Conceptually, TME has a basis in scientific thought, which is attractive to all members of the modern MDT with background training in basic science. The theory behind it is that cancer spread will tend, initially at least, to remain within the embryologic hindgut “envelope.” The gut spent

its early fetal existence actually outside the abdomen. When secondarily rectum and mesorectum became “plastered” back onto the retroperitoneal structures and into the developing pelvis, they retained their midline lymphovascular integrity and remained separate from the surrounding paired organs and parietes. Their adherence to them is by a collagenous cobweb of areolar tissue, which allows a degree of movement, is recognizable by the surgeon as a “surgical dissection plane” at about the 10-mm stage, and is almost entirely avascular. In a number of publications, the author has drawn attention to this “holy plane of rectal surgery” and attempted to point out the value of painstakingly following the perimesorectal avascular plane around the midline hindgut into the depths of the pelvis as a practical surgical policy. This was eventually shown to improve local recurrence rates in a dramatic way. Straying into the field of cancer spread within the mesorectum was, and still is, in conventional practice, an extremely common cause of involved surgical margins and residual pelvic disease: straying out can damage the autonomic nerve layers and is a common cause of impotence. Publications from the Karolinska Hospital, Solna, Sweden, demonstrate that more than one half of all local recurrences referred these for investigation are associated with residues of mesorectum left behind by the surgeon. In other words, inadequate TME, that is, incomplete emptying of the central compartment (within the nerve layer) is a far more important course of failure than ignoring the internal iliac and other compartments outside the visceral mesorectal “core.” This is of great practical importance because, although a challenging dissection, TME is a standard teachable reproducible operation. The lateral compartments are much more varied and difficult, and much less rewarding—perhaps best left to a few high-volume specialist surgeons along with other procedures such as sacrectomy extended because of threatened margins or secondary nodal spread.

Some workers in the past postulated a physical barrier to the spread of cancer at this interface that I call the “holy plane”: it seems intrinsically more probable, in the light of Judah Folkman’s work, that tumor angiogenesis is impeded by the avascular nature of the areolar interface between midline hindgut and surrounding parietes. So it is that embryology is the true key to defining the oncologic package that will encompass the relevant field of spread. The surgeon should bear in mind that the tapering hindgut “package,” surrounded by the “holy plane,” is inserted into the funnel-shaped sloping levators, which merge with the

parietal voluntary skeletal external sphincters distally.

THE MESORECTUM FOR THE SURGEON—THE PLANES OF THE PELVIS

Surgical Anatomy

The original idea of TME was born from the practice of surgery. The mesorectum only becomes a reality for each individual surgeon from enthusiasm for slow, meticulous, painstaking dissection in difficult but achievable planes. These, once recognized and identified, become the defining objectives of the surgery and the redefined building blocks of the anatomy.

Once the surgeon has grasped the new system of anatomy, as Stelzner originally did from his diagram, it also becomes clear that the basis for the planes does indeed lie in the embryology (Fig. 154.4).

The innermost “holy plane” is that which surrounds the midline hindgut within its lymphovascular envelope—the core—while the two surrounding lamellae comprise a neural layer and a Wolffian ridge layer, which develop from the paired structures outside the hindgut. This concept has been made relatively simple to comprehend by the Japanese suggestion of comparing pelvic anatomy with the layers of an onion.

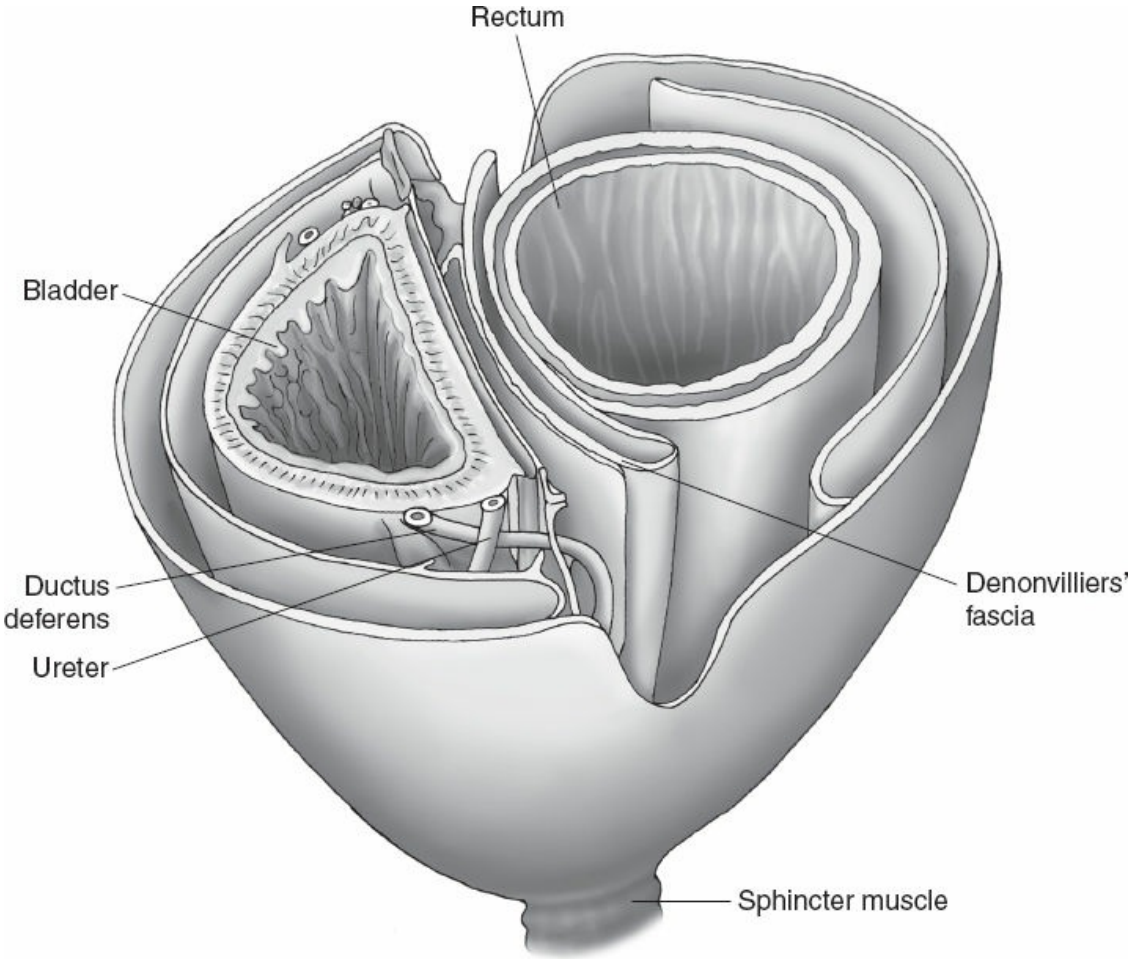

Figure 154.4. The fascial layers of the pelvis (after Stelzner). "Like the layers of an onion—or two onions with Denonvilliers' septum between."

Much of surgery of the whole gastrointestinal tract is a question of pursuing the planes between embryologically separate lymphovascular entities. The careful and thoughtful surgeon who is mobilizing any part of the large intestine by sharp dissection becomes aware of a choice of two relatively avascular, and therefore surgically satisfying planes, which are of special value in his or her journey down into the pelvis. The innermost "holy plane" envelopes the integral visceral mesentery of the hindgut or "mesorectum." This "safety margin" is a complete fatty and lymphovascular surrounding on all aspects in the middle third of the rectum, which constitutes the greater part of the organ and the most common site for cancer. In the upper third, the anterior aspect is covered only by the peritoneum with "mesorectum" at the back and the sides as the peritoneal reflection tapers forward toward the "cul-de-sac" or rectovesical pouch. In the lower third of the rectum, little or no fatty tissue intervenes

between the anterior aspect of the rectum and the back of the prostate. Posteriorly, the prostate has an important posterior condensed fascial covering called Denonvilliers septum. The surgeon has to divide this layer from above to enter the plane between the rectum and the prostate in the male. The upper part of the septum is usually adherent to the anterior mesorectal fat of the middle third. In the female, the middle third has a rather thin and tenuous fatty layer between the rectum and vagina with Denonvilliers fascia being often scant and difficult to identify, certainly a recognizable condensed "septum" is often not found as in the male. Is this perhaps because of its dissolution during childbirth or sexual activity? I use the term "Denonvilliers septum" to describe the shiny anterior surface of the excised middle third of the specimen and its distal continuation to fuse with the back of the prostate (Figs. 154.2 and 154.3). This seems logical because Denonvilliers septum is recognized by some embryologists as the downward prolongation of the peritoneum, which has become distally obliterated as a cavity. Fritsch has preferred to call it the "rectogenital septum," which certainly conveys the reality of a substantial rectangular or trapezoidal layer—like a "bib" between hindgut behind and vesicles and prostate in front. Just as peritoneum is the integral surface of the anterior aspect of the upper intraperitoneal third of the rectum, Denonvilliers septum is integral to the fatty anterior mesorectum in the middle third in the male. Denonvillier was one of the great French surgeon anatomists who described anatomical concepts of importance to surgeons —how far ahead of his time he was! It is only now that, improved vision in open surgery and the amazing magnification available to the robotic surgeon, his description of "two layers" of his septum begins to become apparent during operations on the live human. It is now clear to surgeons that, in the human male at least, the trapezoidal "bib" with defined lateral margins just medial to the all important neurovascular bundles is indeed a reality.

Posteriorly and posterolaterally, the areolar plane is well defined around the globular expanding bilobed mesorectum. A condensation of the fascia called the rectosacral ligament or Waldeyer fascia often presents a barrier to the surgeon posteriorly below the promontory. It is essential that this be positively divided either with diathermy or scissors. Beyond it, the plane is easy to recognize except that the forward angulation demands strong anterodistal retraction to facilitate direct visualization. Understanding the importance of this forward angulation is critical to mastering the traction

and counter-traction instruments necessary in open, laparoscopic, and robotic TME. Confusingly, the middle third of the rectum is often called the horizontal segment because MRIs are typically viewed as if the patient is vertical.

AUDIT OF THE MESORECTUM BY THE PATHOLOGIST

For proper independent audit, the surgeon should not cut the specimen except to open the bowel away from the tumor to let in the fixation liquid. The pathologist Quirke identified that there is a high positive predictive value of circumferential margin involvement (CMI) for the subsequent development of locally recurrent cancer. This implies that completeness and intactness of the specimen are crucial factors—ideally that it should be one recognizable block of tissue whose orientation and former relations can be identified. While "specimen-orientated surgery" has become the established practice in our unit, recognition of the features of the TME specimen and the freedom of its margins from cancer involvement become the key factor of audit. In most cases, naked-eye inspection provides the initial necessary quality control, with microscopic examination of the suspected areas of margin involvement as a logical primary objective for the surgeon. Visual inspection of the front of a well-performed TME specimen should show three clear landmarks (Fig. 154.5):

- The cut edge of the peritoneal reflection (Fig. 154.5)
- The smooth shiny anterior surface of the anterior mesorectum of the middle third—Denonvilliers fascia—or the rectogenital septum
- The almost bare anterior aspect of the anorectal muscle—in the lowest ARs or APE specimens only

Laterally, the fatty mesorectum expands distally beyond an anteroposterior groove made by the nerve erigentes so that an embryologically perfect specimen has a lateral dilatation distally, corresponding with the part related to the inside of the levator muscles beyond their origins from the pelvic sidewall. Posteriorly, a perfect specimen exhibits perfectly curved "buttocks" with a central midline groove corresponding to the anococcygeal raphe (the pubococcygeus muscle)—the most posterior of the levator muscle bundles.

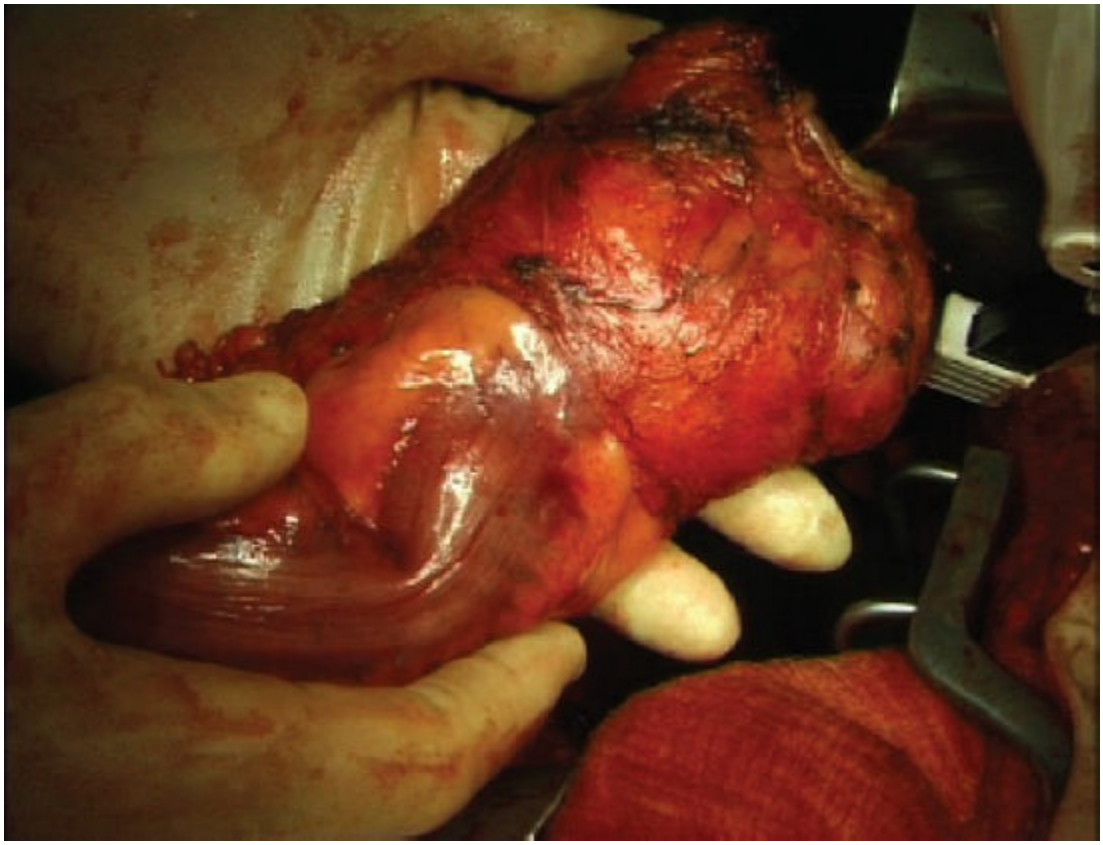

Figure 154.5. Front of a total mesorectal excision specimen.

MULTIDISCIPLINARY TEAM MANAGEMENT

Modern Imaging—Fine-Slice High-Resolution MRI

The great step forward of the new millennium is the establishment by Brown, Blomquist, and others that specialized fine-slice high-resolution MRI can visualize this “holy plane” before the surgery and thus predict the detail of the oncologic specimen that the surgeon endeavors to remove, its probable contours, and their relationship to the tentacles of tumor. TME principles are now more readily comprehended by nonsurgeons in the MDT because of the development by these specialist MRI radiologists of images that are far superior to anything previously achievable. The fine-slice high-resolution methods are demonstrably superior to any x-ray–based modality, which inevitably suffers limitations in differentiating tumor tissue from muscle wall. MRI demonstrates, for the first time, the contours of the mesorectum and the distribution of the cancer within it. The recent “Mercury” study from the Pelican Center in Basingstoke has demonstrated reliable equivalence between MRI prediction and histopathologic reality (Fig. 154.4). It also demonstrates that a 1-mm mesorectal “clearance” does indeed predict a “safe margin,” provided the

surgeon is faithfully following the “holy plane.”

Lymph Nodes Close to the Margin

The pelican Mercury Study showed that extramural vascular invasion was an even more important prognostic indicator than nodal involvement at the N1 level. We therefore take this as an indication for giving preoperative CRT.

Conversely, nodal “threats” by proximity to margin did not appear to lead to local recurrence (0/63). This almost certainly reflects the extra care taken by the surgeon to keep clear of such a node by the surgeon who is thus forewarned by the MRI.

This clearance on MRI between cancer within and mesorectal fascia without can be reliably used to predict the need for neoadjuvant “downstaging.” Also, it can warn the surgeon when the mesorectal margin is in danger of being breached during surgery. It can thus provide a “workshop guide” for the detailed surgery, whether this can be performed laparoscopically or open. This may become particularly crucial as a “route map” for laparoscopic surgeons as they increasingly extend their dissections into the challenging depths of the true pelvis where the inability to feel the cancer can be a serious disadvantage. We emphasize the importance of displaying MRIs in the OR during the actual surgery, and the robot might well be adjusted to show them within the console during the operation.

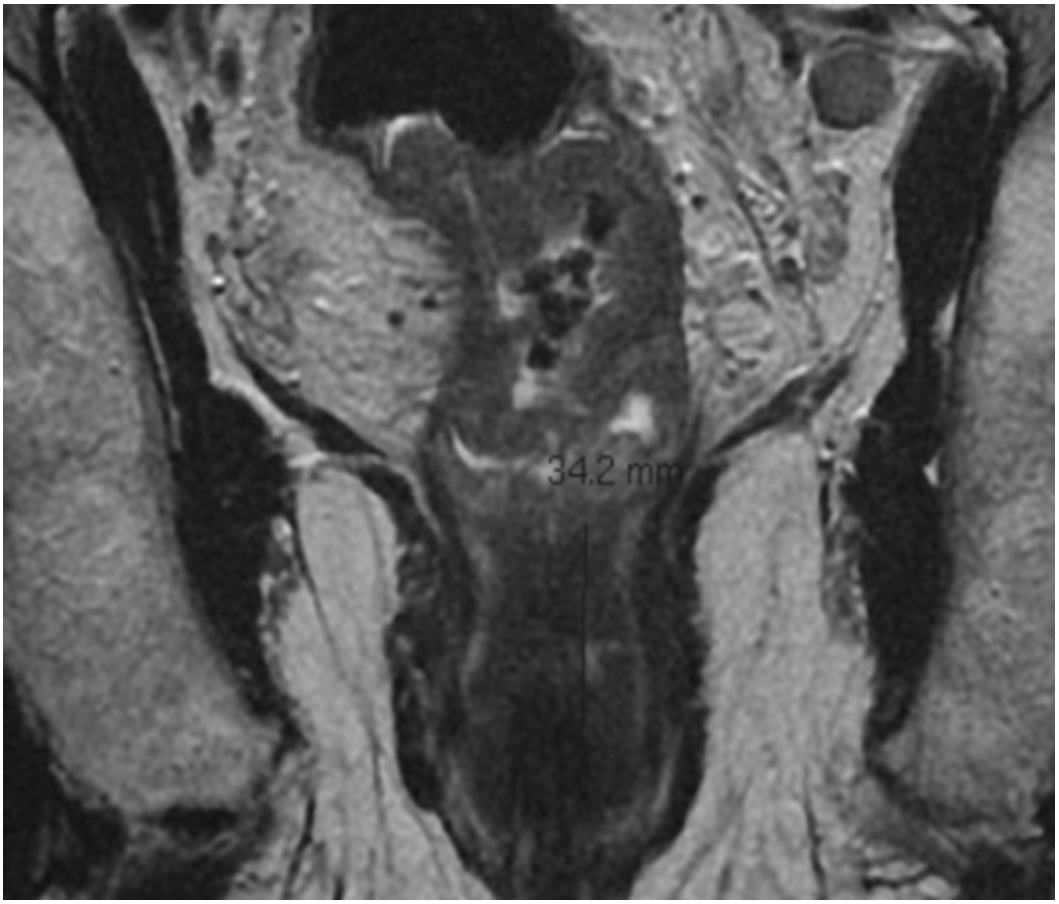

Figure 154.6. Coronal oblique magnetic resonance imaging showing large low rectal cancer with lower margin at 4.5 cm, but clear margin within puborectal sling.

CRITICAL MRI DECISIONS IN LOWER-THIRD CANCERS

One focal area of current controversy centers on the anatomic and embryologic fact that the mesorectal envelope tapers down in this (infralevator) lower third to appear very thin indeed—particularly on the crucial coronal oblique MRI cuts on which decisions in modern MDTs are made (Fig. 154.6). On such an MRI it is extremely tempting to predict that this tapering and narrowing area of the mesorectum will constitute a hazardous margin; thus, a decision may be made to administer preoperative downstaging neoadjuvant therapy or even choose APE for fear of margin involvement, when in fact, a carefully orientated axial oblique sequence with the axial cuts precisely at right angles to the tumor segment may demonstrate a potentially safe clearance. Figure 154.7 shows anterior black “excrescences” of extramural venous cancer spread. In such cases, where the cancer is below the levator origins on MRI, it is essential

that an experienced surgeon examines the patient to establish free mobility of the tumor in reference to the sphincter in the conscious patient (with muscle tone). In the author's opinion, this clinical observation on the sphincter complex and adjacent organs does almost invariably mean that a TME will be an achievable surgical objective. It does not confront the other tendentious issue of the higher incidence of internal iliac and particularly obturator node involvement in tumors <4 cm from the anal margin.

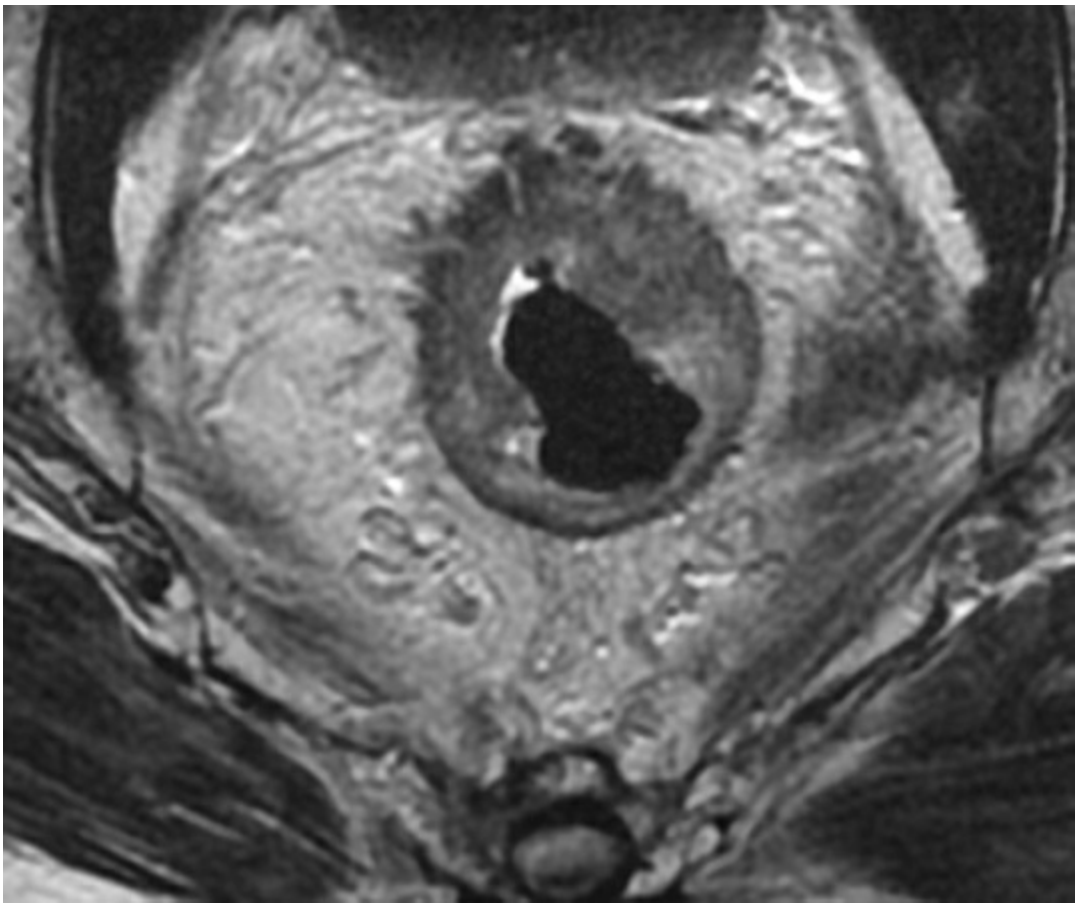

Figure 154.7. Axial magnetic resonance imaging of anterior cancer with EMVI extending close to but just 1 mm clear of the anterior mesorectal margin.

MDT management is now mandatory for all major malignancies in the United Kingdom and is increasingly a standard practice in many institutions throughout the world. The focal point of the decision-making process is becoming the MRI images, which can be readily understood by all, but the surgeon must always have the last word. Nevertheless, the idea that the decision to do an AR or APE is finally made in the OR is disappearing fast. It is wise to have the patient's permission but the

conscientious modern surgeon and MDT will almost always have decided ahead of time.

SUMMARY OF THE MULTIDISCIPLINARY TEAM SEQUENCE

The TME concept can now be extended to embrace a multidisciplinary six-stage process. It is essential that each case is discussed at two meetings: (a) before the operation for overall planning and (b) after receipt of the histopathology reports—for reasons of audit quality control, follow-up, and further adjuvant therapy.

Preoperative: Multidisciplinary Team 1

Clinical
CT to exclude metastatic disease and comorbidity. Various sequences, especially including coronal obliques in the long axis of the anal canal (for low rectal tumors) and fine slice (3 mm) axial obliques at right angles to the tumor segment to assess margins (Fig. 154.1).
Phased-array-coil fine-slice MRI, no endorectal coil—no bowel preparation.
MDT planning.
Preoperative neoadjuvant therapy in cases selected on the basis of preoperative MRI staging of the pelvis plus whole-trunk CT for the detection of metastases.

Postoperative Review of Patient Recovery Specimen and Histology: Multidisciplinary Team 2

Detailed precision surgery—TME or "TME plus." "TME minus" or "partial TME" for upper one third cancers implies that the mesorectum is divided 5 cm below the tumor and a rectal and mesorectal remnant remain—in the interests of creating a "smaller" operation with no temporary stoma.
Detailed audit of the specimen after removal with special emphasis on naked-eye assessment of mesorectal integrity and microscopic evaluation of the margins.
MDT assessment and decision regarding postoperative therapy.

The Surgery

Surgery TME for the surgeon comprises six basic principles:

Perimesorectal “holy plane” sharp dissection by monopolar diathermy and scissors under direct vision. Three-directional traction and countertraction is a vital principle for diathermy dissection as it is essential that the areolar tissue be “on stretch” if “holy plane” dissection is to be accurate (Fig. 154.8).

“Specimen-orientated” surgery and histopathology, of which the object is an intact mesorectum with no tearing of the surface and no CMI—naked eye or microscopic.

Personal naked-eye assessment as audit for obvious CMI as the principal immediate outcome measure. Combined with objective assessment of the whole specimen by the pathologist, this confirms the optimal planning and execution of the surgery. Surgeons and oncologists may also base postoperative therapy on this pathology report, though these must always be a sense of the “horse having bolted” if cancer has been exposed and CRT had not been given before surgery. This was a failure of either planning or surgical technique.

Recognition during surgery of, and preservation of, the autonomic plexuses and nerves, on which sexual and bladder function depend.

A major increase in anal preservation and reduction in the number of permanent colostomies by skilful extension into the depths of the pelvis.

Stapled low pelvic reconstruction, usually using the Moran triple stapling technique, plus creation of a short colon pouch or a side to end anastomosis to low rectum or anal canal.

Before the Operation—Bimanual Pelvic Examination

CT scans and colonoscopy report should always be at hand in the operating room. Never commence surgery without having examined the patient digitally when awake plus performing bimanual examination under anesthesia. This is especially true in the female, so as to establish whether the tumor is fully mobile on the posterior vaginal wall. MRI may already have demonstrated invasion but it is still of value to confirm it. The decision as to whether to excise a part of the posterior wall is finally made at this time by a combination of rectal and vaginal examination, and the latter must never be omitted. Sometimes, if AR is possible, a disc of the posterior wall may be circumscribed around an area of tethering using the angled-point diathermy from below. This is often best performed before the abdominal dissection is started. Routine excision of the posterior vaginal wall is not usually necessary unless it is actually involved.

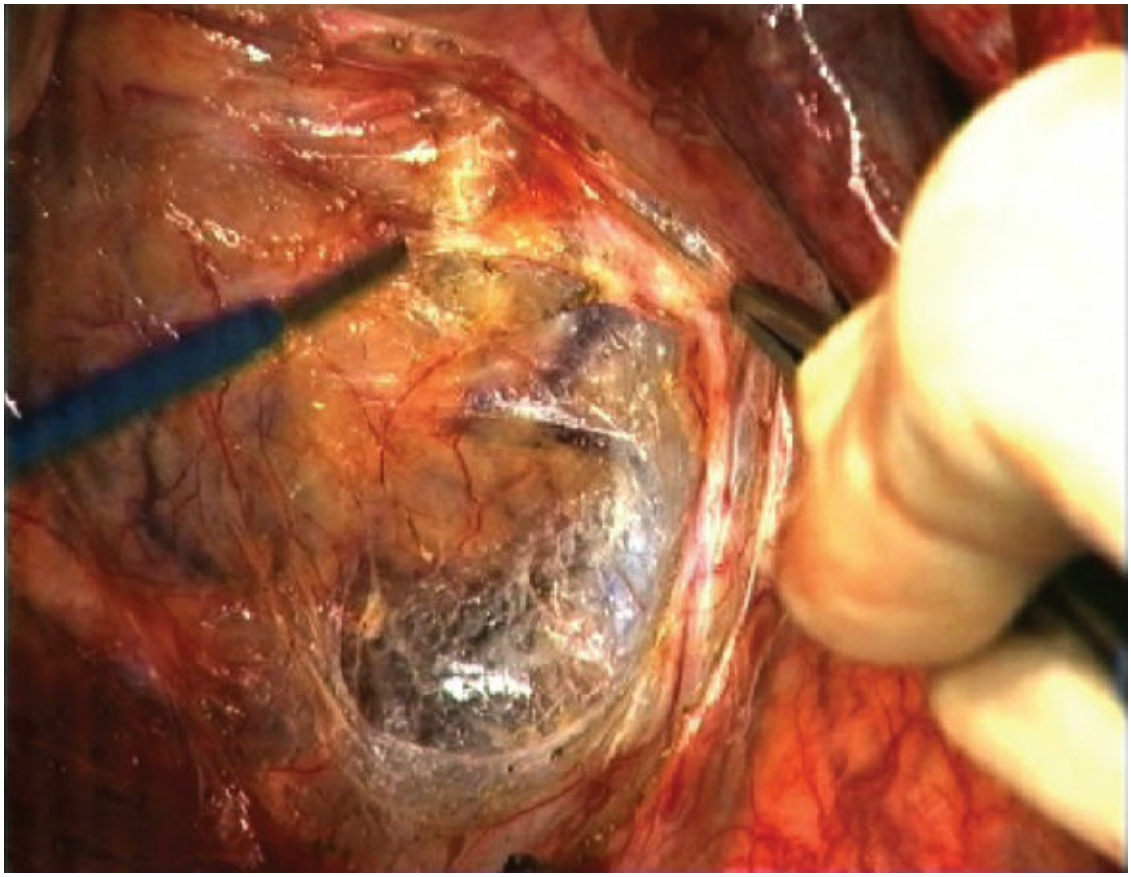

Figure 154.8. Areolar dissection.

Steps of the Operation

The key principle is that dissection should only proceed in the areolar tissue plane (the “holy plane”) within (and thus sparing) the autonomic nerve plexuses, the nonvisceral presacral fat pad (when present), the parietal sidewall fascia of the small pelvis, the hypogastric plexus, the vesicles and the prostate in the male, and the vagina in the female. All of the dissection should be performed sharp with diathermy or scissors under direct vision with good light (Fig. 154.6). Throughout, the dedicated assistants should provide three-directional traction to open up the planes for the operator—diathermy can only be used safely when the areolar tissue is on stretch. Compared with traditional methods of manual extraction, the difference in time can be considerable. A careful TME plus pouch to anus reconstruction takes 3 to 5 hours according to the detail of the patient’s build and the particular cancer; a conventional APE was often completed in 1 hour.

The Incision—Open Surgery

A long midline incision is made from the symphysis pubis to within a few

centimeters of the xiphisternum. If possible, at least 5 to 7 cm is best left at the top as this facilitates tidy packing away of the small intestine in the right upper quadrant.

Some young ladies may prefer a suprapubic skin crease incision combined with a vertical midline between the rectus muscles.

Laparoscopic Anterior Resection

The author takes a major interest in this area of extending laparoscopic practice but continues himself to perform open surgery for rectal cancer as detailed. The principles remain the same and there is no doubt that excellent clearance of relatively small cancers can be achieved laparoscopically and by some surgeons of the great majority. The author would suggest that only very experienced laparoscopic gastrointestinal surgeons should embark upon the deep dissection for cancer and that special caution, if not total avoidance, is appropriate for very large cancers, especially in narrow male pelvises. The elevation of an intact mesorectal package, safely encompassing a large cancer, requires carefully applied but substantial upward traction, which is very difficult to achieve with laparoscopic instruments. At present, the author would counsel great caution with tumors >8 cm in any dimension, but most importantly in axial diameter. A further area of limitation is the cross-clamping and washout of the anorectal muscle tube for which laparoscopic instrumentation often remains imperfect. Multiple bites with the endo GIA often go hand in hand with the catching of some of the puborectal sling posteriorly rather than a clean join to the smooth muscle tube.

At the time of going to press, rather few laparoscopic instruments exist that bend effectively round a large cancer to apply upward traction in a safe gentle way. The use of small “peanuts” or gauze pledgets is infinitely better than applying graspers to the mesorectal surface which can so easily be torn. Graspers may be applied to cut peritoneal edges and special expanding retractors can, to some extent, replace the crucial forward and lateral retraction for which the St. Marks’ retractor is key in the open operation.

OPEN SURGERY

Manual Palpation and Inspection—Laparotomy

This must be thorough, with particular emphasis on liver and peritoneum.

Careful assessment of the para-aortic nodes in the lesser sac is easy to forget. At this stage, it is a good routine to review the CT scan and the colonoscopy report and to palpate the whole gastrointestinal tract carefully.

Packing

Careful packing and retraction of the intestines upward and to the right is crucial to provide clear access to the pelvis. Adhesions in the right lower quadrant commonly require division. “Starting right”—the pedicle package—the clue to the top of the “holy plane” (Fig. 154.9). Starting correctly involves three-directional traction on the colon and retroperitoneum to identify the plane between the back of the pedicle package and the gonadal vessels, ureter, and preaortic sympathetic nerves —all of which must be carefully preserved. The key to this phase is the recognition of the shiny fascial-covered surface of the back of the pedicle —like a tapering longitudinal “sausage” with the inferior mesenteric vessels within. This must be gently lifted forward. It is usual in open surgery to start on the left of the sigmoid mesocolon. It is equally satisfactory, as commonly performed in laparoscopic surgery, to start on the right. In either case, the identification of the shiny fascial envelope behind, what I like to call the “pedicle package,” is crucial to proper entry into the pelvis and to the preservation of the nerves.

High Ligation of the Inferior Mesenteric Vessels

With the pedicle package lifted gently forward the dissection behind it can be extended up to its proximal end; separate high ligations of the inferior mesenteric artery and vein can be performed with the pedicle controlled by the left index finger with the surgeon standing on the patient’s left side (Figs. 154.10 and 154.11). The artery is taken 1 to 2 cm anterior to the aorta so as to spare the sympathetic nerve plexuses; the vein is divided above its last tributary close to the pancreas. These two high ligations are an integral part of the otherwise avascular planes, which need to be developed upward extensively for a full mobilization of the splenic flexure. The need for this is dictated by the decision to perform a TME and therefore an anastomosis 3 to 6 cm from the anal verge. The mobilized colon must lie without tension in the hollow of the sacrum.

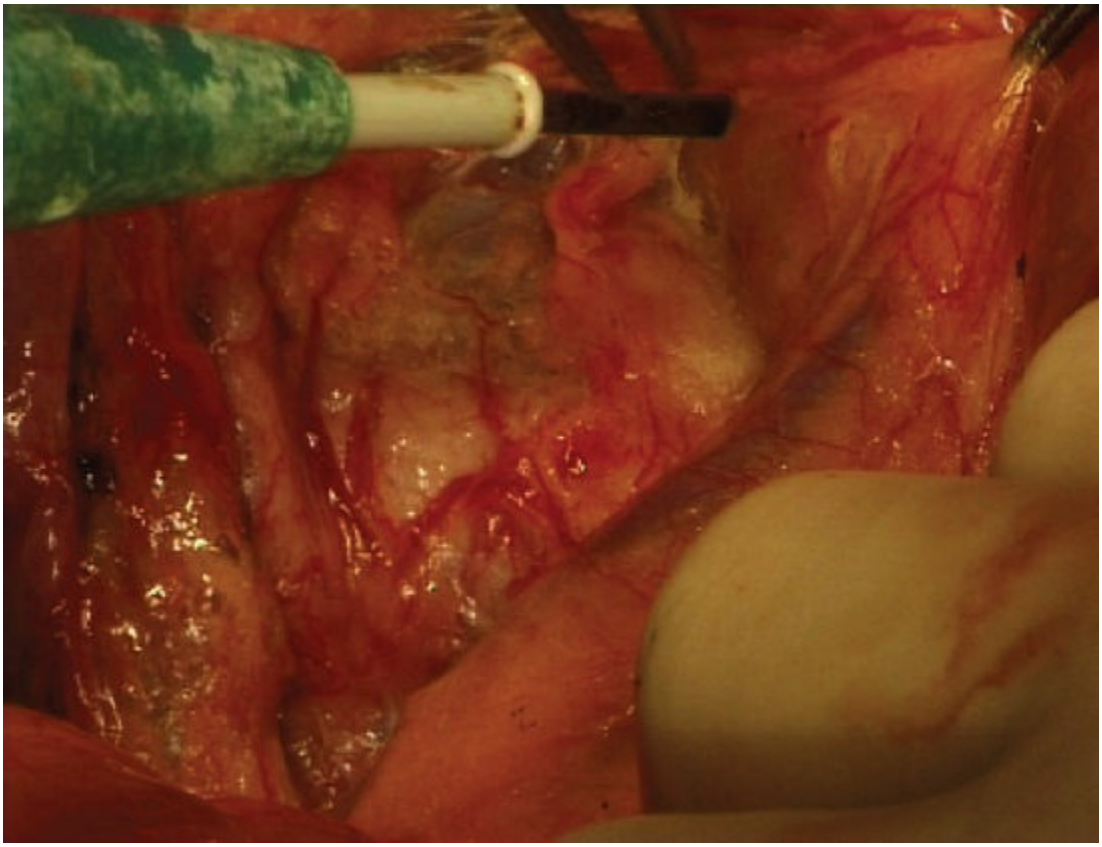

Figure 154.9. Pedicle package. “Starting right.”

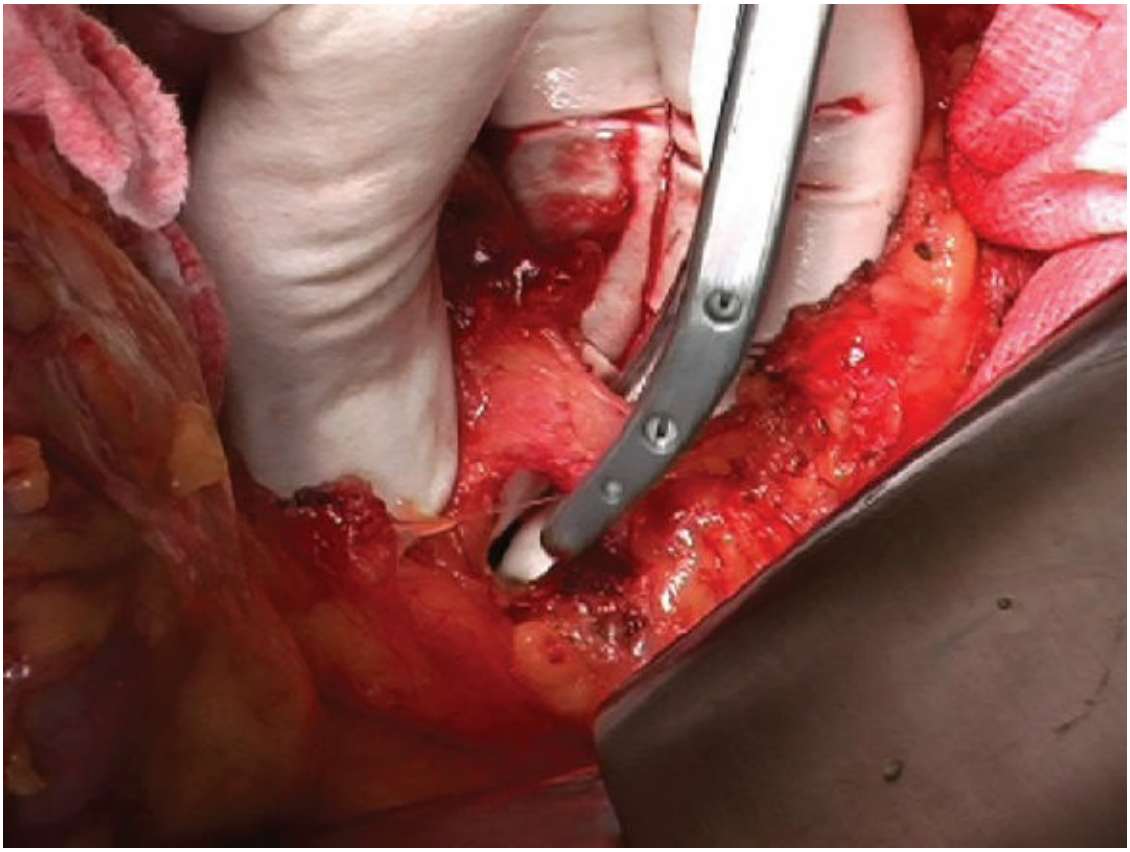

Figure 154.10. High ligation of artery.

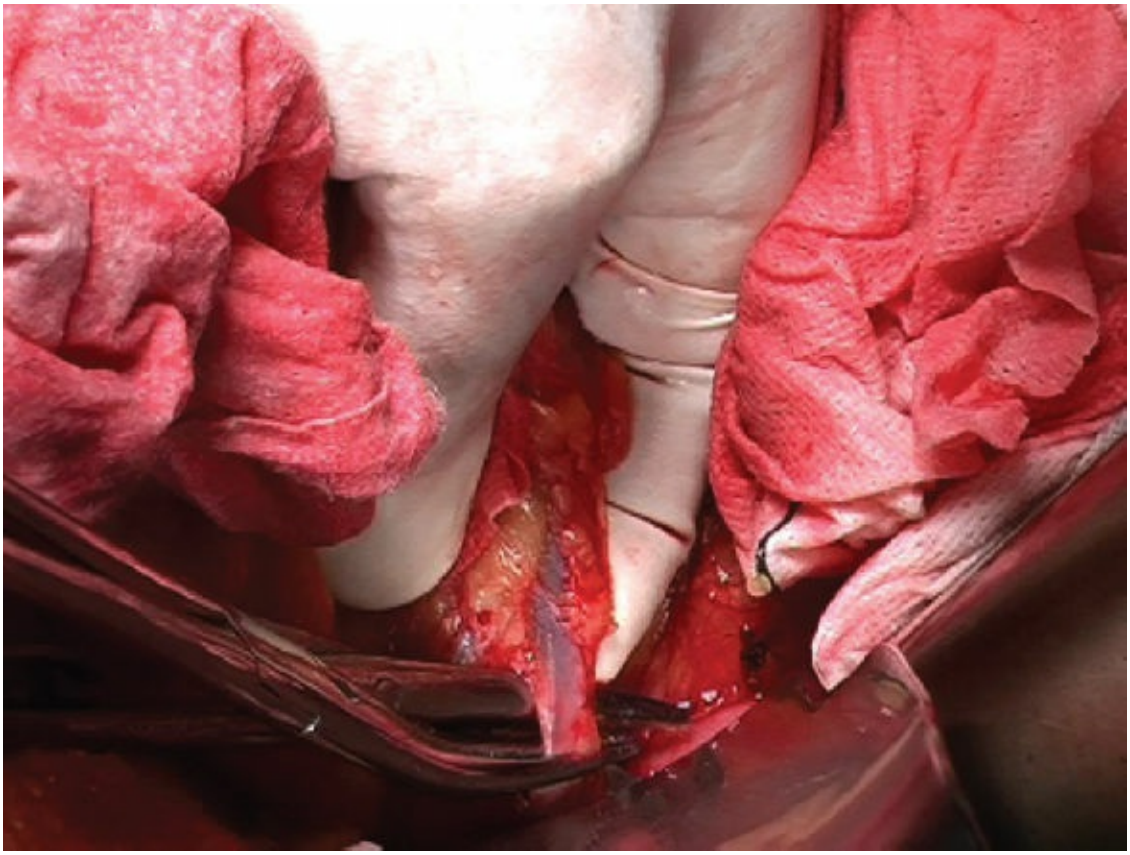

Figure 154.11. High ligation of vein.

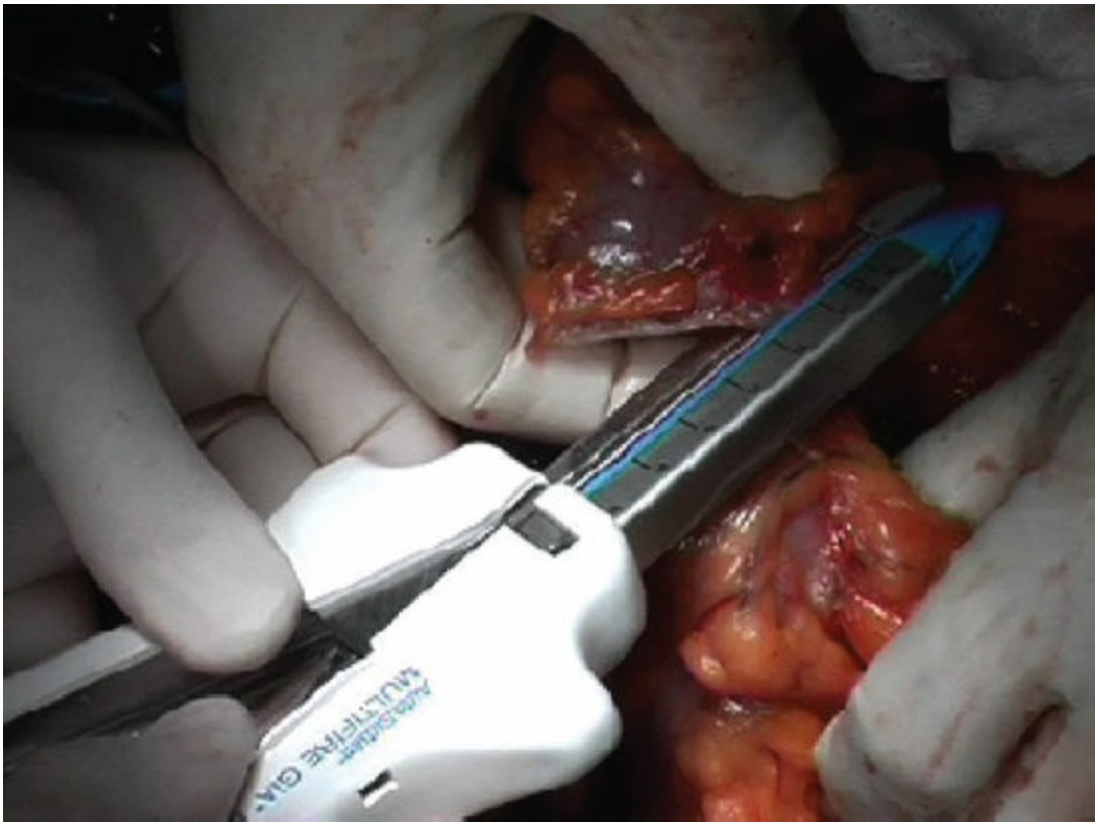

Figure 154.12. Division of convenience.

The ascending left colic artery and either the accompanying inferior mesenteric vein or its last tributary from the left colon may also need to be divided separately to complete the vascular isolation of the specimen with full mobilization for ultra-low pouch anastomosis.

In a minority of cases, a particularly long and healthy sigmoid may obviate the need for this full mobilization process, which is not entirely without risk (e.g., to the spleen itself). Thus, it is logical, if a decision is made to use such a long healthy sigmoid and thus avoid the splenic flexure, to ligate the inferior mesenteric artery just distal to the ascending left colic, which is essentially a part of its primary blood supply. Particular care over the ligation is necessary as the stump will pulsate vigorously.

The "Division of Convenience"

The sigmoid mesentery and the sigmoid colon are divided well above the cancer (Fig. 154.12). This is an important step in every cancer dissection as optimal mobility of the top of the specimen facilitates gentle opening of the perimesorectal planes by traction and countertraction in any direction throughout the pelvic dissection. After the division, there is also the best possible visualization of the pelvis with all of the gut to be retained drawn upward and to the right. Most laparoscopic surgeons do not find that this division helps them.

Commencing the Pelvic Dissection

The surgeon is now optimally placed to identify the key planes that must be developed circumferentially around the mesorectum. He or she starts at the back and then follows identifiable areas of the "holy plane" at various points on the mesorectal circumference in a stepwise manner. If lower down in the pelvis, bleeding in one area is troublesome due to inaccessibility, it is sensible to tackle the opposite circumference so that pressure is applied while progress continues.

High Posterior Dissection

There is no real substitute in open surgery for the St. Marks' retractor or my own reverse concavity (Heald Retractor)—both available from Bolton Surgical of Sheffield—or from many instrument manufacturers. Forward traction demonstrates the shiny posterior surface of mesorectum within the bifurcation of the superior hypogastric plexus. This plane is extended

downward toward and eventually beyond the tip of the coccyx, step by step as other sectors of the circumference are developed.

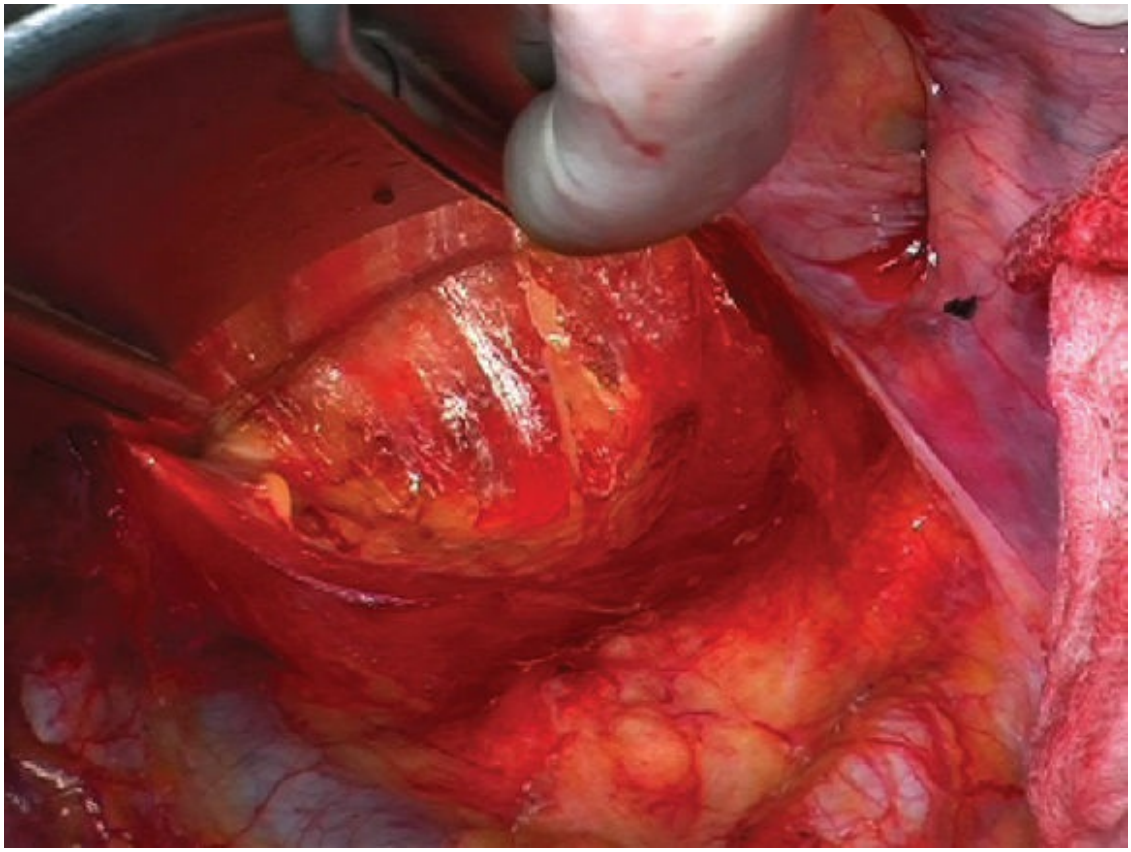

Figure 154.13. Rectosacral ligament.

Division of the Rectosacral Ligament or Fascia

This condensation may constitute an apparent barrier to downward progress posteriorly, requiring positive division with scissors or diathermy (Fig. 154.13). Just in front of it, within the mesorectum, the superior rectal vessels can often be seen through the back of the mesorectal fascia, and around them cancerous nodes are likely to occur only millimeters away. An intact shiny visceral fascia over these must be jealously guarded and tearing avoided at all costs. This poses one of the greatest dangers of blunt manual extraction or of any haste or roughness, since the rectosacral ligament may be stronger than the surface fascia over the nodes. Thus, tearing into the lymphatic field by the inserted hand becomes a real risk and must have occurred frequently in the past. Sharp dissection under direct vision is crucial and lighting essential. A further safety factor in identifying positively the “holy plane” posteriorly in front of the presacral fat pad (when present) is that one avoids the risk of tearing thin-walled

presacral veins, which often have no valves and can bleed prodigiously when cut or torn. These will never become a problem if the correct plane is followed and tearing is avoided; if they should be torn, a small pack and a considerable period of anterior dissection away from them will provide the safest way forward. The key to this dissection is always to remain on the yellow mesorectal anterior and medial side of the dissection plane, which is held widely open by traction and countertraction.

Lateral Pelvic Dissection

This involves forward extension of the plane around to the sides, gently easing the adherent hypogastric nerves laterally off the mesorectal surface under direct vision. The freedom to lift the divided rectosigmoid forward often means that the tangentially running hypogastric nerves are first positively identified at this stage, the superior hypogastric plexus itself only becoming obvious proximal to the nerves after they have been dissected away from the mesorectal surface on each side. The superior hypogastric plexus may have been ensheathed by fatty tissue and not immediately recognized as a nerve bifurcation.

These nerves are far more important than hitherto appreciated because they subserve many of the functions of orgasm in both sexes, while the inferior, more distal plexus is necessary for the more obvious parasympathetic function of erection—certainly in the male and presumably clitoral function in the female as well.

The “Lateral Ligament” Area

These so-called ligaments were the subject of an international consensus conference in Tokyo where I asserted that they did not actually exist (Figs. 154.14 to 154.17). The following account represents a personal view of the difficult anatomy in the distal anterolateral sector as experienced by the operating surgeon in the live patient.

The holy plane is followed downward toward the vesicles with the expanding plexiform band of inferior hypogastric plexus outside it, but increasingly adherent to it. In essence, there is no actual ligament, but there is an area of adherence between mesorectum medially and plexus laterally: small branches of nerves and vessels penetrate through at this point but none generally reaches more than 1 to 2 mm in diameter. The key nerves entering this flattened band from above are largely sympathetic hypogastric nerves, curving distally from the superior plexuses and more

distally the “erigent” parasympathetic nerves coming forward to it from behind. These arise from the front of the roots of the sacral plexus (especially S3, out of sight behind the parietal sidewall fascia). This fascia is quite robust laterally and the surgeon will note that he or she usually cannot even see the internal iliac vessels, which are outside it. Posteriorly, these “erigent pillars” from the roots around S3 curve forward outside the parietal fascia but medial to the branches of the internal iliac vessels. Together they form a layer of the “onion”—inside this layer the holy plane, outside a “tiger country” of internal iliac vessels and veins, which can cause serious bleeding (Figs. 154.15 to 154.18).

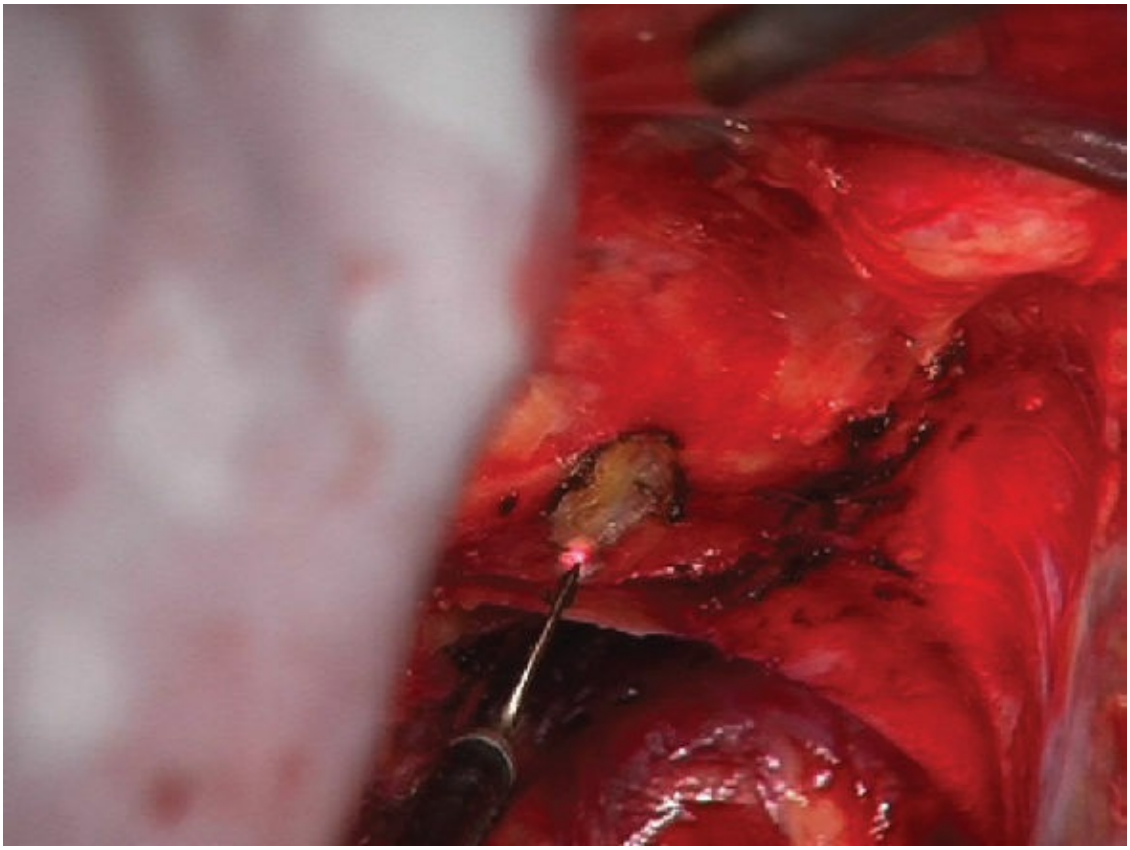

Figure 154.14. Dividing the lateral “ligament.”

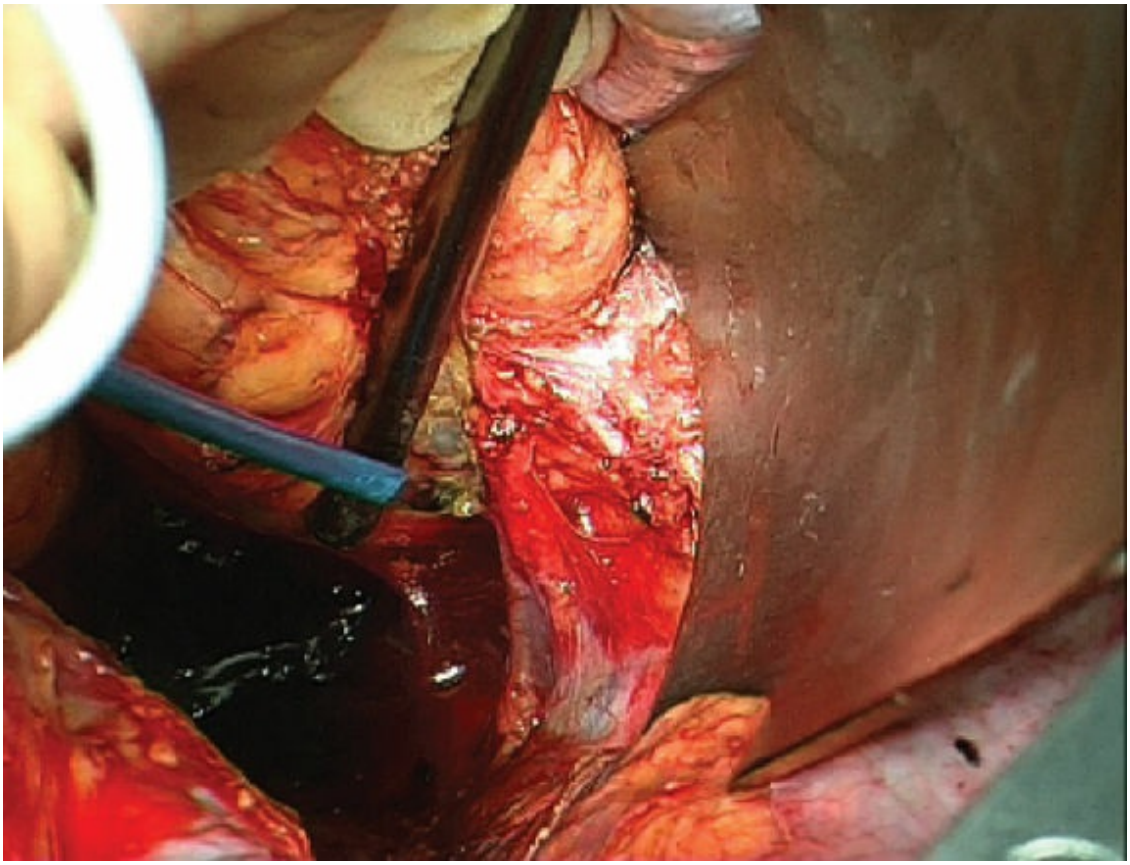

Figure 154.15. “Lateral ligament” area.

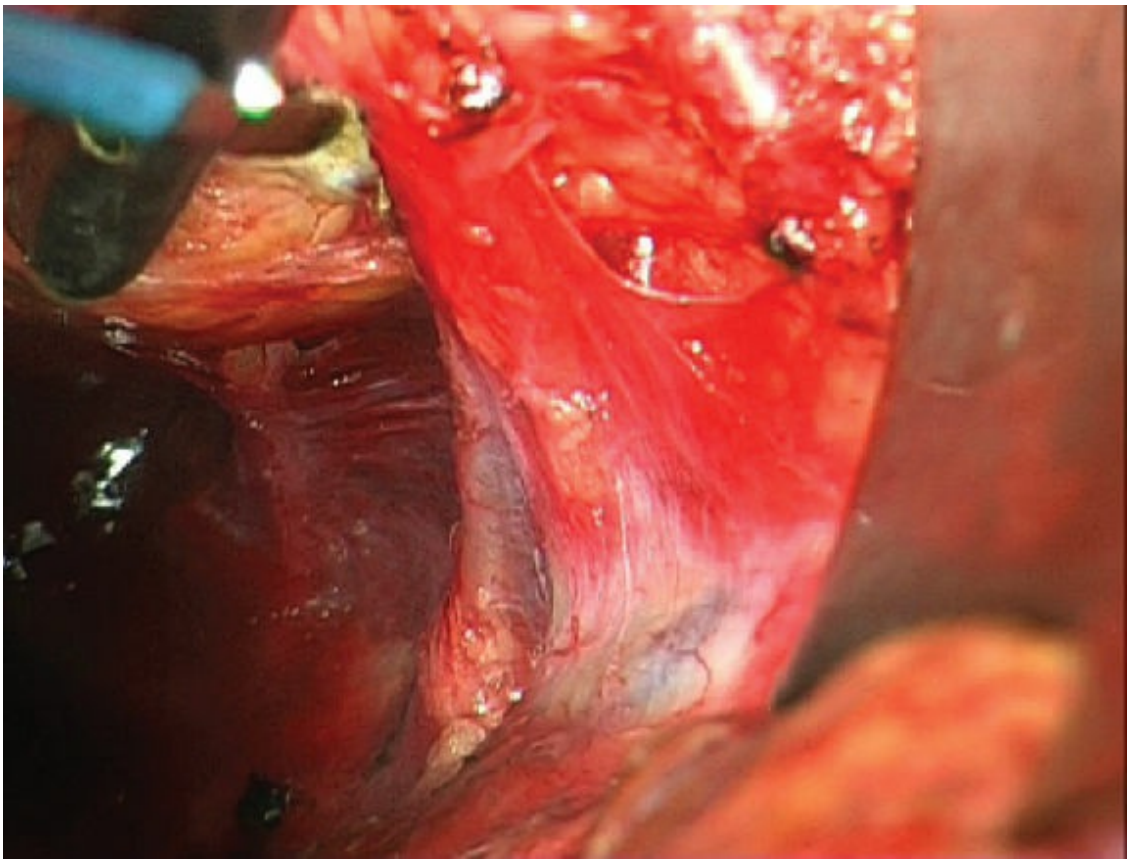

Figure 154.16. Erigent pillar.

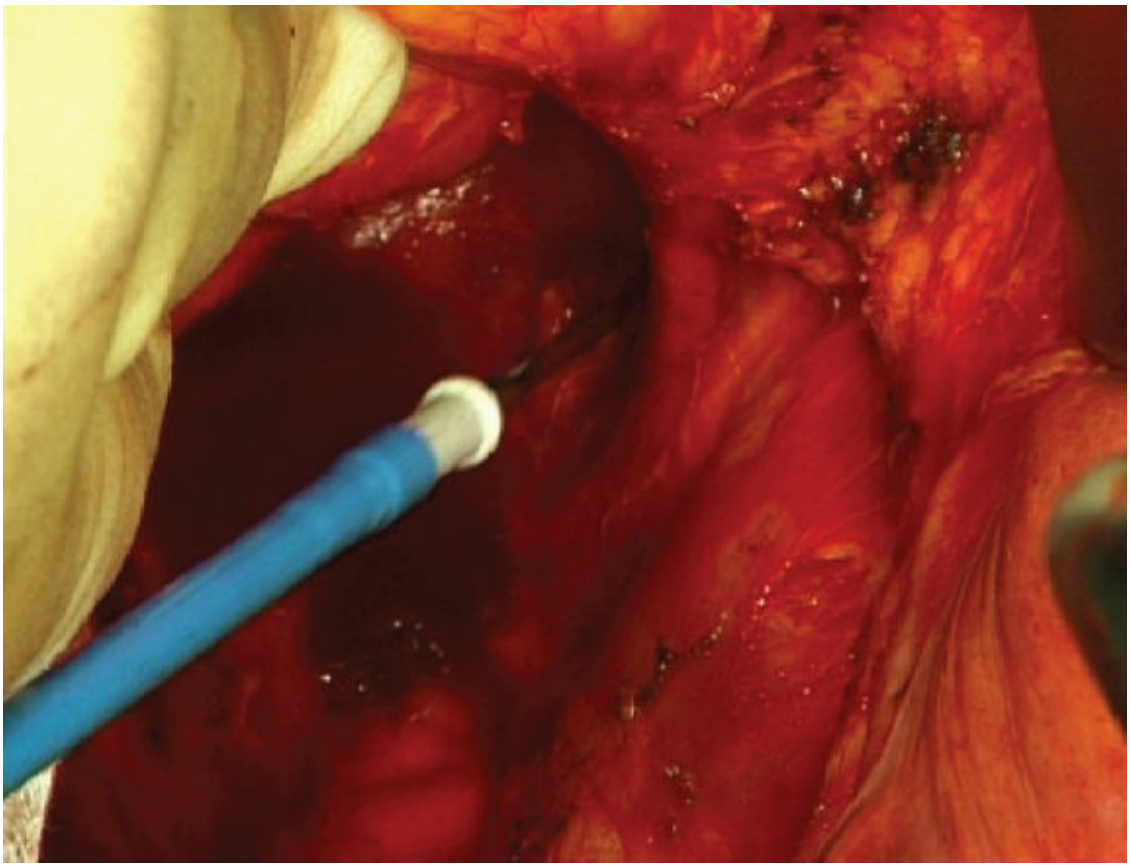

Figure 154.17. Bifid root.

A little way behind the vesicles the erigent pillars pierce the fascia to join the inferior hypogastric plexus and often contribute nerve branches to the mesorectum and rectum. These “neural T junctions” are the nearest structures to “lateral ligaments” that the most careful surgeon will find with precise dissection. Another often described structure that I believe to be found only rarely by the surgeon during this dissection is a true middle rectal artery. I believe that in past days what the surgeon believed to be a middle rectal artery was most often a lateral intramesorectal artery, and the so-called “stalk” being divided represented a “coning in” to the mesorectum.

The surgeon dissecting perfectly between the mesorectum and the inferior hypogastric plexus discovers nothing more than a tiny vessel that requires no more than a touch of diathermy. Similarly, Sato and Sato have shown by careful anatomic studies in cadavers that a true middle rectal artery exists in <20% of patients and then on one side only. When the surgeon “cones” or tapers in too far medially, he comes across a

substantial intramesorectal vessel, when too far lateral a pelvic sidewall vessel. Thus, the clamp and cut routine implied a poor quality of the dissection, damaged nerves, and left a substantial residue of dangerous tissue, probably all a part of the prodigious 30% to 40% local recurrence rate that was once commonplace.

Neither of these is a true middle rectal vessel since neither is passing from the internal iliac to the rectum. “Coning in” does, of course, compromise the oncologic quality of the “block dissection” because it implies that part of the distal mesorectum is being left in the pelvis. A more distal vessel from the prostatic branch or from the pelvic floor is often found later and lower down where it can cause troublesome bleeding. We feel that the minimal nature of a true middle rectal blood supply also implies a minimal lymphatic component. In our view, this is a less common mode of spread than is often believed in Japan or it is even possible that there is an ethnic difference with this regard. It is our belief that most surgeons have in the past thus strayed either outward into the plexus or inward into the mesorectum and created surgical artifacts that they have called “lateral ligaments” because they tethered the rectum at these points and “middle rectal arteries because they bleed ferociously.” If the cancer is truly adherent at this point, or if preoperative MRI shows invasion, then “straying” outward to the internal iliac becomes justified, though it may cause damage to the nerves involved, which can be avoided in the standard TME operation for most cancers. The surgeon should generally attempt to dissect at this point of adherence precisely between the outer aspect of the mesorectum and the triangulated neural band of nerve plexus that should be left intact. This technique can be dubbed “mesorectal fat surface dissection” because no actual loose areolar tissue exists in those areas where mesorectum and plexus are adherent. The final specimen will often lack the shiny fascial covering over this area.

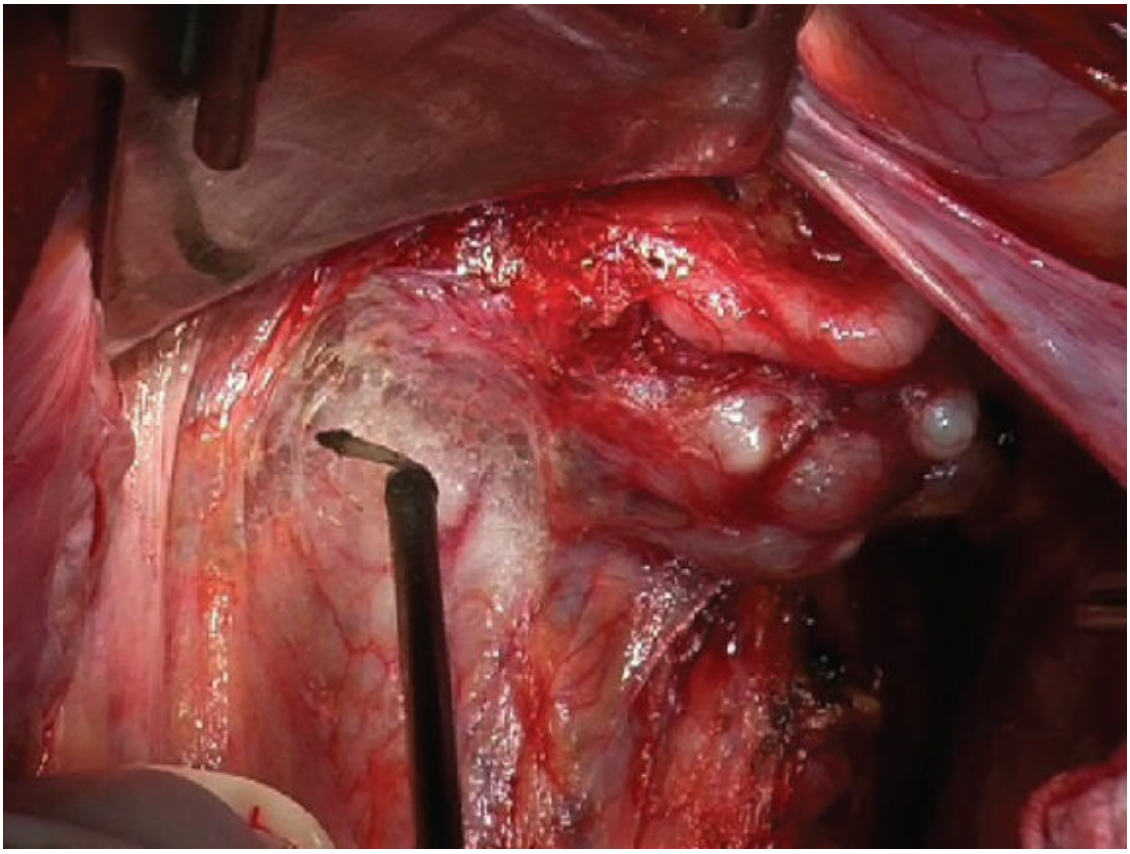

Figure 154.18. Vesicles and Denonvilliers' fascia.

The Anterior Dissection—Denonvilliers Septum

Dissection anterolaterally and anteriorly following the correct plane forward will encompass the peritoneal reflection that remains on the specimen, and thus allows positive identification of the backs of the seminal vesicles (Figs. 154.18 and 154.19). Forceful forward retraction on these with a St. Mark's retractor will facilitate the development of the areolar space between the vesicles and the smooth front of the mesorectal specimen (Fig. 154.17). We call this smooth surface that is generally adherent to and clearly a part of the mesorectum Denonvilliers fascia or the rectogenital septum. As one works distally, there comes a point where this fascia must be divided transversely as it becomes adherent to the posterior capsule of the prostate. Particular care is necessary during this step to avoid damage to the neurovascular bundles (of Walsh) that constitute the distal condensation of the inferior hypogastric plexuses, joined by numerous veins and small arteries; hence the title neurovascular.

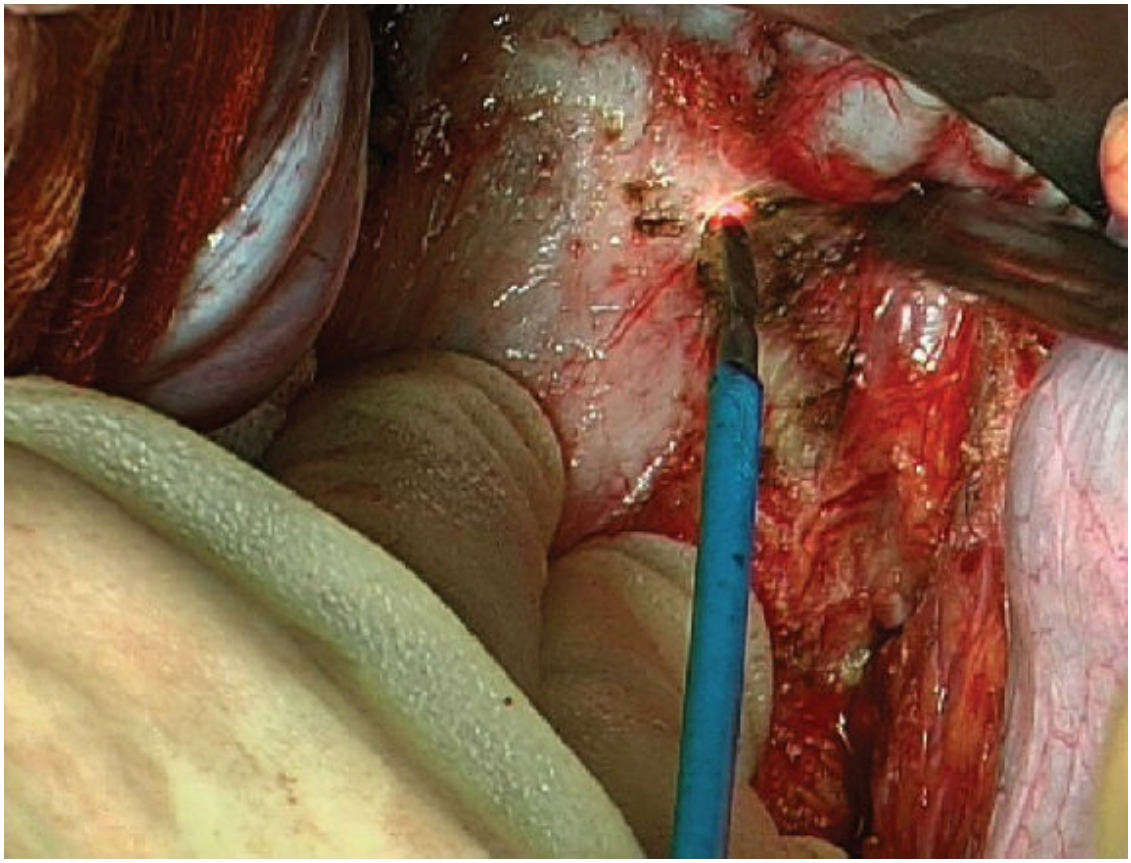

Figure 154.19. Cutting through Denonvilliers fascia.

In a low anterior tumor, this can be exceedingly critical: It is essential to avoid exposing malignant tissue on the front of the specimen at the very point where the nerves are curving acutely medially. Since they are often impossible to see in open surgery because of forward angulation behind the vesicles, bladder, and prostate, they are in particular danger. In addition, surgeons who “take a slice off the back of the prostate” are highly likely to cause impotence because of the close relationship of the neurovascular bundles to the back of the prostate.

Hand in hand with this anterior dissection goes the development of the lateral sidewall dissection. The whole area of the rectoprostatic interface is a major current challenge in technical surgery—both open and laparoscopic.

The Face-Down Position (The Kocher/Holm Position) for Extra Levator Abdominoperineal Excision

True understanding of what happens to these nerves after they leave the area of vision of the abdominal operator has only become possible for us since introducing the prone jackknife position. This provides posterior

access to the rectoprostatic interface so that the lowest part of the rectum can be gently dissected clear of the nerves as they course toward the back of the penis. Figure 154.27 is a unique picture of the neurovascular bundles from behind after removal of the rectum. More detail for the dissection is provided later.

The Nervi Erigentes or "Erigent Pillars"

The parasympathetic erigent nerves form posteroanterior lateral "pillars" on the pelvic sidewall—the distal margin of the neural layer of the "anatomical onion" (Figs. 154.14 to 154.17; see also Fig. 154.21). Cadaver dissections have led us all to be taught that the pelvic parasympathetic outflow is tripartite S2–3–4. However, to the surgeon, there is no doubt that a recognizable landmark is often a single or bifid "pillar" comprising a nerve root arising from the front of the S3 component of the main sacral plexus (Fig. 154.17), which is out of sight posteriorly. The pillar-like appearance is in part due to the forcible forward traction on the prostate and bladder to see the structures during an open operation, and this tends to bow the nerves medially and thus make them stand out. This retraction does not occur to the same extent in a laparoscopic operation, which may account for the reported higher incidence of nerve damage recorded from several centers. These pillars and the hypogastric plexuses curve medially toward the back of the prostate, where they form the neurovascular bundles, which taper toward the urethra at the apex of the prostate. Here they become the erectile nerves of the corpora cavernosa or cavernous nerves. The pillars or roots arise outside the parietal fascia that they penetrate obliquely at the point of adherence to the anterolateral aspect of the mesorectum (Fig. 154.18). Further forward and more medially, as stated above, removal of a "slice of prostate" will probably cause impotence and is not often really necessary. This part of the low anterior dissection is made more confusing by the *perineal body*—the midline fibrous interdigitation of the transverse perineal muscles. The surgeon often finds dissection through this confusing because he is not in a proper "surgical plane," but, at this one point, this is good because the front of the cancer specimen and the urethra are rather close together and a little perineal body tissue on each is probably optimal.

Dissection of the Most Distal Mesorectum

The anatomy of the insertion of the mesorectal "package" into the pelvic

floor becomes difficult for the surgeon to grasp from above because of its inaccessibility behind the vesicles and prostate and behind the vagina in the female (Figs. 154.20 and 154.21). The situation is further complicated by the fact that the levators are like a “flower pot” in continuity with the tube of external sphincter distally. Conceptually, and because of the distortion introduced by upward traction, surgeons tend to think of the pelvic floor as being much flatter than it is in vivo, especially if an assistant applies upward pressure on the perineum. If one doubts this, a careful look at the layers on a coronal MRI scan will make it evident. A clear three-dimensional perception of the now globular bilobed mesorectum in the depth of the pelvis and the surrounding neural lamella is the most elusive and challenging conceptual acquisition for the aspiring rectal cancer surgeon.

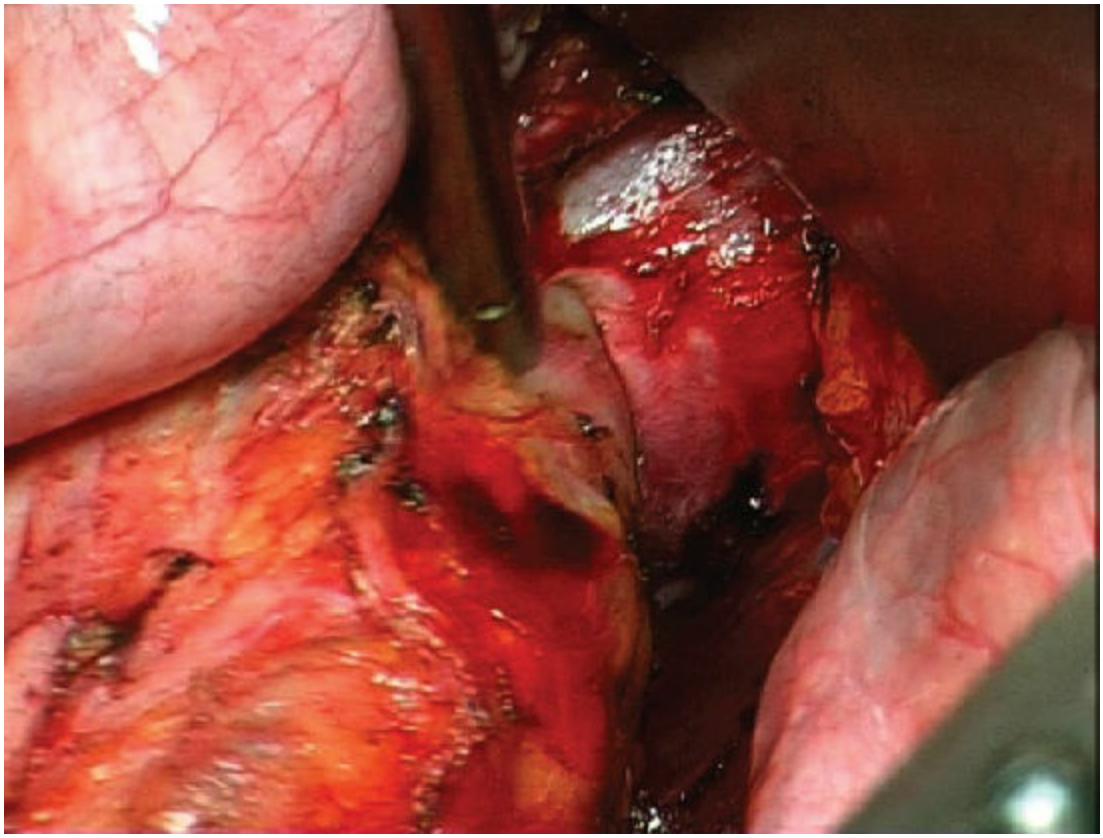

Figure 154.20. The tapering mesorectum.

Careful pursuit of the plane at this level eventually liberates the mesorectal package and takes the operator down to a clean muscle tube. Although crossed by a few small arteries and veins from the puborectal sling and some slips of sphincter muscle, the “holy plane” here becomes the intersphincteric plane, which is familiar to proctologists from below—

a tube of red skeletal muscle outside a tube of whiter smooth muscle within.

Partial Mesorectal Excision (i.e., High Anterior Resection and Mesorectal Transection)

Below which level of, or what height of tumor above the anal verge does TME become necessary? Height measurement, by general agreement, is from the anal verge in the conscious patient using a rigid sigmoidoscope. In the new world of MRI, the MRI height should also be recorded, and there is an argument for considering as truly "low" cancers extending below the origins of the levator muscles on the coronal slice. Heights measured under anesthesia need to be from the dentate line since the external sphincter dilates and retracts (add about 1.5 cm). Care is necessary: any instrument can push a mobile tumor up; flexible ones often give falsely high measurement. With these qualifications it can be said that, in our view, most cancers with the lower edge at or below 12 cm should have TME as the key component of a radical cancer operation because the mesorectum is the primary field of lymphovascular spread. However, the decision as to whether the smaller *partial* mesorectal excision is adequate is finally confirmed after the mobilization has been completed to the point where the mesorectum must be liberated from the adherent inferior hypogastric plexus—the region usually referred to as the "lateral ligament." It has long been a convention and a very sound rule, borrowed from German surgical practice, that a minimum of 5 cm of mesentery should always be excised both proximal and distal to any colorectal cancer. While muscle tube margin may safely be reduced to 1 cm in the interest of anal conservation, we have always believed that, if less than a TME is contemplated, a minimum of 5 cm of mesorectum distal to the lower edge of the cancer must be dissected in the perimesorectal (holy) plane. If, therefore, after initial mobilization there is a clear 5 cm of mesorectum, then tapering into the mesentery, in the interest of making a more minor operation and a higher anastomosis, becomes acceptable.

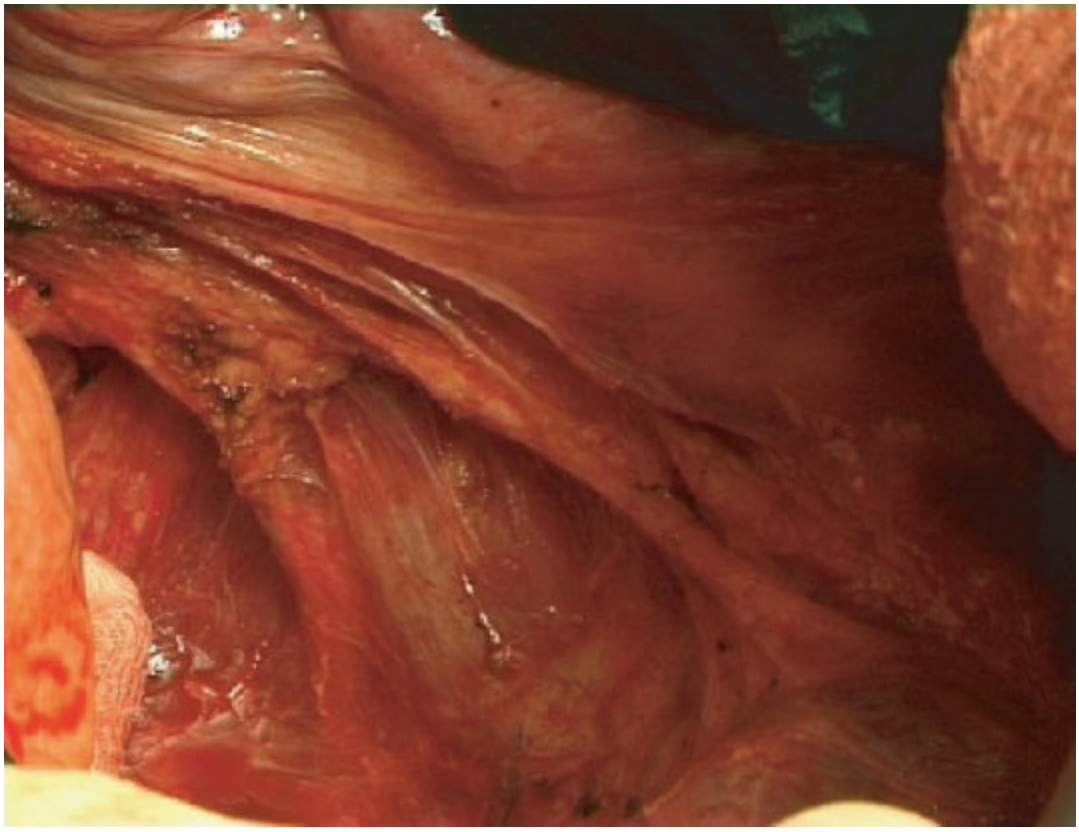

Figure 154.21. Pelvic sidewall and plexuses.

The operation then becomes perimesorectal mobilization, mesorectal transection, AR, and primary anastomosis for rectal cancers above around 12 cm. Either 5 cm of mesorectum distal to the tumor or the whole mesorectum must be removed intact with the same preoccupation with clear circumferential margins.

MANAGEMENT OF THE ANORECTUM DISTAL TO THE CANCER—STAPLING TECHNIQUES

The Avoidance of a Permanent Colostomy

In >90% of rectal cancers, it is technically feasible, though not necessarily optimal in terms of future function, to extend the dissection down to a clean muscle tube where a cross clamp may be applied with a “finger and thumb” clearance beyond the lowest edge of the cancer (Figs. 154.22 to 154.24). This is a difficult and challenging moment requiring both skill and experience. We have developed a preference for the use of the long linear stapler in place of the right-angled clamp (the Moran triple stapling technique). The first TA-45, TA-30, or PI-30 (Covidien) staple line seals the muscle tube so that the anorectal lumen beyond can be washed out

with water or a tumoricidal solution. The risk of incorporating viable exfoliated intraluminal cells in the second staple line is thus eliminated and a second TA-45 or TA-30 is fired through the washed bowel, while the anatomy is distorted by upward traction on the first (pathologist's) stapler. This process, in our view, justifies the cost of a second stapler because of the greater security against spillage of potentially malignant bowel contents. Only this washed staple line remains within the patient.

The first of these two linear staple lines should be safely clear of the palpable distal edge of the cancer. This is usually, though not absolutely invariably, the microscopic edge. Downward spread along the muscle tube is not a significant factor in recurrence—a 2-cm clearance is more than adequate and 1 cm plus the "donut" is acceptable when the survival of the anal sphincters depends on it. Careful examination of the bowel end in the upper stapler will confirm clearance; no frozen section is generally necessary. Only after checking this should the distal (patient's) staple be removed. In the unlikely event of the upper staple line being through the cancer, the distal one could be pulled up hard and a further cartridge fired beyond the distal one.

Figure 154.22. Washout transanally.

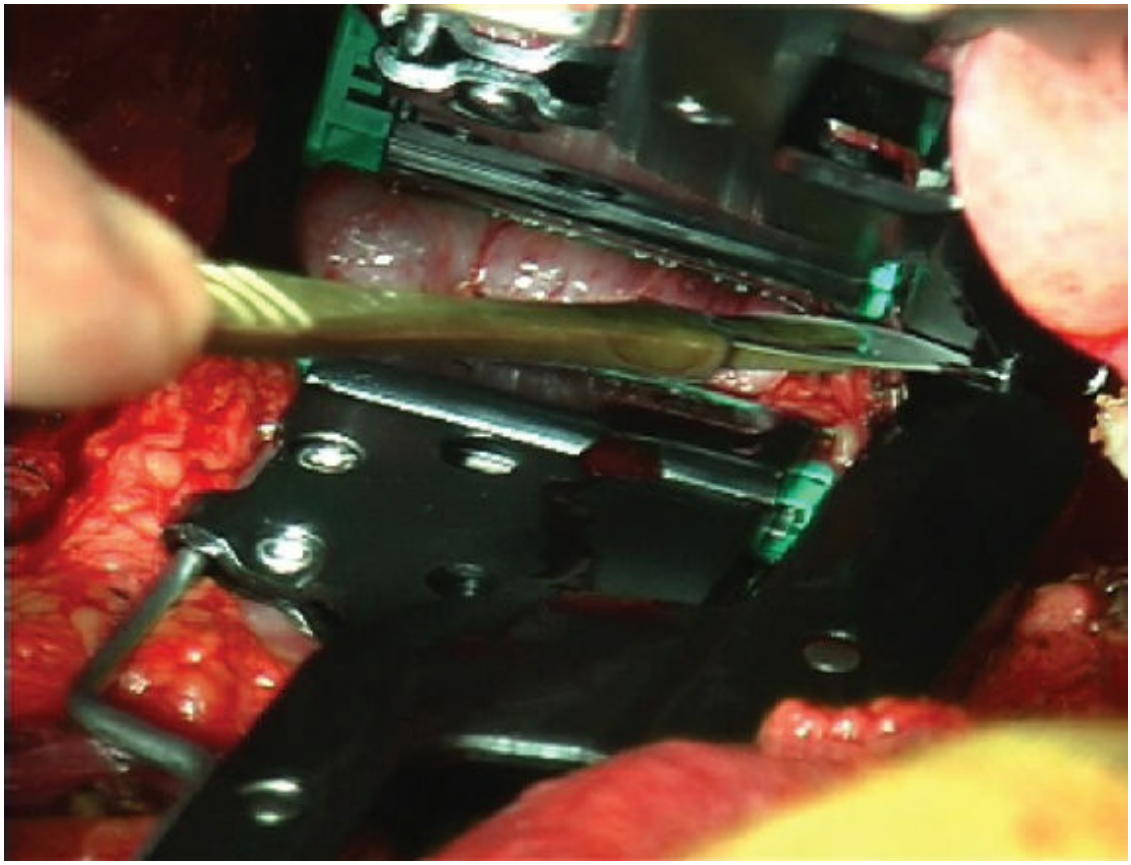

Figure 154.23. Division after washout.

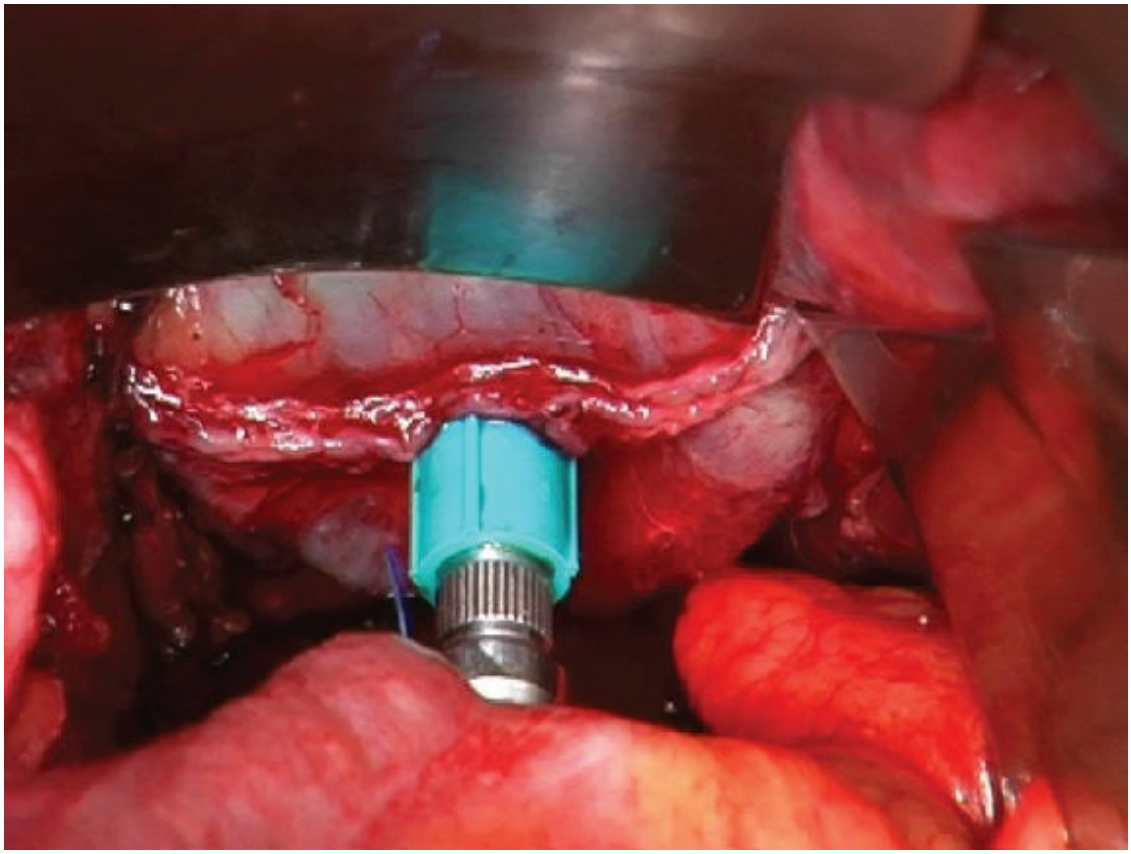

Figure 154.24. Linear plus circular stapling.

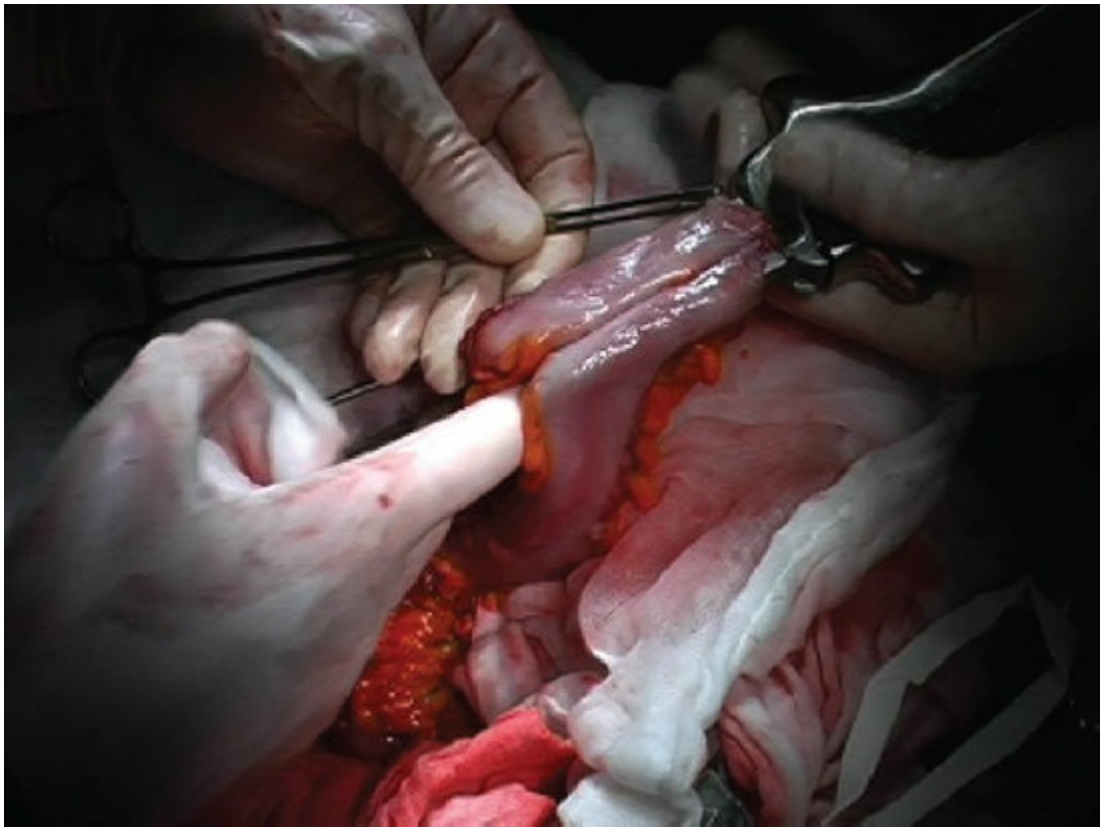

Figure 154.25. Short 2 × 5 cm colon pouch.

The Colon Pouch or Coloplasty?

Several variations of pouch construction are available—typically, a GIA-60 is inserted 5 cm from the end of the fully mobilized colon to create a J pouch (Fig. 154.25). The anvil of the CEEA-31 staple anvil is inserted into the same colostomy, which is "purse stringed" around the shaft with 00 Surgipro. The body of the circular stapler, usually the CEEA-31, is inserted from below transanally. It is essential with ultra-low anastomoses to be certain that only the internal sphincter is purse stringed into the instrument. To this end it must be confirmed from above that only one thickness of muscle can be felt around the periphery of the cartridge. Adequate length of colon from the splenic flexure mobilization is essential for the pouch to lie without tension in the hollow of the sacrum, and demonstrably pulsatile blood supply at the top is the essence of success. Two low-suction Abdovac drains are used for 48 hours unless there is copious drainage when they may need to be left for longer. The objective is to avoid hematoma in the hollow of the sacrum, which may become infected, form an abscess, and point into the bowel at or near the

anastomosis, thus creating a “late leak” around 10 to 20 days later.

THE “BUILDING BLOCKS” OF THE CANCER SPECIMEN

The Mesorectum (TME)

From the tapering pedicle at the top down the globular bilobed expansion at the bottom, this core specimen is the objective of cancer surgery for all middle and lower third cancers.

TME Plus

Where directly involved by visible and palpable cancer spread, or indeed when adherence implies the possibility of such adherence to the adjacent mesorectal margin, it may be necessary to excise in continuity with the TME the following, in selected cases. In modern practice, these extra building blocks can usually be predicted on MRI and appropriate plans made in advance.

TME Plus—The Levators, Ischiorectal Fossa, and Perianal Skin Extra Levator Abdominoperineal Excision

Conventional APE has in many countries earned a poor reputation in the last decade. Extra care is required to perform the perimesorectal dissection that is inherent in TME, but only as far distally as the origin of the levator muscles from the pelvic sidewall, that is, the obturator internus muscles.

Exposed circumferential margins are almost twice as common after conventional APE than after AR, except in units where special care has been taken. This implies that the operation is often less well done than it could be. We believe that the conventional performance of APE in the United Kingdom, particularly involving synchronous combined excision by two surgeons, has often been less precise than a fastidious AR performed from above—largely because the planes cannot be readily defined and followed, and possibly because of the moving target created by the other operator.

Optimal performance of an APE, especially when undertaken for a laterally spreading cancer, should incorporate a covering of levators and the surgeon should avoid the lowermost “holy plane” dissection within them (i.e., to avoid dissection in the lowest part of the plane where it is within contact with the levators). In this way, a more generous clearance of the cancer may be achieved and the commonly observed “waist” on the

specimen avoided. This “waist” is 3 to 5 cm from the anal verge, corresponds with the location of the low cancers that require APE, and has been the common site for perforation and/or exposed cancer margins in the past.

The Prone Jackknife Position for the Perineal Dissection

The views into the pelvis from “behind” are considered by many surgeons to be superior to those in the conventional steep Trendelenburg position. In particular, spectacular access is provided if the coccyx is excised with the cancer. This also means that provided all the abdominal operation has been completed, the colon and rectum can be fully delivered below to provide maximum access to the interface between cancer specimen and prostate. It can, and even make possible the visualization and preservation of the cavernous nerves (Figs. 154.26 and 154.27).

The author has a particular preference for the avoidance of removing the macroglobular ischiorectal fat so well adapted to sitting upon (and also elegant in a swimming costume!) (Fig. 154.28). Apart from rare extremely advanced cancer, whose MRI clearly shows invasion through the levator muscle, the inferior hemorrhoidal vessels and lymphatics are *not* a field of spreads for adenocarcinoma; even when a cancer threatens or invades the sphincters from within, the face-down APE can therefore usually be commenced in a tidy bloodless way following a perfect surgical plane outside the external sphincters but within the macroglobular fat. This reduces the ultimate size of the dead space and hopefully the need for plastic surgeons’ assistance to fill it.

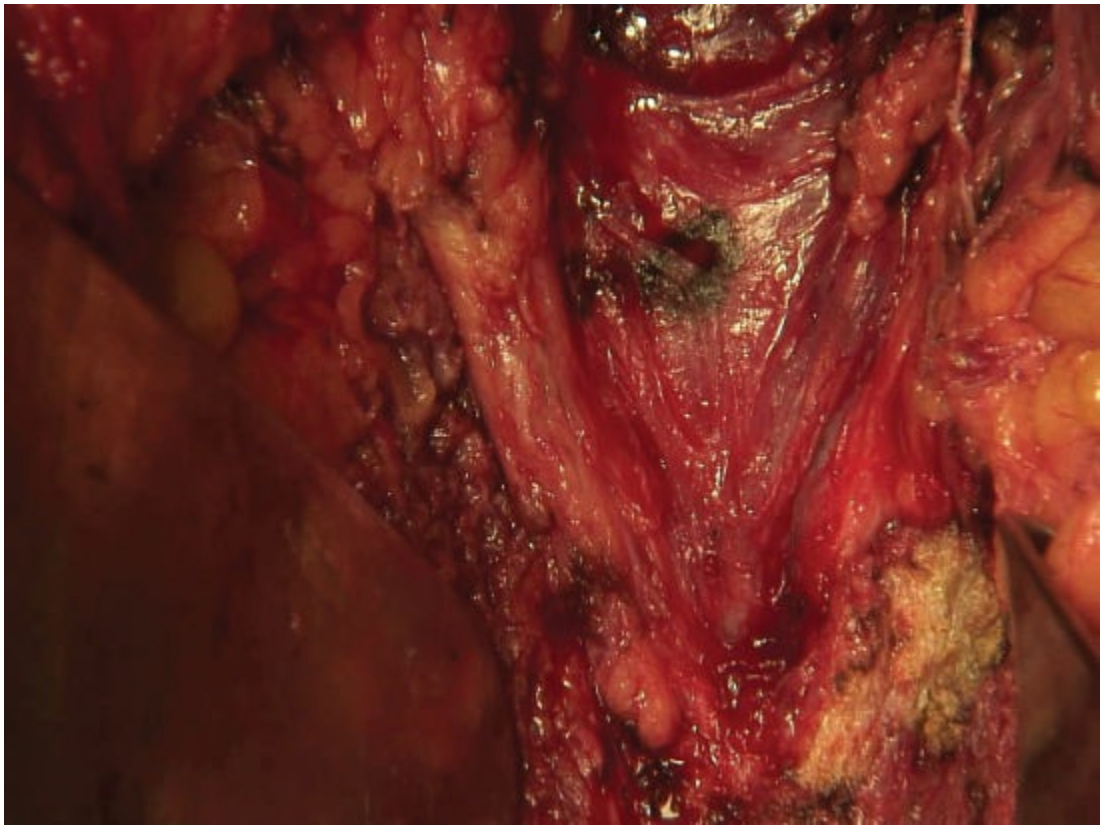

Figure 154.26. Patient face-down—abdominoperineal excision specimen just removed right puborectal sling shows white with right neurovascular bundle just medial to it.

Once the coccyx has been liberated by diathermy and osteotome, the presacral fascia is incised—hopefully on to the gauze swab left on the abdominal side. It is then relatively simple, using a ligature device to divide almost all the origins of the levators wide out near their origins from the obturator internus muscles.

As this dissection progresses, the liberated bowel segment can be eased downward to open the recto prostatic planes (12 o'clock), upward through the transverse perineal muscles and perineal body (6 o'clock), and then laterally (3 and 9 o'clock). The advantage becomes even greater as the neurovascular bundles are carefully identified coursing toward the bulb of the penis. Random fatty tissue tends to obscure these and it helps to identify them if a ligaclip has been placed on the top of the neurovascular inferior hypogastric plexuses by the abdominal operator.

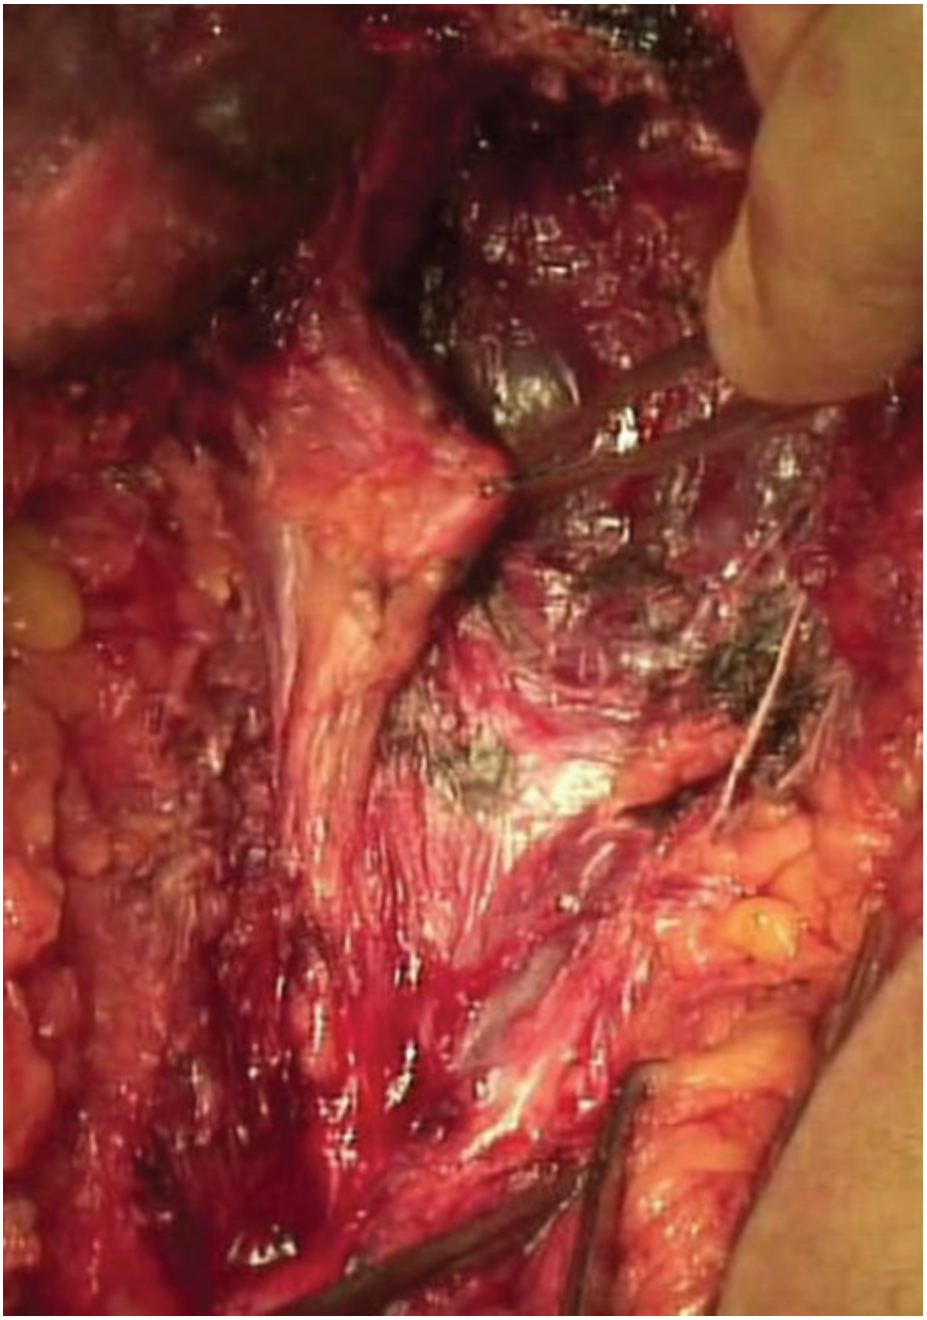

Figure 154.27. Patient face-down clip was placed at the most distal visible point of left hypogastric plexus. Patient now face-down and left neurovascular bundle drawn medially just behind seminal vesicles.

The key to not damaging these hitherto unrecognized nerves is care in dividing the puborectal sling which can be seen just after its division on the right side of the prone male in a white divided muscle bundle in close proximity to the longitudinally running nerve bundle, now called the cavernous nerves.

The *urethra* is not far away anteriorly—it should always have a

substantial (easy to feel) catheter in place—even if this is removed at the end and its function taken over by the supra-pubic catheter, which is our preferred routine for both AR and APE.

The perineal body is worrying for the surgeon because it is fibromuscular and dissection through it is not in a recognizable surgical plane. The rectourethralis remains something of a practical challenge but the essence of this part of the procedure is carefully to find a safe covering for the urethra on one hand and for the tumor specimen on the other.

The ideal APE specimen is a perfect TME with its distal component wrapped in levators and sphincter muscles (Fig. 154.29). Does the space left by extralevator APE require surgical "filling"? Various techniques exist for the swinging of musculocutaneous flaps to combat the poor healing. This is so common since radiotherapy, hence frequently used in APE. The author's personal preference is for the MR to be used, applying similar principles to those outlined above but using as the defined margin the plane outside the anal sphincters and levator muscles.

This latter plane very rarely breaches, therefore, APE in the author's opinion does not routinely require radiotherapy.

An ideal alternative to closure by plastic surgery is to mobilize the cecum to fill the pelvic cavity possibly plus the omentum when adequate. A biologic mesh such as Permacol can be added for extra safety.

The Option of Starting the Operation From Below

There are considerable advantages in commencing the operation from below with the patient in the prone jackknife position. This is particularly true if there are likely to be major problems with the abdominal surgery—as, for example, when performing APE for a local recurrence after AR. Commencing from below has the advantage that the patient does not need to be turned completely twice (i.e., at the end of the major procedure). The disadvantages are that the pneumoperitoneum necessary for a laparoscopic "top end" may not be achievable and that "turning" may be required. Starting at the perineal end, however, is in the author's view, a crucial advantage if APE is being performed for low local recurrence as it provides optimal tissue planes for the dissection around the cancer before the inevitable difficulties with a second time round pelvis are encountered.

Figure 154.28. ELAPE specimen in situ after careful dissection between anorectal musculature (*central*) and preserved ischiorectal “cushions” laterally coccyx excised (*central top*).

Figure 154.29. Perfect ELAPE specimen showing nice mesorectal planes above and sphincter and levator wrap around more distal mesorectum.

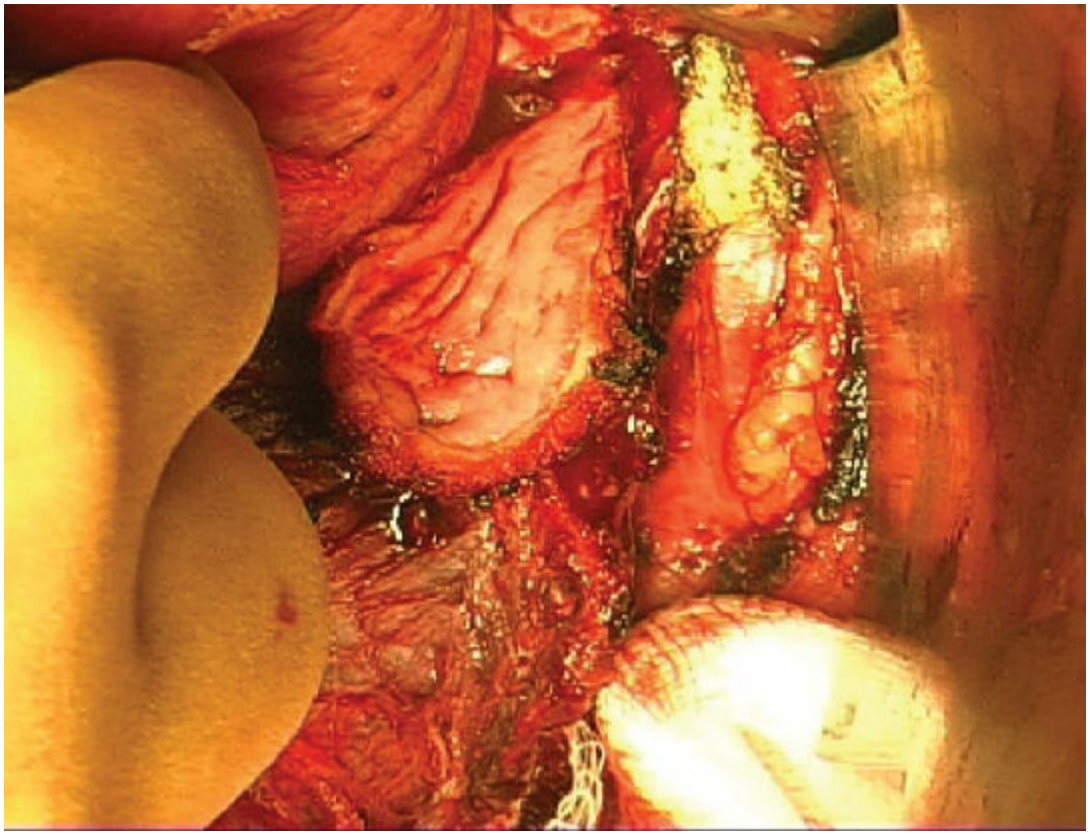

Figure 154.30. Sometimes a disk of vagina.

The Posterior Vaginal Wall

Bimanual examination via the rectum and the vagina in the anesthetized patient is essential (Fig. 154.30). If there is free mobility of the cancer on the posterior vaginal wall, then it need not be excised. If tethered over a small area, a disc of vagina may be taken with the tumor, or in a case that requires APE, because of proximity to the sphincters, the whole or most of the posterior wall from the perianal skin upward may need to be removed. We now only perform this once standard procedure when there appears no alternative due to the anterior extension of the cancer, as ultimate vaginal function may be much impaired. When it does have to be excised, it is not essential for the vagina to be resutured though the long-term function and lubrication must be in some doubt.

Other organs occasionally requiring en bloc removal on account of direct invasion seminal vesicles. These can sometimes provide an extra anterior safety margin, and the most anterior “layer” of vesicles sometimes has a dissectible, though vascular, plane between it and the adherent or invaded posterior vesicles.

One or both ureters—in a modern hospital the management of the ureter

shortened by the excision of its lower part will be in the hands of a urologist. If not, ureteroureterostomy over a ureteral stent is a perfectly achievable solution.
Ileum.
The folded-over sigmoid—with advanced sigmoid cancer, when the colon is folded down and invading the anterior aspect of the upper rectum, an extensive en bloc resection of both may be required. A large tumor mass blocking the upper true pelvis is a formidable undertaking for which ureteric stenting is a wise precaution.

Neoadjuvant Chemoradiotherapy May Be Considered First

One or both hypogastric plexuses.
Parts of the neural lamella may have to be removed in continuity with the primary or even a node—going laterally until a clear plane can be identified.

Other Pelvic Sidewall Structures

Appendix
Small like appendix etc.
Uterus, ovaries, and adnexal structures
Bladder

Block dissection of an internal iliac compartment is possible, but has not been part of our routine. When there are obvious extramesorectal lymph nodes, we will usually excise these as cleanly as possible, preferably without damaging the autonomic nerves.

The Basingstoke Experience of Total Mesorectal Excision 1978–1997

In 1998, we published data on 519 consecutive surgical patients with adenocarcinoma of the rectum, receiving surgical treatment for cure or palliation under the direct supervision of or performed by one surgeon. These may be important data as follow-up approached 20 years and use of radiotherapy and chemoradiotherapy had been so minimal and recent that they can be regarded as “virtually pure” surgical results updated follow-up references are provided, but these data stand for this reason. Cancer-specific survival of all surgically treated patients, including those considered palliative or with metastases on presentation, was 68% at 5

years and 66% at 10 years. The local recurrence rate was 6% (95% confidence interval, 2% to 10%) at 5 years and 8% (95% confidence interval, 2% to 14%) at 10 years. In 405 "curative" resections (no obvious residual disease), the local recurrence rate was 3% (95% confidence interval, 0% to 5%) at 5 years and 4% (95% confidence interval, 0% to 8%) at 10 years. Disease-free survival in this group was 80% at 5 years and 78% at 10 years. An analysis of histopathologic risk factors for recurrence indicated only the Dukes stage, extramural vascular invasion, and tumor differentiation as variables in these results.

CONCLUSION

Rectal cancer surgery is probably the most rewarding of all the challenges to the aspiring gastrointestinal surgeon. Arguably, there is no cancer operation where proper decisions, the judicious selective use of adjuvant therapy, and, most of all, surgical skill of the highest order can bring so much benefit to the patient. Cancer cure, normality of bowel function, avoidance of a lifelong stoma, and sexual function—all of these hang in the balance for the patient. The profession still has a long way to go in using its many skills and disciplines to deliver what is possible and affordable to every patient. In doing so, it will advance the science and craft of pelvic surgical anatomy in a very important way.

EDITOR'S COMMENT

Please refer to the Editor's Comment in chapter 154a

154A Advances in Total Mesorectal Excision

Steven Nurkin, Rupen Shah, Aaron Saunders, and Steven N. Hochwald

HISTORY OF RECTAL CANCER TREATMENT

The treatment of rectal cancer continues to evolve with the use of magnetic resonance imaging (MRI) for preoperative staging and improved understanding of the oncologic appropriateness of administration of chemotherapy (neoadjuvant vs. adjuvant) and radiation therapy (long course vs. short course). However, what has remained a constant is the importance of a complete total mesorectal excision (TME).

Until the 1980s when Prof. Richard Heald brought about a renewed interest in the circumferential margins, pelvic dissection was mostly carried out in a blunt fashion. Abdominoperineal excision (APE), an operation originally described by Ernest Miles in 1908, conceptualized this procedure as a cylinder of maximal size that "empties the whole pelvis." His was an attempt at defining in advance an area of tissue to be excised by the surgeon. He considered that lymphatic spread occurred in all directions as illustrated in Figure 154a.1A, and believed that local recurrences he encountered was due to a failure to encompass the spread that had occurred into the ischioanal fat via nodes around the inferior hemorrhoidal (rectal) vessels. He observed that the "perineal portion of the operation should be carried out as widely as possible so that the lateral and downward zones of spread may be effectively extirpated."

This was however a very morbid operation, associated with sexual and autonomic dysfunction and packing of the dead space for several months. In addition to the morbidity of the procedure, a permanent colostomy (or the "abdominal anus" as it was referred to in Dr. Miles's writings) was inevitable. However, this notion of spread to the ischioanal fossa/ischiorectal fat has never been proven and surgical experience teaches us otherwise; hence, the concept of spread from adenocarcinoma of the rectum into the mesorectal fat and supralevator lymphatic tissue

gained acceptance (Fig. 154a.1B). This concept of the field of spread with the embryologic and anatomical understanding of the development of the hindgut and its mesentery described below was the basis for the excellent outcomes of a TME popularized by Dr. Heald.

In 1996, he published his experience with 115 patients in whom curative resection was attempted. Priority was given to complete excision of the visceral rectal mesentery or the mesorectum. At a median follow-up of 4.2 years, three pelvic recurrences had developed and the corrected cumulative probability of survival at 5 years was 87% and the disease-free survival by Dukes stage was A, 94%; B, 87%; and C, 58%. Patients with lower tumors had similar oncologic outcomes to those with high tumors, when treated by anterior resection (AR) and a total excision of the mesorectum. Based on this evidence, he concluded that it was often safe to limit mural clearance and thus preserve the anal sphincters, provided that the mesorectum was excised intact with the cancer.

