack-knife position. The hemorrhoidopexy kit contains a dilator, a clear plastic anoscope, an operating anoscope, and stapler (Fig. 9). The dilator is placed in the anal canal, and the clear plastic anoscope is sutured to the perianal skin to evert the dentate line. Next, the operating anoscope with depth markings is used to place a circumferential submucosal purse-string suture 3 to 4 cm proximal to the dentate line, about 2 cm proximal to the hemorrhoidal pedicle. Caution must be taken to avoid placing a full-thickness suture, especially in women as injury to the vagina and subsequent rectovaginal fistula can occur. After placement of the purse-string suture, the vagina should be checked digitally to ensure the absence of suture. Once the purse-string suture is complete, it is tied to the anvil of the stapler. The anvil is then mated with the stapler, and the stapler is fired. The specimen appears as a ring of mucosa and submucosa.

Complications of PPH and excisional hemorrhoidectomy are similar. In some cases, if the staple line is too close to the dentate line, the patient will have significant postoperative pain, so care must be taken to place the purse-string suture at the correct level. Staple line bleeding at the time of the initial operation should be controlled by oversewing the entire staple line. Rare complications such as rectovaginal fistula, pelvic sepsis, staple line stricture, and rectal perforation have been reported, and most complications result from misplacement of the purse-string suture. PPH outcomes are similar to hemorrhoidectomy however; long-term recurrence is higher with stapled hemorrhoidopexy. Overall, PPH patients have less pain, faster recovery, and better quality of life scores compared with excisional hemorrhoidectomy patients.

Doppler-Guided Hemorrhoid Artery Ligation and Mucopexy

Doppler-guided hemorrhoidal artery ligation (DGHAL) is a technique that utilizes one of two patented anoscopes, the THD (transanal hemorrhoid dearterialization) or the HAL (hemorrhoid artery ligation). Both systems utilize Doppler guidance to isolate the hemorrhoidal arteries for ligation. Typically used on grade II to III hemorrhoids, it allows selective and specific ligation of the hemorrhoidal arteries, reducing arterial inflow to the hemorrhoids and returning the tissues to normal physiologic condition. Up to 90% of patients had improved symptoms, with less postoperative pain than other surgical options, because all suturing is done proximal to the dentate line.

Similar to other hemorrhoid procedures, the DGHAL is performed in the operating room in the prone jack-knife position. The proprietary anoscope is placed in the anal canal to 6 to 7 cm from the anorectal junction. The vessels are localized with the attached Doppler, usually about 2 cm above the anorectal junction (Fig. 10). A *Z*-stitch is placed at this location through the slot on the anoscope, and ultimately six sutures are placed. For patients with grade III or IV hemorrhoids, a mucopexy, or "rectoanal repair," can be added to help draw up and flatten out the tissues. Overall complication rates are low and are mostly related to bleeding and recurrence.

Open Transanal Hemorrhoidopexy

Open transanal hemorrhoidopexy can be performed alone or in conjunction with other operative procedures. It involves suturing the

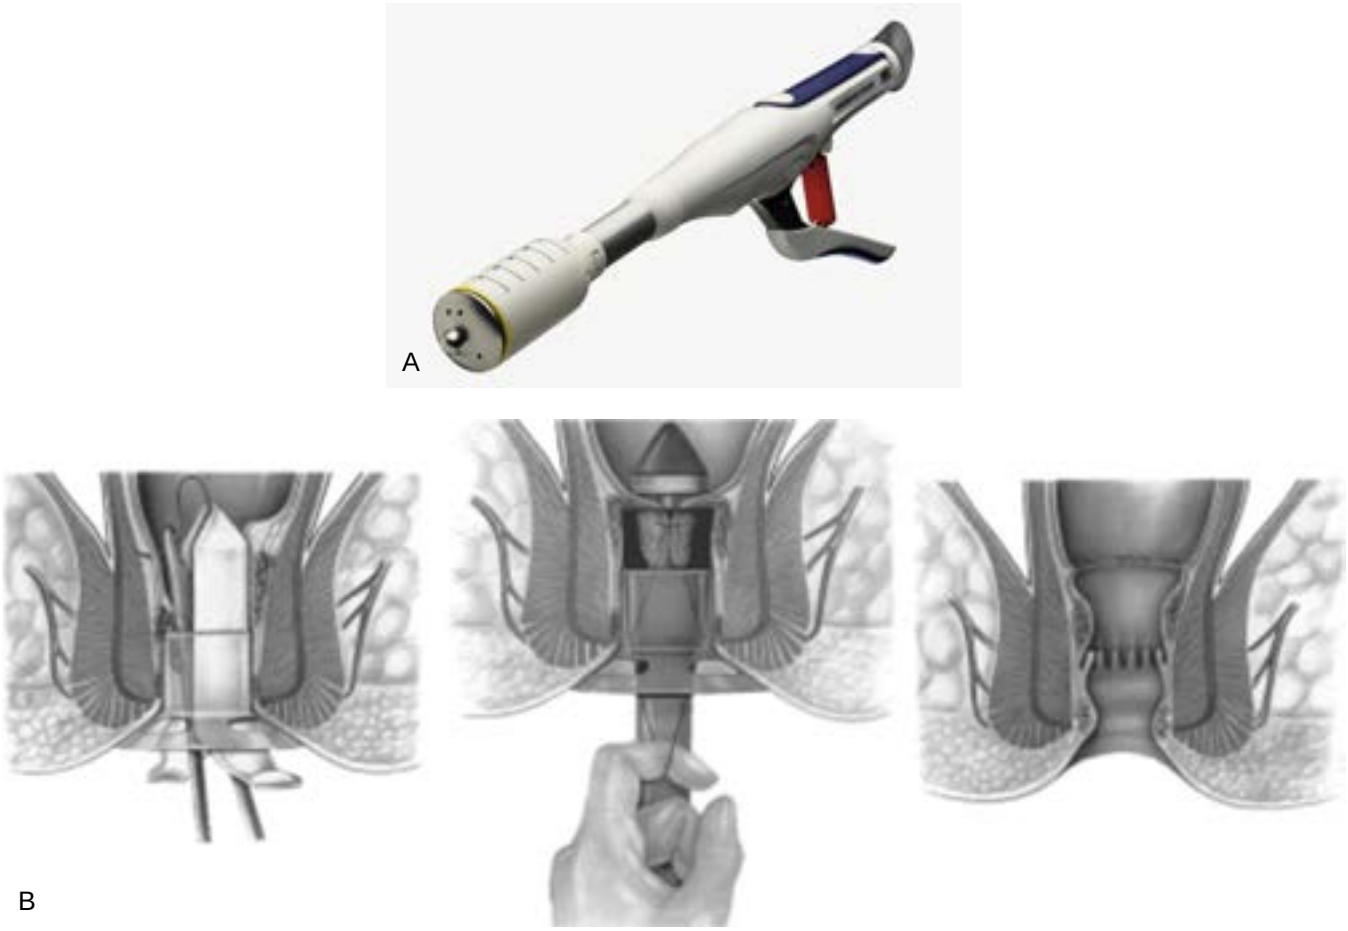

FIG. 9 **(A)** EEA hemorrhoid and prolapse stapler with DST Series technology. **(B)** Stapled hemorrhoidopexy technique. A purse-string suture is applied 4 cm above the dentate line *(left)*. The stapler is advanced into the rectum, and traction is held on the suture *(center)*. The staple line is shown after completion of the procedure *(right)*. (**A** *courtesy Medtronic, copyright 2019.)*

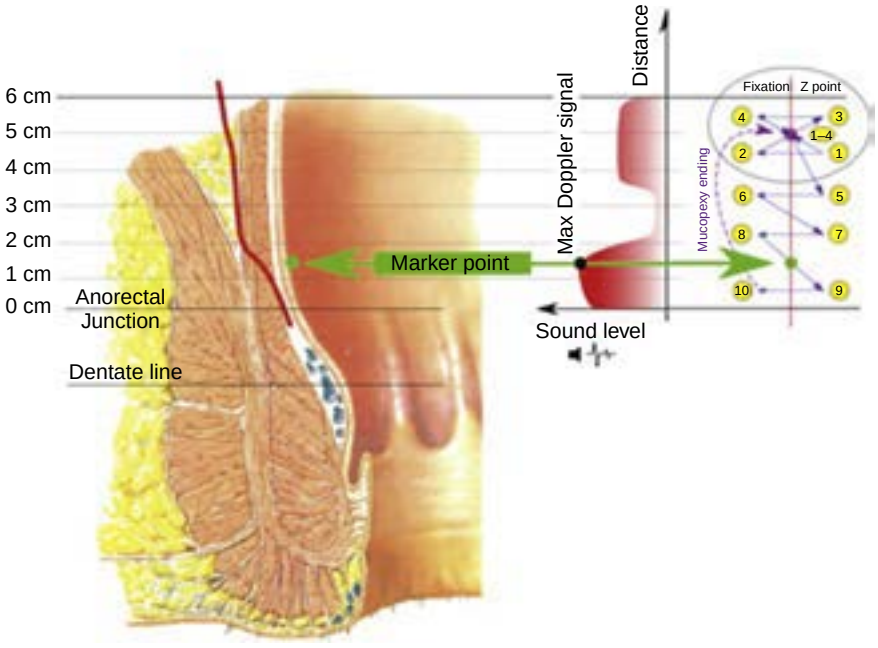

FIG. 10 Schematic of transanal hemorrhoidal dearterialization and mucopexy. *Marker point* denotes the location of the best Doppler signal for hemorrhoidal ligation. A *Z*-stitch is placed at this location for ligation alone. For higher-grade hemorrhoids, mucopexy with running suture is performed starting proximally and encompassing the ligation point, pulling the redundant mucosa up into the rectum *(right side of image). (From Ratto C, de Parades V. Doppler guided ligation of hemorrhoidal arteries with mucopexy: a technique for the future. J Visc Surg. 2015;152:S15–S21.)*

anal mucosa to the rectal wall using a *Z*-stitch. At 4 cm from the anal verge, a suture including mucosa and submucosa is placed through the rectal wall and then at the upper level of the hemorrhoid tissue near the vascular pedicle. Before tying the suture, a 1-cm strip of mucosa between the two sutures is excised after injection of lidocaine with epinephrine. The suture is then tied down, drawing the prolapsing hemorrhoid higher into the anal canal. Our practice is to perform this procedure, with or without excision of the intervening tissue, during other operative treatment for the hemorrhoids, and it can be a useful adjunct. Complications related to bleeding and thrombosis are most common. Recurrences may be managed with a repeat procedure.

Postoperative Considerations

Surgical hemorrhoidectomy is a very safe procedure. Postoperative urinary retention occurs in up to 15% of patients and can be partially mitigated with fluid restriction. Postoperative bleeding occurs in 1% to 2% of patients. Early bleeding is considered an operative complication, but bleeding 7 to 14 days later is a known complication resulting from absorption of sutures. All patients with significant bleeding must return to the operating room. During the examination under anesthesia, most often no active bleeding is seen, but all suture or staple lines should be oversewn. Rarely more serious complications will occur as mentioned previously. Overall, most patients will have postoperative pain and should be given multimodal analgesics to help reduce narcotic usage. Oral regimens of nonsteroidal antiinflammatory drugs (NSAIDs) as well as acetaminophen should be given around the clock. Sitz baths to help reduce discomfort should be utilized liberally. Constipation and diarrhea should be avoided, and appropriate stool modifiers should be offered if necessary. Studies have shown that use of topical calcium channel blockers in the postoperative period reduced overall pain and allowed patients to resume normal activities sooner. Overwhelmingly the greatest improvement has been with the use of liposomal bupivacaine, which has demonstrated overall reduction of pain scores and greater interval in opioid usage in the postoperative period.

SPECIAL SITUATIONS AND COMPOUNDING CONDITIONS

Pregnancy

Pregnant patients are susceptible to increased hemorrhoid symptoms because of the complex physiologic changes that result in increased intraabdominal pressure and reduced venous return. Labor-related straining further complicates the problem. Bleeding and pain are the most common symptoms, and symptoms present at any time during pregnancy, but most often in the third trimester.

Treatment is almost always conservative and nonoperative as most hemorrhoid symptoms will regress in the postpartum period. Unless the hemorrhoids are thrombosed or strangulated, surgery should be avoided. Stool softeners, sitz baths, and cooling ointments should be used liberally.

Portal Hypertension

PH is another condition that will result in increased rectal bleeding, and many of these patients have rectal varices on examination that may resemble hemorrhoids. Bleeding in the setting of PH should be treated conservatively. RBL is contraindicated because of the risk of delayed bleeding. Sclerotherapy and suture ligation of the hemorrhoids can be offered if conservative therapy fails. Ultimately, reducing portal pressure with a transjugular intrahepatic portosystemic shunt is the terminal procedure. Caution should be taken to avoid any bedside or office-based procedures in these patients because bleeding, even from small injection sites, can be brisk and difficult to control.

Immunocompromised Patients

Managing hemorrhoid symptoms in immunocompromised patients can be challenging. Conservative measures are first line as the risk of poor wound healing and pelvic sepsis is increased after surgical hemorrhoidectomy in this cohort. For patients on immunosuppressants that can be stopped, preference is to have 1 week off medication before the procedure. In patients with poorly controlled HIV or AIDS, sclerotherapy is the procedure of choice. Preprocedure antibiotics should be considered in this population and discussed with the patient and the patient's other physicians. Patients with well-controlled HIV have a risk similar to non-HIV patients.

Crohn's Disease

In patients with Crohn's disease, symptomatic hemorrhoids are rare. Symptoms are more likely related to the Crohn's disease when a careful history and examination are made. Anal fissure and anorectal abscess are much more common than symptomatic hemorrhoids. Treatment should always be conservative, and maximal management of the Crohn's disease is imperative. Elective operations for hemorrhoids in patients with proctitis should be avoided. Acute, painful thrombosis may be excised with a small incision.

SUMMARY

Hemorrhoidal disease is very common among adults in the United States given the incidence of constipation and low-fiber diet. Symptoms must be carefully elucidated by the physician, and a thorough physical examination and anoscopy are crucial to confirming the diagnosis. Colonoscopy should be ordered to confirm outlet bleeding and rule out proximal source. Conservative management with dietary and lifestyle changes are the mainstay of treatment in every patient. Fiber supplementation and proper toilet hygiene are imperative. When failure of conservative therapy is noted, patients with grade I to II hemorrhoids and some with grade III will benefit from office-based procedures. They can be repeated safely to obtain optimal results. Those with grade III and IV hemorrhoids or who fail office-based procedures have multiple surgical options depending on anatomy and patient preference. The operation should be tailored to the patient. Care should be taken when managing patients with special circumstances as not every procedure is suitable.

Management of Fissure-In-Ano

Vernissia Tam, MD, MS, and Heather L. Yeo, MD, MHS

INTRODUCTION

Anal fissures are one of the most common conditions seen in a colorectal surgery practice. Patients present with sharp tearing or cutting pain during and after bowel movements, often accompanied by hematochezia. The pathogenesis is believed to be precipitated by hard stool or diarrhea passing through the anal canal, causing mucosal trauma. The trauma causes pain and tightening of the sphincter. Increased sphincter tone and decreased blood flow along with repeated trauma prevent fissures from healing, forming the key targets for treatment.

On anorectal examination, 75% to 90% are located in the posterior midline, and acute fissures appear as a longitudinal tear in the anal canal, distal to the dentate line (Fig. 1A). After 6 to 8 weeks, chronic fissures may present with a skin tag or sentinel pile, with exposed fibers of the internal sphincter visible at the base, and heaped-up granulation tissue at the edges (Fig. 1B). Up to 20% may be located in the anterior midline, and off-midline fissures should prompt evaluation into other underlying infectious, immunosuppressive, or malignant etiologies (Fig. 1C).

NONOPERATIVE MANAGEMENT

Dietary and Lifestyle Modifications

There is no single recommendation for treatment that is best for all patients. Nonoperative treatment success will partially depend on patient compliance with lifestyle modifications and topical agents. The decision to escalate to surgery involves the degree of improvement with conservative measures, the risk for incontinence, and patient preference. For severely symptomatic patients who do not have risk factors for incontinence and can accept a small risk of long-term incontinence, surgery may be offered up front for the highest likelihood of healing and lowest risk of recurrence. It is our preference to only use this in very select cases.

Over 50% of acute fissures will resolve with conservative measures and warrant a trial of nonoperative management. Initial recommendations include increased fiber intake (25 to 35 g per day) via diet or supplements, increased hydration, and warm sitz baths. Fiber combined with sitz baths alone has been reported to heal up to 87% of acute fissures. The combination of these conservative measures with a topical analgesic (e.g., 2% lidocaine, EMLA cream) and a sphincter relaxant is a reasonable first-line treatment. Failure of symptoms to improve in 6 to 8 weeks warrants reevaluation and escalation of treatment. A biopsy should be performed on all long-standing fissures to rule out malignancy.

FIG. 1 **(A)** Acute posterior midline fissure. **(B)** Chronic fissure with sentinel tag. **(C)** Off-midline fissure associated with Crohn's disease. *(**B** and **C** courtesy Dr. Kelly Garrett.)*

Topical Sphincter Relaxants

Topical nitroglycerin releases nitric oxide and relaxes the internal anal sphincter (IAS), producing healing rates between 49% and 68%. Doses between 0.2% and 0.8% can be applied 2 to 4 times per day. However, effects are short-lasting (approximately 90 minutes), which may require diligence and frequent reapplication. The most significant side effect is headaches and lightheadedness, which may be mild to severely disabling and can lead to noncompliance and cessation of treatment.

Topical gels containing nifedipine or diltiazem similarly relax the internal sphincter and encourage blood flow. Oral doses are available but may lead to orthostatic hypotension. Studies comparing topical nitrates to calcium channel blockers have showed conflicting results, and both are considered equivalent, with selection largely based on provider preference and pharmacy availability. We prefer a dose of 2% to 5% topical diltiazem cream applied 2 to 3 times daily. If tolerated, oral doses of 60 mg twice-daily have been successfully described.

Chemical Denervation

Botulinum A toxin (Botox, Allergan Inc.) chemically paralyzes the internal sphincter, which lowers the resting anal pressure and increases blood flow. Injections can be performed as an outpatient or clinic-based procedure. We prefer treatment with 60 to 100 units diluted in 2 to 5 mL sterile saline solution. Four divided doses are injected into the intersphincteric groove directed toward the IAS in four quadrants. Depending on sphincter tone, another 1 mL is injected on either side of the fissure (Fig. 2).

Effects of Botox are not compromised with patient noncompliance, and results are longer-lasting than topical relaxants. However, the long-term durability of cure is not as clear, and recurrence has been reported to be as high as 40% at 4 years. Nevertheless, there are decreased rates of permanent incontinence compared with surgical sphincterotomy. In a Cochrane review of nonsurgical therapy for anal fissure including 23 studies and 1236 patients, topical nitroglycerin was found to be better than placebo in healing fissures (49% vs. 36%, $P < 0.0009$), though nearly 50% of those initially cured had a recurrence. Botox and calcium channel blockers were equally efficacious to nitroglycerin and benefited from fewer adverse events. Overall, no medical therapy approached the superior efficacy of surgical sphincterotomy.

OPERATIVE MANAGEMENT

Manual dilation of the sphincter muscle using fingers, various retractors, and pneumatic balloons has been abandoned secondary to poor outcomes including incontinence, recurrence, trauma, and patient discomfort. Fissurectomy has been proposed to address the chronic anatomic changes that may prevent a fissure from healing. Minimal debridement or "trimming" eliminates the fibrosis, sentinel pile, and rolled edges back to healthy tissue that may encourage a fissure to heal. It has limited success when used alone but may be performed in conjunction with chemical denervation, sphincterotomy, or advancement flaps.

Lateral Internal Sphincterotomy

LIS is the gold standard surgical treatment for chronic fissures, offering the highest rates of healing (up to 95%) and low recurrence with durable results. It can be performed as an open or closed approach, with equivalent rates of healing and recurrence. In a Cochrane review of 2056 patients in 27 studies analyzing 13 different procedures, there was no difference between open versus closed LIS in fissure persistence and incontinence risk.

In the open approach, a small radial incision is made over the intersphincteric groove. The internal sphincter muscle is dissected out and exposed before dividing under direct visualization (Fig. 3). The overlying incision can then be closed with an absorbable suture.

Our group favors the closed approach. In the closed approach, a blade is inserted in the intersphincteric groove parallel to the muscle fibers. The blade is then turned 90 degrees, and the IAS muscle fibers are divided against a finger inserted into the anal canal, without going through the mucosa. Manual spreading of the divide fibers in a gentle sweeping motion in the anal canal can confirm adequate division and separation (Fig. 4). The cut typically includes all fibers below the dentate line.

The overall rate of transient disturbed continence from a systematic review was 14% among over 4500 patients, with <1% reporting accidental defecation or stool seepage. Although there are some studies reporting higher rates of permanent incontinence following the open technique, results are inconsistent, and both open and closed sphincterotomies are well-accepted approaches.

To reduce the risk of incontinence, a tailored sphincterotomy has been proposed by dividing the IAS to the height/internal apex of the fissure, rather than the dentate line, which may result in excessive division. This approach should be considered in populations at higher risk for postoperative incontinence, including women who may have shorter anal canals and less muscle, multiple vaginal deliveries, or prior obstetric injuries; individuals with other sphincter or perineal injuries; and individuals with inflammatory bowel disease.

Advancement Flaps

Patients with persistent or recurrent fissures after LIS are challenging to manage. Repeat LIS is not recommended given the high risk of permanent incontinence, especially in patients without increased sphincter tone. These patients without evidence of increased sphincter tone may benefit from a fissurectomy combined with a dermal advancement flap. Two common advancement flap techniques are the *V-Y flap* and *house flap.* A V-Y flap is created from the perianal skin, where the apex of the *V* is pulled proximally and sutured to the proximal apex of the fissure (Fig. 5). In a house flap, the base of the

pentagon-shaped flap is sutured to the proximal apex of the fissure, while the external "house roof" is closed linearly (Fig. 6).

SPECIAL CONSIDERATIONS

LIS for patients with preexisting fecal incontinence or risk factors should be offered cautiously so as not to worsen or permanently induce incontinence. These would include women with obstetric trauma or previous sphincter injuries.

When fissures are off midline, underlying disorders should be considered such as Crohn's disease, human immunodeficiency virus (HIV), tuberculosis, anal cancer, sexually transmitted infections, or other immunosuppressive or infectious etiologies such as human papilloma virus (HPV) and syphilis. In such cases, biopsies and cultures are helpful for diagnosis. Patients who are immunocompromised secondary to chemotherapy will often present with diarrhea; nonoperative management and chemical denervation with Botox is recommended.

Perianal morbidity is a common phenotype of Crohn's disease, and Crohn's-related fissures generally should not be treated with sphincterotomy. Medical management directed at the patient's Crohn's disease will heal the majority of anal fissures. Patients who are constipated should be treated with fiber supplementation and increased hydration. Topical diltiazem and Botox denervation are recommended for nonoperative management, with early involvement of gastroenterology.

Management of Anorectal Abscess and Fistula

Amy J. Thorsen, MD

Approximately 100,000 patients in the United States will seek care for anorectal sepsis each year. The mean age of presentation is 40 years (range 20–60 years). Adult males are twice as likely to develop an anorectal abscess and/or fistula compared with females. Anorectal abscesses and fistulas can be thought of as two successive phases of the same infectious process, with an abscess representing the acute phase of infection and a fistula denoting the chronic phase of suppuration and fistulization. Thus it is not surprising that 30% to 70% of anorectal abscesses are associated with a concomitant anorectal fistula, and that 30% to 40% of patients develop an anorectal fistula after undergoing treatment for an anorectal abscess.

Management of anal abscess and fistula includes four basic principles: (1) control the septic process (drain the pus), (2) define the involved anatomy, (3) treat the underlying process without

compromising sphincter function, and (4) minimize recurrence risk. Although many presentations are straightforward, complex and recurrent disease challenge even the most experienced surgeon. It is crucial for surgeons managing this disease to understand the regional anatomy, treat patients in the context of their comorbid conditions (such as Crohn's disease), and apply the appropriate surgical technique. Improper management can lead to potentially life-threatening sepsis or significantly impact a patient's quality of life by causing chronic discomfort and socially-inhibiting problems with personal hygiene.

ANORECTAL ABSCESS

Etiology and Classification

The anal glands lie within the intersphincteric space and empty into the rectum through 10 to 15 crypts of Morgagni located circumferentially at the dentate line. When this drainage is blocked, pressure builds as the septic source grows and propagates along paths of least resistance within or through the intersphincteric space. The potential pathways of suppurative extension delineate the anatomic spaces of anorectal sepsis: intersphincteric, submucosal, perianal, ischiorectal, postanal (subdivided into superficial and deep by the anococcygeal ligament), and supralevator space (Fig. 1).

The intersphincteric abscess, located at the site of the anal glands, tracks craniocaudally between the sphincter layers. A submucosal abscess represents the least extensive suppurative process, located just beneath the mucosa above the dentate line. Perianal abscesses descend through the intersphincteric space to the subcutaneous tissue around the anus and below the sphincter complex. The ischiorectal space encircles the external sphincter caudad to the levator ani

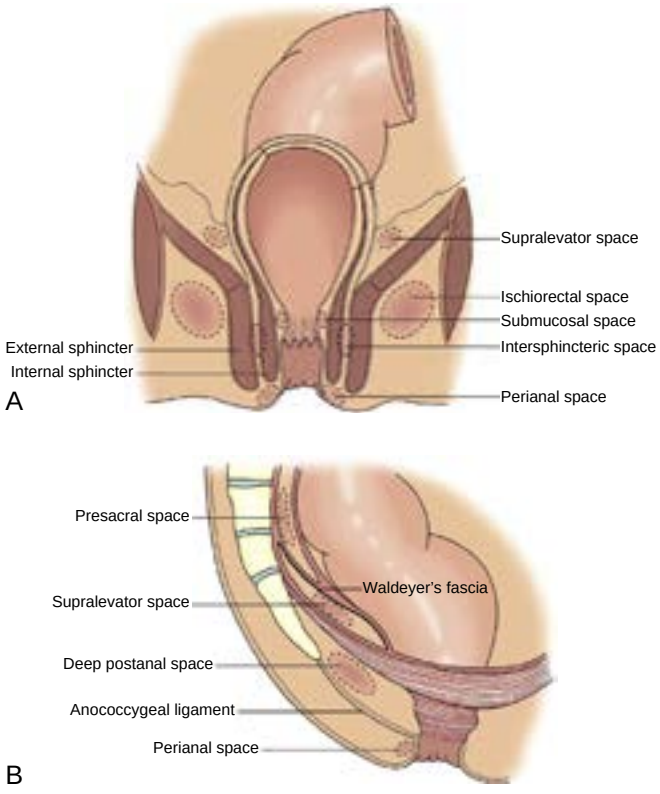

FIG. 1 Anal sepsis and fistula. Classification of anorectal abscesses by location. **(A)** Coronal view. **(B)** Sagittal view. *(From Yeo CJ, et al.* Shackelford's Surgery of the Alimentary Tract. *ed 7. Philadelphia: Saunders; 2007.)*

BOX 1 Causes of Anorectal Abscess

Cryptoglandular
Iatrogenic (anorectal or genitourinary surgery)
Perineal trauma
Radiation injury
Inflammatory bowel disease
Acquired immunodeficiency syndrome
Invasive fungal infection
Hidradenitis suppurativa
Diverticulitis
Anal fissure
Osteomyelitis
Foreign body
Malignancy (carcinoma, adenocarcinoma, hematologic malignancy)

Data from Becks DE, et al, eds. *The ASCRS Textbook of Colon and Rectal Surgery.* 2nd ed. New York: Springer-Verlag; 2011.

complex and medial to the ischial tuberosities; an ischiorectal abscess occurs from the extension of sepsis laterally from the intersphincteric space or caudally from the supralevator space. The postanal space is located posteriorly, between the levators (cranially) and the external sphincter (caudally); this space may be solely involved, or infection may extend laterally to the ischiorectal fossa, forming the so-called *horseshoe abscess.* The postanal space is divided into the superficial and deep postanal spaces by the presence of the anococcygeal ligament. Deep postanal space infections may be missed if this ligament is not penetrated during operative drainage. Supralevator abscesses, located above the levators as the name implies, are caused by cranial extension of cryptoglandular sepsis or by caudal extension of an intraabdominal process, such as diverticular disease, that perforates through the peritoneum.

Understanding the anatomic spaces of anorectal sepsis is imperative in deciphering the patient's presentation and planning the appropriate intervention that attains adequate drainage and reduces complications such as systemic sepsis, recurrence, fecal incontinence, and complex fistula formation. Although the cryptoglandular theory is believed to be responsible for the vast majority of anorectal abscesses, it is crucial to identify contributing conditions or alternate causes such as those displayed in Box 1. The impact of these factors and etiologies on the nature of the disease and treatment strategy will be discussed later in the chapter.

Presentation and Diagnosis

Anal pain independent of defecation is the most common complaint, given almost one-half of anorectal abscesses are in the perianal space. Swelling and fever are often present. Associated symptoms or medical history suggestive of or including inflammatory bowel disease and immunocompromised status should also be gathered. On anorectal examination, an indurated bulge with fluctuance and cellulitis near the anal verge is indicative of perianal abscess. Intersphincteric abscesses are unique in their lack of external examination findings but cause exquisite tenderness on digital rectal examination. Ischiorectal abscesses typically have gluteal findings of induration, tenderness, and fluctuance several centimeters away from the anal verge without tenderness on digital rectal examination. Abscesses limited to the postanal space may have localized tenderness posterior to the anal verge, but without apparent induration or fluctuance. Induration or fluctuance between the posterior anorectum and coccyx will be noted on bimanual examination. Supralevator abscesses may have no anorectal findings unless there is a downward extension of sepsis into the ischiorectal fossa; fluctuance above the levators may be noted on digital rectal examination. Further evaluation with

pelvic imaging should be considered to exclude their presence if a supralevator component is suspected. Anoscopy, rigid proctoscopy, and flexible sigmoidoscopy can be performed to evaluate the rectal mucosa for inflammatory bowel disease, but it is often not tolerated and should not be pressed. Patients who cannot tolerate an examination should undergo an examination under anesthesia (EUA).

The majority of patients with a suggestive history and physical examination can be managed with bedside drainage or operative evaluation and treatment. Radiologic imaging, however, is useful in some acute situations and helpful with more chronic or recurrent anorectal sepsis. CT is helpful in patients with associated abdominal symptoms or findings or with the clinical suspicion of a supralevator abscess. A pelvic CT scan should not be relied upon to exclude drainable anorectal infection; purulence can be present without definitive CT findings. Undrained anorectal infection can lead to severe systemic infection and destruction of the anal sphincter complex, resulting in functional morbidity. Endoanal ultrasound and MRI are not generally available or tolerated in the acute setting of anorectal abscess. Both, however, can be useful adjuncts in delineating the anatomy of complex, multiple, or recurrent fistula-in-ano.

Operative Evaluation and Drainage

Surgical drainage remains the definitive treatment of anorectal abscesses. Bedside drainage under local anesthesia using 1% lidocaine with dilute epinephrine is often well tolerated for perianal abscesses and small ischiorectal abscesses. After infiltrating the area with local anesthetic, a curved incision is made over the abscess. The incision should be oriented over the side of the abscess closest to the anal verge without transgression into the sphincter complex; this is done so if a fistula forms (an estimated 50% occurrence), it is more likely to have a simple, short tract. The temptation to drain an abscess over its most fluctuant point or at the furthest point from the verge should be avoided to prevent potential creation of a long fistula tract. A hemostat or finger is used to probe the wound, breaking down all loculations and defining the extent of disease. An ellipse of skin at least 1 cm in size incorporating the initial incision is excised to prevent premature closure of the skin. Hemostasis can be achieved with direct pressure, silver nitrate, or local anesthesia with epinephrine. The cavity is irrigated, and dry gauze is applied externally with the expectation of ongoing drainage. Packing the wound should be avoided because it subjects the patient to more pain and slower healing without the benefit of improved resolution of sepsis.

Large ischiorectal abscesses and those that must be approached transanally (intersphincteric, some supralevator, horseshoe, and deep postanal space infections) are most appropriately done in the operating room under monitored anesthesia care (MAC) or general anesthesia. A preoperative antibiotic with gram-negative coverage is administered. The anorectal region is best exposed with the patient in the prone jack-knife position and the buttocks taped widely apart, but the high lithotomy position is often adequate. A headlamp to improve visualization is recommended. Commonly used instruments include the Hill-Ferguson, Fansler, or Pratt bivalve retractors, fistula probes, curettes, 16- or 18-gauge angiocaths, and dilute hydrogen peroxide. The perianal region is inspected, noting any induration, fluctuance, or dermatologic abnormalities. A digital rectal examination is performed followed by anoscopy, looking for mucosal bulging, induration, sphincter defects, or other abnormalities. A biopsy should be performed on ulcerations, suspicious nodules, or perianal lesions to exclude neoplasia. A biopsy should be performed on recurrent abscess or fistula tracts as well in an effort to diagnose underlying inflammatory bowel disease, chronic infections (such as tuberculosis or actinomyces), or the rare malignancy. If the site of purulence is not obvious, an 18-gauge needle can be used to aspirate in suspected areas. Culture data is rarely helpful, but it may be so in patients with recurrent infections, nonhealing wounds, a history of methicillin-resistant *Staphylococcus aureus,* or underlying HIV infection in whom atypical microbes may be present.

For a large ischiorectal abscess, ipsilateral counterincisions can serve to establish adequate drainage rather than a large incision that resects overlying healthy tissue and prolongs healing unnecessarily. Digital exploration of the abscess cavity is prudent to ensure that extension into the postanal space or the contralateral fossa is not present. Packing is usually unnecessary and impractical for the patient to exchange. An alternate means of drainage utilizes a stab incision overlying the abscess, as close to the anal verge as possible, and the insertion of a 10- to 16-French mushroom catheter into the cavity. The catheter is secured with an anchoring suture and left in place for 1 week. The catheter is removed once a tract is well established, although it can be left in for prolonged periods in cases of large or recurrent infections.

Drainage of a postanal space abscess deserves special note. A radial incision is made from the posterior anal verge toward the coccyx. Subcutaneous tissue is divided, and the underlying fibers of the external sphincter are spread with a hemostat clamp. The anococcygeal ligament is then divided to access the postanal space. This fibrous ligament may take a bit of force to separate. A digit is inserted to explore the extent of suppuration. If a horseshoe abscess is present, elliptical counterincisions over the involved ischiorectal fossa are created. Penrose drains can be looped between incisions to maintain patency. If an underlying fistula is noted, a noncutting seton is placed to prevent recurrent sepsis (Fig. 2). A second staged procedure to later address the fistula can be planned.

Intersphincteric abscesses are addressed transanally. The mucosa overlying the bulging/fluctuant anal canal is vertically divided with cautery. This exposes the underlying internal sphincter muscle with its circumferential transversely oriented muscle fibers. A fine-tipped hemostat is passed through the internal sphincter into the suppurative intersphincteric space and directed cephalad. The internal sphincter is divided over the hemostat with electrocautery. This generally does not compromise fecal continence, but patients should be informed of that small risk as part of informed consent. An alternative but less common method involves a stab incision at the anal verge in the intersphincteric groove and insertion of a small mushroom catheter into the affected intersphincteric space. The catheter is removed or backed out after sepsis has resolved.

The source of the supralevator abscess determines its treatment, which is why preoperative imaging can be helpful when a supralevator component is suspected. Descending abdominal or pelvic sources are typically addressed with CT-guided percutaneous drainage; more complex or severe intraabdominal disease may warrant transabdominal surgery or fecal diversion. Ascending cryptoglandular sepsis travels either through the intersphincteric space or through the levators from the ischiorectal fossa. The intersphincteric source is treated with transanal or transrectal drainage; incorrect surgical drainage through the ischiorectal fossa creates a suprasphincteric fistula. Conversely, the supralevator abscess with an ischiorectal source should be drained via skin incision to drain the ischiorectal fossa; transrectal drainage would be inappropriate and create an extrasphincteric fistula. A Malecot catheter may aid drainage of a supralevator abscess when accessed through the ischiorectal fossa (Fig. 3).

Primary Fistulotomy

Fistulotomy at the time of incision and drainage of the anorectal abscess was once a contentious issue. Proponents argued that the presence of sepsis aided in defining the fistula tract; laying open the tract would reduce recurrence. Edema and inflammation from the suppurative process, however, may increase the risk of creating a false tract when probing and can make it difficult to accurately assess the degree of sphincter involvement. A general consensus has been reached, however, that primary or "prophylactic" fistulotomy submits a majority of patients who would never have recurred or developed a fistula to sphincterotomy and its attendant risks of fecal incontinence. Primary fistulotomy should only be selectively performed in the most straightforward of superficial or low

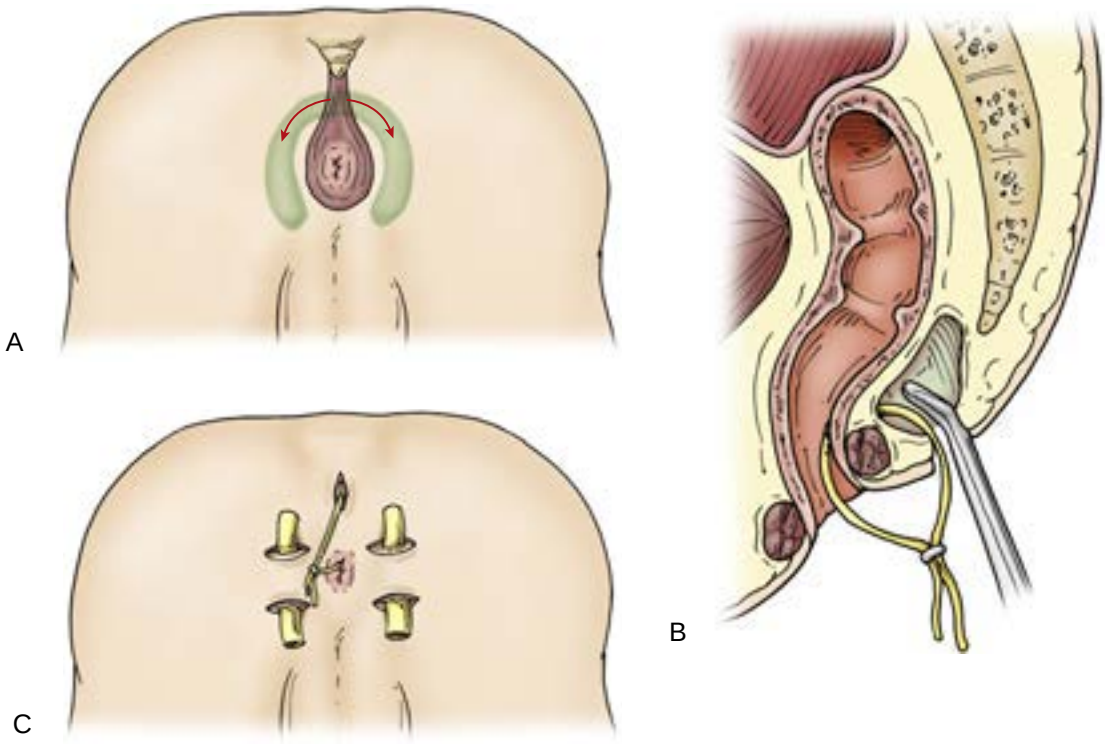

FIG. 2 **(A)** Horseshoe abscess shows that the deep postanal space is a window to the ischiorectal fossa bilaterally *(arrows)*. **(B)** The deep postanal space is drained through a radial incision in the posterior midline. A clamp is placed in the postanal space to ensure adequate drainage. If an internal opening is identified, a seton is placed through the fistula tract, encircling the posterior sphincter. **(C)** Counterincisions drain the ischiorectal fossa. Placement of Penrose drains through the tracts ensures adequate drainage of the abscess cavities without significant soft-tissue loss. *(Courtesy Gaio Lakin, PhD.)*

transsphincteric fistulas, and provided that the anticipated benefit of healing outweighs the potential risk of fecal incontinence. Care must be taken to avoid creating false passages in the inflamed field while searching for the internal opening. Once the tract is cannulated with a fistula probe, the overlying tissue is divided and the wound is left open to drain. Primary fistulotomy is contraindicated in the elderly and in women with anterior fistulas, as well as in patients with compromised fecal continence, Crohn's disease, AIDS, and high transsphincteric fistulas.

