This unified view of transplantation was controversial, in part because it was incompatible with dogmas that made up much of the foundation of transplantation immunology. One point of contention was our view that historically rooted alternative engraftment mechanisms (listed in Table 119.3) were either epiphenomena or "variants or stages" of the clonal exhaustion-deletion that followed the key event of leukocyte migration. In addition, the role of small numbers of persistent cells (the microchimerism) in perpetuation of long-term graft survival was not yet clear. Finally, the crucial mechanism of clonal exhaustion-deletion was still generally considered to be only a theory. Although we did not know it at the time, precisely these issues were being addressed independently in Zurich but in the context of immune responsiveness and unresponsiveness to noncytopathic microparasites (see later discussion).

TABLE 119.3 Mechanisms of Immune Nonreactivity

Essential

1. Clonal exhaustion-deletion
2. Immune ignorance

Alternative

1. Special recipient cells: T-regulatory, suppressor, veto
2. Antibodies: idiotypic, "enhancing"
3. Cytokines: self-perpetuating combinations
4. Inhibitory molecules: down regulation
5. Graft secretions: soluble HLA antigens
6. Antigen presentation: defective or deviant
7. Anergy: absence of second signal, or cytokine exhaustion

TOLERANCE FROM THE INFECTION PERSPECTIVE

The major histocompatibility complex-restricted mechanisms of T-cell recognition of, and response to, noncytopathic microorganisms, and to allografts, had been elucidated by Zinkernagel and Doherty in the 1970s,

but the mechanisms of acquired immune nonreactivity remained a puzzle. During the early 1990s, Zinkernagel and his associates in Zurich formally proved in mouse infection models that the antipathogen T-cell response could be exhausted and deleted, and concluded that this was the explanation for the carrier state that may develop after infection with noncytopathic (intracellular) viruses. As with transplantation, the critical step was migration of the pathogen or its peptide to host lymphoid organs. The presence of virus that failed to reach these destinations was not recognized by the host. This was termed *immune indifference* (now called *immune ignorance*). In essence, Zinkernagel et al. had clarified the interrelationship of immunity and tolerance to pathogens, and had defined tolerance in terms of two essential mechanisms: immune ignorance and clonal exhaustion-deletion. Moreover, they placed these mechanisms in the same dynamic context of antigen migration as that of transplantation.

Once the viral antigen reached lymphoid destinations and induced a cytolytic T-lymphocyte (CTL) response, the outcomes in the highly controlled models of lymphocytic choriomeningitis virus infection were determined by the balance between the amount of virus antigen and the number of induced antigen-specific CTLs. Analogous to the maximal flood of passenger leukocytes migrating from a transplanted organ, the critical period was during the first few days or weeks of viral replication. If the CTLs were induced in sufficient numbers, the result was disease control; if not, the result was clonal exhaustion-deletion and a carrier syndrome that ranged from asymptomatic to progressively more serious disease states. No matter what balance was established acutely, perpetuation of this balance (whether immunity, deletional tolerance, or some stage in between) depended on persistence of antigen with access to host lymphoid organs. The ability of small amounts of persistent virus to survive was attributed to its relocation in nonlymphoid sites that were inaccessible to host immune effector mechanisms. From these protected niches, the virus migrated secondarily to host lymphoid organs and could sustain immunity or, alternatively, maintain tolerance. Thus, persistent antigen was a two-edged sword.

THE BOUNDARY BETWEEN IMMUNITY AND TOLERANCE

The analogies between transplantation and infection were summarized in 1998 and generalized to other branches of immunology in the following

statement: “Migration and localization are the governing factors in immunologic responsiveness or unresponsiveness against infections, tumors and self, and against xenografts and allografts.” All of the clinical scenarios of transplantation, and those resulting from infection by noncytopathic pathogens, could be correlated with the routes of migration and the ultimate localization of the respective antigens. The “gray area” between unequivocal immunity and durable tolerance included a diversity of transplant outcomes short of outright acute irreversible rejection, as well as a panoply of analogous virus carrier states; all represented different degrees of partial tolerance. Such immunologic “compromises” included chronic allograft rejection and its analog, chronic hepatitis.

The Rejection Option

Organ Transplantation

The antigen migration is essentially the same with transplantation of the liver and any other surgically revascularized whole organ (Fig. 119.2A). Movement of the passenger leukocytes is selective at first to host lymphoid organs, where a clonal antidonor T-cell response is induced. The CTLs then target the transplanted organ as well as the peripheralized cells of the source graft (Fig. 119.2A).

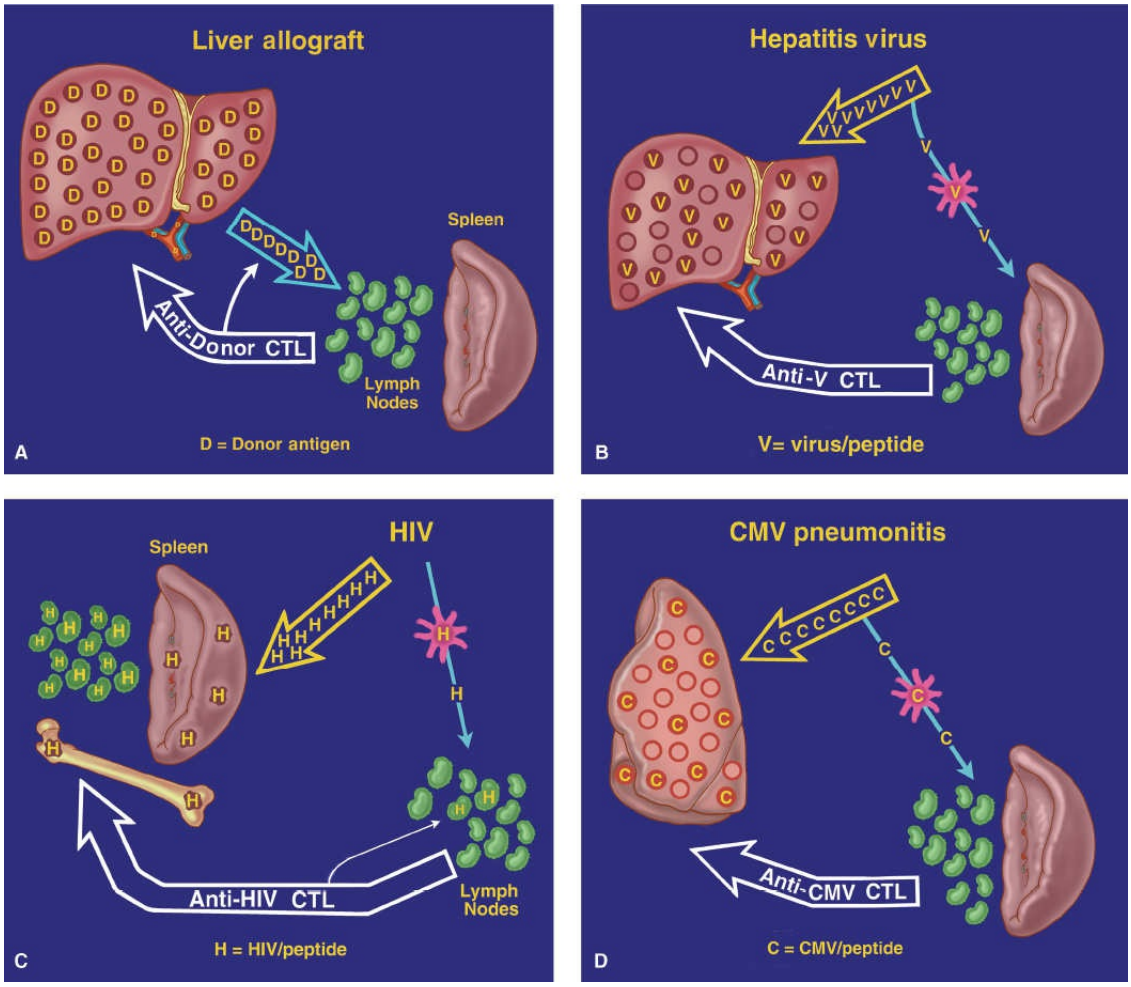

Figure 119.2. The consequences of antigen spread and localization (see text) with liver or other kinds of organ transplantation (**A**), with a viral hepatitis infection (**B**), with a HIV infection (**C**), and with a pulmonary cytomegalovirus (CMV) infection (**D**). CTL, cytolytic T-lymphocyte.

Infection

The migratory principles after infection by noncytopathic microparasites are the same as those of passenger leukocytes, but the details differ as both the pathways of microorganism migration and the targets of the CTL response are dictated by the tropism of the various pathogens (Fig. 119.2B–D). For example, because of the liver tropism of the hepatitis viruses, the quantity of viral antigen that migrates to host lymphoid organs is small compared with that homing to the liver (Fig. 119.2B). At the lymphoid organs, virus-specific CTLs are induced by infected antigen-presenting cells displaying complexes of major histocompatibility complex molecules and peptides derived from the pathogen. Because the induced CTLs then destroy infected host cells no matter where these “nonself”

cells are located, the principal disease expression is hepatic (Fig. 119.2B).

The Tolerance Option Without Immunosuppression

Organ Transplantation

Exceptions to the outcome of immunity (i.e., rejection) in untreated transplant recipients are rare. However, lifetime tolerance to liver allografts occurs without therapeutic manipulation in about 20% of outbred pig recipients, and with near 100% regularity using selected donor-recipient rat strain combinations and the majority of mouse strain combinations. Less well leukocyte-endowed mouse heart and kidney allografts also reliably self-induce tolerance, although in far fewer strain combinations. These models of spontaneous transplantation tolerance demonstrate that graft-induced immune nonreactivity is a normal potential option of the immune response (Fig. 119.3A). Importantly, the "spontaneous tolerance" may be abrogated in some of these models by administering immunosuppression.

Infection

After most infections by noncytopathic parasites, the balance between antigen and antigen-specific CTL tilts within a few weeks to immunity. The exceptions in which protective immunity frequently does not develop constitute a collection of some of the world's most difficult-to-treat diseases (e.g., AIDS, hepatitis, and malaria).

Figure 119.3. Organ-induced tolerance. **A.** Spontaneous tolerance induced by the liver in experimental models in which the host-versus-graft immune response induced by the migratory donor leukocytes is too weak to eliminate the donor antigen and is exhausted and deleted (the rise and fall of the *continuous thin line*). Maintenance of engraftment depends on small numbers of persistent donor leukocytes (microchimerism). The less well leukocyte-endowed heart and kidney also can "self-induce" engraftment but in a much smaller number of models. **B.** Immunosuppression-aided tolerance in organ transplant models in which the recipient response that normally would cause rejection (*dashed line*) is reduced into a deletable range (*continuous thin line*) with a short course of early posttransplant immunosuppression. Lifetime tolerance after stopping immunosuppression was first convincingly demonstrated in canine liver recipients. **C.** A self-defeating consequence of excessive prophylactic overimmunosuppression (depicted with multilayered bars) with which clonal exhaustion-deletion is impaired. The initially overtreated recipient may be committed to unnecessarily high maintenance immunosuppression, an undesirable effect of too much immunosuppression that was not recognized until 2001. Tx, transplantation.

THERAPEUTIC IMPLICATIONS

Infections With Noncytopathic Microorganisms

In 1994, Zinkernagel and Hengartner discussed the comparative pathophysiology of HIV (a retrovirus) and hepatitis B virus ([HBV] a DNA virus) in the context largely developed with their studies of the lymphocytic choriomeningitis virus (an RNA virus). The authors argued that the consequences of HIV were caused principally by virus-specific cytotoxic T-cell-mediated immunopathology rather than by direct cytolytic effects or any other mechanism. The essence of their argument is shown in Figure 119.2C. After HIV antigen delivery to lymphoid organs by infected dendritic cells or other antigen-presenting cells, a CTL response is induced that targets CD4 (T helper) and all other infected cells. In an unknown number of cases, the CTL response is strong enough to establish disease control. However, the classical outcome is immunodeficiency. With the selective destruction of infected CD4 cells and eventual decimation of the infected antigen-presenting cell population, the inadequately renewed HIV-specific CTL clone is easily exhausted and deleted, and eventually

the entire CTL population dwindles. The outcome from the events shown in Figure 119.2C depends on the balance established at an early time between the amount and localization of the virus versus the CTL response. A similar pathogenesis, but with variable targets and outcomes, pertains with all noncytopathic microparasites, for example, hepatitis (Fig. 119.2B) and cytomegalovirus (Fig. 119.2D).

From this point of view, Zinkernagel and Hengartner had suggested in 1994 that the foremost therapeutic objective under most circumstances is to limit the extent of the infected cell targets, or in clinical terms, to reduce the viral load and restrict its spread. This has since been accomplished in HIV patients with zidovudine and protease inhibitors. It was also pointed out that once a large target is established, the deliberate resurrection of a strong CTL response could have the disastrous consequence of widespread host cell killing. It was suggested that a better option under these circumstances might be the administration of T-cell-directed immunosuppression in just the right amount to prevent the CTL-mediated destruction of massive numbers of host cells, but not so much that runaway viremia would merely expand the target for attack from a recovering CTL clone. Thus, the therapeutic aims in an intractable noncytopathic pathogen infection would be to predict, monitor, and equilibrate beneficial balances between the pathogen distribution and the absence of an immunopathologic T-cell response.

The Organ Engraftment Objective

Comparable antigen/CTL balances must be found and kept stable for successful transplantation. The best chance to establish a balance selectively favoring tolerance is during the first few posttransplant weeks, during which the maximal donor leukocyte migration provides the optimal conditions for reciprocal exhaustion-deletion of the double-immune response (Figs. 119.1 and 119.3). It was obvious that this one-time-only window of opportunity could be narrowed or closed by so much prophylactic immunosuppression that clonal activation is subverted. To the extent this were to occur, later reduction of the primary overtreatment predictably would lead to recovery of the ineffectively deleted clone with the clinical consequence of delayed rejection (Fig. 119.3C). Yet, the penalty of too little immunosuppression during the critical early period may be irreversible rejection. In 2001, it was suggested that this dilemma could be addressed by application of one or both of the therapeutic

principles depicted in combination in Figure 119.4.

The first principle (shown alone in Fig. 119.3B) consists of administration of no more posttransplant immunosuppression than the amount needed to prevent irreversible immune-mediated damage. Because of histocompatibility and other confounding parameters in the human population, such ideal immunosuppression in individual patients cannot be accurately predicted. With the second principle (recipient pretreatment), host global immune responsiveness can be reduced by nonmyeloablative conditioning before arrival of donor antigen, thereby bringing the anticipated donor-specific immune response into a more easily controllable and deletable range (Fig. 119.4). The two principles have been combined in a practical regimen using a single large dose of an antilymphoid antibody before transplantation followed by minimalistic posttransplant tacrolimus monotherapy with the intent of eventual weaning (Fig. 119.5). Satisfactory results in liver (Fig. 119.6) and other kinds of organ recipients with reduced overall exposure to immunosuppression have been obtained with the striking exception of liver recipients, whose chronic end-stage hepatic failure was caused by hepatitis C virus (HCV; discussion follows).

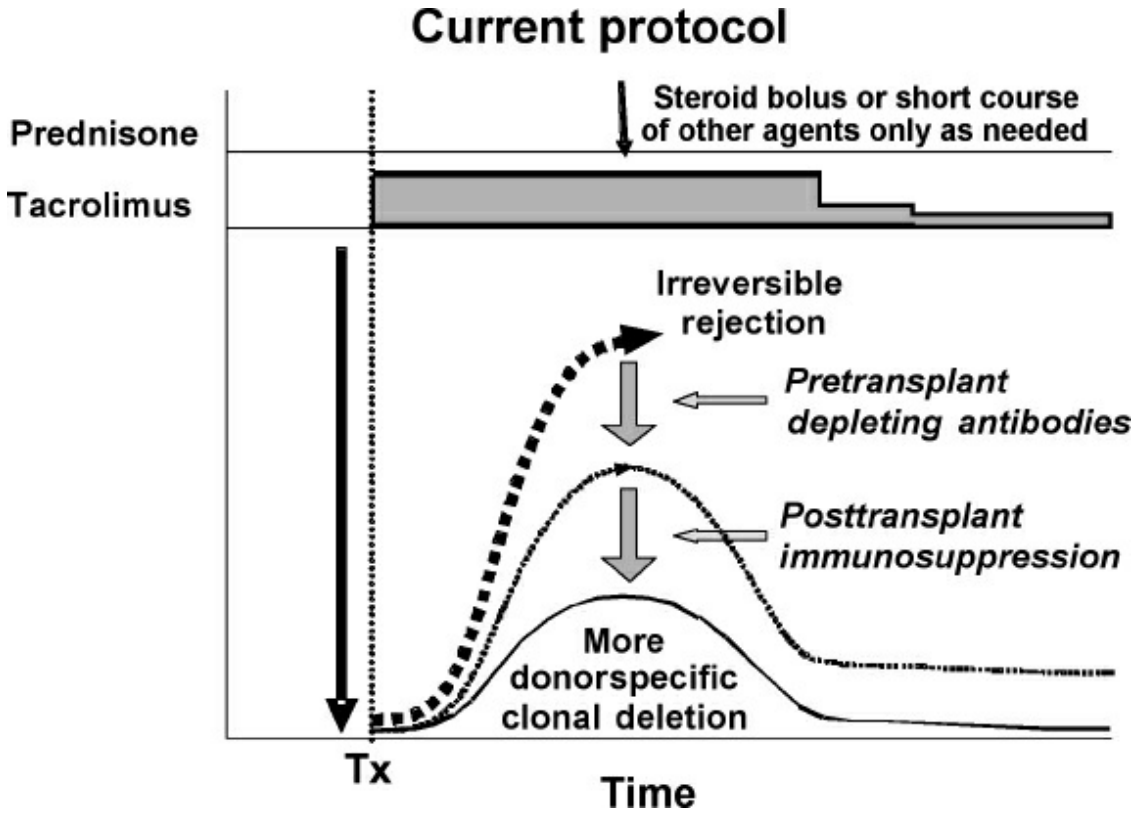

Figure 119.4. Protocol of "tolerance friendly" immunosuppression introduced at the University of Pittsburgh Medical Center. An antilymphoid antibody infusion prior to arrival of an allograft

reduces the anticipated antidonor response into a more readily deletable range and allows maintenance treatment to begin with daily monotherapy to which other agents are added only for rejection. Weaning from the monotherapy may be possible later. The inverted curve at the bottom shows the usually silent graft-versus-host reaction shown more clearly in Figure 119.1. Tx, transplantation.

The frequency and extent to which drug weaning can be accomplished in hepatitis-free liver recipients with such tolerance-facilitating immunosuppression have yet to be determined. Complete stoppage of treatment has been attempted only in a few of these recent cases. However, the feasibility of liberation from immunosuppressive drugs is evident from observations of our first 210 liver recipients: 184 at the University of Colorado (between 1963 and 1980) and 26 at the University of Pittsburgh (in early 1981). As of 2006, 35 (17%) of the 210 patients had reached or passed their posttransplant silver anniversary (Fig. 119.7). Thirty-two patients (15%) were still alive from 24.5 to 35.7 posttransplant years (mean, 27.1 ± 31 SD) and 3 died after 25 years from lung disease (no. 42 in Fig. 119.7), widespread metastases from colon carcinoma (no. 82), and *de novo* HCV infection (no. 93).

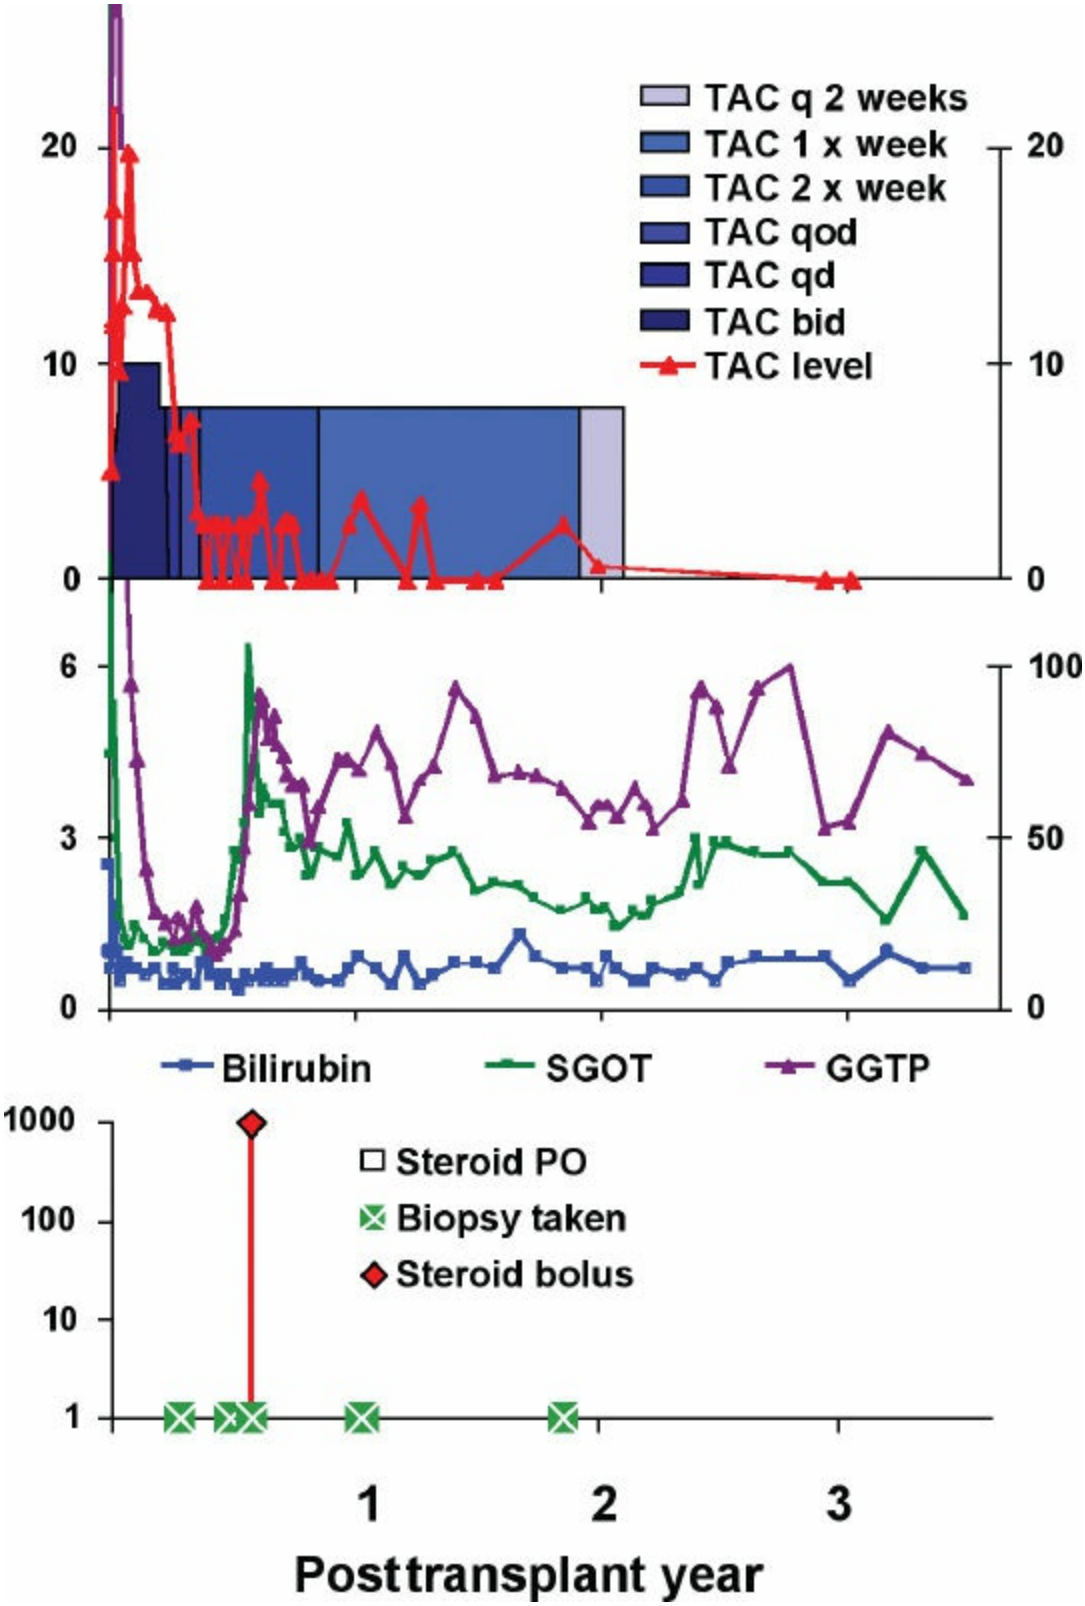

Figure 119.5. An example of the strategy shown in Figure 119.4. A woman with a hepatic hemangioendothelioma who was infused with 5 mg/kg antithymocyte globulin (Thymoglobulin) prior to liver allograft revascularization. Tacrolimus monotherapy was reduced from daily to every other day at 100 days, and to once per week by 10 months. Treatment was stopped at 22 months. She has

been immunosuppression-free for 5 years. Serum bilirubin and measures of hepatic parenchymal function have been normal throughout. Although enzyme levels have been stable, these have hovered at a high normal range or slightly above since a rejection at 6 months, which was treated with 1 g methylprednisolone. SGOT, serum glutamic-oxaloacetic transaminase; GGTP, gamma-glutamyl transpeptidase.

Importantly, 16 of the 35 quarter-century survivors had periods of 3 to 31 years off immunosuppression, as indicated by the green portion of the horizontal bars in Figure 119.7. In 5 of these 16 recipients, immunosuppression was resumed, but not because of breakthrough rejection in any case. The reason for treatment reinstitution in two patients was liver retransplantation necessitated by intractable biliary tract complications (no. 202 in Fig. 119.7) or because of HCV hepatitis (no. 125). A third recipient, whose cyclosporine-based immunosuppression was stopped after 11 years, was returned to treatment 6 years later because of cadaveric kidney transplantation (no. 192). The other two recipients, who were asymptomatic and had rejection-free biopsies, were restarted on treatment because of patient and physician anxiety (nos. 64 and 105 in Fig. 119.7).

The Price of Chronic Immunosuppression

The consequences of a decision to resume immunosuppression without a clear justification may not be evaluable for years, or decades. When a detailed account of our 210 first recipients was published in the June 1993 issue of *Hepatology*, 50 (23%) of the patients had survived for at least a decade (maximum, 23 years). However, 7 had died from 1 to 11 years after their 10th anniversary, leaving 43 (20.5%) survivors. Rejection had not caused any of the late deaths. Instead, the most common lethal etiologies were hepatitis, other infections, malignant neoplasms, and drug-specific side effects. The same pattern has been apparent in the further shrinkage of survivors between 1993 and 2005 (from 43 to 32) for reasons other than rejection. Chronic immunosuppression clearly has been the principal direct or indirect cause of late mortality.

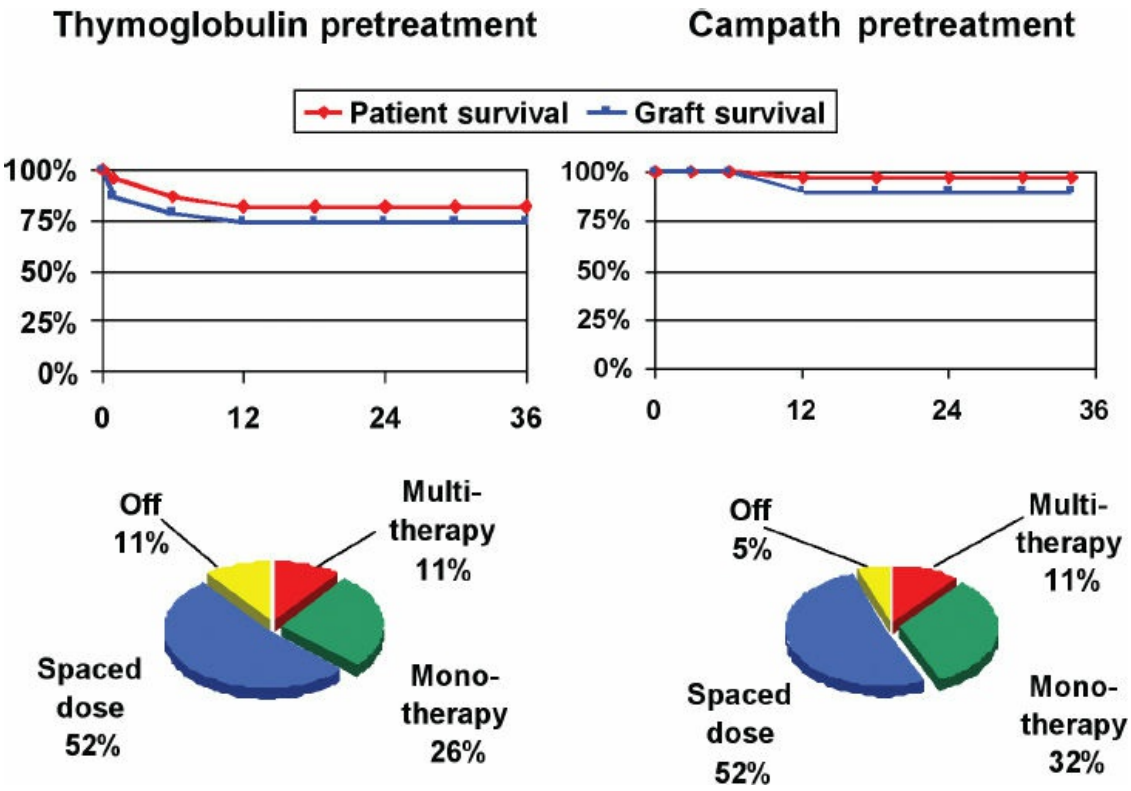

Figure 119.6. Patient and graft survival (*above*) and maintenance immunosuppression (*below*) of hepatitis-free primary liver transplant recipients treated in Pittsburgh with the principles of immunosuppression shown in Figure 119.4 and exemplified in Figure 119.5. *Left:* pretreatment was with an infusion of 5 mg/kg rabbit antithymocyte globulin (Thymoglobulin) (*n* = 23). *Right:* pretreatment was with 30 mg alemtuzumab (Campath) (*n* = 38).

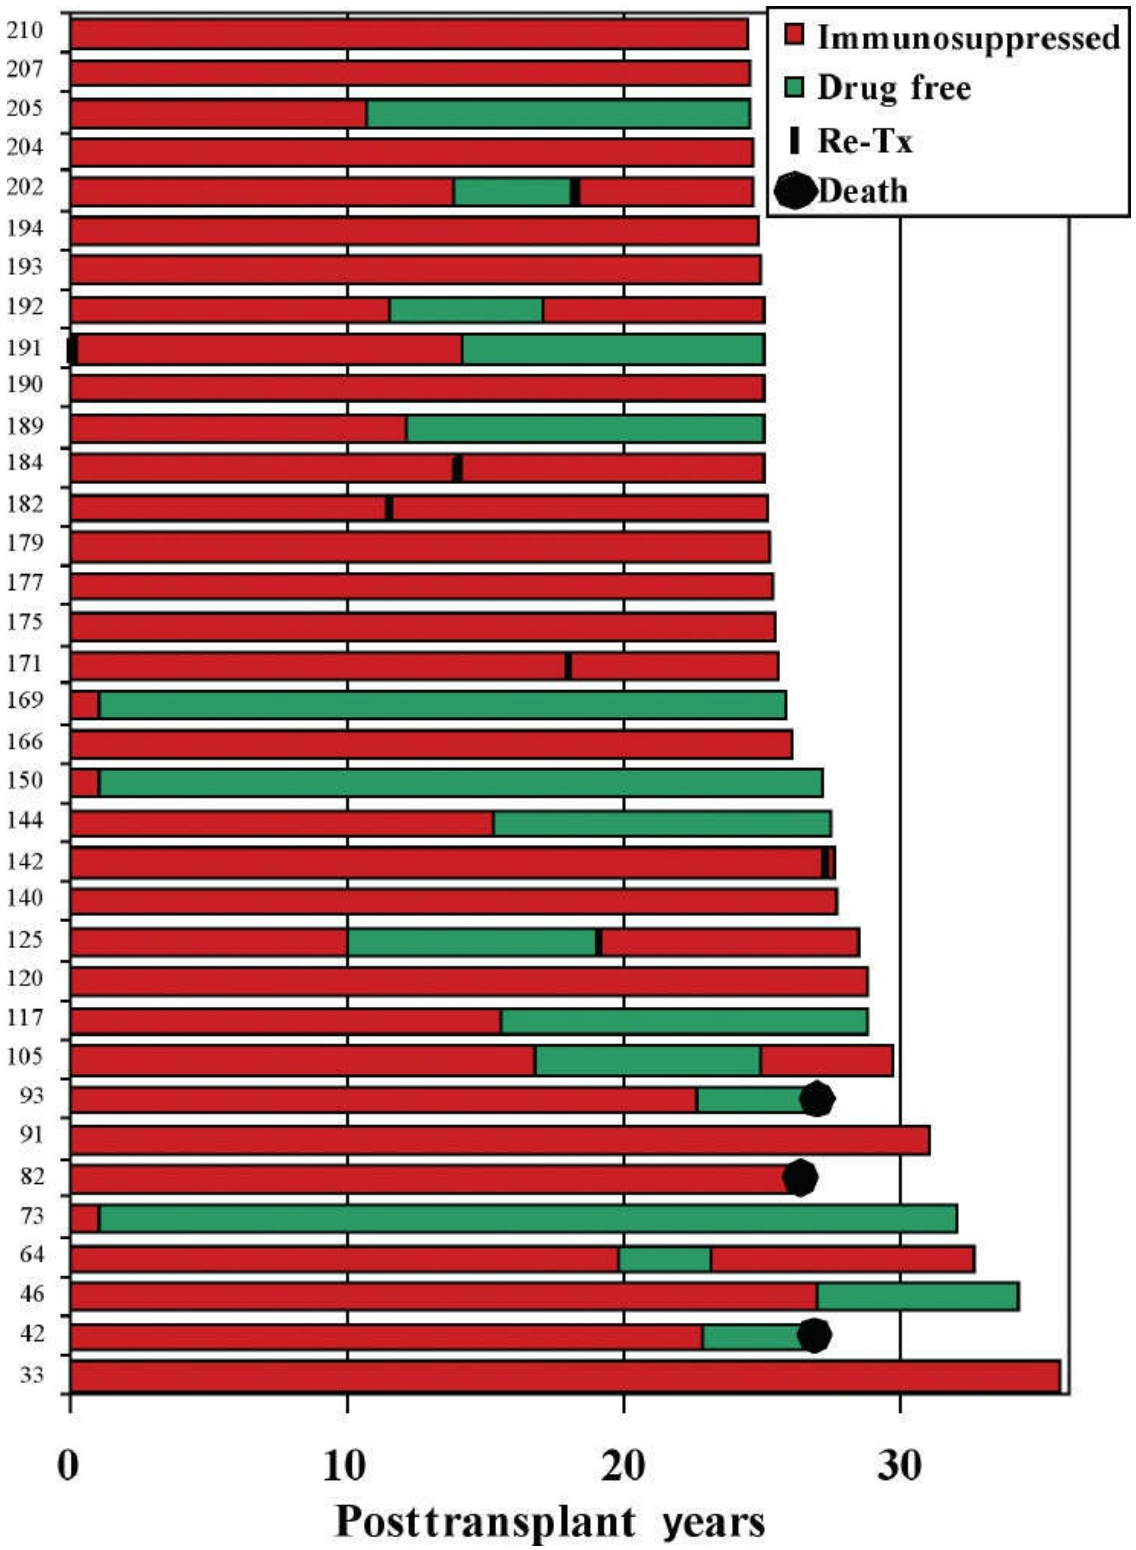

Figure 119.7. The 35 patients from the first 210 who survived 25 or more years after liver replacement at the University of Colorado (*n* = 184) or University of Pittsburgh (*n* = 26). The times on (red) and off (green) immunosuppression in individual patients are displayed in the horizontal bars. Note that 6 of the 32 still-surviving recipients as of 2006 had retransplantation (Re-Tx) 11 to 28 years after the primary procedure.

Organ Engraftment in HCV-Infected Patients

Although the importance of reducing or eliminating long-term immunosuppression is clear, when the tolerogenic strategy depicted in Figure 119.5 was applied in HCV-infected liver recipients, the results fulfilled the 1994 prophecy of Zinkernagel and Hengartner. First, the lymphoid depletion caused viremia. Then, when later attempts were made to wean from tacrolimus monotherapy, the heavily infected liver graft was targeted by recovering CTL, resulting in early and severe recurrent HCV disease. With recognition by Eghtesad et al. of what had happened, the explanation also was apparent for the worldwide epidemic of HCV recurrence that was associated with the various regimens of viremia-inducing heavy multiple drug immunosuppressions. Because strong prophylactic immunosuppression cannot be administered indefinitely without fatal consequences, such treatment eventually must be reduced. The consequent CTL recovery was leading to widespread destruction of infected allograft cells.

In contrast, light but continuous double-drug immunosuppression with tacrolimus and prednisone allows the systematic development of a relatively asymptomatic carrier state: a stable equilibrium between HCV and HCV-specific CTL. Thus, treatment protocols that minimize disease recurrence in HCV-infected liver allograft recipients must balance the desire to reduce immunosuppression or induce allotolerance with the need to prevent antiviral immunopathology. Avoidance of the epidemiologic implications of producing HCV-carrier recipients, and of the probability of insidious disease recurrence, will depend on containment of the viral load with HCV-specific drugs.

Tumor Surveillance

By the late 1960s, there was convincing evidence that immunosuppression in organ recipients could result in accidental engraftment of donor malignancies, accelerated growth of tumor metastases, or the development of new malignancies. Because the highest risk from these consequences has been in liver recipients, liver transplant centers have become hot beds of oncology research. Two tumors have been of particular interest because of their etiologic association with intracellular microorganisms: posttransplant lymphoproliferative disorders with the Epstein-Barr virus and hepatocellular carcinoma with HBV. The posttransplant lymphoproliferative disorders, most of which are B-cell lymphomas,

provided the first unequivocal proof of immune surveillance of a human malignancy when they disappeared after withdrawal of T-cell-directed immunosuppression.

The possibility of preventing virus-associated tumors with vaccines was demonstrated by Hilleman with proof of principle studies in primates of the simian virus 40 (SV_{40} virus), and extended to humans 20 years later with the recombinant HBV vaccine trials. The HBV-associated hepatoma scourge was virtually eliminated in immunized Asian populations. The research and therapeutic opportunities opened by these and other observations are too vast to dwell on here, beyond emphasizing that the mechanisms of immune reactivity and nonreactivity to tumors are the same as those of transplantation.

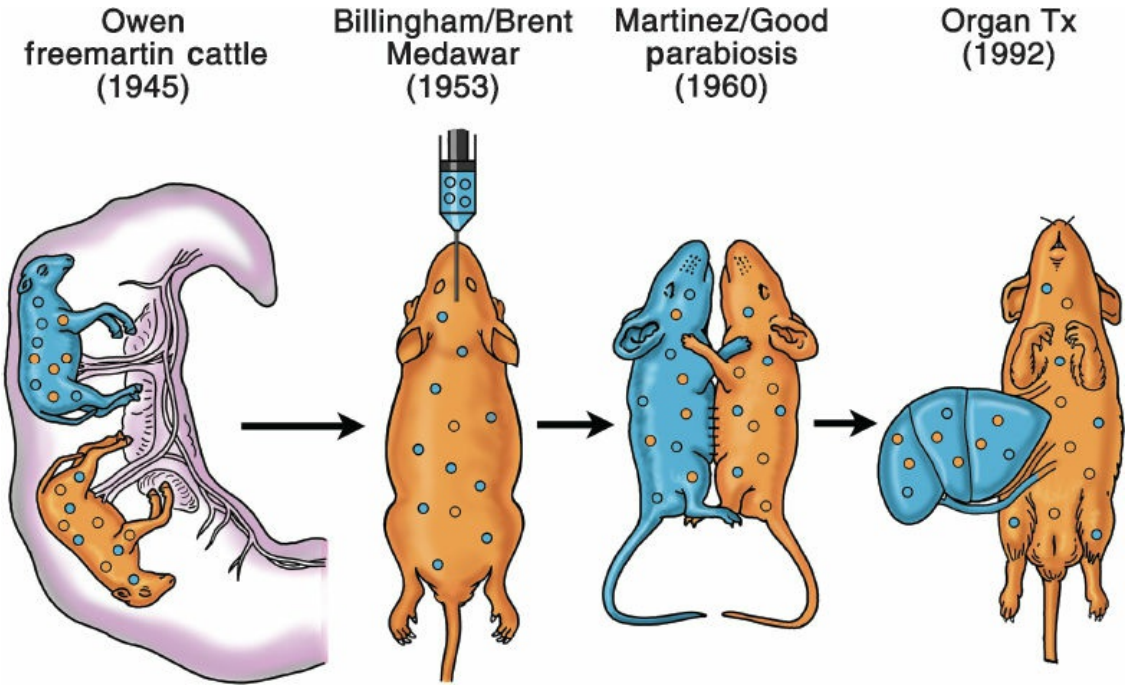

Figure 119.8. The relation of organ-induced engraftment (*right*) to classic models of spontaneous donor leukocyte chimerism-associated tolerance. Tx, transplantation.

Autoimmunity

The chimerism-dependent mechanisms of nonreactivity to allografts, all of which depend on mobile leukocytes, can be identified in a continuum of classic tolerance models that began with the observation by Owen of mixed blood cell chimerism in freemartin cattle, and ended in 1992 with the discovery of microchimerism in liver and other kinds of organ recipients (Fig. 119.8). Of historical interest, Paul Ehrlich recognized more

than a century ago that a patient's tissues could be destroyed by an immune system run amuck. Ehrlich's term of *horror autotoxicus* is today's autoimmune disease. He postulated that there must be mechanisms to prevent this by "a regulatory contrivance as yet undescribed." In the context of immunology described here, the contrivance that Ehrlich envisioned consisted of the mechanisms that have made transplantation feasible.

A NEED FOR CLOSURE

A coherent profile of immune function and governance has emerged from the studies of transplantation and infection summarized here. However, mechanisms of nonresponsiveness other than the essential ones of immune ignorance and clonal deletion (listed in Table 119.3) have generated a large body of historical and recent publications. In turn, these model-specific and poorly understood alternative mechanisms have become elements of recurring immunologic dogmas and theories. It may be asked if assigning them essential roles in transplantation tolerance is justifiable. Evidence of their existence derives from phenomena observed in experimental models in which the immune system is drastically perturbed (e.g., under conditions of lymphopenia) or the antigenic barriers to transplantation are significantly weakened (e.g., transplantation across minor histocompatibility mismatches). To complete the picture, it will be necessary to definitively determine the conditions for the development of these phenomena and to accurately assess their functional significance.

CONCLUSION

The article entitled "The Evolution of Liver Transplantation" published in 1982 in *Hepatology* concluded with the statement that "what was inconceivable yesterday, and barely achievable today, often becomes routine tomorrow." Liver transplantation proved to be a prime example. But the accomplishment was more than the addition of the crucial centerpiece for the treatment of otherwise lethal end-stage hepatic disease. Liver transplantation was from the beginning, and will continue to be, an instrument of scientific discovery in multiple fields, and above all in immunology.

Note: Some contents of this chapter were first published as an article in *Hepatology* (2006;43(2 Suppl 1):S151–63) and are reprinted with permission and slight modifications.

EDITOR'S COMMENT

It is a sad note that Dr. Thomas E. Starzl, who performed the first successful liver transplant in a patient in 1967, passed away on March 4, 2017 at the age of 90. As a tribute to the lasting contributions that he and his teams at the University of Colorado and the University of Pittsburgh Medical Center over the years, we complement the chapter on Liver Transplant with this special comment by Dr. Thomas Starzl in association with Dr. Noriko Murase.

The name Thomas Starzl needs no introduction to anyone in the world. He has been a pioneer in the field of transplantation, specifically liver transplantation, having conceived of it, worked at it in difficult fashion, and finally brought it to the point where it is. While limited to academic medical centers, it is performed thousands of times a year all over the world. It is another example in which work in the clinic, as Dr. Starzl points out, then makes its way to the laboratory to continue to enhance what has been started clinically. The fact that most of the great advances in medicine are actually surgical in the 20th century, including in no particular order, transplantation, blood transfusion, vascular surgery, cardiac surgery, parenteral nutrition, and endocrine treatment for various diseases. Thomas Starzl carried out his great work at the beginning without much NIH support. He did this seemingly directed by himself, with enormous focus on what was an almost maniacal desire to perfect liver transplantation. The early years were not easy and required enormous expenditures of energy, people, time, and devotion to a goal that at that time seemed distant. Yet, it was accomplished and tens of thousands of patients all over the world owe their lives to the late Dr. Starzl and his group.

Allotolerance has been the “holy grail” of transplantation. The argument in this wonderfully conceived and written chapter, meticulously documented, is the proposal that perhaps less is more; in other words, in order to induce allotolerance, what is needed is not the type of immunosuppression that devastates all the immune mechanisms in the organism, but some type of balanced chimerism, if you will, into which the proposal of a pretransplant, antilymphocytic agent given in high dosage is then combined with a more moderate single-agent immunosuppression, in this case tacrolimus, with the ultimate hope of winning tolerance. This proposal alters the way in which we have traditionally done immunosuppression. The exception seems to be HCV-infected patients. Here, the goal is somewhat different: to induce allotolerance with the implications of the need to prevent autoantiviral immunopathology. This is the balance that Dr. Starzl had sought. As usual, the particular point is meticulously documented as he asks for global scientific resolution of the issue. This is the legacy of Dr. Starzl’s immense contributions to this field.

E. Christopher Ellison and J.E.F.

120 The Associating Liver Partition and Portal Vein Ligation for Staged Hepatectomy (ALPPS) Approach

Kenneth K. Tanabe, Fernando Andrés Alvarez, and Eduardo de Santibañes

BACKGROUND AND PATHOPHYSIOLOGY

Liver resection is the treatment of choice to prolong survival and offer a chance of cure for patients with primary or secondary liver malignancies. Significant improvements in imaging modalities, surgical techniques, anesthesia, chemotherapy regimens, and the expansion of resectability criteria among surgeons have increased the fraction of patients treated with resection. Nonetheless, resection is not always possible due to tumor location, involvement of critical vasculature, distribution in the liver, insufficient liver remnant, or patient comorbidities. *Resectability* in modern liver surgery has shifted from being limited by what is resected to being limited by what remains after resection. Oncologic liver surgery necessarily balances two objectives that are at times in conflict: achieving negative margins and preserving sufficient liver parenchyma to minimize the likelihood of liver failure. Major hepatectomies are often required to achieve an R0 resection, and these are associated with substantial rates of morbidity and mortality. Posthepatectomy liver failure (PHLF) is the main cause of death after major liver resections and is closely related to the volume and quality of the future liver remnant (FLR). In general, at least 30% of total liver volume (TLV) should be left behind after a major liver resection in healthy livers and at least 40% in patients with diseased liver parenchyma. Several strategies have been developed to minimize the risk of PHLF and expand resectability. These strategies may be grouped into those that reduce tumor burden (e.g., conversion chemotherapy, endovascular procedures such as intra-arterial chemotherapy or radioembolization, local ablation techniques) and those that tend to

increase the size of the FLR (e.g., preoperative portal vein embolization [PVE], two-stage resection procedures). For patients whose FLR size is regarded as insufficient to sustain liver function in the postoperative course, portal vein occlusion of the tumor-bearing lobe has become the gold standard to induce hypertrophy of contralateral healthy lobe. Right PVE is best used before surgery when the FLR is tumor-free, while portal vein ligation (PVL) is usually applied as part of two-stage procedures for patients with bilobar disease who initially require tumor removal in the FLR. Yet, when using the abovementioned classical approaches of portal vein occlusion, up to 40% of patients never arrive to tumor resection either because of insufficient hypertrophy or because of disease progression during the long interval periods (4 to 12 weeks) typically required to achieve hypertrophy. Moreover, recent studies have shown that patients who fail to complete the second stage usually have worst survival than patients treated with chemotherapy alone.

The most recent innovation in the field of staged liver resections is termed *A*ssociating *L*iver *P*artition and *P*ortal vein ligation for *S*taged hepatectomy (ALPPS). As originally described, the technique consists in right PVL combined with in situ splitting of liver parenchyma during the first stage, followed 7 to 10 days after by a second stage in which resection of the diseased hemi-liver is completed. This new approach considerably accelerates FLR hypertrophy and reduces the time interval between stages. This results in a higher rate of R0 resections—above 95% in most series published. The mean FLR hypertrophy obtained with ALPPS is around 85% (range: 45% to 200%) within a median time interval of 7 days (range: 6 to 14 days), where up to 80% of patients achieve a sufficient hypertrophy in <10 days. This hypertrophy profile is clearly faster than with the traditional strategies. A recent comparative study from the Mayo Clinic in Rochester demonstrated that ALPPS was significantly superior to PVE in terms of both the pace of hypertrophy (84.3% in 8 days vs. 36% in 40 days; $P < 0.001$) and the kinetic growth rate (32.7 cc/day vs. 4.4 cc/day; $P < 0.001$). Furthermore, the ALPPS has proven to be an effective salvage procedure to induce further hypertrophy and allow resection in patients who fail to achieve a sufficient FLR volume after PVE or PVL. Increasing evidence in both animals and humans indicates that rapid FLR volumetric increase observed in ALPPS is accompanied by histologic and molecular features of hepatocyte cell proliferation. Surgical interruption of bilateral cross portal circulation was initially considered to be the main catalyst of

enhanced liver hypertrophy; however, the exact stimuli remain poorly understood and are most likely multifactorial. The phenomenon could be explained by any or all of the following mechanisms: (1) PVL impairs collateral circulation and causes redistribution of portal blood flow and hepatotrophic factors to the FLR; (2) parenchymal partition creates surgical trauma that induces the systemic release of circulating proliferating factors; (3) a preconditioning phenomenon for the FLR whereby the diseased hemi-liver acts as a transitory auxiliary liver that assists the growing FLR in metabolic, synthetic, and detoxifying functions; and (4) FLR inflow modulation by the arterialized auxiliary liver may play an important role by alleviating acute hemodynamic stress on the FLR.

After it was first performed in 2007 by the German surgeon Hans Schlitt, ALPPS gained rapid acceptance in Germany. Subsequently, after the first formal reports in 2011 its worldwide spread has triggered many debates among the surgical community, many of which focus on the relatively high morbidity and mortality rates in most series published. The increasing interest for the ALPPS approach and the great passion involved in its development prompted the initiation of the international ALPPS registry in 2012, with over 600 patients enrolled, and the celebration of the "1st ALPPS International Consensus Meeting" at Hamburg in February 2015.

INDICATIONS AND CONTRAINDICATIONS

Preoperative multidisciplinary evaluation is mandatory for every patient with liver tumors and they should be considered eligible for surgery on a case-by-case basis taking into account risks, oncologic rationale, and resectability.

Indications: Patients with marginally resectable liver tumors are potentially eligible for ALPPS if an insufficient FLR is present. On preoperative computed tomography (CT) scan or magnetic resonance imaging (MRI)-based volumetric planning, an FLR of <30% of TLV in healthy livers or <40% in patients with cholestasis, steatosis, fibrosis, or long-course chemotherapy is generally used to define FLR insufficiency. If preferred, an FLR to body weight ratio of <0.5% could also be used to determine an insufficient FLR volume in patients with normal liver or <0.8% when abnormal liver parenchyma is present. We further restrict ALPPS to patients with an insufficient FLR and at least one of the

following: (1) a tumor margin close to the FLR or its vascular pedicles; (2) bilobar disease with contraindication for PVE as single stage strategy; (3) failure of PVE/PVL; or (4) the need for a large hypertrophy (>65%) in an extremely small FLR (e.g., single segment). With respect to tumor origin, the most accepted and frequent indication is colorectal liver metastases (CLM). In such patients, response to preoperative systemic therapy is a very important consideration, as they are the most likely to benefit from a surgical approach. If resectable extrahepatic disease is present, it should be treated either before or during ALPPS stage 1, in order to avoid stimulation of distant tumor metastases by circulating growing factors that are released after stage 1. We make an exception to this rule in cases of CLM with limited resectable pulmonary disease.

Contraindications: Unresectable lesions in the FLR or unresectable extrahepatic metastases, severe portal hypertension, high anesthesiologic risk, medical contraindications to major hepatectomy, inability to achieve an R0 resection, unresectable primary tumor or tumor progression on chemotherapy constitute contraindications to performing ALPPS. Although advanced age per se is not an absolute contraindication, above the cutoff of 67 years old there is a significantly higher risk of worse perioperative outcomes. In addition, ALPPS should also be used with utmost caution for indications other than metastatic liver tumors. ALPPS for peri-hilar cholangiocarcinoma and gallbladder carcinoma have been associated with higher morbidity (up to 83%) and mortality (up to 71%) in the international registry.

PREOPERATIVE PLANNING

In general, preoperative work-up does not differ from that of other major liver resections. Preoperative staging should include state-of-the-art abdominal imaging, which includes a multislice CT scan of the chest, abdomen, and pelvis utilizing tri-phase contrasted acquisitions, as well as a contrasted MRI for a better assessment in patients with small lesions, a fatty liver or having received preoperative chemotherapy. The use of F-18 fluorodeoxyglucose positron emission tomography (18 FDG-PET/CT) scan should be considered, especially in cases of tumor recurrence in patients with a previous liver resection or suspected distant metastasis. Regardless of which imaging technique is used, the accurate assessment of number and location of hepatic lesions is crucial for adequate treatment

planning and successful therapy. Liver volumetry (either by CT or MRI) including both TLV and FLR volume is mandatory before planning any major liver resection. If tumor volume is small, TLV may be calculated by imaging-based volumetry, but we generally rely on the following formula instead for calculation of ideal TLV: −794.41 cc + 1,267.28 cc × body surface area (M^2). Nuclear imaging techniques such as 99mTc-galactosyl serum albumin scintigraphy or 99mTc-mebrofenin hepatobiliary scintigraphy (HBS) have recently gained wider acceptance as they are capable of measuring both volume and sectorial FLR function, therefore potentially identifying patients at higher risk for PHLF. The group from the Academic Medical Center (AMC) in Amsterdam proposed an FLR function (FLR-F) cutoff corrected for the body surface area of 2.69%/min/m^2 using anterior projections only, able to predict PHLF in patients submitted to major hepatectomy regardless of the type and severity of parenchymal liver disease.

SURGICAL TECHNIQUE

The ALPPS approach is a two-stage major hepatectomy with a short interval between stages. The technique as originally described consists of a right PVL combined with in situ splitting of liver parenchyma during the stage 1, followed by a completion surgery performed at surgeon discretion once FLR sufficiency has been assured, usually within 7 to 10 days (Fig. 120.1). This approach involves a more invasive and time-consuming first surgical procedure, followed by a second procedure that is shorter and technically much simpler. This strategy has been adopted by most centers as the classical ALPPS technique. Some important aspects of the ALPPS technique as well as the several proposed variations will be summarized in this section.

Classical Technique

Stage 1: The abdominal cavity is approached by either a bilateral subcostal incision with midline extension or a J-shaped incision. A midline laparotomy can also be used if a simultaneous open resection of a primary colorectal tumor is planned. Resecting the primary during stage 1 rather than during stage 2 is recommended since an auxiliary liver is present during the interval period (Fig. 120.2). When a simultaneous low rectal resection is necessary, it is recommended to strongly consider fecal diversion in order to avoid the potentially catastrophic scenario of a

symptomatic anastomotic leakage in these patients. The initial step of the operation entails a detailed exploration of the abdominal cavity and intraoperative Doppler ultrasound (IOUS) examination of the liver to accurately assess the number, size, and location of all lesions. If bilateral lesions are present, a complete tumor resection (clean-up) of the FLR is performed, in order to allow for subsequent hypertrophy of only nontumor-bearing parenchyma. Subsequently, the portal vein of the diseased hemi-liver is divided and either total (up to the inferior vena cava) or partial (up to the middle hepatic vein) parenchymal transection is carried out as for a future right trisectionectomy (Fig. 120.3). Regardless of the type of transection, the middle hepatic vein should never be transected in order to assure a proper outflow of the diseased hemi-liver. The anterior approach, with or without the "hanging maneuver," may also be used to help liver transection, reduce tumor manipulation, and reduce inflammation and adhesions created by full right liver mobilization. Partial transection (to approximately the depth of the middle vein) has been demonstrated to offer similar FLR hypertrophy yet significantly lower morbidity than total transection (38.1% vs. 88.9%; $P = 0.049$) and zero mortality in the initial report at the Hospital Italiano de Buenos Aires. If partial transection is performed, we prefer to routinely use the anterior approach. Total transection should be performed when a tumor is located deep in the parenchyma and too close to the FLR boundaries in order to isolate the tumor and prevent FLR invasion. The ALPPS stage 2 is technically more difficult if partial transection was performed in the stage 1. The confirmation of complete deportalization of the diseased hemi-liver by IOUS is of paramount importance to avoid technical failures, typically related to a portal vein trifurcation that leads to ligation of only the right anterior or the right posterior portal branch. At the end of the procedure, it is advisable to perform a trans-cystic hydraulic test and cholangiography in order to prevent postoperative biliary leaks (Fig. 120.4), which have been reported at high rates in initial series (20% to 87%) and associated with increased morbidity and mortality. Bile duct ligation should never be performed as it might lead to cholestasis, infection, and bile leaks with increased risk of mortality. If the gallbladder is present, cholecystectomy is typically performed in stage 1 to provide exposure for and facilitate right portal dissection. Vasculobiliary structures in the diseased hemi-liver are marked with vessel loops, and a long tie is placed in the cystic duct to facilitate their identification during the stage 2. Finally, with the aim of

minimizing adhesions, some surgeons have proposed placement of a plastic sheet or biologic agent between both cut surfaces, or placement of the diseased hemiliver in a plastic bag. However, good results have been reported without the use of any material at the liver partition site. Two drains are placed in the abdominal cavity, one in-between the transection lines and the other in the right subphrenic space.

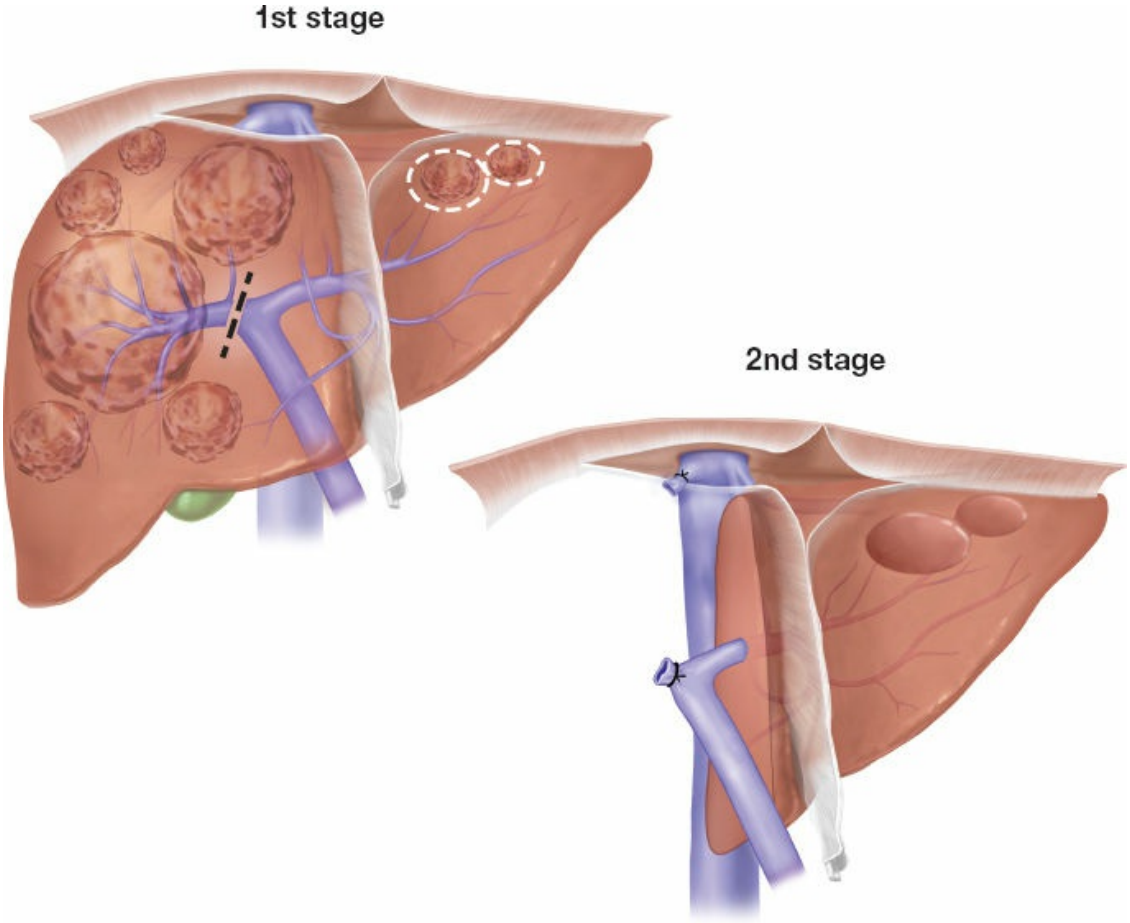

Figure 120.1. Diagram of procedures involved in the ALPPS approach. The stage 1 involves ligation of the right portal vein, resection or ablation of tumors in the FLR, and splitting of the parenchyma delineating the section(s) of liver to subsequently be resected. The stage 2 involves division of the right hepatic artery, right bile duct, and right venous drainage to allow resection of the tumor-bearing liver.

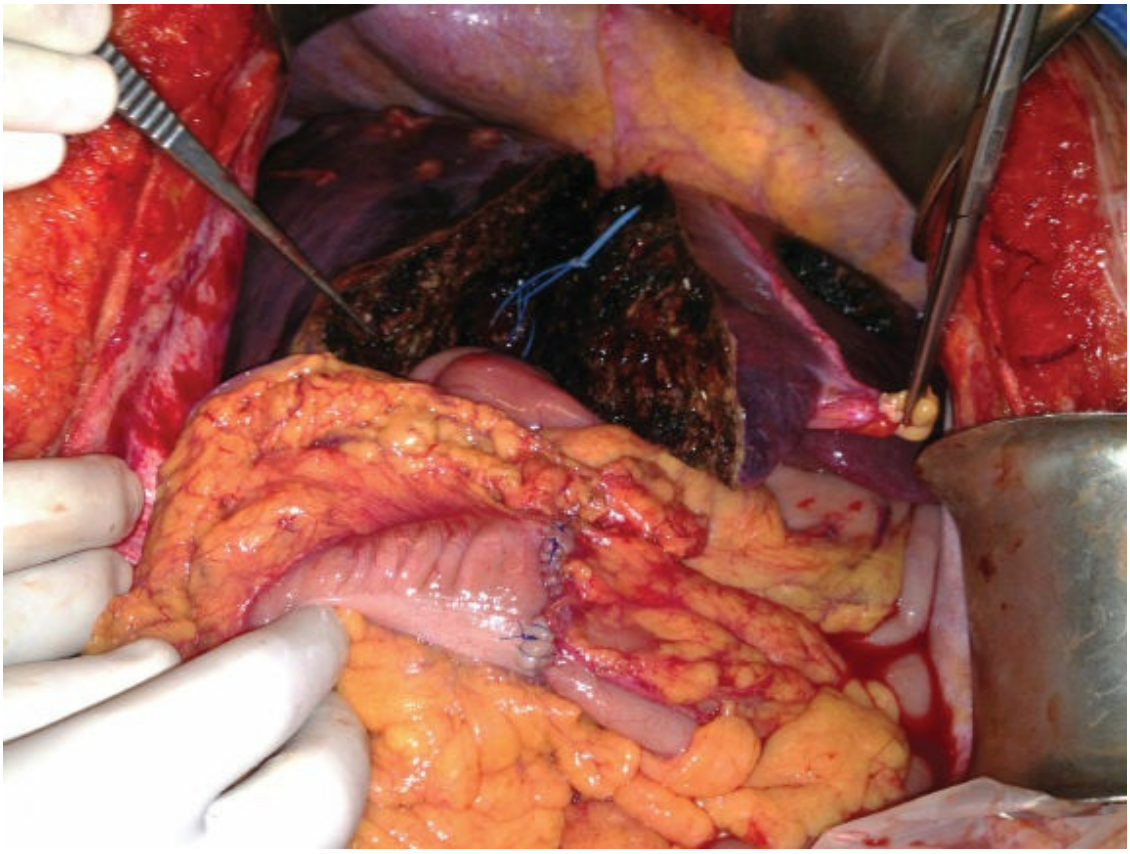

Figure 120.2. Simultaneous colectomy performed during ALPPS stage 1. Anastomosis after colectomy is shown in the foreground and the split liver parenchyma is shown with a blue vessel loop marking the right main glissonian vasculobiliary pedicle. A tumor has been resected from the FLR.

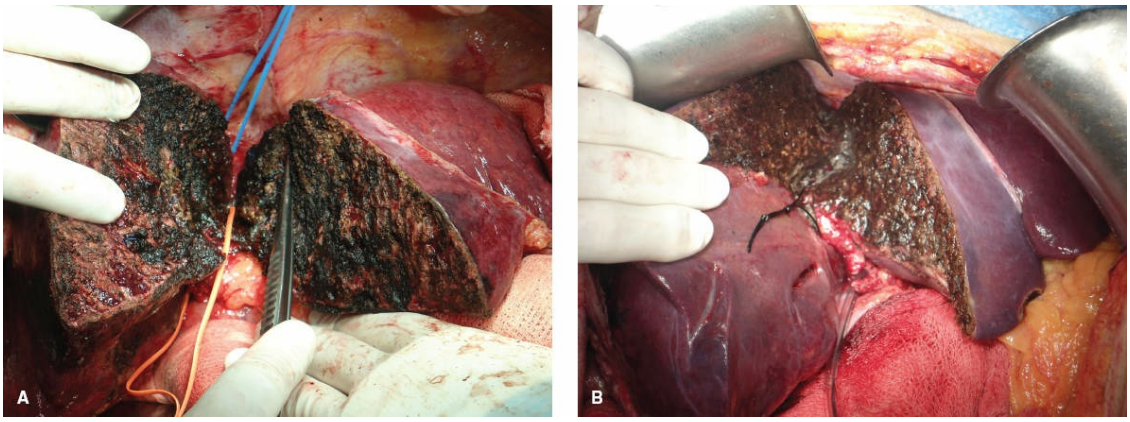

Figure 120.3. Parenchymal transection variants in ALPPS stage 1. **A.** The liver parenchyma has been totally divided between the diseased hemi-liver and FLR. A red vessel loop has been left to mark the right main glissonian vasculobiliary pedicle, and a blue vessel loop marks the right hepatic vein. **B.** In this case, partial parenchymal transection has been carried out. The suture with two knots marks the right main glissonian vasculobiliary pedicle.

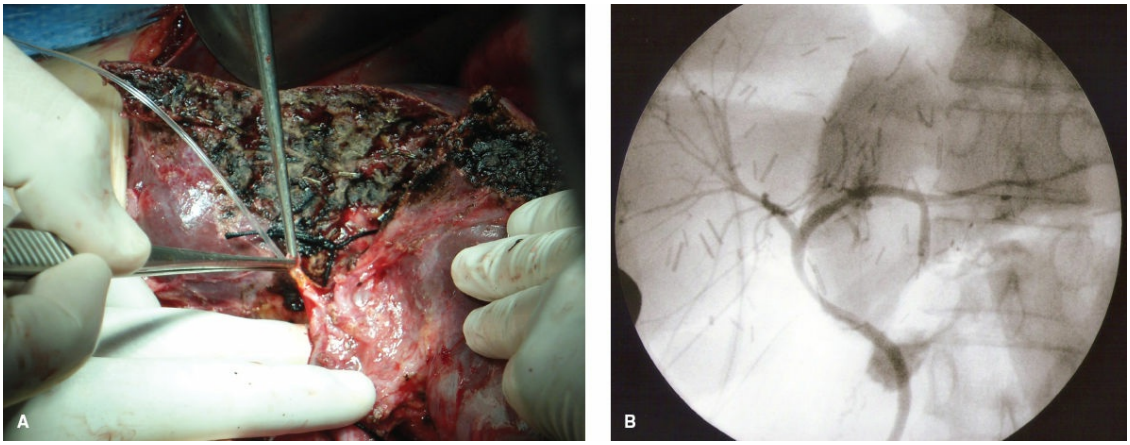

Figure 120.4. Biliary evaluation. **A.** The cystic duct is cannulated to perform a trans-cystic hydraulic test with either saline solution, propofol, or methylene blue to evaluate for evidence of biliary leaks. **B.** Intraoperative cholangiogram performed with this catheter shows an intact biliary tree and no evidence of biliary leaks.

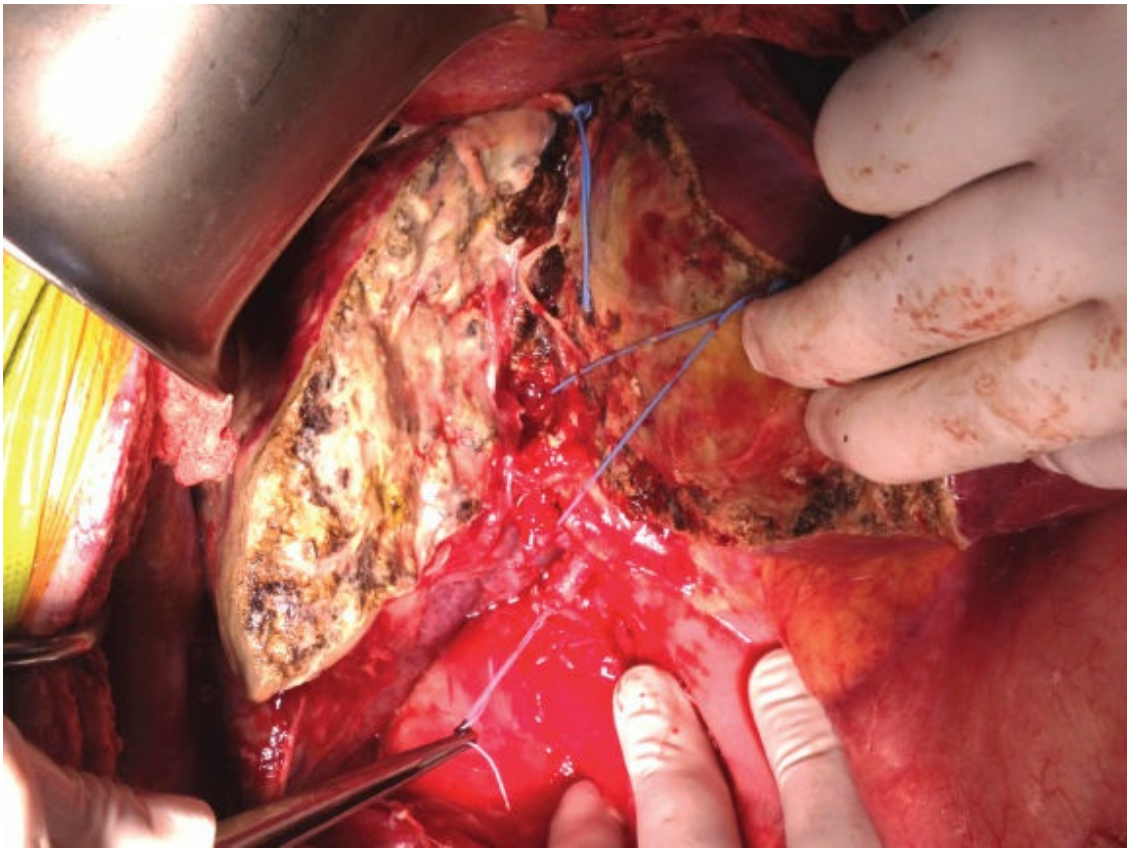

Figure 120.5. ALPPS stage 2. Once the plane between the diseased-right hemi-liver and FLR is divided with finger fracture to break up lax adhesions, the vasculobiliary structures of the diseased hemi-liver are easily recognized following the vessel loops around them. The blue stitch under traction is the cystic duct, while the right main glissonian vasculobiliary pedicle and

the right hepatic vein are marked with blue vessel loops in the depth of the transection plane.

Stage 2: Abdominal exploration is performed carefully after dividing adhesions. The vasculobiliary structures of the diseased hemi-liver are recognized by identifying the vascular tags around them (Fig. 120.5). The resection of the tumor-bearing lobe is achieved using vascular staplers for all vasculobiliary structures and the remaining liver parenchyma if present (Fig. 120.6). Finally, it is strongly recommended to perform an intraoperative cholangiography and hydraulic test through the cystic duct in order to prevent postoperative bile leaks.

Variations of the Classical Technique

Many different technical variations of the ALPPS approach have been proposed. Even though the original technique consisted on a right trisectionectomy, different technical variations have been later proposed, including the "left ALPPS," the "right ALPPS," and the so-called "rescue ALPPS" in patients with failed PVE/PVL. An additional alternative preserving only segments 1 and 4 as FLR after performing a left lateral sectionectomy has also been reported. However, concerning FLR variants in ALPPS, the most important breakthrough was accomplished after demonstrating that monosegment remnants can be safely left behind when applying the ALPPS approach. This constitutes an important paradigm change in liver surgery, given that resectability has been traditionally defined as the complete tumor removal preserving at least two contiguous Couinaud segments with intact vascular inflow, outflow, and biliary drainage.

Given that ALPPS has been associated in preliminary series with increased incidence of major complications and mortality, many different technical innovations and refinements have been introduced with the aim of improving outcomes. For example, a group from Murcia in Spain described the application of a tourniquet around a parenchymal groove of no more than 1 cm in the transection line and labeled this modification "ALTPS" (associating liver tourniquet and portal ligation for staged hepatectomy). Despite the theoretical attractiveness of the tourniquet, the 64% morbidity and 9% mortality in their series of 22 patients did not reflect a real improvement in terms of patient safety compared with most ALPPS series. Some have proposed substituting the parenchymal

transection with radiofrequency or microwave ablation (RALPP, LAPS) to create a virtual liver partition consisting of a necrotic plane between the diseased liver and FLR. These approaches provided a similar hypertrophic profile than the standard ALPPS approach but with only minor complications, no mortality, and a high feasibility of being performed by laparoscopy. The application of percutaneous interval PVE instead of PVL as method of portal vein occlusion, also known as "Hybrid ALPPS," is undoubtedly one of the most promising innovations among the different ALPPS proposals. This approach avoids portal pedicle dissection during first stage and thereby facilitates a less difficult second stage because of fewer adhesions. Finally, we recently published our latest ALPPS variation that we employed at Hospital Italiano de Buenos Aires, the so-called "Mini-ALPPS." This new proposal inverts the current paradigm, transforming the classical large stage 1 into a much less invasive procedure that could be performed by laparoscopy, and leaving the main surgical procedure for the stage 2. This variation incorporates partial parenchymal transection, intraoperative PVE and avoids portal pedicle dissection and liver mobilization, with the aim of maximally reducing the surgical impact of ALPPS first stage to promote rapid patient recovery and facilitate stage 2 (Fig. 120.7). This new philosophy seems promising and could in the future improve both safety and oncologic outcomes.

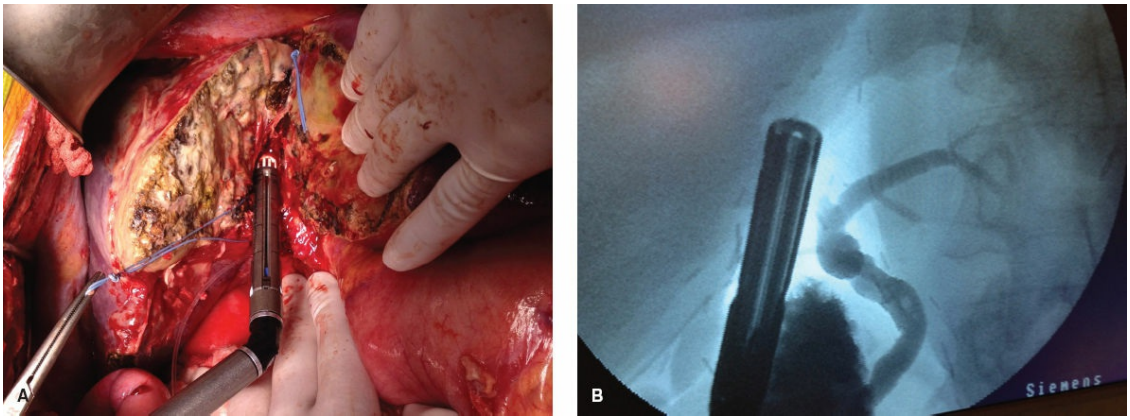

Figure 120.6. ALPPS stage 2. **A.** Traction is placed by one of the vessel loops held with a Kelly clamp allowing en bloc transection of the right main glissonian vasculobiliary pedicle with a vascular stapler. The blue vessel loop at the top of the field marks the right hepatic vein, which will subsequently be divided with another application of the vascular stapler. **B.** A trans-cystic cholangiogram is performed before firing the stapler to assure its correct position over the right bile duct and avoid accidental injuries of the bile duct bifurcation.

Given the existence of many technical variants with different names, the founding members of the International ALPPS registry have recently reported a “consensus” terminology in order to establish a common language to adequately compare and further develop different variants of the original ALPPS technique.

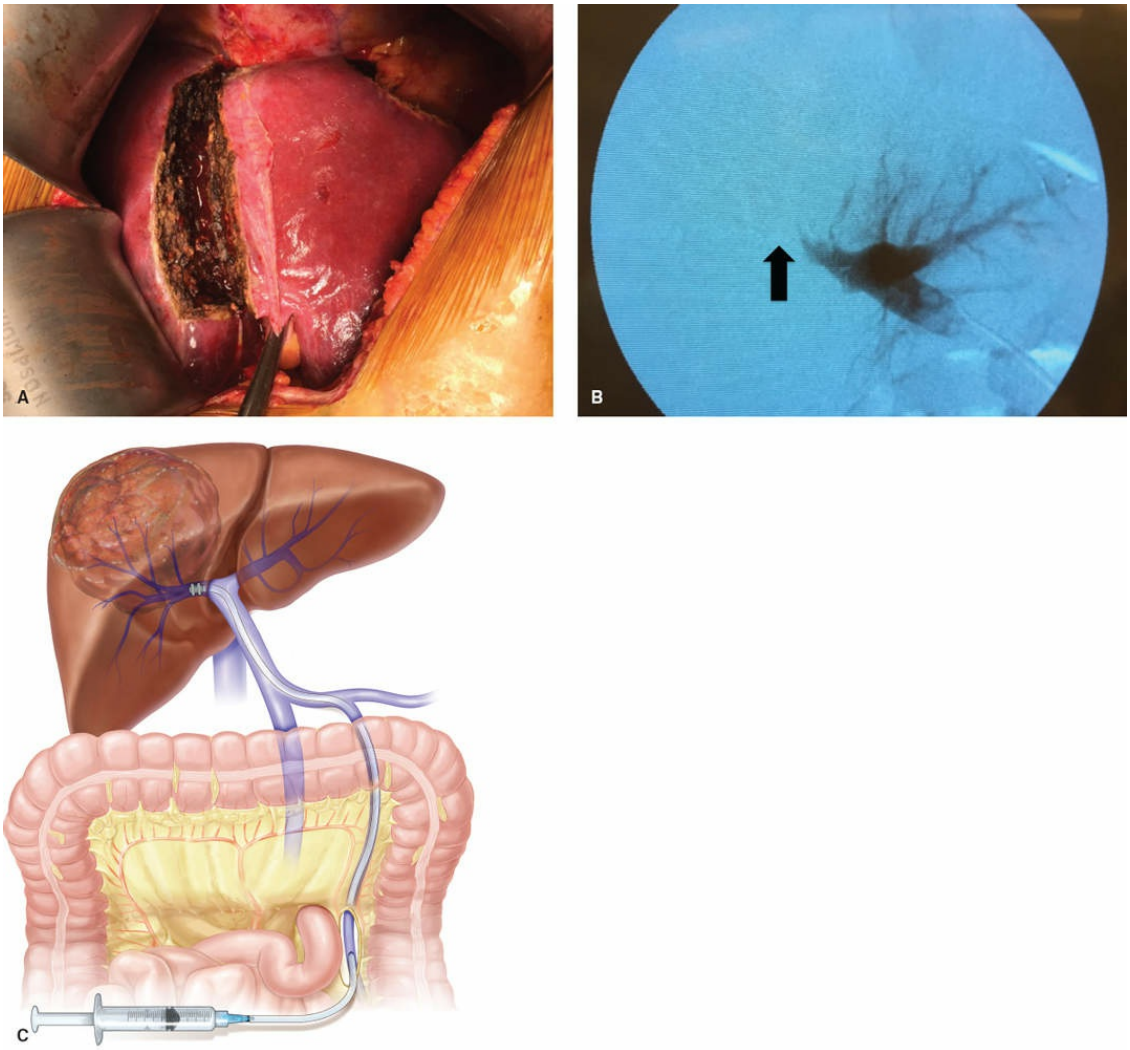

Figure 120.7. “Mini-ALPPS.” **A.** Partial parenchymal transection in the plane between the diseased hemi-liver and the FLR (down to the level of the middle hepatic vein, without any moblilization of the liver). **B.** Intraoperative right portal vein embolization via the inferior mesenteric vein. **C.** Diagram of the “Mini-ALPPS” procedure.

POSTOPERATIVE CARE

Patient management during the interval period between both stages is of paramount importance to reduce complications of ALPPS. After stage 1, early extubation is applied whenever possible and the patient is managed either directly in the general ward or at the intensive care unit (ICU) for the first 24 to 48 hours depending on patient comorbidities and/or intraoperative events. Once stabilized and without active complications, the patient is transferred to general ward. Oral nutrition is initiated as soon as possible, once the clinical condition is appropriate and maintained

during the interval period until reoperation. If oral intake is not tolerated, parenteral nutrition should be started without delay. During the interval period between stages, clinical evaluation and laboratory tests following the trend of transaminases, bilirubin, and international normalized ratio (INR) are performed. Volumetric measurement of the FLR is routinely performed on the sixth postoperative day after the first stage. In case of insufficient hypertrophy, an additional CT volumetry is performed weekly until a sufficient FLR volume is achieved. Stage 2 should be undertaken only when volumetric studies have demonstrated FLR sufficiency and the patient has returned to good medical condition. When a patient has a compromised clinical status, active complications, abnormal liver function tests on day 5 after stage 1 or a MELD score above 10, the stage 2 must be delayed or even abandoned in order to avoid mortality. If the patient is in good condition but FLR volume remains insufficient, the patient can be discharged home and readmitted for stage 2 once FLR sufficiency has been achieved, as assessed by periodic outpatient evaluation.

Although volumetry is still the standard method for determining whether a patient can safely undergo a major liver resection, the fact that PHLF remains the most important cause of death in the ALPPS Registry indicates that the established volumetric criteria being used to judge FLR sufficiency before reoperation might not be sufficient, particularly when taking into account that these volume measurements are applied to liver parenchyma that is growing extremely fast. Even though previous studies have observed proliferative and architectural changes at histologic level accompanying macroscopic FLR hypertrophy in ALPPS, rapid liver volume growth may not correlate with an immediate corresponding equal increase in function. In line with this notion is the observation of histologic findings of hepatocyte immaturity in nontumorous FLR parenchyma. Results from some studies suggest that FLR volumetric increase precedes its functional increase.

Even though there is agreement that stage 2 should be postponed until a satisfactory function has been reached, the key question yet unanswered is how good the FLR function has to be in order to avoid PHLF. In such scenario, the use of HBS, a more sophisticated tool capable of evaluating sectorial liver function, has been proposed to help determine the best timing for stage 2. In a previous study, we found that none of the patients with an FLR representing at least 30% of total liver function by HBS (%FLR-C) before stage 2 developed PHLF. However, a major drawback

of the %FLR-C is that it does not take into account if the overall liver function is indeed good or not, which could lead to misinterpretations and errors in clinical judgment. This fact, along with the impossibility of using the 2.69%/min/m² FLR-F cutoff proposed by the AMC group in Amsterdam since it was not established using modern HBS assessment of liver function (Gmean and SPECT analysis), leads us to develop a new formula to measure FLR function during ALPPS interval. *The Hospital Italiano de Buenos Aires Index* (*HIBA-index*) is a dynamic measure that represents the proportion of radionuclide accumulating in the FLR during the phase between 150 and 350 seconds postinjection and is calculated using the area under the time–activity curves (AUC) with the following formula expressed as $\%: HIBA\text{-}index = \frac{AUC\ liver - AUC\ blood\ pool}{AUC\ field\ of\ view} \times \frac{FLR\ counts}{Total\ liver\ counts}$ Between 2011 and 2016, 20 out of 39 patients (51%) underwent HBS before completion of ALPPS stage 2 at the Hospital Italiano de Buenos Aires. After comparing the individual performance of three interstage FLR functional parameters (%FLR-C, FLR-F, and HIBA-*index*), a HIBA-*index* with a cutoff value of 15% was found to be the most accurate parameter to predict clinically significant PHLF after ALPPS stage 2. The predicted risk of PHLF in patients with a HIBA-*index* lower than 15% was 80%, whereas no patient with a HIBA-*index* higher than 15% developed PHLF. This practical cutoff value may become of paramount importance to avoid futile indication of ALPPS stage 2, as current standard volumetric criteria have so far proved insufficient to adequately guide the safe timing of ALPPS stage 2 (Fig. 120.8). Given the increasing evidence supporting the use of HBS to quantify sectorial liver function, we encourage the routine use of this complementary noninvasive low-cost exam to facilitate decision making in every institution performing ALPPS (Fig. 120.9).

COMPLICATIONS AND THEIR MANAGEMENT

Single center and cooperative experiences with ALPPS reveal relatively high morbidity and mortality rates (Table 120.1). A meta-analysis including 295 patients with different tumor origins revealed a 90-day mortality of 11% and morbidity (Clavien-Dindo grade ≥IIIa) of 44%. More recent data from the ALPPS registry on 528 patients reveal better results, with an overall 90-day mortality of 8.9%. Of the different tumor types, CLM has shown the best safety profile, with a morbidity grade

(Clavien-Dindo ≥IIIa) of 29% and a 90-day mortality of 5% in 228 patients. Nonetheless, these morbidity and mortality rates are relatively high, and may be explained at least in part by the obligatory "learning curve" that typically exists for new innovations. Furthermore, ALPPS is composed of two complex surgical procedures instead of only one, which is being applied in patients with high tumor burden and prolonged chemotherapy regimens. More recent series of ALPPS, limited to patients with CLM that have a response to chemotherapy reveal results that compare favorably with most reported series of two-stage hepatectomies. For example, the morbidity and mortality of ALPPS do not appear significantly different to the recently reported 84% morbidity and 10% mortality from 87 patients who underwent a major hepatectomy after PVE or PVL at the Beaujon Hospital in France for initially unresectable CLM. Among 65 patients who underwent a two-stage hepatectomy at the MD Anderson Center in the United States, a 49% morbidity and 6.4% mortality were reported, and these figures included only the second stage. Similarly, the morbidity and mortality of two-stage hepatectomies in 59 patients at the Hôpital Paul Brousse in France were 59% and 7%, respectively. Furthermore, a recently published study from this last group comparing match populations of ALPPS and two-stage resection found nonsignificantly different 90-day mortality (0% vs. 5%; P = 0.891) and major complication rates (41% vs. 39%; P = 0.999) between this strategies.

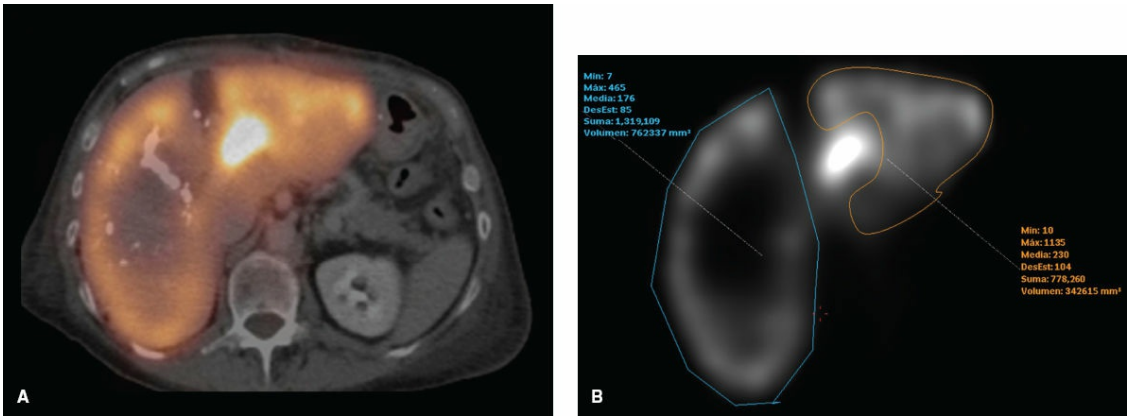

Figure 120.8. Hepatobiliary scintigraphy during ALPPS inter-stage interval in a 71-year-old woman with colorectal liver metastases. **A.** 3-dimensional distribution of function within the liver volume is calculated using a contrast-enhanced CT-scan linked to the SPECT images as a reference. **B.** Volumes of interest are manually outlined around the diseased hemi-liver and

the future liver remnant.

Possible complications after both ALPPS stages are essentially the same as in any major hepatectomy. The most frequent complications managed medically include PHLF, right pleural effusion, respiratory infections, and acute renal insufficiency. Data from the International Registry showed that the reported incidence of PHLF ranges from 14% after stage 1 to 31% after stage 2, even when theoretically sufficient FLR volumes are achieved. As noted previously, the rapid volumetric increase during ALPPS may not correspond to an immediate and equivalent increase in function. Preliminary reports using HBS for sectorial FLR function evaluation indicate a diffuse drop of total liver function after the stage 1 in patients who suffer from PHLF, most likely due to a loss of function in the excluded liver that is sharper than the function gain of the FLR. Regarding surgically managed complications, the most frequent are biliary fistula (12% to 25%), perihepatic collections, intra-abdominal bleeding and intra-abdominal septic complications from extrahepatic procedures. Even though morbidity rates are similar after stage 1 and 2, >90% of deaths occur after stage 2 and PHLF remains one of the most important causes of death (up to 77% of deaths) in most series. Age over 67, biliary tumors, operative time more than 5 hours during stage 1, and the administration of red blood cell transfusions during either stage have been identified as significant risk factors for severe complications and 90-day mortality. In addition, recent data from the ALPPS registry indicate that patients who develop PHLF after stage 1 or have a MELD score ≥10 before stage 2 are at higher risk, with an adjusted odds of 90-day mortality of 3.9 (CI 1.4 to 10.9) and 4.9 (CI 1.9 to 12.7) respectively. A recent prospective study at the Hospital Italiano de Buenos Aires found that total parenchymal transection was an independent risk factor of postoperative complications.

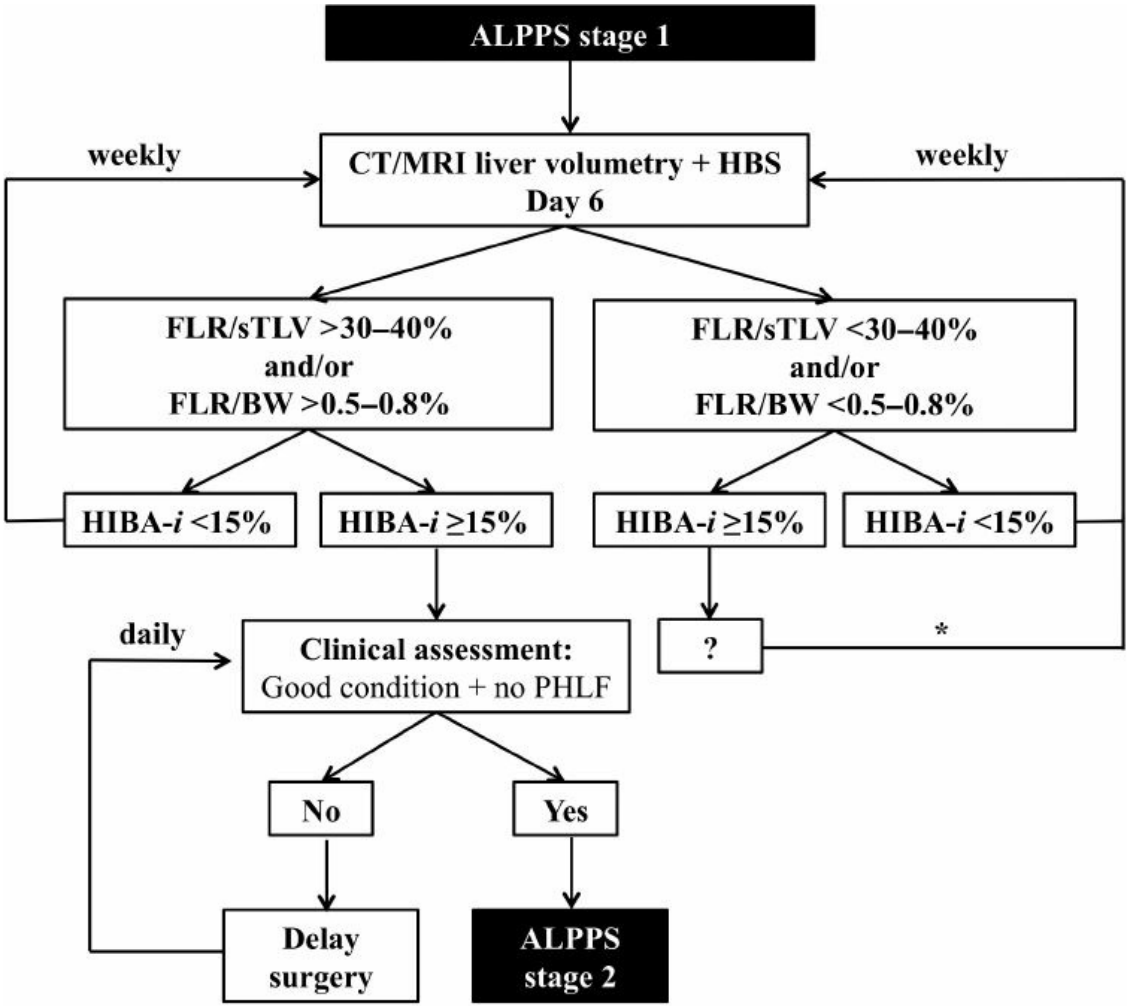

Figure 120.9. Current decision-making algorithm in the Hospital Italiano de Buenos Aires: volumetric assessment of the future liver remnant (FLR) is generally performed 6 days after stage 1 with computed tomography (CT) or magnetic resonance imaging (MRI). If sufficient volume is achieved, hepatobiliary scintigraphy (HBS) with a HIBA index (HIBA-*i*) ≥15% allows proceeding to stage 2. Assessment of patient general condition is always mandatory before completion of surgery.

The general management of complications does not differ from any other liver resection, and although they should be aggressively and treated early, their prevention is of utmost importance. Morbidity and mortality during ALPPS have been associated in most series with inappropriate patient selection, unsuitable timing of the second stage, and errors in clinical judgment due to the lack of experience with the application of this new technique. In order to increase ALPPS safety, current recommendations are based on the three pillars that determine outcomes: (1) *Patient selection*, the best candidates are patients younger than 67 years

old with CLM who respond to chemotherapy; (2) *Operative technique*, partial parenchymal transection without sacrificing the middle hepatic vein, intraoperative cholangiography and hydraulic test at both stages, avoidance of simultaneous pancreatic resections in case of metastatic neuroendocrine tumors, as well as fecal diversion in case of simultaneous left colonic or rectal resections are key rules, IOUS for cases of operative PVL to ensure ligation of all target portal branches; and (3) *Timing of second stage*, the 1-week interval dogma needs to be abandoned and patients should be operated once volumetric and functional studies have demonstrated FLR sufficiency, and only if patients are without complications and in good clinical condition, without complications, having normal liver function tests, and the MELD score <10, regardless of the number of days needed to achieve this status.

OUTCOMES

Even several years after the inaugural publication of ALPPS and adoption of this approach by many centers, there remains a dearth of high-quality evidence in the existing literature, represented primarily by single-center, retrospective studies with limited numbers of patients. And given the novelty of the approach, the patient follow-up is necessarily short. The results obtained so far come from centers using different selection criteria, including heterogeneous groups of patients treated for different underlying pathologies, with variable use of chemotherapy and different technical variations being applied. These facts make very difficult the interpretation of outcome data from an oncologic point of view.

In general, there is already a good evidence demonstrating that ALPPS is superior to classical approaches in terms of tumor resectability and

achieving an R0 resection (Table 120.2). A multicenter comparative experience demonstrated that ALPPS had a higher efficacy in terms of achieving complete tumor resection when compared with PVE/PVL (83% vs. 66%; $P = 0.027$). The higher rate of complete resection is explained by the observations that nearly all patients achieve sufficient hypertrophy, the short interval makes tumor progression between stages unlikely, and liver splitting prevents direct tumor infiltration of the FLR. With regard to surgical margins, recent meta-analytic data from six studies including 295 patients showed an R0 resection rate of 91%. However, when it comes to oncologic outcomes, probably the most important question still unanswered is if the higher tumor resectability rates observed with ALPPS are translated into improved overall survival (OS) and disease-free survival (DFS). While the available evidence does not definitively answer this question, recent studies suggest that patients with CLM have similar short-term oncologic outcomes compared with patients treated by traditional surgical approaches. A recent comparative multicenter study showed that tumor recurrence occurred at a comparable rate in both groups at 12 months, with 54% in ALPPS and 52% in PVE/PVL. The largest available data from the ALPPS registry in patients with CLM indicate so far a 1- and 2-year OS of 76% and 62% as well as a DFS of 59% and 41%, respectively, with a median DFS of 14 months. This median DFS is more than acceptable when compared to the 7.5 months of median DFS recently reported in the updated experience from the Hôpital Paul Brousse in two-stage liver resections. Furthermore, the subgroup of CLM patients from the ALPPS Registry with age ≤60 years exhibited the best OS, being 88% and 74% at 1 and 2 years respectively, with a median survival of 24 months. Even though only short-term follow-up is available, this survival figures (on an intention to treat basis) are similar or even better than that in the few existing series of two-stage hepatectomies, despite the fact that most reports analyzed only the survival of patients who completed the second stage. Moreover, the 64% 3-year OS in patients with CLM from the German group leaded by Hans Schlitt compares favorably with that of conventional staged approaches. On the other hand, at the Hospital Italiano we have treated 39 patients with the ALPPS approach, 26 of whom (67%) had CLM. In this specific subgroup, 96% of patients had received preoperative chemotherapy and 62% received more than six cycles. The disease-specific OS and DFS at 3 years in our series of CLM are 49% and 9%, respectively. Such results should not be surprising in the light of an

aggressive tumor biology, as demonstrated by the fact that more than 80% of our patients had a node-positive primary cancers, synchronous presentation of their liver metastases, and bi-lobar metastases. Even more controversial data come from a recent study reported by the Paul Brousse group, aiming to compare the survival of ALPPS (n: 17) against two-stage liver resections (n: 41) for CLM as intent-to-treat analysis. Surprisingly, even though DFS was not significantly different between both strategies, they found that estimated 2-year OS was lower after ALPPS than two-stage hepatectomy (42% vs. 77%; $P = 0.006$). However, the results from this small sample study have to be interpreted carefully, as there could be potential selection biases inherent to its retrospective design. Furthermore, the positive margin rate in ALPPS was 64% versus 29% in the two-stage group, and later salvage surgery for liver recurrence was less often performed after ALPPS than after 2-stage hepatectomy. Therefore, in our opinion current evidence does not allow any firm conclusion regarding the oncologic superiority or inferiority of ALPPS compared with classical approaches. Results of randomized controlled trials are necessary to clarify this important issue.

TABLE 120.2 Outcomes of ALPPS Compared to Classical Two-Stage Hepatectomy in Patients With CLM of Largest Series With Available Data

	Author	Year	*N*	Major Morbidity (%)	Mortality (%)	OS (Years) 1	OS (Years) 2	OS (Years) 3	DFS (Years) 1	DFS (Years) 2	DFS (Years) 3
Classical 2-Stage	Lamb et al.	2013	459	40%	3%	—	—	59%	—	—	20%

CLM, colorectal liver metastases; OS, overall survival; DFS, disease-free survival.

CONCLUSIONS

ALPPS represents a significant advance in liver surgery as it induces a fast and robust liver hypertrophy in patients with insufficient FLR. ALPPS benefits include: (1) FLR hypertrophy unparalleled in its rapidity; (2) robust hypertrophy, most beneficial in patients with extremely small FLR; (3) aggressive FLR clean-up, with the possibility of leaving single liver

segments as sufficient liver remnant; (4) reduced interval between stages with fewer adhesions, easier definitive resection, and lower dropout rate from progression; (5) single hospitalization for both stages in the majority of patients; (6) ability to achieve liver hypertrophy even after unsuccessful PVE/PVL; and (7) higher resectability rates compared to classical approaches. However, it remains uncertain if the observed higher rates of tumor resectability translate into improved long-term survival compared with classical approaches. Recent evidence indicates that ALPPS can be performed with acceptable morbidity and mortality in experienced centers, comparable to that of conventional two-stage hepatectomies. Moreover, the safety profile of ALPPS will most likely improve in the future as a consequence of better patient selection and technical refinements as more experience is gained. Appropriate candidates for ALPPS presently are patients with failure of PVE/PVL or extensive bilateral CLM where an extremely small FLR might result as a consequence of tumor clean-up, and notably if there is tumor close to FLR boundaries. Given that ALPPS is a surgical innovation under development, it should be performed only at high-volume specialized centers, in patients selected by a multidisciplinary team and inside the ALPPS international registry.

EDITOR'S COMMENT

ALPPS has been shown to dramatically induce rapid hypertrophy of the future liver remnant. This is a novel method of performing two-stage hepatectomy for patients that would otherwise not be resectable with traditional two-stage hepatectomy because of inadequate FLR. The procedure combines parenchymal transection with portal vein occlusion followed by hepatectomy in a second procedure performed in close proximity to the first procedure. The invention of this procedure, like the discovery of many other medical therapies and procedures, was quite serendipitous. Dr. Schlitt in Regensburg, Germany planned to perform an extended right hepatectomy on a patient in 2007, however, intraoperatively found the FLR to be inadequate. He then transected the liver parenchyma along the falciform ligament to facilitate performing the hepaticojejunostomy and performed right portal vein ligation to induce hypertrophy of the left lateral segment. He found, surprisingly, by a CT on postoperative day 8 that the left lateral segment had grown substantially. He proceeded to perform an extended right hepatectomy with good patient outcome (de Santibanes E, Clavien PA. Playing Play-Doh to prevent postoperative liver failure: the "ALPPS" approach. *Ann Surg* 2012;255:415–7). This is the first time a chapter dedicated to this procedure has been published in Mastery of Surgery. This in itself shows the growing recognition for the value of ALPPS for selected patients. Dr. Tanabe has very elegantly described this novel procedure and the technical details of performing the operation and the patient population in which to consider this procedure for. The adoption of this procedure has not been uniform, and especially slow to take hold in the United States, likely because of the high morbidity and mortality that has been associated with it.

Initially the mortality rates, even at experienced centers were reported up to 20% (Schadde E, Ardiles V, Slankamenac K, et al. ALPPS offers a better chance of complete resection in patients with primarily unresectable liver tumors compared with conventional-staged hepatectomies: results of a multicenter analysis. *World J Surg* 2014;38:1510–9; Nadalin S, Capobianco I, Li J, et al. Indications and limits for associating liver partition and portal vein ligation for staged hepatectomy (ALPPS). Lessons Learned from 15 cases at a single centre. *Z Gastroenterol* 2014;52:35–42). To decrease the morbidity and mortality, modifications from the initially described procedure have been undertaken such as mini-ALPPS, minimally invasive ALPPS, hybrid ALPPS, or terminal branches portal vein embolization liver partition for planned hepatectomy (TELPP) to name a few. Procedural modifications aimed to improve outcomes and safety include anterior approaches with minimal dissection, partial transection of liver parenchyma, PVE instead of operative ligation and tourniquet application or ablation instead of parenchymal transection. Mini-ALPPS reverses the aggressiveness of the surgical stages and essentially limits the first-stage operation to promote rapid recovery and then follows with the more complicated second stage. The first stage consists of partial transection of the liver parenchyma (no more than 3 to 5 cm in depth), minimal portal dissection, and PVE performed by accessing the inferior mesenteric vein thus avoiding portal dissection. The second stage then completes the resection. Hybrid ALPPS uses a combination of in situ splitting the liver with anterior approach, right PVE postoperatively by interventional radiology and finally second-stage hepatectomy. There are many modifications to the procedure currently published in the literature, all with the goal of reducing morbidity and mortality of ALPPS, and as research proceeds some of these modifications may be found to be an improvement from the initially described procedure.

One of the most critical learning points for surgeons adopting this procedure is not in the technical details of the surgery but in selecting the proper patients. This holds true in many surgical procedures and specialties but is especially important for a procedure with the potential for such high morbidity and mortality as ALPPS. A risk score has been published to assist in quantifying the risk to a patient who may have a futile outcome (Linecker M, Stavrou GA, Oldhafer KJ, et al. The ALPPS risk score: avoiding futile use of ALPPS. *Ann Surg* 2016;264(5):763–71). This paper developed a score based on 528 patients entered into the ALPPS registry from over 38 centers. The primary outcome examined was 90 day or in-hospital mortality from the time of the first surgery. Nine percent of patients had an in-hospital or 90-day mortality in this study. This is much lower than previously published mortality rates. Independent risk factors associated with poor outcome in the pre-stage 1 model includes age >67 years and biliary tumors. The pre-stage 2 model includes major complications after stage 1, elevated bilirubin or creatinine and cumulative pre-stage 1 score. Model scores were given for each of the risk factors. The model predicted

mortality of up to 50% for patients with a score of 6.9. Interestingly in this study, the FLR volume and the hypertrophy after stage 1 were not predictive of mortality.

Implementing new surgical procedures and techniques in the United States is not regulated by any government entity like diagnostics, drugs, and medical devices. Adopting new technologies and procedures in surgery is critical to continue to advance the field but must be done in a responsible fashion. Many new procedures were initially criticized before becoming widely accepted. When the first laparoscopic appendectomy was performed in 1980 by Dr. Kurt Semm, a German gynecologist, he was criticized harshly with colleagues reporting that "only a person with brain damage would perform laparoscopic surgery" (Bhattacharya K. Kurt Semm: a laparoscopic crusader. *J Minim Access Surg* 2007;3:35–6). In the early 1990s when laparoscopic cholecystectomy was performed, it was fraught with naysayers about the approach but also had much higher complications initially than the open procedure. The initial series of laparoscopic cholecystectomies had significant morbidity with several fold higher rates of bile duct injury compared with the open procedure (Southern Surgeons Club. A prospective analysis of 1518 laparoscopic cholecystectomies. The southern surgeons club. *N Engl J Med* 1991;324:1073–8; Williams LF Jr, Chapman WC, Bonau Ra, et al. Comparison of laparoscopic cholecystectomy with open cholecystectomy in a single center. *Am J Surg* 1993;165(4):459–65). However in less than 10 years, laparoscopic cholecystectomies were performed routinely with much improvement in complication rates and obvious benefits such as decreased postoperative pain and decreased length of stay, but still with higher rates of bile duct injury. Subsequently the adoption and education of future surgeons was not structured and consisted of loosely organized courses and training. Most recently, the use of the robotic platform for some procedures has become commonplace such as robotic prostatectomy but less common for others such as pancreaticoduodenectomy. Marketing has been credited by skeptics as to the rapid rise in robotic prostatectomies. Proponents of the procedure may point to a multidisciplinary collaboration between physicians and centers of excellence for propelling this to the most common technique for prostatectomy and most common robotic procedure in the United States.

The implementation of ALPPS has been slow and more methodical than many previous technologies or procedures. This may be because a company is not involved in marketing or profiting from a new piece of equipment for the ALPPS procedure. A registry was created by Drs. Santibanes, Lang, and Clavien to record outcomes of all cases performed across the world. The registry now has over 800 patients enrolled with over 300 hundred institutions participating and 32 projects registered and completed or in progress. To prospectively evaluate this procedure, a multicenter randomized trial of ALPPS versus Two-stage hepatectomy for colorectal liver metastasis is open to accrual. The trial is open to any center participating in the registry that has performed more than five cases. Many papers have now been published using the registry

data from the early learning curve to most recently the ALPPS risk score. The group should be commended for being transparent and inclusive when creating the registry and opening the clinical trial. This will be critical in evaluating the effectiveness and safety of ALPPS and its adoption worldwide as an option for patients that would otherwise have no other surgical alternatives.

E THE PANCREAS

121 Surgical Anatomy of the Pancreas

Petros Mirilas, Marios Loukas, and Lee J. Skandalakis

SURGICAL ANATOMY OF THE PANCREAS

The pancreas is a bland appearing yellowish organ situated in the retroperitoneum. Early historical descriptions of this gland are hardly more than a list of names of those who noticed it during their dissections, before moving on to more interesting organs. It was only with identification of the digestive enzymes by Claude Bernard in 1850 that the pancreas became recognized as a complete organ with an important function, and thus, worthy of study.

The retroperitoneal location and anatomic relationships of the pancreas combine to make its surgical removal difficult. Sir Andrew Watt Kay wrote in 1978, “For me, the tiger country is removal of the pancreas. The anatomy is very complex and one encounters anomalies.” The embryogenesis of the pancreas and its deep retroperitoneal anatomy are responsible for the designation “tiger country.” Prior to exploration, the surgeon should know whether the patient’s pancreas contains any anomalies of the parenchyma (annular pancreas or divisum), ductal system (divisum, obstruction, or aberrant location), or vasculature (replaced right hepatic artery behind the pancreatic head or other arterial anomalies). At operation, the surgeon must consider these possibilities, even if they are not evident on preoperative imaging. Furthermore, the pancreas is surrounded by numerous structures (i.e., the duodenum, stomach, spleen, left adrenal gland, transverse mesocolon and colon, left kidney, right ureter, and jejunum) making dissection of and around the pancreas potentially risky to multiple organs. The pancreas lies transversely in the retroperitoneal space, between the duodenum on the right and the spleen on the left. It is related anteriorly to the stomach, to the omental bursa

above, the greater sac below, as well as to the transverse mesocolon. It is a fixed organ. Figures 121.1 and 121.2 demonstrate the relationships of the pancreas and surrounding organs.

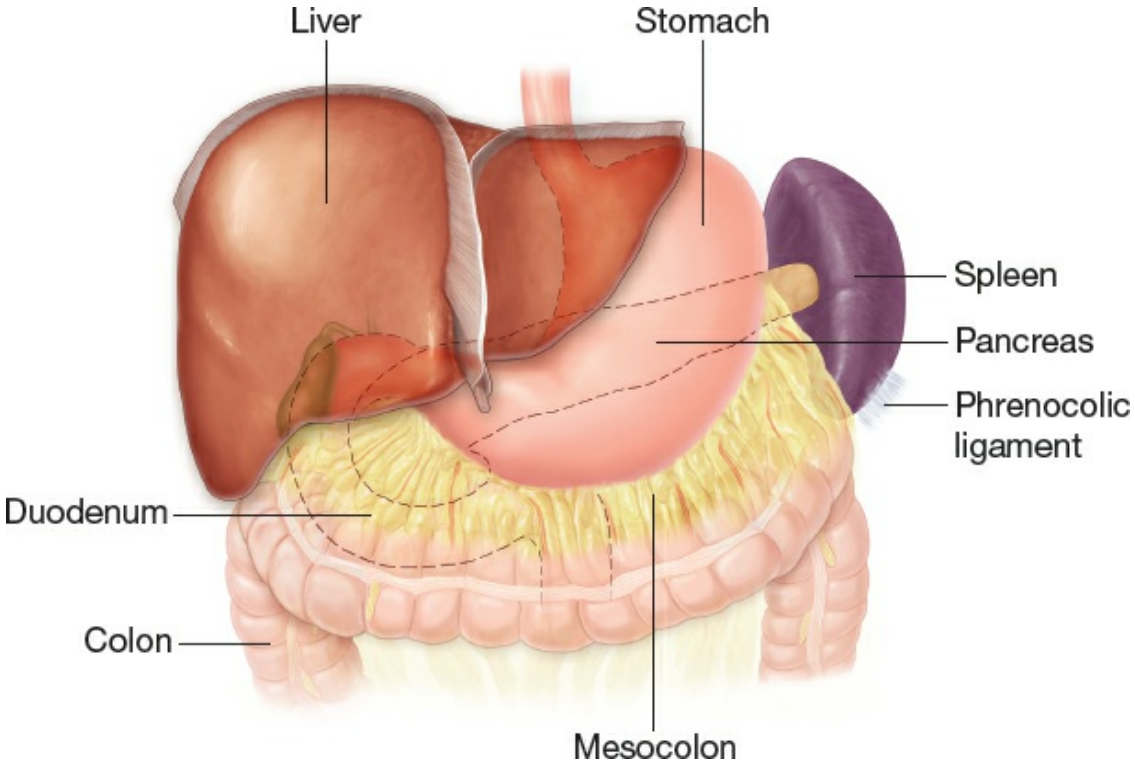

Figure 121.1. Anterior relationships of the pancreas.

EMBRYOLOGY

The pancreas develops from two buds originating from two endodermal primordia respectively: the dorsal diverticulum and the ventral diverticulum of the foregut (Fig. 121.3). The ventral pancreas develops at 4.5 to 5th week from the hepatic diverticulum, which also gives genesis to the gallbladder and the extrahepatic biliary ducts. The ventral pancreas is developmentally associated with the bile duct. The dorsal pancreas arises a bit earlier (4th week) in the mesentery of the duodenum (mesoduodenum) and has its own pancreatic duct.

With growth and development of the bile duct, the ventral pancreas is separated from the duodenum and the respective pancreatic duct exits at the common junction with the bile duct. “Rotation” of the duodenum brings the ventral pancreas and pancreatic duct-bile duct junction in the mesoduodenum to a caudal and posterior position to the dorsal pancreas. When the two pancreatic primordia come into contact, they fuse (end of 6th week). The ventral primordium forms the uncinate process and the

posterior head of the pancreas. The anterior head, the body, and tail are derived from the dorsal primordium.

The ducts follow the fusion of pancreatic primordia and join. The ventral duct usually persists and unites with the distal part of the dorsal pancreas to form the main pancreatic duct. The proximal part of the dorsal pancreas either persists and forms the accessory pancreatic duct, or disappears.

The secretory acini derive from the ducts (3rd month) and appear as clusters of cells around the duct endings. The acini secrete pancreatic enzymes and are the responsible for the exocrine pancreatic function. The pancreatic islets are endocrine cells and also originate from the terminal ducts. The islets organize into islands (Fig. 121.4), which comprise endocrine cells of various cell types. Each cell type secretes a different hormone, including glucagon (A cells), insulin (B cells), and somatostatin (D cells). In addition to the acinar and endocrine cells, the terminal ducts also give rise to the ductal epithelium.

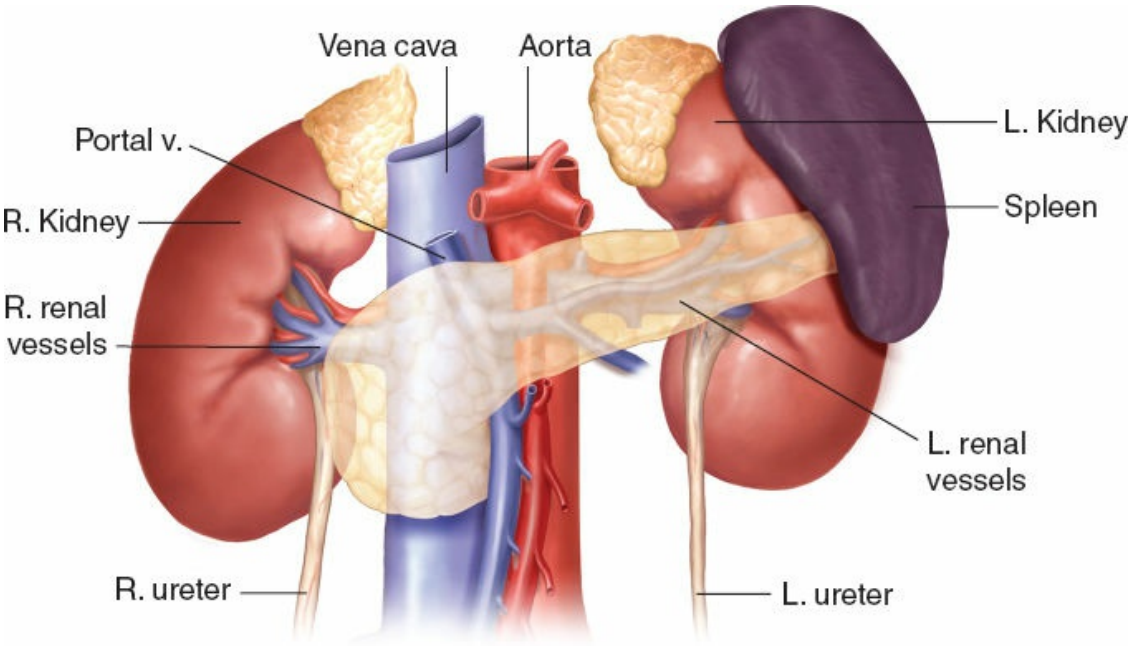

Figure 121.2. Posterior relationships.

The development of the omental bursa coincides with repositioning of the viscera of the upper abdomen (see Embryology section in chapter “Anatomic considerations of gastroduodenal surgery”). The mesentery of the duodenum (mesoduodenum) bends to the right, resulting in positioning the pancreas in contact with the posterior abdominal wall (Fig. 121.5A,B). Thus, the head of the pancreas and the second portion of the duodenum

become retroperitoneal organs. The peritoneum of the right side of the pancreas fuses with the parietal peritoneum of the posterior abdominal wall. The body and tail of the pancreas similarly become retroperitoneal when the peritoneum of the left side of the pancreas fuses with the posterior peritoneum (Fig. 121.5C,D). Thus the pancreaticorenal ligament disappears and the peritoneum around the spleen connects directly to the posterior wall with the splenorenal ligament. These changes create an avascular plane behind the pancreas called the fascia of Treitz, given by the fusion of the two leaves of peritoneum. It is this plane that permits surgical mobilization of the gland at the time of surgical exploration.

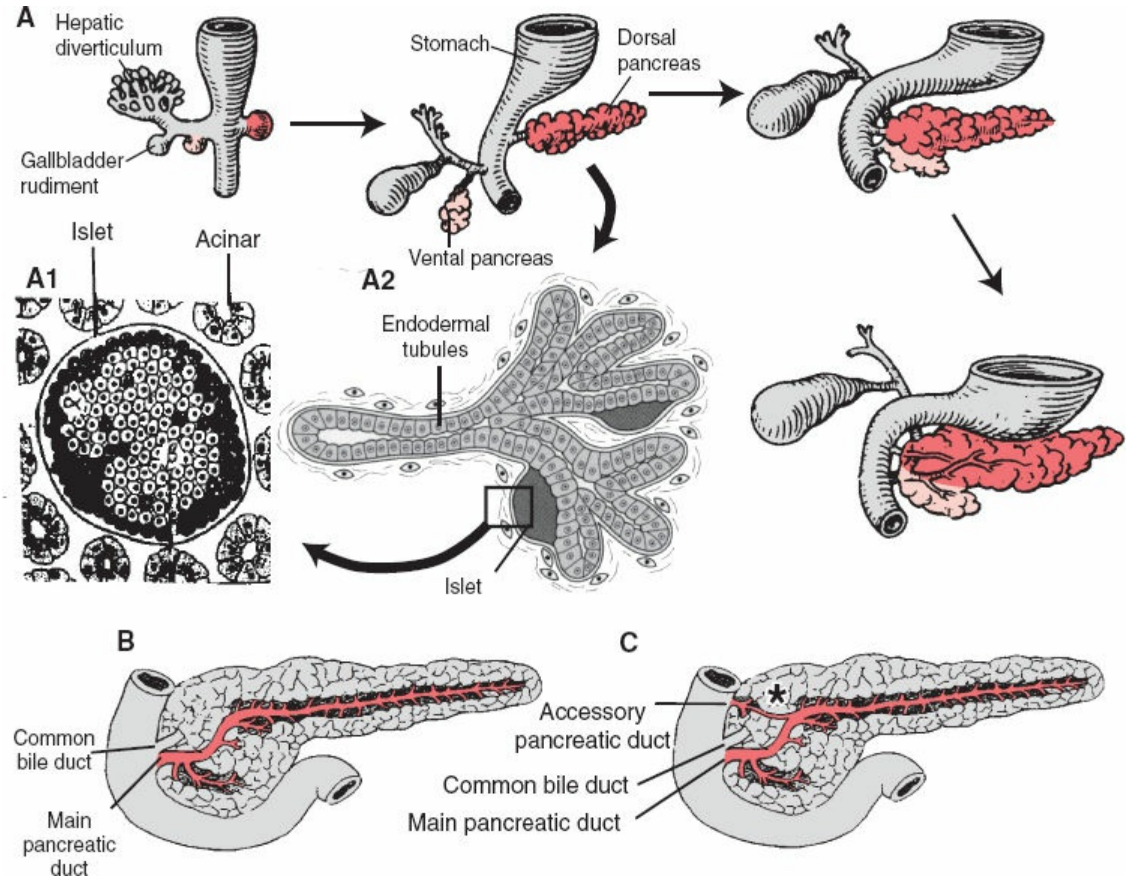

Figure 121.3. (**A**) Sequence of events in the development of the pancreatic buds from Week 4 through Week 7. Note that within the pancreatic buds endodermal tubules branch repeatedly to form the exocrine (acinar) pancreas (see **A2**). Subsequently, endodermal cells bud from the endodermal tubules to form the endocrine (islet) pancreas (see **A1**). (**B**) Normal pattern of the main pancreatic duct (48% incidence in the population). (**C**) Accessory Pancreatic Duct (33% Incidence in the Population). Note that the proximal one third of the dorsal pancreatic duct persists (*). (From Dudek RW. High-Yield Systems:

Gastrointestinal Tract. Philadelphia: Lippincott Williams & Wilkins, 2010.)

CONGENITAL ANOMALIES

Agenesia–Aplasia–Hypoplasia

Aplasia means failure of development, while agenesia is failure to form. With respect to pancreatic primordial, both conditions result in growth retardation and early death. Hypoplasia means incomplete development and is often compatible with life. There are case reports of absence of portions of dorsal pancreatic origin, including the distal body and tail. The uncinate process is absent in 10% of pancreatic head specimens.

Hyperplasia–Hypertrophia

Hyperplasia is the increase in cell number, and hypertrophia is the growth in volume and size of existing cells. Beckwith–Wiedemann syndrome (neonates with increased body weight, macroglossia, and omphalocele) may manifest with islet cell hypertrophy and hyperplasia with resultant hyperinsulinemia, and severe hypoglycemia. For the most part, treatment is conservative; however, partial pancreatectomy may be necessary in cases refractory to medical therapy.

Pancreas Divisum (Isolated Ventral Pancreas)

This malformation represents failure of the ventral and dorsal pancreas to fuse, resulting in the main and the accessory pancreatic ducts draining separately in the duodenum.

Pancreas divisum is encountered in 10% of specimens. It is also an incidental finding in 3% of patients undergoing endoscopic retrograde cholangiopancreatography (ERCP). In the subset of patients with pancreatitis, the incidence increases to 12%, suggesting that pancreas divisum predisposes to development of pancreatitis. Pancreatitis may occur due to stenosis or infraction of one or both pancreatic ducts. Others suggest that there is no association between pancreas divisum and pancreatitis. Insufficiency of the minor papilla may also play a role in development of pancreatitis.

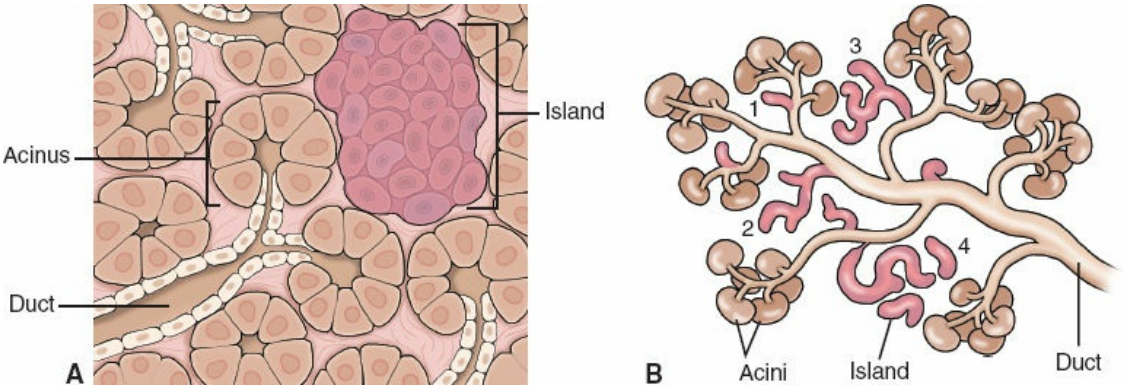

Figure 121.4. Differentiation of the human pancreas. **A.** Section, at 14 weeks, demonstrating the origin of acini and islands from ducts. (From Lewis FP. The development of the liver. In: Keibel F, Mall FP, eds. *Human Embryology.* Philadelphia: JB Lippincott; 1912.) **B.** Four progressive stages (1 to 4) in the organization of islands. (Published in Arey LB. *Developmental Anatomy: A Textbook and Laboratory Manual of Embryology.* 7th ed. Philadelphia, PA: WB Saunders; 1965. Copyright © 1965 Elsevier.)

Annular Pancreas

This malformation is characterized by a ring-like, thin, flat band of pancreatic tissue surrounding the second part of the duodenum at the origin of the ventral pancreas. The annulus is usually complete (Fig. 121.6) and may constrict the duodenum, resulting in poor gastric emptying, abdominal pain, and weight loss. The pattern of the pancreatic duct may also be affected, as there is usually a wide duct from the ring that meets the main pancreatic duct.

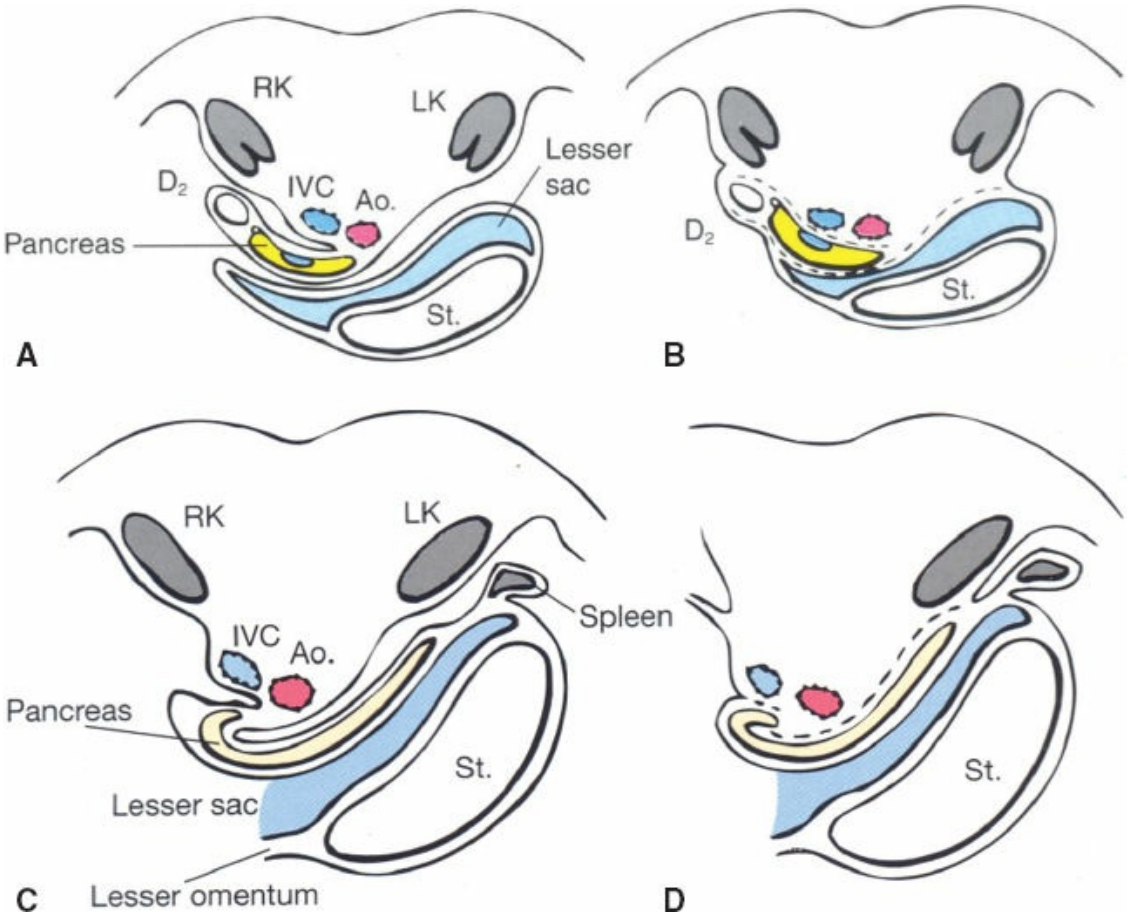

Figure 121.5. Schemas to show the fixation of duodenum and pancreas to the posterior abdominal wall. Transverse sections from the head of the pancreas and descending part of the duodenum (**A** and **B**) and from the body and tail of the pancreas (**C** and **D**). **A.** Duodenum and pancreas in the mesentery of the duodenum (mesoduodenum). **B.** The mesogastrium bends further and touches the peritoneum of the posterior abdominal wall. The two leaves of peritoneum fuse and form an avascular plane behind the duodenum and pancreas. The portal vein is embedded in the head of the pancreas. **C**. The mesentery continues from the stomach to the spleen (gastrospenic ligament) and, after enveloping the spleen, to the pancreas (splenopancreatic ligament); the body and tail of the pancreas are still contained in the mesentery which meets the posterior wall as the pancreaticorenal ligament. **D**. The body and tail of the pancreas fuse with the posterior wall, creating an avascular plane (*dashed line*). D2, second part of the duodenum; RK, right kidney; LK, left kidney; IVC, inferior vena cava; Ao, aorta; St, stomach. (Republished with permission of John Wiley & Sons, Inc. from O'Rahilly RO, Müller F. *Human Embryology and Teratology*. 3rd ed. New York: Wiley-Liss; 2001:252, permission conveyed through Copyright Clearance Center, Inc.)

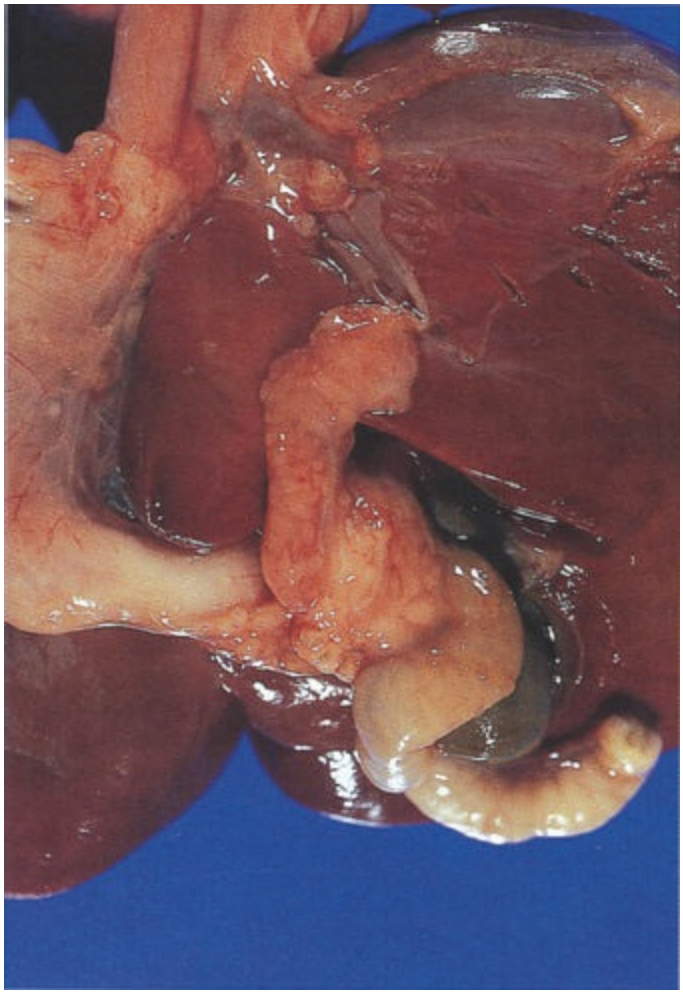

Figure 121.6. Annular pancreas. The annular pancreas wraps around the first portion of the duodenum. Note the lobulated appearance of the pancreatic tissue. (From Noffsinger AE, Fenoglio-Preiser's Gastrointestinal Pathology, 4th edition (2017); Wolters Kluwer.)

Several unconvincing theories have been proposed for the embryogenesis of the annular pancreas (Fig. 121.7). According to the most usually cited, an extension of the ventral pancreas may hook around the right side of the duodenum and fuse with the dorsal pancreas.

The anomaly is congenital; the affected neonates present with bilious vomiting. The radiographic finding of a "double-bubble" (air in the stomach and upper duodenum) with no air caudally signifies complete obstruction of the duodenum. The condition can also be encountered in adults, as 50% of patients present with symptoms in adulthood. Duodenoduodenostomy or duodenojejunostomy is the proper surgical correction. Division of the annular ring will likely result in injury to the pancreatic duct and should not be performed.

Ectopic, Heterotopic, and Accessory Pancreas

Ectopia and heterotopia of the pancreas signify development of pancreatic tissue in abnormal position. The term *accessory pancreas* is used when the original pancreas is in its normal place and there is additional pancreatic tissue in other positions. Accessory pancreatic tissue may be found in the neighboring organs such as the stomach and duodenal wall. Less frequently, the umbilicus, ileum, the colon, the gallbladder, or the omentum is affected. A Meckel diverticulum is an antimesenteric true diverticulum located 2 feet from the ileocecal valve. It is found in 2% of the population and can harbor two types of heterotopic tissue—pancreatic and gastric mucosa.

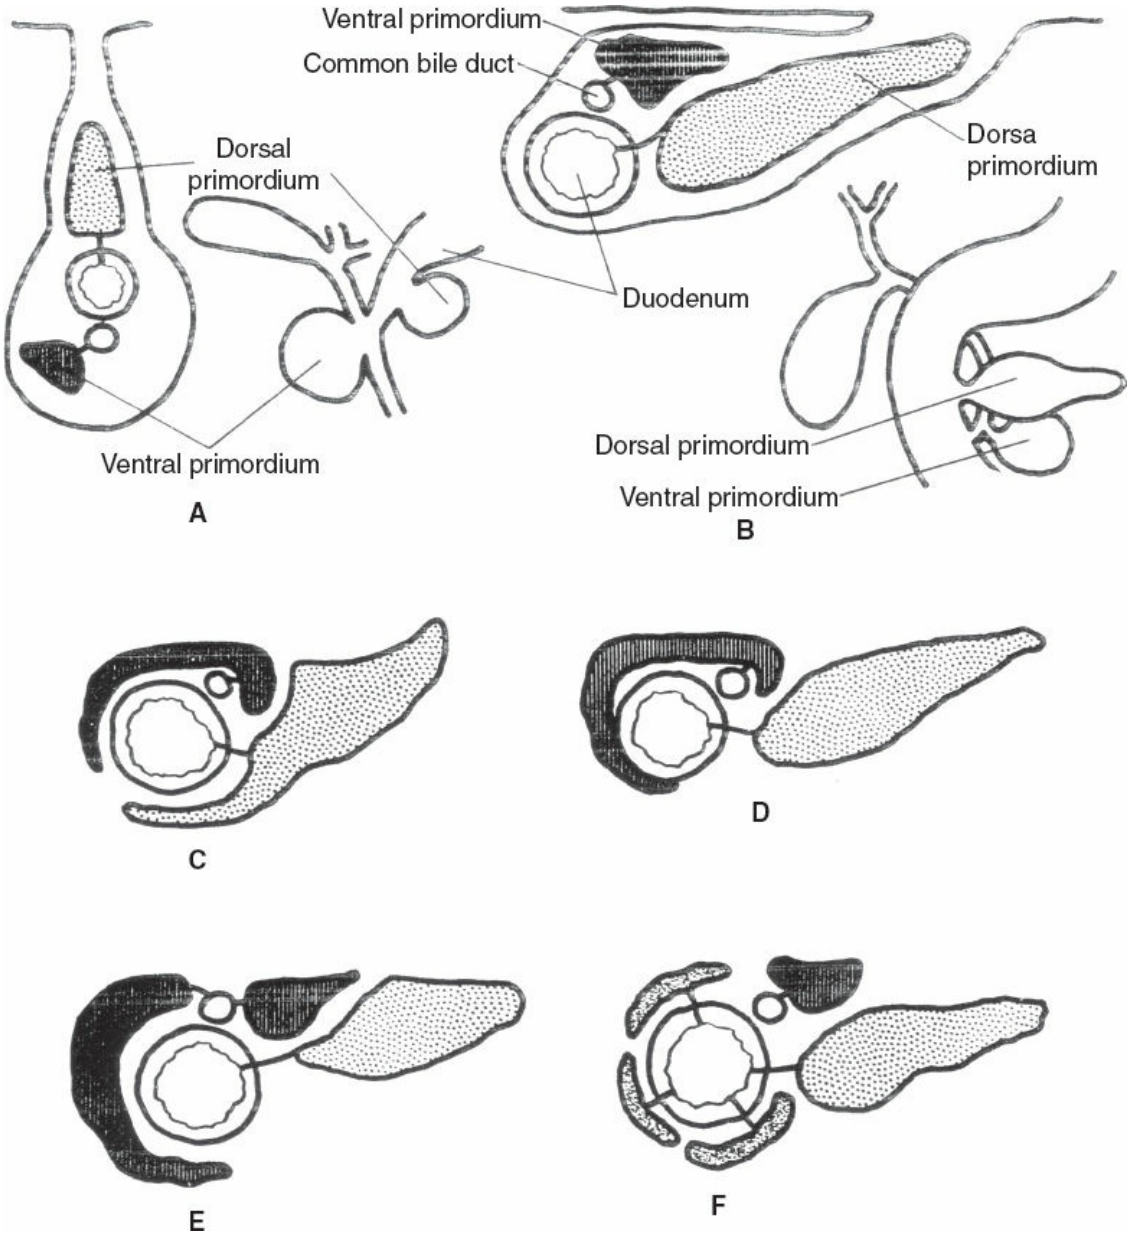

Figure 121.7. Several theories of the embryogenesis of annular pancreas. **A.** Normal relationship of dorsal and ventral pancreatic primordia at 6 weeks. **B.** At 7 weeks, just before the fusion of the primordia. The ventral primordium was migrated to the left, posterior to the duodenum. **C.** Hypothetical hypertrophy of both lobes, eventually coalescing to form the annulus. **D.** Hypothetical adhesion of the distal tip of the ventral primordium to the duodenal wall prior to its migration. **E.** Persistence of a hypothetical left ventral lobe, based on an assumption that the ventral lobe was originally a paired structure. **F.** Formation of the annulus by fusion of aberrant pancreatic tissue from the duodenum. (From Skandalakis JE, Gray SW, Ricketts RR, et al. The pancreas. In Skandalakis JE, Gray SW. *Embryology for Surgeons*. 2nd ed. Baltimore, MD: Williams & Wilkins; 1994.)

In most cases, the accessory pancreatic tissue is functional. Several theories regarding development of accessory pancreas have been described, including metaplasia of pluripotent endodermal cells into pancreatic cells and transplantation of pancreatic cells into the duodenum.

Neuroendocrine Tumors of the Pancreas

It is unclear if these tumors are congenital; however, a discussion regarding their localization facilitates understanding of pancreatic endocrine development. These tumors develop two distinct regions of the pancreas, which, topographically correspond to portions of the ventral and the dorsal anlagen.

Topographically, the area originating from the ventral pancreatic diverticulum is known as the gastrinoma triangle (Fig. 121.8), which is bounded by the cystic duct, the border of the second and third part of the duodenum, and the junction of the neck and body of the pancreas. In this triangle, 80% of gastrinomas, PPomas, and somatostatinomas are encountered, while insulinomas and glucagonomas, which develop from the islets concentrated in the dorsal bud, are more common (80%) in the neck, body, and tail.

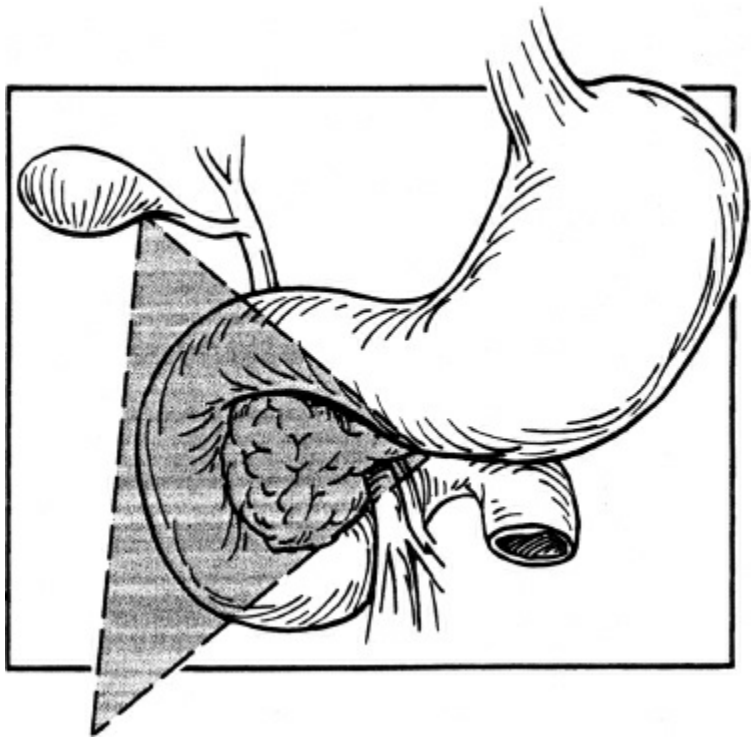

Figure 121.8. Gastrinoma triangle (Pessaro triangle). (From Bell RH Jr. Atlas of pancreatic surgery. In: Bell RH Jr, Rikkers LF, Mulholland MW, eds. *Digestive Tract Surgery: A Text and Atlas*. Philadelphia, PA: Lippincott-Raven; 1996:963.)

Localization of gastrinomas in peripancreatic sites, in the duodenum, and at the head of the pancreas is compatible with an origin from the ventral pancreas. It has been suggested that stem cells dispersed during the turn of the pancreatic diverticulum, and were entrapped by lympoid tissue or duodenal wall. This idea explains the increased localization of gastrinomas in sites outside the pancreas (40%) and in the lymph nodes (40%). These gastrinomas are distinct, as they are more often associated with development of hepatic metastases and poorer prognosis.

PERITONEAL RELATIONS OF THE PANCREAS

The pancreas lies in the retroperitoneal space, with its axis horizontal, from the descending part of the duodenum to the right until the spleen to the left. The tail of the pancreas is covered by peritoneum anteriorly and posteriorly as it projects into the splenorenal ligament. All the rest parts of the pancreas are retroperitoneal.

The transverse mesocolon attaches to a horizontal zone, from the right kidney, on to the descending duodenum and pancreas up to the left kidney, where it joins the base of the phrenocolic and splenorenal ligament (Fig.

121.9). The upper leaf of the mesocolon continues with the posterior leaf of the lesser omentum. Cranially to the zone of attachment of the mesocolon, the pancreas is covered by the peritoneum that forms the posterior wall of the omental bursa. The lower leaf of the mesocolon covers the lower anterior surface of the neck and body of the pancreas. From there, on the right, the peritoneum passes over the third and fourth part of the duodenum and continues as right leaf of the mesentery proper. On the left, the peritoneum continues immediately as parietal peritoneum of the greater sac.

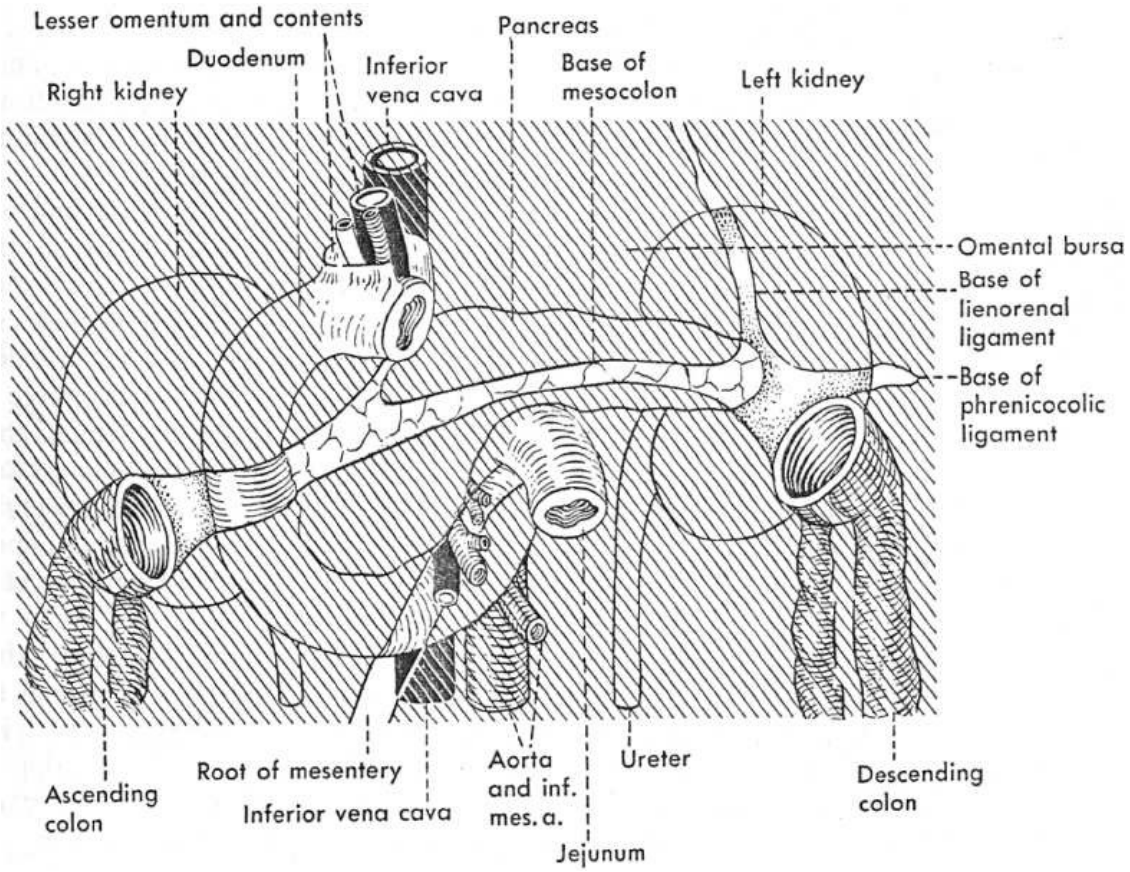

Figure 121.9. Peritoneal attachments onto the duodenum and pancreas. The oblique shading represents the parietal peritoneum. (From Hollinshead WH. *Anatomy for Surgeons, Vol. 2: The Thorax, Abdomen, and Pelvis*. New York: Hoeber-Harper; 1956:413, Fig. 299.)

PARTS OF THE PANCREAS

Anatomical Parts

Head

The head of the pancreas is flat and has an anterior and a posterior surface

(Fig. 121.10). The anterior surface is adjacent to the pylorus and the transverse colon. The anterior pancreaticoduodenal arcade can be seen on the ventral surface of the head of the pancreas, coursing roughly parallel to the duodenal curvature.

The posterior pancreaticoduodenal vascular arcade runs along the posterior surface of the head. This surface of the pancreatic head is close to the hilum and medial border of the right kidney, the right renal vessels and the inferior vena cava, the right crus of the diaphragm, and the right gonadal vein.

The head of the pancreas may be related to the third part of the common bile duct (CBD) in a variety of ways (Fig. 121.11).

Uncinate Process

An extension of the head of the pancreas (which is variable in size and shape) passes downward and slightly to the left from the principal part of the head. It further continues behind the superior mesenteric vessels and in front of the aorta and inferior vena cava. In sagittal section, the uncinate process lies between the aorta and the superior mesenteric artery (SMA), with the left renal vein above and the duodenum below (Fig. 121.12). If the junction of the superior mesenteric and portal vein is low, the anterior surface of the uncinate process is related to the superior mesenteric vessels and the portal vein.

The uncinate process may be absent, or it may completely encircle the superior mesenteric vessels (Fig. 121.13). If the process is well developed, the neck of the pancreas must be sectioned from the front to avoid injury to the vessels. Short vessels from the SMA and vein supply the uncinate process and must be carefully ligated and divided during a pancreatic head resection. An anomalous right hepatic artery (accessory or replaced) may pass through the uncinate process.

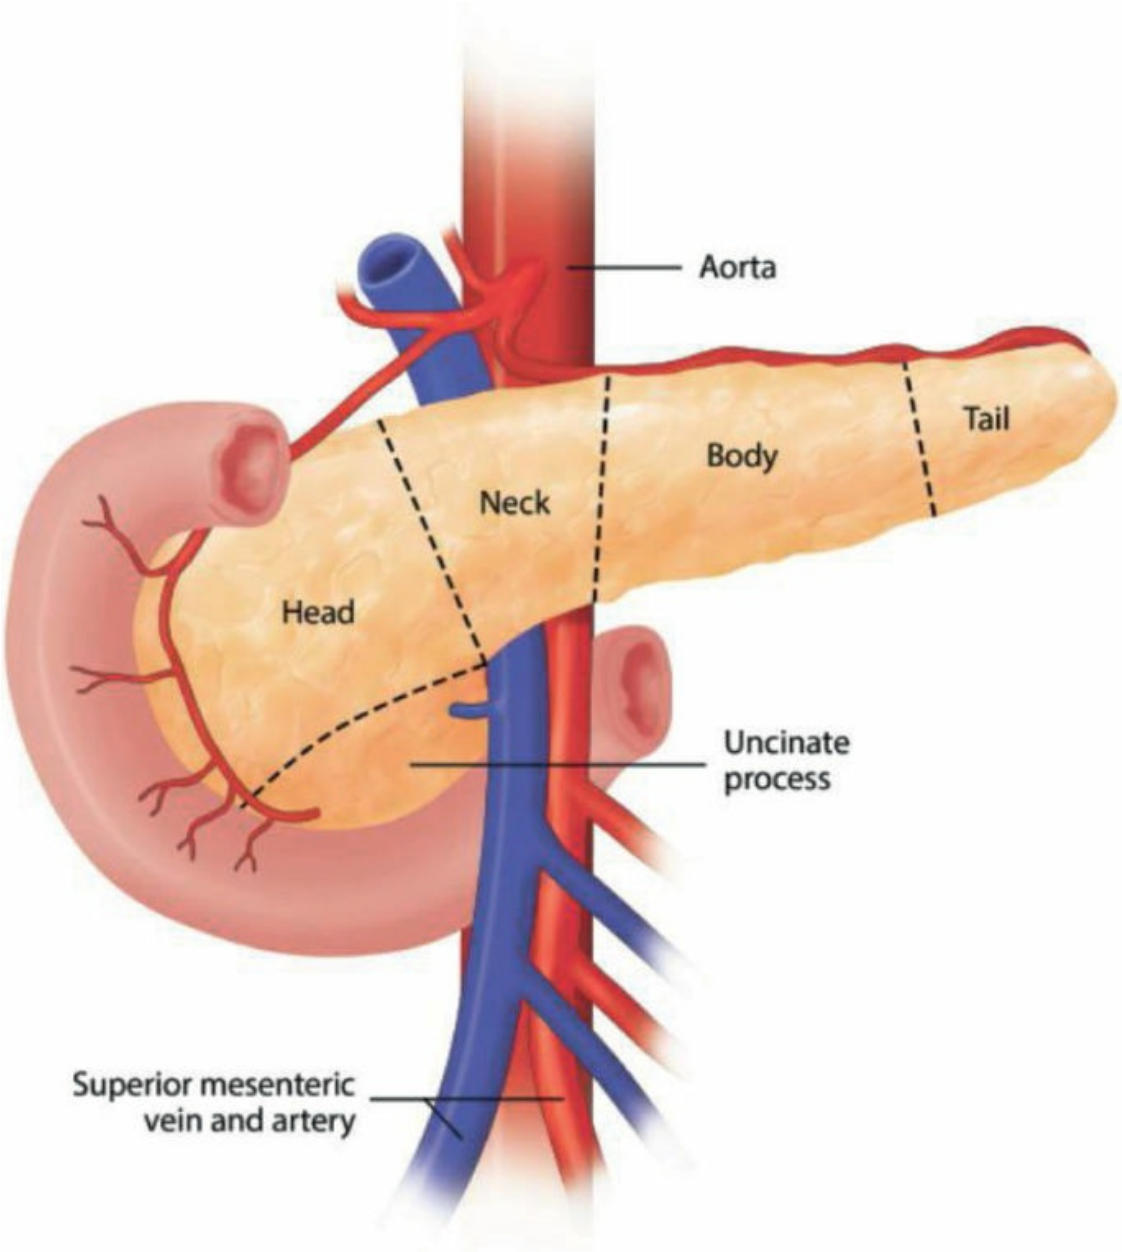

Figure 121.10. The five parts of the pancreas. The line dividing the body and tail is entirely arbitrary. (Modified from Skandalakis JE, Gray SW, Rowe JS Jr. *Anatomical Complications in General Surgery*. New York: McGraw-Hill; 1983.)

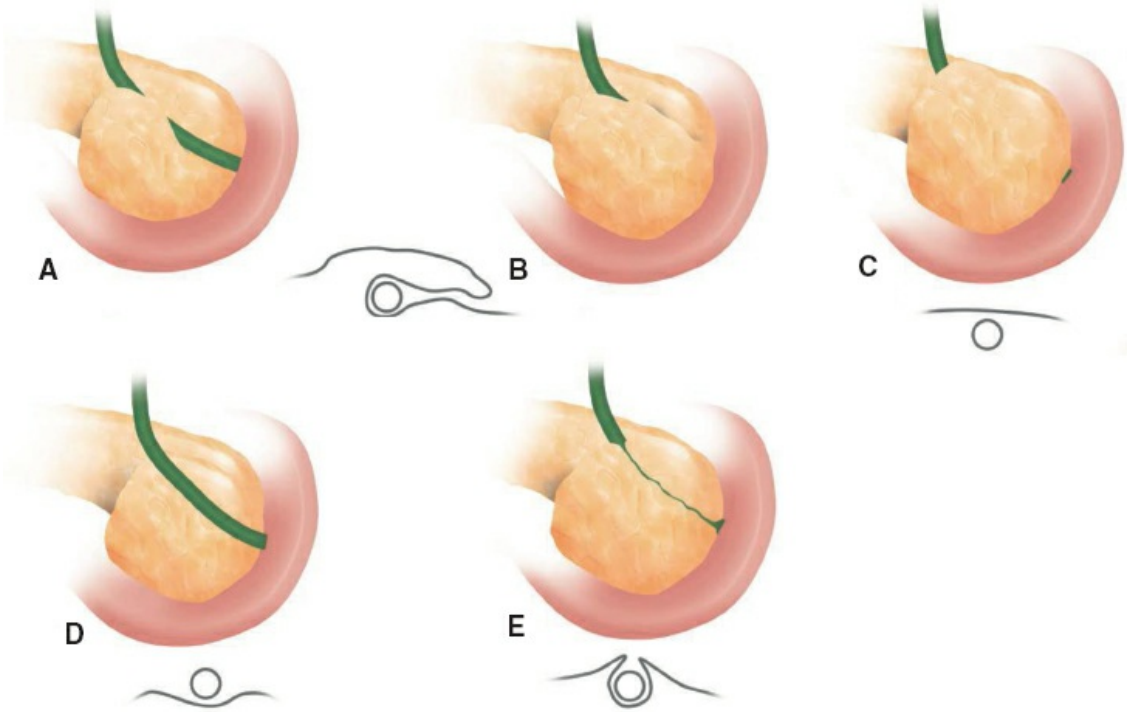

Figure 121.11. The relation of the common bile duct to the posterior surface of the pancreas. **A, B.** The most common arrangement (44%); the duct is partially or wholly covered by a tongue of pancreas. **C.** The duct lies within the pancreas (30%). **D.** The duct lies free in the surface of the pancreas (16.5%). **E.** The duct is covered by two small folds of pancreas (9%). (Modified from Skandalakis JE, Gray SW. *Embryology for Surgeons*. 2nd ed. Baltimore, MD: Williams & Wilkins; 1994.)

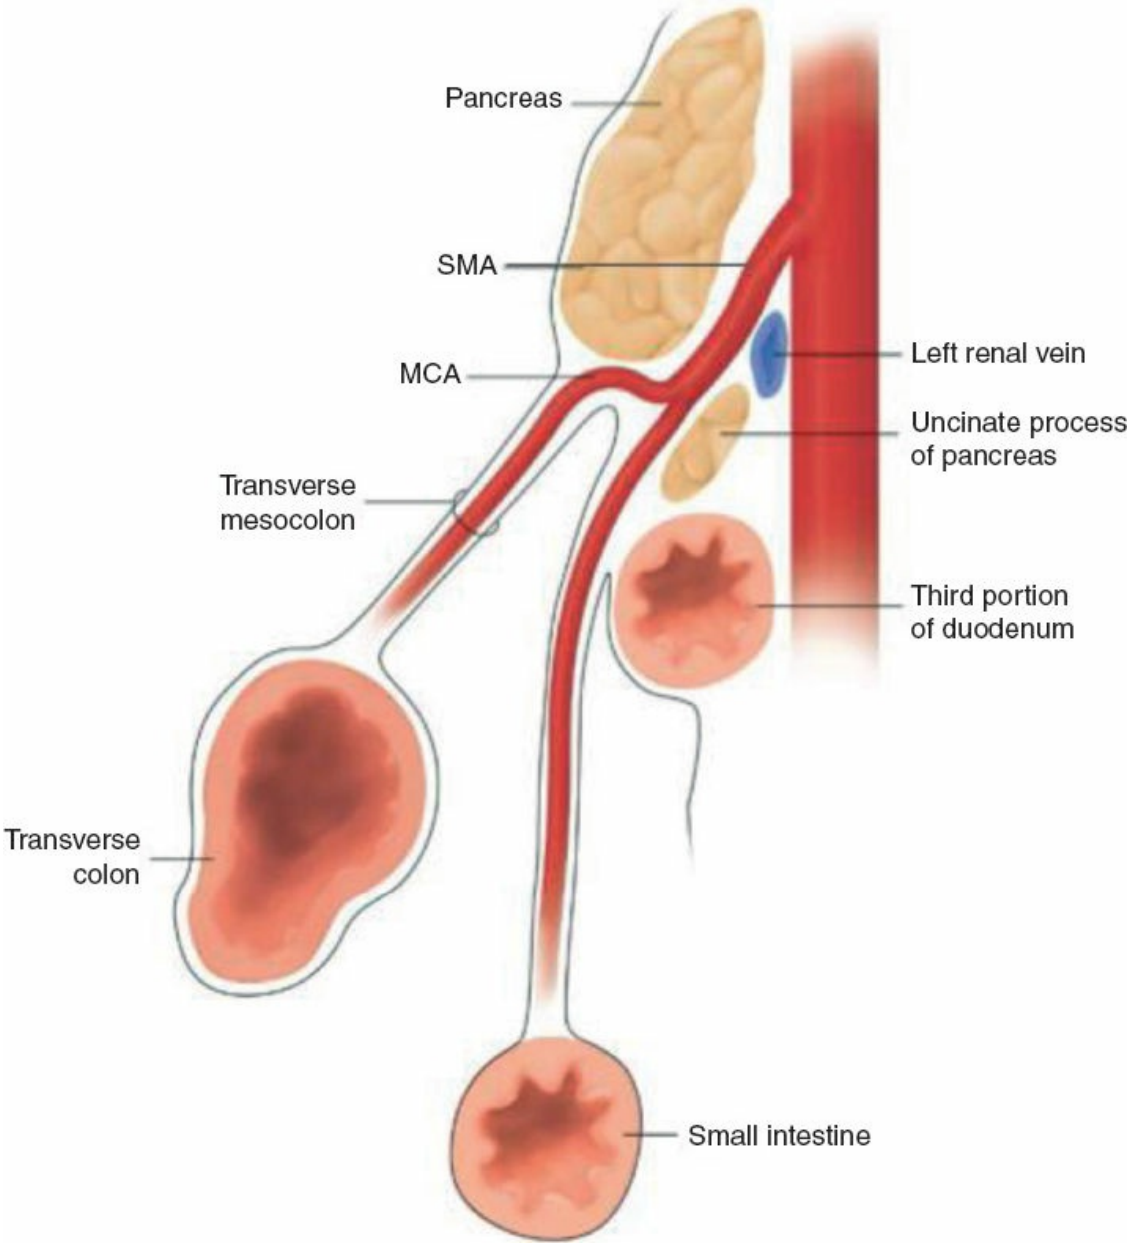

Figure 121.12. Highly diagrammatic sagittal section through the neck of the pancreas. The uncinate process and the third portion of the duodenum lie posterior to the superior mesenteric artery (SMA) and anterior to the aorta. The middle colic artery (MCA) leaves the SMA to travel in the transverse mesocolon. (Published in Akin JT, Gray SW, Skandalakis JE. Vascular compression of the duodenum: presentation of ten cases and review of the literature. *Surgery* 1976;79:515. Copyright © 1976 Elsevier.)

Neck

The neck of the pancreas is defined by the location of the superior mesenteric vessels running behind the gland, and by the beginning of the portal vein dorsal to the pancreas. This pancreatic segment is 1.5 to 2.0 cm long, and it is partially covered anteriorly by the pylorus.

The vascular relations of the neck of the pancreas are extremely important, because if these vessels are involved in pancreatic cancer, pancreatectomy is impossible. The gastroduodenal artery passes to the right of the neck and provides origin for the anterior superior pancreaticoduodenal artery (see Fig. 121.23). Posterior to the neck, the portal vein is formed by the confluence of the superior mesenteric and splenic veins. Near the inferior margin of the pancreatic neck, one can often see the terminations of the inferior pancreaticoduodenal vein and right gastroepiploic vein where they drain into the superior mesenteric or splenic veins or into the portal vein proper. The inferior mesenteric vein drains, with essentially equal frequency, into the splenic vein, the superior mesenteric vein (SMV), or the portal vein (see Figs. 121.30 and 121.31). Elevation of the neck and ligation of any anterior tributaries of the portal vein, if present, are necessary for many pancreatic resections. If hemorrhage occurs, evaluation of the entities found behind the neck is extremely difficult.

Body

The anterior surface of the body of the pancreas is covered by the posterior layer of peritoneum of the omental bursa that separates the stomach from the pancreas. The omental tuberosity (tuber omentale), a blunt upward projection of peritoneum from the body, contacts the lesser curvature of the stomach at the attachment of the lesser omentum. The body is also related to the transverse mesocolon, which divides into two leaves: the superior leaf covers the anterior surface and the inferior leaf passes inferior to the pancreas. The middle colic artery emerges from beneath the pancreas to travel between the leaves of the mesocolon.

Posteriorly, the body is related to the aorta and the origin of the SMA—

and to that portion of the celiac plexus related to these—to the left crus of the diaphragm, the left kidney and its vessels, the left adrenal gland, and the splenic vein. Small vessels from the pancreas enter this vein. They must be ligated during pancreatectomy if the splenic vein and the spleen are to be preserved.

Tail

The tail of the pancreas is relatively mobile; its tip reaches the hilum of the spleen. The relation of the tail to the splenic hilum is variable (Fig. 121.14). Together with the splenic artery and the origin of the splenic vein, the tail is contained between two layers of the splenorenal ligament. The outer layer of this ligament is the posterior layer of the gastrosplenic ligament and runs behind the short gastric vessels. Commonly, a caudate branch arises from the left gastroepiploic or an inferior splenic polar branch and passes to the tip of the tail of the pancreas. The vascular anatomy in this location is quite variable and care should be taken during dissection to avoid inadvertent vascular injury, especially during a laparoscopic approach.

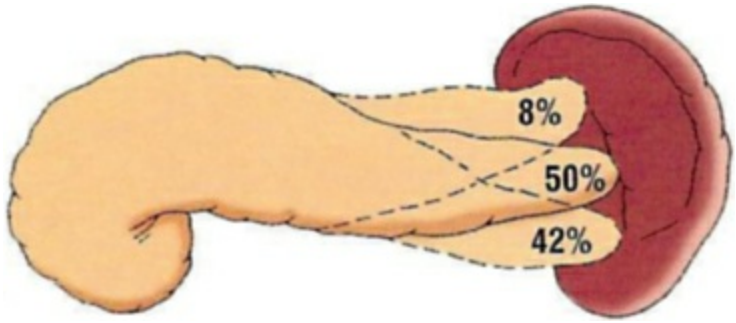

Figure 121.14. Relations of the tail of the pancreas to the splenic portas. (From Skandalakis JE, Skandalakis LJ, Kingsnorth AN, et al. Pancreas. In: Skandalakis JE, Colborn GL, Weidman TA, et al., eds. *Skandalakis' Surgical Anatomy: The Emryologic and Anatomic Basis of Modern Surgery*. Vol. 2. Athens, Greece: Paschalidis Medical Publications; 2004.)

Surgicoanatomical Segments

Similar to the segmentation that can be found in the liver, kidney, spleen, and other organs, anatomicosurgical segments have been described for the pancreas. Two segments were designated, the right (cephalocervical) segment and the left (corporocaudate) segment (Fig. 121.15). The segments of the pancreas are separated by a poorly vascularized area. They

are connected by the pancreatic duct and often by a small artery, the inferior pancreatic artery (see below) (Fig. 121.16). Both segments can be used for transplantation.

PANCREATIC DUCTS

Anatomy and Variations

The pancreatic ducts lie anterior to the major pancreatic vessels. The main pancreatic duct arises in the tail of the pancreas. Through the tail and body of the pancreas, the duct lies midway between the superior and inferior margins, slightly more posterior. It crosses the vertebral column between the 12th thoracic and 2nd lumbar vertebrae.

Fifteen to 20 short tributaries enter the duct at right angles in the region of the body and tail; superior and inferior tributaries tend to alternate. The main duct may receive a tributary draining the uncinate process, and, in some individuals, the accessory pancreatic duct empties into the main duct. Small tributary ducts in the head may open directly into the intrapancreatic portion of the CBD.

The main duct turns caudad and posterior upon reaching the head or neck of the pancreas. At the level of the major papilla, the duct turns horizontally to join the caudal surface of the CBD and enters the wall of the duodenum, usually at the level of the second lumbar vertebra.

The accessory pancreatic duct (of Santorini) may drain the anterosuperior portion of the head, either into the duodenum at the minor papilla or into the main pancreatic duct. Because of the developmental origin of the two pancreatic ducts, several variations are encountered. The usual configuration is seen in Figure 121.17A. The accessory duct (Santorini) is smaller than the main pancreatic duct (of Wirsung) and opens into the duodenum on the minor papilla. Configurations in Figure 121.17B–E show examples of progressive reduction in size of the accessory duct.

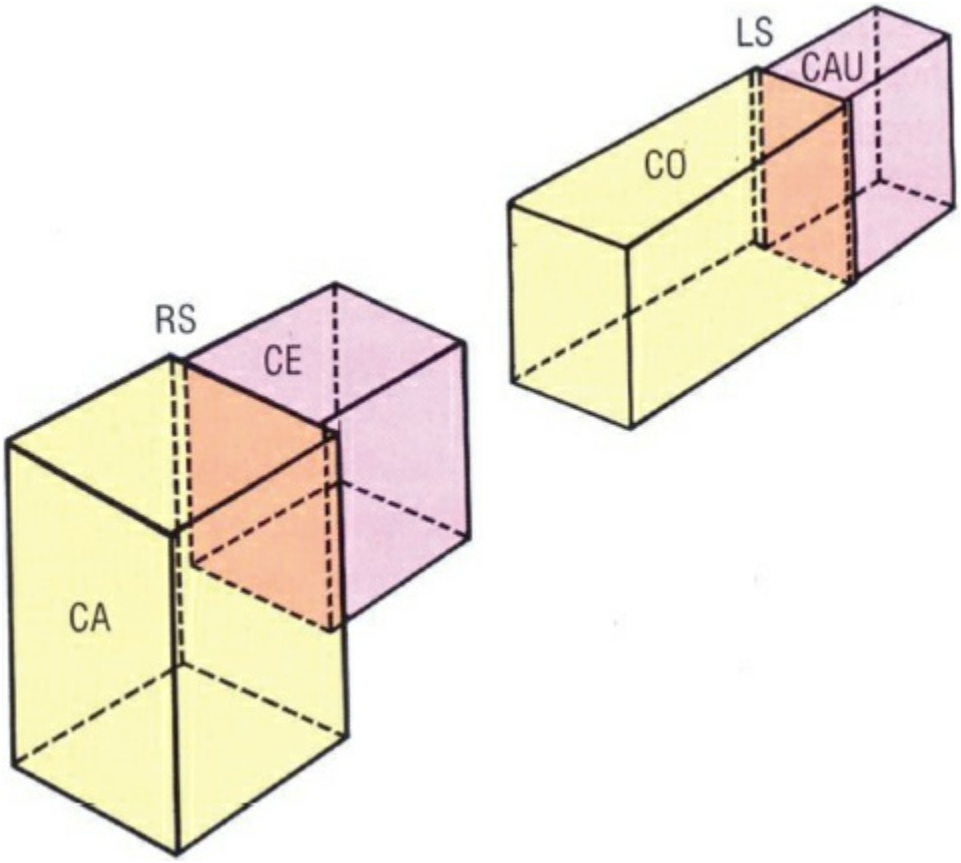

Figure 121.15. Diagrams of the surgicoanatomical segments of the pancreas. RS, right (cephalocervical) segment; LS, left (corpocaudate) segment. The right and left pancreatic segments are artificially separated at the pauci-arterial area. CA, caput (head); CE, cervix (neck); CO, corpus (body); CAU, cauda (tail). (From Skandalakis JE, Skandalakis LJ, Kingsnorth AN, et al. Pancreas. In: Skandalakis JE, Colborn GL, Weidman TA, et al., eds. *Skandalakis' Surgical Anatomy: The Emryologic and Anatomic Basis of Modern Surgery*. Vol. 2. Athens, Greece: Paschalidis Medical Publications; 2004.)

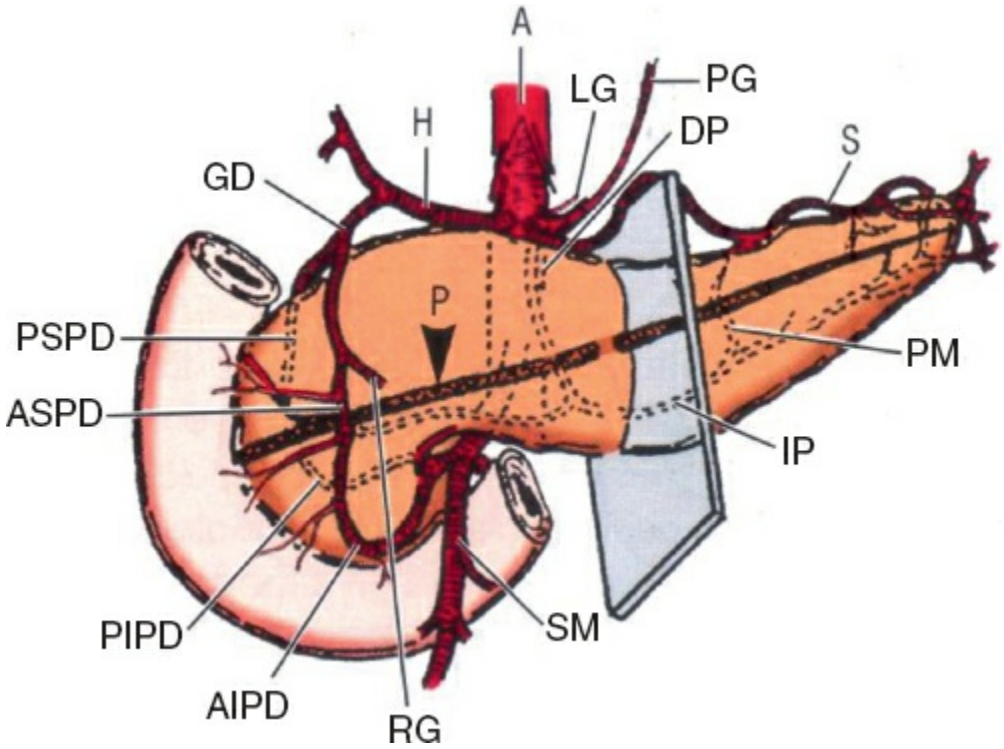

Figure 121.16. Surgicoanatomic segments of the pancreas. The intersegmental plane has been drawn on the left of the superior mesenteric artery. The right and left segments are united intraparenchymally only by the inferior pancreatic artery. A, aorta; LG, left gastric artery; PG, posterior gastric artery; DP, dorsal pancreatic artery; S, splenic artery; PM, pancreatic magna artery; IP, inferior pancreatic artery; SM, superior mesenteric artery; RG, right gastroepiploic artery; AIPD, anterior inferior pancreaticoduodenal artery; PIPD, posterior inferior pancreaticoduodenal artery; ASPD, anterior superior pancreaticoduodenal artery; PSPD, posterior superior pancreaticoduodenal artery; GD, gastroduodenal artery; H, hepatic artery; P (*arrow*), pancreatic duct. (From Skandalakis JE, Skandalakis LJ, Kingsnorth AN, et al. Pancreas. In: Skandalakis JE, Colborn GL, Weidman TA, et al., eds. *Skandalakis' Surgical Anatomy: The Emryologic and Anatomic Basis of Modern Surgery*. Vol. 2. Athens, Greece: Paschalidis Medical Publications; 2004.)

In approximately 10% of individuals, there is no connection between the accessory duct and the main duct (Fig. 121.17D). This fact is important to remember when contrast medium is injected into the main duct. There is no minor papilla in 30% of individuals (Fig. 121.17B–E). In some individuals who have a minor papilla, the terminal portion of the accessory duct is too small to permit the passage of any quantity of fluid. Three

papillae have been seen.

Length, Width, and Capacity of the Pancreatic Ducts

ERCP has made the determination of the length, diameter, and capacity of the pancreatic ductal system possible. The greatest diameter of the main pancreatic duct is in the head of the pancreas (2.6 to 4.8 mm), just before the duct enters the duodenal wall. From this diameter, the duct gradually tapers (2.0 to 3.5 mm) toward the tail (0.9 to 2.4 mm) (Fig. 121.18). Like the bile duct, the pancreatic duct is constricted in the wall of the duodenum. Reported length of the main pancreatic duct varies from 175 to 260 mm.

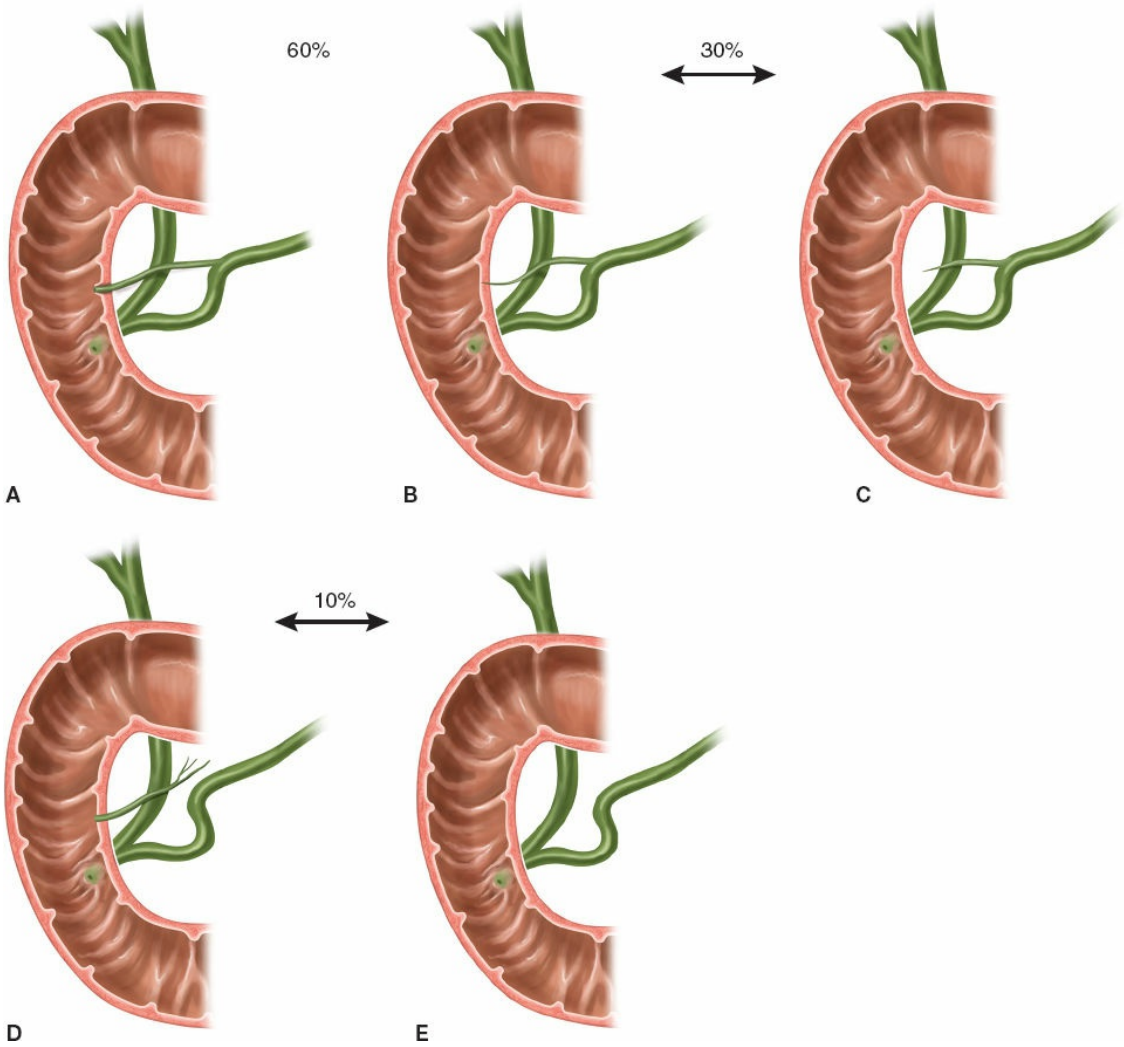

Figure 121.17. Variations of the pancreatic ducts. Degrees of suppression of the accessory duct. **A.** Both ducts open into the duodenum (60%). **B, C.** The accessory duct ends blindly (30%). **D.** The accessory duct does not communicate with the main duct (10%). **E.** The accessory duct is absent.

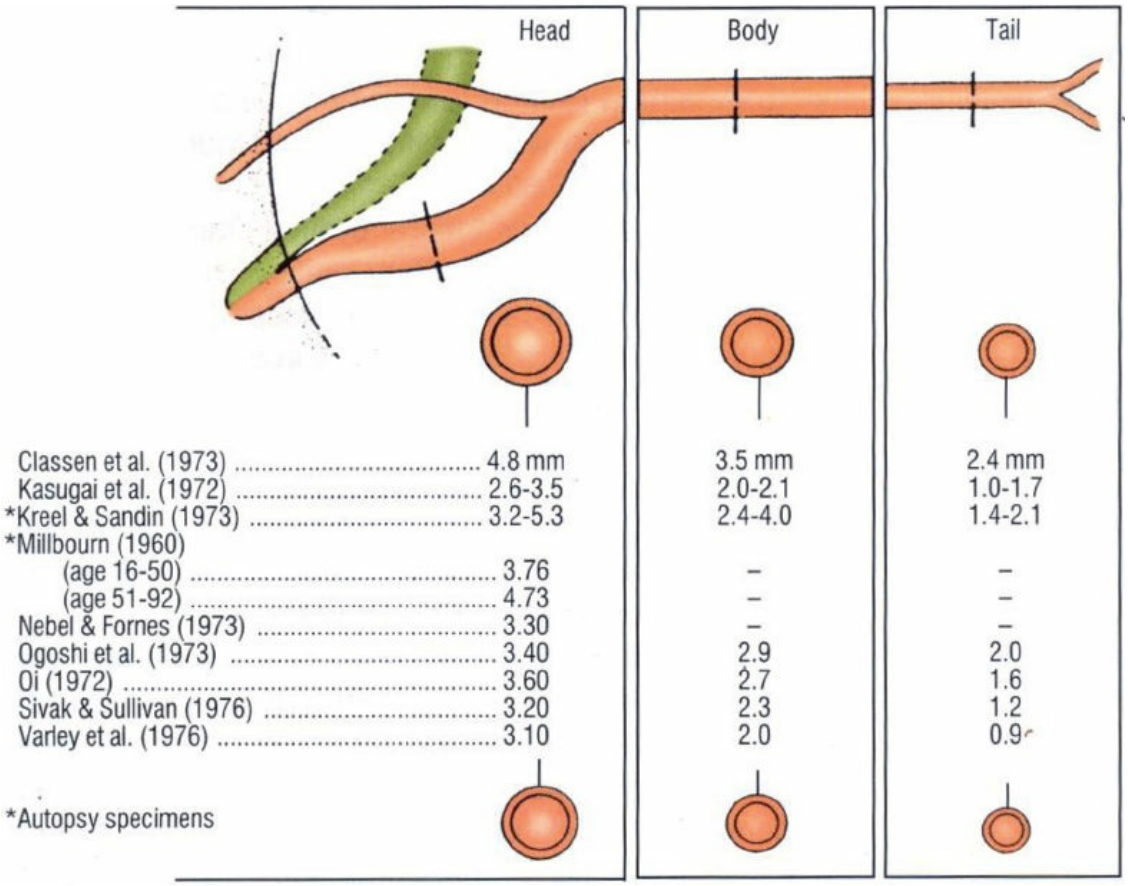

Figure 121.18. Diameter of the main pancreatic duct as reported by several authors. (From Skandalakis JE, Skandalakis LJ, Kingsnorth AN, et al. Pancreas. In: Skandalakis JE, Colborn GL, Weidman TA, et al., eds. *Skandalakis' Surgical Anatomy: The Emryologic and Anatomic Basis of Modern Surgery*. Vol. 2. Athens, Greece: Paschalidis Medical Publications; 2004.)

The normal pancreatic ductal system is quite small. Two to 3 mL of contrast medium fills the main pancreatic duct in the living patient; and 7 to 10 mL fills the branches and the smaller ducts. In autopsy specimens, 0.5 to 1.0 mL has been found to be sufficient to fill the duct system.

Major Duodenal Papilla and Hepatopancreatic Ampulla

There is confusion in the literature about the correct name, definition, and distinguishing points of the major duodenal papilla (often referred to as the papilla of Vater) and the hepatopancreatic or biliaropancreatic ampulla (often referred to as ampulla of Vater). The papilla is a nipplelike projection of duodenal mucosa, located where the main pancreatic duct and the CBD drain into the duodenum. The hepatopancreatic ampulla is the union of the lumen of the CBD with that of the pancreatic duct.

Major Duodenal Papilla

This papilla commonly bears the name of Abraham Vater (1684–1751), although there is controversy as to whether this eponym is historically accurate. As such, the most useful term is major (or greater) duodenal papilla.

The papilla is situated on the posteromedial wall of the second portion of the duodenum, 7 to 10 cm from the pylorus. Rarely, the papilla may be in the third portion of the duodenum, to the right of the superior mesenteric vessels.

Viewed from the mucosal surface of the duodenum, the papilla is found where a longitudinal mucosal fold meets a transverse mucosal fold to form a "T" (Fig. 121.19). The papilla may be difficult to distinguish as it may be covered by one of the transverse folds. On the other hand, too much traction may erase the folds. The papilla is "prominent" and easily identified in 60% of their specimens.

During duodenal exploration, if the papilla cannot be identified, compression of the gallbladder to induce effluence of bile or connotation of the cystic duct and passage of a probe to the papilla can help identify it. Uncommonly, a duodenal duplication cyst in the second portion may obscure the papilla.

Hepatopancreatic (Biliaropancreatic) Ampulla

Although the ampulla is named after Vater, there is much evidence that it was first described by Santorini. Vater actually described a diverticulum of duodenal mucosa, now referred to as perivaterian diverticulum.

The ampulla is a dilatation of the common pancreaticobiliary channel adjacent to the papilla and below the junction of the two ducts. The extent to which the CBD and the pancreatic duct are separated in the duodenal wall varies, and the ampulla is of variable length (Fig. 121.20). In cases where a septum is present at the duodenal orifice, the ampulla is considered absent (Fig. 121.20B). The CBD and the pancreatic duct may even open independently upon the papilla (Fig. 121.20C).

Figure 121.19. The “T” arrangement of the duodenal mucosal folds at the site of the major papilla. The papilla is rarely this obvious. This illustration by Santorini was published posthumously in 1775.

Michels collected data from 25 investigators representing 2,500 specimens and concluded that an ampulla was present in 64% of cases. Actual measurements of the distance between septal edge and papillary tip range from 1 to 14 mm, with 75% being 5 mm or less. The following classification, consisting of three types, was suggested by Michels and is the most useful.

Type 1. The pancreatic duct opens into the CBD at a variable distance from the opening in the major duodenal papilla (Fig. 121.20A,B).
Type 2. The pancreatic and bile ducts open close to one another, but separately, without an ampulla, on the major duodenal papilla (5%) (Fig. 121.20C).
Type 3. The pancreatic and bile ducts open into the duodenum at separate points without an ampulla (9%).

The basic embryologic explanation for the above three types is that growth of the duodenum absorbs the proximal bile duct up to its junction with the pancreatic duct. When absorption is minimal, there is a long

ampulla and the junction of the ducts is high in the duodenal wall (Fig. 121.20A) or even extramural. With increasing absorption of the terminal bile duct, the junction lies closer to the duodenal orifice until the ampulla does not exist (Fig. 121.20B). Maximal resorption results in separate orifices for the main pancreatic duct and the CBD (Fig. 121.20C).

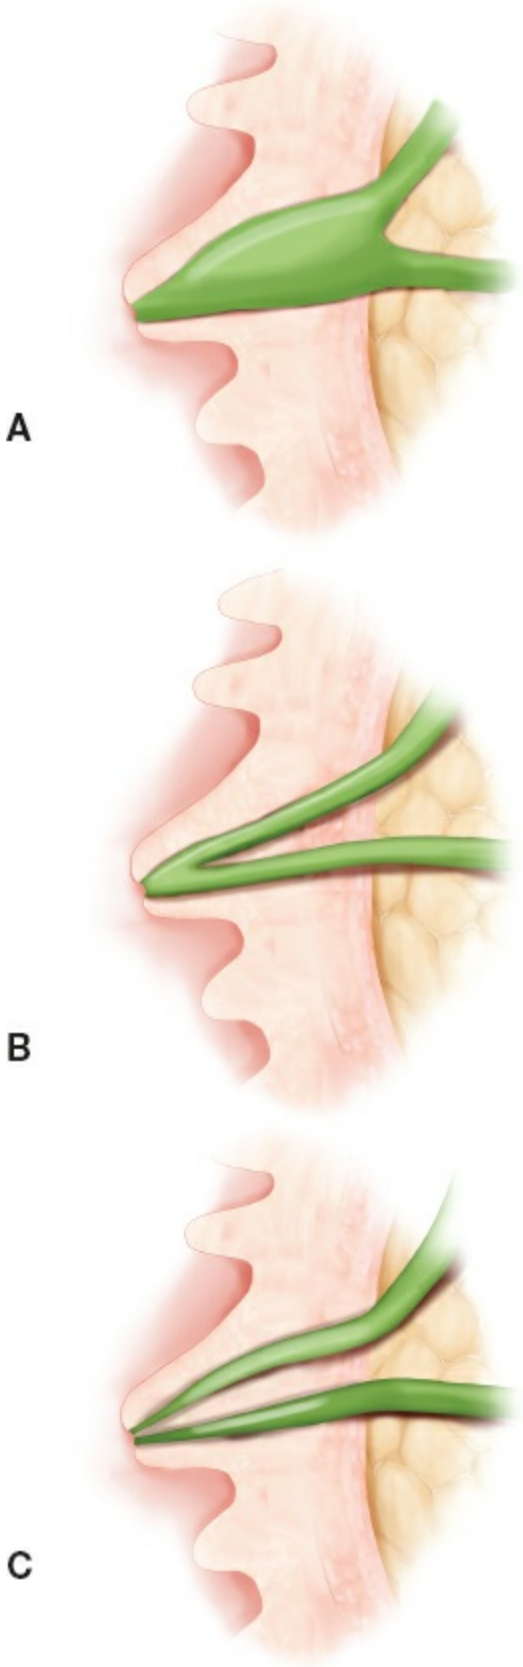

Figure 121.20. Variations of the common bile duct and the main pancreatic duct at the duodenal papilla. An ampulla is present in **A**; it is absent in **B** and **C.**

Smooth muscle ensheathes the ampulla forming the sphincter of the hepatopancreatic ampulla, which belongs to the broader sphincter complex of Boyden in the hepatopancreaticoduodenal area (see below).

The blood supply of the ampulla of Vater is not well defined, and may share common territory with the distal CBD and the pancreatic duct. The arterial plexus of the ampulla is mostly given by the posterior superior pancreaticoduodenal artery. The retroduodenal artery also provides small braches to the ampulla (Fig. 121.21**).** Dorsal and ventral branches are usually balanced, but dominance of either dorsal or ventral branch may happen.

During surgical or endoscopic sphincterotomy, or sphincteroplasty the incision should be at the 10 to 11 o'clock position and run 5 to 8 mm in length to minimize the risk of hemorrhage from a retroduodenal artery or anomalous right hepatic artery originating from the SMA, as these two vessels are located between the distal CBD and duodenum.

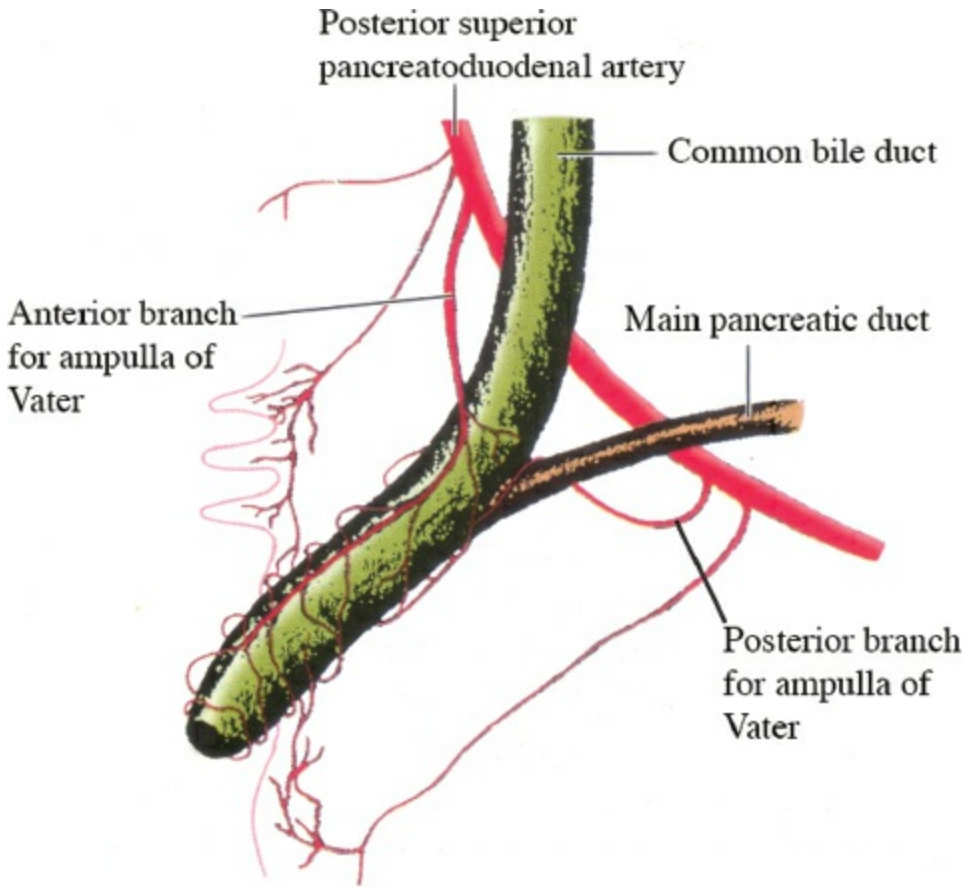

Figure 121.21. Blood supply of the hepatopancreatic (biliopancreatic) ampulla. The posterior superior pancreaticoduodenal artery crosses the common bile duct and gives rise to anterior and posterior branches. (Modified from

Skandalakis JE, Skandalakis LJ, Kingsnorth AN, et al. Pancreas. In: Skandalakis JE, Colborn GL, Weidman TA, et al., eds. *Skandalakis' Surgical Anatomy: The Emryologic and Anatomic Basis of Modern Surgery*. Vol. 2. Athens, Greece: Paschalidis Medical Publications; 2004.)

Sphincter of Boyden/Sphincter of Oddi

The present concept is that several sphincters composed of smooth-muscle fibers surround the intramural portion of the CBD, the main pancreatic duct, and the ampulla, if present (Fig. 121.22). This complex has a separate embryonic origin from that of the duodenal musculature and is functionally separate. Although the anatomy was well described by Boyden and others, the terminology remains confusing. We call the entire sphincter complex the sphincter of Boyden in recognition of his contribution to our understanding of the anatomy of this region, but it was originally described by Oddi in 1887, and other authors refer to it as the sphincter of Oddi.

The sphincteric complex may be as short as 6 mm or as long as 30 mm, depending on the obliquity of its path through the duodenal wall. In some instances, the sphincter may extend beyond the duodenal wall into the pancreatic portion of the bile duct, which is relevant when performing sphincterotomy.

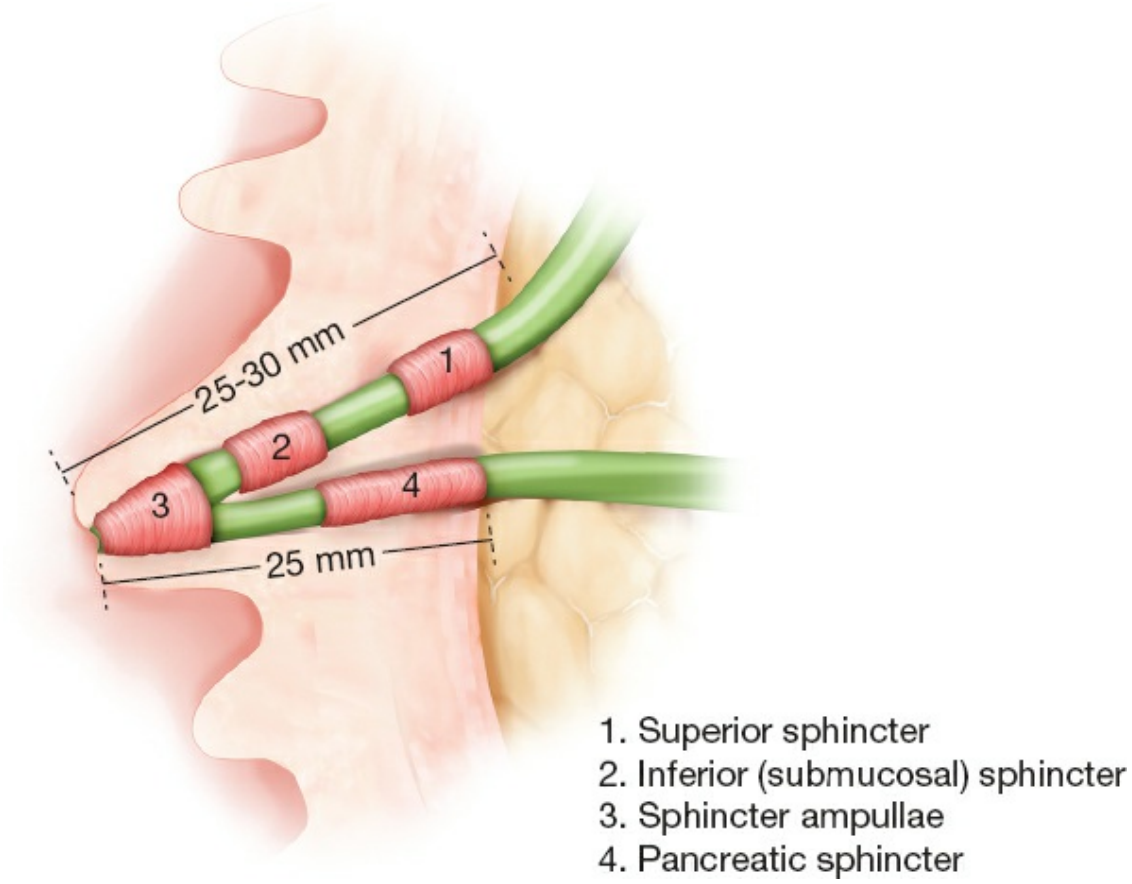

Figure 121.22. The four entities composing the sphincter of Boyden. The measurements are from White (1973).

Minor Duodenal Papilla

The minor duodenal papilla is situated approximately 2 cm cranial and slightly anterior to the major papilla. It is smaller, and does not bear the characteristic mucosal folds that mark the major papilla. It is debatable if the minor papilla is present in all people, as studies of specimens range from finding it in 0% to 100% of cases.

An excellent landmark for the minor papilla is the gastroduodenal artery, situated anterior to the accessory pancreatic duct (Santorini) and the minor papilla. During gastrectomy, duodenal dissection should end proximal to or at this artery. It becomes important in the few patients in whom the accessory duct carries the major drainage of the pancreas.

VASCULAR SYSTEM

The vascular system of the pancreas is complex and nontypical, with many different patterns.

ARTERIAL SUPPLY OF THE PANCREAS

The pancreas is supplied with blood from branches arising from both the celiac trunk and the SMA (Figs. 121.23 and 121.24). Variations are common. The head of the pancreas and the concave surface of the duodenum are supplied by two pancreaticoduodenal arterial arcades that are always present. These are formed by a pair (anterior and posterior) of superior arteries from the gastroduodenal branch of the celiac trunk. These arteries join a second pair of inferior arteries from the SMA. These vascular arcades lie on the surface of the pancreas but also supply the duodenal wall, which is why duodenal-preserving pancreatectomy is a complex endeavor.

At the neck of the gland, the dorsal pancreatic artery usually arises from the splenic artery, near its origin off the celiac trunk. More rarely, it may arise from the celiac axis (as a fourth branch) or even from the SMA. During laparoscopic distal pancreatectomy, this branch is at risk of injury, especially when the splenic artery is dissected out at its origin from underneath the pancreas. The dorsal pancreatic artery courses downward dorsal to the neck or body of the pancreas and ends in right and left branches. A right branch of the dorsal pancreatic artery supplies the head of the pancreas and usually joins the posterior arcade. It may also anastomose with the anterior superior pancreaticoduodenal (ASPD) artery. The left branch of the dorsal pancreatic artery is typically the transverse, or inferior, pancreatic artery. The left and right branches of the dorsal pancreatic artery characteristically lie within a groove on the inferior margin of the pancreas.

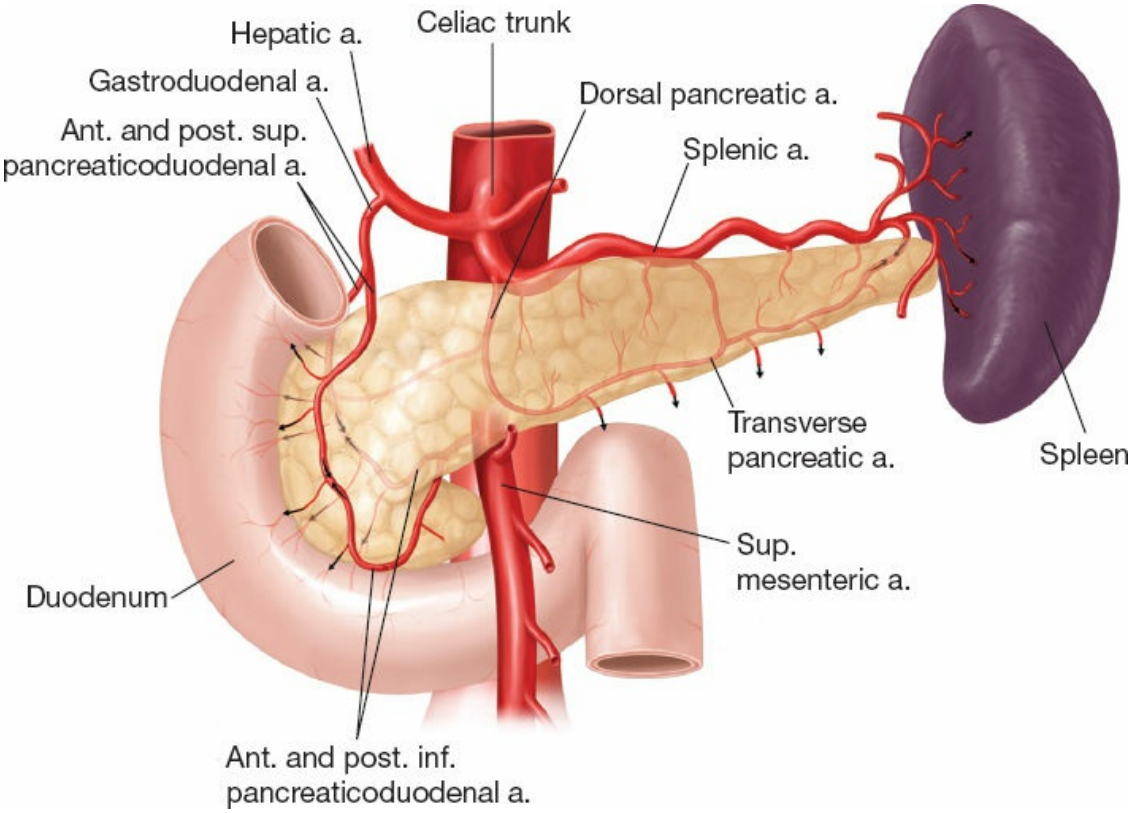

Figure 121.23. Anterior view of the major arterial supply to the pancreas (the left and right gastric arteries are omitted).

Pancreatic Arcades

The pancreatic or preferably pancreaticoduodenal arcades are formed by the union of the anterior superior and anterior inferior, posterior superior and posterior inferior, pancreaticoduodenal arteries. The anterior and posterior arcades give pancreatic and duodenal branches. The latter are also known as arteriae rectae and supply the surfaces of the duodenum indicated by their names. It is evident that any effort to separate the duodenum from the head of the pancreas will seriously affect the blood supply of the duodenum and is therefore avoided.

The pancreatic arcades vary in position, but it is generally accepted that the posterior is farther from the pancreaticoduodenal groove than the anterior one. The length of the arteriae recta also varies, but usually it does not exceed the 3.5 cm. The arcades are complete in the vast majority, but there have been reports that the arches are incomplete in about 25%.

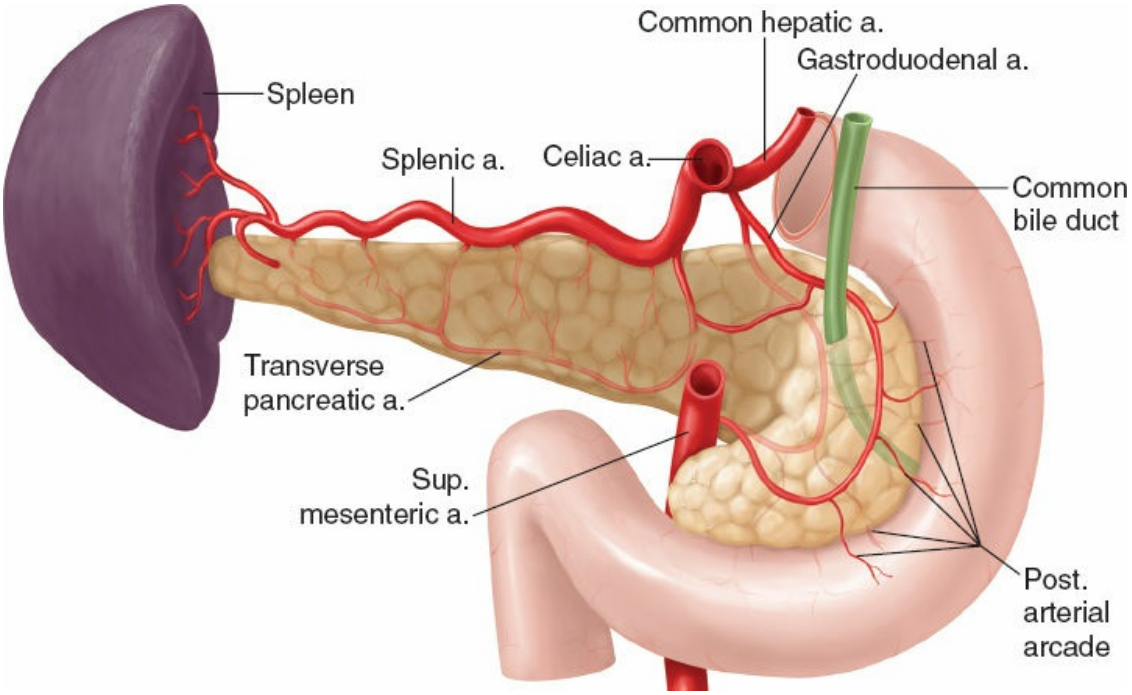

Figure 121.24. Posterior view of the major arterial supply to the pancreas (the left and right gastric arteries are omitted).

Anterior Superior Pancreaticoduodenal Artery

The ASPD artery is the end one of the two end-arteries of the gastroduodenal artery—the other one is the right gastroepiploc artery (for details on the gastroduodenal artery, see the chapter "Anatomic Considerations in Gastroduodenal Sugery"). The ASPD artery arises from the gastroduodenal at about the lower border of the duodenum.

The ASPD artery lies on the anterior surface of the head of the pancreas, where it contributes 8 to 10 branches to the anterior surface of the pancreas and the duodenum. In its course, the ASPD artery may be entirely upon the anterior surface of the head or partly embedded in it. The main stem of the APSD ends by anastomosing richly with the anterior inferior pancreaticoduodenal (AIPD) artery at the lower margin of the pancreatic head. According to Hollinshead, the lower part of the anterior arcade (given by ASPD and AIPD arteries) is closer to the pancreaticoduodenal groove than the upper part, and enters the head of the pancreas, to lie finally, at its lower origin posterior to the pancreas (Fig. 121.25).

Posterior Superior Pancreaticoduodenal Artery

The posterior superior pancreaticoduodenal (PSPD) artery arises from the

gastroduodenal artery. This is true in more than 90% of the cases. In small percentages, it may arise from a right hepatic artery from the SMA, from the common hepatic artery, or from the dorsal pancreatic artery (Fig. 121.26).

The gastroduodenal artery also gives the supraduodenal and retroduodenal arteries, which are much smaller branches than the PSPD. These are given off prior to the PSPD artery (see Figure 32 in the chapter "Anatomic Considerations in Gastroduodenal Surgery") and provide arterial supply to the first part of the duodenum and distal bile duct. Either or both of these arteries can arise separately or as branches of the PSPD artery.

The PSPD artery is given off the gastroduodenal artery above the upper border of the head of the pancreas. If the gastroduodenal artery lies to the left of the CBD, as usually happens, the PSPD artery passes in front of the CBD onto the posterior surface of the pancreas. The course of the PSPD artery follows the curvature of the duodenum and unites with the posterior inferior pancreaticoduodenal (PIPD) artery. As mentioned above, the posterior arcade tends to follow the duodenal curve less closely than the anterior arcade.

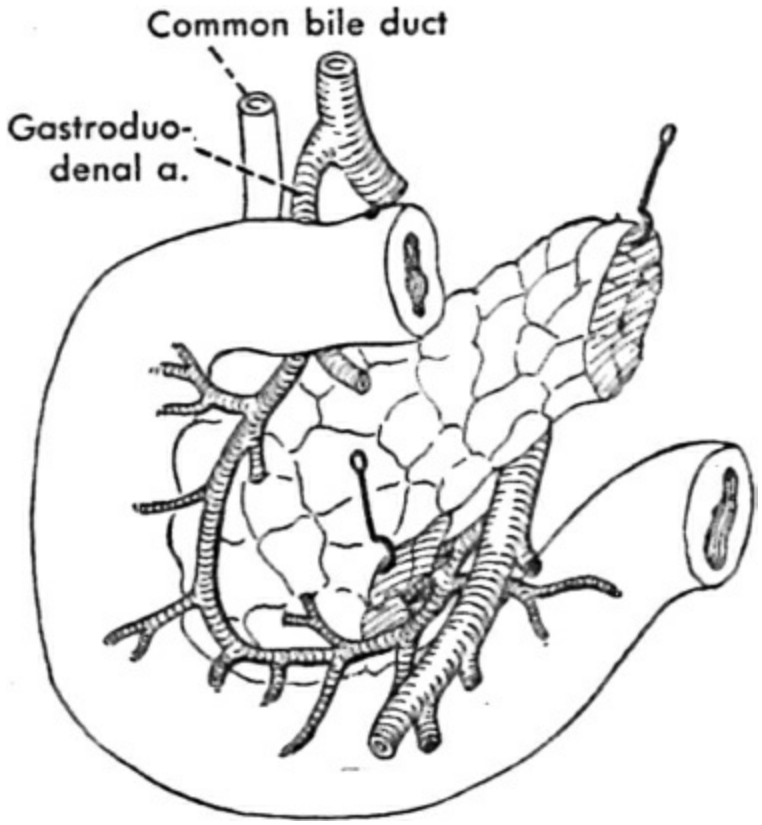

Figure 121.25. The anterior pancreaticoduodenal arcade. The

anterior superior pancreaticoduodenal artery, a terminal branch of the gastroduodenal has been separated from the right gastroepiploic (cut-off) behind the duodenum. The anterior inferior pancreaticoduodenal artery arises from the posterior surface of the superior mesenteric artery by a common stem with the posterior inferior pancreaticoduodenal artery (disappearing behind the pancreas). (From Hollinshead WH. *Anatomy for Surgeons, Vol. 2: The Thorax, Abdomen, and Pelvis*. New York: Hoeber-Harper; 1956.)

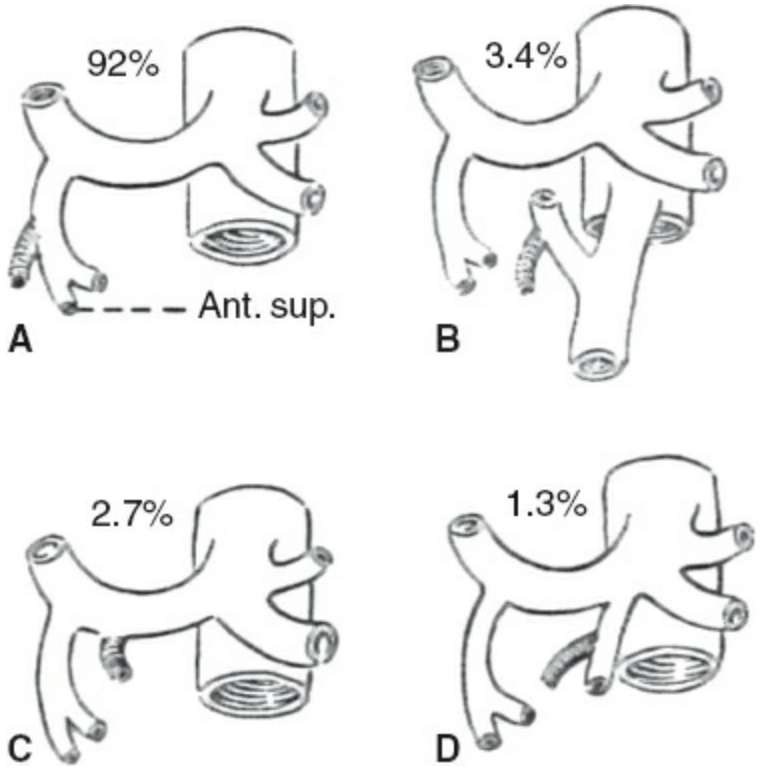

Figure 121.26. Origins of the superior pancreaticoduodenal arteries. The anterior superior (Ant. sup.) pancreaticoduodenal artery is always a terminal branch of the gastroduodenal. The posterior superior pancreaticoduodenal artery (shaded) usually arises from the gastroduodenal (**A**). In the percentages indicated, it might arise from a right hepatic branch of the superior mesenteric artery (**B**), from the hepatic artery (**C**), or from the dorsal pancreatic artery (**D**). (From Hollinshead WH. *Anatomy for Surgeons, Vol. 2: The Thorax, Abdomen, and Pelvis*. New York: Hoeber-Harper; 1956.)

The posterior arcade passes posterior to the intrapancreatic portion of the CBD. Like the anterior arcade, the posterior arcade may be doubled or tripled, with the extra arcades joining the PIPD artery or the SMA. The

posterior arcade may also anastomose with an aberrant right hepatic artery from the SMA, either separately or in combination with the anterior arcade.

Inferior Pancreaticoduodenal Arteries

The AIPD artery arises from the SMA at or above the inferior margin of the pancreatic neck. It may form a common trunk with the PIPD artery. In the first part of its course, the AIPD artery passes through the substance of the head of the pancreas. Then, it obtains a more superficial position toward the anterior surface of the head of the pancreas. The PIPD artery retains its posterior position, behind or embedded in the pancreas.

The AIPD and PIPD, both or just one vessel, may arise from the first or second jejunal branches of the SMA. Ligation of the jejunal branch endangers the blood supply to the fourth part of the duodenum, which may result in necrosis or stricture. Occasionally, a PIPD artery arises from an aberrant right hepatic artery off the SMA.

Branches of the Splenic Artery

The splenic artery courses to the left along the posterior surface of the body and tail of the pancreas, looping above and below the superior margin of the organ. This pathway may become more tortuous with age. If the posterior gastric artery is not present, the first major branch of the splenic artery is the dorsal pancreatic artery, which usually joins one of the posterosuperior arcades after giving off the inferior (transverse) pancreatic artery to the left.

The course of the inferior pancreatic artery is variable. It may be doubled or absent. It may or may not anastomose with the splenic artery in the body and tail of the pancreas (Fig. 121.27). The inferior artery often joins the gastroduodenal artery or the ASPD artery to the right. If anastomotic connections are absent, thrombosis of the inferior pancreatic artery may produce emboli, infarction, and necrosis of the tail and possibly of the distal body of the pancreas.

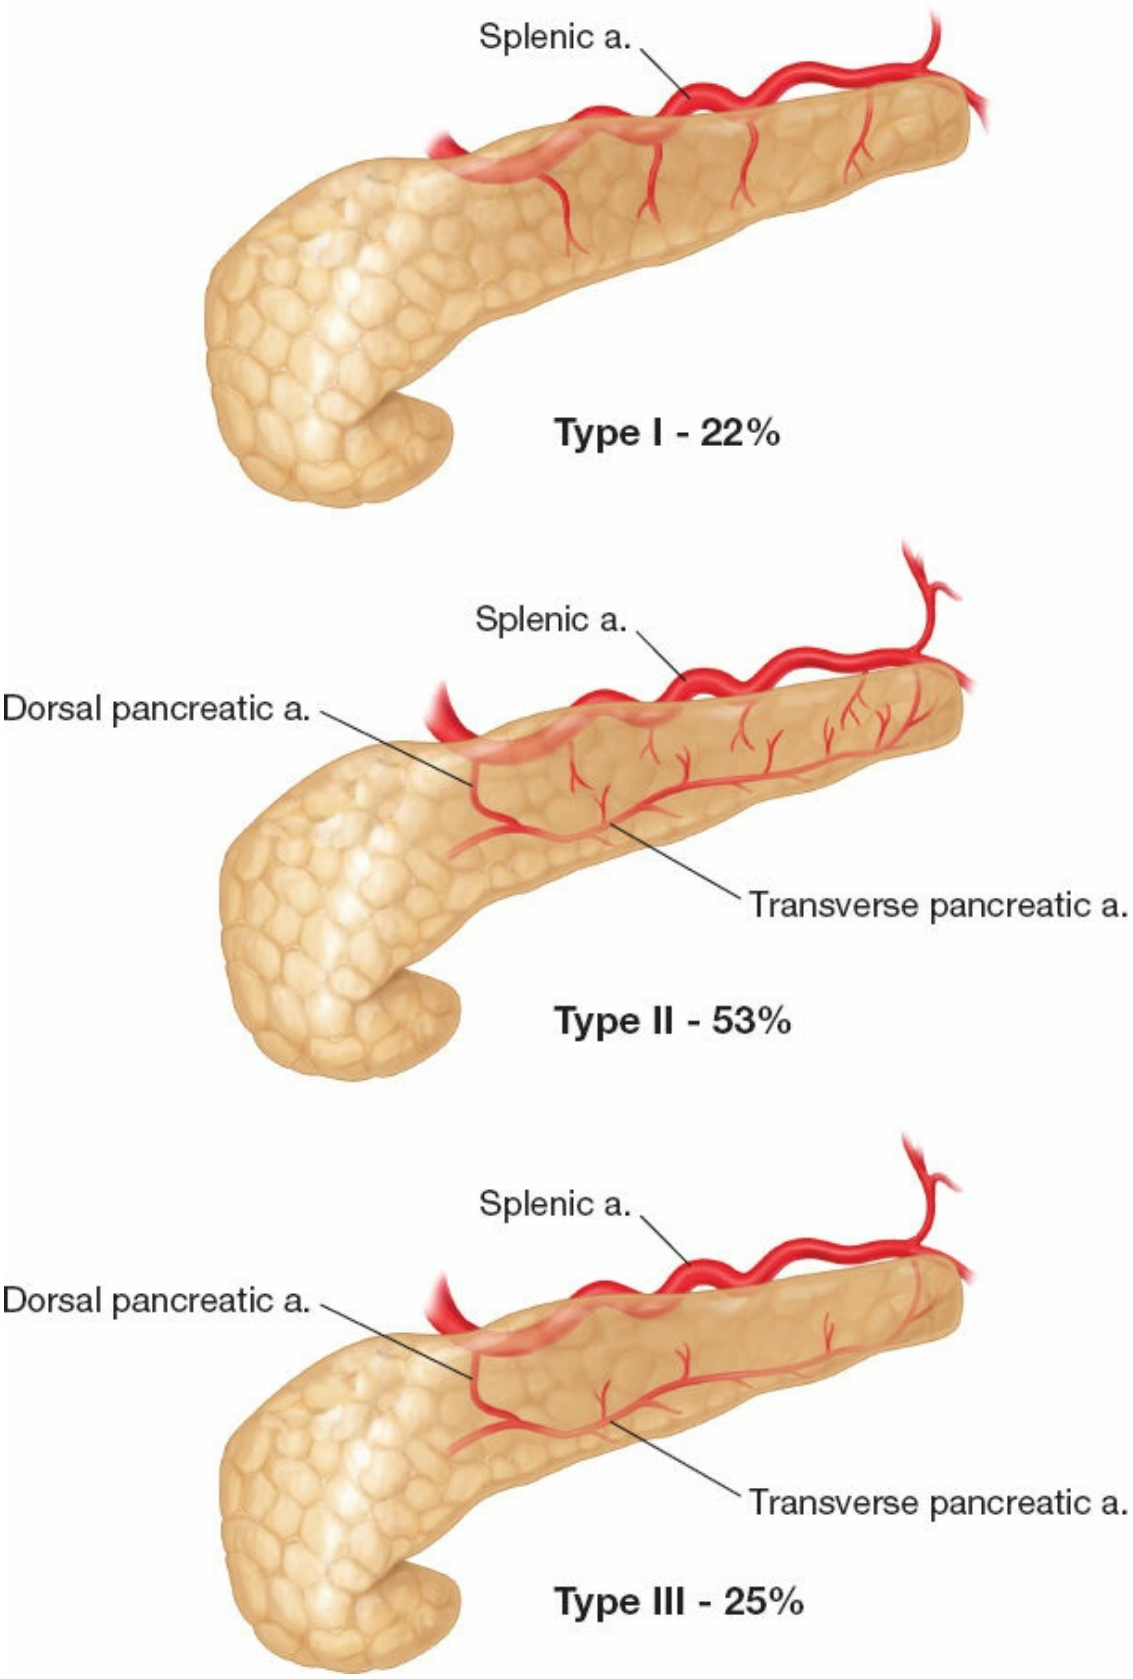

Figure 121.27. Diagram of the possible configurations of the blood supply to the distal pancreas. Type I (22%), blood supply from the splenic artery only. Type II (53%), blood supply from splenic and transverse pancreatic arteries with anastomosis in

the tail of the pancreas. Type III (25%), blood supply from splenic and transverse pancreatic arteries without distal anastomosis. This type is susceptible to infarction from emboli in the transverse artery.

Great Pancreatic Artery

The great pancreatic (pancreatica magna) artery arises from the splenic artery and reaches the pancreas near the junction of the body and tail. This artery commonly anastomoses with the inferior pancreatic artery.

Caudal Pancreatic Artery

The caudal pancreatic artery arises from either a distal segment of the splenic artery, the left gastroepiploic artery, or a splenic branch at the splenic hilum. It anastomoses with branches of the great pancreatic and other pancreatic arteries. The caudal pancreatic artery supplies blood to accessory splenic tissue when it is present at the hilum.

Anomalous Hepatic Arteries

The common hepatic artery (Fig. 121.28A) is usually a main branch of the celiac trunk, which arises cranial to the pancreas. The surgeon must always look for a possible anomalous hepatic artery before proceeding with a pancreatic resection. These aberrant arteries may be in addition to (accessory) or in place of (replaced) normal hepatic arteries.

In 2.0% to 4.5% of persons, an anomalous common hepatic artery arises from the SMA. It is related to the head or neck of the pancreas. Occasionally it passes through the head (Fig. 121.28B). It subsequently passes behind and to the right of the portal vein.

More commonly, an anomalous right hepatic artery arises from the SMA. This artery may pass behind the CBD or behind the portal vein (Fig. 121.28C). In a landmark study, an aberrant right hepatic artery was present in 26% of bodies examined by Michels. It may give off the inferior pancreaticoduodenal arteries.

An anomalous left hepatic artery presents a problem in operations on the pancreas only when it arises from the right side of the SMA (Fig. 121.28D) or from the gastroduodenal artery (Fig. 121.28E). Michels found an anomalous left hepatic artery in 27% of specimens, arising most commonly from the left gastric artery.

Anomalous Middle Colic Artery

A middle colic artery may pass through the head of the pancreas or between the head and the duodenum (Fig. 121.29). It may arise from the superior mesenteric, the dorsal pancreatic, or the inferior pancreaticoduodenal arteries.

VENOUS DRAINAGE OF THE PANCREAS

In general, the veins of the pancreas parallel the arteries and lie superficial to them. Both veins and arteries lie posterior to the ducts in the body and tail of the pancreas. All pancreatic veins drain into the inferior mesenteric, splenic, or portal vein (Figs. 121.30 and 121.31).

Veins of the Head of the Pancreas

Four pancreaticoduodenal veins form venous arcades, draining the head of the pancreas and the duodenum. The ASPD vein joins the right gastroepiploic vein. The right gastroepiploic receives a colic vein and forms a short gastrocolic vein. This becomes a tributary to the SMV. Otherwise known as the gastrocolic trunk, this vein should be identified, ligated, and divided before dissecting cephalad along the anterior aspect of the SMV during pancreatectomy (Whipple resection, extended distal pancreatectomy, or central pancreatic resection).

The PSPD vein enters the portal vein above the superior margin of the pancreas. The anterior and PIPD veins enter the SMV together or separately. Other small, unnamed veins in the head and neck drain independently into the SMV and the right side of the portal vein. While, in general, there are no anterior branches of the portal-SMV junction, there may be some exceptions, which bear relevance in pancreatic neck dissection.

Veins of the Neck, Body, and Tail of the Pancreas

The veins of the left portion of the pancreas form two large venous channels: the splenic vein above and the transverse (inferior) pancreatic vein below. A smaller superior pancreatic vein can sometimes be identified.

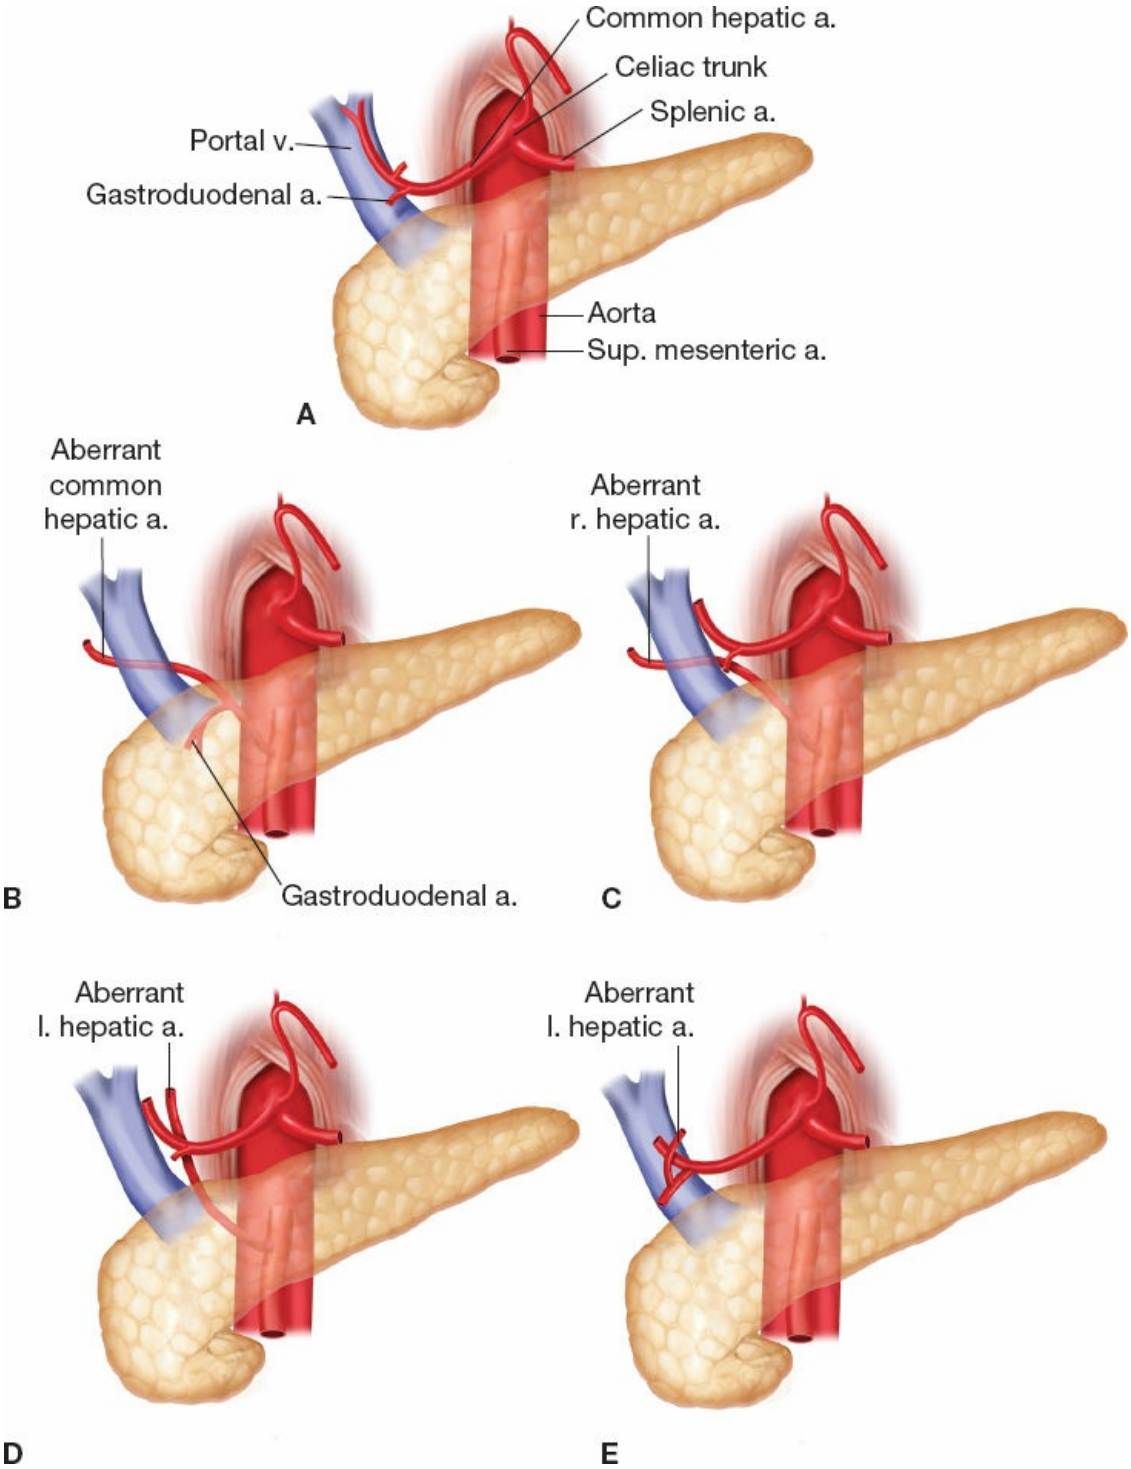

Figure 121.28. Variations of the hepatic arteries. **A.** Normal configuration; the common hepatic artery arises from the celiac trunk. **B.** An aberrant common hepatic artery arises from the superior mesenteric artery. **C.** An aberrant right hepatic artery arises from the superior mesenteric artery. **D.** An aberrant left hepatic artery arises from the superior mesenteric artery. **E.** An aberrant left hepatic artery arises from the gastroduodenal artery. These aberrant arteries may be accessory to, or may replace, normal hepatic arteries.

The splenic vein may receive from 3 to 13 short pancreatic tributaries. In a few instances, one such tributary enters the left gastroepiploic vein in the tail of the pancreas. The inferior mesenteric vein terminates in the splenic vein in approximately 38% of individuals, and the left gastric vein has a similar ending in 17% of individuals. The inferior pancreatic vein may enter the left side of the SMV, the inferior mesenteric vein, or occasionally the splenic or the gastrocolic veins.

Portal Vein

The portal vein is formed behind the neck of the pancreas by the union of the superior mesenteric and splenic veins. The inferior mesenteric vein enters at this junction in approximately one third of cases, directly into the splenic vein in another third, and into the SMV in the final third of cases.

The portal vein lies behind the pancreas and in front of the inferior vena cava, with the CBD on the right and the common hepatic artery on the left. In the absence of disease, the portal vein and the SMV can be separated easily from the posterior surface of the pancreas.

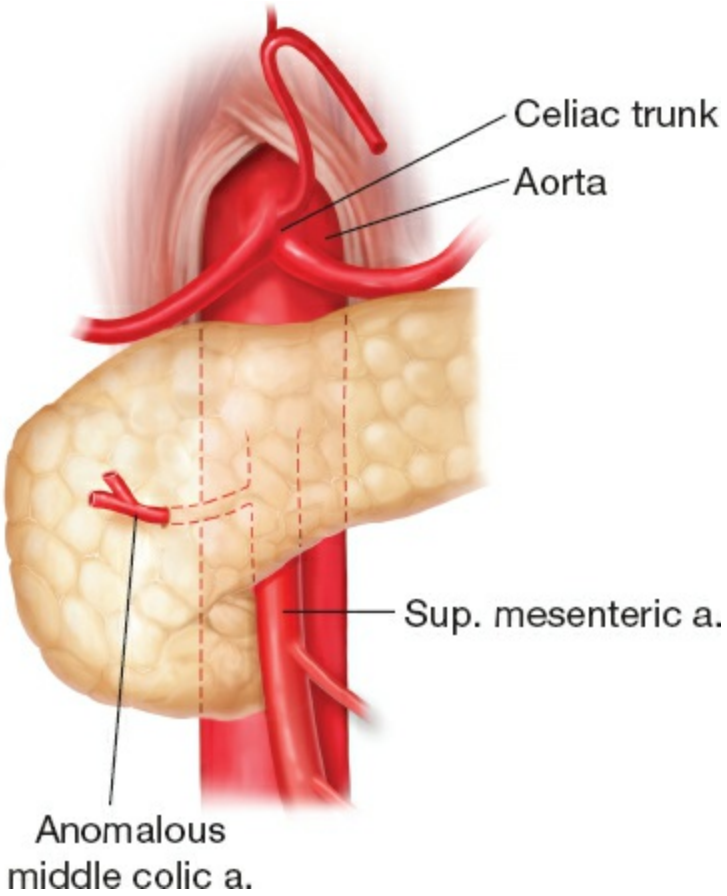

Figure 121.29. An anomalous middle colic artery passing through the head of the pancreas.

Rarely the portal vein may lie anterior to the pancreas and the duodenum (preduodenal portal vein; for embryogenesis of this congenital anomaly, see Embryology section in the chapter “Anatomic Considerations in Gastroduodenal Surgery”).

SURGICAL CONSIDERATIONS

The right branch of the dorsal pancreatic artery anastomoses with the PSPD artery. This branch typically does not provide enough blood for survival of the head and duodenum after the arcades are ligated. Preservation of the duodenum is difficult during pancreatic head resection due to shared blood supply.

The PSPD artery is the main supply for the ampulla through the epicholedochal plexus.

Injury may occur to the ASPD artery during the Puestow side-to-side pancreatojejunostomy.

The superior and inferior pancreaticoduodenal arteries should not be ligated until the neck of the pancreas can be elevated from the underlying vessels. Premature ligation could cause necrosis of the head of the pancreas and duodenum.

Noncommunication between the splenic and transverse pancreatic arteries is possible. It can result in infarction of a portion of the pancreatic tail. This may present as a stricture and may mimic malignancy.

Ligation of the splenic artery and vein will result in splenic infarction, and necessitates splenectomy unless the short gastric vessels are maintained between the stomach and the spleen. It is possible for the spleen to remain viable on these small vessels. Spleen-preserving distal pancreatectomy with splenic vessel sacrifice is known as the Warshaw technique. A small percentage of patients who undergo this procedure will develop delayed complications, such as splenic congestion, and bleeding gastric varices, and will require subsequent splenectomy.

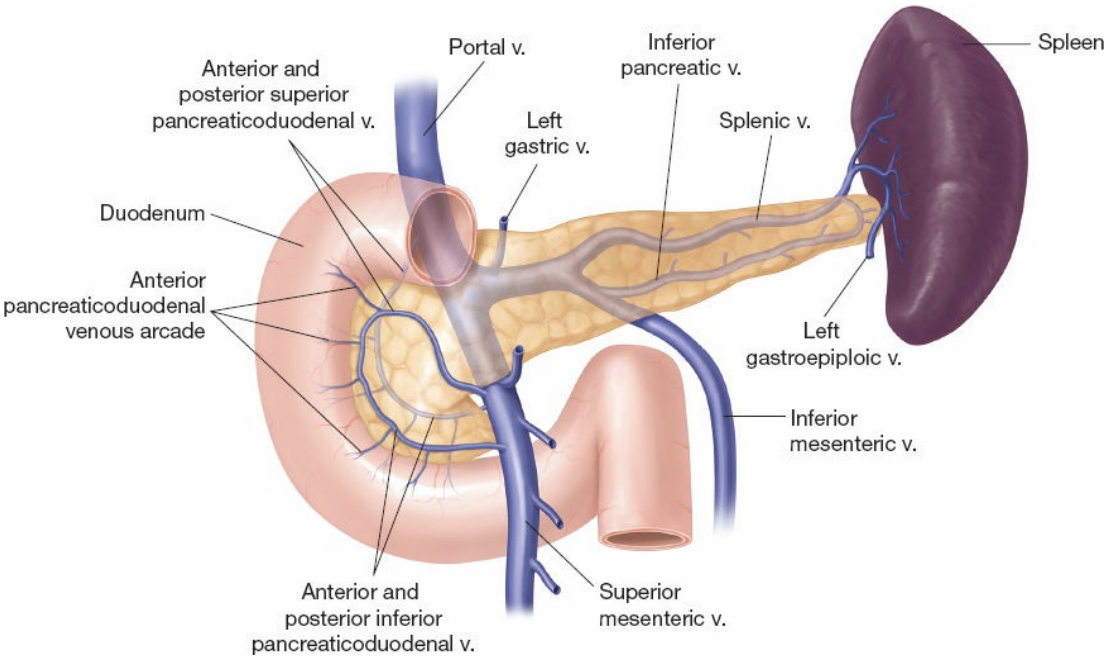

Figure 121.30. Anterior view of the venous drainage of the pancreas.

Collateral circulation can develop as a result of stenosis of the SMA or celiac artery. Abnormal blood flow through the pancreaticoduodenal arcade is found during angiographic examination.

Ligation of both pancreaticoduodenal arterial arcades results in duodenal ischemia and necrosis.

Veins of the pancreatic parenchyma are located posterior to the ducts and anterior to the arteries.

Pancreatic veins enter the lateral side of the portal vein or SMV from the pancreatic head and uncinate process. These are of varying sizes, and are a risk of tearing during pancreaticoduodenectomy. Furthermore, this is a common location of tumor invasion, which may necessitate resection and reconstruction of the portal vein and/or SMV to obtain clear margin.

The anterior surface of the portal vein is usually devoid of branches.

Laparoscopic management of pancreatic vasculature requires knowledge of the anatomy and potential anomalies. Visualization is often enhanced with angled scopes, allowing dissection in planes that would not be visible in open approaches. By contrast, new views open possibilities to new complications, such as inadvertent injury to hepatic or renal vasculature. Improvements in dissecting and ligating devices such as ultrasonic shears, bipolar cutting devices, and surgical staplers have allowed the area of laparoscopic pancreatic surgery to expand.

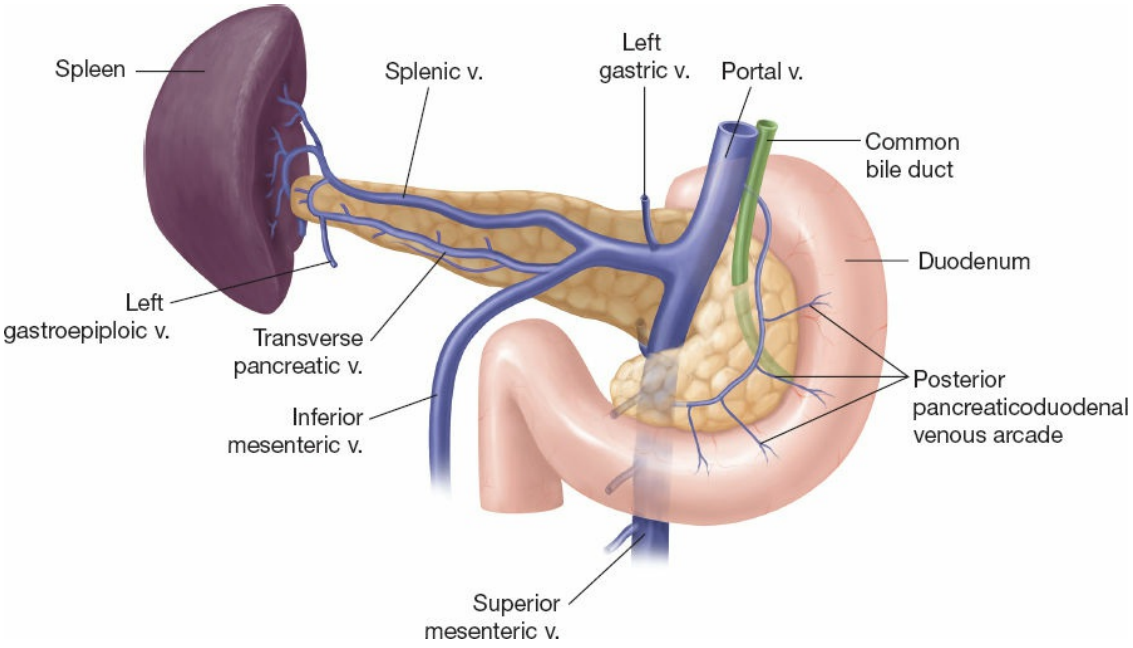

Figure 121.31. Posterior view of the venous drainage of the pancreas and the tributaries of the hepatic portal vein.

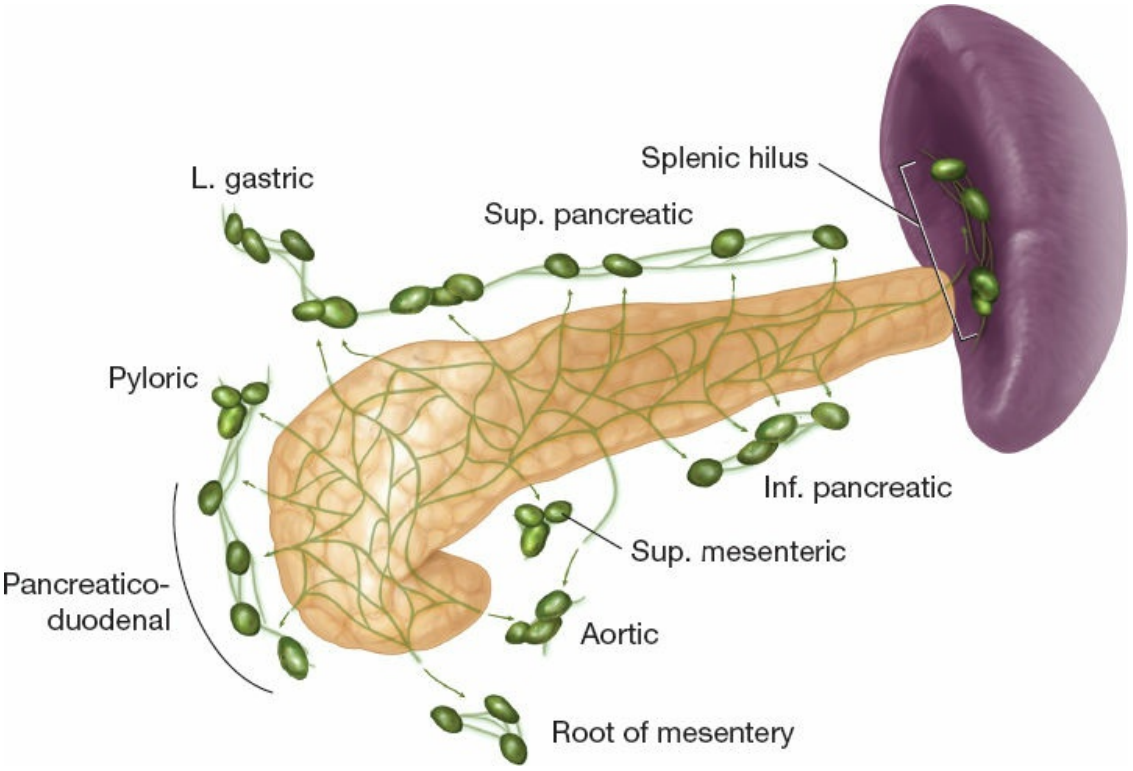

Figure 121.32. Lymphatic drainage of the pancreas. Flow is toward the nearest margin of the pancreas.

LYMPHATIC DRAINAGE OF THE PANCREAS

In general, lymphatic drainage of the pancreas is centrifugal to the surrounding nodes (Fig. 121.32). Attempts to map specific drainage basins

of the pancreas are uncertain; thus, no “standard terminology” for the nodes exists. The lymphatic vessels of the pancreas arise in a rich, perilobular, interanastomosing network. Channels course along the surface of the gland and in the interlobular spaces along with the blood vessels. Cubilla et al. divided the peripancreatic lymph nodes into five main groups with subgroups (Fig. 121.32): (i) Superior: superior head, superior body, and gastric; (ii) Inferior: inferior head and inferior body; (iii) Anterior: anterior pancreaticoduodenal, pyloric, and mesenteric; (iv) Posterior: posterior pancreaticoduodenal and CBD; and (v) Splenic: lymph nodes at hilum of spleen and at the tail of pancreas.

Superior Nodes

The collecting trunks of this group of nodes arise from the anterior and posterior superior half of the pancreas. Most end in the suprapancreatic lymph nodes located along the superior border of the pancreas. The names of the nodes typically reflect the areas drained, such as the superior head and the superior body. Some lymphatics occasionally terminate in the nodes of the gastropancreatic fold or in the lymph nodes of the hepatic chain.

Inferior Nodes

These collecting trunks drain the anterior and posterior lower half of the head and body of the pancreas. They lead into the inferior pancreatic group of lymph nodes, most of which are located along the inferior border of the head and body of the pancreas. Furthermore, they may extend into the superior mesenteric and left lateroaortic lymph nodes. Although infrequent, a collecting trunk may terminate directly in a lumbar trunk.

Anterior Nodes

Two collecting trunks run along the anterior surface of the superior and inferior portions of the head of the pancreas. They extend to the infrapyloric and anterior pancreaticoduodenal lymph nodes. They may also extend to some of the mesenteric lymph nodes located at the root of the mesentery (mesenteric-jejunal nodes).

Posterior Nodes

The posterior nodes follow the posterior surface of the superior and inferior portions of the head of the pancreas. They drain into the posterior pancreaticoduodenal lymph nodes, CBD lymph nodes, right lateroaortic

lymph nodes, and some nodes at the origin of the SMA. Lymphatics of the CBD and ampulla of Vater also end in the posterior pancreaticoduodenal group.

Splenic Nodes

The splenic lymphatics originate from the tail of the pancreas. They drain into nodes at the hilum of the spleen, splenophrenic ligament, and inferior and superior lymph nodes of the tail of the pancreas. A few lymphatic channels end in the lymph nodes superior and inferior to the body of the pancreas.

Surgical Considerations

The surgeon should be familiar with the anatomic topography of the peripancreatic nodes.

No lymphatic communications exist between the pancreas and the lymph nodes of the greater and lesser curvatures of the stomach; thus, omentectomy (lesser or greater) is generally not performed in conjunction with pancreatectomy.

Lymph flows from the pancreas to the duodenum. Furthermore, pancreatic cancers may directly invade the duodenum; thus, en bloc resection in cancer cases is the standard. Duodenectomy is not necessary to improve lymphatic harvest for pancreatic cancer.

Lymphatics of the anterior surface of the head of the pancreas terminate in the anterior pancreaticoduodenal and subpyloric nodes, and those on the posterior surface in the posterior pancreaticoduodenal nodes. Both groups are connected to the central superior mesenteric nodes and follow the superior mesenteric lymph flow.

The lymphatics of the anterior surface of the head and neck of the pancreas are associated with the common hepatic and superior mesenteric nodal group, which drain to a node situated to the right of the origins of the celiac trunk and the SMA. Behind this node lies another that receives drainage from the posterior surface of the head. The lymphatics of the left half of the pancreas terminate in a node to the left of the celiac trunk and SMA. Both the right and left nodes drain into the abdominal aortic nodes.

The lymphatics of the head and body of the pancreas do not drain toward the tail of the pancreas or the splenic nodes. Rarely, however, the lymph vessels from the tail of the pancreas can terminate in the superior body and inferior body subgroups of nodes.

The posterosuperior part of the head may follow the bile duct and the hepatic artery and terminate in the hepatic nodes.
The upper part of the body of the pancreas drains to the superior pancreatic nodes and may have few connections to the hepatic nodes.
The lower part of the body is drained toward the inferior pancreatic, central superior mesenteric, and paraaortic nodes.
The tail of the pancreas drains to the splenic nodes.
It is well known that pancreatic cancer disseminates rapidly because of the retroperitoneal position of the pancreas and its rich lymphatic and venous drainage. In particular, pancreatic exocrine adenocarcinomas appear to have an unusually efficient biologic capacity to metastasize.
A total pancreatectomy may include removal of 70 nodes. The Whipple partial pancreatectomy may involve removing 33 nodes.
To date, extended lymph node dissection for pancreatic cancer is associated with increased patient morbidity without evidence of improved patient survival; however, other data suggest that the ratio of positive to total lymph nodes assessed is important.
Node counts following surgery are dependent on surgical technique, pathologic assessment, and patient factors. Current consensus guidelines suggest assessment of 15 nodes in a pancreatic cancer resection to provide adequate staging.

NERVE SUPPLY OF THE PANCREAS

Innervation of the pancreas is by the sympathetic division of the autonomic nervous system through the splanchnic nerves and by the parasympathetic division through the vagus nerve (Fig. 121.33). These nerves generally follow blood vessels to their destinations. However, some authorities (Hollinshead) claim that, while the nerves to the duodenum follow the vessels, those to the pancreas (pancreatic plexus) arise directly from the celiac and superior mesenteric plexuses and enter the posterior surface of the pancreas (as shown in Fig. 121.33).

The sympathetic and parasympathetic divisions provide efferent (motor) fibers to the wall of the blood vessels, the pancreatic duct, and pancreatic acini. Furthermore, both contain visceral afferent (pain) sensory fibers. The distribution of these in the pancreas, however, is not well understood.

Preganglionic sympathetic innervation is from the greater and lesser thoracic splanchnic nerves. The former is composed of preganglionic efferent fibers from the 5th to the 9th or 10th thoracic segments. The latter

is composed of fibers from the 9th and 10th or the 10th and 11th segments. Some fibers may be contributed by the least splanchnic nerve.

The sympathetic nerves pierce the diaphragmatic crura to reach the celiac and superior mesenteric ganglia. Postganglionic fibers arising from neurons in these ganglia accompany branches of the celiac and superior mesenteric arteries to reach the pancreas.

Some afferent fibers cross over the midline in the celiac plexus. The celiac ganglion contains cell bodies of efferent fibers for the pancreas. Cell bodies of afferent fibers are in the dorsal root ganglia at the same spinal nerve levels as those that contribute the preganglionic sympathetic fibers. Interconnections of the afferent fibers from the pancreas with other sensory fibers from the body wall are presumably responsible for referral of pancreatic pain to the surface of the abdominal wall. Pain fibers from the pancreas pass cranially within the greater and lesser thoracic splanchnic nerve; they leave it by way of white communicating rami and enter the intercostal nerves. Then, the affected intercostal nerves perceive (project) the pain as coming from the respective area on the anterior abdominal wall, i.e., the major splanchnic nerve to the 5th to 9th dermatomes and the lesser to the 9th and 10th; thus the pain is located on the epigastrium, from below the nipple (5th dermatome) to the umbilicus (10th dermatome).

Parasympathetic innervation is by way of the celiac division of the posterior vagal trunk. The efferent fibers are preganglionic axons from cell bodies in the dorsal motor nucleus of the vagus nerve in the brain. The preganglionic vagal fibers synapse with terminal ganglion cells within the pancreas. The postganglionic fibers terminate at pancreatic islet cells. Almost 90% of the fibers carried by the vagus nerve are sensory in function, having to do with stretch, chemoreception, osmoreception, and thermoreception. These afferent fibers are processes of sensory neurons located in the sensory ganglia of the right vagus nerve at the jugular foramen of the skull. Vagal fibers pass through the esophageal hiatus of the diaphragm, usually as anterior and posterior trunks. The posterior trunk divides into a posterior gastric and celiac division near the lesser curvature of the stomach. The neuronal processes of the celiac division of the posterior vagus traverse the nerve plexuses at the origins of the celiac and superior mesenteric arteries and accompany the branches of these arteries to reach the organs supplied by them. None of the fibers carried by the vagus synapse within the celiac ganglia.

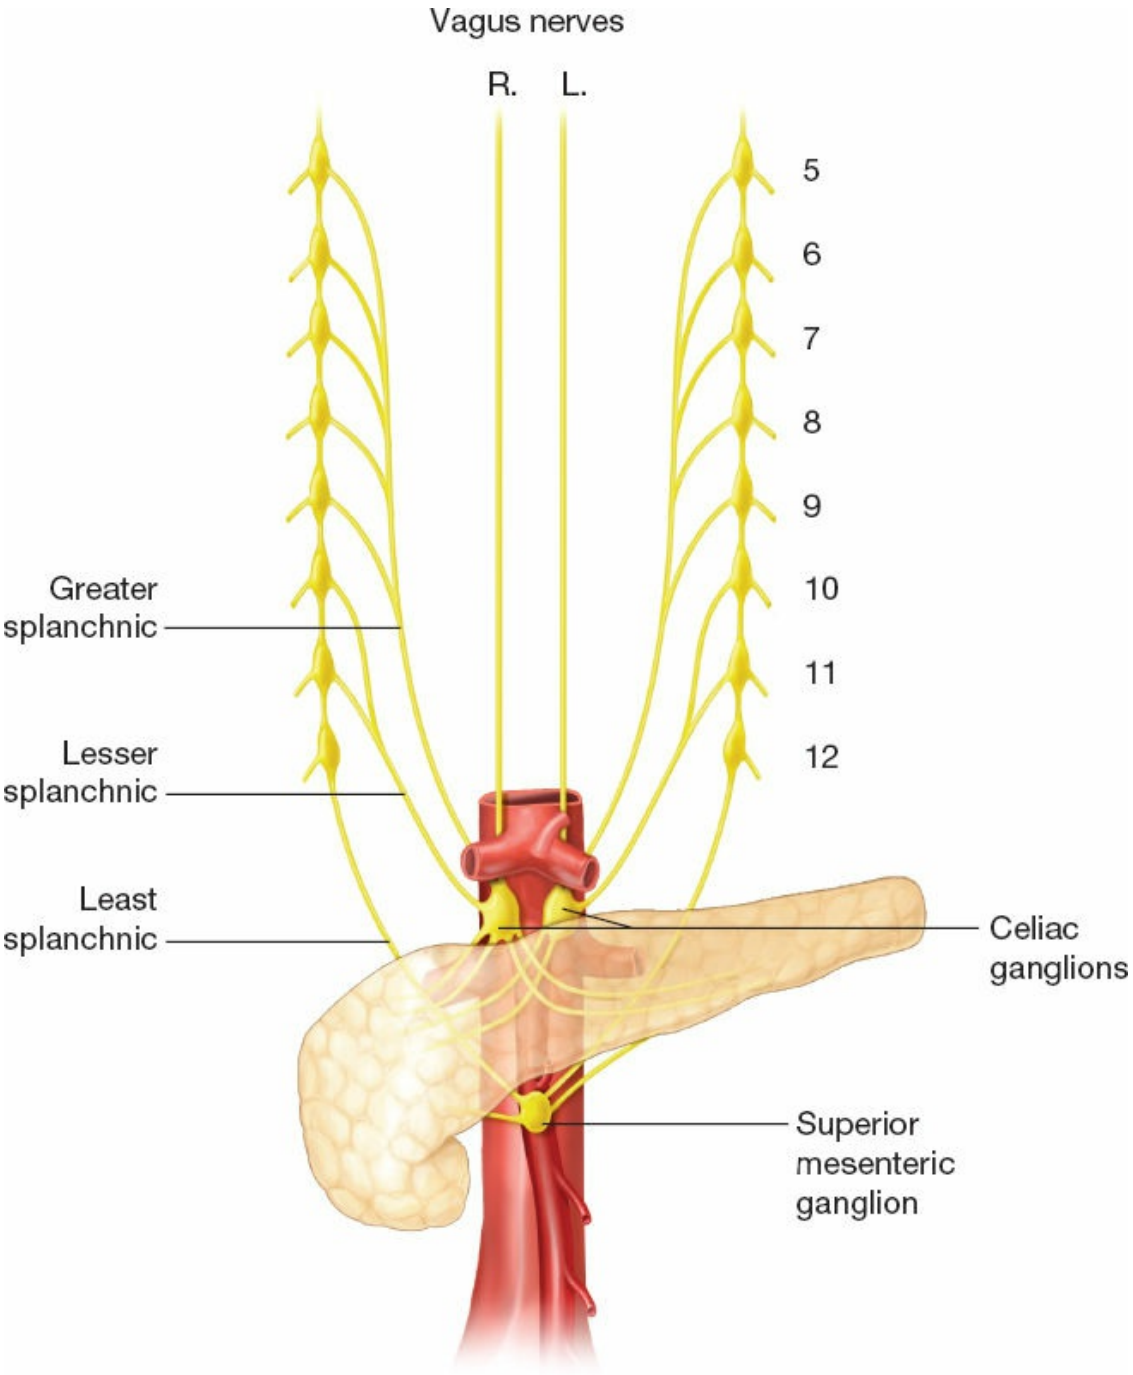

Figure 121.33. The nerve supply to the pancreas.

Two conditions commonly regarded as producing intense pain are pancreatic cancer and chronic pancreatitis, both of which have been linked to various procedures blocking the splanchnic nerves and celiac ganglia for pain management (splanchnicectomy, endoscopic ultrasonography [EUS]-guided celiac injection, percutaneous computed tomography [CT]-guided injection, operative injection at the time of laparotomy, thoracoscopic neurolysis, magnetic resonance imaging [MRI]-guided celiac plexus block

and paravertebral anesthesia).

A major complaint of chronic pancreatitis patients is the so-called “abdominal pain syndrome,” which is characterized by severe intermittent or by long-lasting and persistent pain. No current hypothesis on mechanisms of pain initiation and pain perpetuation in chronic pancreatitis can explain the various symptoms. However, several hypotheses about mechanisms of pain generation in chronic pancreatitis have been postulated; these include “increased intraductal pressure,” “interstitial hypertension,” “pancreatic fibrosis via single or multiple strictures,” “pancreatic ischemia,” and “pancreatic pseudocysts.” There is increasing evidence that pain in chronic pancreatitis and pancreatic cancer is triggered by pancreatic neuropathy. Damage to intrapancreatic nerves seems to support the maintenance and exacerbation of neuropathic pain. In chronic pancreatitis, intrapancreatic nerves are invaded by immune cells. This observation led to the hypothesis that neuro-immune interactions play a role in the pathogenesis of chronic pancreatitis and the accompanying abdominal pain syndrome. Specifically for chronic pancreatitis, two unique theories for the etiology have emerged: (i) pancreatic ductal hypertension and (ii) neural and perineural inflammation and fibrosis of the pancreas.

In contrast to patients with chronic pancreatitis, pancreatic cancer patients do not present with characteristic clinical symptoms, particularly in the early stages of the disease. Nonetheless, the two leading symptoms observed in pancreatic cancer patients at admission to the hospital are weight loss (92%) and jaundice (82%). Similarly, pancreatic cancer cells infiltrate the perineurium of local nerves, which may in part explain the severe pain experienced by the patients. Furthermore, perineural invasion extending into extrapancreatic nerves may preclude curative resection and thus often leads to local recurrence. In recent years, the involvement of a variety of neurotrophins and neuropeptides in the pathogenesis of pancreatic pain was discovered. Whereas the etiology of chronic pancreatitis is less concrete, pancreatic cancer pain is usually related to tumor invasion of the celiac and/or mesenteric plexus.

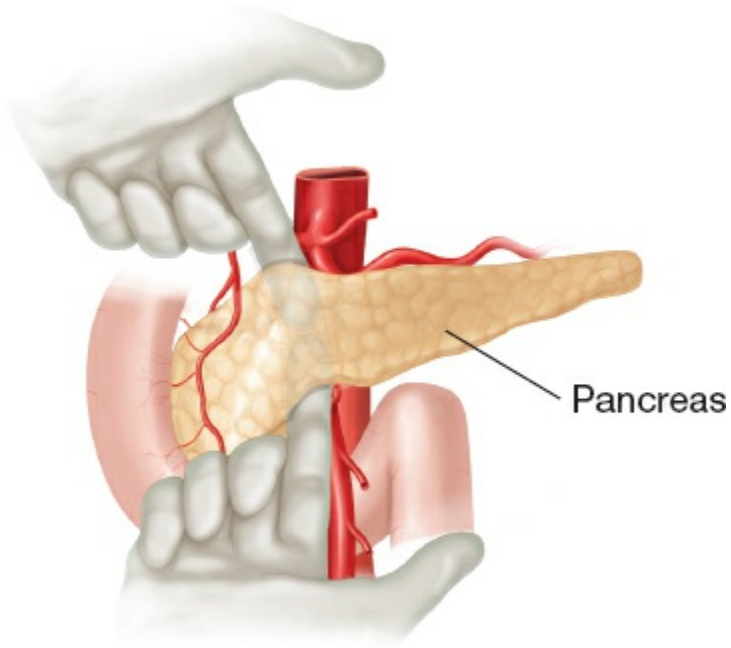

Figure 121.34. Exploration of the pancreas. The surgeon's fingers are shown passing behind the neck of the pancreas, which should separate easily from the underlying blood vessels.

Patients with pancreatic lesions suffer from back pain. The explanation to this may be related to somatic innervation by the spinal cord segments of the structures upon which the pancreas lies. Hollinshead notes, "Because of the close relationship between the pancreas and the body wall the parietal nerves innervating the latter may also be involved by pancreatic disease." Another explanation is that has been given is that visceral pain afferents result on excitation of somatic receptor neurons.

Surgical Considerations

The pain fibers of the pancreas ascend from the celiac plexus via the thoracic splanchnic nerves, namely the greater and lesser nerve. These nerves communicate with the thoracoabdominal nerves that refer the pain to the upper abdomen. Pain management aims at the celiac plexus and/or the splanchnic nerves.

Neurolytic treatment (block) at the celiac plexus requires exact details of anatomy of the plexus. The celiac plexus comprises right and left ganglia, found at the level of the celiac artery. The ganglia often join with each other and surround the aorta. The celiac plexus is located in the periaortic fat at the level of diaphragmatic hiatus and celiac artery. Between T12 and L2, we commonly meet two to five celiac ganglia.

Neurectomy of the splanchnic nerves is best effected by thoracoscopic

splanchnicectomy that gives an excellent view of the thoracic splanchnic nerves (Fig. 121.34). The target will be the greater and the lesser nerve.

Sympathectomy will not affect the pain produced by the direct stimulation of somatic nerves on which pancreas lies; this pain travels through somatic innervation.

Exploration of the Pancreas

Surgeons operating on the pancreas need to be familiar with the anatomy and diagnostic/imaging options. In most cases, when a pancreatic concern arises, a CT scan is performed. This should be a helical CT with thin cuts (2 mm) and appropriate timed contrast administration to obtain arterial and portal venous phase images. Beyond this, the surgeon can decide if further imaging with aid in surgical decision making. Other diagnostic options include dedicated pancreatic MRI, EUS with fine needle aspiration (FNA), and ERCP.

At exploration, it is valuable to understand potential transperitoneal, subperitoneal, and retroperitoneal manifestations of pancreatic diseases. Transperitoneal spread implies the process penetrates through the peritoneal layer and disseminates into the peritoneal cavity. Pseudocyst formation in the lesser sac is a typical example of transperitoneal disease process, as a ductal rupture extends transperitoneally into the space between the anterior surface of the pancreas and the posterior wall of the stomach. Pancreatic cancer can do this as well, and studies have assessed the significance of positive peritoneal cytology, and found this to be consistent with distant metastatic disease. Laparoscopic assessment is useful for identifying this finding prior to laparotomy. Many centers will perform diagnostic laparoscopy for high-risk patients with a cancer diagnosis. These include patients with high CA19–9 levels, indeterminant lesions on preoperative imaging, relatively poor performance status, and cancers of the body and tail.

Subperitoneal spread occurs when disease processes spread along the subperitoneal space of the peritoneal ligaments between the two layers of the peritoneum. The peritoneal layer need not be breached. This mode of spread is common in acute pancreatitis, in which the leakage of enzymes dissects into the subperitoneal space of the peritoneal ligaments and produces inflammation, edema, fat necrosis, and retroperitoneal pseudocysts. Pancreatic adenocarcinoma commonly invades the adjacent peritoneal ligaments subperitoneally, but unlike pancreatitis

adenocarcinoma tends toward local invasion. Pancreatic adenocarcinoma also commonly spreads via periarterial and perineural infiltration in the subperitoneal space.

The pancreas can be approached by dividing the gastrocolic ligament (part of the greater omentum) or the hepatogastric ligament (part of the lesser omentum). The gastrocolic ligament is incised widely providing good exposure of the entire pancreas if necessary. If this exposure proves to be inadequate, the hepatogastric ligament can be divided also (with preservation of the anterior branch of the vagus that runs in the upper part of the ligament toward the liver), and upward traction can be applied to the stomach. This route is useful in patients with exceptionally ptotic stomachs.

To palpate the head of the pancreas, kocherization of the duodenum is necessary. Mobilization of the duodenum is accomplished by mobilizing the hepatic flexure of the colon and then incising the peritoneum lateral to the second part of the duodenum. Next, the left index and middle fingers are placed posterior to the duodenum and the head of the pancreas, with the left thumb anterior. Palpation of the head of the pancreas and the pancreatic portion of the CBD is then possible. Lymph nodes can sometimes be felt at the distal portion of the CBD, near the upper part of the posterior surface of the head of the pancreas.

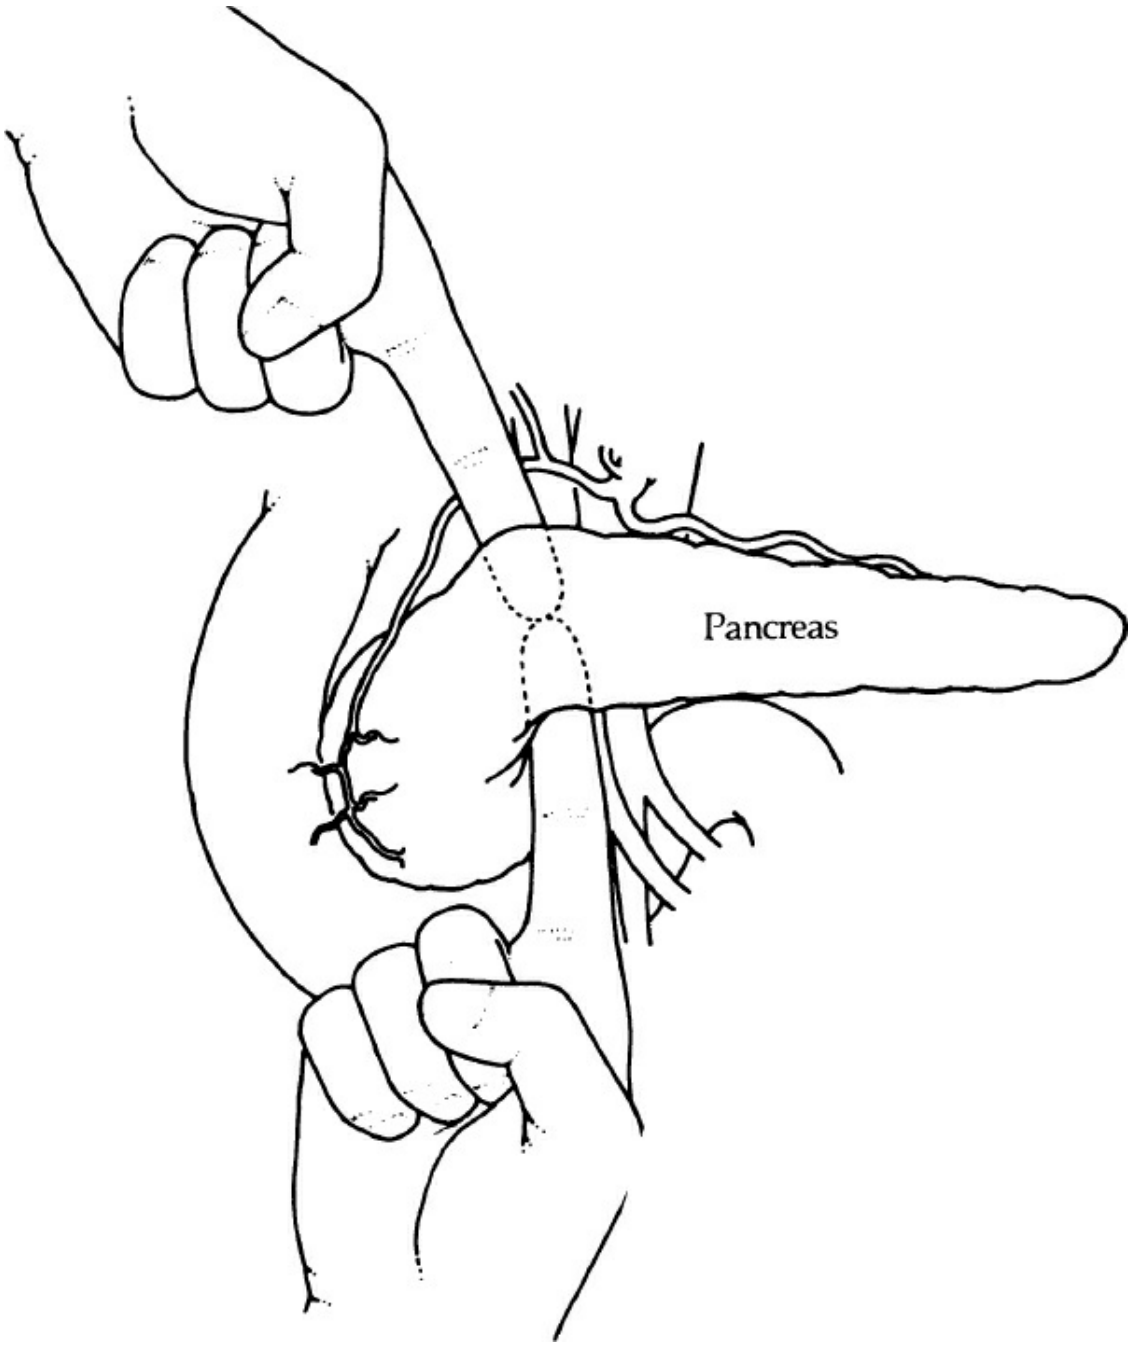

Figure 121.35. Exploration of the pancreas. The surgeon's fingers are shown passing behind the neck of the pancreas, which should separate easily from the underlying blood vessels. (From Skandalakis JE, Gray SW, Rowe JS Jr, et al. Anatomical complications of pancreatic surgery. *Contemp Surg* 1979;15:17.)

The surgeon can use his or her left or both index fingers to continue the exploration posterior to the neck of the pancreas (Fig. 121.35). The surgeon's left hand approaches the neck from above, with the left index finger posterior to the neck, and the right hand comes from below, with the right index finger also posterior to the neck. Palpation of the SMA pulse

and its proximity to the tumor was once thought to be a valuable way to assess resectability; however, this generally represents a crude assessment and the better method for assessing the arterial margin is by good quality preoperative imaging.

The ability to separate the neck from the underlying superior mesenteric and portal vein confluence is another maneuver used to assess resectability of pancreatic cancers. Vein involvement does not imply the tumor is unresectable, and being able to create the space between the pancreatic neck and the portal-SMV confluence does not provide the surgeon with confidence that the tumor is removable with completely negative margins. For further technical descriptions of specific operative maneuvers, please refer to the chapters relating to the particular procedure.

When gaining exposure to body of the body of the pancreas, it is necessary to detach the gastrocolic ligament from the transverse colon. This is time-consuming, but it provides improved visualization of the entire lesser sac.

Approach through the mesocolon is sometimes used to drain pancreatic pseudocysts. Disadvantages to this route include limited exposure of the pancreas and risk of injury to the middle colic blood vessels.

Mobilization of the splenic flexure inferiorly provides exposure to the spleen, and the tail of the pancreas.

An exciting novel area of exploration is laparoscopic pancreatic surgery. Recent reports show that laparoscopic distal pancreatectomy is associated with reduced blood loss, greater likelihood of splenic preservation, fewer postoperative complications, shorter hospital length of stay, and equivalent cancer-related outcomes (margin status, node harvest, and overall survival). The laparoscopic approach provides excellent visualization of retroperitoneal structures not typically observed in open approaches. Specific operative technique is beyond the scope of this chapter, and the reader is referred to the suggested reading list for more information.

ACKNOWLEDGMENT

The authors wish to thank the medical illustration team at St. George's University, Grenada, West Indies: Jessica Holland, MS, CMI; Angélica Ortiz, MScBMC; Charles Wesley Price, MS, CMI; and Xochitl Vinaja, MS; for the creation of color illustrations in this chapter.

EDITOR'S COMMENT

The authors present a spectacular update of this chapter on surgical anatomy of the pancreas. The color illustrations new to the seventh edition are clean and add to the readers understanding as well as enjoyment of this chapter. Anatomy is sometimes boring but not when presented with such beautiful illustrations. The illustrations are so clean and accurate that one wish when operating in "Tiger Country" everything is as illustrated. The reality is unfortunately the contrary. For this commentary I have chosen to present some pearls on exposure and resection of the pancreas that I have learned over the years and will comment on lymph node primaries in gastrinoma and annular pancreas another pancreatic anomaly related to the complex process of fusion of the ventral and dorsal buds.

The pancreas is a difficult organ to approach by open or laparoscopic surgery. The organ is "hidden" in the retroperitoneum. The head is in intimate approximation to the duodenum and the tail so adjacent to the splenic hilum as shown in Figure 121.14. It lies posterior to the stomach in the lesser sac. Inferiorly it is adjacent to the mesentery of the colon and ligament of Treitz. Superiorly are the celiac axis and its branches. The pancreas head is more anterior than the body and tail and the gland runs at a slight angle from the anterior to posterior toward the tail which is the most posterior portion lying adjacent to the spleen and overlying the left adrenal gland and superior pole of the left kidney. The neck of the pancreas lies over the spine, accounting for its propensity for injury in forceful blunt abdominal trauma.

Exposure of the pancreas requires several steps. First complete mobilization of the duodenum must be accomplished with an extensive Kocher maneuver in order to be able to examine and palpate the head of the gland. The mobilization should be carried proximal with division of the lateral duodenal attachments stopping short of the hepatoduodenal ligament. This is a relatively avascular plane. As the surgeon lifts the head of the gland, the assistant can provide traction by gently pulling the duodenum and head to the left side of the patient and anteriorly. The inferior vena cava will come into view. The junction of the second and third portions of the duodenum and the proximal fourth portion should continue to be mobilized from posterior attachments until the surgeon can clearly see the left renal vein entering the inferior vena cava. The surgeon hand can palpate the portal vein and superior mesenteric artery anterior to the plane of dissection. The attachments are usually avascular. If the vein and artery are surrounded by a malignant tumor, the surgeon should be able to appreciate this. The inexperienced surgeon may stop the dissection short of this resulting in inadequate assessment of resectability and lead to exposure problems later in the course of a planned pancreaticoduodenectomy during the takedown of the ligament of Treitz and full mobilization of the fourth portion of the duodenum.

I think it is important to realize the variations in the uncinate process as

described in Figure 121.13. This has implications for pancreaticoduodenectomy in patients with uncinate process primary tumors.

The next step in exposing the pancreas is to enter the lesser sac to expose the anterior surface of the gland. This can be accomplished by dividing the avascular attachments of the omentum from the colon. I prefer to divide the gastrocolic omentum inferior to the course of the epigastric vessels. This is less time consuming than the former and avoids having to gain later exposure around a large fatty omentum attached to the stomach. The dissection is carried laterally to the short gastric vessels. Medially the dissection is carried beyond the neck of the gland stopping just short of the right gastroepiploic vein. If one is exposing the body and tail of the pancreas, the avascular posterior attachments between the stomach and anterior surface of the pancreas are divided allowing the antrum to be elevated anteriorly. Then inferiorly the retroperitoneum overlying the inferior edge of the pancreatic body can be incised and the glands mobilized by a combination of sharp and blunt dissection.

For a Whipple procedure dissection would continue at the point of right gastroepiploic vein to expose the anterior surface of the superior mesenteric vein as it becomes the portal vein. Although located inferiorly on the superior mesenteric vein, the middle colic vein may come into play at some point and may need to be divided. The traction necessary to gain exposure particularly in the obese patients may cause avulsion of the vein and troublesome bleeding. As described in the chapter, the surgeon will need to assess resectability of a pancreatic head lesion by passing her or his finger behind the neck of the pancreas in the avascular plane anterior to the portal vein. This looks easy in the illustration, but it is not. The space should be approached inferiorly along the superior mesenteric vein by dividing the overlying fibrofatty tissue. Continued superior dissection will identify the right gastroepiploic vein that should be divided and preferably in my experience suture ligated. In so doing the anterior surface of the superior mesenteric vein just inferior to its junction with the portal vein will be identified exposing the avascular plane between the neck of the pancreas and the anterior surface of the portal vein. The dissection of the space posterior to the stomach is the same for a planned pancreaticoduodenectomy as that described above. This will allow identification of the gastroduodenal artery; a critical step of the procedure as division of this vessel is required to complete the Whipple procedure. In some cases the artery requires division in order to further assess resectability and greater exposure of the superior aspect of the portal vein. As pointed out in the chapter, the blood supply to the duodenum and head of the pancreas are rich and hence division of the gastroduodenal artery may be done without proceeding with the Whipple procedure if unresectable disease is subsequently identified.

At this point a comment about the various anomalies of the hepatic artery is warranted. First, contrast-enhanced CT reconstruction in both the axial and coronal planes will usually demonstrate the anomalous vessels. The most

common variation is the right hepatic artery coming off the superior mesenteric artery. The artery usually originates posteriorly and inferiorly from the superior mesenteric artery and courses behind the portal vein exiting in the vascular groove and then coursing to run lateral to the common bile duct. I have found that this does not make the dissection more difficult. Rather there is natural plane created by the course of the anomalous right hepatic artery which facilitates the dissection of the superior portion of the head of the gland from the mesenteric vessels. The gland in these cases may receive direct branches from the right hepatic artery rather than the superior mesenteric artery. The anomalous common hepatic artery in my experience branches off the superior mesenteric artery more superiorly and close to the SMA origin. One needs to do a meticulous dissection in these cases so as to avoid injury to the common hepatic artery. I have seen one case in which the common hepatic artery coursed through the body of the pancreas requiring meticulous dissection in order to preserve the vessel during division of the pancreas.

For an open distal pancreatectomy, I have found that after the above exposure the spleen should be mobilized. This allows the tail of the pancreas to be completely mobilized from the retroperitoneum. Usually blunt dissection can effectively dissect the tail of the gland to the point at which the inferior mesenteric vein is identified. At this point small arteries and veins may require division with energy, clips or ties. If the spleen is not to be preserved, the dissection is continued medially. The splenic artery and vein are divided and ligated. In some cases, it may be easier to divide the next of the pancreas prior to dividing the splenic vein. If splenic preservation is intended, then the short gastric vessels should be preserved and dissection performed medial to lateral with preservation of the splenic artery and vein. Either open or by laparoscopic approach distal pancreatectomy with splenic preservation requires division of the pancreas neck as the initial step as the pancreas should be divided first. There are numerous small branches as the author’s note feeding the pancreas as direct branches from the splenic artery as well as draining veins feeding into the splenic vein. If the vein and artery must be divided, the spleen may retain blood supply from the short gastric vessels as described by Warshaw. In my experience splenic preservation with dissection of the splenic vein and artery is technically less demanding if done with the laparoscopic approach. In this approach, the spleen does not need to be mobilized.

The authors discuss the embryology of the pancreas and how this may be related to gastrinomas occurring outside the pancreas. They refer to suggestions that stem cells may be dispersed during the turn of the pancreatic diverticulum and entrapping neuroendocrine cells in the duodenum and lymph nodes. The duodenum is the site of at least 50% of gastrinomas and this may explain gastrinomas at this site. However, gastrin-producing cells are known in the antrum, pyloric area, and proximal duodenum. The frequency of lymph node primary gastrinomas is highly variable inmost reported series. In our experience less than 5% of primary tumors are what initially thought to be lymph node

primary gastrinomas and recurrence is high following resection indicating the possibility of an undetected primary with a metastatic node rather than a lymph node primary. The NIH group has reported a greater incidence. This will be further considered in the chapter on neuroendocrine tumors of the pancreas.

The description of the ampulla of Vater, the minor papilla, and pancreas divism are pertinent and will be expanded upon the chapter on surgical sphincteroplasty. As you read that chapter coming back to this section may be helpful.

Finally, although rare, additional discussion of annular pancreas is warranted as this may present in childhood as well as adults. As noted the pancreas develops from a dorsal and ventral bud that first appear of the primitive foregut at around the fifth week of gestation. As described in this chapter, the pancreas is formed by fusion of the ventral and dorsal analog. Annular pancreas results from failure of the ventral bud to rotate with the duodenum, resulting envelopment of duodenum by pancreatic tissue. The incidence is 5 to 15 per 100,000 adults (Ravitch MM. The pancreas in infants and children. *Surg Clin North Am* 1975;55:377). This is shown in Figures 121.6 and 121.7.

Three major theories have been proposed to explain the development of annular pancreas: (1) Lecco's theory which hypothesizes that there is adherence of the ventral bud to the duodenal wall prior to rotation, resulting in encirclement of the duodenum (Laughlin EH, Keown ME, Jackson JE. Heterotopic pancreas obstructing the ampulla of Vater. *Arch Surg* 1983;118:979), (2) Baldwin's theory (Baldwin W. A specimen of annular pancreas. *Anat Rc* 1910;4:299) in which it is theorized that there is enlargement of the left ventral bud, and (3) hypertrophy and fusion of the ventral and dorsal buds prior to rotation.

In annular pancreas, the annulus is usually comprised of a band of pancreatic tissue that encircles the second portion of the duodenum. On occasion, this encirclement is incomplete. The pancreatic band is usually interspersed in muscularis of the duodenum, although it can also be free. There are a number of variations of pancreatic ductal anatomy in annular pancreas. The most common are: (1) the annular duct connects directly to the main pancreatic duct or (2) the duct of Wirsung follows the course of the annular pancreas going around the duodenal circumference entering the major papilla. In addition, approximately one third to one half of patients with annular pancreas also have pancreas divisum. The ductal anatomy is usually well seen on a MRCP.

Two thirds of patients with annular pancreas are asymptomatic. Clinical presentation of the symptomatic patients occurs in two distinct age groups; the neonate and the adult. As pointed out in the chapter, in the neonate the primary symptom is difficulty tolerating feedings and nonbilious vomiting. Treatment is a bypass with duodenojejunostomy. Resection of the annulus should be avoided in the neonate as well as the adult since it is associated with pancreatitis, pancreatic fistula formation, and incomplete relief of obstruction. In the adult presentation is between the ages of 20 and 50. The presentation may be related

to partial duodenal obstruction or abdominal pain. Imaging will diagnose the annular pancreas. Some adult patients may present with acute or chronic pancreatitis and rarely biliary obstruction. Treatment is based on the clinical presentation.

The pathogenesis of pancreatitis in individuals with annular pancreas remains unclear. It is hypothesized that pancreatitis may result from fibrosis leading to partial obstruction of the pancreatic duct in the head of the pancreas. The pancreatic fibrosis is usually limited to the annulus and adjoining pancreatic head (Cunha JE, de Lima MS, Jukemura J, et. al. Unusual clinical presentation of annular pancreas in the adult. *Pancreatology* 2005;5:81; Glinsky NH, Lewis JW, Flueck JA, et al. Annular pancreas associated with diffuse chronic pancreatitis. *Am J Gastroentrol* 1987;882:681). The body and tail are usually normal. Pancreatic stones may develop as a result of the obstruction and in such cases of recurrent or chronic pancreatitis pancreaticoduodenectomy may be necessary to alleviate the symptoms.

E. Christopher Ellison

Sometimes when reviewing a component which is written in a commentary, one comes upon something written by a master. That master however did not rise de novo but came from a background of masters who raised the author. As is the way of Master of Surgery, we have that in this commentary where Dr. Ellison is the master. He rose from giants who trained him and they deserve to be recognized; those masters are the late Drs. Robert M. Zollinger, Olga Jonasson, and Jay L. Grosfeld, and Drs. Larry C. Carey, Dr Hiram C. Polk, Frank H. Lewis, Kirby I. Bland, and Josef E. Fischer.

122 Selection of Surgical Therapy for Chronic Pancreatitis

Peter Muscarella and William H. Nealon

INTRODUCTION

Chronic pancreatitis (CP) can result in substantial misery for people afflicted with this disease and may present unique challenges for surgeons and other health care professionals who manage these patients. In the modern era, it is crucial for pancreatic surgeons to work closely with a multidisciplinary team in order to optimize patient outcomes and to minimize the risk of what too commonly occurs in our experience: either inappropriate care or no care at all. Unfortunately for these patients, the association of this disease with ethanol abuse, the chronicity of symptoms, and the recidivism of presentation to emergency departments seeking adequate pain control all serve to have practitioners approach these patients with indifference and neglect. For this and other reasons, these patients may wander from practitioner to practitioner (surgeons, gastroenterologists, and primary care physicians) without ever being advised that there exist interventions, particularly surgical, which have a considerable statistical likelihood of success. The primary indication for interventions, and particularly for surgery, in CP is chronic unremitting abdominal pain, commonly requiring chronic narcotic analgesics.

The hallmark for establishing the diagnosis of CP is the documentation of some element of permanent injury to the pancreas. This permanent alteration can be structural (gland calcification, secondary ductular dilatation, main pancreatic duct [MPD] dilatation, irregularity, narrowing/stricture, or stone formation). There may be pseudocyst formation. In as many as 30% of patients there may be clinically relevant bile duct dilatation, and in a smaller percentage duodenal narrowing. For most patients, surgery is offered in order to improve quality of life and decrease pain and narcotic dependence. There are a subset of patients with complications of pancreatitis who may require surgical intervention as well. Numerous surgical procedures have been described and their results

have been compared to other procedures as well as to endoscopic management. One precept of surgery has historically been to preserve as much functioning pancreatic parenchyma as possible when choosing the most appropriate operative procedure to perform. Given the fact that each patient has a varying degree of preoperative endocrine or exocrine insufficiency, making a careful decision can be challenging. The purpose of this chapter is to review the various surgical options for the management of CP with particular emphasis on patient factors and outcomes in order to help pancreatic surgeons determine selection and timing of procedures as well as appropriate patient evaluation and preparation.

BACKGROUND

CP is characterized clinically by severe abdominal pain that may radiate to the back. Patients are often dependent on narcotics by the time that they are referred to a pancreatic surgeon. This is of considerable importance in determining the need for surgical intervention as improvement in quality of life and pain are the major goals of most interventions. Because alcohol plays a role in the etiology of CP for the majority of patients, it is not uncommon for patients to transfer their alcohol addiction to prescription narcotics and they may be convinced that narcotics are essential for their ongoing health care. It is crucial to establish early on that the main goal of intervention will be to render them completely free from their dependence on narcotics. Patients who are unwilling to proceed under these terms may not be psychologically ready for surgical intervention and outcomes can be adversely affected. Patient care can also be frustrating when the patient and the surgeon are not aligned with regard to goals of therapy. Patients with CP will often have exacerbations of pain that lead to emergency department evaluation and admission to the hospital. It is important to differentiate true CP from recurrent acute pancreatitis. In this disorder, patients have multiple recurrent episodes of acute pancreatitis that are characterized by pain and serum pancreatic enzyme elevation. These patients are usually asymptomatic in between acute episodes while patients with true CP typically have chronic pain. The phenomenon of “minimal change pancreatitis” has been described for patients with pain that is characteristic of that of pancreatitis, but for whom diagnostic evaluation has been unremarkable. These patients fall into a larger category of undifferentiated chronic abdominal pain and caution should be taken prior

to undertaking pancreatic surgery as the only benefit may be as a placebo.

As CP progresses, pancreatic function becomes impaired and is manifested by exocrine and endocrine insufficiency. Patients who develop diabetes require special attention. It is important to work with primary care physicians and endocrinologists in order to optimize glycemic control prior to surgical intervention. Insulin administration is essentially always necessary for the management of what has been termed pancreatogenic, or type 3, diabetes. Oral hypoglycemic agents offer minimal benefit. Symptoms of exocrine insufficiency include weight loss and steatorrhea. Measurement of fecal fats and elastase activities can help to confirm the diagnosis and management is with oral enzyme supplements. Measurement of serum fat-soluble vitamin concentrations should be considered with replacement as necessary.

Patients can present with a variety of complications of CP and some of these may prompt endoscopic or surgical intervention. Biliary dilatation is seen in as many as 30% of patients and clinically meaningful strictures occur in 10% to 15% of patients. Fortunately, cholangitis associated with CP is quite rare as is frank jaundice. We caution that ERCP and biliary stent placement be avoided at almost all times. If a stent is placed a cycle ensues. Once the stent is removed the patient develops cholangitis because the stricture remains. This prompts replacement of the stent and the cycle repeats itself.

Duodenal strictures can also occur and these can be managed surgically, but the selection of procedure should be based on anatomic and patient-specific criteria. Splenic vein thrombosis is not uncommon in patients with CP and no specific therapy is necessary unless gastric varices develop, in which case splenectomy should be considered as part of the treatment. The stated frequency of meaningful variceal bleeding with sinistral portal hypertension is no more than 2%. Pancreatic pseudocysts can be seen in CP as well. Again, there are numerous treatments available, but appropriate therapy should always address the underlying pancreatic duct abnormality. Many years ago, the observation was made that pseudocyst drainage could be combined with simultaneous ductal decompression with a Puestow procedure. We later demonstrated that duct drainage alone is sufficient in the management of pseudocysts associated with CP.

Finally, the possible presence of cancer should always be considered, particularly in older patients. Patients with CP have a 20-fold increased risk of pancreatitis as compared to matched controls, although the actual

frequency does not reach 1%. Cancers may not be obvious on imaging studies that are obscured by the chronic inflammatory changes commonly seen in CP. Symptoms of pain, jaundice, weight loss, and new onset of diabetes are nonspecific and can be seen in both CP and pancreatic cancer.

Etiology and Pathogenesis

Histopathologic evaluation of CP demonstrates loss of normal pancreatic acinar cells with atrophy and replacement of the normal pancreatic parenchyma with fibrosis and chronic inflammatory cells. There may be some preservation of ductal remnants and islet cells. It is believed that the diabetes seen in CP is related to prevention of release of insulin in the milieu of dense fibrosis.

There are myriad causes for CP and some of these may be multifactorial. Alcohol is the causative factor in up to 80% of patients with CP. Interestingly, as many as 50% of patients with alcoholic CP stop drinking because of the pain. Unfortunately, by then they have nearly all become dependent upon narcotic analgesics. In the absence of alcohol as the etiologic cause, the clinician should seek out other causes. Referral for professional substance abuse treatment is encouraged, but long-term success rates are poor. Complete abstinence from alcohol should be encouraged for most patients with CP, particularly those with alcoholic pancreatitis. Given the fact that the purpose of surgery is the relief of pain which we define as free of all narcotics, it is key to initiate discussions of drug detoxification starting from the first encounter with the patient.

Idiopathic pancreatitis is stated to be the second most common cause of CP. Genetic abnormalities are being increasingly recognized as a causative factor in many patients with CP. It is likely that some cases of idiopathic pancreatitis may be due to as yet unidentified genetic mutations and research continues on affected kindreds in order to identify potential abnormalities. Known causes of familial or hereditary pancreatitis include mutations in the cationic trypsinogen (*PRSS1*), cystic fibrosis transmembrane conductance regulator (*CFTR*), and serine protease inhibitor, Kazal type 1 (*SPINK1*) genes. Referral to a genetics counselor can be considered for patients with idiopathic CP, particularly the young and those with a positive family history for pancreatitis or pancreatic cancer. Patients with hereditary pancreatitis have a 40% life-time incidence of developing pancreatic cancer and this should be considered when selecting strategies for surgical treatment and surveillance.

Ductal obstruction by tumors, stones, or strictures can be considered as a cause for CP, but these abnormalities are just as likely to have arisen as a result of it. In fact, one method for inducing CP in experimental animals is to create a partial obstruction of the pancreatic duct. The most common understanding of the natural course of CP starts with an excessively viscid pancreatic juice leading to plugging of the secondary ductules inducing a low-grade inflammatory response resulting in fibrosis formation and subsequent main duct scarring.

Tropical pancreatitis is relatively common in tropical, underdeveloped areas such as southern India, Nigeria, Uganda, Southeast Asia, and some areas of South America. Patients develop chronic calcific pancreatitis, pain, and pancreatic insufficiency. Etiologic factors that have been implicated include malnutrition, cassava ingestion, genetic abnormalities, and trace element deficiencies. Pancreatic surgery has been used for the treatment of chronic pain, but this disease is rarely encountered by surgeons in developed nations. Systemic disorders such as hypertriglyceridemia, hypercalcemia, and autoimmune pancreatitis account for a minority of patients with CP. These disorders should not be ignored in the evaluation of CP, but have frequently been considered prior to referral to a pancreatic surgeon. Primary treatment should be directed toward the underlying disorder. Autoimmune pancreatitis is a rare disorder that typically presents with a characteristic appearance on cross-sectional imaging that has been referred to as a “sausage-like” appearance. This is probably the most specific diagnostic abnormality. Serum IgG4 levels may be elevated on IgG subclass evaluation, but normal levels do not rule out the possibility of autoimmune pancreatitis. The identification of autoimmune pancreatitis is crucial for these patients as they respond well to steroids or other medical therapies and surgical intervention is rarely needed. Although gallstones are the most common cause of acute pancreatitis in the United States, their role in the pathogenesis of CP appears to be minimal and most patients have already had their gallbladders removed prior to development of CP. Only 15% of CP patients have had prior episodes of acute severe pancreatitis.

Diagnosis and Evaluation

Patients with CP usually will have a long history of pain, admissions to the hospital, ED visits, increasing narcotic use and a uniform message by a cast of physicians, including surgeons, that no intervention exists for their

predicament. As time passes, patients may become dependent upon massive doses of narcotics. They typically have sustained significant nutritional deficit. One should determine the degree of pancreatic insufficiency and replacement therapy should be initiated so that nutritional deficits can be corrected prior to undertaking operative intervention. It is important to gauge the patient's quality of life and narcotic requirements as improvement in these are the primary goals of surgical therapies. Objective measurement by quality-of-life assessment is encouraged and provides a baseline. Numerous laboratory tests and endoscopic and imaging modalities have been used to evaluate CP with varying sensitivities. It should be emphasized that the diagnosis of pancreatitis is suggested by clinical features of pain and pancreatic insufficiency and confirmed by imaging abnormalities. Imaging modalities are also useful to identify complications of CP and to help determine appropriate surgical therapy with particular attention paid to pancreatic duct abnormalities and anatomic distribution of parenchymal changes.

Laboratory evaluation is largely performed to identify causes of pancreatitis and to assess for pancreatic insufficiency. Serum amylase and lipase levels, while useful for the evaluation of acute pancreatitis, are generally normal in these patients even during acute exacerbations and this may be due to the so-called "burnt-out" pancreas. Unfortunately, due to the absence of laboratory abnormalities during an episode of exacerbation, these patients can be inappropriately sent home in spite of severe symptoms. Elevated serum pancreatic enzyme levels can be seen in patients with pancreatic pseudocysts. Serum glucose and HgbA1C determinations should be performed for the evaluation of endocrine insufficiency and fecal fat concentrations and elastase activities can help to quantify exocrine insufficiency. With regard to etiologic factors, serum triglycerides, calcium levels, IgG subclasses, and CA 19-9 levels should be obtained when appropriate. Liver function tests should be obtained and can be particularly useful for identifying clinically significant biliary strictures.

Cross-sectional imaging by computed tomography (CT) and/or magnetic resonance imaging (MRI) are the initial imaging modalities of choice for patients with CP. Findings on CT typically demonstrate gland atrophy or hypertrophy with a large head of the pancreas, typically composed of dense scar tissue. Duct abnormalities such as dilation, irregularity, and dilatation of the secondary ductules traditionally termed secondary ductular ectasia, intraductal and parenchymal calcifications, and

varying degrees of acute inflammation may be seen (Fig. 122.1). CT is particularly useful for identifying calcifications, which may not be visualized with MRI imaging. MRI with magnetic resonance cholangiopancreatography (MRCP) offers much information and may be complementary to CT imaging. Low attenuation changes and inflammatory changes may be present in early CP that might not be identified on CT imaging. Furthermore, MRCP offers high-quality, noninvasive imaging of the pancreatic and bile ducts. Years ago, the gold standard was ERCP. Fortunately, post-ERCP acute pancreatitis is extremely uncommon in patients with CP. ERCP may still have a role for early CP in which the only structural abnormalities are secondary ductular ectasia. This subtle change is not well demonstrated by MRCP. In addition, MRCP offers visualization of the distal pancreatic duct in cases of duct obstruction that would not be visualized using ERCP. Cross-sectional imaging also offers potential to identify most complications, such as pseudocysts, that might require intervention.

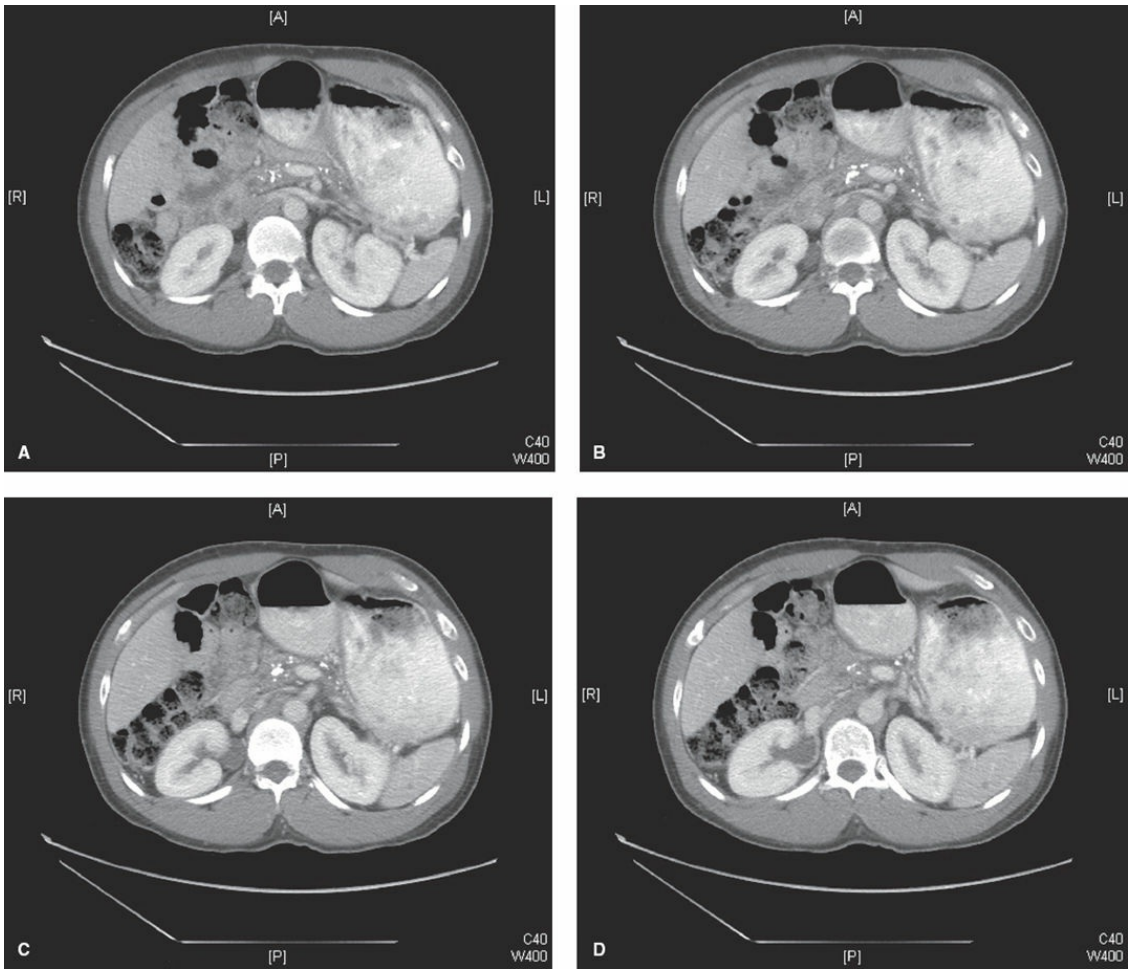

Figure 122.1. Computed tomography (CT) images demonstrating

characteristic imaging findings seen in chronic pancreatitis including gland atrophy, parenchymal calcifications, and duct abnormalities.

ERCP is almost exclusively used for therapeutic procedures and not diagnosis. EUS is a common diagnostic measure that can be overly sensitive in the evaluation of CP. Nonhomogeneity of tissue may lead to a diagnosis of CP when none exists. The Rosemont classification has been developed in order to standardize reporting of EUS findings, and abnormal findings are subclassified as major or minor criteria. Major criteria include hyperechoic foci >2 mm, major duct calculi, and lobularity in noncontiguous lobules while minor criteria include cysts, duct dilation, irregular duct contour, dilated side branches, hyperechoic duct walls, hyperechoic strands, hyperechoic foci, and lobularity in contiguous lobules. Disadvantages of EUS for diagnosis include inter- and intraobserver variability and nonspecific changes that may be associated with other factors such as male sex, age, obesity, and cigarette smoking. Blind EUS-guided final-needle aspiration (FNA) for the diagnosis of CP is not beneficial and should be discouraged, although FNA cytologic evaluation and cyst fluid analysis can be helpful for the evaluation of suspicious solid lesions and cysts. Notably, the sensitivity of EUS-FNA for detecting cancer in patients with CP is lower than that for patients with otherwise normal parenchyma. Inflammatory infiltrates may obscure malignant cells. EUS is recommended for the evaluation of pancreatic cystic lesions, particularly those with suspicious features on cross-sectional imaging.

PATIENT SELECTION AND PREPARATION FOR SURGERY

As is the case for so many surgical procedures, proper patient selection and preparation is a critical determinant of outcomes and may be more important than selection of procedure in this complex group of patients. In the modern era of health care, the evaluation and treatment of patients with CP mandates cooperation and coordination among a multidisciplinary team of providers that may include experts in pancreatic surgery, medical pancreatology, therapeutic endoscopy, interventional radiology and abdominal imaging, endocrinology, genetics, nutrition, pain management, psychiatry and social services. This is elective surgery and time should be

taken to maximize medical management. Endoscopic therapy has been evaluated and generally is not definitive. There is no question that surgery is preferable in patients with an inflammatory mass in the head of the pancreas. EUS-guided celiac plexus neurolysis is statistically better applied for palliation in patients with pancreatic pain associated with cancer. Improvement in pain after nerve ablation can be useful to confirm that the pancreas is the source of pain in patients with early CP.

Since a major goal of surgery is to render patients narcotic independent, almost all patients being considered for surgical treatment will have varying degrees of narcotic addiction as this can be challenging to manage before and after surgery. Due to the psychosocial issues that are so commonly associated with CP, many patients have essentially severed their relationships with referring physicians and primary care physicians. Appropriate management of CP in patients with an addictive personality, chronic pain syndrome, and subsequent narcotic dependence creates an enormous clinical challenge. The surgeon has a vested interest in the successful "detox" of these patients as this defines the success of the operative procedure. The pancreatic surgeon may become responsible for this aspect of the patient's care. At times a partnership with either a dedicated primary care physician, gastroenterologist, or pain specialist may be available. Unfortunately, referral to "pain clinics" and psychiatrists are often disappointing. There should be a clear establishment of goals of narcotic therapy and that the ultimate goal is to render the patient free from their addiction. Surgeons who prescribe narcotics should be aware of State Medical Board rules regarding prescription of narcotics for chronic pain. Patients should be seen in the office whenever a prescription is provided and documentation of an encounter is mandatory. Urine toxicology screens and query of regional databases tabulating recent prescriptions by the patients are encouraged when writing narcotic prescriptions. Noncompliant patients should be referred for substance abuse therapy and can be released from the physician's practice if they remain noncompliant.

SURGICAL PROCEDURES, SELECTION, AND OUTCOMES

Numerous procedures have been described for the treatment of CP. Over the last several decades there has been a gradual shift in surgical philosophy from formal resections (Whipple procedures), to drainage procedures, to hybrid procedures combining some element of a lesser

resection, with or without ductal drainage. There are advantages and disadvantages to all of these procedures, but the goal of all procedures should be to provide relief of symptoms while preserving organ function and minimizing surgical morbidity and mortality. Commonly performed procedures over the past 15 to 20 years employ varying degrees of pancreatic head resection, typically in the form of an “excavation” of the head of the pancreas using the C-loop of the duodenum as an anatomic boundary. An awkward term of “pacemaker” of the pancreas has been invoked as the epicenter of pain in CP. We are more comfortable simply stating that a large inflammatory mass may certainly be seen as a source of ongoing pain, which a drainage procedure alone would fail to address. The role for distal pancreatectomy (DP) for the treatment of CP is relatively limited with success rates for durable pain relief of only 50%. Denervation procedures have a limited role.

Finally, there has been considerable recent enthusiasm for the radical operation of total pancreatectomy with islet cell autotransplantation (TPIAT). Enthusiasm is a key descriptor, as much of this literature seems oddly promotional rather than investigational. This procedure remains highly controversial among experienced pancreatic surgeons. The primary and potentially damaging controversy lies in the exhortation by highly enthusiastic advocates of this operation that one should avoid conventional surgery for CP and move directly to TPIAT because some technical aspects of that operation are more challenging after conventional surgery. They attempt to paint a dark picture for the successes of conventional surgery when success rates between 75% and 90% have been reported in large series, including series reported by one of the authors over several decades. At least as disturbing is the fact that every report on TPIAT has been composed of a population unlike any other report on the management of CP, often predominantly female as compared the male dominance of all other reports. There is always a significant percentage of patients who have been given a diagnosis of “minimal change” CP. If one goes to the root report on this diagnosis one finds a 1992 article from “Gut” in which a surgeon and a pathologist review in minute detail 16 patients with unexplained abdominal pain. They describe a long list of obscure histologic findings that the pathologist admits would never have been found using conventional pathologic specimen handling practices. It is on the basis of this paper that the diagnosis has emerged. Having reviewed the pathology reports from more than a dozen TPIAT patients with this

diagnosis, in every case the specimen is described as “normal pancreas.” Outcomes after this operation are discussed later in this chapter.

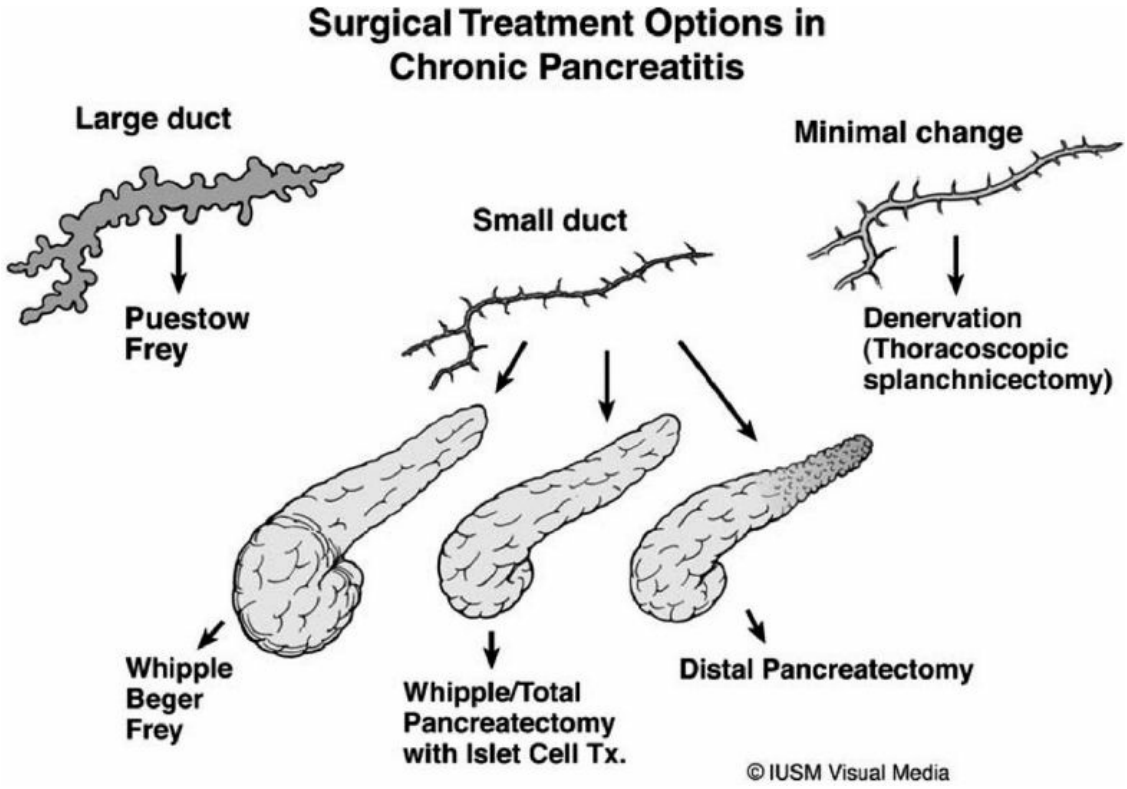

Figure 122.2. Types of operation based on anatomic and morphologic variables in chronic pancreatitis. (Reprinted from Howard TJ, Browne JS, Zyromski NJ, et al. Mechanisms of primary operative failure and results of remedial operation in patients with chronic pancreatitis. *J Gastrointest Surg* 2008; 12(12):2087–95; discussion 2095–6. Copyright © 2008, with permission from Springer.)

Various algorithms for choice of surgical procedure based on imaging findings have been suggested. These are usually based on the size and configuration of the pancreatic duct, presence and location of inflammatory lesions, evidence of biliary stricture, and overall gland morphology (Fig. 122.2). In general, patients can be classified by duct diameter into what is termed “small duct” and “large duct” CP. Drainage procedures can be employed for patients with large duct disease, often in combination with organ preserving excavations of the head of the pancreas. Formal resections (Whipple procedures) may be performed in patients with small duct disease or in those who have previously failed after a drainage procedure. Specific rationale for choice of procedures and outcomes are reviewed below.

Pancreaticoduodenectomy

Pancreaticoduodenectomy (PD) is typically performed for malignant or premalignant periampullary lesions, but considerable experience with this procedure for CP has been reported throughout the years. Although many pancreatic surgeons feel that outcomes are better and risks lower for the duodenum-preserving pancreatic head resections (DPPHR), PD is often performed by surgeons with little knowledge or experience with other choices. The great majority of American surgeons who identify themselves as pancreatic surgeons base that description on prior fellowship training in surgical oncology. Thus, their experience is often limited to formal resections, either PD or distal resection. Potential disadvantages of PD include high morbidity and higher rates of postoperative pancreatic insufficiency. We recommend that PD be reserved for selected patients, such as those with duodenal and/or biliary strictures, suspicion for or confirmed malignancies, or as a salvage procedure following the failure of less extensive procedures.

In a 5-year randomized trial of PD versus the Beger procedure, the authors found that patients in the Beger group had a lower incidence of nausea, vomiting, and diarrhea and improved quality of life and pain control. There were no differences in weight or pancreatic insufficiency. Notably, two patients in the Beger group required reoperation for biliary strictures. Based on these results and other previous reports, the authors concluded that the Beger procedure provides better outcomes than PD. A meta-analysis published in 2008 evaluated four trials comparing PD with DPPHR showed decreased blood loss, decreased hospital length of stay, and improved pancreatic exocrine function, weight gain, occupational rehabilitation, and quality of life in the DPPHR group. Both operations were equally effective regarding pain relief with 75% to 90% patients being pain free in follow-up. Another meta-analysis published in 2014, this time analyzing five studies, demonstrated improved global quality of life and decreased diarrhea and fatigue in the DPPHR group versus the PD group (Table 122.1). There were no differences identified in any of the other outcomes measured including pain, pancreatic function, or mortality. The authors of both meta-analyses concluded in favor of the head excavation procedures.

A 15-year follow-up report of a randomized trial of PD versus the Frey procedure in 64 patients raises questions about the long-term mortality associated with PD. Although there were no differences in pain or

pancreatic insufficiency, physical quality of life was improved in the Frey group. More notably, long-term mortality in the PD group was 53% versus 30% in the Frey group with mean survivals of 11.3 and 13.5 years. These findings underscore the considerable mortality associated with CP and further favor the excavation of the head of the pancreas rather than PD. In contrast, a study of 33 patients undergoing Frey or Berne procedures for CP showed that a relatively high number of patients require reoperation. In this study, seven patients required additional procedures for biliary strictures or cancer. As compared to the initial procedures, the morbidity associated with redo procedures was considerably higher, particularly with regard to pancreatic fistula, intra-abdominal infections, and the need for reoperation in the early postoperative period. The authors suggest, although well shy of statistical significance, that the need for reoperation with its associated considerable morbidity could be prevented by performing PD as the initial procedure. A large, multicenter randomized trial comparing outcomes for PD versus DPPHR has been designed and is currently accruing patients in order to better determine the optimal surgical procedure for patients with head dominant CP (ChroPac-trial).

Duodenum-Preserving Excavations of the Head of the Pancreas

Historically the operations available for use in the surgical management of CP were limited to the Puestow, or longitudinal pancreaticojejunostomy, and PD. During the late 1970s and into the 1980s several procedures were introduced (Fig. 122.3). The DPPHR was introduced by Beger in Ulm, Germany. In this procedure, which is now referred to as the Beger procedure, the pancreatic body/neck is divided as in a conventional Whipple and then the head of the pancreas is excavated to the boundary created by the C-loop of the duodenum. In the next decade, Frey introduced a procedure that was composed of a standard Puestow procedure combined with an excavation of the head of the pancreas in a manner essentially identical to the Beger procedure. Thus, one can describe the Beger procedure as a modified Whipple and the Frey procedure as a modified Puestow, or drainage procedure. In the end, the DHPPR procedures differ little with regard to technique or outcomes (Table 122.2).

TABLE 122.1 Results of a Meta-Analysis Comparing Outcomes for

Duodenum-Preserving Pancreatic Head Resections (DPPHR) Versus Pancreaticoduodenectomy (PD) for the Management of Chronic Pancreatitis

Outcome	Comparison	Effect Size, RR/WMD (95% CI; P; I^2)
Pain relief	DPPHR vs. PD	RR 1.08 (0.88–1.33; 0.46; 43%)
Morbidity	DPPHR vs. PD	RR 0.54 (0.20–1.46; 0.22; 77.6%)
Blood replacement	DPPHR vs. PD	WMD—1.28 (–2.32 to –0.25; 0.02, 88.7%)
	Frey vs. ppPD	WMD—2.09 (–2.30 to –1.87; 0.01, 0%)
Operation time	DPPHR vs. PD	WMD—53.03 (–134.96 to 28.89; 0.20; 99.2%)
	Frey vs. ppPD	WMD—112.45 (–164.07 to –60.84; 0.01; 88.6%)
Pancreatic fistula	DPPHR vs. PD	RR0.39 (0.08–1.97; 0.26; 0%)
Delayed gastric emptying	DPPHR vs. PD	RR0.23 (0.05–1.11; 0.07; 32%)
	Frey vs. ppPD	RR 0.06 (0.01–0.46; 0.01; 0%)
Hospital stay	DPPHR vs. PD	WMD—4.32 (–6.46 to –2.00; 0.01; 60.7%)
	Exclusion of Büchler et al.	WMD—5.26 (–6.67 to –3.86; 0.01; 0%)
Exocrine insufficiency	DPPHR vs. PD	RR 0.20 (0.06–0.66; 0.01; 57.7%)
Endocrine insufficiency	DPPHR vs. PD	RR 0.49 (0.22–1.09; 0.08; 0%)
Weight gain	DPPHR vs. PD	RR 1.93 (1.33–2.81; 0.01; 46.1%)
Occupational rehabilitation	DPPHR vs. PD	RR 1.36 (1.07–1.71; 0.01; 0%)
Quality of life	DPPHR vs. PD	WMD 25.07 (18.83–31.31; 0.01; 57.1%)

P values of 0.01 include all data of <0.01.
CI, 95% confidence interval; DPPHR, duodenum-preserving pancreatic head resection; I^2, degree of statistical heterogeneity; 0–25%, moderate; 26–50%, average; 51–100%, high statistical heterogeneity; PD, pancreatoduodenectomy; ppPD, pylorus-preserving Whipple procedure; RR, relative risk; WMD, weighted mean difference.
Reprinted from Diener MK, Rahbari NN, Fischer L, et al. Duodenum-preserving pancreatic head resection versus pancreatoduodenectomy for surgical treatment of chronic pancreatitis: a systematic review and meta-analysis. *Ann Surg* 2008;247(6):950–61, with permission from Wolters Kluwer.