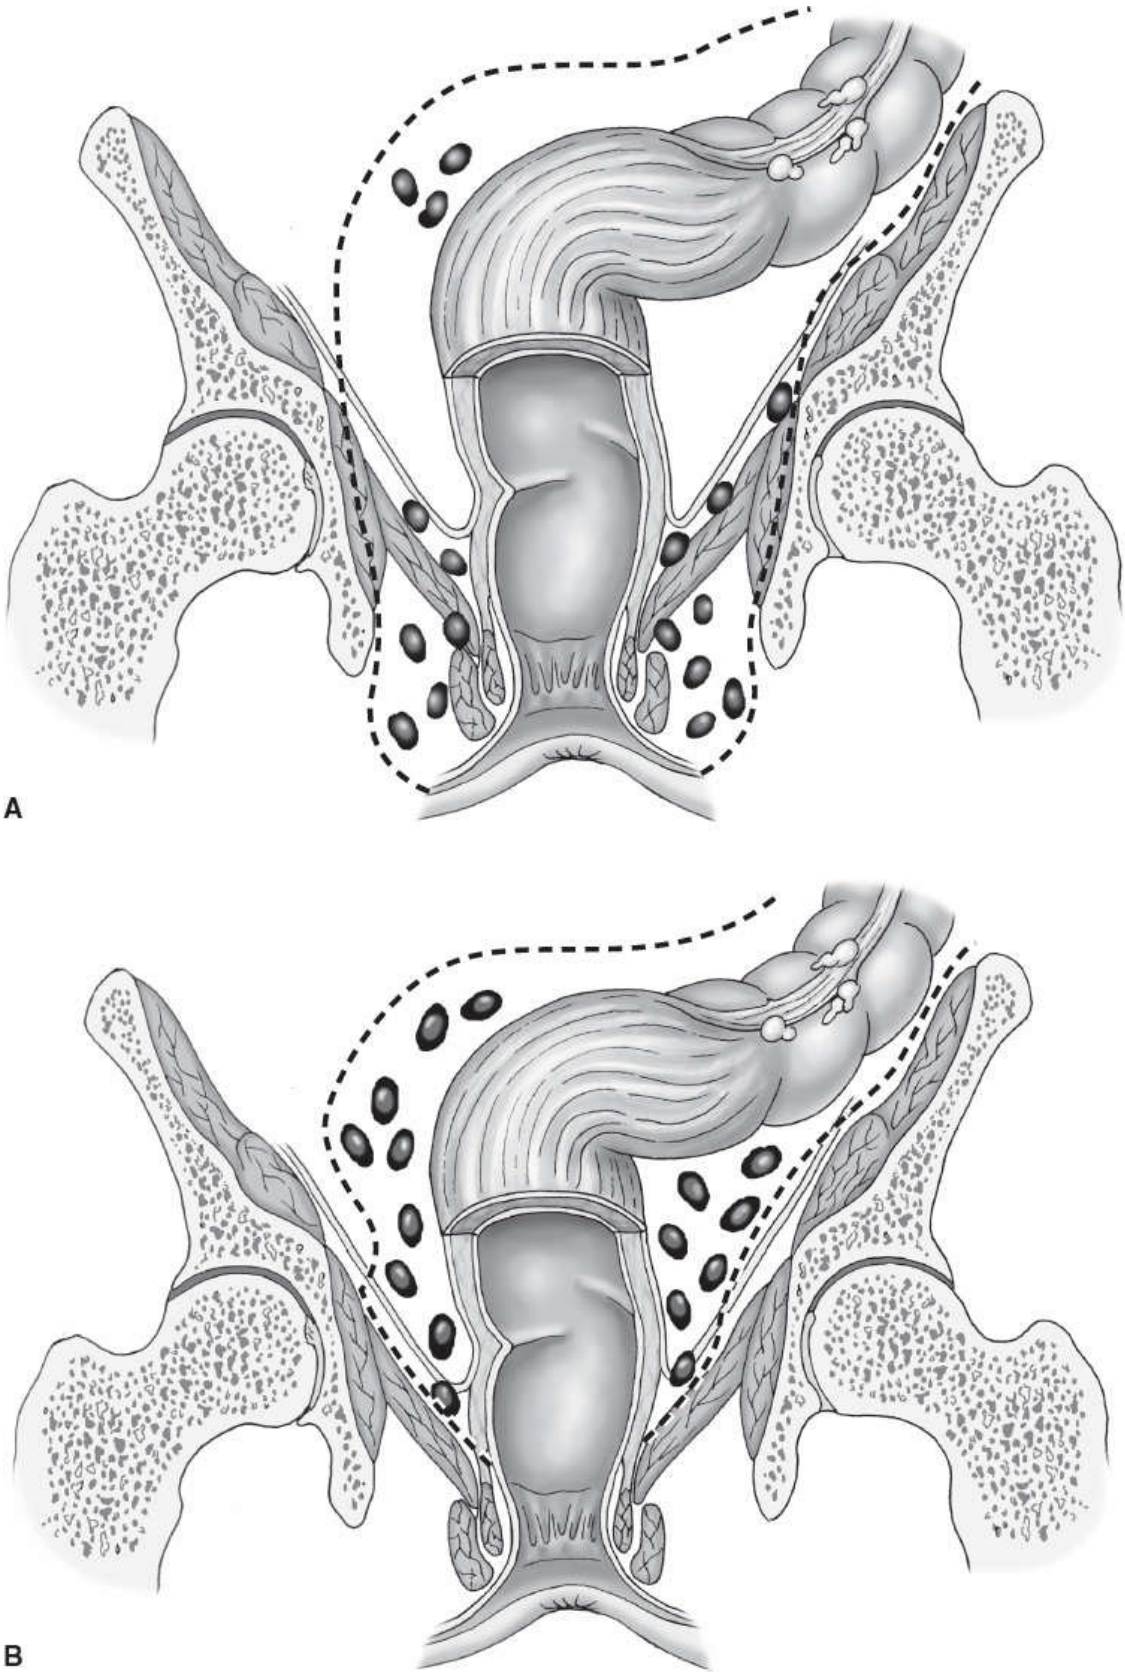

Figure 154a.1. **A:** Mile's original concept of "highly dangerous tissues" spread to many nodes in the ischiorectal fossa and upper surface of the levators. **B:** Heald's concept of spread of rectal cancer to the mesorectum and supralevator field.

This technique was groundbreaking as local recurrence rates were reduced from as high as 30% to 40% without TME to as low as <5% with TME. Subsequent studies have confirmed this and it is now generally accepted that a local recurrence rate of <5% to 10% should be expected if proper TME techniques are employed.

Embryologic and Anatomical Considerations

The belief that the spread of cancer will tend to remain within the embryologic hindgut "envelope" was presumably the basis for a precise mesorectal excision along embryologically/anatomically defined planes. The gastrointestinal tract, or the primitive gut as it is referred to during fetal development, is derived from the endoderm. The primitive gut is divided into the foregut, midgut, and hindgut and are attached to their mesenteries which envelop blood vessels and lymphatics. The hindgut is comprised of the distal third of the transverse colon, descending colon, the rectum, and the anal canal. The primitive gut spends its early fetal existence outside the abdomen. As development continues, the mesentery adheres to the retroperitoneum and in case of the rectum the mesorectum adheres posteriorly into the developing pelvis while retaining its midline integrity and remaining separate from the surrounding parieties. The mesorectum is of crucial importance in rectal cancer as it contains all the blood vessels, nerves, lymphatics, and lymph nodes through which cancer may disseminate. Importantly, the adherence of the mesorectum is by collagenous loose areolar tissue and is an avascular surgical plane. This was referred to as the "*holy plane of rectal surgery*" by R. J. Heald. Cancer spread initially respects this natural embryologic plane and hence precise surgical dissection along this defined plane enables an oncologically sound resection and a low incidence of local recurrence.

The anterior and lateral mesorectum is covered by a layer of visceral peritoneum, above the level of the peritoneal reflection and is fixed and surrounded by a layer of fascia below the peritoneal reflection. The mesorectum is generally of greatest volume posteriorly with significantly less volume anteriorly. Below the level of the peritoneal reflection the mesorectum gradually decreases in size to a point of maximal waisting at the level of the levator ani muscle (Figs. 154a.2 and 154a.3).

In addition to the oncologic advantages of a complete TME which minimizes local recurrences, the functional outcome and quality of life with regard to autonomic nerve preservation and decreased genitourinary

dysfunction is important. The plane of dissection for TME, if carefully followed, reduces chance for injury to both sympathetic and parasympathetic nerve supply to the urogenital system. The sympathetic nerves of the pelvis originate from the T12 to L3 ventral nerve roots, which form the *superior hypogastric plexus*. The superior hypogastric plexus gives rise to the hypogastric nerves distal to the aortic bifurcation, and these may be associated intimately with the visceral fascia of the mesorectum. *Nervi erigentes*, that carry the parasympathetic innervation to the pelvis, arise from the S2 to S4 ventral nerve roots. These join the sympathetic hypogastric nerves on the pelvic sidewall to form the *inferior hypogastric plexus* (Fig. 154a.4).

Injury to the pelvic autonomic nerves can be associated with significant genitourinary dysfunction. Damage to the sympathetic hypogastric nerves can result in increased bladder tone and reduced bladder capacity, as well as with retrograde ejaculation in men. Damage to the parasympathetic system can result in voiding difficulties from increased tone in the bladder neck, as well as with erectile dysfunction in men and impaired vaginal lubrication in women.

Preoperative Evaluation Including Imaging

A thorough *history and physical* is one of the most important aspects of the preoperative evaluation of patients with rectal cancer. A detailed history regarding the patient's symptoms like bleeding; pain; tenesmus; change in bowel habits; incontinence (both fecal and urinary), if any; and sexual dysfunction should be obtained. Any history of perineal trauma (obstetric or otherwise) should be factored into the decision-making process for patients who are candidates for a low pelvic anastomosis. A *digital rectal examination*, paying attention to the distance of the tumor from the anal verge, the location of the tumor (anterior, posterior, or lateral) relationship to the top of the sphincters (anorectal ring) and the tone of the anal sphincters should be made. While assessing the tumor on digital examination, any suspicion of fixation to adjacent structures (e.g., vagina, prostate, sacrum or pelvic sidewall) should also be noted. In women, with tumors in the anterior wall of the rectum, a complete pelvic examination should be performed to assess for invasion of the vaginal wall.

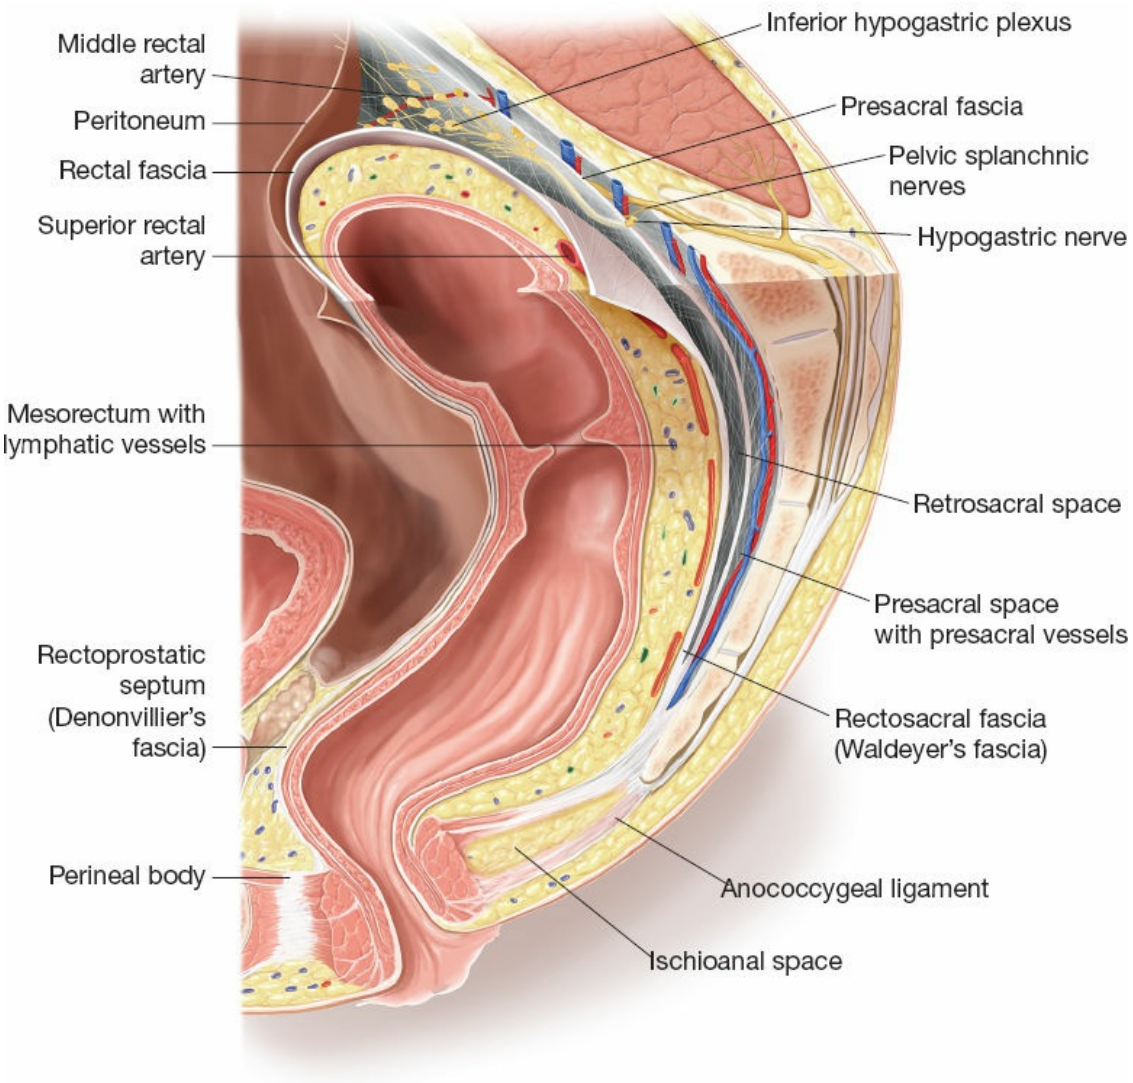

Figure 154a.2. Sagittal section of the pelvis highlighting the mesorectal plane and its relationship to the retrorectal and presacral spaces posteriorly and the Denonvillier fascia anteriorly.

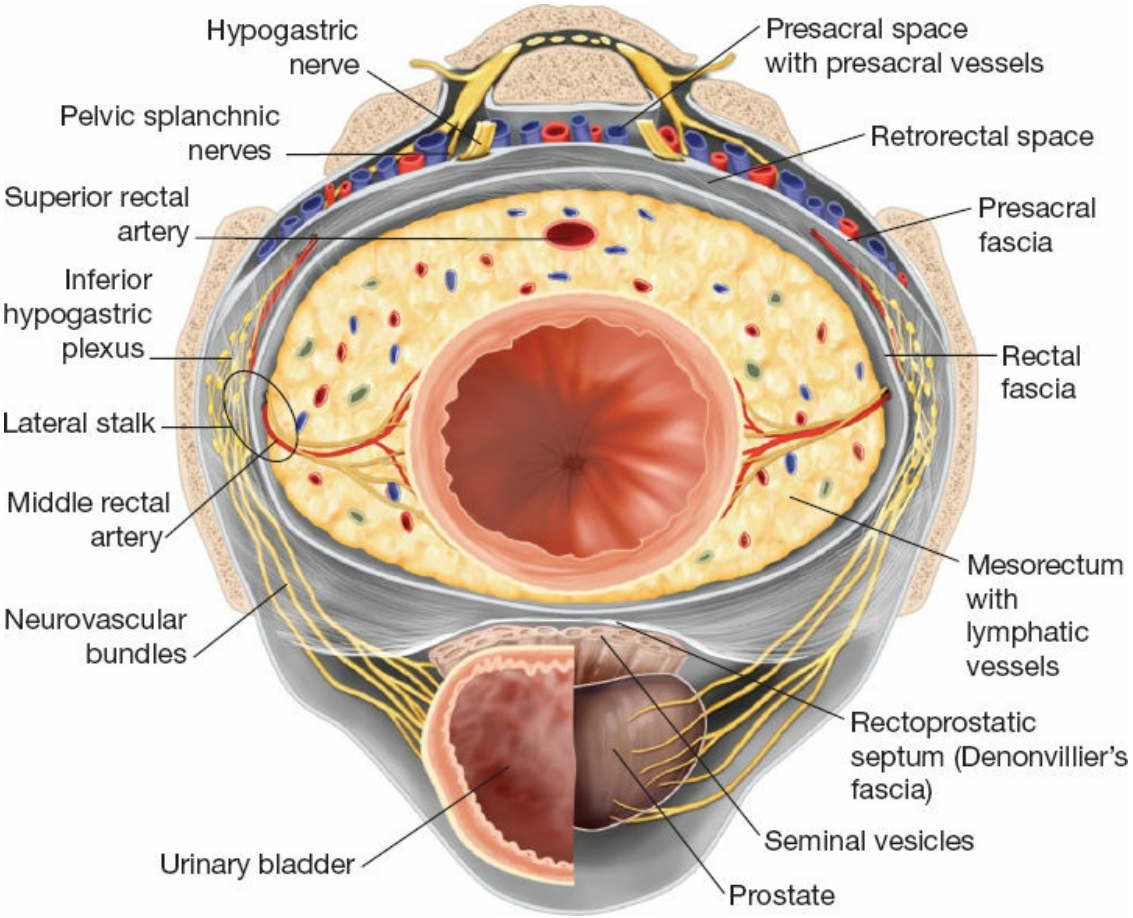

Figure 154a.3. Transverse section through the male pelvis highlighting the relationship of the mesorectum to the pelvic structures. Note the relationship of the middle rectal vessels to the inferior hypogastric plexus.

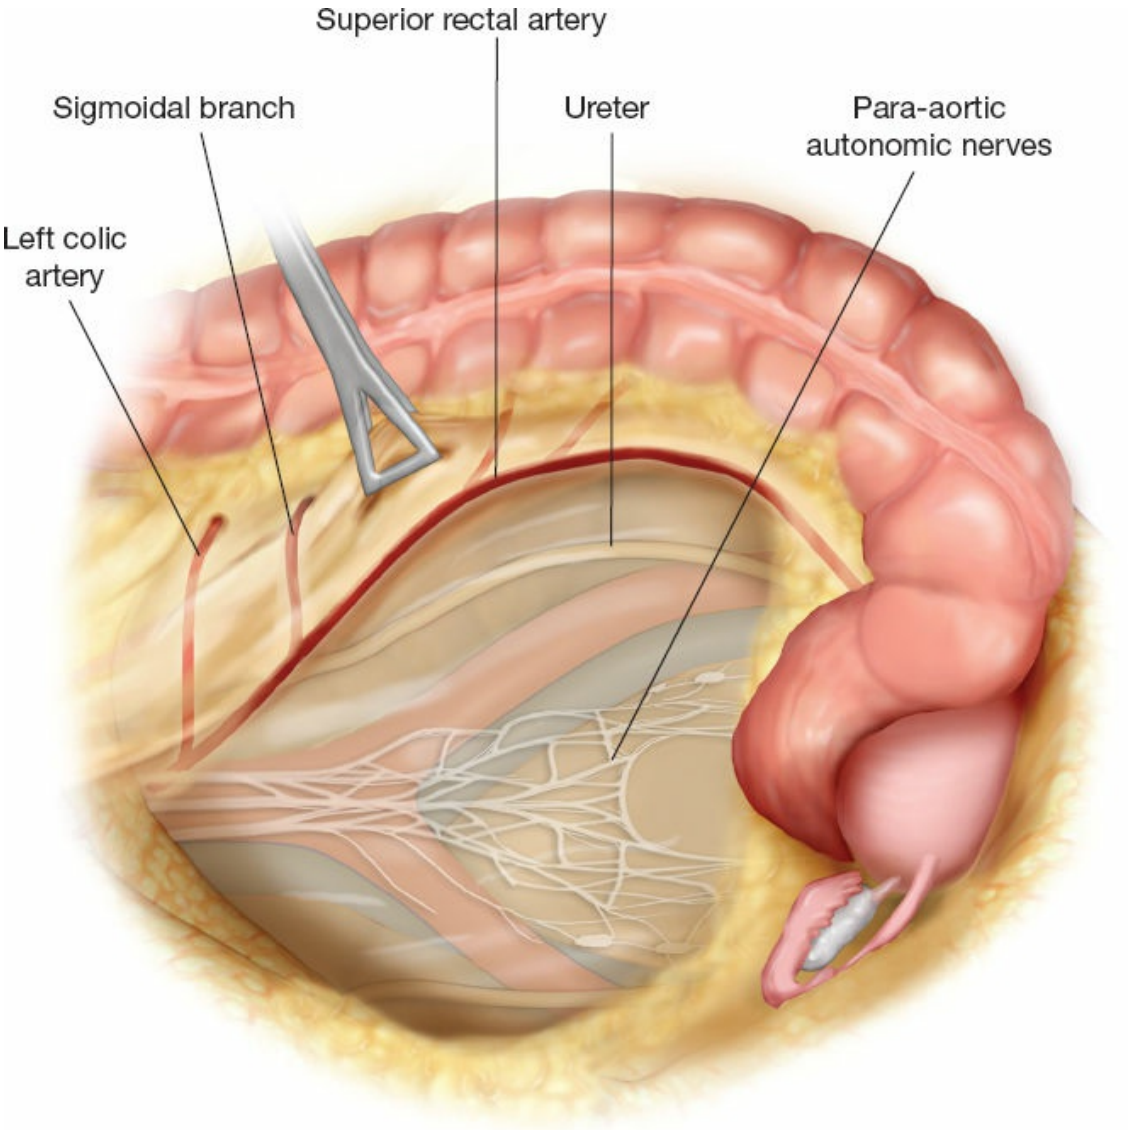

Figure 154a.4. Pelvic autonomic nerves seen after the TME is begun and the sigmoid colon and rectum are retracted anteriorly.

Sigmoidoscopy (flexible/rigid) is often performed during the patient's initial clinic visit by the surgeon to assess tumor location and distance from the sphincter complex. A *colonoscopy* serves two purposes: (1) to ensure that there are no synchronous lesions proximally in the colon and (2) visualize and biopsy the lesion in question to confirm the diagnosis via histopathology. A diagnosis preoperatively is especially important in the present era where locally advanced rectal cancers are treated in a multimodal manner with chemotherapy +/− radiation as an integral part of presurgical treatment.

After a diagnosis is confirmed, a CT scan of the chest, abdomen, and pelvis is useful to rule out distant metastatic disease. CT scans can localize

the tumor in the rectum and can also show extension of the tumor into the surrounding structures but CTs are unable to delineate the depth of invasion through the layers of the rectal wall. To define the pre-therapy T and N stage accurately, endorectal ultrasound (ERUS) and MRI play a very important role. As we know, the risk factors associated with local recurrence are the T and N stage, distance of the tumor to the mesorectal fascia, histologic grade of the tumor, and the presence of extramural lymphovascular and perineural invasion.

Pelvic MRI with high-resolution T2-weighted images provides the best evaluation of the rectal wall and perirectal fat/mesorectum. On T2-weighted images, three layers with alternating signal intensity can be easily identified. The inner mucosa and submucosa appears hyperintense, the middle layer consisting of muscularis propria appears hypointense, and the outer layer of perirectal fat appears hyperintense. Distinguishing a T1 from a T2 lesion on an MRI can be difficult and this is where an ERUS is helpful. This is particularly useful when local excisional procedures using transanal endoscopic microsurgery (TEM) and transanal minimally invasive surgery (TAMIS) platforms are being considered. MRI is more accurate when trying to differentiate between T3 and T4 tumors and the relationship of the tumor to the mesorectal fascia and adjacent pelvic structures. This is particularly important for the surgeon for operative planning. The MERCURY trial was a multicenter study in rectal cancer patients that compared the depth of tumor extramural invasion between preoperative MRI and final pathology in 311 patients undergoing surgery. In this study, MRI could reliably predict involvement of the mesorectum with accuracy to within 0.5 mm in 95% of cases. In their follow-up results after a median follow-up of 62 months, circumferential resection margin (CRM) as predicted by MRI and pathologic margins were found to be equally good predictors for local recurrence, disease–free survival, and overall survival.

However, accuracy of nodal (N) staging with rectal cancer remains comparatively poor. Most imaging modalities use size criteria to determine lymph node involvement and the cut off values are variable across studies. Reported sensitivity and specificity of MRI in predicting lymph node metastases is about 65% to 75%. Alternative criteria like signal heterogeneity and border irregularity are now being considered and we await future studies and changes in technology to help with improvement in pretreatment nodal staging (Figs. 154a.5 to 154a.7).

Key Steps of a Total Mesorectal Excision

After incising the peritoneum lateral to the sigmoid colon on the left side just above the pelvic brim, the underlying left ureter can be seen, distinguishable from the gonadal vessels which are present lateral to it. Once seen, the left ureter should be gently dissected laterally away from mesorectum and the vascular pedicle. After this maneuver, the sigmoid colon is retracted to the left and the peritoneum is incised to the right of the midline and the vascular supply of the rectum can now be approached from either side of the mesentery. Alternatively, if there are significant inflammatory changes or obscuration of tissue planes on the left side of the sigmoid colon, the dissection can commence on the right side a few millimeters anterior to the base of the sigmoid colon mesentery. In fact, many surgeons advocate starting in this location on all patients as dissection is performed just posterior to the superior hemorrhoidal artery and ensuring preservation of the hypogastric nerve plexus. The sigmoid colon is transected in a convenient location prior to pelvic dissection. If there is concern for proximal nodal disease or colon length for a tension-free anastomosis, the inferior mesenteric artery (IMA) should be transected at its origin. Otherwise, after division of the superior hemorrhoidal artery and lateral peritoneal reflection, it is important to find the correct plane of dissection. Mobilization of the splenic flexure and/or transection of the inferior mesenteric vein (IMV) may be required to ensure adequate length for a tension-free anastomosis. While establishing the “holy plane” posteriorly, it is important to stay anterior and medial to the hypogastric nerve plexus. The main trunk tends to be very close to the mesorectum proximally before the branches separate and run along the pelvic side walls.

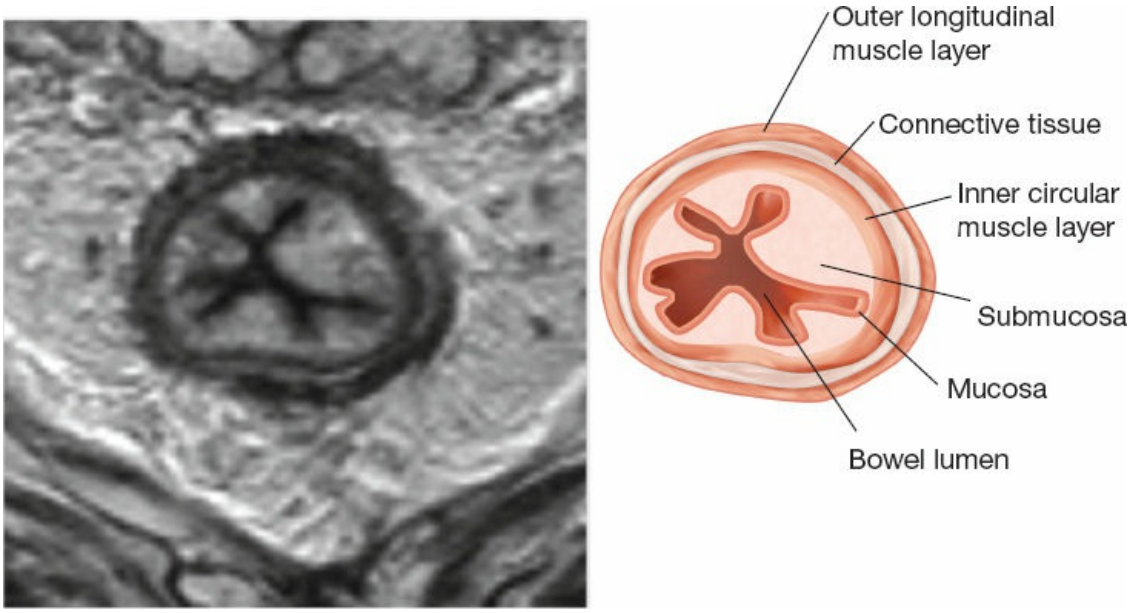

Figure 154a.5. Transaxial view demonstrating the layers of the bowel wall. (This image was acquired after radiotherapy, and hence the exaggeration of the layers due to tissue edema.)

With continuous traction on the rectosigmoid with the nondominant hand or retractor, the posterior dissection plane is established. The key to finding this plane and adhering to it is the anterior traction. This can be facilitated using a St. Mark's retractor in open cases or with an atraumatic bowel grasper in minimally invasive approaches. The posterior dissection should continue downward sharply as far as the coccyx so that the entire mesorectum can be removed with the specimen. Hand dissection should not be performed as injury to the nerves in close proximity to the mesorectum will occur. It is important to complete the posterior rectal dissection under direct vision and with excellent lighting. Care must be taken to follow the curve of the sacrum which necessitates a gentle arc curving slightly anteriorly as the dissection proceeds into the deep pelvis.

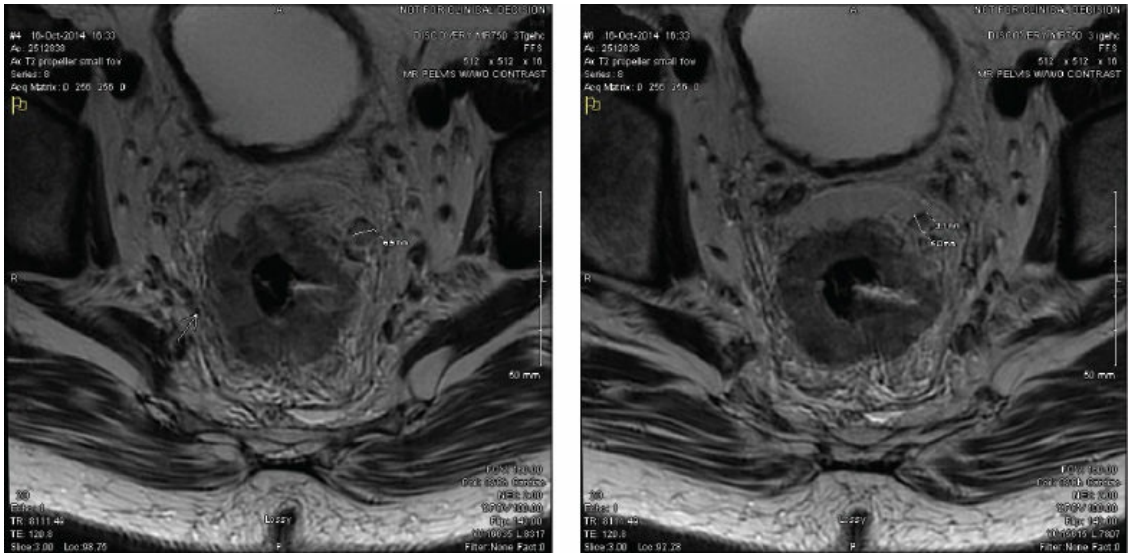

Figure 154a.6. MRI showing the threatened CRM (**left**) and enlarged lymph nodes (**right**) in the mesorectum.

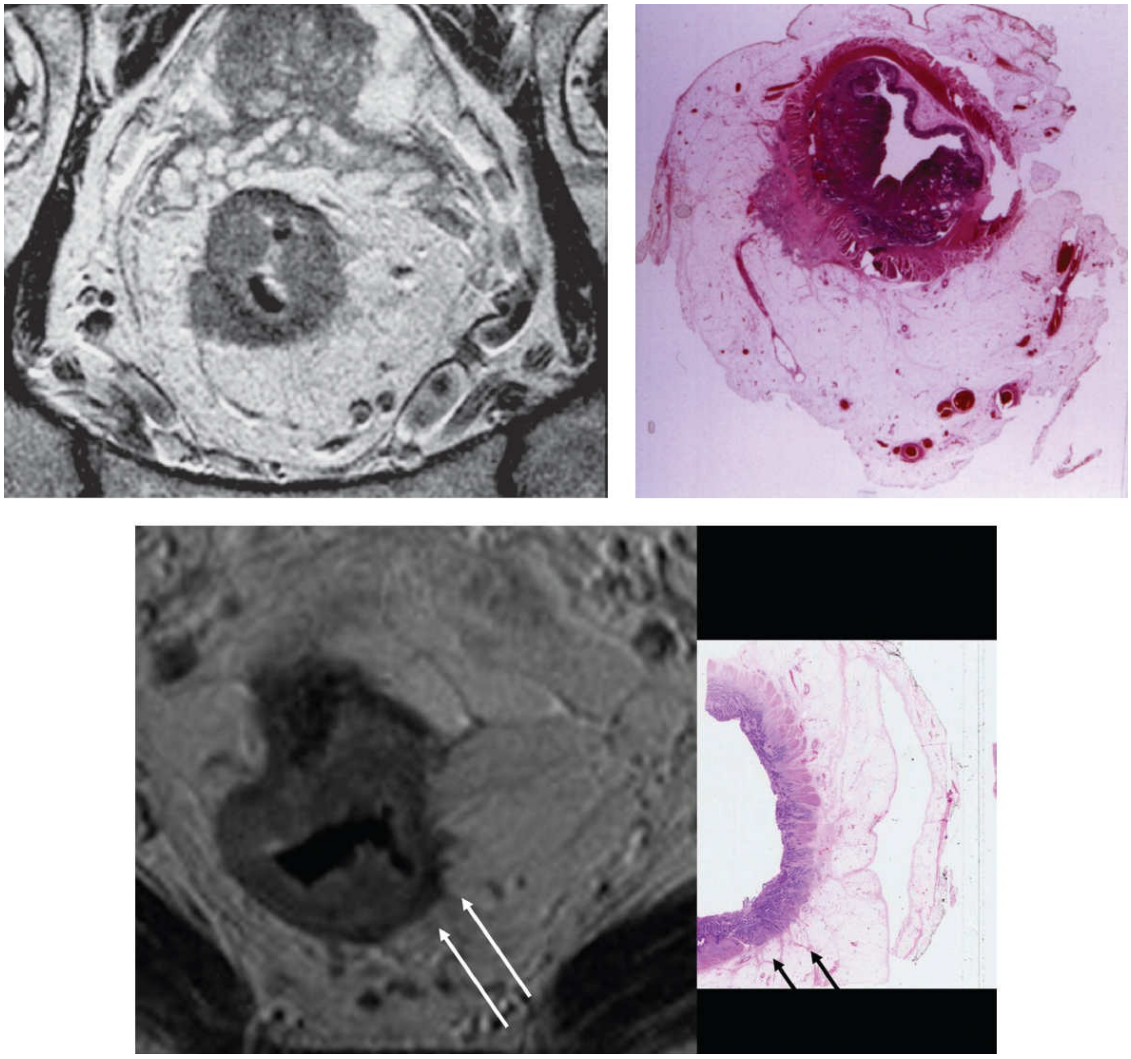

Figure 154a.7. MRI and histopathologic correlation of tumor spread. (Images courtesy of Dr. Gina Brown, Royal Marsden and Imperial College, London, UK.)

One of the risks of posterior deviation from the “holy plane” as dissection proceeds caudally is tearing thin-walled presacral veins, which often have no valves and can bleed vigorously when cut or torn. In addition to completing the posterior dissection, the dissection can proceed partially up the lateral sides of the rectum ensuring the correct mesorectal planes are followed. Once the posterior rectal and some of the lateral dissection is complete, attention is turned toward the anterior dissection (Fig. 154a.8).

For the anterior rectal dissection in women, it is sometimes useful to suture the uterus and fallopian tubes to the abdominal wall. This makes access to the rectum, particularly the anterolateral planes, much easier. The bladder is retracted away from the rectum and the incision on the

peritoneum is then carried down caudally on either side and then joined anteriorly at the level of the rectouterine/rectovesical pouch. Anterior traction with a St. Mark's retractor improves exposure and helps delineate this plane well. The plane is gradually deepened until the base of the bladder and both seminal vesicles or the vaginal wall are reached. Denonvillier fascia lies between the anterior rectal wall and the prostate. We do not routinely include this fascia in our resection unless the patient has an anteriorly based tumor and it is oncologically necessary to achieve negative margins (Fig. 154a.9).

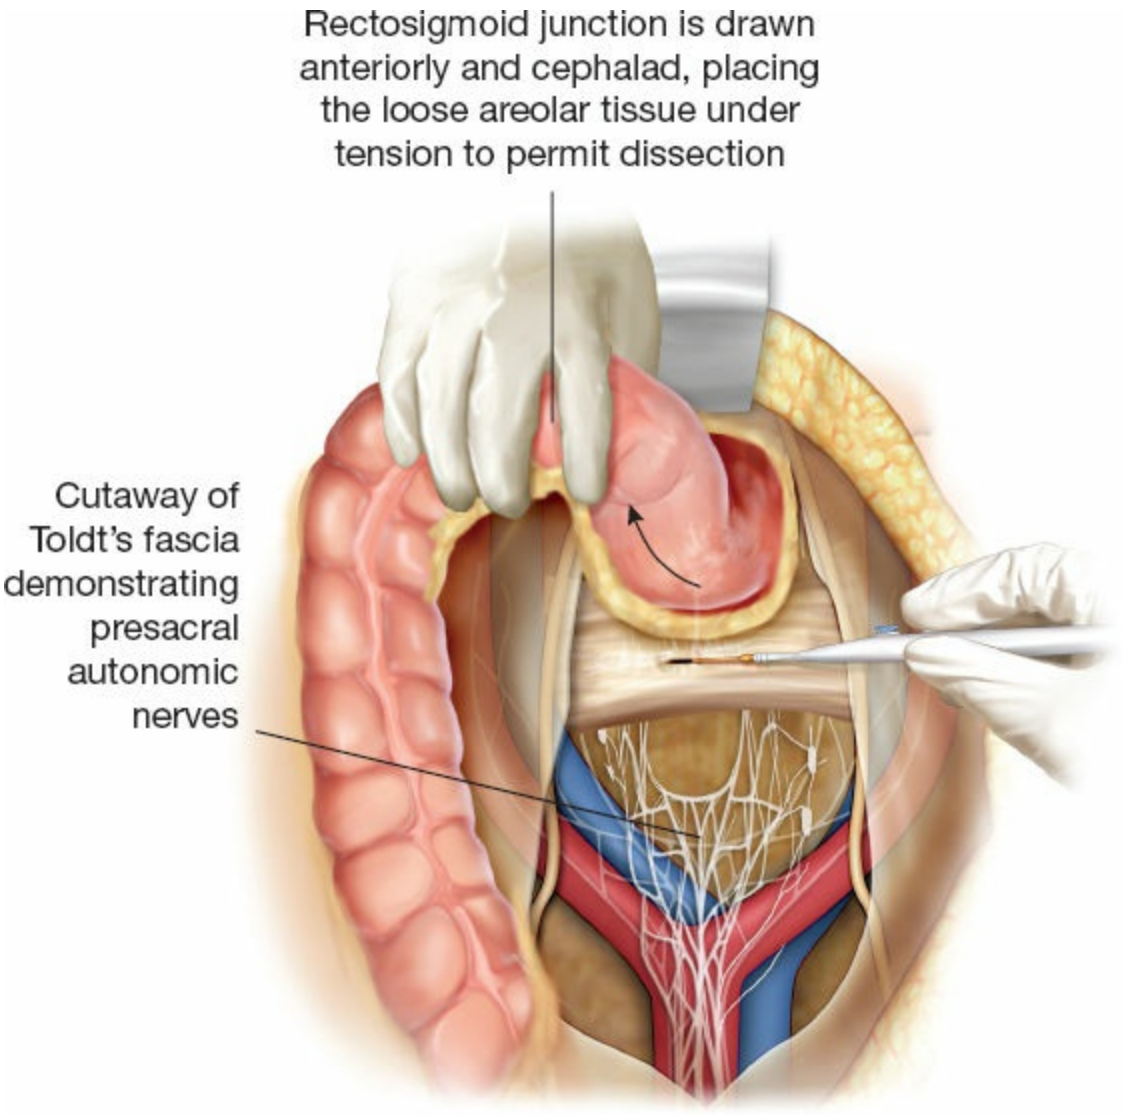

Figure 154a.8. Posterior dissection.

For the lateral dissection, the rectum is retracted superiorly and laterally toward the opposite side so as to put these tissues under tension. We prefer to divide these lateral attachments with an energy device as the middle

rectal artery can be a troublesome source of bleeding here. The dissection at this level should be carried out as close to the mesorectal envelope as possible, so as to avoid the *nervi erigentes.* A rectosacral or anosacral ligament can prevent complete posterior mobilization of the rectum down to the levator muscles. If necessary, this should be divided (Fig. 154a.10).

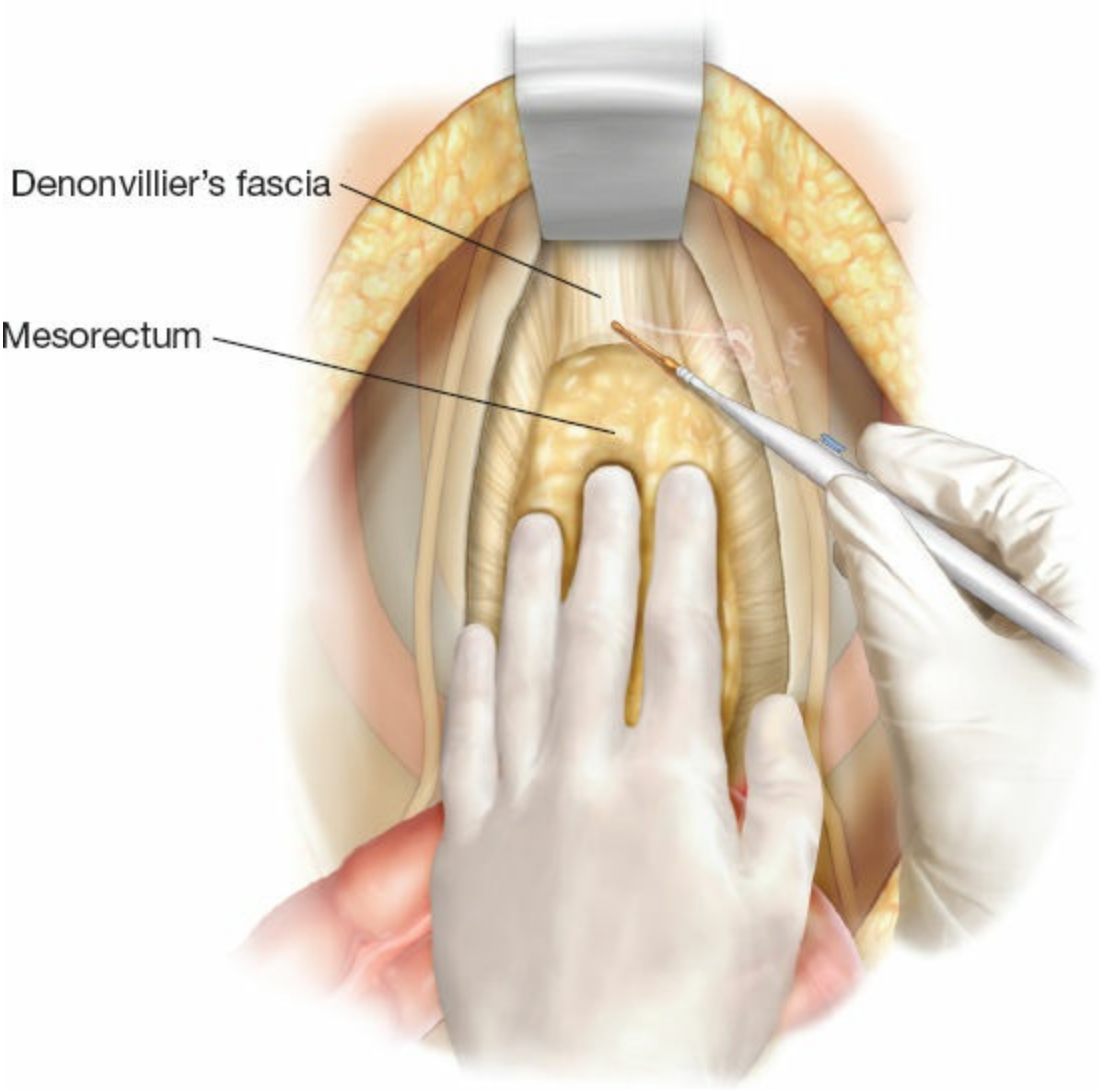

Figure 154a.9. Anterior dissection.

Regardless of which approach is used to perform this operation, open, laparoscopic, or robotic, oncologic clearance with functional preservation should be the goal.

Evidence Regarding Minimally Invasive Approaches to Performing TME

Several randomized trials and other retrospective studies have evaluated a

laparoscopic approach to radical resection of rectal cancer. The *Conventional versus Laparoscopic-Assisted Surgery in Colorectal Cancer (CLASICC) trial* conducted by the United Kingdom Medical Research Council randomized 794 patients between 1996 and 2002 in a 2:1 fashion to laparoscopic or open resection. Of these, 326 were rectal cancer patients: 87 had abdominoperineal resection (APR) and 239 had AR. Surgical resection was undertaken according to every surgeon's current practice. Poorly differentiated, very low rectal lesions (<5 cm from the anal verge) were treated by APR. The trial design required that every surgeon had performed at least 20 laparoscopic-assisted resections. In every center, a gastrointestinal pathologist ensured consistent reporting of resection specimens according to an agreed and established technique that focused on the completeness of resection and extent of the CRM. The trial found that patients undergoing laparoscopic AR were more likely to have a positive radial margin, but long-term survival outcomes were the same. However, local recurrence rate in patients undergoing AR or APR was 9.7% in the laparoscopic group and 10.1% in the open group. Of note, the study also captured a learning curve among participating surgeons; 38% of laparoscopic operations were converted to open in the first year of the trial, but this decreased to 16% by year 6.

The *COlorectal cancer Laparoscopic or Open Resection (COLOR) II Trial* was a multicenter, phase 3 trial that randomized 1,103 rectal cancer patients from 2004 to 2010 to laparoscopic (n = 739) or open (n = 364) surgery. All procedures were required to comply with the principles of TME or partial mesorectal excision if the cancer was localized in the upper part of the rectum. Unedited recordings of five consecutive laparoscopic TMEs were evaluated. The respective pathology reports of these five cases were reviewed to confirm completeness of the specimens. The laparoscopy group had lower median blood loss (200 mL vs. 400 mL), but longer median operative time (240 minutes vs. 188 minutes). This trial found no difference in short-term morbidity or mortality, or pathologic quality of the specimen. At 3 years, the rate of locoregional recurrence was 5% in each of the groups. Long-term follow-up reported by the COLOR II investigators showed no significant difference in either 3-year disease-free survival (74.8% in the laparoscopic group vs. 70.8% in the open group) or overall survival.

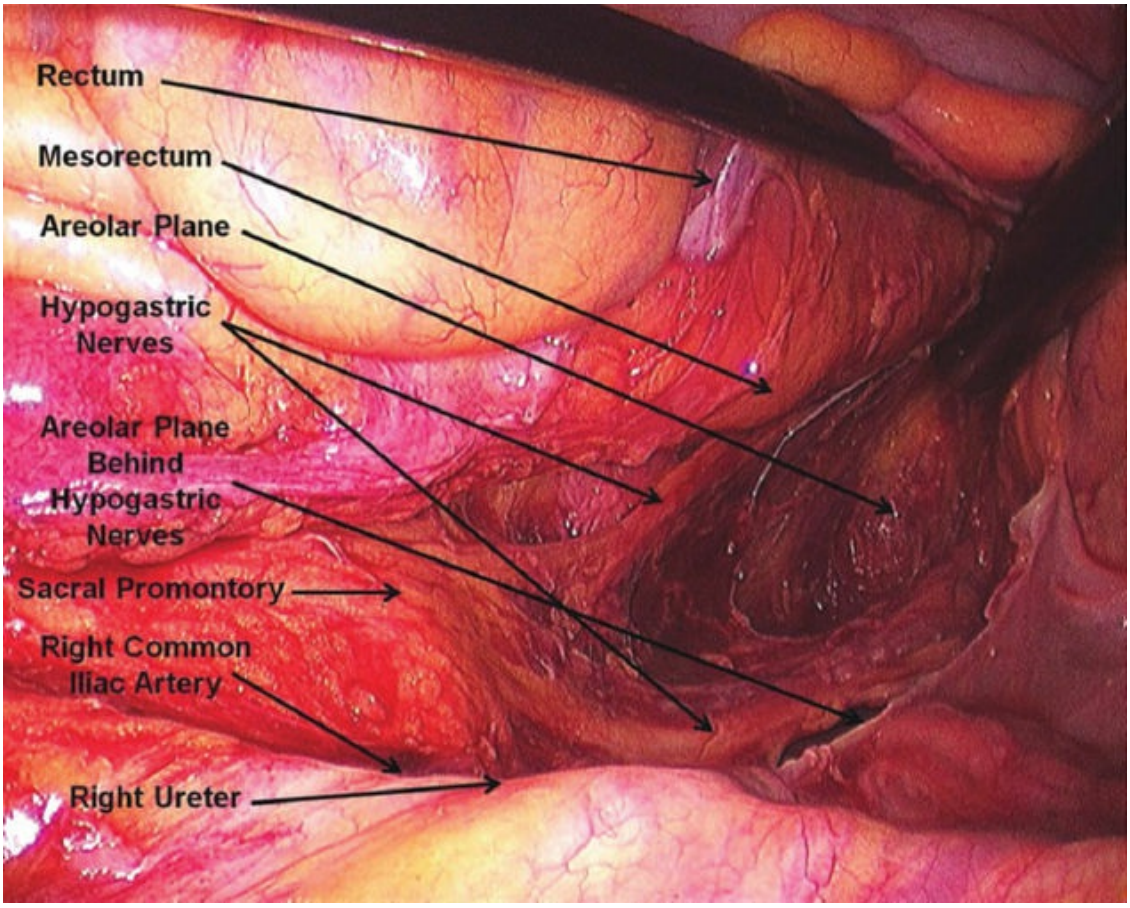

Figure 154a.10. An intraoperative image during a laparoscopic TME highlighting the key structures with the rectum retracted anteriorly toward the abdominal wall.

The *Comparison of Open versus laparoscopic surgery for mid and low REctal cancer After Neoadjuvant chemoradiotherapy (COREAN)* trial randomized 340 patients with mid- and low-rectal cancers after neoadjuvant treatment to open or laparoscopic surgery. Surgery was done 6 to 8 weeks after completion of preoperative chemoradiotherapy, by seven surgeons from three hospitals who had experience with a median number of 75 (range 28 to 150) cases of laparoscopic colorectal resection before the trial. These surgeons were qualified through live demonstrations held by the Korean Laparoscopic Colorectal Surgery Study Group. Each surgeon submitted a videotape of their laparoscopic rectal surgery, which was reviewed by a trial steering committee to assess the surgeon's oncologic technique, including the level of inferior mesenteric vessel ligation, TME quality, and preservation of autonomic nerves. There was no statistical difference in the positive CRM rates between the two groups (4.1% in the open group vs. 2.9% in the laparoscopic group) and the macroscopic quality of the TME specimen was also similar between the

two groups. In addition, there was no difference in the local recurrence rates between the two groups.

The primary end point of 3-year disease free survival was not statistically different between groups (79.2% in the laparoscopic group vs. 72.5% in the open group). A limitation of the study was that there was a statistically significant difference in final staging between patients in the open and laparoscopic arms, with the laparoscopy group having a lower pathologic tumor stage (ypT) and a higher nodal stage (ypN). However, multivariate analysis adjusting for this difference did not suggest an effect on the trial results.

The *American College of Surgeons Oncology Group (ACOSOG) Z6051* trial randomized 486 patients between 2008 and 2013 with rectal cancer within 12 cm of the anal verge, after receiving neoadjuvant treatment, to laparoscopic or open resection. The primary endpoint, unlike previous trials, was a composite of circumferential radial margin greater than 1 mm, distal margin without tumor, and completeness of TME as a composite. A 6% noninferiority difference was chosen between laparoscopic and open resection according to clinical relevance estimation. This composite was higher in the open resection arm (86.9%) versus laparoscopic resection arm (81.7%) and hence favored open resection. Long-term follow-up data regarding oncologic outcomes is awaited.

The *Australasian Laparoscopic Cancer of the Rectum Trial (ALaCaRT)* was another randomized noninferiority trial using a design similar to the ACOSOG Z6051 trial, with the primary endpoint set as a composite of complete TME, circumferential margin of at least 1 mm, and distal margin of at least 1 mm. A total of 475 patients were enrolled between 2010 and 2014; 237 of these had open resection and 238 had laparoscopic resection, with randomization stratified according to level of the rectal tumor. Successful resection was achieved in 82% of the laparoscopic cases and 89% of the open cases; hence, could not prove noninferiority of the laparoscopic approach. Follow-up data regarding recurrence and survival in the longer term are anticipated.

When considering laparoscopic resection for rectal cancer patients, it is important to note that none of the randomized trials included patients with more locally advanced rectal cancers. The trials excluded clinical T4 tumors, or in some cases tumor invasion within 1 to 2 mm of mesorectal fascia or nodal involvement of mesorectal fascia, so conclusions of these trials cannot be clearly extrapolated to these patients in practice.

Based on the results of the current trials summarized above, two studies (ACOSOG Z6051 and ALaCaRT) failed to show comparable quality of resection in the laparoscopic group compared to the open group. Whether this translates into oncologic differences for the patient remains to be seen.

More recently, robotic approach to performing TME has gained popularity. The degree of freedom that the robotic instruments provide in the confines of a narrow pelvis and superior three-dimensional visualization are arguably the strengths of this approach. Collinson et al. reported the design of a large, randomized, international multicenter trial known as the *RObotic versus LAparoscopic Resection for Rectal cancer (ROLARR) trial*. Enrollment began in 2011 and randomized 400 patients to laparoscopic or robotic TME. The primary endpoint was rate of conversion to open surgery, as a surrogate for ease of the robotic-assisted technique. Other endpoints included CRM, morbidity, 30-day mortality, local recurrence, disease-free survival, overall survival, patient reported bladder and sexual function, and other quality of life measures. Preliminary results presented at a national meeting reported CRM positivity rates of 6.3% in the laparoscopic group and 5.1% in the robotic group with an OR of 0.79 (0.35 to 1.76). Formal publication of the results is pending.

As there are more options for the surgical treatment of rectal cancer, the appropriate choice for an individual patient is becoming more difficult. The TME principles remain relevant regardless of the surgical approach selected. At the present time, open surgical resection with careful TME remains the standard of care against which all other techniques must be judged.

Transanal TME

The latest technical iteration for TME is the transanal total mesorectal excision (TaTME). As most commonly described, a combination of laparoscopic and transanal approaches is used, and two teams can work simultaneously. The laparoscopic team performs high ligation of the inferior mesenteric vessels and mobilization of the splenic flexure if needed, and proceeds with dissection of the sigmoid colon and proximal rectum as in a conventional laparoscopic approach. The transanal team begins with placement of a purse–string suture to close the rectal lumen at the level of the distal resection margin (prior to manipulation of the bowel by the laparoscopic team). A transanal surgical platform of the type used for TAMIS is then inserted. Cautery is used to divide the rectum and

mesorectum caudal to the purse–string suture and identify the mesorectal fascia. Sharp dissection in the mesorectal fascial plane is then performed in a "down-to-up" fashion until a "rendezvous" with the laparoscopic team's dissection plane is achieved. The specimen may be removed transanally or transabdominally and an anastomosis may be created with a diverting ileostomy if necessary.

Pathologic Evaluation of TME Specimen

The quality of the excised mesorectum and evaluation of the CRM are the most significant predictors of local recurrence in patients undergoing a TME for rectal cancer. Hence, pathologists play a key role in the evaluation of these specimens as a comprehensive pathologic evaluation not only provides important prognostic information but also provides critical feedback to the surgeon regarding their technical performance and quality assurance.

Gross visual inspection of the TME specimen should demonstrate three clear landmarks:

1. The cut edge of the peritoneal reflection and the whole "cul-de-sac."
2. Smooth shiny anterior surface of the mesorectum of the upper half (rectogenital septum) or middle third (Denonvillier fascia) of the rectum.
3. Anterior aspect of the anorectal muscle in ultralow AR and APR specimens only.

TABLE 154a.1 Assessment of TME Specimen

Mesorectum	
Mesorectal plane (complete)	Intact mesorectum with only minor irregularities No defects deeper than 5 mm No coning toward the distal margin of the resection specimen Smooth CRM on transverse sections
Intramesorectal plane (nearly complete)	Moderate bulk to the mesorectum One or more defects greater than 5 mm deep within the mesorectum Moderate coning No visible muscularis propria Irregular CRM on transverse sections
Muscularis propria plane (incomplete)	Exposed muscularis propria Moderate to marked coning Irregular CRM on transverse sections
Sphincter complex	
Extralevator	Cylindrical specimen with no waist effect Levators removed en bloc
Sphincter plane	Slight waist effect No significant defects or perforations
Intrasphincteric/submucosal plane	Significant waist effect Perforation or missing areas of muscularis propria

The CRM refers to the nonperitonealised bare area of rectum and a positive CRM is defined as direct tumor extension (either contiguous or discontiguous) or the presence of a positive lymph node within 1 mm of the radial, nonperitonealised soft tissue edge.

The CLASSIC study of the Medical Research Council in the United Kingdom and the Dutch TME trial defined a standardized protocol for proper assessment of the quality and completeness of the mesorectum. Table 154a.1 outlines the approach developed by Philip Quirke for the assessment of a TME specimen.

Correlations of MRI findings with gross pathologic findings should preferably be documented in the pathology report and sections submitted accordingly. Transverse slices should be inspected to note the following: (1) extent of tumor and the closest distance of the tumor to the CRM (the closest point is specified as anterior, posterior, right/left lateral); (2) areas suspicious for extramural vascular invasion; (3) any positive lymph nodes and their relationship to the CRM; and (4) other pertinent pathologic findings (diverticula, polyps, adhesions, etc.).

Having a standardized template for pathologic evaluation of a TME specimen should be established as the pathology report contains

information that would risk stratify a patient's chances for local recurrence and help with decision making with regards to surveillance and adjuvant treatment (Fig. 154a.11).

It is clear that TME for rectal cancer can be performed in many patients through open, laparoscopic or robotic approaches. However, the difficulty of performing an adequate margin negative resection with nerve preservation in certain patient populations such as obese males should not be underestimated. As laparoscopic and robotic approaches are improving but remain just tools helpful in reducing the negative impact of surgery on our patients, consideration of the appropriate surgical approach requires much thought and expertise. We await the final results of some current clinical trials (ACOSOG Z6051 and ALaCaRT). In addition, future trials comparing robotic, laparoscopic and open surgical approaches with endpoints including margin negative resections, local recurrence, morbidity and functional outcomes will allow for proper choice of technique.

A critical component to the management of rectal cancer includes a multidisciplinary approach, providing optimal patient care. More recently, the OSTRiCH Consortium (Optimizing the Surgical Treatment of Rectal Cancer) and the Commission on Cancer (CoC) which is a quality program of the American College of Surgeons have formulated plans for a National Accreditation Program for Rectal Cancer (NAPRC), with the goal of ensuring that patients with rectal cancer receive appropriate care using a multidisciplinary team.

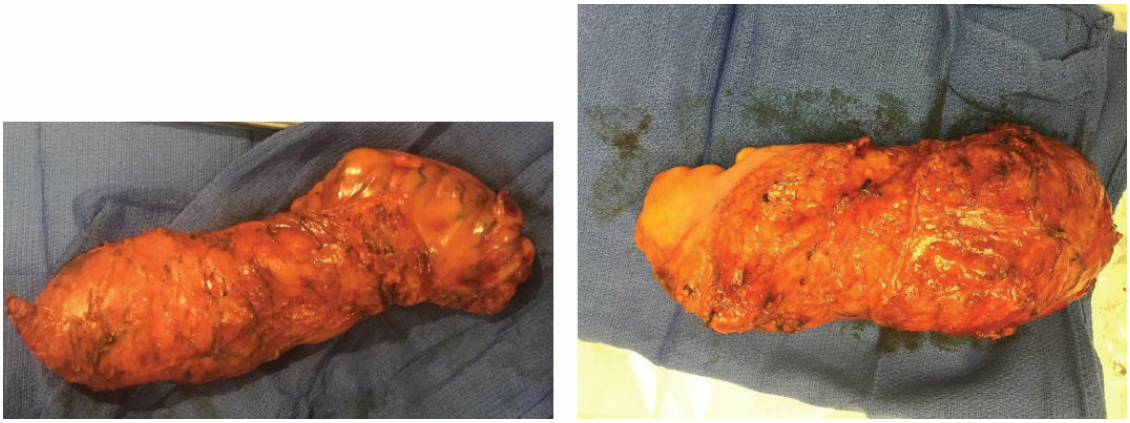

Figure 154a.11. An example of a TME specimen.

ACKNOWLEDGMENTS

We would like to acknowledge the contributions of Prof. Richard J. Heald,

both for the previous version of this chapter and, more importantly, for his pioneering work in the surgical treatment of rectal cancer.

EDITOR'S COMMENT

Before we actually devote ourselves to various pertinent papers that have been recently written, we would like to use this opportunity to congratulate Professor Heald on a magnificent contribution to contemporary surgery as well as to recognize contribution on advances in total mesorectal excision by Professor Hochwald and his group. History has taught us that new innovations do not

come easily and there were probably many times when Professor Heald felt ridiculed and his contribution was minimized. Professor Heald, despite his prominence, stayed at Basingstoke, which is appropriate, that he may have been taken for task for not being in a "major" center. All of that has changed. Total mesorectal excision (TME) is now accepted around the world as the appropriate way to proceed in resection for carcinoma of the rectum in which the long-term survival has been improved by ~15% or perhaps even greater, as well as a decrease in the bladder and sexual dysfunction with a carefully done dissection.

However, all is not well in the world of carcinoma of the rectum, as Mulsow J and Winter D writing in *Arch Surg* (Extralevator abdominoperineal resection for low rectal cancer: new direction or miles behind? 2010;145:811–2) draw attention to the poor results for abdominoperineal resection for low rectal cancer, which has been modified, apparently not appropriately, and thus one does not get a clean resection. The subtitle of the article is "New Direction or Miles Behind?," a clever pun, but in Figure A given in this very brief paper, one can see clearly that the dissections around "Morson's waist" were meant to be a cylinder, that is, for the same reason as Miles resection was originally criticized. That cylinder made the Miles resection, which had to be done in haste given the anesthesia of those days and the absence of blood transfusion, brutal and destructive. The difficulty, as quoted by Marr R et al. (The modern abdominoperineal excision: the next challenge after total mesorectal excision. *Ann Surg* 2005;242:74–82) is that the current oncologic results are simply unacceptable because the circumferential resection margin (CRM) have been positive in up to 40% in some series. This of course "negatively effects" local control and overall survival. Davies M et al. (Management of the asymptomatic primary in the palliative treatment of metastatic colorectal cancer. *Colorectal Dis* 2009;11:845–8) reviewed the incidence of local recurrence in 200 consecutive cases with a diagnosis of rectal cancer of which 139 underwent a curative resection. Of these, 40 underwent Miles resection with curative intent, and two of whom experienced local recurrence (5%) at 1½ and 2 years. Overall recurrence rate for all operations with curative intent was 2.6%. They conclude that, "Tumors at the anorectal junction should not be dissected off the pelvic floor, but radically excised en bloc with the surrounding levator ani, as a cylinder, as originally described by Miles." In a similar vein, Holm T et al. (Extended abdominoperineal resection with gluteus maximus flap reconstruction of the pelvic floor for rectal cancer. *Br J Surg* 2007;94:232–8) propose an extended abdominoperineal resection with a gluteus maximus flap reconstruction of the pelvic floor for rectal cancer. This initiative, supposedly to go external to the levators, would promote a low perforation rate and a lower recurrence rate. The recurrence rate is 7%, that is, 2 patients out of 28, a small number. However, healing postradiation is delayed in ~30% and a flap closure is a problem.

Davies M et al. (Local recurrence after abdomino-perineal resection. *Colorectal Dis* 2009;11:39–43) report good outcomes in abdominoperineal

resections and make the statement that one does not need to resect the iliac nodes (although we are not sure who said that one needs the iliac nodes resected). They state that the closest point to the CRM is anterior and one must teach to do this without perforation, which of course will yield local recurrence. How all of these now stack up against the adage of the late, great Professor John Goligher, "If you haven't made the patient impotent, you have not cured the rectal cancer," we do not know. Professor Heald, who has emphasized postoperative sexual function, has shown very nicely that you do not make the patient impotent if you do the operation correctly. The difference between these various techniques and Professor Heald's results is his insistence that one does not go in the midline cutting the nerves with clamps as shown in Figure 154a.1 and this is not necessary for a good oncologic result. I am certain that this debate will be continued but it is good that people are bringing up matters of technique as against sexual function, which is important even to people in their 70s.

One way of improving the functional results, especially that of sexual function, is to cut down on the delay of patients coming to medical attention following the appearance of the first symptom. Mitchell E et al. (Influences on pre-hospital delay in the diagnosis of colorectal cancer: a systematic review. *Br J Cancer* 2008;98:60–70) point out that especially when there are serious symptoms such as pain that time from the first pain to diagnosis is 7.5 months in cancer of the rectum and only 5 months in colon cancer. This may explain the advanced colorectal disease and the fact that it presents at a more advanced stage than carcinoma of the colon, which is not in such a tight place.

Langenbach M et al. (Delay in treatment of colorectal cancer: multifactorial problem. *World J Surg* 2003;27:304–8) showed that delay from first symptoms correlated with stage of cancer. The delay in rectal cancer was 224 days or 7 months and colon cancer 149 days or 4+ months, similar to MacDonald. Five months or certainly 7.5 months lead to advanced growth of the neoplasm in a bad place and the ability to get to the patient earlier may give them a better functional result as well as an oncologic result.

There is a feeling that one can prevent an anastomotic dehiscence or an anastomotic leak with diversion. This does not appear to be the case, as Tsikitis VL et al., writing from the Mayo Clinic with many well-known colorectal surgeons as coauthor (Postoperative morbidity with diversion after low anterior resection in the era of neoadjuvant therapy: a single institution experience. *J Am Coll Surg* 2009;209:114–8), reviews a retrospective case series including patients who were treated with neoadjuvant therapy and had rectal cancer resection with curative intent from 1996 to 2007. The study comprised 237 patients with a mean age of 59 years receiving 5-flurouracil-based infusion therapy and 45 to 54 Gy of radiation. Of these patients, 43% had coloanal anastomosis and 57 underwent anterior resection. Anastomotic dehiscence occurred in nine patients; seven of the nine were diagnosed as pelvic abscesses (2.1%) and two patients needed re-exploration. There was no mortality and

early overall postoperative morbidity was 26%. For some reason, which is not clear, patients who were not diverted had a lower leak rate at 2.2% than those who did (4.4%). It is possible that the functionality of having the stool go through the area reduces the leak rate. However, in a randomized prospective trial, Matthiessen P et al. (Defunctioning stoma reduces symptomatic anastomotic leakage after low anterior resection of the rectum for cancer: a randomized multicenter trial. *Ann Surg* 2007:246:207–14) also showed that in a randomized controlled trial the functioning loop stomas, while less common, while associated with symptomatic anastomotic leakage after lower anterior resections, nonetheless decreased the number of sequelae of these anastomotic leaks.

An ambitious project was undertaken by Paun BC et al. (Postoperative complications following surgery for rectal cancer. *Ann Surg* 2010;251:807–18) in which the authors attempted to benchmark 53 prospective cohort studies and 45 randomized controlled studies. As many as 36,315 patients were included in the trials, of which 24,845 had an anastomosis. The anastomotic leak rate seemed high (that is 11%), and pelvic sepsis in 29 studies was 12%. In 75 studies, mortality was 2% but continued to improve by years published. Wound infection, studied in 50 papers, was 7%, which seems excessive. To explain the heterogeneity of leak rate, age, median tumor height (in other words, distance from the anus), and method of detection (radiology vs. clinical) were statistically significant. In the paper by Tsikitis (previously quoted), age, ASA class, and cardiovascular disease were significant for the percentage of leaks. They did not mention whether there was a difference between those who were diverted and those who were not, with leak rate.

The possibility that functional flow of stool through an area may result in a lower leak rate or in some other benefit was hypothesized by Kirzin S et al. (Benefits of perineal colostomy on perineal morbidity after abdominoperineal resection. *Dis Colon Rectum* 2010;53:1265–71) in a paper, which compared perineal colostomy on perineal morbidity after abdominal peritoneal resection. Patients between 1993 and 2007 who underwent abdominoperineal resection for rectal adenocarcinoma were compared. Of 110 patients, an iliac colostomy (i.e., a standard colostomy) was carried out in 41 patients and a perineal colostomy group, something which we are not familiar with in this country, in 69. There were fewer instances of pelvic perineal morbidity ($P = 0.008$) and fewer instances of wound dehiscence ($P = 0.02$) in the perineal colostomy group with a shorter healing time of 35.3 versus 45.1 days, $P = 0.04$. As they state in the article, the benefits from perineal colostomy were statistically significant in patients who received radiation in terms of pelviperineal morbidity ($P = 0.01$) and healing time, 50.8 versus 35.9 days, respectively ($P = 0.02$). No differences were found between patients who had not received radiation therapy and indeed it is difficult to know what that signifies.

Row D and Weiser M (An update on laparoscopic resection for rectal cancer. *Cancer Control* 2010;17:16–24) investigated the status of laparoscopy in mid to

low rectal cancer. The principal outcome they looked at was positive CRMs identified in 14% of the patients with open resection and 16% of those with laparoscopic resection, but in the group who underwent anterior resection alone, CRM positivity was 12% in the laparoscopic group versus 6% in the open group ($P = 0.19$). Despite the higher rate of CRM positivity in the laparoscopic group, there was no statistically significant difference in survival rate between groups (68.4% laparoscopic vs. 66.7% in the open group; $P = 0.55$) and no difference in the 3-year overall survival rate in patients undergoing anterior resection (74.6% vs. 66.7%, respectively). Of significance, differences in CRM positivity did not translate into differences in a 3-year local recurrence rate (7.8% for the laparoscopic group vs. 7.0 for the open group; $P = 0.70$).

At the present time, the status of laparoscopy has emerged as a valuable adjunct compared to autonomic nerve-sparing TME. This is evident in the updates provided by Professor Hochwald. As pointed out in Chapter 154a, a robotic approach to performing TME have gained popularity. In addition the transanal TME combined with a laparoscopic approach has emerged as the latest technique to accomplish TME. Regardless of the techniques chosen to the complete TME, the principles as outlined by Professor Heald hold true today. As pointed out by Professor Hochwald, open surgical TME remains the standard against which all other techniques should be compared.

155 Open and Minimally Invasive Sphincter-Preserving Radical Resection for Malignant Disease of the Middle and Lower Thirds of the Rectum

Wolfgang B. Gaertner and Robert D. Madoff

INTRODUCTION

Approximately 40,000 new cases of rectal cancer occurred in 2015, and of these 40% were confined to the rectal wall. Despite a steady decrease in incidence and mortality since 1975, colorectal cancer remains the second leading cause of cancer deaths in the United States.

There have been several key advances in the management of rectal cancer, but none so important as standardization and improvement in surgical resection. There is general agreement that optimal surgical treatment involves total mesorectal excision (TME) with an R0 excision (microscopically negative margins of the excised specimen), regardless of approach (open, laparoscopic, or robotic). The addition of preoperative imaging by computed tomography (CT) of the chest and abdomen to rule out metastatic disease and by magnetic resonance imaging (MRI) of the pelvis to assess local tumor extent, as well as pathologic assessment and audit has also contributed to improved results. The benefits of neoadjuvant chemoradiotherapy for locally advanced tumors are now generally accepted, with good evidence for both downstaging and downsizing, as well as decreased local recurrence. However, no significant differences in survival or sphincter-sparing procedures have been demonstrated.

The complexity of decision making in the management of rectal cancer is undoubtedly best coordinated by a multidisciplinary team, which is crucial for individualized treatment strategies, and must balance between the desired effect on the disease and the short- and long-term side effects associated with treatment. Currently, the goals for treating rectal cancer have broadened to include securing local and distant oncologic control,

minimizing treatment-related morbidity and mortality, optimizing functional outcomes, and promoting rapid recovery after operative treatment with prompt return to normal activities.

ANATOMY

Anatomy is the mother discipline of all surgical interventions, and this holds especially true for rectal cancer surgery. The rectum and the anal canal are the last segments of the gastrointestinal tract responsible for mediating fecal continence and coordinating defecation. The rectoanal segment measures 15 to 20 cm long and extends from the rectosigmoid junction at the sacral promontory to the anal orifice. The rectal wall differs morphologically from the colon by the confluence of taeniae coli to a continuous longitudinal smooth muscle layer, permanent semilunar transverse folds, and the absence of fatty appendices epiploica. Most of the rectum is not covered by peritoneum, with only its upper ventrolateral two thirds related to the peritoneum and reflecting on to the bladder and seminal vesicles in men or uterus and posterior vagina in women (pouch of Douglas).

The rectum narrows at the level of the anorectal ring and becomes the anal canal, which extends down and backward to the anal orifice and measures 2.5 to 4 cm long (Fig. 155.1). The anal canal is divided into an upper and lower segment separated by a transitional zone at the dentate line. The transitional zone exhibits 8–12 vertical anal columns (of Morgagni) containing terminal branches of the superior rectal artery. At the lower end of the anal canal, an intersphincteric groove (anal verge) is palpable between the internal and external anal sphincters. Whereas the “surgical” anal canal is defined as from the anorectal ring to the anal verge, the “anatomical” anal canal is confined from the dentate line to the anal verge.

Perirectal Tissue Planes and Spaces

Comprehensive understanding of the topographic anatomy of the fascia and spaces surrounding the rectum is an essential prerequisite for rectal cancer surgery. Rectal mobilization along the correct planes will achieve oncologically safe margins and preservation of urogenital functions. The inner surface of the pelvic wall and the pelvic muscles (internal obturator, levator ani, coccygeal and piriformis muscles) are covered by the parietal pelvic fascia (Fig. 155.2). The visceral pelvic fascia (endopelvic fascia)

ensheathes the pelvic organs, including the rectum. In contrast to the urogenital pelvic organs, the rectum is enveloped by the rectal (“proper” or mesorectal) fascia. Anteriorly, the mesorectal border is the rectogenital septum (Denonvilliers fascia), and posteriorly it is the presacral fascia. The presacral fascia is part of the parietal pelvic fascia and is separated from the mesorectal fascia by the retrorectal space. Opening the retrorectal space reveals loose areolar connective tissue, also described as “angels hair.” However, at the level of the fourth sacral vertebra, the mesorectal fascia fuses with the presacral fascia. This bridge of connective tissue can be quite thick and is also termed rectosacral or Waldeyer fascia. On both sides, the rectum is loosely connected to the pelvic wall by condensed connective tissue, traditionally described as lateral rectal ligaments. These ligaments do not provide substantial mechanical fixation and serve primarily as vascular and nervous pedicles or stalks, with small branches from the middle rectal arteries and autonomic nerve fiber branches from the hypogastric plexus.

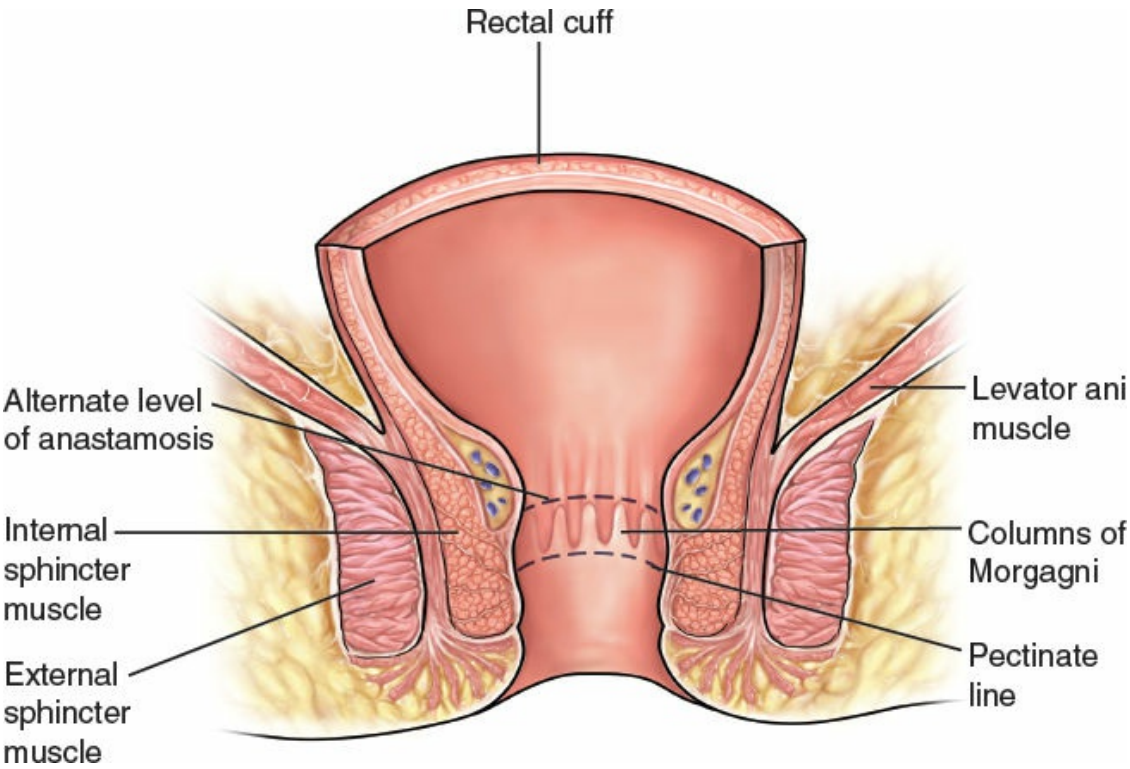

Figure 155.1. Anorectal anatomy.

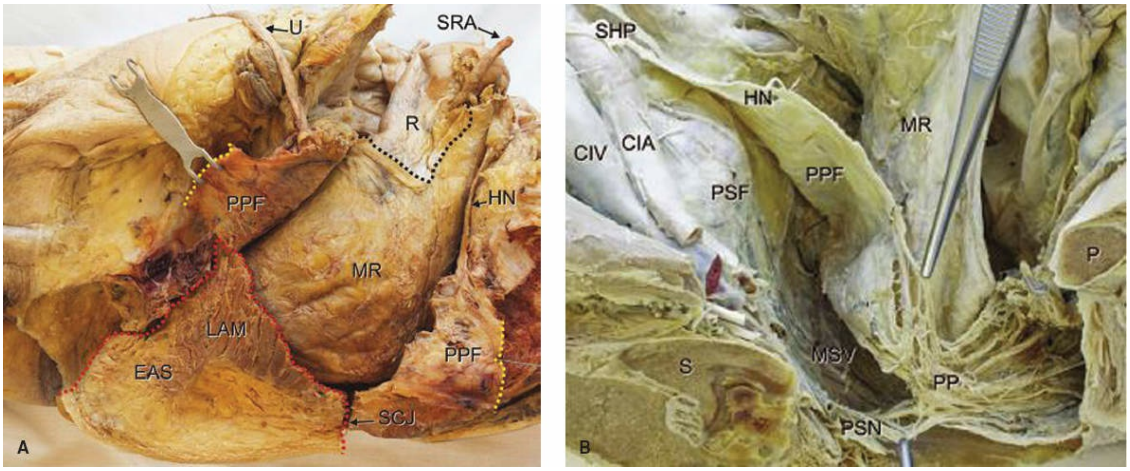

Figure 155.2. **A.** Male pelvis with left hemipelvis removed parasagittally. The left parietal pelvic fascia (PPF) containing the pelvic plexus is divided (*dotted yellow lines* represent the transection line) half-way between the sacrum and the posterior wall of the urinary bladder and prostate. The *dotted black line* shows the peritoneal reflection, and the *dotted red line* delineates excision planes. PPF, parietal pelvic fascia; MR, mesorectal fascia; EAS, external anal sphincter; LAM, levator ani muscle; R, rectum; SRA, superior rectal artery; SCJ, sacrococcygeal junction (divided); HN, hypogastric nerve; U, ureter (reflected). **B.** Female pelvis with right hemipelvis removed parasagittally. The rectum covered by its mesorectum is reflected anteriorly. The parietal pelvic fascia (PPF) is lifted up with the upper forceps to demonstrate the course of the superior hypogastric plexus (SHP). The pelvic splanchnic nerves (PSN) are highlighted with the lower forceps on their course from the sacral roots to the pelvic plexus (PP). HN, hypogastric nerve; PSF, presacral fascia; MSV, median sacral vessels; CIA, common iliac artery; CIV, common iliac vein; P, pubic bone (superior branch); S, sacrum. (Modified from Stelzner S, Holm T, Moran BJ, et al. Deep pelvic anatomy revisited for a description of crucial steps in extralevator abdominoperineal excision for rectal cancer. *Dis Colon Rectum* 2011;54(8):947–57.)

Autonomic Nervous System

The rectum and upper anal canal, including the internal anal sphincter, is controlled by the autonomic nervous system. Sympathetic nerves control urinary bladder filling and mediate ejaculation, while parasympathetic nerves are responsible for controlled micturition, filling of the cavernous bodies (erection in males and swelling of the clitoris in females), and for lubrication of the external genitalia. The lumbar sympathetic nerves form

the inferior mesenteric and superior hypogastric plexuses, which enclose the inferior mesenteric artery (IMA) up to 5 cm from its origin. Therefore, a high arterial ligation without damaging adjacent sympathetic nerve fibers is virtually impossible. The superior hypogastric plexus then enters the pelvis in front of the sacral promontory and divides into the left and right hypogastric nerves (Fig. 155.3). These nerves often appear as intermingling strings and not a single defined nerve. The presacral fascia is intimately associated with the hypogastric nerves, and care must be taken during the posterior rectal dissection to avoid injury to these structures. Gentle cephalad traction on the rectum helps visualize the course of the hypogastric nerves down to the inferior hypogastric plexus.

Parasympathetic innervation of the rectum is provided by the pelvic splanchnic nerves, which derive from the sacral spinal cord (S2 to S4). Because of their function, they are also termed erigent nerves or *nervi erigentes.* The pelvic splanchnic nerves pierce the presacral fascia at the left and right sides and join the inferior hypogastric plexus. The inferior hypogastric plexus or pelvic plexus is an extensive network of sympathetic and parasympathetic nerves that extends anteriorly in a fan-like fashion radiating from the seminal vesicles to the upper aspect of the perineal body in men or along the lower lateral posterior wall of the vagina in women. Terminal branches consist of cavernous nerves that are responsible for erectile functions and innervation of the internal urethral sphincter.

Autonomic innervation of pelvic organs is characterized by a certain functional redundancy, represented by abundant bilateral ramifying nerve plexi with collateral nerve fibers that connect both sides of the pelvis. Thus, the intact contralateral side may compensate unilateral damage. However, the impact of nerve injury after TME should not be underestimated because of this.

Vascular Supply and Lymphatic Drainage

The rectum, including the upper anal canal, receives its blood supply by the IMA via the superior rectal artery. The middle and inferior rectal arteries originate from the internal iliac vessels and contribute to the blood supply of the lower anal canal and minor parts of the rectum via intramural anastomoses. The middle rectal arteries are small and inconsistent (present bilaterally in 10% of individuals), and approach the inferior rectum via the rectal pedicles. The inferior rectal arteries diverge from the internal pudendal arteries located within Alcock’s canal and approach the anal

region via the ischioanal space. The posterior anal canal and internal anal sphincter receive additional blood supply by the median sacral artery, a small vessel that arises from the posterior aspect of the abdominal aorta, superior to its bifurcation.

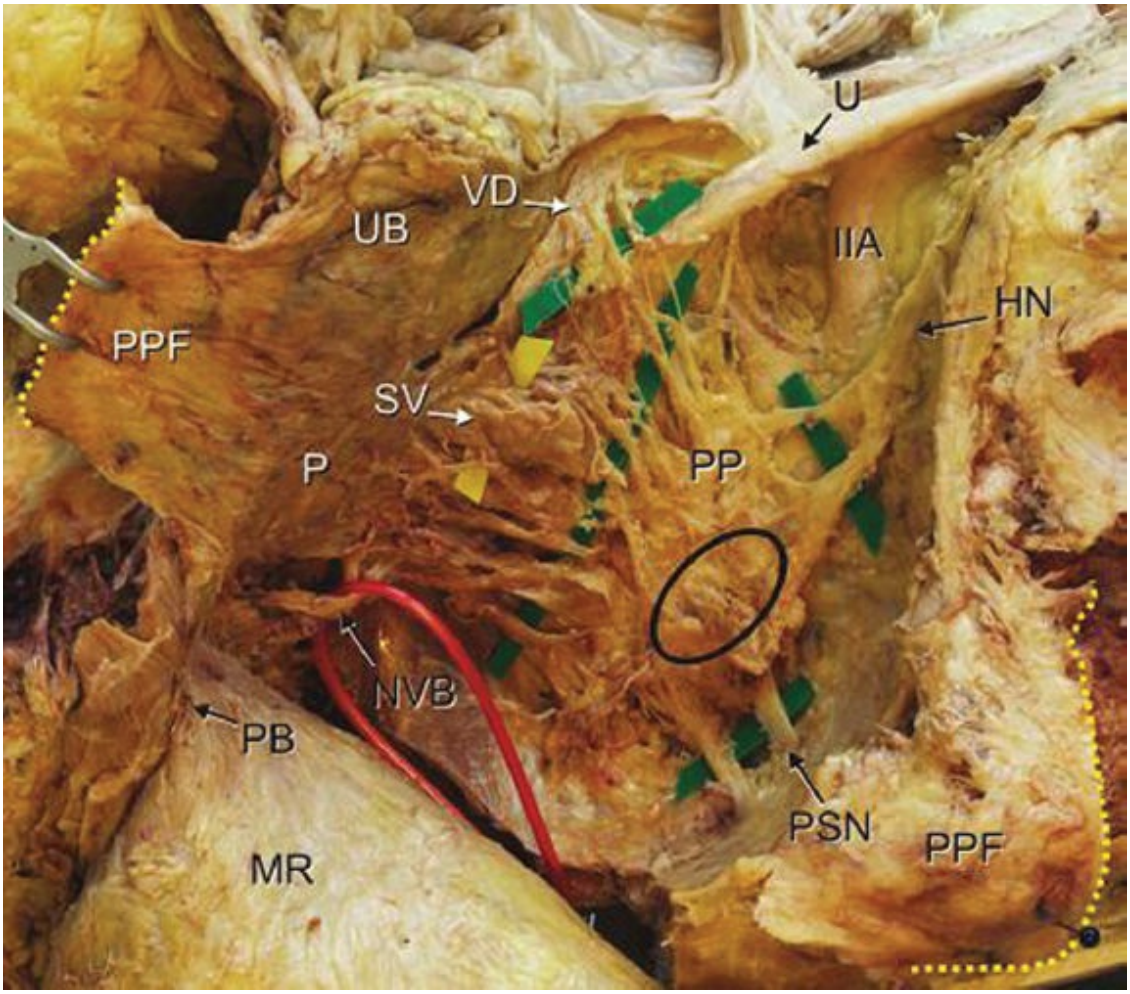

Figure 155.3. Male pelvis with left hemipelvis removed parasagittally. The rectum with the surrounding mesorectum (MR) is pulled out of the pelvis but still attached anteriorly at the region of the perineal body (PB). The left parietal pelvic fascia (PPF) is divided (*dotted yellow lines* show the transection line) and reflected to reveal the autonomic pelvic nerves: the right hypogastric nerve (HN) originating from the superior hypogastric plexus and the pelvic splanchnic nerves (PSN) emerging from the sacral roots join at the pelvic plexus (PP) from which fine branches (*green strips*) diverge in fanlike pattern toward the distal ureter (U), vas deferens (VD), seminal vesicles (SV, *yellow strip*), urinary bladder (UB), and prostate (P). The stumps of the nerves diverging into the rectum (T-junctions) are marked with a *black circle*. The right neurovascular bundle (NVB, *red vessel loop*)

extends toward the apex of the prostate coming into close proximity to the perineal body (PB) and the anterior surgical resection plane. IIA, internal iliac artery. (Modified from Stelzner S, Holm T, Moran BJ, et al. Deep pelvic anatomy revisited for a description of crucial steps in extralevator abdominoperineal excision for rectal cancer. *Dis Colon Rectum* 2011;54(8):947–57.)

The lymphatic drainage from the rectum is analogous to the blood supply, mainly in a cranial direction along the superior rectal and inferior mesenteric vessels, toward the visceral lymph nodes. One anatomical study found a mean of 8.4 lymph nodes in the mesorectum. Lymphatic drainage may also take place via the rectal pedicles toward the internal iliac lymph nodes. Lymphatic spread through this route is commonly seen with locally advanced tumors with pelvic wall invasion. The lower anal canal and perianal region have somatic lymphatic drainage toward the inguinal and external iliac lymph nodes.

CLINICAL PRESENTATION

Patients with rectal cancer may present in three ways: (1) suspicious signs and symptoms; (2) asymptomatic individuals diagnosed by screening; and (3) emergent presentation with intestinal obstruction, peritonitis, or acute gastrointestinal bleed.

Most patients with early-stage rectal cancer have no symptoms and are diagnosed as a result of endoscopic screening. Because of the increasing use of endoscopic colorectal cancer screening, an increasing number of rectal cancers are being diagnosed in asymptomatic patients; however, a majority are still diagnosed after the onset of symptoms.

Symptoms of rectal cancer are typically due to growth of the tumor into the lumen or adjacent structures. Typical signs and symptoms include hematochezia, otherwise unexplained iron deficiency anemia, and a change in bowel habits. Less common presenting symptoms include rectal pain or pressure, tenesmus, diarrhea, fecal seepage, and fecal incontinence. Fecal seepage and incontinence are typically associated with tumors invading the anal sphincter complex, and obstructive symptoms such as abdominal distension, nausea, and vomiting are most commonly associated with obstructing tumors.

Approximately 20% of patients diagnosed with rectal cancer in the United States have distant metastatic disease at the time of presentation. Rectal cancer can spread by lymphatic and hematogenous dissemination,

as well as by contiguous and transperitoneal routes. The most common metastatic sites are regional lymph nodes, liver, lungs, and peritoneum. Signs and symptoms commonly associated with the presence of metastatic disease include right upper quadrant pain, abdominal distention, early satiety, and cervical adenopathy. Tumors arising in the distal rectum may present with inguinal adenopathy and metastasize initially to the lungs because the inferior rectal veins drain into the inferior vena cava rather than into the portal venous system.

Although uncommon, patients with rectal cancer may have atypical presentations. These scenarios typically involve locally advanced tumors and include perianal and rectovaginal fistulas, contained perforation with fistulization to adjacent pelvic organs, rectal prolapse, and fever of unknown origin. *Streptococcus bovis* bacteremia and *Clostridium septicum* sepsis are associated with underlying colorectal malignancies in 10% to 25% of patients. Also, colorectal cancer ultimately proves to be the site of origin of approximately 6% of adenocarcinomas of unknown primary sites.

INDICATIONS AND CONTRAINDICATIONS

Despite advances and refinement in neoadjuvant treatment strategies, the mainstay of rectal cancer management continues to be surgical. While carefully selected early rectal cancers are amenable to transanal excision, the vast majority requires radical resection. Contraindications of radical resection include medically unfit patients, unresectable abdominopelvic disease (unamenable to multivisceral resection with R0 resection margins), and incurable metastatic disease in the absence of complicated factors such as obstruction, impending obstruction, and uncontrollable hemorrhage.

The clinical indications for minimally invasive proctectomy are the same as those for traditional open proctectomy. Postoperative adhesions and obesity can make the laparoscopic approach more difficult; however, the robotic approach has eased these difficulties in our experience because of improved visualization, greater freedom of movement, and the ability to perform fine dissection in confined surgical fields. Furthermore, obese patients have shown greater short-term benefits when the operation is successfully completed laparoscopically. Patients with poor cardiopulmonary function tolerate prolonged pneumoperitoneum poorly and should be monitored closely by an experienced anesthesia team.

With regard to disease-related factors, bulky, locally invasive and perforated tumors often preclude adequate visualization and are better

managed through a laparotomy. Hand-assisted laparoscopic surgery (HALS) is useful in selective patients with bulky tumors. In our experience, patients who require a vertical rectus abdominis myocutaneous flap for pelvic reconstruction are better managed with an open approach as well given that flap harvesting requires a midline laparotomy incision regardless of the approach used for proctectomy.

PREOPERATIVE PLANNING

Patients are routinely staged with full colonoscopy, CT of the chest, abdomen, and pelvis; and MRI of the pelvis; and those with locally advanced tumors or suspicion for metastatic disease undergo interval imaging after neoadjuvant chemoradiotherapy for appropriate staging. The addition of endorectal ultrasound is helpful in selective cases of early rectal cancer with an uncertain degree of rectal wall invasion on MRI. The decision to perform a sphincter-preserving rectal resection largely depends on the quality of preoperative imaging. Diffusion-weighted imaging and dynamic contrast-enhanced MRI have significantly improved the preoperative assessment of patients with rectal cancer by allowing surgeons to accurately evaluate the topography of rectal tumors in the pelvis, assess the degree of invasion of the rectal wall and adjacent structures or organs, and detect lymph node metastases and vascular invasion (Fig. 155.4). Routine discussion with an experienced radiologist is a key factor in our practice to help accurately plan a sphincter-preserving proctectomy with TME and R0 resection.

Operative treatment is typically performed 10 to 12 weeks after completing neoadjuvant chemoradiotherapy, and all cases are discussed at a multidisciplinary session. Repeat flexible or rigid proctoscopy and digital rectal examination are key to assess tumor characteristics and location, anal sphincter function and possible tumor-invasion, as well as response to neoadjuvant therapy. Patients should also have a baseline carcinoembryonic antigen (CEA) level.

Mechanical bowel preparation plus oral antibiotics (metronidazole and neomycin) is given the day before surgery, and patients are allowed a liquid diet up to 2 hours before arrival to the hospital. Consumption of high-carbohydrate supplements is highly recommended 2 to 3 days before surgery. As part of an enhanced recovery after surgery (ERAS) protocol, all patients routinely receive preoperative anti-inflammatory agents, nausea prophylaxis, an opioid antagonist, and appropriate pharmacologic

and mechanical venous thromboembolism (VTE) prophylaxis. All patients are marked preoperatively by an enterostomal nurse in case fecal diversion is intended or required. Both transversus abdominis plane (TAP) blocks with a long-acting anesthetic or epidural anesthesia are strongly encouraged to reduce postoperative narcotic consumption.

In the operating room, patients are placed in the modified lithotomy position with stirrups. Insertion of ureteral catheters is also encouraged in cases that may require extensive pelvic dissection, reoperation, and previous pelvic radiotherapy.

Even with appropriate preoperative planning and despite the location of a given rectal tumor, one must always be aware of the possibility of an abdominoperineal resection. This must be discussed with the patient preoperatively and included in the informed consent document. Patients with moderate to poor anal sphincter function are better served by an abdominoperineal resection, and this should be discussed preoperatively as well. Preparation of the operating room and operative team should include a brief discussion of the operative steps and any potential special requests or needs during the operation. In our experience, it has been helpful to discuss the need for an additional operative set-up for perineal dissection, changes in positioning, intraoperative endoscopy, and frozen-section analysis.

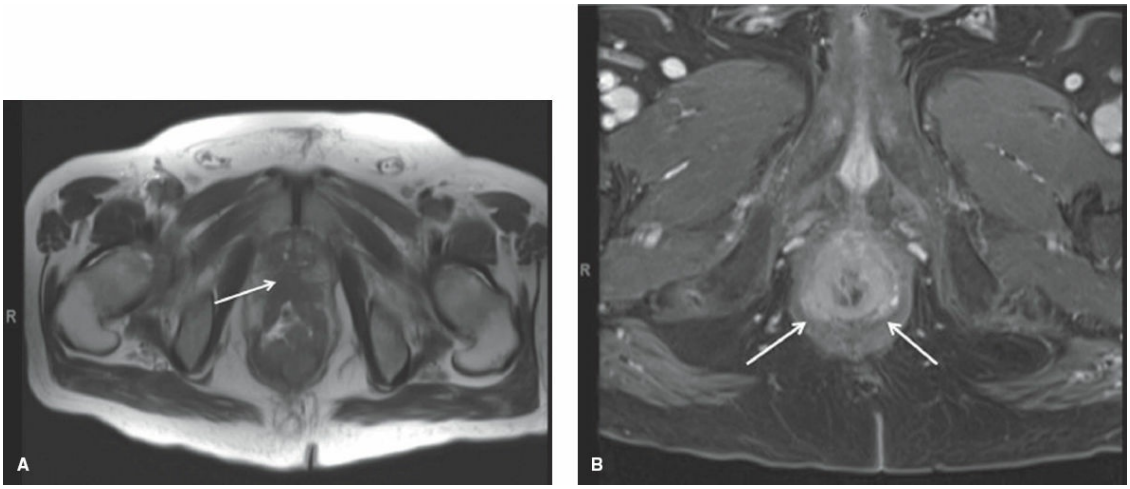

Figure 155.4. Pelvic MRI showing a large bulky rectal cancer with invasion of the prostate (**A**; *arrow*) and bilateral levator ani muscles (**B**; *arrow*).

SURGICAL TECHNIQUE

Regardless of approach (open or minimally invasive), the surgical

technique of proctectomy with TME is the same. For open proctectomy, a lower midline laparotomy incision is preferred and the use of a wound-protector and self-retaining surgical retractor is highly recommended. With a minimally invasive approach (robotic, pure laparoscopy, or hand-assisted laparoscopy), access to the peritoneal cavity varies and options include a hand-assisted incision, open trocar placement (Hassan technique), and closed technique with a Veress needle or an optical viewing trocar. Trocar placement varies according to patient anatomy and surgeon preference. Our preference is shown in Figures 155.5 to 155.7. After entering the peritoneal cavity, the intra-abdominal viscera and peritoneal surfaces should be evaluated to exclude metastatic disease. The presence of ascites should be noted and documented. However, cytology of ascites fluid in the absence of suspicious metastatic disease has little to no impact or benefit. The small bowel is then displaced or packed into the upper abdomen, and the patient is placed in the Trendelenburg position.

Colon Mobilization and Division of Blood Supply

Colon mobilization is then initiated using a medial-to-lateral or lateral-to-medial technique (Figs. 155.8 and 155.9). It is our preference to use the medial-to-lateral technique, especially with a minimally invasive approach as it allows for early identification of the left ureter, dissection of the retroperitoneal attachments from the colon mesentery, and dissection of the vascular pedicle (IMA and inferior mesenteric vein [IMV]). After the medial-to-lateral dissection is complete, the splenic flexure and lateral attachments of the descending colon and sigmoid colon are taken down. In cases where the splenic flexure is high and not easily accessed, mobilization is facilitated by taking down the transverse colon attachments medially first and then continuing laterally to the splenic flexure.

After adequate colon mobilization, the IMA is ligated with sutures, clips, or a stapler with a vascular load (white or gray) (Fig. 155.10). “High ligation” is defined as ligation of the IMA just beyond its origin from the aorta, and “low ligation” is defined as ligation of the IMA just beyond the takeoff of the left colic artery. Consensus does not exist on the optimal level of arterial ligation for rectal cancer operations from an oncologic standpoint. Two systematic reviews have assessed the impact of the level of IMA ligation in rectal and descending colon cancer operations, and one randomized controlled trial has been conducted assessing this topic. Although both reviews found insufficient evidence to support high

ligation, one found increased lymph node retrieval, more accurate tumor staging, and a trend for improved survival with the high ligation technique. The only randomized controlled trial found no significant differences in 12-year survival, anastomotic leak (AL) rates, overall morbidity, and 30-day mortality rates between patients undergoing high IMA ligation or not. It is our practice to perform high ligation of the IMA as well as IMV ligation as required for lengthening the descending colon mesentery but not for additional oncologic benefits.

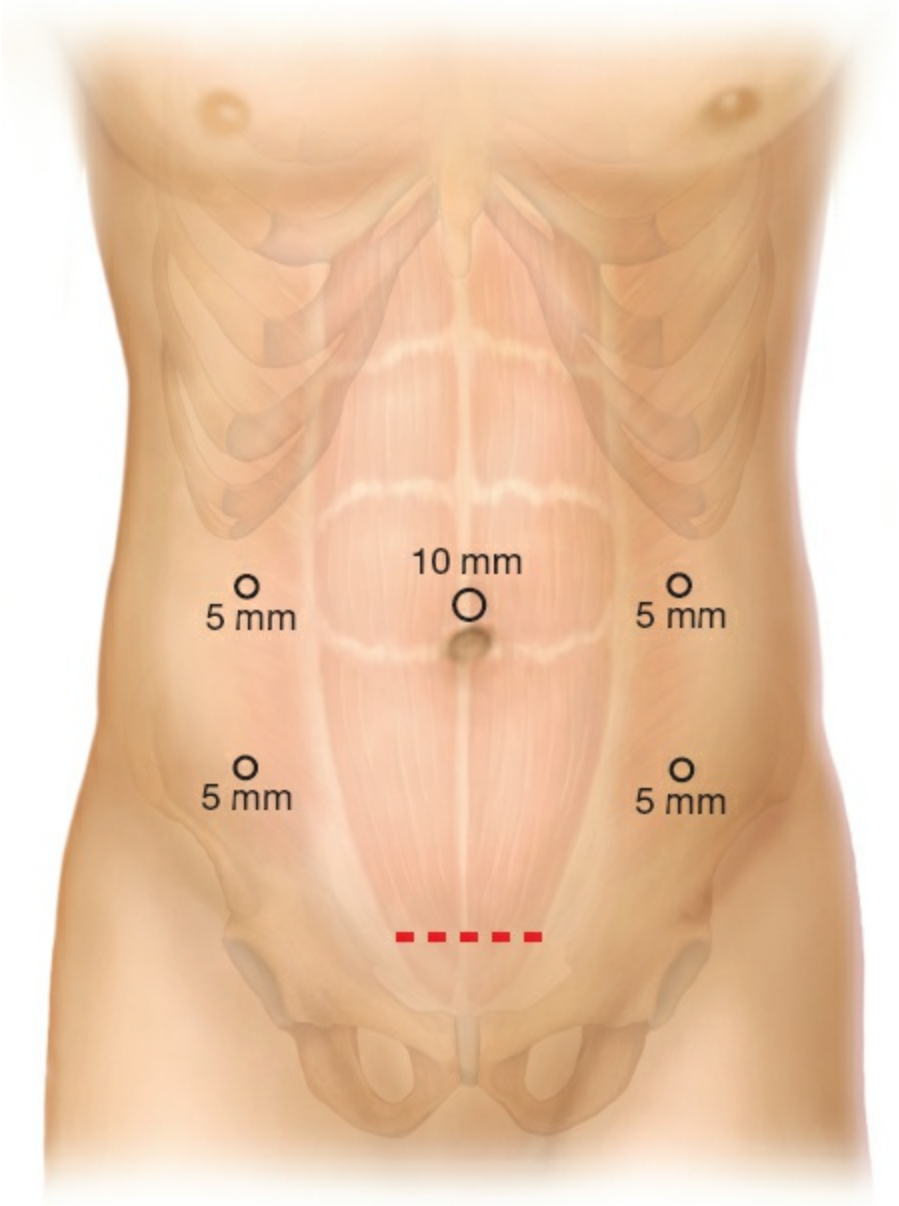

Figure 155.5. Trocar placement for laparoscopic proctectomy. The peritoneal cavity is typically accessed through a left upper quadrant or supraumbilical port. The left-sided ports are optional and are most useful for takedown of the splenic flexure. The right

lower quadrant port should be placed at the pre-marked ileostomy site. A 12-mm port can be placed at the right lower quadrant or mini-Pfannenstiel incision to allow insertion of a laparoscopic stapler. The mini-Pfannenstiel incision allows for anvil placement and specimen extraction. (Figure 15.1 from Laparoscopic Low Anterior Resection with Transanal Anastomosis or Colonic J Pouch Creation [Wexner/Fleshner].)

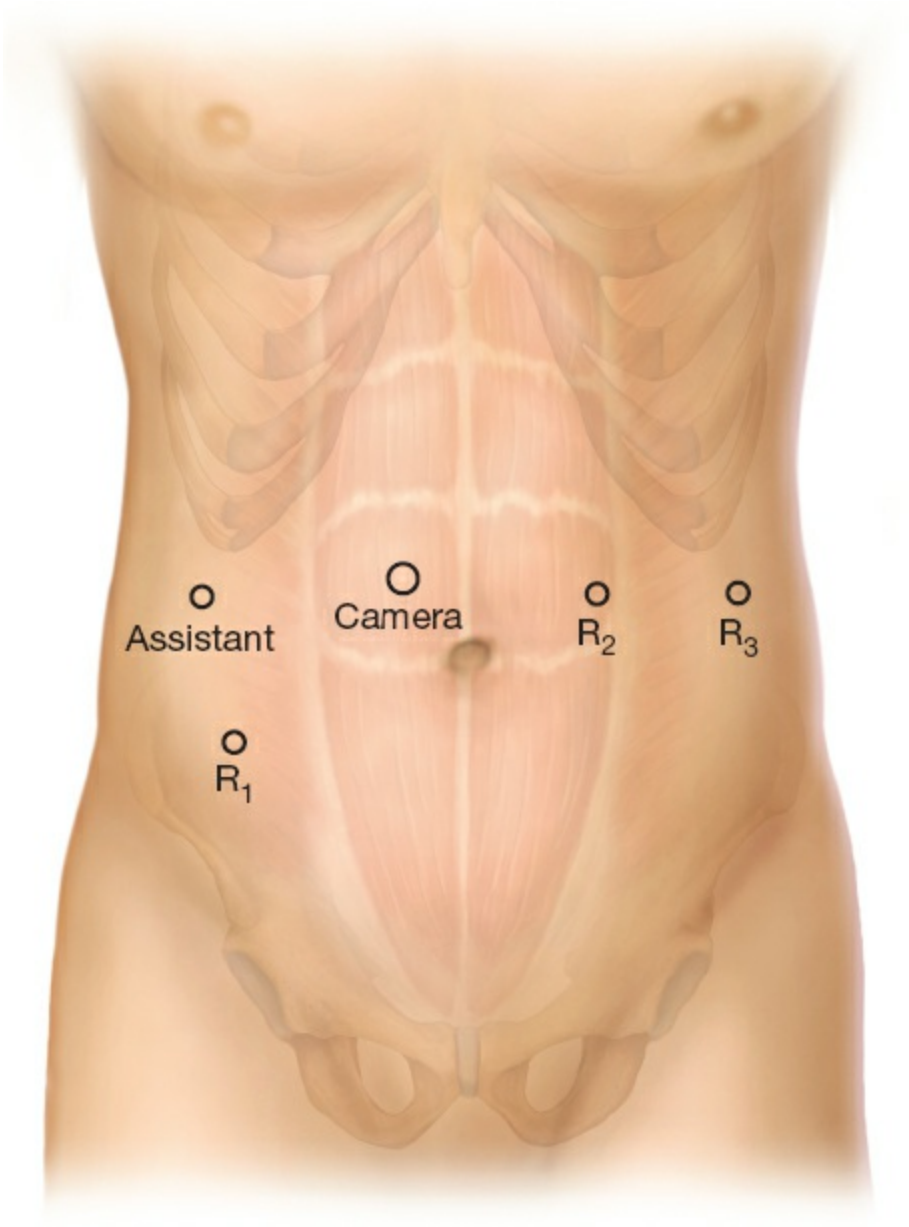

Figure 155.6. Trocar placement for laparoscopic robotic-assisted proctectomy. Access to the peritoneal cavity typically occurs via the left upper quadrant or with an open (Hassan) technique. A 12-mm port will be required at R1 if a robotic stapler is to be used. (Figure 17.5 Hybrid Robotic and Fully Robotic Procedures [Wexner/Fleshner].)

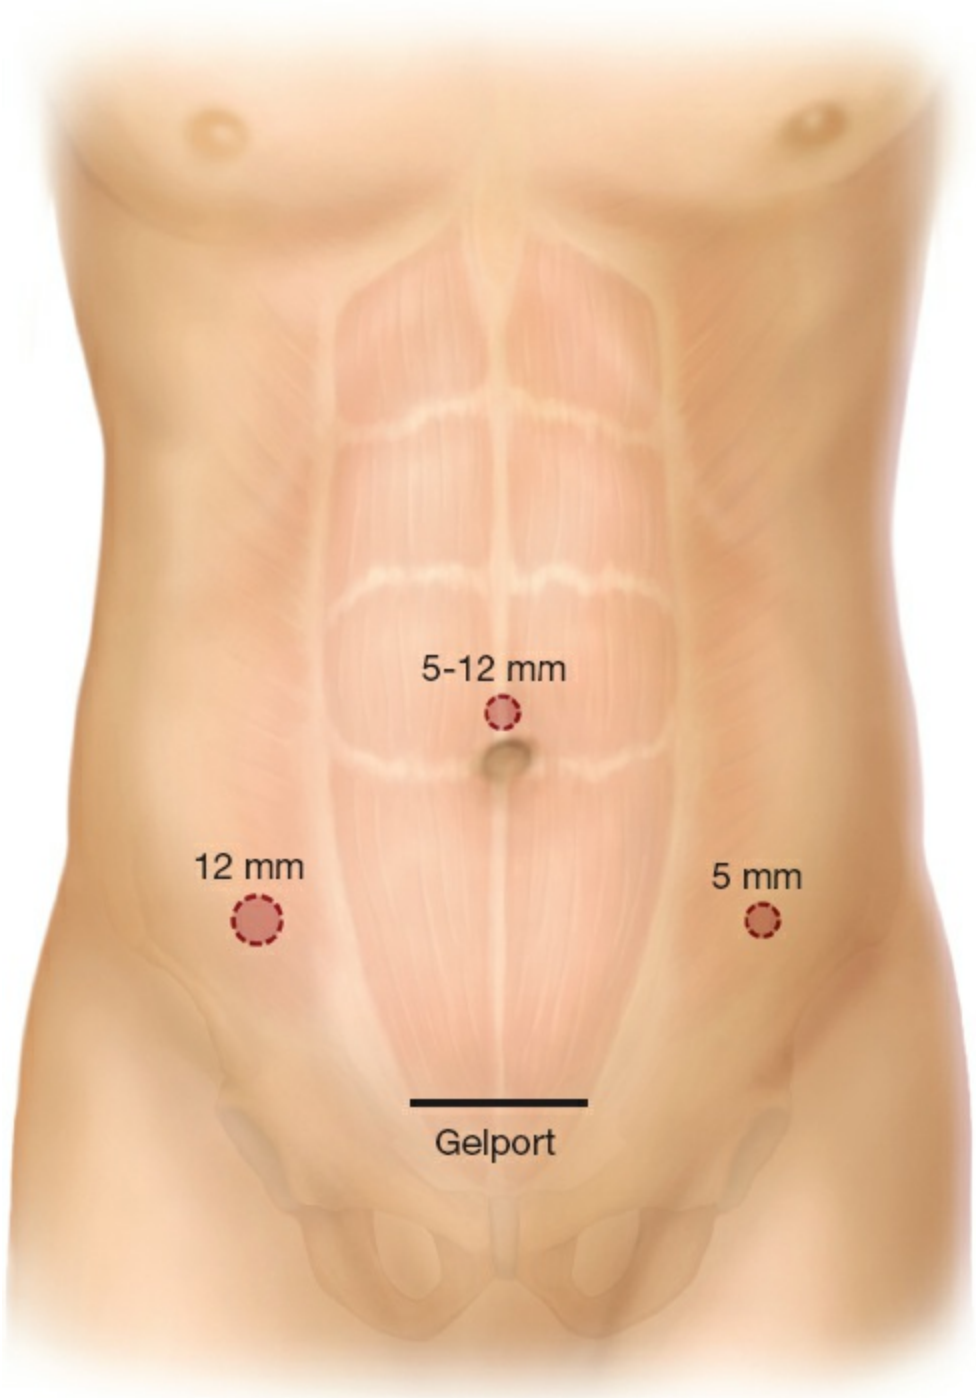

Figure 155.7. Trocar placement for hand-assisted laparoscopic proctectomy. The hand-assisted gelport may be placed at the lower midline or as a Pfannenstiel incision. (Figure 2 from Low Anterior Resection: Hand-Assisted Laparoscopic Surgery Technique [Albo].)

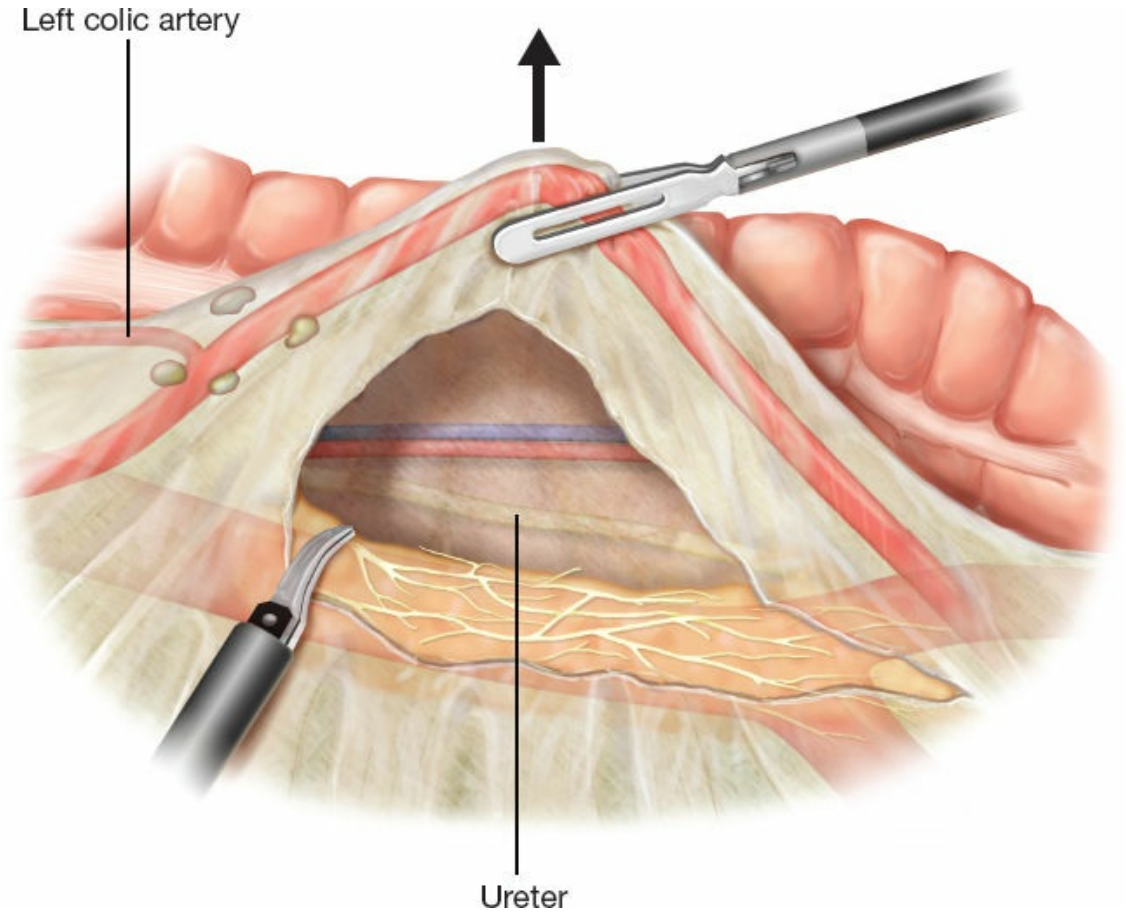

Figure 155.8. Anatomy seen with a medial-to-lateral technique during a laparoscopic low anterior resection. At the level of the sacral promontory, the inferior mesenteric artery is tented anteriorly toward the abdominal wall, allowing for dissection parallel and deep to the artery. Note the left colic artery is preserved. Nerve fibers from the sympathetic plexus lay below the artery, and are swept down and preserved. Prior to transection, identification of the left ureter is vital to ensure it is not inadvertently transected with the vascular bundle. (Figure 15.2 from Laparoscopic Low Anterior Resection with Transanal Anastomosis or Colonic J Pouch Creation [Wexner/Fleshner].)

After vessel ligation, the mesentery is transected and the colon is divided at the descending-sigmoid colon junction with a linear or transverse stapler. This step is especially helpful with the open approach as it facilitates rectal retraction. The descending colon should then be assessed for adequate blood supply and length. To ensure appropriate length for a tension-free anastomosis, the proximal margin should easily reach the pubic symphysis.

Total Mesorectal Excision and Autonomic Nerve Preservation

The fundamental components of TME include the following principles:

- Anatomic dissection under direct vision following the fascia propria of the mesorectum.
- Excision of an intact specimen without tissue tears or involvement of the distal or circumferential margins.
- Intraoperative recognition and preservation of autonomic nerves to reduce postoperative genitourinary dysfunction.
- Personal assessment of the surgical specimen for immediate feedback regarding completeness of resection.

Dissection of the rectum continues into the pelvis, mobilizing the mesorectum off the sacrum along the avascular plane of the endopelvic fascia. TME requires dissection under direct vision along the areolar plane located between the mesorectum at the visceral fascia (fascia propria) and the pelvic parietal (presacral) fascia (Fig. 155.11). As a helpful visual guide to proper dissection, the parietal fascia is usually “whiter” than the visceral fascia. This plane continues laterally with careful dissection around the mesorectum, keeping the integrity of the endopelvic fascia intact. Firm anterior and lateral retraction of the rectosigmoid can facilitate the dissection at the pelvic brim and posteriorly in the retrorectal space. Bilateral hypogastric nerves and ureters should be identified and avoided (Fig. 155.12).

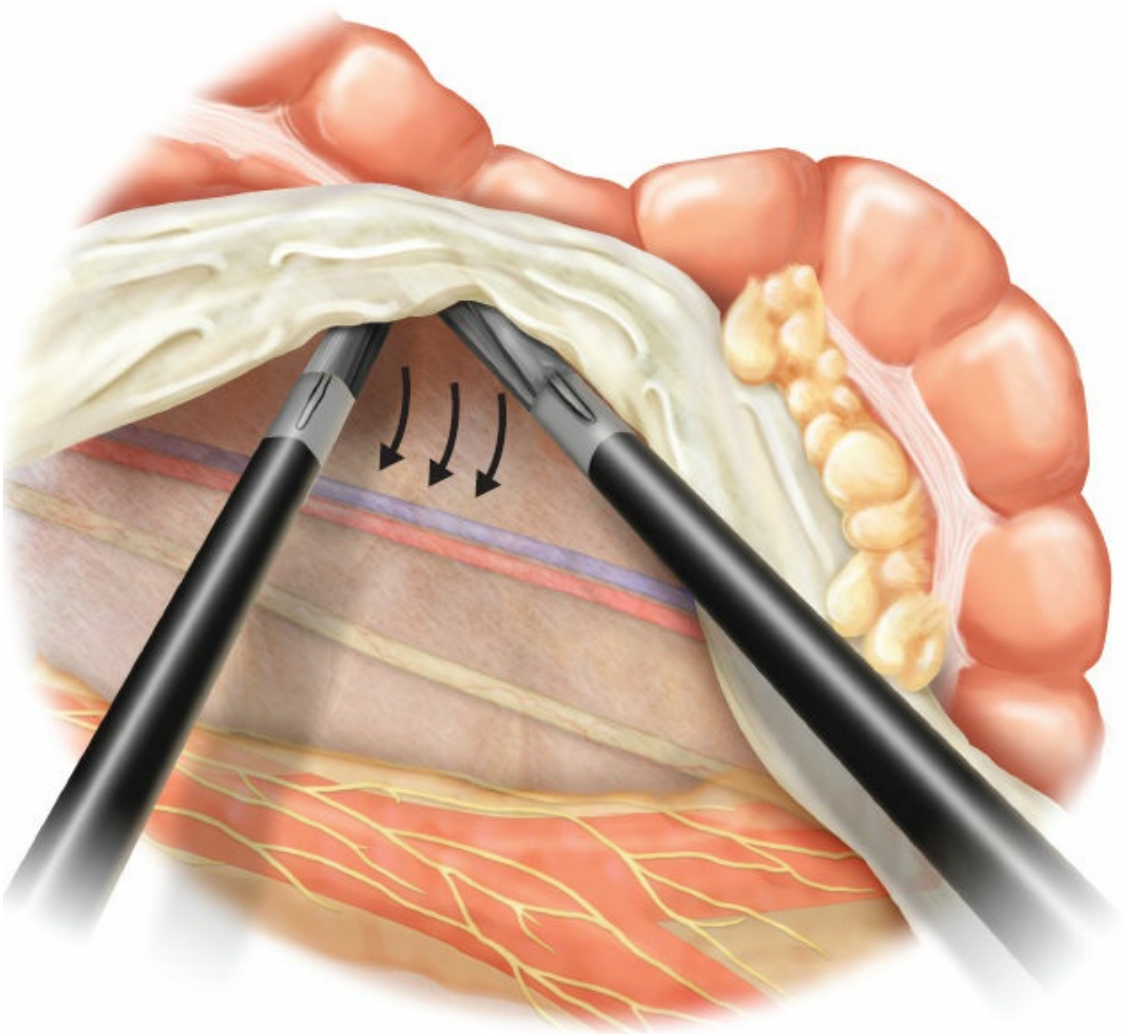

Figure 155.9. The medial-to-lateral dissection is facilitated by reverse Trendelenburg with left side elevated. Retractors are placed under the mesentery to keep tension on the line of Toldt and retroperitoneum. Open bowel graspers elevate the mesentery allowing for a wider line of traction during the dissection. Dissection follows the retroperitoneum to the lateral sidewall, superiorly to the splenic flexure and inferiorly toward the iliac fossa. Care must be taken to ensure that the ureter and retroperitoneal structures remain with the retroperitoneum, and the plane of dissection does not veer under the distal edge of the pancreas. (Figure 15.3 from Laparoscopic Low Anterior Resection with Transanal Anastomosis or Colonic J Pouch Creation [Wexner/Fleshner].)

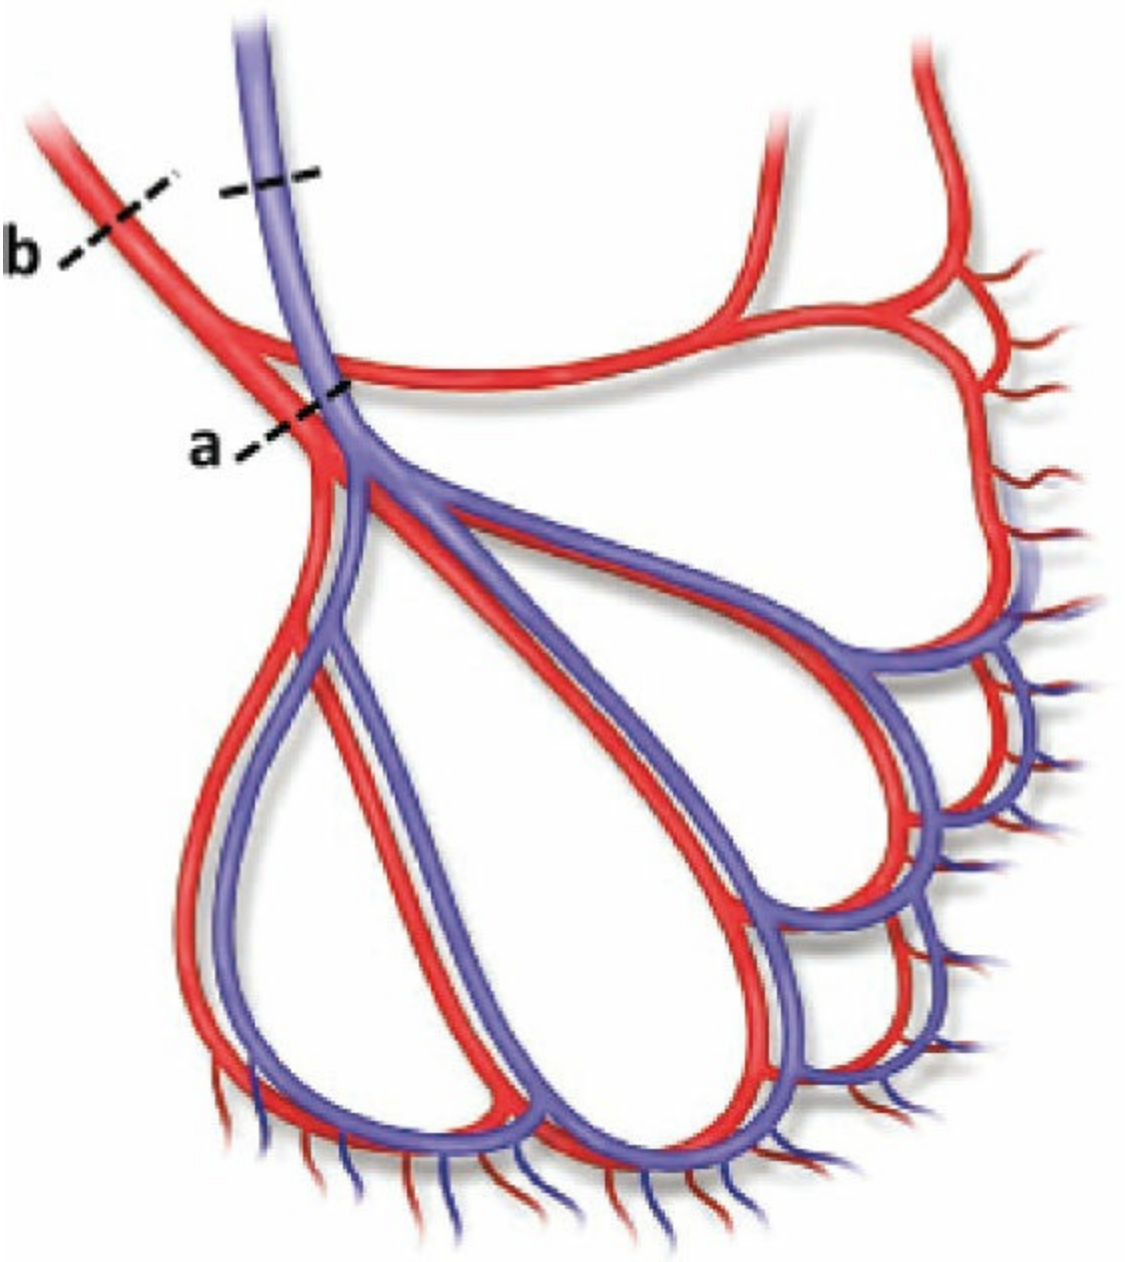

Figure 155.10. Vascular division sites of the inferior mesenteric artery (a. low ligation, b. high ligation), and inferior mesenteric vein. (Figure 17.7 Hybrid Robotic and Fully Robotic Procedures [Wexner/Fleshner].)

After the retrorectal dissection is complete, the peritoneum is incised at the rectouterine or rectovesicle fold at the cul-de-sac starting anteriorly and then extending laterally to connect to the posterior-lateral dissection. Anteriorly, the plane between the rectum and the seminal vesicles and prostate or posterior vaginal wall is dissected under direct vision. We do not routinely excise Denonvilliers fascia unless the tumor involves the anterior rectal wall. Once the dissection is complete, the endopelvic fascia

envelope is maintained resulting in a bilobed mesorectum covered by an intact “shiny” mesorectal fascia (Fig. 155.13).

The autonomic nerves are exposed to trauma at the following locations and operative steps: at the base of the IMA during vessel ligation, at the mesosigmoid colon during mobilization of the sigmoid colon near the sacral promontory, during lateral pelvic sidewall dissection, and just lateral to the seminal vesicles in male patients or the cardinal ligaments in female patients.

Transanal TME

Transanal TME (taTME) is an emerging technique in rectal cancer surgery. Despite significant improvements in operative technique, the laparoscopic and robotic approaches to TME still present a technical challenge, particularly in the case of a low rectal cancer in an obese male patient with a narrow pelvis. Achieving adequate exposure deep in the pelvis and cross-stapling the rectum just above the pelvic floor can be very difficult. Furthermore, an adequate distal rectal margin for distal rectal tumors may be difficult to assess with the laparoscopic approach. Transanal TME has been developed to facilitate dissection in the low pelvis and accurately assess the distal rectal margin approaching the rectum from below (“down to up”) with a combination of laparoscopic and transanal minimal invasive surgery (TAMIS) to perform a full TME (Fig. 155.14). The rectum is divided via a transanal approach without a stapler, leaving an open stump. The surgeon then has the options of performing a stapled anastomosis after closure of the rectal stump with a purse string suture, or a handsewn coloanal anastomosis.