If a fistula is easily identified at the time of abscess drainage, an alternative treatment option is partial fistulotomy and seton placement. Although this commits the patient to a second-stage procedure, draining seton placement should prevent recurrent anorectal sepsis and, once healed, allow the surgeon to assess the patient's anorectal function and tolerance of a second-stage fistulotomy or plan for a different fistula repair.

Antibiotics and the Immunocompromised Patient

Most patients do not require antibiotic therapy after surgical drainage; antibiotics in general do not improve healing, reduce recurrence, or definitively decrease fistula formation after appropriate surgical drainage. In certain populations, however, antibiotics are warranted. Patients with large areas of cellulitis, signs of systemic sepsis or shock, prosthetic heart valves, or various conditions of immunocompromise warrant prolonged oral or parenteral antibiotics. Immunocompromised patient groups include those with diabetes mellitus, chronic corticosteroid use, acquired immunodeficiency syndrome, bone marrow transplant recipients, and active chemotherapy.

In contrast with all other patients with anorectal infection, profoundly neutropenic patients are often not addressed with surgery. The degree and duration of neutropenia is directly related to the incidence and prognosis of anorectal infections. In general, patient with absolute neutrophil counts (ANC) below 500 per cubic millimeter often do not mount sufficient immune response to develop suppuration. Therefore, patients with a low ANC and without fluctuance do not have a target for surgical drainage; prolonged, broad-spectrum antibiotics are recommended. Efforts to correct the neutropenia by holding chemotherapy and by administering neutrophil growth factors are employed. This vulnerable patient population must be monitored closely, given that a suppurative process may develop as the neutrophil count increases; imaging or EUA with aspiration may be useful adjuncts to identify a drainable source. Progressive sepsis, obvious fluctuance, or expanding soft tissue infection are indications for surgical evaluation, drainage, or debridement.

Necrotizing Perianal Skin Infection

Necrotizing perianal skin infections are destructive, life-threatening infections that must be quickly differentiated from the more common anorectal abscess and infection on initial presentation because immediate surgical debridement offers the only chance at survival. Rapid development of severe anorectal pain that is out of proportion to findings on examination is the classic harbinger of a necrotizing infection. Risk factors include diabetes, chronic renal disease, obesity, smoking, underlying neurologic disease (such as dementia or spinal cord injury) that prevents early detection or communication of symptoms, and previous anorectal infections. Tender, irregular red, violaceous, or black macules and blisters in the perianal region are early signs of this dangerous process. These infections may be associated with crepitus, induration, or gangrene. Septic shock and electrolyte disturbances may develop. Anorectal sepsis with severe systemic manifestations should be quickly recognized and evaluated in the operating room; radical debridement of all nonviable tissue is

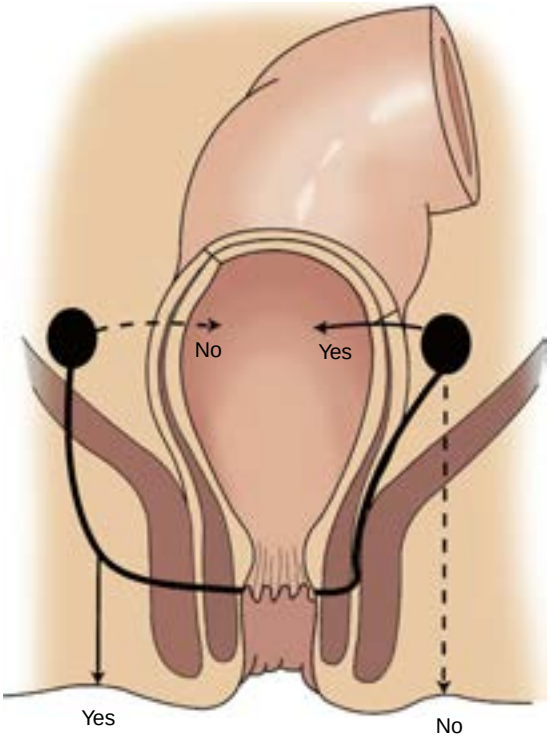

FIG. 3 Drainage of a supralevator abscess *(black ovals).* On the right, the supralevator abscess is associated with a transsphincteric fistula and passage through the ischiorectal fossa; often there are associated findings of an ischiorectal abscess. This abscess is drained via the skin and ischiorectal fossa; transrectal drainage would be inappropriate because it would result in an extrasphincteric fistula. On the left, the supralevator abscess is associated with an intersphincteric fistula and should be drained transrectally; drainage across the ischiorectal fossa would create a suprasphincteric fistula. Supralevator abscesses also may be addressed via computed tomography–guided percutaneous drainage (alone or in combination with transrectal/transgluteal approaches), particularly when they are caused by downward extension of an intraabdominal process such as diverticulitis. *(From Yeo CJ, et al.* Shackelford's Surgery of the Alimentary Tract. *ed 7. Philadelphia: Saunders; 2007.)*

necessary. Patients will require supportive management in the intensive care setting and empiric coverage with broad-spectrum antibiotics. Transfer to a tertiary center with hyperbaric oxygen capability should be considered if infection persists after initial debridement. By limiting the growth of anaerobic and other forms of bacteria and by boosting the effects of antibiotics and the immune system, hyperbaric oxygen is emerging as a powerful adjunct in treating this disease process and promoting healing. The need for fecal diversion is debatable and should only be considered in the subacute setting after hemodynamic stability is well established.

FISTULA-IN-ANO

Etiology and Classification

The cryptoglandular theory suggests that the acute suppurative process of anorectal sepsis originates at one of 8 to 10 anal glands located at the dentate line. These glands originate in the intersphincteric space and penetrate the internal sphincter with their ducts. They can become blocked and allow bacteria to cause infections which propagate along the path of least resistance until the growing pressure is released by surgical or spontaneous drainage. A fistula is the chronic sequelae of this process if the tract fails to heal and epithelializes. Although the cryptoglandular process is responsible for the vast majority of fistulas, other etiologies can instigate chronic inflammation and epithelialization along an abnormal communication between the skin and anorectum (see Box 1).

Although a perianal abscess is described by the anatomic space in which it forms, an anal fistula is most commonly classified in terms of its relationship to the internal and external anal sphincters. In 1976, Park et al. published the classification system that is used currently. Figure 4 depicts the four classes of fistulas. Each of these fistula classes can be further complicated by the presence of circular and/or high blind tracts that branch off the fistula tract into the intersphincteric space or ischiorectal fossa, but do not drain independently. Another type of fistula not included in the anorectal classification scheme is the superficial fistula, which is essentially a skin bridge with an underlying subcutaneous tract that does not involve the sphincter complex; this can be a result of scarring after recurrent infections and surgery, premature healing of an anal fissure, or another process, such as hidradenitis.

Fistulas can be further categorized as "simple" or "complex" fistulas. A complex fistula has features that increase the risk of recurrence and/or incontinence after intervention, either by its own anatomy or by patient factors. Table 1 defines features of complex fistulas, which includes most fistula classes except subcutaneous, intersphincteric, or low transsphincteric fistulas.

Presentation and Diagnosis

Patients will frequently, although not always, have a history of a previous perianal abscess that spontaneously drained or required surgical intervention; patients may experience initial healing and have a recurrent abscess or other symptoms weeks, months, or even years after the index infection. Some patients will experience continual drainage and intermittent swelling months after recovering from an acute abscess, indicating a persistent tract from the internal opening to an either open or closed external opening.

Patients describe intermittent anal pain, pruritis, drainage that is mucoid, bloody, or feculent, or occasionally blood per rectum caused by friable granulation tissue at the internal opening. Cyclic discomfort and swelling that is relieved after spontaneous drainage is a common feature. Patients should be queried regarding gastrointestinal symptoms suggestive of inflammatory bowel disease and their current level of fecal continence. A history of anal surgery, anal infections, radiation, trauma, obstetric trauma, and systemic disease including inflammatory bowel disease, hematologic malignancy, or immunosuppression should be elicited, given these factors may affect continence and healing with many types of surgical interventions. On examination, the external opening is easily identifiable as an inflamed pyogenic granuloma; a palpable cord may be present and suggest the path of the tract. When less active, the external opening may be more subtle and appear more like a subtle dimple or scar. The internal opening can occasionally be palpated on digital rectal examination as a nodule or pit and is usually at the dentate line. Anoscopy, when tolerated, can assist in visualizing the internal opening as well as assess whether a distal proctitis is present. Further endoscopy can be considered in a patient with symptoms suggestive of inflammatory bowel disease.

Routine diagnostic imaging is typically unnecessary for patients with anal fistula, however imaging may be helpful in patients with a suspected occult anorectal abscess, recurrent or complex fistula, an unrevealing EUA, or suspected or confirmed anal Crohn's disease. Preoperative endoanal ultrasound (EAUS) may help preserve anorectal function by measuring sphincter involvement; EAUS can successfully predict the amount of sphincter that would be divided if primary fistulotomy is performed as well as identify undrained sepsis, complex anatomy, and high blind tracts (Fig. 5). MRI appears to have higher sensitivity in evaluating secondary extensions, suprasphincteric tracts, and extrasphincteric tracts in complex fistulas when compared to EAUS and has been shown to alter surgical

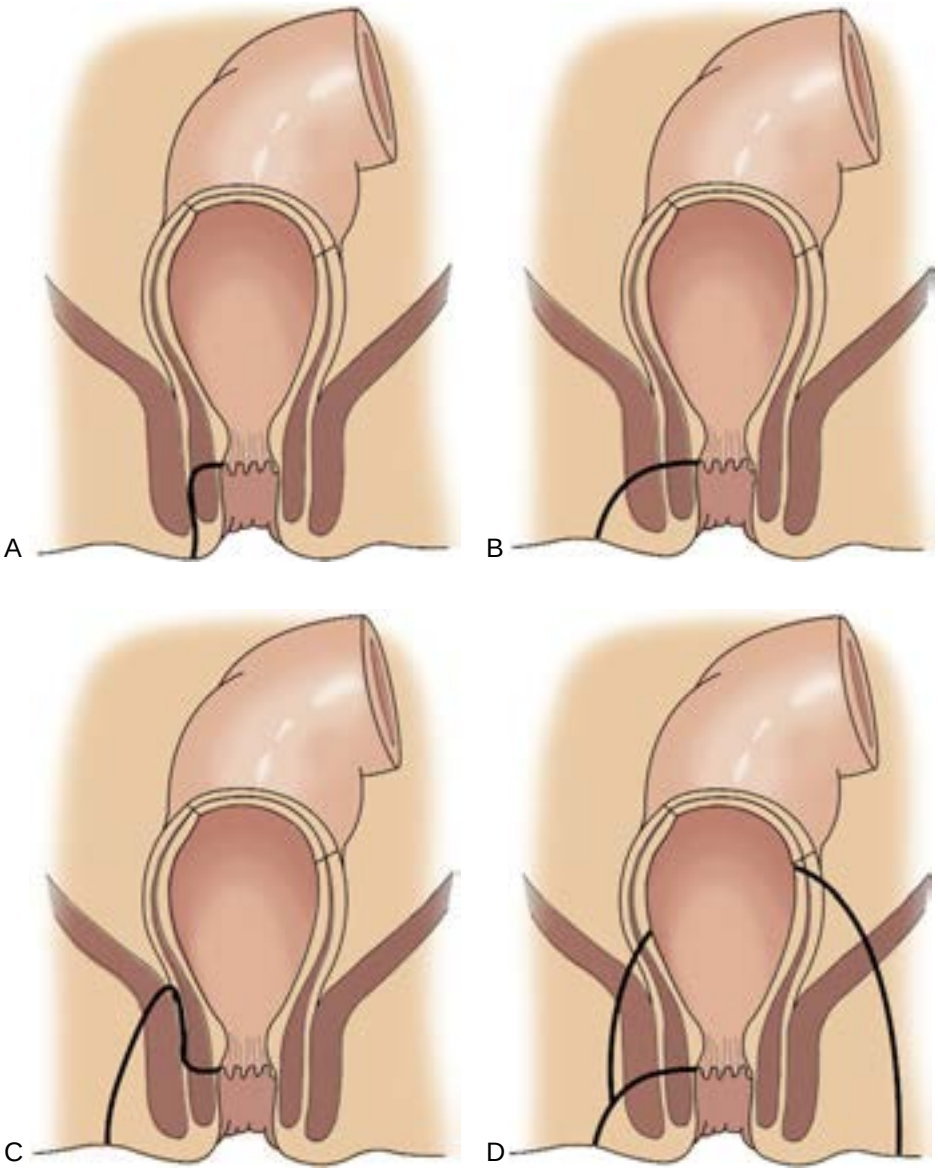

FIG. 4 Classification of anal fistulas. **(A)** Intersphincteric: the tract remains in the intersphincteric plane. **(B)** Transsphincteric: the fistula tract passes from the intersphincteric plane through the external sphincter muscle. *1*, uncomplicated. **(C)** Suprasphincteric: there is an upward extension of the fistula tract in the intersphincteric plane. The tract then passes above the level of the puborectalis muscle and continues downward through the ischiorectal fossa to the perianal area. **(D)** Extrasphincteric: there is a tract that passes from the skin of the perineum through the ischiorectal fossa and the levator muscles before entering the rectal wall. This fistula may be a consequence of an extension of a transsphincteric fistula or secondary to trauma, anorectal disease, or pelvic inflammation. *(Modified from Yeo CJ, et al.* Shackelford's Surgery of the Alimentary Tract. *ed 7. Philadelphia: Saunders; 2007.)*

TABLE 1 Features of Complex Fistulas

Anatomy	Comorbid Conditions
Multiple fistulas	Compromised fecal continence
Suprasphincteric fistulas	Inflammatory bowel disease
Extrasphincteric fistulas	Refractory diarrhea
Associated high blind tract(s)	Anterior fistulas in women
High transsphincteric fistulas (>30% of anal sphincter length)	Immunodeficiency or compromised wound healing
	History of regional radiation
	History of obstetric trauma
	Elderly patients
	Prior anorectal surgery

approach and decrease recurrence rates. Transperineal ultrasound may be a lower-cost, less-invasive imaging option with similar diagnostic accuracy compared to EAUS and MRI, although it is less widely available. CT lacks adequate resolution to identify tracts and their relationship to the sphincters and levators with comparable accuracy. When imaging is indicated, the best option may be based on local radiologic expertise.

Surgical Treatment

There are four tenets of fistula surgery: (1) define the fistula anatomy, (2) ensure the resolution of sepsis, (3) assess and preserve anal sphincter function, and (4) minimize recurrence risk. Maintaining these principles are critical at each step of treatment.

Define Fistula Anatomy

The anatomy of a fistula includes the internal and external openings, the course of the intervening tract(s), and the presence of any blind tracts or sinuses. The internal opening is described by its location

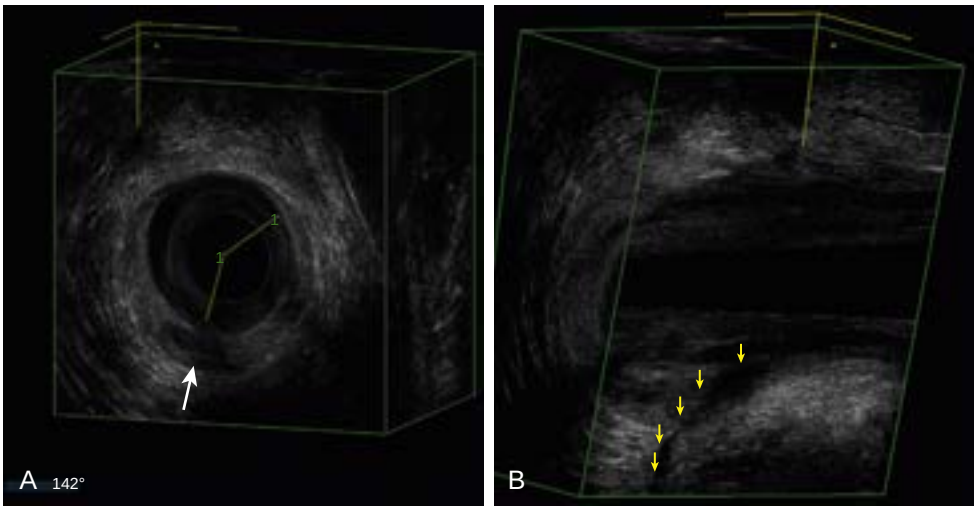

FIG. 5 Ultrasound scan of right posterior transsphincteric fistula. (A) Coronal view revealing a 142-degree internal sphincter defect on the left side from a previous hemorrhoidectomy. The hypoechoic internal opening of a right transsphincteric fistula is noted by the *arrow*. Given the edge of the internal sphincter defect abuts the fistula tract, ligation of the intersphincteric fistula tract procedure may not be feasible. **(B)** Angled sagittal view showing the hypoechoic transsphincteric fistula. Note the internal opening *(arrows)* nears half the length of the hyperechoic external sphincter; therefore, a fistulotomy would not be appropriate. *(Courtesy Amy Thorsen, MD.)*

and relationship to the dentate line, whereas tracts are delineated by their relationship with the sphincter complex and levators. Fistula anatomy can be estimated by office examination but is most definitively assessed in the operating room with an EUA. The patient may usually be consented for a definitive procedure, with the caveat that if a more complex fistula or unexpected findings are discovered during operative evaluation, a staged procedure may be required to preserve sphincter function and ensure successful surgical treatment. The patient is placed in the prone jack-knife position with the buttocks taped widely apart; some surgeons prefer high lithotomy or left lateral positioning. The perianal region is inspected, identifying evident external openings, suspicious lesions, or scars, which can be probed. Goodsall's rule predicts that an external opening posterior to a transverse line across the anus drains to a posterior midline internal opening, while those that open anterior to the line have short, radial courses to the internal opening. Although Goodsall's rule is accurate for a majority of the posterior external openings, it has been shown to be less accurate in women with anterior openings.

Digital rectal examination is performed to assess for undrained sepsis and location of the internal opening. Anoscopy is used to identify the internal opening and to note any signs of proctitis or malignancy. A fistula probe is inserted into the external opening and gently advanced toward the anticipated internal opening with subtle redirection as resistance dictates. The fistula tract should easily accept the probe without the sensation of tissue destruction; a false tract must not be created as it will only serve to complicate the disease and neglect the primary tract. The internal opening may also be identified by injecting dilute hydrogen peroxide into the external opening with an angiocatheter. If the internal opening is not easily identified, the surgeon should not persist to find or create one. Once the internal and external openings are identified, the tract can be cannulated with the fistula probe; if the tract is not cannulated fully, the tract may be curved. Curving the fistula probe or straightening the tract with a Kocher clamp may facilitate cannulation. Once cannulated, the type of fistula is established by determining its relationship to the internal and external sphincter complex, the levators, and presence of multiple fistulas or blind tracts. The percentage of sphincter complex caudal to the tract is determined by palpating the apex of the sphincter complex in relationship to the probe. Low transsphincteric fistulas are defined as those that involve less than 30% of the external sphincter complex.

If the tract cannot be fully cannulated, the external opening is enlarged toward the anal verge, a curette is used to debride the tract, and the operation is terminated. This approach may be associated with a higher risk of recurrence but avoids creating an iatrogenic false internal opening at a false location. Adjunctive imaging with ultrasound or MRI to better identify fistula anatomy is performed after 3 to 6 weeks to allow for inflammation related to surgery to subside.

Ensure the Resolution of Sepsis

For many patients with complex fistulas or an obvious fistula at the time of operative treatment of anorectal sepsis, a conservative, staged approach with the initial placement of a seton is most appropriate. This allows the possibility of multiple options to treat the fistula in the future without compromising sphincter integrity.

For a patient treated initially with a seton, a second-stage procedure can be considered when the internal opening is less than 5 mm and the tract is simple, narrow, and without an associated cavity. Ongoing sepsis, as evidenced by pus, cellulitis, induration, or a persistent cavity, prevents healing and closure of the tract; any efforts to close the fistula definitively will likely fail. In the setting of persistent infection, a fistulotomy can be performed only in a simple intersphincteric or low transsphincteric fistula to simultaneously address the sepsis and the fistula. Complex fistulas with persistent sepsis should be considered to have an undrained source of infection. They can be addressed with debridement of the tract around the seton, widening of the external opening, and a search for a high blind or circular tract. If additional treatable sources of the persistent sepsis cannot be identified or sepsis continues despite these approaches, imaging is pursued.

Assess and Preserve Anal Sphincter Function

Although a controlled anal fistula with or without a seton can cause significant discomfort and problems with personal hygiene, fecal incontinence is far more disruptive to a patient's quality of life. For that reason, preservation of continence is always a priority when choosing the proper management strategy. Division of the internal

TABLE 2 Management Strategy by Fistula Classification

Type of Fistula	Fistulotomy	Seton*	LIFT	Advancement Flap	Fibrin Glue	Collagen Plug	Address Intraabdominal or Pelvic Source

Extrasphincteric						X	X

LIFT, Ligation of intersphincteric fistula tract.
*Seton placement can be a first stage or definitive treatment option.

sphincter is usually well tolerated without much effect on continence, especially in men. Division of the distal third of the external sphincter is considered "safe" in healthy male individuals; this can be considered in the posterior external sphincter in women without preexisting sphincter dysfunction. The degree of sphincterotomy tolerated without affecting continence is undoubtedly patient-dependent. Careful analysis of a patient's risk for incontinence includes an assessment of their current degree of continence, prior anorectal surgery, trauma, and obstetric history as well as associated conditions that may cause diarrhea or inhibit healing. Women in particular are vulnerable to incontinence as a result of a shorter sphincter complex, anatomic and neurologic injury to the pelvic floor sustained during childbirth, and loss of elasticity and muscle attenuation associated with aging and menopause. Patients with active inflammatory bowel disease involving the anorectum and immunodeficiencies often heal poorly and suffer recurrent or metachronous fistula disease. Sphincter-preserving techniques are preferred in these patient populations. Table 2 provides a guide to choosing the proper surgical technique, although it does not take into account relevant patient factors.

Minimize Recurrence Risk

Complex fistulas are a frustrating disease process because they are prone to recurrence despite meticulous surgical technique. Although primary fistulotomy has the lowest recurrence risk, it also is associated with the highest risk of incontinence because of inherent disruption in the sphincter complex. All other sphincter surgical procedures, although they preserve the muscular anatomy, are associated with much higher recurrence risk. This must be considered in an informed consent discussion with patients. Reported outcomes in many of these described procedures vary widely; a surgeon's personal experience with a procedure may be the most important factor in reducing recurrence.

Fistulotomy

Fistulotomy can be done at the time of abscess presentation, at the time of initial fistula presentation, or as a second-stage procedure in appropriately selected patients. Regardless of timing, a fistulotomy is only appropriate in low-risk patients with a superficial, intersphincteric, or low transsphincteric fistula. Once the anatomy of the fistula is determined, the tract is cannulated and the tissue overlying the probe is divided with electrocautery. The tract is debrided with a curette to remove debris and granulation tissue. The deepithelialized wound, now effectively a ditch instead of a tunnel, is allowed to heal by secondary intention.

For larger wounds, wound healing can be accelerated and bleeding avoided by marsupialization of the wound; this is performed by sewing the wound edges to the base of the wound with a continuous locking absorbable suture. Marsupialization can prevent both the premature epithelization of the wound edges before the deeper base heals and the subsequent formation of a subcutaneous fistula.

Sphincter-sacrificing procedures have the highest success rates, generally over 90%, but are also associated with some degree of fecal incontinence in up to 40% of patients in some series. Hence fistulotomy is usually not appropriate for high or complex fistulas. Factors related to recurrence after fistulotomy include branching of fistulas, failure to accurately identify the internal opening, and fistulas associated with Crohn's disease.

Seton

A noncutting seton allows for ongoing drainage of sepsis and promotes fibrosis and maturation of the fistula tract as well as resolution of any abscess cavity, often in preparation for a second-stage procedure. After the fistula tract has been defined and debrided, the external opening is opened slightly toward the anal verge. Circular, high blind tracts, and long subcutaneous tracts are appropriately laid open or drained and curetted. A thin silastic band, vessel loop, or nonabsorbable suture is threaded through the tract and secured in a loop or omega shape with several interrupted silk sutures. The seton should not be tight; a hemostat should easily fit between the skin and loop without tension. The second-stage procedure, either fistulotomy or a sphincter-preserving operation, is usually performed 6 to 10 weeks later, although a waiting period of 3 to 4 months is advised for more complex fistulas and abscess cavities. Setons used in this fashion for complex fistulas have success rates of 62% to 100%, depending on patient factors and the choice of the secondary procedure. For some Crohn's or other high-risk patients, seton placement can be the definitive operation; it is left in place for prolonged periods (years) to prevent recurrent sepsis without the intention to perform a second-stage procedure due to the likelihood of failure or iatrogenic incontinence.

In rare situations, a seton can be used to perform a slow, controlled fistulotomy in complex fistulas. Historically, a cutting seton was used when the risk of incontinence from a traditional fistulotomy was considered to be too high. The cutting seton is tightened at interval office visits to gradually divide the fistula and involved sphincter muscle. Cutting setons have high success rates in resolving anal fistulas, however some studies report some level of impaired continence in up to 67% of treated patients. Hence cutting setons should be used very selectively.

LIFT

Ligation of the intersphincteric fistula tract (LIFT) is a relatively new sphincter-preserving technique first described in 2007. This procedure is most often performed as a second-stage procedure for a transsphincteric fistula after a mature tract has developed. A draining seton may be used before the LIFT procedure to allow for fibrosis of the tract, but this has not been clearly shown to affect the success rate of the LIFT procedure.

With the patient in the prone jack-knife position with the buttocks taped widely apart, the fistula tract is cannulated with a probe. The external opening is widened to allow for drainage (Fig. 6). A 1- to 2-cm curvilinear incision is made with electrocautery over the palpated intersphincteric groove superficial/distal to the fistula tract. A Lonestar retractor (CooperSurgical) deployed along the anoderm edges provides excellent exposure. The intersphincteric

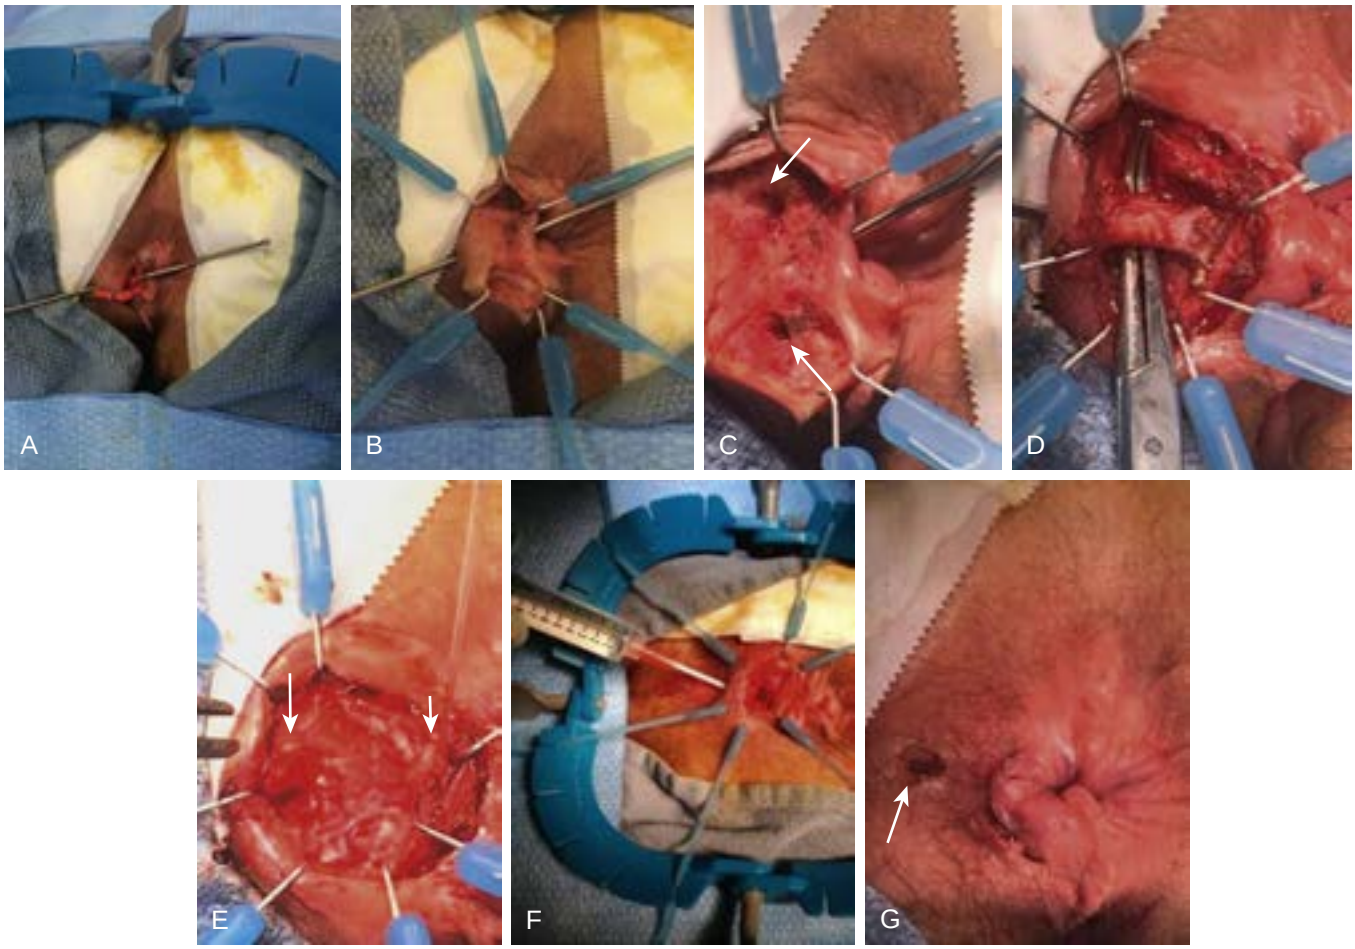

FIG. 6 **(A)** The fistula tract is cannulated. **(B)** A curvilinear incision is made overlying or slightly distal to the intersphincteric groove. A Lone Star retractor (Cooper Surgical) is helpful for exposure. **(C)** The intersphincteric plane is developed on either side of the tract *(arrows)*. **(D)** Dissection continues around the tract until it is isolated. The probe is removed. **(E)** Division and ligation of the fistula tract. The tract is encircled with a Vicryl (Ethicon) tie, and the tract is ligated at the border of the internal anal sphincter *(right arrow)*. If a long tract is present, it can be excised, and the tract near the external anal sphincter is either ligated or imbricated with Vicryl suture *(left arrow)*. **(F)** The repair is tested by injecting hydrogen peroxide into the internal and external openings. The ligated ends can also be probed to ensure closure. If there is a leak, the fistula opening is further imbricated. **(G)** The external opening *(arrow)* is slightly enlarged, and the distal aspect of the tract is debrided with a curette. *(Courtesy Jeffery J. Morken, MD.)*

plane is bluntly developed with a fine-tipped hemostat. The fistula tract is circumferentially isolated with care to avoid disrupting it. The probe is removed, and both distal and proximal ends of the intersphincteric tract are suture-ligated with 3-0 absorbable suture. The tract is sharply divided with a scalpel. The external opening is injected with hydrogen peroxide; if there is a persistent leak, the intersphincteric opening of the external sphincter is oversewn until there is no longer a leak. Some authors test the internal opening with peroxide as well to ensure proper closure of the proximal portion of the tract. The anoderm is reapproximated with a running absorbable suture. Very high fistula tracts or those that track long distances within the intersphincteric space may be difficult to properly isolate in the intersphincteric plane and not good candidates for this approach.

A meta-analysis of 1378 LIFT procedures from 26 studies demonstrated an overall success rate of 76%, an overall complication rate of 14%, and a low rate of fecal incontinence of 1.4%. Horseshoe anatomy, Crohn's disease, and prior fistula surgery were risk factors for failure. Some failures result in resolution of the external sphincter involvement, converting the fistula to a simple intersphincteric fistula that is more amenable to fistulotomy. Because of this, secondary healing after surgical reintervention can be as high as 77% to 86%.

Endorectal Advancement Flap

The endorectal advancement flap is a sphincter-preserving operation used as a second-stage procedure for high fistula tracts, suprasphincteric tracts, and low tracts in high-risk patients with healthy rectal mucosa (see Table 1). For lesions below the dentate line, fistulotomy or a dermal advancement flap is preferred to prevent the creation of a mucosal ectropion that can form if the rectal mucosa is brought down to near the anal verge. Patients may undergo a preoperative bowel preparation. Performed under general anesthesia, the prone jackknife position is preferred for most fistulas, although the lithotomy position is often used to address posterior midline internal openings. The seton is removed, and the internal opening serves to mark the apex of the flap (Fig. 7). Beginning at the internal opening, a flap is created by distal-to-proximal dissection with electrocautery including mucosa, submucosa, and a few fibers of the internal sphincter (partial thickness). To ensure adequate perfusion, it is crucial that

FIG. 7 Mucosal (Martin's) advancement flap. A longitudinal incision is made over the strictured area in the anal canal. Proximal rectal and anal mucosa are then undermined through a transverse incision starting at the proximal end of a previously made longitudinal incision. The flap is then sutured to the distal edge of the internal anal sphincter, leaving open the most distal aspect of the wound. *(From Liberman H, Thorson AG. How I do it: anal stenosis.* Am J Surg. *2000;179:325.)*

the base (proximal end) of the flap is wide, at least two to three times the width of the apex. The trapezoidal-shaped flap is typically 2 to 4 cm long to allow for tension-free closure caudal to the level of the original internal opening. Care should be taken to avoid excessive handling of the flap, which can result in hematoma formation and tissue compromise. The fistula tract is debrided with a curette, and the external opening is widened to allow for drainage. Absorbable suture is used to close the internal opening, and the integrity of the closure is tested with injection of hydrogen peroxide at the external opening. The tip of the flap with the internal opening is excised, and the flap is gently pulled distally over the internal opening to the dentate line, but not below it, to prevent ectropion formation. Wound edges are reapproximated with interrupted absorbable suture.

Fistula healing after endorectal advancement flap repair is reported in 66% to 87% of patients with cryptoglandular disease. Factors associated with failure include prior radiation, Crohn's disease, active proctitis, prior abscess drainage, rectovaginal fistula, smoking, malignancy, obesity, and having more than one prior attempted fistula repair. An endorectal advancement flap may be repeated after a failed flap procedure or performed after other failed approaches including LIFT, with healing rates that range between 57% and 100%. Changes in bowel continence have been reported in up to 35% of patients treated with the procedure.

Other Continence Preserving Procedures

Synthetic and biologic materials such as fibrin glue and fistula plugs were once promising additions to the armamentarium of fistula treatment. Their general principle is obliteration of the internal opening and fistula tract. Their primary benefit was a minimal risk profile, as they pose no risk to continence, are easily repeated in the case of recurrence, and do not preclude subsequent surgical management. However, more recent evaluations reveal low success rates, so the procedures as standalone procedures have been relatively abandoned. The use of fistula plugs or biologic mesh has been described to augment the success of the LIFT repair however evidence that this leads to superior results is limited.

Minimally invasive approaches to anal fistulas that use endoscopic or laser closure techniques such as video-assisted anal fistula treatment (VAAFT), fistula laser closure (FiLaC), and endoscopic clipping using an over-the-scope clip (OTSC) device have been described in small, single-institution series with limited follow-up and various degrees of industry support. Although short-term healing appears comparable to LIFT and endorectal advancement flap repairs, long-term results are unavailable. All of these techniques require specialized equipment and expertise, and their use is generally not recommended at this time.

Anal Stenosis

Chassidy Grimes, MD, and Dana Hayden, MD

BACKGROUND

Anal stenosis is a narrowing of the anal canal. The narrowing can be anatomic, in which normally pliable anal mucosa is replaced with fibrotic tissue. This scarring can be isolated or circumferential and can vary in length. The narrowing can also be functional as a result of a hypertonic internal sphincter. The causes of anatomic stenosis can be further subdivided into congenital, primary, and secondary causes (Box 1). The most common cause of secondary stenosis is surgery, most likely occurring after multiquadrant hemorrhoidectomy when large areas of anoderm are removed. The literature cites that up to 87% of cases are secondary to hemorrhoidectomy (Liberman & Thorson, 2000; Katdare & Ricciardi, 2010; Khubchandani, 1994). Stenosis may also result after procedures such as low anorectal anastomosis or fistulectomy (Chiarelli et al., 2018). This chapter focuses on the diagnosis and management of anatomic secondary anal stenosis.

DIAGNOSIS

The diagnosis of anal stenosis is largely clinical, taking into consideration the patient's surgical and medical history as well as physical examination findings. The patient will often present with complaints such as constipation, obstipation, painful bowel movements, bleeding, and small-caliber stools (Farid et al., 2010; Chiarelli et al., 2018). Alternatively, they can have diarrhea caused by chronic laxative use or overflow from subsequent upstream rectal dilation. It is recommended that an anorectal examination be performed under anesthesia to both minimize patient discomfort as well as distinguish

BOX 1 Causes of Anatomic Stenosis

Congenital

Imperforate anus
Anal atresia

Primary

Senile

Secondary

Postsurgical
Laxative abuse

Trauma
Chronic diarrhea
Malignancy

TABLE 1 Grading of Anal Stenosis

Severity	Level of Stenosis
Mild: Anal canal can be examined by a lubricated index finger or medium Hill-Ferguson retractor.	Low: Involvement at least 0.5 cm distal to the dentate line
Moderate: Forceful dilation is required to insert a lubricated index finger or medium Hill-Ferguson retractor.	Middle: Involvement 0.5 cm distal and proximal to the dentate line
Severe: Forceful dilation is required to insert a lubricated little finger or small Hill-Ferguson retractor.	High: Involvement 0.5 cm above the dentate line

between a functional and anatomic cause of stenosis. Under anesthesia, the internal sphincter will relax, leading to resolution of the stenosis if it is functional. With true scarring and stricture, the stenosis will remain regardless of muscle relaxation. Anoscopy and proctoscopy can be useful in determining the extent of stenosis and assess the health of the rectal mucosa (Liberman & Thorson, 2000; Katdare & Ricciardi, 2010). It is important to look for any firm tissue, ulcerations, or outgrowths within or surrounding the area of stenosis and biopsy when appropriate to rule out malignancy as a cause. Grading of anal stenosis proposed by Milson and Mazier is based on severity and level of involvement within the anal canal (Table 1). This classification may help guide the next steps in management (Milsom & Mazier, 1986).