Just as in a conventional Whipple procedure, preliminary measures for the Beger procedure include a generous Kocher maneuver so that "bimanual palpation of the head of the pancreas is possible." The lesser sac is opened along the gastrocolic omentum. The omentum is reflected superiorly and the transverse mesocolon is reflected inferiorly. The procedure requires division of the pancreatic neck over the portal/superior mesenteric vein (SMV) junction followed by local resection of the head of

the pancreas leaving a rim of 5 mm of residual pancreatic tissue along the medial border of the duodenum and between 5 and 10 mm at the floor of the excavation. The intrapancreatic portion of the common bile duct (CBD) is usually preserved, although the duct can be opened and incorporated into the reconstruction in order to allow for improved biliary drainage. Proponents of all of these procedures suggest that careful dissection and division of inflammatory fibrous tissue around the CBD should provide adequate decompression for biliary strictures. Reconstruction for the Beger procedure requires creation of two pancreaticojejunal anastomoses to the same Roux limb of jejunum, one encircling the edges of the excavated head and an additional anastomosis between the more proximal Roux limb and the remnant of the ventral pancreas. The opened intrapancreatic choledochotomy can be included in this anastomosis if one has been made. The pancreaticojejunostomy at the head of the pancreas simply requires sutures placed in the typically firm remnant rim around the C-loop of the duodenum. The anastomosis to the distal remnant can be performed using a standard duct-to-mucosa reconstruction, inversion pancreaticojejunostomy, or one can incorporate the rigid edge of pancreatic tissue as one often does in a Puestow or Frey procedure. For case with a particularly dilated dorsal pancreatic duct or a chain-of-lakes appearance, reconstruction with a longitudinal pancreaticojejunostomy can be considered. The Beger procedure has become popular in Europe, but is not performed frequently in the United States.

The Frey procedure was initially described in 1985 and essentially combines a local resection of the head of the pancreas with a longitudinal pancreaticojejunostomy. For this procedure, the head of the pancreas is excavated in a nearly identical fashion. First observed during a visit to Ulm in the early 1990s, one of the authors learned the crucial step of placing a series of deep sutures, using a CT-1 needle, circumferentially around the C-loop of the duodenum and maintaining a 5-mm rim. Each of these sutures are tied and clamped. This measure greatly reduces the risk of hemorrhage during excavation. Hemostasis and occasional ligation of the gastroduodenal artery is necessary. Ligation of the right gastroepiploic artery as it exits the plane between the pylorus and the head of the pancreas is mandatory. The anterior inferior pancreaticoduodenal artery should be identified overlying the uncinate process and may also require ligation. The dissection is carried posteriorly with the surgeon’s opposite

hand beneath the head of the pancreas until a plane lying over the intrapancreatic CBD is identified and entered. The MPD is opened along the entire length of the dorsal pancreas prior to the head resection and reconstruction is performed with a single anastomosis between a Roux limb of jejunum and the pancreatic duct and head defect (Fig. 122.4). It is crucial to begin by completing the posterior row using interrupted sutures. Care should be taken to assure that the distance between the sutures on the pancreas always exceed the distance between the Lembert sutures on the jejunum. Without taking this precaution one will be challenged by what proves to be a size mismatch between the open jejunum and the opening in the body and head of the pancreas. None of these sutures should be tied until that row is completed. For the anterior row one should first place the corner sutures, now directed inside-out on the pancreas. All sutures on the anterior row should be tied as you go. After the corners, place a central suture and then divide the distances in half. In this manner, you will achieve a uniform closure. The Frey procedure has become quite popular among American surgeons. It is felt that the risks of hemorrhage are decreased because the need for establishing a plane in the dense fibrosis often associated with CP posterior to the pancreatic neck and anterior to the portal vein-SMV is eliminated.

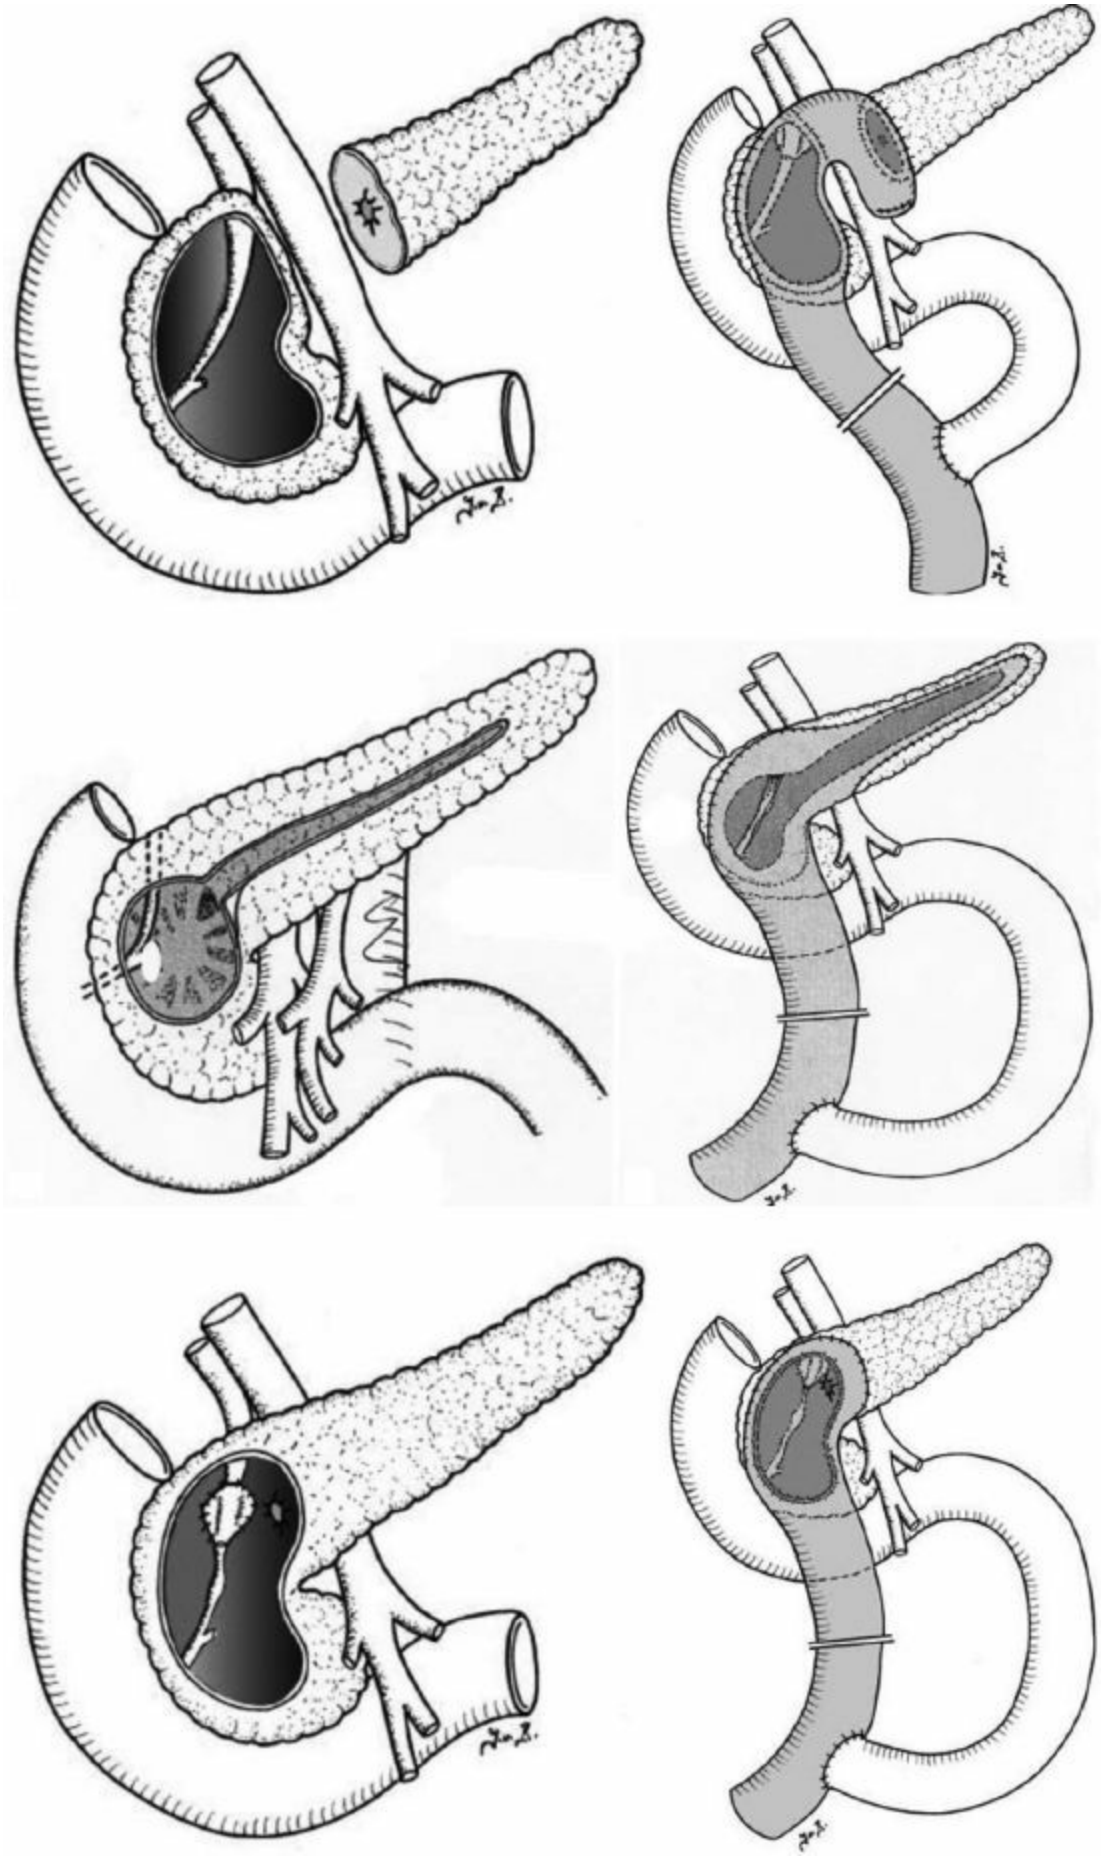

Figure 122.3. Duodenum-preserving pancreatic head resections (DPPHR): Beger procedure, Frey procedure, and Berne modification of the Beger procedure. (Reprinted from Strobel O, Buchler MW, Werner J. Duodenum-preserving pancreatic head resection: technique according to Beger, technique according to Frey and Berne modifications. *Chirurg* 2009; 80(1):22–7. TABLE 122.2 Duodenum-Preserving Pancreatic Head Resections and Their Defining Characteristics

Procedure	Duodenum Preservation	Extent of Pancreatic Head Resection (E-Extended, L-Limited)	Neck Transection	Lateral Pancreatico-jejunsotomy
Beger	+	E	+	–
Frey	+	L	–	+
Berne	+	E	–	–

The Berne modification of the Beger procedure, or "central pancreatic-head resection," was described by Markus Buchler in 2001 in an attempt to achieve the benefits of the Frey and Beger procedures while minimizing their disadvantages. The procedure essentially involves an extensive, local resection of the head of the pancreas with preservation of the duodenum. For this procedure, the pancreatic neck is not transected. The pancreatic duct is essentially marsupialized to the surrounding pancreatic tissue (the bile duct can be as well if it is opened during the procedure) and reconstruction is performed between the edges of the head remnant and a Roux limb of jejunum. Reports indicate that the procedure can be performed with minimal mortality (1%) and morbidity (16%). In our opinion, there exist few indications for this modification. Currently, the procedure is performed only in selected centers with virtually all of the literature coming from a single center in Germany.

Data comparing DPPHR with PD have been discussed. There are relatively few studies comparing the various procedures to one another. In a randomized, prospective trial of 74 patients undergoing Beger or Frey procedures, no differences were identified between the groups for the parameters of quality of life, pain control, somatic symptoms, long-term

survival or mortality, and pancreatic insufficiency. These results suggest that both procedures offer similar outcomes for the treatment of CP. In another study comparing the Beger procedure with the Berne modification, the authors found the Berne procedure was associated with decreased operating room time and hospital length of stay. There were no significant differences in quality of life 2 years following surgery, but three patients who underwent Berne procedures required reoperation for ongoing pancreatitis and/or biliary strictures. This is consistent with other studies indicating that less invasive procedures are associated with lower rates of long-term failure due to biliary obstruction.

Distal Pancreatectomy

DP with or without splenectomy is commonly performed using a variety of open and minimally invasive techniques for the management of benign and malignant lesions of the pancreas with acceptable morbidity, mortality, and outcomes. In our study of minimally invasive pancreatectomy, 23% of patients developed endocrine insufficiency. This procedure is rarely indicated for the management of CP except in the exceedingly unusual circumstance where the inflammatory changes appear to be confined to the tail of the pancreas on imaging studies. Concern for underlying malignancy is a reasonable indication as well. The clear disadvantage of distal pancreatic resection versus drainage procedures for CP is the uniformly poor successes for pain relief. In the event that a patient has survived an episode of severe necrotizing pancreatitis with complete ductal disruption, or in patients who have sustained a ductal injury after trauma such as is seen after seat-belt injuries, the “disconnected duct syndrome” may be encountered. This entity nearly always results in localized CP in the remnant pancreas toward the spleen. This can be managed with a DP/splenectomy. We have reported managing this problem with significant success utilizing a lateral pancreaticjejunostomy to the remnant duct. Importantly, there is an increased risk of pancreatic insufficiency and surgical complications with the distal resection.

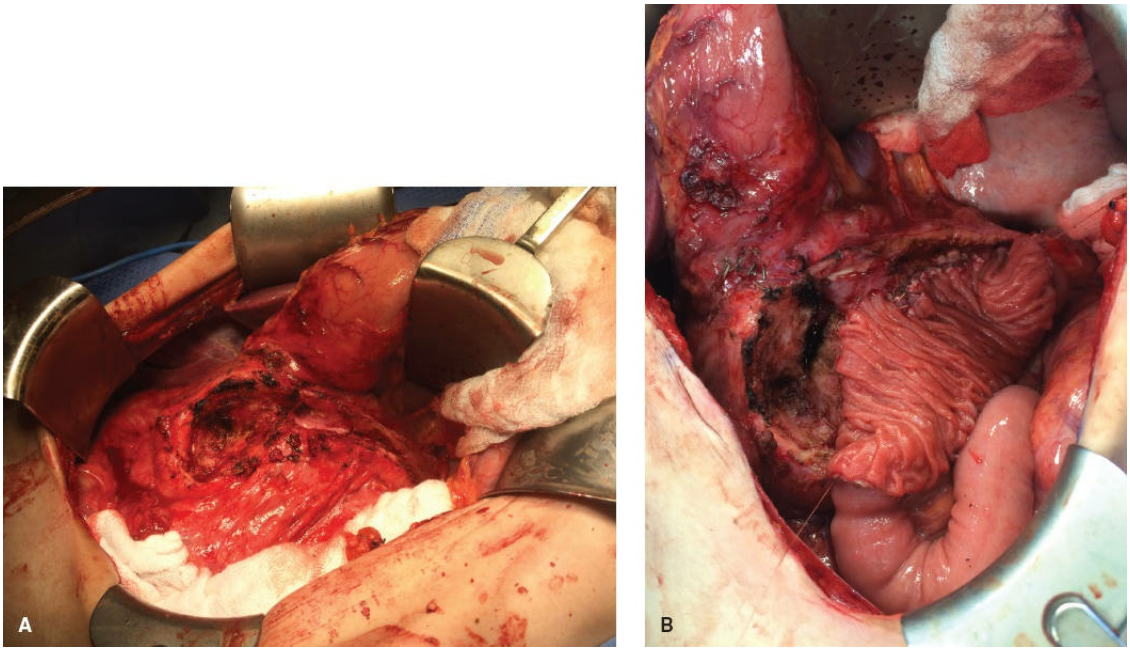

Figure 122.4. Frey procedure. **A.** Excavated pancreatic head and opened dorsal pancreatic duct. **B.** Reconstruction is performed using a single-layer, interrupted, absorbable suture.

Drainage Procedures

Drainage procedures such as the lateral pancreaticojejunostomy (LPJ or Puestow procedure) remain popular with American pancreatic surgeons. We reserve its use for patients with atrophic glands and essentially no inflammatory mass in the head of the pancreas (Fig. 122.5). The terms Puestow procedure and Partington–Rochelle are applied randomly to this procedure. Of historic note, before the more established procedures were validated, several authors examined the simple postulate that since the duct contained no valves one might solve the apparent obstructive and resulting dilatation of the duct by simply opening the duct at the ampulla or at the end of the tail. Doubollet explored the former without success and Duval promoted the latter with a small opening in the tail of the pancreas and a pancreaticojejunal anastomosis. Puestow, in our opinion, deserves credit for the longitudinal anastomosis, in spite of the fact that he essentially proposed this element in combination with Duval's tail resection. Partington–Rochelle simply excluded the tail resection for what became the LPJ as it currently exists today. For the Puestow procedure, again a generous Kocher maneuver is performed and "bi-manual" assessment of the head of the pancreas is performed. The entire pancreas is widely exposed after the gastrocolic ligament has been divided, the transverse mesocolon reflected inferiorly, and the omentum and stomach are reflected

superiorly. Often, dense adhesions can be encountered between the posterior surface of the stomach and the anterior surface of the pancreas. The inferior, allegedly avascular border of the pancreas should be mobilized so that the body and neck can be better palpated by placing the fingers posterior to the body of the pancreas and the thumb on the anterior surface of the body of the pancreas. In this manner, the duct can be palpated and an angiocatheter placed into the duct to confirm its location. Next, using electrocautery, the ductotomy is performed over the angiocath. Once entered, a tonsil clamp can assist in following the course of the duct. Incision is carried to the left toward the tail and well past the genu of the MPD into the uncinate process. It is in this location that an inflammatory mass may be encountered and the decision might be made to convert to a Frey procedure. It is common to encounter brisk bleeding as the uncinate is divided. The surgeon should be prepared with sutures for ligation if this occurs. Simple use of electrocautery for the vessels considerably raises the risk of postoperative hemorrhage. The pancreaticojejunostomy is performed in an essentially identical manner as described for the Frey procedure.

The advantage of the LPJ procedure is that it allows for adequate decompression of a dilated pancreatic duct while minimizing the morbidity, mortality, and pancreatic insufficiency associated with pancreatic resections. Ideal candidates for the procedure are patients with dilated ducts or multiple areas of stricturing and dilation throughout the length of the duct without an associated inflammatory mass in the head of the pancreas. The procedure may also be useful for patients who have obstructing intraductal stones. We have reported that duct drainage alone is sufficient in the management of pancreatic pseudocysts associated with CP. No simultaneous management of the pseudocyst is required (Fig. 122.6). It is generally taught that the procedure is neither feasible nor efficacious unless the pancreatic duct is at least 5 to 7 mm in diameter. Izbicki and colleagues have reported a series of 41 patients with “small duct” disease for whom extended drainage with “V-shaped” excavation along the length of the pancreatic duct was performed, essentially creating an LPJ in patients with small ducts (Fig. 122.7). The authors demonstrated that the procedure could be performed with no mortality and acceptable morbidity, and provided increased quality of life and decreased pain. There was a moderate incidence in diabetes (43%), although 78% of patients experienced preserved exocrine function. Postoperative imaging

demonstrated excellent drainage of pancreatic ducts in all but one patient.

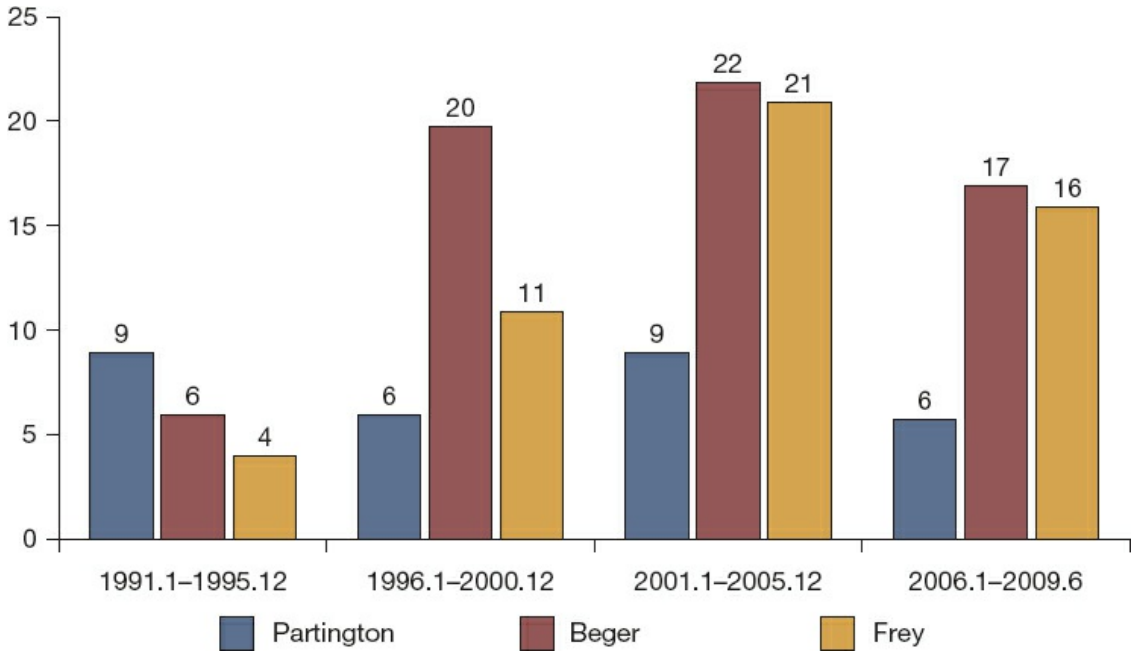

Figure 122.5. The number of studies published from January 1991 to June 2009 concerning Partington (lateral pancreaticojejunostomy or Puestow), Beger, and Frey procedures. These data suggest that pancreatic surgeons are increasingly utilizing the combined duodenum-preserving pancreatic head resections (DPPHR) while interest in pure drainage procedures appears to be waning. (Reprinted from Isaji S. Has the Partington procedure for chronic pancreatitis become a thing of the past? A review of the evidence. *J Hepatobiliary Pancreat Sci* 2010;17(6):763–9. Copyright © 2010 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

The LPJ has been shown to result in a high rate of pain relief in most patients (Table 122.3). Some have questioned the long-term durability of these outcomes. It is conceivable that some of these data are antecedent to the general acceptance of the added excavation of the head of the pancreas when a large, dominant inflammatory mass in the head of the pancreas exists. A 2007 review of American literature and a survey of members of the Pancreas Club indicated that many U.S. surgeons continue to favor the LPJ and have limited experience with any one of the excavation procedures. Preservation of endocrine function over time is a potential advantage to Puestow procedures. One of the authors has published data, including a long-term follow-up of a randomized controlled trial of operated and nonoperated CP patients that is published in the Cochrane

reviews, indicating that LPJ delays progressive loss of function when compared to nonoperated patients.

Endoscopic Interventions

Little mention has been made here of endoscopic therapies for CP, but at least one well-designed randomized prospective trial and a recent Cochrane review both demonstrated that LPJ provides superior outcomes to endoscopic therapy for patients with pain, dilated ducts, and no inflammatory mass in the head of the pancreas. Patients undergoing endoscopic therapy frequently require numerous procedures and many eventually undergo surgery after endoscopic failures.

Denervation Procedures

The rationale for performing denervation procedures is based on the theory that pain related to CP is mediated by neural changes processed through the celiac ganglia and autonomic nervous system. These procedures essentially include chemical neourolysis procedures that can be performed

percutaneously, endoscopically, or at the time of open surgery and open or thoracoscopic thoracic bilateral splanchnicectomy procedures. Chemical neurolysis is a good option for patients who are not candidates for surgical procedures and can provide good short-term pain relief, although recurrence occurs almost universally. Neurolysis may be useful to confirm that pain is related to CP in patients for whom there is a question of etiology, or as a bridge to more definitive surgery while preoperative optimization of health and compliance are being established. Thoracic splanchnicectomy is a complex procedure that has little role in the management of CP pain, although the procedure enjoyed a period of enthusiasm some 10 or more years ago.

Total Pancreatectomy With Islet Cell Autotransplantation (TPIAT)

Total pancreatectomy has traditionally been considered to be an almost prohibitive surgery due to considerable problems with postoperative pancreatic insufficiency, particularly brittle diabetes, and has been generally reserved as a remedial operation in cases where other procedures have failed. In order to minimize problems with postoperative endocrine insufficiency and preserve endocrine function, the procedure of total pancreatectomy with islet cell autologous transplantation (TPIAT) was initially developed in 1977. Only 140 of these procedures were performed worldwide until 2001, but several centers developed a renewed interest in the procedure in the early 2000s and relatively large series of reported

results have emerged in the literature.

The procedure essentially involves performing a total pancreatectomy, including resection of the duodenum, distal bile duct, and spleen (Fig. 122.8). Pylorus-preservation is generally preferred and reconstruction is performed with a hand-sewn choledochojejunostomy and an antecolic duodenojejunostomy. Care is taken to preserve the arterial blood supply (gastroduodenal artery and splenic artery) for as long as possible during the procedure in order to minimize islet cell ischemia. In “true” CP one will encounter considerable dense inflammatory adhesions with at times intimate adhesion to the portal vein-SMV juncture as well as the splenic vein, splenic artery, hepatic artery, and superior mesenteric artery. We apply the term “true” in describing CP in discussing this literature because, as previously mentioned, essentially all major reports on TPIAT are composed of a markedly atypical patient population and includes diagnoses, such as “minimal change CP,” which we believe have no place in the analysis of conventional CP.

Care is taken to preserve the arterial blood supply (gastroduodenal artery and splenic artery) for as long as possible during the procedure in order to minimize islet cell ischemia. Some surgeons will divide the pancreas prior to completing the resection of the head and hand off the specimen for islet cell harvesting in order to minimize harvesting time, although this could potentially decrease islet cell yield. For cases in which prior CP surgery has been performed, there may be additional challenges to dissection. The reconstruction is performed while islet cell harvesting is performed. Following this, the abdomen is closed temporarily and the patient remains under general anesthesia.

Figure 122.8. **A.** Surgical field following resection of the specimen for total pancreatectomy and islet cell autotransplantation (TPIAT). **B.** Resected specimen on the back

table.

For the islet cell harvesting, the pancreatic duct is cannulated with an IV angiocath through which a collagenase solution is infused (Fig. 122.9A). The specimen is brought to a certified laboratory for the remainder of the harvesting. Mechanical and chemical digestion of the pancreas is performed in a Ricordi chamber containing stainless steel ball bearings (Fig. 122.9B). Samples are periodically collected and observed with dithizone staining. When the islet cell yield appears to be suitable, the digestion is terminated with cold University of Wisconsin transplant solution. The chamber is emptied and digested tissue is washed away. At this point, all that remains is an islet cell pellet that is resuspended in 5% albumin with heparin (Fig. 122.9C and D). At this point, the abdomen is reopened and the islet cell suspension is infused directly into the portal vein under gravity pressure (Fig. 122.9E). Once the islet cell transplantation procedure has been completed, the catheter is removed from the portal vein, drains are placed, and the abdomen is closed. The patient should be maintained on an insulin drip in order to tightly control postoperative blood sugars as hyperglycemia has been shown to inhibit islet cell establishment and growth within the hepatic parenchyma. Daily insulin and C-peptide levels can be measured and there is usually evidence of insulin production in the early postoperative period. Close collaboration with a dedicated team of endocrinologists is strongly encouraged during all phases of the perioperative period. All patients will require some insulin administration following surgery.

TPIAT can be performed safely in experienced hands. Outcomes are modest at best. Considering that the classic CP patient is alcoholic, at least in the past, and also likely chronically narcotic dependent, we would argue that this population is immensely challenged by adding potentially brittle diabetes to their medical issues. Some of this reality is undoubtedly mitigated by the fact that the standard population to whom this operation is offered is not made up of a majority of ethanol abusers, as is seen in every report on the conventional operations for CP. Insulin dependence is seen in 60% to 70% of patients after TPIAT and narcotic dependence exceeds 60% in nearly all series in spite of the absence of all pancreatic tissue. The authors of many of these papers have presented creative metrics. For the question of the presence or absence of viable islet cells, they measure C-peptide which certainly confirms the presence of insulin production, but

does not equate to insulin independence. For their successes in pain relief, they rely upon a metric known as Morphine Equivalents. The patient remains narcotic dependent but may require fewer morphine equivalents. The reports on operative complications for TPIAT must again be viewed through the prism of this highly selected population. Considering that many of their patients lack the dense fibrosis seen in classic CP, it would be anticipated that their rate of complications should be lower than is seen after conventional surgeries for CP. Average blood loss for TPIAT is 635 mL with operating times of about 9 hours and hospital length of stay of 15 days. This is considerably more than results for conventional procedures and appears primarily to be related to nutritional and endocrine issues. Complications can occur in 68% of patients, although most are not life threatening.

Although there are many strong proponents of the TPIAT, we have mixed feelings. We would strongly advocate for separating the two categories of patients. As previously explained, the diagnosis of “Minimal Change CP” has no place in the discussion of classic CP. These are distinctly different clinical entities. They likely represent recurrent acute pancreatitis (RAP). We readily admit that we see few viable operative interventions for this diagnosis (RAP), and in that setting, we may recommend this procedure. We particularly admonish against the urging by advocates for TPIAT that conventional CP procedures be avoided. This is based upon the perspective of decades of strong evidence to favor their use when compared to the modest successes reported for TPIAT. Again, the utilization of this operation for the nonclassic CP patients may be warranted. The two diagnoses need to be evaluated separately. Good results have been reported for patients with hereditary pancreatitis for whom CP fibrosis is uncommon. Islet yields are considerably better in that setting. Again, this represents a different cohort compared to classic CP. In the case of classic CP there may be a role for TPIAT as a salvage procedure for patients who have undergone unsuccessful previous surgery for CP. Patients must have preserved endocrine function and this is generally evaluated preoperatively by insulin response to glucose tolerance testing or a mixed-meal challenge.

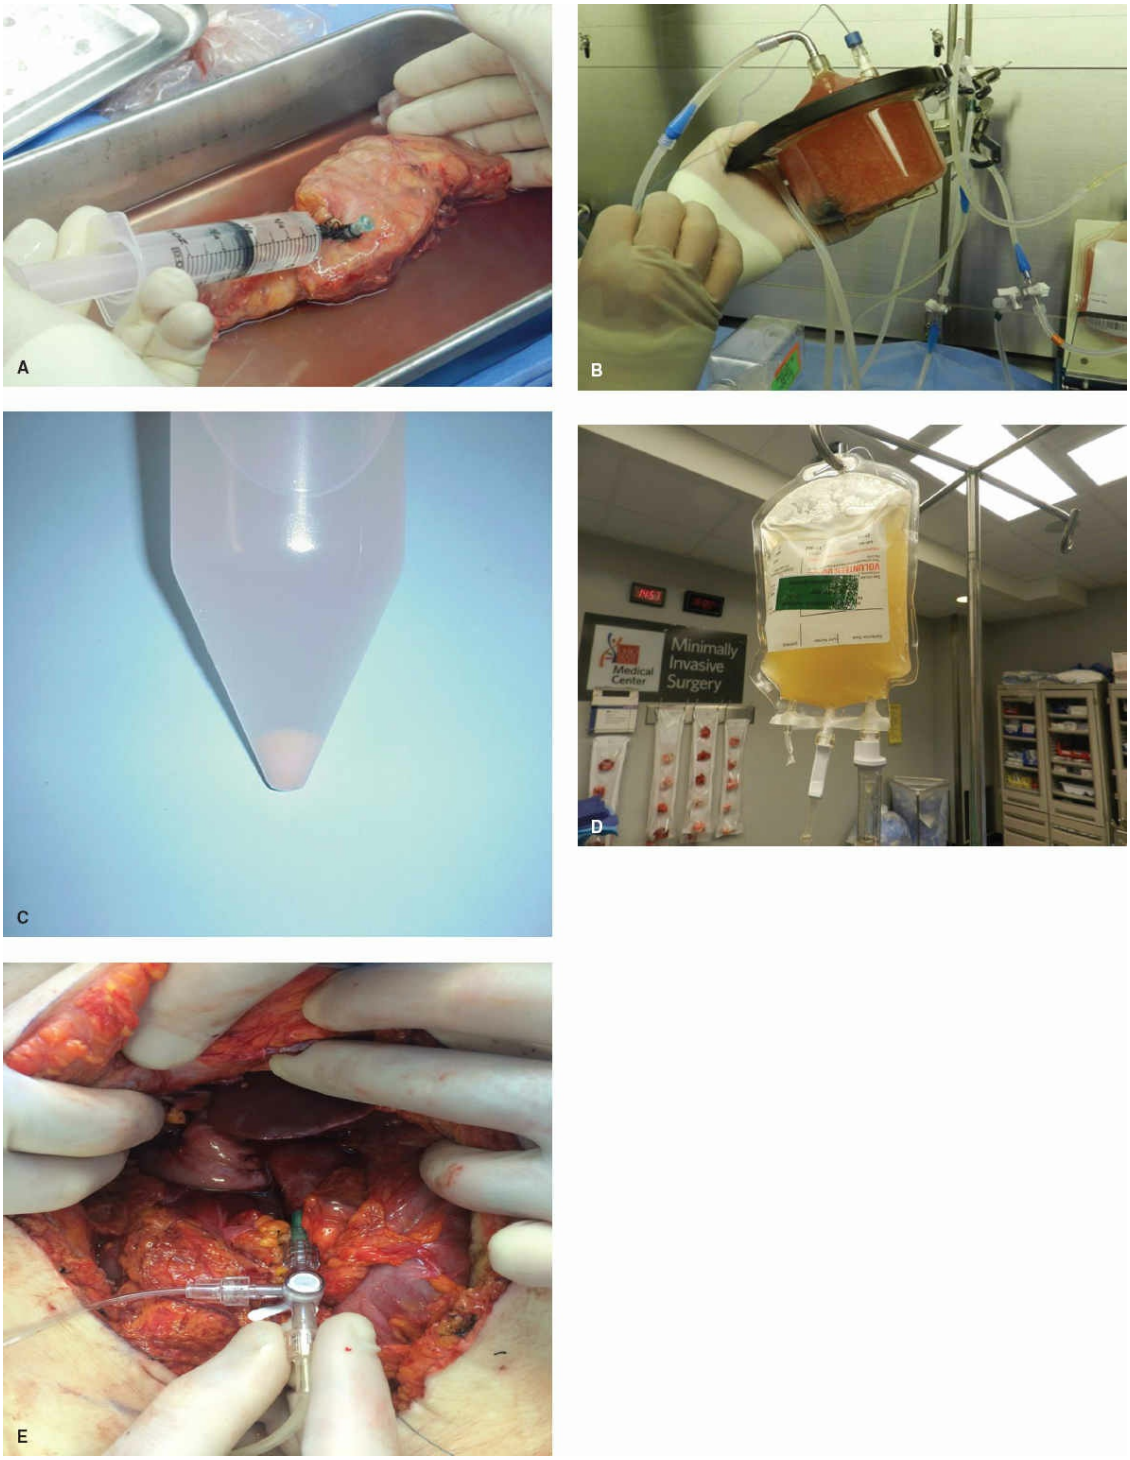

Figure 122.9. (**A**) Prior to islet cell harvesting for TPIAT, the pancreatic duct is cannulated with an angiocatheter and infused with collagenase solution. (**B**) Mechanical and chemical digestion of the pancreas is performed in a Ricordi chamber containing stainless steel ball bearings. (**C**) Following extraction, the islet cell pellet is resuspended in (**D**) heparinized 5% albumin. (**E**) Direct islet cell infusion into the portal vein.

CONCLUSIONS

There are a variety of procedures that have been described for the management of CP and selection of procedure depends on patient- and surgeon-related factors such as imaging findings and surgical experience. Appropriate patient selection is crucial for good outcomes following surgery for CP. The goals of most procedures should be to improve pain control and quality of life while maximizing preservation of organ function, although some procedures are performed for complications of CP and suspicion of malignancy. Patients should demonstrate commitment to their care and surgeons and patients should be aligned regarding goals of surgery. These should be clearly established prior to undertaking any procedure. Patient noncompliance can be an indication for forsaking surgical options or even terminating the patient–physician relationship. Current data support performing what we have termed the excavation of the head of the pancreas (Beger, Frey, Berne). Be reminded that these represent modifications of the traditional procedures of resection (PD) and drainage (Puestow). In the end, each of these procedures are quite similar. As a consequence of lack of experience on the part of most nonpancreatic specialists, one should consider either resorting to the traditional techniques or referral to experienced surgeons in dedicated centers.

EDITOR'S COMMENT

The authors present an excellent review of the diagnosis and classification of chronic pancreatitis as well as the selection of various procedures for treatment. At the outset, I think the surgeon should understand that the treatment of chronic pancreatitis is multidisciplinary and ideally should involve gastroenterology, behavioral medicine and primary care, pain management, nutrition services as well as the surgeon. The comments of the authors are pertinent in the emphasis of the psychosocial implications of this disease that interface with every aspect of treatment. My commentary will focus on the practical aspects of the selection of surgical treatments for chronic pancreatitis.

The worldwide incidence of chronic pancreatitis (CP) ranges from 1.6 to 23 cases per 100,000 population per year. In the United States, CP results in more than 120,000 ambulatory visits and more than 56,000 hospitalizations annually. Some studies state that the global incidence of CP is between 2 and 200 per 100,000 persons and has been increasing year over year (Garg PK, Tandon RK. Survey on chronic pancreatitis in the Asia-Pacific region. *J Gastroenterol Hepatol* 2004;19:998–1004). In this report, India had the highest incidence of CP in the world at approximately 114 to 200 per 100,000 persons and the incidence of CP in China was approximately 13 per 100,000 persons. The annual incidence in France is about 7.8/100,000. Abdominal pain is the presenting symptom in more than 90% of patients with CP. Interestingly, the mechanism of abdominal pain is still not clear. It is generally accepted that pancreatic duct hypertension, pancreatic inflammation, and peripancreatic immune cell infiltration play an important role in the causation of the abdominal pain. In addition, at initial presentation there may be varying degrees of

exocrine and endocrine insufficiency. Surgical procedures designed to alleviate pain rarely if ever alter the natural progression of CP. If not initially present these conditions will develop during the progression of the disease. In my experience exocrine insufficiency usually predates the development of diabetes which usually is apparent about 10 years into the disease process. Although most cases are caused by excessive alcohol use there is increasing awareness that tobacco use may be a catalyst leading to CP. Some cases related to autoimmune pancreatitis or hereditary pancreatitis. The disease may be classified in phases. The early phase 1 to 5 years is characterized by acute pancreatitis episodes, pain and hospitalization. The middle phase occurs from 5 to 10 years. During this time acute symptoms are reduced, but morphologic changes of the pancreas lead to the formation of strictures of the bile and pancreatic duct and pseudocysts as well as chronic pain and the development of early pancreatic insufficiency. The late phase is beyond 10 years with worsening exocrine insufficiency and development of diabetes.

The median survival in CP is about 15 years. The death rate of patients is estimated as: 15% at 5 years, 34% at 10 years, 48% at 15 years, 62% at 20 years, 72% at 25 years, and 76% at 30 years (Levy P, Domínguez-Muñoz E, Imrie C, et al. *United European Gastroenterol J* 2014;5:345–54). In many studies that look at survival in CP, death was due to extrapancreatic consequences of alcohol, and tobacco over use such as lung or esophageal cancer, cirrhosis of the liver, or myocardial infarction.

It is well established that CP cannot be completely cured. The purpose of surgical therapy for CP is to relieve symptoms, especially pain; to improve the patient's quality of life; and to treat complications. In is generally known there seems to be a significant correlation between the severity of abdominal pain and the extent of intrapancreatic neural damage. Even though the mechanisms of pain have not been fully elucidated, accumulating evidence point to a process of neural inflammatory cell infiltration. This is hypothesized to lead to pancreatic neuritis eventually resulting in the formation of a dense neural network of nerve connections within the pancreas. Pain management strategies include the intake of pancreatic enzyme supplements, cessation of alcohol intake and smoking, and analgesic therapy. In case of persistence of symptoms or suspicion of pancreatic cancer, surgical procedures come into play. Decompression (drainage), resection, neuroablation, and decompression combined with resection are commonly used methods for the surgical treatment of CP. The methods of decompression and surgical resection are reviewed below.

The role of various imaging techniques is reviewed very nicely by the authors. As they point out there is little role for ERCP in establishing the diagnosis. Instead MRI is the preferred technique of diagnosing CP followed by CT and US. MRCP will demonstrate ductal dilation and pancreatic masses. The MRI is usually sufficient to detail the abnormal anatomy and aid the surgeon in planning an operation. If there is a mass it should be biopsied by EUS.

One major controversial issue about the treatment of painful obstructive CP

is whether surgical therapy is superior to endotherapy. Endoscopic treatment may involve sphincterotomy, stenting or stone removal. Prospective studies have shown that short-term pain relief is equivalent in endoscopic and surgical procedures. However, after 3 to 5 years after surgery is found to be superior in long-term pain reduction and weight gain. In order to analyze this issue, Díte et al. Additional studies have shown that nearly 50% of patients who undergo endoscopic treatment will eventually require surgery. Following chapters will review specific surgical procedures and outcomes.

The authors briefly comment on ablative techniques. In the past, there was some interest in thoracic sympathectomy. This has not gained wide support. Percutaneous celiac blocks are of variable effectiveness. These techniques have been replaced by blocks performed by endoscopic ultrasound. The results are satisfactory but require repeat treatment as the longevity of the treatment is not substantial.

My final comment is on minimal change chronic pancreatitis. This entity was first described by Walsh et al. (Minimal change chronic pancreatitis. *Gut* 1992:33:1566–71). They reported 16 cases. Partial resection was performed in 12 and 8 required total pancreatectomy. The histology of resected specimens showed chronic inflammatory changes accompanied by subtle noninflammatory changes in all but one. This is sometimes referred to as image negative chronic pancreatitis or noncalcific pancreatitis. EUS once thought to be of value in the diagnosis of this entity has recently been challenged by studies showing that patients without EUS criteria of CP had on histology fibrosis, atrophy, and inflammation. Medical treatment has generally poor results. The recent trend is to recommend total pancreatectomy and islet autotransplantation for this disease. The initial results seem promising but I advise caution before recommending this to your patients. As the authors note many of the pancreata have a normal histology. The long-term viability of the islet auto transplant is not fully established. In the end, the patient may be trading one disease for another that may be worse. My advice is proceed cautiously!

E. Christopher Ellison

123 Operative Interventions for Chronic Pancreatitis

Keith D. Lillemoe and Chad G. Ball

INDICATIONS FOR OPERATIVE INTERVENTION

Achieving effective treatment for patients with severe complications of chronic pancreatitis is one of the most difficult challenges in surgery. The essence of this disease process is the progressive destruction of the pancreatic parenchyma and its replacement with fibrotic tissue. Over time this often leads to both endocrine and exocrine insufficiencies. Irrespective of etiology (ethanol abuse; hypercalcemia; hyperlipidemia; certain medications; cationic trypsinogen mutation [PRSS1], pancreatic secretory trypsin inhibitor [SPINK1], and chymotrypsinogen C [CTRC] genes; cystic fibrosis; autoimmune disease; prior severe acute pancreatitis with necrosis; pancreatic ductal obstruction from developmental abnormalities [pancreas divisum]; sphincter of Oddi dysfunction; or obstruction from trauma or neoplasm), pancreatitis is also a disease that displays a notably worse actuarial survival compared to age-matched controls. The most significant complications associated with chronic pancreatitis are pain (50% at 15 years), diabetes (75% at 15 years), and exocrine insufficiency (80% at 15 years). Operative procedures to treat chronic pancreatitis, regardless of type, are classically indicated for specific symptoms including: (a) intractable pain (60%), (b) biliary obstruction (<5%), (c) duodenal stenosis (<5%), and (d) the need to exclude a diagnosis of malignancy (30%). Less common indications include: (a) bleeding, (b) complicated pseudocyst or walled off pancreatic necrosum, and (c) sinistral hypertension. In summary, chronic pancreatitis becomes an operative disease only when there is a need to treat complications of the underlying pathology.

Although intractable pain represents the most common indication for operative intervention, the precise etiology of this discomfort remains unclear. Popular theories defining the origin of pain include (a) ductal hypertension, (b) parenchymal hypertension, and (c) neural inflammation

among the primary afferent neurons. The neuronal theory holds particular weight given the dramatic increase in both the number and the size of nerves found within the gland in patients suffering from chronic pancreatitis.

Despite the above-mentioned operative indications, it is crucial to recognize that chronic pancreatitis is often a direct consequence of complex and long-standing social factors. More specifically, the surgeon must address the overall psychology of the patient, their ability to follow a treatment plan that includes abstinence from alcohol, cessation of smoking, as well as a commitment to engage in physician-guided weaning of narcotics after the operative procedure. Without this thorough evaluation on the part of the surgeon, and commitment on the part of the patient, a significant percentage of patients who undergo operative procedures will fail to achieve a successful therapy. This philosophy can be extended to all causes of chronic pancreatitis in that the underlying etiology must always be eliminated. As an example, if a patient continues to consume alcohol following an operation that results in insulin-dependent diabetes, the chances of life-threatening complications are substantial.

The technical armamentarium of the pancreatic surgeon currently includes both duodenal-preserving and drainage procedures (Frey, Beger, Puestow, Duval), as well as formal resection interventions (distal pancreatectomy, pancreaticoduodenectomy, total pancreatectomy +/− islet cell autotransplantation). The selection of one technique over another should be based on the primary location of disease (head versus body/tail), the size of the pancreatic duct, and the presence of a stricture of the bile duct and/or duodenum (and finally the potential risk of cancer in a new lesion). The use of these various operative interventions in the modern era also reflect a shift in the indications paradigm from parenchymal-based (1950s to 1980s), to duct size–based (1980s to 1990s), to resection and drainage-based (current) philosophies. In cases selected for a pancreaticoduodenectomy, the vast majority of the pancreatic inflammatory process should be located in the head of the gland. This view is particularly important for those who believe that the epicenter of inflammation, and therefore the “pacemaker” of intractable pain, is located in the head of the gland. Additional advantages of this procedure include concurrent decompression of a bile duct and/or duodenal stenosis, as well as the ability to safely perform a reconstruction in the presence of a small

pancreatic duct. Finally, pancreaticoduodenectomy is the appropriate "cancer operation" should consideration of the malignancy be part of the differential diagnosis.

It is interesting to note that multiple studies evaluating pancreatic duct size and pressure measurements have failed to consistently demonstrate a direct relationship between duct abnormalities and pain scores. In addition, significant numbers of chronic pancreatitis patients have essentially normal size pancreatic ducts (so-called "small-duct" or "minimal-change" chronic pancreatitis) but have significant pain. This can even occur early in the course of their disease. Furthermore, studies evaluating total pancreatectomy with islet cell autotransplant have shown that even this dramatic procedure fails to relieve pain in all patients, implying that more than simple mechanical mechanisms are at work in chronic pancreatitis.

Traditional dogma indicates that patients with chronic pancreatitis should experience pancreatic "burn out" (i.e., resolution of epigastric pain) with the long-term avoidance of surgery and intervention. This hypothesis is clearly incorrect given that patients randomized between medical and surgical interventions had significantly less pain over the ensuing 10 years of follow-up if they underwent surgery. A recent randomized trial also compared endoscopic with surgical interventions for chronic pancreatitis. This study was stopped early due to clear superiority at the interim analysis within the surgical arm.

In summary, the surgeon's choice of specific operative intervention for patients with chronic pancreatitis is reliant upon a strong understanding of the limitations and benefits of each procedure. This chapter will continue to discuss each common option.

PREOPERATIVE EVALUATION

Patients with chronic pancreatitis can present with a wide variety of clinical symptoms. The most common hallmark however, is chronic epigastric pain that is nonremitting in nature and radiates through to the back. Although the intensity of this symptom can be extreme, the correlation between radiologic changes reflecting long-term pancreatic damage and the intensity of the pain itself are often not well aligned. Not surprisingly, many of these patients arrive for assessment with a long history of chronic narcotic use/dependence. Of course, these patients can also present with complications of their endocrine and exocrine malfunction as well.

In addition to a thorough history and assessment of a patient's social risk factors, preoperative evaluation is heavily dependent on the use of modern diagnostic imaging. Options include, but are not limited to, contrast-enhanced computed tomography (CT), magnetic resonance cholangiopancreatography (MRCP), endoscopic ultrasound (EUS), endoscopic retrograde cholangiopancreatography (ERCP), and contrast-enhanced ultrasound (CEUS). Each technique offers varying degrees of information on both the pancreatic duct and the gland itself. The appropriate selection of these diagnostic techniques is crucial in both determining whether the extent of disease is appropriate for surgical management and also in guiding the choice of the most appropriate operative procedure for each individual patient based on ductal anatomy and gland morphology. A triple-phase intravenous contrast helical CT (fine-cut pancreas protocol) is typically the initial noninvasive imaging test for pancreatic disease. Helical CT displays the anatomy of the pancreas gland in considerable detail. It can also easily define pancreatic calcifications, inflammation, necrosis, atrophy, and masses. MRCP can be quite useful for noninvasively defining the anatomy and pathology of both the bile ducts and the pancreatic duct. MRCP can be especially helpful in the cases where the ampulla of Vater is not accessible (i.e., the patients who have previously undergone Roux-en-Y or Billroth II reconstructions). Specific EUS criteria exist to define parenchymal (echogenic strands, hyperechoic foci, calcifications, lobular contour, cysts) and ductal (wall hyperechogenicity, irregular duct wall, visible side branches, strictures, stones) disease, but technique is highly operator dependent. It also allows a biopsy for a potentially concerning discrete lesion as well. CEUS can be particularly helpful in identifying the "stiffness" of the pancreas gland. Finally, ERCP provides direct imaging of the pancreatic and bile ducts and is the gold standard for diagnosing chronic pancreatitis. ERCP also allows therapeutic stenting of biliary and pancreatic duct strictures both as temporary measures for short-term management or definitive treatment.

SURGICAL TECHNIQUE—OVERVIEW

Pancreaticoduodenectomy (Pylorus-Preserving)

Resection of the pancreatic head in the setting of chronic pancreatitis can be accomplished by means of either a pylorus-preserving pancreaticoduodenectomy (PPPD; Fig. 123.1) or the classic Whipple resection (including an antrectomy). Multiple randomized trials have failed

to show any significant differences between the two procedures in terms of either relative ease of performance or short- or long-term outcome in the patients with pancreatic cancer. As a result, the choice between procedures for either chronic pancreatitis or cancer is usually made on the basis of individual surgeons' preferences. Our preference is typically the pylorus-preserving modification. Preoperative mechanical bowel preparations are optional. Antibiotics directed at enteric bacteria are administered at induction of anesthesia. Antibiotic consideration must also account for the patients who have had biliary or pancreatic duct stents. Wound protectors are recommended to reduce the incidence of surgical site infections.

The peritoneal cavity is entered through an upper midline. The round ligament is divided at the liver and the portion between the liver and the umbilicus is excised. A fixed abdominal wall retractor system of the surgeon's choice is engaged after a wound protector is placed. Especially in the cases where a malignancy must be ruled out, the liver, the omentum, and the peritoneal surfaces are inspected and palpated. Any suspicious lesions are biopsied and submitted for frozen-section analysis.

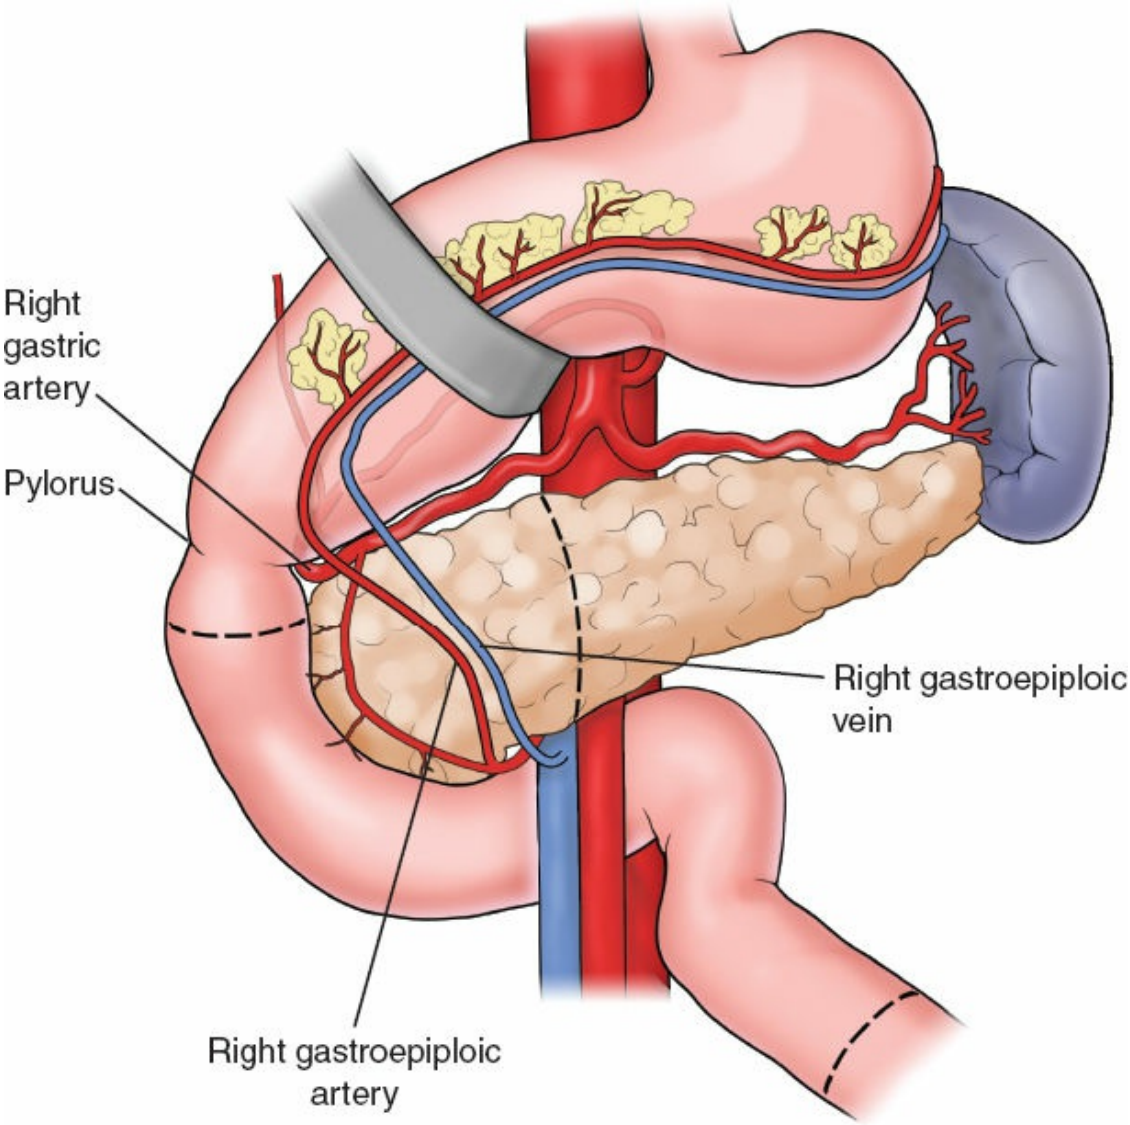

Figure 123.1. The areas to be resected with the pylorus-preserving pancreaticoduodenectomy are depicted: Head of pancreas, duodenum (parts 2, 3, and 4), and segment of proximal jejunum. The entire head of the gland is removed. The right gastroepiploic vessels are divided near their origins. The right gastric artery is divided away from the stomach near its origin. This allows the neurovascular supply of the antrum and pylorus to be preserved and may minimize the incidence of delayed gastric emptying.

Operative assessment begins with a wide Kocher maneuver and mobilization of the duodenum and the head of the pancreas from the underlying inferior vena cava and aorta. When the duodenum and head of the pancreas have been mobilized sufficiently, a hand is placed under the duodenum and the head of the pancreas to palpate the local anatomy. The lesser sac is then opened widely by incising the lesser omentum and by

removing the entire greater omentum off the transverse colon. Every attempt is made to preserve the greater omentum. The hepatic flexure of the colon is also mobilized and retracted downward out of the operative field early in the operative procedure.

Our preference is to dissect the superior mesenteric vein (SMV) and portal vein as an initial step. The inflammatory response associated with chronic pancreatitis can be considerable making this dissection somewhat tedious; therefore, early control is important if bleeding is encountered at any point in the case. Identification of the portal vein is greatly simplified if the common hepatic duct is divided early in the dissection. Once the hepatic duct has been divided, the anterior surface of the portal vein is easily and quickly identified. The lymph node tissue lateral to the hepatic duct and the portal vein should be dissected off the structures to be included in the surgical specimen. This is somewhat less important in cases of chronic pancreatitis where a malignancy is not the primary concern. It must be remembered that important variations in the hepatic arterial anatomy, including a replaced right hepatic artery, may be encountered during this dissection. If the appropriate plane is found along the anterior surface of the portal vein, it is often possible to pass the index finger of the left hand on top of the vessel posterior to the first portion of the duodenum and the neck of the pancreas (because usually there are no veins joining the anterior surface of the portal vein). If this maneuver proves difficult, which is not uncommon in cases of chronic pancreatitis because of adherence of the fibrotic pancreas gland to the SMV and portal vein, the gastroduodenal artery should be identified where it originates from the common hepatic artery. Once adequate dissection has been carried out, the artery should first be clamped with a nonoccluding vascular clamp; then, if the hepatic artery pulse is preserved, divided, and ligated with 2-0 silk ties. (The initial clamping of the gastroduodenal artery with a vascular clamp confirms that the arterial supply to the liver will not be interrupted should either variations in hepatic arterial anatomy or important collateral circulation be present in the face of celiac artery stenosis.) After the artery has been divided and ligated, an additional ligature of 3-0 polypropylene should be placed on the proximal stump. Division of the gastroduodenal artery unroofs part of the tunnel through which the index finger is slipped, thereby greatly facilitating the separation of the portal vein from the posterior aspect of the first portion of the duodenum and the neck of the pancreas. It should be re-emphasized that

severe inflammation and/or scarring around the portal vein mandates extensive caution and precision when dissecting around the portal vein. Portal vein injuries can be catastrophic due to an inability to quickly expose the underlying venous injury in the context of a hard inflamed pancreatic gland.

Once the anterior surface of the portal vein has been dissected posterior to the neck of the pancreas, the next step is to identify the SMV and dissect its anterior surface. This is most easily accomplished by extending the Kocher maneuver past the second portion of the duodenum to include the third and fourth portions. During this extensive kocherization, the first structure encountered anterior to the third portion of the duodenum is the SMV. The anterior surface of the vein can then be cleaned and dissected under direct vision by retracting the neck of the pancreas anteriorly. This dissection is continued until it connects to the portal vein dissection from above.

In a PPPD, the duodenum is first mobilized and divided ~2 cm distal to the pylorus with a gastrointestinal anastomosis (GIA) stapler. The posterior surface of the proximal first portion of the duodenum is dissected until the lesser sac is entered. At this point, the soft tissue attachments from the inferior border of the duodenum to the inferior border of the pancreas are divided. The right gastroepiploic vessels, which can be sizable, are clamped, divided, and ligated. In a similar fashion, the soft tissue areolar attachments found superiorly are divided with the electrocautery. The right gastric artery, which originates from the common hepatic artery, is also ligated.

In a classic Whipple procedure, an antrectomy is performed. The right gastroepiploic arcade and the right gastric vessels are divided to permit mobilization of the antrum. The stomach is then divided with a GIA stapler, usually at the level of the incisura. At this point, if the gastroduodenal artery was not divided earlier, it is identified, divided, and ligated as described (see above). During this step, particular care must be taken to ensure that the lumen of the common hepatic artery is not encroached on by one of the proximal ties.

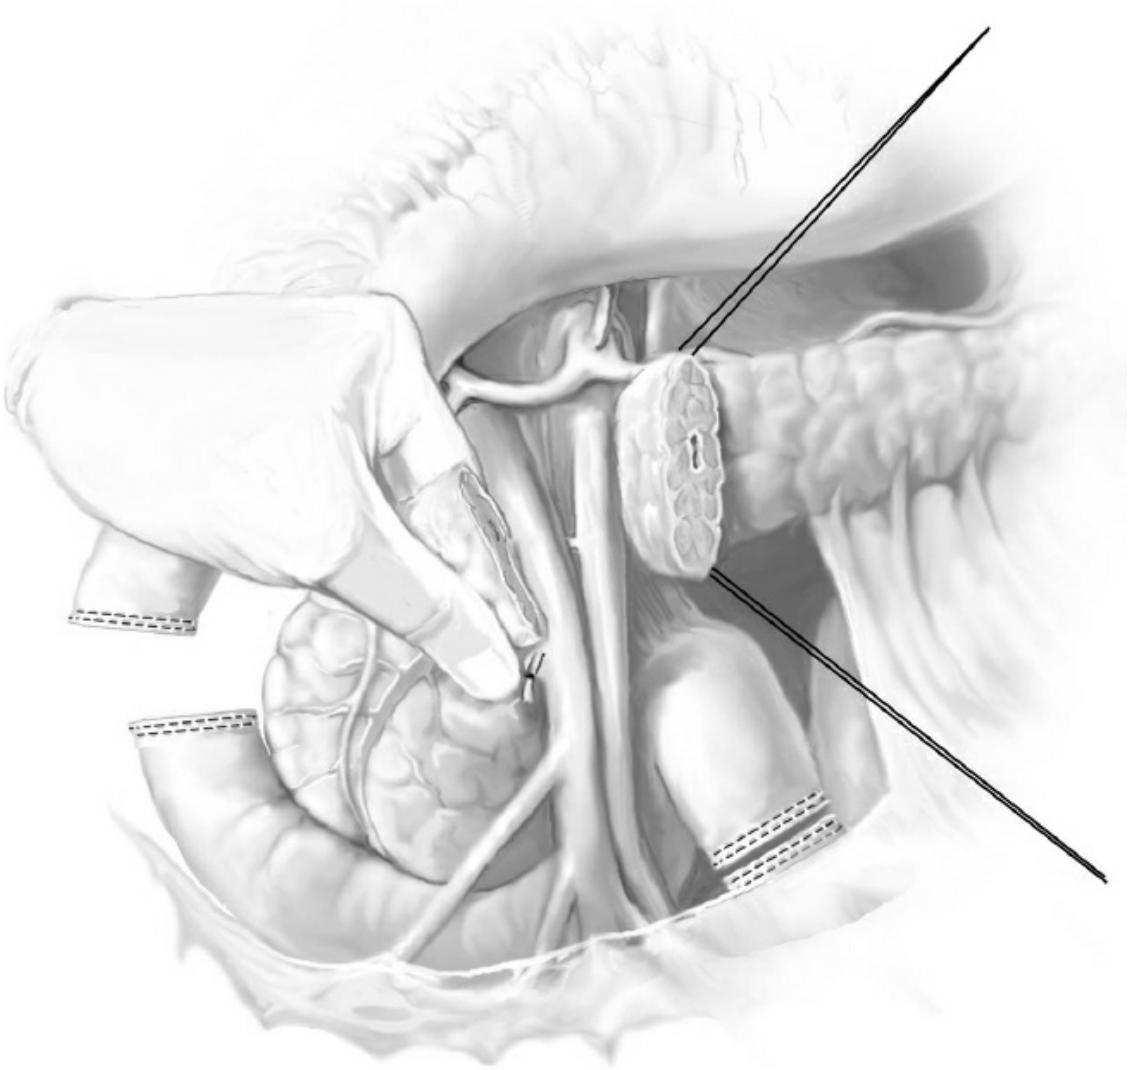

Figure 123.2. Hand compression of the specimen is used to control blood loss while the retroperitoneal attachments of the dorsal medial pancreatic head and uncinate process are divided from the superior mesenteric artery. The surgeon on the left side of the patient places his or her left hand on the stout lymph node—laden mesentery attaching the dorsal head and uncinate process to the SMA area. As this "mesentery" is sequentially divided from cephalad to caudad along the SMA, the hand pressure controls bleeding from the specimen and the clamps control bleeding from the SMA side.

The neck of the pancreas is then divided with the electrocautery, with care taken not to injure the underlying SMV and portal vein. The head of the gland is then reflected to the right and head and the uncinate process of the pancreas is dissected away from the portal vein and SMV. In the patients with chronic pancreatitis, this dissection can again be difficult because of adherence between the fibrotic gland and the SMV. Great

caution must be taken for all dissection around the SMV and portal vein to prevent a major vascular injury and subsequent hemorrhage. If a replaced right hepatic artery is present, its origin from the superior mesenteric artery (SMA) will be encountered at this point and must be preserved. The uncinate process can then be divided between clamps flush with the SMA, then ligated with 2-0 silk ties; alternatively, either an energy-based vessel-sealing system or ultrasonic shears may be used. The SMA is completely exposed during this dissection, which proceeds from cephalad to caudad, as shown in Figure 123.2. Unlike PPPD for cancer, the extent of this dissection, and therefore the inclusion of the lymphatic tissue adjacent to the SMA, is less critical in the patients with chronic pancreatitis. As a rule, there are two large veins joining the SMV inferiorly that must be dissected free, doubly ligated, and divided. The first jejunal branch can often be spared via cautious dissection.

Once the uncinate process has been completely divided, the specimen is attached only by the third portion of the duodenum. At this point, the upper abdomen is copiously irrigated with an antibiotic solution, inspected for hemostasis, and packed. The transverse colon, along with the greater omentum, is reflected cephalad. The proximal jejunum and the ligament of Treitz, along with the fourth portion of the duodenum, are dissected free, and the dissection is continued until it meets the right-side upper abdominal dissection. A hand-held energy device is often the most efficient method of achieving this mobilization. At a convenient point where there is a wide vascular arcade, the proximal jejunum is divided with a GIA stapler ~10 to 12 cm distal to the ligament of Treitz. The proximal jejunum is then grasped with a Babcock clamp and retracted cephalad. The mesentery to the proximal jejunum is divided between clamps and ligated with 2-0 silk suture (or divided with a vessel-sealing energy device). Alternatively, dividing the jejunum early, before dividing the uncinate process, can help with retraction and exposure especially in the face of local inflammation.

When division of the mesentery is complete, the specimen is free and can be removed from the operative field. The bile duct, the pancreatic neck, and the uncinate margins should be tagged. If there is any concern for malignancy, frozen-section analysis of all margins should be completed before reconstruction. The pancreatic bed should be carefully inspected for hemostasis.

If there is concern regarding the ductal system in the pancreatic

remnant, the residual duct can be interrogated via a probe, and/or imaged by intraoperative sonography or less commonly a fluoroscopic pancreatogram. This ensures complete main duct decompression. A partial longitudinal incision and lateral pancreaticojejunostomy to the body and tail may be indicated if there are significant chain-of-lake strictures seen on ductal evaluation, as displayed in Figure 123.3.

There are several technical options for restoring GI continuity after a pancreaticoduodenal resection. Our preferred technique is to bring the end of the divided jejunum through the transverse mesocolon to the right of the middle colic vessels in a retrocolic fashion and to perform an end-to-side pancreaticojejunostomy, as indicated in Figure 123.4. A row of interrupted 3-0 silk Lembert sutures is placed between the side of the jejunum and the posterior capsule of the end of the pancreas. A small enterotomy, matching the size of the pancreatic duct, is made in the jejunum, and an inner layer of interrupted 5-0 absorbable monofilament sutures is placed to create a duct-to-mucosa anastomosis, as displayed in Figure 123.5. Meticulous stitch placement is crucial, and many surgeons use some degree of magnification to complete the anastomosis in small ducts. Optional placement of a pediatric feeding tube (either externalized or cut short) positioned across the anastomosis should be considered as a temporary indwelling stent. This stent can be particularly helpful in constructing the anastomosis itself. The anastomosis is completed with an outer layer of 3-0 or 4-0 Lembert sutures placed between the anterior pancreatic capsule and the jejunum. This layer should be completed in a fashion to invaginate the gland into the seromuscular layer of the bowel. A popular alternative to this duct-to-mucosa technique is to create an enterotomy approximately the same size as the pancreatic neck and to place an inner continuous layer of 3-0 absorbable synthetic suture material circumferentially around the entire gland. (The pancreatic duct can be incorporated into the running suture line either posteriorly or both anteriorly and posteriorly.) The neck is then invaginated 1 to 2 cm into the lumen of the bowel, and an outer interrupted layer of 3-0 silk is placed to complete the anastomosis. The biliary-enteric anastomosis is performed 6 to 10 cm distal to the pancreaticojejunostomy. An end-to-side hepaticojejunostomy is fashioned with a single interrupted layer of 4-0 absorbable synthetic suture material. Generally, there is no need for a T-tube or a stent.

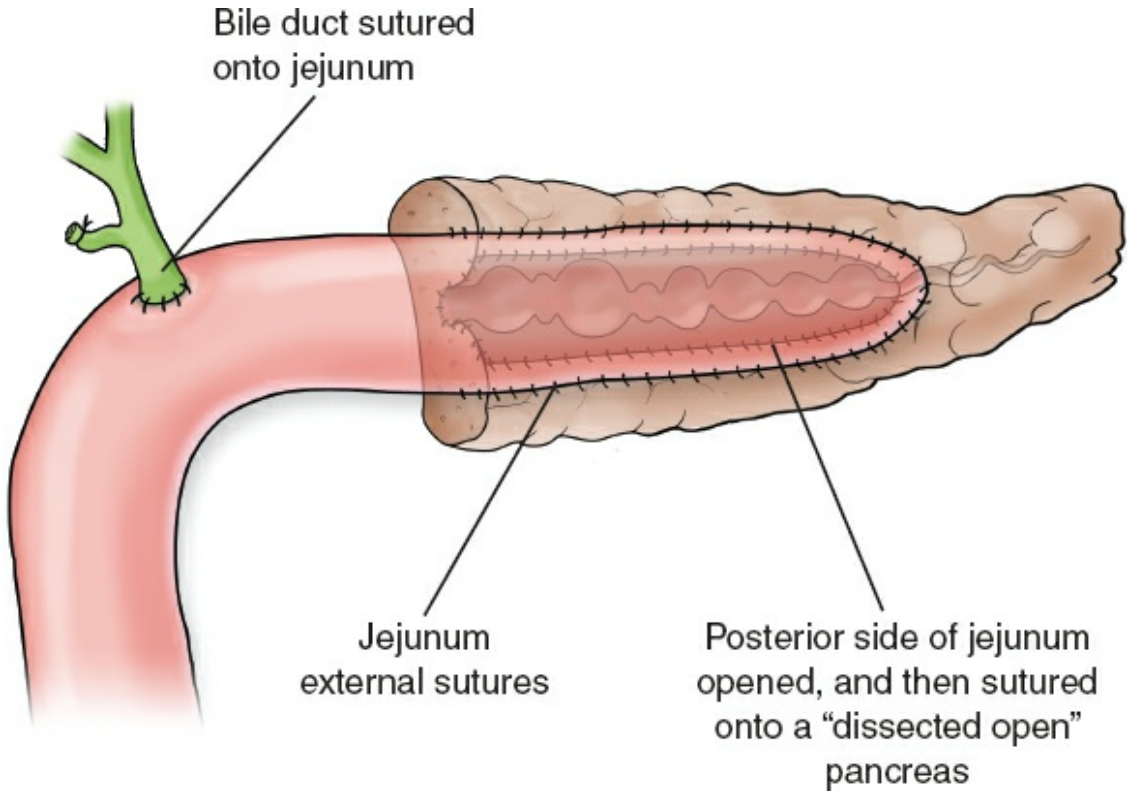

Figure 123.3. If multiple strictures from chronic pancreatitis are present in the pancreatic remnant, then the duct must be decompressed using a lateral pancreaticojejunostomy much like with the Puestow lateral drainage procedure.

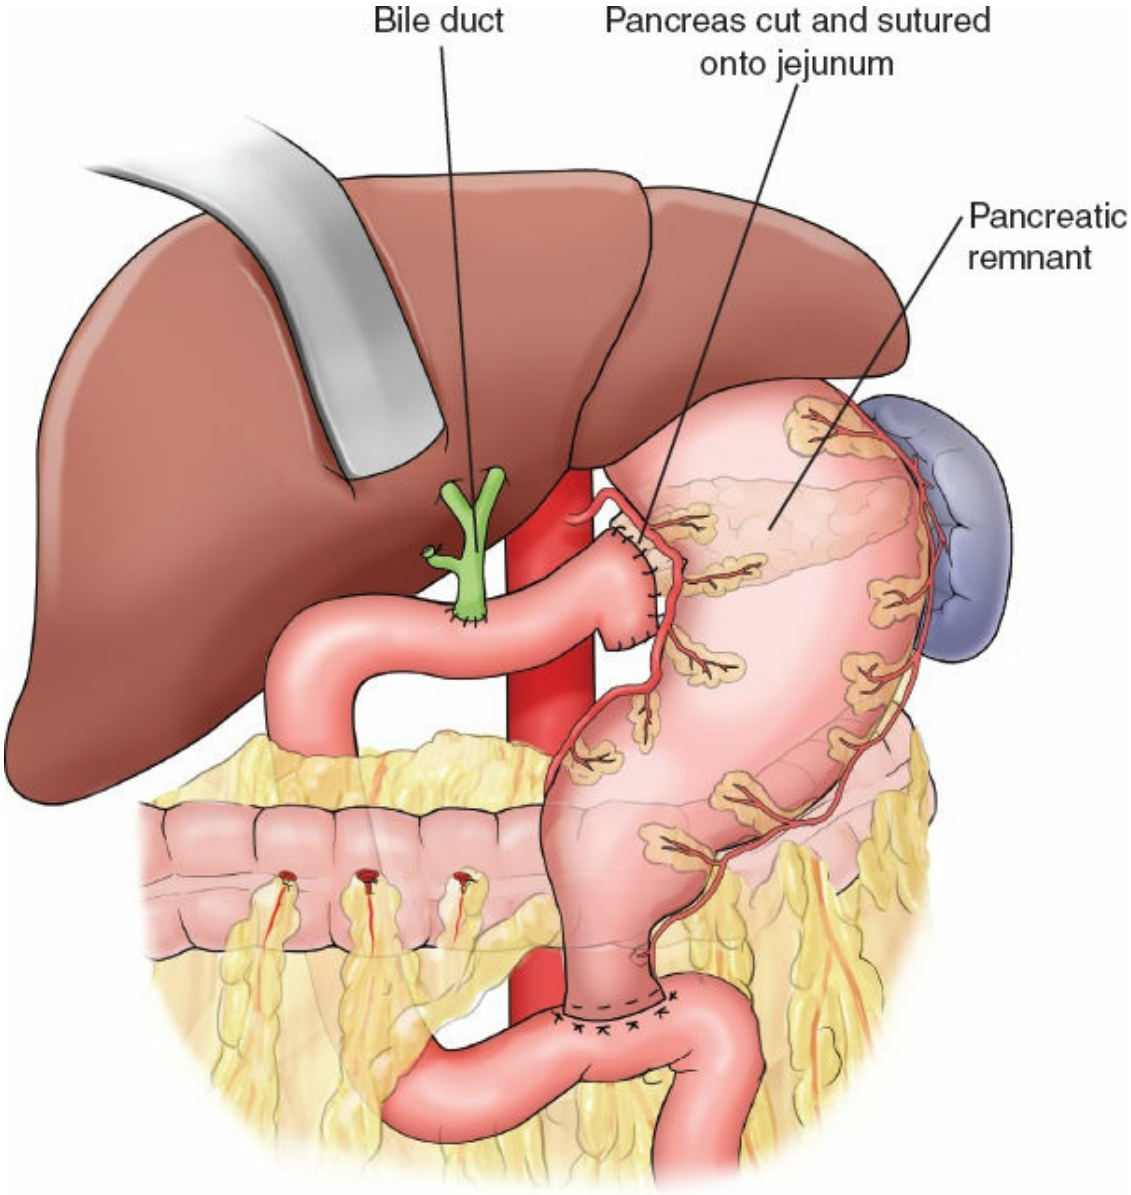

Figure 123.4. Reconstruction of the pancreatic duct and bile duct are in a retrocolic fashion. The end-duodenal to side-jejunostomy is in an antecolic position to isolate the duodenal anastomosis from the pancreatic anastomosis and to minimize delayed gastric emptying if the latter should leak.

Approximately 25 cm distal to the biliary-enteric anastomosis, an end-to-side duodenojejunostomy is performed with an inner continuous layer of 3-0 absorbable synthetic suture material and an outer interrupted layer of 3-0 silk. Some experienced pancreatic surgeons prefer to perform the duodenojejunostomy further distally in an antecolic position, in the belief that doing so reduces the incidence of early postoperative delayed gastric emptying. If an antrectomy was performed, the medial half of the gastric staple line can be reinforced with interrupted 3-0 silk seromuscular

Lembert sutures. The gastrojejunal anastomosis is completed to the lateral (greater curvature) aspect of the staple line as a two-layer Hofmeister-style anastomosis.

The abdomen is copiously irrigated. The jejunal loop is tacked to the rent in the transverse mesocolon with interrupted 3-0 silk sutures. The defect in the retroperitoneum previously occupied by the fourth portion of the duodenum is closed with a continuous 3-0 silk suture. Two closed suction Silastic drains are generally placed in the vicinity of both the hepaticojejunostomy and the pancreaticojejunostomy, which are brought out through a stab wound in the right upper quadrant. The abdomen is closed in a standard fashion.

In summary, the patients with a diagnosis of chronic pancreatitis who are eligible for a pancreaticoduodenectomy represent a highly selected subgroup. They display head-predominant disease in the setting of intractable pain, and not infrequently have a concurrent biliary duct stricture or duodenal stenosis. These patients do not typically overlap with those who would benefit from a pancreas-sparing procedure or distal pancreatectomy. If these prerequisites are strictly adhered to, the patients will have an excellent chance at good relief of their disabling pain.

Longitudinal Pancreaticojejunostomy (Puestow)

Puestow and Gillesby modified Duval's (1954) procedure to include a longitudinal opening along the main pancreatic duct within the neck, body, and tail of the gland. They also invaginated the distal gland into a Roux-en-Y limb of the jejunum. Partington then modified this procedure again to construct a side-to-side longitudinal pancreaticojejunostomy (now coined the "Puestow procedure").

The Puestow procedure is an excellent approach to pancreatic ductal decompression in cases where a definitive stricture is noted in conjunction with a significantly dilated upstream pancreatic duct (>5 mm) (Fig. 123.6). Patients with other sequelae of chronic pancreatitis such as biliary and/or duodenal obstruction or walled-off pancreatic necrosis or pseudocyst formation are best served with a different approach because the Puestow procedure will not address these concurrent issues.

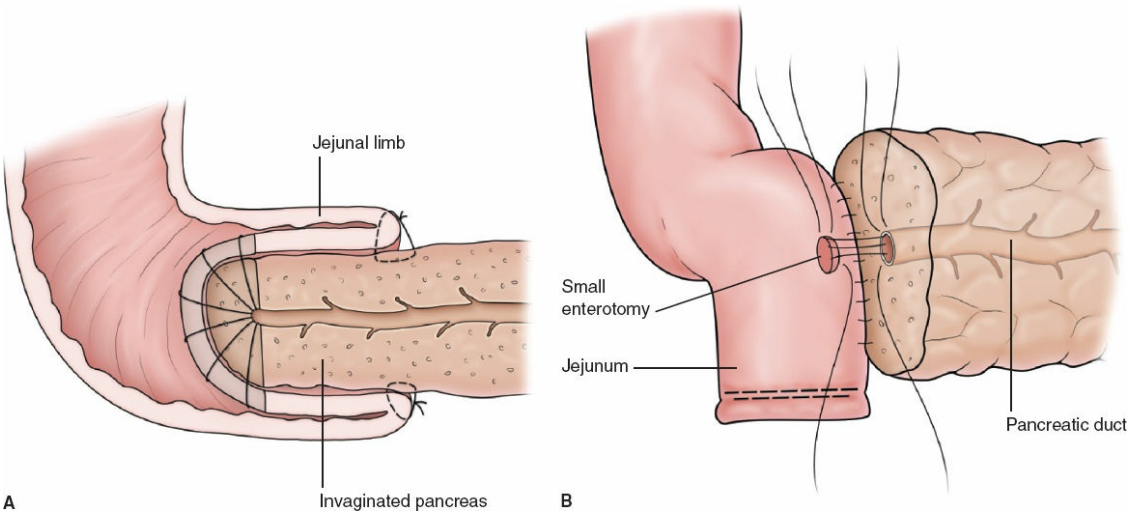

Figure 123.5. A. In the pancreaticojejunostomy, the end of the pancreas is invaginated into the end of the jejunum for ~2 cm. The anastomosis is done with an outer interrupted layer of 3-0 silk and an inner continuous layer of 3-0 absorbable synthetic suture material. **B.** In an alternative approach, an end-to-end mucosa-to-mucosa pancreaticojejunostomy is again done in two layers with an outer layer of interrupted 3-0 silk sutures and an inner layer of interrupted 4-0 absorbable synthetic sutures.

The peritoneal cavity is entered through an upper midline incision. The round ligament is divided at the liver and the portion between the liver and the umbilicus is excised. A fixed abdominal wall retractor system of the surgeon's choice is engaged after a wound protector is placed. A dual-ring wound protector is recommended.

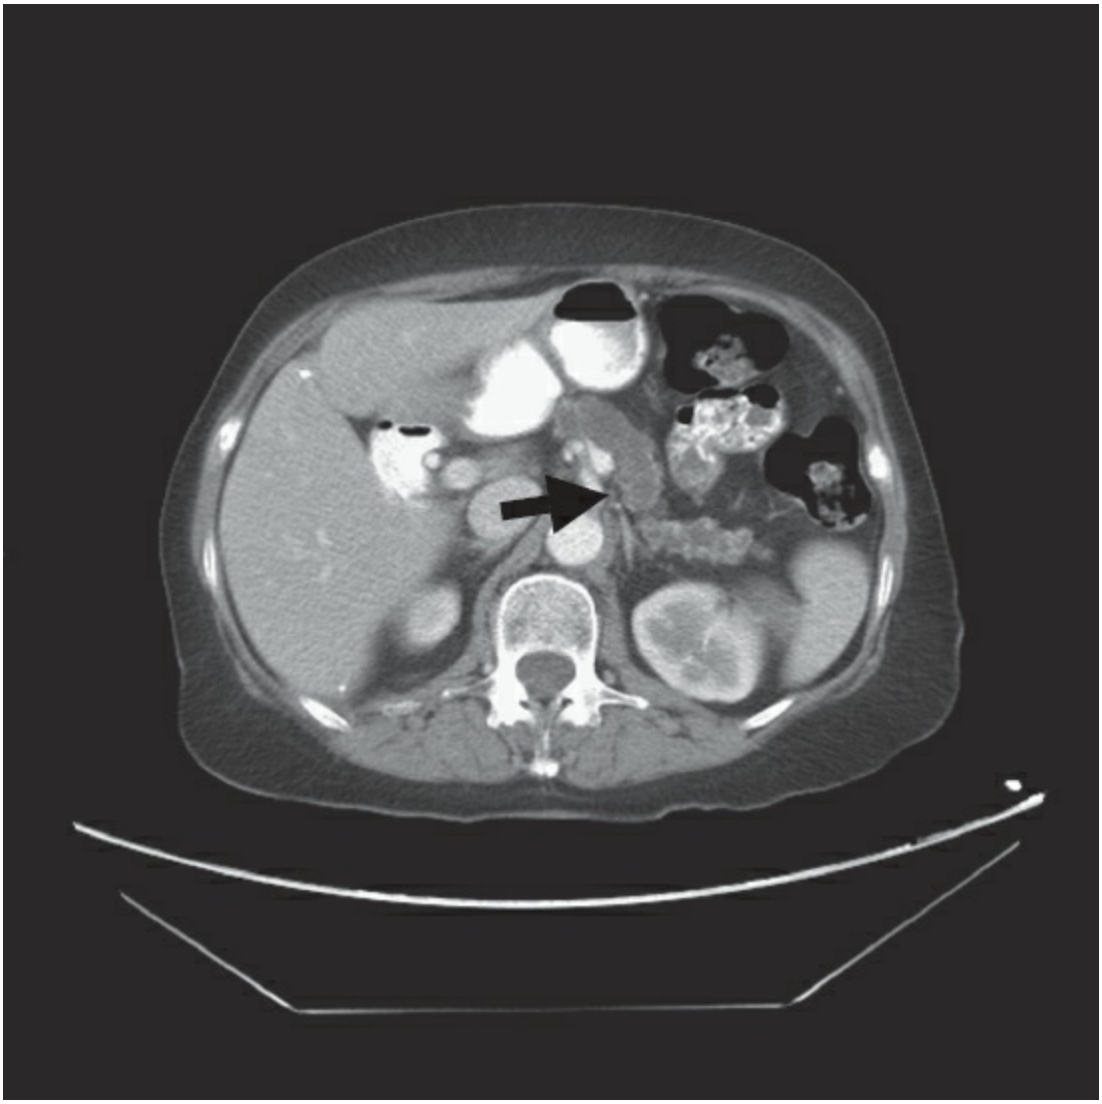

Figure 123.6. Dilated, irregular pancreatic duct throughout body and tail of pancreas indicated by *black arrow* in a patient with alcohol-associated chronic pancreatitis. The patient was symptomatic with abdominal pain from chronic pancreatitis and had an excellent response to a Roux-en-Y lateral pancreaticojejunostomy.

Operative assessment can begin with a wide Kocher maneuver and mobilization of the duodenum and the head of the pancreas from the underlying inferior vena cava and aorta. This is not mandated however, particularly when the procedure is limited to the pancreatic body/tail. The lesser sac is opened widely by incising the lesser omentum and by removing the entire greater omentum off the transverse colon. Any adhesions between the back wall of the stomach and the ventral surface of the pancreas are divided. The short gastrics are not divided. Every attempt is made to preserve the greater omentum. The hepatic flexure of the colon

is also mobilized and retracted downward out of the operative field early in the operative procedure. If a patient has not yet undergone a cholecystectomy, one is generally recommended. The gland is then evaluated both by digital inspection (palpate for the duct itself and potential stones) and ultrasonography to identify the pancreatic duct in particular. The perceived location of the duct should align well with the preoperative cross-sectional imaging. If the precise position of the duct is difficult to identify using these techniques, a 21- or 22-guage needle on a 10-cc syringe can be utilized to localize the duct (confirmed by aspiration of pancreatic juice). If blood returns within the syringe, it is typically venous from the underlying splenic vein. The needle should be immediately withdrawn and digital pressure applied for 5 minutes. If it is still difficult to identify the duct, a limited transverse parenchymal incision can be employed with the use of electrocautery. Once the duct is identified, it is then opened using electrocautery along its entire dilated length (ventral surface). The duct itself should also then be widened to ensure long-term patency with the planned jejunal anastomosis. All stones should be removed from the duct. Any obvious strictures should be biopsied and evaluated via frozen section.

Once the pancreatic duct is opened widely, the jejunum (approximately 20 to 30 cm from the ligament of Treitz) is divided using a GIA stapler and the staple line on the downstream side is oversewn with 3-0 sutures. The mesentery is then divided using ties or an energy device down through the outer vascular arcade. Following completion of the eventual pancreaticojejunostomy, a side-to-side jejunojejunostomy is created to ensure patency of the Roux-en-Y reconstruction. This is typically about 50 cm distal to the pancreaticojejunostomy. We utilize a handsewn two-layer, technique for the jejunojejunostomy, with closure of the associated mesenteric defect using interrupted figure-of-eight 3-0 sutures.

The Roux limb for the pancreatic anastomosis should be delivered via a small defect in the mesocolon. This defect is typically to the right of the middle colic vessels, but can also be better placed elsewhere depending on the specific anatomy of the patient. A lateral pancreaticojejunostomy is then fashioned. Two corner sutures are first placed between the apices of the opening along the pancreatic duct and the antimesenteric side of the small bowel. These are placed such that the knots will be on the outside of the anastomosis once tied down. The length of small bowel must be carefully assessed as it tends to stretch once opened, and the bowel is

opened with the electrocautery in a hemostatic manner (Fig. 123.7). The suture line is carried between the small bowel and the cut edge of the pancreas, using interrupted 3-0 silk sutures, creating the inner aspect of the pancreaticojejunostomy (Fig. 123.8). Full thickness bites of both the small bowel and pancreas are essential to avoid any leakage of pancreatic juice. Care is taken to incorporate both the pancreatic capsule and the duct mucosa when possible. The superior suture line is completed in a similar manner to complete the anastomosis (Fig. 123.9). This pancreatic jejunal limb is locked into place at the mesocolon level with interrupted 3-0 sutures. Closed suction drainage is generally not required given the low leak rate of this anastomosis between a healthy jejunum and a hard pancreatic gland.

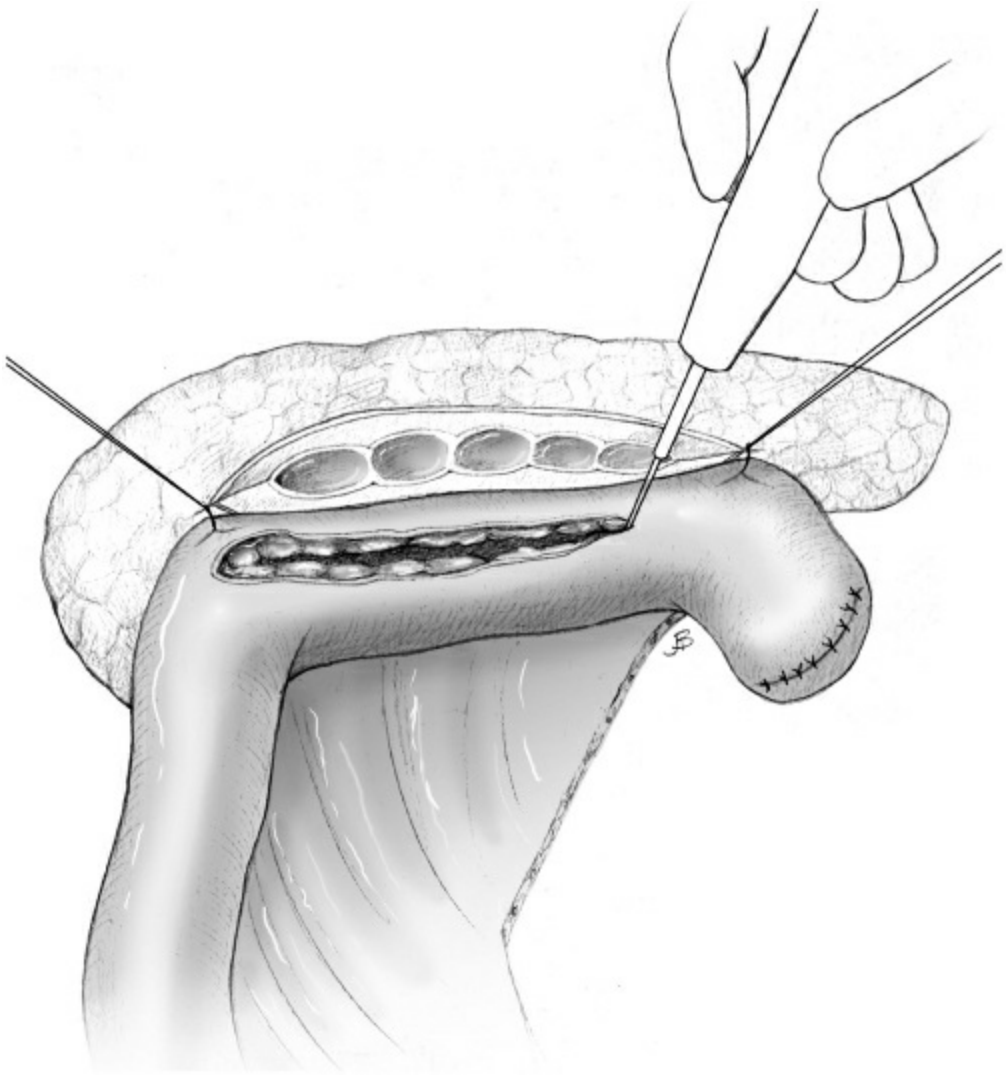

Figure 123.7. The Roux-en-Y limb is brought alongside the pancreas in an isoperistaltic fashion. The longitudinal pancreatic ductotomy is visible. Two corner stitches are placed between the

jejunum and the apices of the ductotomy. An enterotomy is then made lengthwise along the jejunum, in parallel to the pancreatic ductotomy.

It is reasonable to note that some surgeons also perform a celiac plexus neurolysis as an adjunct to this procedure to assist in addressing ongoing pain. A solution of 50% ethanol is injected into the area of the celiac plexus that is identified by palpation along the aorta, at the level of the thrill of the celiac artery. A 20-cc syringe is filled with the ethanol solution and fitted with a 21- or 22-gauge spinal needle. Then, 10 mL of the 50% ethanol is injected along each side of the aorta at the level of the celiac axis. If a nonoperative approach is selected for a chemical celiac plexus neurolysis, endoscopic targeting is far superior to percutaneous approaches (more than double the response rate).

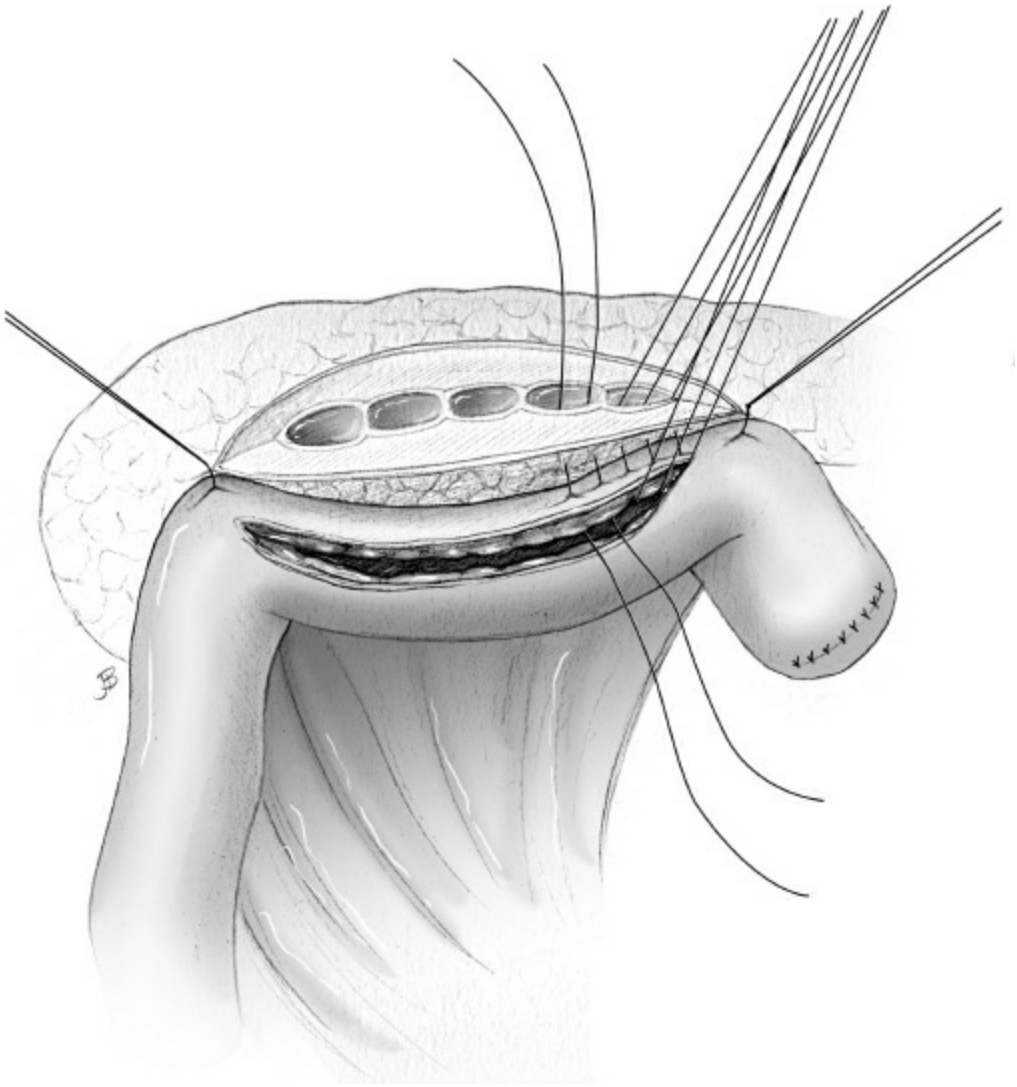

Figure 123.8. Interrupted 3-0 silk sutures are placed along the

inferior row of the pancreaticojejunostomy. Full thickness bites of the small bowel are first taken followed by a thickness bite of the transected edge of the pancreas. Both the pancreatic capsule and the pancreatic duct mucosa are incorporated in a single suture when possible. Note that these sutures are placed such that the knots will be on the inside aspect of the anastomosis once tied down.

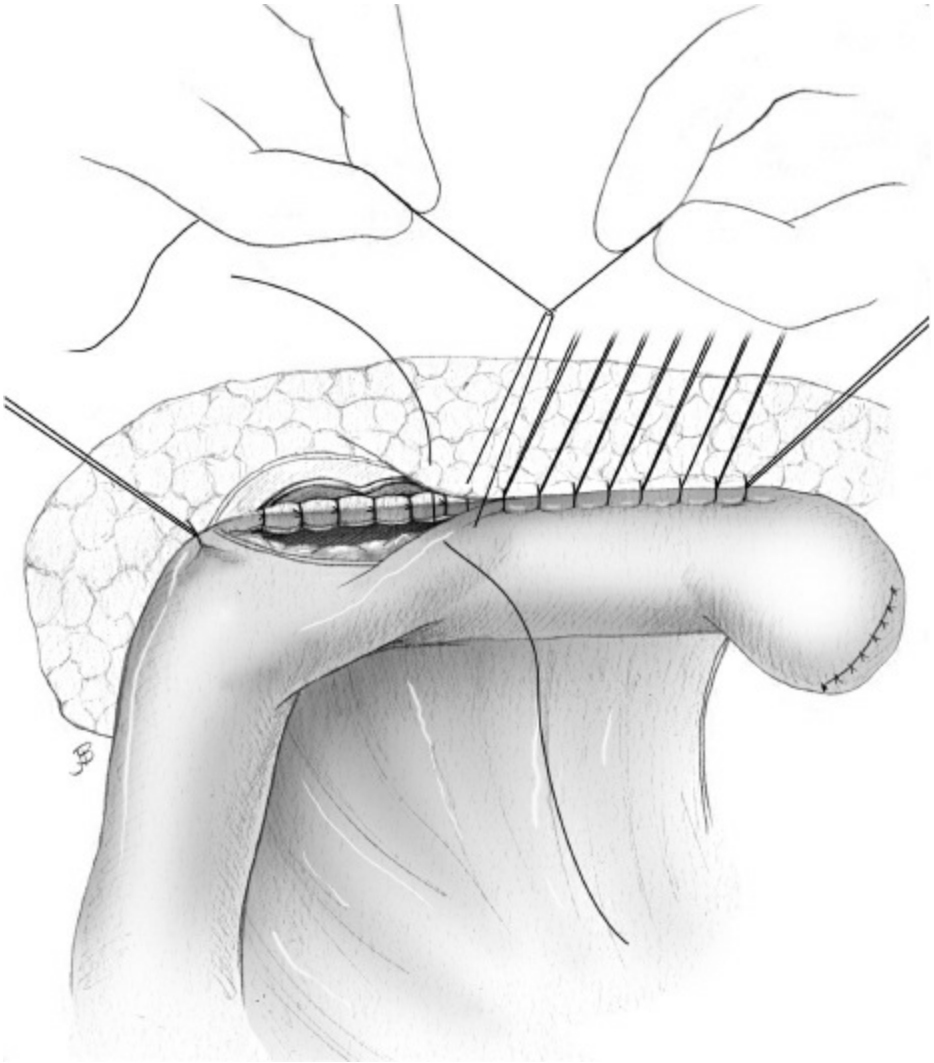

Figure 123.9. The superior row of the anastomosis is fashioned using 3-0 silk sutures, taking a full thickness bite of the jejunum from serosa to mucosa. The cut edge of pancreas is then taken with a full thickness bite, incorporating pancreatic duct and then capsule. The knots for this superior row are left on the outside of the anastomosis.

Frey/Beger Procedure

The Frey or Beger procedures combine both resectional and drainage

methodologies. They are particularly helpful for patients who present with a concurrent inflammatory mass in the head of the pancreas. These procedures will be described in the next chapter.

SURGICAL OUTCOMES

The success of PPPD for treating complications associated with chronic pancreatitis (typically intractable pain) have been reported by numerous authors over the past decade. Whereas perioperative mortality remains less than 2%, postoperative complications still approach 40%. Given these early results are similar to, or potentially better than, PPPD for patients with a malignancy, this procedure can be considered appropriate for those suffering from chronic pancreatitis. The frequently demonstrated volume–survival relationship for pancreatic resection and malignancy also appears to apply to resections for chronic pancreatitis. Perioperative mortality following pancreaticoduodenectomy is better regardless of indication if patients are referred to a high-volume center. In studies that include long-term follow-up (up to 8 years), resolution of intractable pain following PD has been observed to be as high as 88% with an associated return-to-work rate approaching 70%. Unfortunately, long-term mortality due to progression of the disease also ranges from 8% to 32%.

Given the myriad of operative procedures commonly described for the patients with complications of chronic pancreatitis, randomized controlled trials (RCTs) are particularly helpful in comparing various approaches/techniques. In the short term, it appears that pancreaticoduodenectomy is associated with significantly more complications (29% to 40%) than either the Frey (0% to 19%) or Beger (18%) procedures. More specifically, in five RCTs comparing pancreaticoduodenectomy to both types of duodenal-sparing pancreatic resections, the Frey and Beger procedures each displayed lower rates of subsequent diabetes mellitus and exocrine insufficiency. In other centers with extensive experience using the Frey and Beger operations, however, both duodenal-sparing procedures appeared to provide no significant benefit in terms of long-term pain control, exocrine insufficiency, endocrine function, quality of life scores, or survival when compared to pancreaticoduodenectomy. This is in part supported by the concept that during a pancreaticoduodenectomy (and therefore similar to a Frey or Beger procedure), most of the pancreatic tissue being excised is nonfunctional and fibrotic in nature. Furthermore, the typically delayed

development of endocrine failure after pancreaticoduodenectomy is further evidence of continued fibrosis in the pancreatic remnant, and not an overexcision of functioning tissue. It must also be remembered that methodologically sound comparisons of published studies are difficult due to a general lack of reported standard selection criteria for resection.

In the Indiana experience, patients with recurrent pain after a pancreaticoduodenectomy for chronic pancreatitis have been divided into two groups (mean time to pain recurrence is 47 months). There may be either a stricture at the pancreatojejunostomy (up to 80% of the patients with recurrent pain) or there has been progression of their pancreatic disease (20%). In the former, a remedial operative procedure to revise the anastomosis is associated with a 50% success rate. These operations should target only anastomotic abnormalities identified radiographically, and must not represent “fishing” expeditions. Among all patients who required operative revision, the 1-, 5-, and 10-year mortality rates were 8%, 18%, and 33%, respectively.

Upon review of the literature for lateral pancreaticojejunostomies (Puestow, Beger, Frey), all procedures are also associated with a low operative mortality and morbidity. Large series report operative mortality of less than 1%. As a result of the fibrotic nature of the pancreatic parenchyma, pancreatic anastomotic leaks are uncommon (2% to 4%). Overall complication rates approximate 20%. The initial reported intensity of pain relief is high (90%) across most published studies. With long-term follow-up however, only 45% to 50% of patients report persistent pain relief. Recurrent pancreatic duct strictures, particularly in the head of the pancreas, remain a source of long-term failure for patients undergoing longitudinal pancreaticojejunostomy. These patients are candidates for subsequent surgical intervention, often with resectional approaches. It has also become clear that taken as a whole, the available evidence indicates that lateral pancreaticojejunostomy rarely exacerbates exocrine or endocrine insufficiency of the pancreas, and may have some mild beneficial effect on both challenges. More specifically, despite a long-term progression to exocrine and endocrine insufficiency of nearly 30%, there is some evidence that patients managed surgically show a lower progression to pancreatic insufficiency when compared to those treated with medical management only. Presumably, this is related to improved drainage of the gland.

TABLE 123.1 Therapeutic Targets for Pancreatic Procedures

Procedure	Type	Pain	Biliary Obstruction	Duodenal Obstruction
PPPD	Resectional	X	X	X
Puestow	Drainage	X		
Frey	R+D	X	+/– X	
Beger	R+D	X	+/– X	

Given the increasing use of nonsurgical therapies (i.e., endotherapy) for patients with chronic pancreatitis, a sound understanding of the interactive role of these procedures with operative resections and drainage is crucial. Endotherapy can include papillotomy, pancreatic and biliary stenting, mechanical stone removal, lithotripsy, as well as combinations of the above. Whereas an in-depth discussion of each is beyond the scope of this chapter, a recent RCT has saddled endotherapy with a higher complication rate as well as significantly lower overall relief of pain. Patients undergoing endotherapy also required significantly more interventional procedures compared to the operative group. Although many endoscopic techniques have the ability to temporize patient complaints and alleviate their symptoms in the short term, the findings of this RCT are not overly surprising given the limited durability of many endotherapy interventions. Specific issues include poor stent patency and stone/calcification recurrence. The success of formal resective procedures such as pancreaticoduodenectomy in treating intractable pain is also highlighted by an obvious referral bias. Unfortunately, many of the patients referred to surgeons have already undergone numerous failed nonoperative/endotherapy approaches, and therefore represent the most difficult and opiate-dependent subgroup possible. The last remaining option for these patients is often an operative intervention such as pancreaticoduodenectomy.

SUMMARY

The role of surgical intervention for treating the complications of chronic pancreatitis (intractable pain, biliary obstruction, duodenal stenosis) and/or the need to rule out a malignancy are clear. Up to 90% of the patients, if properly selected, can achieve an improvement in their pain with an associated return-to-work rate approaching 70%. Patients who benefit most from a pancreaticoduodenectomy, as well as both purely drainage procedures and combined resection/drainage interventions for chronic

pancreatitis represent a highly selected cohort. The appropriate selection of a specific surgical intervention from a menu of choices is absolutely critical for long-term success and symptom resolution/improvement (Table 123.1). Successful care of these patients is also reliant upon a thorough evaluation of social factors (alcohol ingestion and smoking), selection of the proper operative approach, as well as a multidisciplinary care plan that involves many of our colleagues (chronic pain service, gastroenterology, interventional radiology, nutritionists).

EDITOR'S COMMENT

The authors describe the technique and outcomes of both pancreaticoduodenectomy and longitudinal pancreaticojejunostomy in chronic pancreatitis. Dr. Lillemoe is a world authority on the Whipple procedure and other pancreatic operations having trained under the iconic John Cameron.

It must be emphasized that careful patient selection is critical to obtaining superior outcomes. A clear understanding of the anatomic changes resulting from the chronic pancreatitis is critical. MRCP and EUS are most helpful in this regard. Of utmost importance is to verify that the patient considered for an operation for chronic pancreatitis has been abstinent for 1 year. Failure rates are high in those that continue to drink alcoholic beverages. In the ideal setting the surgeon is part of a collaborative team of a gastroenterologist, behavior medicine specialist and primary care physician, and a nutritionist. This could be defined as a virtual medical home for chronic pancreatitis. In addition caution is advised in recommending resection as treatment for minimal change pancreatitis as outlined in the preceding chapter. Again in these settings a multidisciplinary approach is advisable.

The technique described for the Whipple procedure for chronic pancreatitis is very similar to the one we use. They point out the need for the surgeon focus on variations in arterial anatomy which is particularly true in these cases because of the associated pancreatic inflammation and induration. A wide Kocher maneuver facilitates the operation as does a wide opening into the lesser sac. I agree with Dr. Lillemoe that approaching the portal vein and SMV early in the dissection is wise. Dividing the common hepatic duct opens the spaced anterior to the portal vein. Dividing the gastroduodenal artery after carefully identifying the anatomy of the hepatic artery further facilitates this portion of the dissection. Dissection along the inferior edge of the pancreas and the vascular groove is essential prior to dissection the neck of the pancreas and lifting it off the portal vein. As pointed out the associated inflammation can make this extraordinarily difficult. Injury to the vein may occur if there is adherence of the pancreas to the portal vein. In some cases placing vessel loops

around the SMV inferiorly and the portal vein superiorly may be of benefit so as to allow better control if there is injury to the vein. As pointed out the neck can be bluntly dissected with a finger or a large blunt clamp. Once the dissection of the neck is completed it can be encircled with a vessel loop or Penrose drain to allow traction which makes further dissection easier. If the surgeon enters the anterior surface of the portal vein bleeding will be brisk and difficult to control. Initially control may be achieved with bimanual pressure applied posteriorly under by placing a hand under the uncinate process. The hand is initially placed through the space opened by the Kocher maneuver. Lifting the hand upward and placing the thumb over the neck of the pancreas anteriorly allows pressure to be placed while vascular isolation is obtained. Once this is completed the bleeding should slow down. The neck of the pancreas can then be completely divided and this will expose the portal vein which can be repaired under direct vision with fine monofilament nonabsorbable sutures. Once the bleeding is controlled the surgeon can then return to the operation.

Once the specimen is removed reconstruction is completed. The pancreas is usually quite firm and the pancreatic duct may be enlarged. An end-to-side pancreaticojejunostomy is completed using jejunal pancreatic sutures for stabilization and a mucosal to mucosal duct anastomosis. In some cases the duct is very dilated, greater than 7 to 8 mm, and it may be lengthened and extended 4 to 5 cm along the anterior surface of the gland and a longitudinal pancreaticojejunostomy created. Pancreatic anastomotic stenting is not necessary in the majority of pancreaticoduodenectomies for chronic pancreatitis.

The first step in the longitudinal pancreaticojejunostomy is wide exposure of the head, body, and tail of the pancreas in the lesser sac. The pancreatic duct is usually seen as a bulging structure on the anterior surface of the gland. It is best identified in the mid body of the pancreas. The dilated duct can be palpated as a soft and compressible area in a firm pancreas. The use of intraoperative ultrasound is sometimes of help in localizing the duct. Once identified, I place a 25-gauge needle in the duct. The fluid should be crystal clear. The duct can then be opened longitudinally going on to the head of the pancreas up to the gastroduodenal artery and laterally to within 1 cm of the tip of the tail, if possible. All of the pancreatic stones should be removed. I have never had to divide the gastroduodenal artery. After creation of the Roux-en-Y jejunal limb it is brought into a retrocolic position and placed over the pancreas. I use a single layer absorbable monofilament suture to create the pancreaticojejunostomy. Although leak from the pancreaticojejunostomy is infrequent, I usually use a closed suction drain. If there is a mass-like enlargement of the pancreatic head it may be resected as described in subsequent chapters. In patients with small-duct disease (duct size <5 mm), a longitudinal pancreaticojejunostomy may not be feasible. Izbicki and his colleagues (Longitudinal V-shaped excision of the ventral pancreas for small duct disease in severe chronic pancreatitis: prospective evaluation of a new surgical procedure. *Ann Surg* 1998;227:213–9)

described a procedure in which a V-shaped wedge of tissue from the pancreas is removed and pancreaticojejunostomy is performed to the edge of the wedge defect in the pancreas rather than the duct.

Bleeding from the pancreas is the most frequent intraoperative complication. Bleeding can be controlled by suture ligation or application of energy. Postoperative gastrointestinal hemorrhage may occur and should be approached with CT angiography or celiac angiography and embolization if it occurs late, and potentially reoperation if it occurs in the first 48 hours. The bleeding is usually from the gastroduodenal artery or a branch of the splenic artery. In patients with symptomatic biliary obstruction and dilation of the bile duct, jaundice, or cholangitis, the biliary tree should be drained at the time of the pancreaticojejunostomy. If the bile duct is obstructed in the head of the pancreas the same loop may be used to create a choledochojejunostomy. I usually place the pancreaticojejunostomy as the first anastomosis. Alternatively a choledochoduodenostomy may be performed. In addition if there is an adjacent pseudocyst the same jejunal limb may be used to perform a cyst jejunostomy.

124 Parenchyma-Sparing, Limited Partial and Total Pancreatic Head Resection for Inflammatory Tumor, Cystic Neoplasia, Neuroendocrine Adenoma, and Low-Risk Periampullary Malignant Tumor

Hans G. Beger, Bettina M. Rau, and Bertram Poch

Inflammatory tumors, cystic and neuroendocrine neoplasms, and periampullary adenomas are growing entities of pancreatic diseases. With the use of diagnostic and screening computed tomography (CT) scans, magnetic resonance tomography (MRT), and positron-emission tomography (PET), benign tumorous lesions of the pancreas are increasingly detected and discovered fortuitously, including when they are still small in size. Additionally, new generation CT and MRT scans provide more accurate noninvasive assessment for tumor staging regarding the ability to distinguish between solid and cystic, slow-growing noncystic neoplasms and fast-growing tumors, which may have the potential of transformation to cancerous lesions. Neoplastic tumors and a tumorous mass in the pancreatic head are challenging lesions, whether to observe or treat and thus how to operate?

In chronic pancreatitis and tropical nutritional chronic pancreatitis as well, an inflammatory mass in the head of the pancreas is frequently found in combination with local tissue pathomorphology and ductal changes. A tumor mass of the pancreatic head is observed in chronic pancreatitis more frequently in European and Asian than in American institutions. Local complications, including pseudocystic cavities, inflammatory head mass, leading to common bile duct (CBD) stenosis and compression or occlusion of the portal vein and stenosis of the periampullary duodenum, are frequent in alcoholic chronic pancreatitis. According to epidemiologic

studies, an association between chronic pancreatitis and pancreatic cancer developing years after diagnosis is observed in 1.8% to 8% of cases.

Cystic neoplastic lesions of the pancreas were first histologically identified in 1978 by Campagno and Oerdel. The prevalence of cystic neoplasm of the pancreas varies depending on the imaging procedure used, and is detected with a rate of 2.6% by multislice CT, 13.5% by magnetic resonance imaging (MRI), and 44.7% by magnetic resonance cholangiopancreatography (MRCP). Intraductal papillary mucinous neoplasia (IPMN), mucinous cystic neoplasia (MCN), and solid pseudopapillary neoplasia (SPN) are the most frequent and challenging benign cystic tumors of the pancreas. They display an increased risk for malignant transformation, which varies within the entities of cystic neoplasms. Pancreatic neuroendocrine tumors (PNETs) are relatively rare, accounting for 10% of all benign tumorous lesions of the pancreas. Through the application of high-resolution imaging technology, more PNETs are found as incidentalomas. The most frequent endocrine adenomas are insulinomas, presenting as islet-cell cancer in only 5% to 10% of cases. All gastro-pancreatic neuroendocrine tumors are considered to be potentially malignant.

The standard surgical treatment for benign tumors is currently multiorgan resection. For pancreatic head lesions, a pancreaticoduodenectomy (PD) type resection is performed, while for tumors in the body and tail, a pancreatic left resection with or without splenectomy is applied. However, the respective surgical procedures are associated with a substantial loss of functional pancreatic and extrapancreatic tissue regarding the stomach, duodenum, biliary tree, and spleen. PD and pancreatic left resections still carry considerable postoperative morbidity and risk of mortality.

The recent evolution of local surgical procedures for benign pancreatic tumors includes tumor enucleation, pancreatic middle-segment resection, and local resection of tumors of the pancreatic head applying duodenum-preserving total or partial head resection. They have the potential to preserve exocrine and endocrine pancreatic functions and for low procedure-related postoperative morbidity. The results after duodenum-preserving local pancreatic head resection compare favorably with published multi-institutional results after application of classical Whipple resections. A recently published meta-analysis revealed no change when comparing the exocrine and endocrine pancreatic functions before and

after duodenum-preserving total pancreatic head resection (DPPHR-T). However, when comparing DPPHR-T with PD, pancreatic functions after PD showed a significant decrease in short- and long-term outcomes, contrary to the results after DPPHR-T. Multi-institutional reports on the outcome after PD documented a considerably high level of severe postoperative complications and a substantial mortality risk of 2% to 7%. The impairment of endocrine pancreatic functions after PD has recently been reported; 18% of preoperative nondiabetic patients suffered postoperatively new onset of diabetes mellitus, while 48% of those with diabetes mellitus showed a deterioration in their medication requirements after PD.

The long-term status of the endocrine functions, determined by oral glucose tolerance testing, indicated an apparent complete preservation of the preoperative level after limited total pancreatic head resection, whereas after PD the glucose metabolism showed a significant deterioration. Determination of the plasma cholecystokinin level after food stimulation exhibited a significant reduction after PD compared to a nonchange after limited total pancreatic head resection. A similar difference was found postoperatively when determining the plasma secretin level over a 2-hour period following oral food stimulation, with PD patients showing a significant reduction compared to limited total pancreatic head resection. The postoperative deterioration of gastrointestinal (GI) motility determined by the propagation of phase III motility migration complex (MMC) in the upper GI tract showed a return to a normal physiologic level in DPPHR-T patients after a mean of 18.8 ± 4.3 postoperative days, whereas after PD, the phase III MMC remained reduced until 40.6 ± 4.8 postoperative days. When comparing nine patients after pylorus-preserving PD with six patients after limited, total pancreatic head resection with conservation of the duodenum and CBD, the mean plasma motilin level on the first appearance of phase III MMC after PD was significantly lower than in patients after limited total pancreatic head resection, who displayed almost normal values.

DIAGNOSTIC MAKE-UP

The diagnosis of tumors of the pancreas is based on contrast-enhanced CT as the gold standard. Endoscopic retrograde pancreatography and MRCP provide additional information about the duct changes, of the main pancreatic duct, side branches, and the intrapancreatic segment of the

CBD. In patients with advanced chronic pancreatitis, approximately 30% to 50% display narrowing of the intrapancreatic segment of the CBD with cholestasis and dilation of the extrahepatic biliary duct. In benign cystic neoplasm, the most important diagnostic goals are lesion size and location, the presence of solid tissue structures respectively of nodules, and the involvement of the pancreatic main duct and side branches. To evaluate the endocrine and exocrine functions, an oral glucose tolerance test, a pancreo-lauryl test, and fecal chymotrypsin estimation are recommended.

INDICATION FOR DUODENUM-PRESERVING PARTIAL OR TOTAL PANCREATIC HEAD RESECTION

Patients suffering benign tumorous lesions of the pancreatic head, which are associated with upper abdominal complaints, should receive surgical treatment (Table 124.1). Tumors detected as incidentalomas but suspected to be a cystic neoplasm of the IPMN, MCN, and SPN type are recommended for surgical treatment when the patient is fit for surgery. According to international guidelines, all IPMN lesions of the pancreatic main duct are recommended for surgical treatment. Side branch IPMN ≤2 to 3 cm have a lower risk of malignant transformation. However, should patients be fit for a surgical treatment, operative treatment is suggested. All patients suffering serous pseudopapillary neoplasm are candidates for surgery because of the high probability of a cure. MCNs are predominantly located in the body and tail of the pancreas, but up to 30% of MCNs are located in the pancreatic head; a size of ≥4 to 5 cm is a strong criterion for surgical treatment. Whenever imaging data indicate a suspicion of a malignant tumor inside the cystic neoplasm, a tumor extirpation should be performed without delay.

TABLE 124.1 Indications to Duodenum-Preserving Pancreatic Head Resection

1. Chronic pancreatitis with inflammatory mass of the pancreatic head,
   - CP +Common bile duct stenosis
   - CP +severe stenosis of duodenum
   - CP +compression of PV/SMV
   - CP +dystrophy of peripapillary duodenum
2. Pancreas divisum causing:
   - Chronic pancreatitis or recurrent acute pancreatitis (children/adults)
3. Cystic neoplasms:
   - IPMN, MCN, SCA, SPN
4. Benign neuroendocrine tumors (>2–3 cm)
5. Low-risk periampullary cancer (T1N0)
   - Adenoma and carcinoma of papilla of Vateri
   - Adenoma and carcinoma of peripapillary duodenum
   - Lower common bile duct cancer
6. Maljunction of biliopancreatic ducts
7. Severe injury of the pancreatic head in children with duct rupture (pancreatic trauma grades III and IV)

CP, chronic pancreatitis; PV, portal vein; SMV, superior mesenteric vein; IPMN, intraepithelial papillary mucinous neoplasm; MCN, mucinous cystic neoplasm; SCA, serous cyst adenomas; SPN, solid pseudopapillary neoplasia.

Most of the neuroendocrine tumors of the pancreatic head are benign, non-functioning tumors. Patients suffering a PNET of >1.5 to 2 cm are candidates for surgical treatment, irrespective of the functional status of the adenoma, according to international guidelines. A tumor enucleation should be performed in patients suffering an adenoma of up to 2 to 3 cm, possibly by laparoscopic approach. The limitations of enucleation are tumor proximity to the pancreatic main duct and a size >3 cm. Endocrine tumors with close contact to the duct should undergo tumor extirpation with an anastomosis of the pancreas using an excluded jejunal loop to avoid development of a pancreatic fistula of grade B/C (Table 124.2).

TABLE 124.2 Indications to Limited Partial or Total Pancreatic Head Resection

Which Pancreatic Head Resection Procedure to Apply?

1. **Partial pancreatic head resection (DPPHR-P):**
   Benign TM: IPMN, MCN, SCA >4 cm; CBD not involved
   Neuroendocrine TM ≥3 cm
   Severe pancreatic head trauma: Grade III/IV in children
2. **Subtotal pancreatic head resection (DPPHR-P):**
   Chronic pancreatitis with inflammatory mass
   or/and CBD stenosis
   or/and compression of PV/SMV
   or/and prepapillary PMD stenosis + distal duct dilation
   Pancreas divisum
3. **Total pancreatic head resection with segment of duodenum and CBD (DPPHR-T):**
   Large cystic neoplastic TM extended to anterior and posterior pancreatic head
   Cystic neoplasm and duodenal wall involvement
   Cystic neoplastic TM + carcinoma in-situ
   T1N0 low-risk cancer of papilla, prepapillary CBD, peripapillary duodenum
   Chronic pancreatitis with duodenal dystrophy
   Large islet-cell tumor
4. **Total pancreatic head resection with conservation of duodenum**
   Cystic neoplasm and tumor adherence to CBD
   Bilio-pancreatic maljunction

DPPHR-T has been successfully applied in cases of low-risk periampullary carcinoma of the papilla, duodenum, and the intrapancreatic CBD (Table 124.2). DPPHR-T with resection of the intrapancreatic segment of the CBD is applied in patients who suffer bilio-pancreatic maljunctions of the duct communications in the pancreatic head. A variety of institutional reports document successful application of partial pancreatic head resection for pancreatic head injuries of grades III to IV in children after blunt abdominal trauma (Table 124.2). Patients who suffer advanced chronic pancreatitis causing medically intractable pain and/or an inflammatory mass in the head of the pancreas and/or a narrowed intrapancreatic CBD associated with stenosis of the pancreatic main duct are candidates for a subtotal pancreatic head resection (Table 124.2). Children who suffer a pancreas divisum that has developed to chronic pancreatitis are successfully treated by duodenum-preserving subtotal pancreatic head resection, when pancreatic duct stenting has failed to improve the children's complaints.

SURGICAL TECHNIQUE

The surgical technique of partial, subtotal, and total pancreatic head resection comprises three principal technical steps (Table 124.3).

Exposure of the Pancreatic Head

The pancreatic head is exposed, dividing the gastro-colic and the duodenocolic ligaments, preserving the gastro-epiploic vessels. The duodenum is mobilized by a Kocher maneuver, avoiding extensive tissue dissection. After identification of the superior mesenteric vein at the lower margin of the pancreatic head, preparation of a tunnel between the portal vein and the pancreatic neck is performed. Should a tumorous lesion be present in the pancreatic head, the tunneling can be performed without major difficulties by blunt dissection. When an inflammatory tumor is found in chronic pancreatitis, the tunneling should be performed cautiously by blunt dissection along the wall of the superior mesenteric vein toward the portal vein. The common hepatic artery is identified superior of the pancreas and looped. The ligamentum hepato-duodenale is opened and the CBD identified and marked with a loop.

A tumor in the anterior level of the dorsal and ventral segments of the pancreatic head should be identified intraoperatively by ultrasonography. To make the dissection of the tumorous lesion from pancreatic tissue easier, a suture is placed through the wall of the lesion. The dissection through the pancreatic tissue outside the wall of the tumor is performed using dissection devices. Vessels are identified before transection and ligated using 6 × 0 sutures. After completion of tumor dissection, a frozen section investigation is recommended to test for cystic neoplasm. For reconstruction, an excluded jejunal loop is prepared for the anastomosis of the pancreatic head, performing a two-layer end-to-side or side-to-side anastomosis. A Roux-en-Y anastomosis completes the reconstruction after partial pancreatic head resection (Fig. 124.1A,B).

TABLE 124.3 Surgical Steps of Partial or Total Parenchyma-Sparing Duodenum-Preserving Resection of the Pancreatic Head for Benign Tumors and Low-Risk Periampullary Malignant Lesions

1. Exposure of the pancreatic head: Limited Kocher mobilization
2. Partial pancreatic head resection:
   after identification of tumor location and size (IOUS)
   local extirpation of the tumor with a few mm of pancreatic tissue, 2 frozen sections
   Total resection of pancreatic head:
   tunneling of pancreatic neck along the portal vein groove, transection pancreatic head preserving the neck,
   transection of the CBD above the pancreatic head,
   suprapapillary and infrapapillary dissection of the pancreas from the duodenal wall
   transection of the peripapillary duodenal segment.
3. Reconstruction after partial tumor extirpation: anastomosis with excluded jejunal loop (e-s) after total pancreatic head resection and segment resection of duodenum and CBD for DPPHR-S (+segment of duodenum):

Anastomoses	Duodenum:duodenum	e-e
	CBD–duodenum	e-s
	Pancreas–jejunum/stomach	e-s

Roux-en-Y anastomosis of jejunum

Subtotal Head Resection

A subtotal head resection has become a standard procedure for chronic pancreatitis with an inflammatory mass in the head of the pancreas. The resection of the pancreatic head is initiated with the transection of the pancreas at the duodenal edge of the portal vein, preserving the pancreatic neck (Fig. 124.2A). At the cut surface of the left pancreas, meticulous hemostasis using monofilament, 5/6×0, nonabsorbable sutures is performed. After rotation of the pancreatic head and the duodenum to the right, small branches entering the portal vein and the superior mesenteric vein from the pancreatic head tissue are carefully ligated. The head of the pancreas is resected, using the knife or a dissection device, from the retroperitoneal surface of the pancreas toward the uncinate process (Fig. 124.2B). The subtotal resection of the pancreas is concluded by excising the pancreatic head tissue at a distance of 5 mm from the duodenal wall. The intrapancreatic CBD segment is easily identified when using an intraductal Foley catheter introduced by a subpancreatic CBD incision. The wet weight of the operative specimen after subtotal pancreatic head resection is between 25 and 55 g. It has not proved to be necessary to preserve the anterior superior pancreatico-duodenal artery to ensure the normal blood supply to the duodenal wall. The supraduodenal vessels, the posterior superior pancreaticoduodenal arcade, and the mesoduodenal vessels maintain the blood supply of the suprapapillary duodenum. In most

cases, decompression of the intrapancreatic CBD can be achieved by dissecting the pancreatic tissue along the wall of the CBD. The dorsal capsula of the pancreatic head should be preserved. When an inflammatory process in the wall of the intrapancreatic segment of the CBD causes narrowing, a 15 × 5 mm tangential wall segment is resected to create an internal biliary fistula (Fig. 124.2D). The remaining pancreatic head along the duodenal wall after subtotal resection of the pancreatic head has a shell-like form 5 to 8 mm distant from the duodenal wall. Meticulous suturing of any bleeding vessels using 5/6×0 nonabsorbable suture material should be performed. The reconstruction is executed by excluding a jejunal loop and suturing a two-layer end-to-side anastomosis, applying a duct-to-mucosa technique (Fig. 124.2C). At a distance of 5 to 8 cm from the pancreatic anastomosis, a side-to-end anastomosis with the shell-like rest of the pancreatic head is performed as a two-layer anastomosis. For restoration of the food transit, a typical Roux-en-Y anastomosis is created 20 cm distal from the pancreatic anastomosis. When creating a biliary fistula of the intrapancreatic CBD segment, anastomotic suturing is unnecessary, because drainage of the bile occurs via an excluded jejunal loop (Fig. 124.2D). In patients with a dilated main pancreatic duct and multiple fibrotic duct stenosis of the main pancreatic duct and the first-order side branches, a longitudinal opening of the pancreatic main duct up to the tail of the pancreas is performed. The reconstruction is achieved by performing a side-to-side anastomosis as a Partington-Rochelle modification of the drainage of the pancreatic main duct (Fig. 124.2E). A double-layer suture between the jejunum and the pancreatic tissue is executed using nonabsorbable material.

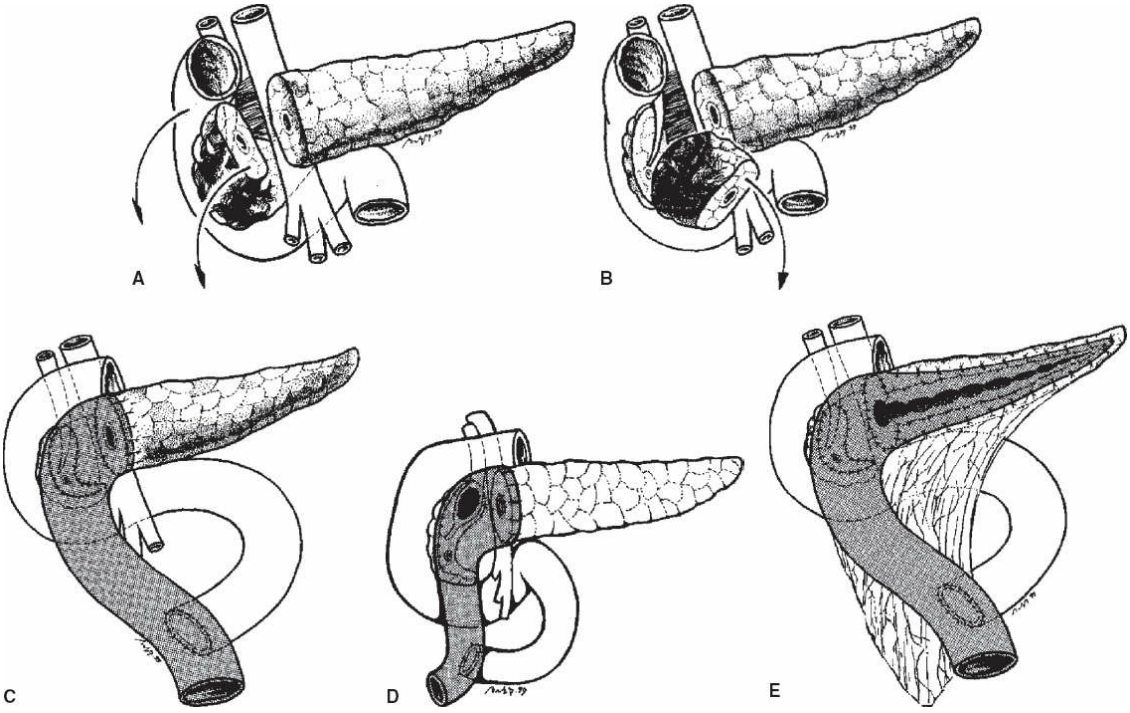

Figure 124.2. **A.** Duodenum-preserving subtotal pancreatic head resection: Tunneling and transection of the pancreatic head preserving the neck. **B.** Subtotal resection after rotation of the pancreatic head. **C.** Reconstruction using an excluded jejunal loop. **D.** Modification of duodenum-preserving subtotal pancreatic head resection with internal biliary anastomosis. **E.** Modification of subtotal pancreatic head resection with duct drainage: modification of the Partington-Rochelle procedure.

Total Pancreatic Head Resection Including the Periampullary Segment of the Duodenum and the Intrapancreatic CBD

The most frequent indications for a total pancreatic head resection and segment resection of the duodenum and CBD are large IPMN tumors, cystic neoplasm suspected of harboring a solid nodule, cystic lesions with inflammatory infiltration of the duodenal wall, insulinoma suspected to be malignant, and growing ampullary and peripapillary adenomas. After transection of the pancreatic head along the duodenal edge of the portal vein, the pancreatic head is mobilized up to the wall of the duodenum. After identification and looping of the common hepatic artery and transection of the pancreatic head toward the papilla along the duodenal wall, transection of the anterior branch of the superior gastroduodenal artery is necessary. Preservation of the posterior branch of the superior pancreaticoduodenal artery is recommended whenever possible. Dissection of the uncinate process is performed, with preservation of the

mesoduodenum facilitated by traction of the loop around the infrapapillary duodenum (Fig. 124.3A). Preservation of both the mostly visible anterior branch of the inferior pancreaticoduodenal artery and the posterior branch of the inferior pancreaticoduodenal arcade is recommended. Transection of the duodenum 2 to 4 cm above and below the papilla of Vater completes the total pancreatic head resection (DPPHR-S) (Fig. 124.3B). The transection of the CBD is performed at the level of the entrance of the CBD into the pancreatic head. In case of resection of a neoplastic lesion, a frozen section of both the resection margin and the solid tissue mass of the tumorous lesion are necessary to exclude an advanced infiltrative malignant process. The first step of reconstruction is the end-to-end anastomosis between the proximal and distal duodenum. After exclusion of the first jejunal loop and the interposition of the aboral loop to the left pancreas, a two-layer duct-to-mucosa end-to-side with the left pancreas is executed (Fig. 124.3C). The CBD is end-to-side sutured to the postpyloric duodenum or the jejunal interponate. The total pancreatic head resection is completed by a Roux-en-Y anastomosis between the jejunal loops. The implantation of the left pancreas into the stomach is increasingly used; performance of a more extensive mobilization of the pancreatic body is necessary, but is a disadvantage of this type of anastomosis.

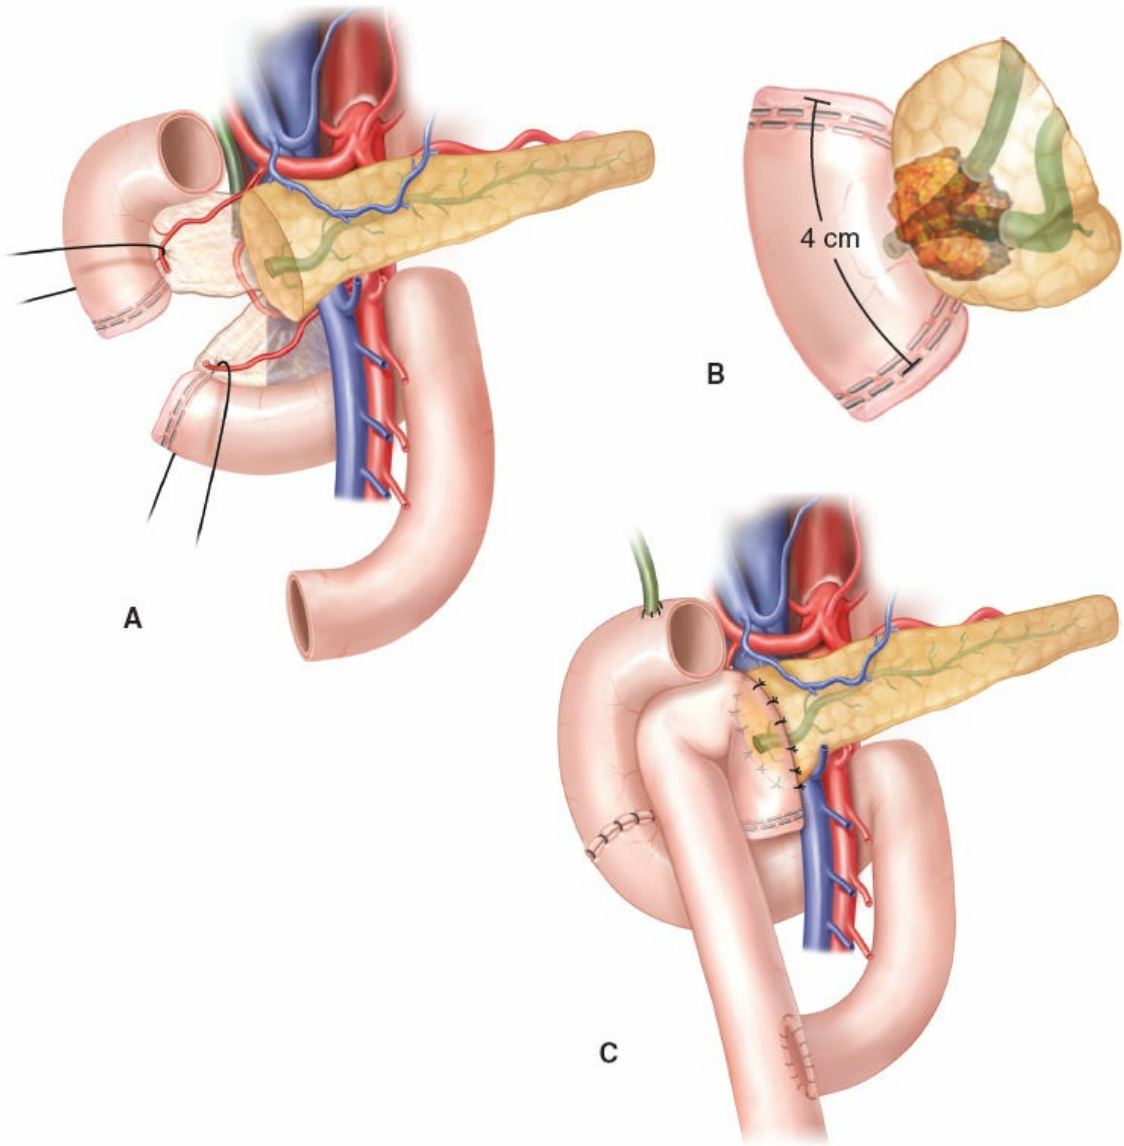

Figure 124.3. **A.** Duodenum-preserving total pancreatic head resection additionally resection of a segment of the duodenum and common bile duct. Dissection of the pancreatic head from the duodenum (DPPHR-S). **B.** Operative specimen after total pancreatic head resection additionally segment of duodenum and CBD. **C.** Reconstruction after total pancreatic head resection with additional segment resection of the periampullary duodenum and the CBD. The first jejunal loop is used for anastomosis with the pancreas.

Total Pancreatic Head Resection, Preserving the Duodenum

A total pancreatic head resection, preserving the duodenum (DPPHR-T), is performed in patients suffering a large cystic neoplasm located in the ventral or dorsal segment of the pancreatic head, which causes narrowing of the intrapancreatic CBD. In patients with a neuroendocrine tumor

located in the pancreatic tissue between the CBD and duodenum and patients suffering biliopancreatic maljunction, a DPPHR-T but resecting the intrapancreatic CBD, is a frequently applied modification to DPPHR-T (Fig. 124.4A). Dissecting the tumor-bearing tissue around the CBD implies a risk of injury to the CBD and of interruption to the nutritional blood supply of the prepapillary CBD. Biliary fistula and ischemia-related stenosis of the prepapillary CBD are observed as procedure-related local complications. Resecting the intrapancreatic CBD and creating a biliary anastomosis using the postpyloric duodenum or the jejunum of the excluded loop is a safe procedure, which avoids biliary complications (Fig. 124.4B). Total pancreatic head resection preserving the duodenum and CBD can be executed elegantly by an anastomosis with the stomach (Fig. 124.4C).

Results After Subtotal Duodenum-Preserving Pancreatic Head Resection

Clinical observation, immunologic data, and molecular-biologic indicators underline the hypothesis that the pancreatic head is the pacemaker of chronic pancreatitis. Resection of the pancreatic head removes the local complications and renders most of the patients pain-free in the long-term outcome.

In terms of hospital mortality rates, frequency of relaparotomy and complications, subtotal pancreatic head resection offers the major advantages of low postoperative morbidity (Table 124.4). A benefit of the application of subtotal resection of the pancreatic head in advanced chronic pancreatitis is the preservation of the endocrine and exocrine functions. In terms of oral glucose tolerance testing after duodenum-preserving subtotal head resection, glucose metabolism is completely maintained early postoperatively in most of the patients (Table 124.5). A small group of patients experienced an early postoperative improvement toward normalization of glucose metabolism. Pancreatic head resection results in a decrease of the preoperatively increased glucagon and somatostatin levels in the peripheral blood, enhancing a decrease of the anti-insulinic effect of these hormones. After a median follow-up of 5.7 years, 39% of the patients had normal findings in the oral glucose tolerance test and 17% had a reduced glucose tolerance, whereas 44% had insulin-dependent diabetes mellitus due to the natural course of chronic pancreatitis (Table 124.6). In terms of the pain status after an observation

period of up to 22 years, 79% of the patients were completely pain-free while 9% continued to experience upper abdominal pain. Further episodes of acute pancreatitis with the need for hospitalization in the late follow-up, with a median of 5.7 years and range up to 22 postoperative years, were occurred in only approximately 12% of the patients (Table 124.6). Regarding the quality of life after subtotal duodenum-preserving pancreatic head resection, approximately 66% of the patients were professionally rehabilitated. After a median observation period of 5.7 years, the late death rate after subtotal pancreatic head resection was between 3.6% and 13%. Of the patients who suffered mortality in the late follow-up period, 50% did so following development of GI-tract cancer (Table 124.6). In comparison with the classical PD, the subtotal duodenum-preserving pancreatic head resection offers the major advantage of preserving the extrahepatic biliary tree, stomach and duodenum. The results of five randomized controlled trials demonstrated the superiority of the duodenum-preserving technique compared to classical PD for patients suffering from advanced chronic pancreatitis. The coring-out technique of Frey is a modification of the Partington-Rochelle duct drainage procedure, resulting in duct decompression. However, according to Frey's publication, the inflammatory mass tissue in the head of the pancreas is conserved, because he propagates only coring-out the anterior region of the pancreatic head toward the duct. In contrast, the wet weight of the tissue specimen after duodenum-preserving subtotal head resection is reported to be 25 to 55 g of the pancreatic head.

Results After Partial and Total Pancreatic Head Resection Applied for Neoplastic Tumors

Total pancreatic head resection with segment resection of the periampullary duodenum and resection of the intrapancreatic segment of the CBD are applied in patients with IPMN of the main and mixed duct

type (Table 124.7). IPMN lesions are predominantly located in the pancreatic head, as it is observed for serous cyst adenomas (SCA). MCN is found in the pancreatic head only in 25% to 32%. Total pancreatic head resection with segment resection of the duodenum and CBD is successfully used in patients suffering a cystic neoplastic tumor with an in-situ carcinoma and for patients with a low-risk malignant cancer of the periampullary region originating from the papilla and ampulla, the intrapancreatic CBD, and the peripapillary duodenum (Table 124.7). The different techniques of tissue resection of the pancreatic head—partial or total head resection—are determined by size, type, and location of the tumor. The selection of the extent of tissue resection is an additional advantage of the duodenum-preserving pancreatic head resection by tailoring the extent of the surgical resection of pancreatic head tissue. In a systematic review of a series of articles published up to March 2015 applying limited pancreatic head resections, 29% of the patients had a total pancreatic head resection with segment resection of the duodenum and CBD, 38% underwent total pancreatic head resection but with preservation of the duodenum, and 32% received a partial pancreatic head resection. In terms of the early postoperative morbidity, severe postoperative morbidity was observed in 12.7% of patients using the Clavien-Dindo classification, with a severity score >3 (Table 124.8). Pancreatic fistula grades B and C were observed in 14% out of a total of 20% of 462 patients. Resurgery was 2.7%, rehospitalization 3.2%, and hospital mortality 0.4% (Table 124.8). A systematic review of 503 patients, who had undergone a duodenum-preserving pancreatic head resection, revealed a low level of pancreatic fistula grades B and C, a low level of reoperation, and a very low level of hospital mortality. A delay of gastric emptying was observed in the majority of patients after total head resection with segment resection of the duodenum and CBD, whereas it was less frequently observed after DPPHR-T and almost absent after partial pancreatic head resection.

The major benefits of the duodenum-preserving pancreatic head resection procedures are conservation of pancreatic and peripancreatic GI-tract tissue and maintenance of endocrine and exocrine pancreatic functions in the short- and long-term outcomes. Meta-analysis data demonstrated conservation of the endocrine functional capacity of the pancreas after total head resection. Similar results have been published after testing of the exocrine pancreatic functions. On evaluation of the endocrine pancreatic functions by determining HbA1C and blood glucose after oral glucose tolerance testing, both methods accordingly confirmed maintenance of the level of glucose metabolism in the short- and long-term outcomes after a limited head resection. In contrast, the results after application of PD showed postoperatively a significant decrease in glucose metabolism with a significant increase of new onset of diabetes mellitus. In total, 6.8% of cystic neoplastic lesions were found to be in-situ carcinoma by the final histologic assessment while 2.4% showed a minimally invasive carcinoma. In 20 of 504 patients (4%) extirpation of a low-risk periampullary cancer was performed (Table 124.7). In the vast majority of patients with a cancerous lesion, a total pancreatic head resection with segment resection of the duodenum and CBD was applied. After a median follow-up of 62.6 months, the frequency of tumor recurrence was 2.9%. No patient who suffered a cancerous lesion—carcinoma in-situ, minimal invasive carcinoma, or low-risk periampullary carcinoma—developed a recurrent disease in the long-term follow-up period.

EDITOR'S COMMENT

The authors describe the parenchyma-sparing, limited partial and total head resection for inflammatory, benign, or low-risk periampullary malignant tumors. This procedure was first described by Professor Hans G. Beger, and the senior author and his colleagues reported results in a classic paper in 1980 and 1990 (Duodenum-preserving resection of the head of the pancreas in severe chronic pancreatitis. Early and late results. *Ann Surg* 1989;209:273–8). It is an honor to have him contribute this chapter as Professor Beger is a leading authority in the surgical management of chronic pancreatitis. As the authors state a pancreatic head mass associated with chronic pancreatitis seems more common in Europe than in the United States or Asia. Although the use of duodenal-preserving pancreatic head resections is less common in the United States, they are gaining momentum based on prospective studies showing equivalent morbidity and mortality to the Whipple procedure and pain control while yielding better nutritional outcome for the patient (Mihaljivic AL et al. Beger's operation and the Berne modification: origin and current results. *J Hepatobiliary Pancreat Sci* 2010;17:735–44).

The operation of a duodenum-preserving pancreatic head resection is technically challenging. However, new developments in energy devices have facilitated the dissection of the head of the pancreas. In Beger procedure, the

pancreas is dissected at the level of the portal vein. The pancreatic head is removed and the duodenum is preserved with a thin layer of pancreatic tissue. If the bile duct is obstructed, it can be opened and an internal anastomosis with the residual pancreatic head can be performed. The reconstruction is performed with two anastomoses, of the pancreatic tail remnant and of the residual pancreatic head with a single Roux-en-Y jejunal loop as shown in Figure 124.2C.

The expected outcome of the Beger procedure for chronic pancreatitis is very good with excellent pain relief. Pancreatic endocrine and exocrine function are better than after a pancreaticoduodenectomy. In addition, GI continuity, duodenal motility, and duodenal endocrine function are maintained. The latter is important for coordinating GI endocrine function. Hence, nutritional status of the patient may be superior to a Whipple procedure. It is important for the reader to know that the procedure does not change the natural progression of the cellular damage chronic pancreatitis and both exocrine and endocrine function will deteriorate over time.

Specific results for the Beger procedure demonstrate pain relief of 80% to 85% in a 5-year follow-up study and another 14-year follow-up study reported 78.8% of pain-free subjects. Diabetes incidence after DPPHR ranges within 8% to 21%, and some patients may have improvement in glucose metabolism. This may be related to duodenal preservation and more normal and coordinated postprandial GI endocrine function. Complications include risk of duodenum ischemia usually related to inadequate perfusion of the posterior branch of the gastroduodenal artery. This may result in perforation or development of duodenal stricture. In addition, stricture of the bile duct may develop.

Other techniques for duodenal-preserving pancreatic head resection in chronic pancreatitis include that described by Professor Charles Frey et al. (Description and Rationale for a new Operation for Chronic Pancreatitis. *Pancreas* 1987;2:701–7) and Bern modification. The Frey procedure is a modification of the Beger that is a combination of the Beger- and Partington-Rochelle procedures. Compared to the Beger procedure, the resection in the pancreatic head in the Frey-modification is smaller and combined with a lateral pancreaticojejunostomy to drain the entire pancreatic duct toward the tail. In contrast to the Beger procedure, reconstruction can be performed with one single anastomosis. This procedure is not suitable in patients with a large inflammatory mass in the pancreas without stenosis of the distal pancreatic duct as is not uncommonly observed. However, it appears advantageous in patients with less severe inflammation in the head combined with an obstruction in the distal pancreatic duct.

The Berne modification (Klaiber U et al. Duodenum-preserving pancreatic head resection: 10-year follow-up of a randomized controlled trial comparing the Beger procedure with the Berne modification. *Surg* 2016;160:127–35) represents a technical simplification of the Beger procedure with equal outcome. The removal of the pancreatic head can be performed with identical

extent compared to the Beger procedure. However, in contrast to the Beger procedure, the pancreas is not divided at the level of the portal vein, which is often difficult because of inflammation and portal hypertension. The reconstruction can be performed by one single anastomosis between a jejunal loop and the continuous pancreatic resection rim. As in the Beger procedure, a bile duct obstruction can be managed by internal bile duct anastomosis. The Bern modification of DPPHR appears ideal for patients with an inflammatory mass and without stenosis of the distal pancreatic duct.

If duodenal-preserving pancreatic head resection is chosen for treatment of chronic pancreatitis, an intraoperative biopsy and frozen section is advisable to rule out pancreatic adenocarcinoma unless a preoperative biopsy or tissue sampling for cytology has been performed. If the frozen section is suspicious for malignancy or if a cancer is suspected, then a pancreaticoduodenectomy is the best operation.

We have not employed this technique for IPMN, mucinous cystic neoplasms, and neuroendocrine tumors of the pancreas. However, the level of evidence local resection compared to standard oncologic resections appears presently low (Beger HG et al. Limited surgery for benign tumours of the pancreas: a systematic review. *World J Surg* 2015;39(6):1557–66). For localized side, branched IPMN, cystic mucinous neoplasms or benign neuroendocrine tumors with no suspicion of malignancy duodenal-preserving pancreatic head resection, central pancreatectomy, or local excision may make sense. Indeed, local excision techniques applied for benign tumors have equivalent postoperative morbidity and mortality with the Whipple operation with the advantages of conservation of pancreatic functions. However, in my opinion there is insufficient evidence to show that these procedures are equivalent to standard pancreaticoduodenectomy. As for main duct IPMNs, our group favors pancreaticoduodenectomy if the lesion is in the head of the pancreas or uncinate process. It is important to appreciate that based on the Mayo experience all patients with intra- or postoperative evidence of invasive carcinoma at the resection margin should undergo further resection to achieve a negative margin and that patients with evidence of IPMN at the transection margin (even with changes of high grade dysplasia) may not achieve any benefit from further resection. The incidence of recurrence in the residual gland is about 10 and not infrequently occurs 5 to 10 years from the initial procedure. The point is that main duct IPMNs have a propensity for malignant transformation and represent a field abnormality of the pancreas. Application of limited duodenal-preserving pancreatic head resection in this group of patients would require multicenter randomized prospective trials.

In my experience, all neuroendocrine tumors 2 cm or greater should be treated with an operation to achieve oncologic control. In most cases for a tumor in the head of the gland, this requires pancreaticoduodenectomy. Smaller tumors may be locally excised if the pancreatic duct is not too close to the lesion. Unfortunately, most of the time the duct is very close to the tumor and local

excision results in a pancreatic fistula that is difficult to control. Hence, pancreaticoduodenectomy is necessary in most cases. Neuroendocrine tumors at the neck of the gland are amendable to central pancreatic resection. We have applied this technique exclusively to small insulinomas as they are benign in 90% to 95% of patients.

E. Christopher Ellison

125 Necrosectomy for Acute Necrotizing Pancreatitis

Peter Muscarella and E. Christopher Ellison

INTRODUCTION

Acute pancreatitis remains a challenging and common problem for pancreatic surgeons and other health care professionals who manage these patients. Patients with severe acute pancreatitis (SAP) often present with a considerable systemic inflammatory response and varying degrees of organ dysfunction. These patients are at risk for the development of local complications of pancreatitis including pancreatic necrosis, pseudoaneurysms and bleeding, fistulas and strictures, and infected pancreatic necrosis (IPN). The development of IPN is known to be associated with almost universal mortality without adequate source control. Open necrosectomy was used successfully in the past to decrease mortality, but resulted in considerable morbidity such as fascial dehiscence, incisional hernia, and gastrointestinal fistulas. Considerable advances in the understanding and management of SAP have been made over recent years with regard to definitions and nomenclature, severity scoring, management of the early systemic response and organ failure, nutritional support, the role of antibiotics, patient monitoring and timing of intervention, and minimally invasive approaches for necrosectomy. Numerous studies have shown that both delays in intervention, and minimally invasive approaches, result in improved outcomes and decreased complications, although there is a lack of data proving that minimally invasive necrosectomy improves mortality compared to open necrosectomy for IPN. As is the case with so many other diseases that we treat, advances in knowledge and technology have mandated a multidisciplinary approach for the management of patients with SAP.

Acute pancreatitis is a common problem encountered by pancreatic surgeons and accounts for nearly 220,000 hospital admissions per year in the United States. Pancreatitis represents the most common gastrointestinal diagnosis for patients being discharged from the hospital and the frequency

of admissions has increased by 30% over the last decade. Approximately 80% of cases of acute pancreatitis represent a mild, self-limited disease. These patients do not develop ongoing systemic symptoms, organ failure, or local complications such as necrosis. Patients are treated with fluids and bowel rest, and symptoms resolve quickly over a few days. For patients with an initial attack of mild acute pancreatitis, a limited investigation for the etiology should be undertaken and steps should be taken to minimize the risk of recurrent acute pancreatitis. For example, cholecystectomy should be performed at the time of initial hospitalization in all patients who are fit for surgery and alcohol cessation should be encouraged for patients with alcohol-induced pancreatitis. The remaining 20% of patients will have a more severe form of pancreatitis that is associated with acute illness, organ failure, local complications, and considerable mortality. Approximately 15% of patients with SAP will develop pancreatic necrosis and IPN occurs in 30% to 70% of these patients. These patients will require some form of necrosectomy, but still have mortality rates that range from 19% to 24%. Although there is some controversy regarding the management of sterile necrosis, most pancreatologists would agree that there is no benefit for intervention in cases of sterile necrosis and that these procedures should be reserved for symptoms and persistent collections in patients who go on to develop walled-off pancreatic necrosis (WOPN) (Fig. 125.1).

Goals of therapy for patients with SAP and pancreatic necrosis include accurate severity scoring, the implementation of early measures to treat the massive systemic inflammatory response and support organ function, appropriate imaging and monitoring for local complications, accurate diagnosis of IPN, and appropriate timing and intervention for IPN. The importance of avoiding iatrogenesis cannot be stressed enough. Patients with SAP can be very ill and commonly exhibit signs and symptoms of sepsis. This may prompt inexperienced or poorly informed clinicians to initiate unnecessary or potentially dangerous therapies such as antibiotics, percutaneous catheter drainage, or surgical intervention due to a genuine desire to help the patient in the context of a critically ill patient for whom no specific therapy is being utilized other than supportive measures. In general, these interventions should be avoided and clinicians should be encouraged to exercise patience in managing individuals with SAP. Such interventions should be reserved for patients with proven infections, which are unlikely to occur in the early phases of SAP. There is no “fast-track” in

these situations. The damage to the pancreas most certainly occurred prior to presentation to the hospital and it is the physician's job to support the patient and manage sequelae as they arise. The purpose of this chapter is to review the evaluation and treatment of SAP with particular emphasis on techniques and outcomes for the management of IPN.

Figure 125.1. Computed tomography (CT) image from a patient with walled-off pancreatic necrosis (WOPN). There is a large fluid collection replacing the body and tail of the pancreas. Note the lack of contrast enhancement and compression of the stomach that lies anterior to the collection.

CLINICAL PRESENTATION

Etiology

There are numerous causes for AP (Table 125.1), although alcohol and gallstones account for the vast majority of cases, representing more than

one third of cases each. The pathogenic mechanisms through which alcohol causes AP appear to be multifactorial and complex. Although alcohol is responsible for a considerable number of cases of AP, most heavy drinkers will not develop AP suggesting that other cofactors (possibly genetic) are involved. There is some controversy regarding the contribution of smoking to acute pancreatitis, as this is a common habit among heavy drinkers. There is no clear causal relationship between smoking and AP, although it is generally agreed that prolonged smoking accelerates the progression of pancreatitis. There are also numerous theories regarding the underlying pathogenesis of gallstone pancreatitis, although choledocholithiasis and biliary involvement are known to incite AP. The role of the so-called biliary sludge is more controversial, but well-designed studies indicate that cholecystectomy is associated with a decreased incidence of recurrent AP in patients with biliary sludge on right upper quadrant ultrasonography. The effect of cholecystectomy, endoscopic biliary sphincterotomy, and bile acid therapy on the incidence of recurrent AP in patients with sludge identified on more sensitive tests such as magnetic resonance imaging (MRI) or endoscopic ultrasonography (EUS) is less clear.

Endoscopic retrograde cholangiopancreatography results in AP in 5% to 10% of patients undergoing these procedures and the etiology is usually clear in these cases. The underlying pathophysiology appears to be related to increased pancreatic duct (PD) pressures and trauma as technically difficult procedures and aggressive contrast injection into the PD are commonly associated with AP. Consequently, ERCP is typically reserved for therapy in patients with pancreaticobiliary disease and has been largely supplanted by other tests such as magnetic resonance cholangiopancreatography (MRCP) and EUS for diagnosis. Prophylaxis with various agents, such as protease inhibitors and nonsteroidal anti-inflammatory drugs (NSAIDs), have been evaluated in an attempt to decrease the incidence of post-ERCP pancreatitis, although the results are inconsistent, and none of these agents are widely used for this purpose at the current time. Trauma and surgery can result in pancreatitis and the cause is usually obvious in these cases. Specific treatment is individualized and generally focuses on management of fluid collections, sepsis, and associated duct disruptions if they are present. PD obstruction can certainly cause AP and the underlying lesions generally represent strictures, anatomic abnormalities, and benign or malignant tumors. There

is clearly a relationship between pancreatitis and pancreatic cancer. Pancreatic cancer can certainly present as AP and the grossly abnormal imaging so often seen in patients with SAP can easily mask malignant tumors that can often escape detection even under the best of circumstances. Clinicians should always be cognizant of the possibility of pancreatic cancer in patients with unexplained AP, particularly older patients. There has been considerable controversy related to congenital PD abnormalities and their relationship with AP. Pancreas divisum occurs in 5% to 10% of the normal population and represents an embryologic failure of fusion of the dorsal and ventral ducts resulting in the majority of the pancreatic exocrine secretions draining through the minor papilla. The incidence of pancreas divisum in the AP patient population appears to be similar to that of the general population, suggesting that this may not be a true cause of AP. Surgical and endoscopic minor duct sphincterotomy or "sphincteroplasty" were commonly recommended in the past, but appear to offer no benefit at this time.

Adapted from Trivedi CD, Pitchumoni CS. Drug-induced pancreatitis: an update. *J Clin Gastroenterol* 2005;39(8):709–16; with permission from Wolters Kluwer Health, Inc.

Toxins and drugs are a rare, but probably underreported, cause of AP. Every medical student is fascinated with the possibility that their patient may have received a scorpion sting, but this is an exceedingly rare cause of pancreatitis in most areas. Toxins present in gila monster venom, however, may be indirectly associated with AP as a peptide found in gila monster saliva forms the basis for the glucagon-like peptide 1 (GLP-1) receptor agonist class of agents used for the management of diabetes and these are known to result in AP. It is less clear whether other diabetic medications are associated with AP. Innumerable other medications have been reported to be associated with AP and these are generally organized by class

(antimicrobials, cardiovascular agents, neuropsychiatric agents, antineoplastic agents, anti-inflammatory agents, GI agents, hormones, and immunomodulators). It is likely that drug-induced pancreatitis is more common than most clinicians appreciate, as many cases may be ascribed to alcohol or other causes, and the diagnosis is essentially one of exclusion. There are really no specific tests that can be used to determine whether AP was caused by a specific medication and the timing of prescription may not temporally relate to the onset of AP. Nevertheless, astute physicians should suspect drug-induced AP in high-risk subpopulations such as geriatric patients on multiple medications, HIV+ patients, cancer patients, and patients receiving immunomodulating agents.

Metabolic and other causes are rare, but will eventually be seen by most physicians who treat AP frequently. Serum triglyceride levels are markedly elevated in patients with AP related to hypertriglyceridemia, typically in the thousands. There is some evidence that elevated triglyceride levels may be associated with persistent organ failure in patients with SAP, regardless of the etiology. Hypercalcemia is a rare cause of AP and can be primary or secondary. Our group has seen at least two cases of hypercalcemia-related AP in patients with disseminated neuroendocrine tumors, essentially representing a paraneoplastic syndrome. Autoimmune pancreatitis is a rare disorder that typically presents with a characteristic appearance on cross-sectional imaging that has been referred to as a “sausage-like” appearance. This is probably the most specific diagnostic abnormality. Serum IgG4 levels may be elevated on IgG subclass evaluation, but normal levels do not rule out the possibility of autoimmune pancreatitis. The identification of autoimmune pancreatitis is crucial for these patients as they respond well to steroids and other medical therapies.

Genetic abnormalities are increasingly recognized as the causative factor in many patients with AP. It is likely that some cases of idiopathic pancreatitis may be due to yet unidentified genetic mutations and research continues on affected kindreds in order to identify potential abnormalities. Known causes of familial or hereditary pancreatitis include mutations in the cationic trypsinogen (PRSS1), cystic fibrosis transmembrane conductance regulator (CFTR), and serine protease inhibitor, Kazal type 1 (SPINK1) genes. Referral to a genetics counselor can be considered for patients with idiopathic AP, particularly the young and those with a positive family history for pancreatitis or pancreatic cancer. Recent

research into the molecular mechanisms leading to AP based on the cationic trypsinogen and SPINK1 gene products offers great insight into the underlying pathophysiology that most likely occurs in all patients with AP and this appears to be based on inappropriate intraacinar activation of trypsinogen. The activated trypsin subsequently cleaves other proenzymes resulting in a complex cascade of events that result in autodigestion of the native pancreatic tissue and the consequent release of inflammatory mediators responsible for the systemic inflammatory response and related organ failure (Fig. 125.2).

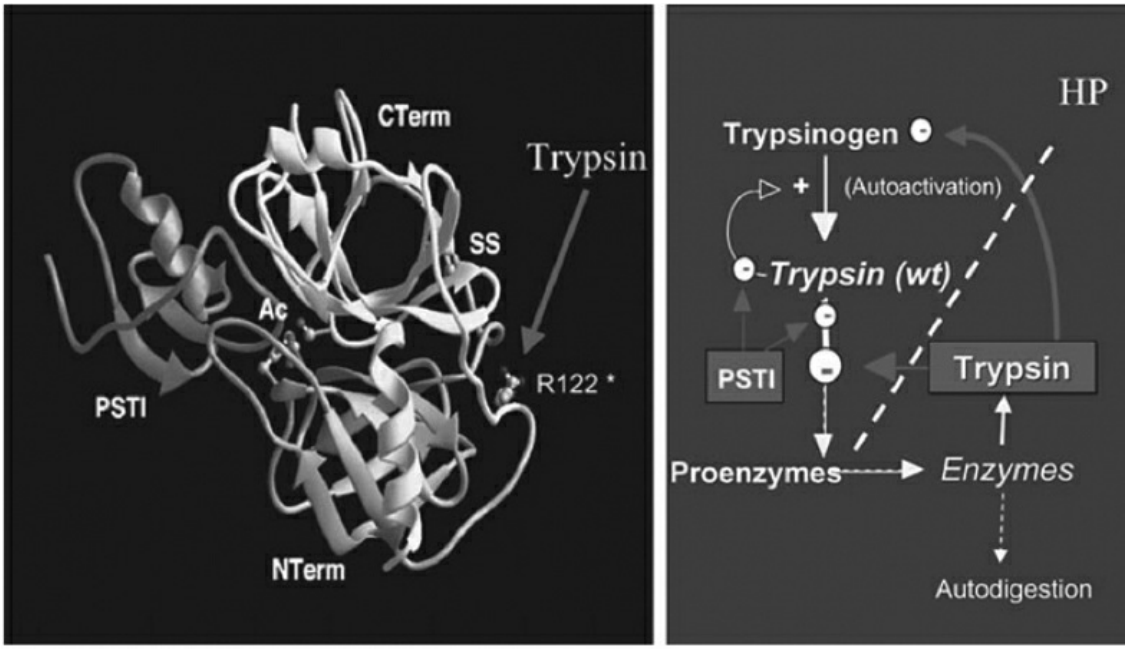

Figure 125.2. Molecular model for trypsin inactivation. Trypsinogen is made by the pancreas in an inactive form. Trypsinogen is normally cleaved in the intestine by enterokinase and contributes to the activation of essentially all of the other digestive enzymes. Inappropriate pancreatic activation of trypsinogen results in acute pancreatitis. The trypsin inhibitor SPINK1/PSTI blocks the active site and prevents trypsin from activating other trypsinogen molecules and digestive enzymes. In order to further protect the pancreas from activated trypsin activity, normal trypsin attacks itself at arginine #122 (R122). This causes destruction of activated trypsin and prevents an ongoing cascade of intrapancreatic enzymatic activation. The PRSS-1 mutation is located at R122. This elegant model explains how mutations of PRSS-1 or SPINK1/PSTI can result in hereditary pancreatitis and offers insight into the pathogenesis for other forms of pancreatitis. and chronic pancreatitis. *Pancreatology* 2001;1(6):566–71. Copyright © 2001, with permission from Elsevier.)

Signs and Symptoms

Patients with AP almost universally present with the acute onset of severe epigastric abdominal pain that often radiates to the back. This is commonly ascribed to a precipitating alcohol binge or a fatty meal, although it should be clear that food itself is not a cause of AP and there is very little evidence that "stimulation" of the pancreas by enteral feeding results in persistent inflammation or adversely affects outcomes for SAP. In fact, the frequent observation that enteral nutrition provides benefit for patients with SAP suggests quite the opposite. Patients may have varying degrees of organ failure depending on severity and can be quite ill with hypotension, tachycardia, respiratory distress/failure, and acute kidney injury (AKI). Nausea and vomiting can be seen, but are generally not the predominant clinical symptoms. NG decompression can be useful for these patients, but is generally not otherwise beneficial. Physical examination findings are generally nonspecific, although there are some rare signs that are extremely specific for AP. Patients generally will have diffuse abdominal tenderness, particularly in the epigastric region, with abdominal distension. The abdomen is generally soft, but may become more distended and rigid for patients who receive aggressive resuscitation and this can lead to abdominal compartment syndrome in some cases. Peritoneal signs are generally absent, although patients generally complain of severe pain. Their presence should suggest the possibility of other acute abdominal processes that may require emergent surgical intervention. Grey-Turner and Cullen's signs represent flank and periumbilical ecchymosis that can result from retroperitoneal edema and bleeding. Although these can be seen with other disorders, they are classically associated with SAP. Pancreatic panniculitis represents small erythematous skin lesions that can be present throughout the body, but are generally identified on the dorsal aspect of joint surfaces (Fig. 125.3). These are quite rare, but may occur when systemic levels of pancreatic enzymes are high enough for digestion of soft tissue to occur. This can be seen in patients with pancreaticoportal or pancreaticosplenic fistulas.

Diagnosis

The diagnosis of acute pancreatitis should be based on clinical presentation

and laboratory studies. Patients with the characteristic presentation of abdominal pain who are noted to have elevated serum pancreatic enzyme levels should be given a diagnosis of acute pancreatitis. Serum amylase and lipase levels can both be measured and these tests may offer complementary information. Serum amylase is generally less accurate. False-positive results may be seen in patients with disorders resulting in increased salivary amylase (mumps, parotitis) or macroamylasemia. False negatives may be seen in several situations. Patients with a history of chronic pancreatitis may develop a “burned-out” pancreas due to acinar atrophy and these patients can have acute exacerbation with considerable inflammation of the pancreas, yet have normal serum amylase levels. Extremely elevated serum triglyceride levels can interfere with the assay for measuring serum amylase, and these values will appear normal. Finally, patients with a delayed presentation may have normal serum amylase levels, as they may have peaked prior to presentation and were unmeasured. Serum amylase generally peaks prior to serum lipase. Serum lipase levels are considered to be more sensitive than amylase levels and may be more useful in patients with a delayed presentation.

Radiologic evaluation should be reserved for selected patients, as the diagnosis of acute pancreatitis is generally not made based on the results of imaging studies. For the majority of patients with mild AP, abdominal imaging is completely unnecessary. Computed tomography (CT) imaging can be useful for patients for whom the diagnosis remains questionable, or for patients in whom other diagnoses are being considered. CT imaging is also considered to be mandatory for the evaluation of patients with SAP as it provides considerable information about complications of pancreatitis such as fluid collections, fistulas, and pancreatic necrosis. The timing of CT imaging for these patients has been the subject of some debate, but most pancreatologists would agree that it is reasonable to wait several days after presentation because necrosis might not be apparent on early imaging. Furthermore, the use of intravenous (IV) contrast may be dangerous in patients with compromised organ function as it can exacerbate AKI. Some investigators have evaluated MRI for the evaluation of SAP, but this has not become widely adopted.

Figure 125.3. Pancreatic panniculitis. Characteristic painful and erythematous skin lesions that are generally located on the dorsal aspect of joint surfaces in patients with acute pancreatitis.

Severity Scoring and Nomenclature

Due to the stark contrast in clinical course and outcomes between patients with mild AP and SAP, an accurate and early determination of severity should be performed for all patients with AP. Numerous severity scoring systems have been utilized and these are based on clinical parameters, physiologic data, and/or radiologic findings. Perhaps the most well-known system is the Ranson criteria, which are based on 11 clinical parameters that are measured at the time of initial presentation and 48 hours after admission (Table 125.2). Mnemonic for Ranson criteria are GA LAW and C HOBBS. Ranson criteria have been shown to accurately predict mortality for AP and most health care providers are familiar with their use. Patients with ≥3 criteria are considered to have SAP. Disadvantages of Ranson criteria include missing data for patients transferred to a tertiary care center many days after their initial presentation and the inability to track changes in severity over time. The APACHE II scoring system is a physiologic scoring system that involves the collection of variables and the

calculation of a combined score. An APACHE II score ≥8 is considered to signify SAP. This scoring system is more complex, but does offer the advantage of allowing for the evaluation of trends in severity over time and has become popular with intensivists who manage SAP. Radiologic severity scoring systems, such as the computed tomography scoring index (CTSI), utilize CT imaging data that usually include the presence and extent of pancreatic necrosis and peripancreatic fluid collections. These systems provide objective scoring of pancreatic imaging findings, but are clearly not useful for triaging patients to undergo CT imaging.

TABLE 125.2 Ranson Criteria for the Evaluation of Acute Pancreatitis Severity

At admission:
Age in years >55 years
White blood cell count >16,000 cells/mm^3
Blood glucose >11 mmol/L (>200 mg/dL)
Serum AST >250 IU/L
Serum LDH >350 IU/L

48 hours:
Serum calcium <2.0 mmol/L (<8.0 mg/dL)
Hematocrit fall >10%
Oxygen (hypoxemia PaO_2 <60 mm Hg)
BUN increased by 1.8 or more mmol/L (5 or more mg/dL) after IV fluid hydration
Base deficit (negative base excess) >4 mEq/L
Sequestration of fluids >6 L

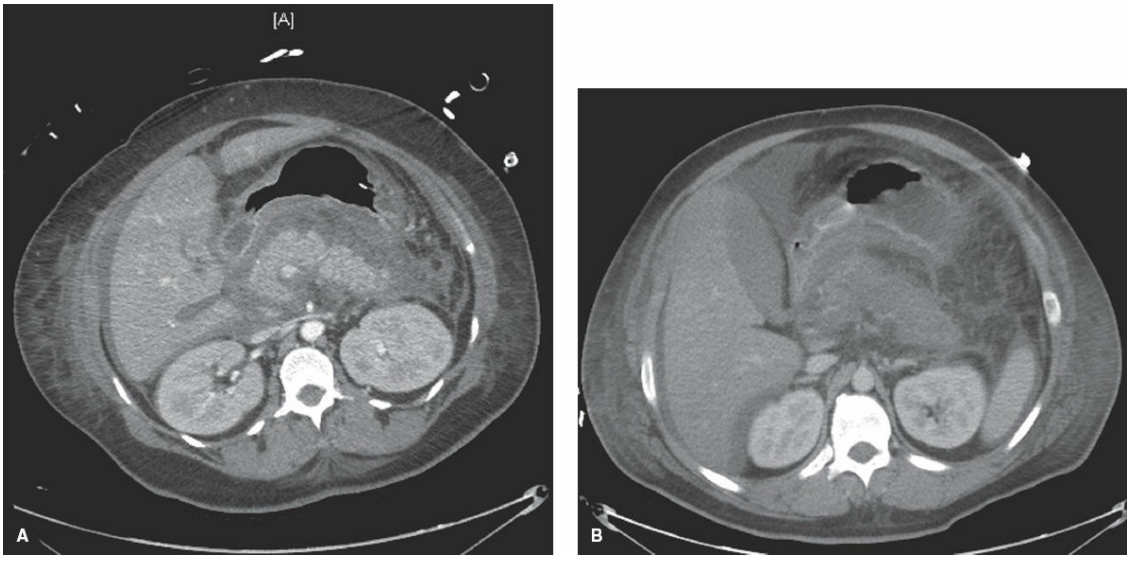

Figure 125.4. Computed tomography (CT) images from patients with acute edematous interstitial pancreatitis (**A**) and necrotizing

pancreatitis (**B**). Both studies demonstrate findings of pancreatic edema, swelling, and inflammation. Contrast enhancement of the pancreatic parenchyma is absent in the patient with necrotizing pancreatitis.

The revised Atlanta classification and definitions were published in 2012 in order to standardize reporting of research and improve communication between physicians caring for patients with AP. This consensus report addressed several areas of concern that include diagnosis, severity scoring, phases of disease, and an appropriate classification of imaging findings. According to the revised Atlanta classification, the diagnosis of AP can be made when two of three criteria are met: (1) characteristic abdominal pain; (2) serum amylase or lipase activities greater than three times the upper limit of normal; and (3) characteristic findings on cross-sectional imaging. Onset of pancreatitis is defined as the time of onset of abdominal pain, not the time of admission or transfer. Types of AP are classified as either acute edematous interstitial pancreatitis or necrotizing pancreatitis, with or without fluid collections (Fig. 125.4). Severity is further divided into mild, moderate, and severe forms. Mild acute pancreatitis is characterized by lack of organ failure, moderate acute pancreatitis by transient organ failure, and SAP by persistent organ failure. Phases of pancreatitis are described as early (<1 week) and late (weeks to months). Although organ failure and a severe systemic inflammatory response can be seen in the early phase, IPN is exceedingly rare during this time. Perhaps one area that has caused the most confusion among clinicians caring for patients with AP is the classification of peripancreatic fluid collections. The revised Atlanta classification has nicely addressed this issue by characterizing these fluid collections according to timing (> or <4 weeks) and the presence or absence of pancreatic necrosis (Table 125.3). The ambiguous term “pancreatic abscess” has been abandoned. Although there can be disagreement regarding some of the classifications and definitions described in the consensus report, this represents an important attempt to provide uniformity, and physicians who provide care for patients with AP should be familiar it.

TABLE 125.3 Revised Atlanta Definitions of Peripancreatic Fluid Collections

	Timing (Weeks)	Presence of Necrosis
Acute peripancreatic fluid collection	<4	–
Pancreatic pseudocyst	>4	–
Acute necrotic collection	<4	+
Walled-off necrosis	>4	+

INITIAL MANAGEMENT

As alluded to previously, the most important thing that clinicians can do for patients with AP during the initial management of the disease is to perform early and accurate measurement of disease severity. Regardless of the system or definitions used, all decision-making that follows is based on this determination. For patients with mild AP, symptoms will resolve within several days. Treatment for these patients should consist of bowel rest, IV fluids, and observation. A careful history, limited laboratory evaluation, and right upper quadrant abdominal ultrasonography should be performed in an attempt to identify the etiology. The underlying cause should be addressed if possible. For patients with gallstone pancreatitis, cholecystectomy should be performed at the time of the initial hospitalization in an effort to prevent a subsequent episode of SAP. Cholecystectomy is typically deferred for patients with SAP or local complications such as fluid collections. Once symptoms have resolved, and the pancreatic enzyme levels appear to be normalizing, the patients' diets can be advanced and they can be discharged with appropriate follow-up.

Timely intervention can be life saving for patients with SAP. Early transfer to an intensive care unit at a tertiary care center specializing in pancreatitis management should be considered in order to allow for aggressive fluid resuscitation, physiologic monitoring, and support of organ dysfunction. CT imaging with IV contrast should be performed for all patients with SAP in order to identify local complications, including necrosis. It is generally agreed that this study can be deferred for 5 to 7 days in order to allow for necrosis to evolve, and possibly to minimize the risk of renal toxicity due to IV contrast material.

There has been considerable research regarding the use of nutritional support in patients with SAP. Most studies indicate that total parenteral nutrition (TPN) is associated with an increased risk of adverse outcomes, particularly infections, as compared to enteral nutrition with feeding tubes.

Most studies comparing these modalities utilize nasojejunal feeding tubes. There is a common misconception among clinicians that feeding proximal to the duodenum somehow results in pancreatic stimulation and promotes ongoing inflammation. Clinical data really do not support this supposition as numerous studies have shown that the nasogastric, and even a trial of oral feeding, can be safe in patients who tolerate them. We recommend a trial of oral feeding or nasogastric feeding in patients with SAP. If this is not tolerated, feeding through a nasojejunal or postpyloric feeding tube should be instituted. TPN should be reserved for patients who do not tolerate nasoenteric feeding, or for patients in whom there are issues with feeding tube placement. Withholding nutritional support altogether is probably not beneficial for these patients.

The use of prophylactic antibiotics in an effort to decrease the incidence of IPN was controversial in the past. Furthermore, clinicians are inclined to start antibiotics during the initial inflammatory phase of SAP because of numerous clinical findings that can lead them to believe that an infection is present such as tachycardia, fever, and organ failure. Current guidelines universally recommend against starting antibiotics in these patients as numerous randomized, prospective trials and comprehensive reviews have demonstrated no benefit for prophylactic antibiotics. Again, there is universal agreement that infection is exceedingly rare in the first week. Antibiotics should be reserved for patients with proven iatrogenic infections or for those in whom IPN is proven or suspected, usually more than 1 week after presentation. Although IV antibiotics are appropriate for the treatment of IPN, they should not be used in lieu of adequate source control except in selected patients.

Numerous agents such as octreotide and anti-inflammatory molecules have been evaluated as specific therapy for AP with somewhat mixed findings. None of these therapies have demonstrated proven benefit in well-designed studies. As such, there are really no targeted therapies for AP that are currently in use.

MANAGEMENT OF PANCREATIC NECROSIS

Sterile Necrosis

It is generally accepted that patients with sterile pancreatic fluid collections, with or without necrosis, should be treated conservatively with observation and serial imaging. It is our practice to perform periodic imaging studies as an outpatient until fluid collections have resolved.

Intervention should be reserved for symptoms and infection. Symptoms generally include abdominal fullness, possibly with a palpable mass, pain, difficulty eating, weight loss, and pain. For patients with areas of WOPN that fail to resolve and result in symptoms, there are several options for management including percutaneous catheter drainage, endoscopic drainage, and open or laparoscopic internal drainage. Percutaneous catheter drainage is relatively noninvasive, but has many disadvantages. Particulate debris may not adequately drain through the small catheters and effective management is generally labor intensive, requiring multiple procedures with upsizing and placement of multiple catheters. There is also a risk of introducing infection into a sterile collection in cases of inadequate drainage. Numerous studies have shown that PD involvement, as documented by duct disruption or communication, is associated with a high rate of recurrent collections in patients undergoing percutaneous drainage. Furthermore, fluid collections associated with isolated distal pancreatic segments that arise when a portion of the middle of the pancreas has essentially been destroyed by pancreatitis are not likely to resolve unless some sort of internal drainage or resection of the isolated segment is provided. It is for these reasons that we recommend liberal use of pancreatography by ERCP or MRCP for planning of therapy in patients requiring drainage of WOPN.

Endoscopic transgastric and/or transpapillary drainage of WOPN has become more widely accepted and decision-making regarding treatment of these patients should involve multidisciplinary consultation with medical pancreatologists and advanced therapeutic endoscopists. Transgastric endoscopic drainage is performed under sufficient anesthesia. EUS is utilized in order to identify the area of WOPN and access to the fluid collection is gained using a needle-knife. The tract is then serially dilated over a wire under fluoroscopic visualization and one or more stents are placed in order to maintain internal drainage. In the past, standard plastic endoscopic stents were utilized, but larger metal stents are currently available and these may provide durable internal drainage in patients with duct involvement (Fig. 125.5). In cases where the endoscopist is able to create a large communication with the cavity, endoscopic debridement and removal of particulate debris can be performed. For some patients with proximal PD strictures or limited areas of duct involvement, transpapillary PD stenting can facilitate transgastric drainage of WOPN.

For patients who are not candidates for, or fail endoscopic drainage,

open or laparoscopic internal drainage can be performed. The procedure is generally referred to as cystgastrostomy, but many pancreatic surgeons now refer to this procedure as transgastric necrosectomy. Access is gained to the abdomen through an open incision or laparoscopically. A transverse anterior gastrotomy is created with cautery or energy. Stay sutures can facilitate visualization and allow for minimizing the length of the gastrotomy. The area of WOPN is usually identified by visualization of a bulge in the posterior wall of the stomach or palpation. Intraoperative ultrasonography (IOUS) can facilitate identification of the area of WOPN. The collection should be aspirated with an 18-gauge needle prior to entering the cavity in the rare event that a pancreatic pseudoaneurysm is present. Once the location is confirmed by aspiration of cyst fluid, an incision is created in the posterior gastric wall and continued through the wall of the cavity. Fluid is then aspirated and the length of the communication should be extended to 3 to 5 cm. Mechanical debridement of necrotic material is then performed. The wall of the cavity should be sent for frozen section in order to rule out a cystic neoplasm, but this would be fairly unlikely in a patient with a history of pancreatitis resulting in WOPN. The communication is then marsupialized with interrupted sutures and the anterior gastrotomy can be closed with a stapling device. Gastrojejunostomy feeding tube placement can be considered for patients with malnutrition.

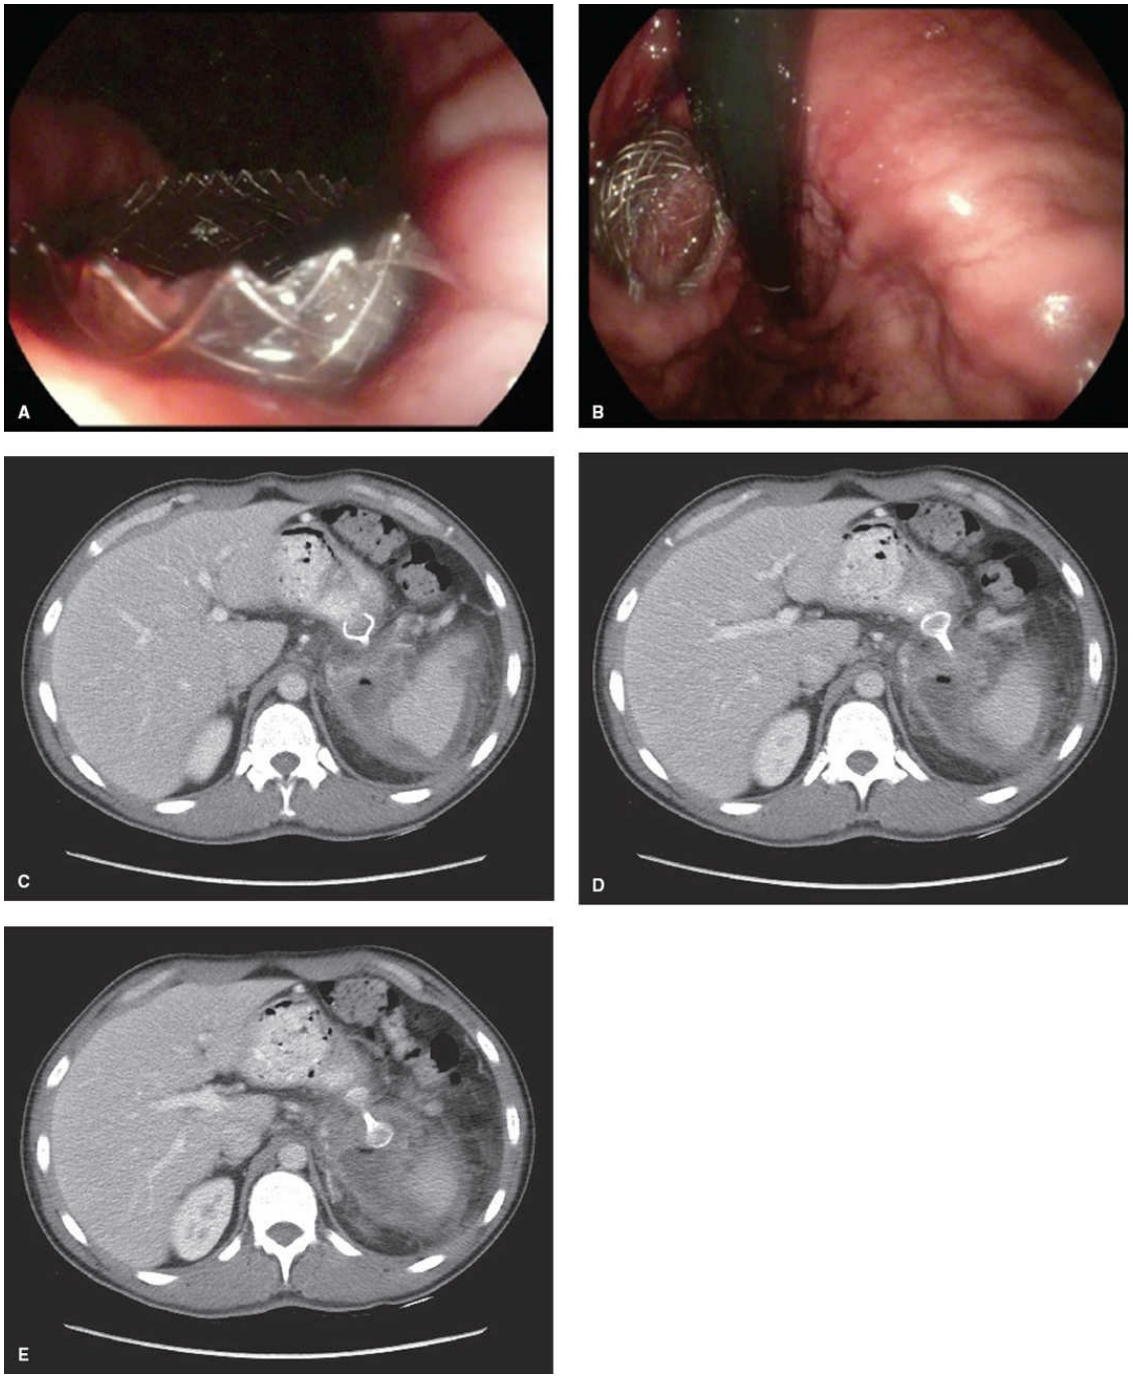

Figure 125.5. Transgastric endoscopic drainage of pancreatic necrosis. Endoscopic images (**A** and **B**) and computed tomography (CT) images (**C** to **E**).

Infected Pancreatic Necrosis

Pancreatic necrosis is complicated by infection in approximately 30% of patients. It is unusual for IPN to develop in the early phase of SAP, although this can happen rarely. It is generally agreed that intervention for drainage and mechanical debridement is required for patients who develop

IPN. Until recently, open necrosectomy has been the treatment of choice, but the procedure is associated with numerous disadvantages. These include stress of surgery in patients who are already extremely ill and often malnourished, and the risk of complications such as bleeding, abdominal wall defects, and small bowel fistulas. There have been considerable advances in minimally invasive techniques and their outcomes over the last two decades and these findings have resulted in significant changes in the management of IPN.

The diagnosis of IPN should be considered in any patient with SAP with necrosis who develops signs of infection, or clinical deterioration, after the acute inflammatory phase has resolved. It is important to rule out iatrogenic infections such as pneumonia, urinary tract infection, Clostridium difficile colitis, and catheter-associated bloodstream infections as these are common in this group of patients. Classically described indicators of IPN include the presence of air on imaging (emphysematous pancreatitis), positive fine-needle aspiration (FNA) culture of infected pancreatic fluid (Fig. 125.6), or unexplained clinical deterioration after resolution of the initial inflammatory phase. The presence of air within the necrotic cavity on imaging is thought to be the result of gas-producing organisms in patients with IPN, but fistulous communication to the GI tract is increasingly recognized as a cause for air. Nevertheless, gastrointestinal contamination of sterile necrosis will result in infection and should prompt intervention in appropriate clinical circumstances. Although emphysematous pancreatitis is certainly an indication for intervention in patients with IPN, it is a rare finding and the absence of air does not rule out the possibility of infection. FNA culture of pancreatic fluid was considered to be the gold-standard test for the diagnosis of IPN in the past, although many modern pancreatologists will proceed with intervention in patients with suspected IPN since the initial step is usually percutaneous catheter drainage. That being said, aspiration of sterile appearing fluid by the interventional radiologist should prompt reconsideration of catheter placement since management of sterile fluid collections is generally conservative and catheter placement can result in infection in these cases. False-negative FNA cultures can occur and do not rule out the possibility of infection. Unexplained clinical deterioration of patients with necrotizing pancreatitis after initial resolution of the inflammatory phase should be considered to be an indication for intervention. As stated previously, this would be extremely rare before 7

days following initial presentation and usually does not occur until at least 14 days. Unless patients are clinically unstable, it is usually wise to defer treatment until 3 to 4 weeks after presentation as this has been shown to result in improved outcomes. Although it was thought that undrained IPN was associated with 100% mortality in the past, there are selected patients who may be treated with antibiotics and supportive management alone. Criteria for conservative management include clinical stability with no signs of sepsis. Patients with IPN can be generally classified into two groups: (1) those with sepsis and organ failure and (2) those with failure to progress. Sepsis, organ failure, and critical illness related to IPN usually present earlier and their management is more difficult. Initial catheter drainage may reduce abdominal pressures and provide source control sufficiently to allow for deferred definitive minimally invasive or endoscopic drainage. Patients who do not respond to catheter drainage and who are not candidates for minimally invasive or endoscopic therapy due to critical illness may benefit from traditional open necrosectomy. The development of IPN with failure to progress can happen weeks to months after the initial presentation and is associated with a much lower mortality. These patients can also be treated with minimally invasive strategies and tolerate multiple procedures much better.

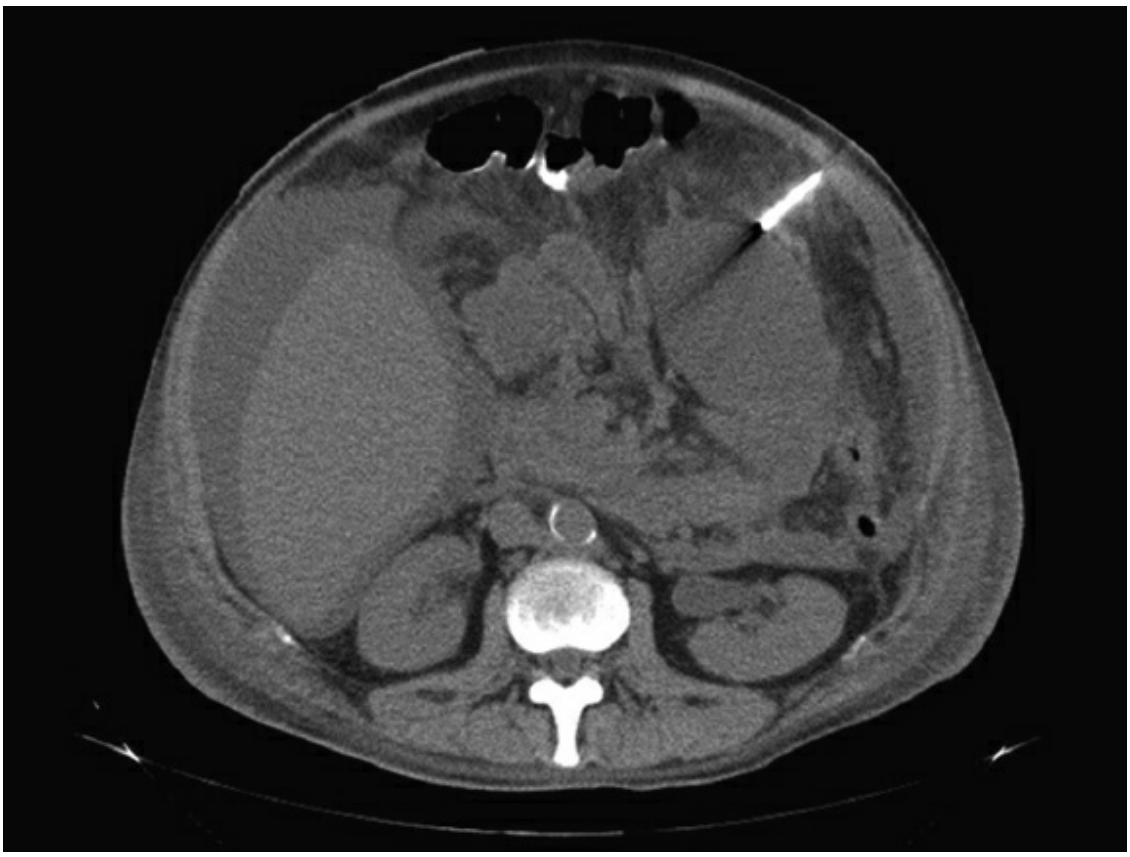

Figure 125.6. CT-guided fine-needle aspiration (FNA) culture in a patient with suspected infected pancreatic necrosis.

There are currently a variety of techniques available for the management of IPN and there has been a trend toward minimally invasive management, including percutaneous, endoscopic and minimally invasive surgical techniques. Furthermore, there is good evidence that minimally invasive techniques can be useful for controlling sepsis temporarily in unstable patients who are poor candidates for surgery, even if they eventually require more invasive procedures for complete debridement. Decision-making for therapy should be made on an individual basis with input from members of the multidisciplinary team including surgery, therapeutic endoscopy, interventional radiology, and critical care.

PERCUTANEOUS CT-GUIDED CATHETER DRAINAGE AND THE "STEP-UP" APPROACH

As treatments for IPN evolve, the role of percutaneous catheter drainage continues to change. The main advantage is that this is the least invasive technique with a relatively low risk for complications. There are numerous disadvantages. The procedures must be performed in interventional radiology under image-guidance and require skilled interventional radiologists who are willing to attempt these procedures. There must be a suitable window for accessing collections, but this can generally be performed through the left flank safely. Risks include bleeding, introduction of infection into sterile collections, and injury to adjacent structures such as the colon or spleen. If the catheter is passed through the pleura, this can lead to effusions or empyema. Since there is a considerable amount of particulate debris and necrotic material, this technique frequently requires multiple catheter exchanges, upsizing, and placement of additional catheters consuming considerable time and resources. Nevertheless, this technique has been become more popular recently after the publication of studies demonstrating improved outcomes.

A recently published randomized, multicenter trial comparing open necrosectomy to a "step-up" approach suggests that this strategy should be considered for most patients with IPN. Patients with IPN were randomly assigned to open necrosectomy or a "step-up" approach, including percutaneous catheter drainage followed by minimally invasive retroperitoneal necrosectomy through the drain tract if necessary.

Percutaneous catheter drainage alone was successful in 35% of patients assigned to the “step-up” group, although 60% of patients eventually required necrosectomy and two patients died before they were able to undergo any further procedures. The median time interval between catheter drainage and necrosectomy was 10 days. There was a decreased incidence in new-onset multiple-organ failure in the “step-up” group (12% vs. 40%), but there were no differences in mortality (19% vs. 12%). Other benefits associated with the “step-up” approach included decreased risk of incisional hernia and endocrine insufficiency. Other studies have demonstrated that surgery can be avoided in almost 50% of patients and that sepsis can be suitably managed in most patients with percutaneous catheter drainage.

ENDOSCOPIC TRANSLUMINAL DRAINAGE AND NECROSECTOMY

Open and minimally invasive necrosectomy are frequently associated with complications and there have been considerable technical advances in endoscopic therapies for the management of pancreatic necrosis in recent years. These techniques may involve transluminal endoscopic drainage procedures or direct endoscopic necrosectomy (DEN) (Fig. 125.7). These procedures require skilled advanced therapeutic endoscopists and may not be suitable for critically ill or unstable patients. DEN has been shown to be superior to endoscopic drainage alone for the management of WOPN. The DEN procedure is performed under general anesthesia with the use of carbon dioxide insufflation. After initial endoscopic evaluation, the area of necrosis is identified with standard linear echoendoscopy (EUS). An endoscopic needle catheter is used to puncture the area of necrosis and fluid is aspirated and sent for culture and Gram stain. Water-soluble contrast is injected into the area off necrosis and this is visualized fluoroscopically. A guidewire is then advanced into the cavity and the needle is withdrawn. The tract between the stomach and the cavity is then serially dilated with endoscopic balloons. Endoscopic debridement through the tract can then be performed with a therapeutic endoscope using snares, nets, and forceps. Once adequate debridement has been performed, the necrosis cavity is vigorously irrigated and endoscopic stents are placed in order to provide ongoing drainage. The procedure is usually tolerated well, but can be time consuming.

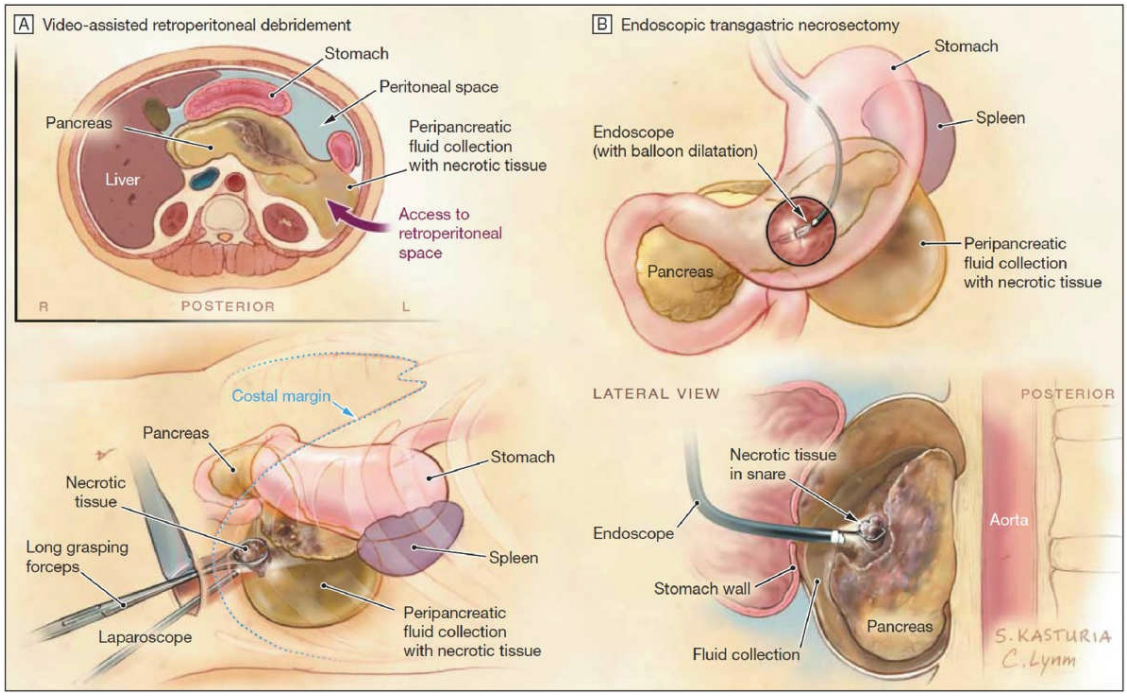

Figure 125.7. Comparison of endoscopic transgastric and minimally invasive surgical approaches for pancreatic necrosectomy. Access to the infected cavity is usually by a retroperitoneal approach through the left flank for surgical management, while endoscopic access is generally achieved through the posterior wall of the stomach using endoscopic ultrasound (EUS) guidance as necessary. (Reprinted from Bakker OJ, van Santvoort HC, van Brunschot S, et al. Endoscopic transgastric vs surgical necrosectomy for infected necrotizing pancreatitis: a randomized trial. *JAMA* 2012;307(10):1053–61, with permission from the American Medical Association).

Recent data for the DEN procedure provide encouraging results for the management of IPN. Results from the PENGUIN trial demonstrate that DEN results in reduced overall inflammatory states and lower rates of new-onset multiple-organ failure and complications as compared to open necrosectomy. A recent matched cohort study comparing DEN to the "step-up" approach demonstrated improved efficacy in that 11/12 patients were managed with endoscopy alone while 9/12 patients in the "step-up" group required surgical intervention. DEN was also associated with decreased antibiotic use, pulmonary failure, endocrine insufficiency, shorter length of stay, and decreased health care utilization. It is likely that these techniques will continue to improve and will be utilized for more patients with IPN in the future.

MINIMALLY INVASIVE SURGICAL NECROSECTOMY

Minimally invasive surgical techniques for the management of IPN are well described and have been developed as the field of minimally invasive surgery has expanded and become widely accepted for the treatment of many surgical diseases. Specific advantages for the management of IPN include the potential for effective debridement of particulate matter and disruption of loculations, the use of small incisions, and the avoidance of laparotomy and associated complications such as abdominal wall defects and bowel fistulas. Access can be approached through the anterior abdominal incisions or the flank and retroperitoneum, usually along the tract of a pre-existing percutaneous drain catheter. As described previously, minimally invasive techniques are commonly used as part of a "step-up" strategy for patients who fail percutaneous catheter drainage alone, although they can be utilized for primary therapy as well.

Traditional surgical dogma has dictated that complete debridement of all infected and necrotic material is essential for the treatment of IPN. Experience with minimally invasive techniques suggests that this is not true since many patients improve with catheter drainage alone. It is clear that minimally invasive approaches are associated with decreased systemic inflammatory responses. Although repeated procedures may be necessary, these usually result in minimal physiologic effects on the patient. This indicates that multiple small procedures may be preferable to one large procedure. An additional advantage of most minimally invasive surgical procedures is that direct access to the necrotic cavity prevents contamination of the peritoneal cavity that is associated with open necrosectomy. There are essentially three types of procedures that have been described: (1) anterior laparoscopic necrosectomy; (2) trangastric "endoscopic" necrosectomy; and (3) retroperitoneal necrosectomy with or without video assistance.

Laparoscopic necrosectomy through an anterior approach is similar to traditional open necrosectomy except that access to the abdomen is gained through ports with peritoneal insufflation. A window is created in the gastrocolic ligament in order to enter the infected cavity. Alternatively, collections in the right or left paracolic gutters can be entered laterally after mobilization of the colon on that side. Removal of infected fluid and debris can be performed with a suction irrigator and instruments. Large pieces of debris are collected in an endocatch bag and removed prior to the end of the procedure. Large sump drains are placed in the cavity and can

be used for irrigation following surgery. Although this procedure does offer many of the benefits of minimally invasive surgery, it is technically demanding and visualization can be difficult in critically ill patients who may be swollen and on high levels of ventilatory support. In addition, there is a risk of peritoneal contamination. As such, this procedure is rarely performed.

Transgastric “endoscopic” necrosectomy is essentially a variation of the more commonly performed transoral endoscopic drainage and necrosectomy procedures. For these procedures, access to the lumen of the stomach is gained by placing a percutaneous gastrostomy tube and replacing it with a specifically designed laparoscopic port that allows for transluminal visualization and instrumentation. The necrotic cavity is then identified as a bulge in the posterior gastric wall. This is punctured and a guidewire is inserted under fluoroscopic visualization. The tract can then be fenestrated with monopolar cautery and necrosectomy is performed with 3-mm laparoscopic instruments under direct visualization. Tract patency is maintained by placement of large-bore pigtail catheters. This technique clearly requires advanced endoscopic and minimally invasive surgical skills. Access through a gastrotomy appears to be inferior to standard transoral endoscopic techniques. It is likely that this procedure will be replaced by standard endoscopic approaches as experience and technical advances improve.

As minimally invasive surgical approaches for the management of IPN have evolved, access through retroperitoneal incisions, usually on the left side through a previously placed image-guide percutaneous catheter tract, have become the preferred technique. These procedures can be performed through a single port or multiple adjacent ports, with or without video-assisted guidance. For procedures utilizing direct visualization, assessment and debridement of the necrosectomy cavity can be facilitated with the use of a flexible endoscope, an operating nephroscope, or a rigid rectoscope. Various terms have been used to describe these procedures, the most common being video-assisted retroperitoneal debridement (VARD) and laparoscopic intracavitary pancreatic necrosectomy (Lap-ICPN) (Fig. 125.8). After positioning and draping, access to the necrosectomy cavity is gained by creating an incision along the tract of the catheter and performing dilation. This can be facilitated with the use of flexible guidewires and fluoroscopic visualization. Drainage of fluid and debridement of necrotic debris can be performed under direct visualization

or directly through the ports with intermittent inspection of the cavity with the laparoscope. Care must be taken to avoid injuring pulsatile structures as bleeding can be catastrophic and might require conversion to a standard open procedure. Pulsatile irrigation can be useful for performing gentle debridement around pulsatile structures. Upon completion of debridement, large drain catheters are placed through the tract and sutured to the skin. Red rubber Robinson catheters, 32-French chest tubes, and sump drains can all be used. Drains allow for continued drainage, postoperative irrigation of the necrosectomy cavity and access for additional procedures when necessary.

OPEN NECROSECTOMY

Open necrosectomy was considered to the standard treatment for IPN in the past, but has slowly been replaced by minimally invasive techniques and conservative approaches for reasons previously alluded to. Although some have called for an end to this procedure altogether, it is appropriate for surgeons who care for patients with SAP and IPN to be familiar with and comfortable performing this technique in the rare circumstance that it is required. Acceptable indications for open necrosectomy include: (1) lack of equipment or expertise in performing advanced minimally invasive techniques; (2) complications of pancreatitis mandating an open surgical approach such as intestinal perforation or necrosis; and (3) as salvage therapy for patients who fail or suffer complications of alternative techniques.

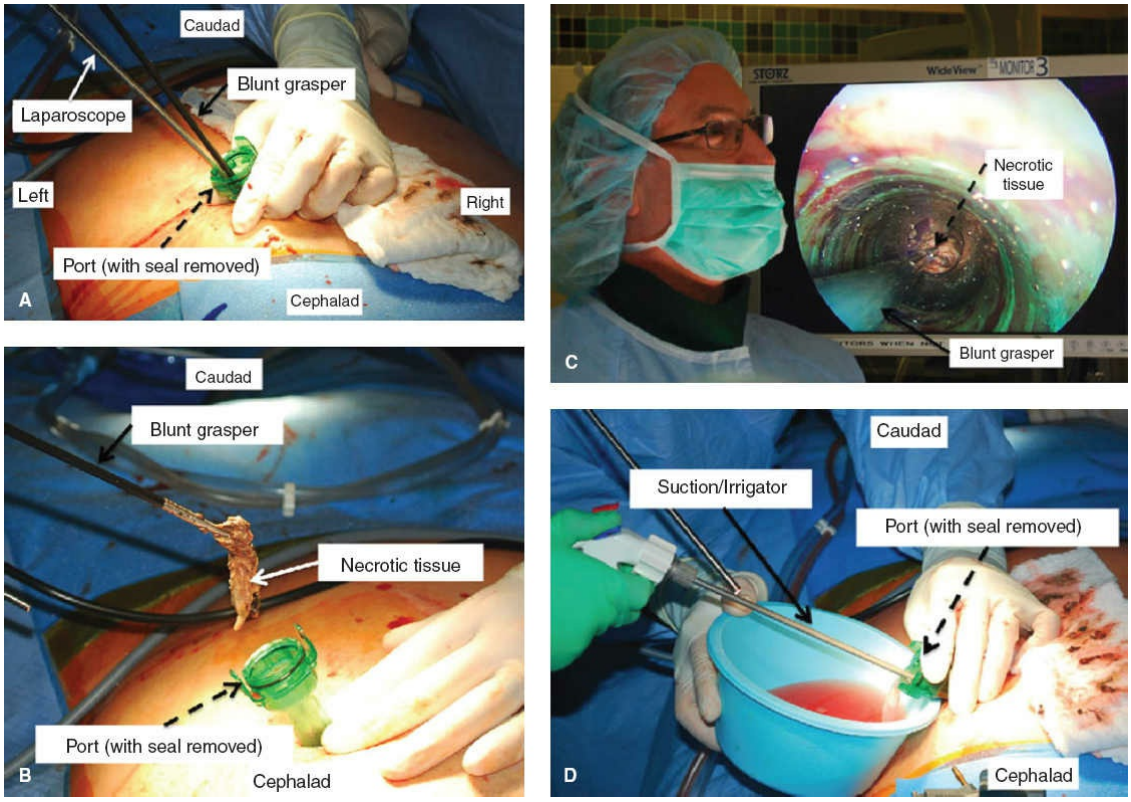

Figure 125.8. Minimally invasive retroperitoneal necrosectomy. Access is generally achieved using ports placed at the site of a percutaneous drain catheter, usually in the left flank (**A**). Debridement of necrotic tissue is performed using instruments placed alongside or through a working port of the instrument used for visualization (**B** and **C**). Irrigation of the cavity can be performed intraoperatively (**D**). (Reprinted from Fink D, Soares R, Matthews JB, et al. History, goals, and technique of laparoscopic pancreatic necrosectomy. *J Gastrointest Surg* 2011;15(7):1092–7. Copyright © 2011, with permission of Springer.)

Open pancreatic necrosectomy is generally performed through a midline incision, although retroperitoneal approaches may be appropriate for selected patients, generally those with failure to thrive and loculated collections close to the flank. The procedure is performed under general anesthesia with appropriate monitoring. Patients are generally already on therapeutic antibiotics. It is important to confirm that tissue levels are adequate by reviewing the dosing schedule, but no additional prophylactic antibiotics are necessary. The abdomen is entered through a midline incision and explored. Ascites may be present and this should be drained and cultured. Fluid can be sent for amylase if there is a concern for pancreatic ascites. The small bowel should be evaluated and may be adherent to the transverse mesocolon. This should be freed up if possible,

but an extensive lysis of adhesions may result in small bowel injury and should be performed at the discretion of the surgeon. The necrotic cavity is generally located posterior to the stomach and is most commonly entered through the gastrocolic ligament using blunt dissection. Care should be taken to avoid injury to the crossing or gastroeploic vessels as there can be considerable bleeding and hemostatic maneuvers such as suture ligation can be challenging and may result in visceral ischemia. Some collections may require drainage through the transverse mesocolon or through a lateral approach after mobilizing the left or right colon as necessary. Limited dissection is recommended and the goal of performing adequate debridement with minimal intervention should be considered when performing these procedures. Murky, purulent, or green fluid can be encountered upon entering the necrosectomy cavity and this should be aspirated and a sample sent for Gram stain and culture. Adequate and thorough debridement of necrotic debris should be performed through the site of access. Although instruments such as ringed forceps and sponge sticks can be utilized, these may result in injury to major vascular structure such as the splenic vessels. In our experience, manual debridement using the surgeon's fingers or hand is best and allows for appropriate debridement while avoiding unnecessary injuries. Upon completion of debridement, the cavity should be irrigated and temporarily packed while other maneuvers are performed if necessary. This will allow the surgeon to assess for hemostasis at a later time. Cholecystectomy should be considered for stable patients, particularly those with gallstones or gallbladder sludge. This can generally be performed safely in almost all cases if the surgeon is patient and utilizes the standard dome-down approach for open cholecystectomy. Intraoperative cholangiography may be performed at this time, but can be challenging. Feeding tube access should also be considered. We favor the use of gastrojejunostomy tubes as these allow for gastric decompression and jejunal feeding. Passing the jejunal limb through the pylorus and duodenum can be challenging, but is usually possible. Alternatively, separate gastrostomy and jejunostomy tubes can be placed, but we feel that there are higher risks for complications associated with jejunostomy tubes such as bowel obstructions and leaks. At this point, the packs should be removed and the necrosectomy cavity evaluated. If hemostasis is an issue, packs can be left in placed with plans for reexploration, usually in 24 to 48 hours. Two large bore sump drains are placed in the cavity and brought out of the abdomen

through separate stab incisions in the right upper quadrant. A drain can also be left in the gallbladder fossa if there is concern for a potential bile leak from an inflamed cystic duct stump. Every effort should be made to close the fascia primarily as an open abdomen is clearly undesirable. These patients will require further procedures for abdominal wall closure or ventral hernia repair and are at risk for complications of the open abdomen including bleeding and small intestinal fistulas. Certainly, most of the disadvantages of open necrosectomy are related to abdominal wall defects and small bowel fistulas. If the fascia cannot be closed, a variety of techniques can be used to manage the open abdomen including negative pressure devices, Velcro patches, or prosthetic mesh. The skin should be left open and packed to heal by secondary intention. Drains should be secured to wall suction postoperatively and the sump ports can be flushed if they become occluded with debris. The sump ports should not be clamped. As the patient begins to recover, the sump drains can slowly be advanced until they are removed, usually many weeks after surgery. We have found it useful to actually cut the drains 3 to 4 cm from the skin 1 to 2 weeks after surgery and place an ostomy appliance over both of them to facilitate ambulation and allow for protection of the surrounding skin. Although pancreatic fistulas are reported to be common after open necrosectomy, we have found that drainage will resolve in almost all patients if this drain management strategy is followed.

CONCLUSIONS

The management of acute pancreatitis continues to evolve as technology and our understanding of the disease improves. Treatment of pancreatic necrosis and IPN remains challenging with considerable associated morbidity, mortality, and health care costs. The initial management of SAP is generally conservative and consists of appropriate severity scoring, imaging, nutritional support, and resuscitation in an intensive care setting. Antibiotics should be reserved for patients with confirmed IPN or iatrogenic infections. It is important to evaluate the patient for the underlying cause and address this if necessary, but some patients may never have an etiology identified. It is rare for IPN to develop less than 7 to 14 days after initial presentation and outcomes are generally improved if interventions can be delayed for as long as possible. There are a variety of treatment strategies available for IPN including percutaneous, endoscopic, minimally invasive, and open surgical techniques. There has been a trend

toward minimally invasive management, commonly utilizing a “step-up” approach employing percutaneous drainage followed by minimally invasive retroperitoneal necrosectomy if necessary. These approaches result in decreased morbidity and resource utilization, but the effects on overall mortality remain unclear. Endoscopic drainage and necrosectomy offer an appealing alternative with many potential advantages. Open necrosectomy should be performed rarely, but continues to play a role for management in selected patients, and surgeons caring for patients with SAP should be familiar with this procedure.

126 Management of Complications of Acute and Chronic Pancreatitis: Endoscopic, Laparoscopic, and Open Approaches to Pancreatic Pseudocysts and Pancreatic Necrosis

Gary C. Vitale, Brian R. Davis, and Michael Bahr

Advancements in endoscopic and laparoscopic technology have greatly reduced the morbidity suffered from complications of acute and chronic pancreatitis. Advanced endoscopic techniques allow safe access to peripancreatic fluid collections (PFCs) and necrosis following severe pancreatitis thus reducing the surgical morbidity. The Dutch Pancreatitis Group's (PENGUIN Study 2012) "step-up" approach demonstrates in randomized controlled trials that combinations of endoscopic and percutaneous therapies have lower endpoints of death or major morbidity when compared with an open surgery group. Aggressive treatment and novel therapies for debridement and drainage of pancreatic necrosis are providing better outcomes through a reduced incidence of multi-system organ failure and pancreatic insufficiency. Early use of minimally invasive therapies can preserve greater function of the pancreas while limiting the complications of this complex inflammatory process. The purpose of this chapter is to assist the surgeon in selecting the proper treatment options to maximize patient outcomes in this morbid complex disease.

PFCs were initially defined by the Atlanta Classification described by Bradley (1993). The revised Atlanta Classification (2012) categorizes collections into four categories based on computed tomography (CT) findings. Acute fluid collections occur within the first 4 weeks following an attack of acute interstitial edematous pancreatitis and may resolve spontaneously. Pancreatic pseudocysts are defined as having a fibrous wall of granulation tissue and result from fluid collections persisting more than 4 weeks after the onset of an episode of acute or chronic pancreatitis.

According to Jacobson (2005), pancreatic necrosis (>25%) is a risk factor for pseudocyst development, and these fluid collections persist and form pseudocysts in 5% to 15% of patients with acute pancreatitis and up to 40% of patients with chronic pancreatitis. Acute necrotic collections occur in the early phase of acute necrotizing pancreatitis before demarcation, and walled-off necroses (WONs) occur 4 weeks after the onset of pancreatitis with an identifiable capsule. The presence of irregular wall definition, fat attenuation, and debris distinguish WON from pseudocysts. Surgical laparotomy has previously been the procedure of choice for pancreatic, necrosis but endoscopic and laparoscopic techniques have become routine whether treating pseudocysts or WON.

CHOICE OF TREATMENT FOR PANCREATIC PSEUDOCYST

Most patients with pancreatic pseudocysts can be managed nonoperatively if presenting symptoms are well controlled. Up to 40% of acute pseudocysts reabsorb after pancreatitis resolves. When pancreatic pseudocysts are large enough to cause symptoms (6 cm or greater) the success of conservative therapy is low (between 3% and 39%) according to Bradley (1979). More recent studies by Vitas and Sarr (1992) have demonstrated that approximately half of acute pancreatic pseudocysts remain asymptomatic regardless of size or duration. Pseudocysts greater than 6 cm in diameter that demonstrate symptomatic complications of abdominal pain, nausea, and early satiety should be considered for therapeutic intervention. Observation for cyst resolution should occur for 6 weeks following the incidence of pancreatitis to allow for cyst maturation.

Mouli et al. (2013) recently published in meta-analysis involving 324 patients finding that primary nonoperative management of infected necrosis without necrosectomy was successful in 64% of cases. Study of interventions in pancreatic necrosis demonstrate improved survival when the immune system encapsulates the necrotic tissue with lowest mortality of 8% with intervention at 30 days compared with 45% in the 15- to 29-day group and 75% in the 1- to 14-day intervention group.

Endoscopic retrograde cholangiopancreatography (ERCP) should be performed for pseudocysts resulting from blunt abdominal trauma since there is a high incidence of pancreatic duct disruption in these cases. Complications from pancreatic pseudocysts include infection, hemorrhage, rupture, obstruction, and malignancy. Most commonly, patients present for

surgical therapy complaining of persistent abdominal pain, gastric outlet obstruction, jaundice, and dyspepsia with weight loss.

Percutaneous drainage can be utilized for the treatment of immature and infected pseudocysts. This technique can be complicated by formation of an external pancreatic fistula, secondary infection of the pseudocyst, as well as a high recurrence rate. Another risk of percutaneous drainage is that drain infections have been reported as high as 50%. Contraindications to percutaneous drainage include intracystic hemorrhage and pancreatic ascites. Heider (1999) reviewed the use of percutaneous catheter drainage in 66 patients, which demonstrated successful drainage in only 43% of patients with a 16% mortality rate and a 64% incidence of complications. Comparison of outcomes between endoscopic and percutaneous drainage demonstrate that patients managed by endoscopic procedures had fever interventions (1.8 vs. 3.3), lower rates of residual collections (21% vs. 67%) and lower needs for surgical intervention (4% vs. 11%).

The most effective treatment of pancreatic pseudocysts involves internal drainage into the enteric lumen whether performed by endoscopic transmural versus transpapillary therapy, laparoscopic pseudocyst enterostomy, or standard laparotomy. Pancreatic resection is also indicated when there is severe pancreatic duct disruption or a suspicion of malignancy. Procedure selection depends on the condition of the patient; the size, number, and location of the pseudocysts; the presence or absence of communication of the pseudocyst with the pancreatic duct; the presence or absence of infection; and any suspicion of malignancy. Endoscopic pseudocyst drainage is applicable in approximately 80% of PFCs located in the central region of the pancreas and is less invasive, less expensive, and carries a lower risk of creating an external pancreatic fistula than laparotomy or laparoscopic techniques.

ENDOSCOPIC DRAINAGE

The endoscopic approach is the procedure of choice for pancreatic pseudocyst drainage, and is becoming more effective in debridement of pancreatic necroses (WON). The index ERCP should demonstrate a complete pancreatogram. Endoscopic transpapillary drainage is effective for pseudocysts that communicate with the pancreatic duct while endoscopic transmural drainage offers the best results in the management of suitably located pancreatic pseudocysts that complicate chronic pancreatitis. Technically, endoscopic management of pancreatic

pseudocysts is most effective when either there is communication with the pancreatic duct for transpapillary drainage or there is a visible indentation of the enteric lumen for a transmural approach.

The use of endoscopic ultrasound (EUS) to assist pseudocyst and WON drainage further enhances the success of these procedures. EUS allows visualization and puncture of the targeted collections independent of a visible bulge into the stomach and color Doppler allows avoidance of vessels in the puncture tract. EUS also allows distances of up to 2 cm to be traversed safely in approach to pseudocysts and WON. More extensive necrotic debris, severe pancreatic duct disruption, or deep retroperitoneal extension of necrosis should lead the surgeon to use adjuvant therapy such as percutaneous drainage or video assisted retroperitoneal debridement.

INDICATIONS

Endoscopic Techniques

Transpapillary Drainage

To obtain transpapillary drainage the ampulla is injected to opacify the biliary and pancreatic ductal systems. Biliary access is obtained by directing the sphincterotome superiorly and anteriorly in the ampulla toward the 11 o'clock direction. Sphincterotomy is first performed on the bile duct and then selectively on the pancreatic duct. Selective pancreatic sphincterotomy is accomplished by directing a guidewire with a hydrophilic tip inferiorly in the 3–4 o'clock position, posterior and to the right of where the biliary orifice is located. If the anatomy demonstrates pseudocyst opacification, an attempt is made to pass a guidewire through the ampulla and pancreatic duct into the cavity. A straight tip hydrophilic guidewire is attempted at first followed by an angled tip wire. A stent with appropriate length and a caliber of 7 French is then passed over the guidewire into the pseudocyst (Fig. 126.1A to C). Decompression of the pancreatic duct including stenting can be helpful when there is direct communication with the pseudocyst. The transpapillary approach reduces the risk of hemorrhage and retrogastric perforation.

The stent remains in the pancreatic duct until the pseudocyst resolves or significantly decreases in size. Stent removal, reevaluation, and replacement should occur in 6 to 8 weeks. If the tail of the pancreas is not opacified at initial ERCP, it is likely that the distal duct is obstructed and may be feeding the pseudocyst. In these cases, concomitant transmural drainage may be necessary to adequately drain the tail if the cyst is

enlarging. A magnetic resonance cholangiopancreatogram (MRCP) should be done in these cases to determine pancreatic tail duct anatomy to direct future therapeutic options.

Transmural Drainage

Upon examination of the gastric or duodenal lumen, those patients with pseudocyst indentation of the enteric lumen are candidates for transmural drainage by direct cyst-gastrostomy or duodenostomy. Previous University of Louisville techniques included access to the pseudocyst with a needle knife followed by wire exchange and stent insertion. The most current techniques in endoscopic transmural drainage have introduced the use of the Cremer cystotome, first described in 1990, which combines a removable electrocautery needle knife with a circumferential 10-French electrocautery ring to allow for cyst puncture, guidewire passage, and cyst-gastrostomy enlargement using a single catheter. The cystotome facilitates difficult cyst access since no catheter exchange is necessary and the guidewire can be passed directly through the cutting device. This cystotome allows for rapid advancement of a guidewire into the cyst cavity when the visual field is obscured by fluid. Guidewire placement into the cyst cavity before catheter removal facilitates rapid stent deployment. Other advantages include the ability to perform cystography, and the small cauterized cyst-enterostomy prevents hemorrhagic complications. This is currently the preferred technique at the University of Louisville.

The pseudocyst is then drained with one to two 10-French stents, side by side (Fig. 126.2A to G). Double stenting is more effective than a single stent because the pseudocyst can drain alongside the stents as well as through them. Single stents can be encased by gastric mucosa and induce infection when their lumen becomes occluded. Since these stents remain in place long term, drainage alongside the stent may be more important than drainage through the stent, thus supporting the use of double stenting. The University of Louisville experience routinely dictates leaving stents in place for approximately 1 year. Stents are removed after 1 year unless the tail of pancreas depends on stenting for duct drainage as determined by ERCP or MRCP. If MRCP identifies a disconnected duct in the tail of the pancreas, transenteric stents can be left in place indefinitely to facilitate drainage.

Plastic stent–related adverse events can be as high as 18% in regard to premature occlusion as a result of the small diameter of the working channel leading to inadequate PFC drainage. Nasocystic irrigation

(Siddiqui et al., 2013) assists in pancreatic necrosis debridement and maintains stent patency in collections with evidence of infection or extensive debris. Larger caliber diameter stents enable more effective resolution of PFCs and WON. Gardner et al. (2012) reported a goal of initial cyst-enterostomy of 15 to 20 mm with placement of multiple plastic stents or a single fully covered self-expanding metallic stent (FCSEMS). Gardner found that larger cyst-enterostomy size has been correlated with clinical success of pancreatic necrosectomy. Recent trials of FCSEMS for pancreatic pseudocyst and WON have demonstrated a success rate of 78% to 100%. Complications of stent deployment include risk of migration, abutment against the luminal wall causing bleeding and injury and lack of apposition of the cyst-enterostomy leading to risk of fluid leak and perforation.

Issues with metallic stenting lead to the development of the novel “saddle-shaped” fully covered AXIOS TM lumen opposing metallic stent LAMS (Xlumena, Mountain View, CA). The AXIOS LAMS has proximal and distal flanges that ensure luminal apposition between the enteral and cyst wall. Initial visualization for LAMS deployment has been performed using EUS followed by initial puncture with a 19-gauge needle and a 0.035-in guidewire. The tract was then dilated with a 6- to 8-mm wire guided balloon or an 8- to 10-French Soehendra dilator followed by LAMS deployment over a catheter. Siddiqui et al. (2016) in a multicenter retrospective review demonstrates successful deployment of the AXIOS stent with PFC resolution in 100% of pseudocysts and 88.2% of WON. Patients who failed endoscopic drainage had occlusion of the LAMS with debris and were sent for surgical necrosectomy. A benefit of LAMS up to 15 mm in size was that it allowed direct endoscopic debridement of WON by passage of the endoscope through the stent lumen (Fig. 126.3). Romanelli et al. (2011) describe a peroral endoscopic stapler (SurgAssist™ SLC 55 Power Medical Interventions, Langhorne, PA) with creation of cyst-enteric anastomoses between 5.5 and 8 cm to further facilitate pancreatic necrosectomy (Fig. 126.4).

EUS-Guided Transmural Pseudocyst Drainage

An innovation that has allowed for more effective drainage of pancreatic pseudocysts and prevention of hemorrhagic complications is the use of EUS. EUS is especially attractive in patients who have a small window of entry into the pseudocyst determined by CT, in patients in whom there is no enteric indentation, when the patient has a coagulopathy or thrombocytopenia, or where there are varices between the enteric lumen and pseudocyst. Studies have demonstrated that EUS has a superior safety

profile when compared with esophagogastroduodenoscopy EGD-directed transmural drainage. EUS enables identification of collateral vasculature, providing a safe window for transmural drainage. A prospective randomized trial performed by Varadarajulu (2008) demonstrated significantly greater technical success for EUS-guided drainage (100%) than for EGD-directed transmural drainage (33%), adjusting for luminal compression by the pseudocyst. Park (2009) addressed the issue of luminal compression and technical success rates in a prospective randomized trial. This trial demonstrated a success rate of 94% for EUS-guided drainage compared with 72% for EGD-guided drainage (Fig. 126.5).

Endoscopic Drainage of Abscesses and Walled-Off Necrosis

Infection and abscess formation in a pancreatic fluid collection has previously been associated with failure of endoscopic therapy. Pancreatic abscesses can be found in 2% to 5% of patients admitted to the hospital for pancreatitis with an incidence as high as 25% in severe pancreatitis. Surgical laparotomy has been associated with a mortality rate from 10% to 59% and a morbidity rate as high as 60% to 93%. Percutaneous drainage of these collections carries a rate of pancreatic fistula formation as high as 39%. The Louisville experience (35 patients) reported by Vitale (2009) demonstrated an 80% success rate in draining pancreatic abscesses (15-month follow-up) utilizing both transmural and transpapillary drainage techniques. Similar studies by Binmoeller (1993) and Venu (2000) demonstrated success rates of 74% to 80% on long-term follow-up for abscess drainage. The Louisville experience demonstrated independent predictors for successful outcome including location of the cyst in the pancreatic head, insertion of multiple stents into the pseudocyst cavity, and drainage of the pseudocyst cavity for longer than 6 weeks. Moderate abscess debris was the primary independent predictor for failure of

endoscopic drainage in this study.

Direct Endoscopic Necrosectomy

The presence of extensive necrosis within a pancreatic fluid collection has been defined by the Revised Atlanta Classification (2012) as WON. Baron et al. (2002) compared resolution of pancreatic fluid collections in a series of 138 patients, demonstrating a 92% rate for chronic pseudocysts compared with 74% in acute pseudocysts and 72% in the setting of pancreatic necrosis. Gardener (2009) demonstrated successful resolution of WON in 88% of patients who underwent direct endoscopic necrosectomy compared with resolution in 45% of patients who received standard transmural drainage. Direct endoscopic necrosectomy begins with transmural access to a pancreatic fluid collection with fistula tract dilation between 8 and 20 mm. Necrotic pancreatic tissue identified within the cavity is then removed using a combination of several devices including 10-French irrigation probes, 15-mm stone retrieval balloons, Roth retrieval baskets, stone retrieval baskets, tripod retrieval forceps, rat-toothed and pelican forceps. The goal of necrosectomy is to uncover pink granulation tissue lining the wall of the collection. Stenting is then used to maintain the

patency of the transmural access site to allow further drainage of fluid and necrotic debris. Voermans (2007) described serial transmural pancreatic debridement under direct vision including nasocystic catheter irrigation with a long-term (16-month) success rate of 93%. Gardner et al. (2011) described the largest series to date (104 patients) with direct endoscopic necrosectomy with successful resolution of WON in 91% with a median of 3 debridements.

Figure 126.4. SurgAssist Stapler for power medical interventions.

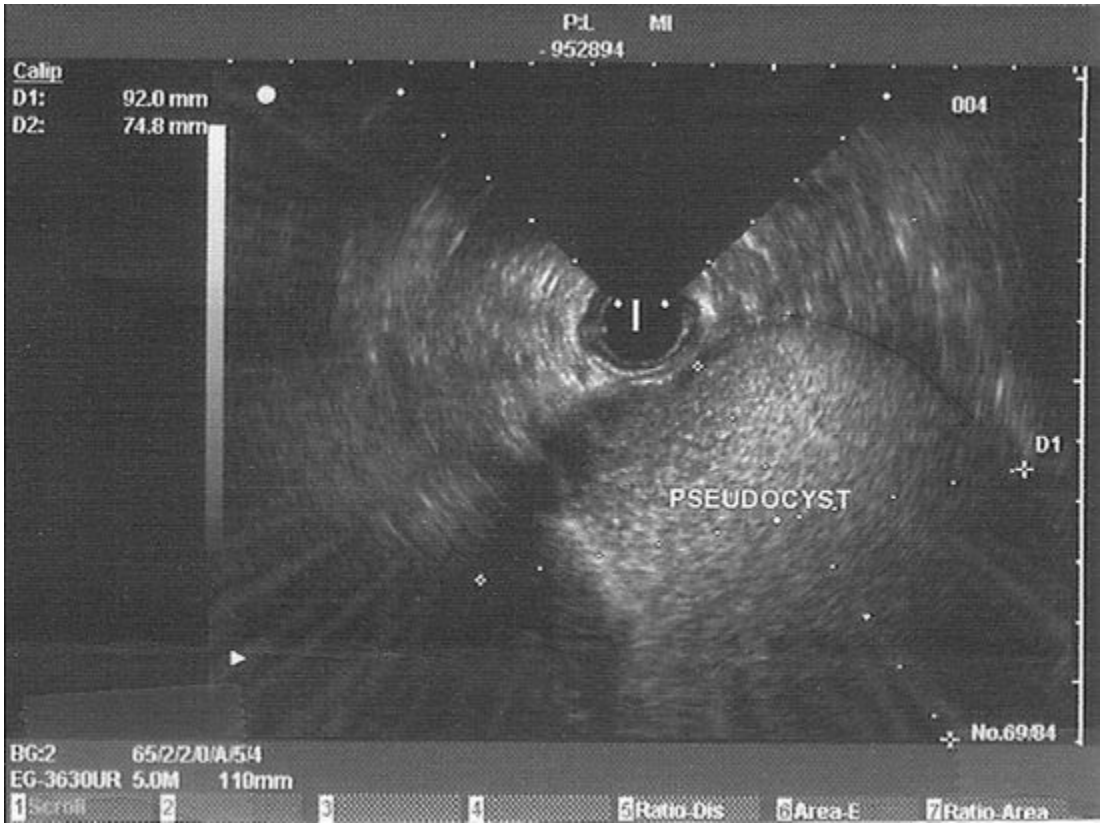

Figure 126.5. Picture of EUS gastroscope and ultrasound pictures of pseudocyst.

Further innovations in direct endoscopic necrosectomy have challenged the limitations to clearance of necrotic debris. Hydrogen peroxide irrigation during endoscopic necrosectomy has been demonstrated to reduce the number of interventions to a median of 1.4 by Abdelhafez et al. (2013). Spraying of a 0.1% to 0.2% solution under direct vision over tightly necrotic debris followed by irrigation with saline helped loosen necrotic material that was removed with suction or Roth net. Additional innovations include deployment of an endoscopic vacuum-assisted closure device into the pancreatic cavity that allowed for demarcation and debridement of necrotic tissue. Varadarajula et al. (2012) described a multi-gateway approach for WON >8 cm where two transmural fistulas are created to facilitate rapid drainage with one channel serving as irrigation and the other as an exit conduit for necrotic debris.

Step-Up Approach: Endoscopic Versus Minimally Invasive Necrosectomy

Complications and choice of therapeutic options in necrotizing pancreatitis carry a significant long-term cost to the critically ill patient. The Dutch Pancreatitis Group published results from a randomized controlled trial of

a “Step-up Approach” (2010) that compared minimally invasive to open necrosectomy. The minimally invasive approach was composed of percutaneous or endoscopic drainage (35%) followed by retroperitoneal video-assisted necrosectomy (65%). The minimally invasive approach demonstrated significant decreased incidence of multiorgan failure, incisional hernia, and new-onset diabetes. The PENGUIN trial (2012) reported randomized comparison of endoscopic and minimally invasive retroperitoneal necrosectomy with similar findings and a reduced incidence of pancreatic fistulas of 10% versus 70%. The critical difference was that minimally invasive necrosectomy was used to treat patients earlier (average 34 days) in the course of the disease who suffered from sepsis versus (average 54 days) endoscopic necrosectomy.

Video-Assisted Retroperitoneal Debridement (VARD)

Video-assisted retroperitoneal pancreatic debridement is an integral part of the “step-up approach” when percutaneous drainage (PCD) does not provide adequate drainage to adequately resolve complications of infected pancreatic necrosis. Percutaneous drainage followed by VARD is best utilized for extrapancreatic collections (perinephric space and paracolic gutters) that cannot be accessed by transenteric techniques. The rationale behind percutaneous drainage is to drain infected fluid under pressure to temporize sepsis thus allowing further encapsulation or absorption of the necrotic pancreatic collection. The PANTER trial (2010) demonstrates that 35% of patients can be successfully treated by endoscopic drainage alone. This same trial introduced the “step-up approach” demonstrating that PCD and VARD significantly reduce end-points of morbidity and multisystem organ failure when compared with laparotomy.

Gambiez (1998) was the first to report a large series (20 patients) treated with retroperitoneal video-assisted drainage. His technique utilized a 23-cm mediastinoscope inserted through a 6-cm incision centered on the 12th rib. The spleen and the colon were mobilized anteriorly without entering the peritoneum and necrotic pancreatic tissue was debrided by blunt dissection. The overall mortality from this study was 10% with a short- and long-term complication rate of 30% and a technical success rate of 85%. Horvath et al. (2001) were first described VARD utilizing laparoscopic visualization along PCD tracts in a series of six patients. The laparoscopic technique starts with a 5-cm incision between the left lower costal margin and the iliac crest in continuity with a percutaneous drain tract that is utilized to gain access to the retroperitoneum. Two 12-mm

ports are placed side by side within the drain tract with subsequent insufflation and visualization of pancreatic debridement with a 10-mm laparoscope and blunt laparoscopic instruments. Two large bore drains are placed through the incision for large-volume saline lavage and drainage of the cavity. In this study there was no noted mortality and an overall technical success rate of 66%. The largest series to date of retroperitoneal laparoscopic–assisted access (47 patients) is described by Connor (2005). The technique in this study has been described as sinus tract endoscopy that involves dilation of a percutaneous drain tract with pancreatic debridement through an operating nephroscope. Santvoort et al. (2007) performed a case-matched comparison of the retroperitoneal laparoscopic–assisted approach with laparotomy demonstrating a comparable postoperative complication rate with a significant decrease in mortality with the laparoscopic approach (6% vs. 40%). Horvath et al. (2010) confirmed the benefits of VARD over laparotomy in a multicenter prospective study in the reduction of complications and multisystem organ failure. VARD has been associated with a complication and mortality rate of 35% and 13%, respectively compared to cohorts of open necrosectomy that report complication rates of 34% to 95% and mortality of 11% to 39%. The most common complications associated with VARD are pancreatic fistulae (17%) and bleeding requiring intervention (13%). These minimally invasive interventions have demonstrated significantly decreased mortality when compared with surgical laparotomy for pancreatic necrosis, although the techniques need to be perfected in large series to reduce complications.

Complications and Management

Complications of endoscopic procedures can include perforation, bleeding, and infection. De Palma (2002) reported experience in 49 patients with endoscopic drainage. Complications included stent blockage with pseudocyst infection in three patients, pseudocyst wall perforation in one, and massive hemorrhage requiring surgery in one patient. De Palma also reported a complication rate of 24.5%. Eight patients had pseudocyst infections; five patients had pancreatic necrosis while three had clogged stents. Other complications included two patients with bleeding and two with mild pancreatitis following the procedure. Sharma (2002) studied 38 patients with transmural drainage, demonstrating a 13% complication rate with one hemorrhagic complication, one perforation, and three pancreatic pseudocyst infections.

Complication rates of approximately 30% have been reported for direct endoscopic necrosectomy. Recent systematic review (2011) of 1,100 necrosectomy procedures in 260 patients demonstrated a morbidity rate of 27% and mortality of 5%. Bleeding is the most common complication and may occur during direct debridement of necrotic material. Perforation or disruption of the cavity wall is another severe complication. Gardner et al. (2011) described successful nonoperative management of five patients with perforation. Other complications of necrosectomy include infection of necrotic materials, air embolism, gallbladder perforation, stent migration, fistula, and bowel obstruction. Endoscopic drainage of pancreatic fluid collections and necrosectomy are aggressive interventions in critically ill patients, so endoscopists should have multidisciplinary backup available at their institution in the event of complications.

Recurrent Pancreatic Pseudocyst

Endoscopic pancreatic pseudocyst drainage has a reported recurrence rate from 8% to 20%. Recurrences are most common in patients with alcohol-induced pancreatitis. In the study by Sharma of 38 pseudocyst drainage procedures, after a 44-month follow-up, three patients had symptomatic recurrence and three had asymptomatic recurrences (16%), all initially presenting with alcohol-induced pancreatitis. De Palma (2002), with a follow-up of 26 months, demonstrated a 20.9% recurrence rate. The etiology of recurrent pancreatic pseudocysts usually involves the obstruction of a cyst-enterostomy or stent in the presence of persistent pancreatic disease or ductal stricture. Hookey (2007) reported the largest series to date (116 patients), with an overall clinical success rate with pseudocyst resolution in 87.9%. Collections recurred in 15.5% of cases at a median of 7 months. Necrotic drainage was associated with significantly higher failure rates for endoscopic drainage and a higher incidence of recurrence in this series. Factors that predict failure of endoscopic therapy include necrotic cavity size >15 cm, deep retroperitoneal extension, presence of diabetes mellitus, and comorbid conditions.

Systematic review of multiple series by Aljarabah (2007) demonstrated that recurrence rates following endoscopic pseudocyst drainage of 14.4% were comparable with those reported after open surgery (5% to 20%). These results suggest that pancreatic pseudocysts that complicate acute necrotizing pancreatitis with significant pancreatic necrotic debris would be drained best by the surgical approach. Surgical pseudocyst drainage is also best suited for cysts with a wall thickness of greater than 1 cm and

those located in the tail of the pancreas. A series followed by Lawrence (2008) demonstrated that out of 29 patients with pancreatic pseudocysts and complete duct disruption, 50% had recurrent fluid collections following surgical and endoscopic pseudocyst drainage and required long-term follow-up for symptoms related to this disorder.

Conventional Surgery

In acute pancreatitis, the incidence of subsequent pseudocyst formation is between 5.1% and 16%. It has been estimated in many studies that the spontaneous resolution of these acute cystic collections can vary from 40% to 85%. However, those cystic collections that persist often require intervention with drainage or resection. Despite the innumerable number of ways to approach pancreatic and peripancreatic fluid collections that have been ever evolving over the past decade, open surgical drainage is still an important part of contemporary pancreatic surgical techniques. The "gold-standard" approach to pancreatic cystic drainage is changing in the present era; with many more experts considering open techniques less standard than endoscopic methods. As a matter of fact, for a pancreatic surgeon to encounter a patient whom has not had an endoscopic evaluation of their pancreas and cystic fluid collection prior to referral is certainly the minority. We reserve open surgery for patients with: recurrent pseudocysts, pseudocysts with concomitant duodenal and/or biliary stenosis, symptomatic pseudocysts with associated main duct dilation, and those cysts that have been either nonamenable or refractory to minimally invasive drainage techniques. Moreover, reoperative pancreatic surgery for poorly drained peripancreatic fluid collections especially in the setting of inadequate dependent drainage by prior cyst-gastrostomy is becoming more commonplace as the sizes of pseudocysts drained by endoscopic methods are becoming more aggressive. Conventional surgery does offer an additional advantage of a more definitive pathologic diagnosis via intraoperative wedge resection of the cyst wall to rule out neoplasm as well as affording excellent access for retroperitoneal and cystic contents debridement in the setting of pancreatic necrosis with or without concomitant infection. Open techniques are generally divided into external drainage, internal drainage via cyst-enterostomy, and pancreatic parenchymal resection.

Cystic lesions of the pancreas are becoming increasingly recognized due to advances in imaging techniques. With this increased frequency

comes the need for improvements in diagnostics in order to rule out neoplastic cystic lesions and cystic sarcoma. Neoplastic cysts of the pancreas are easily misdiagnosed as pseudocysts often resulting in inappropriate drainage rather than resection. The differential diagnosis between inflammatory pancreatic pseudocysts and noninflammatory cystic neoplasms can usually be made by examining CT imaging characteristics in conjunction with an adequate patient history. Patients in whom radiographic modalities and history afford little diagnostic accuracy, transcutaneous cyst aspiration and fluid analysis can aid operative decision-making. Though not the focus of this chapter, the differential diagnosis of cystic lesions including: intraductal papillary mucinous neoplasms (IPMNs; either main-duct and/or side-branch), mucinous cystic neoplasms, serous cystadenomas and cystadenocarcinomas, solid pseudopapillary tumors, lymphoepithelial cysts, and other true epithelial cysts are among a few of the types of noninflammatory cystic lesions of the pancreas that can often be seen and further classified by EUS with transcystic fluid analysis by fine-needle aspiration (FNA) and cytologic evaluation.

Surgical management of pancreatic pseudocysts has been successful with a low morbidity and mortality rate. Usatoff (2000) reported on 112 patients consecutively treated for pancreatic pseudocysts resulting from pancreatitis. The overall morbidity rate was 28%, with an operative mortality rate of 1% and a cyst recurrence rate of 3%. Vitas and Sarr (1992) and Yeo et al. (1990) cite similar mortality rates approaching 1%. The choice of surgical procedure depends on a multitude of factors, namely: size, number, and location of the pseudocyst(s); the presence of infection; suspicion of malignancy; communication of the cyst with the main pancreatic duct; and vascular involvement.

Resection versus drainage is usually the first decision to make after operative intervention has been chosen. Pancreatic parenchymal resection is usually reserved for patients with cystic lesions confined to the distal body and/or tail of the gland, those lesions where diagnosis is ambiguous, heterogeneous lesions, and those lesions without well-formed walls amenable to suturing techniques.

We tend to reserve external drainage for those patients in whom operative drainage was required early in the inflammatory process where a well-formed cystic wall had not had the time to form and parenchymal resection would not be possible. The choice of surgical technique for

internal drainage is merely based on cyst geometry and location. Cyst-enteric communication via cyst-gastrostomy or -duodenostomy is considered for fluid collections that closely juxtapose the enteric lumen to reduce the risk of bleeding from the surrounding pancreatic parenchyma. The preferred technique for cysts that are either not indenting the gastroduodenal lumen or are large enough to not allow dependent drainage by cyst-gastrostomy is cyst-jejunostomy, especially if there are more than one cyst requiring drainage or an associated main pancreatic ductal dilation. Another concern is the presence of associated pathologies of duodenal stenosis with symptomatic gastric outlet obstruction, biliary strictures, and pancreatic strictures which usually require Roux-en-Y bypasses at the time of cyst-enterostomy.

Timing of Drainage

The key to successful management of any patient with a history of inflammatory pancreatitis and its subsequent sequelae is whether or not to intervene, and if so when is the correct timing of said intervention. As outlined by the 1992 Atlanta International Symposium, there is certainly a difference between an acute pancreatic fluid collection and an acute pancreatic pseudocyst. The timing of intervention is critical to success as well as reduction of perioperative risk. If intervention is performed too early, often there is need for parenchymal necrosectomy in tissue that has not been well demarcated resulting in hemorrhage, pancreatic fistulae, and poor source control of infection. However, if intervention is delayed the potential for pseudocyst rupture, hemorrhage, and infection are increased. Building on canine models from the 1950s, Edward Bradley and colleagues' clinical experience with the management of pancreatic pseudocysts lead to seminal publications in the 1970s citing the need for 6 weeks since the onset of clinical symptoms and/or 6 cm in size as cutoffs for operative intervention. Once the cyst wall had reached 4 to 6 weeks, the fibrous inflammatory capsule was often thick enough and had enough integrity to allow for suturing techniques without gross leak and/or hemorrhage. Moreover, physiologically the acute inflammatory process of pancreatitis had become more subacute and stable at this time interval without further progression of disease.

Current evidence has been challenging the prior dictums of 6 weeks and 6 cm for intervention, especially in patients with asymptomatic cystic disease. Definite indications for drainage are the presence of symptoms,

persistent progressive enlargement of the cyst, complications such as infection, hemorrhage, rupture, obstruction, and the suspicion of malignancy. Shatney and Lillehe (1981) analyzed 114 patients from the perspective of timing and operative intervention. Their study demonstrated that patients undergoing surgical therapy during the first 6 weeks following pseudocyst formation had higher morbidity, mortality, and recurrence rates than those treated later in the course of disease. Continued observation and radiographic surveillance by ultrasound or CT should be followed in patients with acute PFCs that develop less than 4 to 6 weeks since the onset of clinical symptoms. Observation should continue in those patients whom are asymptomatic, especially if the overall size of the cyst is less than 6 centimeters or the cyst is decreasing in size. Vitas and Sarr (1992) addressed operative versus expectant management in patients with acute pancreatic pseudocysts, and found that nearly 50% of acute cystic collections remained asymptomatic regardless of size and duration. Significant debate still exists regarding the management of asymptomatic cysts that are greater than 6 cm in size, and most clinicians now agree that the decision for intervention in these patients need to be made on a case-by-case basis with special attention given to concomitant biliary and duodenal disease as well as the complexity of medical comorbidities. Therapy is indicated in patients with symptoms and cysts that are increasing in size and greater than 6 cm, those pseudocysts that are increasing in size, those cysts that demonstrate signs of infection, or the suspicion of malignancy. If malignancy is not a concern or if parenchymal resection is not needed or not possible, then the preferred surgical therapy in these patients is internal drainage. The presence of serum isoamylase is a reliable indicator for the safety of internal pseudocyst drainage as it seems to predict a patient population that has developed more of a chronicity to their pancreatitis inflammation. Warshaw and Rattner (1985) observed that in the presence of serum isoamylase, 14 of 14 pseudocysts were suitable for internal drainage whereas those patients possessing an absence of isoamylase, 4 of 5 pseudocysts, required external drainage regardless of the length of the prior observation period.

Elective Versus Urgent Surgery

Approximately 87% of surgical interventions for pancreatic pseudocysts are elective. Urgent surgical intervention involves a higher postoperative morbidity of 67% versus 10%. Hemorrhagic complications of pseudocysts

can occur with erosion into peripancreatic vasculature, resulting in hemorrhage and pseudoaneurysm formation. Dynamic CT angiography is the most useful initial diagnostic tool for evaluation if hemorrhagic sequelae are suspected in this patient population. Selective visceral angiography is the procedure of choice for pseudoaneurysm localization and treatment, and ever-evolving endovascular techniques in these situations with angioembolization and occlusive stenting modalities have avoided open surgical treatment.

Emergent surgical intervention is indicated in patients whom are hemodynamically unstable or those in whom endovascular techniques for pseudoaneurysmal bleeding were unsuccessful. Massive hemorrhage occurs in 5% to 10% of patients with pseudocysts, and inflow and outflow control with proximal and distal ligation of the affected vessel is the method of choice for vascular control. The most common presentation is bleeding directly into the GI tract from surrounding vessels (splenic artery, pancreaticoduodenal arcade, gastroduodenal artery, left gastric artery, hepatic arteries), followed by intraperitoneal/retroperitoneal bleeding and finally hemosuccus pancreaticus from intrapancreatic vascular arcades is possible, though rare. Balthazar (2001) reported that out of 1,910 patients diagnosed as having pancreatitis, 26 developed hemorrhagic complications (1.3%). The cause of hemorrhage was a bleeding pseudoaneurysm in 16 (61%); diffuse bleeding with pancreatic necrosis in 5 (19.5%); and hemorrhagic pseudocysts in 5 (19.5%). In a study by Carr (1996), 16 patients presented with pancreatic pseudoaneurysms. Ten patients initially underwent surgery and six were initially treated with endovascular therapies. The surgical morbidity rate was 62% with three deaths (30% mortality), compared with an endovascular embolization morbidity of 50% and no mortality. The study demonstrated an increased risk of mortality in patients undergoing emergent surgical therapy complicated by necrotizing pancreatitis. The mean size of the pseudoaneurysms that required intervention for secondary complications was 13.9 cm compared with a mean size of 7.7 cm in the endovascular group.

TECHNIQUE

General Considerations

If open internal drainage is the choice of surgical management, the method to establish a cyst-to-enteric system drainage is at the discretion of the surgeon. No method has clearly emerged as being superior in all patients.

Newell et al. analyzed 98 patients, 39 of which underwent cyst-gastrostomy and 59 had cyst-jejunostomy drainages. Their conclusions found that cyst-gastrostomy was faster and had a shorter hospital stay whereas cyst-jejunostomy had a lower rate of GI bleeding but a higher rate of intra-abdominal abscess formation. Most importantly, the two procedures had equivalent rates of morbidity, mortality, and recurrence. Large pseudocysts (>10 cm, or complex geometry) often need more gravity-dependent drainage and it is the preference of these authors to perform cyst-jejunostomy in this patient population due to the many reoperative surgeries we have performed due to inadequate drainage with cyst-gastrostomy and subsequent infection.

Cyst-Gastrostomy

Preoperative assessment of the pseudocyst geometry will dictate such operative decision-making due to size, location, thickness of the inflammatory wall, and proximity to surrounding structures, most especially perigastric vascular anatomy to minimize intraoperative bleeding and/or postoperative hemorrhage or pseudoaneurysm formation. We begin by making a generous midline or subcostal incision and then attempting to gain access to the lesser sac through the gastrocolic ligament. We feel this to be an important step as true postinflammatory collections such as a pseudocyst will be fused to the posterior wall of the stomach and not allow access at this site, whereas noninflammatory collections such as those seen in cystic neoplasms often still have a preserved plane of dissection. Once an appropriate location is chosen for cyst-gastric anastomosis, two stay sutures are placed on the anterior wall of the stomach and it opened with electrocautery directly over the site of proposed posterior stomach-anterior pseudocyst capsule connection. After the anterior gastric wall is opened and gastric contents evacuated, a spinal needle is used to aspirate an aliquot of the cyst contents. A right-angled clamp is placed flush with the gastric luminal mucosa on the needle before it is removed to gauge the depth of penetration needed to access the pseudocyst cavity thereby giving reference to the overall thickness of the wall itself. Sometimes we do send the cyst contents to microbiology to assess for organismal growth and/or to the chemistry laboratory to look for mucin, CEA, and amylase contents. Electrocautery is then used to incise the posterior gastric wall directly over the site of needle localization, and this can be aided by intraoperative ultrasound in cases of cyst location

ambiguity. Once accessed, an elliptical portion of the posterior gastric wall is removed, often ~4–6 cm in size but at least large enough for cystic decompression. A portion of the cyst wall that is removed is sent to pathology for cytologic evaluation to rule out malignancy. The posterior gastric wall is then affixed to the anterior wall of the pseudocyst capsule with 2-0 or 0 absorbable suture in a figure-of-eight, full-thickness fashion in four quadrants to improve exposure. Our preference is to then oppose the posterior gastric wall to the anterior pseudocyst capsule circumferentially with interrupted 2-0 absorbable sutures in a figure-of-eight fashion spaced ~7–10 mm apart. This interrupted method is not only hemostatic but does not run the risk of loosening as the tissue edema subsides in comparison to a running, continuous suture. After the cyst contents have been evacuated and the frozen section of the wall has returned as benign, hemostasis is assured and the anterior gastric wall is closed with either stapling techniques or suturing in two layers. We also do leave a nasogastric tube for decompression down alongside the anastomosis for the first few postoperative days. In addition, we have utilized a mobilized omental pedicle flap over the anterior gastric wall closure as a kind of modified Graham patch in those patients whom potential gastric leak could present to be an issue.

Though covered elsewhere in this chapter regarding laparoscopic techniques for pseudocyst drainage, analogous stapling techniques may be utilized to affix the cyst wall to the posterior wall of the stomach after the anterior gastric wall has been entered as outlined above. Our preference is a thick load (blue or green) GIA 75-mm linear cutting stapler between the posterior gastric wall and the pseudocyst capsule after access has been obtained by electrocautery. It should be noted that we rarely utilize this method as those patients that have been chosen for open surgical techniques often have a very thick inflammatory capsule and obtaining good hemostasis after crushing and stapling techniques is quite difficult. Moreover, as the edema of the inflamed tissue subsides, the staples can become loosened leading to a staple line disruption and subsequent leak.

Cyst-Duodenostomy

As with most periduodenal manipulations, if the native anatomy and lumen can be maintained the postoperative physiology seems to be more normal. We begin this procedure with a wide Kocher maneuver if possible to allow for better exposure through the lateral wall of the duodenum as

well as minimizing any undue tension with the cyst-duodenal anastomosis as well as the closure of the lateral duodenal wall. The point of maximal indentation is chosen and then two stay sutures are placed along the antipancreatic side of the duodenum and the lateral duodenal wall is opened longitudinally with electrocautery. Special attention is given to the location of the ampulla at this time, and if this cannot be located then we either perform a concomitant cholecystectomy with transcystic catheter access and cholangiography in those patients whom have not has a cholecystectomy, or a needle cholangiogram directly into the common bile duct in those patients whom have already undergone cholecystectomy. Once the native ampulla has been identified, the location as well as depth of the pseudocyst cavity is again localized with needle aspiration. If access to the cyst is proximal to the ampulla in the first or proximal second portion of the duodenum we tend to utilize intraoperative ultrasound as well as Doppler to identify both the common bile duct as well as major surrounding vasculature such as the gastroduodenal arterial arcade before access is obtained to the cyst cavity. If the cyst seems to be indenting the duodenal lumen distal to the ampulla, then the posterior duodenal wall is open, a portion of the wall sent for frozen sectioning, and the pseudocyst wall is affixed to the duodenal wall in a manner similar to that performed with the cyst-gastrostomy listed above. It is important to note that the plane of the pancreatic parenchyma should be noted during the placement of each suture as inadvertent impingement of the pancreatic duct and/or the intrapancreatic portion of the bile duct could lead to significant postoperative complications. For this reason, we do often perform completion needle-access cholangiography to ensure unperturbed biliary drainage upon the completion of the cyst-duodenostomy. The lateral duodenostomy is then closed in two layers, usually in a longitudinal fashion without luminal narrowing. A small silastic drain is left posterior to the duodenum along the anterior aspect of the inferior vena cava, keeping in mind to not have this directly opposed to the duodenal closure; omental pedicle flaps are often used here for tissue buttressing as well.

Cyst-Jejunostomy

Cyst-jejunostomy is our preferred choice of drainage if open techniques are needed as it seems to give the best dependent drainage and affords the greatest variability to “tailor make” the connection based on the cyst location and geometry. A direct loop cyst-jejunostomy with or without a

Braun enteroenterostomy, though an accepted technique, is generally not performed. Leakage or dehiscence from the anastomosis with a loop cyst-jejunostomy leads to an uncontrolled pancreaticoenteric fistula and disruption of oral intake, whereas a Roux-en-Y reconstruction can be managed with percutaneous drainage if necessary without interrupting enteral nutrition.

The jejunum is usually divided ~15–30 cm distal to the ligament of Treitz with a 75 mm GIA linear cutting stapler. We tend to choose a position along the proximal jejunum that will reach to the anterior gastric wall in an antecolic fashion and divide the jejunum at this location, thereby ensuring that there is enough length to reach the pseudocyst capsule. If there is foreshortened mesentery or the patient is morbidly obese, the peritoneum along the mesentery can be perforated as to provide additional length. When the pseudocyst is bulging through the transverse mesocolon, a small rent can be made into the transverse mesocolon/pseudocyst capsule at this location and the cyst-jejunal anastomosis can be made in a similar fashion to that described above for cyst-gastrostomy and cyst-duodenostomy. Alternatively, if the lesser sac can be entered through the gastrocolic ligament, then a small rent can be made in the transverse mesocolon and the Roux limb of jejunum can be brought up through this rent an anastomosed to the pseudocyst capsule within the lesser sac. The mesenteric defect is then closed, and the Roux-en-Y is completed with either an end-to-side or side-to-side jejunojejunostomy for drainage of the biliopancreatic limb distal to the site of cyst-jejunal anastomosis.

Although it is unusual, if there are multiple pancreatic pseudocysts that do not seem to communicate to one another they can be drained serially with two or more cyst-jejunal anastomoses. Care must be taken to space these connections appropriately so as not to lead to serosal ischemia. Moreover, the consideration for a longitudinal pancreaticojejunostomy (Puestow) procedure for drainage of pancreatic pseudocysts which communicate to a dilated pancreatic duct is also an acceptable method of ductal decompression as well as cyst drainage.

LAPAROSCOPIC DRAINAGE

Evolution of laparoscopic pancreatic pseudocyst drainage has followed different strategies, but all have relied upon the basic tenets of pancreatic surgery. The first tenet is that the pseudocyst should be drained in a dependent location based on the cysts anatomic location. The second tenet

is biopsy of the cyst wall to rule out a cystic neoplasm. The third tenet is to perform adequate pseudocyst exploration and debridement. The final fourth tenet is to maintain hemostasis whether through the use of a stapler or through an interrupted suture ligation.

Indications for laparoscopic pseudocyst drainage are the same as described previously for endoscopic interventions (Table 126.1). Symptomatic pseudocysts greater than 6 cm in size that have been present for more than 6 weeks are considered for drainage. Pseudocysts associated with an inflammatory mass or a dilated duct with calculi within the head of the pancreas may be best treated by pancreatic head resection (Whipple procedure). Patients with pancreatic ductal strictures and pseudocysts in the tail of the pancreas can be treated with a distal pancreatectomy. Pseudocyst communication with the main pancreatic duct is not a contraindication to laparoscopic drainage, except in patients with multiple pancreatic duct strictures. Consideration for an ERCP-placed stent in the pancreatic duct in combination with laparoscopic drainage may be helpful in preventing recurrence.

The laparoscopic approach is best suited for pseudocysts that demonstrate debris and pancreatic necrosis since laparoscopy provides improved pancreatic drainage and direct visualization for debridement. The argument has been made that larger size of the opening made with laparoscopy is a distinct advantage in cases with significant necrosis and may lead to quicker recovery with a single intervention in comparison to the endoscopic approach. This has not been subjected to comparative trial but does make sense. Some authors have described delayed debridement of infected pancreatic necrosis through a cyst-gastrostomy in patients with a favorable response to systemic antibiotics. This approach should also be considered for patients in whom suspicion of carcinoma requires biopsy and inspection of the pseudocyst wall. Other possible candidates for the laparoscopic approach include patients with portal hypertension or coagulopathy. The laparoscopic treatment of pseudocysts may confer an advantage in those with chronic pancreatitis and ongoing alcohol abuse because this approach minimizes disruption of other intra-abdominal organs with minimal dissection allowing for easier reoperation especially when attempting more extensive pancreatic debridement or a subtotal pancreatectomy. A secondary advantage of the laparoscopic approach is the ability to remove the gallbladder if necessary at a single operation.

Localization of the Pseudocyst

The standard of care for localization of pseudocysts prior to drainage is a CT with thin cuts through the pancreas. Pseudocysts that are asymptomatic or less than 6 cm in diameter can be managed conservatively and those greater than 10 cm in diameter should be managed operatively because of the high incidence of complications. ERCP should also be completed prior to surgery because it may affect treatment options since up to 80% of pseudocysts demonstrate a pancreatic duct stricture or duct disruption. Intraoperative needle aspiration is most commonly used to localize the pseudocyst. Finding the pseudocyst can sometimes be difficult and if it is anticipated to be problematic preoperatively a transgastric catheter can be placed by CT or US guidance into the pseudocyst to mark the potential best spot for transgastric drainage. Laparoscopic ultrasound and EUS have also been utilized for cysts that do not readily indent the enteric lumen.

TABLE 126.1 Indications for Therapeutic Intervention for Pancreatic Pseudocysts

Clinical Presentation and Complications

Local complications
Infection of pancreatic pseudocyst
Hemorrhage into pancreatic pseudocyst
Rupture (can cause pancreatic ascites, shock, and peritonitis)

Involving adjacent organs
Gastrointestinal tract:
Esophagus (secondary achalasia, mechanical dysphagia)
Stomach (clinically relevant gastric outlet stenosis, fistula, intramural gastric mass)
Duodenum (clinically relevant duodenal stenosis, fistula)
Colon (clinically relevant colonic stenosis and/or rectal bleeding)
Liver (stenosis of the common bile duct with jaundice due to compression)
Vascular:
Arterial (erosion of gastroduodenal and/or splenic artery)
Venous (thrombosis of portal and/or splenic vein)
Spleen (splenic rupture)
Genitourinary tract (stricture, fistula, ureter obstruction)
Chest (pancreaticopleural fistula, pleural effusion, mediastinal extension)
Skin (subcutaneous fat necrosis)

Symptomatic pancreatic pseudocyst
Abdominal distension
Nausea and vomiting
Pain
Upper gastrointestinal bleeding

Relative indications for intervention in asymptomatic pancreatic pseudocyst
Pseudocyst >5 cm, unchanged in size and morphology for more than 6 wk (Bradley, 1993)
Pseudocyst >4 cm and extrapancreatic complications in patients with chronic alcoholic pancreatitis (Gouyon et al., 1997)
Cyst wall >5 mm (mature cyst) (Beckingham et al., 1999)
Chronic pancreatitis with advanced pancreatic duct changes (Gouyon et al., 1997)
Suspected cystic pancreatic tumor (requiring surgery) (Levy, 2006 and Ridder, 1996)

The Intragastric Cyst-Gastrostomy Approach

Way and Gagner (1994) were the first to perform laparoscopic pancreatic pseudocyst drainage using an intragastric approach. Initially, a Veress needle is used to gain insufflation of the abdomen and a periumbilical trocar is placed for visualization of the stomach. Stomach insufflation is then achieved using a nasogastric tube or gastroscope. Pneumoperitoneum is maintained at 8 to 10 mm Hg while the stomach is inflated and transgastric ports are placed through the fascia into the stomach. Multiple techniques have been described for placing these transgastric ports, including specialized trocars with balloons at their tip that can be cinched

up to the gastric wall, radially dilating trocars (Inner-Dyne Inc., Sunnyvale, CA) that are placed into the stomach over a Veress needle to create a seal with the stomach, and standard laparoscopic trocars sutured in place with purse-string sutures. Three trocars are placed through the greater curvature of the stomach, accommodating an intragastric laparoscope and two operating instruments (Fig. 126.6).

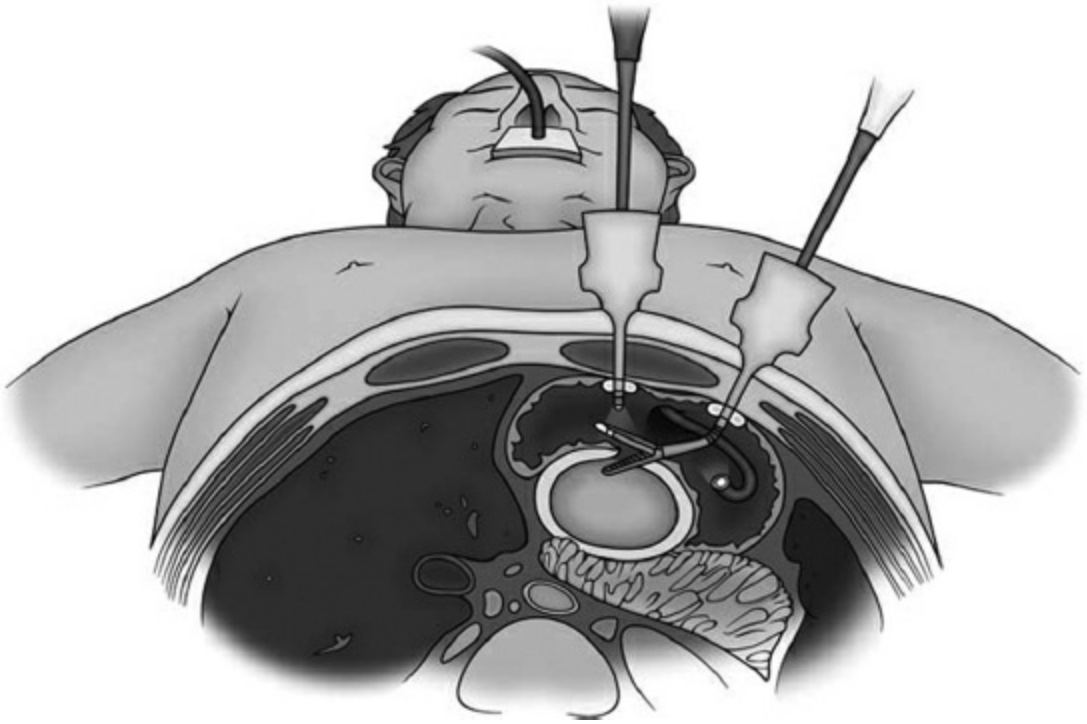

Figure 126.6. Intragastric approach to pancreatic pseudocyst drainage. (From Rosen MJ, Heniford BT. Endoluminal gastric surgery: the modern era of minimally invasive surgery. *Surg Clin North Am* 2005;85(5):989–1007.)

The cyst is localized with either needle aspiration or a laparoscopic ultrasound. The cyst cavity can be entered with either hook electrocautery or harmonic scalpel dissection. A wedge of the cyst wall is sent for frozen section to rule out a cystic neoplasm. A cyst-gastrostomy is then fashioned for a length of 4 to 5 cm using either the harmonic scalpel or a laparoscopic stapler. If the collection of necrotic debris is extensive a larger opening is made. When the harmonic scalpel is used, then the gastrostomy is usually reinforced with interrupted sutures to prevent bleeding complications. After the cyst-gastrostomy is complete, the trocars are withdrawn and the gastrostomies are closed using figure-of-eight sutures. Park and Heniford (2002) describe a variation of this technique

where the stomach is insufflated and intragastric ports are placed directly through the skin into the stomach without creating a pneumoperitoneum. This technique utilizes a stapler to complete the cyst-gastrostomy. This technique obviates the need for pneumoperitoneum and gastrostomy closure utilizing mini laparoscopy instruments that are 2 mm in diameter. The main limitation of the intragastric approach is that it can be technically difficult secondary to a limited operative space and bleeding from the friable cyst-gastrostomy.

The Anterior Transgastric Cyst-Gastrostomy Approach

The technical challenges of the intragastric approach led to the development of the anterior transgastric approach in which a 5- to 6-cm gastrotomy is performed (Fig. 126.7). An anterior gastrotomy allows improved access to the posterior wall of the stomach. A laparoscopic stapler is placed through the gastrotomy to create a cyst-gastrostomy that is hemostatic. Gibson et al. (2014) demonstrate good results using a new port dilating system. The “Step Port” dilating system (Covidien PLC) facilitates access and the first stapler application. The port is inserted through the abdominal wall, through the posterior wall of the stomach after anterior large gastrotomy and then dilated. After it is expanded there is a 12-mm access to the cyst cavity with radial pressure maintained by the dilating sleeve. After cyst aspiration the port is removed with a suction cannula being left in place to maintain access as the stapler is placed. The anterior gastrotomy is then closed with interrupted sutures or a stapler. The primary disadvantage to this procedure is the creation of two gastrotomies with an increased risk of spillage of gastric contents. This would seem to be a minimal risk and the exposure of the posterior gastric wall for more traditional laparoscopic dissection may outweigh any small increased risk of infection or leakage.

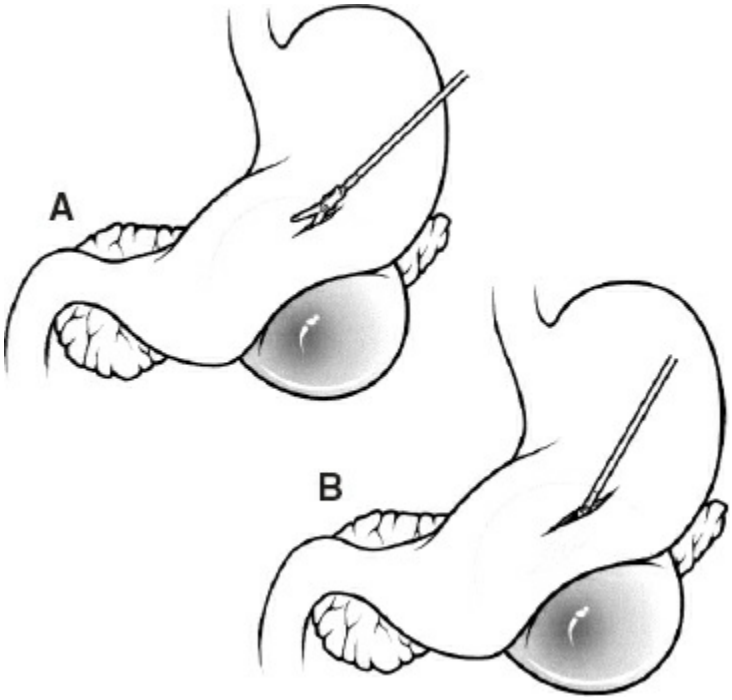

Figure 126.7. Cystostomy performed through anterior gastrostomy.

The Lesser Sac Approach

Park and Heniford (2002) describe a technique that addresses the risk of gastric spillage by approaching the pseudocyst through the lesser sac and creating a single gastrotomy for effective dependent pseudocyst drainage. The surgery is started with the patient in lithotomy position, and pneumoperitoneum is created with a Veress needle. A periumbilical port as well as a left upper quadrant port and a subxiphoid port are placed. The gastrocolic omentum can be divided using an ultrasonic dissector, diathermy, or stapler. The posterior wall of the stomach is then divided from the pancreatic pseudocyst. Needle aspiration is used to localize the pseudocyst, and a cystotomy is made with cautery proceeding to a cyst wall biopsy. The stomach is simultaneously explored using a gastroscope to determine the optimal position for a posterior gastrotomy. A gastrotomy is then made juxtaposed to the pancreatic cyst, and a laparoscopic stapler is introduced to fashion a large cyst-gastrostomy. Laparoscopic instruments can be inserted into the cyst to break loculations and debride necrotic pancreas. The opening in the cyst-gastrostomy is then closed using interrupted sutures (Fig. 126.8). Following completion of the cyst-gastrostomy the gastroscope insufflates the stomach under direct laparoscopic visualization to ensure an airtight anastomosis.

The Cyst-Jejunostomy Approach

This approach was developed to obtain the most dependent and anatomic drainage for pseudocysts that are not easily accessible through the stomach. The operation is begun with the patient in the lithotomy position and two trocars are placed lateral and superior to the umbilicus on the left. A third trocar is placed in the upper abdomen just lateral to the right rectus muscle. A fourth left lateral, upper abdominal trocar is also placed for the laparoscopic stapler. Pseudocyst localization through the transverse mesocolon is determined by visual inspection, aspiration decompression, or laparoscopic ultrasound. The preferred site of pseudocyst access is just superior and lateral to the ligament of Treitz. Cyst-jejunostomy can be created either with a loop of jejunum or with a Roux-en-Y reconstruction. Roux-en-Y reconstruction is preferred because it lessens the risk of pseudocyst infection and the potential leakage of intestinal contents. For Roux-en-Y reconstruction, the jejunum is transected approximately 30 cm distal to the ligament of Treitz and the pseudocyst is opened through the transverse mesocolon. Laparoscopic instruments can be used to disrupt loculations and debride pancreatic necrosis. An enterostomy is then performed in the jejunum and a lateral cyst wall-to-jejunal anastomosis is performed with a laparoscopic stapler. The cyst-jejunostomy is then closed with a running permanent suture layer. The jejunojejunostomy is created 50 to 60 cm distal to the cyst-jejunostomy to prevent reflux of enteric contents into the cyst cavity.

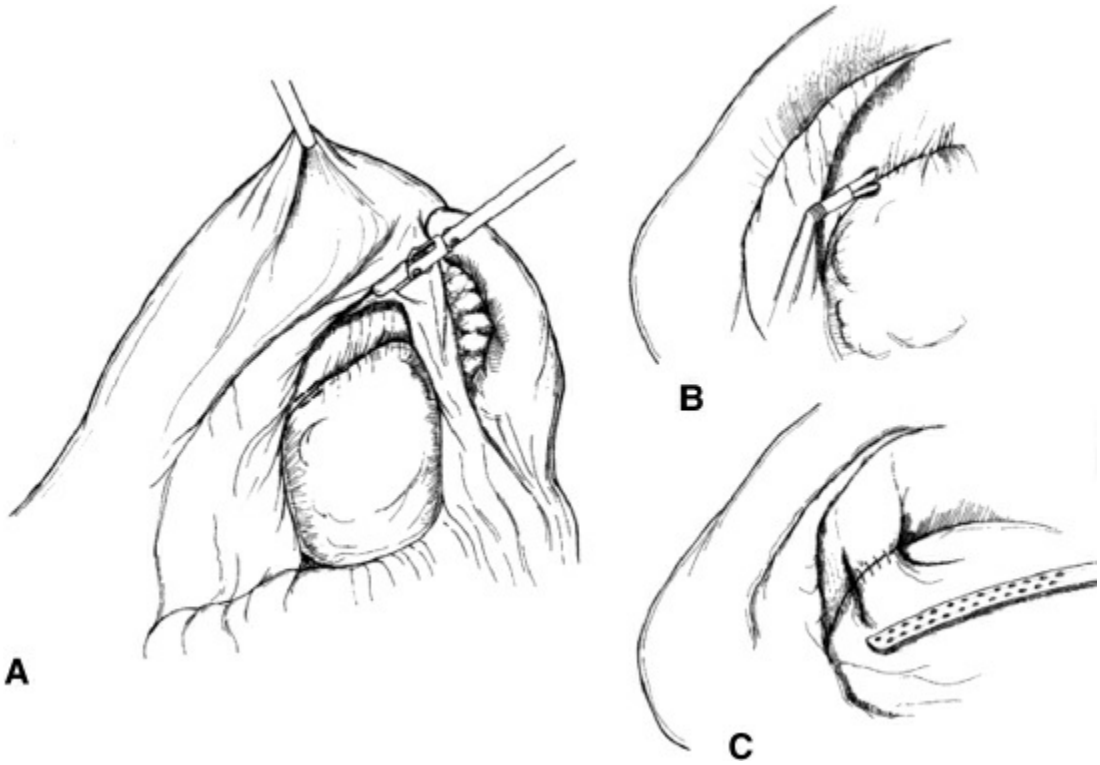

Figure 126.8. The lesser sac approach to pancreatic pseudocyst drainage.

Results of Laparoscopic Pancreatic Pseudocyst Drainage

Way, who first described intragastric laparoscopic pseudocyst drainage (1994), later (2000) reported a series of 18 patients, with successful completion of the procedure in 14 of these patients. Four patients had to be converted to an open approach due to bleeding at the cyst-gastrostomy. All patients in this series were noted to have resolution of the pseudocyst on long-term follow-up. Trias (1995) described modification of the intragastric technique using a stapler for creation of the anastomosis, which reduced bleeding complications. The intragastric approach proved technically demanding and led to the development of the anterior transgastric approach first described by Obermeyer (2003) in a series of five patients with a mean length of hospital stay of 7.5 days with no complications or recurrences. Khaled et al. (2014) demonstrated shorter operating time, shorter hospital stay, and smoother recovery with the laparoscopic approach compared to open in a matched cohort study. In that study operating time was 62 versus 95 minutes favoring the approach, hospital stay was shorter 6.2 versus 11 days for laparoscopic and morbidity less 10% versus 60% in the laparoscopic group. The single death in this study of 54 patients occurred in the open group.

Hauters (2004) compared the outcomes of the intragastric and anterior transgastric technique in six patients. This study found comparable results between the two techniques, with no differences in the length of hospital stay or pseudocyst recurrence. Teixeira (2003) reported a series of nine patients who received laparoscopic cyst-jejunostomy. This study demonstrated a minor complication rate of 20% with no major complications or mortality, with total resolution of the pseudocysts and no recurrences. The largest single series in the literature (28 patients), described by Park and Heniford (2002), uses all four described approaches to pseudocyst drainage and detailed a mean postoperative length of stay from 3 to 4 days, depending on the procedure performed. The most common complication noted was bleeding from the cyst-enteric anastomosis, which was managed with blood transfusions and did not require operative intervention. Long-term follow-up demonstrated cyst resolution with two recurrences. One patient developed necrotizing pancreatitis requiring serial debridements and another required conversion to external pseudocyst drainage with a sump drain. Aljarabah (2007) reviewed the outcomes of laparoscopic pseudocyst drainage in 118 patients, sampled from multiple different series in the literature, revealing a mean length of hospital stay of 5.7 days with resolution of pseudocyst in 98.3% of patients.

TABLE 126.2 Ten Steps of Laparoscopic Transgastric Endoluminal Cystogastrostomy and Pancreatic Debridement

1. Intra-abdominal access and placement of four ports
2. Transgastric laparoscopic ultrasound of the pseudocyst
3. Insufflation of the stomach via gastroscope
4. Creation of three small gastrotomies and transgastric placement of balloon trocars
5. Endoluminal ultrasonic confirmation of pseudocyst cavity
6. Creation of a posterior gastrostomy
7. Cystgastrostomy anastomosis performed with linear stapler and suture reinforcement
8. Debridement of pseudocyst
9. Placement of nasogastric tube into pseudocyst cavity
10. Closure of gastrostomy sites

Laparoscopic Pancreatic Necrosis Debridement

Laparoscopic approaches for pancreatic pseudocyst drainage can also be utilized to debride infected pancreatic necrosis. Initial description of the feasibility of these techniques was by Gagner (1996) who operated on eight patients using transgastric, retrogastric retrocolic, and retroperitoneoscopic approaches to debridement. These techniques resulted in no mortalities and in a 25% reintervention rate for complications. Cuschieri (1998) described a laparoscopic infracolic approach in three patients, opening the lesser sac through the root of the transverse mesocolon to debride the pancreas with pulse irrigation and graspers. The largest series to date from Parekh (2006) evaluates laparoscopic-assisted pancreatic necrosectomy in 19 patients. This technique utilized a hand port for digital dissection and two 12-mm trocars to perform necrosectomy using an infracolic approach. This series demonstrated an 11% mortality and 26% morbidity rate, with 74% of patients experiencing therapeutic successful after initial debridement using this approach. The emphasis on reducing surgical morbidity has led to the development of retroperitoneal laparoscopy-assisted access approaches utilized to debride necrotic pancreas. Worhunsky et al. (2015) report on laparoscopic transgastric debridement with success using a single procedure in 19 of 21 patients with a mean hospital stay of 5 days. Gerin et al. (2015) describe a laparoscopic-assisted open cyst-gastrostomy and pancreatic necrosis debridement technique with good results. Simo et al. (2014) report on 22 patients treated with a laparoscopic transgastric endoluminal cyst-gastrostomy of which 15 were completed laparoscopically. Median time between cyst presentation and surgery was 86 days and average length of stay was 14.9 days. Mean operative time was 220 minutes with 8 complications, with one procedure related bleeding requiring operative intervention. Table 126.2 itemizes steps in this procedure. Although critics of minimally invasive necrosectomy argue that minimally invasive approaches are and Simo et al. (2014) higher risk due to limited and inadequate exposure for hemorrhage control, Cirocchi et al. (2013) demonstrate the opposite. Meta-analysis of 336 patients, 215 of who underwent minimally invasive necrosectomy, demonstrated that postoperative multisystem organ failure occurred in the minimally invasive group in 21% versus 49% in the open group ($P < 0.0001$). Incisional hernia was more common in the open group not unexpectedly. There was a higher incidence of diabetes and postop pancreatic enzyme requirement in the open necrosectomy group. No difference was found for mortality,

intra-abdominal bleeding or fistula development. Another benefit of this approach is shown in a study by Kulkarni (2015) which demonstrates pancreatic fistula formation rate of zero with transgastric technique for debridement of pancreatic necrosis.

Overall it would appear that minimally invasive approaches to pancreatic pseudocyst and necrosis in selected cases can be performed safely and with an efficacy equaling or exceeding open operative results.

EDITOR'S COMMENT

A single commentary will address the materials in Chapter 126 by Vitale and Chapter 125 by Muscarella. Dr. Gary Vitale from the University of Louisville is a leading authority on interventional endoscopic techniques. Dr. Peter Muscarella, currently at Albert Einstein and working at Montefiore, is a busy general surgeon and who during his time at Ohio State was the go to surgeon for necrotizing pancreatitis. The perspectives of each are valuable contributions.

Pancreatic Cysts

Not all pancreatic cysts are pseudocysts. The first priority is for the physician to establish if the cyst is of the inflammatory variety or a neoplastic cyst. If it is a cystic neoplasm then the worst thing one can do is an enteric drainage. If there is no history of pancreatitis or for that matter lack of a recent or remote acute abdominal episode in a patient without any history of alcohol use or gallstones and imaging without showing any acute changes of the pancreas or peripancreatic tissues, then the patient likely has a cystic neoplasm of the pancreas. Today we are fortunate to have available endoscopic ultrasound (EUS) to permit examination of the cyst and cyst sampling for amylase, tumor markers, and cytology. In the past we had referrals of patients with recurrent "pseudocysts" after cyst-gastrostomy that in fact had serous cystadenocarcinoma, mucinous cystadenocarcinoma, or other cystic neoplasms. The incidence of these occurrences can be greatly reduced by appropriate diagnostic testing including EUS.

As pointed out by Dr. Vitale not all pancreatic pseudocysts require drainage. Indeed, up to 40% will resolve spontaneously during a period of observation. Today we still honor the "6-week rule." That is the surgeon or endoscopist should wait a period of 6 weeks prior to drainage. Many cysts will resolve or decrease in size during this period and may not need drainage. In addition, the time allows the inflammatory process to create a fibrous adherence between the cyst and surrounding structures.

Since the last edition there has been a great deal of enthusiasm for endoscopic and nonsurgical methods to drain pancreatic pseudocysts. Surgical

drainage is the standard to which all treatment modalities should be compared. In comparative studies endoscopic techniques appear equally effective to surgical approaches.

Catheter Drainage

Caution is advised in routine percutaneous aspiration of a presumed pancreatic pseudocyst. It must be recognized that it is useful for initial treatment of an infected pseudocyst, to establish a diagnosis or as a temporizing measure. Percutaneous catheter drainage is the procedure of choice for treating infected pseudocysts, allowing for rapid drainage of the cyst and identification of any microbial organism. However with an uninfected pseudocyst, the failure rate is 54% with a 63% recurrence rate. In addition, this technique has a relatively high risk of infecting the pseudocyst. Percutaneous catheter drainage is contraindicated in patients who are poorly compliant and cannot manage a catheter at home. It is also contraindicated in patients with strictures of the main pancreatic duct and in patients with cysts containing bloody or solid material. It is generally recognized that percutaneous drainage has a higher complication rate and inpatient mortality rate than surgical drainage.

Endoscopic Drainage

Endoscopic drainage may be either transmural or transpapillary (via endoscopic retrograde cholangiopancreatography [ERCP]). Both modalities require careful patient selection to ensure success and safety. Based on the most current literature endoscopic treatment of pancreatic pseudocysts has the same clinical success, recurrence, complication, and mortality rate as surgical treatment but with a shorter hospital stay and lower costs. It is becoming the preferred drainage technique and first therapy for pancreatic pseudocysts. There has been an evolution to using endoscopic ultrasound to guide the transmural cyst-gastrostomy. This technique allows visualization vasculature adjacent to the pseudocyst thereby helping the endoscopist to avoid such structures when draining the cyst and placing a stent. In addition, flexible metal stents rather than plastic stents are used to prevent premature closure of the of cyst-gastrostomy. Dr. Vitale covers this in detail. Two recent studies are instructive.

Zhao X et al. (Endoscopic versus surgical treatment for pancreatic pseudocyst. *Dig Endos*c 2016;28(1):83–91) systematically searched PubMed and the Cochrane Library to identify all comparative trials investigating endoscopic versus surgical treatment for pancreatic pseudocyst. In this study the main outcome measures included treatment success rate, adverse events, recurrence rate, length of hospital stay, and hospital cost. They identified five comparative studies with 255 participants for a meta-analysis. The surgical group exhibited a higher treatment success rate than the endoscopic group (OR, 0.43; 95% CI, 0.20–0.95; P = 0.04). However, there was no difference in the rates of adverse events (OR, 0.67; 95% CI, 0.33–1.36; P = 0.27) or recurrence

(OR, 1.53; 95% CI, 0.37–6.39; *P* = 0.56) between the endoscopic and the surgical groups. Evidence from included studies demonstrated that the endoscopic group was associated with shorter length of hospital stay and lower hospital cost compared to the surgical group.

Saul A et al. (EUS-guided drainage of pancreatic pseudocysts offers similar success and complications compared to surgical treatment but with a lower cost. *Surg Endosc* 2016;30:1459–65) retrospectively reviewed data obtained prospectively from 2000 to 2012. This report included 64 procedures in 61 patients: 21 (33%) cases were drained endoscopically guided by EUS and 43 (67%) cases were drained surgically. The clinical success of the endoscopic group was 90.5 compared to 90.7% for the surgical group, with a complication rate of 23.8% and 25.6% and a mortality rate of 0% and 2.3% for each group. The hospital stay was lower for the endoscopic group: 0 (0 to 10) days compared with 7 (2 to 42) days in the surgical group. The cost was lower in the endoscopic group ($P < 0.001$). The recurrence rate was similar in both groups: 9.5% and 4.5%, respectively ($P = 0.59$). The two recurrences found in the endoscopic group were associated with stent migration, and the recurrence in the surgical group was due to the type of surgery performed (open drainage).

Another study compared percutaneous and endoscopic techniques. Kean MG, et al. (Endoscopic versus percutaneous drainage of symptomatic pancreatic fluid collections: a 14-year experience from a tertiary hepatobiliary centre. *Surg Endosc* 2016;30(9):3730–40) reported a retrospective comparison of endoscopic transmural drainage or percutaneous drainage for the initial management of patients with symptomatic pancreatic fluid collections between January 2000 and December of 2013. There were 164 patients included in the study; 109 patients underwent endoscopic; and 55 had percutaneous drainage alone. There were no procedural deaths. During the 14-year study period, the incidence of endoscopic drainage increased. In the 109 patients who were managed by this technique, treatment success was 70% compared to 31% in those managed by percutaneous drainage. Those patients managed by endoscopic techniques required fewer interventions (median of 1.8 vs. 3.3), had lower rates of residual collections (21% vs. 67%) and need for surgical intervention (4% vs. 11%). Interestingly, in the endoscopic group treatment for walled-off pancreatic necrosis was 67% compared to 72% for pseudocysts. The authors concluded that compared to percutaneous drainage, endoscopic drainage was associated with higher rates of treatment success, lower rates of reintervention, including surgery and shorter lengths of hospital stay. This has been the experience at our center as well.

Transpapillary Drainage

Although transpapillary drainage may be safer and potentially more effective than transmural drainage in some situations, it requires cyst communication with the pancreatic duct. In addition, this technique is technically challenging because it requires wire passage and stenting through the pancreatic duct to the

pseudocyst. The success rate is about 80%. The recurrence rate is 10% to 14%, and, in most series, the complication rate (mainly pancreatitis) is approximately 13%. Endoscopic drainage seems the preferred modality. Yang D et al. (Transpapillary drainage has no added benefit on treatment outcomes in patients undergoing EUS-guided transmural drainage of pancreatic pseudocysts: a large multicenter study. *Gastrointest Endosc* 2016;83:720–9) studied whether transpapillary drainage should be used in conjunction with transmural drainage and found that it was unnecessary.

I think it is important to consider situations in which endoscopic drainage may not be considered the first line of treatment. First the cyst needs to be in close proximity to the stomach. Usually within 1 cm is required. If there has been hemorrhage into the pseudocyst surgical drainage is preferred. Also giant pseudocysts may not respond well to endoscopic drainage and may require a surgical approach and possibly a Roux-en-Y cyst-enterostomy.

Walled-Off Pancreatic Necrosis

We have come a long way in the treatment of walled-off pancreatic necrosis and infection. Recall in the 1990s these patients required multiple debridements and packing and some surgeons even advocated for the placement of zippers to allow ready access to the pancreatic bed and peripancreatic tissues. Advances in interventional radiology, endoscopy, and minimally invasive surgery are responsible for a paradigm shift in the treatment of this complication of acute pancreatitis. The chapter by Muscarella nicely outlines the progression of acute pancreatitis to necrosis and infection. The controversial issues are the role of antibiotics in pancreatic necrosis, the timing of intervention and the type of intervention; surgery, laparoscopy, step up approach, endoscopic or dual modality (percutaneous and endoscopic).

The development of pancreatic infection is associated with the development of a progressive necrosis and systemic inflammatory response leading to a high morbidity and mortality. There is general agreement that in mild pancreatitis there is no need to use antibiotics; in severe pancreatitis there has been an ongoing debate on whether to use antibiotics to prevent secondary pancreatic infection in an attempt to decrease associated mortality. A nonsystematic review of current evidence, meta-analyses and randomized controlled trials found mixed evidence to support or refute the role of prophylactic antibiotics in acute pancreatitis (Mourad MM, Evans RPT, Kalidindi V, et al. Prophylactic antibiotics in acute pancreatitis: endless debate. *Ann R Coll Surg Engl.* 2017;99(2):107–12). Indeed the majority of studies have failed to demonstrate much benefit from routine antibiotic use. Data from the authors clinical unit suggest minimal benefit of their routine use, and observed that the mortality of those treated with antibiotics was 9% compared to 0% for patients not treated with antibiotics. In addition, in the antibiotic group the morbidity was 36% compared to 5% in the nonantibiotic group. It is our current practice that antibiotics should be used in patients who develop sepsis, infected pancreatic

necrosis, multiple-organ dysfunction syndrome or pancreatic and extrapancreatic infection. Elevation of inflammatory markers such as C-reactive protein, procalcitonin, or interleukin-6 levels may prompt antibiotic therapy. Unfortunately, in several studies there is no clear benefit to prophylactic antibiotics. In sum, there remain many unanswered questions regarding the indications for antibiotic administration and the patients who benefit from antibiotic treatment in acute pancreatitis.

As indicated in the previous paragraph there has been a substantial evolution in the surgical management of pancreatic necrosis. It is known that pancreatic or peripancreatic tissue necrosis confers substantial morbidity and mortality. New modalities have created a wide variation in approaches and timing of interventions for necrotizing pancreatitis. The dogma for many years was that patients with pancreatic necrosis should not undergo surgical debridement before 30 days. Earlier surgery was associated with increased morbidity and bleeding complications. Unfortunately owing to the heterogeneous nature of pancreatic necrosis and the variability of the disease itself, it is difficult to compare studies or even conduct randomized controlled trials. We have a variety of techniques that can be applied but the treatment for each patient requires an individual approach. A sampling of the current literature below underscores the difficulty in making sweeping recommendations for the treatment of walled-off pancreatic necrosis from clinical experience.

A review by J van Grinsven summarizes the current the state (Timing of catheter drainage in infected necrotizing pancreatitis. *Nat Rev Gastroenterol Hepatol* 2016;13(5):306–12). He and co-authors indicate that “the current standard treatment of infected necrosis is a step-up approach, consisting of catheter drainage followed, if necessary, by minimally invasive necrosectomy.” He goes on to challenge the current international guidelines recommending that catheter drainage be postponed for 4 weeks until the stage of “walled-off necrosis” (WON) has been reached. He argues that this “recommendation stems from the era of primary surgical necrosectomy” and “postponement of catheter drainage might not be necessary” and “that earlier detection and earlier drainage of infected necrosis may improve outcome.” As high-level evidence and consensus are lacking future clinical, preferably randomized, studies should focus on timing of catheter drainage in patients with infected necrotizing pancreatitis.

Additional insight can be gained by reviewing the results of an online survey including case vignettes that was sent to 118 international pancreatologists (van Grinsven J, van Brunschot S, Bakker OJ, et al. Diagnostic strategy and timing of intervention in infected necrotizing pancreatitis: an international expert survey and case vignette study. *HPB (Oxford)* 2016;18(1):49–56). The purpose of this study was to evaluate the use and timing of fine-needle aspiration (FNA), antibiotics, catheter drainage, and (minimally invasive) necrosectomy. The response rate was 74% (N = 87). The authors concluded that “the step-up approach was observed to be the preferred treatment strategy in infected

necrotizing pancreatitis among expert pancreatologists. However, there was no uniformity regarding the use of FNA and timing of intervention in the first 2 to 3 weeks of infected necrotizing pancreatitis."

In this study the specific results were:

1. None of the respondents used FNA routinely, 85% selectively, and 15% never.
2. Most respondents (87%) used a step-up approach in patients with infected necrosis.
3. WON was considered a prerequisite for endoscopic drainage and percutaneous drainage by 66% and 12%, respectively.
4. 55% routinely postponed invasive interventions after infected necrosis was diagnosed, whereas 45% proceeded immediately to intervention.
5. There was a lack of consensus about timing of intervention on day 14 with proven infected necrosis (58% intervention vs. 42% noninvasive) as well as on day 20 with only clinically suspected infected necrosis (59% intervention vs. 41% noninvasive).

In the United States, a recent systematic review of the MEDLINE database using PubMed was performed to explore current practice (Mowery NT, Bruns BR, MacNew HG et al. Surgical management of pancreatic necrosis: A practice management guideline from the Eastern Association for the Surgery of Trauma. *J Trauma Acute Care Surg* 2017;83(2):316–27). Topics of investigation included operative timing, the use of adjuvant therapy and the type of operative approach. Eighty-eight studies were included and underwent full review. Increasing the time to surgical intervention had an improved outcome in each of the time periods evaluated (72 hours, 12–14, 30 days) with a significant improvement in outcomes if surgery was delayed 30 days. The use of percutaneous and endoscopic procedures was shown to postpone surgery and potentially be definitive. The use of minimally invasive surgery for debridement and drainage was shown to be safe and associated to less morbidity and mortality. The authors recommend (Systematic review/guideline, level 3):

1. In adult patients with pancreatic necrosis, pancreatic necrosectomy be delayed until at least day 12.
2. During the first 30 days of symptoms with infected necrotic collections, surgical debridement only if the patients fail to improve after radiologic or endoscopic drainage.
3. With documented infected necrosis, patients should undergo a step-up approach to surgical intervention as the preferred surgical approach.

Shenvi S et al. (*Pancreatology* 2016;16(5):778–87) conducted a randomized controlled trial to attempt to determine the optimum timing of surgical intervention in patients with infected pancreatic necrosis not responding to percutaneous drainage. Patients who did not improve by day 10 after percutaneous drainage were included in the present study and were managed

with step-up approach with the intention to avoid surgery. Of 35 patients, 24 patients were managed by percutaneous drainage alone and 11 patients required surgery. In patients who did not require surgery; levels of serum high sensitivity C-reactive protein, interleukin-6 and prealbumin showed a falling trend. This group also had higher baseline albumin and higher albumin at 4 weeks. The step-up approach with the intention to avoid surgery had a success rate of 68.5%. However, this study failed to predict the optimal timing of surgery after percutaneous drainage. The treatment groups were very heterogeneous and patients who needed surgery were more ill at the time of admission, had higher incidence of organ failure, and spent more time in the ICU compared to patients who did not need surgery. Hence no conclusions could be made regarding the definitive timing of intervention.

Sugimoto M et al. (Better outcomes if percutaneous drainage is used early and proactively in the course of Necrotizing pancreatitis. *J Vasc Interv Radiol* 2016;27(3):418–25) tried to make a case for earlier intervention. Between September 2010 and August 2014, they studied 39 consecutive patients with pancreatic necrosis in whom CT-guided percutaneous drainage was the primary treatment. The indication for percutaneous drainage was the clinical finding of uncontrolled pancreatic juice leakage rather than infected necrosis. Subsequent to drainage, the protocol called for the drains to be proactively studied with fluoroscopic contrast medium every 3 days to ensure patency and position. Drains were ultimately maneuvered to the site of leakage. These 39 patients were compared with 43 patients from the Pancreatitis, Necrosectomy versus Step-up Approach (PANTER) trial. The CT severity index was similar between studies (median of 8 in each). Time from onset of acute pancreatitis to drainage was shorter in the present series (median, 23 days vs. 30 days). The total number of procedures (drainage and subsequent fluoroscopic drain studies) per patient was greater in the present series (mean, 14 vs. 2). More patients in the PANTER trial had organ failure (62% vs. 84%), required open or endoscopic necrosectomy (0% vs. 60%), and experienced in-hospital mortality (0% vs. 19%; $P < 0.05$ for all). They concluded that even though patients in the present series had a similar CT severity index as those in the PANTER trial, the former group showed lower incidences of organ failure, need for necrosectomy, and in-hospital mortality. They further opined that the use of a proactive drainage protocol early, before the development of severe sepsis, appeared to be effective. This treatment protocol seems labor intensive, but may be beneficial.

In summary, for walled-off pancreatic necrosis antibiotics should be reserved for patients with evidence of systemic inflammatory response and elevated biomarkers of sepsis. Although the timing of intervention is controversial, there seems to be a consensus that planned percutaneous drainage of the WON be done to avoid open surgical intervention. This is usually followed by percutaneous minimally invasive necrosectomy or endoscopic necrosectomy. I am certain that continued experience will further define the treatment paradigms for pancreatic necrosis.

E. Christopher Ellison

127 Pancreaticoduodenectomy and Total Pancreatectomy for Cancer

Douglas B. Evans, Parag P. Tolat, and Kathleen K. Christians

Pancreatic cancer (PC) is a rising public health threat and is anticipated to account for over 48,000 cancer-related deaths by 2030—a death rate which will be surpassed only by lung cancer. Significant advances in surgical technique have resulted in decreased perioperative morbidity and mortality after pancreatic resection, but this has not changed the median overall survival duration of patients with localized operable PC. One of the most revolutionary changes in the management of PC has been a greater appreciation for the early metastatic potential of PC; tumor biology which has important implications for treatment sequencing. A growing number of clinicians and scientists now support the hypothesis that the majority of patients with PC have systemic disease at the time of diagnosis, even in the absence of radiographic evidence of distant metastases. Therefore, treatment strategies have evolved to prioritize early systemic therapy for patients with localized PC. At present, the majority of patients who undergo surgical resection for localized PC receive an operation as part of a multimodality program which most often includes neoadjuvant therapy of some kind, either on- or off- of a clinical trial.

Pancreaticoduodenectomy was first formally described by Whipple, Parsons, and Mullins in 1935 in the *Annals of Surgery*. The original operation was completed in two stages. The first stage consisted of a gastroenterostomy, ligation of the common duct, and cholecystogastrostomy. Three to 4 weeks later, the descending portion of the duodenum and a portion of the pancreatic head were resected and the ducts of Wirsung and Santorini were ligated. The pancreas was not internally drained, but rather, was simply ligated. Between 1927 and 1935, 80 cases were reported and were associated with an operative mortality rate of 35%. By 1945, modifications of the two-stage procedure were numerous, and Whipple himself “condemned” the operation, advocating instead the one-stage procedure with choledochojejunostomy and implantation of the pancreatic duct into the jejunum. Waugh and Clagett

from the Mayo Clinic reported in 1946 that a pancreaticojejunostomy, choledochojejunostomy, and a retrocolic, antiperistaltic gastrojejunostomy distal to the biliary and pancreatic anastomoses were the most effective operation. Waugh and Clagett stated that the objective of an operation for the cure of malignant lesions in any location should be constant; (1) the procedure should provide a reasonable opportunity for cure, (2) the operative mortality should not outweigh the prospects for cure, and (3) the patient should be left in as normal a condition as possible. These basic principles still stand true today.

Recent advances in surgical technique, anesthesia, and critical care have resulted in pancreaticoduodenectomy now being considered a very safe operation when performed at major referral centers by experienced surgeons. If patients are selected appropriately and the operation is performed carefully, perioperative mortality should be rare and certainly less than 1% to 2%. Achieving such a low surgery-related mortality rate is a function of the level of experience of the individual surgeon as well as the institution. High-volume hospitals tend to have more surgeons specializing in specific procedures, more consistent postoperative care, better-staffed ICUs, and greater resources to deal with postoperative complications. In 2017, support has emerged, in the medical and lay press, for major pancreatic surgery to be limited to hospitals which perform 20 or more pancreatectomies per year. A reasonable level of experience with major pancreatic resection is necessary to achieve good results.

Current treatment strategies for patients with localized PC are based on knowledge of the disease’s natural history and patterns of treatment failure. Patients who receive multimodality therapy that includes pancreaticoduodenectomy for adenocarcinoma of the pancreatic head have a long-term survival rate approaching 30% and a median survival of 3 years or greater based on biomarker profile and pathology results. While vastly improved over the past decade, this relatively modest median survival mandates that treatment-related morbidity be low and treatment-related mortality be rare. Accurate preoperative imaging and proper surgical technique can minimize local recurrence. Routine use of multimodality therapy (systemic therapy and chemoradiation) maximizes survival duration by treating the microscopic metastatic disease present in most patients at the time of surgery. Operations resulting in grossly positive margins (R2 resections) offer no survival benefit over chemotherapy and radiation alone. Therefore, pancreaticoduodenectomy

should only be performed when there is a reasonable expectation that all gross disease can be removed. In addition, the development of endoscopic stents has allowed most patients with locally advanced, unresectable disease to avoid laparotomy for biliary or gastric decompression. This chapter focuses on the proper use of preoperative diagnostic studies and the technical maneuvers involved in the performance of pancreaticoduodenectomy and total pancreatectomy. Investigational techniques for early diagnosis and details of multimodality therapy are beyond the scope of this chapter but have been reviewed in recent publications listed in suggested readings.

PRETREATMENT DIAGNOSTIC EVALUATION

Advanced imaging technology has improved preoperative clinical staging so that "exploratory surgery" to determine resectability for known or suspected pancreatic or periampullary cancer is not necessary and should not be performed in 2017.

Preoperative evaluation should include a detailed history and physical examination (including functional status), chest imaging, laboratory studies including tumor markers (CA 19-9 and CEA at present, and an expanded list of biomarkers will be available soon), contrast-enhanced pancreas-protocol computed tomography (CT) of the abdomen and further evaluation of comorbid conditions as indicated. CT allows assessment of the tumor's relationship to the superior mesenteric artery (SMA), the superior mesenteric vein (SMV) and SMV-portal vein confluence (SMV-PV), the celiac artery (CA), and hepatic artery (HA). CT also defines any arterial or venous aberrations (replaced left or right HA, inferior mesenteric vein [IMV] draining directly into the SMV, jejunal branch of the SMV draining anterior to the SMA, etc.) and highlights potential lymph node or extrapancreatic metastases. Clinicians can then place the patient into one of four categories based on appropriately performed CT imaging: (1) resectable, (2) borderline resectable, (3) locally advanced (now to include type A and type B), and (4) metastatic. These categories help guide multidisciplinary management as will be discussed later in this chapter.

The aim of a pancreas-protocol CT is to delineate/detect the primary pancreatic tumor, to define tumor-vascular relationships (e.g., abutment or encasement), and to detect metastatic disease (e.g., locoregional lymph nodes, liver, peritoneum, and lung bases). This is accomplished by

advanced imaging with multidetector CT (MDCT). MDCT has rapidly evolved over the last several years and has become commonplace in most radiology departments. The advantages of MDCT are that it allows for improved spatial resolution (three-dimensional submillimeter isotropic voxel resolution) and rapid image acquisition to optimally evaluate the pancreas and peripancreatic structures. To achieve high spatial resolution, MDCT has been designed with detector elements with projected resolution of 0.4 to 0.7 mm at isocenter and submillimeter detector rows of 0.5 to 0.75 mm. MDCT systems can be configured at 16-channel (or slices), 64-channel, 128-channel, 256-channel or variant configurations by the manufacturer. The advantage of larger detector row systems (64-channel or greater) is rapid image acquisition in the z or longitudinal (cranio-caudal) axis.

Intravenous contrast medium is required for pancreas-protocol CT. Optimal contrast enhancement depends upon appropriately linking the iodine delivery system with image acquisition at defined circulation phases/times. Contrast delivery should be on the order of 4 to 6 mL/sec (350 to 370 mg of iodine/mL), preferably via an 18- to 20-gauge intravenous catheter placed in an antecubital vein and delivered via a programmed power injector. Individual patient circulation times vary considerably and it is critical that the contrast delivery be tailored to each individual patient. This can be done either with a preliminary mini test-bolus or bolus-tracking software. For pancreatic imaging, the stomach and duodenum are distended with 800 mL of water (negative enteric contrast) administered 15 to 30 minutes prior to the study and an additional 200 mL of water immediately prior to the scan.

The “pancreatic phase” (or late arterial phase) is the phase of optimum pancreatic parenchymal enhancement and is a capillary phase acquisition occurring 15 seconds after abdominal aortic arrival of the contrast medium following the peripheral intravenous bolus injection. Antecubital vein to abdominal aortic circulation time can vary between 12 and 30 seconds in individual patients, thus explaining the critical role of circulation timing in providing consistent reproducible pancreatic contrast enhancement. The pancreatic phase also corresponds in timing to the initial opacification of the SMV and PV which predictably occurs 10 to 15 seconds after aortic arrival of contrast material in the SMA. Thus, while this phase provides optimum delineation of the pancreas and peripancreatic arteries (Fig. 127.1), the opacification of the splenic vein, SMV, and PV is not yet at

peak.

A second phase, commonly referred as the “portal-venous phase” (or hepatic phase) occurs 45 seconds after the pancreatic phase (Fig. 127.2). In this phase, the spleen becomes uniformly homogeneous (previously heterogeneous in the pancreatic phase) and the hepatic vein becomes uniformly enhanced/homogeneous (previously unenhanced in the pancreatic phase). In addition, the liver parenchyma becomes more enhanced than the pancreas (previously less enhanced than the pancreas in the pancreatic phase) due to contrast material inflow from the portal vein into the hepatic sinusoids. The two phases as defined, “pancreatic” (or late arterial) and “portal-venous” (or hepatic) phases, have different roles in the evaluation of pancreatic pathology.

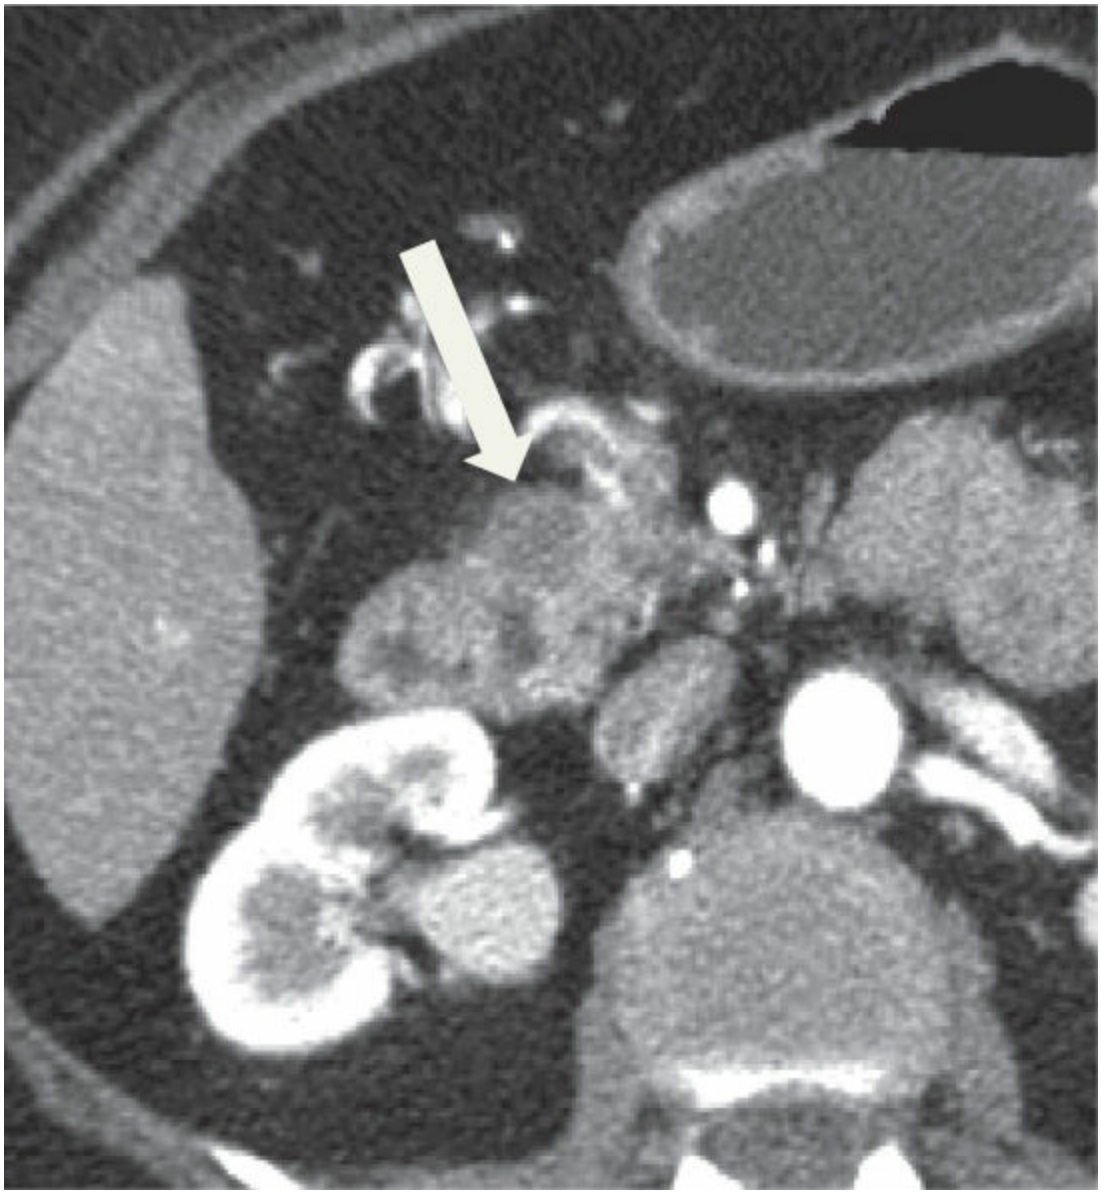

Figure 127.1. Axial CT image in the late arterial phase of a resectable adenocarcinoma of the pancreatic head at the pancreaticoduodenal groove (*arrow*). Note the tumor is distant from the SMA and SMV with no evidence of abutment.

The pancreatic phase provides maximum contrast differentiation between tumors and pancreatic parenchyma. Relatively hypovascular, hypoattenuating tumors (most commonly pancreatic adenocarcinoma) or hypervascular, hyperattenuating tumors (most commonly neuroendocrine tumors) against the normal background pancreatic parenchyma, are best seen in the pancreatic phase. In addition, the pancreatic duct and intrapancreatic common duct are best defined in the pancreatic phase. Finally, arterial anatomic variants (aberrant or replaced right HA and left HA) and critical tumor-arterial relationships (e.g., abutment or encasement with the celiac, HA, splenic artery, and SMA) are best delineated in the pancreatic phase.

The portal-venous phase best delineates the portal and mesenteric venous systems allowing delineation of venous anatomy/variants (e.g., IMV draining directly into the SMV or the jejunal branch of the SMV draining anterior to SMA) and critical tumor-venous relationships (e.g., abutment or encasement of the PV, splenic vein, SMV-PV, and/or SMV and its proximal tributaries including gastroepiploic, middle colic and jejunal veins). Peripancreatic lymphadenopathy and hepatic metastases are generally best defined in the portal-venous (or hepatic) phase. However, the liver is also completely imaged in the pancreatic phase and metastases from pancreatic adenocarcinoma may be recognized as ring enhancing lesions that become uniformly hypoattenuating in the hepatic phase.