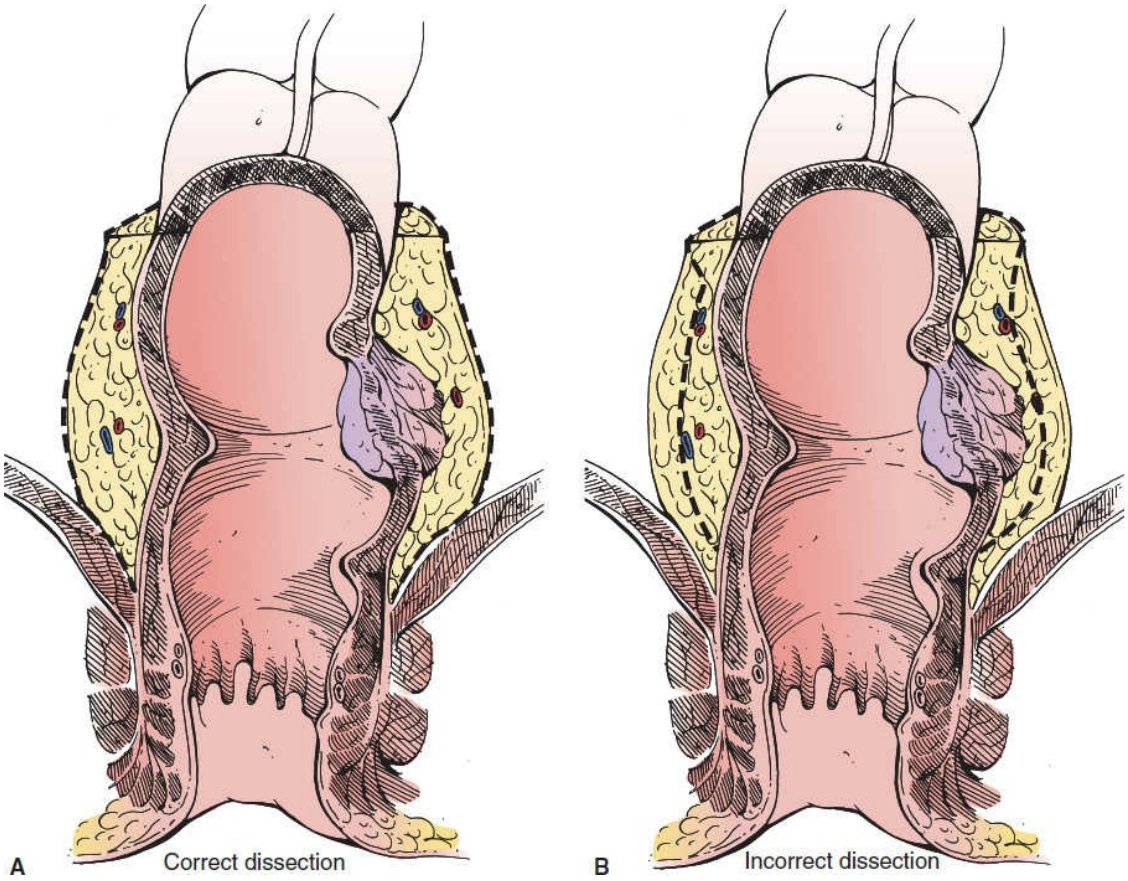

Figure 155.11. Correct total mesorectal excision dissection versus an incorrect dissection. The dissection should proceed between the mesorectal fascia and the pelvic wall fascia.

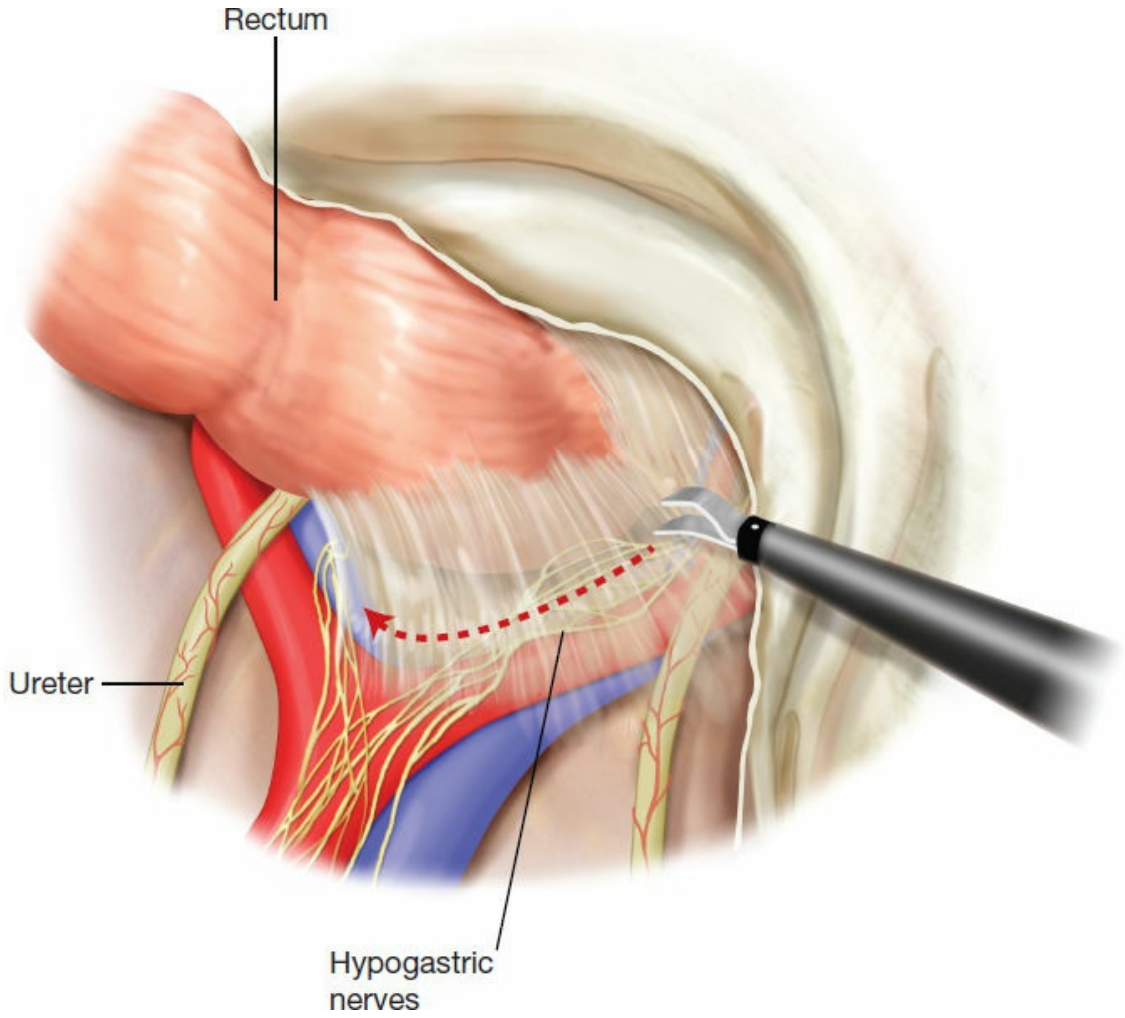

Figure 155.12. Entering the appropriate plane for mesorectal dissection is critical to oncologic resection. By reflecting the rectosigmoid junction anteriorly and superiorly, a plane may be visualized on the right side of the mesorectum. Sharp dissection should be performed in this avascular plane. (Figure 15.5 from Laparoscopic Low Anterior Resection with Transanal Anastomosis or Colonic J Pouch Creation [Wexner/Fleshner].)

Distal Resection

After the rectum distal to the tumor is dissected free, it is then transected with a stapler. With the open approach, a TA or Contour stapler with a green load is used. If a coloanal anastomosis is planned, the distal rectal transection is performed transanally (Fig. 155.15). With the laparoscopic and robotic approaches, it is especially helpful to perform flexible sigmoidoscopy intraoperatively to assure a negative distal margin, as the rectum cannot be palpated and because of the lack of tactile feedback with the robotic approach. In our experience, the articulation provided by the robotic stapler allows for distal rectal transection close to the anorectal

ring, and compares favorably to the laparoscopic staplers. The robotic approach can also facilitate the placement of a purse-string suture on an open rectal stump in preparation for a single-stapled circular colorectal anastomosis.

Figure 155.13. Bilobed mesorectal specimen covered by an intact mesorectal fascia.

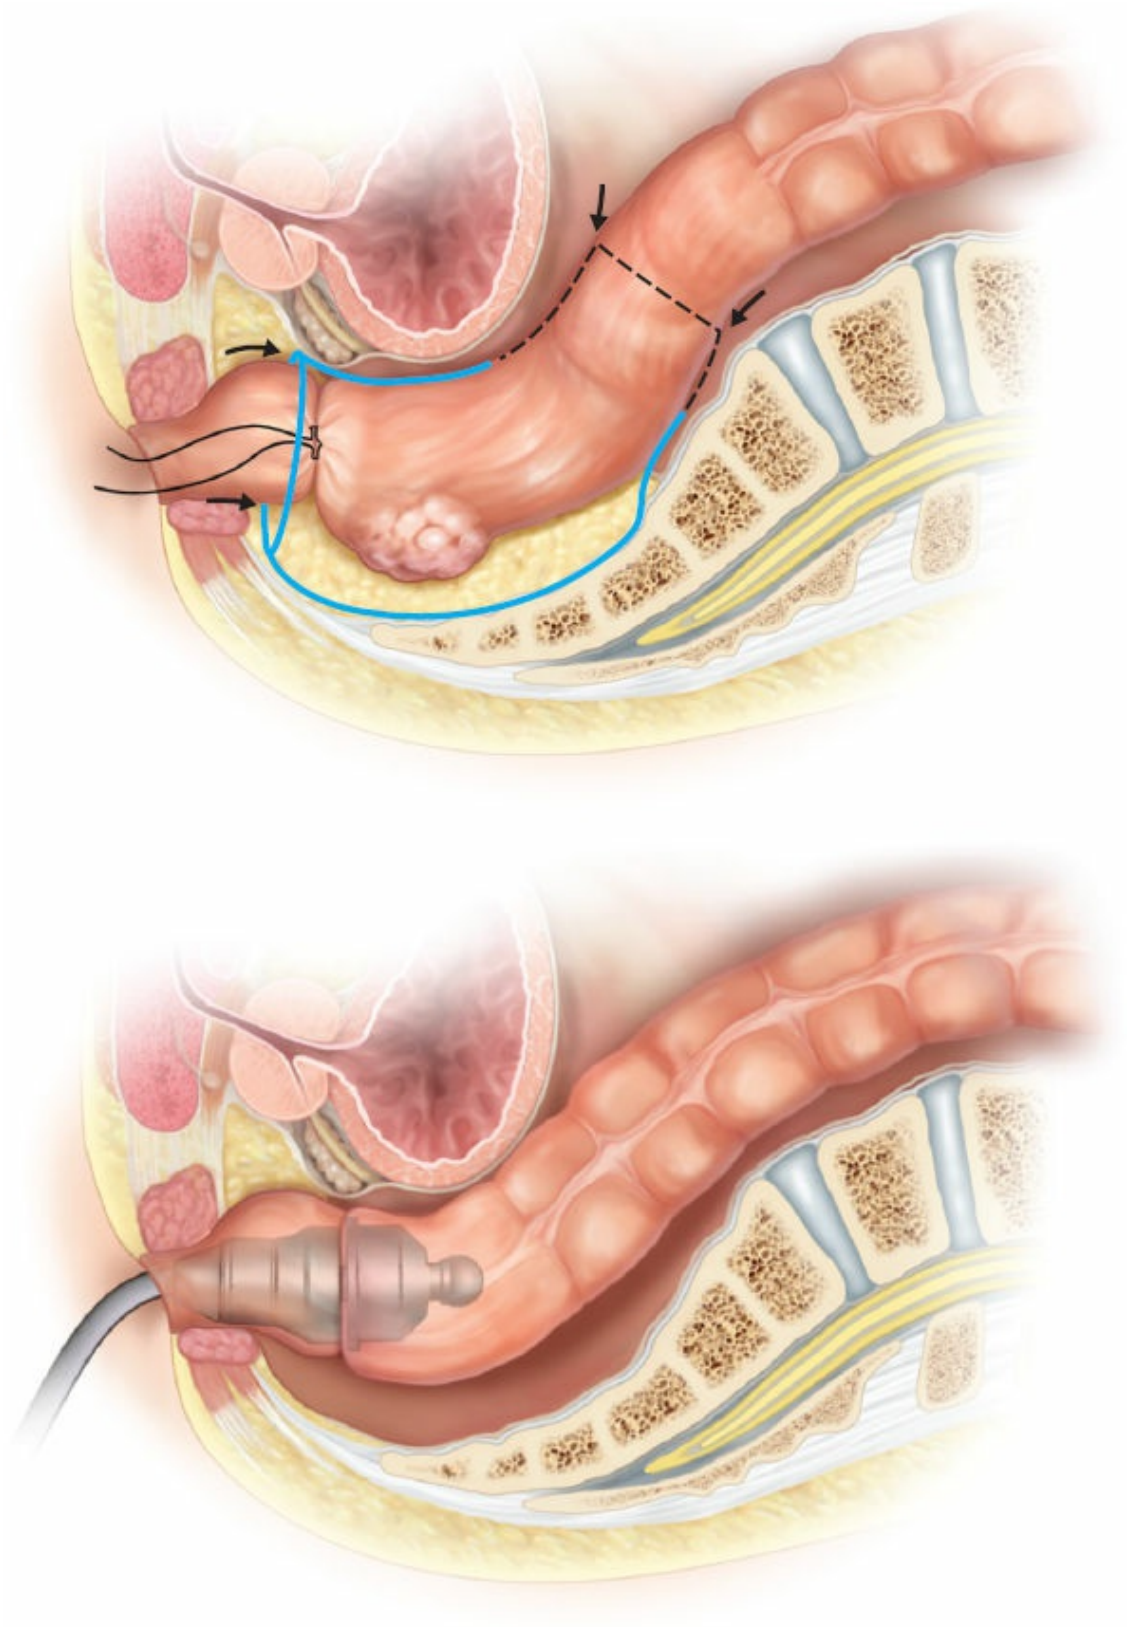

Figure 155.14. Rectal transection and dissection planes for transanal total mesorectal excision (TaTME). The distal rectum is closed from inside and transected below the tumor and the TaTME dissection (*blue lines*) meets the abdominal (open or laparoscopic) dissection (*black lines*).

For high and mid rectal cancers, radical resection with a partial TME 5 cm distal to the tumor and perpendicular to the rectum is performed. For middle to distal rectal cancers, the TME dissection is always taken down to the level of the pelvic floor. In patients with acceptable preoperative anorectal function, ideal body habitus and pelvic anatomy, sphincter preservation is usually possible for rectal tumors that would allow for at least a 1 cm distal margin. Some surgeons will perform an intersphincteric resection with sutured coloanal anastomosis instead of APR. Rullier and colleagues proposed a classification of distal rectal cancers with a standardized surgical approach according to the distance of the tumor from the anorectal ring and degree of invasion of the anal sphincter complex (Fig. 155.16). For an intersphincteric resection, the patient is kept in modified lithotomy, a Lonestar retractor is used to expose the anus, and the distal mucosal margin of resection at the dentate line is accessed through a circular incision. The incision is carried into the intersphincteric plane, preserving the external sphincter and sometimes the distal internal sphincter for continence. The abdominal and perineal dissections are then connected just above the puborectalis muscle. The posterior plane is the safest to initially enter. The anterior dissection is most difficult, and care must be taken to avoid the vagina in females and the prostatic urethra in males. The anterior dissection can be facilitated by placing a finger or sponge-stick into the vagina.

When the specimen is removed, the quality of the specimen is assessed. If there is concern for inadequate negative margins, immediate microscopic analysis should be performed. Pathologists play a key role in the evaluation of the specimen, including the quality assurance of surgical performance, as well as evaluation of the circumferential resection margin (CRM). Since proper pathologic assessment of a TME specimen provides important prognostic information, as well as critical feedback to surgeons regarding technical performance, it is important to have and follow adequate guidelines for the macroscopic handling of these specimens. Complete evaluation involves assessment of the specimen in both its fresh and fixed states, with observations made on both the external appearance and cross-sectional slices. Based on Quirke's grading system, the College of American Pathologists has published guidelines to grade TME specimens (Table 155.1). As an additional quality indicator, the surgical specimen should contain at least 12 lymph nodes but this is rarely achieved

after neoadjuvant chemoradiotherapy.

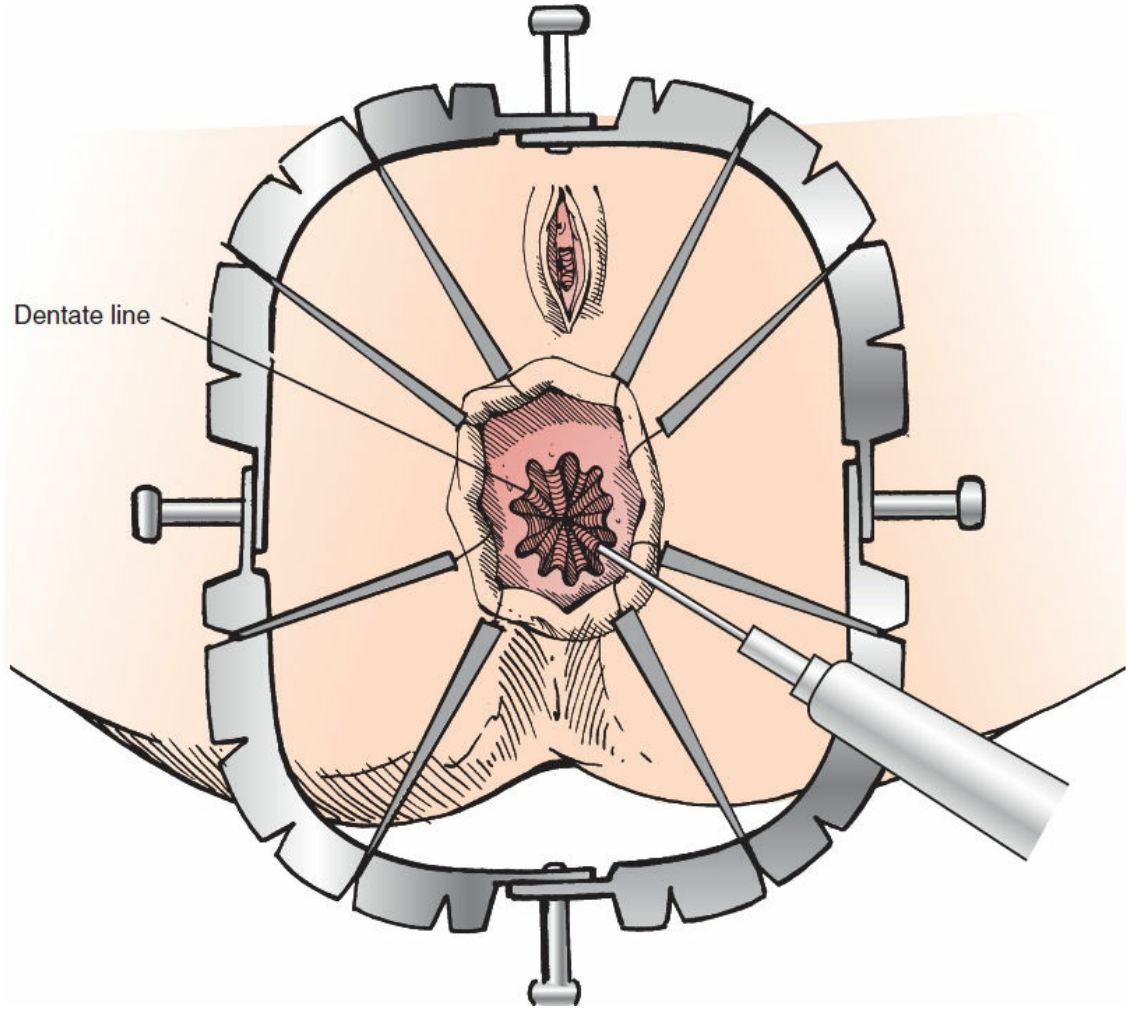

Figure 155.15. Perineal dissection with the patient in lithotomy position. Lidocaine with epinephrine is injected into the submucosa and the dentate line is incised. An intersphincteric dissection is then performed with either partial or complete excision of the internal anal sphincter.

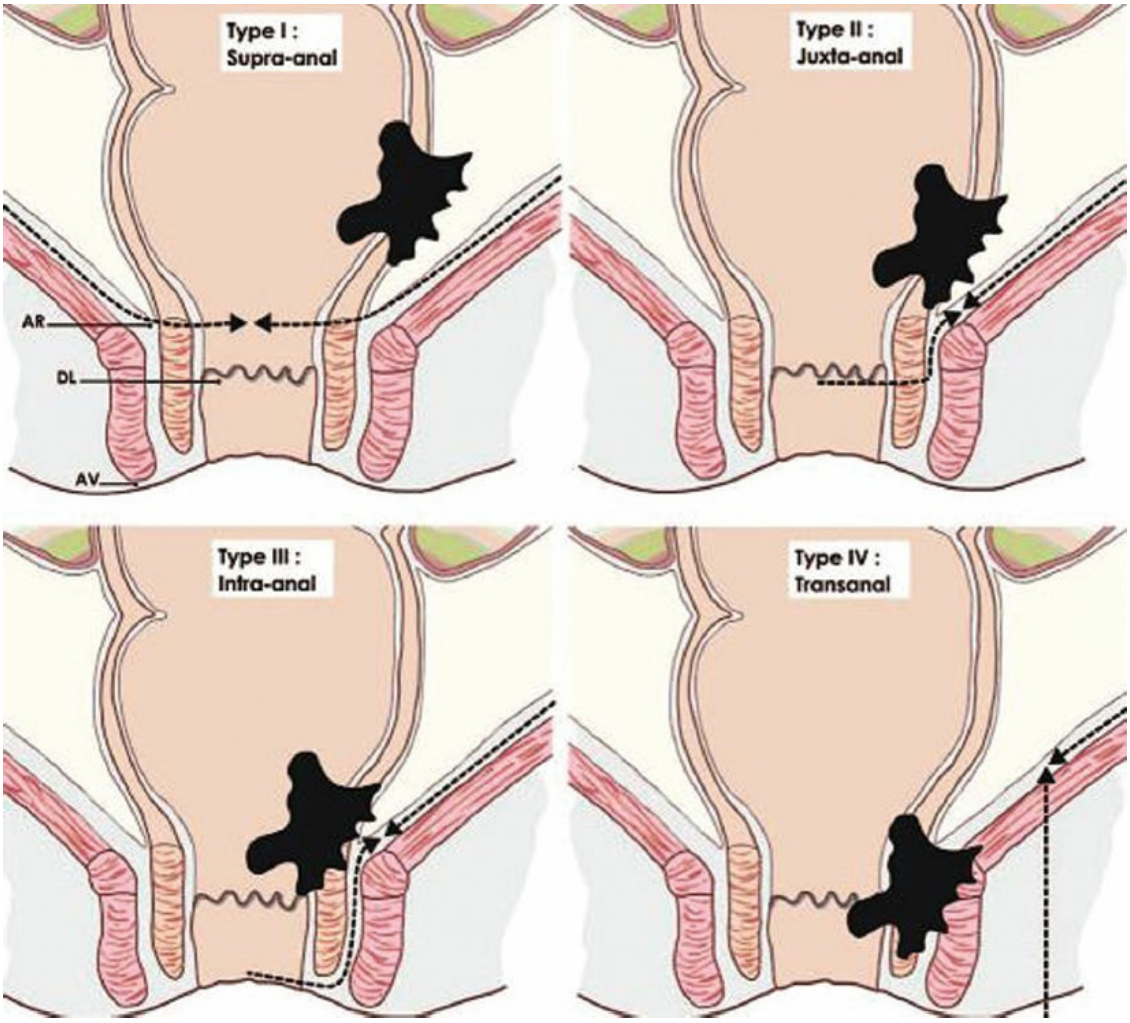

Figure 155.16. Surgical classification of low rectal cancer. Type I are supra-anal tumors (>1 cm from the anal sphincter) and treated by conventional coloanal anastomosis; type II are juxta-anal tumors (<1 cm from the anal sphincter) treated by partial intersphincteric resection; type III are intra-anal tumors (internal sphincter invasion) treated by total intersphincteric resection; and type IV are transanal tumors (external sphincter invasion) treated by APR. AR, anal ring; DL, dentate line; AV, anal verge. The *dotted line* represents the surgical dissection plane. (Modified from Rullier E, Denost Q, Vendrely V, et al. Low rectal cancer: classification and standardization of surgery. *Dis Colon Rectum* 2013;56(5):560–7.)

TABLE 155.1 Guideline for Grading TME Specimens

Incomplete	Nearly Complete	Complete
■ Little bulk to the mesorectum ■ Defects in the mesorectum down to the muscularis propria ■ After transverse sectioning, the circumferential margin appears very irregular	■ Moderate bulk to the mesorectum ■ Irregularity of the mesorectal surface with defects >5 mm, but none extending to the lamina propria ■ No areas of visibility of the muscularis propria except at the insertion site of the levator ani muscles	■ Intact bulky mesorectum with a smooth surface ■ Only minor irregularities of the mesorectal surface ■ No surface defects >5 mm in depth ■ No coning toward the distal margin of the specimen ■ After transverse sectioning the circumferential margin appears smooth

Reconstructive Techniques

There are several methods to reconstruct the rectum. A straight end-to-end anastomosis can be done with hand suturing, stapling, or transanal suturing. Reconstruction after low anterior resection (LAR) for mid and proximal rectal cancers can be performed with a straight end-to-end colorectal anastomosis without significantly sacrificing function. In a retrospective evaluation of patients comparing straight coloanal anastomosis *versus* colonic J-pouch, Hida et al. determined that the functional results are equivalent if the distance from the anal verge to the anastomosis was >8 cm but showed improved functional results with the colonic J-pouch when the distance was <8 cm. A colonic J-pouch should be used for reconstruction when the distance from the anal verge to the anastomosis is between 5 and 8 cm, but is particularly helpful for improved functional outcome when the distance from the anastomosis to the anal verge is ≤4 cm. The colon J-pouch is made using a stapled technique to create a 6-cm reservoir by making an enterotomy at the apex of the pouch (where the colon is folded onto itself) and introducing a linear cutting stapler along the antimesenteric aspect of the colon (Fig. 155.17). Some surgeons place additional sutures along the antimesenteric aspect of the colon to maintain proper configuration of the pouch and to take tension off the end of the staple line.

One disadvantage of the colonic J-pouch is that some patients cannot accommodate a large and somewhat bulky pouch in the pelvis. For this reason, some authors have recommended transverse coloplasty as a means to restore the rectal vault, but this technique has largely fallen in disfavor because of reports demonstrating higher leak rates with transverse

coloplasty (Fig. 155.18).

Anastomotic Techniques

The type of anastomosis depends upon a number of factors, including level of connection, patient body habitus, surgeon experience and preference, and whether or not diversion is planned.

An end-to-end anastomosis can be performed in one of three ways: (1) handsewn, (2) single-stapled, or (3) double-stapled. A handsewn anastomosis is commonly performed with an open approach and when the anastomosis is high in the pelvis. A single-stapled anastomosis can be technically challenging as it involves placing a purse-string suture at the rectal stump deep in the pelvis but, when feasible, it is preferred because there are no crossing staple lines. As suturing in confined surgical fields has become easier with the robotic approach, reports of single-stapled anastomosis have become popular with this minimally invasive approach. The double-stapled anastomosis is technically easier but involves two staple lines—one linear staple line across the distal end of resection at the rectal stump and the other, an end-to-end circular staple line. It is important with a low connection to ensure that the anastomosis does not incorporate the levator muscles or the vaginal wall anteriorly in females. With a double staple technique, there are typically one or two points of staple line intersection.

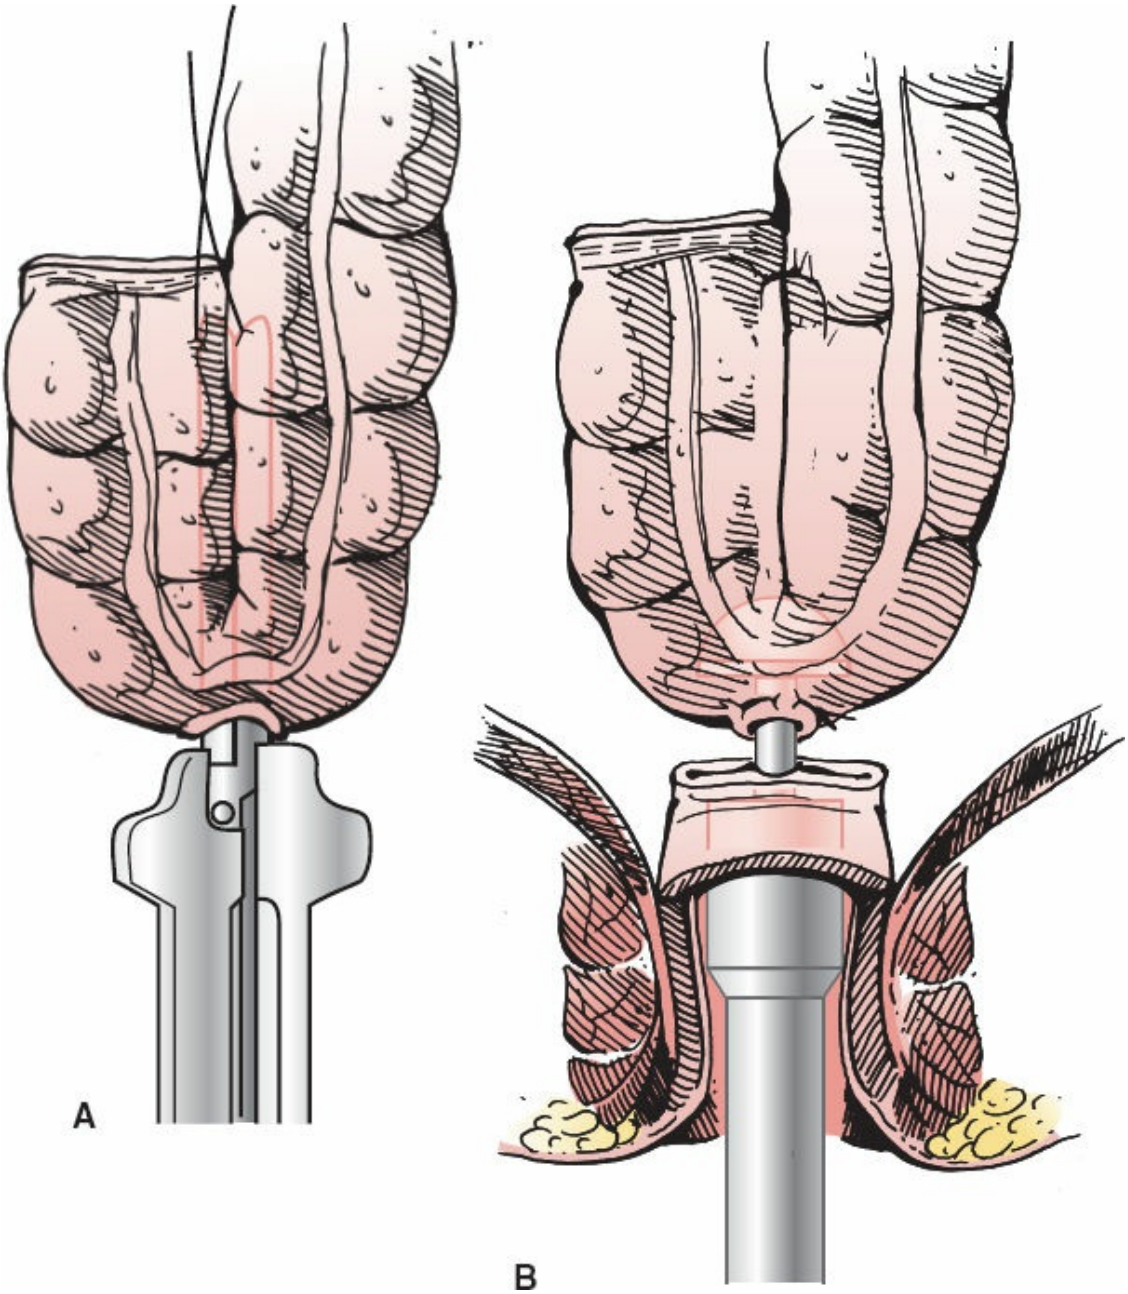

Figure 155.17. Construction of a colonic J-pouch after an ultra low anterior resection. The distal colon is folded back on itself to make a "J" and a 6-cm common channel along the antimesenteric aspect is then created using a stapling device. The J-pouch is then anastomosed to the anus using a circular stapler or in a handsewn manner.

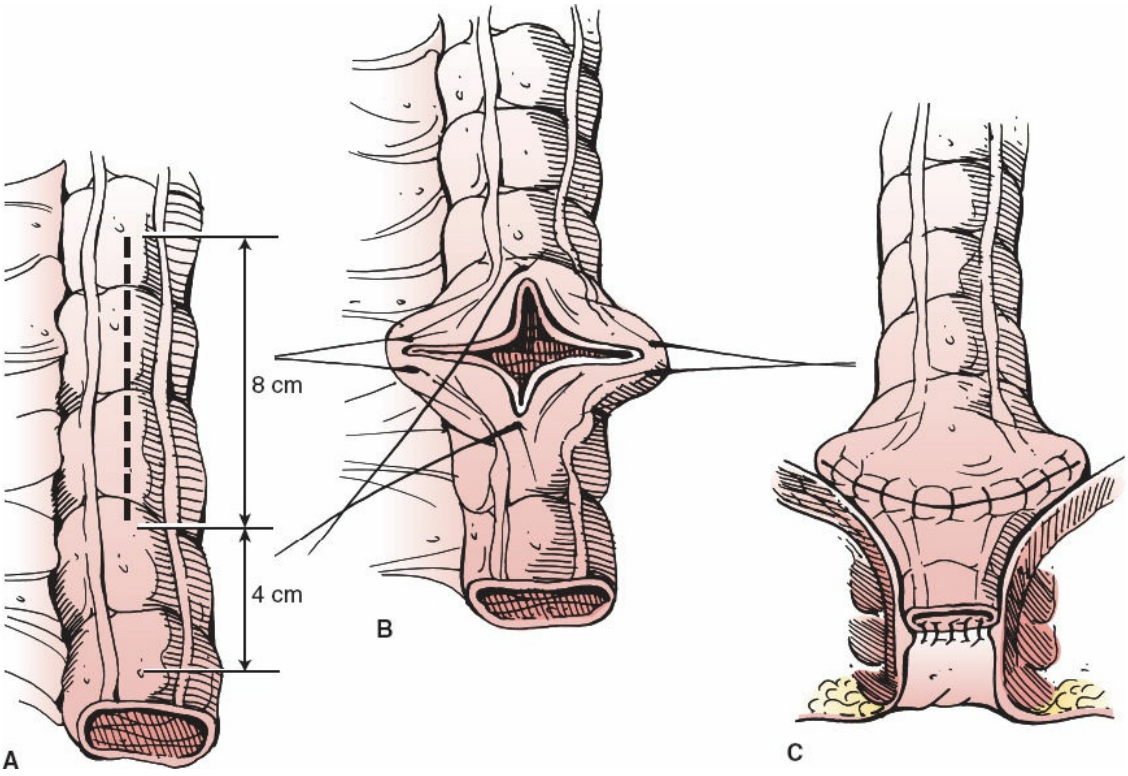

Figure 155.18. Construction of a transverse coloplasty. A longitudinal colotomy approximately 8 to 10 cm in length starting 4 to 6 cm from the distal colon resection margin is closed with a single layer of polyglycolic acid sutures in an interrupted fashion.

The Baker side-to-end anastomosis is preferred by some surgeons (Fig. 155.19). Similar to other reconstruction techniques, the Baker anastomosis is thought to improve postoperative defecatory function by providing a reservoir. It is important to keep the blind end of colon relatively short (2 to 3 cm) in order to avoid fecal stasis.

A handsewn coloanal anastomosis is performed with a perineal approach in cases where an intersphincteric dissection has been performed. This is done with the patient in modified lithotomy position where access is possible to both the abdomen and perineum simultaneously. Prior to delivering the colon through the anus, 2-0 Vicryl sutures are placed at the dentate line, incorporating generous bites of the internal sphincter muscle at the four cardinal aspects (Fig. 155.20). Interrupted sutures are then placed between the four quadrant stitches.

The use of drains in the pelvis is controversial. We do not hesitate to place a closed-suction drain in the pelvis if hemostasis is not perfect. On the other hand, there is little evidence that routine pelvic drain placement reduces the incidence of pelvic sepsis or anastomotic failure.

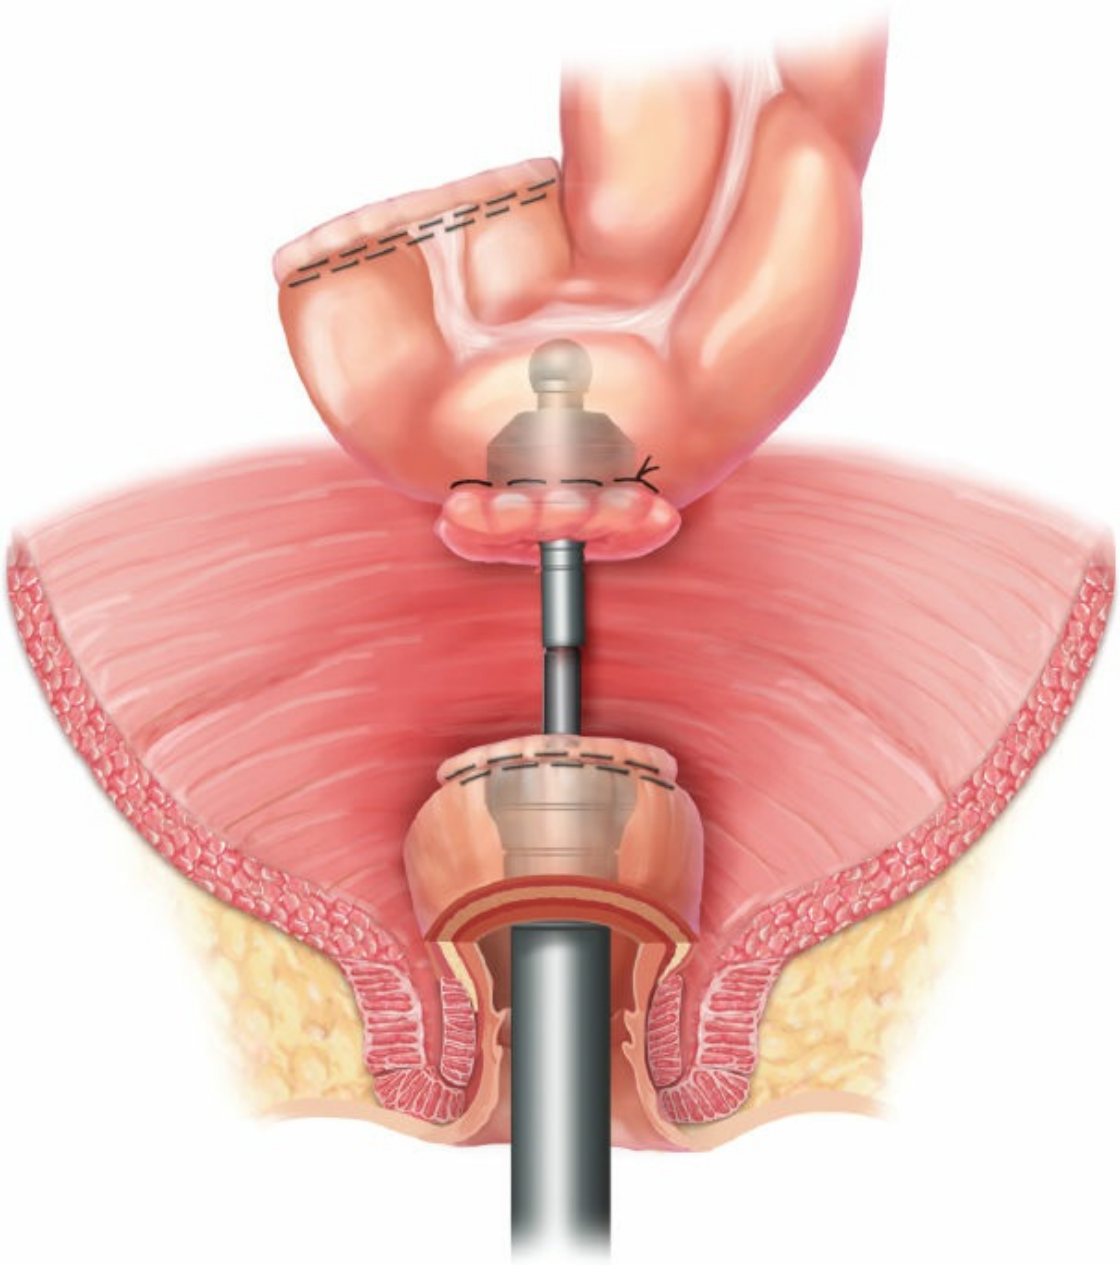

Figure 155.19. An end-to-end circular stapler is introduced through the rectum and the anvil brought out through the side of the colonic wall in order to create a circular side-to-end (Baker) stapled anastomosis. Note the side limb should be approximately 3 cm. (Figure 16.3 from End-to-End, Side-to-End Anastomosis [Wexner/Fleshner].)

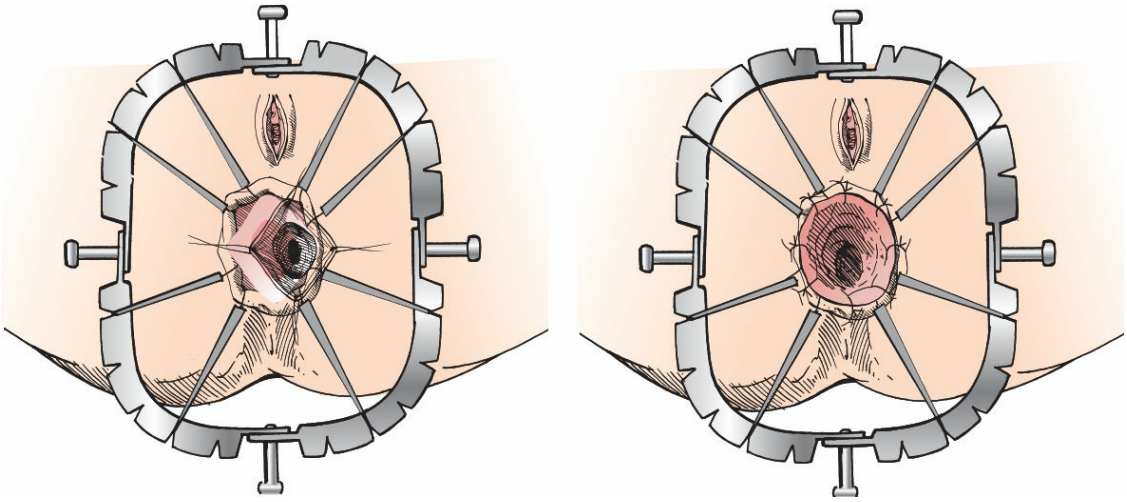

Figure 155.20. Coloanal handsewn anastomosis. This can be straight or a colonic pouch can be created if there is adequate length. Full-thickness bites are taken through the descending colon wall and the transected lower border of the internal sphincter, including the overlying anoderm. Four corner sutures are placed at 12, 3, 6, and 9 o'clock positions and left untied until one or two full-thickness bites have been placed between each corner suture.

Hydro-Pneumatic Testing

All colorectal anastomoses should be tested by gently insufflating the anastomotic site with air while submerged in fluid. Intraoperative anastomotic testing is widely accepted among surgeons, but its role and impact have not been well studied until recently. Ricciardi and colleagues reviewed the outcomes of 998 patients undergoing left-sided colorectal anastomoses without proximal diversion. Intraoperative air leaks were noted in 65 of 825 tested anastomoses (7.9%). A clinical leak developed in 48 patients (4.8%); 7.7% occurring in anastomoses with a positive air leak test compared to 3.8% in anastomoses with negative air leak test. When air leak testing was positive, suture repair alone was associated with the highest rate of postoperative clinical leak (12.2%) compared with diversion (0%) or reanastomosis (0%). In our practice, we divert all patients with mid and low rectal anastomoses. In the setting of a positive hydro-pneumatic test, it is our preference to perform reanastomosis when feasible. However, when a small anastomotic defect is identified and reanastomosis is difficult, primary suture repair (if feasible) with diverting loop ileostomy is preferred. Very low ALs can be repaired transanally, and significant leaks from low rectal stapled anastomoses are usually better-off

by conversion to a sutured coloanal anastomosis.

Diversion

Anastomotic complications are more common with distal rectal anastomoses and include leak and stricture. Complication rates also increase with radiotherapy, tension, or tissue ischemia. Temporary diversion is especially helpful in patients with a low colorectal anastomosis (<5 cm) and in the setting of preoperative radiotherapy. Diversion helps decrease the problems associated with AL and is typically done with a loop ileostomy. In our practice, all patients with a low anastomosis (<6 cm), particularly those with preoperative radiotherapy, undergo diversion.

A loop ileostomy is performed by making a circular skin incision at the preoperative marked site in the right lower quadrant. The subcutaneous tissue and anterior fascia are incised with electrocautery and the anterior rectus muscle is split. The rectus muscle is retracted, and the posterior sheath is exposed and incised. The loop ileostomy is matured without a stoma bridge in an everted Brooke fashion after the abdomen is closed.

POSTOPERATIVE CARE

Nasogastric tube suction is not usually required. Patients are allowed to have a liquid diet the evening of surgery and can be advanced according to return of bowel function. The urinary catheter is kept for 3 to 4 days. Patients are encouraged to ambulate the day after surgery and pneumatic compression stockings are removed once patients are fully ambulatory. Pharmacologic VTE prophylaxis is continued the day after surgery and is continued for up to 30 days in patients who are high risk for VTE (cancer, morbid obesity, and inflammatory bowel disease). Drains, if present, are typically removed before discharge from the hospital. Postoperative enterostomal teaching is essential to all patients with a new stoma.

COMPLICATIONS AND THEIR MANAGEMENT

Anastomotic Leak

AL is the most morbid complication following rectal cancer surgery, with reported incidences ranging between 1% and 19%. Male gender, preoperative radiation, body mass index, smoking, hypoalbuminemia, immunosuppression, American Society of Anesthesiologists score above

II, renal disease, emergency surgery, and extraperitoneal anastomoses have been identified as risk factors in selective studies. Intraoperative risk factors also include blood loss/transfusion and duration of surgery more than 4 hours. Although AL has been reported as an independent risk factor for local recurrence and death from cancer, these results have not been consistently duplicated and remain debatable. Protective stomas have shown to lessen the infectious and functional consequences but not the prevalence of AL.

AL is defined as a breach in the surgical joint between two hollow viscera with or without active leak of luminal contents, but the term involves a spectrum of clinical severity, ranging from a small, contained leak without systemic symptoms to diffuse peritoneal contamination with severe sepsis and multisystem organ failure. Patients typically present with fever, abdominal pain, and elevated inflammatory markers between postoperative day 5 and 7, and CT is the most commonly used diagnostic tool. Abscess adjacent to the anastomosis with or without air or rectal contrast in its interior is the most common radiologic finding. Early AL (24 to 72 hours) is usually related to severe ischemia, mechanical failure from poor technique, or stapler misfiring, and requires prompt reoperation because of the amount of peritoneal contamination. Contained leaks with mild systemic manifestations are commonly managed with percutaneous drainage and intravenous antibiotics with good results. However, if a patient clinically worsens or fails to improve, reoperation with reanastomosis or fecal diversion is warranted. In our experience, only selective patients with AL, minimal peritoneal contamination, and mild systemic manifestations are candidates for reanastomosis with diverting loop ileostomy.

Reanastomosis is not feasible with low rectal anastomoses. Large anastomotic defects with severe abdominopelvic sepsis and irreversible colon ischemia are better managed with abdominal washout, wide drainage, and end colostomy. With low rectal and coloanal ALs without significant pelvic sepsis, we perform transanal drainage with transanal repair, when feasible.

OUTCOMES

Oncologic Outcomes

In most series, local recurrence rates are less than 7% in patients undergoing TME even when no adjuvant therapy is given. The impact of

neoadjuvant treatment including short- and long-course radiotherapy with or without chemotherapy plus TME in two European randomized controlled trials confirmed the local control benefit even in the setting of optimal surgery, with 5-year local recurrence rates of 6% compared to 12% to 13% with TME alone. Despite no significant differences in long-term survival or sphincter-preserving operations, neoadjuvant chemoradiotherapy is currently well accepted in the United States and continues to play a significant role in the management of rectal cancer.

Despite a significant increase in the rate of sphincter-preserving surgery, most radical resections for rectal cancer in the United States result in a colostomy. The determining factor in performing a sphincter-preserving operation is the ability to obtain an adequate distal margin. When distal intramural spread occurs, it is usually within 2 cm of the tumor unless the lesion is poorly differentiated or widely metastatic. A randomized prospective trial conducted by the national surgical adjuvant breast and bowel project did not demonstrate significant differences in survival or local recurrence when comparing distal margins of <2 cm, 2 to 2.9 cm, and >3 cm. Shorter distal margins may be acceptable in patients with very low rectal cancers undergoing a sphincter-preserving operation but should be confirmed by a frozen section as previous reports have outlined the detrimental effect of tumor within 1 mm of the CRM.

Reports supporting acceptable oncologic results with distal margins <1 cm are mainly of retrospective nature, low numbers, limited follow-up, and discrepant survival reporting. These studies have shown local recurrence rates ranging from 6% to 12%, and median survival rates between 3 and 5 years of 70% to 82%, with no significant differences when compared to distal margins >1 cm. Predictive factors of recurrence after ultra-LAR with a distal margin <1 cm have included distance of the tumor from the anal verge, tumor stage (specifically lymph node metastases), and R1 resection (microscopically positive margins).

The decision whether to partially or completely excise the internal anal sphincter and obtain an R0 resection depends on specific location of the rectal cancer and its relation to the anal sphincter complex. Rullier and colleagues proposed a classification of low rectal cancers with standardization of surgery according to the type of tumor (I: supra-anal, II: juxta-anal, III: intra-anal, and IV: trans-anal). Of 404 patients with low rectal cancers, the authors found no difference in local recurrence (5% to 9% vs. 6%), distant recurrence (23% vs. 23%), and disease-free survival

(70% to 73% vs. 68%) at 5 years between ultra-low (types II to III) and conventional (type I) sphincter-preserving surgery.

Outcomes after taTME are being increasingly published. Most reports are single-institution experiences with small numbers and relatively short follow-up. Lacy et al. recently reported their experience with 140 taTME operations and showed a macroscopically complete TME specimen in 97% of patients, with a 2.3% local recurrence rate and a 7.6% rate of systemic recurrence at a mean follow-up of 15 months.

A recent controversy in rectal cancer surgery that deserves discussion is the assessment of the distal margin and feasibility of sphincter-preserving radical resection after neoadjuvant chemoradiotherapy. Distal rectal cancers that are thought to require abdominoperineal resection and have a good clinical response to neoadjuvant therapy may appear to be amenable to a sphincter-preserving radical resection because of tumor downstaging. Complete tumor disappearance on pathologic examination of the surgical specimen (complete pathologic response) is achieved in 10% to 30% of the patients. These results have led to a therapeutic dilemma regarding possible change in the operative strategy in these patients. Madbouly and colleagues evaluated the outcomes of 45 patients with distal T3 rectal carcinoma who were thought to require abdominoperineal resection before long-course neoadjuvant chemoradiotherapy but because of successful downstaging underwent colorectal (n = 9) and coloanal (n = 36) anastomosis. Criteria for changing operative strategy to sphincter preservation were tumor downsizing that would allow for a 1 cm distal safety margin above the anal sphincters with a free potential CRM on pelvic MRI. No positive margins were reported. At a mean follow-up of 57 months, local recurrence occurred in 8.8% of patients and disease-free survival was 87%. Changing operative strategy from abdominoperineal resection to a sphincter-preserving proctectomy after downstaging by neoadjuvant chemoradiotherapy requires further evidence and remains investigational.

Functional Outcomes

Low Anterior Resection Syndrome

Bowel dysfunction following LAR has been well recognized and reported. This so-called ‘‘low anterior resection syndrome’’ or LARS represents a constellation of symptoms that include increased stool frequency, bowel fragmentation, fecal urgency and incontinence, and seriously impacts

patients' quality of life. A variety of studies have reported an incidence of between 25% and 50% of LARS depending on syndrome classification and patient follow-up, but significant variability exists in the reporting of outcomes after anterior resection and the majority of studies do not use a validated assessment tool. This has led to the development of an internationally validated scoring system assessing the severity of LARS, the LARS score (Fig. 155.21).

The aim of this questionnaire is to assess your bowel function. Please tick only one box for each question. It may be difficult to select only one answer, as we know that for some patients symptoms vary from day to day. We would kindly ask you to choose one answer which best describes your daily life. If you have recently had an infection affecting your bowel function, please do not take this into account and focus on answering questions to reflect your usual daily bowel function.	
Q.1: Do you ever have occasions when you cannot control your flatus (wind)?	
No, never	0
Yes, less than once per week	4
Yes, at least once per week	7
Q.2: Do you ever have any accidental leakage of liquid stool?	
No, never	0
Yes, less than once per week	3
Yes, at least once per week	3
Q.3: How often do you open your bowels?	
More than 7 times per day (24 hours)	4
4–7 times per day (24 hours)	2
1–3 times per day (24 hours)	0
Less than once per day (24 hours)	5
Q.4: Do you ever have to open your bowels again within one hour of the last bowel opening?	
No, never	0
Yes, less than once per week	9
Yes, at least once per week	11
Q.5: Do you ever have such a strong urge to open your bowels that you have to rush to the toilet?	
No, never	0
Yes, less than once per week	11
Yes, at least once per week	16
Add the scores from each 5 answers to one final score.	
Interpretation: 0–20: No LARS, 21–29: Minor LARS, 30–42: Major LARS.	

Figure 155.21. Low anterior resection score questionnaire.

Temple and colleagues also developed an assessment tool for LARS, a 41-item bowel function survey that was completed by 129 patients who underwent sphincter-preserving surgery between 1997 and 2001. Patients had a median of 3.5 stools/day and 37% were dissatisfied with their bowel function. The five most common symptoms were incomplete evacuation, clustering, food affecting frequency, unformed stool, and gas incontinence. This instrument also detected significant differences between patients with preoperative radiation versus postoperative radiation versus no radiation; local excision versus LAR versus coloanal anastomosis; and handsewn versus stapled anastomosis.

LARS has been shown to correlate with the manometric disappearance of the rectoanal inhibitory reflex as a measure of internal anal sphincter function and anorectal sampling. This alteration amounts to poor discrimination between liquid or gaseous rectal contents. The most obvious mechanisms potentially responsible for cases of LARS include mechanical tear of the anal sphincter muscles upon stapler insertion, poor

neorectal capacity, a short length of the descending colon, and impaired neo-rectal compliance. Neoadjuvant radiotherapy and autonomic denervation may also be contributing factors to poor functional outcomes. Although early data suggested that the functional outcome for patients undergoing restorative LAR could be improved by the utilization of a neorectal reservoir, long-term studies have shown minimal overall functional differences after 2 years of follow-up.

Current treatment of LARS is fairly inconsistent with no real consensus as to an effective treatment algorithm. Therapies include loperamide, rectal irrigation, the use of pelvic floor physiotherapy (biofeedback), and sacral nerve stimulation (Interstim). Biofeedback has been effective in several small studies, including LARS patients with mild to moderate symptoms. A recent systematic review of seven studies including 43 patients with LARS treated with sacral nerve stimulation showed an overall success rate of 71% at a median follow-up of 15 months, which is comparable to that seen in patients with fecal incontinence from any cause. When intractable fecal incontinence occurs, surgical treatment must be considered. Fecal diversion with end colostomy is often the best option after chronic and progressive fecal incontinence.

Genitourinary Dysfunction

Disturbances to bladder and sexual functions are well-known sequelae of rectal cancer surgery. Bladder dysfunction may consist of difficulty emptying the bladder and incontinence. Sexual dysfunction may include dyspareunia and decreased ability to achieve orgasm in women, and erectile dysfunction, absence of ejaculation, and retrograde ejaculation in men. With careful autonomic nerve preservation, postoperative genitourinary and sexual dysfunction can be reduced from 25% to 75% to as low as 10% to 28%. Bladder dysfunction in particular has been shown to decrease from 9% to 40% to 0% to 11% with TME and autonomic nerve preservation when compared to conventional rectal resection. Additional factors that may influence genitourinary dysfunction after TME include pre- and postoperative radiotherapy and preoperative genitourinary function. A total of 597 patients from the Dutch TME trial were assessed after a median follow-up of 5.1 years, and 39% of patients reported urinary incontinence. No significant differences in urinary function were found in those patients who received short-course preoperative radiotherapy.

Moderate to severe sexual dysfunction after radical rectal cancer

surgery is multifactorial and has been reported in up to 76% of patients, with significantly higher rates in female patients. Data regarding sexual function are difficult to obtain. Plus, impairment of bowel and bladder functions after rectal cancer surgery has a significant influence on sexual function, and this may be interpreted incorrectly when evaluating incontinent patients. Other factors that may contribute to sexual dysfunction such as the patient's psychological response to the cancer, scar or ostomy, and the reaction of the sexual partner have not been examined. Bruheim et al. investigated sexual function in 241 males after long-course radiation therapy for rectal cancer with a median follow-up of 4.5 years after surgery. Patients who received radiotherapy had significantly poorer scores for erectile function, orgasmic function, intercourse satisfaction, and overall satisfaction with sex life when compared with non-irradiated patients. The prevalence of moderate and severe erectile dysfunction was 86% in irradiated patients compared with 55% in the surgery-alone patients. Most studies assessing sexual function after rectal cancer surgery lack information on the preoperative sexual status of patients; therefore, it is reasonable to assume that rates of sexual dysfunction are likely lower than what is reported. Hendren and colleagues reported that 35% of men and 47% of women had sexual problems before treatment.

Patients with mild to moderate sexual dysfunction seldom are treated, mainly because of lack of discussion between patients and practitioners; therefore, data on treatment options are scarce. The use of phosphodiesterase inhibitors has been shown to be safe and effective for the treatment of erectile dysfunction after TME for rectal cancer. Although laparoscopic TME has not shown to significantly decrease the incidence of genitourinary dysfunction compared to open TME, enthusiasts of robotic TME have reported improved visualization of pelvic nerves during TME that may lead to fewer nerve injuries. A small prospective study including 69 patients showed that robotic TME (n = 39) was associated with earlier recovery of normal voiding and sexual function compared to patients who underwent laparoscopic TME (n = 30) up to 12 months after surgery. Long-term functional results after robotic TME are lacking.

EDITOR'S COMMENT

Doctors Gaertner and Madoff provide an outstanding review of surgical approaches to malignant disease of the middle and lower thirds of the rectum. Any formal discussion on the current rationale for treatment of rectal cancer is, I believe, incomplete without a historical perspective on the evolution of the surgical management of this entity. France became the epicenter for early attempts at oncologic surgical treatment of rectal cancer in 1739, as Jean Faget is credited for undertaking the first resection of the rectum for a perforated rectal cancer (Craney, 1980), (Corman, 2000), (Lange, 2008). Jacques LisFranc

de St. Martin then performed the first successful perineal excision of a rectal tumor in 1826 (Craney, 1980). His technique was later modified by Aristide Verneuil, who described removing the coccyx to allow for better exposure and a more complete excision (Craney, 1980), (Lange, 2008). Paul Kraske, a professor at the University of Freiburg, presented a lecture at the Fourteenth Congress of the German Society of Surgery on the subject of the transsacral approach to the removal of rectal cancer in 1885 (Craney, 1980), (Kraske, 1984). Although the latter half of the 19th century saw an explosion of new surgical techniques from surgeons including Carl Gussenbauer, J. Hochenegg, and Arthur Norton for removing rectal carcinoma, the mortality of these procedures was reported to be between 11% and 22%, with a recurrence rate of almost 80% (Craney, 1980). Sir William Miles hypothesized that the high recurrence rate could be reduced by extensive mesenteric lymphadenectomy as part of an abdominoperineal resection of the rectum (Miles, 1908), (Zbar, 2007), (Miles, 1910).

Claude Dixon's 1948 presentation to the American Surgical Association, in which he reported on his series of 426 procedures to extirpate lesions from 20 cm to 6 cm above the dentate line in a two-staged procedure, ushered in the concept of sphincter-sparing anterior approaches to rectal cancer. His results, with a 2.6% mortality and 64% 5-year survival, suggested that patients with select rectal cancers could undergo successful sphincter-sparing procedures (Lange, 2008), (Dixon, 1984). Allan Parks subsequently presented his series of 19 patients who underwent anterior resections for lower rectal lesions (Ruo, 1999). Perhaps the most important inflection point in the chronology of sphincter-sparing procedures for rectal cancers was the introduction of the surgical stapler. Mechanical stapling has not only broadened the population of patients who might benefit from sphincter-sparing procedures, but has also improved the safety of anterior resections for cancer (Moran, 1996).

The successful management of patients with middle to lower rectal cancer is predicted on multidisciplinary care that frequently includes radiologists; surgical, medical, and radiation oncologists; and physical therapy specialists who specialize in pelvic floor disease. As highlighted in the chapter, the goals of this team should include oncologic control, minimizing morbidity and mortality, optimizing functional outcomes, and promoting rapid return to preoperative function.

Current discussions around preoperative measures to improve oncologic control center on the use of neoadjuvant chemoradiation for locally advanced tumors. Two randomized trials, the Swedish Rectal Cancer Trial and the Dutch Colorectal Cancer Group Trial, demonstrated improved local control with surgery after neoadjuvant chemoradiation compared to surgery alone (van Gijn, 2011), (Folkesson, 2005). The German Rectal Cancer Study Group Trial (CAO/ARO/AIO-04) established the superiority of preoperative chemoradiation over postoperative therapy, with local recurrence rates of 7.1% and 10.1% in the pre- and postoperative therapy arms, respectively (p = 0.048) (Saur, 2012).

Taken together, these data support the use of neoadjuvant therapy of the treatment of locally advanced rectal cancers. Future work should focus on the optimal radiation dose to be delivered in the preoperative setting. The Swedish and Dutch trials demonstrated good results with a compressed radiation treatment cycle of 25 Gy over 5 fractions, while the German trial employed 50.4 Gy delivered over 28 fractions. A reasonable observer would ask how these treatment schedules impact the conduct of the operation, sphincter preservation, and long-term local control. As we move toward bundled payments for cancer care, it will be important to understand how these treatment modalities affect long- and short-term treatment costs. Another interesting aspect of neoadjuvant chemoradiation is the management of patients who have a complete response to therapy. Given the rate of complete response is reported to be as high as 20%, can we avoid or modify surgical approaches in this very select population of patients?

New surgical techniques have arisen over the past three decades due to the growth of minimally invasive procedures. Approaches to rectal tumors have matured from the aforementioned open procedures to robotic procedures for tumors deep in the pelvis. It has been reported that up to 40% of all rectal resections are performed via a minimally invasive approach (Migaly, 2016). However, the evolution of surgical technique is not without controversy. Doctors Gaertner and Madoff have appropriately suggested that open procedures be applied to individuals with bulky lesions, locally invasive and/or perforated tumors, cardiopulmonary compromise, and those who undergo rectus flap coverage for pelvic reconstruction. On the other hand, the authors clearly advocate for laparoscopic approaches in obese patients in whom complete total mesorectal excision (TME) might be aided by magnification and placement of surgical instruments in the pelvis. Although significant Level 1 data support the use of minimally invasive techniques for colon cancer, a comparable body of evidence does not exist for similar approaches for curable, locally advanced rectal cancer (Fleshman, 2016). The recently reported ACOSOG Z6051 and A La CaRT pathology data demonstrate that the use of laparoscopic resection compared with open resection fails to meet the criteria for noninferiority for pathologic outcomes (Fleshman, 2015), (Stevenson, 2015). On the other hand, the European COLOR II and Korean COREA trials demonstrate comparable pathologic outcomes (Bonjer, 2015), (Jeong, 2014). A meta-analysis of these four trials currently underway might provide clearer direction with respect to the utility of laparoscopic approaches to rectal cancer. The application of robotic TME has sparked considerable controversy among experienced surgeons. Although single institution reports have suggested that robotic TME has comparable operative, perioperative, and oncologic outcomes relative to open and laparoscopic procedures (Shin, 2016), (de Jesus, 2016), this technology has not been evaluated in multi-institution trials in the same manner as laparoscopic procedures.

The authors give an outstanding review of the key technical aspects of low

anterior resections (LAR), including appropriate ligation of the inferior mesenteric artery and the conduct of an appropriate TME. These aspects deserve a brief review. My practice is to perform a high ligation of the inferior mesenteric artery to facilitate enhanced nodal retrieval and adequate tumor staging. A complete TME has been shown to improve outcomes even in with neoadjuvant chemoradiation (Fleishman, 2015). As is appropriately described by the authors, high and midrectal cancers require excision of the mesorectal envelope at least 5 cm distal to the tumor and perpendicular to the mass. Mid to distal cancers necessitate TME to the level of the pelvic floor.

The widespread use of neoadjuvant therapy for locally advanced rectal cancers raises questions on the appropriate timing of operative intervention after the completion of radiation therapy. The authors typically wait 10 to 12 weeks after the completion of neoadjuvant chemoradiation. Interestingly, recent data from the National Cancer Database suggest that an inflection point 56 days after the end of radiotherapy is associated with the highest likelihood of complete resection and pathologic downstaging. Moreover, the risk of margin positivity increases in those who undergo surgery after 8 weeks from the end of radiotherapy (odds ratio [OR] 1.40, 95% CI 1.21 to 1.61, $p < 0.001$) (Sun, 2016).

Sphincter function is perhaps the most important quality of life measure for patients undergoing LAR for rectal cancer. As many as 90% of patients undergoing LAR report fecal incontinence, increased bowel movement frequency, and emptying difficulties (Bryant, 2012). Data from the Dutch TME trial suggest that 39% of patients who had a TME alone and 62% of those treated with surgery and preoperative radiotherapy were incontinent at 5 years (Peeters, 2005). Pelvic floor rehabilitation (PFR), including pelvic floor muscle training, biofeedback training, and rectal balloon training, has been accepted as a standard technique for the treatment of fecal incontinence (Allgayer, 2005), (Lundby, 2011). Visser et al. undertook an outstanding review of five studies in which 286 patients underwent PFT (Visser, 2014). Three studies included patients with anterior resection syndrome after LAR, while the remaining studies included a series of patients after LAR. The authors of this review conclude that PFR is useful for improving the functional outcome after LAR. The data are extracted from studies of limited quality, but the available evidence points to the effectiveness of the procedure. I invite readers to review this excellent meta-analysis and consider incorporating PFR in the management of their patients undergoing LAR.

I commend the authors on an outstanding chapter on sphincter-sparing preserving techniques for the treatment of rectal cancer. Future considerations, including the continuing role of multidisciplinary care of this patient population as well as minimally invasive surgical techniques, will define the role of the surgeon as we continue to make strides in the management of this disease.

John H. Stewart, IV

156 Abdominoperineal Resection for Rectal Cancer

Carrie Y. Peterson and Julio Garcia-Aguilar

HISTORICAL PERSPECTIVE

The treatment of distal rectal cancer has changed dramatically in the last few decades. In order to understand the rationale behind the principles advocated in this chapter, it is worthwhile to briefly describe the historical aspects of surgery for rectal malignancies.

The surgical treatment of rectal tumors did not become feasible until the early 19th century, after the introduction of the colostomy by the French surgeon Jean Amussat. Early surgeons performed two sequential operations: first, a mini-laparotomy to create a colostomy, followed several days later by a distal proctectomy through the perineum. The inability to remove the mesorectum and the high rate of perineal fistulas were significant limitations to this operation. The results were poor, and patients suffered significant morbidity. Those who survived the morbidity eventually succumbed to recurrent disease.

W. Ernest Miles is credited with describing the modern abdominoperineal resection (APR) in 1908. He observed in detailed autopsy studies that most recurrences arose in the mesentery along the superior rectal vessels or the lymph nodes located at the bifurcation of the left common iliac artery. The operation he devised was performed in one stage that included both an abdominal procedure and a perineal procedure. It entailed the creation of an abdominal colostomy and removal of the entire pelvic colon and pelvic mesocolon below the common iliac artery; the lymph nodes at the bifurcation of the common iliac artery; as well as the anus, ischiorectal fat, and levator muscles at their origin. Although this operation was associated with a high mortality rate, the results were an improvement over previous procedures, and APR became the standard treatment of rectal cancer for most of the 20th century. O. V. Lloyd-Davies popularized the synchronous, two-team approach, with the patient in lithotomy position, which is often performed today.

Two crucial aspects of Miles' original operative principles were lost in practice for many decades: the removal of the entire mesorectum and the lateral division of the levator muscles. Most surgeons in the mid-20th century were performing dissection inside the mesorectum, in order to avoid the vascular and neural pelvic structures located laterally. Incomplete excision of the mesorectum leaves behind portions of the lymph node–bearing fat surrounding the rectum, and may even expose the tumor itself, which led to high rates of local recurrence. The need to remove the entire mesorectum via precise, meticulous dissection of the areolar plane outside the fascia propria was reintroduced by Bill Heald in 1982. He and others demonstrated significantly reduced local recurrence rates utilizing this precise surgical technique, and they taught this technique to many surgeons over the decades. For an impeccable description of this operative technique, we refer the reader to Dr. Heald's exceptionally well-written chapter in this volume.

The second important aspect to be re-emphasized was the need to divide the levator muscles laterally, close to their insertion in the pelvic sidewall, to produce a cylindrical specimen. While Miles' original description emphasized the importance of this step, many surgeons divide the levator ani muscles closer to the rectal wall after dissecting down the mesorectum for some distance. This happens when surgeons extend the abdominal dissection progressively closer to the levator muscles along the mesorectal plane, often in hopes of performing a sphincter-sparing procedure. Because the very distal portion of the rectum contains no mesorectum and is in direct contact with the pelvic floor, the dissection gets progressively closer to the bowel wall, and possibly the tumor (Fig. 156.1). This increases the risk of a positive circumferential resection margin and the risk of local recurrence in these "waisted" or "coned-in" specimens, as demonstrated in Figure 156.2.

These deviations from the original procedure described by Miles are thought to be the main reasons why APR for low rectal cancer has been associated with a greater risk of recurrence and reduced overall survival, compared to low anterior resection for higher rectal tumors. The cylindrical, or extralevator, APR is an attempt to avoid these shortcomings by emphasizing complete excision of the mesorectum and lateral division of the levator muscles.

INDICATIONS AND CONTRAINDICATIONS

In most patients with adenocarcinoma located in the lower rectum, the decision for an APR is based on an inability to obtain a negative circumferential resection margin *around* the distal tumor, rather than a negative distal margin *below* the tumor. A digital rectal examination and rigid proctoscopy provide valuable information about the relationship of the tumor to the anal canal. A tumor that lacks clear separation from the anorectal ring or is "fixed" to deeper structures suggests extension laterally beyond the mesorectal plane or bowel wall. Contrast-enhanced magnetic resonance imaging (MRI) of the rectum provides axial, sagittal, and coronal views that can demonstrate the relationship of a tumor to the levator muscles and the external anal sphincter with a high degree of accuracy (Fig. 156.3). Endorectal ultrasound (ERUS) may also be very sensitive in demonstrating invasion of the anal sphincter complex and evaluating the extent of lateral invasion of the tumor. However, the

accuracy of ERUS depends on operator experience and grasp of technique, is susceptible to operator interpretation, and is not as easily reproducible and reviewable.

If the tumor is determined to be amenable to a sphincter-sparing procedure, neoadjuvant chemoradiation therapy may also be considered. This is done in an attempt to downstage the tumor. For further details, we refer the reader to the excellent chapter in this volume on sphincter-preserving surgery. However, in our experience, this rarely changes the surgical plan. The possibility of residual tumor cells being left behind after resection may raise the risk of future recurrences. We suggest that the surgeon determine if sphincter preservation is a possibility at the time of the patient's initial consultation and seriously reconsider any changes to this plan. The temptation to dissect along the mesorectal plane past the level of the tumor in an attempt to save the anus may compromise the oncologic validity of the operation.

Tumor extension beyond the rectum into surrounding organs is not a contraindication for surgery in a patient otherwise fit for a major procedure. There is some long-term survival benefit for patients undergoing extended multivisceral resections (also known as pelvic exenterations), with a 5-year overall survival of 45% or higher. However, resection of retroaortic or pelvic sidewall lymphadenopathy or a palliative APR in the setting of distant metastases is controversial, as these procedures appear to provide minimal long-term benefit. While a digital rectal examination finding of a tumor fixed to deeper structures is indicative of further tumor extension, the best imaging study for evaluating extra-rectal extension is a high-resolution MRI of the pelvis. We review these studies closely with our radiologists to aid preoperative planning.

APR is also the operation of choice for patients with anal squamous cell carcinoma that persists or recurs after chemoradiation therapy, because these tumors usually involve the anal canal and levator muscle. Occasionally, APR is required for less common tumors of the anorectal region, such as anal melanoma, sarcoma, or gastrointestinal stromal tumor, and an extended APR is sometimes required for vulvar, vaginal, or prostate cancers that involve the distal rectum or anal sphincter. An APR can also be performed for benign indications as part of a total proctocolectomy, as in patients with familial adenomatous polyposis syndrome or inflammatory bowel disease. In these cases, a cylindrical dissection is not warranted, given the lack of malignancy. Furthermore, the

perineal wound can be large after extralevator resection, resulting in long-term complications not justified in the setting of benign disease. The dissection plane for a total proctectomy or APR in the setting of benign disease begins in the intersphincteric plane and is carried proximally along the distal rectum into the mesorectal plane, thus preserving as much of the pelvic floor for closure as possible. For further details, we refer the reader to the chapter on sphincter-sparing rectal dissections and the discussion of intersphincteric dissection.

PREOPERATIVE PLANNING

Although APR-associated mortality has decreased dramatically in the last century, APR is still a formidable operation associated with significant morbidity. Patients should undergo medical clearance prior to surgery and should also be marked for a colostomy and counseled by a certified stoma therapist. Patients must be informed about the potential risks and complications of the procedure and possible long-term outcomes, in particular sexual and urinary dysfunction. The necessity of full mechanical bowel cleansing prior to surgery is a subject of some debate, but it is our preference. At the very least, patients should receive an enema to cleanse the rectum of fecal matter.

Extent of Resection

It is paramount to understand the extent of resection needed well before the day of the operation. Close review of imaging and a physical examination can help identify areas of concern. We strongly recommend a

multidisciplinary approach and early involvement of specialists such as gynecologic oncologists, urologists, and orthopedic surgeons when needed. The most commonly involved adjacent structures are the anterior structures: either the prostate in males or the posterior wall of the vagina in females. Posterior vaginal involvement does not pose a significant issue when planning a resection, especially if the patient has already had a hysterectomy. The posterior wall can be removed en bloc with the rectum and the defect closed with the perineal flap. Functionally, however, the patient may develop strictures and have difficulties with intercourse once healed. If prostatic involvement is suspected, the impact can be considerably greater. Generally speaking, the function of the bladder after an extended APR with prostatectomy is very poor, and urinary diversion with an ileal conduit is often needed. Posterior extension of a tumor involving the sacrum can be a significant challenge, and for more information we refer the reader to the chapter by Dr. Solomon discussing extended resections and pelvic exenterations. Another source of potential concern is pelvic sidewall lymphadenopathy. Distal rectal tumors can disseminate in this fashion via the iliac chain, and in this setting, extended pelvic sidewall lymphadenectomy can be of benefit.

Ostomy Marking

All patients who are anticipated to need an ostomy should see a licensed enterostomal therapist prior to surgery. The therapist will identify the optimal site for ostomy placement and educate the patient about ostomy care. This can alleviate many fears and misconceptions, resulting in improved acceptance and coping. Since the end colostomy in an APR is permanent, it is ideal to locate it in a spot that makes appliance application and changing easy for the patient. Proper location can also help minimize the risk of parastomal hernia formation.

Abdominal Dissection—Minimally Invasive versus Open Technique

Consideration should be given to planning the approach for each individual patient. The abdominal portion can be performed through a laparotomy or by using minimally invasive techniques. When a ventral rectus muscle flap is planned for the perineal reconstruction, a large laparotomy incision is needed for flap harvesting. We therefore use an open procedure in such cases. There have been a few reports of rectus flap

harvesting using the robotic platform, but this approach is not widespread. If the surgeon is considering other reconstruction options, or if a flap is not needed, a minimally invasive approach is ideal. Patients derive significant benefit from minimally invasive surgery, including reduced pain and faster recovery. Our preference is to utilize the robotic platform for all pelvic work when possible, as the visualization and dexterity are much improved over traditional laparoscopy. However, this is potentially less important in an APR than in a low anterior resection, where very distal dissection, often below the level of the coccyx, is needed. Robotic techniques above the level of the pelvis can be challenging in obese patients, as achieving exposure and retraction of the intra-abdominal contents is sometimes difficult, and an experienced assistant is extremely helpful. Male patients with a narrow pelvis and large mesorectum can be challenging using any technique, but the laparoscopic approach in these patients may be particularly difficult because of the straight instruments and limited range of motion.

Perineal Dissection—Prone versus Lithotomy

For the perineal portion of the operation, we prefer to place the patient in the prone jackknife position. This allows for maximum exposure, keeps the dissection away from the table edge, and may facilitate lateral division of the levator muscles. Some studies indicate that prone positioning is associated with lower perineal wound infection rates and lower local recurrence rates. This positioning may be challenging for some surgeons, however, as the anatomy appears “upside down” compared to other anorectal surgeries. We encourage all surgeons who make APR part of their regular practice to become comfortable and facile in this position, as there are distinct advantages.

Very obese patients may not tolerate the prone jackknife position well, as their large abdomen may lead to restricted ventilation. An alternate position for very obese patients is a left lateral (Sims) position, with the knees tucked. The right buttock can be taped up and away, allowing exposure without restricting ventilation. We have used this positioning with great success. The high lithotomy, also known as the Lloyd-Davies position, is another alternative. This is ideal when a two-team approach is planned so that perineal dissection and abdominal dissection can take place synchronously. The high lithotomy position can also be helpful in obese patients, or those with complex unstable airways, as anesthesia access to

the airway is unencumbered.

When the perineal portion of the operation is performed in the prone position, a few special considerations should be made in advance. First, an additional operating table should be prepared to shorten turnover time. Second, discussing the order of the specific steps of the operation with the surgical teams beforehand can facilitate timing and coordination. For example, if a ventral rectus abdominis flap is planned, the tissue will need to be dissected, mobilized, and sutured to the proximal rectum prior to closing of the abdomen and maturing of the ostomy—all of which is done before the patient is turned to the prone position. If a urologic procedure is required, as in a pelvic exenteration, this may also need to be performed while the patient is in lithotomy. Careful planning of every aspect of the surgical procedure ahead of time will help synchronize the surgical teams and keep the operation moving forward.

Perineal Reconstruction Options

Primary closure of the perineal wound is associated with a significant risk of wound infection and dehiscence and even perineal hernia. Reconstruction of the perineum using a number of flaps is aimed at reducing the risk of short- and long-term complications, particularly in patients undergoing extended perineal resection. Unfortunately, these reconstructive procedures are associated with specific morbidity. The use of a rectus muscle flap can lead to abdominal wall hernias at the midline incision or parastomal hernias. Another option is gluteal advancement flaps, particularly useful when the perineal portion of the procedure is performed with the patient in the prone position. A gracilis muscle flap is yet another option, but often this approach is less advantageous, as the flap doesn’t contain any skin and is rather small in size. In general, we reconstruct the perineum when the patient has any of the following: large defect with margins well away from the anal sphincter complex, preoperative or previous radiation therapy, poor nutritional status, or other comorbidities that significantly increase the risk of perineal wound infections. Most patients with large distal rectal adenocarcinoma and anal squamous cell cancer will require flaps, while patients with small tumors or nonmalignant conditions may not. The involvement of plastic surgeons in preoperative decision-making regarding reconstruction will be of great benefit.

Pain Management

Pain management is an important issue, and one that should be addressed with patients. When a laparotomy is planned, an epidural to help with postoperative pain control is ideal. Unfortunately, the distribution of anesthesia in an epidural does not make it possible to cover both the midline abdominal wound and the perineal wound. We often choose the abdominal wound, as the pain here can lead to splinting and postoperative reduction in ventilation. Transversus abdominis plane blocks, which are an injection of local anesthetic into the plane where the somatic nerves traverse, can also help with postoperative pain control. These blocks are best utilized in minimally invasive surgery or other limited incisions, as the plane of anesthesia is less predictable and the effect is limited to a maximum of 12 hours.

SURGICAL TECHNIQUE

Anatomical Relationships and Considerations

As we have seen, an APR requires both an abdominal and a perineal approach to completely excise the rectum and anal canal. During the abdominal part of the procedure, the superior rectal vessels are controlled, the rectum and mesorectum are dissected, and a colostomy is created. During the perineal part, the rectum and anus are detached from their surrounding structures and the specimen is removed prior to closure of the wound. The boundary between the abdominal and perineal part of the procedure is delineated by the levator ani—an important landmark in an APR.

The key to a successful APR is a perfect understanding of the anatomy of the rectum and anus, the vessels and nerves of the pelvis, the pelvic floor musculature, and the ischiorectal fossa. The pelvic floor, also known as the pelvic diaphragm, comprises the levator ani and coccygeus muscles. The levator ani muscle is a thin, broad layer composed of several smaller muscles (puborectalis, pubococcygeus, and iliococcygeus) that insert in the inner wall of the pelvis and unite with the muscle of the opposite side to form part of the funnel-shaped pelvic diaphragm. These are the muscles divided during an APR; the coccygeus muscle, located in the same plane as the levator ani muscles but more posterior, is usually not.

The rectum corresponds to the distal 15 cm of the large bowel, but neither its beginning nor its end is sharply defined. The rectum contains

the three internal valves of Houston, which are occasionally used as a reference to locate rectal lesions. However, it is more practical and reproducible to describe the tumor location by measuring the straight distance from the anal verge, the palpable intersphincteric groove at the distal-most aspect of the anal canal. Another important landmark is the anorectal junction, which is palpated at the proximal-most aspect of the anorectal ring, corresponding to the puborectalis and the top of the external sphincter muscle.

The mesorectum is the visceral mesentery containing the terminal branches of the superior rectal vessels and the lymphatic drainage of the rectum. The upper third of the rectum is located above the anterior peritoneal reflection. It is covered with peritoneum in the front and on both sides and has a posterior mesorectum attached to the concavity of the sacrum, which is a continuation of the mesentery of the sigmoid colon. Below the peritoneal reflection, the rectum is completely extraperitoneal. The mesorectum here is thick posteriorly in the middle third of the rectum, where it has a characteristic bilobar appearance. Then it tapers off distally, as the rectum funnels down toward the anorectal ring. At this very distal aspect just above the anorectal ring, there is no appreciable mesorectum. The longitudinal layer of the muscularis propria of the posterolateral rectum is in direct contact with the levator muscles. Anteriorly, the mesorectum is either absent, as in the upper intraperitoneal portion of the rectum, or reduced to a thin layer of areolar tissue in the mid and distal rectum.

The fascia propria of the rectum, a thin, glistening membrane surrounding the mesorectum below the peritoneal reflection, is also thinner anteriorly than posteriorly. Anteriorly, a remnant of the embryologic peritoneal cul-de-sac, known as Denonvilliers fascia, separates the mesorectum from the urogenital structures. The anatomical appearance of Denonvilliers fascia varies, from a barely visible translucent membrane to a distinct, tough, leathery layer of connective tissue. Posteriorly, the fascia propria extends from the promontory to Waldeyer fascia, a condensation of connective tissue spanning the area from the fourth sacral vertebra to the anorectal ring. Here the mesorectum is separated from the presacral fascia by loose, avascular tissue. This is the correct plane, between the fascia propria of the rectum and the presacral fascia, for dissection during a proctectomy.

Below the peritoneal reflection, the mesorectum also intermingles

laterally with the connective tissue of the autonomic nerves that pass from the pelvic plexus to the rectum. These bilateral condensations of the endopelvic fascia, known as lateral ligaments, connect the pelvic sidewall with the mesorectum. In some individuals, the lateral ligaments contain accessory middle rectal vessels. The middle rectal artery usually runs immediately above the levator muscles.

The blood supply of the rectum comes primarily from the superior rectal artery, which is the continuation of the inferior mesenteric artery after it gives off the left colic artery. The superior rectal artery gives several sigmoidal branches before diving into the mesorectum, where it gives multiple branches to the rectum. The lower portion of the rectum also receives blood supply from the internal iliac vessels. The middle rectal artery, an inconsistent branch of the inferior vesicle artery, is usually located deep in the pelvis, running over the levator muscle. The inferior rectal artery is a branch of the pudendal artery and provides blood supply to the anal canal and anal sphincter. The middle and inferior rectal vessels anastomose with the upper rectal vessels to supply enough blood to the entire rectum. The superior rectal vein has a parallel course to its homonymous artery, on its way to join the left colic vein to form the inferior mesenteric vein draining into the splenic vein. As in other locations, the superior, middle, and inferior rectal veins follow the course of their arteries. While the superior rectal vein joins the left colic vein to the inferior mesenteric vein and drains into the portal system, the middle and inferior rectal veins drain into systemic circulation through the internal iliac veins. These anastomoses represent the potential portosystemic communication that becomes relevant in patients with portal hypertension.

The anatomy of the autonomic pelvic nerve system is particularly relevant. The hypogastric plexus, located in front of the aorta, contains preganglionic sympathetic fibers originating from the lumbar sympathetic trunk that converge at the level of the aortic bifurcation into two well-defined hypogastric nerves, which course laterally over the internal iliac vessels toward the lateral pelvic sidewall. There they join the splanchnic pelvic nerves, containing postganglionic parasympathetic fibers from S3 to S4, to form the pelvic plexus. Branches of the pelvic plexus provide innervation to the distal ureter, vas deferens, seminal vesicles, urinary bladder, prostate, and even the distal rectum in some patients. The distal pelvic plexus also forms the urogenital neurovascular bundles that pass anterior to Denonvilliers fascia. The pudendal nerve, originating from the

sacral plexus, contains sensory, motor, and parasympathetic fibers that provide most of the innervation of the perineal region. Damage to any of these nerves during an operation can result in significant urinary, sexual, and sensory dysfunction.

Open Abdominal Dissection

In an open APR, the abdominal portion can be performed through a lower midline or low transverse laparotomy. While the transverse incision causes less pain, is cosmetically more appealing, and has a lower incisional hernia rate, a midline laparotomy is preferred when the rectus muscle is used for reconstruction of the perineal wound.

As in any other colorectal cancer procedure, the operation begins with a thorough examination of the abdomen and pelvis. The sigmoid colon is mobilized by dividing the attachments and adhesions to the lateral abdominal and pelvic sidewall. The incision is carried cephalad toward the splenic flexure and distally toward the pelvis. The mesentery of the sigmoid and descending colon is lifted from the retroperitoneal attachments, exposing the left gonadal vessels and the left ureter (Fig. 156.4). It is important to remain in the retromesocolic plane, as deeper dissection into the retroperitoneal fat can lead to increased bleeding and damage to the gonadal vessels and the left ureter. The sigmoid colon is retracted anteriorly and laterally to expose the root of the sigmoid mesentery. Next, an incision is made in the peritoneum to the right side of the base of the sigmoid mesocolon, proximal to the promontory. A plane is developed underneath the superior rectal vessels in the loose areolar tissue, between the origin of the inferior mesenteric artery and the promontory (Fig. 156.5). Care should be taken to avoid injuring the superior hypogastric plexus, situated between the superior rectal vessels and the bifurcation of the aorta. The hypogastric nerves can be seen as two thick, band-like structures just lateral to the midline, as dissection continues inferior to the sacral promontory.

Once the ureter is identified and kept securely in the retroperitoneum, the superior rectal vessels are isolated between the origin of the left colic vessels and the first sigmoidal vessels and ligated. We do not routinely divide the left colic artery but recommend a careful dissection of any enlarged lymph node around the bifurcation of the inferior mesenteric artery. However, a complete dissection of the origin of the inferior mesenteric artery carries the risk of damaging the hypogastric plexus. The

mesentery of the sigmoid colon is then divided toward the point of the sigmoid colon that has been chosen to create the end sigmoid colostomy. The sigmoid colon itself is divided by using a linear stapler. The proximal end of the divided sigmoid colon and the descending colon should be sufficiently mobilized to ensure a tension-free, well-vascularized colostomy.

The areolar space behind the fascia propria of the rectum is opened by anterior reflection of the stump of the superior rectal vessels and the proximal rectum, away from the promontory. The areolar tissue separating the mesorectal fascia from the parietal pelvic fascia can be easily identified in this view. In the beginning of this dissection, it is important to identify and protect the bilateral hypogastric nerves, which can be seen as two thick bands in the lateral aspects of the areolar space. The dissection is then carried inferiorly along the concavity of the sacrum as far as the sacrococcygeal junction and extended from the midline laterally (Fig. 156.6). Distally, the pelvic splanchnic nerves should be preserved, as they course from the lateral pelvic sidewall near the anterior sacral foramina to join the pelvic plexus.

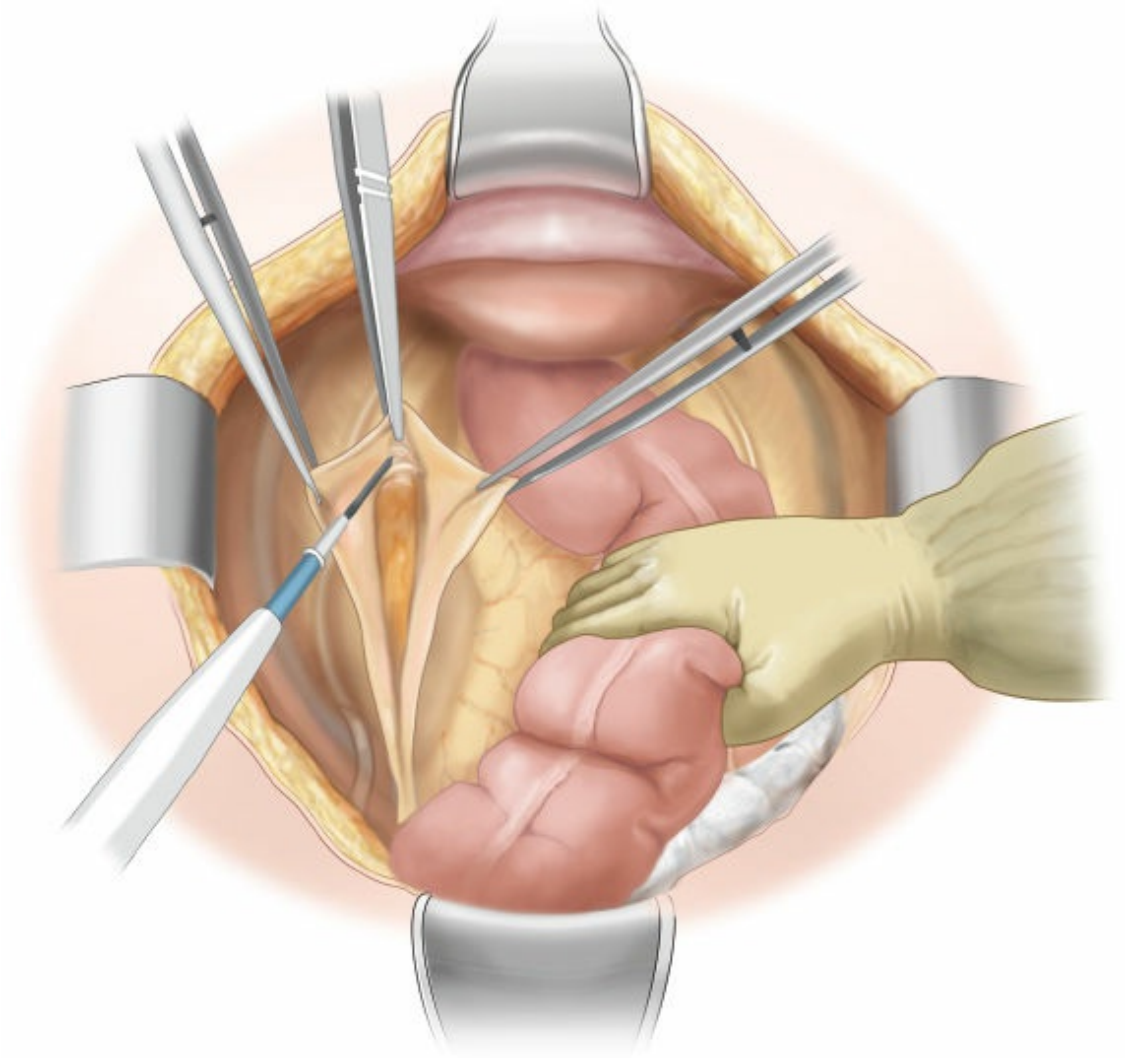

Figure 156.4. Lateral mobilization of the sigmoid colon, exposing the left ureter and gonadal vessels. (©2016, Memorial Sloan Kettering Cancer Center.)

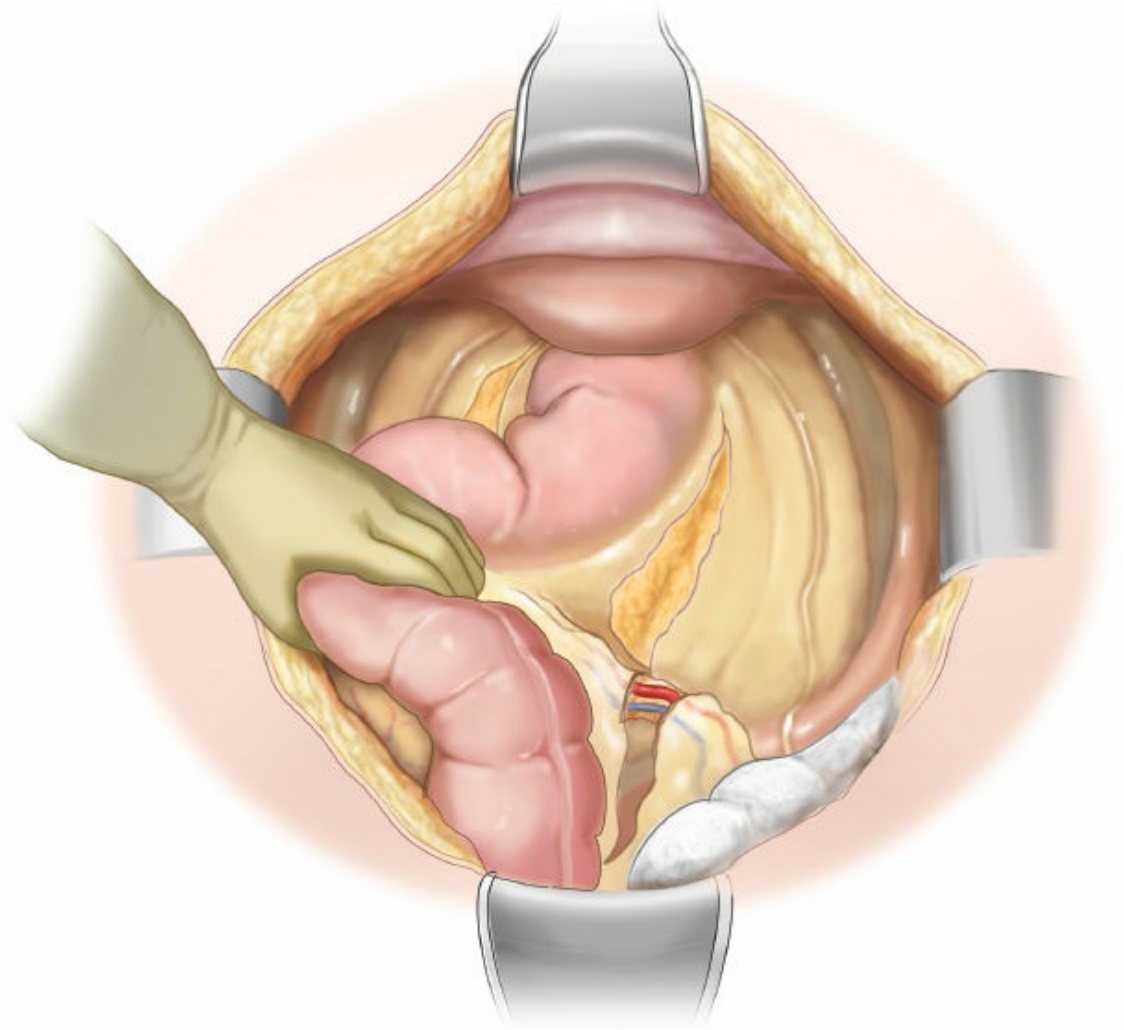

Figure 156.5. Exposure of the superior rectal vessels at the origin. (©2016, Memorial Sloan Kettering Cancer Center.)

We find that a St. Mark's pelvic retractor or a Wiley renal vein retractor —along with strong tension from the surgeon's nondominant hand on the rectum—can help place the areolar plane on tension and expose the proper plane for dissection. Division of the areolar connective tissue should be done using electrocautery or other sharp dissection (Fig. 156.7). Blunt finger dissection is extremely imprecise and can lead to a poor-quality resection plane and thereby compromise the oncologic validity of the operation. In addition, blunt dissection may damage the pelvic nerves and lead to impotence or retrograde ejaculation, as well as severe pelvic bleeding that can be difficult to control.

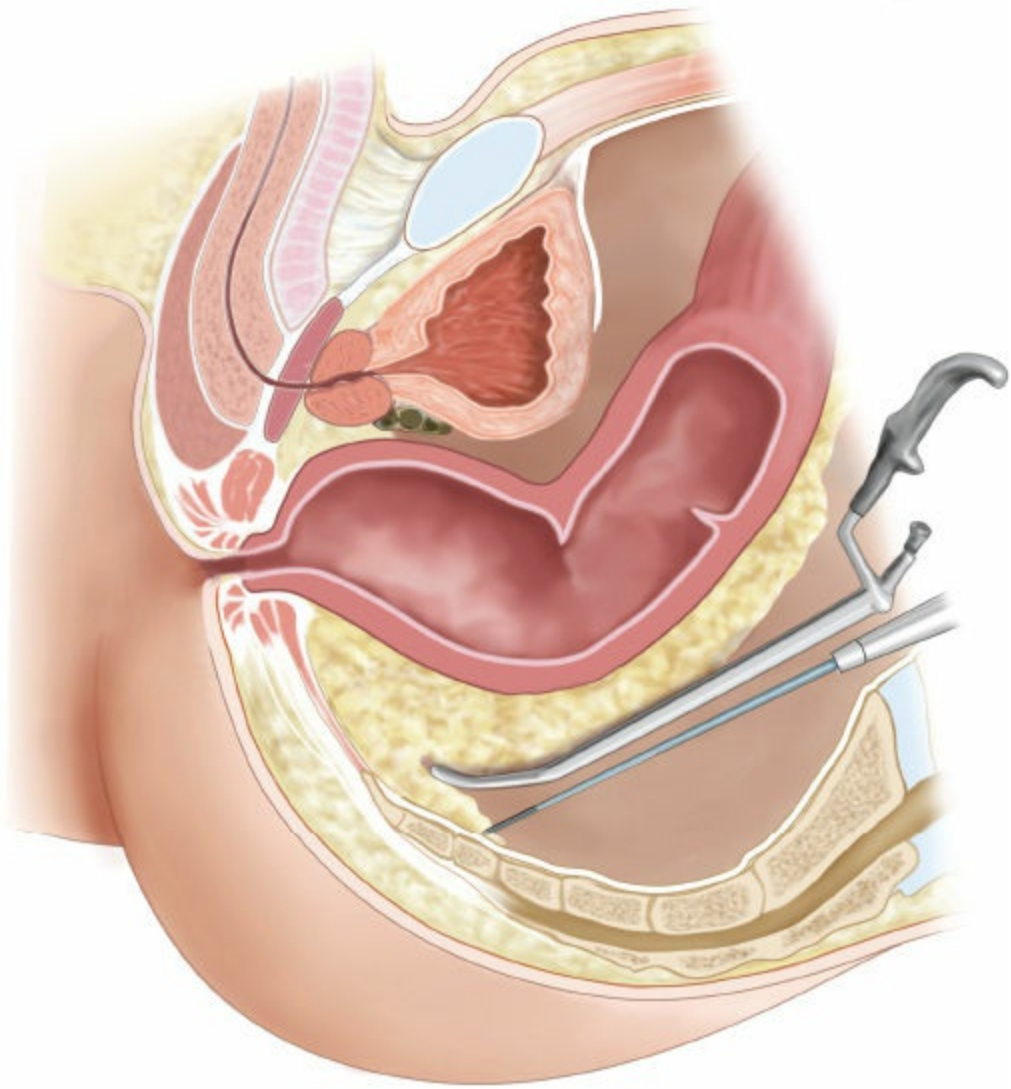

Figure 156.6. Posterior dissection in the areolar space between the mesorectal fascia and the presacral fascia. (©2016, Memorial Sloan Kettering Cancer Center.)

The lateral stalks are then exposed by providing traction on the rectum to the contralateral side of the pelvis and are divided using electrocautery. A forceful retraction can bring the parietal pelvic fascia and the pelvic plexus too far medially and within reach of the electrocautery, resulting in injury. The dissection is continued laterally until the origin of the levator muscle is reached. Finally, the peritoneum is opened anteriorly in the cul-de-sac. Dissection is carried to the level of the prostate in men and halfway down the vagina in women (Fig. 156.8). The anterior dissection can be performed in different planes, depending on the location of the tumor in the circumference of the rectum. For anterior tumors, dissection should proceed in front of Denonvilliers fascia to avoid dissecting into the tumor. For other tumors, dissection can be safely performed behind Denonvilliers

fascia to preserve the nerves of the prostatic plexus. The line along the sacrococcygeal junction, the upper portion of the levator muscles, and the upper prostate/mid-vagina represents the landmark where the perineal dissection will meet the plane dissected from the abdomen.

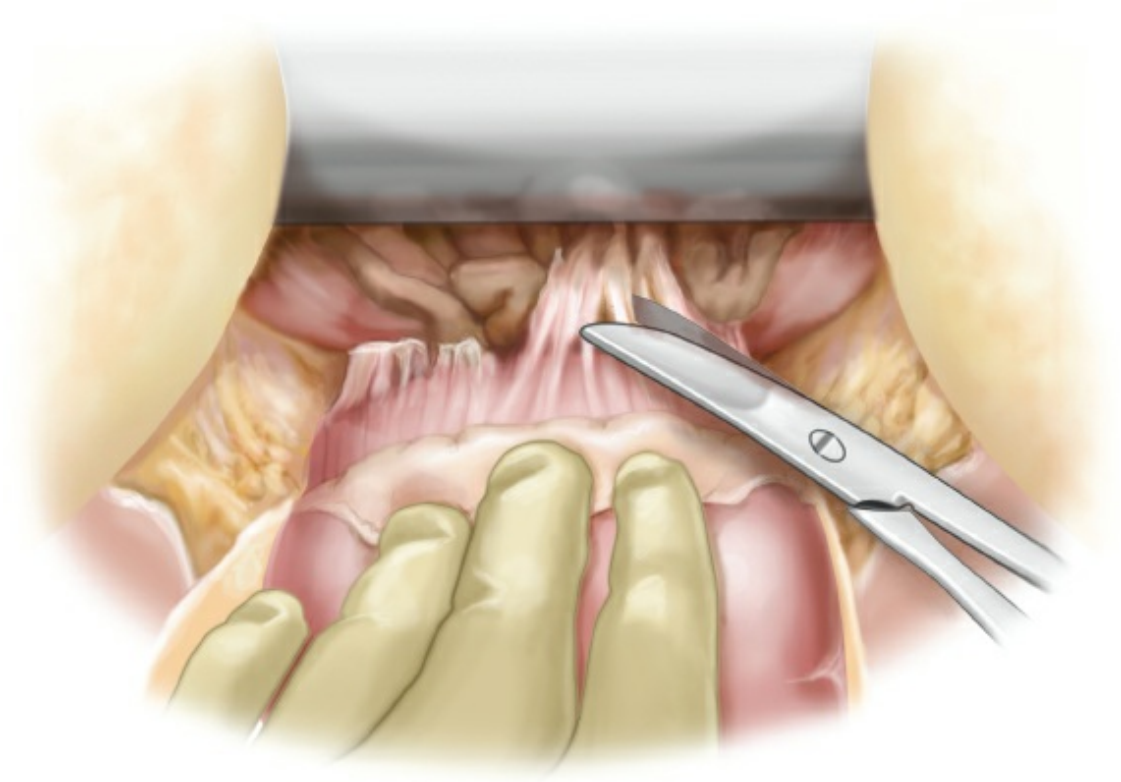

Figure 156.7. Anterior dissection behind the seminal vesicles. (©2016, Memorial Sloan Kettering Cancer Center.)

Minimally Invasive Abdominal Dissection

While the principles and steps are the same as those of the open approach, a minimally invasive approach, whether laparoscopic or robotic, is often facilitated by changing the order of the steps. We have found that, after placement of the ports (Fig. 156.9), the best way to begin the operation is to dissect at the inferior mesenteric artery extending into the retromesocolic plane in a medial-to-lateral fashion. The sigmoid colon is held up and retracted anteriorly. The peritoneum at the base of the sigmoid mesentery over the right iliac artery is incised to enter the areolar space behind the superior rectal vessels. The pneumoperitoneum will facilitate dissection in the areolar plane, and the surgeon, using sharp electrocautery dissection in the areolar tissue, gently opens this plane. The retromesocolic plane is gently opened by using traction and countertraction with the

graspers. The surgeon should be careful not to dissect too posteriorly behind the ureter and gonadal vessels, lifting them from the retroperitoneal position and exposing them to potential injury. Once the ureter is identified and kept out of harm's way, the inferior mesenteric artery can be fully isolated and divided at a location appropriate to the resection.

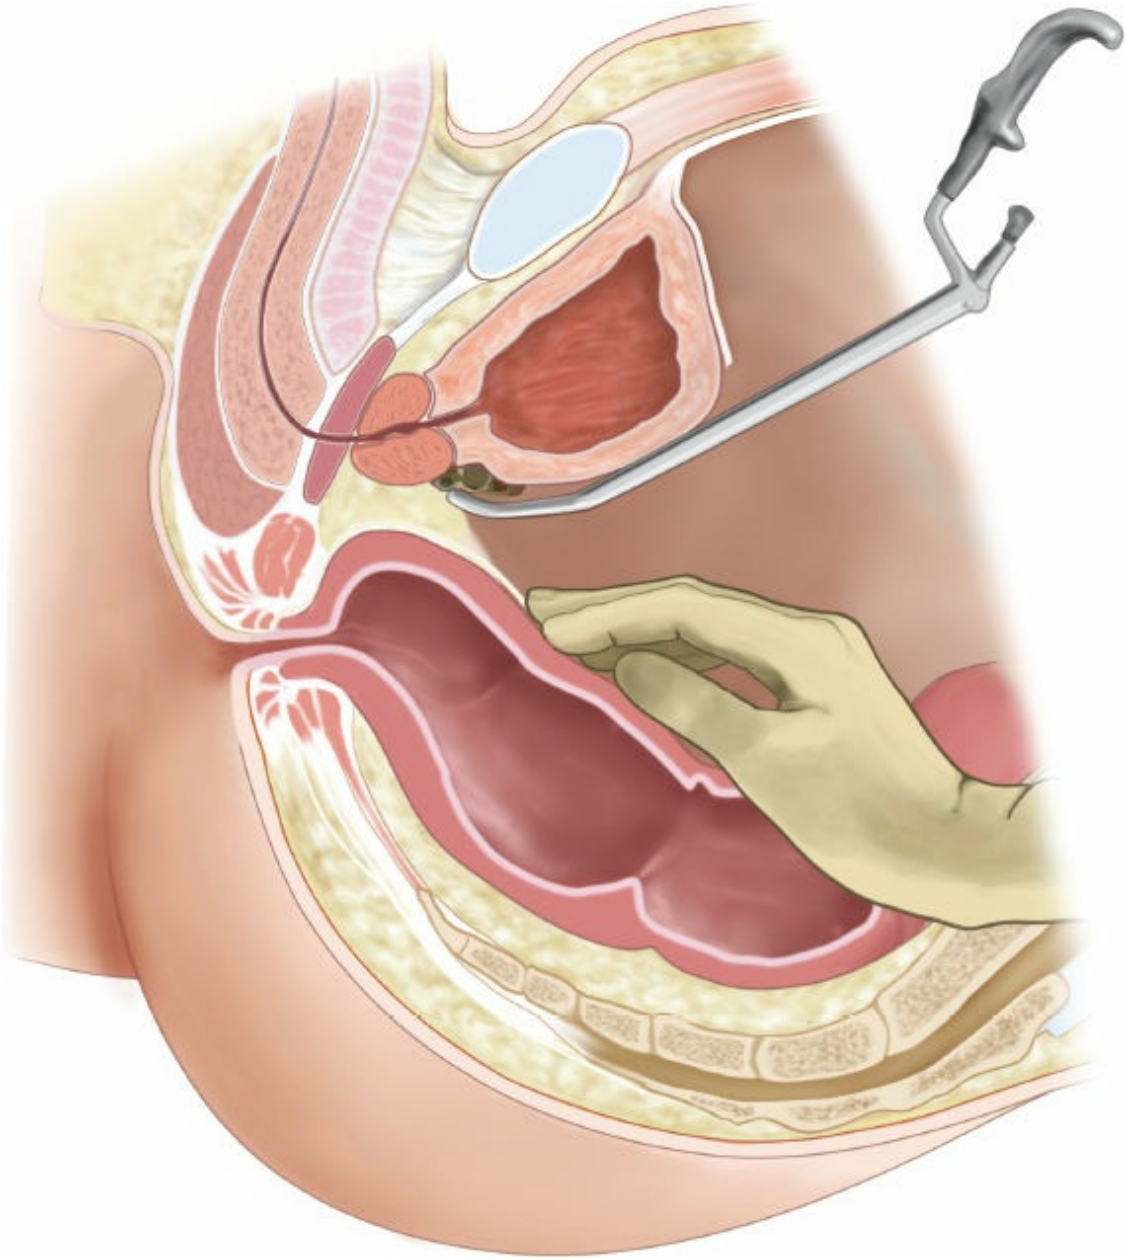

Figure 156.8. Anterior dissection behind the prostate. (©2016, Memorial Sloan Kettering Cancer Center.)

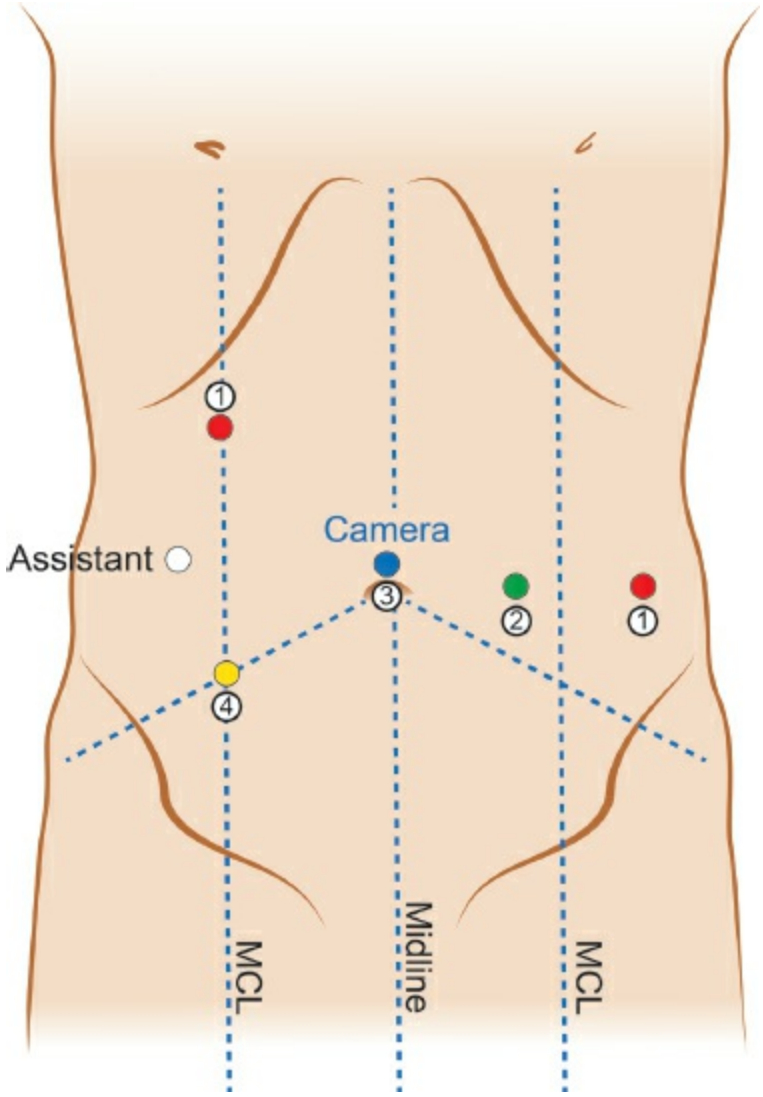

Figure 156.9. Trocar positioning for a robotic APR. The robot is positioned to the left of the patient. Arm 1 can be positioned in the right upper quadrant for the dissection and division of the superior rectal vessels. Arms 4 and 2 are the operating arms for the perineal portion of the procedure, while arm 1, positioned in the left lower quadrant, is used for retraction of the prostate or vagina. Trocar 3 is usually positioned at the site intended for the stoma. (©2016, Memorial Sloan Kettering Cancer Center.)

The retromesocolic dissection then continues laterally, mobilizing some of the descending colon and the sigmoid colon. When this portion of the colon is mobilized sufficiently, the surgeon should then incise the pelvic peritoneum in both sides of the mesorectum and sharply enter the posterior areolar space behind the mesorectal fascia. With the rectum continually on tension, sharp dissection of the areolar tissue in the mesorectal plane begins posteriorly and extends laterally. As in an open APR, care should

be taken to avoid the nerves at the sacral promontory and pelvic sidewall. It is often necessary to switch back and forth with the assistant: first retracting to the left, then to the right, to obtain good exposure and tension on the mesorectum and expose the proper plane. We find it helpful to wrap 15 cm of vaginal packing around the rectum. Using this as a "handle" helps to protect the mesorectum during this part of the dissection. (Vaginal packing is preferable to umbilical tape because it has radiotracers and can be seen on an x-ray if left in the abdomen.) In addition, the division of the proximal colon should be done after the rectal dissection, to facilitate intraoperative retraction of the upper rectum during the pelvic portion of the procedure.

Once the posterior dissection has reached the pelvic floor, we then extend our peritoneal incision anteriorly. When performing this procedure robotically, we have found that using a grasper in the third arm, placing the open blades into the cul-de-sac, and lifting up will help provide good exposure to the plane anterior to the rectum. If a laparoscopic approach is used, this is often a key step for the assistant. Then anterior peritoneum can be incised, and the dissection is extended to just below the cervix or seminal vesicles. Once fully mobilized to the pelvic floor, as described above, the sigmoid mesentery can be divided using a vessel-sealing device, and the proximal colon can be divided using a laparoscopic or robotic stapler. As the specimen will be removed via the perineal wound, no incision in the abdominal wall to extract the specimen is needed. However, we do place a grasper on the end colon in order to identify it easily when creating the ostomy, prior to switching to the prone position.

Perineal Part: Prone Position

When the abdominal part of the procedure is finished, it is advantageous to proceed with placing pelvic drains, closing the incision, and maturing the colostomy, leaving the distal rectum in situ for extraction during the perineal phase. The drains should be secured to the proximal portion of the specimen to facilitate placement into the pelvis when the patient is in the prone position. In addition, if a ventral rectus abdominis muscle flap is the chosen reconstruction technique, this should be performed prior to closing the abdomen and repositioning the patient. The flap should be secured with a small stitch to the proximal specimen, so that it can be located easily when necessary.

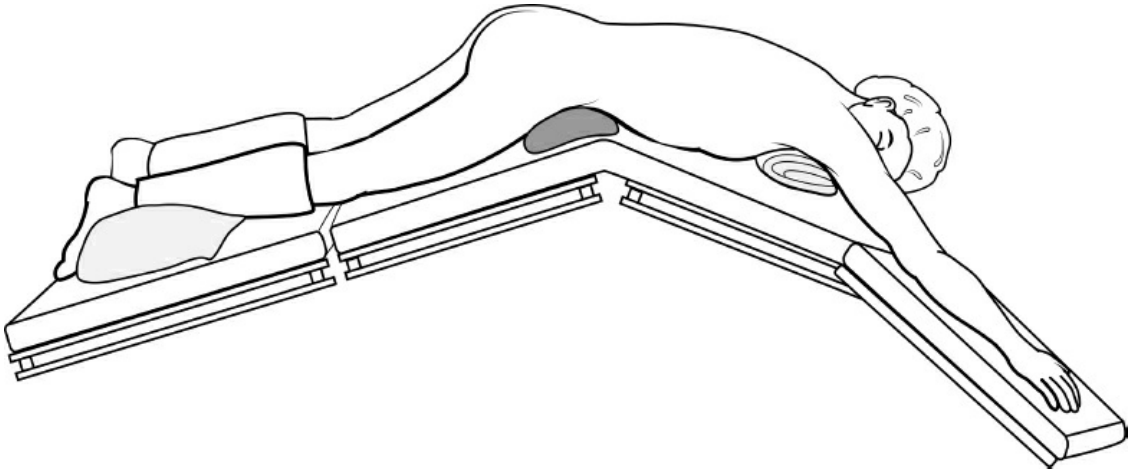

Figure 156.10. Prone jackknife position for perineal dissection, with padding under the chest, hips, knees, and feet. (©2016, Memorial Sloan Kettering Cancer Center.)

When ready to reposition the patient, we have found it best to use a second operation table set up for the prone position (Fig. 156.10). The patient can then be transferred in one step. A large hip roll is placed at the level of the break in the additional table, and a second, smaller roll is placed closer to the head of the table to support the upper portion of the patient's chest. This table is positioned alongside the original table, and the patient is flipped in one turn. The now-vacant lithotomy table is then quickly removed from the room. Armrests should be available and placed parallel to the head of the table to support the patient's arms as they are extended over the head. A soft pillow is used to support the patient's feet and pad the knees. The patient should be secured to the table across the chest as well as the legs. The bed is then moved into a deep flex position to bring the perineal area up, and the buttocks are secured laterally with tape. Rectal washout and closure of the anus with a heavy silk suture are done before prepping and draping. Sometimes a split table is used to separate the legs, allowing the surgeon to stand in the midline with one assistant on each side.

The perineum is then prepped with antiseptic solution and draped. An elliptical incision is made outside the lateral edge of the external sphincter and can be extended posteriorly if further dissection is needed. The incision should be lateral to the external sphincter muscles and medial to the ischial tuberosity. Palpating the tuberosity and placing the incision one to two finger breadths medially facilitates the medial incision. Posteriorly, the incision should be placed midway between the anus and the coccyx and can be extended if needed. Anteriorly, the incision should divide the

perineal body. For tumors that do not penetrate the anal sphincter or the levator musculature, a narrower incision can be utilized, and the dissection can be carried along the external sphincter muscle, thus preserving the ischiorectal fascia for wound closure (Fig. 156.11). A Lone Star Retractor (CooperSurgical, Inc.) works well for superficial exposure once the skin incision is made. If the resection is performed for anal disease such as recurrent anal squamous cell cancer, a wider resection margin can be used. In this setting, it is important to stay in the same plane as the dissection is extended superiorly. The dissection is done using electrocautery, watching for and controlling the perforating vessels as well as the inferior rectal arteries, seen laterally, which may bleed profusely. A number of additional retractors can be helpful in the deeper portions of the operation, such as a Sklar Gelpi Retractor (Sklar Surgical Instruments) or cerebral self-retaining retractors.

It is generally a good approach to palpate the coccyx and aim the posterior dissection toward a just-anterior location, to join with the posterior mesorectal dissection (Figs. 156.12 and 156.13). Some surgeons routinely remove the coccyx, but we do not feel this is routinely necessary unless the coccyx is involved by the tumor or additional exposure is needed. The perineal approach makes it much easier to perform a coccygectomy, or even a limited sacrectomy, as the incision can be extended posteriorly with excellent visualization and without risk of contamination. Dividing the anococcygeal ligament at the tip of the coccyx provides access to the posterior pelvis for joining the mesorectal dissection (Fig. 156.14). Once the two dissection planes (the abdominal mesorectal plane and the perineal plane) have been connected posteriorly, just anterior to the coccyx, the surgeon should divide the levator muscles beginning at the apex of the ischiorectal fossa, close to their insertion on the tendinous arch covering the obturator internus (Figs. 156.15 and 156.16). We find that placing the index of the nondominant hand into the pelvis and “hooking” the levator muscles facilitates this division. The puborectalis should be divided anteriorly before the transverse perineal muscle is reached.

At this point, the rectum, still attached anteriorly to the prostate or vagina, should be delivered through the wound to facilitate exposure for the anterior dissection. The distal portion of the anterior dissection—the separation of the distal rectum and anal canal from the perineal body—is best performed from proximal to distal, following the anterior surface of

the prostate or vagina, and from medial to lateral, rather than from the bottom (Fig. 156.17). The perineal approach affords better visualization of the neurovascular bundle (the distal portion of the pelvic plexus) and can help avoid injury to the urethra. It is important to stay in the correct plane, and palpation can facilitate this. In males, palpating for the urethra and urinary catheter can help avoid injury. In women, placing a finger in the vagina can help to define the plane of the rectovaginal septum.

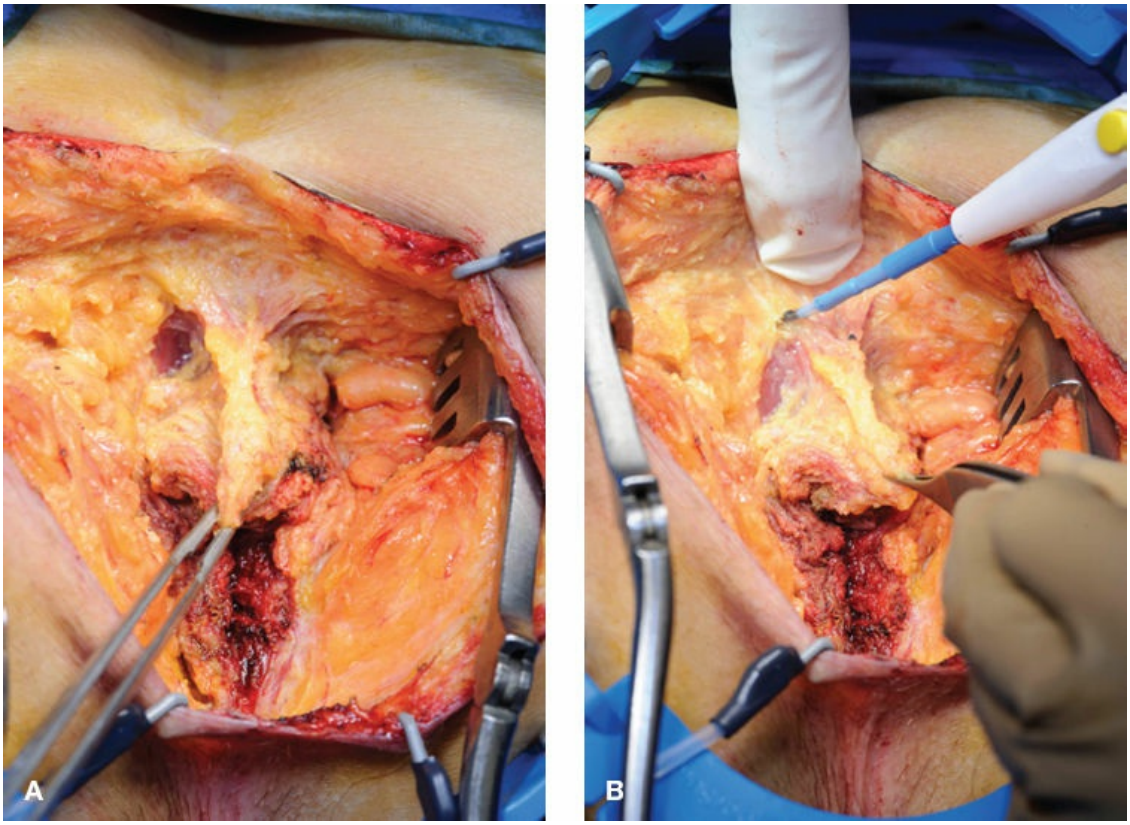

Figure 156.12. Exposure (**A**) and division (**B**) of the anococcygeal ligament. (©2016, Memorial Sloan Kettering Cancer Center.)

Once the specimen is removed, the pelvic cavity is irrigated. Pelvic drains placed previously during the abdominal phase of the procedure are repositioned as needed, and the perineal defect is closed. For primary closure, we prefer a meticulous, multilayered closure with large absorbable sutures, to approximate the ischiorectal fat, and a layer of nylon sutures in a vertical mattress pattern to approximate the skin (Fig. 156.18).

Reinforcing the perineal closure with a biologic absorbable mesh anchored to the coccyx, coccygeus muscles and pelvic side-wall along the insertion of the levator muscles is often used to prevent wound dehiscence and perineal hernias in patients with larger perineal defects. Alternatively, there are a number of reconstructive options using homologous tissue. The ventral rectus abdominis muscle flap is mostly used in open procedures done in the lithotomy position, but it can also be used when the perineal portion is done in the prone position. In this case, the flap is mobilized when the abdomen is open and the patient is in the supine position prior to abdominal wall closure or colostomy maturation. The flap is then tagged with a suture and positioned deep in the pelvis for easy retrieval during the

perineal phase. The bilateral V-Y advancement gluteal flaps are an excellent alternative, especially if there is concern about retaining the integrity of the abdominal wall. These flaps are done in the prone position and allow for excellent tissue coverage, even for posterior vaginal reconstruction. Gracilis muscle flaps have also been described, with good results. No differences in outcomes or morbidity have been noted between different reconstruction options, and the strategy should be individualized based upon each patient's needs and functional limitations.