MANAGEMENT

Nonoperative Management

Management of anal stenosis depends on severity of stenosis and the patient's symptoms. It is generally accepted to start with conservative measures. This involves management with a high-fiber diet, adequate hydration, and stool softeners. In addition, gradual manual anal dilation can be performed. The initial dilation can be performed under anesthesia with subsequent serial dilation done by the patient at home with a finger or a small plastic dilator. Dilation may be considered controversial given the risk of incontinence, as it may lead to hematoma formation within the intersphincteric space causing further scarring (Khubchandani, 1994). Although there are associated risks, some patients respond well to dilation. It should be considered particularly in cases of Crohn's disease and radiation therapy where large perineal surgical operations are not advised (Kashkooli et al., 2015; Liberman & Thorson, 2000; Lightner et al., 2020). Most cases of mild and moderate stenosis can be managed conservatively. For cases of severe stenosis, it is still recommended to begin with medical management, although patients are likely to require surgery (Brisinda et al., 2009).

Operative Management

Surgical management is considered in cases of moderate to severe stenosis or for those patients who failed medical management. There is a wide variety of options for surgical management. In cases of anastomotic stricture, a step-up approach should be considered. Initially, dilation can be performed, followed by circular stapler resection or stricturoplasty, and then finally transabdominal resection of the anastomosis with repeat anastomosis as the last option (Kraenzler et al., 2017). For other anatomic strictures, anoplasty is the treatment of choice. The overall goal of anoplasty is to divide the stricture and deliver more pliable, healthy anoderm into the area without tension, thereby relieving the stenosis. This can be done with a variety of surgical techniques.

Stricturoplasty

Stricturoplasty involves release of the stricture. The stricture is divided longitudinally and closed transversely. This method can provide symptom relief for the patient but can lead to subsequent scarring and recurrent stenosis (Duieb et al., 2009; Katdare & Ricciardi, 2010).

Mucosal Advancement Flaps

During mucosal advancement flaps, the scar is excised and if there is also scarring of the underlying sphincter, a sphincterotomy is performed (Fig. 1). A transverse incision is made at the dentate line, and the rectal mucosa is undermined and advanced to the distal edge of the internal sphincter to cover the defect (Rakhmanine et al., 2002). The external portion of the wound is left open. Although there is a small risk of mucosal ectropion, this is a good option for midlevel stenosis because of minimal complications and symptom relief (Casadesus et al., 2007).

Y-V Advancement Flap

This technique begins with a Y-shaped incision at the area of stricture, and then it is carried on to the perianal skin, creating a V (Fig. 2). The V portion of the incision is taken down to the

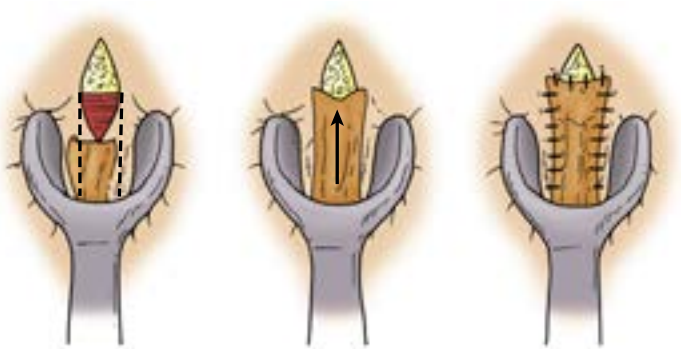

FIG. 1 Mucosal advancement flap. *(From Fleshman JW. Fissure-in-ano and anal stenosis. In: Beck DE, Wexner SD, eds:* Fundamentals of Anorectal Surgery, *ed 2. London: Saunders; 1998.)*

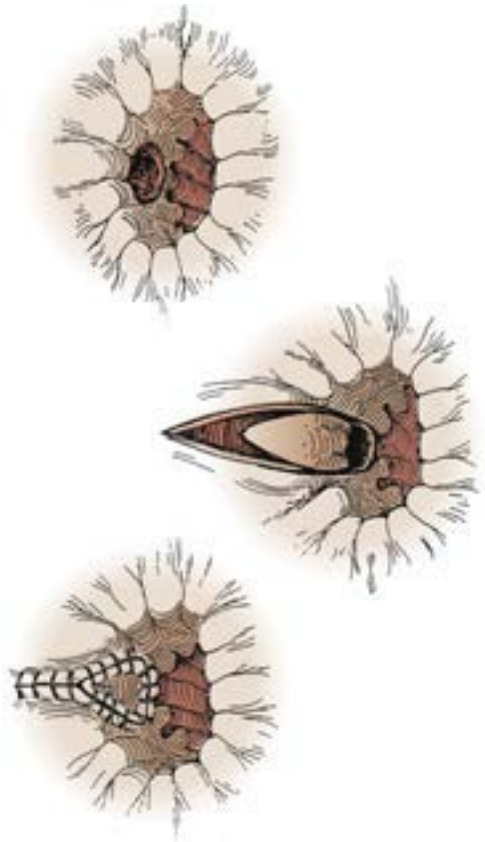

FIG. 3 V-Y flap. *(From Fleshman JW. Fissure-in-ano and anal stenosis. In: Beck DE, Wexner SD, eds:* Fundamentals of Anorectal Surgery, *ed 2. London: Saunders; 1998.)*

subcutaneous tissue, which contains the blood supply to the flap (Gingold & Arvanitis, 1986; Liberman & Thorson, 2000). The apex of the V is advanced into the anal canal and affixed to the internal sphincter and rectal mucosa. This technique can be done bilaterally but is not considered adequate for coverage of a stenosis >25% circumference of the anal canal (Brisinda et al., 2009).

V-Y Advancement Flap

An initial vertical incision is created to incise the scar tissue (Fig. 3). A V-shaped incision is then made with the apex lying on the perianal skin. Similar to the Y-V flap, the V is carried down to the subcutaneous tissue. The broad-based portion is advanced and affixed to the dentate line with the final Y-shaped incision. This technique is useful for the management of low, severe anal stenosis (Angelchik et al., 1993).

House Flap

The initial incision is longitudinal and created from the dentate line to the area of stenosis (Fig. 4). Two transverse incisions of equal width are then created on both ends of the longitudinal incision. A house-shaped flap is then created with the width of the base matching the width of the transverse incisions and is carried down to subcutaneous tissue with the apex overlying the perianal skin. It is then advanced into the anal canal to cover the defect and sutured in place (Christensen et al., 1992). This technique is useful for stenoses that extend from the dentate line onto perianal skin. It also avoids the narrow apex involved in Y-V advancement flaps, which are subject to ischemia (Alver et al., 2008; Casadesus et al., 2007). House flaps can be performed bilaterally and cover large areas of stenosis (Chiarelli et al., 2018).

Diamond-Shaped and U-Shaped Flap

For a diamond-shaped flap, the scar is incised with a vertical incision that is carried on to perianal skin to make a diamond shape (Fig. 5).

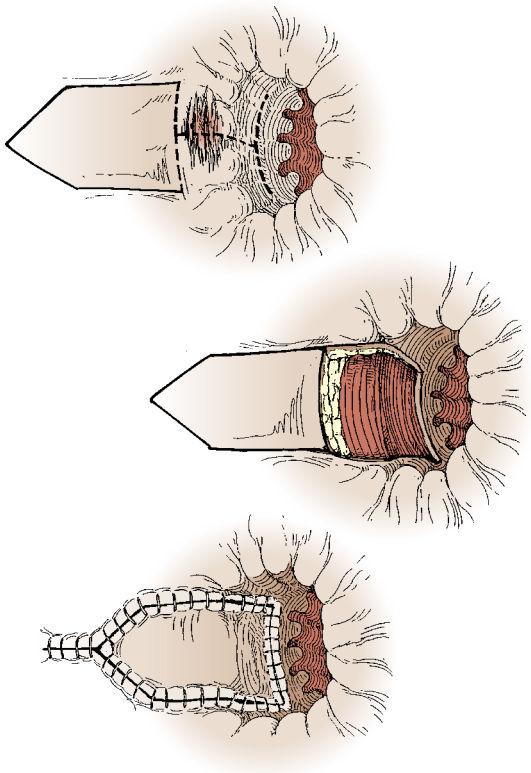

FIG. 4 House flap. *(From Fleshman JW. Fissure-in-ano and anal stenosis. In: Beck DE, Wexner SD, eds:* Fundamentals of Anorectal Surgery, *ed 2. London: Saunders; 1998.)*

The flap is advanced into the anal canal and sutured (Liberman & Thorson, 2000). The U-shaped flap is performed in similar fashion (Fig. 6). It is useful for management of strictures with associated mucosal ectropion, but the donor site is not closed, making it a less desirable technique (Brisinda et al., 2009).

Rotational S Flap

This technique is used is cases of extensive and circumferential anal stenosis that require excision of a large amount of skin (Handaya & Sunardi, 2019) . An S-shaped incision is created, with the midportion carried down to the dentate line transversely (Fig. 7). The wide portions of the S are then rotated down to the dentate line and sutured. One limitation of the S flap is that it does not release the stricture as effectively as the previously described advancement flaps (Brisinda et al., 2009).

POSTOPERATIVE CARE AND COMPLICATIONS

The majority of these procedures can be performed in an outpatient setting but may require admission depending on the extent of dissection or surgeon preference. Postoperative care typically involves adequate pain control, a strict bowel regimen that ensures soft stools, and sitz baths or showers to keep the wounds clean (Chiarelli et al., 2018). Complications include wound infection, flap ischemia, fecal incontinence, failure to correct stenosis, recurrent stenosis, and ectropion (Brisinda et al., 2009; Casadesus et al., 2007). Complication rates are relatively low, and good patient satisfaction has been demonstrated with diamond, Y-V, and house flaps (Farid et al., 2010).

SELECTION OF SURGICAL TECHNIQUE

Given the multitude of options, Duieb et al. described an algorithmic intraoperative approach to deciding which technique to use. First, an initial longitudinal incision through the stricture is created, assessing

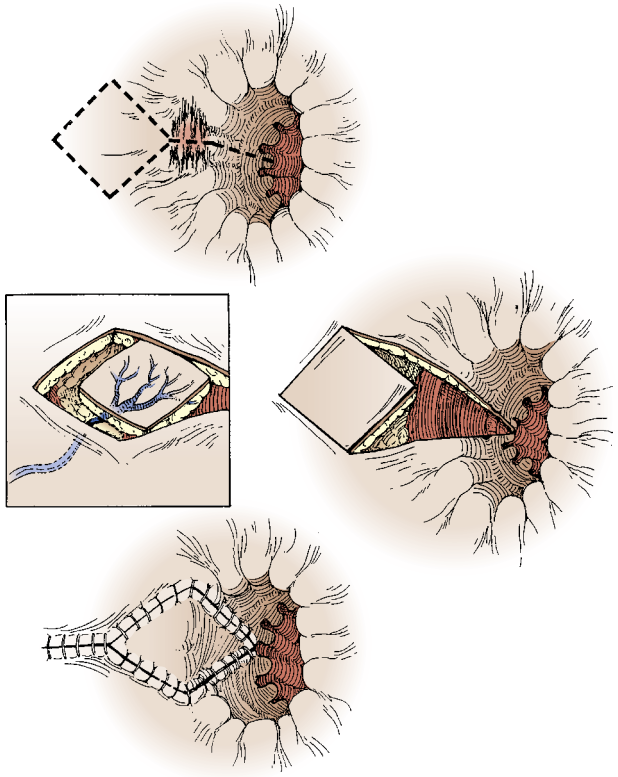

FIG. 5 Diamond flap. *(From Fleshman JW. Fissure-in-ano and anal stenosis. In: Beck DE, Wexner SD, eds:* Fundamentals of Anorectal Surgery, *ed 2. London: Saunders; 1998.)*

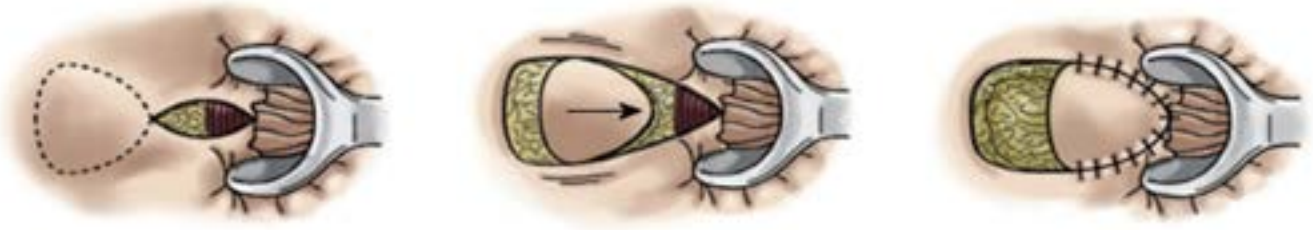

FIG. 6 U flap. *(From Fleshman JW. Fissure-in-ano and anal stenosis. In: Beck DE, Wexner SD, eds:* Fundamentals of Anorectal Surgery, *ed 2. London: Saunders; 1998.)*

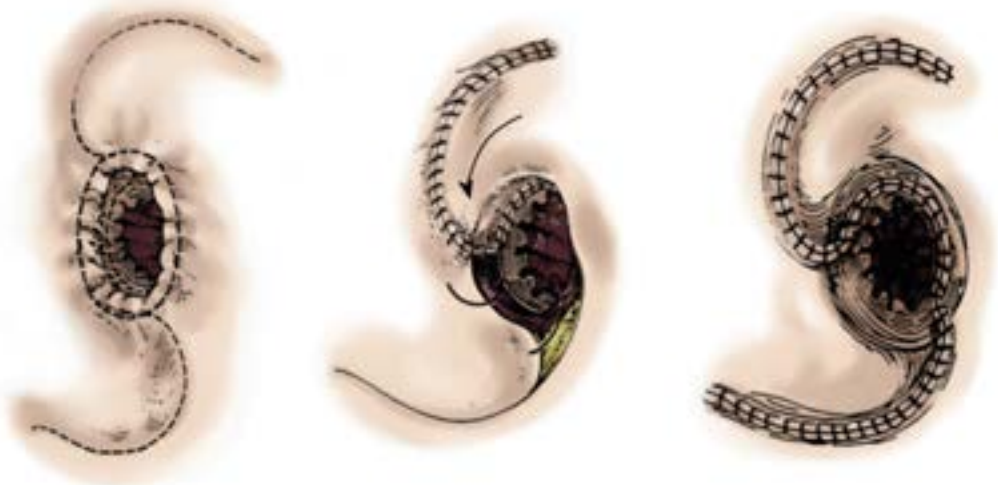

FIG. 7 Rotational flap. *(From Fleshman JW. Fissure-in-ano and anal stenosis. In: Beck DE, Wexner SD, eds:* Fundamentals of Anorectal Surgery, *ed 2. London: Saunders; 1998.)*

for a sphincter component, and sphincterotomy is performed when necessary. Next, primary transverse closure is attempted if there is no tension. If excessive tension is present, then a Y incision is created via extension of the initial longitudinal incision, and a Y-V flap is attempted. If there is continued tension, the Y incision is extended to create a diamond flap. Even though low complication rates were reported, this approach was only performed in a small subset of patients and by only one surgeon (Duieb et al., 2009). It does not consider the different patterns and extent of stenosis and is solely based on tension. Farid et al. reported on 60 patients with anal stenosis. They demonstrated that house flap reconstruction achieved greater anal caliber while maintaining continence and significantly improved quality of life when compared with Y-V and diamond-shaped flaps (Farid et al., 2010). In conclusion, there is no clear consensus on which technique is superior. Selection of approach is ultimately based on surgeon experience and should be individualized based on surgical history and anatomy, taking into consideration the benefits and limitations noted with each of the procedures.

Management of Pruritus Ani

Matthew D. Price, MD, and Chady Atallah, MD

DEFINITION

Pruritus ani is a dermatologic condition characterized by an itching or burning sensation of the perianal region. Although this condition can be seen in any age group, patients often present in their third to fifth decade of life after having attempted multiple over-the-counter or home remedies with little success. Pruritus ani affects 1% to 5% of the population with a male-to-female ratio of 4:1. Primary idiopathic anal pruritus is responsible 50% to 90% of the time. Secondary causes include infections or infestations, dermatologic inflammatory diseases, premalignant and malignant neoplasms, and benign anorectal or systemic diseases (Box 1).

ETIOLOGY

Primary/Idiopathic Pruritus Ani

Primary or idiopathic pruritus ani is diagnosed after all secondary causes have been ruled out and no pathologic etiology can be identified. Fecal soilage, moisture, and various nonspecific offending agents are thought to act as triggers. C-fibers, a class of nonmyelinated nerve fibers found in the somatic sensory system, are believed to play a key role. Scratching to relieve the itch is known to cause further excoriation and inflammation, which leads to further stimulation of nerve fibers. This process is known as the *itch-scratch cycle*. A key step in treating this condition is breaking the itch-scratch cycle. Additionally, increased levels of histamine, bradykinin, and kallikrein have been associated with the condition.

Certain foods have been associated with primary/idiopathic pruritus ani including coffee, caffeinated beverages, citrus fruits, chocolate, alcoholic beverages, tomatoes, and spicy foods (Box 2). These foods have been shown to alter bowel habits and can act as irritants to the perianal skin.

Secondary Pruritus Ani

Infectious

Fungal infections, particularly Candida, are relatively common causes of pruritus ani with an estimated frequency of 10% to 43%. Similar to most fungal infections, these usually occur in moist or sweaty environments such as skin folds in elderly or obese patients. Immunosuppressed patients or patients taking antibiotics are more prone to developing Candida-related anal pruritus. Antifungal powder, good hygiene, and keeping the affected areas dry are important steps in treatment. Oral antifungals can be used in cases of severe infections. Several case reports have associated streptococci and *Corynebacterium minutissimum* with pruritus ani, but they are found much less commonly than fungal infections.

Sexually transmitted diseases are common causes, particularly in patients practicing anoreceptive intercourse. *Neisseria gonorrhoeae, Chlamydia trachomatis, Treponema pallidum,* herpes, *Molluscum contagiosum,* and *Condyloma acuminatum* have all been implicated.

BOX 1 Causes of Secondary Pruritus Ani

Infectious
Bacterial infection (Staphylococcus, Streptococcus, Erythrasma)
Sexually transmitted infection (Gonococcus, Chlamydia)
Fungal infection (Candida, dermatophytes)
Parasites (pinworms, scabies)
Viral infection (Herpes virus, Condylomata, Molluscum)

Dermatologic
Contact dermatitis
Atopic dermatitis
Perianal psoriasis
Lichen sclerosus
Seborrheic dermatitis

Anorectal
Hemorrhoids (external, prolapsing internal)
Fistula-in-ano
Anal fissures
Hidradenitis suppurativa
Fecal incontinence
Perianal Crohn's disease
Skin tags
Chronic diarrhea
Pilonidal disease

Malignant
Anal canal cancer
Anal margin cancer
Rectal cancer
Bowen's disease
Extramammary Paget's disease

Systemic Disease
Diabetes mellitus
Leukemia
Lymphoma
Chronic renal failure
Iron-deficiency anemia
Hyperthyroidism
Hyperbilirubinemia

BOX 2 Food Products That Contribute to Pruritus Ani

Caffeine-containing products (colas, coffee, tea, energy drinks)
Citrus fruits and vegetables
Carbonated beverages
Chocolate
Tomato
Beer
Spicy and acidic foods
Refined carbohydrates
Nuts

Parasitic perianal infections are rare including pinworm *(Enterobius vericularis),* scabies *(Sarcoptes scabiei),* and pediculosis pubis. Nocturnal pruritus ani in children is characteristic of pinworm infections. The nematodes of the pinworm usually reside in the large intestine during the day then lay their eggs in the perianal region at night, resulting in local irritation. Oral albendazole is used for treatment.

Dermatologic

Eczema, or atopic dermatitis, is the most common dermatologic condition responsible for anal pruritus. It is usually an allergic response to a wide variety of inciting agents including laundry detergents or topical creams. Identifying the inciting factor can be difficult, but eliminating exposure is key to treatment.

Psoriasis can cause anal pruritus, although it more commonly affects extensor surfaces of the extremities. Several series show that 4% to 8% of patients presenting with pruritus ani have psoriasis. Treatment of psoriatic anal pruritus involves topical steroids for brief symptomatic improvement followed by maintenance topical calcipotriene, salicylic acid, or ultraviolet light.

Other less common dermatologic causes of pruritus ani include lichen sclerosus, seborrheic dermatitis, lichen planus, and lichen simplex chronicus.

Anorectal Diseases

Benign anorectal conditions such as external and internal hemorrhoids, anal fissures, fistulae, hidradenitis suppurativa, perianal Crohn's disease, anal skin tags, and pilonidal disease are commonly found in patients with pruritus ani. Management of the specific condition is associated with improvement in pruritus.

Malignant or premalignant anorectal processes can result in pruritus ani and should be considered at presentation including cancers of the anal canal, anal margin, or even the lower rectum. Bowen's disease (perianal squamous cell carcinoma in situ) and Paget's disease (cutaneous adenocarcinoma in situ) are the most common premalignant lesions. If Paget's disease of the anal canal is discovered, further endoscopic evaluation of the colon is needed to rule out an underlying carcinoma.

Miscellaneous

Other causes of anal pruritus include radiation-induced perianal dermatitis from cancer treatments, systemic diseases including uremic or cholestatic pruritus, and excessive moisture of the perianal skin from urinary incontinence or vaginal discharge. Treatment is dependent on the specific condition.

EVALUATION AND DIAGNOSIS

History

Evaluation of a patient presenting with anal pruritus begins with a thorough history and physical examination. Patients can present with a range of symptoms from mild irritation to severe, unrelenting pain. Timing of symptoms can vary from worsening pruritus with bowel movements to persistent pruritus throughout the day, or even nocturnal symptoms. Bleeding can be present, though anything more than spotting on toilet paper would warrant further workup for other pathologies. Symptoms can be longstanding or recent onset. Patients usually present to a specialist after having trialed several forms of treatment either on their own or as directed by their previous providers. A patient's bowel and cleansing habits should be discussed, including bowel frequency, diarrhea, anal incontinence, excessive wiping, scented soaps, or prepared wipes. Sexual history should be ascertained. Dietary habits should also be assessed for potential triggers (see Box 2).

Physical

Physical examination begins with inspection of the perianal area, perineum, and genitalia. Physical findings can range from completely normal to severe widespread excoriations. The Washington Criteria has often been used to stage the appearance of perianal skin according to severity of disease and should be documented with each encounter to track treatment response (Table 1). Secondary causes

TABLE 1 Washington Hospital Staging Criteria

Stage 0	Normal-appearing perianal skin
Stage I	Erythematous and inflamed perianal skin
Stage II	White, lichenified perianal skin
Stage III	Lichenified skin with coarse ridges and ulceration

must be ruled out with anoscopy, and when indicated cultures or biopsies should be taken. Indications for biopsy include any nonhealing wounds, ulcerations, or lesions suspicious for malignancy. Microbiologic testing should be pursued based on clinical suspicion. Any perianal drainage should be sent for bacterial and viral culture. Patients with diarrhea should have their stool cultured and evaluated for ova or parasites. Flexible sigmoidoscopy and colonoscopy with biopsies should be performed whenever inflammatory bowel disease or malignancy remain on the differential.

MANAGEMENT

Initial treatment of pruritus ani should be directed toward treatment of any secondary causes identified. Once secondary causes have been treated, symptom relief, healing of impaired skin, and prevention of further damage should be the goals. It is important to inform patients early on that there will likely be a period of trial and error as an instant cure is unlikely.

Education and Lifestyle Modifications

Patients should be instructed to not scratch the area so as to begin to break the "itch-scratch cycle" and prevent further excoriation and irritation. As poor anal hygiene is a known trigger, time should be spent educating on proper anal hygiene including gentle cleansing of the perianal area with water and unscented soaps followed by cool air-drying or dabbing with toilet paper after each bowel movement. Scented soaps and prepared "baby wipes" should be avoided. The anal region should be kept dry. This can be achieved by placing a cotton ball in the gluteal fold after cleansing. Overzealous hygiene with aggressive scrubbing should be cautioned against as this too can lead to further excoriation and worsen the cycle. Though uncommon in the United States, bidets followed by patting dry the area with unscented toilet paper has been shown to be an effective method of maintaining good anal hygiene. If chronic diarrhea impedes proper perianal hygiene, fiber supplements or stool bulking agents should be prescribed.

Loose-fitting clothing should be used to allow for natural aeration. Home and over-the-counter remedies should be discontinued when initiating a stepwise treatment to rule out possible confounding factors. Dietary modifications should be made to avoid foods that have shown to be associated with the condition, including caffeine, spicy and acidic foods, chocolate, tomatoes, and carbonated beverages (see Box 2).

Medical

Following initiation of lifestyle modifications, topical agents can be used for further treatment and symptom management. Hydrophobic barrier creams that include zinc oxide such as Calmoseptine, Desitin, and Balmex are helpful to allow for healing and long-term prevention. Antihistamines, both topical and systemic, have been shown to decrease nocturnal itching. Topical capsaicin, a component of chili peppers, has been shown to suppress the histamine-mediated itch-scratch response. Topical steroids can be considered once infectious causes have been ruled out. Topical cortisone cream is effective in relieving pruritic symptoms, however long-term use is associated with atrophy of the skin, thus treatment is usually limited to 2-week periods. Though steroids are rarely curative, they can be effective in breaking the itch-scratch cycle and allow time for the skin to heal.

Lack of clinical and symptomatic improvement within 2 weeks of full lifestyle modification and topical therapy warrants further evaluation for missed secondary causes. Other treatments that have been studied, though with limited data, include topical tacrolimus ointment for 4 weeks leading to decreased itch intensity and frequency. Intradermal and subcutaneous injection of the perianal region with methylene blue has shown resolution of symptoms in 20% to 88% of patients. Methylene blue is thought to destroy sensory nerve endings resulting in hypoesthesia of the perianal region. Initial trials of methylene blue were complicated by several patients developing full-thickness skin necrosis, though the technique has since been modified. Patients should be counseled that the methylene blue will often permanently color the treated area blue.

Surgical Management of Fecal Incontinence

Sarah Stringfield, MD, and Alessandro Fichera, MD

INTRODUCTION

Fecal incontinence (FI) is defined as the uncontrolled passage of feces or gas over at least 1 month's duration in an individual who had previously maintained control. Fecal incontinence is a common condition, affecting up to 11% of men and 26% of women older than 50 years of age. It is the second leading reason for admission to nursing homes and is present in up to 50% of institutionalized patients. True prevalence may be even higher, as social stigma surrounding incontinence likely limits reporting. Fecal incontinence has a profound negative impact on quality of life and generates a substantial financial and logistical burden to healthcare and society.

Continence depends on the complex relationship between the anal sphincter and pelvic floor musculature, rectal reservoir function, stool consistency, and neurologic function. Conditions that alter any of these factors may result in FI. General categories of causes of FI include structural abnormalities, functional disorders, neurologic etiologies, and congenital malformations (Table 1). In women, the

TABLE 1 Causes of Fecal Incontinence

Category	Examples
Acquired structural abnormalities	Obstetric injury History of anorectal surgery Rectal or hemorrhoidal prolapse Anal or rectal fistula Sphincter-sparing rectal resection Trauma
Functional disorders	Diarrhea Inflammatory bowel disease Irritable bowel disease Hypersecretory tumors Fecal impaction (paradoxical diarrhea) Radiation proctitis Physical disabilities Psychiatric disorders
Neurologic disorders	Pudendal neuropathy Spinal injury or surgery Multiple sclerosis Dementia Central nervous system disorder Spina bifida
Congenital disorders	Imperforate anus Cloacal defect

leading cause is obstetric injury. Treatment is challenging and must be individualized to each patient based on the underlying cause.

DIAGNOSTIC EVALUATION

A variety of diagnostic tests can be performed to help determine the cause of the patient's fecal incontinence and quantify the severity of their symptoms (Table 2). Patients presenting with FI require a thorough history and physical examination. Direct and specific questions must be asked to understand the type and extent of incontinence. This can include awareness of continence episodes (urge vs. passive incontinence), timing and frequency of symptoms, stool characteristics and habits, and other associated symptoms such as prolapse, drainage, and urinary or sexual dysfunction. A detailed obstetric and surgical history is essential. Underlying disease processes such as diabetes, stroke, inflammatory bowel disease, or certain medications may contribute to FI.

A thorough anorectal physical examination should be performed. Essential components of the examination include assessing the anal sphincter tone and pelvic accessory muscles at rest as well as during squeeze and Valsalva maneuvers. The patient should be evaluated for the presence of pelvic organ prolapse, masses, perianal skin irritation, hemorrhoids, fissures, and fistulas.

There are many validated patient-reported scoring systems that can be used to quantify the severity of fecal incontinence. A commonly used system is the Cleveland Clinic Florida Fecal Incontinence Score (Wexner scale), which assesses the frequency of five parameters (incontinence to solid stool, liquid stool, gas, wears a pad, and lifestyle alteration) and sums it into an aggregate score. Additional scoring instruments include the Fecal Incontinence Severity index, Fecal Incontinence Quality of Life score, and the St. Mark's Incontinence score. All scoring systems emphasize different symptoms and may be limited by the subjectivity of the reporting, failure to include coping mechanisms, and lack of objective physiologic test data. Although the scoring systems provide a useful way to quantify severity of incontinence, they do not have the ability to accurately predict outcomes.

TABLE 2 Diagnostic Evaluation and Workup

Study	Components and Examples
Patient history	Awareness of incontinence episodes Timing and frequency of episodes Stool characteristics Stool habits Other associated symptoms (prolapse, drainage, urinary or sexual dysfunction) Obstetric and surgical history Medications Underlying diseases
Physical examination	Sphincter tone at rest and squeeze Pelvic accessory muscles during squeeze and Valsalva Anatomic abnormalities: prolapse, masses, hemorrhoids, fissure, fistulas Perianal skin irritation
Patient-reported scoring systems	Cleveland Clinic Florida Fecal Incontinence score Fecal Incontinence Severity index Fecal Incontinence Quality of Life score St. Mark's Incontinence score
Endoanal ultrasound	Sphincter integrity
Anorectal physiology	Manometry Anorectal sensation Volume tolerance Compliance Electromyography
Defecography	Prolapse Rectocele/enterocele Positional instability

Objective testing predominantly assesses sphincter integrity and anorectal function. Endoanal ultrasound is the most sensitive means to confirm whether a sphincter defect is present in patients with suspected sphincter injury and determine the size of the defect. Ultrasound can identify defects in both internal and external anal sphincters (Fig. 1). Anorectal physiology testing includes manometry, anorectal sensation, volume tolerance, and compliance, and it helps define the elements of dysfunction. Although findings do not consistently correlate with the severity of FI or predict outcomes, this type of testing can help define the elements of dysfunction and guide management. Pudendal nerve terminal motor latency and electromyography may be useful in select circumstances. Defecography, either with MRI or fluoroscopy, may be useful in cases of pelvic organ prolapse to visualize positional instability and identify involved pelvic compartments. Colonoscopy should be performed in patients with bleeding, those with a change in bowel habits, and those who meet national screening guidelines.

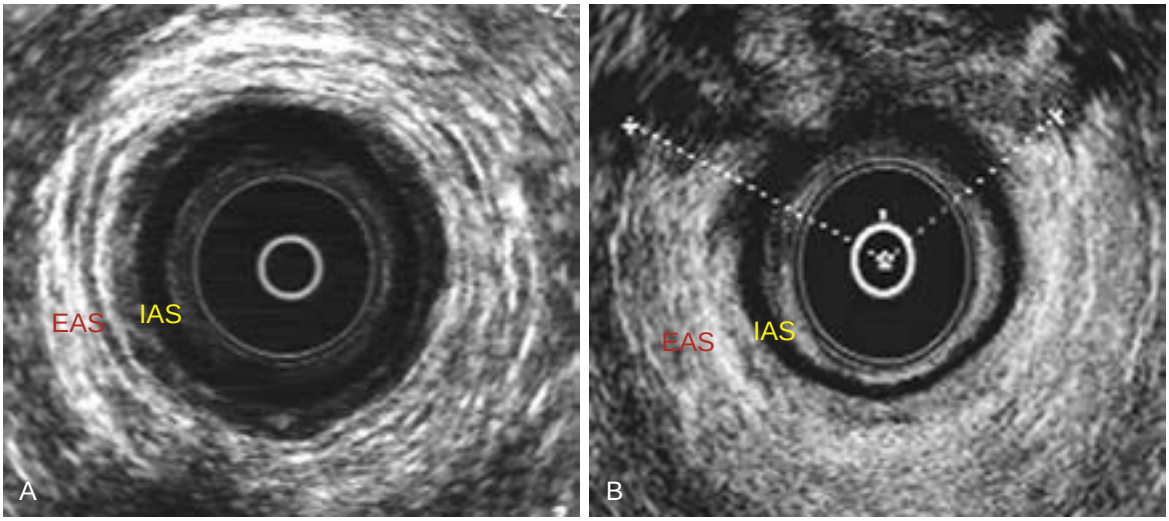

FIG. 1 Endoanal ultrasound evaluation of anal sphincters. (A) Intact sphincter complex. **(B)** Approximately 110-degree anterior sphincter defect. *IAS*, Internal anal sphincter (*dark ring*); *EAS*, external anal sphincter (*white ring*).

NONOPERATIVE MANAGEMENT

Medical Management

Initial management of FI for all patients, regardless of etiology, should be nonoperative. The goal is to control symptoms and attempt to correct any modifiable factors contributing to the patient's presentation. Up to 20% to 50% of patients can improve after starting medical management and lifestyle changes, which avoids surgery in many patients. Initial steps include optimizing stool consistency, slowing bowel motility, and minimizing the average stool load in the rectum, particularly before sleeping or leaving home. These changes can often be accomplished with habit changes and dietary modifications as well as pharmacologic and bowel management interventions. Common foods that promote urgency or diarrhea should be avoided. This includes caffeine, sugar replacements, and lactose. Dietary fiber supplementation may improve stool consistency in patients with diarrhea, prevent seepage, and promote complete evacuation. Antidiarrheal medications such as loperamide and diphenoxylate-atropine can also help thicken stools and decrease frequency. Cholestyramine can be helpful in patients with bile acid diarrhea, usually those with a history of cholecystectomy or terminal ileal resection. Irritable bowel syndrome can be treated with tricyclic antidepressants and drugs such as alosetron or eluxadoline. Bowel management programs start with patient education regarding regularity and timing of bowel movements in relation to the gastrocolic reflex. Timing meals and reducing stool load in accordance with planned events or sleeping can prevent episodes of incontinence in these situations. Scheduled enemas can reduce stool load and are therapeutic in patients with fecal impaction and overflow incontinence. Incontinence pads and barrier creams for perianal skin care are useful adjunctive treatments.

Biofeedback

In patients with some degree of preserved voluntary sphincter contraction, pelvic floor physical therapy and biofeedback therapy can improve symptoms. The sessions focus on strengthening and re-coordinating the pelvic floor and sphincter function in response to rectal distension. The patient is monitored during the biofeedback sessions and counseled on appropriate muscle contraction, relaxation, abdominal pressure, and breathing techniques. Subjective benefits have been noted in up to 64% to 89% of patients who participate in the therapy. Long-term results and objective benefits are less clearly defined. The approach is simple, noninvasive, and without any adverse side effects, and it should be offered to any patient who may be a candidate.

TABLE 3 Surgical Targets and Options

Goal	Options
Correction of anatomic abnormalities	Overlapping sphincteroplasty Prolapse repair Fistula repair Hemorrhoid treatment/excision Cloaca or keyhole deformity repair
Enhancement of sphincter function	Sacral nerve stimulation Radiofrequency energy administration Injection of bulking agents Tibial nerve stimulation
Sphincter replacement or support	Artificial bowel sphincter Implantation of magnetic anal sphincter Graciloplasty Cerclage (Thiersch procedure) Pelvic sling system
Diversion	Colostomy Ileostomy
Reduction of fecal load	Antegrade continence enema

SURGICAL MANAGEMENT

Patients who fail medical management may be offered a surgical option. There are many options for surgical interventions, and the approach typically depends on the etiology of the incontinence, severity of the symptoms, and several patient factors (Table 3). The initial approach should typically correct any anatomic abnormalities that may be contributing to incontinence, as restoration of normal anatomy may normalize function. This can include rectal or hemorrhoidal prolapse, rectovaginal or anal fistulas, and cloacal or keyhole deformities. If symptoms persist, then incontinence-specific approaches may be considered. While many incontinence-specific

options exist, many are not frequently used or require medical devices that have been taken off the market. The most common and efficacious surgical interventions include sacral nerve stimulation, sphincteroplasty, and fecal diversion.

Sacral Nerve Stimulation

Sacral nerve stimulation (SNS) is a technology initially developed for urinary incontinence but was demonstrated to have benefits for FI as well. The device stimulates the S3 nerve root by delivering mild electrical pulses. The exact mechanism by which it improves urinary and fecal incontinence is not fully understood. SNS has been approved by the US Food and Drug Administration (FDA) for use in treatment of FI in the United States since 2011 and can be performed in most patients with FI. Patients with sphincter defects up to 120 degrees can see a reduction in severity and frequency of FI episodes with implantation of SNS.

The procedure is performed in two stages. During the first stage, a tined lead is placed under fluoroscopic guidance along the S3 nerve root (Figs. 2 and 3). The procedure is performed under monitored anesthesia care or general anesthetic with a short-acting paralytic agent. The patient is placed prone, and exposure of the buttocks and feet are maintained to visualize motor responses. Access to the S3 foramen is obtained with a hollow needle under fluoroscopic guidance. Appropriate needle placement is confirmed by stimulating the needle with an electrical impulse and confirming appropriate motor response. Motor responses of S3 stimulation include pelvic bellows and ipsilateral big toe plantarflexion. Using Seldinger technique, a wire and subsequently a tined lead is placed through the S3 foramen and along the S3 nerve root. The lead is tunneled laterally to a subcutaneous pocket and coupled with an external wire. The external wire is tunneled out of the skin several centimeters removed from the subcutaneous pocket and coupled with an external battery pack. The external wire and battery pack are bandaged, and the patient is instructed to avoid showering during the trial period.