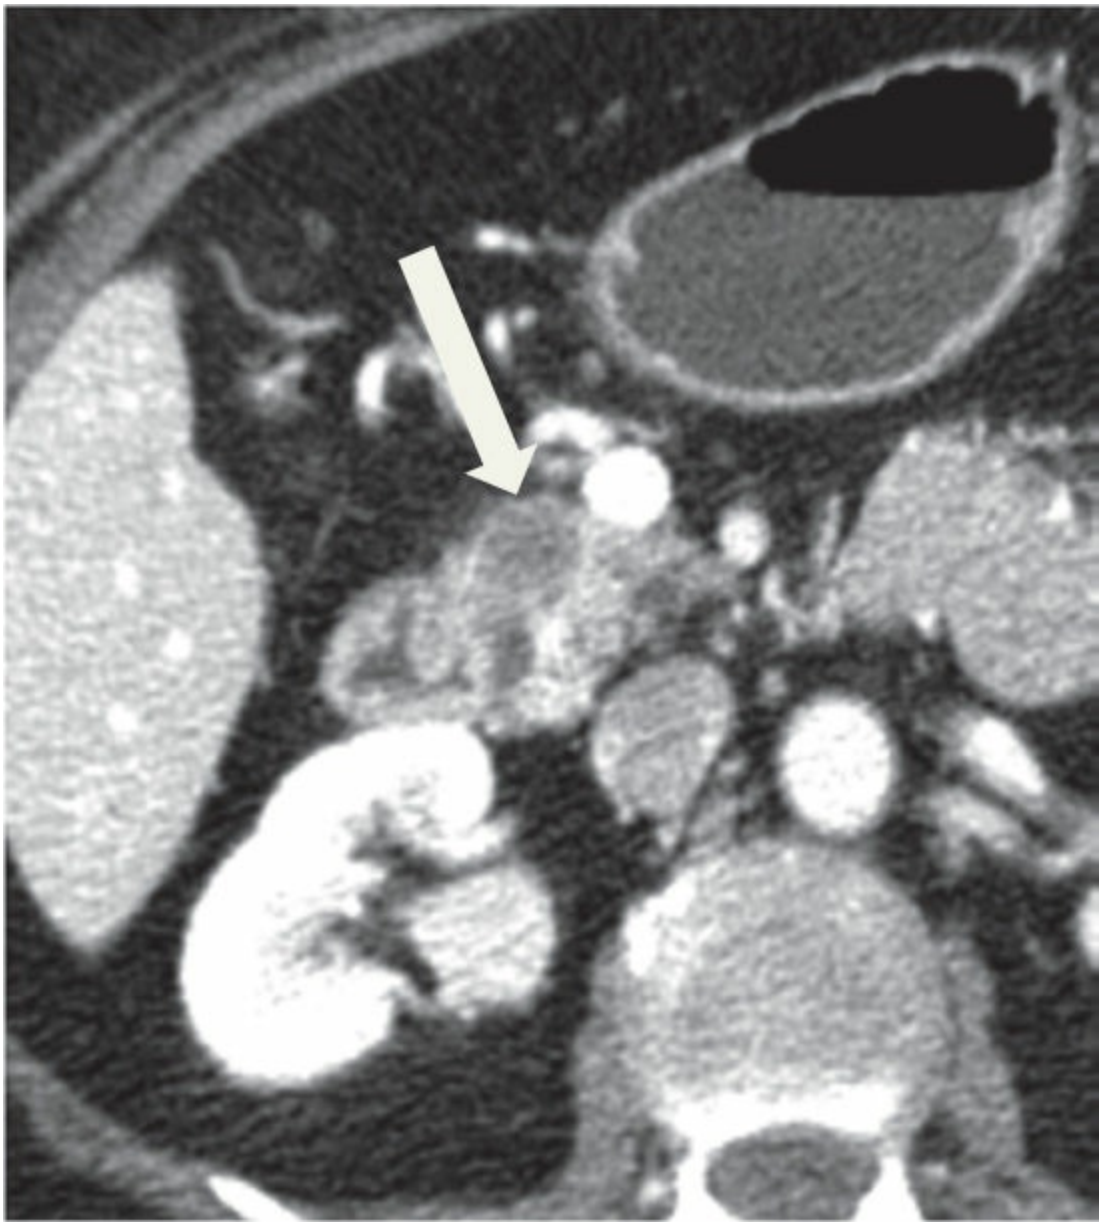

Figure 127.2. Axial CT image in the portal-venous phase of a resectable adenocarcinoma of the pancreatic head at the pancreaticoduodenal groove (*arrow*). Note the tumor is separate from the SMA and SMV with no evidence of abutment.

Our current algorithm for the diagnosis and treatment of patients with presumed or biopsy-proven adenocarcinoma of the pancreatic head or periampullary region is illustrated in Figure 127.3. CT imaging should always be performed prior to any interventional (endoscopic) procedures to avoid procedure-related pancreatitis which can make accurate imaging impossible. Patients with a visible mass on pancreas-protocol CT should then undergo endoscopic ultrasound-guided fine-needle aspiration biopsy (EUS-FNA) for tissue diagnosis. Cytopathologists should, whenever

possible, be present in the endoscopy area at the time of the procedure to provide immediate assessment of the adequacy of the biopsy specimen. Their presence at the time of EUS-FNA has considerably improved the diagnostic yield of this procedure to well over 90%. Patients who are jaundiced will then undergo ERCP with placement of an endobiliary stent (preferably as a combined procedure with EUS). Those patients with a low-density mass in the pancreatic head on CT imaging and a positive tissue diagnosis are eligible for neoadjuvant therapy (hopefully as part of a clinical trial). In those patients with tissue diagnosis of cancer, we prefer a metal stent (vs. plastic) to avoid stent occlusion during neoadjuvant therapy.

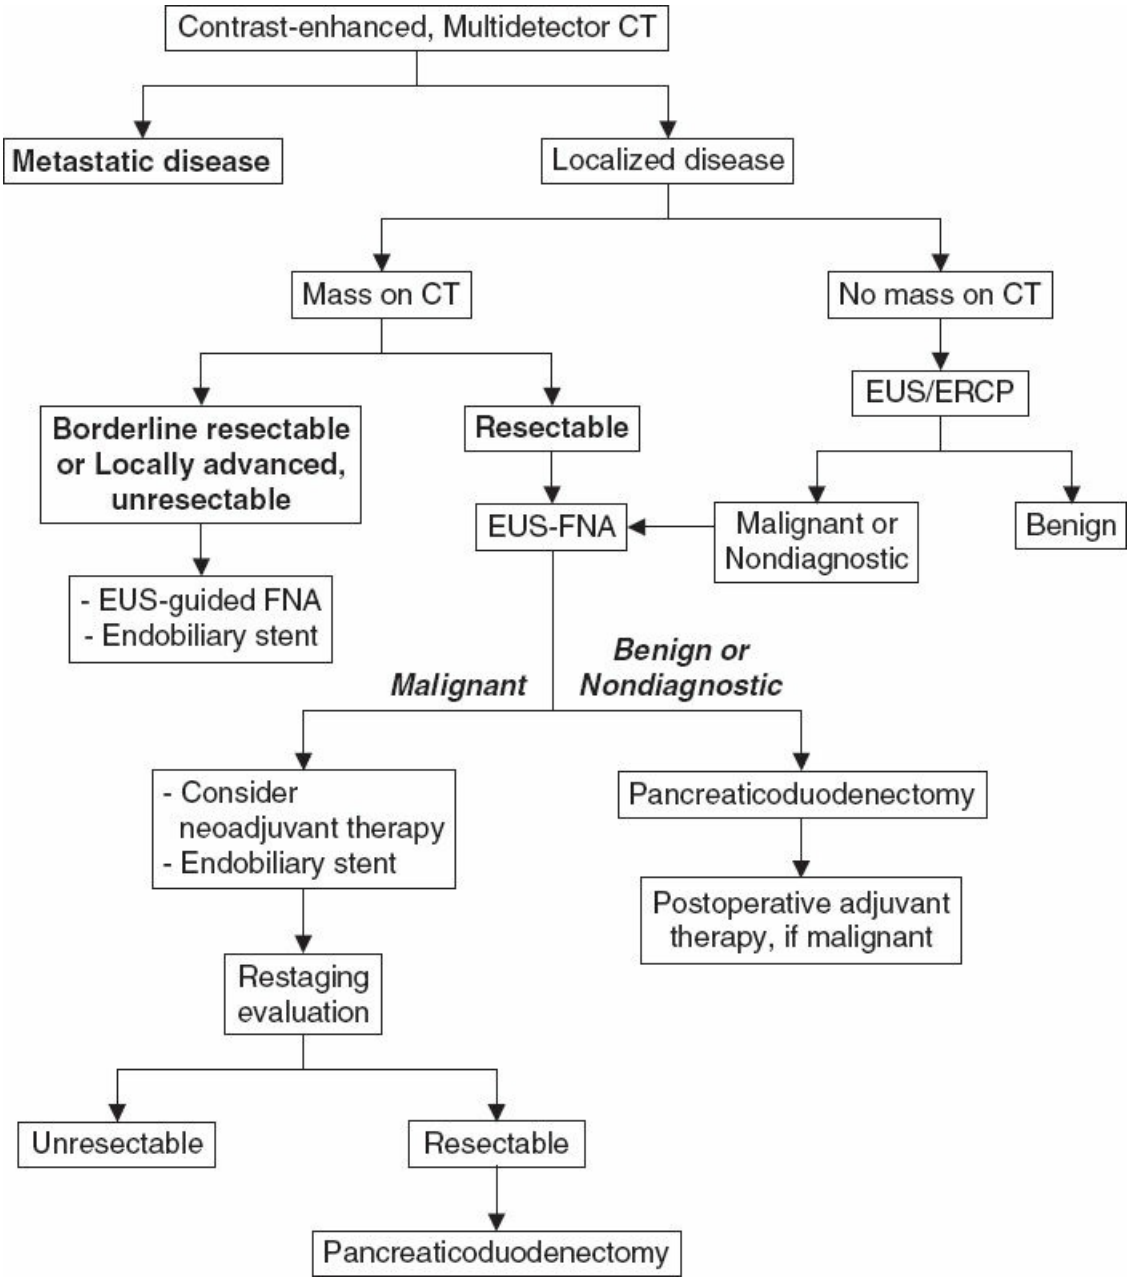

Figure 127.3. Management algorithm for patients with suspected or biopsy-proven adenocarcinoma of the pancreatic head or periampullary region. Patients without a histologic or cytologic diagnosis of adenocarcinoma who have a low-attenuation, resectable mass in the pancreatic head on MDCT undergo endoscopic ultrasonography (EUS)-guided fine-needle aspiration (FNA) biopsy. This management philosophy is based on the ongoing use of protocol-based neoadjuvant therapy at our institution. In the absence of a mass on CT, diagnostic EUS has become the appropriate next step. When there is no obvious mass to biopsy, or if pretreatment biopsies are nondiagnostic, patients who have clinical and radiologic findings suggestive of a malignant bile duct stricture or periampullary neoplasm undergo pancreaticoduodenectomy. In 2017, it is unusual to consider pancreaticoduodenectomy for a diagnostic dilemma in the absence of a tissue diagnosis of cancer. Endoscopic retrograde cholangiopancreatography (ERCP) is performed in patients with biliary obstruction as both a diagnostic study (when the etiology of the biliary obstruction is not apparent), or as a therapeutic modality to place an endobiliary stent when surgery is to be delayed (for the delivery of preoperative therapy).

Patients with extrahepatic biliary obstruction without a CT-defined mass in the pancreas also undergo EGD/EUS. Endoscopic evaluation may discover an ampullary tumor or related pathology, and EUS may define a mass in the pancreas or distal bile duct not seen on CT. If the etiology of biliary obstruction remains unclear, ERCP (or magnetic resonance cholangiopancreatography [MRCP]) is usually necessary. At the time of ERCP, a malignant obstruction of the intrapancreatic portion of the common bile duct (CBD) is characterized by an abrupt cutoff, or irregular stenosis of the CBD. This is in contrast to the long, smooth tapering stricture often seen in chronic pancreatitis or a filling defect or meniscus found in choledocholithiasis. In a patient who presents with extrahepatic biliary obstruction, a malignant-appearing stricture of the intrapancreatic portion of the CBD, and no history of recurrent pancreatitis or alcohol abuse, the absence of a mass on CT or EUS images does not exclude carcinoma of the pancreas or bile duct. Instead, the results of EUS, with or without FNA, should be considered within the clinical context, as a complement to CT and ERCP findings. If a tissue diagnosis is not obtained, and the biliary stricture is malignant in appearance, pancreaticoduodenectomy is the next logical intervention assuming the

patient is of suitable operative risk. However, in 2017 this is an uncommon scenario.

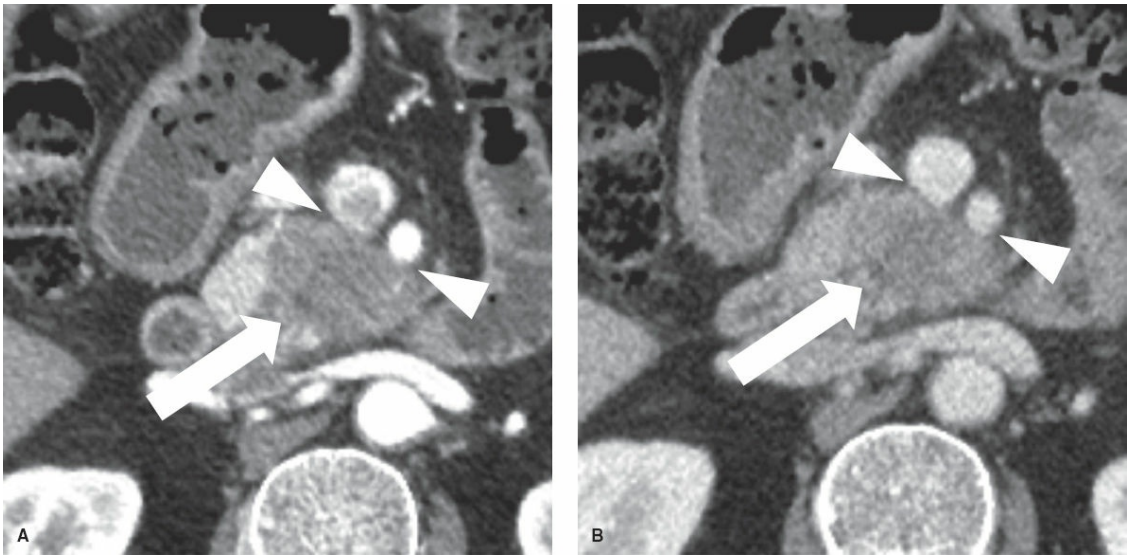

Figure 127.4. Axial late arterial (figure A) and portal venous (figure B) CT images of a borderline resectable adenocarcinoma of the pancreatic head/uncinate process (*arrow*) with tumor abutment (*arrowheads*) of the SMA and SMV. Note the low-attenuation soft-tissue that abuts the SMA and SMV for 180 degrees or less and obliterates the expected normal fat plane.

For patients with a pancreatic head mass, CT imaging is used to define the extent of disease. Classifications include resectable, borderline resectable, locally advanced or metastatic. Usually patients characterized as resectable or borderline resectable are considered eligible for pancreaticoduodenectomy.

CT criteria for a resectable tumor include: (1) the absence of extrapancreatic metastatic disease; (2) absence of, or minimal, abutment/distortion of the SMV-PV confluence; and, (3) no direct tumor extension to the HA, celiac axis, or SMA, to include a clear soft tissue plane around these vessels. Many experts are taking a more conservative view of venous involvement and define resectable tumors as those with no radiographic evidence of SMV and PV abutment, distortion, tumor thrombus, or venous encasement. The extent of SMV-PV abutment/encasement allowed to still be considered a resectable tumor remains an area of controversy but is of limited importance for those clinicians who prefer a neoadjuvant treatment approach to all patients with biopsy-proven localized PC.

Borderline resectable patients are described to encompass three types: Type A patients have tumor-artery abutment of ≤180 degrees of the circumference of the SMA or celiac axis (Fig. 127.4), tumor abutment or encasement (>180 degrees) of a short segment of the HA (usually at the origin of the gastroduodenal artery [GDA]), or short segment occlusion of the SMV, PV, or SMV-PV confluence with a suitable PV above and SMV below for reconstruction. Type B patients have CT findings suspicious for, but not diagnostic of, metastatic disease—most commonly indeterminate lesions in the liver. Type C patients are borderline resectable due to a marginal performance status as well as those with severe pre-existing comorbidities requiring protracted evaluation that precludes immediate operation. This category does not include those patients with no potential for eventual operation due to pre-existing medical comorbidities which cannot be significantly modified. Colon and/or mesocolon invasion is not included in the definition of borderline resectable cancer, both because it is not quantifiable, and because removal of the mesocolon or colon is unrelated to the risk for a margin-positive resection.

Patients with borderline resectable tumors as defined above should not be taken directly to surgery. The rationale for delivering neoadjuvant therapy to patients with borderline resectable tumors is based on: (1) the early treatment of micrometastatic disease which exists in the majority of patients—systemic therapy is provided for a systemic disease; (2) providing a time interval to gauge the aggressiveness of the cancer in order to select patients for surgery who have stable or responding disease. Those with disease stability or treatment response have the greatest likelihood of achieving clinical benefit from surgery; and (3) the potential for tumor downstaging (tumor destruction, particularly at the periphery) to maximize the potential for an R0/R1 resection.

Locally advanced tumors are defined as those with encasement (>180 degrees) of adjacent arteries (Fig. 127.5) or an occluded SMV-PV with no technical option for resection and reconstruction. Locally advanced tumors are considered unresectable in the absence of surgical excision of the celiac or superior mesenteric arteries—arteries which traditionally would not be removed at the time of pancreatectomy for pancreatic adenocarcinoma. With regard to the CA, increasing experience has demonstrated the safety of celiac resection in carefully selected patients with tumors of the pancreatic body which have responded to induction therapy. However, the SMA is even more complicated and we are not yet

at a point, with this disease, where we are resecting and reconstructing the SMA. The unresolved question is what degree of SMA abutment (<180 degrees) or encasement (>180 degrees) should be approached surgically. Because the visceral arteries have a perineural sheath which envelopes them, there is often a plane of dissection between the adventitia of the artery and the neural sheath which allows for sharp dissection of the tumor off of the artery. Because complete 360-encasement would require that one cuts through tumor to separate the SMA from the tumor, SMA encasement of this magnitude is considered nonoperable at our institution. Our threshold for considering surgery following induction therapy, based on the degree of SMA encasement, is evolving and our current thoughts on how to objectively classify the locally advanced patient are described in Table 127.1.

TABLE 127.1 Classification of Locally Advanced Pancreatic Adenocarcinoma Into Type A and B and the Comparison to the Definitions Used for Resectable and Borderline Resectable Disease

Vascular Structures Which Determine the Stage of Disease for Localized Pancreatic Cancer		Resectable	Borderline Resectable	Locally Advanced	
				Type A	Type B
Tumor-Artery Anatomy	**SMA** (usually pertains to a tumor of the head or uncinate process)	No radiographic evidence of abutment or encasement	≤180 degrees (abutment)	>180 degrees (encasement) but ≤270 degrees	>270 degrees encasement
	Celiac artery (usually pertains to a tumor of the pancreatic body)	No radiographic evidence of abutment or encasement	≤180 degrees (abutment)	>180 degrees (encasement) but does not extend to the aorta and amenable to celiac resection (with or without reconstruction)	>180 degrees and abutment/encasement of the aorta
	Hepatic Artery (HA) (usually pertains to a tumor of the pancreatic neck/head)	No radiographic evidence of abutment or encasement	Short segment abutment/encasement without extension to celiac artery or HA bifurcation	>180 degrees encasement with extension to celiac artery and amenable to vascular reconstruction	>180 degrees encasement with extension beyond bifurcation of proper HA into right and left hepatic arteries
Tumor-Vein Anatomy	**SMV-PV**	≤50% narrowing of SMV, PV, SMV-PV	>50% narrowing of SMV, PV, SMV-PV **with** a distal and proximal target for reconstruction	Occlusion **without** obvious option for reconstruction.	
Traditionally Considered for Resection After Neoadjuvant Therapy		Yes	Yes	No	No

SMA, superior mesenteric artery; SMV, superior mesenteric vein; PV, portal vein; SMV-PV, superior mesenteric-portal vein
Modified from Evans DB, George B, Tsai S. Non-metastatic pancreatic cancer: resectable, borderline resectable, and locally advanced-definitions of increasing importance for the optimal delivery of multimodality therapy. *Ann Surg Oncol* 2015;22(11):3409–13.

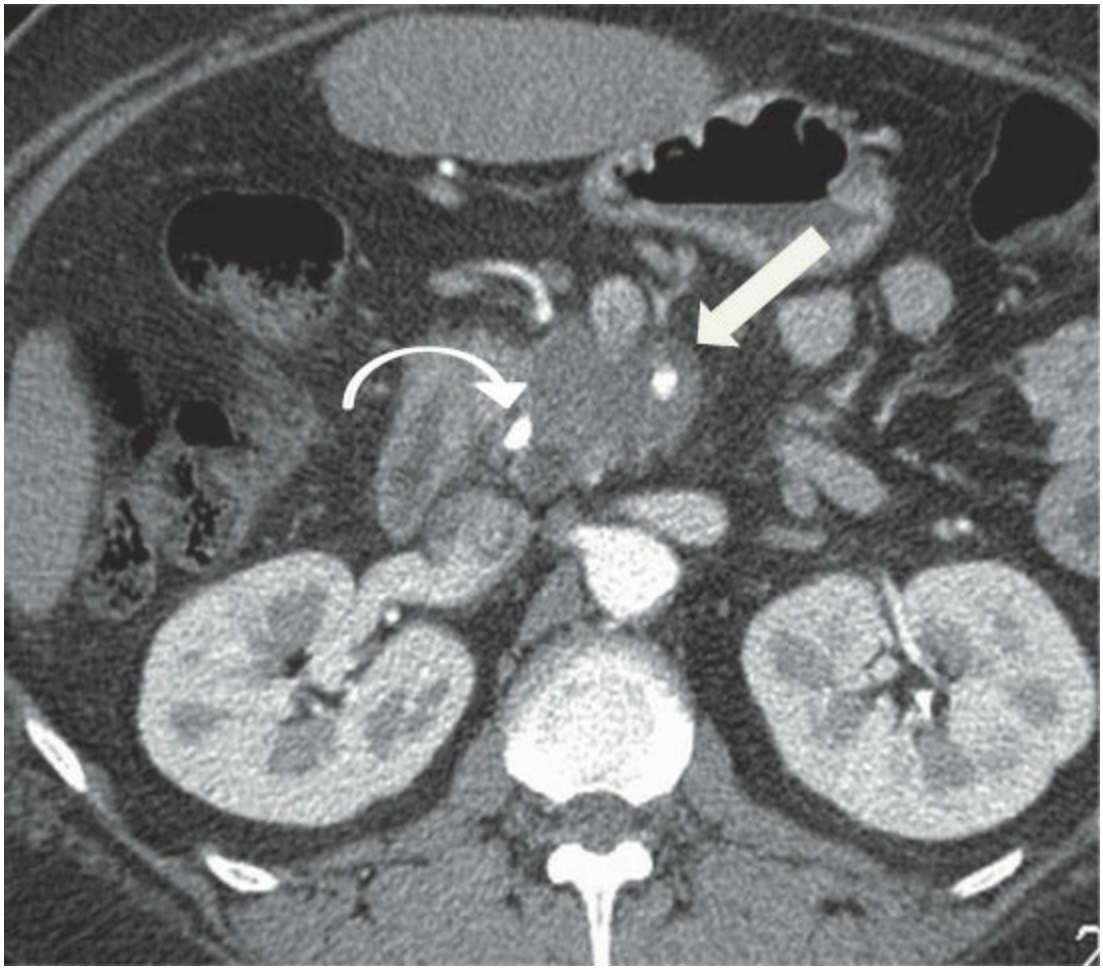

Figure 127.5. Axial CT image in the late arterial phase of a locally advanced adenocarcinoma of the uncinate process of the pancreas with tumor encasement of the SMA (*arrow*). Note the low-attenuation soft tissue which encases the SMA for 360 degrees of the vessel. A plastic endobiliary stent is in the bile duct (*curved arrow*).

Laparoscopy has been used in patients with radiographic evidence of localized PC to detect extrapancreatic tumor not seen on CT imaging, thereby allowing laparotomy to be limited to patients with localized disease. Laparoscopy prior to laparotomy (under a single anesthesia induction) is routinely used by the authors in patients with biopsy-proven or suspected potentially resectable PC in whom a decision has been made to proceed with pancreaticoduodenectomy. Data are not available to support the cost-effectiveness of laparoscopy's routine use as a staging procedure under a separate anesthesia induction prior to treatment planning. In addition, laparoscopy should not be a substitute for inadequate CT imaging.

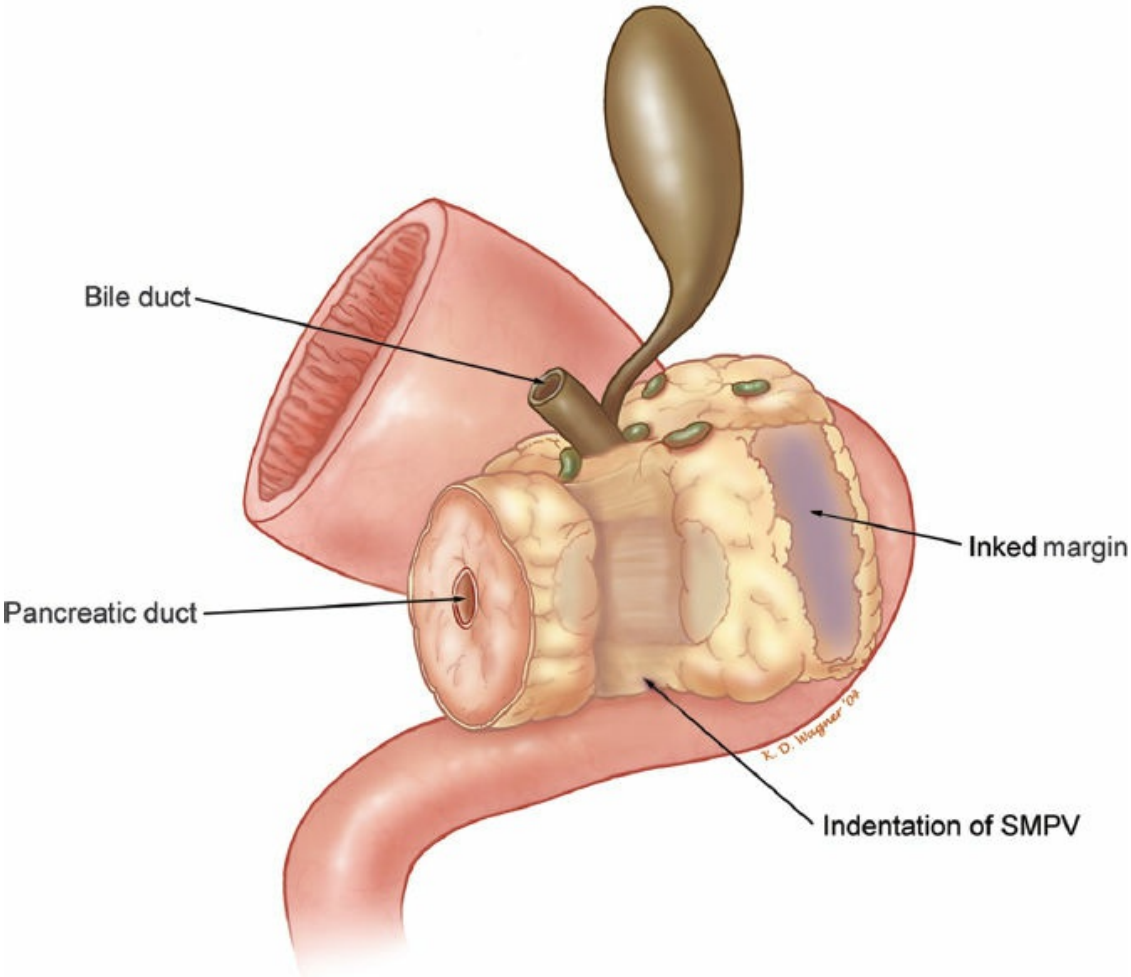

Figure 127.6. Illustration of a standard pancreaticoduodenectomy specimen as it appears when sent to the pathology suite. The SMA margin (also termed retroperitoneal margin, mesenteric margin, or uncinate margin) is the tissue adjacent to the superior mesenteric artery and should be inked for evaluation of margin status. Complete permanent-section analysis of the pancreaticoduodenectomy specimen requires that it be oriented to enable the pathologist to accurately assess the SMA margin to determine the adequacy of resection (R status). SMPV, superior mesenteric-portal vein.

The SMA margin of resection is the soft tissue margin adjacent to the proximal 3 to 4 cm of the SMA (Fig. 127.6). This margin has also been referred to as the retroperitoneal margin, uncinate margin or the mesenteric margin of resection. The surgical technique described herein emphasizes the direct identification of the SMA and removal of all perivascular and lymphatic tissue to the right of this vessel. This more aggressive retroperitoneal/mesenteric dissection combined with the other components of multimodality therapy improves local disease control, alters patterns of

recurrence, and represents a logical strategy to maximize length and quality of patient survival.

PANCREATICODUODENECTOMY

Pancreaticoduodenectomy involves removal of the pancreatic head, duodenum, gallbladder, and bile duct with or without removal of the gastric antrum. It represents the standard surgical procedure for neoplasms of the pancreatic head and periampullary region. While there is a growing body of literature on the use of laparoscopic and robotic pancreatectomy, this chapter will focus on the principles of open surgery. The criticisms of minimally invasive pancreaticoduodenectomy have included the morbidity/mortality associated with the learning curve (for each individual surgeon) and the marked increase in postpancreatectomy arterial hemorrhage from the GDA stump, the common hepatic artery (CHA), and the SMA. Indeed, arterial complications are of great concern even in the most experienced centers. The potential complications associated with a modest midline incision are rarely life threatening and therefore, the future of minimally invasive pancreaticoduodenectomy remains controversial at the time of this writing of *Mastery*.

At the time of surgical exploration for pancreatic head cancer, a Kocher maneuver was commonly taught to be the first step performed to allow assessment of the relationship of the tumor to the SMA by palpation. By mobilizing the pancreatic head and duodenum from their retroperitoneal attachments, the surgeon attempts to palpate a plane of normal tissue between the firm tumor and the posterior pulsation of the SMA. In reality, this step is a crude assessment subject to individual surgeon bias. The relationship of the tumor to the right lateral wall of the SMA is the most critical aspect of the pretreatment staging evaluation. This tumor-vessel relationship must be accurately evaluated prior to taking the patient to the operating room (on preoperative high-quality CT imaging) and cannot be accurately assessed intraoperatively following a Kocher maneuver. In addition, for larger tumors, for those tumors containing significant peritumoral fibrosis, or for reoperative cases, palpation of the relationship of the primary tumor to the SMA after Kocher maneuver with any reasonable degree of accuracy is usually impossible.

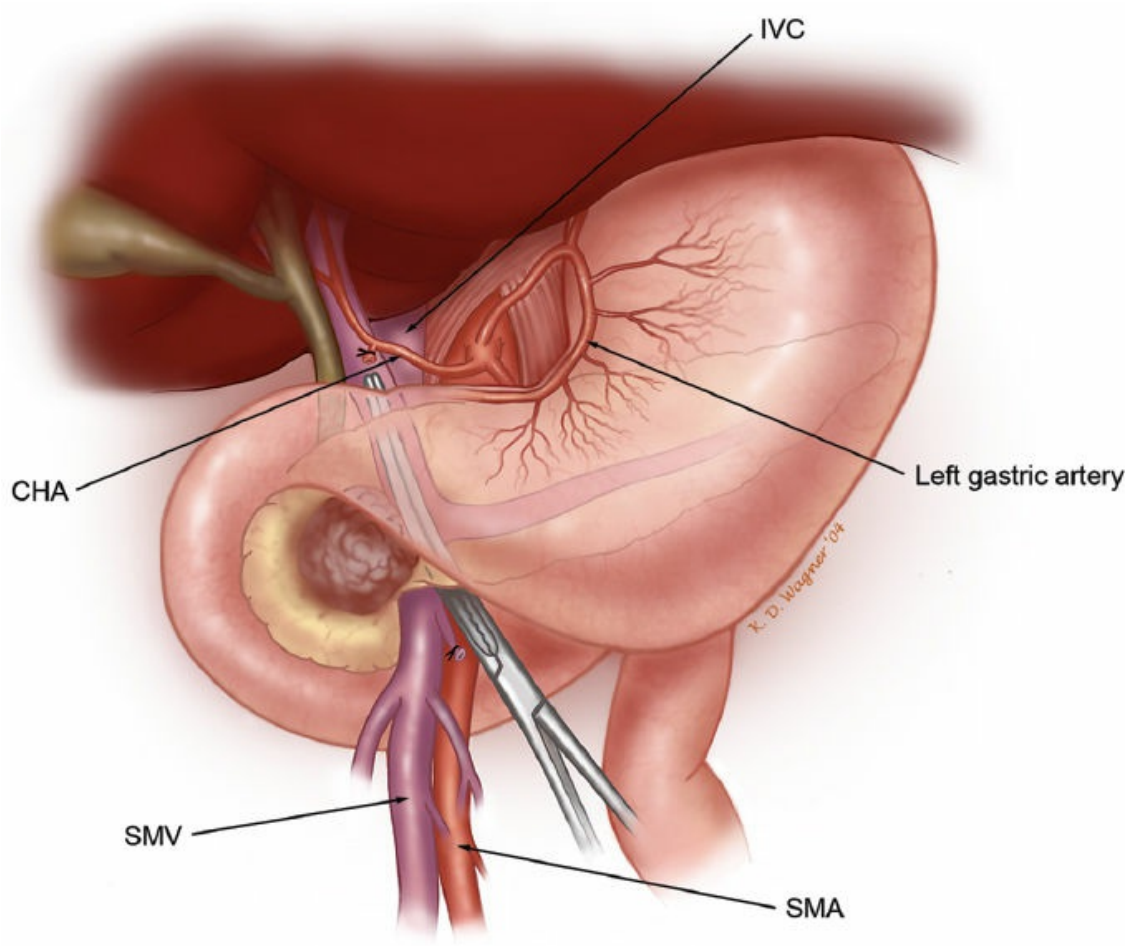

Figure 127.7. Illustration demonstrating a maneuver commonly performed early in the operation to detect tumor invasion of the superior mesenteric vein (SMV) or superior mesenteric-portal vein confluence. We do not perform this maneuver because a tumor-free plane often can be developed despite fixation of the tumor to the lateral or posterior wall of the SMV. This maneuver may incorrectly suggest that tumor adherence to the SMV does not exist, and may result in unnecessary bleeding if the SMV or portal vein is injured. CHA, common hepatic artery; SMA, superior mesenteric artery; IVC, inferior vena cava.

The second maneuver traditionally performed to assess resectability is to develop a plane of dissection between the anterior surface of the SMV-PV confluence and the posterior surface of the neck of the pancreas to exclude tumor involvement of the SMV or SMV-PV confluence (Fig. 127.7); such tumor involvement, in the opinion of most surgeons, precludes resection. However, the rationale for this maneuver early in the operation is also unclear. Tumors of the pancreatic head or uncinate process are prone to invade the lateral or posterior wall of the SMV-PV

confluence, not the anterior wall. The anterior wall is rarely involved in the absence of encasement of the celiac axis or SMA origin (as seen with locally advanced tumors of the pancreatic neck or body), and this finding should be visible on preoperative CT images. In addition, the relationship of a pancreatic head tumor to the lateral and posterior walls of the SMV-PV confluence (and the SMA) can be directly inspected only after dividing the stomach/duodenum and the pancreatic neck, by which point the surgeon has already committed the patient to resection. Therein lies the rationale for detailed preoperative imaging using high-quality, contrast-enhanced CT, with laparotomy undertaken only in patients who have operable tumors as defined on CT. Both of the above described maneuvers are founded in surgical tradition rather than surgical anatomy—they are not accurate techniques for the assessment of resectability of a primary carcinoma of the pancreatic head.

PANCREATIC RESECTION

Our recommended technique for pancreaticoduodenectomy utilizes a modest midline upper abdominal incision (after routine laparoscopic exploration confirms the absence of extrapancreatic metastatic disease). Lymph node biopsy for frozen-section analysis is uncommonly performed. Positive lymph nodes are a prognostic factor (along with poorly differentiated histology, microscopically positive resection margins, etc.) predictive of decreased survival duration. In a good-risk patient with localized, resectable PC, we do not view lymph node metastases as an absolute contraindication to pancreaticoduodenectomy when performed as part of a multimodality approach to PC. Therefore, in general, we do not perform random lymph node sampling for frozen-section analysis at the time of pancreaticoduodenectomy. However, each case should be considered individually such as in the case of a high-risk patient (due to medical comorbidities) with perhaps an unfavorable response to induction systemic therapy (high serum level of CA 19-9); suspicious adenopathy, if positive on intraoperative frozen section, may be viewed as a contraindication to proceeding with pancreaticoduodenectomy.

The surgical resection is divided into the following clearly defined steps:

1. The purpose of Step 1 is to isolate the infrapancreatic SMV and separate the colon (and its mesentery) from the duodenum and pancreatic head (Fig. 127.8). The lesser sac is entered by taking the

greater omentum off of the transverse colon, and the loose attachments of the posterior gastric wall to the anterior surface of the pancreas. The hepatic flexure of the colon is mobilized from its retroperitoneal attachments. The visceral peritoneum along the inferior border of the pancreas from a point medial to (to the patient's left of) the middle colic vessels is incised and carried out laterally (to the patient's right) and inferiorly to expose the junction of the middle colic vein and the SMV. The middle colic vein may enter directly into the anterior surface of the infrapancreatic SMV or arise as a common trunk with the gastroepiploic vein (gastrocolic trunk). If the middle colic vein and gastroepiploic vein share a common trunk, the common trunk can be preserved (and the gastroepiploic vein divided) or the entire trunk divided. Otherwise, the gastroepiploic vein is left intact and divided later in the operation following pancreatic transection. When necessary, the middle colic vein can be divided proximal to its junction with the SMV; this is often needed when operating on obese patients where a traction injury of the middle colic vein may occur if the vein is not divided. Division of the middle colic vein is especially important when dealing with large tumors or tumors extending inferiorly from the uncinate process. In fact, the base of the transverse mesocolon and the anterior leaf of the small bowel mesentery can be left attached to the tumor and resected en bloc with the pancreatic head. Such caudal or inferior tumor extension is not a contraindication to pancreaticoduodenectomy but does add complexity during this step when the infrapancreatic SMV needs to be identified.

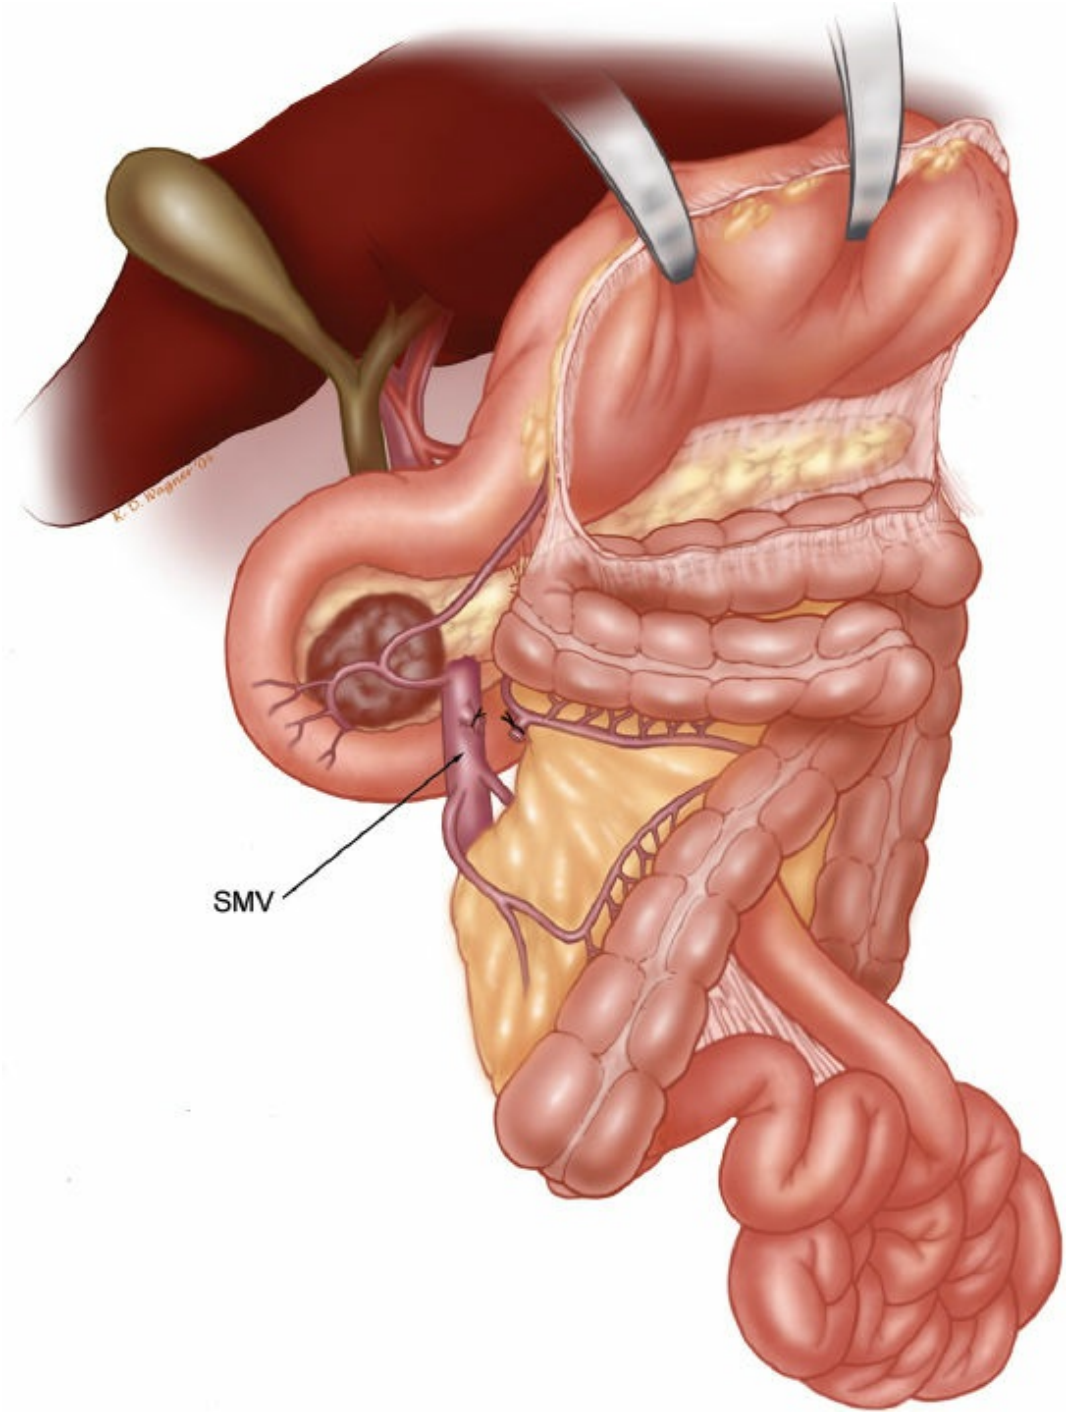

Figure 127.8. Illustration of Step 1. The lesser sac is entered, and the hepatic flexure of the colon is taken down. The inferior body of the pancreas is identified at the level of the proximal body of the gland. The visceral peritoneum and root of mesentery is incised from this point, in a lateral direction, heading toward the junction of the second and third portions of the duodenum in an effort to expose the anterior wall of the superior mesenteric vein (SMV). The SMV is exposed at the inferior border of the neck of the pancreas adjacent to the uncinate process. The middle colic vein and gastroepiploic

vein often arise from a common trunk which occasionally also involves the right colic vein. Any or all of these veins may require ligation and division to safely expose the SMV. When the need for venous resection is anticipated, the entire right colon and the root of the small bowel mesentery are mobilized in the fashion of Cattell and Braasch. This involves incision of the visceral peritoneum to the ligament of Treitz and allows anterior reflection of the colon off of the duodenum and pancreatic head. This maneuver is also helpful when operating on obese patients with thick mesentery and a deep abdomen. When dealing with a reoperative situation (previous unsuccessful attempt at resection) or with tumor extending into the root of mesentery, we may not identify the SMV early in the operation and expose this vessel after pancreatic transection by following the anterior surface of the portal vein in a caudal direction—this maneuver should only be considered by the most experienced pancreatic surgeons.

Mobilization of the retroperitoneal attachments of the small bowel and right colon mesentery is performed in patients with uncinate tumors extending into the small bowel mesentery and in some patients who require venous resection and reconstruction or when visual access to the posterior aspect of the SMA is needed due to tumor abutment in this difficult area. This maneuver was first described by Cattell and Braasch for exposure of the duodenum. The visceral peritoneum of the small bowel mesentery is incised to the ligament of Treitz, thereby mobilizing the small bowel mesentery. When complete, this maneuver allows cephalad retraction of the right colon and small bowel, exposing the third and fourth portions of the duodenum.

Occasionally, when there is extensive inflammatory change or scarring at the root of mesentery usually due to a prior attempt at resection, we may not identify the SMV early in the operation. In such cases, the SMV will be exposed during Step 6 when the pancreas is divided in a caudal direction from the level of the portal vein. Due to lack of vascular control, this can be dangerous but it is a valuable technique for the experienced surgeon who deals with more complicated pancreatic resections, especially in a reoperative setting.

2. The Kocher maneuver is begun at the transverse portion (third portion) of the duodenum by identifying the anterior aspect of the inferior vena cava. All fibrofatty and lymphatic tissue medial to right gonadal vein

and anterior to the inferior vena cava is elevated, along with the pancreatic head and duodenum (Fig. 127.9). The Kocher maneuver is continued to the left lateral edge of the aorta, with exposure of the anterior surface of the left renal vein. The right gonadal vein serves as a good landmark coursing anterior/medial to the right ureter thus helping prevent inadvertent ureteric injury. The Kocher maneuver is extended superiorly to widely open the foramen of Winslow. A complete Kocher maneuver is necessary for the subsequent dissection of the pancreatic head from the SMA (Step 6). Particularly important is the division of the leaf of visceral peritoneum that is posterior to the mesenteric vessels; incision of this portion of peritoneum, as it extends from the retroperitoneum to the right lateral aspect of the root of the small bowel mesentery, is necessary prior to performing the SMA dissection.

3. The portal dissection (Fig. 127.10) is initiated by exposing the CHA proximal and distal to the right gastric artery and the GDA. The CHA is exposed by removing the large lymph node(s) which lies directly anterior to this vessel; this cluster of lymph nodes is in continuity with the nodes extending laterally into the retroportal space and also medially, along the left gastric artery origin. When removing the lymph nodes anterior to the CHA, try to avoid entering the left gastric vein which runs transversely and enters the portal or distal splenic vein —this vein can be preserved or ligated if necessary. The right gastric artery, and subsequently the GDA are ligated and divided. The GDA often has a small proximal branch which may originate anteriorly or just along its right lateral border. It is often helpful to ligate and divide this branch separately to obtain adequate length on the proximal GDA such that it can be safely ligated and divided. If tumor extends to within a few millimeters of the GDA, proximal and distal control of the HA is obtained and the GDA is divided flush at its origin. The resulting arteriotomy can be closed with interrupted 6-0 Prolene (Ethicon, Inc., Somerville, NJ) sutures. Overly aggressive dissection at the GDA origin can result in intimal dissection of the HA; this is avoidable and usually the result of blunt dissection due to inadequate vascular control of the proximal and distal HA. Dissection of the HA should be performed with gentle, sharp dissection, especially in patients who have received prior external-beam radiation therapy and in those with extensive scar formation from prior surgery. Division of the GDA allows mobilization of the hepatic (common-proper) artery off of the underlying PV. The PV can be found within the triangle

formed by the CHA (superiorly), GDA (laterally), and the superior border of the pancreas (inferiorly); the PV is deep (posterior) and also medial to the CBD. The PV should always be exposed prior to dividing the common hepatic duct. Cholecystectomy is then performed and the common hepatic duct is transected at its junction with the cystic duct. An anomalous location of the right or left HA should come as no surprise based on careful review of the preoperative CT and careful palpation of the porta hepatis prior to division of the bile duct. A replaced or an accessory right HA arising from the proximal SMA (or occasionally directly from the aorta) may course posterolateral to the PV. Rarely, the entire CHA may arise from the SMA (type IX hepatic arterial anatomy). If the foramen of Winslow was initially obliterated due to adhesions, it should have been re-established at the time of the Kocher maneuver (Step 2). Access to the foramen of Winslow is necessary to palpate the porta hepatis and appreciate the pulsation of an anomalous HA. Rarely, the right HA arising from the proper HA courses posterior to the PV. Following transection of the bile duct, biliary fluid cultures may be sent and any indwelling endobiliary stents are removed. Intraoperative bile cultures may be used to guide therapeutic antibiotic treatment postoperatively in the event of an intra-abdominal or superficial wound infection. A gentle bulldog clamp is placed on the transected hepatic duct to prevent the contaminated bile (if a stent has been in the bile duct, the bile is no longer sterile) from gaining free access to the abdomen until the time of bile duct reconstruction.

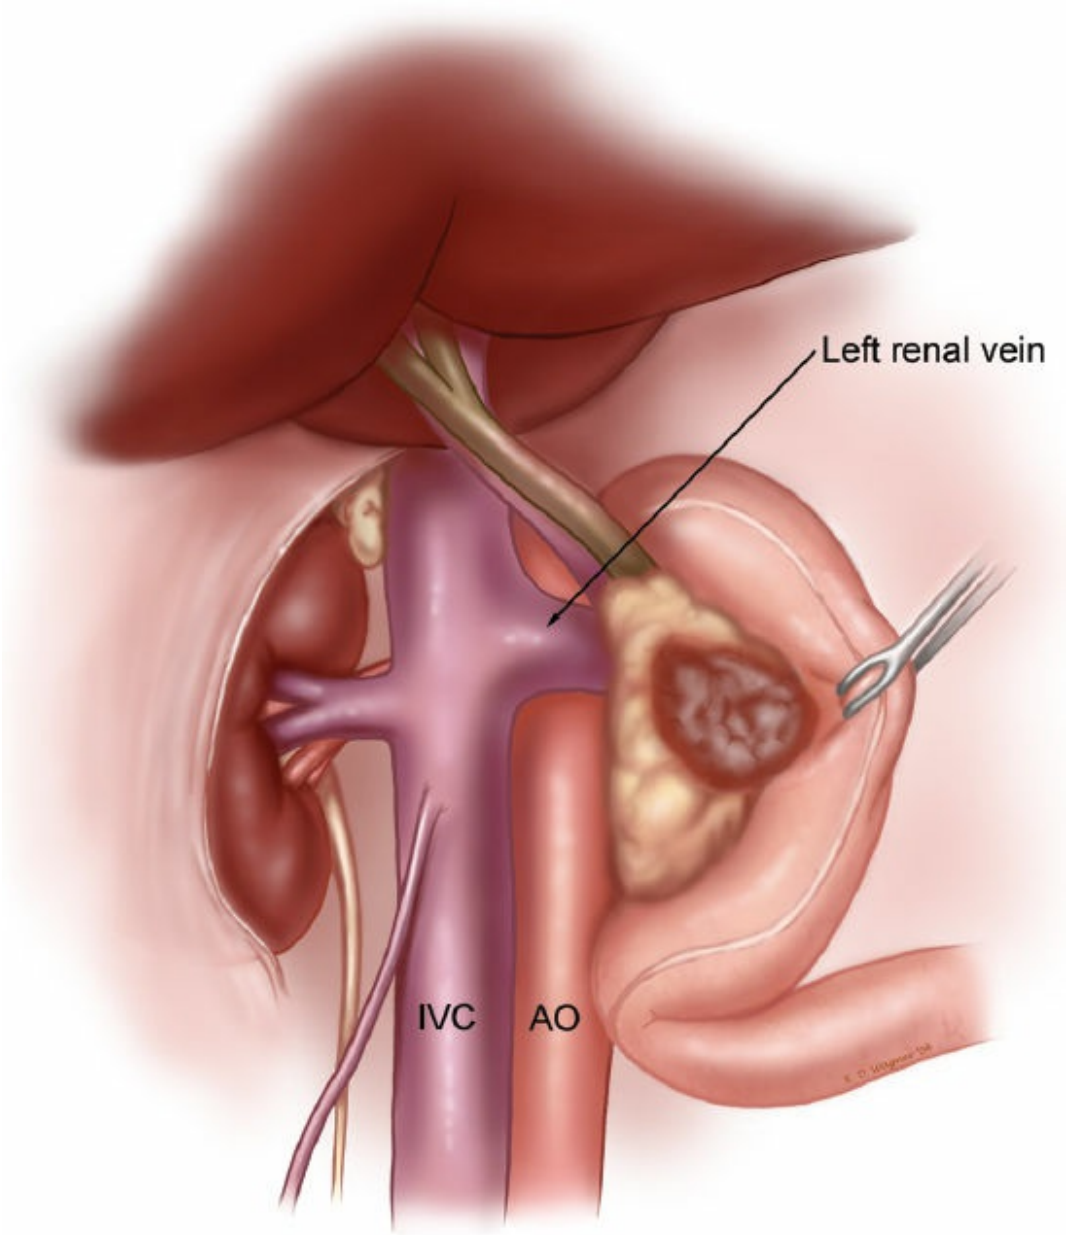

Figure 127.9. Illustration of Step 2. A Kocher maneuver has been performed by first identifying the inferior vena cava (IVC) at the level of the proximal portion of the transverse segment of the duodenum (D3). One can then mobilize the duodenum and pancreatic head off of the IVC in a cephalad direction thereby removing all soft tissue anterior to the IVC. The right gonadal vein is usually preserved, if possible, as it serves as a good landmark to help prevent inadvertent injury to the underlying ureter (which is usually posterior and slightly lateral to the gonadal vein). Note that the Kocher maneuver is continued to the left lateral border of the aorta (AO). An accessory renal artery (which is an end artery) may travel anterior to the IVC and should be seen and preserved; rarely, the main right renal artery may be anterior to the IVC.

The anterior wall of the PV is further exposed following division of the common hepatic duct and medial retraction of the CHA. The PV itself should be identified but not extensively mobilized until Step 6, at which time the stomach and pancreas have been divided. The superior pancreaticoduodenal vein is a constant venous tributary of the PV which drains the cephalad aspect of the pancreatic head and is located at the superolateral aspect of the PV. Bleeding caused by traction injury to this venous tributary may be difficult to control at this time in the operation.

4. The stomach is transected with a gastrointestinal stapler at the level of the third or fourth transverse vein on the lesser curvature and at the confluence of the gastroepiploic veins on the greater curvature (Fig. 127.11). The extent of gastric resection is probably of little importance and we often divide the stomach more distal in location thereby performing a very modest antrectomy. The terminal branches of the left gastric artery are ligated and divided along the lesser curvature of the stomach prior to gastric transection. When opening the lesser omentum, one should specifically look for an accessory or replaced left HA arising from the left gastric artery. Overly aggressive division of the filmy lesser omentum in a caudal direction can easily injure a replaced left HA. The omentum is then divided at the level of the greater curvature transection with the harmonic scalpel (Ethicon Inc., Somerville, NJ) or LigaSure device (Valleylab, Boulder, CO).

   Pylorus-preservation may be considered in patients with small periampullary neoplasms, but should not be performed in patients with bulky pancreatic head tumors, duodenal tumors involving the first or second portions of the duodenum, or lesions associated with grossly positive pyloric or peripyloric lymph nodes. To ensure adequate blood supply to the duodenojejunostomy, the anastomosis is created no more than 2 cm distal to the pylorus.

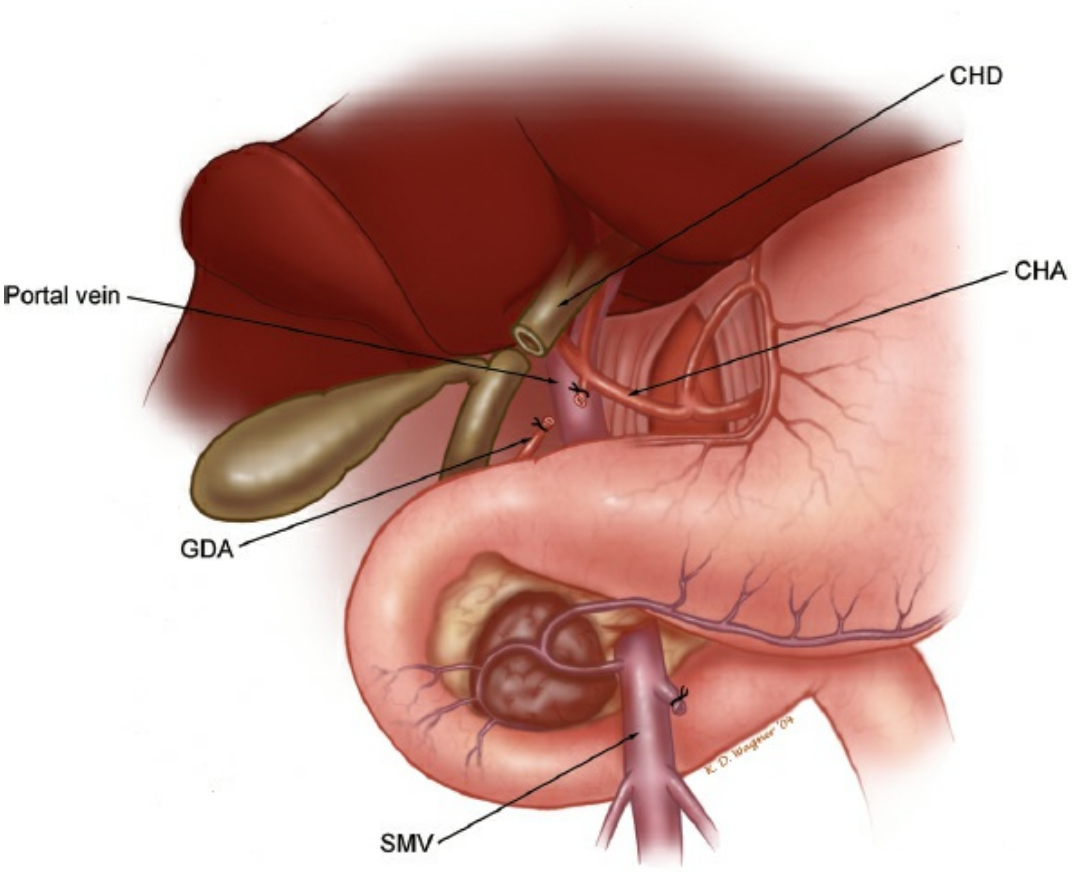

Figure 127.10. Illustration of Step 3. Dissection of the porta hepatis begins with identification of the common hepatic artery (CHA), by removal of the large lymph node which commonly sits anterior to this vessel. The CHA is then followed distally to allow identification and ligation and division of the right gastric artery (not shown) and the gastroduodenal artery (GDA). This allows the CHA-proper hepatic artery to be mobilized cephalad and medial off of the underlying anterior surface of the portal vein (PV). The PV is always identified prior to division of the common hepatic duct (CHD). Careful palpation of the porta hepatis prior to division of the bile duct should alert one to the possibility of an accessory or replaced right hepatic artery traveling posterior to the bile duct and lateral to the portal vein. The CHD is divided at the level of the cystic duct. SMV, superior mesenteric vein.

5. The loose attachments of the ligament of Treitz are taken down with care to avoid injury to the IMV. The jejunum is then transected with a linear GIA stapler approximately 7 to 10 cm distal to the ligament of Treitz, and its mesentery is sequentially ligated and divided (Fig.

127.12). This can be done with ties, the Harmonic scalpel or the LigaSure device. This dissection is continued proximally to involve the fourth and third portions of the duodenum. The duodenal mesentery is divided to the level of the aorta, allowing this devascularized segment of duodenum and jejunum to be reflected beneath the mesenteric vessels into the right upper quadrant.

6. The oncologically most important and difficult part of the operation is Step 6. After traction sutures are placed on the superior and inferior borders of the pancreas, the pancreas is transected (usually with electrocautery) at the level of the PV. If there is evidence of tumor adherence to the PV or SMV, the pancreas is divided more distally (to the patient's left) in preparation for segmental venous resection. The specimen is separated from the SMV by ligation and division of the small venous tributaries to the uncinate process and pancreatic head (Fig. 127.13). Complete removal of the uncinate process from the SMV is required for full mobilization of the SMV-PV confluence and subsequent identification of the SMA. Failure to fully mobilize the SMV-PV confluence risks injury to the SMA (because it is not adequately exposed) and often will result in a positive SMA resection margin. The more difficult it is to expose the SMA, the more important it is to do this dissection—the SMA is unlikely to be injured if the surgical team can see it. The SMA dissection should result in removal of all of the mesenteric soft tissue adjacent to (to the right of) the SMA (Fig. 127.14). In addition, exposure of the SMA is necessary for direct ligation of the inferior pancreaticoduodenal artery (IPDA) or arteries. Mass ligation of the IPDA(s) with mesenteric soft tissue is a major cause of postoperative hemorrhage as this vessel retracts from its poorly placed tie or ligature; again often a preventable complication.

   Once the pancreatic head and uncinate process are completely separated from the SMV and SMV-PV confluence, one may experience bleeding from the specimen due to venous hypertension. This bleeding indicates that the IPDAs from the SMA are still intact. One option is to leave the superior pancreaticoduodenal vein (located at the superolateral aspect of the PV) intact until the more caudal inferior IPDA is ligated. This usually does not limit the mobilization of the SMV at the level of the uncinate process and still allows exposure of the SMA.

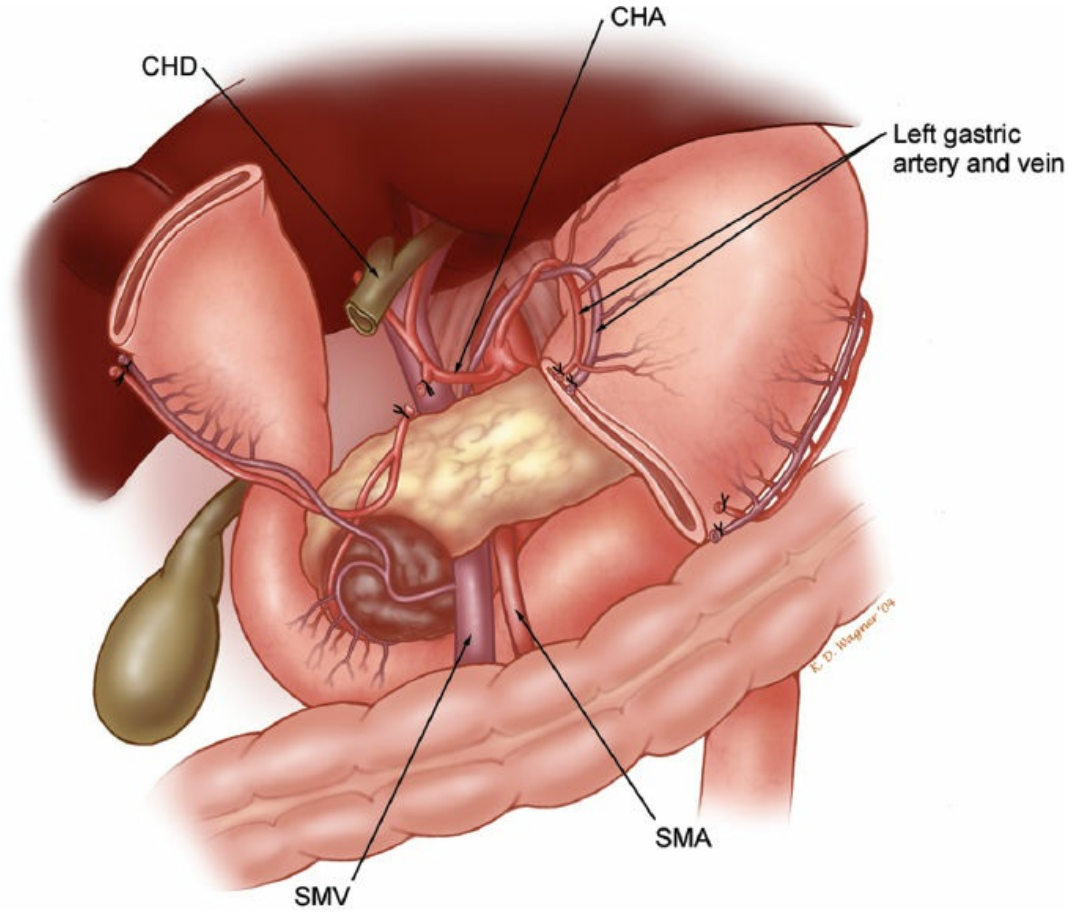

Figure 127.11. Illustration of Step 4. The antrum of the stomach is resected with the main specimen by dividing the stomach at the level of the third or fourth transverse vein on the lesser curvature. CHA, common hepatic artery; CHD, common hepatic duct; SMA, superior mesenteric artery; SMV, superior mesenteric vein.

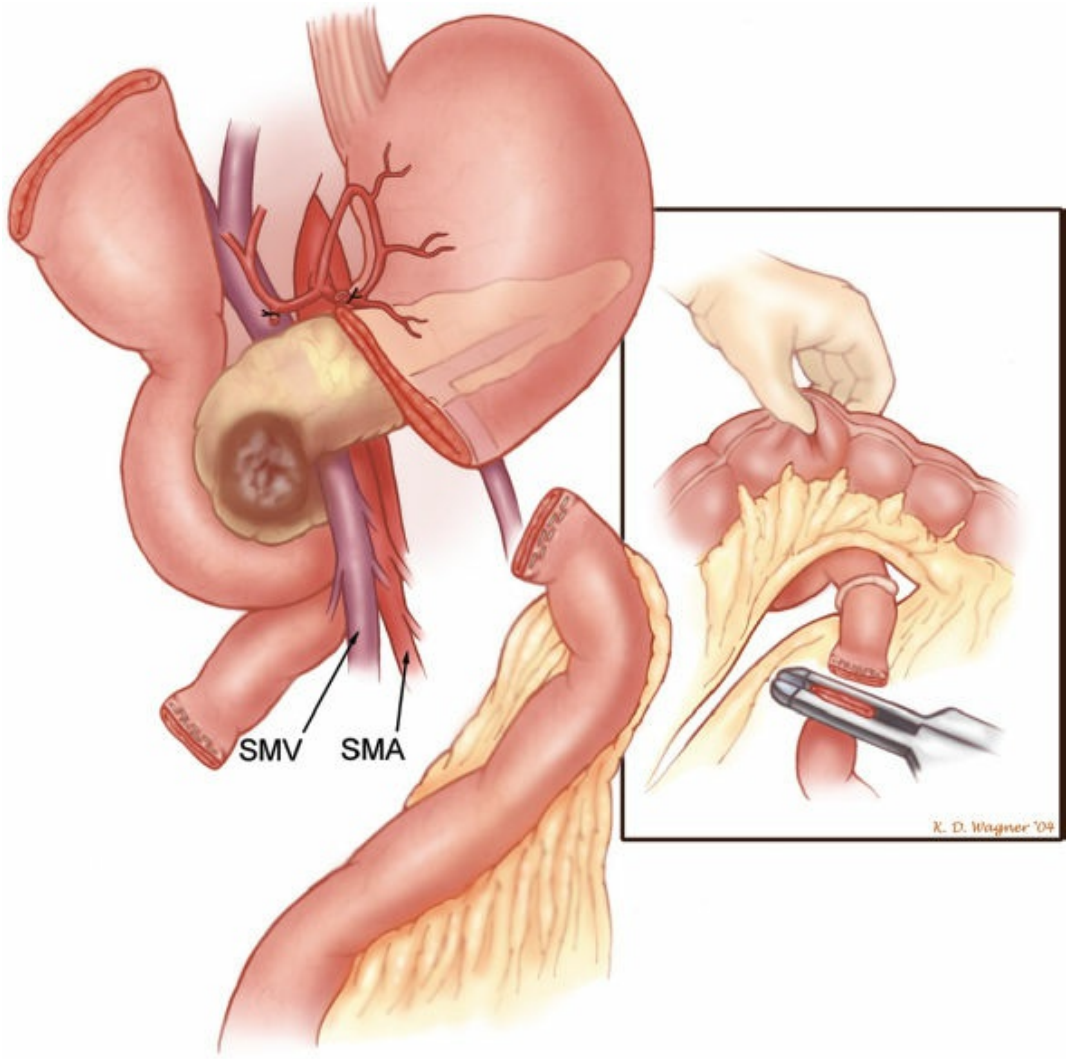

Figure 127.12. Illustration of Step 5. Transection of the jejunum is followed by ligation and division of its mesentery. The loose attachments of the ligament of Treitz are taken down, and the fourth and third portions of the duodenum are mobilized by dividing their short mesenteric vessels. The duodenum and jejunum are then reflected underneath the mesenteric vessels in preparation for the final and most important part of pancreaticoduodenectomy. SMA, superior mesenteric artery; SMV, superior mesenteric vein.

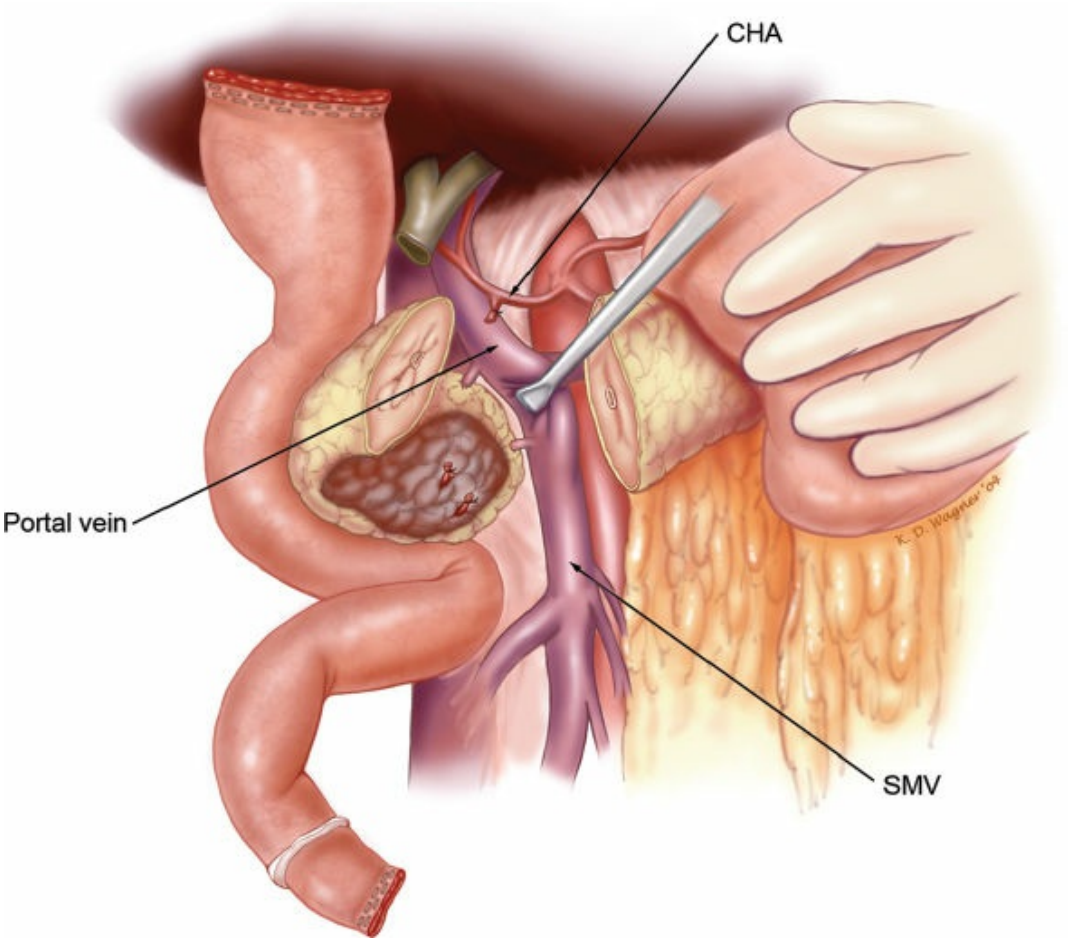

Figure 127.13. Illustration of Step 6. The pancreatic head and uncinate process are separated from the superior mesenteric-portal vein confluence. The pancreas has been transected at the level of the portal vein and the pancreatic head is reflected laterally, allowing identification of small venous tributaries from the portal vein and superior mesenteric vein (SMV). These tributaries are ligated and divided. There is one fairly constant venous tributary of the portal vein to the most cephalad pancreatic head often referred to as the superior pancreaticoduodenal vein. Some surgeons prefer to leave this venous branch intact until they have divided at least one of the more caudal inferior pancreaticoduodenal arteries (off of the superior mesenteric artery) thereby minimizing venous hypertension in the specimen which contributes to increased blood loss during this portion of the dissection. CHA, common hepatic artery.

Proper mobilization of the SMV involves identification of the jejunal branch of the SMV (also often referred to as the first jejunal branch). This branch originates from the right posterolateral aspect of the SMV (at the

level of the uncinate process), most often travels posterior to the SMA, and enters the medial (proximal) aspect of the jejunal mesentery (Fig. 127.15). Rarely, the jejunal branch may course anterior to the SMA, a situation which makes this dissection a bit easier. The jejunal branch usually gives off at least two venous tributaries to the uncinate process; these tributaries should be divided (Fig. 127.15B). If tumor involvement of the SMV (at the level of the jejunal branch) prevents dissection of the uncinate process from the SMV, the jejunal branch should be divided (in this case we expose the SMA medial to the SMV before dividing the jejunal branch). Injury to the distal SMV at this level, or a tangential laceration in its jejunal branch (as it courses posterior to the SMA), is difficult to control and probably represents the most frequent cause of iatrogenic SMA injury as one attempts to suture a venous injury prior to adequate exposure of the SMA (which is just medial in location and can be injured with a suture quite easily). Once the uncinate process is separated from the distal SMV, medial retraction of the SMV-PV confluence allows one to expose the SMA if it had not been exposed previously. As noted above, if mobilization of the distal SMV is challenging, exposure of the SMA medial to the SMV is a helpful technique and one that is under-utilized. This will also allow for medial exposure of the jejunal branch of the SMV and separation of the specimen from the SMA and the SMV at the level of the uncinate process. The specimen is then separated from the right lateral wall of the SMA, which is dissected to its origin at the aorta (Fig. 127.16). Direct exposure of the SMA avoids iatrogenic injury and ensures direct ligation of the IPDA(s). Most patients have two IPDAs that are identified and ligated at their origins from the SMA. As mentioned previously, the soft tissue adjacent to the proximal 3 to 4 cm of the SMA represents the SMA (or retroperitoneal) margin. A grossly positive SMA margin (R2 resection) should not occur if high-quality preoperative imaging is performed and accurately interpreted. A microscopically positive SMA margin (R1) can result from tumor spread along perineural sheaths and does not always result from direct tumor extension.

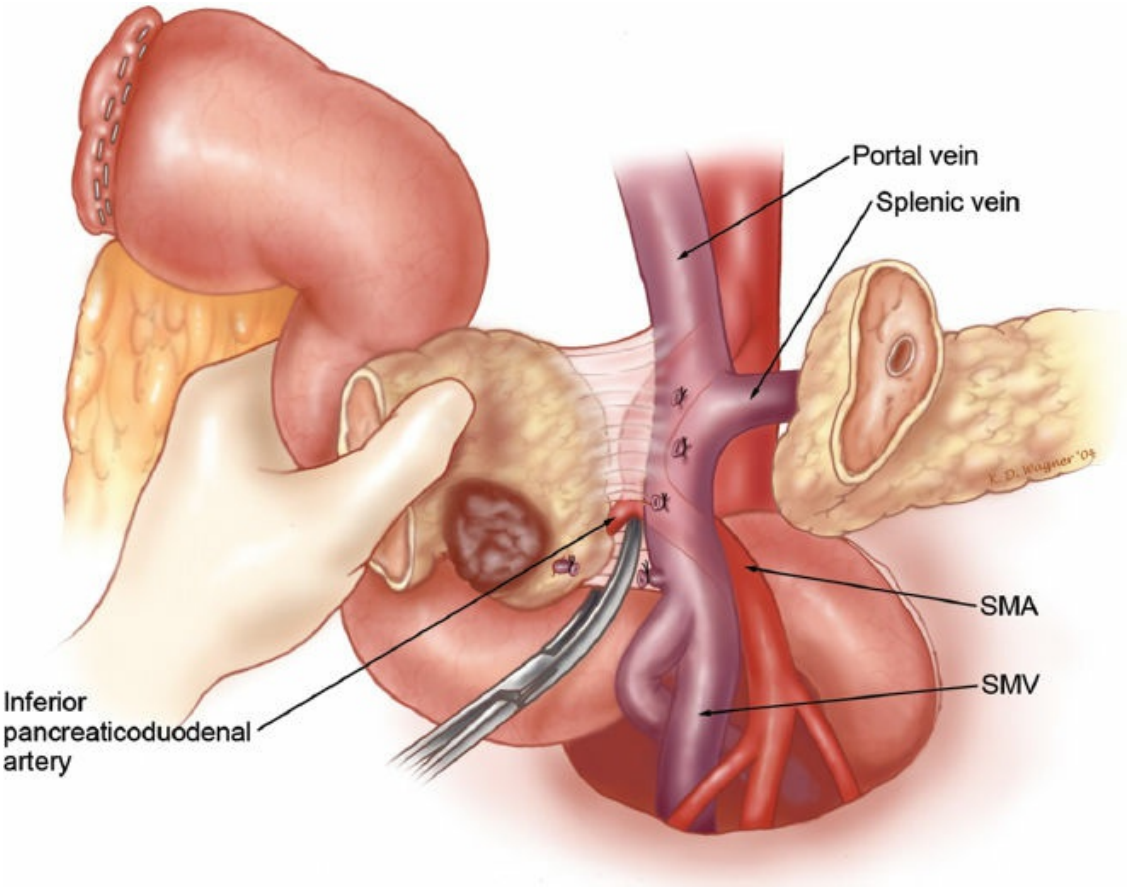

Figure 127.14. Illustration of attempted removal of the pancreaticoduodenectomy specimen from the mesenteric vessels without mobilization of the superior mesenteric vein (SMV) and direct identification of the superior mesenteric artery (SMA). This maneuver should not be performed, as it risks injury to the SMA and inadequate control of the inferior pancreaticoduodenal arteries due to their mass ligation with adjacent soft tissue. Failure to directly identify and individually ligate the inferior pancreaticoduodenal arteries is the major cause of postoperative hemorrhage. SMA injury and postoperative hemorrhage are avoidable complications if the SMA is routinely exposed for identification (rather than the surgeon relying on palpation). This technique also facilitates a complete retroperitoneal/mesenteric dissection minimizing the potential for a margin positive resection.

Frozen-section evaluation of the pancreaticoduodenectomy specimen is limited to analysis of the pancreatic and common hepatic duct transection margins. Positive resection margins on the biliary or pancreatic duct mandate further resection until clear margins are achieved. Changes due to chronic pancreatitis may result in dysplastic cells at the pancreatic

transection margin on frozen-section evaluation. Further resection of the pancreas should be performed only if there is histologic evidence, on frozen-section analysis, of invasive carcinoma at the margin. Low-moderate grade dysplasia without carcinoma is not usually an indication for further pancreatic resection. Invasive carcinoma extending along the main pancreatic duct is uncommon in the absence of adenocarcinoma in the background of intraductal papillary mucinous neoplasm (IPMN).

Complete permanent-section analysis of the pancreaticoduodenectomy specimen requires that it be oriented for the pathologist to enable accurate assessment of the SMA margin and other standard pathologic variables. By removing all tissue to the right of the SMA, further resection at this margin is not possible. However, the SMA margin must be identified and inked, it cannot be accurately assessed in a retrospective fashion.

To summarize, the operation as described above emphasizes full mobilization of the SMV-PV confluence, exposure of the SMA, and removal of all mesenteric soft tissue and perineural tissue to the right of this vessel. Direct exposure of the SMA should be a routine part of pancreaticoduodenectomy, will minimize the risk for iatrogenic injury of this vessel, and will ensure direct ligation of the IPDA(s) thereby minimizing the chance for early postoperative intra-abdominal hemorrhage. The high incidence of local recurrence following pancreaticoduodenectomy mandates that greater attention be paid to the SMA margin—the soft tissue margin along the right lateral border of the proximal 3 to 4 cm of the SMA.

Vascular Resection

Venous resection should only be performed in carefully selected patients who have tumor adherence to the SMV or SMV-PV confluence but no evidence of tumor extension to the SMA or celiac axis. With high-quality CT imaging, the need for venous resection should be anticipated and the surgical strategy decided preoperatively, thereby obviating lengthy operating room delays from indecision and increased morbidity/mortality from technical misadventures. Surgeons who perform pancreaticoduodenectomies should be familiar with standard vascular techniques for resection and reconstruction of the SMV-PV confluence.

Steps 1 through 5 of pancreaticoduodenectomy are completed as described above. If a Cattell–Braasch maneuver had been performed, the right colon is returned to its normal anatomic position, removing the

clockwise twist in the mesentery that often occurs during the retroperitoneal/mesenteric dissection; this is important to do before segmental resection of the SMV-PV confluence. Tumor adherence to the lateral wall of the SMV-PV confluence prevents dissection of the SMV and PV off the pancreatic head and uncinate process, thereby inhibiting medial retraction of the SMV-PV confluence (and lateral retraction of the specimen). Historically, division of the splenic vein was considered standard practice. This allowed complete exposure of the SMA medial to the SMV and provided increased SMV and PV length (PV no longer tethered by the splenic vein) for a primary venous anastomosis following segmental vein resection (Fig. 127.17). The retroperitoneal dissection is then completed by sharply dividing the soft tissues anterior to the aorta and to the right of the exposed SMA leaving the specimen attached only by the SMV-PV confluence. Vascular clamps are placed 2 to 3 cm proximal (on the PV) and distal (on the SMV) to the involved venous segment, and the vein is transected, allowing tumor removal. A generous 2- to 3-cm segment of SMV-PV confluence can be resected without the need for interposition grafting if the splenic vein is divided. Venous resection is always performed with inflow occlusion of the SMA (Rommel tourniquet) to prevent small bowel edema (which makes pancreatic and biliary reconstruction more difficult). Systemic heparinization (2,500 to 4,000 U of systemic heparin) is employed prior to occluding the SMA. The free ends of the vein are reapproximated using interrupted 6-0 Prolene sutures. It is very important to mark the anterior surface of the SMV and PV with a marking pen prior to venous resection to prevent a small twist in the SMV when performing the anastomosis.

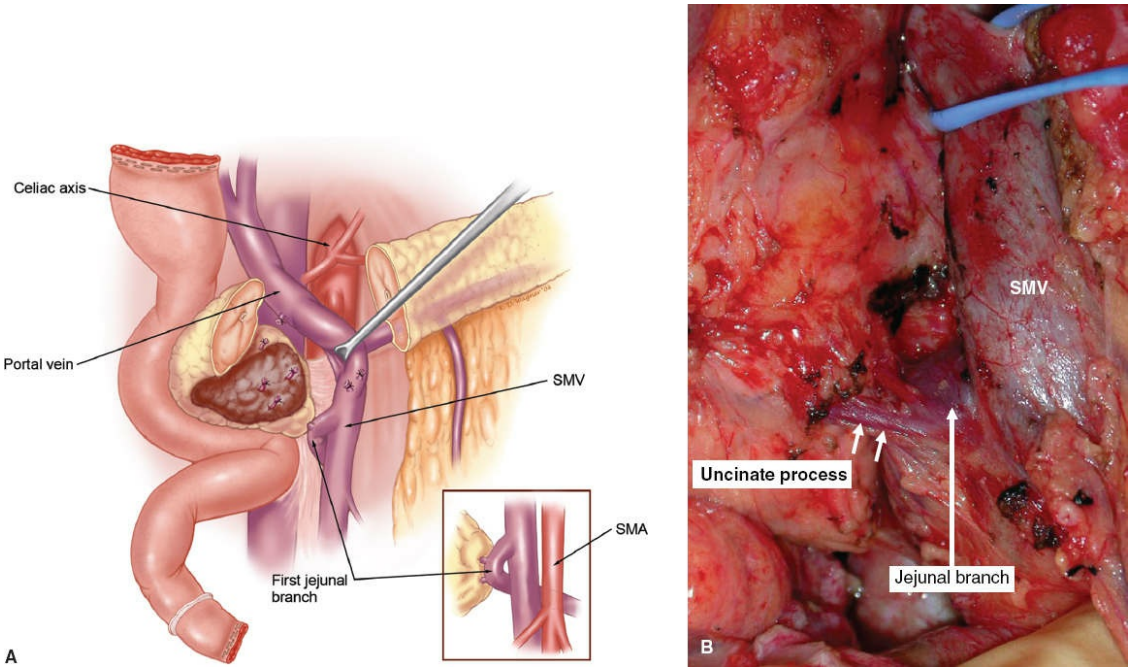

Figure 127.15. Illustration (**A**) and intraoperative photograph (**B**) of the important surgical anatomy of the superior mesenteric vein (SMV) at the level of the uncinate process. The SMV usually bifurcates into two main branches, one to the ileum and one to the jejunum. Adequate venous return from the small bowel requires that one or the other of these two main SMV tributaries are intact. The jejunal branch of the SMV (often referred to as the first jejunal branch) drains the proximal jejunum, travels posterior to the superior mesenteric artery (SMA), and enters the SMV along its posterolateral wall. The jejunal branch usually has a few venous tributaries that drain the uncinate process (*inset*). If necessary, the jejunal branch can be divided. The most feared complication during this part of the operation is a tangential laceration of the jejunal branch extending posterior to the SMA. In an attempt to control such an injury, poorly placed sutures may result in an injury to the SMA. Very rarely the jejunal branch will travel anterior to the SMA which simplifies this part of the operation. Intraoperative photograph (**B**) of the jejunal branch of the SMV and a small venous tributary (*white arrows*) to the uncinate process.

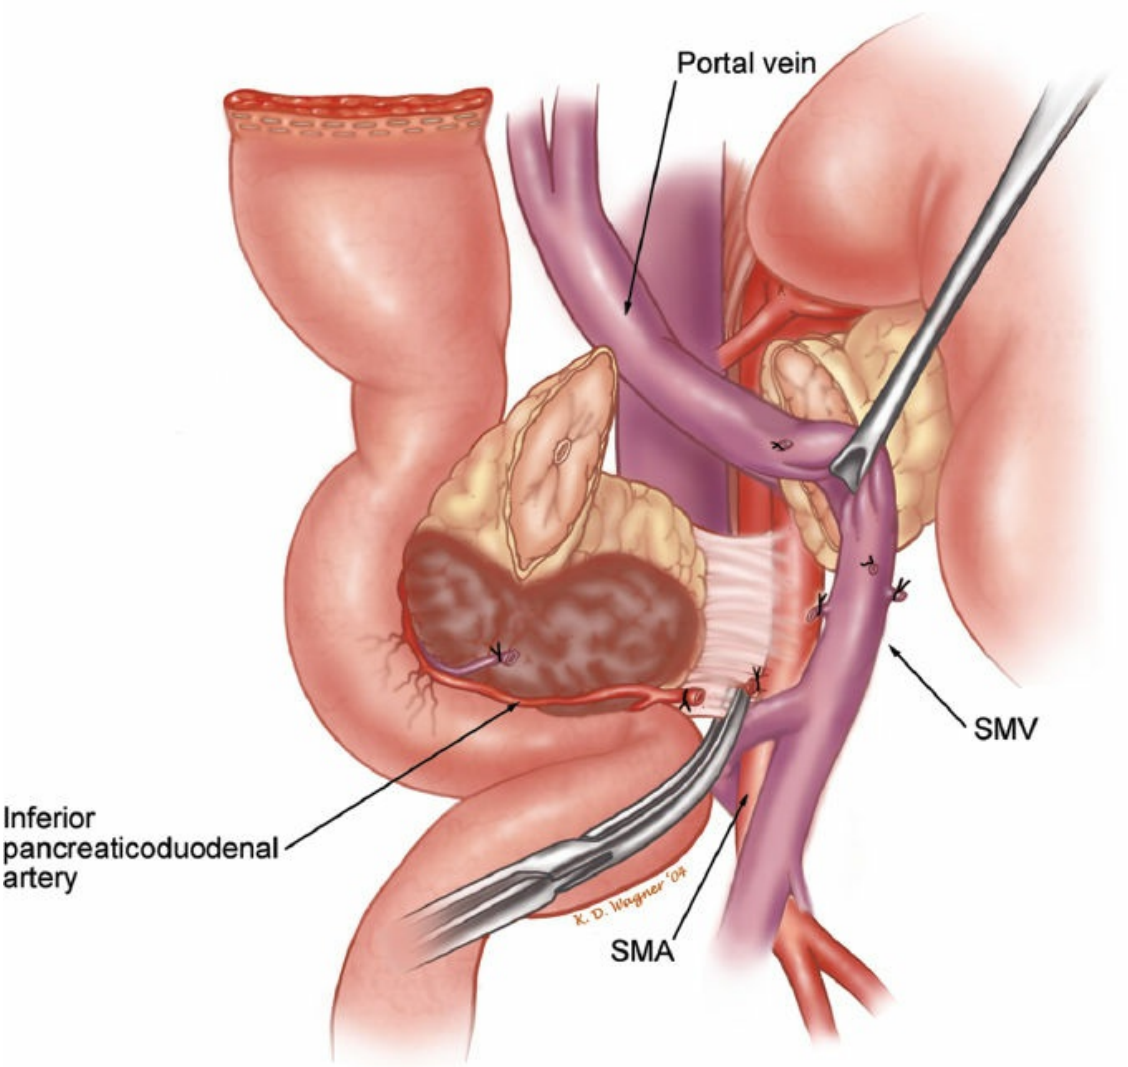

Figure 127.16. Illustration of the continuation of Step 6, and the final step in resection of the specimen. Medial retraction of the superior mesenteric-portal vein confluence facilitates dissection of the soft tissues adjacent to the lateral wall of the proximal superior mesenteric artery (SMA); this site represents the SMA margin. The inferior pancreaticoduodenal artery (or arteries) is identified at its origin from the SMA, ligated, and divided. SMV, superior mesenteric vein.

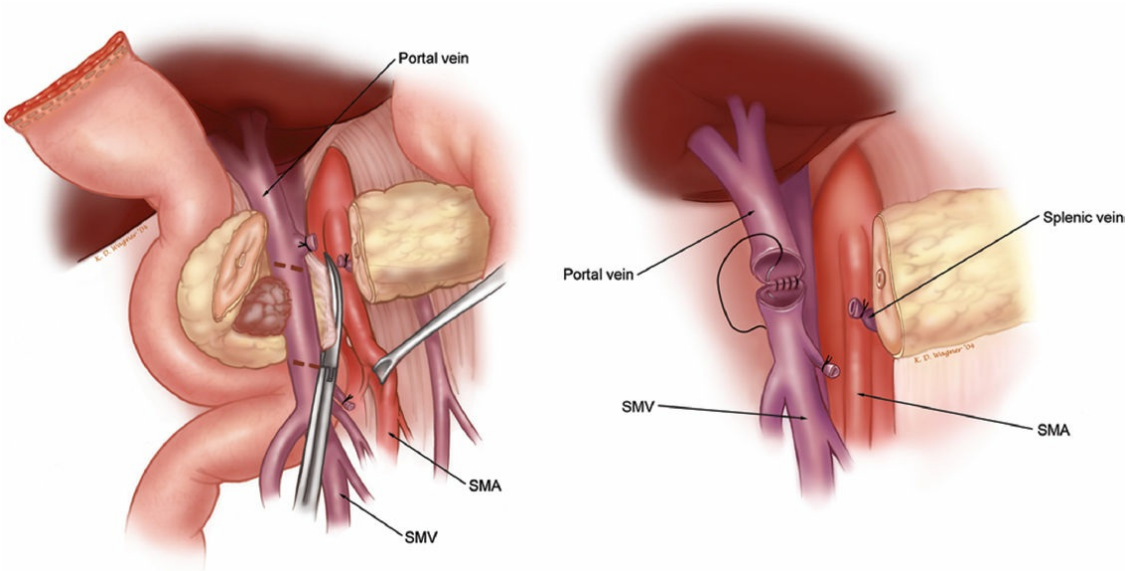

Figure 127.17. Illustration of the final step in pancreaticoduodenectomy when segmental venous resection is required and the decision is made to divide the splenic vein. In the early experience with resection and reconstruction of the superior mesenteric-portal vein (SMPV) confluence, splenic vein ligation was routine. Currently, we ligate the splenic vein only when the tumor involves the splenic vein confluence. By dividing the splenic vein, the superior mesenteric artery (SMA), which is identified medial to the superior mesenteric vein (SMV), can be exposed to its origin from the aorta and the pancreatic head removed from the right lateral border of the SMA. This dissection is considerably more difficult when the splenic vein-SMV–portal vein confluence is intact. The tumor is then attached only by the SMPV confluence, which can be divided proximal and distal to the involved segment. Reconstruction is performed (during inflow occlusion) by an end-to-end anastomosis of the portal vein and the SMV with 6-0 interrupted Prolene sutures. The anastomosis can be run (as shown) or interrupted; the authors frequently interrupt the anastomosis, especially when there is a size discrepancy between the portal vein and the SMV.

Upper gastrointestinal hemorrhage due to sinistral portal hypertension following splenic vein ligation can occur. This is possible if the IMV enters the SMV rather than the splenic vein; something which is usually apparent on preoperative CT imaging. In contrast, when the IMV enters the splenic vein, it provides a route for collateral (retrograde) venous flow (when the splenic vein is divided) from the splenic vein to the systemic venous circulation. When the splenic vein must be divided and the IMV

does not enter the splenic vein, we prefer to create a splenorenal anastomosis to allow decompression of the stomach and spleen into the systemic venous circulation.

Ideally, the splenic vein–PV junction should be preserved if possible, especially if the IMV enters the SMV. However, splenic vein preservation is possible only when tumor invasion of the SMV or PV does not involve the splenic vein confluence (Fig. 127.18). Preservation of the splenic vein–SMV–PV confluence significantly limits the mobilization of the PV and prevents primary anastomosis of the SMV after segmental SMV resection unless it is limited to ≤2 cm. Therefore, most patients who undergo SMV resection with splenic vein preservation require an interposition graft. Our preferred conduit for interposition grafting is the (left) internal jugular vein. Preservation of the splenic vein adds significant complexity to venous resection because it prevents direct access to the most proximal 3 to 4 cm of the SMA (medial to the SMV). Venous resection and reconstruction can be performed either before the specimen has been separated from the right lateral wall of the SMA or after complete mesenteric dissection by separating the specimen first from the SMA. Both techniques require significant experience with pancreaticoduodenectomy and are described in detail in previous publications (see Suggested Readings). The different forms of venous resection and reconstruction are illustrated in Figure 127.19.

An aberrant right HA may arise from the SMA as an accessory right HA (type VI, VII, or VIIIb hepatic arterial anatomy), in which case a normal right HA also arises from the celiac axis; ligation of the accessory artery in such a case would not affect hepatic or bile duct arterial flow. A replaced right HA arising from the SMA (type III or VIIIa), unlike an accessory right HA, represents the only direct arterial inflow to the right hepatic lobe. Because the right and left hepatic arteries communicate within the liver, ligation of the right HA should be tolerated assuming a normal level of serum bilirubin and normal PV flow. However, because the proximal bile duct receives virtually all of its arterial supply from the right HA following interruption of cephalad flow from the GDA, we prefer to revascularize the right HA when possible. In addition, following pancreaticoduodenectomy and the resulting hepaticojejunostomy, there will be life-long communication of the biliary system with the gastrointestinal tract resulting in contaminated bile and the risk for hepatic abscess in the setting of “relative” ischemia of the right hepatic lobe due to

right HA ligation. Fortunately, an accessory right HA arising from the SMA infrequently requires resection at the time of pancreaticoduodenectomy because the majority of resectable tumors are located more anteriorly in the pancreatic head or uncinate process. Rarely, the entire CHA may arise from the SMA (type IX). Failure to recognize this anatomic variant and inadvertent ligation of the HA may result in fatal hepatic necrosis.

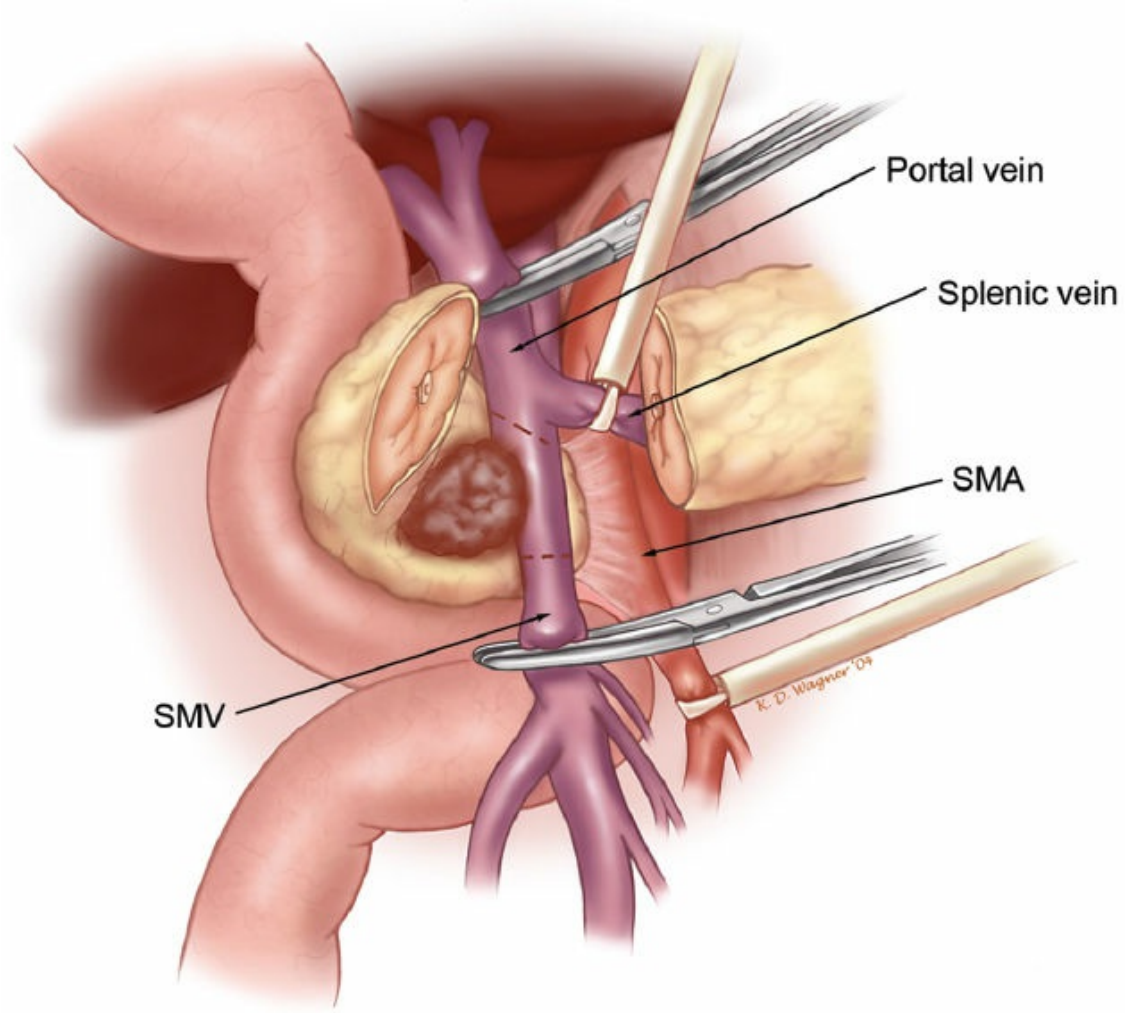

Figure 127.18. An illustration of resection of the superior mesenteric vein (SMV) with splenic vein preservation. The intact splenic vein tethers the portal vein, making a primary anastomosis impossible in most cases. With the splenic vein intact, one cannot complete the dissection of the specimen from the right lateral border of the superior mesenteric artery (SMA) to the origin of this vessel in standard fashion. Therefore, options include either placing the graft prior to specimen removal, or separation of the pancreatic head from the SMA by medial rotation of the specimen as described by Leach et al (see

Suggested Readings). Segmental resection of the SMV with splenic vein preservation adds significant complexity to this operation but prevents the potential complications of hypersplenism (which may result in mild to significant thrombocytopenia, thereby possibly complicating the delivery of cytotoxic chemotherapy) and sinistral portal hypertension (with the risk for gastroesophageal varices and hemorrhage).

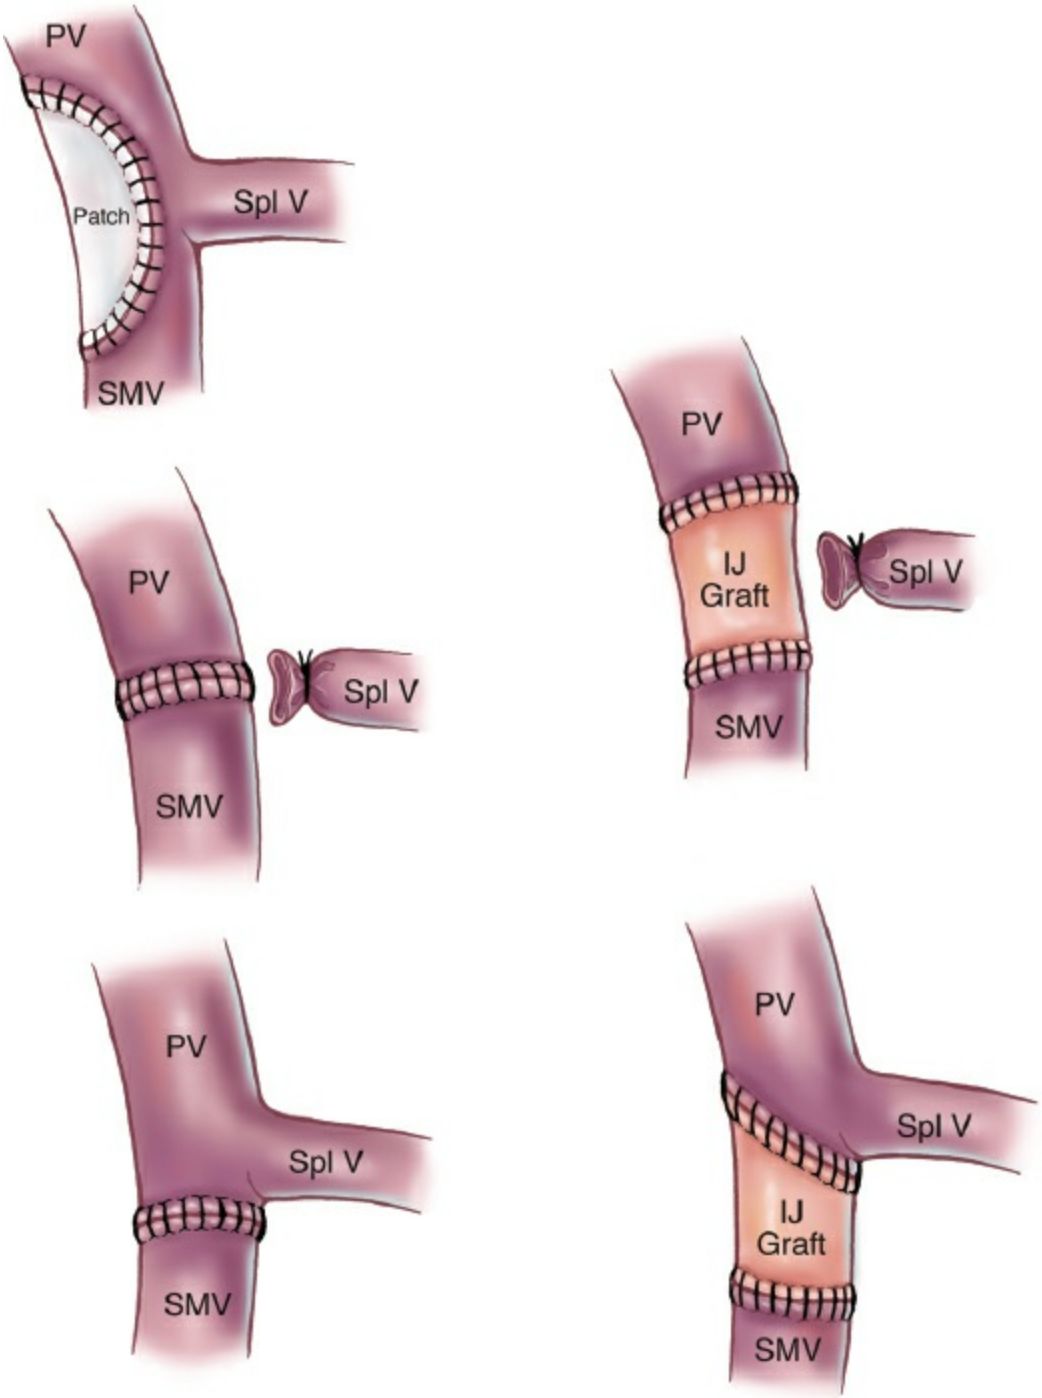

Figure 127.19. Illustration of the different types of venous reconstruction used at the time of pancreaticoduodenectomy.

When a patch is needed we use the saphenous vein and when an interposition graft is needed we use the left internal jugular (IJ) vein. PV, portal vein; SMV, superior mesenteric vein; Spl V, splenic vein. (Modified from Tseng JF, Raut CP, Lee JE, et al. Pancreaticoduodenectomy with vascular resection: margin status and survival duration. *J Gastrointest Surg* 2004;8(8):935–50; with permission of Springer.)

Celiac axis stenosis with compensatory retrograde flow in the GDA from the SMA may result from atherosclerotic disease, median arcuate ligament syndrome, or inflammatory entrapment (the latter two being the most common). We always assess the HA pulse at the time of surgery; if the pulse is significantly decreased in intensity or disappears upon ligation of the GDA, the CHA is then dissected to its origin at the celiac axis (and the diaphragmatic median arcuate ligament divided) in an attempt to differentiate extrinsic compression (most common) from atherosclerotic disease. If flow is not improved, a reversed saphenous vein interposition graft between the aorta and the HA at the site of the GDA origin is performed.

PANCREATIC, BILIARY, AND GASTROINTESTINAL RECONSTRUCTION

Reconstruction after pancreaticoduodenectomy proceeds first with the pancreatic anastomosis.

1. The pancreatic remnant is mobilized from the distal splenic vein and proximal splenic artery for a distance of 2 to 2.5 cm. Failure to adequately mobilize the pancreatic remnant results in poor suture placement at the pancreaticojejunal anastomosis, especially in large patients with deep abdominal cavities. Injury to the proximal splenic artery can occur when mobilizing the pancreatic remnant if one does not appreciate the location of this vessel. The transected jejunum is brought through a generous incision in the transverse mesocolon to the left of the middle colic vessels. By using a defect in the transverse mesocolon to the left (rather than right) of the middle colic vessels, the jejunal mesentery is under no tension as it extends directly cephalad. The jejunum is brought retrocolic rather than retroperitoneal (posterior to the mesenteric vessels in the bed of the resected duodenum). A one- or two-layer, end-to-side, duct-to-mucosa pancreaticojejunostomy is performed. If the pancreatic duct is not dilated, we use a small Silastic

stent (Dow Corning, Midland, MI) (Fig. 127.20). The anastomosis between the pancreatic duct and the small bowel mucosa is completed with 4-0 or 5-0 monofilament sutures (we prefer PDS). Each stitch incorporates a generous bite of the pancreatic duct and a full-thickness bite of the jejunum. The posterior knots are tied on the inside and the lateral and anterior knots on the outside. Prior to the anterior sutures being tied, the stent (when utilized) is placed across the anastomosis so that it extends into the pancreatic duct and small bowel for a distance of approximately 2 cm.

When the pancreatic duct is not dilated and/or the pancreatic substance is soft, one can perform an anastomosis that invaginates the cut end of the pancreas into the side of the jejunum using a running, double-armed, 4-0 nonabsorbable monofilament suture. This technique is rarely used by the authors because even a nondilated pancreatic duct can usually be anastomosed using a careful duct-to-mucosa technique. Another option for the high-risk anastomosis (soft gland, nondilated duct) is a pancreaticogastrostomy as recently championed by Dr. George Kazantsev and colleagues.

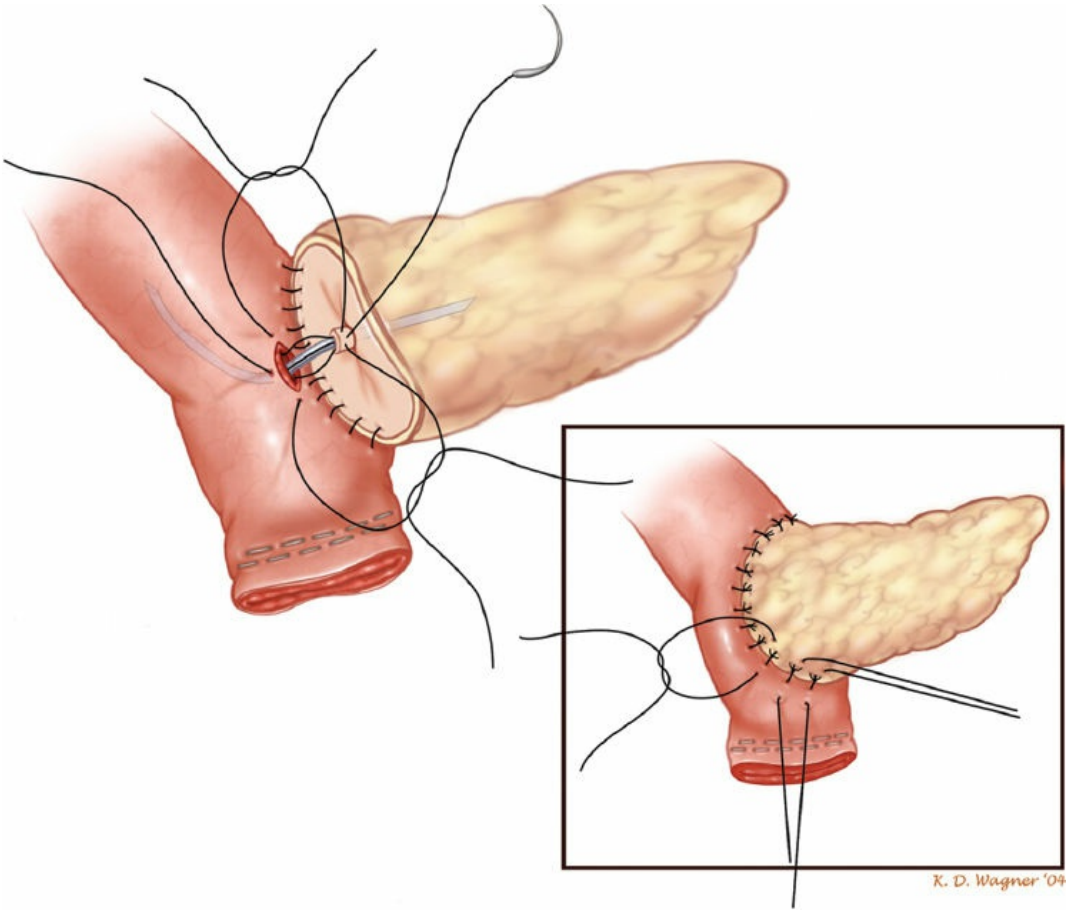

Figure 127.20. Illustration of pancreaticojejunostomy. A two-

layer, end-to-side, duct-to-mucosa retrocolic pancreaticojejunostomy is performed with (when the pancreatic duct is not dilated) or without a small stent. When used, the stent (4 to 5 cm long) is sewn to the pancreatic duct with a single absorbable monofilament suture.

2. A single-layer biliary anastomosis is performed using interrupted 4-0 or 5-0 absorbable monofilament sutures (Fig. 127.21). An interrupted technique is utilized to avoid purse-stringing of the anastomosis. It is important to align the jejunum with the bile duct to avoid tension on the pancreatic and biliary anastomoses. A stent is rarely used in the construction of the hepaticojejunostomy even when the bile duct is not dilated.
3. An antecolic, end-to-side gastrojejunostomy is constructed in two layers. Starting from the greater curvature, approximately 6 cm of the gastric staple line is removed. A posterior row of 3-0 silk sutures is followed by a full-thickness inner layer of running monofilament sutures; the anterior row of silk sutures completes the anastomosis. The distance between the biliary and gastric anastomoses should be at least 50 cm, thereby allowing the jejunum to assume its antecolic position (for the gastrojejunostomy) without tension, and also preventing bile reflux into the liver. An antecolic gastrojejunostomy is favored to prevent possible outlet obstruction caused by the colonic mesentery. Finally, the jejunal limb should be aligned so that the efferent limb is adjacent to the greater curvature of the stomach. A 10-Fr feeding jejunostomy tube may be placed distal to the gastrojejunostomy. Prior to abdominal closure, the abdomen is carefully irrigated and the small bowel is run to ensure proper alignment. In patients with endobiliary stents, the bile is contaminated and often has had free access to at least the right upper quadrant of the abdomen when completing the biliary anastomosis; careful irrigation may prevent postoperative infectious complications. The use of drains remains an active area of controversy in the field of pancreatic surgery, and many surgeons still drain both the hepaticojejunostomy and the pancreaticojejunostomy (the authors do not). We do place a single drain in the right upper quadrant as lymphatic leak is common following the dissection described above and a drain for 3 to 4 days prevents ascites formation. We remove this drain when the output is less than approximately 200 to 250 mL/day; we do not check amylase levels in the drain fluid. Finally, the mobilized falciform ligament (carefully preserved when the abdomen

was opened) is placed between the HA, at the level of the GDA stump, and the afferent jejunal limb to cover the GDA stump (Fig. 127.22). A tongue of omentum can be utilized if the falciform is attenuated. This is a simple strategy to minimize the risk for pseudoaneurysm formation at the site of the GDA stump in the event of a pancreatic anastomotic leak and resulting abscess formation. Indeed, careful attention to the use of vascularized tissue to cover the CHA can come very close to eliminating vascular complications associated with this operation.

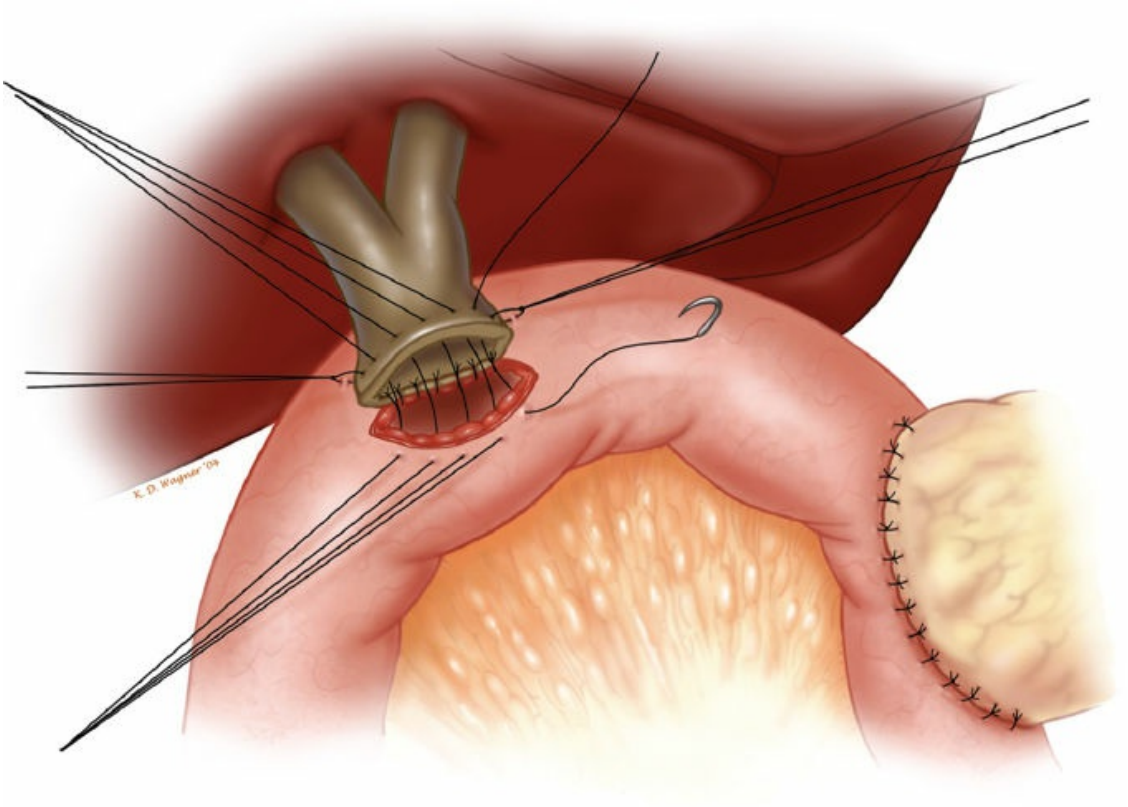

Figure 127.21. Illustration of hepaticojejunostomy. A one-layer, end-to-side hepaticojejunostomy is performed with 4-0 or 5-0 absorbable monofilament sutures distal to the pancreaticojejunostomy. A stent is rarely placed in this anastomosis. Care is taken to allow enough distance between the pancreatic and biliary anastomoses so the falciform ligament can be placed between the anastomoses anterior to the hepatic artery and posterior to the jejunal limb.

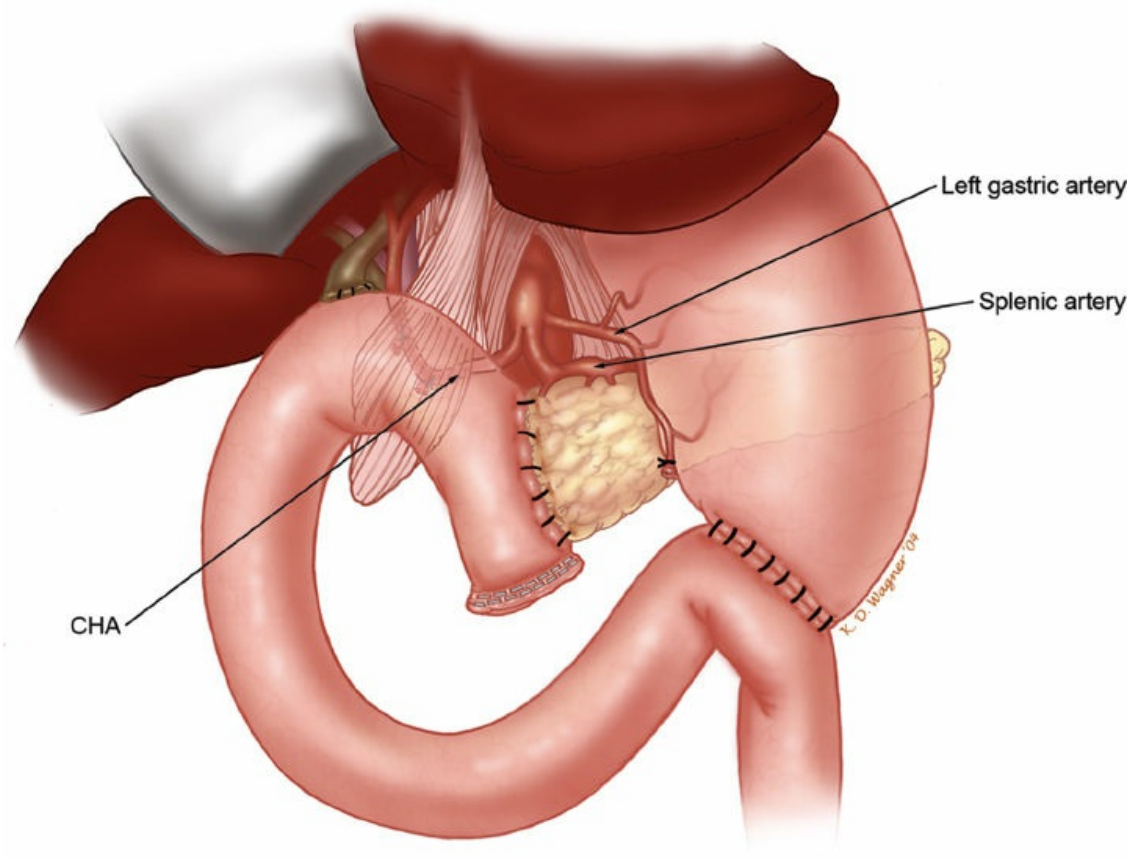

Figure 127.22. Illustration of the completed reconstruction after pancreaticoduodenectomy. The falciform ligament, mobilized upon opening the abdomen, is placed over the hepatic artery to cover the stump of the gastroduodenal artery, thereby separating the hepatic artery from the afferent jejunal limb. We are careful to leave at least 50 cm between the biliary and the gastric anastomoses to prevent the possible complication of reflux cholangitis. CHA, common hepatic artery.

PYLORUS PRESERVATION

Pylorus preservation in combination with pancreaticoduodenectomy was first described by Traverso and Longmire in 1978. Since then, increasing numbers of pancreatic surgeons have employed this modification of the procedure, particularly for patients with benign disease or small periampullary lesions. Proponents of the technique argue that preservation of the antropyloric pump mechanism results in improved long-term upper gastrointestinal tract function with enhanced weight gain. Detractors of pylorus preservation counter that the reported improvements in gastrointestinal function and nutrition are small, if any, and that they come at the expense of an increased incidence of early postoperative delayed gastric emptying. Further, leaving the distal stomach and duodenum may

compromise margins of excision and prevent adequate peripyloric lymphadenectomy. Published data to date involve retrospective comparisons that have yielded mixed results. Despite the controversy, most pancreatic surgeons would agree that pylorus preservation should not be performed for patients with bulky tumors of the pancreatic head, duodenal tumors involving the first or second portions of the duodenum, or lesions associated with grossly positive pyloric or peripyloric lymph nodes.

The steps in pylorus-preserving pancreaticoduodenectomy are identical to those in standard pancreaticoduodenectomy except in the approach to the antrum, pylorus, and duodenum (Steps 3 and 4). Pylorus preservation involves proximal division of the gastrointestinal tract beyond the pylorus and, most importantly, preservation of sufficient blood supply to the proximal duodenum and preservation of vagal innervation to the antrum and pylorus. Therefore, appropriate caution must be exercised during the portal dissection to avoid unnecessary injury to the nerves of Laterjet. This is the fundamental technical difference in the pylorus-preserving procedure and is essential to avoid postoperative gastroparesis. The duodenum is divided approximately 2 to 3 cm beyond the pylorus with the linear gastrointestinal stapler (Ethicon, Inc.) and the gastroepiploic arcade divided at that level. The staple line is removed prior to performance of the duodenojejunostomy so as to leave approximately 2 cm of duodenum distal to the pylorus. A short segment of duodenum ensures adequate vascularity of the remaining duodenum as the right gastric artery is divided (stomach blood supply based on the left gastric artery and the short gastrics from the splenic artery). The pylorus is often gently dilated with a Kelly clamp or an index finger. The duodenojejunostomy is performed in an end-to-side fashion in a single layer (author’s preference) with monofilament absorbable sutures (Fig. 127.23).

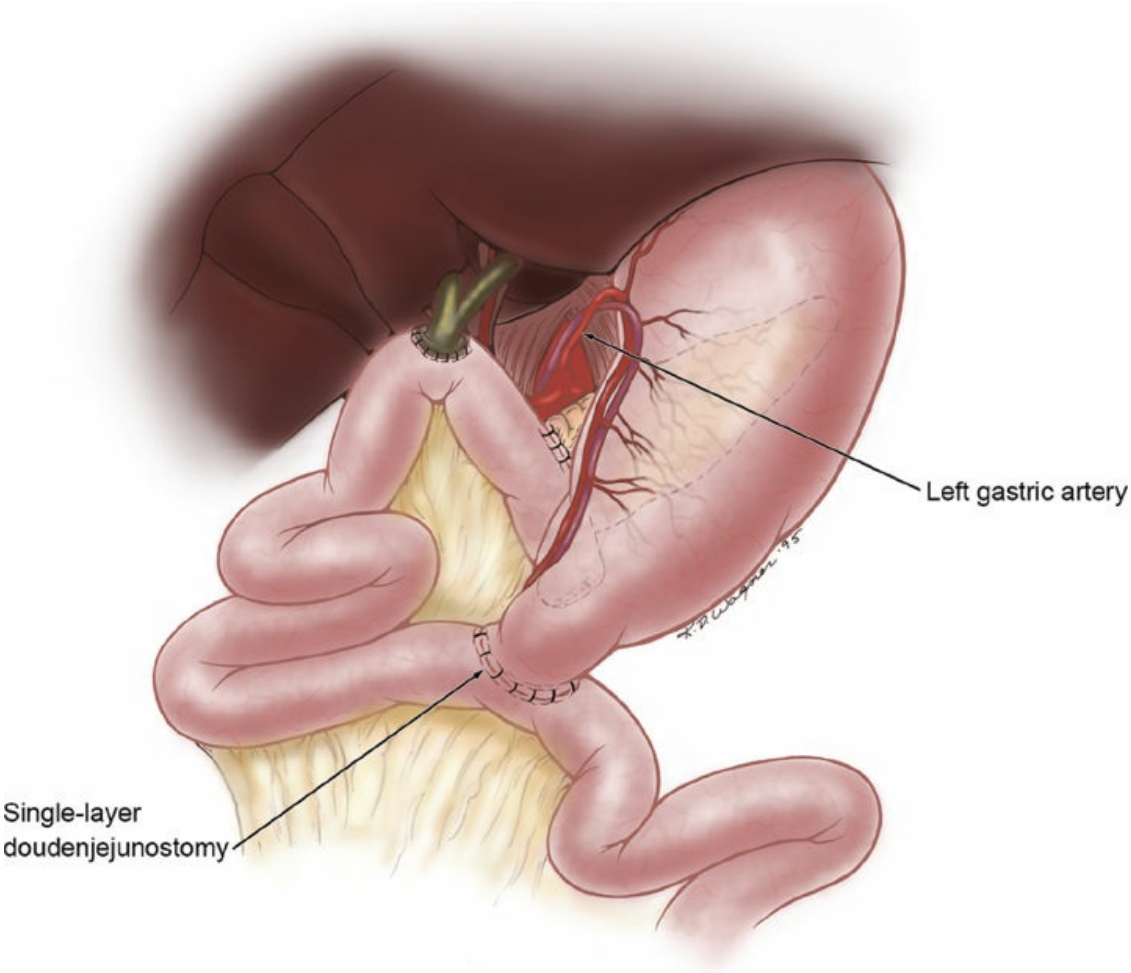

Figure 127.23. Illustration of the completed reconstruction following pylorus-preserving pancreaticoduodenectomy. The duodenojejunostomy can be placed either retrocolic or antecolic (colon not shown in this illustration); we prefer an antecolic anastomosis so that there is no potential for obstruction of the jejunum as it exits the transverse mesocolon. When pylorus preservation is performed, we often place a jejunostomy tube distal to the duodenojejunostomy due to the concern for poor gastric emptying in the first couple weeks following surgery.

TOTAL PANCREATECTOMY

Traditionally, total pancreatectomy was rarely performed for adenocarcinoma of the pancreas but is being considered more often now that we have much more effective systemic therapies and patients are presenting with more complicated local tumor anatomy after a lengthy period of systemic therapy (in the absence of metastatic disease). The presenting complaints of most patients with pancreatic body tumors are pain and gastrointestinal dysfunction due to tumor invasion of the neural

plexus surrounding the celiac axis and SMA, symptoms which should alert the surgeon to the potential for celiac or SMA encasement.

Total pancreatectomy is accomplished by identifying the proximal splenic artery and dissection of the left upper quadrant of the abdomen, following Steps 1 and 3 of our six-step pancreaticoduodenectomy. After identification of the infrapancreatic SMV and completion of the portal dissection, the proximal splenic artery is exposed and if possible, ligated (but often not divided). The greater omentum is separated from the left side of the transverse colon, and the splenic flexure is mobilized. The peritoneum lateral to the spleen is then incised in a cephalad direction to the gastroesophageal junction. The short gastric vessels are ligated and divided, allowing medial and cephalad retraction of the stomach. Mobilization of the spleen and pancreas from their retroperitoneal attachments to the kidney and adrenal gland is then completed. The IMV is divided if it enters the splenic vein, and the mesenteric root divided from the left lateral border of the SMV to the left lateral border of the aorta, staying anterior/lateral (to patient's left) to the SMA. Exposure of the SMA inferior to the neck of the pancreas will allow the dissection to proceed directly anterior to this vessel under direct vision. If possible, it is important to leave several of the autonomic nerves on the adventitia of the SMA to preserve some degree of small bowel innervation and prevent rapid gastrointestinal transit. Division of the splenic vein is often delayed until the completion of Steps 4 (gastric or duodenal transection) and 5 (ligament of Treitz, proximal jejunum, and duodenum). Then, in preparation for completion of the retroperitoneal dissection, the spleen and distal pancreas are again reflected medially (left to right), exposing the distal splenic vein–SMV junction; the splenic vein is then ligated and divided usually with the vascular stapler (Fig. 127.24). The splenic artery was ligated (but often not divided) prior to division of the splenic vein. However, exposure of the origin of the splenic artery may not be optimal for division until after the splenic vein has been divided.

When dealing with tumors in the pancreatic neck, there are two noteworthy technical points:

1. Preservation of islet cell function is particularly important in younger patients with cystic neoplasms, solid pseudopapillary neoplasms, or islet cell (neuroendocrine) tumors. When a tumor arises in the pancreatic neck or proximal body of the pancreas, a complete distal pancreatectomy may leave only a small portion of pancreatic head and

uncinate process. In so doing, the patient may not have adequate islet cell mass for normal glucose metabolism and therefore may become insulin dependent. Therefore, in patients with relatively small tumors of the pancreatic neck of favorable histology (i.e., neuroendocrine carcinoma, solid pseudopapillary neoplasm, mucinous cystic neoplasm), segmental resection of the pancreatic neck and proximal body (otherwise termed central or middle-segment pancreatectomy) with preservation of the splenic artery and vein is preferred to ensure adequate islet cell reserve. Reconstruction requires Roux-en-Y pancreaticojejunostomy to the remaining segment of distal pancreas.

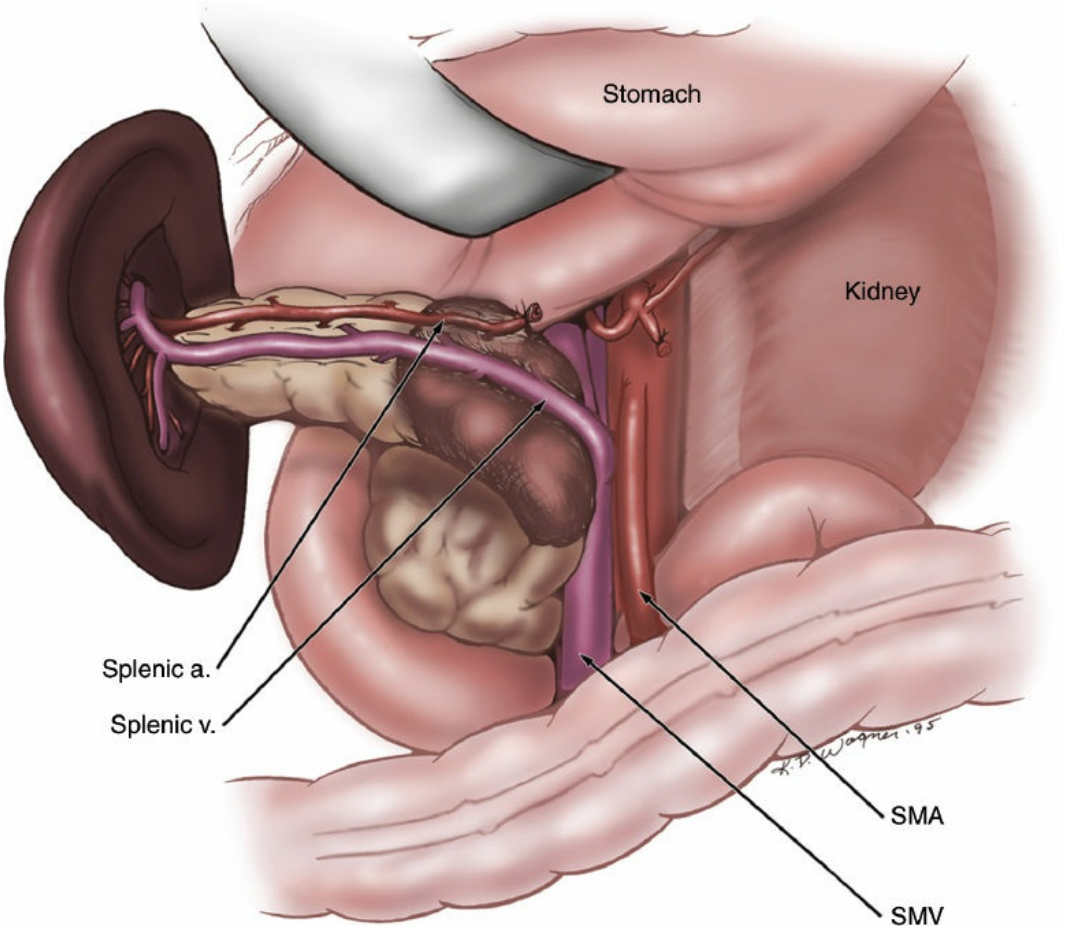

Figure 127.24. Illustration demonstrating medial rotation of the spleen and distal pancreas as performed when completing a total pancreatectomy. In this illustration, the splenic artery has been divided in preparation for division of the splenic vein at its junction with the superior mesenteric vein (SMV). However, as discussed in the text, while we always *ligate* the splenic artery before *dividing* the splenic vein, frequently we delay *dividing* the splenic artery until after the splenic vein has been divided – once the splenic vein has

been divided, the exposure to the celiac-splenic artery junction is much improved. It is important not to narrow the SMV during ligation of the splenic vein. The authors prefer to close the SMV-splenic vein junction with either a vascular stapler or a running 6-0 Prolene suture. SMA, superior mesenteric artery.

2. In occasional patients with tumors of the pancreatic neck, it may be unclear both on preoperative CT scans and intraoperatively whether the patient should undergo extended right (pancreaticoduodenectomy) or left (distal) pancreatectomy. Because most surgeons desire to perform the less complicated procedure, one might elect to perform distal pancreatectomy, only to discover on frozen-section analysis that the pancreatic transection margin is positive and that completion pancreaticoduodenectomy is needed. This situation can be avoided by completing the proximal pancreatic transection prior to committing to distal pancreatectomy. Frozen-section analysis of the proximal transection margin, if negative, enables one to perform a distal pancreatectomy with negative margins. A positive proximal transection margin requires extended pancreaticoduodenectomy. In either situation, total pancreatectomy may not be necessary.

When distal pancreatectomy is performed, the most important step is identification and suture ligation of the pancreatic duct. Those who prefer to staple the pancreas (possible when the pancreas is not too thick) note that the staple line secures the pancreatic duct, preventing its retraction into the pancreatic substance. One can even consider an additional 5-0 monofilament suture for the pancreatic duct within the staple line. When the pancreas is divided just medial to the intrapancreatic portion of the CBD, the pancreatic transection line is virtually always too thick for a stapling device and suture closure (we often use pledgets) is necessary. Again, identification of the pancreatic duct is critical to prevent pancreatic leak. We routinely bring the mobilized falciform ligament through the lesser omentum and allow it to cover the stump of the splenic artery and the pancreatic transection site—analogous to the use of the falciform ligament following pancreaticoduodenectomy discussed previously.

PERIOPERATIVE MANAGEMENT AND COMPLICATIONS

As with all complex surgery, a good outcome after pancreatectomy

depends on meticulous perioperative care. Intraoperative hemodynamic management includes an arterial line in all patients. Antibiotics are given on induction and re-dosed, if indicated, based on length of the operation and the individual drug pharmacokinetics. We always culture the bile in patients with indwelling biliary stents and in such patients, continue the antibiotics (culture-directed) for a minimum of 3 days after surgery. Patients with vascular resections/reconstructions are prescribed aspirin, 300 mg per rectum daily, beginning in the recovery room and prophylactic subcutaneous heparin if the INR is less than 1.5. Glucoses are followed at regular intervals and the diabetes management team consulted for anyone who will require insulin at discharge from the hospital. Limited sips of clears are allowed as soon as the patient is awake and alert, presuming the NG is in place and functional. For patients with jejunostomy tubes, jejunostomy feeding is initiated at a rate of 10 mL per hour on postoperative day 2 and then slowly increased daily if gastrointestinal function has returned. With the institution of an oral diet, low-rate jejunostomy feeding is converted from continuous to nighttime administration. Patients are frequently discharged receiving supplemental continuous or nighttime jejunostomy feedings.

Fevers occurring after postoperative days 3 to 4 demand careful evaluation. Potential sources of fever include those common to all major abdominal surgery; pneumonia, deep venous thrombosis, central line sepsis, urinary tract infection, and wound infection. Patients who undergo pancreaticojejunostomy are at risk for the development of intra-abdominal abscess as a result of leakage from the pancreatic anastomosis. Because leaks from either the biliary or gastric anastomoses are very uncommon, intra-abdominal sepsis is considered to be due to a pancreatic anastomotic leak until proven otherwise. The study of choice for evaluation of presumed intra-abdominal sepsis is CT of the abdomen and pelvis with IV contrast. The finding of a localized fluid collection in the region of the pancreaticojejunostomy should be considered for CT-guided aspiration and drainage. Selective use of CT-guided aspiration is based on the general condition of the patient, standard laboratory evaluation (especially the degree of leukocytosis) and the presence or absence of an air-fluid level in the fluid collection. Percutaneous catheter drainage is indicated if the aspirated fluid appears grossly purulent or confirmed positive on Gram stain. It is common to identify nonloculated ascitic fluid on postoperative CT scans in pancreatectomy patients; this finding rarely represents

infection or anastomotic leak and does not demand aspiration or drainage unless clinical signs of infection persist and another source of infection has not been identified. Pancreaticojejunostomy anastomotic leaks generally close once adequate drainage is established. Octreotide and antibiotics are utilized when treating established pancreatic anastomotic leaks that have required percutaneous drainage.

Postoperative gastrointestinal or drain tract bleeding should prompt immediate evaluation with arteriography. While very uncommon, an arterial-enteric fistula occasionally occurs in the postoperative setting (rarely before postoperative day 10). The most common cause (when the operation is done open using the technique described herein) is a pancreatic anastomotic leak with surrounding inflammation and infection resulting in blowout of the GDA stump. This complication is much more common in patients who undergo a minimally invasive pancreaticoduodenectomy (laparoscopic or robotic) possibly due to the use of energy devices near visceral arteries and/or the frequent use of clips and staple lines rather than surgical ties to secure the GDA and the IPDAs. Gastrointestinal or drain tract bleeding represents a true emergency; the only patients likely to survive are those in whom the diagnosis is made immediately. The HA may be embolized or stented. Surgical control of hemorrhage from the stump of the GDA is exceedingly difficult in a postoperative pancreaticoduodenectomy patient and carries a higher mortality than that associated with management in the interventional radiology suite or hybrid OR room.

Patients are ready for discharge when they are afebrile, independent with the majority of self-care, and have adequate caloric intake from either oral intake, or a combination of oral and jejunostomy feedings. All patients are discharged on enteric coated aspirin (DVT prophylaxis), acid suppression (usually an H_2 blocker) and pancreatic enzyme replacement.

SUMMARY

A detailed preoperative assessment of resectability prevents needless laparotomy in patients with advanced PC, and a standardized technique of tumor resection minimizes perioperative complications. Pancreaticoduodenectomy is divided into six well-defined maneuvers. Attention to detail and a standardized approach to postoperative care minimize patient morbidity and hospital stay. Optimal results can be achieved with careful attention to patient selection for surgery,

preoperative assessment of resectability, surgical technique, and postoperative care. Importantly, all physicians involved in the care of patients with localized, potentially resectable (or borderline resectable) PC should support available clinical trials.

ACKNOWLEDGMENTS

The authors would like to thank Wendy Behrs for assistance with manuscript preparation. The Pancreatic Cancer Program at MCW is grateful for the courageous patients and families who have formed the basis of our experience and reinforce the importance of multimodality care.

EDITOR'S COMMENT

In this cogently written and beautifully illustrated chapter, Dr. Evans and his team once again make another invaluable contribution to *Mastery* and to the field of complex gastrointestinal surgery at large. A master of his craft, Dr. Evans distills what is perhaps the most complicated operation in all of GI surgery into a simple, well-defined series of 6 steps, making this chapter required reading for any surgical trainee preparing to scrub on this procedure. Perhaps even more importantly, in this chapter Dr. Evans and colleagues summarize several other critical contributions that they have made to this field, including: (1) the safety of endobiliary stent placement to permit the administration of neoadjuvant therapy and to potentially obviate the need for a palliative biliary bypass; (2) the paramount importance of high-quality, cross-sectional preoperative imaging to define tumor resectability; (3) the concerted

emphasis on the systemic nature of the disease of pancreatic cancer and thus the rationale for neoadjuvant therapy prior to surgery; and (4) the technical contributions of the direct identification and dissection of the proximal SMA during PD (to limit injuries to this vessel and to achieve a wider SMA margin) as well as the safety and feasibility of venous resection and reconstruction in patients with borderline resectable tumors.

Though these contributions when considered today seem almost laughably self-evident, it was not all that long ago (certainly during my residency training) when these assertions were actually viewed as *laughable.* Indeed, for decades the standard approach to the newly diagnosed patient with a cancer in the head of the pancreas was immediate surgery, for even if the patient was deemed to be unresectable at the time of surgery either due to local tumor invasion (however that was assessed!) or the presence of occult metastatic disease, a double bypass (choledochojejunostomy and gastrojejunostomy) was nonetheless "necessary" for palliation even though most patients had no symptoms of gastric outlet obstruction. For those deemed to be resectable, the SMA was rarely if ever directly identified and dissected, in preference for the surgeon palpating and protecting the SMA with his or her left hand while bluntly clamping, cutting, and tying the tissues to the right of the unvisualized SMA. Venous resection and reconstruction was simply out of the question—tumor stuck to the vein was simply left on the vein. Rarely was consideration given to the administration of neoadjuvant chemotherapy and/or radiotherapy as a means to shrink the primary tumor or to serve as a biologic test to distinguish those patients most likely to benefit from radical surgery. It was Dr. Evans and the group at M. D. Anderson who preached this gospel at meetings and published the neoadjuvant therapy trials and technique papers throughout the 1990s and 2000s that formed the principles of how we define resectability and treat pancreatic cancer today.

The vast majority of patients with pancreatic cancer present with metastatic or locally advanced disease, and historically, neoadjuvant chemoradiation therapy rendered approximately one third of these locally advanced tumors resectable. However, despite resection, these patients often recurred, with a median survival of less than 2 years (Andriulli A et al. Neoadjuvant/preoperative gemcitabine for patients with localized pancreatic cancer: a meta-analysis of prospective studies. *Ann Surg Oncol* 2012;19:1644–62). With the demonstration in the ACCORD trial of the superiority of the chemotherapy regimen of fluorouracil, leucovorin, oxaliplatin, and irinotecan (FOLFIRINOX) over gemcitabine in the treatment of metastatic pancreatic cancer (Conroy T et al. FOLFIRINOX versus gemcitabine for metastatic pancreatic cancer. *N Engl J Med* 2011;364:1817–25), it was a rational choice to extend these data to the locally advanced setting to learn whether neoadjuvant FOLFIRINOX might increase the rate of tumor resectability. Indeed, preliminary data from both the MGH (Ferrone C et al. Radiological and surgical implications of neoadjuvant treatment with FOLFIRINOX for locally advanced and borderline resectable pancreatic cancer. *Ann Surg* 2015;261:12–17) and Dr.

Evans' group at the Medical College of Wisconsin (Christians KK et al. Neoadjuvant FOLFIRINOX for borderline resectable pancreas cancer: a new treatment paradigm? *Oncologist* 2014;19:266–74) examining patients with locally advanced or borderline resectable pancreatic cancers receiving neoadjuvant FOLFIRINOX +/– chemoradiation therapy demonstrate that the regimen is safe and is associated with high rates of R0 resection and (though very preliminary) encouraging survival outcomes. Interestingly, the traditional imaging criteria for resectability appear to no longer be accurate after treatment with FOLFIRINOX, which though it effectively kills the tumor, it replaces the tumor abutting vessel wall with fibrosis abutting vessel wall (Ferrone CR et al. Radiological and surgical implications of neoadjuvant treatment with FOLFIRINOX for locally advanced and borderline resectable pancreatic cancer. *Ann Surg* 2015;261:12–7), and these two entities are not distinguishable radiographically. As such, a more aggressive surgical approach is recommended even in the face of posttreatment imaging demonstrating borderline resectability, as a significant percentage of these patients will have negative resection margins.

Though many studies have confirmed the safety of portal/superior mesenteric vein resection and reconstruction at the time of PD, one might reasonably ask how often the vein is histologically invaded by tumor and what the impact on survival is. Roch AM et al. (Significance of portal vein invasion and extent of invasion in patients undergoing pancreatoduodenectomy for pancreatic adenocarcinoma. *J Gastrointest Surg* 2016;20:479–87) at Indiana University studied 90 patients undergoing vein resection at the time of PD from 2000 to 2014 and found that 58% of the vein specimens showed evidence of histologic invasion by the cancer but that such invasion did not significantly influence overall survival (14 vs. 21 months, $p = 0.08$) but was associated with a significantly shorter median disease-free survival (11.3 vs. 15.8 months, $p = 0.03$), predominantly due to a higher rate of local recurrence. Wang J et al. (Histologic tumor involvement of superior mesenteric vein/portal vein predicts poor prognosis in patients with stage II pancreatic adenocarcinoma treated with neoadjuvant chemoradiation. *Cancer* 2012;118:3801–11) at M. D. Anderson evaluated 85 patients with stage II pancreatic cancer who underwent neoadjuvant therapy followed by PD with vein resection from 1999 to 2007. Similar to the findings of the group at Indiana, they found that 67% of patients had histologic evidence of tumor invasion of the vein and that such patients tended to have larger tumors as well as a higher rate of R1 resection. However, in contrast to the findings of the Indiana group, Wang et al. found that tumor involvement of the vein was in fact an independent predictor of both disease-free and overall survival, though the depth of tumor invasion into the vein wall did not correlate with prognosis. Most authors would still agree that provided that a portal/mesenteric vein resection can be performed safely that it should be offered to patients undergoing PD for pancreatic cancer, as a certain percentage of these patients will enjoy long-term survival. Furthermore, the vein should be

carefully evaluated histologically for evidence of tumor invasion, as this appears to be a poor prognostic factor.

Dr. Evans and his group at MCW do not routinely place a drain near the pancreaticojejunostomy to monitor for, and to manage, a potential pancreatic fistula. Rather, they opt for a right upper quadrant drain to control a potential lymphatic leak, and they do not routinely check drain amylase values. Now there are few topics in all of pancreatic surgery more controversial than that of whether to place a drain after PD. The Memorial Sloan Kettering group demonstrated in both a prospective randomized trial (Conlon KC et al. Prospective randomized clinical trial of the value of intraperitoneal drainage after pancreatic resection. *Ann Surg* 2001;234:487–93) and in a large follow-up retrospective study (Correa-Gallego C et al. Operative drainage following pancreatic resection: analysis of 1122 patients resected over 5 years at a single institution. *Ann Surg* 2013;258:1051–58) that patients who had operative drains placed did not experience decreased rates of pancreatic fistula but in fact had higher rates of serious morbidity, infectious complications, and readmission. They concluded that routine prophylactic drainage after pancreatic resection could be safely abandoned. However, this viewpoint was seriously challenged by the subsequent publication of a prospective, randomized, multicenter trial of PD with and without routine intraperitoneal drainage (Van Buren G et al. A randomized prospective multicenter trial of pancreaticoduodenectomy with and without routine intraperitoneal drainage. *Ann Surg* 2014;259:605–12). In this trial, 137 patients were randomized to either the drain (n = 68) or no drain (n = 69) groups, and there were no differences in the baseline clinicopathologic or treatment characteristics of these two groups. PD without drainage was associated with an increase in the number and severity of complications as well as a higher incidence of gastroparesis, intra-abdominal fluid collections and abscesses, the need for a postoperative percutaneous drain, and a prolonged length of stay. In fact, the Data Safety Monitoring Board terminated the study prematurely because of an increase in the mortality rate from 3% to 12% in the no-drain group. As a result, these authors cautioned against the routine abandonment of intraperitoneal drains after PD. I seriously doubt that we've heard the last word in this debate.

In sum, it is particularly gratifying to see how far we have come in the multimodality treatment of localized pancreatic cancer. Cloyd et al. (Preoperative Therapy and Pancreatoduodenectomy for Pancreatic Ductal Adenocarcinoma: a 25-Year Single-Institution Experience. *J Gastrointest Surg* 2017;21:164–74) from M. D. Anderson recently published their 25-year (1990–2014) single-institution experience of more than 620 patients treated with neoadjuvant therapy and PD for pancreatic cancer. Despite increases in case complexity, with more operations performed for borderline resectable and locally advanced tumors and requiring vascular resection, locoregional recurrence rates have remained similar while overall survival rates have improved significantly, such that the median survival for the most recent 5-year

cohort (2010–2014) is more than 43 months, a truly astounding number for such a deadly malignancy. Undoubtedly, further improvements in survival will require significant advances in systemic therapies for this disease.

128 Operative Management of Pancreatic Trauma

David V. Feliciano

ANATOMY

The retroperitoneal pancreas crosses the upper abdomen at the level of the first and second lumbar vertebrae, and "posttraumatic pancreatitis" occasionally results from a spinal fracture at this level. The gland has a thin mesothelial capsule and is 15 to 20 cm in length, 1.0 to 1.5 cm in thickness, and ~3.0 cm in width.

The proximity of the pancreas to all the major named vessels of the upper abdomen complicates operative management of injuries, especially in patients with penetrating trauma. The head of the pancreas has a shared blood supply with the duodenum through the anterior and posterior branches of the superior and inferior pancreaticoduodenal arteries. In addition, the head overlies the inferior vena cava, right renal vessels, and the left renal vein as it enters the cava. The uncinate process encompasses the inferior pancreaticoduodenal artery and wraps around the superior mesenteric vein and artery. The neck of the pancreas overlies the superior mesenteric vein and may have to be divided to expose injuries to the confluence of this vein and the splenic vein or to the proximal portal vein. The body of the pancreas lies over the visceral portion of the suprarenal aorta (origins of celiac axis, superior mesenteric artery, and bilateral renal arteries) and the left renal artery and vein. Finally, the body and tail of the pancreas encircle or are intimately adherent to the splenic artery or vein.

The duct of Wirsung (main pancreatic duct) passes through the entire length of the gland just above a line halfway between the superior and inferior edges and enters the left side of the common bile duct to form the ampulla of Vater. The duct of Santorini (accessory pancreatic duct) most commonly branches out superiorly from the duct of Wirsung in the neck of the pancreas and enters the duodenum at the minor papilla ~2.5 cm proximal to the major papilla.

ETIOLOGY AND PATHOPHYSIOLOGY

Isolated injuries after blunt abdominal trauma are noted in only 20% of the patients with pancreatic injuries, and the most common associated injuries are to the duodenum, liver, and spleen. Associated injuries including to the vessels previously mentioned are almost always present in patients undergoing laparotomy for penetrating wounds and depend on the location of the wound. Wounds of the head of the pancreas are most commonly associated with perforations of the stomach and transverse colon. Wounds of the body and tail of the pancreas are associated with injuries to the stomach, transverse colon, splenic flexure of the colon, splenic vessels, and the spleen.

CLINICAL PRESENTATION

A direct blow with compression of the upper abdomen and its viscera/vessels against the spine is the most common blunt mechanism of injury. Examples would include compression from the lower rim of the steering wheel in an unrestrained driver in a deceleration-type motor vehicle crash, by a misplaced lap-style restraint device in a child, or by direct contact with the handlebars of a bicycle in a frontal crash. Many patients with blunt injuries to the pancreas have minimal clinical symptoms and signs when first evaluated after trauma. The major reason for this is the retroperitoneal location of the organ, which precludes the early development of peritonitis. The second reason is the tamponading effect of the retroperitoneum which may prevent significant blood loss in the absence of other vascular injuries or extravasation of pancreatic juice from the injury. Therefore, the surgeon cannot rely on the traditional serial physical examinations, diagnostic peritoneal lavage, or surgeon-performed ultrasound to make an early diagnosis of a blunt injury.

When symptoms are present, the most common is deep epigastric steady pain occasionally associated with nausea and vomiting. Pain in the upper lumbar area has not been a common complaint in the author’s experience unless a fracture of an adjacent vertebra is present. Because the epigastric pain is usually mild, it was not uncommon in the pre-CT era for a patient with a major injury such as complete transection of the pancreas over the spine to be discharged from the emergency room with a missed diagnosis.

Patients with penetrating wounds to the abdomen that injure the pancreas almost always have associated intra-abdominal injuries as noted

earlier and present with the classic indications for an emergency laparotomy, namely, peritonitis, hypotension, or, rarely, evisceration.

DIAGNOSIS

With the difficulty in making a diagnosis of a blunt pancreatic injury as described earlier, there is reliance on laboratory testing and the use of contrast-enhanced CT in the modern era. Unfortunately, the laboratory finding of hyperamylasemia on admission to the emergency center is not a precise marker for an injury to the pancreas. Salivary rather than pancreatic amylase elevations are present in 30% to 40% of patients admitted with trauma associated with acute alcoholic intoxication. Also, approximately one third of patients with blunt transection of the pancreatic duct have a normal amylase level on admission. Therefore, the presence of hyperamylasemia, while raising suspicion of a pancreatic, duodenal, or enteric injury, does not mandate an exploratory laparotomy in the absence of the aforementioned hypotension, peritonitis, evisceration, or CT-evidence of a significant pancreatic injury (to be discussed). A progressive rise in the amylase level over the first 24 to 48 hours of hospitalization is, however, strongly suggestive of injury to the pancreas or duodenum or for the development of the rare entity of posttraumatic pancreatitis.

Contrast-enhanced CT using a 128-slice scanner is the current diagnostic modality of choice in hemodynamically stable and asymptomatic or minimally symptomatic patients with possible or suspected injuries to the pancreas. This would include patients who have sustained blunt abdominal trauma or those who have sustained a penetrating injury to the flank or back. In the latter groups, triple-contrast (intravenous, oral or by nasogastric tube, and rectal) CT has been performed for 30 years. Its use, however, has decreased significantly in recent years with the increased resolution available with modern multislice CT scanners. CT findings *suggestive or diagnostic* of injury to the pancreas are listed in Table 128.1. Injuries to the pancreas noted on contrast-enhanced CT or at laparotomy are defined according to the Organ Injury Scale developed by the American Association for the Surgery of Trauma in 1990 (Table 128.2). As with most other Organ Injury Scales, these range from Grade I (minor pancreatic contusion or superficial laceration) to Grade V (massive disruption of the pancreatic head). Pitfalls in diagnosing pancreatic injuries include the presence of minimal extraperitoneal fat in some patients, artifacts from dense oral contrast, and

nonopacification of adjacent duodenum or small bowel so that the edges of the pancreas are difficult to define.

TABLE 128.1 CT Diagnosis of Pancreatic Injuries

Suggestive of Injury
Fluid in the lesser sac
Fluid between pancreas and splenic vein
Hematoma of transverse mesocolon
Thickening of left anterior renal fascia
Duodenal hematoma or laceration
Injury to spleen, left kidney, left adrenal gland
Chance (transverse) fracture of lumbar spine, especially in a child
Diagnostic of Injury
Parenchymal hematoma or laceration
Obvious transection of the parenchyma/duct with fluid in the lesser sac
Disruption of head of pancreas
Diffuse swelling characteristic of posttraumatic pancreatitis

Adapted from Feliciano DV. Operative management of pancreatic trauma. In Fischer JE, ed. *Fischer's Mastery of Surgery*. 6th ed. Philadelphia, PA: Wolters Kluwer; 2012:1480–5.

In the presence of an equivocal CT with or without associated hyperamylasemia or when CT is not available, endoscopic retrograde cholangiopancreatography (ERCP) is appropriate to rule out an injury to the main pancreatic duct. A separate classification system of pancreatic injuries diagnosed by ERCP is available as well. There are minimal data on the use of MRCP in assessing a possible traumatic ductal transection.

NONOPERATIVE MANAGEMENT

In the absence of hypotension, peritonitis, evisceration, and CT scan evidence of significant injuries to other organs or vessels, Grade I and II

pancreatic injuries (do not involve duct) are managed nonoperatively. This would include a parenchymal hematoma in the head of the pancreas which may cause transient obstructive jaundice (Fig. 128.1). Though a rare Grade II injury ("major contusion/laceration") may progress to a parenchymal pseudocyst (Fig. 128.2), it is very uncommon to have to intervene for a peripancreatic fluid collection during the period of observation with this low magnitude of injury. A follow-up abdominal CT scan at 5 to 7 days after injury is appropriate when a significant Grade II injury is present or earlier whenever new symptoms in the upper abdomen or increasing hyperamylasemia develop.

TABLE 128.2 Pancreas Organ Injury Scale of the American Association for the Surgery of Trauma

Grade[a]	Type of Injury	Description of Injury	ICD-9[b]	AIS-90
I	Hematoma	Minor contusion without duct injury	863.81–863.74	2
	Laceration	Superficial laceration without duct injury		2
II	Hematoma	Major contusion without duct injury or tissue loss	863.81–863.74	2
	Laceration	Major laceration without duct or injury or tissue loss		3
III	Laceration	Distal transection or parenchymal injury with duct injury	863.92–863.94	3
IV	Laceration	Proximal[c] transection or parenchymal injury involving ampulla	863.91	4

PREOPERATIVE PREPARATION

In all patients who are to undergo an emergency or urgent laparotomy after sustaining abdominal trauma, preparations are similar. An identification bracelet is placed on the patient, venous blood is withdrawn for routine laboratory tests and for type-and-crossmatch of blood products, and an intravenous line is initiated at the same site.

Rapid evaluation of the patient's pericardial sac (rule out tamponade after either blunt or penetrating trauma), pleural cavities, and abdominal cavity is attained by a surgeon-performed ultrasound using a 3.5-MHz probe in an adult.

A second- or third-generation cephalosporin antibiotic is administered intravenously. A nasogastric tube and a bladder catheter are inserted in either the emergency room or operating room depending on the patient's hemodynamic state. In patients who are in ATLS Class III or IV shock, a phone call is made to the blood bank to initiate a massive transfusion protocol. This protocol now commonly known as "damage control

resuscitation" emphasizes the administration of blood and blood products (rather than overuse of crystalloids such as lactated Ringer's solution) for the patients who are bleeding. While rarely attained, the desired goal of "damage control resuscitation" is to infuse packed red blood cells, fresh frozen plasma, and platelet packs in a 1:1:1 ratio. An example of such a protocol (after administration of the initiation package) is as follows.

PRBC	FFP	Platelet	Cryo
6 u	6 (AB)	1 aph.	—
6 u	6 (TS)	—	10 u pooled
6 u	6 (TS)	1 aph.	—
6 u	6 (TS)	—	10 u pooled

Figure 128.2. A 60-year-old woman with posttraumatic pseudocyst in the head of the pancreas after a motor vehicle crash.

In one recent study (June, 2016) a massive transfusion protocol directed by viscoelastic assay thromboelastography (TEG) rather than conventional coagulation tests (INR, PTT, fibrinogen, D-dimer) resulted in improved

survival in injured patients.

As hypothermia occurs in patients in shock, those undergoing evaluation in poorly heated trauma rooms or CT-suites, or during subsequent prolonged trauma laparotomies, prophylaxis against this problem is initiated in the emergency center. Standard maneuvers would include wrapping the patient's head and covering the trunk and lower extremities with a warming device and infusing all blood products and fluids through in-line warmers.

SURGICAL TECHNIQUE

Operative management of pancreatic trauma is determined by complete visualization of the organ to assess the magnitude of the parenchymal injury and to see if a ductal injury is present or not. During a "damage control" laparotomy in the patient with associated injuries and intraoperative hypothermia, acidosis, and a coagulopathy, detailed inspection of the pancreas is delayed till a reoperation once peripancreatic hemorrhage is controlled. In more stable patients a Kocher maneuver is necessary to properly visualize an injury to the head or neck of the pancreas, whereas the body of the pancreas is approached by dividing the gastrocolic omentum and the retroperitoneum on the inferior edge of the pancreas to allow for circumferential palpation of the gland. Injuries to the distal body and tail of the pancreas are evaluated by division of the gastrocolic omentum and elevation of the spleen and tail of the pancreas as in performing a distal pancreatectomy. All hematomas surrounding the pancreas or under the thin mesothelial capsule of the pancreas are explored after either blunt or penetrating trauma.

Injuries to the main pancreatic duct are usually characterized by extensive fat necrosis in the lesser sac, even if the patient's exploratory laparotomy has occurred shortly after trauma. Other intraoperative indicators of transection of the main pancreatic duct are listed as follows: (a) leakage of clear pancreatic fluid; (b) complete transection of the gland; (c) central perforation from gunshot wound (Fig. 128.3); (d) blunt laceration including half the width of the gland (Fig. 128.4); and (e) significant disruption of the parenchyma at any location. When there is a stab wound or blunt laceration that may involve the duct, a brief period of observation is appropriate. Clot is evacuated from the area of injury, any local bleeding is cauterized or sutured, the surgeon puts on magnifying lenses, and the area of injury is observed for 3 to 5 minutes. The presence

of clear fluid draining from the area of trauma indicates that an injury to the main duct is present. On occasion, it may be necessary to inject the patient with l mg/kg secretin intravenously to stimulate pancreatic secretion during the period of observation.

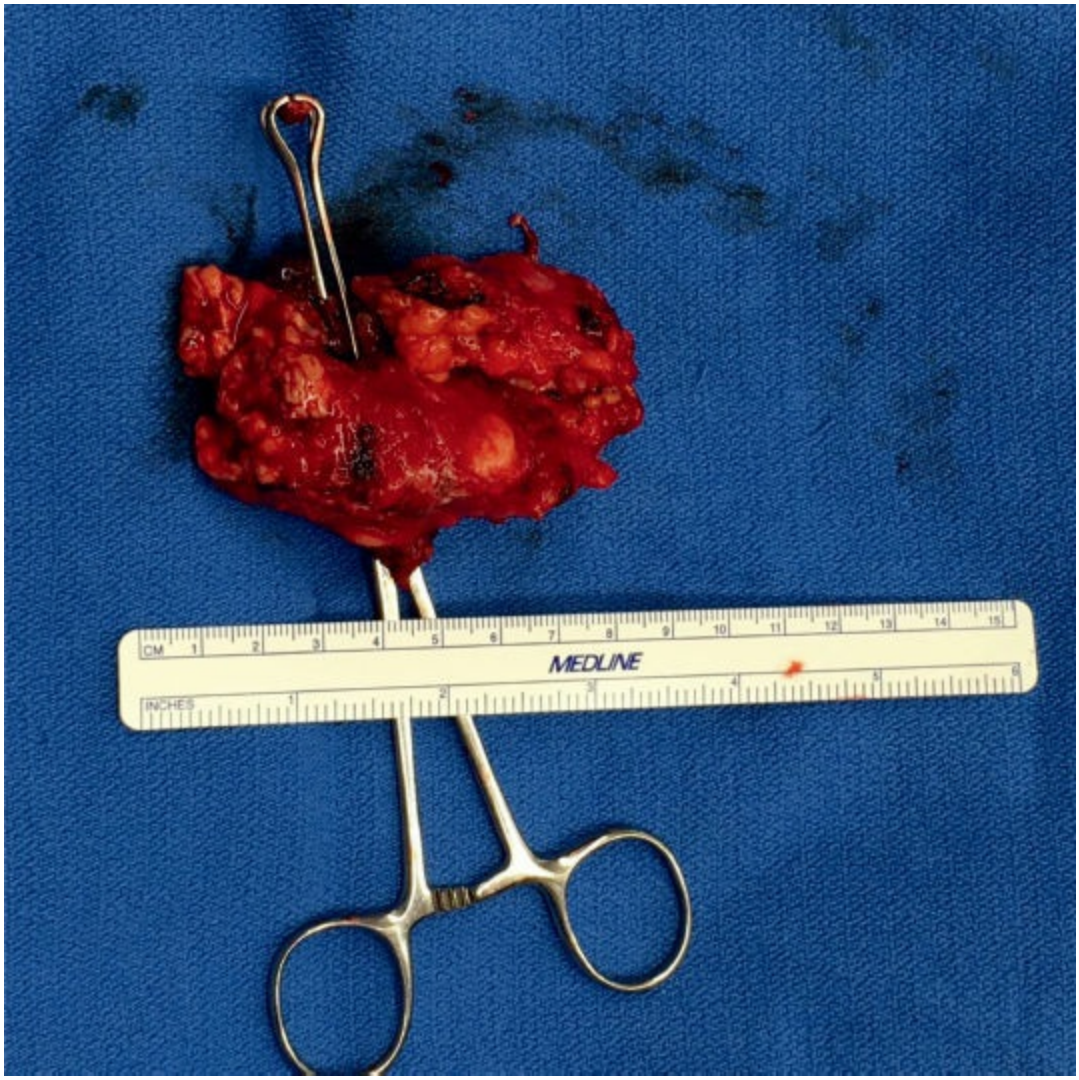

Figure 128.3. Bullet wound through mid-pancreas mandated distal hemipancreatectomy at first reoperation after an original "damage control laparotomy."

Some textbooks recommend intraoperative pancreatography to assess the status of the duct in a hemodynamically stable patient. One option is to perform a very distal pancreatectomy, cannulate the pancreatic duct with polyethylene tubing or a 5-French pediatric feeding tube, and inject 3 to 5 mL of contrast. This approach is not recommended as it includes removal of normal distal pancreas and an uninjured spleen, as well as the risk of a postoperative pancreatic fistula. The second option is to open the

duodenum, cannulate the papilla, and perform a retrograde pancreatogram. The disadvantage of this approach is that it converts whatever pancreatic injury is present into a combined pancreaticoduodenal injury. The third option is to perform a cholecystocholangiogram or cystic duct cholangiogram using methylene blue/saline solution while the anesthesiologist injects intravenous fentanyl. The fentanyl causes spasm of the sphincter of Oddi, and this would direct the methylene blue/saline solution toward the pancreatic duct with any extravasation demonstrating the point of injury.

Figure 128.4. Pancreatic injury evident based on peripancreatic fluid. Axial reconstruction of a contrast-enhanced abdominal CT study performed on an 8-year-old present following blunt abdominal trauma shows low attenuation consistent with fluid in the peripancreatic retroperitoneum (*arrow*). (From Iyer RS, Chapman T (2016). Pediatric Imaging The Essentials; Wolters Kluwer).

TABLE 128.3 Operative Options for Pancreatic Injuries

Parenchymal, but no ductal injury
- Omental plug vs. none
- Closed suction drain vs. none

Ductal transection in tail, body, neck
- Distal pancreatectomy with or without splenectomy
- Roux-en-Y distal pancreatojejunostomy

Ductal transection in head, macerated head, destruction of ampulla, combined pancreaticoduodenal disruption
- Whipple procedure

Combined pancreaticoduodenal injuries
- Simple repair (duodenum)/drainage (pancreas)
- Complex repair(s)—consider adding diversion procedure
- Resection

Table 128.3 lists operative options for pancreatic injuries. In the absence of a ductal injury, there are no convincing data that a Grade I ("minor contusion/superficial laceration") or Grade II ("major contusion/major laceration") pancreatic injury noted at a laparotomy for other injuries needs to be drained. Some surgeons tack a pedicle of viable omentum into a Grade I or II laceration to plug any small ductal leak and bring macrophages to the area of injury (Fig. 128.5), though there are no data documenting the value of this adjunct.

With Grade III or some Grade IV injuries (transection of the duct to the left or right of the superior mesenteric vessels), one option is distal pancreatectomy with splenic salvage in a child or adolescent or without splenic salvage in an adult (Fig. 128.6). When splenic salvage is to be performed, fine ties are placed on pancreatic vessels on the splenic artery and vein side and small metal clips on the pancreatic segment to be resected. If the distal, hemi-, or subtotal pancreatectomy is to include a splenectomy, the splenic artery and vein are suture-ligated with 4-0

polypropylene sutures 2 cm proximal to where the pancreas is to be divided. This maneuver along with the coverage of the vessels by a viable omental pedicle isolates the vessels from any distal leak of the pancreatic stump in the postoperative period.

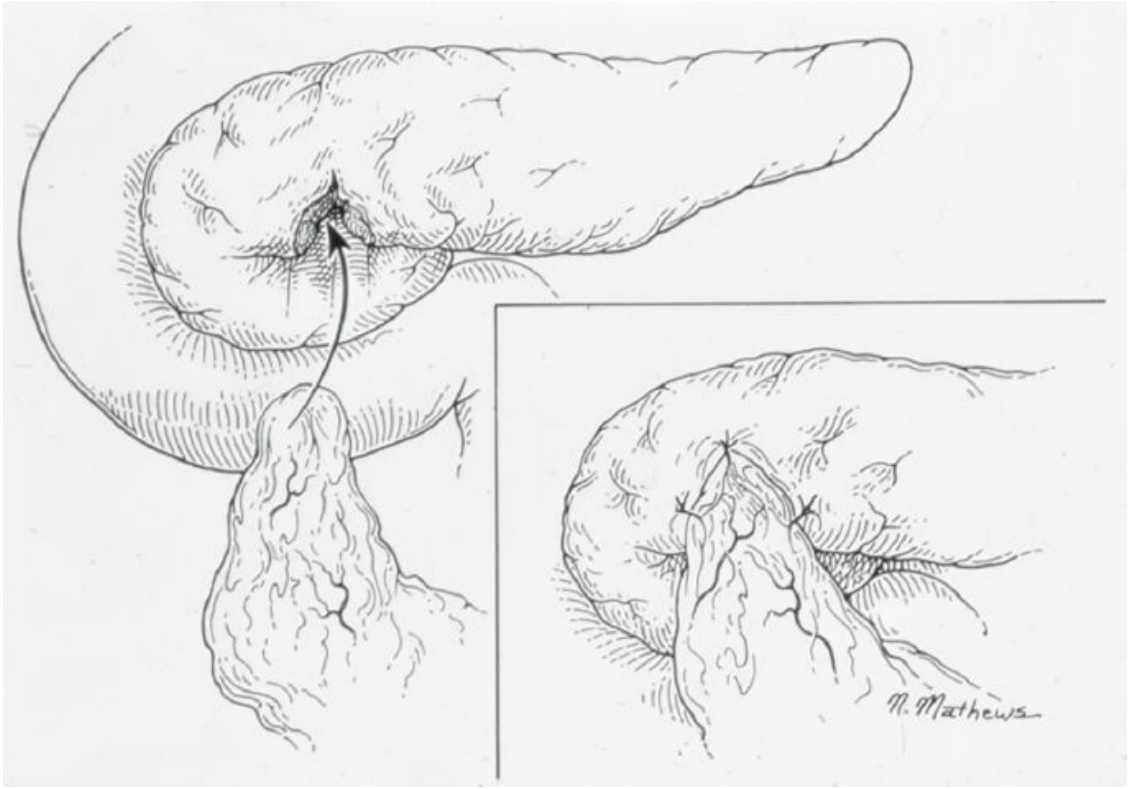

Figure 128.5. A pedicle of viable omentum may be tacked to a Grade I or II pancreatic laceration to plug any leak from a small duct. (From Cushman JG, Feliciano DV. Contemporary management of pancreatic trauma. In: Maull KI, Cleveland HC, Feliciano DV, et al., eds. *Advances in Trauma and Critical Care*, Vol. 10. St. Louis: Mosby; 1995:309–36, with permission.)

Either sutures or staples can be used to close the stump of the remaining pancreas. Some surgeons ligate the open end of the pancreatic duct prior to parenchymal closure, but there are no clear-cut data that this changes the incidence of postoperative pancreatic fistulas from this site. One popular approach to closure is to use absorbable sutures placed in a U-stitch fashion with knots tied on the anterior pancreas. As most elective distal pancreatectomies are performed laparoscopically in the modern era, the use of a stapler to close the parenchyma has become more popular. It should be emphasized, however, that there are no convincing historical data that staple closure leads to a lower postoperative rate of pancreatic

fistulas as compared to suture closure. There are preliminary data that closure with newer staplers that create two triple-staggered rows of titanium staples may decrease the fistula rate as compared to previous reports.

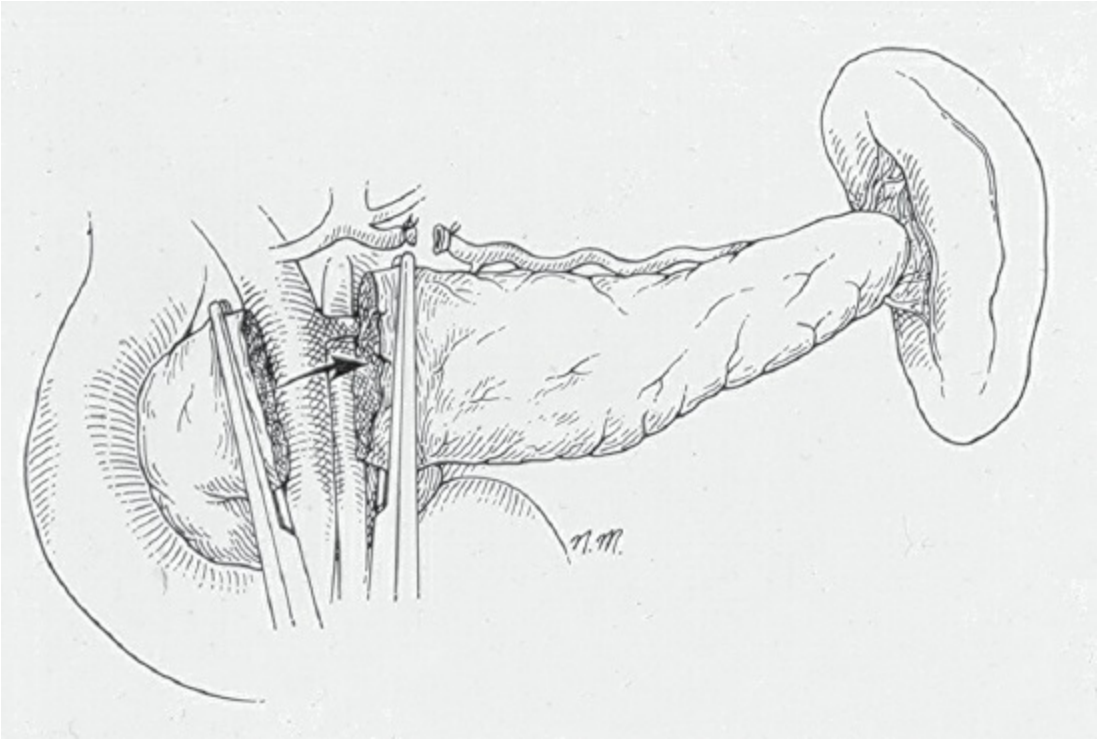

Figure 128.6. Distal pancreatectomy with splenectomy is most commonly performed after ductal transection in the neck of the pancreas or to the left of the mesenteric vessels. (From Cushman JG, Feliciano DV. Contemporary management of pancreatic trauma. In: Maul KI, Cleveland HC, Feliciano DV, et al., eds. *Advances in Trauma and Critical Care*, Vol. 10. St. Louis: Mosby; 1995:309–36, with permission.)

Another option to manage a ductal transection in the body or neck of the pancreas is oversewing or stapling the proximal end of the transection and performing a distal Roux-en-Y end-to-end or end-to-side pancreatojejunostomy (Fig. 128.7). As this option is appropriate in only the most stable patients with more proximal transections (to the right of the superior mesenteric vessels; Fig. 128.6) and no significant associated injuries, it is not commonly performed in adults (only five times in the author's personal experience). The advantage is preservation of 70% to 80% of the pancreas depending on the level of the transection for the rest of the patient's life. The operative technique includes completion of the

parenchymal transection, oversewing or stapling of the proximal end, and a cuff-type pancreatojejunostomy in one of the conformations listed earlier. Because this operation is usually performed on a normal (soft) pancreas, one option is to place a polyethylene tube stent through the anastomosis to theoretically lower the incidence of a postoperative pancreatic fistula. The stent is first passed through the abdominal wall in the right upper quadrant and then though the Roux limb ~5 cm from the pancreatojejunostomy *after* the posterior suture time has been completed. Finally, it is placed into the pancreatic duct for a distance of 2 cm and secured in place with a 3-0 absorbable suture attached to the end of the duct. The anterior anastomosis is completed, and one or two closed suction drains are placed nearby.

Ductal transections in the head of the pancreas are difficult to manage because of the thickness of the pancreas. Either of the two options described earlier for transections more to the left are appropriate, but technically more challenging. There is *no* indication to perform an anterior Roux-en-Y pancreatojejunostomy over both ends of the transection to "sump" the area as illustrated in older textbooks.

In the rare patient with combined pancreaticoduodenal destruction, maceration of the head of the pancreas, or destruction of the ampulla of Vater, a Whipple procedure is indicated. In hemodynamically stable patients, it is appropriate for an experienced surgeon to complete the Whipple procedure immediately. In some patients with blunt trauma, much of the dissection has been completed by the injury itself. When patients have associated injuries, hypotension, and signs of intraoperative "metabolic failure," bleeding from the area of injury is controlled and peripancreatic/periduodenal packs are placed. Closed suction drains may be placed underneath the packs to aspirate any bile or pancreatic juice not absorbed by the packs. As patients undergoing such damage control procedures after abdominal trauma often have marked distension of the midgut (perhaps less with the new blood-banking paradigm using 1 RBC:1 FFP:1 platelets), choosing the time of reoperation is difficult. In general, once the patient's hypothermia, acidosis, and coagulopathy have resolved, oxygenation and ventilation are reasonable, and there is an appropriate urine output, reoperation is indicated. In the borderline patient, the Whipple operation should be performed in two stages—resection, and then reconstruction. A Witzel jejunostomy should be performed in all these patients to allow for early postoperative enteral feeding once the patient is

stable and edema of the midgut starts to resolve. Some surgeons use postoperative subcutaneous injections of somatostatin analog to lower the incidence of pancreatic fistulas after Whipple resections or distal pancreatectomies performed in injured patients. Prospective data using this agent in large numbers of patients with major pancreatic trauma are lacking.

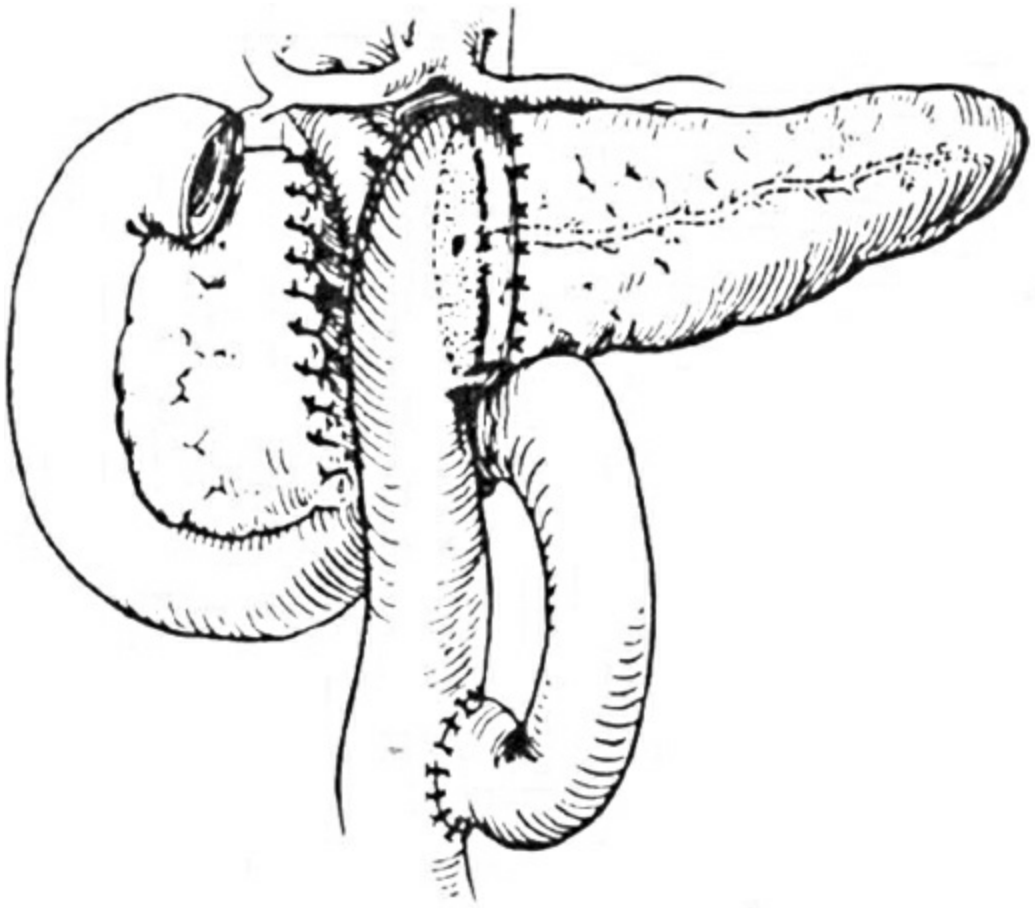

Figure 128.7. Oversewing of proximal segment and distal Roux-en-Y pancreatojejunostomy to preserve parenchyma in a patient with an AAST Grade IV injury. (Drawing adapted from Letton AH, Wilson JP. Traumatic severance of pancreas treated by Roux-Y anastomosis. *Surg Gynecol Obstet* 1959;109:473–8. Copyright © Elsevier.)

Combined pancreaticoduodenal injuries, particularly those involving the head of the pancreas and the C-loop of the duodenum, are more common in patients who have suffered penetrating wounds. The general principle of management when one of these organs is severely injured and the other is not, or when both organs are severely injured but resection is not indicated, is to perform an appropriate repair for each and place closed

suction drains in the area. Enthusiasm for adding a diversion procedure has decreased significantly in recent years presumably related to the lack of perceived benefit. As these procedures have only been used in patients with the most complex injuries (severe duodenal or combined pancreaticoduodenal), it has always been true that these subgroups of patients have the most postoperative complications. Diversion procedures modulate the severity of complications, a fact overlooked by the younger generation of trauma surgeons.

Pyloric exclusion with gastrojejunostomy is the easiest and most commonly performed diversion procedure. Through a dependent gastrotomy, the pyloric muscle ring (not the prepyloric antrum) is grabbed with Babcock clamps at the 12 o'clock and 6 o'clock positions. A #1 polypropylene suture in two layers is used to close the longitudinal slit in the pylorus created by separating the Babcock clamps. An antecolic gastrojejunostomy is then performed to allow for postoperative feeding. The pylorus remains closed for 2 to 3 weeks and then reopens in 94% of individuals, thereby protecting the injured duodenum as it heals. Should a duodenal fistula occur from the breakdown of the repair, it will be an end rather than a side fistula as the pylorus is closed. All patients in whom the gastrojejunostomy is performed should be screened for the presence of *Helicobacter pylori* in the stomach before discharge. An alternate approach is to perform the "Cali" pyloric exclusion described at the Hospital Universitario del Valle, Universidad del Valle, Cali, Colombia. This modified approach involves passing a nasojejunal feeding tube through the pylorus, performing the pyloric exclusion tight against the feeding tube, and eliminating the antecolic gastrojejunostomy. The second diversion procedure is the *duodenal diverticulization* originally described in 1968. This procedure includes a truncal vagotomy, antrectomy, gastrojejunostomy, tube duodenostomy, choledochostomy, and external drainage of the duodenal repair. While accomplishing diversion of esophageal and gastric secretions away from the duodenal repair, it sacrifices normal vagus nerves and the gastric antrum/pylorus. In addition, the insertion of a choledochostomy tube into a normal 4 to 6 mm common bile duct would be considered to be unwise technically by most surgeons. The third diversion procedure is the *triple tube approach* described at Denver General Hospital in 1978. Some combination of decompressive tubes such as a Stamm gastrostomy, tube duodenostomy or retrograde jejunostomy (into duodenal C-loop) and a standard Witzel jejunostomy for

enteral feedings is inserted. Decompression of the healing duodenum is obviously achieved by proximal, local, or retrograde tube decompression, though there is a risk of associated gastrointestinal leaks from the numerous new tubes inserted for decompression or feeding.

In a review of 1,000 patients undergoing operation for a pancreatic injury in 1995, the most common procedures were simple drainage (72.6%), distal or subtotal resection (16.9%), other (7.1%), Whipple (1.8%), and diversion (1.7%).

POSTOPERATIVE MANAGEMENT

In the patients who have undergone a pancreatic resection or the rare diversion procedure because of a combined pancreaticoduodenal injury, postoperative somatostatin analog at a dose of 50 to 100 μg subcutaneously every 8 hours for 5 to 7 days is used in some trauma centers. As noted previously, there are no prospective data in favor of this approach. This agent can be administered intravenously as well, but should not be mixed with a total parenteral nutrition solution as it loses its efficacy.

Early nutritional support via a nasojejunal feeding tube or Witzel jejunostomy is imperative in the patients who needed a resection or diversion. A postoperative pancreatic fistula or abscess will increase the catabolism related to the stress of trauma, and this can be reversed more quickly with early enteral feedings.

Peripancreatic closed suction drains are left in place for 7 to 10 days after a resection or diversion is performed. Should a postoperative pancreatic fistula occur, the daily volume is monitored and the drain left in place till drainage ceases.

COMPLICATIONS AND RESULTS

In the aforementioned review of 1,000 patients with pancreatic injuries, the most common postoperative intra-abdominal complications were a pancreatic fistula in 6% (range 3% to 17%), intra-abdominal abscess in 5% (range 5% to 18%), and postoperative pancreatitis in 2% (range 1% to 13%). Mortality obviously depends on the mechanism of injury, magnitude of the pancreatic injury, and the presence of associated injuries to the gastrointestinal tract, liver, and abdominal vessels. Overall mortality in review articles is ~20% and has a wide range (stab wound 2.8% to 5%; gunshot wounds 15.4% to 22%; blunt trauma 16.9% to 19%; shotgun

wounds 46.1% to 50%). In the patients undergoing operative management of combined pancreaticoduodenal injuries, major postoperative complications in one series from 1987 included pancreatic fistulas (26%), intra-abdominal abscesses (17%), and duodenal fistulas (6%), and the overall mortality was 29.5%.

EDITOR'S COMMENT

We are honored to have Dr. Feliciano write this chapter on pancreatic trauma. He needs no introduction and is considered by all a leading authority in the management of trauma. Pancreatic injury is challenging because of the difficulty in establishing the diagnosis as well as the complexity of associated injuries. Duodenal and pancreatic injuries are uncommon, occurring in 3% to 5% of patients sustaining abdominal injuries. Injury to these retroperitoneal structures may be suspected based upon the injury mechanism and the identification of injury to organs in close proximity to the duodenum or pancreas. Approximately 75% to 85% of blunt injuries to the duodenum and pancreas are caused by motor vehicle crashes. The usual mechanism is the forceful compression of these fixed retroperitoneal organs between the vertebral column and steering wheel or seatbelt. Falls and assaults account for the remainder of blunt injuries to these organs. Blunt duodenal and pancreatic injury may also result from bicycle accidents in which the duodenum and pancreas are crushed between the spinal column and bicycle (or motorcycle) handlebar. Penetrating injures may occur as well. Gunshot wounds are more common that stab wounds.

Associated injuries are common. In a review of 1,153 cases of duodenal injury by Asensio et al. (Management of duodenal injuries. *Curr Probl Surg* 1993;30:1023–93.), there were 3,047 associated injuries. The liver was the most commonly injured organ, accounting for 17%, duodenum and pancreas (12%), small bowel (12%), colon (12%), and stomach (9%). A second review by Asensio et al. (Management of pancreatic injuries. *Curr Probl Surg* 1999;36:325–419.) included 3,465 injuries involving the pancreas. In this report, there were 7,526 associated injuries. The liver was also the most commonly injured, accounting for 19% of associated injuries followed by the stomach (16%), spleen (11%), colon (8%), and duodenum (8%). The close proximity of the major vascular structures to the pancreas and duodenum, including the aorta, vena cava, and portal vein, predisposes them to associated injury with subsequent exsanguinating hemorrhage. In the first review discussed above, major abdominal veins were injured in 10% of patients, mostly involving the inferior vena cava, and major arteries (usually the aorta) were injured in 7% of patients. Penetrating injury is more likely to result in vascular injury, with one review documenting that 37% of patients with penetrating pancreatic injury had major vascular injuries (Vasquez JC, Coimbra R, Hoyt DB, et al. Management of penetrating pancreatic trauma: an 11-year experience of a level-1 trauma center. *Injury* 2001;32:753–9). Stone and Fabian reported that major venous injuries were present in 20% of patients with blunt duodenal injury, but

there were no associated arterial injuries (Stone HH, Fabian TC. Management of duodenal wounds. *J Trauma* 1979;19(5):334–9).

I think it will be helpful to review the classification of duodenal and pancreatic injuries. The most widely used injury classification system is from the American Association for the Surgery of Trauma (AAST) (Moore EE, Cogbill TH, Malangoni MA, et al. Organ injury scaling, II: Pancreas, duodenum, small bowel, colon, and rectum. *J Trauma* 1990;30:1427–9). It should be emphasized that injury management is not dictated by grade, yet such injury scales provide a standard way to describe and communicate the severity of injury. Injury severity is based on findings of computed tomography or during exploratory laparotomy.

Duodenal Injury Scale

- Grade I: Hematoma involving a single portion of duodenum or partial-thickness laceration without perforation
- Grade II: Hematoma involving more than one portion or disruption of <50% circumference or major laceration without duct injury or tissue loss
- Grade III: Laceration with disruption of 50% to 75% circumference of second portion or disruption of 50% to 100% circumference of first, third, and fourth portions
- Grade IV: Laceration with disruption of >75% circumference of second portion or involving ampulla or distal common bile duct
- Grade V: Massive laceration with disruption of duodenopancreatic complex or devascularization of duodenum

Pancreas Injury Scale

- Grade I: Minor contusion without duct injury or superficial laceration without duct injury
- Grade II: Major contusion without duct injury or tissue loss or major laceration without duct injury or tissue loss
- Grade III: Distal transection or parenchymal/duct injury
- Grade IV: Proximal transection or parenchymal injury involving ampulla
- Grade V: Massive disruption of the pancreatic head

Grade I and II injuries are the most common. With these injuries, nonoperative management is safe and preferred. Contrarily, nonoperative management is not supported for penetrating injuries. Regardless of the mechanism of injury, patients with pancreatic duct disruption require intervention. At exploration, the pancreas may exhibit a hematoma and this should be explored. It is very difficult to diagnose pancreatic ductal injury at the time of exploration in this type of injury, and hence, it is advisable to place a closed suction drain over the pancreas.

Nonoperative management includes gastrointestinal decompression and

nutritional support. For patients with obstructing duodenal hematoma, a nasogastric tube is placed and parenteral nutrition initiated. Imaging should be repeated 5 to 7 days after the injury. If the obstruction has resolved, an oral diet can be initiated. After 14 days, if the obstruction is still present, laparotomy is warranted. Careful follow-up is essential to monitor for complications that indicate the need for surgical exploration.

Velmahos GC et al. (Velmahos GC, Tabbara M, Gross R, et al. Blunt pancreatoduodenal injury: a multicenter study of the Research Consortium of New England Centers for Trauma (ReCONECT). *Arch Surg* 2009;144(5):413–9) support the role of nonoperative management. They reported a retrospective multicenter study evaluating the outcomes of 230 patients with blunt pancreatic and/or duodenal injury. They found that of the 97 patients managed nonoperatively, 10 patients (6 pancreatic, 3 duodenal) failed nonoperative management and required surgery.

As described by Dr. Feliciano, in those patients who require operative intervention, the initial consideration is stabilization of the patient and then laparotomy. Management of the injury is based on the finding as described in the chapter. In my opinion, for transection, the distal pancreas should be resected in the stable patient. If the patient is unstable, it may be prudent to close the proximal pancreatic stump and place a pediatric feeding tube or other silastic catheter to exteriorize and control the drainage of the distal pancreas with a planned pancreaticojejunostomy in 3 months. Doing a pancreaticojejunostomy in the acute setting is difficult at best and likely to result in a pancreatic fistula and will take too much time exposing the patient to the cold environment of the OR and delay stabilization and continued resuscitation in the ICU. Likewise, this is no time for the surgeon to do a Whipple procedure unless needed to control bleeding and, then it may be a better option to do damage control and come back another day to do the reconstruction.

E. Christopher Ellison

129 Splanchnic Denervation of the Pancreas for Intractable Pain

Joshua S. Tierney, Gary C. Vitale, and Keith D. Lillemoe

INTRODUCTION

The management of intractable pain can be one of the most challenging aspects of caring for patients with either chronic pancreatitis or pancreatic cancer. The pancreas is innervated by the autonomic nervous system for the neurohormonal regulation of the organ's endocrine and exocrine function. The visceral afferent pathway of these autonomic nerves transmits pain in the diseased state. Past research regarding the precise etiology of pancreatic pain has focused on two main theories: pancreatic ductal hypertension and inflammatory damage of the intrapancreatic nerves, more recently termed *pancreatic neuritis.* The former is often a component of the pain in chronic pancreatitis, which provides the rationale for treatment with endoscopic and surgical drainage procedures of the pancreatic duct. Pancreatic neuritis is a result of inflammatory and/or malignant cells that infiltrate and damage intrapancreatic nerves, thereby stimulating the afferent pain pathways. Studies have shown that the intensity of abdominal pain correlates with increasing levels of malignant or inflammatory cell infiltration into the perineural tissues of the pancreas in patients with both pancreatic malignancy and chronic pancreatitis. These two theories fail to account for various complexities such as the upregulation of pain mediators, neurohormonal changes, and abnormal feedback mechanisms (i.e., sensitization) that develop over time in patients with chronic pain. The anatomic basis of pancreatic pain is afferent nociceptive nerve endings in the pancreatic parenchyma that are stimulated by inflammation, high pressure, ischemia, and exposure to pancreatic proteases. The long processes of these nerve endings pass first through the celiac plexus and then coalesce through the greater (T5 to T9), lesser (T10 to T11), and least (T12) splanchnic nerves in the thorax to the nociceptive neuron located in the dorsal root of the spinal cord. The pain signal is then transmitted via second- and third-order neurons in the central nervous

system. Techniques to interrupt the pain signal through the celiac plexus and splanchnic nerves are the focus of this chapter.

The pain is typically in the upper epigastrium and radiates toward the T12 to L2 region of the lower spine. It is described as sharp, dull, or boring in quality and can be exacerbated by eating. There is often associated nausea, anorexia, weight loss, and depression. Significant variability exists from patient to patient regarding the nature and severity of the pain, highlighting the importance of an individualized approach to treatment. Patients with chronic pancreatitis can have one of two pain patterns: either short, relapsing episodes of pain lasting days to weeks separated by pain-free intervals or a more prolonged course with unremitting and severe pain. Patients with chronic pancreatitis were once thought to enter a “burn-out” phase where late in the course of their disease the pain gradually abates as the pancreas atrophies and looses function, but recent prospective studies suggest that the pain actually becomes more resistant to treatment later in the course. For patients with pancreatic cancer, the pain is initially poorly localized and can vary in nature and severity from day to day and week to week. As the disease progresses, the pain often becomes unremitting and severely debilitating, with studies suggesting that patients with poorly managed pain have shorter survival. The development of effective treatment strategies for chronic pain of pancreatic origin is central to improving the quality of life and well-being for these patients.

ANATOMY

The celiac ganglion innervates the upper abdominal viscera and is the largest plexus of nerves in the abdominal aortic sympathetic plexus. It contains both preganglionic and postganglionic sympathetic fibers, preganglionic parasympathetic fibers, and visceral afferent (pain) fibers. The celiac plexus is composed of bilateral celiac ganglia, located in front of and on both sides of the abdominal aorta at the level of the celiac artery. Plexus fibers cross in front of the aorta both above and below the celiac axis. Organs innervated by the celiac ganglia include the stomach, liver, gallbladder, pancreas, adrenal glands, kidneys, and intestines to the level of the transverse colon. The sympathetic plexus ganglia vary in number from one to five on each side of the aorta, and range from an aggregate size of 0.5 cm to 4.5 cm. Without extensive dissection, the origin of the celiac artery can be identified intraoperatively by palpation of the common hepatic and splenic arteries, the two most consistent arterial branches off

the celiac artery. Radiographically, the plexus can be found by identification of both the celiac and superior mesenteric arteries.

The splanchnic nerves, usually three (greater, lesser, and least), consist primarily of preganglionic sympathetic and accompanying visceral afferent fibers. These nerves vary much in their origin; however, the greater splanchnic nerves usually arise from the 5th through 9th thoracic ganglia (Fig. 129.1). The unison of these roots forms a nerve of considerable size (larger than the continuation of the sympathetic trunk into the abdomen) that descends on the front of the vertebral column and pierces the muscular part of the diaphragm to end in the celiac ganglion. The lesser splanchnic nerve usually arises from the 9th and 10th (and sometimes 11th) thoracic sympathetic ganglia. It runs parallel and medial to the greater splanchnic nerve but lateral to the sympathetic trunk. The least splanchnic nerve is identifiable in some patients and arises from the last thoracic sympathetic ganglia at T11 or T12. The nerve trunks are constituted at or above the level of the 10th thoracic vertebra, and descend along the spine where they are bound by the parietal pleura. The lesser splanchnic nerve generally supplies the submesenteric organs and forms from the trunks of the 10th and 11th thoracic ganglia and runs parallel to the greater splanchnic nerve in the chest. All nerves penetrate the crus of the diaphragm and enter the abdomen. The greater splanchnic nerve ends in the celiac ganglia, the lesser splanchnic nerve ends in the aorticorenal ganglion, and the least splanchnic nerve in the renal plexus. The vagus nerves run in the lower thoracic cavity along the esophagus below the parietal pleura. The role of the vagal fibers in the transmission of pain sensation from the pancreas is unclear. Bilateral vagotomy has been advocated in early series of celiac plexus neurolysis (CPN) as a method of increasing the completeness of splanchnic denervation. Currently, most surgeons limit their operation to the splanchnic nerves as the postvagotomy sequelae of delayed gastric emptying and diarrhea can often be formidable.

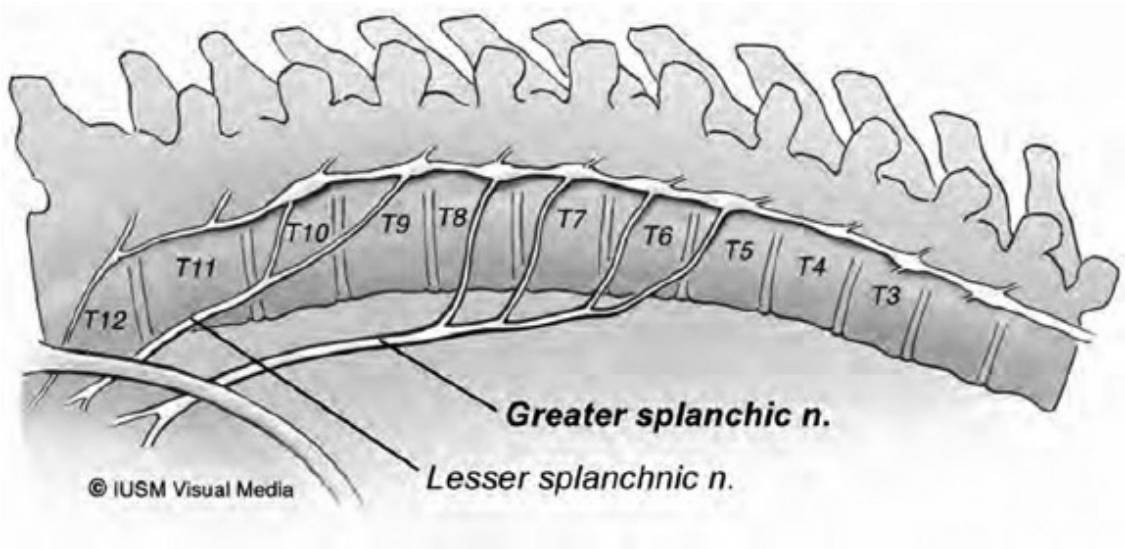

Figure 129.1. Diagram showing the standard location of the greater splanchnic nerve as viewed through the right chest in the prone position. It is composed of the rami communicans of the 5th through the 8th thoracic sympathetic ganglia, funneling down toward the diaphragm. The lesser splanchnic nerve is derived from fibers arising from the 9th and 10th thoracic sympathetic ganglia and courses parallel to the greater splanchnic nerve.

PAIN MANAGEMENT AND INDICATIONS FOR SPLANCHNIC DENERVATION OF THE PANCREAS

Chronic Pancreatitis: The initial management of pain in patients with chronic pancreatitis begins with imaging studies to identify any readily treatable complications, such as pancreatic pseudocysts, biliary or duodenal strictures, or cancer. In addition, it is important to identify patients with a dilated pancreatic duct, with or without pancreatic duct strictures or stones, who may be candidates for endoscopic or surgical drainage procedures. Surgical drainage has been shown to be more effective and durable than endoscopic stenting in this setting. The importance of alcohol abstinence and a low-fat diet must be stressed to the patient. A trial of pancreatic enzyme supplementation is often advocated as a pain relief adjunct to reduce the native production of pancreatic proteases, but the benefit is usually limited. A step-wise approach to pharmacologic pain relief is recommended, beginning with nonsteriodal anti-inflammatory drugs (NSAIDs) and adding opioids as needed in increasing potency and frequency until adequate relief is achieved. Using multimodal therapy with antidepressants and gabapentoids in an effort to reduce opioid use is recommended. Pregablin is the only adjunct that has

been shown to reduce pain and opioid use for patients with chronic pancreatitis in a randomized controlled trial. The medical management of pain in chronic pancreatitis is summarized in a position statement by the American Gastroenterologic Association (AGA) (see Table 129.1).

Failure of the above measures to provide extended symptomatic relief should lead to the consideration of surgical management as guided by the anatomic features of the gland. With careful patient selection, a 70% to 80% long-term success rate in achieving postoperative pain control can be anticipated. There are little data to support concomitant use of CPN during pancreatectomy or drainage procedures for chronic pancreatitis. If in the end all medical, endoscopic, and surgical measures have failed to provide relief, consideration is then given to performing bilateral thoracoscopic splanchicectomy (BTS). At our institution, this procedure is usually reserved as a rescue option for patients who have failed surgical management, but for those who are high-risk surgical candidates or otherwise refuse surgery, it can be offered earlier in the treatment algorithm. Endoscopic ultrasound-guided celiac plexus block (EUS-CPB) is also an option and readily employed in some centers even as an adjunct prior to consideration of surgery. The efficacy of EUS-CPB is limited to up to 10 weeks of pain relief and thus can require many repeated interventions. Celiac plexus block (CPB) refers to the instillation of long-acting local analgesic (usually 0.1% bupivacaine with or without the addition of a steroid) to temporarily inhibit function of the celiac plexus function thereby reducing pain, whereas CPN refers to injections of absolute ethanol to permanently destroy nerve fibers in order to facilitate longer pain relief. CPN induces a dense fibrotic process that could complicate future surgery and is thus not usually employed in the setting of chronic pancreatitis.

In our experience, currently in press, BTS is less effective in achieving resolution of abdominal pain and reduction in opioid use in patients with chronic pancreatitis than in the population with pancreatic malignancy. We performed BTS in 75 patients with chronic pancreatitis from July 1998 to March 2016. After 32 months follow-up, 57% of patients still experienced abdominal pain and only 32% of patients had a reduction in opioid use. This likely has to do with the longer length of time patients live with chronic pancreatitis. This long duration of chronic pain and opioid use promotes the sensitization of pain pathways to essentially become stuck in the “on” position independent from stimulus. Some patients still have pain

even after the most aggressive measures such as total pancreatectomy. This has led some surgeons to advocate for early surgical treatment of chronic pancreatitis before sensitization has occurred. A few retrospective studies support this, showing improved outcomes when surgical treatment occurs within 3 years of the diagnosis. A recent systemic review from 2104 examined outcomes of 484 patients from 16 studies who underwent BTS for chronic pancreatitis and found that preoperative opioid use was associated with worse postoperative pain scores suggesting that early BTS prior to sensitization will improve outcomes in this patient population. More research is needed to elucidate the most effective timing for surgery and splanchnic denervation for pain relief in chronic pancreatitis.

TABLE 129.1 American Gastroenterologic Association (AGA) Medical Position Statement on the Treatment of Pain in Chronic Pancreatitis

Initial therapy			
Abstain from alcohol	Nonnarcotic analgesics	Low-fat diet	Quality of life questionnaire
No response			
	Gastric acid suppression	8-week trial of high-dose pancreatic enzymes	
No response			
	Consider endoscopic therapy		
No response			
Watchful waiting versus narcotic analgesics versus surgery			
Surgery decided			
Small ducts		Large ducts	
Nerve ablation		Surgical Drainage	
Pancreatic resection			

Pancreatic Cancer: Survival of patients with locally advanced, unresectable pancreatic cancer is 6 to 12 months while patients with metastatic disease to the liver or peritoneal cavity survive approximately 3 to 6 months. The preferred initial pain management in these patients includes the use of transdermal or long-acting narcotic analgesics to provide a steady-state basal plasma level, supplemented with the intermittent use of short-acting narcotic analgesics for breakthrough pain. As in medical treatment of chronic pancreatitis, antidepressant medications

are also used as an adjunct to pain medication in patients with pancreatic cancer. The majority of patients with advanced pancreatic cancer will have pain requiring increasing doses of opioid analgesics during the course of their illness. EUS-CPN, image-guided CPN, or BTS are three minimally invasive neurolytic procedures that are commonly employed in this setting.

The trials comparing the efficacy of CPN versus BTS are either nonrandomized or small in size and have not clearly identified superiority of either procedure. The choice of which to employ is dependent on local expertise. EUS-CPN has been shown to have reduction in pain scores in 70% to 80% patients with pancreatic malignancy, but studies have failed to demonstrate a reduction in opioid use. Minor complications such as diarrhea and transient hypotension occur in 21% and the risk of serious complications is approximately 0.2% and includes reports of serious bleeding, visceral injury, and one report of paralysis from spinal cord ischemia. A systematic review examined the efficacy and safety of non–EUS-guided CPN compared with standard treatment in five randomized controlled trials involving 302 patients with unresectable pancreatic cancer (four computed tomography [CT] or fluoroscopy-guided CPN trials, one intraoperative CPN). The primary outcome of pain was lower in the CPN group on a visual analog scale (VAS) at 2, 4, and 8 weeks (weighted mean difference [WMD], 0.60; 95% confidence interval [CI], −0.82 to −0.37). Opioid usage (in mg/dL oral morphine) was also reduced at 2, 4, and 8 weeks (WMD, 85.9, 95% CI, −144.0 to 129.9). Our experience with BTS in 48 patients with pancreatic malignancy found that after 8 months follow-up, only 27.6% of patients had ongoing abdominal pain after the procedure and 67% had weaned off opioids completely. Complications from BTS are rare and reported to be between 4% and 16% and include chylothorax and pneumothorax.

In patients where the tumor is found to be unresectable at the time of laparotomy, intraoperative chemical CPN should be done in conjunction with appropriate surgical palliative procedures such as biliary bypass and/or gastrojejunostomy. This procedure is indicated whether or not the patient has significant pain at the time of surgery as the natural history of the disease includes pain that becomes progressively more severe and unrelenting as the malignancy progresses. The same technique is applicable whether the tumor arises in the head, body, or tail of the gland. The data do not support prophylactic CPN in patients who undergo a complete R_0 surgical resection despite the fact that almost 50% of such

patients will eventually develop retroperitoneal tumor recurrence as a component of disease relapse and pain recurrence with this development. This question was definitively answered in 2015 with the first prospective, randomized, double-blind placebo controlled trial by Yeo and colleagues comparing ethanol CPN to saline injection in 467 patients with resectable pancreatic malignancy. They found no statistically significant difference in pain between preoperative baseline and at 12 months follow-up between the two groups.

OPERATIVE TECHNIQUES

Open CPN

Open CPN has become a standard approach to pain management in patients with advanced, unresectable pancreatic cancer who require laparotomy to perform palliative bypasses or for patients who were either found to be unresectable at laparotomy or found to have occult metastatic disease. The procedure was first described by Copping and colleagues in 1969. In an update of their series in 1978, including 41 patients with pain due to pancreatic cancer, 88% of patients experienced relief of pain postoperatively. Most patients underwent palliative biliary and gastrojejunal bypass at the same operation. These results were compared with a group of historic controls in which only 21% of patients had pain control after similar palliative procedures. Since that time, this procedure has been advocated by a number of authors in anecdotal reports describing successful control of pain in the majority of patients. In 1993, a prospective, randomized, placebo-controlled study of this treatment was completed with results demonstrating that open chemical neurolysis with a 50% alcohol solution significantly reduces or prevents pain in patients with unresectable pancreatic cancer when compared with a placebo injection with saline. This beneficial effect was observed in all randomized patients including both subgroups of patients, those with and without preoperative pain. Interestingly, this study also showed a significant improvement in survival in patients with significant preoperative pain who received the alcohol neurolysis when compared with placebo, implying that better pain control and a reduced requirement for narcotic analgesics may prolong survival as well as improve the quality of life in patients with end-stage pancreatic cancer.

Through an upper midline or bilateral subcostal incision, the abdomen is entered and careful assessment of the tumor for resectability is done.

After determining that the cancer is unresectable, the operating surgeon's focus should switch from aggressive tumor extirpation to palliation. After completion of the appropriate operative bypasses of the biliary system and/or gastric outlet, chemical neurolysis should be considered. Forty milliliters of a 50% alcohol solution is prepared in a sterile fashion by diluting 20 cc of absolute ethanol with 20 cc of sterile injectable saline solution (1:1). A 20-cc syringe with a 22-gauge spinal needle is used for delivery of this solution to the para-aortic tissues. The lesser omentum is incised over the bare area and the celiac axis can be palpated through the retroperitoneum as it arises from the aorta, behind the stomach, near the diaphragmatic crura. A palpable thrill due to the high blood flow through the celiac axis is usually apparent. The operating surgeon, using his or her left hand, then straddles the celiac axis putting the index finger on the splenic artery and the middle finger on the common hepatic artery while stabilizing this orientation with the thumb on the left side of the abdominal aorta (Fig. 129.2). The 22-gauge spinal needle is then advanced into the soft tissue on both sides of the aorta—both below and above the level of the celiac artery (10 cc of 50% alcohol solution is injected into all four quadrants). Both before and episodically during the injection, the syringe should be aspirated to ensure that the inferior vena cava, coronary vein, aorta, or adjacent lumbar vessels have not been inadvertently cannulated. If blood flow is obtained with this maneuver, simply withdraw the needle, reposition, aspirate again, and resume infiltration of the ethanol solution into the para-aortic soft tissue. Instillation of at least 40 cc of 50% ethanol solution is considered necessary in order to achieve an adequate celiac neurolysis.

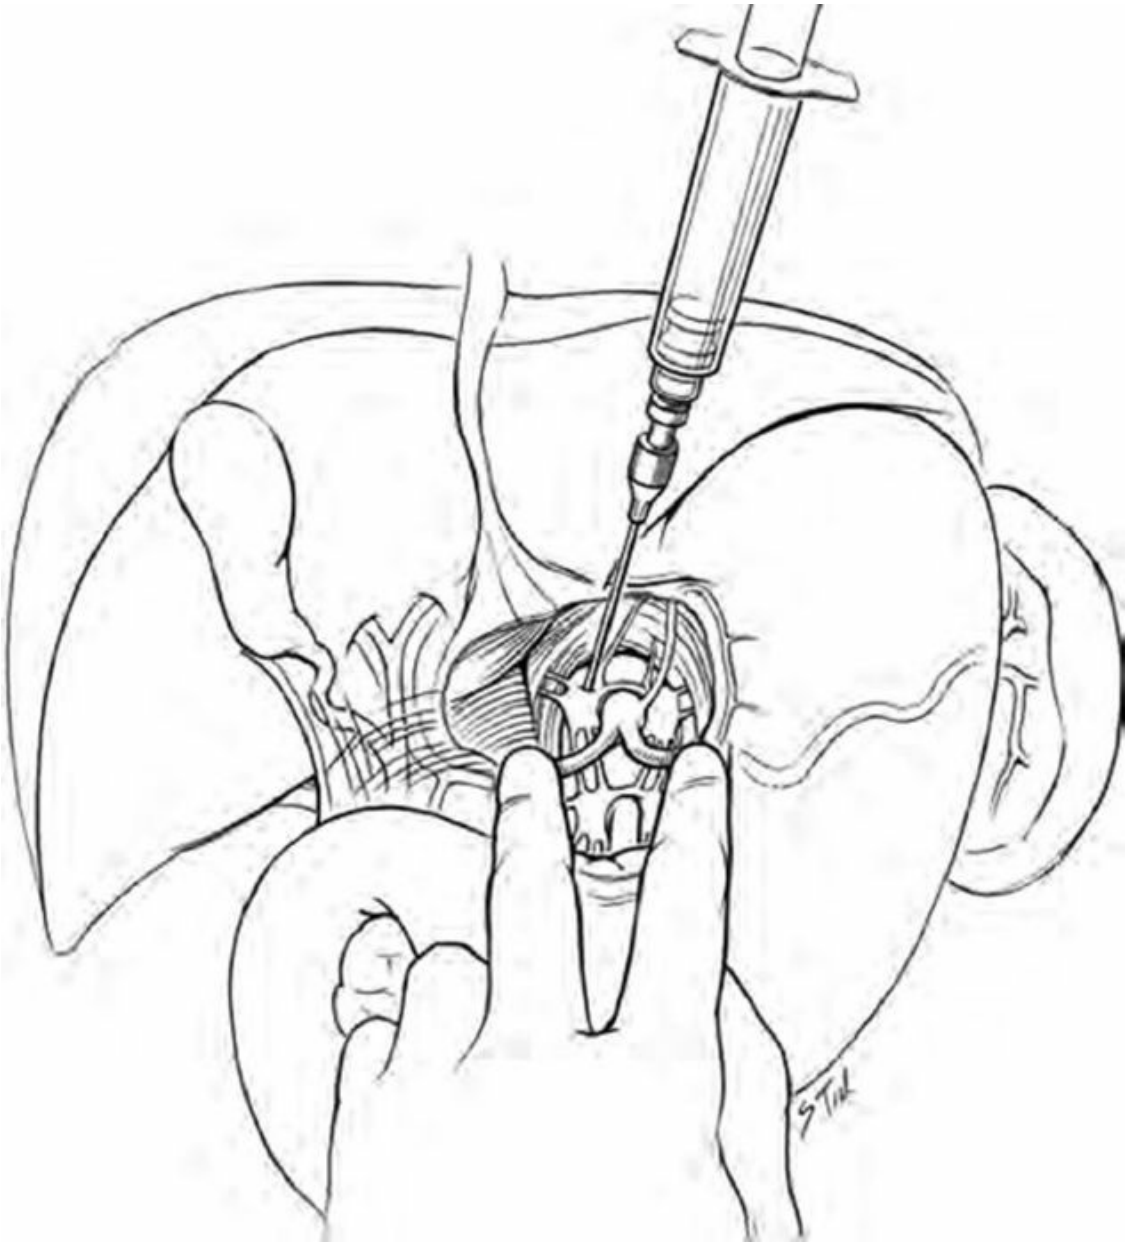

Figure 129.2. Intraoperative celiac plexus neurolysis. After incising the avascular area of the hepatogastric ligament, the celiac trunk is palpated by placing the surgeon's left index finger on the splenic artery and the left third finger on the common hepatic artery while steadying their hand by abutting their thumb to the left lateral aspect of the aorta. The surgeon's right hand uses the 10-cc syringe to inject 50% ethanol into four quadrants around the celiac axis.

After completing the injection in all four quadrants, the sites are inspected for hemostasis. If minor bleeding is observed, the area is packed and compressed for a short period of time. At the time of injection, the anesthesiologist should be notified of the procedure. Occasionally, with an

adequate sympathetic blockade, some degree of hypotension may be observed. This situation can generally be managed easily by the anesthesiologist giving additional intravenous fluids or the judicious use of pharmacologic blood pressure support. As a general rule, CPN is quite well tolerated with fewer complications, and it requires no alteration in the postoperative management of patients undergoing laparotomy and palliative bypass procedures for unresectable pancreatic cancer. Mild complications include bleeding and postural hypotension, both are generally self-limiting and easily managed. Bleeding can generally be controlled by direct pressure intraoperatively. During the first attempts at postoperative ambulation, the patient should be observed for any evidence of orthostatic hypotension. However, this effect, if noted at all, is seldom long lasting. In patients who have only had exploration and biopsy for tissue diagnosis in which a CPN is also done, oral intake can be resumed as tolerated, and the patient can be discharged as soon as possible after the procedure. Serious complications are rare but include diarrhea, gastroparesis, chylothorax, retroperitoneal abscess, superior mesenteric vein thrombosis, extradural abscess, and reversible paralysis. There has been a single case report of paraplegia after CPN.

The predominant reasons for failure of pain control following CPN are either poor localization of the injection to the celiac plexus or use of an inadequate volume of neurolytic agent. With large tumors involving the pancreatic neck/proximal body, or tumors with extensive associated celiac lymphadenopathy, identification of the appropriate intraoperative anatomy is often problematic and these patients are often better approached percutaneously using CT guidance as a separate procedure after recovery from the operation. Pain relief even with a successful CPN will often be poor when the tumor is extensive enough to involve somatically innervated sites in the abdominal wall, Glisson capsule, or the diaphragm.

Bilateral Thoracoscopic Splanchnicectomy

The transthoracic approach for pancreatic splanchnic denervation has gained increasing popularity particularly in today’s era where endoscopic stenting technology and expertise have, in many cases, obviated the need for palliative gastrojejunostomy and/or biliary bypass in patients with unresectable pancreatic malignancy and intractable pain. Pancreatic denervation to interrupt the flow of painful stimuli from the pancreas through the central nervous system has conceptually intrigued surgeons

since its first report by Mallet-Guy in 1943. The ability to relieve pain from chronic pancreatitis with a single therapeutic intervention without disrupting the pancreas or digestive tract or reoperating through a scarred abdomen remains an extremely attractive option for these patients as well. In 1993, two groups combined the theories of Mallet-Guy with the technology of video thoracoscopy to report on the use of thoracoscopic splanchnicectomy to treat the pain from pancreatic cancer. This provided the surgical community a simple, straightforward procedure to address the vexing problem of pain from advanced pancreatic malignancy. The operation was extended to patients with chronic pancreatitis, modified to include bilateral nerve ablation through a posterior approach, and patients were screened by the use of a differential epidural anesthetic to identify those individuals who would have a high likelihood of success with the procedure.

Our technique of BTS is similar to that as described in a report by Jones et al. The procedure is performed under general endotracheal anesthesia using a single lumen endotracheal tube. Early in our experience we used a double lumen tube for dual lung ventilation, but we have found that insufflation of the thorax is sufficient to provide working space without the necessity of having an anesthesia team facile in placement of a double lumen tube. An orogastric tube is placed to decompress the stomach, which when distended can elevate the left diaphragm and obscure exposure. Patients are placed in the prone position with arms extended and flexed at the elbow. Great care is taken to adequately pad all pressure points. With respirations suspended by the anesthesia provider, a 5-mm trocar is placed at the inferior scapular apex on the side chosen to begin the procedure (Fig. 129.3). Carbon dioxide is insufflated to achieve a target pressure of 8 mm Hg. After confirmation of trocar placement with a 30-degree 5-mm thoracoscope, respirations are resumed and a second trocar is placed two intercostal spaces below and 2 cm anterior to the first trocar under direct vision. After the splanchnic nerves are identified inferior and medial to the sympathetic trunk, the pleura is incised on both sides of each of the nerves using the heal of the right angle cautery. The tip of the right angle is then used to elevate and divide each of the nerves. Occasionally, mediastinal fat or thickened parietal pleura due to prior pleural disease (effusions, inflammation) obscures identification of the nerves. In this situation, we open the entire length of the mediastinal pleura in a cephalad-to-caudad direction perpendicular to the vertebral bodies. The greater

splanchnic nerve is then identified by following small ramus fibers from the 5th to 8th sympathetic ganglia up to where they coalesce into the main trunk. The trunk of the greater splanchnic nerve is then divided with the hook electrocautery (Fig. 129.4). The dissection of the mediastinal pleura then is continued inferiorly to the diaphragm to expose rami communicans from the 8th to 12th intercostal space (lesser and least splanchnic nerves). These small branches are then disrupted using the hook electrocautery when identified. We try to limit inferior mediastinal dissection on the right side when possible as the thoracic duct resides in this location and can be vulnerable to injury. Some surgeons advocate for the division of the main sympathetic truck, but we have found this to be unnecessary and is prone to troublesome venous bleeding. If bleeding is encountered, direct pressure with a laparoscopic Kittner is usually sufficient to achieve hemostasis. Resisting the urge to coagulate bleeders with electrocautery is good advice as this will sometimes result in more profuse bleeding. After successful splanchnicectomy, insufflation is released, the working port trocar is removed and the lung is reinflated under direct vision, then finally the camera trocar is removed. Port sites are closed with a deep layer 3-0 Vicryl suture and the skin is closed with 4-0 Vicryl suture, and then the procedure is repeated on the contralateral side. The usual operative time is 20 to 30 minutes per side. A chest x-ray is obtained immediately in the postanesthesia recovery unit and then again on the morning of the first postoperative day to check for an immediate and delayed pneumothorax, respectively.

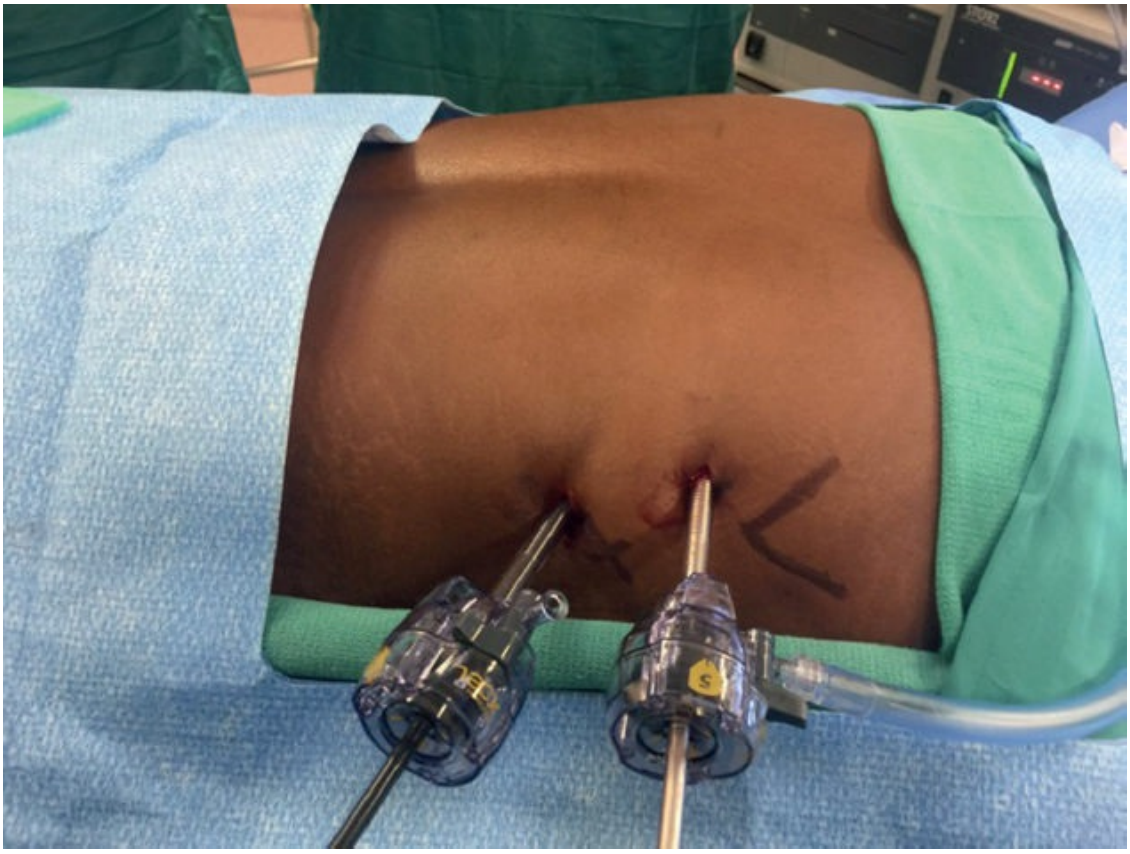

Figure 129.3. This image shows the trochar positioning for bilateral thoracoscopic splanchnicectomy. In our setup, we use the rib space just caudal to the tip of the scapula as the landmark (marked with a “V” in the picture) for placement of the first 5-mm port for the camera. The second 5-mm working port is placed one rib space caudal and slightly anterior to the camera port.

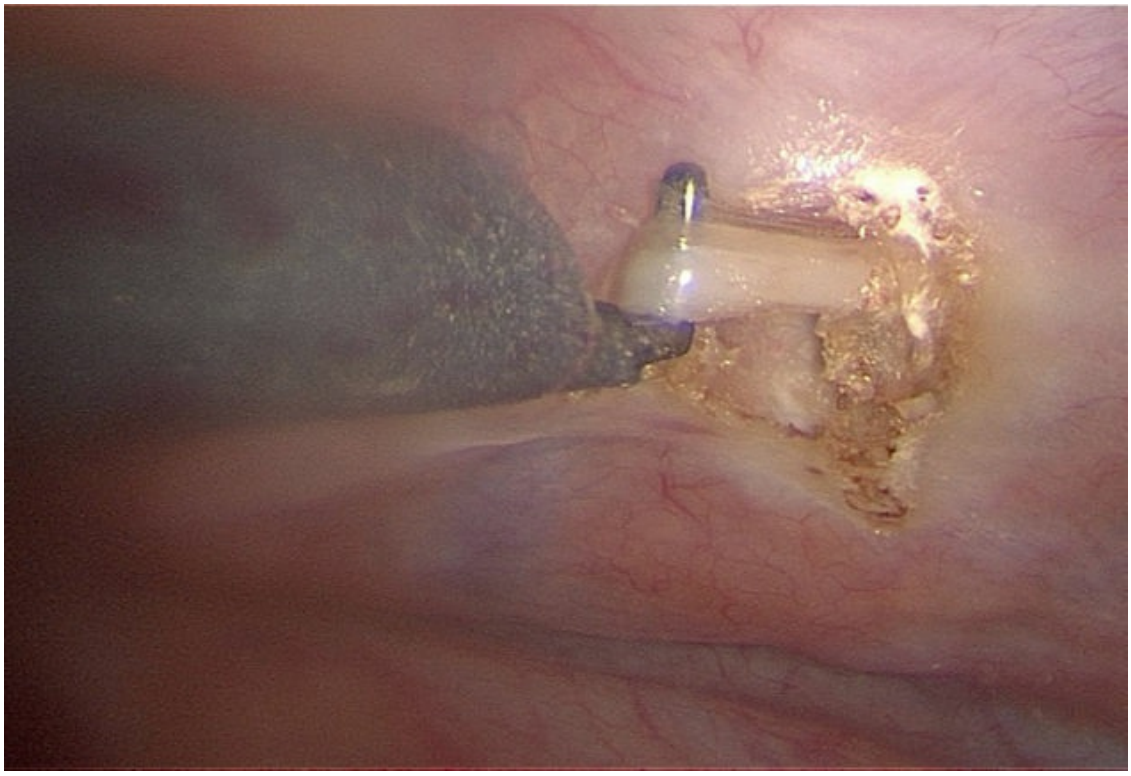

Figure 129.4. Intraoperative photo demonstrating our technique using the hook cautery to dissect and transect the splanchnic nerves.

Perioperative morbidity rate in our own series of 123 patients from June 1998 to March 2016 was low at approximately 4%. These consisted of 1 chylothorax requiring reoperation, 1 persistent pneumothorax, and a total of 3 other patients who required chest tubes for pneumothoraces. The postoperative hospital stay for most patients is short at 12 to 24 hours, usually only requiring one night in the hospital. The 30-day readmission rate was 8% for the pancreatic malignancy group and 5% for the chronic pancreatitis group. There were no deaths and no conversions to open thoracotomy. These low rates of morbidity were confirmed in a systematic review in 2008 of 302 patients undergoing BTS for chronic pancreatitis, which found an overall morbidity of 16.6%, a 1.3% conversion rate to open thoracotomy, a 1.3% reoperation rate to manage complications, and a 0% mortality. The most common causes of failure from this operation are either misidentification of the greater splanchnic nerve or incomplete mobilization of the nerve (particularly T7 and T8 in the inferior part of the dissection) to ensure that all rami communicans through the splanchnic nerve to the abdomen are ablated.

This systemic review from 16 published series on outcomes of BTS in

patients with chronic pancreatitis found a success rate of 90% during the first 6 months, but these rates diminished with the length of follow-up evaluation to approximately 50% at 3 years. In the more recent systemic review from 2014, analyzing opioid use and BTS in patients with chronic pancreatitis that was mentioned earlier in the chapter found a median success rate of 62% in this patient population. These results are more in line with our group's experience that both the short- and long-term success of BTS is generally poor in chronic pancreatitis with only 57% initial success rate of pain reduction and only 32% of patients being off opioids at long-term follow-up. This is in stark contrast to outcomes of BTS in the population with pancreatic malignancy where we have found outcomes of pain palliation and opioid reduction to be excellent. It is now recognized that patients who have become sensitized to opioid pain medications preoperatively have less successful long-term pain control likely related to a permanent hyperalgesic state that is not ameliorated by splanchnicectomy. This highlights the importance of proper timing and patient selection when BTS is considered for treatment of chronic pain in patients with pancreatic malignancy or chronic pancreatitis. Although when successful, pain palliation has been associated with improvement in these patients' quality-of-life indices.

CONCLUSION

Splanchnic denervation has a role in managing intractable pancreatic pain in properly selected patients with pancreatic malignancy and chronic pancreatitis.

EDITOR'S COMMENT

The authors present a very pragmatic view of pancreatic pain and its management. In preparing this commentary, I found an excellent article that reports consensus information. I highly recommend that the interested reader review this article. A recent publication by the United European Gastroenterology Group (Löhr JM, Dominguez-Munoz E, Rosendahl J, et al. United European Gastroenterology evidence-based guidelines for the diagnosis and therapy of chronic pancreatitis (HaPanEU). *United European Gastroenterol J* 2017;5:153–99) summarizes the answers of 12 multidisciplinary review groups to 101 questions. The consensus opinions were arrived at by an extensive review of the literature by this group of European authorities. In response to questions on pancreatic pain in chronic pancreatitis (CP), they concluded in the article:

1. The most disabling and dominant symptom in patients with chronic pancreatitis is pain. It is usually the first symptom. **(GRADE 1B, strong agreement)**
2. There is no evidence to support "burnout" of those pain symptoms in all patients with ongoing chronic pancreatitis. Although some reports describe this phenomenon, it is extremely variable and shows no consistent pattern. **(GRADE 2C, moderate agreement)**
3. There is no convincing evidence that the development of endocrine and exocrine pancreatic insufficiencies is associated with pain relief and "burnout." (**GRADE 2C, moderate agreement)**
4. Quality of life is reduced by pain intensity and the pain pattern over time (constant vs. intermittent pain). **(GRADE 1A, strong agreement)**
5. In the individual patient, pancreatic and extrapancreatic complications may contribute to pain and should be thoroughly investigated, particularly if pain symptoms are worsening. **(GRADE 1B, strong agreement)**
6. Cessation of alcohol and possibly smoking will improve pain in CP. **(GRADE 1B, moderate agreement)**
7. Pancreatic enzyme supplementation is not effective in alleviating pain in CP. **(GRADE 1B, moderate agreement)**
8. Antioxidants are not recommended for pain treatment in CP. Although there was one study in India that supported this treatment, it could not be reproduced in the west. This is thought to be due to the difference in etiologies of CP (tropical calcific pancreatitis in India and alcohol-related etiology in the United States). **(GRADE 1B, moderate agreement)**
9. Pain in CP should be assessed using an approach that should include evaluation of pain intensity, pain pattern, and its impact on daily function and QoL. **(GRADE 1B, strong agreement)**
10. The standard guideline for medical analgesic therapy in CP follows the principles of the "pain relief ladder" provided by the World Health

Organization (WHO). **(GRADE 1B, strong agreement)**

11. Treatments such as EUS-guided plexus block, splanchnic nerve block, spinal cord stimulation, transcranial magnetic stimulation, and acupuncture may be effective in selected cases of painful CP. The paper references use of intrathecal morphine pumps and spinal cord stimulation. **(GRADE 1C, moderate agreement)**
12. Resection, decompression, or mixed surgical techniques achieve pain relief that is maintained over time in approximately 80% of patients. However, the conclusion was that as studies were not sham-controlled, the effect of surgery is still debatable. **(GRADE 1B, strong agreement)**

It is apparent that pain continues to be a major factor in causing disability in chronic pancreatitis. There is no "silver bullet" that is effective correcting the pain associated with this condition. A multidisciplinary approach is highly recommended.

E. Christopher Ellison

The treatment and evaluation of chronic pain is among the most difficult in evaluation of chronic pain especially in chronic pancreatitis. It is particularly difficult because patients have had so much experience that it is difficult whether pain is real or not. My own experience with these patients is that it is extremely difficult to know who has pain and who is habitulalized with drugs. Although there are "experts" who claim they can tell who is real, I doubt it.

Thus, my own approach is to give chronic drugs once the testing characteristics have been done. In such patients, one should administer chronic pain medicine instead of having to steal to get pain meds at gunpoint.

There are institutions which claim they can tell who is legitimate and who is not. I doubt it, but maybe I am wrong. This is a tough area and I am happy not to confront this too often.

F INTRODUCTION TO PORTAL HYPERTENSION

Josef E. Fischer

INTRODUCTION TO THE TREATMENT OF PORTAL HYPERTENSION

The treatment of portal hypertension has become a critical issue in preserving lives of cirrhotic patients. Whereas previously in this country alcoholism was the principle reason for bleeding esophageal varices, the increased incidence of hepatitis B and hepatitis C have resulted in a reservoir of patients that may bleed from esophageal varices and ultimately are candidates for hepatic transplantation. In considering hepatic transplantation, it is important to carry out whatever therapy for portal hypertension one can and at least try to preserve the opportunity to carry out a liver transplant later. The principal anatomic necessity means that whatever mechanism one uses to carry out the control of bleeding esophageal varices, it should, whenever possible, leave the porta hepatis free of previous surgery.

For the most part, many centers of liver transplantation will also deal with patients with bleeding esophageal varices. This is done either by endoscopy, as detailed elsewhere in this section, either by injection or by rubber band obliteration of bleeding esophageal and gastric varices. When these techniques fail, a transjugular intrahepatic portosystemic shunt (TIPS) procedure is done, in which one provides an egress of high-pressure portal flow from the portal system into the systemic system by means of a shunt traversing the hepatic parenchyma. For the most part, in the present state of knowledge, TIPS cannot be used as definitive therapy for bleeding esophageal varices, but are used as a bridge in patients who must by necessity undergo liver transplantation in the finite future. The stenosis rate of the TIPS conduit is high, ranging between 30% and 50% or even higher at the end of the first year. Thus, there are many techniques for actually dilating stenoses so that the patient can undergo subsequent hepatic transplant.

However, there remains a group of patients in whom cessation and arrest of bleeding esophageal varices and gastric varices cannot be accomplished with TIPS and other means of controlling the often-torrential hemorrhage. In these patients, shunt surgery then becomes a necessity.

In addition, there are a group of patients, mostly Class A patients, in whom the state of hepatic function is such that it is thought they can survive for a long period of time without liver transplant. In these patients, some type of shunt surgery, which is described in the subsequent chapters, then becomes a necessity. The hypothetical equation in carrying out shunt surgery is to do enough to decrease portal pressure to a reasonable level so that bleeding from esophageal varices stops in this instance and can be prevented from happening again. The obverse of this equation is to provide enough forward portal pressure to allow hepatic perfusion so that hepatic failure is not the result of shunt surgery. In order to understand the complexities of this pressure equation, it is necessary to understand the basics.

The liver is supplied by two perfusion systems, the hepatic artery, a splanchnic artery that is usually responsible from between 20% and 25% of hepatic flow under normal circumstances. The portal vein is not generally oxygen-deprived; thus, the hepatic artery, rather than most organs supplying all of the essential oxygenation, supplies only 50% of the oxygen requirement of the liver. The portal vein, which normally supplies between 75% and 80% of the flow, also supplies 50% of the oxygen requirement of the liver, as well as the lion’s share of nutrients derived from the gut and its absorption of nutrients. The liver, sitting astride the portal vein, absorbs and processes and, in some cases, stores for release into the general circulation the nutrients, which appear in the portal vein. The liver probably processes nearly 100% of the carbohydrate presented to it. It also processes the majority of the amino acids presented to it, notably the aromatic amino acids, of which two in particular, phenylalanine and its hydroxylated product tyrosine, are principal components of hepatic protein synthesis, but also form the substrate for the sympathetic nervous system as well as many of the amines, which perform vital functions within the brain. Lipids are separately absorbed, and are usually absorbed in their triglyceride form in the lymphatics, which then enter the venous system through the thoracic duct and thus do not pass through the liver.

The age-old question that has persisted for a century is, does the liver

require all of the nutrients that pass through it for its own structural integrity, including structural protein synthesis, or does it only require a portion of it, and the rest can be distributed to the periphery? The evidence that is slowly building up seems to indicate that the liver does in fact require all of these nutrients in order to maintain its integrity. This is surprising, because some of the older, classic data from the 1950s and 1960s indicate that, of a protein load that is given enterally in dogs, only approximately 21% ends up as amino acids, which are available in the general circulation. More than half finally end up as urea, after going through gluconeogenesis. The question this raises is, if there is something special about the glucose which is produced from protein, is it required at a certain place at a certain time? With the advent of knowledge of the cytoskeleton, in which the location of various nutrients as close to the various enzyme systems that do not float free in the cell as a bag but are firmly fixed to the cell membrane, or other aspects of the cytoskeleton, there appears to be an answer to this important question. The answer is that glucose, which is created through gluconeogenesis, does end up as glycogen immediately adjacent to certain enzyme systems, which then use the substrate for specific functions such as aerobic glycolysis, as our laboratory showed in the 1990s and in the first years of this century.

Aerobic glycolysis produces considerably less adenosine triphosphate than glucose that goes through the Krebs cycle—considerably less. However, it is important because of its location in the cytoskeleton to a series of membrane-bound enzymes that make the glucose, which ends in glycogen, a very valuable commodity for essential cellular functions. It has also created the controversy as to whether lactate, which remains elevated in response to epinephrine (James JH, et al. Lactate is an unreliable indicator of tissue hypoxia in injury or sepsis. *Lancet* 1999;354:505; James JH, Fischer JE. Epinephrine and gut lactate production. *Crit Care Med* 2001;29:454; James JH, et al. Stimulation of both aerobic glycolysis and Na(+)-K(+)-ATPase activity in skeletal muscle by epinephrine or amylin. *Am J Physiol* 1999;277:E176)—and thus overresuscitating a patient simply on the basis of elevated blood lactate, when in fact every other parameter indicates complete resuscitation—may be injurious to the entire organism.

In addition to the nutrients that course in the portal vein, there are trophic factors that seem to be essential for the integrity and normal functioning of the liver. Beginning in the late 1950s and in the early 1960s, there was a great deal of interest in insulin and glucagon and other putative

peptides that appear to originate in the pancreas. In addition, the needs of regeneration of the liver appear to involve a substance known as *ileal factor,* which results from grinding up ileum and giving it in experiments of hepatic regeneration. This probably consisted of the vascular endothelial and epidermal growth factors and also some putative peptides present in the liver, which were essential, and not only permissive, for hepatic regeneration.

As bridging necrosis and replacing the reticulum elastic framework with fibrosis occurred in a liver that was progressively being destroyed by whatever disease was operant, the resistance to portal flow, either presinusoidal, sinusoidal, or postsinusoidal, depending on the pattern of the disease, elevated the resistance to portal flow. Under normal circumstances, flow would drop. Here, however, a feature of portal hypertension enters, and that is the presence of pumps, as it were, in which arterial admixture with portal flow provided increased positive pressure to the portal vein perfusion, thus maintaining portal flow to the liver. To the surgeon, portal flow is a nuisance. It results in variceal bleeding, collaterals around the rectum, gastric varices, the caput medusae at times, and large variceal collaterals in adhesions in the abdominal wall, varices around such structures as ileostomies, which, of course, are deleterious to the entire organism. To the liver, however, portal hypertension is probably a good thing, an attempt to maintain flow despite increased resistance. Thus, in all of the chapters that follow, there is always the question of balance: balance between forward perfusion of portal flow to the liver, and decompressing the portal system sufficiently so that the patient did not exsanguinate from variceal bleeding.

Early studies from Rousselot in the 1950s revealed that following end-to-side portacaval shunt and using flow meters around the hepatic artery so that those patients that did well following end-to side hepatic portacaval shunt were those who had the ability to increase hepatic artery flow to take the place of portal flow and perfuse the liver. I prefer to look at this phenomenon as indicating the stage of liver disease. Those patients who could increase their portal flow had an earlier stage of cirrhosis, and for those who could not, that inability to increase hepatic artery flow indicated a late stage of the disease. Unfortunately, the advent of transplantation decreased research in this area, so that for many of the mystical concepts concerning hepatic regeneration, trophic factors necessary for the integrity of the liver now became irrelevant if one was going to replace a diseased

liver that was fibrotic with a newly transplanted liver in which the portal flow was delivered, and normal hepatic function might result.

Finally, as one reads these various chapters and reads the claims of various individuals concerning specific shunts: For example, as one will read in the subsequent chapter, there were claims made that a distal splenorenal shunt was somehow magical and could prevent the inexorable desire, as it were, of blood at high pressure to seek a lower pressure. Indeed, Maillard et al. (Chandler JG Selectivity of the distal splenorenal shunt. *Surgery* 1979;86:663), among others, demonstrated by primitive angiography that within 24 hours of the distal splenorenal shunt, collaterals between the portal system and the systemic system arose rather quickly, thus robbing the liver of forward flow. The answer was the portal azygos disconnection—an operation that is beyond the technical abilities of most surgeons—to prevent this phenomenon from occurring. However, I believe this is futile, and our own studies have shown that in time, comparing distal splenorenal shunts with central splenorenal shunts, forward flow decreases progressively and the rates of encephalopathy, as a good mark for diminished hepatic function, proceeded at the same pace (Fischer JE, et al. Comparison of distal and proximal splenorenal shunts: a randomized prospective trial. *Ann Surg* 1981;194:531).

These are the choices one has to make in portal hypertension. The idea that somehow one can magically lower the pressure, leaving some portal hypertension to perfuse the liver, is superior to one shunt or another may be a goal that cannot be reached. However, what is clear is that there are certain operations that do preserve some portal flow; these are either small interposition shunts, distal splenorenal shunts, and/or central splenorenal shunts whose diameter is controlled, as Dr. Robert Linton taught me when I was his resident and a young staff person, so that forward perfusion of the liver occurs.

This whole area remains a fascinating area of physiology in which surgeons have always been interested because it applies directly to the welfare of their patients.

130 Anatomy of the Portal System and Experience With Portacaval Shunt

Marshall J. Orloff

INTRODUCTION

The excellent chapter on Anatomy of the Portal System by Drs. Richard Bell and Alan Koffron in the 5th and 6th editions of *Mastery of Surgery* bears repeating in substantial part. Therefore, much of it is presented in the 7th edition. It is supplemented by a detailed description of the side-to-side portacaval shunt (PCS) and a section titled "Author's Experience with Portacaval Shunt," based on the experience of the author with over 4,000 PCSs over a period of 54 years.

The word *portal* is derived from the Latin word *porta*, meaning "gate" or "passage." In Babylon, the livers of sacrificed animals were interpreted to predict the future. The Babylonians considered the liver the seat of the soul; the port of entry to this structure was therefore accorded special significance. Similarly, for modern surgery of the liver, pancreas, and portal hypertension, the portal vein has special importance. Knowledge of its anatomy and variants is crucial to ensure surgical success in performing such procedures.

DESCRIPTIVE ANATOMY

The portal vein arises from the postduodenal plexus of the embryonic vitelline veins. Rarely, the preduodenal plexus persists, giving rise to a portal vein that lies anterior to the duodenum. This anomaly, which is potentially lethal if it is not recognized and the portal vein is transected during surgery in this area, is associated with annular pancreas, malrotation, and biliary tract anomalies.

In the adult, the portal vein and its tributaries have no valves—those that existed during fetal circulation having been resorbed. Thus, the portal system can be decompressed at any point by creating a connection to the

systemic venous system. The vein delivers blood from the spleen, the pancreas, and the digestive tube to the liver. It provides ~75% of hepatic blood flow and 50% of the oxygen delivery to this organ.

The portal vein can be thought of as the trunk of a tree, with the visceral veins (superior mesenteric, inferior mesenteric, and splenic) forming the roots, and the intrahepatic portions of the right and left portal veins forming the branches (Fig. 130.1). The vascular delta formed by the mixing of portal venous and hepatic arterial blood in the sinusoids of the liver then drains into the inferior vena cava (IVC) through the three hepatic veins.

The portal vein trunk is 4.8 to 8.8 cm long, with an average length of 6.4 cm, and 0.6 to 1.2 cm wide, with an average width of 0.9 cm. It is formed behind the neck of the pancreas, at the level of the second lumbar vertebra, by the confluence of the superior mesenteric vein (SMV) and the splenic vein (Fig. 130.2). In approximately one third of the population, the inferior mesenteric vein joins the portal vein directly at this point, forming a trifurcation; in the remaining cases, it drains into the splenic vein (38%) or the SMV (29%). The portal vein then passes to the right and cephalad behind the first portion of the duodenum and into the hepatoduodenal ligament, which forms the ventral boundary of the foramen of Winslow. Within the hepatoduodenal ligament, the portal vein lies posterior to the hepatic artery and common bile duct, usually slightly to the left of the duct. It bifurcates in the porta hepatis at the right aspect of the hilar plate—a thickening of the liver's fibrous capsule at the hilum. The right branch, which supplies the right hepatic lobe, is shorter (0.5 to 1.0 cm long), wider, and more variable than its sinistral counterpart. It often divides into anterior and posterior branches at its point of entry into the liver parenchyma. The more constant and longer left portal vein, with a 4-cm average length, supplies the left hepatic lobe and runs left in the hilar plate as the pars transversa until it enters the fissure for the ligamentum venosum. At this point, the vein receives the attachment of the ligamentum venosum and then curves anteriorly, becoming the pars umbilicus, which ends by attaching to the ligamentum teres hepatis in the umbilical fissure. The caudate lobe is supplied by two to three branches arising from the bifurcation of the portal vein or from its right or left branches.

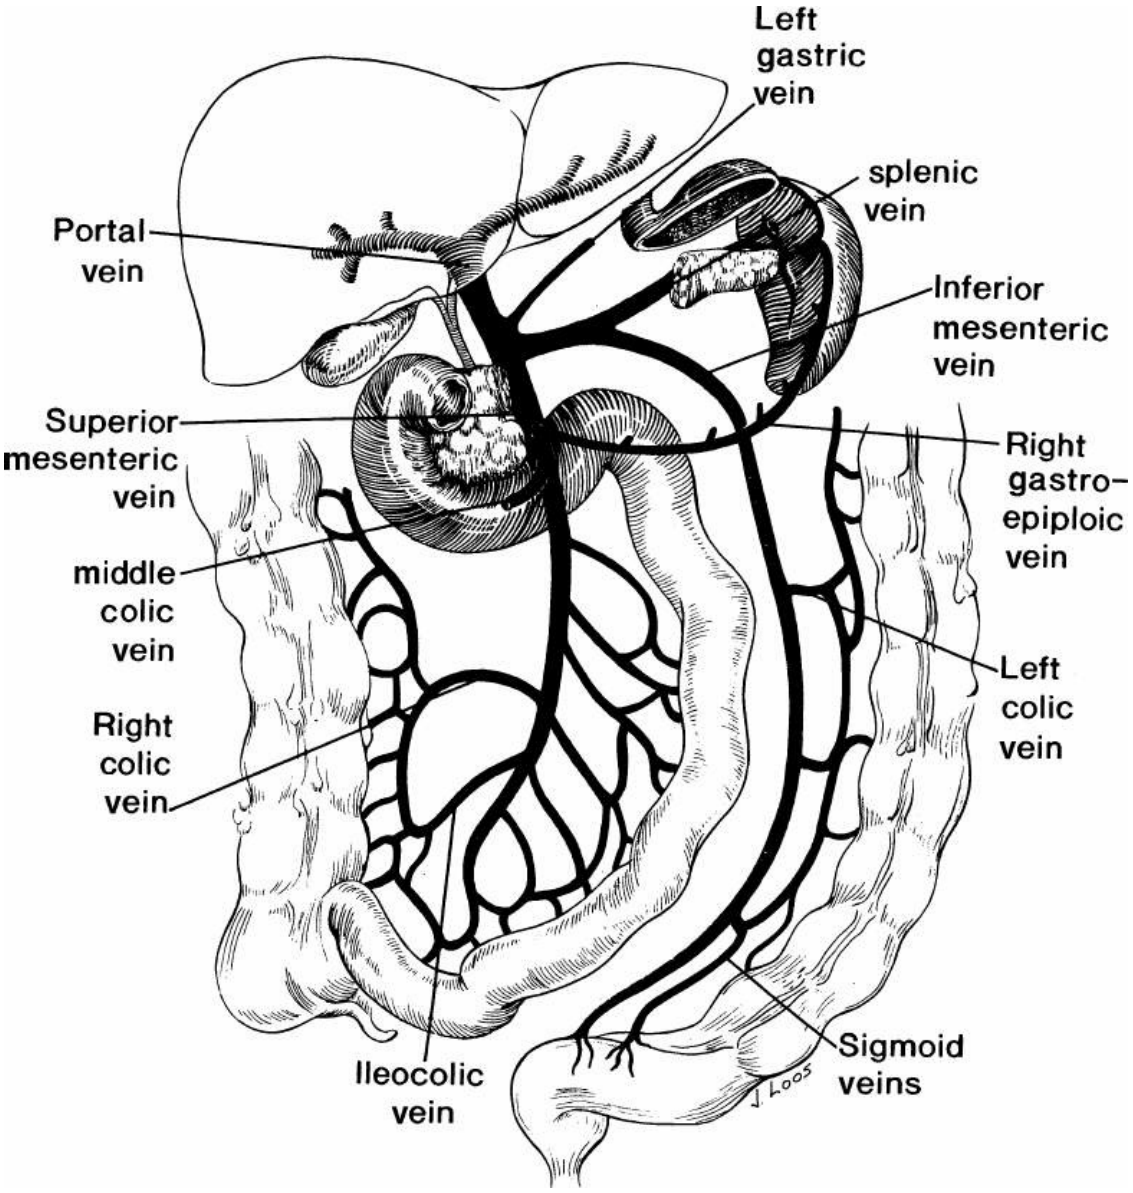

Figure 130.1. Overview of the entire portal venous system within the abdominal cavity. (Data from Monsen H. Anatomy of the portal system. In: Nyhus LM, Baker RJ, eds. *Mastery of Surgery*, 2nd ed. Boston: Little Brown and Company, 1992; and from Williams PL, Warwick R, eds. Gray's Anatomy, 36th ed. New York: Churchill Livingstone, 1980.)

Of great importance to the surgeon are the sundry side branches that feed into the portal vein as it forms behind the pancreas and runs cephalad in the hepatoduodenal ligament (Fig. 130.2). The portal vein usually receives the pancreaticoduodenal vein(s) and the pyloric vein, which is also known as the *right gastric vein.* More variable in their point of insertion is the coronary vein, which is also known as the *left gastric vein*, and the accessory pancreatic vein. The superior pancreaticoduodenal vein

usually enters the right aspect of the portal vein at or just above the superior margin of the pancreas. The inferior pancreaticoduodenal vein usually enters the right aspect of the SMV just before it joins the splenic vein to form the portal vein proper. In ~38% of cases, there is only a single pancreaticoduodenal vein, which joins the portal vein at the same juncture as the superior pancreaticoduodenal vein. The pyloric vein is present in 80% of the population and, in 75% of the population, terminates in the anterior aspect of the portal vein (inside the hepatoduodenal ligament), within 3.0 cm of the portal vein bifurcation. The coronary vein inserts at the superior aspect of the junction of the splenic and SMVs in 60% of the population, in the portal vein proper in 25% of the population, and in the splenic vein (just before its junction with the SMV) in 15% of the population. In a series of 92 dissections, 29 specimens had an accessory pancreatic vein terminating in the superior aspect of the midportal vein.

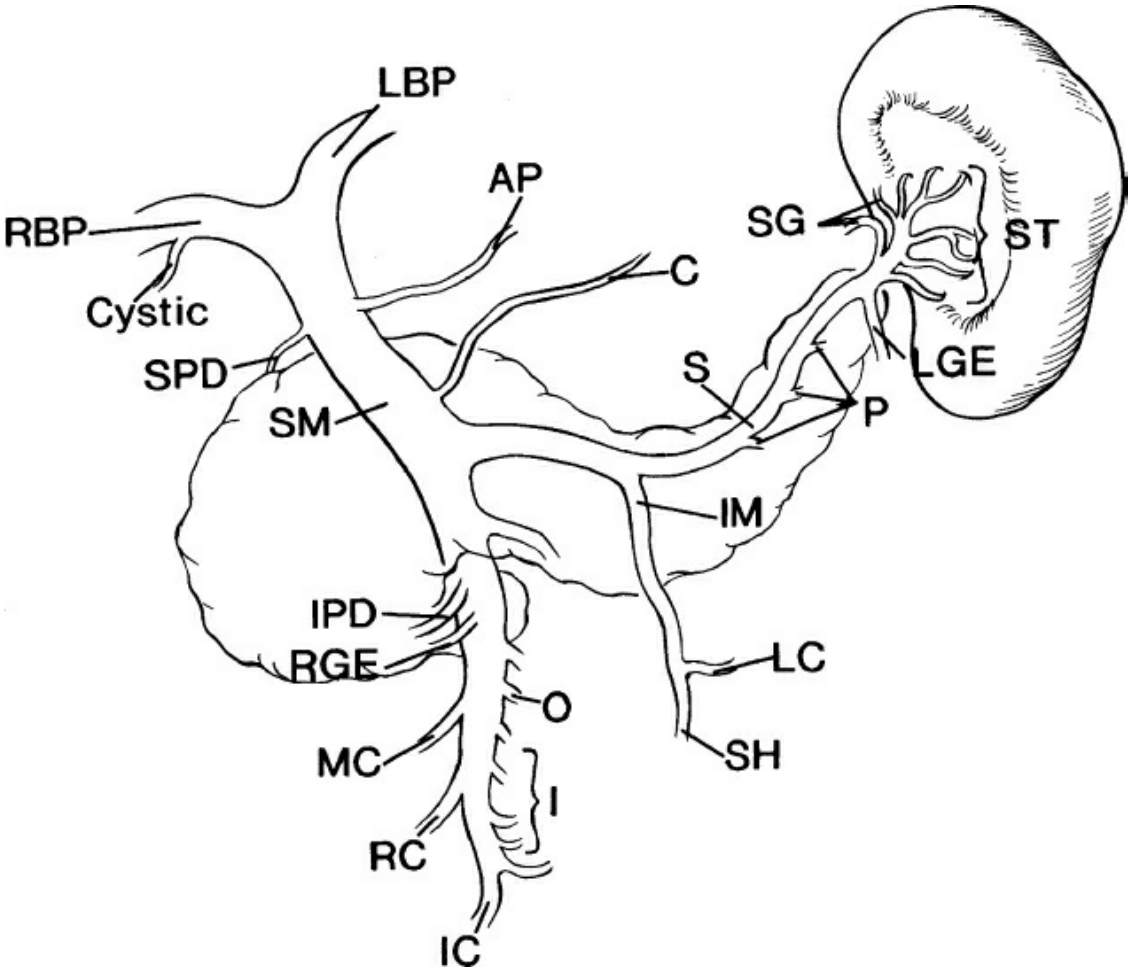

Figure 130.2. Anatomy of the extrahepatic portal venous system. AP, accessory pancreatic vein; C, coronary vein; I, ileal veins; IC, ileocolic vein; IM, inferior mesenteric vein; IPD, inferior pancreaticoduodenal vein; LBP, left branch of portal vein; LC, left

colic vein; LGE, left gastroepiploic vein; MC, middle colic vein; O, omental vein; P, pancreatic veins; RBP, right branch of portal vein; RC, right colic vein; RGE, right gastroepiploic vein; SG, short gastric veins; SH, superior hemorrhoidal vein; SPD, superior pancreaticoduodenal vein; ST, splenic trunks. (Modified from Douglass B, Baggenstoss A, Hollinshead WH. The anatomy of the portal vein and its tributaries. *Surg Gynecol Obstet* 1960;91:564. Copyright © Elsevier.)

Another anatomic aspect of the portal system that is of importance to the surgeon are the points of communication between the portal and systemic (caval, azygos, and hemiazygos) venous systems (Fig. 130.3). Normally, these anastomotic channels are small, but the combination of portal hypertension and the lack of valves in the adult portal system lead to reversal of flow, with consequent dilatation and tortuosity. Clinically, the most important portosystemic anastomoses are the veins of the proximal stomach and distal esophagus, which receive flow from the coronary and short gastric veins and drain into the superior vena cava via the azygos system (labeled *1 and *2 in Fig. 130.3). Dilatation and tortuosity in this plexus of relatively unsupported veins results in varices that can rupture, causing exsanguinating hemorrhage. Other significant anastomotic areas shown in Figure 130.3 include the following:

1. The submucosal venous plexus in the rectum between the superior hemorrhoidal veins (the portal system) and the middle and inferior hemorrhoidal veins (the caval system) (labeled *4). Large bleeding rectal varices, although uncommon, can arise here in patients with portal hypertension.
2. The paraumbilical veins, which connect the left portal vein via a recanalized umbilical vein to the epigastric venous network of the abdominal wall, which drains into the caval system (labeled *3). This plexus can become the variceal “caput Medusae” in patients with portal hypertension and produce the Cruveilhier–Baumgarten syndrome. Unintentional transection of these varices during surgery that involves the anterior abdominal wall can result in significant blood loss.
3. Retzius veins: a group of small but numerous retroperitoneal veins that connect abdominal viscera, both tubular and solid, with the caval system via intercostals, phrenic, lumbar, and renal veins (labeled *5). In the patient with portal hypertension, bleeding from these veins can

make any upper abdominal operation dangerous depending on the amount and location of retroperitoneal dissection required.

4. Finally, significant venous collaterals can form in surgical adhesions, making reoperative surgery and stomal takedowns more dangerous in patients with portal hypertension.

APPLIED ANATOMY

Portosystemic Shunts

One of the common categories of surgical operations in which a detailed knowledge of portal anatomy is essential is that of portosystemic shunts. Because the portal venous system contains no valves, it is possible to decompress the system and relieve portal hypertension by connecting the portal vein or its tributaries to the systemic venous system at a number of sites, provided the systemic vein is of sufficient size to handle the large portal blood flow. Figure 130.4 shows various types of portosystemic shunts. Not shown is the TIPS, which is a radiologic procedure that creates a side-to-side shunt within the liver. A detailed review of the various causes of portal hypertension and the advantages and disadvantages of the several kinds of shunts is beyond the scope of this chapter. Rather, the anatomic points of portal vein anatomy relevant to performance of a side-to-side portacaval shunt (SSPCS) are discussed since, in the large experience of the author with the treatment of portal hypertension, the direct SSPCS has been used in over 90% of the patients.

The indications for an SSPCS are (a) bleeding esophageal or gastric varices due to portal hypertension caused by cirrhosis of the liver or, much less commonly, by other liver diseases such as schistosomiasis; (b) bleeding from portal hypertensive gastropathy unresponsive to pharmacologic therapy; (c) Budd–Chiari syndrome (BCS) with occluded hepatic veins and patent IVC; (d) intractable ascites unresponsive to nonsurgical therapy; and (e) failed TIPS.

The position of the patient on the operating table is crucial and can make the difference between an easy and difficult operation (Fig. 130.5). Specifically, the patient is placed on the operating table with the right side elevated at an angle of 30 degrees to the table, and the table is adjusted so as to widen the space between the right costal margin and right iliac crest, and make it possible to perform the operation easily through a long right subcostal incision.

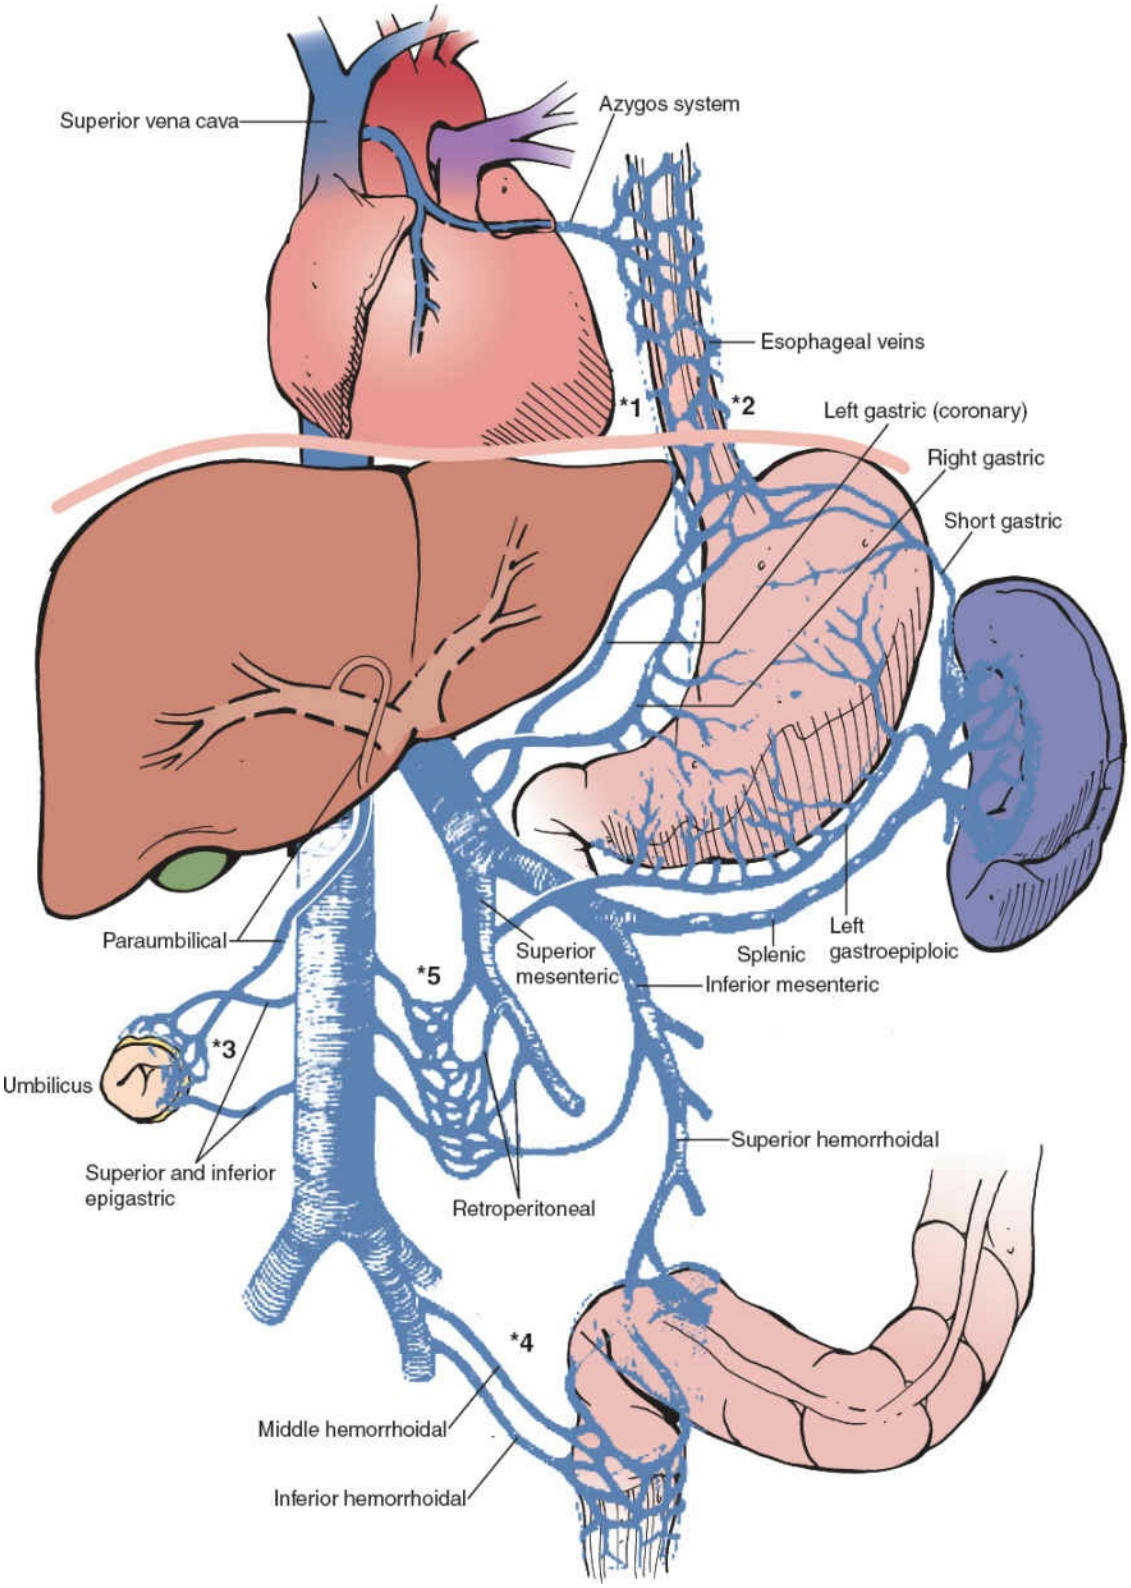

Figure 130.3. Sites of formation of portosystemic collaterals in patients with portal hypertension. Connections between the portal and systemic venous system are normally present, but they carry increased flow when there is a block to portal venous flow through the liver. The sites of portosystemic collateral connections shown in this figure are (**A**) from the portal vein

through the right and left gastric veins to the esophageal veins and the hemiazygos vein to the superior vena cava labeled *1 and *2; (**B**) from the superior mesenteric vein (SMV) through retroperitoneal veins to the inferior vena cava (IVC) labeled *5; (**C**) from the left portal vein through the (recanalized) umbilical vein to epigastric veins to the vena cava labeled *3; and (**D**) from the inferior mesenteric vein through the superior hemorrhoidal vein to the middle and inferior hemorrhoidal veins to the iliac veins labeled *4.

Figure 130.4. Types of portal-systemic venous shunts used to relieve portal hypertension.

Once inside the peritoneal cavity, retractors are placed and the posterior peritoneum overlying the IVC is incised with electrocautery by an extended Kocher maneuver (Fig. 130.6). The anterior surface of the IVC is cleared of fibroareolar tissue, and the IVC is isolated around its entire circumference by blunt and sharp dissection from the entrance of the right and left renal veins, below, to the point where it disappears behind the liver, above. The IVC is encircled with an umbilical tape (Fig. 130.7). To accomplish the isolation, several tributaries must be ligated in continuity with fine silk ligatures and then divided. These tributaries often include the right adrenal vein, one or two pairs of lumbar veins that enter the posterior surface, and the caudal pair of small hepatic veins from the caudate lobe of the liver that enter the anterior surface of the IVC directly from the liver.

When the IVC has been mobilized completely, it can be lifted up toward the portal vein (Fig. 130.8). Failure to isolate the IVC circumferentially is one major reason for the erroneous claim that the SSPCS often cannot be performed because the portal vein and IVC are too widely separated.

The superior retractor is repositioned medially so that it retracts the liver at the point of entrance of the portal triad. The portal vein is located in the posterolateral aspect of the portal triad and is approached from behind. The fibrofatty tissue on the posterolateral aspect of the portal triad, which contains nerves, lymphatics, and lymph nodes, is divided by blunt and sharp dissection. This technique is a safe maneuver because there are no portal venous tributaries on this aspect of the portal triad. As soon as the surface of the portal vein is exposed, a vein retractor or Gilbernet retractor is inserted to retract the common bile duct medially. The portal vein is mobilized circumferentially at its midportion and is encircled with an umbilical tape (Fig. 130.9). It is then isolated up to its bifurcation in the liver hilum. Several tributaries on the medial aspect are ligated in continuity with fine silk and divided.

Using the umbilical tape to pull the portal vein out of its bed, the portal vein is cleared to the point where it disappears behind the pancreas. The tough fibrofatty tissue that binds the portal vein to the pancreas must be divided (Fig. 130.10). Several tributaries that enter the medial aspect of the portal vein and one tributary that enters the posterolateral aspect are

divided. It is usually not necessary to divide the splenic vein. Wide mobilization of the portal vein is essential for performance of a side-to-side portacaval anastomosis. Failure to mobilize the portal vein behind the pancreas is a second major reason for difficulty in accomplishing the side-to-side shunt. In some patients, it is necessary to divide a bit of the head of the pancreas between right-angled clamps to obtain adequate mobilization of the portal vein. Bleeding from the edges of the divided pancreas is controlled with suture ligatures. Division of a small amount of the pancreas is a very helpful maneuver and we have never observed postoperative complications, such as pancreatitis, from its performance. Before incising the pancreas, the surgeon should insert his index finger into the tunnel between the portal vein and the pancreas to determine by palpation if there is a replaced common hepatic or right hepatic artery arising from the superior mesenteric artery and crossing the portal vein. Since the portal venous blood flow to the liver is diverted through the PCS, ligation of the hepatic arterial blood supply may be lethal.

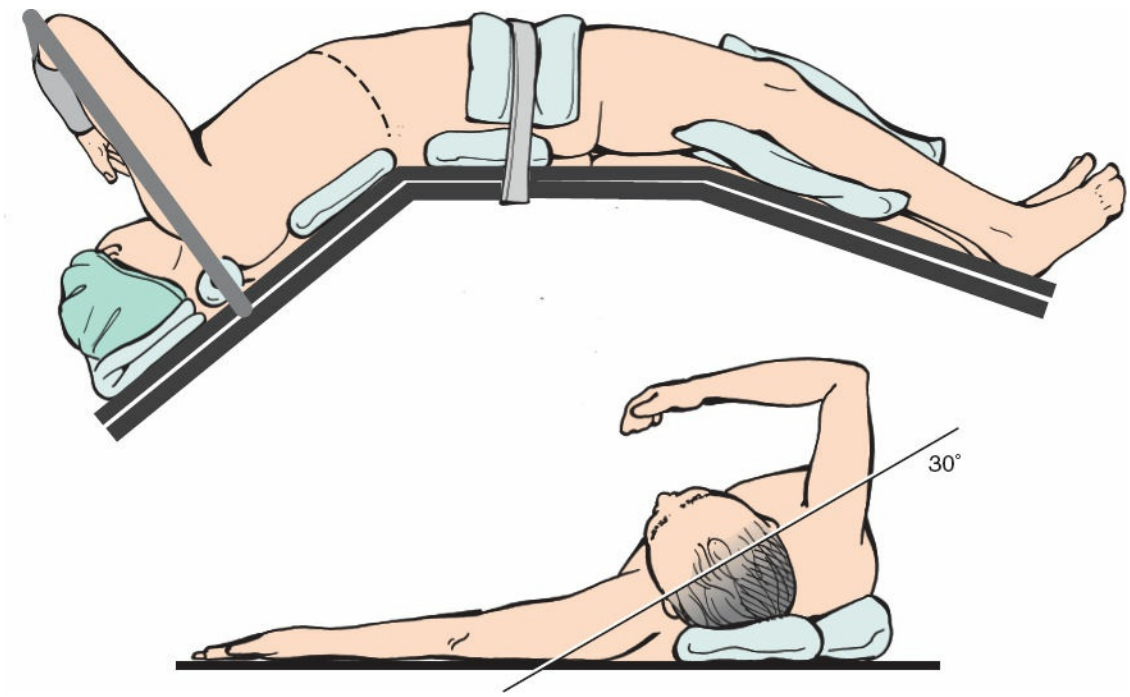

Figure 130.5. The position of the patient on the operating table in preparation for a side-to-side portacaval shunt. The table is “broken” at the level of the costal margin and at the knees so as to widen the space between the right costal margin and right iliac crest, and to make it possible to perform the operation easily through a right subcostal incision, which extends from the xiphoid to well into the flank and is made two fingerbreadths below the costal margin.

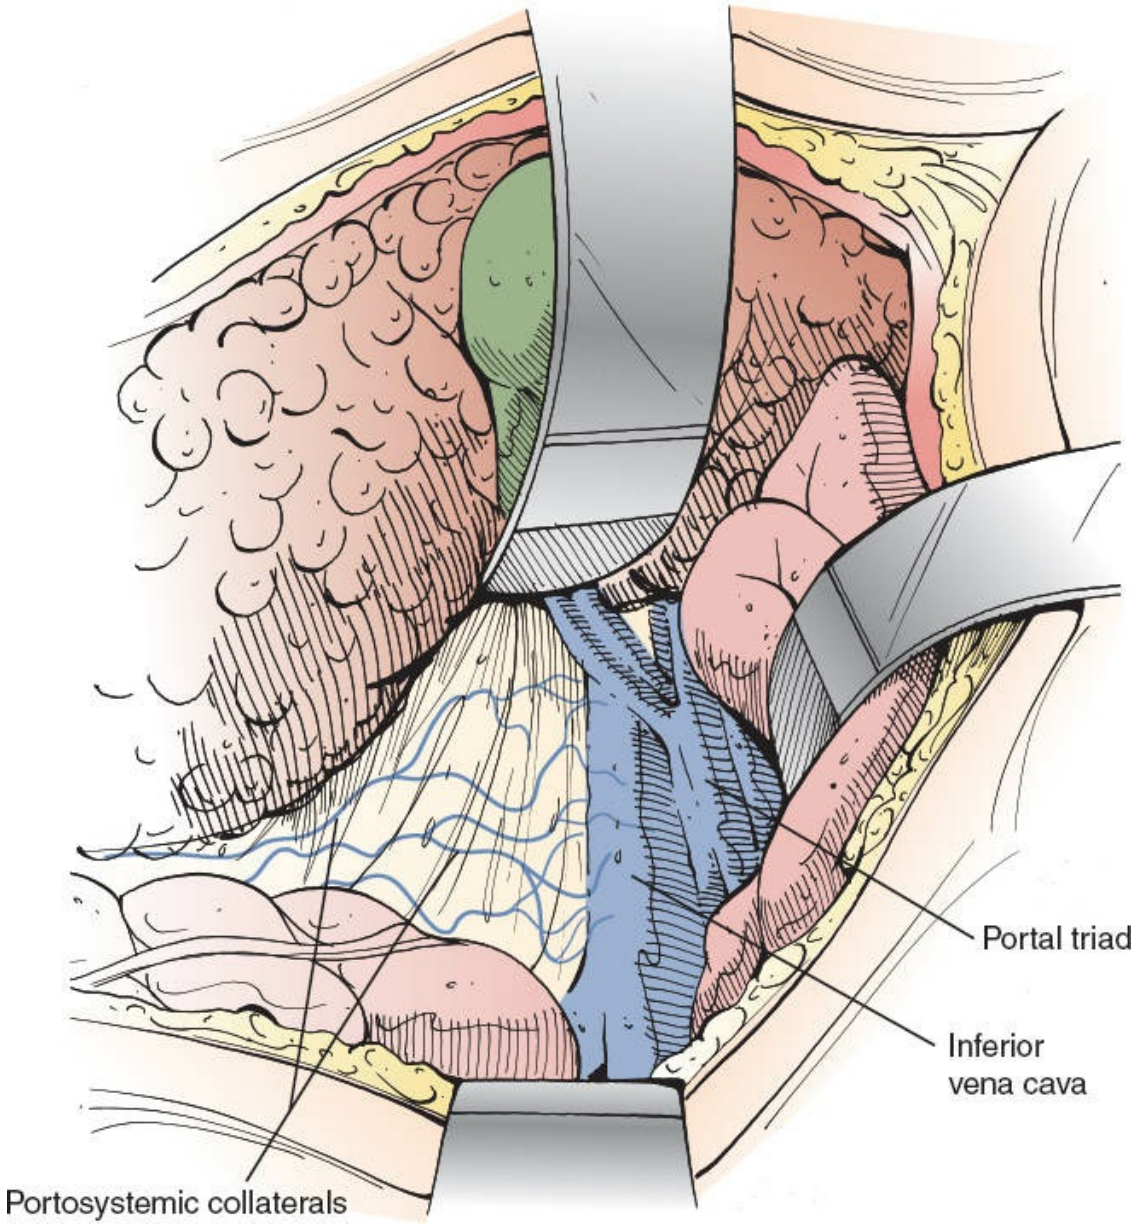

Figure 130.6. Exposure of the operative field for a side-to-side portacaval shunt.

To determine the adequacy of mobilization of portal vein and IVC, the two vessels are brought together by traction on the umbilical tapes that surround them (Fig. 130.11). It is essential to determine that the two vessels can be brought together without excessive tension. If this cannot be done, it is almost always because the vessels have not been adequately mobilized, and further dissection of the vessels should be undertaken. Resection of part of an enlarged caudate lobe of the cirrhotic liver, recommended by some surgeons to facilitate bringing the vessels together, is associated with some difficulties and, in our opinion, is neither

necessary nor advisable.

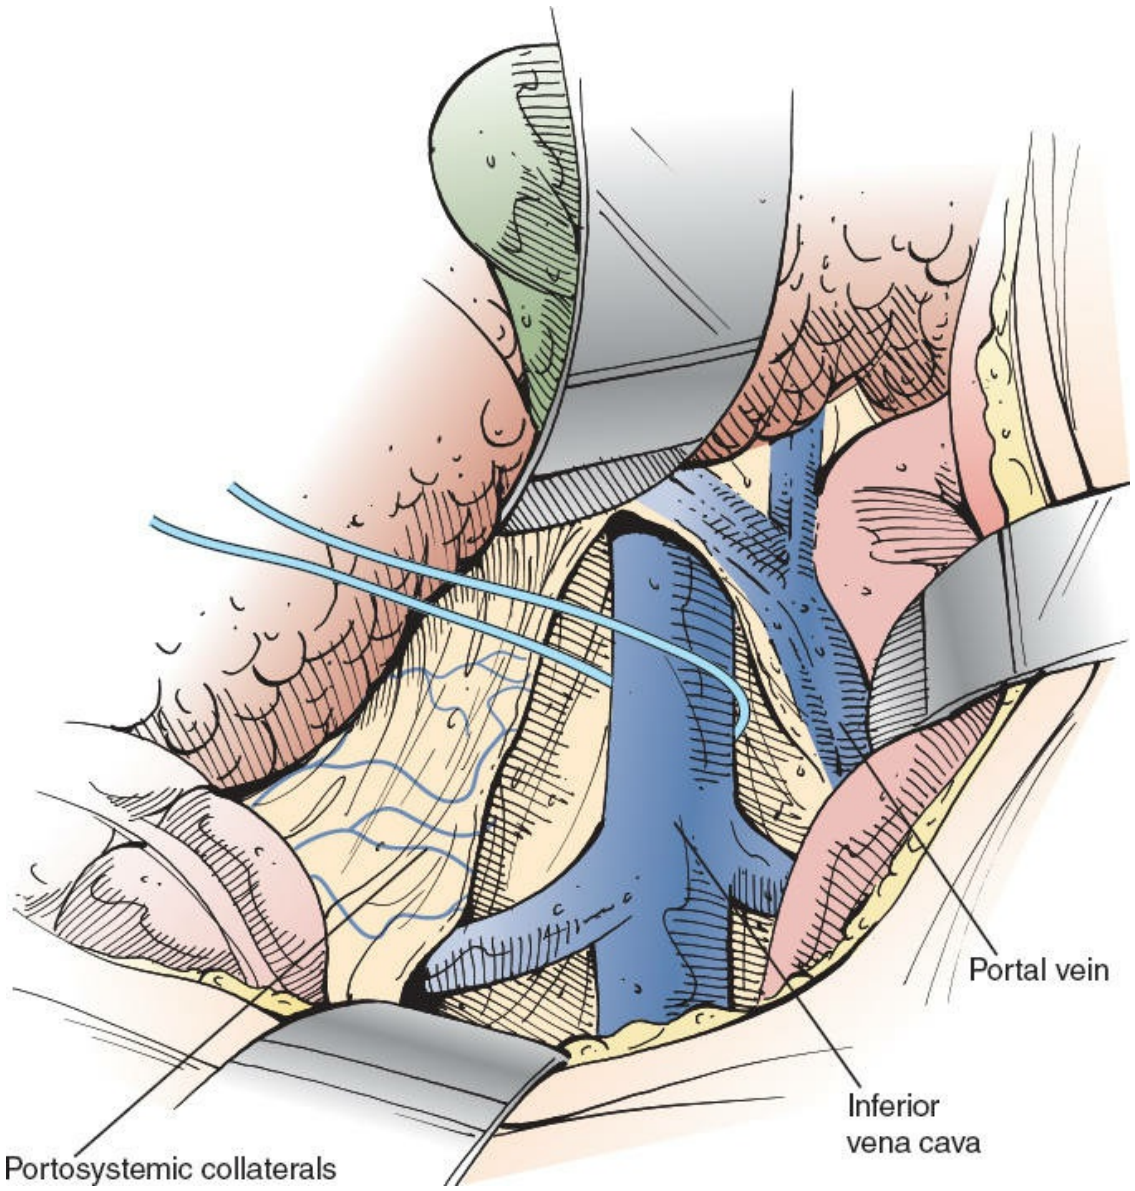

Figure 130.7. Isolation of the inferior vena cava (IVC) around its entire circumference from the entrance of the right and left renal veins below, to the point where it disappears behind the liver above. The IVC is encircled with an umbilical tape.

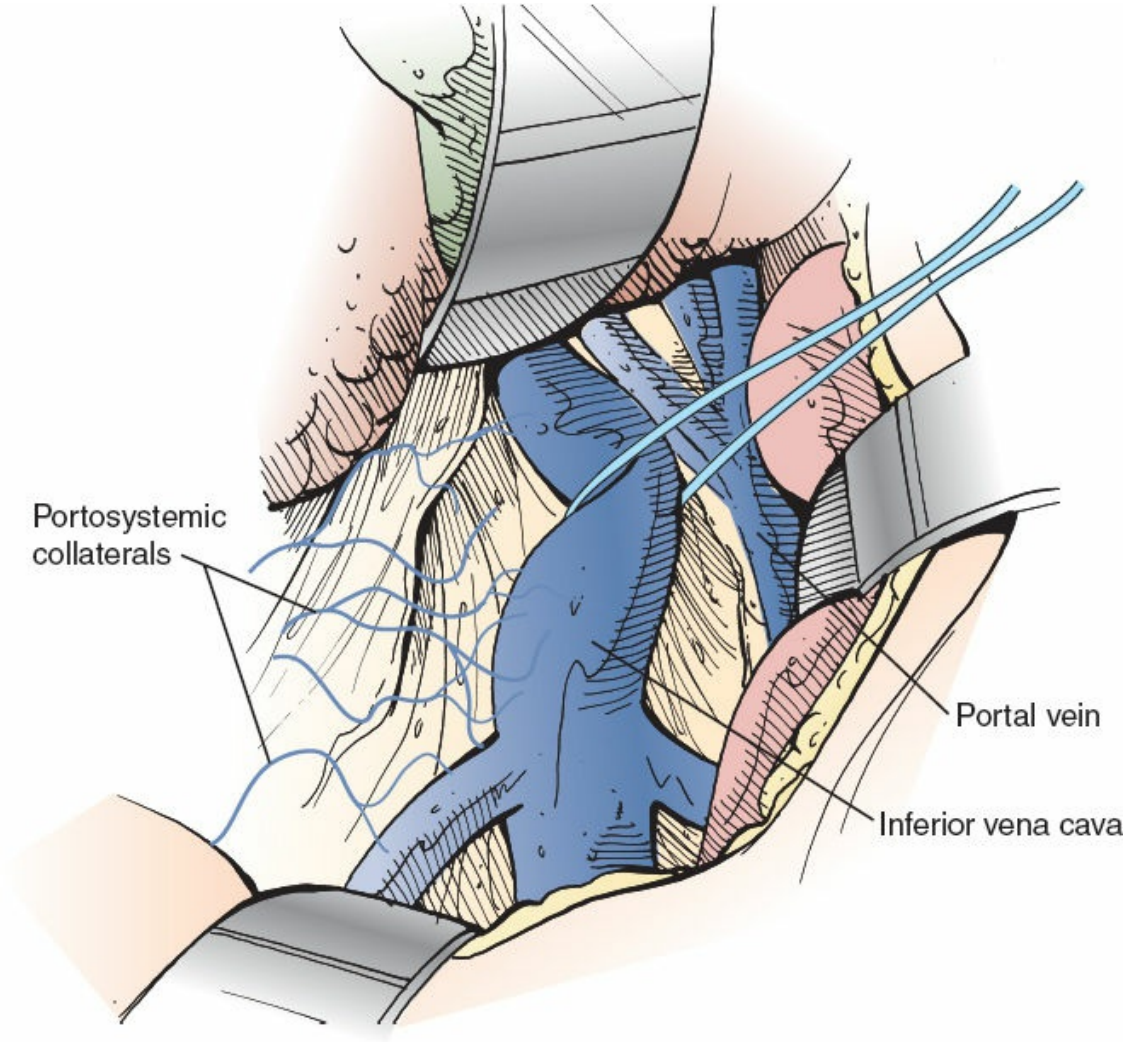

Figure 130.8. Testing the adequacy of IVC mobilization. When the IVC has been mobilized completely, it can be lifted up toward the portal vein. Failure to isolate the IVC circumferentially is one major reason for the erroneous claim that the side-to-side portacaval shunt often cannot be performed because the portal vein and IVC are too widely separated.

Pressures in the IVC and portal vein are measured with a saline (spinal) manometer by direct needle puncture before performance of the portacaval anastomosis. A portal vein-IVC pressure gradient of 150-mm saline or higher represents clinically significant portal hypertension. Most patients with bleeding esophageal varices (BEV) have a portal vein-IVC gradient of 200-mm saline or higher.

The steps in performing the side-to-side portacaval anastomosis are as follows:

1. A Satinsky clamp is placed obliquely across a 5-cm segment of the anteromedial wall of the IVC in a direction parallel to the course of the

overlying portal vein and the IVC is elevated toward the portal vein. A 5-cm segment of the portal vein is isolated between two angled vascular clamps and the portal vein is depressed toward the IVC, bringing the two vessels into apposition (Fig. 130.12).

2. A 2.0- to 2.5-cm long strip of the IVC and a 2.0- to 2.5-cm long strip of the portal vein are excised with scissors (Fig. 130.13). It is important to excise a longitudinal segment of the wall of each vessel rather than simply making an incision in each vessel. A retraction suture of 5/0 silk is placed in the lateral wall of the IVC opening and is weighted by attachment to a hemostat to keep the IVC orifice open. The clamps on the portal vein are momentarily released to flush out any clots and then the openings in both vessels are irrigated with saline.
3. The anastomosis is started with a posterior continuous over-and-over suture of 5/0 vascular suture material. The posterior continuous suture is tied at each end of the anastomosis.
4. The anterior row of sutures consists of an everting continuous horizontal mattress stitch of 5/0 vascular suture material started at each end of the anastomosis (Fig. 130.14). The suture started at the inferior end of the anastomosis is discontinued after three or four throws and is deliberately left loose so that the interior surface of the vessels can be visualized as the anastomosis is completed. In this way inadvertent inclusion of the posterior wall in the anterior row of sutures is avoided. The suture started at the superior end of the anastomosis is inserted with continuous tension until it meets the inferior suture, at which point the inferior suture is drawn tight and the two sutures are tied to each other. Before drawing the inferior suture tight, the clamps on the portal vein are momentarily released to flush out any clots, and the anastomosis is thoroughly irrigated with saline.
5. Upon completion of the anastomosis, a single interrupted tension suture is placed just beyond each end of the anastomosis to take tension off the anastomotic suture line. The clamp on the IVC is removed first, the clamp on the hepatic side of the portal vein is removed next, and finally, the clamp on the intestinal side of the portal vein is removed (Fig. 130.15). Bleeding from the anastomosis infrequently occurs; it can be controlled by one or two well-placed interrupted sutures of 5/0 vascular suture material.

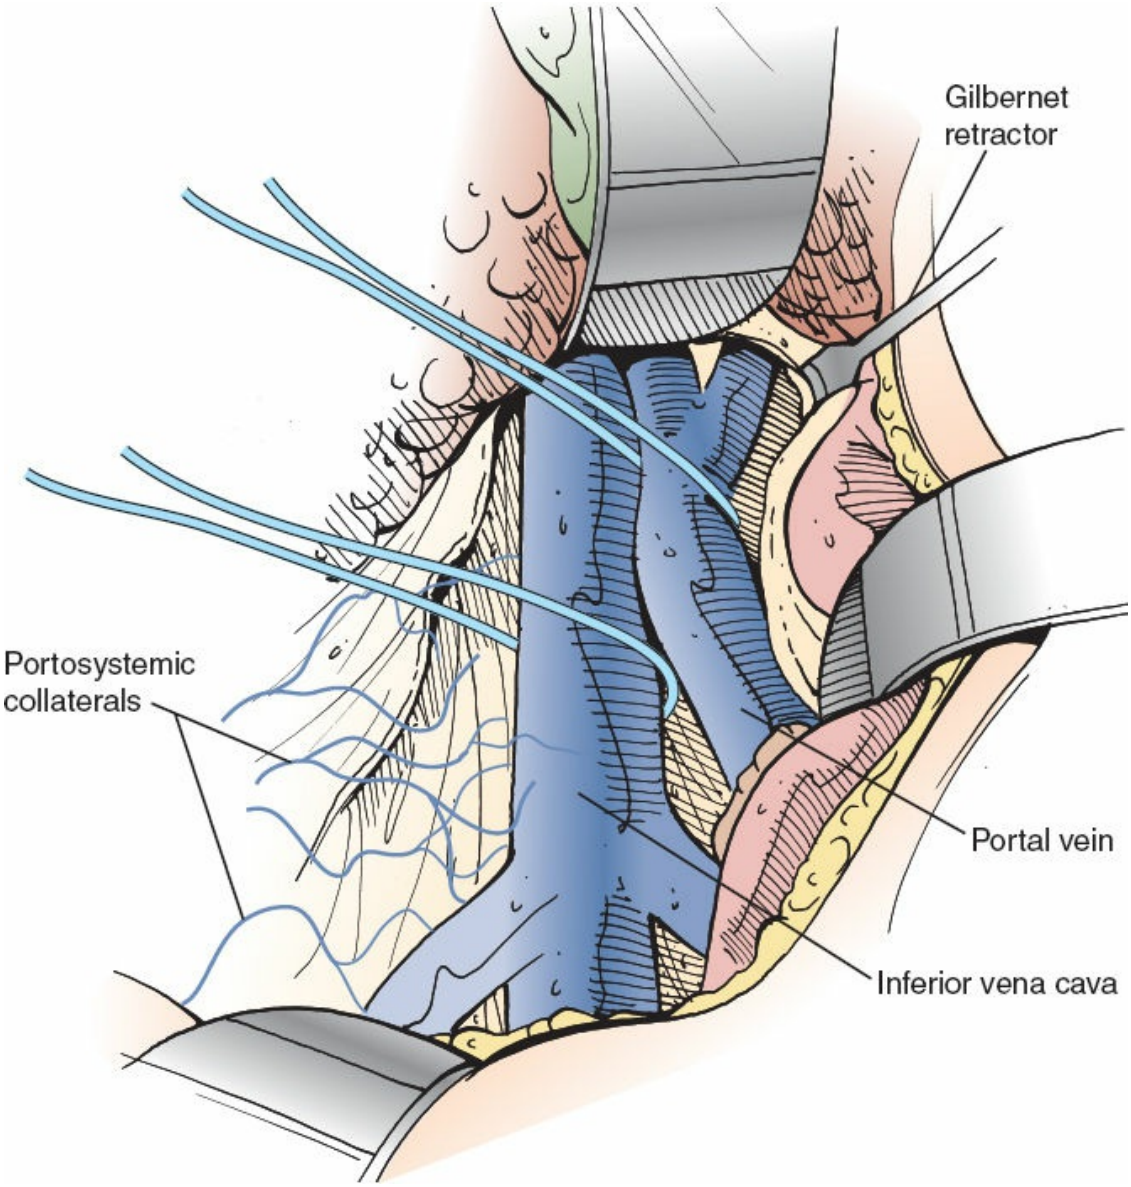

Figure 130.9. Isolation of the portal vein. The portal vein is mobilized circumferentially at its midportion and is encircled with an umbilical tape. It then is isolated up to its bifurcation in the liver hilum.

Pressures in the portal vein and IVC must be measured after the anastomosis is completed. Usually, the postshunt pressures in the portal vein and IVC are identical. A pressure gradient of >50-mm saline between the two vessels indicates an obstruction in the anastomosis, even when no obstruction can be palpated. In such circumstances, the anastomosis should be opened to remove any clots and, if necessary, the entire anastomosis should be taken down and redone. It is essential that there be no more than a 50-mm saline gradient between the portal vein and IVC to achieve permanently adequate portal decompression and to avoid ultimate

thrombosis of the shunt.

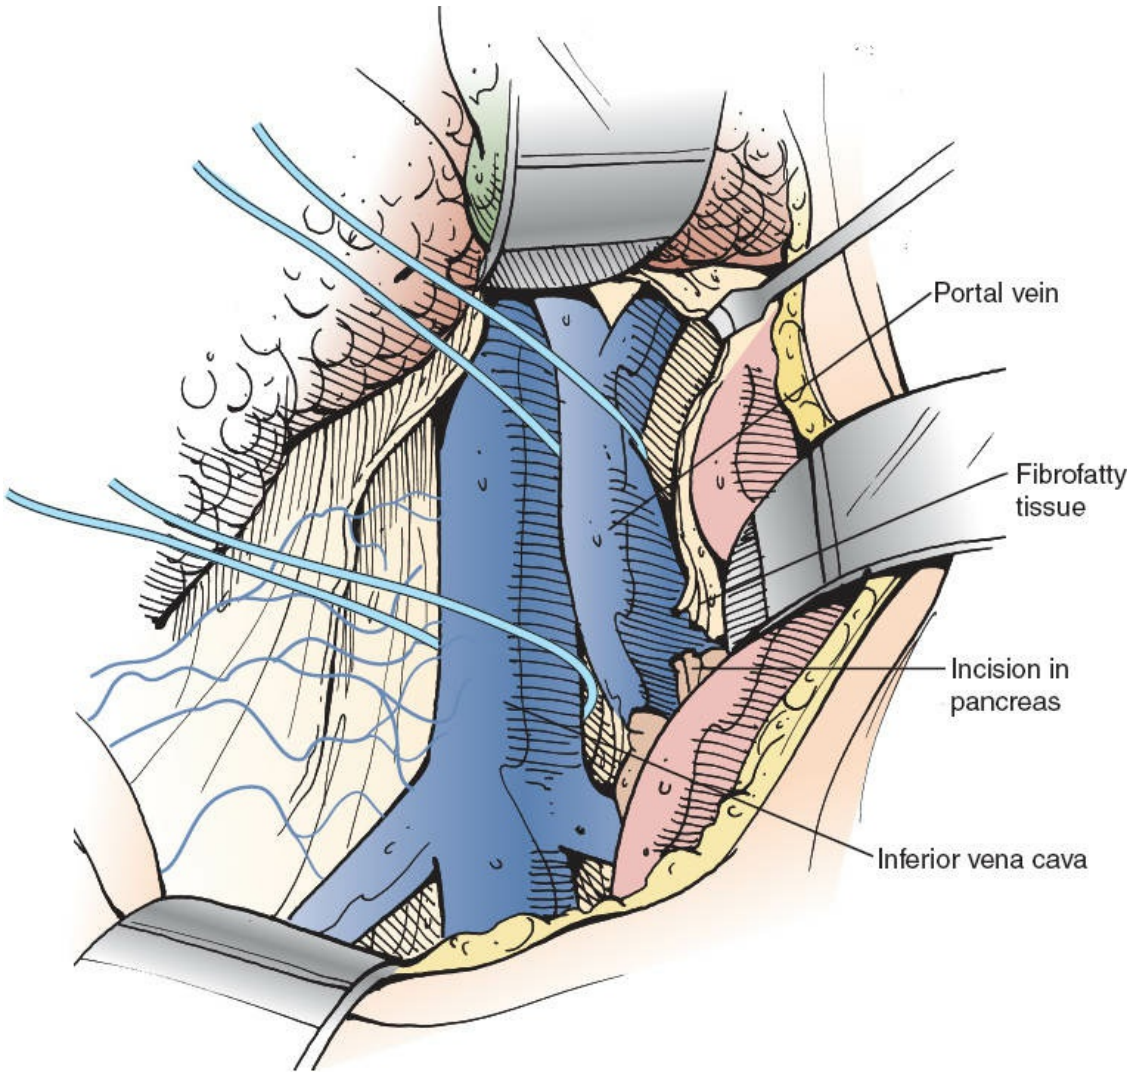

Figure 130.10. Mobilization of the portal vein behind the pancreas. Using the umbilical tape to pull the portal vein out of its bed, the portal vein is cleared to the point where it disappears behind the pancreas. The tough fibrofatty tissue that binds the portal vein to the pancreas must be divided. Wide mobilization of the portal vein is essential for performance of a side-to-side portacaval anastomosis. Failure to mobilize the portal vein behind the pancreas is a second major reason for difficulty in accomplishing the side-to-side shunt. In some patients, it is necessary to divide a bit of the head of the pancreas between right-angled clamps to obtain adequate mobilization of the portal vein. Before incising the pancreas, the surgeon should insert his or her index finger into the tunnel between the portal vein and the pancreas to determine by palpation if there is a replaced common hepatic or right hepatic artery arising from the superior mesenteric artery and crossing the portal vein. Since the portal

venous blood flow to the liver is diverted through the portacaval shunt, ligation of the hepatic arterial blood supply may be lethal.

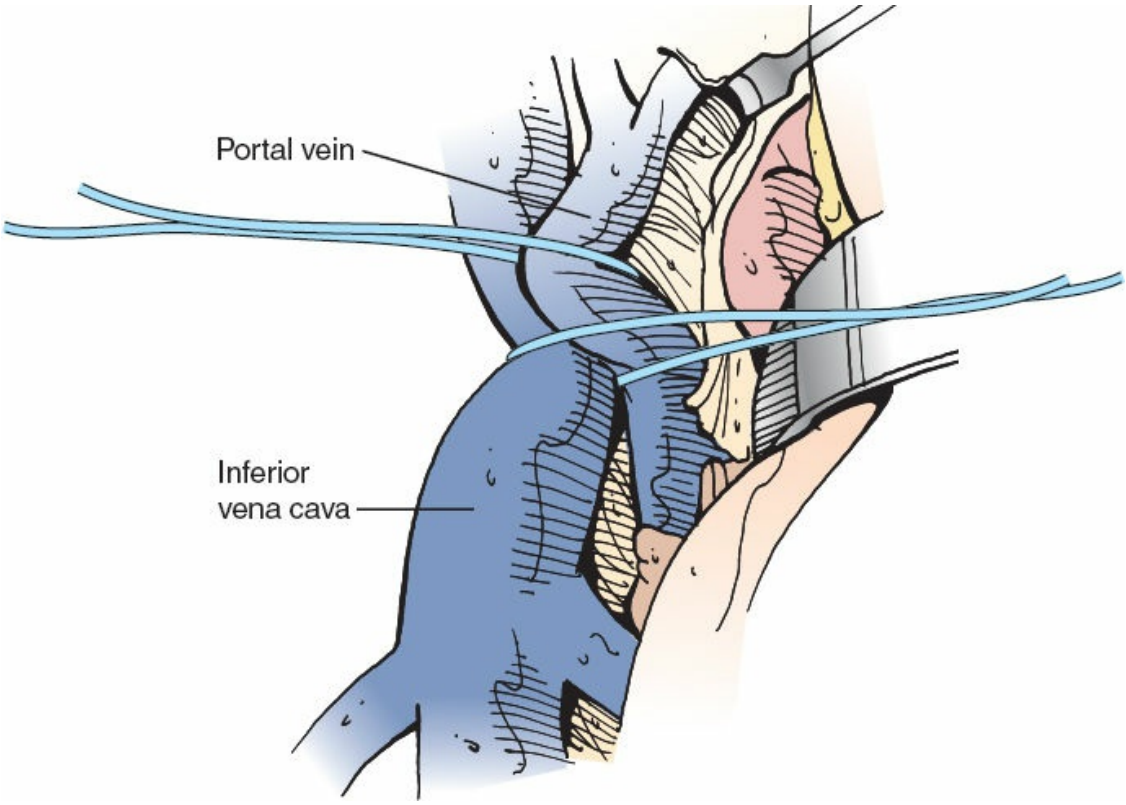

Figure 130.11. Testing adequacy of mobilization of portal vein and IVC. To determine the adequacy of mobilization of portal vein and IVC, the two vessels are brought together by traction on the umbilical tapes that surround them. It is essential to determine that the two vessels can be brought together without excessive tension. If this cannot be done, it is almost always because the vessels have not been adequately mobilized, and further dissection of the vessels should be undertaken. Resection of part of an enlarged caudate lobe of the cirrhotic liver, recommended by some surgeons to facilitate bringing the vessels together, is associated with some difficulties and, in our opinion, is neither necessary nor advisable.

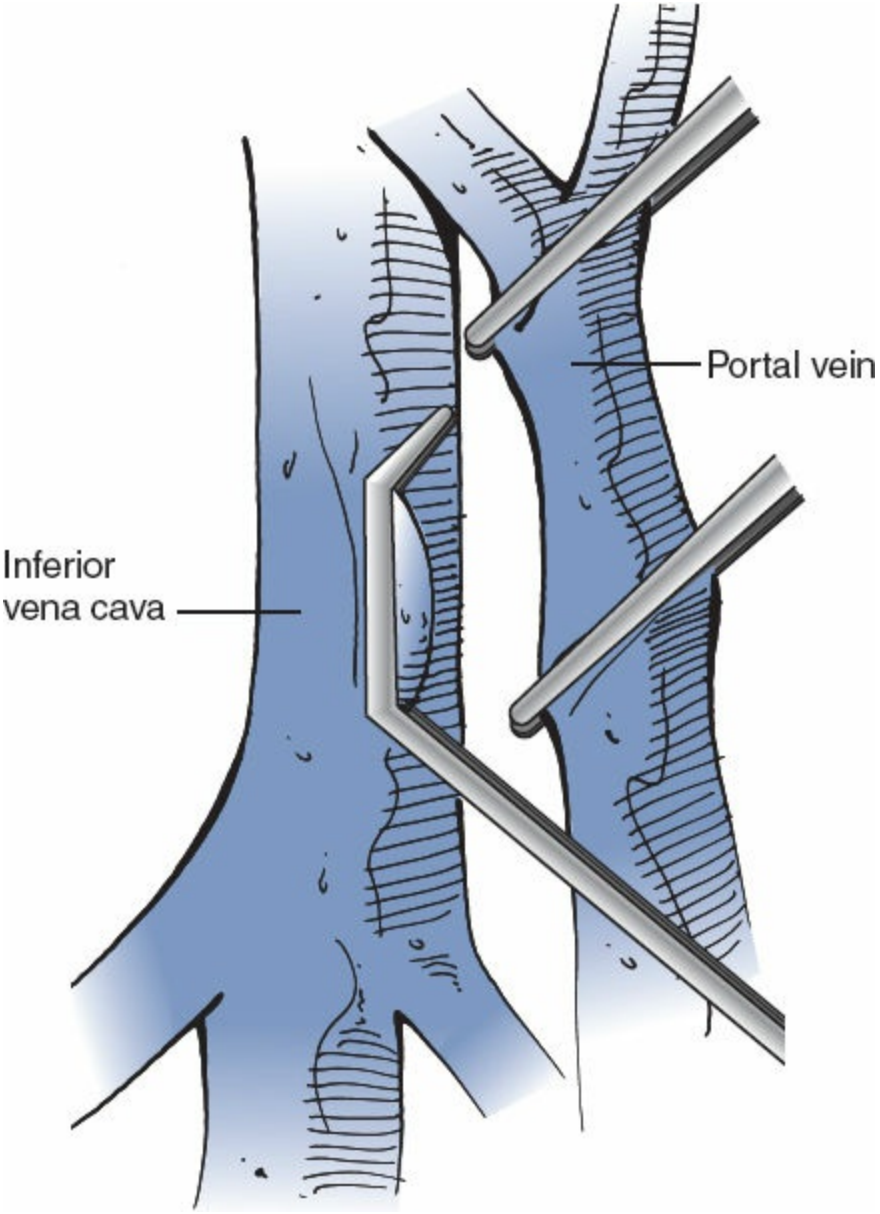

Figure 130.12. Clamping the IVC and portal vein in preparation for a side-to-side portacaval anastomosis. A Satinsky clamp is placed obliquely across a 5-cm segment of the anteromedial wall of the IVC in a direction parallel to the course of the overlying portal vein and the IVC is elevated toward the portal vein. A 5-cm segment of the portal vein is isolated between two angled vascular clamps and the portal vein is depressed toward the IVC, bringing the two vessels into a position.

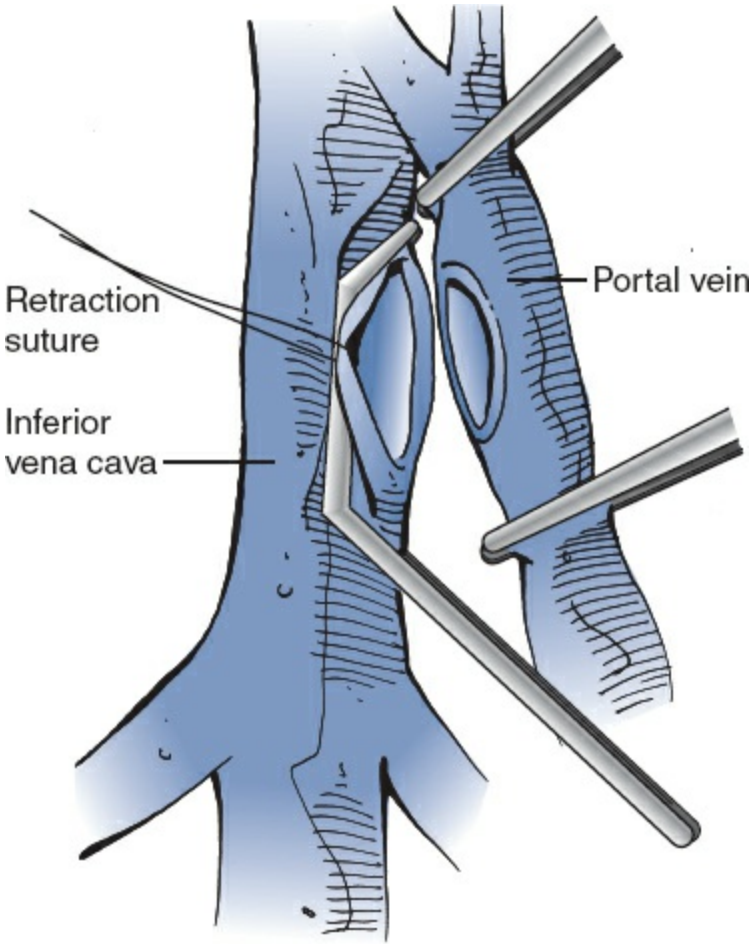

Figure 130.13. Excision of a segment of the wall of each vein in preparation for the side-to-side portacaval anastomosis. A 2.0- to 2.5-cm-long strip of the IVC and a 2.0- to 2.5-cm-long strip of the portal vein are excised with scissors. It is important to excise a longitudinal segment of the wall of each vessel rather than simply making an incision in each vessel. A retraction suture of 5-0 silk is placed in the lateral wall of the IVC opening and is weighted by attachment to a hemostat to keep the IVC orifice open. The clamps on the portal vein are momentarily released to flush out any clots and then the openings in both vessels are irrigated with saline.

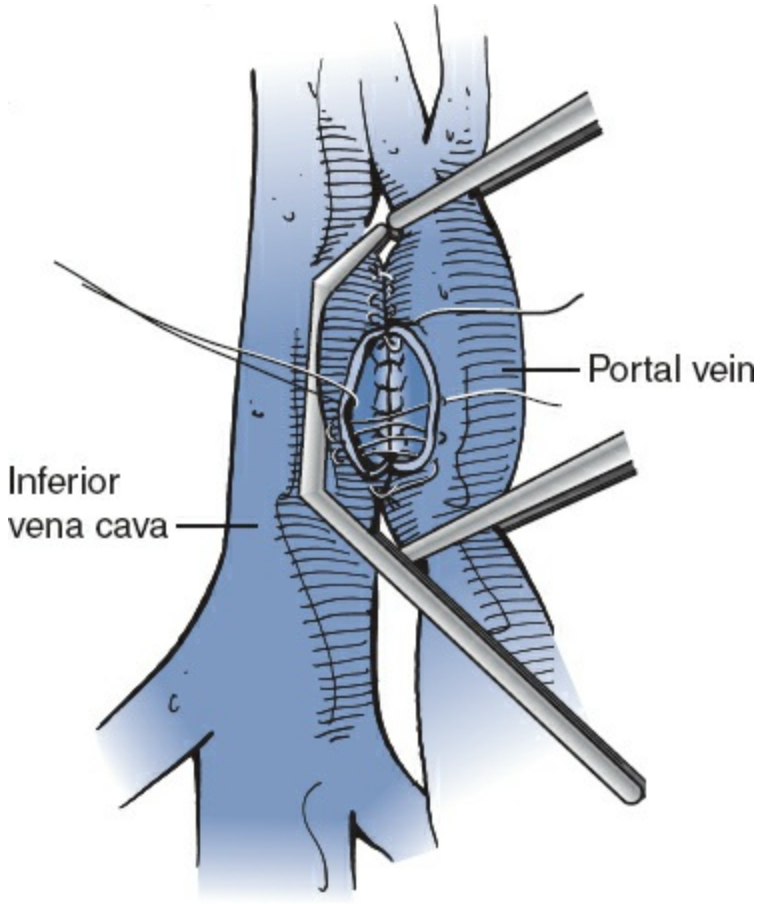

Figure 130.14. Suturing the IVC and portal vein together in a side-to-side portacaval anastomosis.

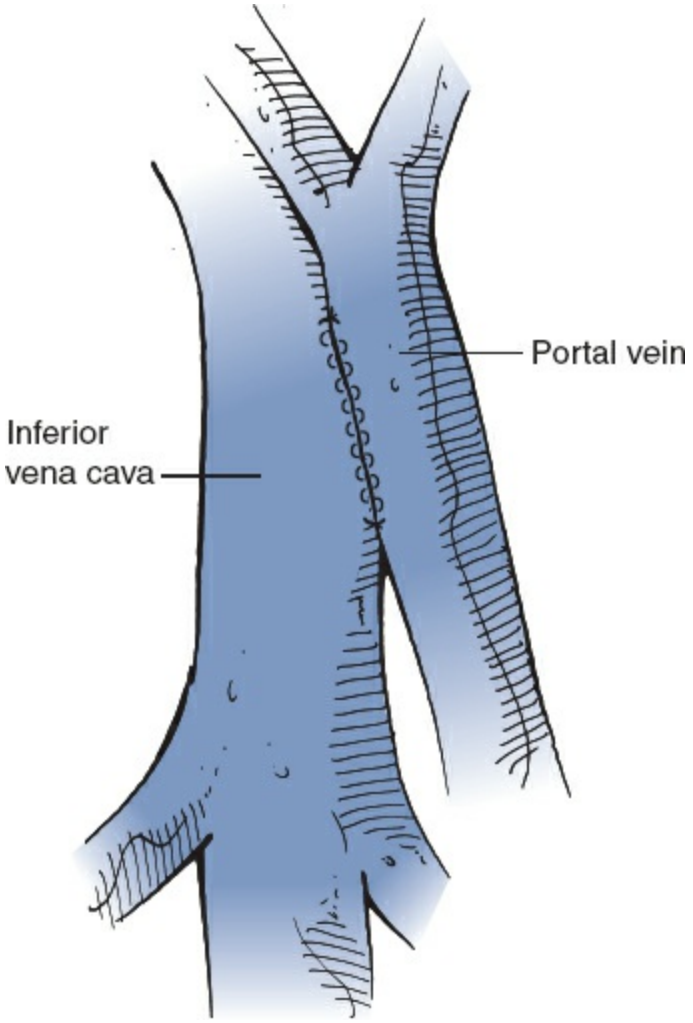

Figure 130.15. The completed side-to-side portacaval anastomosis. Pressures in the portal vein and IVC must be measured after the anastomosis is completed. Usually the postshunt pressures in the portal vein and IVC are identical. A pressure gradient of >50-mm saline between the two vessels indicates an obstruction in the anastomosis, even when no obstruction can be palpated. In such circumstances, the anastomosis should be opened to remove any clots and, if necessary, the entire anastomosis should be taken down and redone. It is essential that there be no more than a 50-mm saline gradient between the portal vein and IVC to achieve permanently adequate portal decompression and to avoid ultimate thrombosis of the shunt. (Republished with permission of SPRINGER-VERLAG BERLIN/HEIDELBERG, from Orloff MJ, Orloff MS, Orloff SL. Portacaval shunts: side-to-side and end-to-side. In: Clavien PA, Sarr MG, Fong Y, Georgiev P, eds. *Atlas of Upper Gastrointestinal and Hepato-Pancreato-Biliary Surgery.* Berlin Heidelberg: Springer-Verlag, 2007:687–702, permission conveyed through Copyright Clearance Center, Inc.)

In summary, the following are important points:

1. The position of the patient on the operating table is crucial and can make the difference between an easy and difficult operation.
2. A long right subcostal incision is associated with many fewer postoperative complications than a thoracoabdominal incision and is much to be preferred.
3. Use of the electrocautery throughout the operation substantially reduces the operating time and the blood loss.
4. Bleeding from the many portosystemic collateral vessels is best managed by pressure with gauze sponge packs, particularly as most of the bleeding stops as soon as the portacaval anastomosis is completed and the portal hypertension is relieved. Attempts to control each of the bleeding collaterals with ligatures and sutures prolong the operation and increase the blood loss. The objective is to decompress the portal system as rapidly as possible.
5. Circumferential mobilization of the IVC between the entrance of the renal veins and the liver is essential for the side-to-side anastomosis and is neither hazardous nor difficult to perform. Apposition of the two vessels is greatly facilitated by elevation of the vena cava toward the portal vein.
6. Mobilization of a long segment of portal vein, which includes division of the tough fibrofatty tissue that binds the portal vein to the pancreas and sometimes includes division of a bit of the head of the pancreas, is essential for the side-to-side anastomosis and sometimes for the end-to-side anastomosis.
7. Beware of the replaced hepatic artery crossing the portal vein behind the head of the pancreas. Palpate it with the index finger in the tunnel between the head of the pancreas and portal vein. Ligation of the hepatic artery may be lethal.
8. Resection of an enlarged caudate lobe of the cirrhotic liver to facilitate apposition of the two vessels is hazardous and unnecessary.
9. Pressures in the IVC and portal vein should always be measured after completion of the PCS. A pressure gradient of >50-mm saline is unacceptable and requires revision of the anastomosis.

AUTHOR'S EXPERIENCE WITH PORTACAVAL SHUNT

Emergency Portacaval Shunt

BEV is a common and highly lethal complication of cirrhosis of the liver. The mortality rate associated with BEV is highest during the period

surrounding the episode of acute bleeding. It is clear that emergency treatment of acute bleeding is of paramount importance in the care of patients with portal hypertension and esophagogastric varices. Accordingly, for the past half-century, the author and his colleagues have conducted and published prospective studies of emergency therapy, and particularly of emergency portacaval shunt (EPCS). Our studies have been distinguished by three features: (1) all patients ("all comers") with BEV as a result of cirrhosis of the liver, regardless of their condition, have been included without selection; (2) the specific emergency treatment undergoing evaluation has been administered within 8 hours of initial contact; and (3) our studies have been prospective, meaning that a well-defined protocol was consistently used and data were collected online.

One of our recent and most definitive studies have been two randomized controlled trials (RCT), supported by a grant from the National Institutes of Health. The first of these RCTs compared endoscopic sclerotherapy (EST) with EPCS in cirrhotic patients with acute variceal hemorrhage. A total of 211 unselected, consecutive patients with cirrhosis and acute BEV who required at least 2 units of blood transfusion were randomized to EST (n = 106) or EPCS (n = 105). Diagnostic workup was completed within 6 hours and EST or EPCS was initiated within 8 hours of initial contact. Long-term EST was performed according to a deliberate schedule. Ninety-six percent of patients underwent more than 10 years of follow-up, or until death. The percent of patients in Child's risk classes were: A, 27.5; B, 45.0; and C, 27.5. EST achieved permanent control of bleeding in only 20% of patients; EPCS permanently controlled bleeding in every patient ($P \leq 0.001$). Requirement for blood transfusions was greater in the EST group than in the EPCS patients. Compared with EST, survival after EPCS was significantly higher at all time intervals and in all Child's classes ($P \leq 0.001$). Figure 130.16 shows the 15-year Kaplan–Meier estimated survival plots for the EST and EPCS groups, overall and according to Child's risk classes at the time of entry in the study. As expected, survival rate was related to the severity of hepatic disease.