Perineal Part: Lithotomy Position

As discussed above, lithotomy is the most comfortable patient position for most surgeons. The orientation of the anatomy is familiar, and there may

be specific reasons to consider this position for the perineal part of the dissection. We find it helpful to place a large metal or plastic tray across the lap of the operating surgeon, to allow easy access to frequently used instruments. In addition, care should be taken to keep a sterile field under the patients' buttocks. The operation proceeds as described above for the prone position. However, anterior dissection can be more difficult in lithotomy, given the reduced exposure. The surgeon must be in the correct plane, feeling for the urethral catheter in males and the vagina in females.

POSTOPERATIVE CARE

Postoperative care after an APR is relatively routine. We advocate an enhanced recovery strategy, permitting early ingestion of clear liquids and advancing to low-residue diet as tolerated, with limited intravenous fluid resuscitation, early ambulation, and a pain control strategy to minimize the use of narcotics. Because of the extensive pelvic dissection and concomitant risk to the nerves, the urinary catheter remains in place until at least the third postoperative day.

Post-APR drain management is a subject of controversy. After a primary closure of the perineum, the pelvic drain is often removed prior to discharge, because the pelvic peritoneum can reabsorb any peritoneal fluid that is secreted. If a rectus flap is used, additional drains are often needed in the abdominal wall, and the pelvic drain remains in place until output has diminished significantly and the wounds are healing well. These drains sometimes remain in place for as long as 2 weeks.

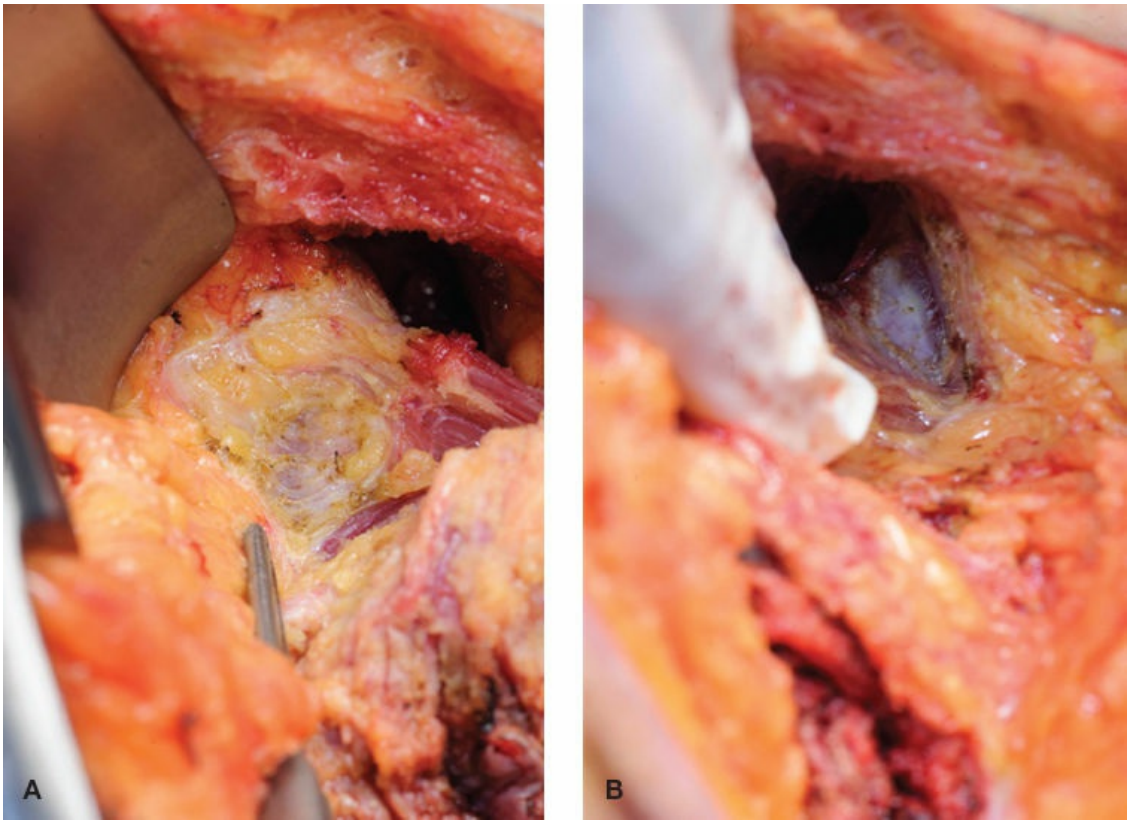

Figure 156.15. Division of the left (**A**) and right (**B**) levator muscles. (©2016, Memorial Sloan Kettering Cancer Center.)

To protect the perineal wound, physical activity is restricted. If the closure was primary, the patient should avoid sitting for 4 to 5 weeks following surgery, to allow the wound to fully heal. Often, the perineal sutures remain in place for 3 to 4 weeks, as this area has a high incidence of wound dehiscence and infection. If short-duration sitting is absolutely necessary, as is usually the case in the car ride home from the hospital, patients should employ a soft pillow. They should avoid using a foam ring, which can lead to increased pressure in the perineum and disrupt blood flow. If the perineum was closed with a flap, the patient should also be instructed to avoid bending at the waist for a similar duration of time, to

prevent placing undue tension on the reconstruction.

MANAGEMENT OF COMPLICATIONS

The most significant source of morbidity following an APR is the perineal wound. The rate of wound infections in the perineum is as high as 40%, often due to the large excision required and the necessity for preoperative radiation. Thus, using healthy autologous tissue can help reduce these complications. Wound infections necessitate opening the wound. Because of the high risk of evisceration—since there may be no fascia or muscle to support the pelvic floor—this procedure must often be done in the operating room. The wound is irrigated, necrotic tissue is removed, additional drains are placed as needed, and the wound is closed if possible. If the wound cannot be closed, a negative-pressure dressing can be employed, with a good rate of success. We have even seen good results using synthetic prosthetic devices (silicone breast implants) to fill the defect. Generally though, we do not recommend using such synthetic materials in contaminated fields.

Genitourinary and sexual dysfunction is prevalent after APR, occurring in up to 50% of patients. Good surgical technique, including identification and protection of the pelvic nerves, goes a long way toward preventing such dysfunction. Fortunately, in some patients the dysfunction is relatively minor, and function often continues to improve for 12 months following surgery. However, a significant minority of patients sustain permanent dysfunction.

Stoma-related complications, particularly parastomal hernias, are a significant long-term consequence of APR. The findings of several well-designed studies support the use of preperitoneal prosthetic mesh for constructing permanent ostomies. The extent of the operation and the risk of mesh-related complications are important considerations, and for these reasons we avoid permanent mesh placement during the initial surgery. However, if a symptomatic parastomal hernia does occur, placement of permanent mesh during the repair operation should be strongly considered.

OUTCOMES

APR performed in the lithotomy position is associated with a risk of intraoperative bowel perforation and positive circumferential margins, both of which contribute to higher rates of local recurrence and mortality compared with low anterior resection. Even with neoadjuvant chemoradiation, this trend remains, with the rate of local recurrence as high as 30%. While the etiology is likely multifactorial, intraoperative patient positioning may play an important and influential role.

The evidence regarding the positioning of the patient during the perineal portion of the APR is mixed. In small, single-institution studies, prone positioning for cylindrical APR was associated with reductions in the rates of local recurrence (to 6%) and perineal wound infections (to 11%). A single-institution randomized controlled trial also found decreased rates of circumferential margin involvement and local recurrence for cylindrical APR performed in the prone position, although at the cost of higher rates of chronic perineal pain. In the authors' opinion, the position of the patient during the perineal portion of the APR procedure is a matter of preference, and the surgeon should use the approach he or she feels more comfortable with.

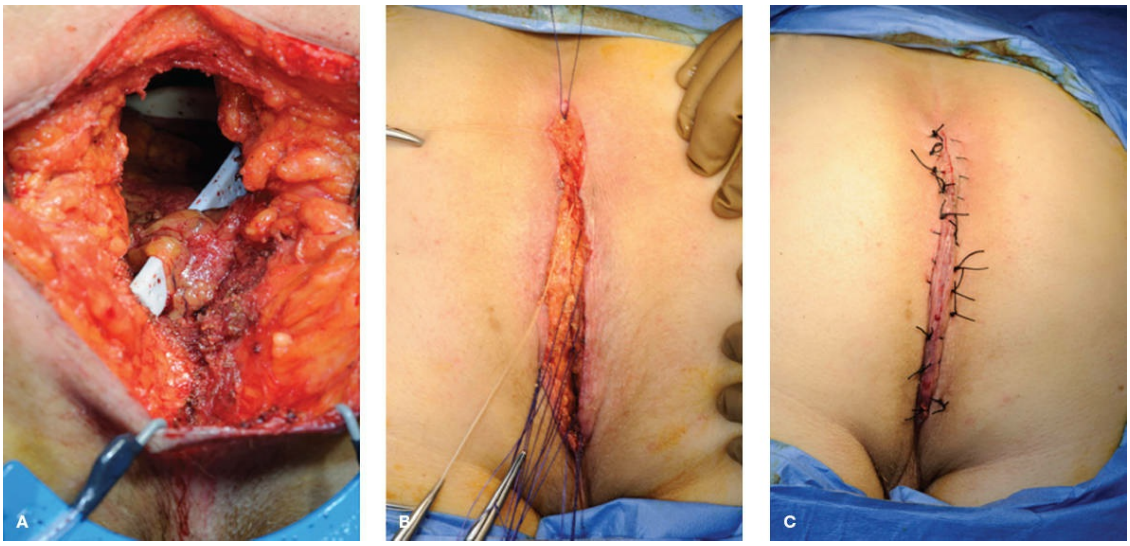

Figure 156.18. **A.** Perineal defect after removal of the specimen. **B.** Approximation of the fat of the ischiorectal fossa with absorbable sutures. **C.** Closure of the skin with nonabsorbable

sutures. (©2016, Memorial Sloan Kettering Cancer Center.)

Overall, oncologic outcomes following an APR for distal rectal cancer are poorer than outcomes following surgery for higher rectal cancers. In patients with clinical stage II or III disease treated with neoadjuvant chemoradiotherapy and optimal surgery, the 5-year survival rate after an APR is close to 70%, compared to 85% after a sphincter-preserving surgery. However, rectal cancer care does not always follow best-practice guidelines and such deviations can increase local recurrence rates and reduce long-term survival.

EDITOR'S COMMENT

We have two chapters on the same surgery but with differences. I am familiar with them because in my early years at the Massachusetts General Hospital I pursued saving the rectum, at least partially, but saving the rectum was a widely criticized practice at the time, though in my experience I had very few recurrences.

Dr. Garcia-Aguilar is describing the "old-fashioned" abdominoperineal resection which does not very often allow the patient to avoid a colostomy. Both of the techniques, described in the two chapters can be utilized.

Professor Garcia-Aguilar's procedure is the 1908 procedure which Professor Miles described. Its purpose is to "cure the cancer." That is what Dr. Claude Welch did at the Massachusetts General Hospital. Few patients moved their bowels via the rectum. Many patients were cured. Many had recurrences and died while trying to save the rectum. My own view is that in good hands recurrences occurred but not often.

157 Abdominoperineal Resection for Rectal Cancer

Steven Nurkin, Aaron Saunders, Rupen Shah, and Steven N. Hochwald

INTRODUCTION

Current investigations in rectal adenocarcinoma are developing paradigms of management that emphasize minimally invasive surgery, less radical resections, and even organ preservation—complete omission of any radical resection from the initial treatment plan. However, there undoubtedly remains a population of patients with rectal cancer in whom the best oncologic outcome can be achieved by an abdominoperineal resection (APR, also known as abdominoperineal excision, or APE). Initially described by Sir Ernest Miles at the beginning of the 20th century, this treatment was for decades the standard of care for the surgical management of all rectal cancers. Now, many patients can be managed with restorative proctectomy, often with excellent results. Unfortunately, patients with very low rectal tumors have not achieved the high rates of margin negativity and low rates of local recurrence brought about by total mesorectal excision (TME) in mid- to high-rectal tumors. To address this, the approach to APR in low rectal tumors has been re-evaluated, and variations on the classic operation have been developed, each with different indications and important distinctions in technique. The choice between these techniques is driven by patient and tumor characteristics, and the successful operation is based upon a detailed understanding of the anatomy, with a meticulous approach to dissection.

CLINICAL PRESENTATION

Rectal adenocarcinoma in general will often present with blood per rectum, and possibly anemia, as well as a change in the caliber or character of the stool. Symptoms of rectal fullness or tenesmus may also be present. In the patient destined for an APR, there may be signs of anal sphincter or pelvic floor involvement, such as fecal incontinence and anal pain. Tumor

perforation with perirectal abscess may also occur.

INDICATIONS AND CONTRAINDICATIONS

In general, an APR for malignant disease should be reserved for patients with very low rectal adenocarcinomas in whom sphincter preservation is not possible, or patients with anal squamous cell carcinoma (SCC) that has not been successfully treated with chemoradiation therapy. The options for surgical approach to APR are based upon concentric anatomic tissue planes. The basic concept is that the resection should target the tissue plane outside of the tumor's apparent extent of invasion, in order to achieve a margin-negative resection.

The intersphincteric variation of APR creates the narrowest perineal wound of the APR techniques, and may be appropriate for patients whose rectal tumors have no levator involvement, who suffer from fecal incontinence at baseline, or who are very high risk for an anastomotic leak, either from the standpoint of poor capability for wound healing or of inadequate physiologic reserve to withstand a septic insult. However, these patients might also be treated with a very low Hartmann procedure, avoiding a perineal wound altogether.

The extralevator approach to APR (also known as extralevator abdominoperineal excision, or ELAPE) is a technique in which the levator muscles are not dissected away from the tumor or the mesorectum and are removed en bloc with the specimen (Fig. 157.1). This approach is indicated for patients who have tumors within a centimeter from the dentate line, or low rectal tumors with a threatened circumferential resection margin (CRM) in whom a sphincter saving procedure may not be oncologically possible (Fig. 157.2).

The ischioanal variation of APR entails incising the levator muscles at their lateral insertions and performing dissection along the outside of the fat pad of the ischioanal fossa and along the fascia of the obturator internus muscle. This is the widest of the perineal dissection approaches, and is indicated in patients with tumors that involve the perianal skin, ischioanal fat, or levator muscles with direct tumor invasion, perforation, or formation of abscesses or fistulous tracts.

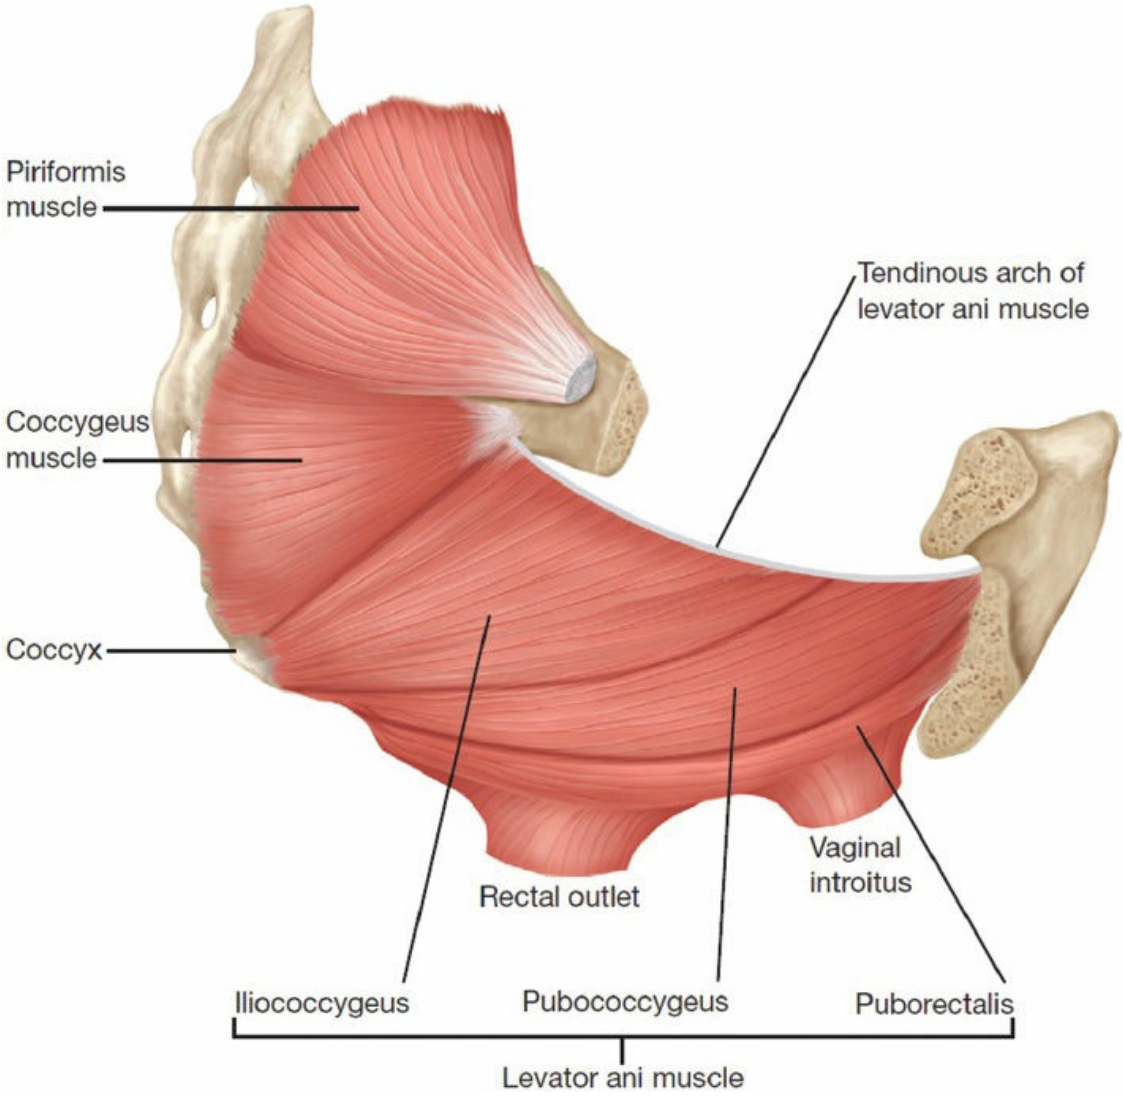

Figure 157.1. Illustration of the levator ani complex with musculoskeletal anatomic relationships. Varying amounts of this pelvic floor are resected with different approaches to APR.

At best, an APR has the potential for significant morbidity. Risks for significant bleeding and injury to adjacent structures such as pelvic nerves, prostate, and vagina, are higher than for low anterior resection. The most frequent complications occur in relation to the perineal wound, including dehiscence and/or infection. For this reason, patients of advanced age and with poor performance status and physiologic reserve should be counseled carefully about the risks and benefits of surgery. It should be considered that for some, the morbidity of this operation may decrease their expected survival relative to palliative chemoradiation. These findings may be considered a relative contraindication to APR.

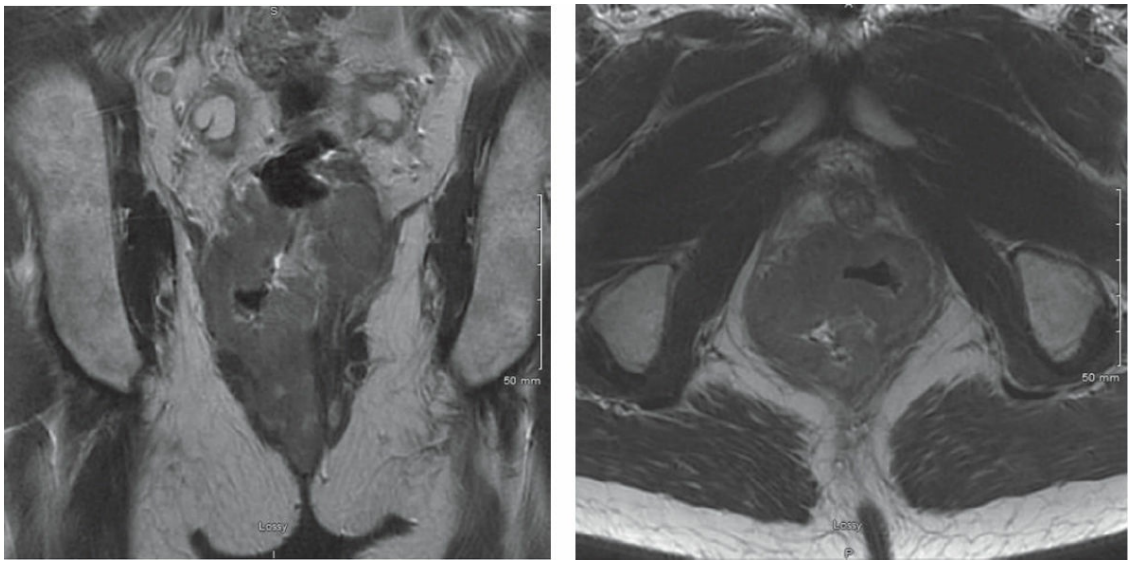

Figure 157.3. Selected images from a pelvic MRI demonstrating a locally advanced rectal tumor with invasion into the sphincter

complex and levator muscles.

WORKUP AND MULTIDISCIPLINARY TREATMENT PLANNING

The initial interview should include a detailed history establishing the baseline urinary and sexual function of the patient, and whether the patient experiences fecal incontinence. A digital rectal examination should be performed, and note should be taken of the relationship of the tumor, including possible fixation or invasion, to the surrounding structures. Staging workup should include computed tomography (CT) scan of the chest, abdomen, and pelvis, as well as a baseline carcinoembryonic antigen (CEA) level. In addition, endorectal ultrasound (ERUS) or, preferably, magnetic resonance imaging (MRI) of the pelvis provides invaluable information about the extent of local tumor invasion and regional lymph node involvement (Fig. 157.3). The MERCURY trial evaluated 408 consecutive rectal cancer patients at several European centers with MRI, and assessed the correlation between the MRI prediction of curative surgery and final margin status. The trial found a 91% accuracy of MRI in predicting a negative resection margin in patients going to primary surgery, and a 77% accuracy rate among patients who had received neoadjuvant treatments.

Review of a rectal MRI should carefully assess for invasion of the levator muscles or the sphincter complex. By definition, any tumor that appears to invade the levator ani complex is at least a clinical T3 (stage II, according to the *AJCC Cancer Staging Manual*, 7th ed.), and standard treatment often includes neoadjuvant chemotherapy and/or radiation therapy followed by surgery. Multiple randomized clinical trials have demonstrated that neoadjuvant chemoradiation therapy in stage II and higher rectal cancer decreases rates of local recurrence following surgery. Furthermore, the Dutch Trial combining neoadjuvant chemoradiation and total mesenteric excision (TME), which has also been shown to be an independent factor in the reduction of local recurrence rates, demonstrated the lowest reported rates of local recurrence, yet. Current multimodal treatment is capable of achieving local recurrence rates of 5% or lower. This has served to emphasize the importance of well-coordinated multidisciplinary treatment of patients with rectal cancer to achieve optimal outcomes.

SHIFTING PARADIGM REGARDING PERINEAL MARGIN

Of note, while outcomes improved for rectal cancer overall, the population requiring APR for curative resection remained a negative outlier, associated with higher rates of positive CRMs and tumor rupture at time of surgery. These findings prompted a renewed interest in wider dissection through the pelvic floor and perineum in order to more consistently achieve margin-negative resections, and the extralevator approach to APR gained increasing support. More recent investigations have not uniformly shown that extralevator dissection leads to better outcomes than conventional APR, with both techniques achieving local recurrence rates approaching those for patients treated with sphincter-preserving TME when margin-negative resection is achieved. These studies have confirmed that CRM involvement or tumor perforation are associated with higher rates of local recurrence, emphasizing the importance of keeping the dissection plane well away from the edge of the tumor. It is clear, then, that successful extirpation of disease involving the distal rectum in particular must begin with a thorough and accurate assessment of the tumor's extent of invasion.

PREOPERATIVE PLANNING

Following neoadjuvant therapy, the patient should be restaged with CT scans of chest, abdomen, and pelvis, and rectal MRI. It is important to recognize that the extent of tumor invasion seen on MRI guides the surgeon in selecting the plane of dissection through the pelvic floor. In some patients with locally advanced disease, MRI may also show tumor invasion into adjacent organs or structures, such as prostate, vagina, bladder, branches of the iliac vessels, sacrum or pelvic sidewall. In such cases, the surgeon plans for a more radical operation involving en bloc resection and reconstruction of adjacent organs; it may be prudent to invite additional surgical specialists to be available to assist in the surgery, as needed.

Sometimes underappreciated in preparation of the patient for an APR is the creation of a permanent end colostomy. It is critical that attention be paid to appropriate selection of a site for this colostomy. The patient should be observed and marked in the preoperative area in the seated, standing, and bending positions, taking care to identify a location for the

stoma that will be surrounded by flat, smooth skin that is free of creases, scars or radiation damage, and is easily visible and accessible to the patient. Ideally, the patient should receive education prior to surgery about the nature and care of a colostomy. A preoperative visit with a trained enterostomal therapist is helpful.

The question of bowel preparation remains controversial. It is our practice to perform a full Nichol's colon preparation, that includes oral antibiotics and mechanical preparation, prior to surgery, with the intent of reducing infectious wound complications in the postoperative period.

SURGICAL TECHNIQUE

In our practice, it is common to perform an APR with a minimally invasive approach, often with robotic assistance for the abdominal dissection. The principles of the operation are the same as in conventional open surgery, with minor variation in the typical order of steps. The selection of the approach should depend primarily on the experience and comfort level of the operating surgeon, as the primary consideration must be safe and oncologically sound surgery, ideally with preservation of autonomic innervation and baseline urogenital function.

Positioning

It is our preference to place the patient in the Lloyd-Davies position, and perform both the abdominal and perineal portions of the operation without repositioning the patient. Some surgeons, however, prefer to begin with the patient supine with legs apart, and complete the abdominal portion of the surgery, including construction of the colostomy and closure of all abdominal wounds. The patient is then repositioned in a prone jack-knife orientation for the perineal dissection. Proponents of this latter approach cite improved visualization of the anterior pelvis, which facilitates dissection of the specimen off of the prostate or vagina, and the pelvic nerves. Still others will start the surgery in the prone jack-knife position and perform the perineal dissection, and then place the patient in the supine position to continue with laparoscopic removal of the specimen and formation of the colostomy. Advantages of maintaining the Lloyd-Davies position throughout, however, are that two teams may work simultaneously, and difficult dissection maneuvers in the deep pelvis can sometimes be facilitated by alternating approaches between the abdomen and perineum.

Abdominal Dissection

The approach to the abdominal dissection for an APR proceeds in much the same fashion as for a low anterior resection. For the minimally invasive approaches, the initial access to the abdomen and creation of pneumoperitoneum is achieved with placement of a Veress needle in the left upper quadrant of the abdomen, confirming intraperitoneal placement with a saline drop test, and beginning abdominal insufflation with a goal pneumoperitoneum pressure of 15 mm Hg. Planning for the location of port sites then depends on the laparoscopic or robotic equipment to be used and the preferences of the surgeon. The key principle is that port placement should facilitate full range of motion and appropriate traction and countertraction during surgery. A diagnostic laparoscopy is performed, inspecting the liver and peritoneal surfaces to evaluate for the possibility of metastases. The small bowel is retracted to the right upper quadrant with the aid of Trendelenburg positioning and placing them left side up. It may be necessary to suspend the uterus by the use of sutures passed through the abdominal wall.

Once access and exposure has been achieved, a minimally invasive operation begins with mobilization of the sigmoid colon, using a medial-to-lateral approach. This dissection begins with an incision of the peritoneum just medial to the right iliac artery. Lifting the peritoneal edge allows pneumodissection to assist in exposure of the target plane, which is then followed cephalad. The sigmoid colon is lifted up, placing the inferior mesenteric artery (IMA) pedicle on tension and allowing more lateral dissection in the alveolar plane between the mesocolon and the retroperitoneum. Retroperitoneal tissues are dissected with care to avoid injury to the hypogastric nerve plexus. Following this dissection cephalad will reveal the origin of the IMA. The superior rectal artery is then isolated and divided with a laparoscopic or robotic vessel sealing device (Fig. 157.4). Conventional descriptions of the operation describe high ligation of the IMA (which, when performed, should be at a location a few centimeters away from the aorta, to avoid injury to hypogastric nerves), but it is our opinion that an adequate oncologic resection for low rectal tumors requiring APR can be performed in cases of clinically negative nodes and low risk for lymphatic metastases, allowing preservation of the IMA trunk and the left colic artery. This serves to maintain better perfusion to the left colon beyond the watershed area and, therefore, to the level of the colostomy. However, when preoperative or intraoperative

findings suggest significant regional lymphadenopathy, the conventional high ligation of the IMA should be performed.

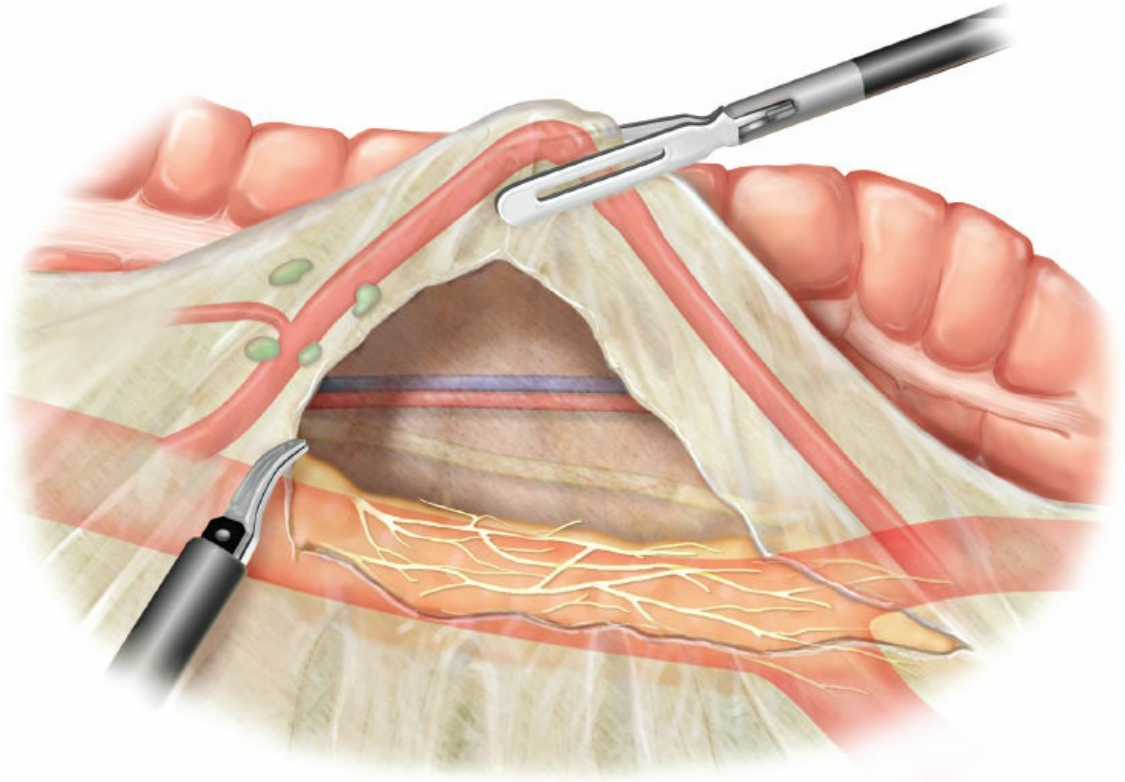

Figure 157.4. The inferior mesenteric artery (IMA), origin of the left colic artery, and superior rectal artery are exposed. The superior rectal artery is isolated and may be divided with a vessel sealer or other mode of ligation, unless clinically positive nodes are encountered, in which case a high ligation of the IMA is performed with care taken to preserve the hypogastric nerve trunks.

Continuing in this plane will expose the hypogastric nerves, gonadal vessels, and ureter. In some cases, the sigmoid colon may be tethered laterally, and it may be necessary to release these attachments before sufficient anterior traction can be placed on the sigmoid to reveal the vascular pedicle and facilitate the medial-to-lateral dissection. In this situation, it is crucial to recognize that the colon must be pulled toward the right upper quadrant and dissection should proceed more medially than posteriorly. It is a common mistake for the operating surgeon to expose and follow the plane just lateral to this, and begin to dissect more posteriorly toward the quadratus lumborum muscle and toward the lateral edge of Gerota fascia. Following this plane at the level of the pelvic brim

would threaten the ureter and iliac vessels, and should be avoided. When there is sufficient mobility of the sigmoid to retract anteriorly, the dissection between the mesocolon and the retroperitoneum continues until the lateral peritoneal leaflet is reached and incised, entering the left paracolic gutter. As this dissection proceeds laterally, it is helpful to place a laparoscopic or robotic instrument behind the dissected mesocolon and lift it anteriorly. This provides the best exposure and tension at the leading edge of the dissection plane.

The apex of the mobilized sigmoid is lifted anteriorly, and should be observed to reach the abdominal wall without tension. The location for transection of the sigmoid is selected such that the cut end can be brought out for colostomy formation without further mobilization. In some cases, this will be not be possible, and division of the remaining line of Toldt superiorly and mobilization of the splenic flexure may be necessary. Once adequate mobilization is achieved, the sigmoid mesocolon is divided at the intended transection site, using an energy device. This controls the remaining sigmoidal vessels. All mesenteric tissue is dissected away from the bowel wall, and the colon is divided with a stapling device.

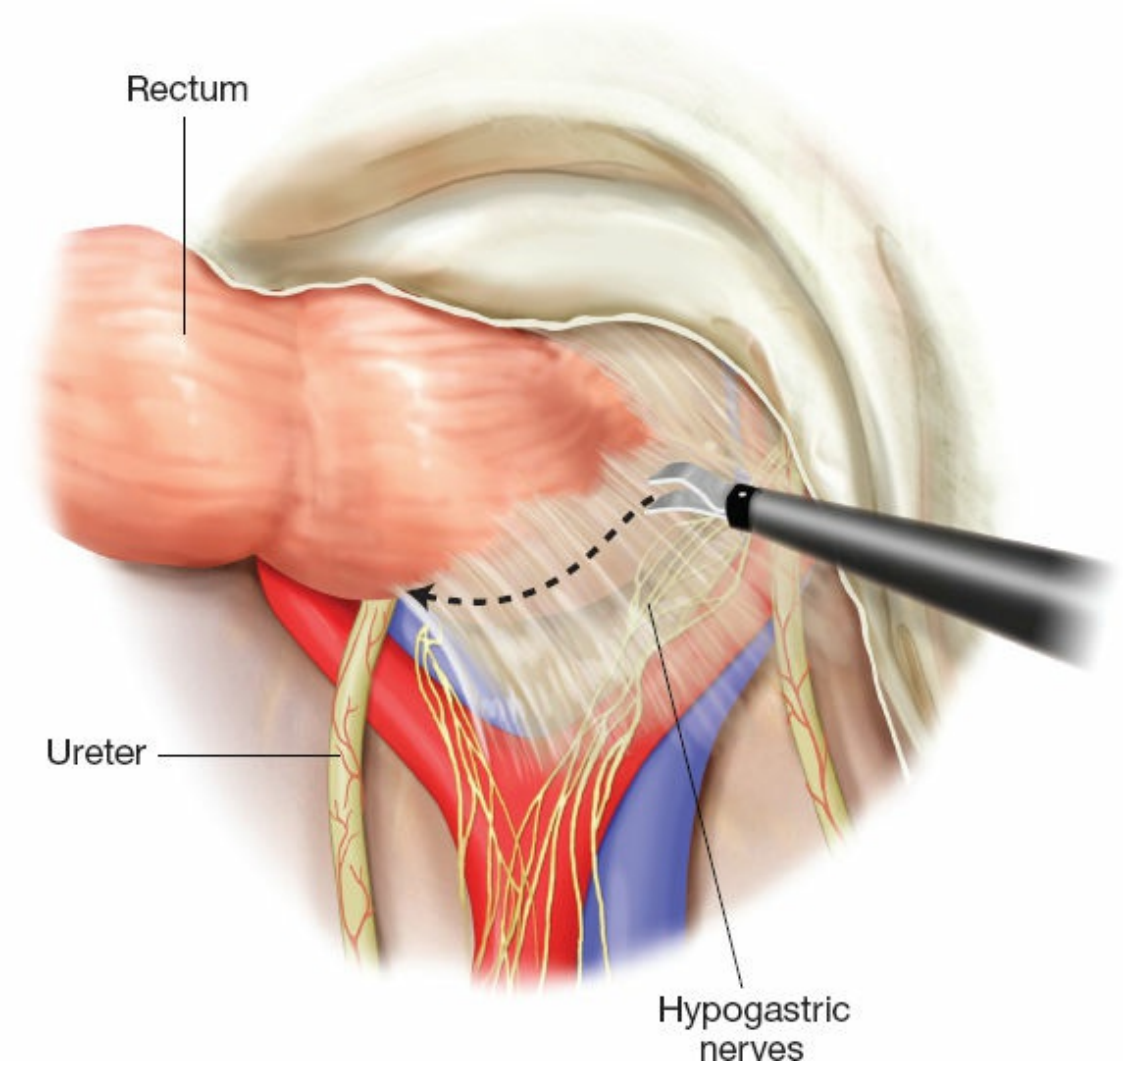

Figure 157.5. Anterior retraction of the rectum provides exposure for the posterior TME dissection. Care is taken to preserve the hypogastric nerves by meticulously following the mesorectal fascia and sweeping the posterior tissues away from the specimen.

Attention is turned to the rectal dissection. Previous maneuvers have already exposed the sacral promontory and the distal sigmoid colon is now retracted anteriorly, exposing the posterior point of entry for dissection along the mesorectal fascia (Fig. 157.5). Dissection from this point proceeds according to the principles of TME, discussed in more detail elsewhere in this volume. Side to side dissection proceeds first posteriorly in the alveolar plane between Waldeyer fascia and the mesorectum, and then anteriorly in the alveolar plane between Denonvillier fascia and either the seminal vesicles and prostate or the vagina (Fig. 157.6). This progressively exposes the middle rectal pedicles laterally, which are

ligated and divided with an energy device. For extralevator and ischioanal approaches to APR, this dissection stops when the superior-most extent of the levator muscles is encountered.

It is important to note that the TME dissection in a conventional APR would have continued inward along the superior surface of the levator muscles, which narrows the diameter of the cylinder that had until this point been preserved by the TME approach, and can create an hourglass shape, or so-called “waist,” at the inferior portion of the final resected specimen (Fig. 157.7). Unless the preoperative evaluation has shown the tumor to be well away from the levator muscles (in which case the patient may have been a candidate for restorative proctectomy, or a very short Hartmann pouch) this maneuver should be expected to compromise the oncologic result of the operation, and must be avoided.

While we have so far described a minimally invasive approach, the principles for the open operation are the same, with the general exception of the technique for colon mobilization. A lower midline laparotomy is used and a self-retaining abdominal wall retractor is placed. The patient is placed in Trendelenburg position, and the small bowel is packed away from the field. Mobilization of the left colon is then typically performed in a lateral to medial fashion (though some surgeons still prefer medial to lateral), beginning with incision of the white line of Toldt in the left paracolic gutter with medial traction on the colon. This exposes the alveolar plane between the mesocolon and the retroperitoneum, and dissection proceeds medially, revealing the ureter, gonadal vessels, and hypogastric nerves. The medial peritoneal leaflet is opened, the superior rectal artery is ligated proximally, and the mesocolon is divided up to the intended colon transection site, where a stapling device is used. The rectal dissection is performed on identical principles, facilitated by frequently adjusted retraction using St. Mark’s or Heald retractors. The middle rectal pedicles are divided as above, and dissection stops at the superior edge of the levators.

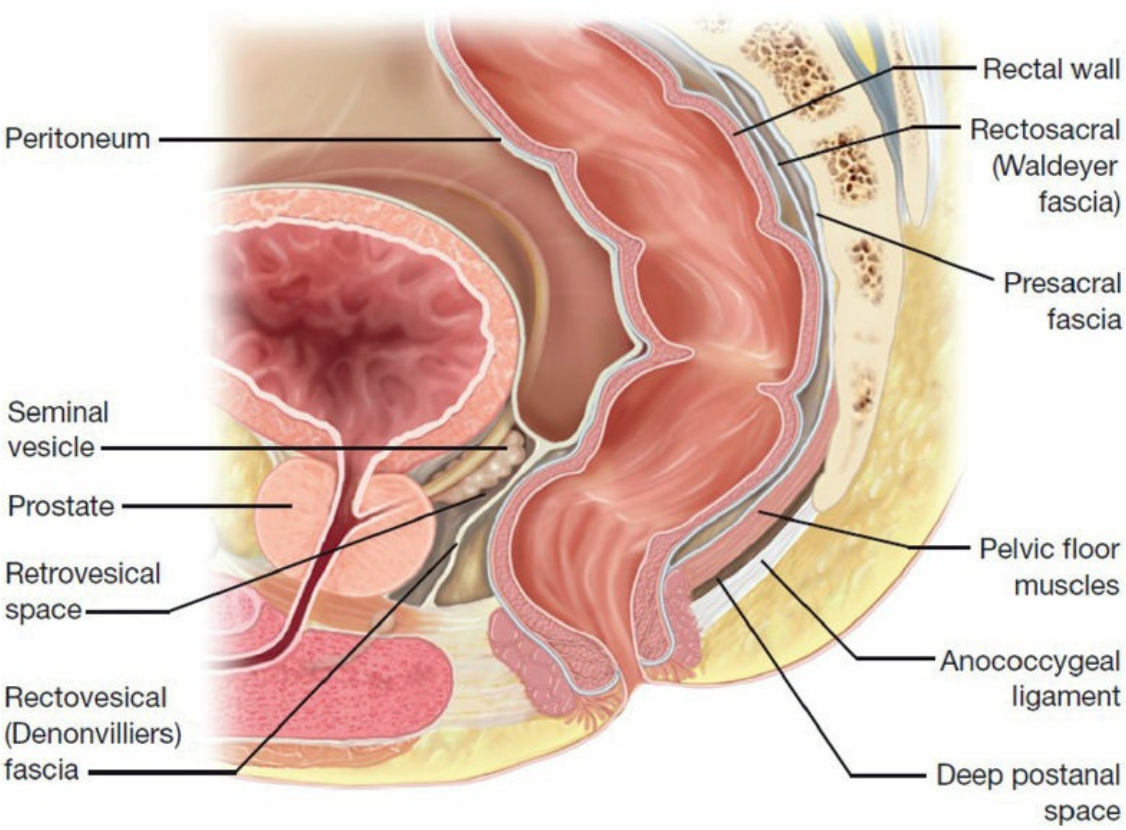

Figure 157.6. Anatomy of the low pelvis and perineum, highlighting important structures for orientation in TME and APR.

Intersphincteric Dissection

The exception in this discussion is the intersphincteric APR. As mentioned above, this approach is reserved for situations in which the tumor does not threaten the levators, but the patient is not a candidate for an anastomosis due to comorbidities or baseline incontinence. In this case, dissection in the abdominal portion of the procedure continues along the pelvic aspect of the levator muscles until the sphincter is reached. The perineal approach to dissection begins with placement of a self-retaining anal retractor (Fig. 157.8). The anoderm is incised just caudal to the intersphincteric groove, and the anal canal can then be occluded with an Allis clamp or suture. Dissection then proceeds circumferentially between the internal and external sphincter muscles in a cephalad direction and into the pelvis to join with the TME dissection plane on the superior edge of the levator muscles (Fig. 157.9). The specimen is then removed and the perineal defect is closed in layers.

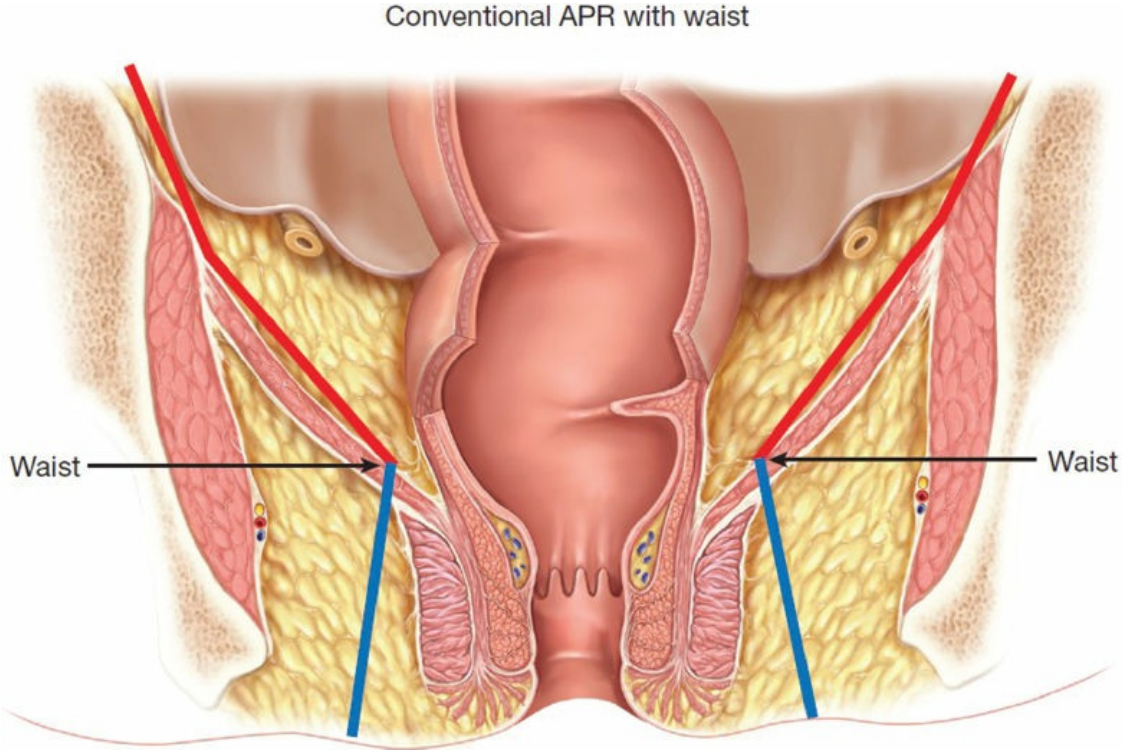

Figure 157.7. Illustration of dissection planes in conventional APR, potentially impinging upon what would be the margin for a low-lying, full thickness rectal tumor.

Extralevator Dissection Versus Conventional APR

The perineal dissection for a conventional APR begins with an elliptical incision around the anal sphincter complex, and includes dissection in a cephalad direction through the levator muscles near their medial insertions to connect with the TME dissection (Fig. 157.10). However, this may compromise the surgical margin of a low-lying rectal tumor. Consequently, an extralevator dissection is sometimes necessary to achieve a margin-negative resection of a tumor that appears on preoperative imaging or examination to threaten invasion into the levator muscles. When extralevator APR is performed, the perineal dissection begins with a circumferential perianal incision, created as an ellipse with the posterior apex over the tip of the coccyx and the anterior apex over the perineal body. The anus is closed with suture and/or Allis clamps. It is helpful to begin with the posterior dissection first, following the outer margin of the sphincter complex in the direction of the coccyx, which will be felt through the intervening fat on palpation. Dissection proceeds through the anococcygeal ligament, the distal Waldeyer fascia, and into the pelvis. Beginning in this relatively hypovascular tissue improves

subsequent exposure for lateral dissection and ultimately maximal mobility for retraction of the distal rectum and sphincter complex when dissecting away from the prostate or vagina. A self-retaining retractor is placed, and frequently adjusted to maintain outward traction on the circumferential edges. Countertraction away from this is provided by the nondominant hand; this places the intended dissection plane on tension laterally and allows dissection on the outer border of the sphincter complex and levator muscles in a cephalad direction until the lateral edges of the levator muscles are reached. The levator muscles are divided at the level corresponding to the distal extent of the pelvic dissection. Once the posterior and lateral dissections are complete, the distal end of the specimen is grasped with the nondominant hand and traction in a cephalad and posterior direction exposes the plane for anterior dissection. It must be noted that the membranous portion of the male urethra can be pulled into the path of dissection at this point, and dissection must proceed with caution until the posterior surface of the prostate is revealed. Cephalad dissection then continues just away from the posterior surface of the prostate, to avoid troublesome bleeding or parasympathetic nerve injury. In the female patient, dissection away from the posterior wall of the vagina is performed, except in the case where the tumor is adherent to the vaginal wall. In this situation, the posterior wall of the vagina is resected en bloc with the specimen, and the vagina is repaired with interrupted sutures. Once the distal specimen has been circumferentially freed, it can then be removed and careful attention paid to hemostasis.

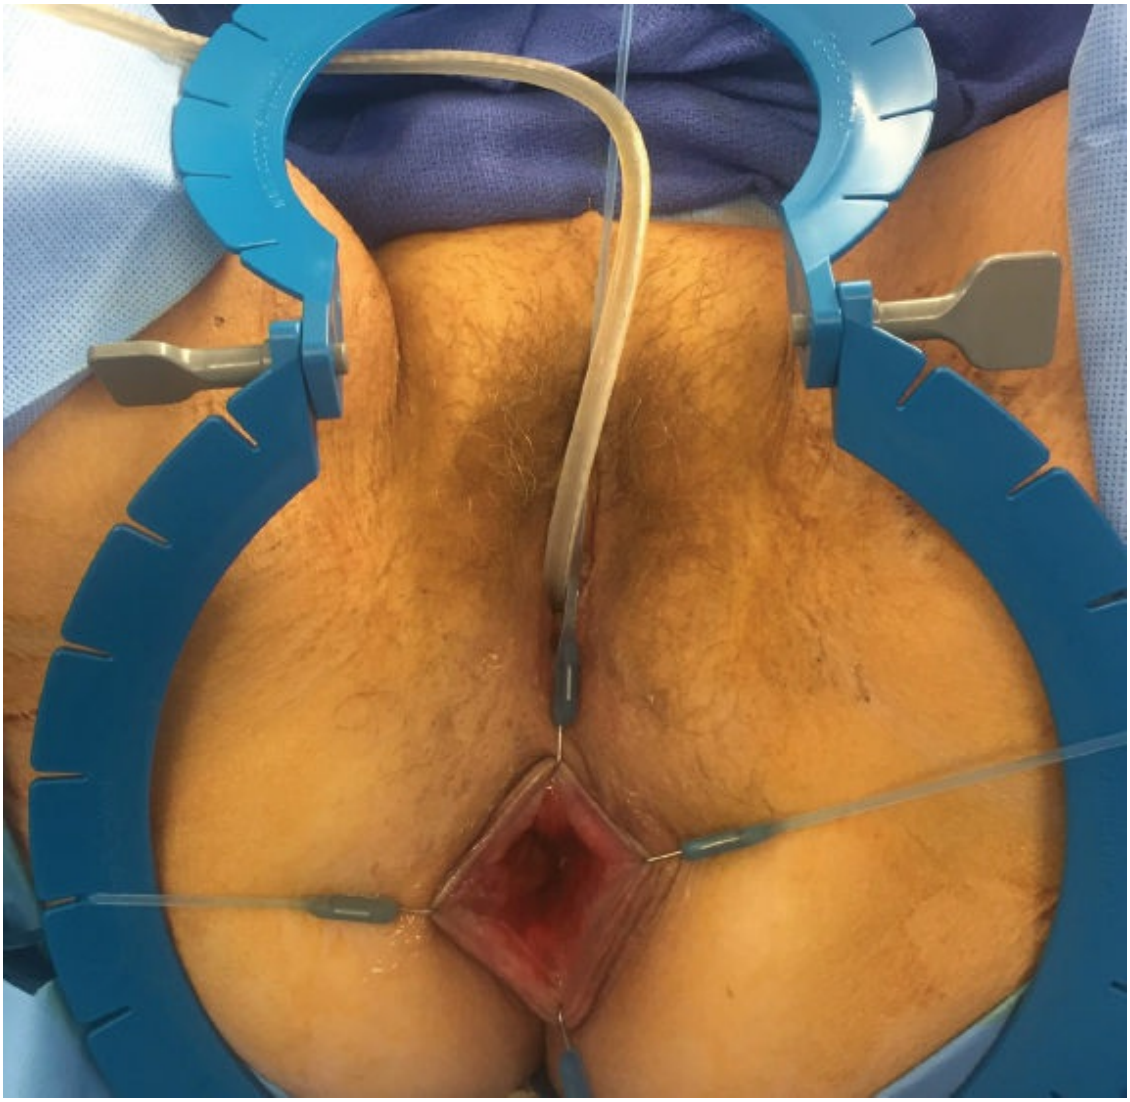

Figure 157.8. A self-retaining retractor (Lone Star®) in place for intersphincteric dissection.

Ischioanal Dissection

Ischioanal dissection entails maximal clearance of the perirectal and perineal tissues, and is similar to the original Miles operation in terms of tissues included in the specimen. The incision created can be similar to that for extralevator dissection, except in cases of perianal fistulas or tumor invasion. In this situation, the incision should include any affected perianal skin with a margin of at least 2 cm. The anus is closed and a self-retaining retractor is placed, with periodic adjustments often necessary to maintain appropriate traction and countertraction on the tissues for dissection. Dissection begins posteriorly toward the coccyx and through the distal Waldeyer fascia into the pelvis, then is directed laterally toward the ischial tuberosities. The fascia of the internal obturator muscle is exposed, and

followed superiorly (Fig. 157.11). Depending on the size, laterality, and local invasiveness of the tumor, an ischioanal dissection may be necessary only on one side, while an extralevator dissection may be performed contralaterally. The anterior dissection is performed in the same fashion as the extralevator approach described above, and the specimen is removed.

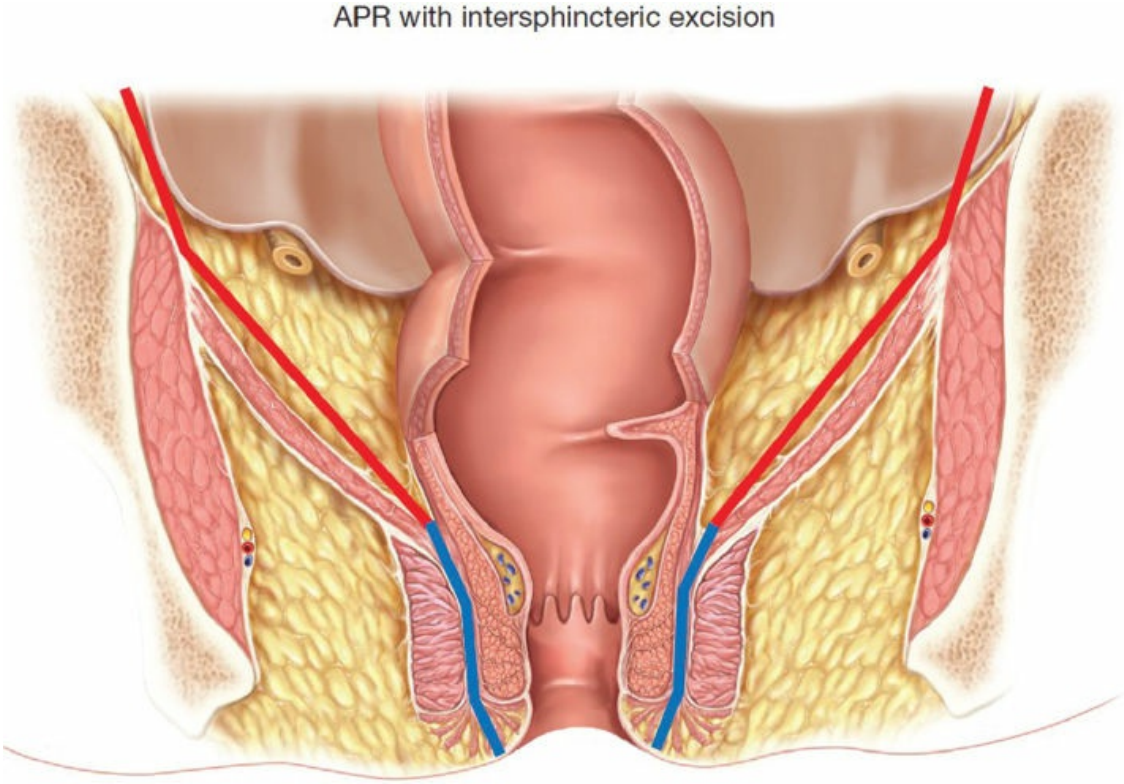

Figure 157.9. Illustration of the planes for intersphincteric dissection in APR.

Management of the Perineal Wound

Reconstruction options depend upon the patient's anatomy and body habitus, preoperative radiation exposure, and the extent of resection. In some cases, a primary repair will be possible, especially in intersphincteric APR or in cases where a tumor is lateral and some of the levator ani complex on the contralateral side can be preserved and used for closure. In many cases, however, a primary closure would result in undue tension on the suture lines, and dehiscence is a common complication. When considering reconstruction for APR patients, it is important to recognize two distinct issues. There is, first of all, the defect through the pelvis and perineum, associated with the problem of a potentially high-tension closure between tissues that are tethered to contralateral bony insertions. This defect predisposes patients to fluid collections, and small bowel may

fall into the dead space, and lead to development of a perineal hernia. In addition, there is the issue of a skin closure that is prone to infection and separation, especially in patients who have undergone pelvic radiation. A well-perfused rotational flap to cover this defect appears to be associated with decreased risk of superficial wound infections. Other considerations in reconstruction include possible mesh placement at the pelvic inlet, to prevent perineal herniation and placement of closed suction drains within the pelvic defect or deep to layered closures when there is concern for postoperative hemostasis or residual or potential dead space that would predispose to fluid collection and abscess formation.

In complex situations, assistance from a plastic and reconstructive surgeon can be helpful, to perform rotational muscle flaps to fill in dead space and provide an alternative to a high-tension closure of the deep tissues and of the skin. These techniques are able to lower rates of wound complications, but carry the potential for morbidity at the donor site. Common options for rotational flaps include rectus abdominis, gracilis, or gluteus muscles. The vertical rectus abdominis myocutaneous (VRAM) flap provides a good amount of tissue bulk for filling the pelvis, and can be performed with the same exposure as that achieved in open APR, obviating the need for additional incisions and closures. In minimally invasive cases, however, the VRAM flap becomes less practical. Gracilis muscle flaps often provide relatively lower volume for filling the pelvis, although bilateral gracilis muscle flaps can be performed. An advantage of this option is the relatively lower functional morbidity of harvesting the gracilis muscles. The gluteus option can provide an adjacent source of muscle bulk for filling the defect.

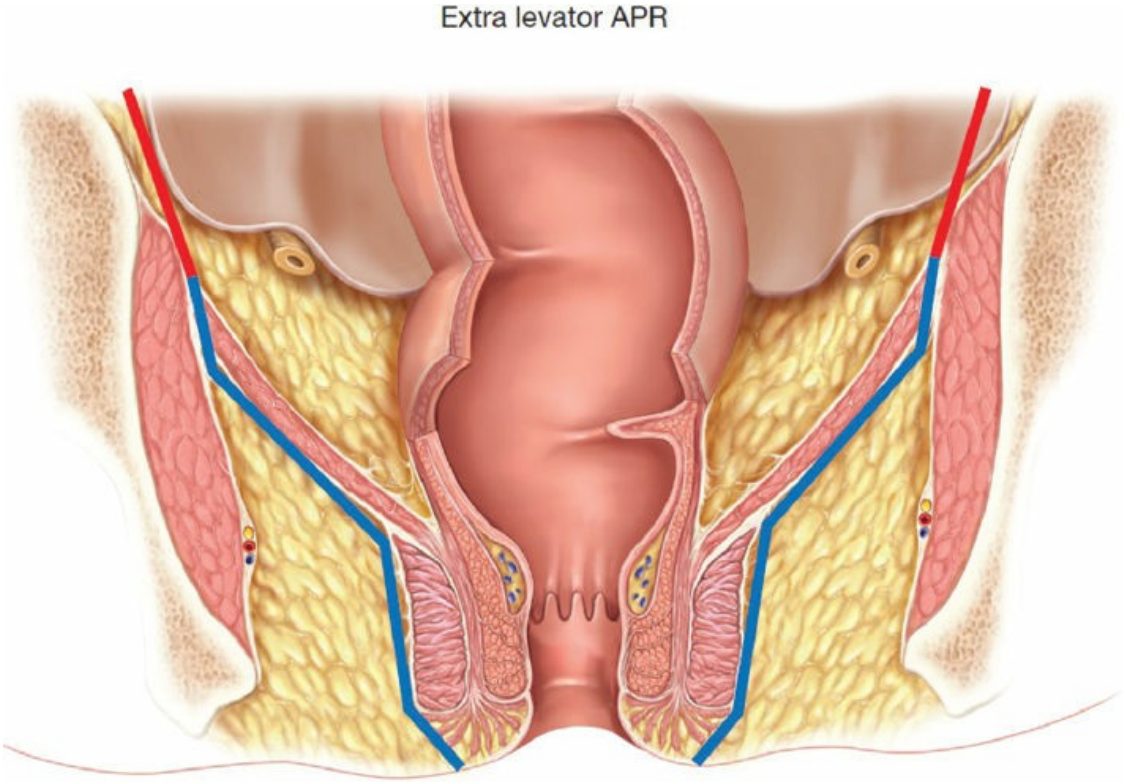

Figure 157.10. Illustration of the planes for extralevator dissection in APR.

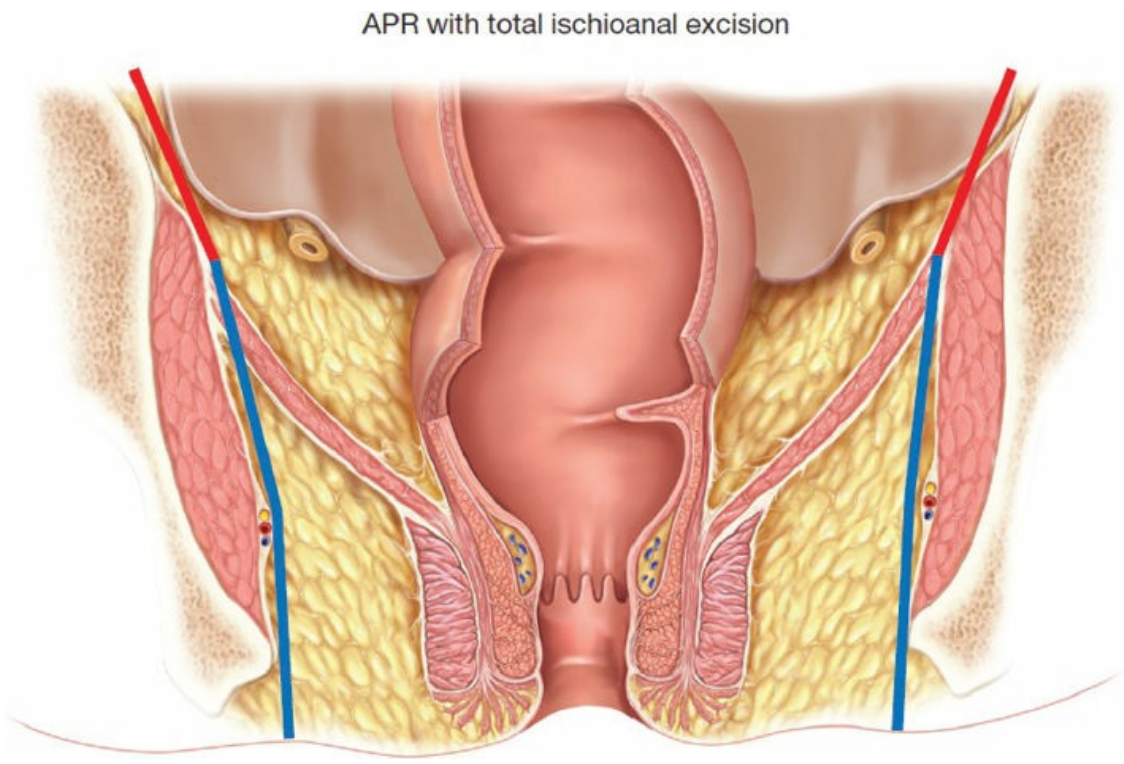

Figure 157.11. Illustration of the planes for ischioanal dissection in APR.

Figure 157.12. Final closure of a V-Y fasciocutaneous gluteal advancement flap. (Courtesy Dr. Steele and Dr. Campbell.)

In the prior edition of this text, the chapter on APR by Dr. Steele and Dr. Campbell described a fasciocutaneous V-Y flap option for closure. A V-shaped incision is made to one side of the perineal wound, carried down through the deep fascia and onto the gluteal muscle. The fascia is mobilized from the gluteus muscle with preservation of the perforators supplying the skin. The medial portion of the resulting flap is de-epithelialized and placed into the perineal defect, where it is sutured to the contralateral levator muscle. The remaining medial edge of epithelium is sutured to the contralateral wound edge, and the rest of the wound is closed with the V-Y technique (Fig. 157.12). In the female patient in whom a posterior vaginal defect has been created, epithelium can be retained on the medial portion of the flap and sutured into the posterior vaginal defect.

When a primary closure is performed, it should be constructed in multiple layers. The lateral edges of the levator muscles are approximated with interrupted or figure-of-eight stitches of 0 Vicryl or PDS. Any remaining ischioanal fat can be approximated with interrupted sutures to minimize dead space. Subcutaneous and deep dermal stitches are placed with 2-0 or 3-0 Vicryl to distribute tension as much as possible, and the skin is closed with mattress stitches, allowing enough space for fluid

drainage, if necessary.

POSTOPERATIVE CARE

Patients recovering from APR can be managed according to principles of enhanced recovery after surgery (ERAS), pioneered in the field of colorectal operations. A clear liquid diet and oral nonnarcotic analgesics are generally safe beginning immediately after recovery from the anesthetic. Early mobility and ambulation is encouraged, except in cases where complex flap reconstruction may require a period of bedrest.

COMPLICATIONS

The most common complication following APR is infection or separation of the perineal closure. Close attention should be paid to the perineum in the immediate postoperative phase to monitor for fluctuance, erythema, drainage, or skin separation. It may be necessary to judiciously remove some of the superficial sutures in cases where there is concern for undrained superficial fluid collections. When infection and dehiscence occur, management commonly includes negative pressure wound therapy in a wound that is sufficiently clean, or frequent gauze dressing changes in cases where the wound needs to be inspected at least once per day or where such dressing changes will facilitate debridement of wound exudate. In the patient with dehiscence of a primary closure, consultation with a plastic and reconstructive surgeon may be appropriate for delayed flap reconstruction of the defect.

Among patients with locally advanced rectal cancer with invasion into adjacent organs, complete or partial pelvic exenteration may be necessary. Patients treated with exenteration and even APR are at increased risk for nerve injury and resulting genitourinary dysfunction. Urinary incontinence or retention may develop, and long-term management with suprapubic catheter drainage may be necessary. Patients may also develop sexual dysfunction, including erectile dysfunction in men and loss of vaginal lubrication in women.

CONCLUSION

The management of rectal cancer is in evolution. Refinements of multimodality therapy are being researched to optimize oncologic outcomes, reduce morbidity and improve quality of life. Suboptimal care

can lead to significant morbidity, and it is therefore critical that an experienced multidisciplinary team treat patients with rectal cancer. With current understanding of the pathophysiology, and improved surgical techniques, most patients can have curative surgery with sphincter preservation. In selective cases, however, this may not achieve optimal oncologic results. While APR is one of the most morbid of operations for rectal cancer, it remains an indispensable tool in managing this disease. We continue to look for ways to reduce the morbidity through minimally invasive techniques, optimal perineal wound management, and preservation of genitourinary function. When performed with meticulous attention to the anatomy and to surgical planning for the achievement of a margin-negative resection, it can be accomplished with both good functional and oncologic outcomes.

EDITOR'S COMMENT

If skin cancer is excluded, colorectal cancer is the third most common cancer diagnosed in both men and women in the United States. The American Cancer Society's estimates for the number of colorectal cancer cases in the United States for 2017 are 95,520 new cases of colon cancer and 39,910 new cases of rectal cancer. Overall, the lifetime risk of developing colorectal cancer is: about 1 in 21 (4.7%) for men and 1 in 23 (4.4%) for women. Colorectal cancer is the

third leading cause of cancer-related deaths in women in the United States and the second leading cause in men. It is expected to cause about 50,260 deaths during 2017. The death rate (the number of deaths per 100,000 people per year) from colorectal cancer has been dropping in both men and women for several decades. This is likely multifactorial and related to increased screening and improved treatment. As a result, there are now more than 1 million survivors of colorectal cancer in the United States.

One of the most interesting parts about AP resection to me is how infrequently it is needed compared to 20 or more years ago given advances in low rectal resection techniques, adjuvant, and neoadjuvant therapy. In general, a 1-cm distal margin is recommended in sphincter-preserving surgery for rectal cancer. A recent systematic review of the literature identified 17 studies showing results in relation to margins of approximately less than 1 cm (948 patients) versus greater than 1 cm (4,626 patients). In most studies, pre- or postoperative radiation therapy was administered. In total, the local recurrence rate was 1.0% higher in the less than 1-cm margin group compared to the greater than 1-cm margin group (95% confidence interval [CI] –0.6 to 2.7; P = 0.175). The local recurrence for less than 5-mm distal resection margin was 1.7% higher (95% CI –1.9 to 5.3; P = 0.375). The authors of this systematic review designed to evaluate the impact of distal resection margin on local recurrence in rectal cancer concluded, “In the selected group of patients, less than 1-cm distal margin did not jeopardize oncologic safety.”

Resection of low rectal cancers is a complex procedure. As outlined in this chapter, higher rates of positive circumferential resection margins and tumor rupture at the time of surgery necessitate a careful and skilled approach to these tumors. The volume–outcome relationship in surgery has been demonstrated for many complex and high-risk procedures such as esophagectomy, pancreatectomy, and abdominal aortic aneurysm repair. It’s no surprise that a volume–outcome relationship is apparent in rectal cancer resection. A retrospective population-based cohort study utilizing the Surveillance, Epidemiology and End Results (SEER)-Medicare linked database identified 2,815 rectal cancer patients aged 65 and older who had surgery for a primary tumor diagnosed in 1992–1996 in a SEER area. Hospital- and surgeon-specific procedure volume was determined as well as mortality at 30 days and 2 years, overall survival, and the rate of abdominoperineal resections. Neither hospital nor surgeon-specific procedure volume was significantly associated with 30-day postoperative mortality or rates of rectal sphincter-sparing operations. Surgeon-specific volume was associated with 2-year mortality and remained an important predictor even after adjustment for hospital volume. Surgeon volume was also better than hospital procedure volume at predicting long-term survival. Another study evaluating more recent data identified 47,000 patients from the Nationwide Inpatient Sample who underwent surgery for rectal cancer from 1988 to 2006. Univariate analysis was used to identify patient and hospital factors associated with sphincter preservation. In this analysis, the overall rates

of sphincter preservation were consistently higher in high-volume and urban hospitals, and among patients who are female, white, and younger. A Cochrane systematic review examined surgeon caseload and specialization on outcomes after colorectal cancer surgery. For rectal cancer, there was a significant association between high-volume hospitals and improved 5-year survival but not with operative mortality. Higher hospital volume was associated with significantly lower rates of permanent stomas and APR.

High-volume surgeons and specialists also achieved lower rates of permanent stoma formation. For low rectal cancers, referral to a high-volume specialist is appropriate.

As discussed toward the end of this chapter, in patients with locally advanced primary or recurrent rectal cancer, pelvic exenteration may be offered. A systematic review on this topic included a total of 23 studies with 1,049 patients. The complication rates for pelvic exenteration ranged from 37% to 100% (median, 57%) and the perioperative mortality rate ranged from 0% to 25% (median, 2.2%). The rate of local recurrence ranged from 4.8% to 61% (median, 22%). The median survival for primary advanced rectal cancers was 14 to 93 months (median, 35.5 months) and 8 to 38 months (median, 24 months) for locally recurrent rectal cancer. Based on this review, the authors conclude "*Although the human costs and risks are significant, the potentially favorable survival outcomes make this acceptable in the absence of other effective treatment modalities that would otherwise result in debilitating symptoms that afflict patients who have advanced pelvic malignancy.*"

The concept of Enhanced Recovery after Surgery (ERAS) pathways in colorectal surgery patients is covered briefly in this chapter. The international, multicenter ERAS registry data were reviewed (2008–2013) to examine the impact of compliance with different parts of an ERAS bundle on outcomes. A total of 1,509 colonic and 843 rectal resections were undertaken in 13 centers from 6 countries. Median length of stay for colorectal resections was 6 days, with readmissions in 9.2%, complications in 40%, and reoperation in 7.1% of patients. Laparoscopic surgery was associated with reduced complications and length of stay. Increasing ERAS compliance was correlated with fewer complications and shorter primary hospital admission. Shorter hospital stay was associated with preoperative carbohydrate and fluid loading, and totally intravenous anesthesia. Longer stay was associated with intraoperative epidural analgesia. Reduced postoperative complications were associated with restrictive perioperative intravenous fluids. We've come a long way from the era when I was a resident 20 years ago when all patients were NPO after midnight, had an epidural placed preoperatively, a nasogastric tube until they passed gas, and a gradual progression from clear liquids, to full liquids, to a general diet over a course of several days.

Dr. Nurkin and colleagues have written an excellent description of the technical details regarding abdominoperineal resection for rectal cancer. The descriptions and accompanying illustrations of the intersphincteric resection,

extralevator, and ischioanal resection techniques are especially informative. This is a great chapter for residents and surgeons who perform rectal resections for cancer.

158 The Approach to Reoperative Pelvic Surgery in Rectal Cancer

J. Joshua Smith and Jose G. Guillem

ETIOLOGY AND PATHOPHYSIOLOGY

In spite of significant improvement in neoadjuvant and surgical treatment for primary rectal cancer over the past 20 years (e.g., chemotherapy, radiation, and adherence to the surgical principles of total mesorectal excision [TME]), a 5% to 10% rate of local recurrence remains. Local recurrence rates vary by center—ours is <3% over a 5-year period (unpublished data). Possible explanations for local recurrence include inadequate surgical technique in completeness of TME, circumferential margin positivity, and rectal tumors located at <5 cm from the anal verge. Management of a local recurrence in the pelvis is important as it directly impacts patient quality of life and survival. We define local recurrence as tumor in the true pelvis, including the neorectum, associated mesentery, pelvic sidewall, pelvic viscera, neurovasculature, and adjacent bony anatomy (see Fig. 158.1 for examples). We have observed that 50% of the patients who recur are resectable, and are candidates for an R0 resection. This is important as we have noted median disease-free survival (DFS) and disease-specific survival (DSS) following an R0 resection is 31 and 66 months (DFS and DSS respectively) versus 8 and 23 months (DFS and DSS, respectively) for R1 or R2 resections. The Mayo experience demonstrated a 5-year survival of 37% in patients undergoing R0 resection for recurrent rectal cancer compared to 16% in those undergoing an R1 resection. A recent US analysis demonstrates 5-year overall survival of 50% in patients undergoing R0 resection for recurrent rectal tumors versus 18% for those patients undergoing an R1 resection. Recent analyses from Europe show a similar trend in locally recurrent rectal cancer where 3- and 5-year survival rates for R0 resection were 55% and 40% while they were 42% and 16% for R1 resections. These data suggest that inability to achieve an R0 resection is associated with very poor long-term survival.

When the goal is an R0 resection, the patient must be carefully selected

using a combination of factors in the decision-making process to operate including history, symptoms, physical exam, and radiologic images to delineate the anatomy. It is important that rectal MRI is used and that the imaging capture the entire pelvis. Multiple radiographic means have been studied to determine the best method of detection. It is beyond the scope of this chapter to cover this topic in depth, but the basics will be mentioned. Our current approach is to obtain a good quality computed tomography (CT) chest, abdomen, and pelvis followed by a dedicated magnetic resonance imaging (MRI) of the rectum/pelvis for characterizing local anatomy and to determine resectability.

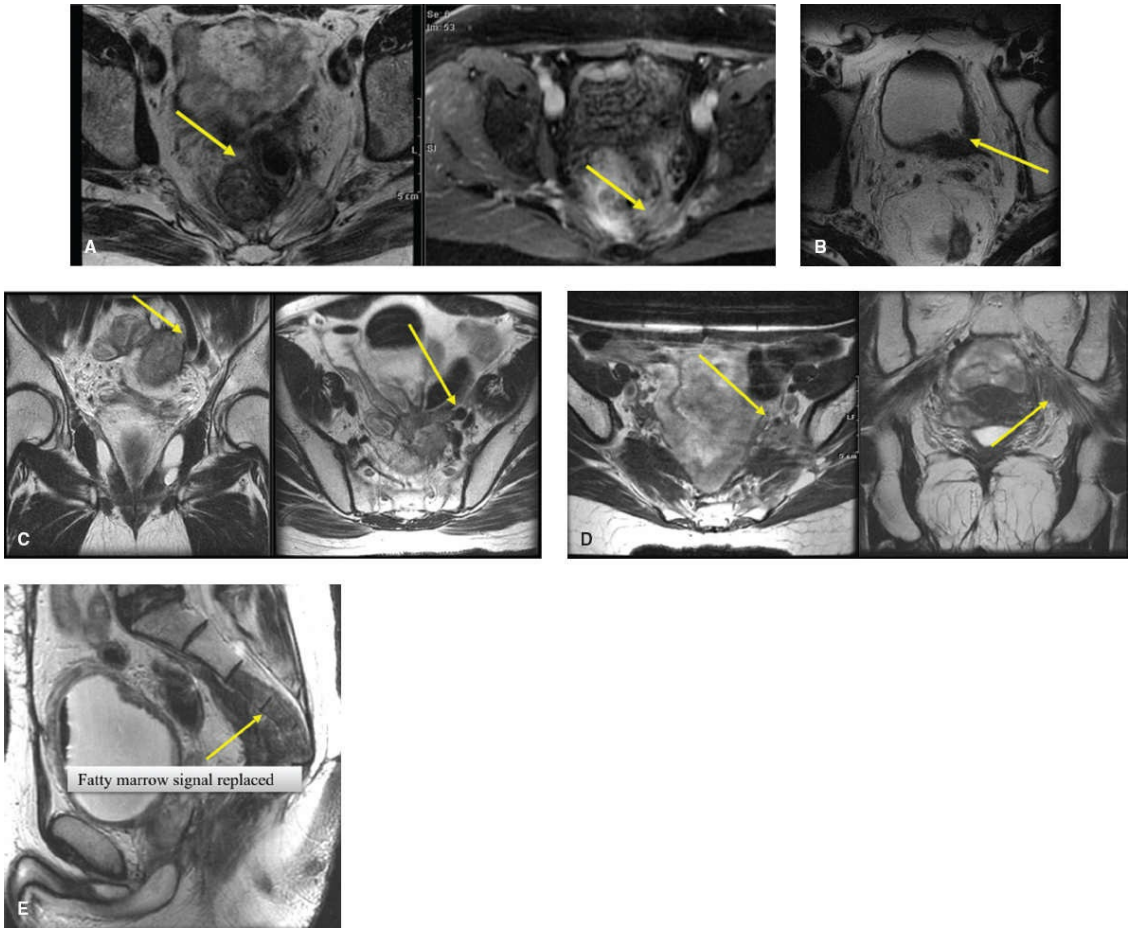

Figure 158.1. MRI examples demonstrating the spectrum of structures that can be implicated in rectal cancer recurrence. Shown are MRI examples of local recurrence involving the (**A**) neorectum, (**B**) the bladder, (**C**) the external iliac artery, (**D**) the sciatic nerve, and (**E**) the sacrum. All views are T2 and axial. (Images courtesy of M. Gollub, MD.)

Considering the clinical outcomes after surgical resection for recurrent rectal cancer, review of a database of 634 patients undergoing resection for recurrent rectal cancer between 1990 and 2000 to determine predictors of survival after surgery and intraoperative radiation therapy (IORT) yielded 111 patients. Of these, 100 patients had substantive follow-up and had undergone surgical resection and IORT. Clinicopathologic variables were assessed and only complete resection with microscopically negative margins and the absence of vascular invasion in the recurrent specimen predicted improved outcomes as indicated above (better DFS, DSS, and local control). In a UK study of 119 patients brought to the operating room for IORT and planned complete resection of locally recurrent colon and rectal cancer between 1994 and 2000, an R0 resection was achieved in 61

patients. These patients were then compared to those who underwent R1, R2, or palliative procedures (*n* = 38, 7, and 13, respectively). Of note, when recurrence was axial only or axial and anterior, then R0 was achieved more often than recurrences in other locations. Especially notable were the lateral recurrences, which were significantly less likely to be associated with an R0 resection. In light of these findings, relative contraindications to surgical resection of rectal cancer recurrence in the pelvis are sciatic pain and/or lateral recurrence versus central recurrence. Palliative resections can be contemplated for symptomatic recurrence even with metastatic disease as long as a safe diversion approach can be planned.

CLINICAL PRESENTATION

It is well known that local recurrence rates have markedly decreased (historical rates of 25% to 30% vs. more recent rates of <10% in randomized trials) due to better multi-modality treatments including TME; however, patients still present with both local and distant recurrences within 2 years of surgical resection of the primary tumor. Patients who present with recurrent disease have a variety of complaints. The most common complaints include pelvic pain, sciatic irritation, bowel and/or bladder dysfunction. The patient should undergo a full work-up led by the surgeon, including complete history and physical examination, restaging via CT chest, abdomen and pelvis in addition to an MRI of the rectum and/or pelvis depending on anatomical region of interest. These studies will help determine the likelihood of an R0 resection. Once all of the data are in hand, we recommend discussion of these cases in a disease-management team (DMT) setting to allow all relevant disciplines an opportunity to optimize the care of the patient.

INDICATIONS AND CONTRAINDICATIONS

Each patient must be willing to undergo an extensive operation that may require prolonged recovery, decrease in functional status, and post-operative complications. Patients with poor baseline function, low motivation, or with significant burden of comorbidities may not be the best candidates for a pelvic recurrence operation. Relative contraindications for surgical salvage include advanced distant metastases, multifocal disease in the pelvis, and upper sacral invasion or vascular encasement in the setting of unresectable distant disease.

PREOPERATIVE CONSIDERATIONS

Given the complexity of clinical presentation, extent of disease, and multimodality therapeutic options, it should be reiterated that the patient with recurrent rectal cancer is best discussed in a multidisciplinary DMT. Regarding radiation therapy, if a patient has been previously radiated, additional preoperative radiation may or may not be advantageous. However, if no prior pelvic radiation, then preoperative chemoradiation is appropriate. Use of IORT is usually reserved in our hands for recurrent disease (e.g., local failure after multimodality treatment and low anterior resection [LAR]) and can be combined with an abdominoperineal resection (APR) or an exenteration if surgical margins are a concern. In unique situations where an R0 resection seems unlikely and external beam radiotherapy is no longer an option, systemic chemotherapy may be considered preoperatively in carefully selected cases.

Preoperative planning aims to assess likelihood of an R0 resection and the need for en bloc resection, involved organs, and need for additional surgical expertise in resection or reconstruction (e.g., urology, gynecology, vascular, orthopedics, neurosurgery, and plastics). For example, in a redo LAR or an APR, the seminal vesicles or the pelvic ureter could be compromised (see Fig. 158.2), and in an anterior exenteration, the bladder or iliac vessels could necessitate sacrifice and need for subsequent reconstruction or revascularization. Recurrence in a woman with a prior hysterectomy usually requires an exenteration as the bladder is typically involved and must be resected en bloc. In terms of total pelvic exenteration (TPE) or need for sacral resection, multiple teams are often required to achieve an en bloc R0 resection, reconstruction, and urinary and fecal diversion. It is important that all teams that are anticipated to be involved have seen the patient preoperatively and are available on the scheduled operative date. These colleagues may include vascular surgery, plastic surgery, orthopedic surgery, urology, and radiation oncology. We recommend that an epidural for pain control be placed in the preoperative holding area. Proper site marking must be done preoperatively with a visit to the enterostomal nurse. The patient must understand that first and foremost the surgeon must adhere to *Primum non nocere* and that there might be a point during the operation where the attending surgeon decides to stop. Lastly, the expectations of all parties involved including the patient, family, and involved healthcare providers must be carefully communicated preoperatively and documented to avoid unnecessary

disappointments or unrealistic outcomes.

Another item of discussion with the patient is quality of life and expected return to activities of daily living after the operation. Most patients with recurrent rectal cancer who require external beam radiation therapy, extensive pelvic dissection, and intraoperative radiation therapy have reported poor functional and quality-of-life outcomes after sphincter preservation especially with coloanal anastomoses. Furthermore, when it comes to reconstruction, usually for cancers at 7 to 8 cm from the anal verge, restoration of continuity can be difficult even with a combined abdominopelvic approach. Therefore, even if sphincter preservation is technically achievable, it may not always be the best option for the patient given the poor functional results and quality of life that follows. As alluded to above, in the setting of unresectable disease, even a palliative diversion is helpful in maintaining some quality of life.

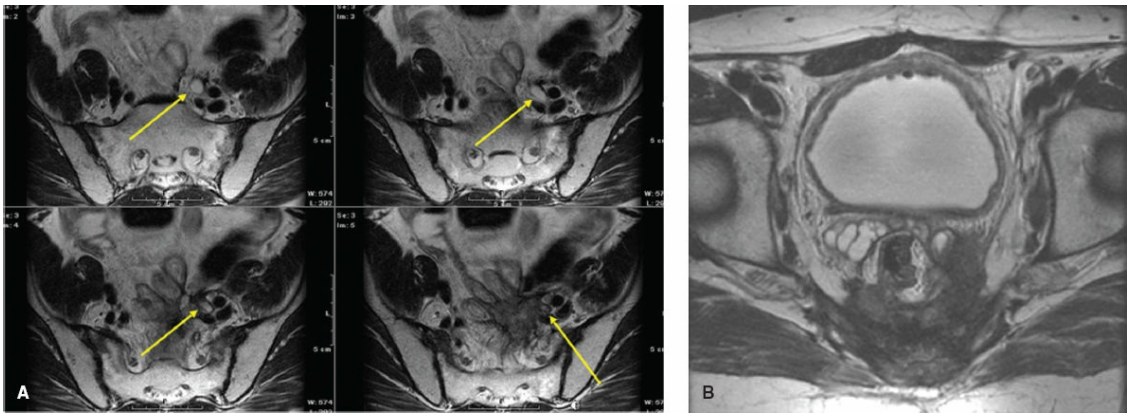

Figure 158.2. Radiographic evidence of pelvic ureter or seminal vesicle involvement by MRI. Shown are MRI examples of local recurrence involving the (**A**) ureter and the (**B**) seminal vesicles. All views are T2 and axial. (Courtesy of M. Gollub, MD.)

SURGICAL TECHNIQUE

The patient is usually placed in the Lloyd-Davis position and then moved to the prone position. In selected cases, especially those with an anteriorly based recurrence where a TPE is not planned, repositioning in the prone position for the perineal portion of the procedure enhances visualization of the anterior plane and helps secure an R0 resection. The general conduct of the operation is outlined generally in Table 158.1. Based on the level of recurrence and need for flaps (e.g., rectus abdominis vs. gracilis or the need for both), the positioning becomes critical to accommodate all teams involved. After all teams have agreed on the positioning and urology has

performed a cystoscopy and placement of bilateral ureteral stents, then the patient is explored and a determination of resectability is made. A small incision is made initially to rule out carcinomatosis, and then further exploration can be pursued. Diversion and restorative options are always on the mind of the experienced surgeon. To further assess resectability, we often proceed with a splenic flexure mobilization in order to get into the posterolateral spaces and to determine if an R0 resection is feasible. An axial location of the recurrence is best for optimal resectability versus a posterior or lateral recurrence or a purely perineal recurrence. An important point to reemphasize is that R0 resection in our hands was much more likely with an axial recurrence versus when a lateral component affecting the pelvic sidewall was present. It is prudent to dissect deep and posterior as far as possible then to proceed anteriorly with urologic support as needed. Movement into the lateral planes is usually reserved for the latter portion of the operation, but space-specific approaches can be tailored according to the recurrence location. Indications for vascular sacrifice may include local tumor invasion and/or dense tumor abutment in the absence of distant metastatic disease. The colorectal surgeon must be prepared to take the external iliac and the common iliac if necessary.

TABLE 158.1 Conduct of the Operation in the Setting of Recurrent Rectal Cancer

2. Cystoscope and urethral stent placement
3. Skin preparation
4. Limited exploration to rule out carcinomatosis
5. Extend the incision
6. Mobilize the colon as necessary (e.g., splenic flexure)
7. Determine resectability
8. Determine diversion or restorative options
9. Call in surgical colleagues/ consultants
10. Intraoperative radiation therapy
11. Reconstruction, flap coverage, and closure

The indications for a sacrectomy are institution-dependent due to local expertise and skill. Resection of a part or the entire sacrum is sometimes required in order for the surgeon to obtain clear posterior margins where the tumor is invading or abutting the sacral bone. In many centers, sacral invasion is a contraindication to surgical resection, but there are some data to suggest that pelvic exenteration with sacrectomy in the management of recurrent rectal cancer is increasing with respectable results. S1, S2, and S3 can be sacrificed, but when anticipated preoperatively the sequelae of taking these nerves should be clearly discussed with the patient. To be specific, S1 sacrifice can lead to difficulties in ankle flexion. S2 and S3 are usually taken only unilaterally as bilateral sacrifice can lead to fecal and urinary incontinence and possible sexual dysfunction. In the case of TPE, this is less of an issue as the rectum and bladder are resected with upstream diversion via colostomy and ileal conduit. Bilateral sacrifice of S4 is associated with impotence for males.

A word of caution should be emphasized for the conduct of the operation: do not burn bridges. For example, in the case where a restorative resection is planned and desired by the patient, do not transect the bowel until you are certain that there are ample length and adequate vascular supply to redo an anastomosis. Similarly when a mucus fistula is

planned, ample length of the distal limb is required to avoid rectal stump dehiscence. It is best to remove the seminal vesicles en bloc and to determine the level of ureteral transection if need be with the urologist's input once en bloc resection is thought to be prudent. Another pearl of wisdom is careful attention to prior anastomoses while honoring oncologic principles. For example, do not apply excess traction on anastomotic limbs from prior resections as this may disrupt the anastomosis and result in intraoperative fecal and/or tumor contamination. In addition, try to accomplish as much mobilization as possible from the abdominopelvic region prior to moving toward the perineal portion of the resection. Liberal consultation with the displayed preoperative imaging is encouraged, and continual reassessment of the anatomy is the key to success. As the late, Lahey Clinic Master Colorectal Surgeon, Dr. Malcolm C. Veidenheimer would say, "Do the easy portions first." If the patient underwent an inadequate TME during the initial resection, there might be an opportunity to enter a "virginal plane." Unfortunately, this is not always the case, and the surgeon should review the prior operative reports and discuss the case with the prior surgeon whenever possible.

Use of IORT should be considered when the margins might be close in an area not amenable to safe resection. IORT is thought to help eradicate microscopic tumor cells within a few millimeters of the final resection margin. Clearly the appropriate infrastructure has to be in place for IORT to be administered safely, and we use a specially designed and dedicated operating room suite for this purpose. When a complete resection with negative margins can be achieved along with use of IORT following preoperative external beam radiation therapy, improved outcomes can be expected. These data underscore the importance of approaching the patient with the clear purpose of performing a complete resection and procuring microscopically negative margins.

Following a major pelvic or en bloc resection, there is often the need to fill the space to avoid complications of bowel incarceration and deep space fluid collections with resultant infection and to promote optimal healing conditions. Anatomical structures that can be readily used to fill this space include the uterus, a pedicled omental flap, or a myocutaneous flap. If the patient has received prior pelvic radiation in the distant past with a long interval to the planned surgical intervention (>6 months), the delivery of nonradiated tissue into the field also promotes robust wound healing and decreases the incidence of perineal wound complications without

adversely affecting abdominal incisional hernia rates. If a partial or total vaginectomy is anticipated, this should be discussed preoperatively and reconstruction options reviewed with plastic surgery colleagues. Another population in which to consider a flap would be elderly female patients who are at increased risk for urethral obstruction from posterior contraction, scar, or irregular urethral angulation following a posterior vaginectomy.

When determining optimal wound coverage options, the principle of opposing nonradiated, well-vascularized tissue without tension is central to proper healing and minimizing the risk of a surgical site infection and wound dehiscence. Oftentimes, use of a well-placed myocutaneous flap abides by this principle. In review of the literature, it appears that there is an association with less wound complications and better outcomes when flaps are utilized (see Table 158.2). Although there may be exceptions, in general, rates of wound complications are threefold more common with primary closure versus with myocutaneous flap reconstruction. Review of the literature indicates no level I data, but limited, nonrandomized studies support flap reconstruction instead of primary closure of perineal wounds after APR especially in cases where the pelvis has been previously irradiated in the distant past (>6-month interval). Although studies do not provide definitive evidence favoring one type of flap over the other (e.g., gracilis vs. rectus abdominus vs. V-Y myocutaneous gluteal flap), we and others prefer using a rectus abdominis flap. This is especially the case when filling large surgical defects such as those left behind when performing a TPE.

TABLE 158.2 Primary Versus Myocutaneous Flap Coverage of the Resultant Perineal Defect in APR or TPE Cases

Study	*N*	Patient Groups	Design	Primary Versus Flap Wound Complication Rate	Conclusion; Supports Use of Flap?
Radice, *Br J Surg* 1999 PMID 10201777	57	20 primary + 24 omental + 13 flap	Prospective cohort	15 vs. 21 vs. 0% (n.s.)	Yes (variable time period)
Shibata, *Ann Surg One* 1999 PMID 10030413	40	24 primary + 16 flap (gracilis)	Case-control	46 vs. 12% ($p = 0.03$)	Yes (variable preop XRT)
Chessin, *Ann Surg One* 2005 PMID 15827789	78	59 primary + 19 flap (VRAM), all preop XRT	Prospective cohort	44 vs. 16% ($p = 0.03$)	Yes
Persichetti, *Ann Plast Surg* 2007 PMID 17667411	35	25 primary + 10 flap (gracilis)	Case-control	10 vs. 0% ($p = 0.03$)	Yes
Butler, *JACS* 2008 PMID 18387476	111	76 primary + 35 flap (VRAM), all preop XRT	Case-control	30 vs. 9% ($p = 0.01$)	Yes
Lefevre, *Ann Surg* 2009 PMID 19801930	95	27 primary + 42 flap (VRAM)	Case-control	17 vs. 26% (n.s.); dehiscence 12 vs. 0% ($p = 0.02$)	Equivocal but less dehiscence
Chan, *Colorec Dis* 2010 PMID 19341404	51	21 primary + 30 flap (24 VRAM, 6 gracilis)	Prospective cohort	14 vs. 17% (n.s.)	Equivocal but variable application of RT

The table shows multiple studies indicating the rates of wound infection or dehiscence after either flap or primary closure in APR, TPE, or recurrent rectal cases requiring tissue coverage. References and PubMed Identifiers (PMIDs) are displayed.

POSTOPERATIVE CARE

The care of the patient undergoing major pelvic reoperative surgery and reconstruction of the perineum for a recurrent rectal cancer is complex and requires special and precise planning and attention. First, a special bed should be used to minimize pressure points and to promote comfortable repositioning for the patient and ease of use by the nursing staff. Next, we do not permit sitting for 6 weeks. We employ aggressive physical and occupational therapy from the first postoperative days as long as it does not jeopardize flap reconstruction wound integrity. We liberally use drains and keep them in place until they are nearly dry. Meticulous care of the wounds should be a priority, and we use negative pressure vacuum dressings on the surface of the wound. In diabetic patients and/or those with >3 cm of subcutaneous fat, we generally leave perineal sutures in place for at least 3 to 4 weeks and remove them once the wound is "crusty."

Multidisciplinary care is instituted right away and involves nursing staff, physician staff, enterostomal nurses, physical and occupational therapists and case managers.

COMPLICATIONS, MANAGEMENT, AND OUTCOMES

Mortality after recurrent rectal cancer surgical intervention is <10% in most modern series while rates as high as 30% have been quoted. In our own institutional experience, operative mortality is <1%. Refined surgical technique and enhanced multidisciplinary care improve outcomes.

However, most patients face some sort of morbidity after the operation and a majority of these problems are due to wound issues in the reoperative/radiated pelvis. One of the most feared complications is dehiscence of the perineal wound and/or flap necrosis after a complex tumor resection and reconstruction with a myocutaneous flap. Patients at increased risk have the following characteristics: obesity, diabetes, malnutrition (e.g., hypoalbuminemia, cachexia), active smoking, corticosteroid usage, and history of prior radiation therapy. In our series of 55 patients undergoing TPE, we noted a 40% perineal wound infection rate and 20% rate of grades 3 to 5 abscesses. A series of 90 patients from Denmark with rectal cancer s/p TPE noted a 20% wound infection rate, 7% intra-abdominal abscess rate, and flap necrosis in 5% with <5% "wound rupture" rates. A recent NSQIP review of >7,000 patients noted 303 patients undergoing TPE and noted a 29% wound complication rate and a 3% rate of wound disruption. In addition, predictors of SSI in pelvic exenteration, APR, or LAR included the following: obesity (1.43 adjusted OR [1.23 to 1.67]), diabetes mellitus (1.24 adjusted OR [1.02 to 1.51]), pelvic exenteration versus APR/LAR (1.23 adjusted OR [1.03 to 1.71]), return to the OR (4.99 adjusted OR [4.02 to 6.19]), or OR duration >4 hours (1.34 adjusted OR [1.15 to 1.55]). In addition, other significant factors associated with SSI were male sex, disseminated cancer, pulmonary disease, and serum albumin.

General surgical principles apply and include early recognition of wound breakdown and aggressive treatment in the operating room to obtain the best exposure and to maximize patient comfort. Recently, we have had good experience with early use of negative pressure vacuum therapy. Creative use of wound sponges, topical dressings, and skin protectant agents must be employed. Even the most difficult of wounds (see Fig. 158.3) can be managed and brought to a reasonable end with diligence, patience, and careful attention to patient nutrition, positioning, and comorbidity management (see Fig. 158.3). This patient had a number of the aforementioned risk factors (e.g., obese, diabetic, prior irradiation for cervical cancer), and in spite of the use of a well-vascularized flap, the patient experienced wound dehiscence and the need for wound salvage. Additional potential complications include pelvic DVT, deep space infections amenable to IR drainage or requiring operative washout, postoperative bleeding or excessively poor bowel or bladder function necessitating proximal bowel diversion, or decompression of the urinary

system.

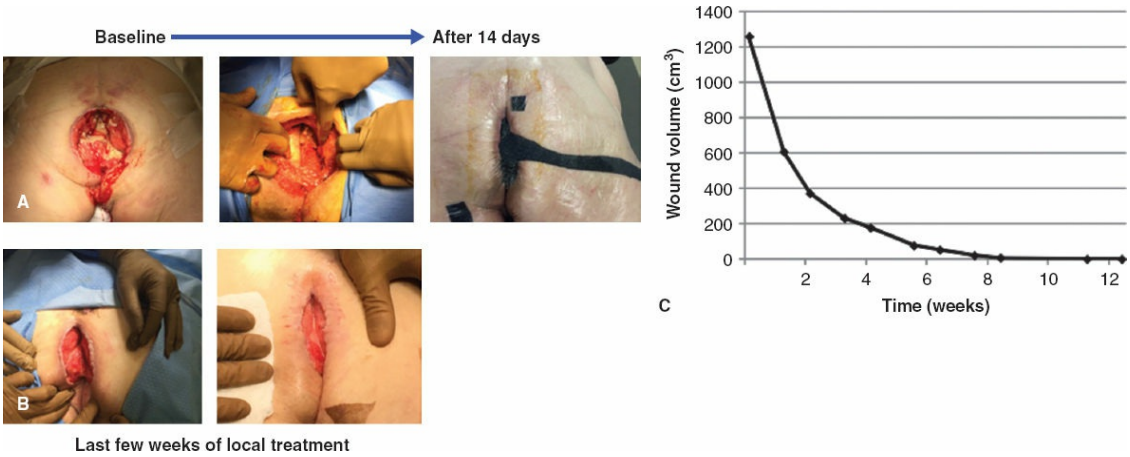

Figure 158.3. Pelvic wound dehiscence and final outcome after judicious multidisciplinary management. **A.** Shown is a patient in the prone position. The patient is s/p TPE with wound dehiscence 2 weeks postdischarge. The patient is an obese, diabetic woman with history of irradiation for cervical cancer prior to diagnosis of rectal cancer. Initial wound status upon diagnosis of dehiscence is shown followed by two photographs of progress over the first 2 weeks with serial debridement, washout, and negative pressure dressing changes. **B.** Wound status is shown after several treatments and at approximately 1 week prior to discharge home with local wound care only. **C.** The wound volume reduction over time is shown with the use of a negative pressure dressing system with irrigation features (used in the early 3- to 4-week phase).

SUMMARY

Reoperative pelvic surgery in rectal cancer is complex; requires seasoned surgical judgment; demands multidisciplinary contributions; and makes exacting demands on the surgeon, hospital, and patient. In a well-equipped center that can provide the necessary preoperative, intraoperative, and postoperative care, salvage surgery for recurrence can be completed safely with good outcomes. In addition, durable survival can be achieved when an R0 resection can be completed. The colorectal surgeon should expect some degree of postoperative complications in the reoperative case for recurrent rectal cancer and must be wary of critical risk factors and respond to early signs of wound infection or flap loss in order to expedite source control and subsequent healing to get the patient back to a functional status.

EDITOR'S COMMENT

Drs. Guillem and Smith describe an orderly approach to reoperation in pelvic surgery. The prospect of reoperative pelvic surgery can, however, be a daunting one. As many things with in surgery, this can be made simpler with proper preoperative planning and with an organized approach. If one has the luxury of being able to wait, much as is described in the chapter for surgery for small bowel obstruction, waiting for several months until adhesions become softer is always advisable. This will be possible if one is operating on a patient to reestablish intestinal continuity, that is, if a patient has had a previous Hartmann procedure and one is planning to close a colostomy. However, this will not be possible, if the patient has a recurrent cancer and one is treating a malignancy. One can sometimes "buy time" and facilitate the surgery by giving a patient who has *not* received prior radiation therapy, external beam radiation therapy

with a concomitant radiation sensitizing chemotherapy such as 5-fluorouracil or capecitabine. These will, in some cases, downstage the tumor and facilitate subsequent surgery. Although encountering patients with recurrent rectal cancer who have not had prior radiation therapy is becoming less common, it is always important to determine whether or not the patients have received this type of therapy.

As the authors note, it is always vital to exclude metastatic disease before operating. In cases, elimination of pelvic disease is important even in the presence of metastatic disease. Having uncontrollable pelvic disease in my opinion is not a good option even in the presence of metastatic cancer, simply because pain control in this scenario is *extremely* difficult and surgical eradication of this is preferable. Palliative reoperative surgery may be necessary to treat fistulas or in an attempt to relieve pain, and patients must understand that the pain may or may not be relieved with surgery. It may also be performed to relieve bowel obstruction and is frequently associated with a high morbidity and mortality, and patients must be made aware of this as well. A lengthy and detailed preoperative discussion with the patient is essential (Boostrom SY, Dozois EJ. Recurrent pelvic surgery. *Surg Clin North Am* 2013;93(1):199–215). However, a recent report from a high-volume center questions the utility of performing palliative exenteration in terms of both durable palliation of symptoms and improved quality of life (Quyn AJ, Solomon MJ, Lee PM, et al. Palliative pelvic exenteration: clinical outcomes and quality of life. *Dis Colon Rectum* 2016;59(11):1005–10). This same group has reported on the usefulness of MRI in predicting an R0 resection in such reoperative cases (Brown WE, Koh CE, Badgery-Parker T, et al. Validation of MRI and surgical decision making to predict a complete resection in pelvic exenteration for recurrent rectal cancer. *Dis Colon Rectum* 2017;60(2):144–51). Sadly, the availability of good quality pelvic MRI for rectal cancer staging is something that is still not ubiquitously available in the United States.

The authors propose first making an initial incision to ensure that there is no carcinomatosis and then proceeding on with the formal operation assuming that this is not the case. One aspect the authors have not mentioned is the prospect of what to do if there is difficulty in terms of reestablishing intestinal continuity. As is referred to in the section on anatomy, in cases in which extensive left-sided colon resections have already been performed, a very useful technique is the concept of the retroileal colorectal anastomosis. This can provide for a tension-free colorectal anastomosis by leading the transverse or right colon through a defect in the mesentery adjacent to the ileocolic vessels. Another variation of this is to completely mobilize the right colon and rotate the entire right colon so that a direct end-to-end colorectal anastomosis can be fashioned. Another point, in a difficult pelvis, I have always found it easier to enter the pelvis from posteriorly in patients who have had multiple previous pelvic operations. No matter how daunting the pelvis may appear, *posteriorly* these planes are often much more supple and easier to enter than anteriorly. Also a

point to remember, in patients with very dense pelvic fibrosis, attempts to reestablish intestinal continuity will most likely lead to poor functional results due to decreased compliance of the pelvis.

One of the most important points, if not *the* most important point, in operating on these patients is the utilization of specialists. Because of significant scarring from previous radiation, as well as due to tumor involvement, it is not unusual to have to excise and reimplant ureters or to perform adjacent organ (i.e., bladder) resections, in essence anterior, posterior, or formal pelvic exenteration. With extirpative procedures, the aid of a plastic and reconstructive surgeon is essential in avoiding wound complications. This obviously has to be planned ahead of time. In facilities that do not have access to plastic surgeons, I would very strongly urge for referral of patients to facilities where this is available. The addition of flap coverage to these large wounds greatly aids in postoperative recovery and healing (Devulapalli C, Jia Wei AT, DiBiagio JR, et al. Primary versus flap closure of perineal defects following oncologic resection: a systematic review and meta-analysis. *Plast Reconstr Surg* 2016;137(5):1602–13). In patients who have previously undergone pelvic radiation therapy, there is a high rate of perineal wound breakdown; these wounds heal slowly and the use of vacuum-assisted closure devices is problematic. Such devices can be made to work very effectively. It is difficult finding nurses with the necessary skill to do this so that the vacuum seal is maintained and so that this sponge change process is not unduly painful for the patient.

With the recent increase in the use of laparoscopic surgery for rectal cancer, there also has been an increase in the use of laparoscopy in the reoperative approach to recurrent rectal cancer (Akiyoshi T, Nagata J, Nagasaki T, et al. Laparoscopic salvage lateral pelvic lymph node dissection for locally recurrent rectal cancer. *Colorectal Dis* 2015;17(10):O213–6). One concerning problem is the lack of referral of patients with recurrent pelvic disease to surgeons for timely resection and treating them with chemotherapy until the disease has progressed to an unresectable state. We need to make more of our medical oncologist colleagues aware of the leading role of surgery in the management of these patients.

As with many things in surgery, outcomes for reoperative surgery are better at high-volume centers. It is with reoperative pelvic surgery that a surgeon truly attains the “Mastery of Surgery.”

Susan Galandiuk

159 Sacral Resection for Recurrent Rectal Cancers

Peter J. Lee, Michael Solomon, and Kirk K. S. Austin

INTRODUCTION

Approximately 50% of colorectal cancers recur, but 10% of them recur only locally. Historically, patients who did not have surgery died with poor quality of life. The prognosis for inoperable recurrent rectal cancer is poor with a median survival of 9 months and 5-year survival of less than 5%.

There have been significant advances in surgical techniques allowing successful radical extended resection including sacrectomy with no mortality. The critically important advance has been the lateral pelvic dissection with ligation of the lateral pelvic vasculature, thus permitting high sacrectomies without uncontrollable hemorrhage and intraoperative mortality. The extended radical resections with sacrectomy are necessary in recurrent rectal cancer in order to achieve the principal aim of surgical oncology, clear surgical margins (R0). There is no survival difference between recurrent rectal cancer that invades the sacrum compared to those with no sacral involvement as long as R0 margins are achieved. Therefore, internationally there is increasing interest in performing sacrectomy combined with pelvic exenteration for both recurrent rectal cancer and locally advanced primary rectal cancers, which is evident in the growing number of published case series. The largest series, of 100 sacrectomies, quotes a sacrectomy rate of up to 33% of all pelvic exenterations at the RPAH, Sydney, Australia.

The consequence of radical resection is surgical morbidity. A high morbidity rate is well documented, and increases when the resection includes the sacrum, up to 70% to 80%.

The mortality rate following sacropelvic exenteration of the largest series in the 21st century is up to 3.5% and within the last 5 years (2010 to 2015) zero mortality. Complete resection margins (R0) have also been improving with R0 rates of 68% to 100%, and this translates to improved survival, 5-year survival following sacropelvic exenteration of 34% to

46%.

As a result, there has been growing interest in pelvic exenteration surgery for locally recurrent cancer, and the historic absolute contraindications to resection, such as lateral pelvic bone and high sacral invasion, are no longer contraindications. It is essential to bear in mind that despite these advancements in surgical technique and improved outcomes, pelvic exenteration is complex surgery and thus should be performed in specialized units comprising an experienced team of surgeons, anesthetists, intensive care unit staff, as well as oncologists. At the same time, the benefit and risk of morbidity must be balanced and individualized for each patient with locally recurrent rectal cancer.

ETIOLOGY AND INCIDENCE

Local recurrence can occur due to positive macroscopic and microscopic margins at the primary operation and lateral pelvic lymph node disease. Increased risk for recurrence also includes anastomotic leak and peritoneal deposit following surgery, incomplete total mesorectal excision (TME), and omitting radio-chemotherapy for locally advanced primary rectal cancer.

Ten percent of rectal cancers recur only locally, and thus it is postulated that truly locally recurrent rectal cancers are biologically different to those that disseminate. Wong and colleagues support this theory; there are two types of colonic cancers—locally active and those that have the tendency to metastasize.

It was observed that 75% to 85% of patients with locally recurrent rectal cancer recur within the first 3 years following the primary cancer surgery.

CLINICAL PRESENTATION

The clinical presentation and symptoms are related to the location and organ involvement of the pelvic recurrence. The most common symptoms include pain or referred pain, per rectal bleeding and discharge, altered bowel habit or obstruction, and tenesmus. Pain is the most common presenting symptom that is a result of sacral bone, pelvic floor, lateral pelvic wall invasion and/or neural invasion, notably the sacral nerve roots or the sciatic nerve. The latter will produce referred pain to the buttock, hamstrings, and down to sole of the foot. The recurrence can be extensive to involve organs of the anterior compartment of the pelvis, that is the

genitourinary system. When there is bladder involvement, then the symptoms are reflective of a malignant fistula, such as hematuria, dysuria, and recurrent cystitis. If the vagina is involved, then patients complain of PV discharge, bleeding, and dyspareunia.

There is a smaller group of asymptomatic patients who are diagnosed with recurrence detected by routine cancer monitoring. This includes clinical assessment and examination, an elevation of the carcinoembryonic antigen (CEA), colonoscopy, computed tomography (CT) scan, magnetic resonance imaging (MRI), and positron emission tomography (PET) scan. The latter two imaging modalities are essential prior to sacrectomy with pelvic exenteration.

PREOPERATIVE ASSESSMENT AND INVESTIGATIONS

The majority of patients would present to a pelvic exenteration multidisciplinary team with at least a CT scan and colonoscopy. All locally recurrent rectal cancer patients need to be assessed clinically and radiologically to evaluate the stage of their disease.

It is vital that all patients with locally recurrent rectal cancer are discussed and decisions made in a multidisciplinary setting with surgeons, radiation oncologists, medical oncologists, and radiation oncologists. The surgical team comprises colorectal, plastic, orthopaedic or neurosurgeons, urologists, and gynecologists. The team also includes allied health specialties, including stoma therapy, rehabilitation, nutrition, and psycho-oncology.

CLINICAL ASSESSMENT

It is important to ascertain whether the patients have had chemo-radiation at the time of their primary surgery. All patients prior to pelvic exenteration are recommended for chemo-radiation.

Examination under general anesthesia can be helpful in assessing tumor fixation and involvement of other pelvic organs. Preoperative histologic confirmation is not a prerequisite but is necessary when recurrent rectal cancer cannot be conclusively diagnosed with imaging. Biopsy of tissue, cystoscopy and transanal ultrasound are useful and can all be performed during the examination under general anesthesia.

Tumor Marker—Carcinogenic Embryonic Antigen (CEA)

CEA is commonly used as part of surveillance for recurrence. CEA is not elevated with all colorectal cancers and does not determine the extent of recurrence. Earlier studies claimed that an elevated CEA predicts a worse survival but recent studies contest this, thus CEA as a prognostic tool is not commonly implemented.

Computed Tomography

Chest, abdominal, and pelvic CT scan is the first imaging modality of choice to assess for both local and distant recurrence. With the introduction of the PET/CT scan in recent years, this is preferred and is recommended for all patients with recurrent disease.

Magnetic Resonance Imaging

MRI is vital for preoperative locoregional staging of the recurrent disease and planning for surgery. The MRI is the best imaging modality for anatomical and tumor definition. The MRI outlines accurately the tumor(s) and the extent of invasion of adjacent soft tissue and viscera, lymph nodes, vessels, nerves, muscle, and bone. MRI is well renown for the difficulty in differentiating between tumor recurrence and postoperative and postradiotherapy scar tissue, infective and inflammatory tissue. The addition of a PET/CT can be but, not always is, helpful in differentiating malignant tissue. Tissue confirmation by biopsy is then recommended.

Positron-Emission Tomography

PET scan has a high rate of accuracy in the detection of disseminated disease and thus has shown to alter the course of intervention in up to 40% of patients by demonstrating metastatic disease otherwise undetected on conventional imaging.

Limitations of PET/CT scans include difficulty detecting small-sized peritoneal disease, mucinous adenocarcinoma, and differentiating between malignancy and inflammation.

INDICATIONS AND CONTRAINDICATIONS

There are many published lists for indications and contraindications for pelvic exenteration with sacrectomy. The list of contraindications is diminishing as more series are published. A decade ago, pelvic exenteration was contraindicated for high sacral bone invasion (higher

than S2), lateral recurrence involving bone, nerves, encasement of external iliac vessels, ureteric obstruction, and para-aortic lymph node metastases. Traditionally, lateral pelvic wall recurrence was a poor prognostic indicator due to a low R0 rate, of up to only 22%.

Recently these are no longer the absolute contraindications of pelvic exenteration especially since lateral wall and sacral recurrences have been performed with significant improvement of R0 rates. Austin and Solomon reported an R0 rate of 53% with extended lateral resections, including vessels, nerve, ligaments, and bone.

External iliac vessel tumor invasion can be resected and vascular reconstruction performed to achieve R0 resection. Similarly, lateral recurrences with ureteric invasion can be resected with preoperative preparation for different reconstructive procedures undertaken. Reconstruction includes ureterectomy and reimplanttion or if necessary, radical cystectomy and a conduit. An alternative to conserving the bladder when reimplantation is not possible is performing a unilateral nephrectomy with ureterectomy.

The relative contraindications include patient comorbidities, multiple disseminated disease including peritoneal disease, and bone invasion involving above the first sacral vertebra (S1). Palliative resection is also more contentious due to extensive complications and poor survival. Conversely, if R0 resection is not possible, that is, if the planned surgery is not for curative intent, then surgery should not proceed.

Dozois recently published a small series of high sacretomies including a complete sacrectomy and fibula bone pelvic reconstruction. R0 resection was achieved in all nine patients without any mortality. This demonstrates the surgical advancements over the last decade, thus reducing the absolute contraindications for surgery.

Metastatic disease is considered by some to be a relative contraindication rather than an absolute one. There is some evidence to suggest that patients with limited and resectable metastatic disease can have a survival advantage after surgery, some even beyond 5 years. Importantly, this group of patients is highly selective for surgery and therefore represent the minority of pelvic exenteration patients.

In addition to the contraindications, the surgeon must contemplate and balance the high postoperative morbidity with the quality of life implications and patient’s choice. One in five patients in the authors’ experience will elect not to preceed to pelvic exenteration once fully

informed of the magnitude of the procedure and the expected outcomes.

Wanebo, the pioneer and advocate of pelvic exentertation, believed that the number of contraindications would diminish three decades ago when he commented “the definition of resectability has changed in the management of advanced pelvic malignancy.”

SURGERY

Wanebo, the pioneer and advocate for pelvic exenteration with sacrectomy for recurrent rectal cancer, described a two-stage procedure occurring over 3 days—the first stage in the modified Lloyd Davies position and the second stage, 2 days later, completion in the prone position.

A sacrectomy involves an abdominal and a perineal approach. The sacrectomy is performed in the either the prone or lithotomy position depending on the level of sacral transection. The level of sacrectomy also determines the necessity of myocutaneous flap reconstruction of the pelvic floor, while the extent of the tumor determines the number of pelvic organs resected. The nature of the primary colorectal cancer surgery also influences the extent of radical resection. For example, a recurrence involving the sacrum in a previous abdominoperineal resection in a male often would require sacrectomy with radical cystectomy whereas in a female, the uterus may allow preservation of the bladder. Colorectal surgeons predominantly perform the surgery, with plastic, urologic and orthopaedic or neurosurgical disciplines being involved at the appropriate time. Anesthetists and nursing staff specifically trained and experienced in complex pelvic surgery complete the theatre team. A dedicated unit is required as surgery is physically and mentally challenging and can take up to 20 hours, averaging 12 hours.

The principal goal of sacrectomy and pelvic exenteration for locally recurrent rectal cancer is to achieve an R0 resection. R0 is the single most important prognostic factor for survival. Surgery is difficult and complex as the anatomical planes are no longer the same and there are fibrous adhesions due to previous dissection, radiotherapy, and sepsis. These make identifying the margins of the recurrent tumor very difficult and challenging. Intraoperative frozen section is useful to exclude positive margins. Some units utilize intraoperative radiotherapy when there is doubt or compromise to the surgical margins.

CLASSIFICATION

Sacrectomy is divided into high and low. High sacrectomy involves transection at a level or above the junction of S2 and S3. A sacrectomy distal to this level at the lower border of the sacroiliac joint that is S3 and below is classified as a low sacrectomy. Total sacrectomy with autologous fibula graft reconstruction has been performed with success. Total sacrectomy is rare and the least common type of sacrectomy performed in highly specialized units.

Sacrectomy can be performed without the resection of the other compartments of the pelvis, but this is usually not the case. Localized recurrent rectal cancers are a heterogenous group and usually require surgery in more than one compartment. The compartments of the pelvis have been described by Lee, Austin, and Solomon in previous texts and publications (Fig. 159.1). They include anterior, axial, lateral, and posterior compartments.

Posterior compartment: consists of the rectum, pelvic floor (coccygeus muscle), branches and tributaries of the internal iliac vessels, piriformis muscle, sacral nerves S1 to S4, pelvic bone (sacrum and coccyx), anterior sacrococcygeal ligament, medial sacrotuberous and sacrospinous ligaments.

Lateral compartment: consists of the pelvic side-wall structures, ureter, internal iliac vessels, external iliac vessels, piriformis and obturator internus muscle around the ischial spine, coccygeus muscle, lateral sacrotuberous and sacrospinous ligaments attached to ischium, ischium including tuberosity and spine, lumbosacral trunk and sciatic nerve distal to ischial spine, and obturator nerves and vessels.

Anterior compartment: consists of the bladder, prostate, seminal vesicles, vas deferens, urethra, urogenital diaphragm, dorsal vein complex, obturator internus and externus muscle, anterior half of the vagina, anterior pelvic floor muscle (pubococcygeus and puborectalis part of the levator ani), and pelvic bone (pubic symphysis, superior and inferior pubic rami).

Axial compartment: consists of the posterior half of the vagina, uterus, ovaries, fallopian tubes, broad ligament, round ligament of uterus, rectum, pelvic floor muscle (iliococcygeus part of levator ani), lower sacrum (S4 down), and coccyx.

A sacrectomy includes the posterior compartment but may also include the lateral, axial, combination lateral and axial or all compartments depending on the location, size, and the number of organs or structures involved.

High sacrectomy usually, but not always, requires a total pelvic exenteration due to resection of the sacral nerve roots and compromise to the blood supply of the pelvic organs and or tumor involvement of the organs. The bladder can be preserved with a low sacrectomy with preservation of normal function in the majority, up to 67%, but following a high sacrectomy, when the bladder is preserved it becomes atonic and therefore requires a permanent suprapubic catheter. Alternatively, females can be educated in self-catheterization to avoid a permanent suprapubic catheter.

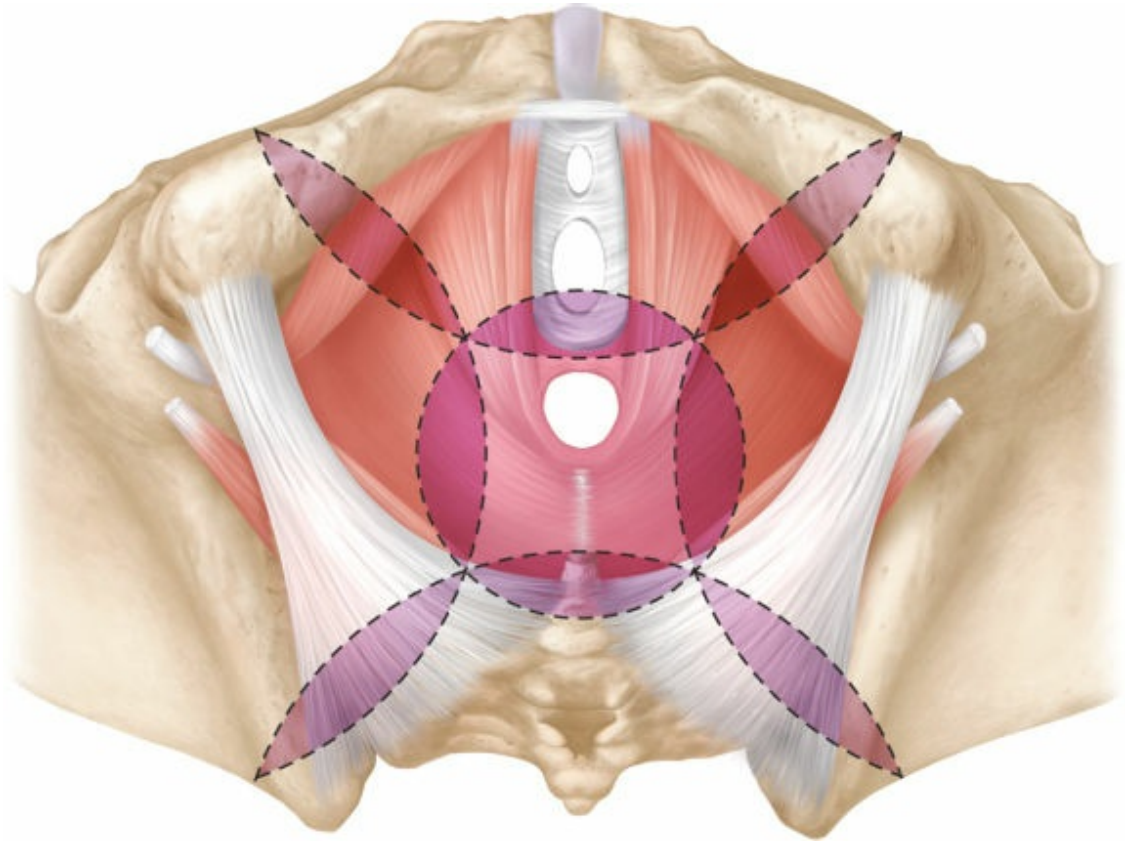

Figure 159.1. The compartments for pelvic exenteration.

SACRECTOMY: THE ABDOMINOPELVIC PHASE

Perioperative Preparations

Patients without a pre-existing stoma should have bowel preparation the day prior to surgery. Skin marker is used to mark stoma sites and, if required, for an elliptical cutaneous vertical rectus abdominis myocutaneous flap (VRAM flap). The use of ureteric stents can be an important aid, especially if the aim is to preserve the bladder.

The anus is sutured to prevent soiling. The vagina is always included in

the skin preparation. Drape the patient so that the thigh and groin are prepared and exposed in anticipation for a vein harvest if an interposition graft or patch is necessary for an iatrogenic vascular injury or vascular resection.

Positioning

The patient is positioned in the modified Lloyd Davies position with the arms secured by the sides. The patient is lying directly on a gel mattress to prevent slippage during steep Trendelenburg position.

During the perineal phase, the surgeon must pay attention to the duration of bilateral leg elevation and allow for repositioning in the neutral position if the operation is becoming prolonged to prevent compartment syndrome of the lower limbs.

High sacrectomy is performed in the prone position. Low sacrectomy (S3 and below) and partial anterior cortical bone sacrectomy can be performed via the transabdominal approach, thus avoiding the prone position.

Laparotomy

The role during laparotomy is to exclude peritoneal disease. MRI and PET/CT scans can miss peritoneal disease, and if confirmed then surgery should be abandoned. If however, it is only localized small volume disease, for example, in the pelvic peritoneum, then pelvic exenteration should continue. During the adhesiolysis, it is important to avoid enterotomies, especially to the irradiated small bowel, to prevent post operative small bowel leak, and the development of enterocutaneous fistulas.

The appendix is removed if present to avoid a potentially extremely hazardous surgery if appendicitis occurred after the complex surgery of an abdominosacrectomy.

Preparing for Sacrectomy

Any involved segments of small bowel in the pelvis and the rectum are disconnected with a liner stapling and cutting device.

The lateral dissection involves mobilizing the ureters with its surrounding vessels and connective tissue, especially the abdominal portion. To maintain good supply to the abdominal portion of the ureter, the gonadal vessels should be ligated distally in the pelvis. The pelvic portion of the ureters have been in the radiation field and thus resected

minimizing the risk of urinary leak when an ileal conduit is created. If the bladder is preserved, then gonadal vessels should also be preserved if possible. The ureter, especially the left, is invariably displaced due to previous dissection.

The internal iliac vessels are ligated, preferably distal to the superior gluteal branches to promote buttock and perineal skin and muscle flap healing. This has been referred to as “pelvic devascularization” and is recommended to avoid catastrophic pelvic bleeding (Figs. 159.2 and 159.3). Profuse brisk hemorrhage occurs when there is inadvertent injury to the internal iliac vasculature and more difficult to control when it is venous bleeding. This can lead to uncontrollable and fatal hemorrhage. This vascular dissection and ligation innately include a lateral pelvic lymph node dissection.