During a 2-week trial period, the patient keeps a diary of incontinence symptoms and compares it to a diary kept before implantation of the SNS. Lead settings are modified in the outpatient setting until the patient has maximum benefit with minimal discomfort. If the patient sees a benefit, typically 50% or greater reduction in the number of incontinence episodes, then the second stage of the procedure is performed. The patient is positioned in the same way. The external wire is uncoupled from the tined lead and removed. The lateral subcutaneous pocket is opened, and the permanent device is connected to the tined lead and implanted. If the patient does not see a reduction in incontinence symptoms or does not tolerate the device during the trial period, then the lead and external wire are removed during the second phase.

Patients now have the option of having a rechargeable battery or a larger, non-rechargeable battery pack placed that lasts approximately

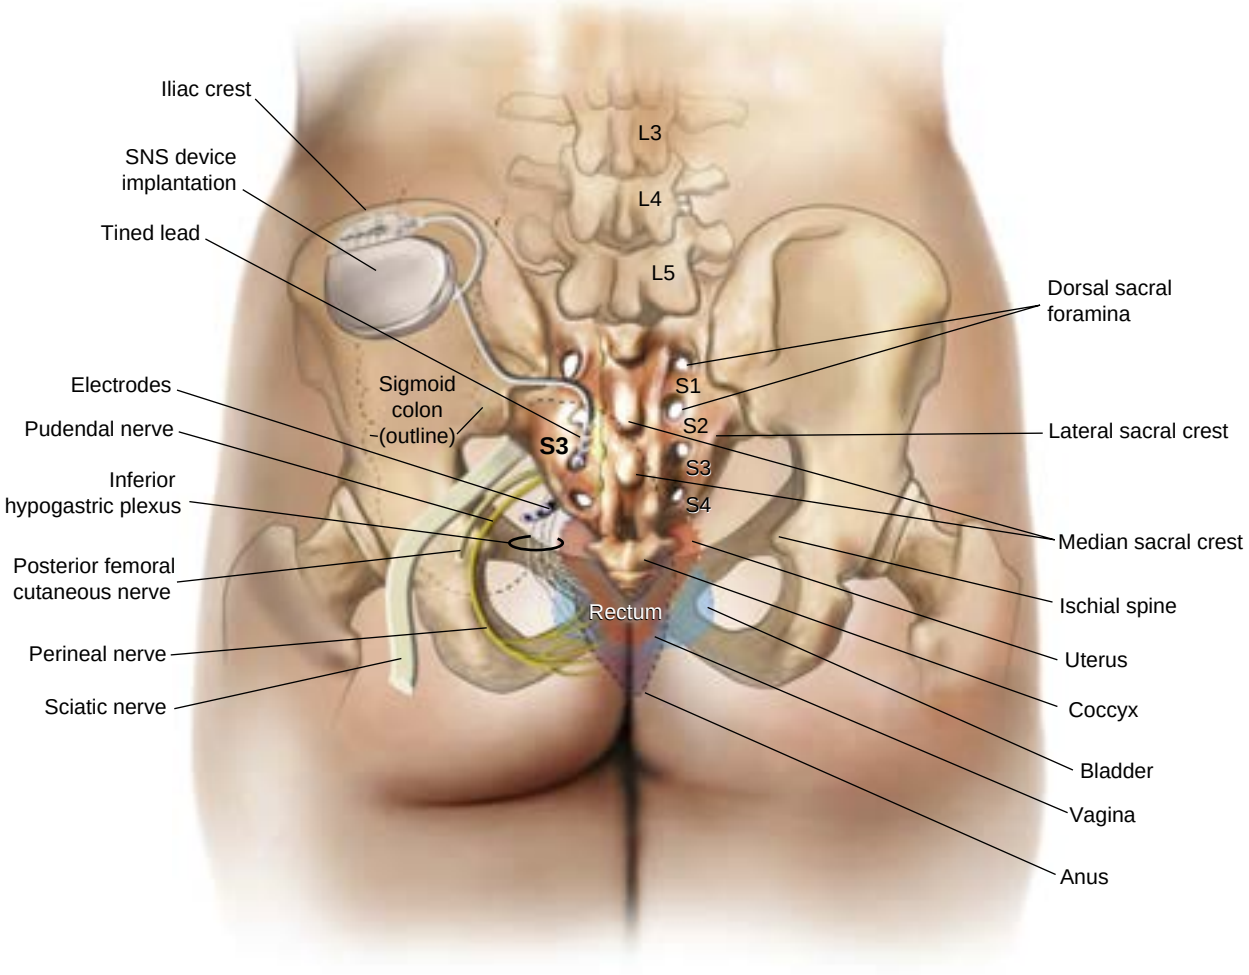

FIG. 2 Sacral nerve stimulator placement and anatomy. *(From Hull T.* Posterior Pelvic Floor Abnormalities. *Philadelphia: Elsevier; 2011).*

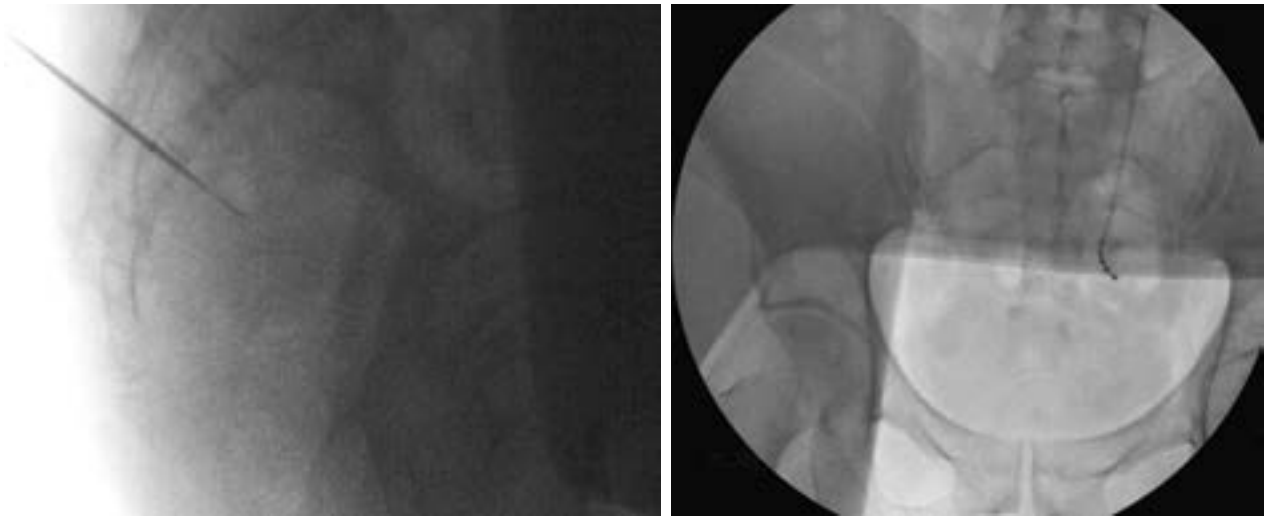

FIG. 3 **Sacral nerve stimulator placement with fluoroscopic guidance.**

5 years. Benefits of the rechargeable battery include smaller size and avoidance of additional operations to change the battery. However, it requires the patient to charge the battery every couple of weeks using a charging device placed on the skin over the battery. The decision of whether to choose a rechargeable or non-rechargeable battery will depend on the patient's ability to charge the device and the risks and benefits of routine battery charging versus surgical replacement every 5 years. Currently marketed SNS devices are MRI-compatible.

The SNS study group reported results of a prospective multi-institutional trial conducted on 133 patients with FI who underwent test stimulation. In this study, 90% of the patients had a 50% or greater reduction in the number of incontinence episodes and underwent permanent battery implantation. At 12 months, 83% of implanted patients reported therapeutic success, which was 75% of overall patients. The mean number of incontinence episodes decreased from 9.4 per week to 1.9 per week at 12 months. At 5 years, 89% of patients had sustained benefit, and 36% reported perfect continence. Risks of SNS are generally minor and include pain and surgical site infection, which are seen in about 10% of patients. Either of these complications can be treated with removal of the device. Reimplantation can be attempted after the infection has cleared, and the contralateral side can be used in either group of patients. At 5 years, 36% of patients required revision or replacement. Overall, SNS placement is an intervention that has low complication rates, is reversible, and has been shown to achieve good long-term improvement in continence. It is now the first-line treatment in many patients who are considered candidates.

Overlapping Anterior Sphincteroplasty

An overlapping anterior sphincteroplasty may be performed in patients with an anterior anatomic defect with the goal of reconstituting the circular configuration of the sphincter muscle around the anal canal. These sphincter defects are most commonly seen in women as a result of obstetric injuries. When sphincter injury is suspected, ultrasound imaging should be performed to confirm. The best postoperative results are seen in patients with defects of 60 to 180 degrees. When defects are seen immediately following delivery, they should be repaired primarily. If the patient continues to have a sphincter defect and symptoms of FI, definitive operative intervention should be delayed for 3 to 6 months to allow time for swelling to subside and for scar tissue to form.

Patients should undergo preoperative mechanical bowel preparation. Patients are placed in the prone jack-knife or lithotomy position. A curvilinear incision is made anterior to the anus within the perineum, and the two sides of the sphincter are identified and mobilized. The ends of the sphincter muscle should be mobilized as much as necessary to allow for an overlap, but not too much in order to avoid pudendal nerve injury or ischemia. An anterior levatorplasty is often performed in conjunction with sphincter repair to approximate the levator muscles. The two sides of the sphincter are reapproximated in an overlapping fashion with 2-0 monofilament sutures. The sutures should be placed within any scar tissue that is present as it holds suture better than muscle. The skin is closed loosely to allow for drainage (Fig. 4).

Short-term results for this procedure are very good, with up to 80% of patients reporting good to excellent functional results. However, the benefits deteriorate over time, and less than half of patients remain continent at 5 to 10 years. This surgical technique is most useful in patients with an associated rectovaginal fistula that requires repair. Repeat anal sphincter reconstruction after a failed sphincteroplasty should be avoided unless other treatment modalities are not possible or have already been attempted and failed. Repeat repairs are unlikely to be more successful than the original repair unless a specific factor responsible for the failure can be identified and avoided.

Fecal Diversion

In patients who fail medical or surgical therapy, those with very large defects that are not amenable to repair, or in cases of patient preference, stoma creation may be offered as an effective solution for FI. In most patients, creation of a sigmoid colostomy is appropriate and provides for an ostomy that is easy to care for. A laparoscopic approach is preferred and feasible in most patients. Stoma placement is important, as many of these ostomies will not be reversed. Trained stoma nurses should be involved in the patient's care both preoperatively and postoperatively. In patients who had a stoma created for FI, 83% reported an improvement in quality of life, and 84% would choose a stoma again.

Additional Surgical Interventions

Several products have been developed to artificially increase anorectal outlet resistance in patients with incontinence caused by a weak or dysfunctional anal sphincter. These include an artificial bowel sphincter, a magnetic sphincter, radiofrequency administration, and injection of bulking agents into the anal canal. Studies of these

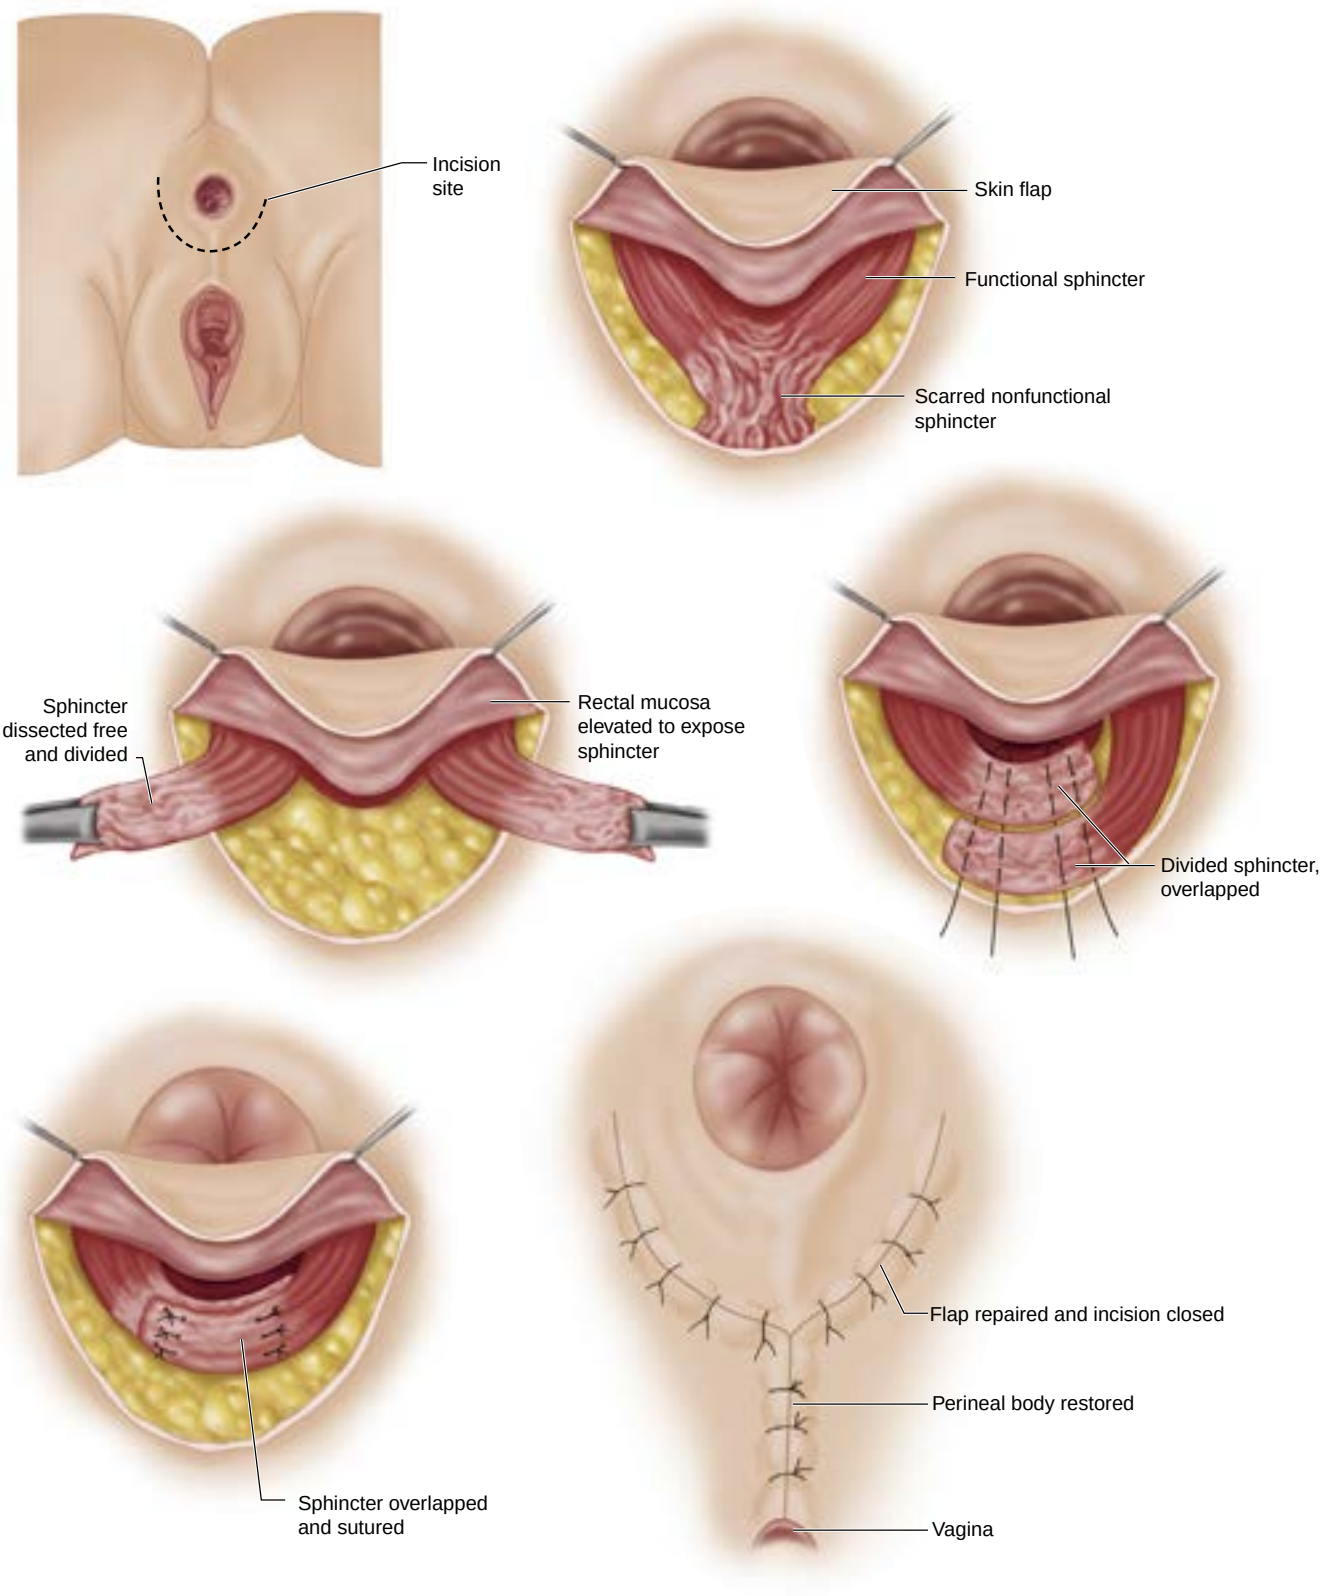

FIG. 4 Overlapping anterior sphincteroplasty. *(From Fleshman JW.* Atlas of Surgical Techniques for Colon, Rectum and Anus. *Philadelphia: Saunders; 2013.)*

products show variable results, and overall evidence for their efficacy is weak. Artificial bowel sphincters provide the best results, however they are associated with high complication rates, with up to 80% of patients requiring explantation or revision within 5 years. Many of these products have been taken off the market in the United States.

Tibial nerve stimulation is a new therapy undergoing evaluation for treatment of FI. Stimulation is delivered with a needle electrode or an adhesive pad. Two randomized controlled trials comparing the therapy to sham neurostimulation have been performed and reported differing results. One trial reported patients undergoing percutaneous therapy to have higher rates of improvement in FI episodes, while the other trial showed similar rates of improvement in both intervention and sham groups. Little is known about the frequency, interval, and intensity of stimulation needed to optimize results of this therapy, but it may be most useful in conjunction with other therapies. Studies regarding this therapy are ongoing.

CONCLUSIONS

Fecal incontinence is a common problem that is often underreported because of its stigma. Evaluation tools include validated scoring systems to quantify symptom severity, anorectal ultrasound, and anorectal physiology testing. Medical management can often provide significant improvement in symptoms. Surgical management depends on the underlying pathophysiology. Current options that have been proven to be most effective at treatment of symptoms include SNS, sphincteroplasty, and diversion.

Rectovaginal Fistula

Eric G. Weiss, MD, and Emanuela Silva Alvarenga, MD

Rectovaginal fistulas (RVFs) are extremely life altering for women who develop this condition, but thankfully it is not common. Regardless of the low incidence, RVFs are vexing problems both for physicians and patients. Expertise in evaluation and management is often needed yet is rarely available in the communities where the patients live and often requires tertiary referral if a patient is not initially being managed in such a center.

Patients can present with a multitude of signs and symptoms, from minor drainage to flatulence via the vagina to frank stool leaking out of the vagina. One can imagine the psychological impact this has on a women's self-image and relationship with her significant other and impact on work life and quality of life overall.

Most series of repairs are small, single-institution procedures and often are limited in the types of procedures performed. In addition, RVF classification varies, and treatment by procedure type is often linked to the fistula classification or its etiology.

This chapter will focus on a variety of repairs and a stepwise process to determine which repairs may be appropriate for which RVFs in the hopes that the most favorable outcomes and least morbidity can be achieved.

ETIOLOGY AND CLASSIFICATION

There are three main etiologies for RVFs: obstetric injury, cryptoglandular sepsis, and Crohn's disease. Each etiology tends to form the fistula by different means, and the locations, other associated injuries, and treatment options vary as a result of these and other factors. Less common but more difficult to manage are those formed as a complication of radiation therapy or following anastomotic complications related to colorectal surgery with stapled anastomoses that have leaked.

Obstetric injury is the most common etiology, typically resulting from an episiotomy or a third- or fourth-degree tear. These fistulas can occur in the immediate postpartum period or can present several weeks to months later with failure of laceration repairs or episiotomy repairs. These are often associated with anterior external sphincter muscle defects and at times clinical fecal incontinence.

Crohn's disease involving the anal canal and/or rectum can lead to a RVF by poor control of the underlying disease resulting in a full-thickness penetration of the Crohn's disease and fistula into the vagina. Often these are associated with some degree of anal stenosis and other perianal manifestations of the underlying Crohn's disease.

Other etiologies as mentioned earlier have a variety of locations, sizes, and factors associated with them depending on which etiology is responsible for formation of the fistula.

Classification can also be useful in planning repairs. Classification is based on several factors including etiology, location, and underlying conditions. Simple fistulas tend to be low in relation to the sphincter mechanism, caused by obstetric or iatrogenic injury, and smaller than 2.5 cm in diameter. Complex fistulas are larger, located higher in the vagina, and associated with other underlying diseases or mechanisms such as radiation therapy, inflammatory bowel disease, or colorectal or gynecologic cancers (Box 1).

EVALUATION

The clinical evaluation, classification, appropriate workup, and multidisciplinary approach is important and should allow for the most optimal control of symptoms before repair and ultimately the most favorable outcomes following surgical management.

A thorough history is required. The timing of the development of the fistula to the inciting event should be well documented because regardless of the type of repair that is appropriate, it is usually necessary to wait an obligate amount of time from the initial event. Obtaining prior operative reports, delivery reports, treatment notes, and prior diagnostic studies is optimal. Obtaining images and not only reports allows for review with radiology and comparison to any future studies. Documenting the patient's current and prior bowel function, continence level, and sexual function is important.

Physical examination in the office should be performed but may be limited as a result of patient discomfort or pain. Visual examination of the perianal skin, anal verge, and vaginal introitus should be performed in all patients. The condition of the skin, any incisions, any secondary fistulous openings, if the anus is patulous, and any readily

identifiable drainage or stool should be noted. Next, a digital vaginal and rectal examination should be performed if possible. Determining the quality of the rectal and vaginal tissue and site of the fistula may be possible. Anoscopic examination and vaginal speculum examination may also be possible in the office. If any of the aforementioned physical examinations cannot be performed in the office, then it may be appropriate to perform an examination under anesthesia either in the operating room or in the endoscopy suite. Ultimately knowing the anatomy of the fistula tract and levels and size of the fistula are mandatory in classification and for surgical planning.

Adjunct procedures including flexible sigmoidoscopy or colonoscopy, contrast enemas, pelvic magnetic resonance imaging (MRI), or computed tomography (CT) may all be necessary. Evaluation of the sphincter muscles with endoanal ultrasound may be useful if there is concomitant fecal incontinence. For patients with Crohn's disease, understanding the distribution of disease with magnetic resonance enterography (MRE) or computed tomography enterography (CTE) may also be required, and communicating with their treating physician about their current medical management may be important and may influence their surgical plan, particularly if they are on steroids or biologics.

Once a surgical plan is decided upon, a thorough discussion and informed consent should occur with realistic outcomes and expectations being discussed. Emphasizing the complex nature of these fistulas, the difficulties in some operations and the less than 100% success rates should be fully discussed.

ABDOMINAL APPROACHES

Abdominal approaches are typically used for higher RVFs, those associated with anastomotic etiologies, and those in which local tissue loss of the rectum and vagina are not amenable to local procedures for repair and reconstruction. Often, the rectum as it is at the time of diagnosis is unsuitable for a local repair because of a concomitant stricture or chronic leak or sepsis in addition to the known RVF. Thus, resection and reanastomosis are required. This most commonly results from fistulas caused by anastomotic leaks that initially form a pelvic abscess and drain into the vagina for decompression. Alternatively, mobilizing the rectum during proctectomy can devascularize the posterior vaginal wall, or a portion of the vaginal wall can unfortunately be incorporated into the staple line during stapling, leading to a RVF.

Regardless, once the decision to perform an abdominal approach has been reached, specific considerations for the conduct of the surgery to minimize complications and appropriate discussion and informed consent is necessary to set reasonable expectations. As this is likely reoperative pelvic surgery, timing of abdominal reentry is important. A minimum of 3 months and at times 6 months or more should be the waiting time before attempting a redo-anastomosis with takedown/closure of the fistula. One does not want to get into the situation of a hostile abdomen, multiple enterotomies, or worse, an aborted procedure. Ureteral stent placement should be strongly considered. Liberal use of a diverting ileostomy with appropriate preoperative counseling and stoma marking should be utilized.

Although minimally invasive approaches may be attempted and at times completed, often conversion to laparotomy or an initial plan for laparotomy may be made. As long as there is a well-thought-out plan and specific situations leading to conversion before complications, it is appropriate to approach in this fashion. The approach regardless is to initially either develop adequate working space if minimally invasive or full entrance in the abdomen if via laparotomy. Once that is accomplished, the next step is to get everything out of the pelvis except the colon/rectum heading down to the fistula and anastomosis. Once this is achieved, the next step is to get back into the pelvis. Often this is best approached by going posterior and into the presacral plane, going distal to the anastomosis and fistula, and then coming around laterally and anteriorly with the colon or rectum now only attached to the vagina. Next is separating the fistula, which at times leads to larger defects in the colon, rectum, and/or vagina. Once the fistula is divided, than one needs to get to healthy rectum below that level. Once that is achieved, then one can redivide the rectum distally. This typically requires a small TA type stapler such as a TA-30/45 or Contour stapler. Once stapled and divided, the colon or rectum above the anastomosis or fistula can be brought out of the pelvis. Next, adequate reach for a tension-free colorectal or coloanal is necessary. This may require division of the inferior mesenteric artery and vein, full mobilization of the splenic flexure, and at times more complex maneuvers such as derotation or the creation of an ileal mesenteric window. If technically possible, closure of the vaginal opening should be performed but may not be possible. At times, repairing transvaginally may be necessary as opposed to transabdominally, depending on exposure. Consideration of having gynecology available might help mitigate the difficulties in performing the closure transvaginally. Adequate blood flow can be assessed in traditional ways, but consideration for indocyanine green (ICG) angiography should also be utilized liberally. Once the stapled anastomosis is performed, flexible endoscopy with air leak testing and assessment should be performed. Based on the results of the endoscopy, conduct of the surgery, blood loss, patient stability, and the patient's ability to tolerate an anastomotic leak, a proximal diversion with a loop ileostomy should be considered. Typically, prior radiation therapy, an anastomosis less than 4 cm from the anal verge, or a less than ideal anastomosis should be diverted.

Consideration for omental pedicle interposition should always be considered at this point. If adequate omentum is present, it can be made into a pedicle based on the right or left gastroepiploic vessels and then brought down into the pelvis anterior to the anastomosis and posterior to the vaginal defect/repair to act as a physical separator, keeping the repair and anastomosis separated. There are multiple methods of securing the flap within the pelvis, but often it will stay in place just based on the narrowness of the distal pelvis and interposition within the rectovaginal septum.

PERINEAL APPROACHES

Transanal Fistulotomy

Transanal fistulotomy entails the direct opening of the entire fistula tract. This method is preferably indicated for superficial fistulas and should be performed after the fistula tract is well defined by the

local fibrosis. This is normally promoted by a pretreatment period of draining seton once the local infection has been treated and the tract has matured. In the operating room setting, the seton is removed, and the residual fistula tract is curetted and cut open.

The procedure results in high rates of a long-lasting fecal incontinence, likely caused by a combination of the violation of the anterior anal canal, where sphincter muscle is sparser, and a resulting deforming wound defect.

Despite its theoretical indications, the transanal fistulotomy has fallen out of favor for the management of RVFs.

Endorectal Advancement Flap

The endorectal advancement flap (ERAF) is the most standard treatment for low-lying simple posttraumatic RVFs. It is a compelling approach, especially when there is a concern for fecal incontinence as it does not cause any surgical division of the external sphincter muscle.

Advancement of the anterior rectal wall with the aim to obliterate the internal opening by sliding a flap of healthy rectal wall consisting of mucosa, submucosa, and a circular muscle from proximal to cover the opening and suture it into place was first described by Noble in 1902 and since then has been extensively reported with slight modifications.

Preoperatively, patients undergo bowel preparation with either oral mechanical bowel preparation the night before the surgery or two sodium phosphates enemas the morning of the surgery.

The patient is placed in the jack-knife prone position over a Kraske roll. The buttock is taped widely apart, and the patient is prepped and draped in normal sterile fashion. Exposure can be further optimized by effacing the anus with the use of a Lone-Star retractor. A lighted Hill-Ferguson retractor or a Pratt bivalve anoscope is placed into the anal canal to expose the anterior rectal wall. The fistula tract is identified and assessed by a probe passed from the vaginal side. Using Bovie electrocautery, a U-shaped flap is outlined with its apex sited distally to the location of the fistula. The rectal wall is incised through the mucosa, submucosa, and down to the internal sphincter for a partial-thickness flap. The base of the flap should be two to three times as wide as the apex to ensure adequate blood supply of the flap. Care should be taken to avoid making a hole in the repair. The flap is raised for a distance sufficient to allow tension-free anastomosis, normally 4 to 5 cm. Once the flap is created, the fistula tract is debrided and closed by approximating the fibers of the internal sphincter. Additional mobilization might be required to allow to the edges of the internal muscles to be sutured over the fistula opening. The closure is performed in one or two layers using interrupted 2-0 Vicryl sutures. After hemostasis is reassured, the distal end of the flap containing the fistula is trimmed, and the healthy flap is anastomosed distally (Fig. 1). The vagina side is left open for drainage.

The addition of a biologic graft to reinforce the rectovaginal repair has been described by some surgeons. A manufactured

porcine small bowel submucosa is sized accordingly and employed in the rectovaginal space, with the flap sutured over the graft.

The overall success rate for ERAF for RVF is short term. It ranges widely in the literature from 29% to 93%. Most publications are made up of heterogeneous series of varying sizes, with mixed complex and simple fistulas and diverse closure techniques including ERAF alone or in combination with other approaches.

Flap failure is a dreaded complication. The most common cause for flap failure is retraction of the anastomosis, ischemia, and consequent necrosis with dehiscence of the anastomosis leading to flap loss and a potentially larger rectal defect after surgery.

Flap loss within 7 days is considered early failure and has been reported to be up to 6%. Late flap loss/failure rates range from 16% to 37%. Hence, enough flap mobilization for a tension-free anastomosis is paramount. Crohn's disease, complex fistula, and recurrent fistula and prior failed attempts at fistula repair are a risk factor for ERAF failure. Main contraindications to the ERAF include active Crohn's disease, acute anal abscess, and scarred or stenosed anorectum.

If an associated sphincter defect is present and a concomitant sphincter repair is performed, the success rate of the ERAF for RVF is higher and has been found to be as high as 100% in a small series of patients with obstetric low RVFs by Chew et al.

All women with an obstetric-related RVF should undergo evaluation for occult sphincter injury.

Fibrin Glue

The injection of fibrin glue can be performed for low RVFs with an intact rectal sphincter complex. The procedure is performed in the operating room. After the fistula tract is debrided, a fibrin adhesive is injected into the fistula tract until it exits the secondary opening. The theory is that the glue seals the fistula while also promoting fibrous tissue ingrowth and subsequent fistula healing without violating anorectal anatomy. Although this procedure does not threaten continence and causes minimal disruption to tissue planes, reported healing rates less than 60% have been frustrating enough to cause the fibrin glue to have a very limited place in the management of RVFs. The advantage is that potential future repairs are possible (Bhama et al., 2019).

Fistula Plug

The currently available fistula plug is made from lyophilized porcine intestinal submucosa, (Surgisis Biodesign Button; Cook Surgical) which provides a matrix for ingrowth of connective tissue. As for the fibrin glue application, the fistula tract is first curetted, the plug is prepared as per manufacturer recommendations, and with the guidance of a suture tied to the tip of the plug, the plug is passed from the rectum to the vagina until it is snug in the tract. The plug is the then sutured to the rectal mucosa. The excess fistula plug is trimmed flush to the opening at the vaginal side and sutured or not sutured to it; both ways have been described (Fig. 2).

The plug is costly, and there has not been enough experience with this technique. Reported results are extremely variable, with some series reporting an over 75% failure rate.

Like the fistula glue, the fistula plug carries very low complication rates with preservation of sphincter function and no violation of the perineal planes, however it is rarely performed.

TRANSVAGINAL REPAIRS

Transvaginal Approach Vaginal Advancement Flap

This approach is more extensively described in the gynecologic literature. In this instance, a flap is created in the vaginal wall instead.

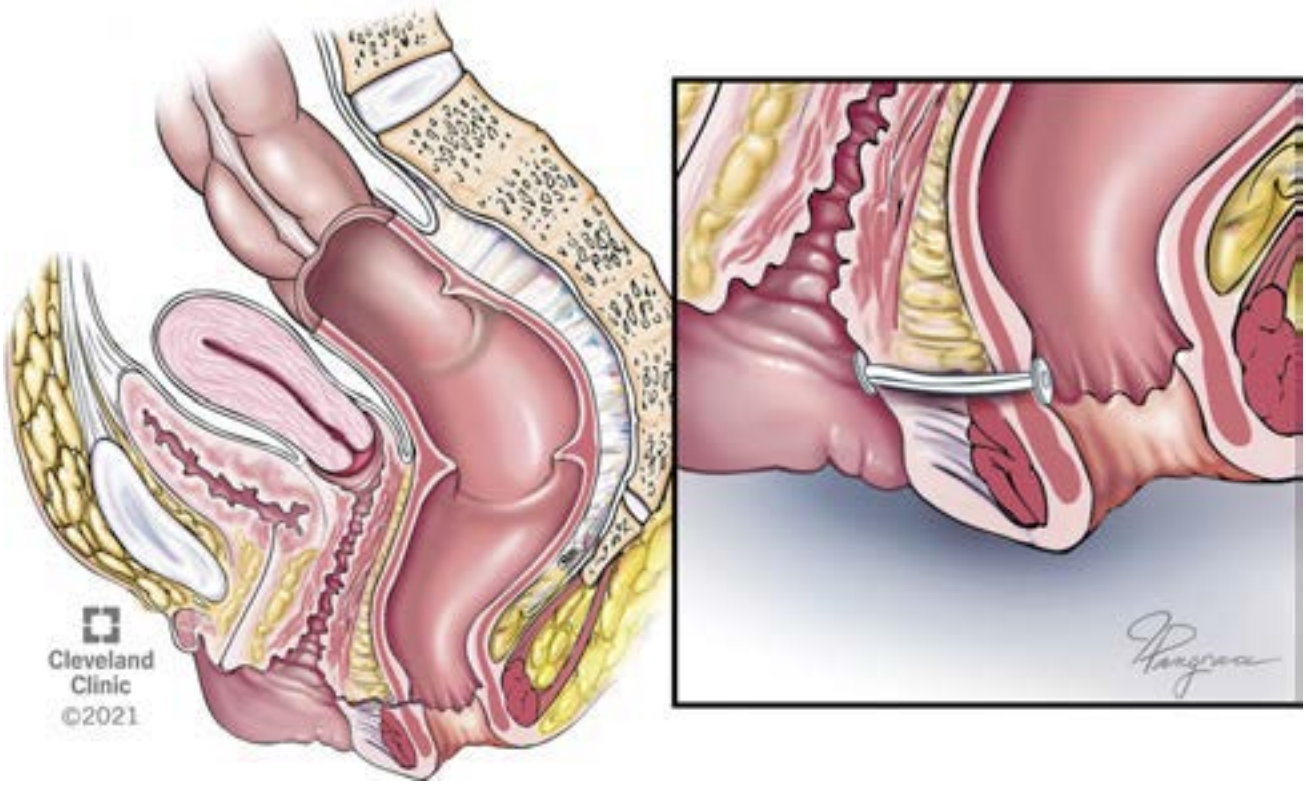

FIG. 2 Fistula plug. Plug placement within the rectum and the vaginal openings. (From Cleveland Clinic Center for Medical Art & Photography. Copyright 2021. All Rights Reserved.)

Supporters of this procedure emphasize optimized access and ease when mobilizing the flap and closing the opening of the fistula from the vaginal aspect compared with the transanal approach. They also claim a better-quality flap with well-vascularized vaginal tissue.

As the rectal advancement flaps, a flap of the vaginal mucosa is raised, the fistula tract is resected, the apex of the flap is trimmed to excise the fistula opening, and it is sutured into position to close the wound. An important technical aspect with this method is that the rectal mucosa still should be repaired. Because the rectal side constitutes the infected, high-pressure side of the fistula, failing to address the rectal mucosa significantly decreases the chances of a successful repair. The rectal wall is typically closed with interrupted absorbable sutures.

Despite published satisfactory success rates and described technical advantages of the approach, the transvaginal repair has been less commonly used than the ERAF. This is perhaps because of the theoretic possibly of increased pressure from the rectal side or an ongoing infection process compromising the vaginal flap.

A transvaginal advancement flap may be a good option when the rectal mucosa is diseased, such as in Crohn's disease, or when an ERAF has previously failed. Small series have reported a transvaginal flap for Crohn's-related RVF, with a success rate up to 93%, with fecal diversion.

Bhome et al. described a flapless transvaginal technique for the repair of primary and recurrent low- and mid-level RVF of varying etiology in which the fistulotomy and the closure of the rectum is performed from the vaginal side followed by closure of the rectovaginal septum and vagina. The authors reported 15 cases of RVF. The healing rate was 67% in a median follow-up of 48 months. Seven patients had fecal diversion. They concluded that the method was a safe, effective, faster, and technically less challenging alternative to ERAFs.

Transperineal Repairs

Most of the transperineal approaches are accomplished by a transverse or circumlinear incision made over the mid portion of the perineal body, dissection of the rectovaginal septum, division of the RVF tract, closure of the fistula openings in the rectum and vagina, and layered closure of the incision. These approaches include the transperineal repair with levatorplasty, ligation of the intersphincteric fistula tract (LIFT), and sphincteroplasty. The episioproctotomy is a transperineal approach in which a fistulotomy is carried out with transection of full-thickness of the perineal body followed by subsequent sphincter repair.

Transperineal Ligation with a LIFT Procedure

The LIFT procedure has been performed for management of transsphincteric fistulas-in-ano with acceptable success rates. More recently, the technique has been incorporated as an alternative for treatment of RVFs. The fistula tract is identified with use of a fistula probe, and a transverse or semi-circumferential incision is performed at the mid-portion of the perineal body. Then the subcutaneous tissue is dissected toward the intersphincteric groove, and the intersphincteric plane is entered and mobilized from the rectal mucosa posteriorly through approximately one-third of the circumference of the anus and rectum. The fistula tract is isolated and completely transected in this plane. The dissection extends in the rectovaginal septum 2 to 3 cm proximal to the fistula. The fistula openings in the mucosa of the rectum and vagina are closed or imbricated with interrupted, absorbable sutures. A bioprosthetic graft can be interposed in the intersphincteric plane and is advocated by some authors. Benefits of this method include its low impact on fecal continence and low complication rates. Sphincteroplasty can be combined if there is an associated sphincter defect. An ERAF can be included depending on the state of the rectal wall (Fig. 3).