An important factor responsible for the success of EPCS was a low incidence of early and long-term PCS thrombosis, which was determined yearly by ultrasonography. The shunt remained permanently patent in 98% of the patients. This outcome was consistent with our past experience with ~2,500 SSPCSs in which occlusion of the anastomosis developed in only

0.5%.

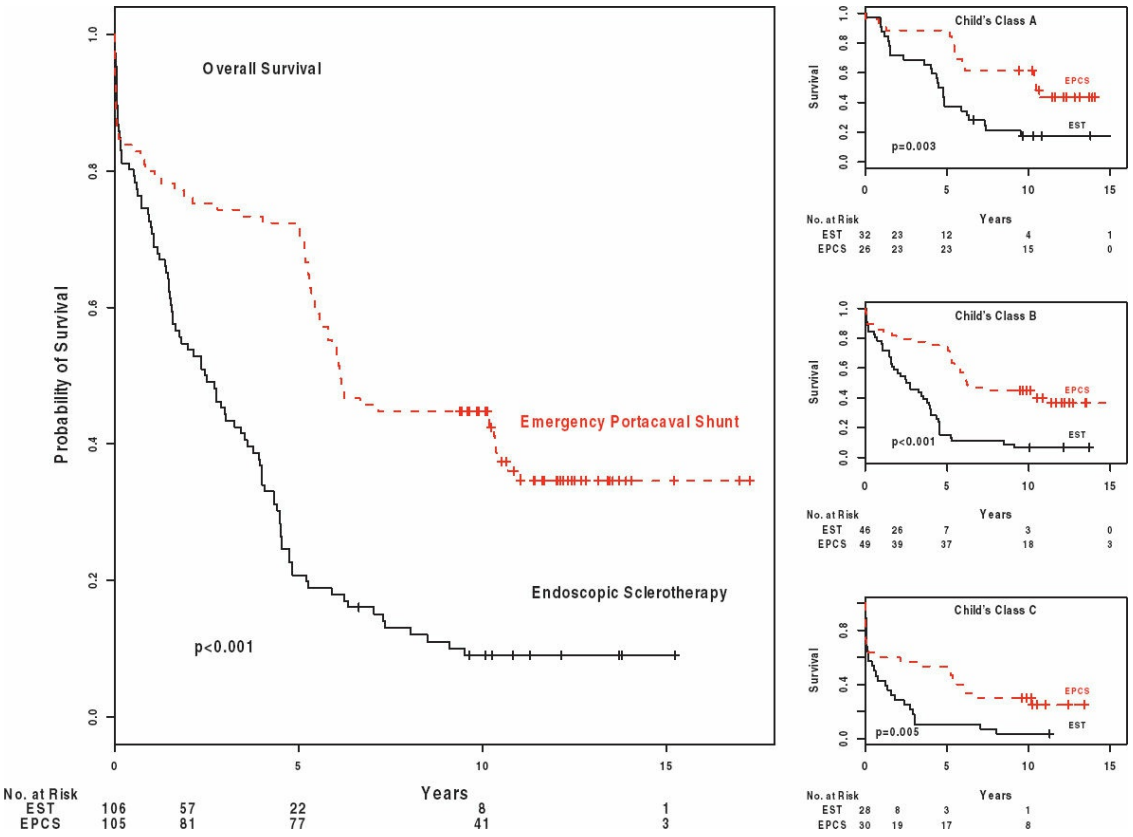

Figure 130.16. Kaplan–Meier estimates of overall survival, and survival in Child's risk classes A, B, and C in a randomized controlled trial (RCT) of endoscopic sclerotherapy (EST) versus emergency portacaval shunt (EPCS) in 211 unselected patients with bleeding esophageal varices (BEV) due to cirrhosis. (From Orloff MJ et al. Randomized trial of emergency endoscopic sclerotherapy versus emergency portacaval shunt for acutely bleeding esophageal varices in cirrhosis. *JACS* 2009;209:25–40. There is a widespread belief that portosystemic shunts are associated with a high incidence of portal-systemic encephalopathy (PSE), and that this serious complication undermines and indeed negates the life-saving benefits achieved by surgical control of bleeding. In our recently reported RCT, PSE was quantitated by a "blinded" senior faculty gastroenterologist during regular follow-up that was 100% and lasted for more than 9.4 years or until death. Four variously weighted components of PSE were graded on a scale of 0 to 4: (a) mental state, (b) asterixis, (c) number connection test, and (d) arterial blood ammonia. The incidence of recurrent PSE in the two groups of patients over a period of 15 years is shown in Figure 130.17.

PSE occurred in 35% of EST patients and only in 15% of EPCS patients ($P \leq 0.001$). These results were facilitated by rigorous, frequent, and lifelong follow-up that included regular counseling on dietary protein restriction and abstinence from alcohol, and by long-term patency of the PCS in 98% of patients. Furthermore, these results call into question the practice of avoiding PCS because of fear of PSE, and thereby foregoing the life-saving advantage achieved by surgical control of bleeding.

An important part of our first recent RCT was continuous assessment of disability to create a Disability Index (DI) based on nine factors: (a) change in Child's class, (b) recurrent PSE, (c) number of PSE episodes, (d) number of blood transfusions, (e) number of readmissions to the hospital, (f) days of hospitalization during readmissions, (g) alcoholism, (h) return to work, and (i) PCS patency. These factors were assigned numerical weights from which a DI score was calculated. The lower the DI score, the less was the disability. Overall, DI score was significantly lower (i.e., better) in patients treated by EPCS than in those treated by EST throughout the long period of follow-up ($P < 0.001$).

Another important assessment included in our RCT was a determination of the total costs of care of EPCS and EST. All hospital and outpatient facility charges and all professional fee bills from our medical center and from referring hospitals and physicians were obtained continuously for every patient entered in the RCT for 10 years. Mean charges per year were \$168,100 in the EST patients and \$39,400 in the EPCS patients ($P < 0.001$). EPCS was strikingly superior to EST with regard to direct costs of care measured for 10 years.

Liver transplantation (LT) is the only curative treatment of cirrhosis, and some transplant centers have considered BEV in cirrhosis to be an indication for LT. This issue was examined as part of our RCT. The analysis was supplemented by 1,300 unrandomized cirrhotic patients in whom we had previously performed PCS, with 100% follow-up. Only 4 RCT patients (2%) and only 19 unrandomized PCS patients (1.5%) underwent LT. Mean 1- and 5-year LT survival rates were 0.68% and 0%, compared to 81% and 73% after EPCS. We concluded that cirrhotic patients with BEV seldom require LT-provided bleeding is permanently controlled, as occurs following EPCS. Furthermore, should LT be required, numerous studies have shown that PCS does not increase mortality rate or complications. LT is beset by a number of limitations that include unavailability of donor livers, failure to qualify for LT for medical,

social, and economic reasons; and lifelong costs that are more than three times those of EPCS.

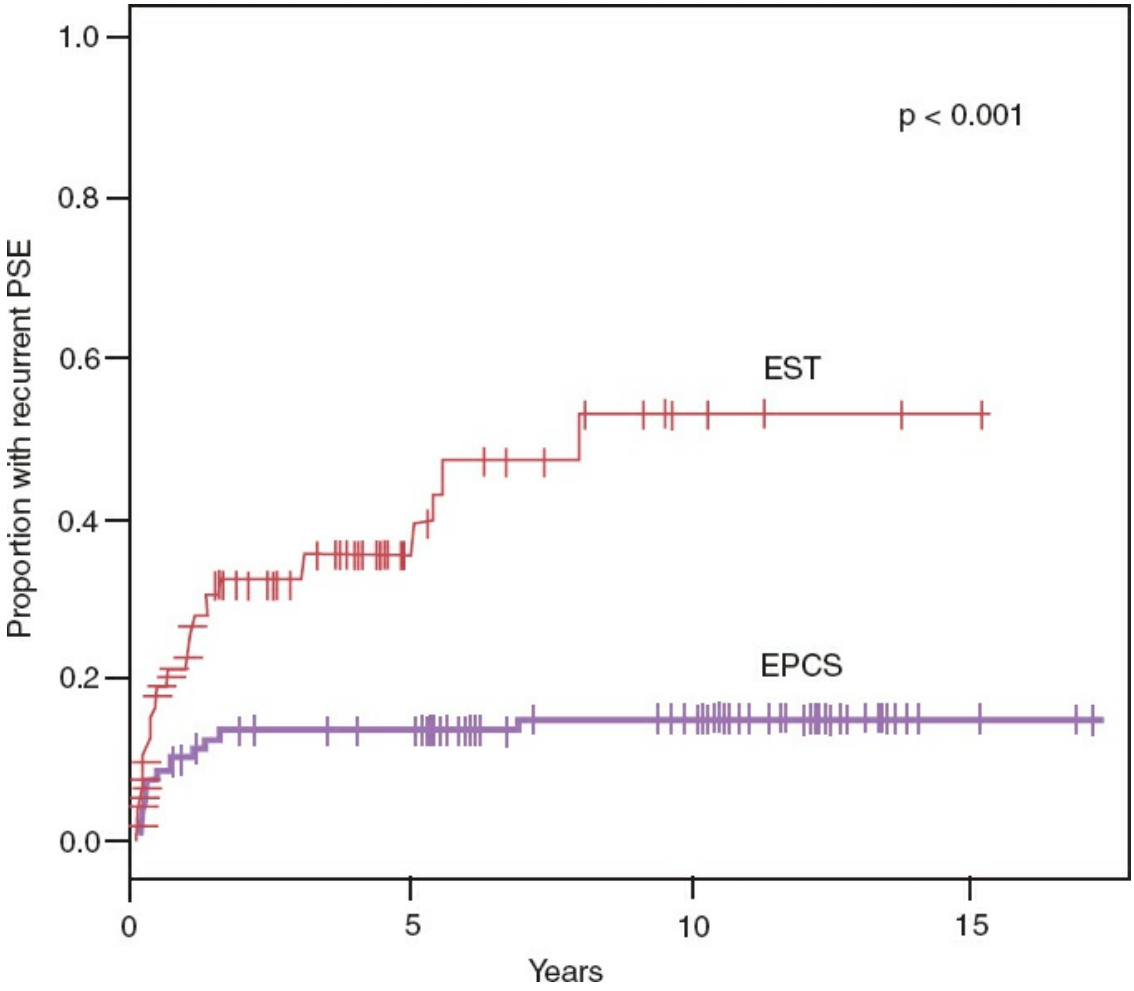

Figure 130.17. Incidence and timing of recurrent portal-systemic encephalopathy (PSE) in patients who were randomized to EST (*n* = 93) or EPCS (*n* = 89) and survived >30 days and were discharged from the hospital.

Alcoholic cirrhosis is the most common cause of BEV. Yet, it has been proposed that portosystemic shunts should be avoided in alcoholic cirrhosis because, according to retrospective, unrandomized observations of elective treatment of BEV by portosystemic shunts, survival rate was significantly lower in alcoholic than in nonalcoholic cirrhotics, especially with regard to distal splenorenal shunt. We examined this important issue in our RCT and found no difference between alcoholic and nonalcoholic cirrhotics with regard to (a) permanent control of bleeding, (b) survival, (c) incidence of PSE, (d) improvement in Child's class, (e) QOL, and (f) cost of care.

EPCS is infrequently used today because of the belief, unsubstantiated by long-term randomized trials, that PCS causes frequent PSE and liver failure. The main use of PCS today is as rescue therapy when endoscopic and pharmacologic therapies have failed. Since the protocol of our RCT involved crossover rescue PCS when EST failed, we had the unique opportunity to evaluate in 50 patients the widely used practice of rescue PCS for EST failure to permanently control BEV. EPCS was strikingly superior to EST as well as to the combination of EST and rescue PCS in regard to all outcome measures, specifically bleeding control, survival, incidence of PSE, improvement in liver function, DI, and cost of care ($P < 0.001$) (Fig. 130.18). The results of every aspect of our RCT strongly support use of EPCS as the first line of emergency treatment of BEV in all forms of cirrhosis.

In our second recent RCT currently in press, we compared TIPS and EPCS in 154 unselected, consecutive cirrhotic patients ("all comers") with acute BEV. TIPS ($n = 78$) and EPCS ($n = 76$) were compared with regard to effect on survival, control of bleeding, PSE, disability index, and economic costs. Diagnostic workup was completed within 6 hours and TIPS or EPCS was initiated within 24 hours. Regular follow-up was accomplished in 100% of patients and lasted for 5 to 10 years in 85%, and 3 to 4.5 years in the remainder.

The clinical characteristics of the two groups were similar, and the distribution of Child's classes A, B, and C was almost identical. TIPS was successful in controlling BEV for 30 days in 80% of patients, but achieved long-term control of BEV in only 22%. In contrast, EPCS controlled BEV immediately in all patients, and permanently in 97% ($P < 0.001$). TIPS patients required almost twice as many units of blood transfusion as EPCS patients. Survival rate at all time intervals and in all Child's classes was significantly greater following EPCS than after TIPS ($P < 0.001$) (Fig. 130.19). Median survival was over 10 years following EPCS, compared to 1.99 years following TIPS. Stenosis or occlusion of TIPS was demonstrated in 84% of patients who survived 21 days, 63% of whom underwent TIPS revision, which failed in 80%. In contrast, EPCS remained permanently patent in 97% of patients. Recurrent PSE was threefold more frequent following TIPS than after EPCS, 61% versus 21%. In conclusion, EPCS was uniformly effective in treatment of BEV, while TIPS was disappointing. EPCS accomplished long-term survival while TIPS resulted in a survival rate that was less than one fifth that of EPCS.

The results of this RCT in unselected, consecutive patients provide further support for use of EPCS as a first-line emergency treatment of BEV in cirrhosis.

Elective Portacaval Shunt

Elective PCS is the most widely used form of portosystemic shunt. In general, it has been used in highly selected patients who have recovered from one or more episodes of BEV and are in sufficiently good condition to undergo a major operation. In general, patients in Child's risk class C have been excluded from elective PCS. We have analyzed our results of elective PCS in 1,000 patients with cirrhosis who were referred to us from other institutions after having recovered from BEV. Eighty-five percent of them had chronic alcoholic cirrhosis with or without chronic viral hepatitis. Child's risk classes were: A, 11%; B, 58%; and C, 31%. Survival rates were 98.4% at 30 days, 95% at 1 year, 71% at 5 years, 65% at 10 years, and 61% at 15 years. Survival rates of EPCS in unselected patients ("all comers") in our RCT were not significantly different from the survival rates in these highly selected patients following elective PCS. During 15 years of follow-up, three patients had recurrent BEV (0.3%), three patients developed thrombosis of the PCS (0.3%), and 7% of patients developed recurrent PSE. Liver function improved in 75% of patients. After 5 years, only 6% of patients were in Child's risk class C compared to 31% in class C preoperatively. It is important to recognize that many patients with BEV died without being referred for elective PCS, and that the patients who were referred to us for elective portal decompression were highly selected and not comparable to the patients in our RCT.

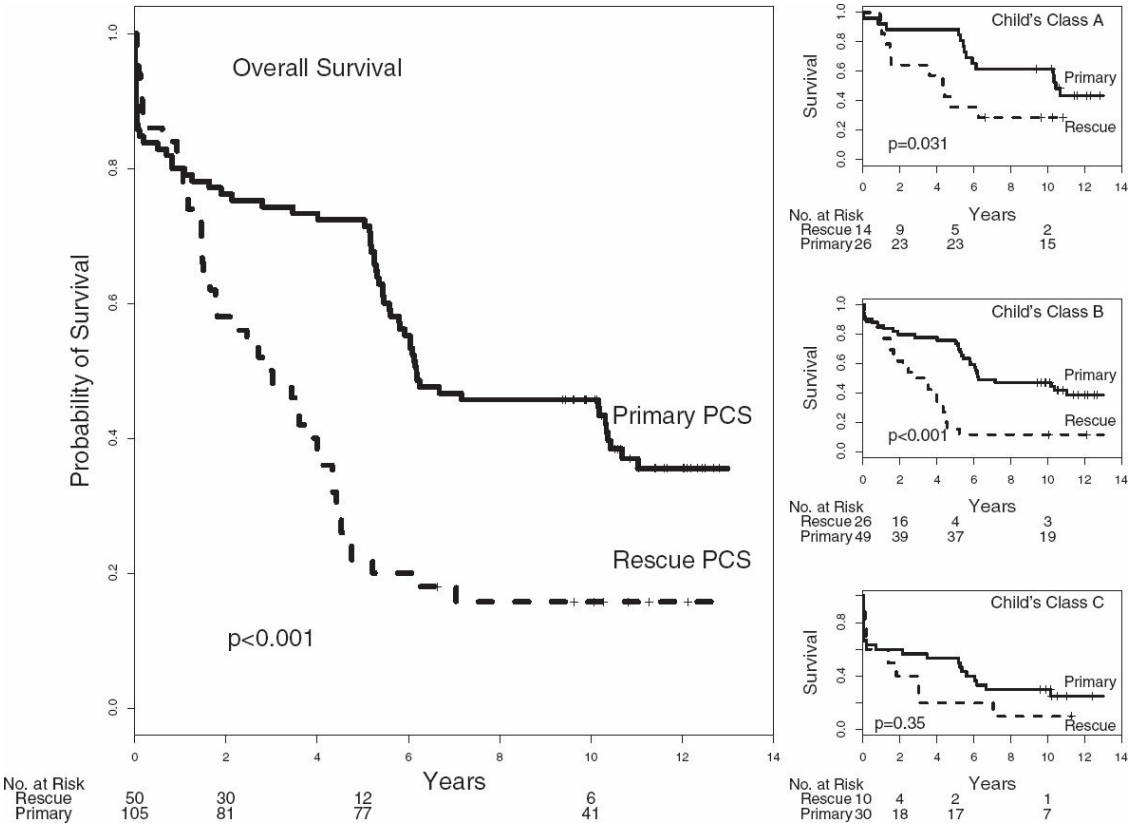

Figure 130.18. Kaplan–Meier estimates of overall survival after emergency portacaval shunt (EPCS, *n* = 50) and after failed endoscopic sclerotherapy (EST) with rescue portacaval shunt (PCS, *n* = 50). (From Orloff MJ et al. Emergency portacaval shunt versus rescue portacaval shunt in a randomized controlled trial of emergency treatment of bleeding esophageal varices in cirrhosis. *J Gastrointest Surg* 2010;14:1782–95.)

Extrahepatic Portal Hypertension

Extrahepatic portal hypertension (EHPH) is responsible for 8.4% of the cases of portal hypertension in our large series. It is usually caused by thrombosis of the portal vein. This condition is strikingly different from EHPH resulting from cirrhosis. The patients are usually much younger and often are children. They have normal liver function, are otherwise in good health, and tolerate variceal bleeding without the development of hepatic decompensation, coagulopathy, PSE, and exsanguination. Except in infancy, they rarely have ascites, and hepatic coma resulting from liver cell failure does not develop. Because the portal vein is obliterated, a direct anastomosis from the portal vein to the IVC cannot be performed for portal decompression. Finally, age and the related technical matter of adequate vessel size influence treatment.

Patients with EHPH come to medical attention usually because of bleeding from esophagogastric varices or splenomegaly. On physical examination, splenomegaly is almost always found, but the liver is not palpable. Liver function tests are usually normal, but hematologic studies often reveal peripheral cytopenia that reflects hypersplenism. The hypersplenism is infrequently severe. Esophagogastroscopy demonstrates varices. Ultrasonography of the abdomen regularly shows occlusion of the PV. Splenic or superior mesenteric arteriography, with indirect portography, is an important diagnostic procedure that provides crucial information about the site of portal obstruction and the size of the vessels available for portal decompression.

The definitive treatment of EHPH is portosystemic shunt. However, emergency shunt operations are rarely necessary. From 1958 to 1999, we conducted a prospective, unrandomized study of portosystemic shunt treatment of 200 unselected, consecutive children and adults with portal vein thrombosis who had bled two or more times from esophagogastric varices. All patients had undergone regular follow-up and 93% have been observed for 10 or more years. Etiology of portal vein thrombosis was neonatal omphalitis in 15%, peritonitis in 7%, umbilical or portal vein catheterization in 7%, trauma in 4%, thrombotic coagulopathy in 3%, and unknown in 65% of the patients. Liver function test results and liver biopsies were normal in all patients, and none had stigmata of liver disease. All patients with an intact spleen had hypersplenism. Esophagogastric varices were demonstrated by angiography, endoscopy, and contrast x-rays. Previous therapy had failed to stop recurrent bleeding in 95% of patients; splenectomy had been tried and failed in 58 (29%) and repetitive EST or variceal banding had been tried and failed in 106 (53%). Ninety-one percent had three or more bleeding episodes. The extent of occlusion and the veins available for PSS were determined by angiography. Thrombosis involved portal vein alone in 134 patients (67%), portal vein and splenic vein in 56 (28%), and portal vein and SMV in 10 (5%) (Fig. 130.20). Accordingly, central side-to-side splenorenal shunt without splenectomy was done in 94 patients (47%), conventional central splenorenal shunt with splenectomy was done in 40 (20%), and mesocaval (SMV-IVC) shunt was done in 66 (33%) (Fig. 130.21). Portosystemic shunt reduced the mean PV-IVC pressure gradient (mm saline) from 296 to 25.

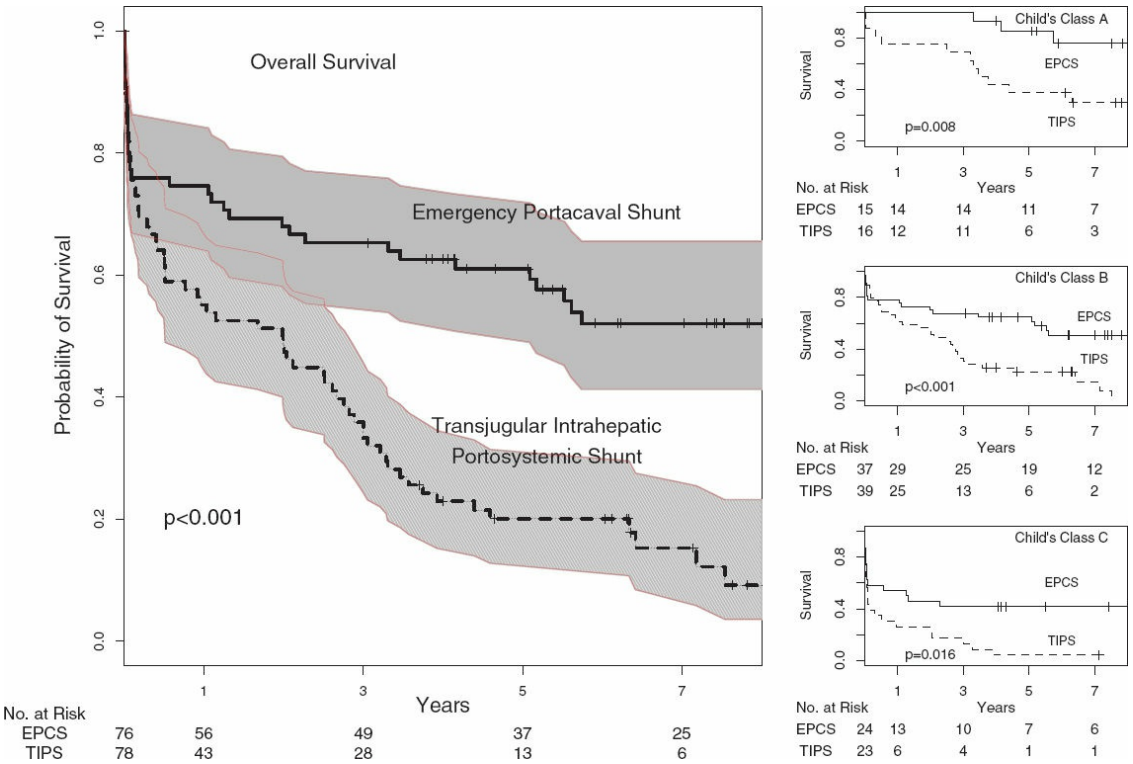

Figure 130.19. Kaplan–Meier estimates of overall survival and survival in Child's risk classes A, B, and C following emergency portacaval shunt (EPCS) (*n* = 76) and TIPS (*n* = 78). Confidence intervals are represented by shaded areas. (From Orloff MJ, Vaida F, Haynes KS, et al. Randomized controlled trial of emergency transjugular intrahepatic portosystemic shunt versus emergency portacaval shunt treatment of acute bleeding esophageal varices in cirrhosis. *J Gastrointest Surg* 2012;16(11):2094–111. Copyright © 2012 The Society for Surgery of the Alimentary Tract, with permission of Springer.)

Postoperative survival to leave the hospital was 100%. 5-, 10-, and 15-year actuarial survival rates were 99%, 97%, and 96%, respectively. Angiography and/or Doppler ultrasonography every 1 to 2 years demonstrated thrombosis of the portosystemic shunt in five patients (2.5%), all of whom developed rebleeding. All other patients remained free of bleeding with patent shunts, normal liver function tests, and no instance of PSE. Hypersplenism was corrected and the platelet count was restored to a level above 100,000/mm^3 in all patients.

Based on our 50-year experience with 100% follow-up of 200 patients, we conclude that PSS is consistently effective in bleeding varices due to PVT and EHPH, resulting in long survival, freedom from rebleeding, and no PSE. No other therapy, including endoscopic therapy, drugs, and TIPS

is consistently effective in this disorder.

Budd–Chiari Syndrome

BCS is a group of disorders in which obstruction to hepatic venous outflow results from occlusion of the hepatic veins and/or the adjacent IVC. The most common conditions that predispose to BCS are hematologic disorders with thrombotic tendencies such as polycythemia rubra vera and paroxysmal nocturnal hemoglobinuria, use of oral contraceptives, and pregnancy and the postpartum period. The pathologic lesion of BCS is thrombosis of the major hepatic veins and/or the IVC, which results in hepatic venous outflow obstruction, intrahepatic and portal hypertension, dilatation of the liver sinusoids, intense centrilobular congestion of the hepatic parenchyma and ischemia, pressure necrosis, and atrophy of the parenchymal cells in the center of the liver lobule. The usual clinical manifestations are abdominal distension due to massive ascites, hepatomegaly, abdominal pain, weakness, wasting, and anorexia. When the IVC is obstructed, an important additional sign is edema of the lower extremities and lower trunk.

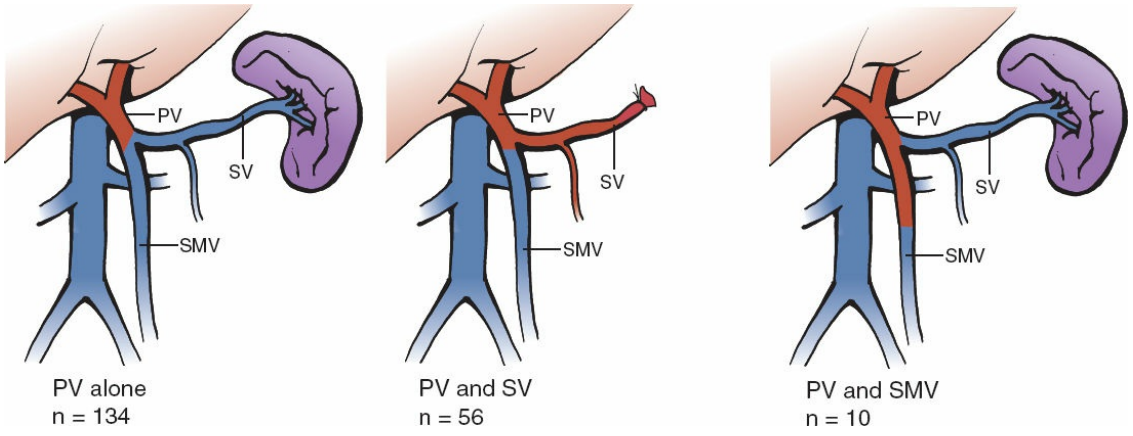

Figure 130.20. Sites of portal vein thrombosis in 200 patients with extrahepatic portal hypertension.

The diagnosis of BCS is based on finding the typical symptoms and signs combined with abnormal results of several diagnostic studies, the two most important of which are angiographic examination of the IVC and hepatic veins with pressure measurements and percutaneous needle biopsy of the liver. Hepatic venography shows occlusion of the major hepatic veins. Liver biopsy reveals the typical lesion of obstruction to hepatic venous outflow, namely, intense centrilobular congestion and centrilobular

loss of parenchyma and necrosis.

On the basis of experiments in our experimental research laboratory that demonstrated relief of BCS in animals by SSPCS, we undertook a prospective unrandomized study of the treatment of BCS in 77 patients. In 39 patients with BCS due to hepatic vein occlusion alone, SSPCS had an operative mortality rate of 2.6%, and 95% of the patients are currently alive 5 to 37 years postoperatively, with freedom from ascites and normal liver function. Eighteen patients with BCS due to IVC occlusion were treated by a bypass procedure that we devised in the experimental laboratory consisting of a high flow combination SSPCS and IVC-to-atrium synthetic shunt graft (Fig. 130.22). There were no operative or long-term deaths, and the shunts have functioned effectively during 5 to 25 years of follow-up. Permanent anticoagulation therapy has been used in all patients with synthetic grafts.

Fifteen patients with advanced cirrhosis in Child's class C were referred too late to benefit from surgical portal decompression, and they were approved and listed for LT. Four patients died from liver failure while on the list awaiting LT, and five patients died after LT. The 5-year survival rate was 67%. It should be emphasized that LT and SSPCS are not competing forms of treatment. SSPCS is the appropriate treatment in the early and middle stages of BCS when portal decompression will sustain life by reversing or stabilizing the liver disease. LT is the appropriate treatment in the late stages of BCS when the liver disease is no longer reversible and when stabilization of progressive hepatic decompensation is not possible. By and large, patients who are candidates for LT should be in Child's class C.

systemic shunt procedures performed in 200 patients with extrahepatic portal hypertension caused by portal vein thrombosis.

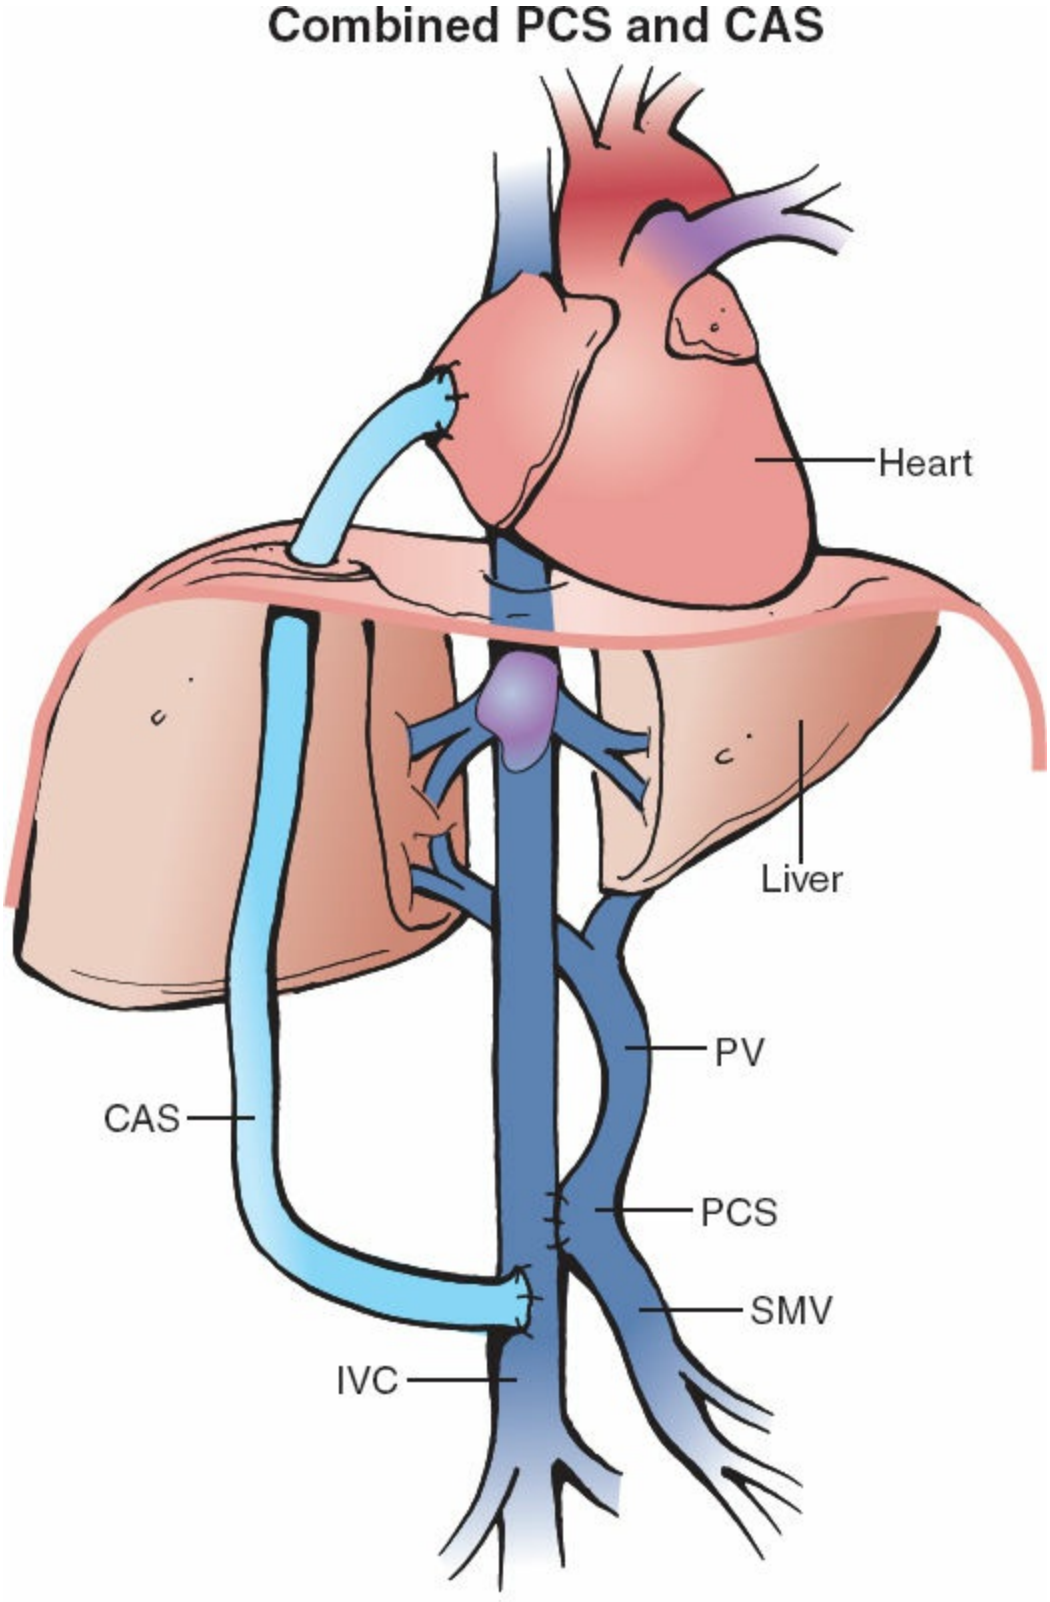

Figure 130.22. Combined side-to-side portacaval shunt and

caval-atrial shunt using a 20-mm ring-reinforced Gore-Tex graft performed in 12 patients with Budd–Chiari syndrome (BCS) secondary to IVC occlusion. PCS, portacaval shunt; CAS, caval-atrial shunt.

EXPLODING SOME MYTHS

1. MYTH #1: EPCS has a high mortality rate. RESPONSE: Our studies over the past 50 years, including our two RCTs in unselected, consecutive patients with BEV, have consistently demonstrated a low mortality rate when the diagnostic workup and operation were undertaken within 24 hours of the onset of bleeding. In our two RCT of this highly lethal disease, EPCS had a 30-day survival rate of 87% and 77%, respectively, and a 5-year survival rate of 73% and 61%, respectively.
2. MYTH #2: EPCS and other uses of direct PCS control bleeding at the expense of an unacceptably high incidence of PSE. RESPONSE: Our studies over the past 50 years, including our recently reported RCT, have consistently demonstrated a low incidence of PSE, which is significantly lower than the PSE incidence following endoscopic therapy of BEV and TIPS. Regular long-term follow-up with emphasis on dietary protein restriction and abstinence from alcohol plays an important role in achieving a low incidence of PSE.
3. MYTH #3: EPCS and other uses of direct PCS produce liver failure by depriving the liver of essential portal blood flow. RESPONSE: A fundamental physiologic response to diversion of portal venous flow is a compensatory increase in hepatic arterial blood flow to the liver. In the final analysis, the long-term improvement in liver function following EPCS observed in all our studies, including our two recent RCTs, provides meaningful objective information that contradicts the suggestion that PCS causes liver failure.
4. MYTH #4: Surgical decompressive procedures that involve the hepatic hilum should be avoided in potential liver transplant candidates because they affect the outcome of LT. RESPONSE: Our RCT demonstrates that LT is seldom required in patients with BEV treated by EPCS. Furthermore, at least 10 reports of retrospective studies in the literature concluded that portosystemic shunts do not affect the results of subsequent LT.
5. MYTH #5: Patients with cirrhosis in Child’s class C should not undergo portosystemic shunts because of a high mortality rate.

RESPONSE: In 1992, we reported the results of EPCS in 94 unselected patients with Child's class C cirrhosis. Eighty percent left the hospital alive, 72% survived 1 year, and 64% survived 5 years. Recurrent PSE developed in 9%. Liver function improved in 82%. In our two recent RCTs, 57% and 42%, respectively, of Child's class C patients treated by EPCS survived 5 years, and none of them developed PSE.

6. MYTH #6: Severe thrombocytopenia in patients with cirrhosis is best treated by splenectomy and is a contraindication to portosystemic shunt. RESPONSE: A substantial number of our patients with BEV have had severe thrombocytopenia. We have undertaken EPCS in many patients with platelet counts below 50,000/mm^3. Effective portal decompression by EPCS has invariably relieved hypersplenism and thrombocytopenia.

PANCREATICODUODENECTOMY

Another category of surgical procedure that requires a working knowledge of the portal vein is pancreaticoduodenectomy. When this operation is performed for a neoplasm of the pancreatic head, it is crucial to determine whether the portal and SMVs are free from tumor invasion as they course posterior to the neck of the pancreas. Exposure of the neck of the pancreas can be considerably improved by division of the right gastroepiploic vein as it courses across the anterior surface of the neck of the gland to insert into the SMV. Portal and SMV involvement by tumor can then be determined before resection, by establishing a "tunnel" underneath the neck of the pancreas, anterior to the portal vein. First, the anterior surface of the portal vein within the hepatoduodenal ligament is identified. Then, with a Kuttner dissector or other blunt-tipped instrument, the anterior surface of the portal vein is gently separated from the posterior aspect of the pancreas. Once a few centimeters have been cleared, the tunnel should be completed from below. This step involves entering the lesser sac, incising the peritoneum over the inferior margin of the pancreas, and identifying the SMV where it runs underneath the pancreas by following the middle colic vein down the cephalad aspect of the transverse mesocolon to the junction of the two veins. The vein (initially the SMV, then the portal vein proper) is gently separated from the posterior aspect of the pancreas. In the absence of neoplastic invasion, the vein should separate easily from the pancreas. The patency of the tunnel can be confirmed with a finger or a long, blunt clamp. It is stated in some texts

that venous tributaries do not enter the anterior surface of the portal or SMV. Others have disputed this observation, however, and cadaveric dissections have documented the frequent insertion of the pyloric vein and the right gastroepiploic vein into the anterior surface of the portal and SMV, respectively. Therefore, this dissection must be performed with care.

Once respectability has been established, pancreatic neck is transected, allowing full exposure of the portal outflow system including the portal vein, SMV, and splenic vein. The head of the pancreas must now be separated from the portal vein. This necessitates the careful identification, ligation, and division of the branches running from the pancreatic head and uncinate process into the right lateral aspect of the portal vein and SMV. These include, with some variability, the superior and inferior pancreaticoduodenal veins, the right gastroepiploic vein, and other anomalous branches arising as a result of the nearby neoplastic process. These venous branches must be managed carefully to control hemorrhage, preserve hepatic arterial inflow in the presence of a replaced right hepatic artery, and preserve the enteric venous outflow.

HEPATIC RESECTION

Knowledge of portal vein anatomy is also useful in performing hepatic resections. As mentioned in “Descriptive Anatomy,” the portal vein usually bifurcates in the fibrous tissue at the right lateral aspect of the hilar plate. It is therefore possible to ligate and divide either branch at this point before resecting hepatic parenchyma when undertaking a formal right or left hepatic lobectomy. Exposure of the right portal vein can be improved by mobilizing the liver (i.e., incising the coronary, triangular, and falciform ligaments) and retracting the right lobe to the left and anteriorly. In 12% of patients, the anterior and posterior branches to the right lobe arise directly from the portal trunk (as opposed to the branching off of a proper right portal vein trunk as it enters the hepatic parenchyma), giving the appearance of a trifurcation in the porta hepatis. The left portal vein can usually be exposed with minimal dissection where it runs as the pars transversa in the left lateral aspect of the hilar plate. When performing a right trisegmentectomy (right lobe plus left medial segment) or a left lateral segmentectomy, the surgeon must be cognizant of the portal blood supply to the left medial and lateral segments, and thus avoid resection through the umbilical fissure. The previously described pars umbilicus of

the left portal vein runs in the umbilical fissure, heading anteriorly until it fuses with the ligamentum teres hepaticus. The portal branches to the left medial segment run from the pars umbilicus in the fissure back toward the right. The branches to the left lateral segment feed from the pars umbilicus in the fissure toward the left (Fig. 130.22). Therefore, in the case of right trisegmentectomy, hepatic parenchymal dissection should be performed to the right of the umbilical fissure to avoid devascularizing the remaining left lateral segment. Conversely, in the case of left lateral segmentectomy, dissection should be performed to the left of the fissure to avoid devascularizing the left medial segment.

IMAGING PORTAL ANATOMY

The modern practitioner of pancreatic, hepatic, and portal hypertensive surgery must not only recognize portal anatomy intraoperatively, but also know the methods to image it preoperatively and postoperatively. Principal reasons for performing such assessments include checking for thrombosis in the portal vein or its tributaries before attempting a portosystemic shunt or hepatic transplant, postoperative documentation of shunt or portal vein patency, and determining proximity to or invasion of the portal vein by neoplasms.

Portography used to be the “gold standard” for imaging the portal vein. However, helical computed tomography (CT) has become the diagnostic tool of choice for imaging the portal vein. Portography and CT are expensive and can result in serious complications. Duplex ultrasonography (DU) costs much less than CT and has no known complications.

Despite potential limitations of ultrasonography, DU is highly sensitive for demonstrating postoperative patency of surgically placed PCSs. It is also useful preoperatively to screen for thrombosis in the portal system. However, if a complete evaluation of the SMV and splenic vein is required but not obtainable by DU, CT should be performed. If DU demonstrates an apparently normal portal vein and an incompletely visualized splenic vein in a patient with an enlarged spleen and bleeding gastric varices helical CT should be carried out to clarify the diagnosis before a surgical procedure is performed. An additional use of DU is for determining patency of the portal vein prior to portosystemic shunt or TIPS. In the emergency treatment of BEV, the author and his colleagues routinely perform DU at the bedside in the ICU, thereby avoiding transport of the bleeding patient to distant facilities. Other imaging procedures are unnecessary in the

emergency situation and only serve to delay treatment aimed at controlling bleeding.

Intraoperative ultrasonography has also proved to be more sensitive and specific than regular ultrasonography, CT, and portography for diagnosing portal venous invasion by pancreaticobiliary carcinomas. Intraportal endovascular ultrasonography is a new diagnostic procedure that may prove even more sensitive in evaluating tumor involvement of the portal vein. These advances in ultrasonic diagnostics may prove particularly useful for preoperative planning in light of recent evidence that tumor invasion of the portal vein is not a contraindication for pancreatic resection.

Magnetic resonance (MR) imaging has become a valuable diagnostic tool in portal vein evaluation. This modality is noninvasive and without significant complications. With improved technology, the spatial resolution is approaching that of CT, further augmented by the ability to perform MR three-dimensional reconstruction. MR angiography and MR venography are superior to DU in imaging the splenic vein and SMV, as well as in detecting either thrombus or deep portosystemic collaterals. More recently, the development of MR cholangiopancreatography has added the ability to accurately define extrahepatic biliary and intrapancreatic ductal anatomy and pathology that may influence operative conduct. Additional uses of MR angiography and MR venography include: (a) planning major hepatic resection in which portal vein resection and reconstruction is a possibility, (b) planning the surgical approach in hepatic transplantation to avoid large collateral vessels in the porta hepatis or manage the removal of the increasing numbers of TIPSs, (c) evaluation and surgical management of the portal vein during live-donor LT, and (d) the ability to simultaneously evaluate arterial, venous, and ductal anatomy using a single imaging modality.

EDITOR'S COMMENT

The contributions of Professor Orloff on portal hypertension remain relevant also an important historical perspective. Most surgeons today have not seen nor will they see let alone do a portocaval shunt or surgical decompression. Indeed Dr. Rosemurgy and his colleagues (Portal hypertension over the last 25 years: Where did it go? *J Am Coll Surg* 2016;222:1164–70) published an article which tracks the disappearance of portal hypertension as a disease treated by general and vascular surgeons. In this study data from the Agency for Health Care Administration for 33,166,201 hospital inpatients in Florida for the periods 1988 to 1992, 1998 to 2002, and 2008 to 2012 were analyzed. They found that "admissions with a diagnosis of portal hypertension dramatically increased: 5,473 patients from 1988 to 1992, 7,366 patients from 1998 to 2002, and 36,554 patients from 2008 to 2012." In addition, endoscopic treatment of esophageal varices increased while the number of decompressive shunts placed nominally increased. The use of endoscopic therapy increased significantly faster than the application of decompressive shunts ($P < 0.0001$). Finally, the percentage of patients who underwent shunting dramatically and significantly decreased ($P < 0.0001$), and surgeons undertook proportionally fewer shunts (42% in 1992 to 4% in 2012; $P < 0.0001$). Importantly, for patients with a diagnosis of portal hypertension, in-hospital mortality progressively decreased, from 9% in 1988 to 1992 to 3% in 2008 to 2012 ($P < 0.0001$). They concluded that in the state of Florida, over 25 years, there has been a sevenfold increase in the number of patients admitted with a diagnosis of portal hypertension, with a 65% reduction of in-hospital mortality. With the advances in endoscopic therapy and TIPS portal hypertension has disappeared from the purview of surgery and has migrated toward the world of medical and endoscopic therapy, probably never to return.

When Dr. Orloff was asked to write the chapter on anatomy of the portal system, he immediately agreed but asked whether or not the namesake of this surgical atlas would be interested in him writing about portosystemic shunts, utilizing his experience in many of the randomized trials that he had done with Jon Isenberg, his GI collaborator, over the years, and giving his results in his approach to portal decompression, which is emergency portacaval shunt, most of the time side-to-side but sometimes end-to-side. Dr. Orloff has written voluminously and worked long and hard in the vineyards of surgery in this area, which some people might consider a thankless task, given the clientele that one deals with. However, I might add that, having dealt with any number of portosystemic shunts, mostly splenorenal shunts as semielective shunts, but there is nothing like a big scar on a patient's abdomen and the presence of two members of Alcoholics Anonymous in the recovery room to get one to change one's ways. The size of the incision seems to have a dramatic effect on future behavior, if something else can substitute, and in this case it is the 12-step

program which has saved, I believe, any number of lives.

Dr. Orloff is not a shy person and has been, as has the editor of this book, the center of some controversies. There are people who have doubted his results. I would say that Dick Bell, who was in the department for a while in Cincinnati, told me that with many of the data, he himself he had done it, and it was true. The key to Dr. Orloff's success has been not so much his skill at doing the shunts which are there but the 8-hour rule. The 8-hour rule is paramount to getting these people through. The alternative, as variceal obliteration, using whatever method you want, including Sengstacken–Blakemore tubes, octreotide or its cogeners, and propranolol and its cogeners, is really to a certain number of patients a death sentence. The reason for that is that the patients will stop bleeding temporarily. Sclerotherapy works well in class-A cirrhotics. The worse the class, the less well it works. The patients who are most at risk, the class-B-minus and the class-Cs, then go through the usual dance of sclerotherapy, stopping variceal bleeding, rebleeding followed by repeat sclerotherapy, at which time they have now received 10 units of blood, in patients whose clotting parameters are not sterling and whose platelet count may be slightly low to begin with. Sengstacken–Blakemore tubes or nasogastric tube or alcoholic stupor or hepatic coma also contribute to aspiration, which may be subclinical, and pneumonia. By the time most surgical services in the country get to a variceal bleeder, they are well down the course of destruction. Dr. Orloff, on the other hand, has a long time ago realized that what happens to patients in the hospital, particularly when they rebleed, vomit, aspirate, develop pneumonia, is something that we do to patients that results in mortality; and the secret therefor, to all of this work is moving rapidly to the operating room, carrying out an expeditious shunt, well done without hemorrhage, making certain that it is done side-to-side when the hepatic side of the portal vein is serving at least temporarily as an exit conduit of hepatic blood flow, and then avoiding all the other horrendous things that happen to these patients if they continue to bleed.

In the editor's technique of doing an emergency portacaval shunt (for elective shunts, he does a central splenorenal shunt *á la* Linton), we first free up the portal vein first in the portal triad. The reason this is done, first of all, is because it is easy, because, as the chapter points out, there are rarely veins on the anterior side of the portal vein, so it is easy to dissect free without getting into troublesome bleeding; and then, once I get the portal vein exposed, I go directly posterior and then start to open the retroperitoneum on top of the vena cava, which is invariably directly posterior to the portal vein, especially when the patient is up on 30 degrees on a roll, as Dr. Orloff's diagrams indicate. Dr. Fischer does not mobilize the vena cava as pictured. The surgeon between sutures will take the rind of large lymphatics by suture ligation as it overlies the IVC, and get out a significant length of vena cava anteriorly, but do not mobilize it from the retroperitoneum unless absolutely necessary. The reason for the ligation is the retroperitoneal rind, as I call it, and anything around the vena cava is that it either bleeds or leaks lymph. One thing one does not need is

a lymph leak, and that is why I will divide the retroperitoneal rind between nonabsorbable macrosutures. I mobilize the vena cava far enough so that one can get a Satinsky clamp on it, and then cut a little section off the anterior part of the vena cava that will accept the anastomosis of the portal vein. The side-to-side shunt is a little more difficult, and needs a little more mobilization of the portal vein, and also some vessel loops on either side in case things get out of hand; but, once one gets the portal vein sufficiently mobilized that it will reach and transects it, I oversew the proximal end with 4-0 Prolene and then take the posterior wall of the portal vein and sew it with a running everting mattress, so that there is never any suture material which is visible within the anastomosis, and then do a horizontal mattress of interrupted 4-0 Prolene and flushing before I take the clamps off.

A side-to-side shunt is probably appropriate in patients with schistosomiasis, although, quite frankly, in Brazil and other countries in which they have a plethora of portal hypertension from schistosomiasis, a splenorenal shunt is basically what is preferred. The side-to-side shunt or the central splenorenal shunt has the advantage of dealing appropriately with patients with ascites, who promptly diureses and letting the liver, which I am certain has fatty infiltration during an acute bleeding episode, sort out which way it wants portal blood to flow. Once the patient abstains from alcohol, so that alcoholic hepatitis is no longer present, the portal flow may be adjusted by the liver itself. Doing an end-to-side portacaval shunt robs the liver of needed nutrients for the rest of one's life, although Rousselot in the 1950s pointed out that those patients who did well after an end-to-side portacaval shunt could increase hepatic artery flow significantly, so as to make up for the lost blood flow of the portal vein. Not really dealt with during those studies by Rousselot was the fact that the portal vein comes from the gut containing most first-class nutrients like glucose and amino acids and fat, and one cannot make that up in hepatic artery flow, although the hepatic artery flow increases substantially in patients who survive and probably have higher concentrations of the nutrients than they ordinarily would, since the liver does not get first-pass clearance.

Once the patient is out of the operating room, then one must be very careful about how one manages coagulation factors, further sclerotherapy, renal functions, electrolyte imbalance, etc., and the ever-present threat of hepatic encephalopathy. I believe that hepatic encephalopathy is caused by amino acid imbalance at the blood–brain barrier and therefore treat these patients should they develop encephalopathy with hepatamine, which is a high branch chain low aromatic amino acid hepatic solution, which has been shown in a number of randomized prospective trials to improve survival.

The other thing about nonportal flow was written about in 1964, I believe, by Dame Sheila Sherlock, the great British hepatologist who held court, which is a statement they use appropriately in the Royal Free Hospital, but to get to the sessions, one had to go up to the roof or climb over the roof with ladders, etc. It was a session well worthwhile of attending. Professor Sherlock pointed out that

patients with extrahepatic portal block, no matter what the etiology, died of premature “aging” in their 40s and 50s but not in their 50s and 60s. I agree there and have always wondered whether the portal vein made the liver depend on a rich nutrient supply, which if it were not supplied started the process of premature death from premature aging.

An occasional patient will have thrombocytopenia because of a highly enlarged spleen and although the portacaval shunt will decrease the number of patients with thrombocytopenia, nonetheless, in Dr. William McDermott’s series in 1962, published in the *New England Journal of Medicine*, there seven patients whose thrombocytopenia did not respond to an end-to-side portacaval shunt.

Likewise, there are a number of patients who will accumulate massive ascites if an end-to-side portacaval shunt was done, and in fact, the hepatic side of the portal vein was decompressing the liver. I have on occasion opened up the left branch of the portal vein as it is in the liver (connecting to the left hepatic vein) and run the saphenous veins subcutaneously dilate the obliterated umbilical vein, which I could open up with a Bakes dilator and anastomose to saphenous veins, decompressing the liver. When I did that the first time, I was surprised to see the blood from the umbilical vein shoot, which is the only way I can describe it, out of the liver under really enormous pressure. However, the patient did decompress and he diuresed his ascites only to die of a perforated pulmonary artery by a Swan-Ganz catheter.

Whereas previously the end-to-side portacaval shunt has been under a cloud and TIPS has been remarkably utilized, that is no longer the case. Pierce et al. (Cost-effective analysis of transjugular intrahepatic portosystemic shunt versus surgical portacaval shunt for variceal bleeding in early cirrhosis. *Am Surg* 2011;77:169–73), carried out a cost-effective analysis of TIPS versus surgical portacaval shunt for variceal bleeding in early cirrhosis. The key to this paper is that reinterventions in emergency portacaval shunt (I do not know how much of an emergency it is, whether they went to the operating room within 8 hours, but I suspect not) showed a reintervention between 6.3% and 11%, rebleeding between 1% and 11%, hepatic encephalopathy between 12% and 26%, and the mortality between 8% and 20% in 30 days. TIPS, however, rebled 10.5% to 30%; the reintervention, which was dilating the TIPS or relating it, 48% to 82%; hepatic encephalopathy 14% to 52%; and mortality of 15% to 40% in 30 days. It is the reintervention rate, which increases the cost of doing TIPS. In dollars per life-year saved, emergency portacaval shunt was 17,771 dollars and TIPS was 21,438 dollars. However, the average life expectancy was 5 years for TIPS and 7 years for portacaval shunt. Thus, it was more than 3,000 dollars per life-year saved, which given the parlous state of our economy, is real money.

The next three papers are from Dr. Orloff’s emporium and represent a variety of papers written principally with Jon Isenberg and Henry O. Wheeler. The first paper is “Randomized Trial of Emergency Endoscopic Sclerotherapy Versus Emergency Portacaval Shunt for Acutely Bleeding Esophageal Varices in

Cirrhosis," Orloff et al. (Randomized trial of emergency endoscopic sclerotherapy versus emergency portacaval shunt for acutely bleeding esophageal varices in cirrhosis. *J Am Coll Surg* 2009;209:25–40) that in a group of 211 consecutive patients with cirrhosis who were unselected and who were known to have acutely bleeding esophageal varices and had required two units of blood were randomized to endoscopic sclerotherapy (EST) or portacaval shunt (EPCS). As many as 106 were randomized to EST and 105 to EPCS. However, Class A was 27.5%, Class B, 45%, and Class C 27.5%. EST achieved permanent control of bleeding in 20% of the patients, and EPCS had permanent control of bleeding in 100% of the patients; requirement for blood transfusions was greater in the EST group than in the EPCS group. The results suggest that there is lesser risk of encephalopathy in the portacaval shunt group than in the sclerotherapy group, especially since portal-systemic encephalopathy developed in 35% of the sclerotherapized patients, which is probably associated with bleeding, and there was only 15% occurrence in the emergency portacaval shunt group.

Orloff et al. (Emergency portacaval shunt versus rescue portacaval shunt in a randomized controlled trial of emergency treatment of acutely bleeding esophageal varices in cirrhosis–Part 3. *J Gastrointestin Surg* 2010;14:1782–95), looked at emergency portacaval shunt versus rescue portacaval shunt; in other words, the patients were randomized for endoscopic therapeutic ablation. Endoscopic therapy, with respect to emergency portacaval shunt was inferior because there were significant differences in outcome as far as survival after 5 years (72% vs. 22%), in 10 years (46% vs. 16%), and at 15 years (46% vs. 0%). Enough said here. Finally, as far as direct costs are concerned, Orloff et al. (Direct costs of care in a randomized controlled trial of endoscopic sclerotherapy versus emergency portacaval shunt for bleeding esophageal varices in cirrhosis–Part 4 *J Gastrointestin Surg* 2011;15:38–47) looked at direct costs in a randomized controlled trial of emergency portacaval shunt versus endoscopic sclerotherapy. Here again, the direct charges for all aspects of care were significantly lower in the patients treated for emergency portacaval shunt and less than emergency sclerotherapy followed by long-term repetitive sclerotherapy.

I think the tide has turned from what it was 5 years ago in that now I think that most surgeons dealing with portal hypertension believe that shunting is a better way to stop and prevent further variceal bleeding, which is the title of the commentary by Pedroso and Koniaris (Shunting: A better way to prevent variceal bleeding. *J Surg Res* 2011;167:e1–3). They have come to the conclusion that portal decompression is a much better way than emergency sclerotherapy.

However, "the horse is out of the barn" and the vast majority of cases are treated nonoperatively today. Impressively the mortality today is less than in the past owing to advances in medical treatment, endoscopic therapy, and TIPS. That said we would merely add that the management of patients with end-to-

side portocaval shunt should theoretically take place within 8 hours of the first encounter and one would get a larger percentage of patients who survive emergency portocaval shunt.

J.E.F. and E. Christopher Ellison

I am grateful to Dr. Ellison for mentioning hepatamine, the high branch chain low aromatic amino acid hepatic solution, which is now accepted worldwide to improve survival.

I remember Dame Sheila Sherlock, the great British hepatologist, with great affection who as Dr. Ellison recalls one took a course in mountain climbing to reach her office by climbing over the roof of her office. Those visits were always delightful even if Dame Sheila could be acerbic at times.

I am also delighted that Dr. Ellison mentions Dr. William McDermott, my mentor, and whose named chair I hold; a great mentor and gentleman who was a profound influence on me.

J.E.F.

131 Small-Diameter Prosthetic Interposition Shunt

Alexander S. Rosemurgy

Operative shunting using partial portal decompression gained popularity through efforts by Dr. Jim Sarfeh et al. in the early 1980s. Numerous publications and works since then have shown that the concept is efficacious and well tolerated. Sarfeh et al. also studied patients undergoing various degrees of partial portal decompression and found that smaller (8 to 10 mm) prosthetic H-graft portacaval shunts lead to superior salutariness relative to larger (12 to 16 mm) prosthetic H-graft shunts because the smaller grafts maintained a more physiologic (i.e., normal) pressure gradient between the portal and systemic venous systems. Utilization of the prosthetic graft ensures the portal vein–inferior vena cava (IVC) stoma will not dilate, thereby maintaining the physiologically important (albeit small) portal vein–IVC pressure gradient. My experience over the last 30 years with partial portal decompression promotes application of small-diameter (e.g., 8 to 10 mm) prosthetic H-graft portacaval shunting for complicated portal hypertension.

Currently, operative shunting for portal hypertension has disappeared except at a few centers across the United States. This is truly unfortunate. This has occurred because of the perceived adequacy of transjugular intrahepatic portosystemic shunts (TIPS), undertaken by radiologists and nonsurgeons. TIPS are convenient for admitting nonsurgeon physicians because they can be ordered, not unlike morning labs. With the progressive exclusion of surgeons in the care of patients with portal hypertension, the role for nonsurgeons has continuously expanded. For example, the American Association for the Study of Liver Diseases recently published self-serving guidelines which recommend that “the decision to perform a TIPS, especially in a high-risk patient, should be reached by a team consisting of a gastroenterologist/hepatologist, interventional radiologist, and where appropriate, a transplant physician.” This statement conveys the widely held belief that surgeon expertise is superfluous in the decision to apply portal decompression and how portal

decompression should be obtained. It is furthermore stated by the National Guidelines Clearinghouse, in cooperation with the guideline authoring organizations, that “as with any complex intervention, the decision to create a TIPS should be reached by a gastroenterologist or hepatologist who is experienced in the management of these patients in concert with an interventional radiologist.” To me, the exclusion of surgeons from the decision process is to the detriment of patient care. The use of polytetrafluoroethylene (PTFE)-covered stents is now preferred in applying TIPS, but without convincing data that it improves outcomes; I doubt it does because covering the stents does not alter the portal hemodynamic changes introduced by TIPS.

Hepatic transplantation has further diminished the role of operative shunting in the management of patients with complicated portal hypertension. Hepatic transplantation has become widely available and represents a potentially curative modality for patients with liver disease, including those with complicated portal hypertension, demonstrating 1-year and 5-year patient survival rates of approximately 90% and 80%, respectively. Hepatic transplantation is, however, predicated upon organ availability, which is limited. In addition, transplantation is encumbered by cost considerations and psychosocial requisites that are often lacking in potential candidates. As well, it must be recognized that the number of candidates for transplantation far exceeds the number of organs allocated. Nevertheless, the possibility, not the probability, for hepatic transplantation has served as an impetus for widespread implementation of TIPS given its supposed efficacy as a “bridge” to imminent transplantation. It must be noted that transplantation after TIPS is almost never “imminent.” This “bridge” is often built but is infrequently crossed, as currently less than 10% of patients undergoing TIPS eventually undergo hepatic transplantation. Furthermore, as alluded to earlier, the portal hemodynamic changes associated with TIPS promote progressive hepatic dysfunction, relative to prosthetic H-graft portacaval shunting, thereby hastening the need for transplantation to forestall death (Table 131.1).

TABLE 131.1 The Impact of Small-Diameter Prosthetic H-Graft Portacaval Shunts and TIPS on Effective Hepatic Blood Flow Measured Utilizing Low-Dose Galactose Clearance

Effective Hepatic Blood Flow	H-graft Portacaval Shunts	TIPS	*P*-value
Preshunt (mL/min)	1901 ± 1819	1684 ± 2162	NS
Postshunt (mL/min)	1662 ± 1035[a]	676 ± 451[b]	$P < 0.03$
P-value	NS	$P < 0.01$	—

[a]More than after TIPS, $P < 0.03$, Student's t-test.
[b]Less than before shunting, $P < 0.01$, Student's t-test.
Adapted from Rosemurgy AS, Zervos EE, Goode SE, et al. Differential effects on portal and effective hepatic blood flow. A comparison between transjugular intrahepatic portosystemic shunt and small-diameter H-graft portacaval shunt. *Ann Surg* 1997;225:601–7; discussion 607–8.

The role of TIPS is important herein only because it is the current alternative of choice to operative portosystemic shunting. TIPS should, however, play a role in the management of patients with portal hypertension, irrespective of the possibility for imminent (i.e., within 6 months) transplantation. TIPS should preferentially be undertaken, relative to operatively placed portosystemic shunts, in patients with a history of, or current, variceal hemorrhage failing or in patients not amenable to endoscopic therapy with concomitant relative contraindications to operative shunting. Relative contraindications to operative shunting include significant congestive heart failure, severe tricuspid regurgitation, severe pulmonary hypertension (mean pulmonary artery pressures >45 mm Hg), severe mitral regurgitation with aortic stenosis, morbid obesity, and/or a hostile abdomen (secondary to significant previous right upper quadrant surgery).

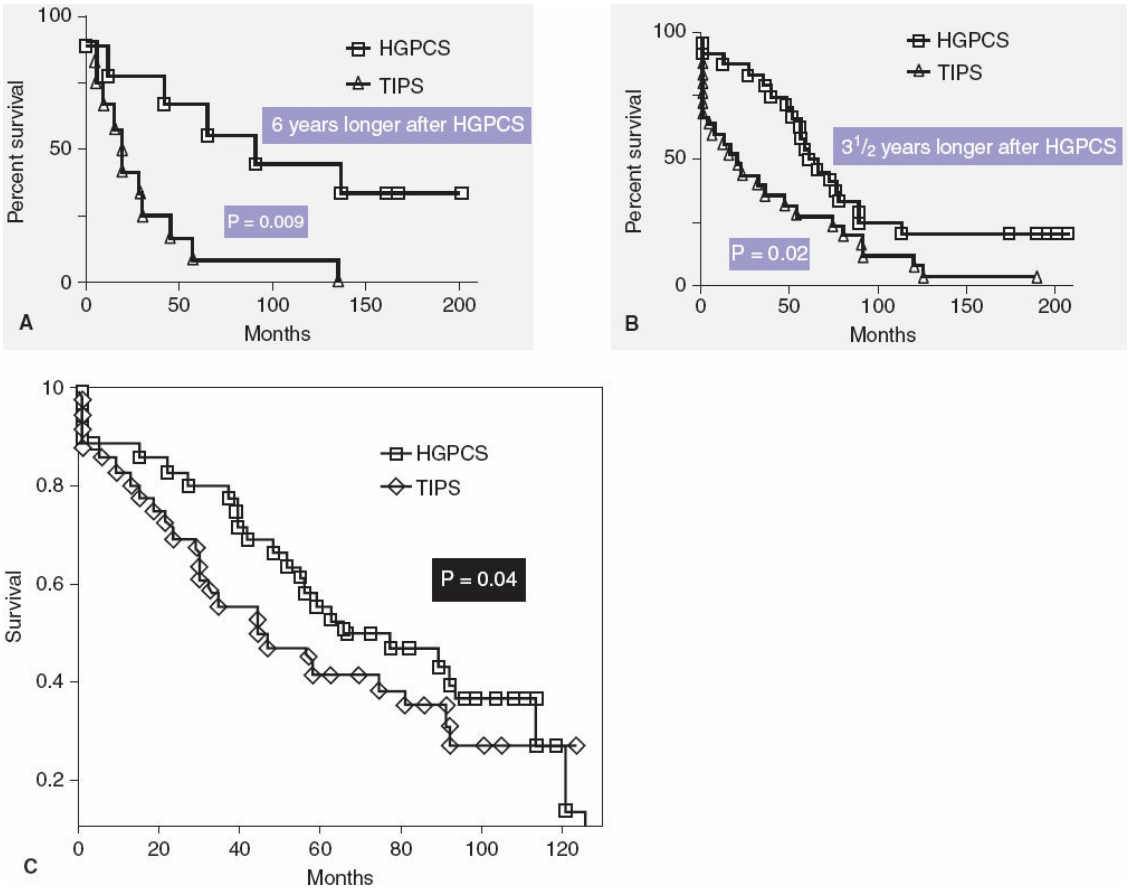

Figure 131.1. Kaplan–Meier survival curves for patients undergoing small-diameter prosthetic H-graft portacaval shunts (HGPCS) or intrahepatic portosystemic shunt (TIPS) with 18-year follow-up with Child class A liver disease (**A**) or Child class B liver disease (**B**). **C**. Kaplan–Meier survival curves for patients with MELD scores less than 13 undergoing small-diameter prosthetic H-graft portacaval shunts (HGPCS) or transjugular intrahepatic portosystemic shunt (TIPS) with follow-up at 10 years.

OPERATIVE INDICATIONS FOR SMALL-DIAMETER PROSTHETIC H-GRAFT PORTACAVAL SHUNTS

Exclusive of the small patient subpopulation mentioned above where TIPS may be preferentially applied, sufficient data exists to support preferential application of surgical shunts, in general, and small-diameter prosthetic H-graft portacaval shunts, in particular, over TIPS in the management of patients with portal hypertension complicated by variceal bleeding refractory to or not amenable to endoscopic therapy. In particular, I have demonstrated a survival advantage for patients with decent hepatic reserve undergoing small-diameter prosthetic H-graft portacaval shunts relative to patients undergoing TIPS (Fig. 131.1); survival was significantly longer

after small-diameter prosthetic H-graft portacaval shunt for patients of Child class A (91 vs. 19 months; $p = 0.009$) or class B (63 vs. 21 months; $p = 0.02$). The survival advantage, I believe, derives from relative preservation of nutrient hepatic blood flow (i.e., effective hepatic blood flow) for patients undergoing small-diameter prosthetic H-graft portacaval shunts (Table 131.1). Therefore, to promote survival, appropriate surgical candidates with adequate hepatic reserve (i.e., Child class A or B or Model for End-Stage Liver Disease [MELD] score less than 13) should undergo small-diameter prosthetic H-graft portacaval shunts. Patients with poor hepatic reserve, defined as Child class C or a MELD score of 13 or more, experience relatively high 30-day mortality rates (e.g., near 20%) irrespective of the type of portal decompressive shunt utilized. Although small-diameter prosthetic H-graft portacaval shunts impart no early survival advantage relative to TIPS for patients with poor hepatic reserve, they do promote preservation of resources (e.g., blood transfusions, intensive care unit (ICU) days, rehospitalizations) after shunting relative to TIPS and should be preferred unless hepatic transplantation is truly imminent (i.e., planned to be undertaken within 6 months). Notably, hepatic transplantation is only very infrequently undertaken in patients having undergone TIPS.

SURGICAL TECHNIQUE

The original approach to prosthetic H-graft portacaval shunting has evolved a bit over the past 30 years: I now use a shorter graft and more often I am forced to remove a portion of the caudate lobe to accommodate placement of the shorter graft. As well, I do not aggressively attempt to ligate collaterals from the portal venous system. If necessary, occlusion of these collaterals can be easily completed during a postshunt transfemoral shunt study, which I routinely obtain on postoperative day 2 to 4 to document patency. Such an approach avoids an intraoperative retroperitoneal retrogastric exploration.

A diligent first assistant is important to the operation. Such an assistant is necessary to suction accumulating ascites while the graft-cava anastomosis is undertaken and to keep the graft full of heparinized saline during portal vein-graft anastomosis. The operating surgeon stands to the patient's right side while undertaking this operation, while the first assistant stands to the patient's left.

After the patient is positioned supine on the operating table, an

endotracheal tube is placed, and then a urinary drainage catheter and a nasogastric tube are placed. Neither vasopressin nor octreotide is given perioperatively, unless there is active bleeding. Although such agents may decrease operative blood loss, I have found that blood loss is not significant without these agents; the operation can be undertaken without significant blood loss and almost always without blood transfusions. Prophylactic antibiotic therapy is always used.

The patient is rolled into a 30-degree left lateral decubitus position by means of a bedsheet rolled tightly and placed just to the right of the spine. After being prepared and draped in the usual manner, the patient is operated on through a transverse upper abdominal incision. The exact placement of this incision depends on the size of the liver, which is often palpable below the costal margin. I place the incision over the liver edge, and generally do not cross the midline. In making this incision, I usually incise only a small portion of the musculature lateral to the rectus muscle. As is my preference, I use a wound protector and Clorpactin solution for irrigation. Once the peritoneal cavity is entered, I irrigate the wound liberally with this solution and place a wound protector so that the wound is bathed by Clorpactin solution throughout the remainder of the operation. A table-mounted Omni bariatric retractor is utilized. All retractor blades are well padded, and the sternal blade of the Omni bariatric retractor is placed in the midportion of the incision to retract it cephalad.

If the falciform ligament is divided during the incision to improve exposure, it is divided carefully because large collaterals may be present. If it is divided, suture ligation of the falciform ligament is usually employed. A case for dividing it can be made, as it is a potential source of venous outflow from the portal system, and thereby, it can promote loss of effective hepatic blood flow. Its preservation is without point, but its division is not routine.

The foramen of Winslow is a key landmark. A limited Kocher maneuver is undertaken, always maintaining orientation with, and beginning at, the foramen of Winslow. High-energy electrocautery is liberally used, although large visible venous collaterals are ligated before division, as are lymphatic channels. A common mistake in the early part of this operation is that, with the patient in a 30-degree left lateral decubitus position, the dissection is undertaken in a much too lateral direction, deviating from the vena cava. With this error in dissection, the renal capsule or hilum is often exposed needlessly. The foramen of Winslow is a

landmark to keep the dissection oriented. The Kocher maneuver does not need to be extensive but just enough to expose approximately 5 cm of IVC to allow for placement of a side-biting vascular clamp. The exposed segment of the IVC should include the portion of the IVC that forms the caudal boundary of the foramen of Winslow. The cephalad portion of this segment of cava may lie dorsal to the inferior tip of the caudate lobe. If necessary, this portion of the caudate lobe is excised to expose the vena cava, so that the portal vein can be bridged to the vena cava easily with a short segment (i.e., 3 cm) of PTFE graft. A portion of the caudate lobe is usually excised. More on this later.

It is very important that the IVC be well exposed medially and laterally so that a vascular clamp can be placed on the IVC easily and without tension, which will insidiously pull the vena cava out of the clamp. I generally try to expose at least half the circumference of a 4 to 5 cm segment of the IVC to facilitate clamp placement and anastomosis. After the IVC is exposed, a traction suture is placed into the loose tissue adjacent to the right side of the IVC. This suture is further placed into the lateral abdominal wall and then tied to retract this tissue laterally to optimize exposure.

Once the IVC has been adequately exposed, attention is turned to the hepatoduodenal ligament. With the splanchnic blade of the Omni retractor placed carefully over a well-padded gallbladder, the gallbladder is retracted toward the patient's left shoulder. This lifts and rolls the gallbladder and the common bile duct ventrally and medially. The hepatoduodenal ligament is opened posteriorly and laterally. This area is rich with lymph vessels, and ligation of lymphatic structures is important in minimizing ascites. The dissection in the hepatoduodenal ligament is undertaken along the length of the ligament, parallel and dorsal to the common bile duct, to minimize chances of ductal injury. Often, the portal vein is not readily identified because of thick lymphatic tissue in this area. Once the portal vein is identified, further dissection should be undertaken only to better define the portal vein. The common bile duct should be retracted ventrally and medially with a vein retractor held by the first assistant to facilitate exposure of the portal vein. Palpation of this area is important to detect and locate an accessory/replaced or aberrant right hepatic artery. Such an artery must not be injured because such an injury can greatly interfere with necessary blood flow to the liver after shunting. If present, an aberrant, replaced, or accessory right hepatic artery should be

retracted with the common bile duct and, thereby, retracted ventrally and medially. As the portal vein comes into view, a Russian forceps is used to grasp the portal vein. A substantial portion of vein should always be grasped to minimize chances of tearing it. Dissection of the portal vein is greatly facilitated with use of a plastic Yankauer sucker (Fig. 131.2). I use this technique because it works, efficiently and bloodlessly. This technique does not injure any side branches off the vein and greatly speeds circumferential dissection of the portal vein.

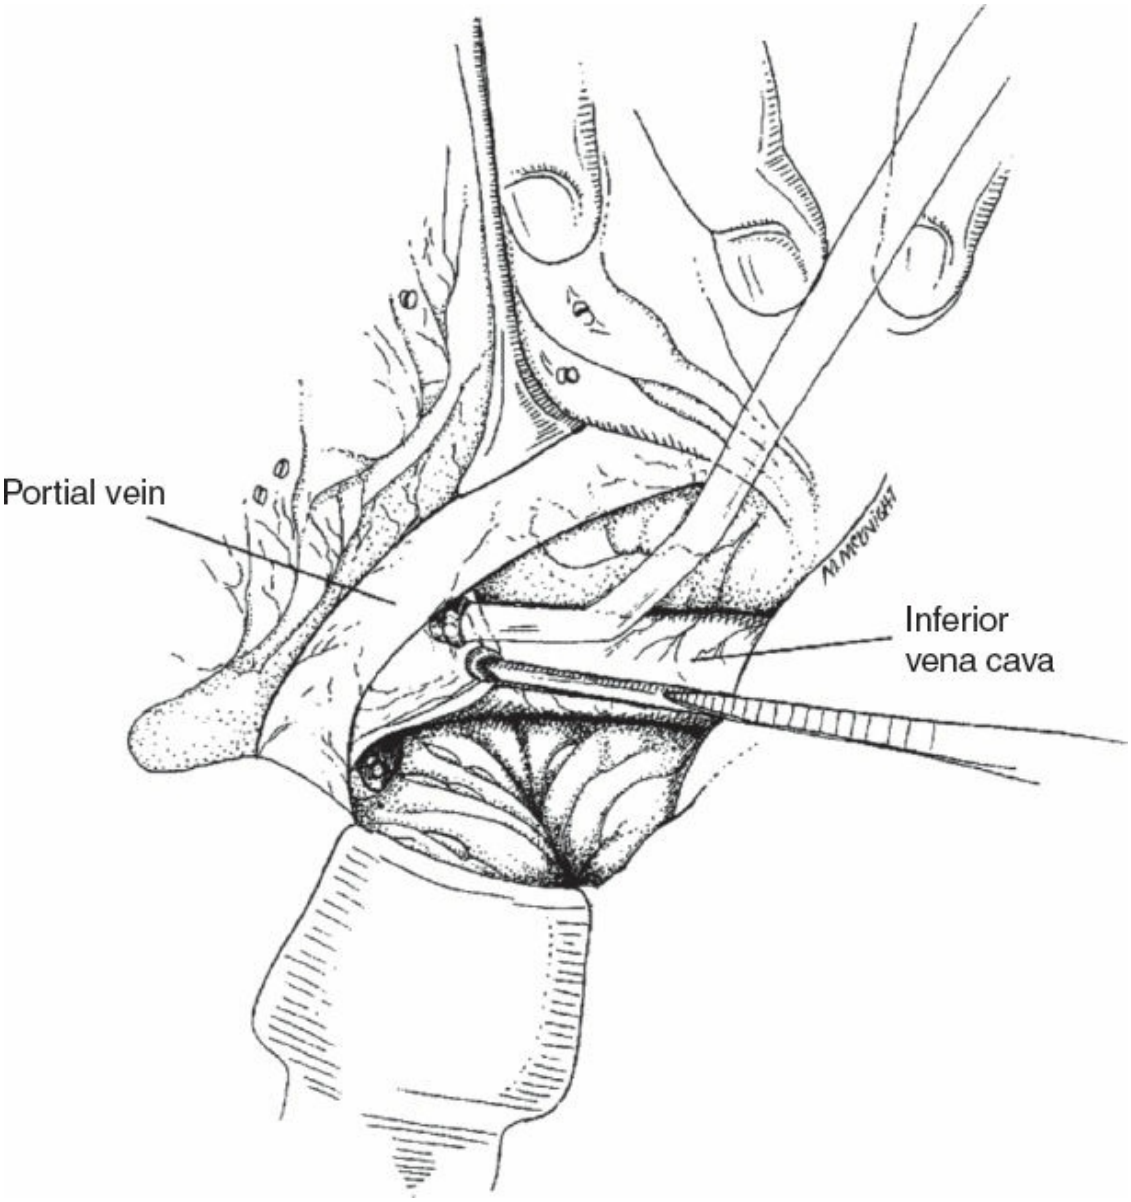

Figure 131.2. The Yankauer sucker is used to raise the portal vein off the tissue of the posterior hepatoduodenal ligament. A Russian forceps is used to minimize chances of tearing tissue. A vein retractor is helpful in the dissection. Here, it is retracting tissue containing the common bile duct ventrally and medially.

The vena cava is seen at the base of this view. A portion of the caudate lobe has already been excised. The line of excision of the caudate lobe lies posterior to the cephalad aspect of the portal vein. The patient's head is to the left. This view is from the patient's right side, where the surgeon is standing.

With Russian forceps holding the enveloping tissue of the posterior hepatoduodenal ligament, a vein retractor is placed under the portal vein, retracting it ventrally and medially. The Yankauer sucker is then used to separate the portal vein from the posterior enveloping tissue. Once this dissection is carried quite medially, the portal vein is released from the vein retractor, and the vein retractor is placed on the tissue ventral to the portal vein. With this tissue, including the common bile duct, drawn ventrally and medially, the portal vein is grasped with the Russian forceps; the ventral surface of the portal vein is freed from overlying structures with the Yankauer sucker. At this point, a right angle may be passed over the ventral surface of the portal vein and around the vein. Circumferentially, the portal vein can thus be controlled by a vessel loop. This vessel loop may useful in subsequent placement of the side-biting Satinsky clamp on the portal vein; it is also helpful if bleeding problems develop because it can provide secure control of the portal vein in the proximal hepatoduodenal ligament. If circumferential control of the portal vein is excessively difficult, lateral exposure of the vein can suffice. Having said all this, I usually do not circumferentially control the portal vein as it seems superfluous.

Pressures in the portal vein and IVC are then measured. I measure these pressures using a 25-gauge needle and a pressure-transducing setup identical to that used for an arterial line. A gradient of about 20 mm Hg is usually present between the portal vein and the IVC before shunting, with a pressure of approximately 25 to 30 mm Hg in the portal vein and approximately 5 to 10 mm Hg in the vena cava. It is important that the pressure measuring system is not moved up or down by the anesthesia team because subsequent measures will then be relatively different.

Externally reinforced PTFE graft, 8 to 10 mm in diameter, is used for the portacaval shunt. This graft is no longer than 3 cm from toe-to-toe and 1.5 cm from heel-to-heel, with the bevels of the graft at 90 degrees to each other. Orienting the bevels at 90 degrees allows the graft to be oriented to both the portal vein and the vena cava, as they are not parallel. The graft is usually 8 mm in diameter. My "rule of thumb" is that the graft should be

about half the diameter of the portal vein. With a large portal vein or if portal pressures or portal vein–IVC pressure gradients do not sufficiently decrease with application of an 8-mm graft, a 10-mm graft is used. The "short" length of the graft usually requires some resection of the caudate lobe, as previously mentioned. The length of the graft is kept short because long-term patency with this length has been a certainty.

Once the graft is cut, it is placed in a syringe full of heparinized saline. With the tip of the syringe occluded by a fingertip, suction is placed on the syringe and air bubbles can be seen to emanate from the graft. With a rather firm tapping on the side of the syringe, the air bubbles are dislodged and, with removal of the suction, the PTFE graft should no longer float, as heparinized saline replaces the dislodged air.

The graft is then placed on the IVC to determine whether a portion of the caudate lobe needs to be excised for graft placement. To remove a portion of the caudate lobe, the caudad tip of the caudate lobe is first grasped using a ringed forceps. Visible collaterals between the caudate lobe and the IVC are ligated, and divided as need be. A vein retractor is placed on the portal vein to ensure that it is not injured. Electrocautery at a high-energy level is used to score and remove the designated portion of the caudate lobe. Traction is placed along the ringed forceps as the cautery is applied to facilitate this excision. This traction pulls the piece of the caudate lobe up and off the vena cava so as to protect the cava. Blood loss during excision of a portion of the caudate lobe is much less than might be expected. Once the portion of caudate lobe is excised, a small cotton gauge sponge is placed over the cut edge of caudate lobe and pressure applied. Pressure for a minute or two will stop most bleeding. Continued bleeding can generally be controlled with electrocautery, but suture ligation may occasionally be necessary.

Once bleeding from the cut edge of caudate lobe has stopped, a side-biting Satinsky clamp is placed on the ventral surface of the IVC. A ringed forceps is used to pull the ventral wall of the IVC "up" to facilitate placement of the side-biting clamp. This clamp should be closed completely so that the vena cava does not slip out of the clamp (Fig. 131.3). Volume loading of the patient before application of the clamp is generally not necessary. Hypotension is virtually never a problem because the vena cava is not completely occluded with this clamping. Once the side-biting Satinsky clamp is placed on the ventral surface of the vena cava, a window must be cut from the vena cava so that outflow from the

graft is promoted; merely opening the vena cava is not sufficient. The window is cut in a downward, or ventral-to-dorsal, direction, rather than in a caudad-to-cephalad direction (Fig. 131.4). The primary orientation of the cut must be downward, otherwise, the window is insufficient and much longer than necessary. The "window" of vein excised should be approximately 4 mm long and 2 mm wide ex vivo. This will provide an adequate hole in the vena cava (Fig. 131.5).

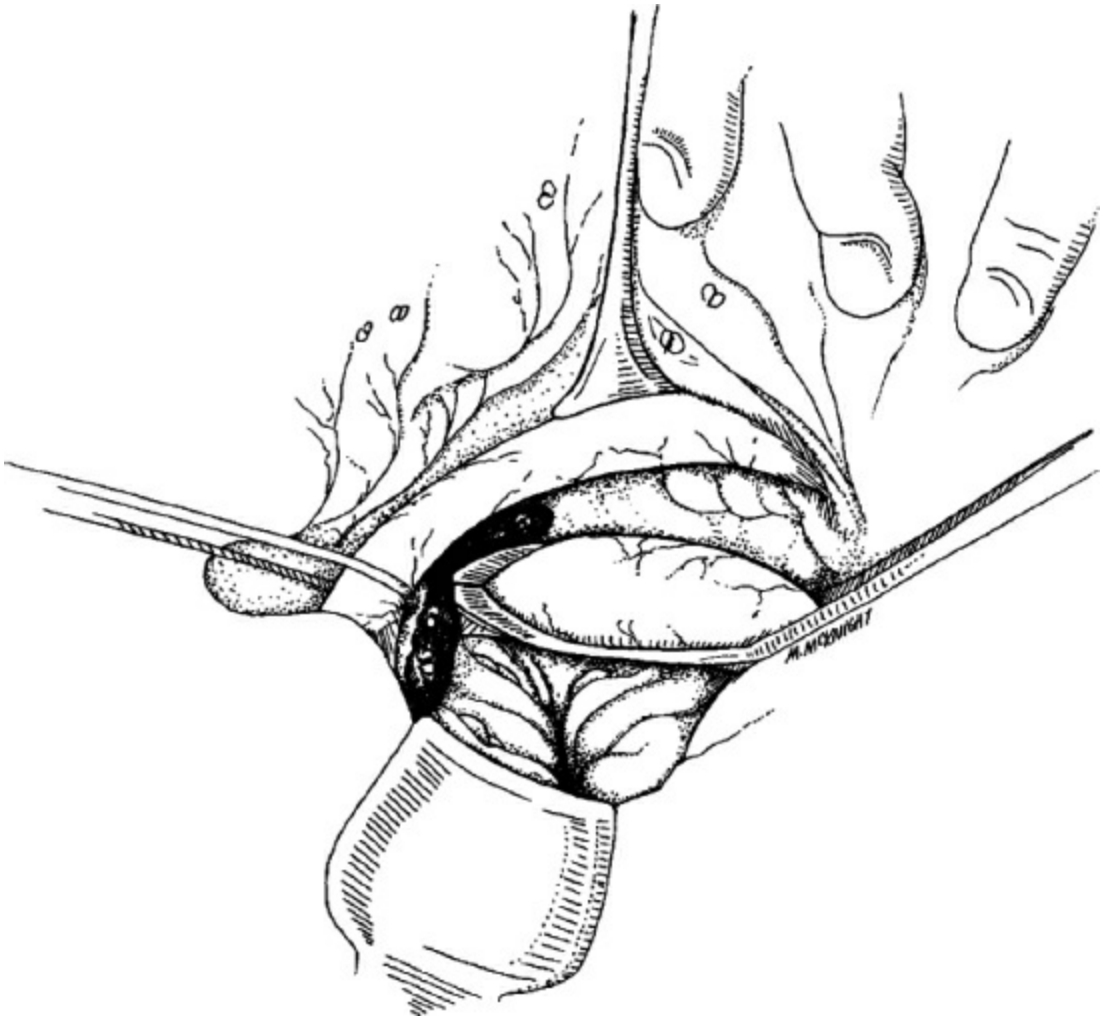

Figure 131.3. A Satinsky clamp has been placed across the anterior surface of the inferior vena cava. A vessel loop is around the cephalad portion of the portal vein. The cauterized edge of the caudate lobe is the black area at the tip of the Satinsky clamp. A generous portion of inferior vena cava is controlled by the Satinsky clamp. The patient is positioned so that the head is to the left in this drawing. This view is from the patient's right, where the surgeon stands.

The graft is placed on the vena cava so that the bevel in the graft allows

the graft to lean cephalad (Fig. 131.5). Suturing with 5-0 polypropylene is undertaken in a running fashion to construct the anastomosis. The suture is initially placed as a horizontal mattress stitch at the most cephalad aspect of the anastomosis (i.e., the "heel" of the graft) (Fig. 131.6). This anastomosis is initiated in this manner so that sewing along the length of the anastomosis is always from inside → out on the vein and outside → in on the graft, allowing easy and precise placement of the sutures in the vein. The back wall (i.e., the left side) of the anastomosis is constructed first. The initial sutures are placed so that the graft is parachuted down on the IVC (Fig. 131.6). This facilitates placement of the first few sutures, which otherwise can be quite difficult to appropriately space and see. Once the graft has been parachuted down on the vena cava, tension is maintained on the suture line as the anastomosis is sewn so that the anastomosis is not loose and so that the sutures need not be tightened with a nerve hook on completion of the anastomosis. Once the midline of the anastomosis (or toe of the graft) is crossed, the suturing returns to the most cephalad aspect of the anastomosis, using the other limb of the double-armed 5-0 polypropylene suture. The front wall (i.e., the right side) of the anastomosis is then completed. Before the knot is tied, a suture is reversed so that the knot is tied across the anastomosis. The anastomosis should be visually inspected for defects and gaps before the suture is tied. As well, a nerve hook may be used to test for tautness of the sutures before the knot is tied.

Figure 131.4. When the vena cava is opened, it should be opened with a not-so-deep and not-so narrow window, as shown in this drawing. A window is cut, as opposed to a simple venotomy in the IVC, to improve graft outflow. This window elongates considerably and easily accommodates the graft anastomosis.

Once the anastomosis has been completed and the knot tied, a right-angled clamp is placed across the graft, and the side-biting Satinsky clamp is removed from the IVC (Fig. 131.7). This tests the anastomosis; it should not leak, and it should bleed only at needle holes and only minimally, if at all. The side-biting Satinsky clamp is then replaced on the vena cava, and the right-angled clamp is removed from the graft. The graft is then vigorously irrigated with heparinized saline delivered as a focused stream through an 18-gauge angiocatheter attached to a 30-mL syringe.

The portal vein-graft anastomosis is now constructed. The common bile duct and accessory right hepatic artery, if present, are retracted ventrally and medially with a vein retractor, well exposing the portal vein. A Russian forceps is used to grab the posterolateral wall of the portal vein and retract it laterally. A right-angled side-biting Satinsky clamp is then placed on the portal vein. Though it may, the clamp does not have to occlude all flow in the portal vein. Clamping of the portal vein must provide sufficient portal vein to work with and be sufficiently secure to prevent bleeding after the portal venotomy. Once the Satinsky clamp has been placed, the posterolateral aspect of the portal vein is opened with a No. 11 blade. Once the vein is entered, Potts scissors are used to lengthen the opening to accommodate placement of the graft. A window does not need to be cut in the portal vein. A 5-0 polypropylene suture is placed in the ventral edge of the portal venotomy to act as a retraction suture, so as to ‘open up’ the venotomy in the portal vein (Fig. 131.8). With this exposure, the posterior wall of the portal vein is then sewn to the graft with a double-armed 5-0 polypropylene suture. The anastomosis is initiated by placing a horizontal mattress suture in the midportion of the posterior wall of the portal vein opening. This suture is passed inside → out on the portal vein and outside → in on the graft with both ends of the polypropylene suture. Once this horizontal mattress suture has been placed, all sewing of this anastomosis is inside → out on the portal vein and outside → in on the graft. When one of the corners is crossed, a rubber-shod clamp is placed on that end of the polypropylene suture, and sewing is initiated with the other end of the suture. As sewing is carried around both the cephalad and caudad corners of the anastomosis, the sutures along the back wall are drawn taut with a nerve hook. This is the last time that this back wall of the anastomosis will be visible, and it is important that the sutures be drawn taut at this time. As the sewing continues toward the middle of the anterior portion of the anastomosis, the clamp on the portal vein is

momentarily opened so that clot and debris within the portal vein are blown out of the portal vein before completion of the anastomosis. After this, heparinized saline is applied liberally to dislodge debris from inside the graft. An 18-gauge angiocatheter, attached to a 30-mL syringe filled with heparinized saline, is placed through the anterior defect in the anastomosis and heparinized saline is injected forcefully down the graft to clear blood and debris. It is sometimes helpful to bend the needle a bit in its middle to facilitate sewing of the ventral aspect of the portal vein-graft anastomosis. The anastomosis is then completed, with one of the sutures being reversed so that the knot is tied across the anastomosis. The clamp on the vena cava is removed first, and is followed by the removal of the clamp on the portal vein (Fig. 131.9). The clamp on the portal vein can sometimes be difficult to remove because space is limited.

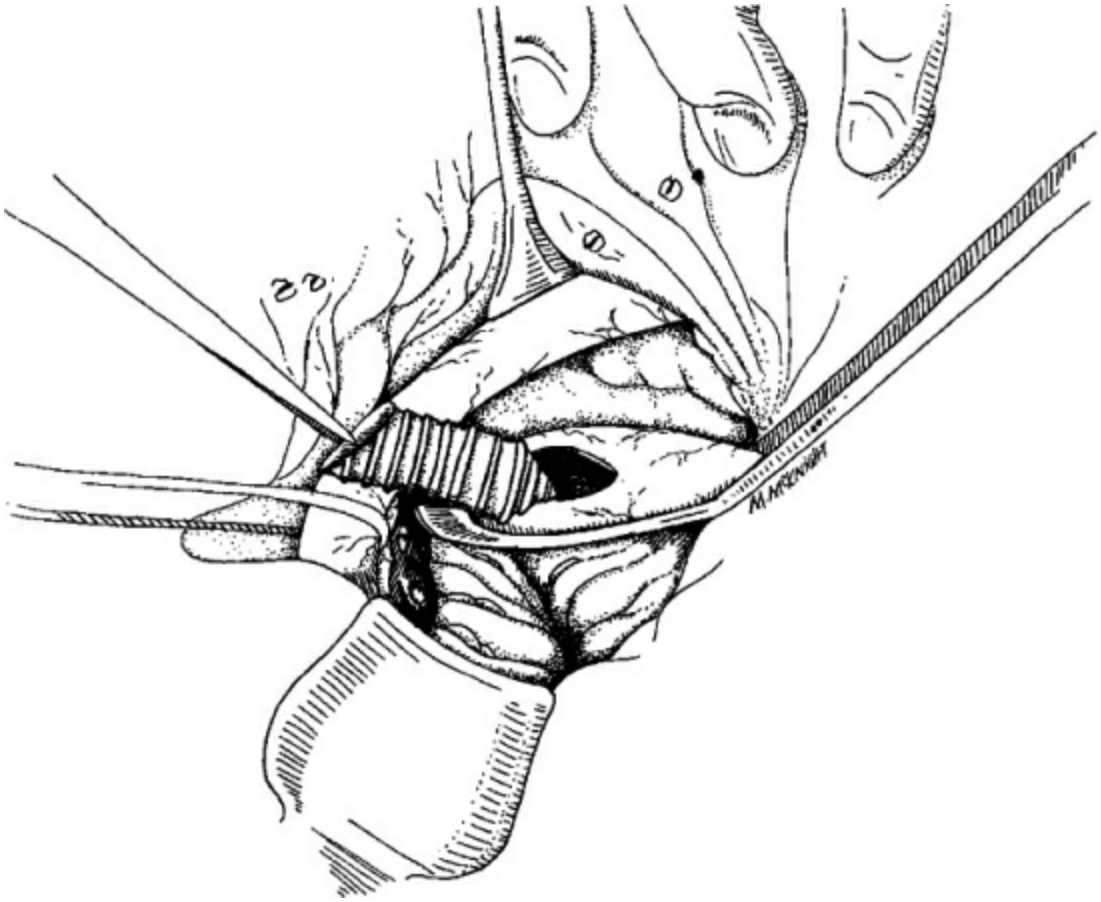

Figure 131.5. A window has been cut in the inferior vena cava. The graft is being placed into position for completion of the anastomosis. Note the orientation of the beveled ends of the graft. The patient's head is to the left. This view is from the patient's right side, where the surgeon is standing.

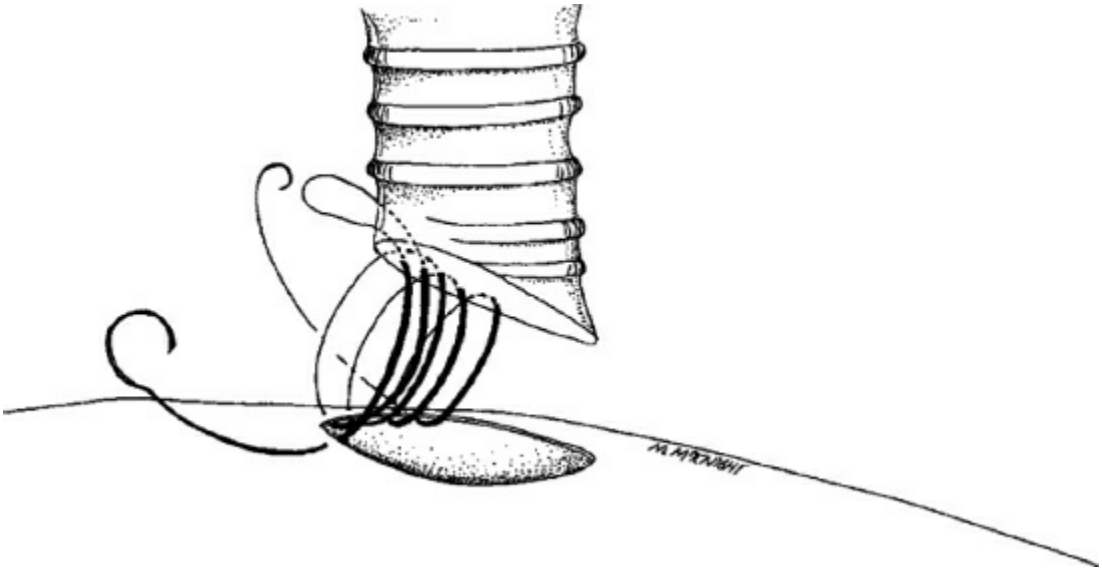

Figure 131.6. The inferior vena cava–graft anastomosis is begun at the cephalad aspect of the anastomosis. The suturing begins with a horizontal mattress suture at the heel of the graft. The left-sided portion of the suture line (i.e., the “back wall” relative to the surgeon standing on the patient’s right side) is constructed first, with sutures being placed inside → out on the vein and outside → in on the graft. After the first few sutures are placed, the graft is parachuted down. This view is from the patient’s right side, where the surgeon is standing.

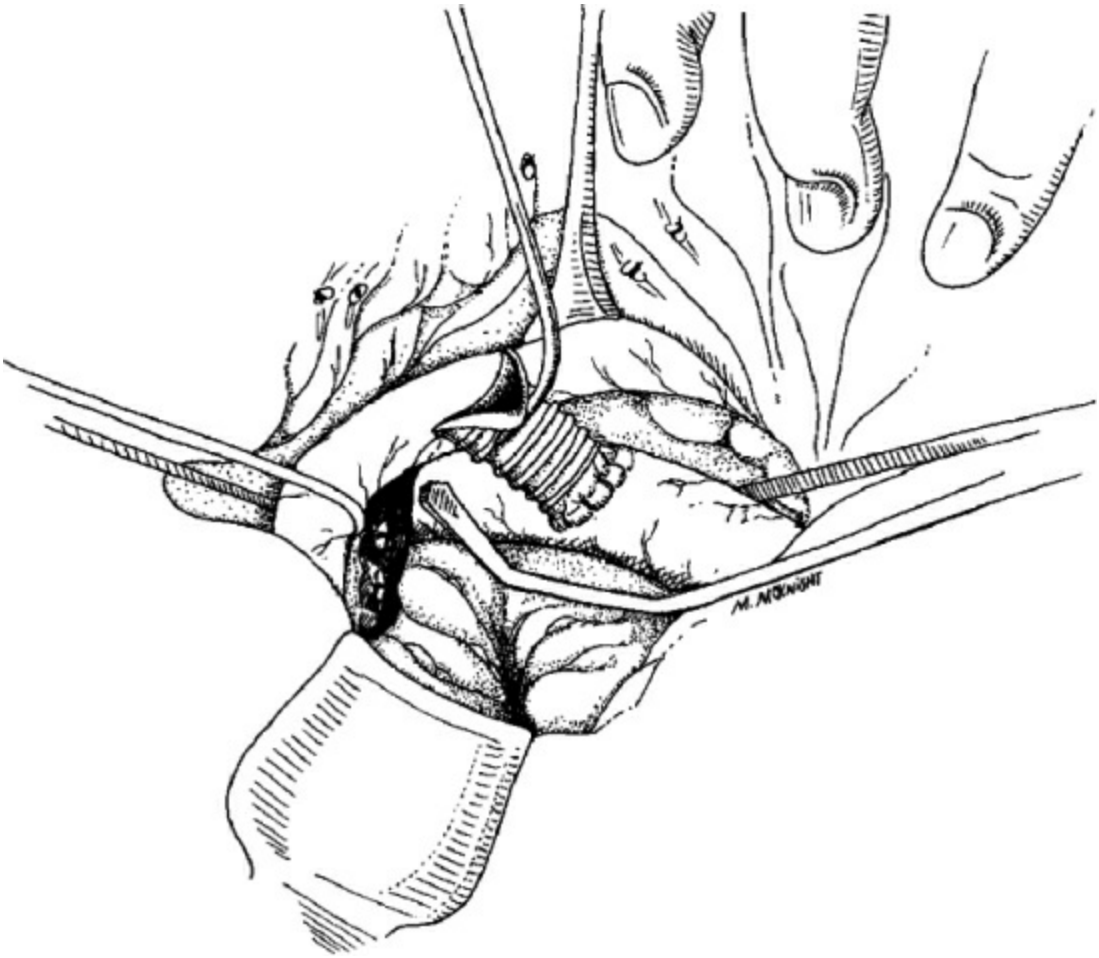

Figure 131.7. After the inferior vena cava–graft anastomosis has been completed, a right-angled clamp is placed to occlude the graft. The Satinsky clamp is then opened, and the anastomosis is tested. The Satinsky clamp is then reapplied and the graft cleansed of blood and debris.

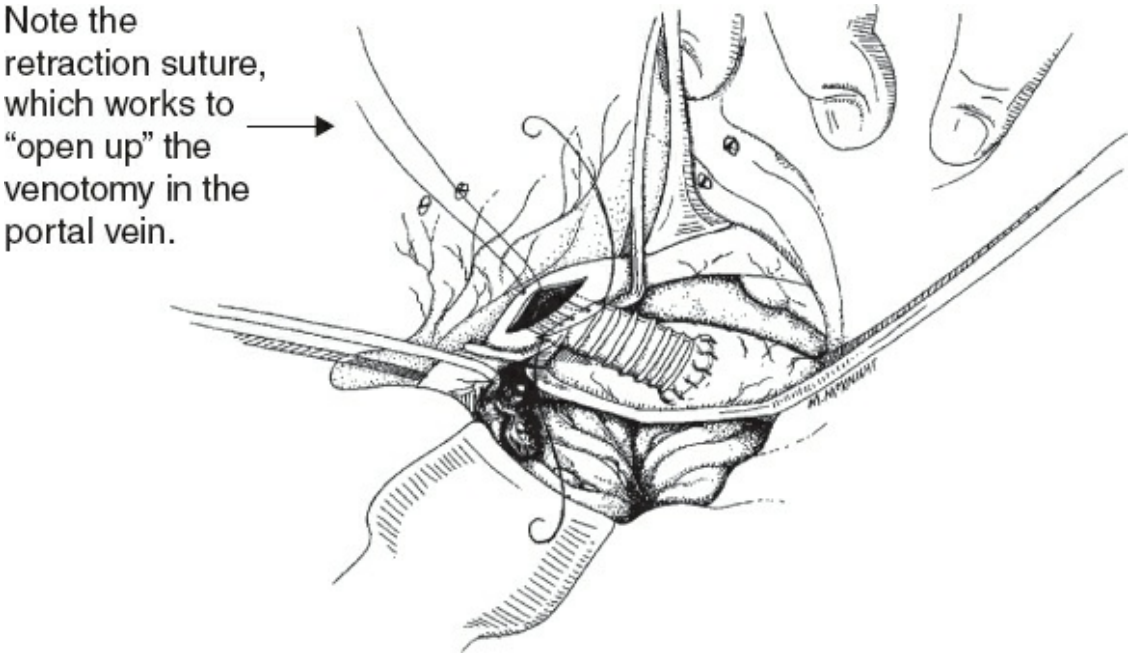

Figure 131.8. With the vena cava again occluded, the lateral wall of the portal vein is controlled with a small Satinsky clamp. The portal vein is opened posterolaterally. A traction suture of 5-0 polypropylene is placed to retract the anterior lip of the venotomy, thereby facilitating placement of sutures along the posterior anastomosis. The graft–portal vein anastomosis is begun in the midportion posteriorly. The anastomosis is begun with a horizontal mattress suture placed inside → out on the vein and outside → in on the graft. This view is from the patient’s right side.

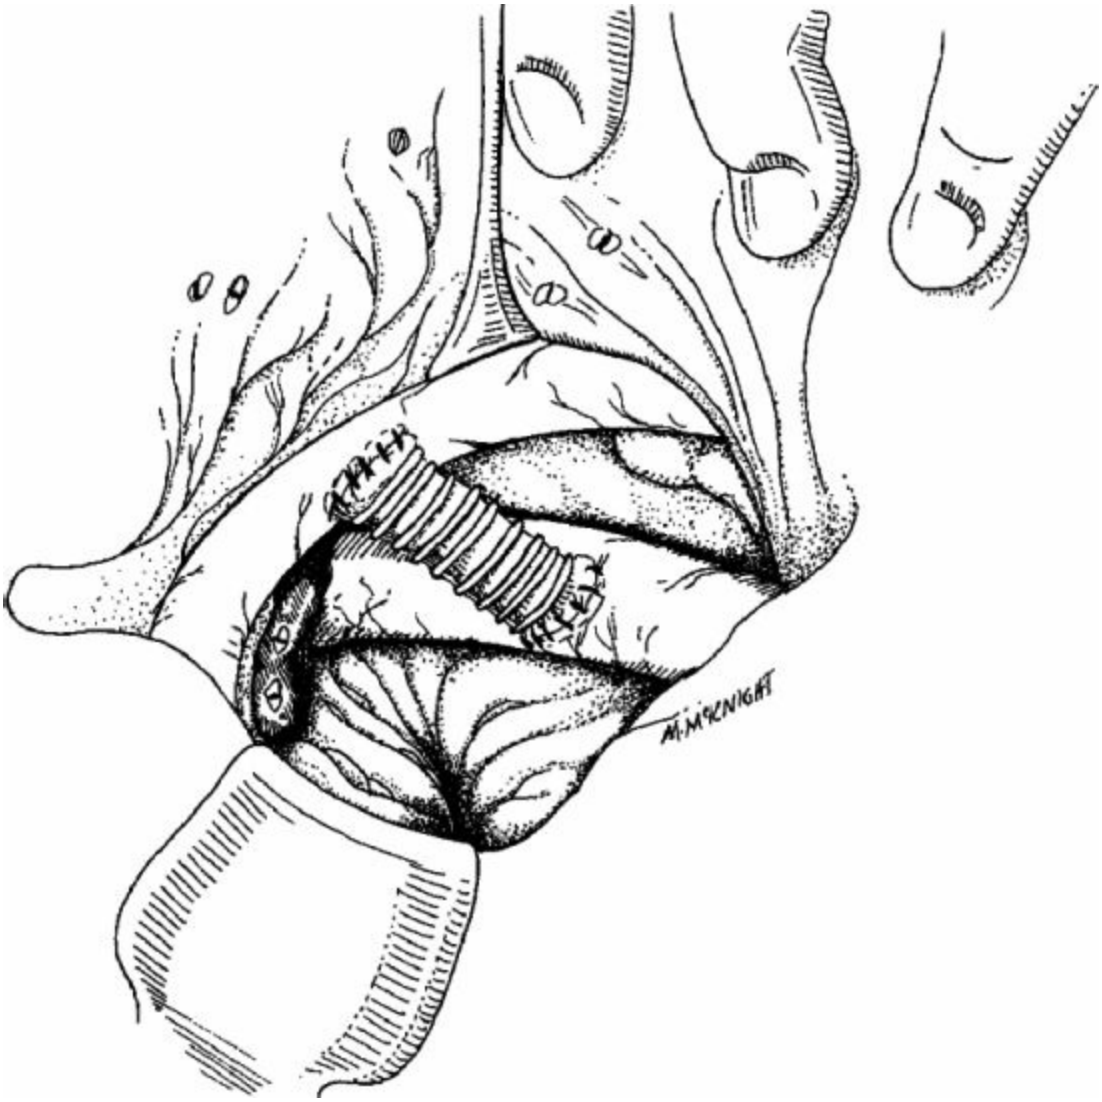

Figure 131.9. The completed prosthetic H-graft portacaval shunt. There should be a thrill in the inferior vena cava just cephalad to the anastomosis once both Satinsky clamps are removed. This view is from the patient's right, where the surgeon is standing.

There should be a thrill in the vena cava just cephalad to the anastomosis. This becomes more prominent over the next few minutes. This thrill should be felt by means of exquisitely light palpation to the vena cava just cephalad to the graft-IVC anastomosis. If no thrill is felt, it is unlikely that the shunt will prove to be patent or sufficiently decompressing.

On completion of the shunt, pressures in the portal vein and IVC are measured again. Pressures in the IVC generally rise a bit with construction of the shunt, and portal pressures should fall significantly. Accordingly, the portal vein–IVC pressure gradient should fall considerably with shunting. With shunting, I look for four things:

1. Pressures within the portal vein should fall by 10 mm Hg or more with shunting.
2. The portal vein–IVC pressure gradient should decrease by more than 10 mm Hg with shunting.
3. The portal vein–IVC gradient should be less than 10 mm Hg on completion of the shunt, with gradients of 6 to 8 mm Hg being common.
4. As mentioned, there should be a thrill in the IVC just cephalad to the cava-graft anastomosis.

If all four parameters are met, postoperative graft patency in the immediate and late postoperative periods is certain.

The vena cava–graft anastomosis is marked by large hemoclips placed on tissue adherent to the vena cava on each side of the anastomosis. These clips allow the radiologist to easily identify and cannulate the anastomosis when undertaking routine postoperative transfemoral cannulation of the shunt. Transfemoral cannulation of the shunt is undertaken to document shunt patency and function (i.e., portal decompression) 2 to 4 days after shunting and during late follow-up, generally at 1, 3, 5, and 10 years after shunting.

The operative field is copiously irrigated, the retractors are removed, and the wound is closed along anatomic layers using large polypropylene suture. Sutures must be placed with good purchase of fascia and in propinquity so that the chances of postoperative ascitic leak are minimized. The fascia is closed in two layers. The polypropylene sutures are started in each corner of the incision and then run to the middle, where they are tied, for both the anterior and posterior layers of rectus fascia. All knots are buried. The subcutaneous tissues are copiously irrigated, and the skin is closed with a running nylon suture if there is ascites before shunting; without ascites, the skin is closed with steristrips. The skin sutures are removed once they are loose, which signals wound contraction, the *sine qua non* of healing. Wound morbidity can be a problem in patients with liver disease, but I have been pleased with this method of wound closure.

EDITOR'S COMMENT

Since the first report by Sarfeh and Rypins (Partial versus total portacaval shunt in alcoholic cirrhosis. Results of a prospective, randomized clinical trial. *Ann Surg* 1994;219:353–61) of a randomized prospective trial of end-to-side portacaval shunts and small-diameter interposition shunt showing the superiority of the latter, numerous institutions have taken up the cry that the interposition shunt should be utilized for patients that fail sclerotherapy and I would add "early" so that the patient does not deteriorate while repeated episodes of sclerotherapy or variceal banding are tried so that the patient gets aspiration pneumonia, hepatorenal syndrome, and so on.

In doing the procedure I have a couple of technical comments. First, I do not think it is necessary to ligate and divide the falciform ligament. Spare it if possible. If the patient gets over the operation, the direction of flow in the liver and its perfusion will change. Rarely, one may want to utilize the falciform ligament and dilate the lumen of the obliterated umbilical vein. The collaterals that exist within the falciform ligament may be utilized spontaneously by the patient (as it were) following recovery, in case of stricture or clot in the portal vein.

I also do not utilize a Kocher maneuver in doing a shunt of any sort that is a portacaval shunt or an interposition shunt. There is too much bleeding and too much lymphatic leakage if one enters the retroperitoneum. If one positions the patient with the right side up about 30 degrees and does a generous transverse or perhaps a Kocher incision, identifies the portal triad first and dissects out the

portal vein, and dissects directly posteriorly to the vena cava it is not necessary to kocherize the duodenum to obtain control of the IVC. The superior mesenteric vein is then relatively easy to find as one follows the portal vein caudal to the superior mesenteric vein. If then one goes directly posterior in the retroperitoneum, the vena cava is right there encased with giant, succulent lymphatics, which need to be divided and suture ligated. The interposition shunt can take place in a relatively clear field without extraneous bleeding and lymphatic leakage that one achieves when kocherizing the duodenum.

Several papers have now begun to pay attention to the fact that endoscopic sclerotherapy or banding does not result in better outcome and going directly, without too much waiting, to some type of portosystemic shunt is the best procedure. Martin Wolff and Andreass Hirner (Current state of portosystemic shunt surgery. *Langenbecks Arch Surg* 2003;388:141–9) had argued vigorously for either selective distal splenorenal shunt (Warren) or the small-diameter interposition shunt, which is the subject of this nice chapter by Professor Rosemurgy. This is especially true if transjugular intrahepatic portosystemic shunt (TIPS) fails to stop the bleeding. While some may argue for orthotopic liver transplantation as the only therapy that significantly prolongs long-time survival in patients with cirrhosis and variceal bleeding, between 20% and 30% of all comers may be Child A class and may not require transplantation. Thus many people might then have flocked to the application of TIPS as a tempering procedure, as a side-to-side portacaval shunt. It can be performed under local anesthesia with a mortality of 0.5% and 4% and probably represents a better option for patients with ascites, poor liver function, and a high operative risk. However, it has a high rate of dysfunction caused by stenosis and occlusion and requires close observation by Doppler ultrasound. It is difficult to give an exact Figure for TIPS stenosis or occlusion but the requirement for one reintervention per year is between 30% and 70%.

The authors quote a mortality in emergency situations from 20% to 60%, which is similar in both procedures. Emergency TIPS in class C has a probability of survival of less than 50% although some papers have noted higher survival. They do accept Dr. Orloff's claims of low mortality but correctly surmise that this is brought about by a very experienced surgical team and avoidance of shock and hypotension by immediate operation and rigorous follow-up. It is nice to see somebody come out in support of portal decompression after everybody has realized that there is no change in outcome in sclerotherapy or banding alone, but there does need to be a randomized prospective trial of TIPS versus at least interposition shunts.

There have been few recent reports on surgical portosystemic shunts reflecting the trend toward TIPS. Historical reports support the efficacy of these techniques. The Italians have reported an extensive experience, however, one must remember that they are dealing with a different group of patients; generally approximately 50% are posthepatitic cirrhosis and the other half are alcoholic cirrhosis. Batignani et al. from Florence (Small diameter H-graft

porta-caval shunt performed at different stages of liver disease. *Hepatobiliary Pancreat Dis Int* 2004;3:516–21) recall 29 cirrhotic patients who underwent either partial portacaval shunt with an 8-mm interposition prosthesis in 20 patients or a 10-mm shunt in 9 patients. Of the patients, 12 (41%) were Child A, 11 (38%) Child B, and 6 (21%) Child C. Eleven of their patients or 38% suffered from hepatic encephalopathy preoperatively. Of the 29, 41% were operated on in emergency/urgency. They documented portacaval pressure gradient with either prosthesis and the early mortality was 14% and morbidity 48%. There are obviously differences between the classes as the patients are divided between Child A and Child B and compared with Child C. Not surprisingly, mortality was 0% in Child A and Child B and 67% in Child C; morbidity was 35% in Child A. Late mortality was 40% in Child A and Child B and 64% (why not 67%?) in Child C. Actual survival at 3 and 5 years was 92% and 75% for Child A, 70% and 60% for Child B, and 0% and 0% for Child C, which raises the question of carrying out an interposition shunt on a Child C patient, although other than allowing the patient to bleed to death I am not certain what one would propose. We all know that Child C patients do not do well but if one does not want to operate on them then one must inform the blood bank so that no further blood is given. As long as blood is given, these patients need to have the benefit of surgery to stop the bleeding but under no circumstance should anybody think that long-term survival is going to occur.

Another historical randomized prospective trial that seems to be correctly designed was by Capussotti et al. (Liver function and encephalopathy after partial vs direct side-to-side portacaval shunt: a prospective randomized clinical trial. *Surgery* 2000;127:614–21) from Torino, Italy. They reported a series of 46 patients who were considered good risks with cirrhosis, of which half had alcoholic cirrhosis and the other half presumably had posthepatitic cirrhosis, randomized for either side-to-side portacaval shunt or partial shunt procedure by a 10-mm interposition H-graft. The side-to-side portacaval anastomosis was of small diameter. It does appear that following the shunt in the direct side-to-side portacaval shunts that the portal vein pressure was 22 cm of water whereas the other was 23. Thus there was not too much diversion of portal flow. However, we need to remember that in the alcoholic group, patients have usually been drinking and once the fat infiltration of the liver is reduced they generally have a greater diversion of flow. At least that is how it would seem since in the follow-up period only three patients in the interposition shunt and nine in the direct suture group ($P = 0.04$) developed hepatic encephalopathy. Also, encephalopathy-free survival was significantly longer in the partial shunt group (interposition $P = 0.025$). This was a highly select group in which only 5 of the 46 patients were operated on under urgent or emergency circumstances. However, given the data, I would agree that a 10-mm shunt that retains its resistance to the bleeding from the liver probably yields better survival.

In addition, the current authors and their group presented two papers in the year 2007 concerning predictors of survival and how the conventional

predictors predict survival with H-graft portacaval shunts (Cowgill SM, Thometz D, Clark W, et al. Conventional predictors of survival poorly predict and significantly underpredict survival after H-graft portacaval shunts. *J Gastrointest Surg* 2007;11(1):89–94) and survival and rehemorrhage after shunting in the same group (Rosemurgy A, Thometz D, Clark W, et al. Survival and variceal rehemorrhage after shunting support small-diameter prosthetic H-graft portacaval shunt. *J Gastrointest Surg* 2007;11:325–32). In both papers the Child class was 10% class A, 28% class B, and 62% class C. Actuarial 5- and 10-year survival by Child class was 67% and 33% for A, 49% and 16% for B, and 29% and 7% for C. They carried out a multiple variable regression analysis and concluded, not surprisingly, that the variation survival was greatest for the Child class, less so by the MELD and DF, Emory Score, with the Child Pugh score not being predictable. I am certain that that is so and the reason probably is that patients' behavior following shunt may be somewhat different.

In the same group and in the second paper in November, cirrhosis was caused by alcohol or hepatitis in 12 and both in 11; the cause was unknown in 21. Thirty-three patients had died by 6 months, 54 by 24 months, 87 by 5 years, 112 by 10 years, generally because of liver failure. Rehemorrhage was documented in three (2%) patients. Thus the authors conclude that variceal rehemorrhage in patients with a well-done, small-diameter prosthetic H-graft is rare. The actual survival was superior than predicted by MELD score.

The study using propensity matching by Hosokawa et al. (Outcomes of surgical shunts and transjugular intrahepatic portosystemic stent shunts for complicated portal hypertension. *Br J Surg* 2017;104:443–51) is helpful. This group concluded that surgical shunting achieved better results than TIPS in patients with complicated portal hypertension and low MELD scores. The study design and data are presented below. The authors reported a retrospective study of 471 consecutive patients undergoing portosystemic shunts from 1994 to 2014 at a single institution. Of these 334 patients with cirrhosis who underwent elective surgical shunting (34) or TIPS (300) for repeated variceal bleeding or refractory ascites were evaluated. Propensity score matching was done and resulted in 31 pairs of patients. The primary study endpoints as described by the authors were overall survival and shunt failure; defined as major variceal rebleeding, relapse of refractory ascites, irreversible shunt occlusion, liver failure requiring liver transplantation, or death. There were no differences in morbidity and 30-day mortality rates between the groups. Shunt failure was found to be less frequent after surgical shunting than TIPS (6 of 31 versus 16 of 31; P = 0·016). The 5-year shunt failure-free survival (77 versus 15%; P = 0·008) and overall survival rates were higher for patients with surgical shunts than TIPS (93 versus 42 per cent; P = 0.00.03737). Multivariable analysis revealed that a MELD score exceeding 14 and TIPSS were independently associated with shunt failure. They found that in patients with MELD scores of 14 or less, the 5-year overall survival rate remained higher after surgical shunting than TIPS (100% versus 40%; P <0.001).

There is very little doubt in our minds that stopping the bleeding and preventing rebleeding is the sine qua non of caring for these patients. We do not know why people persist in having these patients rebleed without doing some kind of decompressive procedure. Perhaps it is because there are few surgeons that have the surgical experience needed or because of the realization that the mortality rates have decreased and that temporizing the bleeding and medical management with lifestyle changes seems to be more effective than previously thought. However, it is nice to see that there are reports that support the better outcomes in portocaval shunts in patients with MELD scores of 14. In these groups the key is to stop the bleeding and keep it stopped.

INTRODUCTION

The goal of any portosystemic shunt is effective decompression of the gastroesophageal veins. There are two distinct types of portosystemic shunts: those that are associated with total diversion of portal blood away from the liver (i.e., total shunts), and those that maintain portal blood supply to the liver (i.e., selective shunts). Examples of total shunts include portacaval, mesocaval, and central splenorenal shunts (CSRSs). An example of a selective shunt is the distal splenorenal shunt (DSRS), for which the terms *selective* and *DSRS* are often used interchangeably. The only other truly selective shunt, the coronocaval shunt, is rarely used today.

The concept of selective shunting was first introduced by Warren and his associates in 1967. These authors emphasized the increased morbidity and mortality associated with liver failure and hepatic encephalopathy after total shunting procedures. They attributed these problems to loss of liver portal perfusion. Their goal for the ideal operation for the treatment of patients with variceal bleeding was to achieve effective variceal decompression while preserving portal blood flow to the liver. The operation they devised to achieve these objectives was the DSRS.

The DSRS is created by anastomosing the splenic end of the divided splenic vein to the side of the left renal vein. The portal end of the splenic vein is oversewn. A functioning DSRS achieves variceal decompression by establishing a route for gastric venous drainage that offers less vascular resistance than the anastomotic channels between the gastric and

esophageal veins. This route is sequentially made of the short gastric and splenic veins, splenorenal shunt, and left renal vein.

The second important goal of the selective shunt is to maintain portal blood flow to the liver. Because the splenorenal anastomosis is not in direct communication with the superior mesenteric or portal veins, the pressure in these vessels remains elevated. Such pressure elevation is crucial in maintaining portal blood flow to the cirrhotic liver in the face of increased vascular resistance. Portal blood flow to the liver, however, can be maintained only if the high-pressure portomesenteric venous compartment is anatomically disconnected from the low-pressure splenic venous zone. This is the rationale for combining the selective shunt with interruption of the coronary gastroepiploic and inferior mesenteric veins. Any overlooked communicating channels between these two pressure zones are likely to develop into a major conduit for diversion of portal blood away from the liver to the decompressed splenic vein.

INDICATIONS

In the early years after the introduction of the DSRS, it was the practice with my group to recommend the procedure for nearly all patients who presented with or had a documented history of variceal bleeding. The only exceptions were the patients with intractable ascites or signs and symptoms of hepatic decompensation. Increased popularity of sclerotherapy in the 1970s prompted us to conduct a prospective trial in which we compared sclerotherapy with the DSRS operation. We concluded that patients who received sclerotherapy with the DSRS as a safety net for sclerotherapy failure had better overall survival than those who received DSRS as their first line of treatment. Meanwhile, reports began to appear in the literature showing improved survival of patients with advanced liver disease treated by liver transplantation. In view of these developments, our current policy is to treat all patients initially with sclerotherapy. Patients with rebleeding after obliteration of the variceal bed are stratified according to their degree of liver function. Patients with adequate liver reserve (Child Class A or B) receive DSRS. Patients with severe liver dysfunction are evaluated for liver transplantation. Patients with intractable ascites are unsuitable for DSRS. Patients with bleeding gastric varices who are good operative candidates are considered for DSRS as initial treatment because these varices are difficult to sclerose.

PREOPERATIVE PLANNING

Preoperative evaluation for DSRS should include liver function tests, liver serologic evaluation, splenoportography, and left renal venography. Hepatic wedge venography and pressure measurement are useful in differentiating between presinusoidal and postsinusoidal portal hypertension. An angiographic evaluation of the inferior vena cava and hepatic veins is indicated in patients with Budd–Chiari syndrome. Liver ultrasonography or computed tomographic scanning is used to determine the liver volume and to uncover nodules that may suggest hepatoma formation. Such nodules should be subjected to biopsy preoperatively for histologic verification. Liver biopsy is also indicated to determine the nature of the underlying liver disease in atypical cases and in patients with clinical evidence of active viral or alcohol-related liver disease.

It is our policy to postpone the operation until the liver function and nutritional status of the patient are maximally improved. Patients who are actively drinking alcohol are referred to appropriate centers, and the operation is deferred until there is a reasonable chance that they will abstain. Patients with ascites are treated medically until the problem is resolved. Intractable ascites is a contraindication to DSRS operation.

SURGICAL TECHNIQUE

The patient is placed in the supine position. Slight hyperextension of the lumbar spine helps improve surgical exposure. The procedure is most commonly performed from a subcostal incision. The incision begins in the left midaxillary line and extends one fingerbreadth below the costal margin, across the midline, to the lateral border of the right rectus muscle. This incision provides excellent exposure, particularly to the region of the tail of the pancreas and hilum of the spleen. It may, however, weaken the abdominal wall. The midline incision (Fig. 132.1) is also adequate for this procedure and has, in fact, become my preference in recent years. In the patients who have previously undergone midline abdominal operations, fewer adhesions may be encountered if the subcostal incision is used. Abnormal bleeding from the skin edges and abdominal muscles is common in patients with portal hypertension. Well-developed venous collaterals are often encountered around the umbilicus and in the falciform ligament. All bleeding should be securely controlled before proceeding with the operation. Persistent incisional bleeding can cause considerable perioperative blood loss in patients with portal hypertension. Another

potential source of bleeding in these patients is the portosystemic collateral veins, which form in the adhesions between the abdominal contents and the abdominal wall. These adhesions should be meticulously divided by appropriate hemostatic techniques.

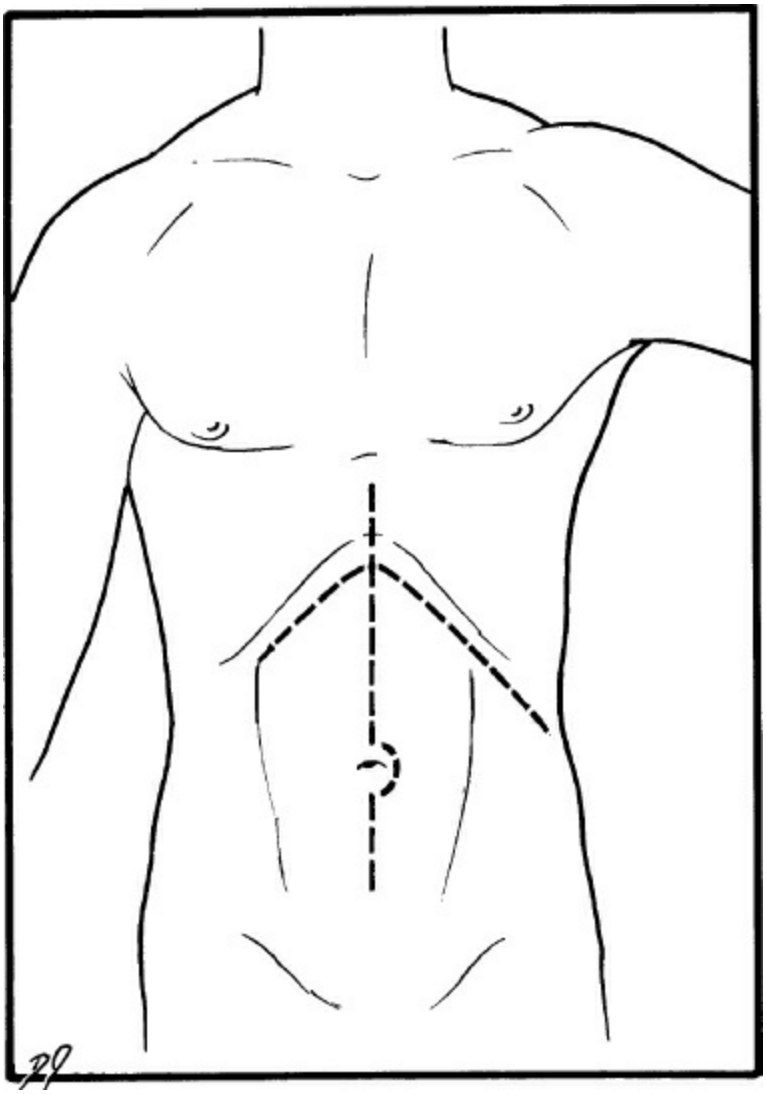

Figure 132.1. Bilateral subcostal and midline incisions, both suitable for the distal splenorenal shunt operation.

After all the adhesions crossing the surgical field are lysed, the abdomen is explored. Any suspicious nodule in the liver is sampled and examined for malignancy. The gallbladder is palpated for stones. In patients with cirrhosis, one should avoid cholecystectomy if at all possible. The morbidity and mortality from this procedure are quite high in such patients. Enlargement of the gallbladder is common among these patients, and this finding should not be mistaken for acute obstructive cholecystitis unless there are obvious signs of acute inflammation.

Adequate exposure is of crucial importance in the DSRS operation because of the depth of the operative field. In our experience, the Omni retractor is extremely useful for this purpose, particularly during dissection of the splenic and left renal veins. It should be remembered, however, that the tissues of patients with portal hypertension are congested and, if injured, can cause troublesome bleeding. This fact is especially true for the mesentery and spleen. Thus, it is important to use gentle retraction and to use proper padding under the retractor blades. The next step is to proceed with devascularization along the greater curvature of the stomach (Fig. 132.2). The gastric vessels are isolated individually, then divided between clamps and ligated according to proper surgical techniques. Devascularization is carried close to the wall of the stomach in a stretch extending from the pylorus to the first short gastric vein. The right and left gastroepiploic veins are suture-ligated for the aforementioned reasons. Next, the splenic flexure is carefully mobilized by dividing its peritoneal attachment to the lower pole of the spleen. The stomach is then retracted superiorly, and the transverse colon is retracted inferiorly, using appropriate retractor blades. This procedure brings the pancreas into view. The stage is now ready for exposure of the splenic vein.

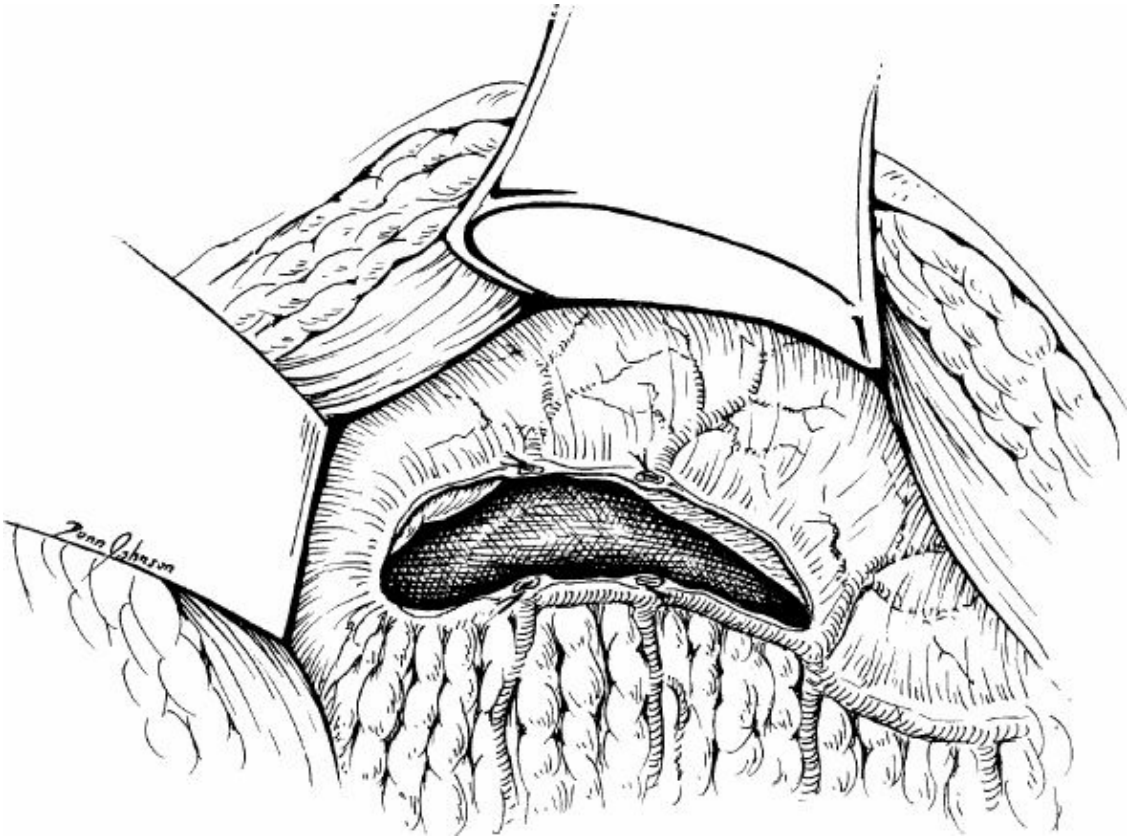

Figure 132.2. The lesser sac is entered by dividing the

gastrocolic ligament. The gastroepiploic vessels are disconnected from the stomach. Both right and left gastroepiploic veins are ligated to prevent mal diversion of portal blood to the decompressed splenic vein.

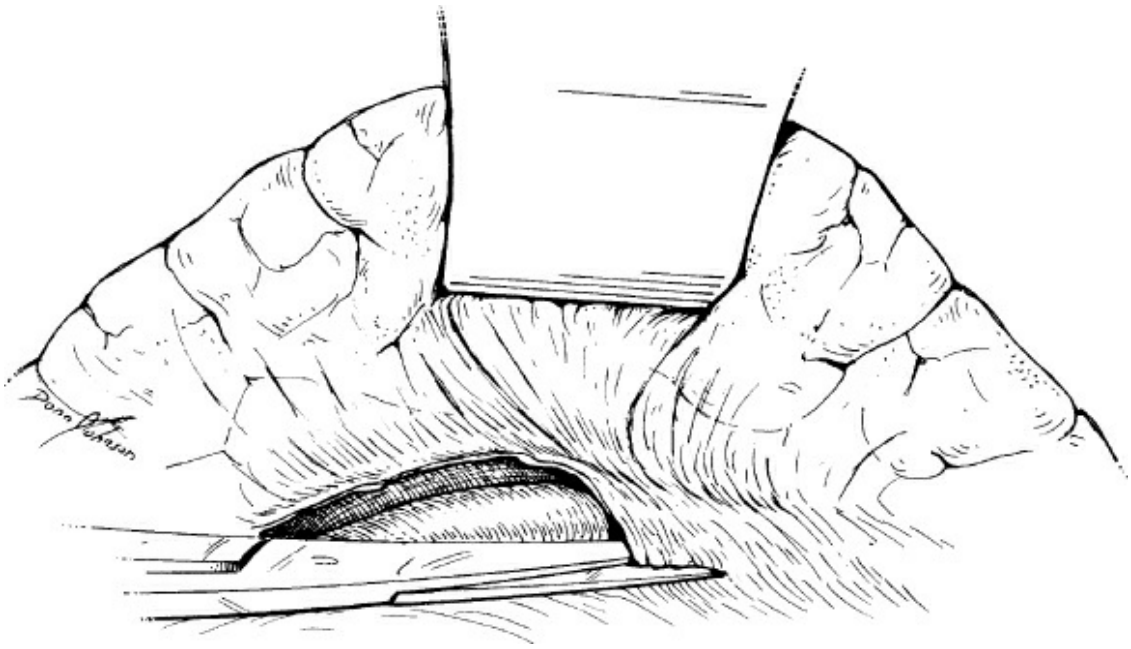

Figure 132.3. The posterior peritoneum is divided along the lower border of the pancreas. The latter is retracted gently to visualize the splenic vein.

We routinely use headlight and magnifying loupes for mobilization of the splenic vein. First, the pancreas is mobilized by dividing the peritoneum along its inferior border (Fig. 132.3). Mobilization of this border is completed before dissection is carried deeper in the retropancreatic space. With the pancreas carefully retracted, the surgeon starts looking for the splenic vein. In most instances, it loops inferiorly as it approaches the superior mesenteric vein. It is, therefore, easier to identify the splenic vein first medially, then to proceed with its mobilization in the direction of the hilum of the spleen. The inferior mesenteric veins may be used as a guide to find the splenic vein unless it is joining the superior mesenteric vein (Fig. 132.4).

The splenic vein should be mobilized first inferiorly, then anteriorly, and posteriorly, leaving dissection of its superior border until adequate length of the vein has been exposed. The pancreatic veins along this border of the pancreas require special handling because they are friable and, if torn, can cause troublesome bleeding. Our technique for isolation of these

veins starts with careful dissection until a sufficient length of the vein is exposed. A fine silk suture is then applied around the mobilized vein and ligated flush with the splenic vein. A fine-tip clamp is applied to the other side, and the vein is transected between the clamps. The pancreatic end of the divided vessel is then ligated using meticulous surgical technique (Fig. 132.5). These veins are sometimes too short to be safely controlled with simple ligatures, in which case it is safer to use 5-0 Prolene to suture the divided veins. Dissection of the pancreatic veins is the most challenging part of the DSRS operation. In my experience, the tearing of these vessels is most often caused by excessive pancreatic retraction, a premature attempt to encircle the splenic vein, or a premature attempt to encircle the pancreatic veins. Another complicating factor in this dissection is the coronary vein, which joins the upper border of the splenic vein in approximately one-fifth of the patients. In some cases, the coronary vein may be as large as the splenic vein. Tearing of the coronary vein can cause severe bleeding and may lead to irreversible damage to the splenic vein. The safest way to deal with this situation is to free the upper border of the splenic vein and encircle it on both sides of the coronosplenic venous junction. Gentle traction on the splenic vein facilitates further mobilization of the coronary vein (Fig. 132.6). The mobilization is continued until there is sufficient room for safe clamping and division of the coronary vein.

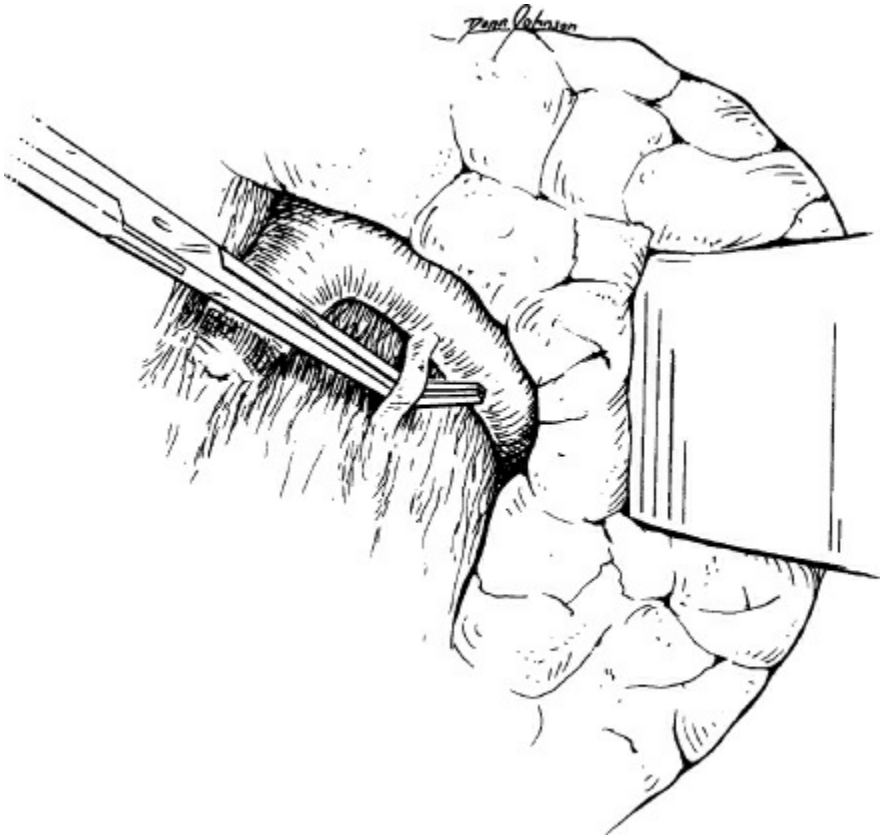

Figure 132.4. The inferior mesenteric vein is identified in preparation for its division. In some cases, the inferior mesenteric vein is used as a guide for the splenic vein.

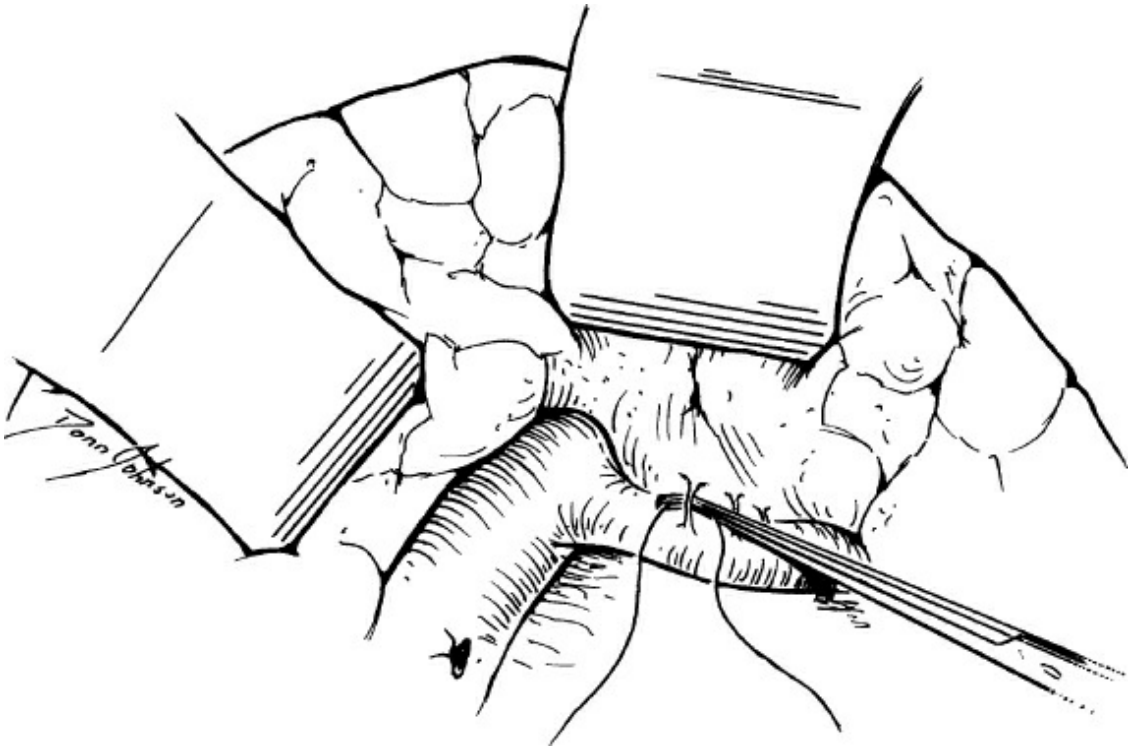

Figure 132.5. Technique for isolation and division of the pancreatic veins. These veins are encircled, ligated, and then

divided using meticulous surgical technique. Laceration of these fragile veins causes troublesome bleeding.

Once an adequate segment of the splenic vein is mobilized, attention is shifted to the left renal vein. This vessel can be approached either above or below the transverse mesocolon. In the superior approach, the colon is retracted inferiorly, and the duodenojejunal junction is exposed. The posterior peritoneum and the underlying tissue are divided along an imaginary line that stretches from the lateral border of the fourth part of the duodenum to the hilum of the left kidney. Once the left renal vein is identified, it is mobilized by dividing as many tributaries as necessary, including the adrenal and gonadal veins (Fig. 132.7).

In the infracolonic approach to the left renal vein, the colon is retracted superiorly, and the third part of the duodenum is exposed. The duodenum is mobilized by dividing the peritoneum along its inferior border, and the dissection is advanced superiorly until the left renal vein is exposed. Once the left renal vein is identified, the colon is retracted inferiorly, and mobilization of the left renal vein is completed as described previously. The advantage of this approach is the ability to locate the left renal vein with minimal untargeted dissection in the retroperitoneal space. This advantage is important because the retroperitoneal tissue of the patients with portal hypertension is often dense and loaded with distended lymph vessels and collateral veins. Any transected tissue in this dissection should be securely ligated to minimize perioperative blood loss and postoperative lymphatic leakage. Uncontrolled lymphatic leakage causes postoperative ascites, and, if the intestinal lymphatics are involved, chylous ascites may develop—a condition that is often difficult to treat.

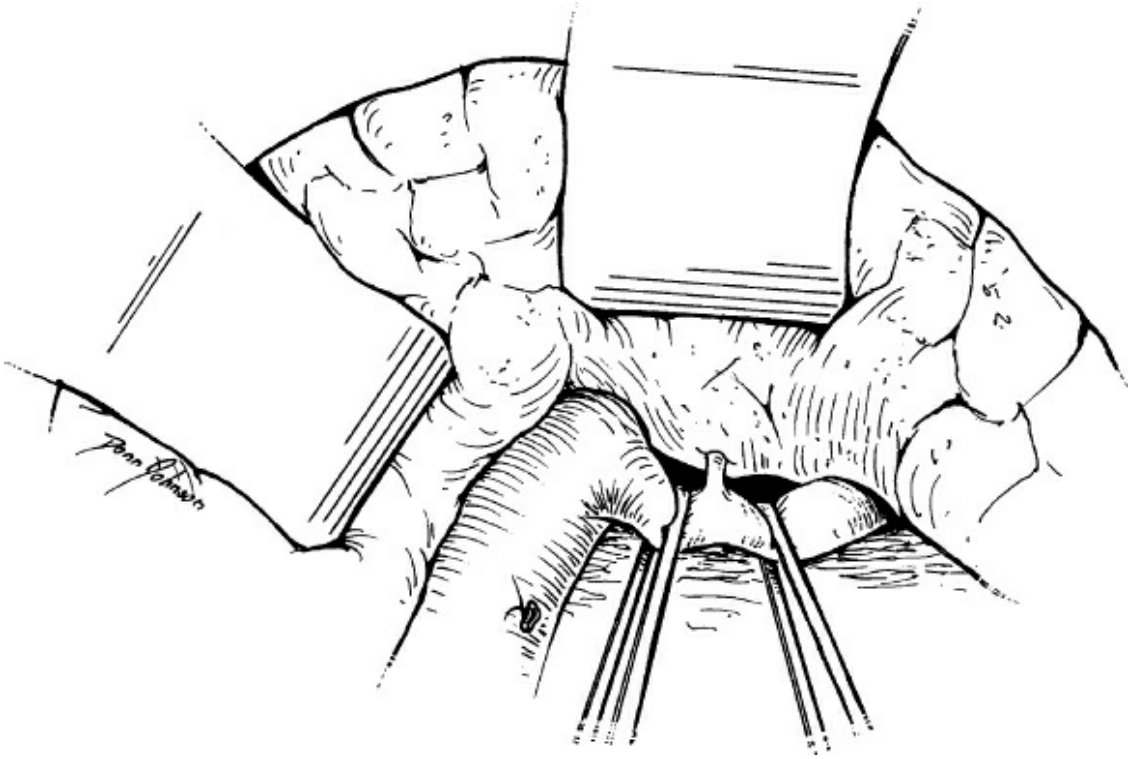

Figure 132.6. Technique for exposure of the coronary vein when it is draining into the splenic vein instead of the portal vein. The splenic vein is encircled on either side of the coronary vein. Traction on the tape encircling the splenic vein facilitates exposure of the coronary vein.

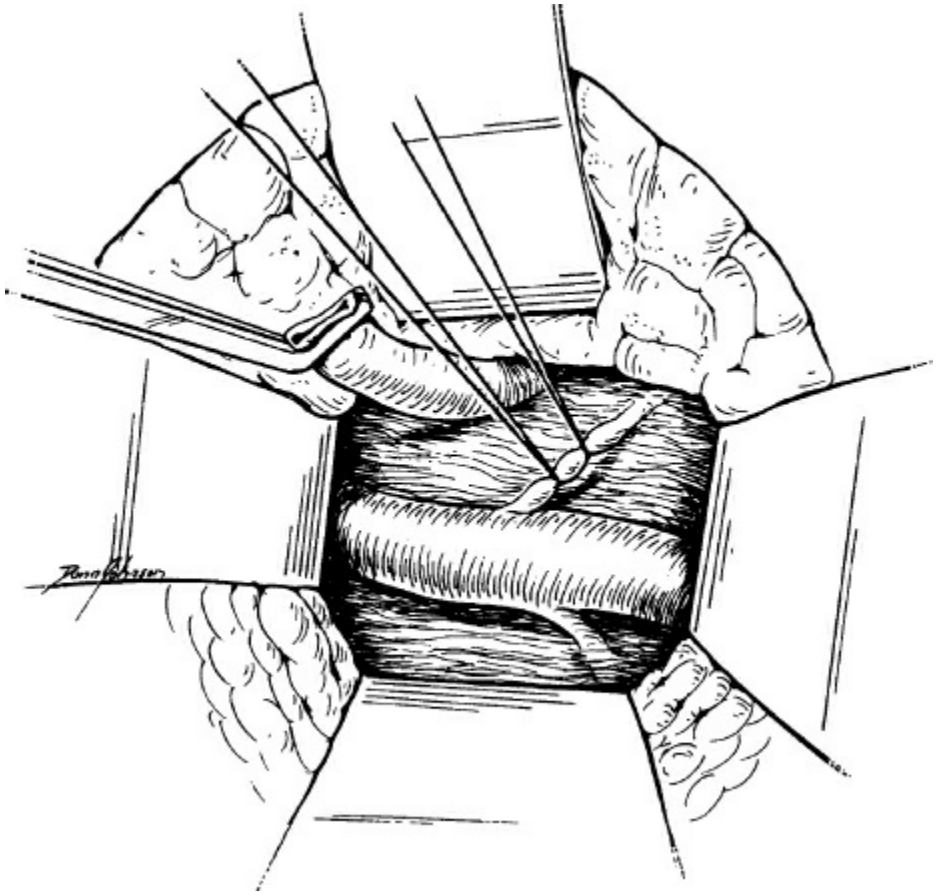

Figure 132.7. The left renal vein is exposed by dividing the overlying peritoneum. The vein is mobilized by dividing its tributaries, including the gonadal and adrenal veins.

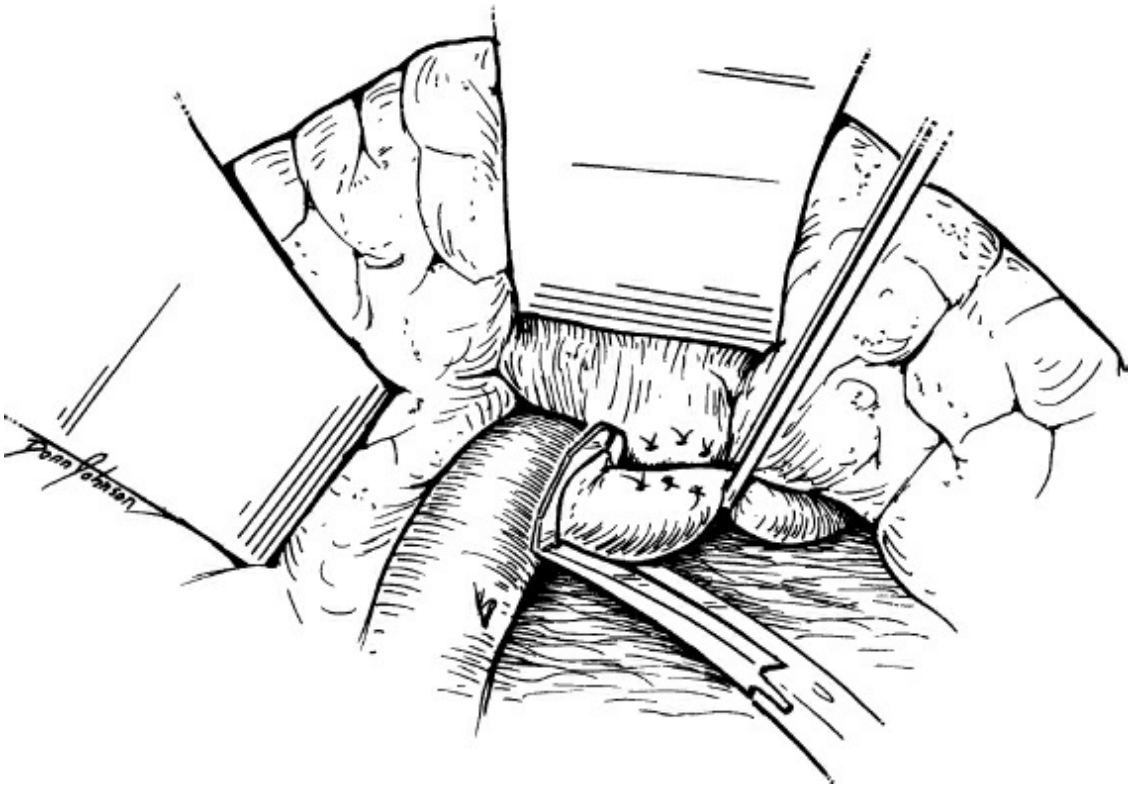

Figure 132.8. The splenic vein has been mobilized and encircled. A Cooley clamp is applied to the splenic vein at its junction with the superior mesenteric vein.

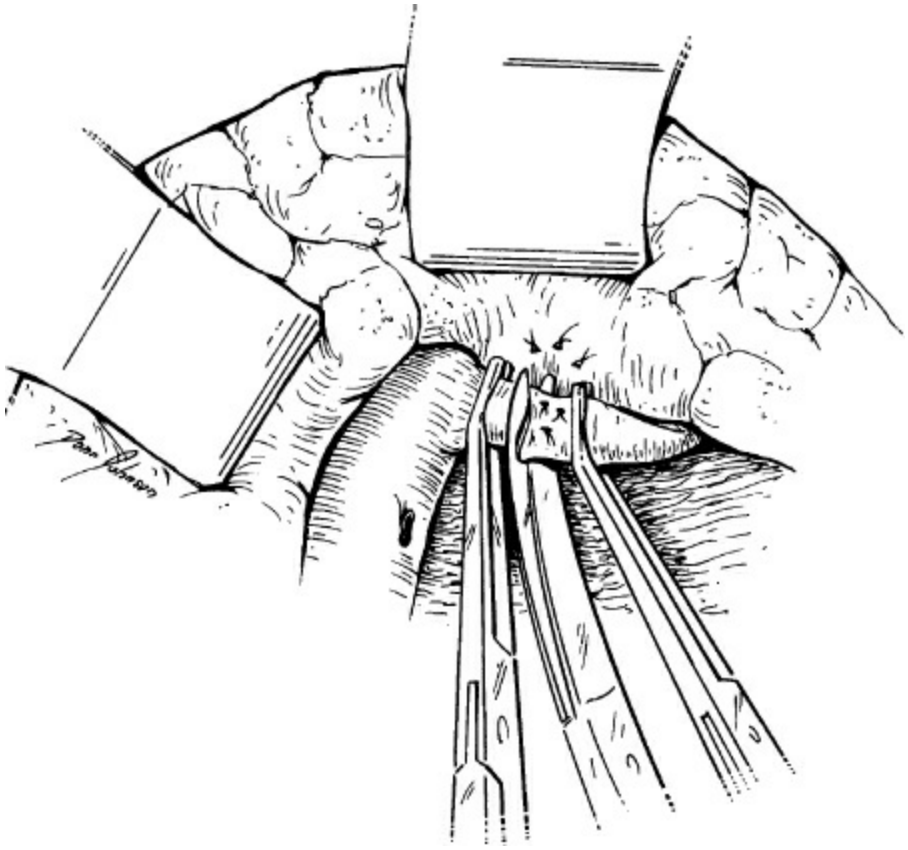

Figure 132.9. The splenic vein is divided between clamps, leaving sufficient rim medially to allow safe control of the stump of the splenic vein. Accidental slippage of the clamp or faulty stump closure may cause bleeding and tearing of the splenomesenteric-portal vein junction.

With the left renal vein fully exposed, the surgeon turns back to the splenic vein, dividing it between vascular clamps near its junction with the portal vein. We use a Cooley clamp on the portal end of the splenic vein flush with the portal vein (Figs. 132.8 and 132.9). It is important to leave a sufficient rim exposed to ensure secure closure of the stump of the splenic vein. A 5-0 Prolene stitch is used for the closure (Fig. 132.10). The splenic end of the splenic vein is now less anchored in place; hence, more of the deeply located pancreatic veins can be readily brought into view (Figs. 132.11 and 132.12). Mobilization of the splenic vein is advanced laterally until an adequate length of the vessel is exposed.

The stage is now set for shunt construction. A Satinsky clamp is applied

to the left renal vein (Fig. 132.13). The splenic end of the splenic vein is then approximated to the clamped segment of the left renal vein. Any apparent tension should be corrected by further mobilization of either of the two veins. It is also important to trim any excess in the splenic vein; otherwise, it will become acutely angulated when circulation is restored. Optimal orientation of the two vessels can usually be achieved by rotating the splenic vein in a clockwise direction for 45 degrees. The shunt is placed as medially as possible in relation to the left renal vein to prevent sharp bending of the splenic vein.

With the two veins properly approximated, shunt construction is begun by removing a disk 10 × 15 mm from the superior wall of the left renal vein (Fig. 132.14). A stay stitch is used to keep the opening in the vein well exposed. The anastomosis is started at the most medial end (or toe) using double-armed 5-0 Prolene. One needle is passed from the outside to the inside of the left renal vein. This needle is used as a running stitch to close the posterior wall. A new 5-0 Prolene corner stitch is then applied at the lateral corner (or heel) of the anastomosis and ligated. One end of this suture is tied to the one used for the posterior row. At this stage, there is one stitch at each corner of the anastomosis. These two stitches are advanced so that the anastomosis is finished in the middle of the anterior row (Figs. 132.15 to 132.19). Both veins are adequately flushed before the anastomosis is completed. The potential purse-string effect of the running suture is minimized by interrupting the suture line at the toe and heel of the anastomosis. In children, we routinely interrupt the entire anterior row to allow for growth.

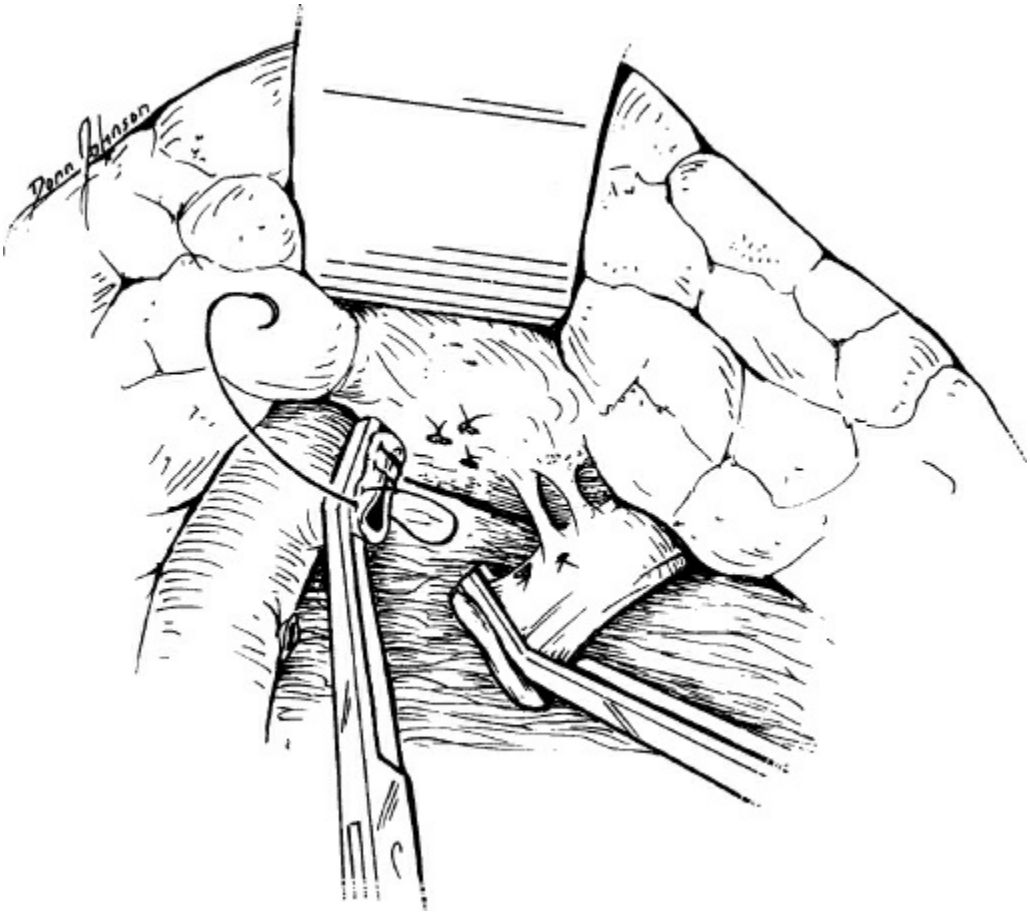

Figure 132.10. Oversewing of the stump of the splenic vein using 5-0 running Prolene.

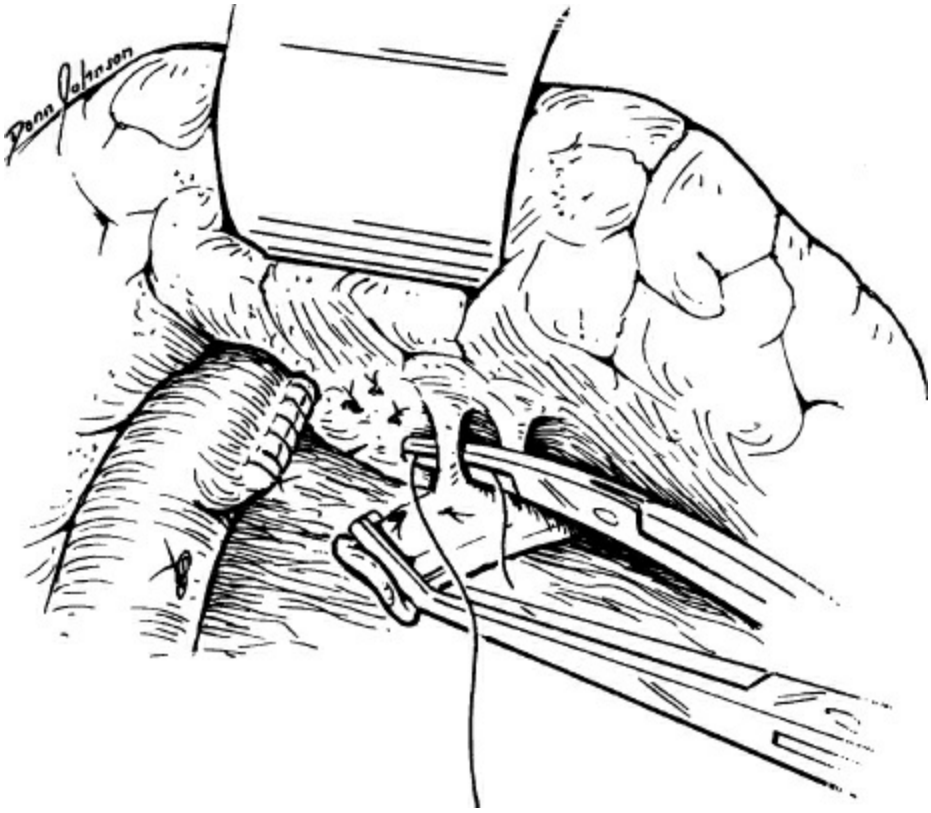

Figure 132.11. The splenic end of the divided splenic vein is retracted inferiorly to expose more of the pancreatic veins laterally.

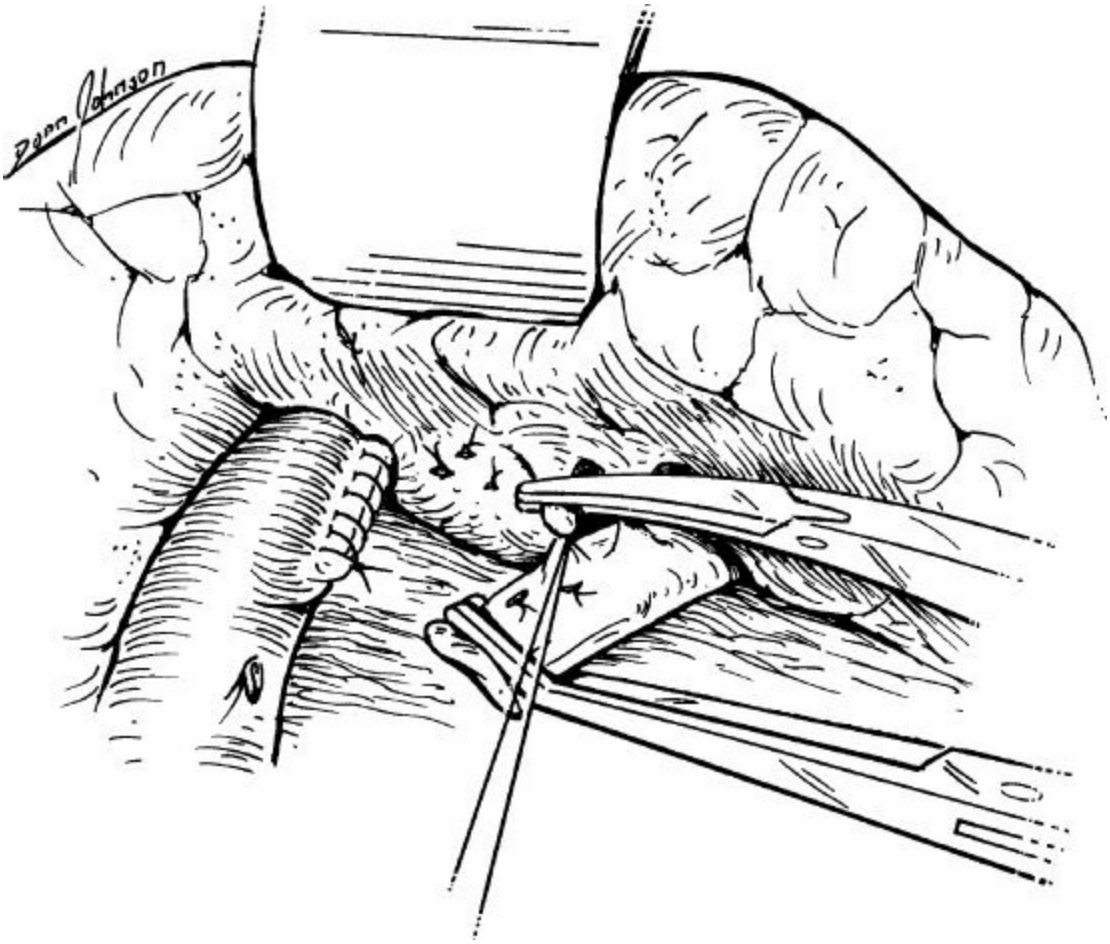

Figure 132.12. The splenic and pancreatic veins are divided until a sufficient length of the splenic vein is disconnected from the pancreas.

The final step in the DSRS procedure is coronary vein ligation. The stomach is retracted anteriorly and superiorly, and the peritoneal fold stretching between the highest point of the lesser curvature and the posterior wall of the lesser sac is exposed. The coronary vein is identified and ligated in this location. Any accessory coronary veins in the region should also be ligated. It is important to protect the nerve of Latarjet while exposing the coronary vein.

The operative field is then thoroughly examined, and any remaining bleeding points or lymphatic leaks are controlled. The abdomen is closed without any drains. Draining the abdominal cavity in the presence of ascites leads to massive postoperative fluid loss and profound electrolyte

disturbances. Abdominal drains also enhance the risk of secondary bacterial invasion.

MODIFICATION OF THE DSRS OPERATION

Temporary Clamping of the Splenic Artery

In patients with hyperdynamic splenic circulation and massive splenomegaly, I routinely clamp the splenic artery until the shunt construction is completed. In patients with schistosomiasis, for example, the spleen, which is usually quite large, grows even larger with clamping of the splenic vein. The difficult exposure is compounded by the extreme engorgement of the pancreatic and splenic veins. The decongestive effect of splenic arterial clamping helps reduce the size of the spleen and congestion in the operative field.

Renosplenic End-to-Side Shunt

In a renosplenic end-to-side shunt (Fig. 132.20), the left renal vein is divided near the hilum of the kidney, and its central (or caval) end is swung upward to be anastomosed to the side of the left renal vein. The total shunt thus created is then converted into a selective shunt by ligating the splenic vein at some point between the renosplenic anastomosis and the portal vein. Patients with portal hypertension tolerate well the interruption of the renal vein because of pre-existing collateral venous circulation. Normally, a longer segment of a free vessel can be procured by mobilizing the left renal vein as compared to the splenic vein. The renosplenic technique is therefore advantageous when a long conduit is needed to cross the gap between these two veins. Compression of the left renal vein by the superior mesenteric artery is a potential problem with this technique and is usually caused by excessive traction on the left renal vein.

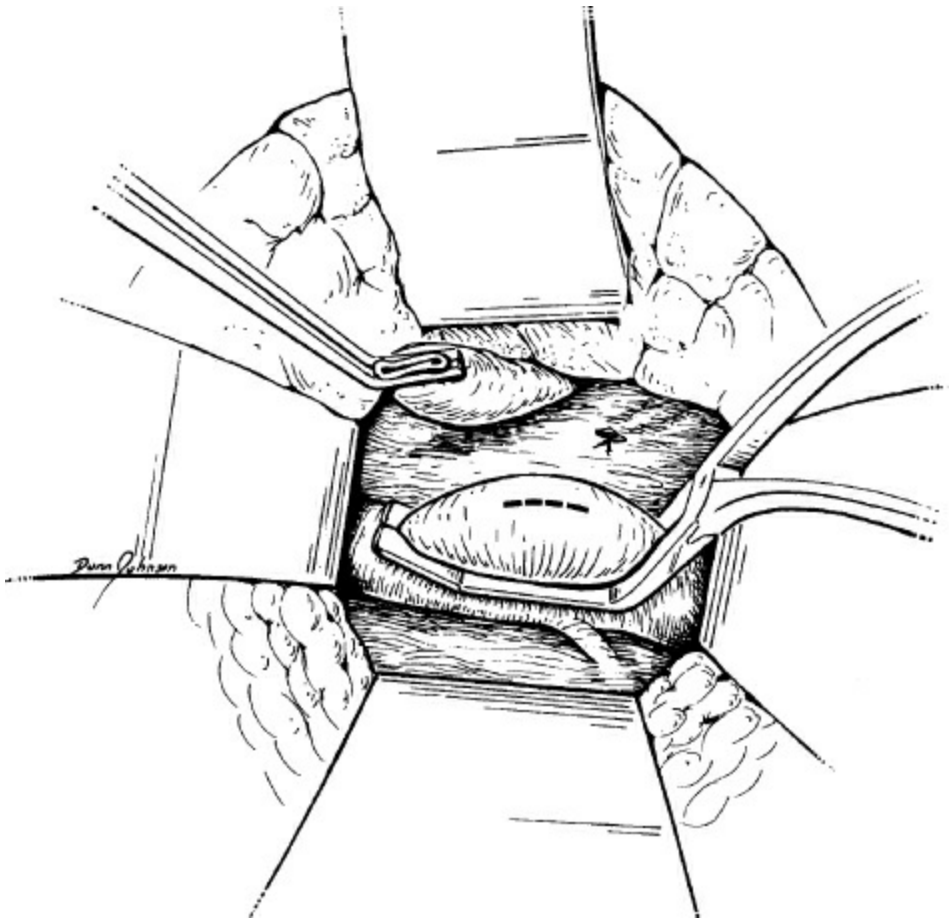

Figure 132.13. A Satinsky clamp is applied to the left renal vein. The more medial the segment of the vein selected for the shunt, the better the angle of the meeting of the splenic and left renal veins.

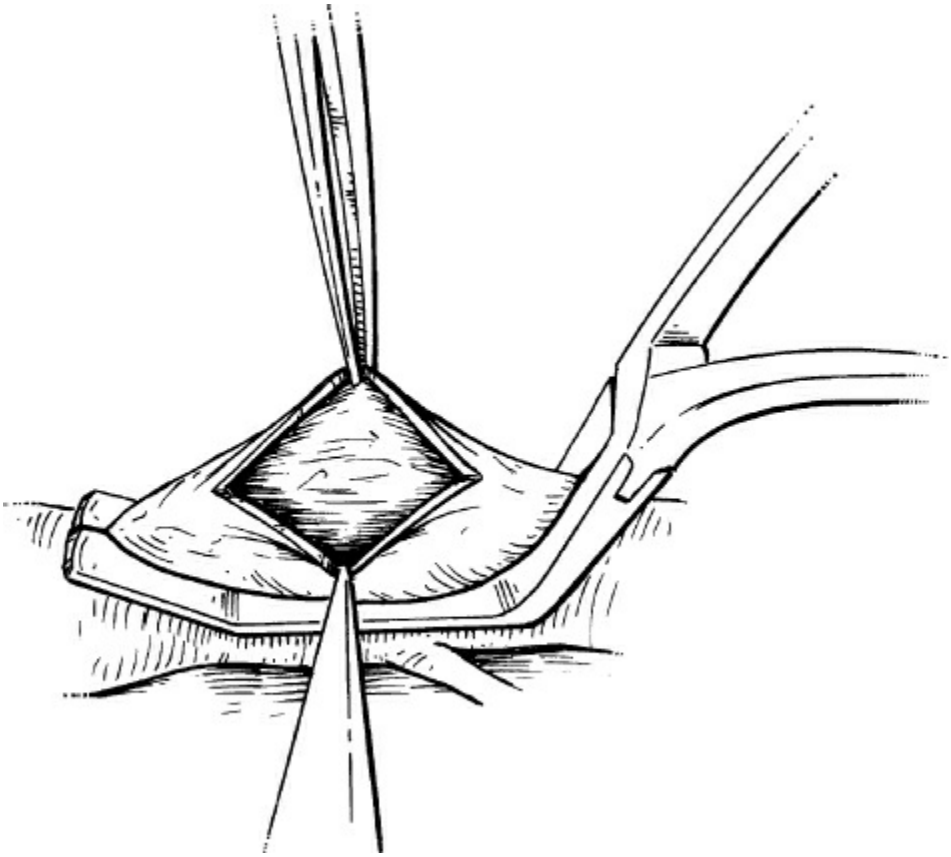

Figure 132.14. A disk is removed from the wall of the left renal vein. Stay stitches may be used to retract on the anterior rim of the vein.

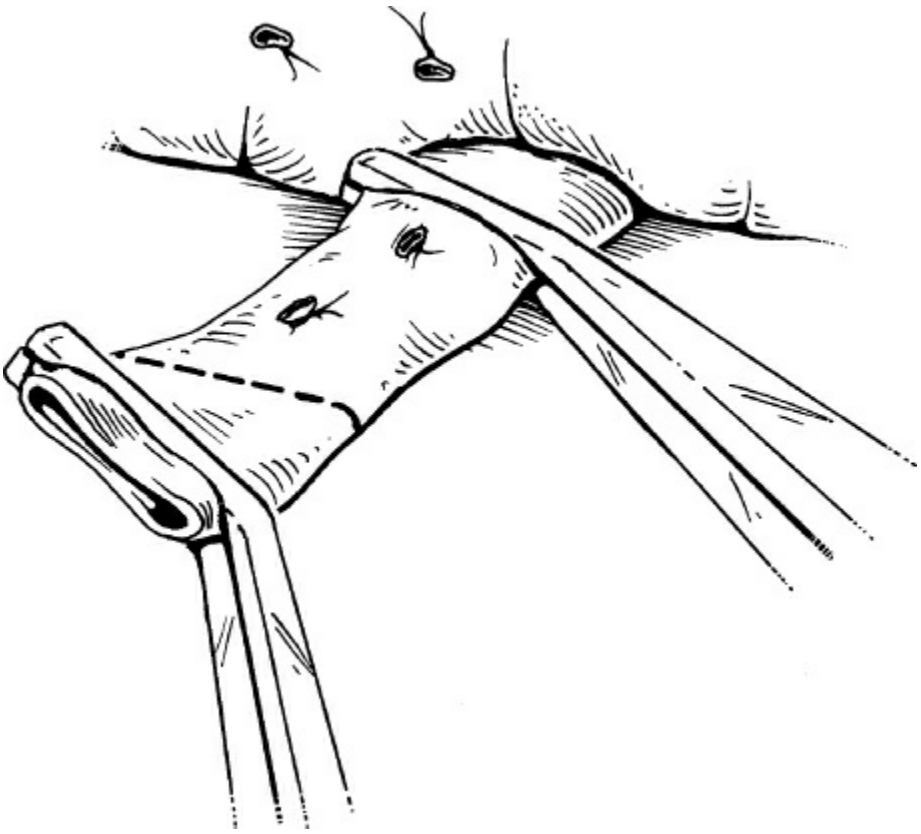

Figure 132.15. The splenic vein is being prepared for the shunt. The vessel is rotated one fourth of a circle clockwise. The splenic vein is shortened to avoid any redundancy that might lead to kinking of the vessel when the flow is restored.

Splenocaval Shunt

For the patients whose left renal veins are absent or unsuitable, a selective shunt can be created by anastomosing the splenic end of the divided splenic vein to the side of the inferior vena cava (Fig. 132.21). The splenocaval shunt is also useful when one is dealing with an unusually tortuous splenic vein. The tortuosity of the vessel is partly corrected as it is stretched in a straight line to meet the inferior vena cava. Conversely, these angulations may be accentuated as the direction of the splenic vein is changed, first inferiorly and then posteriorly, to reach the left renal vein.

POSTOPERATIVE MANAGEMENT

Fluid and electrolyte balance should be monitored carefully because patients with cirrhosis have an increased tendency to retain fluid and salt. The aim is to slow down the rate of postoperative ascitic accumulation. Approximately half of the daily fluid requirement is given as 5% albumin in the first 24 to 48 hours. Ranitidine is administered to reduce gastric

acidity. Cephalosporin is used for antibiotic prophylaxis, with the first dose given 1 hour before operation and the coverage extended during the procedure and for 24 to 48 hours after the operation. Diuretic therapy is started on the third postoperative day in the form of spironolactone. Furosemide (Lasix) may be added in the management of problematic ascites.

QUESTIONS FREQUENTLY ASKED ABOUT THE SELECTIVE SHUNT

How Effective is the Shunt in Preventing Rebleeding?

Rebleeding after a selective shunt occurs in 5% to 7% of cases; this compares favorably with the incidence for total shunts. In an emergency situation, a selective shunt may not be as effective as a total shunt in controlling the bleeding. In most instances, however, recurrent bleeding in the presence of a patent DSRS can be controlled with variceal injection.

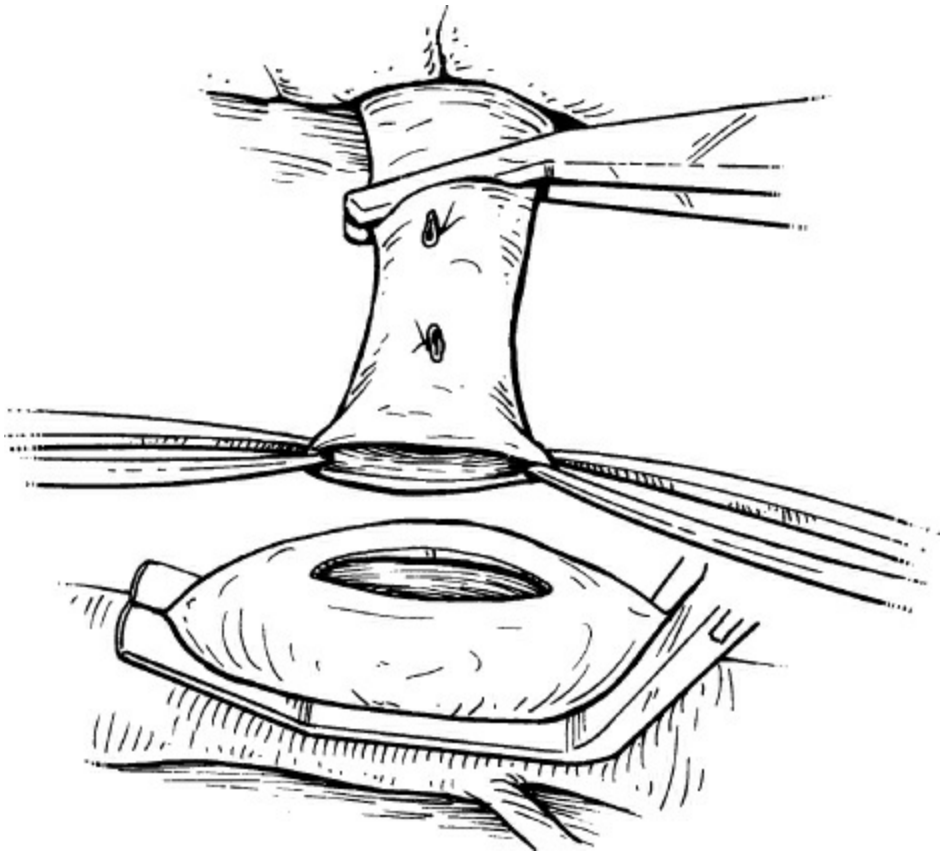

Figure 132.16. The splenic vein is approximated to the left renal vein.

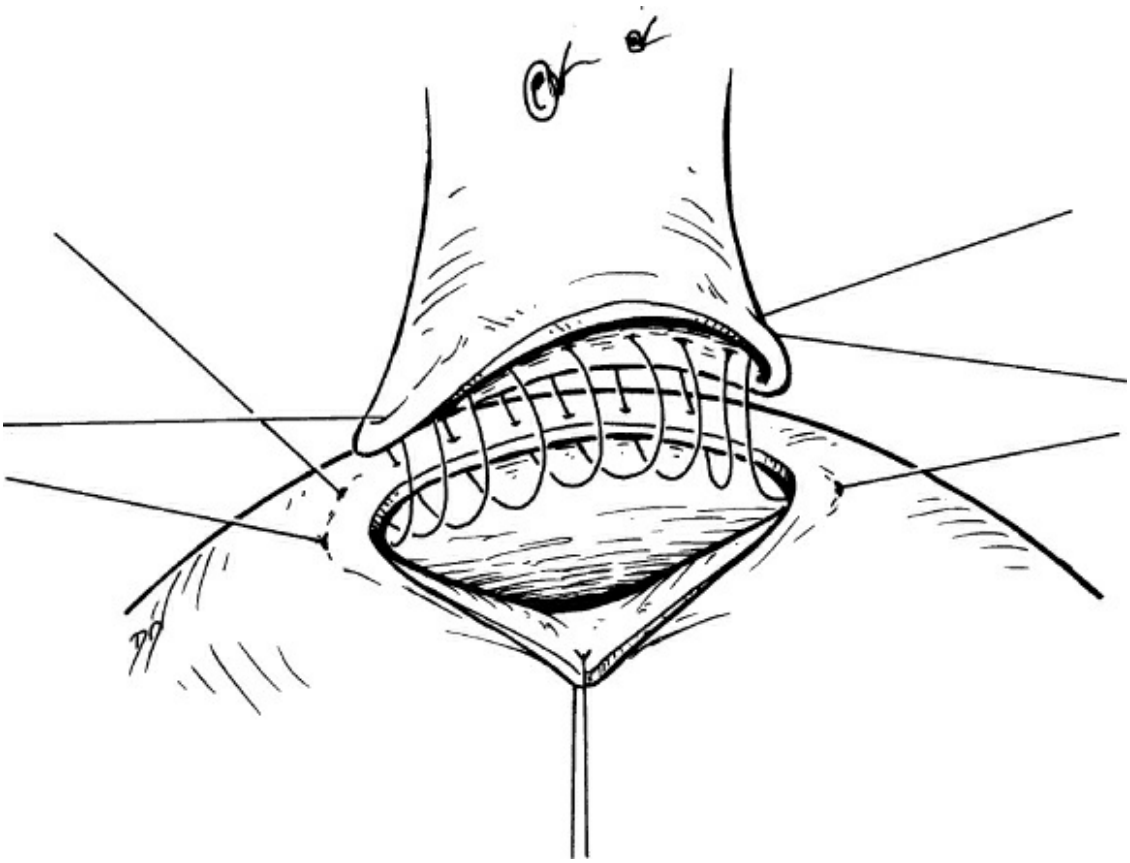

Figure 132.17. Shunt construction: First, double-armed 5-0 Prolene suture is placed at each corner of the anastomosis. The medial corner suture is ligated. One end of this suture is used for the posterior wall.

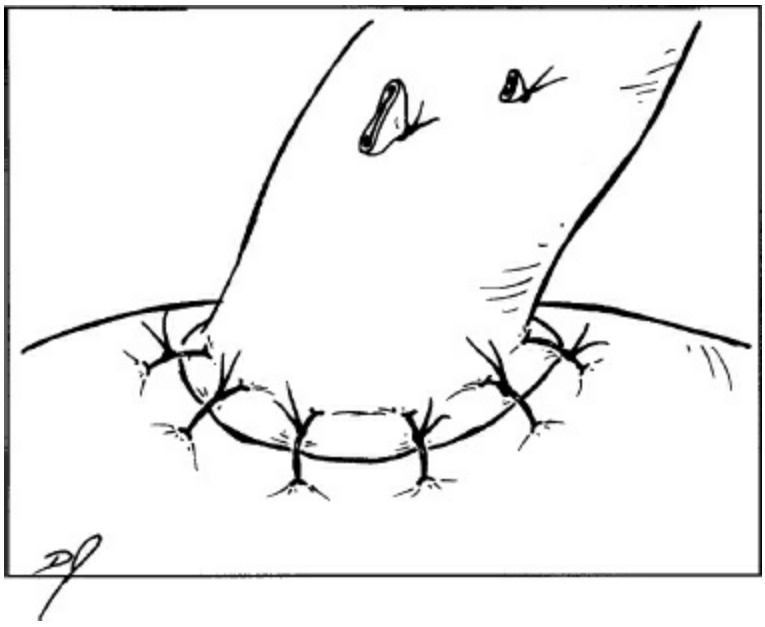

Figure 132.18. Shunt construction. In children, the anterior row of sutures is interrupted.

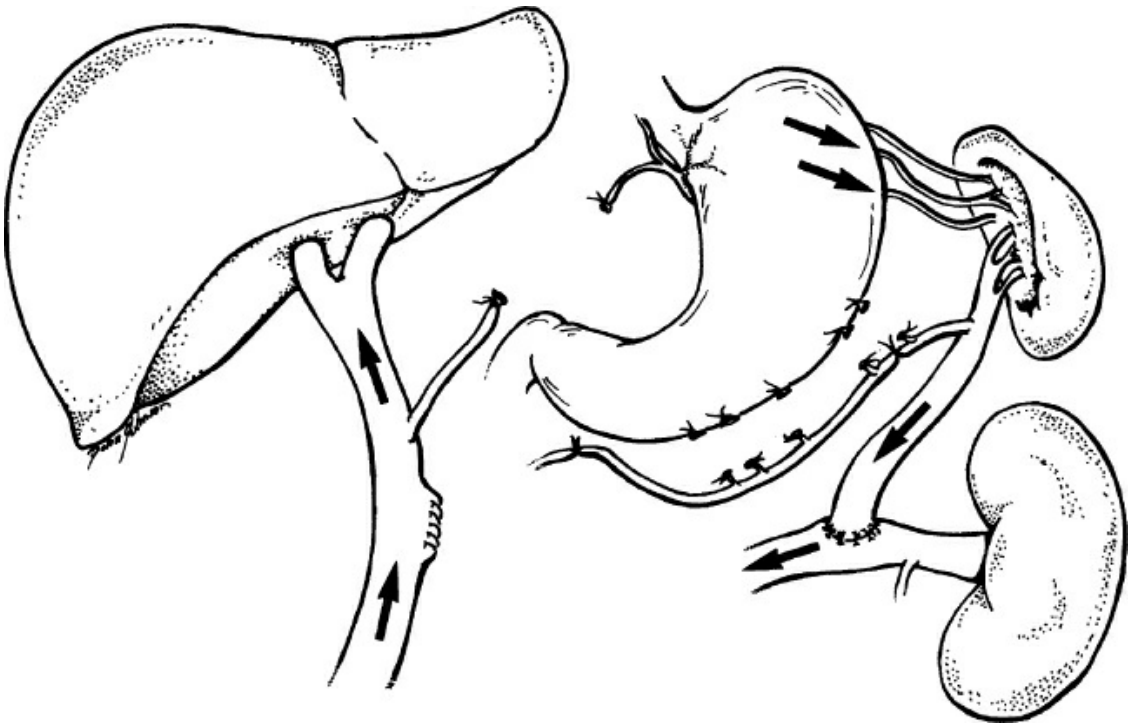

Figure 132.19. A diagrammatic illustration of the distal splenorenal shunt.

What is the Incidence of Shunt Occlusion?

Shunt failure is usually caused by faulty technique. The incidence of this complication should not exceed 5%. Excessive tension, kinking, twisting, and renal venous hypertension secondary to tenting of the left renal vein are among the main causes of early shunt failure. Poor selection of patients may be another reason for this complication. The risk of shunt thrombosis is high in the patients with alcohol-related pancreatitis and a small splenic vein. Late shunt occlusion is rare, but late stenosis has been seen infrequently.

Is There a Role for the Selective Shunt in Patients with Ascites?

Existing preoperative ascites is likely to get worse after DSRS. First, cirrhotic patients with ascites have an increased tendency to retain fluid after major operations. Second, the selective shunt does not correct the major cause of ascites in such patients—the high pressure in the portal and superior mesenteric veins. Third, lymphatic leakage is known to occur after the selective shunt because several retroperitoneal lymph vessels are likely to be transected during mobilization of the left renal vein. Therefore, the selective shunt is not suitable for the treatment of patients who present with intractable ascites. On the other hand, ascites precipitated by the

selective shunt is usually easily controlled with medical treatment. Chylous ascites, however, is more difficult to treat and may require prolonged periods of hospitalization. Intravenous hyperalimentation and repeated paracentesis is the recommended treatment for this condition.

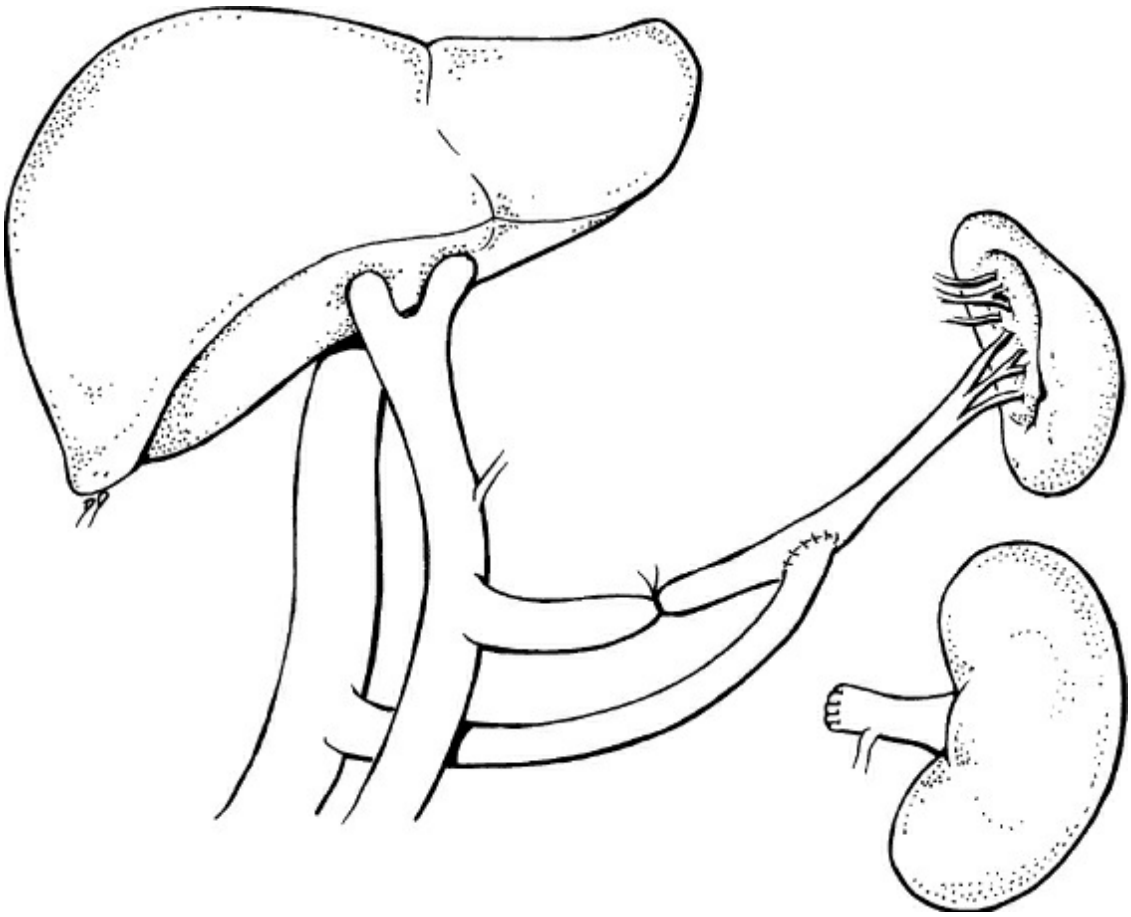

Figure 132.20. Renosplenic shunt. The left renal vein is divided near the hilum of the kidney. The central end of the divided vein is anastomosed end-to-side to the splenic vein. The splenic vein is ligated between the shunt and the portal vein.

What is the Incidence of Encephalopathy After the Selective Shunt?

Early encephalopathy after DSRS occurs in 5% of the patients. This percentage compares favorably with the reported incidence of 30% to 40% after total shunts. Assessment of the available data suggests that encephalopathy seen in the patients with total shunts is more likely to be severe and incapacitating.

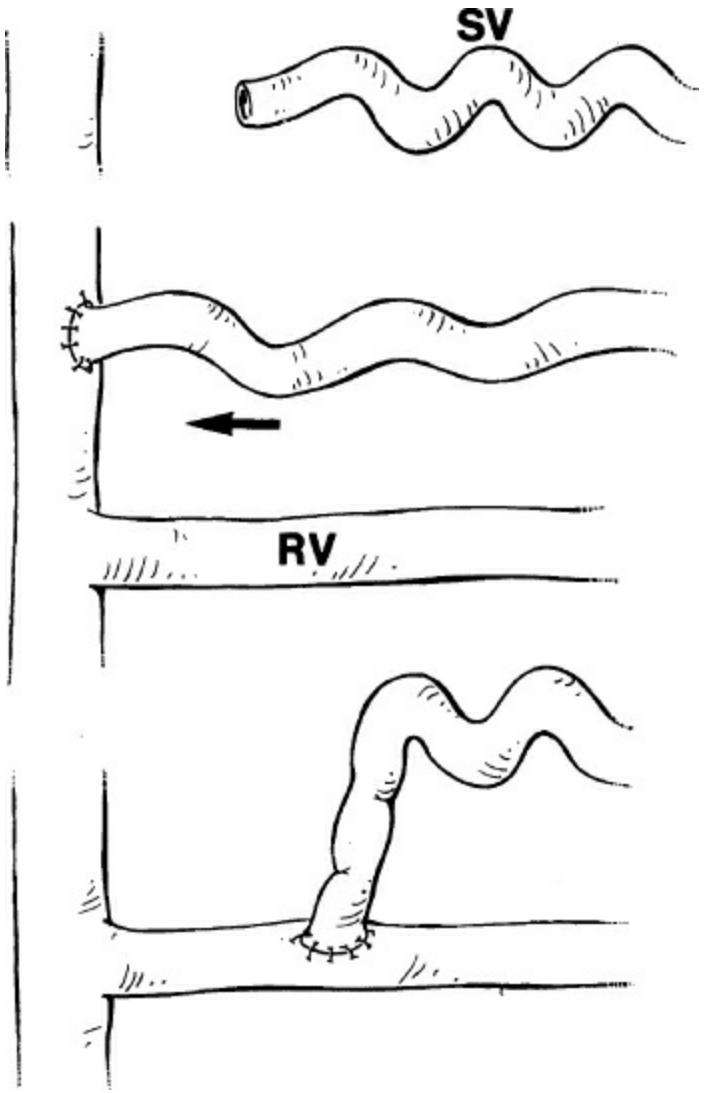

Figure 132.21. A splenocaval shunt is desirable in patients with tortuous splenic vein (SV) because a standard distal splenorenal shunt may be difficult to construct without the risk of kinking the splenic vein. RV, renal vein.

Long-term studies of patients with selective shunts have shown that the incidence of encephalopathy increases from 5% to a range of 10% to 15% in 3 to 5 years. Deterioration of liver function from worsening of underlying liver disease, together with progressive reduction in the level of liver portal venous perfusion, accounts for delayed-onset encephalopathy in these patients.

How Durable is Selectivity of the Selective Shunt?

Early postshunt angiography has shown continuing portal perfusion in most cases. Late follow-up studies, however, have shown progressive formation of collaterals, reduction of portal vein diameter, and decreasing

prograde portal flow after DSRS. Three main routes for mesoportal to splenic venous collaterals have been described: (a) the transpancreatic (pancreatic syphon) pathway, (b) the transgastric pathway, and (c) the colosplenic pathway. It has been proposed that to minimize transpancreatic collateralization, the operation be modified so that the splenic vein is disconnected from the pancreas as far as the hilum of the spleen. Splenopancreatic disconnection, however, adds to the technical difficulty of the operation, and there is some evidence that it may compromise the decompressive effect of the procedure.

Is There a Difference in Survival after Selective as Opposed to Total Shunt Operation?

Studies have shown a trend in favor of the selective shunt in patients who have adequate liver reserve (Child Classes A and B). This trend, however, did not reach statistical significance. Survival advantage of one type of shunt as compared to another is difficult to demonstrate in alcoholic patients. As the majority of these patients continue to drink postoperatively, death from hepatic failure remains high irrespective of the type of shunt operation. Conversely, patients with schistosomiasis tend to live longer because of the relative stability of their underlying liver disease. It is of interest to note that reports from Egypt and Brazil have shown that DSRS does improve survival of these patients.

Operative Technique for CSRS

In CSRS procedure (Fig. 132.22), the spleen is removed and the central end of the splenic vein is anastomosed to the side of the left renal vein. The CSRS diverts all the portal blood away from the liver; hence, it has no physiologic advantage over the portacaval shunt. Furthermore, it may be technically more difficult because of the problems associated with removing the spleen in patients with portal hypertension. In addition, the patency rate of the CSRS may not be as good as the portacaval shunt. Hypercoagulability after splenectomy and a slower flow rate across the shunt may adversely affect shunt patency.

CSRS procedures are performed from an extended subcostal incision. The first step in the operation is to remove the spleen according to standard operative techniques. Because of the hypervascularity of the field, it is advisable to ligate the splenic artery before attempting to mobilize the spleen.

The splenic vein is divided near the hilum of the spleen. After removal of the spleen, the splenic vein is mobilized by dividing the pancreatic veins. These veins are easier to deal with in CSRS than in DSRS because they become less congested after the spleen has been removed. The central end of the mobilized splenic vein is then anastomosed to the side of the left renal vein. The technical aspects of CSRS are similar to those described for DSRS.

POSTOPERATIVE MANAGEMENT

The outline for postoperative care after DSRS also applies to CSRS. Ascites is less of a problem after CSRS. Rebleeding is usually secondary to shunt occlusion. This complication can generally be successfully treated with sclerotherapy because the varices are partially decompressed after removal of the spleen. In contrast, rebleeding associated with DSRS usually requires reoperation. Finally, encephalopathy occurs in 30% to 40% of the patients after CSRS, although the incidence may be falsely reduced if the patients with silent shunt occlusion are not excluded.

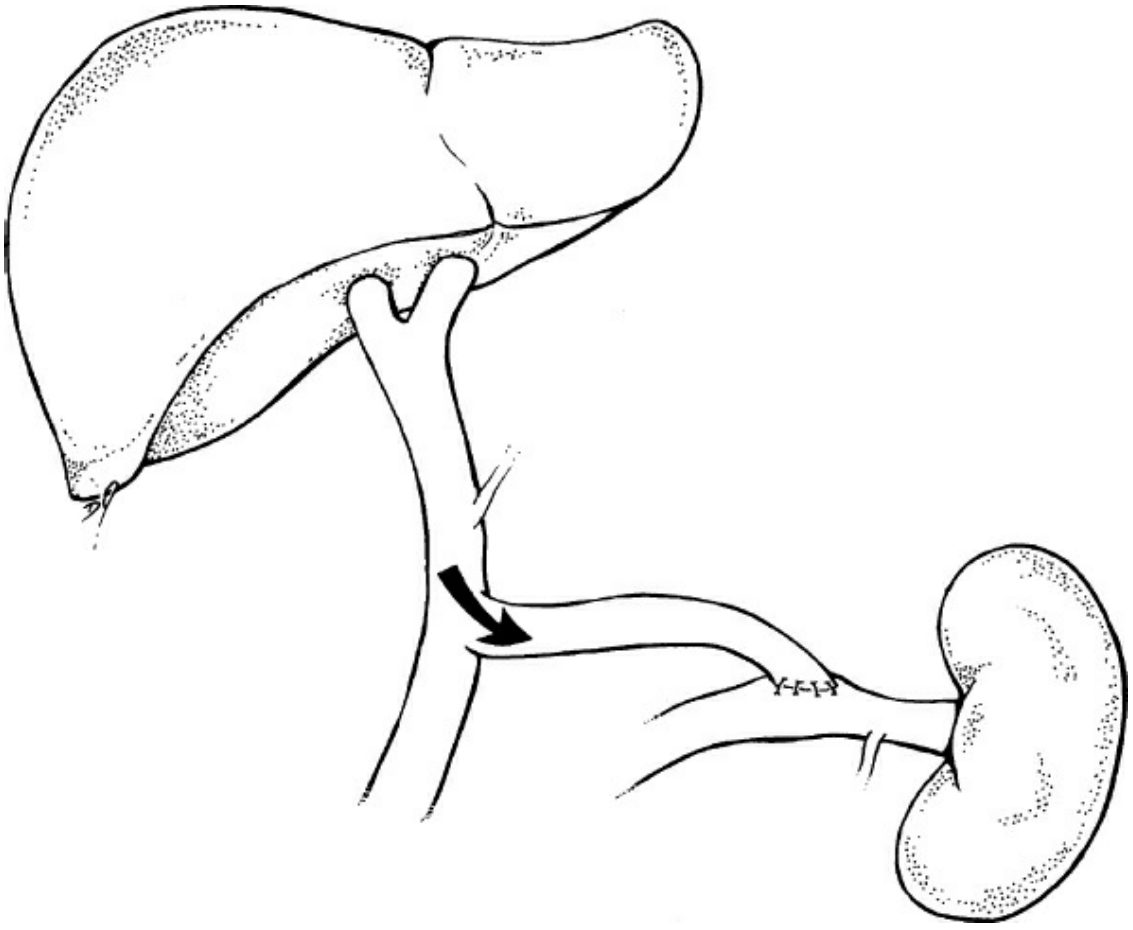

Figure 132.22. A diagrammatic illustration of the central

splenorenal shunt. The *arrow* indicates total diversion of portal blood away from the liver across the shunt to the left renal vein.

133 Central Splenorenal Shunts

Josef E. Fischer

This Chapter can be accessed in the accompanying eBook edition (see inside front cover for access instructions).

INTRODUCTION

The nature of therapy for bleeding varices and cirrhosis has changed dramatically since the introduction and popularization of hepatic transplantation. However, it remains largely believed that unless the patient has demonstrated abstinence from alcohol for a period, it is inappropriate to consider hepatic transplantation. Therefore, arrest of variceal bleeding and the use of shunting procedures remain appropriate, if there is any question as to abstinence.

In considering shunting procedures, it is best that such procedures do not involve the porta hepatis so that future transplantation is not compromised. Thus, the central and distal splenorenal shunts have gained increasing acceptance by those who previously carried out portacaval shunts because they do not interfere technically with the opportunity to do an expeditious liver transplant at some future time. One should not lose sight of the fact that, in a patient with bleeding esophageal varices who shows no signs of stopping despite aggressive therapy, one should move early either to some form of emergency portacaval shunt or to transjugular intrahepatic portosystemic shunt (TIPS), if varices cannot be eradicated by sclerotherapy, to stop the bleeding before the patient becomes coagulopathic and unsalvageable. Although this would make future liver transplantation difficult, it does not render it impossible.

Central and distal splenorenal shunts are generally not emergency procedures, as the decrease in portal pressure is not usually sufficient to arrest bleeding acutely. One should rely on pitressin, or its analogues, somatostatin, iced saline lavage, Sengstaken-Blakemore tubes, and sclerotherapy to provide immediate cessation of bleeding. The patient should be prepared for operation carefully at an interval, in the hospital, if

possible, or at home, with abstinence from alcohol, good nutrition, vitamins, and modest exercise. If the patient is protein intolerant, a high branched-chain amino acid diet should be used to minimize encephalopathy, in addition to lactulose or neomycin, or both. The patient should be admitted to the hospital the evening before operation, and a central venous pressure or Swan-Ganz catheter placed if there is doubt about the cardiovascular status. The prevalence of left-right dissociation makes a Swan-Ganz catheter particularly useful to indicate volume status. Antibacterial washes to the abdomen and chest should have been carried out several days before to minimize the skin bacterial count and vitamin K administered to get a maximum prothrombin time. Because the Child's class is directly related to mortality (Table 133.1), one should seek to obtain maximum improvement in nutrition, albumin, and overall nutritional and functional status before undertaking operation. I used a standard Nichols-type bowel preparation, in the past, with erythromycin and neomycin, in case the colon is entered inadvertently during the procedure, and it is also probably useful in preventing encephalopathy. I do use a mechanical preparation. The patient should be hydrated overnight; 10% glucose or a branched-chain-enriched amino acid parenteral nutrition solution may be used. Perioperative antibiotics are given as a single dose, usually of a first-generation cephalosporin, at the induction of anesthesia, and repeated every 3.5 hours of the operative procedure.

TABLE 133.1 Child's Classification of Liver Cirrhosis

	Class		
Finding	A	B	C
Ascites	None	Controlled	Uncontrolled
Bilirubin	<2.0	2.0–2.5	>3.0
Encephalopathy	None	Minimal	Advanced
Nutritional status	Excellent	Good	Poor

CENTRAL SPLENORENAL SHUNT

The central splenorenal shunt (Fig. 133.1) is carried out through a tenth rib thoracoabdominal incision, as popularized by Linton. The patient should be carefully positioned in the right lateral decubitus position, with the left

side turned up at 45 degrees (Fig. 133.2). The entire abdomen and chest are prepared. The incision is carried out from the area of the umbilicus through the tenth rib proximally to the posterior axillary line. The tenth rib is removed (Fig. 133.3). I find it easier to enter the abdomen through the peritoneum anterior to the tenth rib and then work posteriorly to resect the rib. If the break in the table is properly placed under the opposite tenth rib, the operator is positioned right over the splenic vein and where the renal vein is ultimately located centrally in the operative field (Fig. 133.4).

The key to the operative procedure is not to lose control of the splenic vein or the spleen with respect to hemorrhage and blood loss during the splenectomy. I have found it helpful to ligate the splenic artery before attacking the spleen. This generally can be carried out by identifying the splenic artery at a convenient point at the superior border of the pancreas, passing 2-0 silk ties around it, and ligating it (Fig. 133.5). This decreases the blood loss if there is an inadvertent tear in the spleen. The splenic vein may be encircled with a vessel loop.

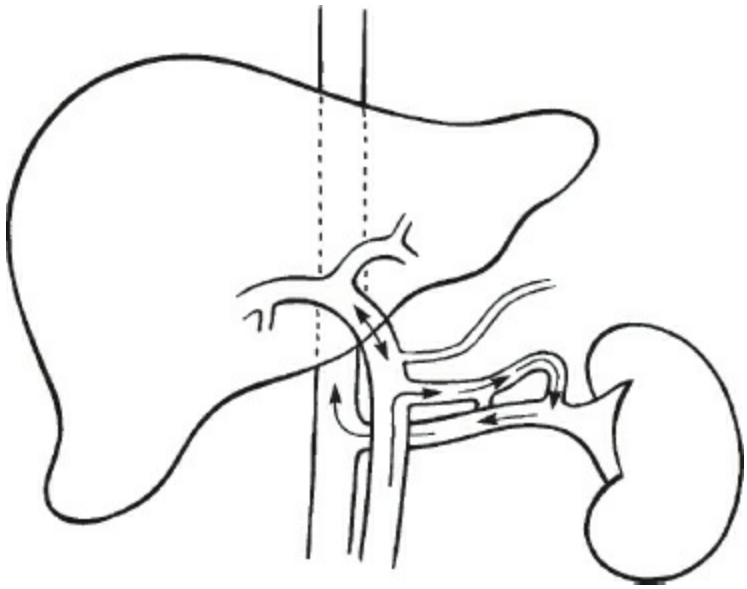

Figure 133.1. The path of flow (*arrows*) after central splenorenal shunt. Intestinal flow and some proximal portal flow tend to be diverted into the shunt. Flow from the short pancreatic branches and the proximal portal vein probably continues to perfuse the liver at a pressure of 10 to 15 mm Hg.

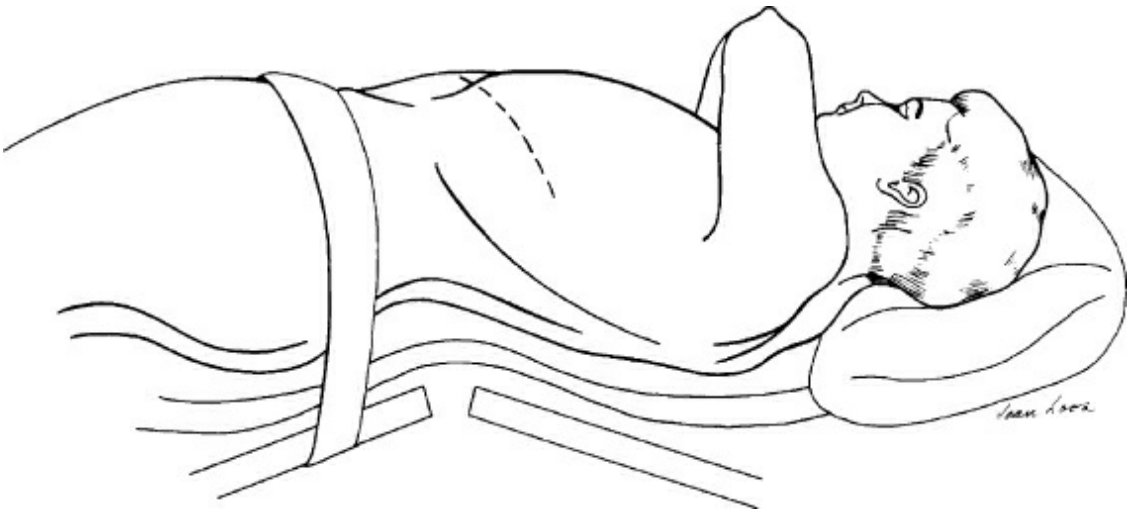

Figure 133.2. Positioning of the patient. The thoracoabdominal incision centered over the 10th rib (*dotted line*) is carried from the midaxillary line toward, but not to, the umbilicus.

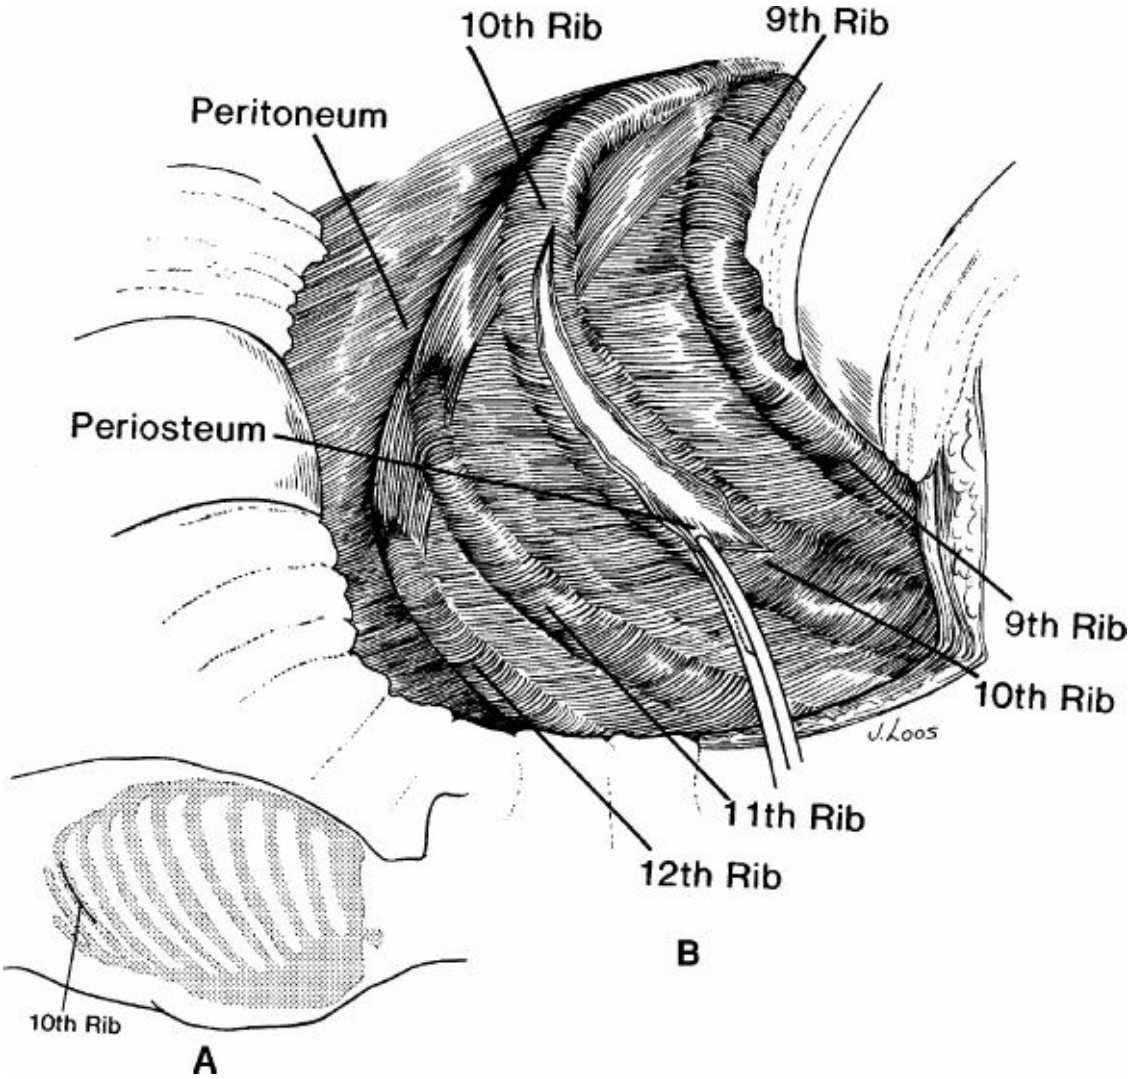

Figure 133.3. **A:** Extent of 10th rib resection. **B:** The 10th rib is resected.

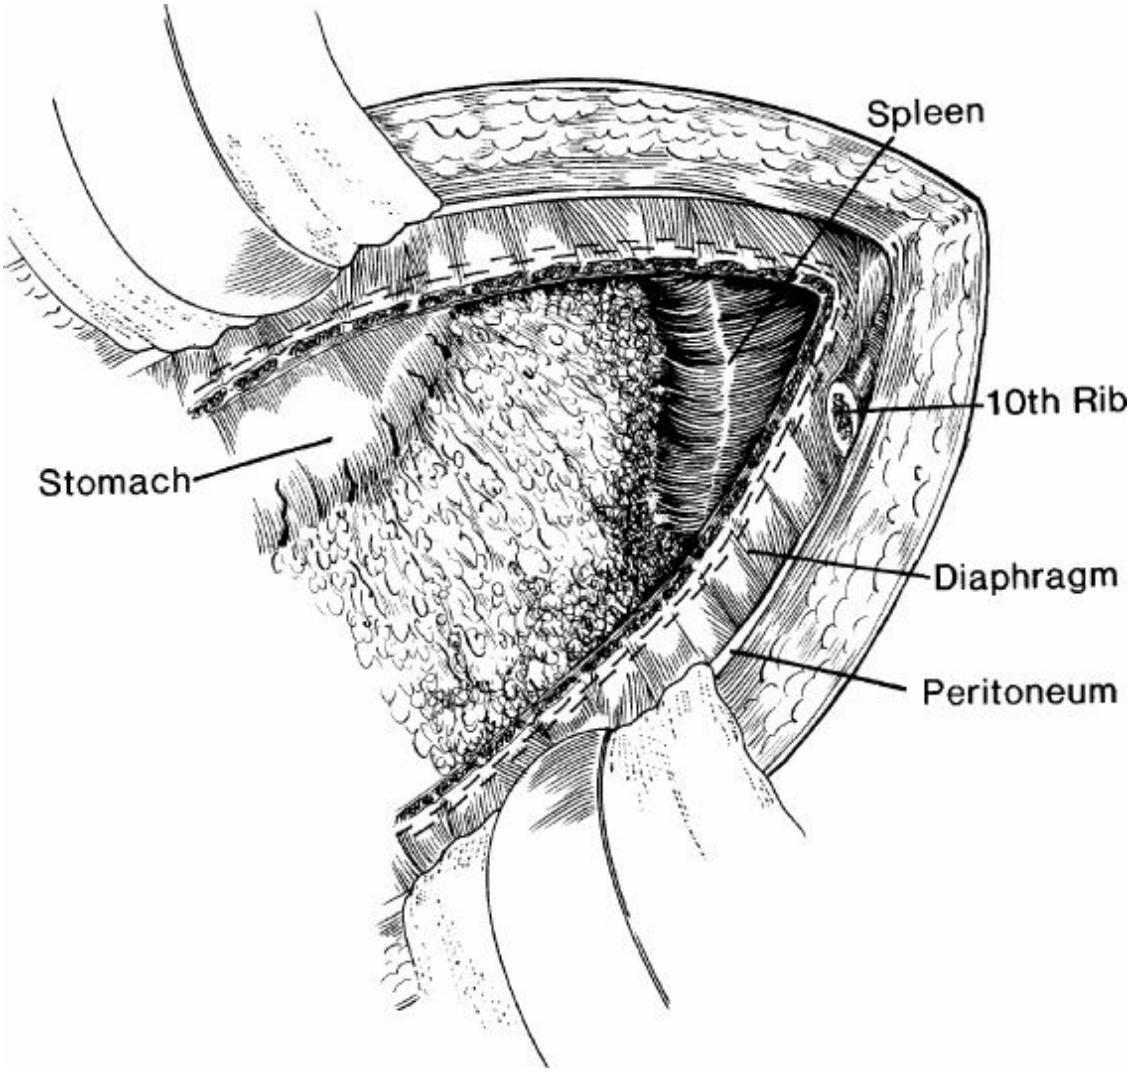

Figure 133.4. View on opening the diaphragm, incising the diaphragm, and oversewing diaphragm cut edges with mattress sutures.

The splenectomy is carried out by taking down the attachments to the colon between Kelly clamps and tying with cotton, if available, or silk if it is not. The retroperitoneum is then entered between Schmitt or Rienhoff clamps and suture-ligated on both sides with 2-0 silk. This is the most tedious part of the procedure, but it is essential if one is to dissect the splenic vein free in controlled fashion. One then proceeds laterally along the entire border of the spleen. It is best to take down the spleen 2 cm lateral to its peritoneal attachment (Fig. 133.6) because one can get a good purchase on the retroperitoneum, and suture ligation is relatively easy; it is also less bloody in that plane. Remember that the basic idea of carrying out a central splenorenal shunt is to get behind the spleen and the pancreas and

bring the pancreas anterior so that the splenic vein, which is a retroperitoneal structure, can be easily identified and managed. Do not try to take out the lateral border of the spleen bluntly; torrential hemorrhage will follow.

The short gastric vessels are then ligated in continuity with 2-0 silk. The highest short gastric vessel may be especially difficult because it is very short and the stomach may be inadvertently entered. The greater curvature should be oversewn with individual 4-0 silk sutures where the short gastric vessels have been ligated to prevent the uncommon complication of perforation of the greater curvature.

After the spleen has been mobilized medially, the hilum is addressed. The splenic vein is then dissected free and its branches are ligated, as are the branches of the splenic artery. If the splenic artery has not been previously ligated, it should be ligated so that postoperative hemorrhage can be avoided. The spleen is then delivered. One must take care not to involve the pancreas in the resection or dissection of the splenic hilum.

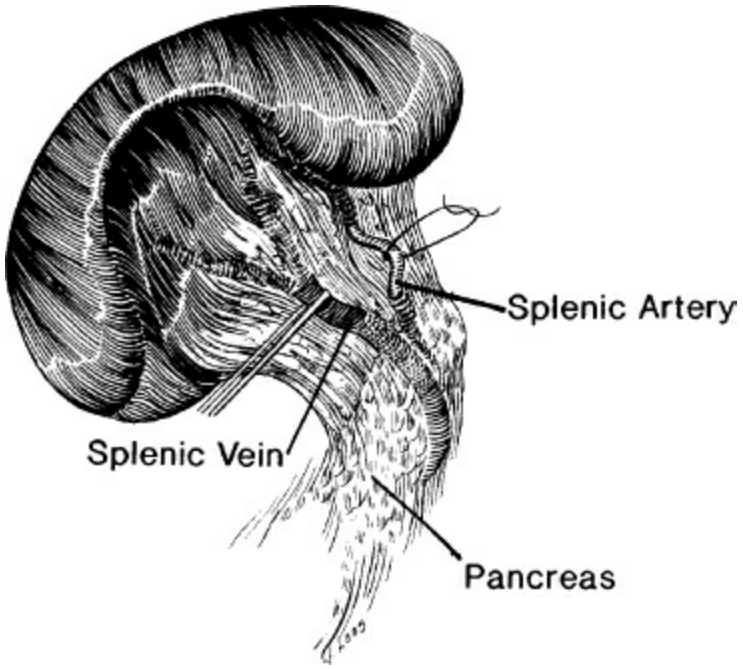

Figure 133.5. Ligating the splenic artery.

After the splenic vein has been isolated and the tail of the pancreas elevated in the wound, the next step is to identify the renal vein (Fig. 133.7). This is to make certain that one does not mobilize too much of the splenic vein, making it redundant. One identifies the renal vein by palpating the upper and lower borders of the kidney and then feeling the

renal artery. Between clamps, and with suture ligation of the divided retroperitoneum, the renal vein is identified. It is necessary to clamp the fatty areolar tissue in this area, not only because of bleeding, but also because of the lymph vessels that abound here and the proximity to the cisterna chyli. The renal vein is identified and vessel loops are then passed around the renal vein. It may be necessary to ligate the adrenal vein later in the procedure to obtain a reasonable spot for the anastomosis.

After the renal vein is identified, an appropriate portion of the splenic vein is dissected out. There are no branches of the splenic vein on the posterior aspect of the splenic vein, and the overlying peritoneum may be sharply divided; the branches of the splenic vein to the pancreas occur laterally at approximately 1-cm intervals. They are fine, but do not be fooled: ripping one of these branches may result in torrential hemorrhage if portal pressure is high, which it usually is. I use the technique of insinuating a right-angle Jacobson clamp, grasping 4-0 silk on either side (Fig. 133.8) and tying it proximal and distal, and then cutting between these silk sutures with a knife. Others may use different techniques, but the purpose is to elevate a portion of the splenic vein from the pancreatic bed.

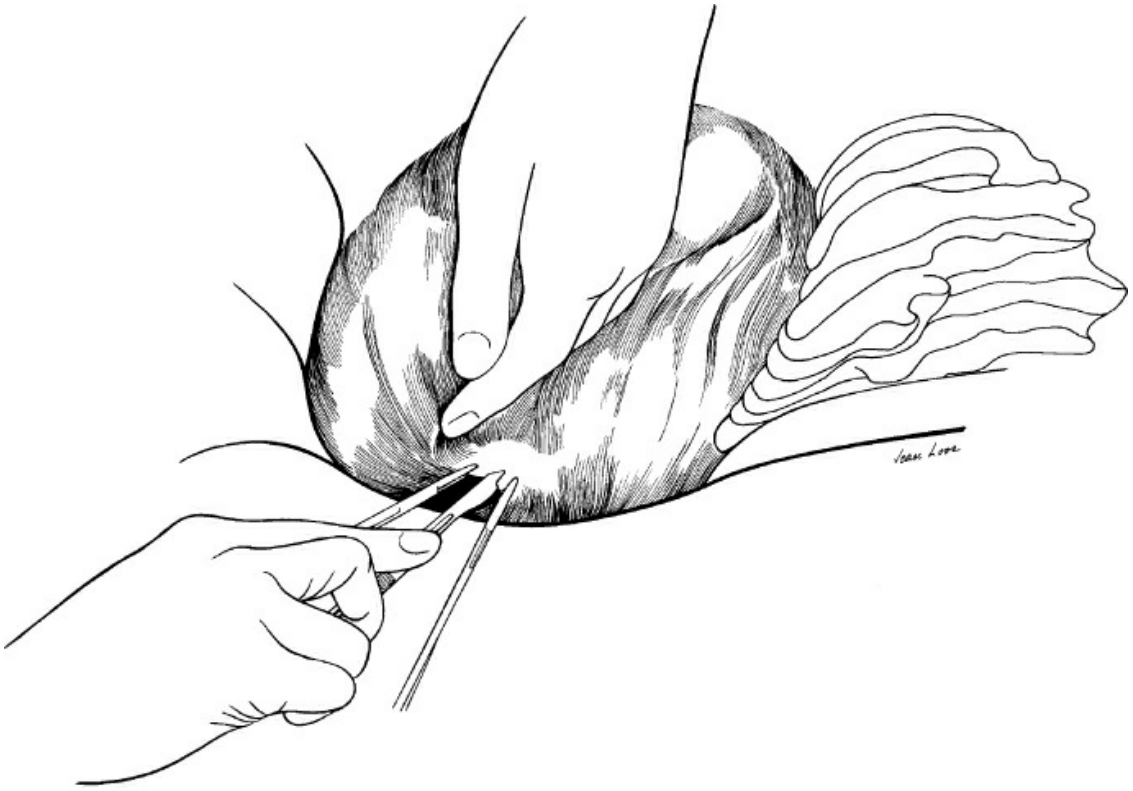

Figure 133.6. The critical maneuver of removing the spleen. Clamps are placed ~2 cm lateral to the splenic edge in the areolar tissue of the retroperitoneum, which contains large

collaterals. These are subsequently suture-ligated with nonabsorbable sutures of 2-0 silk.

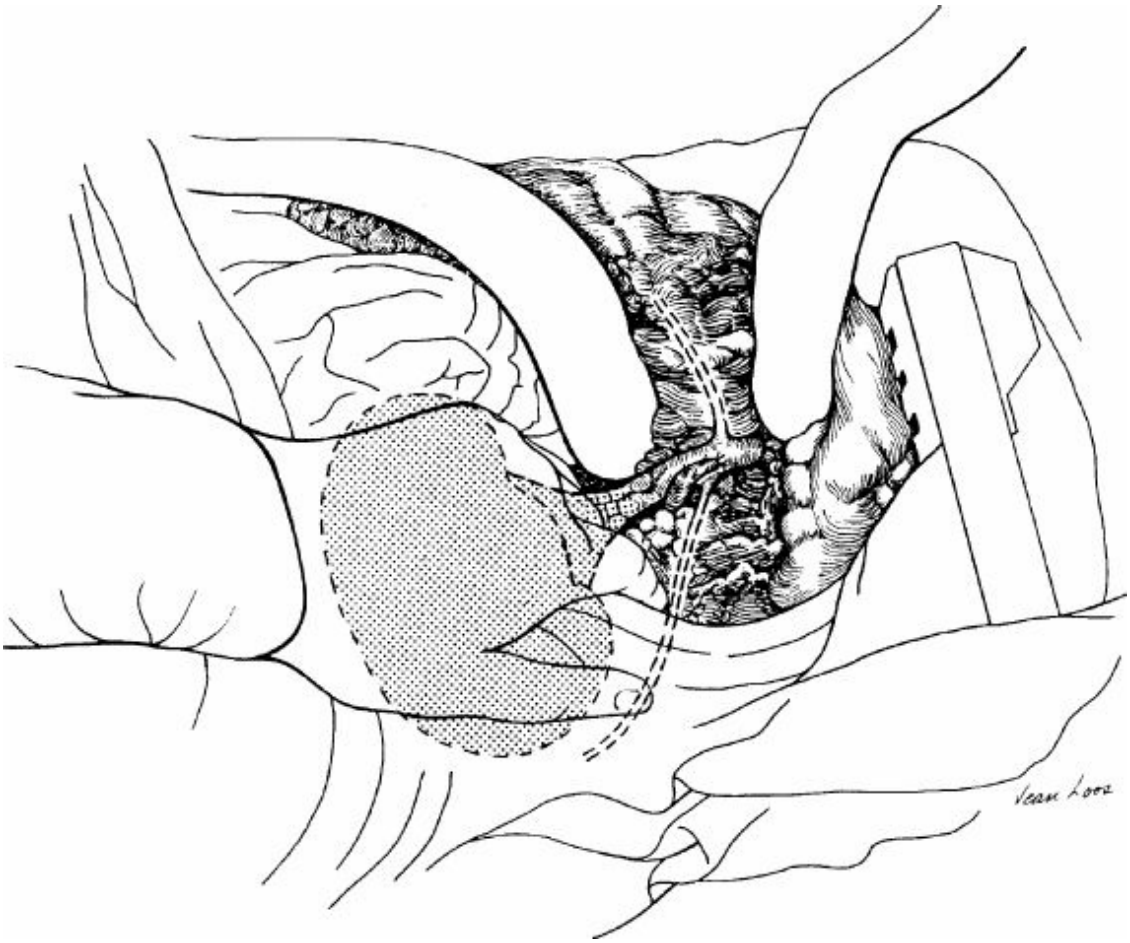

Figure 133.7. Identifying the renal vein.

Once an appropriate portion of splenic vein is elevated, one must then judge what will happen to the anastomosis when the pancreas is replaced back in its natural position. Vascular clamps are then applied to the splenic vein, and a miniature Satinsky clamp is applied to the renal vein. A small ellipse of renal vein is then excised (Fig. 133.9A). The back wall of the splenic vein is then anastomosed in running everting mattress fashion to the renal vein, as illustrated in Figure 133.9B,C. The front wall is then sutured with interrupted horizontal mattress sutures of 5-0 Prolene (Fig. 133.10A). The renal vein clamp is released just before completion of the anastomosis to vent the anastomosis and get rid of clots (Fig. 133.10A,B). The splenic vein clamp is then released. Any leaks are sutured with doubly armed 6-0 Prolene. Dr. Linton frequently liked to resect the tail of the pancreas so that the splenic vein would lie better, whereas I have not found it necessary to do this and it is meddlesome.

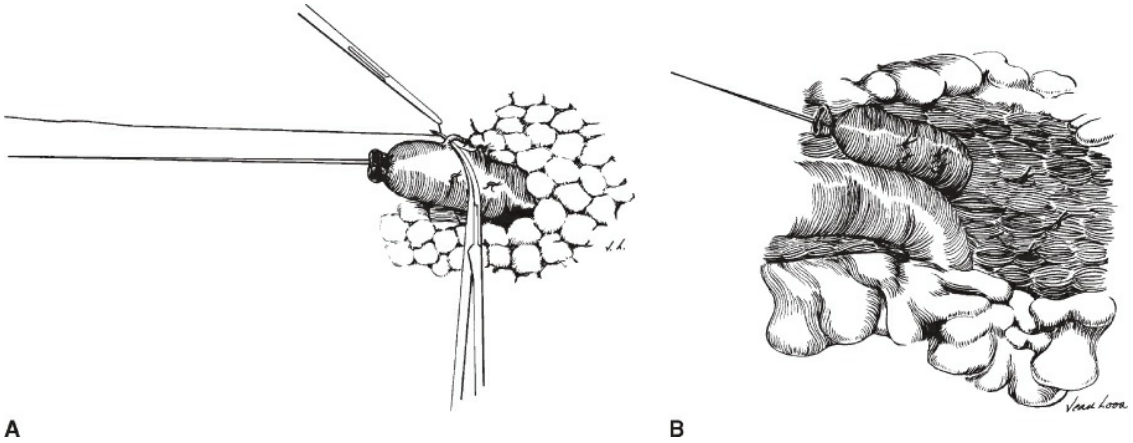

Figure 133.8. **A:** Dissecting the splenic vein. There are short branches, which are paired ~1 cm apart. These must be taken carefully. **B:** A length of splenic vein is now available.

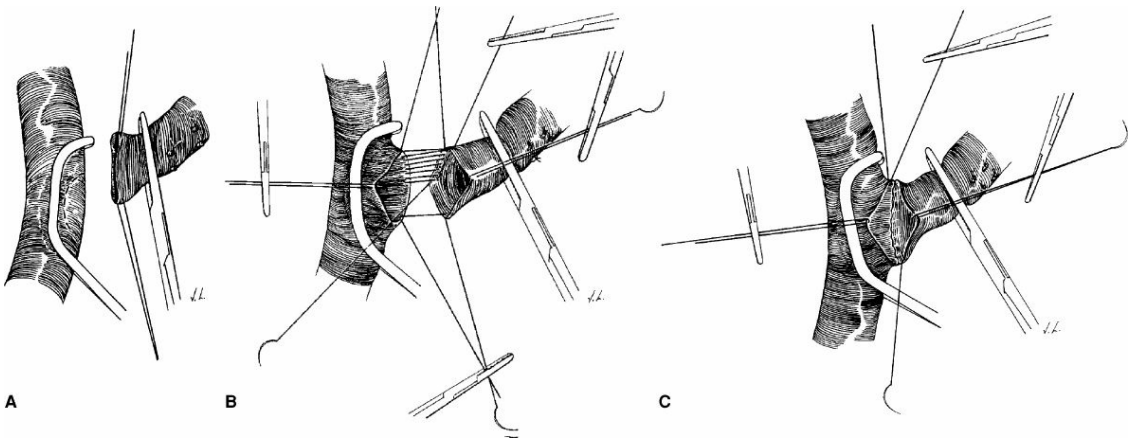

Figure 133.9. **A:** Stay sutures at corners of splenic vein. A specially fashioned Satinsky clamp is placed on the splenic vein and an ellipse is excised. **B:** Stay sutures are placed between the corners of the renal vein incision and the splenic vein. A horizontal everting mattress of 5-0 sutures is then used to bring the two veins together posteriorly. **C:** The horizontal everting mattress is then snugged up posteriorly. Properly performed, there should be little or no suture material showing on the posterior wall.

After irrigation, one should oversew the lateral border of the retroperitoneum where the spleen has been removed with a running suture to secure hemostasis (Fig. 133.11). The abdominal closure is carried out carefully in multiple layers, making certain that if the patient accumulates ascites, there is no ascitic leak. The diaphragm, which has been taken down to provide access to the spleen, is then closed with mattress sutures of 0 silk and a running nonabsorbable suture over the cut edge to secure

hemostasis. It can be expected that ascites will be well controlled. An open shunt can frequently be estimated clinically by measuring serial urinary sodium concentrations. If the concentration is higher than 10 mg/dL, the shunt is almost certainly open.

Postoperatively, sodium-containing fluids are minimized, and the urinary sodium is measured frequently. Abdominal girths are measured to make certain that ascites are not accumulating. The nasogastric tube may be removed on the 2nd or 3rd postoperative day, as gastric ileus usually occurs after this procedure. A chest tube that has been placed in the event of a diaphragmatic leak or bleeding is removed 48 hours postoperatively.

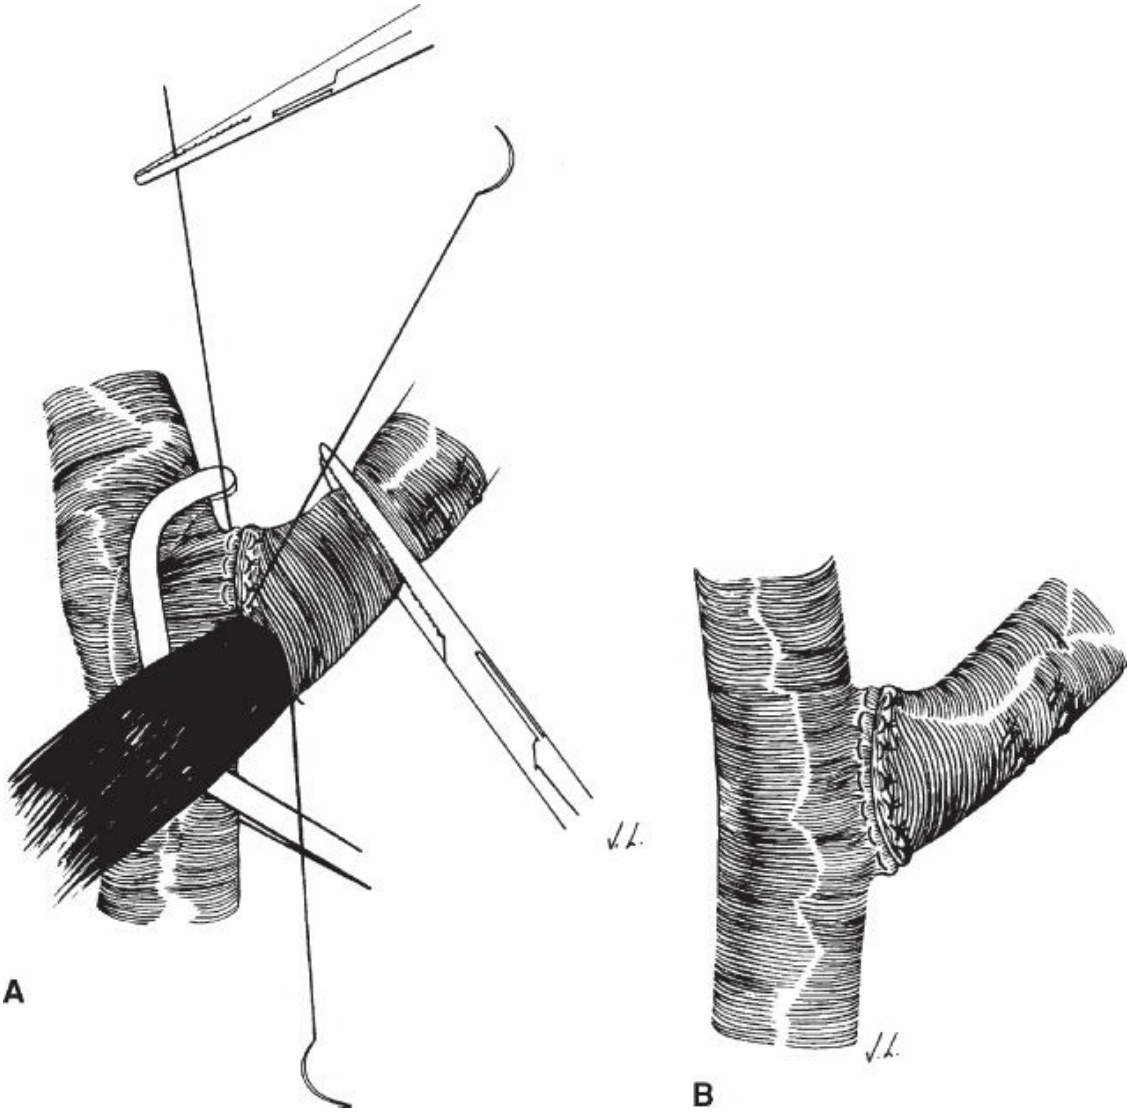

Figure 133.10. A: The anastomosis is partially completed on the anterior wall, with interrupted horizontal mattresses of 5-0 Prolene. The vein is flushed. The remainder of the sutures are then held before being finally tied. **B:** The completed anastomosis. The anastomosis should be between 1.0 and 1.2

cm. The splenic vein is rarely larger than this. A thrill may be felt by placing a finger along the renal vein. It is customary to place a needle through the renal vein and pull back the needle, measuring pressures across the splenic vein. A gradient of >3 or 4 mm suggests that the anastomosis should be redone.

If the patient experiences hepatic failure, it is treated with fluid restriction and total parenteral nutrition with a branched-chain-enriched amino acid solution. Encephalopathy is similarly treated, with the addition of neomycin or lactulose, or both.

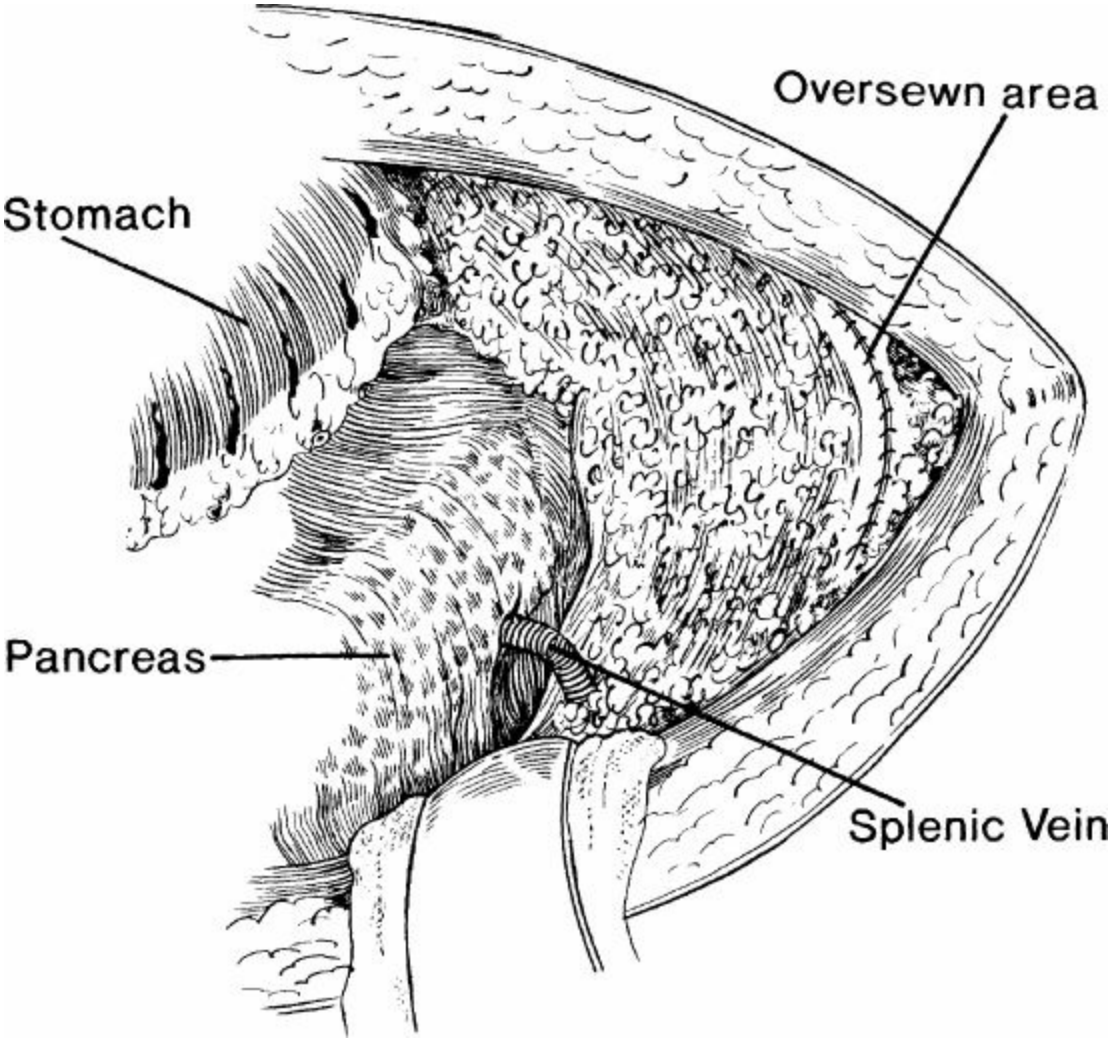

Figure 133.11. Oversewing the cut edge of the splenic bed with a running chromic suture.

The critical aspect of central splenorenal shunt is meticulous hemostasis at the time of operation. Some have used a hypotensive spinal anesthesia, which is perfectly appropriate. However, one must make certain that the

normal blood pressure has been restored before closing. If not, bleeding may supervene postoperatively when normal pressure is restored.

In a time when distal splenorenal shunts have become most popular as a bridge to transplantation, or in relatively good-risk patients who are not thought to require transplantation, the central splenorenal shunt should be performed in patients with tight ascites. The experience of my group and that of others have shown that these patients are not likely to do well after distal splenorenal shunt. Others have argued that the central splenorenal shunt turns into a total shunt before long. This is not true in our experience when we have measured portal flow. The reason is that one must limit the size of the anastomosis to between 1.0 and 1.5 cm. When pressures are measured under these circumstances, the splenic vein pressure should remain between 10 and 15 cm of water so that some flow to the liver persists. The central splenorenal shunt is a side-to-side shunt. However, it should be a small side-to-side shunt, not a total shunt. In this, we disagree with the late Dean Warren and Dr. Salam in Chapter 132, and others who are the devotees of the distal splenorenal shunt, as we have had excellent results with the central splenorenal shunt.

The other group that may benefit from a central splenorenal shunt, as opposed to a distal splenorenal shunt, are patients with hypersplenism. After end-to-side portacaval shunt in McDermott's early series published in the *New England Journal of Medicine* in 1962, there were a number of patients who responded, with amelioration of their hypersplenism, but some did not. Similarly, in our experience, an occasional patient with hypersplenism has not done well from the standpoint of thrombocytopenia. Those patients probably would have done better with a central splenorenal shunt. In addition, patients with schistosomiasis as etiology for their portal hypertension have better outcomes (survival) with splenorenal shunts as opposed to portacaval shunts, and the more normal liver of schistosomiasis does not do well after total diversion.

This remains a good operation that can be performed with low mortality and morbidity, provided it is carefully done. It requires the utmost in surgical technique and gentleness in handling of tissues and, because the splenic vein tends to be a thin vein, one must use maximum care in its anastomosis. However, if one does so, the results are gratifying and many patients continue to do well years after surgery, with a minimum of encephalopathy.

EDITOR'S COMMENT

Variceal bleeding is a problem of significant magnitude in patients with cirrhosis. Treatment alternatives include medical management (beta blocker and/or 5-isosorbide mononitrate therapy), sclerotherapy, endoscopic band ligation, transjugular intrahepatic portosystemic shunt (TIPS), and surgical shunts. There have been many surgical shunts described including portocaval, mesocaval, distal splenorenal, and the distal splenorenal combined with splenopancreatic disconnection. A nonshunting surgical procedure that directly addresses the esophageal varices was described by Sugiura in 1973 (*J Thorac Cardiovasc Surg* 1973:66;677–685). In this chapter of *Mastery*, Dr. Fischer describes the central splenorenal shunt, an operation that many of the younger readers of this text have probably not seen; the advent of the TIPS procedure

has greatly reduced the use of open surgical procedures for the management of portal hypertension. Although many surgeons may not perform this operation, the anatomy of the left upper quadrant, proper surgical exposure, and the management of the spleen and distal pancreas are techniques beautifully described by Dr. Fischer (in this chapter) and relevant to left upper quadrant surgery in general, both laparoscopic and open.

An alternative to the thoracoabdominal incision described in this chapter would be the left-sided "J" incision, otherwise termed the reverse Makuuchi incision (Chang, *Arch Surg* 2010;145:281–284). Makuuchi first described the "J" incision for right upper quadrant surgery involving the liver (Makuuchi, in *Pitfalls and Complications in the Diagnosis and Management of Hepatobiliary and Pancreatic Diseases*. Stuttgart: George Thieme; 1993;86–88) and when combined with a suitable retractor (we prefer the Thompson [Thompson Surgical Instruments, Inc.]), it provides excellent exposure with a relatively modest incision size. For operations involving the left upper quadrant, a similar left-sided "J" incision provides adequate exposure and avoids the need for a thoracic extension.

As described herein, early ligation of the splenic artery is always helpful when performing splenectomy. The splenic artery is often accessible at the superior border of the proximal body of the pancreas where it is both anterior in location and fairly redundant. At this location it can be ligated without injuring venous collaterals that are abundant in the patient with portal hypertension. When separating the splenic vein from the pancreatic parenchyma, a useful devise is the LigaSure vessel sealing system (Valleylab; Boulder, Colorado) that has also been tested in patients with portal hypertension (Yao, *Am J Surg* 2011;202:82–90). While some of the tributaries of the splenic vein are best divided with fine silk ties, the LigaSure can be effectively used for many of the small venous branches. As discussed, medial rotation of the pancreas exposes the splenic vein posteriorly and is the best way to approach this vessel when trying to separate the splenic vein from the pancreas (working along the inferior border of the pancreas is possible but usually takes more time). As also discussed by Dr. Fischer, ligation of the left adrenal vein increases the amount of available left renal vein for the vascular anastomosis and will prevent an iatrogenic tear (in the left renal vein) at the left adrenal vein–splenic vein junction. The LigaSure or a similar vessel-sealing devise can also assist in dividing the tissue anterior to the left renal vein. When beginning the dissection to expose the left renal vein, be aware of the anatomic location of the inferior mesenteric vein to avoid an inadvertent venotomy and unnecessary bleeding.

Successful surgery in the left upper quadrant (for portal hypertension, or benign or malignant disease) requires a three-dimensional understanding of the anatomy, proper exposure, and a detailed plan for the operative procedure. The description of the operative technique for performing a central splenorenal shunt can be used as a template for the creation of many other operative plans—It is detail oriented and each step follows a logical sequence. For the surgeon in

training, this type of approach should be used in the planning of all abdominal procedures.

134 Endoscopic Therapy in the Management of Esophageal Varices

Jake E. J. Krige and Sandie R. Thomson

PORTAL HYPERTENSION

Portal hypertension is a clinical syndrome defined by a portal venous pressure gradient exceeding 5 mm Hg. A portal venous pressure gradient above the critical threshold value of 12 mm Hg causes clinically significant manifestations of portal hypertension in the form of compensatory portosystemic venous collateral formation, increased splanchnic blood flow, and disturbed intrahepatic and pulmonary circulation. These hemodynamic changes give rise to the important complications of portal hypertension, especially when due to chronic liver disease, and include variceal bleeding, hepatic encephalopathy, ascites, hepatorenal syndrome, recurrent infection, and coagulopathy. Esophagogastric varices are part of the collateral venous system that diverts high pressure portal blood via the coronary, short gastric, and esophageal perforator veins *en route* to the azygous system. These varices are the major source of hemorrhage and mortality, although bleeding from congestive gastropathy and anorectal varices and other sites may also occur. Epigastric and abdominal wall collateral vessels may enlarge with recanalization of the umbilical vein, and multiple retroperitoneal collaterals may form, which complicate surgical intervention. Splenomegaly and hypersplenism develop with impeded splenic vein outflow.

Cause

Two mechanisms lead to portal hypertension: (a) increased portal resistance and (b) increased portal flow. Increased resistance to flow is classified as presinusoidal, sinusoidal, and postsinusoidal (Table 134.1). Increased flow is uncommon and is caused by either arteriovenous fistulae

or increased splenic arterial flow. The geographic prevalence and causes of portal hypertension vary widely; while cirrhosis is the most common cause in the Western world, schistosomiasis is the leading cause in many other countries.

Natural History

Variceal bleeding is the final step in a sequence of events initiated by an increase in portal pressure, and followed by the development of varices with a progressive increase in size. A key factor in variceal bleeding is an increase in the hydrostatic pressure inside the varix, with a resultant increase in variceal size and a decrease in wall thickness. Variceal rupture and bleeding occur when transmural variceal pressure and the increased tension in the thin wall exceed a critical value determined by the elastic limit of the vessel wall.

Variceal bleeding is the most serious complication of portal hypertension and substantially alters the natural history of patients with compensated cirrhosis. One third of deaths from cirrhosis are related to portal hypertension, and are due mainly to esophageal variceal bleeding. Up to 20% of initial variceal bleeding episodes are fatal, and as many as 70% of survivors, if inadequately treated, have recurrent variceal bleeding. In Western countries, variceal bleeding accounts for approximately 10% of all causes of upper gastrointestinal bleeding, although this varies geographically depending on the regional prevalence of alcoholic liver disease and viral hepatitis.

TABLE 134.1 Causes of Portal Hypertension

      Congestive heart failure
      Constrictive pericarditis
2. **Increased portal blood flow**
   Increased splenic blood flow
   Arterial-portal venous fistula

Treatment Principles

The ideal treatment of portal hypertension and bleeding varices should be universally effective, safe, easy to administer, and inexpensive. Currently no such treatment exists and the clinician is obliged to select the most appropriate intervention from a menu of available therapeutic options, none of which is ideal or applicable to all patients. The rational treatment of esophageal varices depends on a clear understanding of the risks of rebleeding and the response to each specific intervention. The optimal management of bleeding esophageal varices requires a full appreciation of portal, gastric, and esophageal venous collateral anatomy; the pathogenesis and hemodynamic consequences of variceal bleeding; and the utility of each available therapy at specific stages in the natural history of portal hypertension. Careful assessment of hepatic functional reserve is necessary before selecting the appropriate treatment. The Child–Pugh and the model for end-stage liver disease (MELD) scores are currently the most useful

and practical predictors of survival in cirrhotic patients (Table 134.2). For example, the operative mortality for Child–Pugh grade A patients is less than 5%, while for Child–Pugh grade C it exceeds 25%.

The treatment of variceal hemorrhage has evolved markedly in the past decade. Although these advances in treatment have reduced overall mortality, uncontrolled or recurrent bleeding from varices and the consequences of progressive liver failure remain the commonest causes of early death in alcoholic cirrhotic patients. The spectrum of interventions required to control variceal bleeding and achieve efficient and successful treatment of the severe and potentially life-threatening complications of portal hypertension are invasive, complex, and may necessitate advanced skills. No single modality is applicable to all patients, and knowledge of the alternatives allows the well-informed clinician to choose the appropriate therapy for each clinical situation. A coordinated multidisciplinary team approach integrating the skills of critical care specialists, endoscopists, hepatologists, interventional radiologists, and hepatobiliary and transplant surgeons is essential as each of various therapies may be required at different stages in different patients.

TABLE 134.2 The Child–Pugh Classification of Functional Liver Status

	Number of Points		
	1	2	3
Bilirubin (μmol/L)	<34	34–51	>51
Albumin (g/L)	>35	28–35	<28
INR	<1.3	1.3–1.5	>1.5
Ascites	None	Mild–moderate	Severe
Encephalopathy	0	I/II	III/IV

Grade A: 5–6 points.
Grade B: 7–9 points.
Grade C: 10–15 points.
INR, international normalized ratio.

Endoscopic treatment has become the principal first-line intervention in patients with bleeding esophageal varices, both during the acute event and for long-term therapy to prevent recurrent bleeding. After control of the index bleed, there is a 70% chance of rebleeding. The risk of rebleeding is greatest during the first few days after initial variceal hemorrhage. Survival after variceal bleeding depends largely on the rapidity and efficacy of initial primary hemostasis and the presence and severity of

underlying liver disease and hepatic functional reserve. Early rebleeding has been shown to be a strong predictor of overall mortality, and recurrent variceal bleeding substantially increases the risk of complications, which further contribute to mortality, emphasizing the need for rapid and sustained control of variceal bleeding as the principal imperative of endoscopic intervention.

MANAGEMENT OF ACUTE VARICEAL BLEEDING

Choice of Therapy

The possibility of variceal bleeding should be considered in all patients who present with upper gastrointestinal bleeding and have known risk factors for chronic liver disease or clinical evidence of portal hypertension. The modern management of acute variceal bleeding requires a variety of therapeutic options to be available for use either sequentially or in combination in individual patients (Table 134.3). Several important clinical considerations influence the choice of therapy, as well as the prognosis in individual patients. These include the natural history of the disease causing the portal hypertension, the location of the bleeding varices, residual hepatic function, the presence of associated systemic disease, continuing drug or alcohol abuse, the patency of major splanchnic veins, and the response to each specific treatment.

General Strategy

Variceal bleeding is a medical emergency, and all patients with suspected acute variceal bleeding require urgent hospitalization and resuscitation as for any major hemorrhage. The immediate aims of emergency treatment are hemodynamic stabilization, blood-volume replacement, control of bleeding, support of vital organ function, and prevention of complications due to hypovolemic shock and impending liver failure. Patients should be managed in an intensive or high-care unit with a full multidisciplinary staff complement available. Although variceal bleeding may stop spontaneously in up to 60% of patients, it is not possible to predict which patients will continue to bleed and require further specific emergency therapy. If an experienced medical team is not available at a peripheral hospital, patients should be transferred to a center with appropriate facilities, resources, and expertise as soon as they have been adequately resuscitated and are stable because subsequent management may be complex should bleeding

continue or recur and may later require advanced multidisciplinary investigations and therapy. A suggested management algorithm is given in Figure 134.1.

TABLE 134.3 Management of Acute Variceal Bleeding

Treatment Options
1. Pharmacologic agents
a. Somatostatin
b. Glypressin
c. Octreotide
2. Endoscopic therapy
a. Band ligation
b. Injection sclerotherapy
i. Sclerosants
ii. Cyanoacrylate ("superglue")
3. Balloon tamponade
4. TIPS
5. Surgery
a. Shunt procedures
b. Esophageal transection

TIPS, transjugular intrahepatic portosystemic shunt.

Initial Measures

Many patients with acute variceal hemorrhage also have liver decompensation with encephalopathy, ascites, coagulopathy, bacteremia, or malnutrition. The extent and urgency of initial therapy depend primarily on the severity of bleeding. Stable patients with intermittent bleeding are candidates for endoscopic therapy, while the infrequent patient with exsanguinating bleeding may require balloon tamponade to control bleeding before endoscopy is performed. In the acute situation, the essential history and examination are obtained and basic investigations including full blood count, coagulation profile, liver and renal function, blood group, and cross-match are requested. Ascitic fluid, blood, and urine should be obtained for culture.

Maintenance of a secure airway and prompt resuscitation with

restoration of circulating blood volume are vital and precede any diagnostic studies. Intravenous access is obtained via a wide bore central venous cannula. While blood is being cross-matched, crystalloid solution is rapidly infused until the blood pressure is restored and the urine output (as measured with a Foley catheter) is adequate. Infusions of normal saline may aggravate ascites and must be avoided. Overzealous expansion of circulating blood volume should be avoided as this may cause an increase in portal pressure and precipitate further variceal bleeding. The goal is to maintain the hematocrit between 25% and 30%, and the central venous pressure should be no greater than 2 to 5 cm H_2O, measured from the sternal angle. Hemodynamic status is monitored with continuous blood pressure, pulse, and oxygen recording. Patients who are hemodynamically unstable, or elderly or those who have cardiac or pulmonary disease should be monitored using a pulmonary artery catheter because injudicious administration of crystalloids, combined with vasoactive drugs, may lead to rapid onset of edema, ascites, and hyponatremia. Clotting factors are often deficient and fresh blood, fresh frozen plasma, and Vitamin K_1 are frequently required. Platelet transfusions may be necessary. Sedatives should be avoided if possible. Prophylactic antibiotics have been shown to improve survival and are mandatory.

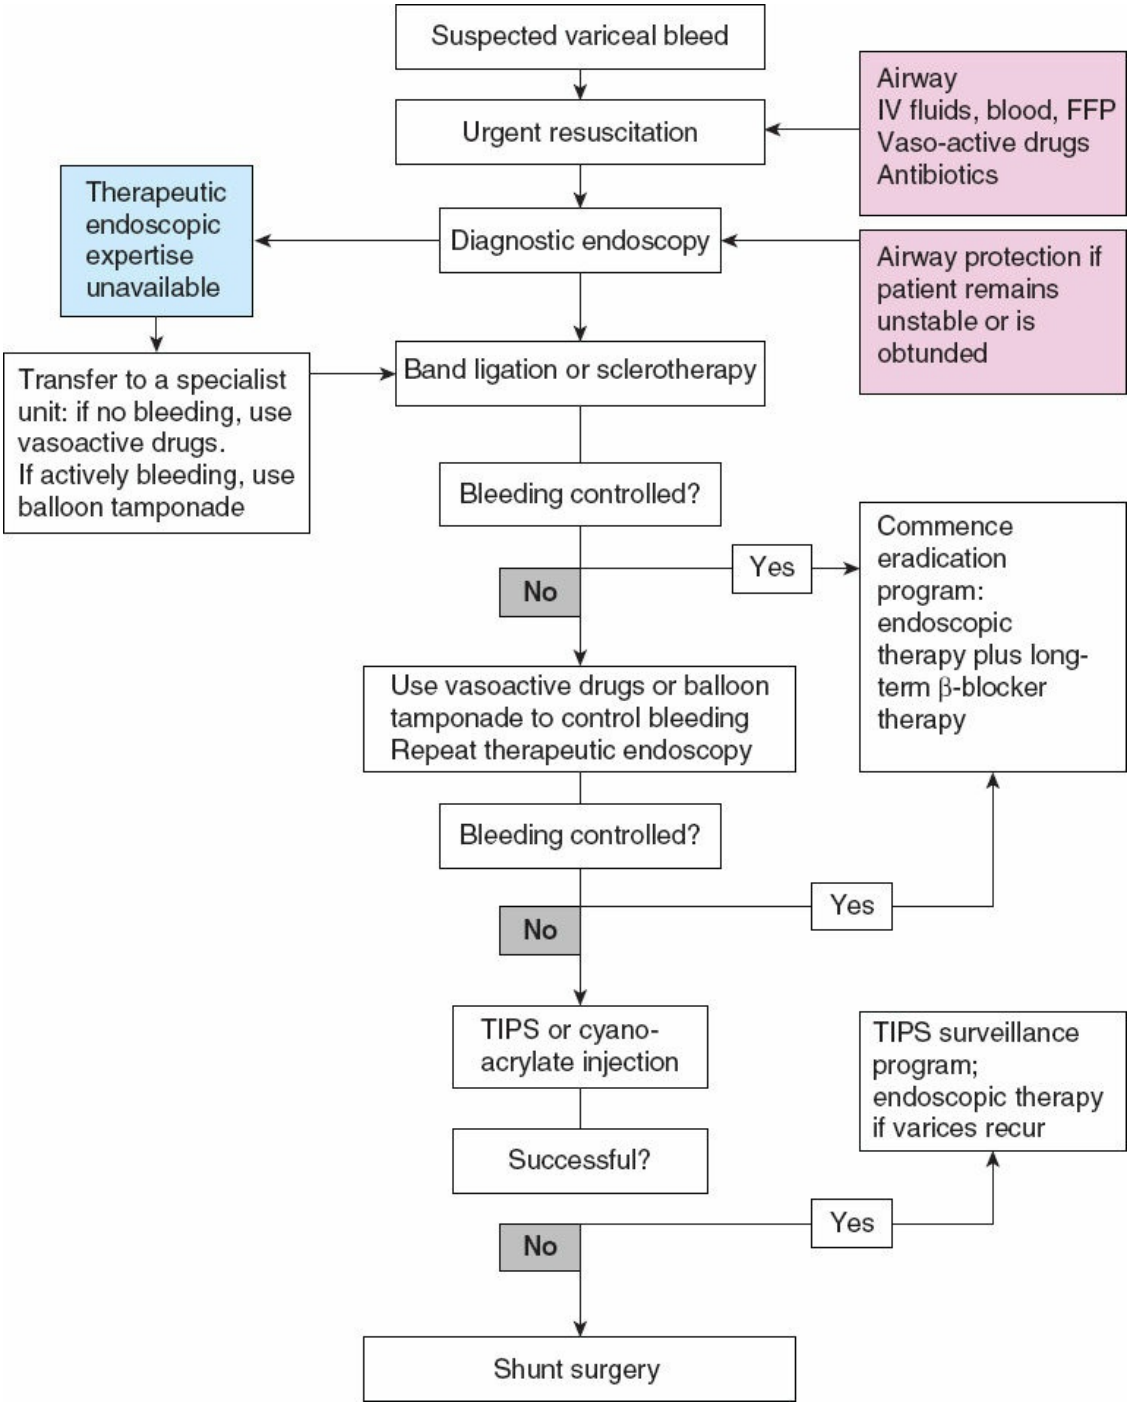

Figure 134.1. Algorithm for the management of acute variceal bleeding.

PHARMACOLOGIC THERAPY

The role of vaso-active drugs is to reduce variceal pressure by decreasing variceal blood flow. The selection of a specific drug depends on local resources. The most widely used drugs are terlipressin, somatostatin, and octreotide. Terlipressin (glypressin), the synthetic analog of vasopressin, has the advantage of being effective in 2 mg intravenous bolus doses

administered 4 to 6 hourly and is simpler to administer. Early administration of glypressin in a French study showed improved survival. Somatostatin reduces splanchnic and hepatic blood flow and is administered empirically as an initial bolus dose of 250 μg, followed by a continuous intravenous infusion of 250 μg per hour. This is maintained until the patient has been free from bleeding for 24 hours. Therapy may be maintained for up to 5 days to prevent early rebleeding. Major side effects with somatostatin are uncommon, although minor side effects such as nausea and hyperglycemia occur in one third of patients. Octreotide is a somatostatin analog with a longer half-life. This is given as an initial bolus of 50 μg followed by an infusion of 50 μg per hour that can also be maintained for up to 5 days. The safety profile of octreotide is similar to somatostatin.

Most endoscopy units recommend that pharmacologic therapy be commenced when a diagnosis of variceal bleeding is suspected and before emergency endoscopy is performed. This policy has the theoretical advantage of controlling bleeding before the initial endoscopy and facilitating both diagnosis and immediate endoscopic therapy.

Emergency Endoscopy and Immediate Endoscopic Therapy

Emergency diagnostic endoscopy is essential to confirm that a patient is bleeding from esophageal varices. Patients with varices can usually be divided into three groups: those with active variceal bleeding, those with variceal bleeding that has stopped, and those who have varices but are bleeding from another site such as a peptic ulcer, hemorrhagic gastritis, or portal hypertensive gastropathy. These other lesions are treated appropriately.

Emergency endoscopy should be performed in an endoscopy unit with all the necessary equipment available. Many units have a fully equipped mobile emergency endoscopy stack that can be wheeled into the intensive care unit or the operating room. It is imperative that full resuscitation facilities are available, together with skilled staff experienced in dealing with emergencies. Two endoscopy assistants should be present throughout the procedure. Adequate monitoring and effective suction are also essential during endoscopy. Emergency endoscopy should not commence until satisfactory venous access and central venous pressure measurement are established and volume replacement and resuscitation procedures including blood transfusions have been initiated to correct hypovolemia. If

bleeding is profuse or if the patient is stuporous, endotracheal intubation is essential before starting endoscopy to protect the airway and avoid aspiration of blood or gastric contents.

Patients with endoscopically proven active variceal bleeding or those in whom variceal bleeding has stopped should have immediate endoscopic intervention using variceal band ligation (Fig. 134.1). If endotherapy is deferred until the next elective endoscopy list in patients who have stopped bleeding, there is a distinct danger of further major acute variceal bleeding during the interval period, with substantial morbidity and mortality. If acute or recurrent major variceal bleeding continues despite endoscopic and pharmacologic therapy, mechanical control by balloon tamponade or esophageal stenting is required.

FAILED EMERGENCY ENDOSCOPIC THERAPY

Endoscopic therapy is successful in controlling acute variceal bleeding in over 90% of patients after one or two treatment sessions. Any patient who rebleeds after two successive emergency endoscopy treatments during a single hospital admission has a prohibitively high mortality if further endoscopic therapy is pursued. Such patients should have a balloon tube inserted, be resuscitated, and then be treated by an alternative technique. A transjugular intrahepatic portosystemic shunt (TIPS) procedure is recommended for patients who continue to bleed despite two endoscopic banding or sclerotherapy sessions. In patients being considered for liver transplantation, a TIPS procedure is now the preferred treatment to provide a bridge to transplantation.

BALLOON TUBE TAMPONADE

Acute esophageal variceal bleeding can be temporarily controlled in most patients by a correctly placed balloon tube (Fig. 134.2). The four-lumen Minnesota tube is the most widely used balloon tube; control of bleeding allows time for resuscitation and planning for management. Although the initial bleeding episode is effectively controlled, if no additional measures are used, 60% of patients will rebleed after removal of the tube with a high associated mortality rate; therefore, endotherapy should be performed when the tube is removed.

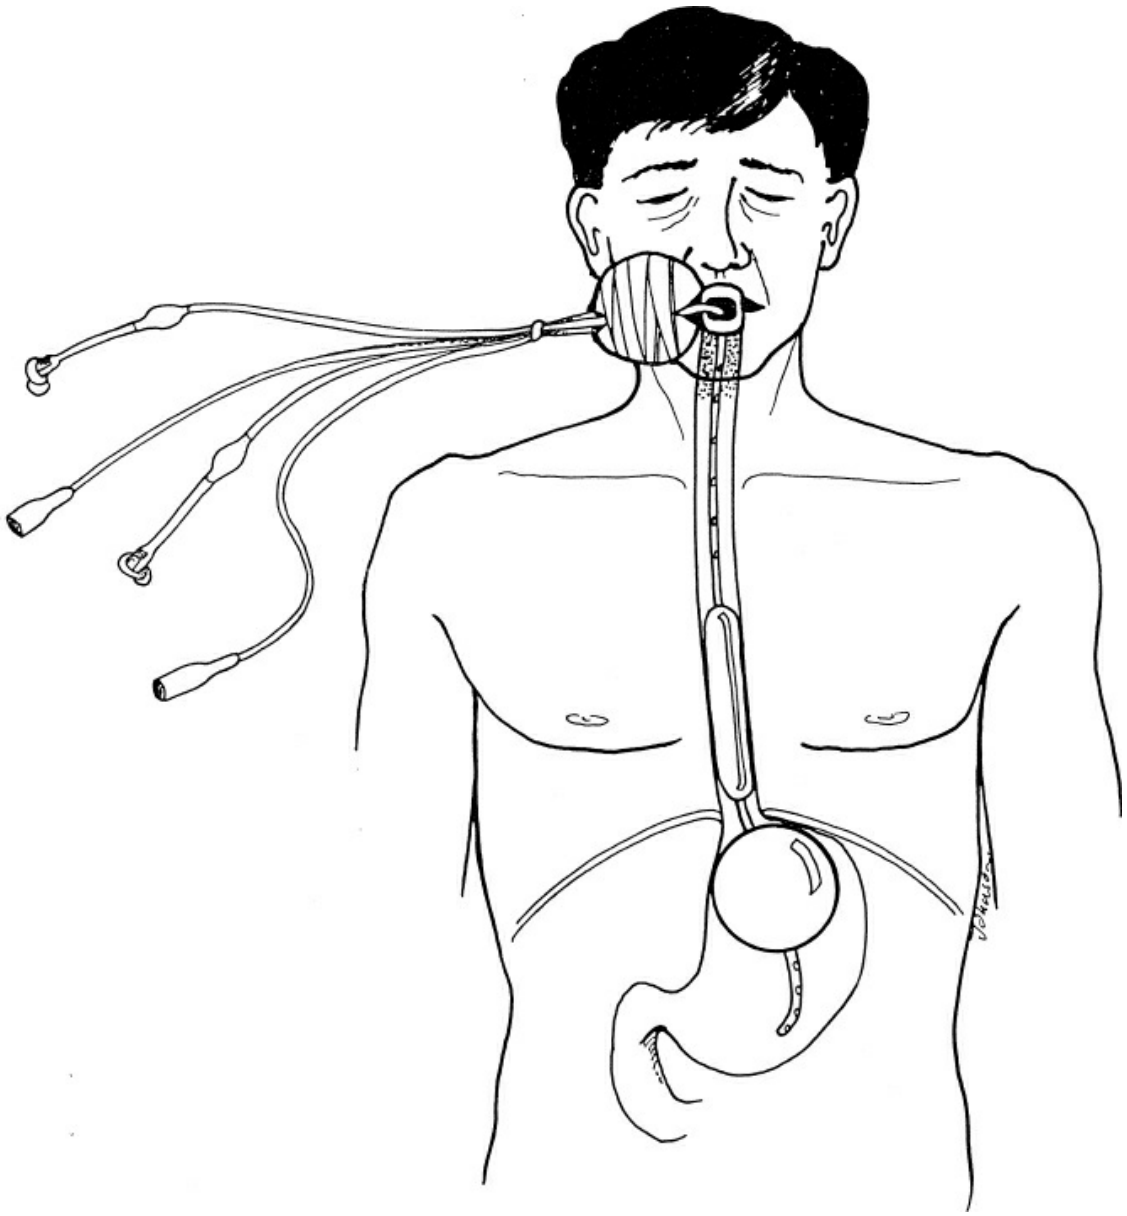

Figure 134.2. Four lumen balloon tube. The gastric balloon that is filled with air is held firmly against the esophagogastric junction by fixing a split tennis ball to the tube outside the patient's mouth.

Before a balloon tube is inserted in a stuporous or comatose patient, the airway should be protected by placing an endotracheal tube to prevent aspiration. A new balloon tube should be used, and the integrity of the balloons should be tested prior to use by inflating them under water to confirm complete air seals. The deflated lubricated balloon tube is passed through a bite-guard via the mouth, after adequate topical pharyngeal anesthesia. Awake patients are instructed to swallow while the tube is being passed. In a stuporous patient, placing the index finger within the mouth assists in guiding the tip of the tube over the posterior tongue and

through the cricopharyngeus, thereby preventing coiling of the tube in the pharynx. At times it may be difficult to negotiate the tube through the cricopharyngeus, particularly in patients who have an endotracheal tube in place. Under these circumstances, a McGill forceps and laryngoscope are used to assist insertion, and the tube is passed under direct vision. The tube is inserted as far as possible until the esophageal balloon is well into the esophagus.

The correct position of the balloon in the stomach is confirmed by injecting air into the aspirating lumen of the gastric tube using a 50-mL syringe and auscultating over the epigastrium, while instilling air. An x-ray of the upper abdomen provides additional confirmation of the correct position of the balloon. Thereafter, the gastric balloon is carefully inflated with 50 mL increments of air until a total of 250 mL has been inserted. The air should be easy to inject; if the tube is kinked or curled in the esophagus, resistance to injection is felt and inflation must be stopped and the balloon deflated. An incorrectly positioned and inflated gastric balloon within the esophagus may perforate the esophagus. The tube is then pulled back until the inflated gastric balloon is positioned firmly against the esophagogastric junction, thus compressing the varices.

The tube is held in place by a split tennis ball that is strapped to the tube just outside the mouth and adjacent to the mouth guard. The central portion of the tube is thereby kept taut between the gastric balloon below and the tennis ball above. This method has proven to be an effective method of maintaining tamponade at the esophagogastric junction, although football helmets have been used to attach the tube by others. Adequate tension on the gastric balloon can be checked regularly at the mouth. The mouth guard helps to protect the patient’s lips from the pressure of the tennis ball. Inflation of the esophageal balloon is not usually necessary as pressure from the inflated gastric balloon on the esophagogastric junction is generally sufficient. If esophageal balloon inflation is used, this is done using a three-way tap and a blood pressure manometer. The esophageal balloon is inflated to 40 mm Hg and the tube is then clamped. This pressure should be checked regularly. The third lumen, which opens in the esophagus, is placed on constant suction to keep the esophagus clear of saliva to avoid aspiration. The fourth gastric lumen is used for either nasogastric suction or for administering medication, such as lactulose to reduce encephalopathy.

Patients with a balloon tube in place should be monitored carefully in

an intensive care unit to avoid complications. The position of the inflated gastric balloon must be checked by an abdominal radiograph. Once the balloon tube has been inserted and tension applied and bleeding has been arrested, resuscitation is continued, clotting defects are corrected, and the patient is made as fit as possible for the necessary subsequent management. The balloon tube should be removed after 6 to 12 hours as a prelude to further endoscopic intervention.

ALTERNATIVE EMERGENCY MANAGEMENT OPTIONS

The main secondary alternatives to primary pharmacologic and endoscopic therapy for acute variceal bleeding are TIPS stenting, portosystemic shunts, esophageal transection operations, and liver transplantation. In patients with recurrent bleeding, it is crucial to identify the cause and site of bleeding, because the management of recurrent variceal bleeding, gastric varices, injection-induced esophageal ulceration, and portal hypertensive gastropathy differs.

A TIPS shunt is the emergency procedure of choice in patients in whom endoscopic therapy has failed to control bleeding. Recent data confirm the utility and efficacy of TIPS stent as a salvage procedure for refractory variceal bleeding unresponsive to endoscopic and pharmacologic treatment. Immediate control of variceal bleeding is achieved in over 90% of patients who have undergone a TIPS stent. However, TIPS in patients with uncontrolled variceal bleeding still has a high mortality. Prognosis is also poor if patients have developed sepsis, require inotropic support and ventilation, or have deteriorating liver and renal function. Established renal failure in a decompensated cirrhotic patient with uncontrolled bleeding is a contraindication to TIPS placement in most units.

The need for emergency surgical shunts to control acute variceal bleeding has diminished dramatically in the past decade due to the improved efficacy of pharmacologic, endoscopic, and radiologic treatment. While a successful surgical shunt effectively stops acute variceal bleeding and prevents recurrent bleeds, the role of emergency shunting procedures is currently restricted to patients who have failed endoscopic therapy and cannot be salvaged by a TIPS stent for technical reasons. This is because emergency shunt surgery has an operative mortality of up to 25%, which is largely determined by the degree of liver decompensation.

A variety of devascularization and transection operations that disconnect the high-pressure portal system from the esophageal varices

have been devised. As a basic principle, the most simple procedure should be used. Simple esophageal transection using a staple gun is the preferred procedure for patients in whom endoscopic therapy has failed and TIPS or an operative shunt is not feasible. Previous sclerotherapy may increase the difficulty and risk of performing the operation due to sclerosant-induced ulceration and periesophageal fibrosis. Esophageal transection combined with extensive esophageal and gastric devascularization is not justified in the emergency setting.

Although emergency liver transplantation has been advocated, it is best performed after initial control of variceal bleeding, preferably using an endoscopic technique, as this will interfere least with a subsequent transplant. For the failures of endoscopic therapy in potential transplant recipients, a TIPS shunt may be used as a bridge to transplantation.

Patients with uncontrolled variceal bleeding and end-stage liver disease, deteriorating renal function requiring inotropic support and on ventilation, and who do not respond to emergency treatment should be considered for conservative treatment only. While this decision poses difficult moral and ethical issues, this category of patients with a high MELD score and a Child–Pugh score over 13 seldom survive despite heroic efforts.

LONG-TERM MANAGEMENT

Evaluation of Liver Function

Once the acute bleeding episode has been controlled and the patient is stabilized, a detailed evaluation is undertaken to identify the cause of the portal hypertension, the severity of any underlying liver disease, and the likely natural history. The comprehensive medical assessment includes documentation of clinical and biochemical factors that might influence variceal rebleeding, liver function, and prognosis. A detailed history is obtained regarding current and previous bleeding episodes, the duration and amount of alcohol intake, family history of liver disease, and previous exposure to viral hepatitis. The physical examination should document the presence of stigmata of chronic liver disease, including jaundice, peripheral and sacral edema, spider angiomata, gynecomastia, palmar erythema, testicular atrophy, Dupuytren contractures, clubbing, fetor hepaticus, flapping tremor, cutaneous purpura, and petechiae. Abdominal examination should note the presence of a firm or nodular liver, splenomegaly, ascites, caput medusa and the Cruveilhier-Baumgarten syndrome with a paraxiphoid venous hum due to retrograde flow in a

patent umbilical vein. Clinical examination, in addition, seeks to establish clinical evidence of encephalopathy with asterixis and cognitive dysfunction.

All patients require full laboratory studies including hematologic, biochemical, and specific serologic testing. Patients' fluid and electrolyte status is evaluated by measuring serum electrolytes, urea, and creatinine. Standard biochemical tests of liver dysfunction include serum albumin, bilirubin, gamma glutamyl transpeptidase, alkaline phosphatase, aspartate aminotransferase, alanine aminotransferase, and alpha fetoprotein levels. All patients should have hepatitis B surface antigen and anti-HBc core antigens tested. Hepatitis C is assessed by antibodies to hepatitis C virus (HCV) using enzyme-linked immunoabsorbent assay with positive results confirmed by recombinant immunoblot assay. Patients without an evident cause of cirrhosis are screened for hemochromatosis including serum ferritin and transferrin saturation levels, alpha-1-antitrypsin deficiency, and Wilson disease. Autoimmune hepatitis is tested by antinuclear and smooth muscle antibodies and serum immunoglobulin G (IgG) levels. In selected patients in whom the diagnosis is unclear, ultrasound-guided plugged or transjugular liver biopsy can be done and transjugular portal wedge pressures measured. Transcutaneous abdominal ultrasound is performed to assess liver size and appearance including the features of steatosis, cirrhosis, atrophy-hypertrophy complex, portal vein patency and diameter, direction of portal vein flow, spleen size, duplex Doppler assessment of portal flow velocity and to screen for an underlying HCC.

Although the risks of recurrent variceal bleeding diminish with time, up to 70% of patients will have further variceal bleeding if left untreated. For this reason, all patients who have had a variceal bleed should be considered for secondary prophylaxis aimed at preventing further variceal bleeds. Endoscopic therapy is the primary treatment of choice. The options and second line alternatives are summarized in Table 134.4 and are detailed below.

Injection Sclerotherapy

In the past, injection sclerotherapy was the most widely used endoscopic treatment. Endoscopic variceal ligation has now replaced sclerotherapy as the first-line endoscopic therapy. If banding is not available sclerotherapy, when used, is performed using a video endoscope and a freehand injection technique. Unlike most other forms of therapy used in the management of

esophageal varices, sclerotherapy techniques are less standardized. The injections may be placed directly into the varices ("intra-variceal") with the objective of thrombosing the varices, or into the submucosa adjacent to the varices ("para-variceal") to produce submucosal edema to stop acute variceal bleeding and to cause thickening of the mucosa to prevent later bleeding. Many endoscopists use a combination of these two techniques (Fig. 134.3).

TABLE 134.4 Long-Term Management Options to Prevent Variceal Rebleeding

Treatment Options
1. Endoscopic therapy
a. Variceal band ligation
b. Injection sclerotherapy
2. Pharmacotherapy
a. β-blockers
b. Other drugs
3. Surgery
a. Shunt
i. DSRS
ii. Portocaval
b. Nonshunt
i. Esophageal transection and esophagogastric devascularization
ii. Splenectomy for gastric varices due to splenic vein thrombosis
4. TIPS
5. Liver transplantation

DSRS, distal splenorenal shunt; TIPS, transjugular intrahepatic portosystemic shunt.

Sclerotherapy is performed with different skill levels and protocols and variable frequencies of injections and endoscopic review. When used, a combined para- and intravariceal technique is preferred for acute variceal bleeding and a predominantly intravariceal technique is used for long-term management when varices are smaller. Our sclerosant of choice is 5%

ethanolamine oleate. Injection treatments are continued at two weekly intervals until the varices have been eradicated and are no longer visible during endoscopic surveillance. Thereafter, the patient is assessed at 3 months and then at 6-monthly and subsequently at yearly intervals. Whenever recurrent varices are diagnosed, a repeat course of sclerotherapy is undertaken until re-eradication is achieved.

Esophageal Variceal Ligation

The use of endoscopic band ligation represented a seminal development in the endoscopic treatment of varices. The concept of endoscopic variceal ligation is similar to the technique used for treating hemorrhoids, and was devised by Stiegmann from Denver, Colorado. Hemostasis is achieved by physical constriction of the base of the varix by a rubber band. Ischemic necrosis of the strangulated mucosa and submucosa trapped within the band occurs, followed by sloughing of the banded varix. The resulting shallow mucosal ulcer re-epithelializes over the next 14 to 21 days, with scarring and shrinkage of the residual varix by maturing fibrous tissue. Two different types of ligating devices are used—(i) the initial single-band delivery system and (ii) the newer multiband ligator. The original Stiegmann apparatus allowed the placement of one variceal band at a time and required the use of an overtube to allow multiple withdrawals and re-insertions of the endoscope. The newer multiband apparatus allows the sequential placement of 8 to 10 bands during a single insertion of the endoscope, obviating the need for an overtube. The multiband variceal ligator has replaced the single shot banding equipment in most endoscopy units. The band ligation procedure is repeated at 2 to 3 weekly intervals until all the varices are obliterated.

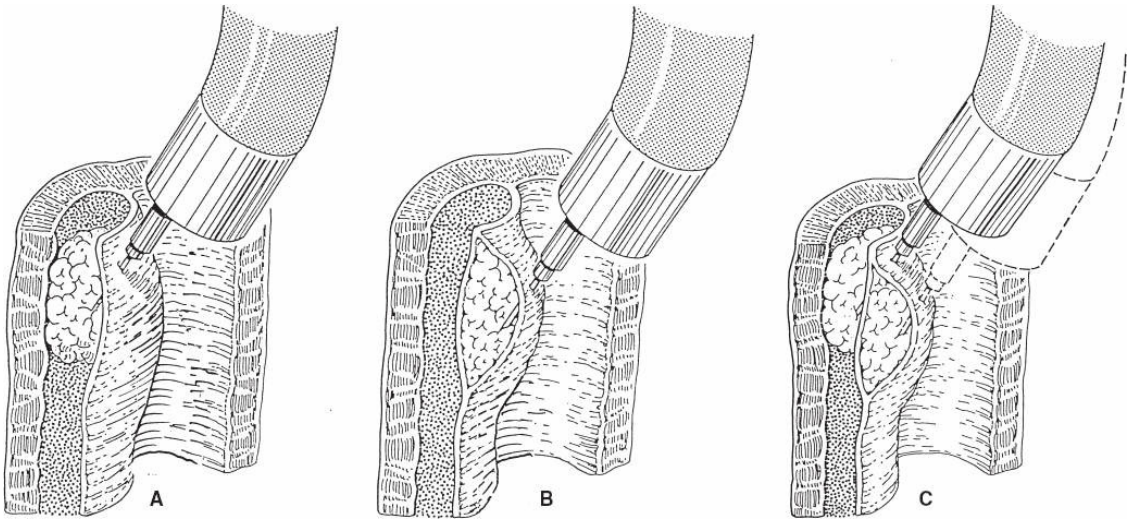

Figure 134.3. Technical variants of injection sclerotherapy. **A.** Intravariceal injection. **B.** Paravariceal or submucosal injection. **C.** Combined intravariceal and paravariceal injections.

Endoscopic variceal ligation has been shown to be as effective as injection sclerotherapy in the emergency management of bleeding esophageal varices. Furthermore, variceal eradication using ligation requires fewer endoscopic treatment sessions, and causes substantially less local esophageal complications. Current data demonstrate a clear advantage for ligation in preference to sclerotherapy in elective variceal treatment. Ligation is now the endoscopic treatment of choice in the management of all esophageal varices.

ALTERNATIVE LONG-TERM MANAGEMENT OPTIONS

Although we prefer endoscopic therapy as the primary therapy for most patients, pharmacologic therapy with propranolol alone or in combination with nitrates is an acceptable alternative primary long-term therapy in selected patients.

Pharmacologic Therapy

The use of nonselective beta-blockers (NSBB) as primary long-term therapy has considerable support in the current literature. Several meta-analyses have concluded that beta-blockers, principally propanolol, significantly reduce the incidence of recurrent bleeding and improve long-term survival when compared with placebo. Unfortunately, β-blockade is not without its drawbacks. There are a number of relative contraindications to β-blockade, including bronchial asthma, chronic obstructive pulmonary

disease, peripheral vascular disease, congestive cardiac failure, and unstable insulin-dependent diabetes mellitus. Once treatment is initiated, β-blocker-induced side-effects may also be a problem. The most common side effects are loss of energy, depression, impotence, and headaches. In a minority of patients, these side effects may be sufficiently severe to cause discontinuation of treatment. Thus, a significant proportion of the population at risk may be unsuitable for treatment with β-blockers or may stop taking the drug as a result of side effects. In addition, one third of patients treated with standard doses of β-blockers do not achieve significant reduction in portal venous pressures.

Where patient compliance is good, long-term propranolol therapy is an alternative to endoscopic management. If patients have a recurrent variceal bleed while on adequate propranolol therapy, endoscopic band ligation should be used to eradicate varices while continuing with β-blockers. The risk of side effects has led to the evaluation of other drugs to reduce portal hypertension. The main group of alternative drugs are nitrates, with isosorbide-5-mononitrate being increasingly used in clinical practice.

SURGICAL SHUNTS

Portosystemic shunts are classified as (i) nonselective, (ii) selective, or (iii) partial. Successful nonselective end-to-side or side-to-side portacaval shunts effectively control acute variceal bleeding and prevent recurrent bleeding, and were the gold standard in the past. Portacaval shunts are, however, major operations in poor-risk patients and may be associated with severe and unpredictable side effects, particularly encephalopathy and deterioration in liver function. The most popular shunts for long-term management at present are the small diameter (8 mm) externally reinforced polytetrafluoroethylene interposition graft between the portal vein and the vena cava and the distal splenorenal shunt. Operative details of these shunts are presented in preceding chapters.

Devascularization and Transection Operations

Although esophageal transection was mainly used for acute variceal bleeding, a more extensive gastric and esophageal devascularization with transection of the lower esophagus has also been used in some centers for long-term management. These major procedures are particularly popular in Japan. Controlled trials have shown that although this procedure is as effective as repeated endoscopic therapy, long-term endoscopic therapy is

simpler and far less costly. Devascularization and transection procedures are generally therefore reserved for patients with recurrent variceal bleeding despite endoscopic and pharmacologic treatment who are not candidates for TIPS and have vasculature unsuitable for shunt operations.

Transjugular Intrahepatic Portosystemic Shunt (TIPS)

Previously major surgery was the only method available to create portosystemic shunts. The advent of TIPS, a nonoperative interventional radiologic stent that can be inserted under local or general anesthesia, has become an established treatment for the complications of portal hypertension. The principal indication is for variceal bleeding refractory to endoscopic and medical therapy.

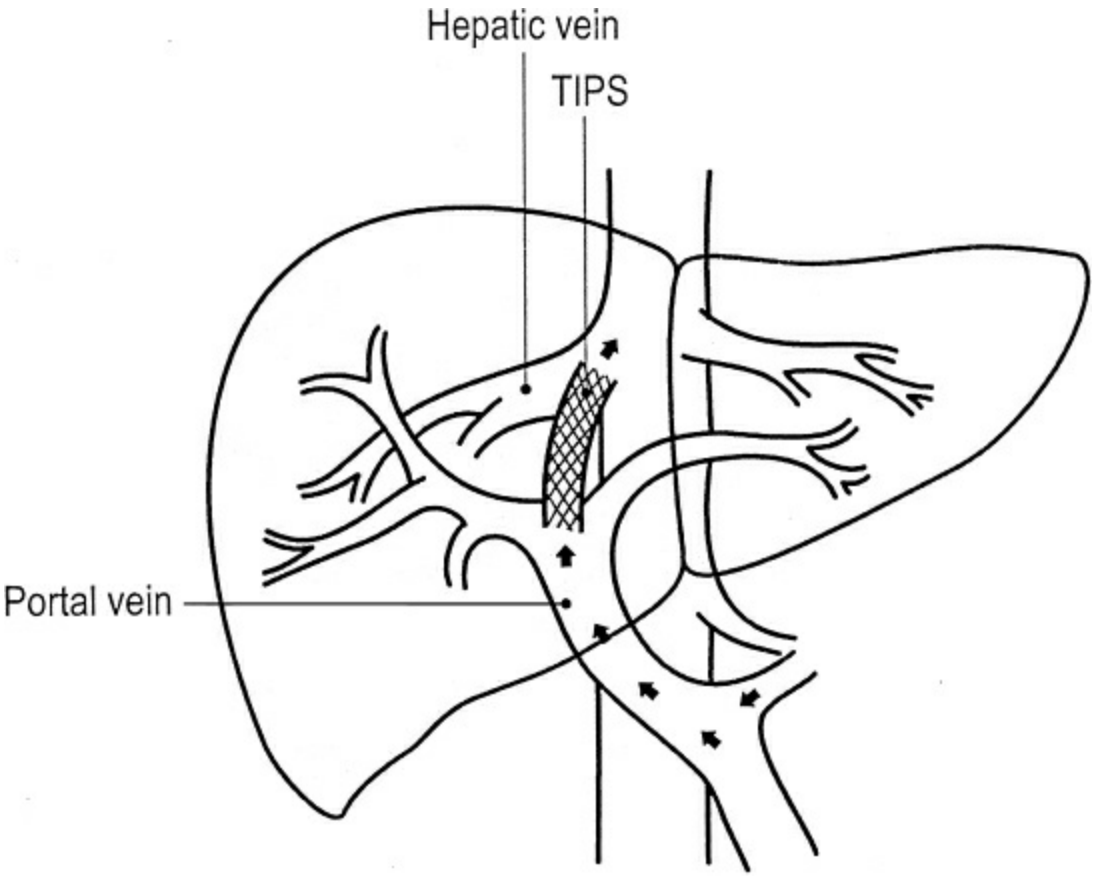

Figure 134.4. Transjugular intrahepatic portosystemic shunt (TIPS). A catheter is passed into the hepatic vein via the jugular vein. A needle, inserted through the catheter, is passed from the hepatic vein through liver tissue into a major portal vein branch. This is followed by the placement of a guidewire and dilatation of the tract through liver tissue with an angioplasty balloon catheter. The tract is kept open and functions as an intrahepatic portosystemic shunt after deployment of an expandable metal

stent.

TIPS insertion can be a technically demanding procedure and should only be performed by an experienced interventional radiologist. Patency of the portal vein should first be confirmed by Duplex ultrasound or other cross-sectional imaging. In principle, percutaneous internal jugular vein access allows a catheter to be passed into the superior and the inferior vena cava. The tip is positioned in the right or middle hepatic vein, and a rigid needle is passed from the hepatic vein through a bridge of intervening liver tissue and into a major portal vein branch. The tract within the liver parenchyma is dilated with a 10-mm angioplasty balloon catheter, and the communication between the hepatic vein and the portal vein is held open by deployment of an expandable metal stent, usually a 10-mm Wall stent (Fig. 134.4). In some patients with persistent varices, the left gastric vein can be embolized with coils during TIPS placement.

The major indication for TIPS is the salvage use in treating failures of endoscopic therapy in patients with refractory or ongoing acute variceal bleeding. The procedure can be performed with low morbidity and mortality by an expert interventional radiologist, even in poor-risk patients. TIPS is an ideal bridge to liver transplantation in patients with acute variceal bleeding as it does not disturb the porta hepatis in patients requiring subsequent surgery.

Disadvantages of the TIPS procedure include the cost (each stent costs in the region of $1,000), particularly when more than one procedure is required. In the past, TIPS procedures used mainly uncovered metal stents that were prone to stenosis and occlusion within 1 to 2 years and that required close surveillance and had high rates of re-intervention. Another disadvantage was the substantial encephalopathy rate. The introduction new covered TIPS stents promises improved of patency rates but requires precise placement.

LIVER TRANSPLANTATION

Liver transplantation is the only treatment that cures the underlying liver disease and the portal hypertension. All patients presenting with variceal bleeding and significant liver decompensation should be considered for hepatic transplantation even though only a small percentage of patients will ultimately become transplant candidates.

In potential transplant candidates with acute variceal bleeding,

emergency endoscopic therapy is considered the treatment of choice. If endoscopic therapy fails to control active variceal bleeding and if a donor liver is not immediately available, an urgent TIPS should be considered as a salvage procedure to control bleeding before transplantation. Once the patient has recovered from the acute variceal bleed, early transplantation should be performed if further evaluation confirms that the patient is a suitable liver transplant candidate. Patients with good liver function can be considered for a distal splenorenal shunt rather than a transplant.

INJECTION SCLEROTHERAPY

Technical Variants

Three basic techniques are used (Fig. 134.3). The aim of direct intravariceal injection (Fig. 134.3A) is to thrombose the varices, thereby preventing recurrent hemorrhage. Paravariceal or submucosal injection (Fig. 134.3B) produces submucosal edema that stops acute bleeding by compression and later causes mucosal thickening, thereby preventing recurrent bleeding. The combined paravariceal and intravariceal technique is used to enhance the advantages of each individual technique (Fig. 134.3C).

Elective Sclerotherapy Technique

Elective sclerotherapy is performed in an outpatient clinic with two assistants trained in endoscopy techniques. One assistant reassures the patient, provides suction of the patient's mouth to avoid aspiration, and ensures that the mouth guard is correctly postioned between the teeth and does not become dislodged. The other assistant advances and retracts the injector needle at the back of the endoscope and administers the sclerosant under the direction of the endoscopist.

The patient is placed in the left lateral decubitus position at the top of the endoscopy bed, with the head on a pillow and the neck slightly flexed. The pharynx and posterior tongue are anesthetized with three puffs of 10% *xylocaine* spray. A small butterfly needle is inserted into a superficial hand vein for administration of sedation. We usually administer small incremental doses of *midazolam* to a total of 2.5 mg. All the instruments, including the endoscope, are checked before use, and commands such as "advance needle" and "retract needle" are rehearsed, if a new or inexperienced assistant is present. Each time an injection is required, this

is indicated by the endoscopist and acknowledged by the assistant. The assistant is instructed to comment if resistance is encountered during injection, as resistance may indicate that the varix is thrombosed or that the needle is not correctly positioned.

The endoscope is inserted through the mouth guard and is passed under direct vision, keeping the lumen of the esophagus in view while controlling the position of the endoscope tip. The complete esophagus is examined and the presence of esophageal varices noted and documented, including their number, size, and extent. In the elective setting, bleeding will usually not be present and a full diagnostic panendoscopy is performed first to exclude other lesions before commencing injection of varices. The presence, position, extent, and size of gastric varices and the degree of portal hypertensive gastropathy are noted and documented.

Once full panendoscopy has been completed, the endoscope is withdrawn into the esophagus and positioned above the esophagogastric junction so that the varices in the lower 5 cm of the esophagus can be injected. The endoscope is maneuvered into position, and the target varix is identified. The assistant advances the needle on instruction, and a small volume of sclerosant solution is injected and discarded into the lumen of the esophagus to ensure that the injector is filled. The endoscopist then inserts the needle directly into the center of the most prominent part of the varix, near to the esophagogastric junction, by advancing the injector a further 5 to 10 mm. Once the needle has been satisfactorily placed within the lumen of the varix, the assistant is instructed to inject 1 mL of sclerosant (Fig. 134.5). If this is achieved without resistance, further sclerosant is injected under instruction. The varix will be seen to distend at the injection site and become paler; this indicates that sufficient sclerosant has been injected into this varix. A total of no more than 5 mL of ethanolamine oleate is usually required for a large varix; smaller varices usually require less sclerosant. Thereafter, any additional varices are injected at the same level. A second injection is placed 2 to 3 cm higher in large varices. Usually, only 2 to 3 mL of sclerosant is injected into the upper site. No attempt should be made to inject the varices while the patient is restless or retching. Such uncontrolled injections may result in laceration of the varix by the needle with resultant major bleeding.

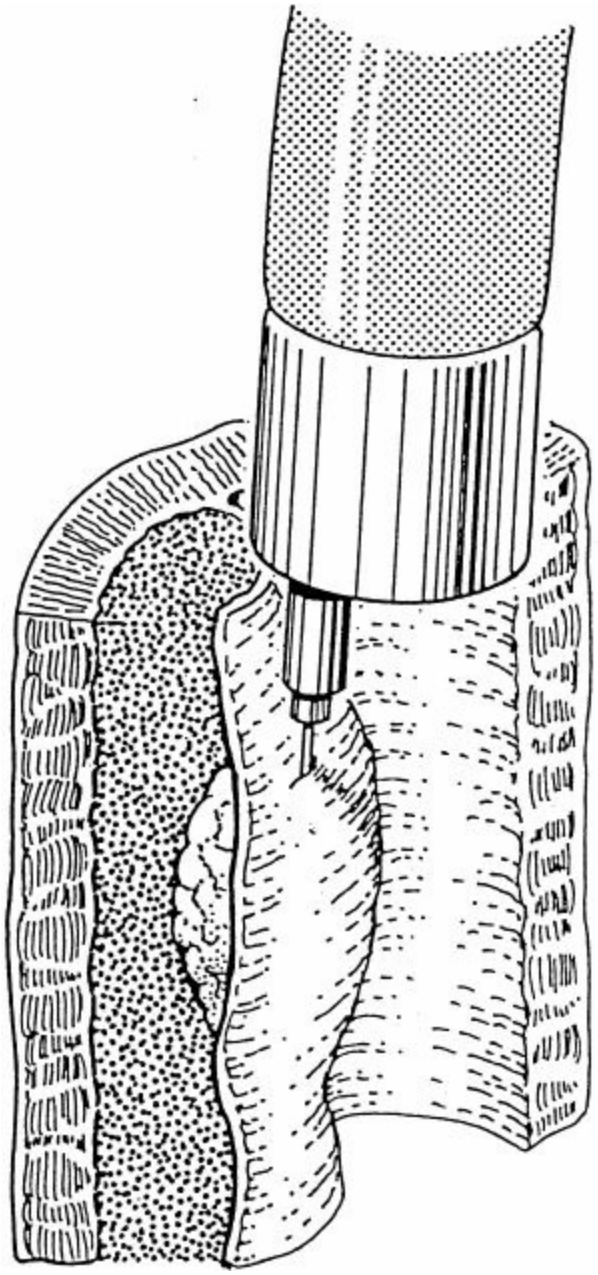

Figure 134.5. Intravariceal injection technique. After an initial test injection of 1 mL of sclerosant, up to 5 mL of ethanolamine oleate is injected directly into the varix immediately above the esophagogastric junction.

After the procedure, the patient is observed in the outpatient endoscopy suite recovery room for an hour. If the patient is stable and there is no pain or discomfort, the patient is discharged home. It is unusual for bleeding to complicate an elective sclerotherapy session.

Subsequent sclerotherapy injections are performed at 2 to 3 weekly intervals until all the varices have been eradicated. Severe local esophageal mucosal ulceration or slough may delay injection of the underlying varix,

but the other variceal channels should be injected. Once eradication of the varices has been achieved, a further endoscopic assessment is performed at 3 months to confirm continued eradication. Further surveillance evaluations are performed every 6 months for 2 years and then annually for life. If recurrent varices are noted at any time, repeat endoscopy and injections are performed at weekly intervals until the varices have again been eradicated.

EMERGENCY SCLEROTHERAPY

Intravariceal Injection

An intravariceal injection technique similar to that described for elective sclerotherapy can be used (Fig. 134.6). However, some endoscopists prefer the combined paravariceal and intravariceal injection technique described below for patients with active variceal bleeding.

Combined Paravariceal and Intravariceal Injection

The needle is inserted in a paravariceal position in the submucosa of the varix immediately superior to the bleeding point, and 1 mL of 5% ethanolamine oleate solution is injected. The objective is to raise a submucosal wheal (Fig. 134.7A) and thereby control the active bleeding by compression (Fig. 134.7B). If this does not completely control the acute bleeding, a further paravariceal injection is performed alongside the bleeding point. Once the bleeding has been controlled, the intervention for that varix is completed by an intravariceal injection of 3 to 5 mL of ethanolamine oleate (Fig. 134.7C). All additional variceal channels are injected either with a combined or an intravariceal technique. Large varices are injected with a further intravariceal injection 2 to 3 cm superior to the initial injection site. If the bleeding is profuse and visibility obscured despite irrigation, sclerotherapy cannot be completed safely, and under these circumstances, a balloon tube is inserted, as described previously.

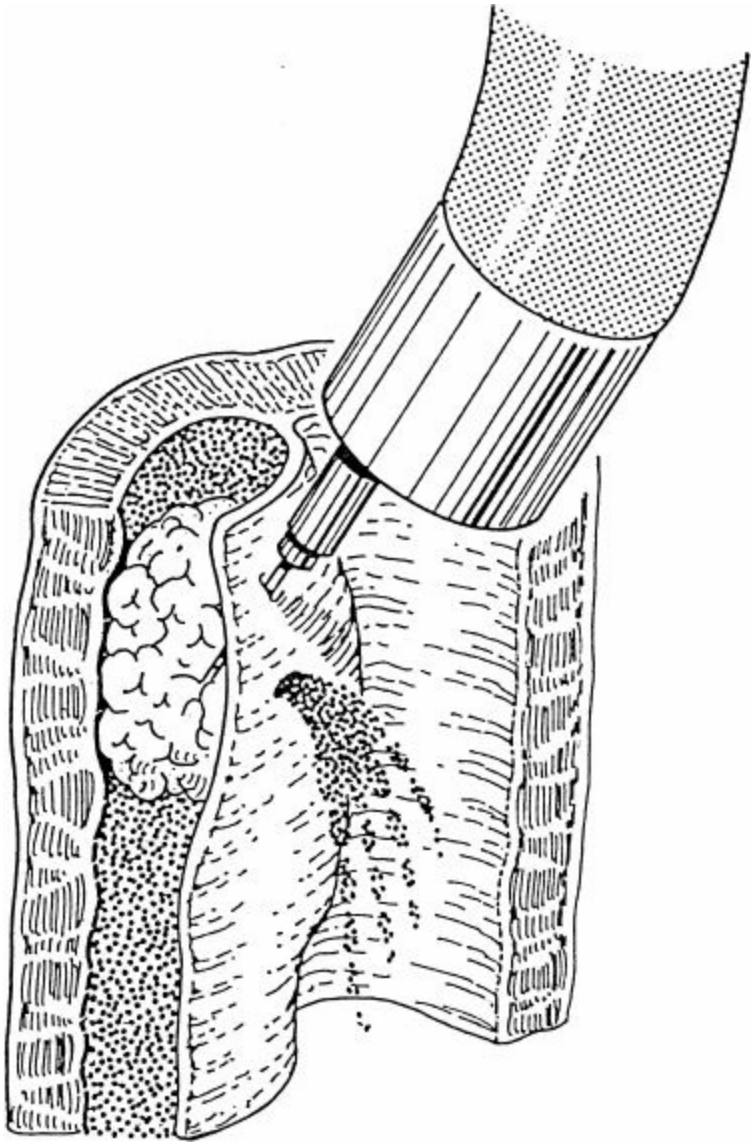

Figure 134.6. Emergency sclerotherapy. An intravariceal injection technique is used to treat an actively bleeding varix.

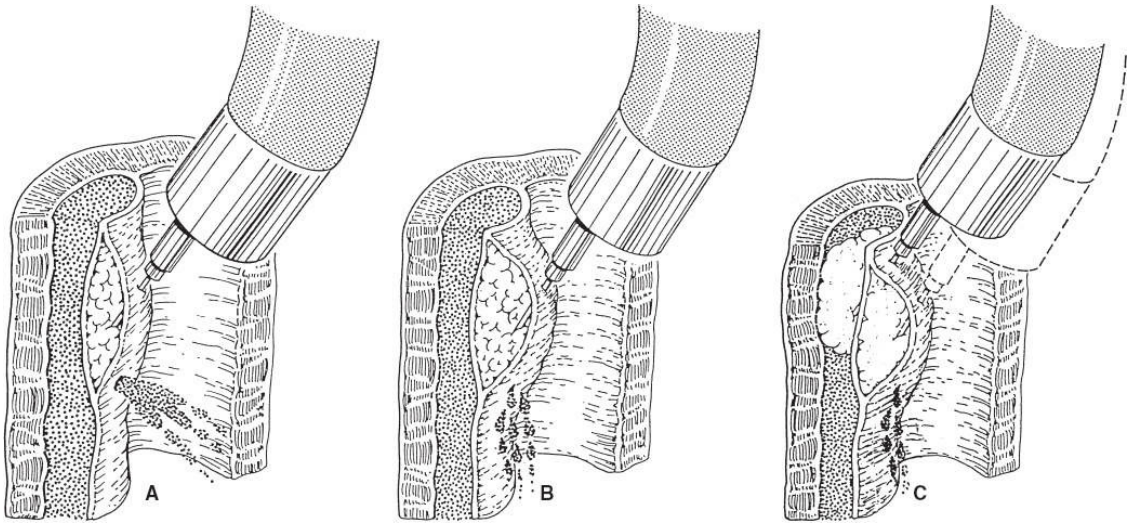

Figure 134.7. Emergency sclerotherapy: Combined paravariceal

and intravariceal technique. **A.** Initial paravariceal injection immediately proximal to the bleeding point. **B.** Bleeding controlled by the paravariceal injection. **C.** An intravariceal injection completes the procedure.

Most patients (70%) respond to a single injection treatment and have no further bleeds. If bleeding does recur, the patient must be re-endoscoped urgently. Further bleeding after two injection treatments during a single hospital admission is defined as failure of emergency endoscopic therapy. If the patient is hemodynamically unstable, a balloon tube should be inserted to control active bleeding. After resuscitation, the patient should have an alternative procedure, which is usually a TIPS procedure, or occasionally, when appropriate, injection of the varices with cyanoacrylate. A recent innovation has been the short-term interim use of self-expanding covered metal esophageal stents instead of a balloon tube to compress bleeding varices. The esophageal stent is removed after definitive treatment.

COMPLICATIONS

The most serious complication after sclerotherapy is esophageal perforation caused by inadvertent esophageal wall injection of sclerosant instead of into the lumen or submucosally. This is fortunately uncommon and usually occurs as a result of excessive sclerosant injected during active bleeding with incorrect positioning of the needle during injection. Less severe complications include a minor injection site leak. This is visible on a contrast swallow and is usually treated with parenteral nutrition or nasogastric feeding through a fine-bore silastic tube and antibiotics. Minor leaks usually resolve on conservative therapy. The most common esophageal complication is mucosal ulceration, which although frequent, is usually of no consequence and heals without further morbidity. Pneumonia may occur in patients with acute variceal bleeding, irrespective of the management used, and may be aggravated by aspiration of blood. With repeated sclerotherapy, complications are cumulative but with increasing endoscopic experience can be either prevented or minimized.

ENDOSCOPIC VARICEAL BAND LIGATION

Single Band Application

The original endoscopic variceal banding device (C.R. Bard, Tewksbury,

MA) has a housing, or outer cylinder and a banding, or inner cylinder. It is completed with a trip wire on the inside and a single latex **O** ring stretched to fit over the banding cylinder (Fig. 134.8). The outer housing cylinder is attached to the end of the endoscope via a silastic friction mount. The banding cylinder is a smaller cylinder fitted with a clasp that allows insertion of the trip wire. It is constructed to fit snugly yet slide smoothly inside the housing cylinder. The trip wire consists of a monofilament strand, to which a flange is attached at the distal end. The small latex **O** rings are mounted on the banding cylinder (Fig. 134.8).

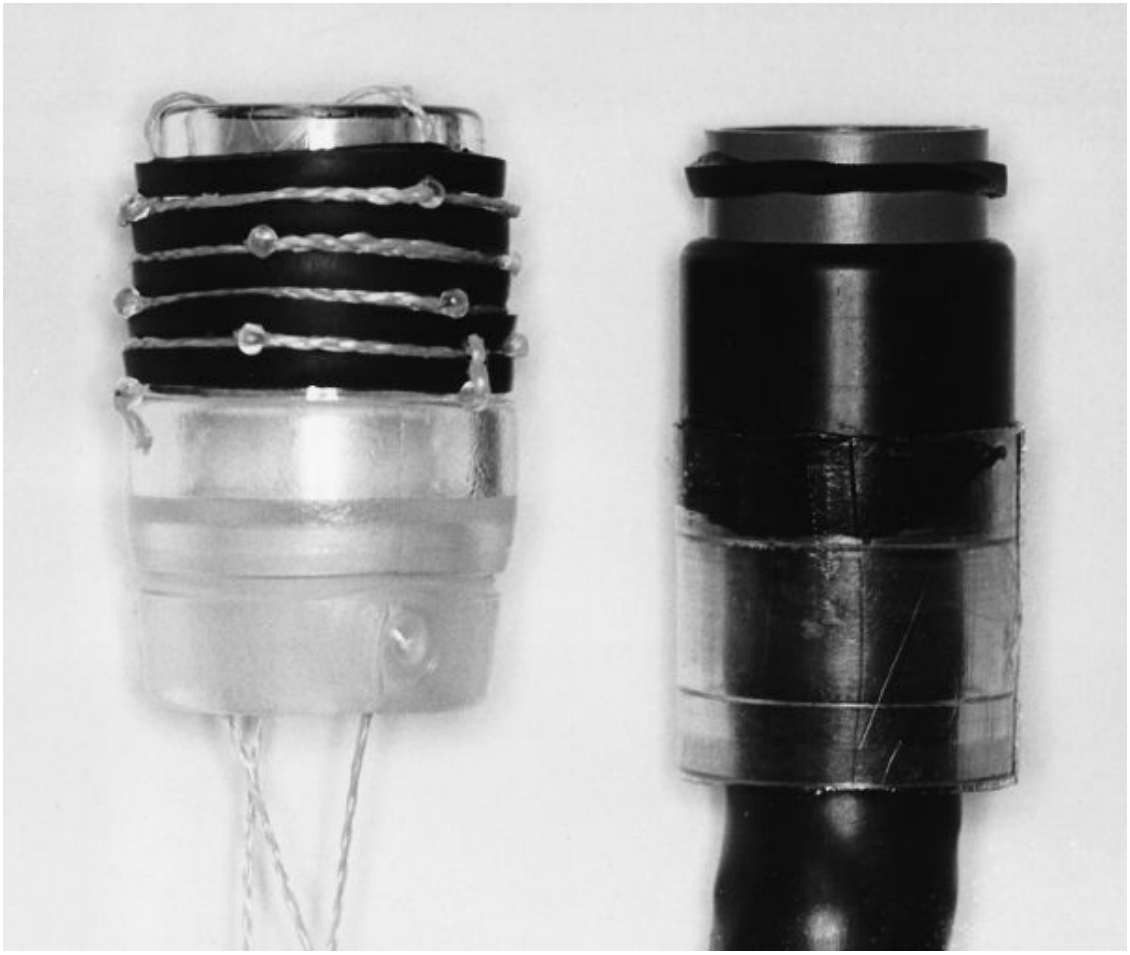

Figure 134.8. Loaded multiband (**left**) and single band (**right**) endoscopic devices.