Lymphadenectomy is performed routinely with or without vascular resection. The lateral wall lymph node dissection commences from the bifurcation of the common iliac artery and continued with the internal iliac chain and ends with the removal of the obturator nodes and at the level of the inferior vesicle vessels. The obturator neurovascular bundle can be resected if the obturator nodes are positive on preoperative imaging.

If the recurrent tumor also involves or abuts the lateral bone, then a lateral pelvic exenteration is performed. This involves the excision of the internal iliac vessels and its branches, sacral nerve roots with or without sciatic nerve, piriformis and obturator internus muscle, sacrotuberous and sacrospinous ligaments, and the ischial bone and spine. The bladder may not routinely be excised, but usually a complete exenteration is performed with a high sacrectomy.

The dissection on the presacral fascia is discontinued at least 1 cm from the recurrent tumor. A metallic pin is inserted into the sacrum at this point and is used as the marker for sacral transection with an image intensifier when the patient is in the prone position. The aim is to transect the sacrum with the pin in the specimen.

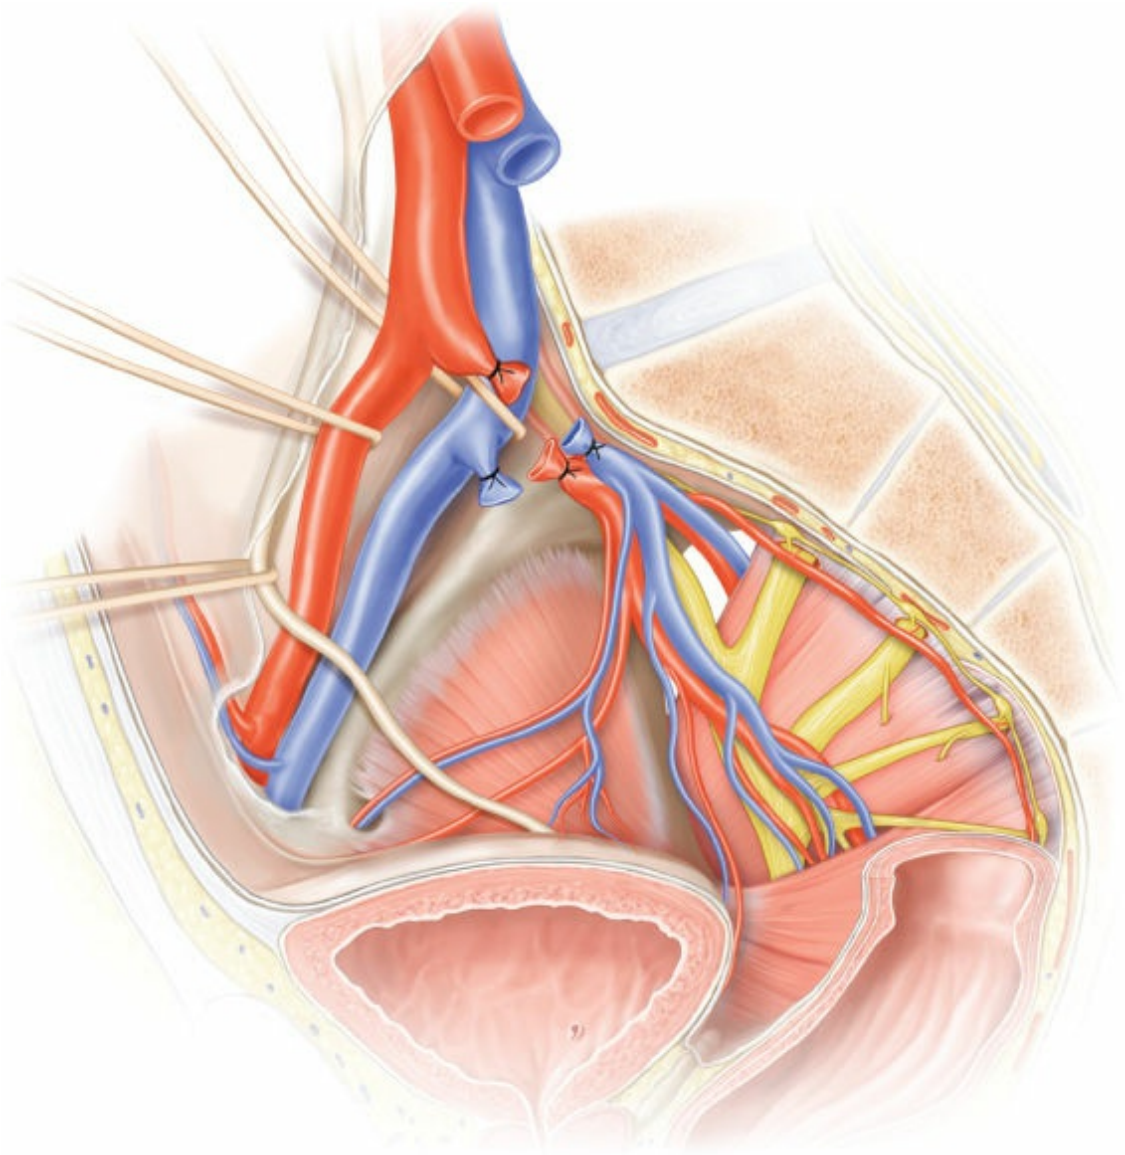

Figure 159.2. Vascular ligation of internal iliac arteries and veins.

High Sacrectomy

A high sacrectomy is performed in the prone position after the abdominopelvic component of the exenteration. The abdominal surgery includes ligation of the internal iliac vessels, mobilization of the pelvic organs, rectum, and possibly the urogentital organs. The sacral nerve roots and sciatic nerve, lateral pelvic bone, the ischial spine, and ischium may need resection if there is extension of the recurrence into the lateral compartment (Figs. 159.2 and 159.3). The stoma and ileal conduit are created and fashioned. The pelvis is packed with surgical sponges to prevent inadvertent damage to pelvic structures during the transection of the sacrum just before closure of the abdominal wall. A pelvic drain is inserted and positioned appropriately. The abdominal wall is closed

primarily, but if a VRAM rectus abdominis flap has been mobilized then polyproprolene mesh reconstruction on the donor side is performed. This is to prevent an incisional hernia.

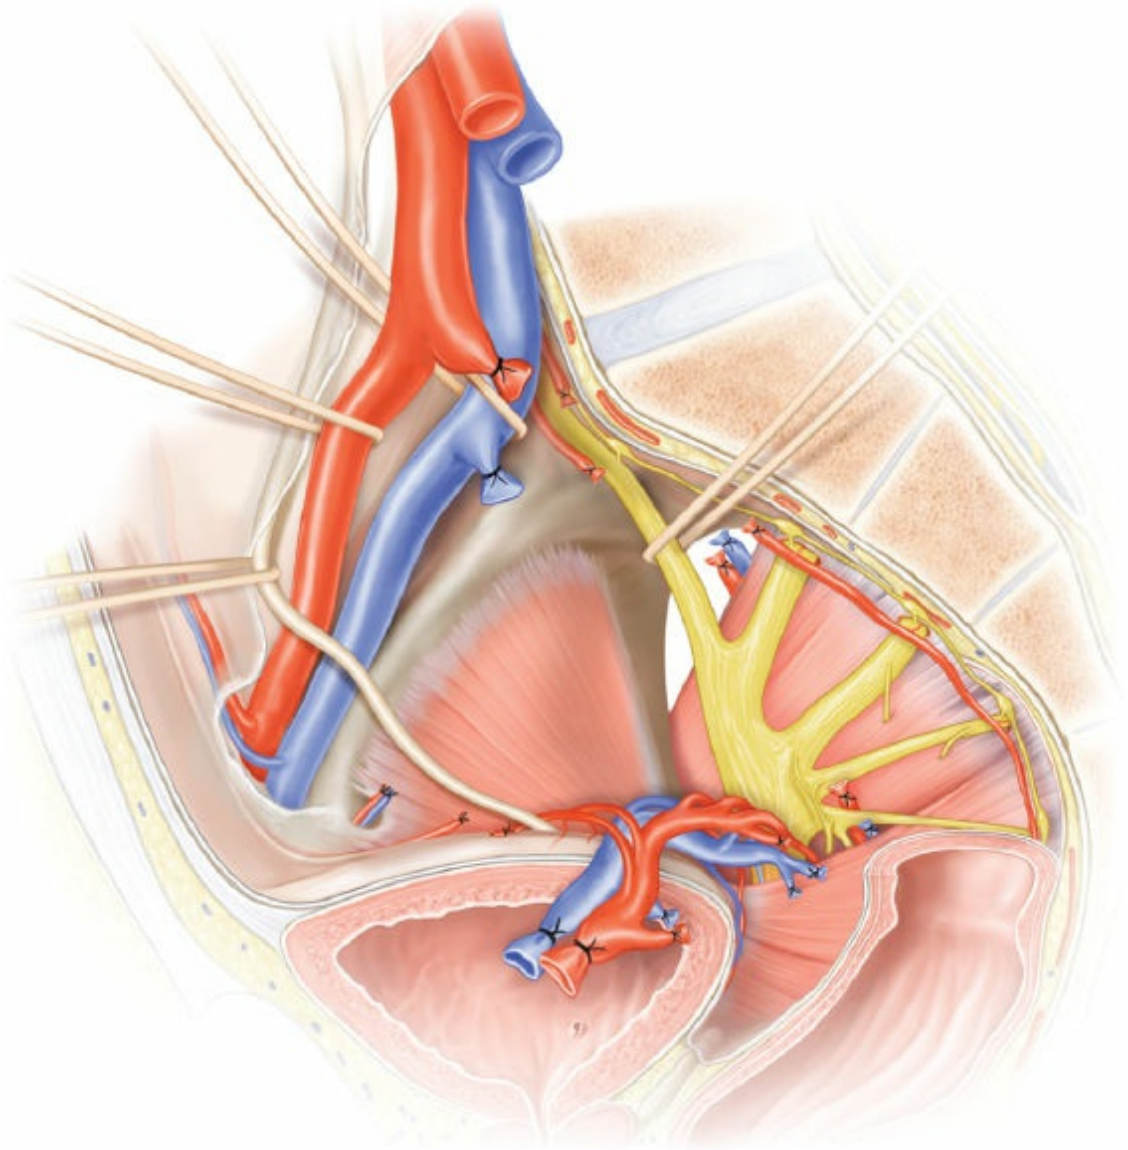

Figure 159.3. Pelvic nerves revealed after internal iliac venous ligation.

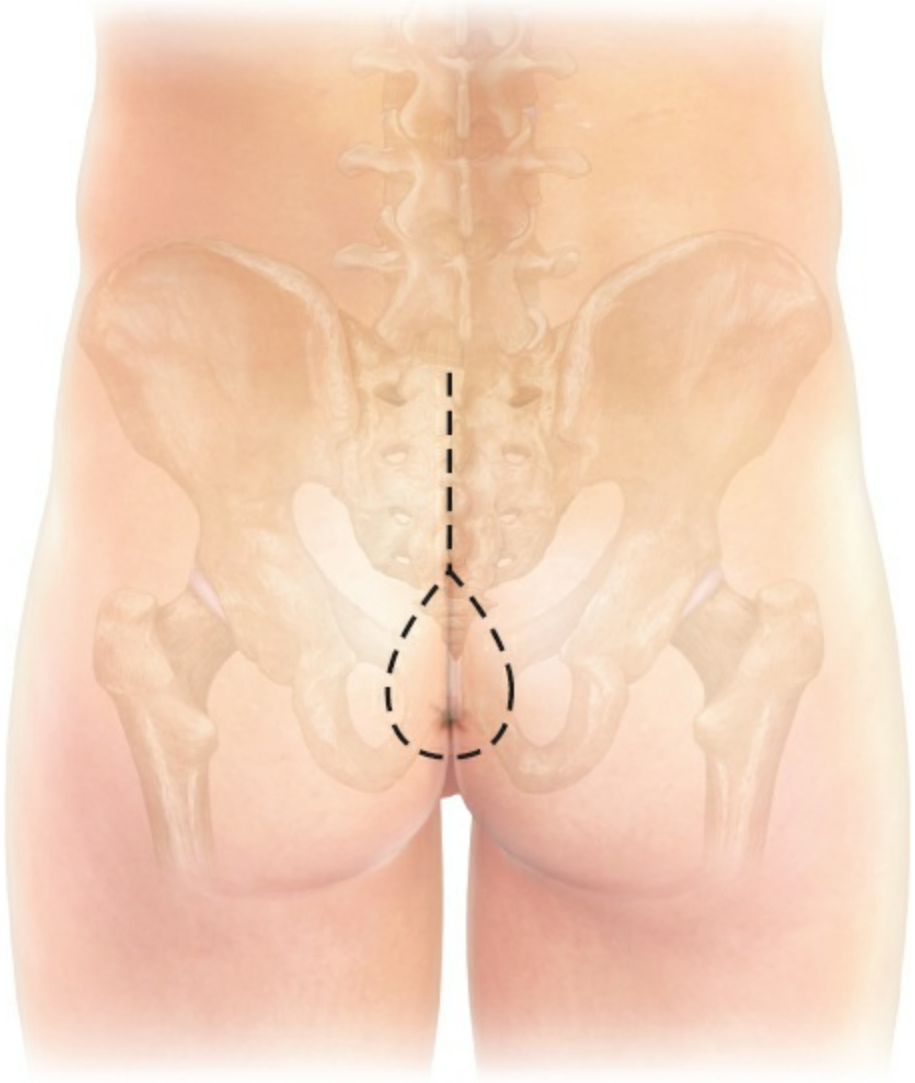

Figure 159.4. Incision for sacrectomy in the prone position (high sacrectomy).

The Perineal Phase

The patient is positioned in the prone jack-knife position, and the surgical site prepared and draped. A racquet-shaped incision is performed, the head of the racquet as the perianal incision (Fig. 159.4). If there is no anus, then a linear incision will suffice. Alternatively, the perineal wound developed during the lithotomy position is continued cephalad to incorporate the sacral wound (Fig. 159.5). The dissection continues until the sacrum is exposed. This involves mobilization and detachment of the gluteus maximus muscles, posterior and lateral sacrococcygeal ligaments, the posterior sacroiliac and sacrotuberous ligaments, and the deepest structure, the sacrospinous ligaments. The detachment of the ligaments exposes the lateral borders of the sacrum and the pelvic muscle deep to it, the

piriformis. Once the piriformis muscle is divided, then the sacrum is ready for transection (Fig. 159.6).

The image intensifier is utilized to locate the previously inserted metal pin. A high sacrectomy requires the ligation of the dura mater prior to transection. The sacrectomy is completed with an oscillating saw (Fig. 159.7). Finally, if not already performed by the perineal surgeon during the lithotomy position, the lateral pelvic dissection is continued caudad to detach the levators from the pelvic bone.

It is vital to preserve lumbosacral and S1 nerve root, and the sciatic nerve to maintain normal motor function of the lower limb. Gait with foot-drop ensues if these nerves are transected; however, patients can still walk. Loss of S2 and lower sacral nerve roots will result in variable sensory loss of lower limb and an atonic bladder but no loss of lower limb motor function.

Low Sacretomy

A low sacrectomy, even as high as the junction of S3 and S4, can be performed in the lithotomy position saving time and effort of repositioning the patient in the prone jack-knife postion and providing dual surgical access for difficult lateral compartment exenteration (Fig. 159.8). The sciatic nerve also lies more laterally in the lithotomy position than in the prone position. In addition, operating in the prone position can be confusing unless the surgeon is familiar with this approach.

Sacrectomy does not always involve the complete transection of the sacrum but rather, the removal of the anterior cortical or partial resection. This is best performed in the abdominolithotomy position.

The main trunk of the internal iliac vasculature is preserved and the distal sacral nerve roots are divided thus organs such as the bladder can be preserved and maintain function.

The perianal surgeon mobilizes the gluteus muscles and the ligamentous attachment from the sacrum. The pelvic floor muscles, and including the obturator internus and piriformis muscles for lateral recurrences, are also mobilized from its lateral bony attachments before sacral transection is performed.

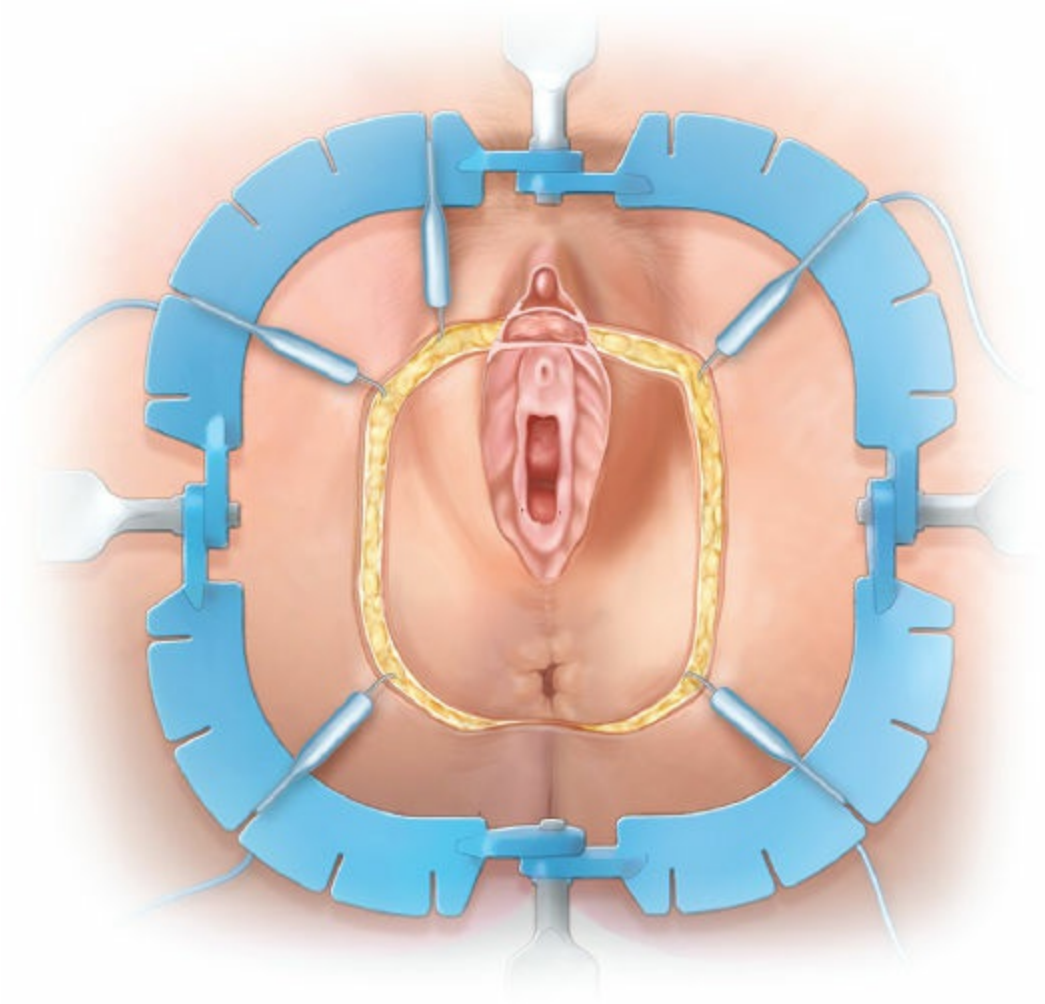

Figure 159.5. Perineal incision during abdomino-lithotomy position (in preparation for the prone position).

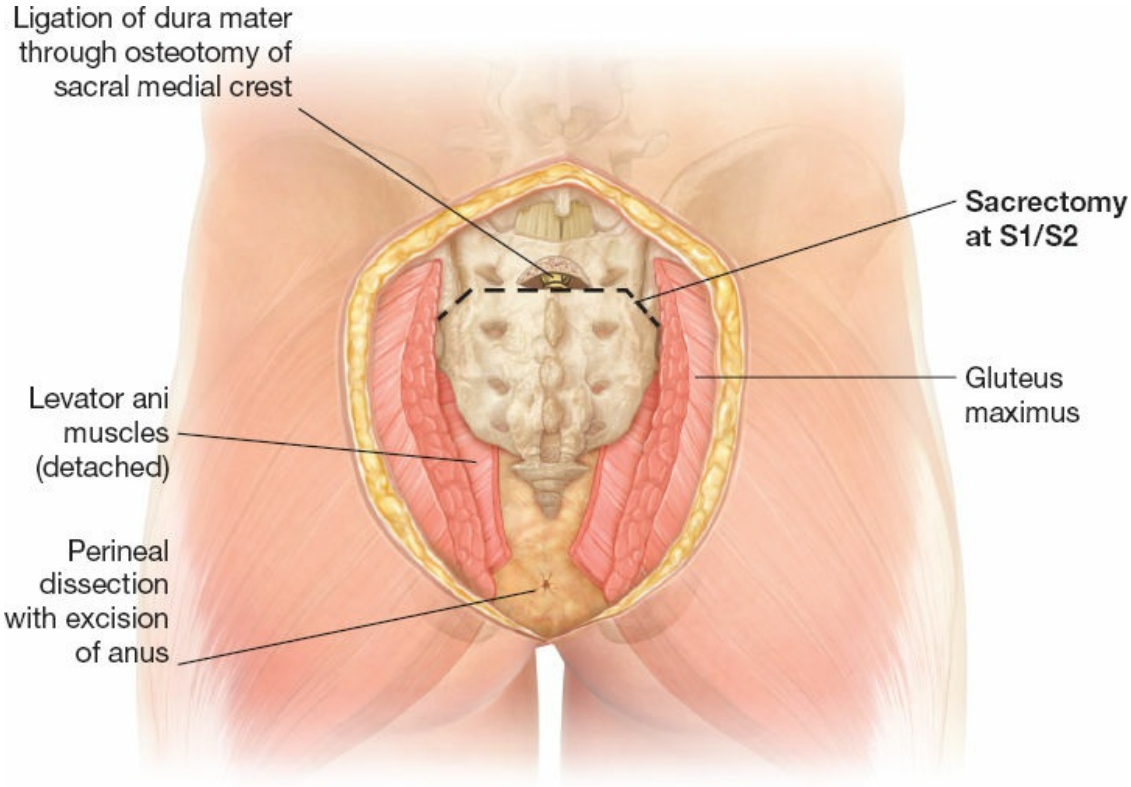

Figure 159.6. Pre-S1/S2 sacrectomy in the prone position.

The presacral fascia is divided at the line of transection to expose the bone. An osteotome is used to transect the sacrum. The perineal surgeon places another osteotome at the posterior surface of the sacrum to protect the skin during the transection.

Hemostasis is achieved more easily once the specimen has been removed simply due to better accessibility.

Perineal wound is closed usually without a musculocutaneus flap unless there is extensive perineal skin involvement with tumor or radiation damage or a complete soft tissue exenteration.

Intraoperative Radiotherapy

Some units have used intraoperative radiotherapy. The median dose of 1,250 cGy has been used and the Mayo Clinic, where 67% (20 of 30 patients) received intraoperative radiotherapy. Doses higher than 1,250 cGy increase the incidence and severity of the neuropathy.

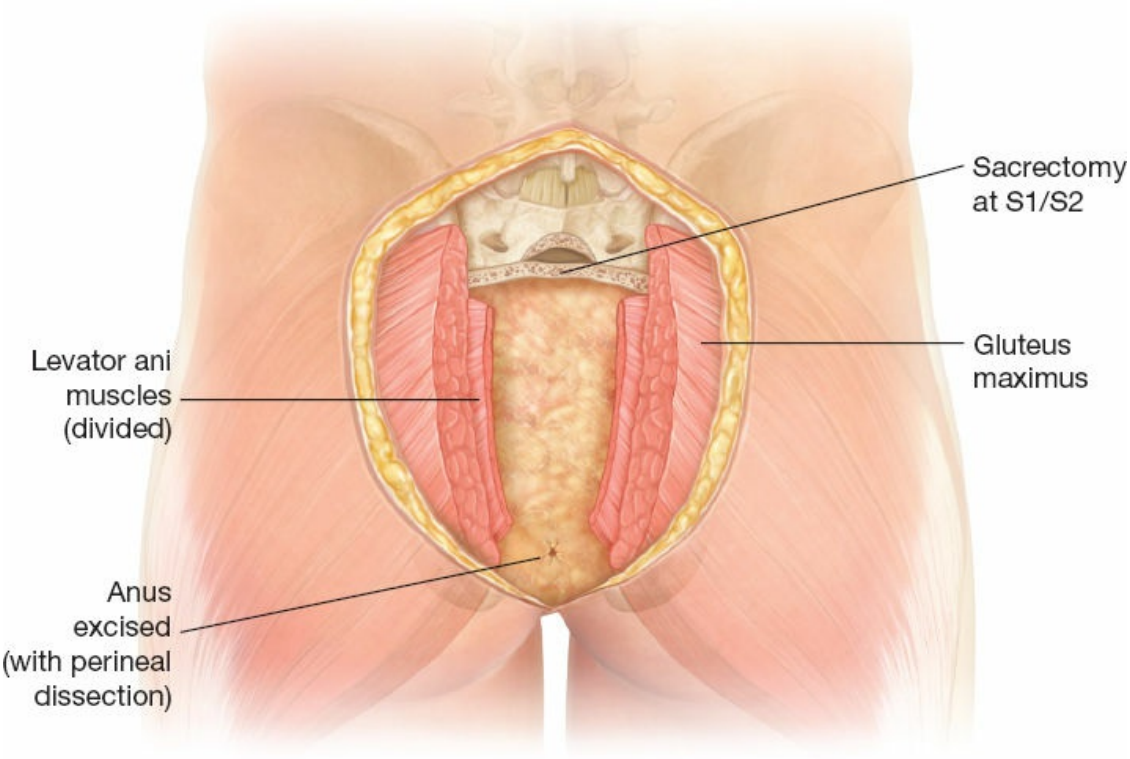

Figure 159.7. Post-S1/S2 sacrectomy.

POSTOPERATIVE CARE

The patient is transferred to the intensive care unit. The patient is usually extubated for pelvic exenteration of duration of less than 10 hours.

Total parental nutrition (TPN) is commenced on the first postoperative day, and nasogastric tube inserted as ileus occurs invariably. Routine postoperative care also includes intravenous antibiotics, analgesia including neuroleptics, deep venous thrombosis prophylaxis with a combination of mechanical calf compressing devices, compression stockings, and subcutaneous anticoagulant.

Patients with VRAM flap reconstruction are initially nursed in a 30 degrees lateral tilt position to avoid prolonged pressure on the flap. After the first postoperative day, depending on the healing of the flap, the patient is allowed to be in the supine position. The patient is encouraged to mobilize on the fifth day.

Usually at day 2 or 3 post surgery, the patient is transferred to the ward with a specialized team of nurses, occupational therapist, physiotherapists, psychologists, dietitian, and cancer care specialist nurse coordinator.

Hospital admission is prolonged and a consequence of the high incidence of morbidity. The mean hospital stay post sacrectomy has decreased from 5 weeks and with more recent studies reporting hospital

admission of 3 weeks. The time to recovery with a stabilized quality of life is at least 3 to 6 months.

COMPLICATIONS AND THEIR MANAGEMENT

Pelvic exenteration with sacrectomy is the most complex pelvic operation for recurrent cancers. Therefore, it is not surprising that complication rates are high, up to 82%. Sacrectomy itself is a predictor of increased morbidity.

Complications are divided into major and minor (Table 159.1), and as high as 40% and 78%, respectively. Interestingly, in the largest series comparing high and low sacrecotmies, there was no difference in major and minor complications rates, but on separate subanalysis, S1 resection showed a significant increased rate of major complications.

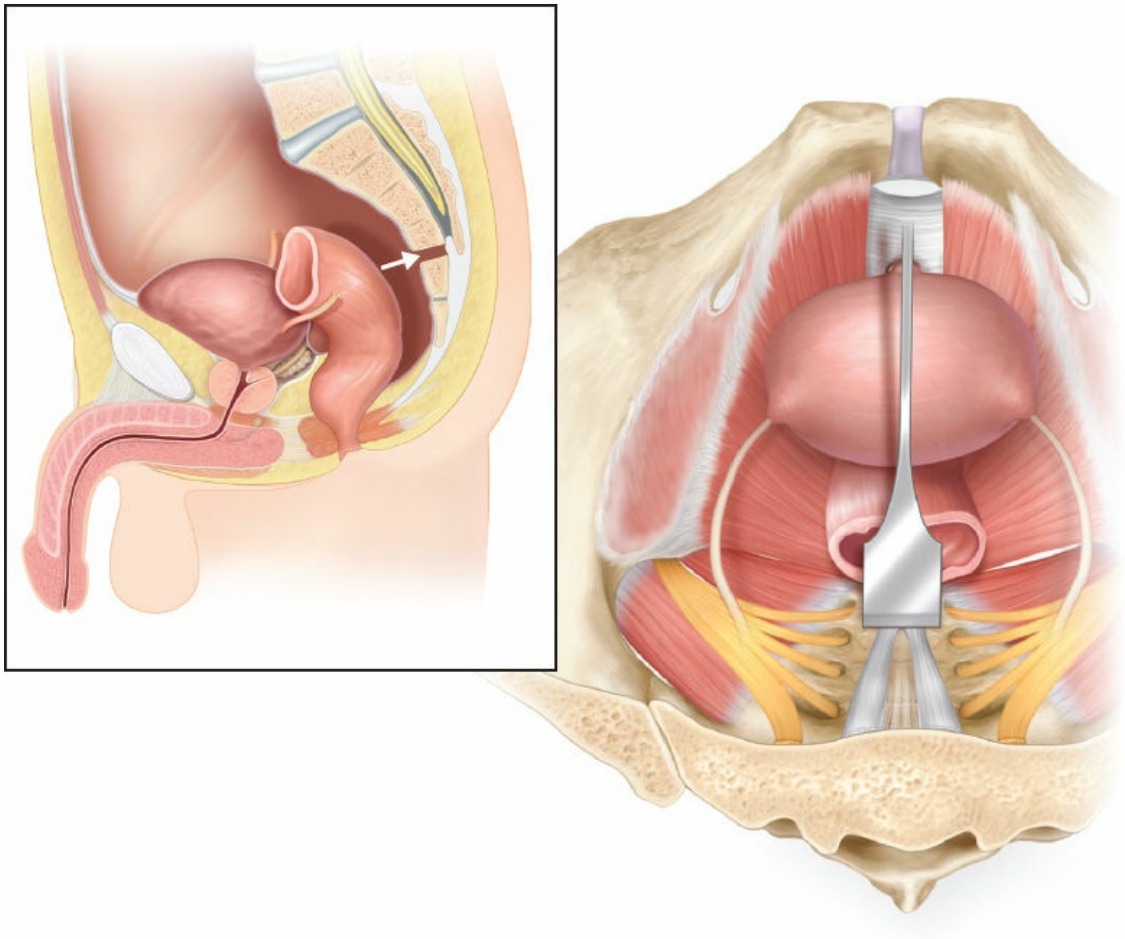

Figure 159.8. Sacrectomy in the abdominolithotomy position.

The most common major complications include sacral wound dehiscence and flap necrosis, pelvic sepsis, and urinary conduit leak.

Reoperations for major complications including percutaneous procedures such as CT-guided pelvic abscess drainage and CT-guided nephrostomies were performed in 38% of sacrectomy patients. Twenty-four percent of patients had reoperations including sacral wound debridement, for small bowel obstruction, repair of enterocutaneous fistulas, and revision of urinary conduit.

Despite the perineal wound and flap being one of the common complications, the selective use of the vertical rectus abdominis myocutaneous flap has not reduced the complication rate.

Prolonged ileus and small bowel obstruction (nonoperative management), neuropathic bladder and urinary incontinence, lower limb neuropathy, deep venous thrombosis, and atrial fibrillation are the most common minor complications.

Most patients develop postoperative ileus, whereas prolonged ileus is less common at 10%. An ileus is the result of a combination of long operative time, prolonged use of narcotic analgesia, radiated bowel and extensive abdominal and peritoneal dissection. Therefore, TPN is recommened for all patients undergoing a sacrectomy.

The level of sacral resection with its respective nerve roots will determine the severity of neurologic complications affecting the bladder and bowel. A high sacrectomy with the resection of S1 to S3 nerve roots will result in bladder and bowel dysfunction. In contrast, low sacrectomies result in lower rates of neurologic dysfunction and comparative to pelvic exenterations without sacrectomy. Interestingly, two more recent studies comparing high and low sacrectomies did not show a significant difference in the rate of a neuropathic bladder. The overall rate of neuropathic bladder was high (47%) and the authors attributed the higher neuropathic bladder rate in low sacrectomies as a combination of loss of lower sacral nerve roots, preoperative radiotherapy, and the nature of tumor invasion.

All sacretomy patients with local recurrent rectal cancer have a colostomy, so bowel function is not an issue. However, when the bladder is preserved, the bladder becomes atonic resulting in urinary retention especially in a patients where S2 vertebra or above is resected.

The Mayo Clinic and the Japanese National Cancer Center have reported significant motor deficit and bladder dysfunction following a high sacrectomy, especially S2 vertebra or above. Neurologic deficit of the lower limbs, where the sciatic nerve was preserved, has been shown to be significantly higher in high sacrectomies. In particular, motor deficit was

higher in high sacrectomies and corresponded to the recurrent tumors abutting the lumbasacral trunk necessitating a partial resection. However, there was no significant difference in the rates of sensory loss and neuropathic bladder when compared with low sacrectomies. Therefore, the cause of an atonic bladder is multifactor and not solely a result of level of sacral transection.

TABLE 159.1 Complications—Major and Minor

Major Complications

Wound/flap

- Deep wound dehiscence
- Deep flap dehiscence
- Flap necrosis partial or full thickness
- Pelvic abscess (CT drainage)
- Sacral osteomyelitis

Cardiovascular

- Myocardial infarct
- Pulmonary embolus
- Middle cerebral artery stroke
- Thrombophlebitis

Gastrointestinal/urologic (reoperation)

- Enteric fistula
- Small-bowel obstruction
- Anastomotic leak
- Urinary conduit leak

Minor Complications

Wound/flap

- Wound infection
- Superficial wound dehiscence
- Minor flap dehiscence

Gastrointestinal (conservative management)

- Prolonged ileus
- Small-bowel obstruction
- Pelvic abscess (no drainage)

Renal/urologic

- Urinary retention
- Urinary incontinence
- Urinary tract infection
- Acute renal failure

Cardiovascular

- Atrial fibrillation
- Deep vein thrombosis

Respiratory

- Atelectasis
- Pneumonia
- Pulmonary oedema
- Pneumothorax

The largest sacrectomy series to date compared the operative outcomes between high and low sacrectomies. High sacrectomies had a significantly longer operation time, greater blood loss but did not translate into an increase hospital length of stay. The level of sacrectomy did not influence the ability to achieve an R0 margin.

TABLE 159.2 Sacretomies for Recurrent Rectal Cancer and Survival Rates

Author	N	HS (%)	R0 (n[%])	5 yr OS (%)	DFS (%)	
					3 yr	5 yr
Moriya *et al.*	57	9 (16)	48 (84)			31
Milne *et al.*	49	21 (43)	36 (74)	38[a]	51[a]	43[a]

Dozois *et al.*	9	9 (100)	9 (100)	30		

HS, high sacrectomy = proximal sacrectomy at S1, S2 vertebra.
[a]Survival rates for R0 margins.
[b]Four patients were for palliative intent (metastatic disease; lung = 2, lung and local = 1, lymph nodes = 1).
[c]19 patients in intermediate sacrectomy but not included as proximal sacrectomy at S2 vertebra was not defined.
[d]Includes proximal transection at L5 (2 patients) and L4 (2 patients).
[e]Three patients were included in R0 after further resection of R1 after frozen section.

Mortality rates have significantly improved over the last 30 years mainly as a result of improved surgical techniques. In the 1990s, Wanebo et al. reported a mortality rate of 5.4% in 63 patients. In the next decade, the mortality rate decreased to 1% to 3.4%. Since 2010, the mortality rate has been zero in all the major reported series for sacrectomies.

PROGNOSIS AND SURVIVAL

Historically, there have been several factors that affected survival. The factors that were shown to have an adverse effect on survival include resection margin status, lateral recurrences, increased number of points of fixity, lymph node status at primary surgery, pain at presentation and sciatic nerve involvement.

Irrefutably, the single most important predictor of survival is R0 resection margins and hence the most important prognostic indicator. Advancements in surgical techniques with extended and radical resection have made the other factors listed above less significant and re-classified as relative indicators. Conversely, if R0 margins are achieved, then the other negative prognostic indicators are no longer as important.

A more recent study published in 2014 by Royal Prince Alfred Hospital, Sydney, Australia reported additional pathologic factors that influenced R0 margins. The involvement of anterior organ, cortical bone invasion, involved local lymph nodes, and lymphovascular and perineural invasion influenced R0 resection margin thus ultimately survival. The authors proposed resecting the pubic bone to achieve an R0 anterior margin and are due to report on their series in the near future. Melton et al., from Memorial Sloan Kettering Cancer Center, also reported anterior organ involvement as a negative prognostic indicator for survival.

The rate of R0 resection margins for sacrectomies has significantly improved in the last decade, ranging from 50% to 93% (Table 159.2). A smaller series from the Mayo Clinic reported R0 rate of 100% in nine patients with high sacretomies including one total sacrectomy and fibula graft bone reconstruction.

Overall 5-year survival rates have been reported in the range of 30% to 46%. Disease-free survival (DFS) rates at 3 years and 5 years are in the range of 26% to 55% and 20% to 43%, respectively. Survival differences have been reported between R0 and R1/R2, ranging from 30% to 58% and 0% to 20%, respectively.

Performing surgery for palliative intent has been shown to be a predictor of both poor disease-free and overall survival. In addition, the inherent high morbidity rates with this type of surgery highlight why palliative pelvic exenteration should not be recommended.

Recurrence after abdominpelvic sacrectomies has been reported as high as 45%. The sites of recurrence include local recurrence only, distant disease alone, and a combination of local and distant disease. The series of nine high sacrectomies from Mayo clinic with 100% R0 margin reported that all patients ultimately died from metastatic disease.

EDITOR'S COMMENT

I would start by commenting the authors on presenting an excellent overview of an exceedingly complex operation. Their elaborate description is a testament to the authors' faculty with this operation. The chapter presents the technical aspects of the operation in an elegant manner with clean, crisp description of operative technique that can be easily followed by the reader.

One of the unintended "side effects" of the authors' exceptional account is the fact that their description almost makes sacrectomy for locally recurrent rectal cancer seem like a relatively straightforward operation. Their description certainly does not do justice to the operative planning, technical complexity, and associated morbidity that this procedure entails. In my opinion, reoperative pelvic surgery for recurrent rectal cancer is one of the most difficult procedures in colorectal surgery. This is particularly true in patients who have received radiation therapy in the past specially if adjuvant radiation was administered after the index operation. Performance of sacrectomy adds yet another layer of complexity to an already challenging operation.

While the authors briefly touch upon the importance of surgeon's experience, I think it is worth to reemphasize the importance of this point. In my opinion, these surgeries should only be performed by surgeons who are highly experienced in reoperative pelvic surgeries. In addition to the surgeon's expertise, a certain level of institutional experience is also mandatory as this procedure requires skilled anesthesia and ICU teams, availability of urology, orthopedic, neurosurgery and plastic surgery support, access to intraoperative radiation and most importantly, a robust postoperative rehab program. Embarking upon these surgeries without the needed experience and institutional support would inevitably result in poor patient outcomes. For those in the early phase of their learning curve, I strongly suggest entailing the help of a senior partner with prior experience in this arena.

Patient selection is of paramount importance for these cases. It makes very little sense to do an exceedingly complex, maximally invasive operation with intentions of accomplishing local control in a patient already harboring metastatic disease. I concur with the authors that a preoperative pelvic MRI to confirm resectability and a PET scan to rule out metastatic disease are essential components of preoperative planning. All patients being evaluated for sacrectomy should be thoroughly discussed in multidisciplinary tumor board to obtain radiology and oncology input before a trip to the operating room is planned.

The authors touch the issue of intraoperative radiation therapy in a very cursory manner, which in my opinion is an integral component of this operation.

As authors have indicated, this operation is marred by a fairly high rate of local failure. It will be truly unfortunate to put a patient through such an extensive operation only to encounter an early recurrence. I think that the gravity and invasiveness of this operation coupled with severe postoperative morbidity and functional limitations that often follow this surgery demand an “all out” approach—one that maximizes the chance of a successful outcome. For this reason, I routinely use intraoperative radiation therapy (IORT) or high-dose radiation (HDR) for almost all recurrent rectal cancer patients requiring a partial sacrectomy or in cases where preoperative MRI imaging indicates threatened surgical margins. While there relative paucity of data evaluating routine use intraoperative radiation with partial sacrectomy, there is plenty of evidence supporting its role in decreasing local recurrence after surgery for recurrent rectal cancer and I feel it is fair to extrapolate these data to partial sacrectomy.

Although not discussed in the chapter, the importance of multidisciplinary team approach cannot be overstated. In my practice, I have always managed these tumors using a multidisciplinary approach entailing help from urology, orthopedics, neurosurgery, and plastic surgery in addition to intraoperative radiation oncology consult. This may just be a reflection of my relative inexperience with this technique compared to the authors. Being a colorectal surgeon, I am not very facile with orthopedic and neurosurgical anatomy and feel out of my domain while operating in those areas. In my experience, having these specialties on board not only improves the quality of operation but also helps in achieving negative margins.

Syed Husain

160 Cytoreductive Surgery and Hyperthermic Intraperitoneal Chemotherapy for Cancers of the Appendix and Colon

Edward A. Levine

INTRODUCTION

Peritoneal metastases complicate the initial diagnosis of colorectal cancer in approximately 10% of cases, and mucinous appendiceal cancer in up to 50% of cases. The peritoneum is the second most common site of metastases (after the liver), found in nearly 50% of recurrent cases, and it is the only site of recurrence in nearly one third of those cases of colorectal carcinoma. Untreated, these patients have an anticipated survival of <1 year. Historically, such patients have been treated exclusively with palliative systemic chemotherapy, and have been approached with therapeutic nihilism. Unfortunately, the efficacy of systemic chemotherapy for peritoneal metastasis lags behind that found for metastatic tumor at other sites, where the 5-year survival rate with “modern” systemic chemotherapy is in the 5% range, with median survival of approximately 20 months.

Isolated peritoneal metastasis is a regional problem. Consequently, the use of an aggressive regional approach, such as cytoreductive surgery (to remove gross disease) along with hyperthermic intraperitoneal chemotherapy (HIPEC), to treat microscopic residual disease, is a promising modality. Clearly, the majority of the benefit is from the resection, and it must be kept in mind that chemo-perfusion will treat to a maximal depth of 5 mm. Therefore, using HIPEC to treat gross residual disease is rarely appropriate.

Complete cytoreduction in the peritoneum is required to achieve a significant survival benefit, similar to surgical therapy for metastatic disease to the liver or lung. Furthermore, it has given rise to a sizable minority of patients who are long-term survivors with good quality of life,

whereas with previous therapies there were essentially none. Despite survival benefits in appropriately selected patients, the procedure can be associated with significant morbidity, particularly for patients with higher volumes of peritoneal metastases, treated at inexperienced centers. This type of case presents a substantial surgical challenge. It is associated with a long learning curve for the surgical teams, and should not be attempted by the occasional operator.

Preoperative Evaluation

Cytoreductive surgery alone or with HIPEC is a substantial operative undertaking, and thorough evaluation is mandatory. The extent of disease in the peritoneal cavity, as well as the lack of extra-abdominal metastatic sites, must be determined with computed tomography (CT) and/or magnetic resonance imaging (MRI) scans. Malignant ascites is a poor prognostic indicator, particularly in patients with high-grade disease. The procedure should be approached with great caution, as complete cytoreduction is not usually possible in this setting. Resection of the primary tumor as well as the metastatic disease must be deemed feasible. Colonoscopy is helpful preoperatively, as there is a significant risk of second primary colonic lesions.

Preparation for the procedure must include evaluation of medical comorbidities, along with cardiopulmonary and nutritional assessments. The best candidates are free of hepatic parenchymal metastases. Peritoneal surface metastases on the capsule of the liver are not a contraindication. Pathologic confirmation of peritoneal disease/dissemination should be obtained.

Frank discussions with the patient regarding the magnitude of the resection's impact on lifestyle, including the possible need for colostomy or ileostomy formation, and the potential loss of mobility and even mortality are required. Patients with preoperative imaging that suggests the need for splenectomy should undergo vaccinations for encapsulated organisms preoperatively. Preoperative consultations by anesthesia, enterostomal therapy nurses (if a stoma is anticipated), and potentially urology (for ureteral stent placement should complex pelvic anatomy from tumor or previous surgery require it) should be obtained.

Preoperative Preparation

Mechanical bowel preparation, with oral antibiotics, is given the day prior

to surgery. Preoperative antibiotics are given intravenously, and deep venous thrombosis prophylaxis using both chemical and mechanical approaches is appropriate. Patients are positioned in the supine position, cushioned as appropriate for the potentially lengthy operative intervention. General anesthesia may be supplemented with epidural catheters for postoperative analgesia. Arterial line monitoring is helpful for most patients. For patients with complex pelvic disease or extensive prior pelvic surgery, placement of externalized ureteral stents by urologic consultants is frequently a time-saving procedure. Patients are typically prepped from the mid chest (should tube thoracostomy be required) to the proximal thigh. Nasogastric and urinary catheters are routinely placed. Core temperature monitoring in the esophagus and/or bladder should be arranged for with the anesthesia team.

Surgical Technique

The goal of cytoreduction is the removal of all grossly apparent disease, while preserving organ function. Although some patients with very low peritoneal disease burden may be approached laparoscopically, most cases are best approached with a generous midline incision. After making the incision, self-retaining retractors are placed. The abdomen must be thoroughly and completely explored at this point, which requires lysis of any pre-existing adhesions. The peritoneal carcinomatosis index is the most commonly utilized descriptor of tumor volume, and should be determined (range of 0 to 39) at this point. An assessment of the extent of visceral involvement must then be undertaken to direct planning for the remainder of the case. Close attention to the extent of small bowel disease is critical. Most low-grade appendiceal cancer cases have relative sparing of the small bowel, which facilitates complete resections. However, the same cannot be said for colonic and high-grade appendiceal carcinoma. Resections that leave the patient with <100-cm small bowel (and attendant permanent short gut syndrome) are rarely if ever warranted. Furthermore, the key assessment is whether the complete cytoreduction is feasible or if a palliative resection is all that can be achieved. The majority of patients (>90%) if properly assessed preoperatively should be able to undergo a complete cytoreduction procedure.

Having evaluated the abdomen and peritoneal disease burden, an operative plan should then be apparent. Clearing the primary tumor (if not resected previously), as well as all gross disease, and determining which

organs must be resected should be thought out carefully. The necessity of peritonectomy procedures should be decided upon so it can be discussed with the operative team at this point.

Some patients will have a significant omental cake that may need to be removed before complete assessment of required resections can be fully evaluated. Since the greater omentum is routinely resected in these cases, there is no need for hesitation. The omentectomy is usually facilitated by entering the lesser sac just outside of the gastroepiploic arcades. If there is disease on the gastroepiploic arteries, it should be resected. However, resection preserving the gastroepiploic vessels can minimize delayed gastric emptying postoperatively. The lesser omentum can be resected off the stomach while preserving the nerves of Latarjet when feasible. The round ligament of the liver should be resected deep into the umbilical fissure of the liver, as it is a common site for metastasis.

The small bowel should be run from the ligament of Treitz to the ileocecal valve, removing nodules from the mesentery as well as the serosa of the bowel. For predominantly mucinous lesions, an ultrasonic surgical aspirator can facilitate resection of small modules particularly on the mesentery. For more sclerotic lesions, an argon beam coagulator or plasma jet dissector can be helpful. Caution must be taken with the serosal implants. If the muscular wall must be resected to clear the implants, they should immediately be repaired with Lembert sutures. If small bowel resection is necessary, measurements *with a ruler* of residual small bowel, beyond the ligament of Treitz, after all resections are completed, should be performed prior to resecting. Rarely should more than two anastomoses be required.

The colon is then run in a similar fashion. For low-grade appendiceal cancers, with peritoneal dissemination, a right colectomy to obtain an adequate lymphadenectomy is rarely required, as the rate of nodal metastasis is quite low. However, for right colonic or high-grade appendiceal cancers, right colectomy is appropriate as part of the cytoreduction. The tenia epiploica is a frequent site of peritoneal metastasis, and these should be resected if diseased. When amputating tenia epiploica, it is important to be cautious not to inadvertently open a colonic diverticulum. Should a colonic diverticulum be encountered, they should be closed with suture and oversewn with 3-0 Lembert sutures. The mesocolon should be cleared in a fashion similar to the mesentery of the small bowel.

The pelvis is dealt with next, and follows clearance of the distal sigmoid colon. The ovary is a common site of metastasis, and should be resected in women with any disease apparent upon the ipsilateral tube or ovary. A hysterectomy is required only if there is disease that cannot be removed from the surface of the uterus. A supracervical hysterectomy is a reasonable choice if disease does not extend beyond the neck of the uterus. If there is disease encroaching upon the neck of the uterus or the cervix, a complete hysterectomy with bilateral salpingo-oophorectomy is appropriate. The pelvic cul-de-sac should be thoroughly inspected as it is a frequent site of “drop metastasis.” This can usually be dissected off the rectum without the need for resection. Should there be significant disease found on the anterior rectum that cannot be removed without resection, proctectomy should be undertaken to remove gross disease. A restorative anastomosis is usually feasible; however, proximal diversion is typically chosen to minimize the risk of anastomotic leak after perfusion. The internal inguinal rings should always be inspected for metastasis and cleared of any grossly apparent disease. This may require resection of the gonadal vessels in some cases.

Pelvic peritonectomy procedures may be required to clear gross disease. They are not required when no disease is apparent. If needed, the stripping of the peritoneum should begin at the superior portion of the bladder and proceed ever deeper into the pelvis. The bladder muscle can be thin at the dome, and care must be taken to avoid cystotomy. However, if tumor is adherent to the bladder, a partial cystectomy can be performed, and closed in two layers with 3-0 absorbable suture. The peritonectomy can be then taken around the cul-de-sac onto either the uterus or the rectum, and laterally onto the pelvic sidewalls if needed.

Attention should then return to the upper quadrants of the abdomen. Involvement of the right diaphragm is much more common than the left in appendiceal cancer cases. If the spleen has disease on its capsule, it should be resected in its entirety, as stripping the splenic capsule is typically associated with prohibitive-loss. The spleen can be resected with the gastrosplenic ligament and omentum as a single unit. The lesser sac is widely exposed at this point and disease should be cleared from it at this time. Should disease be found to be adherent to the stomach, partial gastrectomy is preferred. Total gastrectomy is rarely necessary, and should be undertaken only if it is the limiting site to complete cytoreduction, and in cases where substantial small bowel resection is not necessary, as a

Roux-en-Y reconstruction would be necessary. The lesser omentum should be resected if there is any disease upon it, but need not be done routinely. Lesser omentectomy should spare the vagal branches to the stomach (nerves of Latarjet) if not diseased. If lesser omental disease requires division of both the nerves of Latarjet, a pyloromyotomy should be considered.

The right upper quadrant is then addressed. The porta hepatis should be carefully inspected. Bulk disease on the hepatoduodenal ligament that cannot be cleared is a contraindication to chemotherapy perfusion. The peritoneum on the anterior surface of the hepatoduodenal ligament can be stripped while preserving the vasculature and bile duct. Should disease be found on the gallbladder, a cholecystectomy is indicated. If there is disease on the right diaphragm, mobilization of the right lobe of the liver is required, and should include division of the right triangular ligament. With the liver mobilized to the left, it may be necessary to readjust the self-retaining retractor system to optimize exposure of the diaphragm. A peritonectomy procedure can be performed if required. Frequently, peritoneal disease on the right diaphragm can be stripped entirely as the tumor tends to thicken and stiffen the peritoneum. However, this is not feasible in all cases. Peritonectomy of the right diaphragm should begin just beneath the ribs to proceed more progressively deeper into the abdomen. High-power cautery and good traction/counter-traction facilitate this maneuver. A Cobb dissector can also be quite helpful in stripping the diaphragm (Fig. 160.1). Should disease be apparent in the right gutter, the anterior lamina of Gerota fascia can be resected with the right diaphragm stripping as a single unit. If disease is found on a portion of the diaphragm that cannot be stripped, resection of the diseased diaphragm can be undertaken, with closure with a nonabsorbable suture. A tube thoracostomy can then be placed with fresh gloves and instruments to try to avoid pleural contamination with cancer cells.

Disease on the liver capsule can be stripped as individual metastases if limited in number. If larger areas of disease, or confluent disease is found, the liver capsule can be stripped off by incising the capsule and bluntly removing large areas of capsule. Hemostasis is typically not difficult to obtain after parietal peritoneal stripping, and may be facilitated by high-power cautery or an argon beam coagulator.

Whether to perform restorative anastomoses at this time or after the perfusion is controversial. We have found it advantageous to perform the

anastomosis, prior to perfusion, to allow them to be inspected after the perfusion is complete. While this has the theoretical risk of not perfusing tissue incorporated into the anastomoses, we have not found failure at these sites to be problematic with this approach.

Hyperthermic Intraperitoneal Chemotherapy Administration

The delivery of intraperitoneal chemotherapy can be performed with either an open or closed technique. The open technique requires the abdomen to be open and filled with fluid during the time of perfusion. Since evaporation with chemotherapy vapor will accompany this technique, it may violate occupational and health and safety administration rules. Therefore, most centers use a closed abdominal technique (safety standards vary by state) to avoid this issue. The closed technique requires placement of cannulas for inflow and outflow. Our center uses two inflow and two outflow cannulas, which is a simple system that works well. Inflow cannulas, of 22 French, are placed via small incisions and carried through the subcutaneous tissue into the upper quadrants. The outflow cannulas, of 32 French, are placed in a separate set of incisions, taken through the subcutaneous tissue and positions in the lower quadrants or pelvis. A device to diffuse suction is required on the outflow cannulas to avoid injuries to the bowel. The skin is then temporarily closed with a running suture. Each cannula is also sutured in position. The two inflow and two outflow cannulas are connected with Y-connectors. One-quarter inch tubing is connected to the inflow cannulas, and ⅜-inch tubing is connected to the outflow cannulas.

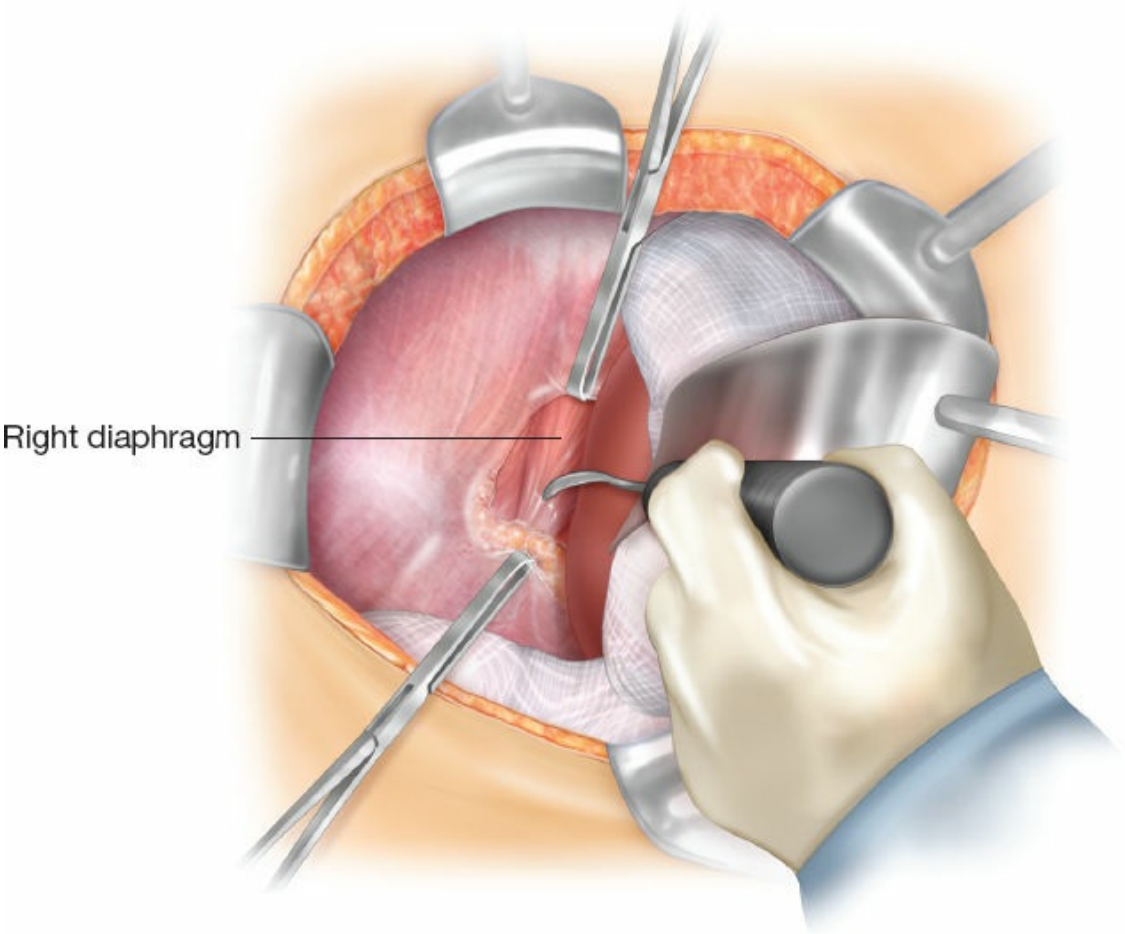

Figure 160.1. Cobb Dissector used for a right peritoniectomy. The peritoneum of the right diaphragm is grasped by Allis clamps and the dissector is dissecting the peritoneum off the muscle of the diaphragm (liver mobilized well to the left).

Thermistors are attached to the inflow and outflow cannulas to monitor temperature. A three liter crystalloid solution is used to prime the circuit. The perfusion pump is associated with a heat exchanger to manipulate the temperature of the perfusate. Gentle manipulation of the abdomen should remove all air from the peritoneal cavity. Toward the end of the extirpative portion of the procedure, communication with the anesthesia service should allow for discontinuation of warning devices to allow the patient to passively cool to approximately 35°C. The perfusate inflow is warmed to 42°C and manipulated to obtain outflow temperatures of 40°C.

With a stable patient and perfusion circuit, the chemotherapy is then introduced. Mitomycin C is the most commonly used chemotherapeutic agent at most centers. Typically 30 mg is given at the initiation of perfusion, with an additional 10 mg dose given into the circuit 1 hour into the perfusion, to maintain drug levels in the circuit. Oxaliplatin is an

alternative agent, more commonly utilized in Europe. We have used a dose of 200 mg/M^2 as a single dose into the HIPEC circuit. Most centers perfuse the peritoneum for 60 to 120 minutes (our protocol is for 120 minutes), at a flow rate of at least 1 L per minute. At the end of the perfusion, the circuit is drained, the abdomen reopened, the retractor repositioned, and the cannulas removed. We usually redose systemic antibiotics at this time as antibiotic levels are washed out with the perfusate.

Re-Exploration and Definitive Closure

After completion of the perfusion, the self-retaining retractor is replaced, all cannulas are removed, and the abdomen is re-explored. Complete hemostasis is then assured. Required anastomoses are inspected or (if not performed prior to perfusion) are then completed. Should a colostomy or ileostomy be required, they are created at this point. The nasogastric tube should be confirmed to be in good position. Typically, a nasojejunal feeding tube is positioned in the proximal jejunum to facilitate early postoperative enteral alimentation. Final counts should then be obtained, and when correct, closure initiated.

Fascial closure is typically performed with absorbable number one suture. The subcutaneous tissue can be approximated if thick and the skin closed. The skin should be closed at the midline, as well as at the cannula sites. If a stoma is required, it is then matured and dressed with an appropriate appliance. After the dressings are placed, patients are typically extubated and taken to the recovery area. Intensive care unit (ICU) monitoring is required for most, but not all, cases. Operative dictation should be completed immediately following the procedure to ensure that all relevant details are crisply recalled. Long-term follow-up is greatly facilitated by notes that include the areas where disease was encountered, the peritoneal carcinomatosis index, and the completeness of resection, as well as the volume and location of residual disease if any.

Postoperative Care

Patients undergoing substantial resection with HIPEC typically stay in the ICU overnight. Antibiotics are discontinued after the day of surgery. Patients are encouraged to be out of bed on the first postoperative day and on their feet the second day. Ureteral stents (if placed) are removed if there are no urinary clots, typically on the first postoperative day, with the

urinary catheter removed on the second day. Patients with nasojejunal feeding tubes have nutrition initiated the day after the procedure. Venous thrombosis prophylaxis is continued with fractionated heparin *and* sequential compression stockings. The sequential compression is discontinued when the patient is fully ambulatory, and the fractionated heparin continued for a few weeks after discharge. Nasogastric tube is maintained on low intermittent suction until motility is confirmed.

Results

Patients with low-grade cancer of the appendix who undergo complete cytoreduction have 10-year survival rates in the 75% range. Those who undergo incomplete cytoreduction have a 5-year survival of approximately 50%. Patients with peritoneal metastases from colon or high-grade appendiceal carcinoma, undergoing cytoreductive surgery with HIPEC, have 5-year survival rates in the 30% range, with a median survival of ~30 months after complete resection. Furthermore, it should be kept in mind that the 30-month survival is typically found after the patients have undergone systemic chemotherapy for months.

There has only been one completed prospective randomized trial evaluating cytoreductive surgery with HIPEC to systemic chemotherapy alone. Reported initially in 2003, the findings from this trial of 105 randomized patients (85% colon, 15% appendix) demonstrated a significantly improved median overall survival with cytoreductive surgery and HIPEC of 22.3 versus 12.6 months in the systemic chemotherapy-alone group. Overall survival was significantly associated with the completeness of resection status ($P < 0.0001$) and the initial volume of disease (PCI) score. This was found despite the 8% perioperative mortality that is two to three times that currently reported at leading centers. Although this study showed impressive and durable results, the findings were tempered by low participation rate, high mortality, and a now obsolete 5-FU/leucovorin chemotherapy regimen. Two other colorectal randomized trials were opened in order to compare cytoreductive surgery followed by EPIC (Europe) or HIPEC (United States), versus cytoreduction with systemic therapy. Unfortunately, both trials were closed due to failure to accrue patients. The utility of the intraperitoneal chemotherapy after cytoreductive surgery is currently being tested in the Protige 7 trial in France, which has completed accrual of 280 patients.

Conclusions

The role of cytoreductive surgery for peritoneal disease is clearly established for appendiceal cancer (as well as ovarian and peritoneal mesothelioma and other primary sites) and is increasing for colon cancer with peritoneal metastases. Long-term survival is possible when complete cytoreduction can be achieved.

Although there are some who have suggested that cytoreductive surgery and intraperitoneal chemotherapy are an alternative to systemic chemotherapy, peritoneal metastasis from colon and high-grade appendiceal cancers may best be approached *with* systemic chemotherapy *and* not in lieu of it. Approaching all patients with peritoneal metastasis with therapeutic nihilism is clearly no longer appropriate. Furthermore, close collaboration between medical oncologists and surgical oncologists experienced in the evaluation of, and operative therapy for, peritoneal disease is important to optimize the survival of patients with metastases from colorectal and appendiceal carcinoma. Based upon currently available data, and unless the results of the Protige 7 trial show otherwise, surgery with intraperitoneal chemotherapy should be considered for patients with isolated peritoneal disease who are otherwise fit.

EDITOR'S COMMENT

Dr. Levine has written an excellent chapter describing the concept of cytoreductive surgery and hyperthermic intraperitoneal chemotherapy (HIPEC) for cancers of the appendix and colon. The concept of tumor debulking surgery for locally advanced abdominal malignancy was first described for ovarian cancer in the 1930s. In the 1960s and 70s, research was beginning to demonstrate that survival in stage II and III ovarian cancer patients was directly related to residual tumor mass after cytoreductive surgery. During about the same time, research was starting to show that hyperthermia as well as intraperitoneal chemotherapy was effective at killing cancer cells. Further studies in the 1980s delivered chemotherapeutic agents at concentrations up to 30 times higher than those safely administered intravenously. As cytoreductive surgery and heated intraperitoneal chemotherapy were combined as a therapeutic approach to intra-abdominal malignancy, it became apparent that the completeness of cytoreduction was associated with survival benefit. In 1995, Dr. Paul Sugarbaker created and described a stepwise approach to cytoreduction in an attempt to standardize and optimize the process.

HIPEC is also known as intraperitoneal hyperthermic chemoperfusion (IPHC) or the Sugarbaker technique/procedure. HIPEC is used most often after tumor debulking for cancers of the appendix, colorectal cancer, ovarian cancer, and gastric cancer. It has also been described for use in mucinous adenocarcinoma of the appendix, mesothelioma, and low-grade sarcoma. Tumor debulking and cytoreduction may include removal of all involved peritoneal areas and even all or parts of involved organs as described in this chapter. These procedures may be 8 to 10 hours long and associated with a significant rate of complications. The volume–outcome relationship has been demonstrated in

many complex procedures, including esophagectomy, pancreas resection, bariatric surgery, and knee replacement, to name a few. At the current time, cytoreductive surgery and HIPEC are performed at a high volume in a small handful of centers across the country. The author of this chapter is from one such center and makes the point that these procedures "present a substantial surgical challenge…associated with a long learning curve for the surgical teams, and should not be attempted by the occasional operator." I would strongly agree that these procedures should be undertaken by only the most highly trained, focused, and collaborative multidisciplinary teams at centers with appropriate resources to manage critically ill patients with potentially significant postsurgical complications.

Minimally invasive surgery has substantially reduced the morbidity of many procedures. Minimal-access cytoreductive surgery with HIPEC has been studied in patients with low tumor burden and with disease of less malignant potential. The PCI score is referenced in this chapter without a clear description. The peritoneal cancer index (PCI) is a scoring system that utilizes tumor size and region of distribution to quantify disease burden. So far, most trials of minimally invasive cytoreductive surgery plus HIPEC have included only patients with low PCI scores. With strict patient selection, laparoscopic cytoreductive surgery and HIPEC have been demonstrated to be a procedure associated with minimal morbidity and mortality and shorter operating times while achieving similar operative and oncologic outcomes to the open procedure. Concerns regarding the ability to complete a thorough examination of the peritoneal cavity have precluded the widespread application of this technique until further evidence is gathered.

The technical descriptions in this chapter include many bits of excellent advice universally applied to almost any surgical procedure. In describing the decision process to proceed with extensive small bowel resection for diffuse disease, the author advises "*measurements with* a ruler *of residual small bowel, beyond the ligament of Treitz, after all resections are completed, should be performed prior to resecting. Rarely should more than two anastomoses be required.*" This is an excellent piece of advice that may also be applied to cases of ischemic bowel and resections in the case of adhesive or inflammatory bowel disease. This falls under the surgical dictum of "measure twice and cut once." When discussing documentation of the procedure performed and operative findings the author advises, "*Operative dictation should be completed immediately following the procedure to ensure that all relevant details are crisply recalled. Long-term follow-up is greatly facilitated by notes that include the areas where disease was encountered, the peritoneal carcinomatosis index, and the completeness of resection, as well as the volume of residual disease if any.*" In the current era of computerized medical records and dictation templates, the necessity of detailed and accurate operative reports has become readily apparent, especially for those of us who perform complex reoperative surgery. An accurate roadmap describing what was encountered and what

exactly was done at the time of an index surgical procedure can be invaluable for patients needing additional surgery or treatment at a later date.

The major controversy surrounding cytoreduction plus HIPEC revolves around the role of hyperthermic intraperitoneal chemotherapy in achieving the observed survival advantage when compared to cytoreduction and systemic chemotherapy. Chemoperfusion has continued to progress since the HIPEC delivery system was first trialed. The potential benefits of the intraperitoneal delivery of antineoplastic drugs are significant. Hyperthermia aids in increased cellular penetration of the drug while synergistically enhancing cytotoxicity. Moreover, vascular stasis of microcirculation occurs in neoplastic cells at temperatures produced by HIPEC, while normal cells experience increased flow. This, combined with the selective accumulation of lactic acid and the resulting lowered level of pH in neoplastic tissue, results in cell death. Drug concentrations achieved through this route cannot be replicated by intravenous chemotherapy and, to some extent, systemic toxicities are avoided.

Potential future directions include improved methods for appropriate patient selection (advanced imaging and possibly genetic tests). Dynamic techniques for accurate intraoperative pathologic diagnosis may prevent unnecessary interventions. Some of these technologies and techniques may enhance the adoption of minimally invasive techniques for addressing peritoneal malignancy. This may include the robotic platform and perhaps telemedicine as a modality for increasing access to surgical expertise for these complex resections. Additional research will define the role of intraperitoneal chemotherapy. Although significant progress has been made in improving survival from intra-abdominal peritoneal malignancy, there is still much work to be done.

161 Management of Retrorectal Tumors

Cindy Kin and Mark Welton

ETIOLOGY AND PATHOPHYSIOLOGY

The retrorectal space is the continuation of the retroperitoneal plane in the pelvis. It is also called the presacral space. This space is a potential space containing loose areolar tissue, fat, and connective tissues. Its anterior boundary is the fascia propria of the rectum that contains the mesorectum, and its posterior boundary is the sacrum and the overlying presacral fascia. The lateral boundaries are the ureters and internal iliac arteries. The superior boundary is the point at which the upper rectum curves away from the sacrum. The posterior boundary of the retrorectal space is technically the rectosacral (Waldeyer) fascia, although we consider tumors arising in the supralevator space that is inferior to the rectosacral fascia to belong to this category as well.

The classification of the different types of retrorectal tumors is based on the etiology of the tumors: congenital, neurogenic, osseous, and miscellaneous (Table 161.1).

Congenital Tumors

Most cystic retrorectal lesions are congenital. Developmental cysts may be epidermoid, dermoid, or enteric. Enteric cysts may be either tailgut cysts (also known as retrorectal cystic hamartomas) or rectal duplication cysts. Tailgut cysts are the most common benign retrorectal tumor in adults. Women are more likely (15:1) to have retrorectal cysts than men.

Teratomas and teratocarcinomas arise from totipotential cells originating in utero, and are classified as mature (benign); immature, probably benign; immature, possibly malignant; or frankly malignant. However, even mature teratomas have malignant potential. Teratomas are the most common type of retrorectal tumor seen in infants and children. Recurrent teratomas often harbor malignancy. Adult sacrococcygeal teratomas are rare and occur more commonly in female patients. Thirty

percent of sacrococcygeal teratomas harbor malignancy at the time of resection. Teratomas and teratocarcinomas are generally well encapsulated, and even those with malignancy do not tend to invade neighboring structures.

Chordomas are rare neoplasms originating from notochordal remnants. Half of all chordomas occur in the pelvis and retrorectal space, and they represent the most common malignant tumor occurring in the retrorectal space. They occur more commonly in men and have a peak incidence in the sixth and seventh decades. They are locally destructive and tend to recur locally, although they don't tend to metastasize.

Anterior sacral meningoceles are also rare congenital lesions occupying the retrorectal space, and are caused by herniation of the theca through a sacral defect into the pelvis. Neural structures may be present in the herniated sac, and this can ultimately lead to neurologic symptoms.

Neurogenic Tumors

Tumors of neurogenic etiology occurring in the retrorectal space include benign tumors arising from the peripheral nerve sheath such as neurofibromas, schwannomas, ganglioneuromas, and ependymomas; and malignant tumors arising from the peripheral nerve sheath such as malignant schwannomas, neurofibrosarcomas, neuroblastomas, and ganglioneuroblastomas. Benign peripheral nerve sheath tumors such as schwannomas and neurofibromas comprise up to 10% of all retrorectal tumors. Malignant retrorectal tumors of neurogenic origin such as neuroblastoma are rare and occur more in children. Malignant schwannomas of the pelvis occur more in adults.

TABLE 161.1 Classification of Retrorectal Tumors

Congenital

Benign	Malignant
Developmental Cysts	Chordoma
Epidermoid	Teratocarcinoma
Dermoid	
Mucus-secreting	
Teratoma	
Duplication of rectum	
Anterior sacral meningocele	
Adrenal rest tumor	

Neurogenic

Benign	Malignant
Neurofibroma	Neuroblastoma
Ganglioneuroma	Ganglioneuroblastoma
Neurilemoma/Schwannoma	Malignant peripheral sheath tumors (malignant schwannoma, neurofibrosarcoma, neurogenic sarcoma)

Hemangioma	Hemangiopericytoma
Endothelioma	Metastatic carcinoma
Desmoid	

Other

Ectopic kidney
Hematoma
Abscess

Osseous Tumors

Primary tumors of the sacrum are very rare. Giant cell tumors are rare bone lesions that are benign in the large majority of cases, although 5% of cases may metastasize to the lungs. Aneurysmal bone cysts are neither aneurysms nor cysts, but rather a neoplastic lesion that may arise primarily (two thirds of aneurysmal bone cysts), or secondarily within an existing bone tumor such as a giant cell tumor or osteosarcoma (one third of aneurysmal bone cysts). Twelve percent of aneurysmal bone cysts occur in

the pelvis and sacrum.

Osteoid osteomas and osteoblastomas are innervated bone-forming lesions. They have been historically classified as one or the other based on size. Tumors 1 cm or less in diameter are classified as osteoid osteoma and those 2 cm and greater are classified as osteoblastoma; those 1 to 2 cm in size are classified as osteoma or osteoblastoma according to other features, including anatomic site, presence of a nidus, and presence of peripheral sclerosis. Osteoblastomas are more likely to occur in the sacrum, while osteoid osteomas are more likely to occur in the extremities. Osteosarcomas occurring in younger patients are more likely to be primary tumors, while those occurring in older patients are more likely to be secondary tumors due to Paget disease or prior pelvic radiation. About half of osteoblastomas are associated with metastases at the time of presentation. Prognosis is poor, with 5-year survival of 33% for patients without metastases at the time of diagnosis. Patients with secondary tumors have overall worse outcomes than those with primary tumors. In patients with primary tumors, sacral location, positive surgical margin, and larger tumor size are poor prognostic factors. Ewing sarcoma presents more commonly in males than females, and tends to affect teenagers and young adults. It is the second most common bone tumor in this age group. Chondrosarcomas may present in patients of any age, and occur most commonly in the pelvis and shoulder. Chondromyxosarcoma is a subtype of this tumor.

CLINICAL PRESENTATION

Back or pelvic pain is the most common symptom of a retrorectal tumor, although the clinical presentation is quite variable and can include neurologic symptoms affecting bowel function, bladder function, or lower extremity function, constipation, difficulty evacuating, or abdominal pain.

Tailgut cysts often go unrecognized or misdiagnosed because of their rarity and the wide variability and nonspecificity of their associated symptoms. About half of patients with tailgut cysts present with symptoms, which are highly variable and nonspecific. Patients may have bowel-related complaints such as constipation, diarrhea, change in stool caliber, rectal bleeding, or difficult evacuation. They may present with pain in the abdomen, rectum, anus, pelvis, back, or lower limbs. They may also present with recurrent perianal infections, and many of them have already undergone prior procedures to drain abscesses. Half of patients

with tailgut cysts have no symptoms at all, and their cysts are found incidentally.

Sacral chordomas most commonly present with pain that is worse with sitting (85% of patients), and cauda equina symptoms of saddle anesthesia and bladder or bowel dysfunction (70% of patients). Adults with sacrococcygeal teratomas most commonly present with pelvic pain or a palpable mass. Anterior sacral meningoceles may be asymptomatic and discovered incidentally, but as they grow they cause pressure on neighboring pelvic structures, causing pelvic pain, urinary retention, and chronic constipation. They have been reported to be a rare cause of cauda equina syndrome, or meningitis or perirectal sepsis if they become secondarily infected.

A presacral ganglioneuroma typically becomes symptomatic when the mass becomes so large that it causes abdominal or back pain, constipation, or bowel obstruction (Fig. 161.1). Other retrorectal neurogenic tumors including neurofibromas and schwannomas can cause similar symptoms of pelvic pain or constipation, as well as neurologic symptoms.

Figure 161.1. MRI T1-weighted images of a ganglioneuroma show a hypointense homogeneous mass. This patient is a young woman who was found to have this pelvic mass during her first gynecologic examination, during which her physicians could not locate her cervix due to the sharp anterior angulation as a result of the mass effect.

Osseous tumors of the sacrum may cause radicular pain or neurologic dysfunction affecting bowel and bladder function.

INDICATIONS AND CONTRAINDICATIONS

Traditionally, it has been recommended that retrorectal tumors should be

surgically resected in order to prevent malignant transformation, prevent secondary infection, alleviate symptoms, and obtain a definitive histologic diagnosis. With advancements in imaging modalities, some authors have recommended that cystic lesions that do not have any suspicious radiologic features may be safely followed with serial imaging rather than undergo resection. However, the authors recommend that tailgut cysts be removed when discovered, not only to relieve symptoms but also because of the small risk of malignant degeneration.

Teratomas should be resected along with the coccyx to reduce the risk of recurrence, especially as recurrence of teratomas is often associated with malignant transformation. Anterior sacral meningoceles should also be resected because they will enlarge with time due to their tendency to enlarge and increase pressure on surrounding structures. Untreated anterior sacral meningoceles may cause neurologic deficitis, meningitis, fistulous connections with the rectum, and urinary complications.

Neurogenic tumors range in malignant potential, and surgical management should be tailored accordingly. Neurogenic tumors in the retrorectal space should undergo surgical resection. Ganglioneuromas, while slow-growing and benign, should be resected to establish a definitive diagnosis, and also for therapeutic purposes given their potential to cause symptoms from mass effect.

Management of osseous tumors of the sacrum varies depending on the pathology, proximal extent of the lesion, and preoperative bowel or bladder function. Patients with malignant tumors should undergo wide resection with adequate margins. Patients with benign distal tumors where bilateral S3 preservation is feasible should also undergo wide resection. Benign sacral tumors that involve S3 and above may be treated with serial embolization. Aneurysmal bone cysts may be treated with arterial embolization, avoiding the morbidity of surgical excision. Sacral giant cell tumors may be treated with intralesional resection/curettage rather than sacrectomy, although wide excision or radiation therapy may be used for patients with more extensive or aggressive disease. The optimal management of Ewing sarcoma of the pelvis remains controversial, with some centers treating with local radiation therapy alone, and others advocating for surgical resection with radiation and/or chemotherapy. Treatment of chondrosarcoma depends on tumor grade, but surgical resection is the mainstay of treatment given the resistance of these tumors to radiation and chemotherapy.

PREOPERATIVE PLANNING

Physical examination of the perineum and digital rectal examination aid in determining the location and size of the lesion. Anoscopy and proctoscopy are necessary for determining whether there is any communication with the anus or rectum, especially in patients who have undergone prior procedures.

Cross-sectional imaging with computed tomography (CT) and/or magnetic resonance imaging (MRI) of the pelvis is key for surgical planning and is often diagnostic. MRI is superior to CT imaging in its ability to differentiate benign from malignant tumors. Cystic lesions are less likely to be malignant than solid or heterogeneous tumors. Other radiologic features that raise the suspicion for malignancy include irregular infiltrating borders and enhancement. For the purposes of surgical planning, imaging can identify the extent of the tumor and its involvement of pelvic viscera and pelvic sidewall structures.

Figure 161.2. CT demonstrates a large thin-walled hypoattenuating lesion posterior to the anorectal junction, consistent with a tailgut cyst. This patient presented with difficulty evacuating stool.

In cases of developmental cysts such as tailgut, dermoid, and neurenteric cysts, CT will demonstrate a thin-walled hypoattenuating nonenhancing lesion in the retrorectal space (Figs. 161.2 and 161.3). In the case of secondary infection or fistula, the cyst may have a thicker wall

with inflammatory changes, and may contain air if there is communication with the rectal lumen. Pelvic MRI is also helpful in making the diagnosis and will demonstrate a thin-walled lesion that is hypointense on T1-weighted images and hyperintense on T2-weighted images (Figs. 161.4 and 161.5). Malignant degeneration is suspected if enhancing focal irregular wall thickening on both T1- and T2-weighted images is seen. The pathognomonic sign of an anterior sacral meningocele is the scimitar sign on plain x-ray, and CT or MRI should be obtained for confirmation.

Figure 161.3. CT demonstrates a large thin-walled hypoattenuating lesion posterior to the anorectal junction, consistent with a tailgut cyst. This patient presented with difficulty evacuating stool.

Sacral chordoma is the most common primary sacral lesion. MRI is commonly used for surgical planning purposes, and will demonstrate a heterogeneous mass with destruction of the sacrum (Fig. 161.6). MRI shows a ganglioneuroma to be a hypointense homogeneous mass on T1-weighted images, and a hyperintense heterogeneous mass on T2-weighted images (Fig. 161.7).

Rectal leiomyosarcoma is a very rare tumor arising from smooth muscle, and most commonly occurring in the distal rectum. If it involves the rectal mucosa, anoscopy or proctoscopy may reveal surface ulceration

and bleeding. CT demonstrates an enhancing heterogeneous multilobulated tumor with cystic necrotic areas (Figs. 161.8 and 161.9).

Figure 161.4. Tailgut cyst. MRI demonstrates a thin-walled lesion that is hypointense on T1-weighted images.

Preoperative biopsy is rarely necessary as preoperative imaging usually provides sufficient diagnostic information. Preoperative biopsy carries the risk of tumor seeding with increased recurrence risk, as well as the risk for secondary infection, so it should only be performed if the results will change management. In some series, biopsy of solid retrorectal tumors has been found to be safe and useful for guiding treatment decisions. For example, in the case of a possible presacral ganglioneuroma versus malignant schwannoma, preoperative biopsy or fine needle aspiration can

be helpful in determining the surgical plan—the former is a benign tumor that does not warrant such an extensive resection that would cause morbid neurologic deficits while complete surgical resection for the latter is the recommended treatment. Even with preoperative fine needle aspiration or biopsy, establishing a firm diagnosis of ganglioneuroma preoperatively can be difficult. While neurogenic tumors are typically indistinguishable from one another on radiographic and neuroimaging evaluation, MRI can help distinguish lesions of pelvic origin from those of spinal origin, as chordomas, teratomas, soft tissue sarcomas, Ewing sarcoma, osteosarcomas, chondrosarcomas, and metastases tend to involve bone.

Preoperative counseling regarding expected functional outcomes is paramount, especially if neurologic deficits are expected. A robust shared decision-making process is necessary in order for patients to make high-quality decisions that incorporate their personal values and preferences regarding their quality of life. Patients who are expected to have fecal incontinence should be counseled about having a colostomy for improved bowel management.

As some retrorectal tumors may be hypervascular, preoperative embolization may decrease surgical blood loss. Ensuring availability of blood products for possible transfusion is also important.

The final important aspect of surgical planning is assembling the necessary surgical team members. Interventional radiologists may be needed for preoperative embolization. Urology may be needed to place ureteric stents. General or colorectal surgeons may be needed to mobilize the rectum off the tumor and often work with neurosurgeons or orthopedic surgeons for the tumor resection, especially when sacrectomy is necessary. Plastic surgeons may be required for reconstruction of the resultant soft tissue defect. The operating room staff needs to be aware of the various steps in the case including changes in surgical teams and repositioning needs. These cases often will take many hours, so it is ideal for these complex and high-risk cases to start early in the morning.

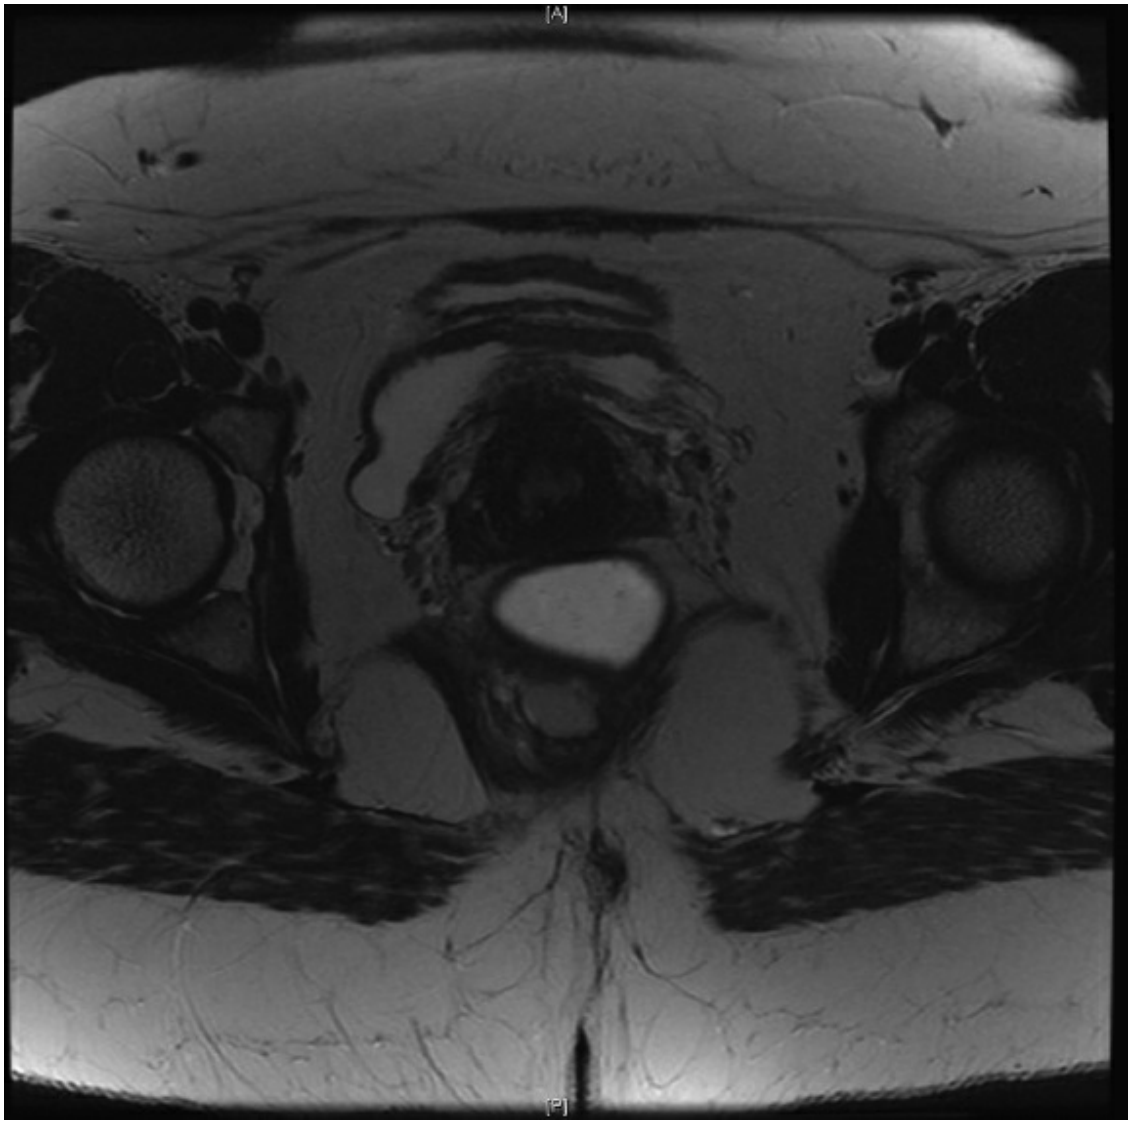

Figure 161.5. Tailgut cyst. MRI demonstrates a thin-walled lesion that is hyperintense on T2-weighted images.

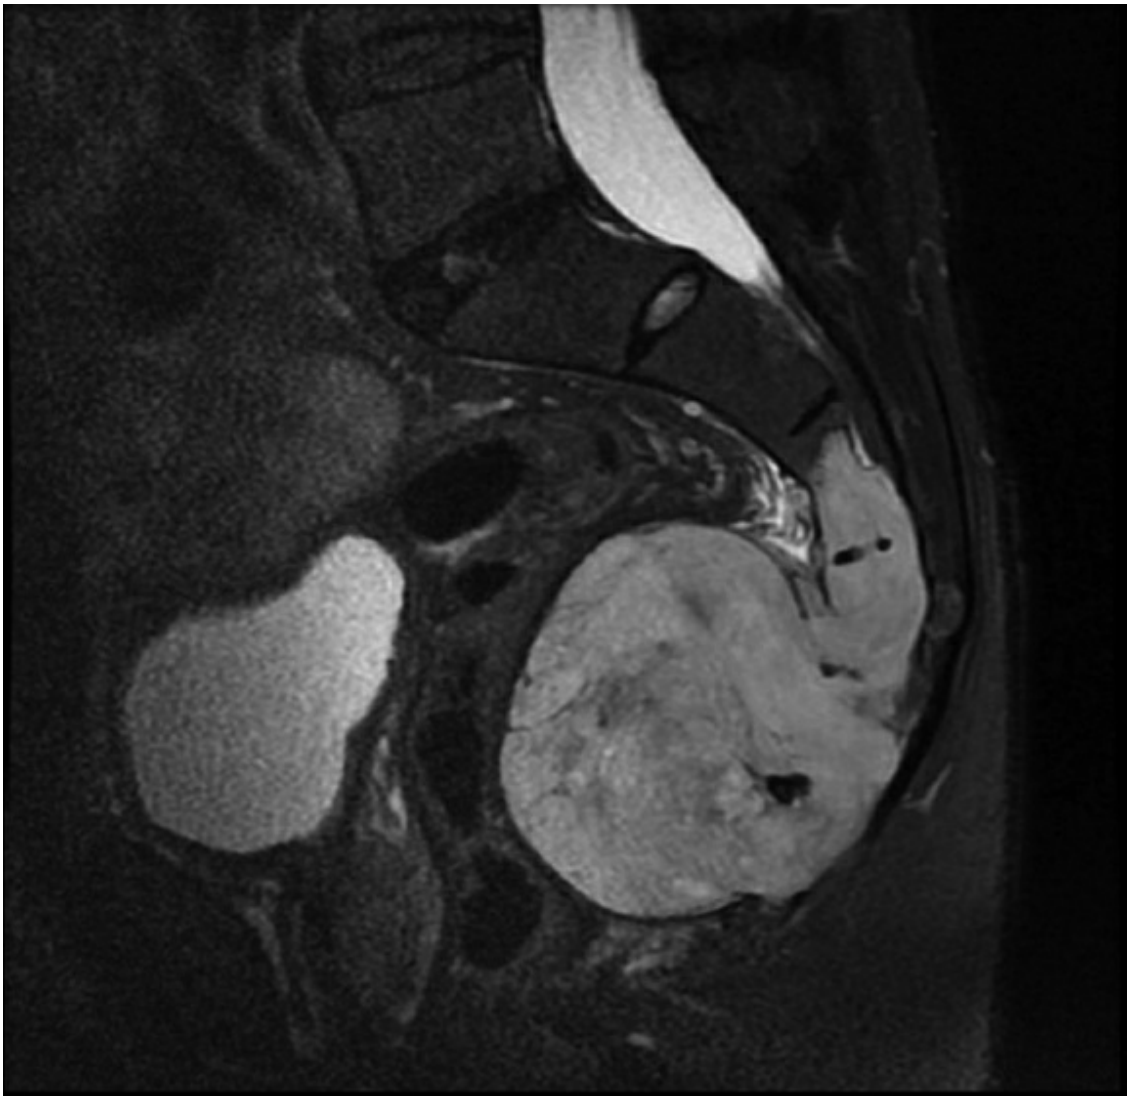

Figure 161.6. Sacral chordoma. MRI is ideal for surgical planning, and demonstrates a heterogeneous mass with destruction of the sacrum.

SURGICAL TECHNIQUE

There are three options for the surgical approach: posterior approach, anterior approach, and combined anterior and posterior approach.

Posterior Approach

The posterior approach can be used for more caudal tumors that are at or inferior to S3 and do not involve the pelvic viscera or pelvic sidewalls. Most tailgut cysts are amenable to this approach, although some are so large that they require a combined anterior and posterior approach. The patient is placed in the prone jack-knife position and the table is flexed. The buttocks are spread using tape. A self-retaining retractor is helpful for

exposure (Fig. 161.10). A vertical midline incision centered over the coccyx or a parasacrococcygeal incision can be used. If a vertical midline skin incision is made, the anococcygeal ligament is divided to gain access to the retrorectal space, taking care not to violate the tumor capsule or cyst wall. Some surgeons prefer a parasacrococcygeal incision, especially if the tumor is larger or extends cranially, to avoid having to divide the anococcygeal ligament. Insertion of the index finger into the anus and rectum may aid in retraction and exposure, as well as identification of the rectal wall. Sterility of the surgical field can be maintained by using sterile adhesive drapes between the anus and the incision site, and changing the surgeon's glove each time a digital exam is performed. Insertion of a sizer into the rectum can also be helpful for identification of the rectal wall. Tailgut cysts should be removed in their entirety to prevent future recurrences and malignant transformation. Complete cyst excision may require distal sacrectomy or coccygectomy; some surgeons routinely perform coccygectomy during tailgut cyst excision because of the possibility that the coccyx is the source of totipotent cells that may lead to recurrence of the cyst if not removed. An associated fistula to the rectum may be present and require rectal wall repair. This is suspected when there have been prior procedures performed for incision and drainage of perianal abscesses, or if the cyst has been secondarily infected (Figs. 161.11 and 161.12).

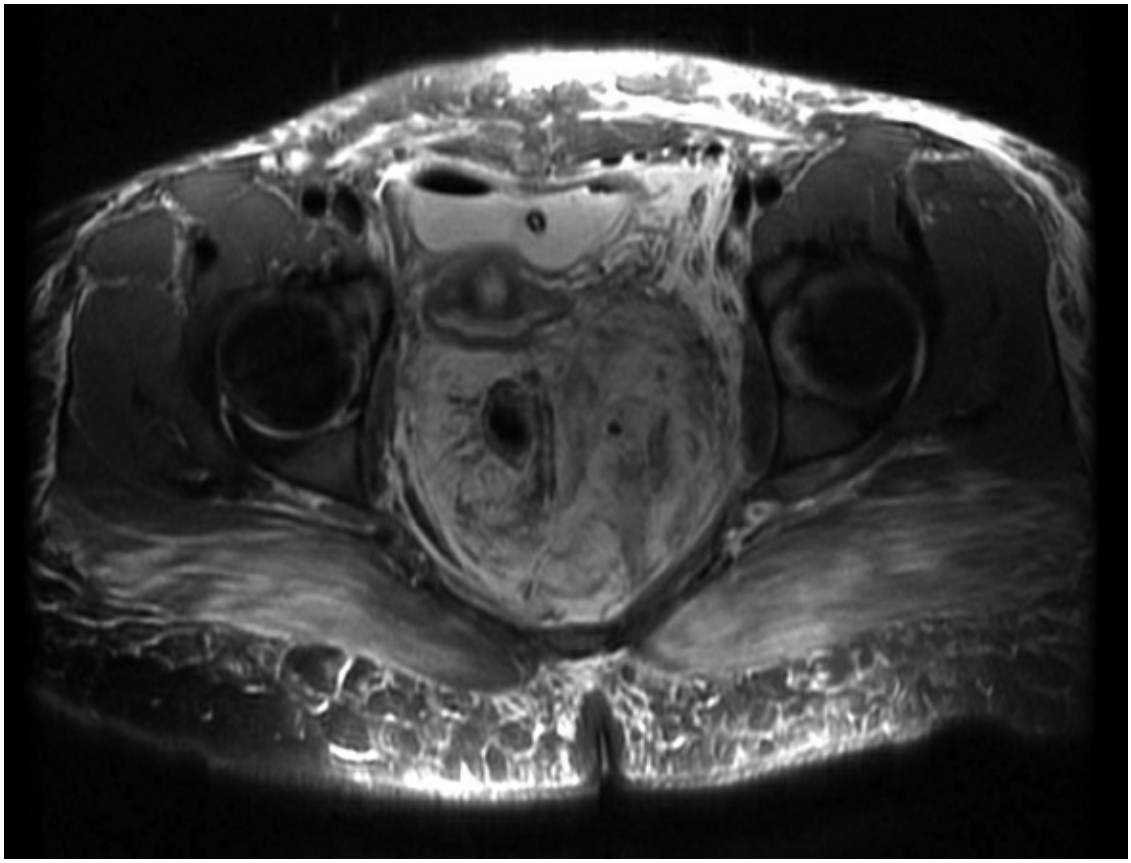

Figure 161.7. T2-weighted images of ganglioneuroma show a hyperintense heterogeneous mass.

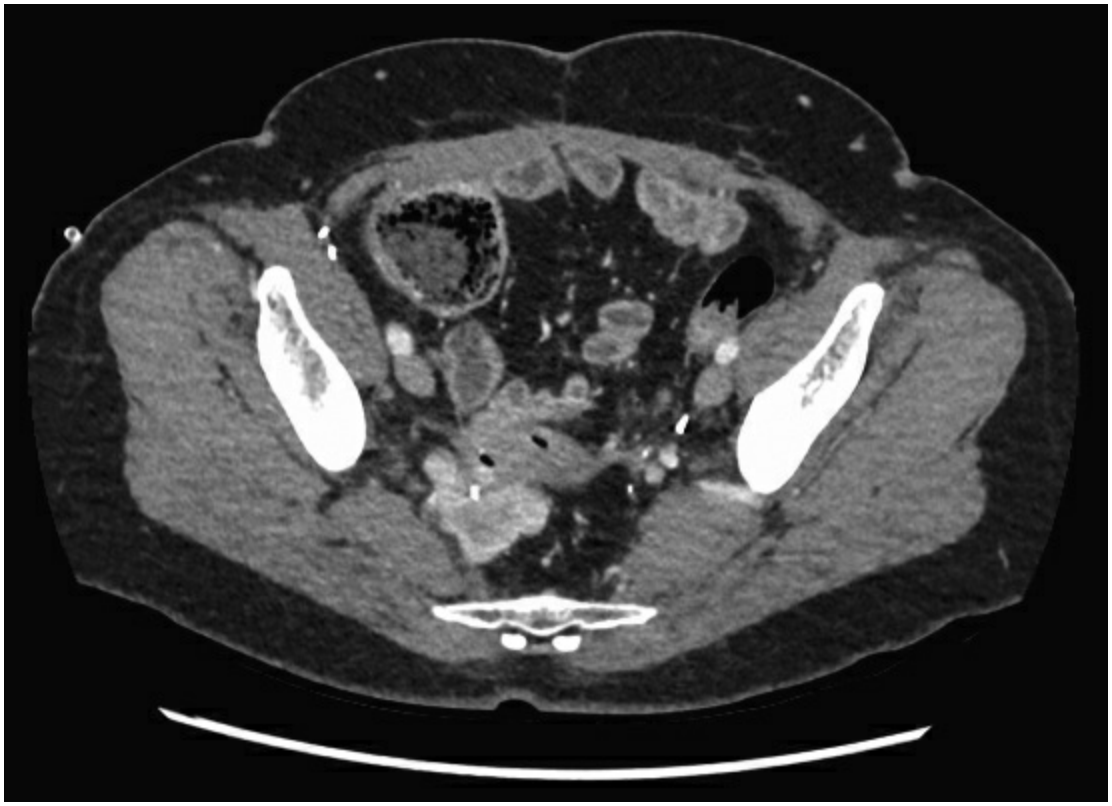

Figure 161.8. This patient had recurrent pelvic leiomyosarcoma

that involved the rectal wall and required redo low anterior resection. CT images demonstrate an enhancing heterogeneous multilobulated tumor with cystic necrotic areas.

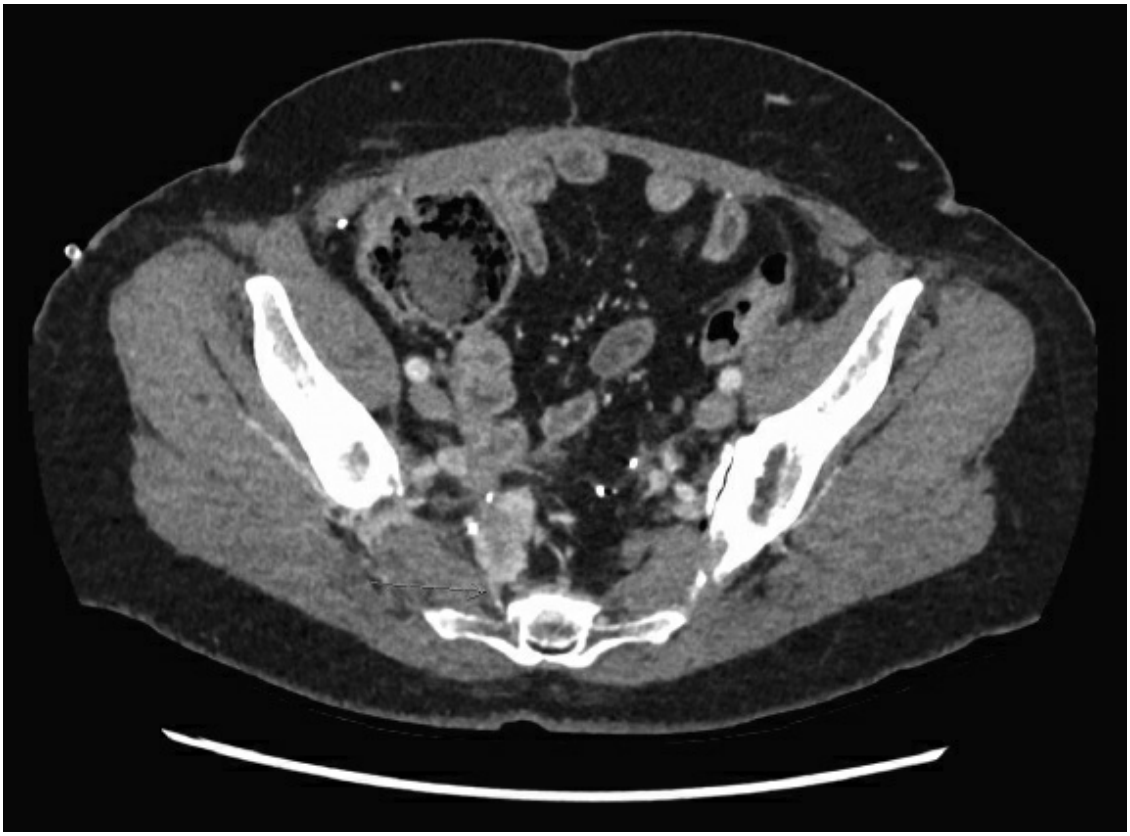

Figure 161.9. This patient had recurrent pelvic leiomyosarcoma that involved the rectal wall and required redo low anterior resection. CT images demonstrate an enhancing heterogeneous multilobulated tumor with cystic necrotic areas.

Figure 161.10. Most tailgut cysts are amenable to resection via a posterior approach.

For distal tumors such as chordomas that directly involve S4 and S5, the origins of the gluteal muscles and sacrotuberous and sacrospinous ligaments will need to be divided to facilitate dissection and division of the sacrum and en bloc resection of the tumor. Dissection around the tumor anteriorly requires recognition of the fascia propria of the rectum anterior to the tumor in order to remain in the right plane. Closure of the posterior defect may require reconstruction with bilateral gluteal flaps, depending on

the extent of sacrectomy.

Anterior Approach

The anterior approach is appropriate for retrorectal tumors that do not require sacrectomy, and which may involve pelvic viscera and the pelvic sidewall structures. The patient is placed in a modified Lloyd-Davies position or a split-leg position (Fig. 161.13). Placement of bilateral ureteric stents may be helpful as the anatomy may be distorted from the tumor. The open anterior approach is performed with a vertical midline incision. The ureters and iliac vessels are identified. One must then determine whether the tumor is involving the rectum or other pelvic organs.

If the tumor is not involving the rectum directly, then the next step is to open the presacral space by incising the peritoneum just posterior to the superior rectal artery. The dissection in the presacral space is continued inferiorly to the pelvic floor, and the peritoneal layer on either side of the rectum is divided to mobilize the rectum completely off the tumor (Figs. 161.14 and 161.15). During this dissection, it is important to remember that the retrorectal tumor distorts the normal contour of the sacrum, and the plane of dissection will be more anterior than usual. Once the rectum is mobilized off the tumor, it is retracted anteriorly and the tumor can then be resected.

The extent of resection depends on which structures are directly involved by the tumor, and whether the tumor is benign or malignant. Nerve-sparing techniques for benign retrorectal neurogenic tumors may preserve function and minimize postoperative morbidity. Intraoperative nerve monitoring decreases the risk of a postoperative motor deficit. In the case of a large presacral ganglioneuroma, complete resection with division of nerve roots causes excessive morbidity for a slow-growing benign tumor. An anterior approach can be employed in which the general or colorectal surgeon mobilizes the rectum away from the tumor, and the neurosurgeons debulk the tumor with the aid of intraoperative neurologic monitoring. Intralesional debulking improves the exposure and allows for identification of nerve roots, so that that capsule may be dissected out as well; however, if the capsule is densely adherent to functional nerve roots, it can be left in place rather than risk neurologic dysfunction (Fig. 161.16). While an anterior intraperitoneal approach via a midline laparotomy is ideal for midline low pelvic tumors, an anterolateral retroperitoneal approach may be used for retrorectal ganglioneuromas that are located

higher and lateral in the pelvis.

Figure 161.11. This patient presented after having undergone incision and drainage of what was thought to be a perianal abscess. She actually had a tailgut cyst that became infected as a result of the first procedure.

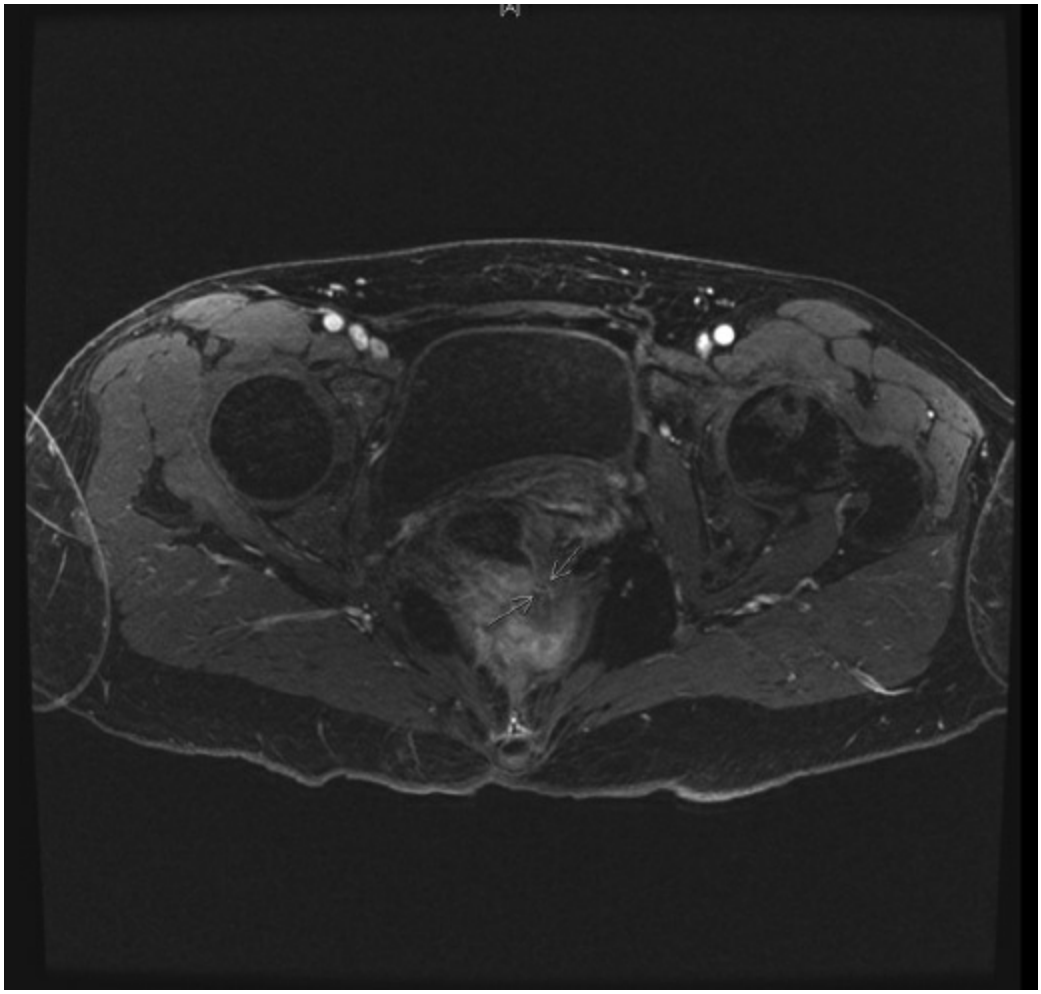

Figure 161.12. This patient underwent drainage of what was thought to be a perianal abscess. The cyst was drained through the rectal wall, resulting in a chronic fistula.

For patients who do not require sacrectomy, but do require rectal resection to remove the retrorectal tumor, often a low pelvic anastomosis is required. Because of the high risk of anastomotic leak associated with these low anastomoses, diverting loop ileostomy is recommended to ameliorate the septic complications in the event of a leak.

Figure 161.13. For the anterior approach, the patient is placed in modified Lloyd-Davies position. This allows for proctoscopic examination of the rectum to ensure no rectal injury during mobilization. This also allows for rectal resection and re-anastomosis or abdominoperineal resection if the tumor directly involves the rectum.

Combined Anterior and Posterior Approach

A combined anterior and posterior approach is necessary if the tumor involves the sacrum and requires sacrectomy, and there is potential involvement of pelvic viscera. Even without direct involvement of the pelvic viscera, tumors that extend proximal to S3 should be managed via a combined approach. The general or colorectal surgeons start with the laparotomy, or via a minimally invasive fashion. Laparoscopic port sites for rectal mobilization include a supraumbilical port and bilateral upper and lower quadrant ports (Fig. 161.17). The authors have found that robotic mobilization offers excellent views of the pelvis, especially in a small space that is largely occupied by an anteriorly bulging tumor. If only rectal mobilization is needed, then the robot should be positioned between the legs so that the arms are targeted toward the pelvis (Fig. 161.18). If proctectomy with mobilization of the left colon and splenic flexure is required, then the robot should be positioned on the patient's left side such that the arms are targeted toward the left lower quadrant (Fig. 161.19). The presacral space is opened by incising the peritoneum just posterior to the superior rectal artery, and continuing that dissection sharply to the pelvic

floor. The lateral peritoneal attachments are incised to mobilize the rectum completely off the tumor. Some surgical teams may elect to place a laparotomy sponge between the rectum and the tumor to serve as a marker for the posterior approach. If only rectal mobilization is performed, a proctoscopy with insufflation is performed to confirm that there is no rectal injury.

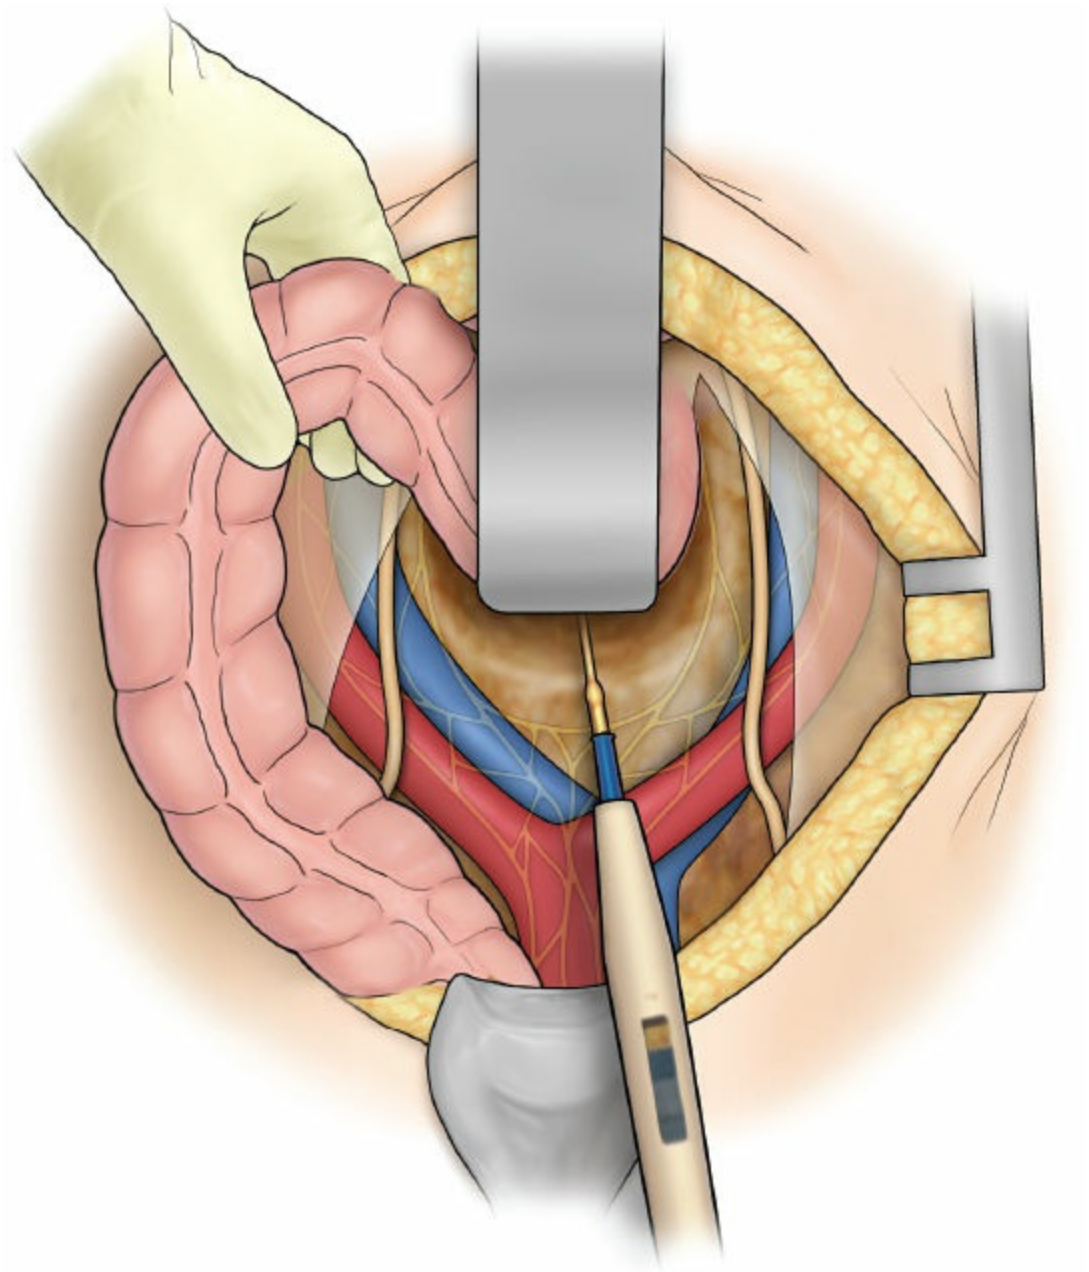

Figure 161.14. Sharp dissection in the avascular plane of the presacral space is performed down to the pelvic floor.

After the rectal mobilization or resection, and closure of the abdominal incision, the patient is then repositioned in prone position and the

sacrococcygectomy with en bloc tumor resection is performed. Intraoperative neurologic monitoring is needed if resection involves dissection around or of the nerve roots. The anesthesiologists need to be aware of this so that they do not administer additional paralytic agents. In cases where a substantial portion of the sacrum is removed, reconstruction with bilateral gluteal muscle flaps may be necessary.

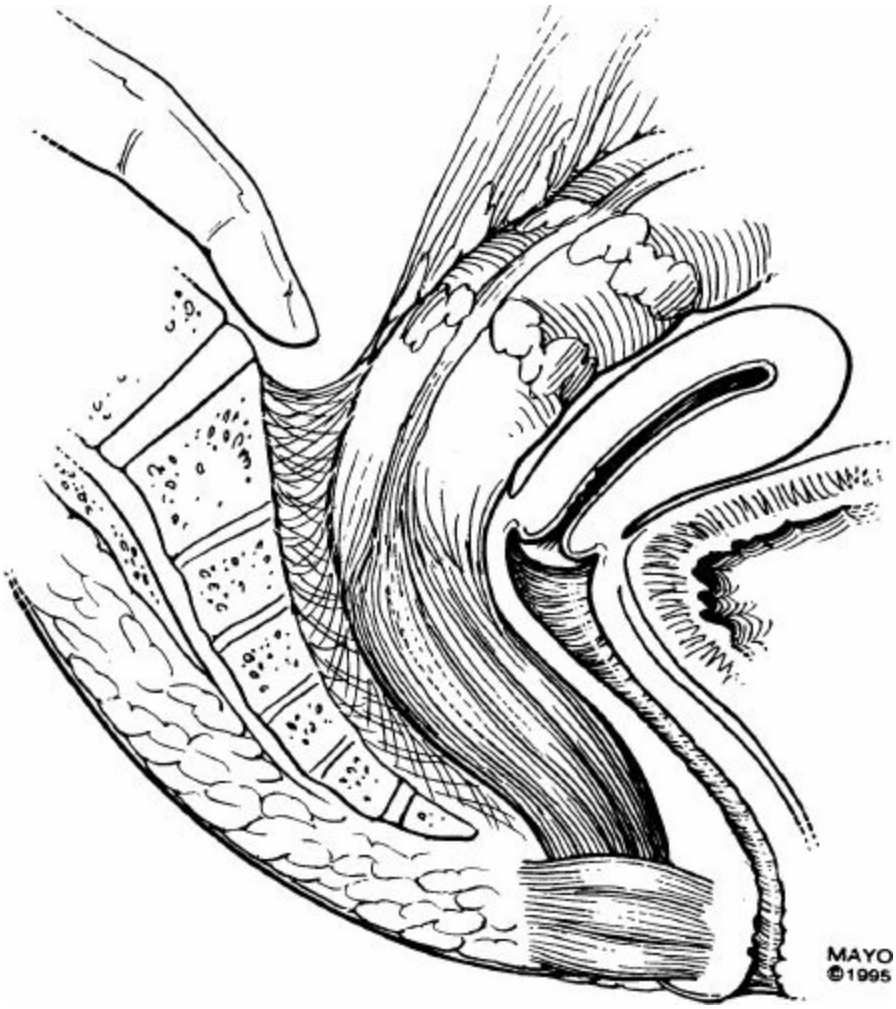

Figure 161.15. The presacral space is entered by retracting the upper rectum anteriorly and incising the peritoneum just posterior to the superior rectal artery.

POSTOPERATIVE CARE

Patients who undergo a posterior surgical approach for tumors like tailgut cysts that do not involve the sacrum have relatively fewer postoperative needs. They can often go home the day of or the day after surgery. Patients who undergo more extensive resections involving sacrectomy have varying postoperative needs depending on the extent of the resection and

any neurologic deficits. Patients who require flaps to cover large defects will often have activity and positional restrictions in order to prevent placing undue pressure on the new myocutaneous flap. Patients who undergo an anterior (laparotomy) approach and mobilization of the rectum off the tumor may experience postoperative ileus.

The need for follow-up imaging and the frequency of follow-up examinations vary depending on the likelihood of recurrence. Tailgut cysts do not warrant follow-up imaging unless malignant degeneration is found. Presacral ganglioneuromas, while benign, should have regular follow-up for at least a year after resection in order to diagnose a potential recurrence, although there are no guidelines for time interval owing to the rarity of this tumor. Malignant tumors require more frequent follow-up to monitor for recurrence.

COMPLICATIONS AND THEIR MANAGEMENT

Complications of tailgut cyst excision include delayed wound healing and pelvic floor dysfunction. Patients who only require a posterior approach for excision are less likely to have postoperative complications than those who require an anterior and posterior approach or those who require sacrectomy.

Patients who undergo sacrectomy are also at risk for wound complications, and also sacral insufficiency fractures. Sacral insufficiency fractures occur in 76% of patients who undergo high-dose radiation for sacral chordomas followed by high sacrectomy, but in no patients who undergo low sacrectomy after high-dose radiation have these fractures. Wound complications including surgical site infection with or without wound dehiscence may occur in up to 30% of patients undergoing sacrectomy for sacral tumors even in highly specialized centers. Risk factors include prior radiation therapy, rectal laceration, larger tumor size, longer operative time, cerebrospinal fluid leakage, history of diabetes, and instrumentation. Other risk factors include prior lumbosacral operations, number of surgeons involved in the case, bowel and bladder dysfunction, and complex soft tissue reconstruction.

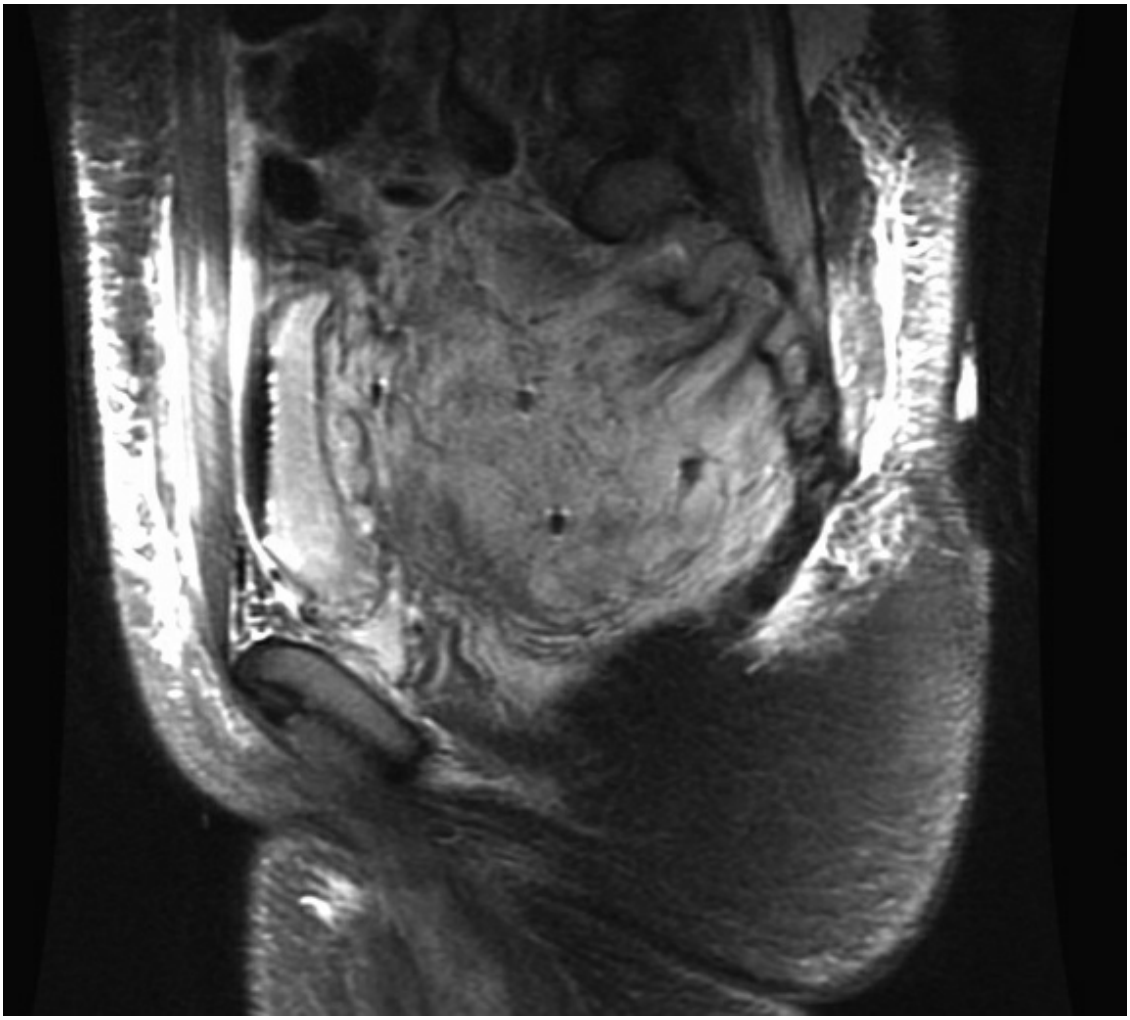

Figure 161.16. Given the benign and slow-growing nature of this ganglioneuroma that involves multiple nerve roots, complete resection of the tumor capsule is not indicated as it would cause significant neurologic deficits.

Anastomotic leak after low anterior resection for retrorectal tumors involving the rectum may occur, and management is dictated by the clinical severity of the anastomotic leak. Minor leaks may be managed with antibiotics and percutaneous drainage, while major leaks may require return to the operating room with proximal diversion or takedown of the anastomosis and creation of an end colostomy.