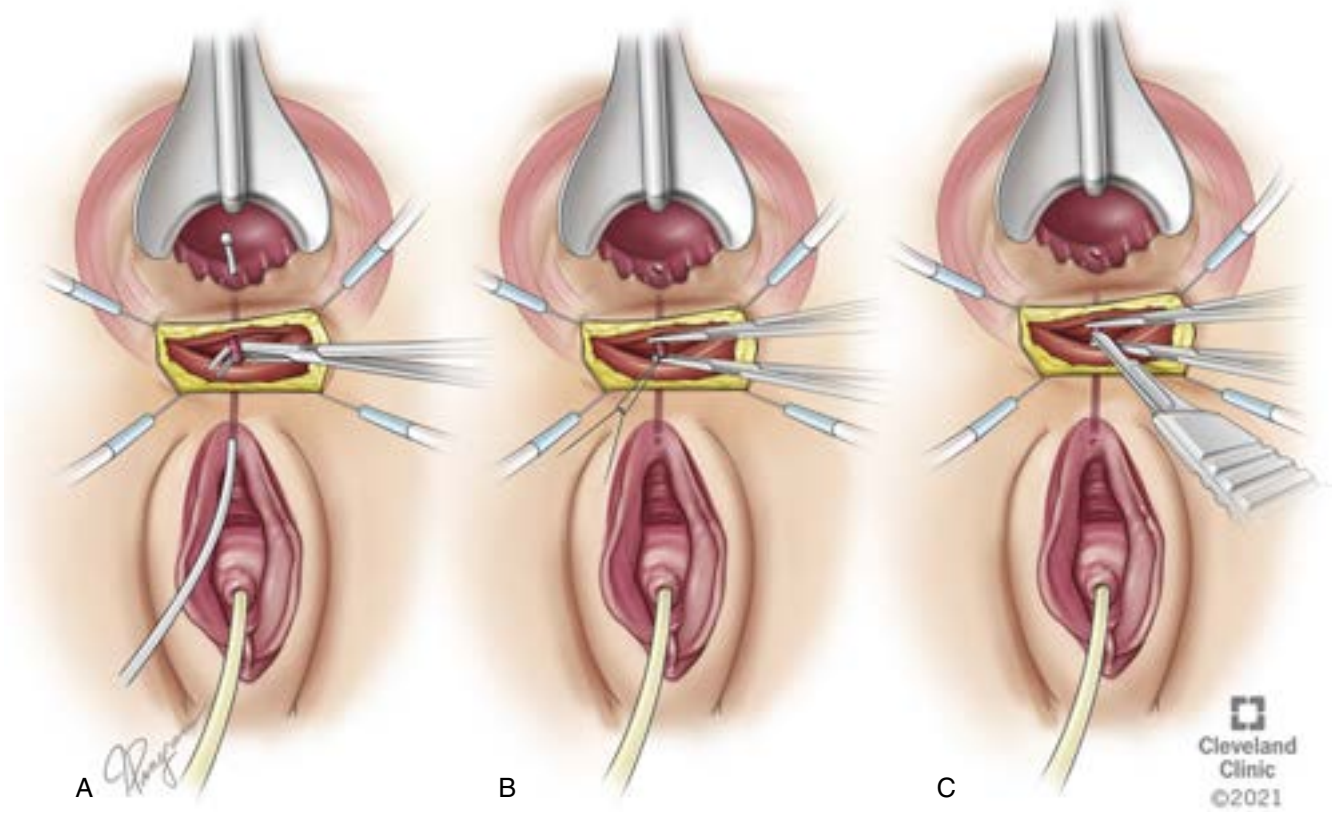

FIG. 3 Ligation of the intersphincteric fistula tract (LIFT). (A) Probe illustrating the rectovaginal fistula tract. **(B)** Closer view of the dissection of the fistula tract at the intersphincteric plane. **(C)** The fistula tract is completely transected in this plane. (From Cleveland Clinic Center for Medical Art & Photography. Copyright 2021. All Rights Reserved.)

There is still no robust experience with LIFT for RVF, with or without bioprosthetic material. Published success rates from a paucity of studies range from 57% to 94%. Ellis et al. published the only series assessing the use of bioprosthetic material added to the LIFT procedure in 27 patients. In this study, an undetermined number of patients underwent concomitant sphincteroplasty. Healing occurred in 81%. Long-term, comparative, randomized controlled studies are needed.

Overlapping Anterior Sphincteroplasty

For patients with RVF who have a palpable sphincter defect and a thin anovaginal septum, an overlapping anterior sphincteroplasty is indicated.

After entering the rectovaginal septum, lateral dissection is undertaken to identify the edges of the external anal sphincter. The scarred edges are grasped with an Allis clamp, and the dissection continues laterally along the external sphincter, until the edges are mobilized enough to come together. To avoid injury to the pudendal nerves bilaterally, care must be taken not to dissect too far laterally. The ends of the external sphincter are then overlapped for 1 to 2 cm and sutured together using a delayed absorbable suture. The incision is then closed in layers, with the medial portion left open for drainage. Patients must avoid straining and hard stools in the postoperative period, which may lead to early failure of the repair.

As described earlier in this chapter, the success rate of the ERAF combined with sphincteroplasty for RVF caused by obstetric injury is higher and has been found to be as high as 100%.

Episioproctotomy

In this technique, the rectum and vagina are separated from one another, the fistula tract is divided, and all tissue between the rectum and vagina is split through the perineal body, converting the fistula into a complete perineal laceration. Next, the vaginal wall is dissected from the perineal body, the rectal mucosa is closed in layers by approximation of the internal and external sphincters, and perineal body reconstruction is performed with or without an interposed muscle between the rectum and vagina with a levatorplasty or sphincteroplasty (Fig. 4). The combined methodology technique is especially suitable to obstetric-related fistulas associated with an extensive sphincteric defect with incontinence as it addresses both issues.

The overall success rate for this technique ranges from 70% to 88% in the literature, with described restoration of continence in 70% to 98% (Khanduja et al.) and significant improvement in both defecatory and sexual function in comparison with ERAF (Hull et al.). The combined interposition of biologic grafts has been described, with a success rate of 80% (Ellis et al.).

The downside of this procedure is that is creates a much larger wound, which can result in a larger fistula with worse incontinence, should the repair fail. Therefore, this procedure should only be performed by or with the assistance of experienced surgeons.

Transperineal Stapled Repair

Lately, a novel procedure utilizing a transperineal stapled transection of the RFV fistula was published in seven patients with RVFs of various etiologies, excluding Crohn's disease and malignancy. The authors performed a concomitant levatorplasty in four patients and sphincteroplasty in two patients. Two patients had a stoma. Their preliminary results reported no recurrence, no complications, and 100% satisfaction rate in a median follow-up of 6 months (range 3–33 months) (Lin et al., 2019).

Interposition Flaps

The gracilis muscle and bulbocavernosus (Martius) flaps are the two most popular pedicled flaps for RVFs. Other flaps have been described but never gained popularity. Those include gluteoplasty with bilateral tongues of the gluteus maximus and Lotus flap, a fasciocutaneous flap that is raised on perforators around the perineum, mostly described in the gynecologic literature.

The interposition of healthy, substantial tissue between the rectum and vagina confers the highest success rates of all transperineal repairs. The bulk added to the rectovaginal septum also increases the distance between the rectum and vagina. The morbidity related to these repairs is not high but includes wound healing complications, pain, dyspareunia, and undesirable cosmesis, particularly with gracilis interposition. Yet for the gracilis muscle interposition, caution is recommended in patients with muscle atrophy, myopathy, or impaired mobility.

These are complex operations, typically performed in tertiary centers by a surgeon with expertise on the technique. Fecal diversion is usually recommended, and most patients had previously undergone fecal diversion because of various prior failed repairs.

Gracilis Muscle Transposition

Gracilis muscle is a resourceful, well-vascularized tissue for perineal reconstruction because of its long length, substantial bulk, and single proximal neurovascular pedicle in most patients. The patient is placed in the Lloyd-Davies position using Allen stirrups or, alternatively, in a frog-leg position with a sterile bump under the knee. The groove between the gracilis muscle and the sartorius muscle is identified in either thigh. Approximately 2 cm above the knee joint, a 4-cm longitudinal incision is made, and the dissection is deepened through the subcutaneous tissue to expose the fascia overlying the tendon of the gracilis muscle. Then fascia is incised, and muscle is mobilized until all perforating vessels are identified. The perforating vessels can be divided and ligated between clamps or with ultrasonic shears or a bipolar cutting instrument. A tunnel under the fascia is created by blunt digital dissection that is gently continued as proximal as possible, with care to stay superficial to the muscle. Next, a second incision is made immediately proximal to the apex of the tunnel, approximately at the mid-medial thigh, immediately posterior to the saphenous vein from 4 to 8 fingerbreadths distal to the anterior superior iliac spine. The fascia is incised, and the muscle is dissected free in a similar fashion. The tendon is subsequently divided distally, and the distal muscle is delivered to the proximal incision.

Another incision is made at a higher level at the top of the thigh. The gracilis muscle is exposed and dissected free to the level of the proximal neurovascular pedicle. Sufficient blood supply is ensured, and sufficient length to reach the perineum is assessed. Following, a tunnel is made from the upper aspect of the upper incision and dissected. The tip of the tendon is exteriorized at the ipsilateral edge of what will become the perineal incision and then securely sutured to the skin. The patient is repositioned in the prone jack-knife position with the thighs fixed. The dissection is initiated with a 5- to 7-cm anterolateral circumanal incision made through the perineal body and deepened into a plane between the subcutaneous and superficial portions of the external anal sphincter and the vagina. Once adequate wide cephalad and lateral mobilization into soft areolar tissue in all directions is accomplished, the edges of the fistula are resected to leave soft and viable tissue for further closure of the fistula. Both the rectal and vaginal sides can be closed directly or with an advancement flap. The muscle is then secured to the apex of the dissection with interrupted Prolene sutures (Fig. 5).

The wound is copiously irrigated. A 15-Fr drain is placed into the bed of the gracilis muscle harvest and secured to the skin using silk suture. A 10-Fr drain is placed through a separate stab incision along the muscle and into the perineal sinus. The perineal incision is closed

using several layers of 2-0 Vicryl suture. All incisions over the thigh are closed with staples.

Healing is assessed by proctoscopy and a water-soluble contrast enema approximately 3 months after surgery. In the absence of a residual or recurrent fistula on the aforementioned studies, an examination under anesthesia is undertaken with anoscopy and probing. If necessary, additional procedures are performed to obtain complete healing of the fistula. When the fistula is no longer identified, the stoma is closed.

Success rates range between 33% and 100% for RVF repair of all etiologies and between 47% and 92% for RVF repair of obstetric etiology.

Bulbocavernosus (Martius) Flap

Dr. Heinrich Martius first described a flap consisting of a pedicled, bulbocavernosus, muscular fat pad graft from either labia majora based on the perineal branch of the pudendal artery. It has been used for a long time by gynecologists and urologists for treatment of uretherovaginal fistulas and later adopted by colorectal surgeons for the repair of low, complex RVFs.

First, the flap is harvested through a longitudinal incision over the labia, and the bulbocavernous muscle is mobilized from the labia with care not to injure the vascular pedicle. Next, the rectum and vagina are separated through a transperineal incision at the vaginal introitus, the fistula is divided, and both the rectum and vagina are closed primarily. A subcutaneous tunnel is created up to the rectovaginal septum, and the graft is placed into the septum and secured in place with absorbable sutures, ensuring that the vascular pedicle is not twisted. The labia and the perineum incisions are then closed (Fig. 6).

To date of this publication, the largest series published included 23 patients with a reported healing rate of 65% (Pitel et al.). In this series, 70% of patients had a diversion stoma. Success rates from smaller series are 65% to 100% (Kniery et al.).

Anal Condyloma

Edward P. Hagen, DO, and Raman Menon, MD

OVERVIEW

Condyloma acuminata, commonly known as *anogenital warts,* is one of the most common sexually transmitted diseases in the United States. It is caused by the highly contagious human papilloma virus (HPV), which infects squamous epithelia. HPV is a small, nonenveloped, double-stranded DNA virus from Papovaviridae family. The incubation period ranges from 3 weeks to 8 months. Most infections are transient and are cleared within 2 years.

There are over 120 distinct HPV subtypes, of which approximately 35 types target the anogenital epithelium and have varying malignant potential. High-risk (oncogenic) types are 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68, 69, and 82. Low-risk (nononcogenic) types are 6, 11, 40, 42, 43, 44, 54, 61, 72, and 81. Ninety percent of condyloma harbor HPV types 6 or 11. HPV types 16, 18, 31, 33, and 35 are occasionally identified in condyloma and are often a coinfection with subtypes 6 or 11. Growth patterns range from focally grouped diminutive warts to large and exophytic carpet-like lesions.

INCIDENCE

An accurate incidence of condyloma acuminata cannot be obtained because the size of the population at risk is unknown and because many cases are likely to be undiagnosed or subclinical. It is estimated that there are 500,000 to 1 million new cases of genital warts annually in the United States. In the United States, 24 million people are currently infected with HPV. Although condyloma affect both genders, recent data reveal that women accounted for 67% of the patient population.

RISK FACTORS

HPV is highly contagious and mostly transmitted through sexual activity. Unprotected vaginal, anal, and oral intercourse along with intercourse at a younger age are risk factors for transmission. Transmission from mother to child during delivery can also occur. Risk factors for development of condyloma include immunosuppression caused by HIV or transplantation, use of injectable drugs, cigarette smoking, and diabetes. Recent data have suggested that African Americans are at increased risk for larger lesions at time of diagnosis, resulting in more frequent need for surgery.

PATHOGENESIS, PRESENTATION, AND DETECTION

HPV invades and infects the basal keratinocytes of the epidermis. The general appearance of condyloma range from small solitary flesh-colored plaques to distinct 1- to 2-mm flesh-colored papules that occur in large clusters (Fig. 1).

The symptoms of infection may vary depending on the number of lesions and their location. The most common sites of occurrence are the perianal skin, anal canal, and genital region. Patients with a small number of warts may be asymptomatic. Other patients, especially those with larger disease burden, may have pruritus, bleeding, burning, tenderness, discharge, or pain. Larger exophytic masses can interfere with defecation, intercourse, or vaginal delivery. Lesions involving the proximal anal canal may also cause stricture.

The lesions are often easily visualized during physical examination of the external anal skin in the office. The extent of involvement should be documented by physical examination and anoscopy, sigmoidoscopy, colposcopy, and/or vaginal speculum examination, as indicated. Application of 5% acetic acid causes the lesions to turn white and can aid with identification. Other lesions may also resemble anal condyloma, and the differential diagnosis

includes benign skin tags, hypertrophic anal papillae, molluscum contagiosum, seborrheic keratoses, hypertrophied sebaceous glands, condylomata lata (secondary syphilis), dysplastic nevi, and anal cancer. A biopsy with histopathologic analysis will confirm the diagnosis.

MANAGEMENT OF ANAL CONDYLOMA

The management of anal condyloma is individualized to the patient and predicated on the size, number, anatomic distribution, and presentation of the lesions. Spontaneous resolution of condyloma has been reported, but most patients require intervention. The goal of treatment is complete destruction of all condyloma, understanding that the underlying viral infection may persist. The choice of medical management, outpatient office treatment, or treatment in the operating room, in our opinion, is based on whether it is an initial outbreak or recurrent disease, the number and distribution of the lesions, and the presence or absence of intraanal lesions (Figs. 2 and 3). There is no evidence to suggest that one treatment is significantly superior to another, and patients should be counseled in advance that recurrence is common and generally occurs within the first few months after treatment. A summary of common treatments is listed in Table 1.

FIG. 1 Anal condyloma.

We have found that managing the initial presentation in the operating room under conscious sedation allows for excellent results. This allows for careful inspection of the perianal skin and anal canal and identification of all lesions with or without the use of counterstaining with acetic acid. Additionally, excision of representative samples from all quadrants with submission for pathologic examination can confirm the putative diagnosis and identify potential patients who may have a high-grade squamous intraepithelial lesion (see further discussion later). Electrocautery fulguration of the remaining condyloma is the mainstay in addressing small to moderate lesions. Use of needle-tip cautery is very useful as it can more precisely target the remaining small condyloma with decreased damage to the surrounding tissue. In this manner, the lesions are fulgurated, first turning white and then forming an eschar that can be removed with a curette. What may appear to be a large carpet of numerous condyloma can be treated in this fashion as the condyloma often have a narrow base, and islands of normal perianal skin can be identified between them. This approach has been shown to be safe and without significant risk of anal stenosis, even with confluent condyloma. One recent small study suggested that argon plasma treatment may be more effective at decreasing relapse in HIV-positive patients, however there can be viable virus in the smoke plumes, which in theory presents a higher risk of transmission to the exposed treatment team.

On rare occasions, one may encounter carpeting of condyloma with a wide base and minimal to no intervening normal perianal skin. In this circumstance, we recommend staging the treatment of the lesions to minimize anal scarring and stenosis. Such patients benefit from treatment in the operating room, where only half the perianal skin is treated and allowed to heal before returning in 3 to 4 weeks to treat the other half.

After clearance of all lesions in the operating room, close office surveillance is critical. Typically, recurrence is limited to a few lesions, which are amenable to topical treatment by the physician in the office or by the patient at home. Trichloroacetic acid (TCA) is a keratolytic and chemically cauterizes the skin. It can be applied very precisely in the office with a small cotton-tipped swab with minimal damage to the surrounding normal skin (see Fig. 2). The most commonly used self-administered topical treatments are imiquimod and podofilox. The best approach to recurrence may be a combination of ablative therapy and topical therapy, with reduced recurrence of condyloma when imiquimod was used as an adjunct to conventional ablation. Recent data suggest that refractory intraanal condyloma in particular may benefit from combined therapy with imiquimod and ablative methods.

FIG. 2 Treatment of anal condyloma before **(A)** and after **(B)** treatment in office with trichloroacetic acid.

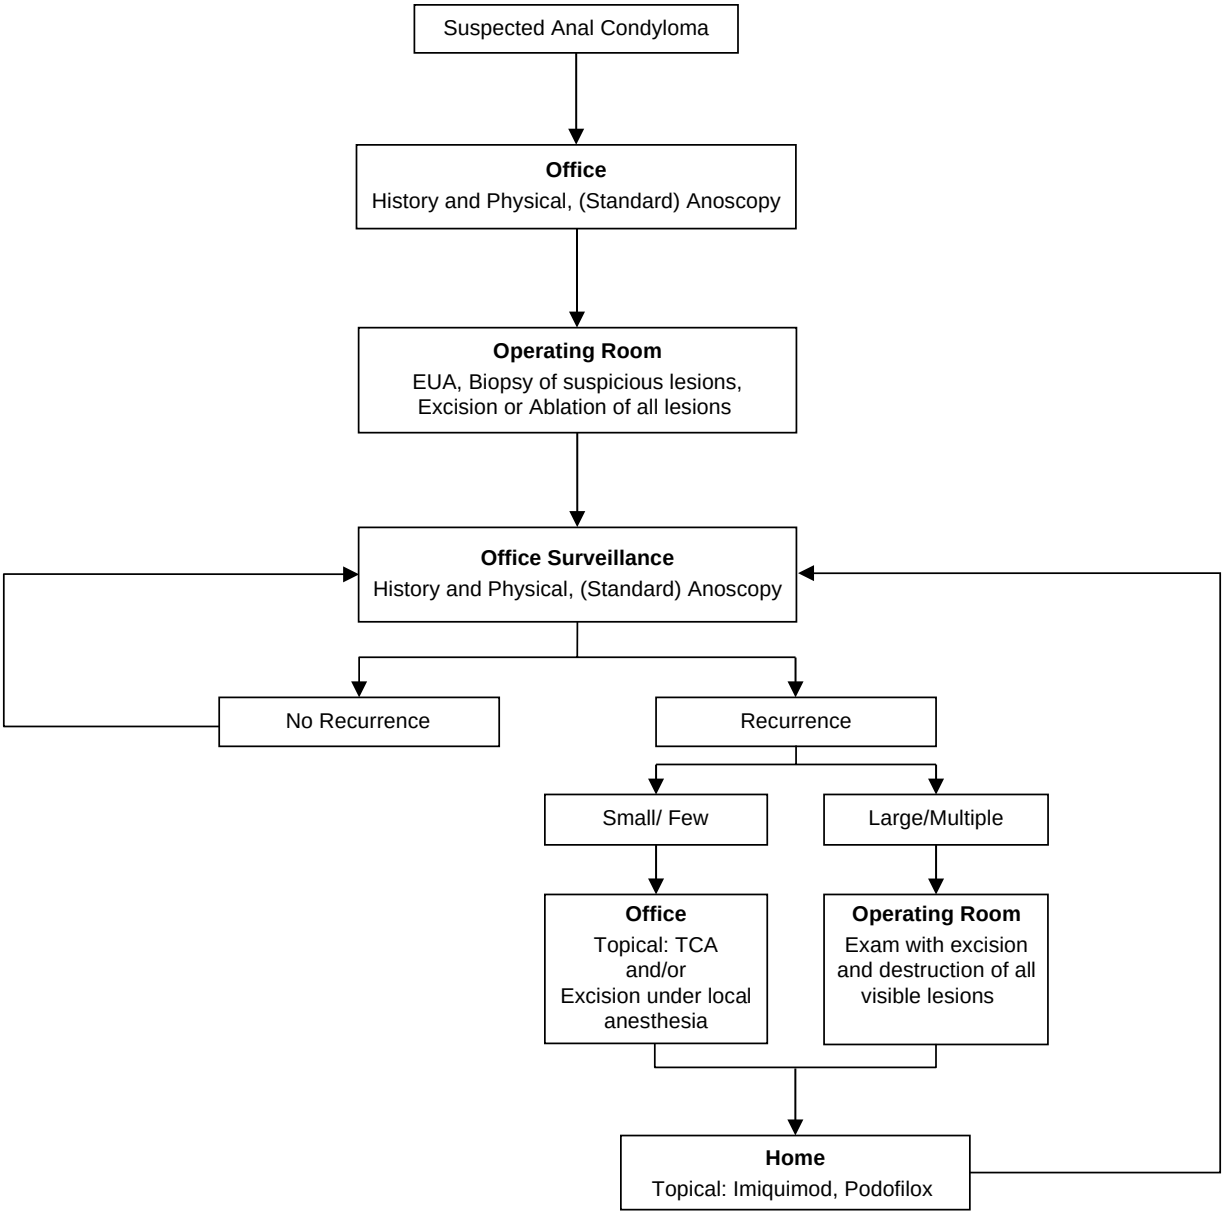

FIG. 3 Treatment algorithm for anal condyloma.

Future treatment may include "therapeutic vaccination" in which a fusion protein antigen of the virus is used to generate an immune response targeting infected cells. This minimizes the risk of attacking healthy tissue while enhancing a CD4/CD8 T-cell response. No vaccine has yet been licensed for therapeutic use at this time, but ongoing investigations are underway.

GIANT CONDYLOMA ACUMINATA

Giant condyloma acuminata (GCA) is a rare, poorly-defined condyloma variant. No formal size criteria has been established, though reports in the literature vary from 1.5 to 30 cm in maximum diameter. It was originally described as lacking malignant potential, however it is now believed that up to 50% of GCA may contain foci of squamous cell carcinoma. The disease is characterized by large, slowly progressive, exophytic, ulcerative, cauliflower-shaped tumors that infiltrate adjacent tissue. It affects men more than women and is associated with immunodeficiency, smoking, and multiple sexual partners.

On clinical examination, one may encounter a palpable tumor mass with bleeding, pain, fistulae, and clinical pruritus. Most practitioners recommend operative management with a wide-local full-thickness excision with 1-cm tumor-free margins. In lesions that involve the anal sphincter complex, abdominoperineal resection may be necessary. Adjuvant treatment with chemotherapy and radiation may also be considered in light of the high risk of recurrence.

ANAL SQUAMOUS INTRAEPITHELIAL LESION

The incidence of squamous intraepithelial lesions is increasing. It has been recognized that these HPV-associated anal dysplastic lesions may be the precursor for anal squamous cell cancer, though the exact timing of transformation is unclear. Risk factors for progression

TABLE 1 Common Treatments for Anal Condyloma

Forms of Treatment	Mechanism of Action	Treatment Instructions	Clearance Rate	Recurrence Rate	Side Effects/ Pregnancy
Imiquimod (Aldara) (Patient-applied)	Induction of pro-inflammatory cytokines	5% cream, applied at bedtime and washed off in the morning three times per week (Monday, Wednesday, Friday) for up to 16 weeks	40%–80%	10%–20%	Irritation, erythema, ulceration, pain, burning, edema, induration Pregnancy: Category C
Podofilox (Condylox) (Patient-applied)	Mitosis interruption	0.5% gel, applied twice daily for 3 consecutive days, followed by 4 days without treatment; not to exceed 4 weeks	65%–70%	20%–35%	Irritation, erythema, ulceration, pain, burning, edema, induration Pregnancy: Category C
Synecatechins (Veregen) (Patient-applied)	Unknown	15% ointment, applied three times per day for up to 16 weeks	55%–60%	5%–10%	Irritation, erythema, ulceration, pain, burning, edema, induration Pregnancy: Category C
5- Fluorouracil (Efudex) (Patient-applied)	Mitosis interruption	5% cream applied daily for up to 10 weeks or 1% cream applied twice a day for 2–6 weeks	50%–75%	25%–50%	Irritation, erythema, ulceration, pain, burning, edema, induration Pregnancy: Category X (contraindicated)
Trichloroacetic acid (Tri-Chlor) (Physician-applied)	Chemical cauterization	80%–90% solution applied to lesions while avoiding uninvolved surrounding skin; may repeat monthly	70%–75%	20%–40%	Irritation, pain, burning Pregnancy: Safe to use
Liquid nitrogen (Physician-applied)	Cryoablation	Apply with applicator whitening the surrounding skin; may repeat monthly	70%–75%	30%	Irritation, edema, necrosis, ulceration, pain Pregnancy: Safe to use
Podophyllin (Podocon-25) (Physician-applied)	Mitosis interruption	25% extract applied to lesions once per week to be washed off by patient 4 hours later for up to six treatments; not to exceed 0.5 mL per application	40%–70%	30%–55%	Irritation, erythema, ulceration, pain, burning, edema, induration; systemic absorption may cause fatal side effects Pregnancy: Category X (contraindicated)
Electrocautery (Physician-applied)	Electrocauterization	Target lesions while minimizing damage to normal skin; repeat as needed	60%–90%	35%	Pain, scarring Smoke plumes may contain viable virus and may pose an infectious risk to healthcare provider Pregnancy: Safe to use
Argon laser (Physician-applied)	Vaporization	Target lesions while minimizing damage to normal skin; repeat as needed	80%	30%–50%	Pain, scarring Smoke plumes have been shown to contain viable virus and pose an infectious risk to healthcare provider Pregnancy: Safe to use
Surgical excision (Physician-applied)	Removal by tangential excision	Target lesions while minimizing damage to normal skin; repeat as needed	60%–90%	40%	Pain, bleeding, scarring Pregnancy: Safe to use

include HIV infection, anoreceptive intercourse, transplantation, and a history of cervical or vulvar neoplasia and lesions with HPV-16.

In patients who are at higher risk for malignant transformation, one may consider performing anal cytology akin to the cervical Pap smear. The terminology used in describing cytologic findings is similar to that of the cervical Pap: atypical squamous cells of undetermined significance (ASC-US) and low-grade (LSIL) or high-grade squamous intraepithelial lesion (HSIL). The finding of HSIL or LSIL from either anal cytology or on biopsy of a condylomatous lesion requires further investigation and workup.

There is controversy on the optimal management and surveillance strategy of patients with HSIL or LSIL. The two general approaches to managing these patients are high-resolution anoscopy (HRA) or expectant management (EM). HRA involves careful inspection of the anal canal with a high-resolution microscope after application of acetic acid (with Lugol's solution counterstaining) to identify other putative dysplastic regions for biopsy or ablation. EM involves frequent office examinations with operative excision of any visible lesions. In a recently published single-institution, retrospective, cohort series, Crawshaw et al. analyzed the outcomes for 424 patients with biopsy-proven LSIL or HSIL who underwent either HRA (220 patients) or EM (204 patients). Only 3 patients progressed to anal squamous cell cancer (1 in the HRA group and 2 in the EM group), with all 3 patients being noncompliant with either treatment or follow-up. Our practice has been to follow the EM pathway for these patients.

HUMAN PAPILLOMAVIRUS VACCINE

Human papillomavirus (HPV) vaccination is an effective method to prevent HPV infection. Three different vaccines are available in United States: a quadrivalent vaccine (HPV4, Gardasil) targeting HPV 6, 11, 16, and 18; a 9-valent vaccine (HPV9, Gardasil 9) targeting HPV 6, 11, 16, 18, 31, 33, 45, 52, and 58; and a bivalent vaccine (HPV2, Cervarix) targeting HPV 16 and 18.

In 2019, the United States Advisory Committee on Immunization Practices (ACIP) combined the recommendations for administering the HPV vaccine series (HPV9, HPV4, or HPV2) to males and females. Their current recommendations are that the vaccine is given routinely at 11 to 12 years of age or until 26 years of age if not started previously. These vaccines can be administered as young as 9 years of age. Catch-up vaccination is also recommended for females 13 to 26 years of age who have not been previously vaccinated, and in 2019 they added males to this recommendation.

No data exist regarding the long-term efficacy of administration of the HPV vaccine in the setting of active or previous HPV infection. Some practitioners advocate vaccinating in this setting as it may confer protection against the other HPV strains to which the patient may not have been exposed. Our practice has been to refer high-risk patients to an infectious disease specialist for further discussion.

Management of Pilonidal Disease

Rebecca L. Gunter, MD, MS, Eric K. Johnson, MD, and Scott R. Steele, MD

INTRODUCTION

Pilonidal disease represents a spectrum of disorders ranging from a simple asymptomatic sinus in the skin up to a large, complex open wound with multiple draining sinuses and infection. It is for this reason that the old nomenclature of *pilonidal cyst* or *pilonidal sinus* should likely be replaced by the more appropriate term *pilonidal disease* (PD). The term *pilonidal* is derived from the roots "pilus" (hair) and "nidus" (nest). PD is believed to be an acquired disease related to trapping of hairs in the natal cleft that leads to local trauma and inflammation. It is common, and although it can affect anyone, it is typically seen in hirsute individuals who have deep natal clefts. Elevated body mass index, poor hygiene, prolonged sitting, and excessive sweating may be additional risk factors. Hair type may be a predictor, with some authors hypothesizing that recently cut short pieces of hair more easily insinuate themselves into the gluteal cleft, and others hypothesizing that hair with barbed ends may more easily become trapped in the gluteal cleft and incite PD.

The typical individual presents with drainage or pain in the area of the gluteal cleft. Patients will often have acute abscesses that require immediate drainage. Definitive surgical management in the face of active infection must be discouraged. Simple abscess drainage may be all that is required or may act as a bridge to definitive surgery. Management with oral antibiotics will fail in the setting of acute abscess, but it may be successful in the inflammatory phase before abscess formation. Diagnosis is based largely on history and physical examination and requires no laboratory or radiographic testing. The presence of midline pits in the sacrococcygeal region coupled with drainage, abscess formation, or an open wound all suggest PD, whereas alternative diagnoses of hidradenitis suppurativa, Crohn's disease, anal fistula, and in rare cases neoplasm should also be considered.

TREATMENT

Treatment options range from simple shaving without surgery to wide local excision and complex flap reconstruction. There are many described methods of treatment. It is the belief of the authors that a surgeon should be familiar with three to four methods of surgical management that address the entire spectrum of disease severity and then work to develop expertise in each of them. It is the disease

severity in fact that should drive the method selected for surgical treatment. Although any method could potentially be used in any situation, it would seem inappropriate to do a complex flap procedure such as a rhomboid flap in the setting of very minor disease. Less-extensive methods will lead to optimal outcomes with lower risk in the setting of mild disease.

Nonoperative Treatment

In selected cases of minor disease, nonoperative treatment consisting of shaving and hygiene measures can be quite successful. Older retrospective studies have shown that patients have more favorable outcomes if shaving is used and surgery is avoided. It should be noted that these data are older and were compiled during the era when wide excision with healing by secondary intention was more common. Laser hair removal has been shown to reduce recurrence of PD in cohort studies, but there are no randomized controlled trials to date to support its use. It may also be reasonable to encourage laser hair removal in the setting of minor disease such as primary treatment. The risk is low, but the cost to the patient may be quite high, and this should be considered. Weight loss and avoidance of prolonged sitting may also help minimize symptomatic PD.

Operative Management

We will focus on several procedures. These techniques can be grouped into basic or simple procedures, intermediate procedures, complex flap procedures, and endoscopic procedures. The literature regarding the success of one procedure over another is mixed and consists mostly of small retrospective cases series, with some randomized controlled trials comparing two or three methods. It is possible to find data supporting the use of any procedure over another; therefore it is critical that a surgeon is familiar with their personal outcomes as they relate to procedural approach. Aftercare by the patient and provider is likely as important as the procedural technique in success. It is imperative that patients keep the operative area clean, perform excellent wound care, and avoid strenuous activity until healing has taken place. Poor wound management and poor decision making will lead to failure.

Principles of Treatment

Several basic principles should be considered when treating pilonidal disease so that optimal outcomes can be achieved, as discussed in the following sections.

Control Sepsis

All acute abscesses must be drained, and any attempt at definitive surgical management in the setting of active infection should be avoided. All PD will be colonized with bacteria, but this is very different from active infection. Primary closure with or without flap reconstruction will fail in the setting of infection and will make future management more difficult.

Do the Least Amount of Work Possible

As stated previously, the anatomy or severity of disease should drive treatment method selection. If the disease is minor, yet the patient requests surgery, a pit-picking procedure (description to follow) plus or minus a small amount of additional excision may be all that is needed. Complex and recurrent disease typically requires a wide excision and flap reconstruction.

Avoid Too Much Excision

The old adage advising excision of all disease down to the post-sacral fascia results in an extremely large and complex wound. This technique should be avoided whenever possible. Excision that is too deep or aggressive has been shown to correlate with disease recurrence/treatment failure.

Unroof All Disease, Debride Granulation Tissue, and Remove Hair

This principle goes part and parcel with the principle of avoiding too much excision. Removal or unroofing of skin overlying active disease may be essential, but do not be tempted to dissect any deeper. It is important, however, to account for all disease. Any hair or debris should be removed, and granulation tissue should be curetted or cauterized. It may be helpful to inject sinuses with methylene blue to ensure that no extensions are missed. Probes may also be used. If the wound is to be closed, adequate irrigation of the wound with saline is encouraged.

Use Off-Midline Excision and Closure

It is essential to attempt to perform an off-midline excision and closure. Wounds located in the midline of the gluteal cleft just do not seem to heal as well as those located elsewhere. Although it may be impossible to keep the entire wound out of the midline, there should be significant effort to minimize the amount of wound in the midline.

Minimize Tension if the Wound Is Closed

Because of the inherent difficulty with wounds located in the region of the gluteal cleft, every effort should be taken to minimize wound morbidity. A "tension-appropriate" closure should be utilized. If this cannot be achieved initially, then tissue undermining or use of a flap should be considered. When flaps are used, it is important to ensure a lack of tension at both the excision site and the donor site. Tension and separation of the operative wound seem to be better tolerated at the donor site because these sites are off the midline.

Change the Anatomy/Flatten the Natal Cleft

It is believed that deep natal cleft anatomy contributes to formation of pilonidal disease; therefore it seems reasonable that any procedure designed to flatten cleft anatomy would lead to lower recurrence rates. Most flap procedures, and certainly the Bascom cleft lift procedure, are designed to do this. The cleft lift procedure in particular combines most if not all of the aforementioned principles into one operation, which has likely contributed to its success. That stated, not all PD requires this to be done.

Never Underestimate the Impact of Postoperative Care

Postoperative management has a significant impact on the ultimate outcome, especially in cases of off-midline closure. Limitations in physical activity, work restrictions, and limitations of weight bearing on the buttock will help minimize wound dehiscence. There are no true prescribed evidence-based recommendations to follow, but clear written instructions should be provided to patients that can easily be followed. These recommendations should be covered in the preoperative discussion as they will sometimes affect a patient's decision to undergo a surgical procedure.

Basic/Simple Procedures

Abscess Drainage

An individual presenting with an acute pilonidal abscess requires only definitive incision and drainage at first. Typically, the abscess "points" to one side of the natal cleft, and this is easily visualized or is palpable. Our recommendation is to incise the abscess cavity just off midline under local anesthetic. It is important to ensure that all loculations are broken up and that all purulence is drained. Initial packing is often employed for hemostasis, but we have not found continued packing to be necessary. Once or twice daily showering with soapy water aids in keeping the wound clean. These wounds will typically close in 1 to 2 weeks, but they can sometimes result in a chronic wound.

Non-Excisional Procedures

Patients with relatively minor disease who wish to avoid an excisional procedure may be candidates for alternate therapies, such as

the injection of phenol or fibrin glue. This procedure begins with removal of hair and debris from the tracts or pits. After administration of local anesthetic, the tracts are injected with phenol to create epithelial destruction and inflammation to encourage tract closure. Alternatively, fibrin glue may be injected to close the tracts. These can be combined with endoscopic techniques to delineate all tracts and thoroughly debride them (discussed later).

Pit-Picking/Simple Bascom Procedure

In cases of mild chronic disease in which the primary complaint is related to midline pits or in cases in which there is a small wound off-midline, this procedure may be considered ideal. It is simple and results in a healed wound rather quickly—usually in 1 to 3 weeks. In most cases, PD shows an affinity for one side of the natal cleft. In cases in which disease is localized purely to the midline in the form of pits, a pit-picking procedure alone is appropriate. In this technique, the central pits are excised using a punch knife of appropriate size (just slightly larger than the pit itself). The knife is inserted to full depth, hair and debris are removed, and the wound is closed primarily. The authors prefer 3-0 Vicryl suture, but any absorbable or permanent suture may be used. This is repeated until all pits are excised. It is not unusual to encounter a bit of bleeding after pit excision, and this can be controlled with needle-tip electrocautery.

In cases in which there is induration off the midline, a true simple Bascom procedure can be performed. Pits are excised as described earlier, and a 2- to 3-cm incision is created just lateral to the indurated area off the midline. A skin and subcutaneous flap is created by dissecting toward the midline pits, ultimately connecting the two areas of dissection. Indurated tissue is excised, the wound is irrigated, and then it is partially closed at the superior and inferior portions leaving the central portion open. A small amount of packing is placed in the open portion of the wound and is removed the next day. Continued packing may be used or omitted per surgeon and patient preference. This technique minimizes excision in the midline and keeps the larger wound in a lateral position, which expedites and simplifies healing (Fig. 1).