The banding technique is the same whether performed for an acute variceal bleed or for an elective banding procedure. A diagnostic panendoscopy is performed first, when possible. After confirming the need for variceal banding, the endoscope is removed and reinserted after backloading an overtube. After reinserting the endoscope into the stomach,

the overtube is carefully advanced and passed through the cricopharyngeus and into the upper esophagus. The endoscope is removed again, and the banding device is attached to the end of the endoscope. A trip wire is passed through the vacuum lock of the biopsy channel entry port and exits via the distal biopsy channel opening. The trip wire is secured to the clasp in the banding cylinder, and the banding cylinder is "backed" into the housing cylinder. The banding cylinder is positioned so that approximately 1 mm of the cylinder protrudes beyond the **O** ring, which is seated against the end of the housing cylinder. The endoscope is reinserted into the patient's esophagus via the overtube. The endoscope is passed repeatedly for each banding procedure and then removed to disconnect the used inner cylinder and replace it with a fresh cylinder with a new **O** ring.

The varix that is to be banded must be clearly identified. The endoscope is advanced under direct vision until the banding cylinder is in full 360-degree contact with the varix (Fig. 134.9A). Once full contact is made, suction is applied. This draws the varix and the surrounding mucosa into the banding chamber (Fig. 134.9B). Once the chamber is completely filled with the varix, a "red-out" view is visible through the endoscope. The trip wire is pulled and the latex **O** ring is dislodged from the inner cylinder and becomes securely fixed around the base of the target varix (Fig. 134.9C,D). A technical disadvantage of the single band applicator is that if several varices must be ligated, the endoscope must be removed and reinserted on every occasion, with a new band for each individual variceal ligation.

The treatment begins with ligation of the bleeding varix or the most inferior part of the target variceal column. Each column has a single band placed at its lower end. Large varices have additional bands placed more proximally, 2 to 5 cm higher up the esophagus. On average, a total of six to nine bands are applied during the initial session, and progressively fewer bands are required at subsequent sessions as the varices decrease in size. After banding, patients are advised to eat soft meals for 24 hours, and are able to eat normally thereafter. Repeated banding treatments are performed at 2-week intervals until the varices have been eradicated.

Multiband Application

The multiband ligator that can deploy 6, 8, or 10 bands is now the endoscopic variceal equipment of choice (Fig. 134.8). The preloaded bands on the cap barrel are deployed one by one by a drawstring that

passes from the ligator through the biopsy channel and is attached to a trigger unit mounted on the biopsy channel port of the endoscope, which allows repeated individual firing of the bands. The multiband system obviates the need for an overtube. As with the single band applicator, treatment begins with ligation of the bleeding varix or the most distal part of the target variceal column (Fig. 134.10). A single band placed at its lower end and the next band applied to the adjacent variceal column at a slighter higher level in a spiral pattern.

Three tips are useful when using the multiband ligator. As the ligating cap and attached bands are larger than the end of the endoscope, the endoscopist may have difficulty passing the tip of the endoscope through the cricopharyngeus and the patient may gag while trying to swallow the enlarged tip of the endoscope. Liberal lubrication with KY jelly and flexing the patient's neck will usually resolve any difficulty in passing the endoscope. The endoscopist should ensure that the silastic friction mount of the banding chamber is snugly attached to the end of the endoscope with no air leaks. The nursing staff confirm that the wall suction is at maximum flow to ensure that the varix will be sucked fully into the ligating chamber and to allow the band to be deployed correctly at the base of the varix and encompass the entire varix.

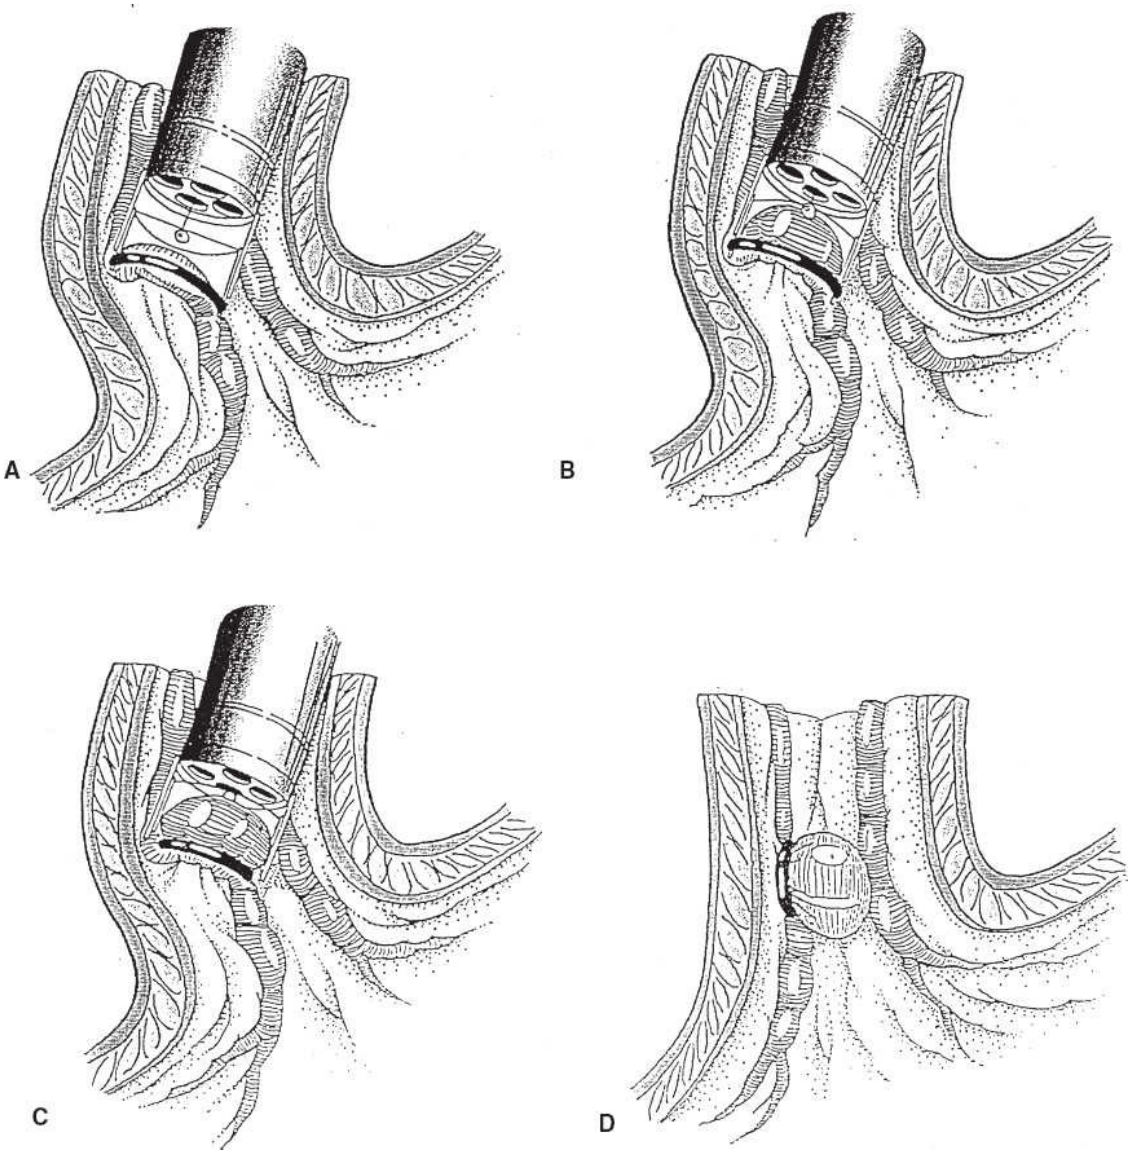

Figure 134.9. Endoscopic ligation of esophageal varices using the flexible endoscope. **A.** Varix is approached under direct vision by the endoscopist. Full contact is made between the end of the ligating device and the tissue to be ligated. **B.** Endoscopist activates the endoscopic suction, which results in aspiration of esophageal mucosa, submucosa, and the varix into the ligating device. **C.** Trip wire (which runs through the biopsy channel of the endoscope) is pulled, which moves the inner cylinder (over which the elastic **O** ring is stretched) toward the endoscope, displacing the small elastic band. **D.** Elastic band encircles the neck of the now ligated tissue, resulting in strangulation and thrombosis.

Technical difficulties with band deployment may occur during major variceal bleeding if blood clot fills the chamber while the endoscopist attempts to suck the bleeding varix into the chamber before releasing the

band. In this situation, elevation of the head of the table and vigorous irrigation through the endoscopy channel will usually dislodge the clot from the chamber and improve visibility. Once the bleeding varix is banded and bleeding is controlled, further bands can be applied to the remaining varices. The multiband variceal ligator is a significant technical advance over the single shot device, but because the unit is disposable and cannot be re-used the current retail cost of $200 per unit has limited its universal use.

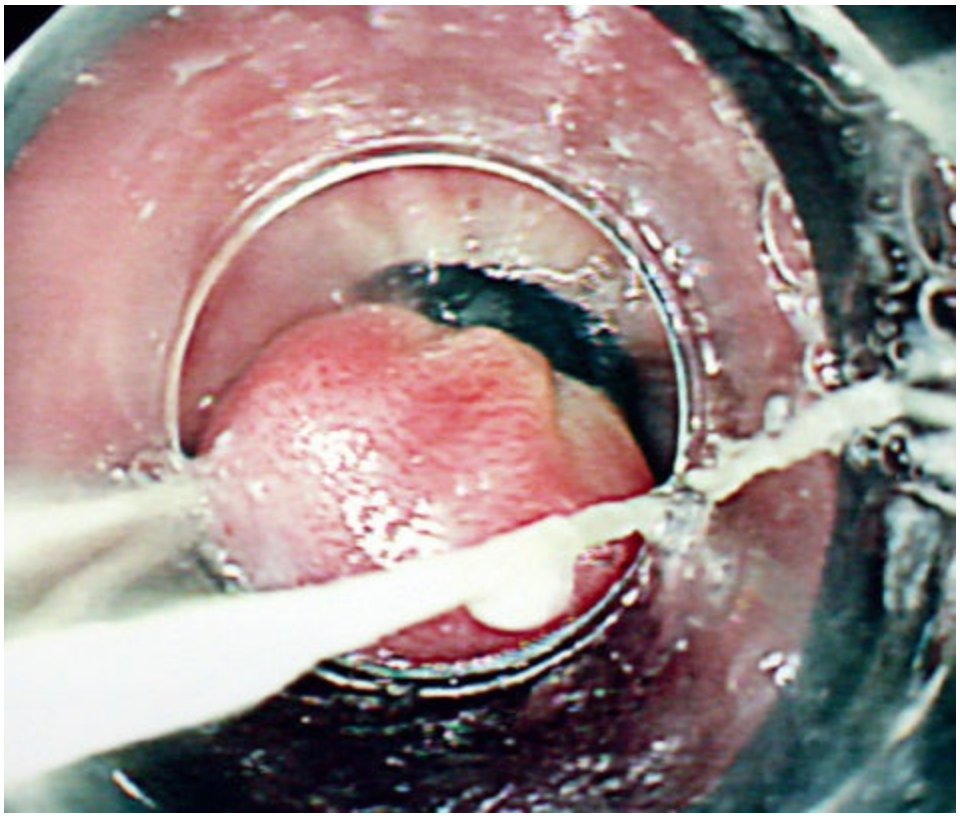

Figure 134.10. Endoscopic view of a ligated varix with a deployed band at the variceal base.

COMPLICATIONS

Complications as a consequence of variceal ligation occur in two categories. The first relates to the overtube and the second to the elastic bands. The esophagus can be injured by inadvertantly pinching the esophageal wall in the gap between the overtube and the endoscope while advancing the overtube over the endoscope. This has led to mucosal tears and rarely esophageal perforation. Overtubes with a new improved design should eliminate this problem. The second problem has been engorgement of the varices in the distal esophagus due to compression by the tube that

may lead to variceal bleeding before banding and that may be life-threatening. If this occurs, the overtube should be withdrawn until the distal end just protrudes through the cricopharyngeus into the esophagus. The engorgement should then resolve. Complications related to the banding itself are uncommon. Bleeding at an ulcer site after the band has fallen off has been a less frequent complication than that occurring with sclerotherapy ulcers. The widespread use of the multiband ligator has eliminated the use of and the complications related to the overtube.

GASTRIC VARICES

Gastric varices are the source of bleeding in 10% to 20% of patients with variceal hemorrhage. However, gastric variceal (GV) bleeding is more severe and has a worse outcome than esophageal variceal bleeding. Gastric varices are classified into four types based on their relationship with esophageal varices and their location in the stomach. Gastro-esophageal varices (GOV) are continuous with esophageal varices along the lesser curve of the stomach for 2 to 5 cm (GOV1) or into the fundus of the stomach (GOV2). Isolated gastric varices occur in the fundus (IGV1) or elsewhere in the stomach including body and antrum (IGV2). Any patient with suspected variceal bleeding should be resuscitated as described above in the section “Management of Acute Variceal Bleeding.” Once endoscopy has identified gastric varices as the source of bleeding, the initial treatment options include therapeutic endoscopic intervention and long-term NSBB, with TIPS, radiologic procedures, and surgery reserved as salvage procedures.

Endoscopic Therapy for Gastric Varices

Endoscopic intravariceal injection of glue is the treatment of choice for bleeding gastric varices and is preferable to either banding or sclerotherapy. which have higher rebleeding rates. Endoscopic gastric variceal injection is performed using tissue adhesives such as N-butyl-2-cyanoacrylate or 2-octyl-cyanoacrylate. Because of the special chemical properties of these tissue glues, particular precautions must be taken and the injection protocol closely observed during injection of the glue. Intravariceal glue injection utilizes a similar technique to conventional sclerosant injection but with several modifications to avoid complications due to spillage or hardening of the glue before completion of the injection.

Histoacryl (N-butyl-2-cyanoacrylate) polymerizes and rapidly hardens

on contact with blood which makes endoscopic injection technically difficult. There are potentially serious risks of equipment damage by tissue adhesives in inexperienced hands and care must be taken to ensure that the adhesive does not come into contact with the endoscope and block the channels of the instrument. It is therefore necessary to dilute the glue with the oily contrast agent lipiodol to retard the chemical reaction and prevent premature polymerisation of the glue in the injection needle. A 50/50 mixture of histoacryl and lipiodol is used for injection. Patients who have allergies to iodine should not receive this therapy because lipiodol is an iodized oil emulsion. The mixture of histoacryl and lipiodol should be prepared immediately before the injection in patients with suspicion of gastric variceal bleeding with each dose containing 1 mL of histoacryl and 1 mL of lipiodol. For the glue injection, a therapeutic gastroscope with at least a 3.2-mm channel is required to allow the injection catheter to pass when the gastroscope is retroverted. A 23-gauge needle attached to a 7-Fr 240-cm injection catheter should be checked before use to confirm free passage through the endoscope channel when in a retroflexed position. This ensures that the needle can be advanced and withdrawn completely within the scope in the stomach.

Because of the rapid adhesive properties of the glue, the patient’s eyes must be protected. The endoscopist and the endoscopy nurses must wear gloves and goggles and should be well versed with the equipment and the injection technique, especially with regard to the needle insertion and withdrawal sequences and injection volumes. The injection catheter is primed with distilled water. Several catheters should be available because the catheters may become clogged with glue and need to be replaced. The 2-mL syringe containing the histoacryl/lipiodol mixture is mixed ready for injection.

The gastroscope is placed in a retroflexed position adjacent to the target varix in preparation for injection and the suction is turned off. The previously prepared catheter is inserted into the biopsy channel, and observed endoscopically. The catheter, with the needle still withdrawn, is advanced without variceal contact to ensure that the direction of the catheter beyond the tip of the scope leads to an appropriate site for injection into the varix. The needle is then advanced and placed directly into the gastric varix. The prepared histoacryl/lipiodol mixture is rapidly injected into the varix, and the catheter is then flushed with water to clear any remaining glue from the catheter. The needle is withdrawn from the

varix but not into the endoscope. The injection process is repeated if another injection of glue is needed. The endoscopist continually insufflates the stomach with air. The needle can now be withdrawn into the sheath and the catheter tip can be used to palpate the injected varix (or varices) to ensure that the varix is hard. If the varix is soft, further injections are needed. It is important not to inject more than 2 mL of histoacryl/lipiodol at a time to avoid embolization. However, several separate injections can be made into one varix during one session. If the needle cannot be retracted into the catheter, the catheter is removed via the biopsy channel and a new catheter is used.

A single injection is usually effective for control of acute bleeding with success rates of more than 90% but repeat injection sessions every 4 weeks may be needed for complete obturation of varices. Complications are uncommon after glue injections if the injection protocol is carefully followed, but may include thromboembolic phenomena involving splenic, renal, pulmonary, and other vessels, needle entrapment in a varix, gastric ulceration, visceral fistula, bacteremia, and sepsis. Interventional radiologic techniques such as TIPS with PTFE-covered stent or balloon-occluded retrograde transvenous obliteration (B-RTO) are effective rescue techniques after failure of first-line therapies. The need for surgical intervention has diminished with the success of endoscopic intervention and is either splenectomy for patients with splenic vein thrombosis or a portal-systemic shunt for those with portal hypertension and preserved liver function. Secondary prophylaxis with NSBB is recommended after variceal eradication.

CONCLUSION

The range of treatment options for bleeding esophageal varices has expanded markedly during the past two decades. Increasingly sophisticated methods of management have developed in response to the evolving understanding of the pathophysiologic processes underlying portal hypertension. Endoscopic treatment has become the principal first-line intervention in patients with bleeding esophageal varices, both during the acute event and in combination with NSBB for long-term prevention of recurrent bleeding. The treatment of both acute and persistent recurrent variceal bleeding is best accomplished by a skilled, knowledgeable, fully equipped, and well-organized team using a multidisciplinary integrated approach. Optimal management should provide the full spectrum of

treatment options, including pharmacologic therapy, endoscopic treatment, interventional radiologic procedures, and surgical shunts with liver transplantation reserved for selected patients.

EDITOR'S COMMENT

Professors Krige and Thomson have written a very comprehensive chapter on the role of endoscopy in the management of esophageal variceal bleed (EVB).

They have also discussed in this chapter about other means of stopping variceal bleeding including balloon tamponade, transjugular intrahepatic portosystemic shunts (TIPS), and surgical shunts. Professor Krige's commitment on the management of EVB is reflected in the series of his published papers starting from 1989 to this date. All his publications are masterly reflected in this chapter on the endoscopic management of esophageal varices.

In this commentary, I will review the steps in management of EVB in the light of my diverse training and clinical practice in Pakistan, Canada, and United States. Management of EVB starts with resuscitation of patients followed by vasopressors and endoscopic intervention. Afterward start of nonselective beta blocker and serial EBL is helpful. These steps have been proven to be effective in control of initial bleeding, reduction of rebleed and mortality. Use of balloon tamponade as a bridge to TIPS in failure of endoscopic intervention is also recommended. Most critical aspect of managing patients with portal hypertension and varices is the timing of the intervention and the severity of liver disease. On review of literature and during clinical practice, I found and readers would agree that there are certain delays in assessing who would fail initial endoscopic intervention and then in timing of TIPS insertion.

There is no doubt that improvement in rebleeding rate and mortality is achieved but the progress has been slow in the last few decades. Endoscopic sclerotherapy (EST) use dates back to 1936, when it was first used. However, its use was ignored until 1970, when Johnston and Rodgers used and controlled bleeding in ~90% of patients (Johnston GW et al. A review of 15 years' experience in the use of sclerotherapy in the control of acute haemorrhage from oesophageal varices. *Br J Surg* 1973;60:797–800). Superiority of endoscopic band ligation (EBL) is well established over EST. EBL not only reduces rebleeding and complications such as esophageal stricture but also mortality. Ulceration, bleeding, perforation, or strictures are uncommon with EBL. Importantly, life-threatening complications of sclerotherapy including mediastinitis, pericarditis, esophageal fistula, and spinal cord paralysis are no more witnessed.

Various octreotide and vasopressin analogs have been used as vasoactive agents in order to reduce rebleeding as an adjunct to endoscopic intervention in late 1990s. I was involved in one of the earliest RCTs in 1998 comparing octreotide combined with EST versus EST alone in adult cirrhotic patients who had EVB. We reported that the combination is more effective than EST alone in controlling and prevention of early variceal rebleed. Overall mortality at the end of hospitalization was similar in the two groups (Shah HA et al. Sclerotherapy plus octreotide versus sclerotherapy alone in the management of gastro-oesophageal variceal hemorrhage. *J Ayub Med Coll Abbottabad* 2005;17:10–4).

Data are scarce on the head-to-head comparison of efficacy of terlipressin and octreotide as an adjuvant therapy. We published a noninferiority trial including 324 patients comparing the efficacy and safety of terlipressin (*n* =

163) with octreotide (n = 161) as an adjuvant therapy to EBL in patients with EVB (Abid S et al. Terlipressin vs. octreotide in bleeding esophageal varices as an adjuvant therapy with endoscopic band ligation: a randomized double-blind placebo-controlled trial. *Am J Gastroenterol* 2009;104:617–23). We found that the efficacy of terlipressin was not inferior to octreotide as an adjuvant therapy for the control of EVB and in-hospital survival. However, a reduction in length of stay was found in terlipressin group which possibly has clinical implications to ultimately cost savings.

In order to reduce the rebleeding after EBL various nonselective beta blockers (NSBB) have been used along with serial ligation. NSBB did reduce the risk of rebleeding from varices, however, no significant benefit was observed in terms of mortality.

Despite the fact, that last 20 to 30 years have seen significant improvement in survival in patients with EVB the progress is slow. Thirty-day mortality has improved from 40% to 50% in early 90s to approximately 20% in the last decade. Substantial improvements in rebleed rates have also been reported in UK and US national databases. Addition of vasoactive agents and NSBB are effective in control of bleed and rebleeds, but fails to show reduction in mortality. Not only it is important to improve on bleeding, rebleeding, and mortality with endoscopic interventions, but also reduction in cost of care must also be targeted. Each patient usually requires three to five sessions of serial EBL after the control of AEVB and use of multiband ligator incurs a reasonable amount of cost. We used an innovative idea of reloading the original ligator set and reusing it for subsequent sessions on the same patient (Abbas Z et al. Cost saving by reloading the multiband ligator in endoscopic esophageal variceal ligation: a proposal for developing countries. *World J Gastroenterol* 2008;14:2222–5). We found that EBL using reloaded multiband ligators for the follow-up sessions on patients undergoing variceal eradication is safe and effective in cost saving.

The improvement in management of patients with EVB has not been reported solely due to advancement in endoscopic intervention, but also accounted by multiple factors. These factors include improvement in access to a quality of high dependency and ICU care, improvement in general supportive measures, use of vasopressors, prophylactic antibiotics, access to endoscopy and NSBB. Access to out of hours emergency endoscopy, multidisciplinary team approach including anesthesiology and interventional radiology services for TIPS have been demonstrated in numerous randomized controlled trials.

Role of balloon tamponade device (BTD) including Sengstaken—Blakemore and Minnesota tube is limited in the control of EVB. Possible indications include unavailability of urgent endoscopy in a remote area to facilitate transfer to a multidisciplinary center; delay in performing endoscopy while patient is exsanguinating, moving patient from emergency or ward to ICU after intubating. Current AASLD and Baveno guidelines recommend the use of BTDs only as a bridge to TIPS within 24 hours in patients with endoscopically

uncontrollable EVB. In this situation BTD may be placed as a temporizing measure for up to 24 hours until definitive treatment such as placement of TIPS. A retrospective study by Nader et al. reviewed 34 patients with BTD usage over a period of 11 years as a bridge to TIPS procedure (Nadler J et al. *Am J Emerg Med* 2017;S0735–6757). Only 59% of patients survive at the time of discharge after TIPS procedure. This paper demonstrated limited utility of BTD in recent era which may further be reduced with endoscopic esophageal stenting. Self-expandable, esophageal covered metal stents are placed endoscopically, without radiologic guidance; they are removable and can be left in place for up to 2 weeks. A recent multicenter RCT involving 28 patients, removable metal stents were compared to BTD in patients with cirrhosis and EVB refractory to initial endoscopic treatment. Survival to day 15 and control of bleeding was better in the stent group. Evidence suggests that use of BTD is on decline and will soon be replaced by esophageal stents.

Hepatic venous pressure gradient (HVPG) has been proven to be the main predictor of developing varices. HVPG of >10 mm Hg has good correlation with various complications of portal hypertension. EVB is unlikely to occur when the HVPG is <12 mm Hg and a HVPG > 20 predicts failure to control bleeding, higher risk of recurrent bleeding within 1 week, higher risk of failure to control bleeding as well as higher 1-year mortality. Unfortunately, use of HVPG in clinical practice is not common. The available approaches to reducing HVPG include vasopressors, NSBBs, and TIPS used in the same order. Evidence is not supportive of significant role of vasoactive and NSBBs in reducing HVPG, hence there is a need to change the order of management of AVB in patients with high risk of rebleed.

Finally regarding TIPS, we know that it has been proven to be very useful but an underutilized intervention. Procrastinating and repeating endoscopies are usual practices that result into delays in contemplating for TIPS. A recent meta-analysis of 12 clinical trials using TIPS showed that it significantly decreased the number of EVB and reduced mortality. Current treatment guidelines recommend the use of TIPS with covered stents in patients who fail endoscopic and pharmacologic treatment. Identification of patients who would fail the endoscopic treatment with HVPG and consideration for early TIPS is the demand of the time.

In the end, I would conclude that there is improvement in management of EVB in terms of control of bleed, rebleeding, and mortality, however, progress is sluggish. There is need to adapt to a proactive approach in patients with EVB with available assessment and intervention tools. Measurement of HVPG is a valuable assessment tool of rebleed and TIPS has been shown to improve the outcomes. Need of the time is to assess patients who would fail initial EBL with the help of HVPG measurement and a proactive approach with early TIPS. Therefore, future research is needed to improve treatment algorithm with available strategies. There is also need for novel endoscopic techniques with better efficacy, lower cost, and fewer adverse events.

G SURGERY OF THE SMALL INTESTINE

135 Small Bowel Obstruction

Susan Galandiuk

INTRODUCTION

The diagnosis and treatment of small bowel obstruction can be one of the most challenging tasks facing the general or specialist surgeon. Both differential diagnosis and timing of intervention may differ significantly, depending upon whether or not the patient has had previous abdominal surgery as compared with patients who have not had prior abdominal surgery. Generally speaking, postoperative adhesions have long been the most common cause for small bowel obstruction; however, this may change with the increasing use of minimally invasive surgery and the presumed lesser incidence of observed postoperative adhesions associated with minimal access surgery. Along with this minimally invasive surgery, we are also seeing an increase in the incidence of small bowel obstruction due to internal hernias. The old adage “the sun never sets on a small bowel obstruction” may still apply, but only in select cases, those with signs of closed loop obstruction or vascular compromise. Discerning this, and differentiating those patients, in whom watchful waiting is in order and those in whom prompt intervention is required, is the surgeon’s priority.

ETIOLOGY AND PATHOPHYSIOLOGY

The etiology of small bowel obstruction can be divided into extrinsic obstruction or intrinsic obstruction (Table 135.1). Extrinsic obstruction occurs most commonly due to postoperative adhesions, but can also be due to volvulus (Fig. 135.1A,B), from obstruction in confined spaces such as hernias as well as due to mesenteric desmoids (in the case of familial adenomatous polyposis) (Fig. 135.2). Hernias that can cause small bowel

obstruction include inguinal and femoral hernias and incisional and internal hernias resulting from prior surgery. Intrinsic compression or obstruction can result secondary to inflammation due to benign disease such Crohn disease, diverticulitis (including Meckel's), tuberculosis, or due to obstruction of malignant disease from primary small bowel neoplasms such as adenocarcinoma or lymphoma or from metastatic disease such as that seen with cutaneous malignant melanoma. Importantly, small bowel obstruction can occur secondary to an obstructing cecal cancer. Obstruction can also occur secondary to foreign bodies, bezoars, or impacted calculi such as is the case with gallstone ileus.

TABLE 135.1 Causes of Small Bowel Obstruction

Extrinsic	
Adhesions	Postoperative
	Inflammatory
Neoplasms	Carcinomatosis
	Desmoids (familial adenomatous polyposis)
Hernias	
Postoperative	Incisional
	Parastomal
	Mesenteric defects
Acquired	Inguinal
	Umbilical
	Femoral
	Diaphragmatic
Congenital	Midgut volvulus
	Malrotation
	Intestinal duplication/cyst
Intrinsic	
Inflammation/stricture	Crohn disease
	Diverticulitis
	Ischemia
	Tuberculosis
	Actinomycosis
Neoplastic	Small bowel adenocarcinoma
	Other primary small bowel neoplasms
	Metastatic neoplasms (malignant melanoma)
Other intraluminal abnormalities	Impacted calculus (gallstone ileus)
	Traumatic hematoma
	Bezoar
	Foreign body

CLINICAL PRESENTATION

In the patient with small bowel instruction, clinical presentation will often reveal a patient with a distended, tympanitic abdomen. It is important to examine the patient for any healed surgical incisions. A patient history is vital, since many patients can now have significant abdominal procedures through barely visible minimal incisions. In a patient older than 50 years, who presents with a small bowel obstruction and a virgin abdomen, the potential for a cecal cancer must always be considered. The patient will frequently report the absence of any bowel movements for a matter of hours or days and often the absence of passing flatus as well. Nausea or vomiting is frequently present.

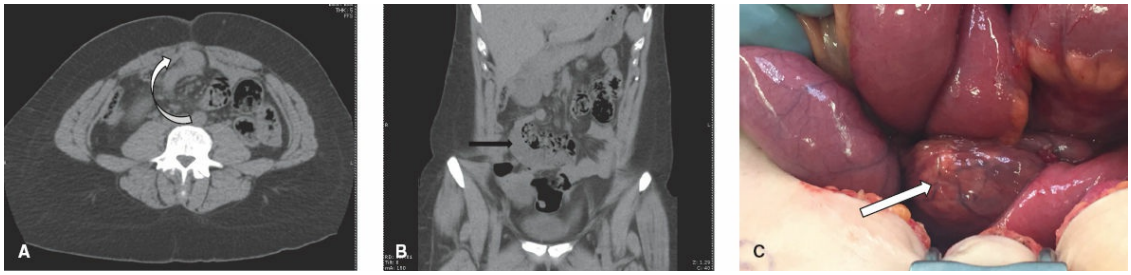

Figure 135.1. **A.** Computed tomography (CT) scan axial view showing volvulus of a loop of small bowel causing small bowel obstruction (*arrow*). **B.** CT scan coronal section showing volvulus of a loop of small bowel causing small bowel obstruction (*arrow*). **C.** Operative findings of case shown in A,B, with loop of small bowel (*arrow*) wrapped around base of small bowel mesentery causing both small bowel obstruction and ischemia.

Plain abdominal films show significant edema between adjacent loops of bowel and a “step ladder”-type appearance with air fluid levels on the upright films (Fig. 135.3A,B). In today’s medical climate with the ubiquitous computer tomographic (CT) scanning, CT scans show dilated loops of small bowel (Fig. 135.4) and may, in some cases, even show a clear transition point or identify the point of obstruction or suggest the etiology of the obstruction (Fig. 135.5A,B). In addition, the oral contrast agent used in CT scans is sometimes useful for helping to resolve small bowel obstructions through its osmotic action. If a small bowel follow-through is to be ordered in a patient with a small bowel obstruction in order to delineate the point of obstruction, it is imperative that only water-soluble contrast media be utilized. This is for two reasons. Gastrografin (diatrozate meglumine and diatrozate sodium solution) administration via nasogastric tube frequently results in a resolution of an adhesive small

bowel obstruction due to its hyperosmolar nature. Secondly, use of barium as a contrast agent can lead to disastrous consequences should an unrecognized perforation be present, or in the event that a subsequent surgery is necessary and barium becomes extravasated within the abdomen, resulting in barium (and fecal) peritonitis.

Figure 135.2. Mesenteric desmoid in a 32-year-old woman with familial polyposis who had undergone a total proctocolectomy. The rapidly enlarging desmoids were causing symptoms of small bowel obstruction until the patient was started on imatinib, which led to substantial symptom resolution.

Clinical evaluation should include a complete blood count and basic metabolic panel. An elevated white blood cell count and/or peritoneal signs are concerning for nonviable bowel. In cases where there is uncertainty, an elevated serum lactate level may be helpful to differentiate ongoing bowel ischemia. It is imperative to obtain a history from the patients regarding any malignancy or abdominal and/or pelvic radiation therapy that they might have received. In addition, it is important to obtain a history of prior vascular disease, embolic disease, or cardiac dysrhythmias that would heighten awareness of the possibility of ischemic bowel. In all patients, but particularly, in the absence of any surgical or medical history, the patient should be carefully examined for the presence of any hernias that might be causing small bowel obstruction. These include inguinal, femoral, umbilical, Richter, and of course, ventral

hernias, if there are any incisions.

CONSERVATIVE THERAPY

Conservative therapy of small bowel obstruction includes intravenous (IV) hydration and close observation. Depending upon the clinical circumstances, it may also include the use of nasogastric tube decompression, stomal decompression tubes, and antiemetics. An essential component of quality care is frequent reexamination of the patient with dated and timed notes in the medical record.

INDICATIONS AND CONTRAINDICATIONS

Small Bowel Obstruction Within 6 Weeks of a Prior Laparotomy

In electing to operate or not to operate on a patient, it is important to determine whether or not the patient has had recent surgery. In the era of laparoscopic surgery, it is more than ever important to obtain a good history since the examination of the abdomen for scars may no longer give even the observant physician accurate documentation of the patient's surgical history. It is important to thoroughly examine the patient for the presence of any hernias, including inguinal, femoral, umbilical, and incisional hernias that might be present and responsible for the patient's symptoms. In the case of the patient developing a small bowel instruction **postoperatively**, it is imperative to consider the timing time of the most recent laparotomy. If the patient has undergone an open laparotomy, it is essential to identify the time of the most recent laparotomy, and if at all possible, **avoid re-operating on that patient during the time from 7 days postoperatively until 6 to 8 weeks postoperatively**. During this time, there is a normal healing process within the abdomen in which "obliterative peritonitis" occurs (i.e., there are incredibly dense intra-abdominal adhesions). Any surgery during this time is fraught with **extreme** difficulty. The chance of performing more inadvertent enterotomies is far higher than the chance of benefiting the patient! Unless the patient has signs of peritonitis or a definition indication for surgery, such an abscess not drainable by other means, an attempt at watchful waiting (**conservative therapy**) should be performed with parenteral nutrition and nasogastric decompression. With the advent of laparoscopy, and the reduced adhesions observed following minimally invasive surgery, this adage has changed somewhat. As there are far fewer adhesions, an

attempted laparoscopy may be warranted, with initial insertion of a port to determine if there are significant adhesions and if an operation can safely be performed. In patients in whom intestinal stomas were constructed, particularly in the case of ileostomies, edema at the level of the fascia is a common cause of postoperative small bowel obstruction. In these patients, digital examination through the stoma is essential and will often confirm this, and placement of a Foley catheter or other decompression tube through the stoma will often result in alleviation of the obstruction. I often utilize a 30-Fr Marlen ostomy straight catheter (Marlen Manufacturing, Cleveland, Ohio) for this purpose, as the holes at the end of the tube are large enough to drain intestinal contents without clogging.

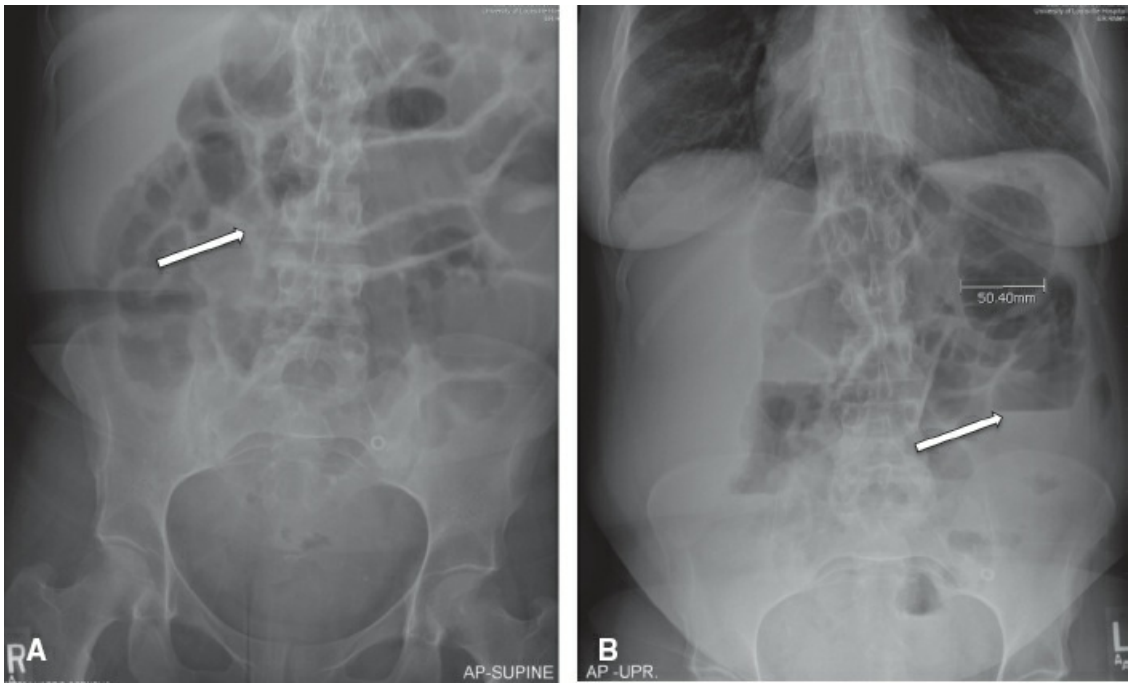

Figure 135.3. A. Abdominal film (supine) in patient with small bowel obstruction showing significant separation of loops of small bowel (*arrow*), indicating significant bowel wall edema. **B.** Abdominal film (upright) in patient with small bowel obstruction showing significant air-fluid levels (*arrow*).

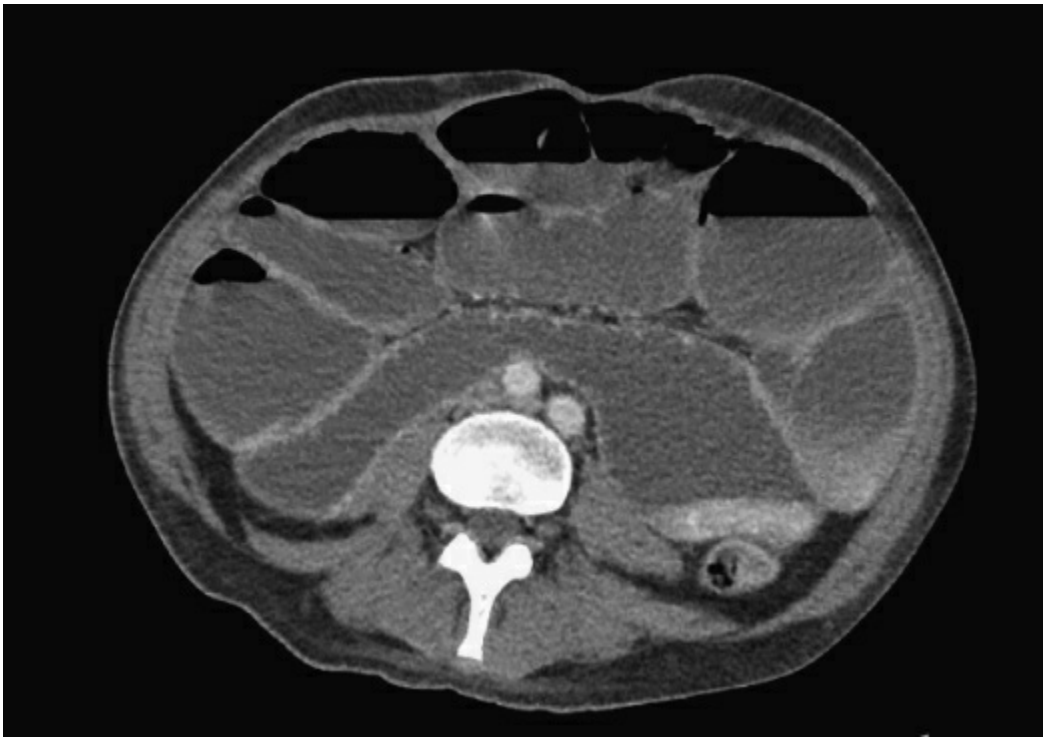

Figure 135.4. CT scan (axial view) showing extremely dilated loops of small bowel indicative of small bowel obstruction.

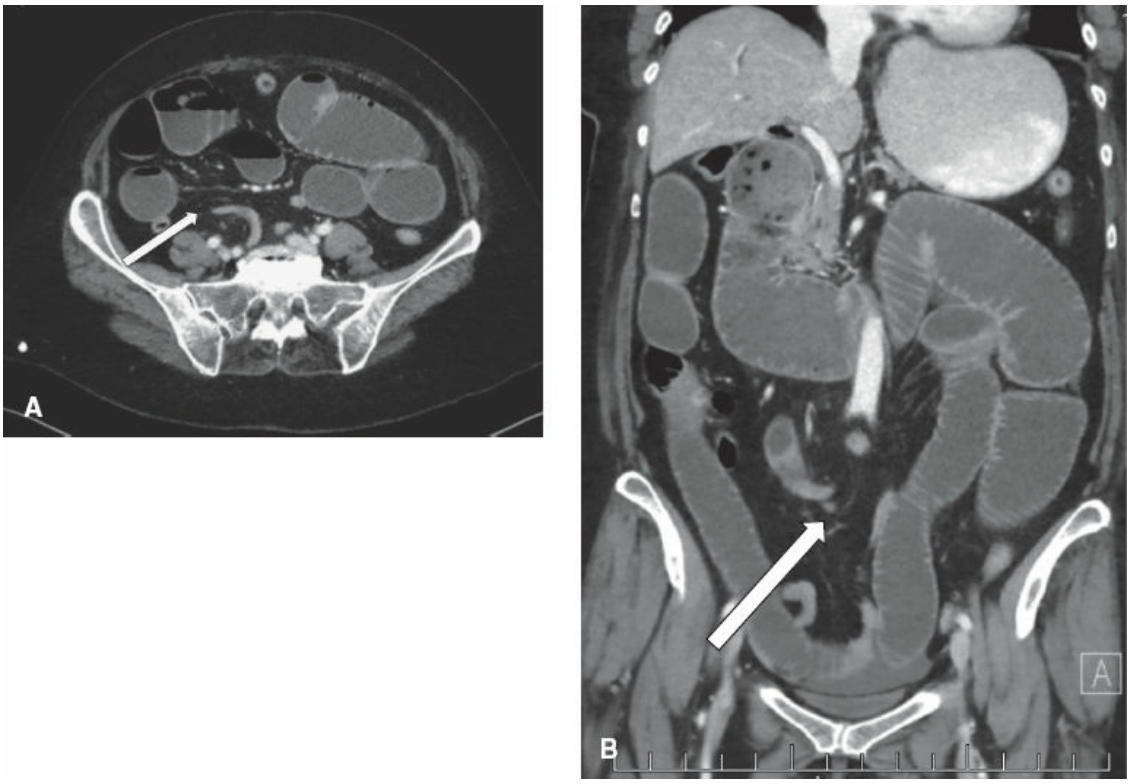

Figure 135.5. CT scan in a patient with small bowel obstruction showing a transition point to collapsed distal bowel (*white arrow*). **A.** Axial view. **B.** Coronal view.

Small Bowel Obstruction Following a Remote Laparotomy

Generally speaking, if a patient presenting with a small bowel obstruction following a remote laparotomy does not “open up” following 72 hours of conservative management, he is unlikely to, and surgery is usually indicated.

Small Bowel Obstruction Without Antecedent Surgery

Conservative therapy in this group of patients must be pursued with caution, as one must assume there is a mechanical source of obstruction unless proven otherwise. Careful serial monitoring of vital signs, physical examination for peritoneal signs, and monitoring of white blood cell count are in order with surgery if there are signs of worsening (**see algorithm,** Fig. 135.6).

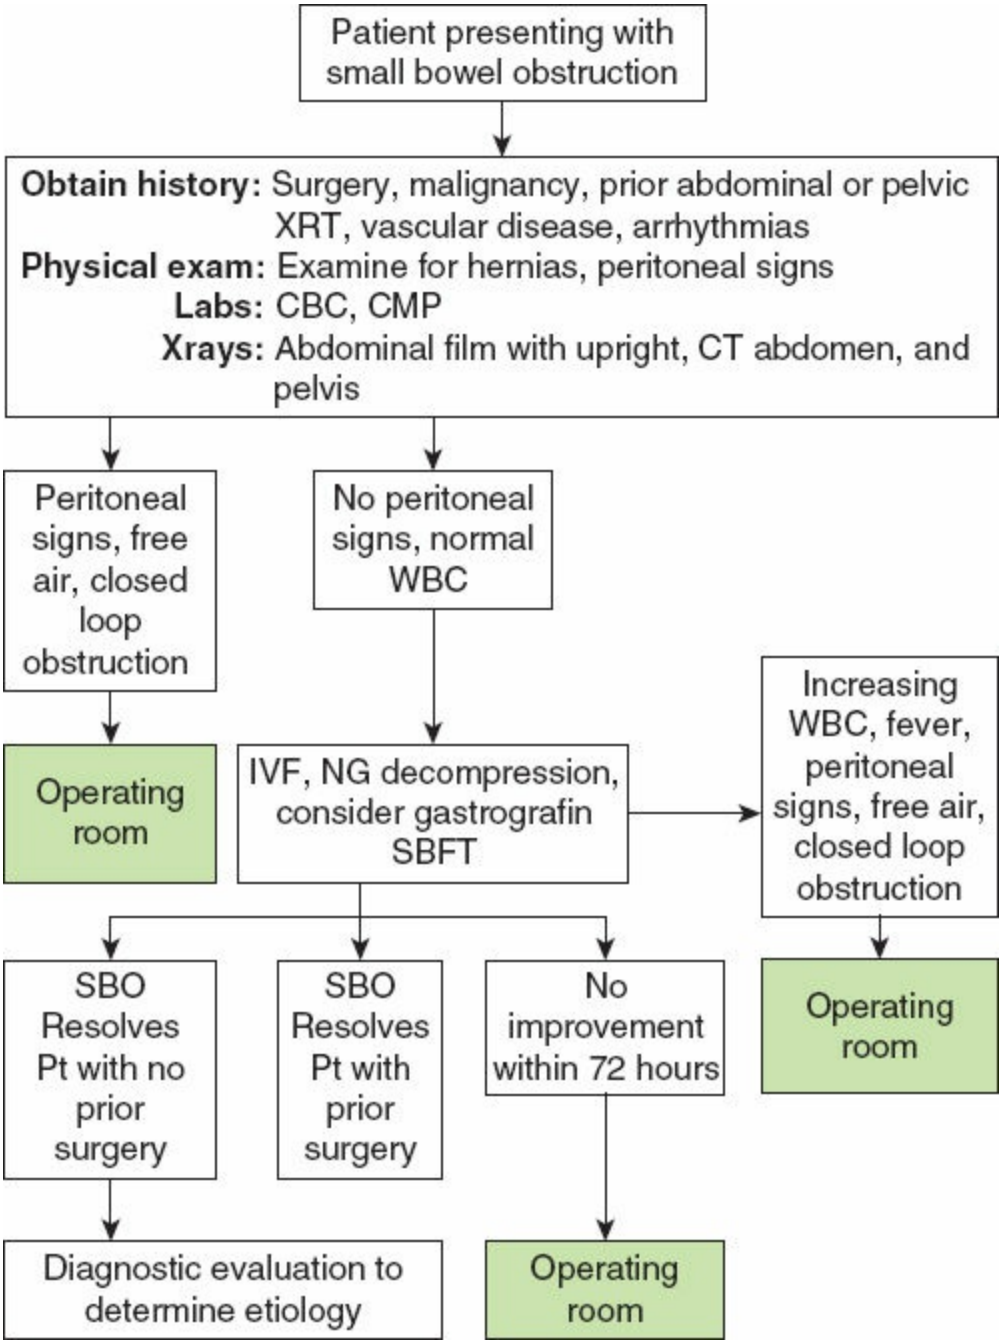

Figure 135.6. Algorithm for management of small bowel obstruction.

PREOPERATIVE PLANNING

Strong consideration should be given to placing a nasogastric tube in patients with small bowel obstruction needing surgical intervention. There is a significant risk of aspiration at the time of endotracheal intubation despite rapid sequence intubation. Great care and expertise are required on the part of the anesthesiologist. There can also be significant coexisting hypovolemia secondary to sequestration of large amounts of fluid within

the obstructed loops of small bowel and associated electrolyte disturbances. A very distended abdomen will also result in a significant degree of respiratory compromise, since there is less ability for normal excursion of the diaphragm.

The choice of mode of surgical access for a patient with small bowel obstruction depends largely on the degree of obstruction and expertise of the surgeon. If the patient has a very grossly distended abdomen with loss of domain, a laparoscopic approach is not feasible and an open approach will likely be required. Much of this is surgical judgment and relies on the expertise of the surgeon. If there is so much distended bowel that one cannot clearly visualize the abdominal contents, it is almost certainly not safe to approach laparoscopically. Patients who have had significant pelvic surgery should be placed in modified lithotomy position, so that one has access to the anal canal and rectum should this be required. In addition, if the patient has had extensive prior surgery, it is always safest to start the incision above or below the prior incision in a "virgin area" of the abdomen and work toward the more difficult area. This is particularly true in patients who have had extensive pelvic radiation and multiple prior abdominal procedures. Care needs to be taken in planning one's own professional schedule to allow an appropriate (lengthy) time for re-operative cases, especially in cases with significant adhesions following multiple prior operations and/or prior pelvic radiation. Preoperative discussion with the patient regarding the possibility of a temporary ostomy and preoperative marking for a stoma are **always** a good idea **even** if you think it unlikely.

SURGICAL TECHNIQUE

Lysis of Adhesions

In the patient with suspected adhesive bowel obstruction in whom one is performing an open lysis of adhesions, it is important to proceed systematically. The skin should be opened sharply with a knife, the subcutaneous tissue divided using electrocautery down to the level of the fascia, being on the lookout for any "Swiss cheese"-type small fascial hernias that may not have been obvious on physical exam. The fascia is best opened sharply using a curved Mayo scissors (Fig. 135.7). This allows only the fascia to be opened without harming the underlying small bowel, which may be densely adherent. Once the midline incision is opened, adhesions are taken down from the anterior abdominal wall on either side

of the abdominal wall by placing a laparotomy sponge on the abdominal contents and a Kocher clamp on the fascia. The assistant retracts gently upward on the fascia, while the operator incises, working from the opposite side of the abdomen, the adhesions from the anterior abdominal wall, while placing gentle downward and medial traction on the laparotomy sponge with his/her nondominant hand (Fig. 135.8A,B). Once both sidewalls have been freed of adhesions, the central abdominal contents are then separated from each other. Loops of small bowel are best separated from each other by upward, outward traction eliminating the need to use forceps or sharp instruments other than the Mayo scissors to incise the adhesions. Sero-myotomies are closed using interrupted sutures as they are made, since in the event that the patient has a prolonged ileus, these may leak. In the event of a prolonged lysis of adhesions, a secure gastrostomy tube should be placed. This is beneficial for both the surgeon and patient. To date, although there are no conclusive studies that adhesion barriers prevent the need for subsequent surgery for small bowel obstruction, if there are extensive adhesions, and no bowel anastomosis, it may be worthwhile to place an adhesion barrier over the bowel at the greatest risk to lessen subsequent adhesion formation.

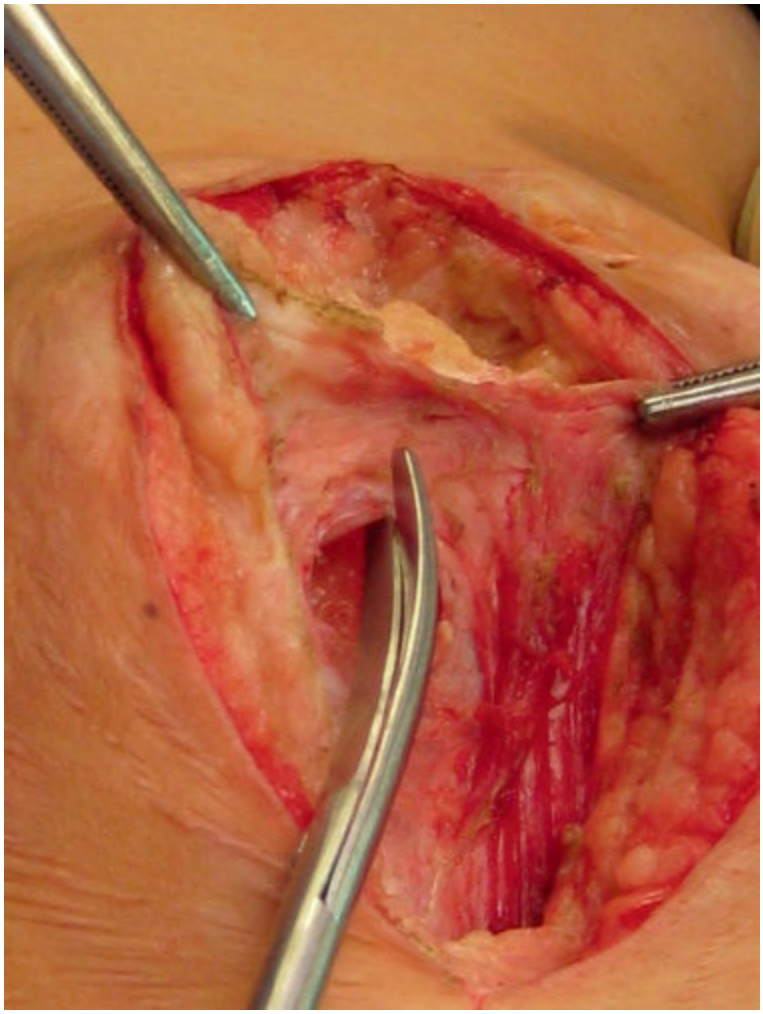

Figure 135.7. Opening of fascia using sharp dissection with a Mayo scissors.

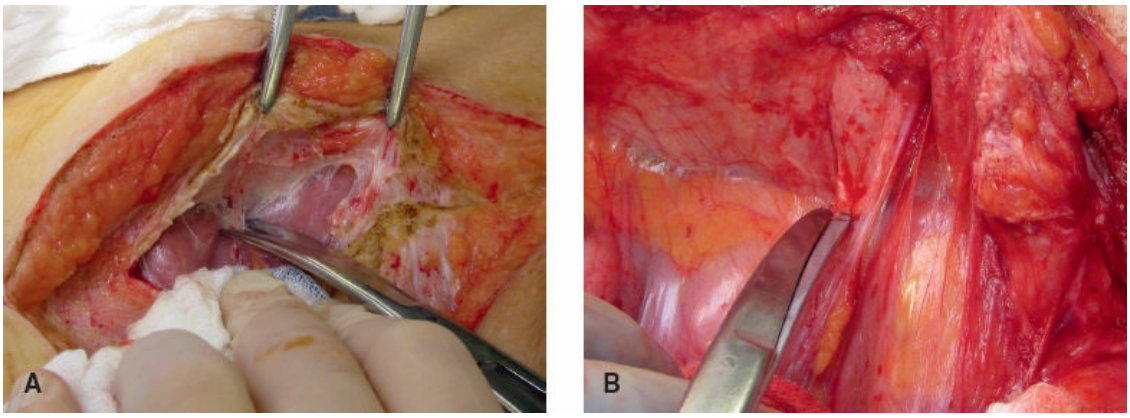

Figure 135.8. **A.** Lysis of adhesions. The surgeon stands on the opposite side of the table, while the assistant applies mild upward traction on the fascia using Kocher clamps, while the surgeon uses his or her nondominant hand to apply gentle downward and medial traction. **B.** The adhesions become clearly visible as filmy areolar tissue that is sharply divided using Mayo scissors.

Laparoscopy

The decision whether or not to approach the patient with small bowel obstruction laparoscopically depends upon a number of factors:

The skill of the surgeon as a laparoscopist
In the case of postoperative small bowel obstruction, the time from the original surgery. Since fewer adhesions form following a laparoscopic surgery, the time guidelines listed above may not always apply following laparoscopic procedures.
If there is tremendous distention of the small bowel and "loss of abdominal domain," a laparoscopic procedure should not be undertaken.
In addition, when establishing a pneumoperitoneum, this should be done under direct vision (i.e., using a Hasson or optical nonbladed trocar).
In performing lysis of adhesions, scissors **without** thermal energy should be used.

Desmoids

If the patient has a history of familial adenomatous polyposis and desmoids are suspected to be the cause of a small bowel obstruction, conservative therapy should be attempted **first**, as these operations are also an extremely difficult, frequently associated with a large amount of blood loss, and may result in loss of large segments of small bowel. Conservative therapy that may mitigate the need for surgery includes long-term medications such as tamoxifen, toremifine, or imatinib.

Crohn Disease

Crohn disease is a common cause of small bowel obstruction. This can occur either through fibrostenosing terminal ileal Crohn disease, or through the more difficult-to-diagnose short fibrotic strictures that can be seen in the jejunum or ileum without other areas of disease involvement (Fig. 135.9). These can lead to significant distention of proximal loops of bowel and are typically treated by stricturoplasty as described in Chapter 140. Ultimately, a surgeon or gastroenterologist familiar with Crohn disease may assist with longer-term care.

Intra-Abdominal Abscesses

Loops of small bowel will often try to "wall off" an infection or abscess. As such, if the bowel becomes entrapped in the inflammatory mass, small

bowel obstruction may occur. This obstruction will sometimes resolve with resolution of the inflammation by nonoperative measures, such as CT-guided abscess drainage, but occasionally surgery is required to sharply separate the small bowel from the inflammatory mass. These cases are always best approached by beginning from the normal area and slowly working toward the area of maximum inflammation, freeing up all noninvolved loops of small bowel and moving them out of the way. Once the isolated loop of bowel is identified, this bowel is subject to less injury if the surgeon's hand is placed posterior to the mesentery and slowly brought up toward the area of inflammation, and the surgeon's thumb and forefinger are used to gently finger fracture or pinch the inflammatory adhesions to divide them (Fig. 135.10).

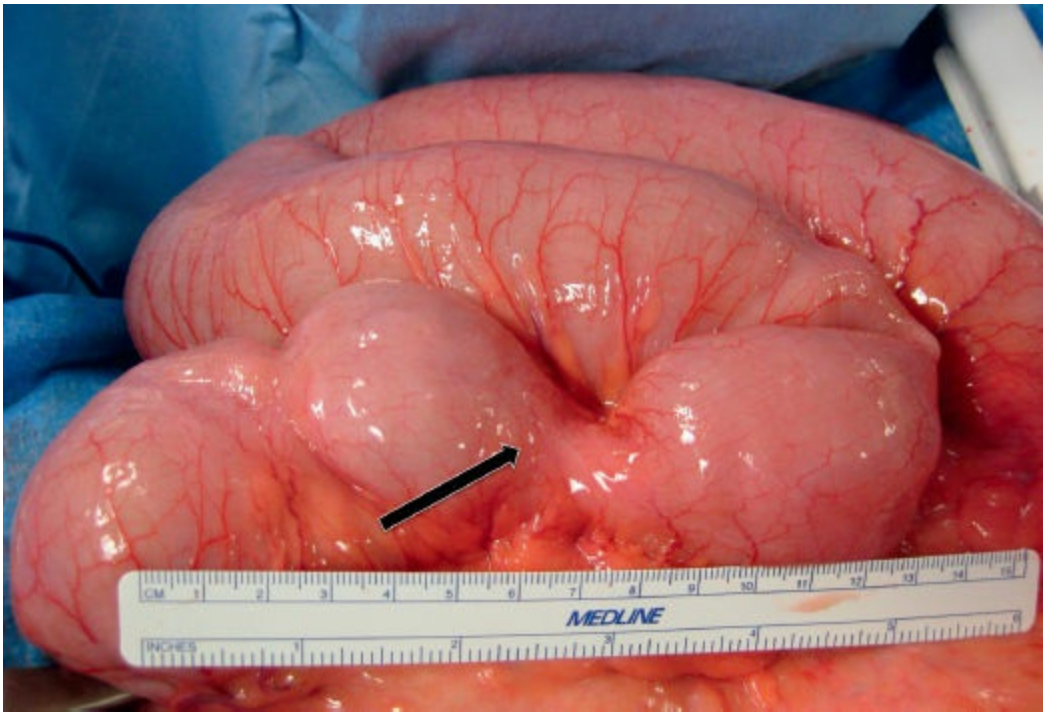

Figure 135.9. A short fibrotic ileal stricture (*arrow*) causing small bowel obstruction in a patient with Crohn disease.

Special Scenario of Small Bowel Adherent in the Pelvis After a Prior Pelvic Procedure

Small bowel tends to become adherent to the low pelvis following the many pelvic procedures. The safest way to approach such adhesions is from posteriorly. Following the root of the mesentery of the small bowel and freeing it up from posterior to anterior are often the safest and with least risk for injury to the bowel. Ureters and prior urinary diversions can

be important concerns.

Radiation

In the patient who has had extensive pelvic radiation, strong consideration should be given to entering the abdomen in an area where the patient has not had prior surgery. This means extending the incision proximally into a virgin area. Severe radiation enteritis gives the bowel a characteristic appearance with thickening and prominence of the blood vessels on the serosa (Fig. 135.11). In some cases, bypassing such segments of bowel may be an option rather than resection.

Assessing for Ischemic Bowel

If there has been a longstanding bowel obstruction and a great degree of luminal distention, there may be concern regarding bowel viability. This impacts whether to perform a resection, and if this is done, whether or not to perform an anastomosis or to divert the patient. Generally speaking, intestinal perfusion can be assessed in a number of ways: (1) visually by inspection, by snipping a small piece of the mesenteric fat and checking for bleeding (if the bowel is to be resected, one can check for bleeding from the bowel edge); (2) Doppler signals at the base of the mesentery; (3) administration of IV fluorescein and illumination of the surgical field with ultraviolet light using a Wood lamp; or (4) indocyanin green angiography whereby indocyanine green is given intravenously, and the surgical field illuminated using near infra-red light and a special imaging system (Spy or Pinpoint, Novodaq, Bonita Springs, FL) (Fig. 135.12).

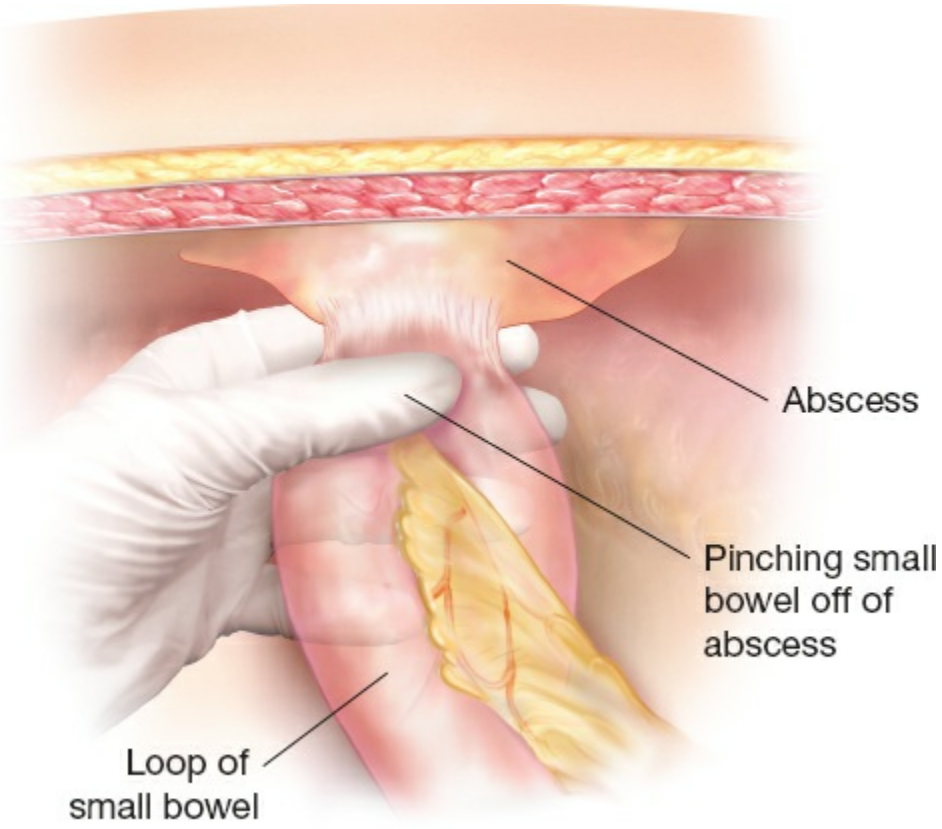

Figure 135.10. Illustration of the approach to separate small bowel from sources of inflammation, such as abscess cavities or intra-abdominal phlegmons. The involved loop of small bowel is freed posteriorly, and the surgeon's hand is placed posterior to the mesentery, and the surgeon's thumb and forefinger are used to apply a gentle "finger-fracture" technique to separate the small bowel from the inflammatory mass.

Figure 135.11. Macroscopic view of severe radiation enteritis affecting the terminal ileum. Note the blanched whitish appearance of the bowel and the prominent appearance of the serosal vessels.

POSTOPERATIVE CARE

Postoperative patient care has taken a dramatic change in the last several years. Patients with small bowel obstruction have already dramatic fluid shifts in their intestines and generally have extremely edematous bowel wall. This can be further exacerbated by excessive administration of fluids postoperatively. While these patients must receive resuscitation, this should be done with careful monitoring. Effort must be made to avoid excessive narcotic use, and to use nonsteroidal anti-inflammatory drugs, epidural analgesia, and other tools of enhanced recovery pathways to minimize postoperative ileus. Agents that reduce the length of postoperative ileus, such as alvimopam, can be utilized in addition to early ambulation. Use of gastrostomy tubes in patients who are expected to have a prolonged ileus lessens pulmonary comorbidity and allows patients some resumption of limited PO intake, which flows out of the gastrostomy immediately.

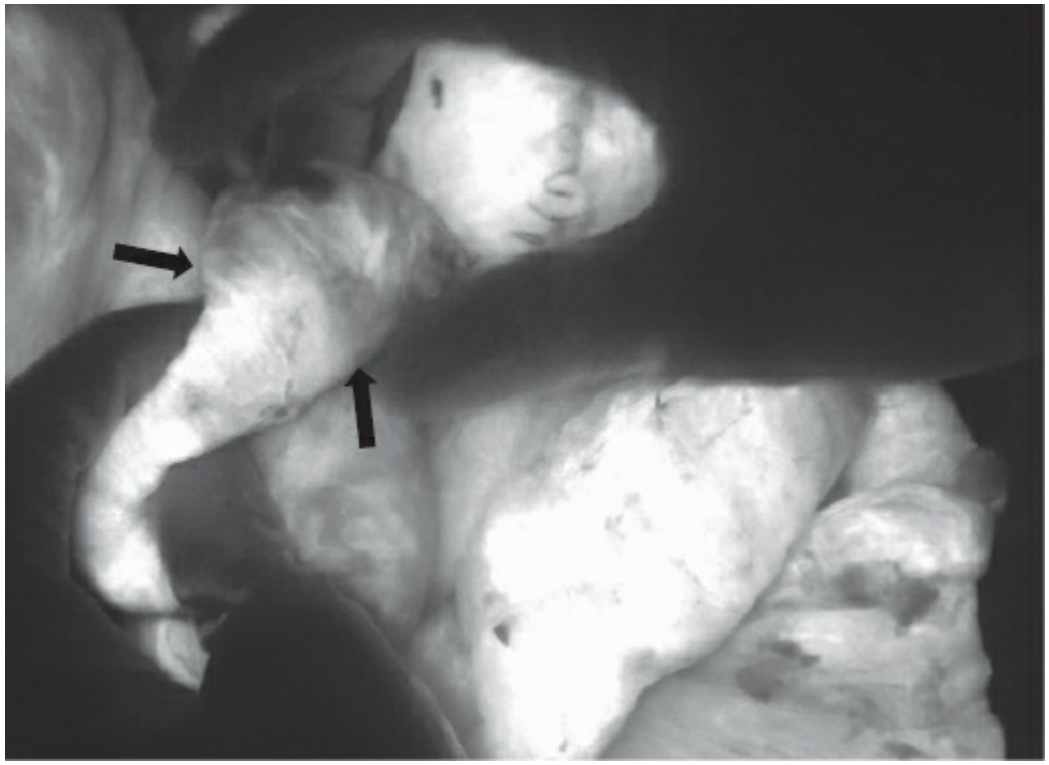

Figure 135.12. Intraoperative photograph of indocyanine green angiography illustrating an area of relative hypoperfusion (*arrows*) in a patient undergoing surgery for small bowel obstruction.

COMPLICATIONS AND THEIR MANAGEMENT

The most feared complication of small bowel obstruction is the occurrence of an entracutaneous fistula following an inadvertent enterotomy at the time of lysis of adhesions. These are best managed according to the same guidelines described elsewhere in this chapter, with respect to reoperation for obstruction following a recent laparotomy. If these enterocutaneous fistulas occur after 7 days postoperatively, the patient should be placed on parenteral nutrition, an ostomy appliance placed over the fistula, and the patient managed conservatively until it is safe to reoperate. This is usually 8 weeks at the earliest, but is frequently later. Timing for reoperation can often be assessed by palpation of the patient's abdomen. If it is soft, the adhesions have softened. If it is firm, the adhesions are firm, and one should wait longer before re-operating on the patient.

Prolonged postoperative ileus is a common complication following operations for small bowel obstruction. This can be lessened by adherence to enhanced recovery pathways as described in the section on postoperative care. In addition, if the patient has a prolonged ileus,

gastrografin injected either through a nasogastric or gastrostomy tube can be helpful for instigating bowel function as described in the Clinical Presentation section of this chapter. Erythromycin ethylsuccinate suspension given per nasogastric or gastrostomy tube can sometimes be helpful in cases of gastroparesis, as can IV metoclopromide.

Short bowel syndrome is defined as <200 cm remaining small bowel. This can occur in cases in which significant resections have already been performed or in patients in whom bowel obstruction has led to ischemia and loss of a large segment of bowel. While in the past, this was seen as a dismal scenario, the development of a glucagon-like-peptide-2 analog, teduglutide, which can be self-administered subcutaneously, has been an important development in care of these patients. Many have a dramatic reduction in the volume of gastrointestinal output and are able to reduce or eliminate reliance on parenteral nutrition or fluids.

OUTCOME

The patient's outcome following small bowel obstruction will largely depend on the responsible etiology. Despite a successful outcome following treatment of adhesive small bowel obstruction, these patients still have a significant lifetime risk of developing another such episode.

EDITOR'S COMMENT

Small bowel obstruction (SBO) is common condition that continues to challenge the general surgeon. Adhesions account for 74% of admissions for SBO. Using the Nationwide Inpatient Sample 2001 to 2011, there were an estimated 3,948,987 SBO admissions. In this study, admissions increased by 3.1% annually, whereas nonoperative management increased by 3.8% annually (Jafari MD, Jafari F, Foe-Paker JE, et al. Adhesive small bowel obstruction in the United States: has laparoscopy made an impact? *Am Surg* 2015;81(10):1028–33). As demonstrated in this study and likely reflected in your hospital, there is an increasing trend to treat SBO due to adhesions nonoperatively. The safety and duration of nonoperative treatment however remain controversial. As many, I was taught to never let the sun rise or set on a patient with intestinal obstruction. Nonoperative treatment requires rigorous attention to repeated and frequent physical examination, serial radiologic examinations in some cases, and laboratory examination to detect early physical and laboratory signs of ischemia. Careful fluid and electrolyte correction is essential as is monitoring urine output and output of the nasogastric tube. Ischemia of the small intestine due to strangulation may cause no increase or change in abdominal pain until perforation occurs. At this point, the patient usually develops constant abdominal pain and peritoneal signs and the high-pitched tinkling bowel sounds, characteristic of SBO, disappear and the abdomen becomes ominously silent. Ideally surgical intervention should take place before perforation.

The pathophysiology of small bowel ischemia in obstruction has been well described. Obstruction occurs resulting in increasing intestinal secretions and hyperperistalsis. With continued dilation, there is increasing pressure placed on intestinal wall causing venous congestion. Nasogastric decompression is usually effective in clearing the excess secretions. However, nasogastric decompression will fail in a closed loop obstruction characterized by an unchanging dominant and isolated air- and fluid-filled loop on serial plain abdominal radiographs. In this situation, the bowel continues to secrete fluid in the obstructed segment increasing pressure in the obstructed segment and on the intestinal wall and eventually the venous pressure exceeds the arterial perfusion pressure. Ischemia occurs resulting in eventual perforation. There is no simple test to diagnose ischemia; hence if nonoperative management is chosen, the surgeon is obligated to follow the patient closely.

Indeed, nonoperative treatment outcomes have been well documented. A retrospective analysis of 123 patients admitted with a diagnosis of adhesive SBO following an initial period of nonoperative treatment was performed to

assess the safety of nonoperative treatment and determine the optimal duration of nonoperative treatment in adhesive SBO (Cox MR, Gunn IF, Eastman MC, et al. The safety and duration of non-operative treatment for adhesive small bowel obstruction. *Aust NZ J Surg* 1993;63:367–71). They found that 70% of patients will have complete resolution of the SBO within 72 hours, the majority within 48 hours. Thirty percent of patients required operative intervention: 2.4% for small bowel strangulation within the first 24 hours, 3% within 48 hours, and 25% longer than 48 hours. There were no deaths in the group having an initial period of nonoperative treatment. The authors concluded in the absence of any signs of strangulation, patients with an adhesive SBO can be managed safely with nonoperative treatment. Most cases of adhesive SBO that will resolve do so within 48 hours of admission. A study reported in 2015 showed that there were no statistically significant differences in the outcomes between immediate and delayed groups regardless of duration of delay. Among patients observed with complete adhesive SBO, 24.6% resolved without surgery or readmission. The authors concluded that delaying operative management did not affect surgical findings or complication rates (Bauer J, Keeley B, Kreiger B, et al. Adhesive small bowel obstruction: early operative versus observational management. *Am Surg* 2015;81(6):614–20). A more recent assessment sponsored by Società Italiana di Chirurgia d'Urgenza e del Trauma (Costa G, Ruscelli P, Balducci G, et al. Clinical strategies for the management of intestinal obstruction and pseudo-obstruction. A Delphi Consensus study of SICUT [Società Italiana di Chirurgia d'Urgenza e del Trauma]. *Ann Ital Chir* 2016;87:105–17) used Delphi methodology to define a consensus in treatment of SBO. The panel recommended a surgical admission, a multidisciplinary approach, and a water-soluble contrast swallow for patients presenting with suspected a nonstrangulated adhesive SBO. Criteria for urgent surgery were agreed to include: presence of strangulated hernia, >10-cm cecal dilatation, ileal dilation >6 cm, signs of ischemia, and persistence of metabolic acidosis. Moreover, they concluded that the protocol for nonoperative management (to be conducted for maximum 72 hours) should include a nasogastric drainage placement, IV fluid and electrolyte replacement, and clinical and laboratory controls each 12 hours. It was recommended that nonoperative treatment should be suspended as there is suspicion of intra-abdominal complications, high level of lactate, leukocytosis (>18.000/mm^3 or Neutrophils >85%), or a doubling of creatinine level comparing admission. Conversely, consensus was not reached regarding the exact timing of computed tomography (CT) scan.

There is controversy regarding open versus laparoscopic exploration for SBO. The laparoscopic approach is becoming more common. A study conducted by Jafari and colleagues noted that above 36.7% underwent operative management and laparoscopy was performed in 26.5% with a 22.5% conversion rate. Operative management increased by 1.8% annually, whereas laparoscopic surgery increased by 8.9% annually and open surgery decreased by 0.6% annually. Laparoscopic small bowel resection increased by a mean of 25%

annually. Interestingly laparoscopic surgery was associated with 24.4% in-hospital morbidity with intra-abdominal abscess/enteric fistulas (8.3%) and ileus (8.9%) as the most common complications. In-hospital mortality was 0.9% with length of stay of 13 ± 9 days. In this study, the majority of patients were operated on hospital day (HD) 1 (43.0%). Patients who underwent laparoscopic surgery 7 or more days after admission had a higher risk-adjusted mortality. There has been an increase in admissions for SBO and an increase in laparoscopic surgery over the past 11 years. There seems to be an increase in mortality and morbidity with surgery >7 days after admission. These results should give us pause and the need to reassess the role of laparoscopy in the surgical management of SBO.

What is the ideal test for the diagnosis of SBO? Plan films usually show multiple air fluid levels. Ileus on plain abdominal films may show an air fluid level but usually not multiple. Contrast studies or CT with IV and oral contrast may be considered. Two older studies looked at this (Fevang BT, Jensen D, Fevang J, et al. Upper gastrointestinal contrast study in the management of small bowel obstruction—a prospective randomised study. *Eur J Surg* 2000;166: 39–43; Burkill G, Bell JC, James RG, et al. The utility of computed tomography in acute small bowel obstruction. *Clin Radio* 2001;56:350–9).

These looked a prospective comparison to determine the sensitivity and specificity of water-soluble contrast examination and contrast-enhanced CT in 65 patients with clinical suspicion of adhesive postoperative SBO. There was no statistically significant difference in sensitivity, specificity, accuracy, positive predictive value, and negative predictive value between the two investigations in differentiating simple from a complete/complicated obstruction. However, CT was quicker to perform, could diagnose closed loop obstruction and strangulation, in addition to finding the cause. However, they noted the high cost of CT and lack of availability at most small hospitals in the developing world. Thus, a water-soluble contrast study may be adequate where CT is not available. A water-soluble contrast study is also useful in differentiating partial from complete obstruction in the early postoperative phase, and thus predicting the risk of development of complications.

CT may help distinguish patients with strangulated obstruction. The presence of pneumatosis of the intestine or air in the portal vein is ominous signs and suggests intestinal ischemia and the need to surgical exploration.

As noted by Dr. Galandiuk, the window for safe reoperation in early postoperative (<6 weeks) small bowel obstruction (ESBO) is short and intimately dependent on elapsed time from the initial operation. Most surgeons would agree with the author's statement "avoid re-operating on that patient during the time from 7 days postoperatively until 6 to 8 weeks postoperatively." How is timing of surgery changed if the original operation was performed by laparoscopy? It is thought that laparoscopic procedures create fewer inflammatory changes than open laparotomies. Hence, it has been hypothesized that it is safer to re-operate early for early SBO after laparoscopic procedures

than open. In a meta-analysis, the risk of early SBO laparoscopic surgery was associated with reduced rates of early (odds ratio 0.62) and late (odds ratio 0.61) bowel obstruction than open procedures (Yamada T, Okabayashi K, Haseqawa H, et al. Meta-analysis of the risk of small bowel obstruction following open or laparoscopic colorectal surgery. *Br J Surg* 2016;103(5):493–503). A recent study suggested operation at or beyond 14 days in patients with early SBO after laparoscopic surgery was associated with fewer complications than after open surgery (Goussous N, Kemo KM, Bannon MP, et al. Early postoperative small bowel obstruction: open vs laparoscopic. *Am J Surg* 2015;209:385–90). The laparoscopic group had a severe complication rate of 5% versus 25% in those having the initial operation by an open approach. They also found that the obstruction was more commonly caused by a focal source following an initial laparoscopic procedure than an open operation (85% vs. 63%). The authors concluded that "laparoscopic approaches confer a lower rate of adhesive disease and severity of complications in early SBO as compared with open surgery even if performed after 2 weeks of index procedure."

Dr. Galandiuk refers to short bowel syndrome and its current management. The aim of treatment is to maximize intestinal absorption; minimize the inconvenience of diarrhea; and avoid, reduce, or eliminate the need for parenteral nutrition and support in order to achieve the best possible quality of life for the patient. Conventional treatments include dietary manipulations, oral rehydration solutions, and antidiarrheal and antisecretory treatments. Teduglutide is a newly available treatment that has some promise. An analog of glucagon-like peptide 2, it has been shown to improve intestinal rehabilitation by promoting mucosal growth and possibly by restoring gastric emptying and secretion, thereby reducing intestinal losses and promoting intestinal absorption. Treatment with teduglutide has been associated with enhancement or restoration of the structural and functional integrity of the remaining intestine. This results in a reduction in diarrhea and an equivalent reduction in the need for parenteral nutrition in patients with short bowel syndrome and intestinal failure (Schwartz LK, O'Keefe SJD, Fujioka K, et al. Long-term teduglutide for the treatment of patients with intestinal failure associated with short bowel syndrome. *Clin Transl Gastroenterol* 2016;7(2)).

SBO continues to be a challenging problem for surgeons. Each patient should be assessed carefully, treated with nasogastric decompression and correction of fluid and electrolyte imbalance. Operative intervention may be required in up to 70% of patients. Nonoperative management requires diligent observation on a surgical service with a low threshold for operative intervention. The risk and benefit of laparoscopic surgery should be carefully considered in each case. It is not the best approach for all patients.

E. Christopher Ellison

136 Metabolic Surgery and Intestinal Bypass for Hypercholesterolemia

Henry Buchwald

This Chapter can be accessed in the accompanying eBook edition (see inside front cover for access instructions).

METABOLIC SURGERY AND THE METABOLIC SYNDROME

In 1978, Richard L. Varco and I published a book titled *Metabolic Surgery*, in which we defined metabolic surgery "as the operative manipulation of a normal organ or organ system to achieve a biological result for a potential health gain." This discipline has actually been practiced for nearly 100 years. The most popular seminal application was peptic ulcer surgery, where various gastrectomies and vagal nerve interventions, carried out on normal tissues, were devised to cure pyloric and duodenal ulcer pathology, which itself remained surgically untouched. Intestinal metabolic surgery originated in 1953 to 1954 with the advent of the jejunoileal bypass for morbid obesity. Over the years, this was followed by gastric bypass, constriction, resection, and distention procedures, as well as gastric and vagal electrical stimulation, independent or in concert with intestinal bypasses, transpositions, resections, and intraluminal barriers—all to achieve weight loss and to ameliorate the comorbidities of obesity.

About 15 years ago, the term *Metabolic Syndrome* was added to the lexicon of diseases. This complex of independent entities was defined as consisting of obesity, type 2 diabetes mellitus, hypertension, and hyperlipidemia. Once designated a syndrome by internists, the nonsurgical specialties have searched for a treatment(s) and a cure, often failing to recognize that bariatric surgery, or more precisely metabolic/bariatric surgery, can resolve essentially all of the manifestations of the metabolic syndrome. It should be stated that the so-called metabolic syndrome has

not been identified with a specific etiologic agent, and, in the light of current knowledge, can be thought to include the primary disease of obesity and three of its comorbid conditions.

In this chapter, we will concentrate on a metabolic surgery procedure—the partial ileal bypass—that was developed specifically for the management of hyperlipidemia, one aspect of the metabolic syndrome, and that does not engender noticeable weight loss.

BASIC RESEARCH ANTECEDENTS

The first partial ileal bypass operation specifically for reduction of circulating cholesterol was performed on May 29, 1963. Since then, the series has grown to approximately 600 patients, and the operation has been performed by many others throughout the world. This procedure was used in a multi-institutional secondary atherosclerosis intervention trial funded by the National Heart, Lung, and Blood Institute in 1972, designated the Program on the Surgical Control of the Hyperlipidemias (POSCH). This study has been the only surgical randomized clinical trial to test the efficacy of cholesterol lowering in the management of atherosclerosis and its clinical manifestations, and the first of the statistically significant trials confirming the clinical benefits of cholesterol, in particular low-density lipoprotein (LDL) cholesterol reduction.

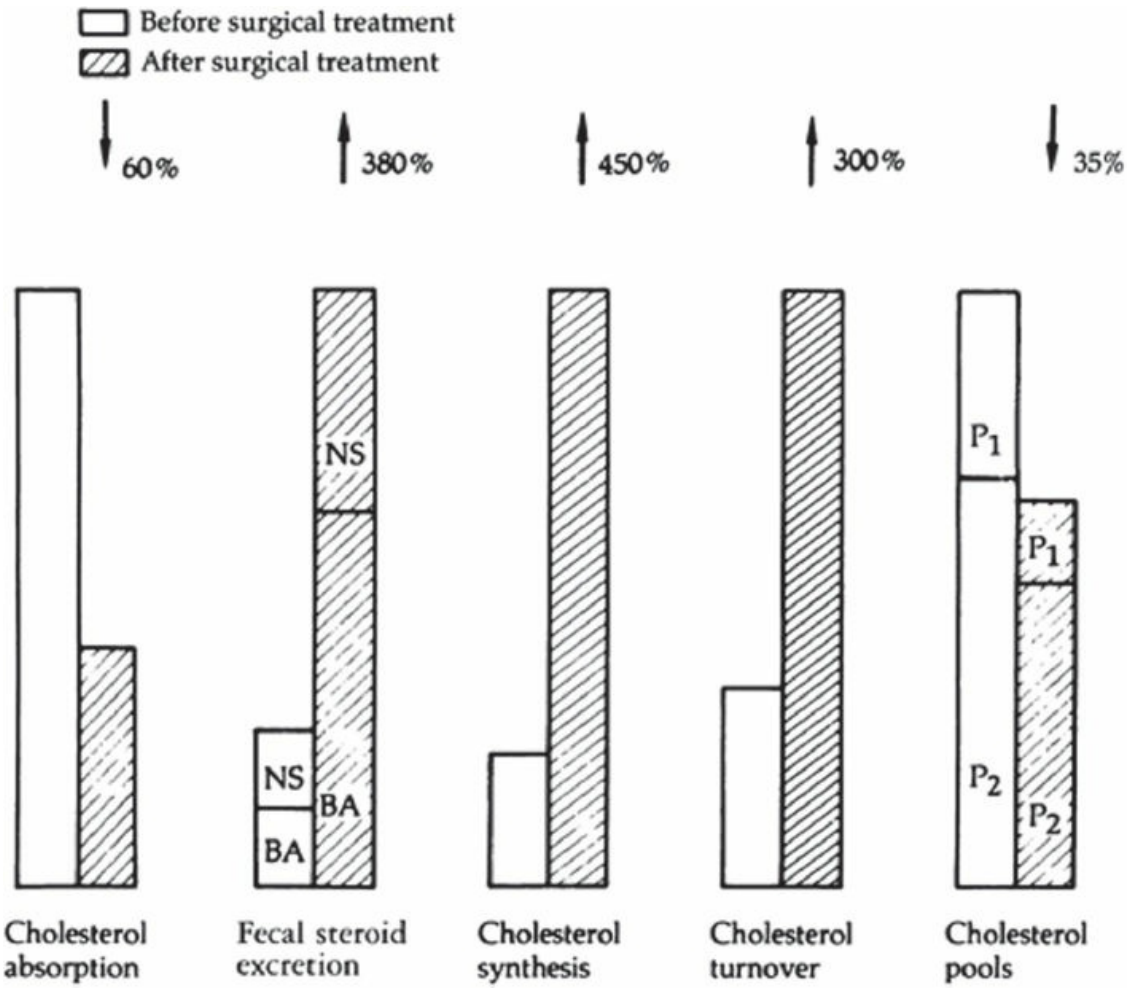

Figure 136.1. Metabolic studies in patients who underwent partial ileal bypass. Preoperative (*open bars*) and postoperative (*crosshatched bars*) values for cholesterol absorption, fecal sterol excretion, cholesterol synthesis, cholesterol turnover, and cholesterol pool sizes. NS, neutral sterols; BA, bile acids; P_1, freely miscible pool; P_2, slowly miscible pool. (From Buchwald H, Moore RB, Varco RL. Surgical treatment of hyperlipidemia. *Circulation* 1974;49(5S1):1, with permission of Wolters Kluwer Health, Inc.)

The rationale for partial ileal bypass is interference with the enterohepatic cholesterol and bile acid cycles to achieve a direct loss of cholesterol from the body and an indirect cholesterol drain by the forced conversion of part of the cholesterol pool to bile acids. This hypothesis has been confirmed in the laboratory and by clinical investigation.

In 1963 my associates and I devised a method of measuring cholesterol absorptive capacity using blood radioactivity levels after a standard oral test dose of ^{14}C-4-cholesterol in butter. In 30 patients studied before and 3

months after partial ileal bypass, the cholesterol absorptive capacity was reduced an average of 60% (Fig. 136.1). Cholesterol absorptive capacity was retested in certain of these patients at intervals throughout the follow-up period. No trend to return to the preoperative cholesterol absorptive capacity was noted. Fecal steroid excretion was measured in selected patients before and after partial ileal bypass, using an isotope balance technique after a single intravenous injection of ^{14}C-4-cholesterol. After the operation, a 3.8-fold increase was seen in total fecal sterol excretion, with a much greater increase in bile acids than in neutral steroids (Fig. 136.1). The same magnitude of sterol excretion was observed in patients studied 1 year after the operation, demonstrating the apparently lasting effect of ileal bypass on fecal sterol excretion.

Using an in vivo method for estimating cholesterol biosynthesis based on the incorporation of tritium from body water into plasma cholesterol, we showed a 5.7-fold increase in cholesterol synthesis at 3 months and at 1 year (Fig. 136.1). Direct and indirect methodologic confirmation of these results has been offered by Miettinen and Moutafis. Understandably, the isotopic cholesterol turnover rate increases approximately threefold after this procedure (Fig. 136.1). Finally, using a method similar to that of Goodman and Noble, we calculated the freely miscible, slowly miscible, and total exchangeable cholesterol pools before and 1 year after partial ileal bypass. The total miscible pool was reduced by nearly one-third, and in each patient a relatively greater reduction was seen in the slowly miscible cholesterol pool than in the freely miscible pool, which suggests a loss of cholesterol from tissues other than the blood, liver, and intestinal mucosa (Fig. 136.1).

There is also information available from the laboratory with respect to partial ileal bypass and the management of atherosclerosis. In adult and infant cholesterol-fed rabbits, my associates and I demonstrated not only prevention of atherosclerosis by partial ileal bypass but also reduction of the lipid content of established atherosclerotic plaques concurrent with their evolution from the proliferative phase to a healing phase.

ATHEROSCLEROSIS AND HYPERCHOLESTEROLEMIA

Atherosclerosis is an ancient disease. Autopsies of Egyptian mummies have disclosed severe arterial occlusive disease. From clinical obscurity through the centuries, atherosclerosis has come to the forefront during the past 50 years. Atherosclerosis today remains the most common serious

affliction in the Western world, and its complications, such as myocardial infarction and peripheral vascular disease, are the leading causes of death in industrialized countries. Approximately 600,000 deaths from coronary heart disease occur in the United States yearly. The deaths from cardiac, cerebral, and peripheral atherosclerotic cardiovascular disease in the United States account for approximately half of the national death rate, exceeding the combined rate for cancer, accidents, and all other causes. This disease is not a geriatric problem. Battlefield autopsies from Korea and Vietnam showed that 45% to 77% of young American soldiers killed in action had evidence of coronary atherosclerotic involvement.

In 1847, Vogel showed that cholesterol was a constituent of the atherosclerotic plaque lesion. Subsequently, a long succession of pathologists, clinicians, and epidemiologists have provided undeniable evidence, terminating in the prospective analyses of the last 30 years, for the tenet that circulating cholesterol concentration is a primary, if not the primary, indicator of atherosclerotic risk and more than likely a major causal agent in the formation of the atherosclerotic plaque.

The average lowering of cholesterol concentration obtained by strict dietary management is 3% to 10%. Drug therapy was equally unimpressive until the 1990s and the introduction of the 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors. These statin agents are effective, convenient, and quite safe. Reported side effects of the HMG-CoA reductase inhibitors include changes in bowel function, headaches, nausea, fatigue, insomnia, and skin rashes. Two to three percent of patients have changes in liver function tests that require discontinuation of these agents. Muscle cramps are not rare with these agents, and myositis has been reported. Rhabdomyolysis leading to acute renal failure has occurred in patients treated with HMG-CoA reductase inhibitors in combination with immunosuppressive therapy after cardiac transplantation and in patients treated with a combination of a statin and gemfibrozil.

SURGICAL TECHNIQUE OF PARTIAL ILEAL BYPASS

Open

The open technique for partial ileal bypass has remained essentially unchanged since 1963. Intestinal preparation is carried out the evening before operation, with a clear-liquid diet, nonabsorbable oral antibiotics, and cathartics; enemas are not used. The skin is antiseptically washed

preoperatively and in the operating room. An intravenous infusion is started through a central catheter and low molecular weight heparin is given. Intravenous administration of antibiotics is begun at the time of incision (2 g of a cephalosporin) and may be maintained for 24 hours after the operation.

General anesthesia is preferred to a regional block because general anesthesia provides better cardiovascular control, an advantage in these patients, who often have threatening arterial disease. Anesthesiologists prefer a gradual barbiturate induction, intubation, and light inhalation anesthesia with muscle paralysis.

Unless a concomitant procedure is planned, entrance is gained into the abdominal cavity by a right lower quadrant transverse incision approximately 2 cm below the umbilicus (Fig. 136.2). As a rule, only the right rectus muscle, the linea alba, and a few centimeters of the oblique muscles are divided. General hemostasis and muscle division are performed with the cautery; the inferior epigastric vessels are ligated. The abdomen is carefully explored, and the nasogastric tube placed by the anesthesiologist in the operating room is appropriately positioned along the greater curvature of the stomach by the surgeon, who stands on the right side of the operating table. Antibiotic-soaked laparotomy pads are inserted along the edges of the incision, and a plastic wound protector (5-in diameter) is placed.

The cecum is delivered into the operative field. On occasion, this necessitates cutting the peritoneal reflection at the white line of Toldt posterior and inferior to the cecum and the terminal ileum, and gentle retroperitoneal freeing of these structures. The appendix, if still present, is removed, with ligature of the appendiceal mesenteric vessels, ligature of the stump with 3-0 chromic catgut, inversion of the stump with a 4-0 nonabsorbable purse-string suture, and reinversion of the area with a 4-0 Z stitch.

The small intestine is next delivered into the field and measured with a marked umbilical tape knotted every 25 cm. The tape is placed along the mesenteric border of the intestine because this surface is less variable in its dimensions than the antimesenteric length. When the operator, measuring retrograde from the ileocecal valve, reaches 200 cm (Fig. 136.3), he or she places marking sutures of different colors through avascular windows in the mesentery and around the intestine. Measurement is then continued to the ligament of Treitz, and 25 cm is added for the duodenum to obtain the

total length of small intestine. In my experience, the intestinal length has varied from 400 to 700 cm. If the measurement is greater than 600 cm, the marking sutures are moved 50 cm cephalad and the segment to be bypassed is increased from 200 to 250 cm.

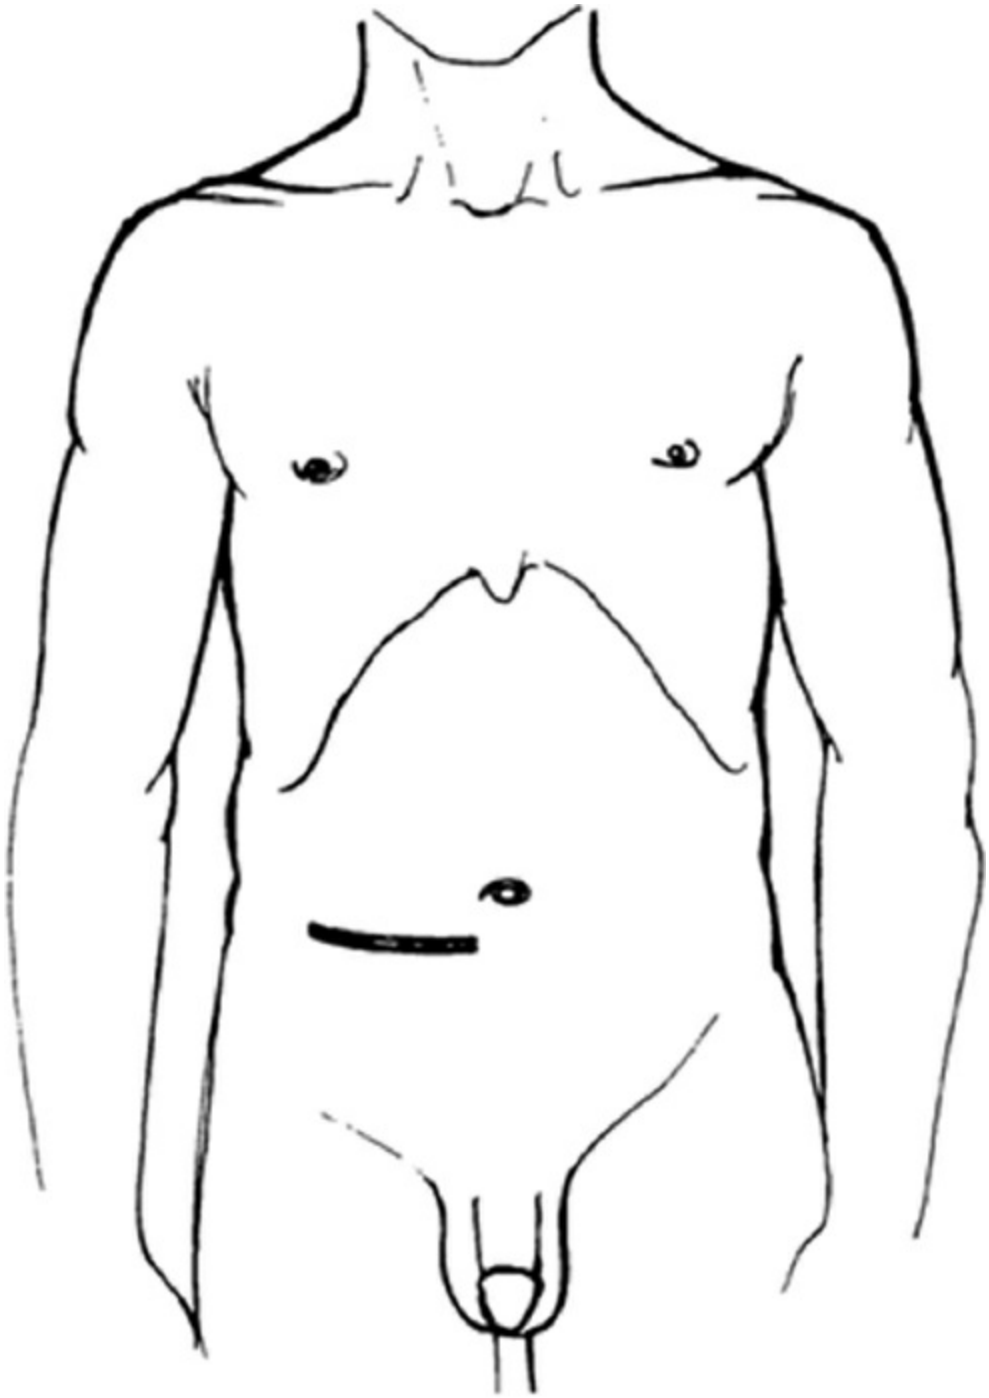

Figure 136.2. Standard incision site for partial ileal bypass.

Between the different-colored marking sutures, a small area of mesentery is cleared, with 5-0 Tevdek (braided polyester, Teleflex

Medical, Mansfield, MA) ligature of mesenteric vessels if necessary. A Dennis clamp is placed straight across the prepared intestine on the distal side, and a Kocher–Allen clamp is placed at a slight angle on the proximal aspect (Fig. 136.4). The small intervening segment of intestine is resected, and the ends of the intestine are cauterized at the clamp margins.

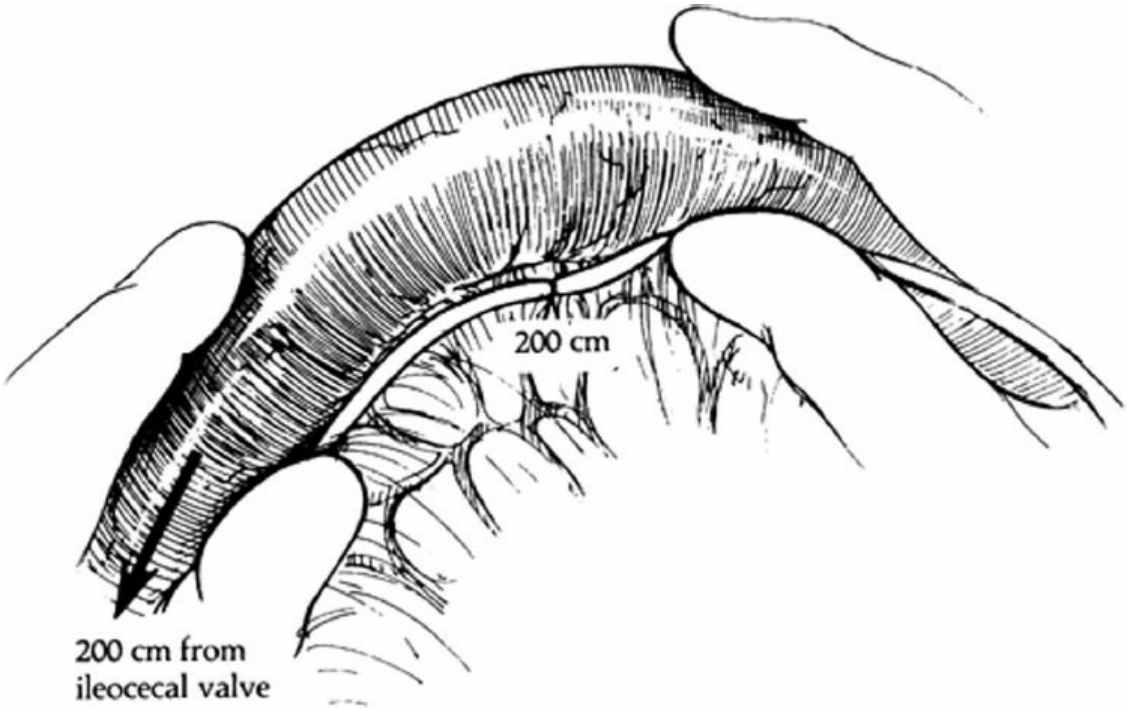

Figure 136.3. Measurement of the small intestine.

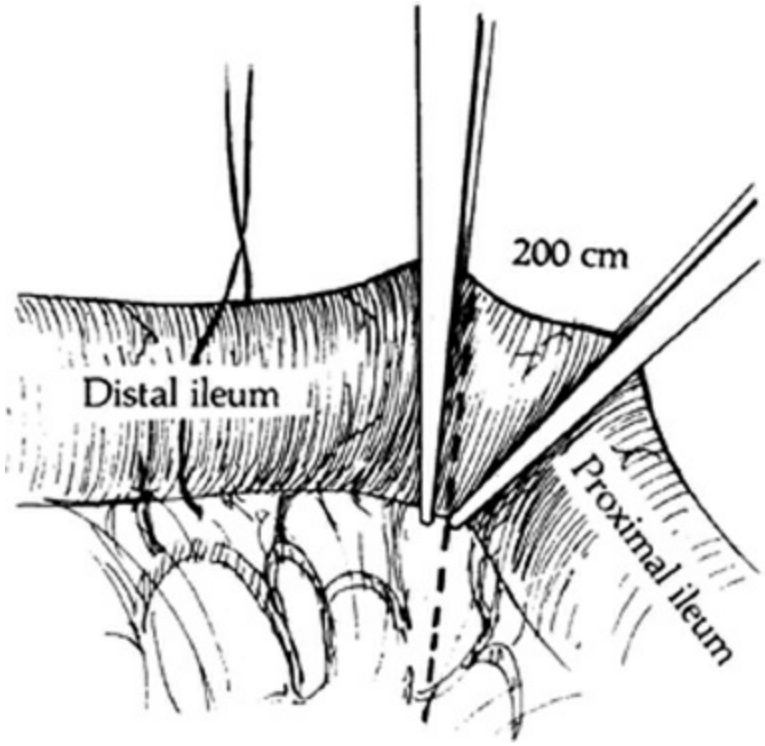

Figure 136.4. Division of the intestine.

The distal end of this division, or what is to become the proximal end of the bypassed segment, is closed in two layers. I prefer an inner row of 4-0 absorbable Vicryl (polyglactin 910, Ethicon, Inc, Somerville, NJ) sutures, taken in a Parker–Kerr manner, and an outer reinverting row of interrupted 5-0 Tevdek sutures. The two corner and the middle sutures are not cut but are retained for future tacking of the closed end of intestine (Fig. 136.5).

Anastomosis is then accomplished between the proximal small intestine and the cecum. The cecum is retained to maximize the water-absorbing surface, and anastomosis is made distal to the ileocecal valve to minimize ileal retention of cholesterol and bile acids and their resorption. Anastomosis is made in an end-to-side manner on the anterior taenia approximately 6 cm above the inverted appendiceal stump (Fig. 136.6). I use a two-layer open anastomosis. The posterior row of interrupted 5-0 Tevdek sutures is placed and, except for the corners, tied and cut. The crushed portion of the ileum is cut off sharply with the clamp, and hemostasis of the fresh surface is obtained by careful use of the cautery. An equidistant incision is made into the cecum, approximately in the middle of the taenia. A whip-lock inner row of 4-0 Vicryl (Ethicon, Inc, Somerville, NJ) sutures is started in the inferior corner, run to the upper corner, taken around the upper corner, and run back in the Connell manner. The anastomosis is then completed by an anterior row of interrupted 5-0 Tevdek sutures in the Lembert manner, with reinforcement of both corners (Fig. 136.7).

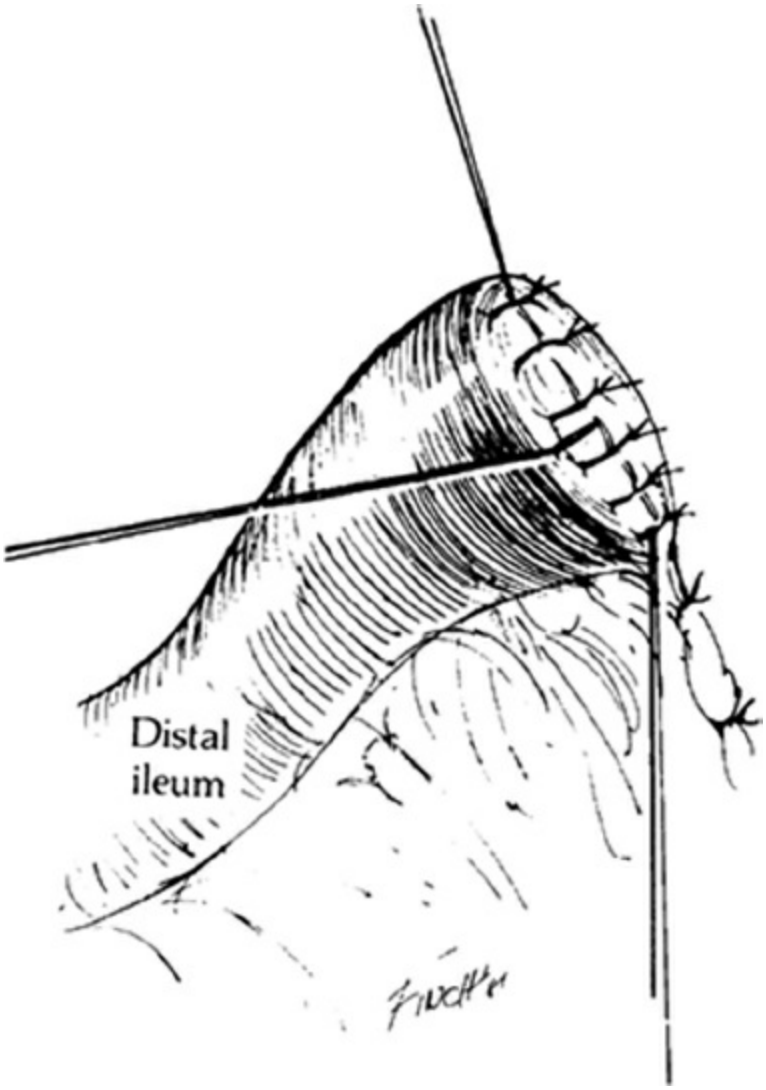

Figure 136.5. Closed end of bypassed segment.

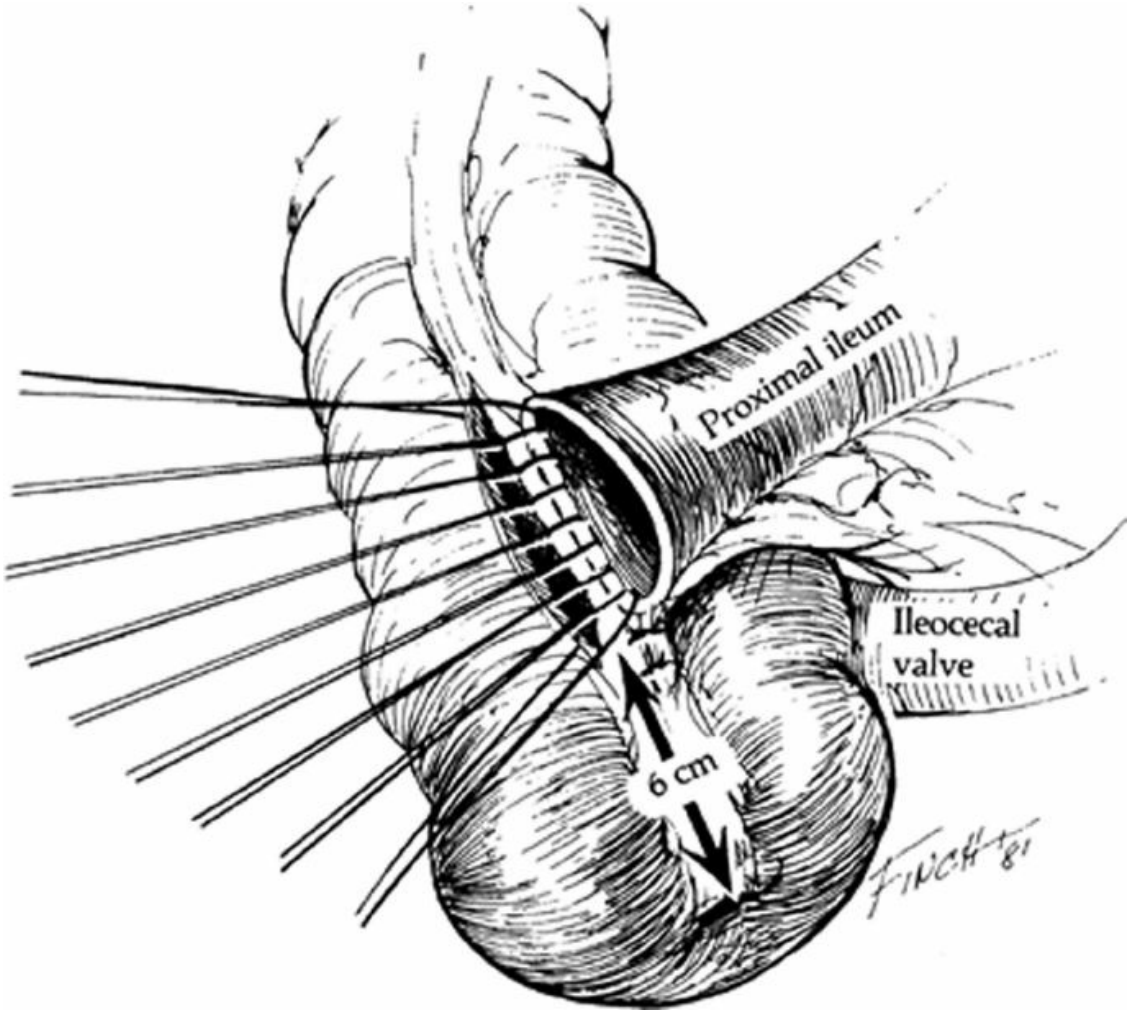

Figure 136.6. Start of end-to-side anastomosis.

The procedure is completed by tacking, with the previously retained sutures, the proximal end of the bypassed segment between the anastomosis and the appendiceal stump, to prevent future intussusception. The small divisional and the large rotational mesenteric defects are carefully closed with interrupted 5-0 Tevdek sutures to prevent internal herniation (Fig. 136.8). The rotational mesenteric defect can be defined by placement of the left hand of the operator below the ileocecostomy and the tacked upper segment of the bypassed intestine.

Surgeons and the scrub nurse change gloves and gowns, and closure is carried out using a separate set of instruments. Closure is done in layers after thorough irrigation with saline solution and antibiotic solution. For the fascial closure, I prefer 00 Tevdek; for the subcutaneous tissues, 2-0 Vicryl; for the skin, a running 4-0 subcuticular Monocryl. No drains are used. A light dressing is applied.

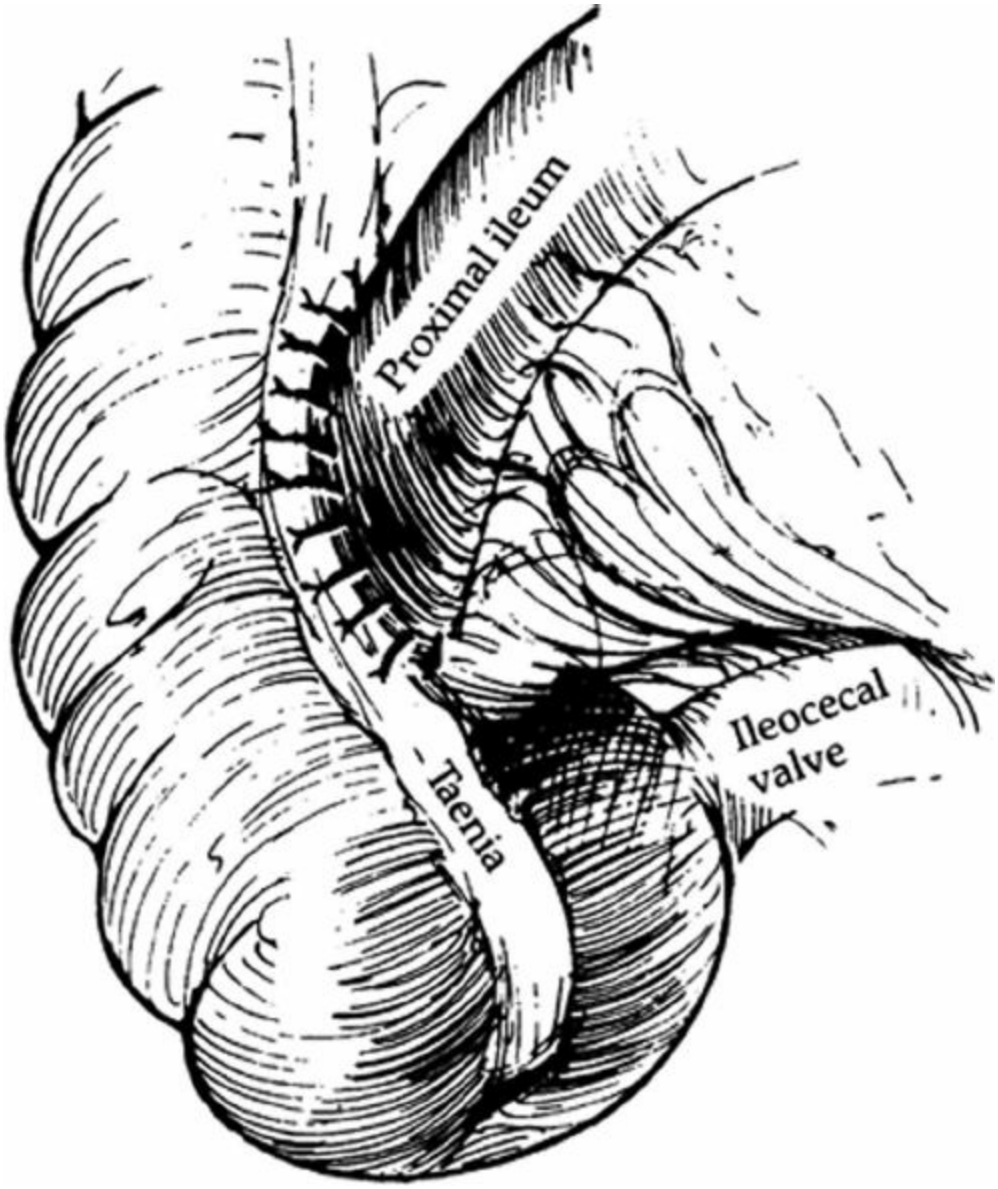

Figure 136.7. Completion of two-layer open anastomosis.

Postoperatively, the patient, as a rule, is extubated in the operating room and may be maintained overnight in the intensive care unit for cardiac monitoring. Early ambulation is instituted, intravenous antibiotics may be maintained for approximately 24 hours, and careful fluid and respiratory management is practiced. The nasogastric tube is removed after demonstrable intestinal activity is present, and diet can usually be progressed rapidly. On the average, the patient is discharged on the 3rd or 4th postoperative day.

Laparoscopic and Stapling

When partial ileal bypass was described and gaining acceptance, there was

no laparoscopic surgery and stapling of intestine was not practiced. Today, a partial ileal bypass can be performed laparoscopically via a 5 to 6 port exposure, using laparoscopic instruments and staples, with essentially the same technical outcome as the open approach.

Further, the procedure can be done by open surgery using stapling instruments. The initial ileal division can be carried out with an intestinal linear stapler; the ileocecostomy can be constructed with the intestinal linear stapler in a side-to-side manner. I have always oversewn all my staple lines with inverting 5-0 nonabsorbable sutures taken in the Lembert manner. This precaution sacrifices speed for safety and a leak-free record for primary intestinal anastomoses.

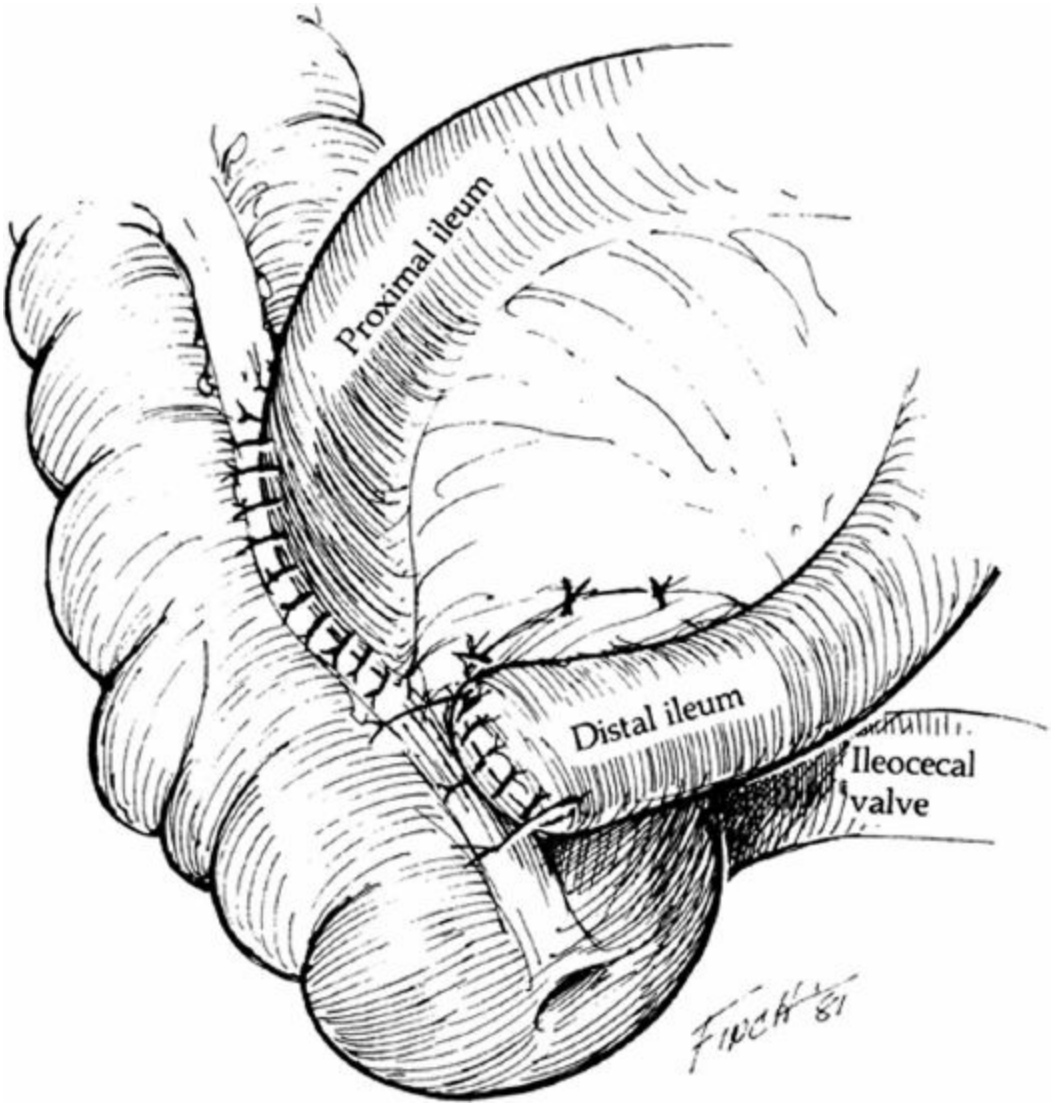

Figure 136.8. Tacking of closed end of bypassed segment and closure of mesenteric defects.

>

Micro-orifice

In 2009, we successfully introduced in the experimental laboratory the micro-orifice technique under intravenous sedation with Propofol and supplemental local anesthesia, and no general anesthesia, abdominal insufflation, and endotracheal intubation. In essence, this approach permits the performance of abdominal surgery, using a 6–7 cm incision, with exteriorization of the bowel and/or laparoscopic instruments and hand assistance. It allows for rapid postoperative recovery and for essentially the same-day or overnight surgery. Metabolic/bariatric sleeve gastrectomies and implantation of stimulating gastric electrodes are being performed clinically in 2011. This approach can readily be utilized for the partial ileal bypass procedure.

SPECIAL SURGICAL CONSIDERATIONS

Approach for Cholecystectomy

When a concomitant cholecystectomy is planned, a supraumbilical transverse or a midline incision is suitable, or laparoscopic technique can be employed. As a rule, for open surgery only a right-sided transverse incision is needed; however, additional superior and inferior exposure can be gained by extending the incision to the left of the midline.

Approach for Pelvic Gynecologic Operations

Although I have performed pelvic gynecologic operations such as tubal ligation and resection and hysterectomy in association with a partial ileal bypass infrequently, I prefer the infraumbilical incision, with extension to the left of the midline when necessary.

Approach for Arterial Operations

Aortic, renal, and iliac arterial reconstructive procedures can be performed, when indicated, concurrently with a partial ileal bypass, if no prosthetic material is used. A transverse infraumbilical incision is usually adequate. The recommendation is that the arterial operation, such as endarterectomy, be done before the intestinal bypass. If a prosthetic graft is used, the partial ileal bypass operation should not be done at the same time. An imminent vascular threat dictates that initial consideration be given to the arterial

operation. If the decision between an arterial operation and the partial ileal bypass is elective, I prefer doing the intestinal procedure first, so that any risk of contamination of the vascular field is avoided.

CLINICAL RESULTS WITH PARTIAL ILEAL BYPASS

Cholesterol

In the original patient series, the average reduction in cholesterol level after partial ileal bypass, from the preoperative but postdietary baseline of 359 mg per 100 mL, was 41.4%. All patients had had appropriate dietary therapy for at least 3 months before the operation; the operation was effective in patients with poor or no response to previous diet or drug programs.

The mean cholesterol reduction in this series for a 9-year follow-up interval is plotted in Figure 136.9. The plasma cholesterol reduction can be seen to have remained essentially unchanged over this entire time span, which indicates the lasting effect of the procedure.

In 1968, my associates and I reported on a study of 24 heterozygous type II patients with an average premanagement plasma cholesterol concentration of 423 mg per 100 mL. Three months after judicious adherence to a stringent low-cholesterol, low-saturated fat diet, an average reduction of 11% in circulating cholesterol was achieved. The average plasma cholesterol level of this cohort 1 year after partial ileal bypass was 224 mg per 100 mL, which represents an additional 42% lowering of the average plasma cholesterol level. Thus, the combination of dietary and partial ileal bypass management is capable of essentially halving the cholesterol concentration (Fig. 136.10).

Results in homozygous type II patients, on the other hand, were disappointing. The postoperative cholesterol levels in our three homozygotes were only 13%, 20%, and 21% below their preoperative values. Balfour and Kim, however, reported better results in two type IIA children: a 42% and a 33% sustained cholesterol reduction for more than 3 years. Other investigators reporting on the use of partial ileal bypass have had clinical results similar to ours, with an average cholesterol lowering of approximately 40%.

My associates and I have published the lipid results of POSCH. Of the 838 participants, 734 (348 control and 386 surgery patients) completed a 5-year lipoprotein evaluation. After partial ileal bypass, the total plasma cholesterol level decreased 23.3% ± 1.0% (mean ± standard error of the

mean) and the low-density lipoprotein cholesterol level fell 37.7% ± 1.2%, in comparison with control values. A significant increase in the high-density lipoprotein cholesterol level of 4.3% ± 1.8% also occurred. The apolipoprotein B-100 level was significantly lower and the apolipoprotein A-1 and high-density lipoprotein 2 levels were significantly higher in the surgical group—all favorable lipoprotein modifications.

Triglycerides

The available triglyceride data are not as extensive as those for cholesterol; nevertheless, marked changes in triglyceride concentration have been well documented. The type IV patients, all with elevated preoperative plasma triglyceride levels, sustained an average reduction of 52%; the response in patients with mixed-type hyperlipoproteinemia was 30% at 1 year; and in the type IIB patients (those with hypertriglyceridemia accompanying hypercholesterolemia), I have seen an average lowering of the circulating triglyceride concentration by 17%. On the other hand, in the type IIA patients, those hypercholesterolemic patients with low or normal preoperative triglyceride concentrations, a paradoxic increase in triglyceride levels of 21% has been seen at 1 year, although even with this increase the average level has remained within the accepted normal range. In POSCH, an average increase in triglyceride level of 19.8% ± 6.5% was observed at 5 years.

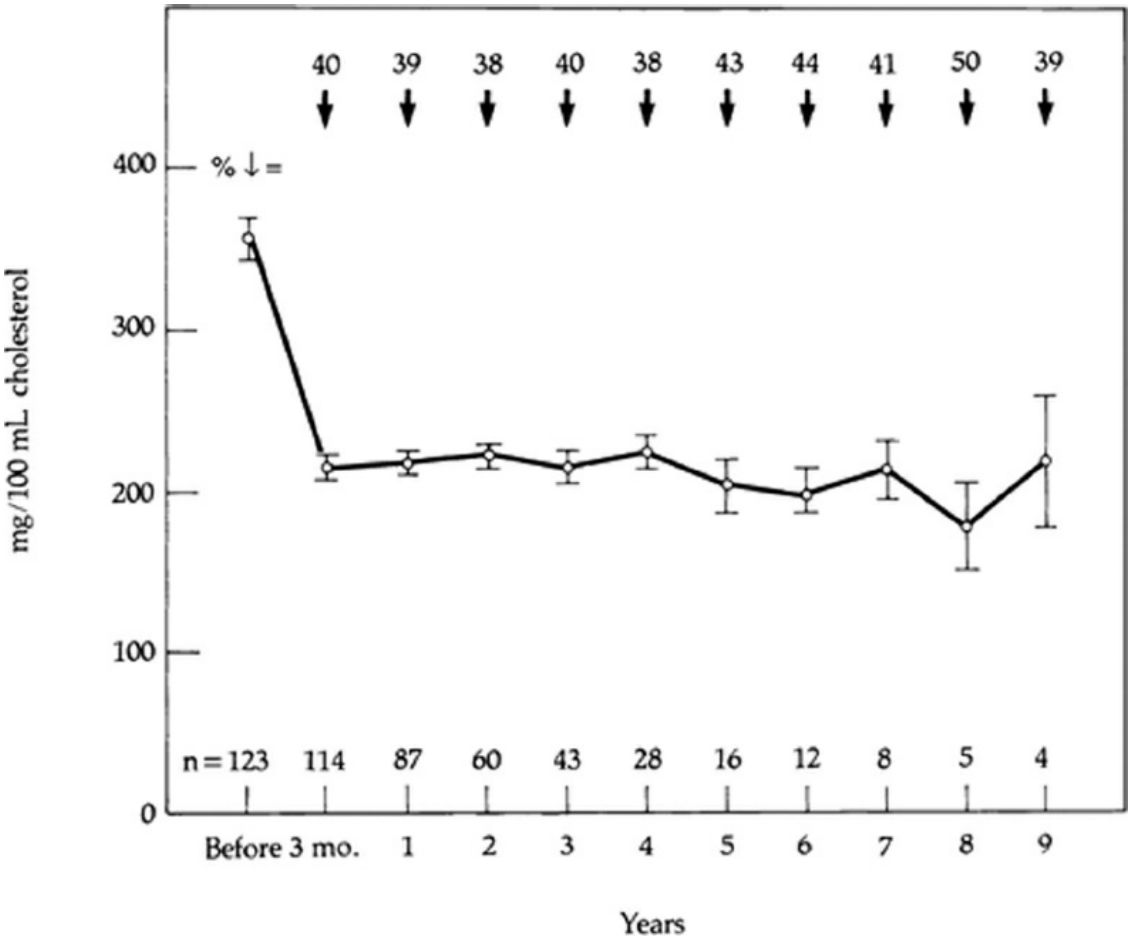

Figure 136.9. Average plasma cholesterol concentrations before and after partial ileal bypass (±1 standard deviation), excluding three homozygous type II patients. Number of patients (*n*) at each time interval is given. (From Buchwald H, Varco RL, eds. *Metabolic Surgery*. New York: Grune & Stratton, 1978, with permission.)

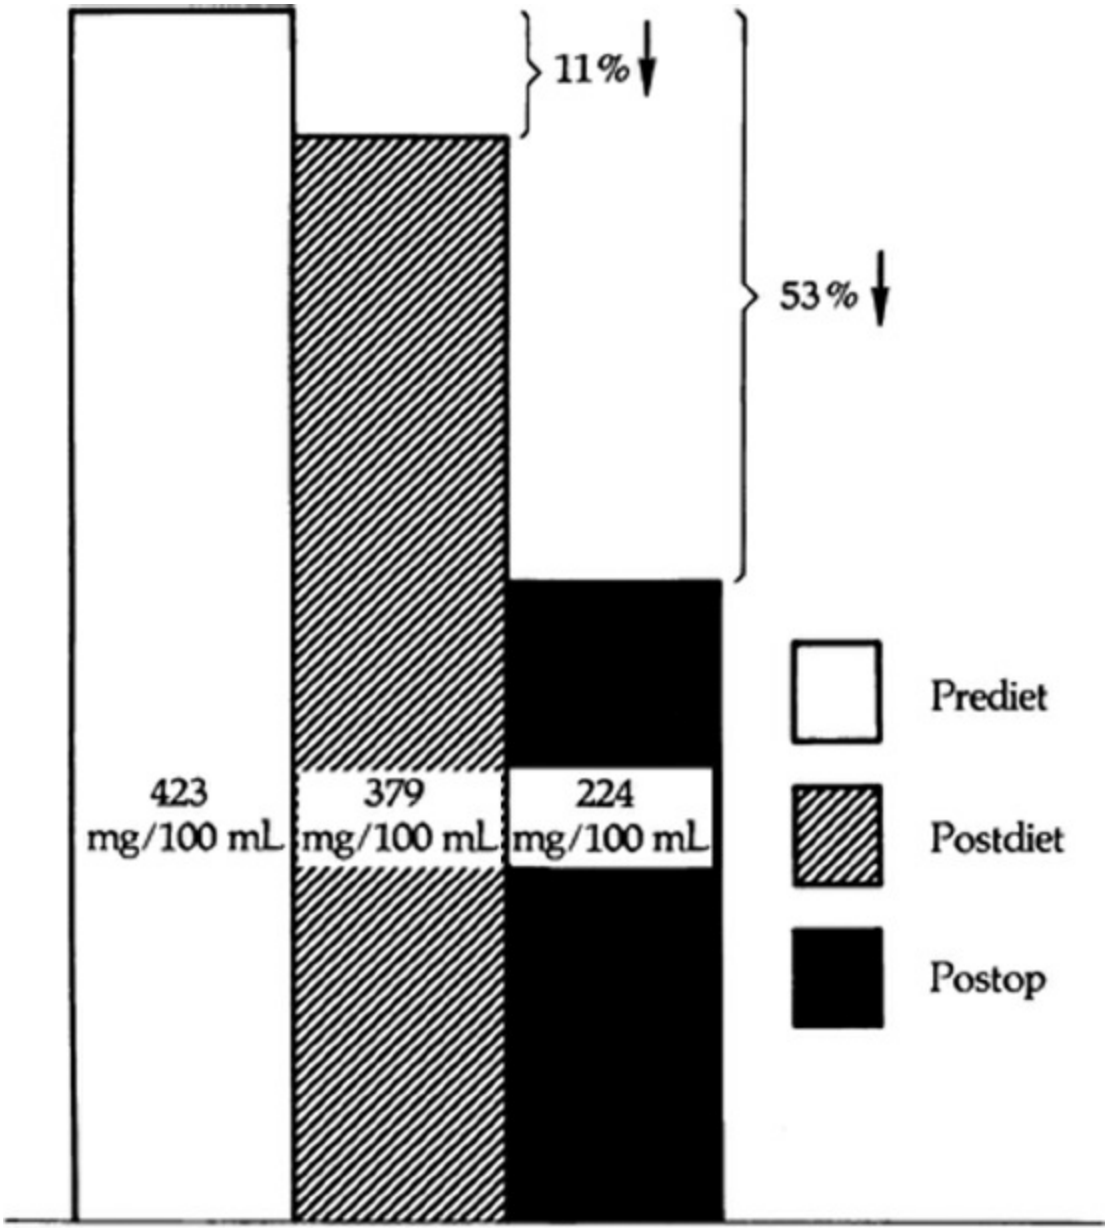

Figure 136.10. Effect of cholesterol-lowering diet and partial ileal bypass on plasma cholesterol levels in 24 type II patients. (From Buchwald H, Moore RB, Varco RL. Surgical treatment of hyperlipidemia. *Circulation* 1974;49(5S1):1, with permission of Wolters Kluwer Health, Inc.)

MORTALITY AND MORBIDITY

Among our patients, one postoperative death occurred, from a myocardial infarction; this yielded an immediately postoperative mortality for partial ileal bypass of well below 1%. An immediately (30-day) postoperative death has not been reported in any other series. Thus, this operation, although often performed in persons with compromised coronary vessels, is safe.

Most patients experience some degree of diarrhea after partial ileal bypass. One year or longer after the procedure, 85% of my patients had fewer than five stools per day when not taking bowel-controlling drugs. With time, patients report an improvement in firmness and consistency of stools.

Occasionally, we have seen the development of a gas-bloat syndrome. A brief course of metronidazole followed by long-term use of this antianaerobe (one 250-mg tablet daily) has usually given total relief.

Minimal long-term weight change is engendered by partial ileal bypass, in sharp contradistinction, of course, to the jejunoileal bypass or other bariatric surgery procedures. No change in serum electrolyte concentrations has been recorded. Vitamin B_{12} absorption may be regained by some patients some time after the operation. This is unpredictable, however, and I have prescribed parenteral administration of vitamin B_{12} routinely every 2 months.

In the POSCH study, we were made aware of an increased incidence of oxalate kidney stones in patients who have had a partial ileal bypass. A controlled trial to test the efficacy of citrate administration in preventing this problem is warranted; preliminary results have been promising. In addition, all patients are recommended to decrease oxalate in the diet and maintain adequate fluid intake.

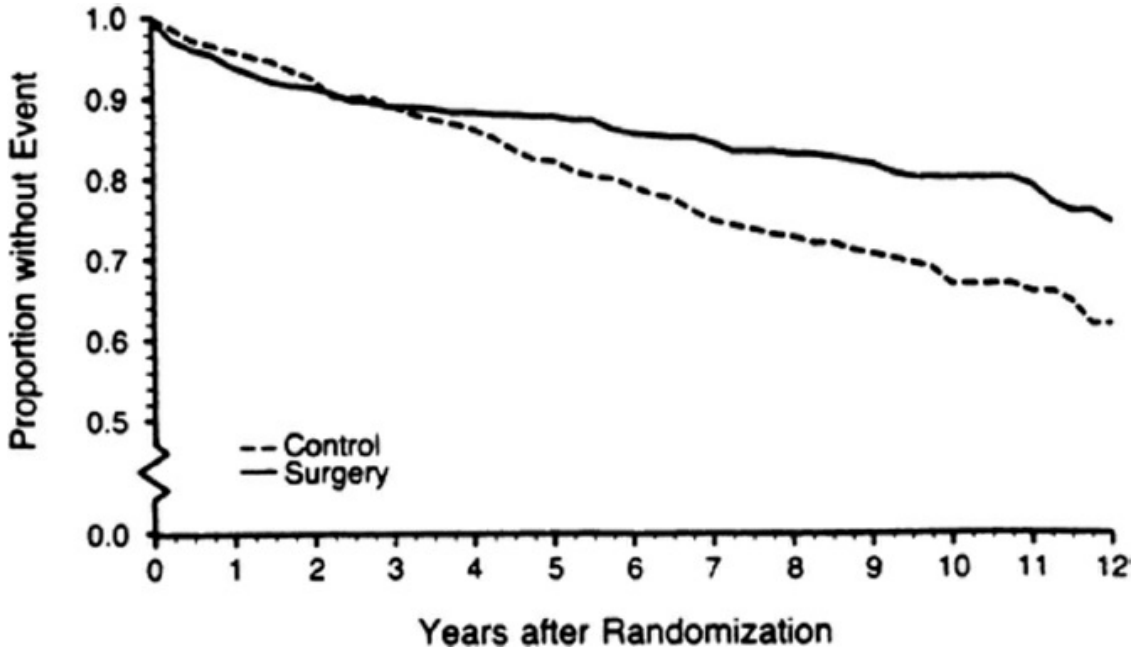

Figure 136.11. Combined end point of death from coronary heart disease and confirmed nonfatal myocardial infarction in the control and partial ileal bypass groups in the Program on the

Surgical Control of the Hyperlipidemias. (From Buchwald H, Varco RL, Matts JP, et al. Effect of partial ileal bypass surgery on mortality and morbidity from coronary heart disease in patients with hypercholesterolemia. *N Engl J Med* 1990;323(14):946. Copyright © 2017 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)

Long-Term Mortality

In the POSCH study, analysis of the combined end point of death from coronary heart disease and confirmed nonfatal myocardial infarction showed a 35.0% reduction in risk ($P < 0.001$) at formal trial termination on July 19, 1990 (Fig. 136.11). All other mortality analyses in POSCH combining overall mortality or coronary heart disease mortality with confirmed or suspected nonfatal myocardial infarctions and episodes of unstable angina showed comparable reductions in risk, with highly significant *P* values. In a data-derived, subgroup analysis, the study population was divided into two groups according to left ventricular ejection fraction. In the subgroup with an ejection fraction of 50% or higher, a 36.1% reduction in overall mortality ($P = 0.052$) was obtained. In the 1990 POSCH analysis, the differences for the end points of overall mortality and mortality from atherosclerotic coronary heart disease did not reach statistical significance.

At 5 years after the trial, statistical significance was obtained for differences in overall mortality ($P < 0.049$) and mortality from atherosclerotic coronary heart disease ($P = 0.03$). Long-term follow-up results for the other POSCH end points included overall mortality in patients with a left ventricular ejection fraction of 50% or higher ($P = 0.01$), mortality from atherosclerotic coronary heart disease in patients with a left ventricular ejection fraction of 50% or higher ($P = 0.05$), mortality from atherosclerotic coronary heart disease and confirmed nonfatal myocardial infarction ($P < 0.001$), confirmed nonfatal myocardial infarction ($P < 0.001$), mortality from atherosclerotic coronary heart disease, confirmed and suspected myocardial infarction, unstable angina ($P < 0.001$), incidence of coronary artery bypass grafting or percutaneous transluminal coronary angioplasty ($P < 0.001$), and onset of clinical peripheral vascular disease ($P = 0.02$). No statistically significant differences were seen between groups with regard to cerebrovascular events, mortality from nonatherosclerotic coronary heart disease, and cancer.

In 2010, we published the 25-year mortality follow-up in POSCH using the POSCH database, supplemented by the 2006 National Death Index. The difference between the control and surgery groups in the restricted mean survival and the logrank (Mantel-Haenszel) statistics were statistically significant, with survival probabilities of 0.57 (surgery group) and 0.51 (controls). Cause of death data indicated a significant increase in cardiovascular deaths in the control group; cancer deaths were also greater in the control group but this was not significant. The most compelling subgroup analysis was a significant increase in survival, starting at 5 years after randomization, in the surgery group for patients with an ejection fraction ≥50%, with relative probabilities of 0.61 (surgery) and 0.51 (control). The estimated incremental increase in years of life expectancy over 25 years of follow-up was, in a sense, disappointing, with 1.0 year overall and 1.7 years in the cohort with an ejection fraction ≥50%. Yet, to the individual patient, this increase in survival was more than a statistically significant outcome; it represented a significant time increment with a better quality of life less encumbered with cardiovascular morbidity.

Xanthomata

I have noted a decrease in size and disappearance of periorbital xanthelasma, subcutaneous xanthomata, and even tendon xanthomata after partial ileal bypass. This phenomenon has not been uniform or predictable; however, it has been reported by others.

Angina Pectoris

Approximately 70% of patients with preoperative angina state that this symptom is reduced or disappears within weeks after the bypass procedure. The specific cause for mitigation of hypoxic symptoms remains unknown, but data relate this finding to an improvement in oxygen release by red blood cells subsequent to cholesterol lowering.

Cardiac Procedures

During the formal POSCH trial, coronary artery bypass grafting was performed in 137 control group patients and 52 surgery group patients ($P < 0.0001$). Repeat operations were required in nine control group patients and two surgery group patients. In addition, 33 control group patients and 15 surgery group patients underwent percutaneous transluminal coronary

angioplasty with or without coronary artery bypass grafting ($P = 0.005$). Three control group patients and two surgery group patients underwent cardiac transplantation. The total number of cardiac procedures in the surgery group was reduced 62% ($P < 0.0001$) compared with the control group. Again, this trend persists to the present.

Arteriographic Results

In POSCH, coronary artery disease progressed in patients in both the control group and the surgery group. However, the percentage of patients with progression was consistently greater in the diet-treated control group than in the group treated with partial ileal bypass and diet: 41% versus 28% at 3 years, 65% versus 38% at 5 years, 77% versus 48% at 7 years, and 85% versus 55% at 10 years ($P < 0.001$ for all comparisons). Furthermore, statistically significant evidence ($P < 0.01$) for angiographic coronary artery disease regression was observed at 5- and 7-year follow-up. In addition, we demonstrated in POSCH that coronary arteriographic changes can be used in atherosclerosis intervention trials as a limited surrogate end point for certain clinical coronary events. This relationship is statistically compelling for overall mortality and coronary heart disease mortality. For an individual patient, changes in the severity of coronary atherosclerosis seen on sequential coronary arteriograms can serve as a prognostic indicator for subsequent coronary events.

CONCLUSIONS

A prominent field in surgery today is metabolic surgery. Partial ileal bypass was a primary example of a metabolic operation; the various bariatric surgery procedures have catapulted metabolic surgery into the national spotlight.

Until the 1990s, partial ileal bypass was the only effective, lasting, and safe means of treating hypercholesterolemia. Subsequently, effective lipid reduction therapy has entered the era of the statin drugs. The results of several excellent drug trials have been comparable with the POSCH findings: reductions of 25% in total plasma cholesterol and 35% in low-density lipoprotein cholesterol in the secondary intervention Scandinavian Simvastatin Survival Study and reductions of 20% in total plasma cholesterol and 26% in low-density lipoprotein cholesterol in the primary intervention West of Scotland study.

Partial ileal bypass, however, remains a therapeutic alternative for

patients for whom various drug regimens have failed or who have experienced toxic effects from drug protocols. We perform several such operations annually, and I have been asked to consult by other surgeons on appropriate lipid therapy, using the partial ileal bypass, when the statin drugs have not proven to be efficacious.

The bariatric surgery procedures, as a rule, markedly reduce plasma total cholesterol and low-density lipoprotein cholesterol. This was clearly indicated in a meta-analysis by Buchwald et al. published in *JAMA* in October 2004. There are morbidly obese patients, however, in whom hypercholesterolemia is of such concern that the primary intervention should consist of a bariatric procedure and a partial ileal bypass. Here I would recommend combining the partial ileal bypass with a strictly restrictive procedure—either vertical banded gastroplasty or laparoscopic adjustable gastric banding.

In retrospect, the POSCH legacy among lipid atherosclerosis trials includes the following: it was the first trial to demonstrate clinical benefits of hypercholesterolemia management, including a statistically significant reduction in overall mortality, the longest follow-up trial (more than 20 years), a trial with both clinical and arteriographic findings that demonstrated the validity of changes observed on serial coronary arteriograms as end points for clinical events, a trial demonstrating benefits in peripheral vascular disease, and a trial supported by public monies through a National Heart, Lung, and Blood Institute grant.

In conclusion, the surgeon has a major role in managing hypercholesterolemia and, even more so, in demonstrating that doing so can result in the prevention, retardation, arrest, and reversal of atherosclerotic disease.

EDITOR'S COMMENT

This experiment, and that is what it is, needs to be taken as a landmark in human experimentation, which actually has been able to show based on metabolic principles that patients with hypercholesterolemia can be dealt with from the standpoint of absorption and their ability to minimize their hypercholesterolemia. Professor Buchwald in the *Annals of Surgery* (251:1034–40) has reported the 25-year incremental life expectancy of intestinal partial ileal bypass and the cause of death in the Program on the Surgical Control of the Hyperlipidemias (POSCH). The POSCH is a randomized controlled trial in

which there are approximately 838 patients; 421 were randomized to surgery and 417 for control. At 25 years follow-up, the restricted mean survival rate was statistically significant with a survival probability of 0.57 in surgery and 0.51 in controls. Cancer deaths were also greater in the control group, but this was not statistically significant. The improvements in survival rate started approximately 5 years following randomization and the expected incremental increase in life expectancy over more than 25 years was unfortunately only 1-year overall life expectancy and in the cohort with an ejection fraction of greater than 50%, it was 1.7 years. As the author says in this very well-written chapter, it is particularly unfortunate that the advantage is only modest but it is at least an attempt to reduce mortality due to hyperlipidemia.

These patients, however, remain heavy and with morbid obesity and an attempt to deal with both the hyperlipidemia and the morbid obesity, Auyang et al. (*Obes Surg* 2009;19:121–4) chose a patient who had a body mass index (BMI) of 45, a 56-year-old female, who underwent both a laparoscopic Roux-en-Y gastric bypass and a partial ileal bypass in 2002. She had sustained excess body loss and her lipid profile has approached normal ranges, albeit with less medication. She experienced no comorbidities related to surgery or hyperlipidemia. The authors conclude that this, in fact, may be the best option for a patient who was morbidly obese and who has hyperlipidemia. I agree with this recommendation. As Professor Buchwald has shown in his long-term 25-year follow-up study, the survival rate is somewhat disappointing with the ileal bypass alone. Nonetheless, it is a start and this “experiment” on humans shows that there may be a better way (gastric bypass) in addition to jejunoileal bypass to ensure prolonged survival.

Ashrafian et al. (*Obes Rev* 2010;11:907–20) summarizes the history of metabolic surgery including both ileal bypass in humans and rodent models and biliopancreatic diversion. It may be that the POSCH study may be the best and earliest program for jejunoileal bypass, but in fact, it has not been the only study. They also point out, how in this particular study, that a number of the operations that have been developed and carried out such as biliopancreatic diversion, adjustable gastric banding, sleeve gastrectomy, and Roux-en-Y gastric bypass have all had experimental studies carried out on experimental animals to devise the operation, which will hopefully be put into place. Not all of the experiments that are carried out in humans worked out as one would hope. For example, the drop of cholesterol from 40% to 75% was shown by partial ileal bypass in white New Zealand rabbits (Buchwald H et al., *Surg Clin North Am* 1967;47:1353–62 and Tijerina O et al., *Surgery* 1988;104:796–805). Regrettably, the results in humans have not proven to be as good as those in rabbits. Atherosclerosis in white New Zealand rabbits appears to be a much more dangerous disease and leads to atherosclerotic lesions much more readily in rabbits than in humans; hyperlipidemic rabbits showed both a decrease in cholesterol and a parallel drop in atherogenesis (Niekirk JL, *Atherosclerosis* 1983;48:242–52). Although the rabbits showed such a parallel increase in

atherogenesis, apparently this did not happen in humans. However, this does not negate the value of the POSCH study that took an enormous expenditure of effort by Professor Henry Buchwald and had a profound effect on all areas of the scientific endeavor including all experiments on humans. It is true that the life expectancy has been disappointing, but it does not negate the value of the studies. As the authors conclude, further insights from these animal models can reveal genetic and molecular systemic effects and obviously they are also concerned about the risk of diabetes, heart disease, and cancer.

Finally, Professor Buchwald and coworkers have continued their research in trying to have new models of metabolic/bariatric surgery, which does not require general anesthesia. In a porcine feasibility study (Buchwald H et al., *Obes Surg* 2010;20:500–5), they have shown that one can do a micro-orifice bariatric surgery under IV sedation in pigs, and thereby achieve a laparoscopic approach to bariatric and experimental obesity surgery. The outcomes of this, I am certain, will bear fruit with various experiments and I wish Professor Buchwald continued success in his various attempts to bring metabolic surgery into its own and enable patients to be benefitted by using animals as experimental subjects before attempting this in humans.

137 The Continent Ileostomy

Eric J. Dozois and Roger R. Dozois

This Chapter can be accessed in the accompanying eBook edition (see inside front cover for access instructions).

INTRODUCTION

The continent reservoir ileostomy, commonly referred to as the *Kock pouch*, comprises an internal ileal reservoir that stores stool and gas between intubations, a stoma and outflow tract needed to intubate and evacuate the contents of the reservoir, and a surgically created biologic valve interposed between the other two components to act as a pressure barrier and provide continence. The major advantages of this operation over the conventional spout ileostomy are the elimination of the necessity for the patient to continually wear an external appliance and a much less conspicuous stoma.

HISTORICAL BACKGROUND AND RATIONALE

Although patients and their caregivers recognize the benefits of proctocolectomy and Brooke ileostomy, a curative operation that restores the patient's health, it has become evident that for many ileostomates, the need to constantly wear an external appliance to collect the effluent of an incontinent stoma can interfere with some of their daily activities and their social life, and can be detrimental to their overall quality of life. Also, the material necessary to pouch the stoma is expensive. Although an incontinent Brooke-type stoma is acceptable to most ostomy patients, primarily because they regain their general health, as many as 40% of these patients long for a better alternative. By surgically devising an internal reservoir capable of collecting the bowel contents and by rendering it continent by adding a valve mechanism so that patients no longer have to wear an external appliance, Nils Kock of Göteborg, Sweden, revolutionized the concept of surgically created continence and unknowingly paved the way for the ileal pouch anal anastomosis.

The construction of an intestinal reservoir to substitute for the loss of rectal capacity evolved rapidly when a U-shaped, double-folded reservoir was designed by Kock and his colleagues. The means to achieve continence, however, were slower to evolve. At first, Kock hoped that continence could be achieved by external compression of the outflow tract brought through the rectus abdominis muscle, but this proved unreliable. Interposition of an antiperistaltic segment of ileum between the reservoir and the stoma also proved inefficient. In 1972, Kock ingeniously devised the intussusception ileal valve, the so-called nipple valve, using an isoperistaltic portion of the outflow tract, which resulted in a far more reliable continence mechanism.

A number of technical refinements were later added to compensate for the weaker mesenteric side of the intussuscepted ileal segment, including stripping off the peritoneum and defatting the mesentery of the valve, placement of “rotation” sutures, reinforcement by a mesenteric sling of synthetic mesh encompassing the outflow tract, and stapling the antimesenteric side of the valve to the side wall of the reservoir.

At the Mayo Clinic, the efforts to construct and perfect the continent ileostomy were spearheaded by Oliver H. Beahrs in the early 1970s. Initially, the valve was made 3 cm in length and anchored in place with through-and-through nonabsorbable silk sutures. Subsequently, and with the hope of reducing valve slippage and valve fistula, the nipple was made longer (5 cm), and was anchored in place with both absorbable sutures and staples, and then interrupted sutures were added between the base of the reservoir and the outflow tract to further anchor the intussusceptum. We have been reluctant to use Marlex mesh, which may result in fistula formation across the nipple valve.

CURRENT INDICATIONS AND CONTRAINDICATIONS

Although the ileal pouch anal anastomosis is now preferred by most patients requiring proctocolectomy, the continent ileostomy remains a viable alternative to the Brooke ileostomy for certain categories of patients, which include (a) patients with an existing conventional Brooke ileostomy with no possibility of an ileal pouch anal anastomosis (no anal sphincter) who want to improve their quality of life, (b) patients requiring a proctocolectomy who wish to preserve continence but are not suitable candidates for an ileoanal anastomosis, most often because of poor anal sphincter function, (c) the rare patients whose daily work takes them away

from toilet facilities for long periods of time and who prefer a continent ileostomy to an ileoanal anastomosis, and (d) patients with a failed ileoanal anastomosis who desire to preserve continence and avoid an external appliance if the failure is unrelated to Crohn disease or severe pouchitis.

Use of the Kock pouch should be discouraged in (a) older patients who may be more prone to postoperative complications, including valve dysfunction, and may not tolerate reoperation, (b) patients with Crohn disease, (c) obese patients, (d) critically ill patients such as those with toxic megacolon, (e) psychologically unfit patients who may not be able to intubate properly or tolerate complications and reoperations, and (f) patients in whom a significant amount of small intestine has already been removed.

THE OPERATION

The distal 45 cm of the ileum is used to construct the reservoir, the valve, and the outflow tract (efferent limb). Beginning 15 cm from the cut end of the distal ileum, a 30-cm segment of ileum is measured and fashioned into a U (Fig. 137.1). The antimesenteric borders of the two 15-cm limbs of the U are approximated with continuous suture of 2-0 chromic catgut. The two limbs are then incised on their antimesenteric borders, with the incision extending 4 to 5 cm longer on the afferent limb than on the efferent limb so that the two limbs separate as the pouch is constructed. A second layer of continuous chromic catgut is used to approximate the mucosa and complete the posterior wall of the reservoir (Fig. 137.2).

The valve is then fashioned. The serosal surface of the efferent limb of the ileum is scarified, with the electrocautery beginning at the pouch and extending for a distance of 10 cm toward the cut end. The peritoneum of that same segment is also stripped from the adjacent mesentery, which is also defatted. These maneuvers are designed to promote the adherence of the ileum and its mesentery when the efferent limb is intussuscepted into the pouch to fashion the valve.

The 10-cm efferent limb is intussuscepted into the pouch to form a nipple valve of ~5 cm in length. The intussusceptum is fixed in place with through-and-through sutures of 2-0 Vicryl (polyglactin 910) and three cartridges of stainless steel staples along both sides of the mesentery, care being taken to avoid injury to the vascular supply, and immediately opposite the mesentery using the GIA (U.S. Surgical Corp., Norwalk, CT, USA) autosuture apparatus (Fig. 137.3). The placement of the staples and

sutures is facilitated by “stenting” the lumen of the intussusceptum with a No. 28 French catheter.

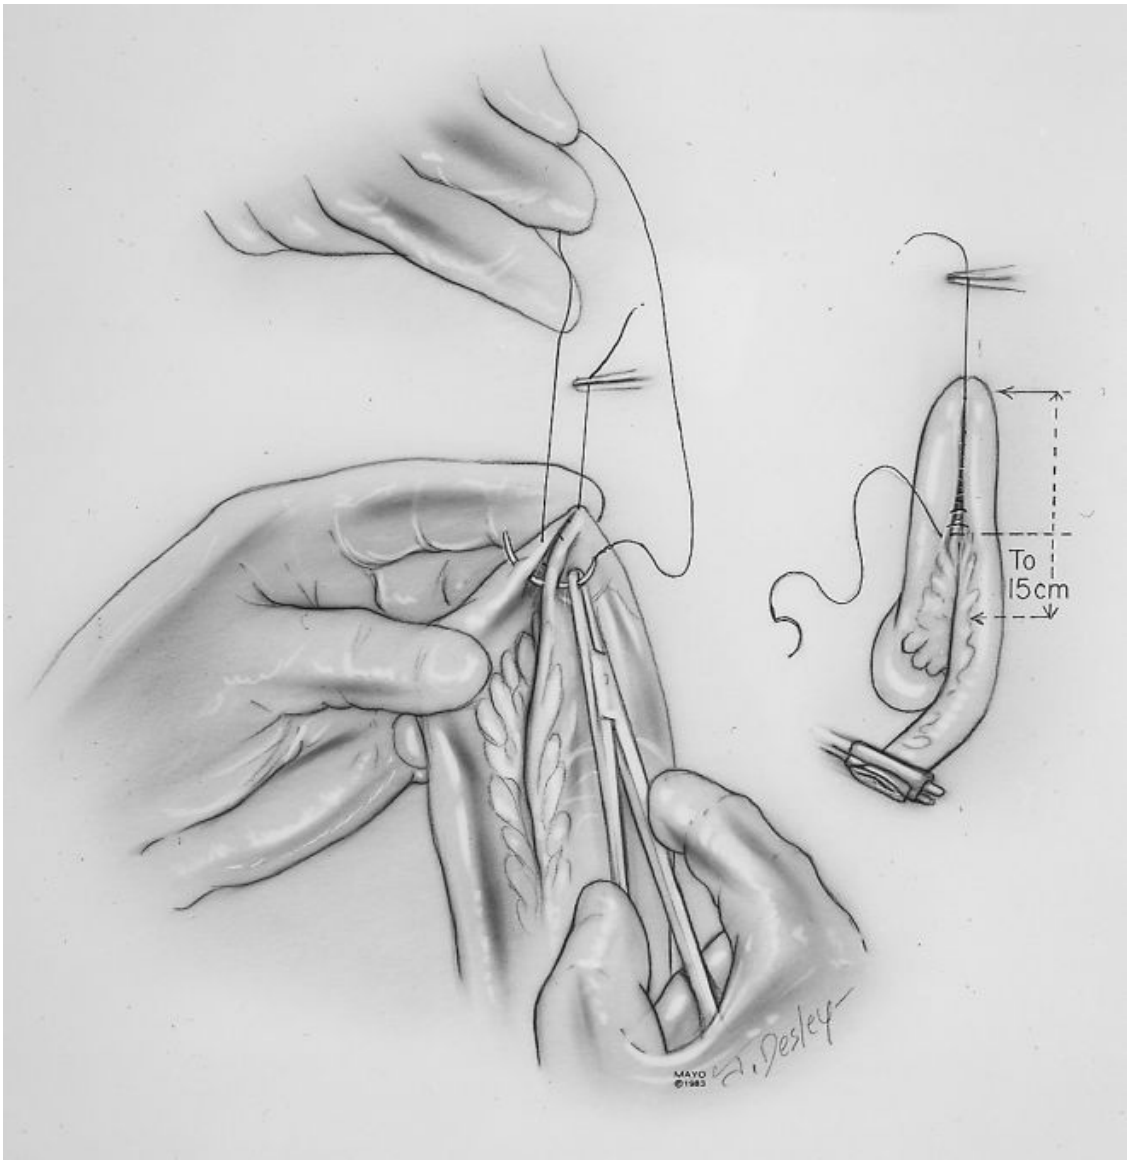

Figure 137.1. The two 15-cm limbs of the folded 30-cm loop are approximated with continuous 2-0 chromic catgut placed near the mesenteric border of the bowel. (Modified from Beahrs OH. Continent ileostomy. In: *Surgical Techniques Illustrated.* Vol 3. Boston, MA: Little, Brown and Company; 1978, with permission.)

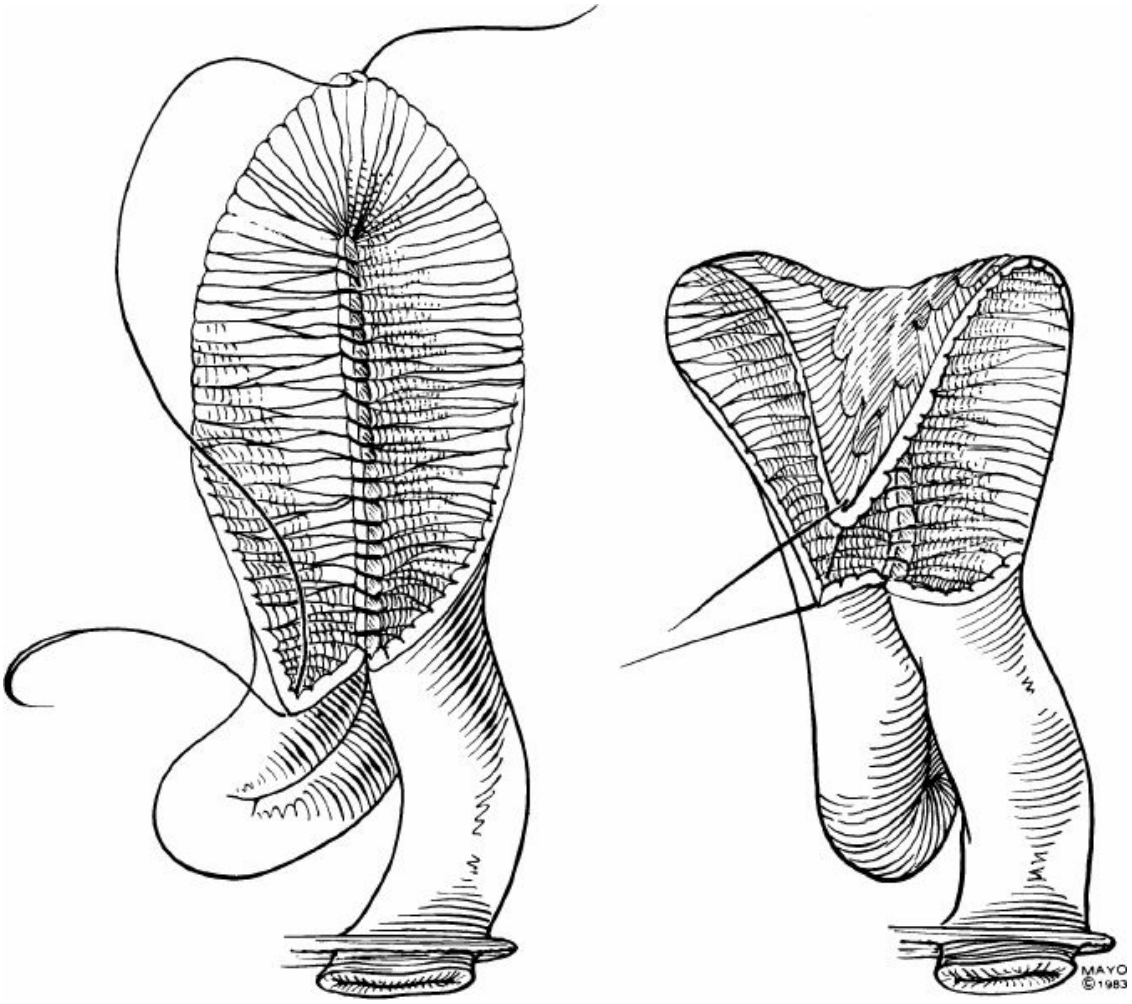

Figure 137.2. The two approximated limbs are incised and a second row of continuous 2-0 chromic catgut sutures is used to approximate the mucosa before the apex of the opened loop is folded over. (Published in Dozois RR, Kelly KA, Beart RW, et al. Continent ileostomy: the Mayo Clinic experience. In: Dozois RR, ed. *Alternatives to Conventional Ileostomy.* Chicago: Year Book Medical Publishers; 1985. Copyright Elsevier.)

The bottom of the U is then folded over to construct the anterior wall of the reservoir, using two layers of continuous 2-0 chromic catgut (Fig. 137.2). The outflow tract is sutured to the base of the pouch with interrupted 3-0 nonabsorbable sutures at the exit of the limb from the pouch to further anchor the intussusceptum in place (Fig. 137.3).

A circumferential defect is created through the abdominal wall just above the pubic hairline in the right lower quadrant, and the outflow tract is brought through the defect and amputated flush with the skin and matured into a stoma with interrupted 3-0 chromic catgut. The length of ileum between the pouch and the stoma should be kept short to avoid

tortuosity and facilitate later intubation of the reservoir. This is aided by suturing the pouch to the undersurface of the anterior abdominal wall so that the nipple valve is perfectly aligned with the stoma (Fig. 137.4).

A No. 28 French catheter is passed through the stoma, efferent limb, and nipple valve, and its tip is positioned within the lumen of the pouch before the incision is closed. A suture of heavy silk is tied around the catheter at the level of the stoma so that the exact position of the catheter can easily be ascertained in the postoperative period. These precautions help prevent pouch perforation or tube slippage during postoperative recovery.

POSTOPERATIVE AND POSTHOSPITALIZATION CARE

In the immediate postoperatiave days, the ileal pouch is irrigated with 25 mL of physiologic saline twice a day to maintain the patency of the catheter, which is connected to a drainage bag. When spontaneous bowel function returns, oral alimentation can be resumed. Before dismissal from the hospital, approximately 8 to 10 days postoperatively, patients are taught self-catheterization by the stoma therapist.

On leaving the hospital, patients are given a catheter designed to drain the pouch (either an ileostomy catheter, M8730 [Atlantic Surgical Co. Inc., Merrick, NY, USA], or an ileal pouch catheter [Dow-Corning Co., Midland, MI]). The Atlantic ileostomy catheter has a diameter of ~9 mm (No. 28 French) and a length of 30 cm, whereas the Dow-Corning ileal pouch catheter has a diameter of approximately 1 cm (No. 30 French) and a length of approximately 64 cm. Each catheter has a thin wall and large holes at the insertion end just proximal to its bullet-shaped blunt tip. The patient keeps the catheter in a small plastic case, which is carried at all times.

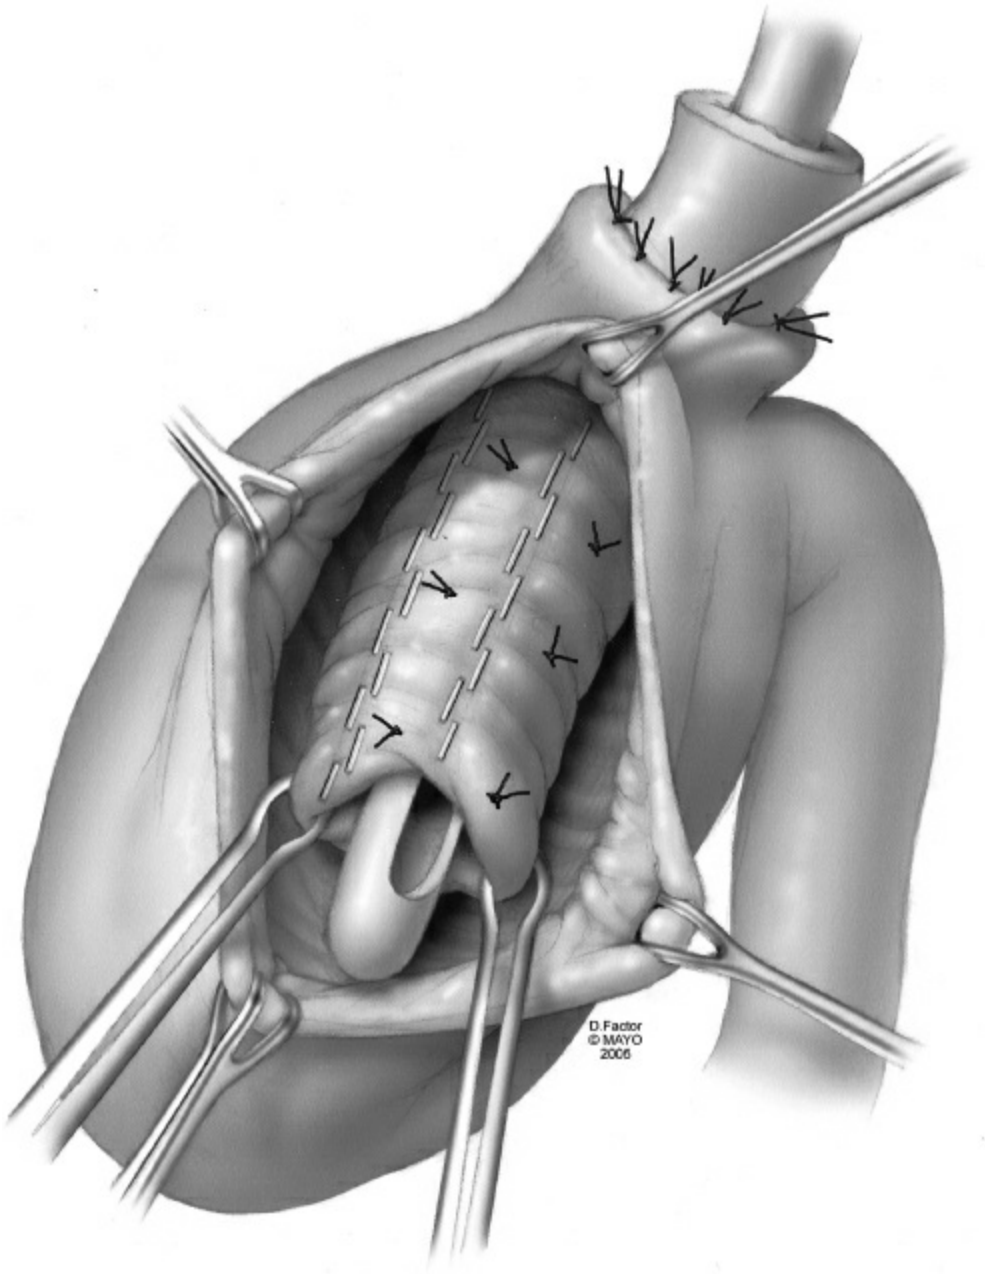

Figure 137.3. Prior to suturing the entire anterior wall of the pouch, the surgically intussuscepted efferent limb is held in place with interrupted sutures of 2-0 polyglycolic acid and three rows of stainless steel staples to form the nipple valve. This is facilitated if done over a catheter. Interrupted sutures of 2-0 polyglycolic acid placed between the base of the reservoir and efferent ileal limb help anchor further the intussuscepted segment within the pouch. Suturing of the anterior wall of the pouch is then completed in two rows. For revisions caused by valve slippage, the same procedure can be performed after the anterior wall of the pouch is reopened and the valve pulled back into the reservoir with Babcock clamps.

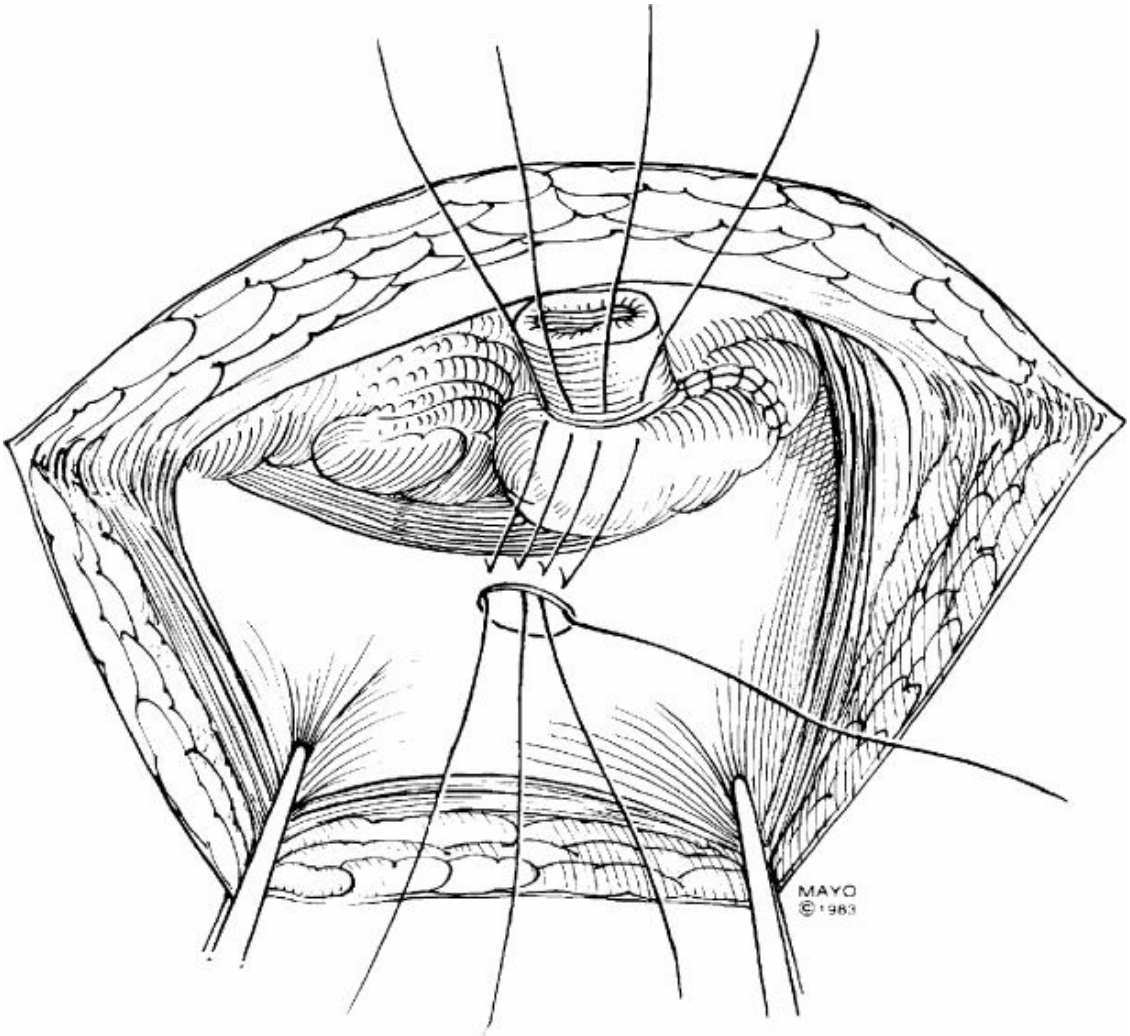

Figure 137.4. The reservoir and outflow tract are anchored to the undersurface of the abdominal wall immediately underneath the stoma site to facilitate future intubation. (Published in Dozois RR, Kelly KA, Beart RW, et al. Continent ileostomy: the Mayo Clinic experience. In: Dozois RR, ed. *Alternatives to Conventional Ileostomy.* Chicago: Year Book Medical Publishers; 1985. Copyright Elsevier.)

When the patient experiences a sensation of fullness, the pouch requires emptying. To empty the pouch, the patient passes the catheter through the stoma into the pouch, usually in the sitting position. The ileal contents spontaneously drain by gravity through the catheter directly into the toilet or another suitable receptacle. The Valsalva maneuver and direct manual compression of the abdomen over the pouch area may at times facilitate drainage, but routine irrigations are not required. The catheter then is removed from the pouch, rinsed clean, and replaced in its case for later use. A soft gauze pad with a waterproof surface is taped over the stoma to

absorb any mucus secreted by the stoma. Patients rapidly become proficient at this procedure, which requires 5 to 10 minutes to complete. None of our patients has ever perforated the pouch with the catheter.

Some patients have found that partially digestible substances, such as seeds, apple skins, celery, and mushrooms, may plug the catheter, so they have avoided these foods. Others, however, have found that all foods can be eaten, provided they are thoroughly masticated before being swallowed.

Four to 6 weeks after operation, restrictions on physical activities are removed. Pregnancy is not contraindicated. Many patients who have undergone this procedure have become pregnant and have delivered healthy babies, either vaginally or by cesarean section.

RESULTS

Between November 1971 and December 1981, 460 patients had a continent ileostomy constructed at the Mayo Medical Center in Rochester, Minnesota. Since 1982 and with the advent of the ileal pouch anal anastomosis, approximately 12 continent ileostomies are either constructed or revised each year.

In our series of patients, no pouch-related deaths occurred intraoperatively or postoperatively. The mean postoperative hospital stay was 10 days. Because of careful patient selection, greater experience, avoidance of a Kock pouch in patients with Crohn disease, and favoring of valve revision over pouch excision when serious complications occur, we have had to excise the reservoir in fewer than 3% of the cases.

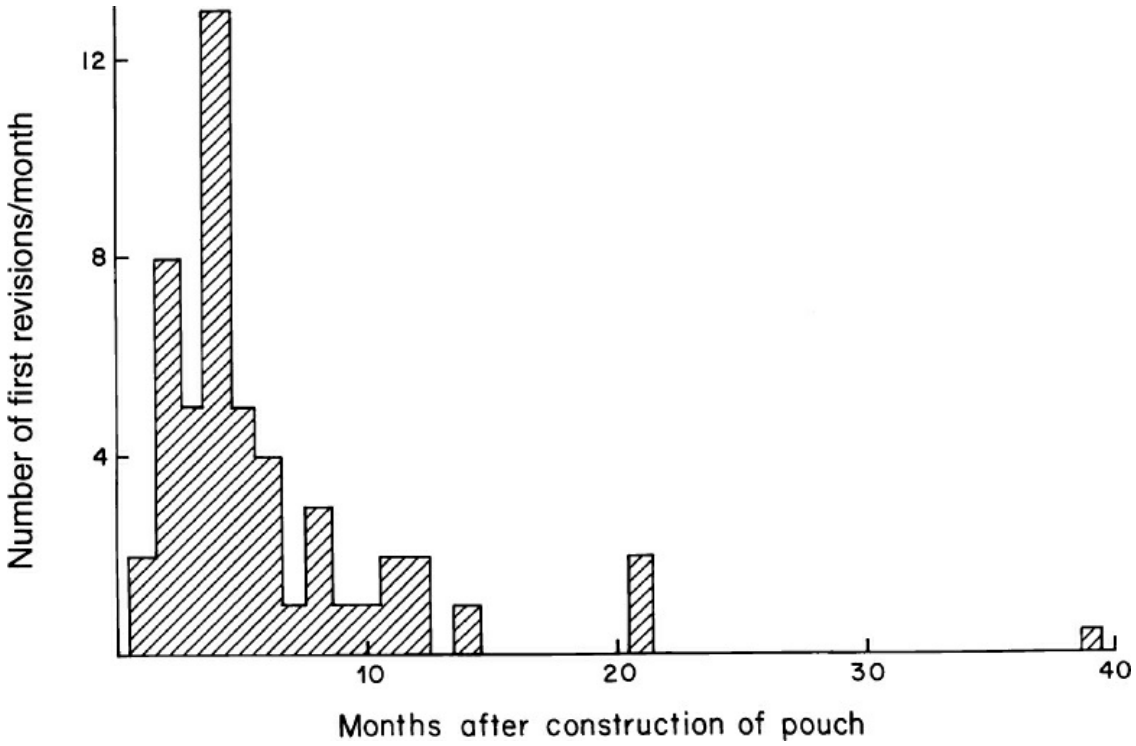

Figure 137.5. The number of patients needing valve revision is greatest 2 to 6 months after the construction of the pouch. (Published in Dozois RR, Kelly KA. The surgical management of ulcerative colitis. In: Kirsner JB, ed. *Inflammatory Bowel Disease.* 5th ed. Philadelphia, PA: WB Saunders; 2000:626. Copyright Elsevier.)

REVISIONAL SURGERY

Persistent difficulties with pouch intubation and/or incontinence related to nipple valve malfunction have necessitated reoperation in 10% to 20% of the patients. In most patients, valve dysfunction occurs within 6 months after construction of the pouch (Fig. 137.5), after which the need for revision decreases dramatically. Malfunction is most often caused by extrusion of the valve and its mesentery, which results in elongation and tortuosity of the efferent limb. As a consequence, the pouch is difficult to intubate as the tip of the catheter may not be maneuvered easily into the pouch lumen, and the pouch leaks. A pouchogram can confirm the clinical suspicion of valve deintussusception. If intubation by the patient or the treating physician is impossible, bowel obstruction will ensue, and a rigid endoscope must be inserted into the pouch lumen to aspirate its contents and place a catheter.

Factors that influence the need for valve revision include age, gender, type of operation, and body habitus (Table 137.1).

Pouch Malfunction from Valve Failure

When valve malfunction occurs, most often reoperation is necessary. The nature of valve revision needed depends on the type of complication and the anatomic configuration of the valve at the time of surgical exploration. After the stoma, the efferent limb, and the reservoir are dissected free from the abdominal wall and fully mobilized, the pouch lumen is entered through an incision in its anterior wall. If the valve has become deintussuscepted into the mesenteric side of the reservoir and outflow tract, the existing nipple valve is pulled back into the reservoir with Babcock clamps and the valve is reanchored with a combination of sutures and stainless steel staples. The pouch incision is closed in two layers, the pouch is again fixed to the undersurface of the abdominal wall, and the stoma is rematured in the same location. If the existing valve cannot be used because of extensive fibrosis, stenosis, or a fistula through the valve, then the stoma, the efferent limb (outflow tract), and the valve are excised and a new valve is created from the afferent limb (inflow tract), which is transected approximately 15 cm proximally (Fig. 137.6A). The proximal cut edge is then anastomosed to the ileal pouch at the site of the excised valve (Fig. 137.6B) after the pouch has been rotated clockwise.

Failed Ileoanal Anastomosis Converted to Kock Pouch

On rare occasions, a poorly functioning ileal pouch–anal anastomosis can be converted into a continent ileostomy using the existing ileal reservoir. In order to qualify for this type of revisional surgery, failure of the ileoanal anastomosis must **not** be attributable to either Crohn disease or severe, recalcitrant pouchitis. Indeed, in our institution, the patients who have had their ileoanal converted to a Kock pouch were the ones with poor functional results primarily due to the result of inadequate anal sphincters, and who had a strong desire to preserve continence.

If the patient still elects to have the failed ileal pouch–anal anastomosis converted to a Kock pouch after detailed and frank discussions about the limitations and risks of such an attempt, the existing ileal reservoir may be used, as long as the pouch can be fully mobilized from the pelvis intact

after disconnection it from the anal canal (Fig. 137.7A). The ileum immediately above the reservoir is then transected 15 cm proximally and serves to construct the valve, the efferent limb, and stoma (Fig. 137.7A,B). The proximal cut end is then anastomosed to the defect in the reservoir, resulting from disconnecting the ileal reservoir from the anal canal area (Fig. 137.7B).

POUCHITIS SYNDROME

Some patients develop a nonspecific inflammation of the reservoir characterized clinically by the sudden onset of diarrhea, cramping, low-grade fever, and, at times, bleeding. Endoscopic findings include mucosal erythema, friability, and easy bleeding. In the majority of patients, symptoms and signs of pouchitis abate readily with administration of oral antibiotics such as metronidazole or ciprofloxacin, which suggests that overgrowth of anaerobic bacteria in the pouch or the more proximal jejunoileum may be responsible for the diarrhea syndrome. In some cases (<5%), however, the pouchitis recurs soon after the discontinuation of therapy or may be recalcitrant to the treatment and may lead to failure.

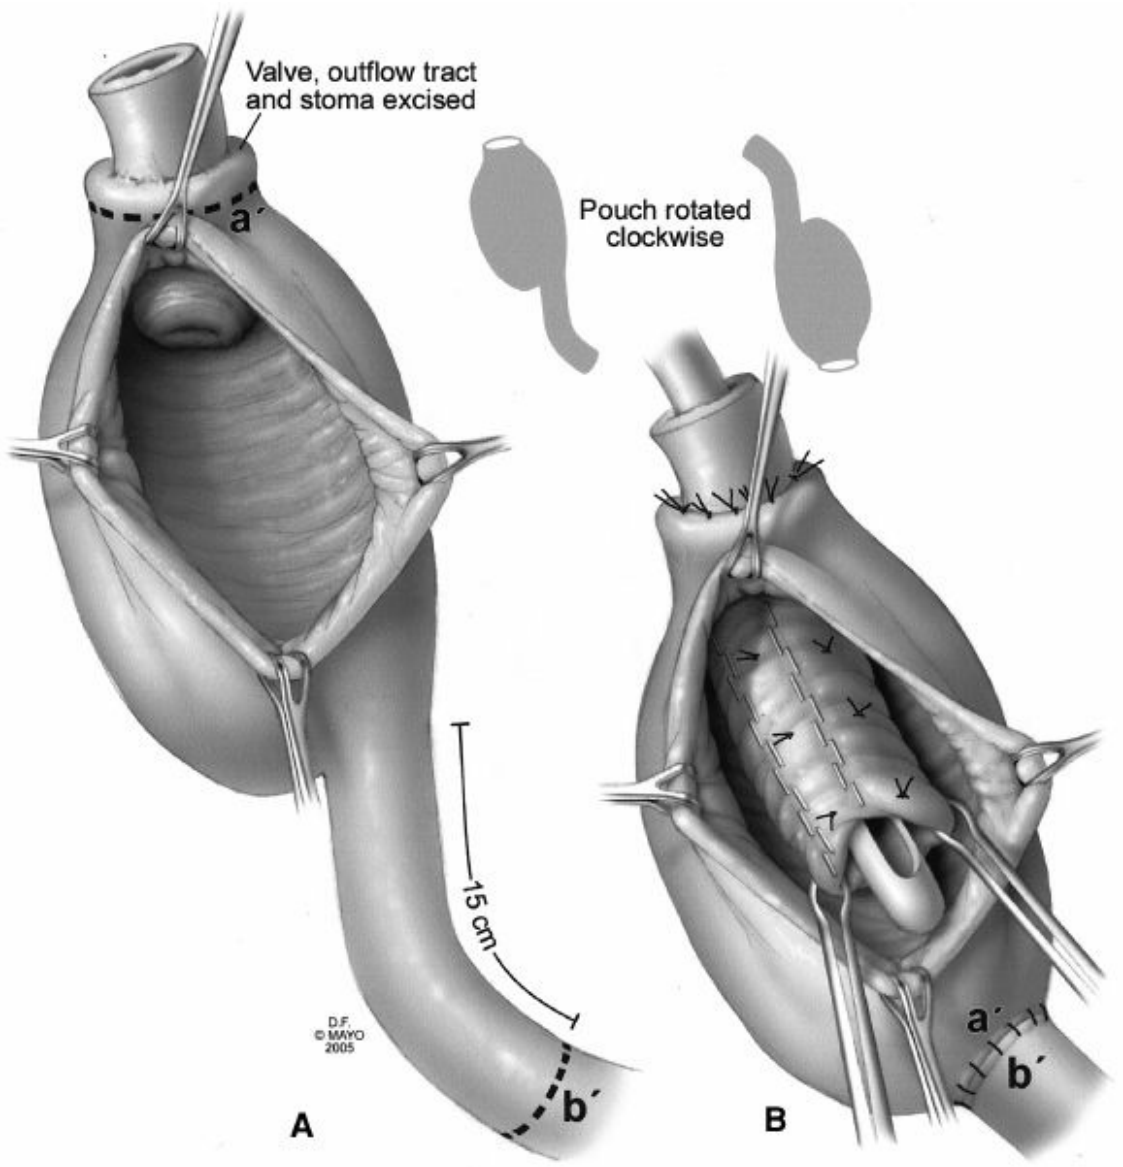

Figure 137.6. If the existing valve cannot be used because of extensive valvular fibrosis, ischemia, or a fistula, the existing outflow tract and valve need to be excised (*dotted line*, a′) (**A**), the pouch is rotated clockwise after transecting the inflow tract, and a new valve, outflow tract, and stoma are reconstructed from the "old" inflow tract (**A**). The operation is completed by suturing the proximal cut end of the inflow tract (b′) to the defect created by removing the dysfunctional valve (a′) (**B**).

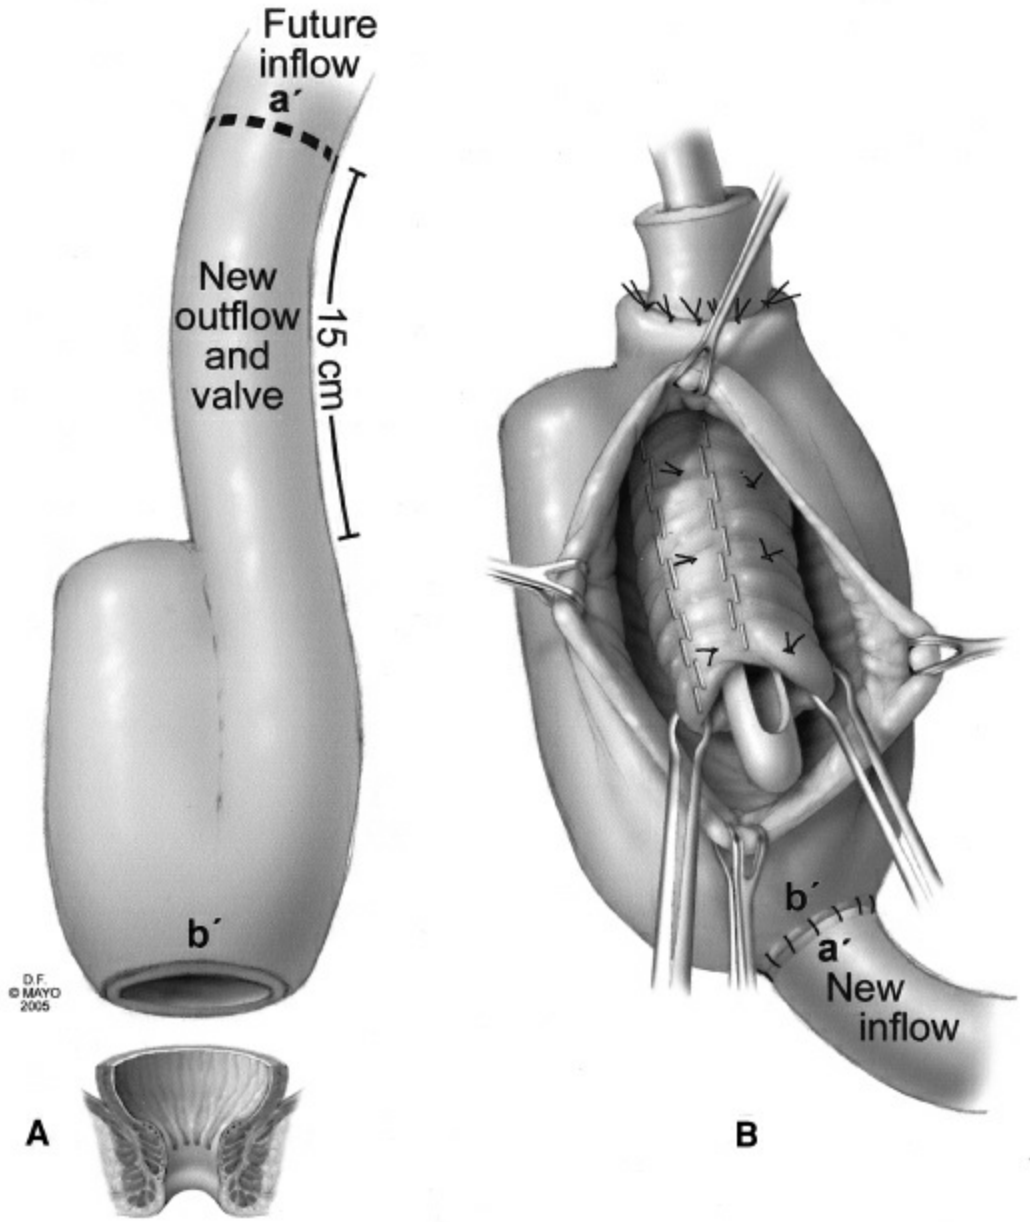

Figure 137.7. Conversion of failed ileoanal anastomosis to Kock pouch. After mobilization of the entire ileal reservoir through an abdominal incision, the ileal reservoir is transected proximal to the anal anastomosis (**A**). The ileum is then transected 15 cm proximal to the pouch. The latter segment of ileum is then used to create the valve mechanism and outflow tract (**B**). The operation is completed by anastomosing the cut end of the proximal ileum (a′) to the transected ileal reservoir (b′), thus creating a new inflow tract.

QUALITY OF LIFE

The crucial consideration in assessing the value of the continent ileostomy is whether it is sufficiently continent for the patient to avoid the need to

wear an external appliance. In our experience, as well as that of the others, >90% of the patients eventually are continent enough that they never have to wear an appliance (Table 137.2). Also, when quality of life after continent ileostomy was compared with that after a Brooke ileostomy, satisfaction was found to be greater, and the desire to change to a different alternative was found to be less in the patients with a Kock pouch than in those with a Brooke ileostomy. Finally, in each performance category, more patients with a Kock pouch than patients with an incontinent Brooke ileostomy improved in their daily activities. Although the role of continent ileostomy is more limited since the advent of the ileoanal anastomosis, our experience as well as that of many others confirms the favorable results of Kock himself, and encourages its continued use in specific circumstances.

Because of its substantial physical and psychological benefits over the conventional ileostomy, the appliance-free continent ileostomy continues to have an important place in the overall armamentarium for dealing with ulcerative colitis or familial polyposis.

[a]Used Barnett continent intestinal reservoir, a modification of the Kock pouch that includes a "living collar" of small bowel wrapped around the outflow tract to help improve continence.

The current refined operative approach offers a high probability of

complete continence. Careful selection of patients further increases the chances of success and reduces the need for reoperation. The operation is most attractive to young people, especially the unmarried, who have great concerns about the social, psychological, and sexual disadvantages of the Brooke ileostomy. The long-term effects of the continent ileostomy are unknown. As yet, metabolic, nutritional, hepatic, renal, and oncologic complications have not appeared after continent ileostomy. The Kock pouch procedure should be done primarily in the centers where the operation is performed in sufficient numbers to enable the surgical team to become proficient, and where careful follow-up is available.

ACKNOWLEDGMENTS

The senior author is deeply indebted to Oliver H. Beahrs for his invaluable teaching of this operation, and to Kathleen Polikowsky and Rosemary Armstrong for their expert assistance in the conduct of several of these operations during a period of more than 20 years.

EDITOR'S COMMENT

It is clear from the writings and the literature that, except for a few centers, namely, University of Gotheborg and the Barnett Clinics, most patients who end up with a continent ileostomy fall into two categories: the first being a failed ileal pouch–anal anastomosis and the second being conversion from a standard ileostomy. As the authors state, many of their patients, in whom they have performed almost 500 procedures, are the patients who would like to have converted a standard ileostomy to a continent ileostomy. The reasons for the standard ileostomy are not difficult to understand. Many patients are quite ill when undergoing proctocolectomy and their focus is on getting better. It is only when they do get better and they review their situation that they would like a better quality of life, which, one suspects, is the principal reason why most patients receive a continent ileostomy.

One should make the point that a continent ileostomy only restores quality of life when, in fact, it is continent, which is of course its Achilles heel. Reoperations are common, and not infrequently—perhaps up to 30% or 40%—one has to deal with a slipped valve. Nor is it necessarily true, as the authors state, that some patients undergo continent ileostomy because they are somewhat tired of having to worry about finding a bathroom when they go outside. Indeed, Berndtsson et al. (*J Wound Ostomy Continence Nurs* 2005;32(5):321) described long-term adjustment for the patients with a continent ileostomy. There were 68 patients (25 male and 43 female) who apparently underwent continent ileostomy and proctocolectomy as their initial operation for ulcerative colitis. The mean time of follow-up was 31 years (range: 29 to 36) and the median subject age at this point was 60, which makes sense as ulcerative colitis tends to be a young person's disease. A 36-item questionnaire was used to assess adjustment to the continent ileostomy, and subjects used a 6-point Likert scale for grading. If they did not like the question, they could avoid it. High median adjustment ratings were found for all 36 statements, but the maximum median rating of 6 appeared on 28 items. Eight items had low median ratings which included embarrassing situations, activity, body image, sexuality, and good care. Despite the analysis, which indicated that

the patients, for the most part, were self-reliant, impediments to bowel evacuation outside the home were common in their responses to the questionnaire, indicating that they had limited outside-the-home activity. Specifically, they mentioned the quality and availability of public restrooms, which reduced their daily activities away from home. Apparently, this finding is for the patients with continent ileostomies and not incontinent ileostomies, which, if occurs, tends to really interfere with activity and requires revision.

The authors state that Kock probably was the person who ultimately was responsible for the concept of the pouch. This subsequently evolved with the aid of Sir Alan Parks, who proposed the S-pouch initially, but with a long spout, which necessitated that these patients catheterized themselves. Lester Martin, a pediatric surgeon in Cincinnati with whom I had the pleasure of working, probably is responsible for taking the concept of the Soave procedure in Hirschsprung disease and, with the mucosal stripping, applying it to the ileal pouch–anal anastomosis with a short spout, thus obviating the need for self-catheterization. Dr. Ollie Beahrs at the Mayo Clinic was among the first to apply the Kock pouch to the American population. The main problem with a Kock pouch is the nipple. There have been innumerable ways of trying to stabilize the nipple so that it does not slip. These methods include through-and-through nonabsorbable sutures, through-and-through absorbable sutures, scarification of the serosa, stripping of the mesentery, Marlex mesh, and stapling. The authors have stated that they have not used Marlex mesh for fear of fistula, which I suppose is a possibility. In the patients whom I have operated on for continent ileostomies, I have tended to use mesenteric stripping, almost to the point of rendering the nipple ischemic (my response to the residents who point out that the nipple is blue is that at least it’s not black). I then use Marlex mesh and four rows of staples. The problem is, however, on the side that is close to the ileal wall, generally the side of the mesentery. And here one must use through-and-through sutures because stapling is too difficult to carry out with the ileostomy adjacent to the wall. This probably provides the most secure form. In addition, a flat abdominal film can always be obtained if one is concerned about slippage, and whether or not the staples form a line then becomes easily known to the surgeon.

Castillo et al. (*Dis Colon Rectum* 2005;48(6):1263) reviewed 24 patients: 13 were operated on for a Brooke ileostomy, who wanted continent; 7 for a failed ileal pouch; 3 for colonic inertia and incontinence; and 1 patient with multiple failed operations for Hirschsprung disease. Twenty-eight revisions were performed in 14 patients (58%), with 6 patients requiring multiple procedures. This is not unusual. Of these revisions, 11 operations were for valve repairs and 12 were for skin level revision for stenosis. Two patients lost their pouches, one because of Crohn disease and the other because of inability to manage the pouch. In a report on a conference in Israel headed by Rachmilewitz, Kock reported on a group of patients; 92% were continent, but some required six revisions. In this chapter the need for revision in 12 months was 29%, but the

average time period before the first revision was 24 months. Total failure rate was 8.3%. Ninety percent of the patients still have their pouches and are satisfied with pouch function, although this was not formally evaluated. The unhappiness with the pouch has led some, including the group headed by Dr. Robert Beart Jr. at the Keck School of Medicine, University of Southern California (Kaiser AM, et al. *Dis Colon Rectum* 2002;45(3):411), to try to adapt a T-pouch valve concept, which has been used for urinary reservoirs by Dr. Skinner and his group in the creation of an ileostomy. The valve is apparently created by embedding a segment of bowel with blood supply intact in a serosa-lined tunnel of two apposed limbs of bowel that will form the pouch reservoir. They reported six patients with complete continence of the pouch. This is an interesting, but sounds like a very complicated, solution to a difficult problem. I have been unable to locate any article written in follow-up of the report.

Another problem that has not received a great deal of publicity is neoplasia in the patients with familial adenomatous polyposis who undergo pouch surgery (Church J, *Dis Colon Rectum* 2005;48(9):1708). We are all familiar with the ileal pouch–anal anastomosis and anastomotic cancers, and this is variously blamed on rectal mucosa, which is not completely stripped or is covered by the pouch. However, the risk factors with adenomas or adenomatous epithelium in contact with rectal epithelium are not known. Therefore, it comes as some surprise that, in this review of the literature, the median time from pouch construction to pouch adenomas was 4.7 years. Eight patients with cancer at the ileal pouch–anal anastomosis site were diagnosed a median of 8 years after pouch construction. What was of interest was that there were eight case reports of cancer described in ileostomy in the patients with familial adenomatous polyposis, in which the problem of a rectal segment interacting with the ileostomy presumably was not present. Here, the median time from construction of the ileostomy to the discovery of the cancers was 25 years, with a range of 9 to 40 years. The author blames fecal stasis, adenomatous epithelium, a germline APC mutation, with the emphasis on fecal stasis, as a recipe for epithelial neoplasia. Although it does happen in ileostomy, it seems to happen much faster in an ileal pouch. One assumes that this is the same possibility that one must be on guard for with a continent ileostomy, in which stasis is a continuing issue.

Pouchitis is a continual problem in these patients, as it is in the patients with ileal pouch–anal anastomosis. My technique differs slightly, not only with the nipple, but in the use of a Malecot or perhaps the Pezzer catheter, which does not run the risk of dislodgement, although it is a little more difficult to get the catheter out, especially if it’s large (No. 28 or 30), without damaging the bowel.

All in all, the continent ileostomy remains a reasonable alternative to the patients who would like to be continent, particularly if sexual difficulties are paramount in their minds. It is true that these patients have second thoughts about the ileostomy, which they may have accepted the first time but not as time went on. After 400 ileal pouch–anal anastomoses, with quite a low complication rate, except for pouchitis (chronic pouchitis in 6%), which I attribute to too long

a spout, to my mind this is a useful alternative under the circumstances in which the sphincter has been removed, and one does not get a wink and total removal of the anal and rectal mucosa.

J.E.F.

138 Technique of Ileostomy Construction and Closure

Harvey G. Moore and Christopher R. Mantyh

INTRODUCTION

Approximately 100,000 people in the United States annually undergo an operation that involves creation of a stoma, including ileostomy. A recent study of National Surgical Quality Improvement Project (NSQIP) data revealed a 37% complication rate for elective cases involving an ostomy, and a 55% complication rate for emergency operations involving ileostomy creation. Ileostomy creation may be a procedure unto itself, or often the last step of a long, often emergent procedure. Consequently, many times the use of an ileostomy for fecal diversion has not been well thought out preoperatively. Furthermore, creation of an ileostomy is often relegated to a junior member of the surgical team, without the benefit of experienced supervision. Common indications for ileostomy, categorized by both the type of ileostomy (end or loop) and the intention of the ostomy (permanent or temporary fecal diversion), are summarized in Table 138.1. In order to achieve optimal results with any ostomy, particularly ileostomy, adequate thought must be given to the risks and benefits of ileostomy creation, the nature of the diversion (small bowel or colon), whether the stoma is temporary or permanent, and the optimal site for ostomy creation. Meticulous care must also be taken in the actual construction of the stoma.

PREOPERATIVE PLANNING

A detailed conversation should occur between the operating surgeon and the patient, family members, and any potential caregivers to discuss the planned procedure, the possibility of a diverting ostomy, the type of ostomy, and whether the ostomy will likely be permanent or temporary. This conversation should occur as early as possible in the preoperative setting to allow the patient as much time as possible to adjust psychologically to the idea of a stoma. The patient should be availed of

potential resources and support groups available through organizations such as the United Ostomy Association and the American College of Surgeons.

Of paramount importance to successful creation of a well-functioning ileostomy is careful preoperative planning of the proposed stoma site. Whenever possible, preoperative consultation should occur with an enterostomal therapy (ET) nurse certified by the Wound, Ostomy and Continence Nurses Society (WOCN) for ostomy site marking. A poorly placed stoma may impact several outcomes including ostomy leakage and resulting skin complications, patient's ability to care for their stoma independently, and overall health care services and costs. Lack of preoperative site marking has been shown in numerous studies to be a risk factor for having a problematic stoma, defined as one that requires extra care and equipment to maintain an appliance for 24 hours. The site selection protocol recommended by the WOCN includes the use of multiple positions (standing, siting, bending at the waist) to identify optimal sites, avoidance of folds, scars, and drain sites, as well as the costal margin and iliac crest, consideration of beltline/clothing, and ideally placement at the summit of the right paramedian infraumbilical fat pad, within the rectus abdominus muscle. Placement through the rectus abdominus muscle likely reduces the risk of forming a parastomal hernia. In obese patients, stoma sites must not be located below a large abdominal pannus where visualization will be poor. Upper abdominal sites may be preferable in obese patients. In the absence of an ET nurse, preoperative site marking is often performed by the operating surgeon. Surgeons performing gastrointestinal surgery should be familiar with the principles of stoma siting. Collaboration between the enterostomal therapist and surgeon regarding choice of stoma site is ideal. Once the optimal site or sites are identified, they can be marked with a permanent marker, or alternatively by using a hypodermic needle and ink to tattoo the skin. The stoma appliance may also be fixed to the proposed site and worn for 24 hours or more to check for proper positioning. At the time of surgery, a needle may be used to scratch the skin at the proposed ostomy site to avoid the marks being washed off during skin preparation.

TABLE 138.1 Indications for Ileostomy Creation

Temporary end ileostomy

Following emergent subtotal colectomy:
- *Inflammatory bowel disease*
- *Clostridium difficile colitis*
- *Ischemia*
- *Lower gastrointestinal hemorrhage*

Following emergent resection of the cecum, ascending colon, or small bowel:
- *Ischemia*
- *Perforation*

Permanent end ileostomy

Following total proctocolectomy:
- *Ulcerative colitis or familial adenomatous polyposis when ileal pouch anal anastomosis (IPAA) contraindicated*
- *Crohn's colitis with severe anorectal involvement*

Severe fecal incontinence

Severe congenital abnormalities

Temporary loop ileostomy

Protection of distal anastomosis:
- *Ileal pouch anal*
- *Ileorectal*
- *Low colorectal/coloanal following low anterior resection*

Colorectal obstruction with incompetent ileocecal valve

Prophylactic diversion for near-obstructing rectal cancer receiving preoperative neoadjuvant chemoradiation

Treatment of anastomotic leak

Temporary fecal diversion
- *Rectal or perineal trauma*
- *Fournier gangrene*
- *Severe fecal incontinence*
- *Radiation proctitis*
- *Pelvic sepsis*
- *Sacral decubitus ulcer*
- *Symptomatic rectovaginal fistula*

Following complex anorectal repair:
- *Sphincteroplasty*
- *Rectovaginal and rectourethral fistula repair*
- *Fistula-in-ano*

Preoperative stomal education should also occur, ideally provided by the ET nurse at the time of stoma site marking. Preoperative education prior to ostomy creation is associated with decreased hospital stay, decreased need for unplanned healthcare interventions after discharge, faster time to proficiency with ostomy care, as well as cost savings. Recommended preoperative topics include GI anatomy and physiology, planned surgical procedure, demonstration of ostomy appliances and other products, and psychological preparation.

SURGICAL TECHNIQUE

End Ileostomy

Indications

An end ileostomy may be constructed as a temporary or a permanent fecal diversion. A temporary end ileostomy may be created following emergent subtotal colectomy for inflammatory bowel disease, *Clostridium difficile* colitis, ischemia, diverticular hemorrhage, or other pathology. An end ileostomy may also be utilized as a temporary fecal diversion following emergent resection of the cecum, ascending colon, or small bowel secondary to ischemia or perforation, in conjunction with a mucous fistula, when a primary anastomosis cannot be safely performed. An end ileostomy is occasionally created as a permanent ostomy following total proctocolectomy for ulcerative colitis or familial adenomatous polyposis when creation of an ileal pouch with coloanal anastomosis is contraindicated or not technically feasible, and for Crohn's colitis with severe anorectal involvement. A permanent end ileostomy may also be required for severe fecal incontinence or congenital abnormalities (Table 138.1).

Stoma Construction

Patient position (supine or lithotomy) is determined by nature of the procedure that will be performed and whether access to the rectum/perineum will be required (i.e., for colonoscopy or passage of an EEA stapler). Patients receive intravenous antibiotics prior to incision. In elective procedures, the optimal stoma site will ideally have been determined and marked by an experienced ET nurse (Fig. 138.1). In situations where the site has not been previously marked, applying the faceplate of the ileostomy appliance in the right lower quadrant may help identify an appropriate position and avoid positions where the faceplate would contact the costal margin, anterior superior iliac spine, or the umbilicus. In the case of an intraoperative decision to create an ileostomy when no consideration has been given to stoma site, a stoma 5 cm lateral to the midline and 4 cm below the umbilicus will generally be suitable.

In general, construction of an end ileostomy will generally take place in the context of an abdominal operation with a midline incision already made. At the marked site, the skin is grasped and elevated with a Kocher clamp and a 2-cm, nickel-sized circular incision is made with a scalpel or cutting current on the cautery, and the resulting disc of skin is amputated

(Fig. 138.2A). It should be kept in mind that the skin will stretch to create a larger aperture than the original incision. It is not necessary to core out a column of subcutaneous fat; in fact, preservation of the fat provides support for the ostomy and may make parastomal hernia and prolapse less likely. A linear incision is made in the subcutaneous fat and small Richardson retractors may be used to expose the anterior rectus abdominus fascia. A cruciate or linear fascial incision is made and the underlying rectus abdominus muscle is exposed. The fibers of the rectus abdominus can be spread with a large Kelly hemostat and the underlying posterior fascia and peritoneum are incised (Fig. 138.2B). The resulting abdominal wall opening is dilated to allow passage of two fingers (Fig. 138.2C). A Babcock clamp is then placed through the abdominal opening and applied to the distal end of ileum and the small bowel is gently delivered through the abdominal wall with the mesentery in a cephalad orientation, ideally with pushing from inside rather than traction on the Babcock clamp, until 4 cm of small bowel protrudes above skin level. It is not necessary to suture the small bowel serosa to either the peritoneum or fascia. It is important not to devascularize the ileum by stripping excessive mesentery from the bowel wall (Fig. 138.2D). In the case of significant difficulty exteriorizing the ileum, some of the subcutaneous fat can be excised or a small Alexis (Applied) wound protector may reduce resistance.

Figure 138.1. Preoperative marking of the ileostomy site. The

ileostomy is placed in the right lower quadrant of the abdomen in a right paramedian, infraumbilical position. (From Daniel Albo, ed. Chapter 4: End and diverting loop ileostomies: creation and reversal. *Operative Techniques in Colon and Rectal Surgery*. Philadelphia, PA: LWW; 2015:27–40.)

For permanent end ileostomies, it is recommended to close the paracolic gutter to reduce the chance of internal herniation and small bowel obstruction. This can be achieved by running a 2-0 Vicryl suture between the cut end of the ileal mesentery and the cut edge of the paracolic peritoneum (white line of Toldt).

Ideally the midline incision will be closed and covered prior to stoma maturation. The ostomy is immediately matured with the intention of creating a stoma that extends a minimum of 2 cm above the abdominal wall (Brooke ileostomy), as recommended by the ASCRS practice parameters (see Suggested Readings). Full thickness 3-0 absorbable (e.g., Vicryl) sutures are placed in four quadrants through the distal end of the ileum incorporating mucosa and serosa. Each suture is then used to take a seromuscular (Lembert) bite just proximal to the skin, followed by a bite of dermis, all in the same vertical plane (three-point sutures) (Fig. 138.2E). Sutures are marked with a hemostat until all four quadrant sutures are placed. As these are tied, the bowel will evert to form a 2- to 3-cm "nipple" (Fig. 138.2F). One to two additional 3-0 Vicryl sutures are placed between each of the four quadrant sutures, attaching the full thickness edge of ileum to the dermis layer of skin (2-point sutures).

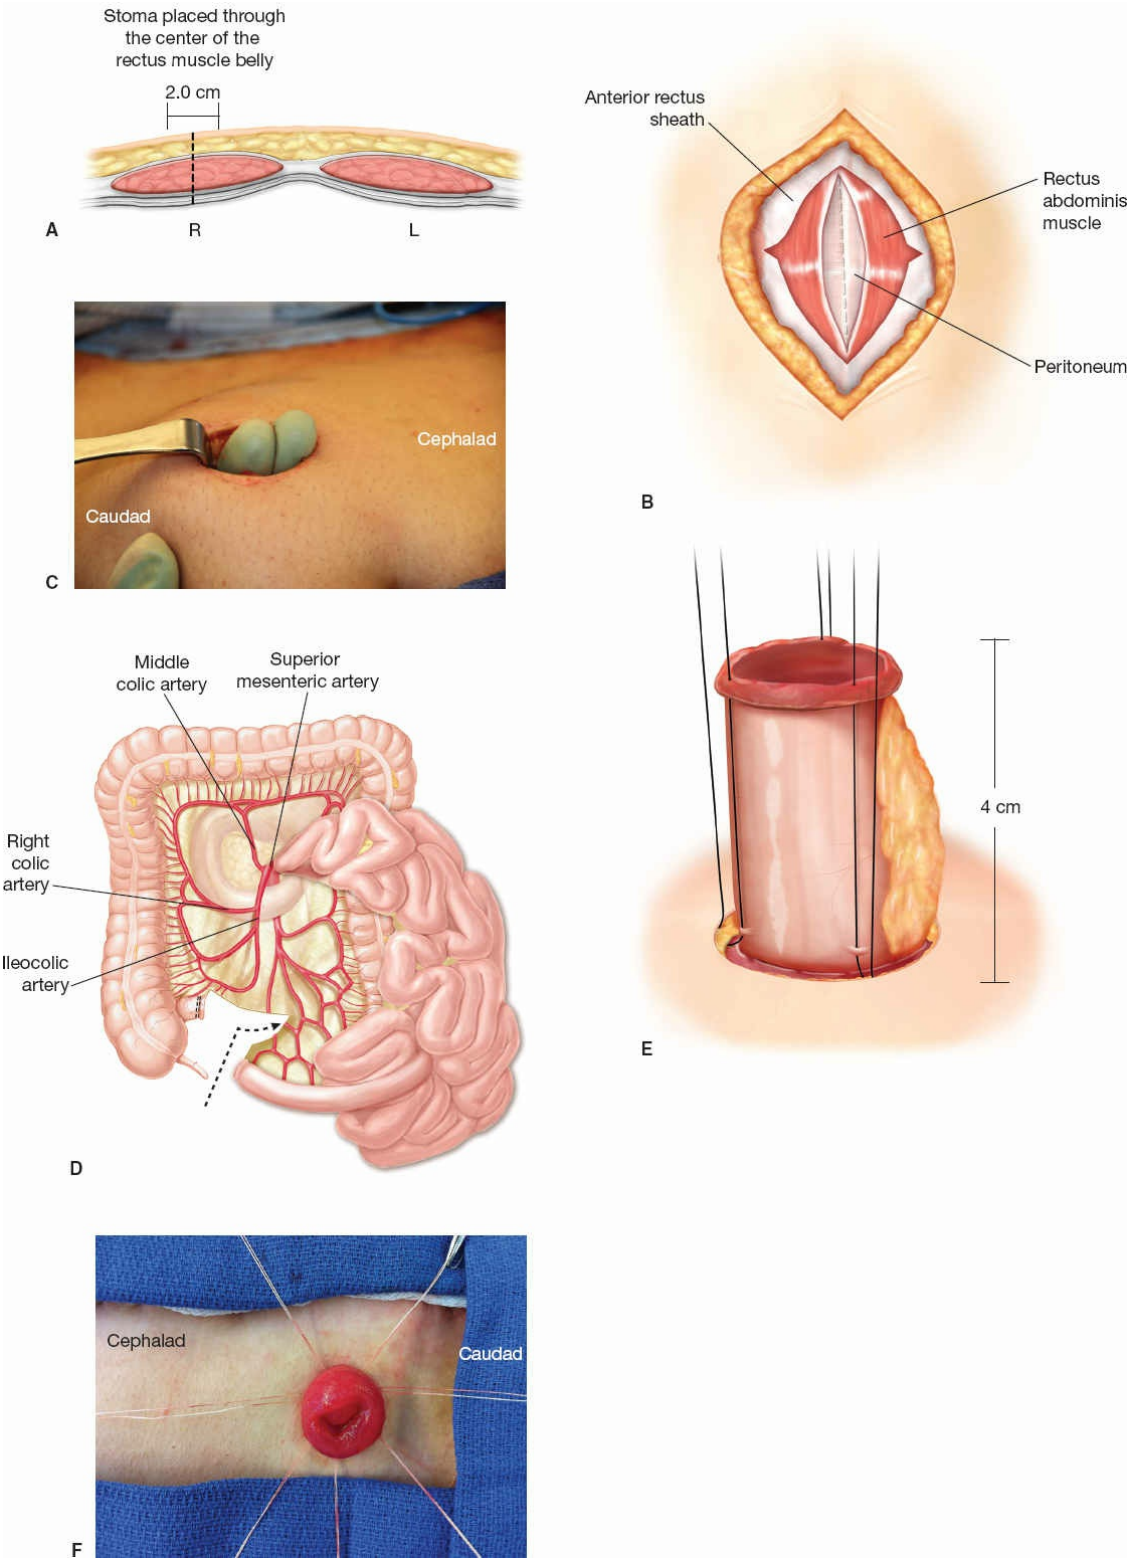

Figure 138.2. Creation of an end ileostomy. **A.** A circular skin incision for the ileostomy is made over the center of the rectus muscle belly and carried through the subcutaneous fat. **B.** A cruciate incision is made in the anterior rectus sheath to expose the underlying rectus muscle. The rectus muscle is split bluntly along the direction of its fibers to expose the posterior sheath and peritoneum. **C.** The peritoneum is incised longitudinally, and the

incision is widened by stretching it with two digits to obtain the desired aperture. **D.** The vascular end arcade and the mesentery are preserved on the ileal segment that is to be used for the end ileostomy (*dotted arrow*). **E.** The ileum is advanced through the abdominal wall stoma aperture so that it protrudes for about 4 cm beyond the skin level. Following removal of the staple line, three-point sutures are placed through the end of the ileum (full thickness), the seromuscular layer at the base of the stoma 4 cm from the end of the ileum, and the dermis, respectively. No epidermis should be included in stitch. **F.** The sutures are placed circumferentially. They are only tied after all of them have been placed, everting the ileum to create a 2-cm–high ileostomy. (From Daniel Albo, ed. Chapter 4: End and diverting loop ileostomies: creation and reversal. *Operative Techniques in Colon and Rectal Surgery*. Philadelphia, PA: LWW; 2015:27–40.)

An appropriate sized aperture is cut in the ileostomy faceplate to just allow the stoma to pass through with a 1- to 2-mm margin. The peristomal skin is cleaned with mild soap and water, and a skin barrier spray is applied. A transparent, drainable, two-piece ileostomy appliance facilitates inspection and frequent emptying without the need to remove the faceplate. An ileostomy bag is attached and oriented to hang sideways off the bed as this will be dependent drainage during the initial postoperative period while the patient is supine.

Loop Ileostomy

Indications

A loop ileostomy is generally used to divert the fecal stream in order to protect a downstream anastomosis such as following an ileorectal anastomosis, an ileal pouch anal anastomosis (IPAA), or following low anterior resection with distal/coloanal anastomosis; particularly following preoperative chemoradiation. Other indications may include colon or rectal obstruction in patients with an incompetent ileocecal valve, prophylactically in patients with near obstructing rectal cancers undergoing preoperative chemoradiation, and rarely in combination with a transverse colon “blowhole” colostomy in patients with fulminant colitis (Turnbull procedure). Other indications include treatment of anastomotic leak, diversion for rectal or perineal trauma and severe perianal infection such as Fournier gangrene, severe fecal incontinence, radiation proctitis, pelvic sepsis, sacral decubitus ulcer, complex anorectal disease such as

symptomatic rectovaginal fistula, and following anorectal repair including sphincteroplasty, rectovaginal, and rectourethral fistula repair, and repair of complex fistula in ano (Table 138.1).

In general, a loop ileostomy is preferred over a loop colostomy when temporary fecal diversion is required. Existing literature, including several randomized trials, supports the fact that both loop ileostomy and transverse loop colostomy effectively divert the fecal stream and minimize the consequences of an anastomotic leak. Although both loop colostomy and loop ileostomy have similar complication rates, their morbidity profiles differ. Loop ileostomy has a lower incidence of infectious complications and prolapse. In addition, patients with a loop ileostomy appear to have a better overall quality of life. However, loop ileostomy is associated with a significant incidence of small bowel obstructions both before and after stoma reversal, and also a higher incidence of dehydration and renal failure. Overall, a loop ileostomy is the preferred fecal diversion of colorectal surgeons and is advocated in the practice parameter on ostomy creation of the American Society of Colon and Rectal Surgeons. However, in certain situations a loop colostomy may be preferable, such as a left-sided colon obstruction with a competent ileocecal valve and impending cecal perforation, where immediate colonic decompression is required.

Stoma Construction

For open cases where loop ileostomy is required, the abdominal wall opening is created in the fashion previously described for end ileostomy. A mobile loop of ileum approximately 20 to 30 cm proximal to the ileocecal valve or ileal pouch that easily reaches the proposed ileostomy site without tension is identified (Fig. 138.3A). It may be useful to mark the afferent and efferent limbs with large hemoclips or different colored sutures in order to assure that correct orientation is maintained (Fig. 138.3B). The chosen ileal loop is carefully grasped with a Babcock clamp placed through the abdominal wall opening and gently pulled through onto the abdominal wall. It is important to avoid twisting the mesentery supplying the loop; the bowel should be oriented with the proximal or afferent limb oriented cephalad. Alternatively, the bowel and its mesentery can be rotated 90 degrees so that the afferent lumen is located caudally, although there is no evidence that the position of the afferent lumen, if matured properly, matters with regard to completeness of diversion. Consideration should be given to the use of a sodium hyaluronate and carboxymethylcellulose-based bioabsorbable membrane (Seprafilm) to

reduce adhesion formation around the ileostomy and facilitate future reversal. In one study, adhesion formation was significantly decreased in cases where Seprafilm was placed around the intrabdominal ileal limb (14% vs. 31%). An avascular window is created in the mesentery at the midpoint of the loop and a tonsil clamp is used to pull an 18-Fr red rubber catheter through the mesenteric window to serve as a supporting rod. The red rubber catheter is cut to the appropriate length and anchored to the skin with 3-0 nylon sutures. Although many surgeons prefer the use of a supporting rod, it may not be absolutely necessary in cases where no excessive tension on the ileal loop is present. There is no need to suture the bowel to the peritoneum or to the anterior fascia. The abdominal incisions are generally closed prior to maturing the stoma to limit contamination of the wound. Following closure of the abdominal incision, the anterior ileal wall is opened with electrocautery 2 to 3 cm distal to the apex of the loop, within the efferent portion of the loop (Fig. 138.3C). The ileal incision should extend to within 2 to 3 mm of the mesentery on either side (75% circumference of loop). Similar to that described for end ileostomy, 3-0 Vicryl sutures are placed through the full thickness of the bowel wall, followed by a seromuscular bite just proximal to the skin, and finally a bite of the dermal layer of skin. These are then tied, everting the bowel and emphasizing the proximal lumen while deemphasizing the distal lumen. One or two additional 3-0 Vicryl sutures are placed between each of the three quadrant sutures, between the full thickness cut edge of bowel and the dermal layer of skin. The distal lumen is also matured by suturing full thickness bowel wall to the dermal layer of skin (Fig. 138.3D). An ileostomy appliance is applied as described above. The edges of the aperture in the ileostomy faceplate are placed beneath the stoma rod on both sides. The stoma rod may be removed 7 to 10 days after surgery.

End Loop Ileostomy

In clinical situations where an end ileostomy is required but technically difficult due to a foreshortened or thickened mesentery and/or thickened abdominal wall in obese patients, one alternative is the end-loop ileostomy. When creating an end loop ileostomy, a loop of ileum just proximal (10 cm) to the closed distal end is brought through the abdominal wall opening and matured as loop ileostomy (Fig. 138.4A). This results in a short efferent limb distal to the loop stoma. The afferent and efferent ileum can be marked with large clips or sutures to ensure proper

orientation. The stapled end of the efferent limb is oversewn with seromuscular 3-0 silk interrupted sutures. If intended to be a permanent stoma, the edge of the ileal mesentery is sutured to the abdominal wall. Following closure of the abdominal incisions and coverage, the loop is matured in the manner described for loop ileostomy (Fig. 138.4B).

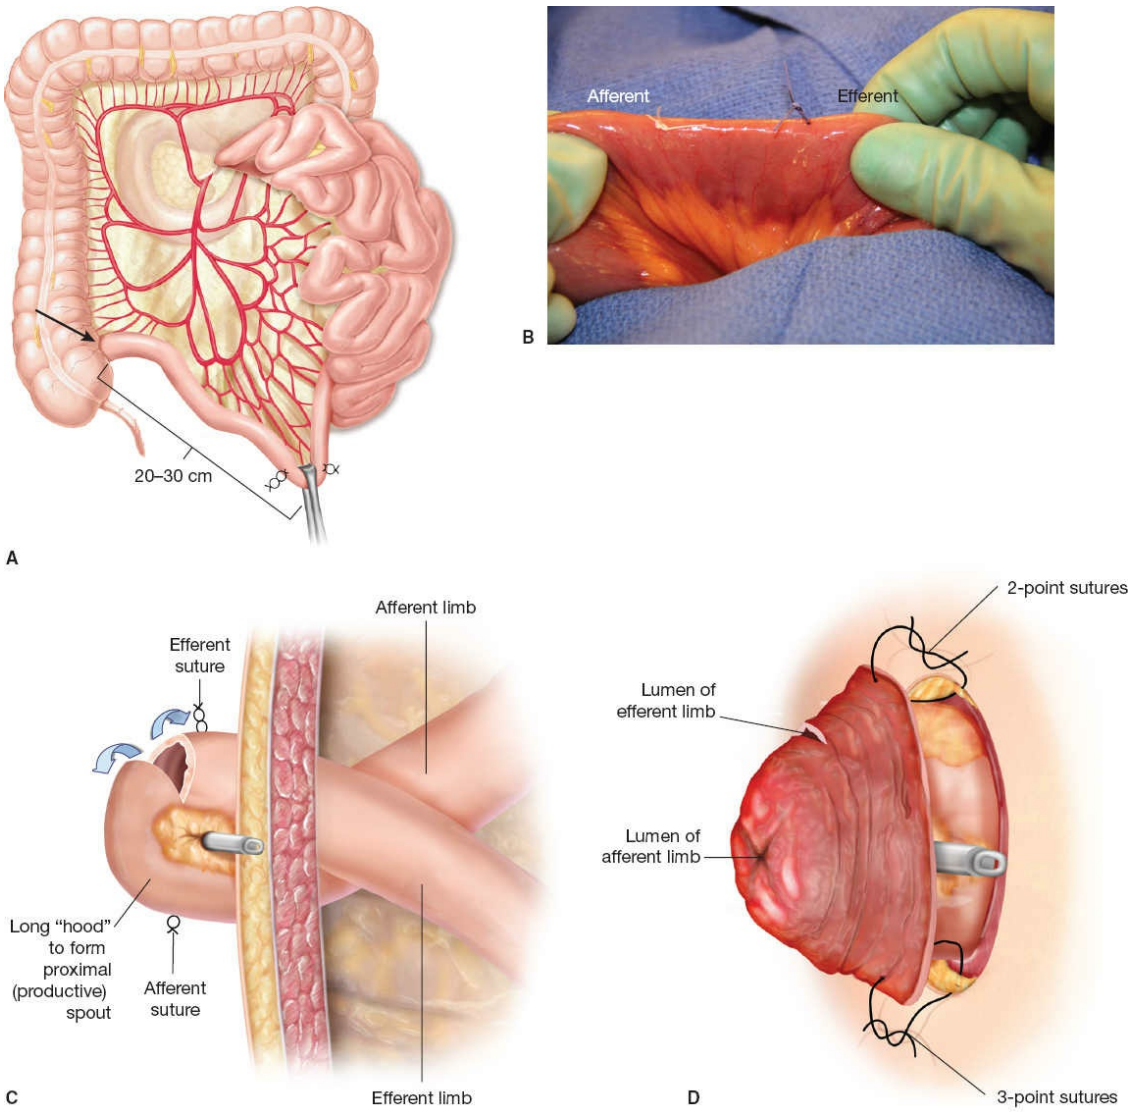

Figure 138.3. Creation of a loop ileostomy. **A.** An ileal segment that is 20 to 30 cm proximal to the ileocecal junction (*arrow*) is identified. The segment's mesentery and vasculature are preserved. **B.** Marking sutures (e.g., sutures of different colors or with differing numbers of knots) are placed on the afferent and efferent limbs. The ileum is advanced through the abdominal wall stoma aperture so that it protrudes for about 3 to 4 cm beyond the skin level. **C.** The ileum is incised 1 cm above the skin level on the efferent limb side for 75% of the circumference to create a large afferent spout. **D.** The loop ileostomy is matured by placing two-point sutures (full thickness through the end of the ileum and the dermis) on the efferent limb and three-point sutures (full thickness through the end of ileum, the seromuscular layer at the base of stoma, and the dermis) on the afferent limb to evert the ileum. (From Daniel Albo, ed. Chapter 4: End and diverting loop ileostomies: creation and reversal. *Operative Techniques in Colon and Rectal Surgery*. Philadelphia, PA: LWW; 2015:27–40.)

Other techniques that may be employed when difficulty is encountered getting the chosen bowel to reach without tension are selective mesenteric vessel ligation and use of upper abdominal sites in obese individuals.

Divided Loop Ileostomy

Although diverting loop ileostomy generally provides excellent fecal diversion, an alternative technique that may result in more complete diversion is the divided loop ileostomy. The procedure involves division of the ileum with a linear stapler 20 to 30 cm from the ileocecal valve (Fig. 138.5A). The stapled proximal limb is brought through the ostomy site such that approximately 4 cm is above the skin. The staple line is removed and the bowel is matured as a Brooke ileostomy with a three-point stitch (full thickness ileum, seromuscular bite just above skin, and dermal bite) technique. The antimesenteric corner of the distal limp is brought through the same abdominal wall opening (Fig. 138.5B). The corner of the efferent limb is excised and matured inferior to the proximal lumen using a two-point stitch (full thickness ileum and dermis). Two transition sutures are used to secure the efferent lumen to the serosa of the afferent limb as well as the dermal layer of skin (Fig. 138.5C). Alternatively, the antimesenteric corner of the efferent limp may be left intact to ensure complete diversion. This type of stoma can generally be reversed without the need of laparotomy, as both limbs of the bowel are located in close proximity within the abdominal wall. A divided loop stoma can sometimes be performed via a local revision of an existing loop ileostomy if fecal diversion is inadequate, but laparotomy may be required.

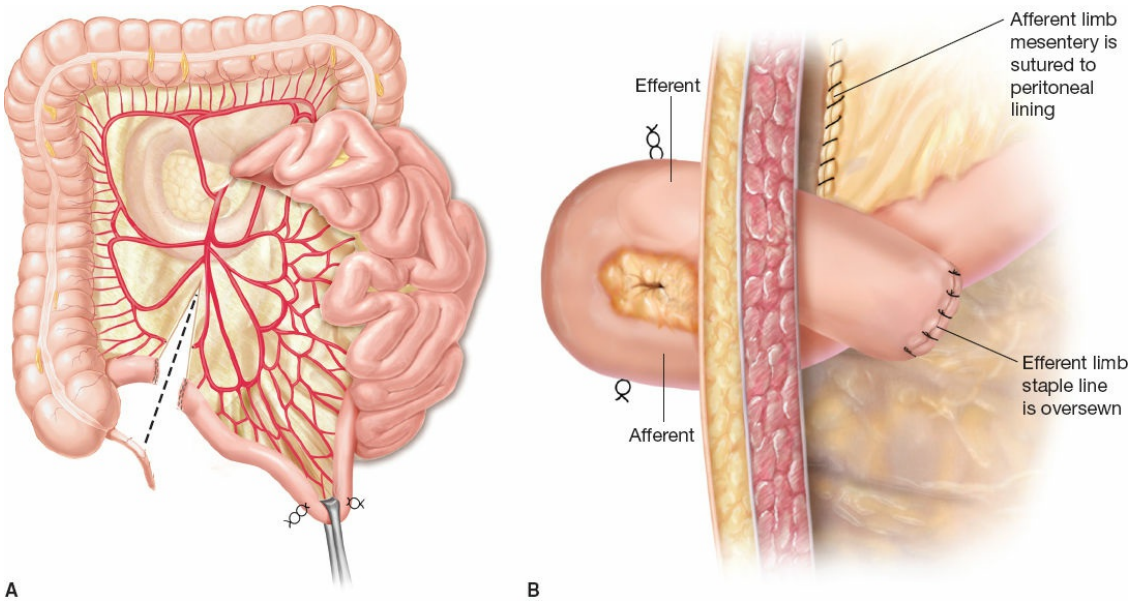

Figure 138.4. Creation of an end-loop ileostomy. **A.** The mesentery and vasculature are divided proximally to obtain as much length as possible. **B.** Marking sutures are placed on the afferent and efferent limbs. The staple line closing off the ileum is oversewn with Lembert sutures and remains in the abdomen. A more proximal segment of ileum to be used for the ileostomy, approximately 10 cm proximal to the oversewn ileal staple line, is externalized so that the afferent limb is in the inferior position on the abdominal wall. The mesentery may be affixed to the abdominal wall to prevent stoma prolapse, torsion, or an internal hernia. (From Daniel Albo, ed. Chapter 4: End and diverting loop ileostomies: creation and reversal. *Operative Techniques in Colon and Rectal Surgery*. Philadelphia, PA: LWW; 2015:27–40.)

Laparoscopic Ileostomy

A diverting loop ileostomy, as well as an end or end-loop ileostomy, can be created laparoscopically, either in the context of a larger laparoscopic procedure or as a primary procedure. Whenever possible, laparoscopic creation of a loop ileostomy is the preferred approach, with all of the reported advantages of laparoscopic surgery including decreased pain and narcotic requirements, shorter hospital stay, earlier return of bowel function, and fewer overall complications. The lack of an incision also facilitates placement of a stoma appliance. In addition, laparoscopic loop ileostomies may be easier to reverse, likely due to decreased peristomal adhesions, and may also have a lower incidence of small bowel obstruction. When performed in the context of a larger colorectal resection, existing ports and camera placement can be utilized to create the ileostomy. When performed as a primary procedure, a supraumbilical Hassan trocar is used as well as suprapubic and left lower quadrant 5-mm trocars. For an end ileostomy, the ileal limb is identified and is carefully elevated to the proposed ileostomy site to ensure it reaches without tension. Care is taken to ensure the mesentery supplying this segment is intact and that it is not twisted. For a loop ileostomy, the terminal ileum is identified and the small bowel is followed proximally until a mobile loop approximately 20 to 30 cm from the terminal ileum is identified. The loop should be able to be elevated easily to the proposed ileostomy site without tension. The bowel is then marked to identify proximal and distal direction with either large hemoclips or laparoscopically placed sutures of different color. At this point, the abdominal wall opening is created as described for

end ileostomy, down to the level of the posterior fascia and peritoneum. A 15-mm trocar is then placed through the peritoneal layer, maintaining the pneumoperitoneum. An endo-Babcock clamp is placed through the 15-mm trocar, and the ileal limb or previously marked loop of ileum is passed to the endo-Babcock clamp under direct laparoscopic visualization. The 15-mm trocar is removed and the ileal loop is gently delivered through the ostomy site until a sufficient loop of ileum is above the abdominal wall. A red rubber catheter is passed through a window in the mesentery for loop ileostomies and secured to the abdominal wall as described above. Pneumoperitoneum can generally be maintained throughout this process and the ileum can be inspected laparoscopically to confirm that the mesentery is not twisted and confirm the proximal and distal orientation of the bowel. The pneumoperitoneum is then released and the ileostomy is matured as either an end or loop ileostomy as described above.

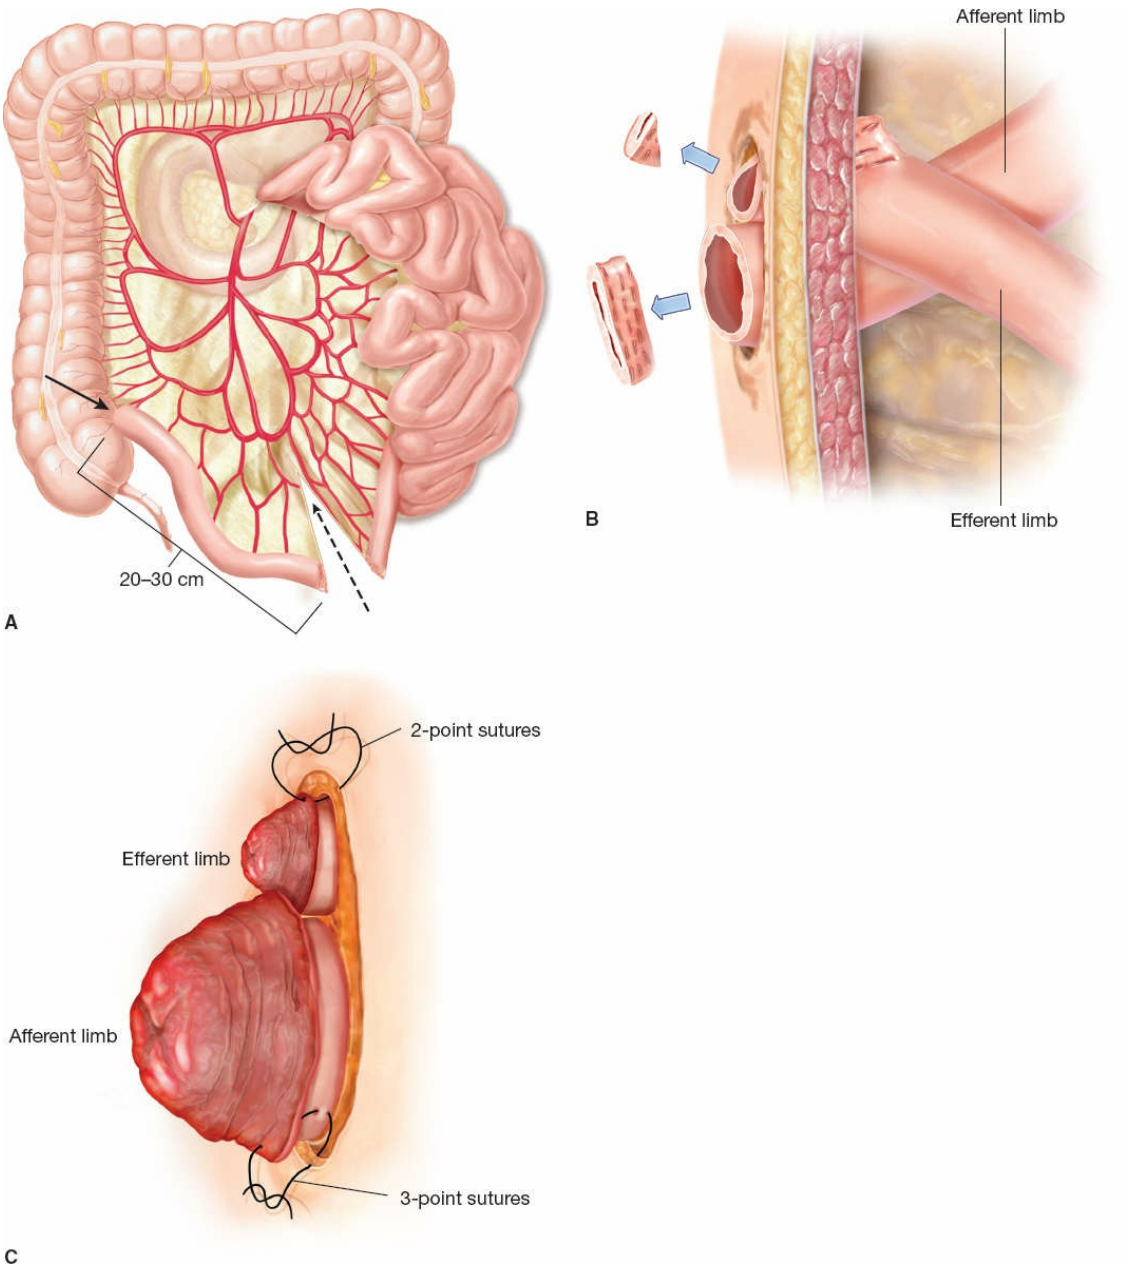

Figure 138.5. Creation of a divided loop ileostomy. **A.** The ileum is divided using a linear cutting stapler, 20 to 30 cm proximal to the ileocecal valve (*solid arrow*). The mesentery and vasculature are only minimally divided (*dotted arrow*). **B.** The stapled afferent limb is advanced through the abdominal wall aperture so that it protrudes for about 4 cm beyond the skin level, and the entire staple line is then cut off. Optionally, if distal decompression is desired for the efferent limb, only the antimesenteric corner is externalized, excised, and matured. The staple line may also be left intact on the efferent limb for total diversion. **C.** The afferent limb of the ileostomy is matured with three-point sutures. The efferent limb can be matured with two-point sutures. (From Daniel Albo, ed. Chapter 4: End and diverting loop ileostomies: creation and reversal. *Operative Techniques in Colon and Rectal Surgery*.

Philadelphia, PA: LWW; 2015:27–40.)

Trephine Ileostomy Creation

An alternative method of minimally invasive ostomy creation involves the use of a small incision at the chosen ostomy site, or so called “trephine” ostomy creation. This technique is successful approximately 89% to 94% of the time (avoidance of laparotomy) and results in function equivalent to open or laparoscopic creation.

Stoma Closure

Traditionally, temporary stoma closure typically occurs at approximate 3 months after creation when used as a protective stoma for a low colorectal or IPAA. Prior to closure, integrity of the anastomosis or ileal pouch is usually confirmed with a contrast enema, although in most cases the contrast enema does not provide any new information not already suspected clinically or seen on other routine imaging. It is also important to rule out distal obstruction. Lower endoscopy may also be performed to inspect the anastomosis or pouch. In the case of a problematic stoma, such as a high output stoma or when there is difficulty with appliance management, early stoma closure may be considered and has been shown to be safe as early as 3 weeks postoperatively assuming the abovementioned diagnostic studies do not reveal any significant anastomotic abnormalities.

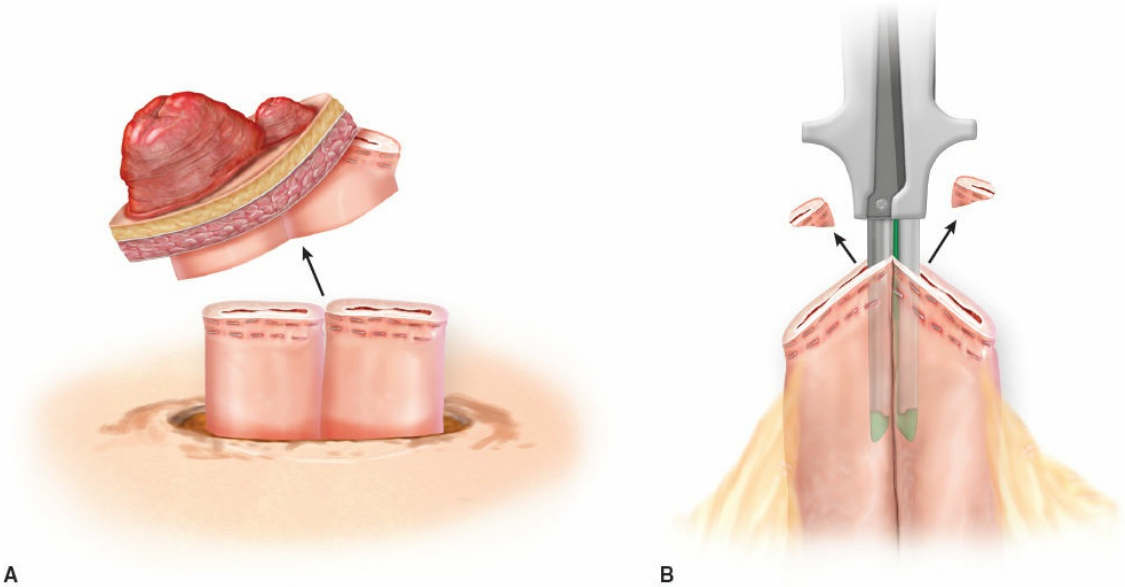

Figure 138.6. Reversal of a loop ileostomy: option 1 (results in

larger anastomotic cross section). **A.** The ileum is mobilized from the abdominal wall. The stoma itself (including the staples in case of a divided loop ileostomy) and adjacent fibrofatty tissues are resected with a linear cutting stapler to a level where both limbs are completely separated. **B.** A side-to-side (functional end-to-end) stapled anastomosis is created with a linear cutting stapler inserted into the antimesenteric aspect of each ileal limb. The remaining ileal opening is closed off with a linear stapler application or by using a hand-sewn technique. (From Daniel Albo, ed. Chapter 4: End and diverting loop ileostomies: creation and reversal. *Operative Techniques in Colon and Rectal Surgery*. Philadelphia, PA: LWW; 2015:27–40.)

Reversal of an end ileostomy typically requires a laparotomy to restore intestinal continuity. Loop ileostomy reversal however can typically be performed through a peristomal incision. The procedure begins with suture closure of the proximal lumen followed by coverage of the stoma with a small gauze dressing and a Tegaderm dressing. The stoma can then be prepped into the operative field with chlorhexidine skin preparation. A peristomal skin incision is made 1 to 2 mm from the mucocutaneous junction and deepened into the subcutaneous fat. This is carried down to the anterior fascia with great care to avoid injury to the small bowel as well as the bowel mesentery. The attachments to the fascia are carefully divided circumferentially and the peritoneal cavity is carefully entered. The surgeon's finger can then be carefully passed along the circumference of the bowel dividing any remaining adhesions until the ileal loop is completely mobilized. A GIA 80 stapler with 3.8-mm staples is used to divide the small bowel just proximal and distal to the stoma (Fig. 138.6A) and the intervening mesentery is divided with an energy device (LigaSure) or suture ligation. Antimesenteric corners of the proximal and distal limbs are cut off, and the arms of the GIA 80 stapler are inserted and the stapler fired a third time to create a side-to-side, functional end-to-end anastomosis (Fig. 138.6B). The common enterotomy is closed with a TA 60 stapler, or alternatively hand sewn with absorbable suture.

Alternatively, a primary transverse closure of the enterotomy at the stoma site may be performed in layers, including a running closure of 3-0 Vicryl followed by Lembert sutures of 3-0 silk (Fig. 138.7A,B). The defect may also be closed with a TA stapler (Fig. 138.7C). Following the anastomosis, the bowel is reduced back into the peritoneal cavity and the fascial opening is closed with interrupted number 1-PDS figure-of-eight

sutures. The stoma site is typically closed partially with a purse string suture of 2-0 Vicryl, followed by packing the remaining wound with betadine-soaked gauze. Alternatively, the wound can be managed by simple wound packing or delayed primary closure. Laparoscopy can be added to traditional loop ileostomy closure with possibly a lower complication rate and shorter length of hospital stay, although additional evidence is required before this technique can be widely recommended.

POSTOPERATIVE CARE

Following ileostomy creation, the patient's postoperative care is dictated by the nature of the operation performed (major colon or rectal resection vs. ileostomy creation alone). In general, postoperative patients are managed by an Enhanced Recovery after Surgery (ERAS) protocol that emphasizes early ambulation and initiation of oral diet, avoidance of nasogastric tubes and drains, narcotic-sparing pain regimens, use of selective peripheral mu-opioid receptor antagonists (alvimopan) and selective pro-motility agents.

Patients receive additional education from an enterostomal therapist in the early postoperative setting, and the patient's discharge needs related to ostomy care are assessed and appropriate arrangements are made. Significant evidence points to the value of postoperative in-hospital stoma education. Recommended education topics include anatomy and function of the ostomy, pouching procedural training, nutrition, clothing, medications, body image, psychological issues, sexual and intimacy issues, common complications including leakage and dermatitis, and available resources including support groups and online resources. Patients who have teaching from an enterostomal therapist as an inpatient seem to have better overall adjustment to having a stoma and view the enterostomal therapist as one of the most important elements of their recovery.

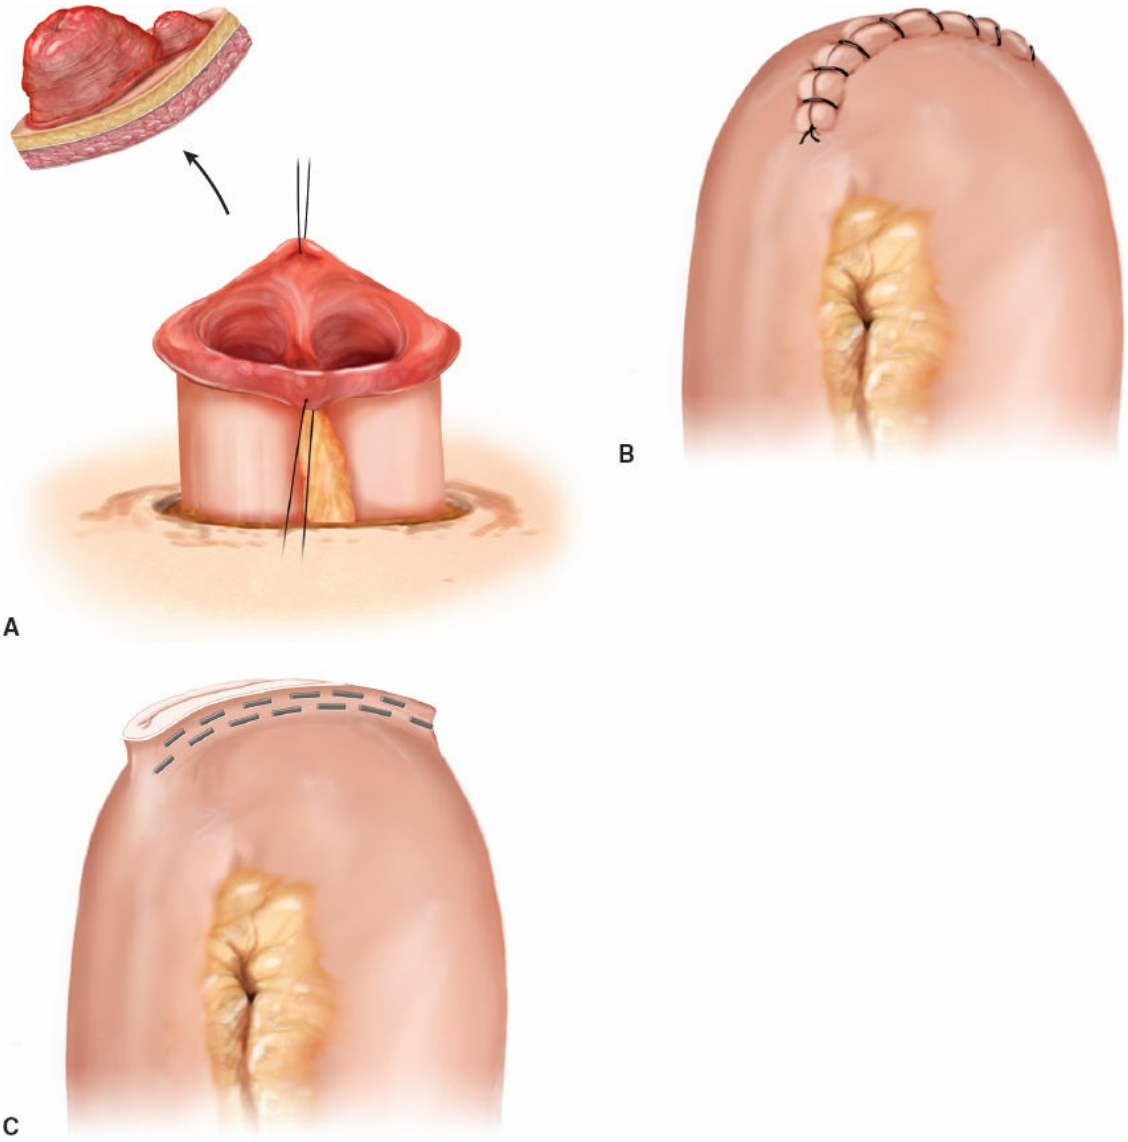

Figure 138.7. Reversal of a loop ileostomy: option 2. **A.** The ileum is mobilized from the abdominal wall. The stoma itself and adjacent fibrofatty tissues are resected sparingly so that the connecting bridge of ileum on the posterior/mesenteric aspect of the loop ileostomy is left intact. (**B**) The ileal defect is closed with a transverse two-layer hand-sewn technique or (**C**) with a linear stapler. (From Daniel Albo, ed. Chapter 4: End and diverting loop ileostomies: creation and reversal. *Operative Techniques in Colon and Rectal Surgery*. Philadelphia, PA: LWW; 2015:27–40.)

Creation of an ileostomy results in loss of the ileocecal valve as well as the water reabsorption provided by the colon, with the resulting risk of dehydration and electrolyte derangement. Early postoperative output can often be >1,000 mL/day; however, adaptation occurs with increased ileal water reabsorption over several weeks' time. Daily output should ideally

between 500 and 750 mL. Patients are educated on the importance of maintaining adequate hydration and are given discharge prescriptions for Lomotil (diphenoxylate and atropine) tablets with instructions on how to titrate to stoma output. Other medications that may be helpful in managing high ileostomy output include psyllium (Metamucil), cholestyramine (Questran), loperamide (Imodium), and tincture of opium. If necessary, arrangements may be made for the patient to receive outpatient vitamin B_{12} supplementation. A custom fit stoma belt may be made for the patient prior to discharge.

Outpatient follow-up with the enterostomal therapist is arranged prior to discharge. Outpatient follow-up is also a vitally important aspect of overall perioperative care. Shorter postoperative hospital stays make in-house teaching more challenging, which often needs to be supplemented with outpatient or in-home ostomy care teaching and support. A number of studies have shown that postdischarge ostomy support is associated with fewer ostomy-related problems, more independence, improved ostomy adjustment, and improved quality of life.

Following ostomy reversal patients are managed by the same ERAS pathway and are often discharged as early as POD 1, once adequate PO intake allows the use of oral pain medications. Data from our institution support the safety of ileostomy reversal in the ambulatory setting with a 23-hour postoperative stay. Patients and their families are generally taught to manage dressing changes at the old ostomy site.

COMPLICATIONS AND MANAGEMENT

Ileostomy Creation Patients

Skin Irritation and Pouching Issues

Over 80% of patients may experience one or more stoma-related complications. Common problems include skin irritation (up to 60%), appliance fixation difficulties (up to 50%), and peristomal leakage of the ileal effluent (up to 40%). Because of the liquid nature of the ileal effluent, the incidence of leakage is more frequent and consequences of leakage are more severe in patients with an ileostomy compared to a colostomy. Undoubtedly the incidence of leakage and pouching difficulties is much higher in patients with suboptimal stoma siting. Comprehensive stoma management is beyond the scope of this chapter, but consultation with an experience ET nurse is likely to resolve many of these issues, likely with

simple changes in the type of stoma appliance and other stoma care. However, as ET nurses are not universally available, surgeons who create intestinal stomas should be familiar with basic principles of stoma management, including common ostomy products. Issues related to ileostomy retraction may be dealt with simply by choosing an appliance with a convex faceplate that results in more protrusion of the stoma above the level of the skin. As with other stoma-related complications, consideration should always be given to whether an ileostomy may be safely reversed as a definitive way to solve many of these problems.

Stoma Necrosis

Although ischemia of a new ileostomy, particularly a loop ileostomy, is unusual, careful attention to the color of the mucosa is important. Use of a transparent stoma bag in the early postoperative period facilitates inspection. Edema and swelling and some venous congestion are relatively common, but a dark or black stoma requires immediate attention. Superficial mucosal necrosis may occur in up to 20%, but full thickness ischemia/necrosis occurs much less frequently (1% to 5%). The level of bowel ischemia can often be assessed with a Vacutainer tube and a flashlight; if stoma necrosis extends below the fascia, immediate operative revision is required to avoid peritonitis. If only the very distal mucosa is necrotic, this can generally be managed expectantly with likely mucosal sloughing revealing viable mucosa underneath.

Dehydration, Renal Failure, Readmission

Following creation of an ileostomy, patients are at significant risk for dehydration, both as an inpatient in the perioperative period and following discharge. Outpatient dehydration often results in readmission and in severe cases acute kidney injury. Use of an ileostomy care pathway that includes careful patient measurement and tracking of output with prompt notification of the patients care team may reduce the incidence of dehydration with resulting readmission and renal failure. In one study, readmissions for dehydration were reduced from 15.6% to 0% following implementation of an ileostomy care pathway. Avoidance of foods associated with diarrhea such as those high in glucose and fat may also be helpful.

Prolapse

Stomal prolapse occurs more commonly in loop stomas compared to end

stomas, and more commonly in loop colostomy compared to loop ileostomy. A contributing factor to stoma prolapse may be an unnecessarily large opening in the abdominal wall, and indeed stomal prolapse is often associated with a concomitant parastomal hernia (see below). Minor degrees of prolapse don't necessarily require treatment, as long as the stoma functions properly, but may require modifications of the ostomy appliance. In patients with pronounced prolapse, consideration should be given to the possibility of stoma reversal, which will eliminate the problem and often can be done via a peristomal incision in the case of loop ileostomies. Ostomy reversal does not differ from that for nonprolapsed loop ileostomies. In the case of a permanent ileostomy or in cases when reversal will not be possible for a prolonged period, local revision with stoma mobilization, resection of redundant ileum, and rematuration can often obviate the need for laparotomy.

Bleeding

The finding of bright red blood in the ostomy is often determined to be the result of direct mucosal trauma to the stoma from the edge of the appliance faceplate. Enlargement of the aperture cut in the appliance to assure 1 to 2 mm of clearance for the bowel will generally solve this problem. If bleeding is judged to be intraluminal, endoscopic evaluation of the bowel proximal to the stoma may be required.

Parastomal Hernia

Parastomal hernia in many cases is due to an opening in the abdominal wall that is too large. Siting the stoma through the rectus abdominus muscle may reduce the incidence of parastomal hernia. In the case of a temporary ileostomy, conservative management of a nonincarcerated and/or minimally symptomatic parastomal hernia until the ileostomy can safely be reversed, along with primary repair or mesh repair of the resulting fascial defect, is generally the best approach. In the case of permanent ileostomies, relocation of the ileostomy with repair of the original site may be required.

Parastomal hernia repair, either laparoscopic or via laparotomy, may be performed with either prosthetic or biologic mesh. Although the use of prosthetic mesh has historically been discouraged due to a perceived risk of mesh infection and erosive injury to the bowel, the literature reveals a mesh infection rate of only 2% to 2.6% and only one case of mesh erosion in 16 reported studies.

Laparoscopic repairs appear to have equivalent rates of recurrence to open repairs, although the two options have not been compared in a randomized trial. The two most common procedures performed laparoscopically are the keyhole/slit mesh technique, in which an aperture is cut to accommodate the bowel as it exits the abdominal wall, and the Sugarbaker technique, which is essentially an underlay of the ostomy site with the stoma limb exiting the mesh lateral to the fascial defect. Reported rates of recurrence for the keyhole technique range between 21% and 73%, compared to 7% and 15% for the Sugarbaker technique.

Stone Formation

Patients with ileostomies suffer from urinary stones in 12% of cases and may also have a higher incidence of gallstones. Both of these problems may be more pronounced when there has been resection of terminal ileum. Urinary stones seem to result from high levels of uric acid with formation of uric acid crystals and secondary precipitation of calcium oxylate. Treatment involves avoidance of dehydration, uric acid monitoring and possibly treatment with allopurinol, and avoidance of foods high in oxalate such as spinach and leafy vegetables. Gallstone formation is most likely due to loss of terminal ileum with resulting loss of bile salt reabsorption, rather than the ileostomy itself. Depletion of the bile salt pool results in decrease solubility of cholesterol and formation of gallstones. Bile salt binders such as cholestyramine may be helpful.

Small Bowel Obstruction/Food Bezoars

Small bowel obstruction may occur in up to 20% of patients undergoing an ileostomy, and is more frequent following loop ileostomy than after loop colostomy. Although the obstruction may be related to adhesions from the underlying surgical procedure and not from the ileostomy itself, ileostomy-related causes include internal herniation, looping or volvulus around the stoma, incarcerated parastomal hernia, mechanical obstruction at the ileostomy site due to angulation, inadequate fascial opening, and food bezoars. Management depends on the cause of the obstruction and generally includes initial expectant management with nasogatric tube decompression and intravenous hydration, unless peritonitis or signs of bowel ischemia are present. If imaging suggests volvulus around the ostomy, prompt surgical intervention is indicated. In temporary ileostomies, obstruction at the level of the stoma due to angulation or other technical issues can often be managed by stoma catheterization with a

urinary or red rubber catheter until stoma reversal is possible. Consideration should also be given to the possibility of obstruction due to a food bolus or bezoar. Careful digitalization of the stoma with a lubricated finger may identify an intraluminal bolus obstructing the stoma; gentle irrigation with saline through a red rubber catheter may resolve the obstruction in many cases.

Ileostomy Reversal Patients

Small Bowel Obstruction/Anastomotic Leak

Despite the lack of a formal laparotomy for loop ileostomy reversal, the procedure is not trivial and is associated with a reported morbidity of 17%, a 0.4% to 0.6% mortality, a 4% incidence to conversion to laparotomy, and a 7% incidence of small bowel obstruction. This should be considered when weighing the risk-benefit ratio of a protective loop ileostomy. Studies of stapled anastomosis versus hand-sewn closure of the stoma reveal an incidence of ileus of approximately 13% regardless of technique. There was a trend toward less frequent bowel obstruction with stapled anastomosis, but also a slight increase in anastomotic complications. The anastomotic leak rate is approximately 2% with either technique. Management of small bowel obstruction following DLI reversal does not differ from that for small bowel obstruction in other postoperative scenarios. Management options for anastomotic leakage after diverting loop ileostomy reversal depend on clinical severity and include bowel rest and antibiotics, percutaneous drainage of contained abscesses/collections, and laparotomy with end ileostomy and mucous fistula.

Wound Complications

The incidence wound infection depends on the manner in which the ileostomy site is managed. Purse string suture closure is associated with a wound infection rate of 0% to 7%, compared to up to 20% after delayed primary closure and up to 37% following primary closure.

EDITOR'S COMMENT

The chapter by Moore and Mantyh addresses many aspects of ileostomy construction and closure. Ileostomies have come into the spotlight over the last few years with the special emphasis on readmission as a measure of quality care of surgical patients. Readmission of patients with temporary ileostomy has been a topic of many recent publications as readmissions following ileostomy closure have occurred in over one quarter of patients undergoing this procedure (Fish DR, Mancuso CA, Garcia-Aguilar JE, et al. Readmission after ileostomy creation: retrospective review of a common and significant event. *Ann Surg* 2017;265(2):379–87). In a study of 1,114 new ileostomates in two large urban hospitals over a 30-month period, 39% of patients returned to hospital of which 28% of patients required readmission. Dehydration was the most common

reason for hospital admission. There have been several publications proposing pathways directed at postoperative patient education to decrease hospital readmission rates (Nagle D, Pare T, Keenan E, et al. Ileostomy pathway virtually eliminates readmissions for dehydration in new ostomates. *Dis Colon Rectum* 2012;55(12):1266–72; Hardiman KM, Reames CD, McLeod MC, et al. Patient autonomy-centered self-care checklist reduces hospital readmissions after ileostomy creation. *Surgery* 2016;160(5):1302–8). Nagle and her colleagues showed that such a pathway was able to decrease hospital readmission rates from 35% before initiation of this pathway to 21% after its implementation. Similarly, Hardiman and colleagues were able to decrease their readmission rate following ileostomy closure from 28% to 20% following introduction of a patient-centered checklist. It is this author's preference that such patient education material is discussed with the patient both before and during hospital admission and also then be given to the patient on a laminated card, which is provided at the time of hospital discharge. So many of the numerous sheets of paper that are given to patients on discharge are meaningless information and need to be supplanted by something more likely to be noticed and not discarded or misplaced.

While it is not mentioned in nearly sufficient data in Table 138.2 in this chapter, there are some detailed recommendations elsewhere in the chapter that give the essence of care. The reader is encouraged to refer to the chapter on Care of Stomas for more details regarding management. One of the most important points is that a majority of complications can be avoided by selection of a good stoma site. This is made all the more important by the changing body habitus of our population. According to recent data from the National Institute of Health Overweight and Obesity Statistics, more than two thirds (68.8%) of adult Americans are considered to be obese or overweight (https://www.niddk.nih.gov/health-information/health-statistics/Pages/overweight-obesity-statistics.aspx). In such patients who are undergoing a variety of procedures, such as anterior resection for cancers, sigmoid resection for diverticular disease, ileostomy diversion may be the preferred method of diversion, not only for the ease of closure, but for the much greater ease of constructing and ileostomy in an overweight, obese, or even super-obese individual as compared to a colostomy.

One should note that these readmissions have not been reduced to zero. Patients with ileostomy can be readmitted for other reasons, such as intra-abdominal infection, and intestinal obstruction. A symptom of both of these can be initially increased stoma output; patients can become weak and thoroughly dehydrated, especially in patients with heart disease and/or diuretic therapy. If this is foreseen, it is very easy for the patient, in their hometown and with their primary care physician and/or referring doctor, to get simple intravenous therapy as an outpatient, check up on what they are using for antidiarrheal medications, and many readmissions and related travel can be readily avoided. If the diarrhea is a manifestation of small bowel obstruction, this will soon

become apparent.

TABLE 138.2 Management of Common Ileostomy Complications

Skin irritation/ pouching difficulty		■ Consultation with WOCN-certified ET nurse ■ Consider convex appliance for retracted stoma ■ Try alternative ostomy appliance/products ■ Consider reversal
Stoma necrosis	Viable above fascial level	■ Expectant management
	Nonviable at fascial level	■ Emergent re-exploration and stoma revision
Dehydration/ renal failure	Prophylactic management	■ Use of ileostomy care pathway ■ Avoidance of foods causing diarrhea ■ Stool modification and antimotility medications ■ Rehydration
	Treatment	■ Slow output with antimotility medications
Prolapse	Minor, asymptomatic	■ Expectant management, modify appliance, consider reversal
	Large, symptomatic	■ Stoma reversal if possible vs. local revision
Bleeding	Peristomal	■ Enlargement appliance aperture to avoid mucosal trauma
	Luminal	■ Management as for GI bleed, endoscopic or angiographic evaluation
Parastomal hernia	Temporary ileostomy	■ Symptomatic management, reversal when clinically safe, primary or mesh repair of defect
	Permanent ileostomy	■ Stoma relocation with repair of fascial defect vs. laparoscopic/open Sugarbaker mesh repair
Stone formation	Urinary stones	■ Allopurinol ■ Avoidance of foods high in oxylate ■ Maintain hydration
	Gallstones	■ Bile salt binders (cholestyramine)
Small bowel obstruction/ food bolus	Likely adhesive etiology	■ Expectant management with NPO, NGT
	Concern for volvulus around stoma or internal herniation	■ Emergent operative management
	Due to food bolus stoma-level obstruction	■ Digitalization of stoma, gentle saline irrigation, intermittent stoma catheterization

Because of the numerous complications associated with ileostomies, there have been attempts to omit them from care, for example, in the case of patients undergoing anterior resection for rectal cancer. In a recent randomized prospective trial in which patients were randomized to receive temporary diversion with ileostomy versus no diversion, the absence of a stoma was associated with a significantly higher anastomotic leak rate (Mrak K, Uranitsch S, Pedross F, et al. Diverting ileostomy versus no diversion after low anterior resection for rectal cancer: a prospective, randomized, multicenter trial. *Surgery* 2016;159(4):1129–39). In yet another study, in an attempt to reduce the complications of loop ileostomy, investigators undertook early closure of ileostomy following surgery for rectal cancer, randomizing patients to have their ileostomies closed between 8 and 13 days postoperatively, as compared to more than 12 weeks postoperatively (Danielsen AK, Park J, Jansen JE, et al. Early closure of a temporary ileostomy in patients with rectal cancer: a multicenter randomized controlled trial. *Ann Surg* 2017;265(2):284–90). They found fewer complications following the index operation up to 1 year postoperatively in those patients undergoing early ileostomy closure. It is likely that our practice will continue to evolve as we identify more ways in which to minimize morbidity of diversion, while maximizing its benefits.

Susan Galadiunk

I find it difficult to believe that there is this much difficulty with ileostomies. Instead of trying to explain it away (a variation of "blame the patient") I think the blame should be placed squarely on the shoulders of the surgeon—sloppy anastomosis, a rush to get out of the OR, and a rush to discharge the patient. In my experience, one should wait until the effluent decreases, the effluent thickens, and the patient knows how to control the ileostomy. Ostomy nurses in the postop period can assist until the patients and those who surround the patient know how to care for him or her. I thought the days of "blaming the patient" are over, but it seems that I am wrong.

139 Gastrointestinal-Cutaneous Fistulas

Josef E. Fischer and Amy R. Evenson

Enterocutaneous fistulas (ECFs) represent a catastrophic complication of abdominal disease, usually following surgical procedures. At least 85%, and perhaps as many as 95%, follow abdominal operations. Spontaneous fistulas usually occur as a complication of inflammatory bowel disease, cancer, or radiation. Spontaneous fistulas complicating cancer usually occur in advanced disease, and the prognosis, for the most part, is poor. Modern management strategies have resulted in improved overall mortality from upward of 50% to 60% between the 1940s and 1950s to between 10% and 20% from the 1960s through the turn of the century. At present, in the proper hands, mortality may range from only 0% to 2%, usually from complications of sepsis.

When a fistula follows operation, it is usually the result of an unrecognized enterotomy or leaking anastomosis, often because of poorly prepared or distended bowel, or emergency operation with the patient nutritionally or immunologically in suboptimal condition. A fistula may also follow inadequate blood supply to the bowel or, in many situations, distended or weakened small bowel due to a delay in relieving partial or near-total intestinal obstruction.

Recently, a new cause has appeared for postoperative fistulas and this is gastrointestinal cutaneous fistulas following open or especially laparoscopic ventral abdominal herniorrhaphy. The fistula seems to be caused by one of two etiologies: the first being an inadvertent enterotomy; the second, and more common, is the use of permanent mesh which may become infected and erode into the bowel, or a fastening tack that may injure the bowel inadvertently causing arcing of an electrical current which may in turn also cause bowel injury. In the case of the infected mesh, it is rare for fistula to close without removing the offending mesh. Rarely, mesh removal alone is sufficient for the fistula to close without bowel resection. Frequently, however, bowel resection is also required. At the present rate of presentation, this may become one of the more common

causes of gastrointestinal fistula, as in some series antecedent ventral abdominal herniorrhaphy is responsible for 10% of ECFs.

ETIOLOGY AND PREVENTION

ECFs result from one of the following several conditions:

1. Extension of bowel disease to surrounding structures;
2. Extension of adjacent nonbowel disease to normal bowel;
3. Inadvertent or unrecognized injury to the bowel; or
4. Anastomotic disruption.

As stated earlier, 85% to 95% of fistulas occur in the postoperative period. Operation for complications of inflammatory bowel disease, resection of malignancy, adhesiolysis for intestinal obstruction, and herniorrhaphy are the most common antecedent procedures. Preoperative factors may increase the likelihood of development of an ECF. These factors include malnutrition, infection, emergency procedures with preoperative hypotension, anemia, hypothermia, or poor oxygen delivery. In elective procedures, these aggravating factors should be corrected prior to operation with nutritional support, bowel preparation, and control of abnormal physiologic parameters such as cardiac output, hyperglycemia, and anemia. Ideally, serum albumin should be >3.3 g/dL (better yet, 3.5 g/dL) and the patient should not have lost >10% or 15% of body weight in the preceding four months. Diabetes should be controlled, and if time permits, 5 days of parenteral nutrition should be administered. Our experience is that within 5 days of adequate nutritional support, the patient begins to feel better and serum transferrin will increase. However, serum albumin will not increase because of the half-life of ~20 days. Mechanical and antibiotic bowel preparation, if feasible, should be carried out, although some doubt the efficacy of both mechanical and antibiotic bowel preparation. The current view is that it is not harmful except for *Clostridia difficile* if antibiotics are given orally as a preparation. All agree, however, that the administration of intravenous antibiotics within one half hour of the incision and maintenance of satisfactory blood antibiotic levels throughout the procedure, which may be prolonged sometimes, are necessary. While this preparation will not obviate the occurrence of fistulas completely, they may diminish their occurrence. Abscesses will be minimized at the very least.

In the patient undergoing an emergency procedure, however,

optimization of resuscitation and performance of a technically meticulous procedure may be the only steps the surgeon can take to prevent ECF. Maintenance of oxygenation, warm room temperatures, optimization of cardiac output, and adequate monitoring may improve the outcome. Sound surgical technique includes an adequate incision, good lighting so that one can visualize the procedure completely, adequate mobilization, and the use of healthy bowel with good blood supply for anastomosis with avoidance of tension, hemostasis, and adequate transfusion, which minimizes the risk of formation of a fistula. In addition, prior to abdominal closure, the bowel should be inspected for inadvertent bowel injury and all enterotomies should obviously be repaired. It is our practice to repair enterotomies when they occur, as they may be difficult to find later. It is our custom to repair serosal injuries with fine nonabsorbable sutures such as 4-0 or 5-0 Prolene when they occur contrary to what some have proposed.

SPONTANEOUS ENTEROCUTANEOUS FISTULAS

Spontaneous ECF most commonly occurs in the setting of inflammation, malignancy, or irradiation. Inflammatory causes of ECF include Crohn disease, and, less commonly, ulcerative colitis, peptic ulcer, appendicitis, diverticulitis, pancreatitis, especially when pancreatic necrosis is treated by repeated dressings, and ischemic bowel. In inflammatory bowel disease, ECFs in the patients with Crohn disease represent a special concern for the surgeon. Often a fistula in these patients will resolve with nonoperative management only with parenteral nutrition, only to reopen on resumption of enteral feedings. Some of the newer, immunologic-type drugs may result in more frequent closure; however, it is not clear that these fistulas once closed will not recur. Our practice to close the fistula nonoperatively when possible and then operate on the patient to resect that portion of bowel when infection in the abdominal wall is quiescent. A second important distinction that is pertinent to the patients with Crohn disease involves whether the patient’s fistula arises in healthy bowel (following resection of the diseased segment) or from diseased bowel not necessarily following bowel resection. The former type is probably no different than in the patients without inflammatory bowel disease and has a high likelihood of spontaneous closure. The latter, as stated earlier, has a lower rate of nonoperative closure. Patients with this type of fistula may benefit from early resection especially if it can be closed spontaneously prior to operation, as these fistulas tend to reopen.

In the patients with malignancy or following radiation therapy, different tactics may be used because many of these fistulas will not close without resection. In patients with cancer, occurrence of a spontaneous fistula is a grave sign indicating a poor outcome. An understanding of the etiology may provide information about the likelihood of successful closure with or without intervention.

It must be remembered that more than one of these predisposing conditions may exist in any patient and the risks are compounded when multiple factors are present.

CLINICAL PRESENTATION

Recognition of a postoperative ECF follows a distinct pattern. The patient does not do well immediately following the operation. There is a slow course with fever and a prolonged ileus as well as a feeling of malaise. Abdominal distention may also be part of the picture. Most of all is a lack of progression and recovery from the original operation with a low-grade fever sometimes up to 101°F or even 102°F and more abdominal tenderness than one would ordinarily expect if the operation were uneventful. On the fifth or sixth postoperative day, a “wound infection” presents which is then drained; defervescence follows and the patient improves. There is some relaxation on the part of the surgeon as perhaps the patient will now do well. However, within 24 hours, enteric contents drain from the wound and the surgeon knows that one is dealing with a gastrointestinal cutaneous fistula.

At this point there is a decision to be made. There are data from experienced centers that indicate that immediate reoperation before 9 or 10 days postoperatively results in 10% mortality, whereas operation between 10 and 120 days results in 20% mortality. However, we would caution operating on the patient at this time. The operation is not risk-free because the patient is in suboptimal condition (i.e., some of the same conditions are present that contributed to this patient getting a fistula in the first place, which include the following: suboptimal nutritional condition, distended bowel, early obliterative peritonitis, and probably a suboptimal immunologic status). Operation at this point may yield another fistula which will make things worse and probably have a higher mortality. A second alternative, and one which I would support, is to accept the fistula, not reoperate, and counsel the patient that one will try nonoperative closure, and that if this does not work, then reoperation after an interval of

4 or 5 months lies ahead. This will be difficult on the patient and his or her family, but this is likely to result in long-term survival. One needs the support and cooperation of the patient and his or her family to be successful.

NUTRITIONAL SUPPORT

As soon as the fistula has been discovered, one evaluates the patient. It is likely that the patient is nutritionally deficient and intravascularly depleted with multiple electrolyte deficiencies, especially sodium, potassium, phosphate, and magnesium. There is often a lack of intravascular volume as the patient has been third spacing. Bowel distention leads to movement of fluid as well as protein and electrolytes into the extravascular space as well as within distended bowel. These need to be replenished. Given the sophisticated electrolyte monitoring available, it is surprising that these deficiencies in electrolytes occur quite frequently—patients escape from tight monitoring. In addition to measuring serum electrolytes, one can get an idea of what the composition of fluid lost is by sending some of the fistula fluid for electrolyte determinations (Table 139.1). This will help maintenance of normal electrolytes in the serum, as one replaces what is being lost.

TABLE 139.1 Electrolyte Composition of Body Fluids[a]

Source	Volume (mL/d)	Na	K	HCO_3	Cl
Gastric	2,000–2,500	60	10		90
Pancreatic	1,000	140		5 90–110	30–45
Bile	1,500	140	5	35	100
Small bowel	3,500	100–130	15	25–35	100–140
Diarrhea	1,000–4,000	60	10–20	10	45–65
Urine	1,500	20–40	20–40		20
Urine + Lasix		40–60	20–40		60–100
Sweat		50	5		55

[a]All electrolyte values are mEq/L.

The patient should be kept NPO and hard candy may be allowed to keep saliva flowing, avoiding sialadenitis. Aggressive restoration of intravascular volume should take place at once, utilizing 5% Albumisol as well as crystalloid. One must be careful as to how much crystalloid is

administered, as one does not want to get an edematous patient after resuscitation, so judicious administration of crystalloid is necessary. Supplementation of magnesium, phosphate, and potassium as well as sodium is required to prevent further electrolyte disturbances. Malnutrition that complicates ECF is multifactorial. Postoperative patients have often endured 1 to 2 weeks of starvation with essentially no oral intake prior to recognition of the fistula. As for those patients with spontaneous fistulas, they have inflammatory bowel disease or malignancies which may lead to poor nutrition for some time. Some patients may have limited absorptive areas of the bowel. Further, ECFs are often accompanied by sepsis and inflammation which increase the metabolic needs.

NUTRITIONAL STATUS

Depleted nutritional status interferes with the ability to resuscitate the patient and is one of the principal determinants of mortality, whereas the ability to reverse poor nutritional status improves outcome. In one large series, patient serum albumin level, at first discovery, was a major factor in survival. Patient serum albumin of <2.5 g/dL had an increased mortality, whereas patients with a normal serum albumin level (>3.5 g/dL) suffered no mortality. Hypoalbuminemia may also inhibit wound healing and may lead to bowel dysfunction, complicating efforts to feed the patient enterally. Other serum markers of nutrition which may predict mortality include transferrin, retinol-binding protein, and thyroxine-binding prealbumin; these should be monitored on at least a weekly basis as it has been shown that they predict morbidity and mortality in patients with ECFs. Enteral feeding, if it can be successfully provided, at least in part, appears to have a salutary effect on hepatic, intestinal, and respiratory integrity. This is true even if most of the direct nutritional support is given parenterally, but the presence of a significant enteral component is certainly beneficial.

The ability to optimize nutritional status in patients with ECFs depends on successful control and, when possible, elimination of sepsis. The leading cause of mortality in contemporary series is sepsis and multiorgan system failure in the patients with ECFs. Fistula formation is only one of several possible outcomes of bowel perforation or anastomotic breakdown. Enteric contents escaping the bowel lumen may be contained in the local abscess or may spill freely throughout the peritoneal or thoracic cavities, or may track through the abdominal wall and form an ECF. Closed-space

sepsis, such as an abdominal abscess, must be drained before the patient will be able to establish positive nitrogen balance. The liberal, early (emphasize early, not repeatedly) use of computerized tomography, ultrasound, or magnetic resonance imaging will allow early identification and percutaneous management of intra-abdominal abscesses. Peritonitis resulting from free circulation of enteric contents requires urgent laparotomy to contain the spillage and prevent further soilage. If all else fails, a proximal diverting enterostomy may be necessary to control local wound sepsis, which is also treated with antibiotics and wound care techniques employed to protect the surrounding abdominal wall.

Intra-abdominal sepsis is not the only cause of catabolic fever. Blood, urine, and sputum cultures should be obtained to evaluate concomitant infections. In considering antibiotic use in patients with ECFs, one must be very judicious in a choice of antibiotics to avoid selection of multi-agent-resistant organisms, and therefore antibiotics should only be used to treat identified infection using the narrowest spectrum agent available for the shortest duration of time. In the classic study written by Soeters in the 1970s, the average number of antibiotics used throughout such a course of a patient with an ECF was eight or nine, emphasizing the need to think very carefully as to whether antibiotics are needed, and if so, what spectrum should be used. In my view, it is better to tolerate a low-grade fever if the patient is not ill rather than use antibiotics which may be needed later in the course. Finally, it is important to remember that when an abscess is drained, a bacteremia occurs and therefore one should refrain from placing a central line for 12 hours following the drainage of an abscess to avoid contamination of a new catheter.

MANAGEMENT

The goal of treating ECFs is to restore bowel continuity, to achieve enteral nutrition, and to close the fistula. Whether achieved with or without surgical intervention, management of this complex patient is probably best conceptualized in stages with specific goals for each stage (Table 139.2). One of my mentors, Dr. Francis D. Moore, long-time Chief of the Peter Bent Brigham (at that time), was a master at dividing complex problems into more easily manageable phases.

Stabilization of the patient with identification of the fistula, initial resuscitation, the steps taken to contain fistula drainage, and the beginning of resuscitation take place within the first 24 to 48 hours. Obvious

abscesses should be drained, the extracellular fluid space minimized, and the intravascular space resuscitated and expanded to normal levels. Electrolyte disturbances should be corrected, hypoalbuminemia treated, and severe anemia corrected by the judicious use of packed cells. If sepsis is present, appropriate antibiotics should be started. Though these important steps should take place within the first 24 to 48 hours, they may not be completed for up to 5 days, at which point the patient should be stable and not overtly septic. Sometime between 7 and 10 days, if the patient can tolerate it, the surgeon and a senior radiologist should carry out fistulograms to see whether operative intervention will finally be required. The decision as to definitive therapy is considerably later and usually takes place 5 to 6 weeks after the initial discovery. If the decision is made that operative therapy will be required, it is purely elective unless the patient is septic, in which case immediate operation is necessary and it is for patient salvage rather than definitive therapy. If the surgeon is not pushed by sepsis to do this definitive therapy, he or she should wait until the obliterative peritonitis subsides, usually at 4 to 5 months with a patient who has been totally restored with the exception of the fistula, and taken to the operating room. Prior to this, the patient must be sustained with appropriate nutritional support, enteral or parenteral or both, and have physical and emotional rehabilitation during the healing phase which is a continuation of that which takes place prior to operation. Following successful operation, continued rehabilitation, nutritional counseling, and emotional support are necessary to return the patient to his or her original level of function.

TABLE 139.2 Phases of Management for Enterocutaneous Fistulae

Phase	Description	Timing
Stabilization	■ Rehydration ■ Correction of anemia ■ Electrolyte repletion ■ Drainage of sepsis ■ Control of fistula drainage ■ Local skin care measures ■ Commencement of nutritional support	■ 24–48 hr
Investigation	■ Fistulogram to define anatomy ■ CT/US/MRI to localize collections and guide drainage	■ 7–10 d
Decision	■ Assess likelihood of nonoperative closure ■ Plan therapeutic course ■ Decide optimal surgical timing	■ 7–10 d to 4–6 wk
Definitive therapy	■ Plan operative approach ■ Bowel resection with end-to-end anastomosis ■ Secure abdominal closure (+/– flap) ■ Gastrostomy ■ Jejunostomy	■ >4 months if spontaneous closure unlikely
Healing	■ Continue nutrition support ■ Transition to total oral/enteral feedings ■ Physical and emotional rehabilitation	■ 5–10 d after closure

CT, computed tomography; US, ultrasound; MRI, magnetic resonance imaging.

PHASE I: STABILIZATION

By the time a postoperative fistula has become apparent, the patient already has significant deficits in lean body mass, intravascular volume, red cell mass, various serum electrolyte, and serum proteins such as serum albumin and acute phase reactants. Resuscitation should begin with protein-containing solutions such as 5% Albumisol, provided there is no sepsis-related capillary leak, as concentrated salt-poor albumin is too expensive. One could begin with some crystalloid; however, one must be very careful not to overwater the patient and make the patient edematous. It is helpful, as stated earlier, to measure the fistula drainage to get some idea as to what electrolytes are being lost and use these values as a guide to replacement. Electrolyte values should be monitored as replacement continues until stable values are achieved. Red cell mass should be

increased to optimize oxygen delivery. Though the current thinking is that a hematocrit of 21% is adequate. This is too low for the patients who are critically ill and opt for a value of a hematocrit of 30 for oxygen delivery. Although some may be happy with a serum albumin in the in the range of 2.5, we believe we are better off with an albumin of 3.0 to 3.3 at the very least in order to make certain that there is not interstitial edema, that the edema does not interfere with wound healing, and that nutrients are absorbed and get to their destination. Albumin should be administered unless there is sepsis-induced capillary leak. Invasive monitoring and central venous or pulmonary artery catheters may be necessary to guide therapy in the patients with poor cardiopulmonary reserve.

DRAINAGE OF SEPSIS

Review of most series of gastrointestinal cutaneous fistulas indicates that sepsis is the most likely cause of death. Because of this, a patient manifesting evidence of ongoing sepsis, such as fever, hypotension, low systemic vascular resistance, elevated white blood cell count especially with a shift to the left, and certainly a positive blood culture, should trigger an exhaustive search for septic foci. In addition to a careful abdominal and chest examination including a careful rectal exam and search for masses or tenderness which are unexplained, a CT scan should be obtained as well as an ultrasound of the abdomen and pelvis which may reveal abscesses that may be drained percutaneously. Before doing so, one should be ready to inject the abscess with water-soluble dye once the percutaneous drain has been placed. One may get information from the early films as to where the abscess is tracking from and thus the etiology of the fistula and the abscess. Pus from the abscess should be Gram stained as well as microbiologic culture along with blood, urine, and sputum samples. Patients with peritonitis, which is uncontrolled, are in terrible shape but must be explored expeditiously to prevent further deterioration and peritoneal contamination. It is highly unlikely that under those circumstances anything other than meticulous debridement and copious lavage with antibiotic solution can be carried out. Any resections and anastomoses are unlikely to hold but proximal diversion may be lifesaving to control ongoing leakage.

CONTROL OF FISTULA DRAINAGE AND SKIN CARE

The goal in the care of these patients is for them to ultimately undergo re-

exploration after 4 months if they do not close spontaneously. In order to do so, one must prevent continued cellulitis of the abdominal wall and destructive infection of the original wound. Fistula drainage must be managed in a way that it can be both contained and quantified. Only very low-output fistulas can be managed with a dry or a wet dressing while the fistula is active. However, should the external opening of the fistula close, an abscess will result. This is, however, so rare that we mention it only in passing. For most patients, it is not possible to care for fistula drainage by dressings alone. I usually manage the effluent from gastrointestinal cutaneous fistulas with homemade sumps created from latex Robinson nephrostomy tubes with a #14 Intracath inserted (Fig. 139.1) so that it breaks the suction at the end of the catheter. An extra hole placed 3 cm proximal to the end of the catheter will help collect the effluent. This catheter is soft at body temperature and will not erode the bowel and does a good job collecting the effluent. These nephrostomy catheters come in sizes from 12 to 36 French, and thus can be customized for the thickness of the effluent. The catheter is connected to continuous wall suction. The skin and subcutaneous tissue should be protected with DuoDerm, Ion exchange resin, which keeps the skin acidic, preventing activation of the pancreatic enzymes, ileostomy cement, and the other protectants. Engaging an ostomy therapist is essential to instruct the nurses on the floor and to maintain the integrity of the skin and the surrounding tissues.

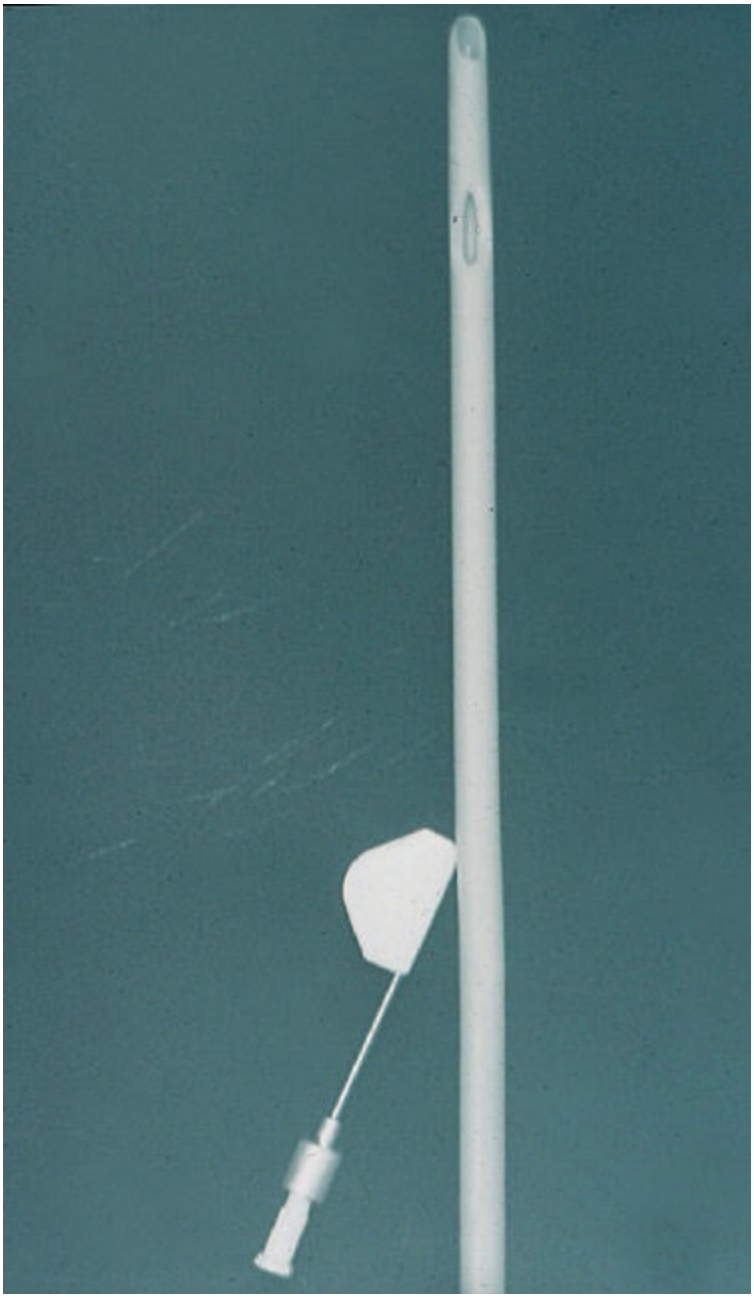

Figure 139.1. Sump system for management of fistulae.

Recently, several groups reported the use of vacuum-assisted closure devices to aid in the management and closure of these wounds. They can be very helpful especially with large open areas in the case of low-to-moderate output fistulas (Fig. 139.2), and a 12- to 14-French nephrostomy catheter is also used at the most distal opening to administer enteral feedings. One must remember that in addition to closing fistulas, these devices can also cause fistulas even when the original fistula has been closed, as we have reported. In addition, some groups advocate the use of split-thickness skin grafts around the fistula opening as a biologic dressing

that reduces protein and fluid loss, thus positively affecting the patient's nutritional status. The contraction induced by split-thickness skin grafts may narrow the fistulous field, but we have not noted this to be definitive in fistula closure. A large defect usually requires component separation or a myocutaneous flap.

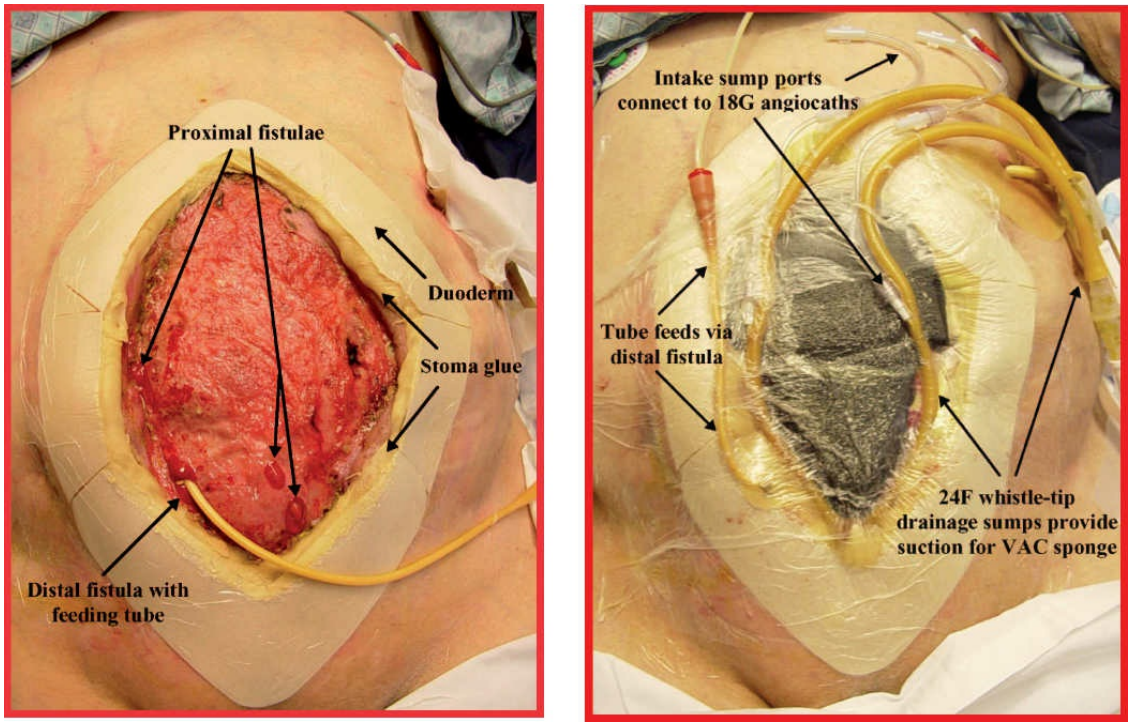

Figure 139.2. Vacuum-assisted closure (VAC) dressing in situ.

REDUCTION OF FISTULA OUTPUT

It is obviously advantageous to have less effluent to contaminate the wound and have to deal with. There are only a few medications which have been used with some efficacy to decrease GI secretions. Histamine H_2 antagonists or proton pump inhibitors reduce the production of gastric acid and output. Sucralfate, a gastric mucosal protective agent, may also reduce gastric output and may contribute to constipation and thus decrease fluid loss. Nasogastric drainage is useful only in cases of distal obstruction or ileus; the long-term use of nasogastric drainage may result in alar necrosis, chronic sinusitis, or distal esophageal stricture particularly in the patients with reflux or hiatus hernia. Pneumonitis is also more common. If the patient has a gastrostomy, this is useful when put to drainage; some consideration should be given for the placement of a Stamm gastrostomy under local with a short transverse left-upper quadrant incision or an endoscopically placed gastrostomy tube which may be more dangerous in

the obliterative peritonitis that follows gastrointestinal cutaneous fistula.

Somatostatin and its long-term analog octreotide have also been proposed in the management of the ECFs to decrease output. There is little question that pancreatic and biliary secretions are generally decreased; however, it is not clear that octreotide has any beneficial long-term effect on spontaneous closure except in biliary and pancreatic fistulas. Octreotide does have adverse side effects on the incidence of gallstones and cholecystitis. Some authors suggest a 48-hour trial of these agents should be attempted, and if the output is decreased, it should be utilized. We do not use octreotide in the management of our patients, as in addition to cholecystitis, hyperglycemia, mucosal atrophy, and interruption of intestinal adaptation are its side effects. There is little question, at least in our minds, that octreotide is efficacious in pancreatic fistulas.

Infliximab, a monoclonal antibody to tumor necrosis factor alpha, has been extensively evaluated and utilized in fistula secondary to Crohn disease, and a recent large randomized controlled trial suggests that maintenance of patients with fistula secondary to Crohn disease with infliximab reduces hospitalizations and the need for surgery in this population. In addition, others have proposed that tacrolimus be given orally in addition to infliximab in these patients. Several small studies have suggested that it may aid in both closing persistent fistulas and allowing patients be weaned from steroid and other immunosuppressive therapy. In addition, there are several case reports of patients with chronic, non-Crohn fistulas that have achieved closure permanently following a single infusion of infliximab. Though these results are intriguing, further studies will be required before a recommendation can be made for the use of these agents in the routine management of ECFs, particularly because acute infection is always a danger.

NUTRITIONAL SUPPORT

Nutritional support should only be delayed to treat or drain sepsis. These patients lose 300 to 500 g of lean body mass daily, so delay is expensive. The best nutritional support is a combination of parenteral and enteral support. The use of enteral support, while desirable, is also accompanied by an increase in fistula output which has no long-term effect, as ultimately this does not affect ultimate closure. However, in reviews of series in which enteral and parenteral nutrition had been compared, the spontaneous closure rate with parenteral nutrition is only slightly higher

than was closure with enteral nutrition. On the other hand, enteral nutrition has distinct advantages with respect to hepatic function and synthesis of short turnover proteins, some possible immunologic advantages, and thickening of the bowel wall should operation be required. However, one must be careful with the administration of enteral nutrition to avoid pneumatosis and other dangers to the bowel especially in the patients whose blood supply may not be optimal ("the challenged bowel"). It takes about 5 or 10 days of judicious increases first in volume and then in osmolality. Thus, one begins with parenteral nutrition to decrease the loss of lean body mass.

Metabolic needs may be estimated using the Harris–Benedict equation and appropriate stress factors, but it usually underestimates the need for protein. Frequent use of a metabolic cart and indirect calorimetry may be helpful as a general guideline. Our practice is to provide 32 calories/kg with a calorie nitrogen ratio of 100:1 later increasing the ratio to 125:1 and 150:1 as sepsis and hypermetabolism decreases. Essential fatty acids should be administered three times weekly in the form of a lipid emulsion, and one can finally provide between 15% and 20% of the caloric needs with intravenous fat. As one is increasing parenteral nutrition, one can begin supplementation with enteral nutrition and must expect an increase in fistula output initially. Monitoring of serum electrolytes, serum albumin, calcium, phosphate, and magnesium should occur every other day as one begins with utilizing the smallest amount of blood possible. Liver chemistries, serum transferrin, retinal-binding protein, and thyroxine-binding prealbumin should be performed weekly. As the patient stabilizes, blood chemistries can be obtained twice weekly and then weekly. Serum transferrin and other short-term proteins may provide prognostic parameters as to outcome.

Enteral support requires 4 ft of small bowel for absorption. It does not matter whether the 4-ft area is connected to the distal stomach or one feeds the fistula and the 4-ft area is distal to the fistula. A small nasoenteric tube can be passed without bothering the patient too much, but it must be in the small bowel beyond the ligament of Treitz to prevent aspiration especially when sepsis may occur suddenly and gastric and enteral motility stop. If enteral nutrition is continued, a sudden cessation of motility may result in aspiration.

One must be very careful of hyperosmolality of the enteral feeds. The manufacturer's recommendations must not be followed because these are

overly optimistic as to the bowel's ability in a sick patient to dilute a hyperosmolar bolus. Remember that many of these patients have what is called a "challenged bowel" and may not be able to increase blood flow sufficiently to dilute a hyperosmolar effect. We have noted that the patients with a nasoenteric tube have a lower incidence of pneumatosis and intestinal necrosis than those with a feeding jejunostomy, for reasons that we do not understand. We generally start tube feedings at an osmolality of 150 milliosmoles/L and gradually increase the osmolality never exceeding 250 to 275 milliosmoles/L, in that way avoiding the possibility of intestinal necrosis. This process takes 5 days or longer, so parenteral nutrition is absolutely essential. It may not be possible to achieve full-strength enteral feeds defined as 320 milliosmoles/L; we do not try and accept 275 milliosmoles/L as the maximum osmolality administered.

PHASE II: INVESTIGATION

Assuming that there is no reason to obtain a CT scan for unexplained fever or other indications of sepsis in which case it should be carried out urgently, one should allow the patient to recover without going down to x-ray for ~7 to 10 days. The x-ray table is hard and the x-ray department is always cold. At this point, the patient begins to feel better, and if one measures transferrin or other short-term proteins, one will see improvement. One can then undertake radiologic examination in order to get some idea of what one is dealing with. I believe that a fistulogram is the only examination radiologically one needs in order to determine what the patient's course is likely to be, provided that one follows the dye distally to make certain that there is no distal obstruction. The radiologic examination should be a collaboration between a senior surgeon and a senior radiologist. Water-soluble dyes should be used, and the early films are most important as these will give detail about the fistula and the surrounding bowel. Small flexible feeding tubes should be utilized to inject all the orifices with spot films obtained. Review of the early films reveal information concerning the diameter of the tract, the site of the bowel wall defect, the health of the adjacent bowel, the presence of strictures or adjacent cavities, the length of the tract between the fistula and the abdominal wall, and distal obstruction. An end fistula represents anastomotic disruption or an inadvertent injury to the bowel wall. These characteristics will enable one to predict whether the patient will close spontaneously or require operation.

We do not obtain additional contrast examinations such as upper gastrointestinal series or barium enemas. These examinations rarely demonstrate fistula tracts and give less information that can be obtained with a well-executed fistulogram. Unless the patient is septic, computerized tomographic scans are unnecessary, although they can reveal unexpected abscesses. If additional studies are required, it is important to avoid the effects of residual contrast on subsequent studies.

PHASE III: DECISION

The goal of this portion of the patient's course is to determine the likelihood that the fistula will close with continued nonoperative management or will require definitive surgical therapy. If surgical intervention is required, usually fistula output, though it may decrease somewhat, will not decrease substantially, suggesting that the fistula will not close. A good marker is that if the fistula does not close spontaneously within 5 weeks of sepsis-free adequate nutrition, it is unlikely to do so if one persists. Ileal fistulas may take longer, up to 40 to 50 days, and are less likely to close, even if the characteristics of the fistula are favorable. Even in the most optimistic series, the closure rate for ileal fistulas was <40%. This is not to say that if fistulas do not close after 5 to 6 weeks, the patient should be operated on at that point in time. Indeed, it takes 4 months for the obliterative peritonitis to subside. In the experience of the Cleveland Clinic, the mortality is 10% in reoperation prior to 10 days and after 120 days, but 20% during that time period. It may be difficult for the patient and the family to wait for that period of time, but it is essential that they understand. In addition, there are certain sites that tend to close, as given in Table 139.3. Fistulas arising from the oropharynx, esophagus, duodenal stump or lateral duodenum, pancreatic and biliary tree, and jejunum are likely to resolve without operative intervention than are fistulas originating from the stomach, ligament of Treitz, or ileum. Longer fistula tract length also suggests a greater likelihood of closure, and short tract for some reason unlikely to spontaneous resolve, perhaps because enteral mucosa grows up to the surface.

Fistulas may be classified according to the amount of fluid drained daily. Small output fistulas are defined as those with <200 mL a day, likely to be colonic in origin. These may close while the patient is ingesting oral diet, and constitute less of a challenge than in the patients with higher outputs. High-output fistulas are usually defined as those that drain >500

mL daily and these carry with them a more complex management challenge.

TABLE 139.3 Predictors of Spontaneous Closure

Factor	Likely to Close	Unlikely to Close
Anatomical location	Oropharyngeal Esophageal Duodenal stump Lateral duodenal Pancreaticobiliary Jejunal	Gastric Ligament of Treitz Ileal
Tract length	>2 cm	<2 cm
Defect size	<1 cm^2	>1 cm^2
Fistula output	Decreasing	Stable or increasing
Surrounding bowel	Healthy	Distal obstruction or stricture Abscess Active inflammation Bowel discontinuity
Etiology	Appendicitis Diverticulitis Postoperative	Crohn disease Malignancy Radiation Foreign body (mesh)
Nutritional status	Well nourished	Malnourished
Sepsis	Absent	Present

The output does not clearly determine spontaneous closure, but most fistulas that close spontaneously demonstrate decrease in output. Thus, close monitoring of fistula output can provide evidence that future closure is likely.

The status of the bowel surrounding the fistula also affects whether nonoperative management will be successful. Those fistulas likely to close arise in otherwise healthy bowel. As stated earlier, the presence of distal obstruction or stricture, adjacent abscess, active inflammation or inflammatory bowel disease, and, of course, intestinal discontinuity diminishes or makes unlikely spontaneous closure. The presence of malignancy, radiated tissue, or foreign bodies makes closure unlikely. A new issue is the presence of nonabsorbable mesh in the repair of ventral hernia defects, and this represents the most rapidly increasing cause of gastrointestinal cutaneous fistulas. Although mesh may be required for the successful treatment of large abdominal wall defects, adhesions between

the bowel and the mesh should be expected unless measures were taken to keep the surfaces separate during the healing phase. Interposition of omentum or placing the mesh as an overlay may minimize the development of adhesions and subsequent fistulas resulting from erosion of the mesh. Once the fistula has developed in association with mesh, the mesh must be removed for spontaneous healing to occur, which happens occasionally. Most often, however, there is sufficient residual inflammation to prevent spontaneous closure.

PHASE IV: DEFINITIVE THERAPY

In most instances, elective operation for closure of ECFs allows one's flexibility to make certain that optimal nutritional resuscitation and complete freedom from other sources of infection are present. Enteral feedings should be tapered in the days preceding the operation to allow for mechanical and antibiotic prep, but parenteral nutrition should be compensated to make up for the lost calories. Intravenous perioperative antibiotics should be chosen based on the review of the patient's microbiologic data and the pattern of known hospital pathogens. An infectious disease consultation may be helpful. The patient and his family should be mentally and emotionally prepared to participate fully in the difficult recovery and rehabilitation that follows procedures of such magnitude. Remember that the ravages of the episode have cost the patient lean body mass not only of peripheral muscle but also of brain protein, which also has undergone breakdown and may require up to a year to a year and a half to restore full mental faculties. The patient should be prepared for the latter eventuality and should not make any decisions concerning career for a considerable period of time, but to be reassured that the recovery will take place.

The surgical team should anticipate a long procedure, and in complicated cases, the reconstructive team may include plastic surgery in the event that a musculocutaneous flap closure to the abdominal wall is necessary or a component separation if the surgeon is not comfortable carrying this out. It is essential, when possible, that the incision be made in a fresh area, free of adhesions. If there is a room above a vertical midline-type incision, which there often is, below the xiphoid this is a good place to start. If not, a fresh transverse incision may allow the best opportunity to enter the abdomen without injury and damage to the adherent bowel. The initial approach is all important. One must enter the abdomen in a fresh

area so as not to perform an inadvertent enterotomy. If this occurs, it changes the nature of the operation and allows a pall to fall over the proceedings. It often takes me between 1 and 2 hours to get into the abdomen. I prefer to use a No. 15 blade, using Kocher clamps to elevate the fasciae (Fig. 139.2). Where there is available incision below, using my index finger to gently peel the bowel from the abdominal wall is the best way to mobilize the small bowel (Figs. 139.3 to 139.6). After a significant space free of bowel has been achieved and the incision lengthened, one probes laterally with the index finger to find a soft space which is always present to enter an area free of adhesions. Once this is achieved, one can develop this area laterally until one can get one's finger behind the adhesions so that one could take down the adhesions from the side and not directly from in front. This lessens the opportunity to create enterotomies. As the opportunity to open the incision without making an enterotomy proceeds, one can use Kocher clamps to elevate the incision away from the underlying bowel, thereby preventing enterotomies, leaving the area of the fistula for last. It is very difficult to clear the area of the fistula from the peritoneum to which it is adherent. However, the area of the fistula and adherent bowel is rarely longer than 12 to 18 in and is usually very stuck, and multiple enterotomies may be impossible to prevent. However, this is generally a short segment of bowel that is usually sacrificed. The goal of the initial phase of the operation is to free whole bowel from adhesions, drain all abscesses, and identify all areas of obstruction; this procedure in the past was called "refunctionization," by Dr. Claude Welch, one of my mentors and the Dean of Boston Surgeons.

The dissection is not likely to proceed in one direction encompassing the entire length of the bowel. It is often easier to tackle areas of least dense adhesions first. My practice is to proceed with a No. 15 blade on the scalpel and Metzenbaum scissors to avoid inadvertent injuries from tension on the bowel. Approaching adhesions from the side rather than head-on minimizes enterotomies. If one is stuck, one should place an antibiotic-soaked laparotomy pad on the bowel and go elsewhere. The fluid in the pad creates edema that facilitates further dissection. If an enterotomy is made inadvertently and the bowel is not intended to be resected, closure should take place at that point and not left for later, as in the long case, there may be soilage to the peritoneum or one may not be able to find the injury later. I used an internal layer of interrupted buried 4-0 silk and an outer layer of 4-0 or 5-0 Prolene interrupted sutures. Prolene

does not cause a microabscess as does 4-0 silk used as the outer layer. I also close serosal tears with 5-0 Prolene interrupted sutures.

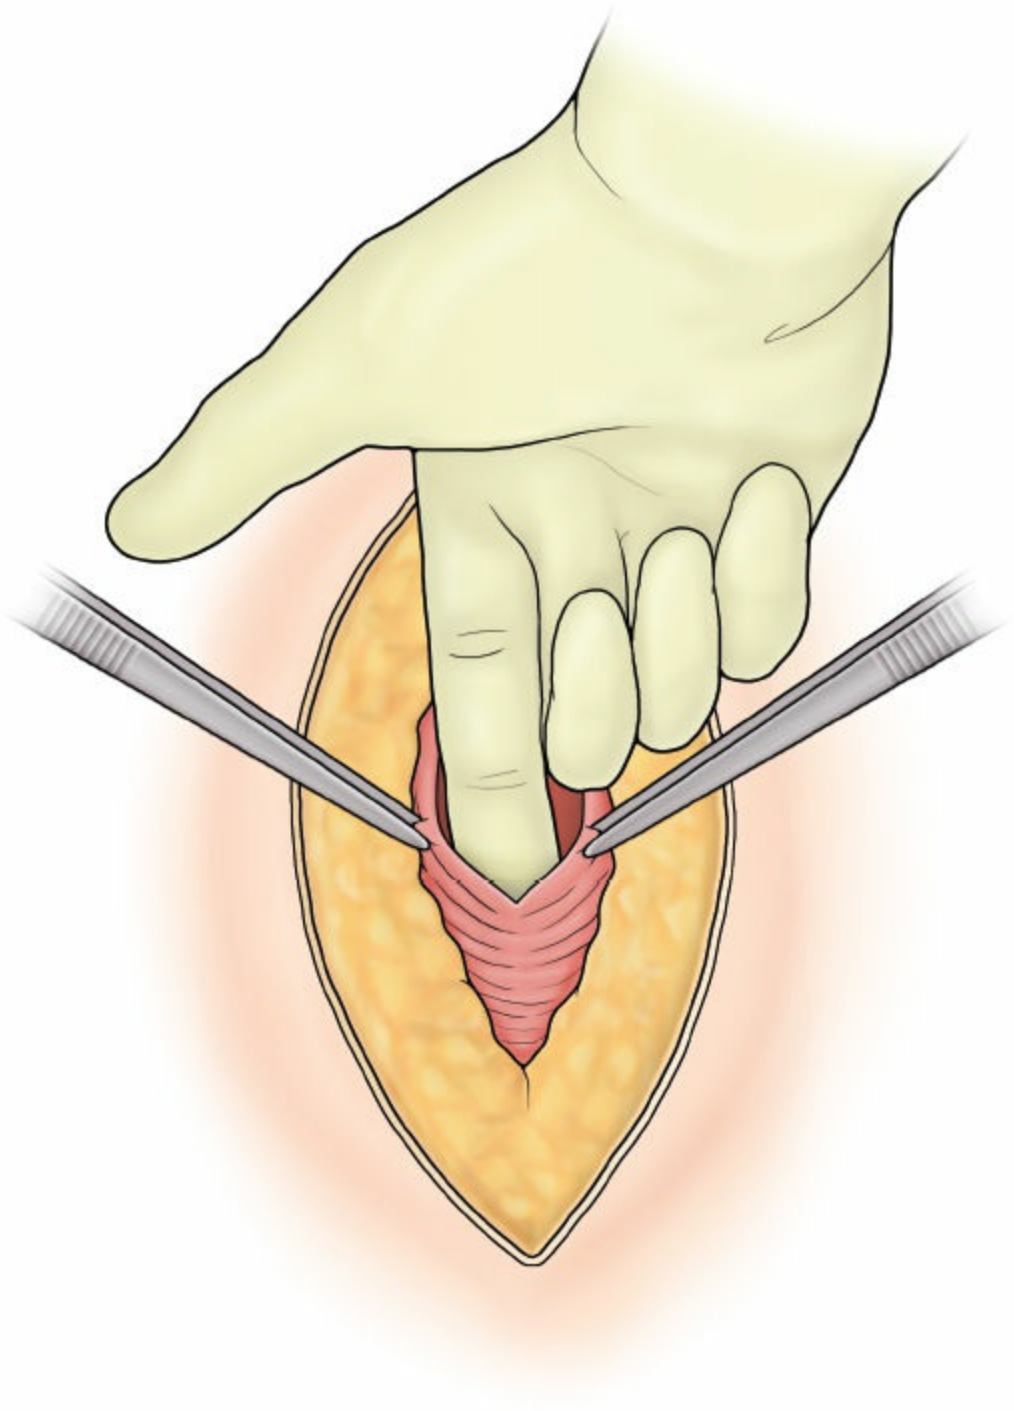

Figure 139.3. Once one has made the skin incision and clears the subcutaneous tissue from the fascia, one lifts up the fascia with Kocher clamps so one can see and then uses either index finger to separate the bowel from the underside of the fascia, without making an enterotomy.

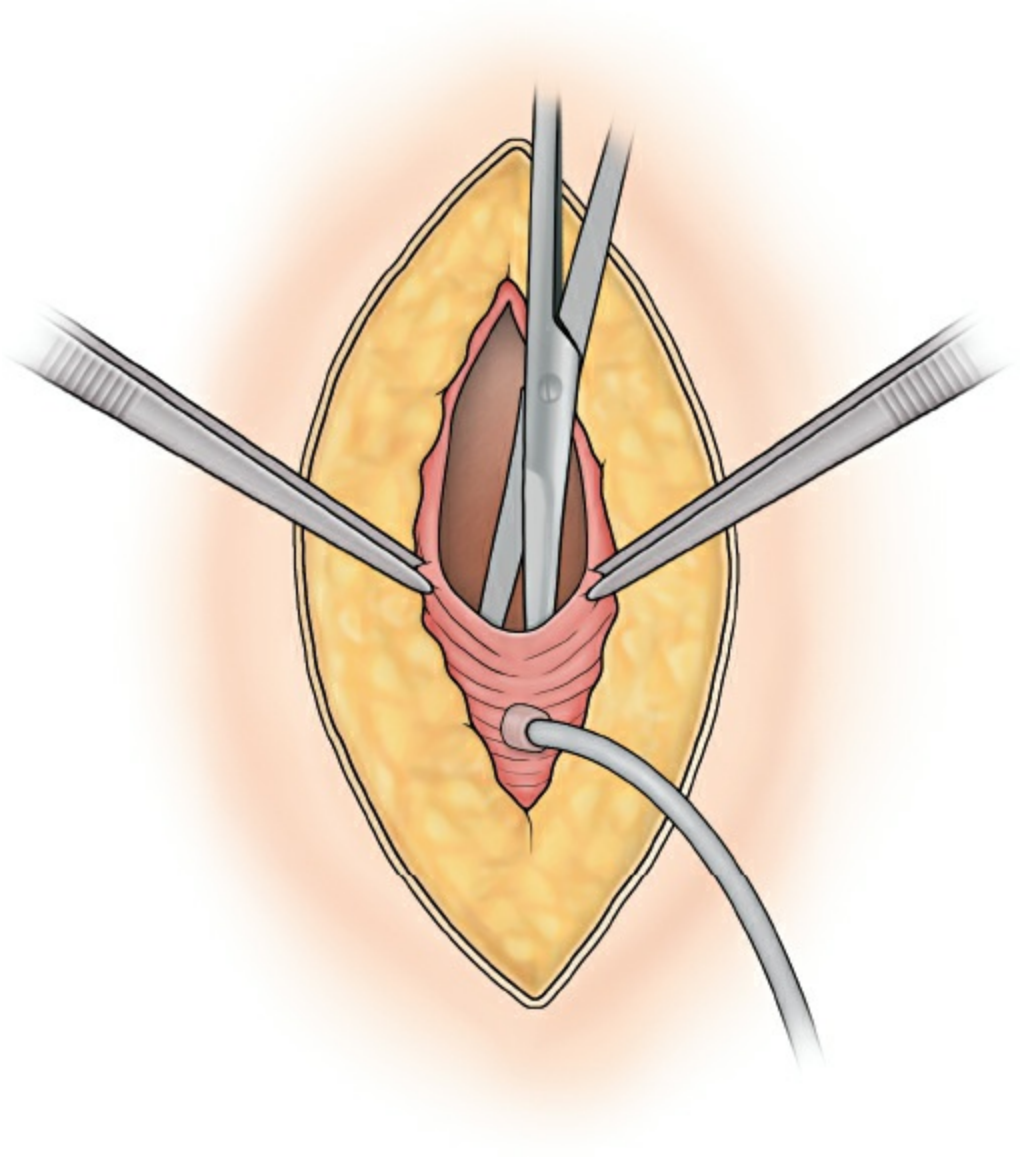

Figure 139.4. Both the skin incision and the fascia incision are lengthened carefully as the underside of the fascia is separated from the bowel and one can see clearly, the fascia may be divided with Metzenbaum scissors or a No. 15 blade scalpel.