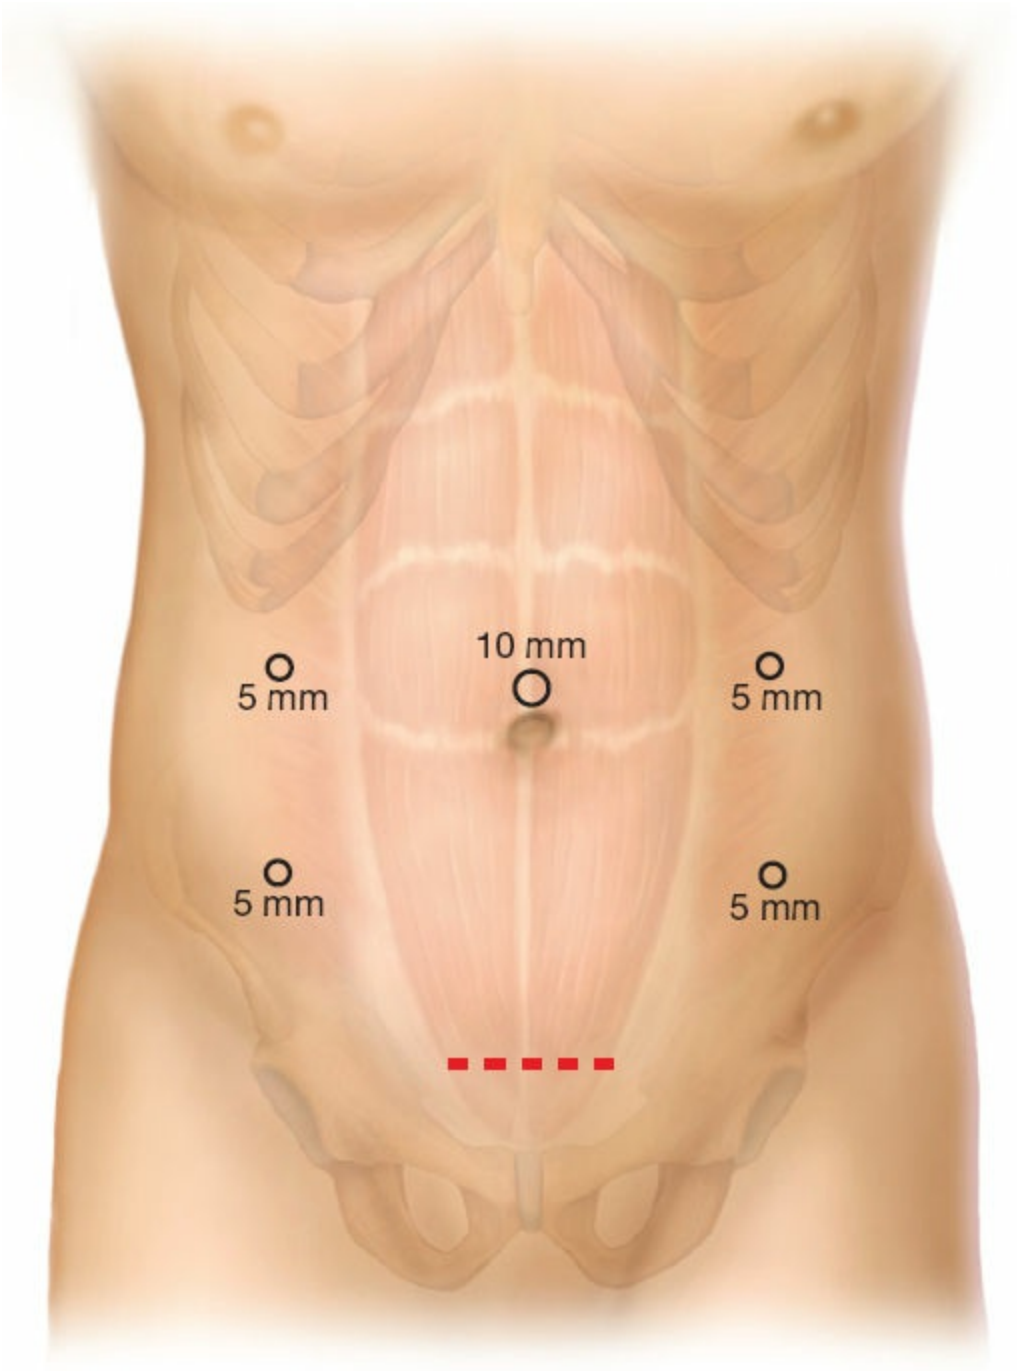

Figure 161.17. Port sites for laparoscopic rectal mobilization or resection.

Chronic pain may occur if there is intraoperative manipulation of the nerve plexuses.

OUTCOMES

The 5-year disease-free survival for benign and malignant retrorectal lesions is 93% and 75%, respectively. The recurrence rate after tailgut cyst

excision ranges from 0% to 16% in multiple small case series.

Overall 5-year survival for all patients with sacral chordoma is 60% based on SEER data, regardless of treatment modality. Patients who undergo surgical resection alone have 82% 5-year overall survival, and those who undergo both surgical resection and radiation have 78% 5-year overall survival. Patients who were treated only with radiation had a 52% 5-year overall survival. This probably reflects the nature of the tumor and resectability; that is, patients with resectable tumors were more likely to undergo surgical intervention and therefore have higher survival rates. Patients with negative surgical margins have a higher 5-year survival than those with a positive surgical margin (86% vs. 67%). Local recurrence occurs in 40% to 46% of patients. Risk factors for tumor recurrence include positive surgical margin and proximal tumor extent.

Patient-reported outcomes among patients undergoing sacrectomy depend on the level of sacral resection. Patients with more caudal resections have better overall physical health, less pain, less interference resulting from pain, better mobility, and better sexual function than those who underwent higher sacrectomies. Postoperative motor, bladder, and bowel function correlates with the level of sacral nerve preservation. Motor function depends on preservation of L5 and S1 nerve roots. Patients with bilateral S1 nerve resection had impaired plantar flexion but were able to walk with support; 56% of patients with bilateral S2 preservation are able to walk normally and 94% of patients with bilateral S3 preservation, and 100% of patients with more distal resections. Patients with bilateral S2 resection had lower scores for bladder function than those with bilateral S3 resection. Normal bladder function occurs in 25% in patients who have preservation of one S2 nerve root, 40% of patients who have preservation of both S2 nerve roots, 73% of patients with preservation of one S3 nerve root, and 83% of patients with preservation of both S3 nerve roots. Patients with bilateral S3 nerve preservation have a lower incidence of urinary leakage and better bladder sensation and lower rates of fecal incontinence compared to those with unilateral S3 nerve preservation. Preservation of both S2 nerve roots results in normal bowel function for 50% of patients, while preserving one S3 nerve root or both S3 nerve roots results in normal bowel function in 70% and 94%, respectively. Finally, preservation of just one S4 nerve root results in normal bladder and bowel function in 100% of patients. Patient-reported outcomes with regard to mental health and physical health were lower in

patients who had preservation of the S2 nerve roots compared with those who had S3 preservation. Patients with preservation of the S2 nerve roots had a better orgasm score than those with preservation of the S1 nerve roots. There are no differences found with regard to mental or physical health or pain between patients who underwent sacrectomy with colostomy or without colostomy.

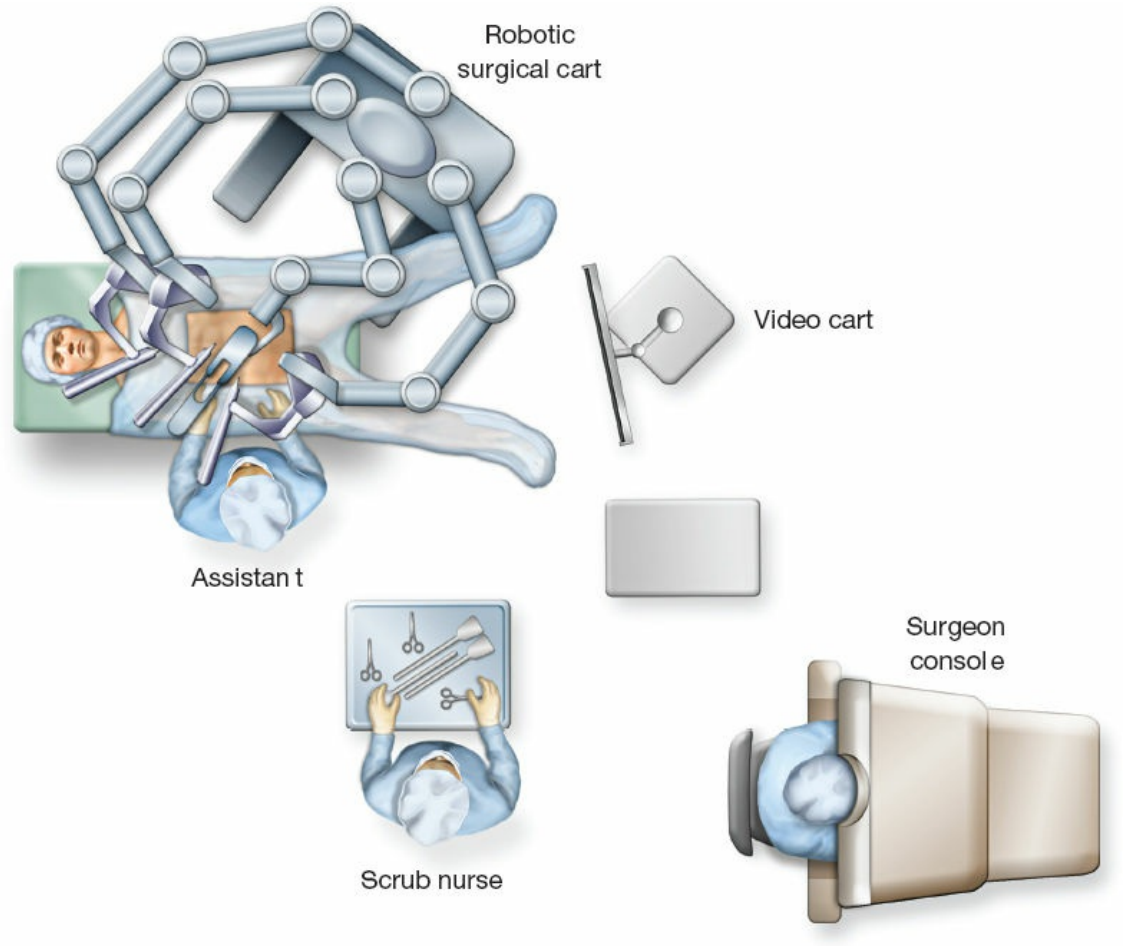

Figure 161.19. Robotic set-up for proctectomy.

SUMMARY

Retrorectal tumors are a heterogeneous group of tumors that require a tailored approach depending on their size, involvement of pelvic structures, malignant potential, and likelihood of recurrence. Preoperative assessment requires high-quality cross-sectional imaging and thorough physical and neurologic examination to assess for anorectal involvement and preoperative neurologic deficits. A thorough discussion of expected outcomes related to quality of life and recurrence risk is necessary. Surgical planning requires attention to the best surgical approach, need for preoperative embolization, involvement of other surgical specialists, and need for intraoperative neuromonitoring.

EDITOR'S COMMENT

Drs. Kin and Welton describe the differential diagnosis, evaluation, and treatment of extremely uncommon retrorectal tumors. Knowledge of their symptoms and differential diagnosis is nonetheless important. Presacral space tumors can have a single or multi-tissue origin from osseous, mesenchymal, or neural tissues (Patel N, Maturen KE, Kaza RK, et al. Imaging of presacral masses—a multidisciplinary approach. *Br J Radiol* 2016;89(1061):20150698). While some of these cause symptoms, many are discovered as incidental findings during imaging performed for other conditions. The majority of presacral tumors are benign, and most patients middle-aged women (Toh JW, Morgan M. Management approach and surgical strategies for retrorectal tumours: a systematic review. *Colorectal Dis* 2016;18(4):337–50). Surgery is generally indicated even in benign conditions due to the risk of malignant change and symptom progression.

Preoperative planning is essential and the availability of magnetic resonance imaging has greatly facilitated the identification of bone involvement, as well as facilitating the differentiation between benign, inflammatory, and malignant lesions (Patel N, Maturen KE, Kaza RK, et al. Imaging of presacral masses—a multidisciplinary approach. *Br J Radiol* 2016;89(1061):20150698). I refer readers to the excellent review "MR imaging of the retrorectal-presacral tumors" (Hosseini-Nik H, Hosseinzadeh K, Bhayana R, et al. MR imaging of the retrorectal-presacral tumors: an algorithmic approach. *Abdom Imaging* 2015;40(7):2630–44).

There has been some change in the philosophy regarding biopsy of solid lesions. While this was formerly discouraged, in many series biopsies of solid tumors are now felt to be safe and useful for guiding treatment decisions. This is true particularly for presacral tumors arising from bone where the appearance on imaging is often not specific enough for diagnosis (Patel N, Maturen KE, Kaza RK, et al. Imaging of presacral masses—a multidisciplinary approach. *Br J Radiol* 2016;89(1061):20150698). In addition, lesions such as Ewing sarcoma and osteosarcoma, among others, could benefit from neoadjuvant therapy. The diagnosis is not established without biopsy. More detail can be found in a systematic review on retrorectal tumors by Toh and Morgan (Toh JW, Morgan M. Management approach and surgical strategies for retrorectal tumours: a systematic review. *Colorectal Dis* 2016;18(4):337–50).

As the authors discuss in their chapter, because of the location of these lesions in the presacral area, any discussion of surgery needs to include a frank, honest discussion of complications such as possible fecal or bladder incontinence with the patient. Typically the S3 nerve root must be preserved at least on one side to maintain bladder and bowel continence. The authors very nicely describe different scenarios of nerve root preservation with respect to the likelihood of retaining bowel and bladder function.

With the increasing refinement and skill of minimally invasive surgery and surgeons, minimally invasive procedures to address these lesions have been described (Nedelcu M, Andreica A, Skalli M, et al. Laparoscopic approach for

retrorectal tumors. *Surg Endosc* 2013;27(11):4177–83). In one series describing nine patients with presacral tumors treated laparoscopically, no lesion was below S4 and the one case that was converted to open involved a large (7.5 cm) schwannoma.

Similar to rectal cancer surgery, there is a high risk of local recurrence. In one large multicenter series of 62 patients with retrorectal tumors, which excluded osseous lesions, 9 patients developed recurrence (14.5%) (Buchs NC, Gosselink MP, Scarpa CR, et al. A multicenter experience with peri-rectal tumors: the risk of local recurrence. *Eur J Surg Oncol* 2016;42(6):817–22). Five of the nine recurrences occurred following treatment of malignant lesions. Most of these patients were asymptomatic, but a palpable mass was present on digital rectal examination. Forty-four percent of patients with recurrence had an R1 resection of the initial tumor, while the remainder had an R0 resection.

These operations are typically multidisciplinary efforts often with the aid of an orthopedic or neurosurgeon and, in some cases, plastic surgeon. Sacrectomy can be associated with formidable blood loss, and not every operating room may be equipped to deal with this. Intraoperative changes in patient position from supine to prone can also pose challenges to anesthesia. In areas where adequate support is not available, serious consideration should be given to referring these patients to centers where such expertise and facilities are available as these are not urgent procedures and this is in the patient's best interest.

Susan Galandiuk

162 Rectal Prolapse: The Open Abdominal Approach

Philip H. Gordon

Complete rectal prolapse is a lifestyle-altering disability that commonly affects older people. Rectal prolapse is the protrusion of the full thickness of the rectal wall through the anal sphincter. More than 100 techniques for its repair have been described indicating that none are entirely satisfactory. This chapter presents the current information about the more popularly used techniques in the repair of complete rectal procidentia. Each procedure has advantages and disadvantages. The particular method of repair used by a surgeon depends on his previous training and exposure to a certain technique, which is modified by his own personal experience. The goals of any operation are to control the prolapse, achieve continence, and correct constipation.

ANATOMY AND ETIOLOGY

There are two theories regarding the etiology of rectal procidentia—a sliding hernia through a defect in the pelvic fascia and an intussusception. Cineradiographic studies support the latter belief, that is, that rectal prolapse is the result of intussusception, or infolding of the rectum, usually beginning 6 to 8 cm from the anal verge. However, the factors that cause intussusception are still unknown. Excessive straining at defecation appears to be an important factor in the pathogenesis of rectal prolapse. The anatomic abnormalities commonly found in patients with this condition are the results of prolonged rectal prolapse, and not the cause. Pathological anatomy of patients with rectal procidentia includes a deep cul-de-sac, a redundant sigmoid colon, diastasis of the levator ani muscle, a patulous anal sphincter, and loss of the posterior sacral curve of the rectum and its sacral attachments.

It was once thought that weakness of the pelvic floor muscle was the main cause of rectal prolapse. However, electromyography shows overactive pelvic floor muscle in some patients and weakness in others.

Fecal incontinence in rectal prolapse is the result of neuropathy of the pudendal nerve due to prolonged stretching, and not from mechanical stretching of the external sphincter by the prolapse, as previously believed.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

These patients may present with a wide range of symptoms including mucous leakage into their underwear and around the anus that causes variable degrees of perineal skin irritation. Rectal bleeding is frequently present. Dull perineal pain or pressure and a feeling of incomplete evacuation are common. Difficult defecation is another common feature. By the time the patients seek medical consultation, about 50% of them already have fecal incontinence. In a review of 32 young adults (<30 years), Sun et al. found 41% had chronic psychiatric disease requiring treatment and these patients experienced significantly more constipation than nonpsychiatric patients (83% vs. 50%). All patients in whom rectal prolapse is suspected should be examined while straining on the toilet. The diagnosis of rectal prolapse is easy if the protrusion comes through the anus (Fig. 162.1). Hidden prolapse, in which the intussusception is above the anal canal, can be diagnosed only by defecating proctography (Fig. 162.2). When the prolapse comes to but not through the anus, it can be easily misdiagnosed as mucosal prolapse or prolapsed hemorrhoids, but the latter are characterized by radial folds rather than circular folds.

INDICATIONS FOR OPERATION

Bachoo et al. tried to determine the best choice of operation for rectal procidentia. All randomized or quasirandomized trials of operation in the management of rectal prolapse were sought. The three primary outcome measures were number of patients with recurrent rectal prolapse, and residual mucosal prolapse or fecal incontinence. Eight trials were included with a total of 264 participants. There were no detectable differences in recurrent prolapses between abdominal and perineal approaches, although there was a suggestion that fecal incontinence was less common after abdominal procedures. There were no detectable differences between the methods used for fixation during rectopexy. Division rather than preservation of the lateral ligaments was associated with less recurrent prolapse but more postoperative constipation, although these findings were found in small numbers.

Ideally, the repair should be chosen not only to correct the prolapse but

also to restore defecatory function and improve fecal incontinence. By and large, the major consideration is the patient's general state of health. At present, for the good-risk patient an abdominal approach is still favored. The recommended procedure would be a pelvic fixation in which the rectum is not completely surrounded anteriorly by a synthetic material. However, a resection might be recommended instead of one of the fixation procedures for an individual who has symptomatic diverticular disease or suffers from severe constipation in association with a very redundant colon. Certainly one would hesitate to insert a foreign body in the pelvis in association with the resection.

Figure 162.1. A typical overt rectal prolapse, with circular mucosal folds.

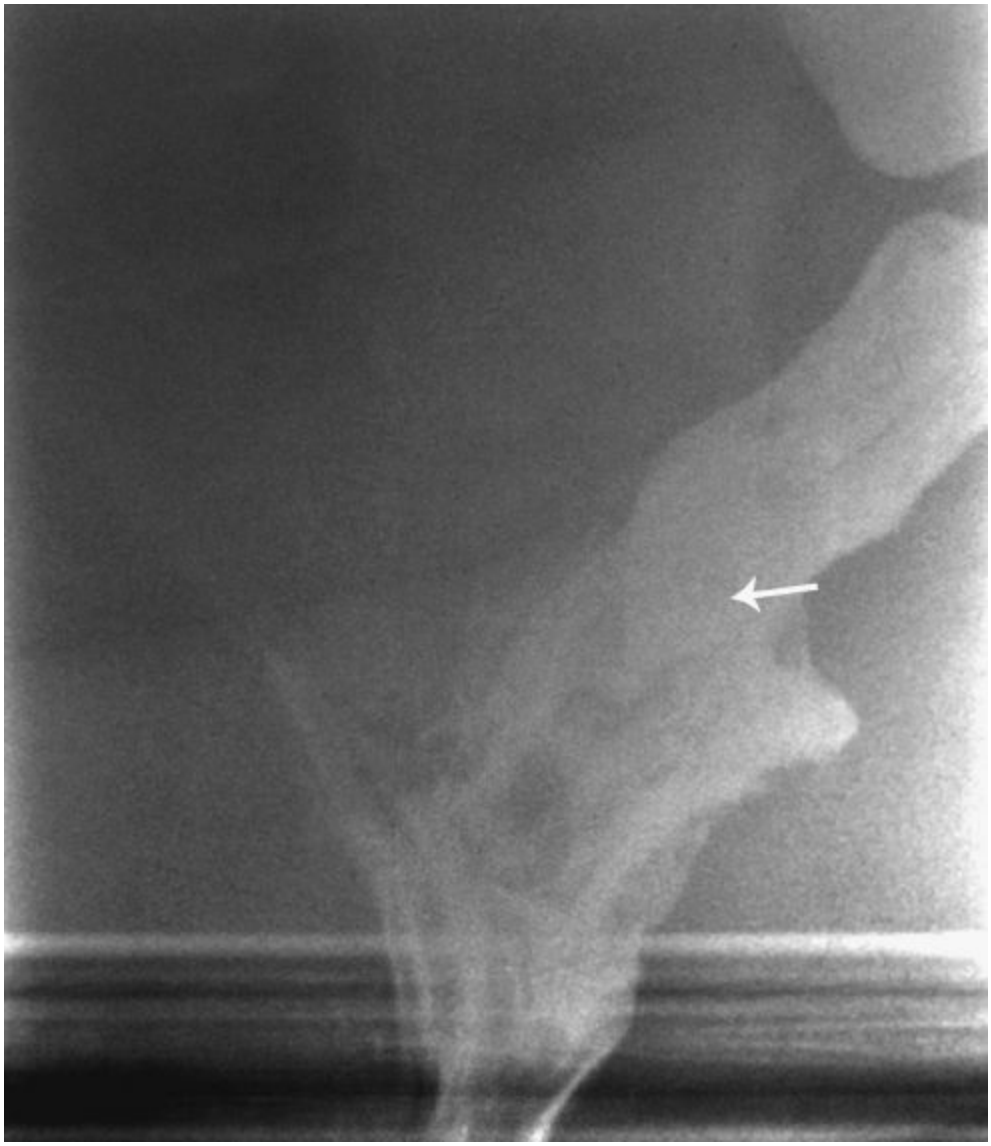

Figure 162.2. Defecating proctogram shows intussusception of the rectum to the upper anal canal (*arrow*).

For poor-risk patients, a perineal approach would be more appropriate, and the Delorme operation or possibly a perineal rectosigmoidectomy (Altemeier procedure) is recommended. For intermediate-risk patients, a perineal rectosigmoidectomy should be considered. For patients confined to a nursing home, amputation of a massive prolapse definitely would facilitate their care.

PREOPERATIVE EVALUATION

All patients with rectal prolapse should at least be examined with a flexible sigmoidoscope to rule out associated abnormalities, especially polyps, cancer, and inflammatory bowel disease. Occasionally, a solitary rectal

ulcer is found. If indicated, a total colonoscopy should be performed. Defecating proctography is indicated if hidden prolapse is suspected.

Anal manometry will not change the surgical approach and is not helpful to predict postoperative functional results. Electromyography and measurement of the pudendal nerve terminal motor latency are useful to confirm the nerve damage to the external anal sphincter and the pelvic floor muscles. Patients with damage to the pudendal nerves usually continue to have fecal incontinence after successful repair of the rectal prolapse.

BOWEL PREPARATION

Despite ongoing controversy, the author continues to prepare patients with a mechanical bowel cleansing. A bowel devoid of stool is easier to handle especially if a resection is anticipated. At present, two sachets of oral Pico-Salex are used the day prior to operation. Antibiotics are also administered preoperatively and our current choice is either cefazolin 2 g intravenous (IV) or piperacillin/tazobactam 4.5 g IV within 1 hour of incision and two postoperative doses q8h. No doubt other options may be equally satisfactory.

WELL'S REPAIR

The anterior mesh sling or Ripstein repair has long been the most popular repair for rectal prolapse in the United States. This technique has been plagued with complications and Ripstein himself abandoned the technique in favor of the posterior sling. The complication rate might be reduced by half if the sling were placed posterior to the rectum leaving the anterior one fourth to one third of the circumference of the rectum free to expand, a principle expounded by Wells.

Ivalon Sponge (Polyvinyl alcohol), a popular material used in the United Kingdom, I understand is not approved by the U.S. Food and Drug Administration. I have successfully used this material for many years. Marlex (polypropylene) and Teflon (polycarbon fluoride) are the most common materials used. Other materials such as Gortex (polytetrafluoroethylene), Prolene (polypropylene, similar to Marlex), and Vicryl (polyglycolic acid) have also been employed. I currently use Parietex—a polyester mesh (Sofradim Production, Trevoux, France).

TECHNIQUE

With the patient in the supine position, after the bladder has been catheterized the skin is prepared with a suitable antiseptic. The abdomen is entered through an infraumbilical transverse incision. With the patient placed in a 20 degree Trendelenburg position, the abdominal viscera are packed away in the upper abdomen with a self-retraining retractor. Dissection is begun by incising the peritoneum on each side of the rectosigmoid, commencing about 5 cm above the pelvic brim (Fig. 162.3). Care is taken to protect the ureters. The presacral space is entered at the level of the sacral promontory, and the rectum is gently mobilized from the sacral hollow (Fig. 162.4). At this point, great care must be taken to ensure that the mesorectum is anterior to the plane of dissection or the intestine may be devascularized and there may be annoying bleeding. At the same time, one should avoid the presacral nerves. Dissection in the presacral plane should be performed with cautery taking care not to injure the rectal wall. Any fibrous bands are cut with scissors or cautery, since tearing will result in troublesome bleeding. Sweeping the hand to each side of the rectum will make the lateral stalks more prominent. The rectum is fully mobilized to the level of the coccyx. Anterior mobilization is begun by continuing the lateral peritoneal incisions distally until they meet in the deepest portion of the cul-de-sac (Fig. 162.5). With the rectum grasped in the left hand, this plane can often be dissected with cautery. Extensive dissection in this plane is not necessary because a deep cul-de-sac is a characteristic anatomic feature in most instances of complete rectal procidentia. The seminal vesicles or vaginal vault is easily reached. The lateral stalks, or at least the upper portion of the lateral stalks on each side, are divided between clamps and ligated. If the rectum is not fully mobilized, redundant rectum remaining below the point of fixation may lead to recurrence of prolapse. Throughout the procedure, meticulous hemostasis is essential since hematoma formation may predispose to infection.

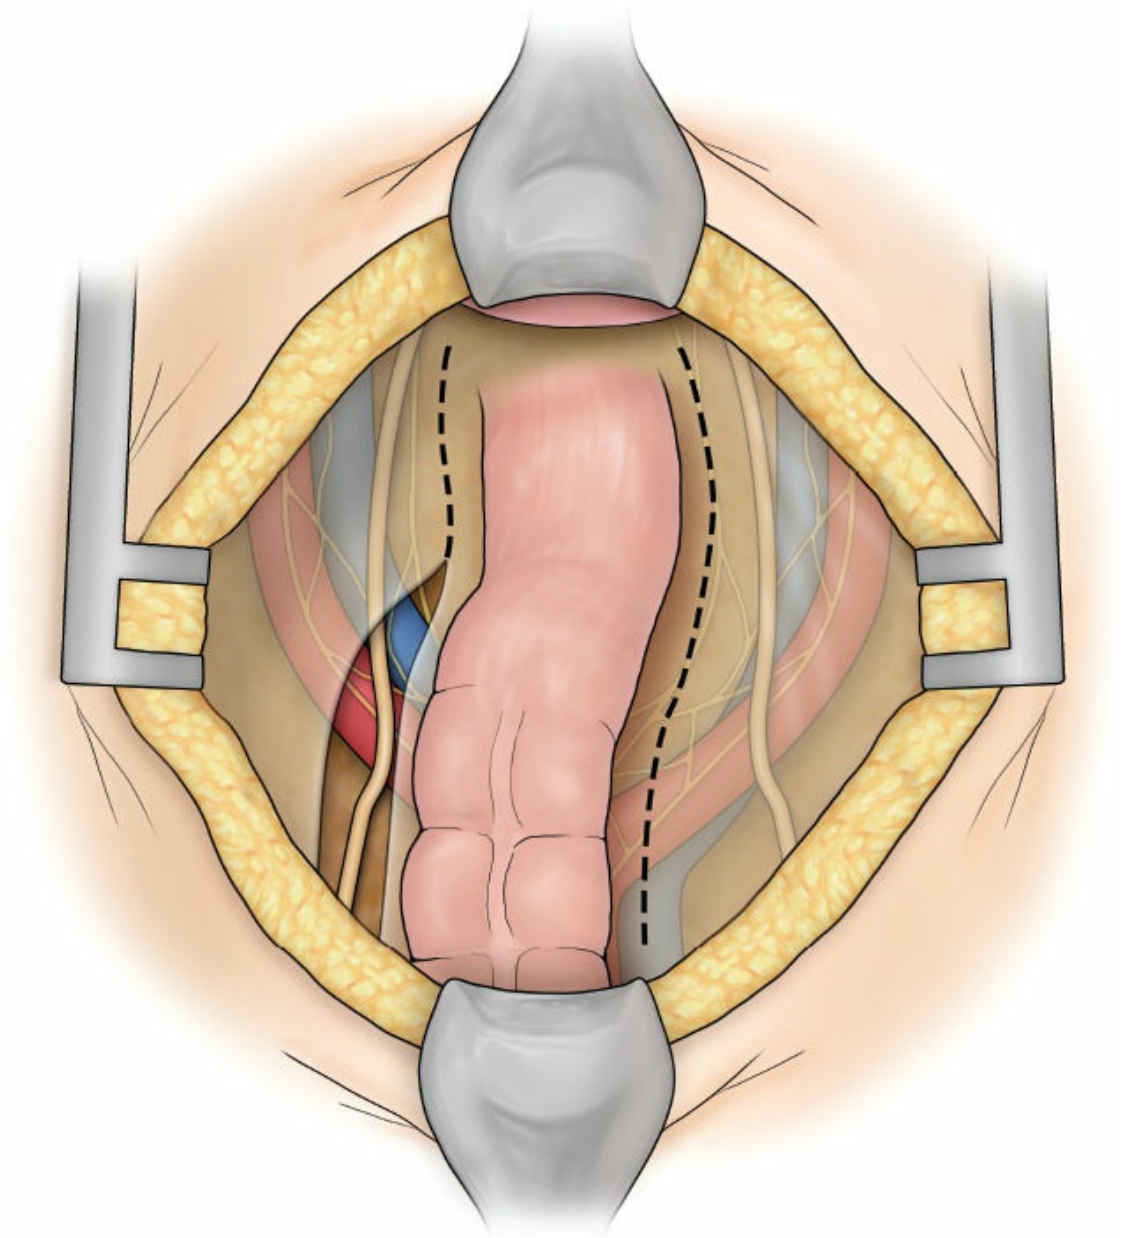

Figure 162.3. Peritoneum incised on both sides of the rectosigmoid, beginning 5 cm above the pelvic brim.

A rectangular sheet of previously sterilized Parietex has three sutures of a nonabsorbable monofilament material such as 00 polypropylene on a noncutting needle pass through the mesh, the presacral fascia, and back through the mesh (Fig. 162.6A). The distal suture should be placed as low as possible deep in the pelvis. The mesh is then "rail-roaded" into the pelvis, and the sutures are tied (Fig. 162.6B).

The mobilized rectum is drawn upward and placed on the front of the mesh sheet, and the lateral extremities of the mesh are folded around to encompass approximately three fourths of the circumference of the rectum.

It is important to leave a portion of the circumference uncovered to prevent constriction of the lumen. Excess mesh is excised. A series of three 000 polypropylene sutures on each side is used to fasten the lateral limbs of the mesh to the anterior aspect of the rectum (Fig. 162.7). Penfold and Hawley point out that care must be taken to ensure that the base of the sigmoid mesocolon is not shortened because this may predispose to sigmoid volvulus. To this end, they recommend the use of a hitch suture. One or two nonabsorbable sutures are inserted between the mesorectum and tissue at the level of the sacral promontory (Fig. 162.8).

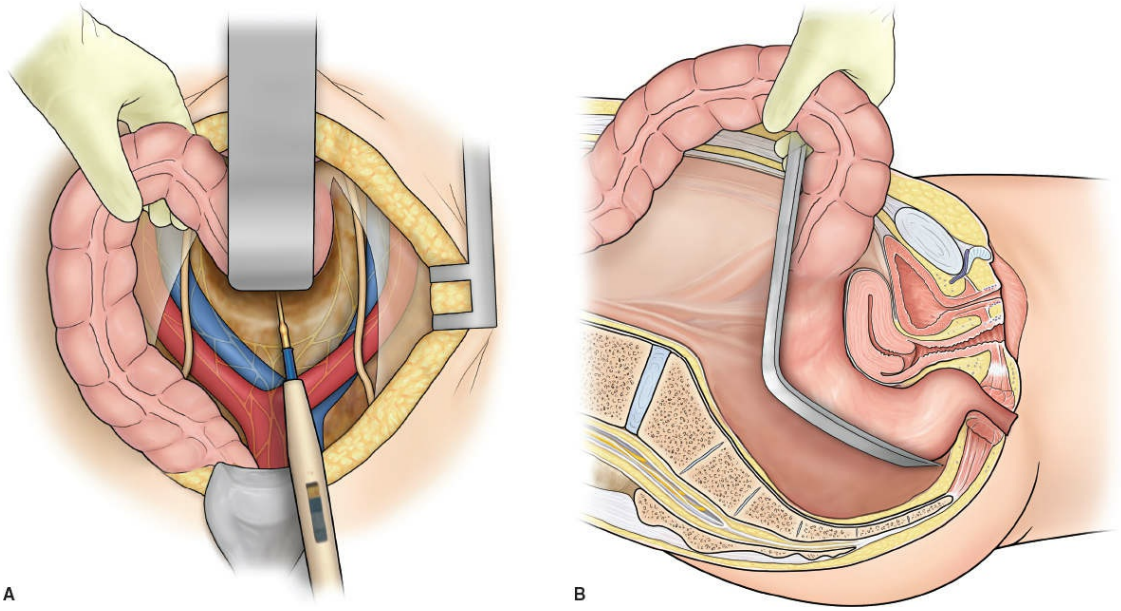

Figure 162.4. A. Mobilization of rectum accomplished by cautery dissection, avoiding presacral plexus of veins. **B.** Sagittal view. Dissection carried down toward tip of coccyx, preserving mesorectum.

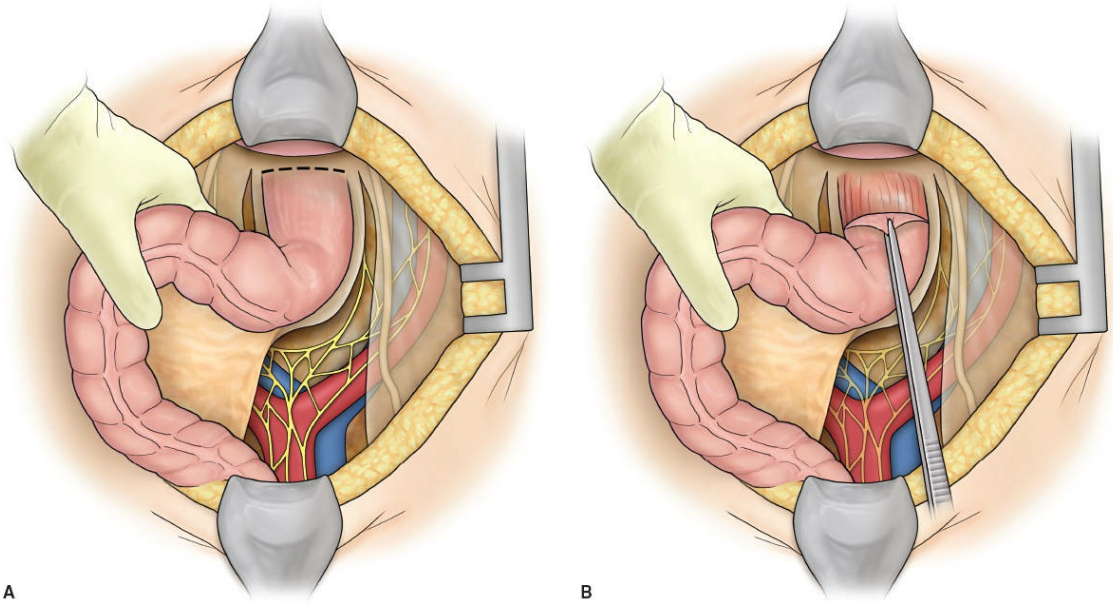

Figure 162.5. **A.** Lateral incisions joined in anterior cul-de-sac. Presacral neural plexus should be left intact. **B.** Sharp dissection frees anterior rectal wall. Peritoneum of anterior cul-de-sac is retracted superiorly.

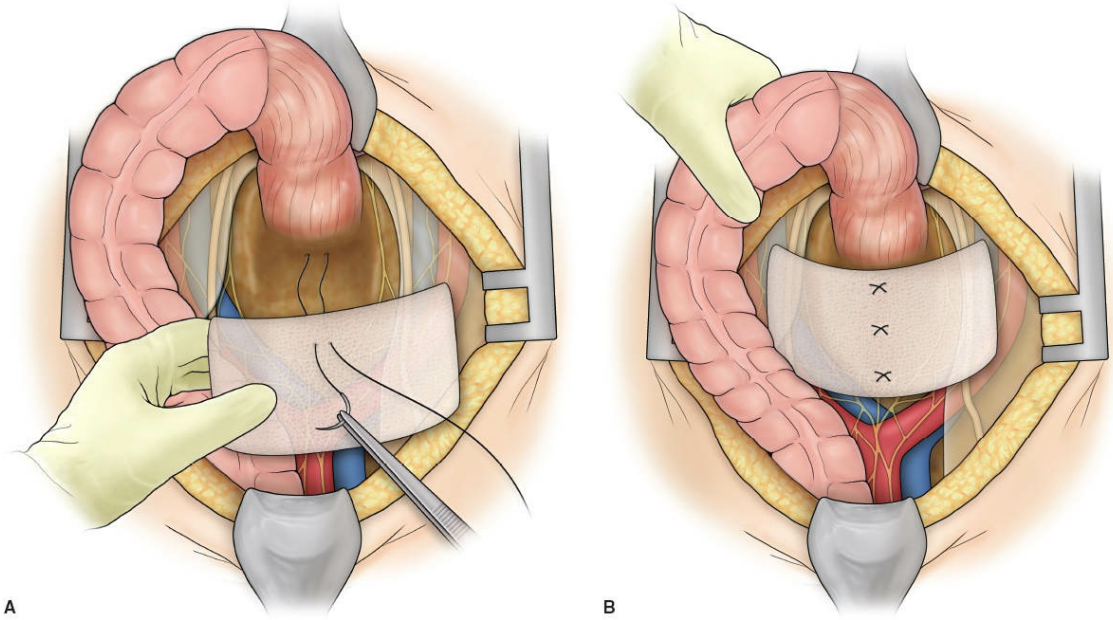

Figure 162.6. **A.** Sheet of Parietex mesh sewn to presacral fascia with interrupted 00 polypropylene suture material on a round needle. Rectum retracted forward, away from sacrum. **B.** Three polypropylene sutures hold the mesh immobile against presacral fascia.

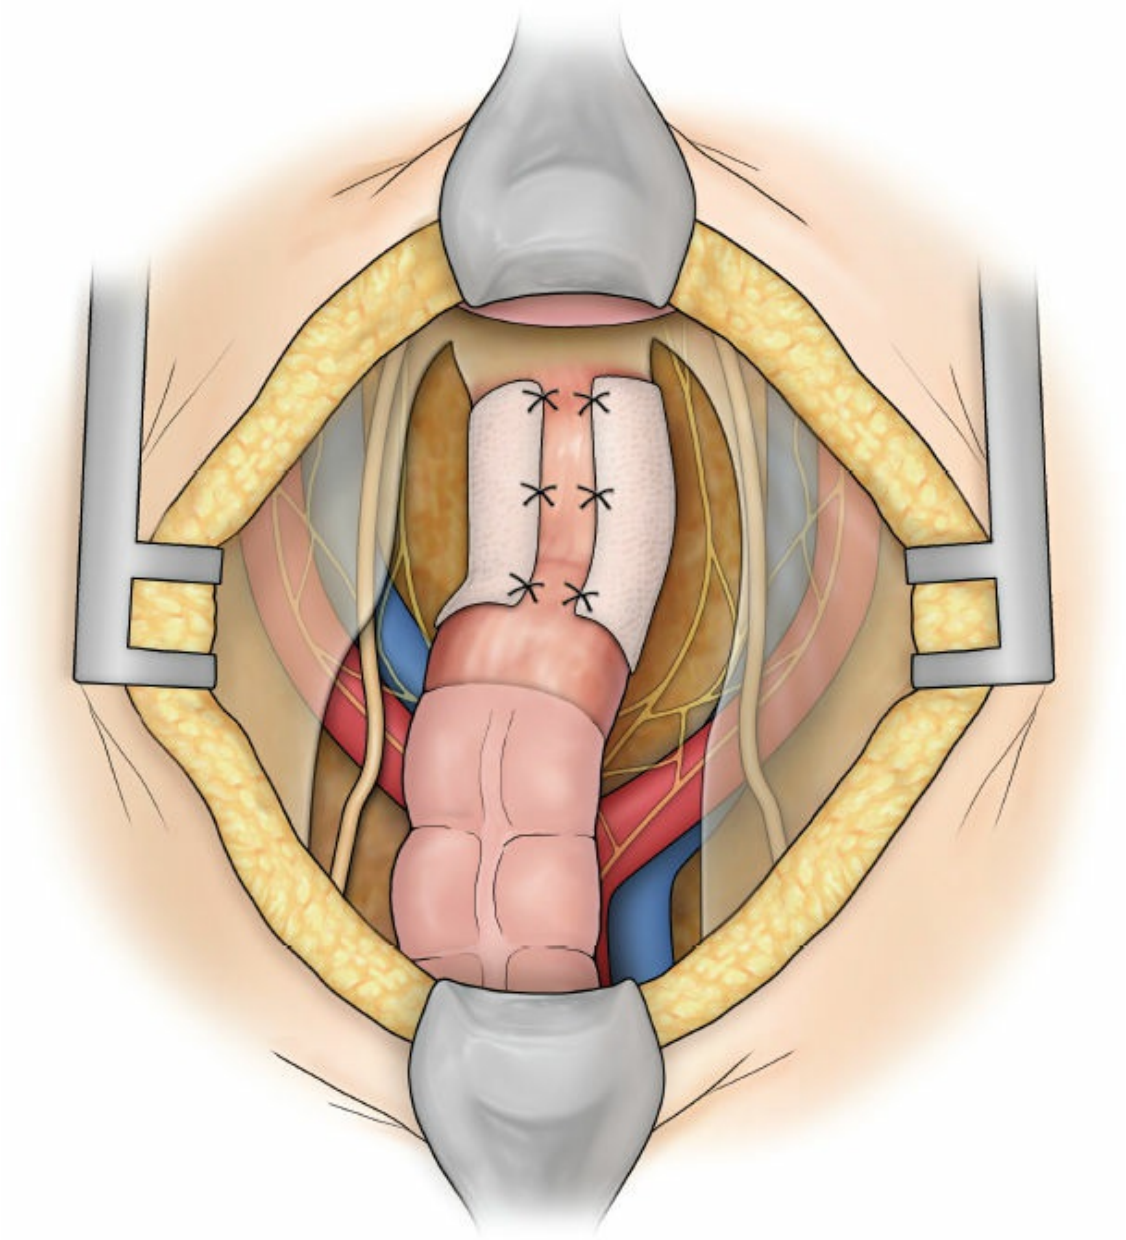

Figure 162.7. Mesh applied to posterior three fourths of circumference and sutured in place with three 000 polypropylene sutures on each side.

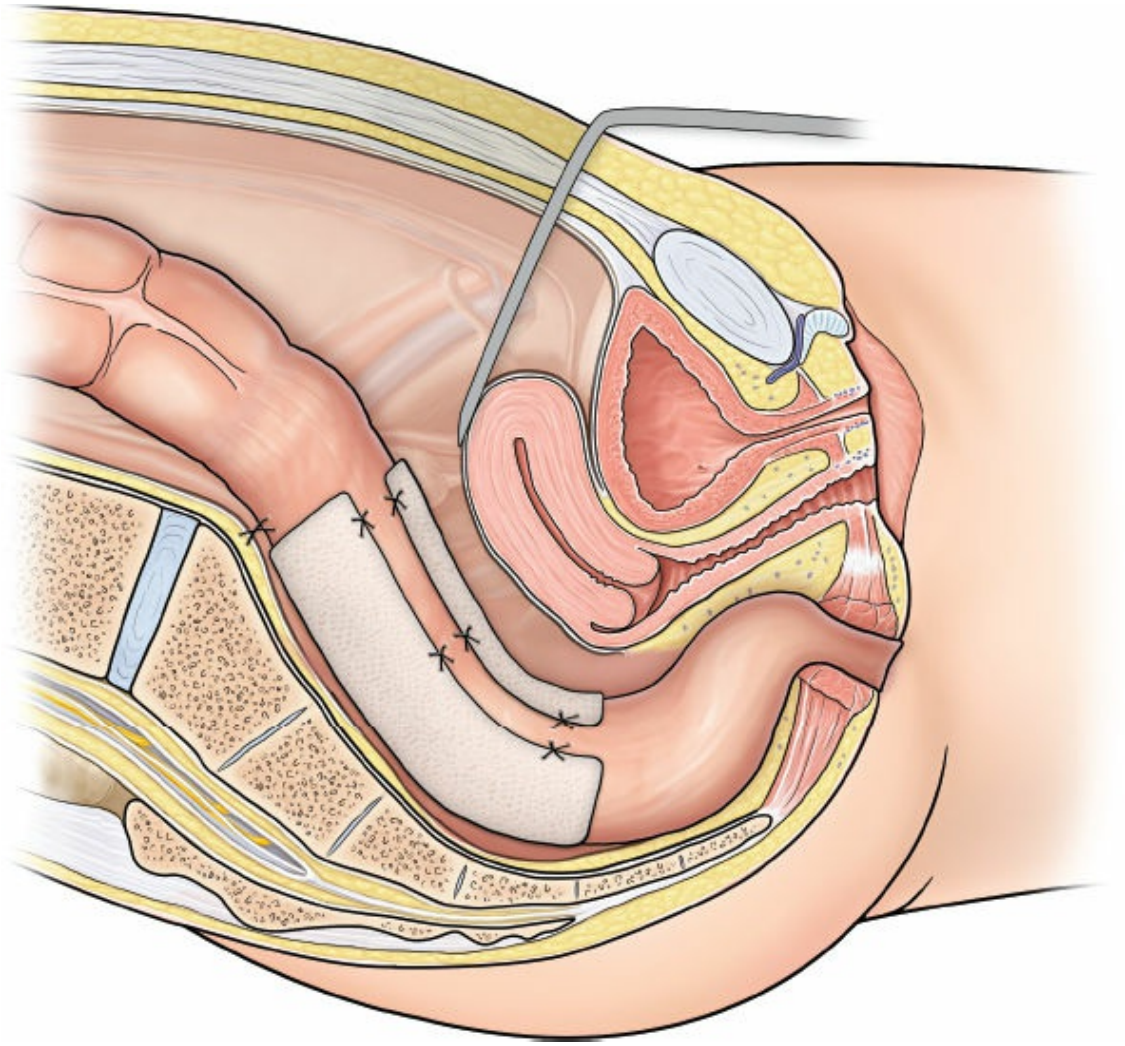

Figure 162.8. One or two additional sutures placed superior to the mesh to hold sigmoid colon and prevent sigmoid volvulus.

The pelvis is copiously irrigated with saline solution. Then the sponge is extraperitonealized by closing the pelvic peritoneum with continuous 000 Vicryl (Fig. 162.9). The abdominal cavity is irrigated with saline solution and closed in layers.

POSTOPERATIVE CARE

IV fluids are given until the postoperative ileus has resolved, usually in 2 or 3 days. Nasogastric suction is ordinarily not necessary. The Foley catheter is removed on the second day.

It is of paramount importance to ensure that the patient does not strain at defecation. To this end, as soon as the patient has begun oral intake, a bulk-forming agent in the form of a psyllium seed preparation is given two or three times a day, depending on how much difficulty the patient

encountered on defecation preoperatively. This preparation may be supplemented by milk of magnesia as necessary. It should be stressed that the incontinence experienced by many of these patients preoperatively may not be improved immediately. Improvement has been noted over a period of many months, and therefore the attending surgeon should be dissuaded from performing any secondary procedure for 6 to 12 months. Minor mucosa prolapse can be treated by the application of rubber band ligatures. For persistent incontinence, the Park's postanal repair should be considered.

OPERATIVE TECHNIQUE OF SIGMOID RESECTION AND SUTURE PROCTOPEXY

This technique was originally described by Frykman and can be performed through a transverse or midline abdominal incision. The patient is placed in the supine position with both legs on Yellowfin stirrups (OR Direct, Acton, MA) or Allen stirrups. A No. 16 Foley catheter is inserted into the urinary bladder. The head of the operating room table is tilted down 30 to 40 degrees, depending on the shape of the pelvis. The entire small bowel is packed to the upper abdomen with moist lap pads.

MOBILIZATION OF SIGMOID COLON AND RECTUM

The lateral peritoneal reflection of the sigmoid colon (white line of Toldt) is incised by electrocautery. The gonadal vessels and the left ureter are identified and swept posteriorly. The peritoneal incision is continued to the left side of the rectum, about 1 cm lateral to the rectal wall, and curves anteriorly to the rectovesical sulcus. Similarly, the peritoneum at the base of the sigmoid mesentery is incised by cautery and continued to the right side of the rectum to unite with the incision on the left side at the sulcus (Fig. 162.10). The sigmoid vessels are taken close to the sigmoid colonic wall to preserve the superior rectal artery. This technique will ensure a good blood supply to the rectum and avoid injury to the presacral nerve.

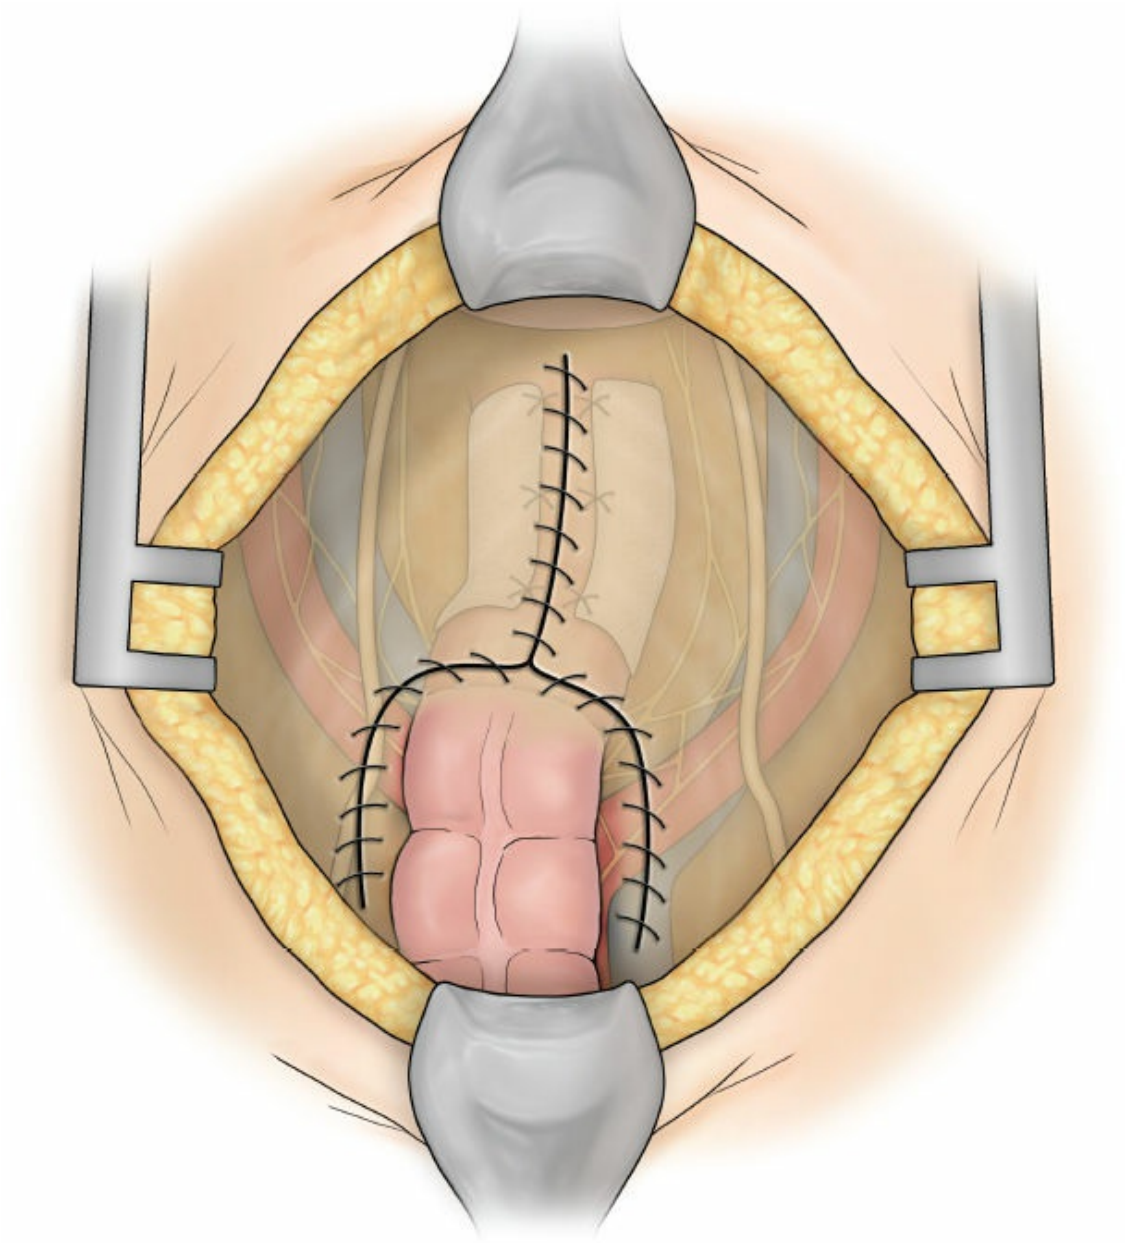

Figure 162.9. Operation completed by closing pelvic peritoneum.

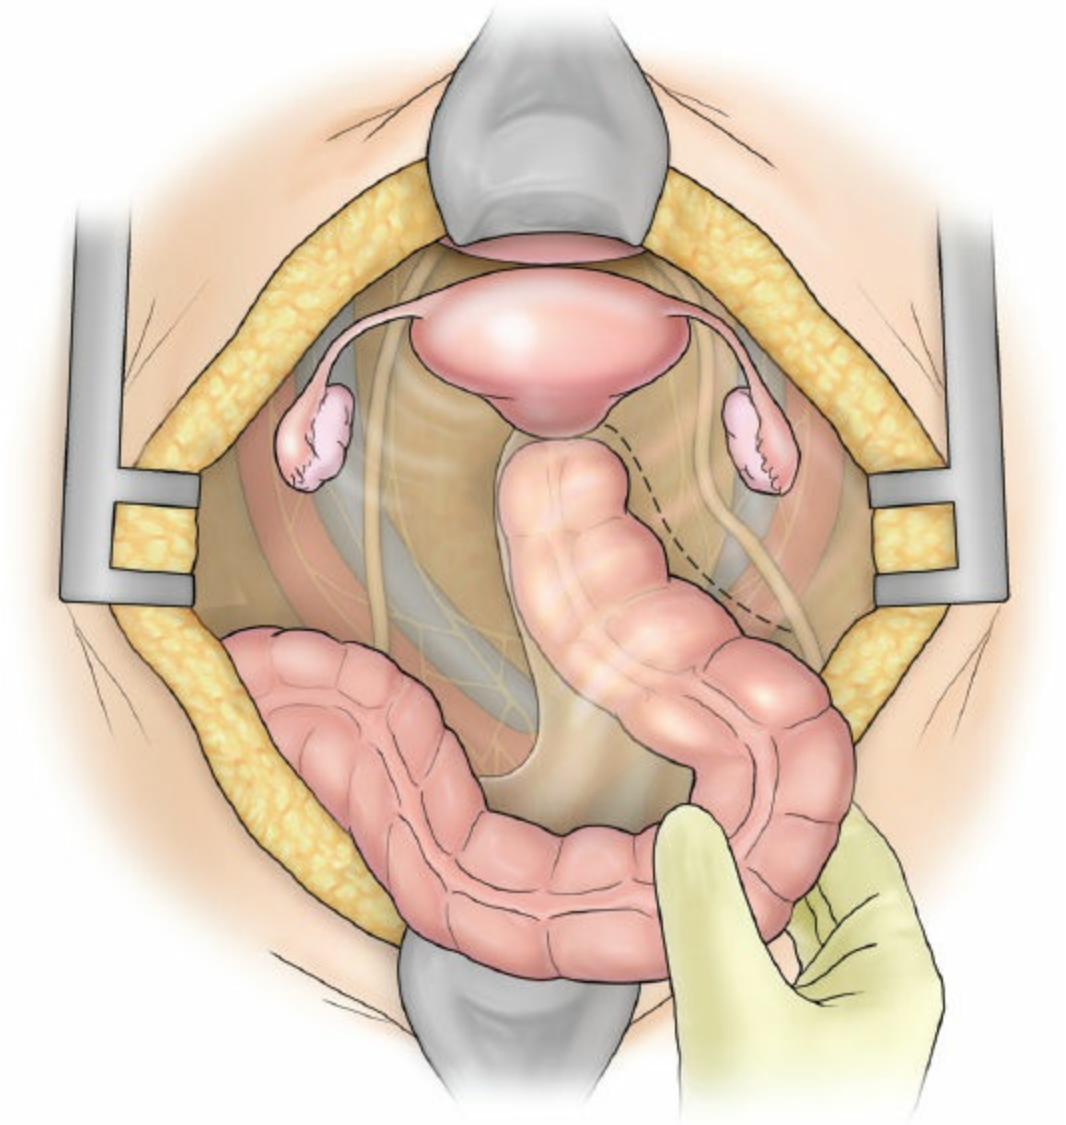

Figure 162.10. Mobilization of sigmoid colon to identify the left ureter. Note the line of incision.

ENTERING THE RETRORECTAL SPACE (POSTERIOR MOBILIZATION)

The surgeon's left hand lifts the sigmoid colon. The right index finger presses firmly on the promontory of the sacrum and the presacral space is entered (Fig. 162.11). A lipped St. Marks retractor is placed behind the rectum and lifted up by the assistant, who stands between the patient's legs. The avascular areolar plane is dissected with electrocautery (Fig. 162.12). This maneuver is continued to the pelvic floor muscles.

SWEEPING THE URETERS AND PELVIC NERVES

With the left hand holding the sigmoid colon, the right hand, with all the

four fingers closed together, is placed behind the posterior rectal wall. The tissues lateral to the right rectal wall are swept away laterally (Fig. 162.13) and then the tissues on the left side are swept away in the same manner. This maneuver should not be taken until the rectum is sharply dissected posteriorly near the pelvic floor muscle. The previous incision of the peritoneum will allow the ureters and nerves to be swept away laterally.

ANTERIOR MOBILIZATION

The assistant, standing between the patient's legs, retracts the uterus and cervix or (in men) the bladder, using the St. Mark retractor. The surgeon's left hand presses on the anterior wall of the rectum over a gauze. The posterior vaginal wall or seminal vesicle will be visualized. With electrocautery, the areolar tissue plane between the anterior wall of the rectum and the vagina or seminal vesicles is entered in the midline. This incision is carried laterally to each side of the rectum. At the lateral edge of the rectum, it is important that the line of incision curve downward to avoid injury to the neurovascular bundles (Fig. 162.14). The dissection is carried about 3 to 4 cm distally. It is advisable that the lateral ligaments that are distal to this level are preserved as preservation is associated with an improvement in continence and reduction in constipation.

RESECTION OF THE REDUNDANT SIGMOID AND ANASTOMOSIS

I prefer a stapled anastomosis with a circular stapler. A point of transaction of the redundant sigmoid colon is selected so that the anastomosis is without too much slack or any tension (Fig. 162.15). A purse-string clamp is applied, a purse-string suture placed, and the bowel transected (Fig. 162.15A). The anvil is inserted into the proximal bowel and the purse-string is tied (Fig. 162.15B). The bowel at the level of the promontory of the sacrum is cleared of fat and blood vessels. The purse-string clamp is again placed at the planned line of resection, the purse-string inserted, and the bowel proximal transected. The circular stapler is inserted through the anus, the anvil engaged in the central shaft, and the anastomosis created (Fig. 162.15C–E).

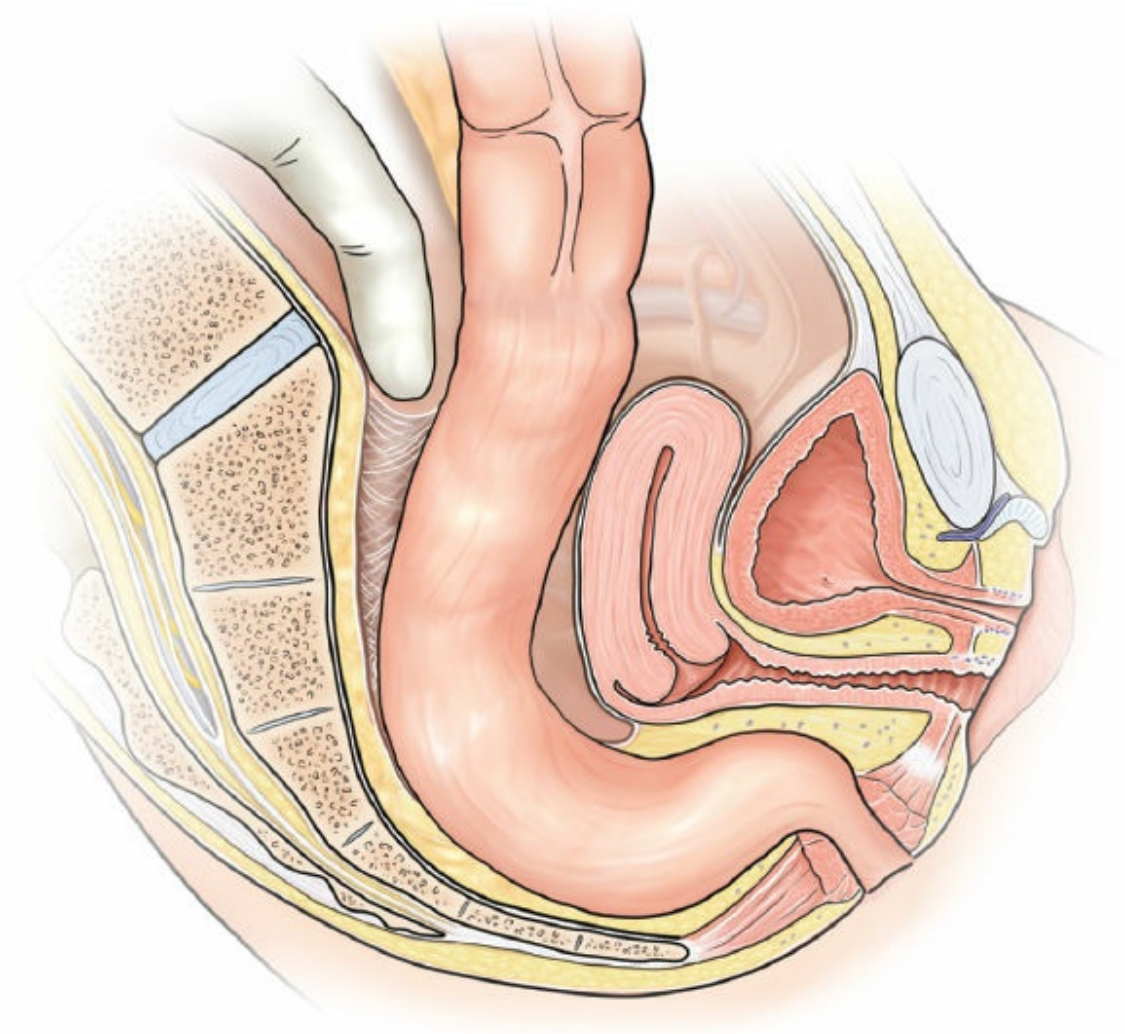

Figure 162.11. Entering the retrorectal space, the right index finger presses firmly on the promontory of sacrum.

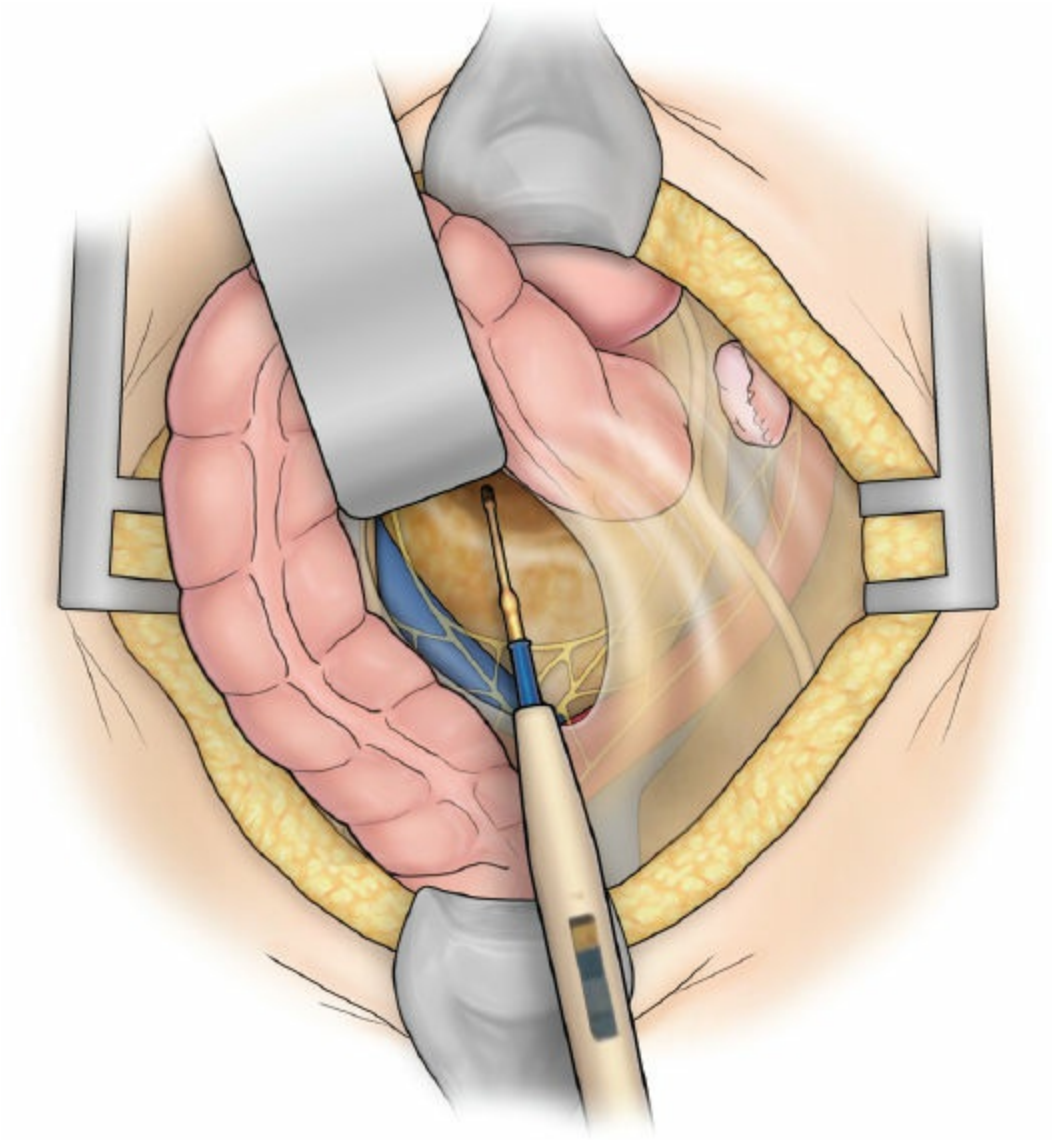

Figure 162.12. Avascular plane dissected with electrocautery.

If a hand-sewn anastomosis is preferred, the anastomosis begins with the posterior wall. Through-and-through full-thickness stitches of 4-0 Vicryl or Dexon are placed at each corner and in the middle, 5 mm from the edges. Two such stitches are placed in between, and the sutures are tied with the knots inside the lumen. Additional stitches are then placed at 5 mm apart. In the anterior wall, full-thickness stitches with only mucosal inversion (Gambee technique) are placed 5 mm from the edges and 5 mm apart (Fig. 162.16). The mesentery and the pelvic peritoneum are not closed.

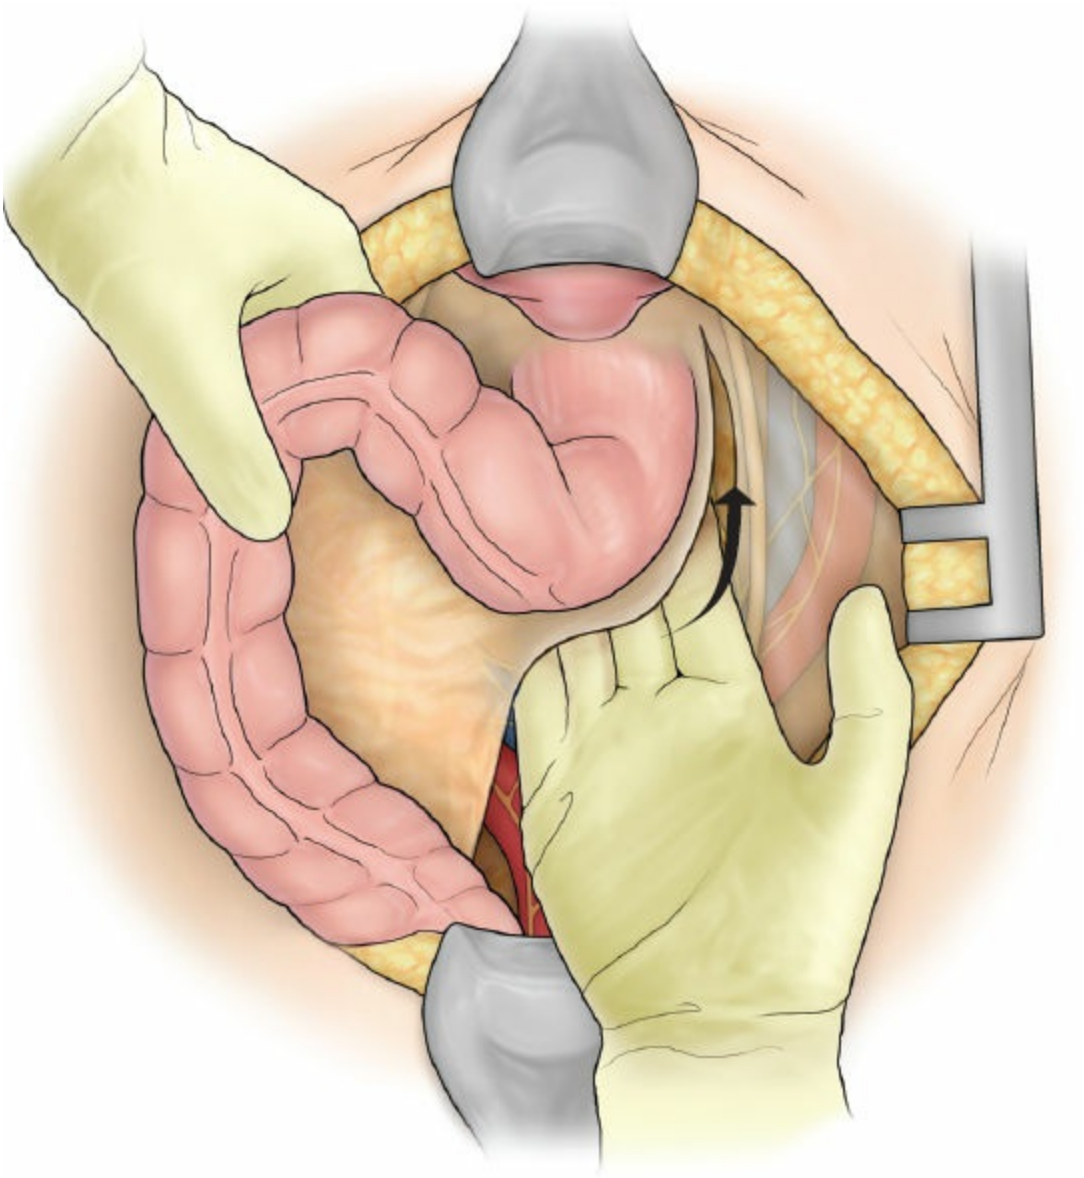

Figure 162.13. Technique of sweeping the ureters and pelvic nerves.

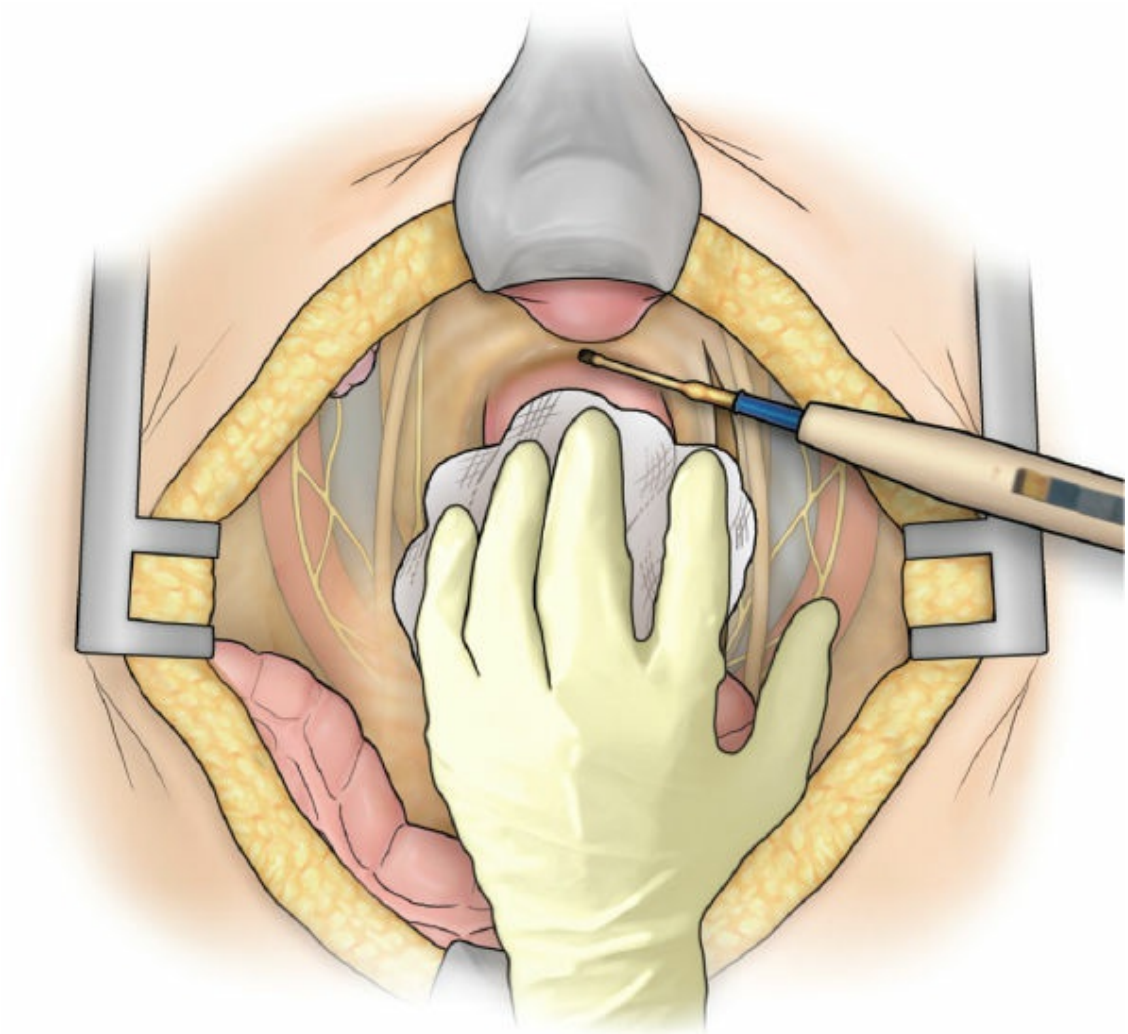

Figure 162.14. Entering the rectovaginal space. The line of incision curves down laterally to avoid injury to the neurovascular bundles.

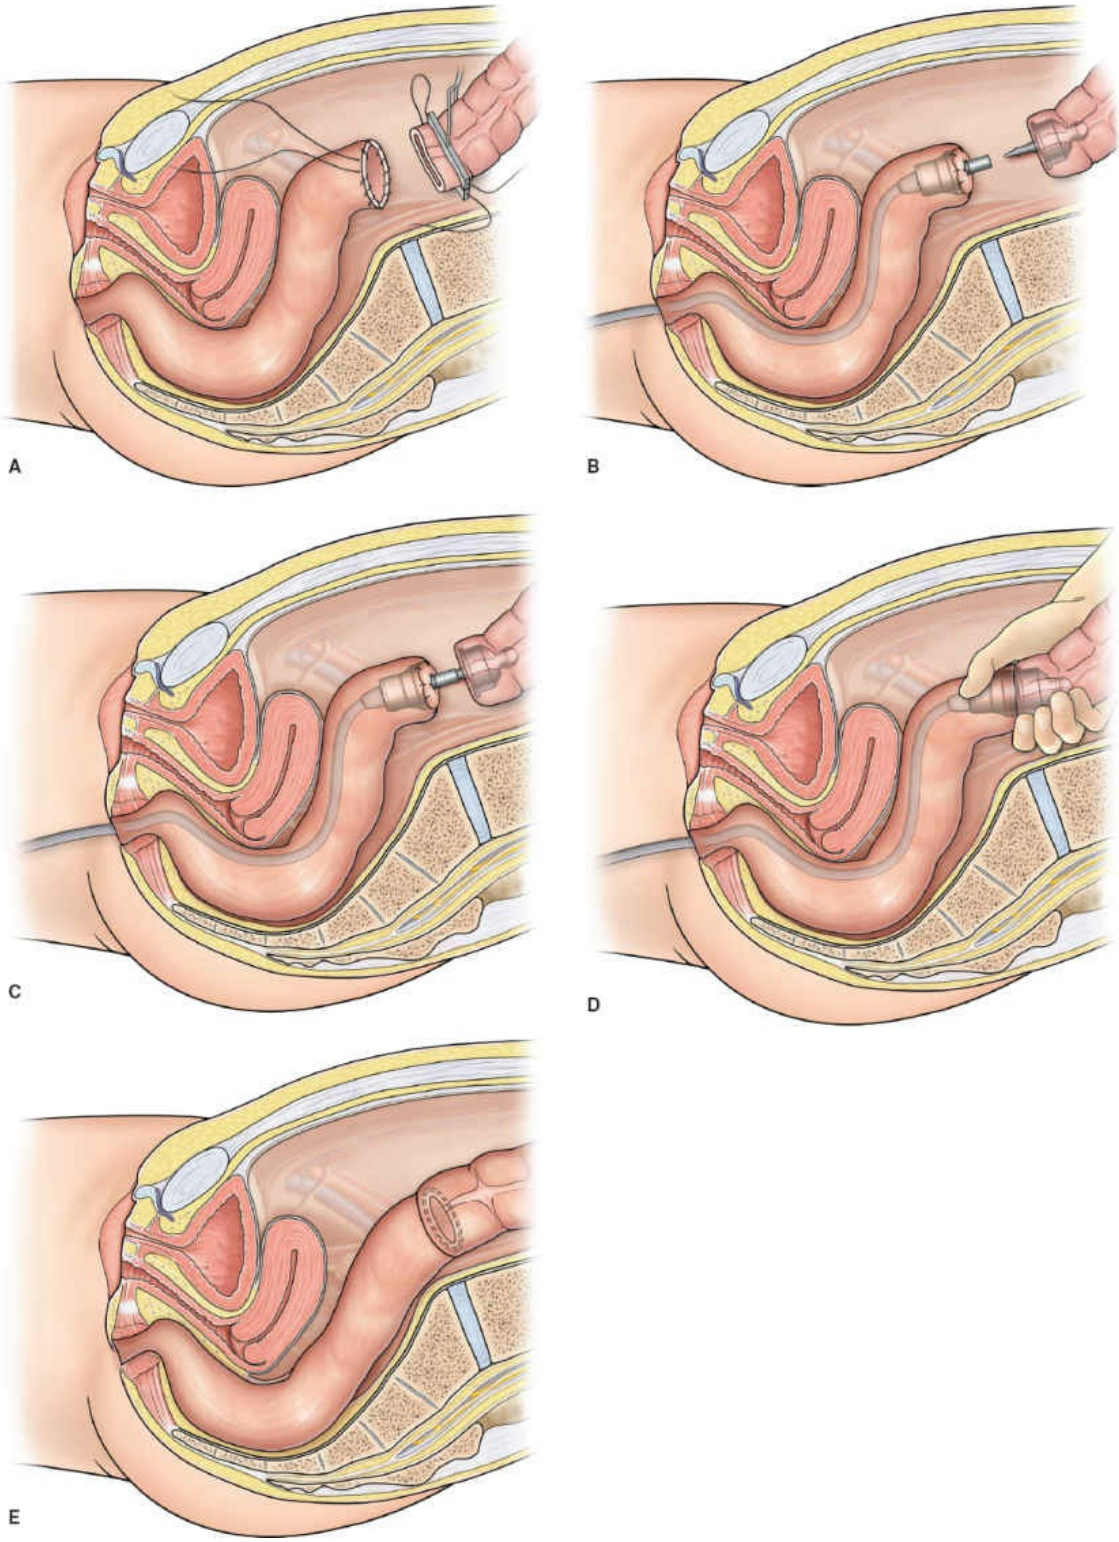

Figure 162.15. Resection of sigmoid colon.

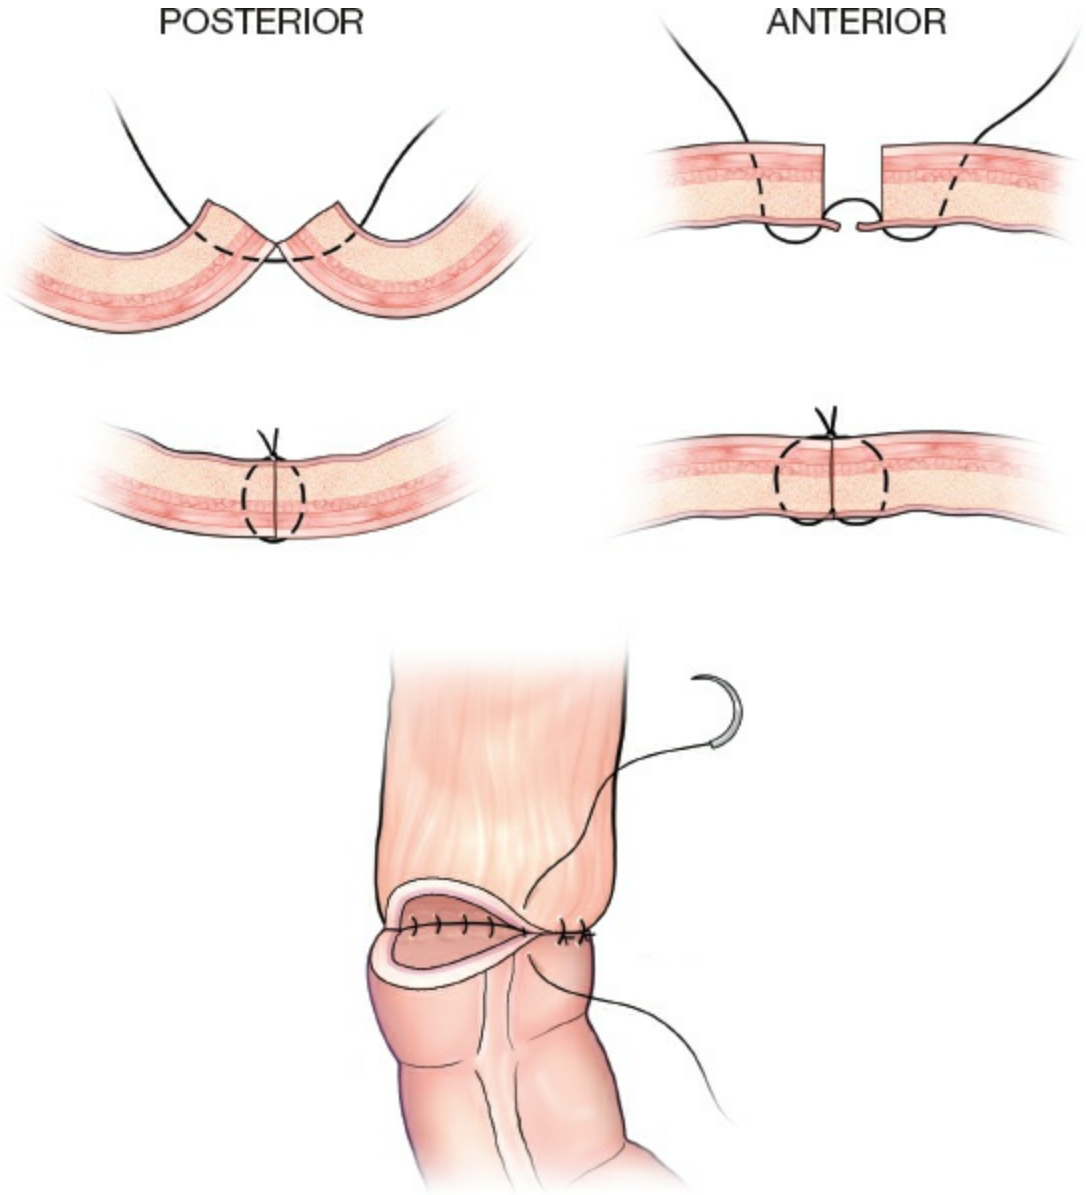

Figure 162.16. Techniques of bowel anastomosis. Insets shows stitches for posterior and anterior walls.

PLACEMENT OF PROCTOPEXY SUTURES

While the rectum is allowed to lie along the curve of the sacrum, sutures of 2-0 Vicryl are placed through the lateral stalks on each side of the rectum and through the presacral fascia in the upper third of the sacrum. Usually one suture on each side can be safely placed. The sutures are tied snugly only after the anastomosis is created (Fig. 162.17).

The abdominal cavity is irrigated with normal saline and aspirated until dry. Unless there is oozing of blood, a pelvic drain is not used. The abdomen is closed in layers.

POSTOPERATIVE MANAGEMENT

IV fluids are instituted. In the absence of nausea and abdominal distention, liquids may be started after the ileus has resolved and the diet is advanced as tolerated. Patients are discharged after their first bowel movement.

COMPLICATIONS: THEIR PREVENTION AND MANAGEMENT

Unfortunately, complications are an inevitable consequence of any operation. Gordon and Hoexter polled the members of the American Society of Colon and Rectal Surgeons, obtaining information on the results of a total of 1111 Ripstein procedures. This review revealed a recurrence rate of 2.3%, and complications directly related to placement of the sling occurred in 16.5% of the patients. The overall reoperation rate was 4.1%. Indications for reoperation included fecal impaction, small bowel obstruction, stricture, pelvic abscess, rectal erosion, and hemorrhage. Reoperations for mucosal prolapses and recurrences were not included in this calculation. Possible reasons for recurrence are intraoperative difficulties that result in failure to secure the mesh adequately to the presacral fascia, failure to secure the mesh to the rectum, or inadequate initial mobilization of the rectum, resulting in the presence of prolapsed rectum distal to the point of fixation. To prevent fecal impaction, considerable care must be exercised to ensure that the sling is not applied too tightly around the rectum.

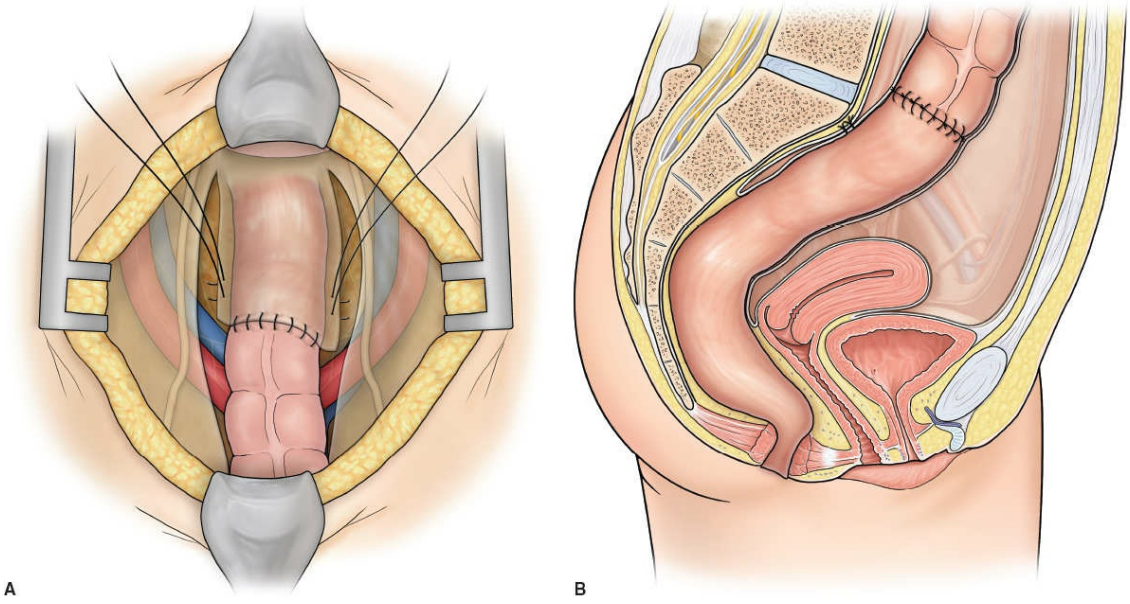

Figure 162.17. **A.** Placement of presacral suture. **B.** Lateral view

of the rectum at completion. Note the rectum lies along the curve of the sacrum.

Presacral bleeding may range from nuisance bleeding to hemorrhages of terrifying proportions. To minimize this complication, care must be exercised during mobilization of the rectum to ensure that the correct plane is developed. Care must be exerted during the placement of sutures into the presacral fascia. If bleeding occurs in this area, the sutures should be tied immediately; failing this, pressure can be used. If this measure also fails, the use of further sutures may control the bleeding.

Strictures were common, but only those that required further operation, either division or removal of the sling or resection of the segment of bowel, were included. The treatment of severe symptomatic strictures includes either division or removal of the sling and in some cases may require resection of this segment of bowel. When the sling requires division, it should be cut laterally because it is fused anteriorly to the rectal wall and injury may be encountered. Prevention consists of avoiding tight application of the sling.

Pelvic abscesses are treated by removal of the sling and drainage, but some may require diverting colostomies. To prevent this complication, care should be taken to avoid placement of sutures through the full thickness of the rectum. Patients should receive a mechanical bowel preparation, and it is probably wise to administer systemic antibiotics.

Small bowel obstruction was described as developing from adhesions of the bowel to the site of the placement of the sling. Treatment is by lysis of adhesions. It may be prevented in part by reperitonealizing the pelvic floor and excluding the sling from the remaining peritoneal cavity.

The exact incidence of impotence was impossible to evaluate, especially since the distribution of men and women was not determined and because many of the patients who underwent the procedure were elderly and experienced the problem preoperatively. The chance of causing impotence can be minimized by careful dissection within the pelvis. However, despite meticulous dissection, young male patients were reported to have become impotent.

Fistulas may arise from piercing the bowel the bowel with a suture or possibly from erosion of the bowel by the sling, perhaps caused by ischemia of the bowel. The late occurrence of this complication may be due to repeated pressure exerted on the bowel wall by stool as it passes

through the sling. Should a fistula arise because of erosion, removal of the sling, closure of the rectum, and a temporary diverting colostomy are required. This complication might be prevented by avoiding excessive tension when placing the sling around the rectum.

An unusual complication is the erosion of the sling into the bladder.

To address the cause of postoperative constipation following rectopexy, division of the lateral ligaments is followed by a higher incidence of constipation than when they are preserved. The complication rate might be reduced by half, if the sling were placed posterior to the rectum, leaving the anterior one fourth to one third of the circumference of the rectum free to expand, a principle expounded by Wells.

Potential complications of the posterior mesh wrap operation are identical to those of the Ripstein procedure with the noted exception that fecal impaction and stricture are not observed postoperatively because of the entire circumference of the rectum is not closed.

A major complication reported with the Wells procedure is the development of pelvic abscesses. This occurrence might be minimized by the use of adequate bowel preparation, by taking care in not transgressing the full thickness of the bowel wall when placing sutures, and by administering prophylactic antibiotics. The treatment of an abscess associated with insertion of a mesh requires removal of the mesh and drainage of the abscess. If the bowel is opened or injured during dissection, a mesh implant should be abandoned.

The intraoperative complications with abdominal proctopexy and sigmoid resection are similar to those of abdominoperineal resection or low anterior resection and are as follows. Bleeding from the venous plexus can be severe and difficult to control. Cutting the rectosacral fascia with long scissors or cautery instead of tearing it reduces the chance to injure these vessels. The needle used to suture the rectum to the presacral fascia may tear the presacral vessels, causing severe bleeding that usually stops when the sutures are tied. Injury to the sympathetic and parasympathetic nerves from mobilization of the rectum is difficult to evaluate. The incidence should be similar to that for total proctocolectomy in patients with inflammatory bowel disease, which is 0% to 17%. Suturing the rectum too close to the wall may cause compression on the anterior wall of the rectum as a result of stretching the visceral peritoneum. Compression must be recognized and corrected by making a vertical incision over the compressed serosa. An alternative method is to place the sutures in the

back of the rectum.

RESULTS OF OPERATIVE TREATMENT OF RECTAL PROCIDENTIA

Varma et al. in their American Society of Colon and Rectal Surgeons Practice Parameters for rectal prolapse noted the perineal approaches result in less perioperative morbidity and pain but recurrence rates are four times higher than those for abdominal operations making the later the preferred treatment of younger and healthier patients. Recurrence rates for suture rectopexy range from 3% to 9%. Rectopexy can produce new-onset or worsening constipation. Recurrence rates for resection rectopexy range from 2% to 5% and major complication rates range from 0% to 20% and relate either to obstruction or anastomotic leaks. Division of lateral stalks during rectal dissection may worsen symptoms of constipation postoperatively but is associated with decreased recurrence rates. Recurrence rates after the Ripstein procedure range from 4% to 10% but complication rates were as high as 50%.

In their review of the literature, Gourgiotis and Boratsis found no reported mortality and recurrence rates ranged from 0% to 27% mostly in the 0% to 3% range for suture rectopexy. For the posterior mesh, rectopexy mortality rates ranged from 0% to 3% and recurrence rates 3%. Improvement in continence occurred in 3% to 40%. Sepsis rates ranged from 2% to 16% with prosthetic rectopexy. For the Ripstien procedure mortality, rates ranged between 0% and 2.5%, recurrence rates between 0% and 13%, and there was a trend toward improvement in continence and a mixed response to constipation. For resection rectopexy, the mortality ranged from 0% to 6.2% with an associated recurrence rate of 0% to 5%. There was an overall reduction in constipation. Continence was improved in most patients.

Russel et al. studied the American College of Surgeons National Surgical Quality Improvement Program and found 1,485 patients who underwent rectal prolapse operations (706 abdominal and 779 perineal). Patients treated with abdominal approaches had significantly higher rates of infectious (9.8% vs. 3.7%) and overall (12.9% vs. 7.6%) complications compared with those treated with perineal operations.

Lee et al. conducted a retrospective study of patients undergoing abdominal (64) and perineal procedures (40). The abdominal group had a lower overall recurrence rate (6.3% vs. 15%). The overall rate of major

complications was similar in both groups (10.9% vs. 6.8%). The patients in the abdominal group complained more frequently of constipation than of incontinence but the opposite was true for the perineal group.

Kosba et al. evaluated the functional outcome of posterior sagittal rectopexy with Prolene mesh for rectal prolapse in 32 young adults. They found fecal incontinence scores reduced from 11.1 to 4.4 and constipation improved in 13 of 15 cases. There was no mortality, a single case of recurrence (3.2%), mucosal prolapse in two patients (6.4%), and mild wound infection in three patients (9.4%).

Riansuwan et al. compared the results of 122 abdominal operations with 55 perineal operations. There were no deaths but the recurrence rates of prolapse were significantly higher for perineal operations (26.5%) versus 5.2% for abdominal operations. They concluded perineal operations were appropriate for the elderly and sick but second-best choice for younger healthier patients.

Karas et al. conducted a randomized controlled trial in 41 tertiary centers in 21 countries to determine the value of rectopexy versus no rectopexy with respect to recurrence rates. There were 252 patients, 116 in the no rectopexy arm compared to 136 in the rectopexy arm. Sigmoid resection was performed more frequently in the no rectopexy arm. There was no significant difference in complication rates (11% vs. 17%). The mortality rate was 0.8%. There was no significant difference in the 5 years recurrence rate (8.6% for no rectopexy vs. 9.5% for rectopexy).

In their Cochrane review, Tou et al. found insufficient data to say which of the abdominal and perineal approaches has a better outcome. Division rather than preservation of the lateral stalks was associated with less recurrent prolapse but more postoperative constipation. Laparoscopic rectopexy was associated with fewer postoperative complications and shorter hospital stay than open rectopexy. Bowel resection during rectopexy was associated with lower rates of constipation.

In a systematic review of the literature on the surgical management of recurrent rectal prolapse, Hotouras et al. found 161 patients who underwent abdominal surgery for their recurrence. With a follow-up ranging from 0 to 23 years, recurrence rates varied from 0% to 15%. Morbidity rates ranged from 0% to 32% with a 4% mortality.

OCCULT (HIDDEN) RECTAL PROLAPSE

Brown et al. conducted a retrospective review comparing the results of

patients undergoing operations for occult (74 patients) versus overt (69 patients) rectal prolapse. Resection rectopexy was the treatment of choice except in patients with fecal incontinence who underwent sutured rectopexy. There were significantly more perineal procedures in overt prolapse compared with occult prolapse (54% vs. 5%). Rectal prolapse surgery reduced the incidence of St Marks grade 4 fecal incontinence from 38% to 19% in the overt prolapse group and from 49% to 22% in the occult prolapse group. The incidence of constipation increased in the occult group from 39% to 50% but decreased in the overt prolapse group from 42% to 35%. They concluded operations for occult prolapse are unlikely to benefit patients whose principle symptom is constipation. Approximately half of those patients whose occult prolapse is associated with fecal incontinence will have their bowel function habit improved by prolapse surgery.

Symptoms associated with internal rectal prolapse include fecal incontinence, incomplete evacuation, straining, and repetitive toilet visits.

EDITOR'S COMMENT

Few topics are associated with as much controversy as the treatment of rectal prolapse. There are few conditions for which as many different types of procedures have been described as have been for rectal prolapse. In reviewing the literature, one is impressed by the heterogeneity of publications, by the differences in the populations studied, procedures performed, length of follow-up, and number of surgeons performing the procedures. It is not surprising that the average surgeon is at a loss of how to proceed with respect to selection of the best procedure for his/her patient.

Similar to other fields, new technology and modes of access have promoted novel methods of surgical repair, resulting in an avalanche of publications which report "superior" results for these techniques as compared to "conventional" procedures. With the advent of both minimally invasive hiatal hernia repair and the prolapse procedure for hemorrhoids, where there was a plethora of articles flooding the scientific literature with very favorable outcomes and large case series, so much so, that one wondered where are all these patients came from! The same is true in the field of rectal prolapse. Suddenly, there are large series of patients treated with new procedures. One wonders what degree of rectal prolapse these patients had, selection criteria for surgery and other important points to determine study and outcome quality. For example, in one large series of laparoscopic ventral rectopexy, one notes that although 919 patients are reported upon, with a median 34-month follow-up, only 26% had external rectal prolapse (Consten EC, van Iersel JJ, Verheijen PM, et al. Long-term Outcome After Laparoscopic Ventral Mesh Rectopexy: An Observational Study of 919 Consecutive Patients. *Ann Surg* 2015;262(5):742–8). It gives one pause to note conclusions of a recent Cochrane review on complete full-thickness rectal prolapse in which 15 randomized controlled trials including 1007 patients were evaluated (Tou S, Brown SR, Nelson RL. Surgery for complete (full-thickness) rectal prolapse in adults. *Cochrane Database Syst Rev* 2015;11:CD001758). The authors concluded

"The lack of high quality evidence on different techniques, together with the small sample size of included trials and their methodological weaknesses, severely limit the usefulness of this review for guiding practice. It is impossible to identify or refute clinically important differences between the alternative surgical operations. Longer follow-up with current studies and larger rigorous trials are needed to improve the evidence base and to define the optimum surgical treatment for full-thickness rectal prolapse."

One of the determinants by which procedures are chosen is the frailty of a given patient and whether they can withstand a general anesthetic. If the answer to this question is no, one selects a perineal procedure (Altmeier or Delorme procedures described in Chapter 163). If they can undergo a general anesthetic, one it is then left to choose between a perineal procedure or an abdominal procedure as Gordon eloquently describes in the preceding chapter. The choice of whether to do a sigmoid resection or solely a fixation procedure depends upon whether there is associated constipation. Although the connotation "open abdominal approach" makes one envision a large painful incision, open rectal prolapse procedures can be done through a relatively "minimally invasive approach" using a Pfannenstiel incision, since mobilization of the proximal colon is not required. The rectopexy can easily be performed through this incision. Gynecologists have long employed this incision and have favored it due to its rapid relatively painless recovery, avoidance of cutting through muscle, and very low rate of hernia formation.

When choosing between abdominal and perineal procedures, it has been generally been assumed that there are lower recurrence rates with intra-abdominal procedures as opposed to perineal procedures; however, there have been only a few randomized prospective trials evaluating this. The recently published Prolapse Surgery Perineal or Rectopexy (PROSPER) trial was one of the few trials albeit its complex design to randomize patients among the different surgical approaches (Senapati A, Gray RG, Middleton LJ, et al.; PROSPER Collaborative Group. PROSPER: a randomised comparison of surgical treatments for rectal prolapse. *Colorectal Dis* 2013;15(7):858–68). This large 293 patient trial showed higher recurrence rates than anticipated (19% following abdominal procedures, 28% following perineal procedures, $p = 0.2$) with a median follow-up of 36 months. The observed recurrence is higher than I believe most surgeons generally quote to their patients during preoperative counseling. Another recent study of laparoscopic rectopexy with 10-year follow-up data showed a 10-year recurrence rate of 20% (Foppa C, Martinek L, Arnaud JP, et al. Ten-year follow up after laparoscopic suture rectopexy for full-thickness rectal prolapse. *Colorectal Dis* 2014;16(10):809–14).

One of the problems with surgery for rectal prolapse is the fundamental etiology of rectal prolapse. In some cases, there is a weak pelvic floor; in others, there is a physiologic reason this has occurred. Interestingly, there has been something of a change in demographic, and we are seeing more men with rectal prolapse, with the increase in extreme physical exertion and significant Valsalva maneuvers associated with heavy construction work and significant weight lifting of extreme training and bodybuilding. Failure to address this behavior postoperatively will of course lead to recurrence, much as with any other kinds of hernia surgery. Weakness in other components of the pelvic floor can also promote recurrence, that is, failure to adequately provide for vaginal fixation or bladder support in a patient in whom this is an issue. Many surgeons do not have the luxury of urogynecology support in their institutions and many of these

problems are often not discovered at the original preoperative assessment. It is, however, worthwhile to perform a vaginal exam in the upright position to ensure there is not an accompanying vaginal vault prolapse that must be addressed at the time of surgery.

One of the issues that is not clearly addressed in the foregoing chapter is the issue of when to perform a repair for rectal prolapse. In many patients, prolapse has existed for years prior to repair. It is thought that much of the incontinence arising in patients with prolapse is due to stretch injury of the pudendal nerve. The longer a rectal prolapse persists, the more neural damage may occur. It is imperative to counsel patients that there *will* be a period of incontinence following the repair until the anal sphincter regains its tone. There are, however, a portion of patients that will have significant *permanent* impairment in continence. Until recently there were no interventions one could offer them other than biofeedback, dietary modification with fiber and antidiarrheals, or at the extreme, colostomy or artificial anal sphincter. Recently sacral nerve root stimulation appears to be a promising option in this subset of patients. Also not addressed in the decision for operation is the danger of an incarcerated rectal prolapse, which although not frequent is a real concern. This condition frequently occurs in frail, elderly individuals. The only thing worse than performing this surgery in the elective situation, is facing this as an emergent situation with vascular compromise of the rectum in the setting of incarceration. In this scenario, one can even find small bowel in the hernia sac mandating *both* and an abdominal and perineal approach. In this circumstance, laparoscopy may be useful to identify if the abdominal contents are compromised after the prolapse has been reduced.

Few procedures provide as much satisfaction neither as repairing a rectal prolapse nor as much frustration as seeing it recurs.

Susan Galandiuk

163 Rectal Prolapse

Elisa H. Birnbaum

DEFINITIONS

Rectal prolapse is the protrusion of the rectum through the anal canal. Intussusception of the rectum is an occult (or internal) prolapse that occurs when the rectum descends toward but does not pass through the anal canal. A complete rectal prolapse (procidentia) occurs when all layers of the rectum prolapse through the anal canal (Fig. 163.1). A partial (mucosal) prolapse occurs when all layers of the rectum are not involved and only the mucosal layer prolapses (Fig. 163.2).

EPIDEMIOLOGY AND CAUSE

The incidence of rectal prolapse is bimodal, although patients of any age can be affected. One peak occurs in children within the first 3 years of life and the second peak occurs after the seventh decade. Rectal prolapse associated with children occurs equally in both sexes and is often associated with a diarrheal illness. Prolapse in children is typically not a recurring problem and can be self-limited. In the elderly, rectal prolapse is more common in women (80% to 90%), and the prevalence of this abnormality increases with age. Many of these elderly women have concurrent pelvic organ prolapse, defecatory disorders, and may be multiparous. Rectal prolapse may also effect institutionalized patients who have neurologic or psychiatric comorbidities (15%). It is possible that chronic constipation and straining to defecate may be a contributing factor in this group of patients.

The exact cause of rectal prolapse is still unclear. It was initially thought to be a type of perineal hernia or a consequence of a pelvic fascial defect. Many patients are found to have a deep pouch of Douglas and associated enterocele. Constipation and straining are felt to be contributing factors (30% to 60%). A wide pelvic inlet and redundant, nonfixed rectosigmoid are commonly found. Pelvic floor atony and a patulous anus may be a result of chronic straining with denervation or stretch injury to

the anal canal. Cinedefecography shows that the rectum initially intussuscepts before prolapsing. Anal physiology testing frequently shows low resting tone, diminished squeeze efforts, and prolonged pudendal motor nerve terminal latency. Pudendal neuropathy may be a result of chronic stretch injury associated with straining. Vaginal prolapse and enteroceles are commonly seen in studies of patients with long-standing rectal prolapse (50%).

CLINICAL PRESENTATION

Rectal pressure, mucus discharge, rectal bleeding, and fecal incontinence are frequent symptoms of rectal prolapse. Chronic constipation and difficulties defecating are common complaints. Once the prolapse occurs, patients complain more of fecal incontinence and rectal bleeding and they do of constipation. Rectal pain is a complaint in early prolapse and may be due to the protrusion of the rectum with normal anal rectal tone. Pain is less of a complaint in patients with long-standing prolapse (probably due to chronic dilatation of the anal canal), but patients do note the uncomfortable sensation of sitting on a mass within their anal canal. Early in the diagnosis, patients will state that the rectal prolapse occurs primarily during defecation. It is not uncommon for symptoms to be attributed to prolapsing hemorrhoids. There may also be spontaneous reduction of the prolapse after defecation. Over time, however the prolapse occurs during any activity associated with increased abdominal pressure and in some patients occurs every time they stand upright. Manual replacement by the patient or their caretakers is common. Mucus discharge and bleeding are common complaints and may be a result of ulceration at the leading edge of the rectal prolapse. Although rare, the rectal prolapse can become incarcerated or strangulated if there is normal tone to the anal sphincter or the prolapsed rectum has become extremely edematous. These patients require urgent or emergent surgery.

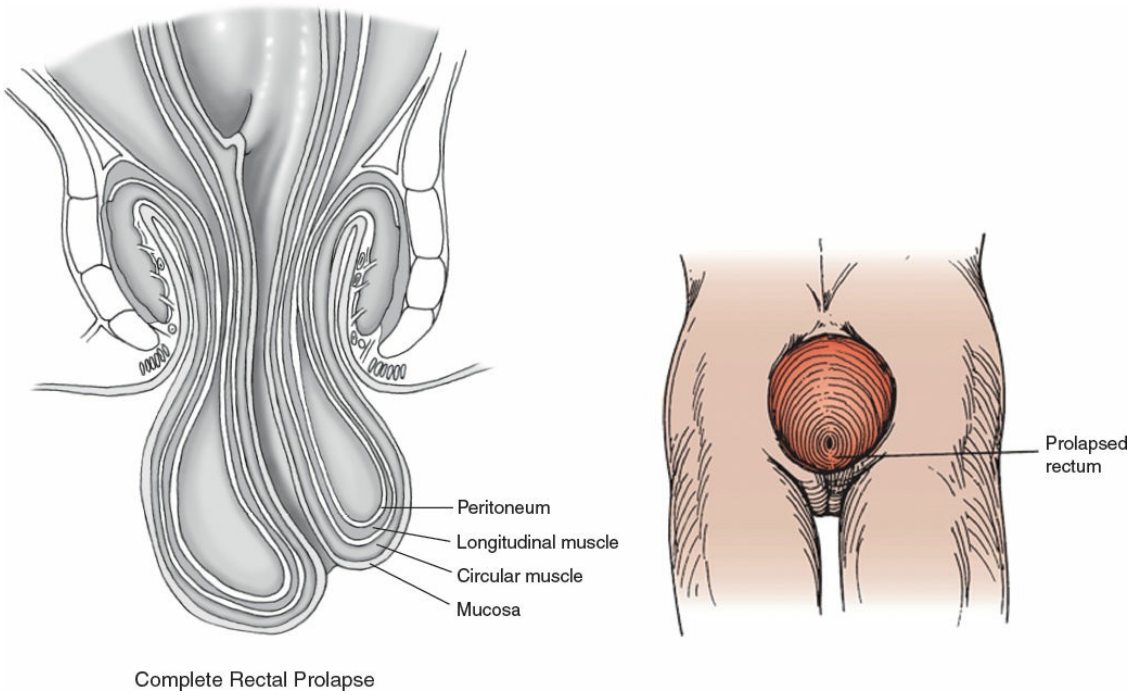

Figure 163.1. Complete prolapse (full-thickness bowel wall). Complete prolapse folds generally circular. (From Lawrence PF. *Essentials of general surgery*. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

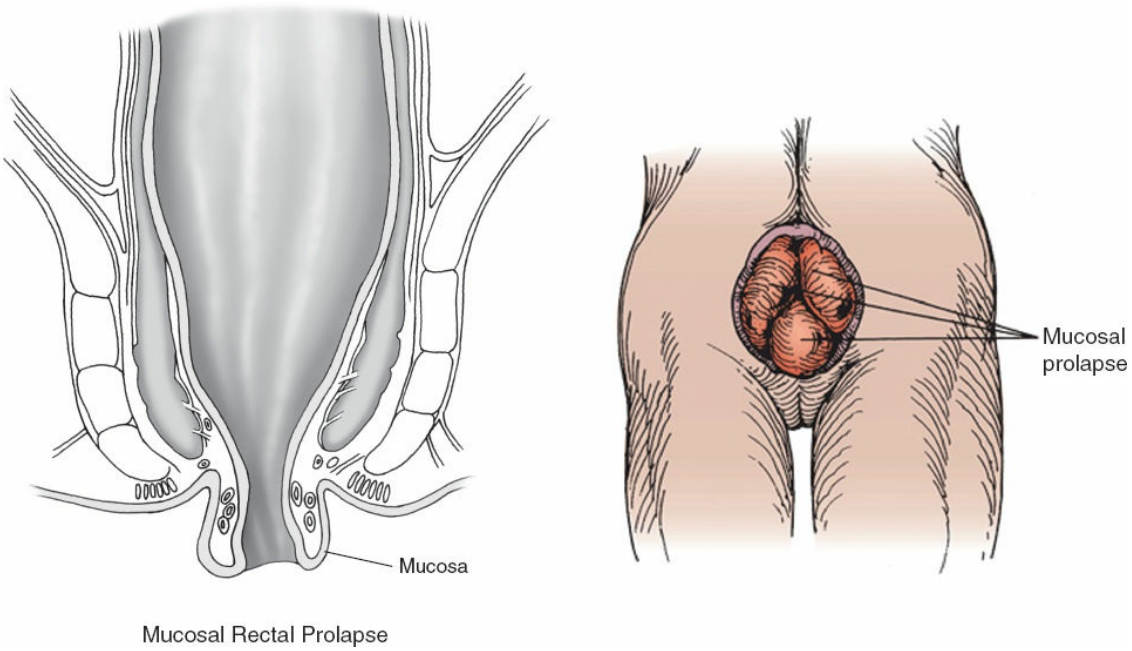

Figure 163.2. Folds in mucosal prolapse usually radial in orientation. Partial prolapse (mucosa only). (From Lawrence PF. *Essentials of general surgery*. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

Although the diagnosis is suspected by history, confirmation should be

made during physical examination. The visualization of the prolapse may be as simple as asking the patient to stand and Valsalva while examining the perineum. It is useful to have the patient strain on a commode to demonstrate the extent of the rectal prolapse. Circumferential rings are typical of a full rectal prolapse; radial folds are more typical of equal full prolapse or prolapsing hemorrhoids. A lax anal sphincter and diminished squeeze efforts are frequently found on digital rectal examination. Proctosigmoidoscopy might reveal an erythematous, edematous rectal mucosa, and possibly a solitary rectal ulcer in the mid rectum. The "leading edge" is typically an erythematous ring seen up proximally 5 to 8 cm from the dentate line on proctosigmoidoscopic examination. Solitary rectal ulcers may be confused with rectal tumors, and biopsies should be obtained to get a more definitive diagnosis.

If the prolapse cannot be demonstrated in the office setting, a defecography or dynamic magnetic resonance imaging (MRI) may be done to demonstrate the redundant, prolapsing rectosigmoid. These tests may also be useful to identify other elements of pelvic organ prolapse such as vaginal prolapse, enterocele, and cystoceles. A complete colonic evaluation with colonoscopy or a contrast enema is necessary to rule out a tumor as the lead point of the rectal prolapse and clear the proximal colon. The anal sphincter may be assessed with anal physiology testing, although the results typically show very low rest and low squeeze pressures. Unilateral or bilateral neurogenic injury to the pudendal nerve may result from chronic stretching of the nerve. Preoperative colonic transit studies should be done for patients with complaints of severe constipation and infrequent bowel function to identify patients who may also have colonic inertia.

SURGICAL TREATMENT

It is often said that more than 100 operations have been cited as forms of treatment for rectal prolapse. Elimination of the rectal prolapse and restoration of continence is the goal of most surgical procedures. Surgical therapy must be tailored to the individual patients and their symptoms. The choice of operation is determined by the patient's age, comorbidities, operative risk, and associated anatomic abnormalities. The surgical approach to rectal prolapse is either transabdominal or perineal. Prior surgical treatment of rectal prolapse or colonic surgery will influence and determine the type of operations that can be offered to patients. For

example, doing a perineal proctosigmoidectomy if the patient had a prior rectal resection places the remaining bowel at risk of being devascularized.

Transabdominal approaches include sutured rectopexy, mesh rectopexy, and resection rectopexy. These approaches can be done as an open laparotomy, laparoscopically or robotically. These procedures can be done in conjunction with the urogynecologist's repair of an enterocele and cystocele. Perineal procedures include perineal rectosigmoidectomy (Altmeier procedure), mucosal sleeve resection (Delorme procedure), and anal encirclement (Thiersch procedure).

The abdominal procedures are associated with lower recurrence rates but higher morbidity rates. These procedures are generally reserved for younger patients who can tolerate general anesthesia. Resection rectopexies may improve the bowel habits of patients who complained of preoperative constipation and in whom have a markedly redundant rectosigmoid. Evacuation difficulties may continue to plague patients after suture or mesh rectopexies that may be due to stenosis by the foreign material or angulation of the redundant rectosigmoid.

Perineal procedures can be done under regional anesthesia to minimize the anesthetic risk for the high-risk patient. These procedures have decreased perioperative morbidity rates, shorter hospital stays, and quicker postoperative recoveries. Fecal incontinence rates and recurrence rates remain fairly high with the Altemeier procedure.

PREOPERATIVE PLANNING

It is our practice to get preoperative anesthesia clearance prior to undertaking surgery in these potentially high-risk patients. At that time the decision for epidural or general anesthesia can be discussed with the patient. Preoperative and postoperative care is similar to any patient undergoing a major pelvic operation. A bowel preparation is typically done the day prior to surgery. Since most of these patients have fecal incontinence, patients and their caregivers should be aware of the implications of the bowel preparation and plan accordingly. Oral antibiotics may be done in conjunction with the bowel preparation and prophylactic intravenous antibiotics are given within an hour of operation. Positioning the patient for the perineal procedures is surgeon dependent. A Foley catheter is placed prior to positioning the patients. Lithotomy position allows anesthesia better control of the airway with epidural anesthesia. The prone jackknife position allows greater flexibility for the

surgeon. The perineum and vagina are prepped in standard fashion.

SURGICAL TECHNIQUE

Anal Encirclement (Thiersch Procedure)

The Thiersch procedure was initially described in 1891 using a silver wire. Since that time other material such as nylon, silicone tubing, and Marlex mesh have been described as a means of preventing rectal prolapse by encircling and reinforcing the anal sphincter. This procedure can be done with local anesthesia minimizing the anesthetic risk in high-risk patients. A Thiersch wire or other synthetic material is used to encircle the anal canal preventing rectal prolapse. Two small incisions are made lateral to the external anal sphincter in the perineum (Figs. 163.3, 163.4 and 163.5). A submucosal tunnel is created around the anus. The mesh is placed through one of the incisions and advanced around the anal canal. The length of mesh and calibration of mesh tension are determined by the surgeon by placing an index finger within the anal canal. The mesh should be snug enough to prevent the prolapse while allowing enough room for elimination of stool.

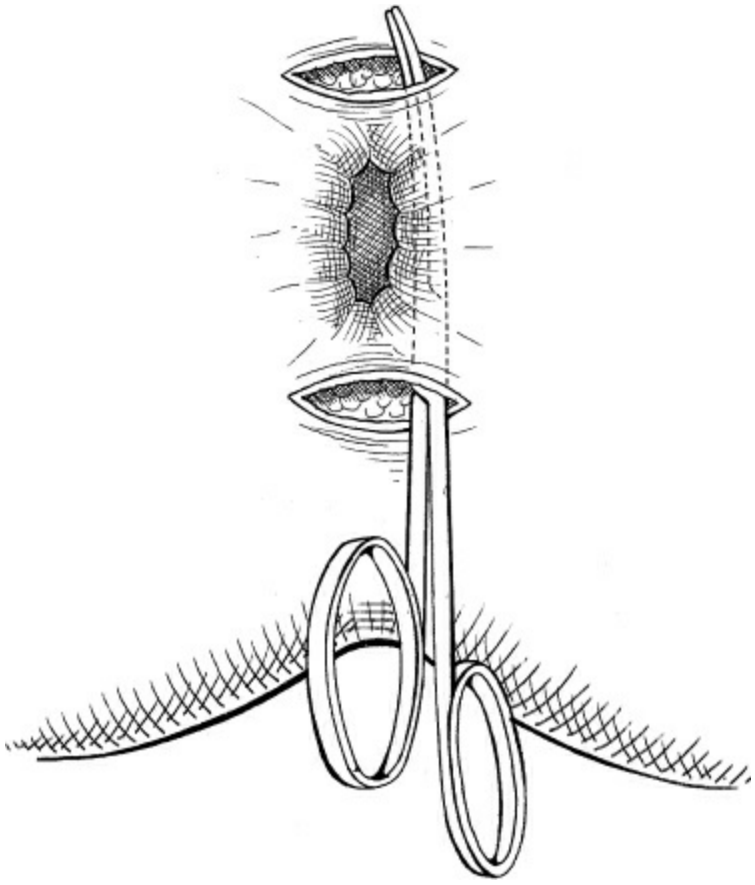

Figure 163.3. Two longitudinal incisions are made and a Kelly clamp is used to create a submucosal tunnel around the anus.

The Thiersch procedure does not eliminate the redundant rectosigmoid nor does it eliminate the rectum from descending into the anal canal. Persistent pressure and recurrent prolapse can occur. In addition, fecal impaction is a common occurrence after this operation (>80%), and stool softeners, laxatives, and enemas are necessary in the postoperative period. Pain is a frequent postoperative complaint, and erosion of the mesh can occur over time. Anal encirclement as a primary treatment for rectal prolapse has fallen into disuse. The only advantage of this operation is that it can be done with local anesthesia. It is generally reserved for moribund patients with limited life expectancies because the septic and mechanical complications are high.

Mucosal Sleeve Resection (Delorme Procedure)

In 1900, Delorme described a way of managing rectal prolapse by excising the rectal mucosal and submucosal layers and plicating the outer muscular layer of the rectum. This procedure avoids a full thickness rectal resection. The muscle plication may aid in improving fecal incontinence by adding bulk to the perineum.

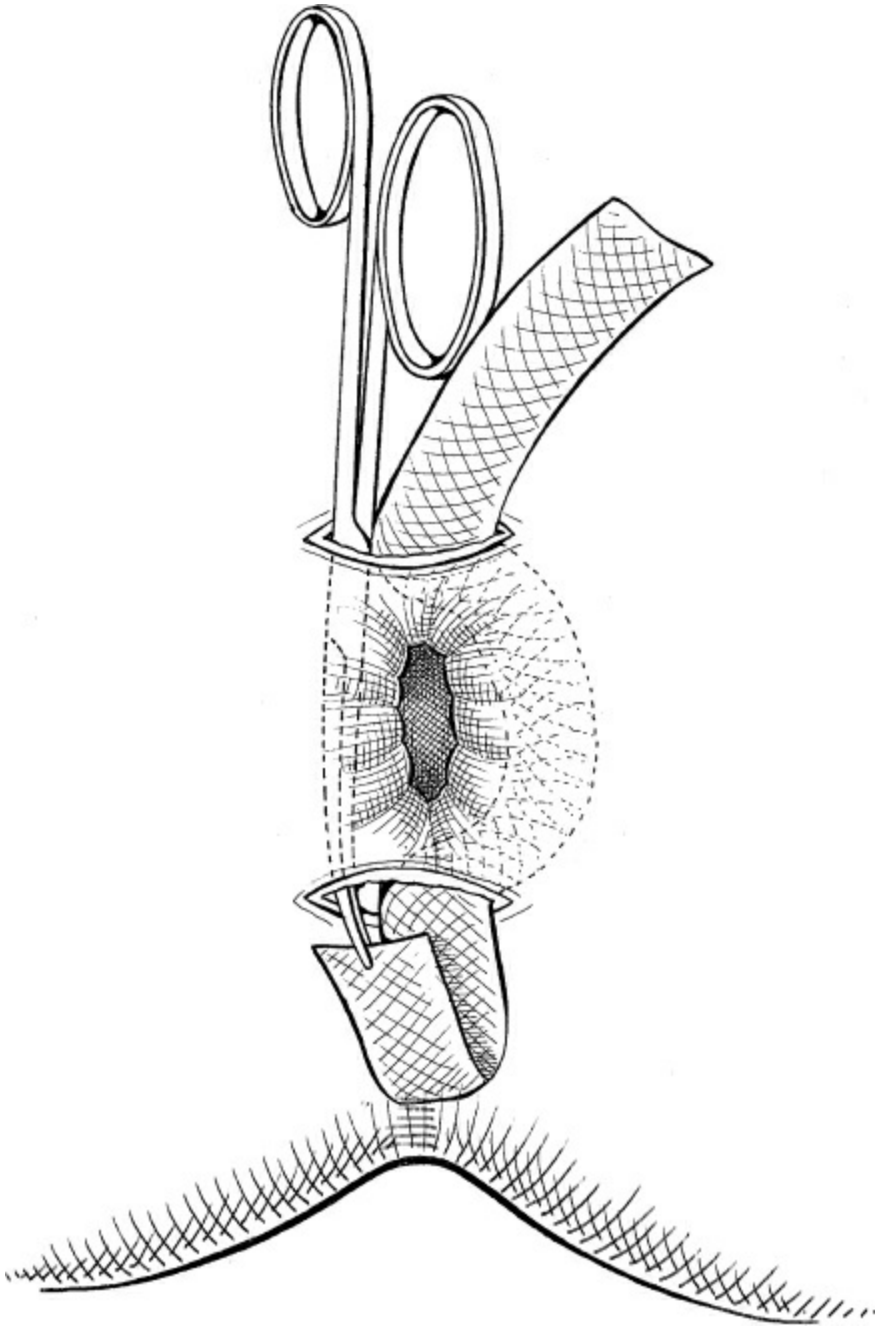

Figure 163.4. A mesh is passed through the submucosal layer to encircle the anus.