Excision With or Without Primary Wound Closure

Many consider the gold standard of surgical management to be simple excision with healing by secondary intention. It is certainly still commonly performed, though many patients prefer to avoid an open wound. Using the principles outlined earlier, the disease should be unroofed ensuring that all hair, debris, and granulation tissue is removed, curetted, or cauterized. Every attempt should be made to minimize the tissue excised and to keep the majority of the wound off the midline. If possible, a simple primary closure can be performed, though the authors' experience is that this often fails. Alternatively, the wound may be left open to heal by secondary intention, and the skin edges may be marsupialized.

This procedure rarely results in a complex wound if patients are appropriately selected. If careful and meticulous wound care is employed postoperatively, the rate of success is reasonably high with this technique—again in appropriately selected individuals. Patients with extensive and destructive disease should not be managed this way as management results in a large and complex wound that rarely heals. Complete healing in the best of cases takes weeks to months. Some have reported the use of negative pressure dressings in this setting, but management of these devices in this location is often challenging. This option may be appropriate with larger wounds if resources are available.

Intermediate Procedures

These procedures involve the excision or unroofing of disease in the midline (or just off the midline) followed by subcutaneous flap mobilization and tension-appropriate closure with or without the use of a closed-suction drain. They are designed to alter the cleft anatomy while minimizing the amount of excision. They also employ an off-midline closure. Patients with mild to moderate disease are ideal for these techniques. Those with extensive or destructive disease are not likely suitable for this type of management. Disease that is very close to or abuts the anal verge may also present a challenge if considering this type of management.

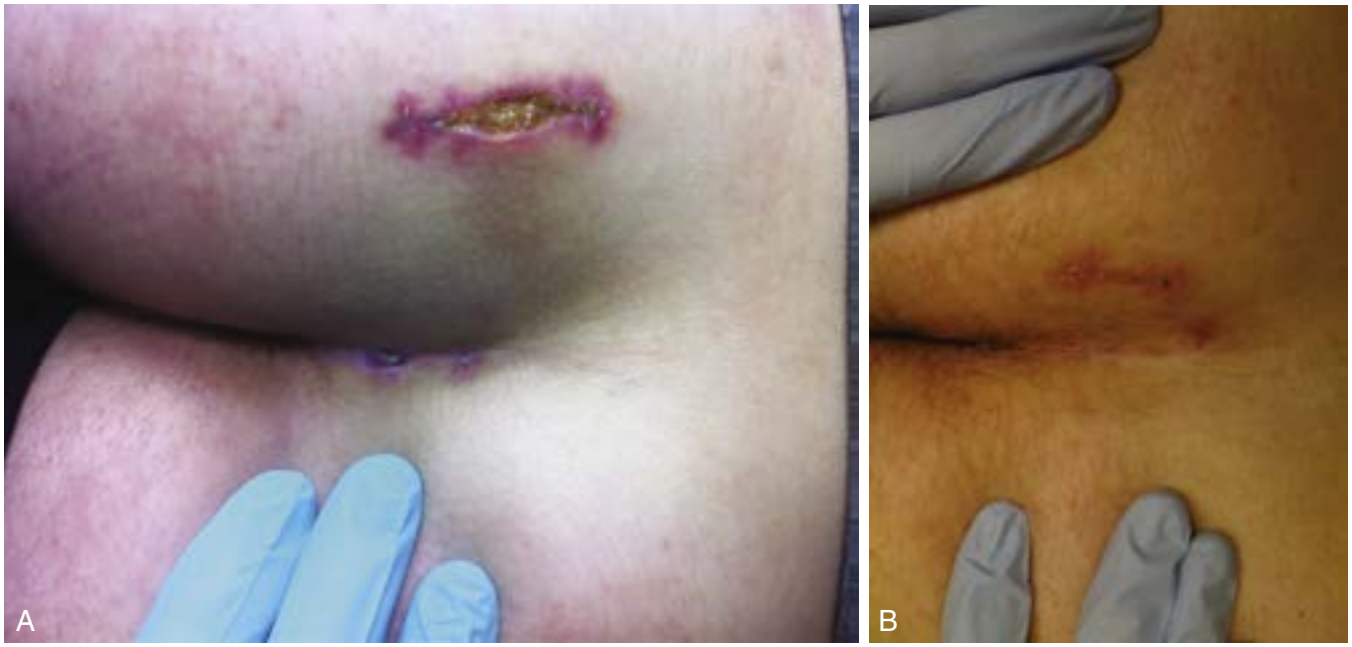

FIG. 1 Two cases treated with the simple Bascom approach (lateral excision and midline pit excision or pit picking). (A) Patient in the early stages of healing. **(B)** Patient near completely healed. *(Courtesy Eric Johnson, MD.)*

Karydakis Flap

Initially, the affected tissue in the midline is excised, which results in an elliptical defect in the natal cleft. A skin flap with a beveled edge is then created and mobilized such that it will reach across midline to facilitate a tension-appropriate primary closure. The wound is closed in layers to obliterate as much dead space as possible. Superficial wounds do not require drainage, but deeper wounds may require employment of a closed-suction drain. Development of seroma places the repair at risk. If a drain is used, the authors leave it in place for a minimum of 3 days and require that the output be 20 mL or less per day for 2 consecutive days. This is a simple procedure to perform and results in some flattening of the natal cleft as well as a closure off the midline (Fig. 2).

Cleft Lift Procedure

This is a simple yet creative procedure originally popularized by the late Dr. John Bascom. It employs all the aforementioned principles and is suitable for most patients who are encountered. Preoperative marking of the patient in the prone position in the operating room is essential to correct performance of this procedure. This is the preferred procedure of the authors for patients with mild to moderate PD. Before a chlorhexidine prep is performed, the "safe-zone" is marked with indelible marker by pressing the gluteal tissue together in the midline. The mark is drawn where the tissue from each side touches in the midline. The buttocks are then taped apart revealing a "wishbone"-shaped mark. This establishes a "safe zone" beyond which no further dissection should be performed. This also ensures a tension-appropriate closure. An additional elliptical/scimitar-shaped mark is placed over the area with more significant disease after skin preparation. This marks the skin that will be excised. The inferior portion of this mark is scimitar-shaped to ensure appropriate closure near the anal verge. After instillation of epinephrine containing local anesthetic, the skin of the diseased area outlined by the elliptical mark is excised. Take care not to excise much if any subcutaneous fat. This will invariably expose some sinus tracts, hair, and granulation, which should all be removed, curetted, or cauterized. A skin/subcutaneous flap, about the thickness of a mastectomy flap, is created by dissecting toward the opposite side safe-zone boundary. Use of skin hooks facilitates this dissection. When the flap is raised inferiorly (near the scimitar), the dissection should be slightly deeper, providing additional thickness to this portion of the flap. Scar tissue in the midline is then released by dividing it into small squares. The flap is mobilized across the midline, and the wound is closed in layers, taking care to obliterate as much dead space as possible. In the majority of cases, a closed-suction drain will not be necessary, though when used it should be managed as described earlier. This procedure results in flattening of the natal cleft with an off-midline closure and is easy to perform (Fig. 3).

Complex Procedures

These procedures consist of a wide excision of severely diseased tissue followed by mobilization of a lipocutaneous flap from an adjacent donor site that is utilized for closure of the complex wound. They will almost always require closed-suction drainage. These procedures are ideal for patients who present with complex, destructive, and recurrent disease. The advantage of these techniques is that they bring thick and healthy tissue into the midline to fill and close large defects. They also flatten the natal cleft, potentially leading to lower recurrence rates. Disadvantages include the time and skill required to perform the procedures as well as the complexity of wounds that result from flap failure. Fortunately, complete loss or dehiscence of a flap is a relatively rare complication if patients are appropriately selected.

Rhomboid Flap

This is a more complex procedure that is quite useful in the setting of complicated PD. The patient is again positioned in the prone position, and a chlorhexidine skin prep is performed. We do administer intravenous antibiotics to cover skin flora. A diamond-shaped area of skin is excised, encompassing all disease. This is typically carried down to the post-sacral fascia, though a more conservative excision may be performed based on the amount of disease present. It is helpful to orient the original diamond- or rhombus-shaped excision just slightly counterclockwise. This ensures that the inferior tip of the rhombus is not located adjacent to the anus, which is the most likely area of postoperative wound separation. This technique is referred to as a *modified rhomboid* or *Limberg flap.* The flap is then mobilized from the donor site, typically the right buttock. The thickness of the flap should be identical to the thickness of the tissue excised from the midline. The flap should be handled gently throughout the case. It is created by incising laterally from the right lateral tip of the rhombus onto the right buttock and then inferiorly (Fig. 4). One must ensure preservation of a thick and wide pedicle to ensure adequate blood

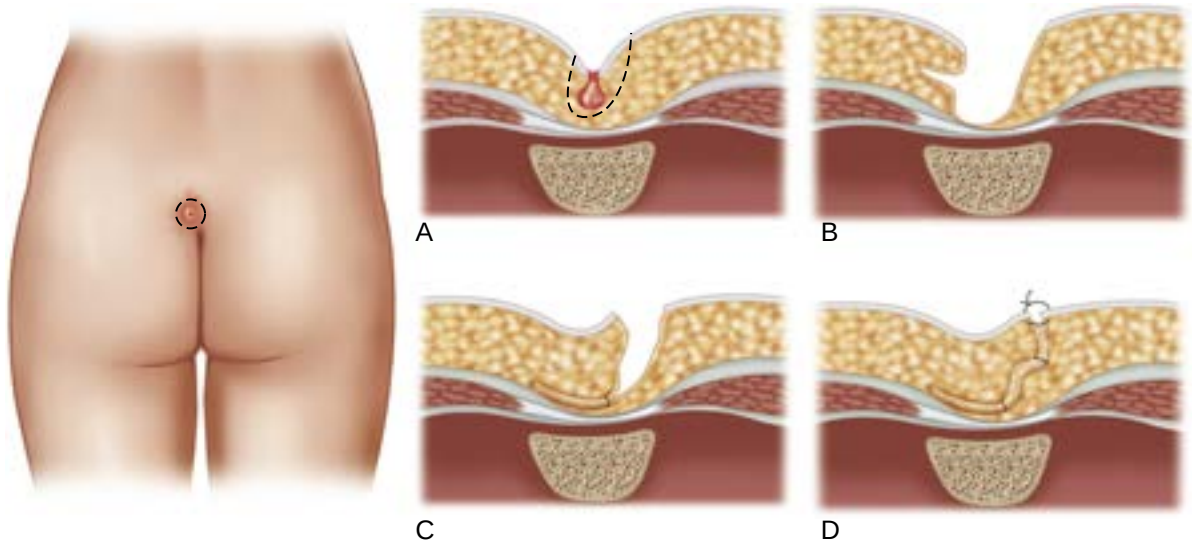

FIG. 2 Karydakis flap procedure. (A) Midline pits are excised. **(B)** Skin flap from one side is raised. **(C)** Skin flap is secured down to the underlying tissue so that the wound is moved off the midline **(D)**.

FIG. 3 Bascom cleft lift procedure. (A) The "safe zone" is marked by pressing the gluteal tissue together in the midline and marking where the skin of each side touches the midline. **(B)** Scimitar-shaped area of diseased skin is excised, curving away from the anal verge and favoring one side of the safe zone. **(C)** Skin flap from the opposite side of the safe zone is raised. **(D)** Skin flap is secured to the underlying tissue, moving the wound off the midline. **(E)** Completely healed wound. *(Courtesy Eric Johnson, MD.)*

supply. It is also wise to mobilize some of the tissue above the flap on the right buttock to minimize tension at the donor site closure portion of the repair.

After adequate flap harvest, it is rotated in a counterclockwise direction to cover the midline. The closed-suction drain should be placed, typically from the right side superiorly, and the flap is then secured to the mid-portion of the wound with a 2-0 absorbable suture. This will often require the help of an assistant. At this point, it is not unusual to feel just a bit unsure of one's ability to close this large wound. Do not worry; it will close. The wound is then closed in layers with absorbable suture. The authors close the skin with a 4-0 monofilament absorbable suture and then cover the wound with surgical skin glue. The drain is managed as referenced earlier (see Fig. 4).

It is imperative to ensure that the patient does not engage in strenuous activity for 4 to 6 weeks after this procedure. This wound is always closed under some tension and is at risk for dehiscence during this period. It is not unusual to develop one or two small areas of wound separation that may drain in the first 1 to 2 weeks after surgery. This is not a serious complication, but it will require some minor wound care for 2 to 4 weeks. These areas almost always close. If they fail to close by 12 weeks postoperatively, we do not hesitate to return the patient to the operating room for minor debridement and primary closure of these areas, which has been uniformly successful (Fig. 5).

Special Situations

In some patients, the extent of disease extends far enough up onto the lower back that it may be impossible to harvest a flap large enough to close the entire wound. We have encountered this several times and have a standard approach that we take in this setting. The key is to excise the portion of the wound involving the natal cleft and nothing more. The portion of the wound above the cleft can be debrided and treated like any open wound. It will heal because it is not in the low midline, as long as one has source control in the natal cleft. The rhomboid flap can be created in the standard fashion, rotated into place, and left with a free edge superiorly (Fig. 6). A negative pressure wound dressing is an excellent adjunct in this setting and will assist with rapid healing.

Although we will not go into an extensive description, the V-Y flap technique is useful in the setting of failed flap repairs. This method allows mobilization of a large amount of tissue into the midline to close large defects. This is the only setting in which we use this technique, as the rhomboid flap is extremely effective as a primary complex technique. When performing these complex flap repairs, patient selection is imperative. It is unwise to embark on an attempt in a patient who is a tobacco user or an uncontrolled diabetic. Those with collagen vascular disorders or documented problems with wound healing should be approached with caution. In terms of procedural timing, we will attempt definitive surgery after abscess drainage when there is no visual evidence of ongoing acute inflammation or infection. If a definitive procedure fails, we wait as long as possible before a salvage procedure—no sooner than 12 weeks (early and rare) and typically between 6 and 12 months. It is important to allow a "failed" procedure time to heal, as they often will.

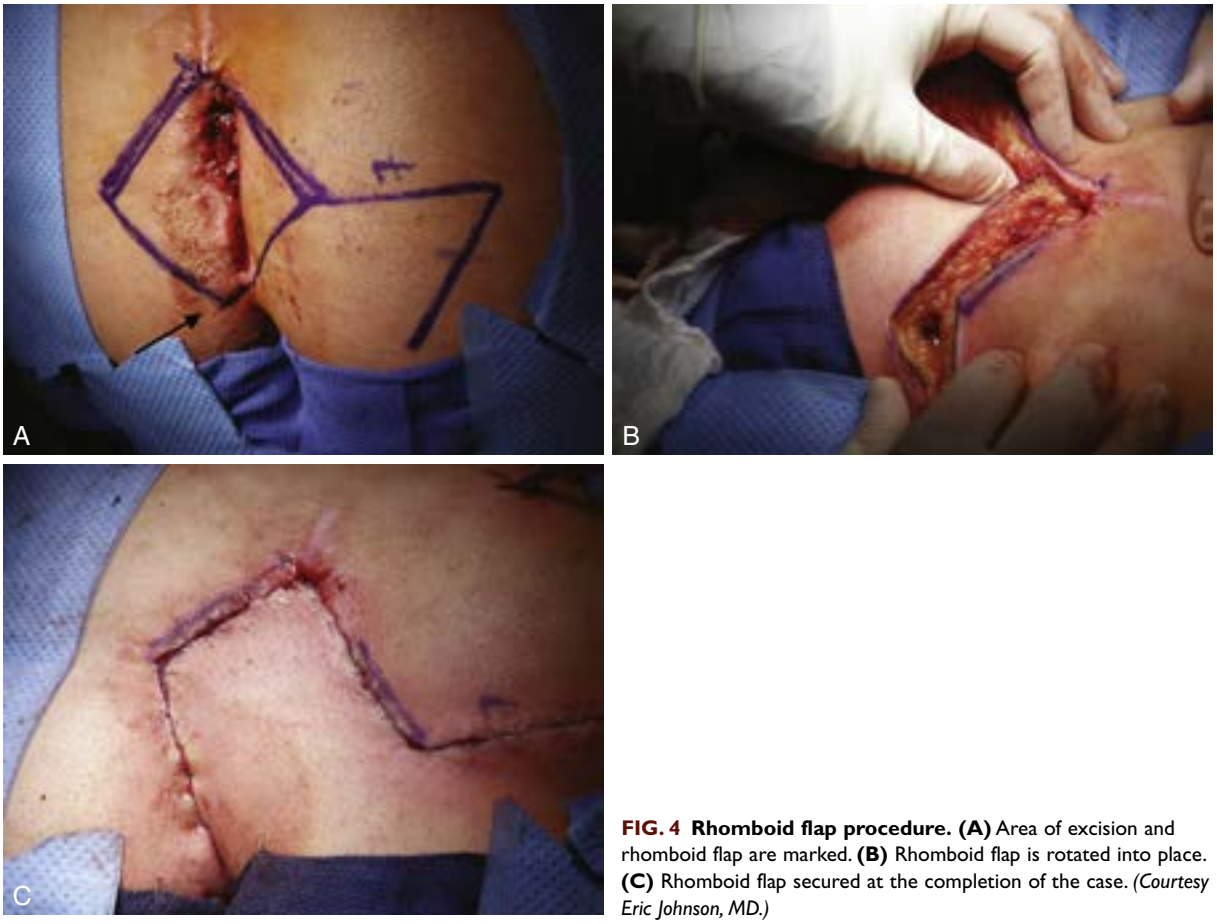

FIG. 4 **Rhomboid flap procedure. (A)** Area of excision and rhomboid flap are marked. **(B)** Rhomboid flap is rotated into place. **(C)** Rhomboid flap secured at the completion of the case. *(Courtesy Eric Johnson, MD.)*

FIG. 5 Patients treated with a rhomboid flap may develop small areas of wound separation during the healing process. These occur commonly and tend to drain for a short time before healing. *(Courtesy Eric Johnson, MD.)*

FIG. 6 Patient who was treated with a rhomboid flap but had disease that extended for a fair distance cephalad. The cephalad portion of the disease was debrided/unroofed and left open. The wound was treated with a negative pressure device and healed without incident. *(Courtesy Eric Johnson, MD.)*

Endoscopic Procedures

Because of the size and morbidity of the wound that is often created using the aforementioned procedures, there is a growing interest in minimally invasive or endoscopic techniques. Using techniques first used to treat perianal fistulae, video-assisted ablation of pilonidal sinus (VAAPS) was developed in 2013. In this procedure, a fistuloscope is used to cannulate and explore all pilonidal openings and their associated internal tracts. Endoscopic forceps are used to remove any hair and debris. Electrocautery is then used to ablate the sinus tracts. Finally, an endobrush or curette is used to remove any remaining debris or granulation tissue. This procedure has also been combined with phenol instillation in the tracts to sclerose the remaining epithelium, destroy any necrotic debris, and promote healing of the sinus. The external openings are left open to drain, and a light dressing is applied. This procedure can be done under local anesthesia with minimal patient discomfort. Early results have been encouraging, with reported healing rates over 90%.

Pneumatosis Intestinalis and the Importance for the Surgeon

Joseph Kim, MD, Ahmed Chatila, MD, Muhammad Hammami, MD, and Eric Goldberg, MD

INTRODUCTION

Pneumatosis intestinalis (PI) refers to the presence of gas-filled or air-filled cysts in the bowel wall. The clinical significance can range from an incidental radiologic finding with an excellent prognosis to manifestation of an underlying intraabdominal catastrophe requiring emergent surgical intervention. Distinguishing benign etiologies from underlying surgical emergencies is crucial and requires a strong understanding of etiologic associations and clinical presentations.

BENIGN CAUSES OF PNEUMATOSIS INTESTINALIS

There are a variety of theories on the pathogenesis of PI. The mechanical theory postulates that PI results from dissection of air through the mucosal or serosal surface of the bowel wall. The bacterial theory postulates that luminal bacteria gain access intramurally and produce gas. Each one of these theories likely has merit with certain etiologic associations. For example, mechanical theory can explain the association of PI with pulmonary conditions such as chronic obstructive pulmonary disease (COPD) or mechanical ventilation where ruptured air blebs can track along the mesenteric root into the bowel wall. The bacterial theory better explains the association of PI with gastrointestinal motility disturbances such as those seen with intestinal pseudo-obstruction or scleroderma or with patients with mucosal disruption such as inflammatory bowel disease. Etiologic associations of PI are outlined in Table 1.

Although most patients with PI are asymptomatic, some can present with symptoms including abdominal pain, obstruction, bleeding, or symptoms caused by the underlying disorder associated with PI. Location of the PI also affects the types of symptoms patients will experience. PI involving the small intestine more often presents with abdominal pain, distention, and vomiting, whereas colonic PI presents with diarrhea or hematochezia. In the absence of complications, the physical examination is typically unremarkable but may demonstrate abdominal distention or a palpable mass on abdominal or digital rectal examination.

PNEUMATOSIS INTESTINALIS RESULTING FROM AN INTRAABDOMINAL EMERGENCY

When PI results from an underlying abdominal catastrophe such as necrotizing enterocolitis (infants), bowel ischemia, or bowel perforation, the symptoms of the underlying surgical emergency dominate the clinical presentation. Signs and symptoms suggesting a surgical emergency include severe abdominal pain, pain out of proportion to the physical examination, fever, vomiting, presence of peritoneal signs such as rebound tenderness, and changes in vital signs such as hypotension, tachycardia, tachypnea, and hypoxia. Patients with an underlying intraabdominal emergency will typically require hemodynamic support in an intensive care unit setting.

IMAGING FINDINGS

PI is not a disease but rather a radiographic finding. It can be discovered on imaging performed for evaluation of abdominal complaints or incidentally discovered on imaging performed for nonrelated issues. Imaging not only helps with establishing a diagnosis of PI, but also with assessing the severity of disease, diagnosing associated complications, and making decisions regarding appropriate therapy.

X-ray

Findings include intramural gas (linear, curvilinear, or circular in appearance) or pneumoperitoneum. However, up to one-third of abdominal plain films fail to diagnose PI.

Computed Tomography

Computed tomography (CT) remains the most sensitive imaging modality in the identification of PI. Findings include intramural gas

TABLE 1 Etiologic Associations of Pneumatosis Intestinalis

Life-Threatening Causes	Pulmonary	Intestinal	Immunologic Conditions	Medications	Infections
Toxic megacolon	Asthma	Inflammatory bowel disease	AIDS	Corticosteroids	Tuberculosis
Mesenteric vascular disease	Chronic obstructive pulmonary disorders	Intestinal pseudo-obstruction	Rheumatoid arthritis	Chemotherapy	COVID-19
Ingestion of corrosive agents	Cystic fibrosis	Peptic ulcers	Scleroderma	Lactulose	*Clostridium difficile*
Trauma	Mechanical ventilation	Pyloric stenosis	Lymphoproliferative disorders		HIV
Necrotizing enterocolitis		Endoscopic procedures	GVHD		Cytomegalovirus
Intestinal ischemia/infarction			Solid-organ transplantation		*Tropheryma whipplei*
Bowel perforation					

AIDS, Acquired immunodeficiency syndrome; *GVHD,* graft-versus-host disease; *HIV,* human immunodeficiency virus.

(Figs. 1 and 2) appearing as either cystic collections of air that are adjacent to the bowel, air collections running parallel with the wall of the bowel, or linear collections of air without characteristic luminal air-fluid levels.

Additionally, CT allows for identification of associated findings that may indicate an underlying surgical urgency or emergency. These include bowel wall thickening, mucosal enhancement, bowel dilation, soft tissue stranding, and the presence of portal venous gas. The presence of portal venous gas is typically an ominous finding and is suggestive of mesenteric ischemia.

Ultrasound

Findings of PI on ultrasound imaging typically include air trapped within the intestinal wall, high-amplitude gas echoes accompanied by shadowing, lack of motion of air over time in the bowel wall, and lack of motion of air with compression.

Magnetic Resonance Imaging

PI is typically seen as circumferential collections of air near or within the bowel wall. Magnetic resonance imaging (MRI) is typically not the diagnostic modality used for the detection of pneumatosis, but physicians should be familiar with its appearance on MRI.

Laboratory Findings

Laboratory findings are instrumental in determining the management needed for PI. Although laboratory findings may be normal or nonspecific, a handful of "red-flag" laboratory values must be considered when evaluating whether PI has resulted from an underlying intraabdominal emergency. Elevations in serum lactate ≥2.0 mmol/L, marked leukocytosis with a predominance of immature white blood cells, elevated hematocrit suggestive of hemoconcentration, amylase > 200 U/L, or a bicarbonate level <20 ml/L can be suggestive of mesenteric ischemia or bowel infarct, which can help guide physicians toward the need for surgical intervention. The strongest predictor of pathologic disease and poor outcomes in PI remains a serum lactate ≥2.0 mmol/L.

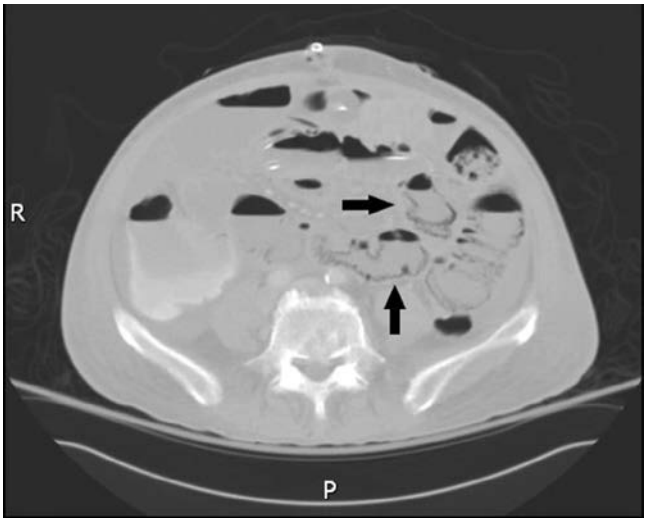

FIG. 1 CT scan of the abdomen demonstrating pneumatosis intestinalis of the small bowel. *Arrows* point to pneumatosis.

Endoscopic Findings

PI can be seen incidentally on both colonoscopy and sigmoidoscopy. The endoscopic appearance resembles submucosal blebs that can vary in size from several millimeters to centimeters in size. They have a pale/bluish appearance and on biopsy can rapidly deflate with an accompanied audible hiss. Diagnosis can be confirmed formally with endoscopic ultrasound, which will demonstrate the air-filled blebs.

Distinguishing Benign from Pathologic Pneumatosis Intestinalis

The management of PI from medical causes (see Table 1) is strikingly different from the management of PI from an underlying intraabdominal catastrophe such as mesenteric ischemia or intestinal perforation. When PI results from an underlying intraabdominal

FIG. 2 CT scan demonstrating portal venous gas.

catastrophe, the prognosis is extremely poor without immediate surgical intervention. Therefore, the most important step in the evaluation is determining whether there is a surgical emergency. As discussed earlier in the chapter, signs and symptoms suggestive of a surgical emergency include fever, pain out of proportion to physical examination, peritoneal signs, and hemodynamic changes such as tachycardia, hypotension, and orthostasis. Laboratory values that are red flags include leukocytosis, hemoconcentration, metabolic acidosis, and lactic acidosis. Most surgical emergencies will be readily evident on CT imaging of the abdomen. If PI is associated with portal venous gas, strong consideration should be given to surgical exploration.

A retrospective study by DuBose et al. on 500 patients with PI showed that a lactate level ≥2.0 mmol/L, hypotension, and/or vasopressor use were highly predictive of PI from mesenteric ischemia. In addition, a prospective study by Ferrada et al. on 127 patients with PI indicated that a lactate level ≥2.0 mmol/L, elevated INR, decreased hemoglobin, and peritonitis were predictive of PI from transmural ischemia. In Ferrada's study, the presence of small bowel involvement, ascites, or adynamic ileus was also associated with PI from transmural ischemia. Recently, a five-factor score ranging from 0 to 11 (low-risk 0–4, intermediate-risk 5–6, high-risk 7–8, and very high-risk 9+) has been proposed for predicting PI from transmural ischemia. The score is based on the presence of small bowel PI, age ≥70 years, heart rate ≥110 beats per minute, lactate ≥2 mmol/L, and neutrophil-lymphocyte ratio ≥10. In a validation cohort, low-risk patients for surgical causes of PI had an observed rate of 0.0% for transmural ischemia, and very-high-risk patients had an observed rate of 82.4%.

Medical Management of Benign Pneumatosis Intestinalis

Patients with PI without evidence of mesenteric ischemia or other intraabdominal emergencies do not require exploratory laparotomy and can be managed medically. However, there is no consensus regarding the best treatment. Expectant management with serial radiographs, abdominal examinations, empiric antibiotics, elemental diet, and oxygen therapy are commonly employed.

The underlying etiologic association of PI should be treated in all patients. This includes removal of offending medications, treatment of inflammatory bowel disease, eradication of intestinal infections, and treatment of pulmonary disease.

Antibiotic therapy typically consists of metronidazole 500 mg orally three times daily until PI clinically and radiographically resolves or for up to 3 months. It is theorized that antibiotics can alleviate symptoms by reducing the amount of gas produced by bacteria. Alternatives to metronidazole include ampicillin, tetracycline, or rifaximin.

An elemental diet has been proposed for symptomatic PI. It is theorized that an elemental diet can decrease production of gas by colonic flora as it is totally absorbed in the small intestine. Other mechanisms of action include alteration of intestinal flora.

Inhalational oxygen and hyperbaric oxygen therapy are effective for patients with moderate symptoms. Although the mechanism of action has not been fully elucidated, it is theorized that high concentrations of O_2 reduce the partial pressure of non-oxygen gases in the venous system and promote diffusion of these gases out of the bowel wall. In addition, oxygen may act as a toxin to anaerobic bacteria in the gut.

Endoscopic puncture, sclerotherapy, or surgical resection can be considered in patients who remain symptomatic with bleeding or obstruction from large blebs of intramural air.

Serial imaging should be conducted every 1 to 3 months until PI resolution is documented. Recurrence of PI is not uncommon and likely results from persistence of predisposing factors (see Table 10).

SURGICAL MANAGEMENT OF PATHOLOGIC PNEUMATOSIS INTESTINALIS

Patients deemed to have PI from transmural ischemia require emergent exploratory laparotomy. Surgical exploration is strongly recommended for these patients presenting with a lactate ≥2 mmol/L, peritonitis, or with hemodynamic changes. Careful clinical correlation with a low threshold for emergent exploratory laparotomy should be considered in those PI patients with small bowel involvement, adynamic ileus, or portal venous gas. Several key considerations are paramount to optimal outcome once the decision has been taken for surgical exploration, as discussed in the following sections.

Constant Communication with the Anesthesiologist

If the patient is in shock, anesthesia can result in a further insult. Ensuring that further vasodilation is kept at a minimum can help maintain adequate perfusion.

Resuscitation to Euvolemia

Hypovolemia increases the chances of further bowel necrosis and renal failure. On the other hand, hypervolemia results in further bowel swelling. Therefore, goal-directed resuscitation using methods such as arterial-line waveform analysis or echocardiography are advisable to maintain strict euvolemia.

How Much to Resect

Patients with transmural ischemia are usually in a state of shock. Minimizing blood loss and operative time is imperative. Consideration should be given to resecting only the areas of necrosis, leaving the patient in discontinuity, if necessary, to allow for better resuscitation.

Avoiding or Delaying an Anastomosis

Unless the cause of ischemia is clearly mechanical and can be relieved in the operating room, consideration should be given that the bowel might be in continued ischemia, which is disastrous for an anastomosis. In this case, the anastomosis would likely fail and place the patient at risk for a second source of intraabdominal sepsis.

Management of Rectal Cancer

Gregory K. Low, MD, and Matthew Mutch, MD

BACKGROUND

The rectum is the distalmost aspect of the large intestine and measures 12 to 15 cm in length. From a surgical standpoint, it extends from the anus at the anorectal ring to the confluence of the taeniae coli at the rectosigmoid junction. Within the pelvis, it is bordered laterally by the pelvic sidewall, posteriorly by the sacrum, and anteriorly by the prostate gland in men and the vagina in women. From an oncologic standpoint, rectal cancer typically refers to tumors within the rectum located at or below the peritoneal reflection.

Current data show that there are approximately 150,000 cases of colorectal cancer per year in the United States. Of these, approximately 45,000 are newly diagnosed rectal cancers. There are approximately 50,000 colorectal cancer related deaths per year, making it the third most common cause of cancer-related death in women and the second most common cause of cancer-related death in men. Overall, the incidence of colon and rectal cancer has been decreasing since the adoption of routine screening. For patients under than age of 50, however, the incidence of both colon and rectal cancer is on the rise, with a rate of 2% to 4% per year. Young-onset colon and rectal cancers are more likely to be left-sided and higher-stage cancers at the time of diagnosis. Therefore special attention should be given to this patient group when they present with symptoms.

Rectal cancer poses a unique challenge to surgeons because of the bony confines of the pelvis and its proximity to other vital structures, which influences the margins of resection. Additionally, there have been many recent changes and evolving practices within the realm of radiation oncology and medical oncology. Overall, the management of rectal cancer is a complex topic that should be approached in a multidisciplinary fashion to give patients the best opportunity for favorable outcomes.

CLINICAL EVALUATION AND CLINICAL STAGING

The most common clinical presentation of rectal cancer is a change in bowel habits. Other presentations include bleeding, iron deficiency anemia, change in stool caliber, presence of a palpable mass, tenesmus, and rectal pain. Tenesmus and rectal pain are late findings and are often indicative of locally invasive lesions. Left untreated, rectal tumors may cause obstruction or perforation, which may significantly complicate management.

The diagnosis of rectal adenocarcinoma is typically secured by biopsy during endoscopy. A complete colonoscopy is preferred if the lesion can be traversed given the 3% to 5% risk of synchronous tumors. In-office evaluation should include a thorough personal history, family history, and a complete physical examination. Anorectal examination should specifically note the tumor's location relative to the anal verge, the sphincter complex, and orientation within the rectum. Rigid proctoscopy (as opposed to flexible endoscopy) is the preferred method for assessment of distance from the anal verge when tumors are not palpable on examination. On rigid proctoscopy, tumors within 12 to 15 cm of the anal verge are considered rectal cancers; on flexible endoscopy, tumors located at or below the third fold are considered rectal cancers. Although not diagnostic, carcinoembryonic antigen (CEA) levels are useful for the purpose of prognosis and posttreatment surveillance, so they should be obtained following a rectal cancer diagnosis.

Rectal cancer staging utilizes the Tumor, Node, Metastasis (TNM) staging system from the American Joint Committee on Cancer (AJCC)/Union for International Cancer Control (UICC), which is currently in its eighth edition. Locoregional staging was historically completed using endorectal ultrasound (EUS), however its use is limited in the setting of bulky disease and posterior tumors. Additionally, EUS is highly operator dependent and does not allow complete evaluation of lymph nodes. More recently, magnetic resonance imaging (MRI) has become the preferred method for locoregional staging. High-resolution, T2-weighted, thin-cut images allow for accurate evaluation of depth of invasion, locoregional lymph nodes, and involvement of the circumferential resection margin.

Regional nodes for rectal cancer include those within the mesorectum and internal iliac drainage pathways. Nodal involvement of the inguinal, external iliac, common iliac, or aortocaval chains is considered metastatic disease. On MRI, both the size and morphology of the nodes are evaluated to aid in identification of clinically positive nodes (Fig. 1). Factors associated with an increased risk of nodal involvement include short axis greater than 9 mm, round shape, irregular borders, and heterogeneous signal intensity.

A key component of locoregional staging is accurate assessment of the circumferential resection margin (CRM), which is the radial margin of the mesorectum removed during total mesorectal excision. On imaging, the presence of a threatened CRM (tumor within 1 mm) is highly predictive of positive radial margins at the time of surgical resection, which translates into poor disease-free survival and overall survival.

Up to 20% of those with colorectal cancer will present with metastatic disease at the time of diagnosis. The most common sites of metastatic disease include the lymph nodes, liver, and lung. Distant metastatic disease should be evaluated with computed tomography (CT) of the chest and abdomen. If there is concern for potential liver metastasis, MRI of the abdomen may be obtained. Similarly, positron emission tomography (PET) is not considered part of the standard

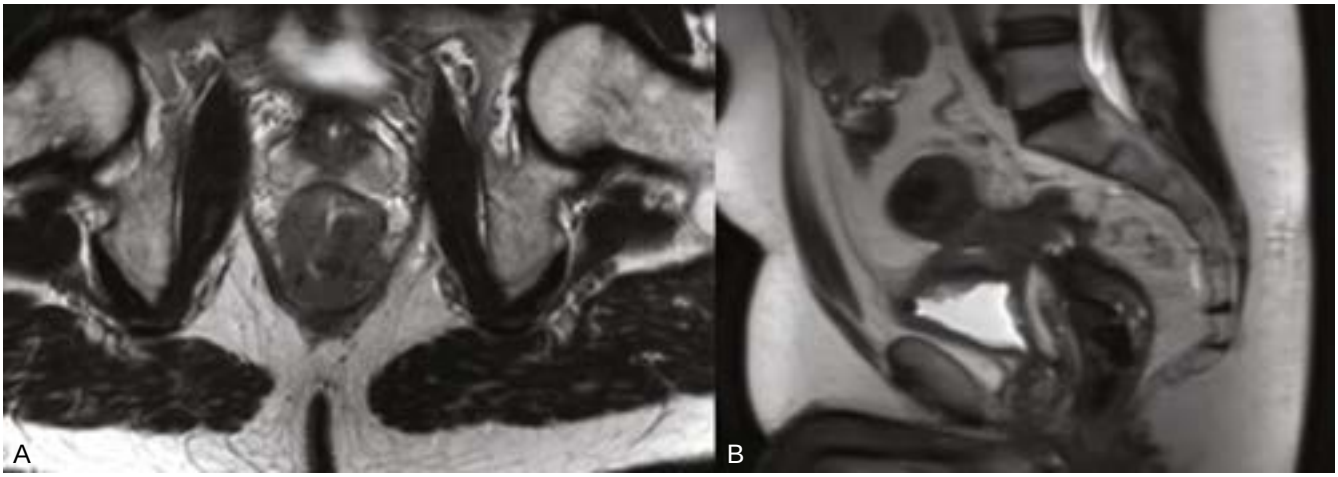

FIG. 1 (A) T3 tumor involving the superior margin of the internal anal sphincter on axial view. (B) T4 upper rectal tumor involving the bladder on sagittal view.

staging workup, but it may be considered in the setting of nondiagnostic CT or to confirm the presence of solitary metastasis before an attempt at surgical resection.

NEOADJUVANT THERAPY

Historically, proctectomy alone in the setting of rectal cancer was associated with 5-year local recurrence rates as high as 30%. Several sentinel clinical trials have transformed the management of locally advanced rectal cancer. The Swedish rectal cancer trial was one of the first studies to demonstrate the benefit of neoadjuvant short-course radiotherapy. However, this trial was criticized because of the lack of standardization of the surgical technique. The Dutch Colorectal Cancer Group addressed this issue by focusing on the concept of the total mesorectal excision. With the standardization of surgical resection, they demonstrated a significant decrease in the local recurrence rate associated with neoadjuvant short-course radiotherapy. Finally, the German Rectal Cancer Group demonstrated that chemoradiotherapy was best in the neoadjuvant setting given issues with significant toxicity and patient tolerance when given after surgery. Until recently, short-course radiotherapy was not widely accepted in the United States. The Polish trial and Trans-Tasman Radiation Oncology Group trial evaluated short-course radiation therapy versus conventional chemoradiotherapy and found no significant differences in local recurrence, disease-free survival, overall survival, or late grade 3 or 4 toxicity.