It is best that the section of fistulized or injured bowel be resected with an end-to-end anastomosis with an inner layer of buried 4-0 silk interrupted sutures with the knots in the lumen and an outer layer of 4-0 or 5-0 Prolene interrupted sutures. Roux-en-Y drainage, simple closure, or wedge resection of the fistula should not be carried out as recurrence is much more common. It should be noted that in the papers in which this was elucidated, this was carried out only when no other option presented itself.

Avoidance of tension and assurance of a good blood supply maximize

the chances of a successful repair. If one is unhappy with the repair and cannot do any better, consideration should be given to the protection of the anastomosis with a loop ostomy proximal to the repair, and closed-suction drains not far but not adjacent to the anastomosis.

Given the magnitude of the laparotomy performed, many patients will have a prolonged postoperative ileus. In order to avoid prolonged nasogastric tube drainage, a Stamm gastrostomy should be carried out making certain to suture the latex tube (#18 French) to the stomach with absorbable suture and the stomach itself and the anterior abdominal wall around the exit hole with nonabsorbable sutures. Similarly, a feeding jejunostomy (#14 latex nephrostomy tube) should be placed with a Witzel tunnel being careful not to narrow the bowel and to surround the exit site with nonabsorbable sutures to the anterior abdominal wall.

Prior to abdominal closure, the entire bowel surface should be run and inspected to ensure that no unrecognized injuries exist. Irrigation with copious amounts of antibiotic solution should be performed. Closed-suction drainage catheters such as Blake drains may be left in the abscess cavities or in raw areas where oozing cannot be controlled. Optimally, the omentum should be placed between the anastomosis and the abdominal incision to prevent formation of adhesions between the bowel and the anterior abdominal wall. Blake or other drains should not be placed next to an anastomosis.

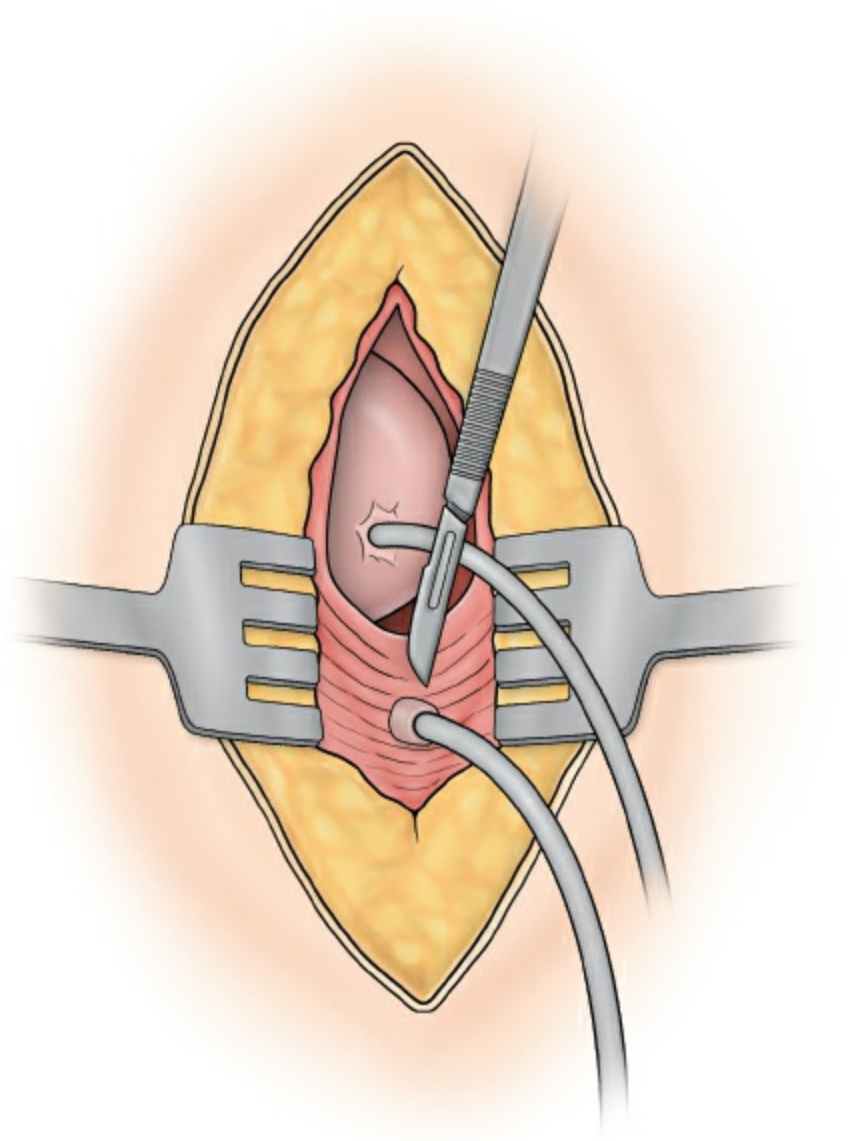

Figure 139.5. Further dissection of the abdomen: The bowel and fistula are clearly seen at the bottom of the wound. The fascia can be incised without fear of enterotomy. The goal is to reach the area where the fistulas are. The really adherent area is rarely longer than 12 in of bowel. Enterotomies are unavoidable but only 8 to 12 in of bowel need to be resected.

A secure abdominal closure is essential with native tissue. When native tissue is not available, a reconstructive team should have been planned for an advanced component separation or a musculoskeletal flap. Without native tissue, it is likely that the fistula will recur.

Several groups recently reported experience with laparoscopic approaches to operative management of ECFs with minimal complications or conversions to open procedures. They may provide advantages over

laparotomy that include decreased pain, faster return of bowel function, and shorter length of stay. As expertise with laparoscopic approaches to complex abdominal problems increases, one can expect to see more procedures performed with these techniques. One must remember, however, that these procedures require advanced laparoscopic skills, and also require a steep learning curve. Given the significant investment in time and resources in these patients, the choice of operation and technique must provide the best possible outcome.

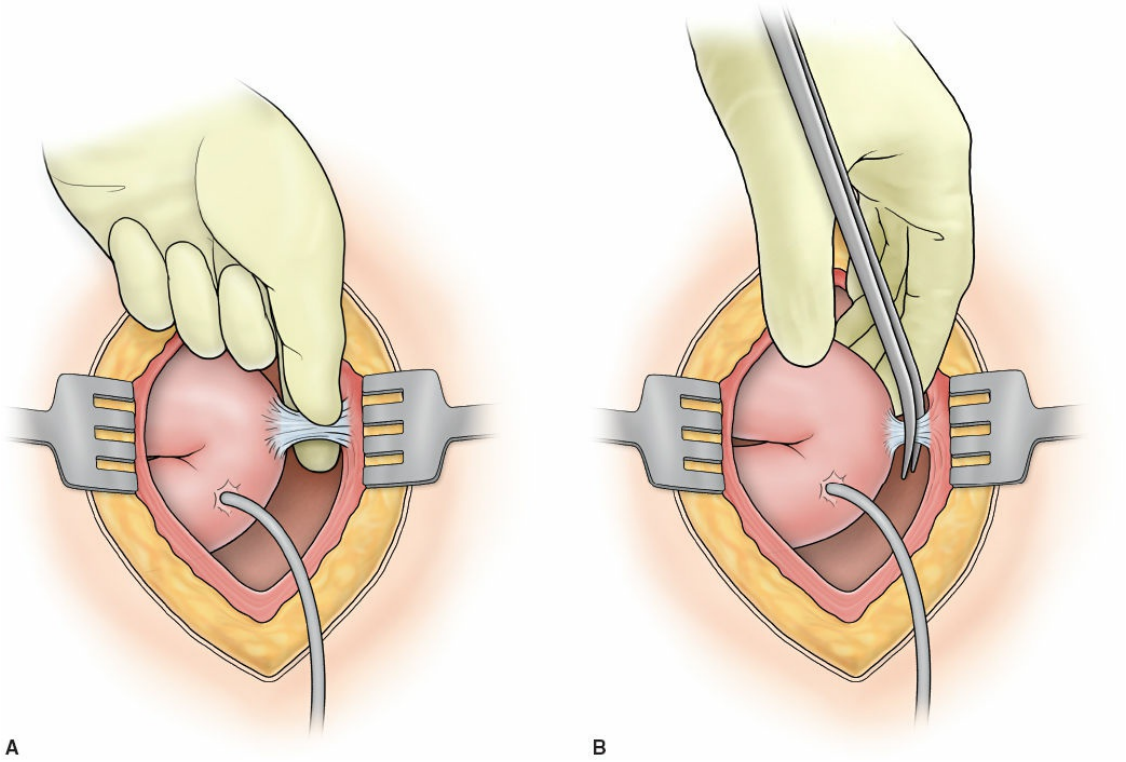

Figure 139.6. Adhesions can sometimes be dealt with by compressing the adhesions from a broad base to a narrow base **A** to **B.** When the adhesion is narrowing and is easily visible, the narrowed adhesion can be sharply divided.

PHASE V: HEALING

Regardless of what approach is used for nonoperative management and closure, nutritional support will be required in the postoperative period. These patients have not eaten for a long time and oral intake in many will be limited. Oral intake is commenced after the postoperative ileus has resolved. The traditional diet advancement protocol (sips of clear liquids to full liquids to a regular diet) may not be attractive to somebody who has not eaten for 4 to 6 months. Appetite is poor especially since one is still

providing artificial nutrition. I typically start patients on a soft diet and, since they have very poor appetite, encourage the patient's family to bring in favorite foods. Liquor or wine may help. Enteral or parenteral feedings may be cycled during the nighttime hours to supplement oral nutrition until the patient is able to consume at least 1,500 calories. Zinc supplementation may improve taste and increase oral intake.

After a 4- to 6-month medical ordeal, patients are often physically and emotionally exhausted. Limitations imposed by cumbersome wound dressings as well as the metabolic and septic challenges endured by these patients often lead to limited ambulation and deconditioning. Use of inpatient physical and occupational therapy can limit some of the losses, but intense rehabilitation will be required upon discharge from the hospital. Social worker or psychiatric consultation services may be required to help the emotional and financial ordeals associated with this disease. A coordinated rehabilitation program may be necessary to allow for patient's successful reintroduction to society and an active lifestyle. A consistent and continued involvement of the senior surgeon in the patient's care is essential as this individual undoubtedly looks up to the surgeon as his or her savior. The senior surgeon must be the final arbiter of the patient's health care.

Hopefully, a nasogastric tube (a gastrostomy is preferred) has not been left in place too long—if it has been, especially with reflux, esophageal stricture may result. Any dysphagia should be promptly investigated.

DUODENAL FISTULAS

Duodenal fistulas are the exception to the rule that fistulas are best dealt with by resection and end-to-end anastomosis. In this case, whether this does result from sphincterotomies, in which case the defect is lateral in the second or third portion of the duodenum posteriorly, or in the duodenal fistulas following a blown duodenal stump following a gastrectomy, resection of the duodenum and pancreas is not appropriate. Instead, we personally have had excellent results bypassing the fistula with a Roux-en-Y gastrojejunostomy. The Roux-en-Y is now preferred as opposed to a Billroth II type of gastrojejunostomy because of the 20% incidence of long-term complications following a gastrojejunostomy as is detailed elsewhere in this volume (Chapters 81 and 82). Though some have argued for a 40 cm distance between the stomach and the anastomosis between the ligament of Treitz and the distal jejunum, the literature would support a 60

cm distance so that bile reflux is completely obviated.

The majority of biliary, pancreatic, and duodenal fistulas will close spontaneously or nonoperatively. Octreotide, 50 to 100 μg every 8 hours, decreases the output and probably decreases the time of closure. In the event that spontaneous closure does not occur, a direct attack on the area is not judicious and will do a lot of damage. Both a Stamm gastrostomy and a feeding jejunostomy as previously described should be included in the procedure to enable early discharge and enteral feedings either at home or in a rehabilitative setting.

We do not believe that a vagotomy should be included in this procedure. In the first place, when gastrectomy has been the antecedent procedure, the ulcer diathesis has already been dealt with. If the procedure is carried out because of the biliary-pancreatic type of injury, there is no ulcer diathesis and a vagotomy is meddlesome.

THE INFLUENCE OF ARTIFICIAL FEEDING ON MORTALITY OF GASTROINTESTINAL CUTANEOUS FISTULAS

Though one would expect that the decrease in mortality accompanied the introduction of TPN, this is not the case. First, some form of nutritional support was introduced in the 1960s, whether this was tube feedings or 10% dextrose, albumin, lipomul (an early and somewhat imperfect fat supplement), large volumes of intravenous amino acids, and 10% dextrose as various forms of oral supplementation. When Dr. Claude Welch had a patient with a gastrointestinal cutaneous fistula, he always had the patient keep a large bottle of peanut butter at the bedside. When I asked him why, he would tell me that peanut butter was sticky and perhaps the fistula would close in that fashion. Of course, peanut butter was a great source of protein and fat. Given these various forms of nutritional supplementation, the mortality actually dropped between 1960 and 1970 probably because of intensive care, more intelligent use of increasingly available antibiotics, and greater expertise in respiratory support.

TABLE 139.4 Mortality

1946–1959	45% (138 patients—MGH)
1960–1970	15% (119 patients—MGH)
1970–1975	19% (145 patients—MGH)
1982–1991	20% (79 patients—UH)

As shown in Table 139.4, the introduction of TPN did not result in any decrease in mortality in two centers that were accustomed to dealing with gastrointestinal cutaneous fistulas. Thus, from the standpoint of parenteral nutrition, it was intensive care rather than a breakthrough in nutritional support which resulted in the decrease in mortality in this catastrophic complication. In my latest series of patients with gastrointestinal cutaneous fistulas which was reviewed by the residents, the mortality was zero in 50 patients. I have no idea why my own mortality dropped so precipitously. The patients were difficult and were referred. However, it indicates that meticulous care, in and out of the operating room, can result in an excellent outcome. Possibly the waiting of 6 months before reoperation was significant.

EDITOR'S COMMENT

Dr. Fischer and Dr. Evenson authoritatively discuss the management of enterocutaneous fistulas, one of the most dreaded complications following abdominal surgery. Little has changed in the management of enterocutaneous fistulas over the last 10 to 15 years, other than the development of more effective wound management products. The development of large wound collector appliances has greatly facilitated the management of high-output and multiple enterocutaneous fistulas. This and the explosion of negative pressure wound appliances have perhaps been the developments that have most aided the surgeon in the overall management of these patients (de Leon JM. Novel techniques using negative pressure wound therapy for the management of wounds with enterocutaneous fistulas in a long-term acute care facility. *J Wound Ostomy Continence Nurs* 2013;40(5):481–8). The availability of special "cut to fit" fistula appliances has made fitting negative pressure dressings around fistulas to aid in wound healing around these sites much easier (Heineman JT, Garcia LJ, Obst MA, et al. Collapsible enteroatmospheric fistula isolation device: a novel, simple solution to a complex problem. *J Am Coll Surg* 2015;221(2):e7–14).

As Dr. Fischer elegantly describes, enterocutaneous fistulas can arise from a variety of causes. The likelihood of healing depends upon whether they arise postoperatively or whether they occur as a result of patient disease and/or distal obstruction. The latter clearly will not heal until the distal obstruction has been relieved and/or the disease has been treated. Examples of such fistulas are those that occur secondary to colon cancer or obstructing Crohn disease. Postoperative fistulas that occur as a result of inadvertently overlooked enterotomies or due to anastomotic leaks can heal with conservative therapy without requiring further surgery, *if* they are associated with a low output or can be made to have low output by antidiarrheal medication, NPO status with intravenous hyperalimentation or the addition of intravenous or subcutaneous somatostatin (Rahbour G, Siddiqui MR, Ullah MR, et al. A meta-analysis of outcomes following use of somatostatin and its analogues for the management of enterocutaneous fistulas. *Ann Surg* 2012;256(6):946–54).

In such circumstances, adjuncts such the judicious use of negative pressure wound therapy, if there is no clearly visible bowel segment in the wound and if the output is low, can often result in healing of low-output fistulas, by promoting formation of granulation tissue over the external opening. One of the

great difficulties with this is that negative pressure therapy to close fistulas is *not* an approved use of this therapy and currently not reimbursed by insurance carriers. This treatment is expensive, being on the order of approximately $150/day. There are few convincing reports of the efficacy of this treatment in the literature, and only small series have been reported (Pepe G, Magalini S, Callari C, et al. Vacuum Assisted Closure (VAC) therapy™ as a swiss knife multi-tool for enteric fistula closure: tips and tricks: a pilot study. *Eur Rev Med Pharmacol Sci* 2014;18(17):2527–32).

There have been reports of other types of "minimally" invasive approaches to close enterocutaneous fistulas. One such method involves the use of large "bear claw" OVESCO over the scope clips (Donatelli G, Cereatti F, Dhumane P, et al. Closure of gastrointestinal defects with Ovesco clip: long-term results and clinical implications. *Ther Adv Gastroenterol* 2016;9(5):713–21). In order to use these clips, the tissue has to be soft enough to allow it to be to be "captured" within the jaws of the clip. Use of such techniques can often save the patient the necessity of having to undergo further operations.

Prevention of fistulas is of course better than treating them. Meticulous attention to surgical technique is important. Another important point is to avoid relaparotomy in a patient after an open procedure if possible in the period between 7 and 8 days postoperatively and 8 weeks postoperatively. During this period of time, there is a normal inflammatory reaction within the abdomen that some have called "obliterative" peritonitis. This is the condition, or part of normal healing where "everything" fuses together and reoperation is EXTREMELY difficult. During this period, reoperation should only be undertaken for life-threatening emergencies. All other conditions should be temporized, with interventional radiology drainage of abscesses, percutaneous gastrostomy placement and intravenous hyperalimentation for small bowel obstruction. In addition, one technique that is very useful at the conclusion of a difficult case where there has been an extensive lysis of adhesions, a lot of intestinal edema, and an abdomen that is difficult to close, is the concept of direct peritoneal resuscitation (DPR). This is a technique on which much research has been done in my own unit pioneered by Dr. Neal Garrison and his colleagues. The effects of peritoneal dialysate fluid to increase intestinal blood supply and reduce intestinal edema are utilized perioperatively. Briefly, large bore (19F) abdominal drains are placed and a temporary "vac pack" type of temporary abdominal closure is performed. The abdomen is continuously irrigated through one drain with Delflex®, a commercially obtainable peritoneal dialysate fluid and the effluent is aspirated through the other drain. In a prospective randomized study in trauma patients undergoing damage control surgery, this technique has been shown to dramatically reduce intestinal edema and facilitate abdominal wall closure (Smith JW, Matheson PJ, Franklin GA, et al. Randomized controlled trial evaluating the efficacy of peritoneal resuscitation in the management of trauma patients undergoing damage control surgery. *J Am Coll Surg* 2017;224(4):396–404). As others have shown, primary

closure of patients with enterocutaneous fistulas can be difficult (Slater NJ, Bokkerink WJ, Konijn V, et al. Safety and durability of one-stage repair of abdominal wall defects with enteric fistulas. *Ann Surg* 2015;261(3):553–7). Adjunctive techniques such as DPR may therefore prove to be very beneficial. I believe it will also result in a decreased gastrointestinal fistula rate in those difficult cases in which a primary closure of the abdomen is difficult, and the intestines are significantly traumatized during the course of a long and difficult procedure. Such a scheme would allow for the intestinal edema to subside, and allow for a more leisurely inspection of the intestines at a second exploration, to ensure that there are no injuries or enterotomies that need repair, with definitive abdominal closure at that time.

A good tip on knowing when the patient is ready for reoperation is simple palpation of the abdominal wall. If the abdominal wall is soft to palpation, this is signifies that the intra-abdominal adhesions have softened and reoperation will be less dangerous. If the abdominal wall is still fairly rigid or stiff on palpation, this means that the adhesions are still fairly dense within the abdomen and an additional waiting period is indicated before reoperation should be attempted.

140 Surgical Treatment of Small Bowel Crohn Disease

Erin O. Lange, Linda Ferrari, Mukta Krane, Fabrizio Michelassi, and Alessandro Fichera

ETIOLOGY AND PATHOPHYSIOLOGY

Crohn disease (CD) is a chronic inflammatory disorder of the gastrointestinal tract that can result in strictures, inflammatory masses, fistulas, abscesses, hemorrhage, and cancer. It may affect any region of the gastrointestinal tract from the mouth to the anus, and often involves multiple sites simultaneously. Crohn, Ginsberg, and Oppenheimer first identified it as a unique clinical entity in 1932.

The pathogenesis of CD remains incompletely understood, but the prevailing theory states that, in patients with a genetic predisposition, exposure to particular environmental stimuli triggers an altered immune response, resulting in inflammation and ulceration of intestinal tissues. The histopathology of CD is characterized by transmural inflammation with multiple lymphoid aggregates seen in the submucosa. Early in the disease process, one typically sees small mucosal ulcerations, called *aphthous ulcers.* These lesions eventually progress to larger ulcerations that can penetrate through the submucosa to form intramural channels with further potential to bore deeply into the bowel wall and create sinuses, abscesses, or fistulas.

The incidence and prevalence of CD are increasing worldwide, with a recent systematic review reporting the highest annual incidence in Australia (29.3 per 100,000), Canada (20.2 per 100,000), and northern Europe (10.6 per 100,000). In the United States, the incidence of new Crohn's diagnoses is 4 per 100,000 annually, with a prevalence rate of 80 to 150 per 100,000. CD is more commonly seen among white patients compared with African Americans, Hispanics, and Asians. CD can affect patients of all ages, but the peak incidence is seen in the second and third decades of life, with equivalent involvement of men and women.

To ensure optimal patient outcomes, a multidisciplinary approach is

essential, with active involvement of gastroenterologists, surgeons, and, for children, pediatricians. Patients with active disease can suffer greatly and often have a poor quality of life due to repeat hospital admissions, medication side effects, poor nutritional status, and risk of malignancy. While treatment for CD is not curative, modern medical therapy can often be effective in limiting and halting disease progression, and may induce long-term remission. In the modern era, surgery is typically required to manage disease complications. The basic principles of surgical therapy for CD emphasize bowel-sparing approaches, anticipating the likely need for future operations. Limited resections without wide margins of normal tissue are appropriate.

CLINICAL PRESENTATION

CD is commonly characterized according to the affected site of the gastrointestinal tract with the small bowel most frequently affected. Any portion of the small bowel may be diseased, but the terminal ileum is most commonly involved, with distal ileal disease with or without involvement of the right colon present in approximately 40% of patients. Proximal small bowel disease without colonic involvement is observed in 30% of patients.

CD may also be categorized by its clinical manifestations and grouped into one of three general entities: stricturing, perforating, or inflammatory disease. These are not truly distinct forms of the disease, but rather are terms that are used to describe the predominant gross pathologic manifestation. Stricturing CD results in the development of fibrotic scar tissue that constricts the intestinal lumen and may result in a partial or complete obstruction. These fibrostenotic scars are not reversible with medical therapy; therefore, surgical intervention is required once they become symptomatic. Perforating CD is caused by deep mucosal ulcerations that can develop into sinus tracts, fistulas, and abscesses. The inflammatory pattern of CD is characterized by mucosal ulceration and bowel wall thickening that may lead to an adynamic segment of intestine with luminal narrowing, causing obstructive symptoms in the small intestine and diarrhea in the colon.

Clinical features vary according to disease location but include chronic diarrhea (>4 weeks with or without blood or mucus), abdominal pain, and weight loss. Ninety percent of patients with CD of the small bowel experience abdominal pain caused by obstructive or septic complications,

which may be associated with fevers, anorexia, or weight loss. Patients may also develop clinical manifestations of disease complications, including abdominal masses, pneumaturia, or perianal pain/swelling. On physical examination, a palpable mass may be present, usually located in the right lower quadrant, representing an abscess, phlegmon, or a thickened loop of bowel. The differential diagnosis for small bowel CD includes irritable bowel syndrome, acute appendicitis, intestinal ischemia, radiation enteritis, intestinal malignancy, pelvic inflammatory disease, endometriosis, and gynecologic malignancies.

Typical laboratory findings in the presence of CD include increased levels of inflammatory markers, especially C-reactive protein and erythrocyte sedimentation rate, iron deficiency anemia, and low levels of vitamin B_{12} and folate. Fecal calprotectin, a neutrophil cytosolic protein, is an effective marker for intestinal inflammation and can be measured if clinical suspicion is high. Ileocolonoscopy and biopsy, ideally performed in a referral center, can demonstrate discontinuous colonic or ileal inflammation or ulceration with a “cobblestone” appearance. Histology characteristically shows patchy or focal inflammation, crypt granularity, and granulomas. However, no test is definitively diagnostic, causing providers to rely on the synthesis of history, physical examination, imaging, and histopathology in making the diagnosis.

INDICATIONS AND CONTRAINDICATIONS

Even with the introduction of more effective medical treatment such as antitumor necrosis factor alpha (TNFα) agents that allow long-term remission, surgery is still required in 70% to 90% of individuals during their lifetime and 50% of those require more than one surgical procedure. Surgical intervention should treat complications and reduce symptoms of disease and is indicated in several scenarios.

Fistulae

One third of patients with CD will develop an intestinal fistula, but this is rarely the primary indication for surgery. Surgical treatment is generally reserved for intestinal fistulas that connect with the genitourinary tract and result in repeated urinary tract infections or renal impairment; enterocutaneous and enterovaginal fistulas that cause the patient personal embarrassment or discomfort; and fistulas that result in the functional bypass of a major intestinal segment, causing malabsorption and diarrhea.

Rarely patients develop cologastric, enteroduodenal, and enterosigmoid fistulae, which are indications for surgical intervention.

Abdominal Abscess and Inflammatory Masses

Abscesses that occur in the setting of CD are often the result of sealed bowel perforations. They are most frequently located in the right lower quadrant of the abdomen or along the descending colon. Most abscesses can be treated initially with percutaneous CT-guided drainage and antibiotics. However, an abscess usually originates from a severely diseased segment of bowel and thus is likely to recur or result in an enterocutaneous fistula if this segment is not resected. Therefore, after successful interventional drainage, elective surgical resection is recommended. The presence of abscesses not amenable to percutaneous drainage, such as multilocular abscesses, multiple interloop abscesses, or inflammatory masses that are refractory to antibiotic therapy, is an indication for surgical intervention.

Perforation

Free perforation of the small or large bowel only occurs in approximately 1% of patients with CD. The clinical signs of peritonitis or the identification of free intraperitoneal air on a plain radiograph or CT scan is diagnostic of free perforation. Once diagnosed, urgent surgery is required, with resection of the perforated bowel and any associated involved segments. A stoma may be necessary in the presence of significant intra-abdominal contamination.

Obstruction

Partial or complete intestinal obstruction may require surgical intervention. A partial obstruction caused by acute inflammation and bowel thickening can often be treated nonoperatively in the acute setting. However, obstructions due to high-grade fibrostenotic lesions will not respond to medical management and are an indication for surgery. In an effort to limit the length of bowel resected, attempts should be made to initially treat these obstructions conservatively with administration of intravenous corticosteroids to decrease local inflammation, nasogastric decompression, and intravenous hydration allowing for resection of the affected area electively after decompression is achieved.

Carcinoma

CD is a risk factor for adenocarcinoma of the small bowel, with relative risk 27 times that of the general population. Small bowel adenocarcinoma occurs in <1% of patients with CD, and its incidence correlates with the duration and extent of disease. Because its radiologic characteristics are similar to inflammatory disease, the diagnosis can be difficult to achieve preoperatively and most cases (73%) are discovered postoperatively. The risk of malignancy also increases in defunctionalized segments of bowel. Therefore, bypass surgery of the small intestine should be avoided.

Intestinal Hemorrhage

Severe hemorrhage in the setting of CD is extremely rare and often requires definitive surgical treatment. Massive gastrointestinal hemorrhage occurs most frequently from Crohn colitis. Hemorrhage from CD of the small bowel tends to be indolent with episodic or chronic bleeding that may require intermittent blood transfusions, but rarely requires emergent surgical intervention. However, the risk of a recurrence is high with spontaneous cessation of a small bowel hemorrhage; therefore, elective surgery of the actively diseased segment should be considered after the first episode of hemorrhage. Angiography or endoscopy can be helpful in identifying the source of bleeding preoperatively, due to the difficulty of locating these areas intraoperatively and the frequency of multiple bleeding sites.

Growth Retardation

Twenty-six percent of children with CD experience growth retardation as a result of either steroid treatment or the malnutrition associated with active intestinal disease. Persistent growth retardation in the face of adequate medical and nutritional therapy is an indication for surgical intervention.

Failure of Medical Treatment

Failure of medical treatment, the most common indication for surgery, occurs when (a) maximal medical treatment proves inadequate, with worsening symptoms or development of disease complications; (b) patients who are asymptomatic on maximal induction medical therapy develop recurrence of symptoms with tapering of these medications that do not have an acceptable safety profile for use as maintenance therapy; or (c) the patient experiences significant treatment-related complications.

PREOPERATIVE PLANNING

A complete assessment of the gastrointestinal tract is required prior to surgery to evaluate the full extent of disease and any associated complications that may require management before surgical intervention. Clinical history and physical examination focusing on abdominal and perianal manifestations of disease can help define the need for further testing.

The use of mechanical bowel preparation is controversial in patients with CD during an acute attack and in the presence of severe diarrhea, and is clearly contraindicated when a perforation or a complete obstruction is present. All patients should be administered prophylactic broad-spectrum antibiotics and DVT prophylaxis, and patients on long-term steroid therapy should receive stress-dose steroids. In the event that the patient cannot undergo primary restoration of the gastrointestinal continuity, a potential stoma site should be marked preoperatively by a certified enterostomal nurse.

To avoid clinical deterioration prior to elective surgery, we instruct our patients to continue to take 5-ASA and steroid therapy as previously prescribed until the day before surgery. Patients on methotrexate are asked to discontinue this medication at least 2 weeks prior to surgery. Given the lack of definitive data to support adverse perioperative effects from anti-TNFα therapy, we often plan the operation to take place between two scheduled infusions, rather than hold any doses.

Poor preoperative nutritional status increases morbidity rates and intra-abdominal septic complications. Crohn's patients suffer nutritional deficiencies from multiple sources: insufficient dietary intake, malabsorption, and systemic inflammation. In cases of malnourished patients, defined using albumin levels <3.5 g/dL, total parenteral nutrition should be considered for 2 to 4 weeks prior to surgery to reestablish nutritional store and reduce the risk of postoperative complications.

Imaging

Small Bowel Radiography

Small bowel follow-through and magnetic resonance enterography (MRE) are the best means for assessing the small bowel for CD. Radiographic abnormalities are often distinctive. With early CD, mucosal granulomas with ulceration and nodularity can be identified. Thickening of the mucosal folds and edema of the bowel wall itself can be demonstrated as the disease progresses. With more advanced disease, cobblestoning

becomes radiographically apparent. Small bowel contrast studies can also provide information regarding thickening of the mesentery and formation of an inflammatory mass or abscess. Such findings are demonstrated by a general mass effect separating and displacing contrast-filled loops of small intestine. Small bowel contrast studies can demonstrate some of the complications of CD, including high-grade strictures and fistulas. It is important to note, however, that small bowel radiography may not identify all such lesions. For instance, many enteric fistulas including ileosigmoid and ileovesical fistulas are not typically demonstrated on contrast radiography. Thus, the absence of radiographic evidence for fistulization does not exclude this possibility. Additionally, small bowel studies may fail to demonstrate all clinically significant strictures. While small bowel imaging may underestimate the extent of complicated CD, when performed by an experienced gastrointestinal radiologist they are very effective as a diagnostic tool. Besides their diagnostic utility, small bowel radiographs can also help in assessing the extent of the disease by identifying the location and length of involved and uninvolved intestine, and by recognizing whether the disease is continuous, or discontinuous with skip lesions separated by areas of normal intestine. Experienced radiologists can also assess areas of luminal narrowing and determine if they are more likely the result of acute inflammatory swelling or are related to fibrostenotic scar tissue. Such a distinction provides valuable information regarding the value of medical therapy versus early surgical intervention.

Endoscopy

Upper and lower endoscopy allows for inspection of mucosal disease and provides an opportunity for biopsies for histologic evaluation. Upper endoscopy is useful in the diagnosis of mucosal lesions of the esophagus, stomach, and duodenum, and can identify and grade the severity of strictures in these regions. Diagnosis of terminal ileal CD can be usually made at ileocolonoscopy.

Computed Tomography and Computed Tomography Enterography

Computed tomography (CT) findings of uncomplicated CD are nonspecific, and routine CT is not necessary for the diagnosis of CD. CT, however, is very useful in identifying the complications associated with CD, including thickened and dilated intestinal loops, inflammatory masses, or abscesses. CT scan can also demonstrate hydronephrosis resulting from

retroperitoneal fibrosis and ureteral narrowing. CT scans are often the most sensitive indicator for the presence of an enterovesical fistula as identified by the presence of air within the urinary bladder.

Computed tomography enterography (CTE) exploits the high spatial resolution and speed of modern CT, using large volumes of neutral oral contrast agents to generate detailed images of the small bowel wall, lumen, and mesentery. In addition, CTE has several potential advantages over barium studies in the identification of fistulizing disease. Unlike traditional fistulography, CTE does not suffer from superimposition of bowel loops, and CTE displays the perienteric mesentery, retroperitoneal and abdominal wall musculature, typically involved by fistulas. Sinus tracts and abscesses can also be readily characterized by CTE. CTE has been shown to have a higher sensitivity than barium small-bowel follow-through, and at some institutions, CTE combined with ileocolonoscopy has become a first-line test for the diagnosis and staging of CD. However, given the recent concerns about radiation-induced cancer arising from medically necessary imaging, particularly for patients with CD who will likely need significant imaging over their lifetime and also carry a baseline increased risk of cancer, the role of CTE in assessing younger patients is being increasingly discussed. Supported by the need for a small-bowel imaging technique that provides the advantages of CTE without exposure to ionizing radiation, magnetic resonance enterography (MRE) has been shown in a recent study to have similar sensitivities for detecting active small-bowel inflammation, although image quality across the study cohort was better with CTE. At present, MRE is considered a valid alternative to CTE when radiation exposure is a concern, particularly as an adjunct to ileocolonoscopy in the diagnosis of CD.

SITE-SPECIFIC DISEASE

Esophagus, Stomach, and Duodenum

Gastroduodenal involvement in CD is reported in only 2% to 4% of cases and is rarely seen in the absence of other disease sites in the GI tract. In general, more than 50% of patients have known distal involvement before the diagnosis of gastroduodenal disease, and approximately 30% of patients present with duodenal and distal CD simultaneously. The most common distribution of gastroduodenal CD is contiguous involvement of the gastric antrum, pylorus, and the duodenal bulb. However, in a series of 89 patients from the Lahey clinic, isolated duodenal disease with gastric

sparing was reported in 40% of patients.

CD of the upper gastrointestinal tract may produce symptoms of nausea, vomiting, dysphagia, or odynophagia and is often misdiagnosed as peptic ulcer disease. The failure of antiulcer medications to resolve symptoms often leads to further investigation, including endoscopy and upper gastrointestinal imaging.

The use of medications to suppress gastric acid secretion and corticosteroid therapy is effective for patients with mild or moderate gastrointestinal CD. However, approximately one third of patients affected by gastroduodenal CD will require surgical intervention in their lifetime, most commonly for obstruction resulting from stenotic disease. Intractable pain, bleeding, and fistulas are also indications for surgical treatment. Options for surgical management of complicated gastroduodenal CD include bypass, stricturoplasty, and, less frequently, resection.

Traditionally, the “gold standard” for treating obstruction of the first and second portion of the duodenum has been to bypass the duodenum via a gastrojejunostomy with a highly selective vagotomy. If the stricturing disease is limited to the third or fourth portions of the duodenum, a Roux-en-Y duodenojejunostomy to the proximal duodenum is preferred over a gastrojejunostomy to avoid development of acid-induced marginal ulceration.

Because gastrojejunostomy carries a high risk of morbidity and disease recurrence, alternatives to bypass procedures have been sought. Given the focal nature of stricturing disease of the duodenum, stricturoplasty is a viable option, with optimal method dictated by the location, length, and number of strictures present. Strictures in the second and proximal third portion of the duodenum can effectively be managed with a Heineke-Mikulicz stricturoplasty. In order to safely accomplish a Heineke-Mikulicz stricturoplasty, the duodenum must be fully mobilized with a generous Kocher maneuver. Strictures of the first and fourth portion of the duodenum are best handled with a Jaboulay and a Finney stricturoplasty, respectively, constructed by creating an enteroenterostomy between the greater curvature of the stomach and the first portion of the duodenum, or the fourth portion of the duodenum and the first loop of the jejunum.

The safety and efficacy of stricturoplasty in the management of obstructive gastroduodenal CD have been studied in a number of series. In a retrospective study conducted by Yamamoto et al., 13 patients underwent stricturoplasty for obstructive duodenal CD. At a mean follow-up of 8

years, 23.1% required further surgery because of early postoperative complications, and 46.2% developed recurrent strictures at the previous stricturoplasty site. Worsey et al. retrospectively compared stricturoplasty to bypass surgery for the treatment of duodenal CD and found that after a mean follow-up of 8 years, 1 of 21 bypass patients (4.8%) required reoperation for recurrent disease, compared to 1 of 13 stricturoplasty patients (7.7%) after a mean follow-up of 3.6 years, a difference that was not significant. They concluded that despite shorter follow-up for stricturoplasty, it afforded the same rates of symptom relief and reoperation, and fewer complications than traditional bypass surgery.

In recent years stricturoplasty, which has the advantage of avoiding a blind-loop syndrome or stomal ulceration, has replaced bypass as the operation of choice for treatment of short obstructive duodenal CD. However, if the duodenal stricture is lengthy, multiple strictures are present, or the tissues around the stricture are too rigid or unyielding, then an intestinal bypass procedure remains the appropriate therapeutic option.

Ileoduodenal or coloduodenal fistulas may also complicate gastroduodenal CD. The fistula usually arises from a diseased ileocolic segment after a previous ileocolic resection or from the transverse colon, and drains into the duodenum or stomach secondarily. Most duodenoenteric fistulas are small in caliber and asymptomatic, and are therefore identified with preoperative small bowel radiography or discovered at the time of surgery. Larger fistulas may present with symptoms of malabsorption and diarrhea caused by the shunting of duodenal contents into the distal small bowel. Most duodenal fistulas are located away from the juncture of the duodenal wall at the head of the pancreas; and, therefore, after adequate mobilization, resection of the primary segment (ileocolic or transverse colon) with primary closure of the duodenal defect is often sufficient. Larger or complex fistulas with a significant degree of inflammation need to be handled with great care at surgery to limit the size of the duodenal defect resulting from resection of the fistula. When a large duodenal defect is present, a Roux-en-Y duodenojejunostomy or a jejunal serosal patch may be required for adequate closure. Duodenal resections are almost never necessary from gastroduodenal CD and should be considered the surgical option of last resort.

Small Bowel

Surgical intervention in patients with CD of the small bowel is limited to

the treatment of acute and chronic complications that do not respond to medical management. A study conducted at the Cleveland Clinic found that with disease of 10 years' duration, 90% of patients with ileocolitis and 70% of patients with only ileal involvement required surgery. The researchers found that the indication for surgery was intestinal obstruction in 55% of patients and intestinal fistulas or abscesses in 32% of patients. Although the surgical approach may differ based on the indication for surgery and the site of disease, adherence to the principle of bowel conservation is preferred.

SURGICAL TECHNIQUE AND OUTCOMES

Small Bowel Resection

A small bowel resection may be performed using a laparoscopic or open approach. Exploration of all four abdominal quadrants and of the entire small bowel for evidence of coexisting CD should always be done as up to 15% of patients will present with skip lesions. If areas of stenosis are suspected but not evident on serosal inspection, a Foley catheter with a balloon inflated to 2 cm and inserted through an enterotomy can be used to assess these sites. Before and after resection, the length of bowel should be measured and documented. The length of the diseased segment, the length of the resected segment, and the distance between strictures should be measured and recorded as well. The margins of macroscopic disease are then tagged with stay sutures, and the diseased segment and its adjacent normal bowel are mobilized and isolated to minimize the possibility of contamination. In addition, the contents of the small bowel are milked either proximally or distally beyond the margins of the potential anastomosis. Matted loops of small bowel or omentum are often found adjacent to the diseased segment, especially if the terminal ileum is involved. Care must be taken to adequately mobilize the affected areas, and mobilization of the ascending colon may be required. The matted loops of bowel can then be separated with a combination of blunt and sharp dissection, and the area to be resected can be inspected. The length of the resection margin has been debated, but numerous randomized trials have reported that disease recurrence is not increased by the presence of macroscopically involved bowel at the anastomotic line, as evidenced by the long results obtained with stricturoplasty or when microscopic involvement is present at the resection margin. As wider margins do not improve surgical outcome, resection margins need only incorporate

grossly apparent disease.

Division of the thickened mesentery of the involved small bowel is often the most challenging aspect of the procedure. Because the extent of mesenteric dissection does not affect long-term results, the mesentery should be divided at the most advantageous level. Sealing devices that employ bipolar technology allow for safe control of vessels up to 7 mm in diameter. These instruments have reduced blood loss and the length of the procedure, and have simplified intraoperative management of the often thickened and friable mesentery of patients with CD. In spite of the technical challenges posed by the hyperemic and thickened mesentery, the risk of postoperative hemoperitoneum requiring surgical intervention has been reported to be <0.5%.

Recently a new antimesenteric functional end-to-end handsewn anastomosis (Kono-S-anastomosis) has been developed to restore intestinal continuity after resections involving either the small or large bowel for CD. Once the segment to be resected has been identified, the extent of resection is based on the principles of bowel-sparing surgery. After the bowel and the corresponding mesentery are mobilized, a small window is created at the proximal and distal resection margins. The mesentery is divided close to the bowel wall using a tissue sealing device. The bowel is then divided proximally and distally with the GIA stapler oriented perpendicular to the axis of the mesentery (Fig. 140.1). The corners of the two staple lines are imbricated and reinforced with 4-0 silk Lambert sutures, and the two stumps approximated by tying together the corresponding corner sutures. The two staple lines are sewn together with interrupted 4-0 silk sutures spaced apart creating the “supporting column.” The spacing of these sutures is used to evenly distribute any mismatch in segment caliber. An antimesenteric longitudinal enterotomy is performed on each stump, starting 1 cm away from the staple line (Figs. 140.2 and 140.3). The length of the enterotomy should facilitate creation of a 7- to 8-cm transverse lumen, with a longer lumen favored on the colon (Fig. 140.4). The anastomosis is performed by closing the longitudinal openings transversely in two layers: the outer layer is created using 4-0 silk Lembert interrupted sutures, and the inner layer using running 3-0 absorbable sutures starting in the middle of the posterior (mesenteric) aspect of the anastomosis and joining together on the anterior (antimesenteric) aspect with no closure required (Figs. 140.5 to 140.7).

A retrospective study conducted by Kono et al. demonstrated that the

median Rutgeerts endoscopic recurrence score (Table 140.1) in the Kono-anastomosis group (2.6, 69 patients) was significantly lower than in the conventional anastomosis (handsewn side-to-side or end-to-end, or stapled side-to-side) group (3.4, 73 patients). At 5 years, the surgical anastomotic recurrence rate was lower in the Kono-S-group than in the control group (0% vs. 15%; p = .0013). The Kono-S anastomosis appears promising in preventing surgical anastomotic recurrence in CD, and a randomized control trial is currently being conducted.

Stricturoplasty

When managing CD of the small bowel, it is important to consider the natural history of the disease. Reoperative rates have been reported to be as high as 60%, especially in patients undergoing resection of the small bowel. With each subsequent resection, the potential for intestinal insufficiency and short-gut syndrome increases. Therefore, nonresectional options such as stricturoplasty have gained popularity as an alternative to lengthy resections in the treatment of stricturing CD of the small intestine. The advantage of a stricturoplasty lies in the preservation of the intestinal absorptive capacity of the normal segments of bowel located between strictures. Stricturoplasties can either be performed alone or in conjunction with a resection. However, they are best performed in the presence of either long segments of stricturing disease or multiple short strictures in which a resection would result in the loss of a lengthy segment of bowel or in patients with multiple prior resections. Stricturoplasties are also indicated when they offer a simpler alternative to resection, as is the case with short recurrent disease at a previous anastomotic site. Stricturoplasties are contraindicated in the presence of generalized intra-abdominal sepsis, acutely inflamed phlegmonous intestinal segments, fistulas, abscesses, or long, tight strictures with thick unyielding intestinal walls. The choice of when to perform a stricturoplasty and what technique is used depends on the number of strictures, the length of each stricture, and the distribution of strictures and intervening normal small bowel.

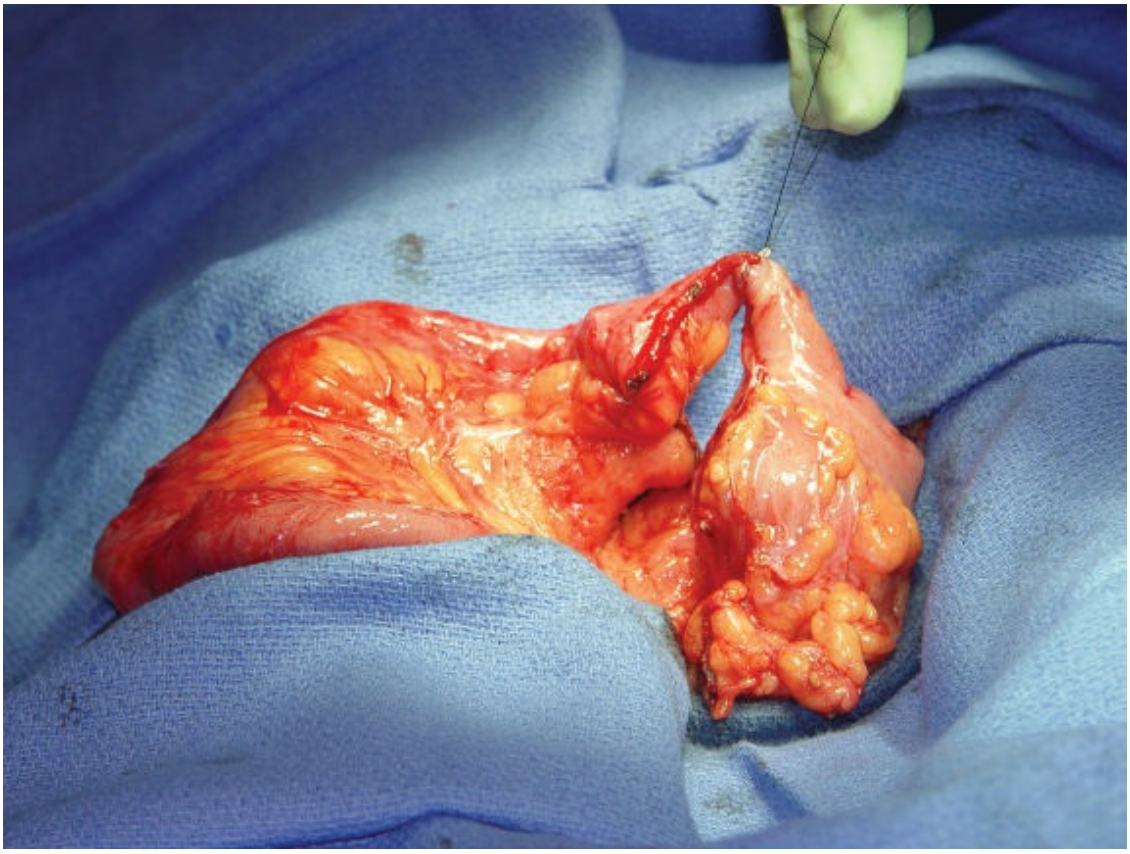

Figure 140.1. Bowel transection perpendicular to the axis of the mesentery.

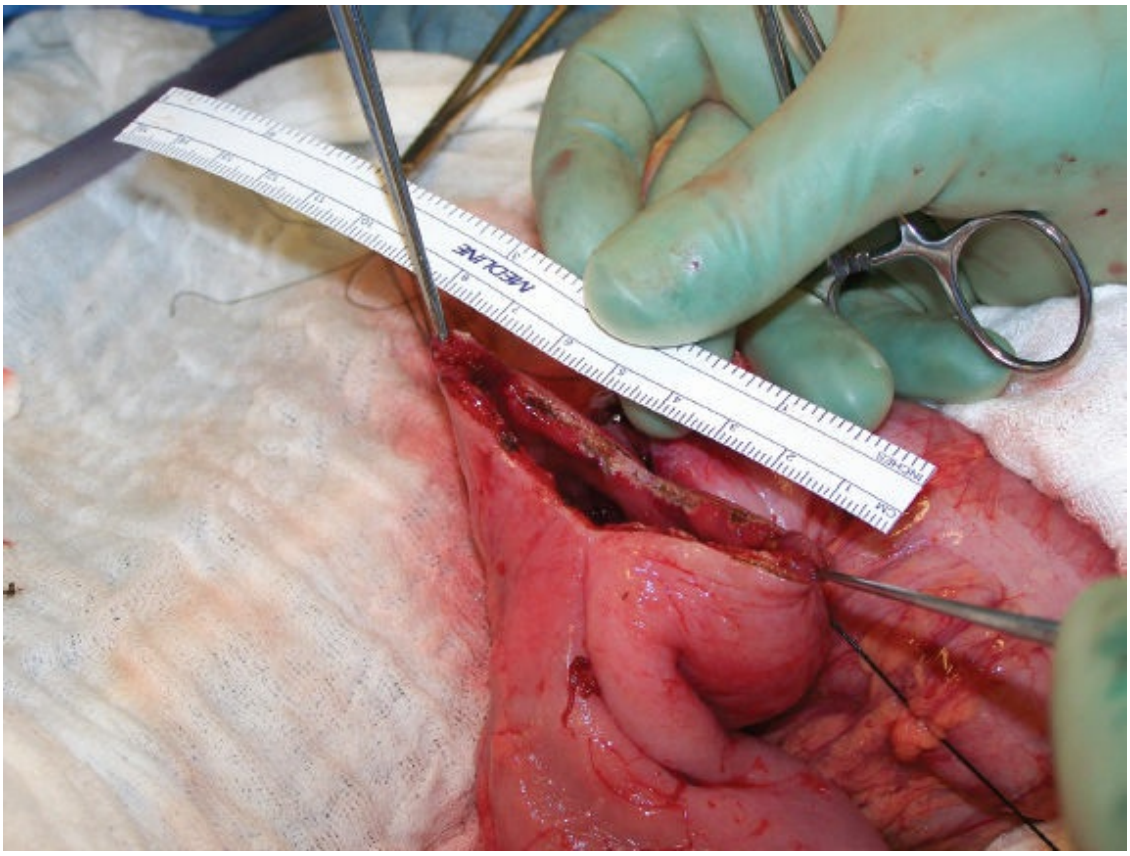

Figure 140.2. An antimesenteric longitudinal enterotomy with a transverse lumen of 7 cm is created on the small bowel.

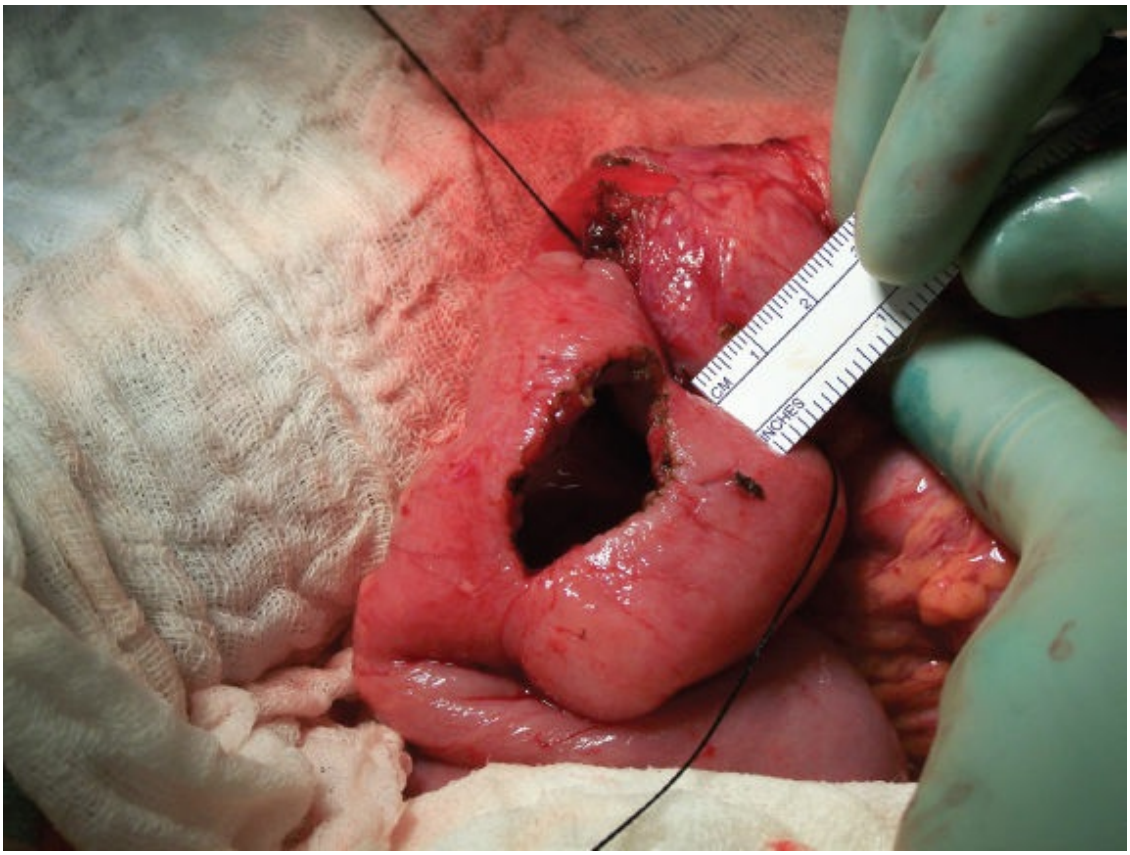

Figure 140.3. The distance between the enterotomy/colotomy and the supporting column should be no more than 1 cm.

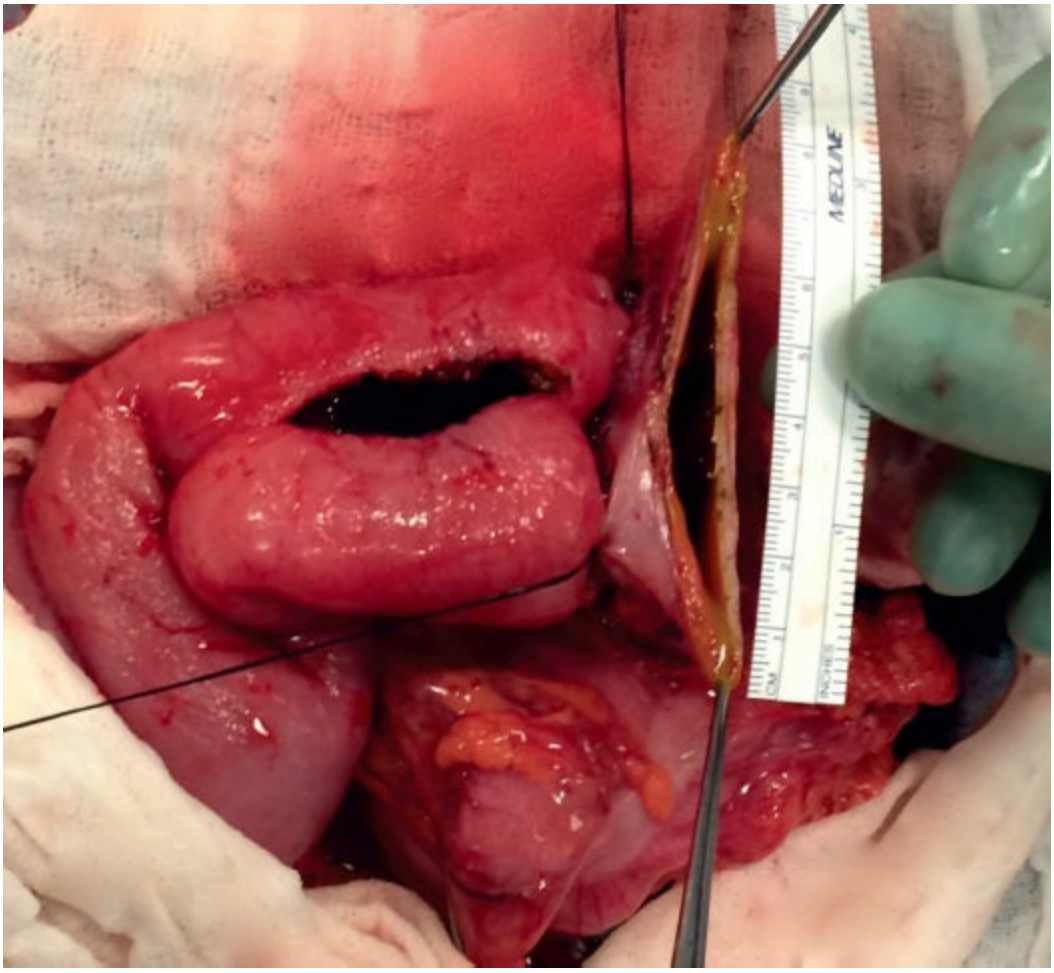

Figure 140.4. Measurement of the enterotomy on the colon side, which should be about 8 cm.

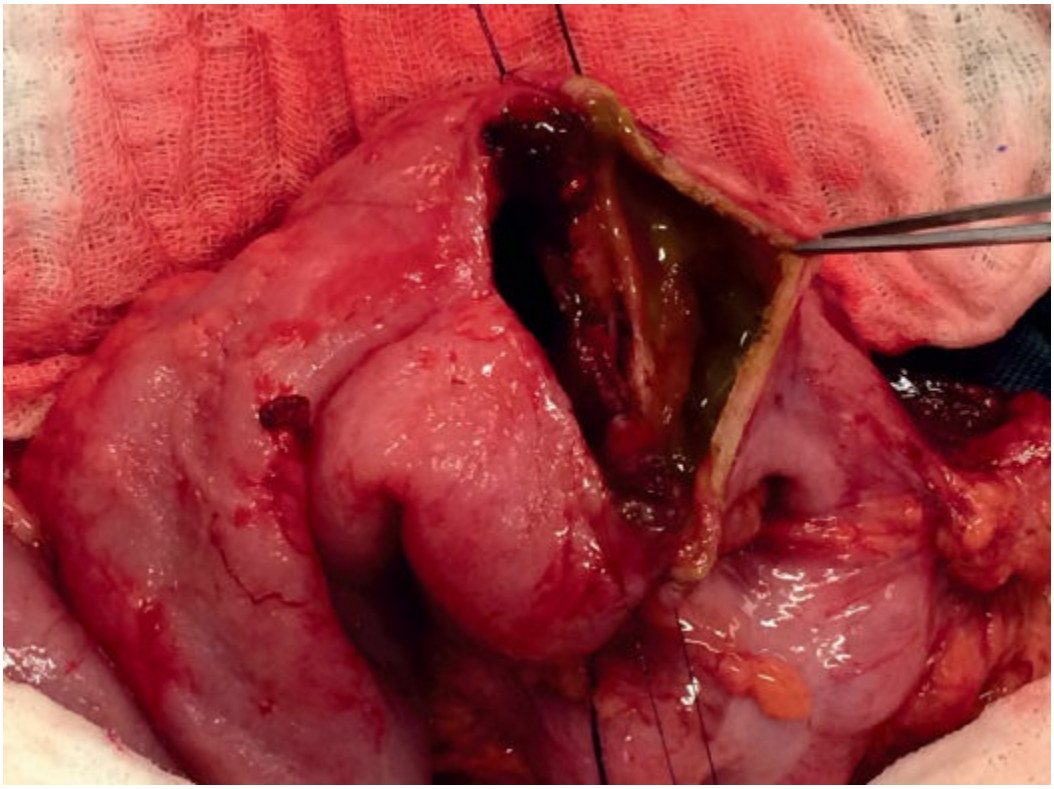

Figure 140.5. The two enterotomies are juxtaposed. Note that the colonic diameter is slightly larger and the difference in caliber is corrected with placement of the posterior outer layer of interrupted sutures.

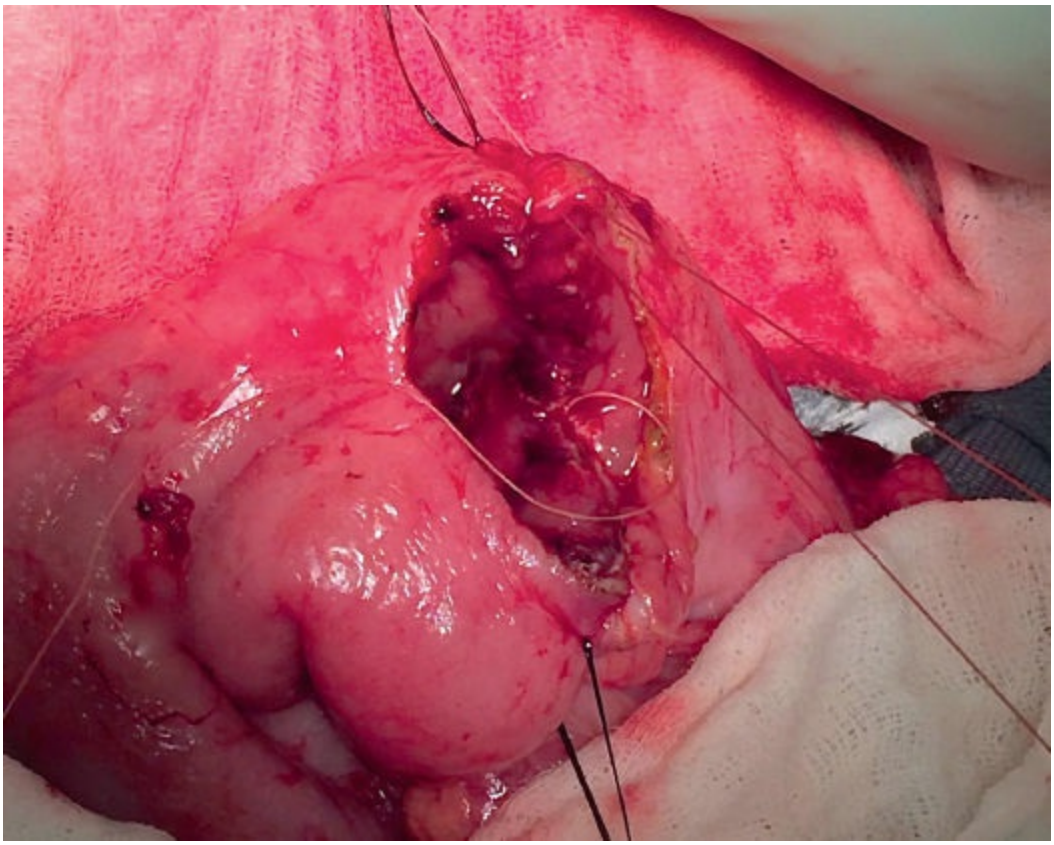

Figure 140.6. The inner layer of the anastomosis is fashioned using two running absorbable sutures starting in the middle of the posterior (mesenteric) wall of the anastomosis and then joining together on the antimesenteric aspect.

Heineke-Mikulicz Stricturoplasty

The most commonly performed stricturoplasty is the Heineke-Mikulicz stricturoplasty; this is appropriate for strictures 2 to 3 cm in length (Fig. 140.8). As with bowel resection, when a stricturoplasty is performed, the entire small bowel must first be inspected with careful attention paid to the location and length of the strictures and the length of the remaining bowel. Two stay sutures are placed along the antimesenteric border approximately 1 cm proximal and distal to the stricture site. A longitudinal incision is made along the antimesenteric border of the stricture. This incision should extend for 1 to 2 cm into the normal pliable bowel on either side of the stricture. Once the enterotomy is made, the area of the stricture should be closely examined. A biopsy with frozen section should be obtained if there is any concern that the stricture may harbor a malignancy. The lumen of the bowel should also be inspected for other areas of stricturing disease. If needed, a Foley catheter can be introduced through the enterotomy, as previously described. Hemostasis should be obtained with precise application of electrocautery. The longitudinal enterotomy is then closed in a transverse fashion with either a single or double suture layer.

Finney Stricturoplasty

The Finney stricturoplasty is appropriate for strictures up to 15 cm in length. A stay suture is placed on the midportion of the strictured site. The strictured segment is then folded onto itself into a U shape (Fig. 140.9). A row of seromuscular sutures is placed between the two arms of the U, and a longitudinal U-shaped enterotomy is then made, paralleling the row of sutures. The mucosal surface is examined and biopsies with frozen section are taken if there are concerns for malignancy. Full-thickness sutures are then placed in a continuous single layer beginning at the posterior wall of the apex of the stricturoplasty and continued down to approximate the proximal and distal ends of the enterotomy. This full-thickness suture line is continued anteriorly to close the stricturoplasty. A row of seromuscular Lembert sutures is then placed anteriorly. One drawback of this procedure is that a very long Finney stricturoplasty may result in a functional bypass with a large lateral diverticulum, which can be at risk for bacterial

overgrowth.

TABLE 140.1 Endoscopic Recurrence Score

Endoscopic Score	Definition	Clinical Recurrence (%)
i0	No lesions	<10
i1	≤5 aphthous lesions	<10
i2	>5 aphthous lesions with normal intervening mucosa or skip areas of larger lesions or lesions confined to the ileocolonic anastomosis	20
i3	Diffuse aphthous ileitis with diffusely inflamed mucosa	50–100
i4	Diffuse inflammation with already larger ulcers, nodules, and/or narrowing	50–100

interupted sutures.

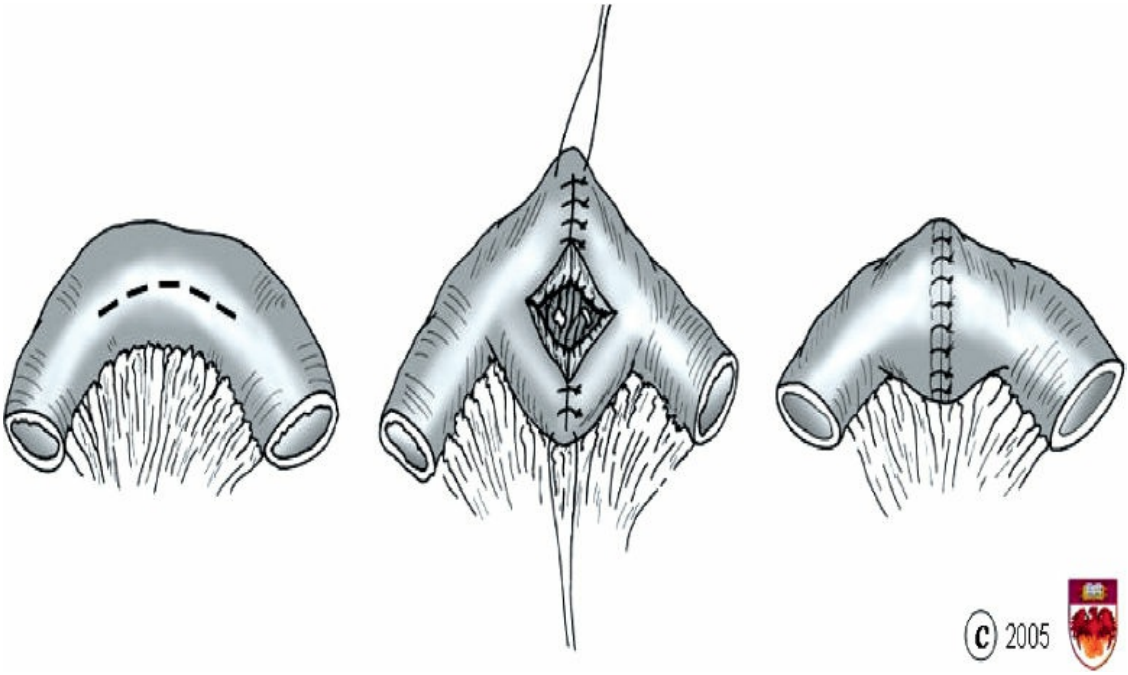

Figure 140.8. Heineke-Mikulicz stricturoplasty. A longitudinal incision is made along the antimesenteric border of the stricture (*dashed line*) and is then closed in a transverse fashion with either a single or double suture layer.

Side-to-Side Isoperastaltic Stricturoplasty (Michelassi Stricturoplasty)

In some cases, multiple stricturoplasties may be required to avoid a long resection. In general, repeated Heineke-Mikulicz or Finney stricturoplasties should be separated from each other by at least 5 cm to avoid forming a bulky segment of intestine and placing tension on each suture line. Patients with multiple strictures that are grouped close together or a long segment of stricturing disease (>20 cm in length) are best managed with an isoperistaltic side-to-side stricturoplasty. With this technique, the mesentery of the strictured segment is first divided at its midpoint and the diseased loop of small bowel is severed between atraumatic intestinal clamps. The proximal and distal ends of bowel are then placed in an isoperistaltic side-to-side fashion. Stenotic regions of one loop are placed adjacent to dilated areas of the other loop. Division of some of the mesenteric vascular arcades may facilitate the positioning of the two limbs over each other. A layer of interrupted seromuscular Cushing stitches using nonabsorbable 3-0 suture is used to approximate the two loops of bowel. Longitudinal enterotomies are then performed on both

loops (Fig. 140.10), with the intestinal ends tapered to avoid blind stumps. After obtaining adequate hemostasis with suture ligation or electrocautery, an internal row of full-thickness 3-0 absorbable sutures is placed anteriorly as a running Connell stitch and reinforced with an outer layer of interrupted seromuscular Cushing stitches using nonabsorbable 3-0 suture.

Unlike resection with primary anastomosis in which the tissue is removed to grossly normal margins and sutures are placed in healthy bowel, stricturoplasty is fashioned in affected bowel and suture lines are placed within scarred and diseased tissue, raising concerns of rapid recurrence and perioperative complications. However, a number of studies have reported that stricturoplasties result in prompt resolution of symptoms and weight gain without a significant increase in dehiscence, abscesses, or enteric fistulas when compared with traditional intestinal resections. In addition, disappearance or attenuation of disease that existed at the stenotic site has been observed. Long-term results from Hurst and Michelassi demonstrate an overall complication rate of 12%, with a dehiscence rate of 1.7%, and a 2- and 5-year recurrence rate of 15% and 22%, respectively. This recurrence rate is similar to that reported in a large series published by Ozuner and Fazio with a 5-year recurrence rate of 28%. Tichansky conducted a meta-analysis of 15 studies addressing stricturoplasties performed for small bowel CD with a follow-up of more than 2 years in most studies. They reported an overall postoperative complication rate of 13% (66 of 506 patients), and a 25.5% recurrence rate requiring 132 surgical procedures. Interestingly, the majority of recurrences occurred at sites distant from the stricturoplasty sites; the rate of recurrence at the stricturoplasty sites was only 8.5%.

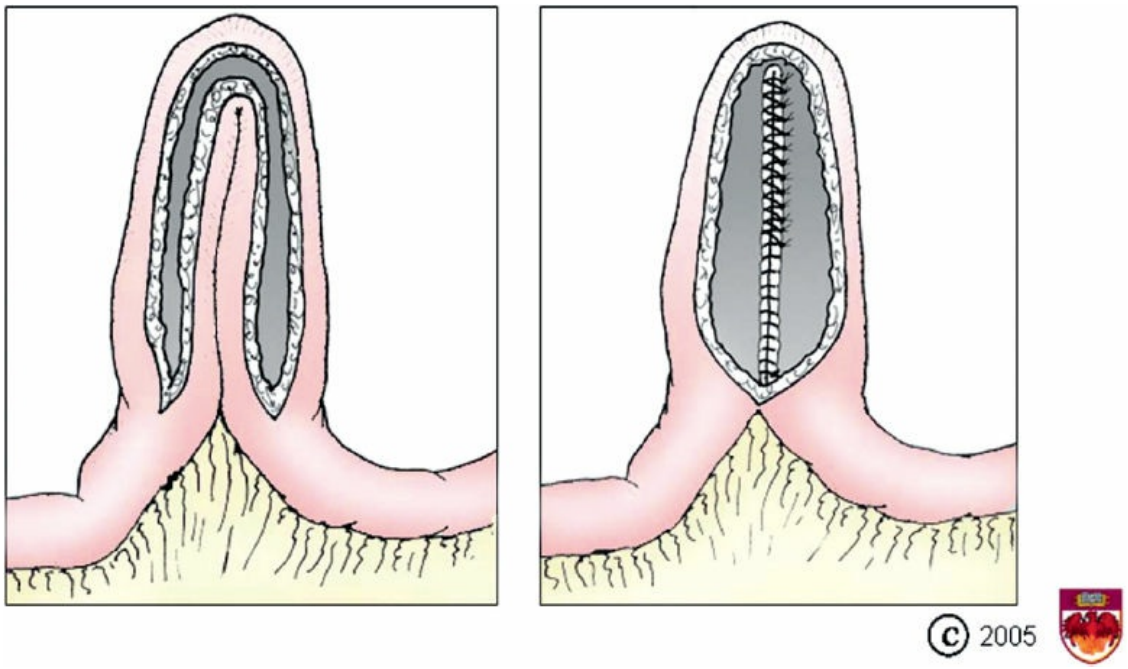

Figure 140.9. Finney stricturoplasty. The strictured segment is folded onto itself in a U shape (**left**). An enterotomy is made over the strictured area and the opposed surfaces of bowel are sutured together.

Although intestinal obstruction is the most common indication for surgical treatment of small bowel CD, fistula or abscess formation may also warrant surgery. For example, in perforating disease, the terminal ileum may adhere to a segment of normal sigmoid colon, resulting in an ileosigmoid fistula. Ileosigmoid fistulas do not generally require surgical intervention in and of themselves; however, many fistulas are associated with symptomatic terminal ileal disease. The surgical treatment of ileosigmoid fistulas consists of simple division of the fistulous adhesion and resection of the ileal disease in approximately 75% of cases. The defect in the sigmoid colon is then debrided and closed. A sigmoid resection may be necessary if the fistulous opening is particularly large, the tract enters the sigmoid colon in proximity to the mesentery, or there is extensive fibrosis.

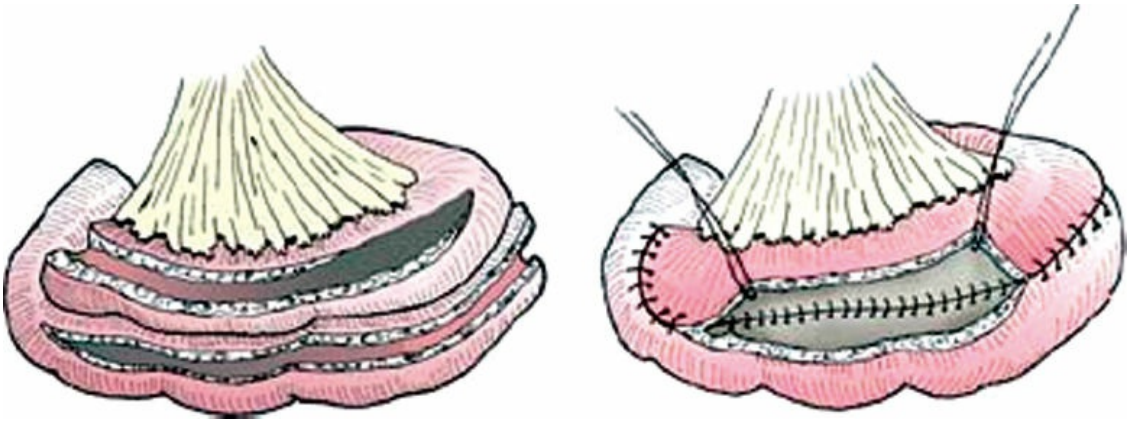

Figure 140.10. Side-to-side isoperistaltic stricturoplasty. The two overlapping bowel loops are divided longitudinally and a side-to-side longitudinal enteroenterostomy is fashioned.

Up to 5% of patients with CD will develop an ileovesical fistula. Most ileovesical fistulas are diagnosed by a history of hematuria or fecaluria and can be managed medically for extended periods of time. However, they usually do not heal, and eventually surgical intervention is required for recurrent urinary tract infections or worsening renal function. Surgical treatment involves resection of the ileal disease with debridement and primary closure of the bladder defect. If the bladder defect is large, an omental flap may be laid over the bladder repair.

Small bowel CD may also be complicated by the formation of intra-abdominal abscesses. These abscesses tend to follow a rather indolent course and may not even demonstrate clinical signs of localized infection. However, when an abscess is suspected or found during the workup of an abdominal mass, a CT scan can delineate its size, location, and relationship to other structures, including the ureters, psoas muscles, duodenum, and inferior vena cava. Most abscesses resulting from CD are small collections contained within the area of diseased intestine and its mesentery, and can therefore be extirpated during the resection of the diseased segment. Larger abscesses are best managed initially with CT-guided percutaneous drainage. Surgical resection of the affected segment of intestine can then be performed 4 to 6 weeks later.

Minimally Invasive Techniques

Minimally invasive approaches for CD offer several perioperative and long-term advantages over an open approach. Two prospective randomized control trials and five meta-analyses or systematic reviews

comparing laparoscopic to open surgery for ileocolonic CD reinforce several pertinent advantages to laparoscopic surgery, despite prolonged operative times: shorter duration of postoperative ileus, shorter hospital stay, lower incidence of early postoperative complications, and fewer postoperative small bowel obstruction. In addition, because of the significantly shorter length of stay, a trend toward lower overall costs was noted with laparoscopic surgery.

Although early reports of laparoscopic surgery for CD reserved this approach for "uncomplicated patients," increasing surgeon experience and improved instrumentation have facilitated a trend toward laparoscopy even for recurrent or fistulizing disease. Goyer et al. compared 54 complex patients with CD, defined as recurrent or complicated by abscess and/or fistula, to an uncomplicated group. Despite longer operative times, more frequent conversion to open, and increased use of temporary stoma, no differences were noted in overall postoperative morbidity based on complexity of disease.

The rate of conversion to open surgery remains high, ranging from 5% to as high as 70%, but more often 20% to 25%. These variations are due to case definition; some series include only ileocolonic resection, while others include those with fistulas, abscesses, and previous operations. Preoperative factors predictive of conversion include history of more than three acute episodes of CD, preoperative steroid use longer than 3 months, preoperative malnutrition, previous abdominal surgical procedures, and extracecal colonic disease. Regarding intraoperative findings, Alves et al. and Casillas et al. demonstrated that the most common reasons for conversion were the presence of a large inflammatory mass, adhesions, ileosigmoid fistula, pelvic abscess, inability to assess anatomy, failure to identify the ureter, and bleeding. More recently, a study from Cleveland Clinic has evaluated which radiologic findings using CT enterography or MRE are predictive of conversion, and identified positive correlations with pelvic fistula ($p = 0.003$), complex fistulas ($p = 0.017$), and pelvic abscess ($p = 0.009$). This study indicates that preoperative imaging can predict intraoperative findings that would lead to a conversion, therefore improving preoperative planning.

With respect to long-term outcomes, laparoscopy is associated with a reduction of adhesions likely facilitating subsequent resections, which is important given that patients with CD are often young and 50% of patients require more than one surgical operation during their lifetime. In addition,

reduction of pelvic adhesions might improve postoperative female fecundity.

Laparoscopic-assisted ileocolic resection is currently the most commonly performed laparoscopic procedure for treatment of CD. Small bowel resection is also straightforward to perform unless the small bowel is affected by a large inflammatory mass or is adherent to other loops of bowel through fistulas or intervening abscesses. Laparoscopic-assisted stricturoplasty is particularly advantageous when conducted with a bowel resection, usually an ileocolic resection. The diseased area or areas can be marked with intracorporeal stitches, exteriorized through a small abdominal incision needed for removal of the resected specimen, and the stricturoplasty performed extracorporeally in standard fashion. Fecal diversion and closure of stomas are good indications for laparoscopy in CD. This may obviate a laparotomy and allows for a full evaluation of the gastrointestinal tract.

Diagnostic laparoscopy is an important and underused tool. It can be especially helpful in unusual circumstances when the diagnosis of CD is unclear, or in the pediatric population. With a systematic approach, it is possible to visualize the entire gastrointestinal tract from the stomach to the rectum, and when combined with intraoperative colonoscopy, one can obtain a detailed road map of the extension of the disease and differentiate CD from other pathologic processes, such as ulcerative colitis or lymphoma. Using this approach, Singh et al. were able to avoid an otherwise unnecessary laparotomy in 14 of 23 patients with an unclear preoperative diagnosis.

Laparoscopic-Assisted Ileocolic Resection

The patient is placed on the operating table in the modified lithotomy position. Rectal irrigation with diluted iodine solution is performed, especially in patients with fistulas involving the rectosigmoid. An epidural catheter is usually inserted at the time of surgery. The sympathectomy achieved with epidural administration of local anesthetics and opioids prevents bowel distention and facilitates exploration of the gastrointestinal tract and handling of the bowel. Every operation for CD, whether open or laparoscopic, should start with a complete examination of the entire gastrointestinal tract, starting from the ligament of Treitz. The patient is positioned in the reverse Trendelenburg position and right lateral decubitus, with the assistant standing on the patient’s left side, retracting the transverse colon into the upper quadrants, and the surgeon standing

between the patient's legs, evaluating the intestine from the ligament of Treitz all the way to the ileocolic pedicle. This maneuver is facilitated by progressively rotating the patient from the reverse Trendelenburg to a full Trendelenburg position and left lateral decubitus. In the presence of skip areas of involvement from CD, these are marked intracorporeally with sutures in order to facilitate retrieval of the diseased segments when the specimen is exteriorized.

A technique with four 5-mm trocars is used (Fig. 140.11A). The 5-mm trocars allow placement of a 5-mm 30-degree camera, which offers the optimal resolution, and introduction of appropriate instrumentation for control and division of the vascular pedicles. After the bowel has been evaluated in its entirety, the surgeon joins the assistant on the left side of the patient (Fig. 140.11B) and the assistant places the ileocolic pedicle under tension. The surgeon dissects the mesentery and divides the ileocolic vessels (Fig. 140.12). The ascending colon is mobilized in a medial-to-lateral fashion in the submesenteric plane to the hepatic flexure (Fig. 140.13). The assistant lifts the colon to allow clear visualization of the submesenteric plane. When the submesenteric mobilization is completed, the lateral colonic peritoneal reflection is divided to the hepatic flexure (Fig. 140.14). The terminal ileum is completely mobilized by dividing the peritoneum at the level of the pelvic rim to allow a tension-free anastomosis through a small incision. It is often necessary to completely mobilize the hepatic flexure in order to facilitate exteriorization of the specimen; this assures avoidance of a difficult anastomosis through a small incision or the need for a larger incision (Fig. 140.15). With a full mobilization accomplished, the instruments are removed and the umbilical port site or the right lower quadrant port site is enlarged, in preparation for the exteriorization of the specimen. The pneumoperitoneum is evacuated and, after having placed a wound protector, the specimen is exteriorized. In the presence of skip areas of disease marked intracorporeally, these are identified and either a resection or a stricturoplasty is performed. In the presence of isolated terminal ileal disease, an ileocolic resection is performed with an extracorporeal anastomosis.

POSTOPERATIVE CARE

Postoperative care in colorectal surgery has significantly changed in the last 20 years. Enhanced Recovery after Surgery (ERAS) was first developed and described by Henri Kehlet in the 1990s, with the aim of

reducing surgical stress response and inducing a faster recovery for patients after an operation. ERAS pathways are based on basic principles that include preoperative, intraoperative, and postoperative patient management. Focused preoperative patient education is targeted to create patient awareness of and cooperation with their care plan, including preoperative fluid and carbohydrate loading, use of antibiotic and thromboembolic prophylaxis, early postoperative mobilization, and stoma teaching when appropriate. Intraoperative guidelines include the use of short-acting anesthetic agents, placement of midthoracic epidural, avoidance of opioid analgesics, avoidance of salt and fluid overload, and maintenance of normothermia and normoglycemia. Postoperative management includes early return to oral fluid intake, early mobilization, prevention of nausea and vomiting, avoidance of fluid overload, use of nonopioid oral analgesia, and early removal of urinary catheters and drains.

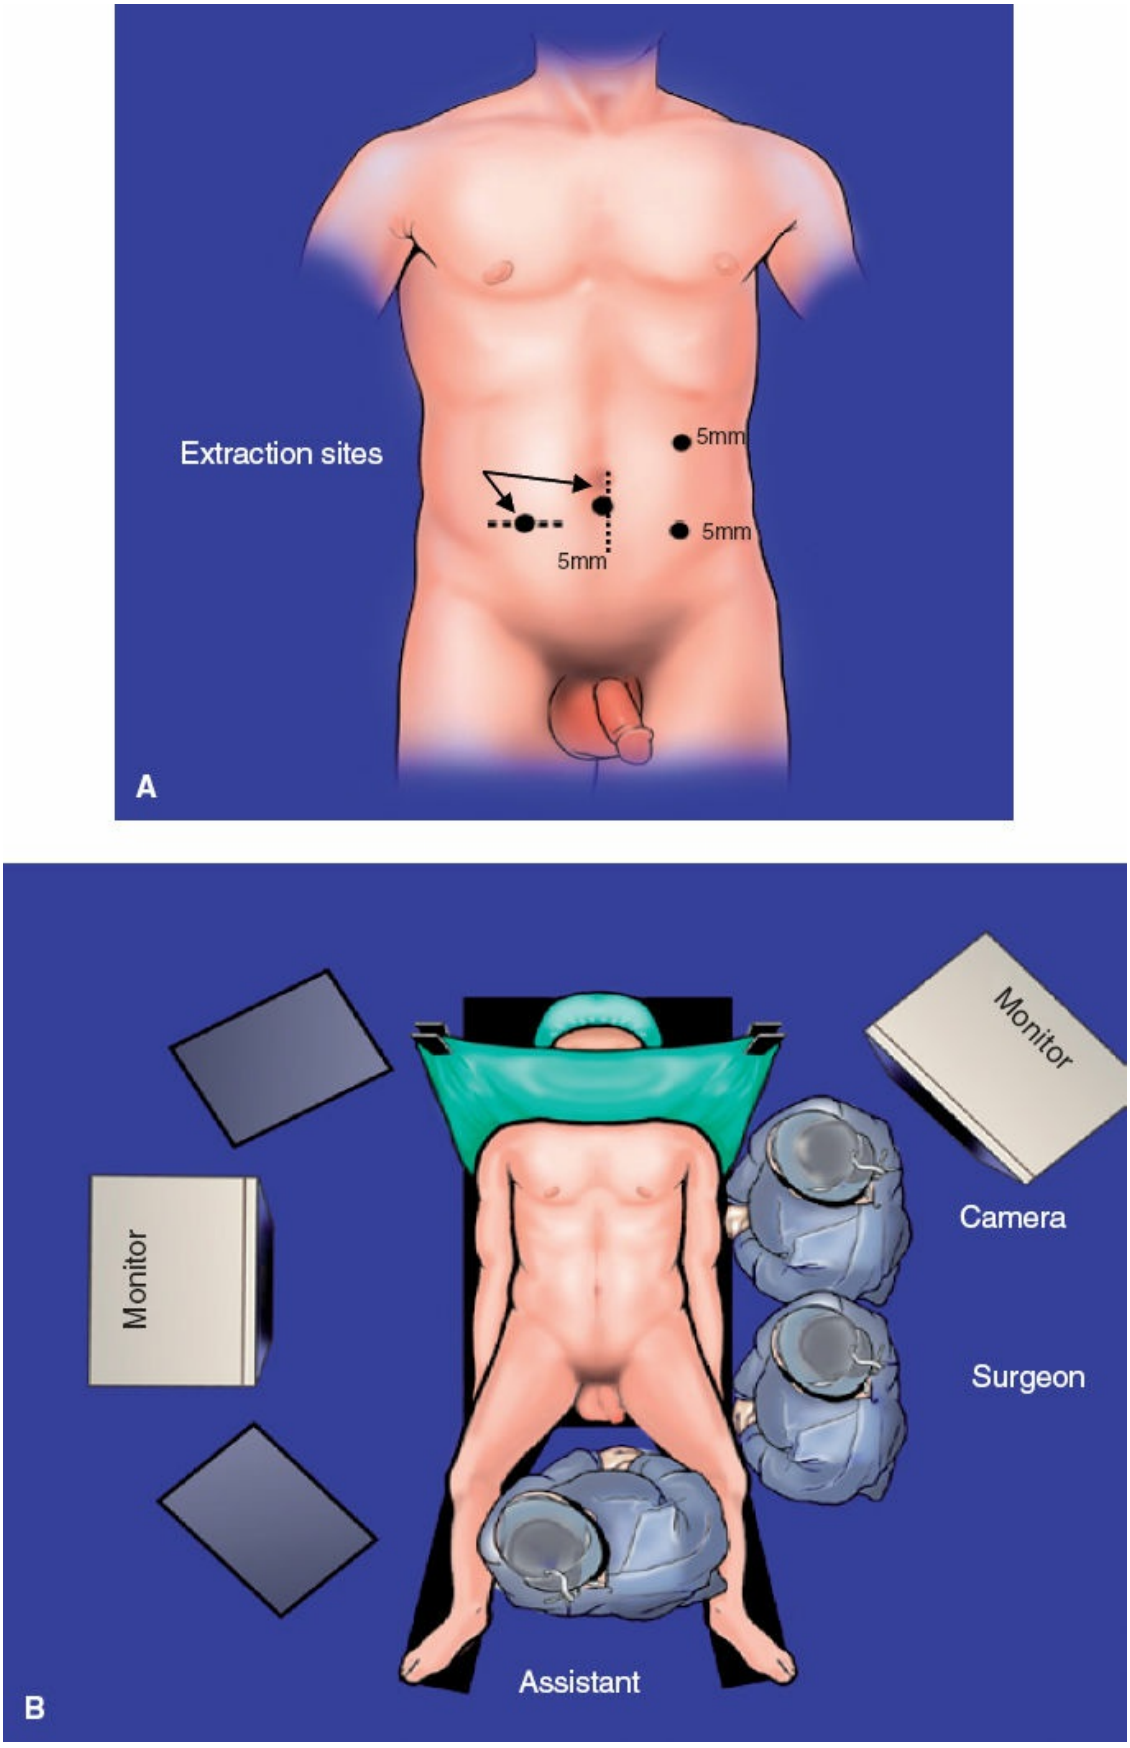

Figure 140.11. Laparoscopic ileocolic resection. **A.** Trocar placement and specimen extraction sites. **B.** Operating room

setup.

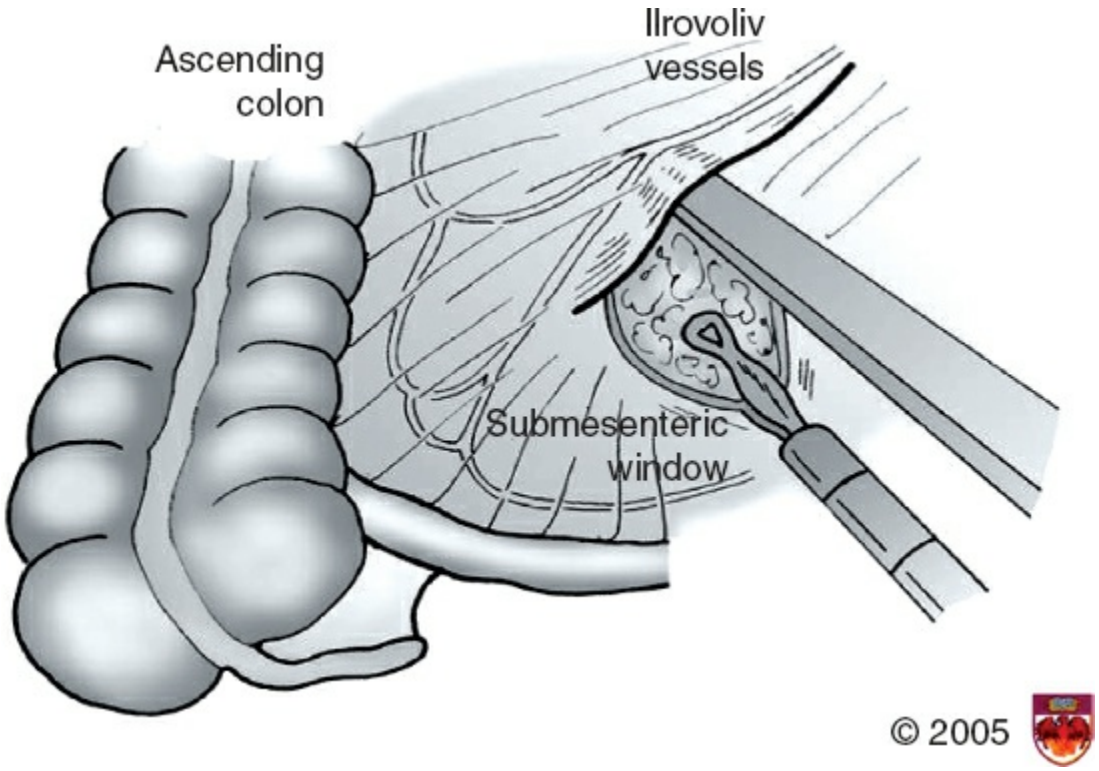

Figure 140.12. Dissection of the ileocolic vessels.

Several studies have demonstrated the advantages of an ERAS protocol in colorectal surgery compared with the standard of care. Two systematic reviews by Spanjersberg et al. and Varadhan et al. have cited shorter hospital stay, decreased morbidity and mortality, and no increase in readmission rates for patients treated under ERAS protocols. ERAS also enhances the benefits of minimally invasive surgery.

Spinelli et al. published the benefits of ERAS in patients with CD who underwent laparoscopic ileocolic resections, compared to a group of patients managed with standard postoperative care. They found that patients enrolled in an ERAS protocol had a significant earlier return of bowel function ($p = 0.002$) and a shorter postoperative hospital stay (5.3 vs. 6.8 days, $p = 0.04$). The lack of preoperative fasting, the use of opioid-sparing intraoperative analgesia and opioid-free postoperative analgesia, prevention and treatment of postoperative nausea and vomiting, and the early mobilization and dietary intake of solids among patients on the ERAS protocol are likely responsible for the faster recovery in this group. Further studies are necessary to evaluate the feasibility and value of the protocol for other operations for CD.

COMPLICATIONS AND THEIR MANAGEMENT

Abdominal septic complications, including abscess and anastomotic leak, are more frequent in patients with CD. Several factors can contribute, including chronic inflammatory status, poor nutritional status, presence of abscess, use of steroids, and recurrent episodes of disease.

Alves et al. reviewed intra-abdominal septic complications after the first ileocecal resection for CD in 161 patients; of these, 15 developed abscess and anastomotic leaks (9%). Multivariate analysis found four independent risk factors for intra-abdominal septic complications: poor nutritional status (defined by weight loss >10% within the last 10 months), intra-abdominal abscess discovered during surgery, preoperative steroid use more than 3 months, and recurrent clinical episodes of CD. Yamamoto et al. reported similar rates of intra-abdominal septic complications (13%); these were significantly associated with preoperative low albumin levels (<30 g/L), preoperative steroid use, abscess at the time of laparotomy, and fistula at time of laparotomy. The intra-abdominal septic complication rate was 50% in patients with all of these four factors, 29% in patients with three risk factors, 14% in patients with two risk factors, 16% with one risk factor, and 5% in those with no risk factor ($p < 0.0001$). While these factors are not all modifiable, poor nutritional status can be improved by total parenteral nutrition before surgery, which allows patients to increase albumin levels and reduce inflammatory status. Careful preoperative evaluation for abscess and fistula may allow better timing of surgery, and coordination with the medical team may facilitate appropriate preoperative steroid taper.

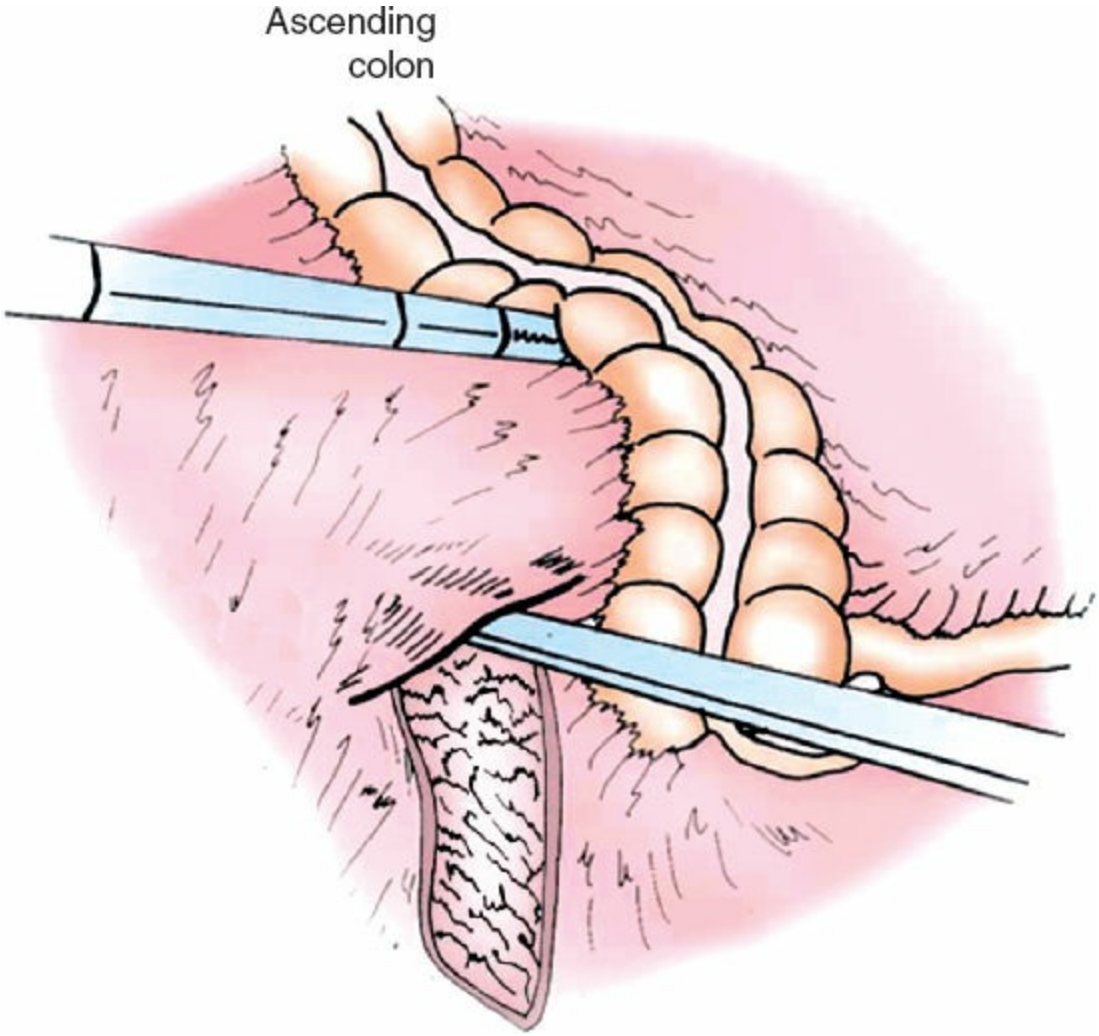

Figure 140.14. Division of the lateral attachments of the ascending colon.

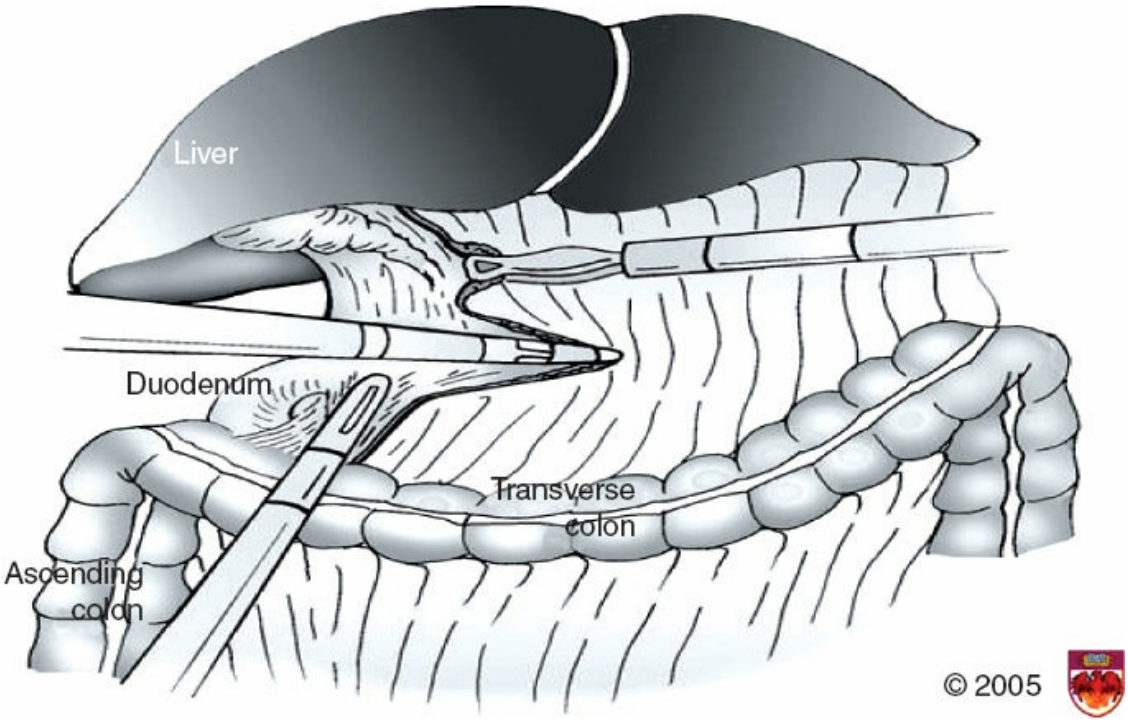

Figure 140.15. Final mobilization of the hepatic flexure.

Inflammatory bowel disease is a well-known risk factor for venous thromboembolism (VTE), with 1.5- to 3-fold increased risk over the general population. Disease flares are associated with increased risk of VTE, with the highest absolute risk in those requiring hospitalization. Multiple authors have reported VTE risk factors for IBD patients, including steroid use, surgery within 90 days, anemia, and prolonged anesthesia time. Compared with non-IBD patients, IBD patients are less likely to present with pulmonary embolism and more likely to have abdominal vein thrombosis. IBD patients with VTE are less likely to be on anti-TNFα agents or 5-ASA derivatives, and more likely to require steroids for disease management.

OUTCOMES

CD is a recurrent disease. Endoscopic evidence of recurrence occurs in 70% to 90% of patients 1 year after intestinal resection. Symptomatic recurrence occurs in 30% of patients at 3 years and 60% of patients at 10 years. After an intestinal resection and anastomosis, recurrence usually develops at or proximal to the gastrointestinal anastomosis; patients with a proximal diverting stoma are more likely to have a recurrence after restoration of intestinal flow. Several factors are related to recurrence: smoking, NOD2/CARD15 gene mutation, young age at diagnosis, short

duration of disease prior to operation, extent of disease >100 cm, and multiple sites of disease.

Smoking doubles the risk of clinical and surgical recurrence. Smoking cessation has a beneficial effect and reduces clinical and surgical recurrence rate to baseline after 10 years.

Recurrence is also influenced by surgical technical decisions such as the type of anastomosis, resection margin, and choice of stricturoplasty versus resection. Endoscopic recurrence usually develops at or proximal to the anastomosis, and luminal diameter seems to play a role; the only randomized control trial (CAST) comparing side-to-side and end-to-end anastomosis after intestinal resection found no significant differences at 12 months postoperation in endoscopic or symptomatic recurrence. More recently, the Kono-S-anastomosis has been suggested to have a protective effect on recurrence. The Rutgeerts endoscopic recurrence score correlates with the likelihood of clinical and surgical recurrence, and can be used in the surveillance period to help guide therapy (Table 140.1).

Fazio et al. conducted a randomized trial enrolling 131 patients undergoing intestinal resection to a limited resection margin (2.5 cm) versus extended margin (12.5 cm). At follow-up, the surgical recurrence was in favor of the extended resection margin (17.5% vs. 25.3%), but the difference was not statistically significant ($P = 0.38$).

A recent systematic meta-analysis by Yamamoto et al. including 1,100 patients with 3,300 stricturoplasties identified a stricturoplasty site-specific recurrence rate of 3%, much lower than would be expect after intestinal resection and anastomosis. This suggests that stricturoplasty may confer a protective effect against recurrence.

The role of anti-TNFα therapy in reducing the incidence of surgical recurrence is still unknown, but the impact of these agents can be inferred from mucosal healing. Regueiro et al. demonstrated in a placebo-randomized control trial that endoscopic recurrences were significantly less frequent in the infliximab group compared to controls at 1 year (9.1% vs. 84.6%, $p = 0.0006$) but the sample size was too small to detect differences in clinical recurrence. Similar results were obtained by Yoshida et al. who found the clinical remission rate with infliximab was 100% versus 68% in the placebo group ($p < 0.03$) at 1 year.

Prophylaxis	Smoking Cessation No therapy ? Metronidazole ? ASA	?ASA 6MP or AZA with or without metronidazole	6MP AZA Anti-TNF

Colonoscopy in 1 to 2 years to assess disease progression and reassign risk class based on endoscopic score.

Postoperative treatment plans, given the limited data regarding pharmacologic prophylaxis, should be tailored to the individual patient. The first step in treatment planning would be to risk stratify the patient as low, intermediate, or high risk as shown in Table 140.2. Treatment is then

modified, if needed, based on clinical recurrence or endoscopic recurrence at the 6- to 12-month interval (Fig. 140.16).

CONCLUSION

Even with improvements in medically induced remission using new regimens including anti-TNFα agents and immunomodulators, surgery is still frequently required for patients with small bowel CD. Key surgical principles include sparing bowel length and utilizing stricturoplasty to help prevent future issues with short bowel syndrome. Risk factors for recurrence, and subsequent need for multiple operations, include smoking, the NOD2/CARD15 gene mutation, young age at diagnosis, short duration of disease prior to an operation, long segment disease, and multiple sites of disease. Patients with CD require thoughtful multidisciplinary management, with close cooperation between the surgeon, gastroenterologist, and other adjunct specialists to design an individualized approach, which optimizes the timing of needed operative interventions.

EDITOR'S COMMENT

Dr. Fichera and colleagues provide a thorough overview of the treatment of CD affecting the upper gastrointestinal intestinal tract and small bowel. Some clarifications are needed, however. The authors list the three different phenotypes of CD, namely inflammatory, stricturing, and penetrating. These have been described as discrete phenomena, any one of which could happen in a particular patient. In reality, these represent a continuum of a disease process that we at any moment are only observing at one snapshot in time. By this I mean is that CD is initially associated with significant inflammation, and edema. At this point, anti-inflammatory medications work well. Over time, and this is frequently over years of disease progression and chronic inflammation, the disease slowly transforms to fibrosis, which as the authors correctly state is not amenable to nonoperative therapy. When this fibrotic process becomes severe enough to cause significant obstruction, Crohn ulcerations proximal to this obstruction will in turn perforate, resulting in a peri-intestinal abscess. Such abscesses then drain spontaneously into whatever structure(s) is/are adjacent to them, be it sigmoid colon, bladder, or skin. Thus, just as the different phenotypes of CD are a continuum in the disease process, just so is the

development of fistula from an intestinal perforation with or without subsequent abscess. This progression of disease has led to development of the "top-down" treatment algorithm increasingly used by gastroenterologists. This top-down method refers to the up-front or initial treatment of CD with anti-tumor necrosis factor α (TNFα) antibody therapy (or other stronger immunomodulators) rather than the traditional initial treatment with anti-inflammatory medications and antibiotics (bottom-up therapy, i.e., starting with safer, less effective drugs initially). It is hoped that initial aggressive top-down treatment with such agents will stop disease progression to the fibrosing and penetrating phenotypes of disease and perhaps avoid surgery.

Notwithstanding the eagerness and enthusiasm for "modern" medical therapy, there is still role for steroids in managing patients with small bowel CD. No medication is as readily available or works as quickly at reducing bowel edema and in some cases reducing bowel obstruction. In patients needing surgery for bowel obstruction due to CD, the worst thing that one can do is have them to taper their steroids prior to surgery. This often results in a worsening of the bowel obstruction.

The authors do not discuss the role of capsule endoscopy in the diagnosis of small bowel CD. I have found this helpful in some cases in which the diagnosis is unclear. Diagnosing an obstruction in these patients can, however, be difficult since the only clue one often has to the obstruction is persistence of the capsule in the same bowel segment for a long time—in some cases hours. The authors also discuss the use of conventional barium small bowel follow-through studies in preoperative patient evaluation. These studies can be very valuable in that they provide functional information about the CD, that is, information about delayed transit, the degree of proximal bowel distention, etc. Barium studies should of course not be performed in the presence of an obstruction, since the barium may become inspisated in the bowel and become a source of major morbidity if the patient comes to surgery. Sadly performing these studies is becoming a lost art nowadays, since many radiologists are loath to touch patients and prefer studies like CT and MR enterography that can be performed long-distance without patient contact. *(This is unfortunately the usual way that patients end up. The only way I know to prevent this is to have the senior surgeons attend to the study and have such studies take place. – JEF.)*

The authors' discussion of intestinal bypass does not mention one of the most historic operations performed in US history, namely the historic bypass that was performed on President Eisenhower many years ago with nonetheless a good outcome with the long follow-up (Michelassi F, Sultan S. Surgical treatment of complex small bowel Crohn disease. *Ann Surg* 2014;260(2):230–5). President Eisenhower was a long-time cigarette smoker, a factor no doubt leading to exacerbation of his CD. His operation went relatively smoothly, he had a nasogastric tube for 5 days, a 3-week hospital stay, and developed a wound infection. Nonetheless, he was able to run for and successfully complete a second term as president. Later in life he ultimately required a lysis of

adhesions for bowel obstruction, but had no further issues with his CD.

The authors' contribution to the field of strictureplasty is substantial (Pappas TN. President Eisenhower's bowel obstruction: the story of his surgeons and their decision to operate. *Ann Surg* 2013;258(1):192–7). It is still a mystery as to why this operation works as well as it does, and why if one operates for another reason on the same patient, months or years later, the areas of bowel that were indurated and severely inflamed at the site of the strictureplasty are now pliable and nearly normal appearing. Also, why are recurrence rates at the sites of Strictureplasty lower than for anastomoses? As with many things in surgery, more questions evolve than answers. One area where I differ with the authors is their praise of energy devices for division of very thickened Crohn's small bowel mesentery. I do not find these devices always to perform as well in this scenario and frequently rely on old-fashioned sharp dissection and suture ligation! *(I agree entirely. – JEF)*

As with many things, we continue to learn about risk factors for surgery and optimizing our patients' condition. With CD there have for years been contradictory reports on the effect of the so-called biologic drugs or anti-tumor necrosis factor α (TNFα) antibody therapy that has been used so widely for treatment. Many studies suggested higher rates of infectious complications in inflammatory bowel disease (IBD) patients receiving these drugs preoperatively, while others found no such relationship. A recent report from a large IBD center suggests that there may be an increased risk of complications in Crohn's patients who have high serum levels of these anti-TNFα drugs preoperatively (Lau C, Dubinsky M, Melmed G, et al. The impact of preoperative serum anti-TNFα therapy levels on early postoperative outcomes in inflammatory bowel disease surgery. *Ann Surg* 2015;261(3):487–96). In comparing patients with high and low serum anti-TNFα drug levels preoperatively, patients with high drug levels had higher rates of postoperative morbidity and hospital readmission. This is not surprising, since TNFα mediates neutrophil chemotaxis and adhesion and patients receiving these drugs are at higher risk of opportunistic infection.

One of the challenges in operating on patients with CD is the risk of disease recurrence. As the authors note, smoking is the one environmental factor definitively associated with a higher risk of recurrent disease. Discussions about behavior modification are an important part of patient care for all physicians taking care of Crohn's patients, be they surgeons or other types of physicians. Recently there has been increased focus on the role of the intestinal microbiome in intestinal disease and the role of probiotics in modifying it. An interesting prospective study of Crohn's patients undergoing ileocolic resection found that patients with disordered intestinal microbial populations at the ileocolic anastomosis were more prone to endoscopically discovered postoperative recurrence (Mondot S, Lepage P, Seksik P, et al.; GETAID. Structural robustness of the gut mucosal microbiota is associated with Crohn's disease remission after surgery. *Gut* 2016;65(6):954-62. doi: 10.1136/gutjnl-2015–

309184. In the future, we may be able to have greater control of disease recurrence rates by combinations of probiotics to modify the intestinal microbiome, postoperative behavioral modification by our patients to avoid harmful environmental factors such as smoking and perhaps other medications to obtain better overall and long-term outcomes in this very challenging set of patients.

H SURGERY OF THE COLON

141 Clinical Anatomy for Procedures Involving the Small Bowel, Colon, Rectum, and Anus

Uri Netz and Susan Galandiuk

INTRODUCTION

A good understanding of anatomy is critical for the surgeon performing colon and rectal procedures. Knowledge and awareness of important anatomical structures can dramatically reduce complications, such as bleeding, ischemia, and nerve damage. Approaching critical structures and planes in the correct fashion and with the proper respect can mean the difference between a straightforward case with minimal blood loss and a surgical nightmare. This chapter does not proclaim to cover all aspects of basic anatomy, but instead focuses on the *practical* aspects of the anatomy, including adjacent structures such as nerves and ureters, which are not part of the gastrointestinal (GI) tract but are very relevant for surgical procedures. We also provide clinical tips and solutions with the purpose of making future operations smoother and safer. For details on other aspects of basic anatomy, please review the Suggested Readings section at the end of the chapter.

SMALL BOWEL ANATOMY FOR COLORECTAL PROCEDURES

The jejunum and ileum together measure approximately 2.5 to 3 meters in vivo (and significantly longer after removal from the body due to loss of longitudinal muscle tone) and are responsible for nearly 90% of the absorption of the GI system (Fig. 141.1). For the surgeon, it is more important to judge the length of small bowel remaining than what has been removed in the past. In general, patients with less than 200 cm of small

bowel remaining are in danger of developing short bowel syndrome. Preserving the terminal ileum is especially important for the absorption of vitamin B12 and bile salts.

The jejunum and ileum are anchored to the posterior abdominal wall by the small bowel mesentery, consisting of a double layer of peritoneum that connects them to the posterior abdominal wall in an oblique direction toward the right iliac fossa (Fig. 141.2). The blood vessels, nerves, and lymphatics branch through the mesentery to supply the intestines. The blood supply of the jejunum and ileum is from the superior mesenteric artery (SMA) that provides blood to several arteries, which branch to form a series of arterial arcades that increase in complexity as one proceeds distally (Fig. 141.3). This marginal arcade is important when performing ileal pouch anal anastomosis. The surgeon can attain additional small bowel length, while still maintaining terminal ileal blood supply, by dividing the ileocolic artery or the SMA (distally to the origin of the ileocolic artery), but not both.

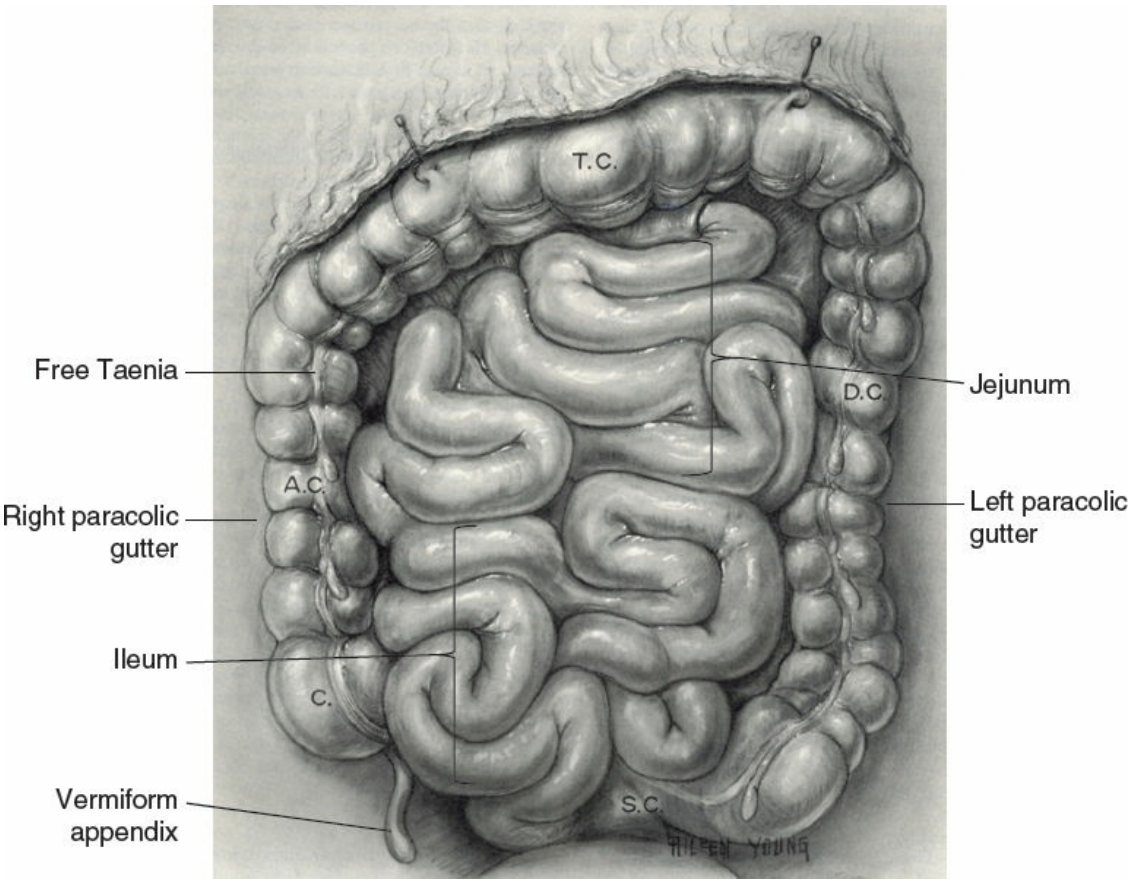

Figure 141.1. The large intestine, with the transverse colon elevated and the greater omentum removed. C is the cecum; A.C., T.C., D.C., and S.C. identify, respectfully, the ascending,

the transverse, the descending, and the sigmoid colon. (With permission from Hollinshead WH. *Anatomy for Surgeons, volume 2. The Thorax, Abdomen and Pelvis*. 2nd ed. New York: Harper and Row; 1971.)

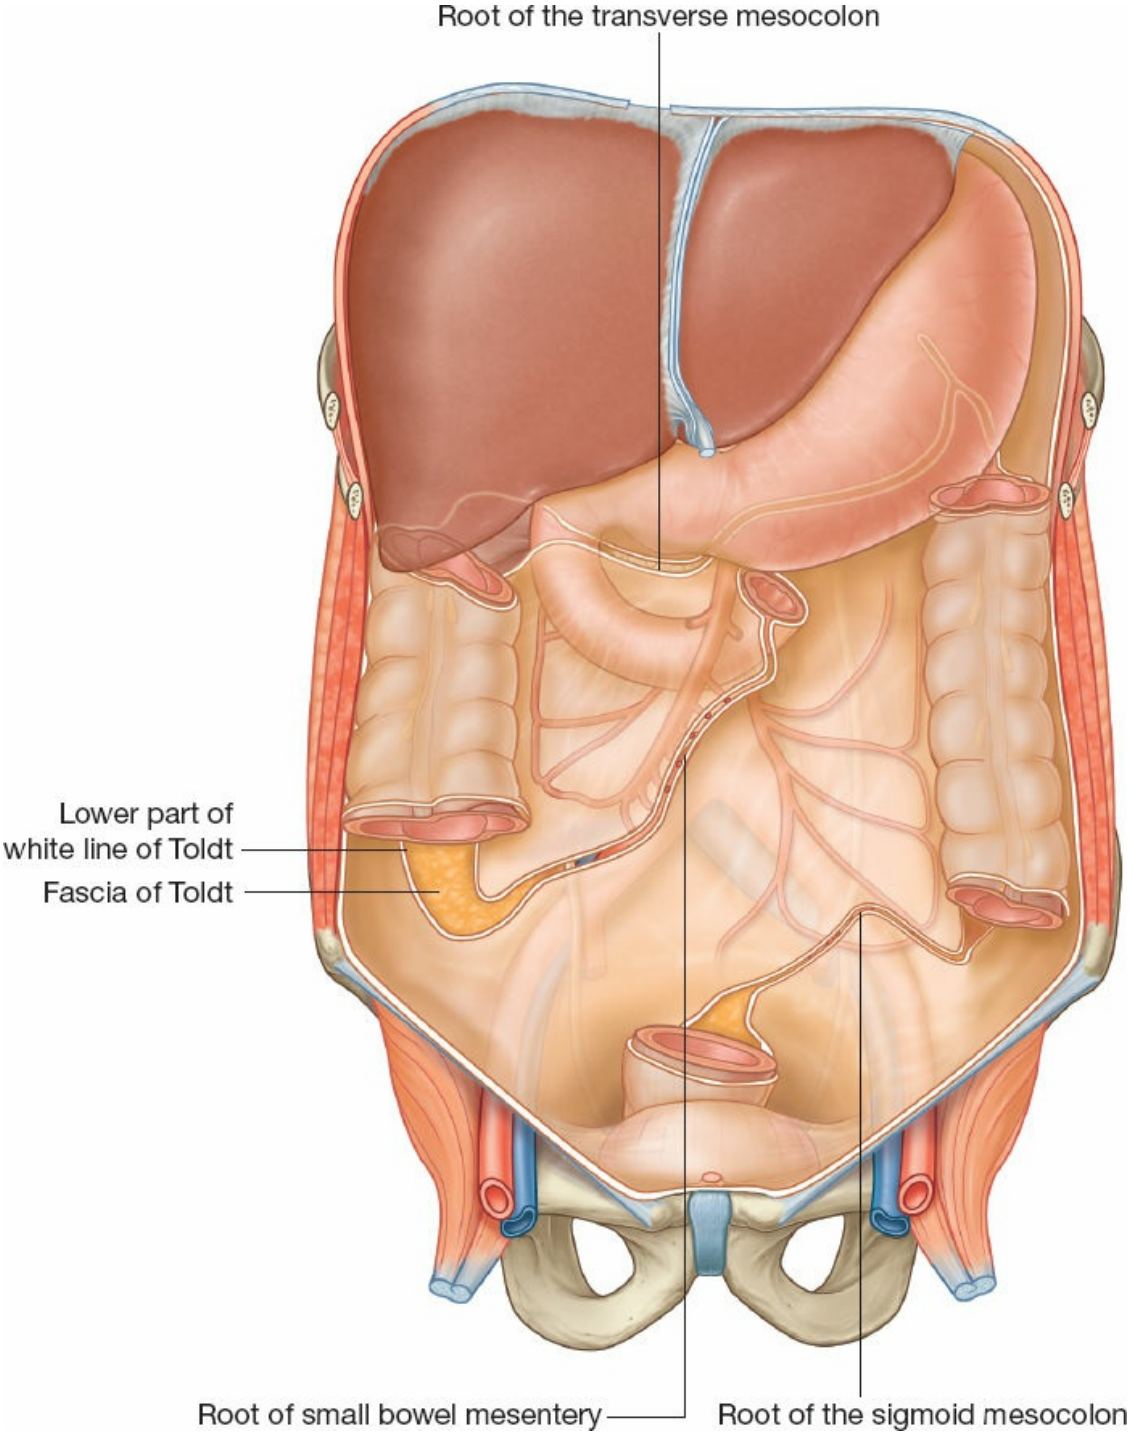

Figure 141.2. Attachment or root of mesentery of small bowel and colon along posterior abdominal wall.

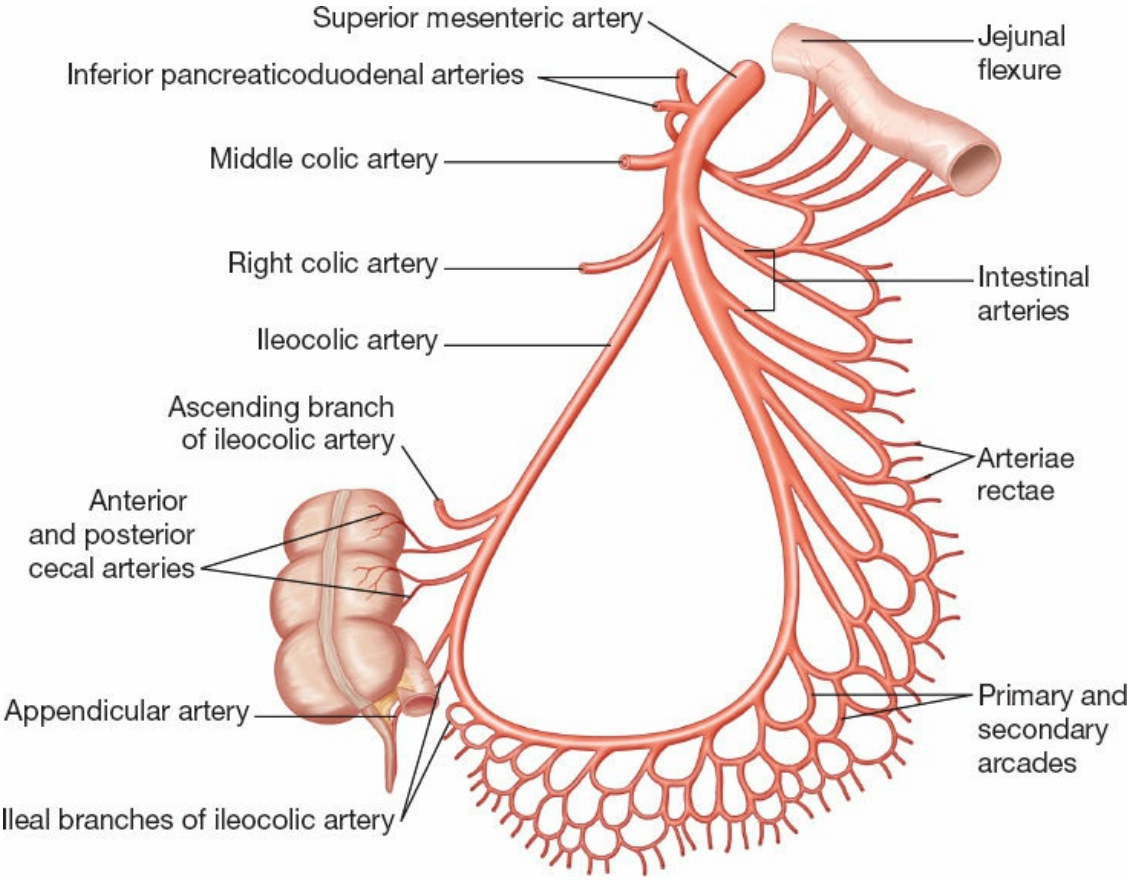

Figure 141.3. The blood supply of the jejunum and ileum; the arteriae rectae are shown very schematically. Other branches of the superior mesenteric artery, and the terminal branches of the ileocolic, are also identified. (With permission from Hollinshead WH. *Anatomy for Surgeons, volume 2. The Thorax, Abdomen and Pelvis*. 2nd ed. New York: Harper and Row; 1971.)

CECUM AND APPENDIX

The cecum is the saccular beginning of the colon. It lies in the right iliac fossa. It is completely covered by peritoneum and is, therefore, considered an intraperitoneal structure (Fig. 141.1). In general, it has no mesentery. It is variably connected to the posterior abdominal wall by the peritoneal reflection. Twenty percent of individuals have a cecum completely free from dorsal attachment (Fig. 141.4). An abnormally mobile cecum in concordance with an abnormally mobile ascending colon can be found in a small proportion of patients and can predispose to volvulus (torsion), or cecal bascule (upwards folding of the cecum), due to the fixation of the hepatic flexure. The wall of the cecum is thin compared to the rest of the colon. In accordance with the law of Laplace, and considering its large diameter, it is the site most likely to perforate in cases such as adynamic

ileus, Ogilvie syndrome, etc. Also, because of its thinness, it is easier to perforate in cases of colonoscopic polypectomy. Most surgeons choose to incorporate the taeniae for cecotomies, cecopexy, and anastomosis, as it includes an extra layer of muscle.

The vermiform appendix originates from the posteromedial border of the cecum. Its size is variable, averaging 5 to 10 mm in diameter and 8 to 10 cm in length. It is most commonly found in a retrocecal position. Locating the appendix in the setting of inflammation and adhesions can be challenging, but one can reliably reach its base by following the anterior taenia to its junction with the other two taeniae.

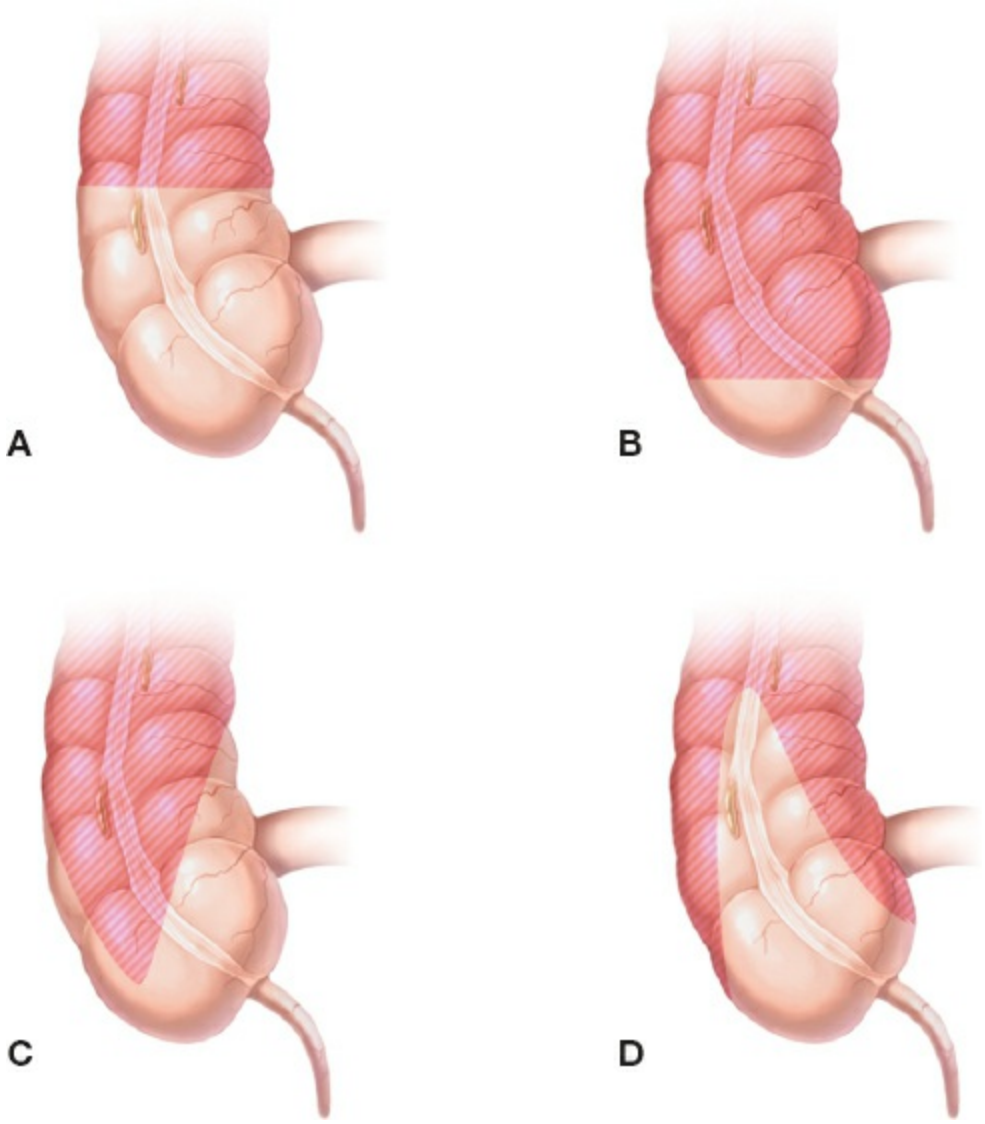

Figure 141.4. Some variations in the posterior peritoneal attachments of the cecum—the areas of attachment are obliquely shaded. (**A**) shows an unattached cecum, the line of peritoneal reflection being on the ascending colon; in (**B**) the cecum is

almost completely fused to the posterior wall; in (**C**) there is an incomplete and oblique attachment; and in (**D**) there is a concave line of attachment enclosing a large retrocecal. (With permission from Hollinshead WH. *Anatomy for Surgeons, volume 2. The Thorax, Abdomen and Pelvis*. 2nd ed. New York: Harper and Row; 1971.)

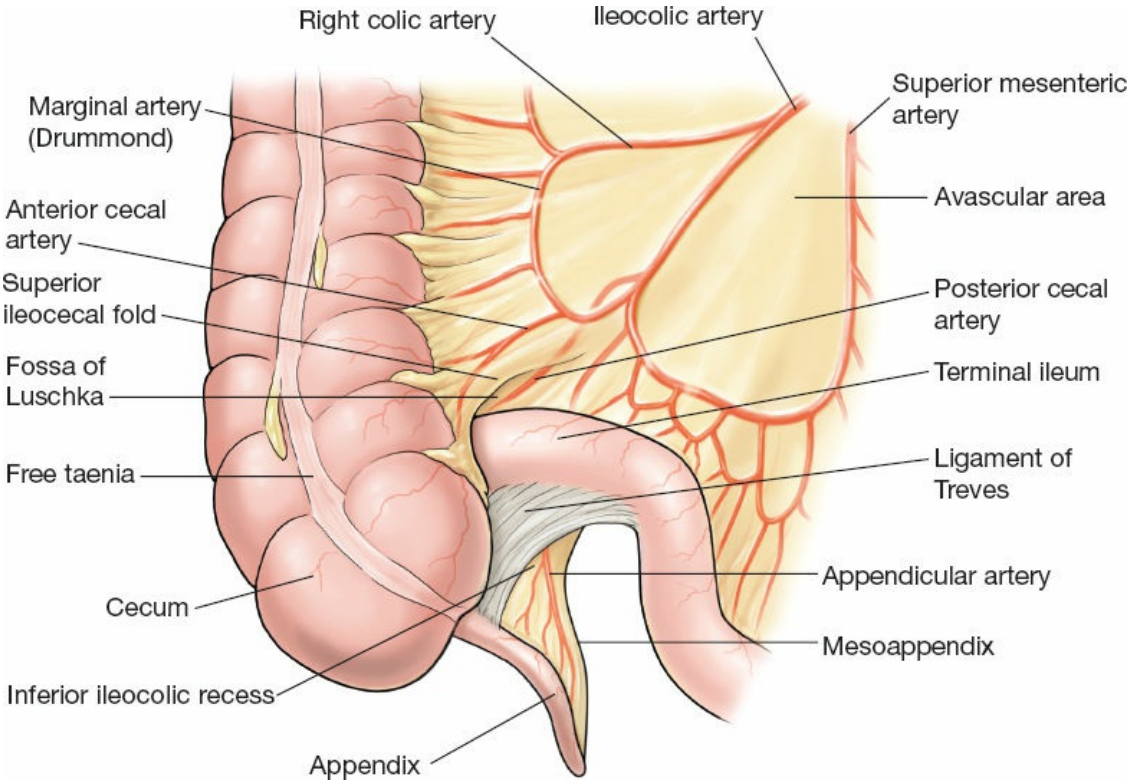

Figure 141.5. The ileocecal region and blood supply. (From Lowry SE, Davidov T, Shiroff AM. Appendicitis and appendiceal abscess. In: Fischer JE, Jones DB, Pomposelli FB, et al., eds. *Fischer's Mastery of Surgery*, 6th ed. Wolter Kluwer; Lippincott Williams & Wilkins. Chapter 149, Figure 3.

The ileum enters the cecum along its medial border (Fig. 141.5). This opening is surrounded by two flaps that protrude into the lumen and contain circular muscle derived partly from the ileal musculature and partly from the cecal musculature. This structure is referred to as the ileocecal valve. The valve's role, however, as a functional sphincter is debatable.

The superior ileocecal recess (fossa of Luschka) lies anterior to the terminal ileum. It is formed by a peritoneal fold, the superior ileocecal or vascular fold, which extends from the mesentery of the terminal ileum, and, after crossing the ileum, attaches to the lowest part of the colon and

cecum. This fold contains the anterior cecal artery (Fig. 141.5). Similarly, the inferior ileocecal recess lies between the mesoappendix and a fold of peritoneum referred to as the inferior ileocecal fold or the bloodless fold of Treves. This fold extends from the antimesenteric border of the terminal ileum to the base of the appendix or the anterior surface of the mesoappendix, or to both areas. This fold contains no sizable blood vessels. Since it is the only part of the ileum that has a fold on the antimesenteric side of the bowel, it can help in the recognition of the ileocecal region. Both folds are perceived to be functionally important in maintaining the correct angulation of the ileocecal valve.

The ileocecal valve is clinically important in cases of large bowel obstruction. A competent valve does not allow the reflux of cecal contents into the small bowel causing a "closed loop obstruction," a surgical emergency, whereas an incompetent valve that allows retrograde flow into the small bowel leads to less distention and a less acute clinical scenario. Surgeons take advantage of the valve mechanism of the ileocecal valve in the creation of continent stomas such as the Indiana Pouch, for urinary diversion, and the antegrade continence enema (ACE) operation, which assists evacuation of colon contents in cases of constipation or neurologic dysfunction.

ASCENDING COLON

The ascending colon begins at the ileocecal junction and extends distally and superiorly to the hepatic flexure (Fig. 141.6). It is usually covered by peritoneum on its anterior and lateral aspects. Posteriorly, it is connected to the peritoneum by the fascia of Toldt, an areolar and relatively avascular tissue. At the hepatic flexure, the colon takes an abrupt turn medially. It is suspended there by the nephrocolic ligament to the Gerota fascia of the right kidney. At the lower pole of the right kidney, the iliacus muscle and the aponeurotic origin of the transversus abdominis muscle lie posterior to the ascending colon.

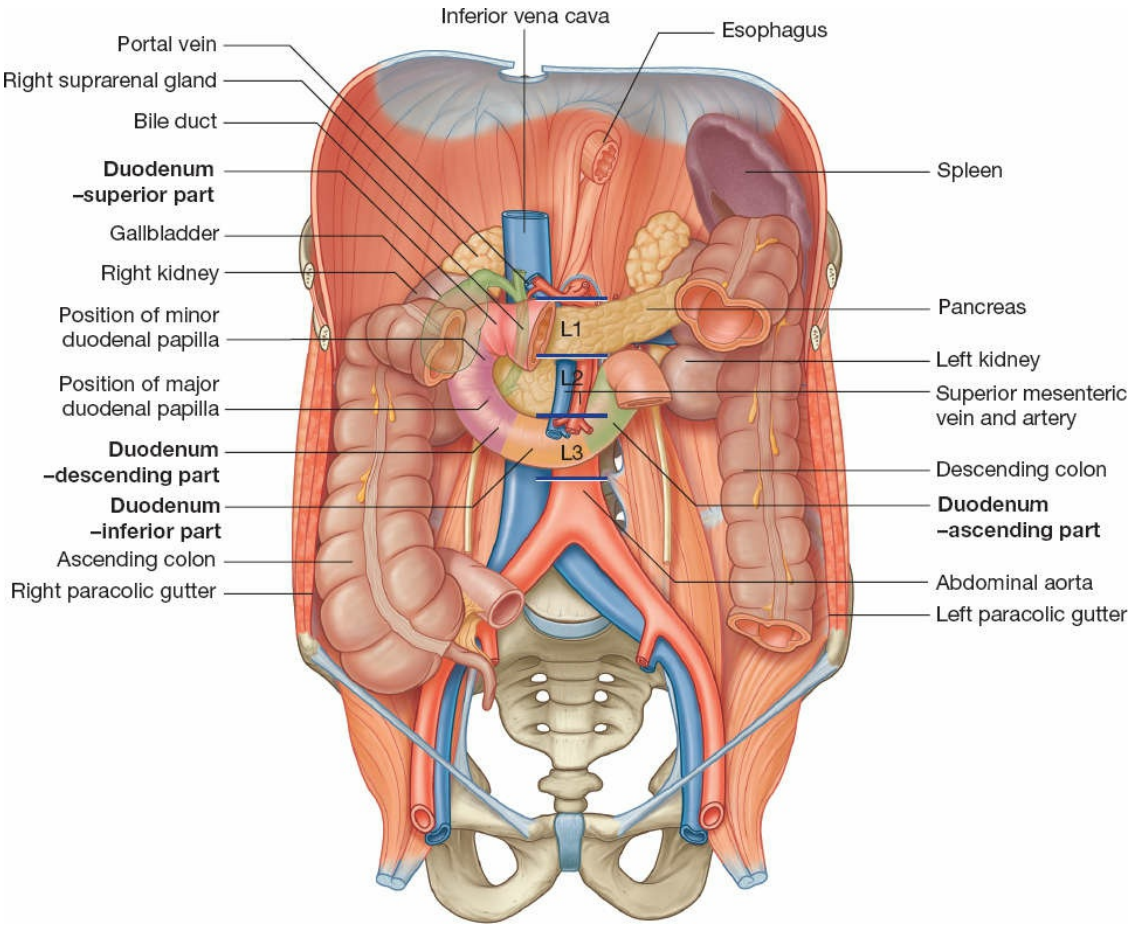

Figure 141.6. Structures posterior to the left and right colic flexures.

The right paracolic sulcus, or gutter, is lateral to the colon. Fluid and pus tend to traverse along this gutter either from the appendicular region to the hepatorenal recess or from the liver and epigastrium to the pelvis.

The ascending colon is best mobilized along the lateral peritoneal reflection by incising the "white line of Toldt" (Fig. 141.2), continuing posteriorly and medially close to the colon, in order to avoid the kidney and right ureter. After releasing the hepatic flexure and lifting the colon medially, one must be aware of the proximity of the second part of the duodenum (Fig. 141.6), which can be injured inadvertently, especially in inflammatory conditions such as Crohn disease or in cases of cancer in which the anatomy can be distorted. In these conditions, it is a common location of fistulas between the duodenum and colon.

TRANSVERSE COLON

The transverse colon begins at the right colic flexure and passes to the left, ending at the left colic or splenic flexure. It is intraperitoneal and

suspended from the posterior abdominal wall by the transverse mesocolon (Fig. 141.2). The transverse colon hangs between the two flexures in a U-shaped curve, which can reach the pelvis in some individuals, depending on body position. This redundancy and shifting position can pose a risk for a volvulus (although rare) and make traversing it (as well as the sigmoid colon) during colonoscopy challenging. Recognizing this variability in position is extremely important when attempting to exteriorize the transverse colon with a "target incision" for a transverse colostomy. Although its posterior relationships can vary due to its mobility, the transverse colon is usually anterior to the hilus of the right kidney, the descending (second) part of the duodenum, and the head of the pancreas (Fig. 141.6). Its cranial surface is in contact with the liver, the gallbladder, the greater curvature of the stomach, and the spleen. Its caudal surface is in contact with the small intestine, and its anterior surface is in contact with the anterior layer of the greater omentum and the abdominal wall.

Just inferior to the spleen, the transverse colon turns downward, forming the left colic or splenic flexure. This flexure is higher and is situated more posteriorly than the right colic flexure. It is suspended from the diaphragm by the left phrenicocolic ligament, a distinct peritoneal fold. The splenic flexure is connected posteriorly via the renocolic, splenocolic, and pancreaticocolic ligaments to the Gerota fascia, which surrounds the left kidney, the lower pole of the spleen, and the tail of the pancreas. These ligaments are usually linked into one continuous avascular connection (Fig. 141.7). The splenic flexure can be completely released without dividing any major blood vessels, if one is in the correct plane. In open procedures, one should approach the splenic flexure after first mobilizing the descending colon and the transverse colon proximal to the flexure. The most common cause of bleeding is from avulsion of a portion of the splenic capsule from excessive downward traction.

DESCENDING COLON

The descending colon begins at the left colic flexure, where the intestine loses its mesentery. Posteriorly, the descending colon is related to the lower pole of the left kidney and lies on top of the iliacus muscle and the aponeurotic origin of the transversus abdominis muscle. Posteromedially, the descending colon is in contact with the left psoas major muscle. The descending colon is similar to the ascending colon with regard to its peritoneal coverage anteriorly and on the medial and lateral sides, with the

fascia of Toldt posteriorly. The left paracolic sulcus (gutter) is immediately lateral to the descending colon. Dissection of the descending colon is best performed on the lateral side from inferior to superior, along the white line of Toldt.

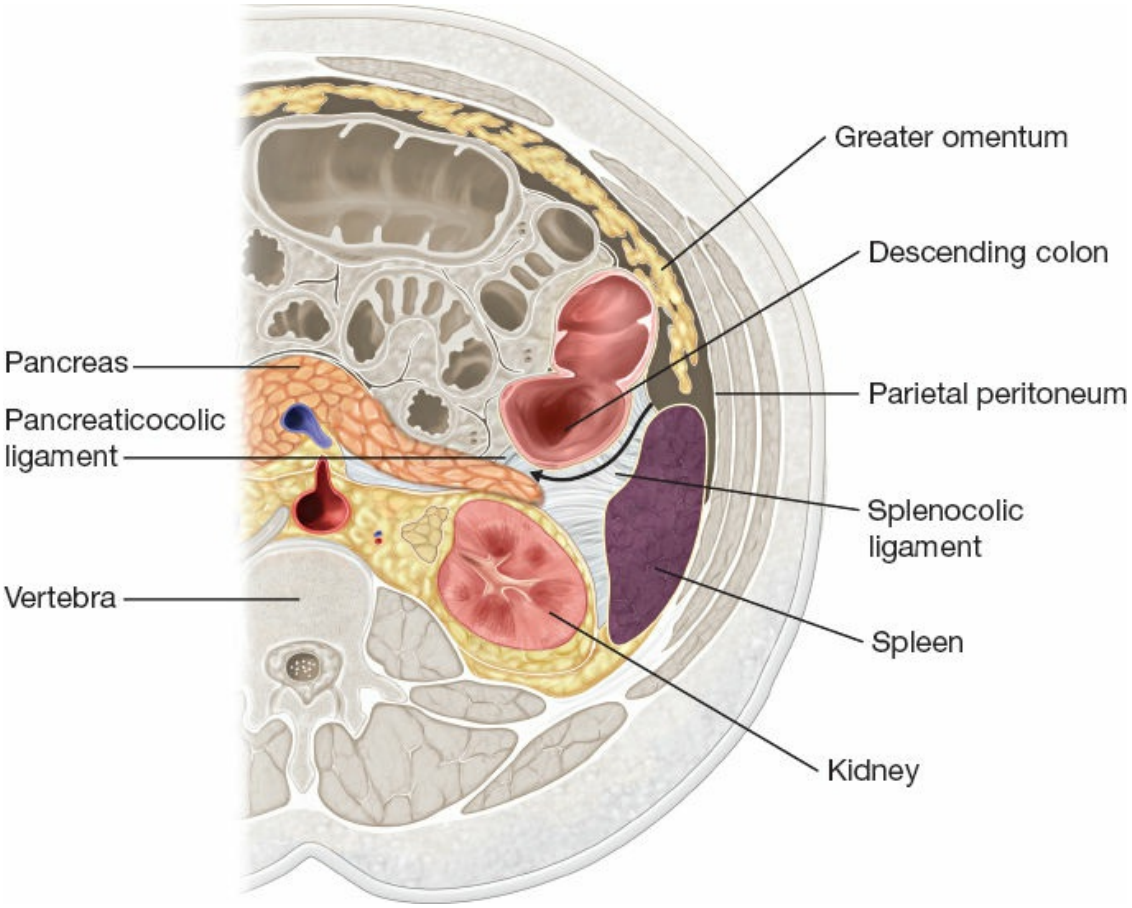

Figure 141.7. Ligaments of the splenic flexure. *Arrow* indicates potential plane of dissection.

SIGMOID COLON

At or below the crest of the ileum, the colon acquires a mesentery, covered bilaterally with peritoneum, and becomes the sigmoid colon. This section of the colon continues inferiorly until it loses its mesentery, usually between the level of the sacral promontory and the S3 vertebra, where it becomes the rectum. The end of the sigmoid colon can also be identified as the point where the colonic taeniae confluence to form a complete longitudinal muscle layer. Reaching the rectosigmoid junction is important surgically when performing sigmoid resection for diverticular disease. If the entire sigmoid colon is not removed, and the distal anastomosis is not made to the rectum, there is a much higher risk of recurrence. The sigmoid

colon is attached at its junction with the descending colon and rectum to the posterior abdominal wall, but mobile throughout its length. This mobile portion is attached by the sigmoid mesocolon, which is connected to the posterior abdominal wall and pelvis, in the pattern of an inverted V (Fig. 141.2). When mobilizing the sigmoid colon, it is important to identify the fold of the sigmoid peritoneum and not to dissect off the lateral pelvic peritoneum in order to avoid injury to the ureter and gonadal vessels.

BLOOD SUPPLY OF THE COLON

The vascular supply to the colon is through the SMA and the inferior mesenteric artery (IMA), both anterior branches of the abdominal aorta (Fig. 141.8). The SMA arises opposite the lower border of the L1 vertebra and descends in a groove on the posterior surface of the body of the pancreas (Fig. 141.6). The artery crosses anterior to the left renal vein, the uncinate process of the pancreas, and the horizontal third portion of the duodenum. It gives off three major branches to the colon. The first branch is the middle colic artery, followed by the right and ileocolic arteries.

The ileocolic artery runs directly toward the ileocecal junction along the root of the mesentery. As this branch approaches the ileocecal junction, it gives off several branches: the anterior cecal artery, which passes in a vascular fold to the cecum; the posterior cecal artery, which passes retroperitoneally behind the cecum; and the appendicular artery, which descends behind the ileum, and enters the mesoappendix (Fig. 141.5). The appendicular artery may also appear as a branch of the posterior cecal artery.

The avascular space between the ileocolic artery and the SMA is useful both as a safe location to initialize dissection of the blood supply in a laparoscopic right colectomy and as a space where the transverse or right colon can be pulled through to gain bowel length in cases of “retro-ileal” colon-rectal anastomoses.

The right colic artery, which approaches the ascending colon retroperitoneally, divides into ascending and descending colic branches. It is absent in a significant proportion of patients.

The middle colic artery enters the transverse mesocolon and divides into right and left branches supplying the hepatic flexure and proximal transverse colon on the right, all the way to the splenic flexure on the left. In about a third of the cases, it is the main blood supply to the splenic

flexure. When lifting the transverse colon, one can follow the middle colic artery to the base of the mesentery to reach the SMA just to the right of the ligament of Treitz (Fig. 141.9). In order to access the proximal SMA, for example, when performing an embolectomy in the setting of acute mesenteric ischemia, it is customary to also release the ligament of Treitz.

The second major artery supplying the colon, the IMA, arises approximately 4 cm above the aortic bifurcation at the level of the L3 vertebra, roughly at the level of the umbilicus in most patients. Its major branches to the colon are the left colic artery, which runs retroperitoneally to the left, dividing into ascending and descending branches, the sigmoidal arteries, usually consisting of two to four branches, and the superior rectal artery, which is the distal part of the IMA, after it crosses the pelvic brim.

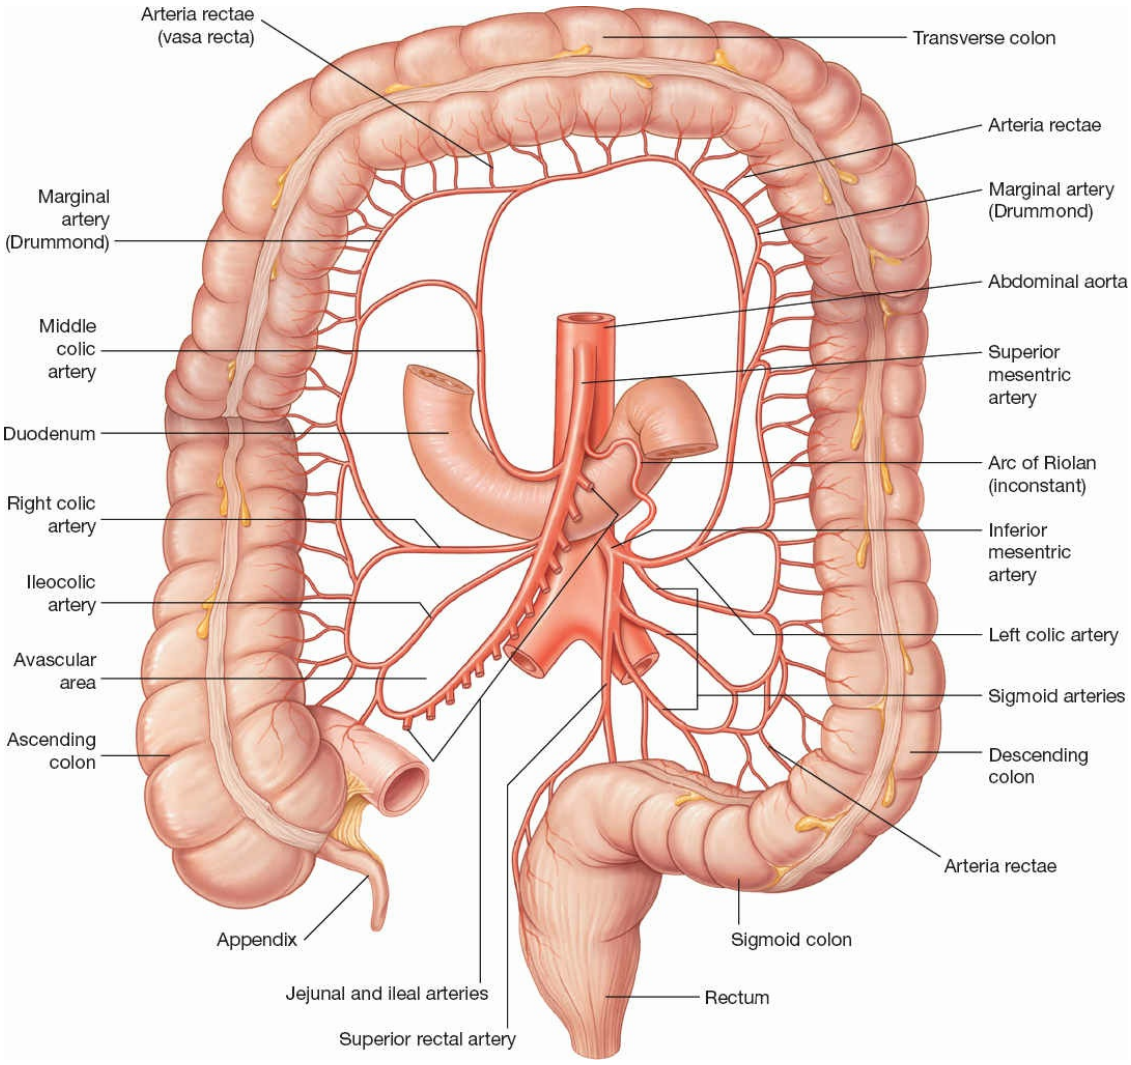

Figure 141.8. The vascular supply to the colon is from the superior and inferior mesenteric arteries. The distribution of these arteries and their branches is shown.

All of the arteries mentioned previously contribute to the formation of a continuous arterial channel that runs along the inner (mesenteric) margin of the colon, from the cecocolic junction to the rectosigmoid junction, and is called the marginal artery of Drummond. The marginal artery is important clinically. When an artery is obstructed for various reasons (emboli, atherosclerosis etc.), the bowel can receive its blood supply through the marginal artery. Surgically, when performing anastomosis low in the pelvis, it is possible to divide the IMA as it comes off the aorta proximal to the origin of the left colic artery to achieve extra colonic length, with the blood supply to the splenic flexure coming from the SMA through the marginal artery.

The meandering mesenteric artery, or “arch of Riolan,” is an

uncommon finding and indicates a collateral vessel that connects the SMA or middle colic artery to the IMA or left colic artery close to the base of the mesentery. It can have an important role in blood delivery in cases of SMA or IMA occlusion (Fig. 141.8).

Venous drainage of the colon generally parallels the arteries through the superior mesenteric veins (SMV) and inferior mesenteric veins (IMV), which contribute to the formation of the portal vein. Importantly, the IMV continues beyond the origin of the IMA superiorly along the window at the base of the mesentery, entering the portal vein adjacent and to the left of the ligament of Treitz, at the base of the splenic flexure mesentery, as a vertically oriented blood vessel (Fig. 141.9). As with the IMA, one can divide the IMV in order to achieve extra colonic length for low pelvic anastomoses.

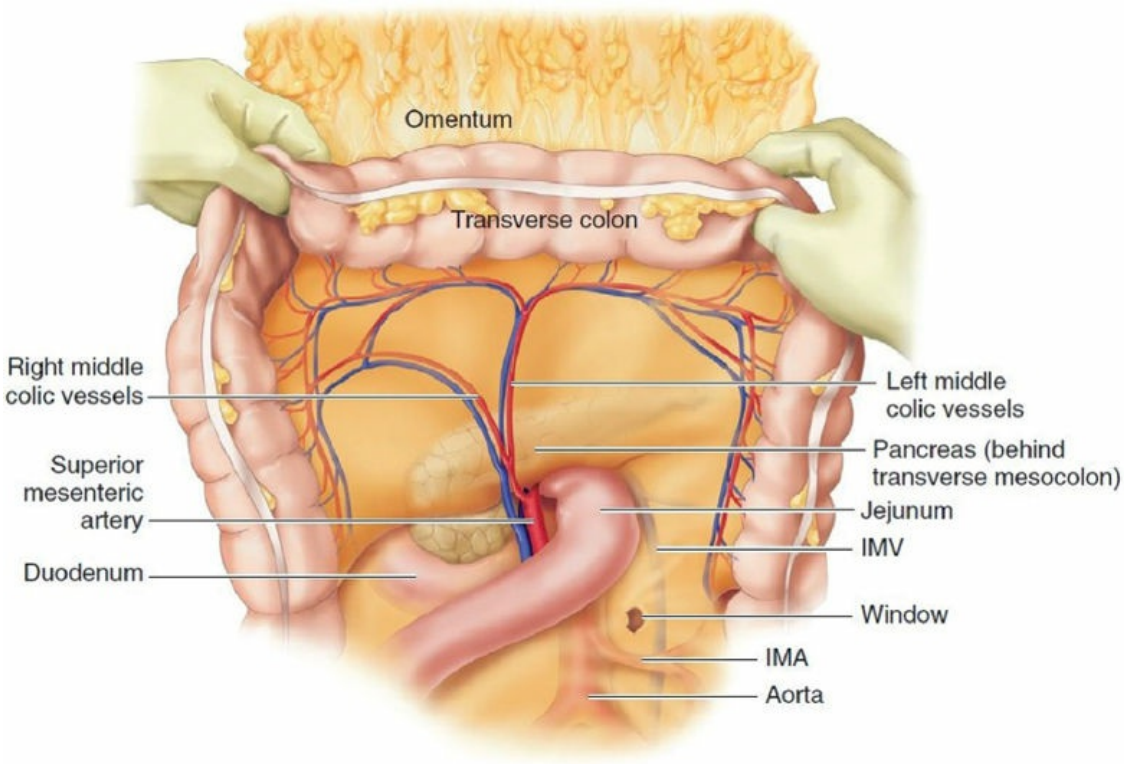

Figure 141.9. The blood supply of the transverse colon. (This figure was published in Hunt SR. Extended left colectomy with right colon-to-colon anastomosis (Chapter 4). In: Fleshman J, ed. *Atlas of Surgical Techniques for the Colon, Rectum, and Anus.* New York: Elsevier; 2013. Copyright Elsevier.)

LYMPHOID DRAINAGE AND INNERVATION OF THE COLON

Lymphoid drainage from the colon generally follows with the regional vascular supply. There are four levels of lymph nodes: epicolic (under the serosa of the wall of the intestine), paracolic (along the marginal artery), intermediate (along the large arteries), and principal (at the root of the superior and inferior mesenteric arteries). Most of the lymphatic drainage goes in this direction, but communications are found between groups of lymph nodes, especially at the level of the paracolic groups. In addition, there is some degree of dual drainage into the superior and inferior mesenteric lymph nodes, from the left third of the transverse colon and from the left colic flexure.

The techniques of total mesorectal and total mesocolic resection have highlighted the importance of performing complete mesenteric lymph node excision when performing surgery for colorectal cancer. The middle colic artery is relatively short, impeding the ability to achieve an adequate lymphadenectomy in cases of transverse colon cancer, leading to poorer outcomes with these types of lesions.

The innervation of the large intestine has both sympathetic and parasympathetic components, which generally follow the blood supply.

THE URETERS

Although the ureters are not part of the GI tract, their location and potential for injury during surgery make knowledge of their course of paramount importance when performing procedures involving the colon and rectum. The ureters begin at the renal pelvis, go downward, along the psoas muscle, under the gonadal vessels, over the junction of the common iliac vessels to external iliac vessels, and then descend into the pelvis (Fig. 141.10).

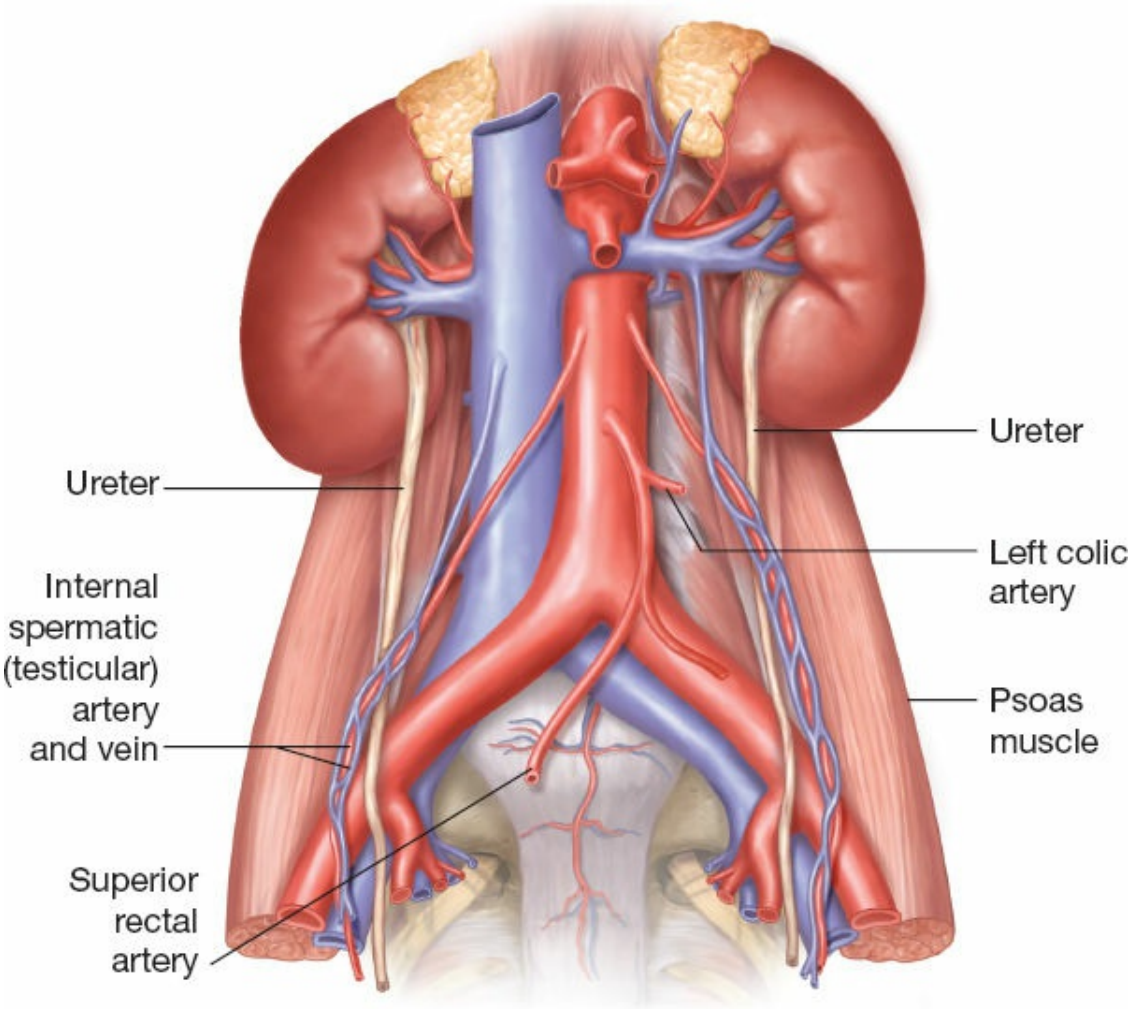

Figure 141.10. The abdominal course of the ureters. The branches of the SMA to the ascending colon that lie in front of the right ureter have been removed. If this were an illustration of a female, the ovarian vessels would be seen crossing the pelvic brim just below and lateral to the ureters. (With permission from Hollinshead WH. *Anatomy for Surgeons, volume 2. The Thorax, Abdomen and Pelvis*. 2nd ed. New York: Harper and Row; 1971.)

The abdominal course of the ureter is identical in men and women. The most consistent place to locate the ureter is where it crosses the iliac vessels. When compressed with forceps, one can see its distinctive peristalsis. On the right, it is slightly closer to the midline and tends to be adjacent to the posterior part of the ascending colon, stressing the importance of developing a dissection plane close to the colon during right colon mobilization.

On the left, the ureter travels close to the IMA, passing under it and then continuing under the attachment of the mesentery at the apex of the inverted “V” of the sigmoid mesocolon through the intersigmoid fossa

(Fig. 141.11).

The pelvic course of the ureter begins after it passes anterior to the internal iliac artery and its anterior division. It then travels along the pelvic sidewall following a medial direction at the base of the broad ligament in the female and over the uterine artery entering obliquely into the urinary bladder. In the male pelvis, the ureter travels medially, posterior to the ductus deferens and above the seminal vesicles before entering the urinary bladder. During or following inflammation, the ureter tends to be pulled medially toward the inflammation. The same is true in the presence of colorectal cancer. Inserting ureteral catheters can sometimes be helpful with ureteral localization in such situations.

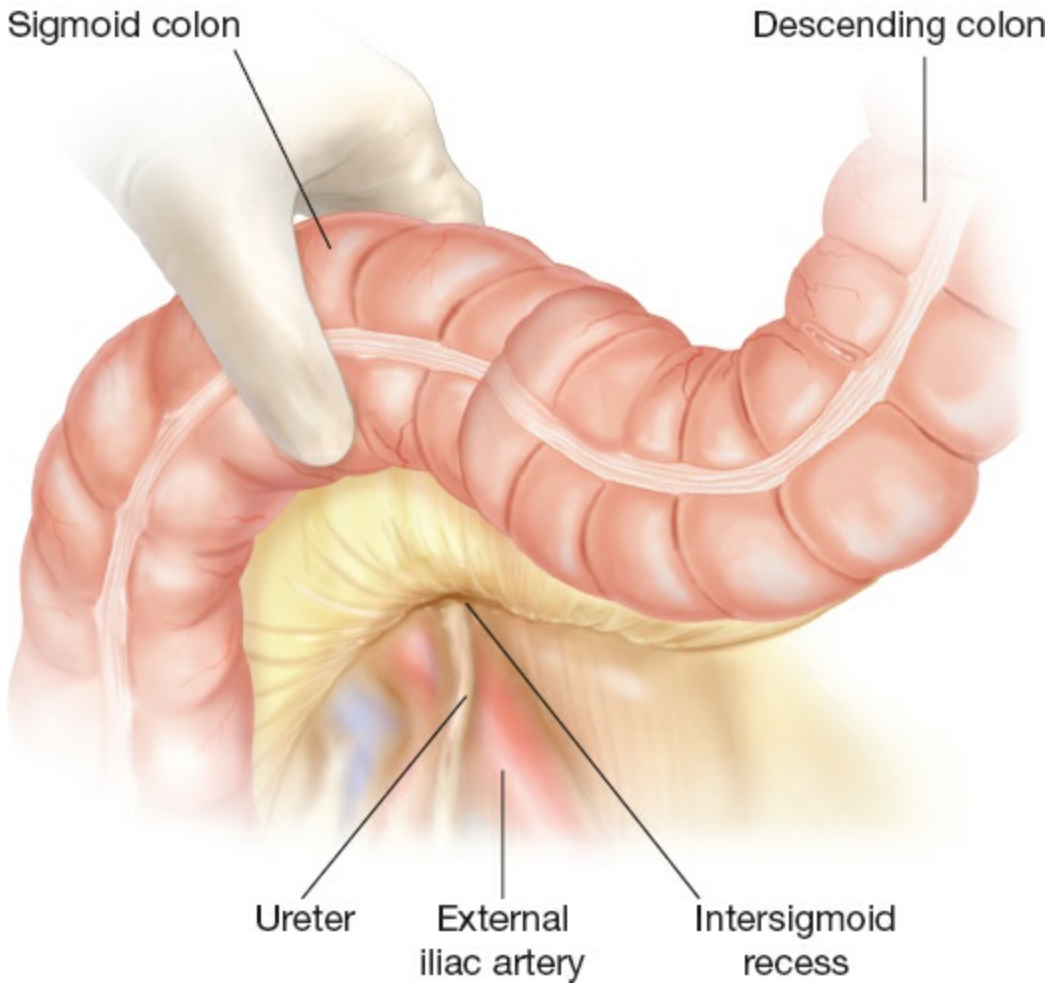

Figure 141.11. The intersigmoid recess, the sigmoid colon being retracted upward and to the right. (With permission from Hollinshead WH. *Anatomy for Surgeons, volume 2. The Thorax, Abdomen and Pelvis*. 2nd ed. New York: Harper and Row; 1971.)

OMENTUM

The greater omentum is largely viewed by surgeons as a protective structure, filling in cavities and helping control spread of infection. It has two parts—the superior gastrocolic ligament composed of two serous layers and the inferior apron-like part, draping over the anterior abdominal cavity, composed of four serous layers. It is usually filled with fat. Its size and volume are highly variable, although in most cases, this is correlated with body weight.

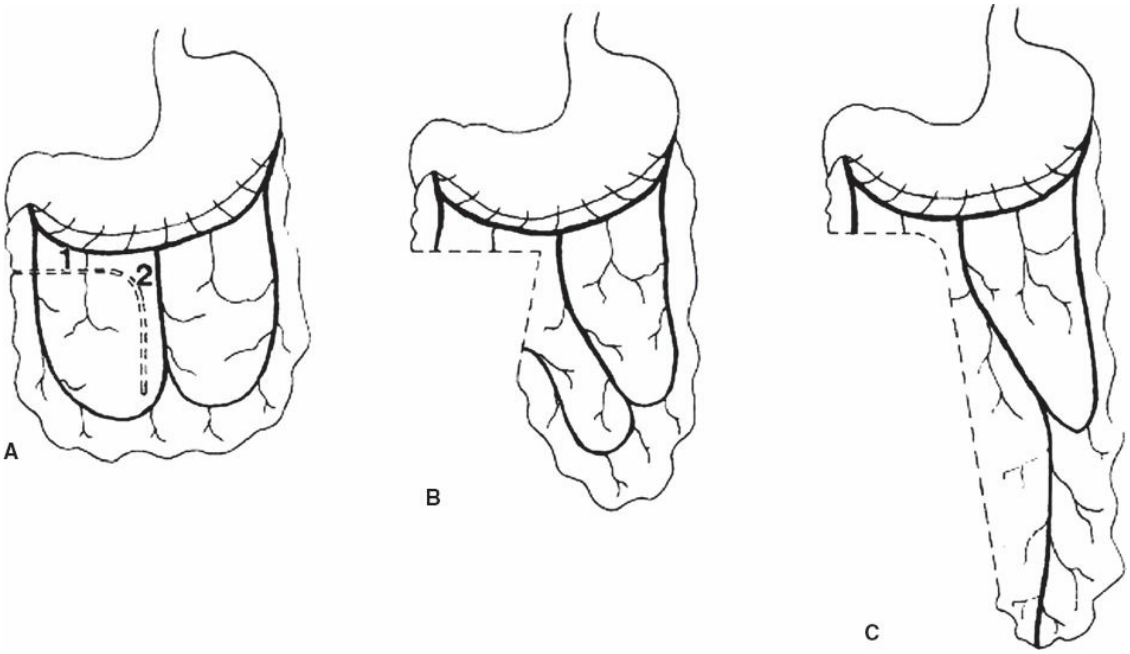

Figure 141.12. Incision and lengthening of the omentum. **A.** Line indicating the course of a transverse incision (1) from right to left below the gastroepiploic arch to the middle omental artery, (2) indicates an oblique, longitudinal continuation of the transverse incision toward the marginal erterial arcade. **B.** The omentum still cannot reach the pelvic floor after a transverse incision has been made as described in (1). **C.** Lengthening of the omental flap after making a tranverse oblique, longitudinal incision as described in (2). The omentum can now easily reach the pelvic floor. (With permission from Topor B, Acland RD, Kolodko V, et al. Omental transposition for low pelvic anastomoses. *Am J Surg* 2001;182:460–4.)

Upwards traction on the greater omentum and downward traction of the transverse colon will reveal an avascular plane adjacent to the colon. This plane is useful when separating these two structures and can be most easily identified close to the midline. On both right and left sides of the omentum, the attachment is more difficult to separate from the transverse

mesocolon.

The greater omental blood supply originates from the left and right gastroepiploic vessels that can be found within the gastrocolic ligament adjacent to the greater curvature of the stomach. They give rise to the left, right, and occasionally middle omental arteries. These arteries traverse in the posterior part of the greater omentum and create arterial arcades between them (Fig. 141.12). When considering an omental transposition, for example, in order to create an omental pedicle that reaches the pelvis, it is possible to ligate and detach one side, achieving extra omental length while the blood supply is adequately maintained by the distal arcade from the other side.

RECTUM

The rectum extends from the rectosigmoid junction to the anus (Fig. 141.13). The distal border being defined by anatomists as the pectinate (dentate) line based on the mucosal surface or defined by surgeons, as the level of the levator ani (about 2 cm above the dentate line). Structurally, the rectum lacks distinct taeniae coli, epiploic appendices, and sacculations (haustra of the colon). The rectum has three lateral curves—the upper to the right, the middle to the left, and the lower to the right—and expands inferiorly into the rectal vault before becoming the anal canal.

For surgeons, the rectum is also divided into thirds, with a total length of around 15 to 20 cm, based largely upon its peritoneal relationships. The superior third is covered by peritoneum anteriorly and laterally, defined as being 10 to 15 cm above the dentate line. The middle part is covered by peritoneum only anteriorly and extends from 5 to 10 cm above the dentate line, while the lower third of the rectum is totally extraperitoneal, extending from 1 to 5 cm above the dentate line. The rectovesicular (males) or rectouterine (females) pouch formed by the peritoneum between the rectum and anterior structures is clinically important as a common location of fluid and pus accumulation, being the lowest dependent part of the peritoneal cavity (Fig. 141.14). This typically is found at the lower part of the middle third of the rectum, except in patients with rectal prolapse, in which it can extend much further distally. The relationship of the rectum to the peritoneal cavity is especially important in cases of colorectal, coloanal, or ileal pouch anal anastomoses, where extraperitoneal anastomoses are more prone to be associated with pelvic fluid collections, since there is no peritoneum with its absorptive capabilities in this area.

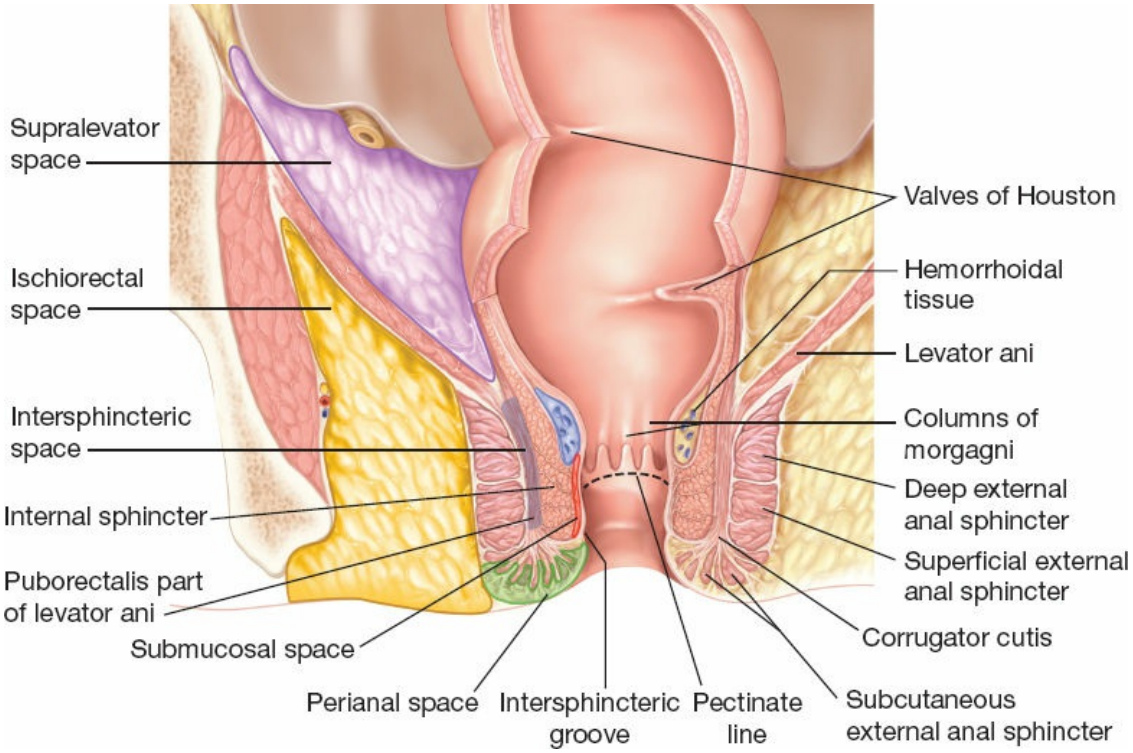

Figure 141.13. The rectum and anus in coronal section.

Anatomic structures adjacent to the rectum are clinically important with respect to direct extension of tumors and/or fistulas. Anteriorly and extraperitoneally in males, the rectum is adjacent to the prostate, seminal vesicles, vas deferens, ureters, and urinary bladder. In women extraperitoneally, the rectum is adjacent to the posterior vaginal wall and uterine cervix, and intraperitoneally to the upper part of the posterior vaginal wall, uterus, tubes, and ovaries. The small bowel and colon fill the intraperitoneal pelvis in both genders. Posteriorly, the rectum is adjacent to the sacrum, sacral vessels, and sacral nerve roots.

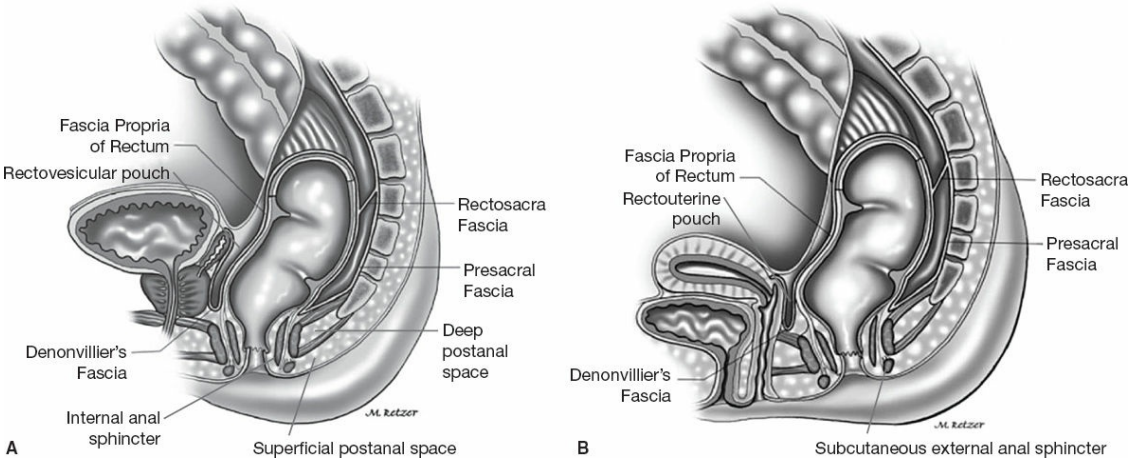

Figure 141.14. Fascial relationships of the rectum: (**A**) male, (**B**)

female. The intersigmoid recess, the sigmoid colon being retracted upward and to the right. (With permission from Jorge JMN, Habr-Gama A. Anatomy and embryology of the colon, rectum, and anus. In: Beck DE, Wexner SD, Hull TL, et al., eds. *The ASCRS Manual of Colon and Rectal Surgery*. 2nd ed. New York: Springer; 2014.)

The mesorectum is the visceral mesentery of the rectum. It is unlike the colonic mesentery in that it does not form a "true" mesentery covered on both sides with peritoneum. Surgically, knowledge of mesorectal planes is very important, as dissection along its border results in a relatively bloodless dissection plane, with reliable excision of the relevant lymphatic tissue and preservation conservation of urinary and sexual function. The mesorectum is relatively thick posteriorly, thinner along the sides, and very thin anteriorly (Fig. 141.15).

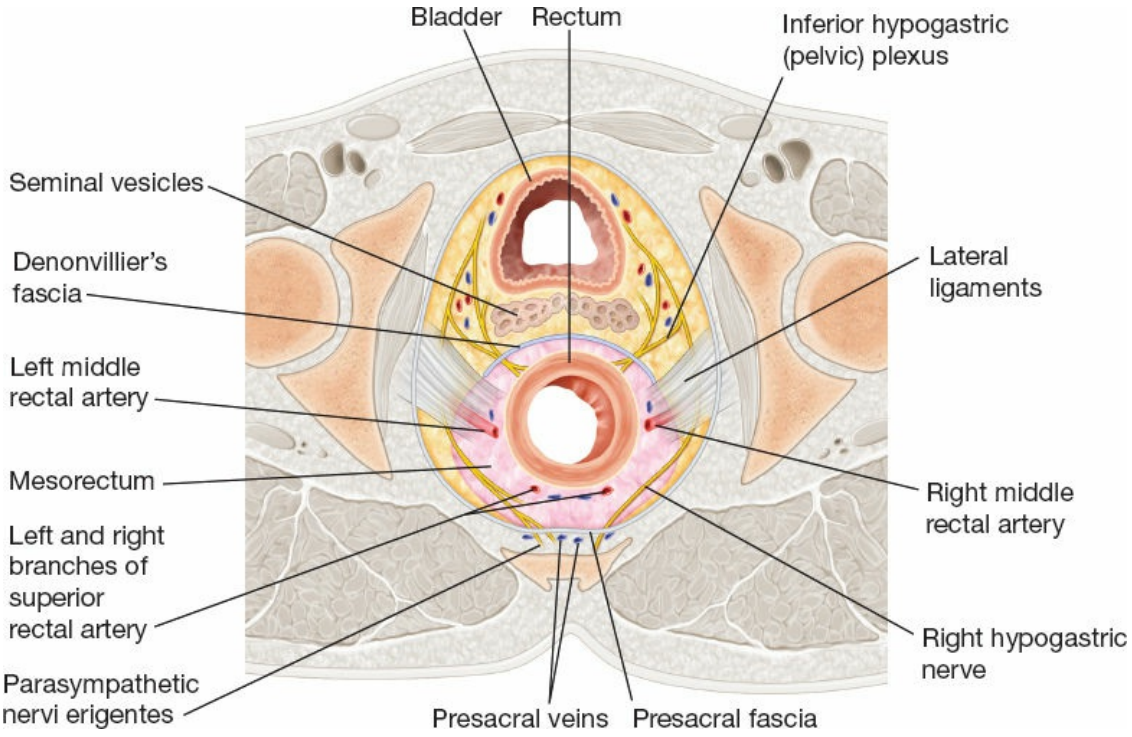

Figure 141.15. Cross-section of mesorectum and surrounding structures.

A good understanding of the extraperitoneal fascial relationships of the rectum is critical in achieving the correct plane of dissection when performing a total mesorectal excision (TME). The rectum itself is covered by the thin visceral fascia propria of the rectum. Anterior to the rectum, a bilaminar extension of the inferior peritoneal reflexion extends to the

perineal body. This fascial layer (Denonvillier fascia) separates the rectum from the previously mentioned anterior structures and is included as the anterior border of the TME. Laterally, the rectum is connected to the pelvic sidewall by the “lateral stalks” or ligaments, which are fibrous condensations of the pelvic fascia, shaped like a triangle with the base on the pelvic sidewall and the apex joining the rectum. These are located low down in the pelvis at the level of the prostate or mid-vagina and can only be appreciated once posterior and anterior mobilization has been performed. When cutting through these structures, it is important to remember that in about a quarter of the cases, a branch of the middle rectal artery traverses them and may cause bleeding. Posteriorly, the mesorectum is limited by the presacral fascia, covering the anterior sacrum and coccyx. The presacral veins, a series of veins on the presacral periosteum, drain into the sacral foramina. Dissection deep to the presacral fascia can cause dramatic, and sometimes life-threatening, bleeding from the underlying presacral venous plexus. Such bleeding can be challenging to control, as the torn vessels tend to retract into the sacral foramina. The rectosacral fascia (Waldeyer fascia) connects the presacral fascia around the level of S4 to the posterior–inferior rectum. It is typically divided close to the presacral fascia during a TME procedure (Fig. 141.14).

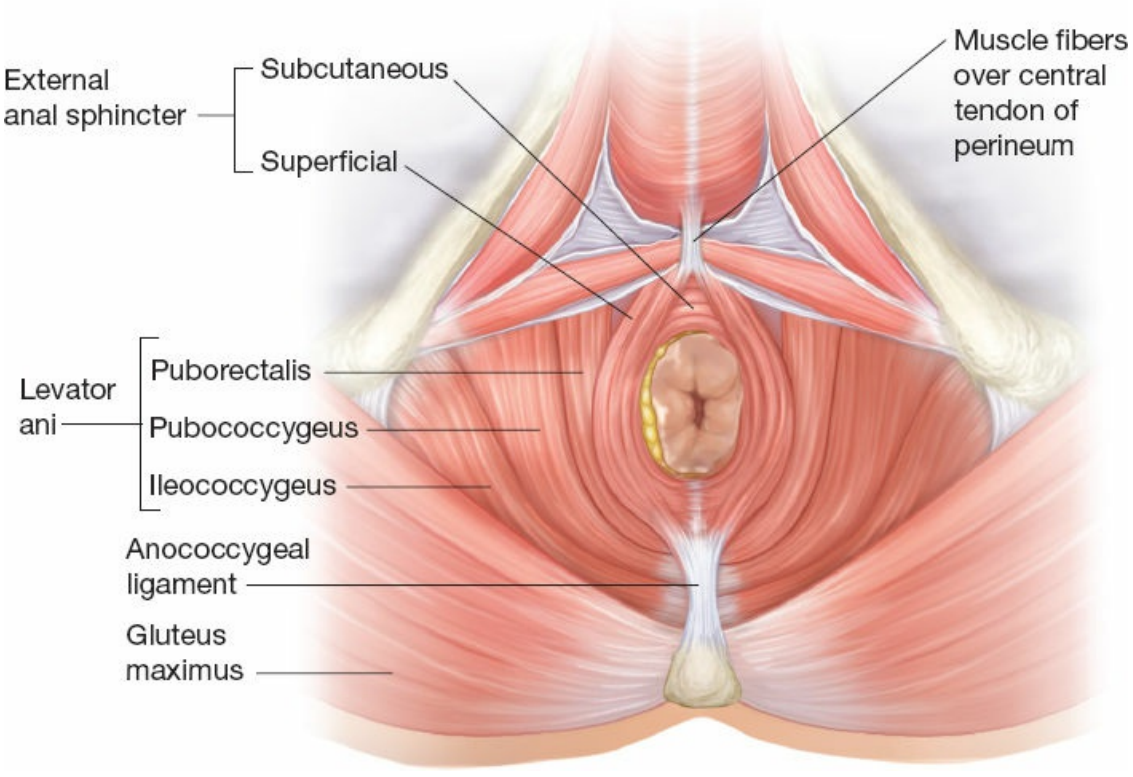

Figure 141.16. The pelvic musculature and innervation from

below. The deep external anal sphincter muscles are hidden under the superficial part.

ANUS

The last portion of the GI tract is the anus (Fig. 141.13). From a surgical standpoint, its length is approximately 4 cm, beginning at the level of the anorectal ring (the levator ani) and ending at the anal verge, where the epithelium acquires skin characteristics (hair, etc.). The dentate line marks the transition from enteric columnar to stratified squamous epithelium.

The internal anal sphincter (IAS), a thickened continuation of the rectal circular muscle, is composed of smooth muscle and is in a state of continuous contraction. By placing the anus under tension with a retractor, one can easily see the groove between the internal and external anal sphincters. This intersphincteric groove is the plane used for left internal sphincterotomy in cases of anal fissure and for intersphincteric or endoanal proctectomy in inflammatory bowel disease or other benign pathology.

The external anal sphincter (EAS), composed of skeletal muscle encircling the anus, has three main divisions: the subcutaneous part, found distally and laterally to the IAS; the superficial portion, which slings around the anus and connects to the coccyx posteriorly, and to the perineal body anteriorly (Fig. 141.16); and the deep part, which is connected anteriorly and contiguously to the puborectalis muscle. The conjoined longitudinal muscle, composed of fibers from the longitudinal muscle of the rectum and fibers from the levator ani, descends between the internal and external anal sphincters and inserts into perianal skin through the subcutaneous EAS as the corrugator cutis.

The levator ani is composed of three parts: the puborectalis, the pubococcygeus, and the iliococcygeus. The maintenance of continence is performed through lateral and circumferential compression by the pubococcygeus and anal sphincters and maintenance of angulation by the puborectalis.

There are a number of anorectal spaces of clinical significance (Fig. 141.13). The submucosal space lies between the anal mucosa and the IAS; it is continuous with the submucosal space of the rectum. The internal hemorrhoidal plexus is found in this space.

The intersphincteric space lies between the EAS and the IAS. The anal glands are found in this space and empty into the anal crypts at the level of the dentate line. Most cryptoglandular infections begin in this space and

spread to other spaces.

The perianal space is at the lowest part of the anal canal, including the subcutaneous EAS, the lower part of the IAS, and the external hemorrhoidal plexus. This space communicates with the intersphincteric space and ischiorectal space and is the most common location for abscesses and hematomas.

The ischiorectal (ischioanal) space is lateral to the EAS, inferior to the levator ani, and medial to the ischial tuberosity and obturator fascia. The pudendal and inferior rectal vessels and nerves traverse this space (see below). The two ischiorectal spaces communicate posteriorly through the deep postanal space (Fig. 141.14) between the levators and the anococcygeal ligament, and between the anococcygeal ligament and the skin through the superficial postanal space. Both postanal spaces are the connection through which horseshoe abscesses commonly form.

The supralevator space is lateral to the rectum, above the levator ani, and is located infraperitonealy. Infections can spread to this space upward through the intersphincteric space or can spread downward to this space from a pelvic source. Haphazard crossing of the levator ani during drainage of an ischiorectal abscess can iatrogenically infect this space.

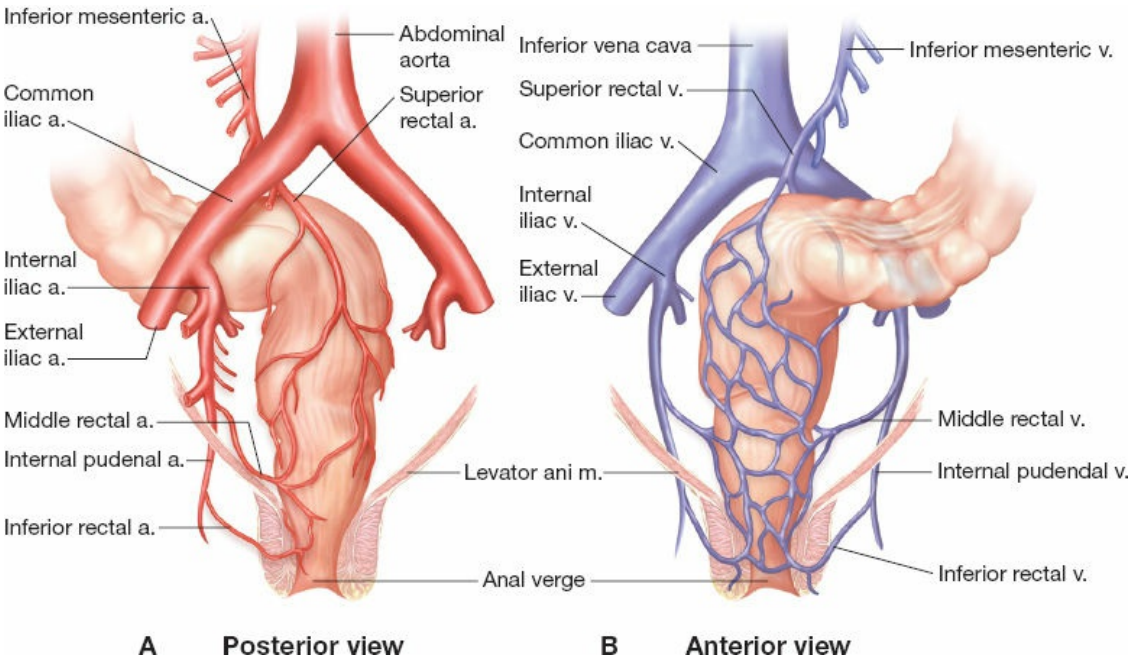

Figure 141.17. The vascular supply to the rectum. **A.** Arteries. **B.** Venous drainage.

ANORECTAL BLOOD SUPPLY

The vascular supply includes the superior rectal artery from the IMA; the middle rectal artery from the internal iliac artery; and the inferior rectal artery from the internal pudendal artery, a branch of the internal iliac artery (Fig. 141.17). The rectum has an intense anastomotic network within its wall connecting these three arteries. This accounts for the fact that the rectum remains viable after dividing the superior rectal artery during sigmoid and anterior rectal resections.

The superior rectal (hemorrhoidal) artery is the main blood supply of the rectum. It is the end branch of the IMA after it gives out the sigmoid branches. The artery descends to the posterior upper wall of the rectum, dividing there into right and left branches, running within the rectal wall down to the dentate line.

The middle rectal (hemorrhoidal) arteries are paired vessels running from the internal iliac vessels to the lower rectum around the level of the levator ani or slightly higher. They are not considered to be a major blood supply to the anorectum and some consider them inconstant. The middle rectal arteries can be injured when dissecting the low anterolateral region close to the levator ani.

The paired inferior rectal (hemorrhoidal) arteries are branches of the internal pudendal arteries and generally supply the anus distal to the pectinate line.

The superior rectal vein generally drains the superior two thirds of the rectum, draining into the IMV and portal system. The paired middle and inferior rectal veins drain the lower rectum and anus and collect into the internal iliac and systemic circulation, accounting for the higher incidence of pulmonary metastases with low rectal cancers, as compared to the hepatic metastases seen with advanced mid and upper rectal cancers. The rich anastomotic connection between the superior rectal venous drainage and systemic circulation classically becomes apparent in cases of portal hypertension causing engorged hemorrhoids and impressive rectal varices.

LYMPHATIC DRAINAGE OF THE ANORECTUM

The lymph from the rectum primarily moves in an upward direction in association with the superior rectal artery, reaching the inferior mesenteric lymph nodes. This is practically the only direction of drainage for the upper two thirds of the rectum. The lower part of the rectum drains in two directions, cephalad toward the inferior mesenteric nodes and laterally and inferiorly toward the internal iliac nodes. Below the dentate line, the

lymph drains toward the inguinal lymph nodes. The latter accounts for the occasional observation of extensive inguinal metastases in patients with aggressive recurrent rectal cancers affecting the distal rectum.

INNERVATION OF THE ANORECTUM

The rectum receives sympathetic innervation from the superior hypogastric plexus forming from branches of L1 to L3, anterior and inferior to the aortic bifurcation, dividing around the sacral promontory to left and right hypogastric nerves, traveling on both sides of the pelvis. Here, they are joined by parasympathetic fibers (nervi erigentes), originating from the S2 to S4 foramina, and form the inferior hypogastric (pelvic) plexus on both anterolateral sides of the rectum (Fig. 141.18). In addition to supplying the rectum, these nerves send branches to the genitourinary system anteriorly.

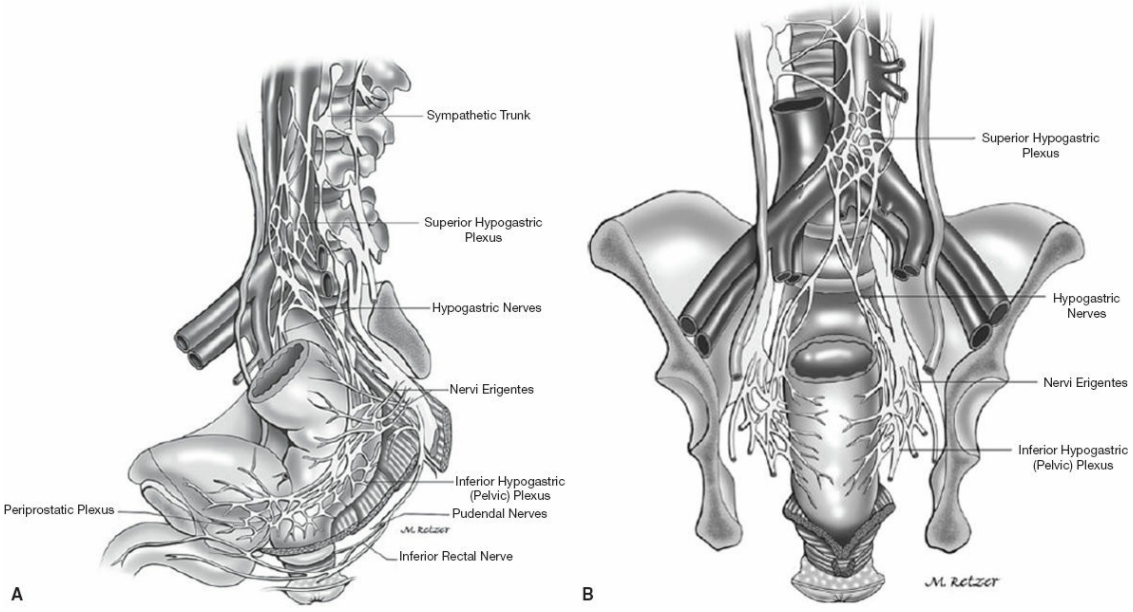

Figure 141.18. Innervation of the colon and anus. **A.** Coronal view. **B.** Sagittal view. (With permission from Jorge JMN, Habr-Gama A. Anatomy and embryology of the colon, rectum, and anus. In: Beck DE, Wexner SD, Hull TL, et al., eds. *The ASCRS Manual of Colon and Rectal Surgery*. 2nd ed. New York: Springer; 2014.)

The autonomic nerves to the pelvis are at risk of injury when performing pelvic operations, highlighting the need to be aware of their location and avoid them, if possible. When ligating the IMA, it is critical to dissect close the underside of the artery so as to avoid injury to the superior hypogastric plexus, which can cause retrograde ejaculation. When

dissecting anterior to the promontory and sacrum, it is important to stay anterior to the presacral fascia and to identify the hypogastric nerves on both sides of the pelvis. The nervi erigentes and pelvic plexus can be injured if the lateral stalks of the rectum are divided too close to the lateral pelvic sidewall and cause disturbances in erectile function. The periprostatic plexus can be injured when dissecting anteriorly to Denonvillier fascia near the prostate and seminal vesicles, which can also cause sexual and bladder dysfunction. In general, when performing a rectal resection for benign disease, one should remain close to the rectal wall to reduce the risk of injuring these plexuses affecting bladder and sexual function.

The pudendal nerve branches off the sacral plexus S2 to S4 and exits the pelvis posterior-laterally between the piriformis and ischiococcygeus muscles. In cases of incontinence, these ventral sacral nerve roots can be directly stimulated (usually S3, but in some cases S2, S4) through the dorsal sacral foramina, stimulating the levator and EAS, promoting continence. This nerve is accompanied by the internal pudendal vessels as it travels through the pudendal (Alcock's) canal on the lateral wall of the ischioanal fossa. It gives out the inferior rectal nerve that travels anteromedially, crossing the ischioanal fossa to supply the EAS as well as sensation to the lower part of the anal canal and the circumanal skin (Fig. 141.16). The pudendal nerve also gives out the larger perineal nerve, which runs forward to the external genitalia, but also innervates the anterior part of the EAS and levator ani and participates in skin innervation of the perineal area.

The pudendal nerve can be found reliably over the ischial spine and can be blocked by infiltration with a local anesthetic. Deep incisions in this region and anteromedially to it for abscess drainage and blunt dissection can injure the pudendal nerve and its inferior rectal branches.

Knowledge of anatomy reduces the incidence of complications; increases surgeon confidence; and provides for smooth, uneventful surgery that is both a joy to learn and teach.

EDITOR'S COMMENT

Dr. Netz and I have endeavored to make this chapter a "*non-traditional*" anatomy chapter. There are many anatomy books that are available to the surgeon to serve as anatomy references, some of which are listed in the Suggested Readings at the end of the chapter. What we wished to do herein is to describe anatomy that is particularly relevant for the surgeon, and to inform the surgeon why the particular anatomy is relevant. There has been a virtual explosion in "anatomy-based" surgery over the last 20 years, where knowledge of anatomy has helped surgeons (1) restore lost organ function, (2) avoid tension on small bowel or colon anastomoses, and (3) provided improved healing by buttressing anastomoses with either omentum, muscle, or other types of pedicled flaps.

Replacement of Organ Function

The ileocecal valve is perhaps the most valuable structural component of the abdomen with respect to replacing organ function. This segment of bowel has been "borrowed" by surgeons to be used in a variety of ways for different continence procedures, utilizing its ingenious valve mechanism for continent urinary diversions (Myers JB, Lenherr SM. Perioperative and long-term surgical complications for the Indiana pouch and similar continent catheterizable urinary diversions. *Curr Opin Urol* 2016;26(4):376–82), as well as it and the appendix for continent catherizable stomas for antegrade continence enema procedures in both children and adults (Chan DS, Delicata RJ. Meta-analysis of antegrade continence enema in adults with faecal incontinence and constipation. *Br J Surg* 2016;103(4):322–7). In addition, with proper knowledge of vascular anatomy, segments of the transverse colon can be utilized to replace the bladder in patients who have received extensive pelvic radiation (Leissner J, Fisch M, Hohenfellner R. Colonic pouch [Mainz-pouch III] for continent urinary diversion. *BJU Int* 2006;97:417–30).

Obtaining Extra Bowel Length

Knowledge of vascular supply can be used to gain bowel length to obtain a tension-free anastomosis. This includes a variety of maneuvers ranging from utilizing the avascular space adjacent to the ileocolic artery to perform a retro-ileal colorectal anastomosis, in cases where the left colon is absent, to division of either the ileocolic or superior mesenteric artery branches, in order to obtain extra mesenteric length so that an ileal pouch can be brought down to the low pelvis with less tension, in cases of ileal-pouch anal anastomosis. In extreme cases, knowledge of vascular anatomy has permitted an ileal pouch to be constructed with ligation of the distal superior mesenteric and ileocolic arteries, but with preservation of the right middle colic and right marginal colon arteries (Chu DI, Tognelli J, Kartheuser AH, et al. Strategy for the difficult-to-reach ileal pouch-anal anastomosis: technical steps of an in vivo application of a mesenteric-lengthening technique. *Tech Coloproctol* 2015;19(11):705–9).

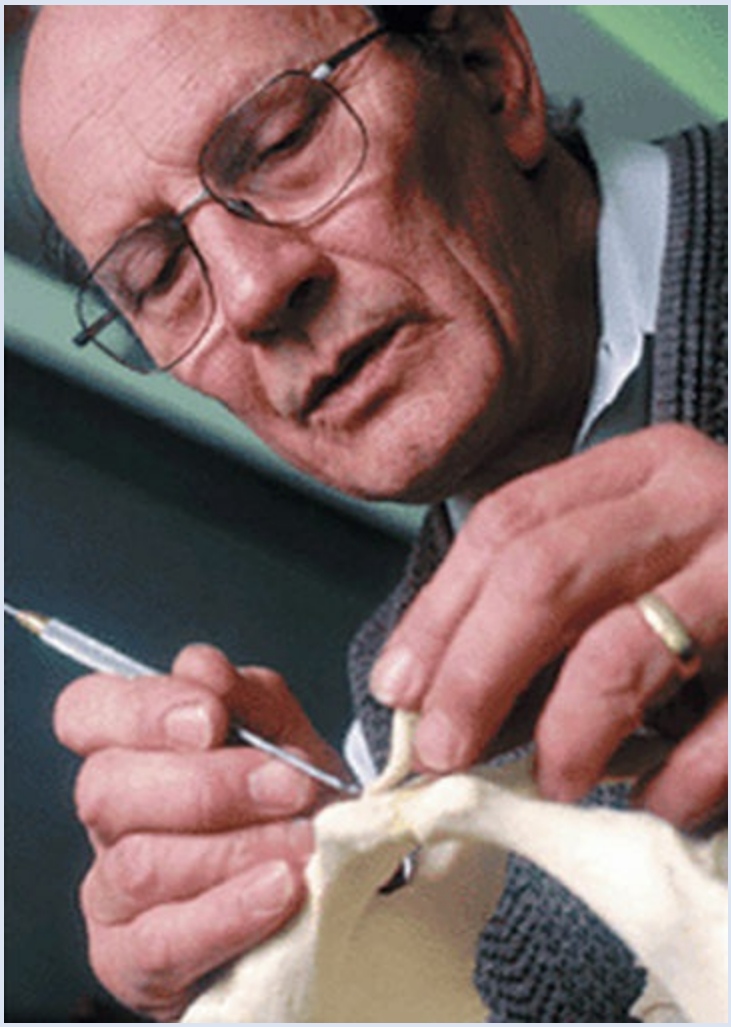
Buttressing Anastomoses/Repairs

With respect to anastomotic healing, knowledge of vascular supply is also important in order to permit surgeons to create omental pedicles. These can be utilized to aid healing following multiple different types of procedures, as well as for creation of vascular pedicled seromuscular flaps from segments of out-of-circuit small bowel (Aho J, Winocour S, Hammoudeh ZS, et al. Seromuscular colonic flap for intrapelvic soft-tissue coverage: a reconstructive option for plastic surgeons when traditionally used flaps are not available. *Case Rep Surg* 2015;2015:563641).

Importance of Anatomical Knowledge in Avoiding Organ Injury

Knowledge of anatomy allows a surgeon to be safe, confident in pursuing surgery knowing where adjacent structures are, and what can be injured at the time of surgery. As a recent study using the National Inpatient Sample (NIS) database has shown, this is still something that is frequently done (Al-Qurayshi Z, Srivastav S, Slakey DP, et al. Risk of intraoperative injury of nearby structures: national trend, distribution, and burden. *J Am Coll Surg* 2016;222(4):624–31). In this study of nearly 64 million inpatient records, 61,667 cases of intraoperative injury were identified, with procedures involving the digestive tract accounting for the largest group (38%). Such injuries were more common in patients over the age of 60 years (odd ratio [OR] 4.00, 95% confidence interval [CI] 3.76 to 4.26, $p < 0.001$). In addition intraoperative injuries were associated with a higher risk of complications (OR 2.44, 95% CI 2.36 to 2.54, $p < 0.001$) as well as a higher mortality (OR 2.33, 95% CI 2.15 to 2.51, $p < 0.001$). Knowledge of anatomy can also predict sites of cancer recurrence and provide for more economical targeted cancer follow-up. For example, cancers of the lower rectum due to their venous drainage through the internal iliac system are more likely to metastasize to the lungs, in contrast to cancers of the upper rectum, draining through the portal system to the liver.

My original intention was to have Robert Acland, author of the well-known *Acland's Video Atlas of Human Anatomy* (Acland's Video Atlas of Human Anatomy. Wolters Kluwer. aclandanatomy.com/) be a coauthor on this chapter. Unfortunately, he was diagnosed with a serious illness and passed away early in 2016 (www.legacy.com/obituaries/louisville/obituary.aspx?pid accessed January 20, 2016). Dr. Acland was a true master of anatomy, a consummate surgeon, and a true artist. His statement "an anatomical structure has no moral obligation to be where you think it should be" was well-known by his many students and residents over the years. His pioneering video-anatomy atlas was created using the most mundane of materials: a rotating plywood disk covered by black velvet. With this, he was able to "choreograph" the most visually stunning, creative video anatomy atlas one could imagine—this truly made anatomy come to life. His attention to detail and joy at dissecting were amazing to watch.



Robert D. Acland, MD

Robert D. Acland graduated from London Hospital Medical College in 1964 with a Bachelor in Medicine (MB), receiving his MBBS from London

University in 1969. He completed internships in the United Kingdom and Tanzania, and residencies in plastic surgery in Glasgow (FRCS in 1969) and London (FRCS in 1970). He first came to Louisville in 1976 at the invitation of Dr. Joseph Kutz of the Kleinert and Kutz Hand Care Center to run their microsurgery laboratory within the Price Institute of Surgical Research at the University of Louisville Department of Surgery and also received a teaching appointment in the department. During this time, he developed some of the first microsurgical instruments and 10-0 sutures and needles that are still in use. He became Professor of Plastic and Reconstructive Surgery in 1986 and held Associate appointments in the Departments of Physiology and Biophysics, and of Anatomical Sciences and Neurobiology. Upon his retirement from teaching microsurgery, he began a second career as a clinical anatomist and became a pioneer in the field of fresh tissue dissection. Dr. Acland established the Fresh Tissue Anatomy Dissection Laboratory for surgeons and students at the University of Louisville, which was the first of its kind in the United States, using a technique of “light embalming” that gave tissues a near-life-like touch and feel. His Video Atlas of Human Anatomy began in 1993 and took 9 years to create. The atlas depicts moving structures—muscles, tendons, and joints—making the same movements that they make in life. While working on his atlas, Dr. Acland developed new effective techniques of anatomical videography using innovative camera rotation techniques to achieve a unique 3-D perspective that gives the viewer a clear three-dimensional understanding of spatial relationships of anatomical structures. Dr. Acland will be greatly missed by all of his friends and colleagues and lovers of anatomy.

Susan Galandiuk

142 The Appendix

Vic Velanovich

INTRODUCTION

Appendectomy remains one of the most commonly performed operations worldwide. Up to 8% of the United States population will have an appendectomy in their lifetime. Although acute appendicitis is the most common indication for appendectomy, the appendix may also harbor tumors with a spectrum of malignant potentials. Options for the management of inflammatory and neoplastic appendiceal diseases have evolved, and a thorough understanding of these options is essential for the practicing general surgeon.

ANATOMY

The appendix is located at the base of the cecum where the teniae coli coalesce. Although this location is constant, the position of the appendix is variable. The appendix is located about 2.5 cm inferior to the ileocecal valve and is attached to the terminal ileum by the ligament of Treves, which the mesoappendix extending from the mesentery contains its vascular supply. The appendix is usually about 6 to 12 cm long, but may reach over 16 cm in length, with a diameter of about 0.8 cm, with a range between 0.3 and 1 cm. The appendiceal position is variable (Fig. 142.1), with the most common being intraperitoneal extending toward the pelvic brim and iliac fossa. However, there are many other appendiceal positions including intraperitoneal retrocecal, extraperitoneal retrocecal (i.e., posterior to the cecum but in the retroperitoneal space), toward the sacral promontory, and anterior or posterior to the ileum. To further complicate matters, malrotation and nonrotation of the intestine can place the appendix in the mid-abdomen or left upper quadrant. In addition, although rare (about 4 per 100,000 persons), appendiceal duplications do occur. These variable positions can lead to atypical presentations of appendiceal disease; and, hence the surgical dictum, “appendicitis should always be in the top three differential diagnoses of acute abdominal pain in any

location."

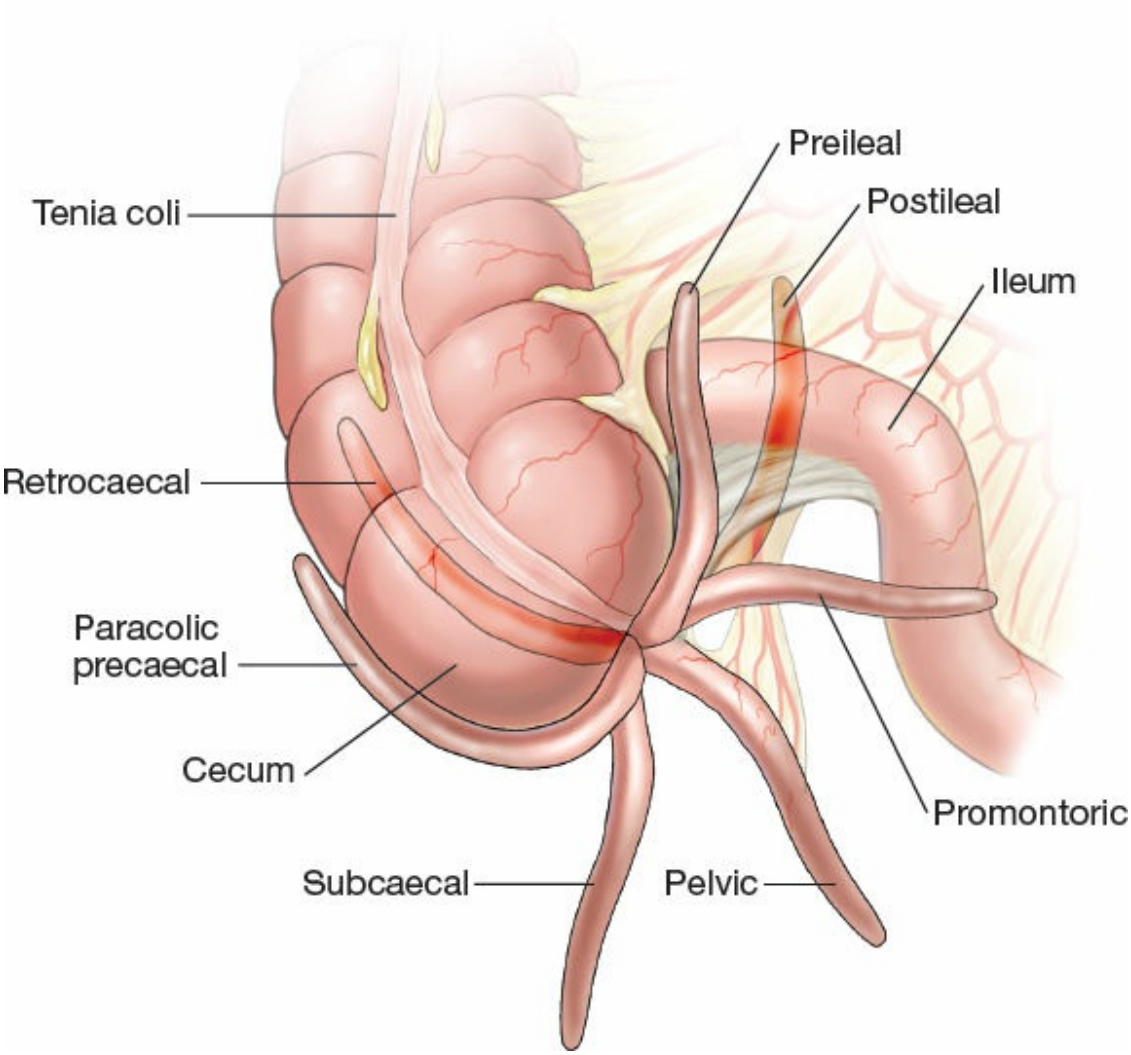


Figure 142.1. Variations in the position of the appendix in relation to the cecum, ileum, and peritoneum.

The blood supply to the appendix is from ileal branch of the ileocolic artery. The appendiceal blood is variable with usually a single appendicular artery, but two or more arteries possible. However, there is no overlap with the blood supply to the cecum.

The appendix can be considered a true diverticulum of the cecum, containing all three intestinal layers and a lumen. In addition, the appendix has a wealth of gut-associated lymphoid tissue which may be immunologically active (the appendix may not be a "vestigial" organ after all). The appendiceal lumen is in continuity with the cecal lumen, with the appendiceal orifice covered by the mucosal fold. Identification of the appendiceal orifice during colonoscopy signifies that the entire colon can

now be visualized and is considered a quality indicator. As humans age, the appendiceal lumen narrows and, eventually, completely obliterates, which is one of the reasons that the incidence of appendicitis decreases with age.

ACUTE APPENDICITIS

Etiology and Pathophysiology

Acute appendicitis is the most common of the appendiceal diseases. Its peak incidence occurs in the second and third decades of life, with a lower rate in children <4 years old and a progressively reducing incidence in adults over 30 years old. However, the risk of mortality occurs at the extremes of age.

Acute appendicitis occurs as a result of obstruction of the appendiceal lumen. In young patients who have an abundance of lymphoid tissue, lymphoid hyperplasia can be the cause of the obstruction. In older patients, fecaliths may be the cause. In either event, the obstruction of the appendiceal lumen leads to accumulation of mucus, which causes increased intraluminal pressure. This pressure leads to occlusion of blood and lymph vessels within the appendiceal wall causing necrosis. With the breakdown of the appendiceal mucosal barrier, colonic bacteria cause infection and further inflammation. This can result in a phlegmon or inflammatory mass. Eventually, there is full thickness necrosis of the appendix, with perforation and spillage of bacteria into the intraperitoneal space. This can result in an intraabdominal/pelvic abscess or generalized peritonitis with progressive sepsis.

Clinical Presentation

The presentation of appendicitis is protean. The “classic” presentation is vague periumbilical pain which over the course of a few hours localized to the right lower quadrant at McBurney point (one third the distance from the anterior superior iliac spine to the umbilicus). This mirrors the progression of midgut visceral pain due to distention of the appendix “hollow viscus” to somatic parietal pain as the peritoneum covering the appendix becomes inflamed. This is generally associated with anorexia; urge to defecate; occasional nausea, diarrhea, and fevers. However, because of the variable location of the appendix, other presentations are possible, such as right flank/back pain, suprapubic/pelvic pain, or

generalized abdominal pain.

Classically, physical examination demonstrated right lower quadrant pain with localizing signs of peritonitis. Other signs of peritonitis associated with appendicitis include Rovsing sign (right lower quadrant pain with palpation of the left lower quadrant), Dunphy sign (right lower quadrant pain with coughing), psoas sign (pain on extension of the right hip), and the obturator sign (pain with internal rotation of the right hip). Patients with appendices extending into the pelvis may also have right lower quadrant pain with a rectal and/or pelvic (in females) examinations.

Laboratory and Imaging Diagnosis

When history and physical examination suggest appendicitis, laboratory testing and imaging may help secure the diagnosis. Although leukocytosis is helpful, up to one third of patients may have a normal white blood cell count. A “left shift” with increased proportion of polymorphonuclear neutrophils and immature cells are typical, but, once again, not always present. C-reactive protein is generally elevated. However, none of these findings carries sufficient sensitivity and specificity to secure a diagnosis.

Although traditionally acute appendicitis was a clinical diagnosis, advances in imaging have improved diagnostic accuracy, leading to a lower rate of negative appendectomy without an increase in perforated appendicitis. Plain abdominal radiographs can be useful if a fecalith or some other intra-abdominal pathology is found (such as free air), but, in general, these films do not aid in diagnosis. Ultrasonography, in skilled hands, can identify an enlarged appendix in patients who present with equivocal findings or women where pelvic pathology may be a concern. However, the overall positive and negative predictive values are in the 80% to 100% range. Although ultrasonography is not as accurate as CT scanning, it may be the imaging test of choice in patients for whom limiting radiation exposure is desirable, such as pregnant women and children.

CT scanning has become the mainstay of imaging. This can be done with “reduced radiation” protocols. Typically, these scans use IV, p.o., and rectal contrast, although there is evidence that these agents may not be required. The signs of acute appendicitis included an enlarged appendix of >6 mm in diameter, thickened appendiceal wall of >2 mm (referred to as the “target” sign), periappendiceal inflammation (fat stranding), presence of a fecalith, and a thickened cecum funneling contrast to the appendix

("arrowhead" sign). With this, diagnosis accuracy can exceed 95% (Fig. 142.2).

Nonoperative Management of Acute Appendicitis

Traditionally, appendicitis has been a surgical disease. Over the last decade, there has been an increased interest in primary nonoperative antibiotic treatment of "uncomplicated" appendicitis. These studies have used a variety of means to diagnose appendicitis preoperatively, a variety of antibiotic regimens, and both open and laparoscopic approaches. This has led to several meta-analyses consolidating the data generated (Table 142.1). Because of the heterogeneity in treatment approaches, it is difficult to make definitive conclusions. However, what can be said is that appendectomy has a "cure" rate for appendicitis approaching 99%, with almost no recurrences of appendicitis, but a measurable surgical complication rate, mostly infectious in nature. Antibiotic therapy has a "cure" rate of 70% to 90%, but with a recurrent appendicitis rate 15% to 30%, yet a small number of serious adverse events. Certain findings, such as the presence of a fecalith increased the risk of recurrent appendicitis, and other factors, such as advanced age, increase the risk of the presence of unsuspected appendiceal neoplasia. Therefore, primary nonoperative antibiotic therapy may be appropriate in selected individuals with uncomplicated appendicitis, and these patients still require follow-up to assess for recurrence.

Figure 142.2. CT scan of acute appendicitis, coronal view. (Courtesy of John Feldman, MD. Tampa General Hospital.)

Nonoperative Management of Appendiceal Phlegmon and Periappendiceal Abscess

"Complicated" appendicitis includes those cases which have already progressed to gangrenous or perforated disease. These cases can have generalized peritonitis, localized phlegmon, or abscess. In those cases with generalized peritonitis, surgery to evaluate infected fluid and appendectomy for infectious source control to prevent further progression

of peritonitis is indicated. However, in patients with localized inflammatory/infectious processes, consensus on treatment is wanting.

TABLE 142.1 Studies Comparing Antibiotic Therapy Only to Appendectomy for Acute Appendicitis

Study	Sample Size	Antibiotic Regimen	Conclusion
Styrud et al., 2006	252	IV cefotaxime/tinidazole p.o. ofloxacin/tinidazole	Acute nonperforated appendicitis can be treated successfully with antibiotics
Farahnak et al., 2007	42	IV gentamicin/metronidazole p.o. amoxicillin/clavulanic acid	
Malik & Bari, 2009	80	IV ciprofloxacin/metronidazole	Antibiotics effective in the acute appendicitis
Hansson et al., 2009	369	IV cefotaxime/metronidazole p.o. ciprofloxacin/metronidazole	Antibiotic treatment safe first-line therapy for acute appendicitis
Vons et al., 2011	239	IV amoxicillin/clavulanic acid	Antibiotic therapy only not noninferior
Salminen et al., 2015	530	IV ertapenem p.o levofloxacin/metronidazole	Antibiotic treatment did not meet criteria for noninferiority
Cochrane Review. Wilms et al., 2001	5 RCTs 901 patients	Various	"Cure" defined as no major complications in 2 wks and no recurrences in 1 yr Antibiotics: 73.4% cured Appendectomy: 97.4% cured

Appendiceal phlegmons can be managed nonoperatively with antibiotic therapy, with or without "interval" appendectomy or by immediate appendectomy. A meta-analysis of nonoperative management reported an overall "failure rate" of antibiotics of about 7%. However, the risk of recurrent appendicitis has been reported to be 7% to 40%. In addition, neoplasia or "important" benign disease has been found in up to 7% of patients presenting with appendiceal inflammatory masses. On the other hand, immediate appendectomy is certainly very challenging in these patients. Surgical complications can occur in up to 20% of patients, with need for cecectomy or ileocolectomy in up to 30%. However, there are almost no recurrences of appendicitis with appendectomy. Therefore, an initially nonoperative approach, with subsequent interval appendectomy is certainly a reasonable strategy, although it cannot be definitively stated that interval appendectomy is mandatory.

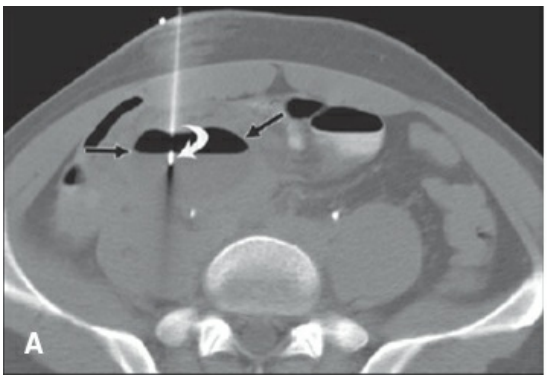

Figure 142.3. CT scan of percutaneous drainage of appendiceal abscess. **A.** Placement of needle into abscess cavity. **B.** Complete drainage of abscess with pigtail catheter left in abscess cavity. (From Marin D, Ho LM, Barnhart H, et al. Percutaneous abscess drainage in patients with perforated acute appendicitis: Effectiveness, safety and prediction of outcome. *AJR* 2010;194:422–9.)

The approach to appendiceal abscess has similar controversy. Approximately 7% of adults with acute appendicitis will present with an abscess. These are generally diagnosed preoperatively because imaging is now a routine part of the diagnostic process. There are three general approaches management: percutaneous drainage with appendectomy, percutaneous drainage without appendectomy, and immediate operative drainage and appendectomy. These approaches have been subject to randomized trials and meta-analyses; yet, a definitive answer remains elusive. Percutaneous drainage is technically "successful" (i.e., the catheter is placed within abscess and pus drained) in about 90% of cases (Fig. 142.3). Ill-defined abscess and extraluminal appendicoliths are predictors of clinical failure. Compared to immediate appendectomy, nonoperative management has overall fewer complications, especially wound infections, ileus, and bowel obstruction. On the other hand, nonoperative management requires more frequent interventions, including additional invasive procedures, such as multiple percutaneous catheters and interval appendectomy. Some of the issues with respect to immediate appendectomy in patients with appendiceal abscess are mitigated by a laparoscopic approach, although still 10% required bowel resection, 13% underwent an "incomplete" appendectomy, and 7% required additional percutaneous drainage. Long term, in patients undergoing nonoperative management, recurrent inflammation and/or abscesses requiring surgery occur in about 20% of cases and a few, but not insignificant number, will have missed neoplasms or other significant benign disease. Depending on specific clinical circumstances, each approach may be appropriate.

Operative Approaches to Acute Appendicitis

Preoperative Preparation

Preoperative preparation of the patient with acute appendicitis is the same as with any patient with an acute abdomen, namely, intravenous access, fluid resuscitation with crystalloids, broad-spectrum antibiotics with

coverage for enteric organism, and general anesthesia with vomiting/aspiration precautions. Of course, special consideration based on the needs of specific patients, such as cardiac or pulmonary medications, must be addressed.

Open Appendectomy

The patient is positioned in the supine position. If the patient has recently voided, a urinary catheter may not be necessary; however, if a long operation is anticipated, a urinary catheter should be placed. A nasogastric tube may also not be necessary if the patient has had nothing per os for an adequate length of time; but, nasogastric or orogastric decompression may be useful if the patient has recently eaten. If the appendix is located in the right lower quadrant, the surgeon has the following choices for the incision: McBurney, modified McBurney, Rockey–Davis (with extensions) (Fig. 142.4), or low midline. In general, the Rockey–Davis incision is the preferred and most commonly used incision because of ease of extending the incision medially (Fowler–Weir extension) or laterally (Rutherford Morison extension) and generally good cosmetic result. A low midline incision can be used if preoperatively there is some uncertainty as to the diagnosis or if it appears to be a very complicated disease and the need for operative flexibility is apparent. The incision is taken to the external oblique aponeurosis, which is divided to expose the internal oblique muscle. The internal oblique and transversus abdominis muscles are split with clamps at right angles to each other until the peritoneum is exposed. The peritoneum is open and the abdomen entered. If purulent fluid is encountered and bacterial cultures desired, now is the time to sample the fluid for cultures.

As much purulent fluid as is feasible is aspirated. Frequently, the appendix can be identified by palpation of a firm, tubular structure. If the appendix is mobile, it can be delivered into the wound. If the appendix is fixed, or retrocecal or retroperitoneal in location, the teniae of the cecum are followed to the base of the cecum and appendix can be identified (Fig. 142.1). Once the appendix is delivered, the mesoappendix can be divided. This can be divided between clamps, then suture ligate the appendiceal artery contained in the mesoappendix (Fig. 142.5) or with a stapling device, as per the surgeon’s preference. Usually, the inflammation is at the distal end of the appendix; therefore, the base of the appendix at the cecum is crushed with a straight clamp, divided and ligated with a 2-0 or 3-0 absorbable suture. The mucosa of the appendiceal stump is obliterated

with electrocautery. Alternatively, the stump can be inverted and secured with a purse-string suture of a 3-0 suture. Stump inversion used to be common practice, but there is no evidence that it is either associated with lower intra-abdominal abscess rates or lower small bowel obstruction rates.

Rarely, the appendix is inflamed and gangrenous to the cecum, in which case division and ligation at the appendiceal base may lead to cecal perforation or fistula. In this circumstance, inclusion of the cecum in the resection is indicated. This is done by mobilizing the cecum by dividing the ligament of Treves and white line of Toldt, as necessary. An appropriate sized stapling device, usually with 3.5-mm staplers, is placed across the cecum with care taken to avoid narrowing or obstructing the ileocecal valve (Fig. 142.6).

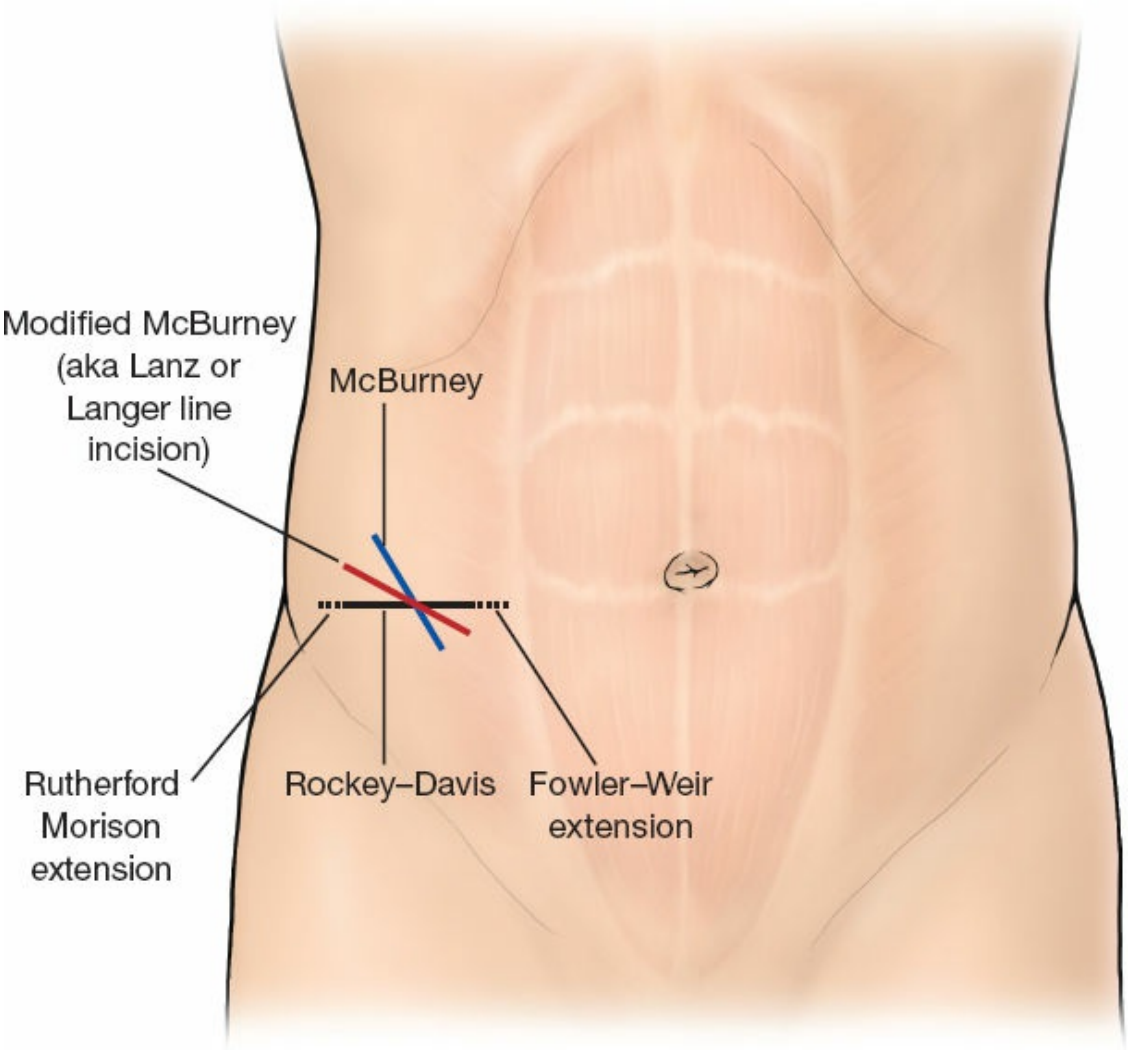

Figure 142.4. Incisions used in open appendectomy. (From Lowry SF, Davidov T, Shiroff AM. Appendicitis and appendiceal

abscess. *Fischer's Mastery of Surgery*, 6th ed. 2012.)

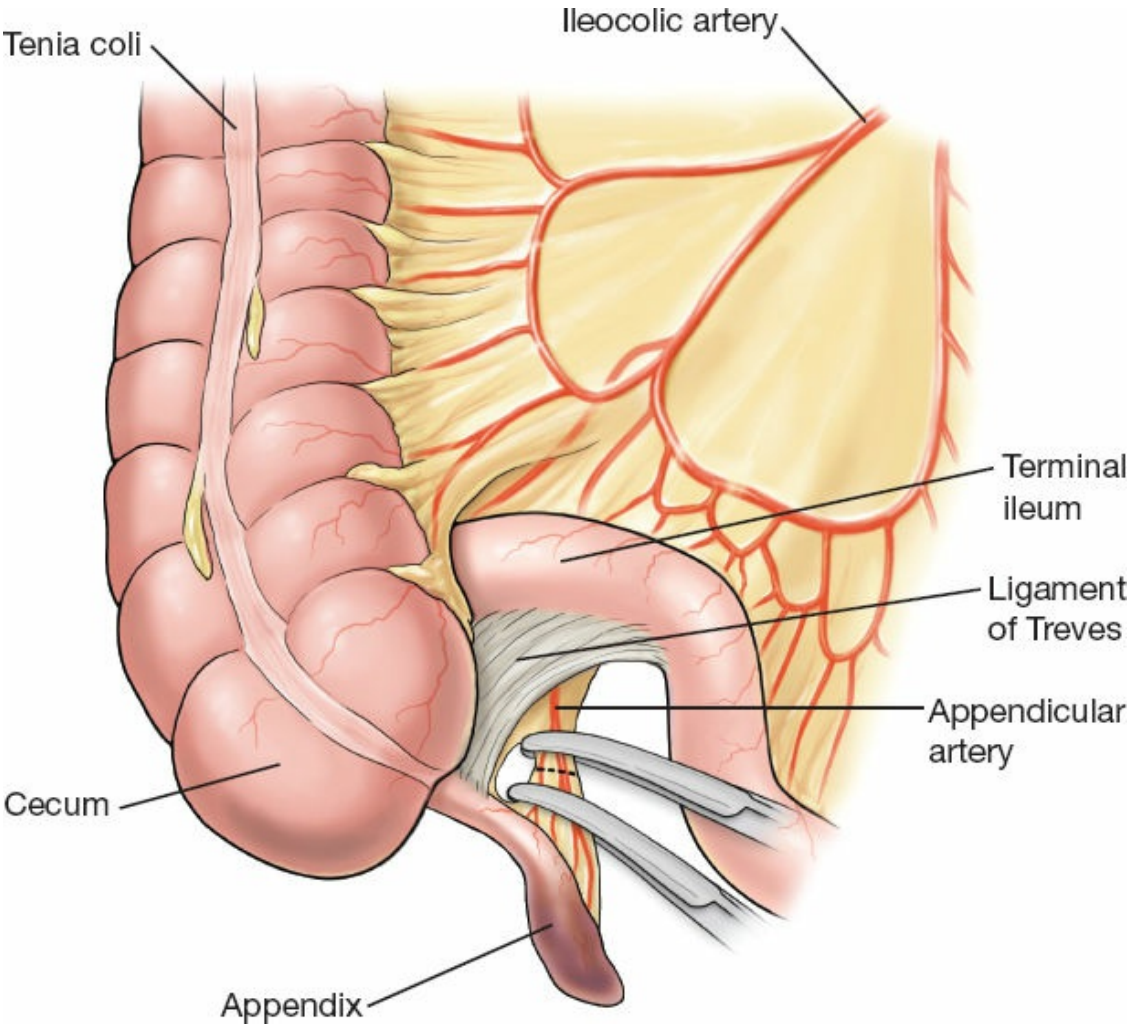

Figure 142.5. Division of the mesoappendix between clamps with subsequent suture ligature. (From Lowry SF, Davidov T, Shiroff AM. Appendicitis and appendiceal abscess. *Fischer's Mastery of Surgery,* 6th ed. 2012.)

The right iliac fossa and pelvis should be aspirated of all purulent fluid. There are differences of opinion on whether the region should be irrigated as well. Those who advocate for irrigation argue that it will reduce the inoculum of bacteria that may lead to postoperative abscess formation, while those that are against cite that it will reduce the number of activated polymorphonuclear neutrophils in the region and potentially spread bacteria to other regions of the abdomen. The abdominal wall is closed in layers with running or interrupted 2-0 or 0 absorbable suture. The skin can be closed as per the surgeon's preference, unless the extent of contamination mandates that the skin be left open.

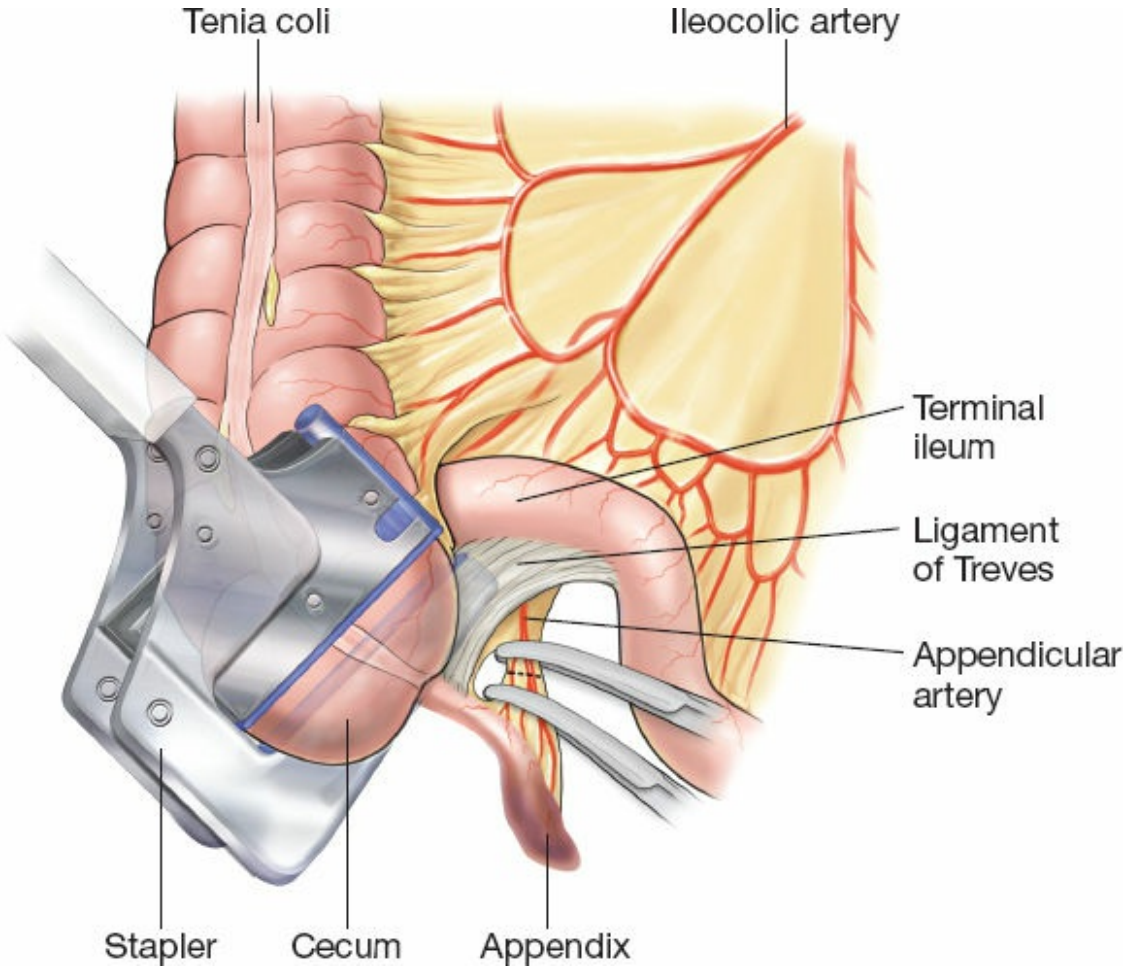

Figure 142.6. Appendo-cecectomy if the base of the appendix is involved with inflammation or necrosis.

Laparoscopic Appendectomy

With the rise of laparoscopy in the 1990s, laparoscopic appendectomy has become the predominate approach to appendectomy. In addition to smaller incisions and better cosmesis, it provides the surgeon with the ability to visually explore the entire peritoneal cavity, in case the original diagnosis of appendicitis was in error.

The patient is positioned supine. However, in a female for whom concern about pelvic pathology exists, a lithotomy position is used. In this case, a uterine manipulator should be placed to allow for maneuvers to optimize visualization of the pelvic organs. A urinary catheter is used to decompress the bladder during the operation.

The abdomen is entered through an infraumbilical incision either with a Veress needle or under direct visualization with a Hasson cannula, as per surgeon's preference. The abdomen is insufflated with CO_2 gas to a pressure of 15 mm Hg. The second port is placed in the suprapubic region

with 12-mm trocar. This will be used for passage of a stapling device, if that is the surgeon's preference. The third port, usually a 5-mm trocar, can be placed in one of two alternate positions, either in the right anterior axillary line at the level or just superior to the umbilicus (my preference) or in the left lower quadrant (Fig. 142.7). At this point, a general diagnostic laparoscopy is done to confirm appendicitis, or seek other pathology if the appendix is normal or if periappendicitis is present.

The appendix is mobilized with laparoscopic graspers with care taken not to rupture the inflamed appendix. Depending on the circumstances, the surgeon can elect to divide the mesoappendix first with an endoscopic stapling device using 2.5-mm "vascular" staples, and then divide the appendix at its base with 3.5-mm "bowel" staples. If the surgeon prefers, the base of the appendix can be secured with an endoloop suture. There has been no reported difference in outcomes between the use of the endoloop or stapler with respect to securing the base of the appendix. If the anatomy presents itself, the surgeon can divide the appendix first, and then the mesoappendix. Alternative to using a stapler for division of the mesoappendix are the endoscopic energy devices, such as ultrasonic harmonic shears or electrothermal bipolar vessel sealing devices. Some advocate that these energy devices can be used for division of the appendix as well.

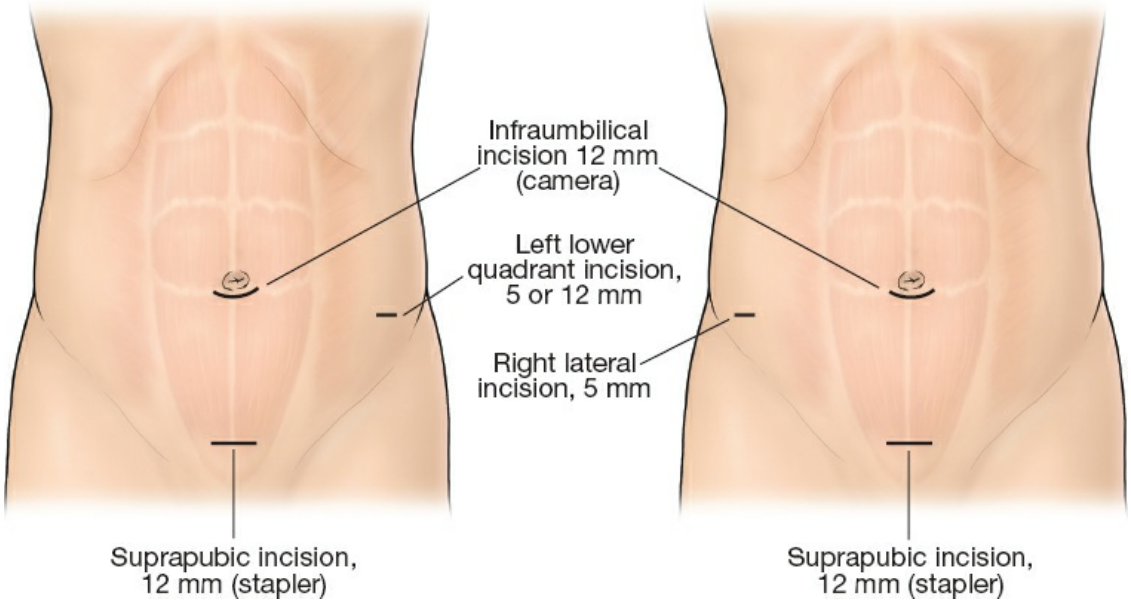

Figure 142.7. Options for port placement in laparoscopic appendectomy.

Once the appendix and mesoappendix are divided, it is placed in an

endoscopic extraction bag and delivered, usually through the suprapubic port. The fascia of the larger port sites should be closed with an absorbable 0 suture and the skin closed as per the surgeon's preference.

Postoperative Care

In uncomplicated acute appendicitis, a single preoperative dose of antibiotics is all that is necessary. The urinary catheter and, if present, the naso/orogastric tube should be removed. Once recovered from anesthesia, the patient may be given liquids and, eventually, food. Discharge to home the same day may be appropriate.

In patients with gangrenous or perforated appendicitis, prolonged antibiotic treatment may be necessary. The most common organisms include *Bacteroides fragilis, Escherichia coli, Enterococcus* spp., other *Streptococcus* spp., *Pseudomonas* spp., and *Klebsiella* spp. Duration of antibiotics depends on patient response. Although some surgeons advocate for specific durations such as 7 or 10 days, a more logical approach is continuation of antibiotics until the patient is afebrile, with a normal white blood cell count and normal white blood cell differential for 24 hours, and then discontinuation of antibiotics. While the patient is hospitalized, venothrombosis prophylaxis is necessary. While the patient is still nothing per os, stress ulceration prophylaxis should be considered.

Complications and Their Management

Although any complication associated with an operation or general anesthesia can occur after an appendectomy, the most common complications are infectious. Wound infections occur proportional to the degree of contamination and whether the wound was closed or left open. In general, as laparoscopic incisions are smaller with less subcutaneous surface area exposed to a bacterial inoculum, laparoscopic appendectomy has a lower wound infection rate compared to open appendectomy. However, intra-abdominal abscess seems to occur more frequently after laparoscopic appendectomy, 9% to 24%, compared to open appendectomy, 3% to 4%. This may be related to spread of bacteria from the right lower quadrant due to insufflation or use of laparoscopic instruments from remote sites.

Outcomes

In general, complete recovery and return to normal life with no effect on longevity is the norm. However, appendectomy may the cause of future bouts of small bowel obstruction, although this is uncommon. Women who suffered from perforated appendicitis, especially with pelvic abscess, have an increased risk of infertility. This does not seem true for uncomplicated appendicitis.

There is data to suggest that in patients over 40 years of age who developed appendicitis, the potential cause is a neoplasm obstructing the appendiceal orifice. Some data suggest that the incidence of colon cancer in this group of patients is 40 times that of the general population. Therefore, some have advocated follow-up colonoscopy of all appendectomy patients greater than 40 years old, especially if there was no prior colonoscopy or a prolonged interval since the last colonoscopy.

SPECIAL CONSIDERATIONS

Incidental Appendectomy

Incidental appendectomy is the removal of a grossly normal appearing appendix while the surgeon is performing another abdominal operation. Although once considered a “routine” practice, over the last 2 or 3 decades, its value has been challenged. The main issue is the decreased incidence of acute appendicitis as one ages weighed against the risk of complications by performing the appendectomy. Although there is no consensus, it is generally felt that incidental appendectomy is not indicated after the age of 25 years. There are some authors who advocate routine incidental appendectomy during laparoscopic hysterectomy or open colorectal procedures, but this is not widely practiced. However, there are some circumstances where it may be of value. These include patients being operated upon for Crohn disease and chronic abdominal or pelvic pain, where elimination of the appendix as a possible source of pain may help in future management. Nevertheless, there are specific contraindications to incidental appendectomy, including active Crohn disease involving the cecum, inaccessible appendix, planned radiation treatment, immunosuppression, vascular grafts, or other intra-abdominal foreign material.

Appendicitis in Pregnancy

Appendicitis in pregnancy is a particularly vexing problem as both the

disease and the diagnostic process can place the mother and fetus at risk. Although the symptoms of appendicitis are similar in the pregnant and nonpregnant woman, as the uterus becomes more gravid, the location of the appendix shifts more laterally and superiorly, occasionally confusing the physical examination. Ionized radiation in the diagnostic process should be avoided; therefore, imaging should include either ultrasound or magnetic resonance imaging (Fig. 142.8). Nevertheless, if suspicious for acute appendicitis is high, surgery should be performed as rupture and pelvic abscess formation can lead to fetal loss. Early in pregnancy, a laparoscopic approach is both feasible and safe. However, late in pregnancy, laparoscopy may be more difficult as the gravid uterus may obstruct visualization and an open approach may be required. This choice is obviously based on the judgment of the treating surgeon.

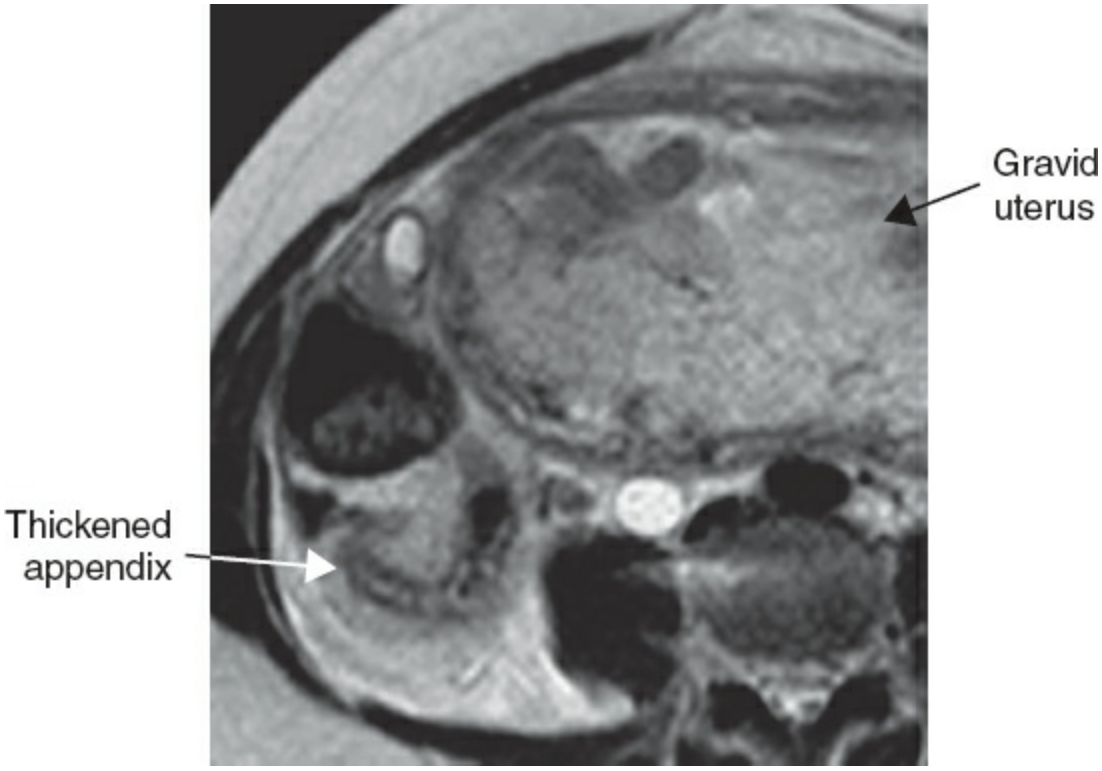

Figure 142.8. MRI in pregnant patient with acute appendicitis. (Courtesy of John Feldman, MD. Tampa General Hospital.)

Stump Appendicitis

Stump appendicitis is the clinical entity of recurrent inflammation of an appendiceal remnant after an appendectomy. The underlying cause is incomplete removal of the appendix during the first appendectomy. The incidence has been estimated to be 1 of every 50,000 appendectomies. The

time interval between the index bout of appendicitis and the stump appendicitis has been reported from as short as 1 week to as long as 50 years. Signs and symptoms are similar to acute appendicitis and imaging with a CT scan can help secure the diagnosis. Treatment is similar to appendicitis, with nonoperative management with antibiotics or “stump appendectomy” being appropriate depending on the clinical circumstances.

Appendiceal Diverticulitis

Diverticuli of the appendix are relatively rare. They are false diverticuli similar to other colonic diverticuli. Unlike the typical cause of acute appendicitis, which is obstruction of the appendiceal lumen, inflammation due to appendiceal diverticuli are due to diverticular rupture. Patients with appendiceal diverticulitis tend to be older, more commonly male, and present with periappendiceal inflammatory masses or abscesses. Having said all this, management is the same as with acute appendicitis from the more typical cause.

Appendicitis in the Elderly

Older patients with the acute abdomen present a special problem. They are subjects to more causes of the acute abdomen and are at a higher risk of adverse events. About 10% of patients >65 years of age presenting with an acute abdomen have appendicitis as the cause, while only about 3% to 4% of all patients with appendicitis will be >65 years of age. In addition, elderly patients are more likely to have complicated appendicitis, such as gangrenous and/or perforated disease. Therefore, the surgeon evaluating the older patient with the acute abdomen needs to consider the myriad of causes and be prepared for many contingences. Because older patients may not have “classic” symptoms, CT scanning is helpful in preoperatively identifying a cause of the abdominal pain. Preoperative preparation must not only be directed at fluid resuscitation and antibiotic therapy, but also at addressing comorbidities and medications that can affect the operation.

Most elderly patients with appendicitis can be approached laparoscopically. In addition to the other advantages of laparoscopic appendectomy, this approach affords the surgeon the opportunity to explore the abdomen for other causes. If the preoperative imaging documents periappendiceal abscess and percutaneous drainage is elected, colonoscopy and interval appendectomy should be strongly considered because of the higher incidence of neoplasm in this group of patients.

Appendicitis in Children

Acute appendicitis is one of the most common diagnoses in children. The peak incidence is in the second decade of life with an incidence of 250 per 100,000 children between the ages of 10 and 17. It is more uncommon in younger children with an incidence of 10 to 20 per 100,000 children <4 years old. However, it is in this age group specifically that the diagnosis becomes more difficult due to appendicitis being an *a priori* uncommon cause of abdominal pain in this age group and the child's inability to provide a description of his or her pain. Ultrasound is a valuable diagnostic tool as it will not expose the child to radiation and can help secure the diagnosis. The combination of the Pediatric Appendicitis Score and Ultrasound of the appendix yielded very high negative and positive predictive values (Tables 142.2 and 142.3).

TABLE 142.2 Pediatric Appendicitis Score (PAS)

Component of PAS	Risk Level	% With Appendicitis
Fever Migration of pain Anorexia Nausea/Vomiting Maximal pain RLQ Guarding Rebound RLQ pain with hopping, cough, or percussion WBC >10,000/mm^3 >75% neutrophils	<4 components: low risk 4–6 components: medium risk 7–10 components: high risk	~5% ~35% ~70%

Adapted from Bachur RG, Callahan MJ, Monuteaux MC, et al. Integration of ultrasound findings and a clinical score in the diagnostic evaluation of pediatric appendicitis. *J Pediatr* 2015;166(5): 1134–9; with permission from Elsevier.

Once the diagnosis is secure, the approach is similar to that of adults. There is data to support nonoperative management with antibiotics. Whether there is a need for an interval appendectomy is unclear. Certainly, the legal guardian of the child needs to be appraised about the risk of recurrent appendicitis. Appendectomy is still considered the standard treatment. Laparoscopic appendectomy is the preferred approach, leading to shorter hospital stay, fewer wound infections, and a more rapid return to normal activity. In patients presenting with periappendiceal abscess, there is support for both immediate laparoscopic appendectomy with operative

abscess evacuation and percutaneous drainage with interval appendectomy. This choice needs to be made individually.

Chronic Appendicitis

The entity of chronic appendicitis is controversial. Certainly, there is no uniformed agreement that this entity exists. Having said this, there is a group of patients with chronic, either unrelenting or recurrent right lower quadrant pain, but without the signs of acute, progressive inflammation or sepsis seen in acute appendicitis. Unlike acute appendicitis, which is pathologically characteristic by transmural acute inflammation with neutrophilic infiltration, ischemia, and necrosis, the pathology of chronic appendicitis shows chronic inflammation with lymphocytes and eosinophils, fibrosis, granulomatous and foreign-body giant cell reaction, and obliteration of the appendiceal lumen. Patients are generally not acutely ill, but complain of right lower quadrant pain of varying character and intensity over the course of several weeks, months, or even years. They otherwise have no signs of sepsis and a search for the cause of the pain has been fruitless. CT scan findings, if present, include an enlarged, dilated appendix with thickening of the appendiceal wall and periappendiceal fat stranding. However, a normal scan is frequently the case.

TABLE 142.3 Positive and Negative Predictive Values of Combining the PAS With Ultrasound Findings

PAS Group	US Positive (%)	US Equivocal (%)	US Negative (%)
Low	73	9	0
Medium	90	13	6
High	97	47	19

Adapted from Bachur RG, Callahan MJ, Monuteaux MC, et al. Integration of ultrasound findings and a clinical score in the diagnostic evaluation of pediatric appendicitis. *J Pediatr* 2015;166(5):1134–9; with permission from Elsevier.

There is no consensus on the management of these patients. Appendectomy may lead to pain relief, although this frequently may not be the case. Therefore, before preceding the surgical extirpation, the patient needs thorough counseling on the vagaries of the diagnosis and possibility that appendectomy may not lead to symptomatic relief.

Periappendicitis

Periappendicitis is inflammation of the serosa of the appendix, but with a normal appendiceal lumen and mucosa. It can be found in 1% to 5% of appendectomy specimens removed for acute appendicitis. The pathophysiology of acute appendix is an “inside-out” phenomenon where luminal obstruction leads to increased intraluminal pressure causing mucosal necrosis and subsequent bacterial invasion and infection. Periappendicitis, on the other hand, is an “outside-in” phenomenon where inflammation starts at the serosal surface of the appendix toward the lumen. The importance of periappendicitis is that the pathology causing the inflammation is not the appendix itself, but from some other intra-abdominal structure. Most commonly, it is pelvic inflammatory disease, salpingitis, diverticulitis, inflammatory bowel disease, or a perforated hollow viscus, such as duodenal ulcer (so-called Valentino’s appendicitis). Occasionally, no other source can be found. Patients present with signs and symptoms of acute appendicitis and the appendix appears inflamed by gross inspection. The concern is that the underlying “true” pathology causing the periappendicitis is left untreated allowing for continuation of source of sepsis.

As acute appendicitis is generally the working diagnosis, an appendectomy is usually performed. Periappendicitis can be suspected when the appendix is transected on the back table and inspection of the mucosa demonstrated no necrosis. In such a circumstance, a search for another cause should be performed. If the appendectomy was done laparoscopically, it is relatively easy to explore the abdomen for another source. If the appendectomy was done open, this can be more difficult through a small Rockey–Davis incision.

APPENDICEAL TUMORS

Neoplasms of the appendix are relatively uncommon. They account for 1% or less of all gastrointestinal neoplasms and are found in less than 2% of all appendectomy specimens. Nevertheless, during the course of routine practice, the general surgeon can expect to encounter these lesions. Understanding the appropriate treatment of these lesions is essential.

There are a variety of tumors which can occur in the appendix (Table 142.4). These can generally be divided into primary and metastatic, and epithelial and nonepithelial. It is not the purpose of this chapter to discuss the treatment of each type of tumor in detail, but address the tumors

generally present in the acute setting.

Carcinoid Tumor/Neuroendocrine Tumor

What has been traditionally referred to as carcinoid tumors are now being categorized as well or intermediately differentiated neuroendocrine tumors, which can arise from the foregut, midgut, or hindgut. Poorly differentiated or high-grade neuroendocrine tumors are often referred to as neuroendocrine carcinomas. Embryologically, appendiceal carcinoid tumors are midgut tumors. It is these midgut tumors that are more likely to cause carcinoid syndrome. The overall annual incidence of neuroendocrine tumors of the appendix is about 0.16 per 100,000, with similar incidence between male and female patients, but a somewhat higher incidence in Caucasian and African American patients compared to Asian and Pacific Islander patients.

TABLE 142.4 Tumors of the Appendix

Primary

- *Epithelial*
  - Benign
    - Hyperplastic polyp
    - Serrated adenoma
    - Colonic-type adenoma
  - Malignant
    - Low-grade mucinous neoplasm/ Pseudomyxoma peritonei
    - Adenocarcinoma/High-grade mucinous neoplasm
- *Nonepithelial*
  - Carcinoid
  - Goblet-cell carcinoid/ adenocarcinoid
  - Mesenchymal tumors
  - Gastrointestinal stromal tumors
  - Neuroma/schwannoma
  - Leiomyoma/sarcoma
  - Lymphoma

Metastatic

- Ovarian
- Colonic
- Melanoma
- Very rare other metastatic tumors

Etiology and Pathophysiology

Neuroendocrine tumors arise from the enterochromaffin cells within the gut. These tumors can retain the capacity for amine precursor uptake and decarboxylation (APUD system). Because of this ability, they can produce a variety of vasoactive substances, including serotonin, substance P, prostaglandins, histamine, and kallikreins. Most of these are removed by the liver during the “first-pass” phenomenon; therefore, the vasoactive

symptoms of carcinoid syndrome generally occur when liver metastasis is present, when these substances are secreted directly into the systemic circulation. However, most neuroendocrine tumors are not hormonally active.

Clinical Presentation

The clinical presentation of neuroendocrine tumors of the appendix can either be insidious or acute. Although not frequent, patients with neuroendocrine tumors of the appendix can present as acute appendicitis and the intraoperative finding of these tumors is unexpected. On the other hand, patient can also present a vague, poorly localized abdominal pain, cramping, bloating, and occasional diarrhea. It is not unusual for these patients to be misdiagnosed as having irritable bowel syndrome. Physical examination is usual not helpful, as palpable masses are rare. Classic carcinoid syndrome symptoms of flushing and diarrhea related to serotonin release is usually associated with liver metastasis.

Laboratory and Imaging Diagnosis

If patients present acutely, laboratory findings are similar to that of acute appendicitis. If a carcinoid tumor is suspected preoperatively, chromogranin A, 24-hour urinary 5-HIAA, and neuron-specific enolase are useful both diagnostically and in follow-up.

CT scanning is the obvious choice in the acute setting, as usually acute appendicitis is suspected. The tumor may not be detected if small in a background of appendiceal and periappendiceal inflammation. However, in the nonacute setting, neuroendocrine tumors are vascular and may be demonstrated as contrast-enhancing tumors with IV contrast during the arterial phase with rapid washout during the venous phase. Not uncommonly, the primary tumor is small, and the mass noted is a mesenteric lymph node metastasis. For patients with contrast allergies, MRI is the alternative imaging modality.

Octreotide scanning is useful in that the whole body may be imaged. The sensitivity for detecting neuroendocrine tumors is around 80%. I-MIBG and PET scanning are generally not as useful.

Management

Management of patient with carcinoid tumors of the appendix depends on presentation. In the acute setting, patients are managed as if they have acute appendicitis. In the nonacute setting, without signs of carcinoid

syndrome, patient management will depend on tumor size and presence of lymph node metastasis. If carcinoid syndrome is present, patients will require preoperative physiologic preparation and planning for surgical management of both the primary tumor and liver metastases, if present.

Preoperative Preparation

If patients present acutely and are diagnosed with acute appendicitis, then preoperative preparation is similar to that of the acute appendicitis patient. If patients present with a preoperative diagnosis of suspected neuroendocrine tumor, then an evaluation of the presence of both a functional tumor and metastatic disease is needed. If a functional tumor is present, especially carcinoid syndrome, preoperative consultation with anesthesia is prudent, as this will influence anesthetic management. Preoperative use of H_1 or H_2 blockers can reduce gastrointestinal manifestations, bronchospasm may need to be treated, octreotide is effective to blunt the manifestations of carcinoid syndrome, antibiotic prophylaxis specifically for carcinoid-related valvular heart disease may be needed, and drugs that release histamine should be avoided. Invasive arterial monitoring and central venous access should be considered.

Operations

Extend of resection of carcinoid tumors of the appendix is depended on the size of the tumor. The majority of tumors are located in the distal appendix and do not involve the base. The risk of lymph node metastasis in well-differentiated tumors <2 cm is low, but can exceed 30% when tumors are >2 cm. Therefore, well-differentiated tumors, <2 cm in size, involving the distal appendix where a margin-negative complete resection can be accomplished can be safely managed with appendectomy alone. On the other hand, incomplete resection by appendectomy, tumors >2 cm, tumors involving the proximal or base of the appendix, invasion of the mesoappendix, high-grade histologic features, lymphovascular invasion, or “mixed” histologies, such as goblet cell or adenocarcinoid features, should be treated with right hemicolectomy with en bloc resection of lymph node bearing mesentery (description of a right hemicolectomy is in another chapter in this book). Special mention should be made of goblet cell carcinoids which have histologic features of neuroendocrine and goblet cell differentiation. These are sometime referred to as adenocarcinoids or mucinous adenocarcinoids. These are more aggressive tumors than well-differentiated neuroendocrine tumors and should be treated more like

adenocarcinomas than carcinoids.

Postoperative Care

In patients who have small, nonfunctional tumors treated by appendectomy, postoperative care is similar to an appendectomy for acute appendicitis. For requiring right hemicolectomy, the patient may be placed on enhanced recovery protocols (see chapter pertaining to colon resection).

Complications and Their Management

The complication profile is similar to that of appendectomy for acute appendicitis. In patients who undergo a right hemicolectomy, the most feared complication is an anastomotic leak. Patients will have persistent or worsening abdominal pain, fevers, and leukocytosis. Evaluation could be done with a CT scan demonstrating intra-abdominal fluid with or without gas, consistent with an abscess, or extravasation of contrast. If the patient is not toxic, this can be treated with percutaneous drainage to create a controlled fistula. If this does not control the source of infection, operation is indicated. If peritonitis is present, then surgical exploration is warranted. If the anastomotic disruption is small, with minimal inflammation, primary repair may be considered. However, the safest choice is creation of an ileostomy after drainage of any intra-abdominal fluid.

Outcomes

The prognosis for carcinoid tumors is generally good with 5-year survival rates approaching 90% for localized disease and 80% for regional disease. Survival diminishes significantly with distant disease falling to 25%. Tumor stage, positive margins, and older age are associated with worsening outcomes.

Low-Grade Mucinous Neoplasms and Adenoma of the Appendix

Etiology and Pathophysiology

Appendiceal adenomas and mucinous tumors are rare tumors. They account for <1% of all appendectomy findings and can run a spectrum of aggressiveness. At the lower end of the spectrum are low-grade mucinous neoplasms, which have been historically called “mucoeles” of the appendix. These tumors arise in the luminal mucosa of the appendix and produce thick, tenacious mucus. These lesions are pathologically flat or villous with associated epithelial mucin. The serosal surface may appear completely normal. The risk with these lesions is that the mucin continues

to fill the lumen and eventually the appendix may rupture. This can lead to peritoneal seeding of mucin-producing cells. The abdomen will start to fill with mucinous ascites, a condition known as pseudomyxoma peritonei. Nevertheless, nodal and hematogenous metastases are uncommon, and even in the setting of pseudomyxoma peritonei, there is controversy as to whether these are truly malignant lesions.

Clinical Presentation

Low-grade mucinous neoplasms of the appendix can be protean in its presentation. These tumors tend to occur in the sixth decade of life, more commonly in women than men. As these tend to be indolent tumors, they are frequently "incidental" findings on imaging for other reasons. When symptoms occur, right lower quadrant abdominal pain is the most common, which can mimic acute appendicitis. An abdominal mass may be present. If the tumor has ruptured, drop ovarian metastasis is common and patient can present with large ovarian tumors, which are frequently confused for the primary tumor. Distention is generally a sign of advancement to pseudomyxoma peritonei.

Laboratory and Imaging Diagnosis

Although patients can present with signs suggestive of acute appendicitis with associated leukocytosis, in general, laboratory findings are unremarkable. CT scan is the most useful imaging test with a dilated, thickened appendix the most common early finding and ovarian masses and mucinous ascites findings consistent with peritoneal dissemination and pseudomyxoma peritonei.

Management

Preoperative Preparation

If patients are presenting with signs of acute appendicitis and the diagnosis of a mucinous tumor is not suspected, then preoperative preparation is the same as for the patient with acute appendicitis. However, if the patients present electively, then the normal preoperative risk assessment depending on comorbidities should be performed. Whether a bowel preparation is performed and how is a matter of choice for the surgeon (see chapter on colectomy).

Operations

For tumors localized to the appendix, an appendectomy is adequate

treatment. Extreme care is taken to prevent rupture of the appendix during manipulation to avoid iatrogenic dissemination of mucin-producing cells. Although controversial, it appears that microscopically a positive margin at the base of the appendix does not increase the risk of local or distant recurrence. The risk of nodal metastasis for T1 and T2 lesions is <6%; therefore, a more extensive resection is not indicated. The need for a right hemicolectomy in more advanced disease is controversial. Some argue that in metastatic disease, right hemicolectomy only increases risk of complications without improvement in survival. On the other hand, for larger T3 or T4 tumors, without dissemination of disease, a right hemicolectomy may be beneficial as the rate of nodal disease is over 30%.

Once pseudomyxoma peritonei occurs, treatment becomes more complicated. At this point, aggressive cytoreductive surgery, including greater and lesser omentectomy, cholecystectomy, peritonectomy of any involved peritoneal surface, and oophorectomy and/or hysterectomy if involved with tumor, should be performed. This is then followed by hyperthermic intraperitoneal chemotherapy (HIPEC). Obviously, this may require referral to a specialized center with this capacity.

Outcomes

Low-grade mucinous tumors are confined to the appendix and generally cured by appendectomy with a very low risk of recurrence. The most important issues come with pseudomyxoma peritonei. This disseminated disease does not directly lead to death, but overwhelmingly affects quality of life. It can lead to secondary causes of death, such as bowel obstruction. Therefore, controlling mucinous ascites is important. HIPEC has been shown to decrease the recurrence rate of pseudomyxoma peritonei and decrease mortality related to the disease. In follow-up, however, up to 13% of patients with low-grade mucinous neoplasms will have synchronous or metachronous neoplasms of the colon. Therefore, colonoscopy is strongly considered in follow-up.

High-Grade Mucinous Neoplasms and Adenocarcinoma of the Appendix

Etiology and Pathophysiology

High-grade mucinous neoplasms and adenocarcinomas are very rare. They account for <0.2% of all appendectomy specimens. These lesions are divided into adenocarcinoma not otherwise specified, mucinous

adenocarcinoma, signet ring cell adenocarcinoma, and undifferentiated adenocarcinoma. The mucinous tumors account for about 40% of all appendiceal adenocarcinomas. Pathologically, these lesions resemble the spectrum of colonic adenocarcinoma; similarly with colon adenocarcinoma and in contrast with low-grade mucinous neoplasms.

Clinical Presentation

Most patients with appendiceal adenocarcinoma are in the fifth to seventh decades of life. There is equal distribution between men and women. Nearly 90% of patients with appendiceal adenocarcinoma will present with signs and symptoms of acute appendicitis. Other presentations include abdominal mass, bowel obstruction, occult or overt gastrointestinal hemorrhage, and signs of metastasis.

Laboratory and Imaging Diagnosis

As the vast majority of patients present with acute appendicitis, the laboratory profile with be that of acute appendicitis. Imaging may show a right lower quadrant mass, although it may be difficult to differentiate this finding with an inflammatory appendiceal mass. CT scanning may show evidence of nodal or distant metastasis.

Management

Preoperative Preparation

As most patients present with acute appendicitis, preoperative preparation is similar to that of the acute appendicitis patient. However, in the rare circumstance where the diagnosis is suspected preoperatively, patients should be prepared as for a right hemicolectomy.

Operation

The operation of choice for locoregional disease is a right hemicolectomy with en bloc mesenteric resection of the draining lymph node basin. However, some suggest that there is no survival advantage for right hemicolectomy in the presence of metastatic disease.

Complications and Their Management

The complication profile is that of a right hemicolectomy (see chapter on colectomy).

Outcomes

The reported 5-year survival of patients with appendiceal adenocarcinoma is 18% to 55%. In general, mucinous tumors have a better survival than nonmucinous tumors.

EDITOR'S COMMENT

Dr. Velanovich has done an outstanding job clearly detailing the controversies in the management of both benign and malignant disease of the appendix. No longer does acute appendicitis equate with need for appendectomy. More patients are being treated nonoperatively with antibiotics with either interval appendectomy or no appendectomy at all. As has been pointed out, clinical

trials have so far shown controversial results with regard to the standard of care for treating uncomplicated acute appendicitis.

In a review of five randomized trials that have evaluated conservative management to primary surgical therapy, the authors concluded that all five trials considered antibiotics alone as an efficient and noninferior option in comparison to surgery. However, primary antibiotic therapy was characterized by a longer length of stay, a higher recurrence rate but a lower rate of postoperative complications compared to primary surgical therapy. Taken one step further, the authors concluded in a reasonable fashion that in high-risk patients, an appropriate treatment regimen with antibiotics was considered for uncomplicated acute appendicitis (Abongwa HK, Cervellin G, Tarasconi A, et al. Antibiotics alone for uncomplicated acute appendicitis in high operative risk adult patients: Analytical review of RCTs and proposal of evidence based treatment decision. *Acta Biomed* 2017;87:334–6).

Nevertheless, the conclusion that antibiotic therapy is equivalent to surgical resection for acute appendicitis is a cause for significant debate. In their review of randomized trials and meta-analysis, Podda et al. concluded that there was a higher rate of treatment efficacy based on 1-year follow-up in the surgical group (98.3% vs. 75.9%, P <0.0001), recurrence at 1 year was reported in 22.5% of patients treated with antibiotics. Rate of complicated appendicitis with peritonitis identified at the time of surgical operation was higher in the antibiotics group (19.9% vs. 8.5%, P = 0.02). No statistically significant differences were found when comparing primary antibiotic therapy and surgical therapy groups for the outcomes of overall postintervention complications (4.3% vs. 10.9%, P = 0.32), postintervention complications based on the number of patients who underwent appendectomy (15.8% vs. 10.9%, P = 0.35), length of hospital stay (3.24 ± 0.40 vs. 2.88 ± 0.39, P = 0.13), and period of sick leave (8.91 ± 1.28 vs. 10.27 ± 0.24, P = 0.06). The authors concluded that with significantly higher efficacy and low complication rates, appendectomy remains the most effective treatment for patients with uncomplicated acute appendicitis.

Laparoscopic appendectomy is clearly accepted as an excellent treatment approach and likely the gold standard in uncomplicated appendicitis. Recently, authors have reviewed the technical feasibility, effectiveness, and safety between single incision versus conventional three-incision laparoscopic appendectomy. In 2013, authors reviewed eight original randomized trials investigating 760 adults and 684 children, 1,444 patients in total, of whom 721 received single incision and 723 received conventional three-port laparoscopic appendectomy. Pooling the results for single incision laparoscopic appendectomy and conventional laparoscopic appendectomy revealed no significant difference in pain scores, wound infection rate, overall complications, and postoperative hospital stay. The authors concluded that single incision laparoscopic appendectomy failed to show any obvious advantages over conventional laparoscopic appendectomy in perioperative and postoperative outcomes. Therefore, it represents a possible alternative to

conventional three-port laparoscopic appendectomy (Gao J, Li P, Li Q, et al. Comparison between single-incision and conventional three-port laparoscopic appendectomy: a meta-analysis from eight RCTs. *Int J Colorectal Dis* 2013;28(10):1319–27).

More recently, in a review of 11 randomized trials of 1,489 patients undergoing single incision laparoscopic versus conventional laparoscopic appendectomy, the patients in the single incision laparoscopic appendectomy group had a significantly shorter hospital duration and return to activity but experienced a longer operating time and higher rate of conversion ($p < 0.00001$). There were no differences between the two groups in pain scores, doses of analgesics, overall complication rates, wound infection, or cosmesis. The authors concluded that single incision laparoscopic appendectomy is safer and more effective that conventional three incision laparoscopic appendectomy in both pediatric and adult patients (Deng LH, Xiong JJ, Xia Q. Single incision versus conventional three incision laparoscopic appendectomy: a meta analysis of randomized controlled trials. *J Evid Based Med* 2016. Doi:10.1111/jebm.12238. [Epub ahead of print]). Differences in interpretation could account for variations in the conclusions from reviews published in similar numbers of patients undergoing laparoscopic appendectomy in contemporary time periods. It is also possible that with technologic improvements in laparoscopic equipment, at present, single incision laparoscopic appendectomy may offer some small benefits over conventional laparoscopic appendectomy.

A concern remains whether laparoscopic appendectomy is appropriate and feasible in complicated appendicitis. In a systemic review and meta-analysis, Yu et al. reviewed two randomized trials and 14 retrospective cohort studies of patients undergoing laparoscopic or open surgery for complicated appendicitis. The meta-analysis showed that laparoscopic appendectomy could reduce the rate of surgical site infections (OR = 0.28, 95% CI: 0.25 to 0.31, $p < 0.00001$), but laparoscopic appendectomy did not increase the rate of postoperative intra-abdominal abscess. Furthermore, the operating time in the laparoscopic appendectomy groups was much longer than that in the open appendectomy groups. However, the length of hospital stays in the laparoscopic appendectomy groups were significantly shorter than those in the open appendectomy groups. The time until oral intake was much earlier in the laparoscopic groups than in the open appendectomy groups. It was concluded that laparoscopic appendectomy was safe for complicated appendicitis and was associated with advantages such as reducing surgical site infection (Yu MC, Feng YJ, Wang W, et al. Is laparoscopic appendectomy feasible for complicated appendicitis? A systemic review and meta-analysis. *Int J Surg* 2017;40:187–97).

The management of patients with appendiceal tumors has become more complicated as knowledge concerning the biology of these tumors increases. Appropriate care is often best performed in a multidisciplinary environment as treatment approaches can vary from appendectomy alone to right

hemicolectomy to hyperthermic intraperitoneal chemotherapy and extensive cytoreductive surgery. The clinical course of appendiceal mucinous neoplasms is determined by the pathologic degree of differentiation and the stage of disease at diagnosis. More than 50% of appendiceal mucinous neoplasms present with diffuse mucinous ascites (Smeenk RM, van Velthuysen ML, Verwaal VJ, et al. Appendiceal neoplasms and pseudomyxoma peritonei: a population based study. *Eur J Surg Oncol* 2008;34:196–201). In a recent pooled analysis of hyperthermic intraperitoneal chemotherapy following cytoreductive surgery in 163 patients with appendiceal mucinous neoplasms, 60 patients had diffuse peritoneal adenomucinosis, 88 had peritoneal mucinous carcinomatosis, and 15 had peritoneal mucinous carcinomatosis with indeterminate features. Complete surgical resection was achieved in 76 patients. Hyperthermic intraperitoneal chemotherapy was used in 79 patients. The median overall survival was 77 months for patients who received hyperthermic intraperitoneal chemotherapy compared with 25 months for patients who did not. In a confirmation of the role of the intraperitoneal chemotherapy, on multivariate analysis, complete surgical resection, histopathologic subtype, and the use of the intraperitoneal chemotherapy were independent predictors of improved overall survival. In addition, a survival advantage for appendiceal mucinous neoplasms was observed at hyperthermic intraperitoneal chemotherapy treating centers (Shaib WL, Martin LK, Choi M, et al. Hyperthermic intraperitoneal chemotherapy following cytoreductive surgery improves outcome in patients with primary appendiceal mucinous adenocarcinoma: A pooled analysis from three tertiary care centers. *Oncologist* 2015;20(8):907–14).

Some appendiceal tumors such as goblet cell carcinoids exhibit unique clinical and pathologic features. This tumor likely arises from intestinal crypt base stem cells and have frequent loss of Notch signaling as well as other mutations which favor them progressing and behaving similar to adenocarcinoma with minimal neuroendocrine differentiation. High-grade versions of appendiceal goblet carcinoids are poorly characterized. In a recent report, high-grade goblet cell carcinoid was found to have distinctive morphology that is recognizable at metastatic sites and recapitulates crypt cells (appendiceal crypt cell adenocarcinoma). Unlike intestinal-type adenocarcinoma, it occurs predominantly in women, is disguised as gynecologic malignancy, and spreads along peritoneal surfaces with only rare hematogenous metastasis. It appears to be significantly more aggressive than appendiceal mucinous neoplasms. An increased understanding of the diverse spectrum of appendiceal tumors, through further molecular investigations, may lead to an enhanced role for targeted molecular therapy for such neoplasms (Shenoy S. Goblet cell carcinoids of the appendix: Tumor biology, mutations and management strategies. *W J Gastrointest Surg* 2016;27:660–9; Reid MD, Basturk O, Shaib WL, et al. Adenocarcinoma ex-goblet cell carcinoid (appendiceal-type crypt cell adenocarcinoma) is a morphologically distinct entity with highly aggressive behavior and frequent association with

peritoneal/intra-abdominal dissemination: an analysis of 77 cases. *Mod Pathol* 2016;29(10):1243–53).

143 Large Bowel Obstruction

Neil H. Hyman and Konstantin Umanskiy

ETIOLOGY AND PATHOPHYSIOLOGY

Large bowel obstruction can be caused by a variety of etiologic factors and is broadly defined as an intestinal blockage distal to the ileocecal valve. The obstruction may be mechanical or functional, partial or complete, intrinsic or extrinsic. The most common mechanical causes of large bowel obstruction are colorectal carcinoma, followed by diverticulitis and volvulus (Table 143.1). Mechanical obstruction should be differentiated from a functional obstruction (e.g., acute colonic pseudoobstruction). The presentation of large bowel obstruction can be acute or subacute/chronic. For example, colonic obstruction in Crohn disease could occur insidiously due to progressive inflammation and fibrosis. Mechanical obstruction due to malignancy or volvulus usually results in rapid onset of symptoms of abdominal distention and pain and can lead to bowel compromise and perforation.

TABLE 143.1 Common Causes of Large Bowel Obstruction

1. Intraluminal mass
   a. intrinsic mass, colonic neoplasm
   b. extrinsic mass such as multivisceral cancer
2. Extraluminal compression
   a. metastatic intra-abdominal disease
   b. retroperitoneal fibrosis
3. Stricture
   a. Diverticular stricture
   b. Crohn disease
   c. Radiation
4. Volvulus
   a. Sigmoid
   b. Cecal
5. Hernia
   a. Inguinal
   b. Ventral/incisional
   c. Internal
6. Intussusception
7. Hirschsprung disease
8. Luminal blockage
   a. foreign body
   b. bezoar
   c. fecal impaction
   d. gallstone
9. Nonmechanical obstruction
   a. Acute colonic pseudoobstruction
   b. Paralytic ileus
   c. Toxic megacolon

CLINICAL PRESENTATION

The symptoms of large bowel obstruction will vary depending on whether the obstruction is partial or complete, and acute versus chronic.

Acute Large Bowel Obstruction

Acute colonic obstruction can be rather dramatic in its presentation, particularly if associated with a closed loop obstruction. Individuals may present with obstipation of several hours to several days duration. This is

usually accompanied initially by colicky abdominal pain progressing to constant pain. On examination, varying degrees of abdominal distention may be present. Vomiting is uncommon but may be present in approximately one third of the patients. Peritoneal signs or signs of systemic toxicity including confusion, fever, chills, and hypotension are ominous finding suggesting colonic hypoperfusion or perforation.

Obstruction due to Colorectal Cancer

Colorectal carcinoma presents with acute intestinal obstruction in 7% to 30% of cases. The majority of colonic obstructions due to malignancy occur at the rectosigmoid junction where the luminal diameter of the bowel is the narrowest. Obstruction at the level of the sigmoid colon is also quite common, while obstruction at the cecum, and ascending and transverse colon typically occurs only when the mass has grown to a very large size. Most of the malignant lesions in the right and transverse colon tend to be diagnosed prior to the onset of obstructive symptoms as patients are likely to present with anemia or abdominal pain. Rectal cancers, though often large at the time of diagnosis, rarely present with symptoms of complete large bowel obstruction, instead causing symptoms of constipation, bleeding, and change in caliber of the stool.

Acute colonic volvulus most often involves the cecum or sigmoid colon as the colon rotates around its long mesentery; volvulus can also involve other segments such as the transverse colon but this is less commonly observed. Sigmoid volvulus, a condition most prevalent in West Africa and Middle East, commonly presents with constipation, abdominal pain, and occasionally vomiting. In the United States, sigmoid volvulus tends to occur in elderly patients with chronic constipation. In contrast, cecal volvulus generally occurs in younger individuals. The clinical presentation of cecal volvulus includes rapid onset of abdominal distention, pain, nausea, and vomiting. Massive bowel distention due to closed loop obstruction can lead to ischemia, perforation, and peritonitis. In the setting of suspected peritonitis, free intraperitoneal air, or sepsis, the patient should be taken to the operating room for urgent resection. Resection with colostomy is typically required in the setting of sigmoid volvulus with compromised bowel, whereas primary anastomosis is still often possible in this setting with a cecal volvulus.

In the patient without evidence of peritonitis, diagnostic workup usually includes plain abdominal x-rays and a computed tomography (CT) scan if necessary. CT imaging often demonstrates a characteristic whirl sign

where the bowel rotates around its mesenteric axis. In the absence of signs of bowel compromise, sigmoid volvulus should initially be treated with endoscopic detorsion and decompression. A rectal tube is subsequently placed for continued decompression of the previously twisted segment, to prevent recurrent volvulus and to prepare the patient for more elective resection. Cecal volvulus is generally addressed directly with right colon resection and anastomosis. Definitive operation, either right colectomy or sigmoid colectomy, is generally indicated during the same admission in order to avoid recurrence, reported to be as high as 86%, and alleviate the potential need for emergency surgery in the future. The decision of whether to perform an anastomosis or a Hartmann's in sigmoid volvulus should be individualized based on the patient's preoperative anal sphincter function, degree of disability, comorbidities, and overall prognosis.

Obstruction due to Intussusception

Patients with colonic intussusception present more commonly with melena or guaiac positive stool and less so with abdominal pain, nausea, or vomiting. CT scan is the most useful diagnostic test often demonstrating a target-shaped area of colon (target sign). Unlike the pediatric equivalent, almost all cases of adult colonic intussusceptions are caused by a pathologic condition that serves as a lead point, such as carcinomas, polyps, Meckel diverticulum, colonic diverticulum, strictures, or benign neoplasms. Malignancy is found in up to 65% of lead points of colonic intussusception. Surgical resection adhering to oncologic principles without reduction is the preferred treatment. Left-sided lesions typically approached in two stages with Hartman procedure and subsequent colostomy takedown. An anastomosis with or without diverting ostomy is a viable option and should be individualized based on intraoperative findings, status of the bowel, and overall patient condition.

Subacute/Chronic Large Bowel Obstruction

Chronic large bowel obstruction may develop over weeks and occasionally even months based on the slow progress of a stricturing process or slow-growing obstructing lesion. Symptoms of chronic bowel obstruction may be characterized as local or systemic. If the stricture is secondary to a neoplastic process, systemic symptoms may include unintended weight loss and anorexia. Obstruction secondary to an inflammatory process, such as seen in Crohn colitis, may include symptoms of general malaise, fever,

chills, or one of the extraintestinal manifestations that accompany the disease. Local symptoms will be similar regardless of the cause and include change in bowel habits, constipation, abdominal distention, lower abdominal pain, and in late stages vomiting with feculent smelling material (stercoraceous vomiting). In some cases, bowel obstruction may be intermittent, such as those associated with self-limited episodes of sigmoid or cecal volvulus.

Chronic Obstruction as a Result of Inflammatory Disease

Colonic obstruction from inflammation may be secondary to an active process (acute diverticulitis or Crohn disease) superimposed on preexisting fibrosis. Chronic colonic strictures may be the sequelae of prior episodes of diverticulitis, pelvic radiation, or a strictured bowel anastomosis. Generally these patients present with chronic constipation and partial obstructive symptoms. Under most circumstances, patient should undergo evaluation to rule out malignancy and subsequently undergo an elective resection. The patients with a limited life expectancy who may not be candidates for resection could be considered for a stent placement; however, stenting should not be viewed as a definitive long-term solution for most patients. A colostomy or ileostomy is always a viable option for those patients who cannot undergo resectional surgery.

Pseudoobstruction, Oglivie Syndrome

Patients with colonic pseudo-obstruction are commonly elderly and typically have a concomitant acute medical comorbidity or recent surgical intervention. Massive dilatation of large bowel can result in ischemia and if left untreated can lead to perforation, which in turn would necessitate urgent operative intervention. All potentially offending agents that reduce colonic motility such as narcotics and anticholinergics should be discontinued. After the causes of mechanical obstruction have been excluded, the patient can be treated with IV neostigmine in a monitored setting if there is no medical contraindication. The side effects of neostigmine include severe bradycardia with hypotension, nausea, vomiting, and bronchospasm. Colonoscopic decompression can also be performed; however this may be technically challenging in the setting of an unprepped bowel and may be associated with an increased risk of perforation. If all nonoperative measures fail to resolve symptoms and the colonic diameter suggests impending perforation, the patient may need to

undergo an operative intervention that could include tube cecostomy, or bowel resection with an intestinal stoma.

INDICATIONS AND CONTRAINDICATIONS

Indications for operative intervention in acute complete colonic obstruction are fairly straightforward. The patient needs to be resuscitated and plans for urgent intervention should be made. In the patients with chronic or partial obstruction, the decision to proceed with an intervention should be based on the severity and trajectory of symptoms over time. The patients with stable chronic colonic obstruction due to a postinflammatory stricture related to diverticulitis or Crohn disease may be well compensated and with properly adjusted bowel regimen may be able to attempt a trial of nonoperative management. Those patients presenting with frequent recurrent episodes of partial bowel obstruction should be considered for an operative intervention. The decision should be based on the patient's functional status, comorbidities including cardiac and pulmonary disease, and overall prognosis. Moreover, the surgeon should prepare and discuss alternative operative strategies in the event that the planned intervention cannot be safely carried out.

PREOPERATIVE PLANNING

A thoughtful diagnostic workup informs surgical decision making. Elucidating the likely cause of the obstruction and the degree of anatomic and physiologic derangement are usually the initial steps in the workup. A careful history with focus on an accurate account of any prior operations, medical comorbidities, and epidemiologic factors can often suggest a specific cause. Although rare, colonic obstruction could occur due to incarcerated inguinal or ventral/incisional hernia that can usually be diagnosed by an attentive physical examination. The presence of fever, tachycardia and peritoneal signs, or other signs suggestive of perforation, usually necessitate an urgent laparotomy.

Plain films of the abdomen will usually suggest the diagnosis of a large bowel obstruction and the most appropriate next step in imaging and/or management. For example, patients with classic radiologic findings of a sigmoid volvulus may be triaged directly to endoscopic decompression. CT evaluation of the abdomen and pelvis has emerged as the most effective diagnostic imaging modality for most patients and can be readily obtained through the emergency department. CT scanning provides for an

accurate diagnosis and can detect additional findings that can further guide the surgical management. Contrast enemas can also be useful in pinpointing the precise localization of the obstruction and determine whether the obstruction is partial or complete.

Surgical planning in the event of complete malignant obstruction depends on the viability of bowel, location of the obstruction, resectability of the tumor, and the overall goals of care. Careful deliberation, including the natural history of the disease, likely treatment options down the line (e.g., chemotherapy) with their potential consequences, patient values and goals, predicted functional outcomes, and available patient support systems, is critical to providing thoughtful, individualized, and expert care. Patients may either go straight to surgery or pursue nonsurgical palliative options. Nonsurgical therapy for malignant obstruction has evolved since the introduction of stents in 1991. Stents have been successfully applied as a bridge to surgery, providing a temporizing measure to allow for preoperative bowel preparation and correction of physiologic derangements. Stents may also enable single-stage resection with anastomosis as opposed to staged operations with an intestinal stoma or may be used as a definitive palliative measure in patients with advanced disease. Stenting by an experienced operator is successful in relieving the obstruction in greater than 90% of cases.

Most patients with malignant large bowel obstructions are treated with surgery. Right-sided lesions are usually best managed with a single-stage colectomy and primary ileocolic anastomosis. Left-sided lesions historically have been approached with a two- or three-staged procedure. Traditional options include preliminary transverse colostomy to avoid acute cecal perforation based on the law of Laplace, followed later by resection of the tumor with primary anastomosis and ultimately closure of the transverse colostomy. This option is seldom necessary or appropriate with the modern armamentarium of treatment options. A Hartmann procedure with resection of tumor and end colostomy followed later by colostomy takedown is another long-standing approach that continues to play a prominent role. Selected patients with left-sided colonic obstruction may be managed with a single-stage procedure (with or without on table colonic lavage) with acceptably low rates of anastomotic and other complications. Obstructions proximal to the sigmoid can usually be managed by subtotal colectomy with ileocolic anastomosis. Synchronous tumors have been found in up to 11% of patients, and most patients would

prefer a single operation without the need for a temporary stoma provided that the functional outcome is acceptable. The role of primary ileorectal anastomosis for obstructing sigmoid lesions is more controversial and requires a more cautious assessment. The addition of on table lavage may be onerous and is probably unnecessary. The decision to perform a protective ileostomy to decrease the chance of anastomotic complications must be individualized based on the specific circumstances.

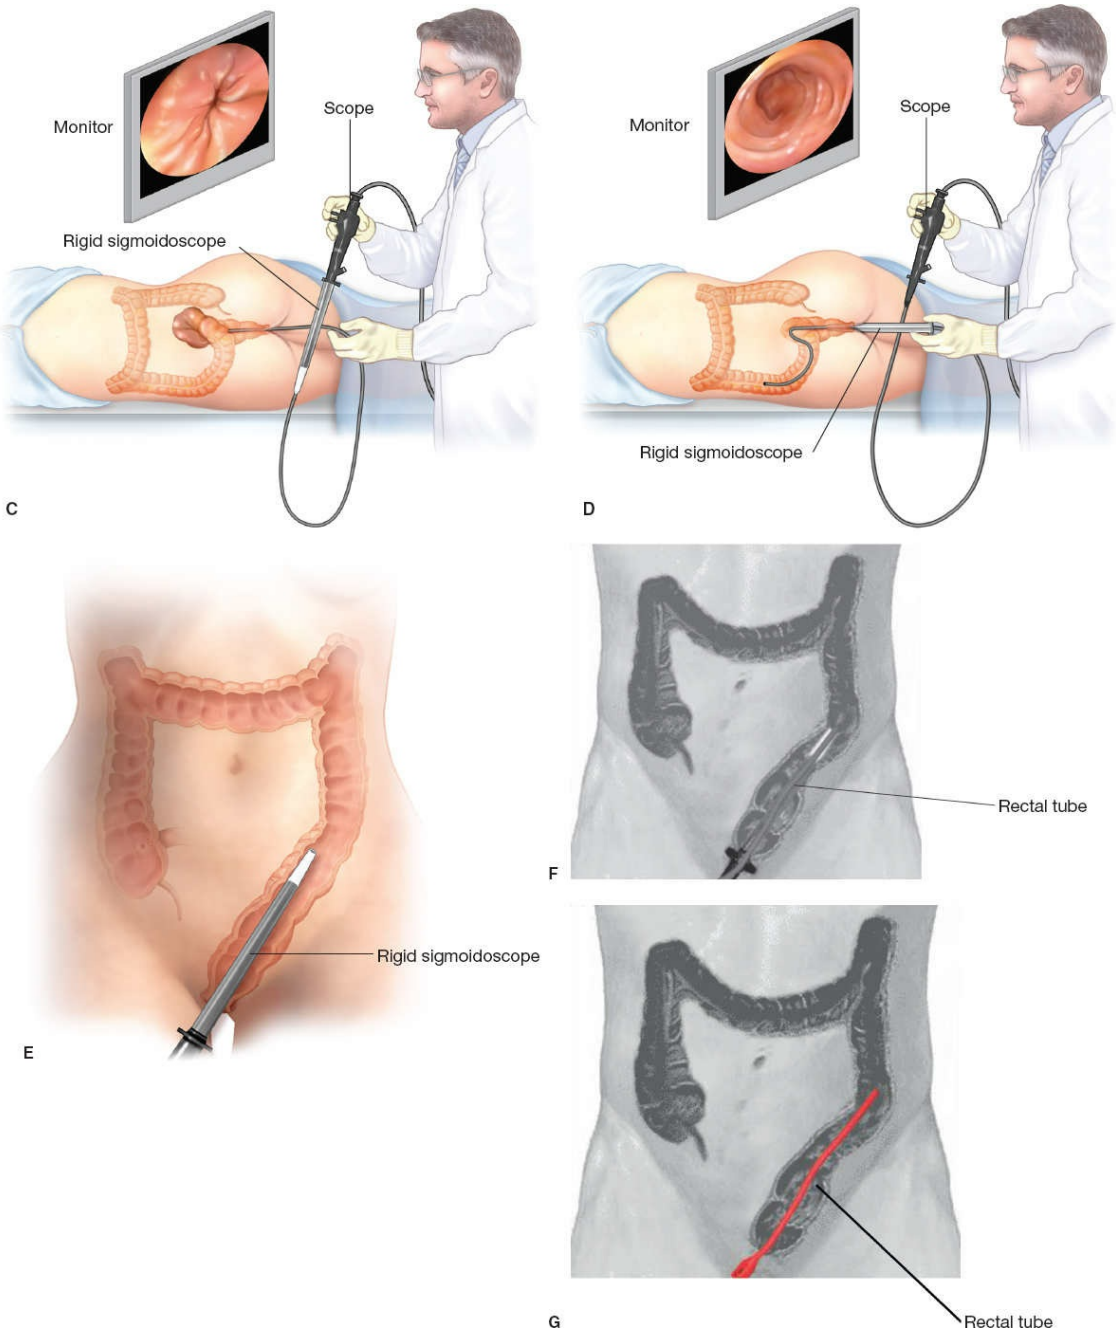

Figure 143.1. A. Flexible and rigid sigmoidoscope equipment. **B.** Rigid sigmoidoscope loaded over flexible sigmoidoscope. **C.** Volvulus detorsed with flexible sigmoidoscope. **D.** Well-lubricated rigid sigmoidoscope advanced into sigmoid colon over flexible sigmoidoscope using Seldinger technique. **E.** Flexible sigmoidoscope is withdrawn while rigid sigmoidoscope is kept in sigmoid colon. **F.** Rectal tube placed into sigmoid colon through rigid sigmoidoscope. **G.** Rigid sigmoidoscope is withdrawn while rectal tube is kept in place and secured to buttocks.

If complete resection cannot be achieved either due to the involvement

of vital organs or widely metastatic disease, a palliative diversion rather than formal resection should be considered. The patient's condition, expected patient survival, burden of disease, and other comorbidities should be taken into account, especially when approaching elderly or frail patients with a limited life expectancy. The goal in these individuals is to address the immediate problem with as little risk of morbidity and mortality as possible while relieving the large intestinal obstruction.

The operative planning for individuals with chronic or partial large bowel obstruction may proceed in a more deliberate fashion, with the degree of obstruction and its progression taken into consideration. In most instances, patients with a partial large bowel obstruction are suitable for primary anastomosis.

SURGICAL TECHNIQUE

The aim of this section is to address the unique technical aspects of management of acute colonic obstruction.

Technique of Colonic Decompression in Sigmoid Volvulus

Colon detorsion in sigmoid volvulus can be accomplished with either rigid or flexible sigmoidoscope. The goals of this maneuver, regardless of the choice of the instrument, are to (1) relieve obstruction due to volvulus, (2) prevent re-volvulization, and (3) allow time for bowel preparation prior to surgery. While the rigid sigmoidoscope provides a wide lumen that would accept a large size decompressive tube, its length may not be quite sufficient to traverse the "whirl" of the volvulus. The surgeon may visualize the "whirl" but it seems to be pushing away as the tip of the rigid sigmoidoscope is advancing. The flexible sigmoidoscope allows for better maneuverability and reliably provides sufficient length to traverse the obstruction. Upon entry into the proximal segment, one encounters a large cavernous lumen of massively distended sigmoid colon. Following endoscopic detorsion, it is common practice to leave a rectal tube, which may be threaded through the working (suction) channel of the sigmoidoscope. The caliber of the rectal tube, however, is limited by the inner diameter of the working channel of the scope. Such small caliber tubes are often not very effective at decompressing and maintaining the "floppy" sigmoid colon in its proper orientation.

A technique combining the benefits of rigid sigmoidoscope with the reach and maneuverability of flexible sigmoidoscope is shown in Figure

143.1. Step 1 (Fig. 143.1A,B): Prior to insertion of the flexible sigmoidoscope, a rigid sigmoidoscope without the attached light source is loaded onto the flexible scope and advanced as far back as possible toward the controls. Step 2 (Fig. 143.1C): Flexible sigmoidoscopy is performed to detorse the colon. Step 3 (Fig. 143.1D): The well-lubricated rigid scope is carefully advanced over the flexible sigmoidoscope, which essentially acts as a guide wire, into the more proximal sigmoid colon. After decompression the colon shortens and the length of the rigid sigmoidoscope is now sufficient to traverse the point of volvulization. Step 4 (Fig. 143.1E): The flexible sigmoidoscope is withdrawn while the rigid sigmoidoscope remains in place. Step 5 (Fig. 143.1F): A large caliber rectal tube can now be placed through the lumen of the rigid sigmoidoscope. Step 6 (Fig. 143.1G): The rigid sigmoidoscope is withdrawn while maintaining the rectal tube in position. The rectal tube is secured to the perianal region with tape or suture and connected to a drainage bag.

Technique of Colon Decompression With Self-Expanding Metallic Stent (SEMS)

Successful preoperative insertion of a self-expanding the metallic stent (SEMS) eliminates the need for a high-risk emergency surgery and may allow elective surgery to proceed in a planned, deliberate fashion following careful preoperative planning and bowel preparation. The first description of endoscopic placement of prosthesis for colorectal disease was by Dohmoto for palliation of rectal cancer using a rigid Celestin tube. Subsequently, Spinelli in 1992 reported endoscopic placement of a self-expandable metal stent for treatment of a malignant rectal obstruction. Since then, there have been numerous publications on the use of SEMS for management of malignant colonic obstruction. There are a variety of SEMS specifically designed for colonic use. Most of the modern SEMS are delivered through the therapeutic channel of the endoscope. The commercially available self-expanding stents for colonic use in United States are uncovered and have various degrees of shortening during deployment. The stent diameter varies between 20 and 30 mm after deployment. Patients with incomplete obstructions who have a lumen wide enough to admit a therapeutic colonoscope are unlikely to benefit from stent placement as this is associated with high rate of migration. Most through-the-scope (TTS) stents insertion is enabled by fluoroscopic

guidance.

Endoscopic colonic stent placement is technically challenging and should be performed by an experienced practitioner, often with previous experience in placement stents in other areas of the gastrointestinal tract such as the esophagus or biliary tree. Patients with colonic obstruction may be clinically ill and unable to tolerate prolonged procedures. The potential for perforation and intraperitoneal spillage of fecal content is a risk that needs to be discussed with the patient and the family prior to the procedure and steps taken to minimize this complication, particularly avoiding dilatation of the stricture. The success rate of the stent placement can be negatively affected by use in a longer stricture, angulation, or challenging anatomy. Distal location of the obstructing lesion is usually more favorable for successful stent placement compared to location within a tortuous segment of sigmoid colon or around the splenic flexure. However, there must be ample room to “seat’ the distal end of the stent far enough above the anal canal to avoid unacceptable local side effects.

The steps involved in the TTS colonic SEMS placement:

1. Adequate endoscopic visualization is critical in allowing optimal stent placement. While formal bowel preparation is not possible in cases of complete obstruction, an enema to clear the distal bowel is required. In those patients who continue to pass colonic contents owing to a partial obstruction, a judicious bowel prep can be attempted. The procedure can be initiated with the patient in the left lateral decubitus position; however, supine position allows for better fluoroscopic imaging and is often preferred. The endoscope is passed to the site of the obstruction. In patients who present with complete obstruction, consideration should be given to use carbon dioxide instead of room air for insufflation; when air is used, the least possible amount should be insufflated to avoid overdistention of the proximal bowel.

   The choice of an endoscope (upper endoscope vs. colonoscope) can be tailored to the location of the lesion; for distal colonic lesions, it is preferable to use an upper endoscope so that the stent can be passed through the working channel. A smaller diameter endoscope that is more flexible can be used to deploy a guidewire that can be left in place. A more rigid therapeutic endoscope can then be advanced over wire loaded through its therapeutic channel. Occasionally, highly trained endoscopists use a side viewing endoscope to allow the guidewire to be deployed through a sharply angulated and obstructing

lesion in the distal colon. The stricture can be further visualized using fluoroscopic contrast injection. Contrast can be injected directly through the working channel of the endoscope to delineate the stricture. However, in the cases of complete obstruction, the contrast may fail to enter the stricture. In such circumstances, the biliary stone retrieval balloon inflated to a large diameter (15 mm) can be advanced and placed against the lesion (Fig. 143.2), enabling contrast material to delineate the stricture.

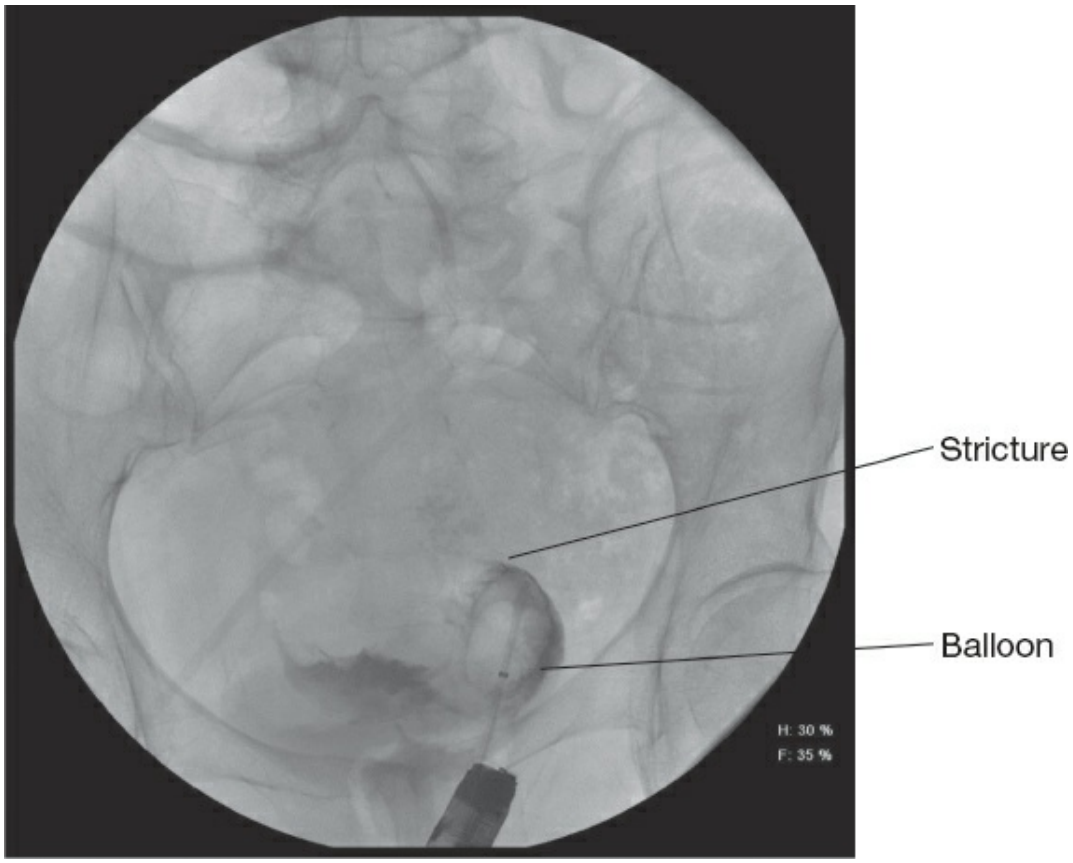

Figure 143.2. Stricture visualization with fluoroscopic contrast injection. Balloon inflated to a large diameter is placed against the lesion. Contrast material is injected through the stricture. (Image courtesy of Andres Gelrud, MD, MMSc Associate Professor of Medicine, University of Chicago.)

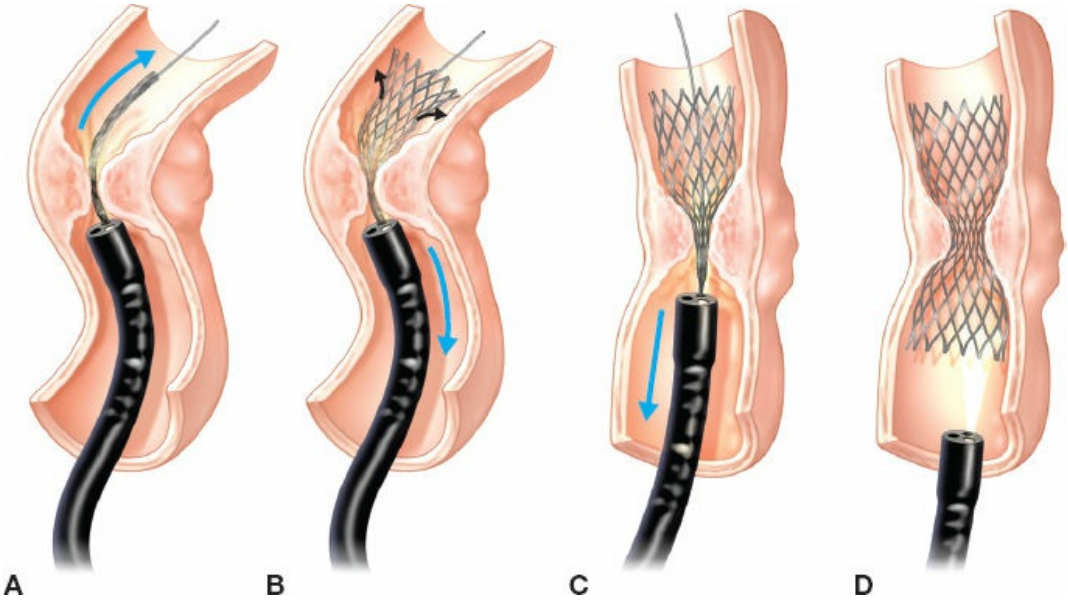

Figure 143.3. A–D. Technique of colon decompression with self-expanding metallic stent (SEMS).

2. The obstruction is then traversed with the guidewire (Fig. 143.3A). Passage of a guidewire is often a rate-limiting step to successful SEMS placement. In the patient with complete obstruction, the technique for traversing a stricture and stent placements is similar to the techniques used during endoscopic retrograde cholangiopancreatography (ERCP); surgeons who have ERCP experience typically have familiarity with appropriate accessories, catheters, and fluoroscopy. Hydrophilic biliary guide wires (e.g., Navipro, BostonScientific, Natick, MAorTerumoGlidewire, and TerumoMedicalCorporation, Somerset, NJ) can be helpful in traversing the lesion (Fig. 143.4A,B). For lesions located at the splenic flexure or with severe angulation, use of the clear cap on the tip of the endoscope similar to the one used during endoscopic mucosal resection may enable a better view.
3. Based on the fluoroscopic imaging, the length of the stent should be determined. The suitable length of the stent should be sufficient to bridge the stricture and extend at least 2 cm on each side of the lesion both proximally and distally. The predeployed stent is advanced through the working channel of the endoscope and position across the lesion (Fig. 143.3B). The stent is then deployed by withdrawing the constraining sheath or unraveling the string, depending on the device used (Fig. 143.3C). The TTS SEMS are deployed from the proximal (oral) end. The surgeon must anticipate some shortening of the stent particularly as it moves away from the scope while the sheaths are withdrawn (Fig. 143.5A,B). Following successful placement of the

stent, flow of fecal material can be observed and correct position can be confirmed by demonstrating a “waist” within the stent (Fig. 143.3D). If the “waist” appears to be very narrow, careful balloon dilatation can aid in stent expansion, but such a maneuver may increase the risk of perforation and should be considered carefully.

The non-TTS SEMS are used less frequently and usually can be deployed with the help of a smaller caliber endoscope. This stent placement requires a stiff guidewire (Savary, CookMedical, Bloomington, IN, or Amplatzwire, BostonScientific) on which the stent is being deployed through the entire length of insertion, since the support of the endoscope is not present. The endoscope is usually utilized to follow the deployment of the stent alongside the guidewire, as the stent is being inserted.

Colonic stenting as a bridge to surgery is designed to allow temporary decompression of the colon, reduce its proximal diameter, and to allow bowel preparation in order to facilitate a one-stage procedure with primary anastomosis. In order to promote decompression after successful stent deployment, a colonic drainage tube can be left across the stent if the immediate passage of stool through the stent is not noted at the time stent deployment. The timing of surgical intervention varies, but often occurs within 2 weeks when the stent is intended as a bridge to definitive surgery, to avoid the risk of stent migration. Perforation is the most severe complication of colonic SEMS, occurring in 3.8% to 10% of patients. Predeployment dilation has been associated with an increased risk of perforation and hence is discouraged. Other potential factors contributing to perforation include puncture of the colonic wall during guidewire passage, erosion of the colonic wall by free wires at the end of the stent, and administration of bevacizumab-based chemotherapy regimens. Stent migration and obstruction are generally delayed complications reported in 10% to 11.8% and 7.3% to 10% of patients, respectively.