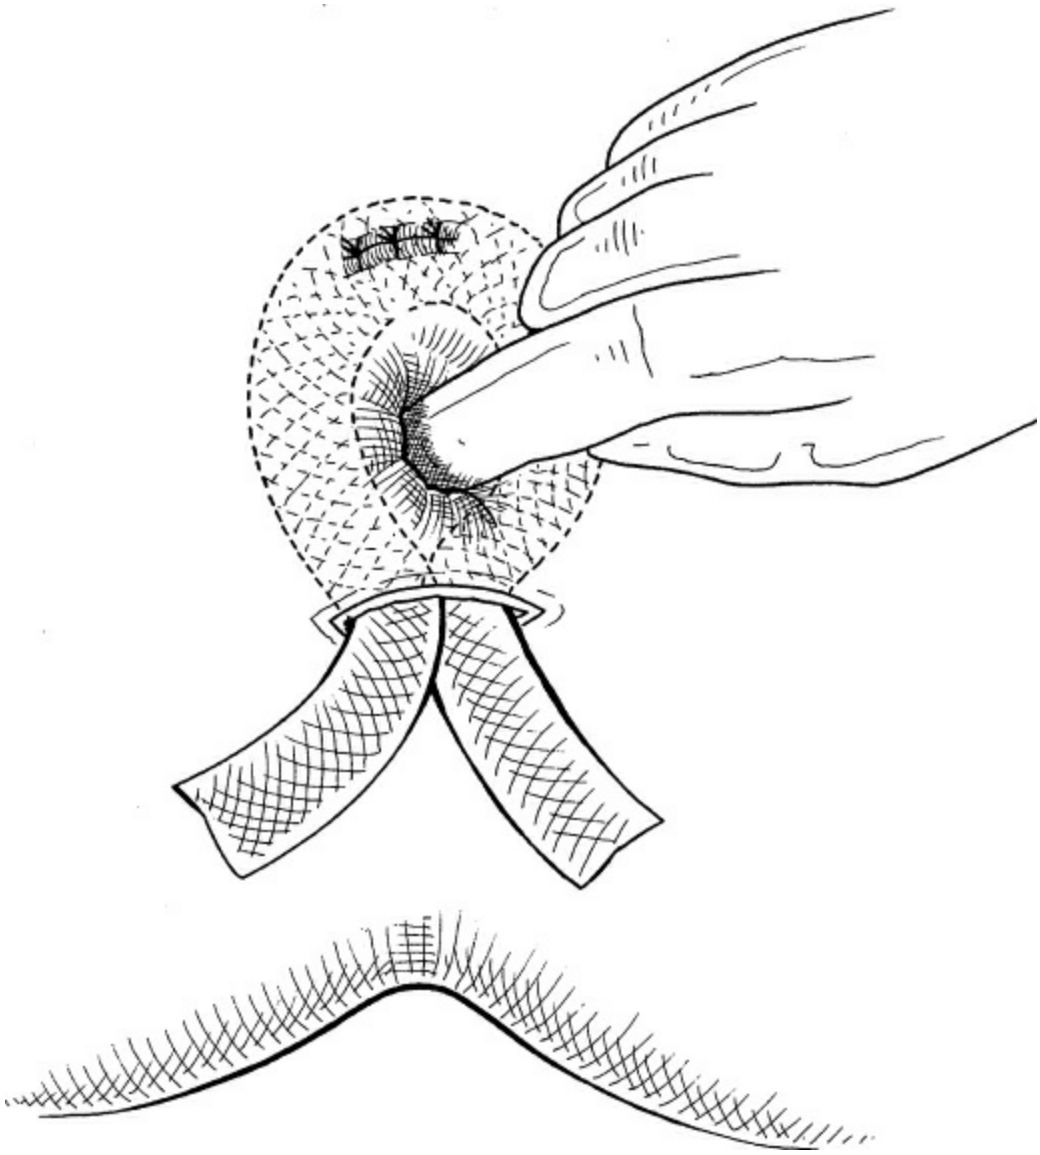

Figure 163.5. Calibration of the mesh tension is performed using a finger inserted into the anal canal.

Once the patient is in position (lithotomy or prone jackknife) and prepped, the rectum is prolapsed through the anal canal using Babcock clamps (Fig. 163.6). The submucosal layer is injected with an epinephrine solution approximately 2 cm above the dentate line to facilitate dissection and decrease bleeding. A circumferential incision is made 2 cm above the dentate line and completed through the mucosal and submucosal layer (Fig. 163.7). Care is taken not to do a full thickness dissection. The electrocautery is used to dissect the submucosal layer circumferentially along the length of the prolapse elevating it off of the underlying muscular layer of the rectum. The extent of dissection is determined by placing traction on the rectum delivering the entire prolapse through the anal canal

until tension is noted. Absorbable sutures are then placed in the muscular layer creating an accordion effect. The sutures are placed longitudinally beginning at the outer edge and ending just above the dentate line (Fig. 163.8). The stripped mucosa is resected after sutures are placed circumferentially around the rectum (Fig. 163.9). The muscular sutures are tied and the mucosal anastomosis is completed with absorbable sutures circumferentially placed around the anal canal (Figs. 163.10 and 163.11).

Although the Delorme procedure can be done with minimal morbidity and a short hospital stay, the recurrence rate is approximately 15% to 30%. The mean time to recurrence is 2 to 3 years. This procedure is not used as widely for treatment of full rectal prolapse because of concerns for recurrence of the prolapse. It is best used for patients with mucosal prolapse or those with short segment full prolapse.

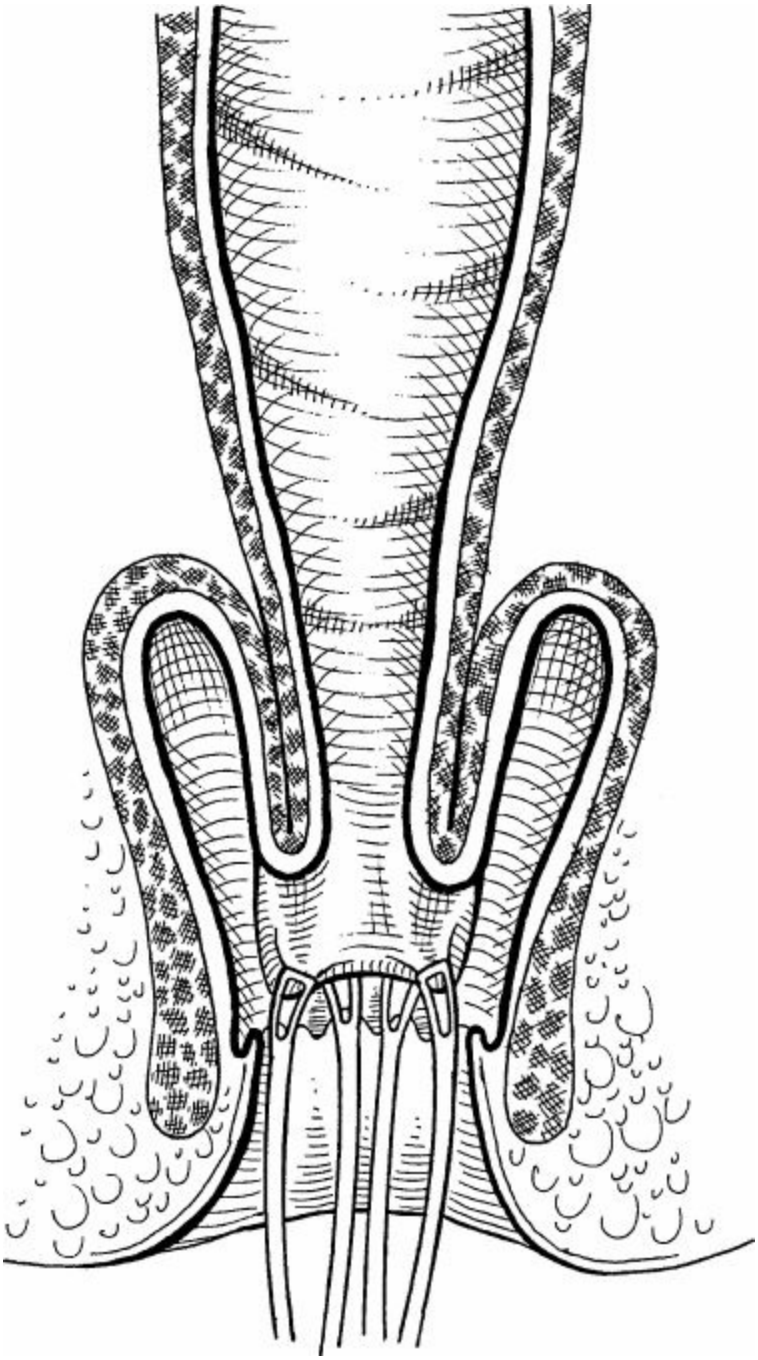

Figure 163.6. Rectal prolapse is delivered through the anus by Babcock clamps.

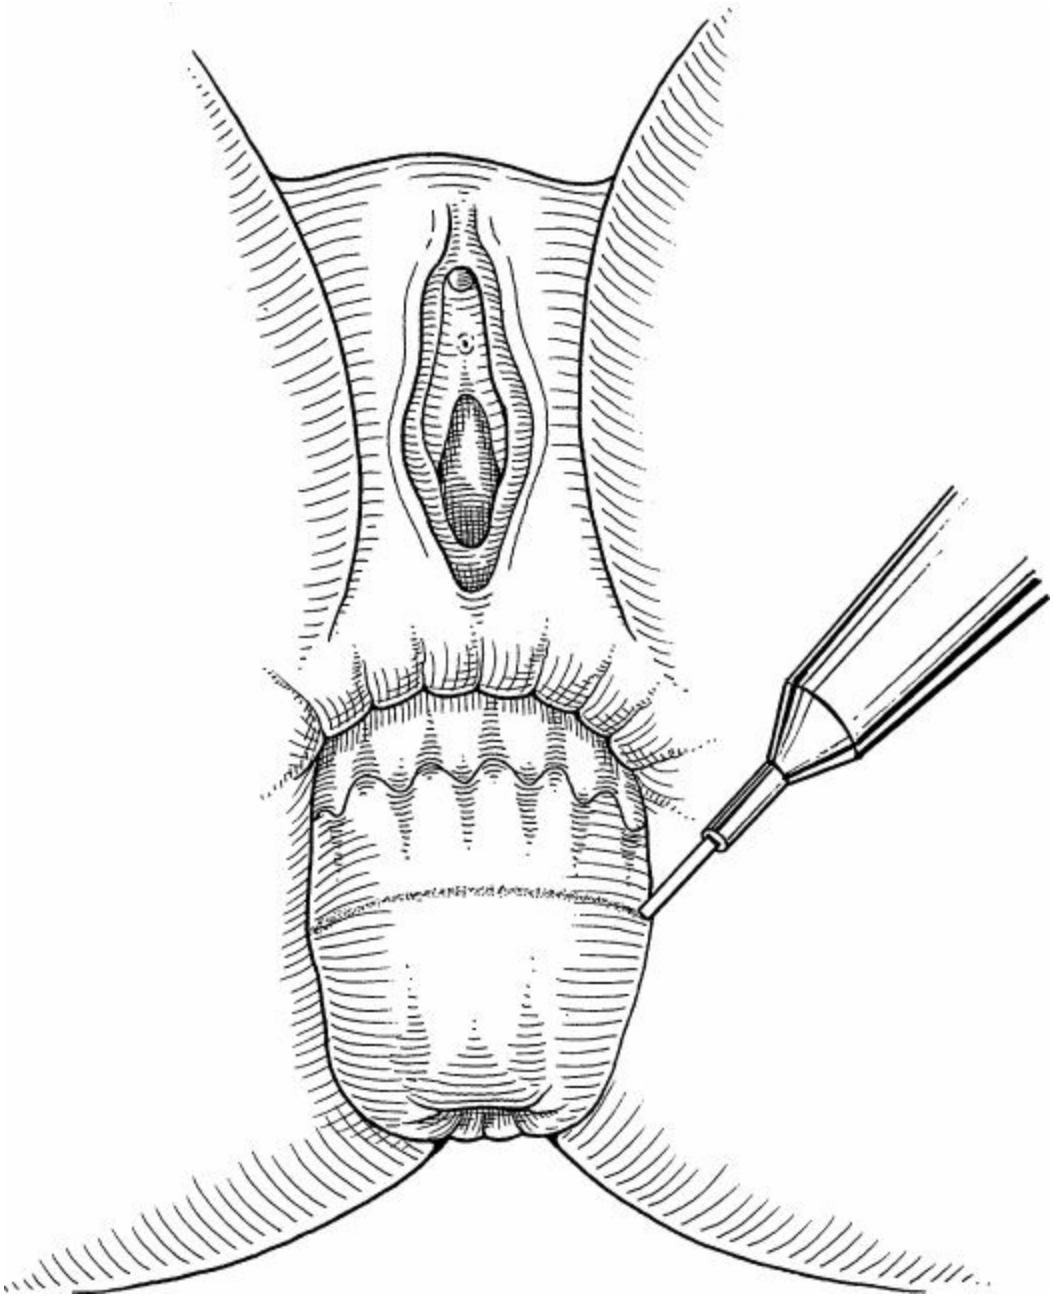

Figure 163.7. Incision is circumferentially marked 2 cm cranially to the dentate line by electrocautery.

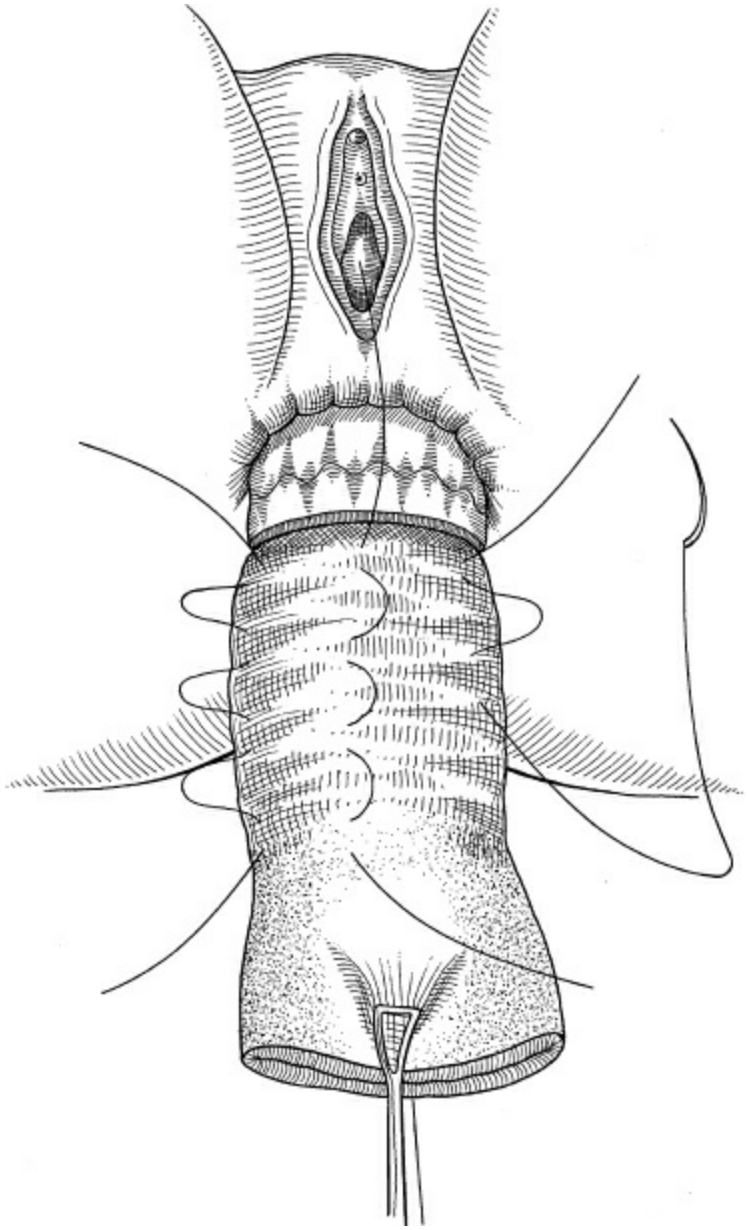

Figure 163.8. After the mucosal sleeve is stripped from the muscularis, plication of this layer is performed using longitudinal sutures.

Perineal Rectosigmoidectomy (Altemeier Procedure)

The perineal rectosigmoidectomy was first described by Mikulicz in 1889 and was the preferred operation for rectal prolapse until the mid-20th century. The variable results may have been secondary to inadequate mobilization of the rectum. In 1952 Altemeier described the perineal rectal sigmoidectomy with anterior levatorplasty. This modification was done to narrow the pelvic floor in an attempt to prevent recurrence and restore fecal continence. Prasad described a modification utilizing a posterior

levatorplasty to recreate the anatomic anal rectal angle in an effort to help patients gain fecal control postoperatively. These procedures can be easily performed under regional or general anesthesia in either the prone jackknife or lithotomy position.

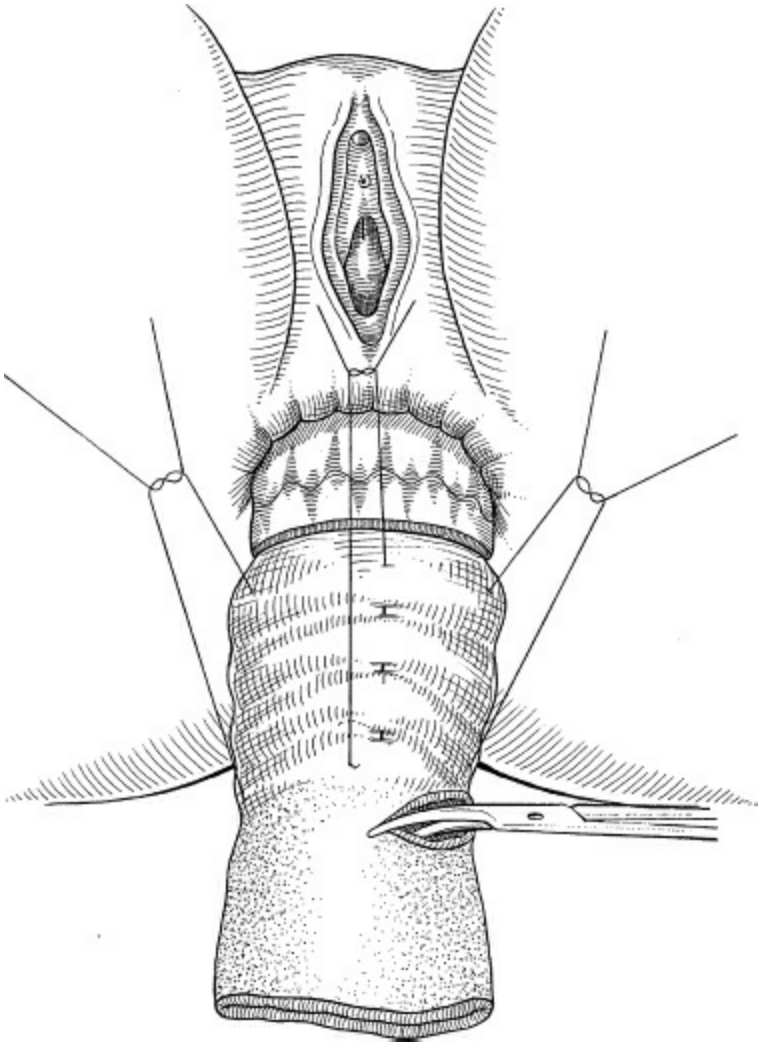

Figure 163.9. Plication of the muscular layer is followed by resection of the excess of stripped mucosa.

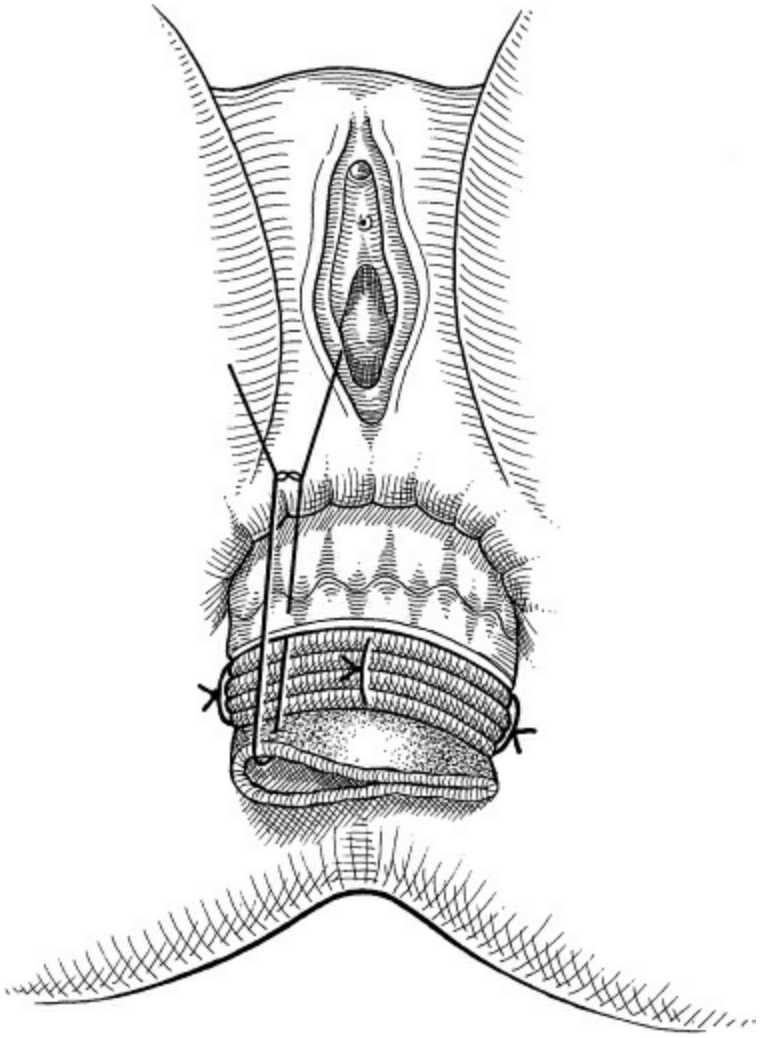

Figure 163.10. Mucosal coloanal anastomosis is performed with interrupted absorbable sutures.

Once the patient is in position and prepped, the rectum is prolapsed through the anal canal using Babcock clamps (Fig. 163.6). The mucosal layer is injected with an epinephrine solution approximately 2 cm above the dentate line to facilitate dissection and decrease bleeding. A Lone Star retractor is useful to evert the anal canal a circumferential incision is made approximately 2 cm above the dentate line (Fig. 163.7). The electrocautery is used to complete the dissection circumferentially. It is helpful to dissect each layer with separate passes of the cautery. After division of the mucosal layer, the dissection of the submucosal layer can be done slowly to minimize bleeding. The blood supply of the rectal wall resides within the submucosal layer. The incision is completed full thickness through the rectal wall. My preference is to then enter the pouch of Douglas between the rectum and vagina and extend the dissection laterally (Fig. 163.12). The posterior mobilization is done after completion of the anterior and

lateral dissection since this is where the redundant mesorectum and mesorectal vessels are found. The rectum is placed under tension, and the redundant mesorectum is divided sequentially (Fig. 163.13). Care must be taken to ensure that these vessels are tied tightly since retraction into the pelvis will occur. Palpation of intraperitoneal contents is feasible through the open pouch of Douglas. Dissection continues posteriorly in the mesorectum to completely mobilize the rectum and occasionally sigmoid colon until all of the redundant bowel has been mobilized. The peritoneum of the pouch of Douglas can be excised and closed with absorbable suture.

A posterior levatorplasty can be done prior to division of the colon (Fig. 163.14). Palpation of the levator ani muscles will ensure correct placement of the sutures. 0 Vicryl or nonabsorbable sutures can be placed. Typically 2 or 3 sutures are necessary to plicate the posterior anal canal. At this time, an anterior plication can also be done using similar sutures. The rectum should fit snugly within the anal canal.

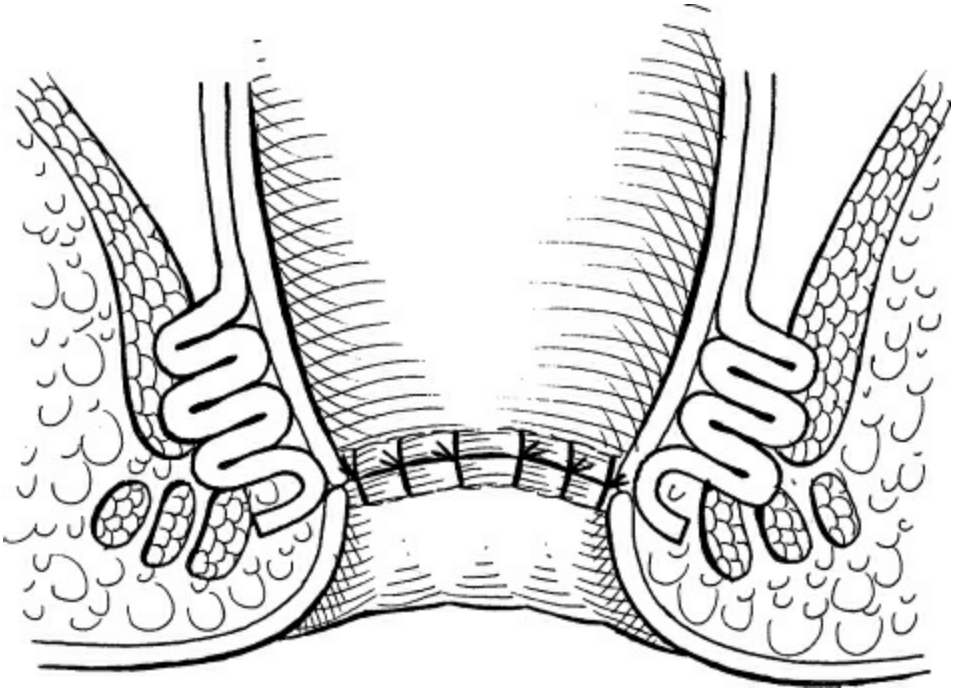

Figure 163.11. Final aspect of the anastomosis and underlying muscular plication.

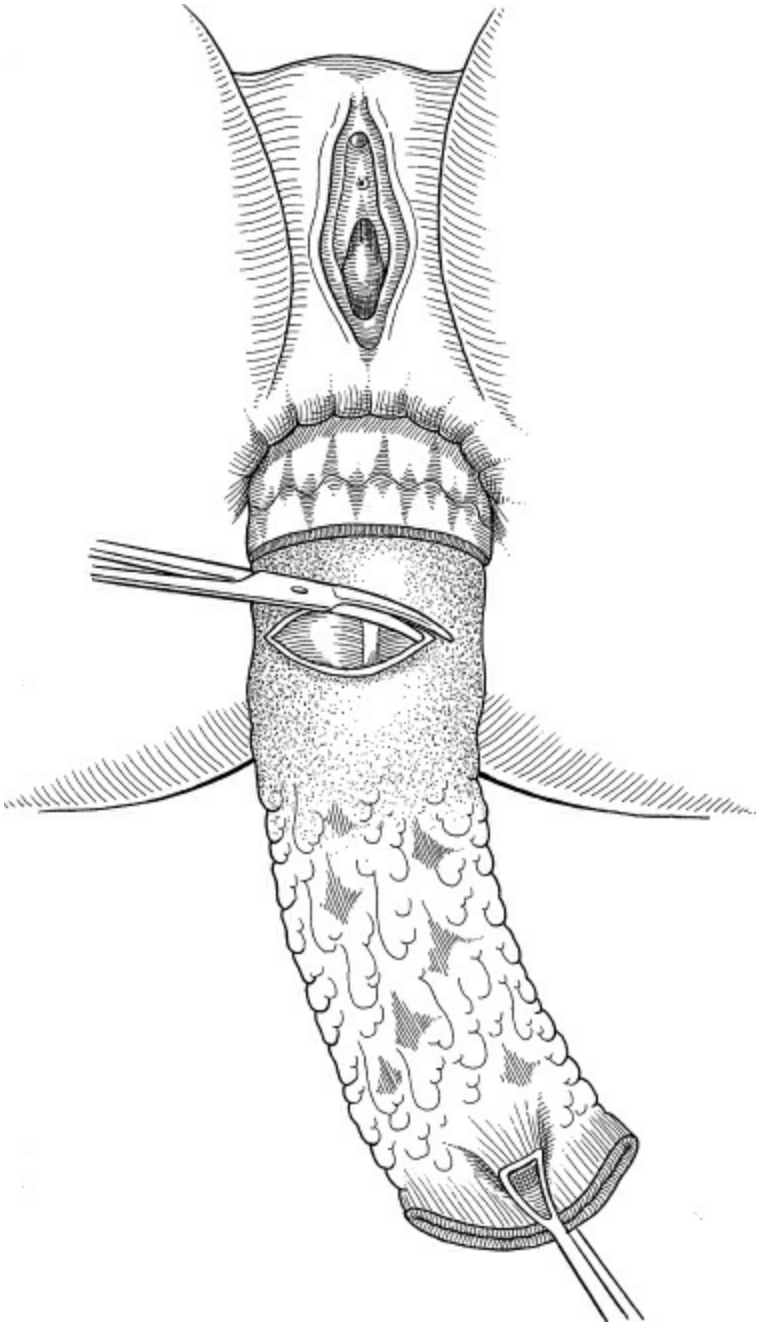

Figure 163.12. After careful mesorectum dissection, the Douglas pouch is opened transversally, facilitating full rectosigmoid mobilization and allowing the intraperitoneal contents to be palpated.

The level of the redundant colon to be transected is identified and marked circumferentially using the electro-cautery (Fig. 163.15). A handsewn or stapled anastomosis can be done at this point. My preference is to do a handsewn anastomosis to control for the size discrepancy between the proximal colon and anal canal. Absorbable anastomotic sutures are placed through the anal mucosa in all four quadrants and

tagged with the needles on. One half of the colon is divided and the anastomotic sutures are placed in their appropriate positions but left untied to prevent tension on the proximal bowel. The second half of the colon is divided and the remaining sutures are placed. It is helpful to tie these sutures after they have all been placed to avoid undue tension on the bowel wall. Placement of the sutures in this manner will ensure proper spacing since there will be a size discrepancy between the proximal colon and anal canal. After the four-quadrant sutures are tied, attention is turned to each quadrant. Sutures are then placed through the anal mucosa and the full thickness bowel wall and tied sequentially. Examination of the anastomosis is done to ensure that there are no defects or tears in the anastomosis.

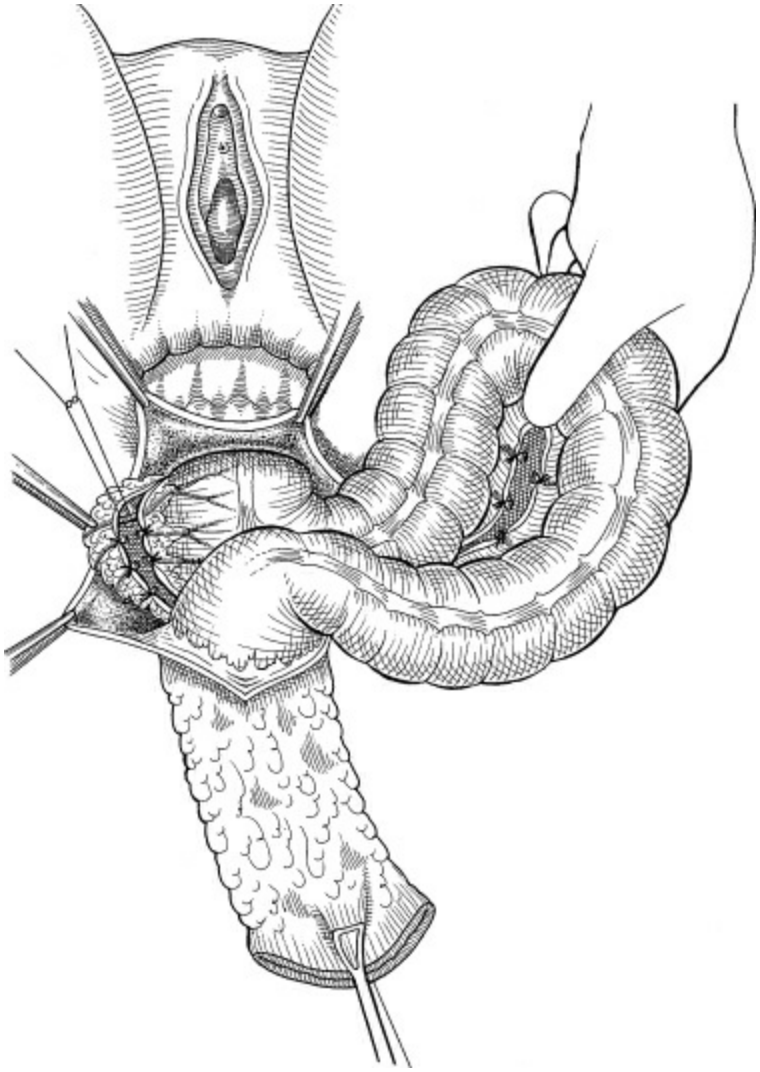

Figure 163.13. Mesocolic vessels are ligated until mobilization of the redundant bowel is complete.

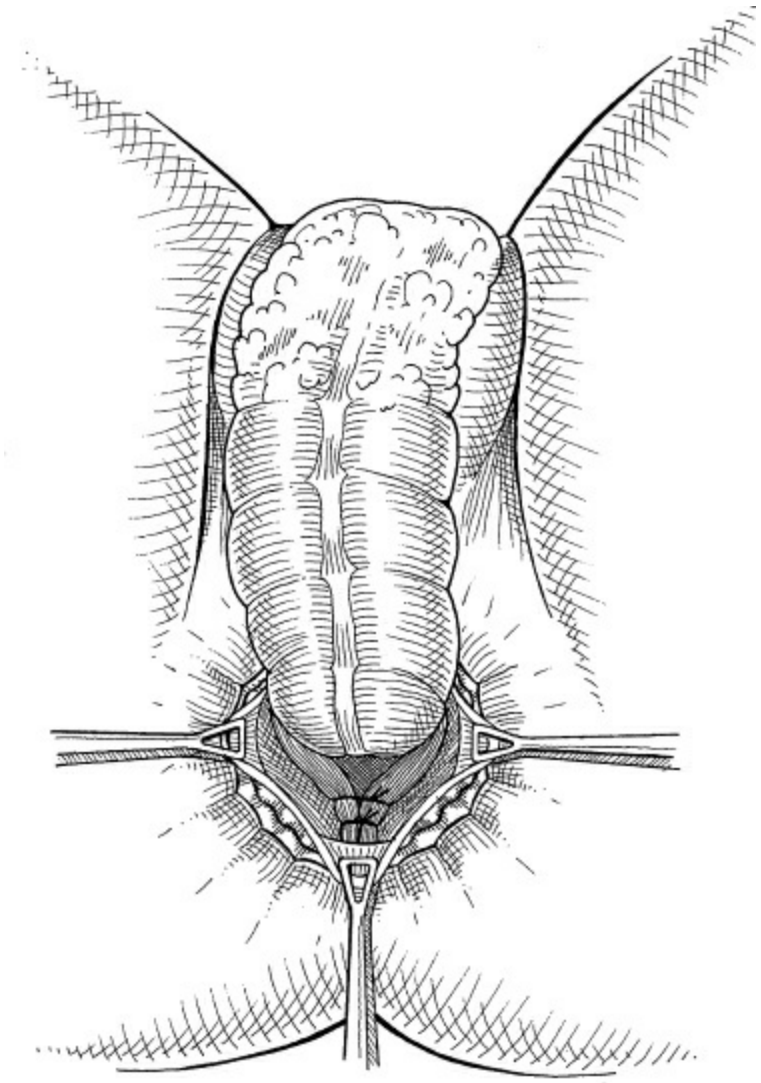

Figure 163.14. Posterior levatorplasty is performed with a 0 Vicryl suture (two to three stitches) until the bowel fits loosely in the opening.

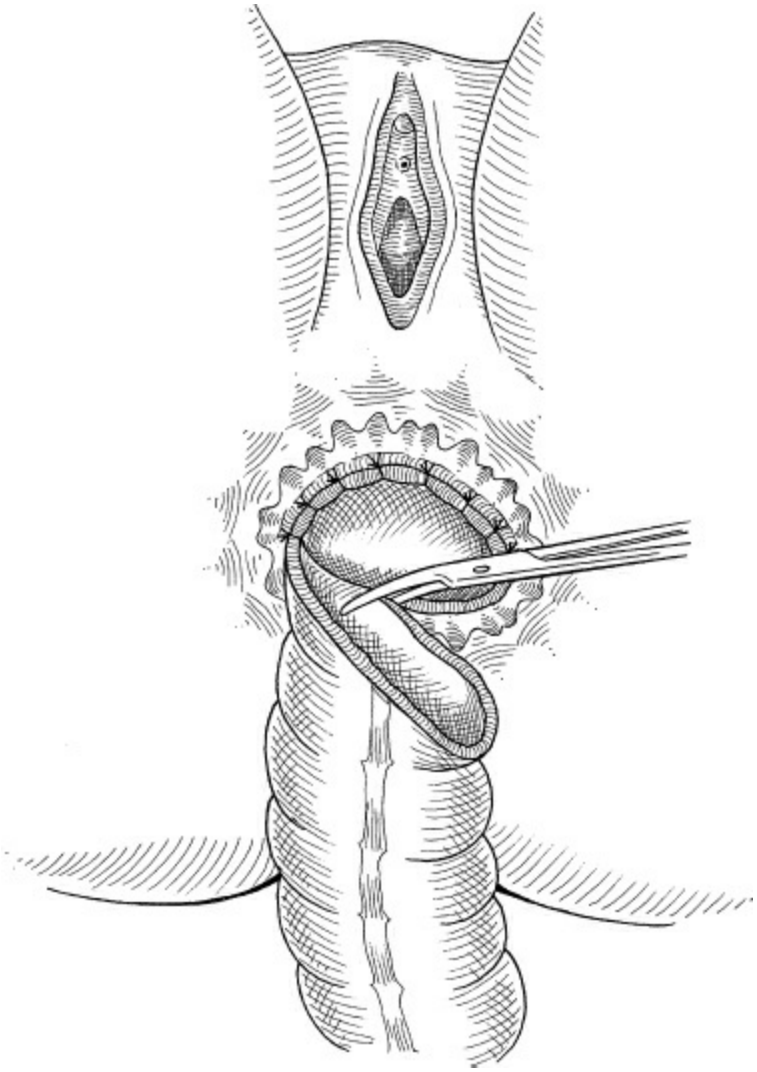

Figure 163.15. Once the anterior half has been cut and sutured, the posterior wall is sectioned and the anastomosis is completed with an interrupted suture.

An end-to-end stapled anastomosis can be performed utilizing a circular stapler (Fig. 163.16). The pursestring is placed on the proximal bowel, and the stapler head is tied in place. A second pursestring is fashioned on the distal bowel around the post of the stapler post. The stapler is then coupled, tightened, and fired making sure that the anastomosis is located above the dentate line (Fig. 163.17).

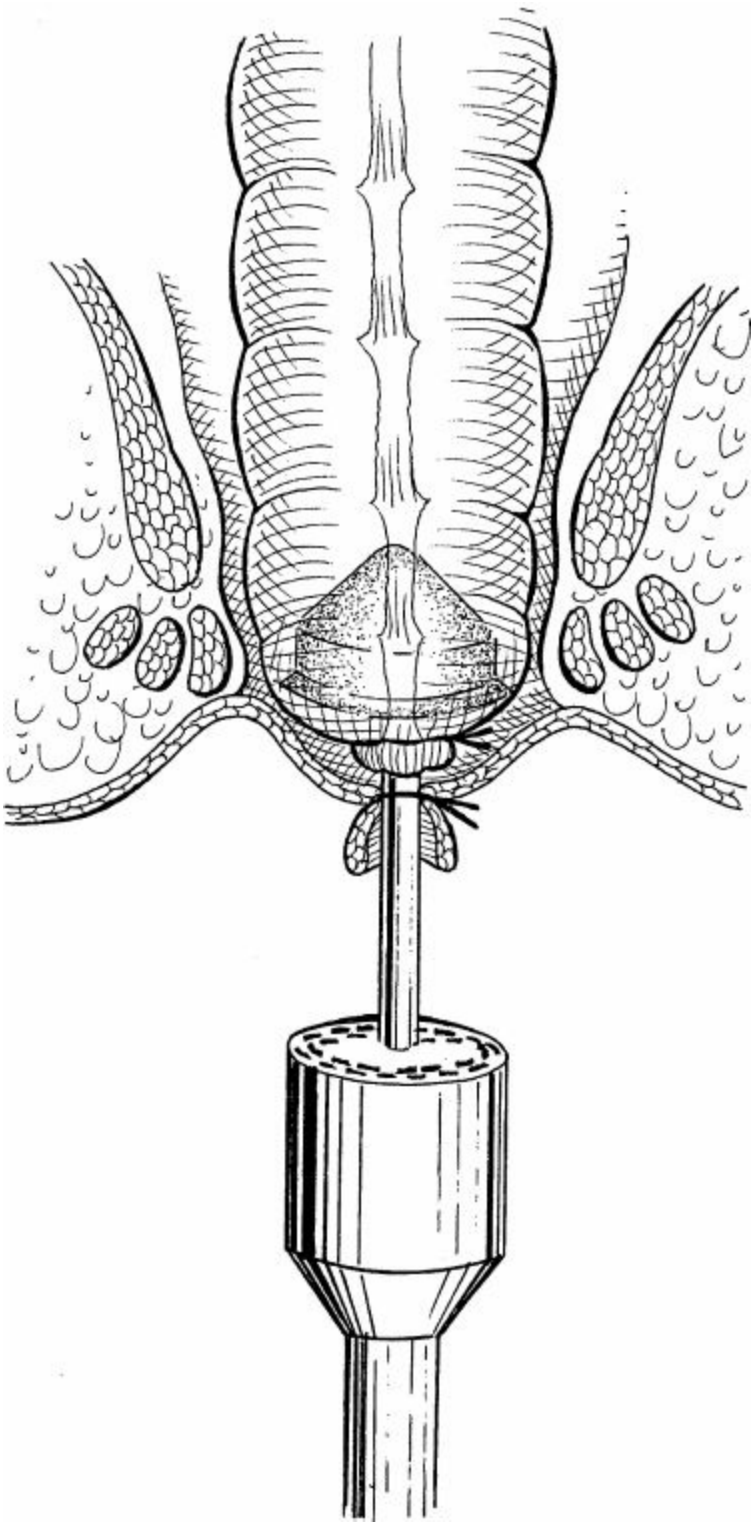

Figure 163.16. Coloanal anastomosis using circular stapling devices.

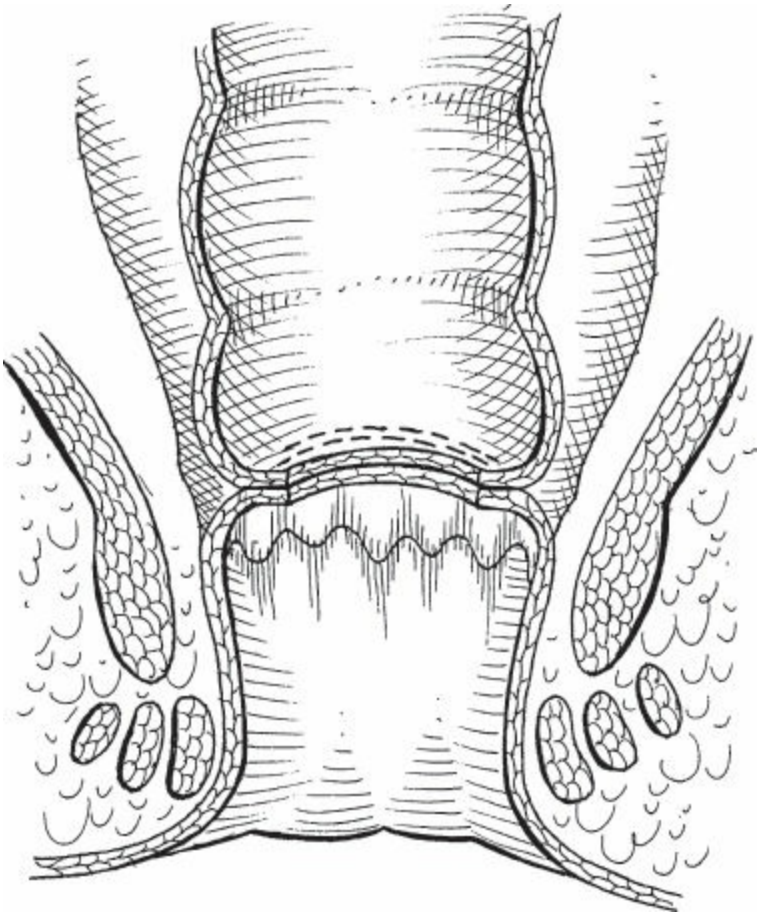

Figure 163.17. Final aspect of a stapled coloanal anastomosis.

POSTOPERATIVE MANAGEMENT

Patients can resume a diet and ambulate as soon as they tolerate it. The Foley catheter is typically removed on the first or second postoperative day. Discharge is done as soon as the patient tolerates a diet, voids, and has some bowel function. Postoperative medications depend on the patient's preoperative bowel function. If the patients have a history of severe constipation, it is our practice to discharge them on stool softeners and laxatives. Laxatives are not generally necessary if the patients have soft stool and incontinence. In general, patients do not complain of excessive pain after these operations. Mild analgesics and warm tub soaks may be useful in controlling the postoperative discomfort. Patients are counseled not to expect the fecal incontinence to improve in the immediate postoperative period. A follow-up appointment is generally scheduled 4 weeks from surgery and at that time a digital rectal examination should be done to ensure anastomotic healing.

COMPLICATIONS

Complications from perineal rectosigmoidectomy range from 0% to 32%. Deaths are rare and may be related to the patient's comorbidities. Pelvic hematomas, abscesses, or anastomotic dehiscence may occur early and require surgical intervention. Several studies have shown that the complication rates for infections and overall morbidity are higher with abdominal operations than for perineal procedures. Age does not seem to be a factor in complications, but there is a significant selection bias for most studies. Late complications include stricturing of the anastomosis that can be treated with digital dilation. Fecal incontinence is the most common postoperative complaint and can be managed with fiber and antidiarrheals, although it is not uncommon for this to be a persistent problem. Recurrent rectal prolapse can occur at variable rates and may be due to an incomplete resection or persistent straining. Studies have shown that recurrences are more common in stapled anastomoses and short specimen lengths. Studies with longer follow-up show higher rates of recurrences and not all patients with recurrences are treated surgically.

EDITOR'S COMMENT

Dr. Birnbaum's chapter on perineal approaches for the treatment of rectal prolapse describes three operations: (1) the Thiersch, (2) Delorme, and (3) Altemeier* (perineal proctectomy) procedures. The Thiersch procedure is rarely performed in adults, as it is associated with significant postoperative complications due to its restrictive encirclement of the anal canal, which can result in problems with subsequent fecal impaction. When utilizing foreign bodies such as mesh bands, this procedure can also be associated with erosion of the device into the rectum or anal canal and/or infection of these foreign bodies.

The Delorme procedure, although anatomically attractive in that it avoids bowel resection and buttresses or plicates the rectal wall, is technically challenging for many surgeons to perform, particularly in a prolapsed rectum, in which the overlying mucosa has become extremely edematous and hyperemic from chronic prolapse. Elagili and colleagues cited the advantages of the Delorme procedure as its shorter hospitalization as compared to a perineal proctectomy and lesser rate of complications (Elagili F, Gurland B, Liu X, et al. Comparing perineal repairs for rectal prolapse: delorme versus Altemeier. *Tech Coloproctol* 2015;19(9):521–5). Although the operation was associated with a higher rate of recurrent prolapse, the authors concluded that if this should occur, the patient can still undergo a repeat transanal Delorme without compromising the vascular supply of the rectum.

In the hands of many surgeons, however, the Altemeier procedure, or perineal proctectomy, is the easiest and most direct approach to treat rectal prolapse, particularly in elderly, frail individuals. Despite the fact that it is in essence a handsewn coloanal anastomosis, and the fact that one enters the peritoneal cavity in almost all cases due to the very low level of the pouch of Douglas in these patients, this procedure has a low morbidity and mortality rate. In a study of over 500 patients undergoing perineal proctectomy over an 8-year

period, Tiengtianthum and colleagues found that both early and late postoperative complication rates were low (5.6% and 3.5%, respectively) and did not differ by age (comparing patients <70 years old, 70 to 79 years of age, 80 to 89 years old and those over 90) (Tiengtianthum R, Jensen CC, Goldberg SM, et al. Clinical outcomes of perineal proctectomy among patients of advanced age. *Dis Colon Rectum* 2014;57(11):1298–303). Dr. Birnbaum describes that this procedure can be done in either the prone or supine position. Because of the very frequent and high number of comorbidities present in these patients, when I perform this procedure it is always done in the supine position with the patient in lithotomy position in “candy cane” stirrups, providing easy airway access for the anesthesiologist. Depending on the frailty of the patient, this procedure can even be performed using only local anesthesia with some accompanying mild intravenous sedation or using a saddle block; however, it is sometimes difficult to find an anesthesiologist who is capable of performing this type of regional anesthesia. Because of their multiple comorbidities, anesthesiologists are frequently leery of administering general anesthesia to these patients. The main portion of the procedure that is associated with discomfort is traction on the mesentery. For this reason, if possible, I prefer to use general anesthesia or local anesthesia with monitored anesthesia care, that is, additional intravenous sedation such as with propofol or midazolam.

Although Dr. Birnbaum describes the use of circular stapled anastomoses, she describes in detail the discrepancy in lumen size between the proximal “pulled-through” colon and the diameter of the very distal rectum/anal canal. This is definitely true and poses a significant risk for a leak even if great care is taken in placing the distal purse string suture. Another variant of a stapled perineal procedure has been described using a combination of linear and curved stapling devices (GIA and Contour staplers, Ethicon Endo-Surgery, Cincinnati, Ohio) (Sehmer D, Marti L, Wolff K, et al. Midterm results after perineal stapled prolapse resection for external rectal prolapse. *Dis Colon Rectum* 2013;56(1):91–6). With this type of approach however, the mesenteric vessels are not ligated. These staple loads are not vascular staplers, many patients undergoing this type of surgery are anticoagulated, and postoperative bleeding from the staple line (and presumably the mesenteric vessels) has been reported despite the authors oversewing their staple lines with absorbable monofilament suture. Although the authors report a short operation time (33 minutes), their operating room time savings are more than offset by consumables in terms of staple loads. I believe that handsewn anastomoses are more reliable. I also prefer, prior to constructing the coloanal anastomosis to perform a posterior levator plication. This sounds complicated, but is easy to do. Several sutures (I use 2-0 polypropylene) are used to bring the right and left levator muscles together posteriorly. This narrows the anal canal, but more importantly helps reestablish a more normal, more acute anorectal angle, which is usually not present in these patients.

There has been a great deal of controversy in the past decade regarding the

possible adverse effects of mechanical bowel preparation on the rate of postoperative complications following colorectal surgery, with sometimes differing outcomes reported for rectal as opposed to colon surgery (Bretagnol F, Panis Y, Rullier E, et al.; French Research Group of Rectal Cancer Surgery [GRECCAR]. Rectal cancer surgery with or without bowel preparation: The French GRECCAR III multicenter single-blinded randomized trial. *Ann Surg* 2010;252(5):863–8; Güenaga KF, Matos D, Wille-Jørgensen P. Mechanical bowel preparation for elective colorectal surgery. *Cochrane Database Syst Rev* 2011;9:CD001544). In this chapter, Dr. Birnbaum describes a preoperative bowel preparation. It is often difficult to give elderly patients preoperative bowel preparation. In many cases, this is associated with significant electrolyte disturbances and dehydration and generally associated with more harm than good. Almost all of these patients are constipated and the rectal prolapse seems to function like a "cork in a bottle." Getting a good bowel prep is difficult! While no one relishes working in a field full of stool, I think it is preferable to have some solid bowel movement in the area, rather than a large amount of liquid diarrhea, as is frequently present when patients have had a mechanical bowel preparation. In many cases, a single preoperative enema can clear the rectum prior to surgery to facilitate the surgeon's work (Pittet O, Nocito A, Balke H, et al. Rectal enema is an alternative to full mechanical bowel preparation for primary rectal cancer surgery. *Colorectal Dis* 2015;17(11):1007–10). This may, however, be difficult as these patients frequently have greatly reduced sphincter tone and often cannot hold enemas well. While we had previously always kept these patients NPO for several days, with the increased use of enhanced recovery pathways we have immediately fed these patients a regular diet and not observed any difference in morbidity, but have noticed a quicker time to bowel function, a happier patient and a shorter hospital stay, all of which are desirable.

Dr. Birnbaum accurately states that incontinence is a frequent problem after these perineal procedures for rectal prolapse. This is definitely true, and is an important part of the preoperative discussion with the patient and family. I typically advise patients that there can be up to a 6-month period of significant incontinence postoperatively. There is typically a chance for continued improvement until the anal sphincter regains its tone. After that, there is less chance for additional functional improvement. The availability of sacral nerve route stimulation (see Chapter 166 Fecal Incontinence by Keighley) may, however, allow for additional improvement in continence in some of these patients.

Because the reservoir function of these patients is lost, that is, the rectum is removed, and the proximal colon is of much narrower caliber, postoperative patients most frequently have multiple smaller bowel movements throughout the day. This is very similar to an anterior resection syndrome and patients must be counseled regarding this. This can be problematic in the older patient who has decreased mobility. Postoperatively, the use of methylcellulose fiber

products (Citrucel), as well as medications such a loperamide, which slows intestinal transit, while at the same time increases internal anal sphincter tone, can help to regulate bowel habits.

There is a high recurrence rate following repair of rectal prolapse. This is due mainly to the pre-existing laxity of the pelvic floor. I typically advise these patients to avoid heavy lifting, that is, anything heavier than 20 lb postoperatively. If a recurrence occurs, this can be treated with a repeat procedure, beginning the rectal transection at the previous anastomosis site.

Susan Galandiuk

---

*Editor's Comment: I must correct something that has bothered me for a long time and that is the unfortunate credit for what was called the "Altemeier" procedure. I was chair at the University of Cincinnati, for 23 years, and during my time Bill Culberston actually did almost all of the procedures, took care of the patients, and got paid next to nothing. Dr. Altemeier received most of the credit, and Bill Culbertson did all the work. After I arrived as chair I doubled Dr. Culbertson's salary. He asked for nothing and was a careful, meticulous surgeon. The procedure should have been called the Culbertson procedure. I am happy to give him the credit that I think he deserves.

164 Anorectal Disorders

Michael R. B. Keighley

Fissure in ANO

CLINICAL PRESENTATION

The principal clinical presentation of fissure in ano is intense anal pain during defecation, often associated with a small amount of bright red bleeding noticed on the toilet paper. There may be perianal swelling from a skin tag and discharge of mucus. There is often a sensation of tearing during defecation, and there may be a dull ache in the perineum 3 to 4 hours after bowel evacuation.

Women are more commonly affected than men, in a ratio of ~58% to 42%, respectively. Most patients are in the third decade of life, but fissure can occur at any age and is well recognized as a cause of pain and constipation in children. Fissure may be exacerbated by a recent episode of constipation and straining. It commonly occurs in women after vaginal delivery. It may occur as a complication of severe diarrhea.

Inspection of the perineum reveals a small, shallow anal ulcer with a sentinel pile and edema, usually in the posterior aspect of the anal margin, particularly in men. Fissures occur anteriorly in 40% of women.

CAUSES

The causes of fissure in ano are unknown. Primary fissure is often associated with alteration in bowel habit, particularly an episode of constipation. Postpartum fissure may be a result of tearing of the anterior aspect of the anal canal during childbirth. Local trauma is believed to be responsible for the initial skin defect that leads to a boat-shaped ulcer, resulting in chronic symptoms.

Primary fissure in ano may be acute. If healing does not occur, the fissure becomes chronic, in which case the ulcer enlarges in size. There is edema around the fissure associated with an anal skin tag. In 10% of chronic fissures, there is a low intersphincteric anal fistula communicating

between the base of the fissure and the dentate line.

Anal fissure is associated with increased resting anal canal pressures. Motility studies reveal ultraslow waves indicative of increased internal anal sphincter activity. Some data suggest that anal fissure is associated with a local reduction in blood flow. Healing of anal fissures is associated with a return to normal anal canal pressures with normal blood flow measurements.

Secondary fissure in ano may occur as a complication of Crohn disease, anal tuberculosis, or acquired immunodeficiency syndrome (AIDS). Occasionally, fissure in ano may complicate a previous operation on the anal canal. Fissures complicating Crohn disease and tuberculosis are often painless. By contrast, anal fissures and ulcers complicating AIDS are often intensely painful and are associated with incontinence and local sepsis.

DIAGNOSIS

Diagnosis of anal fissure can usually be achieved by inspection. Gentle parting of the buttocks reveals an edematous skin tag and a shallow anal ulcer, usually situated posteriorly in men but anteriorly in women. There is puckering of the perianal skin as a result of intense spasm of the anal sphincters. Digital examination is often impossible and should not be attempted in patients with severe pain, because the diagnosis can be made by inspection. In patients with chronic anal fissure, digital examination and proctoscopy are often well tolerated. The fissure has edematous margins and is boat shaped, with the transverse fibers of the internal anal sphincter seen at the base of the fissure.

Sigmoidoscopy should be performed in patients who can tolerate a rectal examination to exclude a primary cause for fissure in ano and any rectal pathology.

TREATMENT: CONSERVATIVE

Nonspecific Medical Therapy

Up to 70% of chronic anal fissures will heal by conservative therapy alone. If patients have a history of chronic constipation, treatment should include a bulk laxative, such as methylcellulose or psyllium hydrophilic mucilloid, with a mild laxative, such as bisacodyl or docusate sodium. Patients should be told to avoid straining and be instructed in basic anal hygiene.

Application of local nonsteroidal preparations to control pain may be

helpful. Local anesthetic agents may be effective, particularly for acute anal fissure. Steroid preparations may be used to reduce inflammation. A wide variety of commercially available ointments and suppositories exist, which consist of local anesthetic and steroid preparations. The cumulative relapse rate after these forms of medical treatment for chronic anal fissure is ~50% at 12 months.

Specific First-Line Therapy: Nitric Oxide Donors or Calcium Channel Blockade

No patient in the United Kingdom today is treated by sphincterotomy for anal fissure unless at least first line, and in some cases, second-line treatment is used because of the fear of bowel incontinence with sphincterotomy.

The most widely used first-line therapy is with nitric oxide donors, usually glyceryl trinitrate cream, but other formulations of topical nitrates give identical results. The cream is applied, where possible, over the fissure after defecation and at night initially, increasing the applications to four times a day if symptoms do not rapidly improve. The principal complication is headache, occurring in 30% to 40%, but if treatment can be tolerated, there is tachyphylaxis in most people such that the headaches do not persist for more than 5 to 6 days. Nitric oxide donors are not tolerated in 20% to 30% because of persistent headache. If patients are able to persist with therapy for 4 weeks, there is complete alleviation of anal pain in 60% to 70%, but in 10% to 20% there may be a relapse of the anal fissure during the next 3 months. Thus, healing is achieved in 45% to 60% of patients in 3 months. For those who relapse a repeat treatment course achieves healing in a further 20% to 30%, overall healing is 60% to 80%.

If patients have a persistent anal fissure and symptoms or cannot tolerate nitric oxide donors the alternative first-line therapy is the use of diltiazem, a calcium channel blocker. Diltiazem cream is used topically over the fissure twice daily initially but up to four applications a day if needed. The preparation is more expensive, but there are virtually no side effects. The outcome in terms of resolution of pain is comparable to those achieved with topical nitrates; pain free at 4 weeks 60% to 70%, with healing at 3 months of 40% to 60%. For those who relapse a repeat course achieves healing in 20% to 30%, overall healing is 60% to 80%.

Specific Second-Line Therapy: Botulinum Toxin

When first-line therapy fails, injection of Botulinum toxin into the intersphincteric plane away from the fissure, usually at 3 and 9 o'clock, with a dose varying from 2.5 to 20 units at each site achieves healing in 40% to 60%. Complications include transient incontinence, hematoma, or sepsis, but these are unusual. For refractory cases, repeat injection can be used. Since transient incontinence is now recognized, patients must be warned about this.

Surgical Principles

Patients with anal fissure can be treated surgically during an office visit or in an outpatient surgical unit, but an operation should not be advised until specific first- or second-line treatment has been vigorously pursued. The purpose of surgical treatment is to reduce excessive activity in the internal anal sphincter. In the past, this was attempted by anal dilatation, but now only sphincterotomy is used and only after very thorough counseling about the risks of impaired continence.

Anal dilation results in disruption of the fibers of the internal and external anal sphincters. Unfortunately, anal dilatation is associated with a variable risk of bowel incontinence depending on risk factors, but incontinence to flatus is common and may be permanent. For this reason, anal dilatation is no longer advised for the treatment of anal fissure and will, therefore, not be described.

The alternative is internal anal sphincterotomy, which results in division of a part of the internal sphincter, but leaves the external sphincter intact. Sphincterotomy may be performed as a subcutaneous, blind technique or may be performed as an open operation. All patients having sphincterotomy must be warned that there is a risk of temporary or even permanent bowel incontinence following treatment. Preoperative bowel preparation with a disposable enema is usually advised. Postoperatively, the patient should be prescribed adequate analgesics and local anesthetic creams, as well as a mild laxative to avoid postoperative constipation. Patients should be warned that there is a 3% risk of postoperative bleeding, and that local pain may continue for 2 to 3 weeks. Flatus incontinence and soiling is usually transient, lasting only 2 to 3 months, but may occur in 20% to 40% of patients. Long-standing incontinence and soiling may complicate internal sphincterotomy and is not confined to patients in whom a part of the external sphincter has been inadvertently divided. It

can occur when the internal anal sphincter alone has been divided.

SURGICAL TECHNIQUE

Closed Lateral Subcutaneous Internal Sphincterotomy

This procedure may be performed with local or general anesthesia. The intersphincteric groove is identified. Twenty milliliters of a local anesthetic with a weak adrenaline solution is infiltrated in the submucosal and the intersphincteric planes. A fine cataract blade is inserted in the intersphincteric groove with the blade lying parallel to the circular fibers of the internal sphincter. The cataract blade is then rotated, so that the blade faces the lumen of the anal canal. With the surgeon's index finger in the anal canal, the cataract blade is advanced toward the index finger so as to divide the internal sphincter, but not the anal mucosa (Fig. 164.1). A small tampon is placed in the anal canal to prevent hematoma.

Open Internal Sphincterotomy

This is the author's preferred surgical procedure. The patient may be placed in the prone jackknife or the lithotomy position, depending on the surgeon's preference. The lateral aspects of the submucosal and intersphincteric planes are infiltrated with a local anesthetic and a weak adrenaline solution. An anal speculum is inserted to expose the lateral aspect of the anal canal. A circumanal incision is made just inside the anal canal and below the dentate line for a length of ~1.0 to 1.5 cm. Scissors are used to develop the submucosal plane so that the anal mucosa can be lifted from the internal sphincter and to develop the intersphincteric plane so that there can be no damage to the external sphincter. Once the lower fibers of the internal sphincter have been clearly separated from other structures, internal sphincterotomy consists of dividing the internal sphincter with scissors for a length of ~2 cm (Fig. 164.2). The results of the closed and open sphincterotomy are comparable. Complete relief of pain and healing of the fissure is recorded in 70% to 90% of patients. It is hardly ever necessary to contemplate a second sphincterotomy for patients with persistent symptoms and in any event this would not be advised on account of the very high risk of permanent incontinence with a second sphincterotomy.

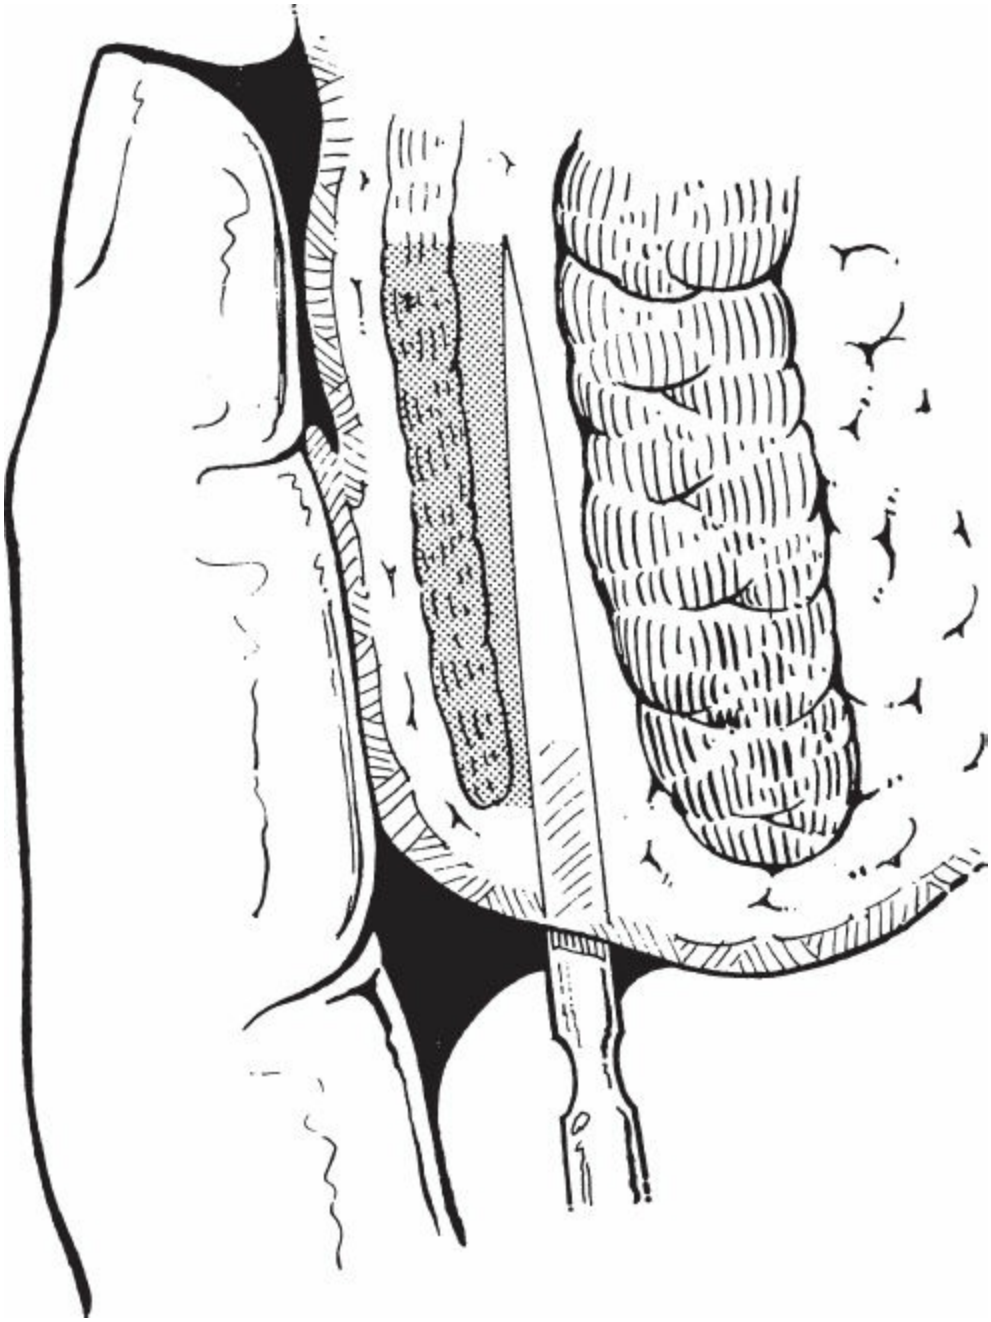

Figure 164.1. Closed lateral subcutaneous sphincterectomy under general anesthetic. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

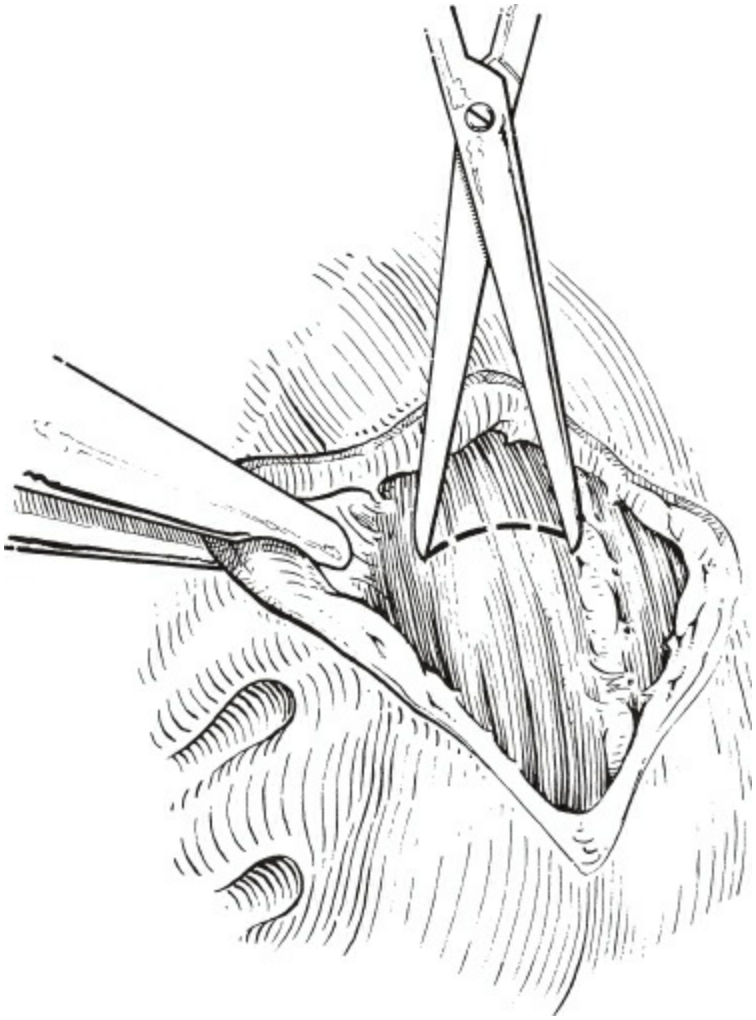

Figure 164.2. Open internal sphincterectomy. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

We never advocate posterior sphincterotomy or excision of the anal fissure, sometimes termed "fissurectomy," because these operations may be complicated by a gutter deformity in the anal canal and thus result in soiling and impaired continence.

Anorectal Abscess

CLINICAL PRESENTATION

Anorectal sepsis usually presents with anal pain, swelling, and fever. There may be associated swelling and discharge around or within the anal canal. Approximately 30% of patients give a history of a previous episode

of anorectal sepsis that has spontaneously discharged or required surgical drainage. Constitutional symptoms are common, and swelling is obvious in patients with ischiorectal abscess, because large volumes of pus under tension give rise to fever, malaise, anorexia, and weight loss. By contrast, swelling may not be evident in patients with intersphincteric and submucous abscesses; similarly, patients with supralevator abscess may have no swelling but have constitutional symptoms. In secondary anorectal sepsis, there may be a history of AIDS, pelvic inflammatory disease, Crohn disease, malignancy, or previous anal surgery.

CAUSES

Anorectal sepsis arises from an infection in an anal gland or as a skin infection. Acute infection of an anal gland results in a chronic intersphincteric collection of pus that spreads upward in the intersphincteric plane causing a supralevator abscess, or downward in the intersphincteric plane causing a perianal abscess. Alternatively, pus may spread through the external sphincter and result in an ischiorectal abscess or may spread through the internal sphincter and result in submucous abscess. Occasionally, as a result of surgical intervention, pus may spread through the levators and cause supralevator collections of pus (Fig. 164.3).

Anorectal sepsis from an infection of an anal gland originates from intestinal organisms; thus, the predominant organisms recovered from culture are *Escherichia coli* and other gram-negative aerobic bacteria or anaerobic organisms from the large bowel, particularly *Bacteroides* species.

Some perianal abscesses arise from an infection in the skin and are merely a manifestation of a boil, furuncle, or carbuncle around the anal canal. True skin infections are almost always staphylococcal in origin and are not associated with an internal communication with the anal canal. Thus, culture of pus is helpful in establishing whether an anorectal abscess may have a coexisting anal fistula. Anorectal abscess with intestinal organisms is associated with an underlying anal fistula in 70% of patients. A fistulous communication with the anal canal virtually never occurs in patients with staphylococcal anorectal sepsis.

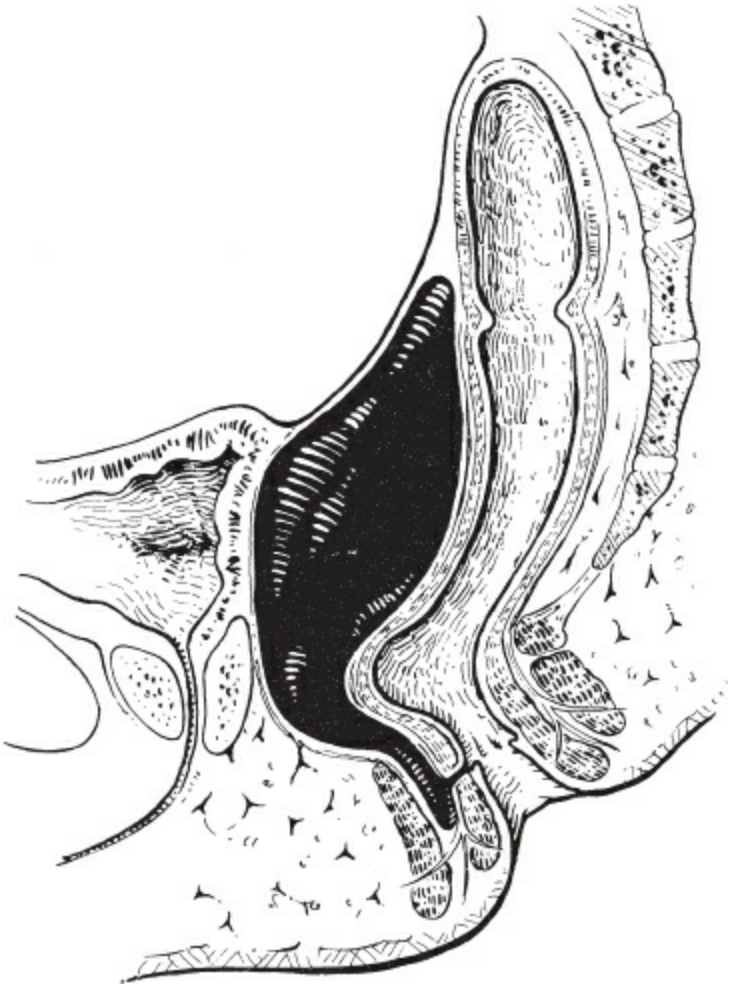

Figure 164.3. Suprasphincteric abscess. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

The five classic sites of anorectal sepsis are (in order of frequency): (a) perianal (60%), (b) ischiorectal (20%), (c) intersphincteric (5%), (d) supralevator (4%), and (e) submucosal (1%) (Fig. 164.4). Supralevator abscesses may occur as a result of upward spread in the intersphincteric space or as a result of overenthusiastic surgical intervention to drain an ischiorectal abscess, creating a track through the levators. Anterior supralevator abscesses are more common in women, and posterior supralevator abscesses are more common in men. Supralevator abscess may occur as a result of disease in the pelvis, such as appendicitis, gynecologic sepsis, colorectal cancer, diverticular disease, or Crohn disease, or as a result of trauma to the large bowel.

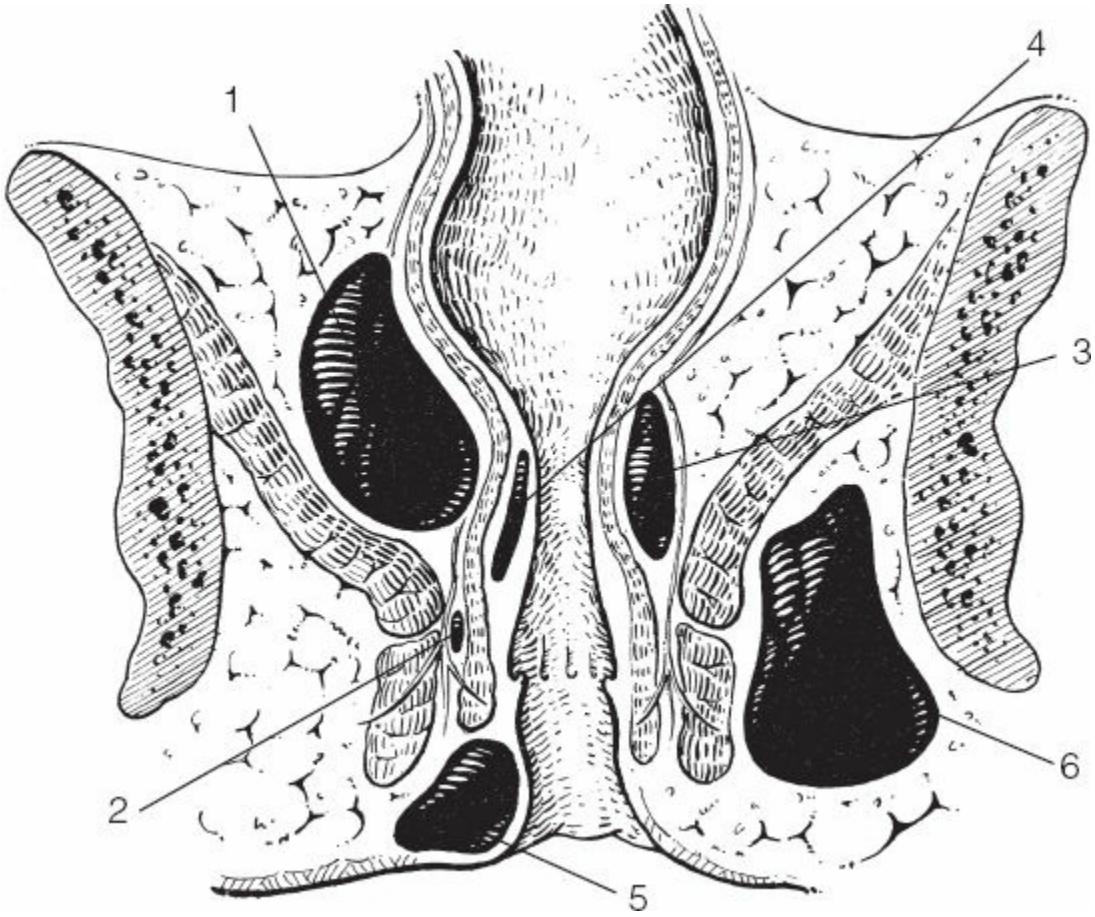

Figure 164.4. Classification of anorectal sepsis. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

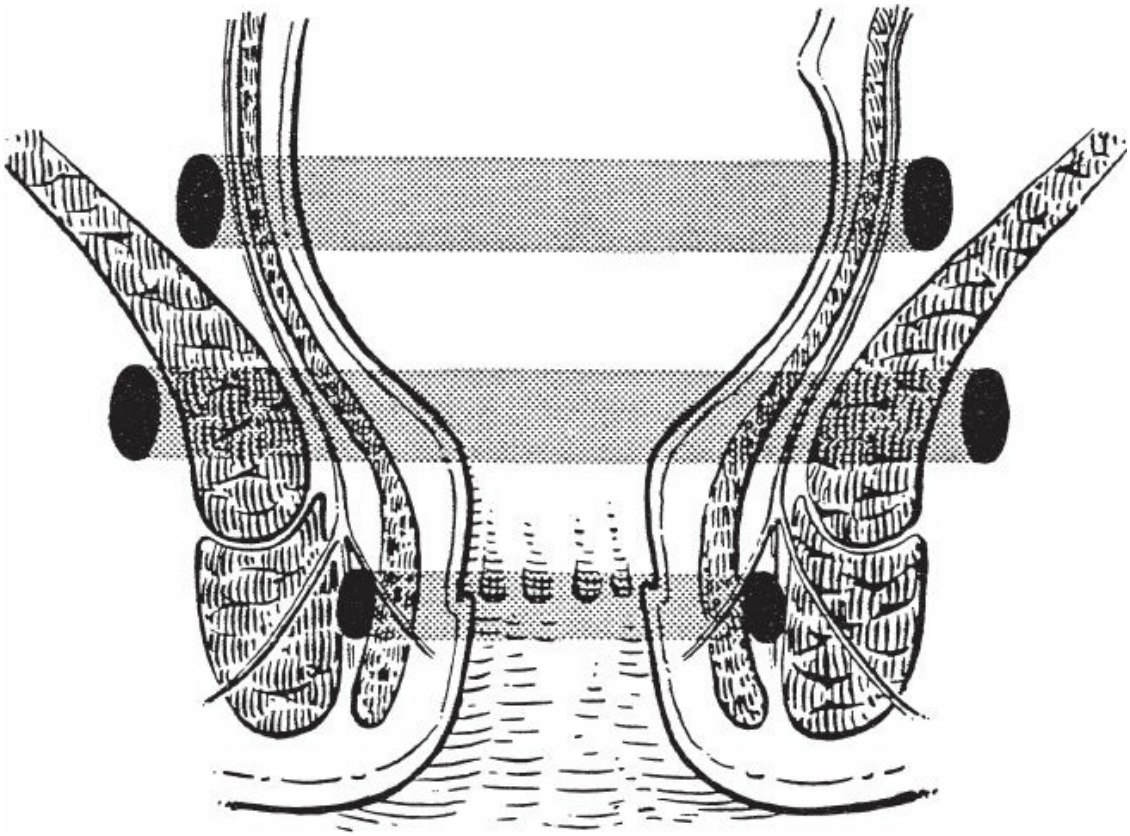

Figure 164.5. Circumferential spread of perianal sepsis. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

Spread of anorectal sepsis may also occur circumferentially in the three spaces surrounding the anal canal: supralevator space, ischiorectal fossa, and intersphincteric space (Fig. 164.5).

DIAGNOSIS

Diagnosis of anorectal sepsis is usually obvious clinically by a large, painful, red swelling over the buttock (ischiorectal abscess) or a small, well-circumscribed, red, tender fluctuant swelling near the anal margin (perianal abscess). Inspection may fail to reveal intersphincteric sepsis or supralevator abscess. The presence of pus may be confirmed by needle aspiration, but in patients who do not have an obvious collection in the ischiorectal fossa or the perianal region, diagnosis may require examination under anesthesia, magnetic resonance imaging (MRI), or anal ultrasonography. In our experience, anal ultrasonography is helpful in identifying intersphincteric and submucous collections, but it is incapable of imaging sepsis in the supralevator space or in the ischiorectal fossa.

MRI has become the investigation of choice for obscure and complex anorectal sepsis.

Proctosigmoidoscopy should be performed to exclude sepsis from a primary cause, such as AIDS, pelvic sepsis, inflammatory bowel disease (particularly Crohn disease), anal malignancy, and sepsis resulting from previous anal surgery.

Conservative Therapy

Conservative treatment is never advised for treatment of anorectal sepsis. The practice of prescribing antimicrobial agents in the hope of resolving infection around the anal canal should be discouraged. Antibiotic therapy simply delays adequate surgical drainage. Delay in drainage results in chronic infection and destruction of tissue, particularly if there is synergistic gangrene and necrotizing fasciitis. Delay is often complicated by extensive fibrosis and long-term impairment of function, with incontinence and stricture.

SURGICAL TECHNIQUE

Our preference is early surgical drainage in almost all instances, except possibly in patients with hematologic disorders associated with neutropenia and thrombocytopenia. The principles of drainage are accurate localization and complete drainage. Careful examination under anesthesia is essential to define the site of infection. Pus is sent for immediate culture, and patients are carefully followed to identify recurrent sepsis or an underlying anal fistula. We do not attempt to identify an underlying anal fistula at the time of primary drainage, because we believe that an attempt to identify and treat the underlying fistula may result in anal destruction and compromise continence. Thus, our policy is careful follow-up and reinvestigation only if there is clinical evidence of underlying fistula. Postoperatively, patients are given analgesics and a mild laxative to prevent postoperative constipation. Careful follow-up is necessary, because there is a 30% risk of recurrence of sepsis and a 40% risk of subsequent anal fistula. In some patients, there may be evidence of underlying inflammatory bowel disease, pelvic sepsis, or sexually transmitted disease, which may become evident only during follow-up.

Drainage of Perianal Abscess

A small perianal abscess is incised using a cruciate or saucer-shaped incision so that pus can be adequately drained. A drainage tube is not inserted. The procedure may be performed in the physician's office under caudal or general anesthesia (Fig. 164.6).

Ischiorectal Abscess

A cruciate incision is made to the site of maximum swelling, pus is allowed to drain, and a finger is gently inserted into the ischiorectal fossa to break down any loculi. It is essential to check that there has been no posterior circumferential spread to the opposite side. A drain is not usually left in situ unless the ischiorectal abscess is bilateral or chronic. These operations are much better performed with the patient under general anesthesia. Great care must be taken not to damage the levator plate, which will convert an ischiorectal abscess into ones with a supralevator extension (Fig. 164.7).

Drainage of Intersphincteric Abscess

These abscesses are difficult to identify and to localize, and examination with the patient anesthetized is essential. A small incision is made transversely just inside the anal canal and below the dentate line. The intersphincteric space is identified and, with scissor dissection, the plane between the internal and external sphincters is exposed. If the intersphincteric abscess is well localized, the internal sphincter is divided and the abscess is drained. A small mushroom catheter is left in situ and sutured into position. Failure to insert a mushroom catheter results in contraction of the sphincter muscles because of postoperative pain and impaired drainage, causing recurrent sepsis.

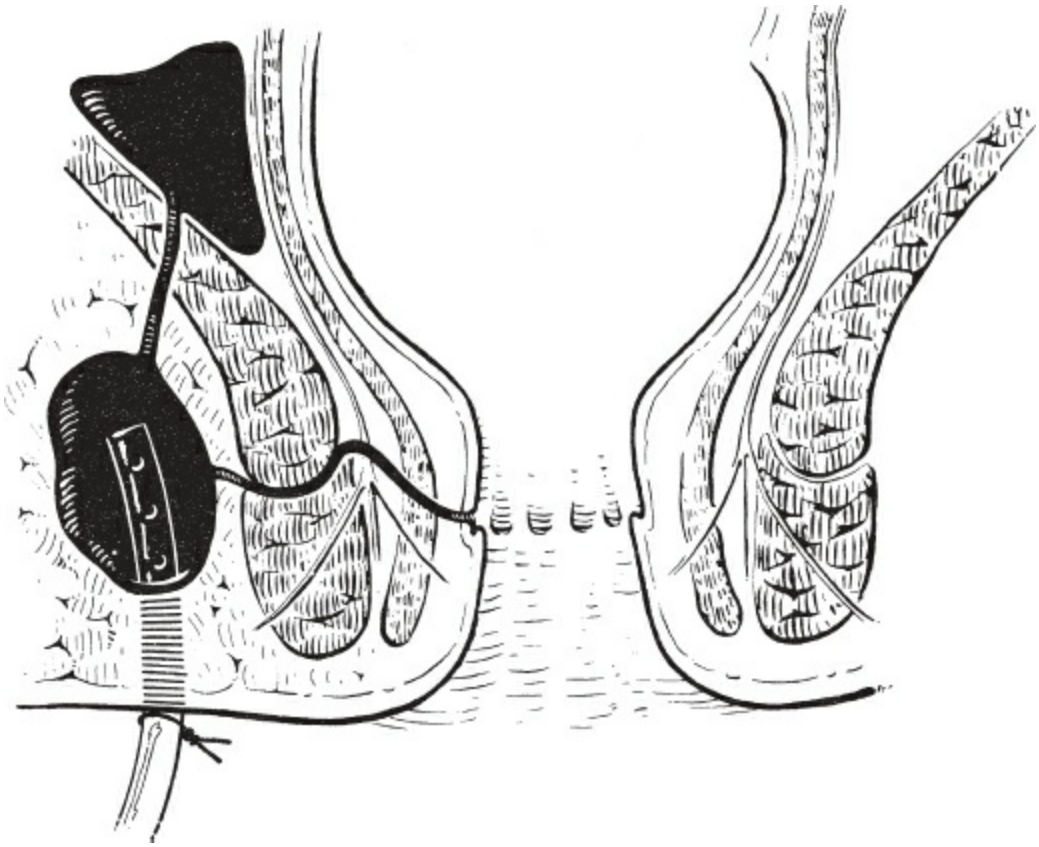

Figure 164.7. Drainage of an ischiorectal abscess and avoidance of suprasphincteric spread. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

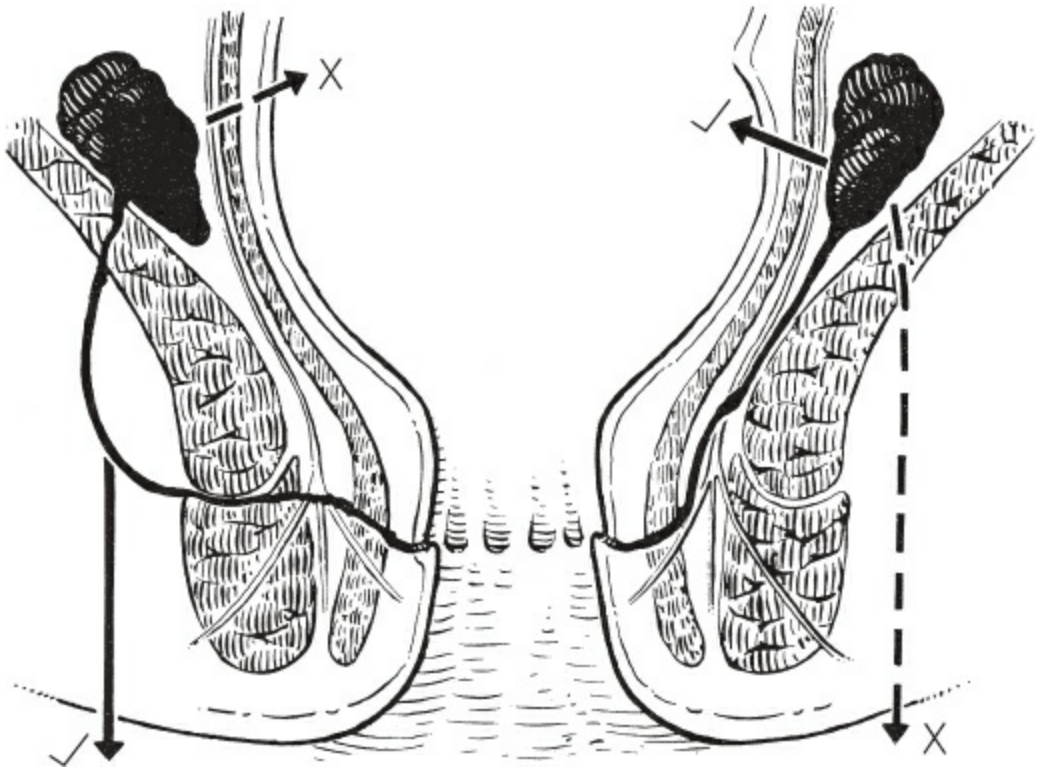

Figure 164.8. Principles of drainage of a supralevator abscess. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

Drainage of Supralevator Abscess

Posterior supralevator abscesses are drained in the manner described for drainage of intersphincteric abscess. The intersphincteric plane is opened posteriorly. It is exposed inside and beyond the puborectalis sling so that the supralevator abscess in the postanal space can be adequately drained. It is essential to suture a mushroom catheter into position. Failure to do so results in recurrent sepsis because of contraction of the puborectalis and sphincters.

Anterior supralevator abscesses are also drained with the patient under general anesthesia using the intersphincteric plane through a transverse anal incision anteriorly. Anterior supralevator abscesses tend to be much more superficial. Again, it is essential to leave a mushroom catheter in

situ. Failure to do so results in a high incidence of recurrent sepsis (Fig. 164.8).

Drainage of Submucous Abscess

With the patient anesthetized, the abscesses are drained using an anal speculum. Drainage involves opening the mucosa above the swelling so that pus can be discharged. It is often wise to combine the operation with internal sphincterotomy to reduce anal spasm postoperatively to facilitate efficient drainage, which might otherwise lead to a high incidence of persistent sepsis.

Anorectal Fistulae

CLINICAL PRESENTATION

Anorectal fistulae present with purulent discharge around the anus and from within the anal canal. Discharge is associated with impaired anal hygiene and soiling. There may be a history of recurrent episodes of anorectal sepsis that have required surgical drainage or that have spontaneously ruptured. In some patients, there may be a history of sexually transmitted disease, inflammatory bowel disease, or malignancy. It is important to exclude rectal malignancy, skin cancer, and a growth complicating long-standing anorectal fistula. Inspection in most cases reveals an external opening around the anal canal but, particularly in patients with intersphincteric fistulae, there may be no apparent external opening.

CAUSES

Most anorectal fistulae are secondary to cryptoglandular infection caused by enteric bacteria. The anal glands lie in the intersphincteric space, and their ducts enter the anal canal to discharge at the dentate line. The acini ramify in the intersphincteric space and some penetrate the internal sphincter muscle and the external sphincter. Pus spreads in the intersphincteric space upward, downward, or laterally and results in an abscess, commonly in the perianal region or in the ischiorectal fossa. These abscesses are treated by drainage or by spontaneous discharge. Once the anorectal sepsis has drained, there is a potential communication from the perianal region to the anal canal at the dentate line. Continued

communication between the two epithelial surfaces results in anorectal fistulae. For many patients, drainage is delayed, or surgical treatment complicates the course of the fistula and results in circumferential spread, if there has been delay, or in high blind tracks if there has been aggressive and inexperienced surgical intervention.

Although most anorectal fistulae are primarily caused by anoglandular infections, a few are secondary to other diseases. Congenital fistulae may occur and may be associated with inclusion dermoids. Chronic pelvic sepsis may result in fistulae if there is an infective process that drains through the levator plate to the perineum from diverticular disease, Crohn disease, large-bowel malignancy, or irradiation injury. Secondary fistulae are common in Crohn disease and are common manifestations, but secondary fistulae should not be regarded as specific, because 7% of patients with ulcerative colitis also develop perianal fistulae. Anorectal fistulae may occasionally complicate tuberculosis, actinomycosis, anal fissure, rectal carcinoma, squamous cell carcinoma, and foreign bodies around the anal canal.

Anorectal fistulae are categorized as primary or secondary. Primary fistulae are further classified by (a) the course of the primary track, which is usually subdivided into intersphincteric, transsphincteric, suprasphincteric, and extrasphincteric; (b) whether there are high blind tracks; and (c) whether there is any evidence of circumferential involvement. Thus, a three-dimensional drawing of the perineum and the anorectum in the coronal and sagittal planes with the smooth and circular muscular sphincter apparatus displayed is necessary to thoroughly identify the course of an anorectal fistula. It must be evident from this complicated classification that treatment of such anorectal fistulae must be directed on an individual basis to the particular anatomic distribution of the track, the presence of high blind extensions, and circumferential spread (Fig. 164.5).

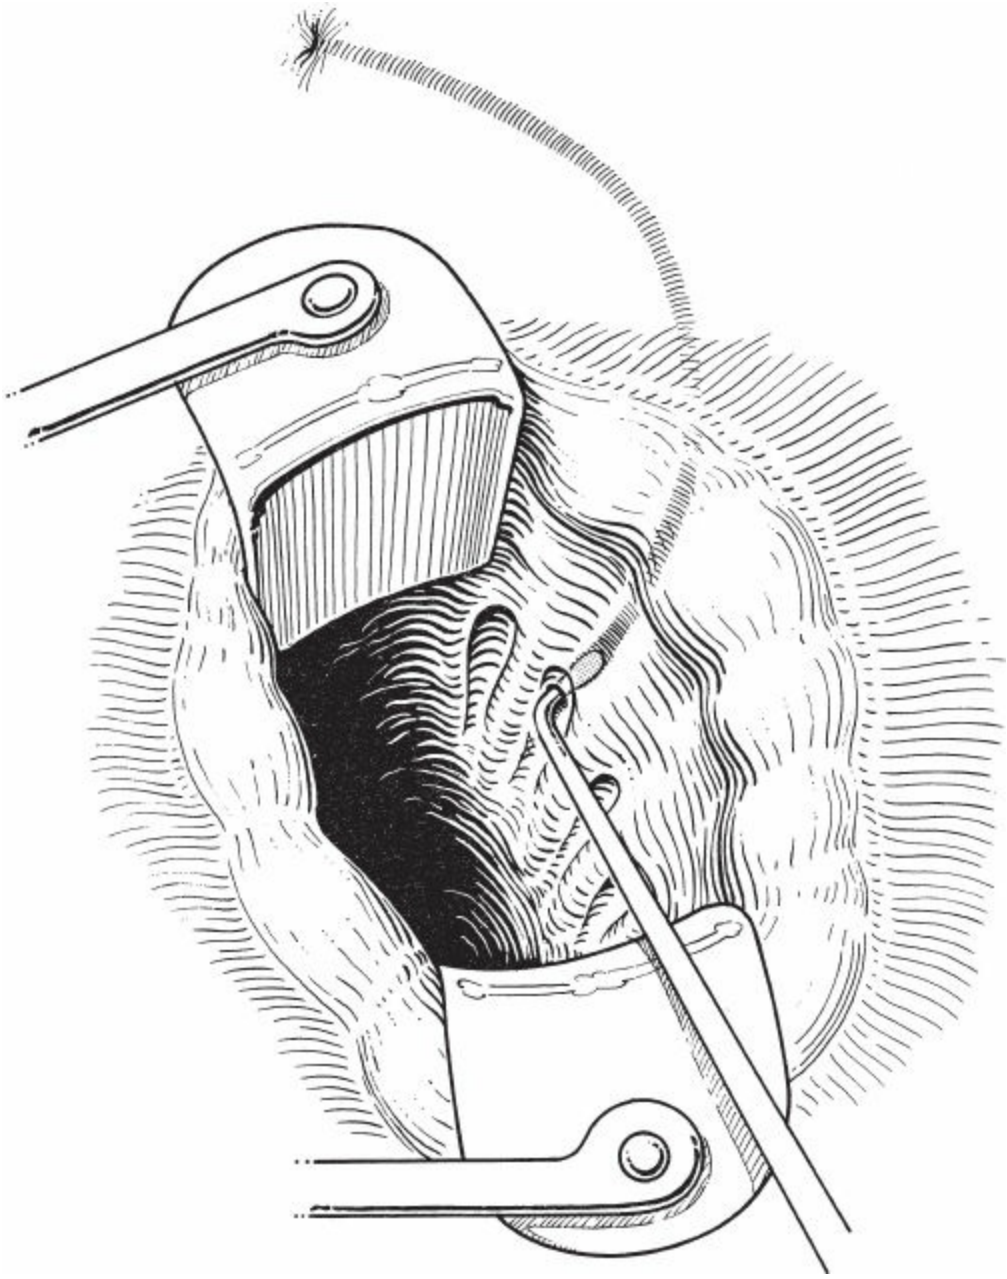

Figure 164.9. Retrograde probing of an anal fistula. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

DIAGNOSIS

Accurate diagnosis of the site, extent, and complexity of the fistula is essential for a successful treatment. Preoperative diagnosis includes careful anal inspection and digital examination, particularly to identify areas of induration and external openings that may discharge pus during rectal examination; proctoscopy to identify the internal opening and any associated anal papillae or skin tags; and proctosigmoidoscopy to exclude

primary colorectal disorders, particularly Crohn disease.

Anorectal ultrasound may be helpful in delineating the course of intersphincteric fistulae, but the focal length of the 7-MHz probe is not sufficiently deep to image beyond the external sphincter or puborectalis. MRI is regarded as the investigation of choice for the delineation of anorectal fistulae, particularly in complex transsphincteric, suprasphincteric, and extrasphincteric fistulae.

It is essential that all patients with anorectal fistulae be examined carefully under anesthesia. The fistula track should be identifiable by a combination of palpation for induration and gentle probing of the fistula track. Often, a combination of external and internal probing is necessary to identify the track (Fig. 164.9). Injection of methyl blue may be helpful but is rather messy, and povidone-iodine is preferred if the technique is to be used. Fistulography may sometimes help delineate the course of a complex anorectal fistula.

TREATMENT

There are a wide variety of techniques for the treatment of anorectal fistulae. We prefer fistulotomy, or “lay open” for low-lying tracks that do not traverse skeletal muscle and seton fistulotomy for almost all other fistula tracks that involve the sphincters or puborectalis. Occasionally, fistulectomy (excision of the fistula track) with an anorectal advancement flap is advised for specialized fistulae, particularly extrasphincteric and rectovaginal fistulae where sphincter function is to be preserved but there is a high rate of recurrent sepsis. Other methods include the fibrin plug, which preserves sphincter function and needs to be sutured into position or otherwise it is likely to migrate and fall out. Early results using the fibrin plug appear to be promising but the same could have been said about methods using glue, thus only time will tell whether the claims made by the manufacturers of the anal plug will prove to be comparable or superior to conventional therapy. Consequently, the results of randomized controlled trials will be needed before the role of the anal plug will be known.

Preoperative bowel preparation with a phosphate enema may be used in complex fistulae. Postoperative management requires the provision of adequate analgesics and laxatives to prevent postoperative constipation. Rigorous follow-up is essential for these patients, as there is a 10% to 20% risk of subsequent anorectal sepsis complicated by recurrent anorectal

fistulae. Follow-up is particularly important for patients with a seton as these frequently require to be changed. Follow-up is also essential to identify any evidence of underlying disease, particularly in patients with complex anorectal fistulae.

Fistulotomy (Lay Open)

The principle of fistulotomy is the identification of the fistula track so that the track can be laid open. Clearly, this method of treatment is inappropriate for patients with extrasphincteric and suprasphincteric fistulae, because the fistula track lies outside the sphincter mechanisms, and any lay-open procedure divides the striated sphincter complex and renders the patient incontinent, usually from a rigid gutter causing soiling. Fistulotomy is thus appropriate only for simple intersphincteric fistulae and low transsphincteric fistulae.

The first and most important maneuver is the demonstration of the primary fistula track. Probing is thus used to define the course of the track and should also identify high blind tracks. If the external opening is located obliquely from the internal opening, there will be some element of circumferential involvement. The course of simple fistulae usually obeys the Goodsall rule (Fig. 164.10). Thus, an external opening lying posterior to the horizontal plane is likely to open into the anal canal at the midline posteriorly, whereas an external opening lying anterior to the horizontal line is more likely to run directly into the anal canal. A malleable fistula probe is gently passed through the fistula track. By use of diathermy, the perianal skin and anal epithelium are divided. The internal sphincter, if involved, is identified and divided. If there is striated muscle superficial to the fistula track, this may be divided provided it consists of only a few fibers. However, if a substantial amount of striated muscle is encountered superficial to the fistula track, division of the muscle is not advisable and a seton is inserted. If a high blind track is found, the track should be loosely curetted and adequately drained through the fistulotomy incision. Provided the fistula track can be safely laid open, any bleeding from the edges should be secured by cautery and gauze dressing applied.

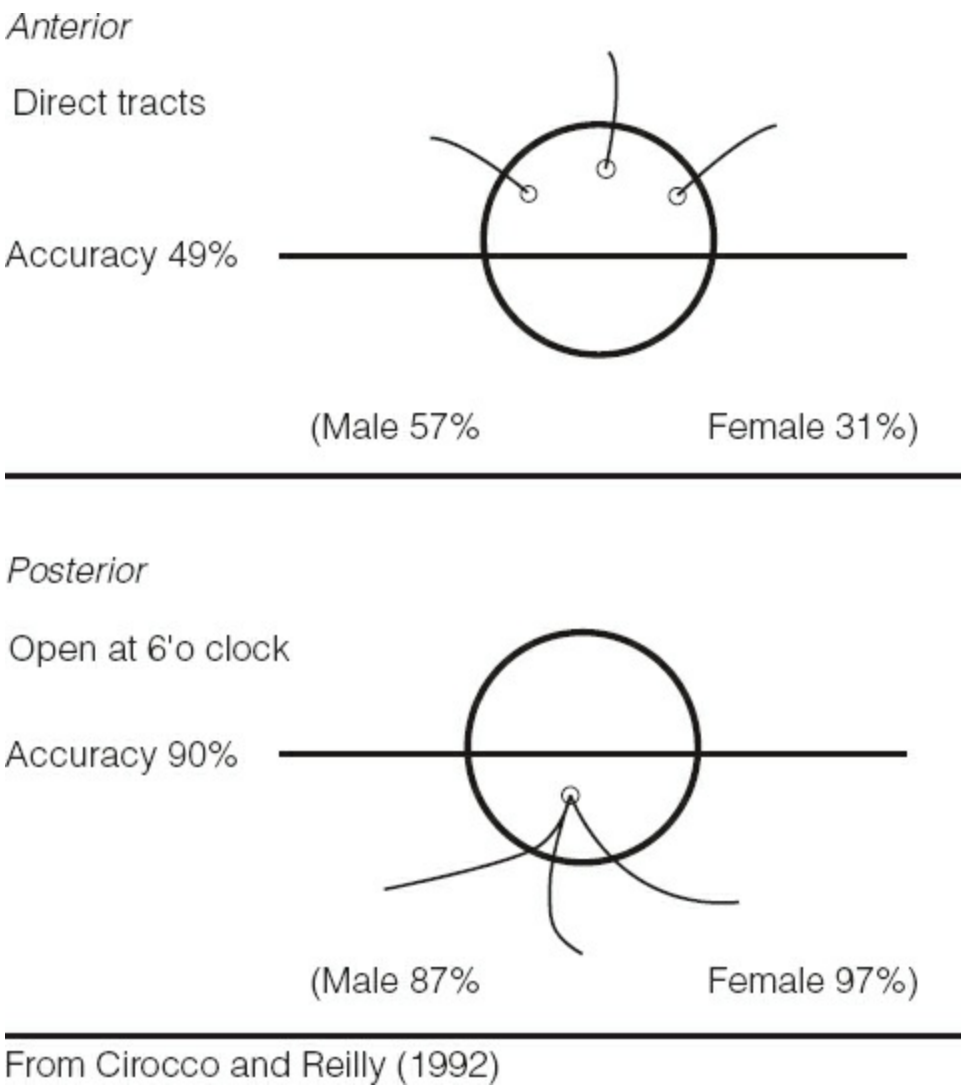

Figure 164.10. Goodsall rule. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

Patients may have more than a single external opening. Multiple anterior openings usually have separate internal openings, which should be dealt with in the same manner by defining all fistula tracks and opening them, provided that this does not involve division of a large amount of striated muscle (Fig. 164.11). For multiple posterior anal fistulae, the tracks usually open at the same site in the midline posteriorly. Furthermore, under these circumstances, there may be a small supralevator collection in the postanal space. Again, each fistula track is opened, provided that this does not involve the division of a large amount of striated muscle. The internal opening is then further explored in the intersphincteric plane to ensure that there is no supralevator component.

Any redundant skin is excised, and an antiseptic dressing is applied.

Seton Fistulotomy

The principle of seton fistulotomy is that any striated muscle lying superficial to the fistula track is encircled by a length of soft rubber or latex tubing, or by using a Prolene or silk tie. The seton is tied loosely and left in situ. Over the following weeks, the striated muscle is slowly divided by the presence of the seton. However, because the process of striated muscle division is relatively slow, the muscle does not therefore spring apart, leaving a defect (gutter), but heals behind the process of division. Consequently, fibrous tissue is laid down in the bed of the fistula as it is slowly divided. This process avoids the gutter deformity, which is usually associated with soiling and minimizes the risks of impaired continence. The problem with this technique is that treatment may take a number of weeks and follow-up is essential. On the other hand, preservation of continence is much better than with fistulotomy, especially for mid or high transsphincteric fistula.

The fistula track is identified by using a probe, as described in the previous section. The perianal skin and the skin of the anal canal are divided. The internal sphincter is also divided, but the striated muscle lying superficial to the fistula track is preserved. Thus, a substantial amount of the fistula is laid open. A vascular rubber sling (sloop) is threaded through the eye of the fistula probe and is delivered around the striated muscle as a seton, but other materials may be used (e.g., latex and Teflon). The seton is tied with multiple knots, and the end is sutured beyond the last knot so that it cannot become untied with patient movement during follow-up (Fig. 164.12). Usually, the patient can be discharged on the same day. Arrangements for follow-up should be made.

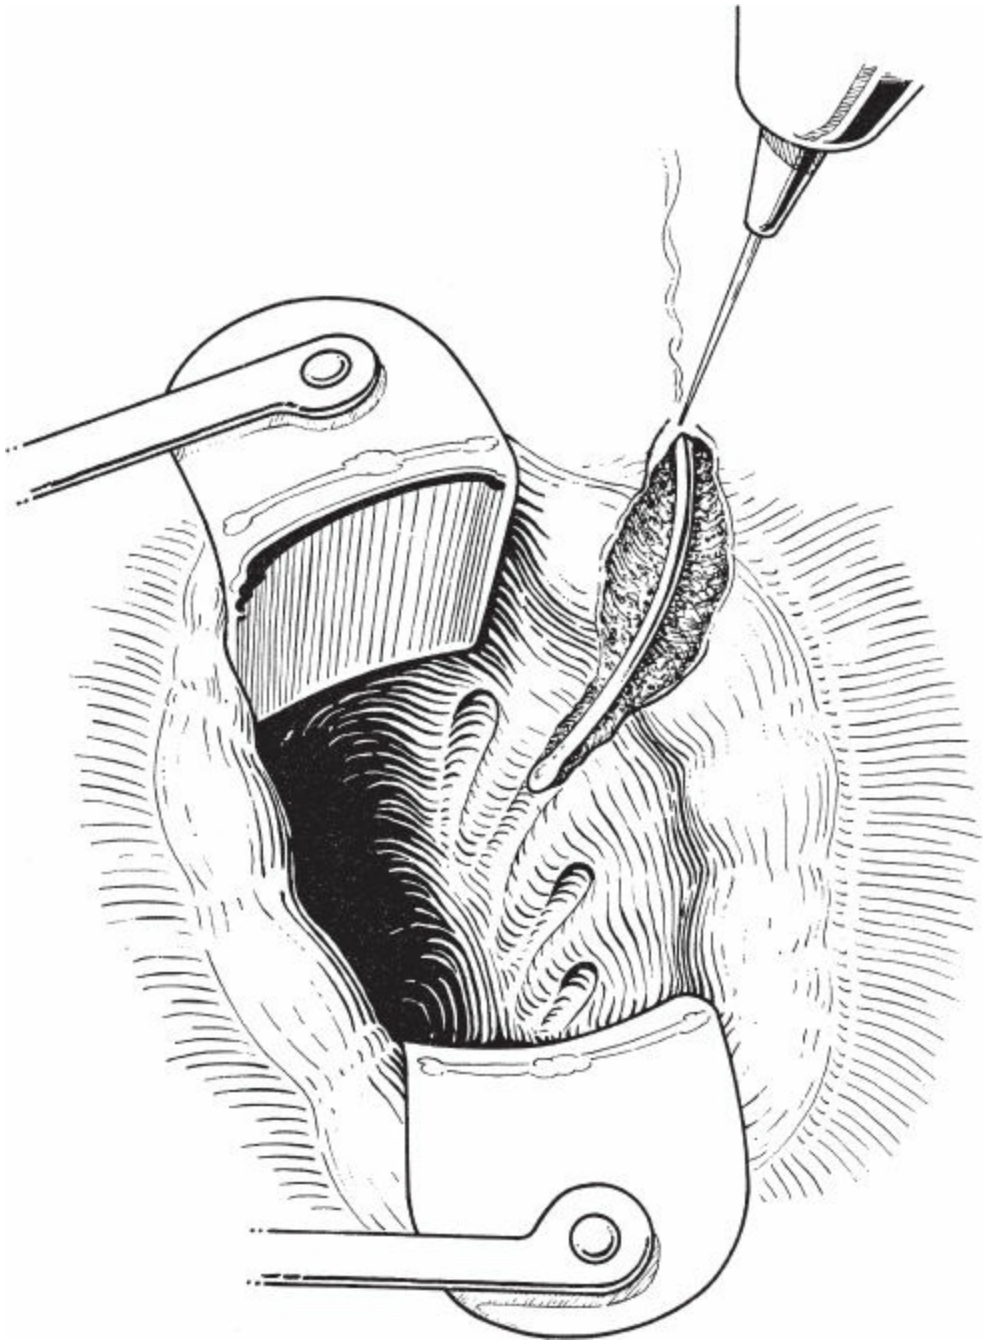

Figure 164.11. Laying open of a low-lying transsphincteric fistula. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

At the first follow-up, the seton usually remains in situ but has already partially divided the striated muscle superficial to the fistula track. A simple method of tightening the seton is by the application of rubber bands beyond the first knot. Commonly, five or six bands should be applied to ensure that the seton snuggly surrounds the residual striated muscle. Alternatively, the seton is replaced and retied. A second follow-up in 1

week should then be scheduled. At the second visit, the seton has usually completely divided the striated muscle and has fallen out. If, on the other hand, it has not fallen out, the seton is replaced and follow-up continues until the track has been divided. Thus, the fistula track is slowly divided during a period of 1 to 6 weeks. The technique is remarkably successful at preserving sphincter function and avoiding the development of a gutter deformity. Careful follow-up is essential to detect recurrent fistula. Careful attention to the wound is also essential to ensure that it does not become infected, and that there is no bridging over the fistulotomy site during healing.

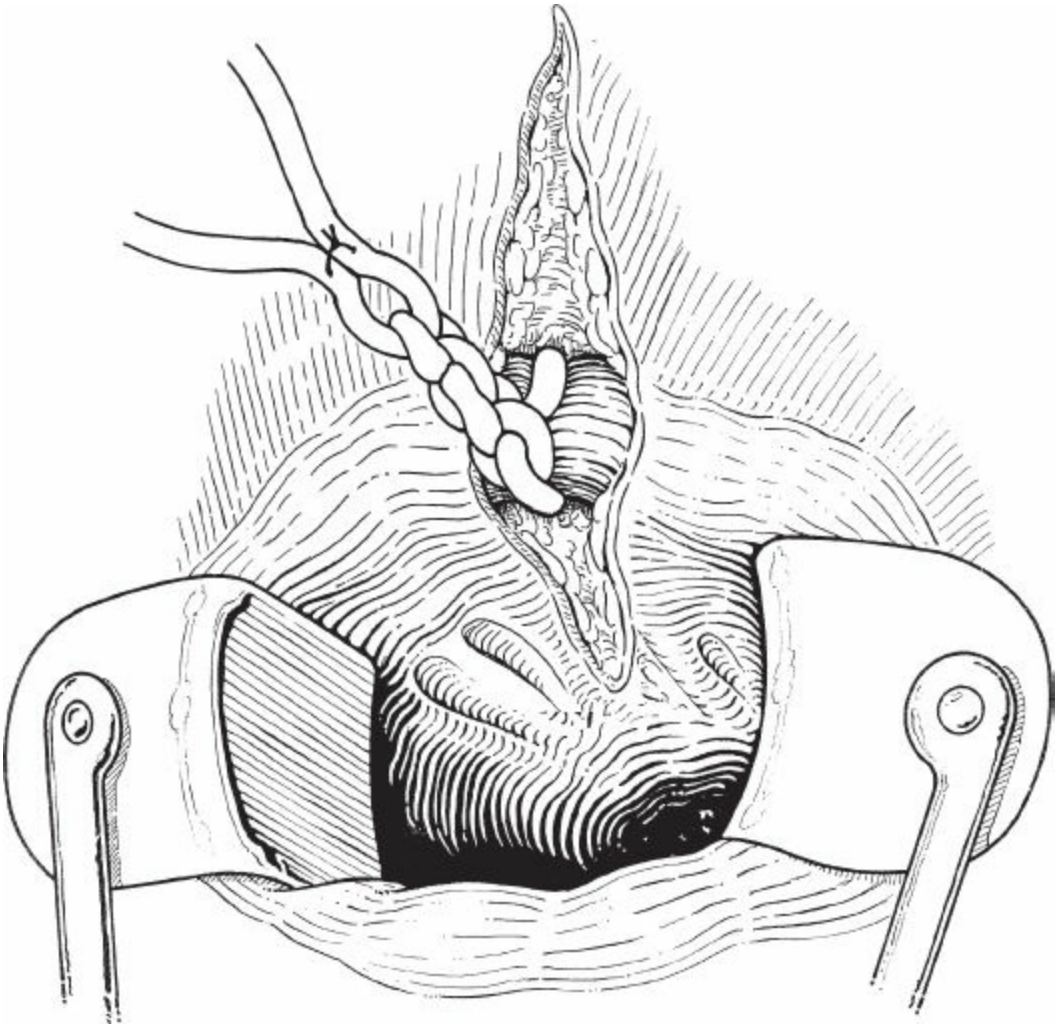

Figure 164.12. Seton fistulotomy. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

Fistulectomy and Anorectal Advancement Flap

Although anorectal advancement with excision of the track should preserve continence and avoid soiling, despite spectacular results reported by some, in this author's experience, sepsis and recurrent fistula are common. In future, the anal plug may replace this technique.

The first part of the operation involves fistulectomy, that is, excision of the fistula track. This can be technically difficult and involves careful dissection using a fine scalpel or diathermy point around the fistula track through to its internal opening. Side tracks must be similarly excised. In complex fistulae, three or four separate fistula tracks will need to be cored out. The defect in the external sphincter may require closure, and some form of drainage procedure is usually needed. The next step is to close the internal opening, usually with an anorectal advancement flap.

The anorectal advancement flap is simply a way of closing the internal opening of the excised transsphincteric fistula. A wide-based curvilinear flap, consisting of mucosa, submucosa, and rectal wall, is advanced from above so as to close the internal component of the fistula without tension, while draining any coexisting sepsis. The technique is fully described and illustrated later in the section on "Rectovaginal Fistula." However, in anorectal fistula, unlike rectovaginal fistula, there is an external perineal orifice that should be thoroughly drained (Fig. 164.13).

Complete Lay Open and Repair

Extrasphincteric and suprasphincteric fistulae may be treated by total fistulotomy (if setons are not used) while ensuring that the divided and striated muscle is marked so that it can be identified at a later date. Once all of the infection has been cleared, a standard sphincter repair is then performed. The alternative is to perform the reconstruction at the time of the primary lay-open procedure. The problem with sphincter repair under these circumstances is that the primary sphincter repair may break down because of coexisting sepsis. We therefore do not advise the technique in the majority of cases and believe that it has been superseded by fistulectomy and advancement flap closure or the anal plug.

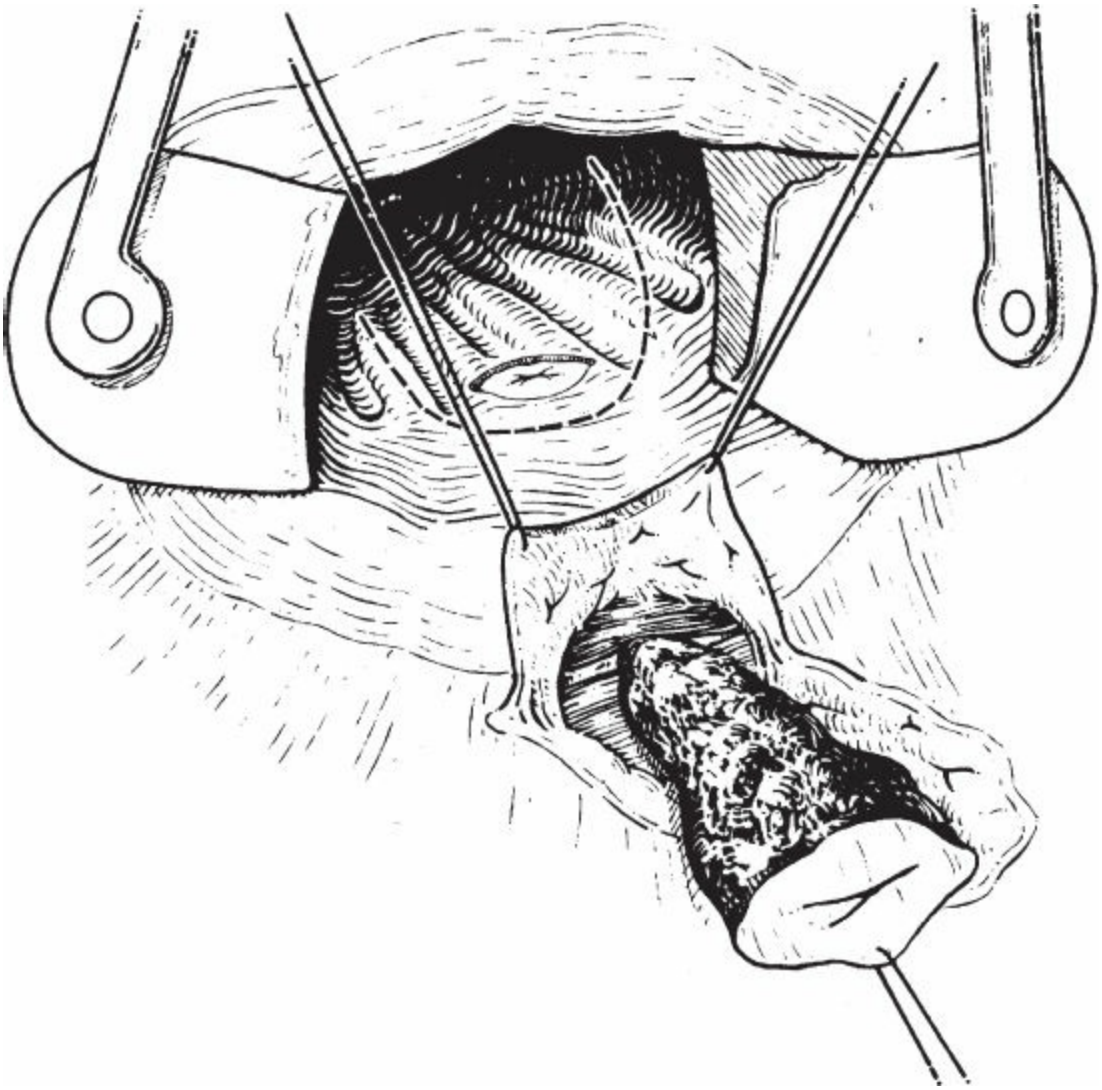

Figure 164.13. Further details of the advancement flap technique. The fistula track is excised from the external opening to the intersphincteric plane. The flap incorporating the internal opening is raised along with full-thickness internal sphincter. The raised flap, with line marking the level of division to excise the internal opening. The advancement flap is sutured to a site distal to the excised internal opening. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

Anal Plug

This attractive method of managing anal fistulae still requires careful evaluation by randomized trails compared with conventional fistulotomy and setons. The principle of this therapy is to preserve anal sphincter function with the avoidance of a gutter by filling the fistula track with a

rod of fibrin, which enhances fibroblastic activity thereby eliminating the fistula track by forming a collagen matrix in the fistula. The disadvantage of this method is that the plug must be held in situ until it becomes incorporated into the healing process. Thus, the usually surgical technique involves identification of the fistula, which is then gently curetted with a fine wire brush or an equivalent bougie to remove the granulation tissue. After irrigation of the fistula, the plug is inserted and sutured into position in the anal canal. Spectacular results have been claimed with avoidance of open wounds, indwelling setons, and preservation of anal continence with avoidance of soiling. Results of trials compared with conventional therapy are awaited.

Hemorrhoids

CLINICAL PRESENTATION

Hemorrhoids usually present with bleeding or prolapse. Patients also frequently complain of discharge of mucus, pruritus, and some discomfort. Symptomatic hemorrhoids are often intermittent. Bleeding is commonly associated with constipation and straining. Similarly, prolapse is more evident during pregnancy or in the puerperium or when the patient is constipated. Hemorrhoids are often associated with skin tags, which may cause irritation and difficulty with anal hygiene. If hemorrhoids prolapse, they may spontaneously return to the anal canal after straining. Further enlargement may require digital replacement; large hemorrhoids may be irreducible. Thus, hemorrhoids may be classified as first degree, piles that never prolapse; second degree, piles that prolapse but spontaneously return; third degree, piles that prolapse and require digital replacement; and fourth degree, piles that are permanently prolapsed.

COMPLICATIONS

Hemorrhoids may be associated with complications, such as massive bleeding, thrombosis, gangrene, and septicemia. Massive bleeding may occur particularly if there is excessive straining or portal hypertension, but such bleeding is rare, and an alternative diagnosis such as bleeding polyps, rectal varices, or anorectal arteriovenous malformations should be sought. Treatment of massive bleeding is by blood transfusion and urgent hemorrhoidectomy.

Thrombosed hemorrhoids present with a history of prolapse complicated by intense pain and swelling. There is an obvious prolapsed internal hemorrhoid with surrounding edema, and the pile itself is hard as a result of venous thrombosis. The condition should be distinguished from external plexus hematoma, which is thrombosis of an external varix and is often unassociated with internal hemorrhoids. External plexus hematoma is a self-limiting condition that resolves during a period of 5 days. It presents with severe anal pain and swelling. Treatment is usually conservative, but for patients in excruciating pain from localized hematoma, evacuation of the hematoma may alleviate pain and result in more rapid resolution. True thrombosed hemorrhoids may resolve over a period of 10 to 14 days, but the process is painful, and the underlying hemorrhoids frequently give rise to more symptoms in the future. Hence, thrombosed hemorrhoids are best treated by emergency hemorrhoidectomy. Evacuation of the hematoma in such cases is often disappointing and does not alleviate long-term symptomatology. Emergency hemorrhoidectomy is infinitely superior to anal dilation because, although dilation controls pain, the thrombosed hemorrhoid persists and subsequently requires treatment.

Strangulated hemorrhoids imply a process of thrombosis and infarction that may be complicated by sepsis or even synergistic gangrene. The history is that of a prolapsed hemorrhoid that becomes painful and tender, subsequently it begins to suppurate, causing a foul-smelling discharge around the prolapse. The hemorrhoid is obvious and is blackish-green, ulcerated, and suppurating. Treatment is by emergency open hemorrhoidectomy. Closed hemorrhoidectomy under these circumstances is dangerous and unsatisfactory, because the wounds invariably become infected and lead to iatrogenic anorectal sepsis and possible sphincter damage. Septicemia is a rare complication of strangulated hemorrhoids. Infected material tracks through the portal venous system causing portal pyemia, and hepatic abscesses if early treatment with antibiotics and local control of the anal sepsis are not established quickly.

Chronic anemia is a further complication of hemorrhoids. It may occur even though the amount of blood loss from the hemorrhoids does not seem to be excessive. Chronic anemia should rarely be presumed to be caused by hemorrhoids, and patients should, therefore, be thoroughly evaluated to ensure that there is no other source of gastrointestinal blood loss. Thus, upper gastrointestinal endoscopy, colonoscopy, and small-bowel radiology

are probably necessary to exclude a primary cause. If no other lesion is identified and the history is compatible with bleeding from hemorrhoids, hemorrhoidectomy is usually advised.

CAUSES

Primary hemorrhoids are present in all individuals. Cross section of the anus in the normal fetus demonstrates some mucosal vascular cushions at the classic hemorrhoidal sites: 3, 7, and 11 o'clock. The vascular cushions correspond with the venous drainage of the anal canal and are distributed in a manner similar to that of the branches of the superior hemorrhoidal artery. There are no valves in the hemorrhoidal veins. Thus, increased intra-abdominal pressure, such as the type that occurs during a Valsalva maneuver or from a space-occupying lesion in the abdomen, is associated with reduced venous return and engorgement of the vascular cushions. Vascular cushions fulfill a normal physiologic function. They lubricate the anal canal and keep the anal canal closed at rest. This mechanism helps to prevent soiling and incontinence of flatus.

Vascular cushions may increase in size under situations in which there is increased intra-abdominal pressure, particularly if there is a history of straining at stool as a result of constipation or a feeling of incomplete rectal evacuation.