Current indications for neoadjuvant therapy include clinical T3, T4, or node-positive disease. Although it is occasionally discussed that neoadjuvant treatment can be considered in the setting of distal T2 disease in hopes of converting a planned abdominoperineal resection (APR) to a low anterior resection (LAR), this concept is not well supported and not currently recommended by clinical guidelines.

Traditionally, neoadjuvant therapy is given as long-course chemoradiotherapy consisting of 1.8 to 2 Gy/day for 25 fractions and a fluoropyrimidine for radiosensitization. Following long-course radiotherapy, proctectomy is typically delayed for 6 to 10 weeks (8 weeks preferred) to allow for ongoing tumor response. Longer wait times have been associated with increased pathologic complete response rates.

Short-course radiotherapy is typically given as 5 Gy/day over 5 consecutive days. Short-course radiotherapy is not a new concept and is commonly utilized in Europe. In recent years, it has garnered more attention and use in the United States given its reduced toxicity, shorter treatment time, and lower cost with no difference in pelvic control, overall survival, or disease-free survival. As opposed to long-course radiotherapy, surgery can be performed within 7 to 10 days after completion of short-course radiotherapy. Although immediate surgery does have certain benefits, recent trials have demonstrated a lower risk of complications for those undergoing delayed proctectomy (5–12 weeks) versus immediate proctectomy (less than 10 days).

Neoadjuvant therapy has greatly improved our ability to provide local control of rectal cancers, but it has not improved survival. Current local recurrent rates for stage II and III rectal cancer treated with neoadjuvant therapy followed by surgery can be as low as 4%, but the risk of distant recurrence remains 25% or greater. In attempts to improve survival and decrease the risk of distant failure, the concept of total neoadjuvant therapy (TNT) was developed. TNT involves administration of radiotherapy and all scheduled systemic chemotherapy in the preoperative period, with the goal of treating micrometastatic disease as soon as possible rather than up to 4 months after initiation of therapy. Radiotherapy may be given in short- or long-course format, and chemotherapy (typically the oxaliplatin-based FOLFOX regimen) can be given as induction (before radiation) or consolidation (after radiation). Current National Comprehensive Cancer Network guidelines recommend TNT for T4 lesions, T3 lesions with threatened margins, and those patients that are medically inoperable. Additionally, TNT may also be considered in T3 lesions, even in the absence of threatened margins and for T1–T2 lesions with positive nodes. TNT has been shown to result in higher pathologic complete response rates compared with chemoradiotherapy alone, and patients are more likely to complete planned treatment without dose reductions compared with postoperative chemotherapy. Whether these benefits translate into improved survival is a topic of ongoing investigation, but there are early data to suggest that TNT followed by surgery may result in improved survival compared with conventional chemoradiotherapy followed by surgery and adjuvant chemotherapy. In addition, a pathologic complete response after completion of TNT opens the door for an organ preservation/watch-and-wait strategy.

MANAGEMENT OF TUMOR-RELATED COMPLICATIONS

Some patients, especially those with locally advanced tumors, may present with complications related to tumor growth before or during neoadjuvant treatment. Tumor-related complications may include large bowel obstruction, bleeding, and perforation, all of which have serious consequences for patients' overall outcomes.

For patients presenting with large bowel obstruction, preoperative fecal diversion should be performed followed by neoadjuvant therapy. Diverting colostomy creation is often preferred as opposed to ileostomy as it avoids problems with dehydration and the risk of a

closed-loop obstruction in the setting of a competent ileocecal valve. Ideally, the stoma should be created distal to the eventual proximal resection margin to minimize complications to the proximal colon, which will be used to make an eventual colorectal anastomosis. Endoscopic stent placement is generally not recommended within the rectum as it results in pain and tenesmus. Partial or near obstructions may resolve with rapid initiation of radiotherapy, but patients should be closely observed for an initial worsening in their symptoms, which would require operative intervention.

Perforation of rectal tumors may result in abscess and/or fistula formation within the pelvis, perineum, or perianal regions. For contained perforations, fecal diversion and drainage of any abscess is necessary before initiating neoadjuvant therapy. Patients with free perforations or who are unstable present significant challenges. Ideally, the patient can be managed with drainage, either abdominally or transperineally, and fecal diversion. Rarely is resection required or recommended as obtaining an R0 resection will be difficult. At the time of radical resection, the perforation cavity and fistula track should be excised given the high likelihood of tumor spillage. Often this will require an abdominal perineal resection, and there may be need for tissue transfer to reconstruct the pelvic floor.

Hemorrhage from a rectal tumor is ideally managed with rapid initiation of radiotherapy as this is effective in over 90% of cases. When this is not feasible, endoscopic management, angiography, and topical treatments should be considered in an attempt to avoid emergency resection.

RADICAL RESECTION

Despite many recent advances in the realm of rectal cancer, radical resection remains the cornerstone of treatment. Radical resection includes resection of the rectum and the associated mesorectum, which contains the blood supply and lymphatics supplying the rectum. The goal of radical resection is to achieve negative distal and radial margins and restore gastrointestinal continuity with preservation of sphincter complex when possible. The gold standard technique for proctectomy was defined by Bill Heald in 1982 and is known as total mesorectal excision (TME). TME involves sharp dissection within the avascular plane between the visceral and parietal layers of the endopelvic fascia, resulting in a complete excision of the involved mesorectum and lessening the likelihood of autonomic nerve injury. As part of standard pathologic assessment, the quality of the mesorectal excision should be graded and reported. The quality of TME is graded as complete (intact mesorectal fascia), near complete (small, <5-mm defects in mesorectal fascia), and incomplete defects (>1 cm or exposure of muscularis propria).

Preoperatively, patients should receive mechanical bowel preparation in additional to oral antibiotics. This combination eliminates the stool burden from the colon and has been shown to reduce the risk of surgical wound infection compared with mechanical bowel preparation alone. If a stoma is planned, preoperative site marking should be performed to ensure a satisfactory location away from large skin folds, scars, or hernias. On the day of surgery, all patients should receive deep vein prophylaxis and intravenous antibiotics for surgical site prophylaxis.

The choice among an open, laparoscopic, or robotic approach is largely up to surgeon and patient preference as there have been no definitive studies that demonstrate significant differences in oncologic outcomes. Compared with open proctectomy, the laparoscopic technique is associated with improved short-term outcomes including less pain, lower rates of ileus, shorter length of stay, and less blood loss. Robotic proctectomy has rapidly increased in utilization in recent years, caused in part by the benefits of three-dimensional visualization and instrument articulation within the pelvis compared with a straight laparoscopic approach. Robotic proctectomy is associated with a lower conversion rate compared with laparoscopic proctectomy, but it is associated with longer operative times and higher costs.

The extent of resection during proctectomy for rectal cancer depends on its location within the rectum, relation to the sphincter complex, and involvement of additional pelvic structures (Fig. 2). For upper rectal cancers undergoing LAR, a distal margin of 5 cm is preferred. For low rectal tumors in which sphincter preservation is being attempted, a margin of 1 cm is acceptable provided that the entire mesorectum has been resected (Figs. 3 to 6).

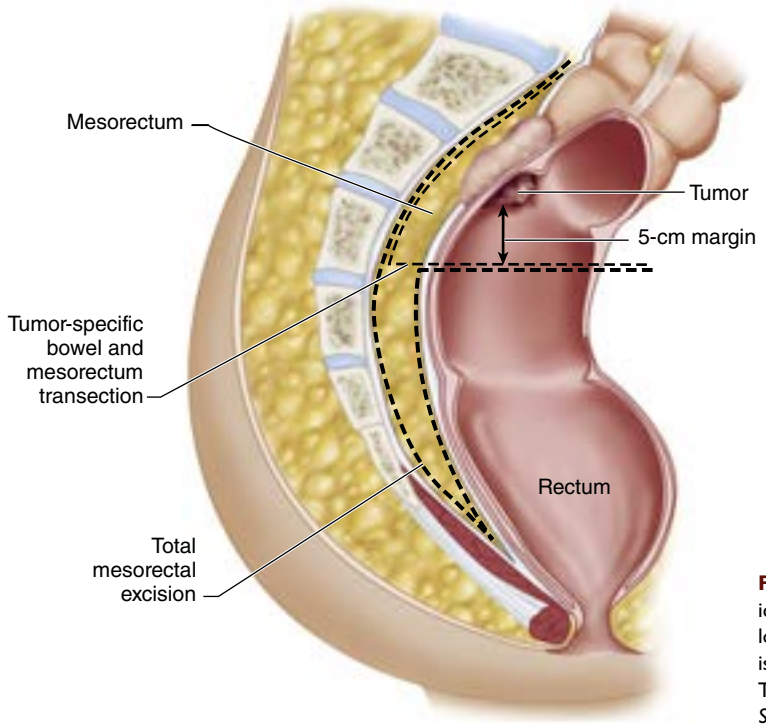

FIG. 2 For upper rectal tumors, tumor-specific mesorectal excision is appropriate. For mid to low rectal cancers, complete mesorectal excision is required. (*From Fleshman, et al.* Atlas of Surgical Techniques for Colon, Rectum and Anus. *Philadelphia: Saunders; 2013*)

FIG. 6 Use traction and countertraction to facilitate division of the anterior peritoneal reflection. *(Courtesy Corinne Sandone. From Cameron J, Sandone C.* Atlas of Gastrointestinal Surgery, *vol 2. 2nd ed. Shelton, CT: People's Medical Publishing; 2014.)*

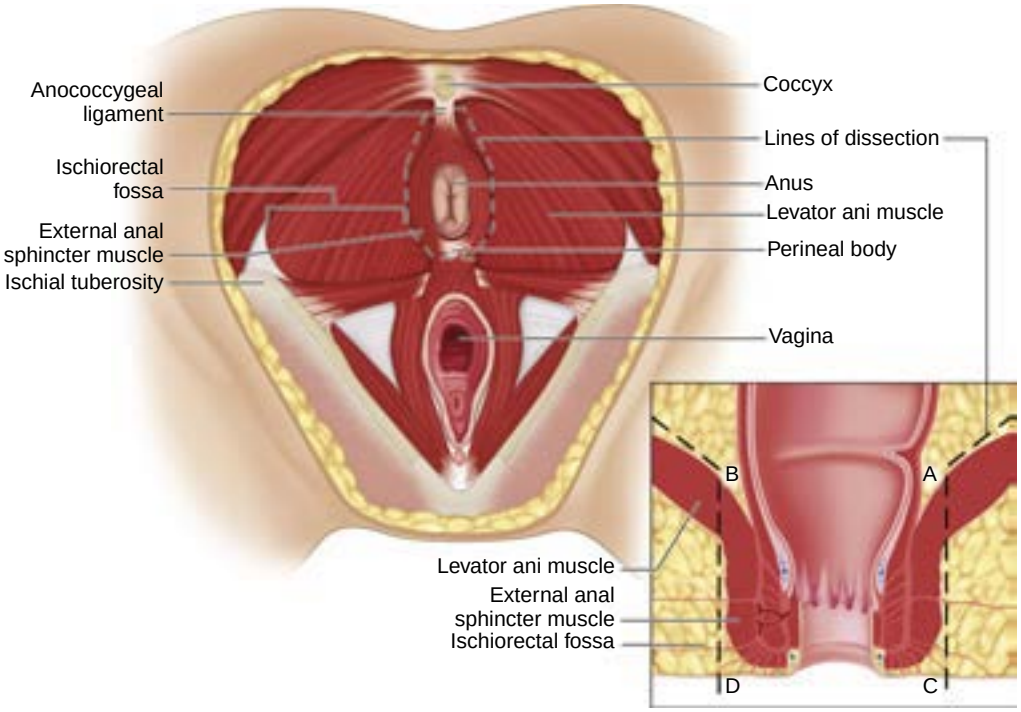

FIG. 7 Pelvic floor anatomy encountered during abdominoperineal resection. The anus, sphincter complex, and portion of the levator ani muscle are divided. The tip of the coccyx can be used as a guide to access the posterior pelvic space and guide the dissection. *(From Fleshman, et al.* Atlas of Surgical Techniques for Colon, Rectum, and Anus. *Philadelphia: Saunders; 2013).*

APR is required when tumors involve the sphincter complex or in those with a locally advanced low rectal tumor that is prohibitive of achieving an adequate distal margin (Fig. 7). For patients with poor preoperative bowel function, fecal incontinence, or chronic diarrhea, an end colostomy/Hartmann resection should be considered. Multivisceral resection refers to removal of the rectum in addition to other pelvic organs including the bladder, prostate, vagina, pelvic floor, and/or sacrum. Soft tissue coverage in the form of rotational or free flaps are often necessary following APR and pelvic exenteration given the large tissue defects in a radiated field.

Regardless of approach, the inferior mesenteric artery (IMA) may be divided either near its origin (high ligation) or just distal to the left colic artery at the origin of the superior rectal artery (low tie). High ligation is necessary in the setting of bulky adenopathy in the IMA chain and to help improve reach for a low anastomosis. The inferior mesenteric vein should be ligated at the ligament of Treitz to allow complete splenic flexure mobilization and improve reach into the pelvis.

Restoration of gastrointestinal continuity is most commonly accomplished using an end-to-end, stapled anastomosis. In appropriately selected patients with an ultra-low rectal cancer, a handsewn coloanal anastomosis may be performed to achieve sphincter preservation. Other options for anastomotic construction include the colonic J-pouch or an end-to-side colorectal anastomosis. In theory, these configurations improve the capacity of the residual rectum and improve function, however most studies demonstrated early improvement in function, but after 2 years there appeared to be no significant differences in long-term outcomes.

Temporary fecal diversion is frequently required during radical resection. In general, it should be performed in patients with a low anastomosis (less than 5 cm), those who received neoadjuvant radiotherapy, those who are immunosuppressed, and in the presence of a positive intraoperative leak test. Diverting stoma creation reduces the rate of clinical anastomotic leak, reduces the rate of reoperation, and increases the rate of salvage of the colorectal anastomosis if a leak does occur. Loop ileostomy is the most common type of diverting stoma created following radical resection given the simplicity of the subsequent reversal operation compared with reversal of an end colostomy. Diverting stoma reversal is typically performed 8 to 12 weeks following radical resection, but this timeline should be modified for patient-specific factors such as the need for adjuvant treatment. Before reversal, patients should undergo a water-soluble contrast enema to evaluate the integrity of the anastomosis.

Complications of proctectomy may range from minor to major, and they potentially have devastating consequences. Anastomotic leak is one of the most feared complications and, after low anterior resection, occurs in 5% to 25% of cases. For stable patients with a contained leak, simple percutaneous drainage may be feasible, but for unstable patients or those with an uncontained leak, reoperation is typically required. Suture repair, drainage, and fecal diversion may be adequate for small anterior defects in stable patients. For larger defects, those with poor tissue quality, or in the face of hemodynamic instability, takedown of the anastomosis and creation of an end stoma may be required.

During TME, pelvic bleeding can arise from the presacral plexus or the pelvic side wall. Presacral bleeding occurs as a result of injury to the presacral venous plexus, while pelvic side wall bleeding often originates from branches of the internal iliac vessels. Depending on the severity, presacral bleeding may by managed with electrocautery or direct pressure, but in the face of massive bleeding, pelvic packing is the most appropriate next step. Muscle fragment welding with a 2-cm area of rectus abdominus muscle or metallic thumbtacks may also be utilized. There are also several commercially available hemostatic agents that can be used such as Floseal or a Denver patch. Ureteral injury can also occur, especially in the setting of locally advanced tumors, and this typically requires reconstruction or reimplantation into the bladder depending on the character and location of the injury. Inadvertent injury to the superior hypogastric plexus during inferior mesenteric artery ligation may result in retrograde ejaculation, while injury to the hypogastric nerves or inferior hypogastric plexus during TME may result in erectile dysfunction and urinary dysfunction.

LOCAL EXCISION

Local excision for rectal cancer avoids the morbidity of proctectomy and may be considered in favorable lesions (Box 1). To be considered for local excision, lesions should be T0 or T1, be less than 3 cm

BOX 1 Criteria for Local Excision of Rectal Neoplasia

Tumor Characteristics

- T0 or T1
- <3 cm in diameter
- <30% lumen circumference
- Mobile on examination
- cN0 on staging imaging

Histopathologic Criteria

- Well to moderately differentiated
- No lymphovascular invasion
- No perineural invasion
- Negative margins after excision

FIG. 8 Full-thickness local excision of rectal neoplasia. *(Courtesy Andrew Russ, MD, and Mark Casillas, MD.)*

in diameter, involve less than 30% of the lumen circumference, be mobile, be amenable to resection with negative margins (3 mm), have no evidence of lymph node disease on cross-sectional imaging, and have favorable histologic features (well-differentiated, no perineural or lymphovascular invasion).

There are various techniques available for local excision depending on the tumor characteristics, location, and surgeon experience. Transanal excision is the simplest of these techniques and may be considered for easily accessible distal lesions. Transanal endoscopic microsurgery (TEM) and transanal minimal invasive surgery (TAMIS) are newer techniques that offer improved visualization and the ability to reach more proximal lesions (Fig. 8). Data show that TEM and TAMIS result in less specimen fragmentation, a lower risk of positive margins, and lower local recurrence compared with transanal excision.

Following local excision, the specimen should be thoroughly reviewed by an experienced pathologist to confirm the margin status and depth of invasion. If there is evidence of deep T1 or T2 disease, high-risk features, or positive margins after local excision, patients should be offered radical resection given the risk of nodal disease.

NONOPERATIVE MANAGEMENT

Following administration of neoadjuvant therapy, some patients will have a complete pathologic response. Following neoadjuvant long-course chemoradiotherapy, this occurs in 10% to 20% of patients. With the increasing usage of TNT has come the realization that up to 50% of patients will have an initial complete clinical response. These patients are candidates for an organ preservation strategy that involves intensive surveillance with MRI, endoscopy, and digital rectal examination. At 2 years, up to 30% of patients will experience local regrowth, and they should be offered radical resection. To date, data demonstrate that regrowth tends to occur luminally as opposed to within regional nodes or as distant metastatic disease. Although national guidelines have slowly started to include watch and wait as an acceptable management strategy in select patients, additional randomized studies are ongoing, and generally it should only be performed in select centers where adequate support and experience are available.

MANAGEMENT OF METASTATIC DISEASE

For the 10% to 20% of patients who present with metastatic disease, multidisciplinary input is essential. Systemic chemotherapy is the mainstay of treatment and should be initiated without delay. For those with isolated liver or lung metastases, resection with curative intent is feasible and is associated with a 5-year disease-specific survival up to 20%. The order of resection or decision to perform a simultaneous resection should be individualized based on the patient's symptoms, overall health, and complexity of planned operations. Outside of an attempt at surgery with curative intent, radical resection should not be performed on asymptomatic primary tumors. However, in the setting of highly symptomatic lesions, radical resection may be required.

POSTOPERATIVE MANAGEMENT/ SURVEILLANCE

For stage II and III patients who received neoadjuvant chemoradiotherapy but not systemic chemotherapy, an oxaliplatin-based regimen should be initiated within 8 weeks of radical resection. In the event a patient underwent upfront surgery for what was thought to be a stage I tumor, postoperative radiation may be administered for high-risk stage II or III disease. Following total neoadjuvant therapy; additional systemic chemotherapy is not generally required.

Following successful surgical management of rectal cancer and completion of all adjuvant treatment, patients undergo surveillance, which is based on the final pathologic stage. Rectal cancer may reoccur luminally at an anastomosis, within the pelvis, in lymph nodes, or as metastatic disease, typically to the liver or lungs. Overall, recurrence rates are higher for rectal cancer than for colon cancer, with local recurrence occurring in 4% to 22% of cases. Early detection is key as it allows for potential salvage or curative surgical procedures.

Most surveillance guidelines focus on the first 5 years after surgical resection as 80% of all recurrences will occur within 3 years of surgery, and 95% will occur within 5 years. Those with stage I disease should receive a colonoscopy at 1 year postoperatively, with no need

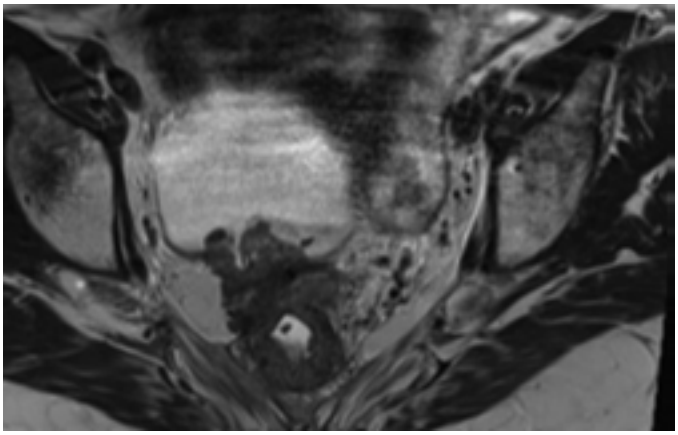

FIG. 9 T2-weighted MRI demonstrating local recurrence after low anterior resection with tumor involvement of the vagina and bladder, which was managed with pelvic exenteration.

for CEA or additional surveillance imaging. For stage II, III, and IV, patients should have a history and physical examination and CEA level every 3 to 6 months for 2 years, then every 6 months for a total of 5 years. CT of the chest, abdomen, and pelvis should be obtained yearly for 5 years, except in the setting of stage IV disease, which warrants imaging every 6 months for the first 2 years and then yearly, for a total of 5 years. All stages should have a surveillance colonoscopy performed at 1 year. For the select patients who undergo local excision, proctoscopy and MRI of the pelvis should be performed every 3 to 6 months for 2 years, followed by every 6 months for a total of 5 years.

Should local recurrence be identified, management is a complex topic that necessitates a multidisciplinary approach (Fig. 9). Treatment options may include additional chemotherapy, radiotherapy, and/or surgical resection depending on the site, extent of disease, and prior treatments. It is imperative to exclude additional distant metastatic disease, so repeat staging with PET/CT should be considered. Upfront treatment with additional chemotherapy is common, especially in the setting of extensive disease. If no prior radiotherapy was given, it should be administered preoperatively, and re-irradiation may be considered in select circumstances. Metastatic disease to the lung or liver may be resected with curative intent when feasible. Surgical resection of local recurrence often requires multivisceral resection, so careful assessment of the patient's expected postoperative function is imperative.

Management of Tumors of the Anal Region

Emilie C. Barnes, MD, and Jose G. Guillem, MD

OVERVIEW AND ANATOMY

The surgical anal canal extends from the anal verge proximally to the upper part of the anorectal ring and typically measures about 4 cm in length (Fig. 1). Histologically, the canal can be divided into three different zones. The zone proximal to the dentate line is composed of columnar and cuboidal cells that are similar to those in the nearby rectal mucosa. The area around the level of the dentate line and valves of Morgagni is known as the *anal transition zone* (ATZ) and is composed of transitional epithelium. The most distal zone is made up of squamous epithelium. The anal margin, located at the intersphincteric groove, is a mucocutaneous junction with non-keratinized squamous epithelium proximally and keratinized squamous epithelium distally that contains hair follicles, apocrine glands, and sweat glands.

The blood supply and lymphatic drainage vary depending on the location within the anal canal. The proximal anal canal is supplied by the superior rectal artery. Venous drainage occurs via the superior and middle rectal veins, and lymphatic drainage occurs via the mesorectal, internal iliac, and inferior mesenteric lymph nodes. In contrast, the distal anal canal (below the dentate line) is supplied by the inferior rectal branch of the pudendal artery, and venous drainage occurs via the inferior hemorrhoidal vessels that drain to the internal iliac veins. Lymphatic drainage occurs via the inguinal lymph nodes. This distinction between the proximal and distal anal canal is important when considering locoregional spread of anal neoplasms.

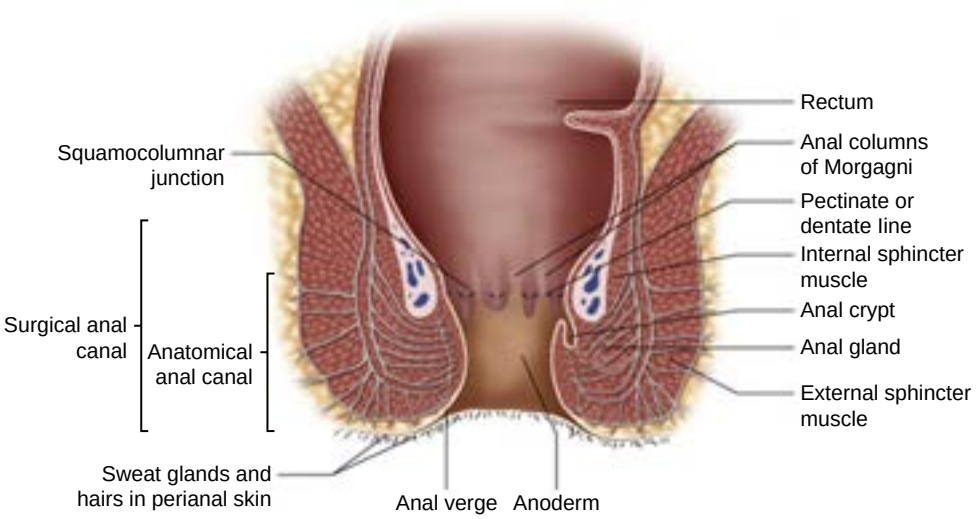

FIG. 1 Anatomy of the anal canal. *(From Steele SR, et al. The ASCRS Textbook of Colon and Rectal Surgery. 3rd ed. Springer; 2016.)*

Although the diagnosis of anal cancer remains rare, the incidence is on the rise and now accounts for about 0.5% of all cancer diagnoses in the United States and roughly 3% of all gastrointestinal malignancies. The vast majority (85%) are of squamous cell histology, followed by adenocarcinoma (5%–10%) in addition to rare lesions such as melanoma, mesenchymal tumors, neuroendocrine tumors (NETs), and lymphoma. Patients often present with rectal bleeding and pain, which can sometimes be confused for benign anal conditions, such as hemorrhoids. Others have no symptoms, and the diagnosis is made incidentally. HPV infection is highly associated with the development of anal cancer, and up to 90% of anal cancers are attributed to this infection. Other major risk factors include older age, smoking, and immunocompromised states, particularly patients with human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) or transplant patients.

SQUAMOUS NEOPLASMS

Human Papilloma Virus and Anal Squamous Neoplasia

Human papilloma virus (HPV) is the most common sexually transmitted infection in the United States. Although there are over 100 subtypes, subtypes 16 and 18 have a strong relationship with the development of anal squamous cell carcinoma (SCC). The Centers for Disease Control and Prevention (CDC) estimates that these two subtypes of HPV account for up to 79% of all anal cancers. The quadrivalent HPV vaccine, which targets subtypes 6, 11, 16, and 18, has been shown to be efficacious in reducing rates of anal intraepithelial neoplasia and the subsequent development of cancer. However, uptake of the vaccine in the United States has been suboptimal. Currently, the CDC recommends routine vaccination for children beginning at age 11 and for all patients up to the age of 26 who have not been previously vaccinated.

Condyloma Acuminatum (Anal Warts)

Condyloma acuminatum, also known as *anal warts,* occurs secondary to HPV infection, most commonly subtypes 6 and 11 (Fig. 2). Other factors that increase the risk of development, larger size, and recurrence after treatment include smoking and immunocompromised states such as HIV. Lesions can present in a variety of ways, including single, multiple, flat, dome-shaped, cauliflower-shaped, skin-colored, erythematous, hypopigmented, or hyperpigmented. Location can also be within the anal canal or on the perianal skin. Evaluation of these lesions should include a complete anogenital examination, including anoscopy and referral to gynecology for vaginal examination with a Papanicolaou (Pap) smear in females.

Although it is estimated that up to one-third of anogenital warts will regress on their own within 4 months of detection, recurrence rates are high, therefore treatment should be offered to all patients. Options include topical therapies such as imiquimod cream, podophyllotoxin, and sinecatechins, with clearance rates ranging from 35% to 75%. Other treatment options include application of trichloroacetic acid (TCA) to cryotherapy and surgical fulguration/excision. Recurrence rates for all of the aforementioned treatments remain high at about 20% to 40% and are likely attributed to persistent HPV infection.

Buschke-Lowenstein Tumor (Verrucous Carcinoma)

The Buschke-Lowenstein tumor, also known as *verrucous carcinoma* or *giant condyloma acuminatum,* is a rare, slow-growing SCC that lacks basement membrane invasion (Fig. 3). As a result, it tends to spread laterally and rarely metastasizes. This tumor presents as an exophytic, fungating, cauliflower-type mass that is strongly associated with HPV (particularly subtypes 6 and 11). The standard of care involves wide local excision and potentially abdominoperineal resection (APR) for more extensive disease. Even with aggressive surgical management, recurrence rates are high (up to 70%), and malignant transformation occurs in up to 50% of cases.

Anal Intraepithelial Neoplasia

Anal intraepithelial neoplasia (AIN) is a premalignant lesion for anal SCC characterized by cellular and nuclear abnormalities of the squamous epithelial cells without extension into the basement membrane. In more recent years, the terminology surrounding AIN has evolved to a two-tier system of *low-grade squamous intraepithelial lesions* (LSILs) and *high-grade squamous intraepithelial lesions* (HSILs). AIN I, which involves replacement of the lower third of the epithelium with abnormal cells, is now considered LSIL. What was formerly described as AIN II/III and involved replacement of greater than one third of the epithelium now corresponds to HSIL. The use of the term *Bowen disease,* which is synonymous with *AIN III* or *SCC in situ,* is no longer encouraged. In addition to HPV infection, major

FIG. 2 Condyloma acuminatum. *(From Fazio V, Church J, et al.* Current Therapy in Colon and Rectal Surgery. 3rd ed. Philadelphia: Elsevier).

FIG. 3 Buschke-Lowenstein tumor. (From Fazio V, Church J, et al. *Current Therapy in Colon and Rectal Surgery. 3rd ed. Philadelphia: Elsevier).*

risk factors for the development of LSIL/HSIL, and eventually SCC, include HIV-positive status, men who have sex with men (MSM), women with a history of cervical dysplasia, and cigarette smoking.

Although the prevention of cervical cancer with screening for precancerous lesions has proven to be effective, it is less clear if the same principles apply to anal carcinoma. There is currently no data to support screening in the general population, however, screening with anal Pap tests may be beneficial in high-risk patients, such as those that are HIV positive, MSM, and females with a history of cervical dysplasia. Unfortunately, there is no current conclusive data to support the use of anal cytology to identify patients at risk for dysplasia, resulting in a reduction in rates of anal cancer, therefore the decision to perform screening anal Pap tests should be a shared decision between patients and providers.

Diagnosis

Most patients with anal squamous intraepithelial lesions are asymptomatic, and diagnosis is made either incidentally or as part of a surveillance program. If symptomatic, the most common symptoms include rectal bleeding, perianal pruritis or irritation, and tenesmus. Diagnosis typically is initially based on cytology and is obtained via anal Pap smear. The Bethesda classification system classifies cells as *atypical squamous cells of undetermined significance* (ACUS), LSIL, HSIL or atypical squamous cells cannot exclude HSIL. Immunohistochemical stains, such a p16, can be used to help differentiate HSIL from other mimics. Abnormal anal cytology should be followed by direct anal examination and tissue biopsy. This can be accomplished with either traditional anoscopy or high-resolution anoscopy (HRA).

Although in some patients LSIL or HSIL regresses without treatment, in others it progresses to malignancy. Patients with HIV are at the highest risk of progressing from LSIL to HSIL. In fact, in patients with HIV, the rate of progression from HSIL to SCC ranges from 8.6% to 19.6%.

Management

All patients with evidence of anal dysplasia should be followed clinically at regular intervals with a history and physical examination. The frequency of these examinations and the addition of HRA is debated and is also dependent on patient risk factors, most importantly HIV status, and provider training with HRA. For patients with LSILs who are HIV negative, examinations can be performed every 6 to 12 months. However, HIV-positive patients with LSILs should be examined more frequently, on the order of every 3 to 6 months.

Local therapy, which includes topical or ablative treatments, is indicated for HSILs and can also be considered in patients with LSILs, given the small but real risk of progression to invasive cancer. Topical options include imiquimod, 5-fluorouracil (5-FU), and trichloroacetic acid (TCA). Imiquimod is an immune modulator that can be directly applied to the anal canal by the patient or provider. One randomized trial in HIV-positive MSM who received either placebo or imiquimod demonstrated 43% resolution or downgrading of their dysplasia with a 61% sustained response at 36 months. Use of this medication is somewhat limited by side effects that include irritation, burning, and erosions. Similar results have been seen with topical 5-FU, with response rates up to 57% (39% with complete response). However, recurrence rates remain high at around 50%. Finally, although it is well tolerated by patients, TCA has been reported to have response rates up to 72%, but with recurrence occurring in about 20% of cases.

Options for local ablative therapy include radiofrequency ablation (RFA), infrared coagulation, and electrocautery. Studies on RFA and infrared coagulation are limited to a small number of retrospective studies that have shown response rates up to 64% (either complete resolution or downgrading of dysplasia) but dramatic recurrence rates, up to 91% in HIV-positive MSM at 17 months. Data on the outcomes regarding infrared coagulation are also limited, but one single-center retrospective study reported an up to 82% treatment response in HIV-positive patients. Recurrence rates have been difficult to estimate because of the number of patients lost to follow-up. Finally, electrocautery ablation has been shown to have initial clearance rates as high as 80%, but recurrence was also extremely common (up to 61%). Surgical excision remains an option for recalcitrant lesions but is challenging with larger lesions and resultant large defects that may require local flaps that may lead to stenosis and/or seepage.

In patients with HSIL who are treated with local topical or ablative therapy, surveillance involves regular follow-up with a complete history and physical examination with the addition of HRA being provider-dependent. Patients with persistent dysplasia or who are HIV-positive should be examined every 3 to 6 months, and those without evidence of persistent dysplasia and who are HIV negative can be seen annually. The ANCHOR study is a randomized controlled clinical trial comparing topical or ablative treatment with active monitoring in preventing anal cancer in HIV-positive patients with evidence of HSIL. As of October 2021, the study was halted after researchers found that treating HSIL lesions significantly reduced chances of progression to anal cancer. Although official results have yet to be published, this randomized controlled trial will hopefully provide the information needed to establish definitive treatment and surveillance strategies for HIV-positive patients with anal intraepithelial lesions.

Squamous Cell Carcinoma

Diagnosis

SCC accounts for the vast majority of anal neoplasms (up to 85%) (Fig. 4). Although many patients are asymptomatic, about 45% present with anorectal bleeding. Unfortunately, this is often attributed to hemorrhoids, which leads to a delay in diagnosis. Other symptoms include anorectal pain, inguinal pain, tenesmus, and change in bowel habits, particularly narrowing of stool caliber. About one-half of patients are found to have localized, node-negative disease at the time of diagnosis, while another one-third of patients are found to be node positive. The remaining 10% to 15% present with evidence of distant metastases.

Initial evaluation should involve a thorough history including evaluation of baseline anal sphincter continence, prior radiation, and assessment of risk factors such as MSM, anal receptive intercourse, and immunosuppression. If HIV status is unknown, this should be included in addition to basic laboratory studies. Physical examination should include a thorough examination of the perianal skin, examination of the inguinofemoral region for adenopathy, digital rectal examination, and anoscopy. Specific attention should be paid to the sphincter tone, size of the mass, and any evidence of fixation to

FIG. 4 Anal squamous cell carcinoma: fungating mass at the anal verge.

surrounding structures, such as the vagina, prostate, coccyx, or pelvic sidewall. Males should undergo a scrotal and penile examination, while females should be referred to gynecology for a cervical examination with Pap smear given the association with other anogenital malignancies. All patients should also be examined for evidence of inguinal lymphadenopathy. Given the risk of a synchronous colorectal neoplasm, a colonoscopy should also be performed.

Staging

Staging of anal SCC is according to the TNM classification system. All patients should undergo radiologic staging with computed tomography (CT) of the chest, abdomen, and pelvis. Magnetic resonance imaging (MRI) of the pelvis is also often obtained for evaluation of the extent of locoregional disease but is not required for staging. More recently, positron emission tomography (PET)/CT has been utilized as an additional imaging modality for assistance with staging as well as for radiation planning. A biopsy with fine-needle aspiration should be performed on any concerning inguinal lymphadenopathy based on examination or imaging.

Treatment

Historically, anal SCC was treated surgically with APR. In 1974, Nigro et al. published the initial case series in which neoadjuvant chemoradiotherapy (5-FU, mitomycin C, and 30 Gy of radiation) was administered before APR. They found that many of the surgical specimens had no evidence of residual disease on final pathology. This realization led to a significant paradigm shift from upfront surgical management to the current standard of care of chemoradiotherapy (CRT).

The current standard of care involves a regimen of mitomycin C and 5-FU or mitomycin C and capecitabine administered concurrently with radiation. A multifield technique is used to administer a minimum radiation dose of 45 Gy over a 5-week period. Additional boosts of radiation are given for lesions greater than T1 or with positive lymph nodes for a maximum dose of 59 Gy. 5-FU is given on days 1 to 4 and from days 29 to 32. Mitomycin C is given on days 1 and 29. Alternatively, capecitabine can be substituted for 5-FU and given 5 days per week for 4 to 6 weeks. The most common side effects of chemoradiation include gastrointestinal side effects such as nausea, diarrhea, bowel incontinence, and abdominal pain, urinary symptoms such as frequency, urinary incontinence, and dysuria, and sexual side effects.

National Comprehensive Cancer Network (NCCN) guidelines recommend that patients should be examined 8 to 12 weeks after the completion of CRT. This should include a digital rectal examination, anoscopy, and palpation of the inguinal lymph nodes. Persistent disease without evidence of progression can be followed clinically with serial examinations every 4 weeks for up to 6 months as tumor regression can continue for up to 6 months after completion of CRT. Repeat biopsy is indicated for any evidence of disease progression or persistent disease at 6 months.

Local excision is reserved for the management of anal cancer in two specific scenarios. First is for the treatment of superficially invasive anal canal cancer, which is defined as anal cancer with ≤3 mm basement membrane invasion and a maximal horizontal spread ≤7 mm. Additionally, local excision with 1-cm margins is indicated for T1N0, well-differentiated perianal SCC.

Posttreatment Surveillance

Patients found to have complete response after CRT should undergo digital rectal examination, anoscopy, and palpation of inguinal lymph nodes every 3 to 6 months for 5 years. Patients who were found to have T3/T4 disease or nodal involvement at the time of diagnosis or required salvage APR should also undergo CT of the chest/abdomen/pelvis yearly for the first 3 years.