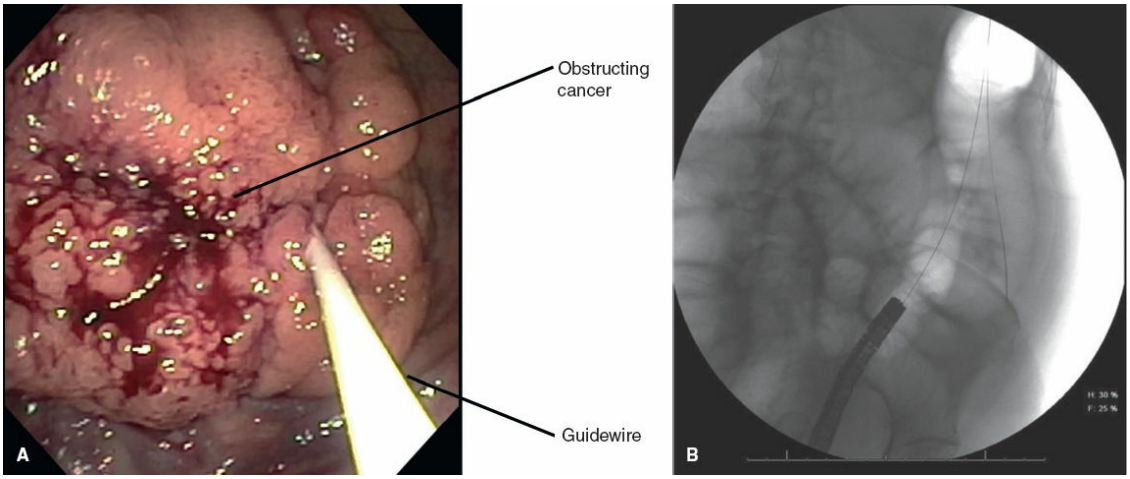

Figure 143.4. A, B. Traversing malignant obstruction with guidewire. (Images courtesy of Andres Gelrud, MD, MMSc Associate Professor of Medicine University of Chicago.)

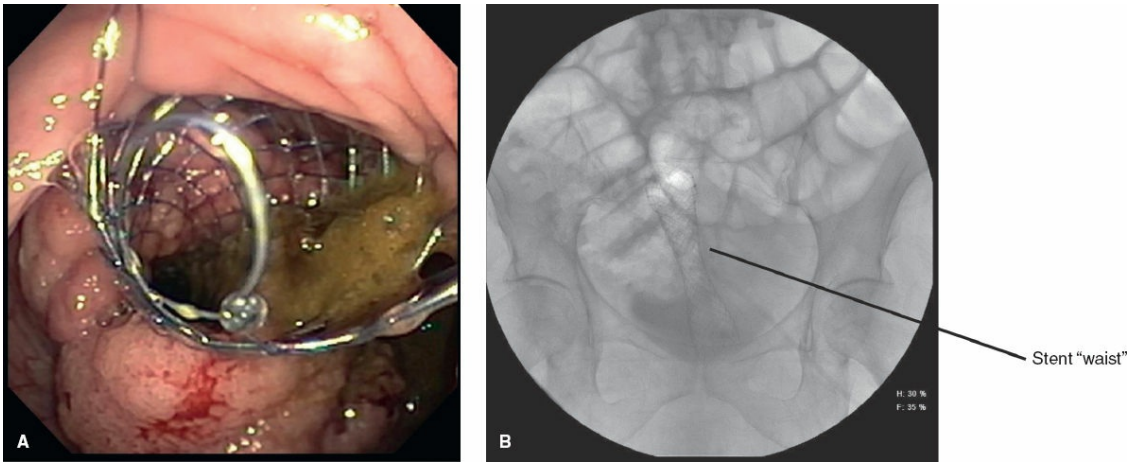

Figure 143.5. A, B. Colonic stent deployed. (Images courtesy of Andres Gelrud, MD, MMSc Associate Professor of Medicine, University of Chicago.)

Stent placement low in the rectum can lead to severe tenesmus. One study of 44 patients that provided long-term follow-up reported a complication rate of 51%, which included stent migration in 22%, obstruction 17%, perforation 7%, and tenesmus in 5%. Colonic stent placement for luminal obstruction secondary to extrinsic lesions is associated with a low success rate including a rate of stent migration of 13% of patients in one study.

The bridge to surgery strategy with the SEMS is currently becoming a more commonly considered initial treatment option for malignant large bowel obstruction. Initial concerns about suboptimal oncologic outcomes due to risk of perforation or tumor dissemination have been addressed in

multiple studies and summarized in a recent meta-analysis. Even though there are no randomized controlled trials validating the efficacy and safety of SEMS as a bridge to surgery (most of the studies were closed prematurely due to the high rates of complications related to SEMS), the wealth of clinical data seems to point toward a reasonable degree of safety and efficacy with stents in appropriately selected patients.

The role of a stent as definitive management of a large bowel obstruction in the palliative setting is probably far more controversial and problematic. From the functional standpoint, stents do usually resolve the "crisis" of an acute large bowel obstruction. However, the tumor-laden segment tends to act as a "functional" obstruction, and patients commonly suffer from symptoms of a low-grade, chronic large bowel obstruction. Quality of life is often superior with a diverting colostomy. Furthermore, the long-term risk of migration, re-obstruction, and perforation should not be underestimated.

Ontable Colonic Lavage With Segmental Colectomy and Primary Anastomosis

Intraoperative colonic irrigation, with or without ontable colonoscopy, can be a useful alternative if stenting is unavailable or unsuccessful. Intraoperative lavage allows for decompression of the proximal colon and provides an opportunity to evaluate the colon for synchronous lesions if desired (e.g., suspicion is raised on preoperative imaging). Successful colonic lavage can be followed by primary anastomosis with or without a diverting ileostomy. Colonic irrigation may be performed in an antegrade fashion by using the appendiceal lumen (Fig. 143.6). This is carried out by inserting a large bore Foley catheter into the cecum through an appendicostomy or distal ileal enterotomy secured with a purse-string suture. The ileal enterotomy may be later used to construct a loop ileostomy if desired. The Foley catheter is connected to a large bag of warm saline solution and infused by gravity. A large corrugated tube, such as anesthesia ventilator tubing, is then placed in the open end of the descending colon proximal to the obstruction and secured with an umbilical tape or a suture to the bowel wall. The other end of the tubing is placed into a bucket on the floor where the effluent is collected. It may be necessary to manually propel solid stool toward the distal end; this maneuver may require mobilization of the flexures and can be cumbersome in dilated, obstructed bowel.

A proximal stoma diversion in addition to a colorectal anastomosis may be a prudent adjunct to the operative procedure. Although relatively high rates of surgical site infections have been reported with this technique, contamination can be minimized with careful technique with a correspondingly lower rate of wound infection. The procedure takes a motivated operating room team and requires thoughtful planning; some surgeons find on table lavage burdensome and unnecessary.

Resection With End Colostomy (Hartmann Procedure)

Preoperative marking, optimally performed by an enterostomal therapy nurse, reduces stoma-related complications and improves patient quality of life for those patients in whom a stoma is being considered. Managing the ostomy is facilitated by appropriate stoma location and construction, and can make the difference between discharge to home versus discharge to a nursing facility based on the ability of the patients to provide independent care of their new ostomy.

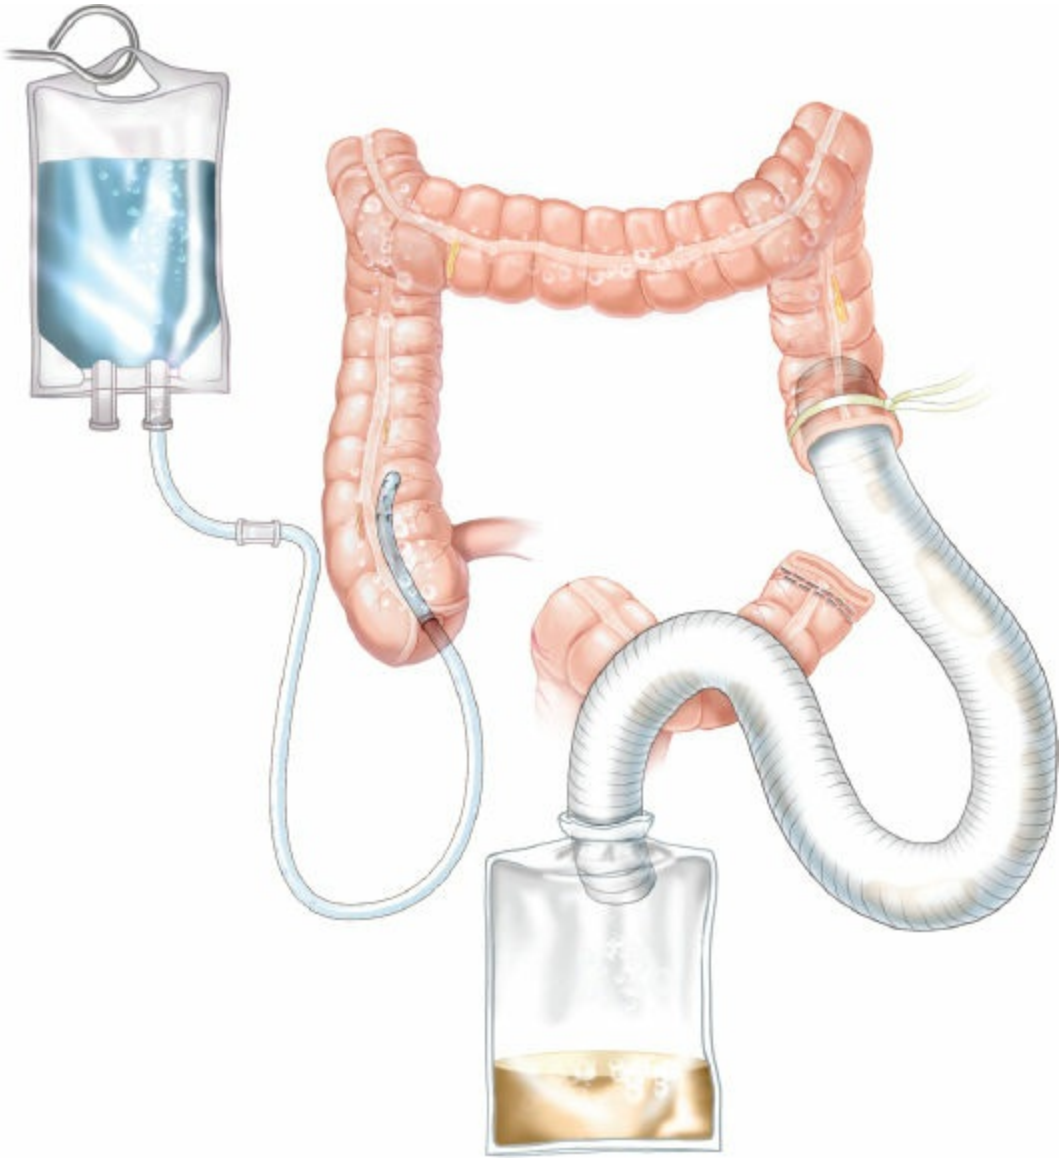

Figure 143.6. On table colonic lavage setup.

While the technical aspects of the Hartmann procedure are well known to most surgeons and are outlined elsewhere in the book, there are certain unique aspects of operating on the massively dilated colon that are worth mentioning in this chapter. Upon laparotomy, the surgeon is often confronted with a markedly dilated colon that occupies the entire operative field and can be exceedingly difficult to manage. Performing a colectomy while handling distended bowel may be fraught with the risk of inadvertent perforation with massive spillage and contamination. The colon may be preemptively decompressed by inserting a Foley catheter through a small opening secured with a purse string at the site of the proposed bowel transection (Fig. 143.7). While the catheter might be insufficient to remove the solid fecal material, it may be sufficient to

decompress some of the air and liquid stool within the colon and decrease the associated distention.

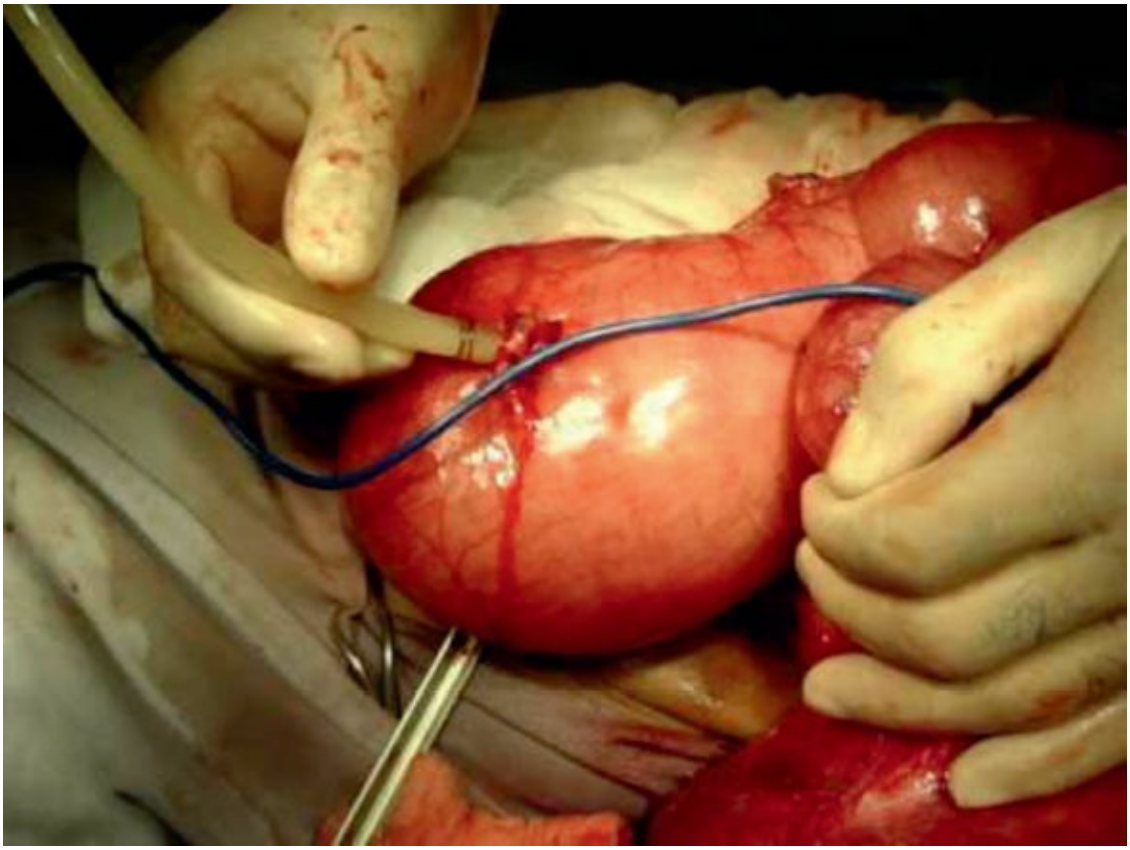

Figure 143.7. Intraoperative colon decompression.

After resection of the affected segment is performed, the distal end of the large intestine should be tacked to the lateral peritoneum and marked with nonabsorbable sutures for identification during the second stage procedure, when colostomy reversal is performed.

In the case of obstructed bowel and a locally advanced malignancy, an optimal oncologic resection may simply not be possible at initial presentation. In this setting, the patient's chance for long-term cure should not be compromised by an ill-fated procedure. It is far preferable to come back another day when the colon is not massively distended, the patient is not physiologically challenged, and appropriate colleagues and specialists are available. If tumor resection cannot be accomplished, a simple loop stoma proximal to the obstructing neoplasm without tumor manipulation represents sound and mature surgical judgment; alternatively, an end colostomy with mucus fistula either through the same site (end-loop colostomy) or through a separate site (Fig. 143.8) may be fashioned. The

opening in the fascia for colostomy construction should be made sufficiently large to admit dilated and thickened colon and its mesentery. Failure to do that may result in stoma congestion or even ischemia leading to complications ranging from delay of ostomy function to frank necrosis requiring colostomy revision.

Loop Colostomy

The technique of construction of a diverting loop colostomy is covered elsewhere in this textbook. A loop colostomy is considered in the setting where a limited palliative operation or a temporizing procedure needs to be performed in a patient who is otherwise deemed not a candidate for a more extensive procedure as described above. Construction of loop colostomy in the setting of a large bowel obstruction often results in an extremely large and difficult-to-manage ostomy that is prone to prolapse, especially if transverse or ascending colon is used. As a result, these types of colostomies often result in poor patient satisfaction.

Loop Ileostomy

Loop ileostomy may be an alternative to diverting colostomy; in many cases of large bowel obstruction, the small bowel maintains its relatively normal caliber if the ileocecal remains relatively competent. Even in the face of a massively dilated colon, the distal small bowel can be identified and brought up as a loop ileostomy. In most instances, colonic distension decreases following ileostomy construction. Colonic decompression can be further facilitated by aspiration and gentle antegrade irrigation of the colon by placing a catheter into the distal end of the loop ileostomy. Similar to a loop colostomy, this approach should be used in the setting where a more extensive operation cannot be performed, or a stent as a bridge to surgery is not possible. In expert hands, laparoscopic loop ileostomy can performed in the patient with even moderate colonic dilatation as long as insufflation and a working space can be established.

POSTOPERATIVE CARE

Postoperative care should be tailored to the procedure that was performed. The patients who underwent successful SEMS placement should be monitored for signs of perforation with serial abdominal exams. Gentle bowel preparation with polyethylene glycol or similar agent could be performed if the patient is actively passing stool. If the patients do not have the desired therapeutic effect, they may be candidates for repeat stenting if the stent has migrated or is otherwise inadequately positioned. In patients in whom a colostomy was constructed, postoperative care should be focused on stoma teaching preferably by a skilled enterostomal therapy nurse. The challenges of managing a new, unexpected ostomy constructed in the face of an acute large bowel obstruction may be exacerbated by the large size of the obstructed bowel that can be difficult to pouch and may have copious output.

COMPLICATIONS AND THEIR MANAGEMENT

Stent-related perforation and migration are the two most worrisome common complications associated with stenting, with reported rates of 2% to 5% and 49%, respectively. Patients may experience transient abdominal pain and bleeding per rectum. Perforations can occur immediately during

or after the procedure but can be delayed, especially when a large-caliber stent with high radial force is used. Perforations are more likely to occur in the sigmoid colon, where angulation and redundancy make stent deployment more technically challenging. In a systematic review, Cirocchi and colleagues reported perforation rates similar to what was described above, but also noted that two of the randomized controlled trials were prematurely discontinued because of high rates of perforation.

Several factors have been associated with a high risk of perforation; patient-related factors include previous radiation therapy, certain types of chemotherapy, and procedural factors such as predilation with a balloon before stent deployment. Radiation therapy appears to predispose to stent-related perforation; however, the data to support this observation are limited. Use of the angiogenesis inhibitor bevacizumab may be associated with an increased risk of post stent perforation.

Stent migration tends to occur within the first 5 to 7 days after stent placement. Factors that contribute to stent migration include suboptimal length of the stent, small caliber stents relative to the diameter of the lumen, and nonobstructing lesions. Stents used for benign strictures are associated with unacceptably high rate of migration (63%). Stent failure is defined as the inability of the stents to restore luminal patency and may occur immediately after stent placement or in a delayed manner after tumor recurrence or progressive growth. Immediate stent failure may be related to technical errors or a mismatch between stent length and stricture length. The rate of immediate stent failure has been reported to be as high as 12% in the postprocedural period; the most common reason is a very tight “waist” in the stent. Stent occlusion after a period of clinical improvement denotes late recurrence of obstruction and may be caused by tumor ingrowth resulting in luminal compromise. Endoscopic intervention often involves placing another stent through the original stent or restoring luminal patency by tissue ablation, often by argon plasma calculation or less commonly by tumor debulking with a laser. In general, experienced endoscopists are able to achieve a rate of technical success higher than 90% and a low rate of procedure-related complications.

OUTCOMES

Emergency surgery remains the most reliable intervention to relieve colonic obstruction, and is effective in 99% of cases. As noted earlier, colonic stenting as a bridge to elective surgery has emerged as an attractive

alternative to emergency surgery in recent years. However, there are no significant differences in 30-day mortality between emergency surgery and colonic stenting group. A recent meta-analysis by Cirocchi and colleagues reported the overall complication rate to be similar: 48.5% in the colonic stent group as compared with 51% in the emergency surgery group. The rate of primary anastomosis was significantly higher following stent placement (65%) compared with the emergency group (55%), and the overall stoma rate was significantly lower in patients who underwent stent placement (45%) compared with emergency surgery (62%); however, the risk of a permanent stoma appears to be similar between the two groups (46.7% vs. 51.8%, respectively). The anastomotic leak rate appeared to be similar between the groups (9% in the stent group and 3.7% in the surgical group), although the authors did not report whether a diverting stoma was constructed at the time of anastomosis. There was no significant difference in the risk of an intra-abdominal abscess or wound infection.

The bulk of experience with stents in the colon has been in the relief of left-sided colonic obstruction. Published reports have demonstrated success rate that ranges from 66% to 100% with a median of 94% and clinical success rate that ranges from 55% to 100% with a median of 91% in the patients undergoing colonic stenting for a palliative indication. In one study, a group of 39 patients with acute left-sided malignant colonic obstruction were randomly assigned to undergo stenting, followed by elective colonic resection, or to immediate surgery. The authors noted no difference in mortality; however, there were significantly less surgical complications in the group who underwent stenting. The number of days spent in the intensive care was also significantly less in the stent recipients. Stent migration occurred in 11% of patients, and approximately 20% of patients require an intervention to reestablish luminal patency. It has been reported that the duration of luminal patency after colonic stent placement can range from 68 to 288 days with a median of the 160 days. The wide range of outcomes highlights the heterogeneity of outcomes in the studies and should be taken into account during preoperative planning and patient counseling.

EDITOR'S COMMENT

In their chapter, Drs. Hyman and Umanskiy provide a good overview of a very common clinical problem, namely management of the patient with large bowel obstruction. Differential diagnosis of such patients can often be challenging, and establishing the correct diagnosis, in other words, differentiating malignant from benign obstruction, is very important with respect to determining the urgency with which to proceed, as well as the goals of the operation. One aspect the authors may not have stressed enough is the increasing frequency of patients under the age of 50 who are being diagnosed with colorectal cancer. Because of this, even in a young patient, one should keep in mind that a large bowel obstruction may be due to malignancy. In our hospitals, it seems that one has to only walk or to be transported across the threshold in a stretcher and one already has undergone a CT scan! Because of this, it is currently easier to establish a diagnosis of volvulus than it once was, when the only diagnostic imaging one had was a plain film of the abdomen. The characteristic signs of volvulus seen on a plain film are not always as characteristic as one would like.

It is always easier to construct an anastomosis at the primary operation, even though one may not wish to do so, than to come back at another sitting to a pelvis that may have significant adhesions and inflammation to do a colorectal anastomosis at another later date. As with all operations for large bowel obstruction, the question of whether or not to divert, in my opinion, is

determined by the resiliency of the patient. In other words, if the patient could tolerate the infectious sequelae if the patient would suffer an anastomotic leak, then if the surgeon deems it prudent and if the circumstances warrant doing a primary anastomosis without diversion, then I believe that it is justified. If, however, the patient's physiologic status is such that they could not withstand the sequelae of an anastomotic leak, if it occurred, then the patient should be diverted. As the authors nicely outline in their chapter, in most cases a loop ileostomy is a preferred diversion. It is easy to construct even in the very obese individual; it is a much more manageable stoma than a transverse loop colostomy and it is easier to close.

In their discussion of colonic stenting as a "bridge to surgery," the authors do mention the controversy regarding stenting patients with colorectal cancer and a possible adverse effect on outcome. There have been several papers that suggest that stents may lead to tumor microperforation and a worse prognosis with respect to the colorectal cancer itself. Kim and colleagues found that there was no difference between the stenting as a bridge to surgery and surgery alone groups with respect to 3-year overall and recurrence free survival (Kim SJ, Kim HW, Park SB, et al. Colonic perforation either during or after stent insertion as a bridge to surgery for malignant colorectal obstruction increases the risk of peritoneal seeding. *Surg Endosc* 2015;29(12):3499–506). However, there was an odds ratio of 46 for seeded metastasis if perforation occurred either during or after stent placement (95% CI 2.0 to 1,047, $p = 0.016$) (Kim SJ, Kim HW, Park SB, et al. Colonic perforation either during or after stent insertion as a bridge to surgery for malignant colorectal obstruction increases the risk of peritoneal seeding. *Surg Endosc* 2015;29(12):3499–506). There has recently been much debate as to whether or not this should be used for patients who are good operative candidates and who have curable cancers. Some publications report no difference in oncologic outcome and report higher rates of laparoscopy with lower conversion rates and lower rates of wound infection (Park SJ, Lee KY, Kwon SH, et al. Stenting as a bridge to surgery for obstructive colon cancer: does it have surgical merit or oncologic demerit? *Ann Surg Oncol* 2016;23(3):842–8). I refer readers, however, to the very extensive and authoritative *Clinical Guidelines* of the European Society of Gastrointestinal Endoscopy (van Hooft JE, van Halsema EE, Vanbiervliet G, et al.; European Society of Gastrointestinal Endoscopy [ESGE]. Self-expandable metal stents for obstructing colonic and extracolonic cancer: European Society of Gastrointestinal Endoscopy [ESGE] Clinical Guideline. *Gastrointest Endosc* 2014;80(5):747–61.e1–75). These guidelines have also been endorsed by the American Society of Gastrointestinal Endoscopists (ASGE). The main points of these thorough, very carefully prepared guidelines are as follows:

- Prophylactic colonic stent placement is not recommended for patients without obstructive symptoms
- Stent placement as a "bridge-to-elective-surgery" is not recommended as a

standard treatment for malignant obstruction due to left-sided colon cancer

- Colonic stents may be used as an alternative to emergent surgery in individuals with a high risk for postoperative death (e.g., patients with American Society of Anesthesiologists [ASA] physical status ≥III and or age ≥70 years)
- Colonic stent placement is the preferred palliative treatment for malignant obstruction except for patients treated with anti-angiogenic agents (e.g., bevacizumab)

These Clinical Guidelines (van Hooft JE, van Halsema EE, Vanbiervliet G, et al.; European Society of Gastrointestinal Endoscopy [ESGE. Self-expandable metal stents for obstructing colonic and extracolonic cancer: European Society of Gastrointestinal Endoscopy [ESGE] Clinical Guideline. *Gastrointest Endosc* 2014;80(5):747–61.e1–75) also clearly state that the outcomes with stenting *extra*-colonic cancer are inferior to those obtained for colonic cancer. Some of these statements have to be taken with caution. In one large multicenter study, it was exactly the ASA ≥III and patients >70 years of age in whom stenting was less likely to be successful (Geraghty J, Sarkar S, Cox T, et al. Management of large bowel obstruction with self-expanding metal stents. A multicentre retrospective study of factors determining outcome. *Colorectal Dis* 2014;16(6):476–83).

The technique of intraoperative colonic lavage has fallen out of favor, largely because it is time-consuming and it adds an additional 45 minutes to an operation. Many have advocated performing this after an operation has concluded, through the efferent limb of a loop ileostomy and through the anastomosis. This is done by inserting an irrigating catheter (such as a large bore Foley) through the efferent limb of the loop ileostomy, and connecting this to a warming 3-liter bag of fluid as would be used for a cystoscopy, and inserting a rigid proctoscope through the constructed colorectal anastomosis and letting the lavaged stool run exit out of the body through the proctoscope into a waste receptacle. There are several reasons for performing a colonic washout. The main reason is to avoid leaving an entire column of stool in a colon that has been diverted especially when constructing a primary anastomosis, i.e., having less stool in the vicinity of the anastomosis. Either method of lavage works, but again they both are time-consuming. Although surgery for large bowel obstruction due to diverticular disease is handled in much greater detail in Dr. Roberts' excellent chapter on diverticular disease (Chapter 149), of importance here is that when operating on patients for large bowel obstruction, there is no need to do extensive surgery for diverticular disease, and the most common mistake that surgeons perform is that they go too low down into the pelvis. Diverticular disease is a disease of the sigmoid colon. Unless there is a fistula to the rectum or some other infection or fistula extending to the pelvis, the rectum does not have to be resected with sigmoid diverticular disease. The proximal margin is determined solely by where the bowel is palpably normal and no

longer affected with the muscular hypertrophy, which characterizes the diverticular disease.

With respect to large bowel obstruction arising in the setting of Crohn disease, as has been discussed in the chapter on colonic Crohn disease by Dr. Fichera (Chapter 150), there is a controversy as to which operation is best. However, the recurrence rates are generally lower with total colectomy than with segmental resection. In the acute setting, however, medical therapy with steroids (hydrocortisone 100 mg intravenously every 6 hours) may result in relief of the obstruction so that an elective operation can be planned and the patient appropriately counseled about all surgical options. Of importance, as has been emphasized in nearly every chapter in this section, *preoperative marking of stoma sites is essential*, even in the emergency cases. This avoids undue morbidity secondary to poor stoma siting, which can also lead to significant amount of added expenses for the patient.

Susan Galandiuk

144 Surgical Treatment of Colonic and Perianal Crohn Disease

Linda Ferrari, Erin O. Lange, Mukta Krane, Fabrizio Michelassi, and Alessandro Fichera

Crohn disease (CD) is a chronic transmural inflammatory process that can affect the entire gastrointestinal tract. Colonic involvement has been observed in 30% of patients and can affect an isolated segment or the entire colon as pancolitis. Crohn colitis may be seen in isolation or, more commonly, in conjunction with small bowel and/or perianal disease. While Crohn colitis is often successfully treated with medical therapy, one third of patients will undergo surgery and up to 25% will require permanent fecal diversion within 10 years from the initial diagnosis.

Perianal CD is a unique phenotype associated with earlier age of onset, more severe luminal disease, and colonic and rectal involvement. About 30% to 70% of CD patients have anal involvement, ranging from minor skin tags to complex fistulae, which may represent the initial presentation of CD or develop later in the disease course. Isolated perianal disease can typically be managed with medical therapy and local operations for treatment of fistula or abscess, with proctectomy rarely required in the absence of rectal involvement (5% to 10% vs. 25% in presence of rectal involvement). However, in cases of severe perianal disease, preservation of sphincter function and continence is challenging even in the hand of experienced surgeons. The introduction of anti-TNFα therapy has increased the success of sphincter preservation.

COLONIC CROHN DISEASE

Clinical Presentation

Isolated colonic involvement without small bowel disease occurs in approximately 25% of patients. The clinical presentation of colonic CD often includes diarrhea (70% to 80%), abdominal pain (45% to 65%), rectal bleeding (30%), and perianal disease (10%). Abdominal pain may be due to colon obstruction or peritoneal irritation caused by transmural

inflammation. Rectal bleeding occurs in 50% of patients with colonic involvement, but it is often of limited severity. Patients with Crohn colitis, as compared to those with primarily small bowel disease, are less likely to experience systemic symptoms such as weight loss and vitamin deficiency, but more likely to have associated extraintestinal manifestations of CD. Manifestations related to disease activity include erythema nodosum (5% to 10%), acute arthropathy (6% to 12%), conjunctivitis (3% to 10%), and aphthous ulceration (10%); those unrelated to disease activity include sacroiliitis (10% to 15%), ankylosing spondylitis (1% to 2%), primary sclerosing cholangitis (rare), gallstones (15% to 30%), and renal calculi (5% to 10%).

Diagnostic assessment should always include colonoscopy, to determine extent of disease, with intubation of the terminal ileum to rule out small bowel involvement, and multiple biopsies for histologic confirmation. The differential diagnosis includes ulcerative colitis, infectious colitis, collagenous colitis, ischemic colitis, Behçet disease, colonic neoplasm, solitary rectal ulcer syndrome, and NSAID colitis.

Indications for Surgery

Patients with CD localized primarily to the colon may present with fistulas, abscesses, toxic megacolon strictures, failure to thrive in the pediatric population, or colorectal cancer (CRC) but the most common indication for surgery is the presence of persistent abdominal pain and diarrhea that is unresponsive to medical therapy.

Fistulae and Abscesses

Patients with Crohn colitis are at risk of developing enterocolic (Figs. 144.1 and 144.2), colocutaneous, and cologastric fistulae as a consequence of full thickness inflammation. Fistulae may also develop as a complication of surgical resection, with fistulas developing from the anastomotic sites. Principles of treatment include resection of the actively diseased segment and repair or resection of the secondarily involved segment (innocent bystander).

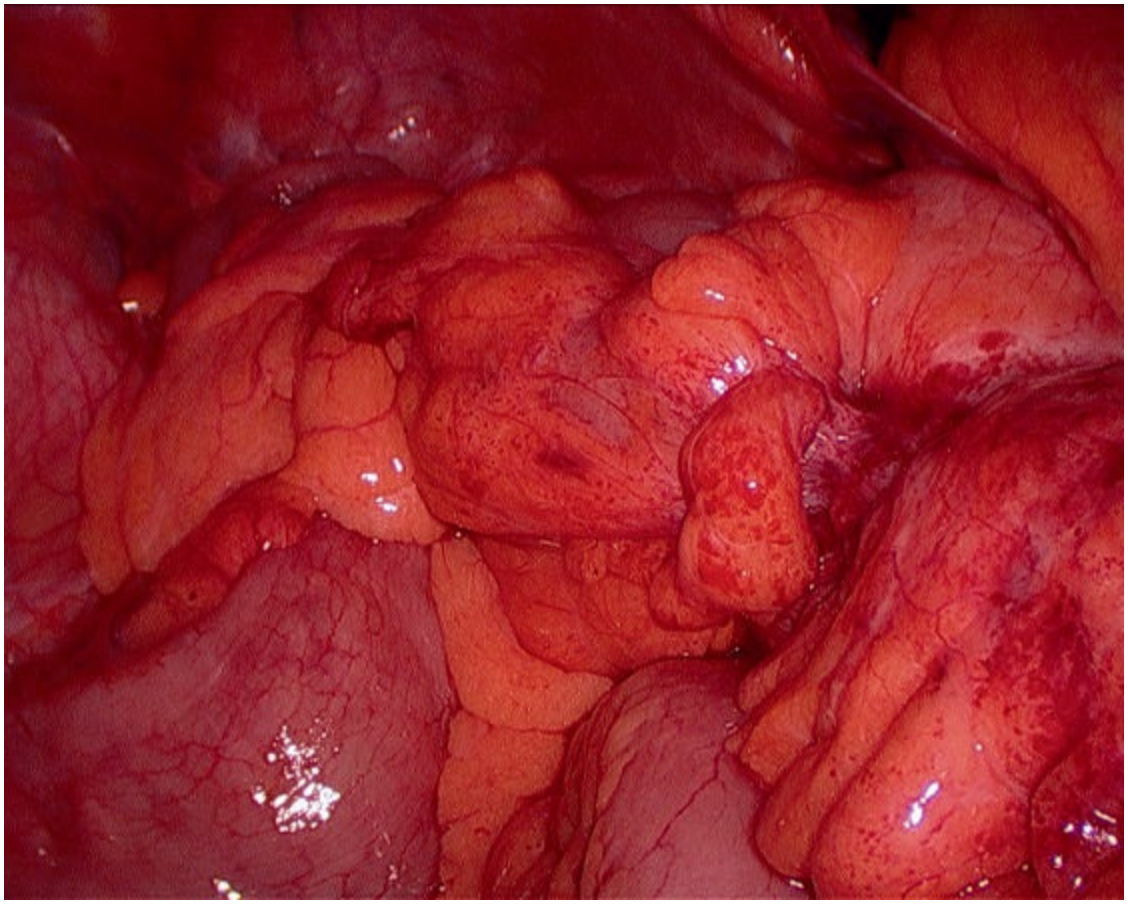

Figure 144.1. Fistula between the small bowel and sigmoid colon.

Abscesses are often related to full thickness bowel involvement and may present in the right lower quadrant, along the sigmoid colon or in the pelvis. Percutaneous image-guided drainage and antibiotics is generally the first line of treatment with subsequent resection of the involved bowel segment after medical optimization due to the high risk for recurrence.

Toxic Megacolon

Toxic megacolon is a rare but potentially fatal complication of pancolonic CD. Unstable patients or patients who do not readily respond to supportive measures, including adequate fluid resuscitation, antibiotics, and medical therapy, require surgery. A subtotal colectomy with creation of an ileostomy is the preferred surgical option. The decision between creating a mucous fistula and closing the distal rectosigmoid stump with drainage is based on the severity of inflammation and general condition of the patient.

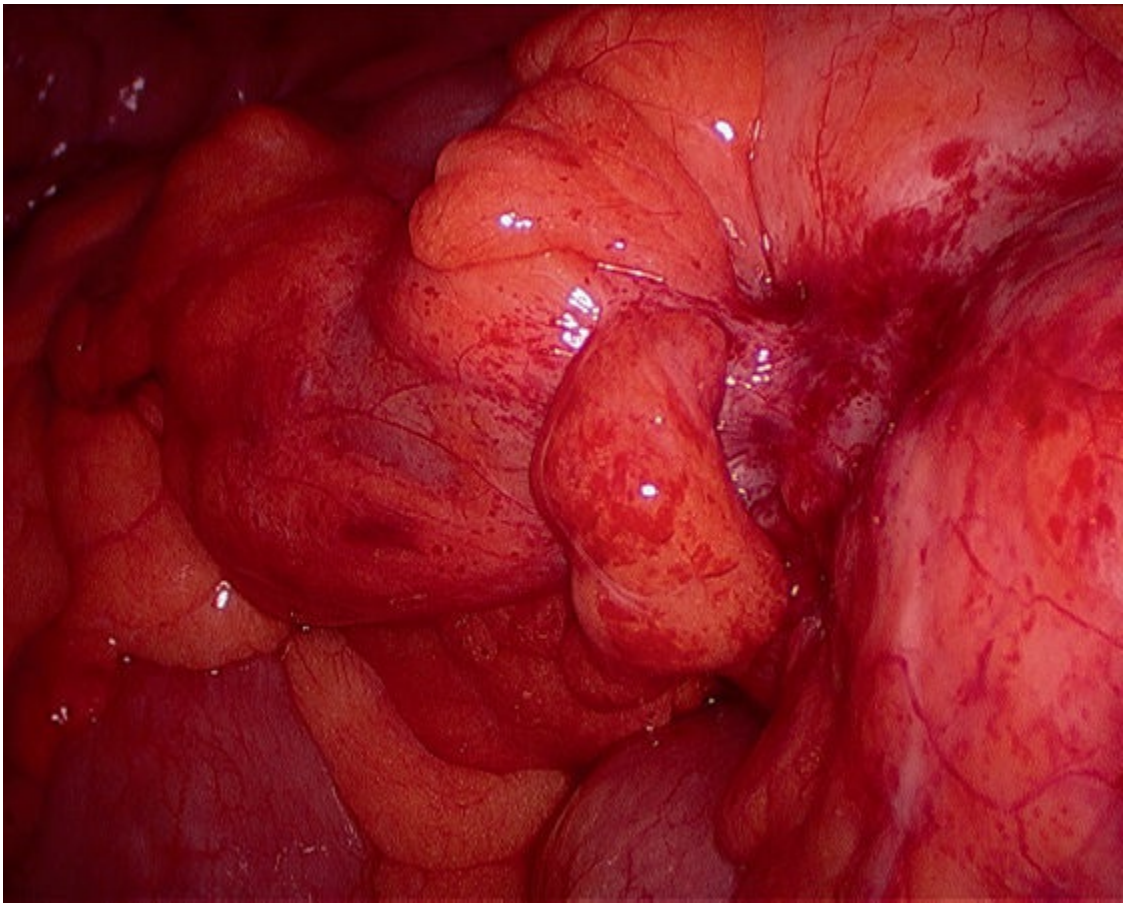

Figure 144.2. Enterosigmoid fistula.

Colorectal Cancer

As in ulcerative colitis, Crohn colitis increases the risk of CRC 4 to 20 times, with direct correlation with extent and duration of disease. Current guidelines mimic those for ulcerative colitis and call for surveillance colonoscopy beginning 7 to 10 years after diagnosis. Colonic resection may also be required for high-grade or multifocal low-grade dysplasia, stenosis preventing complete colonoscopic evaluation or raising concern for malignancy, and extensive pseudopolyposis limiting accurate surveillance.

Preoperative Planning

Colonoscopy

Colonoscopy with ileoscopy is an essential tool in the preoperative evaluation to determine the extent of colonic CD through direct mucosal visualization and to obtain biopsies for histologic evaluation. Characteristic colonoscopic features of CD include aphthous ulcers, longitudinal ulcerations, skip lesions (often with rectal sparing),

pseudopolyps, and strictures.

Due to the increased CRC risk, routine surveillance colonoscopy should begin no later than 8 years after symptoms onset and sooner in patients with a diagnosis of primary sclerosing cholangitis or strong family history of CRC (first-degree relative diagnosed before age 50). Colonoscopy at regular intervals (every 1 to 2 years) may help reduce the incidence of CRC. During the initial colonoscopic evaluation, at least two biopsies should be taken from five sites throughout the bowel, including ileum and rectum, in order to make an accurate diagnosis. However, accurate differentiation between CD and ulcerative colitis can be challenging, even for experienced gastrointestinal pathologists, due to the overlap in clinical symptoms and histologic appearance. Among patients with isolated colonic involvement, 5% to 10% will receive an initial diagnosis of indeterminate colitis, which may be modified later in the disease course.

In addition to routine surveillance, colonoscopy should be performed 6 to 12 months following partial colectomy or ileocolonic resection to evaluate for mucosal recurrence, which typically occurs at the surgical anastomosis or in the preanastomotic segment. Endoscopic recurrence generally precedes symptom relapse and may occur in 70% to 90% of patients within 1 year of surgery.

Chromoendoscopy facilitates detection of dysplastic premalignant lesions in both CD and ulcerative colitis over standard colonoscopy. Topical contrast dyes, such as 0.1% methylene blue or 0.03% to 0.5% indigo carmine, are sprayed segmentally onto the colonic mucosa, which facilitates visualization of mucosal nodularity and topographic abnormalities such as elevation and depression that can be missed on standard colonoscopy. This technique allows the endoscopist to target biopsies to high-risk areas, allowing better detection of dysplasia and malignancy.

Barium Enema

Barium enema (BE) often completes the evaluation of CD patients with colonic strictures or fistulae. Large abnormalities, including masses and high-grade strictures, can be seen on single-contrast studies. Double- or air-contrast studies, in which the rectum is filled with barium and then air, allow fine detailed assessment of the colonic wall and can be helpful in identifying low-grade strictures, mucosal abnormalities, and fistula tracts. This technique can be particularly advantageous for fistulae suspected clinically, but not clearly demonstrated on standard colonoscopy or body

imaging.

Computed Tomography

When an abscess is suspected, preoperative assessment should include CT of the abdomen and pelvis to localize it and to guide preoperative drainage. Preoperative optimization includes control of sepsis and nutritional support when needed.

As previously and more extensively described in the small bowel chapter, computed tomography enterography (CTE) takes advantage of the high spatial resolution and speed of modern CT scanners, and using large amounts of neutral oral contrast agents generates detailed images of the small bowel wall, lumen, and mesentery and it is excellent in identifying fistulizing disease. It has been shown that CTE has a higher sensitivity than barium small-bowel follow through and at some institutions, CTE combined with ileocolonoscopy has become a first-line test for the diagnosis and staging of CD.

However, given the concerns regarding radiation-induced neoplasia and the fact that CD patients will likely requite repeat imaging over their lifetime, magnetic resonance enterography (MRE) has been widely utilized in this patient population and it is currently considered a valid alternative to CTE.

Surgical Technique

Optimal surgical management of Crohn colitis often involves a resection, but the extent of colonic resection depends on the location, extent, and duration of disease, presence of small bowel disease, the urgency of intervention, the presence of complications, and the patient’s general health status.

Right Hemicolectomy

Colonic disease limited to the cecum is almost always associated with terminal ileal disease. In fact, terminal ileitis is often the predominant component of ileocecal disease; thus surgical management usually involves resection to grossly normal margins with an anastomosis between the neoterminal ileum and the proximal ascending colon. Recurrent disease is common at the anastomosis or the preanastomotic ileum, but rarely observed within the distal colon or rectum.

Disease of the entire right colon is also often accompanied by terminal

ileitis. Surgical management consists of a standard right hemicolectomy to grossly uninvolved margins, with an anastomosis between the ileum and the transverse colon. With a standard right hemicolectomy, the anastomosis often lies in proximity to the duodenum, placing the patient at risk, in the event of recurrence at the anastomosis, of a duodenal fistula. Therefore, the procedure should include interposing omentum between the duodenum and the ileocolonic anastomosis when feasible.

Total Abdominal Colectomy and Ileorectal Anastomosis

Total abdominal colectomy with ileorectal anastomosis (IRA) is the operation of choice for multifocal or extensive disease with rectal sparing. IRA is only appropriate if the rectum is truly disease-free on close endoscopic examination, fecal continence is adequate, and the patient does not have extensive perianal septic complications. Recurrence rates of 46% and 60% at 5 and 10 years, respectively, have been reported for CD patients undergoing IRA, as compared to rates of 10% and 21% for patients treated with a proctocolectomy with an end ileostomy. Disease recurrence does not necessarily translate into permanent fecal diversion. Cattan et al. reported that despite recurrence rates as high as 83% at 10 years, approximately 63% of patients still had a functioning IRA. Longo et al. found that 86% and 48% of 131 patients who had undergone a colectomy with IRA had a functioning IRA at 5 years and 10 years, respectively, consistent with other studies reporting 40% to 50% rate of subsequent proctectomy with permanent ileostomy due to recurrent rectal disease.

On the other hand, patients who are medically unfit, malnourished, or with severe acute colitis may require a total abdominal colectomy with creation of an end ileostomy. Management of the rectal stump is controversial. Some surgeons prefer to bring the rectal stump to the abdominal incision and open it as a mucous fistula. We typically prefer to staple it and utilize rectal tube drainage to keep the stump decompressed. After the patient has recovered from the acute episode, an IRA can be performed, depending on the extent of disease, fecal continence, and rectal compliance. Patients who are not candidates for IRA should undergo a completion proctectomy to avoid the risk of cancer in the rectal stump.

Total Proctocolectomy With Permanent Ileostomy

Multisegment colonic disease, especially with distal involvement, is best treated with a total proctocolectomy with permanent ileostomy. In the

absence of significant perianal disease, an intersphincteric proctectomy should be considered to reduce the risk of perianal wound complications associated with a wider dissection. In the presence of active perianal sepsis, a perineal wound should be avoided and the procedure should be performed in two stages leaving a very short rectal stump to be removed at a second stage as a perineal proctectomy. Unfortunately, in cases of extensive rectal and perianal disease, a wider dissection must be performed encompassing the entire sphincter mechanism. When the proctectomy results in extensive loss of perianal skin and subcutaneous tissue, the resulting defect may require tissue transfer such as gluteal, gracilis, or myocutaneous rectus abdominis pedicle flaps for closure.

Ileal Pouch Surgery for Crohn Disease

Restorative procedures such as an ileal pouch-anal anastomosis (IPAA) or continent ileostomy are not recommended for CD patients because of high risk of recurrence resulting in pouch loss and permanent fecal diversion. However, there is a small subset of patients with disease limited to the colon and rectum without any history of small bowel or perineal involvement who have a low risk of recurrence with pouch failure and should be considered for restorative proctocolectomy with a J-pouch ileo-anal anastomosis.

Panis et al. evaluated 31 patients with preoperative diagnosis of CD limited to the colon and rectum who underwent IPAA. Of these, 6 (19%) had short-term complications, including pouch–perineal fistula (2,6%), CD of the pouch (2,6%), pouch–vaginal fistula (1,3%), and abscess (1,3%). Two patients (6%) had a pouch failure, described as need for diversion or excision of the ileo-anal reservoir. After 10 years of follow-up, the rate of CD complications and pouch excision were 35% and 10%, respectively. Another study from Cleveland Clinic reported outcomes of IPAA for CD, and noted that despite higher rates of pouch failure compared with patients with ulcerative colitis or familial adenomatous polyposis (odds ratio 2.0; 95% confidence interval, 1.2–3.3; $p = 0.01$), 82% of patients retained their pouch at 10 years, and good functional outcome was reported. The Cleveland Clinic has also reported on the outcome of IPAA in CD as it relates to the timing of diagnosis (preoperative, immediately postoperative, or delayed postoperative). The overall 10-year pouch retention rate was 71%, with rates for patients with preoperative, immediately postoperative, and delayed postoperative diagnosis reported as 85%, 87%, and 53%, respectively. Complications were more common in the delayed diagnosis

group, with pouchitis (54%), fistula (35%), and IPAA stricture (24%) the most frequently reported.

In summary, IPAA in CD should be reserved for a carefully selected subset of patients with disease limited to the colon and rectum without perianal disease, with adequate sphincter function, and who are motivated to accept possibility of pouch loss over time. We do not offer IPAA for Crohn patients in our practice given the rare presentation of a CD patient with colorectal CD without small bowel or perianal involvement.

Proctectomy

CD limited to the rectum is rare. Surgical management of Crohn proctitis often involves a proctectomy, but the amount of proximal colon that is resected is controversial. Total proctocolectomy with end ileostomy has been recommended for many patients due to risk of stomal complications and recurrent disease in proximal colon after abdominoperineal resection (APR). However, certain patient subgroups who may benefit from preservation of colonic absorptive capacity (elderly patients, patients with a prior small bowel resection at risk for either high ileostomy output or short bowel syndrome), and others who lack any gross evidence of disease in the abdominal colon should still be offered proctectomy and end sigmoid colostomy.

The abdominal portion of the procedure is best performed with the patient in low lithotomy position. The open approach is performed through either a vertical midline or an infraumbilical transverse incision. Irrespective of the surgical approach, it is essential to fully examine the bowel to accurately assess the extent of disease and the presence of any synchronous lesions. In cases of total proctocolectomy, the abdominal colon is mobilized in typical fashion, taking care to assure adequate hemostasis during division of the often thickened and inflamed mesentery. The terminal ileum is divided using a linear stapler in a nondiseased area, minimizing the length of resected small bowel. The proctectomy part of the operation starts by dividing the attachment of the sigmoid colon to the lateral abdominal wall and opening the peritoneum along the lateral reflection. The layer of connective tissue that lies underneath the peritoneum, the fusion fascia, should be incised parallel to the divided peritoneal reflection, allowing the mesentery of the colon to be fully mobilized while the ureters and gonadal vessels remain in the retroperitoneum. The superior hemorrhoidal pedicle is divided using a vessel sealing device and the dissection is carried to a level below the

sacral promontory. The sympathetic neural plexus, which lies directly behind the inferior mesenteric artery, is identified and dissected free of these vessels, safely allowing the subsequent division of the superior hemorrhoidal vessels. The parietal peritoneum is then incised from the point of ligation of the superior hemorrhoidal vessels inferiorly and laterally to gain access to the presacral space. The left and right ureters are identified and the rectum is retracted anteriorly, allowing division of the loose areolar tissue along the presacral space under direct vision using electrocautery. Care must be taken to ensure that the dissection continues in the plane between the fascia propria of the rectum and the presacral fascia, which covers the presacral venous plexus, in order to avoid excessive bleeding from injury of the presacral plexus. Even when in the proper plane, bleeding from small communicating vessels between the rectum and the presacral plexus may be encountered. Thus, mobilization of the rectum with blunt hand dissection should be avoided. They typically follow the dissection plane of mesorectal excision to limit bleeding and to preserve autonomic innervation.

Posterior mobilization of the rectum should continue beyond the level of the coccyx with Waldeyer fascia incised using electrocautery, allowing for clear definition of the lateral ligaments. Anterior and superior traction is then placed on the rectum using a right-angle bowel clamp and the lateral rectal ligaments are divided close to the rectal wall, carefully avoiding injury to the parasympathetic nerves. Following the posterior and lateral mobilization of the rectum, superior traction results in the unfolding of the recesses of the rectovaginal or rectovesical pouch, which greatly facilitates anterior dissection. With the rectum retracted toward the sacral promontory, the anterior dissection of the rectum is carried to the distal border of the prostate in male patients and to the thickening of the perineal body and the anal sphincters in female patients. The rectum should now be circumferentially mobilized to the level of the levator ani muscles. The rest of the rectal dissection is completed through the perineum. In staged procedures, the rectum is closed with a TA stapling device and divided proximally, leaving a short rectal stump to be removed via perineal proctectomy at a later date. A drain is placed deep into the pelvis and brought out through an incision in the lower abdominal wall far from the planned stoma.

To create the stoma, a circular incision is made over the previously marked ostomy site. The subcutaneous fat is divided and the anterior

rectus sheath is opened with a longitudinal incision. The fibers of the rectus muscle are bluntly separated and the posterior rectus sheath is incised. The stapled end of the small bowel (or sigmoid colon if APR performed) is delivered through this incision until it ideally protrudes approximately 4 cm above the skin. The abdominal cavity is irrigated and the celiotomy incision closed. The stoma is matured using interrupted 3-0 absorbable sutures in the standard Brooke fashion. Everting sutures are placed on the antimesenteric edge of the colon, with a full-thickness bite of the intestinal wall, and a subcuticular bite of the skin. After these everting sutures are placed, they are tied, resulting in a stoma that protrudes approximately 1 to 2 cm above the abdominal wall. To allow complete approximation of the mucocutaneous junction, additional simple sutures are then placed between the cut edge of the intestine and the dermis.

The perineal portion of this procedure is performed with the patient placed in the lithotomy or prone position, depending on surgeon preference. The rectum is gently irrigated with a povidone-iodine solution, and a povidone-iodine–soaked gauze is placed into the rectum. The anus is then closed with a purse-string suture at the level of the anal verge. The perineum, including the vagina for female patients, is prepared in sterile fashion. Removal of the specimen is carried out in the intersphincteric plane (Fig. 144.3), beginning with a circular incision in the palpable groove between the internal and external sphincters using a needlepoint electrocautery. In patients with perineal disease, the incision may need to be extended to include the damaged and diseased tissue near the anal canal. The intersphincteric plane is best identified laterally; thus, dissection should begin at the lateral aspects and proceed to connect posteriorly and then anteriorly. The pelvic cavity is entered posteriorly and the dissection is continued until the rectum is completely free. The proximal colon, rectum, and anus are removed through the perineal incision (Fig. 144.4). To close the perineum, the external sphincters are approximated in layers using absorbable suture. The skin edges are trimmed and closed with interrupted absorbable vertical mattress sutures. In the presence of significant perineal sepsis, the skin edges and the subcutaneous tissues may be left open or a flap used to safely close the defect.

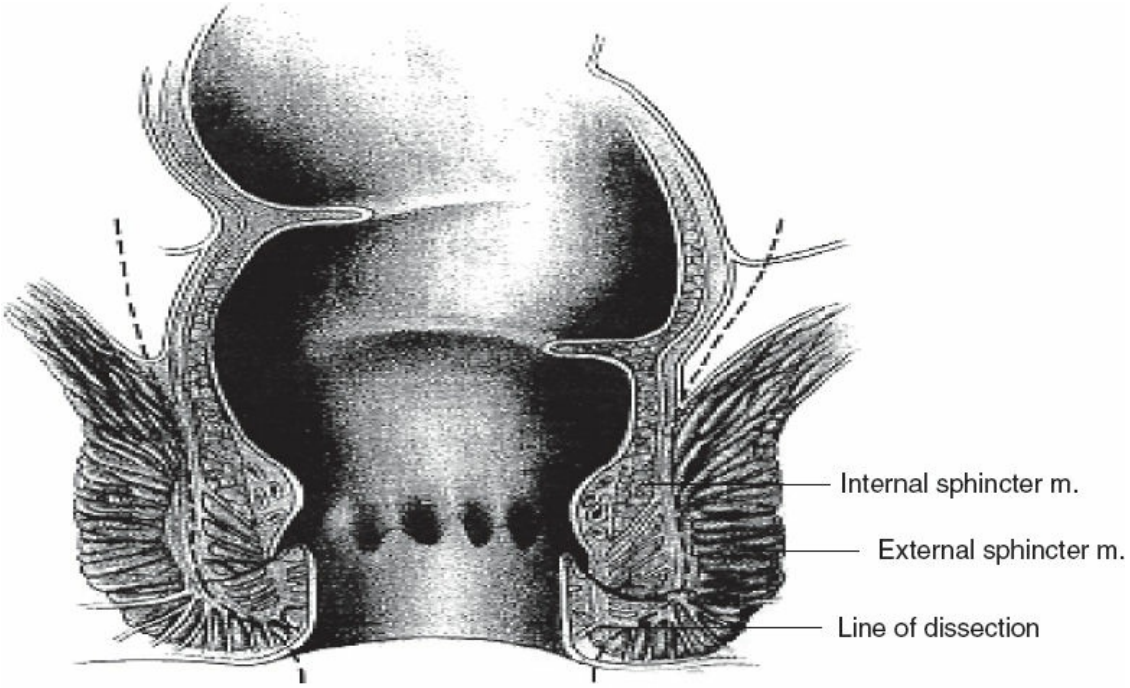

Figure 144.3. The intersphincteric plane (*dashed line*) is chosen as the plane of dissection in a proctectomy for inflammatory bowel disease.

Laparoscopic Total Proctocolectomy for Crohn Colitis

Because Crohn colitis is less common than ileocolic CD, occurring in 30% versus 75%, much of the literature focuses on laparoscopic surgery in the ileocolic region. While operative time is longer in patients with extensive Crohn colitis, our group has noted significant advantages of laparoscopic surgery in this population including reduced intraoperative blood loss, earlier return of bowel function, and shorter length of stay. Some series have also shown a reduction in complications, including wound infection, thromboembolic events, pneumonia, and myocardial infarction. Conversion to an open procedure occurs in only 10% to 16% of cases, and laparoscopic procedures have been performed successfully even in patients with prior abdominal surgery.

Figure 144.4. Specimen after total proctocolectomy for colonic Crohn disease.

To begin the laparoscopic proctocolectomy, the patient is placed in lithotomy position. A 12-mm trocar is introduced into the abdomen using open technique at the ileostomy site. After establishment of pneumoperitoneum and visual exploration of the abdominal cavity, the other 5-mm trocars are introduced in the left lower quadrant, bilateral upper quadrants, and umbilicus.

The small bowel is evaluated in its entirety. Mobilization of the colon then proceeds from right to left by dividing the major vascular pedicles and lateral attachments. The greater omentum is divided distal to the gastroepiploic arcade with the specimen. After the identification of the left ureter and transection of the superior hemorrhoidal pedicle, the rectum is mobilized to the level of the levator ani muscles in the avascular mesorectal plane in a similar fashion as described in the open procedure.

The terminal ileum is divided intracorporeally with an endoscopic stapling device and the proximal end of the terminal ileum is delivered through the future ileostomy site. A soft pelvic drain is placed in the pelvis. All port site incisions are closed and the stoma is matured using Brooke technique. The proctectomy is completed from the perineal side

and the specimen extracted through the perineal incision. The perineal incision and perineum are closed in layers.

Postoperative Care

Enhanced recovery after surgery (ERAS) programs has been used in colorectal surgery over the last 15 years in Europe and more recently in the United States. These programs optimize perioperative care pathways using a multimodality approach to reduce postoperative complications, length of hospital stay, and hospital costs. These protocols include preoperative counseling and education, minimal preoperative fasting, laparoscopic surgical approaches, intraoperative fluid restriction management, avoidance of insulin resistance, use of epidural analgesia and NSAIDs in lieu of systemic narcotics, and early mobilization. CD patients may particularly benefit from a quick return normal state of health. Inflammatory bowel disease (IBD) patients frequently find themselves managing a permanent stoma, making the role of stoma nurses essential in the perioperative period for education and triage of complications such as low stoma output, dehydration, and stoma retraction. Finally, IBD patients often benefit from early return to their preoperative medication regimen, including corticosteroids, immunomodulators, and anti-TNFα inhibitors.

Complications and Their Management

Patients with CD develop more frequent abdominal septic complications, including abscess and anastomotic leak due to chronic inflammatory status, poor nutritional status, steroid use, and recurrent episodes of disease. Alves et al. reported four independent risk factors for intra-abdominal septic complications: poor nutritional status, defined by weight loss >10% within the last 10 months, intra-abdominal abscess discovered during surgery, preoperative steroid use more than 3 months, and recurrent clinical episodes of CD. Patients should be carefully assessed and optimized prior to elective operations in order to decrease the risks of complications.

Yamamoto et al. found that after single-stage proctocolectomy the most common postoperative complications were delayed perineal wound healing (35%), followed by intra-abdominal sepsis (17%) and stomal complications (15%). In 23 patients, the perineal wound healed between 3 and 6 months after proctocolectomy, whereas in 13 patients the wound remained open for more than 6 months. Chronic perineal wound, defined

by lack of healing at 6 months, occurs in 11% to 57% of CD patients. Up to 33% of cases of persistent perianal sinus are not healed at 12 months, after which the chances of spontaneous healing are rare. Surgical treatment for persistent perianal sinus is excision with or without rectus abdominis myocutaneous (RAM) flap for perineal reconstruction.

In addition to delayed wound healing, 30% of Crohn patients experience recurrence at the stoma site after proctocolectomy. Risk factors for stomal recurrence include penetrating phenotype and pre-existing ileal disease. When this occurs, ileoscopy and small bowel imaging should be used to assess the luminal extent of disease and extraluminal complications, such as stoma retraction and fistula. Recurrence of ileal CD after construction of an end ileostomy can affect the peristomal area as well, including enterocutaneous fistulae, stoma retraction, abscess, strictures (with or without obstruction), and parastomal pyoderma gangrenosum. Fistula formation is the result of the penetrating transmural inflammation at the origin of the fistula tract and presents with localized abscess. Patients with recurrent disease at the stoma site may present with small bowel obstruction, with symptoms including reduced or absent ileostomy output, abdominal pain, and vomiting. Although conservative management with nasogastric tube and bowel rest may improve symptoms, most patients eventually need surgical intervention. For all ileostomy complications, after evaluation of disease recurrence and extent of complication, patients should undergo ileostomy revision, often requiring resection of the involved small bowel segment and ileostomy revision either in the same location or resiting to the opposite side of the abdomen.

As we previously described for surgical treatment of small bowel CD, IBD is a risk factor for venous thromboembolism (VTE), with 1.5- to 3-fold increased risk compared to the general population. Disease flares are associated with increased risk of VTE and higher incidence of portomesenteric thrombosis, which may be incidentally discovered in otherwise asymptomatic patients.

Outcomes

In our practice, a prospective analysis of 179 patients undergoing surgical resection for colonic CD revealed a significant relationship between extent of resection and recurrence rates. Patients who underwent a segmental colectomy had recurrence rates of 38% and 55% at 5 and 10 years, respectively, compared with 24% and 30% in patients treated with a total

abdominal colectomy, and 9% and 20% in patients with total proctocolectomy. After adjusting for the extent of disease, the segmental colectomy group had a significantly greater risk of recurrence compared with the total proctocolectomy group, with a hazard ratio of 5.76. Despite higher risk of recurrence, segmental resection, with the benefits of preserving colonic absorptive capacity, may be appropriate for elderly patients or in patients with a prior small bowel resection who are at risk for high ileostomy output. Young healthy patients, whose longer life expectancy creates more opportunity for recurrent disease requiring reoperation, are likely to derive more benefit from a proctocolectomy with ileostomy.

PERIANAL CROHN DISEASE

Clinical Presentation

Anorectal/perianal CD, with or without concurrent bowel disease, is seen in only 5% of patients, and is characterized by the development of fissures, ulcers, fistulae, abscesses, and anal strictures. These often complex lesions occur in about one third of patients with intestinal CD, and are more commonly associated with colitis or proctitis (47%) rather than isolated small bowel involvement (25%). Anorectal CD tends to be recurrent, complex, and progressive. The goal of surgery is control of sepsis and relief of symptoms with preservation of adequate sphincter function. Once diagnosed most CD patients with anorectal disease will require surgical intervention, including incision and drainage of abscess, fistulotomy, or seton placement for deep/complex fistulas.

Anal Stenosis or Stricture

A mild-to-moderate degree of anal stenosis, generally caused by circumferential scarring from chronic perianal inflammation or previous surgery, is common in patients with CD. Mild anal stenosis is rarely symptomatic because of the liquid or semisolid nature of stool in patients with CD, and therefore does not necessitate intervention. If symptomatic, anal stenosis can often be effectively treated with gentle finger dilatation in the office or with sequential mechanical dilatation under conscious sedation or general anesthesia. If symptoms worsen, or if severe sepsis develops, fecal diversion may become necessary. In a previously published series from our group, 41 of 69 patients with CD had anal stenosis as their isolated manifestation of perianal disease. Among these patients, 8 were

asymptomatic and required no surgical intervention. Sixteen of the remaining 33 patients ultimately underwent anal dilatation and 17 underwent proctectomy or creation of a diverting stoma, usually because of concomitant severe rectal disease or fecal incontinence.

Fissures

Anal ulcerations and fissures are often associated with perianal CD. Unlike typical fissures, Crohn fissures are typically multiple, deep, and present in locations other than the posterior midline. Medical management is the first line of treatment, often including anti-TNF–directed therapy. Surgery, including sphincterotomy and anal dilatation, should be avoided because of high rates of nonhealing wounds and subsequent incontinence. Differential diagnosis of atypical deep lateral fissures, particularly those not healing despite conservative management, includes cancer, infection, radiation injury, and HIV. Examination under anesthesia and colonoscopy with ileal intubation and biopsy are needed to accurately direct treatment options for fissures refractory to conservative therapy.

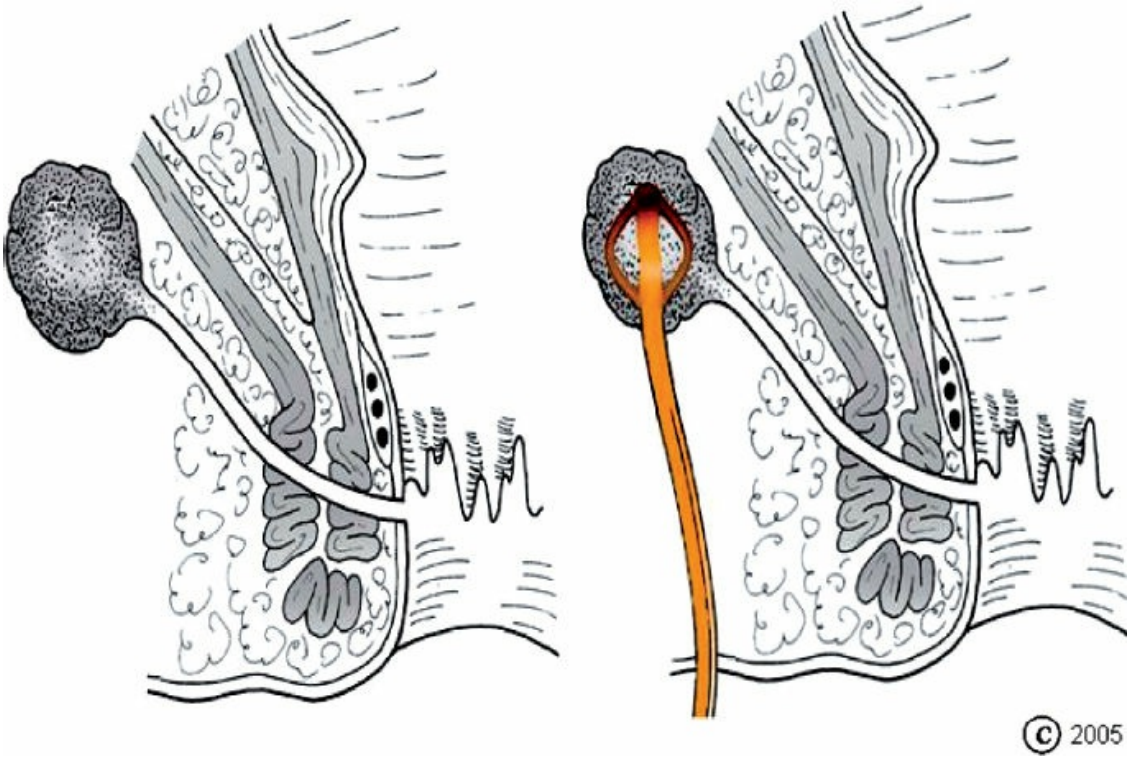

Figure 144.5. Incision and drainage of a perianal abscess with placement of a Pezzer catheter.

Abscesses

Medical management of Crohn associated perianal abscesses with

antibiotics is rarely successful, and surgical incision and drainage are required for definitive treatment. The incision should be placed close to the anal verge in order to minimize the length of any subsequent fistula. Following drainage and washout, the cavity should be packed with ribbon gauze if very superficial, or drained with a Pezzer catheter if deep in the ischiorectal space (Fig. 144.5). If the internal opening of a fistula is easily identified, a loose noncutting seton should be placed along the fistulous tract and through the abscess cavity to ensure adequate drainage. In one reported series, complete abscess cavity healing was achieved in 67.7% of patients when a fistulous tract was not found at the time of the incision and drainage. A fistula-in-ano developed in the remaining 32.3% of patients. Because the majority of patients do not develop a fistula-in-ano, we advise against an aggressive search for an internal fistulous opening beyond a careful anoscopy at the time of initial drainage. This careful and conservative approach avoids the risk of creating a false passage, a complication that can easily occur with aggressive searches for the internal opening in the setting of acute inflammation.

Anal Fistulas

Perianal fistulas may arise from anal crypts or from full-thickness ulcerations in the mucosa of the lower rectum. Fistulization continues through the perirectal tissue and either forms an abscess or erupts through the skin. Initial management of a perianal fistula depends on the severity of symptoms, the complexity of the fistula, and the extent of rectal involvement. The diagnostic evaluation of fistulas should include an examination under anesthesia to determine the extent of disease and the presence of any associated sepsis, ultrasound, or MRI and a colonoscopy with ileal intubation to assess the degree of rectal, colonic, and small bowel involvement. Successful management of perianal fistulas can be achieved with a series of procedures, with the optimal approach dictated by the number and location of the fistulas and the extent of sphincter involvement (Fig. 144.6).

Crohn fistulas can be superficial or deep, and are characterized based on their relationship to the anal sphincters (Fig. 144.7). Asymptomatic or well-tolerated fistulas require no medical or surgical intervention. Symptomatic and uncomplicated submucosal or intersphincteric fistulas are best treated with an initial trial of either metronidazole or ciprofloxacin. These antibiotics are moderately effective in promoting healing of Crohn fistulas and are associated with a low risk for

complication. If a low-lying submucosal or intersphincteric fistula fails to heal with antibiotic treatment, then a surgical fistulotomy can be performed. These low-lying fistulas typically heal well after fistulotomy and the risk of incontinence is low. In our experience, 27 of 33 (82%) symptomatic low fistulas healed permanently with a superficial fistulotomy, a rate of success similar to the 79% reported by McKee and Keenan.

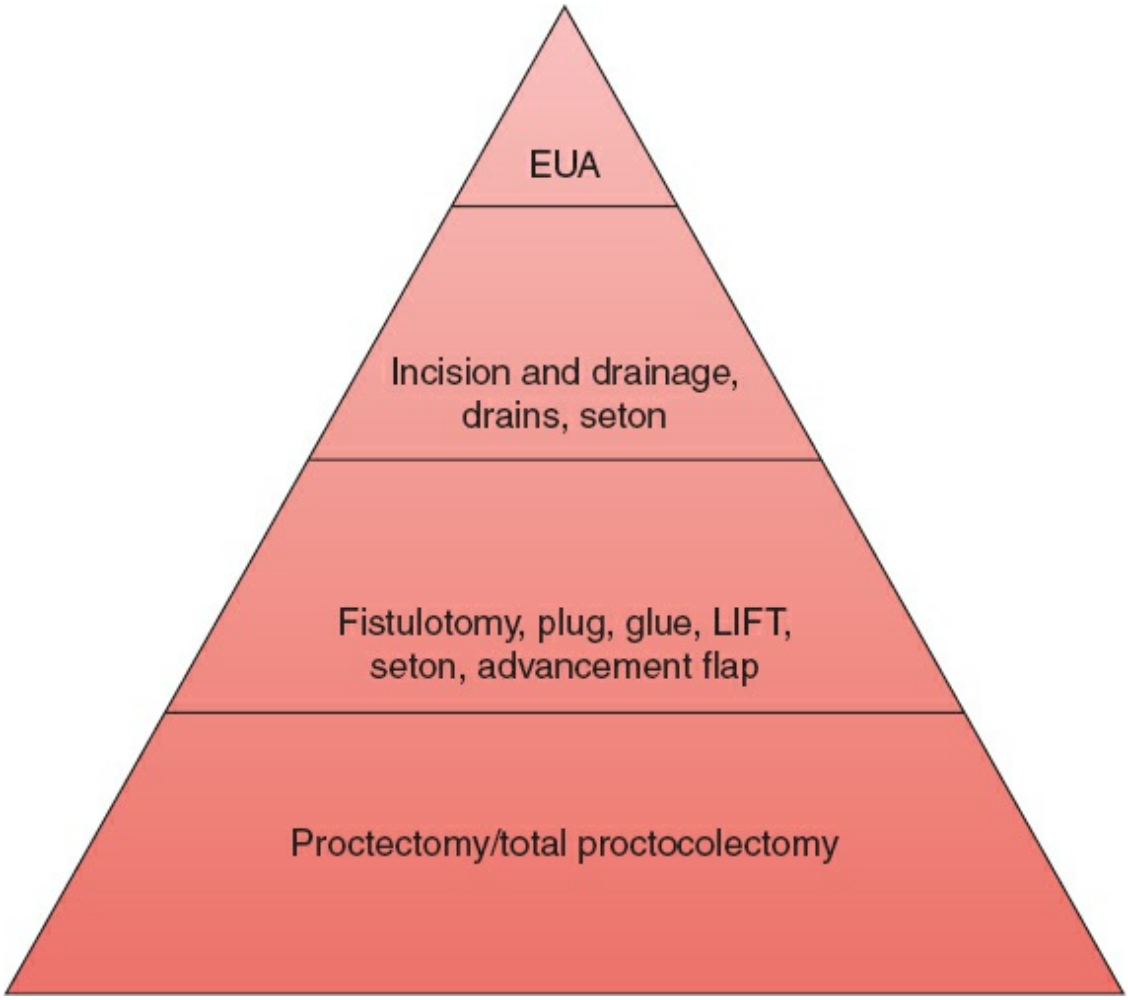

Figure 144.6. Surgical management of fistulizing perianal Crohn disease. The initial step is an Examination under Anesthesia (EUA) to evaluate the extent of the disease. Concomitant sepsis is managed with incision and drainage along with placement of drains and/or setons. If symptoms persist, more aggressive surgical treatment should be considered, including fistulotomy, fibrin plug or glue, endorectal advancement flap, and LIFT. At this level of difficulty, the need for fecal diversion should be evaluated. In case of persistent failure, proctectomy and permanent colostomy is the only option.

Surgical fistulotomies should not be used for suprasphincteric fistulas and should also be avoided for most transsphincteric fistulas. Medical treatment for extensive Crohn fistulas includes the use of 6-mercaptopurine, azathioprine, and cyclosporine. Infliximab is considered superior in promoting healing of perianal fistulas related to CD, with 60% success rate currently reported. Fistula recurrence rates remain high (up to 59% in some series) and initial healing with medical treatment is limited if there is persistent stasis or sepsis within the fistula tract. Setons improve drainage through the tract, and may enhance the overall effectiveness of infliximab (Fig. 144.8). In a series reported by Topstad et al., seton placement, infliximab, and maintenance immunosuppression achieved complete healing in 67% of Crohn perianal fistulas and partial healing in 19%. Typically, the seton is placed prior to the initiation of infliximab therapy. Management of the draining seton in Crohn patients responding to anti-TNF–directed therapy remains controversial.

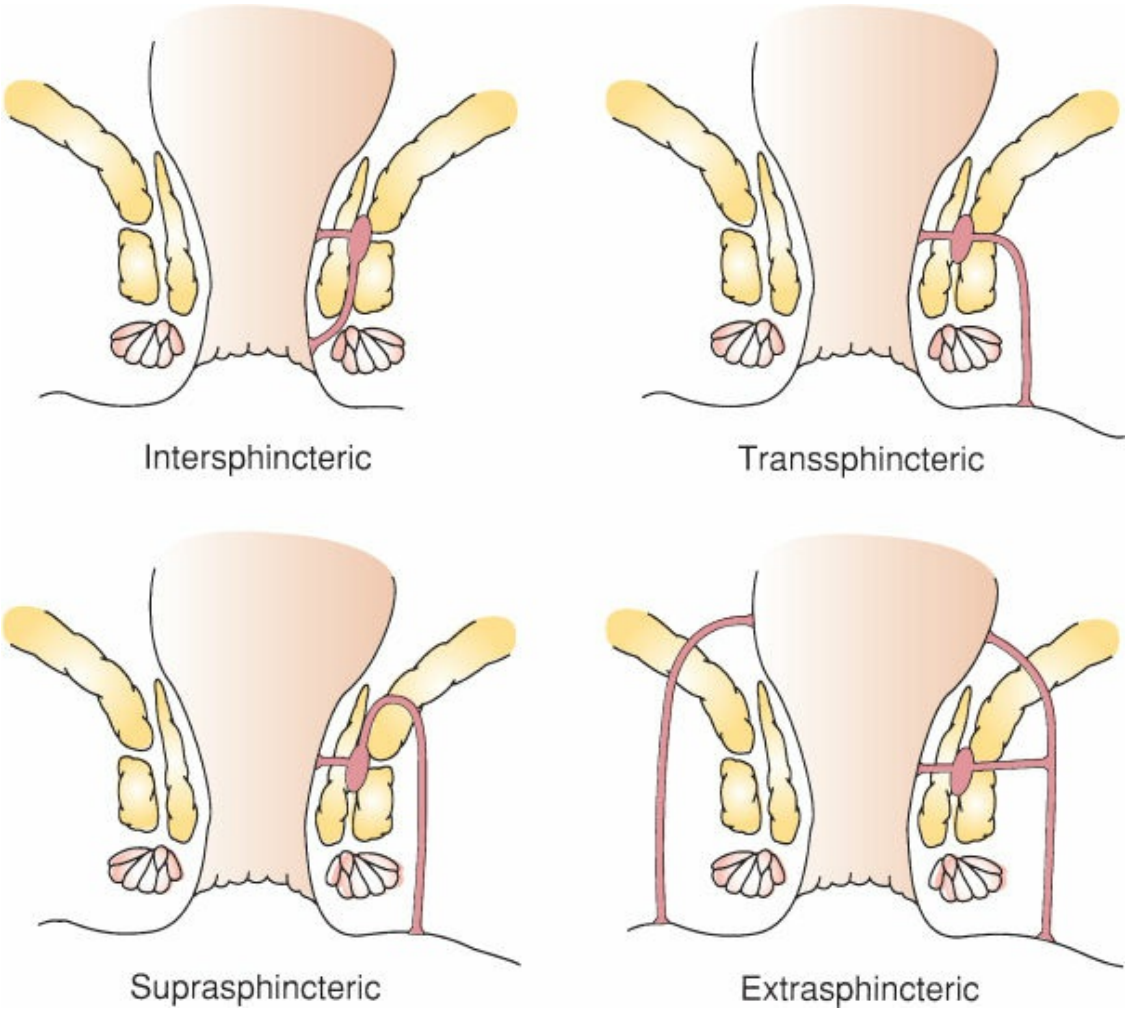

Figure 144.7. Types of fistulas. (From Mulholland MW, Lillemoe

KD, Doherty GM, et al. *Greenfield's Surgery: Scientific Principles and Practice*. 4th ed. New York: Lippincott Williams & Wilkins, 2005; with permission.)

When adequate drainage of the tract has been achieved, and in the absence of rectal disease, a rectal advancement flap is a viable option to close the internal opening of the fistula and promote healing. Kodner et al. reported a 92% success rate in patients with complex fistulas secondary to CD who underwent rectal advancement flaps, with primary healing reported in 17 of 24 patients and secondary healing in 5 of 24 patients. The ligation of intersphincteric fistula tract (LIFT) procedure has been reported with good success in the treatment of transsphincteric fistulas, but there are no reports currently focusing on its utility in Crohn patients. Other sphincter-sparing options, including fistula plug and fibrin glue, may be effective in some fistulas, although their success specifically in CD has not been well studied. One small series by O'Connor et al. reported 80% success in healing Crohn fistulas in 20 patients after use of the fistula plug. However, a systematic review by O'Riordan et al. evaluating the fistula plug reported pooled fistula closure rates of 54% for non-Crohn fistulas and 55% for Crohn fistulas, with only 42 Crohn patients included from 20 studies. If definitive healing cannot be achieved with medical therapy or surgical intervention, many patients have a reasonable quality of life with long-term seton drainage, as this accomplishes the goal of sepsis management and maintenance of continence.

Severe cases of perianal fistulas that do not respond to aggressive medical and surgical management may require fecal diversion.

Diversion of the fecal stream often results in significant relief of local inflammation and can assist in the healing of perianal fistulas, but recurrences are common and intestinal continuity often cannot be restored. Yamamoto et al. found that, in 31 patients who underwent fecal diversion for perianal CD, 81% (25) achieved early remission, but complete remission was only achieved in 26% (8) of patients, with 68% (21) eventually requiring proctectomy. Only three patients (10%) underwent restoration of intestinal continuity at follow-up ranging 3 to 30 years.

Figure 144.8. Complex perianal Crohn disease managed with multiple setons.

Proctectomy is indicated when perianal disease is unrelenting or results in damage to the sphincters, causing debilitating incontinence. However, a combination of catheter drainage, seton placement, and intensive medical therapy results in the avoidance of a proctectomy or fecal diversion in the majority of patients. In our previous experience, 224 of 717 patients with CD presented with anorectal complications. Of these, 139 patients (62%) retained anorectal function, with complete healing in 84 patients, control of sepsis in 25 patients, and observation in the remaining 30 patients. Eighty-five patients (38%) required a proctectomy with a permanent stoma. Patients with rectal involvement had significantly higher rates of proctectomy compared to patients with rectal sparing (77.6% vs. 13.6%, respectively). Therefore, although complete healing and control of sepsis can often be achieved in patients with anorectal CD, the presence of active rectal disease and multiple synchronous complications significantly increases the need for a rectal ablative procedure. Patients should be counseled early regarding the indications for proctectomy and diversion, in order to establish appropriate expectations about their disease course when perianal lesions are present.

CD-associated Anal Adenocarcinoma of the Fistula Tract

The development of carcinoma within a chronic perianal fistula is a rare complication of CD, with an incidence of 0.3% to 0.7% according to Iesalnieks et al. Traube et al. suggested that the environment of constant mucosal regeneration occurring within a fistula may cause dysplastic changes, which may ultimately lead to adenocarcinoma. According to Tokunaga et al., patients with longstanding CD, diagnosed before 30 years of age, and with fecal diversion are at greater risk of developing carcinoma arising in association of perianal fistula. The gold-standard treatment in this case is neoadjuvant radiochemotherapy followed by APR.

Rectovaginal Fistulas

A rectovaginal fistula is a debilitating complication of CD that is characterized by the discharge of stool or gas from the vagina. It is usually caused by a fistula that arises from the anorectum and eventually erodes through the vaginal wall, usually at the introitus. In one third to one half of patients, the rectovaginal fistula is either asymptomatic or presents with minimal symptoms and requires no treatment. However, symptomatic fistulas may result in dyspareunia, perineal pain, difficulty maintaining adequate hygiene, or repeated vaginal infections and must be treated aggressively. Fistulas may be initially treated with antibiotics and, if needed, the insertion of a noncutting seton. Once the infection is ablated, a transrectal or vaginal mucosal advancement flap may be used to aid in the closure of the fistula in patients without significant anorectal disease. A recent systematic review of the literature comparing transanal and vaginal mucosal advancement flap did not show a difference in terms of healing rates between the two approaches with the limitation of small sample size studies.

Preoperative Planning

After conducting a thorough history eliciting the nature and severity of symptoms, the extent of concurrent small- and large-bowel disease, and the degree of functional continence, a physical examination is performed to look for clinical manifestations of perineal CD. If pain or anal stenosis precludes adequate exposure, the patient should undergo an examination under anesthesia. External examination of the anal region may reveal hemorrhoids, skin tags, anorectal abscesses, and anal fissures. A digital rectal examination should be performed to assess the status of the

sphincters and the presence of any anorectal stricture or palpable masses. Anoscopy and proctoscopy should be performed to search for fistulous tracts and to obtain biopsies to confirm the diagnosis of CD. In women, the rectovaginal septum should also be inspected for the presence of fistulas. MRI or ultrasound may be helpful imaging adjuncts, particularly prior to repeat exploration after failed attempt to identify fistula tracts. All suspicious lesions found on physical examination should undergo biopsy to rule out a malignancy.

Surgical Technique

Fistulotomy

The patient is placed in the prone jackknife position. A probe is carefully inserted into the external opening and advanced through the tract until it emerges from the internal opening. The probe should never be passed forcefully. A combination of direct visualization with an anal retractor and digital palpation can be helpful in guiding the fistula probe safely along the tract. If the path of the tract or the internal opening is difficult to find, methylene blue or dilute hydrogen peroxide can be injected into the external opening. The use of transrectal ultrasonography in the operating room may assist in finding the fistula tract. Using electrocautery, the fistulotomy is performed over the probe, starting at the external opening and carried to the internal opening while carefully maintaining meticulous hemostasis. If a significant portion of the sphincters are encountered in the fistulous tract, the fistulotomy is stopped and a seton is placed to drain the remainder of the tract. The seton should be loose to prevent inadvertent cutting or necrosis of the underlying muscle. A curette is then used to clear the unroofed fistula tract of all infected granulation tissue. This material may be sent for culture, particularly in the setting of a concomitant abscess or for cytology if cancer is suspected. Marsupialization of the fistulotomy edges does not provide any advantage other than in presence of bleeding.

Rectal Advancement Flap

A rectal advancement flap can be used to cover the internal opening of a perianal fistulous tract or a rectovaginal fistula if the rectal mucosa is free of active disease. The patient is placed in a prone jackknife position if the fistula opening is anterior and in high lithotomy position if the opening is posterior. After making an incision at the dentate line, a thick, U-shaped flap inclusive of mucosa, submucosa, muscle fibers of the internal

sphincter, and muscularis propria is elevated 4 to 5 cm cephalad with the apex of the flap at the internal opening of the fistula. Using electrocautery, care is taken to obtain adequate hemostasis. The fistulous tract is then curetted and closed in layers with 3-0 or 4-0 absorbable sutures. The distal end of the flap is appropriately trimmed, pulled down over the repaired defect, and secured to the dentate line with a series of interrupted absorbable sutures. A temporary stoma may be considered for the difficult or recurrent repairs, although there are no data in the literature providing evidence that the healing rate is increased by fecal diversion.

CONCLUSION

Colonic and perianal involvement is common in CD, especially in association with small bowel disease. Careful comprehensive evaluation of the entire GI tract is essential in order to plan an appropriate treatment strategy. Patients with colonic disease have an increased risk of malignancy, and require careful surveillance. Perianal disease poses significant challenges to the treating team to achieve a balance between control of the disease and preservation of continence. Unfortunately even with the development of novel and more effective medical therapies proctectomy may still be required in severe disease nonresponsive to medical and surgical management. Multidisciplinary management of these patients is mandatory to achieve optimal outcomes.

EDITOR'S COMMENT

In this chapter, Dr. Ferrari and colleagues discuss the treatment of colonic and perianal CD, two very challenging entities for the practicing surgeon. Treatment of colonic CD has undergone a significant change over the last 20 to 30 years. Much of this has been influenced by the recognition of the important role that the colon plays in water absorption. The other reason for this has been the development of more effective medical therapy, including the so-called "biologic" class of medical therapy for CD. This includes agents such as anti-TNF–targeted therapies, including infliximab, adalimumab, and certolizumab. Recently this category has been expanded to include agents targeting adhesion molecules and those targeting interleukin-12 (vedolizumab, ustekinumab). The

authors in their 2005 publication described a much higher rate of CD recurrence in patients undergoing segmental colon resection for colonic CD than following proctocolectomy. Regular use of these and other similar types of medications postoperatively may lead to improved results with respect to recurrence (Fichera A, McCormack R, Rubin MA, et al. Long-term outcome of surgically treated Crohn's colitis: a prospective study. *Dis Colon Rectum* 2005;48(5):963–9). Time will tell and further studies on this are needed with longer follow-up.

The authors do not describe in detail the clinical criteria used to select a patient to undergo a colon-sparing (i.e., an intestinal continuity-sparing) resection for CD. This can often be a very difficult decision. Rectal sparing is not a very common feature in these patients. In addition to rectal sparing, one must have a patient who has adequate sphincter function. In many of these patients, a useful test to determine how good their results will be after surgery, is to examine how much their colon distends on insufflation of air, either at the time of a colonoscopy, flexible sigmoidoscopy, or proctoscopy. A bowel that has not been affected significantly by transmural inflammation will distend significantly when insufflated with air or carbon dioxide, whereas one that has significant transmural disease will not. Patients who have very significant transmural disease do not have significant reservoir capacity. These individuals will have numerous bowel movements with significant urgency, and will perhaps be better served with having an ileostomy. There have been some efforts to quantify the structural damage in patients who have longstanding CD. One of these has been the recent description of the Lémann Index (Pariente B, Mary JY, Danese S, et al. Development of the Lémann index to assess digestive tract damage in patients with Crohn's disease. *Gastroenterology* 2015;148(1):52–63.e3). This rather complicated index uses both criteria of previous surgical resection, as well as radiologic evidence of strictures among other factors, to try to quantify the degree of structural damage in patients with CD and to permit physicians to follow disease progression over time. This is currently, at least in my eye, a somewhat cumbersome method of patient evaluation. Some type of simpler evaluation method is needed in order to identify exactly how pliable intestinal strictures are and how likely they are to respond to medical therapy. Magnetic resonance imaging (MRI) has increasingly been used to quantify strictures and intestinal anatomy in order to spare Crohn patients from radiation exposure, since many of these will undergo repeated testing over their lifetime. This can also give physicians a good idea of the degree of associated fibrosis and fistulas.

Another area of debate with respect to colon-sparing surgery has been the issue of whether or not to perform segmental resection in patients with CD who have been previously diagnosed with colon cancer or dysplasia. With respect to colon cancer there have already been several studies that have documented the subsequent diagnosis of metachronous cancer (Kiran RP, Nisar PJ, Goldblum JR, et al. Dysplasia associated with Crohn's colitis: segmental colectomy or more extended resection? *Ann Surg* 2012;256(2):221–6; Maser EA, Sachar DB,

Kruse D, et al. High rates of metachronous colon cancer or dysplasia after segmental resection or subtotal colectomy in Crohn's colitis. *Inflamm Bowel Dis* 2013;19(9):1827–32). Maser and colleagues reported that 19 of 47 Crohn patients (40%) undergoing segmental colectomy for colon cancer and 6 of 17 patients (35%) undergoing a subtotal colectomy developed a metachronous cancer. Kiran and colleagues reported on 50 Crohn patients undergoing surgery for dysplasia. In nearly half of the patients undergoing subtotal colectomy or proctocolectomy, the dysplasia was found to be multifocal. In addition, in a personal study in which tumorigenic mutations were tracked longitudinally over years in a small group of patients with longstanding CD, such mutations were seen to spread to other areas of the colon as well as to predate colon cancer by several years (Galandiuk S, Rodriguez-Justo M, Jeffery R, et al. Field cancerization in intestinal epithelium of patients with Crohn's ileocolitis. *Gastroenterology* 2012;142:855–64). If one does encounter a patient with CD that has a CRC, the best course of action in my opinion would be a total proctocolectomy and end ileostomy. With respect to dysplasia, when confirmed by more than one pathologist, the same course is wise.

Moving on to perianal CD, although the authors state that this occurs only in approximately 5% of Crohn patients, this is very dependent upon where one practices and the type of Crohn population one is dealing with. For example, in the area where I practice in Kentucky, perianal CD occurs in approximately 25% of our Crohn population. I believe that this is almost certainly in large part due to the very high rate of cigarette smoking, leading to a much more aggressive Crohn phenotype.

There are many controversies in the treatment of perianal CD, the most important with respect to how aggressive one wishes to treat. As the authors in this chapter highlight, the presence or absence of a significant Crohn anal canal stricture will in many cases determine the likelihood of success of therapy. I have found the presence of a rigid Crohn anal canal stricture to be a very poor prognostic indicator of the ability to avoid permanent fecal diversion. Only in the most motivated patient who is willing to do regular anal canal dilatations using a Hegar or similar dilator is permanent diversion able to be deferred or avoided. It is hoped, similar to colonic CD, that the development of more targeted therapy and earlier institution of such therapy will avoid the development of structural damage such as fibrosis and fistulizing disease, in effect preventing the development of perianal CD, so that local surgery can in fact be avoided. The success of procedures such as plug procedures or procedures utilizing fibrin glue in my experience is poor. In many cases of persistent fistulas, particularly rectovaginal fistulas that have not responded to local attempts at repair, muscle flap procedures such as gracilisplasty may be necessary. Treatment of Crohn perianal fistulas with adipose-derived stem cells may hold promise. In a recent report of a prospective randomized trial at 49 hospitals in 7 European countries and Israel, investigators were able to demonstrate a 50% response rate at 24 weeks in patients with Crohn perianal

fistulas treated with adipose-derived stem cells as opposed to a 34% response rate in patients treated with placebo (Panés J, García-Olmo D, Van Assche G, et al.; ADMIRE CD Study Group Collaborators. Expanded allogeneic adipose-derived mesenchymal stem cells (Cx601) for complex perianal fistulas in Crohn's disease: a phase 3 randomised, double-blind controlled trial. *Lancet* 2016;388(10051):1281–90). Overall, the treatment of perianal CD, as well as colonic CD, continues to challenge both the surgeon's and patient's perseverance and patience.

Susan Galadiunk

145 Surgery for Toxic Megacolon

Scott R. Kelley and David W. Larson

ETIOLOGY AND PATHOPHYSIOLOGY

Toxic megacolon is a syndrome characterized by acute colitis, ≥5.5-cm nonobstructive segmental or complete dilation of the colon, and signs of systemic toxicity. Initially described in 1950 by Marschak and colleagues, toxic megacolon typically occurs as the initial manifestation of a disease process, though it may also be the result of an acute exacerbation of chronic colitis. Although rare, it is most commonly associated with inflammatory bowel disease (ulcerative, Crohn, indeterminate colitis) and pseudomembranous (*Clostridium difficile*) colitis. Other exceedingly rare cases resulting in toxic megacolon include additional infectious colitides (*Salmonella typhi, Shigella, Campylobacter jejuni, Yersinia enterocolitica, Entamoeba histolytica, Cryptosporidium,* Cytomegalovirus), ischemia, chronic obstructive pulmonary disease, diabetes, immunosuppression, kidney failure, cystic fibrosis, chemotherapeutic drugs, Kaposi sarcoma, and colonoscopic overdistention in cases of colitis.

The incidence of toxic megacolon in inflammatory bowel disease ranges from 1% to 5% and has diminished significantly secondary to earlier recognition and better management of the underlying disease. *C. difficile* colitis has seen an increasing prevalence (3%) since 2000, which is attributable to a more virulent strain (BI/NAP1/027) with less responsiveness to standard therapies and a higher relapse.

The pathophysiology is not entirely understood, though local inflammatory mediators such as interleukins and nitric oxide are thought to be contributing factors. Nitric oxide generated by smooth muscle cells and macrophages is increased in the presence of inflammation, and inhibits smooth muscle tone, thus contributing to colonic dysmotility and toxic dilation. Inflammation through all layers of the colon wall may result in bacterial translocation with subsequent bacteremia and sepsis.

INITIAL PRESENTATION

Patients with toxic megacolon often present critically ill (fever, tachycardia, leukocytosis) with abdominal distention and tenderness, tympany, and diarrhea. Symptoms may be nonspecific or masked by medications (steroids, immunosuppressants, narcotics/opioids) or other factors (elderly, debilitated) making a high index of suspicion essential for identification. Opiates/narcotics, antidepressants, antidiarrheal agents, anticholinergics, hypokalemia, and barium enemas are known to induce and exacerbate the condition. Systemic toxicity differentiates patients with toxic megacolon from those with colonic dilation due to other processes (pseudo-obstruction, Hirschsprung disease, neuronal intestinal dysplasia, Chagas disease).

Diagnosis is based on clinical criteria outlined by Jalan and colleagues and includes three components: radiologic evidence of colonic dilation, at least three of the following (fever >38°C/101.5°F, heart rate >120/min, WBC >10.5 × 10^6/L, hemoglobin and hematocrit <60% of normal), and at least one of the following (dehydration, altered consciousness, electrolyte disturbances, hypotension). The diameter of the colon is not as important as the patient's overall clinical picture. The ascending and transverse colon are typically more dilated than the descending and sigmoid, and the rectum is rarely distended.

A multidisciplinary approach to patient management with early surgical consultation is imperative. Mortality rates as high as 20% have been documented in cases of colonic perforation, in comparison to 4% without. Surgery should be aggressively pursued in the face of deterioration or a lack of measurable improvement within 24 to 72 hours given the high complication and mortality rate if surgery is withheld.

INDICATIONS AND CONTRAINDICATIONS

Absolute indications for emergency surgery include diffuse peritonitis, pneumoperitoneum, uncontrolled sepsis, and major hemorrhage. Relative indications for urgent surgery include increasing abdominal pain and/or colonic distention, progressive physiologic deterioration, a lack of objective improvement within 24 to 72 hours, and sustained transfusion requirements. Some advocate continuation of aggressive medical therapy for a period of up to 7 days if clinically stable and no deterioration is appreciated. This must be pursued cautiously and understood in the context of a significantly higher mortality if perforation occurs. Early surgical intervention should be pursued for patients who are

immunocompromised, severely debilitated, malnourished, or have multiple comorbidities.

Initial Management

For patients who do not require emergent surgical intervention, aggressive medical therapy should be pursued with a goal of reversing physiologic defects and the toxic state. Patients should be closely monitored with serial examinations and resuscitated in a critical/intensive care unit. A history of inflammatory bowel disease, immunocompromised status, and recent medications, barium enemas, and travel must be ascertained. Baseline laboratory tests, blood, urine, and stool cultures, and radiographic imaging is carried out. A flat and upright abdominal x-ray can track the progression of colonic distention. Abdominal and pelvic computed tomography may help determine etiology and evaluate for pneumatosis, subclinical perforation, and abscesses. Appropriate intravenous access, placement of an indwelling urinary catheter to closely monitor output, and bowel rest should be initiated. Incentive spirometry is started and pneumatic lower-extremity compression devices placed. Nasogastric tubes do not decompress the colon and are not necessary unless the patient is experiencing emesis. Electrolyte abnormalities should be corrected. Appropriate antibiotics are introduced for infectious etiologies, and if recently treated with steroids, stress-dose corticosteroids should be initiated. Medications that slow colonic motility and function must be avoided. Deep venous thrombosis and gastric acid suppression prophylaxis are recommended. For significant gastrointestinal bleeding and anemia transfusion may be necessary.

Patients presenting with toxic megacolon without a history of inflammatory bowel disease should be empirically treated for *C. difficile* colitis until proven otherwise. These patients are more likely to present with an ileus and therapy should not be delayed since failure to make an early diagnosis will result in worse outcomes.

Positional therapy (knee-elbow or prone for a few minutes every 2 to 3 hours) has been shown to be beneficial in redistributing and expelling colonic gas.

Endoscopy

In patients presenting with an ileus limited lower endoscopy with minimal air insufflation by an experienced endoscopist may be helpful in obtaining

biopsies, evaluating for pseudomembranes, and therapeutically decompressing the colon. Pseudomembranes are seen in nearly 90% of patients with *C. difficile* colitis, though rectosigmoid sparing is present in up to 20% to 30%. Continuously diseased mucosa with deep ulcerations and extensive mucosal pseudopolyps may indicate severe ulcerative colitis, whereas intervening normal mucosa, rake ulcers, and aphthous ulcers is more suggestive of Crohn disease. If decompression is performed, a small bore colonic decompression tube can be placed at the same time and flushed with a small volume of saline every 6 to 8 hours to promote patency.

Clostridium difficile

Treatment for severe complicated *C. difficile* colitis (WBC >15 × 10^6/L, Cr >1.5 mg/dL, hypotension, shock, ileus, megacolon) includes vancomycin 500 mg by mouth every 6 hours and metronidazole 500 mg by mouth or intravenously every 8 hours. For those unable to tolerate oral intake, medications can be administered through a nasogastric tube. Fidaxomicin has not been proven to be more beneficial than vancomycin in cases of complicated *C. difficile* colitis. Patients with an ileus may have vancomycin introduced through a retention enema (500 mg/100 mL normal saline) every 6 hours, or directly instilled colonoscopically since adequate intracolonic concentrations of vancomycin may not be achieved with oral administration. One small study revealed resolution of toxic megacolon in 57% of patients treated with colonoscopic spraying. Another documented resolution after colonoscopic decompression and placement of a small bore decompression tube into the proximal colon is followed by instillation of vancomycin through the tube.

For patients with refractory *C. difficile* infection, fecal microbiota transplantation (FMT) has been shown to have an efficacy rate of >90%, and recently small studies have shown benefit in treating patients with acute colitis and toxic megacolon. FMT is a procedure in which fecal matter is collected from a suitable and tested donor, mixed with liquid, strained, and instilled into the patient. There is no clear consensus regarding the most appropriate method of delivery (upper endoscopy, nasoenteric tube, colonoscopically, enema), preparation, donated volume, or volume instilled. Some advocate fecal transplant if no improvement with aggressive pharmacotherapy is noted within 48 hours, and more than one transplant may be required to obtain maximal benefit.

Inflammatory Bowel Disease

Therapy for patients with severe/fulminant colitis secondary to inflammatory bowel disease includes the initiation of intravenous corticosteroids with a daily dose equivalent of 300 mg for hydrocortisone or 60 mg for methylprednisolone. Higher doses have not been proven to be beneficial, 20% to 40% will fail to respond to therapy, and treatment beyond 7 to 10 days adds no benefit. Increased rates of colonic perforation have not been documented with high-dose steroids. Studies have been unable to confirm any incremental advantage in administering or continuing oral 5-ASA compounds and topical regimens. Intravenous cyclosporine (2 to 4 mg/kg/day continuous infusion) has been shown to be an effective adjuvant (82% response) in those lacking improvement while being treated with maximal medical therapy over a period of 3 to 5 days, though unsubstantiated in cases of toxic megacolon. Tissue necrosis factor alpha (TNF-α) inhibitor infliximab (5 mg/kg) has shown efficacy in a few small studies, though unproven at this time. The utilization of empiric broad-spectrum antibiotics, although routinely administered, has not shown benefit when treating patients with severe colitis lacking infection. Fecal transplant has shown promising results in treating inflammatory bowel disease, though unstudied in the setting of toxic megacolon.

Other Colitides

Management of patients with toxic megacolon associated with colitides other than *C. difficile* or inflammatory bowel disease should follow the same general principles while focusing treatment on the underlying etiology.

PREOPERATIVE PLANNING

For patients undergoing emergent surgery, or failing maximal medical management and requiring urgent surgical intervention, the goal is to continue to stabilize and resuscitate in addition to treating the underlying cause of toxic megacolon. Preoperative endotracheal intubation, hypoalbuminemia, altered mental status, and vasopressor requirements have been shown to be significant predictors of increased mortality. Informing the patient and family of the risks, benefits, and alternatives of operative approaches, the high likelihood of a stoma, and postoperative expectations is imperative. If time permits it is crucial to have the patient

evaluated, educated, and marked for an ileostomy and mucous fistula by an enterostomal therapist.

In the operating room the patient is positioned in a perineal lithotomy position to provide concomitant access to the abdomen and perineum. Stress-dose steroids, if indicated, and broad-spectrum antibiotics are administered. If not already completed a urologic catheter is inserted, pneumatic antithrombotic devices are placed to the bilateral lower extremities, an orogastric tube is placed for decompression, and deep venous thrombosis prophylaxis is administered. Adequate intravenous access, and if necessary lines for monitoring (arterial, central venous) should be placed. Prior to prepping a rigid or flexible endoscope can be carefully inserted to decompress the colon using minimal to no air insufflation. The patient is then prepped and draped in a normal sterile fashion.

SURGICAL TECHNIQUE

The surgical approach for toxic megacolon, whether performed emergently or urgently, most commonly involves a total or subtotal colectomy with creation of an end ileostomy, and possibly decompressive rectosigmoid mucous fistula or subcutaneous exteriorization of a segment of closed distal bowel. Laparoscopic-assisted approaches have historically been avoided secondary to the purported risk of iatrogenic perforation and increased time to perform the procedure, though in the hands of skilled laparoscopic surgeons not an absolute contraindication (Table 145.1).

Exploration and Planning

On entry into the abdominal cavity the goal is to assess for perforation and control contamination if present. If perforation is appreciated laparoscopically conversion to open is recommended. The site of perforation can be used as a point to decompress the colon proximally and distally, followed by suture closure of the defect. The abdomen is then thoroughly lavaged with warm saline, with or without antibiotics (gentamicin, kanamycin), and suctioned to remove gross contamination prior to proceeding with any further exploration or mobilization.

TABLE 145.1 Operative Options

Diversion procedures
- Turnbull procedure
- Loop ileostomy and colonic lavage

Total/subtotal colectomy and end ileostomy with:
- Hartmann pouch
- Mucous fistula
- Subcutaneous exteriorization of proximal rectosigomid stump

Proctocolectomy with end ileostomy
- Conservative proctocolectomy

Restorative procedures
- Ileocolonic/rectal anastomosis
- Ileal pouch anal anastomosis

Exploration is continued and serosal tears that could progress to full thickness defects are oversewn. A walled off perforation may be appreciated and typically occurs in the area of the splenic flexure. Evaluating the tissue quality of the rectosigmoid region prior to resection is imperative to determine whether a Hartmann pouch, mucous fistula, or subcutaneous exteriorization of bowel will be fashioned since some require more length to create than others.

Typically the colon is massively dilated and visualization of the intracoelomic cavity is hindered, which necessitates decompression. For laparoscopic exploration it is helpful to have an experienced endoscopist continually decompress the colon from the perineum to enhance visualization. Techniques to decompress through a laparotomy incision include needle, suction, lavage, and endoscopic.

For needle decompression a purse-string suture using a small needle is placed through the tenia of an accessible portion of dilated colon (Fig. 145.1). A 14-guage angiocath is placed through the middle of the purse-string and the needle is removed leaving the soft flexible catheter sheath in the lumen of colon. The sheath is then connected to suction to decompress gas. Needle decompression works well to decompress gas, though it is too small to decompress stool and blood. If unable to decompress adequately a pool tip suction catheter can be placed through the same defect after making a small colotomy. Once adequate decompression is obtained the

catheter can be removed and the purse-string suture secured (Fig. 145.2).

A good lavage approach, previously described by Khoo and colleagues, is to place a large diameter catheter with multiple distal holes connected to a Y-connector through the ileocecal valve into the right colon. One limb of the Y-connector is connected to irrigation and the other suction. If the catheter becomes clogged it can be readily irrigated. After decompression is achieved the catheter can be removed and the purse-string secured, or pushed into the ascending colon and removed with the specimen (Fig. 145.3).

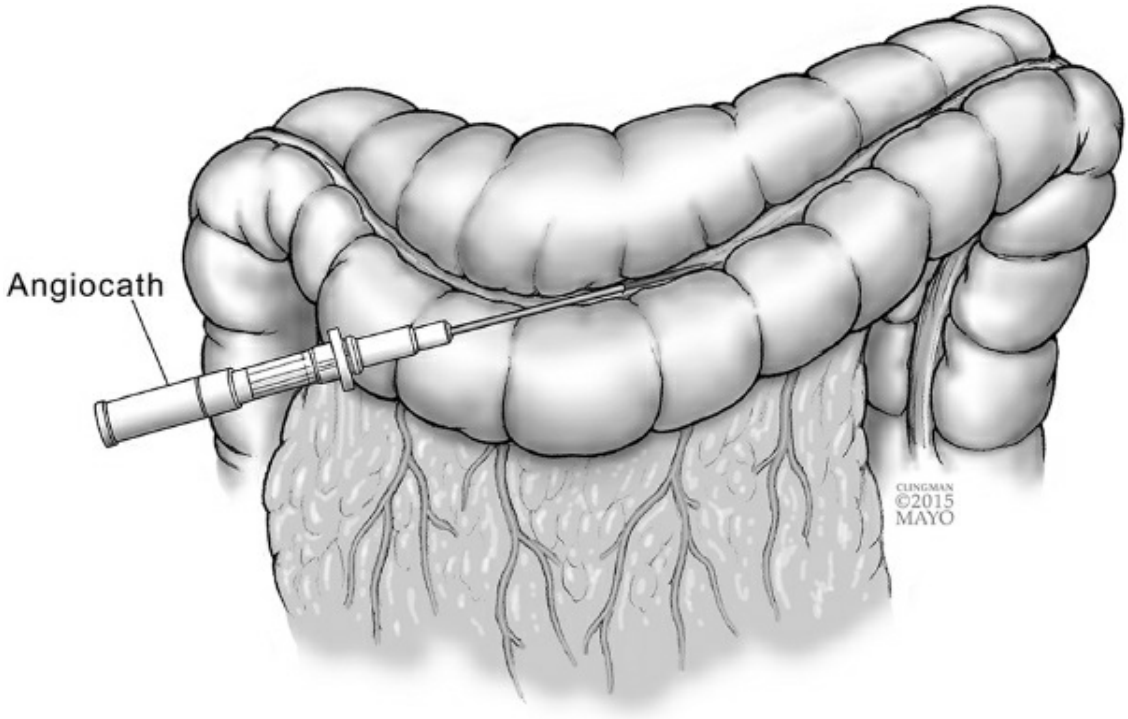

Figure 145.1. Needle decompression of colon. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

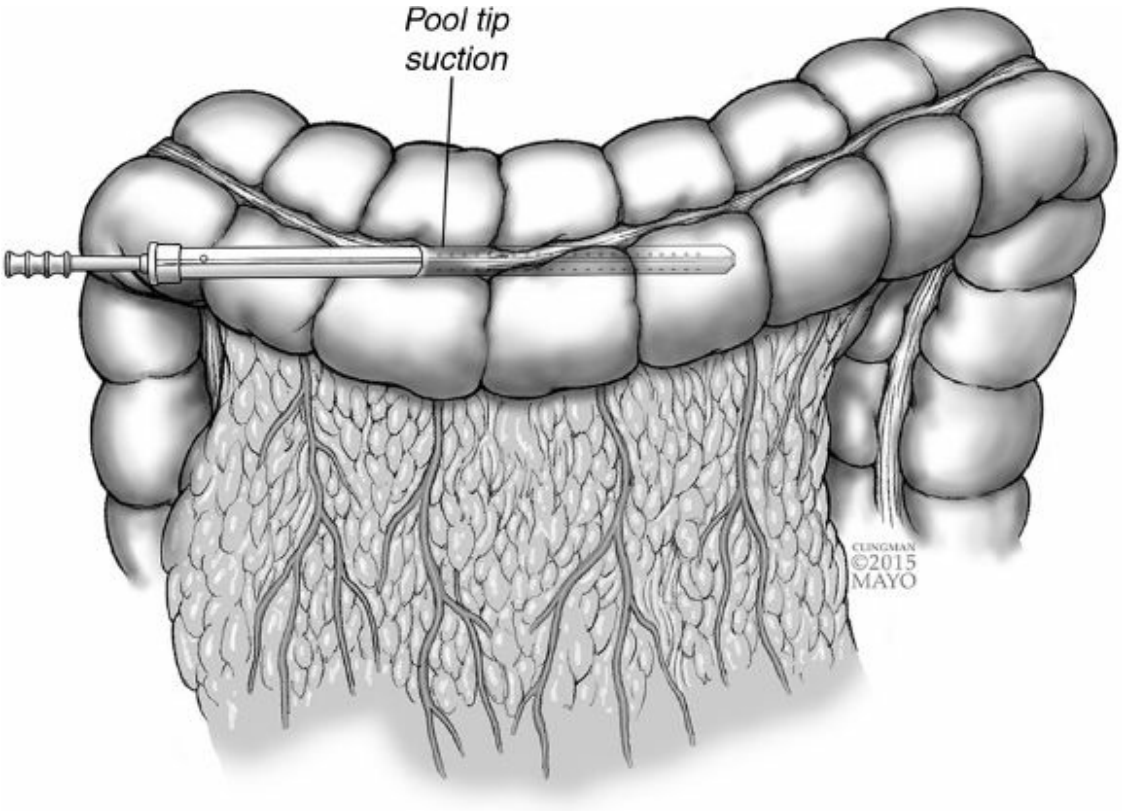

Figure 145.2. Pool suction decompression of colon. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

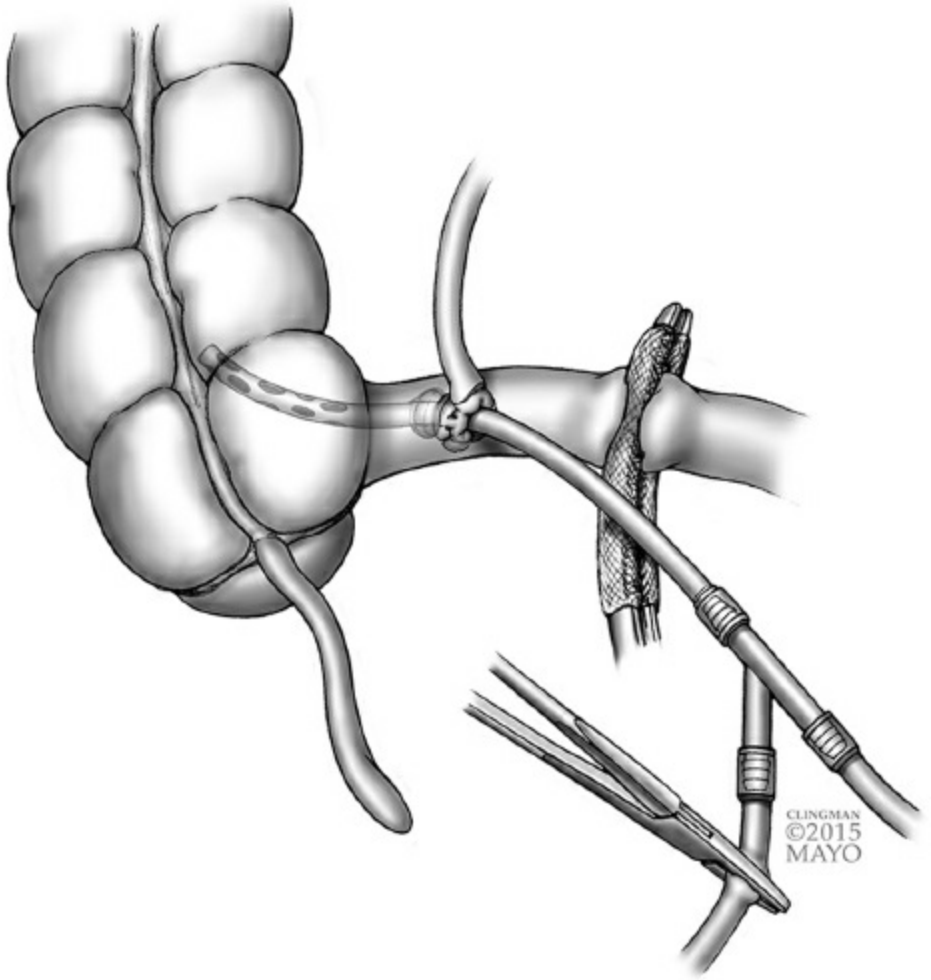

Figure 145.3. Catheter lavage of ascending colon. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

Endoscopic decompression is beneficial for laparoscopic-assisted procedures and newer larger channel flexible endoscopes with water irrigation capability work well, other than for large amounts of solid stool. If not available a rigid large diameter sigmoidoscope is also an option. Both approaches can also be utilized with a laparotomy incision and are sometimes necessary to further decompress the distal colon.

Diversion Procedure (Ileostomy–Colostomy)

Historically, the Turnbull “blow-hole” procedure was used in severely debilitated (septic, malnourished) patients with megacolon who could not withstand a major abdominal operation. A loop ileostomy, skin level transverse colostomy, and if needed a skin level sigmoid colostomy is created. This allows for fecal diversion, minimal handling of the bowel,

and patient convalescence (usually over several months) for future colectomy, but does not eliminate the colitis and physiologic impact of the inflammation on the patient (Fig. 145.4). In rare circumstances (advanced pregnancy and toxic megacolon), the Turnbull approach could be considered. Recent experience in pregnant patients with fulminant disease suggests that total abdominal colectomy and Brooke ileostomy can be completed with low rates of maternal and fetal morbidity and mortality.

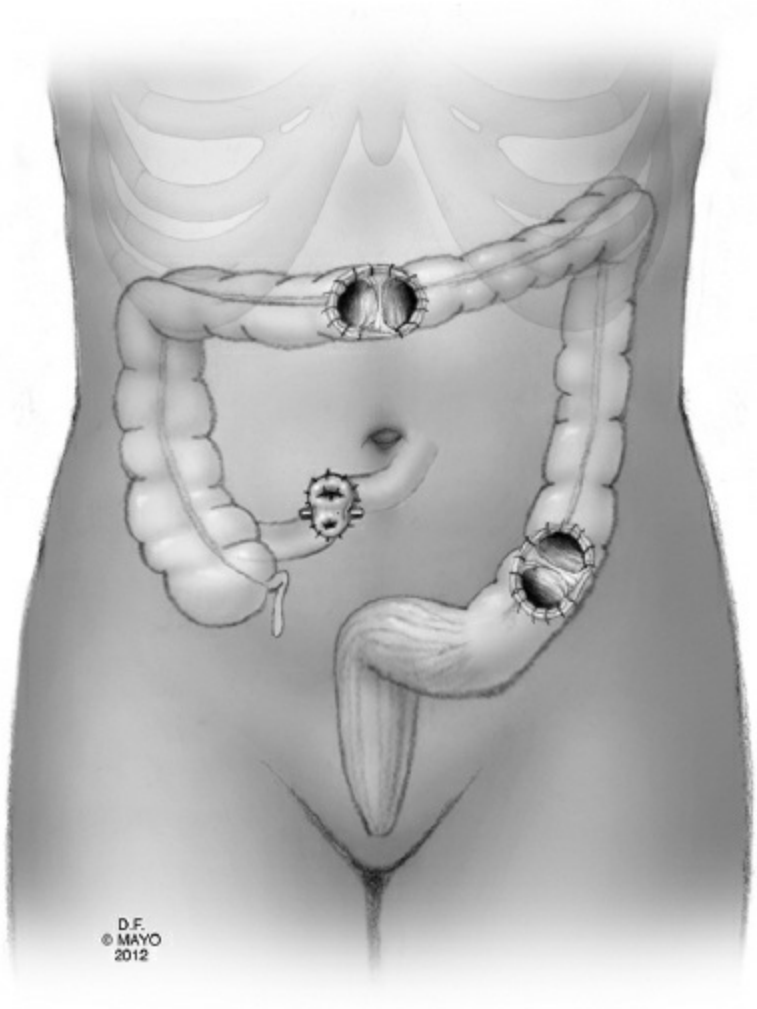

Figure 145.4. Turnbull procedure. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

Colonic Lavage Through Diverting Loop Ileostomy

For patients with severe complicated *C. difficile* colitis creation of a diverting loop ileostomy followed by colonic lavage has demonstrated lower mortality (19% vs. 50%) and higher rates of colonic preservation (39

of 42 patients) based on the protocol developed by Neal and colleagues at the University of Pittsburg. A diverting loop ileostomy is created, laparoscopically if possible, and once the incisions are closed and stoma matured a Malecot or similar catheter is inserted into the distal limb of the stoma and passed into the cecum. The colon is then lavaged with 8 L of warm polyethylene glycol 3350/electrolyte solution in the operating room. A fecal drainage system is employed transanally to collect the irrigant. Postoperatively 500 mg of vancomycin mixed in 500 mL of lactated ringers is instilled in an antegrade gravity-fed fashion over 15 to 30 minutes every 8 hours through the catheter. Metronidazole, 500 mg IV every 8 hours, is continued as well. Any deterioration or lack of improvement following lavage necessitates proceeding with a colectomy.

Subtotal or Total Colectomy

Total or subtotal abdominal colectomy with creation of a Brooke ileostomy and preservation of the rectum for a potential future restorative procedure is most commonly performed and recommended. It eliminates most of the disease and allows for restoration of health. Deferring the proctectomy reduces potential complications (bleeding, infection, autonomic nerve damage) and will simplify a restorative procedure by maintaining pelvic and presacral tissue planes.

Whether open or laparoscopic the principles of colonic mobilization and transection are essentially the same. The colon should be manipulated as little as possible to decrease the chance of an iatrogenic perforation. The mesocolon is typically edematous and foreshortened and care must be taken not to apply excessive traction on either the hepatic or splenic flexures. If the omentum is uninvolved and moves freely it can be separated from the transverse colon; otherwise remove it with the specimen.

Once the colon is completely mobilized, points of transection are decided upon. Proximally a small defect is made in the terminal ileal mesentery staying close to the ileocecal valve and the terminal ileum is transected with a linear cutting stapler. The tissue quality of the rectosigmoid junction is taken into consideration and a decision regarding creation of a Hartmann pouch or mucous fistula is made. If the tissue is not overly thick and friable the rectosigmoid junction can be stapled or transected sharply and sutured closed, although neither approach has been shown to be superior. Oversewing the staple line with interrupted sutures

can be performed. The superior rectal artery is preserved to decrease the possibility of rectal devascularization. In order to more easily identify the Hartmann stump in the future, a long permanent suture can be placed on each side of the transverse staple/suture line. To decrease the risk of a stump blowout, and resultant pelvic and abdominal abscesses, the rectum should be irrigated with a rigid proctoscope prior to leaving the operating room to remove bloody mucous, stool, and pus. A rectal tube can be left in place for at least 48 hours to decompress and decrease pressure on the closed stump. If omentum is preserved it can be mobilized and placed over the rectal stump to potentially decrease issues if breakdown occurs. Studies evaluating the outcome of a retained rectal stump have been conflicting. Some portend that leaving a diseased thickened rectal stump is not associated with increased rates of postoperative pelvic sepsis or complications. Others encourage exteriorization (mucous fistula or subcutaneous placement) of long stumps having found rates of pelvic sepsis as high as 12%, increased disease activity in the retained rectum, and subsequent pelvic dissection for restorative procedures more difficult with a retained short stump.

If a decision is made not to proceed with a Hartmann stump, adequate length must be available to create either a mucous fistula or subcutaneously exteriorize the proximal rectosigmoid stump. A mucous fistula is constructed to decompress the remaining colon and rectum. It can be combined with the end ileostomy, created through a separate stoma extraction site, or incorporated into the inferior edge of a laparotomy or laparoscopic extraction incision. If the bowel wall is too edematous and friable to accept suture it can be extracorporealized and held against the anterior abdominal wall with a moist sponge. Once the inflammation and edema subside the mucous fistula can be matured. In order to avoid a second stoma the closed end of the proximal rectosigmoid stump can be subcutaneously extracorporealized and placed in similar locations as a mucous fistula, or wherever it can reach without tension (Fig. 145.5). In the event the staple/suture line breaks down it will create a controlled mucous fistula instead of opening in the abdomen/pelvis. As with a Hartmann pouch, the subcutaneously exteriorized segment can be irrigated and decompressed for at least 48 hours.

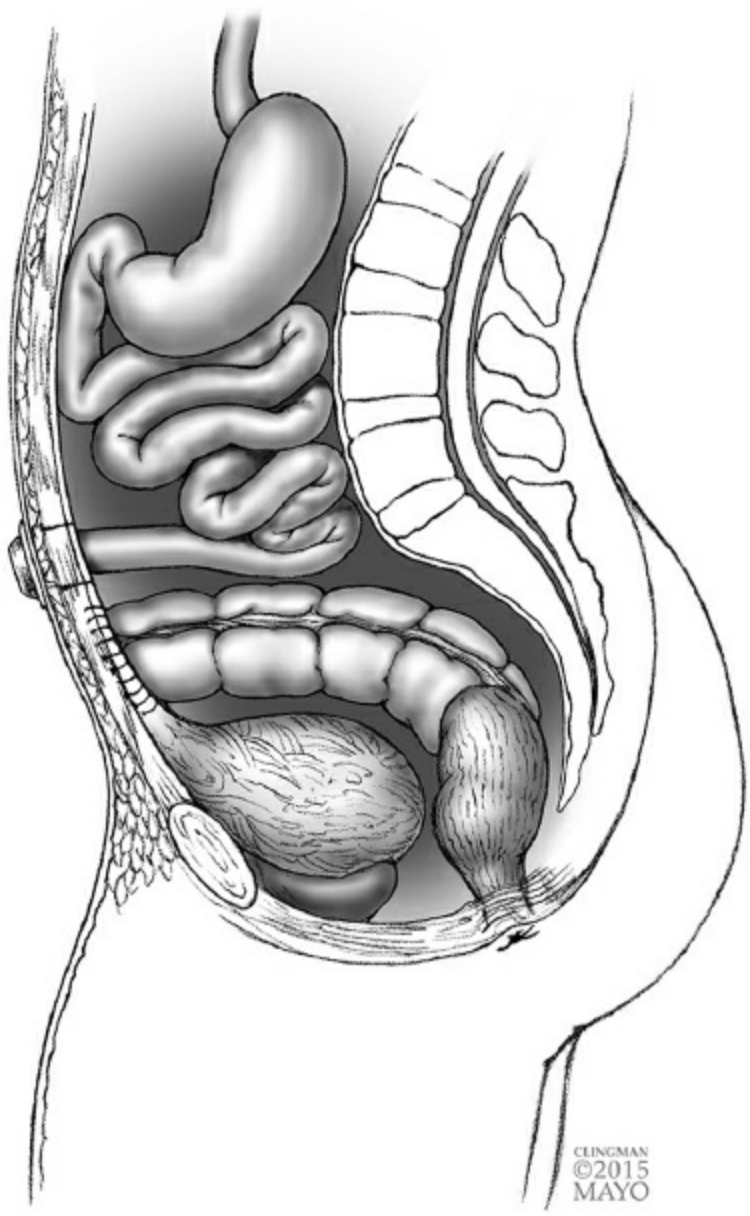

Figure 145.5. End ileostomy with subcutaneously extracorporealized rectosigmoid stump. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

After closure of the abdomen the ileostomy is matured in a standard evaginated Brooke fashion, with an attempted ideal projection of 2.5 cm (Fig. 145.6). A mucous fistula, if present, is matured flush against the skin.

Proctocolectomy With End Ileostomy/Restorative Procedure

A proctocolectomy with end Brooke ileostomy is very rarely performed and typically only in cases of life-threatening rectal hemorrhage, severe disease preventing creation of a Hartmann pouch or mucous fistula,

perforation, or when reestablishment of continuity or a restorative procedure will not be considered in the future.

Reestablishment of intestinal continuity (ileocolonic/rectal anastomosis) or a restorative procedure (ileal pouch anal anastomosis) is not recommended in unstable patients, and should only rarely be entertained when surgery proceeds without issue in stable, healthy, well-nourished patients with good tissue quality. If either is performed protecting the anastomosis with a temporary diverting loop, ileostomy is recommended.

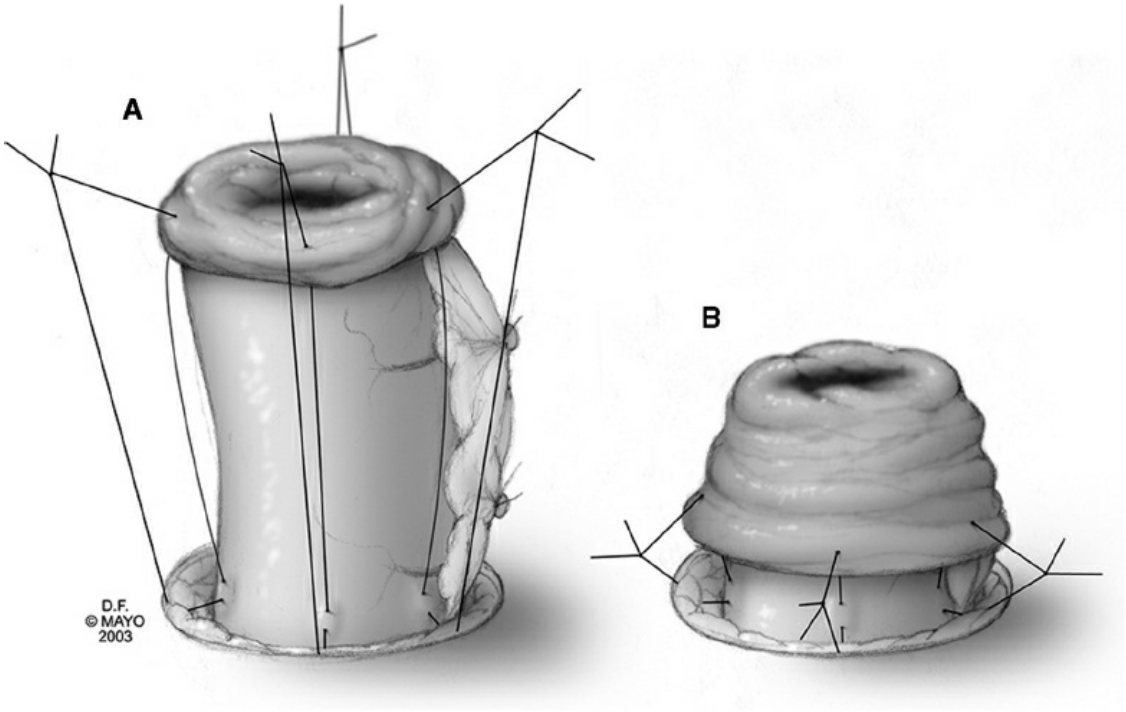

Figure 145.6. End Brooke ileostomy. (Used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

POSTOPERATIVE CARE

Postoperatively resuscitation is continued along with medical management for the underlying cause of toxic megacolon. As signs of systemic toxicity start to resolve intravenous agents are transitioned to oral and the diet is advanced as tolerated. Plans for discharge are made when physiologically stable, tolerating enteral nutrition, and having bowel function. Once comorbidities (debility, protein calorie malnutrition, anemia, cause of toxic megacolon) have resolved/improved dramatically plans for reestablishment of intestinal continuity are pursued if indicated.

COMPLICATIONS AND THEIR MANAGEMENT

According to Teeuween and colleagues the most frequent surgical complications following surgery for severe colitis are wound infection/dehiscence (18.4%), intra-abdominal abscess (9.2%), small bowel obstruction (6.2%), ileostomy-related problems (5.5%), and hemorrhage (4.6%), and the most common medical complications were septicemia (18.0%), pneumonia (11.2%), deep venous thrombosis (7.2%), pulmonary embolism (7.0%), and urinary tract infection (4.3%).

Wound Infection/Fascial Dehiscence

Wound infection and fascial dehiscence is more common in malnourished, anemic, and debilitated patients, especially in the face of intra-abdominal contamination. Facial closure in the presence of contamination should be performed with interrupted inert permanent or delayed absorption monofilament sutures. For contaminated wounds delayed primary closure (around postoperative day 3) of the abdominal incision has been shown to significantly lower the rate of superficial surgical site infection as well as fascial dehiscence, and reduces the mean complete incision healing time and hospitalization. The skin can also be allowed to heal by secondary intention with or without the utilization of a negative pressure wound closure device.

Intra-abdominal/Pelvic Abscesses

For cases of perforation and abdominal contamination the abdomen should be thoroughly lavaged with warm saline, with or without antibiotics (gentamicin, kanamycin), and suctioned until clear. Fibrinous rinds can be manually debrided. Though these maneuvers will not prevent abscess formation, they can decrease the risk. Abscesses can also form from a retained stump leak. Drainage of abscesses through catheters placed percutaneously with radiographic guidance is recommended.

Stomas

Stoma complications including retraction, peristomal skin excoriation, stenosis, prolapse, and herniation can occur, with up to 30% of patients requiring operative revision. Though at the end of the procedure, it is imperative that creation of a stoma is not rushed and proper technique is utilized. Stoma complications can be disastrous for patients, especially for

those with a permanent stoma.

Hemorrhage

In cases of toxic megacolon the mesocolon is typically thickened and inflamed and excessive traction during mobilization can result in tearing of the splenic capsule or thin walled veins. Division and ligation of the mesocolon can also result in hemorrhage, both intraoperatively and postoperatively. If the mesentery is overly thick suture ligatures are utilized to decrease issues with bleeding. For postoperative hemorrhage correction of coagulopathies and transfusion is carried out. If unable to control reexploration is recommended.

OUTCOMES

With maximal medical therapy a large percentage of patients with toxic megacolon can avoid surgery, with one study documenting a rate of 67%, although a high rate of recurrence requiring surgery has also been documented, albeit in earlier studies. Grant and Dozois at the Mayo Clinic prospectively followed 38 patients for an average of 13 years with toxic megacolon (32 CUC and 6 Crohn) successfully treated nonoperatively. Eleven developed a second episode and in total 18 (47%) wound up requiring a colonic resection, of which 15 (83%) were performed on an emergent/urgent basis. In a series from the Cleveland Clinic reported by Fazio only 7 of 115 (6%) patients were successfully treated with medical management, of which 5 eventually required a colectomy in later years.

Although early recognition and better management has decreased mortality rates for inflammatory bowel disease significantly (currently 0% to 2%), the presence of *C. difficile* colitis has been increasing since 2000 with mortality rates ranging from 37% to 80%. Pepin and colleagues, in a multivariate analysis, noted risk factors for mortality were age, preoperative lactate ≥5.0 mmol/L, leukocytosis ≥50.0 × 10^9/L, and albumin less than 15 g/L.

Colonic lavage and FMT both show promising results, tough it is still too early to draw any definitive conclusions.

EDITOR'S COMMENT

Clostridium difficile now is one of the most common hospital-acquired infections in surgical patients. The surgeon needs to be particularly prepared to face the issue of toxic megacolon, perhaps more frequently than ever has existed as a complication either of Crohn colitis or ulcerative colitis, as was true 25 years ago (Autenrieth DM, Baumgart DC. Toxic megacolon. *Inflamm Bowel Dis* 2012;18(3):584–91). Over recent years the rates of toxic megacolon due to infectious colitis have increased, while toxic colitis due to inflammatory bowel disease has decreased. It is estimated that the cost for inpatient hospital services for *C. difficile* infection in the United States currently range from 1.14 to 1.62 billion (https://www.cdc.gov/HAI/pdfs/hai/Scott_CostPaper.pdf)!

The critical nature and the surgeon's role in the care of the patient with suspected toxic megacolon requires immediate attention and a realization that there may be no disease in the colon itself except as a passive edematous conduit for an invasive bacterial infection of its own origin. The *C. difficile*–infected colon is characterized by tremendous edema of the colonic wall; it seldom bleeds and less often perforates. Conversely, the timeliness of surgical

involvement in these patients is absolutely vital and important, assuming that the surgeon uses reasonably good common sense and must be prepared to take the patient to the operating room at the slightest evidence of deterioration. Ileus in a patient with suspected *C. difficile* is an ominous sign. It does not indicate that the patient is better, but that the colon is simply beginning to dilate and that colonic ileus may predispose to massive deterioration of the patient.

There is substantial argument regarding the ideal nonoperative treatment for a patient with *C. difficile* colitis. It is clear that vancomycin and/or metronidazole are the antibiotic agents of choice. Fidaxomicin is an expensive alternative to vancomycin and metronidazole for patients with recurrent disease. Fecal microbiota transplant is a very promising therapy that may supplant surgery (Li YT, Cai HF, Wang ZH, et al. Systematic review with meta-analysis: long-term outcomes of faecal microbiota transplantation for *Clostridium difficile* infection. *Aliment Pharmacol Ther* 2016;43(4):445–57). There are currently significant administrative details, need for family members to donate fecal samples, need for fecal donor hepatitis and HIV testing, and sample processing which are all very time consuming and cumbersome for the very ill patient. In the future, biobanks of frozen samples should make this a much more attractive and manageable option (http://www.openbiome.org/). There has even been a report of fecal microbiota transplantation being used to successfully treat *C. difficile* toxin-induced toxic megacolon (Costello SP, Chung A, Andrews JM, et al. Fecal microbiota transplant for *Clostridium difficile* colitis–induced toxic megacolon. *Am J Gastroenterol* 2015;110(5):775–7)!

If the normal signs of an acute abdomen are present, such as leukocytosis, fever, and tenderness, then one must carefully make clinical judgments as to the likely need for operation. A better bit of news is that it appears to have become clearer, that is, the procedure of choice. The procedure promulgated by the surgeons at the University of Pittsburgh has included a diverting loop ileostomy and access to the colon itself for administration of vancomycin (Neal MD, Alverdy JC, Hall DE, et al. Diverting loop ileostomy and colonic lavage: an alternative to total abdominal colectomy for the treatment of severe, complicated *Clostridium difficile* associated disease. *Ann Surg* 2011;254(3):423–7). The improvement in in-hospital mortality is dramatic. Reports of large series of fulminant colitis up to this time had reported very high mortality rates, such as the report by Sailhamer et al., nearly 35% (Sailhamer EA, Carson K, Chang Y, et al. Fulminant *Clostridium difficile* Colitis: Patterns of Care and Predictors of Mortality. *Arch Surg* 2009;144(5):433–9). Age >70, severe leukocytosis (>35,000/μL), leukopenia (<4,000/μL), or neutrophil bandemia (>10%) and cardiorespiratory failure (intubation or pressor requirement) were independent predictors of mortality.

The Turnbull procedure, with ileostomy, and “blow-hole” transverse colostomy is seldom needed now. The technique that the authors mention, of placing the Hartmann stump subcutaneously in the lower aspect of the incision is one that I practice. This is very useful. In many of these patients, the distal

bowel is very diseased; it does not hold staples well, and despite being oversewn, will tend to dehisce at some point in the postoperative period. If this segment of bowel is left in the pelvis, one then has to contend with a pelvic abscess and treat this with transrectal or interventional radiology drainage, neither of which are pleasant for the patient. When one has, however, implanted the Hartmann stump subcutaneously and this same event occurs, one is left with a simple wound infection. When treated, this is in essence a low output mucus fistula—very safe, low maintenance, and easy to care for. I believe that we are seeing so much less inflammatory bowel disease–related toxic megacolon due to the greatly expanded medical therapy options available for those patients, especially the entire range of “biologic” anti-tumor necrosis factor-α therapies.

Susan Galadiunk

146 Total Proctocolectomy and Inter-Sphincteric Proctectomy for Benign Disease

Javier Salgado Pogacnik and David S. Medich

INDICATIONS FOR TOTAL ABDOMINAL PROCTOCOLECTOMY AND INTERSPHINCTERIC PROCTECTOMY FOR BENIGN DISEASE

Even though restorative total proctocolectomy (TPC) with ileal pouch anal anastomosis (IPAA) has become the treatment of choice for chronic, medically refractory mucosal ulcerative colitis (UC), indeterminate colitis (IC), and familial adenomatous polyposis (FAP), several absolute and relative contraindications exist. In the subgroup of patients, where IPAA is contraindicated, total abdominal proctocolectomy with intersphincteric proctectomy is the procedure of choice. The presence of toxic megacolon in ulcerative colitis patients should preclude an attempt for IPAA. In addition, poor preoperative sphincter functions as well as the presence of intra-abdominal desmoid tumors are absolute contraindications. Relative contraindications are also diverse. Advance age, previous small bowel resections, severe comorbidities, obesity with narrow pelvis, and Crohn disease (CD) are considered relative contraindications. Finally, there are some patients who will opt for TPC with end ileostomy despite being adequate candidates for restorative proctocolectomy for social or personal considerations.

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) has emerged as a growing problem in industrialized nations. In 1875 Wilks and Moxon introduced the term *ulcerative colitis* into the medical linguistic. In 1932 Crohn, Ginzburg, and Oppenheimer published a paper in *JAMA*, describing patients with "regional ileitis." Remarkably the surgeon involved in the care of the majority of the patients, Dr. A.A. Berg, did not want his name included in

the article. Later, Brooke in 1959 and Lockhart-Mummery and Morson in 1960 distinguished Crohn disease from ulcerative colitis. Since then, the incidence of ulcerative colitis and Cronh disease has increased in Western nations and in newly industrialized countries.

Currently 1.4 million persons in the United States suffer from these diseases, causing overall health care cost of more than $1.7 billion. IBD accounts for more than 700,000 physician visits, 100,000 hospitalizations, and disability in 119,000 patients. At some point in their lives 75% of patients with Crohn disease and 25% of those with ulcerative colitis will require surgery.

In developing the clinical decision tools, the standard assessment of the disease activity (as mild, moderate, or severe) is insufficient in guiding the selection therapy. Current *models* have included demographic and disease characteristics as predictors for colectomy, incorporating natural course of the disease, endoscopic disease activity, history of *Clostridium difficile* or *Cytomegalovirus* infection, chronicity of inflammation, and biomarkers (i.e., fecal calproctein).

Surgical management in ulcerative colitis is influenced by the nature of the presentation. In elective cases, TPC with Brooke ileostomy has been traditionally the gold standard in patients who are not candidates for IPAA. Indications include medical intractability, risk of malignancy, presence of incapacitating extracolonic disease, and growth retardation in children.

In addition to these, operative indications in Crohn disease will also depend in the specific anatomic location of the disease. Those patients with extensive colonic disease, proctitis, and ano-perineal sepsis should undergo a TPC with Brooke ileostomy.

Beside these current models, it is imperative for surgeons to understand the types of IBD-associated dysplasia as well as the correlation and risk between IBD and colorectal cancer in order to guide the adequate surgical management. Colorectal cancer has been documented as the cause of death in up to 15% of IBD patients. Presently, there is a vast variety of studies available on dysplasia and risk of progression to cancer in IBD patients, demonstrating the association between immune dysregulation, genetic susceptibility, environmental triggers, and IBD. Surveillance and treatment paradigms are often similar in the two groups despite different pathophysiologies. In both ulcerative colitis and Crohn disease, the incidence of dysplasia and colorectal cancer is increased based upon the duration of colitis, extent of colitis, age at diagnoses, gender (relative risk

in males: 2.6 vs. females: 1.9), severity of inflammation, family history of CRC, and coexisting PSC.

The treatment of IBD-associated dysplasia is guided by each type of dysplasia's risk of synchronous and metachronous lesions as well as the risk of progression to CRC. Because of "field effect" of cellular and molecular changes, both synchronous and metachronous dysplasia and carcinoma are more frequent in IBD population versus sporadic CRC.

	Synchronous Tumor Rate	Synchronous Dysplasia
CD	4%	30%
UC	14%	55%

The surgical decision rules in dysplasia and IBD can be summarized to the following:

1. Low-grade dysplasia (LGD); necessitates examination by second pathologist.
2. LGD versus high-grade dysplasia (HGD) should be viewed similarly, and both require TPC in the appropriate surgical candidate.
3. Multifocal dysplasia mandates a TPC.
4. Flat dysplasia mandates a TPC.
5. Dysplasia-associated lesions of masses (DALMs) mandate surgery.
6. Adenoma-like DALMs; most surgeons will propose surgery.
7. With pseudopolyps or strictures, effective surveillance may be impossible, and therefore it may require TPC.

Familial Adenomatous Polyposis

FAP is an autosomal dominant inherited syndrome caused by the mutation of the APC gene situated on chromosome 5q21, with an incidence of 1:10,000. The main clinical feature as a result of the mutation of this tumor suppressor gene is the development of hundreds of colorectal adenomatous polyps that appear in the adolescence, with capacity of malignant transformation. Once FAP has been diagnosed, the aim is to perform prophylactic surgery. The timing of prophylactic surgery is influenced by the clinical variant of the FAP. Severe polyposis (more than 1,000 colonic or more than 20 rectal polyps) should undergo surgery early in their course. Other clinical variants such as attenuated FAP, milder disease, or

MYH polyposis surgery can be deferred until it is optimal from a social and educational perspective.

The surgical options include colectomy with ileorectal anastomosis, TPC with IPAA and TPC, intersphincteric perineal resection, and permanent end ileostomy. The latter is indicated in patients with intra-abdominal desmoid tumors, poor preoperative sphincter function, or when technically the creation of an IPAA is impossible.

PREOPERATIVE PLANNING

The patient undergoing an elective colorectal procedure should undergo a systematic and comprehensive preoperative risk assessment. Special attention should be given to prior exposure to anesthesia, current medications, allergies, and associated comorbidities. All patients should have a preoperative medical clearance with thorough evaluation of the cardiovascular, renal, hematologic, and nutritional status. In addition to investigating the pulmonary and hepatic function, it is essential to have a detailed discussion about the technical details of the procedure, risks, benefits, different surgical options, as well as to postoperative expectations. Patients who will undergo a TPC with creation of permanent end ileostomy should receive preoperative teaching and stoma marking.

In recent years, the development of enhanced recovery after surgery (ERAS) protocols in colorectal surgery has been implemented and well-documented data have shown abundant advantages. These include shorter length of hospital stay, and postoperative complications. It is our preference in elective noncombined colorectal surgery cases to implement this pathway at our institution. This requires a respectable collaboration of a multidisciplinary team, including surgeons, anesthetists, nurses (in the outpatient clinic, preoperative room, as well as in the surgical ward), physical therapists, and nutritionists. In addition, these guidelines should be conversed with the patient prior to the surgical procedure. Lastly, ERAS colorectal feedback and discussion meetings should be planned methodically every 3 months to analyze compliance as well as discuss improvement approaches.

SURGICAL TECHNIQUE

TPC with intersphincteric proctectomy can be achieved via open and minimally invasive approaches. The later includes straight laparoscopy, hand-assisted laparoscopy, or robotic-assisted techniques.

Minimally Invasive Approach

A structured and specialized surgical team is essential in obtaining an adequate preparation and positioning of the patient. All patients (unless contraindicated) should receive preoperative DVT prophylaxis prior to induction of general anesthesia. In addition, patients should have sequential compression devices in bilateral lower extremities. After general anesthesia is induced, the patient is repositioned in a modified lithotomy position in Yellowfin stirrups. Special attention should be given to avoid sural nerve damage. Both arms should be appropriately padded and tucked. The chest should be tapped to avoid the patient to slide during the procedure. After the patient is satisfactorily positioned, communication with anesthesia is essential to confirm pressure cuffs, peripheral access, and arterial lines are functioning appropriately. In order to minimize the risk of surgical site infection, proper preoperative antibiotic prophylaxis should be given within 30 minutes of skin incision.

I favor on performing hand assisted laparoscopic approach using the Gelport device. A low Pfannenstiel incision is used with the thought of having lowers rates of incisional hernias as well as obtaining superior cosmetic results. As an alternative, a suprapubic midline 5 cm incision can be used. The Gelport device is introduced. A supraumbilical 5-mm balloon port is placed under direct visualization; 15 mmHg of pneumoperitoneum is achieved and subsequently 4 extra 5 mm balloon ports are introduced (Fig. 146.1).

The abdominal cavity is inspected, and dissection is initiated by mobilizing the right colon in a medio-lateral and inferior to superior fashion. The patient is repositioned in Trendelenburg, tilted to the left side. The ileocolic pedicle is identified and using atraumatic bowel graspers, it is tented anteriorly and superiorly (Fig. 146.2A). Using an energy source of the surgeon's preference, the visceral peritoneum over the ileocolic pedicle is scored in a V-shaped fashion. Dissection is carried over Gerota's fascia, identifying the retroperitoneal structures including right ureter, gonadal vessels, as well as the duodenum that is dissected free with gentle blunt dissection (Fig. 146.2B). It is crucial to accomplish adequate traction and counter traction triangulating the instruments in synchronized fashion with the assistant. This maneuver will allow a high ligation of the ileocolic pedicle using the energy source of surgeon's choice. The dissection is carried through the avascular plane superiorly until the inferior border of the liver is encountered and lateral to the abdominal wall. The second step

of the right colon mobilization is to take down the lateral and superior attachments of the proximal transverse colon, and hepatic flexure. Careful traction of this area is required due to the fact that there are vessels of different size that may require ligation. Finally the lateral colonic attachment through the white line of Toldt is completed, mobilizing the right colon to the midline.

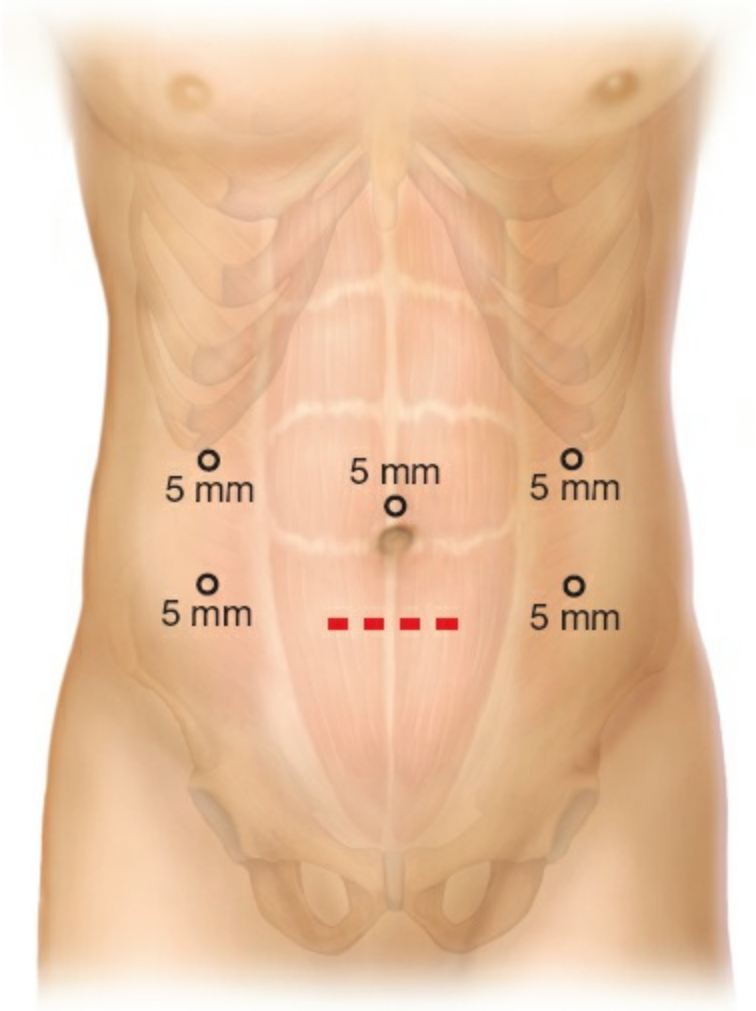

Figure 146.1. Port placement.

Consecutively, the transverse colon is mobilized. The omentum is lifted off the transverse colon, and if possible preserved in order to accomplish an omental flap that will be used to shelter the pelvic inlet. The lesser sac is entered, identifying the posterior wall of the stomach as well as the body of the pancreas. This maneuver allows to clearly recognize the origin of the middle colic vessels that are again ligated safely with the energy device. The dissection is carried caudally toward the splenic flexure.

Step 3 involves the mobilization of the left colon. The patient is placed

in Trendelenburg position tilted toward the right side. The surgeon is positioned in between the legs and both assistants to the right side of the patient (Fig. 146.3). Identification of the duodenal-jejunal junction as well as the origin of the inferior mesenteric vein (IMV) is achieved (Fig. 146.4A). Dissection is carried under the IMV, on top of Gerota's fascia, cephalad until the body of the pancreas is encountered, laterally to the abdominal wall, and caudally to the origin of the inferior mesenteric artery (IMA) (Fig. 146.4B). This avascular plane is very consistent, easy to develop, and facilitates the splenic flexure mobilization. The IMV is taken in a high ligation with the energy device. Subsequently, the visceral peritoneum to the right of the sacral promontory is scored up to the origin of the IMA. The retroperitoneal structures including left gonadal vessels and left ureter are identified and preserved. Once this is accomplished, both planes of dissection are connected, allowing to perform a high ligation of the IMA with preservation of the preaortic sympathetic plexus (Fig. 146.4C). Finally, the lateral colonic attachments are taken from the recto-sigmoid junction cephalad toward the splenic flexure.

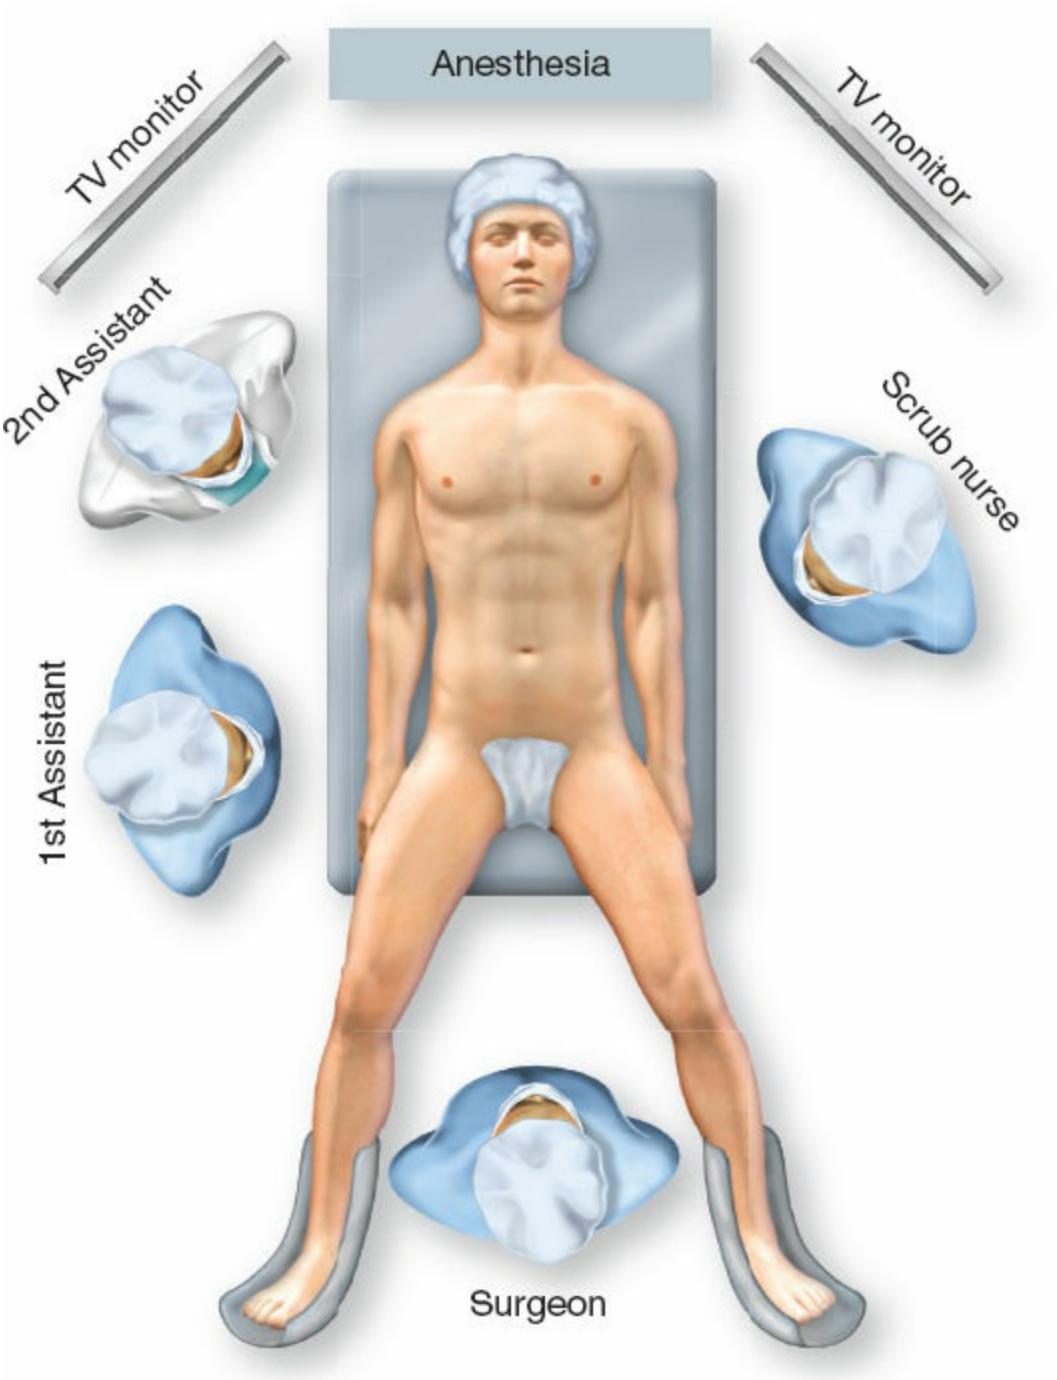

Figure 146.2. **A.** Identification of the ilecolic pedicle. **B.** Right colon medial to lateral mobilization.

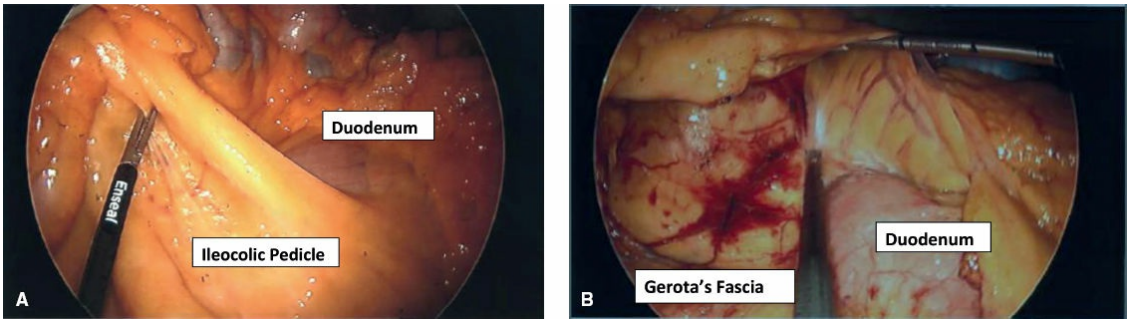

Figure 146.3. Surgical team position.

After the colon mobilization is concluded, it is my preference to deflate the pneumoperitoneum, extract the Gelport lid, and eviscerate the terminal ileum. The two unnamed vessels of the terminal ileum as well as the marginal artery are taken with Kelly clamps and 0-Chromic ties. The terminal ileum is transected with a GIA 60-mm blue load in an antimesenteric to mesenteric orientation. The small bowel is packed in the upper abdomen. The remainder of the colon is eviscerated. The proctectomy is completed directly through the Gelport using lighted St. Mark's or a curved Toy retractor.

I begin the rectal mobilization in posterior and posterolateral plane staying in the potential space between the fascia propria and presacral fascia with special care taken to avoid injury to the superior hypogastric plexus, right and left hypogastric nerves, and lateral pelvic side wall plexus. The mobilization is carried down posteriorly through Waldeyer's fascia to the pelvic floor. Anteriorly, in males it is imperative to carry the dissection on the rectal side of Denovilliers fascia, identifying the seminal vesicles as well as the posterolateral neurovascular bundles and minimizing the use of energy sources that could cause thermal spread injury during this part of the procedure. In women, visualization and preservation of the posterior wall of the vagina should be attained. This maneuver will allow complete mobilization of the rectum down and including the endopelvic fascia.

The perineal dissection can be done with the patient in the modified lithotomy position or repositioning the patient in prone jackknife that will require the creation of the end ileostomy and closure of the surgical wound prior to flipping the patient. Proning the patient has the advantage of better exposure and visualization of the surgical field, leading to superior oncologic outcomes. Furthermore, it allows the surgeon and the assistants to remain in a healthier posture. On the other hand, disadvantages include

the fact it prolongs the operative time, and necessitates an extremely respectable coordination between all team members. My inclination for benign disease is to complete the perineal dissection without modifying the patient's position if the patient's body habitus is favorable.

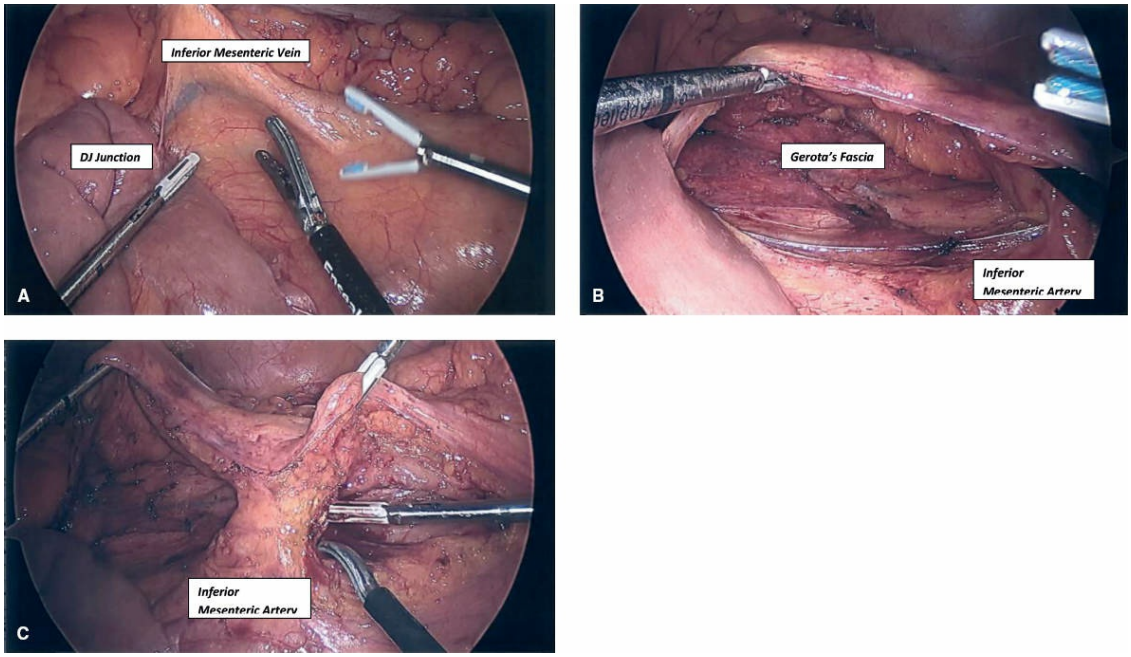

Figure 146.4. **A.** Identification of duodenal-jejunal junction and IMV. **B.** Left side medial to lateral mobilization. **C.** Dissection of IMA.

A 2-0 Surgipro purstring suture is placed in the anus to minimize fecal contamination. An elliptical incision just outside the intersphincteric groove is performed and continued in the intersphincteric groove using bovie electrocautery (Fig. 146.5). It should be approached first, posteriorly through the anococcygeal ligament into the previously dissected pelvis and then laterally. When 270 degrees postero-lateral dissection is accomplished, the specimen is retroflexed out of the anus in order to complete the anterior dissection. In males care must be taken not to injure the urethra and in women the posterior wall of the vagina. After adequate hemostasis is verified, the perineal wound is closed in layers, closing the puborectalis and external sphincter and skin separately with interrupted Polysorb suture. The skin is closed with vertical mattress of 2-0 Polysorb suture with telfa wicks placed between to minimize the surgical site infection rates. The stoma aperture is then made through the right rectus muscle at a site previously marked by the enterostomal therapy nurses. A 19-Fr round Blake drain is placed in the pelvis, and finally the omental

flap is used to obliterate the pelvic inlet to avoid small bowel loops from entering the deep pelvis. Those patients with active perianal sepsis/fistula disease, the tract should be curetted and a 12-Fr mushroom catheter should be left in place in the external os. The external sphincter muscle can be closed leaving the perineal skin partly of completely open in order to decrease surgical site infection rates and postoperative perineal wound complications.

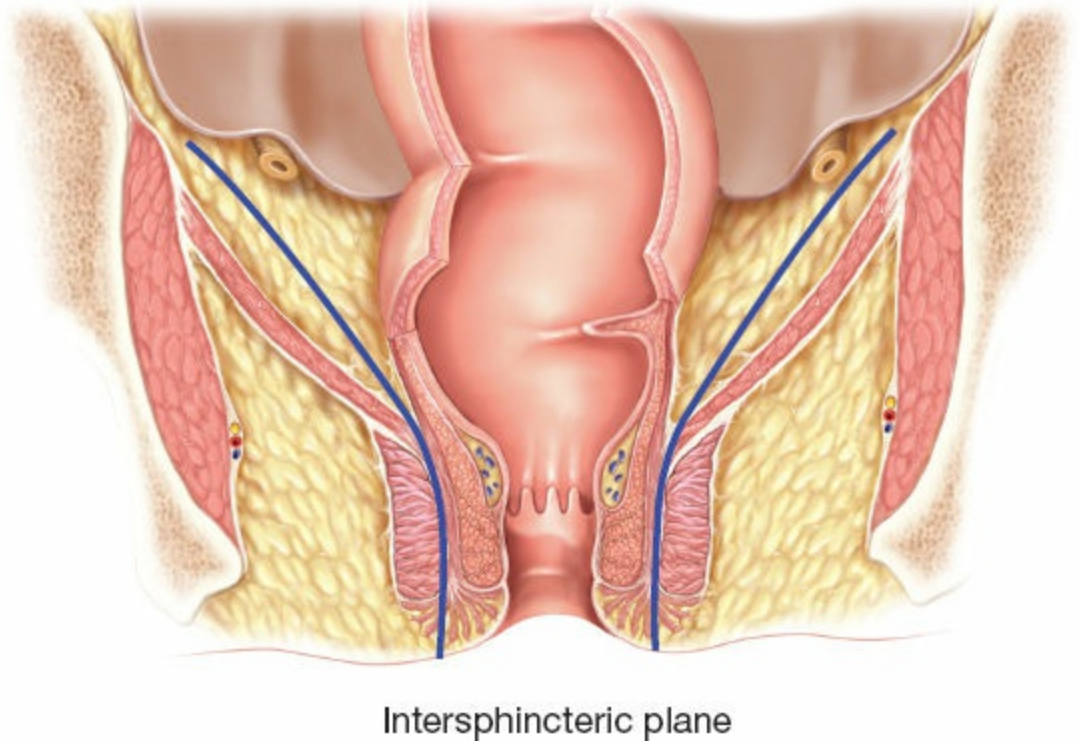

Figure 146.5. Intersphincteric plane.

Conventional Laparotomy

When conventional open surgery is performed, the surgical principles should be maintained. A midline laparotomy is performed and the abdomen is explored in a 4-quadrant systematic fashion, running the small bowel from the ligament of Treitz to the terminal ileum to rule out incidental pathology or the presence of concomitant small bowel Cronh disease. The main difference in the surgical approach is the fact that the dissection of the large intestine is mobilized in a lateral to medial fashion.

POSTOPERATIVE CARE

As part of my preference adhering to the of ERAS protocol, the postoperative care is divided into different phases. Postoperative 0 Phase;

patients are admitted to a monitored bed. Vital signs are obtained every 4 hours for the first 24 hours and then every 8 hours. Patients are encouraged to be out of bed to the chair at least 2 hours ambulate with assistance the night of surgery, elevate the head of the bed, and perform cough and deep breathes every 1 hour while awake. Sequential compression devices are placed in bilateral lower extremities while the patient is in bed. Noncarbonated clear liquid diet is ordered immediately after surgery. Lactated Ringer's is infused for 18 hours at a rate of 40 mL/hr. Pain controlled is focused in minimizing perioperative use of IV narcotics. A lidocaine drip is infused for 24 hours with the concomitant administration of acetaminophen and ketorolac when not contraindicated. Oxycodone immediate release tablet is ordered in a prn (as needed) basis.

On postoperative day 1, the patient is advanced to a GI (easy to digest) diet, encouraging 2,000 mL of noncarbonated clears, and the Foley catheter is removed. Patients and family members receive postoperative stoma care education and teaching.

POSTOPERATIVE COMPLICATIONS

The incidence of postoperative complications after total abdominal proctocolectomy with Brooke ileostomy is usually less when compared to patients undergoing IPAA. Minor complications can occur in up to 39% of patients and major complications in 17%, sometimes requiring reoperation and readmission to the hospital. Perineal wound infection, with delayed healing occurs in up to 25% of patients leading to significant morbidity, and associated frustration of the patient. Intersphincteric dissection improves blood supply to the area and minimizes the surgical wound decreasing wound-related complications. It is my preference to pack the perineal wound with Telfa wicks that will be removed in postoperative day 3. This allows the wound to drain and reduce this event. On those cases when superficial surgical site infection occurs leading to wound dehiscence, local wound care with packing or the use of negative pressure devices may be required for an extensive period of time.

Sexual dysfunction as a result of injury the sympathetic or parasympathetic lateral pelvic side plexus resulting in permanent impotence, retrograde ejaculation, or bladder dysfunction can occur in 1% of the cases. In woman, up to 30% can complain of postoperative dyspareunia as a consequence of perineal scarring. Adherence and knowledge of the precise pelvic anatomy, identification of the nerves, and

minimizing the use of energy devices in specific anatomic sites are mandatory to diminish this complication.

Ileostomy-related complications are diverse. Peristomal dermatitis as a result of pouch dysfunction, stoma prolapse, retraction, and strictures can occur between 5% and 25%. Readmission ates secondary to dehydration as a result of newly formed stoma are reported in 18% of the patients. Identification of factors that might predict readmission could help avoid early discharge and the application of precautionary actions to avoid this preventable ileostomy-related complication. Moreover, the enterostomal care education, adequate preoperative marking, clear understanding of the physiologic changes, and implementation of diaries with strict inputs and outputs will help minimize these events.

Small bowel obstruction as a result of this operation can occur in up to 20% of patients and is usually a consequence of postoperative adhesions formation to the large raw surface area, especially in the deep pelvis. The use of minimal invasive techniques, and when technically feasible the creation of an omental flap pedicle to obliterate the pelvic inlet is recommended.

CONCLUSIONS

Despite the fact that restorative total proctocolectomy (TPC) with ileal pouch anal anastomosis (IPAA) has become the treatment of choice for chronic, medically refractory mucosal ulcerative colitis (UC), indeterminate colitis (IC), familial adenomatous polyposis (FAP), and a select group of patients with Crohn disease (CD), total proctocolectomy with Brooke ileostomy remains a safe and effective operation in the appropriate surgical candidate with outstanding short- and long-term outcomes.

EDITOR'S COMMENT

Drs. Medich and Pogacnik describe the technique of intersphincteric proctectomy that has also been termed "endo-anal" proctectomy, namely the operation whereby the external anal sphincter and levator muscles are left in situ for cases of proctectomy where benign disease is present. This is an important technique in the armamentarium of the busy abdominal or colon and rectal surgeon. It differentiates itself from abdominoperineal resection (APR) for cancer, in that there is a smaller, stronger perineal wound. Unlike abdominoperineal resection for cancer, in which the perineal wound basically consists of fat sewn to fat, with intersphincteric proctectomy the wound is smaller since the external anal sphincter, puborectalis, and levator muscles are left in place and muscle is apposed to muscle in the wound.

The approach to Crohn's perianal disease differs somewhat in the United States and in England. For example, in the United Kingdom, in operating on a patient with extensive perianal Crohn disease, the approach would typically be to perform wide excision and utilize plastic surgeons for flap reconstruction, whereas in the United States, the approach has been more conservative. There are pros and cons to both approaches. With the more extensive use of immunosuppressive medications in this country, the fear that there will be more disturbances of wound healing with more extensive procedures, is in my opinion justified. However, there is the real concern that leaving chronic fistula tracts in situ might be associated with subsequent occurrence of adenocarcinoma in these longstanding fistula tracts. Although this is a real concern, it is of very low incidence.

Although the authors discuss performing this operation for patients with Crohn disease, as well as for those with familial polyposis and those with ulcerative colitis, this type of procedure can also be performed in patients who have received extensive radiation. In fact, in such patients, depending on the scenario one may want to go so far as to leave the anal canal in situ because of the significant wound-healing disturbances.

An important part of preoperative counseling, especially in patients with Crohn disease, is to advise patients that fully one third of patients will have delayed perineal wound healing. These wounds will often dehisce after the patient has been discharged from the hospital and then heal by secondary intention. This will sometimes take months, rarely even years, to completely heal. This will often challenge the patience of both the patient and the surgeon. Treatments that can help hasten wound healing are either cauterization of these wounds with silver nitrate, repeated curettage in the operating room, or if the patient is motivated, packing these wounds with 1/8th strength Dakin solution moistened 4 × 4 gauzes, changed two or three times daily is another treatment alternative. Occasionally, excision of the anal sphincter is required for wound healing to occur (Nisar PJ, Turina M, Lavery IC, Kiran RP. Perineal wound healing following ileoanal pouch excision. *J Gastrointest Surg* 2014;18(1):200–7). In some patients flap reconstruction may be necessary (Kamrava A, Mahmoud NN. Prevention and management of non-healing perineal wounds. *Clin Colon Rectal Surg* 2013;26(2):106–11).

Regarding the indications for total proctocolectomy that are listed in the chapter with respect to the presence of dysplasia, these are controversial. Many gastroenterologists and surgeons would disagree. As with many things in medicine, there has been a pendulum swing regarding the willingness to endoscopically closely follow rather than operate on patients with dysplasia. There has been increasing recognition that the risk of invasive cancer in particular with low-grade dysplasia is low (Allen PB, Kamm MA, De Cruz P, et al. Dysplastic lesions in ulcerative colitis: changing paradigms. *Inflamm Bowel Dis* 2010;16(11):1978–83; Murphy J, Kalkbrenner KA, Blas JV, et al. What is the likelihood of colorectal cancer when surgery for ulcerative-colitis-associated dysplasia is deferred? *Colorectal Dis* 2016;18(7):703–9). While there are many studies one could quote citing both sides of the equation, there are some things that most physicians taking care of these patients agree upon. Having a second pathologist review the finding of dysplasia is paramount. In addition, an adenoma-like dysplasia that is found in a region not affected by colitis, is not necessarily thought to be associated with the colitis, and can be treated like a sporadic polyp, that is, removed endoscopically.

Many raised lesions can be safely removed if the patient is willing to be appropriately and closely followed with surveillance endoscopy. This is an important caveat. If a patient is not willing to undergo very close endoscopic surveillance, this is not a good strategy and colectomy should be performed. Odze and colleagues have an impressive series of patients treated in this manner with long follow-up where endoscopic removal of dysplastic lesions with close follow-up has been shown to be an acceptable and safe strategy (Odze RD, Farraye FA, Hecht JL, et al. Long-term follow-up after polypectomy treatment for adenoma-like dysplastic lesions in ulcerative colitis. *Clin Gastroenterol Hepatol* 2004;2(7):534–41). On the other hand, there are other examples where less than a total proctocolectomy has clearly doomed the patient to development

of multiple cancers, eventually resulting in death (Galandiuk S, Rodriguez-Justo M, Jeffery R, et al. Field Cancerization in intestinal epithelium of patients with Crohn's ileocolitis. *Gastroenterology* 2012;142:855–64). Currently, the only thing that is certain is that we still do not have an ideal biomarker to delineate or assess cancer risk.

147 Ileoanal Pouch Procedure for Ulcerative Colitis and Familial Adenomatous Polyposis

Susan Galandiuk, Jeffrey R. Jorden, Russell W. Farmer, and Josef E. Fischer

INTRODUCTION

Total colectomy and ileal pouch-anal anastomosis (IPAA) has been the operation of choice for the elimination of disease and restoration of intestinal continuity for ulcerative colitis (UC) and familial adenomatous polyposis (FAP) for over 30 years. This operation has its beginnings in pediatric surgery, initially with straight ileoanal anastomosis. It was not until the mid-1970s when ileal "reservoirs" constructed using the terminal ileum led to adequate functional results (an acceptable number of bowel movements and satisfactory continence) and wide clinical adoption of these operations. In the mid-1970s, Sir (later Lord) Allen Parks and Dr. Joshi Utsonimia jointly described IPAA, Parks using an S-pouch and Utsonimia utilizing the much simpler and technically less demanding J-pouch. These operations were initially described with a transanal mucosectomy of the distal rectal mucosa and a hand-sewn ileo-pouch anal anastomosis. Because of its technical demands, this operation was largely only performed by specialists and high-volume surgeons. In the latter part of the 1980s and early 1990s, the technique of stapled IPAA was introduced, in which the mucosectomy was abandoned in favor of leaving a short residual rectal cuff. This had advantages and disadvantages in that it provided improved continence by preserving the transition zone and allowed a larger number of surgeons to perform the procedure, since mucosectomy was no longer needed, and the procedure therefore technically less demanding. It has, however, led to new problems associated with the retained rectal cuff, which in patients with inflammatory bowel disease was associated with residual inflammatory bowel disease with its associated risk of both disease activity and neoplastic transformation and in patients with FAP, the risk of polyp

development, and neoplastic change over time. IPAA can be performed open, laparoscopic, hand-assisted, or robotic-assisted. Major challenges for the surgeon lie in preoperative patient assessment in terms of avoiding healing complications in severely immunocompromised inflammatory bowel disease patients who may still be taking immunosuppressive medications, and deciding which patients are best treated by a standard two-stage as compared to a three-stage approach. As always major technical difficulties lie in getting the small bowel to reach to the anal canal/lower rectum, and complications associated with the temporary ileostomy that is performed in patients taking such immunosuppressive medication or in patients in whom there is excessive tension. This is particularly true in the increasingly obese patients we are encountering.

Normal Physiology Function and Principles

The major physiologic function of the colon is twofold, fluid absorption and a reservoir function in storage of fecal matter. When the colon is removed for a specific disease state, whether it be inflammatory bowel disease or FAP or hereditary nonpolyposis colon cancer, the resulting fecal matter expelled by the small bowel is more liquid due to the lesser amount of water absorbed and is of the consistency of toothpaste or pudding, because there is a loss of reservoir function, it is expelled more frequently. There have been many suggested reservoir formations with IPAA as pouches, J-pouches, H-pouches, and W-pouches, schematically shown in Figure 147.1. For all intents and purposes, the only ones that are used nowadays are the J-pouch in the vast majority of patients and occasionally the S-pouch if there is extreme difficulty in getting the reservoir to reach to the anal canal/lower rectum. Normally, an ileal pouch does not completely empty even in the best of cases. Therefore, constructing a larger pouch does not give you better function, only more fecal stasis.

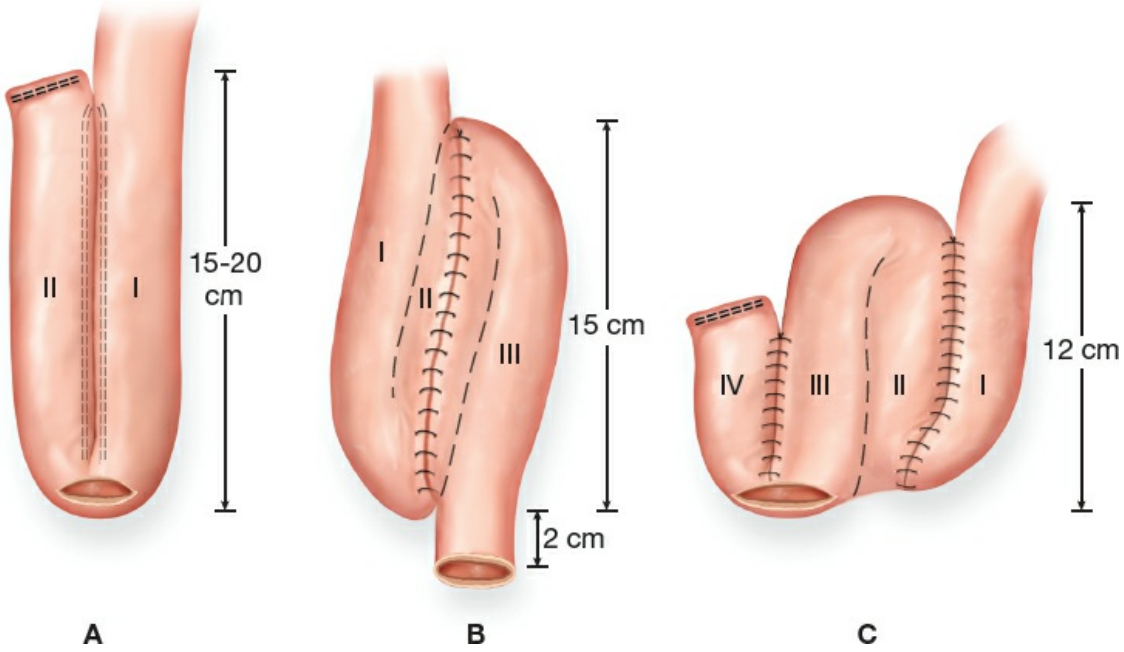

Figure 147.1. There have been many suggested reservoir formations of ileal pouches: J-pouches, H-pouches, and W-pouches, which as shown schematically. The J-pouch has proven the easiest to construct and is most frequently performed.

Also we have learned that with stapled operations preserving the anal transitional zone there is improved continence for both stool and gas, with improved continence both day and night as compared to the hand-sewn IPAA with mucosectomy. However, other factors have to be accounted for. For example, will a patient with FAP follow up? Do the polyps extend to the dentate line? Is there rectal cancer or rectal dysplasia in the lower third of the rectum? Intestinal transit is also important in selecting patients who do well with this operation. There are some patients with severe diarrhea-predominant irritable bowel syndrome who will have very poor functional results following this surgery. This is often very hard to differentiate from the overlying symptoms of inflammatory bowel disease. Similarly, patients requiring radiation therapy for rectal cancer often will have very poor functional results. Because of the rapid cell turnover of small bowel epithelium, these tissues will frequently sustain very significant radiation toxicity and subsequent poor postoperative functional outcome.

CLINICAL PRESENTATION

Indications for IPAA can be broken down into three major categories: inflammatory bowel disease, FAP and other cancer syndromes, and an

"other" category.

Inflammatory Bowel Disease

By far, the vast majority of IPAA procedures performed for inflammatory bowel disease will be performed for ulcerative colitis. However, within the last 10 years, with the improving medical therapy for Crohn disease and the increasing realization that many patients with Crohn disease can do well with IPAA, there has been an increasing willingness on the part of many surgeons to perform IPAA for cases of overt Crohn colitis without perianal or small bowel involvement *provided that the patient understands the significant associated risks* should small bowel disease subsequently develop. This includes development of perianal and pouch fistulae and abscesses, extirpation of the pouch, and permanent ileostomy. *This should not be undertaken without prolonged and in-depth preoperative patient counseling.* There are currently no absolute diagnostic tests to ensure that patients with Crohn colitis will not develop subsequent small bowel or perianal disease and also *no* absolute diagnostic tests to ensure that a patient with colitis limited to the colon is indeed ulcerative colitis and not Crohn disease. Approximately 65% of patients with Crohn disease will not exhibit granuloma on histology and therefore failure to identify granuloma on biopsy is not a sine qua non for the diagnosis of Crohn disease. Similarly, the finding of crypt abscesses is nonspecific. These can be seen in a variety of conditions, and is not diagnostic of ulcerative colitis. There have been many studies discussing the fate of patients with Crohn disease who have undergone IPAA based upon an initial presumed diagnosis of ulcerative colitis. By and large all of the results are less favorable than patients with ulcerative colitis who perform these procedures. Many patients with Crohn disease are willing to take this risk. In patients with ulcerative colitis, overall the chance of a favorable outcome is on the order of 90% to 95%.

Familial Adenomatous Polyposis

For FAP, again the vast majority of patients prefer IPAA to the other option of total colectomy and ileostomy or to the option of subtotal colectomy and ileal rectal anastomosis and every 6-month flexible sigmoidoscopy and polypectomy. In our experience, patients with FAP are notoriously poor at follow-up. In many series, the risk of rectal cancer forming during subsequently follow-up is as high as 30%. For that reason,

many surgeons prefer removing all of the at-risk mucosa (i.e., performing mucosectomy). It is my own preference to perform a hand-sewn IPAA whenever possible to eliminate the need to survey the distal mucosa if a stapled anastomosis can not be obtained very distally, which may be a problem in patients who are very obese or patients with a very long torso.

"Other" Conditions

There are a variety of other conditions in which IPAA may be indicated, such as in cases of pan-colonic inertia, colonic aganglionosis, megarectum among others (Fig. 147.2). Provided that there is normal pelvic floor function and an intact anal sphincter, good results are usually obtained. Overall, functional results are typically better in patients who have IPAA for a noninflammatory condition, as opposed to an inflammatory condition. Many people feel that this is due to a better sphincter function, without pre-existing chronic inflammation, or this may also be due to a less fatigued sphincter secondary to less problems with pre-existing diarrhea.

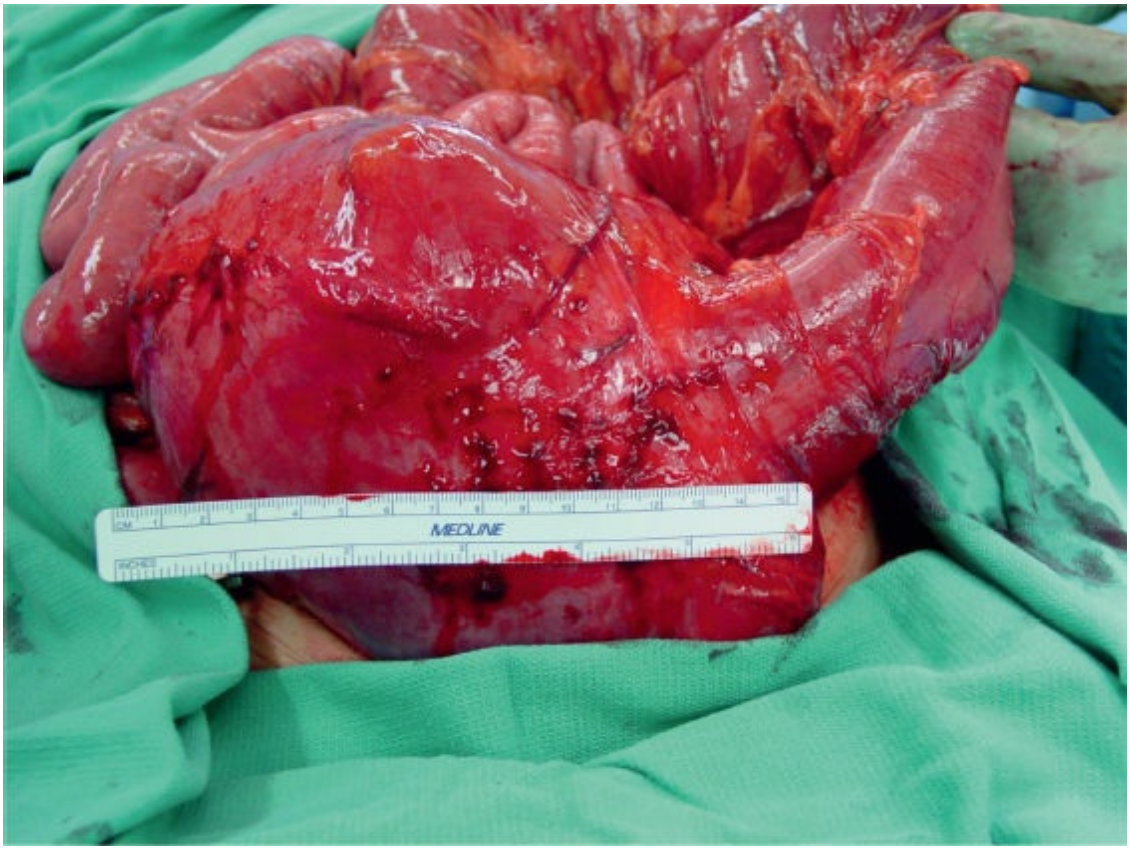

Figure 147.2. Megarectum with pan-colonic inertia, an uncommon indication for ileal pouch-anal anastomosis. The rectum *has not yet been mobilized* and extends well into the

abdomen. Rectum of the patient (*left*); sigmoid colon at right of image.

INDICATIONS AND CONTRAINDICATIONS

Fulminant Colitis

Fulminant colitis is defined as colitis requiring hospitalization, and not responding to maximal medical therapy. These patients are commonly on immunosuppressive medications such as steroids and anti-TNF antibodies or vedolizumab and as such pose a higher risk of postoperative complications. Over the last 5 years, there has been increasing recognition that many of these so-called “biologic” drugs significantly increase the risk of postoperative complications and more and more surgeons are opting for a three-stage procedures: performing a colectomy Hartmann and ileostomy first, followed by the proctectomy and J-pouch fat the next operation, and finally by loop ileostomy closure at the third and final procedure. This is as opposed to the more typical two-stage procedure where the colectomy, proctectomy, and J-pouch would be performed at the first procedure, and the ileostomy closure at the second procedure. In many cases, if the patient has fulminant colitis, one cannot easily distinguish whether or not the patient has Crohn colitis or ulcerative colitis and the disease is termed “indeterminate colitis.”

Toxic Megacolon

Toxic megacolon is defined as patients having such severe colitis that they are septic from it. The mucosa of the colon acts as a barrier to end of toxins within the lumen. If the mucosa sloughs, endotoxin can be absorbed into the blood stream and cause signs of sepsis, namely fever, tachycardia, and leukocytosis. Because of their severe diarrhea, these patients are often hypoalbuminemic. If there is an associated colonic ileus, the patient can develop a “megacolon,” which is defined as a transverse colon diameter greater than 5 cm on a plain abdominal film. In these patients, the bowel is extremely friable and stapling off of the distal colon is often complicated by a Hartmann stump “blowout” due to the extreme fragility of the bowel wall. This can be avoided in many cases by incorporating the Hartmann stump between the leaves of the fascia of the midline incision or the specimen retrieval site so that if this occurs the patient merely has a wound infection and the wound can easily be opened to treat this (Fig. 147.3A,B).

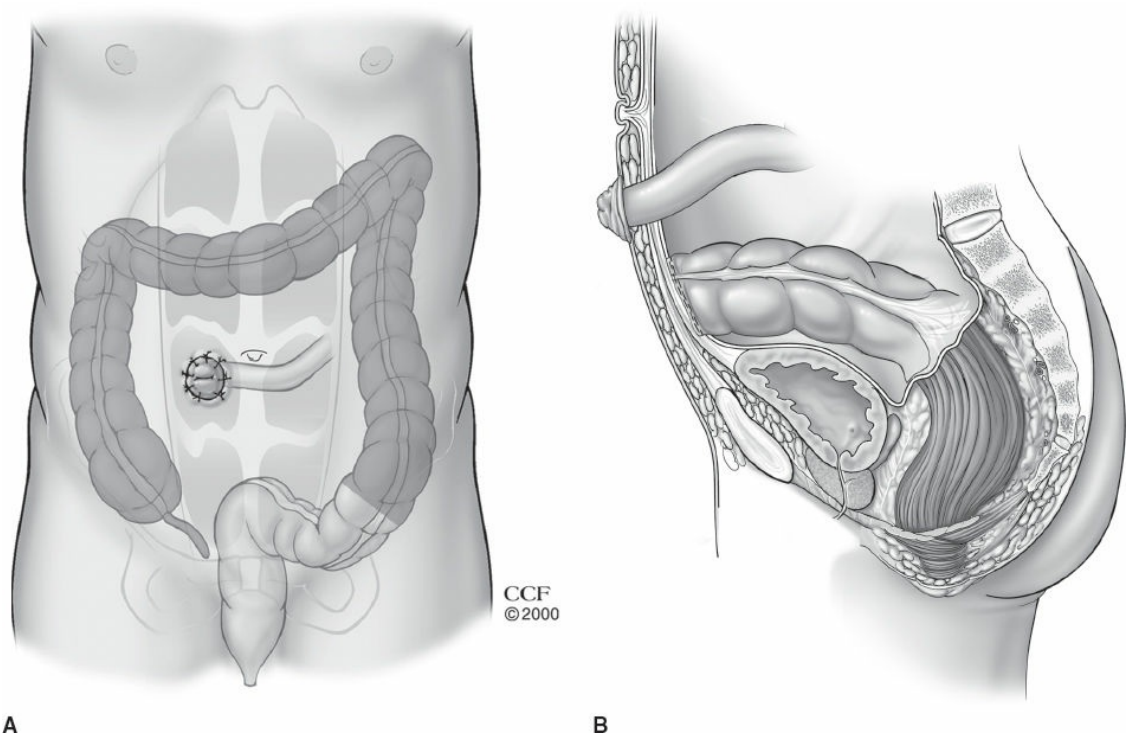

Figure 147.3. A. Subtotal colectomy with end ileostomy. **B.** The Hartmann stump is sutured between the leaves of the fascia of the midline incision or specimen retrieval site (for minimally invasive procedures) and the skin and subcutaneous tissues closed over this. In the event of a Hartmann stump "blow-out" or dehiscence, rather than developing a pelvic abscess and systemic illness, the patient merely has a wound infection that can be treated by local incision and drainage.

Primary Sclerosing Cholangitis

Ulcerative colitis patients with a primary sclerosing cholangitis typically have a higher rate of pouchitis postoperatively and worse functional results than other patients with ulcerative colitis undergoing this procedure. They should be very carefully counseled before undergoing IPAA.

Incompetent Anal Sphincter

Patients who have had prior sphincter injury, especially women with previous childbirth injury should be carefully counseled prior to undergoing IPAA. As patients age, their sphincter function tends to worsen, and many women who have had childbirth injury will have worsening problems with continence. The availability of sacral nerve root stimulation has been a significant improvement in some of these individuals. Incontinence due to sphincter injury must be differentiated

from incontinence due to tenesmus due to severe inflammatory bowel disease.

FAP Patients Requiring Whipple

FAP patients who have significant duodenal adenomatous disease need to be very carefully counseled. Patients with IPAA who subsequently require a Whipple procedure have terrible functional results.

PREOPERATIVE PLANNING

Inflammatory Bowel Disease Elective Versus Urgent

IPAA should never be performed as an emergent operation due to the unacceptable increase in complications. Preoperative planning varies as to whether surgery is elective as compared to urgent. In patients with inflammatory bowel disease, in those patients with significant disease activity, attention should be paid to minimizing rectal disease activity in order to optimize healing of the distal rectal staple line. If there is a very significant distal rectal disease, we favor the use of nightly preoperative 5-ASA suppositories. In addition, if the patients have been placed on oral steroids, maintaining the patients their steroid dose rather than trying to wean them preoperatively helps maintain the rectal mucosa in better condition. Attention should be paid to the patient's nutritional status by monitoring either serum albumin or pre-albumin. With significant weight loss, there may be merit in some attritional supplementation preoperatively either enteral or parenteral. In patients who are significantly malnourished, optimizing this will help lessen complications. If the patient is on anti–TNF-α antibody therapy (infliximab, adalimumab, certulizumab, or similar agents), we prefer to have these withheld for at least one dose prior to surgery. Although there are controversy and conflicting reports, many feel that the use of these drugs prior to surgery is associated with a significantly higher rate of infectious postoperative complications. Many surgeons, in fact, avoid doing two-stage procedures in patients on these medications for this reason.

Familial Adenomatous Polyposis

In FAP patients, there is always a question of the best time to operate in newly diagnosed patients. In adolescents, this is typically done during their summer vacation from school; however, it should not be delayed much

longer as cancers can even develop in individuals below 20 years old.

Preoperative Planning in the Setting of Rectal Cancer

In patients with inflammatory bowel disease or FAP, in whom a rectal cancer has been diagnosed and in whom the patient has expressed a strong desire for a sphincter sparing operation (i.e., IPAA), the cancer should first be staged using endorectal ultrasound or magnetic resonance imaging (MRI). If the patient has a T3 or node-positive cancer, the patient will require neoadjuvant chemotherapy and radiation. There will be far less radiation damage to the terminal ileum if radiation is given preoperatively as compared to postoperatively. In any event, patients with IPAA who have undergone prior pelvic radiation therapy generally do not have good postoperative functional results. They have a greater number of bowel movements and inferior continence as compared to patients who have not undergone radiation therapy.

SURGICAL TECHNIQUE

We will first discuss common aspects of surgical technique irrespective of mode of access. Following this, we will describe issues of surgical technique unique to open, laparosopic, and robotic approaches, respectively.

Common Techniques to Obtain Small Bowel Mesenteric Length Regardless of Method of Access

One of the difficult aspects of surgery is getting the small bowel to reach to the pelvis, specifically to the top of the anal canal. This is difficult in individuals who:

- are obese
- have a short mesentery
- have an extremely long torso
- have had a prior small bowel resection
- have small bowel mesenteric desmoid disease

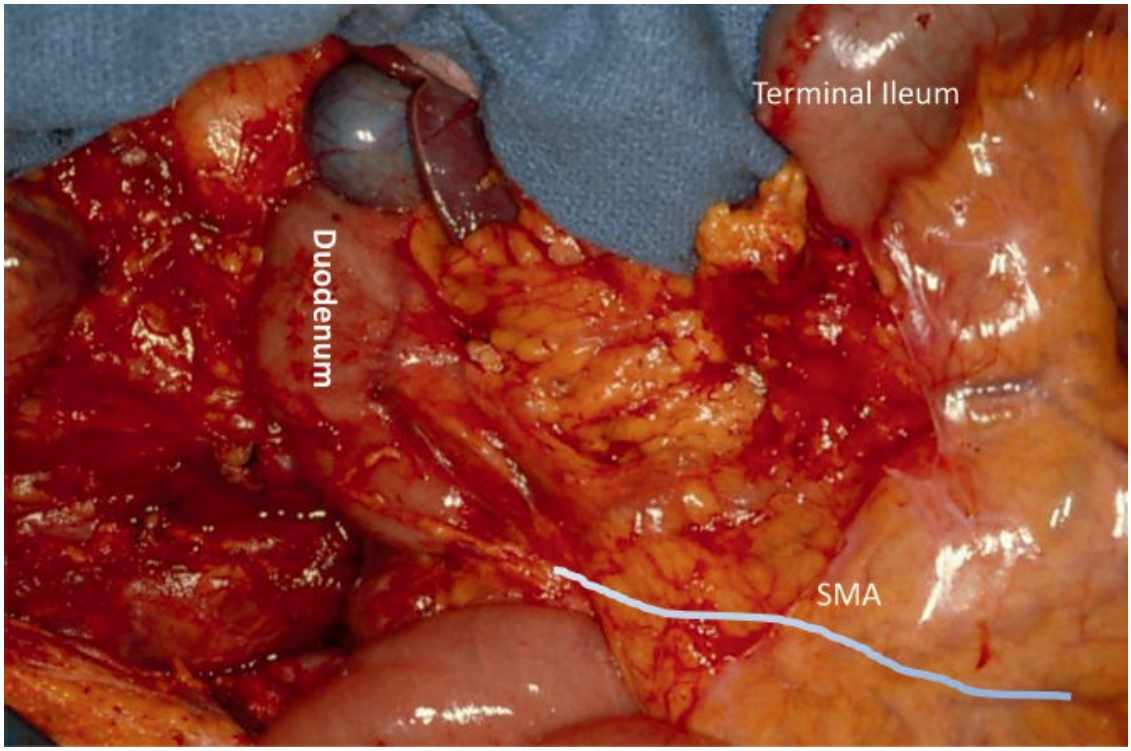

Figure 147.4. Mobilization of the small bowel mesentery away from the retroperitoneum to the level of the third portion of the duodenum and away from the third portion of the duodenum (labeled). The patient's foot is to the left of the photo and head to the right of the photo. Note the course of the superior mesenteric artery (SMA) shown by the white line, for subsequent peritoneal windowing.

The most important technique to facilitate the small bowel mesentery to reach the anal canal is complete posterior mobilization of the small bowel mesentery away from the retroperitoneum to the level of the third portion of the duodenum (Fig. 147.4). If required, scoring of the peritoneum overlying the mesentery on both the anterior and posterior aspects of the mesentery can be performed to gain additional mesenteric length (peritoneal windowing) (Fig. 147.5), division of either the ileocolic or superior mesenteric artery can be done to gain length (Fig. 147.6), or the pouch rotated so that the mesentery is anterior to the pouch. The hand-sewn technique by definition will require a greater amount of mobilization. In performing a hand-sewn anastomosis, either a LoneStar retractor, Gelpi retractors, or sutures are used to efface the anal canal and evert it in order to provide good visualization of the dentate line (Fig. 147.7). This in effect brings the anal canal externally and distally for a distance of approximately 3 cm. Even more mobilization is therefore required than

with a stapled technique where *the reverse is true*; that is, the distal rectum is actually pushed into the pelvis so *less length* is required. There have been many different methods of ileal pouch construction. For all intents and purposes, the majority of pouches that are constructed now, due to their simplicity of construction and good function, are J-pouches that are constructed using two firings of a GIA stapler, either a 75-mm stapler or 100-mm stapler. Conventionally the J-pouch is 15 cm in length, or, if operating on children, is constructed 1 cm in length for each age of the child above 5 years of age. It is important to oversew the blind stapled end of the ileum (the end of the short limb of the "J"), since this is a frequent site of leaks. There are many different ways to construct the IPAA. If it is a stapled anastomosis, this can be done using either through a purse-string or a triple-staple technique. If using a hand-sewn approach, we prefer to perform the stapling through an enterotomy in the mid-portion of the pouch, which is then closed through a standard two-layer technique and a second firing of the GIA stapler used to divide the spur of the pouch. There are occasions when a J-pouch will fail to reach the anal canal. In these circumstances, an S-pouch, which by definition needs to be hand-sewn, may be required. This should seldom be necessary. A major disadvantage of the S-pouch is the fact that it can result in obstructed defecation due to stretching and "kinking" of the efferent limb. This will sometimes require the patient to perform intubation of the pouch to permit defecation. Diversion is performed in patients in whom there is tension, or in patients who are on immunosuppressant medications in whom there would be an increased risk of nonhealing, such as steroids, immuosuppressives, or antitumor necrosis factor antibodies (such as infliximab, adalimumab, or others) or significant malnutrition or other factors that might impair healing, that is, history of radiation. In cases in which there are no adverse factors that might impair healing and no tension, this operation can safely be performed without temporary ileostomy (Fig. 147.8A). When diversion is required, it is typically performed at approximately 40 cm proximal to the ileal pouch (Fig. 147.8B).

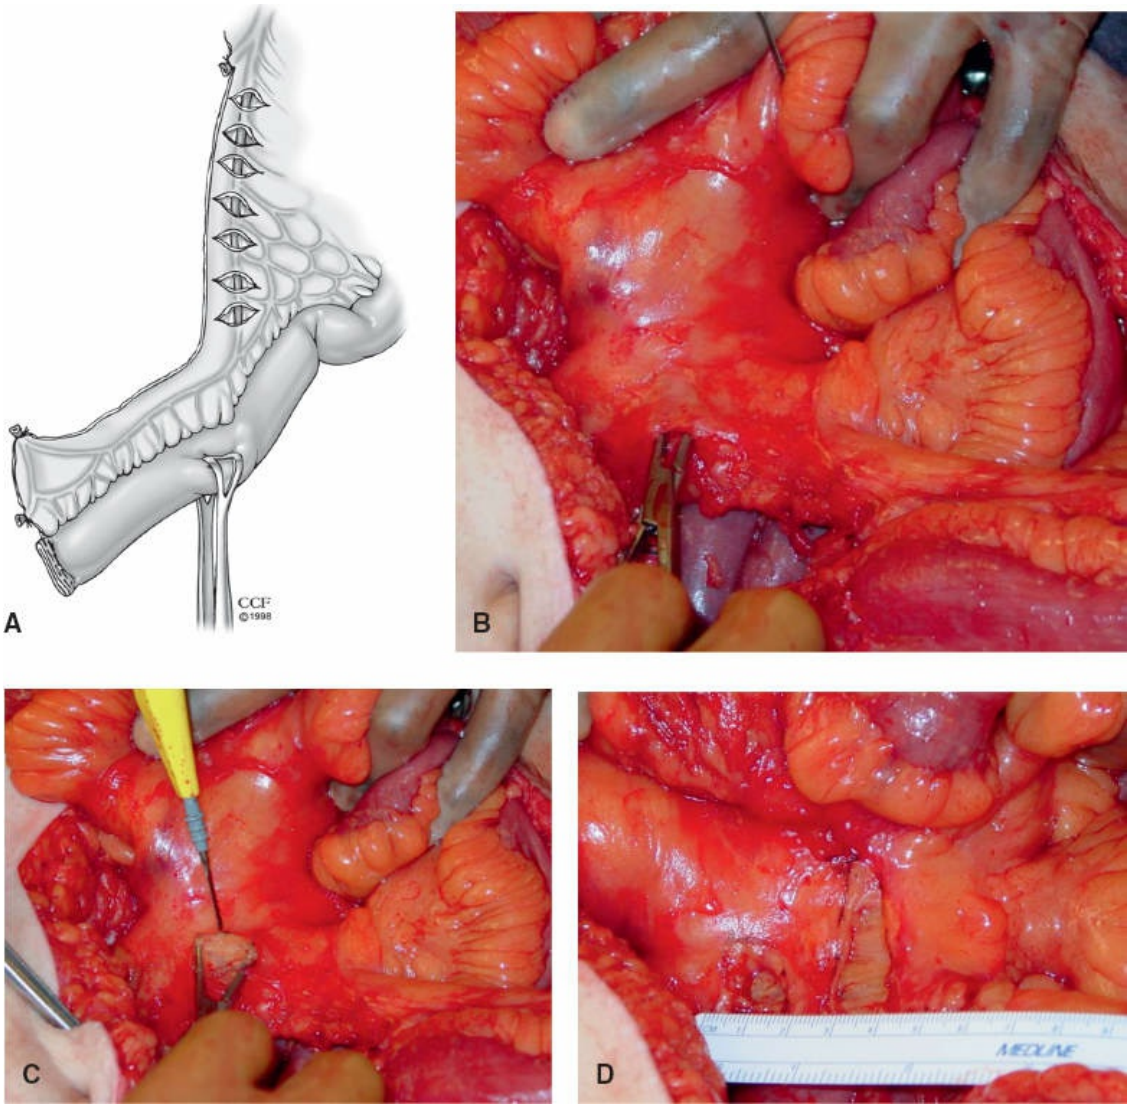

Figure 147.5. **A.** Peritoneal Windowing Schematic presentation. The peritoneum overlying the small bowel mesentery of the bowel used to construct the J-pouch is divided in a step-ladder type fashion, thus gaining several centimeters extra mesenteric length. **B.** Peritoneal Windowing. Intraoperative photo showing a hemostat lifting the peritoneum away from the underlying mesenteric vessels, (**C**) the electrocautery is used to divide the peritoneum, and (**D**) once the peritoneum has been divided, several extra centimeters of mesenteric length are obtained.

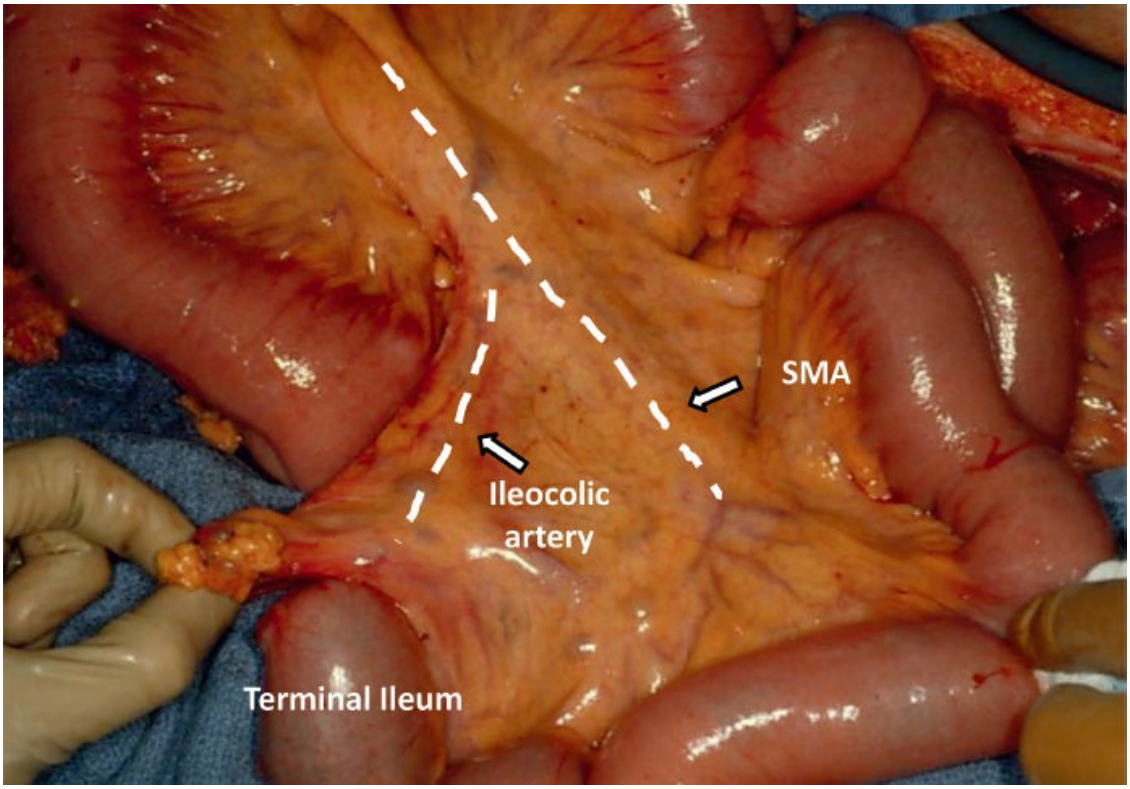

Figure 147.6. Division of either the ileocolic artery (*arrow*) or distal portion of the superior mesenteric artery (SMA) will also obtain an additional 2 to 3 cm mesenteric length.

Diversion can be difficult simply because the blood supply of the ileal J-pouch is tethered along the spine due to the tension involved in bringing the J-pouch to the anal canal. For this reason, the small bowel mesentery is not that mobile and it may be difficult to bring the mesentery to the anterior abdominal wall and through a stoma aperture. This is particularly challenging in the obese patient or the patient with a very thick abdominal wall. It is very helpful for making the closure of the ileostomy technically much less difficult, to wrap the segment of bowel to be used as an ileostomy with a sheet of hyaluronate film (Seprafilm). This greatly reduces peristomal adhesion formation and makes subsequent takedown of the ileostomy much easier. In obese individuals, or those in whom there is significant tension on the pouch, it may be necessary to place the much farther proximal than in patients with an ideal body habitus and those without tension on the IPAA.

Operations for Benign Versus Malignant Disease

IPAA can be performed for benign versus malignant disease. Different techniques need to be undertaken on the left side of the colon. Typically

the inferior mesenteric artery is usually taken high, just for ease of resection of the colon, so the dissection is typically similar. Also, in removing the rectum, total mesorectal excision is typically performed regardless of the indication. However, the major difference in operative technique lies if there is a right-sided colon cancer or possibility of this, that is, large colon polyps that could possibly harbor carcinomas. In performing the dissection on the right side of the colon, it is typical that one would leave both the ileal and colic branches of the ileal colic artery in place, ligating very close to the right colon so that if additional mesenteric length is needed (see below) either the ileocolic or superior mesenteric vessel can be divided to obtain that increased length. If a right colon cancer is suspected or present, this clearly should not be done, and these vessels, as well as a 10-cm segment of ileum, should be resected en block with the colon, and extra mesenteric length cannot be obtained by dividing the ileal colic, since this has already been removed. With respect to rectal cancer, as stated above, if preoperative radiation is required for a stage III rectal cancer, these patients typically would have very poor functional results and one should give serious thought to counseling the patient regarding the choice of operation for this reason. With respect to operations involving a distal rectal dysplasia or a distal rectal cancer, we favor performing a mucosectomy with hand-sewn approach, simply because this removes all affected distal rectal mucosal tissue. However, as stated previously, ileal pouches tolerate radiation poorly and my bias would be to advise a patient against having an IPAA in this setting. However, if this would be performed, it would be performed using a hand-sewn technique.

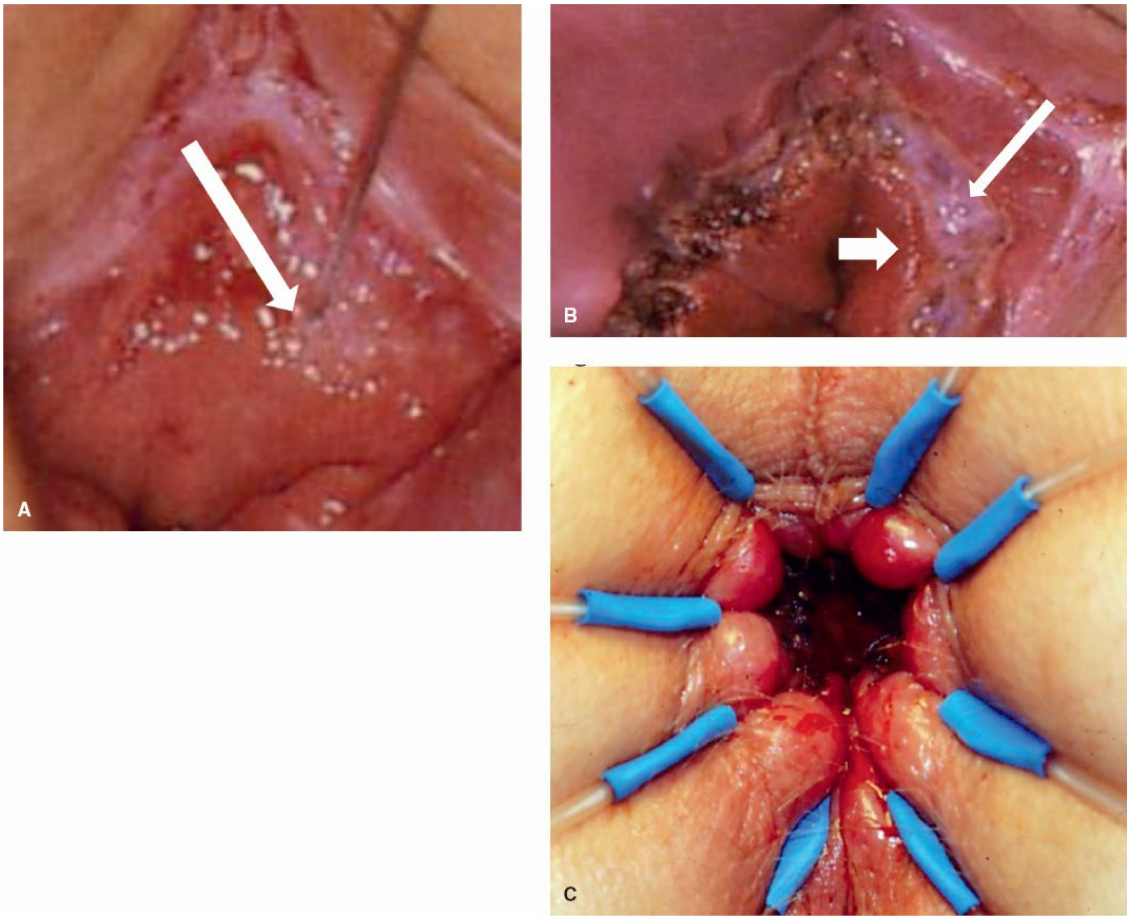

Figure 147.7. Approach with a hand-sewn ileal pouch anal anastomosis. **A.** An epinephrine containing solution such as 0.25% Marcaine with 1:200,000 epinephrine is injected submucosally beginning at the level of the dentate line (shown with *white arrow*). **B.** The electrocautery is used to score the mucosa circumferentially just proximal to the dentate line, exposing the aereolar tissue (*narrow white arrow*) underlying the mucosa (*broad white arrow*) that can then be dissected away from the underlying internal anal sphincter for a distance of 2 cm using the electrocautery. **C.** A Lonestar retractor facilitates construction of the single layer anastomosis using a single layer of 2-0 polyglactin.

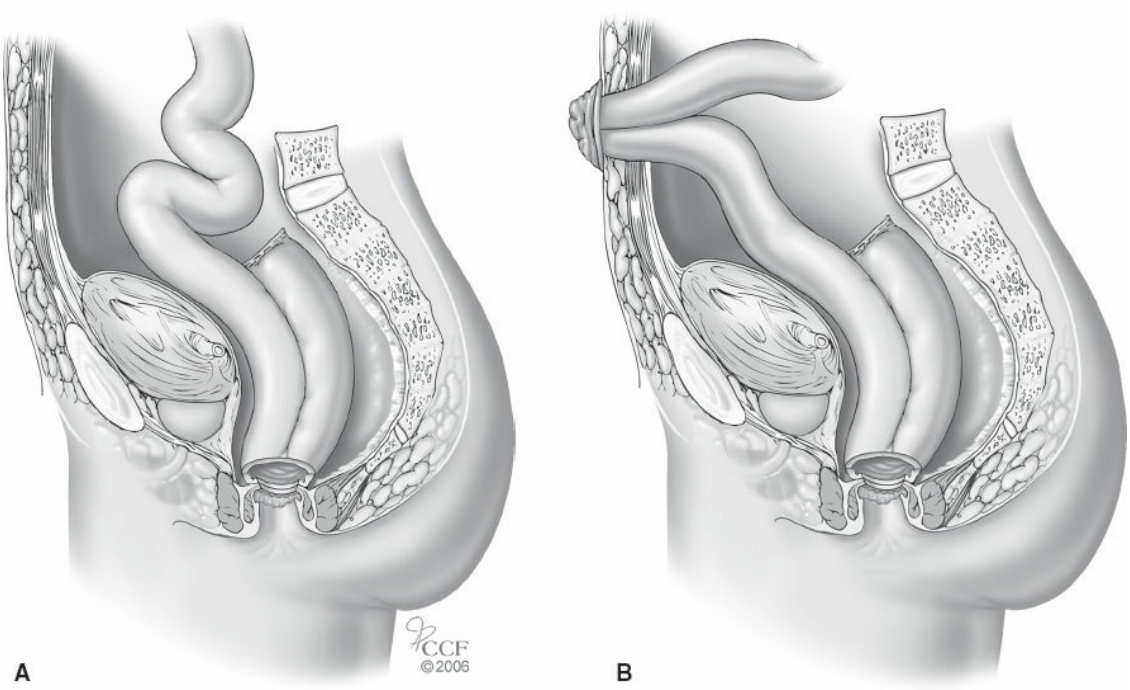

Figure 147.8. **A.** Ileal pouch anal anastomosis without diverting loop ileostomy, **B.** Ileal pouch anal anastomosis with diverting loop ileostomy, the loop ileostomy ideally is located 40 cm proximal to the ileal pouch, in individuals in whom there is tension on the pouch and in obese individuals, it may be necessary to go much further proximally.

Special Considerations for Robotic and Laparoscopic Surgery

In considering patients for minimally invasive procedures, one should consider patient body habitus, prior surgery, and body mass index (BMI). Patients who are significantly overweight may not be suited for this approach, especially the morbidly obese. This approach will also not be appropriate for patients who have had multiple prior extensive abdominal operations with significant intra-abdominal adhesions. In addition, if there is concern about the pouch reaching to the pelvis, such as with prior surgery, prior small bowel resection, or other factors, robotic access limits the number and quality of lengthening techniques that can be reasonably employed. This must not be undertaken unless the surgeon has extensive robotic experience. Total proctocolectomy and IPAA can be performed using either a laparoscopic or robotic approach. Many who perform this operation through a minimally invasive approach prefer to use a Pfannenstiel incision for open creation of the ileal pouch.

If the patient's habitus is favorable, the entirety of the colon and rectum can be eviscerated through an enlarged ostomy site incision. Through this

incision, the pouch can then be created and returned to the abdomen for creation of a stapled IPAA. Special care must be taken in this case to measure the size of the pouch using a pre-cut suture as well as determining the level of anastomotic tension. If this method of pouch creation is chosen, appropriate counseling for the possibility of a visceral hernia at the stoma site must be undertaken with the patient.

The availability of the Xi da Vinci robot has recently allowed for "single-dock" access for what has previously been a multi-dock procedure and allowed for the ability to exchange instruments and exchange the camera more easily. With this newer technology, the arms of the robot can be allowed to rotate and invert. One can combine laparoscopic and robotic approaches if necessary for expediency, with the addition of a 5-mm assistant trocar. The availability of a robotic stapler and vessel sealer has shortened the duration of the operation and improved the ability to reach to the pelvis. Figure 147.9A,B shows suggested port placements for a robotic total proctocolectomy and IPAA using the Intuitive Xi robot. The procedure is begun by initial placement of a periumbilical Optiview 5-mm trocar, which is later exchanged for the DaVinci camera port. Once robotic instruments are placed on the field, the Xi's targeting feature is not used in order to allow for maximum mobility of the arms throughout the case. The right lower quadrant 12-mm port is used for robotic stapling to include major vascular division and visceral division. This is a unique aspect of the Xi, as vascular staple loads are currently not approved for use on any other robotic platform. Until the stapler is needed, we place an 8-mm collar on the larger port to prevent loss of pneumoperitoneum with instrument manipulation. A reducer is available to decrease the inner diameter of this cannula to 8 mm, but it is bulky and requires altered motion of the right hand during dissection, and we often chose not to use it for this reason. Initial placement of the robotic arms is aimed at the pelvis to facilitate pelvic dissection and cecal dissection (Fig. 147.10A,B). The case begins with standard pelvic dissection of the inferior mesenteric artery and medial to lateral access of the sigmoid colon and rectum proceeding with a routine total mesorectal excision and low division of the rectum with the stapler, in anticipation of a stapled IPAA. Following this the cecum/appendix and right colon are mobilized in a lateral to medial fashion so as to preserve the ileocolic artery and maintain distal ileal blood supply for the eventual creation of the pouch. Once the arms are perpendicular to the patient during the dissection, the assigned hands are reversed to complete the

dissection. The change in assignment allows for inversion of the robotic arms around their remote centers, facilitating dissection in the upper abdomen. This positioning is shown in Figure 147.11A,B. The left colon, splenic, and transverse colons are divided from their blood supply using a robotic vessel sealer progressively. This is the most difficult portion of the dissection. With the colonic mobilization complete, a small Pfannensteil incision is made and the specimen extracted. Following this, the ileal pouch is constructed in an open manner through the pelvic incision and a laparoscopic-assisted stapled IPAA is constructed using a 29-mm circular stapler passed through the short remaining rectal stump. Laparoscopy is essential to ensure appropriate pouch positioning and to prevent torsion of the pouch around the terminal branches of the superior mesenteric artery.

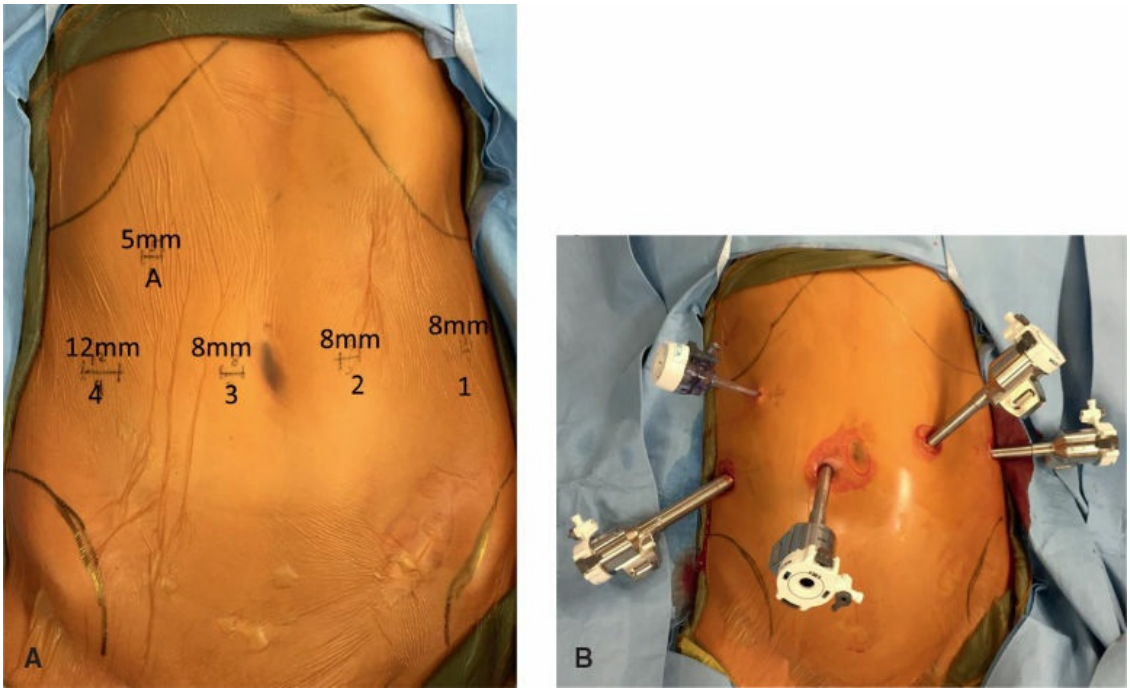

Figure 147.9. **A.** Port placement for a robotic total proctocolectomy and ileal pouch anal anastomosis using the Davinci Xi Robot. The top number indicates port size, the bottom number corresponds to the arm of the Xi patient cart; "**A**" denotes assistant port. **B.** Ports in place.

POSTOPERATIVE CARE

Because of the tension on the mesentery associated with the loop ileostomies in patients undergoing IPAA, it is often necessary for the patient to have convex stoma appliances with a belt in order to obtain good diversion (see Chapter 151). It is occasionally necessary to go farther proximal in the ileum in order to obtain enough bowel length to be able to construct an adequately protruding stoma. In some cases, these patients actually will require intravenous fluids postoperatively due to the high output. The 24-hour stoma output should not exceed 1,000 mL. If this is the case, patients should be started on either 2.5-mg diphenoxylate or 2-mg loperamide before meals and at bedtime. If the 24-hour output still exceeds 1,000 mL, this dose should then be doubled.

COMPLICATIONS AND THEIR MANAGEMENT

Postoperative complications can be divided into early and late postoperative complications. Early postoperative complications include those associated with the stoma, such as high-output ileostomy, obstruction at the level of the ileostomy, sepsis due to peri-pouch complications such as abscess and/or leak.

Late postoperative complications include IPAA stricture formation due to tension, IPAA leak, IPAA fistula, and in women, pouch-vaginal fistula. Pouch-vaginal fistula can occur as a technical complication of surgery, by erroneous inclusion of the vaginal wall into the IPAA as shown in Figure 147.12. Other late complications include the development of Crohn disease in a patient initially diagnosed with ulcerative colitis, as well as the occurrence of pouchitis. Late complications can also include the development of cancers within the pouch or in the anal transition zone. This can occur in both patients with inflammatory bowel disease and patients with FAP. This can occur in patients who have had mucosectomy, as well as in patients who have had stapled IPAA, both in retained mucosa, presumably overlooked areas of mucosa in the event of a mucosectomy, and from even within the ileal pouch itself. Continued surveillance of these patients is therefore warranted.

Pouchitis will occur in approximately 50% of ulcerative colitis patients undergoing IPAA for ulcerative colitis, but is much less common in patients with FAP. This is generally very easily treated with antibiotics such as metronidazole or ciprofloxacin. Pouchitis can, however, also manifest itself as chronic pouchitis, in which patients require chronic suppressive antibiotics to control symptoms of diarrhea. In these cases, one must ensure that there is no distal obstruction, such as a stricture, which impairs emptying of the pouch.

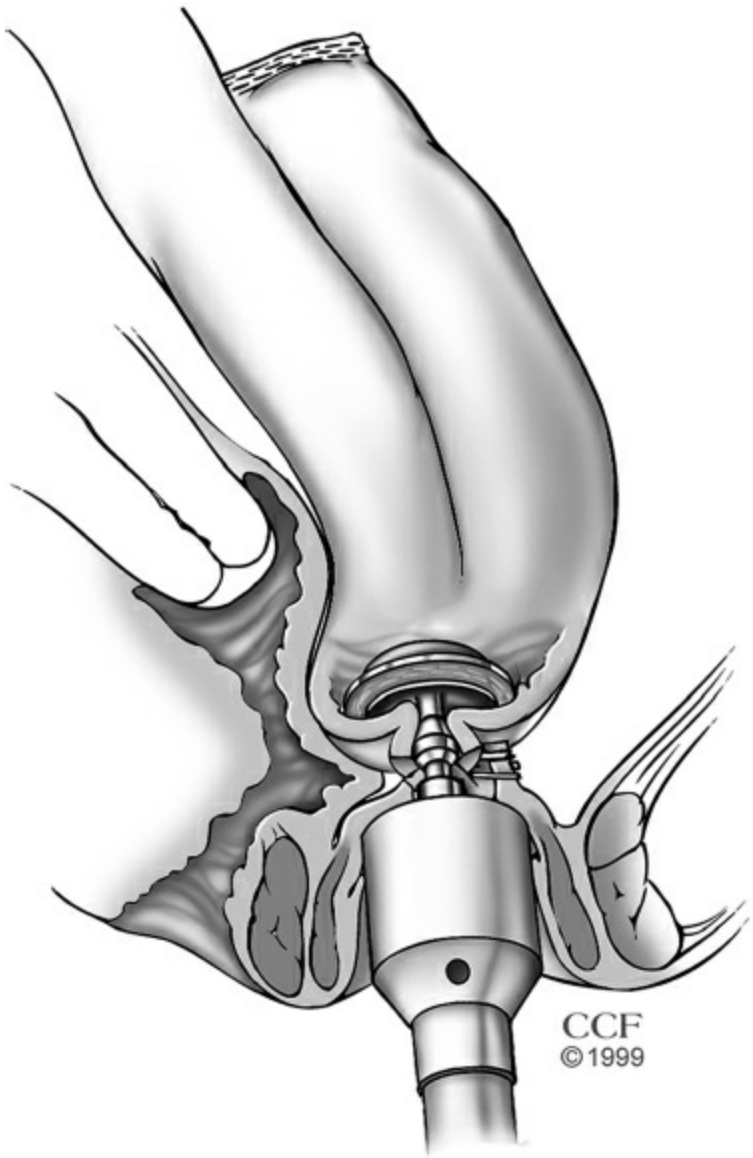

Figure 147.12. Inclusion of the posterior wall of the vagina in the stapled anastomosis will result in a pouch-vaginal fistula.

Technical complications that can predispose to pouchitis include leaving in a long rectal stump, which leads to a complication known as “cuffitis,” in which there is a significant amount of inflammatory bowel disease left behind that can become symptomatic. This can actually require a repeat abdominal approach to remove the retained rectum. This can occasionally be removed transanally with pouch advancement. One can have symptoms of a pouch that is too large that empties inadequately that might require a pouch revision. The frequency of chronic pouchitis where patients require constant suppressive antibiotic therapy to suppress symptoms of diarrhea varies among series, but can in some circumstances be so severe that patients chose to be converted to an end ilesotomy.

Another reason for “pouch failure” is the late diagnosis of Crohn disease. In most cases, this can be treated with medical therapy; however, the presence of aggressive fistulizing disease may require pouch excision and end ileostomy.

OUTCOME

Overall, when performed correctly, IPAA will provide an improved quality of life for the majority of patients with ulcerative colitis and FAP and is currently increasingly performed in patients with isolated Crohn disease after extensive preoperative counseling of these patients describing to them the risk of development of Crohn disease in the small bowel. As more effective treatments for Crohn disease become available, the number of patients who are candidates for this procedure will likely expand. No matter the type of access, key elements of this procedure include adequate mobilization, and a relatively tension-free anastomosis with attention to avoiding rotation of the bowel and avoiding constructing a pouch that is too long and keeping the retained rectum to a minimum.

EDITOR'S COMMENT

Ileoanal-pouch anastomosis (IPAA) is the preferred method of restorative reconstruction after total colectomy and proctectomy for ulcerative colitis and familial polyposis. The concept of an ileal reservoir originated in the 1970s and has gained wide popularity and wide application. The authors outline the historical evolution of the procedure from mucosal proctectomy to stapled IPAA and review the indications and contraindications. As they point out, it is critical to have extensive counseling with the patient prior to the surgery. This should include a detailed discussion of the management of frequent bowel movements and potential complications including pouchitis, pouch fistula, and recurrence of inflammation in cases of indeterminate colitis and anastomotic stricture. In addition, women of childbearing age may need to be counseled regarding fertility. IPAA increases the risk of infertility in women with ulcerative colitis by approximately threefold. Further studies of modifiable risk factors are needed (Waljee A, Waljee J, Morris AM, et al. Threefold increased risk of infertility: a meta-analysis of infertility after ileal pouch anal anastomosis in ulcerative colitis. *Gut* 2006;55(11):1575–80).

Technical considerations include open versus laparoscopic, the role of protective ileostomy or one-stage IPAA, type of reservoir (W, J, or S), the type of anastomosis (hand-sewn vs. stapled). Despite extensive experience, there is much controversy regarding these considerations. Sofo L et al. (Restorative proctocolectomy with ileal pouch-anal anastomosis for ulcerative colitis: a narrative review. *World J Gastrointest Surg* 2016;8(8):556–63) reviewed studies published in the MEDLINE, EMBASE, and Ovid databases through March 2016. They noted that there were few large, randomized, controlled studies which limit the conclusions. They concluded that laparoscopic surgery has no clear advantages compared with open surgery, that one-stage IPAA (no ileostomy) may be acceptable in selected cases, that the long-term results regarding the pouch type show that the W- and J-reservoirs do not differ significantly, although the J pouch is generally preferred by surgeons. Hand-

sewn and stapled ileal pouch-anal anastomoses have their own advantages, and there is no clear benefit of one technique over the other. Although the authors include a section on robotic-assisted procedures, in a PubMed search performed on May 22, 2017, I could find few, if any, reports of applying robotic techniques to IPAA.

Most surgeons have transitioned to using the J Pouch rather than the S or W pouch. One of the not so infrequent problems the surgeon encounters is obtaining sufficient length of the small bowel to allow it to reach the anus. The authors point out several techniques that are illustrated in Figures 147.4 and 147.5. These techniques are critical in obtaining sufficient length.

There is controversy in performing restorative proctocolectomy and IPAA in older populations. The main concern is potential problems with sphincter control. However, most studies show little difference in outcomes. A relatively recent study by Pellino G et al. (Complications and functional outcomes of restorative proctocolectomy for ulcerative colitis in the elderly. *BMC Surg* 2013;13(Suppl 2):S9.) is instructive. They gathered data on a prospective database of patients undergoing IPAA for UC over 70 years of age from January 1990 through January 2010. Patients were compared with randomly selected younger controls in a 1:3 ratio. Patients underwent IPAA in 2 or 3 stages. Demographical data, disease characteristics, comorbidities, concomitant medications, perioperative management, intra- and postoperative complications were analyzed. Function and quality of life were assessed by clinical visit and Inflammatory Bowel Disease Questionnaire, 1 and 3 years after ileostomy takedown. They identify 27 elderly patients who underwent IPAA for ulcerative colitis and compared with them 81 younger patients. Those over 70 years had more comorbidities and higher ASA score. All patients underwent loop ileostomy closure. There were no differences between groups concerning the rate of major complications, but elderly patients had more problems due to high stoma output. They observed that the younger patients experienced significantly more episodes of small bowel obstruction. Using a validated instrument, they detected no significant differences in bowel control or health-related quality except for a higher rate of elderly patients taking antidiarrheal medication at 1 year after surgery but not at the 3-year follow-up. There was a minimal decrease in continence in the elderly group but overall satisfaction was not affected. They conclude and most would likely agree that IPAA can be safely offered to selected elderly UC patients who are highly motivated, as long as they have no preoperative disturbances of continence.

Pouch complications are relatively common, with de novo inflammation of the ileal reservoir (pouchitis) occurring in 12% to 50% of patients. Current medical therapy includes use of antibiotics, mesalamine, corticosteroids, immunomodulators, and probiotics, either alone or in combination. Up to 20% can also develop a Crohn’s disease–like inflammation of the pouch. The hallmark findings are inflammation in the afferent limb (pre-pouch ileitis), presence of proximal small bowel strictures, or perianal/abdominal fistulae

unrelated to surgery. A unique group (4% to 8%) may also develop complications such as pouch fistulas. Diverting ileostomy may be considered or pouch excision in refractory cases.

Recent data indicate that infliximab may be helpful in resolving symptoms and sparing the pouch. Kelly OB et al. (Infliximab to treat refractory inflammation after pelvic pouch surgery for ulcerative colitis. *J Crohns Colitis* 2016;10(4):410–7.) collected and reviewed data from individuals who underwent colectomy and IPAA between 2000 and 2014 for ulcerative colitis. Patients with chronic refractory pouchitis (CP) and Crohn disease (CD)–like outcomes treated with infliximab were included. They reported 152 patients with chronic pouchitis or the CD-like pouchitis. Forty-two were treated with infliximab (33% male; age 32.6 ± 2.6 years, 28.5% CD-like). The initial response rate was 74% (48% complete) with a sustained response in 62.6%, and a complete response in this group was observed in 29.6%. They concluded that infliximab can effectively treat inflammatory pouch complications.

There is continued debate about IPAA versus ileorectal anastomosis in the treatment of familial adenomatous polyposis (FAP). The incidence of FAP is 1 in 7,000 to 12,000 live births. Surgically untreated patients with FAP inevitably develop colorectal cancer because they carry the APC gene. Thus, prophylactic total proctocolectomy is warranted. Although IPAA was the focus of this chapter, there are four surgical options: ileorectal anastomosis, restorative proctocolectomy with IPAA, proctocolectomy with ileostomy, and proctocolectomy with continent ileostomy. Some prefer ileorectal anastomosis because of better functional results and quality of life than with IPAA; however, the risk for rectal cancer is increased by 30%. Inadvertent small mucosal residual islands that carry cancer potential remain even after IPAA. How common is cancer recurrence after IPAA? Smith JC et al. (Adenocarcinomas after prophylactic surgery for familial adenomatous polyposis. *J Cancer Ther* 2013;4(1):260–70) reviewed the literature (1975–2012) and identified 24 studies reporting 92 pouch-related cancers; 15 case reports, 4 prospective and 5 retrospective studies. Twenty three of 92 cancers (25%) developed in the pouch mucosa and 69 (75%) in anal transit zone. The data suggest lifetime surveillance of these patients.

In summary, IPAA has become the standard technique for restorative proctectomy for surgical treatment of ulcerative colitis and FAP. The authors combine an excellent hands-on experience with practical tips to provide the reader with an excellent overview of the procedure.

148 Total Colectomy and Ileorectal Anastomosis

David J. Maron and Steven Wexner

INTRODUCTION

Total colectomy (also referred to as *subtotal colectomy* or *total abdominal colectomy*) is the removal of the entire colon with preservation of the rectum. Intestinal continuity is restored by ileorectal anastomosis, also known as *ileoproctostomy*.

The role of total colectomy and ileorectal anastomosis in the treatment of colonic pathology is being redefined as the understanding of these different surgical pathologies is becoming more elucidated. Total colectomy has been replaced by total proctocolectomy with ileoanal J-pouch reconstruction as the surgical approach for treatment of ulcerative colitis. Patients with Crohn's disease will sometimes require a total colectomy and patients with the attenuated form of familial adenomatous polyposis (FAP) syndrome are also candidates for a total colectomy as the rectum may not be involved by the polyposis. Other patients with neoplastic disease such as hereditary nonpolyposis coli carcinoma syndromes or even sporadic colon cancers may benefit from total colectomy and surveillance of the remaining rectum.

Total colectomy can be performed using a laparotomy; however, advances in minimally invasive surgery have made laparoscopic resection an appealing alternative to open resection. The surgeon may elect not to perform an ileorectal anastomosis at the time of total colectomy based on the patient's overall health and/or clinical condition. Patients who have fulminant colitis with severe anemia, leucopenia or leukocytosis, malnutrition, and severe concomitant systemic diseases are better approached by a multistage procedure. In this situation, the rectal stump is closed and an end ileostomy is created. Alternatively, the proximal aspect of the distal stump may be exteriorized as a mucous fistula, particularly if the rectum is involved by severe inflammation or infection such as in *Clostridium difficile* colitis. Regardless of the choice of either open mucus

fistula or closed Hartmann's stump, the presacral space should be left undisturbed. Violation of the presacral space at the initial operation may lead to presacral hemorrhage and injury to the sympathetic and parasympathetic nerves during subsequent reoperation.

INDICATIONS FOR TOTAL COLECTOMY WITH ILEORECTAL ANASTOMOSIS

Inflammatory Bowel Disease

The surgical treatment of patients with ulcerative colitis is best accomplished by a restorative total proctocolectomy with ileal J-pouch. This procedure has the advantage of removing all or nearly all of the diseased mucosa by removing the entire colon and rectum. A small subset of patients with ulcerative colitis may present with "rectal sparing"; however, this finding is more likely due to enema therapy or a misdiagnosis of Crohn's disease. For those patients with ulcerative colitis who develop toxic colitis or disease that is unresponsive to medical therapy, a total colectomy with creation of an end ileostomy is the preferred operation as it removes the diseased colon but avoids pelvic dissection.

In the past, total colectomy with ileorectal anastomosis was favored by some surgeons for the treatment of ulcerative colitis. Injury to the hypogastric nerves or nervi eregenti during rectal dissection that can lead to postoperative sexual dysfunction, as well as pelvic adhesions that can lead to infertility in females, led some surgeons to recommend this procedure in younger patients. Although this operation has been abandoned, however in select patients, proctectomy may be delayed while the remaining rectum is regularly surveyed with endoscopy and the patient continues to receive both local and potentially systemic medical therapy for ulcerative colitis.

Total colectomy with ileorectal anastomosis may be a good option in patients with Crohn's colitis if the rectum is relatively spared and the patient has satisfactory sphincter function. Indications for surgery in patients with Crohn's colitis include worsening of symptoms despite aggressive medical treatment, development of colonic strictures or fistulae, or the development of colorectal neoplasia. Determining whether a patient should undergo anastomosis at the time of colectomy is dependent on a number of factors. Patients' conditions may vary along the spectrum of

nutritionally replete to profoundly malnourished and markedly immune suppressed. The medical treatment of Crohn's disease with steroids and immune-modulatory drugs exacerbates immune dysfunction and is detrimental to wound and anastomotic healing. In addition, the disease may involve the rectum and anus, which may severely compromise both rectal and anal sphincter function and thus continence. It is therefore necessary to carefully assess for the presence of anorectal Crohn's disease during the history and physical examination. Inspection for ulcers and stenosis is mandatory as the presence of one or more of these entities may preclude anastomosis.

Patients with a history of abscess or fistula should be carefully examined, and the extent and complexity of any fistulous tracts should be documented. Any abscess or fistula should be treated prior to consideration of an ileorectal anastomosis. It may be necessary for the patient to initially undergo a total colectomy with end ileostomy to allow for resolution of anorectal sepsis or fistula. If a patient had undergone a prior fistulotomy causing damage to the anal sphincters, an ileorectal anastomosis may be contraindicated as a patient with poor continence may not be capable of controlling the resultant diarrhea following the procedure. This assessment includes quantification using a validated incontinence score such as the Cleveland Clinic Florida Fecal Incontinence Score (CCF-FIS), as well as anal ultrasonography or pelvic magnetic resonance imaging (MRI).

Anorectal manometric studies can also be helpful in objectively quantifying anal sphincter function and rectal compliance. Examination of the rectum with flexible sigmoidoscopy is also important in assessing the extent of involvement of the rectum by inflammation or scarring. Distensibility can be judged by insufflation of air through the sigmoidoscope as well as during anal manometry. If the rectum is found to be nondistensible due to severe involvement by Crohn's disease, it is best to perform either a total proctocolectomy with end ileostomy or a total colectomy with Hartmann's closure of the rectum.

Many patients with Crohn's disease without anorectal disease or sphincter damage may be well adjusted and tolerant of diarrheal bowel movements. These individuals may prefer to live with mild to moderate diarrhea following an ileorectal anastomosis rather than having an ileostomy. Unfortunately, the risk of subsequent proctectomy and end ileostomy due to progression of Crohn's disease and/or rectal dysfunction

may be as high as 60% to 70%.

Neoplasia

Total colectomy with ileorectal anastomosis may be indicated in patients with specific genetic syndromes that carry a high risk for the development of colon cancer. These neoplastic conditions include FAP, hereditary nonpolyposis colorectal cancer (HNPCC) syndrome, and genetic mutations that lead to sporadic colon cancer. In addition, synchronous or metachronous colon cancers represent high-risk patients who may be managed by a total or completion colectomy with ileorectal anastomosis.

FAP syndrome accounts for <1% of cases of colorectal cancers in the United States. The syndrome is characterized by the presence of hundreds to thousands of colonic and rectal polyps that, if left untreated, will eventually become cancerous. A germline mutation in the adenomatous polyposis coli (APC) gene, located on the long arm of chromosome 5, is responsible for the FAP phenotype, and is inherited in an autosomal dominant pattern with 100% penetrance.

Patients with the APC mutation are often asymptomatic, although some younger patients may present with nonspecific complaints of abdominal pain, diarrhea, or rectal bleeding. Identification of these patients at a young age is very important as phenotypic expression in the form of colorectal polyps typically begins in early adolescence, followed by inevitable progression to cancer by the age of 40. In families suspected of having FAP, surveillance consisting of flexible sigmoidoscopy and genetic testing should begin early in the teenage years. Once polyps are identified, patients should undergo colectomy to reduce the risk of cancer. The majority of patients with FAP will have rectal involvement by polyps and are best treated with a restorative proctocolectomy.

In a small subset of patients with FAP, the rectum may not be involved by polyposis or it may contain only a few polyps. These patients may have attenuated FAP or MUTYH-associated polyposis (MAP), both of which are variants of FAP. Patients with attenuated FAP suffer from APC gene mutation in regions different from the classic FAP syndrome. They typically have fewer than 50 colonic polyps, which tend to develop more proximally in the colon. The age of the onset of polyposis and colorectal cancer in patients with attenuated FAP is later than in classic FAP, averaging in the mid-30s and 50s, respectively. Approximately 10% to 20% of patients with FAP do not have the APC mutation but rather have

MAP, which is an autosomal recessive condition characterized by mutations in the DNA repair gene known as MUTYH. These patients are difficult to distinguish from classic FAP patients but tend to have fewer than 100 polyps and rectal involvement also tends to be minimal. Patients with attenuated FAP or MUTYH-associated polyposis may be good candidates for total colectomy with ileorectal anastomosis.

HNPCC is the most common genetically inherited colorectal cancer disorder, accounting for 2% to 5% of newly diagnosed colorectal cancers. The onset of cancer in patients with HNPCC is usually earlier than in the general population with these patients presenting in their mid-40s as opposed to 60 to 65 years in patients with sporadic cancer. These tumors tend to be located more proximally in the colon, and patients are at increased risk of development of other tumors, including endometrial carcinoma, ovarian carcinoma, and transitional cell carcinoma of the urinary tract.

Prior to identification of the genetic basis of this syndrome, many criteria were used to identify these patients and their family members. The modified Amsterdam criteria are currently used to identify patients with HNPCC by evaluating their family history, which includes: (a) three or more relatives with histologically proven colorectal carcinoma, one of whom is a first-degree relative of the other two; (b) colorectal carcinoma involving at least two generations; and (c) one or more cases of colorectal carcinoma diagnosed before the age of 50 years. Mutations in DNA-mismatch repair genes such as the most commonly affected MLH1, MSH2, and MSH6 are responsible for predisposition to cancer development over a patient's lifetime. These mutations are inherited in an autosomal dominant pattern and lead to approximately an 80% disposition to developing colorectal cancer. Failure of DNA repair during replication, due to defective mismatch repair proteins, leads to development of microsatellite instability (MSI) in the DNA of colorectal cancer. This characteristic finding is often used as a marker for HNPCC as 90% of both cancerous lesions and polyps contain MSI. The revised Bethesda criteria incorporate the findings of MSI in pathologic specimens and are another set of criteria that may be used to identify these patients: (a) colorectal carcinoma identified in a patient <50 years of age, (b) synchronous or metachronous colorectal cancer or other HNPCC-associated cancer, (c) colorectal cancer with finding of MSI in pathologic specimens in patients <60 years, (d) colorectal cancer or other HNPCC cancer in a first-degree

relative with one of these cancers in a family member <50 years old, and (e) colorectal cancer in two or more first- or second-degree relatives along with HNPCC-associated tumors regardless of age.

Patients with known HNPCC or those having a family history of HNPCC should undergo regular endoscopic surveillance with colonoscopy every 1 to 3 years starting at the age of 20 to 25 years or 5 to 10 years earlier than the age of the youngest relative diagnosed with colon cancer. The frequency of screening should increase to every 1 to 2 years after the age of 40. In female patients, screening of the endometrium and ovaries should also be done starting at age 30 to 35 and includes examinations, transvaginal ultrasound, and endometrial biopsy every 1 to 2 years.

The role of prophylactic colectomy in patients with HNPCC is debatable as it may be unnecessary in 15% to 20% of patients who would not develop colon cancer due to the incomplete penetrance of this disease. Patients who refuse yearly colonoscopies or are poorly compliant may be good candidates for a prophylactic total colectomy with ileorectal anastomosis. For patients who have already had a colon cancer associated with HNPCC, total colectomy with ileorectal anastomosis is the ideal procedure to eliminate their risk of subsequently developing a metachronous cancer in the remaining colon. These patients must undergo yearly flexible sigmoidoscopies for surveillance of the rectum, as 6% to 20% will eventually develop a cancer in the remaining rectum. Women who have a strong family history of endometrial cancer in association with HNPCC may also be candidates for prophylactic hysterectomy and salpingoophorectomy.

Total colectomy with ileorectal anastomosis may also be indicated in patients with colon cancer in several specific scenarios. Obstructing cancers of the sigmoid or left colon may result in marked dilation of the proximal colon, making primary resection and anastomosis using the dilated colon unsuitable. Alternatives include a staged approach with Hartmann’s colostomy or the use of on-table washout with primary colonic or colorectal anastomosis. Nonobstructing cancers of the distal transverse or proximal descending colon can also be treated by total colectomy with ileorectal or ileosigmoid anastomosis. This procedure avoids anatomically awkward attempts to restore the continuity of the hepatic flexure to the sigmoid colon or rectum and avoids the possibility of an anastomosis in a vascular watershed region of the colon.

Lower Gastrointestinal Hemorrhage

Severe bleeding from the colon can develop from conditions such as hemorrhagic diverticulosis or an arteriovenous malformation. Oftentimes, the hemorrhage spontaneously stops, possibly due to the resultant hypotension. In patients with ongoing lower gastrointestinal bleeding, aggressive diagnostic evaluation including colonoscopy, radionuclide scanning, and angiography can often localize the bleeding. Choice of localization modality is dependent upon many factors, including patient stability, rate of bleeding, and available institutional expertise. Clinical resuscitation and nonoperative treatment with selective embolization or selective vasopressin infusion of the distal colonic vessels often control the hemorrhage. Colonoscopic investigation in the acute phase may be both diagnostic in terms of localization of the source and therapeutic in terms of its treatment. Therapeutic options include monopolar diathermy, bipolar electrocautery, laser coagulation, vasoconstrictor and/or sclerosant injection, and direct hemoclip placement. Patients rarely present with hemorrhage from two possible sources (typically, angiodysplasias in the right colon and severe diverticulosis in the left colon). These patients may be candidates for total colectomy with ileorectal anastomosis to eliminate both potential sources of bleeding.

Chronic Constipation and Colonic Inertia

A few carefully selected patients with severe chronic constipation that is refractory to medical management may be candidates for total colectomy with ileorectal anastomosis. These conditions are referred to as intestinal motility disorders. When the motility disorder resides within the colon, it is termed colonic inertia. In the majority of cases, the cause for inertia is unknown; however, disorders in motility may be related to specialized neural ganglion in the intestine such as Meissner, Auerbach plexus, or the cells of Cajal.

Patient selection for surgical treatment of functional disorders is critical, and physiologic investigation to distinguish isolated colonic inertia from panenteric dysmotility is very important. Colonic motility is assessed with the use of radiopaque markers; gastric emptying is evaluated with scintigraphy, and small-bowel motility is most easily and inexpensively examined by a lactulose breath hydrogen transit study. While patients with colonic inertia may potentially benefit from a colectomy, patients with panenteric dysmotility typically do not. In addition, pelvic floor

dysfunction in these patients must be excluded as colectomy will not alleviate their symptoms. Anorectal functional assessment including cinedefecography, anal electromyography, and anal manometry can be used to evaluate rectal function and to exclude pelvic outlet dysfunctions such as nonrelaxing puborectalis syndrome.

SURGICAL TECHNIQUE

Open Resection

Although total colectomy can be accomplished with the patient in the supine position, the authors prefer to place the patient in the modified lithotomy position. This position gives the surgeon the advantage of access to the anus for intraoperative colonoscopy or sigmoidoscopy, creating a stapled anastomosis, and for inspection of the anastomosis for integrity. Proper positioning should include placement of intermittent compression stocking or other means for deep venous thrombosis prevention; compression stockings may also assist in preventing sural nerve damage. With the patient in heel and calf stirrups, the rectum can be examined, and if desired, irrigation of the rectum can be performed prior to skin preparation and draping.

The position of the surgical team depend on the experience and the anticipated role of the assistants. If the first assistant is capable of dissection under guidance, it is advantageous for the surgeon to stand on the patient's left side. The surgeon thus has control of retraction and exposure of the right and transverse colon. The following description of technique assumes this arrangement. When the left colon is dissected, the assistant retracts with one hand and dissects with the other while the surgeon laterally displays the tissues to be incised. In a teaching setting, there is sometimes a shifting of positions around the operating table.

A midline incision is standard for gaining access to the peritoneal cavity to perform a colectomy. This approach is preferred for patients with chronic inflammatory bowel disease, which often leads to a shortened colon and mesorectum. A transverse incision below the umbilicus and Pfannenstiel incision are possible approaches for patients with a low body mass index (BMI). Some surgeons prefer a transverse incision with the thought that it is less painful and may decrease the incidence of incisional hernias; however, low incisions may not always facilitate mobilization of the splenic flexure and may interfere with stoma creation.

After inspection of the abdomen, mobilization of the colon begins on

the right side. The surgeon retracts the colon medially being careful to protect the bowel from injury and an incision is made in the peritoneal reflection lateral to the cecum. The peritoneal incision is made close to the cecum to expose the retroperitoneal avascular plane and facilitate dissection of the right colon from its posterior attachments. Electrocautery is usually used to accomplish this incision and minimize bleeding from small peritoneal vessels, but energy-free sharp dissection can also be used. Once the lateral peritoneal reflection is opened, the surgeon inserts the left index finger into the defect, retracting the cecum and right colon more medially as the lateral peritoneum is incised further cephalad (Fig. 148.1). The peritoneal incision should be made close to the colon so as not to unnecessarily expose Gerota's fascia by overly lateral dissection. The gonadal vessels and the right ureter will be exposed in the retroperitoneum; as the dissection proceeds immediately adjacent to the mesocolon, the ureter should remain untouched in the retroperitoneum.

As the dissection is continued cephalad toward the hepatic flexure, the anterior surface of the duodenum is encountered (Fig. 148.2). The mesocolon is separated from the duodenum by division of the filmy tissue attachments, which may contain small vessels. Full mobilization up to the pancreas is unnecessary in most cases; however, in cases where the resection is being performed for cancer, it is necessary to mobilize fully and ligate the mesenteric vessels close to their origins from the superior mesenteric artery. At this point, the hepatic flexure requires separation from its lateral attachments, which contain vessels of varying sizes, some of which are large enough to require ligature. One must be careful during the medial retraction of the hepatic flexure to avoid tearing of the middle colic vein near the superior mesenteric vein. A venous injury in this region is often difficult to control and must be immediately addressed to avoid the rapid and significant blood loss that results from such tears.

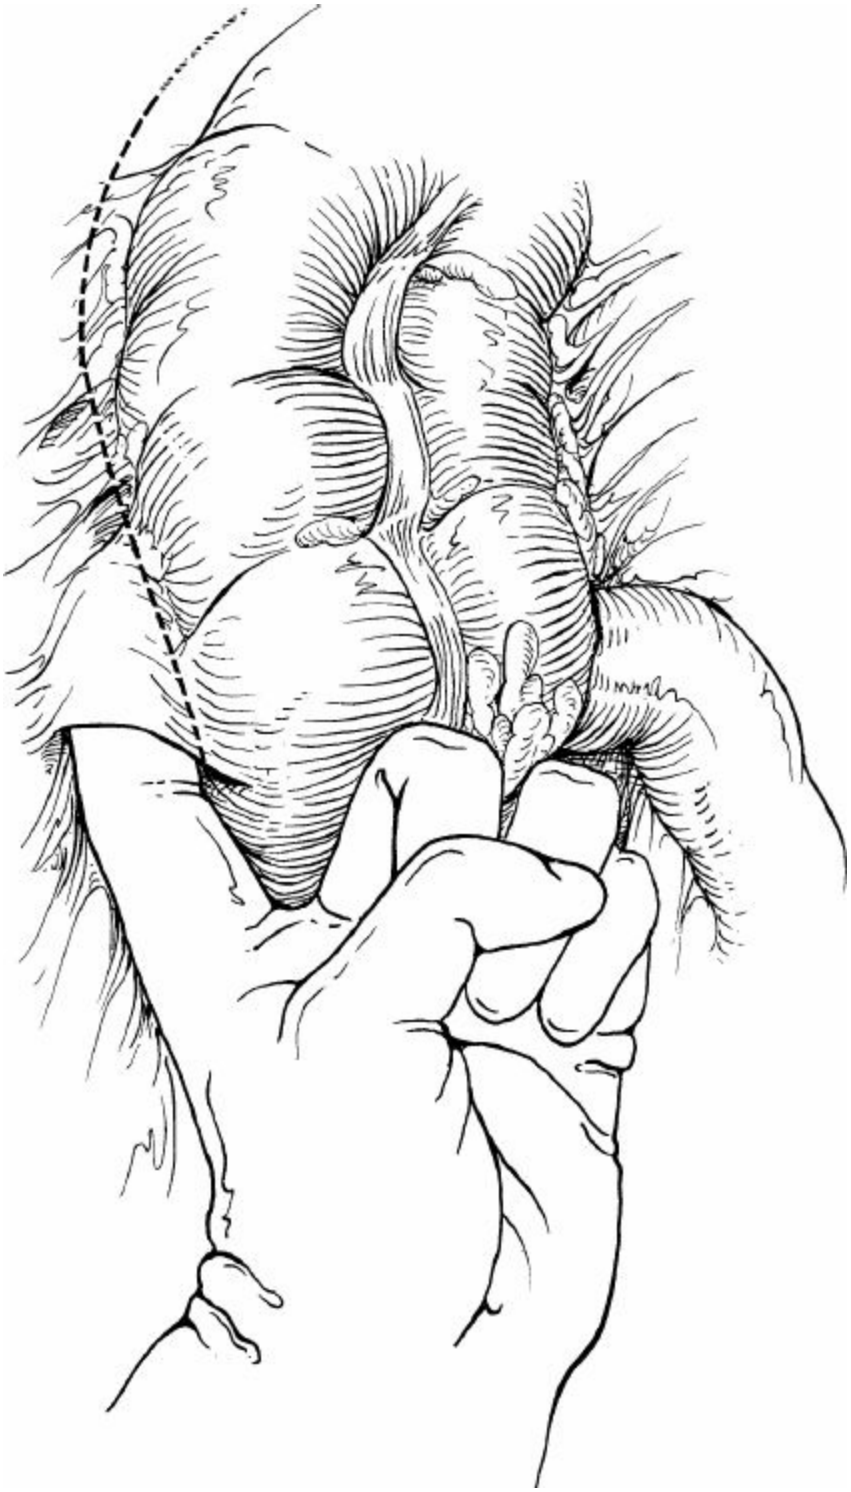

Figure 148.1. Finger beneath peritoneum adjacent to the right colon.

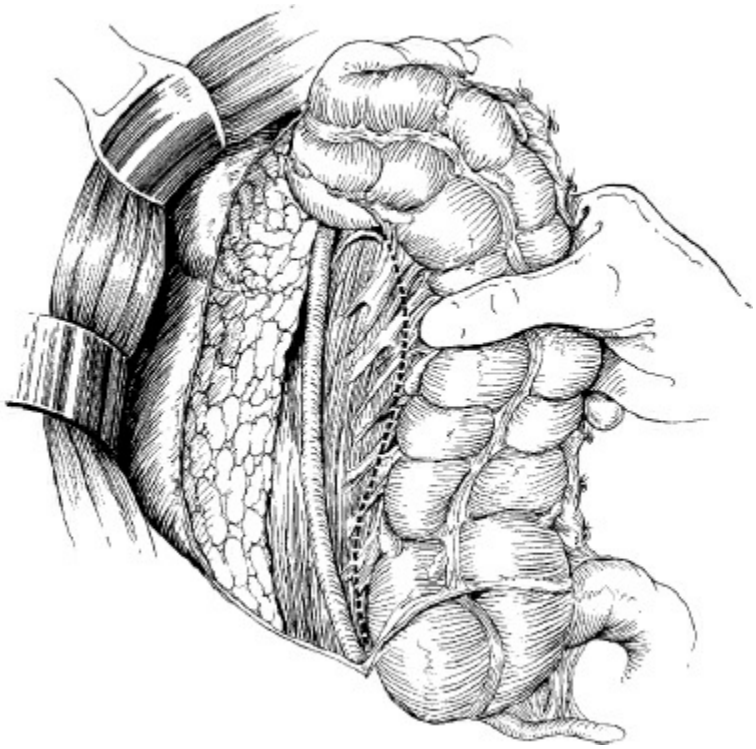

Figure 148.2. Duodenum and ureter exposed behind the right colon.

The decision whether to preserve or remove the greater omentum depends on the preference of the surgeon and the ease of preservation. If it is to be preserved, the omentum is detached from the transverse colon along its entire length to gain access to the lesser peritoneum. If the omentum is to be removed, the gastrocolic ligament is serially divided and ligated distal to the gastroepiploic vessels. Although the omentum may be a valuable “ally” after most abdominal operations, it can also become a “foe” as the source of adhesions and can adhere to both small bowel loops and the abdominal wall. In addition, if the omentum becomes fenestrated, strands may become a source of obstruction.

It is often advantageous to enter the lesser sac to the left of the midline before the hepatic flexure is taken down completely. Once in the lesser sac, adhesions of stomach to the transverse mesocolon are lysed, the gastrocolic ligament is serially divided and ligated distal to the gastroepiploic vessels (Fig. 148.3), and the hepatic flexure is approached from the left.

The mesocolon is left intact until it is fully separated from the gastrocolic, duodenal, and pancreatic attachments. The ileum is divided from the cecum using a linear cutting stapler. The mesentery is then divided by ligating the ileocolic, right colic (if present), and middle colic

vessels at the appropriate level depending on the nature of the underlying disease for which the resection is being done (Fig. 148.4). The ileocolic branches are preserved by ligating the mesentery close to the bowel wall in nonmalignant cases to preserve the vasculature for a possible subsequent ileoanal pouch or to avoid potential injury to structures close to main vessels. If pouch construction is deferred to a later time, preservation of the ileocolic artery and its peripheral branches may protect the essential arcades needed for mesenteric lengthening maneuvers future reservoir construction.

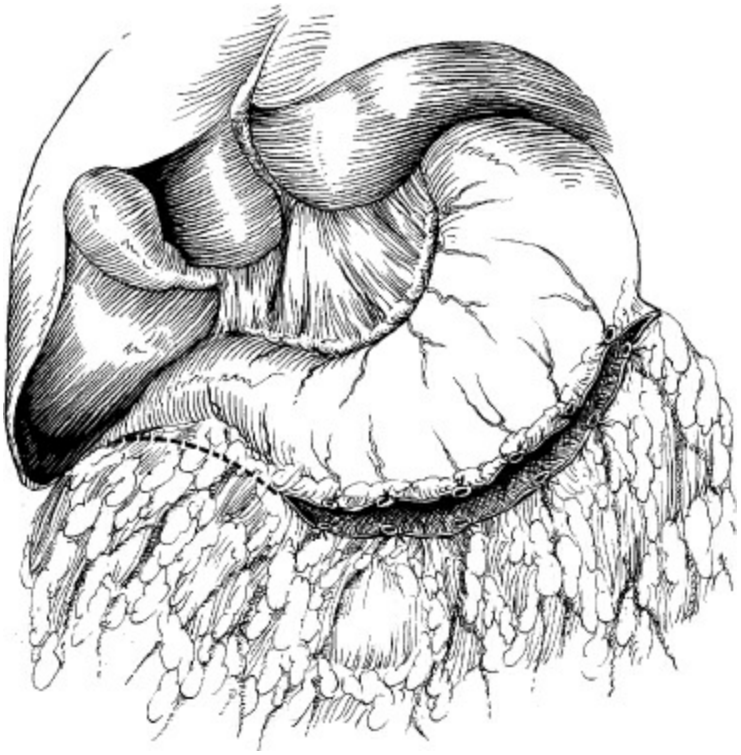

Figure 148.3. Dividing and ligating the gastrocolic ligament between the stomach and transverse colon.

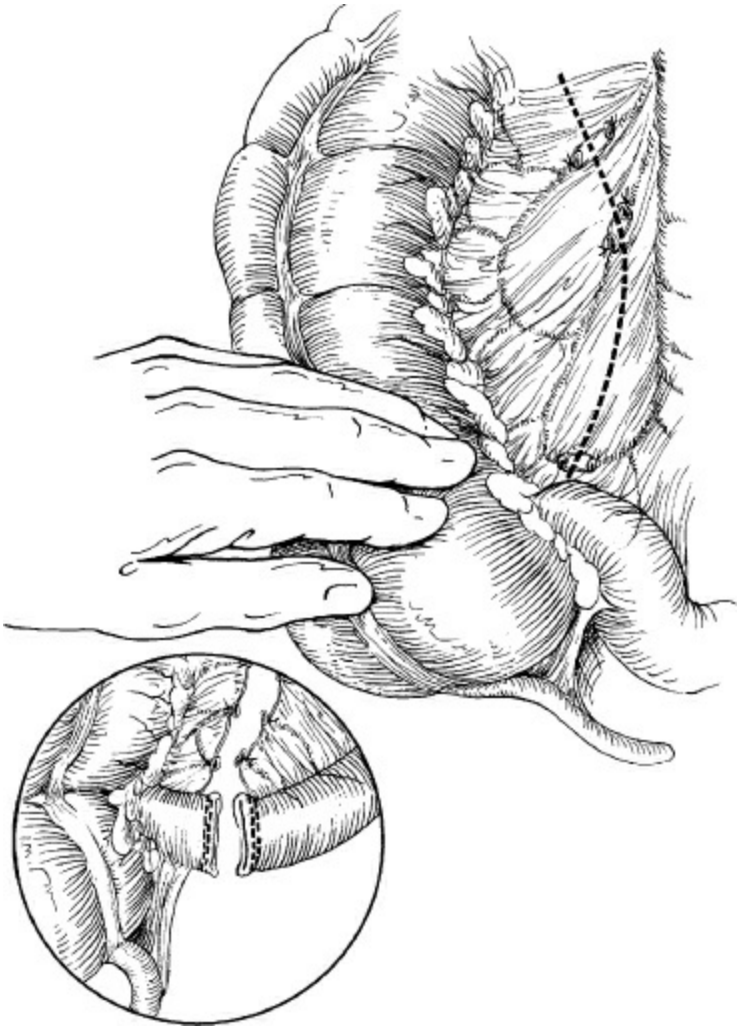

Figure 148.4. Dividing vessels to right colon and dividing the ileum with stapler.

Attention is then turned to the left side of the colon beginning at the sigmoid colon and moving toward the splenic flexure. The sigmoid colon and its mesocolon are medially retracted after which congenital or acquired adhesions of the appendices epiploicae, colon, and mesocolon to the peritoneum are divided. It is again important to remain in this avascular embryologic plane (also referred to as the white line of Toldt) to avoid injury to retroperitoneal structures (Fig. 148.5). Dissecting through fat while mobilizing the sigmoid colon indicates that one has strayed from the correct plane of dissection as the fat may signify an appendix epiploica, the mesocolon, or retroperitoneal tissue. The sigmoid colon is continuously rolled in a medial and slight cephalad direction after division of its lateral peritoneal attachments to facilitate freeing it from the retroperitoneum. As this mobilization is being done, the ureter is exposed and should be laterally swept to avoid injury. Once the sigmoid colon is

medial to the left ureter, it can be freed in a cephalad direction by carrying the peritoneal incision longitudinally and parallel to the course of the colon. As the dissection of the sigmoid colon approaches the pelvic inlet, it is important for the surgeon to be cognizant of the presence of the parasympathetic nerves on the surface of the aorta roughly 1 cm posterior to the superior hemorrhoidal vessels. Once the left ureter is identified, it is unnecessary to continue dissection in this area if the resection is being done for benign disease. Further dissection here may risk injury to nerves and therefore impair ejaculatory function in male patients. The mesocolon is incised at its base on the right side (Fig. 148.6).

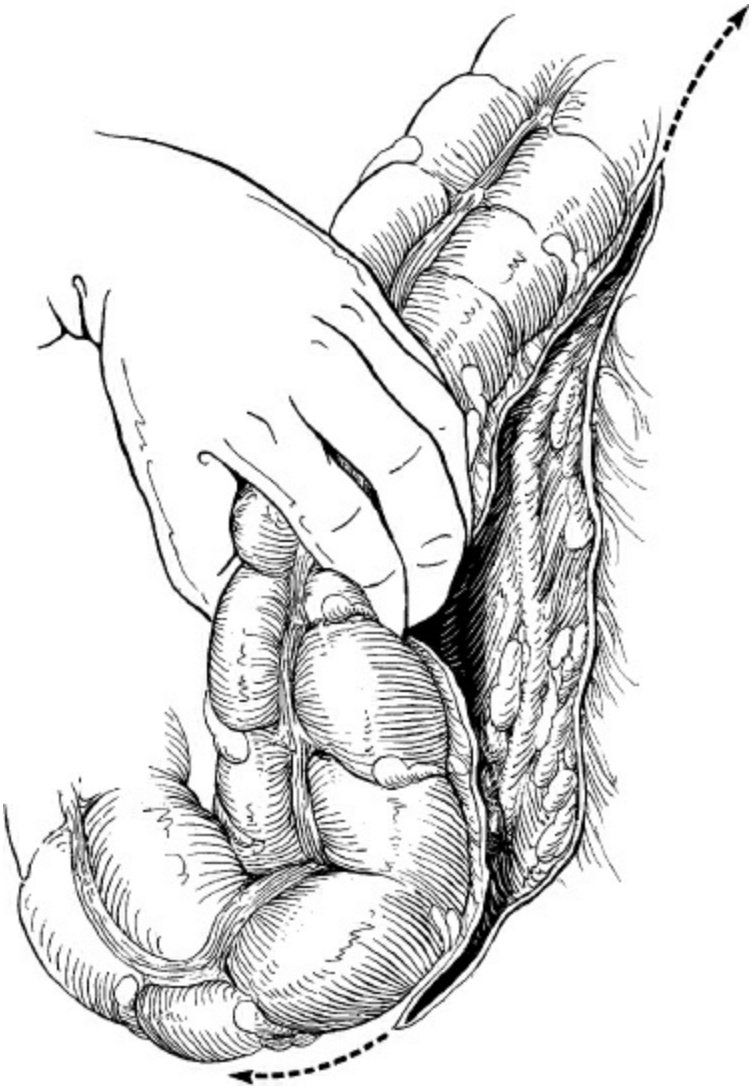

Figure 148.5. Mobilizing the sigmoid and mesosigmoid by dividing attachments laterally.

The descending colon's lateral peritoneal attachments are incised close to the colon to prevent potential dissection into Gerota's fascia. The

splenic flexure is then approached from the left, from below, and from behind as the descending colon is mobilized (Fig. 148.7). The surgeon must be careful when retracting the colon inferiorly or to the right, as traction on the distal transverse colon or omentum may result in avulsion injuries or tears to the splenic capsule and underlying parenchyma. It is important that the dissection remain within a few millimeters of the colon as the flexure is taken down because the omental attachment in this plane is relatively avascular. Once this part of the dissection is accomplished, the remaining omentum is either separated from the colon or the remaining portion of the gastrocolic ligament is ligated thus connecting the plane established earlier during the course of opening the lesser sac; this completes the mobilization of the splenic flexure.

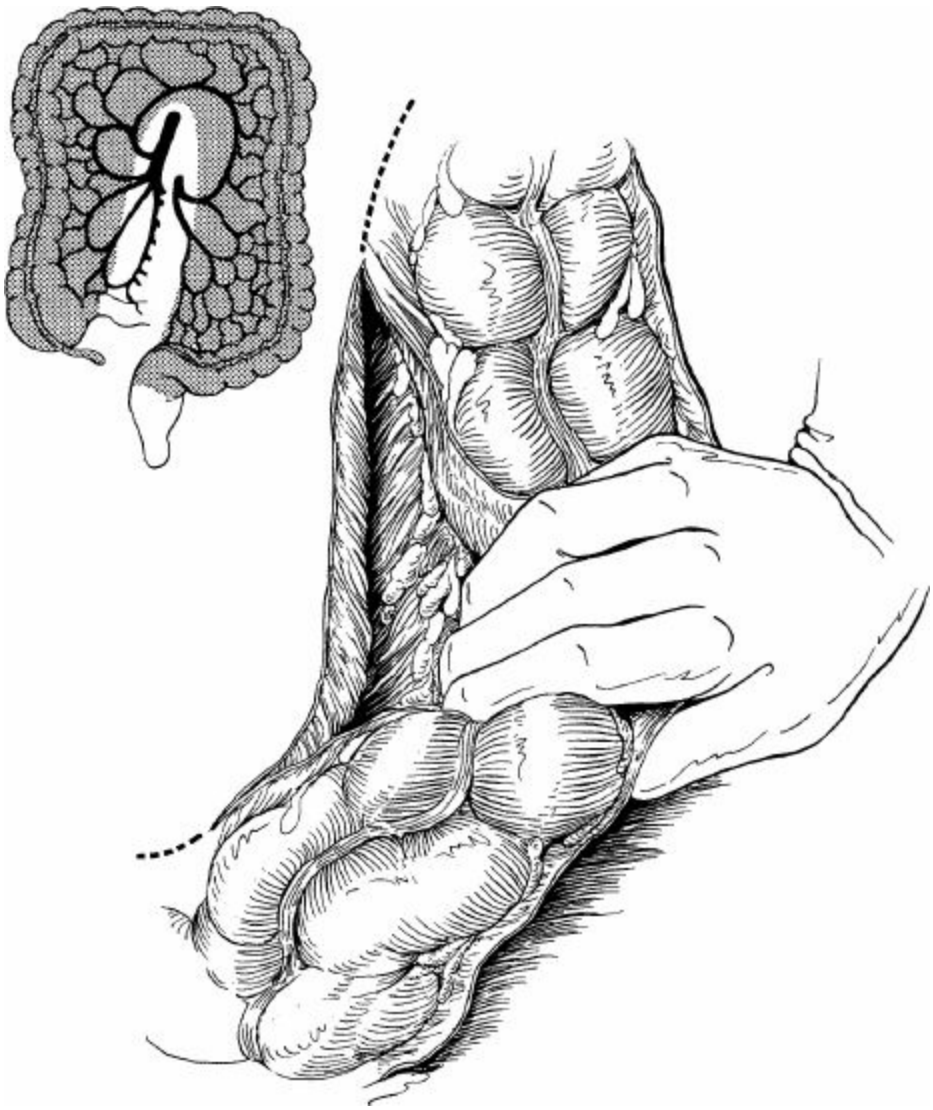

Figure 148.6. Incising the sigmoid mesocolon at base on the right.

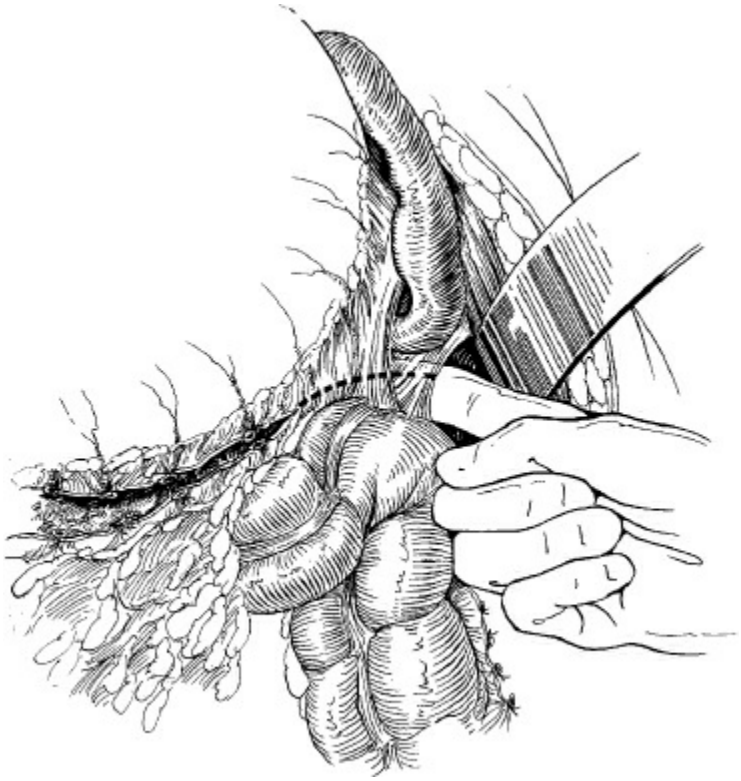

Figure 148.7. Taking down the splenic flexure.

Division of the inferior mesenteric artery and vein should be separately done when the resection is being undertaken for malignant disease. Dissection of the artery should be carried out as close as possible to the vessel to minimize risk of nerve injury, which may occur with traction on the arterial trunk. The inferior mesenteric vein is then ligated at the level of the duodenum. In male patients undergoing total colectomy for colitis or other benign disease, it is preferable to divide the sigmoidal branches near the colon wall, leaving the inferior mesenteric and superior rectal vessels intact to avoid dissection in the vicinity of the sympathetic nerves. Remaining colonic vessels may be divided at either proximal or distal levels contingent upon operative indication and surgeon preference.

The proximal rectum is prepared for transection by division of the mesorectum. The rectosigmoid is a 4-cm long transitional zone at the sacral promontory; here, the taenia coli merge into a confluent circular muscle coat and the lumen widens. The exact level is best confirmed by intraoperative endoscopy. The remaining mesentery is dissected close to the rectal wall, and the rectum is divided between clamps or with a linear stapler (Fig. 148.8) and the entire colon is removed. Prior to creation of an anastomosis, it is the authors' preference to perform a flexible sigmoidoscopy with the pelvis filled with saline to evaluate the staple line

at the rectal transection.

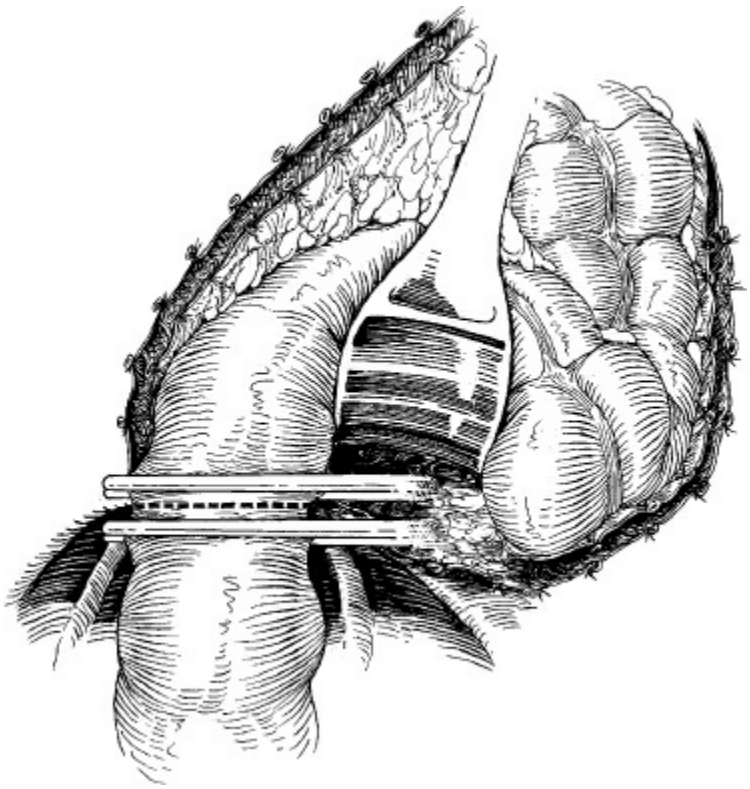

Figure 148.8. Dividing the rectum between clamps.

There are multiple techniques employed to create an ileorectal anastomosis based on the personal preference and experience of the surgeon; both stapled and hand-sewn anastomoses yield similar results. One can perform an end-to-end or end-to-side hand-sewn or stapled anastomosis (Fig. 148.9). In making an end-to-end hand-sewn anastomosis, the ileum may be enlarged by making a longitudinal slit in the antimesenteric border (a Cheatle procedure) to overcome the size discrepancy between the two lumens. If a side-to-end anastomosis is selected, the ileum is opened on its antimesenteric border and arranged so that the cut edge of the mesentery is positioned to the patient's right. The two bowel edges are approximated in a single layer using simple, interrupted sutures.

To create an end-to-end stapled anastomosis, a purse-string suture is placed at the cut edge of the open ileum. An end-to-end stapling device is then inserted transrectally. The stapler is advanced under direct guidance by the assistant who remains at the abdomen to help inspect the rectum and later unite the stapling device for construction of the anastomosis. Once the stapler is positioned so that its head is aligned at the midline of

the rectal stump staple line, the trocar of the instrument is advanced to pierce the rectal staple line. The anvil is then docked into position with the rectal stapler. The device is then closed so that the ileum and rectum are in close apposition and after verification of appropriate bowel and mesenteric orientation is fired. Once fired, the stapler is opened and removed slowly from the rectum. Two intact “donuts” should be obtained. The anastomosis is then checked for integrity and hemostasis by inserting a flexible sigmoidoscope through the anus and insufflating the rectum with air, while the pelvis is filled with saline and the newly made anastomosis is visualized. Alternatively, a distal purse-string suture can be placed by either manual or mechanical means to avoid the double-stapled “dog-ears.” In addition, intravenous indocyanine green assessment can be performed to evaluate both serosal and mucosal perfusion. Drains are usually not required and a diverting loop ileostomy is rarely necessary following total colectomy and ileorectal anastomosis.

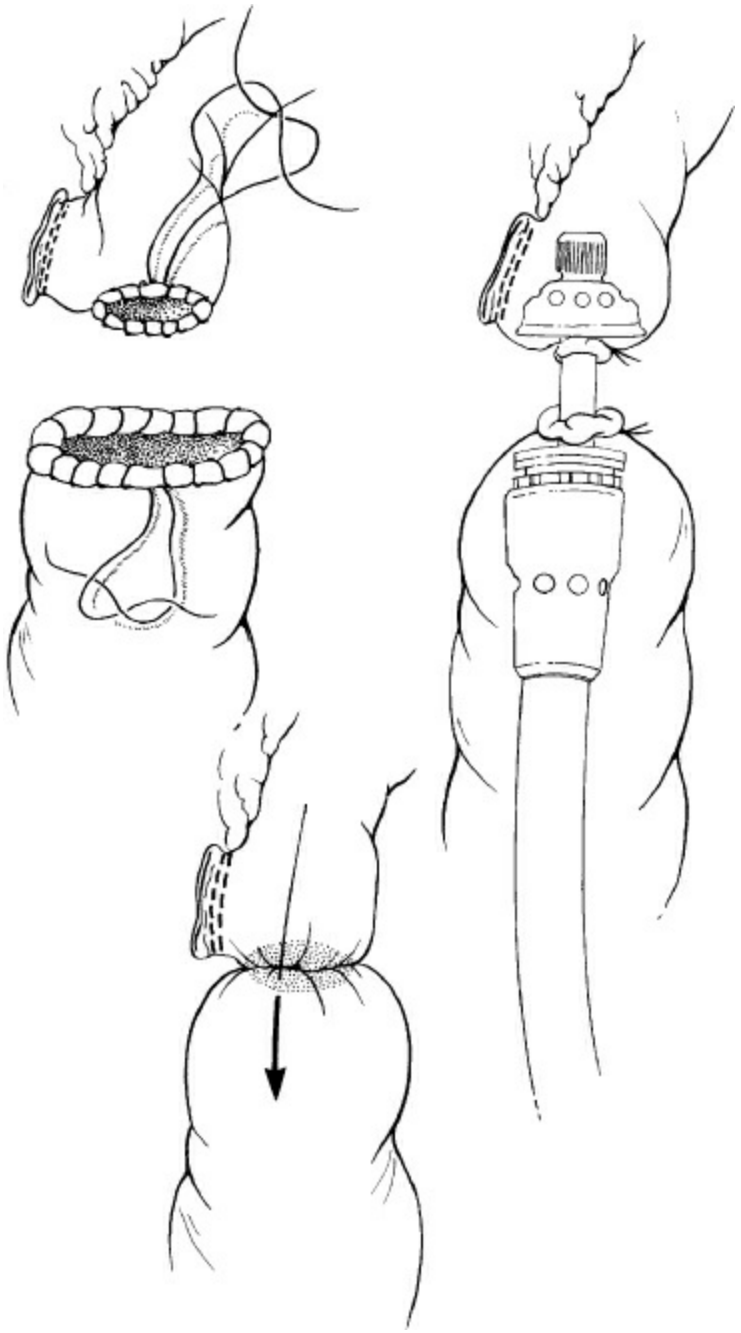

Figure 148.9. Side-to-end ileorectal anastomosis with intraluminal stapler.

Laparoscopic Resection

The principles of laparoscopic resection are similar to those followed during open total colectomy. The patient is positioned in lithotomy with the arms tucked at the patient's side to allow for easier positioning of the operating surgeon and the assistant in relation to the patient's body during the mobilization of the colon. The patient's position may be changed multiple times during the procedure to accommodate retraction of the

colon during mobilization. Placement of the patient in Trendelenburg or reverse Trendelenburg positions with left side up or down helps to facilitate retraction of the colon and to allow for the small bowel to fall out of the operative field by the assistance of gravity. Because of the extremes of position often employed during laparoscopy, securing the patient to an inflatable bean bag may be helpful.

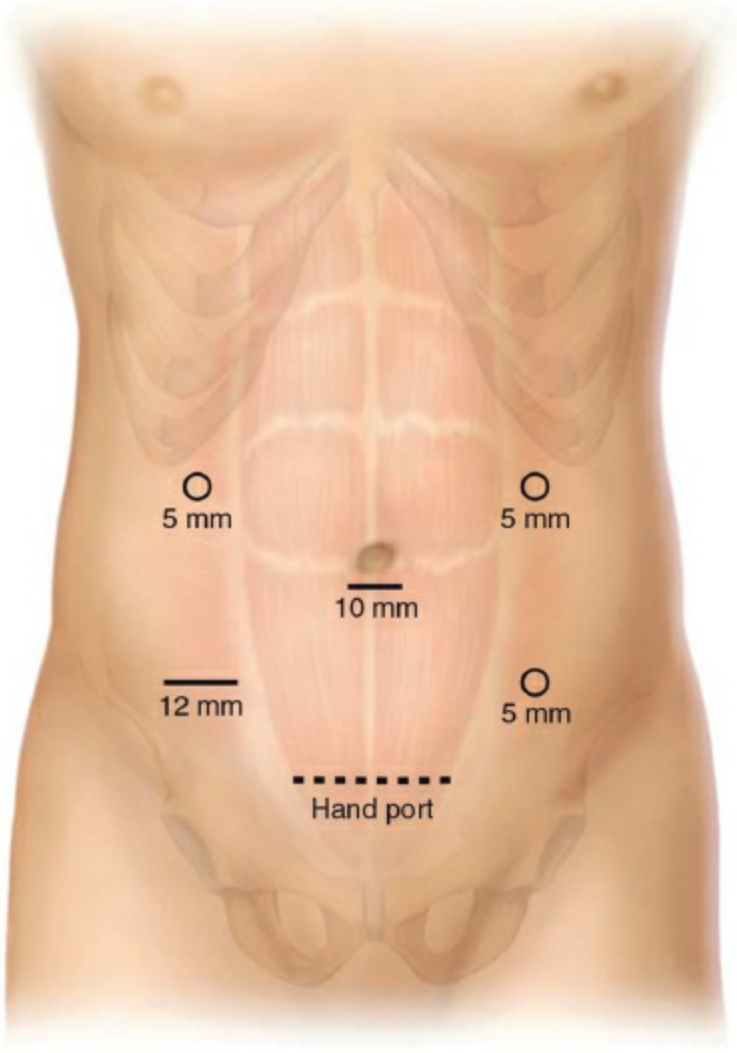

Figure 148.10. Port placement for laparoscopic total colectomy. (With permission from Margolin D. Hand-assisted. In: Wexner SD, Fleshman JW, eds. *Colon and Rectal Surgery: Abdominal Operations*. Philadelphia, PA: Wolters Kluwer; 2011.)

A total of five laparoscopic ports can be used to accomplish colonic mobilization (Fig. 148.10). First, a small midline incision is made just above or below the umbilicus to accommodate a 10-mm port through which a 30-degree telescope is placed. The abdomen is then insufflated

with carbon dioxide to a pressure of 15-mm mercury after which the camera is inserted. Inspection of the peritoneal cavity for adhesions, liver metastasis, or carcinomatosis should then follow. Four additional ports (5- or 10-mm ports, depending on surgeon preference) are then placed under direct visualization in the left upper quadrant, left lower quadrant, right lower quadrant, and right upper quadrant. Using a laparoscopic approach, the colon can be mobilized and devascularized from a lateral-to-medial approach or a medial-to-lateral approach.

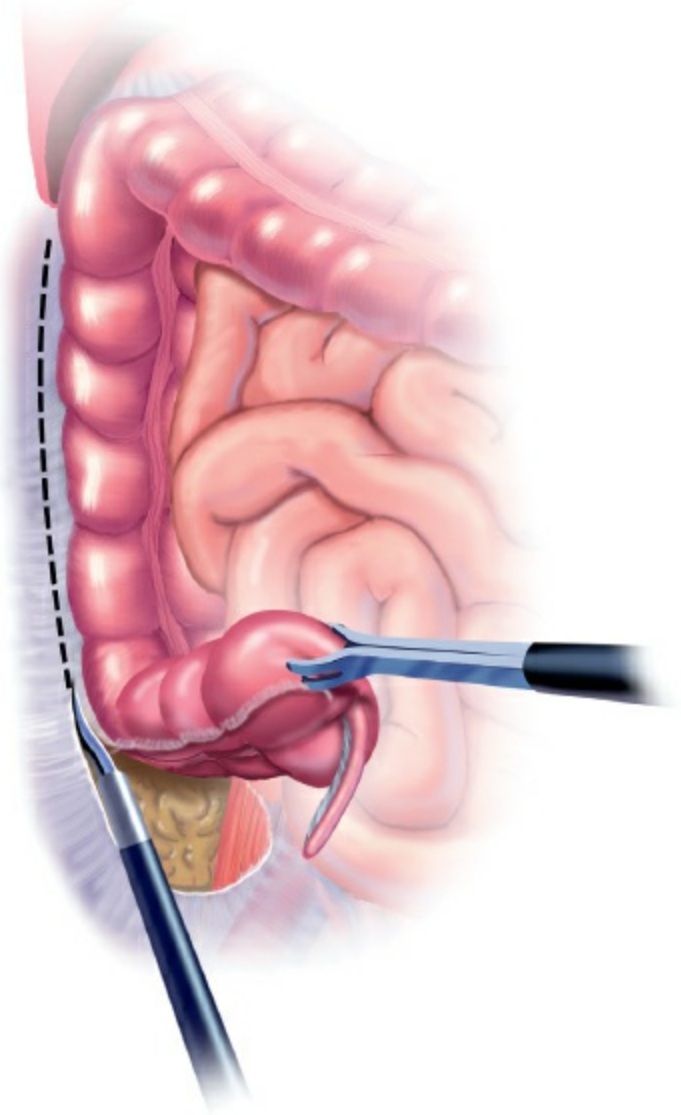

Figure 148.11. Laparoscopic division of the lateral retroperitoneal attachments of the right colon. (Adapted from Atlas of Minimally Invasive Surgery published by Cine-Med Publishing, Inc., 2006, www.cine-med.com.)

Lateral-to-Medial Approach

The right colon is mobilized first after placing the patient in Trendelenburg position with the right side up. Atraumatic bowel graspers are used to retract the colon while an energy source is employed for dissection and mobilization. This step is usually done through the two left-sided ports; however, the positioning of instruments may be interchanged as needed during the procedure to facilitate better retraction and mobilization. The right lower quadrant port may also be utilized to assist in retracting the cecum and the rest of the ascending colon. Once good retraction is obtained, the lateral peritoneal attachments are incised using endoscopic shears or an energy source, similar to that done in the open procedure (Fig. 148.11). The colon is lifted away from Gerota's fascia by maintaining the dissection in a medial direction as the kidney is approached. The duodenum is also visualized at this point and the thin, filmy attachments between it and the colon are divided. The hepatic flexure is reached and its most lateral attachments are separated using an energy source to ligate the small vessels contained in the hepatocolic attachments. As dissection proceeds in this plane, it becomes necessary to approach the transverse colon from a medial direction by opening the lesser sac. It is therefore usually necessary to retract the transverse colon from the inferior aspect by gently by grasping it with an instrument placed in the left lower quadrant port. Placing the patient in a reverse Trendelenburg position at this point improves exposure by allowing the omentum and colon to fall inferiorly along with the small bowel. The lesser omentum can then be retracted by the assistant in an upward direction with a grasper from the right lower quadrant port. The lesser sac is best identified and opened by using an energy source to separate the lesser omentum from its attachment to the colon taking care not to injure the gastroepiploic artery in the process (Fig. 148.12). Once the lesser sac is fully opened, the transverse colon mesentery is fully exposed and any remaining hepatocolic attachments are divided. The dissection is then carried along the transverse colon, opening the lesser sac toward the splenic flexure. As the splenic flexure is approached, the omentum may be more difficult to divide from this medial direction and will likely require that the flexure be mobilized from the lateral position.

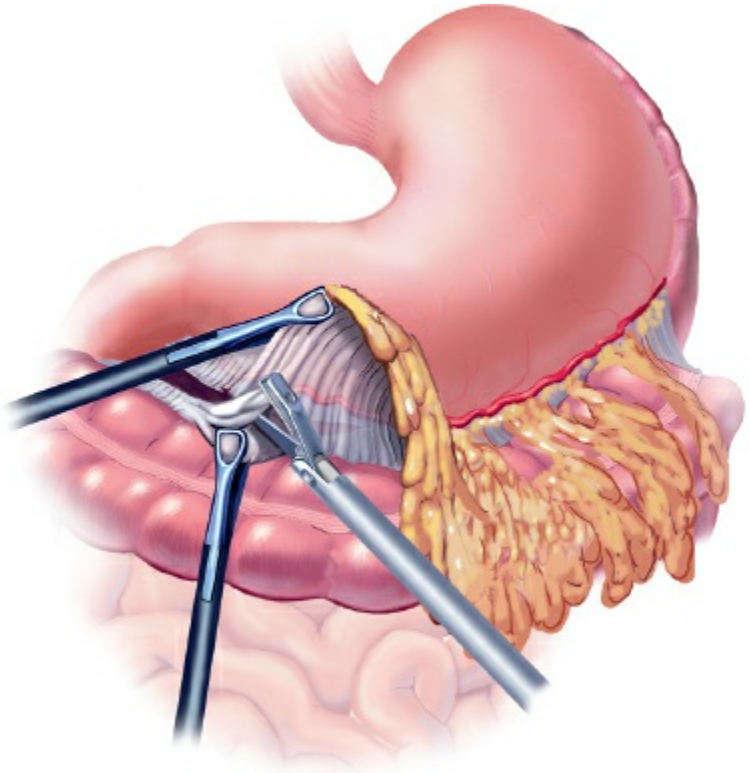

Figure 148.12. Laparoscopic detachment of the omentum from the transverse colon. (Adapted from Atlas of Minimally Invasive Surgery published by Cine-Med Publishing, Inc., 2006, www.cine-med.com.)

Attention is then turned to the sigmoid and descending colon. Mobilization of the sigmoid is done by gentle retraction of the colon with a grasper from a right-sided port while the patient is in Trendelenburg and left side up position. The lateral peritoneal attachments are again incised using an energy source, and the colon is pulled medially as mobilization proceeds and is lifted off of the retroperitoneum (Fig. 148.13). The gonadal vessels are usually encountered and the left ureter can typically be found medial to those vessels. The ureter may be closely associated with the colonic mesentery and will require being gently swept inferiorly as the colon is retracted superiorly and to the right. The descending colon's peritoneal attachments are also incised as the dissection proceeds superiorly, using the same principle of remaining close to the colon wall during the dissection of the descending colon off of Gerota's fascia. The splenic flexure is mobilized by rolling the colon medially with the retracting instrument placed in the right lower quadrant and dividing the retroperitoneal attachments with an energy source from the left lower quadrant port (Fig. 148.14). Placing the patient in the reverse

Trendelenburg position at this point may allow for better exposure of these attachments. The lesser sac is fully opened by resuming the dissection at the gastrocolic ligament and fully separating the colon from its attachments to the stomach and the medial aspect of the spleen. Once the pancreas is exposed, the dissection is complete in this plane.

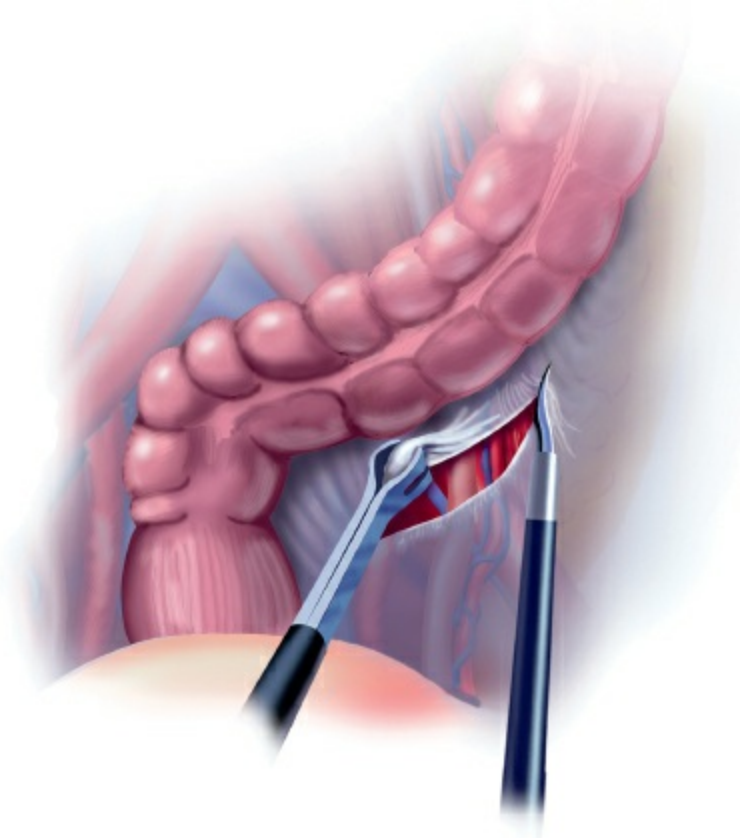

Figure 148.13. Laparoscopic division of the lateral retroperitoneal attachments of the sigmoid colon. (Adapted from Atlas of Minimally Invasive Surgery published by Cine-Med Publishing, Inc., 2006, www.cine-med.com.)

At this stage, all colonic attachments are mobilized and the vessels may be ligated using an energy source. For benign disease, as in the open procedure, it is not necessary to perform a high ligation of the inferior mesenteric artery. The sigmoidal branches near the colonic wall are ligated using an energy source from the right lower quadrant port, and the superior rectal vessels are preserved. The ligation proceeds to the inferior mesenteric vein and left colic artery. If high ligation of the inferior mesenteric artery is necessary, the vascular pedicle is identified at its origin superior to the aortic bifurcation by grasping the sigmoid colon and placing upward retraction of the colon toward the abdominal wall with a

grasping instrument in the right upper quadrant port (Fig. 148.15). The arterial pulsation is identified and the artery is skeletonized and any nerve fibers are dissected and reflected posteriorly. It is critical to ensure that the ureter is protected prior to ligation of the artery by reflecting the colon medially after applying the ligating device around the artery. The artery and separately the vein are ligated and transected near their respective origins. The division of the mesentery proceeds with the energy source located in the left upper quadrant port to ligate the transverse and right colon vessels (Fig. 148.16). Again, for benign pathology ligation of the vessels is accomplished near the colonic wall while for malignant disease ligation of the main vascular pedicles (middle colic and ileocolic arteries) is done near their origin.

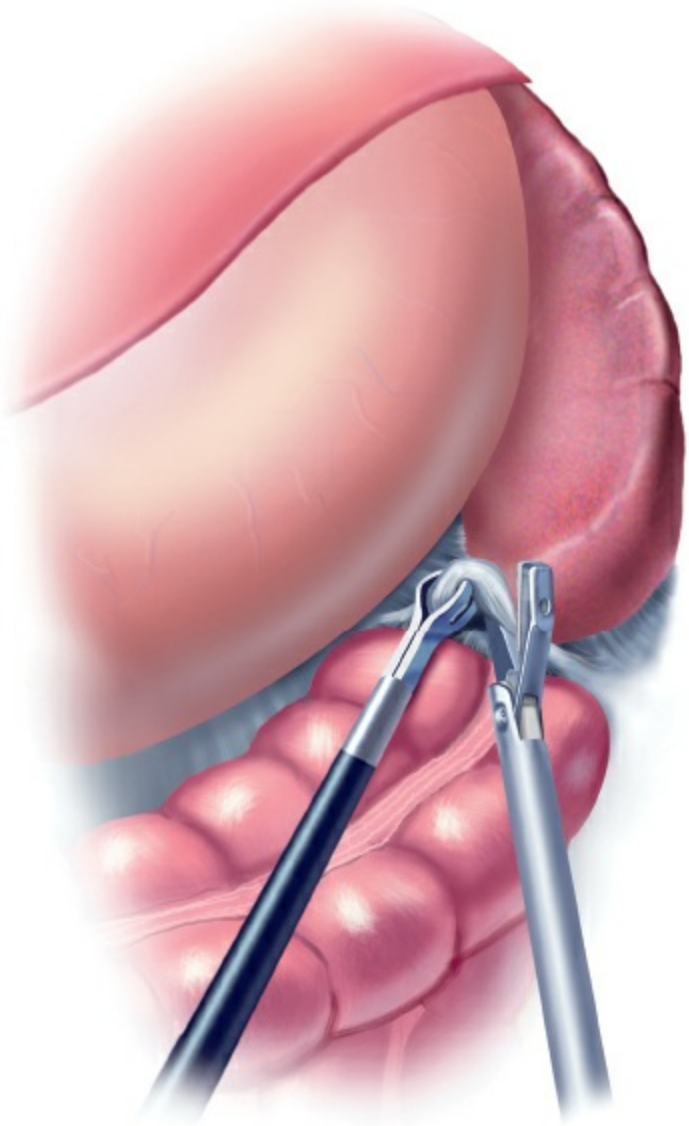

Figure 148.14. Laparoscopic mobilization of the splenic flexure. (Adapted from Atlas of Minimally Invasive Surgery published by

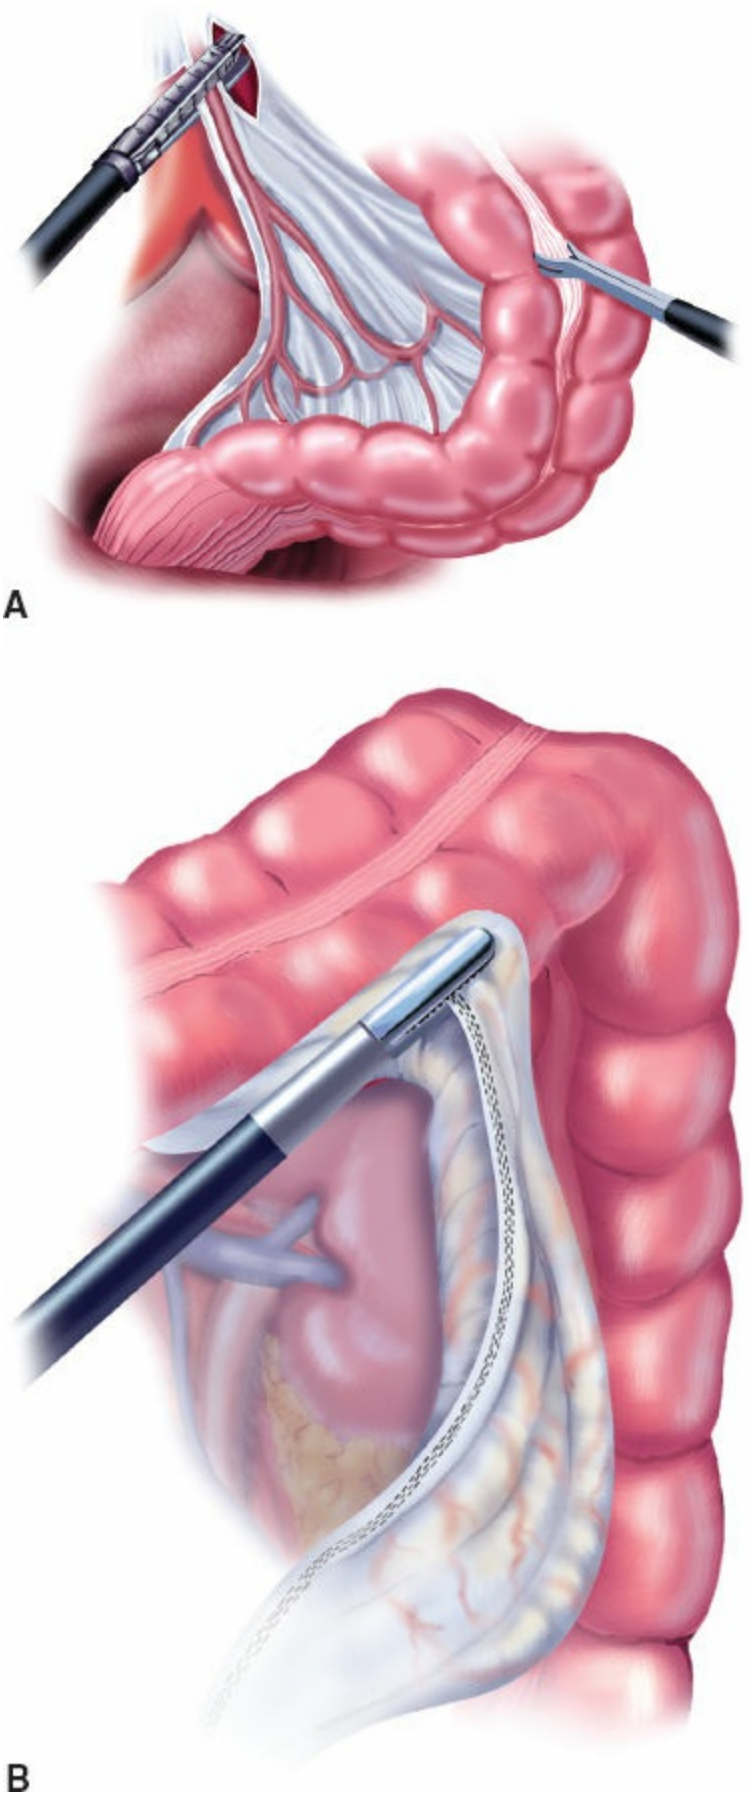

Figure 148.15. Laparoscopic division of the sigmoid and

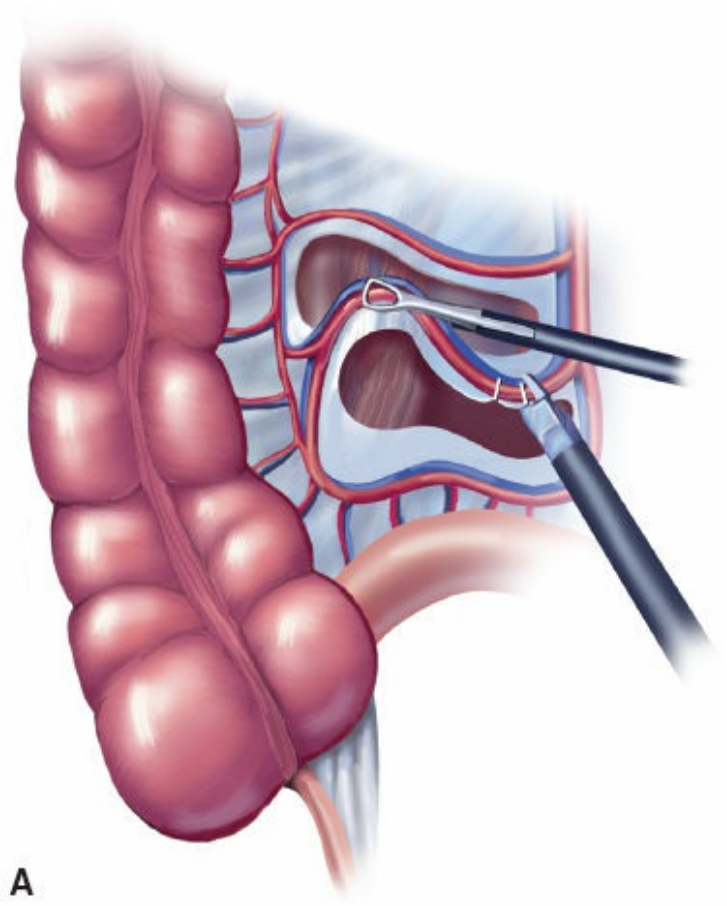
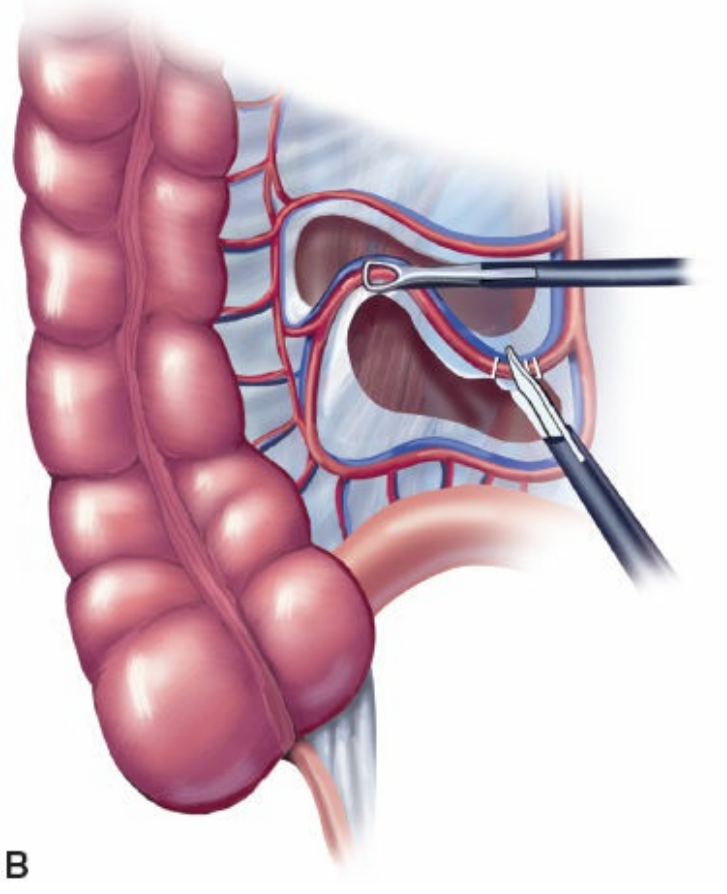
descending colon mesentery. (Adapted from Atlas of Minimally Invasive Surgery published by Cine-Med Publishing, Inc., 2006, www.cine-med.com.)

The ileum is divided using an endoscopic linear cutting stapler that can be placed through the left upper quadrant port. The rectosigmoid junction is also divided in the same manner by grasping the sigmoid with gentle upward retraction while applying the stapling device on the rectosigmoid junction. If necessary, the position of the rectosigmoid junction can be verified by using endoscopy. It is helpful to leave a grasper on the stapled end of the ileum to aid in identifying it after the colon has been removed.

Once the colon is transected, it can be removed from the peritoneal cavity in a variety of ways. If there are no plans to make an anastomosis, the colon may be removed from the future ileostomy incision. If there are plans for making an anastomosis, a small Pfannenstiel, vertical suprapubic umbilical, or port site incision can be made. In patients with inflammatory bowel disease, an iliac fossa incision should be avoided to obviate violation of future potential stoma sites. Regardless of the site selected, wound retraction with a protective expandable retractor is very helpful in maximizing wound size. In general a 3- to 5-cm skin incision is ample for specimen removal.



A



B

Figure 148.16. Laparoscopic division of the right colon mesentery. (Adapted from Atlas of Minimally Invasive Surgery published by Cine-Med Publishing, Inc., 2006, www.cine-med.com.)

The same principles are followed for the creation of the ileorectal anastomosis as during an open procedure. The ileum is brought into the abdominal wound and exteriorized, and the preparation of the anastomosis is done in a similar manner. If a suprapubic incision was made, it may be possible to unite the anvil and stapling trocar under direct vision while the wound is open; however, the laparoscopic approach is generally much easier and affords vastly superior visualization. This method requires closure of the abdominal incision or port and reinsufflation of the peritoneal cavity with carbon dioxide. It is necessary to ensure that the ileum has not twisted around its axis during the process of mobilization or preparation of anastomosis. To verify appropriate orientation, the small bowel should lie in the left side of the abdomen, while the cut edge of the mesentery should be straight and oriented on the right of the patient. A laparoscopic anvil grasper is used from the right upper quadrant port and the anvil is united with the trocar under direct vision after which the stapler is closed and fired. The two resulting “donuts” are checked for completeness. The integrity of the anastomosis is assured by first placing a noncrushing bowel clamp on the ileum and filling the pelvis with saline. The anastomosis is inspected with a flexible endoscope, which has the advantage of directly visualizing the anastomosis and air-testing it while it is submerged under saline. In addition, intravenous indocyanine green assessment can be undertaken to verify sensual and mucosal perfusion.

Medial-to-Lateral Approach

While the laparoscopic lateral-to-medial approach is similar to the dissection in an open colectomy, some surgeons prefer the medial-to-lateral approach. Using this technique, the vessels are ligated prior to colonic mobilization and the lateral peritoneal attachments are kept intact as they help provide retraction by suspension of the colon while the mesentery is being divided. The omentum is first superiorly reflected, and the small bowel is placed on the left side of the abdomen to expose the mesentery of the right colon. The ileocolic pedicle is then identified by grasping the cecum from the left lower quadrant port and placing tension

on the mesentery. The peritoneum overlying the pedicle is incised, and the retroperitoneum is gently swept downward. This maneuver creates a window through the mesentery, which allows identification of the duodenum. For malignant disease, the vessel is ligated at its origin near the duodenum, while for benign processes it should be kept intact and instead its branches divided. After the vessel is divided, the retroperitoneal plane is better exposed and blunt dissection is used to further separate the mesentery from the retroperitoneum. The dissection proceeds superiorly to separate the ascending colon and hepatic flexure from Gerota's fascia. The proximal transverse colon is also carefully dissected from the duodenum in the same manner. Once this step is done, the lateral peritoneal attachments of the ascending colon as well as the hepatocolic attachments that remained can now be divided. The transverse colon mesentery is then placed under tension, and the peritoneum is incised. Division of the mesentery can be approached from the right side by entering the lesser sac at the level of the pancreatic head or by creating a mesenteric window to the left of the middle colic artery and working back toward the hepatic flexure.

Ligation of the sigmoid and left colon mesentery follows the same principles outlined earlier. First, the inferior mesenteric artery pedicle is identified slightly superior to the aortic bifurcation; this can be accomplished by using the sacral promontory as a landmark and tracing the colonic mesentery superiorly up to the aortic bifurcation. Once identified, the inferior mesenteric artery along with the sigmoid colon is lifted superiorly toward the abdominal wall with a grasper placed through the right upper quadrant port. The peritoneal lining inferior to the vascular pedicle is incised to create a window through which the left ureter and pelvic nerve plexus can be identified. The visualization of the ureter is critical to allow it be reflected posteriorly into the retroperitoneum and separated away from the artery. The pelvic plexus of nerves is also reflected posteriorly in the same manner. The artery is skeletonized and ligated at its origin for malignant disease, while the sigmoidal branches are ligated in operations performed for benign disease. Once the artery is ligated, the mesentery is separated from Gerota's fascia and the retroperitoneum by placing an instrument under the colon mesentery with upward traction while using the right lower quadrant instrument to push down and separate the retroperitoneum. The inferior mesenteric vein is then divided, and the dissection proceeds superiorly to separate the splenic

flexure from its posterior attachments. Once this maneuver has been completed, the lateral peritoneal attachments of the sigmoid colon and descending colon are easily divided. The lesser sac is opened in the same manner as the lateral-to-medial approach, and mobilization of the splenic flexure is also completed following the same principles.

Hand-Assisted Laparoscopic Approach

Hand-assisted surgery has emerged as another alternative technique that can be used depending on the preference of the operating surgeon. Proponents claim that the hand-assisted approach may be useful during mobilization particularly when the colon is involved by severe inflammation, which makes grasping and retraction difficult with laparoscopic instruments. Positioning the patient is identical for hand-assisted surgery as for laparoscopy. Incisions differ in that the hand-port incision is made first followed by camera port and other port placement. A Pfannenstiel or lower midline incision is made for the placement of the hand port. Once the hand port is positioned, one may choose to place a trocar directly through the hand port and insufflate gas or place the camera port under direct visualization in the infraumbilical or supraumbilical position prior to gas insufflation. The remaining ports are placed in a similar position and manner as for laparoscopy.

Mobilization of the colon also proceeds in a similar way as the laparoscopic procedure. The most obvious difference is the operator's hand being placed in the hand port to retract and manipulate the colon. The anastomosis is also accomplished in the same manner as mentioned earlier for the laparoscopic approach; however with a lower midline or Pfannenstiel incision, it is often easier to fashion the anastomosis through the incision.

POSTOPERATIVE MANAGEMENT

Enhanced recovery protocols have been developed for the perioperative and postoperative care of patients and have been widely applied in colorectal surgery. The main goals of these programs are acceleration of postoperative recovery, and reducing complications, length of hospital stay, and subsequent readmissions. These goals are accomplished by optimizing the patient's preoperative status and providing education to patients regarding their recovery process and expectations. Preoperative bowel preparation is often not utilized and intravenous fluids are

minimized both intraoperatively and postoperatively. The process also incorporates minimally invasive surgery as the surgical approach of choice as numerous studies have demonstrated decreased recovery times and less postoperative pain. Use of narcotic alternatives including epidural analgesia, regional blocks with local anesthetic agents, and nonsteroidal anti-inflammatory medications may help to reduce narcotic-associated side effects and decrease the length of postoperative ileus. Oral or intravenous acetaminophen, gabapentin, and alvimopan have also been successfully utilized in these pathways. Active prevention of hypothermia as well as high concentrations of oxygen are also elements of many enhanced recovery protocols.

Nasogastric tubes are not routinely used, and patients are given oral clear liquid diets immediately following surgery. Once patients have tolerated clear liquids without evidence of nausea or vomiting, they are offered solid food. Patients are mobilized out of bed early during their hospital course and are encouraged to walk beginning on the first postoperative day. Discharge is possible after the patient meets criteria of adequate oral intake, return of bowel function, and no evidence of complications or infections.

Postoperative care of patients with Crohn’s disease is similar to the care provided to patients undergoing total colectomies for other etiologies. Restarting medical therapy following surgery may decrease the severity or delay the onset of disease recurrence. It is well known that endoscopic recurrence is seen in 70% to 90% of patients 1 year following surgery, 10% to 20% of whom are symptomatic. The timing for restarting medical therapy is not well described is often based mainly on individual practices; however when used, these medications are typically restarted within 4 to 8 weeks following surgery. Patients who were receiving steroids prior to surgery need to continue taking steroids after surgery during an appropriate taper.

COMPLICATIONS

Intraoperative complications include inadvertent injury to nearby structures such as small bowel or the ureters. Small-bowel enterotomies may take place during lysis of adhesions or colonic dissection, and if unrecognized may result in peritonitis and need for subsequent exploration. During laparoscopy injury to the bowel may occur during exchange of instruments, particularly when the patient is tilted to the side.

Ureteral injury is very rare during colonic mobilization; predisposing factors are related to previous surgery involving the retroperitoneal plane, prior radiation, active retroperitoneal and/or pelvic sepsis, and technical errors that occur when straying from the correct surgical plane. The ureters may also be injured during laparoscopic mobilization by thermal spread from various energy sources or from direct injury during dissection. Use of ureteral stents has been demonstrated in aiding the intraoperative recognition of ureteral injury but has not been shown to decrease the incidence of injury. Splenic injuries can also be avoided by careful visualization, retraction, and paracolic dissection as previously detailed. The most common site of injury is the capsule of the inferior pole. Fortunately, most injuries respond to electrocautery and application of topical hemostatic agents.

Surgical wound infections are unfortunately a common complication following colorectal surgery with up to 30% incidence. Measures taken to reduce the risk of wound infection include perioperative antibiotics and tight glycemic control. Some predisposing risk factors such as obesity and other systemic diseases as well as the perioperative use of steroids in patients with inflammatory bowel disease, however, are difficult to control.

Anastomotic leak is more common in patients with inflammatory bowel disease than in patients who undergo total colectomy with other indications. Pelvic abscesses may occur in association with an anastomotic leak or may be due to an infected hematoma or contamination during surgery. Small, contained leaks can usually be managed nonoperatively with bowel rest and percutaneous drainage of associated abscesses. Large leaks or anastomotic disruptions associated with systemic manifestations will require reoperation with proximal diversion and possible resection of the anastomosis. Three to 6 months after the patient has recovered, another attempt at restoring continuity may be considered. Verification of the integrity of the anastomosis can be undertaken by air testing and indocyanine green perfusion assessment.

OUTCOMES

Functional outcomes following subtotal colectomy with ileorectal anastomosis depend on the indication for the operation, presence of rectal disease, age, and comorbid factors. Generally, otherwise healthy patients who undergo this procedure will have between three to five stools per day

for the remainder of their lives. This stool pattern typically does not preclude physical activity or daily life. Diarrhea is not uncommon following total abdominal colectomy and may be accompanied by urgency and even minor incontinence. Bulking agents, cholestyramine, and loperamide hydrochloride or diphenoxylate may help combat diarrhea, and incontinence should also improve once stools slow and thicken.

Some patients undergoing subtotal colectomy for constipation may have persistent symptoms following surgery. Despite having strong evidence of isolated slow transit constipation on preoperative studies, 50% to 80% of patients may have persistent abdominal pain following surgery, although some report improvement in intensity. A smaller number of patients, 6% to 10%, continue to have persistent or recurrent constipation and may still require the use of enemas or laxatives to induce bowel movements. One to two percent of patients require conversion to end ileostomy due to symptoms of intractable constipation.

The risk of developing metachronous rectal carcinoma in patients with FAP varies from 12% to 43%, and necessitates the prophylactic removal of the rectum. In carefully selected patients with attenuated FAP who have fewer or no rectal polyps, leaving the rectum in place may be feasible. Spontaneous regression of rectal polyps following total colectomy and ileorectal anastomosis has been described in up to 50% to 64% of patients. Twenty percent to 38% of patients have complete resolution, while 15% to 26% show partial resolution of the rectal polyps. It is theorized that colectomy is responsible for causing regression of rectal polyps by decreasing rectal mucosal proliferation. The mechanism behind this decrease in mucosal proliferation is attributed to changes in the chemical composition of stool to which the rectum becomes exposed. Changes in the fecal flora, concentrations of primary bile acids, and reduction of carcinogenic factors have all been noted to occur following a total colectomy. These effects may be temporary or permanent, but still do not prevent later redevelopment of polyps and subsequent cancer. Approximately 55% of patients who had initial regression are eventually found to have rectal polyps during long-term follow-up.

Rectal polyps and carcinoma may still develop, and therefore rigorous follow-up is required to identify these patients and perform polypectomy prior to progression to carcinoma. Nonsteroidal anti-inflammatory drugs have been used to induce at least partial regression of rectal polyps; however, their long-term use must be balanced against their potential for

causing harmful side effects.

EDITOR'S COMMENT

Drs. Maron and Wexner accurately describe the different indications for which subtotal colectomy and ileorectal anastomosis are performed, as well as both open and laparoscopic approaches. For the latter, both lateral-to-medial and medial-to-lateral dissection methods and the hand-assisted approach are discussed.

First for some comments regarding indications for subtotal colectomy and then some comments about technical aspects of the procedure: a condition for which colectomy is increasingly performed albeit as a staged procedure, which is not fully addressed, is that of *Clostridium difficile* colitis. This is an increasingly common condition, with a 117% rise in hospitalizations due to this condition in the United States between 2000 and 2005 (Lee DY, Chung EL, Guend H, et al. Predictors of mortality after emergency colectomy for *Clostridium difficile* colitis: an analysis of ACS-NSQIP. *Ann Surg* 2014;259(1):148–56). There is an extremely high morbidity and mortality associated with colectomy for this condition (Bhangu A, Nepogodiev D, Gupta A, et al.; West Midlands Research Collaborative. Systematic review and meta-analysis of outcomes following emergency surgery for *Clostridium difficile* colitis. *Br J Surg* 2012;99(11):1501–13). This led to the development of an innovative treatment approach, which may decrease the rate of colectomy while decreasing morbidity and improving outcome (Neal MD, Alverdy JC, Hall DE, et al. Diverting loop ileostomy and colonic lavage: an alternative to total abdominal colectomy for the treatment of severe, complicated *Clostridium difficile*-associated disease. *Ann Surg* 2011;254(3):423–7), as described by Drs. Neal, Zuckerbraun, and colleagues whereby patients with acute toxic *C. difficile* colitis, rather than undergoing colectomy, undergo a loop ileostomy and intraoperative lavage of the colon with 8 liters of warmed polyethylene glycol, with postoperative antegrade irrigation of the colon with vancomycin via the efferent limb of the ileostomy. In those patients with *C. difficile* colitis or others who have undergone urgent colectomy for reasons such as lower GI bleeding, re-establishing intestinal continuity can be difficult. These patients are often infirm and elderly. The operating surgeon often does not have a perspective of the patients prior to their illness and does not know if they truly would not be better off keeping their ileostomy rather than subjecting them to what might be a major operation with uncertain postoperative functional results. The surgeon who is asked to re-establish intestinal continuity (reverse the ileostomy) may also not be the same surgeon who performed the emergency colectomy complicating matters even more. Performing a gastrografin enema is sometimes useful in assessing the amount of residual rectum. I have seen patients in whom

an overzealous surgeon has resected to the level of the mid rectum at the time of the emergency colectomy, leaving only a small effective amount of residual rectum to act as a fecal reservoir. In such cases, performing a straight ileorectal anastomosis can have disastrous functional consequences for the patient, with large numbers of bowel movements and incontinence due to the loss of reservoir capacity of the rectum. This combined with the more liquid consistency of bowel movements following a colectomy and diminished sphincter function associated with age or due to prior occult obstetric injury can make these patients a virtual prisoner of their home or bathroom, accentuated by the decreased mobility that many of these patients may have due to age-related arthritis. Thus, the decision to reverse a stoma in these patients must be made very carefully. Although the authors nicely describe anorectal physiology testing that does have its role, a very easy, almost primitive, test that I have long utilized is an "oatmeal enema" (Parés D, Duncan J, Dudding T, et al. Investigation to predict faecal continence in patients undergoing reversal of a defunctioning stoma (Porridge enema test). *Colorectal Dis* 2008;10(4):379–85) (people always wonder why we have oatmeal in our office?). Oatmeal can be mixed to a consistency that is similar to a loose porridge-like bowel movement that would be typical after a colectomy. Giving a diverted patient an "oatmeal enema" allows one to assess the patient's ability to retain a mass of similar quantity and consistency as a bowel movement, and allows determination of the time and degree of its retention in different positions, standing, sitting, and walking. Such testing is often as reassuring for the surgeon as for the patient. Typically, I tell the patients that they must be prepared to have as many bowel movements as the number of times they are emptying their ileostomy, although it is often less since the rectum does provide for some significant water absorption. There usually is a period of adjustment before this occurs.

In performing ileorectal anastomosis in someone with Crohn disease or other inflammatory condition or history of inflammatory condition (prior pelvic sepsis), it is important to determine the degree of rectal distensibility on insufflation of air during flexible or rigid sigmoidoscopy as the authors describe. This helps determine the quality of the functional result postoperatively; that is, if the rectal wall distends nicely, the patients will be able to hold their bowel movements and defer defecation if they are not near a bathroom. In contrast, if the rectal wall does not distend well, they have a "lead pipe"-type rectum, will have significant urgency, and will have to rush to the bathroom whenever stool enters the rectum, with little ability to defer defecation.

Hereditary nonpolyposis colorectal cancer (HNPCC) can also be an indication for ileorectal anastomosis and subtotoal colectomy as the authors describe. New developments in this field have occurred that may reduce the frequency for which this operation is needed. The Colorectal Adenoma/Carcinoma Prevention Programme (CAPP) 2 trial focused on 937 patients with HNPCC who were entered into a trial where they were randomly

assigned in a two-by-two factorial design to receive either aspirin 600 mg/day, or aspirin placebo for up to 4 years (Burn J, Gerdes AM, Macrae F, et al. Long-term effect of aspirin on cancer risk in carriers of hereditary colorectal cancer: an analysis from the CAPP2 randomised controlled trial. *Lancet* 2011;378(9809):2081–7). While the initial results of the trial were negative, long-term results showed a dramatic reduction in the incidence of colorectal cancers. At a mean follow-up of nearly 5 years (55.7 months), 18 of 427 patients in the aspirin group had developed a colorectal cancer as compared with 30 of 434 in the aspirin placebo group. For patients who completed 2 years of treatment (258 in the aspirin group, 250 in the aspirin placebo group) the per-protocol analysis showed a hazard ratio of 0.41 (0.19–0.86, $p = 0.02$) and in incidence rate ratio of 0.37 (0.18–0.78, $p = 0.008$). Further studies are needed to establish the optimum duration and dose of aspirin treatment in these patients. It may be that the use of aspirin in such patients may decrease the need for colectomy in the future.

I must stress the importance of excluding pelvic floor disorders prior to performing colectomy for the indication of constipation. Patients who have obstructed defecation (e.g., disorders such as nonrelaxing puborectalis in which their pelvic floor muscles do not relax appropriately to allow feces to pass) do not benefit from a colectomy. In addition, the "obstruction" to defecation from this disorder may actually lead to a greater risk of anastomotic leak due to a relative distal obstruction. There was initial optimism regarding the use of sacral nerve root stimulation for patients with slow transit colonic constipation. Although there have been many contradictory results, results of a recent prospective randomized trial as well as a Cochrane review do not support use of this technology for constipation at present (Dinning PG, Hunt L, Patton V, et al. Treatment efficacy of sacral nerve stimulation in slow transit constipation: a two-phase, double-blind randomized controlled crossover study. *Am J Gastroenterol* 2015;110(5):733–40; Thaha MA, Abukar AA, Thin NN, et al. Sacral nerve stimulation for faecal incontinence and constipation in adults. *Cochrane Database Syst Rev* 2015;8:CD004464). In patients with familial adenomatous polyposis that is not attenuated FAP or MUTYH-associated polyposis, there is a significant risk of rectal cancer development and I am very reluctant to perform ileorectal anastomosis due to this risk of rectal cancer as the authors so well describe.

Lastly, two technical comments regarding subtotal colectomy and ileorectal anastomosis: the authors correctly stress the importance of preserving the ileocolic artery with its branches and ligating these vessels close in proximity to the cecum in patients undergoing colectomy with benign disease that might eventually require an ileal pouch anal anastomosis. This includes patients with familial adenomatous polyposis process and possibly patients with HNPCC or toxic colitis due to inflammatory bowel disease.

In patients who have a very small amount (one half or less) of remaining rectum, function (the number of bowel movements) can be dramatically

improved by constructing an ileal pouch and then performing an ileal pouch rectal anastomosis. When I do this, I do perform a temporary diverting loop ileostomy in these patients, since they are usually frail and just recovered from their earlier severe illness.

Susan Galandiuk

149 Surgery for Diverticulitis

Patricia L. Roberts

Diverticulitis is the fifth most costly gastrointestinal disease in the United States and accounts for approximately 300,000 admissions to acute care hospitals each year. For every patient admitted to the hospital, a much larger number are treated on an outpatient basis. In addition, about one third of colectomies and colostomies are performed for diverticular disease. In the last decade, the recommendations for evaluation and treatment of diverticulitis have changed markedly due to the widespread use of computed tomography (CT) scanning, further understanding of the natural history of the disease based on severity stratification between uncomplicated and complicated disease, and the adoption of minimally invasive techniques including laparoscopic colectomy and laparoscopic lavage.

ETIOLOGY AND PATHOPHYSIOLOGY

Diverticula are acquired lesions associated with aging. They are quite common and occur in 15% of individuals by the fifth decade and increase with time. By the ninth decade, over 70% of individuals have diverticula. While it is widely quoted that 10% to 25% of patients with diverticulosis develop diverticulitis over the course of their lifetime, a recent study suggests that the number is actually only 2% to 5%.

In the United States, over 95% of symptomatic diverticula occur in the sigmoid and descending colon. Diverticula in the sigmoid colon are “false diverticula” representing partial thickness herniations of the mucosa and muscularis mucosa at the point where the vasa recta enter the colonic wall. True diverticula include all layers of the bowel wall and are generally believed to be congenital. Right-sided diverticula may be true or false diverticula.

The classic teaching has been that the aging process and the Western diet that includes inadequate dietary fiber intake are the major risk factors for the development of diverticular disease. The fiber deficiency hypothesis was put forth by Painter and Burkitt based on their

observational studies on diet and stool transit time in Sub-Saharan Africa in the 1970s. The lack of fiber resulting in constipation was felt to lead to mucosal herniation from a process of segmentation, the development of high pressure in the sigmoid colon. They noted that diverticula were rare in underdeveloped nations who had a diet high in fiber and were more common in more developed countries with higher consumption of processed food and low fiber intake. The studies were performed when the life expectancy in such countries was low and thus, it is not clear if diverticula were not noted because the population did not live long enough. The common teaching that nuts, corn, seeds, and popcorn cause diverticulitis has been debunked by a detailed study of over 50,000 individuals in the US male health professionals study. They were followed for 18 years and ingestion of these foods did not increase the risk of diverticulitis. In fact, men who had higher consumption of most nuts and popcorn had a decreased risk of developing diverticulitis compared with men who had a lower consumption of these foods. The US Health Professionals follow-up study of 51,529 men noted the development of 385 new cases of diverticular disease over a 6-year period and noted an inverse association with insoluble fiber intake and the development of diverticular disease.

The ongoing practice has been to continue to recommend a high fiber diet to patients both to prevent the development of diverticula and presumably to decrease recurrent attacks of diverticulitis. Two recent studies have looked at the role of dietary fiber and the development of diverticular disease. Crowe and colleagues performed a prospective cohort study of 47,000 individuals in the United Kingdom assessing dietary factors and the risk of admission to the hospital or death from diverticular disease. Self-reported vegetarians had a 31% lower risk of developing diverticular disease and individuals in the highest fifth of dietary fiber intake had a 42% lower risk of hospitalization for diverticular disease compared with those in the lowest fifth of dietary fiber intake. A somewhat contradictory study was done by Peery and colleagues and looked at 2,014 individuals who were undergoing screening colonoscopy. They were assessed by a questionnaire on dietary fiber intake, and this information was compared to the presence of diverticulosis noted on the colonoscopy report. Diverticulosis was noted in 878 patients (41%). Surprisingly, increased fiber consumption was associated with an increased risk for the development of diverticulosis. In this study,

constipation was not a risk factor for the development of diverticulitis and patients who had regular bowel movements (defined as seven bowel movements per week) had a 34% chance higher risk of developing diverticula than patients with less than seven bowel movements per week.

The relationship between lack of dietary fiber and the development of diverticulitis continues to be evaluated, although there are relatively fewer recent studies. There are additional potential health benefits of fiber, and the current general practice is to continue to recommend a high fiber diet for individuals with diverticular disease.

While the major focus has been on environmental factors, there is increasing evidence of the contribution of genetic factors with respect to the development of diverticular disease. A Swedish study of over 100,000 twins showed that the odds ratio of a sibling developing diverticular disease was 7.15 for monozygotic twins and 3.2 for dizygotic twins. A nationwide study in Denmark showed similar results and suggested that there may be a “young onset cohort” of diverticular disease with high genetic susceptibility. Additional work from the Penn State Colorectal Disease Biobank has shown that mutations in the TNTFS15 gene are associated with a higher risk of severe diverticulitis requiring surgery.

Triggering factors for an attack of diverticulitis are largely unknown. Patients frequently report what they believe to be dietary triggers such as ingestion of a large quantify of popcorn or nuts, but there is no conclusive evidence that such dietary indiscretion causes diverticulitis. Several studies have cited obesity as a risk factor for the development of diverticulitis potentially from low-grade systemic inflammation. We have found a seasonal variation to the development of diverticulitis, similar to appendicitis. Analyzing the Nationwide Inpatient Sample, the largest all payer database of hospital discharges in the United States, the peak incidence of episodes of diverticulitis in the United States is August. Other investigators have shown similar findings and have also correlated low UV light exposure and low vitamin D levels with the development of diverticulitis.

CLINICAL PRESENTATION

The initial presentation for the majority of patients with acute diverticulitis is left lower quadrant pain, fever, and leukocytosis. An abdominal mass or fullness may be present. Patients with a redundant sigmoid colon, which extends from the left lower quadrant to the right side, may also present

with right-sided abdominal pain, which on occasion is confused with appendicitis. Urinary symptoms including pressure and urinary frequency may be present especially if there is a significant inflammatory phlegmon. The presence of pneumaturia or fecaluria is consistent with an associated bladder fistula. Some degree of obstipation may be present. Diarrhea may occur in association with diverticulitis but is more common with infectious diarrhea or inflammatory bowel disease. Bleeding is uncommon and more likely associated with inflammatory bowel disease, colorectal cancer, or ischemic colitis. The differential diagnosis is broad (Table 149.1). While the diagnosis of diverticulitis may be made on the basis of history and physical examination, CT has played an increasing role both in the diagnosis, staging of diverticulitis and for patients with diverticular abscess, the treatment of the disease. For patients presenting in the emergency department, CT is often obtained prior to evaluation and consultation by a surgeon. CT findings associated with a diagnosis of diverticulitis include colonic wall thickening; streaky fat consistent with inflammatory change; and the presence of abscess, extraluminal air, or air remote from the colon (Table 149.2). Ultrasound and magnetic resonance imaging (MRI) may also be used as alternatives; ultrasound is user dependent and may be limited in obese patients. MRI is generally not widely available at many centers for acute evaluation of abdominal pain.

TABLE 149.2 Severity of Computed Tomography (CT) Findings and Associated Outcomes

Severity Grading	CT Findings	Outcome
Moderate	■ Localized thickening of colonic wall ■ Inflammation of pericolic fat	■ Failure of medical treatment, 4% ■ Index episode (nonoperative) associated with 17% incidence of recurrence or complication
Severe	■ Localized thickening of colonic wall ■ Inflammation of pericolic fat ■ AND (at least one) ■ Abscess ■ Extraluminal air ■ Extraluminal contrast	■ Failure of medical treatment, 26% ■ Index episode (nonoperative) associated with 36% incidence of recurrence or complication

Data from Ambrosetti P, Becker C, Terrier F. Colonic diverticulitis: impact of imaging on surgical management: a prospective study of 542 patients. *Eur Radiol* 1002;12(5);1145–9; and Regenbogen SE, Hardiman KM, Hendren S, Morris AM. Surgery for diverticulitis in the 21st century-a systematic review. *JAMA Surgery* 2014;149(3):292–302.

Depending on the severity of disease, patients may be treated as an inpatient or outpatient. Patients who are ideal candidates for outpatient treatment are able to tolerate po; are reliable with no cognitive, social, or psychiatric impairment; are not immunosuppressed; and have no signs of toxicity. Dietary restriction to either clear liquids or a low residue diet is common, but not supported by evidence. Outpatient management compared with inpatient management, when appropriate, saves costs to the health care system. Antibiotics aimed at coverage of gastrointestinal flora have been the mainstay of treatment with the prevailing wisdom that diverticulitis represents a primary bacterial infection with associated microperforation. This presumption has been challenged by an alternate hypothesis suggesting that diverticulitis represents an inflammatory process. Several studies have looked at treatment with no antibiotics with equivalent results to patients treated with antibiotics. The AVOD (antibiotics in uncomplicated diverticulitis) study was a multicenter study that looked at 623 patients with uncomplicated left-sided diverticulitis diagnosed by CT scan. Patients were randomized to be treated with intravenous fluid or intravenous fluid and antibiotics. There was no difference in outcome in patients treated with antibiotics versus those patients who were not treated with antibiotics. A subsequent Cochrane review of three randomized trials of patients with uncomplicated diverticulitis who were randomized to antibiotics or no antibiotics had the same findings. These studies challenge our conventional principles with

respect to treatment of diverticulitis. The studies on omitting antibiotics have been done on inpatients, and there are no studies thus far of outpatient treatment omitting antibiotics.

Following treatment of uncomplicated diverticulitis, the majority of patients improve and have no further attacks of diverticulitis. Current clinical practice guidelines recommend colonic evaluation approximately 6 to 8 weeks following recovery from an attack of diverticulitis to visualize the mucosa and exclude another diagnosis such as inflammatory bowel disease or cancer (in patients who have not had recent colonic evaluation).

MANAGEMENT OF UNCOMPLICATED DIVERTICULITIS AND INDICATIONS FOR SURGERY

The previous teaching for recommendations for surgery was to recommend resection after two attacks of uncomplicated diverticulitis (Fig. 149.1) and after one attack of complicated diverticulitis. The number of attacks is no longer a determinant in recommending surgery, and recommendations are individualized based on a number of patient- and disease-related factors, including the risk of subsequent attacks of diverticulitis, the severity of recurrent attacks of diverticulitis, the risk of perforation and the need for emergency surgery, and the risk for the development of complicated diverticulitis. Despite recommendations that the recommendations for elective sigmoid colectomy following recovery from uncomplicated diverticulitis should be individualized, the following factors (in my opinion) should be taken into consideration:

Risk of subsequent attacks of diverticulitis
Risk of developing complicated diverticulitis after recovery from an attack of uncomplicated diverticulitis
Risk of free perforation and the need for emergency surgery

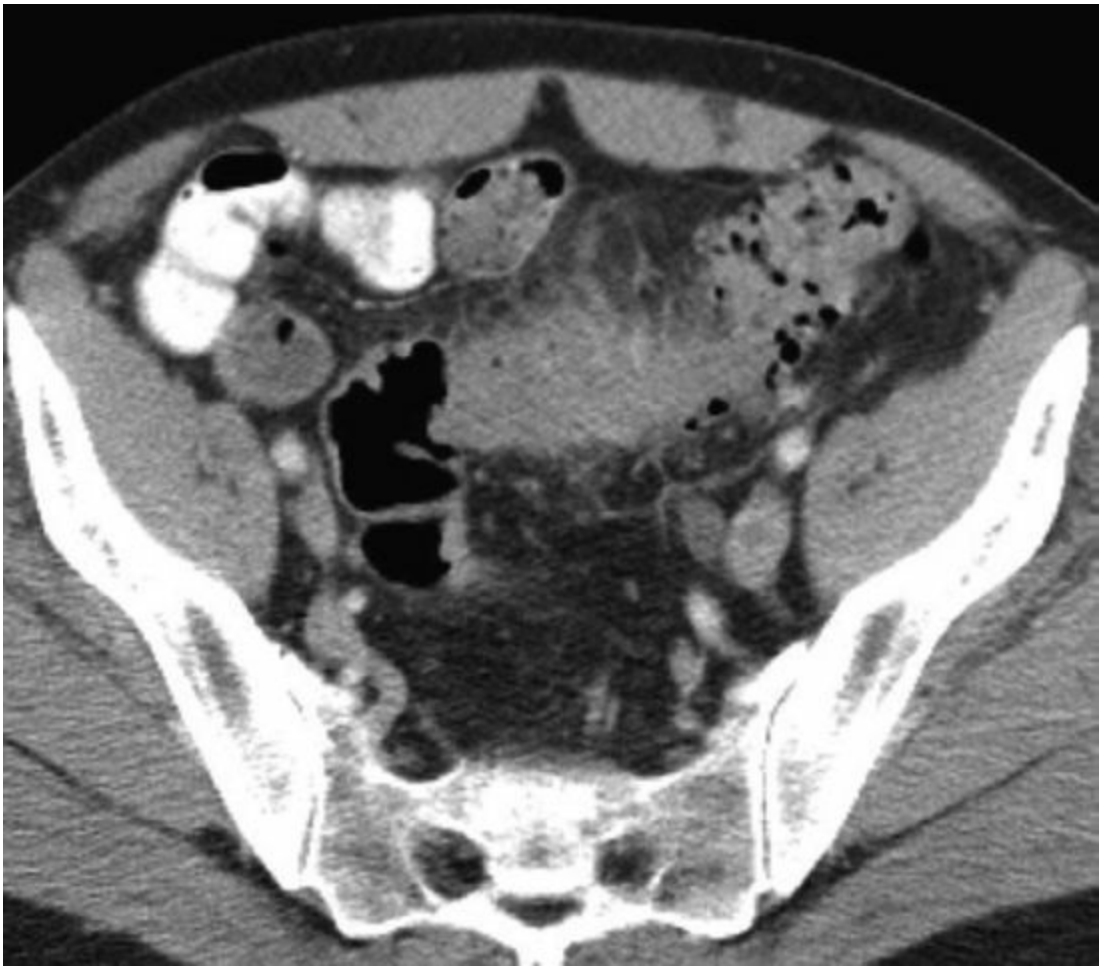

Figure 149.1. CT shows a long segment of uncomplicated diverticulitis.

Risk of Subsequent Attacks of Diverticulitis

Following recovery from an attack of uncomplicated diverticulitis, the risk of developing a subsequent attack of diverticulitis has been quoted as up to 30% to 36%. We have noted a risk of recurrence in 36% of patients who were hospitalized for diverticulitis and diagnosed by clinical criteria in addition to objective findings on CT scan. However, the majority of patients have no further attacks of diverticulitis, and therefore in approaching patients who have had one attack of uncomplicated diverticulitis, we should focus our attention on which patients are at high risk for the development of recurrent attacks of diverticulitis and which patients are at low risk. We have noted that patients with a long segment of diverticulitis (>5 cm) on CT scan and those with a family history of diverticulitis are at increased risk for subsequent attacks. A cohort of patients may also have multiple attacks over a short span of time. These patients most likely have an ongoing attack of diverticulitis that has not

totally resolved or what some groups have called “smoldering diverticulitis.” These patients fail to resolve symptoms despite multiple courses of antibiotics and require sigmoid resection.

Risk of Developing Complicated Diverticulitis

The clinical course of diverticulitis appears to be determined by the first attack. Patients who present with uncomplicated diverticulitis do not necessarily progress to have subsequent attacks of complicated diverticulitis. A number of large studies have noted that the risk of having a subsequent attack of complicated diverticulitis after recovery from an attack of uncomplicated diverticulitis is under 5%.

Risk of Developing Free Perforation/Risk of Requiring Emergency Surgery and Stoma After Recovery From an Episode of Uncomplicated Diverticulitis

Patients have often been counseled to have an elective sigmoid resection after recovery from diverticulitis to avoid requiring an emergency resection and possible stoma with a subsequent attack. However, a number of studies have shown that the most severe attack of diverticulitis tends to be the first attack and an emergency stoma and/or urgent Hartmann resection is rarely required. A population based study reviewed 25,058 patients with diverticulitis from 1987 to 2001. Emergency operation was required by 19.6% of patients on the initial attack. Of those patients who recovered, 5.5% required a subsequent emergency operation (7% of young patients). A systematic review of 85 papers showed that after recovery from one attack of diverticulitis, the risk of urgent Hartmann operation was 1 in 2,000 patient years follow-up. There is a cohort of patients at high risk for subsequent perforation after recovery from an uncomplicated attack of diverticulitis. Patients who are immunosuppressed, have chronic renal failure, or collagen vascular disease have a five times higher risk of perforation with subsequent attacks of diverticulitis and should be considered for resection.

Figure 149.2. CT shows severe diverticulitis with evidence of microperforation and free air.

Severity of Disease and Likelihood of Requiring Surgery

The widespread use of CT scanning as the initial modality in patients with suspected diverticulitis in addition to history and physical examination has allowed for a more thorough assessment and grading of the severity of disease. CT findings in diverticulitis include the presence of diverticular, pericolic inflammation, colonic wall thickening, and the presence of abscess or fistula. The findings that correlate with severe disease include the presence of abscess, extraluminal air, and extraluminal contrast, while the findings associated with mild disease include localized sigmoid wall thickening and inflammation of the pericolic fat (Fig. 149.2). The presence

of any of the severe findings on CT scan predicts a poorer outcome with a greater chance of recurrent disease and the need for surgical intervention. In a study of 312 patients with acute left colonic diverticulitis who underwent CT scanning, the findings of abscess and extraintestinal gas 5 mm in diameter or larger correlated with unfavorable outcome of nonoperative treatment.

We have also noted that patients with a longer segment of disease are more likely to have recurrent attacks of diverticulitis in addition to patients with a family history of diverticulitis. We have developed a scoring system based on points that we have used on inpatients to determine the risk of surgery within 90 days. The points are given for abscess >4 cm (2 points), pericolic free air (2 points), segment >5 cm (2 points), pericolic abscess (5 points), and distant free air (7 points). Patients with 0 to 4 points have a <25% risk of surgery in 90 days, patients with 5 to 9 points have a 25% to 50% risk of surgery, and patients with >9 points have over a 50% risk of requiring surgery within 90 days of presentation.

While recommendations for surgery for uncomplicated diverticulitis are individualized and consider the risks of operative therapy and the comorbid disease of the patient, colectomy should be strongly considered in those patients with multiple attacks of diverticulitis in a short time period and those patients who have ongoing diverticulitis (smoldering diverticulitis) with persistent symptoms. Inability to exclude carcinoma and significant impact on lifestyle are additional factors to consider.

Young Patients and Diverticulitis

The prior recommendations for resection after a single attack of diverticulitis in a young patient (defined as under the age of 50 years old) have been reexamined. From a historical standpoint, diverticulitis in younger patients was previously felt to be virulent and more likely to require surgery. All series of young patients with diverticulitis have a striking male predominance. Earlier series have shown a high rate of resection and may be because patients were operated on for a presumed diagnosis of appendicitis in the pre-CT scan era and found to have diverticulitis. Younger patients seem to have the same rate of recurrent diverticulitis but have many more years of life to develop recurrent disease. The clinical course of acute uncomplicated diverticulitis in young patients is similar to older patients, and therefore resection is generally not required after the first attack of diverticulitis. However, increasing

numbers of younger patients with diverticulitis are being seen and a cohort of younger patients appears to have more severe disease. We recently reviewed 932 patients treated with diverticulitis confirmed by clinical diagnosis and CT scan findings. There were 243 patients (26%) who were 50 years or younger. Young patients compared to the older cohort were more likely to present with severe disease on CT scan (22% vs. 12%) and more likely to have evidence of extraluminal air (22.4% vs. 13.15%, p = 0.014). Additional studies from the state of California have shown an increase in number of sigmoid colectomies and hospitalizations for diverticulitis, which was due to an increasing number of young patients with the disease.

COMPLICATED DIVERTICULITIS

Complicated diverticulitis includes patients with associated abscess, fistula, obstruction, and perforation and is further subcategorized as acute complicated diverticulitis (including diverticular abscess, perforation, and obstruction) and chronic complicated diverticulitis (including diverticular stricture an fistula). A large number of patients with complicated diverticulitis ultimately undergo sigmoid resection, and the goal of treating such patients is to optimize the patient condition and to ultimately convert an urgent or emergent operation into an elective procedure performed as a single stage with primary anastomosis and without the need for fecal diversion.

Diverticular Fistulas

Fistulas associated with diverticulitis may occur to any adjacent organ and include colovesical, colovaginal, coloenteric, and colocutaneous fistulas. Many patients with diverticular fistulas present with relatively fewer abdominal symptoms as the septic process has necessitated to an adjacent organ. Many patients present to another specialist first such as a woman with a colovaginal fistula presenting to a gynecologist with complaints of vaginal discharge.

Colovesical fistulas are the most common. Presenting signs and symptoms include pneumaturia, fecaluria, and polymicrobial urinary tract infections. In taking a history from the patient, there may be no obvious prior attack of diverticulitis. The best test to diagnose a colovesical fistula is a CT scan; the presence of air in the bladder in the absence of prior instrumentation is diagnostic of a fistula. While the majority of colovesical

fistulas occur from diverticular disease, it is important to exclude a diagnosis or colorectal cancer (which would change the operative approach). Cystoscopy or cystogram may also be utilized for evaluation. Colonoscopy is helpful to visualize the mucosa and exclude a diagnosis of a perforating colon cancer. The majority of patients with a colovesical fistula may undergo a single-stage open or laparoscopic sigmoid resection where the fistula is pinched off, omentum (if available) is used to interpose between the anastomosis and the bladder, and a Foley catheter is left in place. The fistula orifice to the bladder is sutured or if not readily apparent left in situ without suture repair. I do not routinely utilize ureteral stents, but they may be considered on a case-by-case basis, particularly in the presence of a significant inflammatory phlegmon. A cystogram is generally performed to confirm healing prior to removing the Foley catheter.

Colovaginal fistulas occur almost exclusively in women who have undergone prior hysterectomy. Presenting signs and symptoms include vaginal discharge and passage of air or stool per vagina. A limited gastrografin enema is helpful to delineate the fistula tract if it is not apparent on CT scan. On occasion a vaginogram is needed to delineate the fistula. A perforated colon cancer can present with similar signs and symptoms, and colonoscopy is helpful to visualize the mucosa. A similar operative approach is used to that of a colovesical fistula, pinching off the fistula (the vaginal side is generally left open for drainage and not sutured) and using omentum to interpose between the vagina and the anastomosis.

Colocutaneous fistulas may occur after percutaneous drainage of a diverticular abscess (in which case resection is generally the next step) or as a consequence of an anastomotic leak after a prior anastomosis. In a large series of 93 patients with colocutaneous fistulas, residual sigmoid colon distal to an anastomosis (i.e., not performing the anastomosis after sigmoid resection for diverticular disease to the proximal rectum) was a major risk factor for the development of such a fistula.

Diverticular Stricture

Strictures and resultant partial large bowel obstruction may also occur as a result of multiple attacks of diverticulitis. Many patients do not present with complete large bowel obstruction but rather with progressive constipation and obstructive symptoms. Once again, endoscopic visualization of the mucosa is helpful to exclude other diagnoses such as

colon cancer, ischemic colitis, or inflammatory bowel disease. Colonic stenting to treat large bowel obstruction from diverticular disease can be considered but is generally less successful than stenting for colon cancer.

Diverticular Abscess

Diverticulitis may be associated with an abscess in approximately 10% of patients hospitalized for diverticulitis (Fig. 149.3). The incidence of diverticular abscess had almost doubled from 5.9% in 1995 to 9.6% in 2005 in review of the discharge data from the Nationwide Inpatient Sample; the increase may be due to increased use of imaging with CT scan for evaluation of abdominal pain with increased detection of abscess and not a true increase in the number of patients with abscesses. A number of staging systems have been used, but the Hinchey system (with modifications thereof) remains the most commonly used (Table 149.3). Smaller abscesses (generally defined as <4 cm) may be treated with antibiotics without the need for percutaneous drainage or repetitive CT scans (particularly if the patient is clinically improving with decreasing pain, fever, and leukocytosis). A recent systematic review and meta-analysis looked at 22 studies with 1,051 patients with acute diverticulitis and abscess (modified Hinchey Grade IB and II). Percutaneous drainage was successful in 49% and antibiotics alone were successful in 14%. Urgent surgery was performed in 30% of patients, while 36% of patients had elective resection. Only 28% of patients had no recurrence of abscess and no surgery in the follow-up period.

Figure 149.3. CT shows adjacent abscess.

Perforated Divertculitis With Purulent or Fecal Peritonitis

The optimal treatment for perforated diverticulitis with associated peritonitis continues to evolve. Options include Hartmann resection, sigmoid resection with primary anastomosis (in selected patients), sigmoid resection and primary anastomosis with proximal diversion, on-table lavage with primary anastomosis, and laparoscopic lavage without resection. Hartmann resection, a procedure initially utilized for rectal cancer, remains one of the most common operations performed for perforated diverticulitis but has a number of drawbacks. Approximately one third of patients never undergo reversal of the stoma. The operation has considerable morbidity and a reported mortality of up to 18.8%. Over the years, a number of other surgical options have been proposed. Fibrin glue with suture repair and omental patching of the perforation has been reported. Two studies (both underpowered) looked at the role of defunctioning the diseased segment with suture of the peroration and proximal diversion versus resection and reached different conclusions. The

role of on-table lavage and subsequently performing a primary anastomosis in approaching patients with colonic emergencies has largely been abandoned since the need for bowel preparation has been challenged by a number of reviews. A systematic review of 569 cases from 50 studies suggested that primary anastomosis with or without diversion was "safe in certain patients with peritonitis" but noted a mortality of 9.9% and an anastomotic leak rate of 13.9%.

TABLE 149.3 Classification of Perforated Diverticulitis

Hinchey Classification
Stage I Pericolic abscess or phlegmon
Stage II Pelvic, intra-abdominal or retroperitoneal abscess
Stage III Generalized purulent peritonitis
Stage IV Generalized fecal peritonitis
Modified Hinchey Classification
Stage 0 Mild clinical diverticulitis
Stage Ia Confined pericolic inflammation/phlegmon
Stage Ib Confined pericolic abscess
Stage II Pelvic, distant intraabdominal or retroperitoneal abscess
Stage III Generalized purulent peritonitis
Stage IV Fecal peritonitis

Published in Hinchey EJ, Schaal PG, Richards GK. Treatment of perforated diverticular disease of the colon. *Adv Surg* 1978;12:85–109. Copyright Elsevier.

An additional trial randomized a total of 62 patients with left-sided colonic perforation (Hinchey Stage III or IV) to either Hartmann resection or primary anastomosis with fecal diversion (ileostomy). There was no difference in outcome after initial resection, and mortality and morbidity were no different. However, the rate of stoma reversal was higher in the primary anastomosis and ileostomy group (90%) compared to the

Hartmann resection group (57%). In addition, there was an increase in serious complications in the Hartmann takedown group and accrual in the trial was stopped.

An additional consideration is whether all patients with evidence of perforation require an operation. It is important to distinguish between patients who have evidence of peritonitis on physical examination and those patients who have CT findings consistent with perforation but no objective findings of toxicity. While many surgeons trained in the 1970s and 1980s were taught that the finding of free air on a chest x-ray or KUB was an absolute indication for laparotomy, the findings of free air on CT imaging do not necessarily translate into a similar recommendation. Dharmarajan and coworkers evaluated CT findings of perforated diverticulitis and devised a grading system based on the local and the amount of abnormal air, which may assist with clinical decision making. I rely more heavily on the clinical status of the patient and based my recommendations on these findings.

There has been renewed interest in the role of laparoscopic lavage without resection for treatment of patients with perforated diverticulitis and purulent peritonitis. The initial series in 1996 included 8 patients with perforated diverticulitis and purulent peritonitis who underwent laparoscopic lavage as the sole treatment with no interval resection. Following lavage, patients were maintained on intravenous antibiotics. At a follow-up of 12 to 48 months, no patients required subsequent resection and no patient required an emergent colostomy. The technique received little attention until the publication of a prospective multi-institutional trial in 2008 of 100 patients with perforated diverticulitis who underwent laparoscopic lavage. Lavage was carried out through umbilical, suprapubic, and right lower quadrant ports, with 4 L of fluid or until the returns were clear. No attempt was made to identify and/or suture the perforation. The median age was 62.5 years, and patients were followed for 36 months. Eight patients were found to have feculent peritonitis and converted to an open Hartmann procedure. Ninety-two patients were managed with laparoscopic lavage and no patient required subsequent resection for diverticulitis. Two patients developed a pelvic abscess in the postoperative period and required drainage and 2 patients presented with a subsequent attack of diverticulitis. The morbidity was 4% and the mortality was 3% much lower than what has historically been reported for the Hartmann procedure.

The role of lavage has continued to evolve. Questions to be answered include which patients should be selected for lavage, should patients have subsequent resection, and what are the long-term results. The number of patients who have undergone lavage remains small and in general includes small nonrandomized single institution studies. Many series include patients initially thought to have perforated diverticulitis but ultimately noted to have perforated colon cancer that highlights the importance of colonoscopic evaluation at some point in the postop period for patients in whom subsequent resection is not recommended. A recent review article evaluated 12 nonrandomized studies of 301 patients with a mean age of 57 years. Although the majority of patients had purulent peritonitis (Hinchey Stage III), 25% of the patients had Hinchey II disease. In the multi-institutional study of 100 patients reported in 2008, 25% of patients also had Hinchey II disease suggesting that some of these patients may have been appropriately treated with antibiotics and/or percutaneous drainage. The combined conversion rate was 4.9%, the complication rate was 18.9%, and the mortality was 0.25%. Subsequent resection was performed in 51% of patients, and the majority of resections were laparoscopic. The ideal candidate for lavage has not been identified, and further classification such as use of the Mannheim peritonitis index or the peritonitis severity score may help define such patients.

A number of clinical practice guidelines have been refined to include a statement on the role of lavage. The Association of Coloproctology of Great Britain and Ireland states that “laparoscopic lavage may play a role in some patients with acute diverticulitis. Whilst this is an alternative to resection in the acute setting for some patients, it is not certain whether it is an acute alternative to delayed resection.” The Clinical Practice Guidelines of the American Society of Colon and Rectal Surgeons states that “in patients with purulent or feculent peritonitis, operative therapy without resection is generally not an appropriate alternative to colectomy.” It was noted that a number of randomized controlled trials were underway that “may clarify the role of lavage in the management of patients with perforated diverticulitis.”

At least three randomized trials have or are in the process of looking at the role of laparoscopic lavage in the treatment of patients with perforated diverticulitis. The largest trial the SCANDIV trial randomized patients to laparoscopic lavage versus primary resection at 21 centers in Sweden and Norway. Of the 509 patients who were screened, 415 were eligible for

enrollment and 199 patients were ultimately enrolled. Patients with feculent peritonitis underwent resection. The primary outcome was severe postoperative complications within 90 days that occurred in 30.7% of patients in the laparoscopic group and 26.0% of patients in the resection group (no statistical difference). Reoperation was much higher in the lavage group (20.3% vs. 5.7%, $p = 0.01$). The authors concluded that lavage did not reduce severe postoperative complications and led to worse outcomes.

SURGICAL TECHNIQUE AND PREOPERATIVE ASSESSMENT

Elective Resection

The goal of treatment for acute diverticulitis is to convert an urgent or emergent operation into an elective procedure. After the decision has been made to proceed with elective sigmoid resection, a 4- to 6-week waiting period is generally recommended to allow the inflammatory phlegmon to resolve and maximize the change of an uncomplicated single-stage resection. For patients who have not had recent evaluation of the colon, colonoscopy is performed to evaluate the more proximal colon and exclude other pathology such as an underlying colon cancer or inflammatory bowel disease. While mechanical bowel preparation is not necessary prior to colon surgery, my preference is for a mechanical bowel preparation. Recent data suggest that the inclusion of oral antibiotics decreases the risk of surgical site infection. Bowel preparation also makes handling of the colon easier (particularly helpful with laparoscopic surgery) and facilitates passage of the stapler through the rectum. Standard intravenous antibiotic prophylaxis is administered as is deep venous thrombosis prophylaxis. Enhanced recovery pathways are used for appropriate patients. Ureteral stents may be employed selectively and are move commonly used for reoperative surgery or in patients with an associated hydronephrosis from the inflammatory phlegmon.

Single-stage sigmoid resection may be performed by an open or laparoscopic technique. A laparoscopic technique results in lower length of stay, quicker recovery, and less pain. Increasing numbers of colectomies for diverticular disease are performed by a laparoscopic approach, and there are increasing data of a lower incidence of surgical site infections and sepsis, less postoperative ileus, and less adhesions with laparoscopic

surgery. The Sigma trial, a prospective randomized trial at five centers of laparoscopic versus open sigmoid resection, showed a longer operating time, less blood loss, less pain, and improved quality of life (as measured by the SF 36) with a laparoscopic approach and more major complications (9.6% vs. 2.5%) with an open approach.

Open Sigmoid Colectomy

The patient is positioned on the operating room table in lithotomy position or if available, our preference is supine with the legs abducted on the split leg table. A Foley catheter is inserted. The abdomen is entered through a vertical midline incision and exploration carried out. For a lateral to medial approach, the line of Toldt is incised and the colon is retracted medially. In the course of the dissection, the ureter and gonadal vessels are identified and preserved. Prior phlegmon or inflammation may make identification of these structures difficult; in such cases, staying close to the bowel and not performing a wide resection of the mesentery mitigate the risk of injury to the ureter. Some studies have suggested that preservation of the superior rectal artery may improve blood flow and decrease the risk of anastomotic leak. Dissection is carried down to the pelvic brim/sacral promontory and distally as needed to allow for passage of a sizer and ultimately the circular stapler. Splenic flexure mobilization is generally performed to facilitate a tension-free anastomosis. The proximal resection margin is soft pliable bowel, and the distal resection margin is the proximal rectum as evidenced by where the tenia splay out. The extent of resection is the sigmoid colon. It is helpful to place a sizer through the rectum to ensure adequate mobilization and subsequent easy passage of the circular stapler. The rectum is transected with a linear stapler, and a pursestring is placed in the proximal bowel. If there has been a significant prior phlegmon, it is occasionally necessary to resection a portion of the rectum to get to pliable bowel. A hand-sewn or stapled anastomosis may be performed; a stapled anastomosis is generally preferred with the circular stapler. An air leak test is performed to test the integrity of the anastomosis by occluding the bowel proximal to the anastomosis and insufflating through a proctoscope or flexible sigmoidoscope with the pelvis filled with saline. Standard abdominal closure is performed.

Laparoscopic Colectomy (Straight)

The preoperative considerations are similar to open surgery with exceptions of consideration of prior surgery and body mass index.

Adhesions from prior abdominal surgery may preclude the ability to safely perform a laparoscopic resection. Morbidly obese patients should be counseled of a higher risk of conversion because of technical challenges with a laparoscopic procedure (although on occasion, a laparoscopic approach is easier than an open approach on such patients) or even the inability of patients to physiologically tolerate Trendelenburg position that is needed in the course of the resection. The patient is placed on the split leg table with the legs abducted or if such a table is not available in modified lithotomy position. The arms are tucked and the patient is secured to the table with a beanbag and with taping.

Entry into the abdominal cavity is either by a Hasson technique (which we prefer) or with a Veress needle and pneumoperitoneum is established. Port placement may vary based on patient anatomy and surgeon preference but generally includes a supraumbilical port, right and left lower quadrant ports, and a right upper quadrant port. A lateral to medial or a medial to lateral approach for mobilization of the colon may be employed depending on the surgeon's preference.

For a lateral to medical approach, the sigmoid and rectosigmoid are retracted medially and incision is made along the line of Told and continued up toward the splenic flexure and down to the sacral promotonory/rectosigmoid junction. The ureter and gonadal vessels are identified. The peritoneum is incised and a window created to ligate the inferior mesenteric artery. The ureter can at times be confused with the superior rectal artery, and both should be identified prior to transection.

With laparoscopic surgery, there has been a trend to perform medial to lateral mobilization. This technique allows for immediate identification of the plan between the retroperitoneum and the mesocolon. The inferior mesentery artery is identified and transected, and the colon is then mobilized along the line of Toldt (Fig. 149.4). Both techniques are safe, and it is helpful for the surgeon to be facile with both techniques. A significant inflammatory phlegmon and foreshortened mesentery as is seen in cases of recurrent diverticulitis can render the medial to lateral technique difficult and at times impossible to accomplish.

Proximal and distal resection margins are identified as outlined above and anastomosis is more commonly done extracorporeally, although an intracorporeal anastomosis may also be performed. Air leak testing is routinely performed.

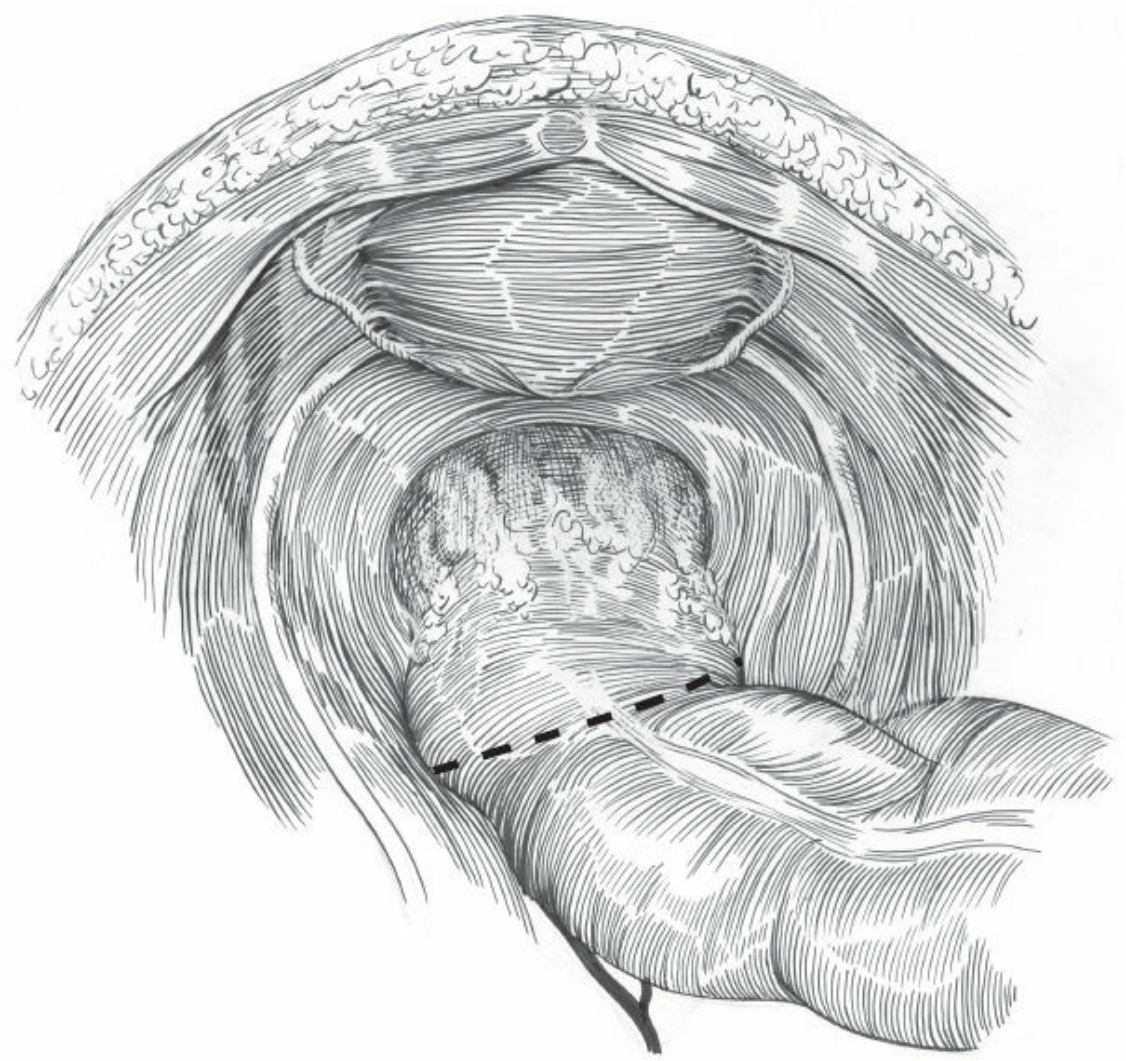

Figure 149.4. The distal resection margin should be in the proximal rectum where there are no diverticula and the tenia splay out.

Hand-Assisted Laparoscopic Sigmoid Colectomy

The indications for use of the hand-assisted laparoscopic sigmoid colectomy are the same as for straight laparoscopic procedures. Hand-assisted colectomy may be used for all procedures or selectively. Earlier studies showed better adoption of laparoscopic surgery with a hand-assisted technique for novices in addition to shorter operative times with no difference in short-term results. Insertion of the hand may facilitate dissection in cases with significant fibrosis or phlegmon where the ability to use a hand to “pinch off” adhesions is helpful. Some studies have shown a lower conversion rate with a hand-assisted technique compared to a straight laparoscopic technique. In addition, if a straight laparoscopic technique is used, a hand-assisted approach may offer an alternative to

conversion of an open procedure.

The patient is positioned on a split leg table with the legs abducted or in a modified lithotomy position if such a table is not available. The incision for the handport can be placed in the midline or as a Pfannenstiel incision. The camera port is placed in the supraumbilical position, with working ports in the right lower quadrant and left lower quadrant. The patient is placed in Trendelenburg position with the small bowel retracted cephalad. A medial to lateral or lateral to medial dissection may be performed. Our preference is the medial to lateral approach that is accomplished by grasping the inferior mesenteric artery with the right hand, incising the peritoneum and ultimately sweeping the ureter and gonadal vessels to the retroperitoneum, transecting the artery with a stapler, endoloop, or an energy sealing device and then proceeding medially to laterally to mobilize the sigmoid colon up toward the splenic flexure and inferiorly to the pelvis. The specimen is ultimately extracted through the hand port and anastomosis generally performed with a circular stapler. Air leak testing is routinely performed. The Pfannenstiel and port sites are closed in routine fashion.

Robotic Sigmoid Resection

Robotic-assisted sigmoid resection may be performed for sigmoid diverticulitis, but the overall benefit of this technique compared to laparoscopic resection has not been determined.

Emergency Procedures

Hartmann Resection

The Hartmann resection was originally described in 1923 as an alternative to abdominoperineal resection in patients with rectal cancer. The procedure quickly became the procedure of choice for the majority of patients who underwent surgery for perforated diverticulitis in the second half of the 20th century, replacing the three-stage procedure of initial colostomy, subsequent resection, and ultimately colostomy takedown that was advocated by Lockhart Mummery and Smithwick. It is commonly performed for perforated diverticulitis associated with purulent peritonitis or fecal peritonitis and for other urgent or emergent resections for diverticulitis. While a laparoscopic approach may be performed, it is more commonly done by an open approach in the emergency setting.

The patient is fluid resuscitated and antibiotics and DVT prophylaxis

are administered. Stoma marking is performed by an enterostomal nurse (if available) or the surgeon. The abdomen is entered through a midline incision and explored. The sigmoid colon is retracted medially and mobilized ultimately identifying ureter and gonadal vessels and if not possible, keeping the dissection and ultimate mesenteric transection as close to the colon as possible. The proximal transection line is ultimately in soft pliable bowel that will have adequate length to bring up a tension-free colostomy in the left lower quadrant. Splenic flexure mobilization is often necessary. The distal transection point is ultimately the proximal rectum; however, one option is to only resect the perforated segment leaving a portion of the distal sigmoid. This facilitates the subsequent reversal surgery as the pelvic peritoneum has not been opened and the residual sigmoid colon may be resected at this time.

Laparoscopic Lavage

Nonresectional treatment for diverticulitis associated with purulent peritonitis has had renewed interest. Laparoscopic lavage is performed with a three-port technique with a camera port in the supraumbilical site and two other working ports in the right upper, right lower quadrant and/or suprapubic area. The diagnosis is confirmed and the abdomen lavaged with saline until the returns are clear. If fecal peritonitis is present or if the site of perforation is noted, most surgeons convert the procedure to a sigmoid resection with fecal diversion. There have been anecdotal reports of laparoscopic repair of the perforation. If lavage is performed, it is essential to ensure the patient has had a recent colonic evaluation and if not, consider colonoscopy to exclude a diagnosis of perforated colon cancer.

Reoperative Surgery

Reoperative surgery for complicated diverticular disease occurs for two main reasons—as a planned procedure to restore intestinal continuity after resection, stoma, and Hartmann closure of the rectum or as an unplanned procedure to treat complications or unanticipated events after initial resection and primary anastomosis. Hartmann takedown still has appreciable morbidity and mortality and up to a third of patients, for a variety of reason, never have the stoma reversed.

Hartmann Takedown (Reversal)

After Hartmann resection for perforated diverticulitis, most patients are eager to proceed as soon as possible with reversal of the stoma. These patients often had never been ill before and had never anticipated leaving the hospital with a stoma after treatment for diverticulitis. Reversal surgery may be undertaken early (<3 months from the initial surgery) or later (>3 months from the initial procedure). There are advocates of each approach and no randomized trials to guide recommendations. Proceeding with Hartmann takedown close to the time of initial surgery has several disadvantages, predominantly due to adhesions and the acute inflammatory response after initial surgery that may lead to a difficult dissection, potential enterotomies, and difficulty with identification of the Hartmann stump. While waiting for at least 3 months will presumably allow the patient sufficient time to heal and facilitate identification of the Hartmann stump, waiting longer may make identification of the stump more difficult secondary to fibrosis.

Prior to surgery, my preference, especially if I have not performed the original procedure, is to perform a gastrografin enema through the rectum to provide an assessment of the length and configuration of the rectal segment and give an assessment of any residual sigmoid colon and/or diverticula. Another advantage to this procedure is that residual fecal residue is evacuated, which ultimately helps with passing the circler stapler and sizer. Colonoscopy or barium enema is performed through the stoma, and my preference is a mechanical bowel prep prior to surgery. The patient is positioned in low lithotomy position or (preferably) on the split leg table with the legs abducted. The procedure may be done in an open or laparoscopic fashion and some have advocated use of a “peek port” to assess the degree of adhesions and then proceeding with either laparoscopic or open surgery. Initial dissection is focused on lysing adhesions of the small bowel to be able to identify the Hartmann pouch; in the majority of cases, this involves lysing all adhesions from the ligament of Treitz to the ileocecal valve. With few exceptions, there are generally small bowel adhesions or omental adhesions to the top of the Hartmann. While some have advocated tacking the top of the Hartmann with a long suture, I have rarely found this helpful. Passing a scope or sizer per rectum is more useful to identify the Hartmann. It is also common for the ovary and fallopian tubes to be adherent to the top of the Hartmann pouch. Ureteral stents can be used at the preference of the surgeon and do not prevent ureteral injury but facilitate the recognition of such injury.

Mobilization of the Hartmann is carried out as needed to be able to easily pass a sizer. My preference is to re-resect the top of the Hartmann pouch. The stoma is taken down and resected, a pursestring suture is placed, and the anvil secured. My preference is a circular stapled anastomosis but a handsewn anastomosis may also be performed. In cases where it is difficult to pass the stapler, the trocar can be brought through the anterior rectal wall, performing an end to colon, and side to rectum anastomoses. Standard air leak testing is performed.

POSTOPERATIVE CARE

Postoperative care following elective colon resection has been relatively standardized with early mobilization, DVT prophylaxis, minimization of narcotic pain medications, and early postoperative resumption of diet. Nasogastric tubes are not routinely used. Enhanced recovery pathways are frequently employed.

Following emergency colon surgery and the fecal diversion, patients are instructed, generally by an enterostomal nurse, in the care and pouching of the colostomy or ileostomy.

OUTCOME AFTER RESECTION

Following resection, combined series report a postoperative infection rate of 10% to 20% with the higher rates including patients with a higher proportion of urgent compared with elective operations.

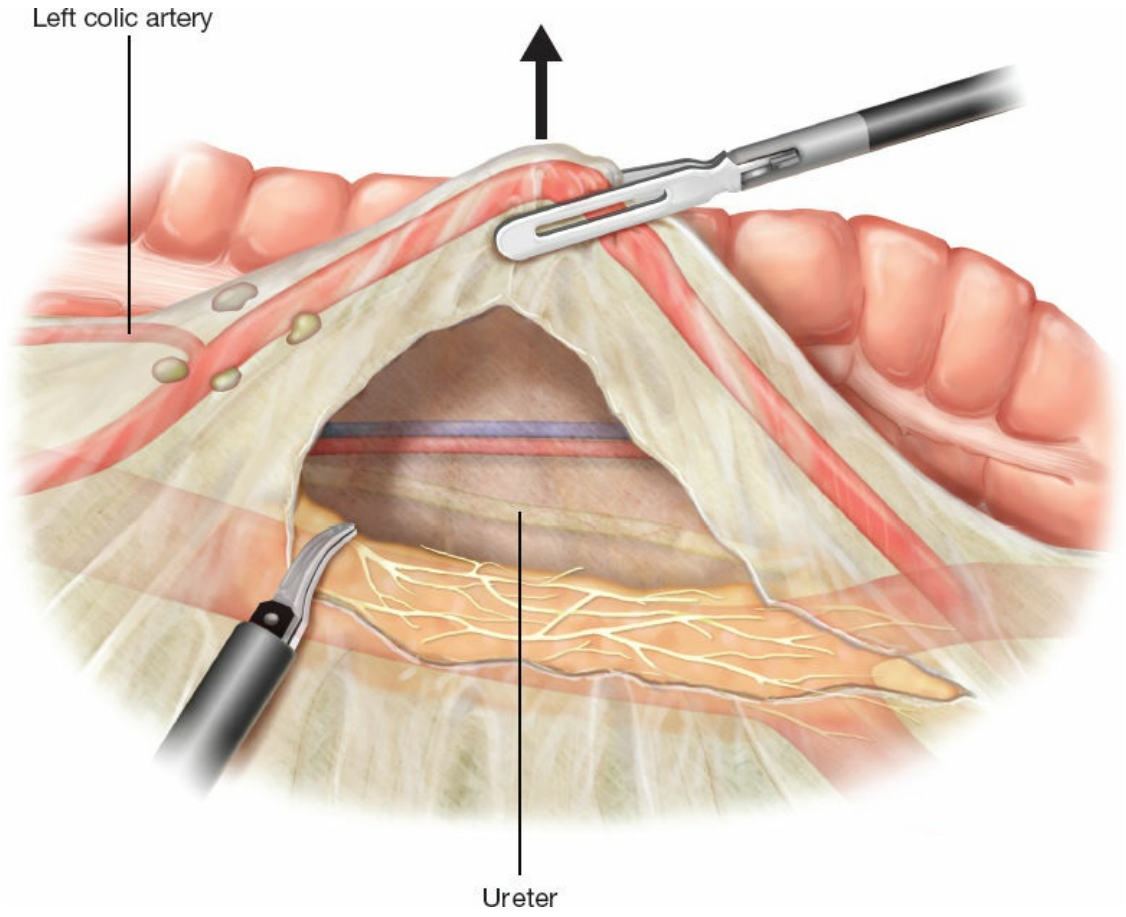

Figure 149.5. During laparoscopic mobilization of the colon during sigmoid resection, a medial to lateral approach is utilized and the inferior mesenteric artery retracted anteriorly toward the abdominal wall. The ureter and gonadal vessels are swept down to the retroperitoneum.

Risk of Persistent Abdominal Symptoms After Resection

In series with patient-reported outcomes, most patients had some relief of symptoms following resection. There are, however, a number of patients who have persistence of abdominal symptoms following resection for diverticulitis in the absence of documented recurrent diverticulitis. Therefore in approaching patients with recurrent abdominal symptoms following resection for diverticulitis, one must distinguish between other causes of abdominal pain such as irritable bowel syndrome and functional disease from recurrent diverticulitis. In one series, 22% of patients noted ongoing diffuse chronic abdominal pain despite sigmoid resection.

Risk of Recurrent Diverticulitis After Resection

Two studies have specifically addressed the risk of recurrent diverticulitis

following sigmoid resection and have similar results. Benn and colleagues reviewed 501 patients who underwent sigmoid resection for diverticular disease at the Mayo Clinic. In 321 patients, the anastomosis was performed to the distal sigmoid colon and 12.5% of patients had recurrent diverticulitis. Anastomosis to the proximal rectum was performed in 180 patients who had a 6.7% incidence of recurrent diverticulitis. The authors concluded that the distal resection margin should be the proximal rectum (as evidenced by the area where the tenia fan out) to decrease the risk of recurrent diverticulitis (Fig. 149.5). A subsequent study at the Cleveland Clinic of 236 patients who underwent sigmoid resection for diverticular disease had similar conclusions and the risk of recurrent diverticulitis was four times higher in patients who had a colosigmoid versus a colorectal anastomosis. Of interest, there has been little focus on the proximal resection margin and clinical practice guidelines suggest that the margin should use "soft, pliable bowel." It has also been suggested that "limited resections" have a greater tendency to develop recurrent symptoms, and the Association for Coloproctology of Great Britain and Ireland has suggested that the splenic flexure should be routinely mobilized in patients undergoing resection for diverticulitis. As the bowel tends to be somewhat foreshortened in diverticular disease, mobilization of the splenic flexure is often necessary to perform a tension-free anastomosis. An additional study showed no relationship between an emergency index procedure and the development of recurrent diverticulitis.

CONCLUSION

Diverticulitis is one of the most common gastrointestinal diseases. The trends in management of acute diverticulitis over the last decade have been guided by a greater understanding of the disease and a more "personalized" approach to the patient. For uncomplicated disease, the evidence suggests that resection may be safely avoided. In the future, selective resection in the acute setting and further refinements in the role of laparoscopic surgery may further drive decision making. The role of triggering factors, UV light exposure and vitamin D, and the role of genetics may allow us to further individualize and improve our management of diverticular disease.

EDITOR'S COMMENT

Fewer operations have undergone such a dramatic change over the last 20 years as have operations performed for sigmoid diverticulitis. Dr. Roberts's chapter clearly addresses many different aspects of surgery for diverticulitis, the chapter containing many priceless pearls of surgical technique hidden among its pages. However, before we address these, some comments are in order about diverticulitis itself especially in today's healthcare environment. It is not unusual for a surgeon to see a patient in the office referred to them for "surgery for diverticulitis." The patient comes, attesting to "x" number of attacks of diverticulitis over an "y"-month period. Invariably, upon questioning, the surgeon learns that these "attacks" were treated by the primary care or referring physician with the antibiotics, usually ciprofloxacin and/or metronidazole, and rarely were accompanied by documentation of fever, leukocytosis, or CT

changes compatible with acute diverticulitis. In many cases, the main symptom initiating prescription of an antibiotic is merely the presence of left lower quadrant abdominal pain. Sadly, much of our current knowledge and literature of diverticulitis is biased by such patients. Do these patients really have diverticulitis? Or do they just have irritable bowel syndrome? That is the real question. Many of these attacks that are empirically treated by family physicians or others with antibiotics, whether by placebo effect or spontaneous improvement on their own, defervesce. Some of these same patients are sent for unindicated operations.

As with the development and wide acceptance of laparoscopic cholecystectomy, the development and dispersal of laparoscopic colectomy has made the indications for colectomy much more “acceptable” for patients, as well as surgeons. As with many other types of operations, the “easier access” provided by laparoscopic surgery has decreased the threshold for surgery in the minds of both the surgeon and the patient. This can be seen most clearly in a recent report by Flum and colleagues using the Washington State Comprehensive Hospital Abstract Reporting System (CHARS) database (Simianu VV, Strate LL, Billingham RP, et al. The impact of elective colon resection on rates of emergency surgery for diverticulitis. *Ann Surg* 2016;263(1):123–9). Review of a 25-year period from 1987 to 2012 showed a more than a doubling in the rate of elective colon resection, with an increase in the number of laparoscopic procedures from 17.5% in 2008 when the laparoscopic code was introduced to 47.5% in 2012! Of note, during this same time period, there was also an increase in the rate of emergent/urgent colectomy, an increase in the number of nonelective percutaneous interventions, as well as an increase in the rate of nonelective hospital admissions for diverticulitis. In other words, the people who were operated upon were possibly not the high-risk patients who are likely to develop complicated diverticular disease. In the US current health care climate, where one would like to optimize resource allocation, this does not bode well!

One of the most valuable items in Dr. Roberts’s chapter is the scoring system she provides to predict the likelihood of patients hospitalized with diverticulitis to require surgery within the next 90 days. Identifying patients at high risk of needing further surgery remains the crux of patient selection in this complicated and heterogeneous group of patients. As a recent systematic review has pointed out, the overall recurrence rate of patients hospitalized for acute diverticulitis remains quite low, with approximately 13% experiencing a recurrence and 4% a second recurrence over 8.9 years follow-up (Morris AM, Regenbogen SE, Hardiman KM, et al. Sigmoid diverticulitis: a systematic review. *JAMA* 2014;311(3):287–97). As is highlighted, the risk of a sepsis decreases rather than increases with each recurrence, stressing proper patient selection in order to identify appropriate individuals to which to recommend surgery.

Among the most useful technical points that Dr. Roberts provides is the importance of constructing the distal anastomosis to the upper rectum and not to

the colon. If one does not do this and constructs a colo-colic anastomosis (with retained distal sigmoid colon) as opposed to a colorectal anastomosis, one has both a higher risk of recurrent diverticulitis and a higher risk of leak and subsequent colocutaneous fistula. Dr. Roberts also stresses the importance of constructing anastomoses using pliable bowel. This applies to the proximal anastomosis using pliable bowel not affected with the muscular hypertrophy of severe diverticular disease to lessen the risk of recurrence of diverticulitis. The use of pliable bowel, however, also applies to the distal bowel, as is the case when there is a significant pelvic phlegmon. In such cases, the proximal rectum may be so indurated that a stapler will not easily close across it. In this scenario, resection of the top segment of the rectum to a softer segment is warranted. The same applies to the Hartmann stump in the setting of closure of a colostomy, where the end of the Hartmann may be too fibrotic or narrowed and may need to be resected further to facilitate construction of the anastomosis.

Other important tips for performing a secure colorectal anastomosis include splenic flexure mobilization to provide for a tension-free anastomosis as well as performing air leak tests whenever one is constructing a colorectal anastomosis. This is not described in detail in the chapter, but merely involves instilling air (via either rigid or flexible sigmoidoscope) just distal to or through the anastomosis, while the colon proximal to the anastomosis is occluded (either with a clamp or manually) and the anastomotic site is covered with saline. Any sign of air bubbles coming from the anastomosis denotes a leak, which can then be repaired primarily and/or diverted with a loop ileostomy at the surgeon's discretion. A gastrografin enema performed prior to planned closure of a Hartmann procedure allows the surgeon to assess the anatomy as well as helping to empty the rectum of retained fecal matter and inspisated mucus, thereby facilitating subsequent transanal passage of a circular stapler.

Lastly, Dr. Roberts touches on an unresolved issue in colon and rectal surgery, the issue of laparoscopic lavage for perforated diverticulitis. This is still an issue of controversy. In the last few months, prospective randomized trials with contradictory findings have been published (Schultz JK, Yaqub S, Wallon C, et al.; SCANDIV Study Group. Laparoscopic lavage vs primary resection for acute perforated diverticulitis: the SCANDIV randomized clinical trial. *JAMA* 2015;314(13):1364–75; Angenete E, Thornell A, Burcharth J, et al. Laparoscopic lavage is feasible and safe for the treatment of perforated diverticulitis with purulent peritonitis: the first results from the randomized controlled trial DILALA. *Ann Surg* 2016;263(1):117–22). This will likely require much more study such as a meta-analysis to assimilate results of multiple trials with different primary outcome measures and sample sizes.

Notwithstanding the above, it is important for the surgeon to be aware of the changing trends in management of diverticular disease. There is now a variety of operations, and types of access that can be chosen from, ranging from traditional open resections, to laparoscopic, to robotic to the ultimate "no touch" surgery of laparoscopic lavage, perhaps combined with suturing of the area of

colonic perforation. In fact, one of my acquaintances who was traveling in England recently told me that his wife had an episode of acute diverticulitis there. She was hospitalized, underwent surgery with a laparoscopic lavage and oversewing of the colonic perforation. All turned out well; however, what a dramatic change in surgical behavior and outcome! Only time and long-term follow-up will tell regarding the ultimate outcome of such procedures. One thing is, however, certain: many patients who undergo conventional sigmoid resection and Hartmann procedure for diverticular disease never have their colostomies closed. Also, such colostomy closure after a Hartmann procedure can in itself be a very morbid procedure and itself result in significant complications and problems for the patient.

Susan Galandiuk

150 Technique of Colostomy Construction and Closure

Aaron Saunders and Moshim Kukar

INTRODUCTION

Multiple methods and indications for colostomy creation exist, and techniques may be tailored to the patient in complex circumstances. The surgeon will select either an end colostomy or a loop colostomy, and should be capable of constructing these both with conventional open maneuvers when laparotomy has been otherwise required, and with minimally invasive techniques, particularly when the only indication for surgery is fecal diversion or decompression. In all cases, a properly functioning stoma that minimizes patient inconvenience and morbidity will depend upon meticulous planning and construction, ideally with thorough preoperative counseling of the patient.

INDICATIONS

Colostomy creation may be necessary after colon or rectal resection for benign or malignant disease. Creation of a colostomy may also be necessary when performing emergency laparotomy for trauma or peritonitis, including proximal diversion for penetrating rectal trauma or when Hartmann procedure is performed for perforated diverticulitis. A colostomy may also be needed for fecal diversion in other situations, such as a patient with incontinence and/or nonhealing decubitus wounds, or for decompression of distal obstruction, as in a patient with an obstructing tumor or benign stricture from inflammatory bowel disease or radiation injury. Indications for colostomy should be considered permanent or temporary, and care should be taken in construction to maximize durability of a permanent stoma, to facilitate future closure of a temporary stoma, and to maximize function and minimize morbidity of both. A permanent colostomy will generally be an end colostomy, while either an end or a loop colostomy can be constructed with the intent for later reversal. When not contraindicated, a loop colostomy should be preferred in patients with

a temporary indication, because reversal of a loop colostomy can often be achieved with less morbidity compared to an end colostomy.

PREOPERATIVE PLANNING

When a colostomy is to be created electively, preoperative counseling and psychological preparation of the patient are desirable. Meeting with an enterostomal therapist at least once prior to surgery is helpful. Print and multimedia materials are also available for patient education, and patients may additionally be referred to support groups for individuals with stomas.

Selecting an appropriate location for colostomy placement is of great importance. The objective is to provide an anatomically stable opening, facilitating reliable placement of an ostomy pouch that will not leak or require frequent replacement. A poorly placed stoma is likely to cause inconvenience and morbidity to the patient and may ultimately require surgical revision. Locating the site for the stoma is frequently made more challenging by obesity, or by prior surgical scars and associated irregularity in abdominal wall musculature. Therefore, when possible, an appropriate site should be identified and marked with the patient awake, and confirmed in supine, seated, and bending positions. An appropriately sized piece of stoma equipment or prepared disk of the same dimensions is used. Particularly when complex surgery is planned, it is prudent to identify acceptable alternative sites. Once the optimal sites are determined, the skin is marked with indelible ink, or in some cases tattooed, so that when the abdomen is prepared and opened and the anatomic relationships are distorted, the correct site is used. The site selected in an average individual is a few centimeters inferolateral to the umbilicus, overlying the rectus abdominis (Fig. 150.1A).

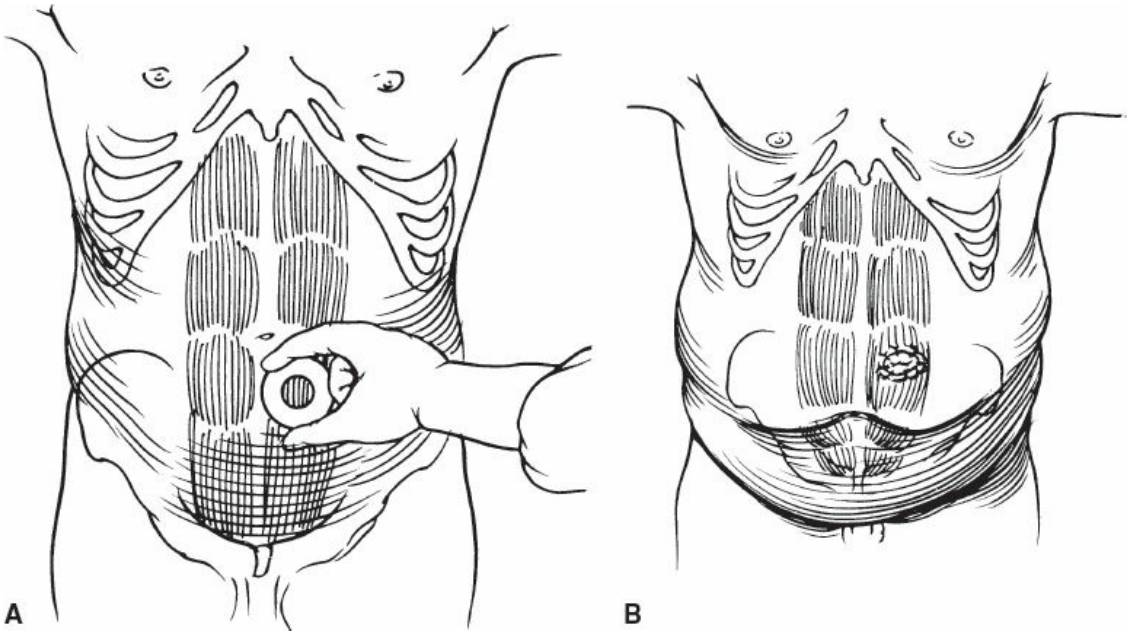

Figure 150.1. In a normal abdomen, the colostomy site is often marked a few centimeters inferolateral to the umbilicus, overlying the rectus abdominis (**A**). In an obese patient, it may be necessary to choose a site in the upper abdomen where it will be visible to the patient and the surrounding skin will be appropriate for pouch placement (**B**).

The primary consideration is that the stoma is constructed where it will be visible to the patient (i.e., not located on the inferior surface of a pendulous abdomen). The stoma should be away from the umbilicus, skin creases, scars, and bony prominences. Skin damaged by radiation or skin grafts should be avoided. In an obese individual with a large pannus, the stoma may be located in the upper abdomen, away from creases, where it will be visible and surrounded by a flat skin surface (Fig. 150.1B).

APPROACH AND EXPOSURE

Laparoscopic Surgery

Both loop and end colostomies can be constructed with either conventional open or laparoscopic techniques. When the sole indication for surgery is creation of a colostomy, we prefer a minimally invasive approach. Initial access is obtained in the infraumbilical midline with a Hasson technique. A vertical incision is carried down to the linea alba, which is exposed with retractors and incised vertically. The preperitoneal fat is divided, and the peritoneum is lifted and sharply opened. A sweep of the surgeon's finger confirms peritoneal entry and absence of adherent abdominal content. Stay

sutures are placed in the fascia and a 12-mm Hasson port is advanced and secured in position. Alternatively, a Veress needle is advanced into the peritoneal space at either Palmer point or infraumbilically, confirming position with a saline drop test. Pneumoperitoneum is then achieved and the laparoscope is inserted with a 5-mm transparent port at the infraumbilical location, allowing visualization of abdominal wall layers and the point at which the port enters pneumoperitoneum.

Based on preoperative planning and findings of laparoscopy, a selection is typically made between the transverse colon and the descending or sigmoid colon for colostomy creation. If the descending or sigmoid colon is to be used, two 5-mm ports are placed in the right upper quadrant and the right lower quadrant, respectively (Fig. 150.2A). If the transverse colon is to be used, the two ports will be placed on the right side of the abdomen and in the hypogastric region, respectively (Fig. 150.2B). If use of a stapling device is necessary, the lower of the two 5-mm ports can be upsized to a 12-mm port. Ports should be placed away from the costal margin, anterior superior iliac spine, and pubis, to prevent a fulcrum effect that would limit range of motion for the laparoscopic instruments. It is crucial to place the ports under visualization, to avoid inadvertent injury to viscera or vasculature.

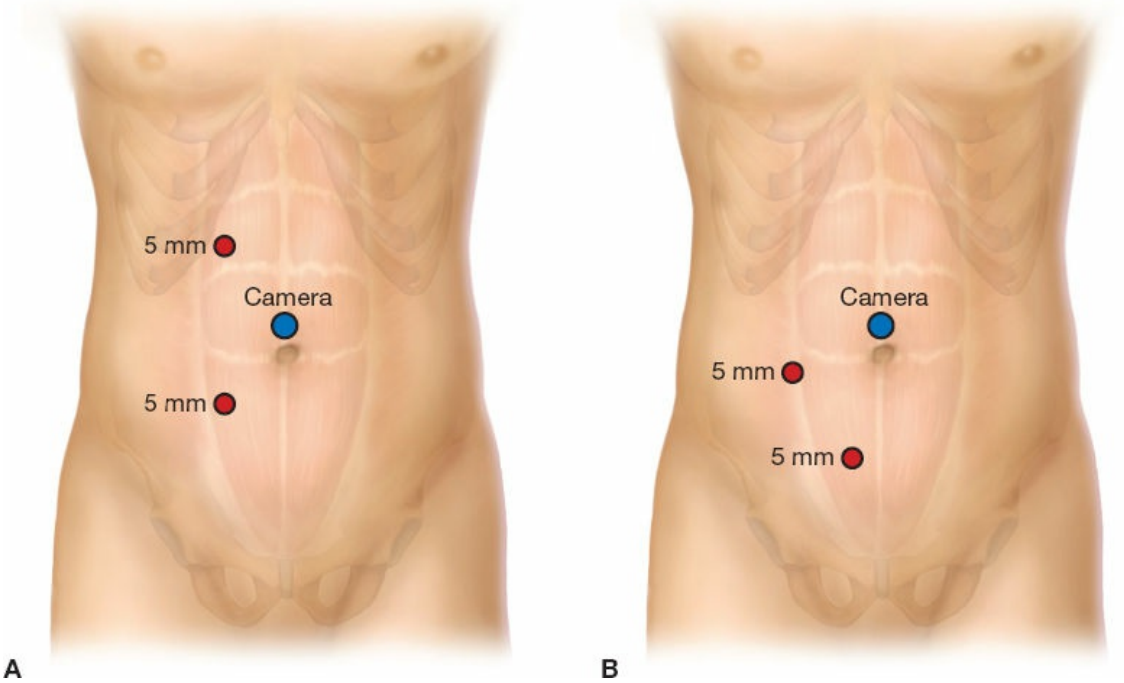

Figure 150.2. Suggested laparoscopic port placement sites for descending or sigmoid colostomy creation (**A**) or distal transverse colostomy creation (**B**).

Open Surgery

When the surgeon considers that stoma creation may be included in an open abdominal operation, or contraindications to pneumoperitoneum or laparoscopy exist, a midline laparotomy incision is recommended so that bilateral rectus sheaths and all quadrants of the abdominal wall are preserved for stoma siting and possible subsequent stoma revision or relocation. The length and position of the incision is dictated by the target segment of bowel for resection or the need for exposure in emergency or trauma laparotomies. A self-retaining abdominal wall retractor is used to provide exposure of the target segment of colon. The small bowel is gently packed away from the field of view. When other maneuvers are included in the operative plan, colostomy construction is typically reserved for the reconstruction phase of the case, after other objectives have been achieved.

PREPARING THE COLON

Unless the selected segment of colon is extremely redundant or has previously been mobilized, it is generally necessary to mobilize the colon from some attachments. The goal is for the colon to reach a level 3 to 4 cm above the skin surface without tension. This helps to protect perfusion and prevent retraction. In laparoscopic cases, it is helpful to remember that pneumoperitoneum exaggerates the distance the colon must cover. Mobilization of the descending colon commences at the peritoneal reflection in the left paracolic gutter, with sharp division extending superiorly along the white line of Toldt (Fig. 150.3). Dissection can then be carried medially in the avascular plane anterior to the gonadal vessels and the ureter. The more obese the patient, the more mobilization may be necessary, and in some cases splenic flexure mobilization is required. Mobilization and preparation of the transverse colon typically includes partial release of the omentum and may also require mobilization of the hepatic or splenic flexure.

It is absolutely essential that the colon to be brought out for colostomy creation has adequate perfusion. Careful observation should confirm that it is pink and appears well perfused. If there is a cut edge, the blood flow should be bright and pulsatile. Doppler examination of the mesenteric blood flow can also be performed to help confirm intact perfusion. This is of particular importance when a colostomy is performed in conjunction with a rectal or rectosigmoid resection for cancer. In this situation, sacrifice of the inferior mesenteric and/or left colic arteries may be

necessary to achieve adequate lymphadenectomy (Fig. 150.4). When this is done, the collateral circulation via the marginal artery to the distal extent of the remaining left colon must be carefully evaluated and preserved. If compromised perfusion of the end intended for colostomy construction is suspected, it should be cut back to a healthy, bleeding edge. If Doppler examination or visual inspection suggests that the marginal artery supply is insufficient, the remaining left colon is removed so that the new transection edge is at the distal transverse colon and perfused via the middle colic artery.

If an end colostomy is planned, the colon is frequently divided with a stapling device, and the stapled end is left in place until it has been delivered through the abdominal wall. If there is an open end or colotomy, it should be closed with suture before it is delivered. This allows the bowel to be brought through the abdominal wall with minimal contamination.

If a loop colostomy is planned, the loop of colon that will reach the marked stoma site with the least tension is identified. Taking care not to injure the blood supply, a window is dissected through the mesocolon adjacent to the bowel wall. A Robinson catheter is placed through this window and both ends are grasped together. These ends will later be delivered through the stoma site and used to place gentle traction on the colon and guide the loop into position.

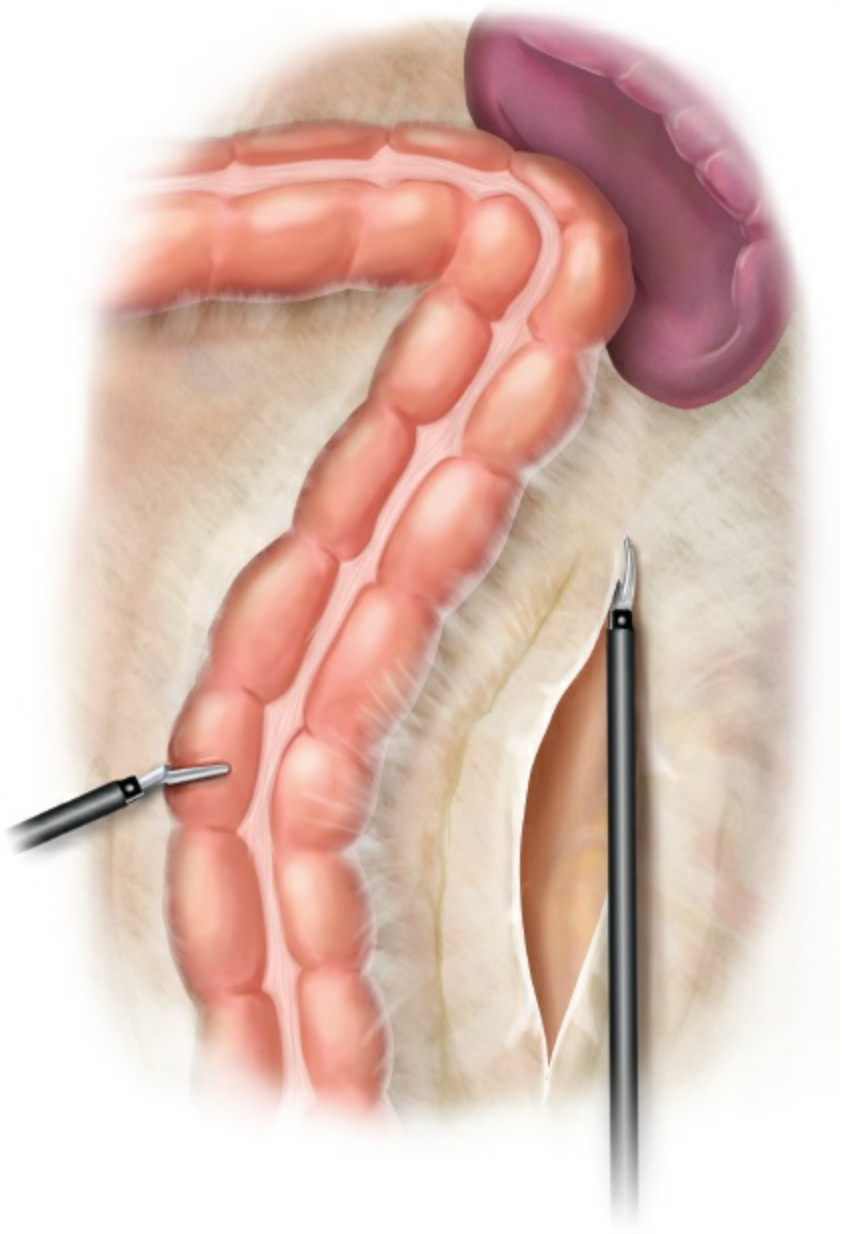

Figure 150.3. Incising the peritoneal attachments of the left colon along the line of Toldt. (Reprinted from Wexner SD, Fleshman JW. *Colon and Rectal Surgery: Abdominal Operations (Master Techniques in Surgery)*; LWW; 2011.)

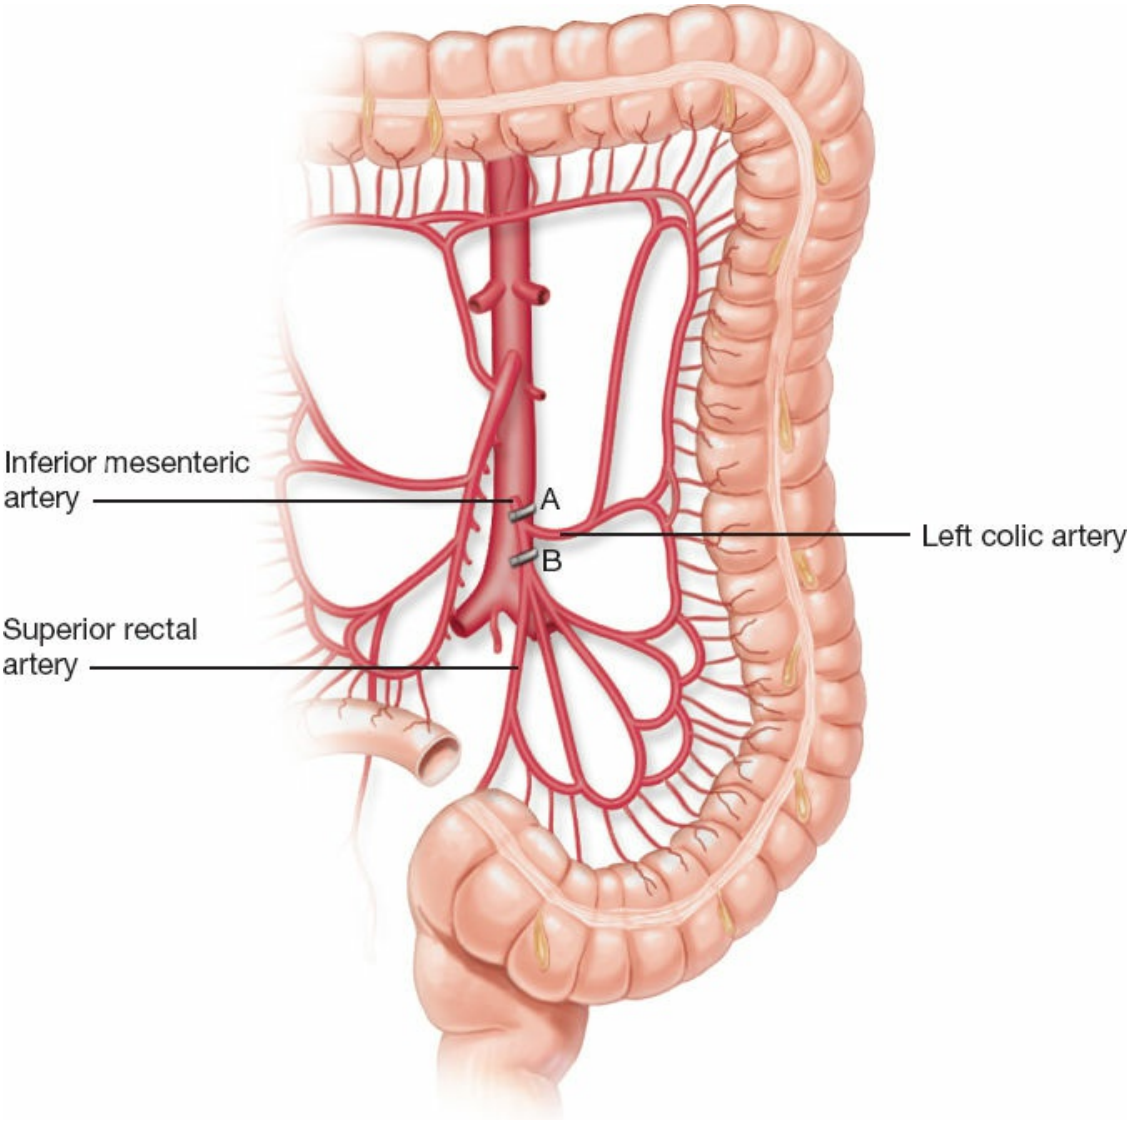

Figure 150.4. A rectal or rectosigmoid resection for cancer may require a high ligation of the inferior mesenteric artery (**A**) for adequate lymphadenectomy, devascularizing the left colic artery so that perfusion to the remaining descending colon is based on collateral flow through the marginal artery. The left colic artery is preserved in low ligation (**B**). (Reprinted from Wexner SD, Fleshman JW. *Colon and Rectal Surgery: Abdominal Operations (Master Techniques in Surgery)*; LWW; 2011.)

PREPARING THE STOMA SITE

Attention is then turned to preparation of the stoma site. In open surgery, the layers of the abdominal wall are held in anatomic alignment with the help of clamps placed at the edge of the rectus sheath and dermis. A circular incision of 2 to 3 cm diameter is made at the marked location using a scalpel or cutting monopolar device, and this disk of skin is

removed. The subcutaneous fat is then incised vertically, down to the anterior rectus sheath. A linear or cruciate incision is made in the anterior rectus sheath, and the exposed rectus muscle is split longitudinally by spreading with a blunt instrument perpendicular to the line of the muscle fibers. This procedure results in little or no bleeding unless the deep inferior epigastric vessels are lacerated posterior to the rectus muscle. Caution should be taken to avoid this injury, as it can cause troublesome bleeding. If necessary, hemostasis is secured by ligating the vessel. In open surgery, this is achieved by reflecting the abdominal wall to reveal the peritoneal surface of the operative field, where the vessel can be exposed. Otherwise, the vessel must be exposed by retracting the rectus muscle fibers through the colostomy site wound.

Once the rectus muscle has been split, the fibers are retracted medially and laterally, and the posterior rectus sheath is longitudinally incised. In open surgery, a lap sponge is held behind the posterior rectus sheath to prevent inadvertent injury (Fig. 150.5A). The opening through all layers of the abdominal wall should be large enough to permit passage of two average-sized fingers up to the second phalanx. Gentle, blunt dilation of the opening may be performed with the insertion of the surgeon's fingers (Fig. 150.5B). Creating an opening larger than this will increase the risk of parastomal herniation or prolapse, although it is sometimes necessary to extend the opening in situations involving bulky mesentery or an unusually thick abdominal wall. The technique of routing the stoma through the split rectus muscle maximizes durability of the colostomy, as the intestine is supported by the rectus muscle fibers as well as the fibers of the anterior and posterior rectus sheaths.

CONSTRUCTION TECHNIQUES

After preparation of the stoma opening, the prepared end or loop of colon is gently delivered through the abdominal wall so that 3 to 4 cm protrudes without tension. This is performed with a Babcock clamp placed through the abdominal wall at the stoma site and placed on the end of divided colon, which is then delivered into position. Alternatively, for a loop, this is accomplished by delivering the ends of the Robinson catheter through the stoma site and placing gentle traction on the colon to guide the portion for loop colostomy into place. Torsion of the colon on its mesentery must be avoided. The protuberant colon should be critically inspected for any signs of ischemia, such as a shift to a dusky or purple hue. If this is

observed, the bowel should be returned into the abdomen. The size of the opening should be assessed to ensure that it is not too tight, potentially causing compression of the blood supply. If it is, the opening is enlarged. The colon should be seen to regain perfusion before the delivery maneuver is reattempted. In laparoscopic cases, visualization is maintained under low-pressure insufflation to confirm the correct orientation of the bowel and mesentery.

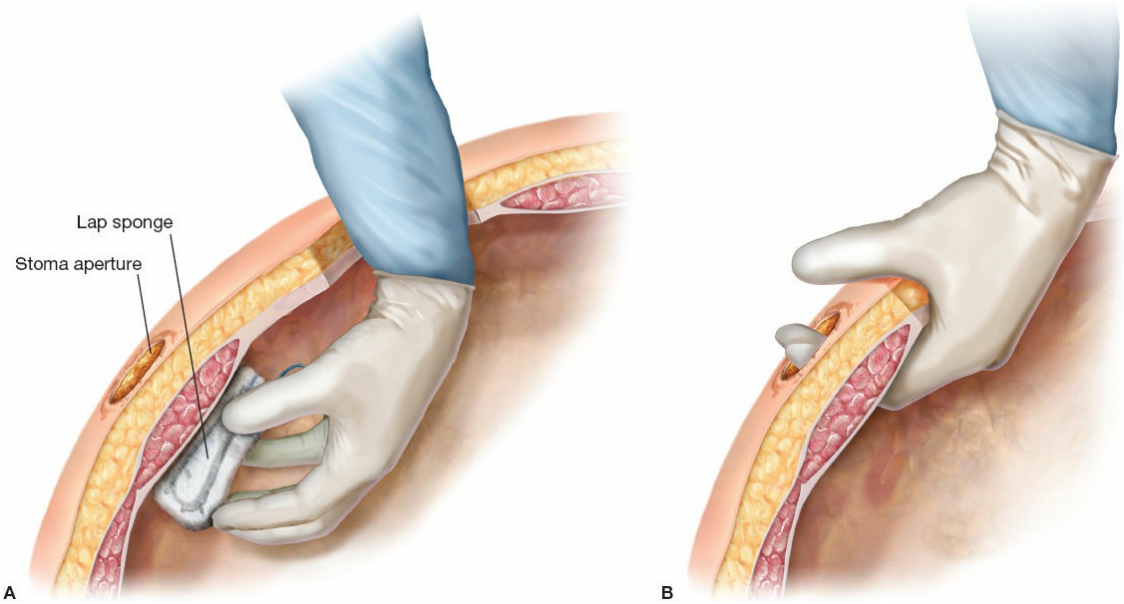

Figure 150.5. A lap sponge may be held behind the abdominal wall to place the tissues on stretch and protect the abdominal organs (**A**). Two fingers are passed through the opening, and may be used to gently dilate (**B**). (Reprinted from Wexner SD, Fleshman JW. *Colon and Rectal Surgery: Abdominal Operations (Master Techniques in Surgery)*; LWW; 2011.)

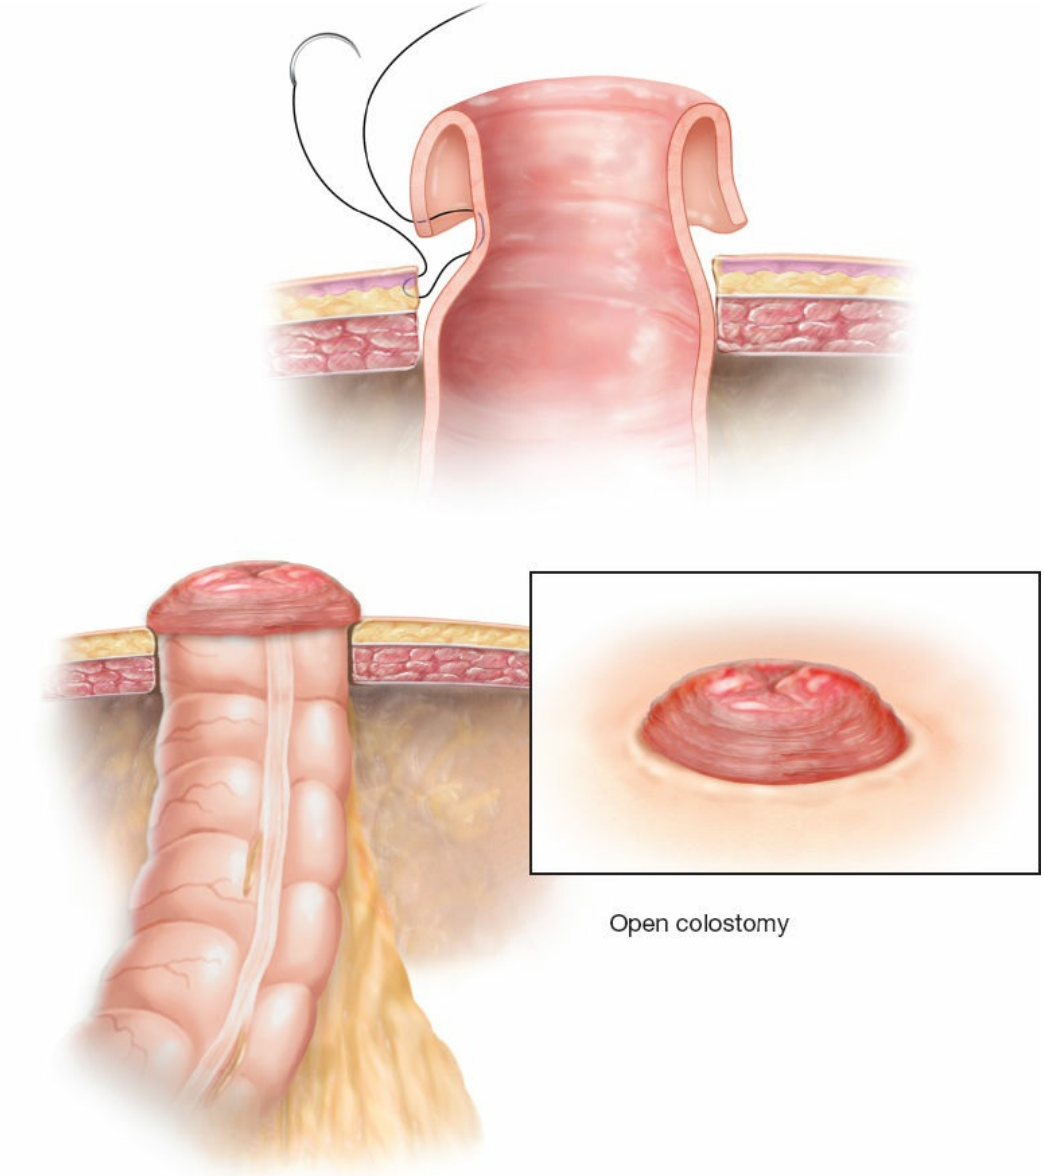
The remainder of the intraperitoneal operation is now completed and abdominal wounds are closed, including the skin. All incisions are covered to prevent contamination during the maturation of the colostomy. For an end colostomy, the terminal staple line or suture line is then excised. It is reassuring to see bright and pulsatile bleeding from the cut edge; judicious use of cautery at the edge may be used to slow this and prevent subsequent hematoma formation. The stoma is then everted with the placement of four to eight sutures at equal intervals around the circumference of the stoma, for a partial Brooke technique, using 3-0 absorbable suture. These are three-point sutures that create eversion of the stoma end by including the dermis, full-thickness colon wall at the cut edge, and a seromuscular “bite”

of colon wall 2 to 3 cm away from the cut edge (Fig. 150.6). Care must be taken to avoid placing a suture through any perfusing vessels. Additional simple stitches are placed to complete approximation of the colon edge to the dermis. Some surgeons elect to mature the colostomy flush with the level of the skin using simple interrupted stitches.

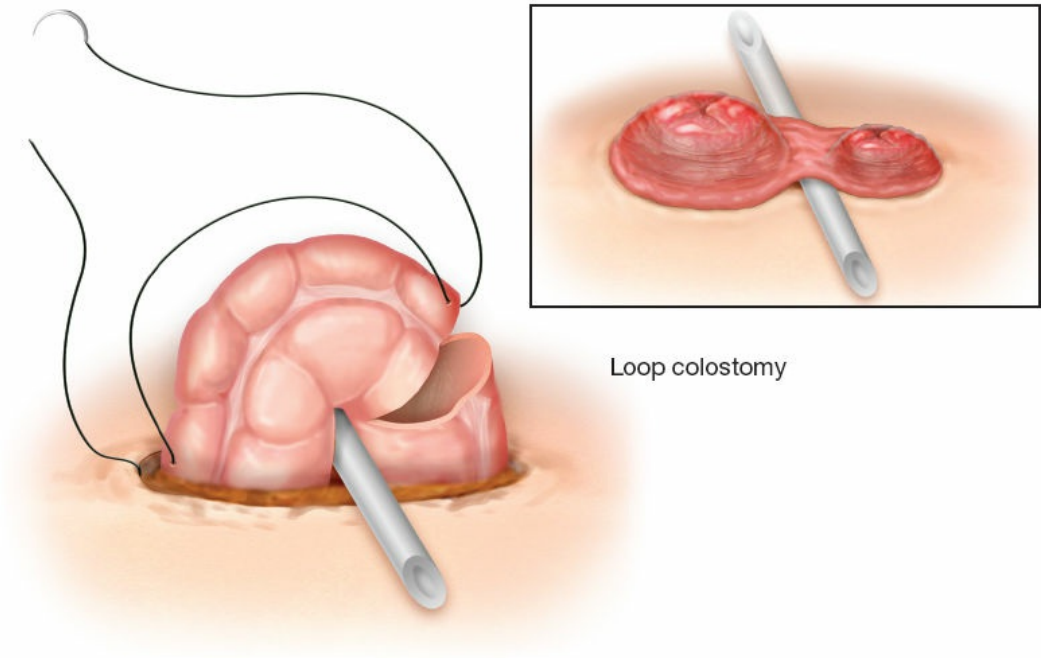
For a loop colostomy, a transverse colotomy is made on the downstream aspect of the loop. This incision should be long enough to allow eversion of the stoma without causing a tear in the bowel wall. Sutures are placed at equal intervals around the circumference of the stoma in the Brooke fashion, as above, and additional simple stitches are placed as needed. The ends of Robinson catheter that was used for are sutured together so that the catheter is used as a bar to prevent retraction. Alternatively, the catheter may be replaced with a commercially available rod for this purpose. This will be removed 1 to 2 weeks later. Once a colostomy has been matured, a stoma appliance is placed. If the stoma works in the early postoperative period, the appliance will prevent contamination of other surgical sites and spare the patient the indignity of fecal spillage.

PROPHYLACTIC MESH PLACEMENT WITH PERMANENT END COLOSTOMY

When creating a permanent end colostomy, as in the case of a patient undergoing abdominoperineal resection, attention is given to minimizing the risk of subsequent parastomal herniation. Reinforcement of the permanent end colostomy with a prophylactic placement of onlay mesh, also known as the modified Sugarbaker technique, has been evaluated in a few small, randomized trials. It is associated with decreased rates of parastomal hernia formation and no difference in other colostomy-related complications. Thus, it appears to be safe, and may prevent subsequent need for reoperation. In this technique, a macroporous, synthetic mesh with antiadhesiogenic coating is placed as an onlay over the intraperitoneal aspect of the colostomy. The mesh should be large enough to cover a 4- to 5-cm margin in all directions from the stoma opening. It is secured to the abdominal wall on three sides (superior, medial, and inferior) with absorbable suture or laparoscopic fixation device, leaving space for the colon on the lateral side.



Open colostomy



Loop colostomy

Figure 150.6. The colostomy is matured with a partial Brooke technique, using three-point sutures that incorporate the full thickness of the bowel wall at the cut edge, a seromuscular purchase of the bowel wall a few centimeters proximal, and the dermis. This creates eversion of the matured stoma.

SPECIAL CONSIDERATIONS

Obesity

The morbidly obese patient increases the difficulty of every aspect of colostomy construction. Preoperative marking of a stoma site on flat skin where the patient will be able to see and reach it becomes both more challenging and more crucial. Colon mobilization must be more extensive to allow the colon to reach the skin without tension. Removal of a portion of omentum from the colon, scoring of the visceral peritoneum leaflets over the mesentery, or even division of the inferior mesenteric vein at the inferior border of the pancreas are all maneuvers that can provide significant additional length, when necessary.

It is unwise to have an opening in the abdominal wall so small that it is a struggle to bring the bowel through. The opening in all layers of the abdominal wall, except the skin, must frequently be made significantly larger in order to allow passage of the colon with its mesentery up to the skin level without compression of the blood supply, which would lead to ischemia and stoma necrosis. Moreover, if the incision in the abdominal wall is too small, attempts to bring the colon to the skin cause trauma to the mesentery and to the blood vessels to the bowel. Although creating a larger defect increases the risk of parastomal hernia formation, this is preferable to having an ischemic or stenotic stoma in the immediate postoperative period. Once the bowel is positioned correctly, a loose layered closure of the abdominal wall defect is performed around the bowel and mesentery within the abdominal wall. Additional interrupted stitches of absorbable suture may be placed between the seromuscular layers of the bowel and the fascia or parietal peritoneum of the abdominal wall to provide support and perhaps decrease the risk of parastomal hernia.

Ascites

When construction of a colostomy in a patient with ascites is unavoidable, every effort should be made to minimize ascites leakage around the stoma site. This can be helped with extraperitoneal tunneling of the colon. The

peritoneum is divided in the paracolic gutter and blunt dissection is used to create a wide tunnel in the extraperitoneal plane to the abdominal wall opening (Fig. 150.7). Additional colon mobilization may be necessary to cover this additional distance without tension. With bowel satisfactorily in position, the tunnel is closed by suturing the cut edge of the peritoneum to the serosa of the bowel and to the mesentery, taking care not to compromise the blood supply to the colostomy.

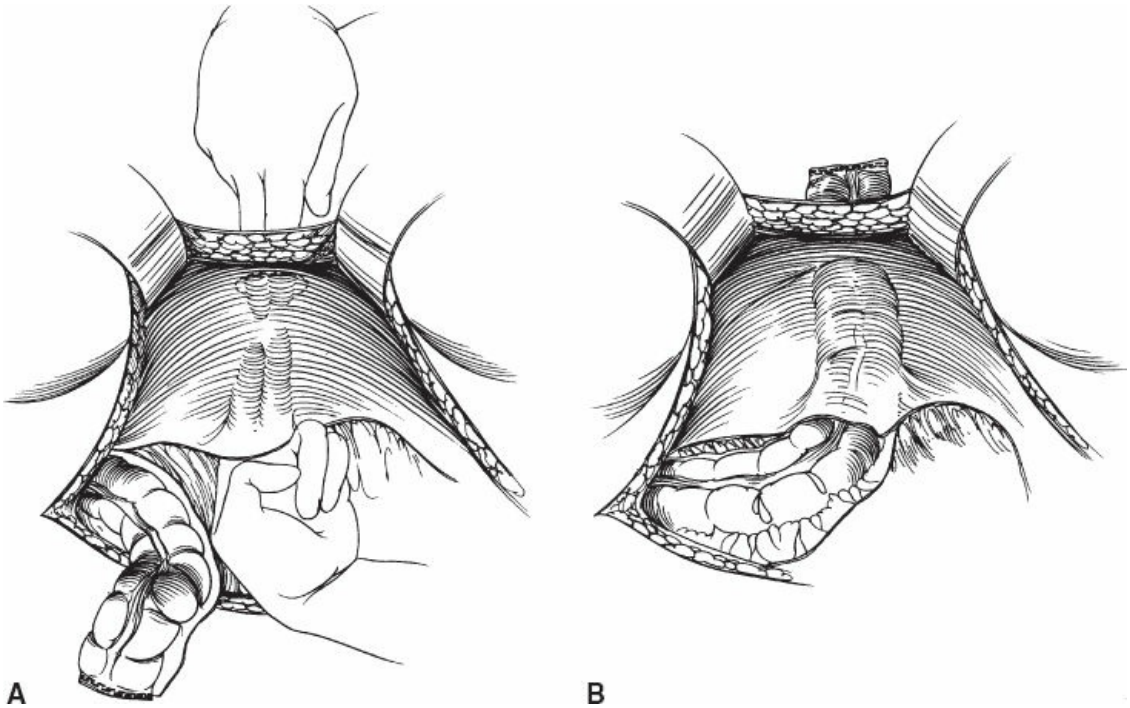


Figure 150.7. An extraperitoneal tunnel for the colon may be created with manual dissection (**A**). The colon is then brought through this tunnel to the skin opening (**B**).

Colonic Obstruction

An obstructed colon may be markedly dilated, with a thickened and edematous wall. Manipulation of the bowel, and colostomy construction, may be facilitated by needle decompression. A large-bore needle (14 to 18 gauge) is placed obliquely through the bowel wall at the site of the intended colostomy, and gas is evacuated. More solid contents are milked proximally and distally as much as possible, to reduce the bulk that must pass through the abdominal wall. The opening in all layers of the abdominal wall needs to be sufficiently large to accommodate the bulk of the bowel without compressing the blood supply. Special care is needed when creating a window through the mesentery, to avoid injury to the

marginal artery. The blood supply to the proximal end of a future anastomosis may depend on this, if the inferior mesenteric artery is ligated as part of a cancer operation, or if mobilization of the descending colon is needed to reach a coloanal anastomosis.

CECOSTOMY

A cecostomy may occasionally be useful for colon decompression in cases of obstruction or refractory pseudo-obstruction, or as a point of fixation and drainage for the cecum after volvulus or a repaired perforation. A tube cecostomy is constructed by first placing two concentric pursestring sutures at the planned tube site. An opening in the cecum is then created and the tube is inserted. The pursestrings and the opening should be appropriately sized for a 30-French or larger Malecot or Foley catheter. The catheter is inserted through the colotomy and the pursestring sutures are tied around the shaft of the tube in layers (Fig. 150.8A). When performed laparoscopically, a 12-mm port may be placed under visualization at the intended cecostomy site and the catheter introduced through this port and into the bowel. The port can then be removed; it may be necessary to cut off the outer end of the catheter if it has a bifurcation or dilation. In open surgery, the catheter is brought out directly through the abdominal wall via a stab incision. Just enough traction is then placed on the catheter to create approximation between the parietal peritoneum and the bowel wall, and this approximation is reinforced with interrupted stitches of 2-0 absorbable suture placed at equal intervals around the circumference of the cecostomy site between the seromuscular layers of the cecum and the abdominal wall (Fig. 150.8B). Postoperatively, tube patency is maintained with irrigation. Leakage around the tube is a risk. Once the need for the cecostomy has passed, removal of the tube typically allows the fistula to close by secondary intention.

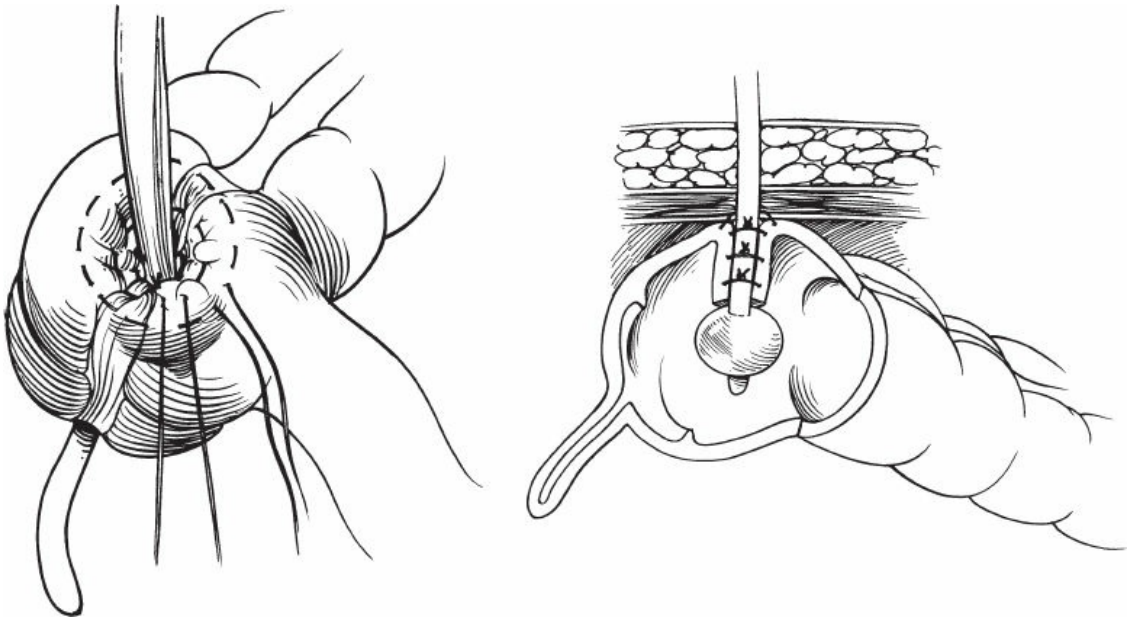

Figure 150.8. Cecostomy construction.

COLOSTOMY CLOSURE

Restoration of bowel continuity and reversal of a temporary colostomy is typically performed between 3 and 6 months after its construction, which allows time for resolution of inflammation and dense adhesions. Waiting longer may be associated with increased rates of complication.

Loop Colostomy Closure

A loop colostomy can usually be closed without opening the abdomen. The colostomy is mobilized by making a circumferential skin incision around the stoma, just outside the mucosal edge (Fig. 150.9). The excised skin is grasped to provide traction, and countertraction is applied on the opposing skin and subcutaneous fat layers to define the plane of dissection (Fig. 150.9). Dissection is carried down circumferentially, exposing the fascial and muscular layers, and then entering the peritoneal cavity. A finger is inserted between the bowel and the abdominal wall, which exposes and allows division of the remaining peritoneal and serosal attachments. The skin and subcutaneous fat are completely trimmed away from the mucocutaneous junction. The bowel edges may need to be trimmed back to healthy tissue, as well. The defect in the colon wall is closed transversely with interrupted absorbable suture (Fig. 150.10). This closure must be performed meticulously. Alternatively, this closure may be accomplished with a firing of a transverse bowel stapling device. When closed, the bowel is irrigated and gently returned to the peritoneal cavity

by methodically returning one limb of bowel, followed by the second. Relaxation of the abdominal wall is helpful in returning the bowel to the abdominal cavity and in repairing the defect in the abdominal wall. The anterior and posterior rectus sheaths are closed transversely with interrupted or figure-of-eight stitches. The skin is closed with a circumferential pursestring stitch in the dermis, using 2-0 PDS (Fig. 150.11). This closure allows drainage and is associated with low rates of wound infection; the wound is cared for with packing changes until healing is complete.

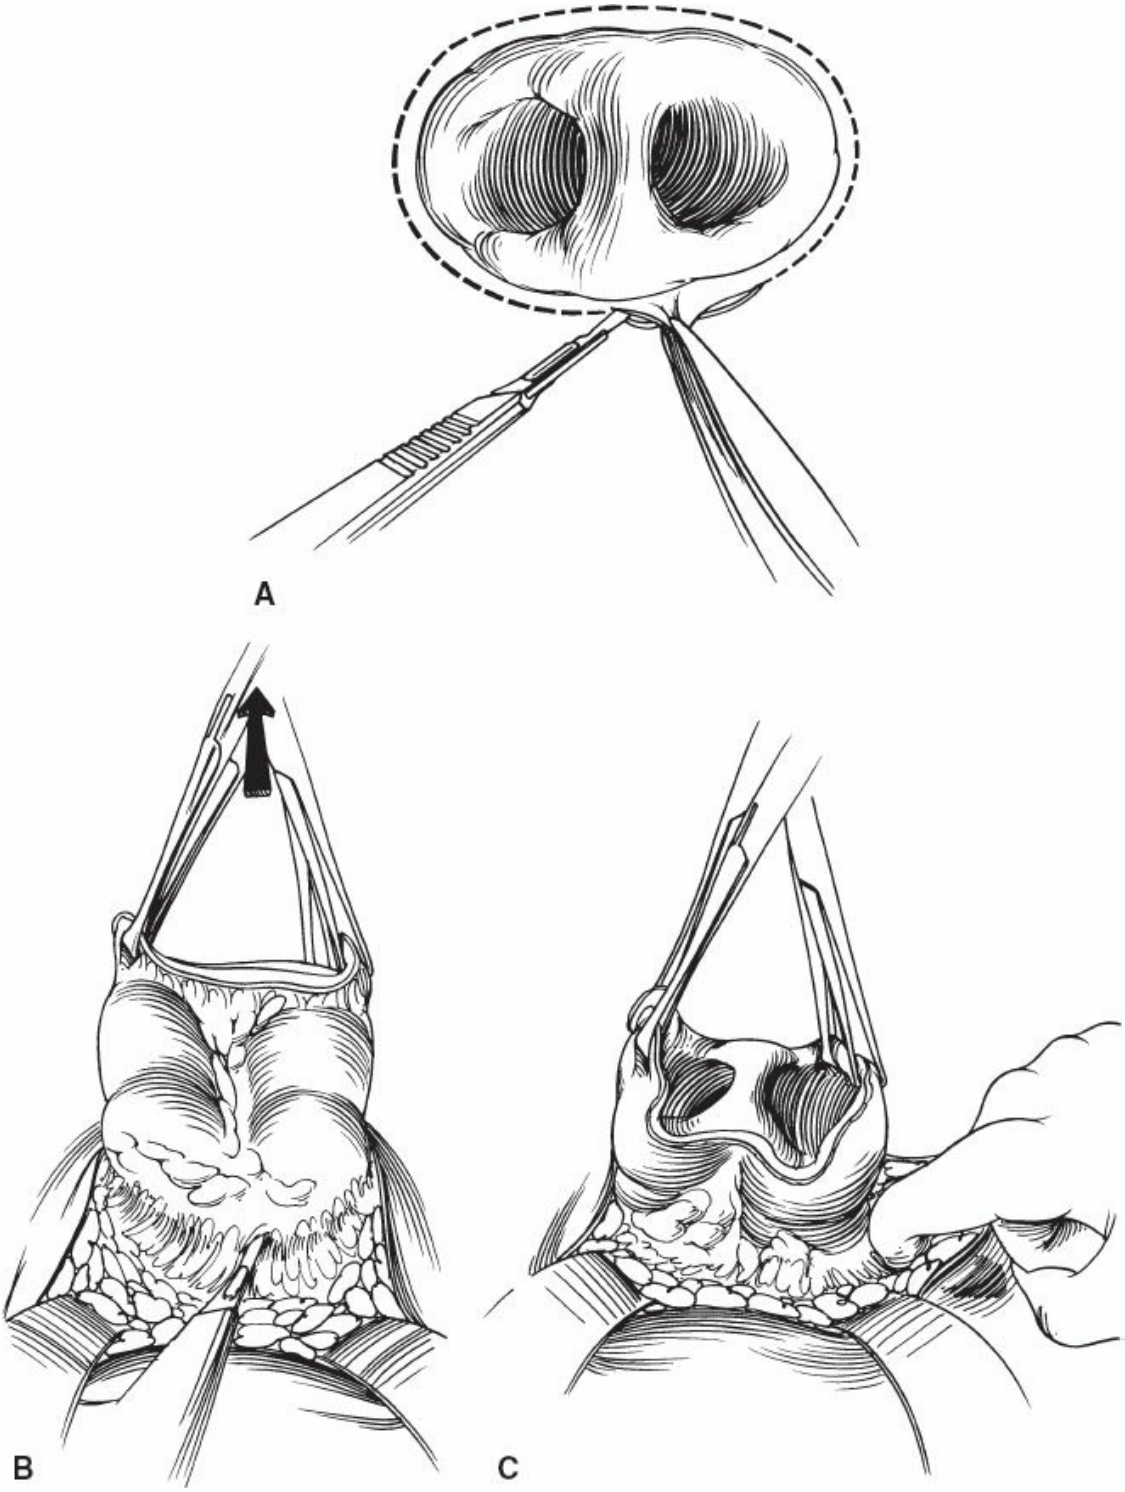

Figure 150.9. A circular incision is made around the stoma, including a thin margin of skin (**A**). Traction and counter-traction facilitates dissection away from the abdominal wall layers (**B** and **C**).

End Colostomy Closure

Closure of an end colostomy requires exposure of the rectum for creation

of a colorectal anastomosis. This can be accomplished with a laparotomy, or with a minimally invasive approach. Laparoscopic access is achieved either with Veress needle insertion into the peritoneal space at the lower edge of the umbilicus followed by insufflation and placement of a transparent port with laparoscopic visualization, or with a Hasson technique in the infraumbilical midline, as described previously. After creating pneumoperitoneum, a 5-mm port is placed in the right upper quadrant, and another in the right lower quadrants (Fig. 150.12). The patient is positioned in Trendelenburg position with left side up and the small bowel is swept toward the liver. The residual rectum must be identified and mobilized from any adhesions, and the end of the stump must be sufficiently cleared to allow creation of an anastomosis. Once this is accomplished, the colostomy is mobilized as described above. The anvil for an end-to-end anastomosis (EEA) stapling device is placed in the end colostomy and secured with a pursestring suture before the bowel is reduced into the abdomen. The anterior and posterior rectus sheaths are closed at the stoma site so that pneumoperitoneum can be maintained. The proximal colon is checked to be sure that it reaches the rectal stump without tension; if necessary, mobilization maneuvers described previously may be employed. The handle of the EEA stapler is deployed via the rectum, and the anvil and post are connected. The device is closed, and a circular stapled anastomosis is created. The anastomosis is submerged with irrigation and the rectum is insufflated, to perform a leak test of the anastomosis. With a satisfactory anastomosis created, pneumoperitoneum is evacuated. A pursestring stitch is placed for partial closure of the dermis at the stoma site.

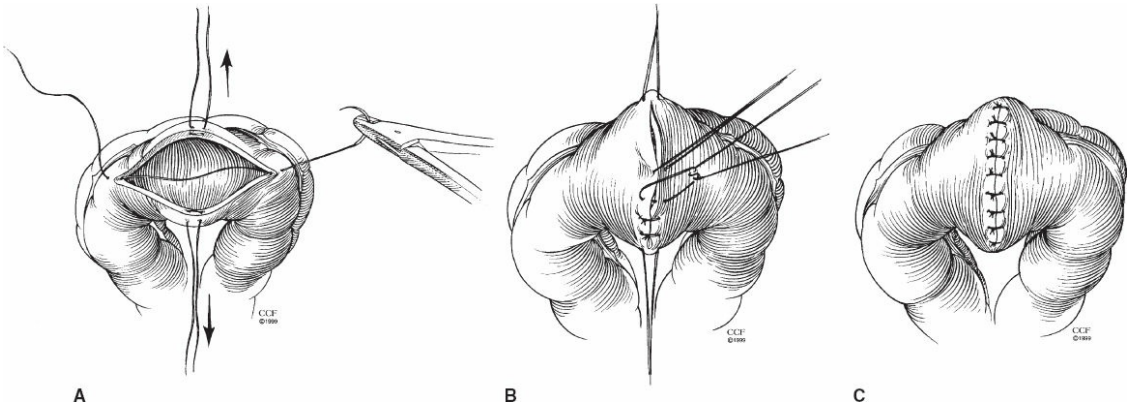

Figure 150.10. The colon defect is closed transversely with interrupted, absorbable stitches. Stay stitches may be placed at the edges, as shown, to maintain a transverse orientation for the

closure (**A**). An additional stitch may be placed in the center of the closure to maintain alignment, as shown (**B**). The remainder of the interrupted stitches are then placed and tied (**C**).

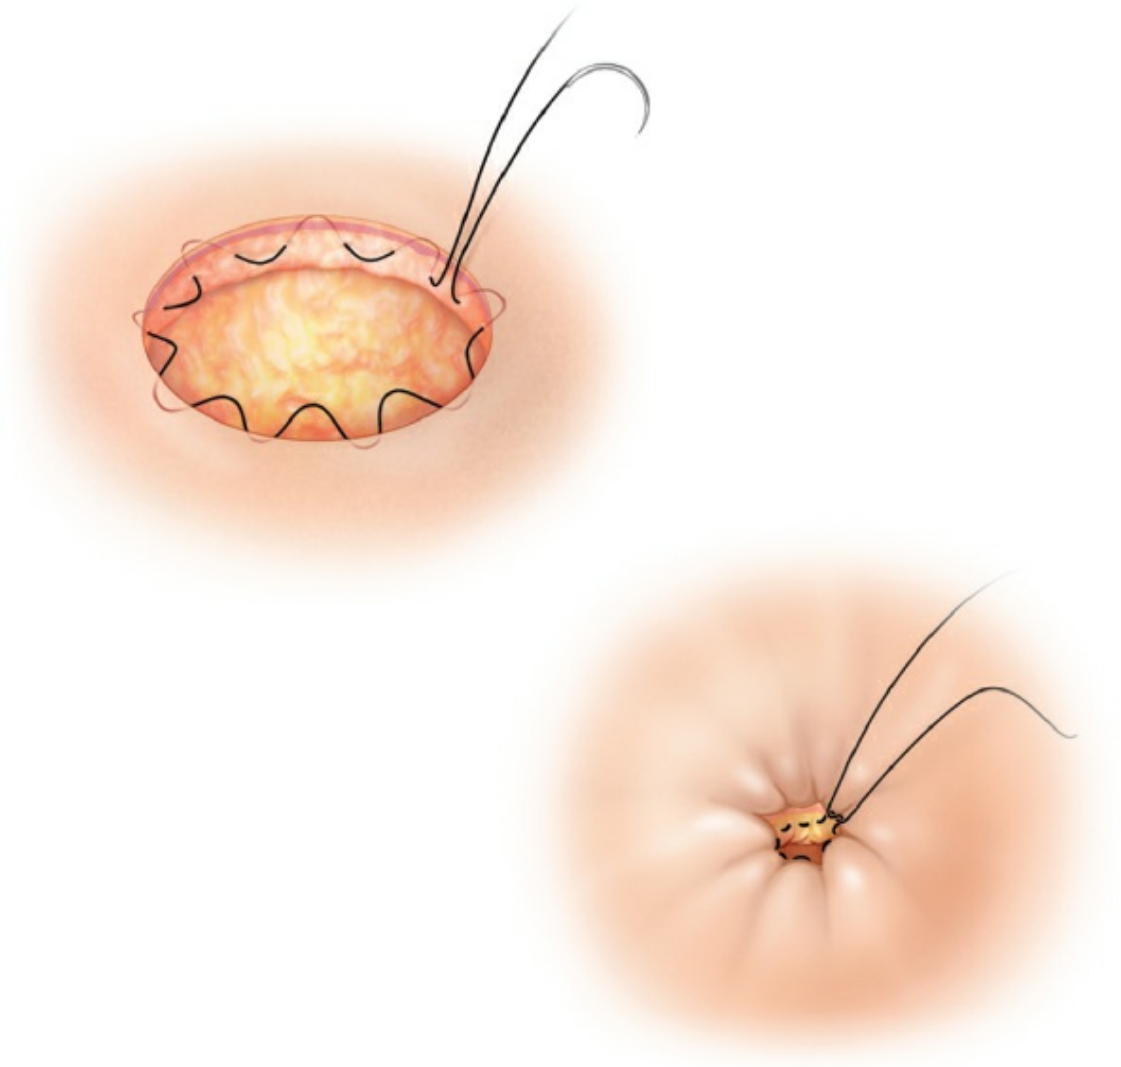

Figure 150.11. A running, circular, pursestring closure can be performed to tighten the stoma closure site to a narrow opening that can be packed and irrigated while healing.

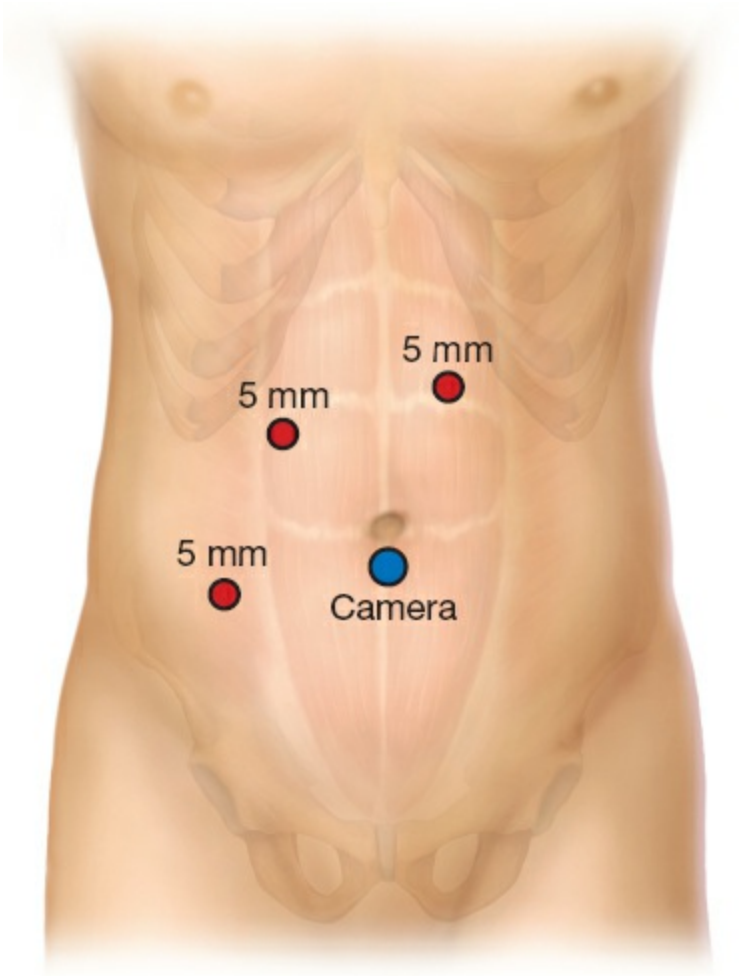

Figure 150.12. Suggested laparoscopic port placement sites for reversal of Hartmann procedure.

POSTOPERATIVE CARE

A follow-up visit from an enterostomal therapist should occur before the patient leaves the hospital. Education for the patient and family during the same admission, with time to practice stoma cleaning and pouch placement, is important to facilitate the patient's smooth transition to colostomy care at home. The appliance placed at the time of surgery may be left in place for the first few days, unless leakage requires replacement or a complication is suspected and the appliance must be removed for inspection of the stoma.

ACUTE POSTOPERATIVE COMPLICATIONS AND THEIR MANAGEMENT

Complications in the immediate postoperative period may include bleeding, ischemia, retraction, or infection. Ischemia of the colostomy may

lead to stoma stenosis. Concern may also arise if the stoma does not produce gas or stool within the anticipated time period, and technical error in construction of the colostomy must be ruled out. If a complication is suspected, the stoma appliance is removed and a careful examination of the colostomy is performed. The color and apparent perfusion of the mucosa is noted. The peristomal skin is checked for erythema or induration. The adjacent abdominal wall is palpated for any abnormal mass. A gloved finger is inserted through the colostomy to confirm patency. If the mucosa is discolored, dusky, or sloughing, a test tube may be used with a light source to examine the mucosal surface of the colostomy lumen. The test tube is inserted gently into the colostomy and allows additional visualization. If the extent of ischemic change is limited, it is often best to observe, and re-examine the stoma at a later time.

In some cases, a bedside exploration of the colostomy may allow successful management of a bleeding or infectious problem. The skin is cleaned and nearby surgical incisions are covered to prevent contamination. Local anesthetic may be used, but is often unnecessary. A few stitches are removed at the suspected location of the problem, which may allow for exposure and hemostasis of a bleeding edge, or probing and evacuation of a hematoma or peristomal abscess. Care is taken not to injure the bowel or its blood supply.

When bedside exploration is unable to control bleeding or infection, a return to the operating room for exploration and stoma revision is necessary. This is also true when extensive ischemia and necrosis is noted within days of surgery, when severe retraction and dehiscence of the colostomy construction occurs, or when torsion or obstruction is identified at the colostomy site.

ACKNOWLEDGMENT

We wish to acknowledge Dr. Ian Lavery, whose work in the previous edition of this text provided a valuable basis for our chapter.

EDITOR'S COMMENT

Dr. Kukar and colleagues provide a thorough description of laparoscopic and open creation of end and loop colostomies as well as cecostomies. The creation of a colostomy often occurs at the conclusion of an emergency operation for an acute abdomen or following a lengthy operation for a pelvic cancer. As such, it may be constructed when the surgeon is tired, thinking that the difficult part of his/her case is already over and therefore, occasionally be constructed with less attention to detail than other portions of the procedure. This is; however, a grave error! In many cases the patient has to deal with the colostomy for the remainder of their life.

As with ileostomy, *failure* to mark a patient for a suitable colostomy site ***prior*** to an operation in which there is a chance of needing diversion is a serious medical error. Even with a seriously ill patient, it takes little time, with the help of a nurse or several assistants to place the patient in a sitting position, in order to identify the patient's major abdominal folds and creases, and to identify the best location for a colostomy. With the increasing obesity of our population, the best site for a colostomy in an obese individual is often in the upper abdomen, where the abdominal wall thickness is often much less than in the lower abdomen. In addition, in very large individuals, the thickness of the lower abdominal wall is not the only problem. There is also often a thickening of the skin of the dependent portion of the pannus, frequently leading to a "peau d'orange" type of skin, with a lower abdominal skin that is almost leathery in consistency, and to which it is difficult for a colostomy appliance to adhere.

Although typical colostomy output is semisolid, the surgeon should be able to modify his or her surgical technique in the presence of patient factors that may affect this. For example, in a patient who has undergone significant small bowel resections, or an ileocolic resection, or in the patient who has undergone significant radiation therapy, or the patient who will be receiving chemotherapy, the colostomy output may be much more liquid. In these circumstances, although a colostomy is typically created flush with the surrounding skin, and generally not protruding more than 1 cm; in these patients, it will be in the patient's interest to create a colostomy that is constructed more like an ileostomy, that is, that is protruding above the level of the skin to a greater degree (>1 cm) in order to facilitate pouching and a leak-proof seal, to prevent subsequent skin excoriation and associated skin breakdown.

Several studies have shown that colostomies constructed in the urgent setting

are frequently never closed. Attention to detail, that is, construction of a good stoma in a good location, is paramount. Many surgeons feel that a transverse loop colostomy provides for good fecal diversion. These types of stomas are; however, notoriously difficult to manage, both because of their size, requiring extremely large stoma appliances, by their difficulty to camouflage under clothes because of their upper and mid-abdominal location, as well as because of their tendency to prolapse that is perhaps greater than for any other stoma location. For this reason, despite its ease of creation, transverse loop colostomies are a type of diversion that I infrequently use.

Colostomies are generally associated with more technical complications during construction relating to intestinal perfusion than ileostomies, particularly in overweight individuals. In one study evaluating 100 patients each with either a loop ileostomy or loop colostomy performed at two centers over a 6-year period, the study authors noted a higher rate of dermatitis and renal insufficiency in loop ileostomy patients. At the time of stoma closure; however, patients with loop colostomy experienced more wound infections and had a longer length of hospital stay (Klink CD, Lioupis K, Binnebösel M, et al. Diversion stoma after colorectal surgery: loop colostomy or ileostomy? *Int J Colorectal Dis* 2011;26(4):431–6). Common postoperative complications such as partial circumference and even full circumference mucocutaneous separations can be managed by good enterostomal therapy. This even applies to cases of full-thickness necrosis extending down to the fascia level. Patients with full-thickness necrosis will; however, develop skin level strictures, which make stoma care difficult. Short of re-operation and stoma revision, these patients can often be managed by colostomy self-dilatation using Hegar dilators on a daily basis performed by the patient. The patient can also be taught to irrigate the colostomy to maintain function without obstructive symptoms. A motivated patient with agile hand function is a prerequisite for this. In patients who are very obese, construction of a proper sigmoid or descending colostomy may involve ligation of the inferior mesenteric artery at its origin, much as one would do for a full cancer resection, in order to gain enough mobility for the stoma to reach to the abdominal wall without tension.

Due to the increasing body mass index seen in patients, particularly in the United States, parastomal hernias involving colostomies are a common postoperative complication. There have been several trials that have evaluated use of techniques to decrease the frequency of hernia formation at the primary operation at which the colostomy is constructed. López-Cano et al. reported results of a randomized, prospective, double blind trial in rectal cancer patients undergoing laparoscopic abdominoperineal resection (López-Cano M, Serra-Aracils X, Mora L, et al. Preventing Parastomal Hernia Using a Modified Sugarbaker Technique With Composite Mesh During Laparoscopic Abdominoperineal Resection: A Randomized Controlled Trial. *Ann Surg* 2016;264(6):923–8). Patients were randomized to undergo placement of a lightweight large-pore composite mesh in an onlay fashion using a modified

Sugarbaker technique versus no peristomal mesh. Patients underwent computed tomography (CT) scanning at a minimum of 12 months postoperatively in order to detect the presence of parastomal hernia. Morbidity did not differ between groups; however, with a median 26-month follow-up, the rate of parastomal hernia was 25% in the mesh group, as compared to 64% in the no-mesh group. In yet another much larger study, the "Dutch PREVENT-trial," a prospective, single-blinded trial in which patients were randomized to undergo standard colostomy construction or construction of a colostomy with placement of a retromuscular lightweight polypropylene mesh above the posterior sheath of the rectus muscle (Brandsma HT, Hansson BM, Aufenacker TJ, et al.; Dutch Prevent Study group. Prophylactic Mesh Placement During Formation of an End-colostomy Reduces the Rate of Parastomal Hernia: Short-term Results of the Dutch PREVENT-trial. *Ann Surg* 2017;265(4):663–9). Patients underwent CT scans if there were symptoms suggestive of parastomal hernia. At 1-year follow-up, 3/67 (5%) mesh patients had developed a parastomal hernia as compared to 24% of the non-mesh group. It should be noted that since both of these studies are European, the mean BMI of patients in all groups in these studies was less than 27, making these populations unlike the typical United States populations. An earlier systematic review and meta-analysis that did not include these two studies also concluded that prophylactic placement of mesh at the time of colostomy construction resulted in a reduced risk of parastomal hernia and a reduced risk of reoperation for parastomal hernia (Wang S, Wang W, Zhu B, et al. Efficacy of Prophylactic Mesh in End-Colostomy Construction: A Systematic Review and Meta-analysis of Randomized Controlled Trials. *World J Surg* 2016;40(10):2528–36). However, this study was limited by the heterogeneity of included studies.

The authors briefly refer to cecostomy construction and supply a Figure illustrating this. Cecostomies work well, provided that they are cared for properly. This requires insertion of a tube of large enough diameter that will not easily clog and which will permit for adequate venting of fecal contents and gas —for example, a 32-French Malecot catheter. In placing such a tube in order for them to function properly it is essential that these tubes are irrigated regularly postoperatively. This involves irrigation of the tube every 2 hours with saline to ensure patency. Another modification of technique that may reduce the incidence of complications is the placement of the Malecot tube through omentum prior to fixing the bowel to the abdominal wall. Recently, successful percutaneous cecostomy placement has been reported for the treatment of selected patients with colon obstruction due to cancer (Tewari SO, Getrajdman GI, Petre EN, et al. Safety and efficacy of percutaneous cecostomy/colostomy for treatment of large bowel obstruction in adults with cancer. *J Vasc Interv Radiol.* 2015;26(2):182–8). In these patients, positioning the catheter tip within luminal gas rather than in a mixed gas/stool collection results in a greater decrease in the maximum colonic distension.

As a final comment, many patients with end colostomies can change the

frequency of bowel evacuation with the technique of colostomy irrigation. In a recent systematic review, colostomy irrigation was found to be associated with a reduction in pouch usage, and allows some patients not to require use of an appliance (Kent DJ, Long MA, Bauer C. Does colostomy irrigation affect functional outcomes and quality of life in persons with a colostomy? *J Wound Ostomy Continence Nurs.* 2015;42(2):155–61). Sadly, many patients with permanent colostomies are never told or instructed about the availability of this technique.

Susan Galandiuk

151 Care of Stomas

Marc C. Osborne and Ann C. Lowry

Approximately 100,000 patients in the United States will have a colostomy or ileostomy created each year. Complications of operations involving an ostomy are unfortunately common. Managing a difficult or problematic stoma has a significant negative effect on quality of life for the patient and leads to increased health care costs in prolonged length of stay, hospital readmissions, increased outpatient care and supplies. This chapter will review the basics of stoma anatomy, proper stoma siting, optimal stoma care, the role of the Wound, Ostomy, and Continence Nurse (WOCN), management of common stoma complications, and patient education.

STOMA ANATOMY AND PHYSIOLOGY

An intestinal stoma is constructed when a portion of the gastrointestinal tract is brought through the abdominal wall, opened and matured by suturing the bowel wall to the skin. Most commonly done to divert the fecal stream, it can also be done to divert the urinary stream as well. The stoma may be constructed as an end, loop, double barrel, or "end-loop" stoma. The stoma may arise from the jejunum, ileum, or portion of the colon. Two other chapters cover the technique of creation of an ileostomy and colostomy (Chapters 138 and 150, respectively). An end stoma is created by dividing the bowel completely and bringing the proximal end through the abdominal wall and matured by everting the opened edge of the end of the bowel and suturing it to the skin. The distal portion may be removed, closed off and left in the abdomen, brought through the abdominal wall at the same site, and left in the subcutaneous tissue for possible later stoma reversal. If the distal bowel is not removed, it will continue to produce mucus and exhibit peristalsis. Patients will occasionally discharge this mucus via the anus and this may be associated with a sensation similar to the urge to have a bowel movement. Patients who have undergone a Hartmann's procedure are encouraged to evacuate this mucus by administering a small tap water enema via the anus twice a month. This may begin 6 weeks after surgery or when the patient seems to

have sufficiently recovered. A loop stoma is created by bringing a loop of intestine through the abdominal wall above the level of the skin. The bowel is partially opened, usually in a transverse manner, and both ends are everted and matured. The proximal loop is usually cephalad and everted to a height greater than the distal limb. A double-barrel stoma is created similarly except that the bowel is completely divided and both limbs are matured. To fashion an end-loop stoma, the bowel is divided and the proximal limb is brought through the abdominal wall as a loop with a short efferent limb. This technique allows for less tension on the mesentery and is particularly useful in patients with a large amount of subcutaneous fat. The stoma is then matured similarly to a loop stoma.

A jejunostomy is created using jejunum; stoma output will be watery, bilious, and high volume. Patients are at the high risk of dehydration, electrolyte imbalances, and need for parenteral hydration and nutrition. Because of these challenges, jejunostomies are usually created in the setting of Crohn disease, trauma, ischemic bowel, or prior bowel resections.

An ileostomy is created from the distal portion of the small bowel. The most common indications are inflammatory bowel disease, familial adenomatous polyposis, cancer, or to protect a distal colorectal anastomosis…All small bowel stomas should protrude at least 2 cm above the skin as this will greatly facilitate proper pouching. Initially after surgery, the stoma output will be watery with volumes exceeding 1 L per day. This can lead to dehydration, which is the most common reason for hospital readmission after creation of an ileostomy. Care pathways and patient education, discussed later, are critical to preventing this complication. With time, the bowel will accommodate and increase its absorption of fluid. Patients can expect 500 to 1,000 cc of output per day with a variable consistency, but mostly commonly that similar to thin oatmeal, and typically with little odor.

A colostomy is created from any portion of the colon, although this is mostly commonly done in the sigmoid and transverse colon. Common indications include cancer, Crohn disease, volvulus, fecal incontinence, trauma, congenital malformation, or neurologic disorders. A colostomy should protrude 1 cm above the skin. The output will vary depending on the stoma location.

A urostomy is usually created using a portion ileum or colon as a conduit, although it can be made as an ureterostomy. This procedure is

typically done by taking a portion of the bowel out of continuity, re-establishing intestinal continuity, and then using the discontinuous loop as a conduit. Normal output will depend on level of hydration and patient weight.

Role of the Wound, Ostomy, and Continence Nurse

The need for nurses with specialty training in the care of patients with stomas has been recognized for decades, dating back to the creation of the first enterostomal therapist (ET) training program by Dr. Rupert Turnbull and one of his patients, Norma Gill, at the Cleveland Clinic. Although the name has changed from ET to Wound, Ostomy, and Continence Nurse (WOCN), these nurses provide significant value to patients. Ostomy surgery creates significant anatomic and physiologic changes for the patient and may result in significant psychosocial challenges. Optimal care for patients undergoing ostomy surgery includes preoperative, perioperative, and postoperative care by an ostomy nurse specialist, such as nurse certified by the Wound, Ostomy, and Continence Nurses Society Certification Board. Studies demonstrate significant differences in the quality of stoma site selection between surgeons and WOCN. Randomized trials demonstrate that ostomy nurse care after discharge results in greater ability of patients to care for themselves independently and improved quality of life. Although the clinical condition or remote location of the patient may not allow for the utilization of WOCN specialists in all circumstances, they should be consulted whenever possible for preoperative teaching and marking, perioperative care and training, and postoperative follow-up.

Ostomy Siting

Creation of the perfect stoma involves picking the optimal site on the abdominal wall for stoma creation and meticulous technique in the operating room. A well-sited stoma will lessen the risk of common complications such as appliance leakage and peristomal skin irritation, improved predictability of appliance wear time, improved patient adaptability to the stoma, and lead to improved patient satisfaction.

Prior to marking the patient, it is important to consider any positioning issues such as posture, mobility, contractures, use of a wheelchair, or walker. Patients should be marked with a marking pen that will not wash off when the patient’s abdomen is prepped. This mark is often protected

with a piece of transparent dressing if done in the outpatient setting.

Begin by asking the patient to remove any clothing covering the abdomen. Examine the patient in the supine, sitting, standing, and bending forward positions to note creases, scars, skin folds, and valleys. One should note where the patient wears their pants. Use a marking pen that will wash off to mark some of these landmarks. Examine the patient in the supine position and identify the rectus muscles by having them raise their head and back off the bed. The ideal site will be through the rectus muscle in the appropriate quadrant for the planned surgery and in the patient's visual field, usually at the apex of either the supraumbilical or infraumbilical ridge. Visualize the site in the supine, standing and sitting positions to ensure that site does not fall into a crease or retract in different positions.

Care should be taken to choose a flat site to allow for easy pouching and avoid scars or creases. A site below the belt line is preferable as it will allow for the concealment of the pouch. However, this consideration should be secondary to ensuring the stoma is visible to the patient and allows for flat pouching surface. The site should be 2 to 3 in away, perpendicularly, from a midline incision. Obese patients and patients with a rounded abdomen may benefit from marking in the upper abdomen since the subcutaneous fat layer is less prominent here. Figure 151.1 details four common stoma sites. Note the supraumbilical and infraumbilical ridge noted mosin the sitting position.

Ostomy Appliances

The ideal pouching system will provide a receptacle to catch the effluent, protect the surrounding skin, and allow for easy emptying and replacement and predictable timing of the need for replacement. Multiple products are available. The appliance will generally consist of a skin barrier (sometimes called a wafer), a pouch, and a closure device. The appliance can come with the pouch and skin barrier connected as a one-piece appliance or separately as a two-piece system. One-piece appliances tend be lower profile (Fig. 151.2A). Two-piece appliances allow for the pouch to be changed without changing the skin barrier (Fig. 151.2B). Most appliances are disposable and are made to last 3 to 7 days. Reusable appliances also have to be changed every 3 to 7 days and require the extra maintenance to wash and reuse them.

The skin barriers consist of a pectin like material surrounded by a strip

of adhesive. Two-piece systems will have an additional plastic ring where the pouch which collects the fluid will attach. Barriers come in either extended or standard wear models. The extended wear models are designed to have the pectin like material breakdown less under exposure to watery output and are usually recommended for an ileostomy or urostomy. Conversely, the appliance tends to be less flexible. The standard wear barrier is recommended for a colostomy. The pectin like material is cut to match the contour of the stoma. Skin barriers come in cut-to-fit or precut models. The cut-to-fit model is cut by the patient usually with the aid of a stencil. During the early postoperative period, the cut-to-fit model is preferred as the stoma changes size often. Similarly if the stoma is not completely round, the cut-to-fit model is often used. The skin barrier may be flat or convex (Fig. 151.2C). Convexity allows the skin barrier to mirror the peristomal skin plane; it is very important with a stoma that lies within a crease or is not sufficiently everted above the skin level. Paste, strips, or rings can be added to the skin barrier to smooth out irregular surfaces, promote a good seal, and protect the peristomal skin (Fig. 151.2D). A stoma belt which connects to the skin barrier can also support the barrier and help provide a good seal.

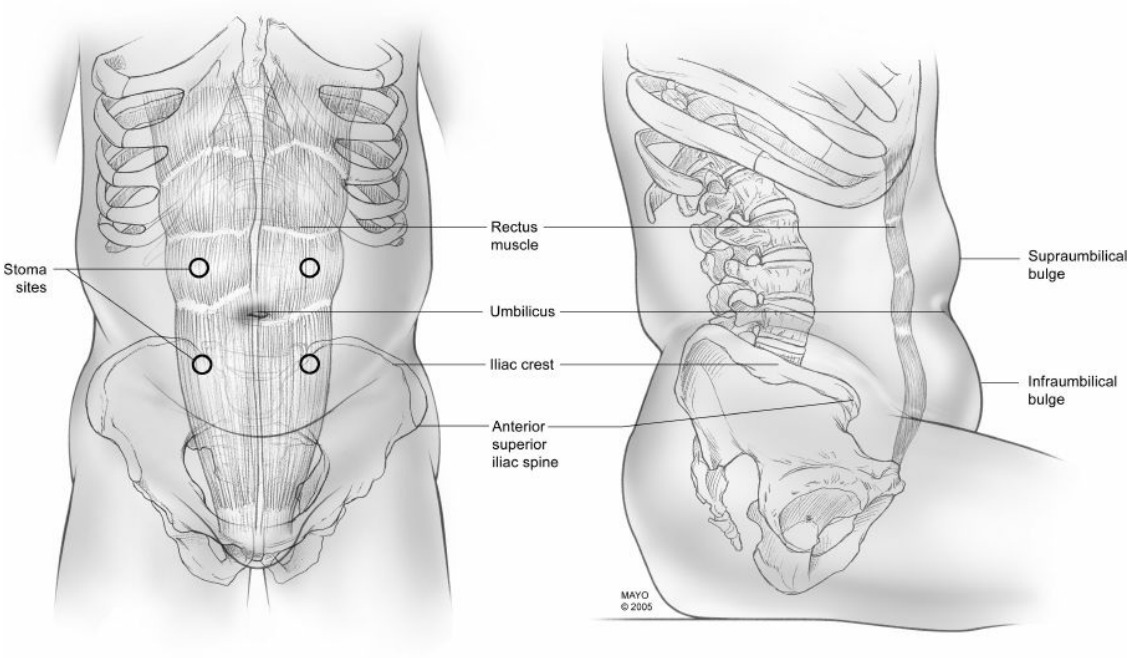

Figure 151.1. Four commonly used stoma sites. (From Fischer J. Masters of Surgery The Gastrointestinal Tract. *Care of Stomas*, Chapter 52. 2012, e38.)

The pouch is the bag that holds the effluent. They are available in either transparent or opaque materials as well as vented or nonvented. The vents often contain a charcoal filter to reduce odor. In the immediate postoperative period, it is recommended to use a nonventing, transparent pouch to allow for easy inspection of the stoma and to identify the presence of gas and stool. The pouch should be emptied when one third to one half full of liquid or gas. A pouch for a urostomy will commonly have a valve which can be turned to empty urine. A pouch for an ileostomy will commonly be open at the end to allow for emptying and will close with a clip or Velcro type mechanism. Some pouches are available in a nondrainable model and require removal from the body to empty and can be reused. Deodorants, either as a powder or spray, are available to reduce the odor from the pouch (Fig. 151.2E).

Peristomal Skin Care

The keys to maintaining healthy peristomal skin are a properly fitting appliance and well constructed stoma. The most common cause of peristomal skin irritation is stool in contact with the skin. The appliance is removed by lifting the edge of the skin barrier and pushing down on the skin. Warm water and adhesive remover help remove the skin barrier without injury to the skin and fully remove any adhesive residue. The skin should be washed with warm water and soap and well dried. Avoid products with alcohol or oil on the skin. Peristomal hair can be shaved or clipped. Properly cutting the appliance to fit the stoma will ensure protection of the peristomal skin. Skin irritation is treated with skin barrier powder and then a skin sealant is applied over the powder to ensure a good seal to the appliance.

Diet, Medications, and Lifestyle

The creation of an intestinal ostomy does not mandate lifelong dietary restriction. However, there are short-term restrictions to prevent a food blockage in the immediate postoperative period. Patients are advised to chew their food well and to cut food into small pieces. For the first 2 to 6 weeks after surgery, patients should follow a low residue diet. A food blockage can occur, particularly with an ileostomy, when highly fibrous food, poorly chewed lodges in the distal small bowel. This produces the typical colic type pain of a small bowel obstruction and patients will note a decreased or watery output. This may lead to abdominal distention,

nausea, and vomiting. Patients are advised to lie in the supine position or in a knee chest position. Massaging the abdominal wall may help. If the symptoms become severe, patient should present to a health care provider for evaluation. Treatment includes IV hydration, NPO, and NG tube decompression. The stoma can be irrigated and this will often dislodge the blockage.

Once past the immediate postoperative state, the patient should introduce new foods slowly. Patients should be advised on how their diet will affect ostomy output, stool consistency, odor, and gas production (Tables 151.1 and 151.2). To avoid excess gas, patients should avoid smoking, use of straws, eating too fast, chewing gum, sucking on ice, drinking carbonated beverages, skipping meals, or gas-forming foods.

Dehydration is common in patients with an ileostomy. A patient with an ileostomy will usually empty their pouch four to six times per day for a total of 1 L output in 24 hours. More than 1 L output per day is defined as high output and puts the patient at the risk of dehydration. Patients should be monitor their output and contact their health care provider when they have high output. Treatment includes increasing fluid intake, particularly an electrolyte rich drink such as a sports drink, and eating more foods that will thicken the stool such as applesauce, bananas, and tapioca. Psyllium will also thicken the stool. Patients may need to take antidiarrheal medications such as loperamide or diphenoxylate. Rarely, tincture of opium or codeine is used for the chronic treatment of high ileostomy output.

Patients with colostomies may choose to regulate the timing of stomal output by irrigating the stoma at regular intervals. Irrigation is done with warm tap water through a catheter attached to a cone inserted into the stoma opening (Fig. 151.2F).

Once a stoma is created, patients may need to have their chronic medications adjusted due to changes in absorption. Time released or coated medications may need to be changed to a chewable or liquid form. Laxatives should not be used in anyone with an ileostomy. In addition, diuretics may need adjustment because of the additive risk of dehydration.

Patients will have concerns regarding the effect of the stoma on their lifestyle; they should be reassured that the stoma will not result long-term activity restrictions. Common questions focus upon bathing, showering, swimming, clothing choices, and sexual activity. Patients may be reluctant to bring these concerns forward; providers may have to elicit them as part of the perioperative teaching. Some patients may have difficulty to adjusting to life with a stoma either related to difficulty in caring or the psychological impact of the stoma or the underlying diagnosis requiring stoma surgery. In addition to optimizing any medical issues, providers should be alert and recognize psychological signs of anxiety or depression. In addition to WOCN, there are multiple avenues for patients to find support and education. The United Ostomy Association of American provides education and support for patients, including a listing of local stoma support groups found at www.ostomy.org.

TABLE 151.1 Affect of Food on Stoma Output

Foods That Thicken Output	Foods That Increase Output	Foods That Increase Gas
Pasta, rice, soda crackers, pretzels	Ice cream	Fried or fatty foods
Cheese, yogurt	Prunes and prune juice, raisins, figs, grape juice, leafy vegetables, large amounts of fruits, rhubarb	High sugar foods
Applesauce, bananas, potatoes	Syrup, cookies, pudding, pastries, cake, pies, chocolate, licorice, caffeine, soda pop, beer, gelatin, spicy foods	Milk, cheese, eggs
Peanut butter, tapioca		Beans, chickpeas, lentils
		Peanuts
		Cabbage, broccoli, Brussels sprouts, cauliflower, beets, rutabagas, turnips, radishes, onions, chives, leeks, lettuce, parsley, corn, cucumbers, pickles, peppers

Patients may bathe, shower, and swim with a stoma. A well-fitted appliance is waterproof and will not leak. Patients may choose to bathe or shower with the appliance off and should be advised to do so when the stoma is less active.

Most patients will be able to wear their regular clothes after surgery. To prevent leakage, it is important that clothing does not limit effluent from reaching the bottom of the pouch. Adjustment in belt lines or clothing choices may be necessary.

Patients who have undergone proctectomy or pelvic radiation are at the risk of sexual dysfunction such as impotence, retrograde ejaculation, dyspareunia, and loss of vaginal lubrication as well as changes in fertility. These risks should be discussed preoperatively. Women with a stoma may get pregnant. Adjustments in the appliance may be needed as the abdominal wall changes during and after the pregnancy.

TABLE 151.2 Food and Stoma Odor

Foods to Add to Reduce Odor	Foods to Avoid to Reduce Odor
Buttermilk	Alcohol, especially beer
Yogurt	Fish
Kefir	Eggs
Parsley	Dried beans and peas
Cranberry juice	Onions and garlic
	Asparagus
	Brussels sprouts
	Green peppers

Perioperative Care Pathways

Recently care pathways have been developed to reduce the morbidity of ostomy creation, especially as it relates to the prevention of dehydration and readmissions, as well empowerment of patients to provide self-care. These pathways include scheduled preoperative, inpatient postoperative, and post discharge visits with a WOCN, structured preoperative and postoperative education with handouts, observation of the patient changing their own appliance prior to discharge, discharge with a graduated cylinder for adequate measurement of ileostomy output, scheduled phone calls from a clinic nurse regarding hydration status, bowel function, and appliance issues.

To assist with preoperative education, the American College of Surgeons developed a home skills kit that patients can use to acquire some of the basic stoma care skills prior to their operation. The kit includes a booklet and DVD with instructions on how to empty and change an appliance, a stoma model and supplies to practice, and an evaluation tool. These kits and the video are available through https://www.facs.org/education/patient-education/skills-programs/ostomy-program.

STOMA COMPLICATIONS

The adage “an ounce of prevention is worth a pound of cure” is never truer than in caring for stomas and dealing with complications. In addition to using proper siting and surgical techniques, regular follow-up with a

WOCN is critical to prevention and treating complications. Unfortunately, minor and major complications are common and are addressed here.

Parastomal Hernia

The risk of a parastomal hernia is directly proportional to the length of time the patient has the stoma. A hernia develops when the fascial opening enlarges around the stoma allowing loops of bowel or intra-abdominal fat to protrude above the fascia. Several small randomized trials have demonstrated that placement of synthetic mesh at the time of permanent ostomy creation can lower the incidence of parastomal hernia formation.

While many patients with a parastomal hernia will be asymptomatic or minimally symptomatic, some notice a change in the fitting of their appliance and require a change to a different system or in the opening of the skin barrier. A hernia belt may reduce symptoms (Fig. 151.2G). Care should be exercised in irrigating a stoma with a parastomal hernia.

Repair should be reserved for patients with significant symptoms or inability to adequately pouch the stoma. Repair of parastomal hernias can be done with primary suture repair, relocation of the stoma, and mesh repair. Primary suture repair is associated with a very high recurrence rate. For patients who no longer require a stoma, presence of a symptomatic parastomal hernia may be an indication for ostomy reversal. Mesh repair can be done with a variety of techniques with placement of mesh in an onlay, retromuscular, and intraperitoneal positions. Intraperitoneal placement may include keyhole, slit, and Sugarbaker techniques. There have been no randomized controlled trials that compare these techniques.

Prolapse

Stoma prolapse is most commonly associated with loop stomas (particularly loop colostomy), obesity, parastomal hernia, increased intra-abdominal pressure, and pregnancy. Either or both limbs of a loop stoma may prolapse. When a prolapse occurs, patients should be assessed for pain, incarceration, bowel ischemia, and condition of the peristomal skin. In most cases, the prolapse can be reduced with gentle continuous pressure on the stoma with the patient in the supine position. Reassurance or a small dose of IV sedation or analgesia to relax the abdominal wall may be necessary to achieve reduction. Application of sugar to the mucosa can draw out edema from the bowel wall and facilitate reduction.

Asymptomatic prolapse can be managed nonoperatively. Patient may

benefit from a hernia belt with a prolapse over belt or a support binder. The pouching system may need to be revised to accommodate changes in the size of the stoma. Obstruction, ischemia, and incarceration are indications for surgery usually with local resection of the prolapsed segment (Fig. 151.3).

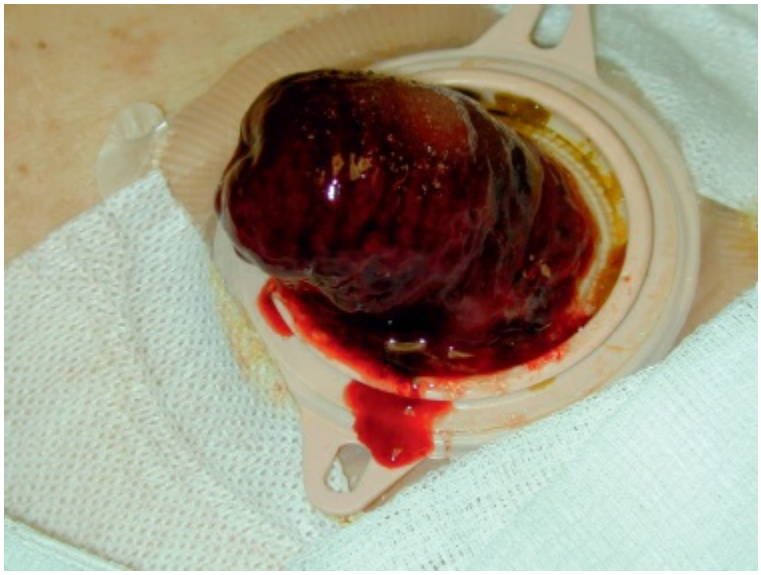

Figure 151.3. Stoma prolapse with ischemia.

Figure 151.4. Mucocutaneous separation.

Mucocutaneous Separation

Mucocutaneous separation between the bowel wall and the skin can occur in the immediate postoperative period and in a delayed fashion. It is important to assess for stoma retraction, or necrosis, abscess, and fistula.

Treatment starts with optimization of general wound healing parameters such as nutrition, smoking cessation, control of diabetes, control of underlying inflammatory bowel disease, and adequate drainage of infection. Avoiding early use of convexity in the pouching system may help prevent early mucocutaneous separation. The area of separation is cleansed with saline and any necrotic tissue is gently debrided. The wound is probed with a swab to assess the extent of separation (Fig. 151.4). The wound is then filled with an absorptive product such as hydrofiber, skin barrier powder, or barrier paste. The skin barrier the opening cut to cover the separation is then applied. The wound is treated daily in this manner. Changing to a two-piece system or any easy to change system may facilitate the multiple appliance changes.

Necrosis

Stomas will naturally become edematous, usually accompanied by a change in the mucosa to a darker red from pink, in the first 24 to 72 hours after surgery. Cyanosis of the mucosa or sloughing indicates necrosis. Hypovolemia, hypotension, edema, and tension or tearing of the mesentery can contribute to stoma necrosis and need to be assessed and addressed. Changing to a transparent pouch allows for frequent inspection. Digital exam of the stoma can ensure that the fascial opening is adequate. The extent of ischemia and necrosis can be assessed at the bedside by inserting a clear test tube into the stoma and inspection with a flashlight. Necrosis that extends below the level of the fascia in a stable patient requires exploration, probable bowel resection, and creation of a new stoma. Necrosis above the level of the fascia can be managed expectantly with surgical intervention reserved for the development of infection or sepsis. Full-thickness necrosis may result in stoma stenosis or mucocutaneous separation.

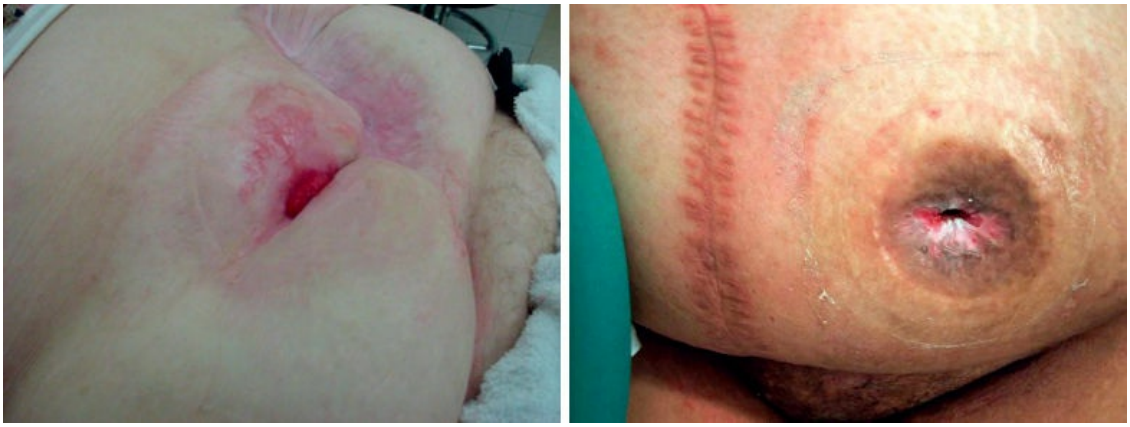

Figure 151.5. Stoma partially retracted in a crease in obese patient.

Retraction

Stoma retraction can occur by two mechanisms. Tension on the mesentery related to obesity or mesenteric edema may pull bowel down to the level of the skin. Alternatively, the skin around the bowel sinks in relative to the regular contour of the abdomen to cause the stoma to sit within a crease. Poor initial siting or significant weight change is common causes (Fig. 151.5).

Patients should be evaluated in both the sitting and standing position without the appliance. Peristomal skin irritation is common due to inadequate seal of the appliance. Often, convexity is added to the skin barrier in the hopes of gaining adequate drainage into the pouch. A stoma belt can also help maintain a seal. Patients with persistent pouching difficulties may require local revision or relocation of the ostomy.

Stenosis

Stenosis can occur at the level of the fascia, the skin or both (Fig. 151.6). It may be an early complication from an inadequate skin opening, ischemia, mucocutaneous separation, or abscess. Late stenosis should trigger assessment for Crohn's disease, malignancy, and scarring. Digital exam determines the degree of stenosis at the skin and fascia. Patients may experience obstructive symptoms with pain and bloating. Output may be erratic and patients may note squirting of stool under pressure.

Figure 151.6. Stoma stenosis.

Short-term relief may be achieved with gentle dilation with the examining finger or a dilator. Repeated dilatation should be avoided as it may cause scarring and further stenosis. A low residue diet may ease symptoms and allow easier passage of stool. Severe cases will require surgical intervention.

PERISTOMAL SKIN COMPLICATIONS

There is a common misconception that the skin around the stoma is expected to be chronically inflamed or altered. In fact, despite being covered by an adhesive, the skin should be of normal color and texture. The most common skin complications are irritant and allergic dermatitis, pseudoverrucous lesions, cellulitis, folliculitis, candidiasis, pressure ulcer, mucosal transplantation, psoriasis, peristomal varices, and pyoderma gangrenosum.

Dermatitis

Dermatitis presents as confluent or uniform erythema, tenderness, and epithelial erosion with resulting moisture. Hypersensitivity to a particular skin care product and chemical irritation from stoma effluent is the most frequent causes of dermatitis. Treatment is aimed at the removal of the underlying offending agent. Use of routine skin care products, such as lotions, should be avoided unless used for a specific indication. A proper sized and fitting appliance can prevent and treat chemical dermatitis from intestinal effluent. Patch testing can be used to identify a specific allergen.

Figure 151.7. Pseudoverrucous lesion.

Pseudoverrucous Lesions or Hyperplasia

Chronic irritation can lead to hyperkeratosis and development of overgrowth, warty-like, lesions within the area of chronic irritation (Fig. 151.7). These lesions are usually gray or red and can bleed easily. Treatment is directed at removal of the offending irritant use of a barrier powder can promote wound healing. Alternatively, silver nitrate may be applied to speed shrinkage of the excess tissue and allow for easier pouching.

Cellulitis, Folliculitis, and Candidiasis

Although all of these are infectious complications, the etiology and treatment of cellulitis, folliculitis, and candidiasis are different. Candidiasis will present in an area of chronic moisture as pustules with a bright red center and advancing border (Fig. 151.8). Treatment includes eradication of moisture and use of topical antifungal powder. Cellulitis is most commonly due to *Staph aureus* and *Streptococcus* species in the setting of ulceration or laceration of the skin. It presents with classic signs of erythema, tenderness, and swelling. Oral and topical antibiotics should be prescribed. Folliculitis is due to traumatic removal of peristomal hair and presents with erythema and pustules of the hair follicles (Fig. 151.9). In addition to topical antimicrobial powder as needed, the patient should be advised on proper techniques regarding clipping of peristomal hair and pouch removal including use of an adhesive removal product.

Figure 151.8. Peristomal candida.

Figure 151.9. Folliculitis.

Mucosal Transplantation

If the suture needle is passed from the mucosa and bowel wall though all the layers of the skin at the time of stoma creation, the needle can seed the epidermis with mucosal cells and create small islands of mucosa within the skin (Fig. 151.10). The consequence is discharge of mucus and irritation of the skin. These areas can be treated with a skin barrier powder to absorb the moisture or be cauterized with silver nitrate or electrical cautery. Good surgical technique includes through the subcuticular layer rather than through the epidermal layer.

Psoriasis

Although the underlying cause is unknown, psoriasis is due to hyperproliferation of the epidermal layer resulting in raised red plaques with a white scaly covering often underneath the skin barrier (Fig. 151.11). There may be a family history of psoriasis or personal history of inflammatory bowel disease. It is usually treated with topical steroids. Referral to dermatology may be warranted.

Figure 151.10. Mucosal transplantation.

Stoma Varices

Portal hypertension and venous engorgement can cause a bluish discoloration of the peristomal skin. Bleeding from these varices can be spontaneous and profuse. Bleeding will usually stop with direct pressure, sclerotherapy, or suture ligation but recurrence is common. For repeated episodes, treatment is directed at the liver disease and portal hypertension with propranolol, transjugular intrahepatic portosystemic shunt, surgical shunt, or liver transplantation.

Pyoderma Gangrenosum

A rare complication, it presents as an exquisitely painful, well-demarcated ulcer often have fibrinous exudate and an underlying necrotizing inflammatory process. It is commonly associated with inflammatory bowel disease, rheumatoid arthritis, and multiple myeloma. Patients should be assessed for underlying ongoing intestinal inflammation. Treatment consists of topical high-dose corticosteroids, topical tacrolimus, pain control, and careful attention to local wound care and pouching concerns.

Figure 151.11. Peristomal psoriasis.

CONCLUSIONS

Caring for a new stoma can be a stressful experience for patients. Complications and difficulty in caring for a new stoma can be avoided with proper preoperative education, meticulous stoma creation, proper siting, and regular postoperative education and follow-up. In addition to training in the basic skills of emptying and changing the appliance, patients will require dietary advice and psychosocial support. In follow up they will need assessment of pouch fit and peristomal skin condition to ensure a successful transition to self care. The skills of a WOCN can prove invaluable in caring for these patients.

EDITOR'S COMMENT

Drs. Osborne and Lowry have written a nice chapter containing practical advice for clinicians with regard to the care of all kinds of stomas. Any surgeon who takes emergency general surgery call is likely to be faced with the prospect of needing to create a stoma and to care for a patient with a freshly created stoma. As nicely described in this chapter, when an ostomy is a planned result of an elective procedure, the involvement of a WOC nurse in advance to help select a proper stoma site and to educate the patient can positively impact the patient experience and outcome. Marking the optimal location for a stoma preoperatively enhances the likelihood of a patient's independence in stoma care, predictable pouching system wear times, and resumption of normal activities. Unfortunately, in emergency settings WOC nurses or surgeons with extensive experience in selecting the proper stoma site or creating an ideal stoma are often not readily available. General surgeons who take emergency call should familiarize themselves with the information in this chapter.

A couple of issues brought forth warrant further discussion. Readmissions

following surgical procedures have become an important quality indicator. The Affordable Care Act introduced the Hospital Readmission Reduction Program, which allows the Centers for Medicare and Medicaid Services to penalize hospitals with greater-than-expected rates of readmission. Reducing readmissions has thus become an integral strategy in controlling costs and improving patient care. The rates of readmission following colon resection have been demonstrated to be around 15%. In the state of Pennsylvania, of the more than 10,000 patients undergoing colectomy in 2011, 14.7% were readmitted within 30 days of the procedure. Construction of an ileostomy was among the most significant risk factors for readmission (odds ratio [OR] 2.31, $p < 0.001$). Strikingly similar findings were observed from colectomy cases abstracted for the National Surgical Quality Improvement Program in the Upstate New York Surgical Quality Initiative from June 2013 to June 2014. The implementation of an "ileostomy pathway" has been demonstrated to decrease readmissions, especially related to dehydration in patients with a new ileostomy. In one such pathway, a standardized set of patient education tools was developed. Patient education started with the preoperative visit. All patients were directly engaged in ostomy management and trained in a stepwise progression. Patients were discharged from the hospital with flow sheets, supplies for recording intake/output, and visiting nurse services. Overall readmission rate was 35.4% in a historical cohort of patients prior to implementation of the pathway and 21.4% after implementation. The readmission rate for dehydration was 15.5% prior to pathway implementation, but dropped to 0% in the study group. An understanding that a patient with a new ileostomy is at the significant risk of readmission is essential to decreasing preventable readmissions in these patients.

Parastomal hernias remain a common and challenging problem for patients, WOCN, and surgeons alike. Parastomal hernias can be painful, may lead to hospital admission for obstruction, and can lead to difficulties getting a stoma appliance to fit correctly. Prevention of parastomal hernias when the stoma is created in the original procedure is an inexact science. The technical nuances of properly placing a stoma in the rectus muscle are well described in this chapter. Some surgeons have taken prevention of stoma formation to the next level and prophylactically place mesh at the time of creation of the original stoma. A systematic review and meta-analysis identified six randomized controlled studies including 309 patients randomized to mesh or no mesh placement at the time of colostomy construction. Parastomal hernia occurred in 24.4% of patients with mesh and 50.3% of patients without mesh. Meta-analysis showed a lower incidence of parastomal hernia (relative risk [RR] 0.42, 95% confidence interval [CI] 0.22–0.82) and reoperation related to parastomal hernia (RR 0.23, 95% CI 0.06–0.89) in patients with mesh. Stoma-related morbidity was similar between mesh group and nonmesh group (RR 0.65, 95% CI 0.33–1.30). The authors conclude that prophylactic placement of a mesh at the time of a stoma formation seems to be associated with a significant reduction in the incidence of

parastomal hernia and reoperation related to parastomal hernia after surgery for rectal cancer, but not the rate of stoma-related morbidity.

When parastomal hernias do occur, surgical repair can be associated with significant potential morbidity and a high recurrence rate. A recently published study evaluated all patients with a parastomal hernia repair registered in the Danish Hernia Database from January 1, 2007 to December 31, 2010. The study included 174 patients with a parastomal hernia repair (142 elective and 32 emergency repairs; 56 open and 118 laparoscopic repairs). Median follow-up was 20 months (range, 0 to 47). A total of 13.2% of patients underwent a reoperation in 30 days because of postoperative complications. Mortality in the first 30 days was 6.3%. After 3 years, the cumulated reoperation rate for recurrence was 10.8% (open 17.2% and laparoscopic 3.8%). A systematic review of the literature included 30 studies and evaluated different techniques of parastomal hernia repair. Suture repair resulted in a significantly increased recurrence rate when compared with mesh repair (OR 8.9, 95% CI 5.2–15.1; $p < 0.0001$). Recurrence rates for mesh repair ranged from 6.9% to 17% and did not differ significantly. In the laparoscopic repair group, the Sugarbaker technique had a lower recurrence rate than the keyhole mesh technique (OR 2.3, 95% CI 1.2–4.6; $p = 0.016$). Morbidity did not differ between techniques. The overall rate of mesh infections was low (3%, 95% CI 2) and comparable for each type of mesh repair. The authors of this systematic review concluded, “suture repair of parastomal hernia should be abandoned because of increased recurrence rates. The use of mesh in parastomal hernia repair significantly reduces recurrence rates and is safe with a low overall rate of mesh infection. In laparoscopic repair, the Sugarbaker technique is superior over the keyhole technique showing fewer recurrences.”

Proper creation of a stoma and how to manage complications from a freshly created stoma are important topics for all general surgeons to understand. The utility of a WOCN in helping patients transition to life with a stoma cannot be overestimated. This is an excellent chapter that does a nice job covering the spectrum of issues pertaining to proper care of a stoma.

152 Open and Minimally Invasive Right Hemicolectomy for Cancer

Martin R. Weiser

INTRODUCTION

Complete surgical resection of a primary nonmetastatic colon cancer is the mainstay of treatment and holds the best chance for potential cure. Adequate resection involves removal of the involved segment of large bowel, mesentery, and associated vascular supply to completely excise the locoregional lymphatics at risk for harboring metastatic disease. Complete mesocolic excision should be performed with evaluation of at least 12 lymph nodes. Laparoscopic colectomy after diagnosis of colon cancer is now an accepted approach, with outcomes comparable to those of conventional open surgical resection. Patients treated with minimally invasive approaches have faster recovery, less pain, and similar perioperative and oncologic outcomes. Robotic surgery has come to the forefront as a modality that provides improved optics and overcomes mechanical limitations of straight laparoscopic surgery. The decision on which technique to proceed with depends on surgeon expertise and experience along with patient- and tumor-related factors.

CLINICAL PRESENTATION

In a representative case, a 62-year-old male presented with weakness and fatigue. Workup including a complete blood count (CBC) revealed anemia with hemoglobin of 7.5 g/dL. Upper endoscopy was unrevealing, and colonoscopy identified a 5-cm lesion in the ascending colon. Biopsy confirmed moderately differentiated invasive adenocarcinoma. A computed tomography (CT) scan of the chest, abdomen, and pelvis with oral and intravenous contrast identified an ascending colon lesion with enlarged lymph nodes along the ileocolic artery but no evidence of distant metastatic disease.

INDICATIONS AND CONTRAINDICATIONS

Indications for right colectomy include invasive cancers or noninvasive neoplastic lesions not amenable to endoscopic removal. Patients with history of malignant polypectomy should undergo colectomy if margins are not cleared or there is a significant risk of nodal metastases. The probability of metastases to regional lymph nodes is related to pathologic features including poor differentiation, vascular or lymphatic invasion, and invasion below the submucosa. In general, the presence of one or more of these features is an indication for resection.

Indications for an extended right colectomy include a cancer located in the proximal to mid-transverse colon, synchronous ascending and transverse colon cancers, and multiple adenomas, which may or may not be part of a genetic syndrome. Extended right hemicolectomy proceeds similarly to a standard right hemicolectomy; however, the middle colic pedicle is ligated at its origin. Anastomosis is then created between the terminal ileum and distal transverse colon or descending colon, depending on vascular supply.

The decision to proceed with a minimally invasive or open surgical approach depends on the surgeon's expertise and experience. There are no absolute contraindications for laparoscopic colon cancer surgery; however, cases with intestinal obstruction, large fistulizing tumors, or previous multiple abdominal surgeries with expected extensive abdominal adhesions can be challenging for inexperienced laparoscopic surgeons. Ultimately, the specific surgical approach should be selected with the goals of maximizing the chance of a margin-negative resection, limiting complications, and optimizing recovery.

PREOPERATIVE PLANNING

Preoperative workup includes a complete history and physical examination, including family history, routine laboratory analysis (including carcinoembryonic antigen), radiographic imaging, and medical evaluation for risk stratification. Patients should undergo a full colonic evaluation, with histologic analysis of the colon lesion, prior to initiation of treatment. In general, if colonoscopy is incomplete, then a short-interval postoperative colonoscopy should be performed. In the setting of near obstructing right colon lesions, resection will include the unseen portion of colon, making the latter recommendation unnecessary. Radiologic staging includes CT of the chest, abdomen, and pelvis with oral and intravenous contrast. MRI and PET scans are used selectively if an abnormality noted

on a CT scan needs further definition and would change surgical management. Preoperative medical consultation is obtained based on the patient's history, including geriatric evaluation for fragile patients and those older than 80 years.

Patients receive mechanical bowel preparation including a clear liquid diet and a polyethylene glycol-based agent, in combination with oral antibiotics, on the day prior to surgery. Although controversial, this approach is supported by recent literature. In a study involving over 8,400 patients from the National Surgical Quality Improvement Program-targeted colectomy dataset, patients receiving mechanical bowel preparation with oral antibiotics had lower rates of surgical-site infection, anastomotic leak, and postoperative ileus than other patients.

Thromboembolism prophylaxis includes preoperative subcutaneous heparin, sequential compression devices, postoperative low–molecular-weight heparin, and early ambulation. Modifications of the Surgical Care Improvement Project (SCIP) measures are followed, including maintenance of normothermia, glucose control, appropriate hair removal, and appropriate use of intravenous antibiotics, including administration prior to incision, re-dosing during the procedure, and discontinuation postoperatively.

Patients are managed according to enhanced recovery pathways and are counseled preoperatively on expectations, including early ambulation on the day of surgery and discharge once tolerating diet and passing flatus. Patients are allowed to consume a clear liquid diet the morning of surgery and are given a complex carbohydrate drink including electrolytes and minerals 4 hours before induction of anesthesia. In the preoperative care unit, patients are given gabapentin, diclofenac, and alvimopan. Epidural catheters are utilized for open surgery, and transverse abdominis plane (TAP) blocks are used for minimally invasive procedures. Intraoperatively, intravenous fluids are limited with goal-directed fluid therapy. Ketamine infusions, minimal opioids, and standardized antiemetics are utilized.

SURGICAL TECHNIQUE

Open Right Hemicolectomy

The patient is positioned supine with arms out. A midline incision is typically used. A self-retaining retractor is placed, and the abdomen is thoroughly explored. The surgeon is on the right, and the assistant is on the left. The assistant retracts the right colon to the left, while the surgeon

incises the lateral peritoneal reflection (white line of Toldt) with cautery (Fig. 152.1). The right colon is mobilized off the retroperitoneum, including Gerota fascia, the duodenum, and the head of the pancreas. Care is taken to avoid traction injury to the small veins around the head of the pancreas, and bleeding at this site often requires suture ligatures for control (Fig. 152.2). The cecum and terminal ileum are then dissected anteromedially with care to identify the right gonadal vessels and ureter. This dissection continues to the third portion of duodenum. The hepatic flexure is taken down similarly with cautery.

The right portion of omentum is generally resected en bloc and divided below the right gastroepiploic arcade. The omentum is dissected off the mid-transverse colon and divided between clamps and ties or with the use of a vessel sealing device. The lesser sac is entered. Next, the ileocolic pedicle is identified by retracting the cecum to the right. The ileocolic vessels are located at the caudal portion of the root of the mesentery. The right colic vessels are variable; they are predominantly a branch of the ileocolic pedicle but in rare circumstances are a separate takeoff from the superior mesenteric artery and vein. The ileocolic vessel is cleared at their junction with the superior mesenteric artery and vein, ligated, and divided between clamps and ties or with a vessel-sealing device.

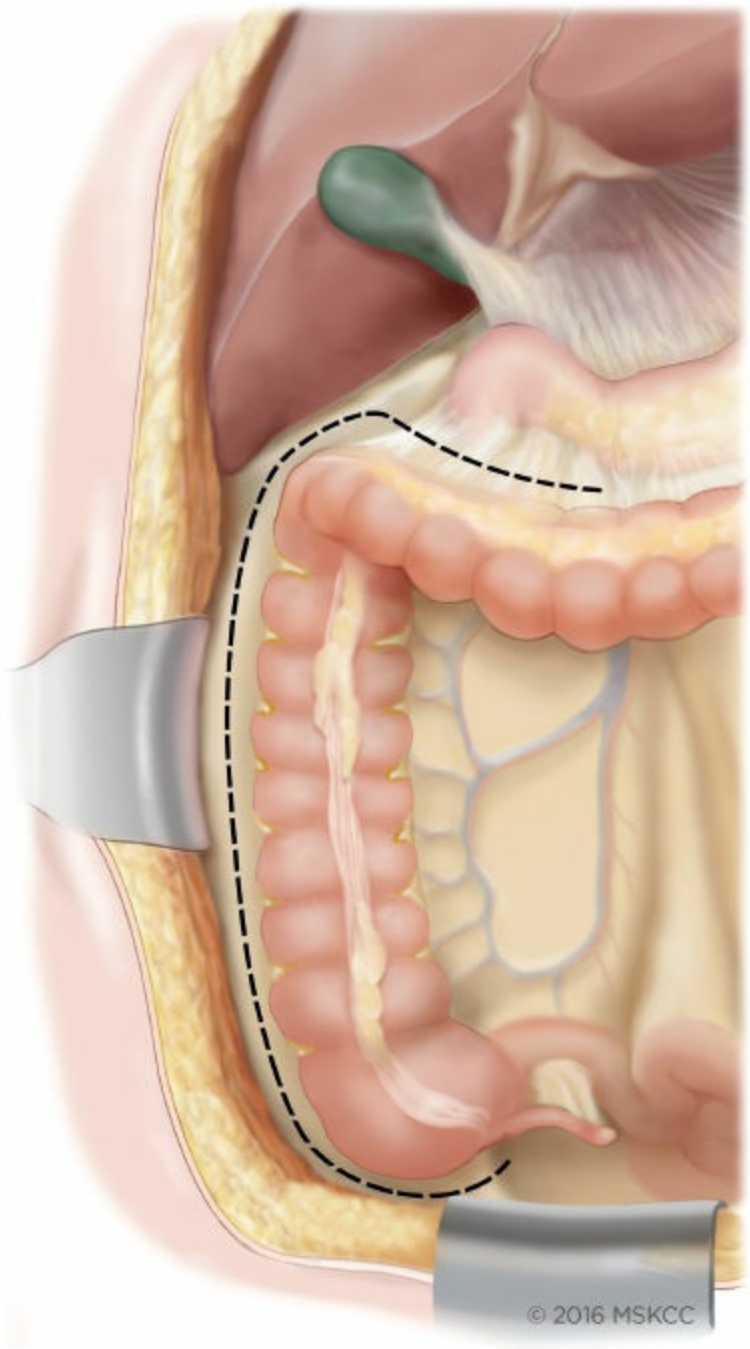

Figure 152.1. In open right hemicolectomy, the assistant retracts the right colon to the left, and the surgeon incises the lateral peritoneal reflection (white line of Toldt) with cautery. (©2016, Memorial Sloan Kettering Cancer Center.)

Dissection continues along the superior mesenteric vein, consistent with the principles of total mesocolic excision, and the middle colic pedicle is identified. Care is taken to resect the right colon mesentery without breach of the visceral fascia. In a standard resection, the right branch of the middle colic pedicle is ligated, and dissection continues along the

mesentery to the proximal/mid-transverse colon. In an extended resection, the middle colic vessels are ligated at their origin with anastomosis between the terminal ileum and distal transverse colon or descending colon (Fig. 152.3). An anastomosis-in-continuity is performed with creation of an enterotomy and a colostomy, deployment of a GIA-80 stapler, and closure of the common enterotomy/colostomy with a TA-90 stapler (Fig. 152.4). A reinforcement suture is placed at the base of the anastomosis, and the mesenteric defect is not routinely closed. The anastomosis is inspected for sufficient vascularity by identifying visible pulsations in the mesentery and checking the color of the mucosa and serosa. Care is taken to ensure proper bowel orientation. A separate, clean set of instruments is utilized for closure.

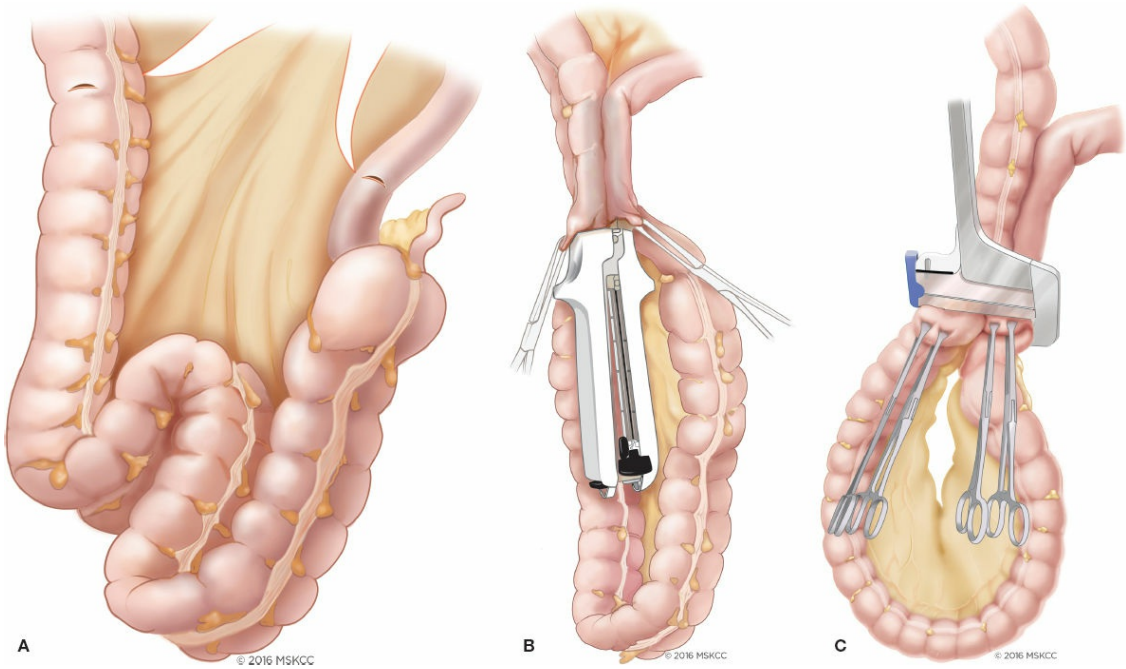

Figure 152.4. Once the colon has been mobilized and pedicles ligated, an anastomosis-in-continuity is fashioned. An enterotomy and a colostomy are then performed (**A**), the GIA 80 stapler is

inserted and deployed (**B**), and the common enterotomy/colostomy is closed by deploying a TA-90 stapler (**C**). (©2016, Memorial Sloan Kettering Cancer Center.)

Laparoscopic Right Hemicolectomy

The patient is positioned supine on the operating room table with both arms tucked, padded, and properly strapped for security. A nonskid cushioned pad is placed under the patient to prevent movement during extremes of tilt. In contrast to the configuration used for open right hemicolectomy, both surgeons usually stand on the left side. Access to the abdomen can be attained via a Veress needle or a cut-down technique utilizing a Hasson trocar. For a Veress needle, the left upper quadrant, 3 cm below the left subcostal border in the midclavicular line (Palmer point), is preferred.

A 5-mm trocar is then placed in the supraumbilical region at the site of planned incision for extraction of the right colon. A zero-degree laparoscope is utilized in this trocar, and then three additional 5-mm trocars are placed in the supraumbilical region and the left upper and left lower quadrants of the abdomen, lateral to the rectus musculature (Fig. 152.5). The patient is put into the Trendelenburg position, and the right side of the table is tilted upward. The omentum is retracted cephalad, and the small bowel is retracted to the patient's left, in order to expose the colonic mesentery and the origin of the ileocolic vessels.

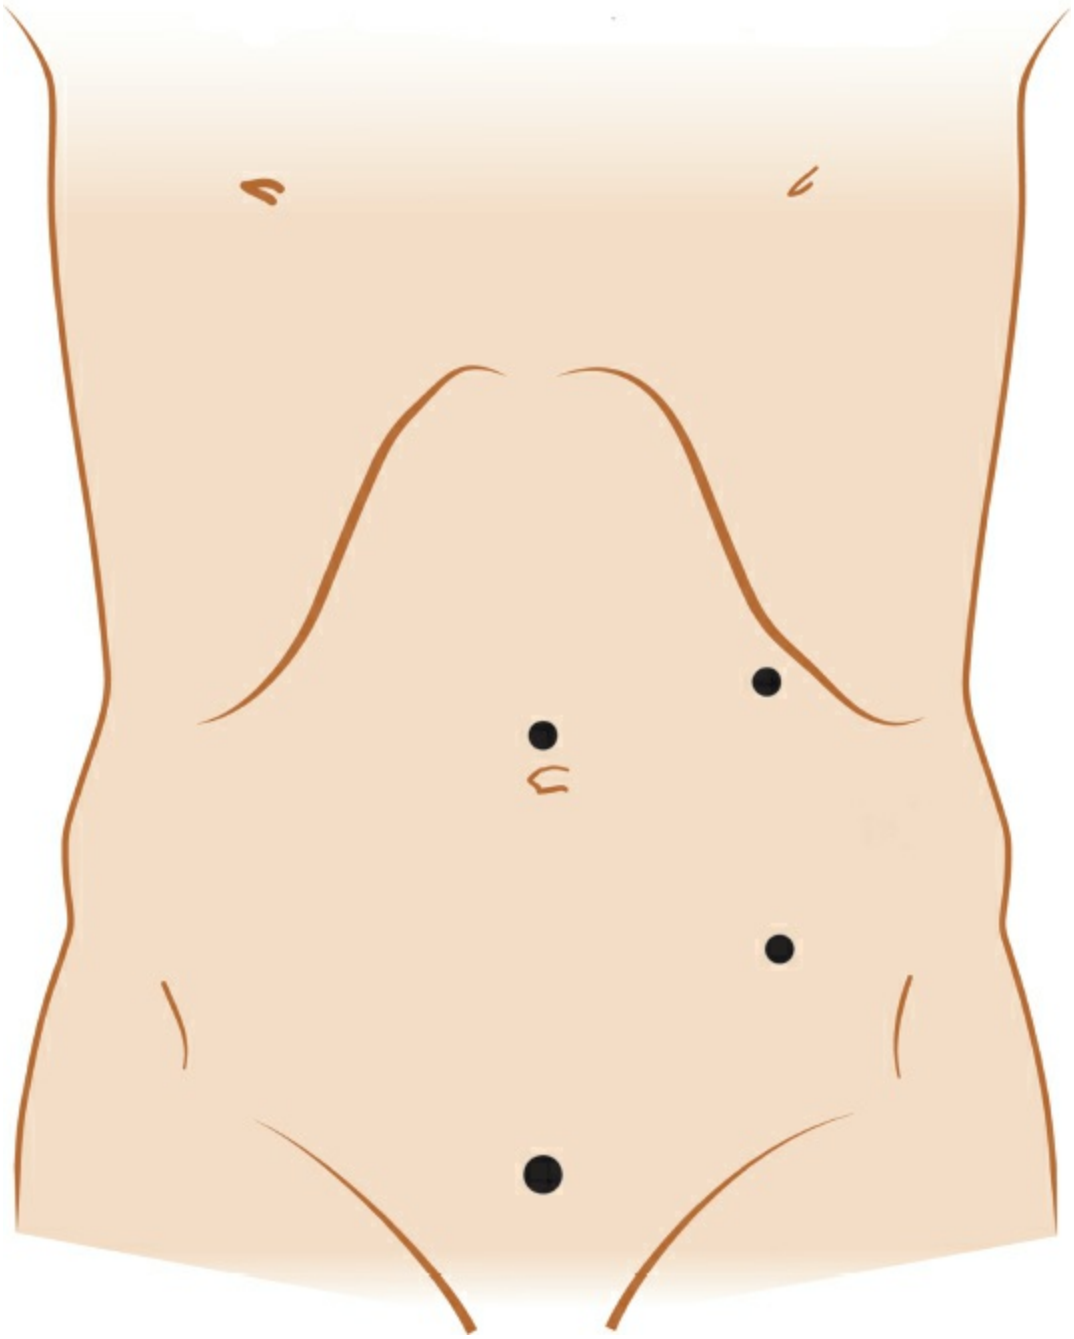

Figure 152.5. Port placement for laparoscopic right hemicolectomy. Filled circle, 8-mm port. (©2016, Memorial Sloan Kettering Cancer Center.)

A medial-to-lateral approach is utilized, and the terminal ileum is placed under tension in the right lower quadrant. The ileocolic pedicle, on tension, becomes apparent, and dissection begins at the level of the duodenum. The peritoneum is incised below the ileocolic pedicle, and in a medial-to-lateral fashion submesenteric dissection proceeds to raise the right colon mesentery off the retroperitoneum, including the duodenum,

Gerota fascia, gonadal vessels, and ureter. Care is taken to avoid breach of the visceral fascial layer around the mesentery. The ileocolic pedicle is cleared, ligated, and divided at its origin with the superior mesenteric artery and vein using a vessel sealing device, endoscopic vascular stapler, or clips. The transverse colon is then placed on tension, and the middle colic pedicle is identified. The transverse mesocolon is scored, and the origin of the right middle colic pedicle is ligated and divided. The mesentery is fully divided to the transverse colon. The omentum is dissected off the distal transverse colon with entry into the lesser sac and prior dissection plane.

Next, the transverse colon is retracted caudal, and the omentum and hepatic flexure attachments are divided medial to lateral. Dissection continues along the white line of Toldt. Again, previous medial-to-lateral submesenteric dissection had freed this area, maintaining the ureter, kidney, and gonadal vessels in the retroperitoneum. The small bowel mesentery is dissected to the level of the duodenum. Finally, the terminal ileum mesentery is divided to the bowel wall. The umbilical port site is enlarged, a wound retractor placed, and the cecum delivered with the help of a laparoscopic bowel grasper. The terminal ileum, right colon, and proximal transverse colon are exteriorized for an anastomosis-in-continuity as outlined for open colectomy. An intracorporeal anastomosis can also be completed laparoscopically with a 12-mm stapler after upsizing the left lower quadrant or suprapubic port. Once the anastomosis is completed, it is returned to the abdominal cavity. The pneumoperitoneum is re-established by closing the wound protector. A final inspection of the abdomen is completed, and the other trocars are removed under direct visualization. The extraction site fascia is closed with interrupted sutures, and the skin is closed with absorbable running suture. Care is taken to avoid the umbilicus when extending the port site for extraction to avoid postoperative hernia.

Robotic Right Hemicolectomy

For the da Vinci Xi platform, the robot is positioned on the patient’s right side. The bedside operating assistant stands on the patient’s left side, and the scrub technician and instrument table should be positioned on the left side near the patient’s feet. The anesthesia team retains its normal position at the head of the bed. The robot is docked from the patient’s right and perpendicular to the operating room table. Video monitors, intravenous

fluid poles, equipment booms, and the anesthesia cart are positioned so as to avoid interference with the cart or robotic arms. Figure 152.6 shows an overhead view of the recommended configuration.

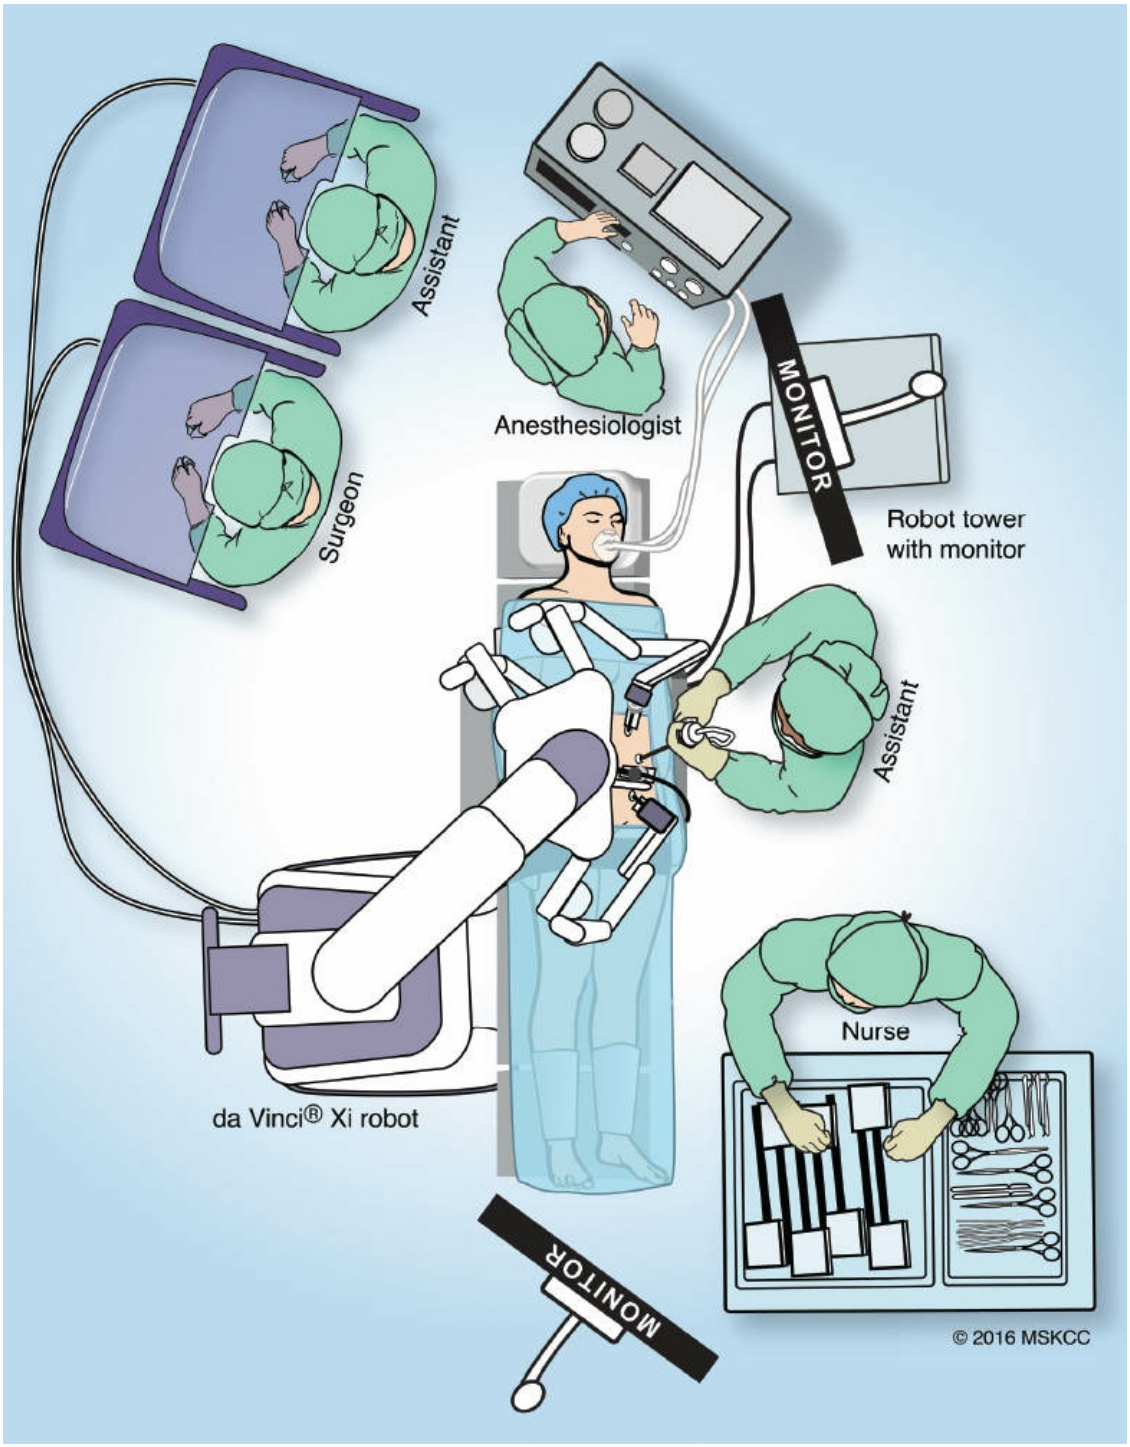

Figure 152.6. Recommended configuration of the operating room for robotic right hemicolectomy. (©2016, Memorial Sloan Kettering Cancer Center.)

A 5-port approach is utilized: 4 robotic ports and an accessory port. Pneumoperitoneum is established with a Veress technique. The umbilical port is placed first. Ports are generally placed midline and to the left of the midline. There is slight variation depending on whether intracorporeal

stapling is planned (Fig. 152.7). Intracorporeal anastomosis utilizes a robotic or laparoscopic stapler introduced through a larger, 12- to 15-mm, supraumbilical port that is extended to become the extraction site. For extracorporeal anastomosis, the specimen is generally extracted via the umbilical port site.

Following placement of ports and prior to docking the robot, the bed's left side is tilted down with slight Trendelenburg positioning. After inspection of the peritoneal cavity, the omentum and the transverse colon are pushed cephalad over the liver tip using laparoscopic instruments. The small intestine is gently moved to the left to expose the ileocolic pedicle and duodenum.

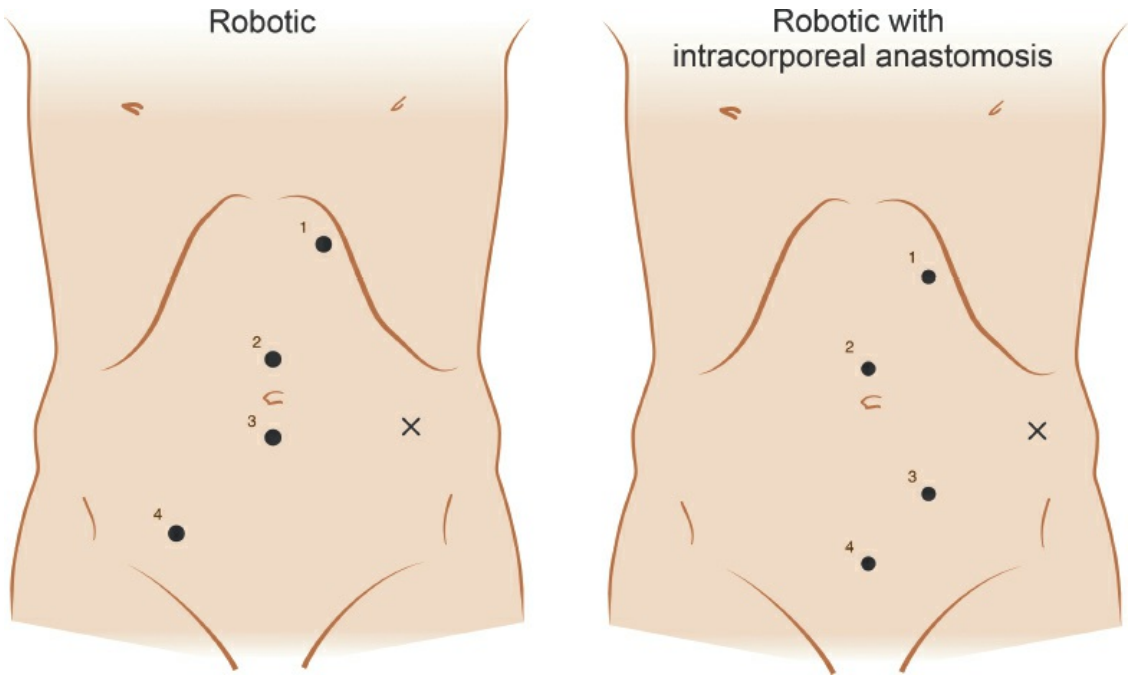

Figure 152.7. Port placement for robotic right hemicolectomy. Filled circle, 8-mm robotic port; ×, accessory port. (©2016, Memorial Sloan Kettering Cancer Center.)

The robotic cart should approach the operating table from the right, perpendicular to the bed. When docking, automatic targeting by focusing the camera on anatomy ensures proper arm alignment to maximize the range of motion and limits arm collision. A robotic 0-degree endoscope is inserted into the #2, supraumbilical port. Arm 1 is typically used with monopolar curved scissors or the robotic vessel sealer. Arm 3 is used with the fenestrated bipolar instrument, and arm 4 is used with the Cadiere grasper. A 5-mm assistant port accommodates the suction irrigator and

laparoscopic bowel grasper used by the bedside assistant during the procedure.

A medial-to-lateral approach is utilized, analogously to laparoscopic right hemicolectomy. The terminal ileum and cecum are retracted to the right lower quadrant with arm 4, which elevates and places the ileocolic pedicle on tension (Fig. 152.8). Using the fenestrated bipolar grasper in arm 3 and the bipolar scissor in arm 1, the peritoneum is incised below the ileocolic pedicle, and the submesenteric dissection is initiated just below the level of the duodenum. Submesenteric dissection continues, visualizing and maintaining the duodenum, Gerota fascia, gonadal vessels, and ureter in the retroperitoneal position (Fig. 152.9). The dissection continues laterally, using the bipolar forceps to provide counter-tension until the abdominal wall is reached. The dissection continues along this plane superiorly and medially over the duodenum and the head of the pancreas.

Once the right colon mesentery is dissected off the retroperitoneum, the vascular pedicles are addressed. Dissecting the anterior wall of the superior mesenteric vein inferior to the ileocolic takeoff facilitates total mesocolic excision and high pedicle ligation. Wristed instruments expedite this dissection. Once the ileocolic artery and vein are ligated and divided, the bedside assistant provides anterior and cephalad retraction on the transverse colon mesentery to facilitate dissection along the superior mesenteric vein. The middle colic vein and then artery are identified, and the right branch is ligated and divided. The right colic pedicle is most commonly a branch of the ileocolic pedicle but on occasion can have separate takeoff from the superior mesenteric vein between the ileocolic and middle colic pedicles. For proximal transverse colon lesions, the base of the middle colic pedicle is ligated and divided, and the gastrocolic vein (gastrocolic trunk of Henle) is divided for resection of the proximal omentum en bloc with the right colon. The mesentery is fully divided to the transverse colon.

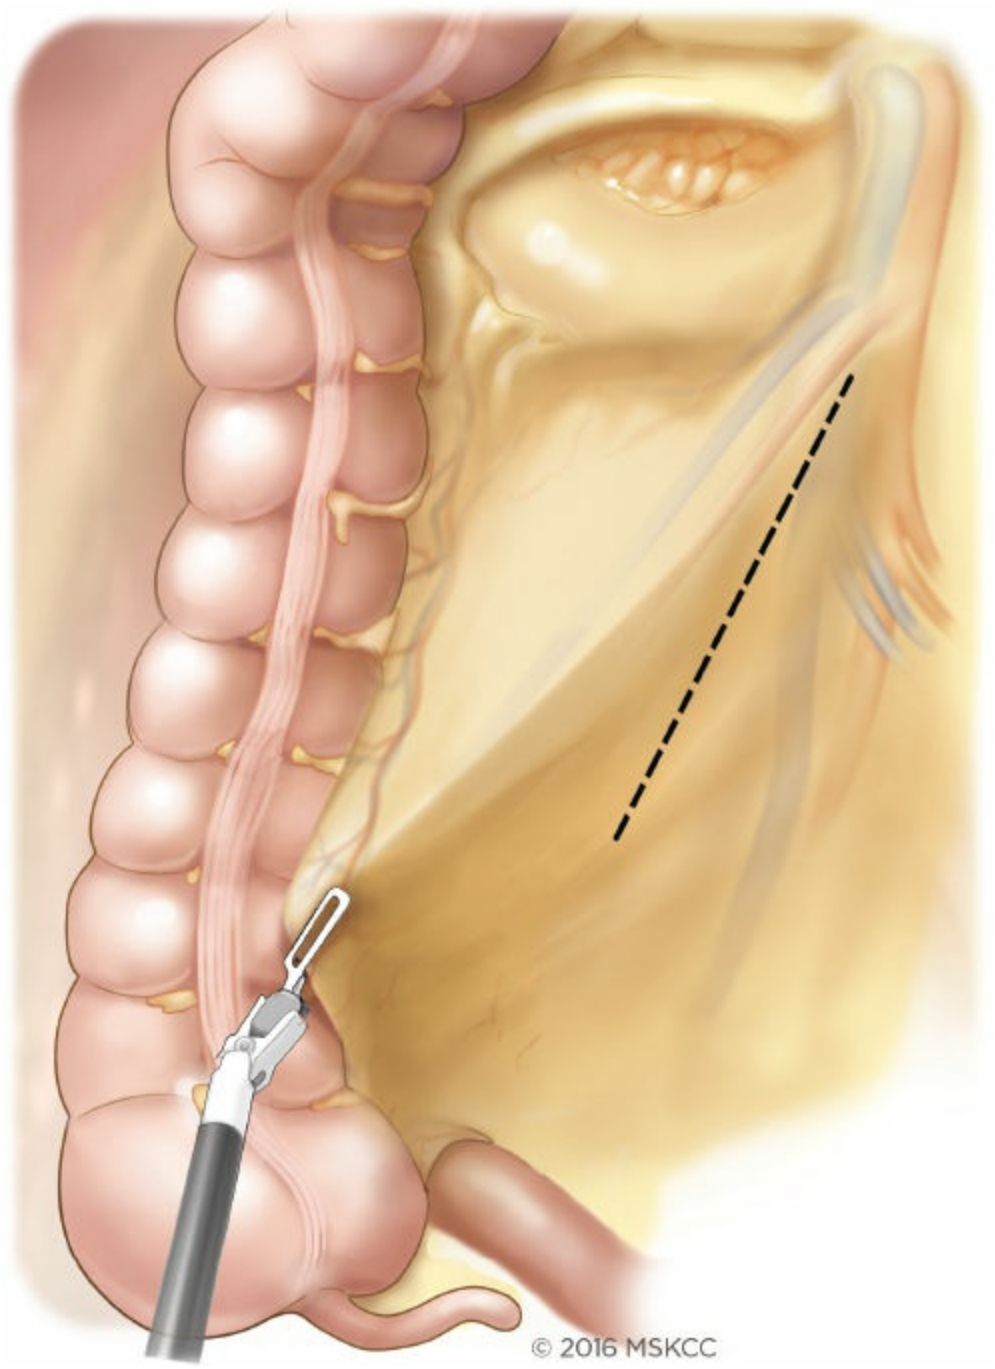

Figure 152.8. The initial step in robotic right hemicolectomy is placing the terminal ileum and cecum under tension to allow identification and incision of the peritoneum below the ileocolic pedicle. (©2016, Memorial Sloan Kettering Cancer Center.)

Next, the omentum is dissected off the distal transverse colon with entry into the lesser sac. The omentum attached to the proximal transverse colon is generally divided outside the gastroepiploic arcade. For proximal transverse colon lesions, the arcade is dissected with the specimen. With the transverse colon placed on caudal tension, omental attachments and the

hepatic flexure are divided in a medial-to-lateral fashion. This dissection is facilitated by previous submesenteric dissection. Arms 2 and 4 provide retraction, while the scissor or vessel sealer divides tissue. Finally, the cecum, appendix, and terminal ileum are mobilized by dividing the peritoneal attachments in the right lower quadrant.

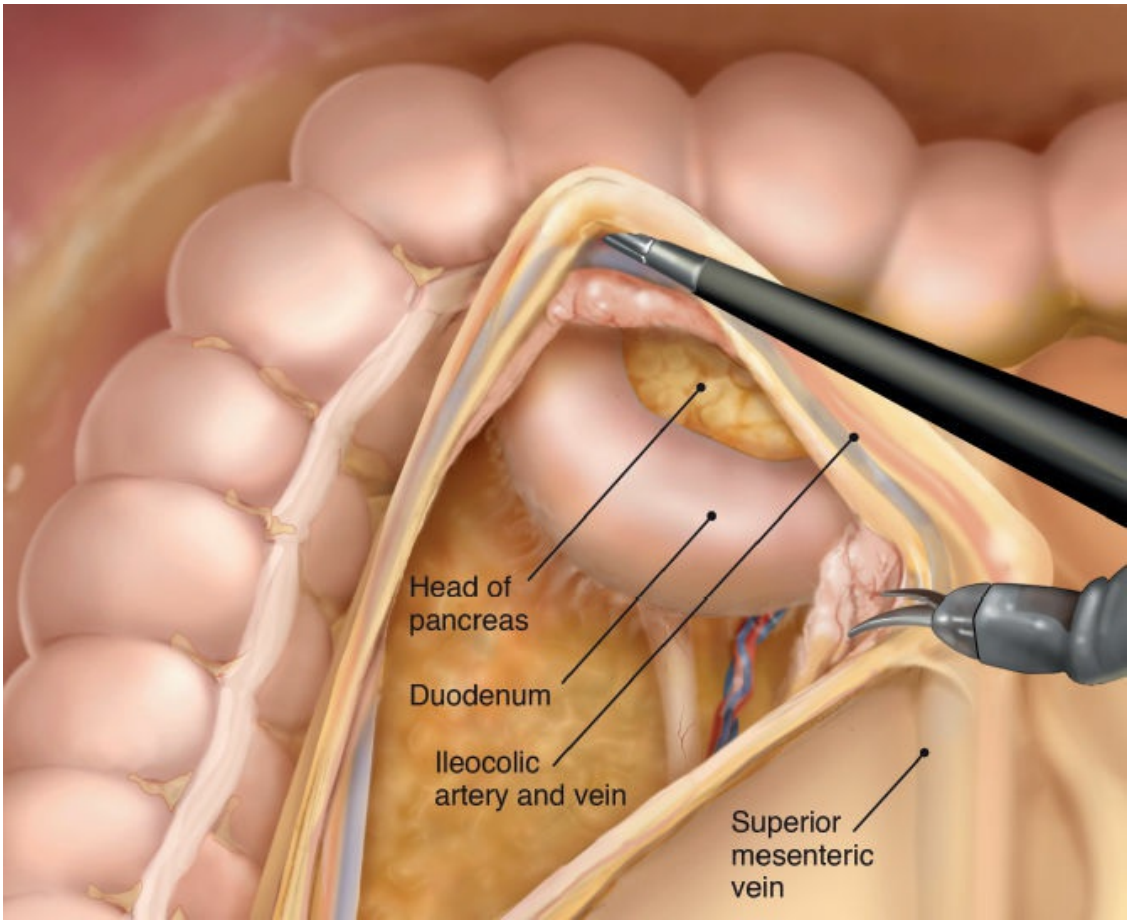

Figure 152.9. Medial-to-lateral dissection of the mesentery off the retroperitoneum, including the duodenum and the head of the pancreas. (©2016, Memorial Sloan Kettering Cancer Center.)

The terminal ileum and cecum are then dissected off the retroperitoneum, and dissection continues, inferior to superior, along the white line of Toldt until the prior superior dissection is met. Again, previous medial-to-lateral submesenteric dissection had freed this area, and the ureter, kidney, and gonadal vessels will be in the retroperitoneum. The small bowel mesentery is freed to the level of the duodenum. Finally, the terminal ileum mesentery is divided to the bowel wall.

For extracorporeal anastomosis, since the entire right colon is mobilized and hemostasis is confirmed, the terminal ileum is held with a laparoscopic

bowel grasper through the assistant port. The robot is then undocked, releasing the robotic arms but leaving the trocars in place. The robotic cart is backed away from the patient. The camera port incision is extended to a length that will accommodate specimen removal, and a wound protector is placed. The terminal ileum and right colon are delivered through the wound protector. An anastomosis-in-continuity is fashioned in a stapled side-to-side, functional end-to-end anastomosis manner. After the procedure is completed, the base of the anastomosis is reinforced with suture, and mesenteric defect is not closed. The wound protector is closed, and repeat insufflation allows for laparoscopic inspection for hemostasis with visualization of port removal. The fascia from the specimen retrieval site is irrigated, and interrupted sutures are used to close the fascia with absorbable monofilament sutures. The extraction site is closed in two layers with interrupted absorbable monofilament facial sutures and absorbable skin sutures.

For intracorporeal anastomosis, the terminal ileum and the transverse colon are divided with a laparoscopic or robotic stapler. An isoperistaltic side-to-side anastomosis is created with alignment of the distal terminal ileum medial and adjacent to the transverse colon. To ensure antimesenteric orientation, an enterotomy and a colostomy are created at the distal aspect of the ileum. The broader jaw of the robotic or laparoscopic stapler is first inserted into the colotomy, and then the ileum is brought over and the slimmer stapler jaw is positioned in the enterotomy. The stapler is deployed, and the common enterotomy/colostomy is closed with intracorporeal interrupted or running suture. The suprapubic stapling port is enlarged (generally by creating a Pfannenstiel incision) for specimen extraction after placement of a wound protector. The wound protector is then closed, insufflation is re-established, the abdomen is inspected for hemostasis, and ports are removed under direct visualization.

POSTOPERATIVE CARE

As mentioned above, patients undergoing colectomy are managed according to enhanced recovery pathways. Patients are given clear liquids in the recovery room and ambulate the day of surgery. Narcotic use is minimized with use of nonsteroidals. The diet is advanced to regular, and the Foley catheter is removed on postoperative day 1. The goal is to discharge minimally invasive surgery patients on postoperative day 2 and

open surgery patients on postoperative day 3. Patients are discharged home on regular diet and nonsteroidals with limitation on heavy lifting, pushing, and pulling.

The National Comprehensive Cancer Network, American Society of Clinical Oncology, and American Society of Colon and Rectal Surgeons all recommend adjuvant chemotherapy for patients with stage III colon cancer. Controversy remains regarding the use of adjuvant therapy for stage II patients, and a medical oncology consultation is advised.

EXTENT OF LYMPHADENECTOMY

Complete mesocolic excision (CME), which includes dissection in the mesocolic plane with central vascular ligation, has been proposed as a means of improving lymph node yield and subsequent outcomes. The goal is to remove the entirety of the mesocolon along embryologic tissue planes with transection of the critical vasculature at the origin. The surgical group in Erlangen, Germany, reported 5-year survival rates of >85% for patients undergoing CME. This technique does require detailed knowledge of anatomical planes and avoidance of any breaches of visceral fascial layers, which theoretically could lead to tumor cell contamination of the peritoneum and metastases. In addition, work from Japan indicates that a D3 lymphadenectomy along with CME may further improve outcomes, in keeping with resecting at least 10 cm proximal and distal to the tumor edge (pericolic lymph node metastases beyond 10 cm are quite rare). D3 lymphadenectomy consists of skeletonizing and ligating the vasculature flush with the origin of the involved vessels (e.g., ileocolic) followed by en bloc removal of the lymphatics along the lateral and ventral portion of superior mesenteric vein to Henle's gastrocolic trunk and final transection of the involved distal vasculature (e.g., right colic and right branch of middle colic vessels) at the respective origins. The principles of CME are sound, and the procedure can be completed using both minimally invasive and open approaches as appropriate for each patient.

OUTCOMES

The laparoscopic approach to colon resection for cancer has several advantages over the open approach, such as shorter hospital stay, reduced postoperative ileus, earlier resumption of oral nutritional intake, reduced pain, and improved cosmesis. A number of prospective randomized trials have proven that laparoscopic colectomy improves short-term outcomes

and provides oncologic outcomes similar to those achieved with open colectomy.

The benefits of robot-assisted colectomy compared to the conventional laparoscopic approach are debatable. Retrospective reviews and a recent meta-analysis indicate that robotic and laparoscopic colectomies are associated with similar complication rates and short-term outcomes. The robotic approach shows trends for lower rates of conversion to open surgery and higher rates of intracorporeal anastomosis. In the only randomized clinical trial comparing laparoscopic to robotic right hemicolectomy, surgical and oncologic outcomes were similar. However, time, operating room charges, and overall costs are higher for robotic colectomy.

Patient selection criteria for robotic right hemicolectomy are similar to those of traditional laparoscopic surgery. Due to the enhanced visualization and increased dexterity provided by the robotic platform, this approach is particularly helpful in patients with bulky lymphadenopathy requiring dissection close to the superior mesenteric artery and vein. The robotic platform also facilitates the performance of a total mesocolic excision.

COMPLICATIONS

With the use of Enhanced Recovery After Surgery protocols and perioperative care bundles, the rate of complications after right hemicolectomy is 5% to 10%. Leak rates are 0.5% to 1% and can usually be managed with bowel rest, antibiotics, and possible percutaneous drainage if clinically necessary. Wound infection rates are <5% and can usually be managed with local care.

CONCLUSION

Complete surgical resection is the mainstay of treatment and holds the best chance of potential cure for patients with primary nonmetastatic colon cancer. Adequate resection entails the removal of the involved segment of bowel, mesentery, and associated vascular supply to completely excise the lymphatics. Precise surgical technique along with CME should allow for complete lymphadenectomy and evaluation of at least 12 lymph nodes for accurate staging. Minimally invasive approaches such as laparoscopic colectomy are preferred; however, the ultimate choice of technique depends on surgical expertise along with patient and tumor factors. Robot-

assisted surgery has come to the forefront as a modality that provides improved visualization, avoids the mechanical limitations of laparoscopic surgical techniques, and does not compromise oncologic outcomes.

EDITOR'S COMMENT

Dr. Weiser in his excellent chapter on right colectomy covers all aspects from open to laparoscopic to robotic, in a tour de force fashion to describe conventional lymphadenectomy, as well as complete mesorectal excision, as well as the Japanese D3 lymphadenectomy. It is clear that wide resection will give superior oncologic results. A minimally invasive procedure with a minimal resection will clearly not help the patient as much. As is true in multiple different areas of this text, Dr. Weiser has shown here, performing a technique well, no matter what type of access, is essential.

Perhaps the prototypical operation today combining the special skill of Colorectal Surgeons, General Surgeons, and Surgical Oncologists are lesions involving the right colon. It is a common operation well done and tolerated nicely by patients well into their eighties and older. Lesions of the right colon are remarkable in that due to the large diameter of the right colon they may often reach a fairly advanced stage prior to diagnosis and may often only be diagnosed based on the presence of the significant anemia. Obstructive symptoms are typically uncommon unless lesions involve the ileocecal valve become quite large. Because right hemicolectomy and in fact segmental colectomy is done by so many different types of surgeons as described above, It has been and will likely continue to be used as a "Quality barometer" by many different types of organizations including insurance carriers, health care bodies such as the centers for Medicare and Medicaid Services (CMS) and others. The death rate for this operation in most teaching hospitals is approximately 1.5% and there is a very narrow range of acceptable practices (mean ± SD 1.56% ± 1.27%) (Billeter AT, Polk HC Jr, Hohmann SF, et al. Mortality after elective colon resection: the search for outcomes that define quality in surgical practice. *J Am Coll Surg* 2012;214(4):436–43; discussion 443–4). Individuals have been encouraged to monitor these rates and use them as an index of overall quality of surgical and anesthesia care, and this is probably an ideal operation for that purpose. There are abundant standards by which one can judge oneself and one should see that they are used and implemented widely.

Several years ago there was much furor among colorectal and general surgeons regarding the explosion of studies regarding the avoidance of bowel preparation and the association of this with improved surgical outcomes of decreased complication rates including lower rates of surgical site infection. This was a relative nonissue in the right colon, since it had been long recognized that one could safely operate in the right colon without a formal bowel preparation.

There has long been recognition that surgical technique is important in conducting cancer surgery. This has often been debated, similar to the debates raging many decades ago regarding the "no touch technique" proposed by Dr. Turnbull. Most recently refinements in technique regarding colon cancer surgery have focused on completeness of mesenteric excision as discussed in this chapter by Dr. Weiser. Hohenberger and colleagues have introduced the concept of complete mesocolic excision (CME) analogous to total mesorectal

excision as proposed by since the mid-1980s. This type of wide mesenteric excision has been associated with impressive 5-year survival rates. Recently, reports of a modified complete mesocolic excision by Cho et al. in a series of nearly 800 patients undergoing this technique for right-sided colon cancer with a mean follow-up of over 60 months, shows an impressive overall 5-year disease-free survival rate of 83% (Cho MS, Baek SJ, Hur H, et al. Modified complete mesocolic excision with central vascular ligation for the treatment of right-sided colon cancer: long-term outcomes and prognostic factors. *Ann Surg* 2015;261(4):708–15). Even their 5-year disease-free survival time for stage III disease was 68.5%.

Several papers have evaluated differences between the Eastern and Western approaches to lymph node and mesenteric resection (Xie D, Yu C, Gao C, et al. An Optimal Approach for Laparoscopic D3 Lymphadenectomy Plus Complete Mesocolic Excision (D3 + CME) for right-sided colon cancer. *Ann Surg Oncol* 2017;24(5):1312–13). Xie et al. reported on the combination of are forming a laparoscopic D3 lymphadenectomy in addition to complete mesocolic excision for right-sided colon cancer with a short follow-up; however, they found that this is technically possible, at the median 12-month follow-up there was no case of recurrence (Kobayashi H, West NP, Takahashi K, et al. Quality of surgery for stage III colon cancer: comparison between England, Germany, and Japan. *Ann Surg Oncol* 2014;21 Suppl 3:S398–404). Several recent studies have stressed the importance of preoperative evaluation of venous anatomy in laparoscopic cases for right colon cancer (Ogino T, Takemasa I, Horitsugi G, et al. Preoperative evaluation of venous anatomy in laparoscopic complete mesocolic excision for right colon cancer. *Ann Surg Oncol* 2014;Suppl 3:S429–35). Also, although right hemicolectomy is generally a simple, straightforward operation, because of the proximity of the duodenum with locally advanced right-sided colon cancer, it can quickly turn into a very difficult operation if it is locally involving the duodenum in some cases requiring partial duodenectomy or even en bloc pancreaticoduodenectomy (Cirocchi R, Partelli S, Castellani E, et al. Right hemicolectomy plus pancreaticoduodenectomy vs partial duodenectomy in treatment of locally advanced right colon cancer invading pancreas and/or only duodenum. *Surg Oncol* 2014;23(2):92–8; Zhang J, Leng JH, Qian HG, et al. En bloc pancreaticoduodenectomy and right colectomy in the treatment of locally advanced colon cancer. *Dis Colon Rectum* 2013;56(7):874–80).

As in many other chapters of Mastery, in the part of Mastery of Surgery devoted to colorectal surgery, Dr. Weiser brings up the issue of enhanced recovery after surgery pathways and emphasizes the earlier mobilization and avoidance of narcotic pain medication to facilitate an earlier hospital discharge. In addition, giving patients a carbohydrate drink 4 hours before induction of anesthesia, has also been shown to result in improved postoperative outcomes, as has been the use of epidural catheters, as well as transverse abdominis plane blocks and goal-directed fluid therapy, all of which he mentions.

The enhanced recovery after surgery (ERAS) concept has gained traction

around the world. It is safe in the majority of patients, but it is the creation of expectations in the patient's mind on the occasion of a preoperative visit that makes this work best, that is, one is expected to be out of bed the night after operation, one is expected to be walking around the hospital unit the next morning, and having some oral intake that same day. This is the essence of the process. If the patient's expectations are realistic, while this comes much later, the most important piece of the case, aside from technical issues, may be in the creation of clear laminated handouts that can be placed in the hands of the patient, and/or the lead caregiver at the time of the final preoperative office visit. These sort of things are lost in the torrent of paper that is thrown at discharging hospital patients in the United States now. This is the time to emphasize things to be watched for in the postoperative care and to address issues of anxiety and unnecessary readmission.

Whether one should or should not use oral antibiotics in addition to the prevailing use of systemic cephalosporins for operative would site evaluation remains to be proven. It is essential to choose a systemic antibiotic whose properties include wound penetration, and persistence in the wound is important. The SCIP program has led to proper preoperative initiation in more than 95% of the cases and termination within a 24- to 48-hour period, in more than 90% of patients. Both of these are desirable trends.

There is a token commentary on venous thromboembolism prophylaxis. Much of this discussion has been distorted by pharmaceutical manufacturers of anticoagulants. Those patients who have had prior thromboembolic events, and/or have severe varicose veins represent a different and legitimate higher-risk group. No one has yet to prove the superiority of these agents over well-used programs of early ambulation and inexpensive compressive hose use in average-risk patients. Do recall that the data very clearly show that VT prophylaxis is not warranted in patients undergoing ambulatory care or outpatient operations.

The open operation is increasingly disappearing for right hemicolectomy. Again, the reader needs to be reminded that transverse incisions are uncommonly well tolerated by elderly patients, and provides the ideal approach to the middle colic vessel. Regarding the extended right colectomy shown in Figure 152.3, in the patient with significant vascular disease, care should be taken to ensure that there is sufficient collateral blood supply. Techniques such as near infrared angiography are useful and are available on many robotic platforms.

153 Open and Minimally Invasive Left Hemicolectomy for Neoplasms of the Descending Colon, Sigmoid, and Upper Rectum

Zuri Murrell and Michael J. Stamos

LEFT COLECTOMY FOR NEOPLASMS OF THE DESCENDING COLON, SIGMOID, AND UPPER RECTUM

Definition

Colectomies for neoplasms in the descending and sigmoid colon, and the upper rectum are surgical operations that are defined by the colorectal vascular anatomy that parallels the lymphatic drainage (Fig. 153.1). Adequate treatment and staging of colorectal cancer is dependent upon the excision (and identification) of a minimum of 12 lymph nodes and obtaining adequate margins of bowel wall and mesentery both proximal and distal to the neoplasm. A left hemicolectomy is generally defined as a resection from the distal transverse colon to the junction of the descending/sigmoid colon. When utilized for cancer, this includes a high ligation of the left branch of the middle colic and left colic arteries, thus ensuring removal of an adequate number of lymph nodes. In reality, this is an uncommon operation, primarily due to the relative infrequency of neoplasms of the descending colon. A sigmoid resection for cancer involves removal of the sigmoid segment of the colon from its junction with the descending colon (or more proximal as needed to attain adequate margins) to the proximal rectum (or recto sigmoid junction), which is identified by the taenia confluence and/or the sacral promontory. This procedure entails a high ligation of the sigmoidal arterial pedicle, or the inferior mesenteric artery (IMA), near its origin. It is important to remember that tumors of the upper rectum are treated similarly to sigmoid colon cancers, with resection as initial treatment in a patient without

distant metastasis. For malignancies of the upper rectum, this should always include a high ligation of the IMA. It is also important to remember that no matter how this operation is performed, the resected specimen should be the same. We will further refer to these various operations as “left-sided colectomies” in this chapter.

Presentation

Colon cancer commonly presents asymptomatically or with minimal symptoms, and is typically discovered by colonoscopy. When symptoms are present, they often include abdominal pain and changes in bowel habits. Upper rectal and sigmoid cancers often present with the passage of bright red blood per rectum. Severe changes in bowel habits can signify a large bulky tumor. Presenting symptoms can impact the planned surgical approach, as up to 20% of patients present with obstruction or perforation.

Preoperative Planning

A successful surgical outcome begins well before the actual operation starts. A detailed history and physical examination are the key, with special attention given to any obstructive like symptoms and presence of any palpable abdominal mass. If present, these findings can portend a large bulky tumor, affecting both the types of imaging studies needed, and the surgical approach (laparoscopic vs. open). The patient should also be thoroughly questioned about any pre-existing anal incontinence as this can be exacerbated by left hemicolectomy, sigmoid colectomy, and an anterior resection due to postoperative alterations in the consistency and volume of stool. A sphincter exam also needs to be performed to determine any sphincter laxity at rest. The external anal sphincter is evaluated by having the patient perform an anal squeeze while a digit is inserted in the anus. If the patient has pre-existing symptoms of anal incontinence and the sphincter complex is weak, there should be careful consideration for the placement of a stoma as opposed to performing an anastomosis.

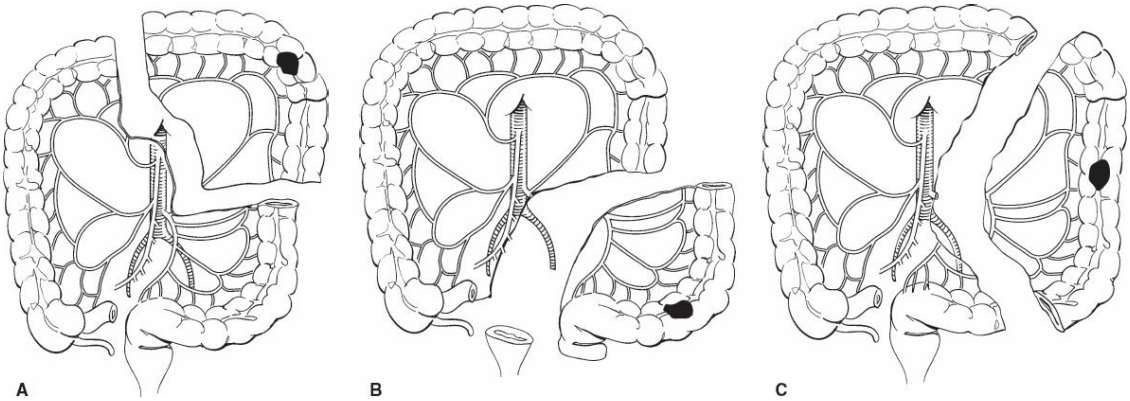

Figure 153.1. Recommended lines of resection for tumors within the various areas of the left colon. Note that resections are based on the vascular supply to the tumor. **A.** Tumors located at the splenic flexure and left colon require resection of lymph nodes along the left branch of the middle colic, left colic, and first sigmoidal pedicles. **B.** Tumors in the sigmoid colon generally require lymphadenectomy along the inferior mesenteric artery. **C.** Rarely, there may be lesions at the junction of the left and sigmoid colon, which lies in the narrow area between the left colic and first sigmoidal pedicles; these may benefit from ligation of the inferior mesenteric artery at its origin to include lymphadenectomy along all the left colic and superior rectal pedicles.

Per NCCN (National Comprehensive Cancer Network) guidelines, a computed tomography (CT) scan of the chest, abdomen, and pelvis should be performed to rule out any distant metastasis, which if present may require further workup and a different initial therapy. The authors recommend the surgeon perform his or her own endoscopy for any tumor within the sigmoid or rectum to properly identify the site of the tumor, as colonoscopy reports are notoriously inaccurate when only the distance from the anal verge is used for tumor localization. For minimally invasive operations, the location of the tumor has to be explicitly defined in order to determine port placement and specimen extraction site. A mechanical bowel prep is performed that empties the colon of stool so that intraoperative endoscopy is possible for tumor and margin determination, and so that the colon can be easily manipulated, especially during minimally invasive surgery.

Intraoperative patient positioning is a common feature of all approaches for a left hemicolectomy, sigmoid colectomy, and anterior resection. The patient is placed in lithotomy position with the arms tucked bilaterally

(Fig. 153.2). The bilateral tucking of the arms prevents brachial plexus injuries and allows for retractor placement in case of conversion to an open approach, and for surgeon comfort during minimally invasive approaches. In cases of morbidly obese patients whose size does not allow bilateral tucking of the arms on the table, the right arm should always be tucked. The lithotomy position allows easy access to the rectum for intraoperative endoscopy, for circular stapler placement for anastomotic creation, and endoscopic leak testing of the anastomosis. Padded Allen-type stirrups are used to help prevent peroneal nerve injury. For minimally invasive approaches, the authors recommend the patient be placed on a foam pad and secured to the bed to ensure the patient does not slip while in steep positional changes that are key to performing this operation successfully. Rotating the bed 10 to 20 degrees counterclockwise before starting can open up the right side of the patient for the surgeon and first assistant, a useful maneuver for a laparoscopic operation. Within 30 minutes before the first incision, preoperative intravenous antibiotics are given; the authors prefer 2 g of cefotetan or 1 g of ertapenem. The authors also like to use a rectal irrigation catheter (30-cc Foley catheter with a large three-way connector), which serves the purpose of further cleaning the colon and allowing creation of an anastomosis in a stool-free environment, and also has the benefit of keeping the distal colon and rectum decompressed during the operation, facilitating handling of the bowel segments and minimizing chance of inadvertent injury.

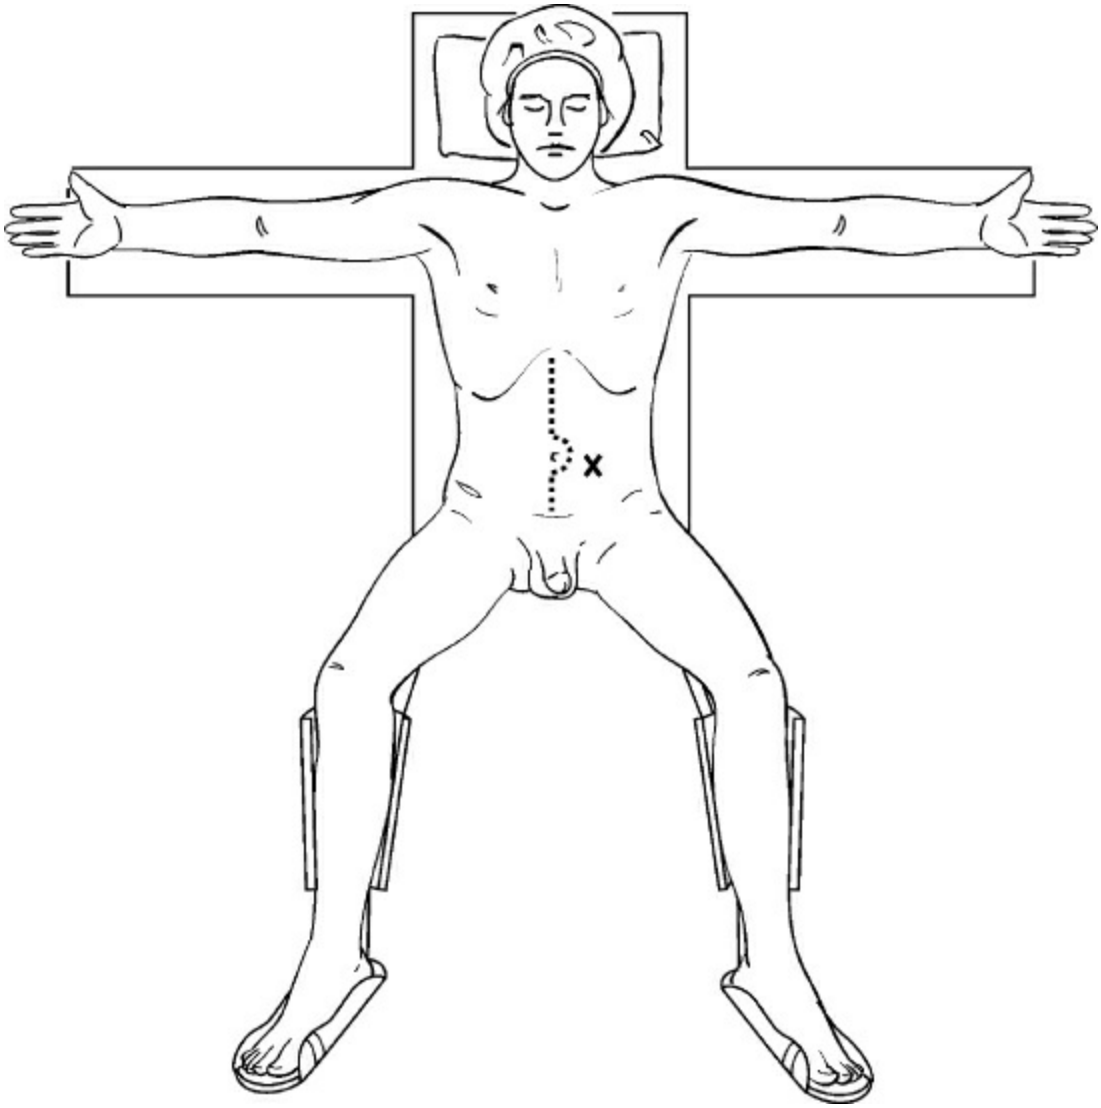

Figure 153.2. Recommended positioning of a patient for left hemicolectomy. Note that the arms are in the abducted position to allow placement of a self-retaining retractor. The patient is marked preoperatively for optimal placement of a colostomy, should this prove necessary. Access to the rectum should be available to facilitate a stapled low anastomosis.

Open Left-Sided Colectomy

The left colon and/or sigmoid can be mobilized from a medial to lateral or a lateral to medial approach. For the open operation, the authors prefer the “traditional” lateral-to-medial approach. However, for surgeons trying to ascend the learning curve of minimally invasive left colectomy, a medial to lateral approach should be utilized to facilitate the understanding of this anatomic perspective. After a midline incision is performed, a self-retracting wound protector is placed in the abdomen. This has the dual

function of keeping the incision free of contamination, and serves as a hands-free retractor that provides excellent exposure. A Bookwalter retractor is our preferred option. The small bowel contents are swept to the right upper quadrant and covered and protected with a moist lap pad. The white line of Toldt is incised from the sigmoid colon to the splenic flexure. The colonic mesentery is elevated off the retroperitoneum, and the left ureter is identified and left alone, while the colonic mesentery is brought to the midline. Mobilizing the ureter is meddlesome and unnecessary and will make any later reoperation much more difficult. The IMA is ligated just distal to the origin at the aorta, or just distal to the left colic takeoff, at surgeon's discretion, and the inferior mesenteric vein (IMV) is ligated just below the inferior border of the pancreas, or at the level at the IMA ligation. The splenic flexure can be taken down by carefully dividing the splenocolonic attachments laterally, and the renocolic attachments posteriorly. Medially, the omentum can be dissected from the anterior surface of the left side of the transverse colon and the lesser sac entered. The mesentery of the distal transverse colon and proximal descending colon needs to be preserved, ensuring that the marginal artery and other collateral vessels (Arc of Riolan) remain intact. This requires mobilization of the mesentery off of the retroperitoneum. Adhesions between the proximal descending colon and the distal transverse colon, which are commonly seen, should be sharply divided at this time to ensure adequate length for the anastomosis. Occasionally the left branch of the middle colic will need to be ligated to allow the creation of a tension-free anastomosis. The bowel is then transected proximally using two Kocher clamps at the selected location, largely based on blood supply and lymphatic drainage, but at least 5 cm proximal to the tumor. The bowel is then transected distally, again 5 cm distal to the neoplasm (2 cm for the rectum), typically using either a GIA stapler or a TA stapler. A 2-0 monofilament suture is then used to secure a purse-string in the proximal segment after dividing the colon just proximal to the Kocher clamp, using Allis clamps to triangulate the bowel and facilitate a baseball stitch purse-string. It is also important to confirm adequacy of blood supply at this time. It is important to shield off the abdominal incision and to "segregate" all instruments from this dirty part of the operation to minimize surgical site infections (SSI). Gloves of all team members are then also changed and an end-to-end stapled anastomosis is performed using a circular stapling device (Figs. 153.3 and 153.4). After firing the circular stapler, the two "donuts"

are inspected to ensure that they are complete. Next the anastomosis is submerged under water and occluded proximally and a flexible sigmoidoscope is used to insufflate air to directly visualize the anastomosis as well as evaluate for a leak. The authors also recommend taking a picture of the anastomosis to have further objective evidence of completeness.

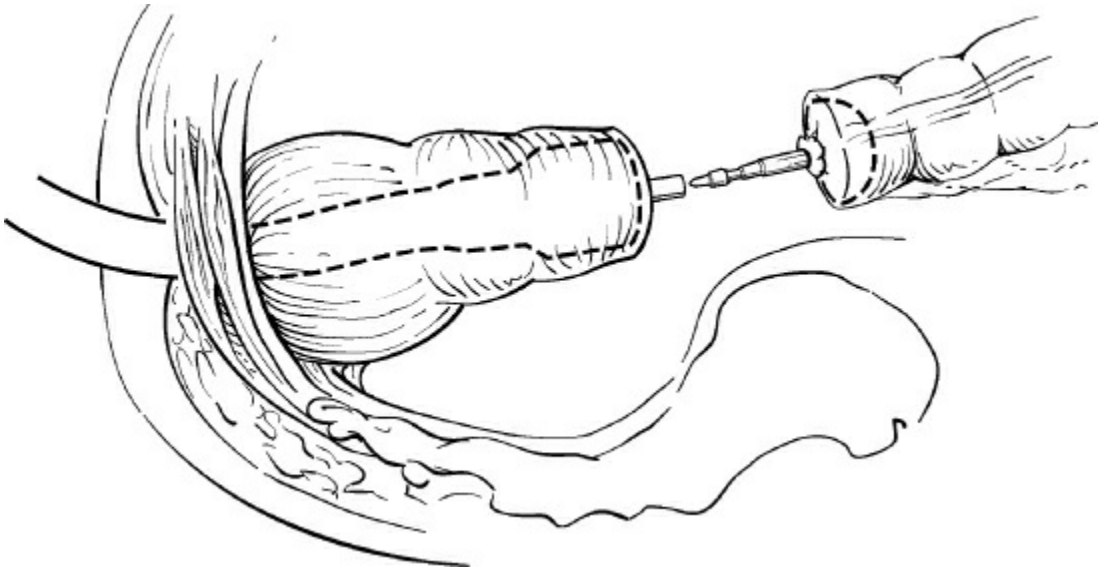

Figure 153.3. The anvil is secured in the descending colon with a purse-string suture, and the shaft of the stapler placed per anus and advanced to the stapled end of the rectum.

Laparoscopic Left-Sided Colectomy

When performing a left-sided colectomy laparoscopically, the importance of the operating room table position through various stages of the procedure cannot be stressed enough. Correct positioning allows gravity to help retract various organs, such as the small bowel, away from the operative field. The positioning for this procedure is the same as previously discussed with the caveat that a foam “egg crate” style pad is placed on the operating room table and the patient is secured to it. This prevents patient slippage and thus possible nerve injury to both upper and lower extremities when patients are in steep Trendelenburg and other gravity-defying positions during surgery.

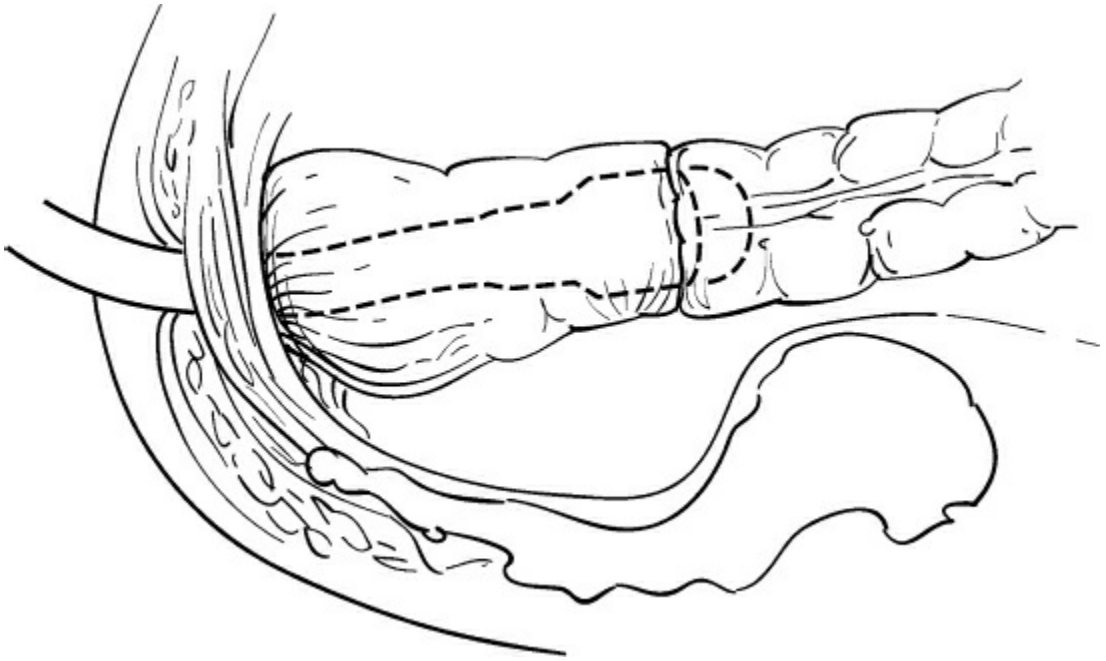

Figure 153.4. The anvil is secured to the shaft of the stapler, closed, and deployed.

This operation is begun by making an incision for a 5-mm trocar 2 fingerbreadths lateral and to the upper right of the umbilicus. The authors prefer this port placement for the camera to provide improved optics for the surgery and decrease tunnel vision as well as to minimize the interference of the small bowel. Many surgeons use the umbilicus for the camera port placement, but the only advantage of this location is cosmetic. After an incision is made, the fascia is elevated, and a Veress needle is placed and a pneumoperitoneum to 15 mm Hg is established. After the 5-mm trocar is placed, the abdomen is explored with the intention of determining if there is any evidence of metastatic disease. Steep reverse Trendelenburg position is used to evaluate the liver, and steep Trendelenburg position is used to evaluate the pelvis. Another 5-mm trocar is placed under direct visualization, at the epigastric area, 2 fingerbreadths below the xiphoid and just to the right of midline to avoid the falciform ligament. A 12-mm trocar (to accommodate a planned stapling device) is placed at the right lower quadrant location, lateral to the rectus abdominis muscle (Fig. 153.5). The patient is then placed in steep Trendelenburg position with the left side slightly tilted up and the small bowel is swept to the upper abdomen away from the pelvis. A medial-to-lateral approach is begun. The mesosigmoid is grasped, exposing the inferior mesenteric vascular pedicle, which is then grasped and elevated via an atraumatic instrument, and the visceral peritoneum is incised with cautery just

posterior to this vessel, and this incision is extended from just distal to the IMA origin down below the sacral promontory in the pelvis (Fig. 153.6). The visceral peritoneum is elevated and a retromesenteric plane is developed. This plane, which is a natural embryonic tissue plane, should be avascular. The atraumatic instrument in the epigastric port is used to elevate the IMA and visceral peritoneum anteriorly, while the instrument in the RLQ port brushes the retroperitoneal structures in a posterior motion, until the ureter is identified (Fig. 153.7). Once this structure is seen and confirmed (by visualizing its vesiculations), the ureter is left in its normal position and this dissection is carried laterally to the posterior medial border of the colon. This dissection is where most errors are seen. Once the IMA is identified and the dissection is to the left of this vessel, it is critical to angle anteriorly to avoid dissecting into the retroperitoneum. This can initially seem counterintuitive due to the angle of the camera and the dissecting device. Once this is done, a high ligation of the IMA vessel can be done in a safe manner, most commonly with a bipolar energy device (Fig. 153.8). The IMV is ligated at the same level, unless a low anastomosis is planned, in which case it is divided more cranially just below the inferior border of the pancreas. The retromesenteric dissection is carried out upward toward the splenic flexure and distally at least 5 cm distally to where the tumor is located. Using the same table position, the lateral dissection is begun. The colon is grasped and retracted medially and the white line of Toldt is incised, typically starting at the sigmoid and carried superiorly to splenic flexure (Fig. 153.9). Midway through this dissection, the patient is placed in the reverse Trendelenburg position. This allows gravity to participate and help drop the colon and flexure into a more advantageous position. It is important to stay close to the colon laterally, and as the splenic flexure is released, the lesser sac can be entered. Alternatively, while in this position, the omentum can be elevated superiorly, dissected off of the distal transverse colon and the lesser sac entered in this fashion, from a medial approach. This medial-to-lateral supracolic approach to the splenic flexure can be very useful in cases of high or difficult splenic flexures. Once the omentum is dissected off of the anterior surface of the left side of the transverse colon, the entire left “hemi colon” should now be freely mobile. As mentioned above in the description of an open left colectomy, adhesions between the proximal descending colon and the distal transverse colon, which are commonly seen, should be sharply divided at this time to ensure adequate length for

the anastomosis. The dissection can be continued medially or even to the right of midline when necessary, depending on the location of the pathology. If indicated by the planned extent of the resection, the mesentery of the middle colic vessels can be divided. Once this mobilization is done, it is important to confirm the planned extent of resection, and to be certain that the proximal site of resection will easily reach into the pelvis to anastomose to the planned site of distal resection without tension. The patient is then placed back into Trendelenburg position and the distal site of resection is fully mobilized. Endoscopic visualization and confirmation of tumor location can be critical at this time for small tumors. Tattoo marks are often not accurate enough to select the resection margins. Once the distal transection site is chosen, the mesentery is then divided with a bipolar device up to the bowel wall. A linear stapler is then inserted into the RLQ trocar and the distal colon divided, typically at the recto sigmoid junction. At this time, the proximal colon staple line is grasped with a locking grasper through the RLQ trocar and a small pfannenstiel incision is made (typically 4 to 6 cm). A transverse incision is made through the fascia, and it is dissected from the rectus muscle superiorly toward the umbilicus and inferiorly down to the pubis. The rectus muscles are then retracted laterally, the linea alba is incised and the peritoneum is entered sharply and a wound protector/ retractor is placed in the wound. The colon is delivered and then divided at the planned proximal resection site, at least 5 cm proximal to the site of the tumor, and sent off of the field for pathologic evaluation. If there is any doubt about the margins or the presence of the tumor within the specimen, it is essential to grossly confirm its presence before proceeding. It is also important to confirm adequacy of blood supply at this time. The proximal end of the colon is then opened, and a circular stapler anvil is inserted after a running 2-0 monofilament purse-string suture is placed. At this time, all dirty instruments are isolated and gloves are changed to avoid contamination. The colon containing the anvil is then returned to the abdominal cavity, a locking grasper is placed through the RLQ trocar and the anvil grasped in preparation for completion of the circular stapled anastomosis, and pneumoperitoneum is reestablished. This can be accomplished with the retractor in place or more easily by closing the pfannenstiel incision. The circular stapler sizers are then placed sequentially transanally into the rectum and guided carefully to the staple line. This is done so the operator learns the luminal course for easy circular

stapler placement, and it also ensures that the stapler will reach the staple line. Once the stapler is placed into position, the anvil and stapler are joined. The stapler spike should come out of the rectal or colon stump adjacent to the staple line. It is the authors' preference to bring it out just anterior to the staple line to avoid stapling through the mesorectum. However, in low anastomoses in female patients it is preferred that the pin is brought out just posterior to the transverse staple line, to avoid possible vaginal entrapment. As the stapler ends are brought together, care is taken to make sure the colon is straight and the mesentery is not twisted, and that the small intestine has not migrated under the descending colon mesentery. In women it is preferred that the pin is brought out posterior to the transverse staple line, to avoid possible vaginal entrapment. After the anastomosis is created, it is air tested as previously discussed. In review, the three key steps in performing a successful laparoscopic left colectomy are high vessel ligation, full mobilization of the descending colon and splenic flexure, and dissection of the omentum from the anterior surface of the colon. These steps ensure the creation of a tension-free anastomosis, and decrease the chance of an anastomotic leak.

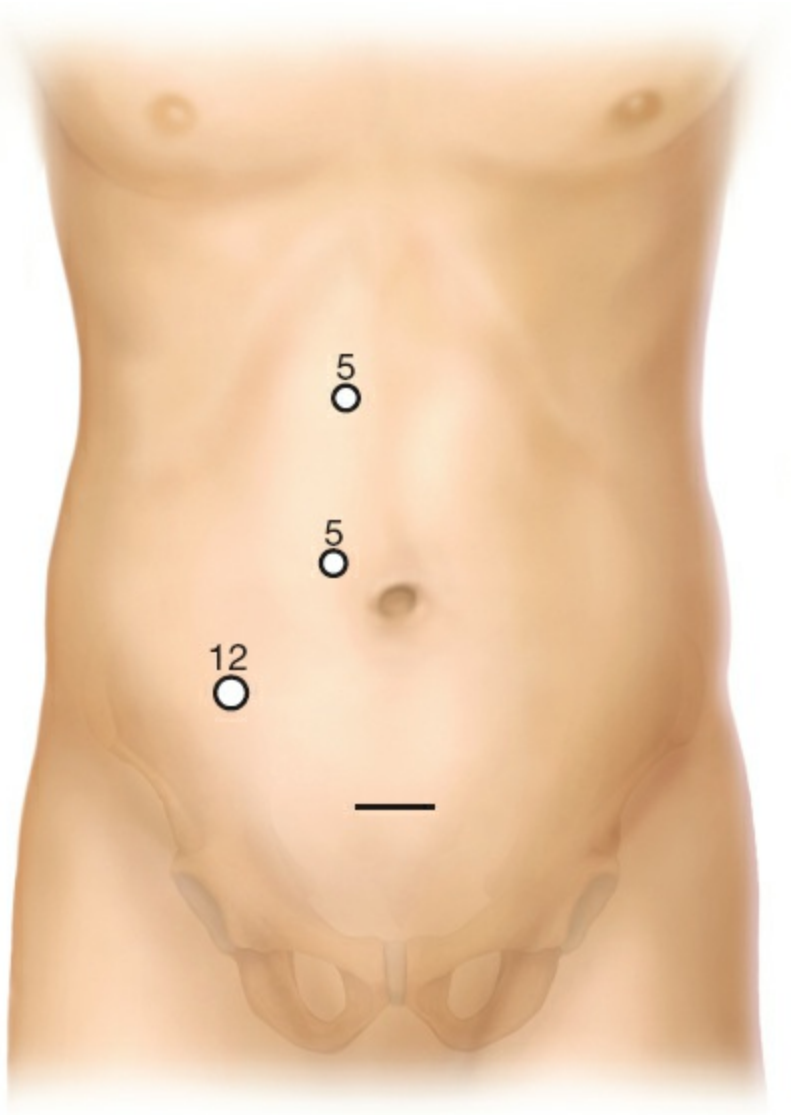

Figure 153.5. 12-mm trocar (to accommodate a planned stapling device) is placed at the RLQ location, lateral to the rectus abdominis muscle.

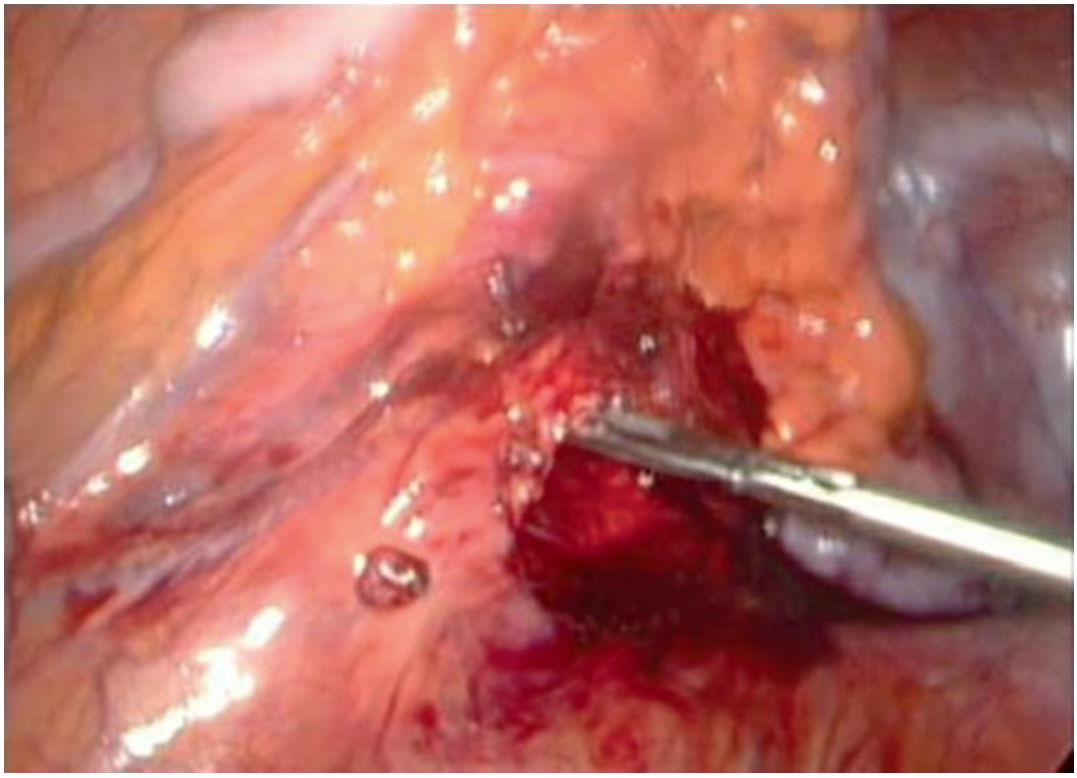

Figure 153.6. The inferior mesenteric vascular pedicle is then grasped, and the visceral peritoneum is incised with cautery just posterior to this vessel.

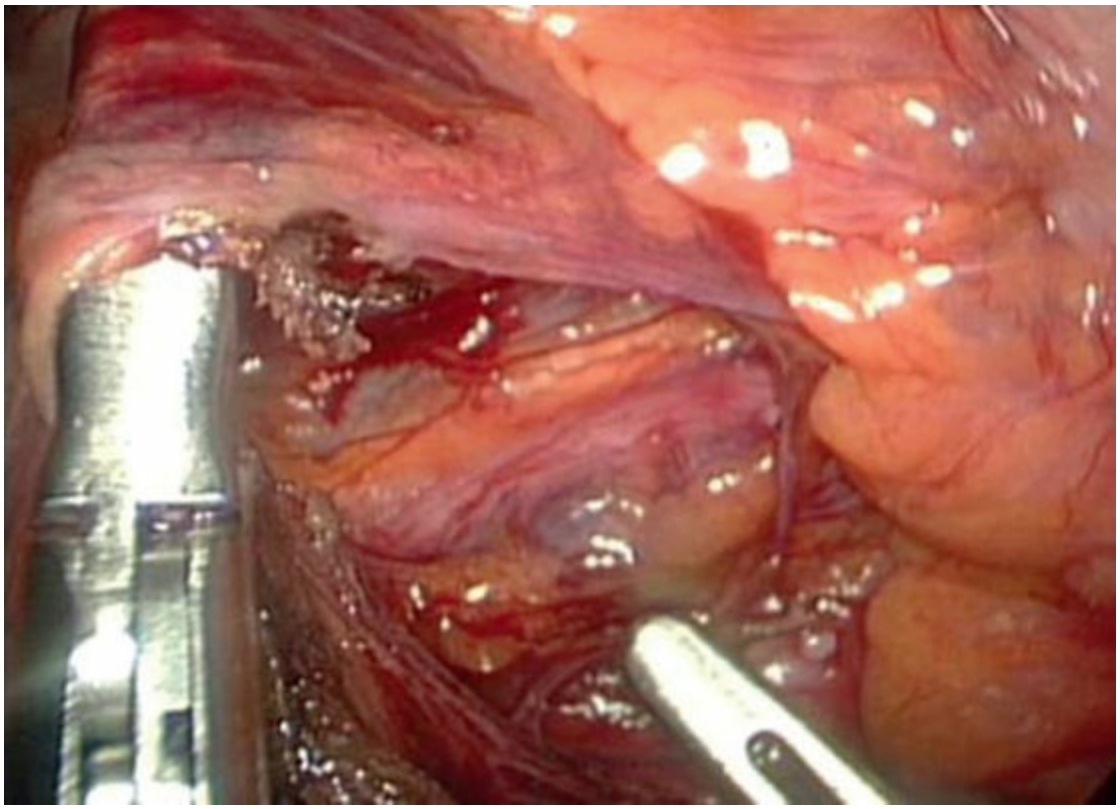

Figure 153.7. The ureter is identified.

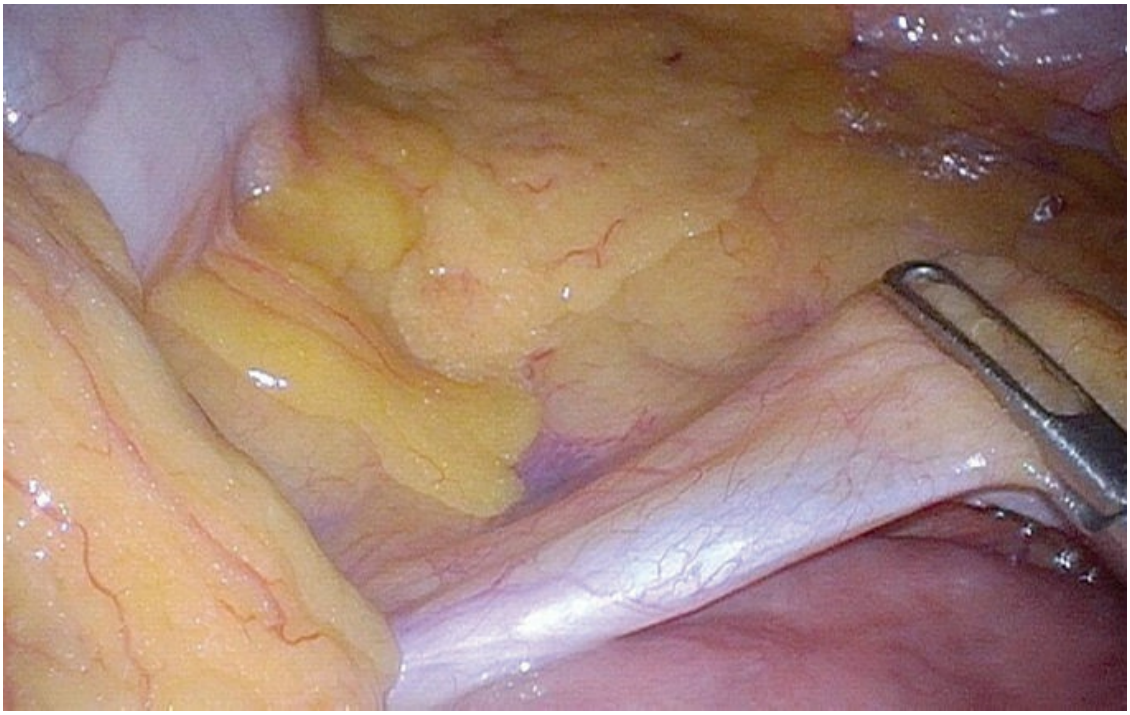

Figure 153.8. High ligation of the IMA.

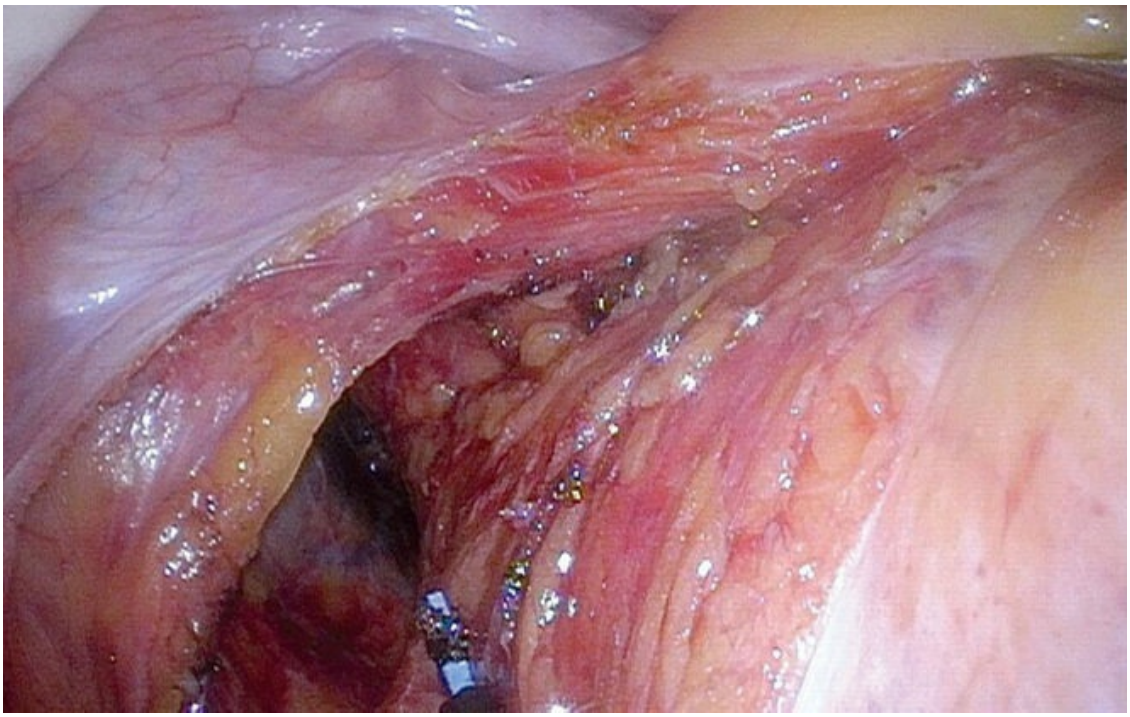

Figure 153.9. White line of Toldt is incised, typically starting at the sigmoid and carried superiorly to splenic flexure.

Robotic Left-Sided Colectomy

The process of performing a left colectomy robotically is similar to the laparoscopic approach with two main differences.

The first is that the operating room table position cannot be changed once the robot is docked. The patient is placed in lithotomy secured on an egg crate, with the table in steep Trendelenburg position with left side up, and is maintained as such throughout the robotic portion of the case. Because of this limitation, it may be necessary to redock the robot for the splenic flexure mobilization, or perform this portion of the operation laparoscopically either in advance or following the robotic portion.

Secondly, the procedures differ in the trocar site placement and number (total of six). Once a pneumoperitoneum is established, the 12-mm camera port is placed 1 cm above the umbilicus. A da Vinci instrument arm port 13 mm (stapler port) is placed along the spinoumbilical line (SUL) 1 cm medial to the mid-clavicular line (MCL). The spinoumbilical line is a line joining the left anterior superior iliac spine and the umbilicus. A second instrument arm port 8 mm is placed 1 cm medial to the left MCL and 2 cm superior to the SUL. A third arm port 8 mm is placed 1 cm to the right MCL, 2 to 3 cm below the costal margin. A fourth port 8 mm is placed 6 to 8 cm superior to the umbilicus on the left anterior axillary line, and the third arm is moved here during the pelvic part of the operation. Lastly a port for the surgical assistant is placed 8 to 10 cm cephalad to the instrument arm and 2 cm medial to the right MCL. It is important to note that all of these measurements are done after insufflation (Fig. 153.10).

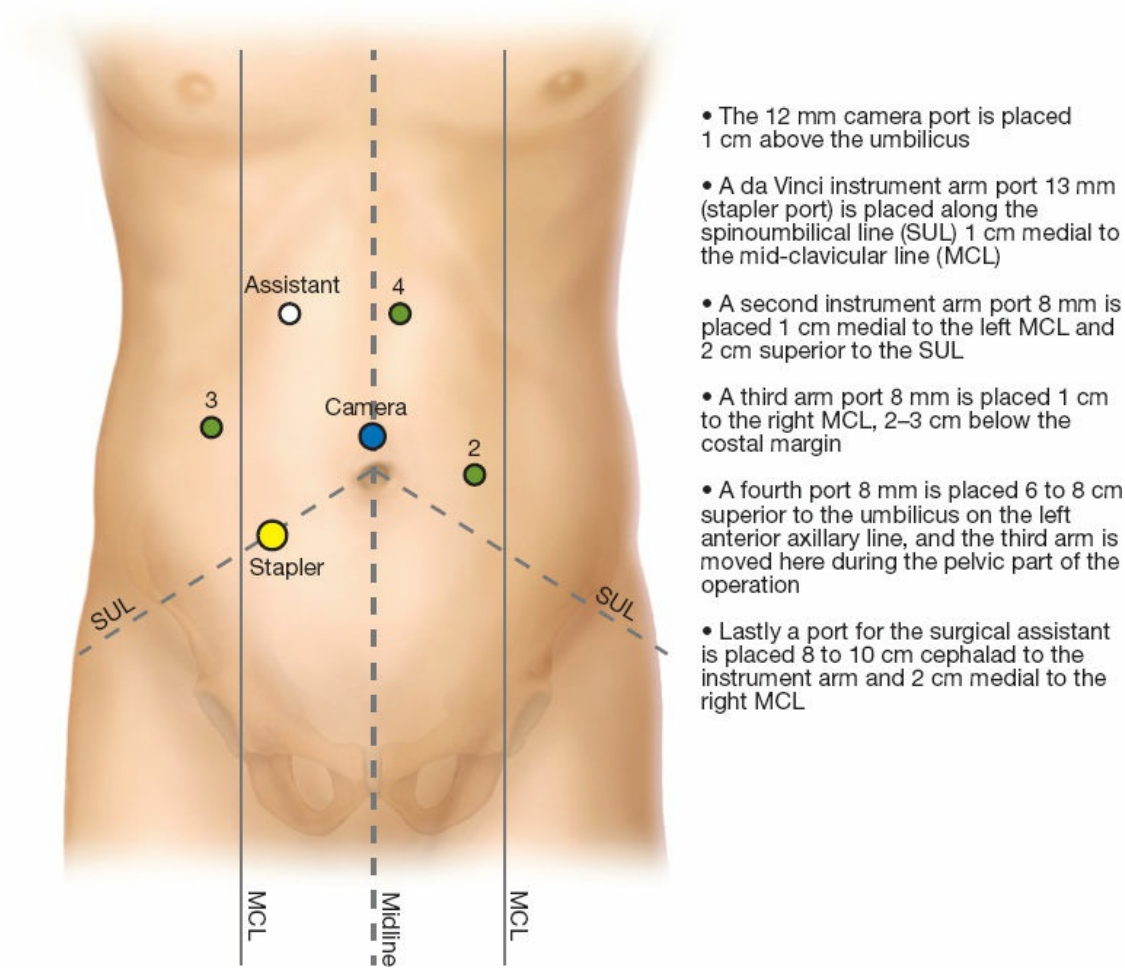

Figure 153.10. Port placement for robotic colectomy.

The patient cart is positioned and the robot is docked. The surgery is performed in a medial-to-lateral approach as with the laparoscopic approach, with a pfannenstiel incision made for colonic extraction.

Anterior Resection

Anterior resections are traditionally done for high rectal and recto-sigmoid cancers that are treated the same as colonic neoplasms, with surgery being the first-line therapy for nonmetastatic disease. It is important that a proper tailored (e.g., not a complete mesorectal excision) mesorectal excision be performed no matter which surgical approach is used. Adoption of a proper mesenteric excision (e.g., TME) has resulted in improved oncologic outcomes with a decrease in loco-regional recurrence.

Preoperative planning for this procedure as well as patient positioning is the same as for a left colectomy.

The authors perform this procedure in an identical fashion to a left-sided colectomy in terms of incision, mobilization, and blood vessel

division. Prior to distal bowel transection however, a proximal mesorectal dissection and excision are done. The aim of this procedure is to remove the upper rectum along with its mesorectum that contains the draining lymph nodes. The retro-mesenteric plane established during the left-sided colectomy is continued inferiorly, anterior to the presacral fascia and staying posterior to the fascia propria of the rectum. This dissection is carried 2 to 5 cm distal to the tumor in the upper rectum. The authors prefer to begin this dissection posterior to the rectum until the distal margin of resection is reached, then proceeding laterally, and lastly anteriorly. It is critically important to divide the mesorectum tangentially with the rectum at the location of the planned distal resection. It is important to be aware of the hypogastric nerves at the sacral promontory, which should be preserved if not involved with tumor (Fig. 153.11). After the distal bowel transection site is identified, the mesorectum is dissected from the rectum, and transected using bipolar energy. The rectum is then transected using a GIA stapler, or alternatively (for an open case) a linear TA stapling device, with a bowel clamp proximally to avoid spillage. The rest of this procedure is performed as previously mentioned in the left colectomy section.

Postoperative Care

The authors have adopted an accelerated recovery program. For the aforementioned operations, we employ the use of our pain team, and patients are given an epidural or a transverse abdominis plane block along with a patient-controlled anesthetic device. Unless a pelvic dissection is done, the foley catheter is removed within the first 24 hours postoperatively, or when the epidural is removed (when used). In cases involving a pelvic dissection, the catheter is removed 3 days after surgery. Clear liquids are started on postoperative day 1 with diet advanced to a regular diet as soon as tolerated. Patients are encouraged to ambulate within 24 hours of surgery. This pathway is adopted for all patients undergoing left colectomy and anterior resection for all surgical approaches, and has been proven safe and decreased patient length of stay.

COMPLICATIONS

Leaks

The most dreaded complication is an anastomotic leak. Two factors

associated with anastomotic leaks include low anastomosis and preoperative chemo-radiation. While these are not major issues in the aforementioned surgical procedures discussed, leaks can still occur (approximately 2% to 5% for the discussed procedures). This complication should be suspected in patients with severe abdominal or pelvic pain, persistent ileus, a high postoperative fever, tachycardia, and an elevated white count. If the patient is otherwise stable, a CT scan can be performed as early as postoperative day 4, and if an abscess is seen it can usually be drained during this procedure. If the patient has diffuse peritonitis, then a reexploration is required with possible resection of the anastomosis and creation of a Hartmann pouch.

Pulmonary Embolus/DVT

This can be a devastating complication that is best “treated” by prevention. For patients whose only risk factors are cancer and surgery itself, 5,000 u of Heparin sq TID is started from within an hour of the incision up to 24 hours in the postoperative period. In addition, sequential compression devices are placed and activated before the operation begins. An additional important step in prevention is early ambulation. Postoperatively, patients should be out of bed and sitting in a chair on the day of surgery, and ambulating by the evening of postoperative day 1 at the latest. Post discharge chemical prophylaxis can be considered in high-risk patients (obese patients, open operations, stage 4 cancer, patients suffering septic complications).

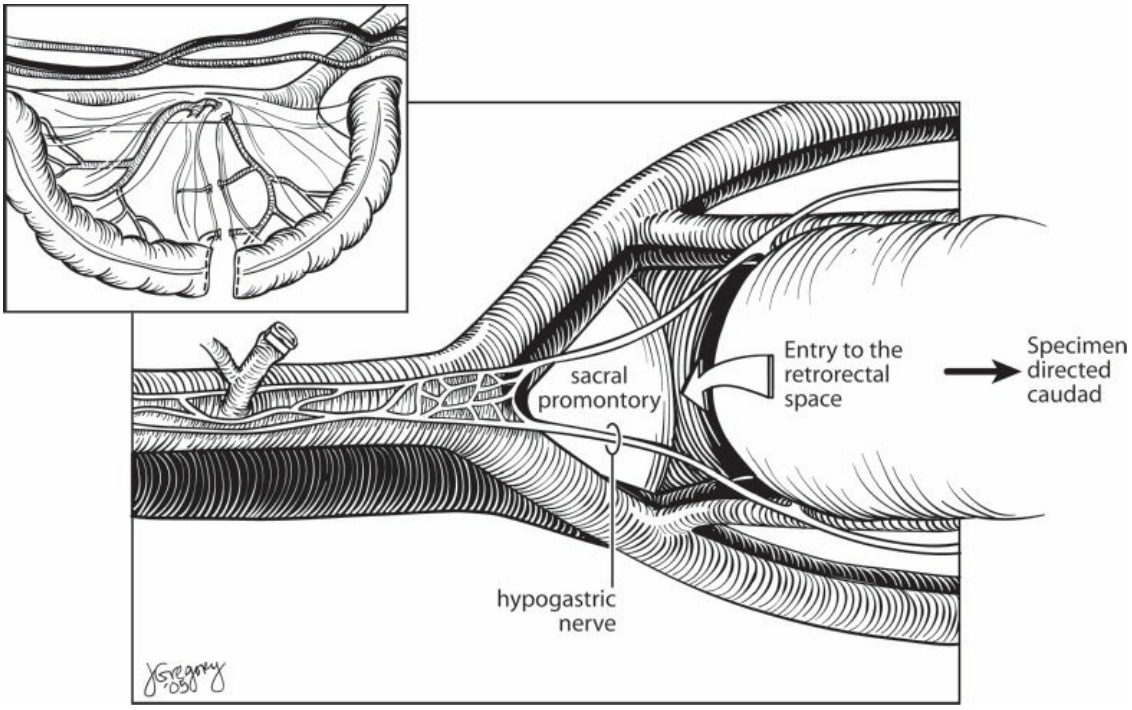

Figure 153.11. Lateral view of the fascia in the pelvis (presacral, fascia propria, retrorectal, rectovesical, Waldeyer fascia).

Urinary Retention

This complication is more common after low anterior resection. It is usually temporary after injury to the hypogastric nerves during pelvic dissection. While the foley catheter can be removed postoperative day one in a typical left colectomy and sigmoid colectomy, the authors leave it in for 3 postoperative days after anterior resection. If the patient is unable to void within 6 hours of removal, the Foley is replaced and the patient will be discharged with it. It is kept for 5 more days and removed as an outpatient.

Retrograde Ejaculation

Damage to the superior hypogastric plexus during high ligation of the IMA, or to the hypogastric plexus at the sacral promontory in male patients, can lead to retrograde ejaculation. This complication is more common in low anterior and abdominal perineal resection. Sildenafil can be effective in treating this postoperative complication.

EDITOR'S COMMENT

Performing a left hemicolectomy for neoplasms of the descending colon, sigmoid, or upper rectum may seem a relatively simple operation. However, if not done correctly it can result in disastrous consequences for the patients in terms of infectious complications, including anastomotic leak, delays in administration of chemotherapy, cancer recurrence, and even death.

Today's operative scenario has become much more complex with different types of access: open, laparoscopic, and robotic; however, sound surgical principles still apply no matter the mode of access. There are major components of preoperative planning that are often overlooked. One of the most common of these that the authors highlight is relying on someone else (often a referring physician) to describe the lesion location. As they state this is most common when one is referred a patient from another physician with a colonoscopy report stating that the lesion is at, for example, "45 centimeters," only for the surgeon to discover intraoperatively that the lesion is at an entirely different area! Always be suspicious if the lesion has not been tattooed and if a discrete anatomic location is not mentioned as well as if the lesion has not been identified by another imaging modality such as a CT scan or by rigid or flexible proctoscopy. It is a common health insurance conundrum as to whether or not the surgeon receiving the referral can recolonoscope the patient to verify lesion location; however, this does clearly avoid this intraoperative scenario of the erroneously located lesion.

There has been an ongoing debate in the surgical world regarding whether or not patients undergoing colon and rectal surgery should undergo preoperative mechanical bowel preparation. There is still no real consensus on this. Most feel that patients undergoing a right-sided colon resection do not require a mechanical bowel preparation. The French Research Group of Rectal Cancer Surgery (GRECCAR III trial) established that there were worse outcomes (major morbidity and infectious complications) when mechanical bowel

preparation was omitted with rectal resections. As the authors here discuss, there is also the technical concern with minimally invasive operations about the bowel not being as easily manipulated if there are large amounts of solid stool within the lumen, in addition to the difficulty of dividing a bowel filled with solid stool using a surgical stapler, or inserting a surgical staplers into a rectum filled with large volumes of solid stool. Most preoperative areas are ill equipped to give patients larger volume enemas the morning of surgery. Although it is old-fashioned, we may actually be seeing the return of the oral antibiotic preparation as this does truly seem to reduce the incidence of wound infections! Colorectal anastomoses most frequently leak due to impaired blood supply and this is often accentuated due to tension. Such leaks can result in anastomotic stenosis. The easiest ways to relieve tension on the anastomosis are (1) division of the inferior mesenteric vein just adjacent to the jejunum at the ligament of Treitz and (2) splenic flexure mobilization. Although these maneuvers take extra time, they are often well worth it in terms of gaining extra mobility of the left colon. The senior author has published on use of intraoperative indocyanine green angiography to assess margin perfusion. This can be done during open, laparoscopic, or robotic procedures and can even be done via proctoscope to assess the anastomosis. Utilization of a stapler of sufficient diameter will also help avoid anastomotic stricture formation. A stapler of a 29 mm diameter minimum should be utilized for the colorectal anastomosis. Several studies have shown that performing an intraoperative leak test for colorectal anastomoses by insufflating air into the rectum in a pelvis filled with water with the bowel above the anastomosis occluded and looking for air leaks will identify many unsuspected leaks. These can then be repaired or the patient diverted with a temporary ileostomy to avoid the untoward sequela of an anastomotic leak.

Over the last decade, use of laparoscopy for colon surgery has increased. There have been several trials documenting the safety of laparoscopic surgery as performed for colon cancer. It is now becoming increasingly recognized that laparoscopic surgery is particularly safe especially for high-risk patients such as the elderly and very elderly (Allardyce RA, Bagshaw PF, Frampton CM, et al.; Australasian Laparoscopic Colon Cancer Study Group. Australasian Laparoscopic Colon Cancer Study shows that elderly patients may benefit from lower postoperative complication rates following laparoscopic versus open resection. *Br J Surg* 2010;97(1):86–91). One of the important points brought out by the authors is the fact that cancers of the upper rectum do not have to be treated with total mesorectal excision, but rather with excision of the portion of the rectal mesentery appropriate to the tumor. One needs to excise the rectal mesentery for 2 to 5 cm distal to the lesion as they state in their chapter. I prefer to error on the 5 cm side and sharply divide the mesentery either with an energy device or by ligation in an open case. The same principles of posterior mesorectal dissection do apply with respect to dissecting the entire posterior aspect of the mesentery away from the presacral space, exactly as if one were performing a total mesorectal excision. It is imperative to open the specimen in

the operating room, in order to ensure that one does indeed have the lesion within the specimen and that one has adequate margins of resection. Notwithstanding completion and reporting of the Clinical Outcomes of Surgical Therapy (COST), and Colon Cancer Laparoscopic or Open Resection (COLOR) and the Conventional versus Laparoscopic-Assisted Surgery in Patients with Colorectal Cancer (CLASSIC) trials, further trials are ongoing in order to confirm the safety and suitability of laparoscopy for more advanced colon cancers. One of the most anticipated trials is that of the Japan Clinical Oncology Study Group. This study has focused on a evaluating laparoscopic versus open D3 (extensive central lymph node) dissection for stage II and III colon cancer. Short-term outcomes have shown lower morbidity (14.3% vs. 22%) in the laparoscopic as opposed to the open surgery group (Yamamoto S, Inomata M, Katayama H, et al.; Japan Clinical Oncology Group Colorectal Cancer Study Group. Short-term surgical outcomes from a randomized controlled trial to evaluate laparoscopic and open D3 dissection for stage II/III colon cancer: Japan Clinical Oncology Group Study JCOG 0404. *Ann Surg* 2014;260(1):23–30). Similar to this concept of performing extensive lymph node dissection for colon cancer is the concept espoused by Hohenberger who has applied the concept of total mesorectal excision to colonic surgery as "total mesocolic excision." Kobayashi and colleagues recently compared the total number of lymph nodes retrieved, number of positive lymph nodes, completeness of the mesenteric dissection plane, and other variables among colon cancer resection specimens from surgeons in England who use a low vascular tie technique, to surgeons in Germany using a total mesocolic excision technique, to surgeons in Japan utilizing a D3 (central) lymphadenectomy technique (Kobayashi H, West NP, Takahashi K, et al. Quality of surgery for stage III colon cancer: comparison between England, Germany, and Japan. *Ann Surg Oncol* 2014;21:S398–S404). Not surprisingly, fewer lymph nodes were obtained with left-sided as compared to right-sided colon lesions. Both the total mesocolic excision and D3 lymphadenectomy specimens yielded more complete mesocolic plane excision specimens with a lower lymph node ratio (number of positive lymph nodes divided by the total number of excised lymph nodes).

Another recent development with respect to surgery for left-sided colonic cancers is the changing philosophy toward colonic stenting. For lesions that may have thought to be partially obstructing, it is now generally accepted that prophylactic stenting is to be avoided as there appears to be a higher rate of local recurrence, and greater chance of perforation. This has been described in a number of studies and guidelines including that of the European Society of Gastrointestinal Endoscopy (Sabbagh C, Browet F, Diouf M, et al. Is stenting as "a bridge to surgery" an oncologically safe strategy for the management of acute, left-sided, malignant, colonic obstruction? A comparative study with a propensity score analysis. *Ann Surg* 2013;258(1):107–15; van Hooft JE, van Halsema EE, Vanbiervliet G, et al.; European Society of Gastrointestinal Endoscopy. Self-expandable metal stents for obstructing colonic and

extracolonic cancer: European Society of Gastrointestinal Endoscopy [ESGE] Clinical Guideline. *Endoscopy* 2014;46(11):990–1053). Whether this is true or not remains to be seen. The role of covered stents in the treatment of anastomotic leaks is still evolving.

In conclusion no matter which type of access we use to resect left-sided and upper rectal neoplasms, adherence to sound surgical principles should yield both good short-term results and the desired superior long-term oncologic outcomes.

Susan Galandiuk

154 Historical Perspectives on Total Mesorectal Excision

R.J. Heald

INTRODUCTION

Since the first chapter of "Mastery" was written, it is surprising how much has changed and how much the author still believes should change further. Rectal cancer is overwhelmingly a disease where surgical detail decides outcomes, but surgeons spend their time in ORs and the world has become "multidisciplinary"—often without the wholehearted involvement of surgeons. Multidisciplinary team (MDT) management should be welcomed and the use of preoperative staging by magnetic resonance imaging (MRI) and of chemoradiotherapy in selected cases are certainly major steps forward. There is little evidence, however, of a major survival benefit from radiation and clear evidence that fertility is abolished, sexual function impaired, and bowel function often grossly damaged by the combination of a low anastomosis with radiation—especially when given postoperatively. MRI can show clearly which patients really need RT, namely, those with threatened margins and others with a poor possibility of survival (e.g., N2 disease, extramural large vein invasion on MRI). There is much to be gained by more selectivity by the preoperative MDT meeting.

The surgery itself presents many new and exciting possibilities. Total mesorectal excision (TME) remains the key objective—can it, however, be achieved as well or better by laparoscopy? Or by the Da Vinci Robot? When truly necessary, can the poor results so often obtained by the "standard" APE be improved upon by superior access, for example, the Kocher Holm position face down with excision of the coccyx?

Repeatedly, the story of progress in this field is of better visualization and more precise dissection, improved hemostasis, and less collateral damage by diathermy (e.g., the use of traverse monopolar and ligature bipolar electricity). Gradually, surgeons performing open, laparoscopic, and robotic procedures are learning to recognize all the components of the

autonomic nervous system of the pelvis. Indeed, they are rewriting the anatomy books as surgical technology advances. A great part of human happiness and dignity depends on the preservation of these crucial nerves. In this chapter, the author has tried to set down the steps that can contribute both to reducing unnecessary damage to them and to ensuring optimal cure rates by the delivery of more perfect specimens.

There are few branches of surgery where care and effort in the craft of surgery yield so much benefit to our patients.

BASIC PRINCIPLES

The implications of decisions made in rectal cancer management are grave indeed—cure of cancer, local control of one of Nature's cruelest malignancies, the necessity for a permanent stoma, the preservation of sexual function, and much more. Decisions regarding both radiotherapy and chemotherapy now present major challenges in a field of ever-increasing complexity, so that multidisciplinary discussion must constantly be recognized by the true long-term consequences for the patient.

We must recognize that, even at its most scientific, surgery is primarily a craft with very special challenges and rewards for excellence. Surgery is not amenable to study by the same methods as those applicable to drugs or medicines or to measurable interventions such as irradiation, yet surgical technique has by far the greatest impact on rectal cancer outcomes. The randomized controlled clinical trial has so far contributed remarkably little to the development of surgical techniques because, particularly in the difficult and complex surgery of cancer, "the devil is in the details." As a basic principle of any cancer operation, however, the block of tissue to be removed should be precisely defined and subjected to scrutiny. Thus, surgical anatomy and histopathologic audit should become exact sciences in their own right and surgical practice refined to include meaningful judgment on the oncologic quality of the specimen by an independent pathologist after every surgical excision. It is rewarding to report that, since the first edition of this book, naked eye evaluation of the excised specimen has become mandatory in Germany. My own teaching workshops always emphasize the importance of "specimen-orientated surgeons," that is, surgeons whose first priority during the procedure is the quality of the fascial covered untorn envelope of tissue that he will extract and which constitutes an optimal TME specimen.

HISTORICAL CONSIDERATIONS

Most of the literature in the Western world has paid scant attention to detail of how the actual dissection around a rectal tumor should be carried out. The diagrams in current textbooks bear witness to the crude manual extraction techniques that bedevil “conventional” surgery for rectal cancer (Fig. 154.1). However, both the Japanese with their special interest in the detailed vascular and neuroanatomy of the pelvis, and we, with our TME initiative, have attempted to improve on the simplistic concept of abdominoperineal excision (APE), an operation originally described in 1907 by the Englishman Ernest Miles. His concept of a cylinder of maximal size that “empties the whole pelvis” was at least an attempt at defining in advance a block of tissue to be excised by the surgeon. This idea, illustrated in Figure 154.2, has dominated the minds of doctors throughout the twentieth century. Indeed, if surgeons had really produced perfect “oncologic cylinders,” there would have been far fewer local recurrences and failures, though the morbidity in terms of sexual and pelvic autonomic function would have been formidable while the dead space would have required packing for many months. The famous John Golligher used to comment, “If you haven’t made the patient impotent, you probably haven’t cured him of rectal cancer.”

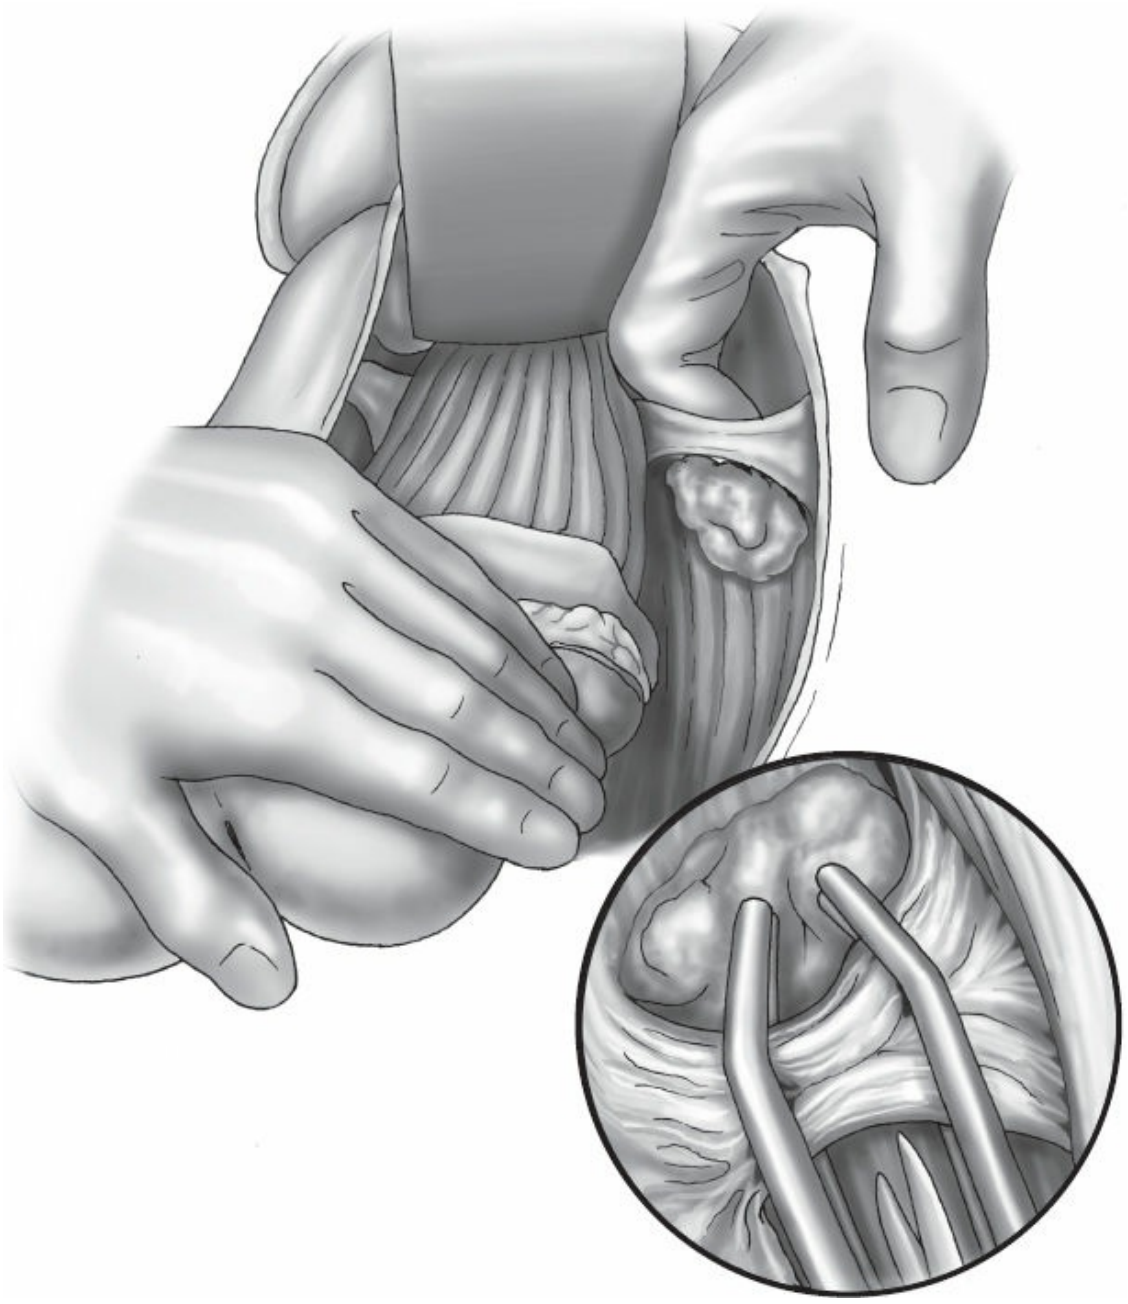

Figure 154.1. This would make a patient impotent.

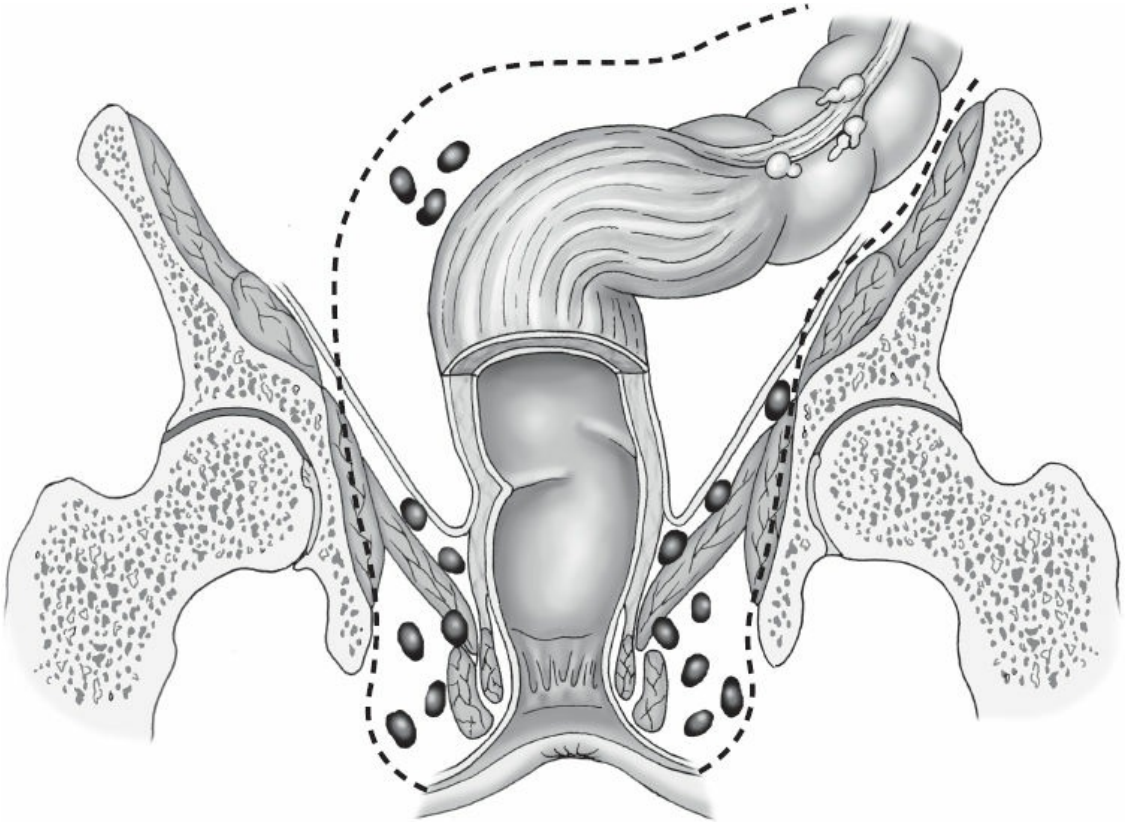

Figure 154.2. Original concept of many nodes in the ischiorectal fossa, and along the upper surface of the levators—Miles' "highly dangerous tissues."

Miles considered that spread occurred, particularly in the lymphatics, in all directions and included very clearly in his diagrams his perception of why he had seen 31 perineal recurrences in the wound of his operations (Figs. 154.2 and 154.3). He believed that the reason for these was that he had failed to encompass by his operation, the spread that had occurred into the ischioanal fat via nodes around the inferior hemorrhoidal (rectal) vessels. The same diagram also shows many nodes sitting on the surface of the levator muscles within the imagined "cylinder" of spread. He clearly also believed that, for this reason, only the widest possible clearance at this level had any hope of curing the patient and it was commonplace for tumors as high as 15 to 25 cm to suffer the same fate. So it was that permanent colostomy became established as the necessary price for cure and became a very common and widely dreaded association of bowel cancer in the public mind. Similar thought processes about spread govern most extended surgical lymphadenectomies, but careful studies of ischioanal fossa node involvement to justify this heavy price have never been undertaken. Furthermore, long surgical experience teaches us that

multiple nodes on the surface of the levators or in the ischiorectal fat such as those in the diagram are simply never seen.

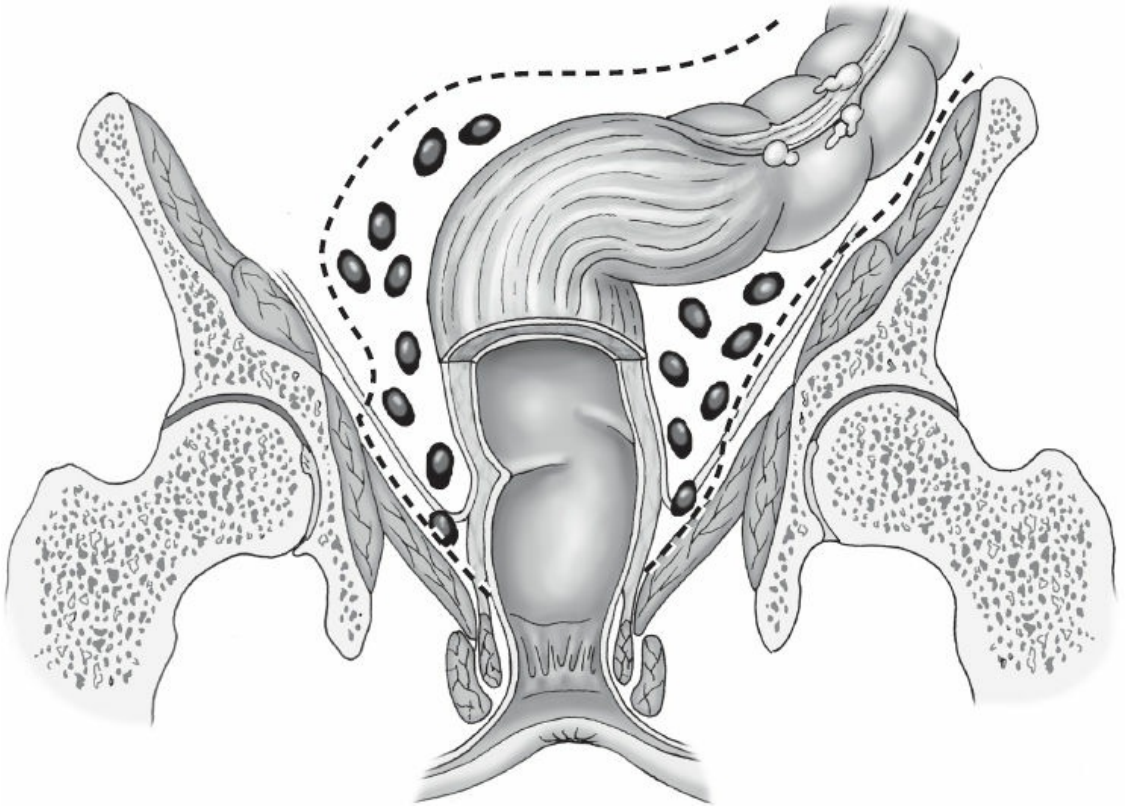

Figure 154.3. Our concept of the field of spread. Adenocarcinoma of the rectum is a visceral (mesorectal) and supra-levator field spread disease total mesorectal excision.

Such studies were certainly not attempted by Miles, who simply regarded the whole of the surrounding cylinder of tissue as "highly dangerous tissues," particularly, "the levators, the ischioanal fat, and the perianal skin."

REDEFINITION OF MILES' "HIGHLY DANGEROUS TISSUES"

So it is that the background to our current attempts to move toward an optimal cancer operation is a standard but empirical procedure designed more than a century ago. Virtually, no detail of how the actual dissection should be effected appears in the literature. The Miles' operation was certainly radical in the sense that it appeared in the diagrams to remove the cancer with much of the surrounding tissue. It was also an operation that could be completed at great speed—often in less than an hour. In the early

years of the last century, such speed often meant the difference between a live patient and a dead one at the end of the operation! However, the term “radical” refers to radix, a root in Latin. Leave part of the root and the plant regrows. In cancer terms, this implies a need for real understanding of where the satellites of cancer commonly occur since the ideal radical cancer operation should encompass only the common fields of spread that do not exact too high a penalty from the patient. The design of the optimal operation that modern surgery can now offer should take into account the field of spread amenable to surgical removal with the primary tumor, the disabilities inflicted by each component of the surgery, and the point in time at which cure becomes impossible by local surgery because metastases have already become established.

The first major steps toward minimizing mutilation can be attributed to many surgeons who embarked upon anterior resection (AR) to avoid sacrifice of the anal sphincters. Initiated on both sides of the Atlantic, before and after World War II, the proportion of rectal cancers undergoing sphincter-preserving surgery has risen steadily to a current level of 90% in specialized units and above 50% in most general hospitals.

Modern rational surgical planning should consider each of the possible fields of spread of rectal cancer in turn, and the disabilities and sacrifices paid by the patient for their removal. In each case, we should, to give the patient what we would wish for ourselves, try to balance the benefit of an extra chance of cure against the functional and anatomic price to be paid. At the time of going to press, this implies that preoperative assessment should supplement full clinical and endoscopic appraisal with a computed tomography (CT) scan of the whole body for metastatic spread and a specialized MRI for the most precise picture of the primary cancer and its locoregional spread. MRI scan for appraisal of the primary cancer within the pelvis.