Treatment of Recurrent or Persistent Disease

After the completion of CRT, up to 10% to 30% of patients have evidence of persistent disease or develop locoregional recurrence. Predictors of persistent or recurrent disease include higher T and N stages at original presentation, HIV-positive status, and inability to complete a full course of CRT. For disease that is localized to the anal canal and/or perineum, salvage APR is indicated. For patients undergoing salvage APR, 5-year overall survival has been reported to be 25% to 60% compared with a 3-year overall survival of 5% for patients who are unable to undergo a salvage APR. Unfortunately, given the effects of prior CRT, patients who undergo salvage APR are at higher risk of developing issues with wound healing and often benefit from reconstructive tissue flaps such as vertical rectus abdominis myocutaneous (VRAM), gracilis, or gluteus flaps.

Metastatic Disease

About 10% to 15% of patients with anal SCC are found to have evidence of distant metastases at the time of diagnosis. Most common locations include the liver, lungs, extrapelvic lymph nodes, peritoneum, bones, and brain. Chemotherapy remains the mainstay of therapy, despite fairly limited data supporting its use. Traditionally the most common regimen was a combination of cisplatin and 5-FU, which boasted response rates around 60%. However, more recently, a randomized controlled trial (InterAAct) was published that specifically compared the traditional regimen of cisplatin and 5-FU to carboplatin and paclitaxel in patients with locally recurrent inoperable or metastatic disease. Although no difference was seen with regard to objective response rate (ORR), reduced toxicity was seen in the cohort receiving carboplatin plus paclitaxel as well as a trend toward longer survival. In the setting of metastatic disease that is refractory to chemotherapy, some small studies examining PD-1/PD-L1 inhibitors have shown response rates up to 24%.

COLUMNAR NEOPLASMS

Adenocarcinoma

Anal adenocarcinoma is rare and accounts for only about 5% to 10% of all anal cancer diagnoses. This form of adenocarcinoma typically arises from two locations: the columnar epithelium of the upper anal canal and from the anal canal glands. The upper anal canal type can often be difficult to differentiate from low rectal adenocarcinoma. The anal canal gland type tends to be associated with chronic anal fistula tracts that are more commonly seen in patients with Crohn's disease. Initial workup and staging includes laboratory tests (including CEA level), colonoscopy, CT of the chest/abdomen/pelvis to evaluate for metastatic disease, and MRI of the pelvis to evaluate locoregional spread. Given the rarity of this diagnosis, there are no randomized controlled trials to help establish the standard of care. Instead, the NCCN guidelines recommend applying the same treatment algorithm that it is used for rectal adenocarcinoma. Although local excision can be considered for well-differentiated T1N0 tumors, most require neoadjuvant chemoradiation followed by an APR. However, with the advent of organ preservation approaches, anal adenocarcinoma may be amenable to preoperative chemoradiotherapy and a possible "watch and wait" approach in the case of a complete clinical response.

Paget's Disease

Perianal Paget's disease is an intraepithelial adenocarcinoma of the perianal skin (Fig. 5). Presentation is frequently nonspecific and can often be mistaken for other skin conditions like eczema or dermatitis. Skin involvement is limited to the apocrine gland–bearing areas and is typically characterized by well-circumscribed erythematous or leukoplakic plaques or as macules with either hyperpigmentation or hypopigmentation. Patients frequently complain of pruritis and, less commonly, bleeding and ulceration. Diagnosis is confirmed with biopsy of the involved skin, which demonstrates intraepithelial

FIG. 5 Perianal Paget's disease.

carcinoma. The classic histologic finding is Paget cells, which are glandular epithelial cells with abundant clear cytoplasm.

Paget's disease can simply represent a primary malignancy of the apocrine glands versus a synchronous or metachronous lesion from another site as there is a high association with rectal, anal, and bladder adenocarcinoma. In fact, up to 70% to 80% of perianal Paget's disease is thought to arise secondary to invasive malignancy from the anus, rectum, or colon. Patients with a new diagnosis of Paget's disease should undergo a thorough history and physical examination as well as colonoscopy. In patients with primary perianal Paget's disease, the standard of care is wide local excision with a 1-cm margin. If Paget's disease is found in association with a locally invasive anorectal adenocarcinoma, neoadjuvant chemoradiation followed by APR is an option.

MELANOMA

Anal melanoma accounts for 1% of all anorectal malignancies and 0.4% to 1.6% of all melanomas. Symptoms are often subtle and nonspecific, most commonly including rectal bleeding, pain, obstruction, and tenesmus in larger lesions. Prognosis of anal melanoma is poor because of the frequently delayed presentation of these patients in combination with the development of early distant metastases. The preferred treatment involves surgical resection, either wide local excision or APR, depending on the extent of sphincter involvement. However, this has not shown to improve median survival, which has been reported as less than 2 years.

NEUROENDOCRINE AND MESENCHYMAL TUMORS

NETs make up about 1% of all anal canal tumors. Most NETs in this location are nonfunctional. Another rare type of anal canal tumor includes mesenchymal tumors, which include smooth muscle tumors and gastrointestinal stromal tumors. Treatment for these tumors typically involves local excision alone, but it may require radical resection if the tumors are large or locally advanced.

MALIGNANT LYMPHOMA

Although rare, both Hodgkin's and non-Hodgkin's lymphoma of the anal canal have been reported. The most common type is high-grade B-cell lymphoma. Like many of the other anal tumors previously discussed, anal lymphoma is associated with immunocompromised states and is more commonly seen in patients with HIV. Treatment is not typically surgical and instead involves chemoradiation.

Cystic Disease of the Liver

Lucas W. Thornblade, MD, MPH, and Yuman Fong, MD

INTRODUCTION

Cysts of the liver are a common phenomenon and occur in approximately 5% to 20% of adults. They are sporadic and largely not associated with familial syndromes. Most cysts of the liver are simple and benign, however a minority of liver cysts and cystic lesions harbor either active malignancy or malignant potential (Table 1). The challenge presented to the liver surgeon is differentiating cysts that are very likely benign (and therefore appropriate for observation or no surveillance at all) from cysts with features of potential malignancy that are better suited to resection. Although most liver cysts are diagnosed incidentally, a minority of cysts cause compressive or mass-effect symptoms, particularly when they become large or bleed, either spontaneously or as a result of trauma. Less commonly, cysts can rupture into the peritoneal cavity, cause biliary compression, become infected, or sustain torsion. Control of masslike, infectious, or hemorrhage-related symptoms are indications for treating cysts of the liver aside from their malignant potential. Cysts or abscesses of the liver from infectious or parasitic causes are beyond the scope of this chapter, however echinococcal cysts and amebic abscesses of the liver must be thoroughly ruled out by patient history, imaging features, and serology testing when appropriate. This chapter reviews (1) imaging characteristics of liver cysts, (2) types of common and uncommon cysts and cystic lesions of the liver, (3) special considerations when working up hepatic cysts, and (4) surgical and nonsurgical approaches to management of hepatic cysts.

Imaging Characteristics

Benign liver cysts are simple, round, fluid-filled cavities that are found within the liver parenchyma and exhibit a single layer of cuboidal epithelialized lining of the cyst wall. They do not communicate with the biliary tree. Simple cysts can be a few millimeters in size or grow to contain several liters of clear simple fluid. Benign liver cysts are slightly more common in the right lobe of the liver and have a slight female predominance. Large and symptomatic simple liver cysts, however, are much more commonly found in females.

Ultrasound is the least expensive and therefore a common first modality for assessment of liver cysts. Ultrasound of liver cysts demonstrates anechoic or hypoechoic features that are consistent with a round, unilocular, fluid-filled structure complemented by posterior acoustic enhancement. On CT scan, benign cysts appear hypodense with Hounsfield unit measurements close to that of water. The walls of benign cysts do not enhance with intravenous contrast and are quite thin. On MRI, the feature of a cystic lesion in the T2 sequence is high attenuation (i.e., bright), and this easily distinguishes the cyst from solid lesions. Cysts are T1 hypoattenuating. The added benefit of MRI in evaluating cysts of the liver is the increased detail provided to differentiate cyst contents as simple fluid from hemorrhage products, protein, and mucin. MRI can also provide detail on features such as subtle mural nodules or projections. Figure 1 presents an example of a large benign cyst on CT and ultrasound imaging.

Benign cysts are round, therefore asymmetry or even ovoid shapes are worrisome features. Benign cysts may have lobulated borders if the cyst wall folds around fixed portal pedicle structures as they grow. The wall of a benign cyst, regardless of the imaging modality, is nearly imperceptible. The absence of additional features adds confidence to the diagnosis of a benign cyst. Specifically, cysts that lack features of wall thickening, wall nodularity, papillary features, septations, or other masses are very likely to be simple and benign cysts. Clinical characteristics must complement the imaging of liver cysts to differentiate them from abscesses and tumors with areas of liquified necrosis. Hemorrhage into a cyst can result in areas of increased density or even the appearance of septation. Calcifications are a feature of echinococcal cysts. Figure 2 demonstrates the compressive effect of a large cyst on surrounding parenchyma resulting in focal biliary dilation.

Types of Cystic Liver Lesions

Benign liver cysts are common. However, the differential diagnosis for non-simple cysts is broad and demands thoughtful consideration.

Mucinous Cystic Neoplasm and Mucinous Cystadenocarcinoma

Mucinous cystic neoplasms (previously *cystadenoma*) are a class of rare cystic lesions found in the liver that are histologically similar to pancreatic mucinous cystadenoma. Morphologically, these cysts have a biliary-type glandular lining with projections and cryptlike invaginations. Their glandular tissue is surrounded by dense fibrous (mesenchymal) tissue described as ovarian-type stroma. Radiographically, mucinous cystic neoplasms appear as complex cysts with thickened and irregular (or even nodular) walls. Ultrasound features include internal echoes. The contents of mucinous cystic neoplasm may be bloody or chocolate colored. Mucinous cystic neoplasms of the liver have malignant potential as they can develop atypia or dysplasia. Over a prolonged period (perhaps >10 years), an estimated 2% to 15% of mucinous cystic neoplasms will degenerate into malignancy known as *mucinous cystadenocarcinoma.* These occur in older adults and have metastatic potential. Mucinous cystadenocarcinomas are overall rare but should definitively be resected along with all mucinous cysts exhibiting worrisome features. Mucinous cystic neoplasms that do not appear to contain malignancy can be

TABLE 1 Types of Cystic Lesions of the Liver and Their Characteristics

Cyst Type	Characteristics	Proposed Treatments
Simple cyst	Round, thin wall, simple fluid	None, observe, sclerotherapy, fenestration
Mucinous cystic neoplasm	Complex cyst, thickened irregular wall, ovarian-type stroma	Observe, enucleation, resection
Mucinous cystadenocarcinoma	Like mucinous cystic neoplasm, may form masses	Resection
Ciliated hepatic foregut cyst	Four-layered cyst, commonly within segments 4A/B	Observe, enucleation
Cystic subtypes of primary liver cancer and metastasis	Complex solid and cystic mass of the liver	Resection
Traumatic cysts	Occur in areas of disrupted liver parenchyma, may develop as a biloma	Observation
Pseudocysts of the liver	Occur as a consequence of adjacent pancreatitis	None
Intraductal papillary mucinous neoplasm of the bile duct (IPMN-B)	Mucin-containing cystic dilations of the bile duct with associated papillary mass, intermittent jaundice	Resection
Polycystic liver disease	Autosomal dominant, ≥20 cysts	Observe, fenestration, transplantation

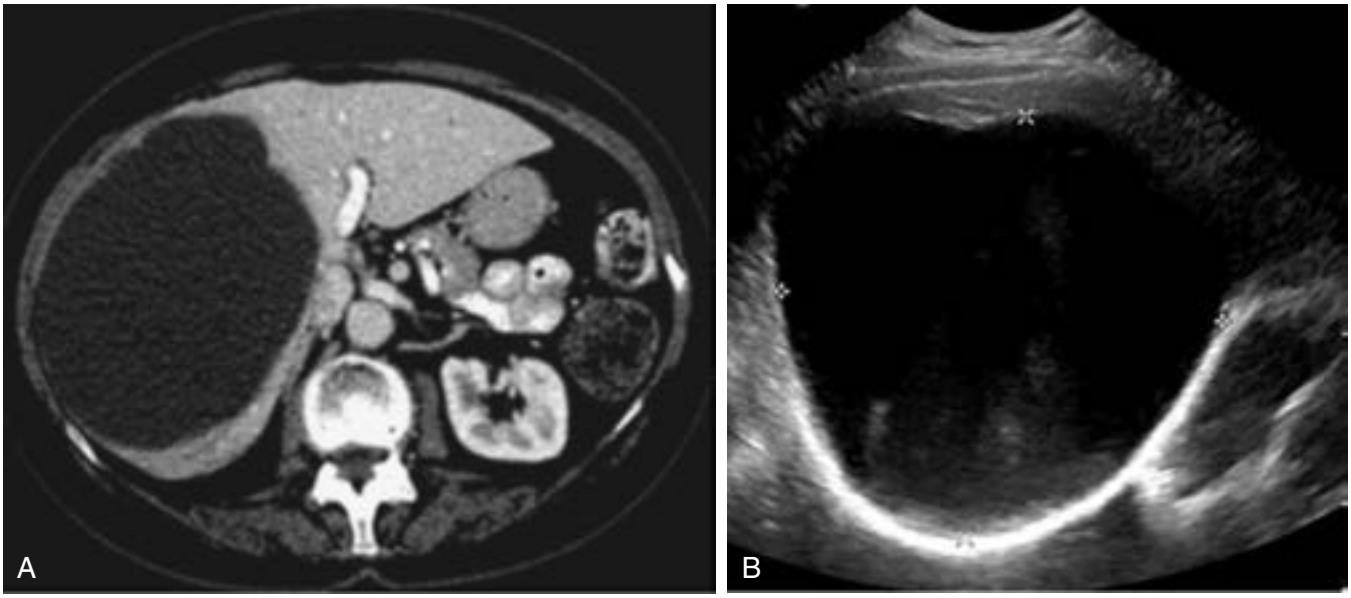

FIG. 1 Simple cyst with homogenous appearance and no wall nodularity on CT **(A),** verified to be a simple cyst by ultrasound **(B).**

enucleated and do not require resection with a margin of normal liver parenchyma. Which patients to take for enucleation, however, remains controversial. In patients who are high risk for liver surgery, observation of mucinous cystic neoplasms is appropriate.

Intraductal Papillary Mucinous Neoplasm of the Bile Duct

The entity known as *intraductal papillary mucinous neoplasm of the bile duct* (IPMN-B) is a mucin-producing solid neoplasm that arises within the liver and has direct communication with the bile ducts. It has only recently been described as it was previously believed to be a papillary subtype of cholangiocarcinoma. Because of its secretion of mucin, like IPMNs of the pancreas, the lesion will appear as a cystic lesion on imaging. The intraductal solid component is made up of frondlike papillary projections that grow along the mucosal surface of the duct. These frondlike projections produce mucin that fills the duct. IPMN-B invariably presents with proximal biliary dilation, though jaundice may be intermittent. Although sampling of these lesions may be low yield, endoscopic retrograde cholangiopancreatography (ERCP) provides diagnostic clarity. Like IMPNs of the pancreas, many IPMN-Bs contain cancer or will degenerate into cancer, therefore resection is recommended. The prognosis for these patients is generally considered favorable compared with cholangiocarcinoma.

Ciliated Hepatic Foregut Cyst

Only a few cases of ciliated hepatic foregut cysts are described each year. These lesions are solitary and histologically have four layers: a

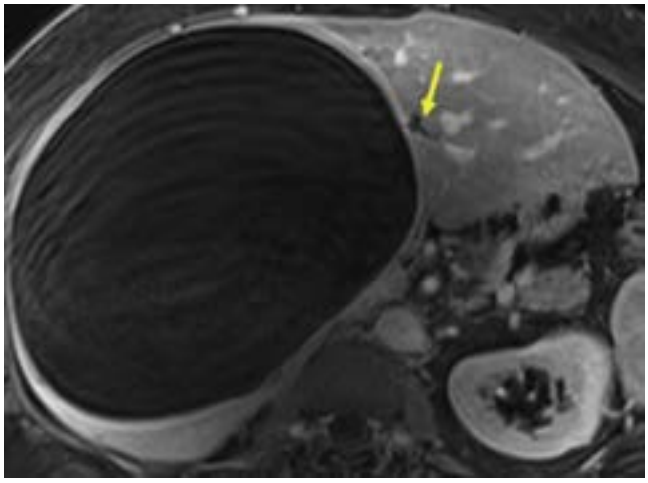

FIG. 2 Very large cysts can cause compression of adjacent structures, including bile ducts *(arrow)*.

ciliated and pseudostratified columnar epithelium, a subepithelial connective tissue layer, a smooth muscle wall, and a tough fibrous capsule. These may present at any age but can cause pain or jaundice. Ciliated hepatic foregut cysts often occur within segments 4A/4B and may abut the gallbladder. They are largely benign; therefore if ciliated hepatic foregut cysts are treated surgically, enucleation is appropriate. Only rarely, squamous cell carcinoma is described within large ciliated hepatic foregut cysts.

Cystic Malignancy

Both primary and secondary malignancies of the liver may present with cystic components. Therefore, one should not deduce that cystic lesions exhibiting any solid component or associated masses are benign. For example, there are cystic subtypes of hepatocellular carcinoma, cystic primary liver sarcoma, cystic metastatic neuroendocrine tumors, and cystic colorectal liver metastases. As with the workup for solid liver lesions, the finding of a cystic mass of the liver warrants a careful history and physical, dedicated liver imaging, tumor markers, consideration of a workup for primary tumor site (e.g., colonoscopy, upper endoscopy), and a biopsy in the case of any diagnostic uncertainty. Intrahepatic ductal dilation associated with a cyst is a sign suggestive of underlying malignancy. Rate of growth can be helpful in elucidating an appropriate level of concern in indeterminate lesions. Because CA 19-9 is expressed by normal biliary epithelium, elevation of this tumor marker may not differentiate cancerous and non-cancerous cystic liver lesions.

Hepatic Pseudocysts and Traumatic Cysts

As a result of severe pancreatitis, inflammation along the hepatoduodenal ligament can cause cystic transformation of these structures resulting in the appearance of cysts within the liver. Like pancreatic pseudocysts, they do not have an epithelial lining. With resolution of pancreatitis, these lesions should resolve and do not require surgical drainage or other intervention unless they become infected. Trauma to the liver can also result in cystic degeneration of tissue over time. Parenchymal disruption may lead to hematomas, which over time coalesce into fluid-filled spaces within the parenchyma or beneath the Glisson capsule. Like other benign cystic structures of the liver, they do not warrant further intervention unless symptomatic. Posttraumatic cysts of the liver may also communicate with the bile duct and therefore should be considered a biloma. Percutaneous drainage of bilomas should be avoided because of the risk of ongoing bile leak. Bilomas may require endoscopic biliary decompression to resolve.

TABLE 2 Mayo Clinic Classifications of Polycystic Liver Disease

Type	Symptoms	Portal Vein or Hepatic Vein Occlusion of Preserved Sector	Area of Relatively Normal Liver Parenchyma
A	Absent/Mild	Absent	
B	Moderate/Severe	Absent	≥2 sectors
C	Moderate/Severe	Absent	≥1 sector
D	Moderate/Severe	Present	<1 sector

Polycystic Liver Disease

Some patients with polycystic kidney disease will also develop polycystic liver disease, and the development of concomitant liver cysts increases with increasing age. By 60 years of age, at least half of patients with polycystic kidney disease will have also developed cystic proliferation in the liver (Table 2). A less common condition is autosomal dominant polycystic liver disease (ADPLD), which is defined as ≥20 cysts of the liver. This occurs in a heritable pattern, typically as a result of mutations in the *PRKCSH* gene that encodes for hepatocystin; mutations in the *SEC63* gene; or loss-of-function mutations in the *ALG8*, *GANAB,* or *SEC61B* genes, which effect polycystin-1 biogenesis. The number of affected alleles determines the extent of cystic degeneration, therefore there is disease heterogeneity. Patients with ADPLD can also develop cerebral aneurysms. Patients with ADPLD do not have concomitant kidney cysts but, whether heritable or otherwise, they may develop hundreds of cysts in the liver that increase in size over time. Because of their multiplicity, cyst resection is often not beneficial to these patients. When liver parenchyma is replaced by a large volume of cysts, synthetic function of the liver is preserved, but patients can develop infections and biliary obstruction and may require numerous endoscopic procedures. Some patients with hepatomegaly will be considered for liver transplantation.

The Mayo Clinic classifications for polycystic liver disease quantify symptoms, extent of normal liver parenchymal preservation, and the status of vascular inflow and outflow (see Fig. 2). This can be used to guide whether patients should be observed, treated with limited resection, or referred for transplantation. Some patients benefit from the use of long-acting octreotide in polycystic liver disease.

Special Considerations

Biliary Cysts

Biliary cysts, elsewhere described as *choledochal cysts,* are saccular or fusiform dilations of the intrahepatic or extrahepatic bile ducts. Biliary cysts alone may be asymptomatic, but all carry an increased risk of cholangiocarcinoma. Based on the location of the cyst and the age of the patient, resection is commonly recommended to prevent degeneration into carcinoma. The proximity to the hepatic parenchyma, biliary bifurcation, or ampulla of Vater will determine whether the patient may require a resection of the extrahepatic bile duct alone or along with liver resection and/or pancreaticoduodenectomy. Characterization of biliary cysts is best facilitated by magnetic resonance cholangiopancreatography (MRCP), and this modality should be employed if there is any diagnostic uncertainty or if lesions are difficult to distinguish from primary liver cysts. Patients with biliary cysts that are considered low risk or who are not surgical candidates may be best followed with serial MRCP. Type V biliary cysts, also known as *Caroli's disease,* can present with diffuse cystic degeneration of the biliary tree.

Extrahepatic Cysts

Occasionally, cysts of the adrenal gland, kidney, or bowel mesentery may be difficult to distinguish from the liver parenchyma. For cases in which imaging modalities are insufficient to differentiate the organ of origin, surgical exploration may be indicated to distinguish and/or treat these larger and sometimes symptomatic cysts.

Cystic Lesions Associated With Infection or Parasites

Any hypodense or fluid-filled lesion of the liver should be viewed with the possibility that the lesion is caused by infection or parasites. Although a thorough review of infectious or parasitic liver abscesses is beyond the scope of this chapter, here we review important considerations in differentiating these lesions from the more common non-infectious liver cysts. A pyogenic liver abscess may result from hematogenous seeding of liver parenchyma with bacteria from elsewhere in the body (e.g., resulting from bacterial endocarditis or diverticulitis). Pyogenic abscesses appear to have a thickened area of rim enhancement and should be easily distinguished from benign liver cysts on intravenous contrast-enhanced CT scan. A history of fever, leukocytosis, abdominal pain, and evidence of an extrahepatic infection will further solidify the diagnosis. Pyogenic abscesses are managed by intravenous antibiotics and commonly benefit from image-guided percutaneous drainage. Liver abscesses that are refractory to antibiotics and percutaneous drainage may require surgical drainage.

Amebic liver abscesses occur as a result of infection from *Entamoeba histolytica,* a protozoa found in tropical areas. It affects males much more commonly than females (10:1) and can present with fever, abdominal pain, and colitis. Serum antibodies are highly sensitive for distinguishing amebic abscesses from pyogenic liver abscesses. Amebic liver abscesses contain a brown fluid that is described as "liver paste." Antibacterial treatment with metronidazole is the principal therapy, and aspiration or surgery may only be required in a minority of treatment-refractory cases.

Echinococcal cysts (also known as *hydatid cysts*) are caused by the larvae of *Echinococcus granulosus,* which is a subtype of tapeworm parasite. This parasite's definitive host is typically dogs and other small carnivorous animals. Infection of humans is uncommon in the United States and is usually seen only in patients who have traveled or lived in South America, Africa, or Asia. Affected humans develop larval cysts most commonly within the liver but also in the lung, spleen, brain, and elsewhere. Echinococcal cysts are spherical and may exhibit septations. The cyst is described as a three-layered structure with an inner germinal layer, a laminated layer, and an outer pericyst layer. Echinococcal cysts classically contain "daughter cysts" within the primary cyst or at the periphery and may also be calcified. Small larval capsules within the cyst are seen on imaging as hydatid "sand." Patients with echinococcal infection may be asymptomatic for many years, though in advanced stages they can present with fatigue, cholestasis, pain, or liver failure. Serology can be used to confirm the diagnosis. Treatment is founded by antihelminthic medications (e.g., albendazole) and may also include surgery or the puncture, aspiration, injection, and reaspiration (PAIR) procedure.

Treatment Considerations

Indications for treatment of liver cysts pertain to the underlying risk of malignancy and symptoms attributable to the cyst or cysts. As stated earlier, lesions with solid components or high-risk features that are concerning for underlying malignancy should be considered for resection with a negative parenchymal margin. When resecting a cystic lesion that may contain malignancy, great care should be taken

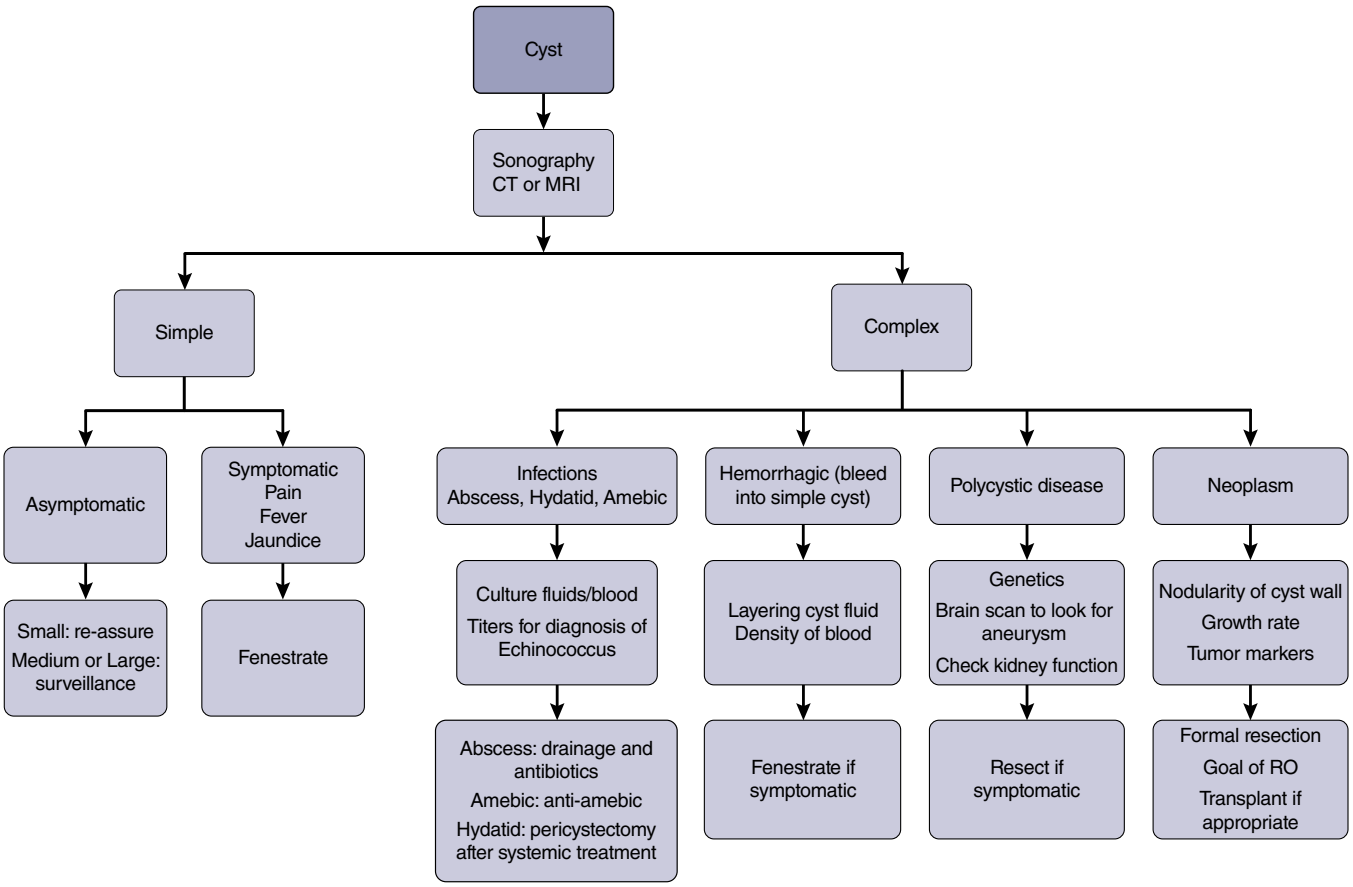

FIG. 3 Flowchart of treatment decisions in managing patients with liver cysts.

to avoid rupture of the cyst because this may cause seeding of the peritoneal cavity with malignant cells and inadvertent dissemination of the cancer.

Although greater than 90% of liver cysts are asymptomatic, large cysts may present with symptoms such as abdominal pain or discomfort, nausea, early satiety, or other compressive symptoms on the stomach and bowel. A sudden increase in abdominal pain may be attributable to hemorrhage within the cyst. Although a patient may have abdominal pain or other digestive symptoms as well as a large liver cyst, the liver cyst may not necessarily be the cause of symptoms as there remains a broad differential diagnosis for abdominal pain. Although typically not indicated, a diagnostic aspiration may be employed to discern whether symptoms improve with a reduction in cyst volume.

Options for treatment of liver cysts include simple aspiration, aspiration with injection of sclerosant, surgical cyst fenestration, enucleation, or resection. The advantage of sclerotherapy is the potential to destroy the epithelial lining and therefore prevent fluid reaccumulation. Before injection of sclerosant, a puncture and test aspiration should be performed to allow space for injection and to confirm that the cyst does not communicate with the biliary tree, which is a contraindication to the use of sclerosant. Agents employed include tetracycline, ethanol, minocycline, and hypertonic saline. Contrast may also be injected to study the cyst anatomy. Up to 90% of small- and medium-size cysts may be successfully treated with sclerotherapy via the PAIR approach.

For large cysts that demand treatment and are not amenable to sclerotherapy, surgical cyst fenestration can provide a durable outcome. This may be performed via a minimally invasive approach and spare a major incision. The goal of this procedure is to unroof the cavity by removing the atrophied parenchyma and capsule overlying the cyst while sparing the vascular structures and bile ducts deep to it. Once laparoscopic or robotic exposure to the cyst is secured, the surgeon begins by aspirating the fluid and evacuating the space. Then the thin roof of tissue may be resected with either a vessel sealer or if thicker, a stapler. Unless there are neoplastic features, the deep cyst wall does not need to be enucleated but can be ablated with cautery or argon beam. Before completing the operation, ensure that any leaking biliary radicles are controlled with suture ligature. A pedicled omental flap may be used to fill the space. Drains should be reserved only if there is concern of infection or bile leakage.

When lesions such as mucinous cystic neoplasms are selected for enucleation, the surgeon should develop the plane between the cyst pseudocapsule and surrounding liver parenchyma. Along this plane, the hepatic veins and bile ducts may be compressed, so care must be taken to avoid disrupting them. Figure 3 presents a simple flowchart of treatment decisions for liver cysts.

CONCLUSION

Most liver cysts are incidental, asymptomatic, and benign and therefore warrant no treatment. In working up a patient with cystic lesions of the liver, bacterial and parasitic infections should be ruled out by history and laboratory tests. Liver cysts should also be differentiated from biliary cysts, which demand a different treatment approach. Cysts displaying asymmetry, nodules, complex architecture, or associated masses should be evaluated for primary malignancy of the liver or metastatic disease. Suspicious cystic liver lesions should be biopsied or simply resected, and mucinous cystic neoplasms of the liver may be enucleated to prevent malignant transformation. In large cysts that are symptomatic, sclerotherapy via PAIR or surgical cyst fenestration can be considered.

Management of Echinococcal Cyst Disease of the Liver

Miral Sadaria Grandhi, MD, and Henry A. Pitt, MD

Echinococcal cyst disease of the liver, also termed *hepatic cystic echinococcosis* or *hydatid cyst disease,* is a zoonosis caused by the canine tapeworm of the genus *Echinococcus*. The disease is endemic in the Mediterranean, Africa, the Middle East, South America, Asia, and parts of Europe in areas where sheep farming is predominant. Dogs (including wolves, foxes, and coyotes) are the primary host for this intestinal tapeworm, and sheep are the major intermediate host. Deer, elk, caribou, yaks, goats, camels, and other livestock also can carry the larval form. Humans become incidental intermediate hosts, and in the United States hepatic echinococcosis is encountered most often either in immigrants or in Americans who have traveled to endemic areas. The combination of immigration and tourism has made hepatic echinococcosis a worldwide disease that may present many years after exposure. Antiparasitic chemotherapy with mebendazole or albendazole alone is not as effective as these agents combined with surgery. Percutaneous aspiration is another treatment option. However, this chapter will focus on the surgical approaches for the management of echinococcal disease of the liver.

PATHOLOGY AND CLASSIFICATION

Echinococcal infections are divided into two distinct subtypes, *cystic* and *alveolar*. Cystic echinococcus is the predominant form. Hepatic hydatid disease is generally caused by fecal-oral transmission of the larval form of the dog tapeworm *Echinococcus granulosus*. Ova are shed in the feces of intermediate hosts (sheep, goats, or other herbivores), inadvertently ingested in contaminated food, and then penetrate the intestinal wall, entering the portal circulation. Once

in the circulation, embryos can infect any tissue, such as the liver (55%–80% of reported cases), lungs (10% to 40% of human cases), brain, or bones. In the liver, *E. granulosus* has a two-layer cyst wall: an inner active cyst wall that consists of a single cell germinal layer, where the echinococcal scolices and daughter cysts develop, and an outer thicker acellular layer (Fig. 1). This outer, reactive fibrous layer is called the *pericyst* and is calcified in approximately 50% of patients.

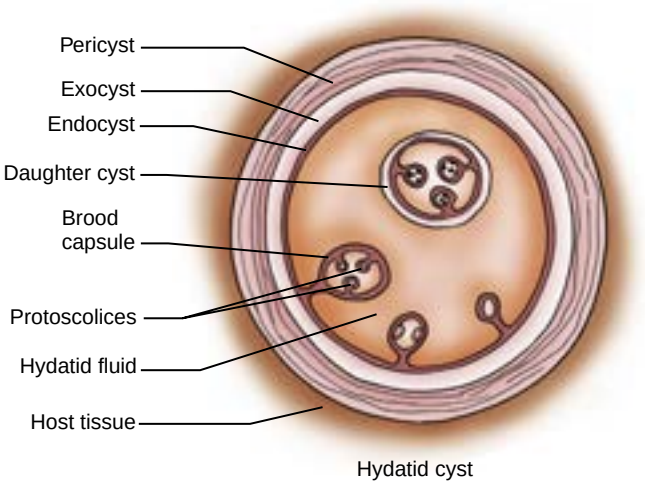

FIG. 1 Structure of echinococcal cyst showing pericyst, exocyst, endocyst, and protoscolices.

Budding of the inner germinal layer within the cyst is termed *daughter cysts* or *hydatid sand.* In approximately one-third of patients, cyst expansion may result in rupture into the biliary tree, erosion through the diaphragm into the pleural cavity, or, rarely, rupture into the peritoneum. On the other hand, mature cysts may become inactive, asymptomatic, further calcified, and be associated with negative serology results.

Alveolar echinococcal infections are caused by *Echinococcus multilocularis,* more commonly found in elk or caribou. *E. multilocularis* is much less common in North America than *E. granulosus* and is mainly endemic to central Europe, Russia, Turkey, China, and Japan. *E. multilocularis* has a high affinity for the liver (99% of cases), causing a hepatic infiltrate, which is a more "tumorlike" form of the disease. Alveolar echinococcosis is fatal in the absence of appropriate treatment, with 5-year mortality approaching 70% and 10-year mortality reaching 94% in untreated patients.

Classification of echinococcal cyst disease of the liver has changed over the past 20 years. In the early 1980s, Gharbi published an ultrasound classification of hepatic echinococcal cysts that divides the cysts into five types (I to V) based on the morphologic imaging appearance. However, in 1995, the World Health Organization Informal Working Groups on Echinococcosis (WHO-IWGE) put forth a standardized classification system that was updated again in 2003 to characterize cysts that incorporate both the functional status of the parasite (active, transitional, or inactive) and the ultrasonographic appearance of the cysts (Table 1, Fig. 2). The WHO-IWGE classification has aided in the selection of optimal therapy and has since been applied to other imaging modalities such as computed tomography (CT) and magnetic resonance imaging (MRI). Resembling the TNM staging classification, the WHO-IWGE also developed a PNM classification system to standardize disease diagnosis and treatment strategies for alveolar echinococcal infections. *P* refers to the size and

location of the parasite within the liver; *N* indicates involvement of neighboring organs; and *M* evaluates the absence (M0) or presence (M1) of distant metastases.

PRESENTATION AND DIAGNOSIS

Patients with echinococcal cyst disease of the liver can have a widely varied presentation that ranges from an extended asymptomatic period to rupture of the cyst into the peritoneal cavity with an acute abdomen and anaphylactic shock. Most patients, however, have uncomplicated disease that may be asymptomatic or present with right upper quadrant pain, fullness from cyst expansion, hepatomegaly, or fever. Obstructive jaundice, cholangitis, and productive cough from rupture into the pleural cavity and the lung are less common presenting symptoms. With the increase in abdominal imaging studies, incidental discovery of a cyst before symptom development is another common presentation. The diagnosis of this disease is centered on clinical findings, imaging, and serology and is confirmed with either demonstration of protoscoleces on direct microscopy or changes in ultrasound appearance that are pathognomonic for cystic echinococcosis.

Laboratory Tests

Evaluation may include various laboratory tests to help establish the diagnosis, including routine complete blood count (CBC) with differential demonstrating eosinophilia in approximately 40% of patients, liver function tests (LFTs) revealing normal or mildly elevated alkaline phosphatase or transaminases, and serum antigen testing. Enzyme-linked immunosorbent assay (ELISA) has a sensitivity of 85% to 89% and has replaced all other traditional immunodiagnostic methods such as the Casoni intradermal test, complement fixation test, indirect hemagglutination test, indirect immunofluorescence antibody test, immunoelectrophoresis, and latex agglutination test. Confirmatory testing can be performed for *E. granulosus* by either immunoblotting or ELISA techniques as well as testing for antigen 5 and antigen B on the hydatid cyst fluid. For alveolar disease, the Em2 antigen has a 99% specificity for *E. multilocular*. Em16 and Em18 were antigens developed to differentiate between active and inactive lesions.

Imaging

Ultrasound and CT are the most widely used imaging modalities for diagnosis of liver cysts, including echinococcal disease of the liver. These studies show position, size, number of cysts, proximity to vascular structures, and evidence of extrahepatic cysts. The WHO-IWGE classification system, which characterizes the cysts based on ultrasound appearance, has standardized cyst description and attempted to facilitate the use of ultrasound as the primary diagnostic tool (see Table 1 and Fig. 2). Because of its low cost and its specificity of 90%, ultrasound is the preferred first-line imaging study worldwide. Classic findings for hydatid cysts are thick unilocular or multilocular walls (often with calcifications) and daughter cysts.