Primary hemorrhoids can be subclassified into those associated with anal hypertension and those associated with reduced anal canal tone. High anal canal pressures are recorded, particularly in men younger than 40 years, with first-degree hemorrhoids that present with bleeding. By contrast, significantly lower resting anal canal pressures are found in patients with prolapsing hemorrhoids and are common in women older than 40 years.

Secondary hemorrhoids occur under pathologic situations of increased intra-abdominal pressure, for instance, in patients with chronic obstructive airway disease or in patients who strain from prostatism or urethral stricture. Secondary hemorrhoids may also occur in patients with ascites, during pregnancy, and if there is a space-occupying lesion, such as an ovarian tumor, a large rectosigmoid carcinoma, or a distended bladder. Secondary hemorrhoids may also develop in patients with portal hypertension. Localized impairment of venous return from rectal disease may cause hemorrhoids, for instance, in rectal carcinoma, or from excessive fibrosis resulting from radiation therapy.

DIAGNOSIS

Some hemorrhoids can be diagnosed solely by inspection. There may be skin tags and descent of the hemorrhoids during straining. When hemorrhoids become evident during straining, they appear as two or three circumscribed swellings, as compared to the circumferential appearance of a full-thickness rectal prolapse. Furthermore, most patients with hemorrhoids do not have a patulous anus, as do patients with rectal prolapse. In large hemorrhoids, the columnar epithelium becomes thickened and undergoes squamous metaplasia. Digital examination is important to detect the presence of anal pathology and to assess anal tone. Hemorrhoids are confirmed by proctoscopy at rest and during straining. Proctosigmoidoscopy is important to exclude any rectal pathology, particularly polyps, proctitis, or a neoplasm. In patients with a history suggesting colorectal pathology, full evaluation of the large bowel by colonoscopy or contrast radiology is desirable.

TREATMENT

The principles of treatment are to alleviate symptoms, not necessarily to improve the appearance of the anal canal. Asymptomatic patients with hemorrhoids do not justify treatment, because the therapy could cause more trouble than the underlying disease pathology. Patients with minor, intermittent symptoms and who are constipated or who strain should be taught to defecate only after an urge, and bulk laxatives should be prescribed to increase the volume of stool. Outpatient treatment is suitable for 85% of all patients with hemorrhoids. However, patients should be warned that outpatient therapy is not always a cure, and that there is a recurrence rate of 20% to 25% during a period of 5 years. Hence, repeat consultation and outpatient treatment are often necessary. Despite this, symptoms can often be satisfactorily alleviated by outpatient therapy, which thereby avoids a painful ablative operation. Hemorrhoidectomy is usually reserved for patients with severe prolapsing hemorrhoids or hemorrhoids with complications. Patients should be warned that hemorrhoidectomy is not only painful, but can also be associated with complications, such as minor impairment of continence, anal stenosis, and early postoperative complications, such as bleeding and sepsis. We no longer advise anal dilatation for treatment of patients with hemorrhoids and a tight anal canal because of the fear of iatrogenic bowel incontinence.

Preoperative preparation is unnecessary for outpatient treatment.

Postoperative follow-up and management depend on the type of treatment used. In our practice, we usually discharge patients after outpatient therapy and indicate that if they develop recurrence of symptoms, another appointment can always be scheduled for further evaluation and repeat outpatient therapy. Postoperative management after hemorrhoidectomy includes the prescription of stool softeners and mild laxatives and an explanation of the risks of complications, such as reactionary hemorrhage, secondary hemorrhage, minor transient impairment of continence, postoperative constipation, and anal stenosis. A single check-up appointment is usually arranged to ensure that there is no compromise of continence and no stenosis, and that there have been no complications.

Conservative Therapy

Conservative therapy consists of bulk laxatives, avoidance of straining, topical application of a local anesthetic, or steroid-based suppositories for pain, and the use of glycerin suppositories if there is any impairment of rectal evacuation.

Outpatient Therapy

The principle of outpatient therapy is to fix the mucosa above the prolapsing hemorrhoid. Outpatient therapy is particularly suitable for first-, second-, and some third-degree hemorrhoids. We prefer rubber-band ligation, but we recognize that many clinicians find injection sclerotherapy satisfactory, although invasive and effective, but sclerotherapy may be more difficult to administer in a busy clinic setting. Photocoagulation is less effective than rubber-band ligation and tends to be reserved for first-degree hemorrhoids. Cryotherapy has been discontinued in our clinic, because it is commonly complicated by mucus discharge.

Rubber-Band Ligation

The principle of this technique is to apply a rubber band to the mucosa above each of the principal hemorrhoids (Fig. 164.14). It is absolutely essential that the pile itself is left undisturbed so that treatment is directed to the mucosa above the hemorrhoid. We prefer the suction-band technique, because it can be undertaken without the need for an assistant. Usually only the two principal hemorrhoids are treated, but in some cases it is entirely feasible to apply three rubber bands. The mucosa is sucked

into the cup of the instrument and the rubber band is advanced, which leaves a polypoidal segment of mucosa snared at its base by the rubber band. Subsequently, the band causes ischemic necrosis and an ulcer above the hemorrhoid, which generates an area of fibrosis and thus prevents the hemorrhoids from slipping down into the lower part of the anal canal to cause symptoms. Treatment by rubber-band ligation is extremely effective; in our experience, 70% of patients are rendered asymptomatic after the first treatment and 90% after two or three treatments if needed. Patients should, however, be warned that there is a 5% risk of a significant bleeding in the first week after treatment, and that ~5% of patients suffer anal discomfort in the first 48 hours. Intense pain after treatment indicates that the rubber bands have been applied too low; occasionally, it is necessary under such circumstances to remove the rubber band with the patient under local, caudal, or general anesthesia. In many patients, it is necessary to administer further band ligation on one or two occasions in order to control prolapse and bleeding.

Injection Sclerotherapy

The principle of injection therapy is to place 2 to 5 mL ethanolamine oleate in the submucosal plexus just above the hemorrhoid. The three principal sites of the hemorrhoids are identified, and the mucosa above each lesion is injected with sclerosant (Fig. 164.15). It is most important not to inject too deeply, particularly anteriorly, because of the risk of entering the prostate, the seminal vesicles, or even the base of the bladder causing hematuria, hematospermia, and prostatitis. Sufficient sclerosant should be injected under the mucosa to raise a white wheal, which eventually ulcerates and causes mucosal fixation, thus preventing the hemorrhoid from descending into the lower anal canal.

Complications of injection sclerotherapy include pain, bleeding, hematospermia, hematuria, urethritis, and retention of urine. Complications are rare, occurring in <2% of patients. Ninety percent of patients require no further injection sclerotherapy. When injection sclerotherapy was compared with rubber-band ligation, results were almost equivalent, but, in our experience, there is a marginal advantage with rubber-band ligation.

Photocoagulation

The photocoagulator probe is applied to the mucosa above each

hemorrhoid, and three or four applications are used above each hemorrhoidal site (Fig. 164.16). A white area of burn is identified after completion of treatment. The treatment itself is somewhat more painful than injection or rubber-band ligation, but there are fewer posttreatment side effects. In our experience, only 70% of patients require no further treatment.

Cautery or Laser Hemorrhoidectomy

A limited hemorrhoidectomy is possible as an intra-anal procedure using cautery or laser. The hemorrhoidal tissue is dissected from the internal anal sphincter, and hemostasis is controlled by contact or spray cautery, or by laser. It is a lesser operation than hemorrhoidectomy and is appropriate for small, second-degree hemorrhoids. There is a risk of secondary or reactionary hemorrhage, but the operation can be performed in the physician's office or as an outpatient procedure.

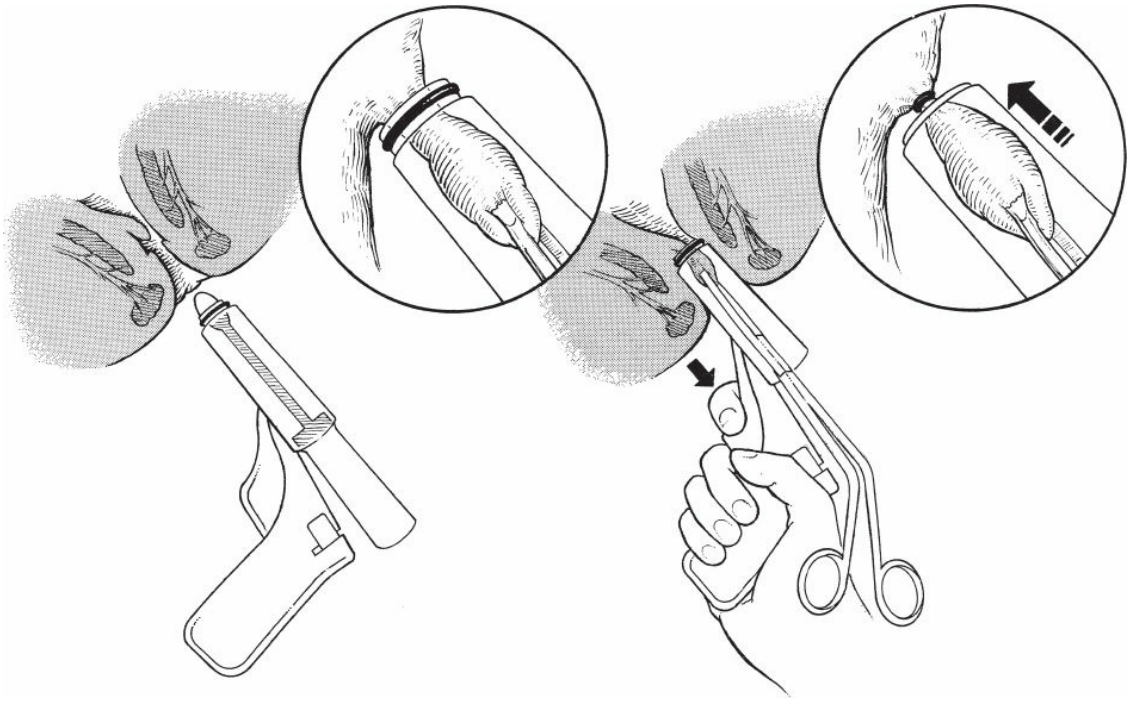

Figure 164.14. Technique of applying bands to the base of the pile using suction banding. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

Figure 164.15. Technique of injecting hemorrhoids. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

Suture Ligation of Hemorrhoids: LigaSure

A technique of intra-anal suture ligation of the hemorrhoid pedicle is practiced by some surgeons using a specific applicator. It is suitable for small, second-degree hemorrhoids, but, in our opinion, recurrent second-degree hemorrhoids are common and we prefer rubber-band ligation.

Hemorrhoidectomy

Hemorrhoidectomy is unfortunately a painful operation, but is usually extremely successful as a means of controlling symptoms from third-degree piles. Patients should be counseled before the operation and informed that postoperative pain is usual. There is also a small risk of reactionary or secondary hemorrhage, scarring from excessive skin loss, and possible impairment of continence from damage to the internal anal sphincter. Rare complications include unhealed open wounds, postoperative fissure, and submucous abscess. In the majority of patients, the operation is extremely successful at controlling prolapse and bleeding.

There are two techniques for conventional hemorrhoidectomy. The operation may be performed as an open procedure so that any discharge of blood, serum, or pus can be drained easily, or a closed hemorrhoidectomy may be performed in which the mucosa and the skin defects are closed, leaving an intact anal canal. By comparing these two techniques, it has

been found that the degree of postoperative pain is identical. Physiologic studies also indicate that internal and external sphincter functions are equally well preserved by the two operations. Thus, the choice of technique is entirely personal. The author has practiced both techniques but tends to favor the open operation, because the risk of postoperative hematoma and sepsis is reduced.

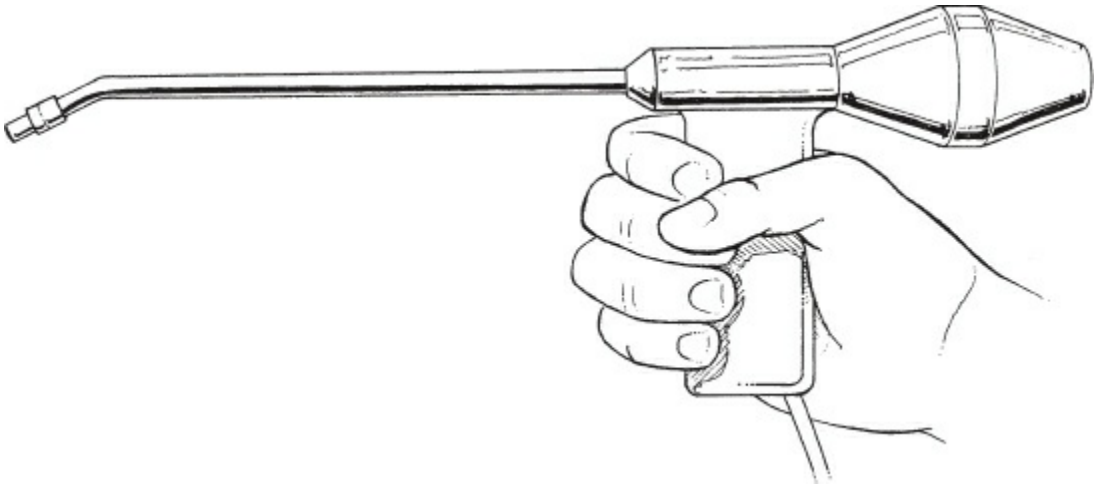

Figure 164.16. Infrared photocoagulation equipment. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

Open Hemorrhoidectomy

The operation may be performed in the lithotomy or prone jackknife position. We prefer lithotomy for open hemorrhoidectomy. We also prefer to use general anesthesia. The patient is placed with the feet in stirrups, and the anal canal is gently dilated. A proctoscope is inserted to identify the site of the three principal hemorrhoids. A weak adrenaline solution (1:200,000) in saline is infiltrated around the skin adjacent to each primary hemorrhoid, and further injection is made in the lower part of the intersphincteric space and in the submucosal plane under the hemorrhoid.

Tissue forceps are then applied to each pile and to the skin adjacent to the hemorrhoid (Fig. 164.17). The author prefers to start with the 7 o'clock hemorrhoid, followed by the 3 o'clock hemorrhoid, and finish with the 11 o'clock hemorrhoid, so that the operation field is not obscured by bleeding. The tissue forceps holding the hemorrhoid and its adjacent skin is grasped in the left hand. A V-shaped incision is made in the surrounding perianal skin with scissors. The cut is deepened toward the anal canal to

reveal the lower fibers of the internal anal sphincter. The sphincter is gently swept away with tissue forceps from the hemorrhoid (Fig. 164.18). The scissors are then used to excise the hemorrhoidal tissue within the anal canal, which leaves the apex of the hemorrhoid with its arterial supply and venous drainage intact for ligature. The pedicle of each hemorrhoid is enclosed in an arterial clip, and the pedicle transfixed using nonabsorbable suture material (Fig. 164.19). Hemostasis is secured from the bed of the hemorrhoid by use of cautery. Only then is the pedicle ligated. The ligature is left long so that if any further bleeding occurs, the pedicle can be easily identified and delivered into the operative field. Each hemorrhoid is dealt with in the same manner. Well-established skin bridges between each V-shaped segment of excised skin must be preserved. At the end of the operation, an anal speculum is inserted to be absolutely certain that there is complete hemostasis. Gauze dressings are then applied to each hemorrhoidal area.

Closed Hemorrhoidectomy

We perform closed hemorrhoidectomy with the patient in the prone jackknife position with the buttocks strapped apart and with 40 degrees of hip flexion. A Fansler proctoscope is crucial to the success of the operation. First, the proctoscope is inserted so that the three sites of the primary hemorrhoidal disease are identified. A maneuver that helps to identify the primary hemorrhoids is the insertion of a soft gauze swab into the anal canal. The swab is withdrawn from the anus after removal of the proctoscope. Removal of the swab usually brings with it the hemorrhoids, which can be readily identified.

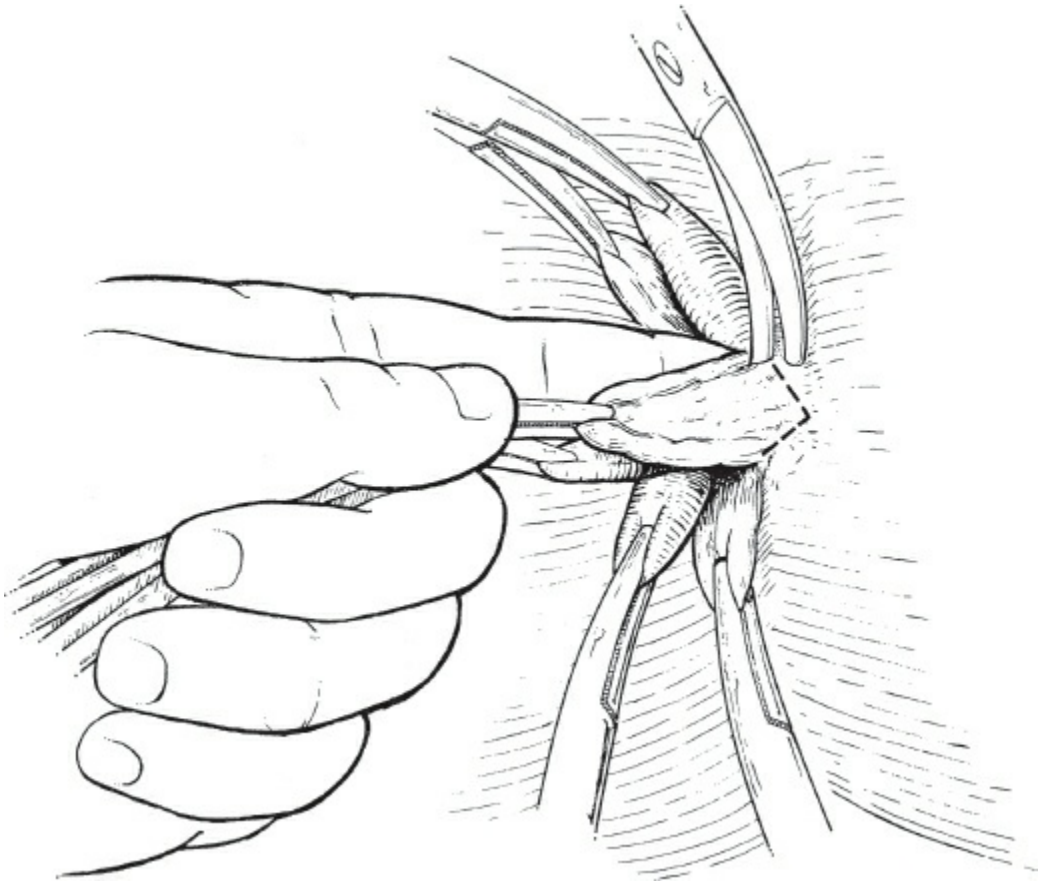

Figure 164.17. A V-shaped incision is made over the anoderm at the base of the hemorrhoid. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

In our clinic, we use general anesthesia for this procedure, but some prefer caudal or regional anesthesia. Even when general anesthesia is used, we strongly advise infiltration with a local anesthetic and a weak adrenaline solution, such as bupivacaine with 1:200,000 adrenaline. Ten milliliters of infiltrate is introduced into the submucosal and subcutaneous planes of each hemorrhoid, so that the hemorrhoidal tissue can easily be separated from the fixed fibers of the internal anal sphincter. Short, curved scissors are used for the excision. The anal skin tag is lifted up with tissue forceps and, by use of the heel of the scissors, the skin tag is cut away from the underlying internal anal sphincter. With a second cut of the scissors, the hemorrhoidal tissue is divided from the wall of the anal canal, which leaves the circular fibers of the internal sphincter readily displayed at the base of the wound (Fig. 164.20). With an adrenaline solution, there is minimal bleeding. The next maneuver is to dissect any residual hemorrhoidal tissue from beneath the cut edge of the mucosa on either side of the defect (Fig. 164.21). This also facilitates creating two mucosal flaps for subsequent closure of the defect. Closure is achieved starting at the apex of the mucosal defect in the depth of the anal canal. We use an absorbable suture on a cutting needle. The apex of the mucosal defect is anchored to the internal anal sphincter at the apex, and a running suture is then used to approximate the cut mucosal edges (Fig. 164.22). At the anal verge, a subcuticular technique is used to approximate the skin to avoid leaving a knot at the perianal apex of the wound. The absorbable suture is thus continued backward into the anal canal, and a knot is tied just below the dentate line. The process of closure usually completely controls blood loss. The same technique is used for each of the three hemorrhoidal components. At the completion of the operation, a Pratt operating proctoscope is inserted to ensure that there is complete hemostasis. If not, any residual bleeding must be secured by underrunning the vessel. Meticulous hemostasis is particularly important in this operation because, with the patient in the prone jackknife position, blood readily runs back into the rectum and may not be obvious to the surgeon. Furthermore, infiltration with an adrenaline solution may mask a source of potential reactionary hemorrhage.

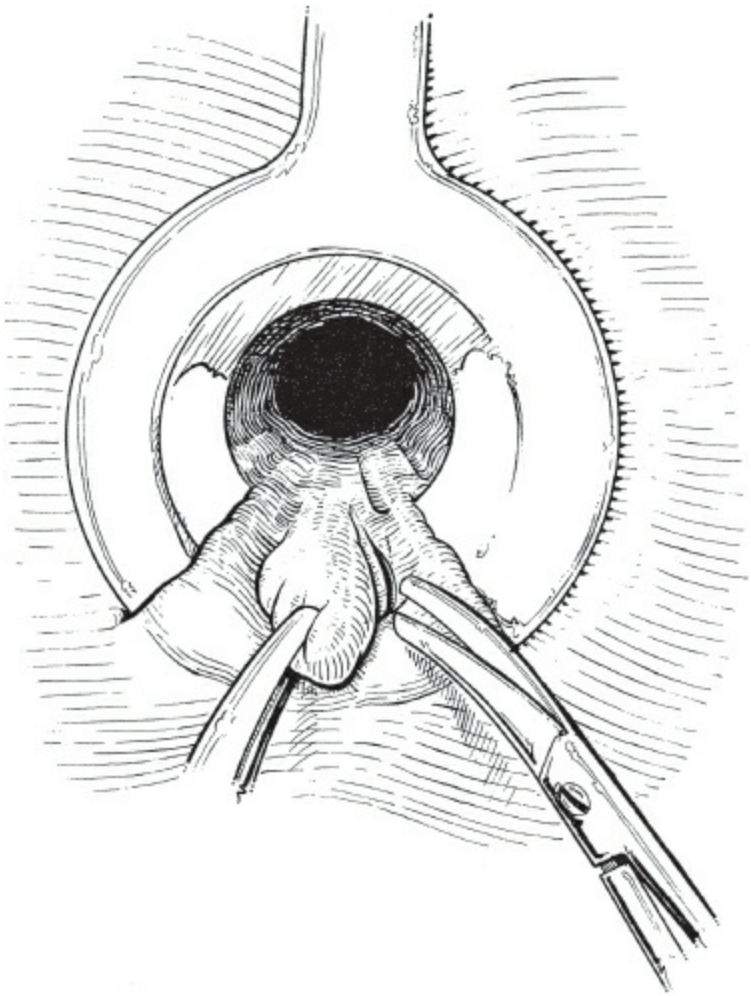

Figure 164.20. Closed hemorrhoidectomy. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

Patients should be warned of the risk of bleeding. They must be given liberal supplies of analgesics and laxatives. If fever develops, patients should return to the doctor as quickly as possible because submucosal and intersphincteric abscesses are a recognized complication of closed hemorrhoidectomy.

COMPLICATIONS OF CONVENTIONAL HEMORRHOIDECTOMY

There are a variety of complications after hemorrhoidectomy, and patients should be warned about them in the consent and counseling process. Reactionary hemorrhage occurs early in the first 24 hours due to restoration of a normal blood pressure causing extensive bleeding from a

vessel that was not secured or where a ligature slipped in the early postoperative recovery phase. Treatment is by emergency relegation of the vessel. Secondary hemorrhage may be major necessitating resuscitation and emergency reoperation. It usually occurs 5 to 8 days postoperatively due to erosion of a vessel from sepsis needing suture ligation and antibiotics. Acute retention of urine is not uncommon in elderly patients. Anal pain postoperatively must be managed appropriately. Where possible, opiates should be avoided altogether. Topical or oral nonsteroidal analgesics are advised and stool softeners with laxatives are essential as patients are immobile and dehydrated. Consequently, fecal impaction is inevitable unless prevented. Impaction only aggravates the pain. Unhealed open wounds or closed wounds that break down should be treated with topical nitrates or Diltiazem creams and regularly assessed. Flatus incontinence and soiling may occur if there has been operative injury to the internal anal sphincter. Anal stenosis should not occur but is a consequence of leaving inadequate skin bridges or, where retained skin bridges slough because the base of the bridges is not wide enough, resulting in ischemic necrosis. Should anal stenosis (the Whitehead deformity) occur after hemorrhoidectomy management can be very difficult? Anal dilatation is usually associated with restenosis requiring repeated anal stretch procedures, which threaten damage to the residual sphincters. Anal skin advancement procedures after excision of a localized stricture might be beneficial. However, in most cases, a complete circumferential defect develops requiring excision with bilateral rotating anoplasty. Anoplasty carries a 20% to 30% risk of sepsis and restenosis.

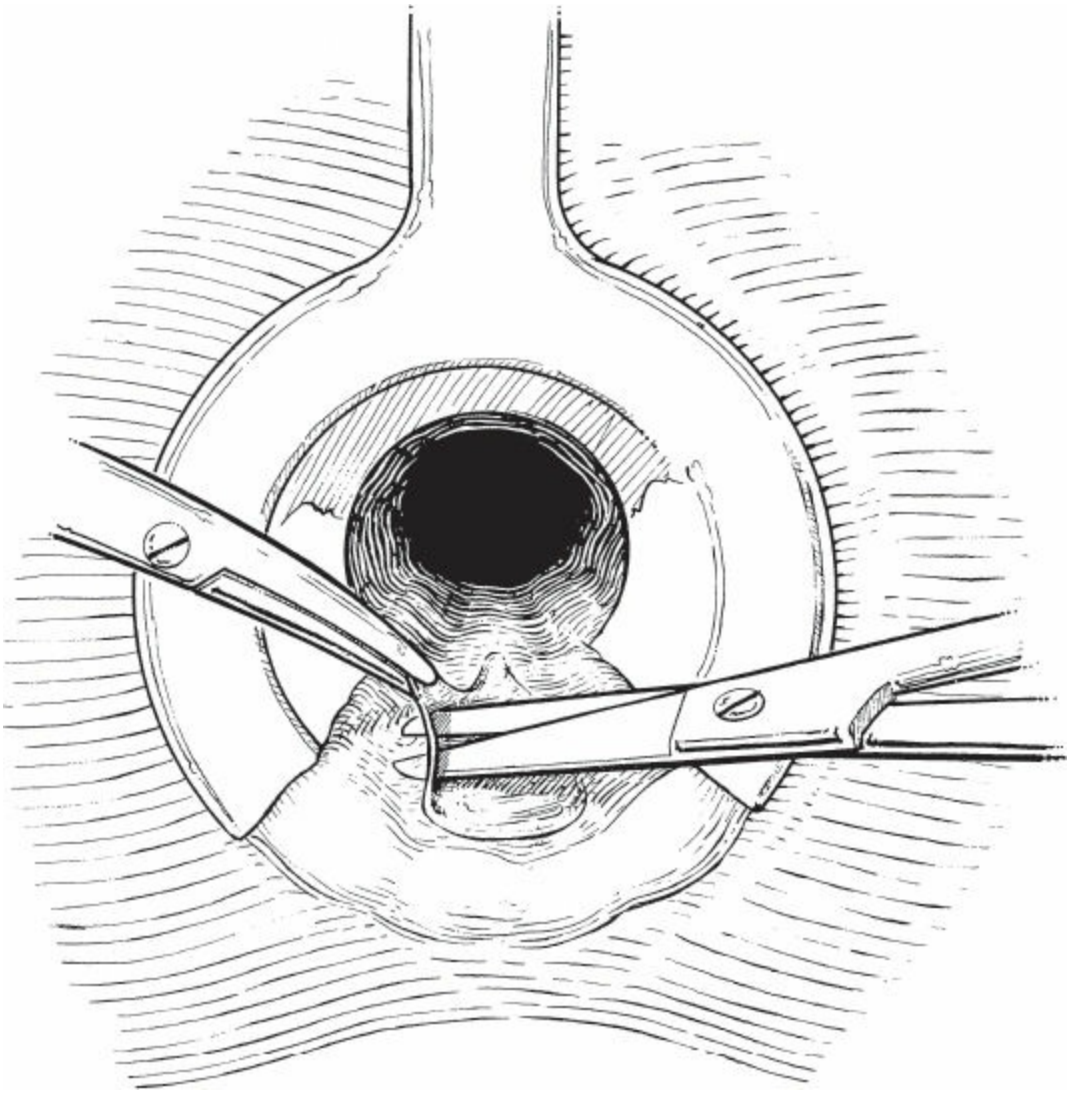

Figure 164.21. Additional vascular tissue beneath the anoderm on either side of the incisions is removed. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

Stapled Hemorrhoidopexy

Stapled hemorrhoidopexy (PPH) has been used for over a decade with both spectacular and disastrous results. The spectacular results reported in 80% to 90% involve an almost painless overnight stay procedure, which is painless and with excellent long-term results. The disasters include rectovaginal fistulae, rectal perforation, sepsis, and chronic symptoms of tenesmus, a feeling of incomplete rectal evacuation and pain (anterior resection syndrome). The reason for this is that the procedure is blind, and

consequently, it is not possible to check that there are no correctable problems during the excision process when the gun is fired.

PPH involves excision of a cylinder of rectal mucosa and submucosa in the top of the anal canal about 2 to 4 cm from the dentate line. Thus, it does not directly deal with skin tags, although skin tags may improve as a result of excision of the anal rectal mucosal cylinder.

In view of the unpredictable results of this operation, patients must be warned that this is a blind procedure and that complications such as rectal (or rectovaginal) injury may occur, there may be bleeding, and that excision of this cylinder of anorectum may cause the anterior resection syndrome. Most informed patients would be wary of consenting to the operation. Thus, it is critical that patients are not pushed into having this new, nearly painless hemorrhoidectomy procedure without careful explanation of the potential complications.

The equipment for the operation (Fig. 164.23) includes an operating proctoscope, which remains sutured in position throughout the operation with an obturator to facilitate the placement of a purse-string suture. The purse-string suture should only include submucosa from the circumference of the anorectum, which must not be too high (Fig. 164.24). Once the purse-string suture has been placed, the stapling gun is introduced, after which the operator cannot be sure what is happening until the gun is fired and the stapling device is withdrawn. Tying of the purse-string suture around the central spindle is facilitated by a hooked probe so that the ends of the purse string can be tightened before the staple gun is closed around the cylinder of tissue, which is then amputated and the residual tissue stapled together (Fig. 164.25). When the circular stapler is removed, the ring of tissue should be inspected to make sure that it is an intact cylinder and it should be sent for histology to ensure that there is no muscle entrapment in the excision. The staple line is then checked for hemostasis and any bleeding vessels should be overrun with a suture. Rectal integrity should also be checked by proctosigmoidoscopy and by bimanual examination in women to ensure that the rectovaginal septum is intact.

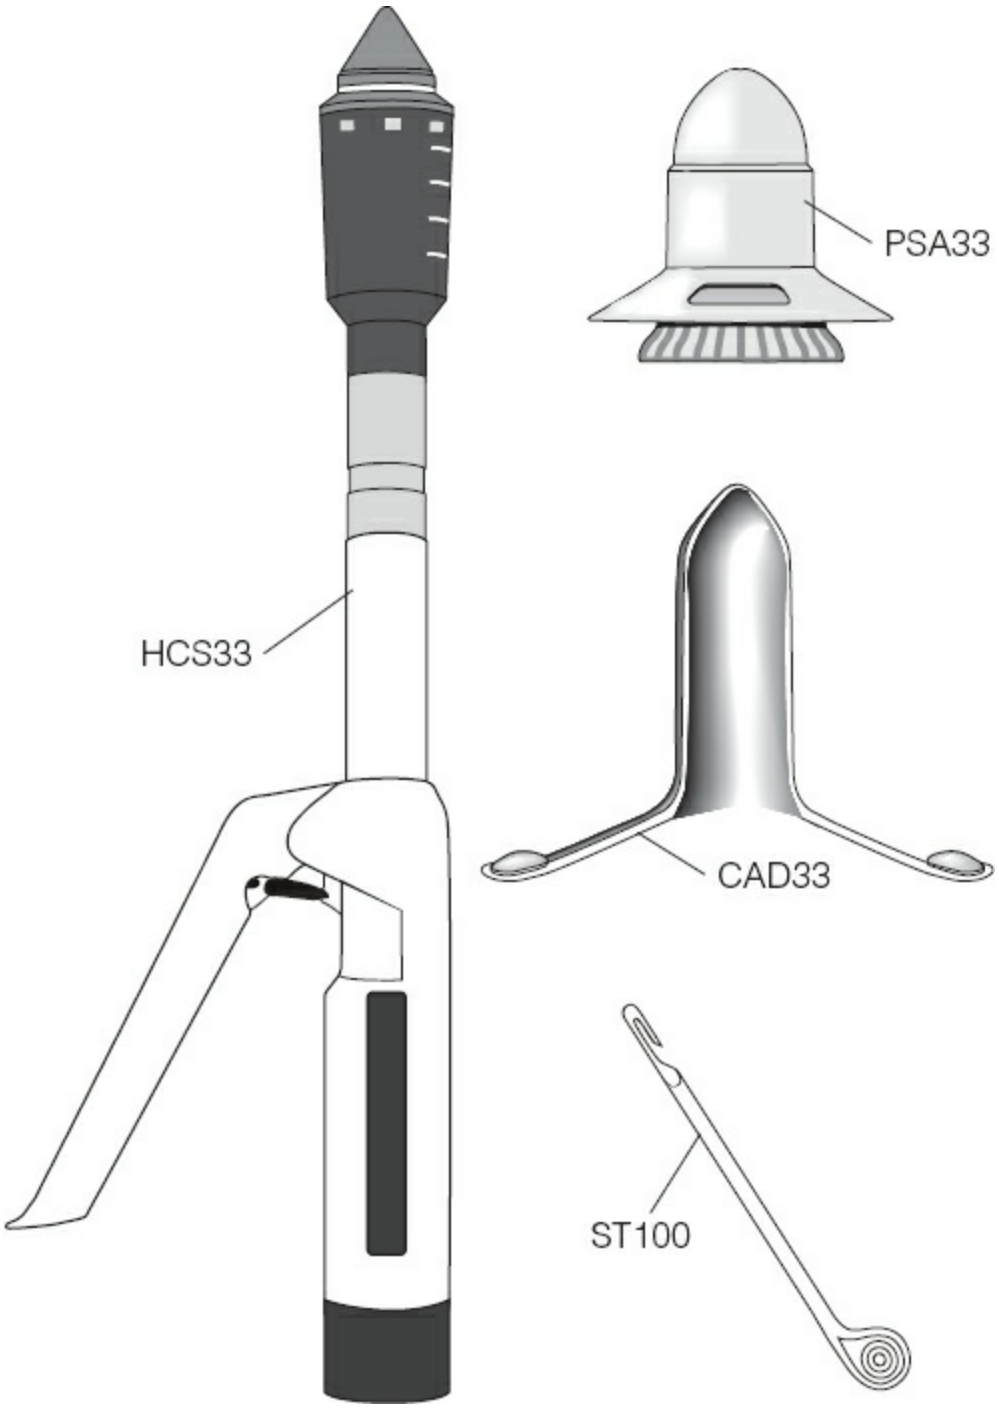

Figure 164.23. Equipment for PPH. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

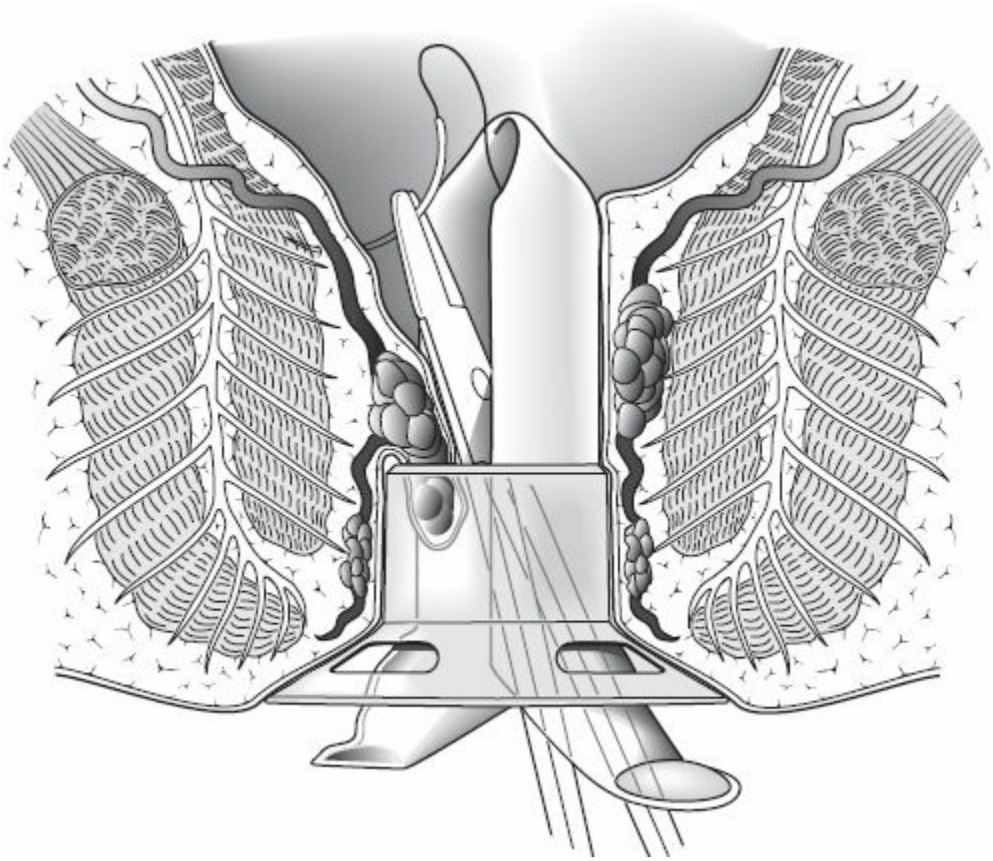

Figure 164.24. Purse string in PPH. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

In the vast majority of patients, the results are spectacular. However, 5% to 10% may develop potentially serious complications or the anterior resection syndrome, which may be permanent.

Anorectal Warts

CLINICAL PRESENTATION

Patients present with small, discrete, papilliferous warts around the perineum or at the anal margin. Some anal condylomata coalesce to form large sessile edematous swellings with hyperkeratinization and discharge of mucus. Anal condylomata may bleed or may give rise to pruritus ani. Associated lesions are common and may occur in the vulva and vagina in women, and on the penis or on the scrotum in men. They may also occur within the urethra and the anal canal, and they may be found on the face and hands.

CAUSES

Anorectal warts are caused by the human papillomavirus. They are usually, but not exclusively, acquired by sexual transmission. Inoculation may occur from the finger or the penis. Homosexual patients may have associated sexually transmitted disease. Thus, many of these patients should be counseled and screened for the human immunodeficiency virus, as well as for gonorrhea, syphilis, chlamydia, hepatitis, *Giardia*, herpes, cytomegalovirus, and lymphogranuloma venereum.

The human papillomavirus is responsible for malignant change; thus, long-standing anal condylomata should be biopsied. The urethra and the anal canal are important sources of reinfection, and so treatment must be directed for the patient or the patient's partner to such potential sources of reinfection.

DIAGNOSIS

Anal warts are obvious on clinical inspection of the perineum. Women should undergo a full speculum examination so as to exclude lesions in the vulva and vagina. All patients should undergo proctoscopy to exclude condylomata within the anal canal. In male patients, the penis, scrotum, and urethra should be inspected.

TREATMENT

Patients with anal condylomata should be screened in a clinic for sexually transmitted diseases for the reasons given previously. The lesions may be treated by topical application of podophyllum resin, by chemo- or immunotherapy, or by surgical excision.

Podophyllum resin is usually applied as a 10% or 20% solution in

benzoin. Long-term studies, however, indicate that only 25% of all patients treated with podophyllum resin achieve complete resolution.

Chemotherapy with colchicine, thiotepa, or fluorouracil (5-FU) has been used. Today, these methods are rarely recommended. There was a vogue for immunotherapy, but long-term studies do not substantiate the early claims of resolution in >80% of patients.

Surgical treatment is by cautery, laser ablation, cryotherapy, or scissor excision. We do not advocate cryotherapy. Laser treatment is highly specific to each lesion and causes less tissue destruction than fine-point high-frequency cautery. However, we prefer scissor excision and recommend the technique of subcutaneous and submucosal infiltration with a weak adrenaline solution, which lifts the condylomata away from the normal skin so that the condylomata themselves can be excised and leave the surrounding skin or mucosa intact (Fig. 164.26). This technique is tedious, but it causes infinitely less tissue destruction than excision by cautery and probably less than that from laser excision. In confluent lesions, it may be necessary to treat patients in more than a single visit. Despite the use of a weak adrenaline solution, bleeding can be quite troublesome after multiple scissor excisions. We do not recommend the use of cauterization to control bleeding, but prefer pressure tamponade. Any lesions in the anal canal must be thoroughly cleared by scissor excision as well as removal of the perianal lesions. Follow-up is absolutely essential, because some patients require treatment more than once, and recurrence is common. The overall recurrence rate is ~40%. Many recurrences are caused by reinfection. Hence, patients must be carefully counseled and their partners screened.

Pilonidal Sinus

CLINICAL PRESENTATION

Pilonidal sinus is associated with small midline pits behind the anal canal over the sacrum and coccyx. There may be lateral openings, particularly if the disease is complicated by sepsis. These sinuses often discharge purulent material that causes poor anal hygiene. Alternatively, the disease may be complicated by acute infection presenting as an abscess. The midline pits often contain hair. The condition principally affects young

people after puberty, is more common in men than in women, principally affects whites, and is rare in Black or Asian patients. The condition may be completely asymptomatic and may disappear with age.

CAUSES

There are two theories about the cause of pilonidal sinus—that the disease is caused by a developmental abnormality and that it is acquired. The developmental theory proposes that there are epidermal rests with hair embedded below the dermis in the midline as a result of failure of fusion. Occasionally, implantation dermoids are seen, but they are quite distinct from pilonidal disease. Most authorities now believe that pilonidal disease is acquired.

The acquired theory suggests that hair is shed from around the perineum or from the head, and that the distal ends of the hair act as drills into small sebaceous or hair follicles. In this manner, hair penetrates or is sucked into the dermis and subcutaneous tissues, which creates minute pits. Subsequently, the pits become infected by skin organisms and give rise to suppuration. The fact that pilonidal disease is more common among barbers, and that it can occur between the web spaces of the fingers, strongly supports the acquired theory.

DIAGNOSIS

Pilonidal disease is easily diagnosed by the typical location of the midline pits behind the anus overlying the sacrum and coccyx. Occasionally, pilonidal disease may form small subcutaneous fistulae around the anal canal, but this is rare. Most sinuses are directed cephalad, and lateral openings are characteristic if previous episodes of sepsis have occurred. Broken hairs can often be seen exuding from the midline pits.

TREATMENT

Management of Pilonidal Abscess

Pilonidal abscess presents as a swelling just lateral to the midline over the sacrum. There is a hot, tender, fluctuant swelling that may exude pus through the midline pit and also may spontaneously discharge at its apex. Treatment in the emergency room is by incision and drainage. Any further treatment is meddlesome at this stage. Thereafter, treatment of the underlying disease is as described in the following sections.

Elective Treatment of Pilonidal Sinus

Elective treatment of pilonidal sinus can be divided into three major categories: (a) minimal surgery, (b) opening of sinus tracks, and (c) excision with or without rotational skin flaps. Before any form of surgical treatment is begun, serious consideration must be given as to whether treatment is likely to cause more morbidity than does the underlying pilonidal disease itself. In many instances, surgical treatment leaves the patient worse, not better. For many patients, treatment involves a chronically discharging open unhealed wound that persists for months or even years and necessitates frequent hospital admission for surgical curettage, as well as repeated office appointments. Furthermore, the natural history of pilonidal disease in untreated patients suggests that, in some, the disease disappears with time.

Minimal Surgery

The principle of minimal surgery is simply to remove hair from midline pits and to keep the buttocks shaved. Many patients with pilonidal disease are not particularly meticulous about personal hygiene. Thus, some form of counseling is necessary to explain the importance of washing the area regularly and to teach how to shave the area. A fine wire brush may be used with local anesthesia to clear the pits and any lateral openings of granulation tissue and hair (Fig. 164.27).

Excision of Pits and Closure of the Presacral Cavity: Bascombe Operation

This is a relatively minor day-case procedure. The midline pits are excised by a fine scalpel blade around each pit down to the presacral cavity and left open. All the pits are drilled out. A lateral incision is then made about 1 cm from the midline so as to expose the presacral cavity deep to the pits. The cavity is opened and the contents are scooped out with a Vulsellum spoon. The incision is then closed primarily (Fig. 164.28).

Fibrin Glue

Spectacular results have been reported with fibrin glue application to the tracks once they have been curetted as described in the preface to this section. “Tisseal” glue (commercially available fibrin plug) is then applied to each of the tracks and any excess wiped away. The healing rates are

comparable to the Bascombe operation, and there is much less postoperative pain.

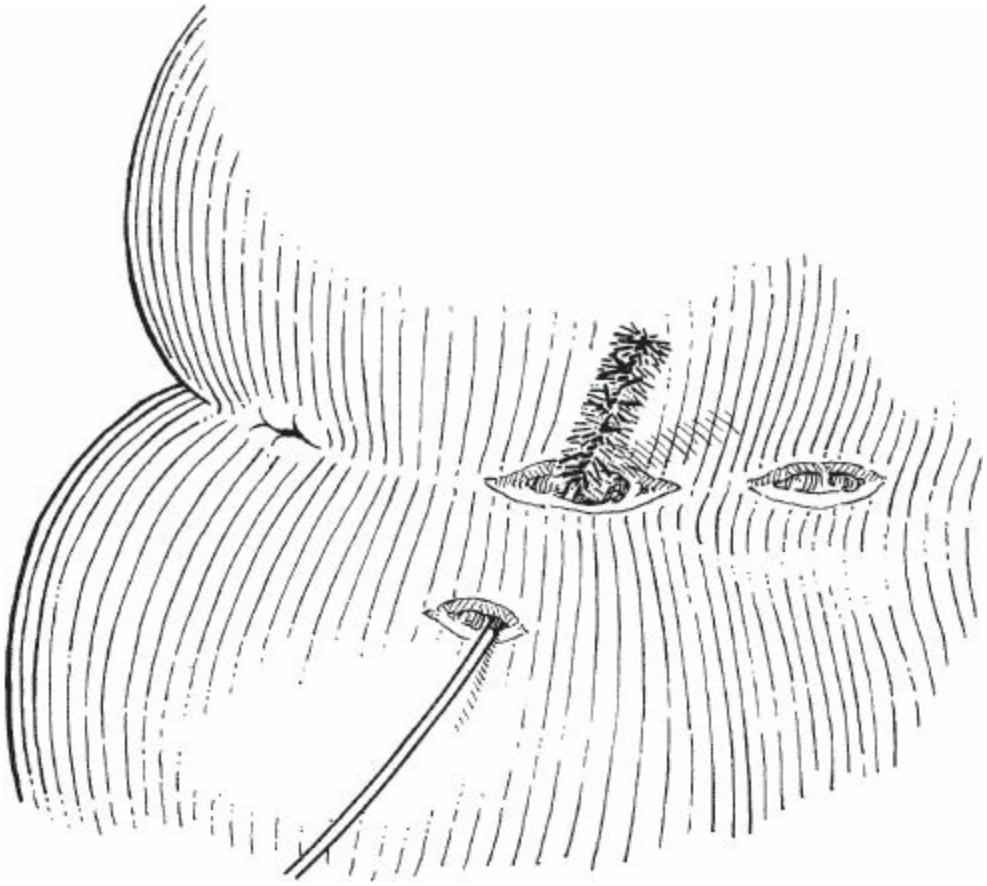

Figure 164.27. Curretting out midline sinuses and their lateral tracks. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders, 2008, Copyright © MRB Keighley MA MS FRCS.)

Lay Open of Sinus Tracks

If minimal surgery does not control episodes of suppuration, the sinuses themselves may be opened as in fistulotomy (Fig. 164.29). A probe is passed through the pilonidal sinuses, and the tracks are carefully opened by dividing the skin with a scalpel blade or by cautery. The granulation tissue at the base of the sinuses is curetted. The edges of the skin are excised so that there is an open granulating wound that must be kept meticulously clean and free of hair by the methods described in the previous section. The superficial wounds may heal completely. If they do not, a skin graft or advancement flap may be used to close the defect.

Excision of Sinus Tracks

Wide excision of the pilonidal area, including all affected skin and subcutaneous tissues down to the presacral fascia, may be needed if all other methods of treatments fail. Excision has traditionally been by midline incision to enclose all the disease process. The wound may be left open, allowed to marsupialize, or closed as a primary procedure. There is a high breakdown rate, mainly because of the shearing forces around the buttocks in young, active patients. The shearing forces can be minimized by placing the incision off the midline as in the Karydakis procedure. Avoidance of midline incisions reduces the risk of nonhealing.

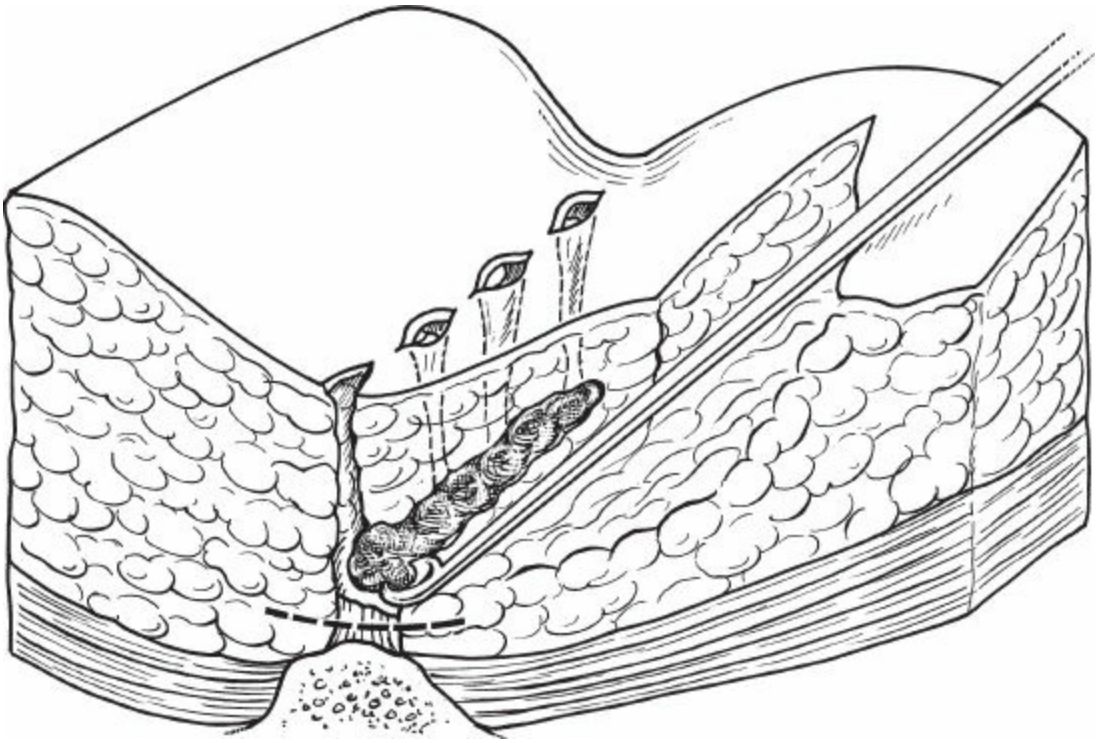

Figure 164.28. The Bascombe operation. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

If the sinus is infected at the time of excision, no attempt should be made to primarily close it. The wound may be left open to granulate and secondary suture may be performed, or a technique of marsupialization may be used, whereby the skin surrounding the defect is sutured down to the presacral fascia.

Primary closure, if it is to be performed, should ensure that there is no dead space and that some form of pressure dressing is used to prevent hematoma that may become secondarily infected. Suction drains may be

used. Alternatively, compression dressings can be applied within the sutures used to close the defect (Fig. 164.30).

Occasionally, there are patients whose primary excision sites have never healed. These postoperative nonhealed ulcers can cause considerable morbidity, and their closure may prove difficult. Techniques that may be used to cover such defects include Z-plasty, the use of the rhomboid flap, or the use of myocutaneous flaps based on the superior gluteal artery and nerve. Under these circumstances, most coloproctologists require the help of a plastic surgeon. However, Z-plasty and rhomboid flap techniques may be used during primary excision and suture.

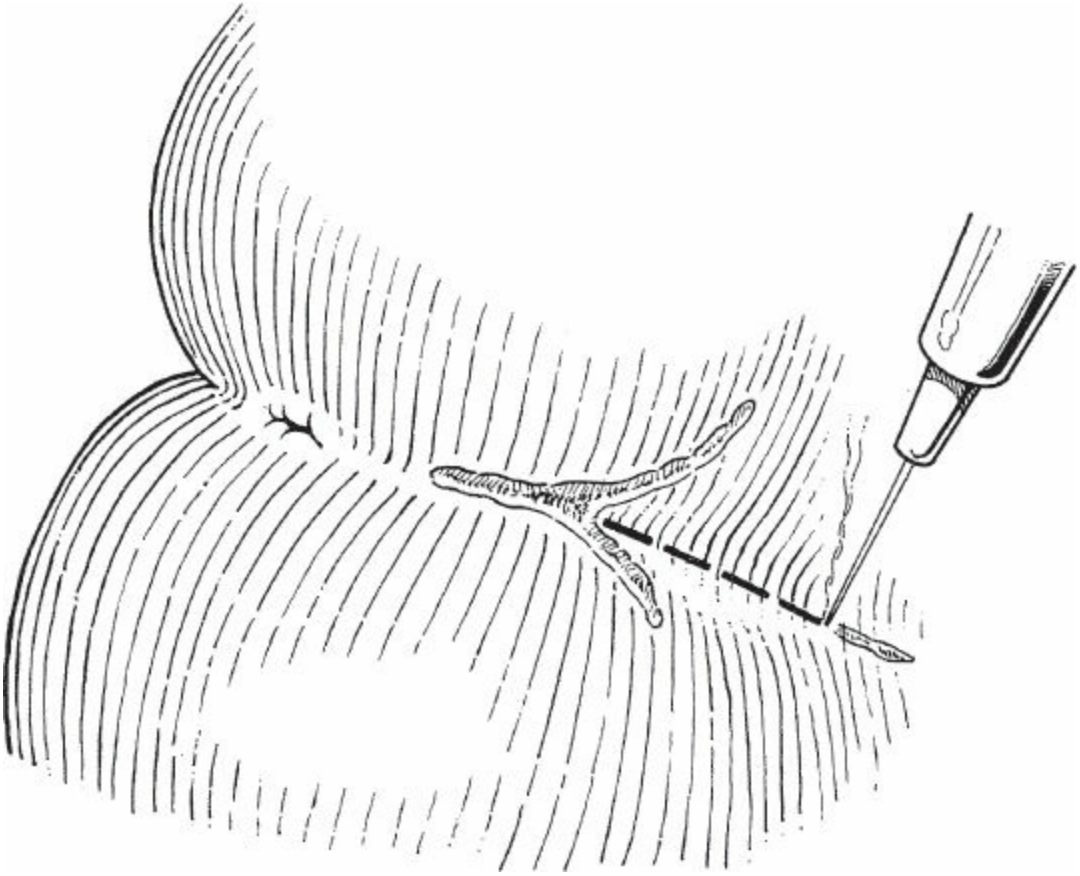

Figure 164.29. Lay open of pilonidal sinus. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

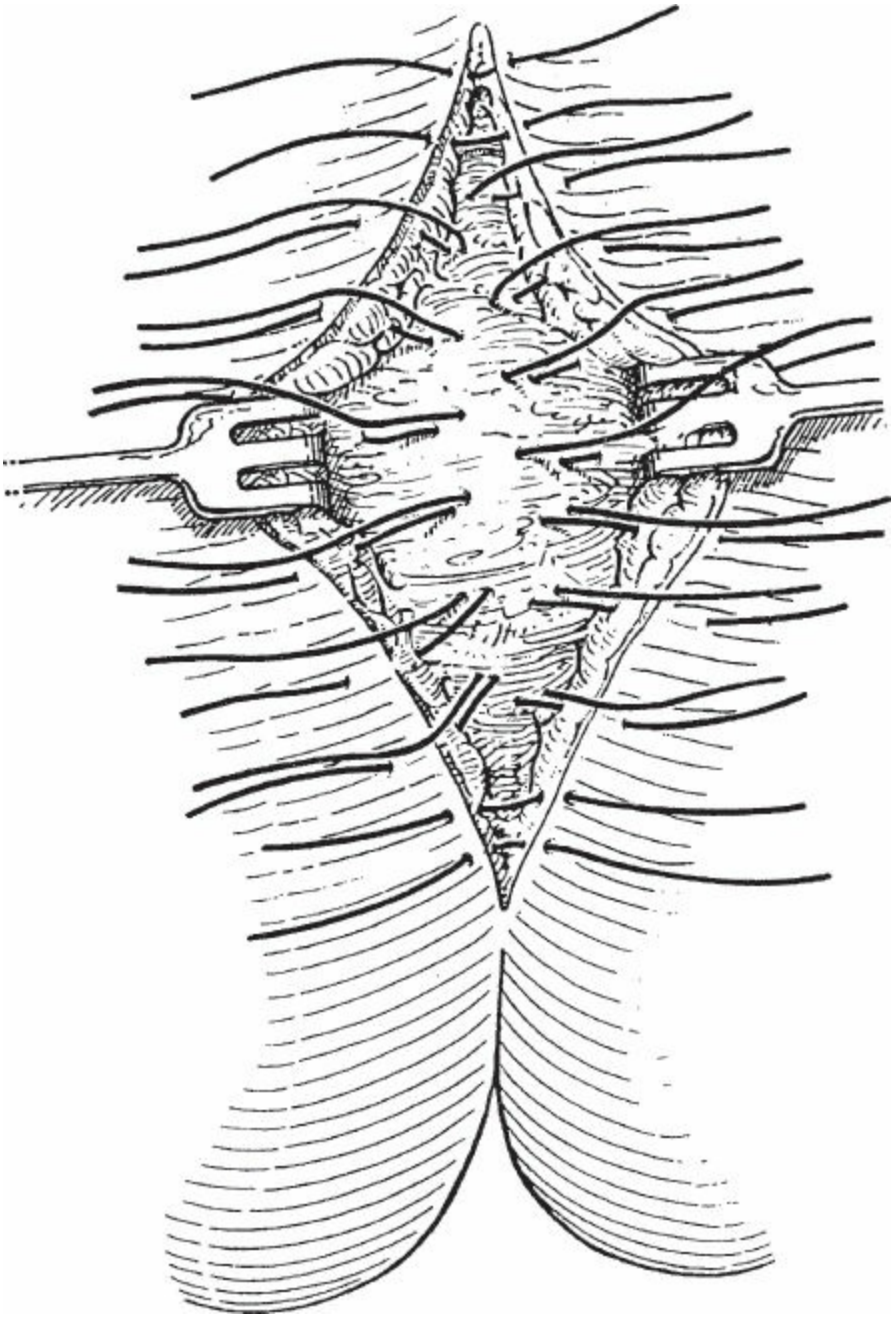

Figure 164.30. Primary excision and closure. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

Karydakis Primary Excision and Closure

The excision is performed using an asymmetrical incision, which deliberately removes much more skin on one side than on the other. The pits in the presacral cavity are excised, and the side of the excision closest to the midline is undermined, so that when the skin is approximated to the other side (the wider skin excision area) the wound lies off center (Fig.

164.31). Antibiotic cover should be used for the procedure and closed suction drainage if hemostasis is other than perfect. Using this technique, achieved primary healing rates of 60% to 90% have been reported.

Hidradenitis Suppurativa

CLINICAL PRESENTATION

Hidradenitis suppurativa never occurs before puberty. Women are affected more commonly than men. The disease presents with skin suppuration and superficial fistulae associated with brawny edema and induration in areas of the body in which there are apocrine glands. One of these areas, the perineum, may give rise to extensive disease that can be difficult to differentiate from perianal Crohn disease, anorectal fistulae, tuberculosis, and anogenital cancer. The typical presentation is of boils, furuncles, induration, and discharging sinuses on the perianal region, the vulva, the groin, or the axilla. The discharge is thin, watery, and offensive. The condition is a form of acne.

CAUSES

It is presumed that there is a hormonal basis for this disease, because it never occurs before puberty. The principal abnormality is the occlusion of apocrine ducts by keratin. Obstruction leads to retention of secretions, and secondary infection resulting in fibrosis, sinus formation, and induration.

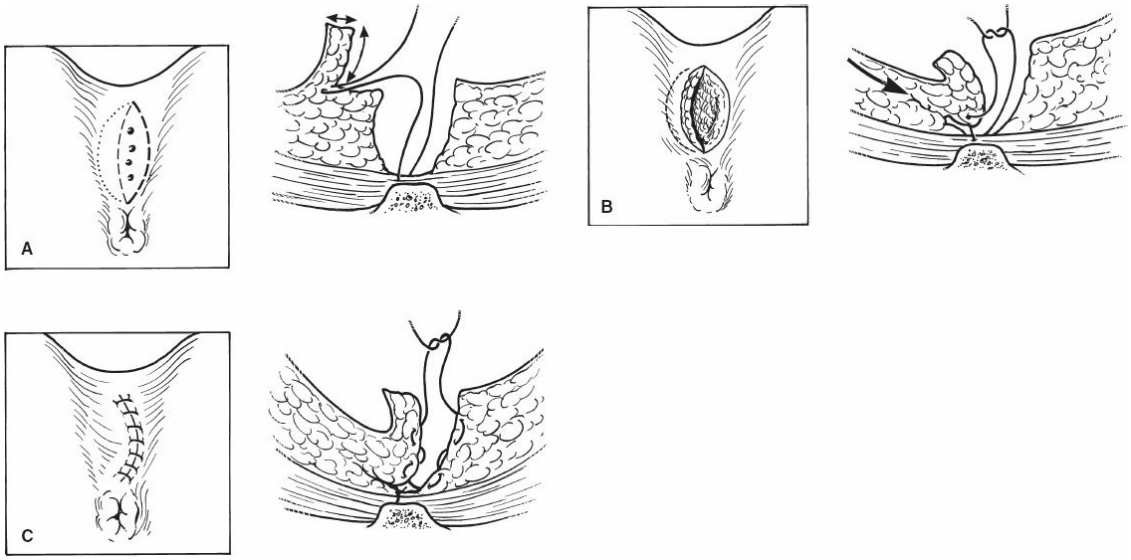

Figure 164.31. Karydakis procedure. **A.** Incision off center. **B.** Lateral mobilization. **C.** Closure off center. (From Keighley MRB,

Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

DIAGNOSIS

Diagnosis of hidradenitis is made by the typical appearance in association with lesions in the groin or the axilla. If there is difficulty in making a diagnosis, excision biopsy may prove necessary.

TREATMENT

Treatment depends mainly on the severity of disease. Some patients with chronic induration and only occasional discharge prefer to accept the morbidity of the disease rather than the morbidity of surgical treatment. Surgical treatment is often extensive, is not always successful, and may be associated with extensive morbidity and prolonged hospital stay. Low-dose antibiotics may be used for prolonged periods to prevent secondary infection, but under these circumstances there is the inevitable risk of bacterial resistance and superinfection. Alternatively, intermittent courses of antibiotic may be used to treat acute exacerbations of the disease or for secondary infective complications. Localized collections of pus may need drainage. With time, the disease often slowly disappears, leaving fibrosis without infection.

Surgical treatment, to be effective at all, requires total ablation of the apocrine area. Hence, all skin and subcutaneous tissues involved in fibrosis, sinus, and fistulae are excised. For perianal disease, this may involve extensive saucerization, which leaves only perianal skin. The defect may be left to granulate, and VAC dressings have proved extremely helpful, particularly for deep cavitating wounds, and if subsequent skin grafting, should be necessary. Alternatively, myocutaneous flaps may be used to cover the defect. For extensive perianal disease requiring wide excision, a defunctioning stoma is often necessary to keep the area clean, allow healthy granulation tissue to form, and facilitate skin grafting.

Rectovaginal Fistula

CLINICAL PRESENTATION

The principal symptom for a patient with a rectovaginal fistula is of the

passage of pus or feces through the vagina. Symptoms may be intermittent or continuous and may result in impaired vaginal hygiene or lead to frank fecal incontinence. Small fistulae are often associated with intermittent symptoms, amounting to a small amount of vaginal discharge sometimes accompanied by the passage of gas through the vagina. Small, low rectovaginal fistulae can be extremely difficult to diagnose, whereas large rectovaginal fistulae are clinically obvious with perianal soiling, fecal incontinence, and severe pelvic sepsis and necessitate urgent surgical management.

CAUSES

Rectovaginal fistulae are classified into three broad anatomic groups: (a) forniceal fistulae, (b) septal fistulae, and (c) perineal fistulae (Fig. 164.32).

Forniceal Fistulae

Fistulae entering the posterior fornix of the vagina arise from disease in the pouch of Douglas or from the upper rectum. The common causes are diverticular disease, carcinoma of the large bowel, Crohn disease of the ileum or large bowel, postirradiation fistulae after treatment of gynecologic malignancy (particularly after hysterectomy), and postoperative fistulae after an intestinal anastomosis in the pouch of Douglas.

Septal Fistulae

Fistulae running through the rectovaginal septum, that is, within the middle third of the vagina, are often large, are usually direct, and are invariably caused by rectal or gynecologic conditions. The rectal causes include rectal carcinoma, rectal Crohn disease, and postirradiation rectovaginal fistulae. Gynecologic causes include carcinoma of the cervix or vagina and severe postobstetric fistulae resulting from pressure necrosis from the fetal head in obstructed labor. These are suprasphincteric fistulae.

Perineal Fistulae

Perineal fistulae often pursue a tortuous course. They run through a part of the perineum or sphincter mechanisms. The fistulae may be small and cause minimal symptoms. Causes of perineal rectovaginal, rectovulvar, and anovulval fistulae include cryptoglandular infections, as in anorectal

abscess and fistula (see previous sections); postobstetric fistulae from sphincter damage associated with a defect between the two viscera (either third or fourth degree obstetric tears); iatrogenic fistulae caused by previous surgical treatment; and fistulae complicating perianal Crohn disease (often cryptoglandular).

DIAGNOSIS

Identification of large fistulae is often not difficult. By contrast, small, tortuous perineal fistulae may prove exceedingly difficult to positively identify. Large rectovaginal fistulae causing fecal incontinence are associated with intense excoriation of the perianal skin and a red, raw vagina, obvious clinically. Vaginal speculum examination is necessary for smaller fistulae to identify the site of the vaginal opening. Perineal fistulae may be difficult to see, but septal and forniceal fistulae are usually obvious. Examination should also include proctoscopy, particularly for perineal fistulae, to identify whether there is an opening at the dentate line, which is characteristic of a cryptoglandular origin. Proctosigmoidoscopy is necessary to exclude rectal malignancy, Crohn disease, and irradiation damage.

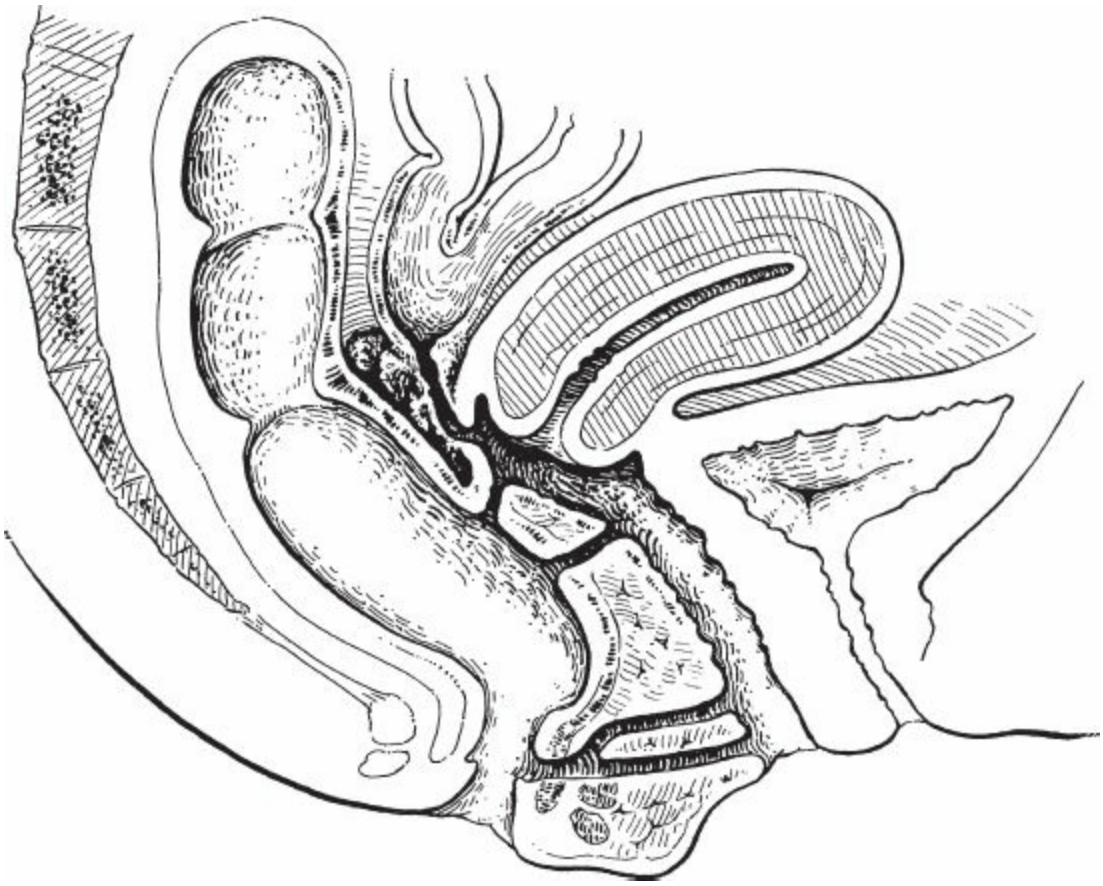

Figure 164.32. Classification of rectovaginal fistulas. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

Special investigations may be helpful in delineating the cause and the course of the fistula. Barium enema examination may be necessary to identify inflammatory bowel disease, but the examination is relatively limited in defining the course of the fistula. Likewise, colonoscopy is useful in identifying inflammatory or malignant disease of the large bowel but rarely demonstrates the internal opening unless it is large. Vaginography may be a helpful method of identifying forniceal fistulae that cannot be demonstrated by speculum examination.

Examination with the patient anesthetized is usually necessary to demonstrate many fistulae, particularly those that are cryptoglandular in origin or that are postoperative. The use of fistula probes and injection of dyes may also facilitate identification. Rectal ultrasound is disappointing in the identification of rectovaginal fistulae except in the septal region, in which they are already obvious clinically. Perineal MRI is particularly helpful in identification of obscure fistulae. Any suspicious fistula should be biopsied to exclude malignancy.

TREATMENT

Preliminary Fecal Diversion

Preliminary fecal diversion is absolutely essential for patients with severe fecal incontinence or where a fistula is complicated by pelvic sepsis.

Definitive Treatment

Disease in the Pouch of Douglas

Disease in the pouch of Douglas causing a fistula through the posterior fornix of the vagina should be treated by resection when possible. Thus, resection is indicated for Crohn disease associated with fistulae, for diverticular disease causing a rectovaginal fistula, and for malignancy, but in these cases radical hysterectomy and partial excision of the vagina may be necessary. Rectal cancer associated with rectovaginal fistulae certainly requires radical resection of the rectum and the uterus and vagina. High postirradiation fistulae should be treated by sleeve coloanal anastomosis and covering loop ileostomy.

Surgical Treatment of Septal Fistulae

A carcinoma of the middle third of the rectum that causes a rectovaginal fistula is usually treated by abdominoperineal excision, hysterectomy, and partial vaginectomy. Occasionally, sphincter-saving procedures are possible with a coloanal anastomosis and covering loop ileostomy. In patients with a rectovaginal fistula complicating severe rectal or perianal Crohn disease, proctocolectomy and end ileostomy are the treatment of choice. Septal fistulae resulting from radiation damage require rectal excision and an end stoma or a sleeve coloanal anastomosis after excision of the fistula with a covering loop ileostomy (Fig. 164.33).

Treatment of Perineal Fistulae

Perineal fistulae can be treated in a number of ways, depending on their location, the patient's condition, and previous surgical procedures undergone by the patient.

Anorectal Advancement

Anorectal advancement and excision of the fistula track is the treatment of choice for postobstetric or cryptoglandular rectovaginal fistulae. The fistula track is first identified by careful probing. The vaginal side of the fistula is completely ignored unless there is sepsis, in which case it is cleared by local excision and curettage. An intra-anal retractor is inserted and, with the patient in the prone jackknife position, excellent exposure of the fistula is obtained. The mucosa surrounding the fistula is infiltrated with a weak adrenaline solution. The anterior aspect of the anal canal is also infiltrated in the submucosal and the intersphincteric plane. A curvilinear incision is made at the level of the fistula or just below it. The internal sphincter at this point is divided transversely, and upward dissection proceeds in the intersphincteric plane for a distance of ~4 to 5 cm. Thus, a flap of mucosa, submucosa, and both internal sphincter and rectal smooth muscle is created, containing opening of the fistula. The fistula is then excised by fine scalpel or diathermy excision through to its origin in the vagina. Any infection in the intersphincteric plane is cleared by curettage. The mucosa and internal sphincter below the transverse incision of the anal canal are dissected free. Once the fistula has been excised, the anal opening is closed with the lower margin of the flap. The lateral margins are then secured with interrupted sutures (Fig. 164.34). It is rarely necessary to defunction anorectal advancement flap unless there is underlying Crohn disease or severe perianal sepsis.

Transvaginal Advancement Flap

A vaginal advancement flap is a useful alternative to an anorectal flap, especially for recurrent fistulas (Fig. 164.35). The problem with vaginal advancements is that tissues are less lax than tissues in the anal canal, and thus it is technically more difficult to bring down mucosa from above to close the defect. Nevertheless, for some postoperative fistulae, particularly after restorative proctocolectomy or a previous coloanal anastomosis, there

is so much scarring in the anal canal that anorectal advancement is impossible; under these circumstances, a vaginal advancement is a more satisfactory option. The technique is identical to that described for rectal mucosal advancement, and the operation may be performed with the patient in the prone jackknife or the lithotomy position.

Transsphincteric Mucosal Advancement

If the internal opening of the rectal component of a rectovaginal fistula is inaccessible through an anal speculum, access may be obtained using the transsphincteric approach or by a posterior rectotomy without division of the sphincters (Fig. 164.36). A posterior rectotomy is preferred to the transsphincteric approach, because it does not compromise sphincter function, but access is slightly more restricted. The patient is placed in the prone jackknife position, and a longitudinal incision is made slightly off the midline from the buttock down toward the anal margin. The upper part of the incision is deepened and, if necessary, the lower aspect of the coccyx is excised. If the sphincters need to be divided, they are carefully marked with sutures before division so that they can be reconstituted with ease at the close of the operation. The rectum is then opened between stay sutures or, in the case of the transsphincteric approach, the entire anorectum is opened to expose the fistula that is excised. Closure involves a rectal advancement flap, which consists of the entire thickness of the rectal wall. Once the defect has been closed, the anorectotomy is then reapproximated in layers—first, the anorectal mucosa, then the internal sphincter, and, finally, the external sphincter, if divided. Closed-suction drainage is usually advisable.

Seton Fistulotomy

Seton fistulotomy is rarely indicated for the treatment of rectovaginal fistulae unless the fistulae complicate Crohn disease, in which case a loose seton provides an ideal method of draining pus.

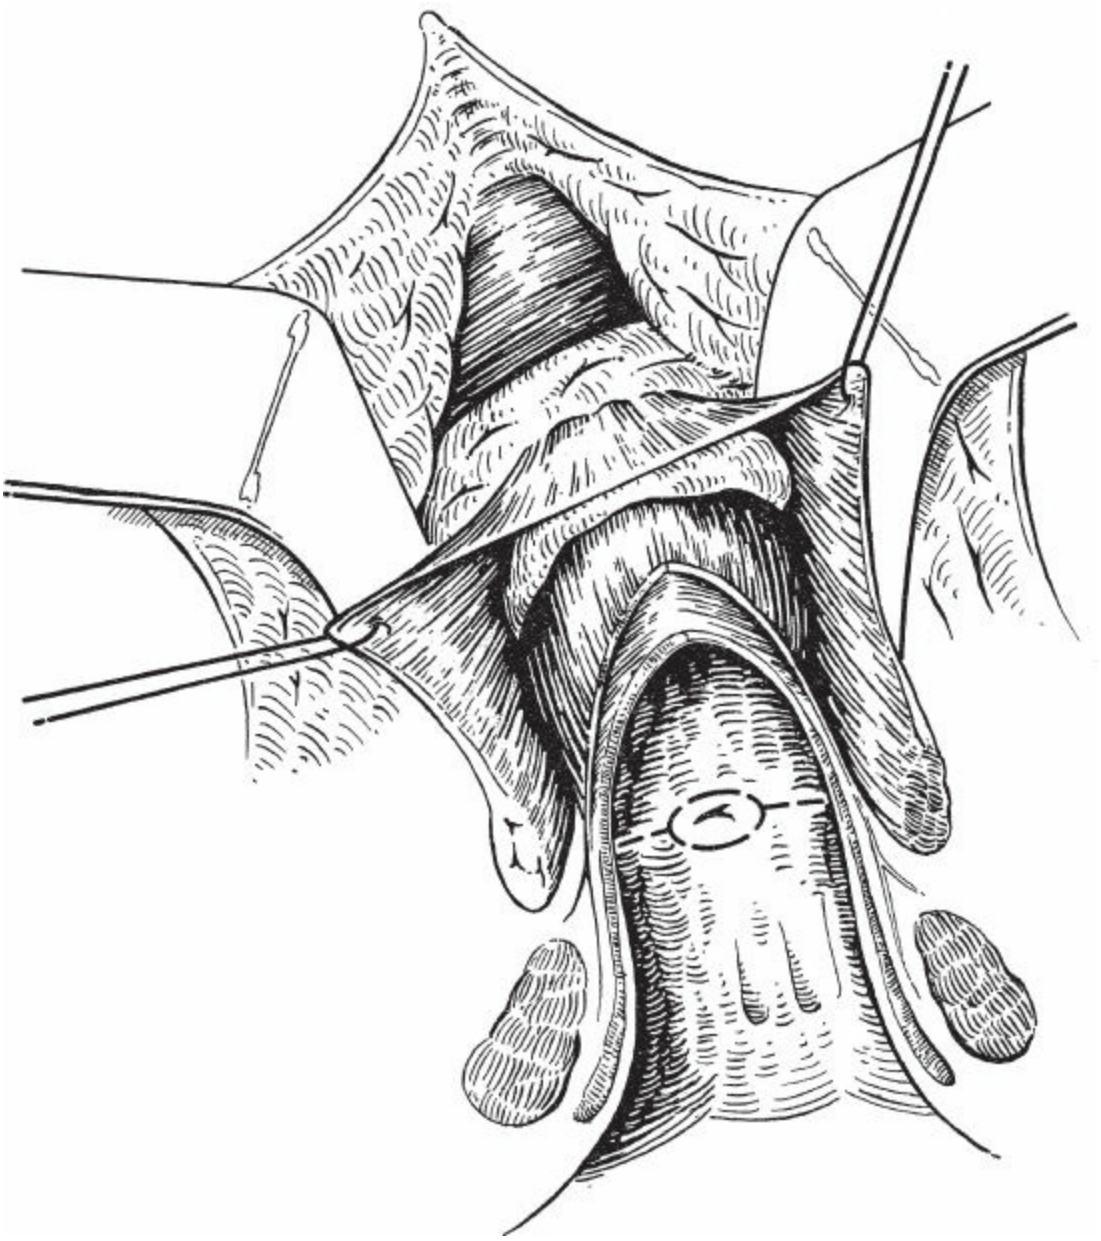

Figure 164.36. Transsphincter repair. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon*. 3rd ed. Philadelphia, PA: WB Saunders; 2008, Copyright © MRB Keighley MA MS FRCS.)

Lay Open of the Fistula and Complete Anorectal Reconstruction

A few fistulae lie superficial to the sphincters. If this is the case, the fistula can be safely laid open.

Postobstetric fistulae involving the anal sphincters may be treated by opening the fistula track and repairing the underlying defect in the sphincter. This method of treatment is particularly appropriate if a postobstetric rectovaginal fistula is complicated by a traumatic sphincter injury. (The technique of sphincter repair is described in an earlier section.) The principle of the procedure is simply to lay open and excise the entire fistula after which the levators, sphincters, and perineal body are repaired (Fig. 164.37). If there is any evidence of sepsis, a proximal stoma might be advisable. If there is localized sepsis, the skin incisions may be left open to granulate.

Special Considerations for Perianal Crohn Disease

CLINICAL PRESENTATION

The following are the hallmarks of perianal Crohn disease:

1. Edematous skin tags
2. Painless fissures
3. Deep cavitating ulcers
4. Complex anorectal sepsis associated with complex anorectal fistulae
5. Rectal strictures

Approximately one third of the patients with Crohn disease develop perianal disease before the macroscopic and symptomatic appearance of any intestinal disease. Hence, in approximately one third of patients, perianal disease is the first manifestation and predates the label of Crohn disease. In 45% of patients, perianal Crohn disease appears at the same time as intestinal disease. In the remaining 25% of patients, perianal disease occurs subsequent to the established diagnosis.

CAUSES

Perianal Crohn disease is a manifestation of a panmural granulomatous condition. In the anal region, it is particularly prominent as a result of nonspecific cryptoglandular infection, as well as enormous lymphoid aggregates found in the anal region. It is thought that the primary process in the anal canal is a penetrating anal ulcer that causes lymphedema, fibrosis, and activation of cryptoglandular infection.

Perianal Crohn disease can be subclassified into benign or aggressive disease. Benign disease often pursues a low-grade course with remission and relapse. Indeed, complete resolution may occur without any specific treatment. Such remission often occurs after surgical treatment or successful medical treatment of the underlying intestinal disease. Benign anorectal disease consists of skin tags, fissures, simple anorectal sepsis, and fistulae. By contrast, certain manifestations of Crohn disease result in progressive anorectal destruction, sepsis, fibrosis, and eventual rectal excision. Aggressive forms of perianal Crohn disease include: (a) deep penetrating anal ulcers, (b) complex anorectal fistulae, and (c) extensive perirectal fibrosis and stricture. The rectal excision rate in patients with aggressive disease during a period of 5 years exceeds 80%.

DIAGNOSIS

Diagnosis of Crohn disease is by the typical clinical syndrome, in

conjunction with typical radiology demonstrating intestinal ulceration, deep fissure, thickening of bowel wall, segmental disease, longitudinal ulcers, strictures, and cobblestoning of the mucosa. When possible, diagnosis should be supported by histopathologic evidence of noncaseating granulomas and deep fissured ulcers associated with transmural disease.

The typical appearances of perianal Crohn disease with skin tags, anal fissures and ulcers, complex anorectal fistulae, and anorectal strictures should be supported by biopsy, when possible, along with full intestinal radiology. The following conditions should also have been excluded: sexually transmitted disease, anorectal tuberculosis, anorectal and anogenital cancer, hidradenitis suppurativa, Behçet syndrome, and anorectal lymphoma.

TREATMENT

Conservative Therapy

Conservative treatment is recommended for asymptomatic perianal Crohn disease. It is particularly appropriate for patients with minor skin tags, painless anal fissures, and simple anal fistulae (including simple and low rectovaginal fistulae), and in patients with other nonspecific anal disease, such as hemorrhoids. In some patients, attempted surgical treatment may compromise continence. Perianal wounds tend to heal slowly. Hence, surgical treatment should be avoided when disease causes no symptoms or is likely to remit spontaneously.

Drainage of Pus

Perianal Crohn disease is likely to cause progressive fibrosis and anal destruction if sepsis is left without being adequately drained. Anorectal sepsis in Crohn disease is complex and should be carefully defined by MRI and examination under anesthesia. The intersphincteric plane is often a source of occult sepsis, and in patients with infective symptoms and in whom traditional drainage identified little pus, the intersphincteric plane should be explored to ensure that this is not the seat of sepsis. Anorectal sepsis is often associated with fistulae. Recurrent sepsis is common; we recommend the use of soft, loosely tied setons to establish prolonged drainage and subsequent resolution. Mushroom catheters can also be used to drain pus, particularly if irrigation is deemed necessary.

Defunction

In some patients, the progression of anorectal disease can be halted and completely resolve by diverting the fecal stream. This method of treatment is particularly appropriate for severe anorectal sepsis and fistulae and in patients with anorectal strictures. Many patients undergoing loop ileostomy for fecal diversion in perianal disease eventually progress to proctocolectomy because, although fecal diversion switches off active disease, the chances of restoring intestinal continuity are <20%. Some patients, however, prefer to live with a loop ileostomy, especially if they are made aware of the potential complications of proctocolectomy.

Selective Treatment

Certain forms of anorectal Crohn disease deserve specific treatment.

Steroid Injection

Local steroid injection may be useful as a means of healing penetrating ulcers complicating Crohn disease.

Dilation

Anorectal dilation may play a useful part in the management of patients with short diaphragmatic anorectal strictures.

Advancement Flaps With Fibrin Glue

Mucosal advancement may play an important role in selected patients with anorectal and rectovaginal fistulae, but because of the risks of sepsis and the relatively poor healing in perianal Crohn disease, coexisting fecal diversion is often advised. In some cases, healing can be promoted by using fibrin glue or the anal plug.

Seton Fistulotomy

Loose seton drainage may be used in selected cases of anorectal fistulae. Each case must be judged on its own merit. Whenever anorectal fistulae are treated in Crohn disease, coexisting sepsis must be adequately drained, and fecal diversion may be necessary.

Proctocolectomy

Proctocolectomy is eventually required in many patients, particularly those with deep penetrating anal ulcers, complex anorectal fistulae, and progressive anorectal stenosis with sepsis. Proctocolectomy in these

patients is difficult. An intersphincteric excision of the anorectum is impossible, and wide excision is often necessary to clear sepsis. These patients have a high rate of unhealed perineal wounds and persistent perineal sinus. Persistent perineal sinus in these patients may eventually require treatment by myocutaneous rectus abdominis flaps. Nevertheless, the quality of life in patients after proctocolectomy for anorectal Crohn disease is usually greatly improved, once patients have accepted that their lives are better with a permanent ileostomy.

EDITOR'S COMMENT

Anorectal conditions comprise a considerable portion of any colorectal practice and an in-depth understanding of anatomy and physiology, as detailed in this chapter, is cornerstone to successful management of these conditions.

The chapter opens with a discussion on anal fissure. As alluded by the author, acute anal fissure often precludes a detailed physical examination due to the severity of associated tenderness. Fortunately, in most cases anal fissure can be readily elicited with gentle effacement of the anal canal and a detailed examination can be deferred to a later date after the fissure has healed. The author describes treatment with suppositories however my preference is to use topical agents (steroids, anesthetics, smooth muscle relaxing agents) for two reasons: first, most patients report extreme pain during suppository insertion resulting in poor compliance and second, suppositories deliver steroids in the distal rectum rather than the site of the fissure—the anal canal. In terms of surgical treatment, sphincterotomy has been the gold standard for decades. There has been a longstanding argument to determine the optimal extent of internal sphincter division. While most accounts suggest dividing internal sphincter to a point just proximal to dentate line, others have advocated "tailored sphincterotomy" using the length of the fissure as a guide. Needless to say that an inadequate sphincterotomy results in persistent symptoms whereas

an overzealous division of internal sphincter will inevitably lead to passive leakage of stool.

The chapter does not address the issue of the so-called “low-pressure” fissure, a condition where a chronic anal fissure exists sans acute inflammatory changes or pain in the area. This condition is a distinct entity in itself and no specific treatment beyond biopsy is necessary unless the patient is symptomatic. Since the etiology is not sphincter hypertonia, measures directed toward decreasing sphincter tone are best avoided. Treatment, when necessary, involves a cutaneous advancement flap.

Next, the author addresses the topic of anal abscess and recommends routine collection of cultures at the time of abscess drainage. Since most patients do not require antibiotics after drainage, cultures rarely provide clinically actionable information and incur unnecessary costs. My preference is to obtain cultures only in cases where an unusual infection (fungus, mycobacterium, MRSA, etc.) is suspected on clinical grounds or postoperative antibiotic use is anticipated due to significant perianal cellulitis or immunocompromised state of the patient.

I agree with the author that the best treatment for anal fistulae is fistulotomy, where feasible. However, simple fistulotomy can only be employed for the treatment of simple, subcutaneous, or intersphincteric fistulae and in selected cases of transsphincteric fistulae with minimal sphincter involvement. Treatment of complex, transsphincteric or extrasphincteric fistulae is a bit more challenging as simple fistulotomy in these cases would inevitably lead to compromised sphincter function. The author reports encouraging results with the use of cutting seton in this situation. In my experience, cutting setons are associated with significant pain which lasts several days after tightening the seton. I have found that local anesthetic infiltration is often necessary and many patients also require narcotics during the immediate period following the cinching of the seton. Furthermore, the procedure requires repeated office visits and interruptions in work resulting in poor patient satisfaction. For these reasons, I have abandoned this technique in favor of staged fistulotomy. This technique typically involves partial division of the fistula and a draining seton is left encircling the residual fistula tract. The patient is given some time to allow healing of the divided sphincter followed, typically in 2 to 3 months, by division of residual fistula tract.

Long-term data for anal plugs indicated recurrence rates as high as 70% to 85%. It appears that success rates are directly dependent on the length of fistula tract; those longer than 4 cm are likely to heal whereas short tracts, specially rectovaginal fistulae, inevitably experience a recurrence after plug insertion. These disappointing results have led to a significant reduction in interest in this modality.

Perhaps the most significant advancement in the field of anorectal surgery over the last decade is the introduction of LIFT procedure: ligation of intersphincteric fistula tract. This ingenious approach, first described in 2009, involves dissection in the intersphincteric plane, identification and ligation of

fistula tract in the intersphincteric groove, and curettage of distal tract. This approach results in sphincter preservation with excellent functional outcomes, however, a good number of patients require a second operation for treatment of intersphincteric fistula or a blind sinus tract. Regardless, LIFT has become the leading procedure for transsphincteric fistulae given its sphincter preserving ability.

Stapled hemorrhoidopexy, also known as procedure for prolapsed hemorrhoids (PPHs) was initially described by Dr. Longo in 1993. As is the case with many novel surgical techniques, the initial results were very encouraging leading to a rapid, widespread adaptation of this technique. Long-term results however, were not very supportive confirmed by recent publication of eTHoS trial, a large randomized trial comparing PPH to conventional hemorrhoidectomy. Given these findings, the initial interest in PPH has waned dramatically over the last few years.

Although not described in this chapter, transrectal hemorroidal dearterialization (THD) certainly deserves a mention here. This novel technique utilizes a Doppler-enabled anoscope to identify the feeding vessels which are then suture ligated. The results so far are comparable to conventional hemorrhoidectomy, however, there appears to be an increased cost associated with this procedure. Very few studies detailing long-term results are currently available.

The section on anorectal condyloma emphasizes the need for a complete screen due to possible coexistence of other STDs. I typically offer HIV screening to all patients with anogenital condylomas and cervical PAP smear to all females as many patients harbor a concomitant cervical HPV infection.

I feel it is imperative to assess structural integrity of sphincter complex with an endorectal ultrasound in all rectovaginal fistula patients. In my experience, many of these patients have sustained significant sphincter trauma and preforming an advancement flap alone will guarantee postoperative fecal incontinence. Instead, an anterior overlapping sphincteroplasty is the treatment of choice, which not only addresses the fistula but also assures optimal functional outcomes after surgery.

Rectal mucosal advancement technique described by the author differs from the standard approach to this operation in two aspects: first, the author describes creation of a flap utilizing full-thickness rectal wall rather than the mucosa alone and second, the author recommends coverage of the primary sinus opening with the lower (distal) mucosal flap rather than the conventional description of advancing the proximal mucosal flap over the sinus opening.

I concur with the author that conservative, nonoperative management is perhaps the best approach for mild perianal Crohn disease that presents with minimal symptoms. The importance of avoiding surgical intervention in these patients cannot be overstated; surgical intervention in many cases results in very slow healing or nonhealing wounds which may in turn be more symptomatic than patient’s original presentation.

No description of perianal Crohn's is truly complete without the mention of biologics. We now have excellent, level I evidence attesting to the efficacy of Infliximab against fistulizing perianal Crohn disease. My approach is to proceed with fistulotomy if the following conditions are met: the fistula is simple, does not involve sphincter complex, and there is no evidence of active proctitis. However, most fistulae in setting of Crohn disease are branching, complex fistulae often encompassing the sphincter complex thus precluding fistulotomy without risking fecal incontinence. In these cases, I proceed with placement of a seton followed by biologic therapy. Given the long lag period between initiation of biologics and clinical response, I typically keep the seton in place for about 8 weeks after the initiation of biologic therapy. Premature seton removal will result in treatment failure, conversely, leaving the seton in situ for a long period leads to epithelialization of the tract necessitating a complete coring out of the tract. I proceed with inducing "surgical remission" with a diverting stoma in cases where seton placement and biologic therapy fail to control symptoms. The patients are then maintained on biologic therapy for a period of 3 to 6 months before stoma reversal is attempted. However, the risk of recurrent Crohn's after restoration of bowel continuity remains very high and many patients with severe perianal Crohn disease ultimately require proctectomy.

Syed Husain

165 Transanal Excision of Rectal Neoplasms

Sam B. Atallah and John R.T. Monson

HISTORY AND EVOLUTION OF TRANSANAL EXCISION

Transanal excision of rectal neoplasms can be performed for removal of benign rectal neoplasms as well as appropriately selected early-stage rectal cancer. Transanal excision has evolved over the centuries. The first documented report of transanal excision of a rectal neoplasm was performed by Jacques Lisfranc (1790 to 1847) in the early 1800s, and was performed prior to Dr. William Morton's (1819 to 1868) discovery of general anesthesia in 1846. Lisfranc performed the operation on a 45-year-old male with a distal rectal neoplasm. The patient was fully awake, and the technique involved the introduction of a speculum with downward traction of the lesion and then the use of "strong short scissors" to circumferentially excise the lesion. The defect was not closed and significant hemorrhage was described. After 2 months in the hospital, the patient was discharged in good condition.

The modernization of surgery to include safe administration of general anesthesia and more sophisticated instruments has enabled transanal excision to develop from peranal techniques, including the Parks' approach and the transcoccygeal Kraske method, to more sophisticated platforms including transanal endoscopic microsurgery (TEM), transanal endoscopic operation (TEO), and transanal minimally invasive surgery (TAMIS). A comparison of these advanced transanal platforms is delineated in Table 165.1. More recently, robotic TAMIS using the da Vinci Surgical System has also been reported, and as next-generation single-port robotic platforms evolve, the role of robotic transanal surgery may increase further.

During the laparoscopic and minimally invasive era, there had been a trend toward minimizing the radicality of cancer surgery in an effort to create a better balance between risks and functional deficits associated with radical surgery and the potential oncologic inferiority of a local

excision. However, this trade-off is only viable if it results in acceptable oncologic outcomes. Conceptually, there has always been a dichotomy between two surgical approaches for curative-intent cancer surgery. In simple terms, they are (a) local excision (LE) that results in organ preservation and (b) standard oncologic resection (SR) that typically removes the entire organ and the associated lymph node basin. For some types of malignancies, LE is a proven method of therapy and examples include excision of dermal melanoma, anal margin early-stage (T1) squamous cell carcinoma, appropriately selected rectal neuroendocrine tumors, and so forth. Perhaps the closest cancer-paradigm to the management of early-stage rectal cancer is early-stage breast cancer, whereby negative margin excision of a tumor (i.e., breast-conservation surgery) coupled with external beam radiotherapy has been shown to render an overall survival equivalent to modified radical mastectomy.

TABLE 165.1 A Comparative Assessment of Advanced Transanal Platforms

TAMIS	TEM	TEO
Developed 2009	Developed 1984	Developed mid-2000s
Manufacturer Applied Medical/Covidien	Manufacturer Richard Wolf	Manufacturer Karl Storz
Disposable	Reusable	Resusable
Flexible	Rigid	Rigid
Low cost	Requires capital investment	Requires capital investment
Shallow learning curve	Steep learning curve	Steep learning curve
Advanced laparoscopic skill	Specialized TEM training	Specialized TEO training
High-quality local excision	High-quality local excision	High-quality local excision
Access to 15 cm	Access to 15 cm	Access to 15 cm
Applicable for transanal TME	Applicable for transanal TME	Applicable for transanal TME
360-degree view	220-degree view	220-degree view
2D monitor, 3D optional	Binocular (3D) or 2D monitor	Binocular (3D) or 2D monitor
Laparoscopic instruments	Specialized TEM instruments	Specialized TEO instruments
CO_2 laparoscopic or valveless	CO_2 using TEM apparatus	CO_2 using TEO apparatus
3.5–4-cm diameter	4.0-cm dia; 12/20-cm shaft	4.0-cm dia; 7.5/15/20-cm shafts
Patient positioned lithotomy	Patient positioned tumor down	Patient positioned tumor down
No evidence of sphincter injury	Transient sphincter injury reported	Transient sphincter injury reported
Nonbeveled	Beveled or straight	Beveled or straight

Typically, local excision of rectal neoplasia is performed via a transanal approach, but a trans-sacral approach for LE of rectal neoplasia has also been described and, although less frequently performed, is still considered a valid alternative to transanal excision. This technique was pioneered by Paul Kraske (1851 to 1930) in 1884 and hence trans-sacral excision is often referred to as the Kraske procedure. Today, the technique is reserved mostly for excision of presacral tumors and repair of rectourethral fistulae in males.

CLINICAL WORKUP

The extent of the clinical workup depends on the histopathology and endoscopic evaluation of the lesion. Benign neoplasms only require a completion colonoscopy to exclude synchronous lesions and consideration of endorectal ultrasound (ERUS) if there remains question of tumor invasion. Any lesion that is benign and not amenable to simple endoscopic retrieval is considered an appropriate candidate for LE, although lesions in the mid and proximal rectum require an advanced transanal platform as they carry an increased risk of peritoneal entry.

For lesions with proven or suspected invasion, ERUS is performed to determine clinical stage. Pelvic 3-Tesla (3T) magnetic resonance imaging (MRI) is a valid alternative to ERUS and is strongly recommended by many experts. The two modalities are often complementary, as ERUS, when performed by an experienced operator, provides excellent information about depth of invasion (T-stage) while rectal protocol 3T MRI provides a better assessment of nodal disease, although neither can accurately detect lymph node metastasis. Importantly, 3T-MRI can determine the status of the circumferential resection margin (CRM) and is thus preferred over ERUS for instances in which the tumor is locally advanced. Serum carcinoembryonic antigen (CEA) level and staging computed tomography (CT) body imaging are also performed to assess for distant tumor metastasis as recommended by national guidelines.

INDICATIONS AND CONTRAINDICATIONS

The indication for transanal excision includes benign neoplasia (e.g., tubular adenoma, villous adenoma) that is not amenable to simple endoscopic retrieval. This also includes neuroendocrine tumors that are ≤1 cm in diameter, or other neoplasms of unknown histology (such as submucosal lesions). Highly selected early stage I rectal cancers can also be removed via the transanal approach provided they are histologically favorable. Thus, the most appropriate lesion for local excision would be a cT1 sm1 lesion that does not exhibit lymphovascular invasion, poor differentiation, and which does not harbor mucinous features on histology. This is particularly true for invasive neoplasms confined to the distal one third of the rectum, because SR carries considerable morbidity and bowel function is often significantly altered postoperatively. Tumors of the proximal one third—even early-stage tumors otherwise fit for local excision—are best managed by SR in fit patients.

Data from the late 1990s including the Cancer and Leukemia Group B (CALGB) 8984 suggested that more advanced stage I lesions such as T2 lesions (which by definition penetrate the submucosa) could be managed by LE and subsequent external beam radiotherapy. However, in clinical practice, T2N0 lesions that were excised locally and treated with adjuvant radiotherapy resulted in an unacceptable rate of local recurrence suggesting that some form of addition therapy is required for cancers beyond the most favorable T1 lesions. More recently, trials on neoadjuvant chemoradiation followed by local excision have been performed with mixed results. In recent years, numerous trials have been either completed or commenced to assess clinical outcomes of neoadjuvant radiation followed by local excision of T2 cancers. These are the ACOSOG Z6041, UK-TREC (TEM and Radiotherapy in Early Rectal Cancer), and the CARTS study (Chemoradiation Therapy for Rectal Cancer in Distal Rectum Followed by Organ-Sparing TEM). Current guidelines recommend that, except for patients enrolled in a study protocol, T2 lesions should be managed by an SR unless the operation is for palliation and/or the patient is too infirm to undergo major abdominal surgery. Single-center experience led by Lezoche (Rome, Italy) has demonstrated that T2N0 lesions that were randomized to undergo upfront chemoradiation followed by LE using TEM versus upfront chemoradiation followed by SR had no difference in survival or loco-regional recurrence rates.

In general, the LE of malignant neoplasia is generally recommended only for patients with histologically favorable, early-stage malignancy (uTis or uT1uN0M0 cancer). More advanced lesions require SR (APR vs. LAR) except in patients who are not medically fit to undergo major surgery. Patients with stage IV disease or locally advanced lesions are not candidates for LE unless the objective is palliation.

SPECIAL CIRCUMSTANCES AND CONTROVERSIES

Accept for palliation, LE is not typically considered an option for locally advanced rectal cancer. However, in patients who have undergone neoadjuvant chemoradiation and have achieved complete pathologic response (cPR), consideration for LE of the tumor scar for the purpose of confirming mural sterilization (ypT0) has been suggested by some authors who plan to enroll patients in a so-called “watch-and-wait” program. Some experts argue that the morbidity from LE of a radiated scar (which often

results in wound dehiscence) can be avoided, especially since cT0 can be sufficiently determined by endoscopic evaluation and additional imaging such as MRI or positron emission tomography (PET) scanning if necessary. Furthermore, mural sterilization does not imply nodal sterilization and approximately 6% to 8% of ypT0 lesions will have node-positive (ypN1) disease on final pathology after SR.

Other special problems relate to confounding variables. For example, in patients who present with synchronous rectal and sigmoid cancer, the overall approach should be determined by the tumor characteristics, staging, and MRI results. There can be a role for LE under special circumstances. For example, a distal T1N0 sm1 histologically favorable adenocarcinoma with a synchronous mid sigmoid adenocarcinoma can be treated by LE for and anterior resection of the sigmoid cancer. Such an approach would spare the patient from the otherwise significant risk of morbidity from pelvic surgery. Specific treatment should be individualized, and it is recommended that all newly diagnosed rectal cancer be presented at a multidisciplinary tumor board.

Controversy regarding LE for rectal cancer remains, as even favorable pT1 lesions have a higher recurrence rate when they are locally excised compared to SR, probably because of occult nodal disease as current imaging techniques (MRI and ERUS) will not detect one third of nodal metastasis, thus understaging a significant portion of patients who would otherwise be recommended to undergo radical resection or at least adjuvant therapy. There may be other factors as well, including the technique used for excision (discussed later). Ultimately, SR for even early-stage rectal cancer still provides lower rates of local recurrence and possibly survival than LE. Thus, the argument for LE is not that the approach is oncologically equivalent to SR, but rather that spares patients the morbidity of a pelvic dissection.

Controversy also remains concerning proximal rectal cancer LE that intentionally violates the peritoneal cavity. Typically, LE for cancer requires a full-thickness excision and removal of a small portion of the mesorectum that lies deep to the tumor. Conventional therapy argues that, from an oncologic standpoint, violating the peritoneum and a noncomplete excision of the mesorectal envelope defy the basic principles of oncologic surgery. Therefore, most experts believe that proximal invasive lesions (T1 cancers between 10 and 15 cm from the anal verge) should be managed by SR and not LE.

PREOPERATIVE PLANNING

Localization of the tumor is critical in determining the general approach to LE. Rigid proctosigmoidoscopy remains the preferred method of determining the tumor's anatomic position with the two key variables being (a) distance from anal verge (or more precisely anorectal ring) and (b) position of the tumor relative to rectal wall and pelvis (e.g., anterior versus posterior). In general, tumors distal to the mid rectal valve are within 10 cm from the anal verge, and thus lie beneath the peritoneal reflection. Thus, proximal to 10 cm (especially for anterior tumors) the operating surgeons should be prepared to manage the closure of a peritoneal entry. This can be accomplished using an advanced transanal platform, but may require laparoscopic assistance for a layered closure and possible placement of a pelvic drain, which is left to the surgeon's discretion.

As described in the section on surgical technique, the patient positioning is sometimes determined by the transanal technique used to perform the excision, and thus it is important to have knowledge of the tumor's position prior to initiating LE.

Preoperatively, patients undergo a mechanical bowel preparation and the administration of parenteral antibiotics less than 30 minutes prior to surgery (e.g., single-dose ertapenem 1 g intravenously). The operation can be completed under general or rarely spinal anesthesia. Most often, particularly when an advanced transanal platform is used and where pneumorectum is essential, general anesthesia with endotracheal intubation is recommended with full muscle paralysis to avoid collapse of the rectal wall (bellowing), which often occurs with diaphragmatic excursion and which is at least partially offset by positive pressure ventilation.

SURGICAL TECHNIQUE

Parks' Transanal Excision

Sir Alan G Parks (Royal London Hospital and St Mark's Hospital, London) described Parks' transanal excision (TAE) in 1968 with a very brief communication of less than two pages that described the technique of full-thickness excision using a ratcheting transanal retractor made of steel and designed for transanal access and exposure. Nowadays, this is referred to as the Parks' retractor and the conventional transanal excision is referred to as the Parks' TAE. In the same report, Parks described the

sleeve excision used for a circumferential villous adenoma, but in his original description of the sleeve excision, an abdominal approach was also used to mobilize the rectosigmoid colon and deliver it through the denuded segment after excising the entire mucosa (leaving in situ the rectal muscle tube) from the portion of rectum containing the neoplasm. Today, advanced transanal platforms, which offer improved reach, allow surgeons to perform the entire sleeve excision from below and thereby obviate the need for abdominal access. Thus, the Parks' TAE is most typically used for full-thickness excision of rectal neoplasia and is increasingly being replaced by the advanced platforms.

The technique of excision requires obtaining exposure with the self-retaining retractor with three steel blades inserted in the rectal vault transanally. There are secured to a ratcheting device that allows for the incremental separation of the blades, which increased the exposure. Typically, this allows for reach to 6 to 7 cm from the anal verge. With the retractor in position and the patient positioned prone-jackknife for anterior lesions and in high dorsal lithotomy for posterior lesions, the Parks' TAE is carried out under direct vision using monopolar cautery or sharp dissection depending on surgeon preference. The objective is full-thickness excision with 1-cm negative margins (Figs. 165.1 and 165.2). Once excised, the lesion is oriented and pinned out and sent to pathology for margin analysis (Fig. 165.3). The surgical defect is then reapproximated using absorbable suture, although some experts believe that closure is not required for small defects in the subperitoneal rectum (Fig. 165.4).

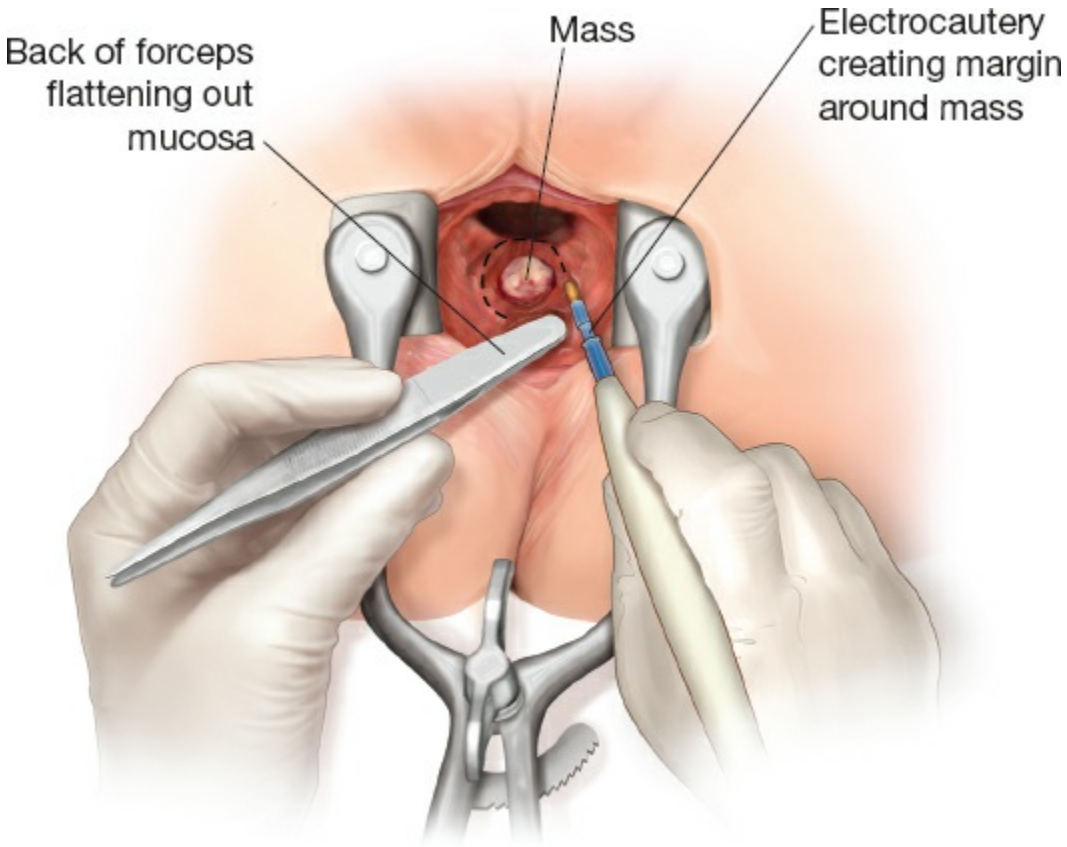

Figure 165.1. Defining the surgical margin. Once adequate exposure is obtained, electrocautery is used to mark out the surgical margin: 1 cm for malignant lesions and 0.3 cm for benign lesions or those of indeterminate pathology. Because mucosal folds can obscure the true margin and lead to a margin that is lesser or greater than intended, using the back of a DeBakey forceps or a handheld retractor such as the Hill-Ferguson retractor can help flatten the mucosal folds, so an appropriate margin can be defined. (Reproduced from Albo D, Mulholland MW. *Operative Techniques in Colon and Rectal Surgery*. Philadelphia, PA: Wolters Kluwer Health; 2015.)

Until the early 1980s, the Parks' TAE was the only method of full thickness excision of rectal neoplasia. Alan Parks (1920 to 1982) died after emergency cardiac surgery and did not live to see the evolution of the TEM era that began shortly after his death.

Transanal Endoscopic Microsurgery (TEM)

Prior to TEM, there was a limited ability to remove benign polyps of the mid and upper rectum using an operating rigid proctosigmoidoscope capable of delivering a snare and allowing for snare polypectomy of benign neoplasia. Gerhard Friederik Buess (Tubingen, Germany; 1948 to

2010), in 1983 and in collaboration with the Richard Wolf Company in Germany, developed a more advanced instrument that melded important principles into one very functional apparatus. TEM was undoubtedly precocious for many reasons. First, TEM utilized instruments very similar to those used for laparoscopy prior to the era of laparoscopic general surgery. Second, the TEM interface was essentially a multichannel single-port, yet this single-port laparoscopy was not developed until decades later in the 2000s. Third, it employed a magnified stereoscopic (three-dimensional [3D]) optical system, which is currently the most advanced vision system employed by laparoscopic systems and is currently the standard vision used on all robotic platforms. Finally, it utilized a sophisticated insufflation system that would allow for the optimal regulation of CO_2 within the rectal lumen and thus provide for stable pneumatics within a small volume. Thus, Gerhard Buess' TEM apparatus unified key technological components into a system that was so durable that it would essentially remain unchanged for three decades and today it is still considered by most the gold standard in allowing for very precise, high-quality LE of rectal neoplasia (Fig. 165.5).

The original indication for TEM was for the local excision of benign neoplasms, and not malignant lesions, with a strong emphasis on using TEM for lesions localized to the mid and upper rectum, as these were out of the range of what could be excised using a conventional Parks' TAE approach. With experience, however, the local excision of early-stage rectal cancer using TEM, particularly for highly selected T1 cancers within the mid and even upper rectum was adapted and during the 1990s this became an acceptable, and perhaps even preferred method of curative-intent surgical treatment. Thus, TEM offered an improved quality for local excision and access to the proximal two thirds of the rectum.

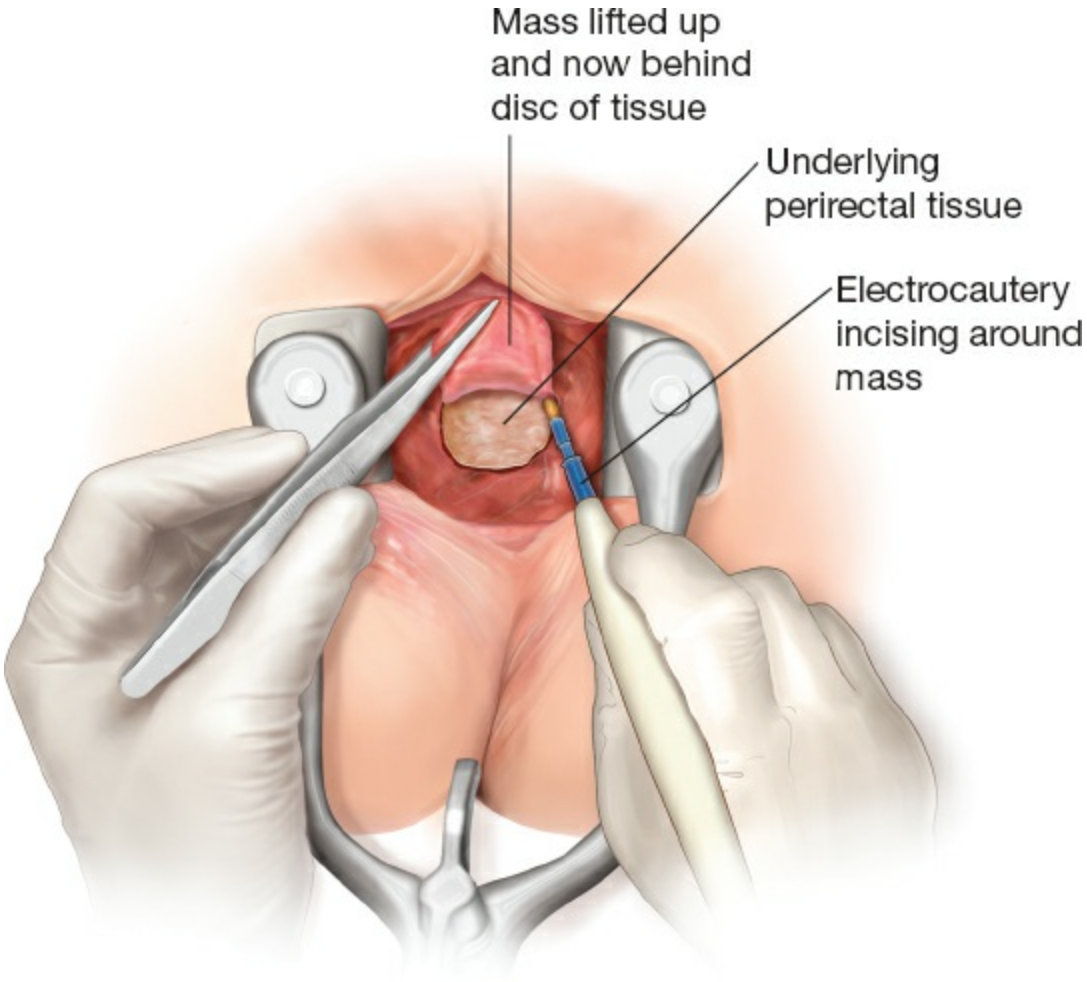

Figure 165.2. Full-thickness excision of the mass. Electrocautery is used to create a full-thickness defect through the rectal wall until the perirectal fat is identified. It is easier to begin at the most distal aspect of the lesion because visualization is better. Once the full-thickness defect is created, the free edge of tissue or a retraction suture is grasped to lift the mass and normal tissue away from the underlying perirectal fat as the excision proceeds proximally along the lateral aspects of the lesion, leaving the most proximal part of excision for last. (Reproduced from Albo D, Mulholland MW. *Operative Techniques in Colon and Rectal Surgery*. Philadelphia, PA: Wolters Kluwer Health; 2015.)

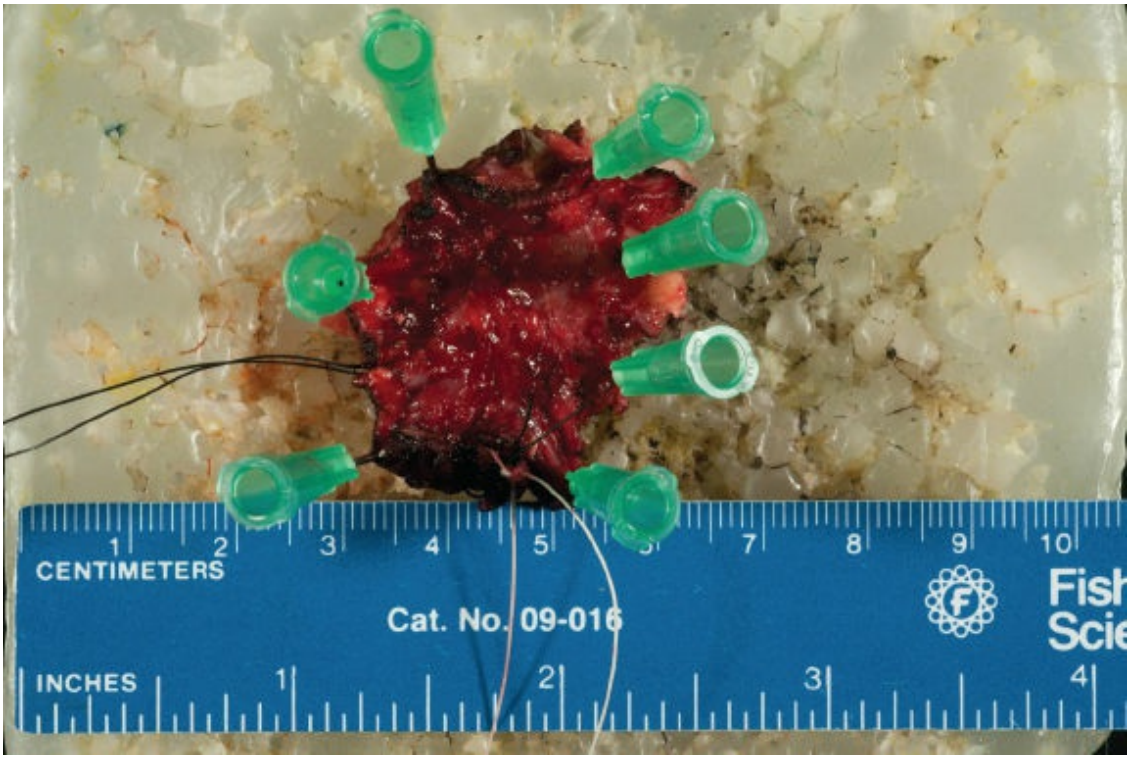

Figure 165.3. Submitting the specimen to pathology. The resected specimen is then secured to a wax board with 22-gauge needles for proper orientation. Because orientation sutures were placed early in the case, there should be no confusion about the specimen orientation. The surgeon then brings the specimen to the pathology suite to confirm orientation with the pathologist and the margins are inked and assessed. If tumor cells are present at any of the margins, additional tissue must be removed. (Reproduced from Albo D, Mulholland MW. *Operative Techniques in Colon and Rectal Surgery*. Philadelphia, PA: Wolters Kluwer Health; 2015.)

While the TEM equipment requires a significant up-front capital investment, the cost-savings argument has been proposed that if lesions could be locally excised with TEM and the need for SR is obviated, then the per-case cost of the operation is significantly lower ($7,775 with TEM vs. $34,018 for low anterior resection based on a study by Cocilovo et al.). More importantly, the significant potential for morbidity from SR—including diminished rectal function due to loss of the rectal reservoir and potentially autonomic nerve injury for the dissection, sexual and bladder dysfunction, possibility of a permanent (and often temporary stoma), and potential for sepsis from anastomotic leak—is negated by the use of TEM.

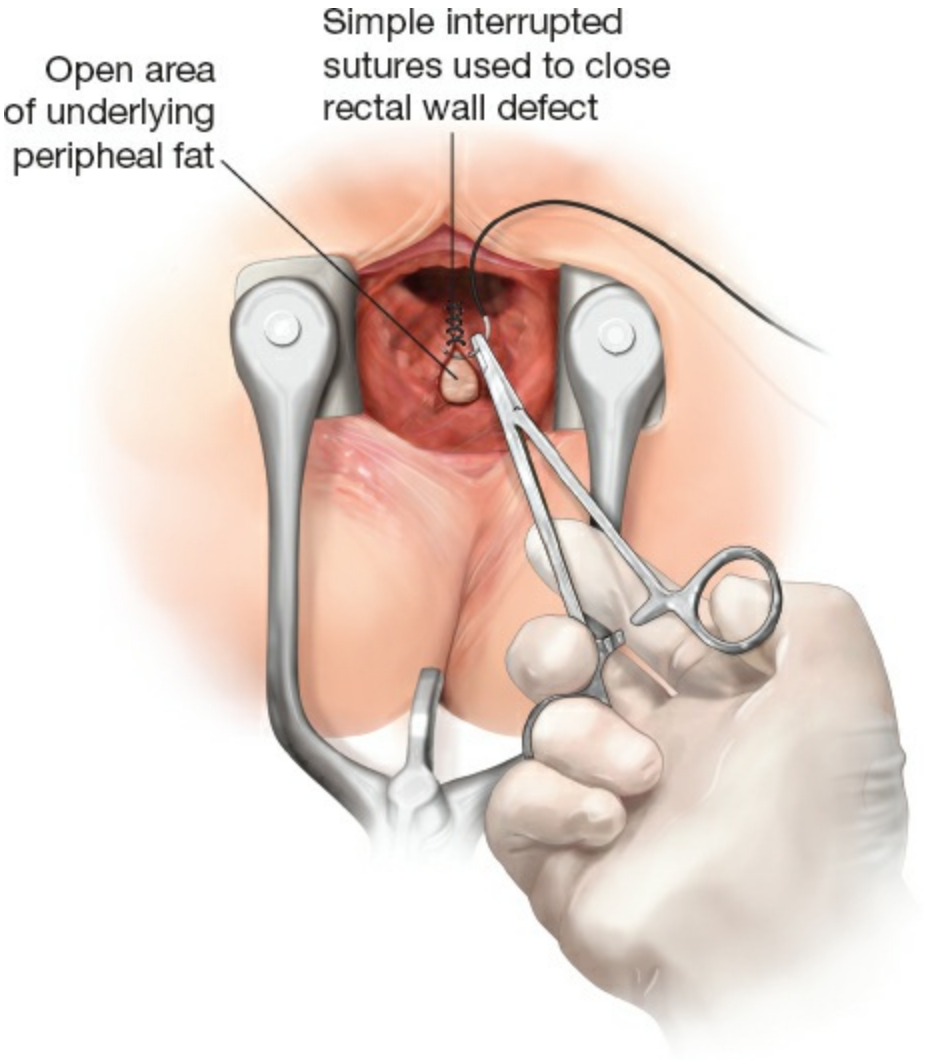

Figure 165.4. Closure of the rectal wall defect. **A.** After appropriate hemostasis is obtained, the rectal wall defect is closed with a 2-0 Vicryl suture. (Reproduced from Albo D, Mulholland MW. *Operative Techniques in Colon and Rectal Surgery*. Philadelphia, PA: Wolters Kluwer Health; 2015.)

TEM Technique and Equipment

The TEM equipment consists of three major components. They are the (1) operating rectoscope (including shaft and faceplate), (2) the optical stereoscope, and (3) the specialized long-shaft instruments that closely resemble laparoscopic instruments, except that the tip has a slight angulation (typically a downward and inward deflection at the instrument's tip making them right or left handed) that facilitates maneuverability within the rectal lumen. Additional components include a stabilizer clamp (Martin's Arm) that attaches to the bed rail and maintains a fixed orientation and a specialized insufflation system designed for

providing pneumorectum and is intended to create gaseous distention within a much smaller volume than the abdominal cavity.

The rectoscope shaft measures 4 cm in diameter and has a beveled end (or optional straight end); the available shaft lengths are 12 cm and 20 cm. An airtight multichannel faceplate allows the admission of four instruments via four sealed and capped rubber sleeves. Through these four ports, the optical lens (6× magnified and stereoscopic), suction device, and two 5-mm long-shafted TEM working instruments are introduced to facilitate LE. The surgeon is able to operate with a 3D view using the stereoscopic eyepiece or with an accessory monocular scope. This optical feed can be transmitted to a standard LCD video monitor. The 5-mm instruments most typically used include right (or left) curved graspers, endoscopic scissors, a needle driver, and a monopolar cautery knife.

As with all transanal excisions, preoperative preparation for TEM includes either full mechanical bowel preparation or alternatively two cathartic enemas on the day of the procedure. Systemic antibiotics should be administered, but a Foley catheter is usually not required. The preoperative planning also requires rigid proctosigmoidoscopy to determine the anatomic position of the lesion to be resected. This is important with TEM, because the patient must be positioned such that the lesion is dependent (at the 6 o’clock position). For example, if the lesion is along the left lateral sidewall at the level of the mid rectum, the patient will be placed in the left lateral position.

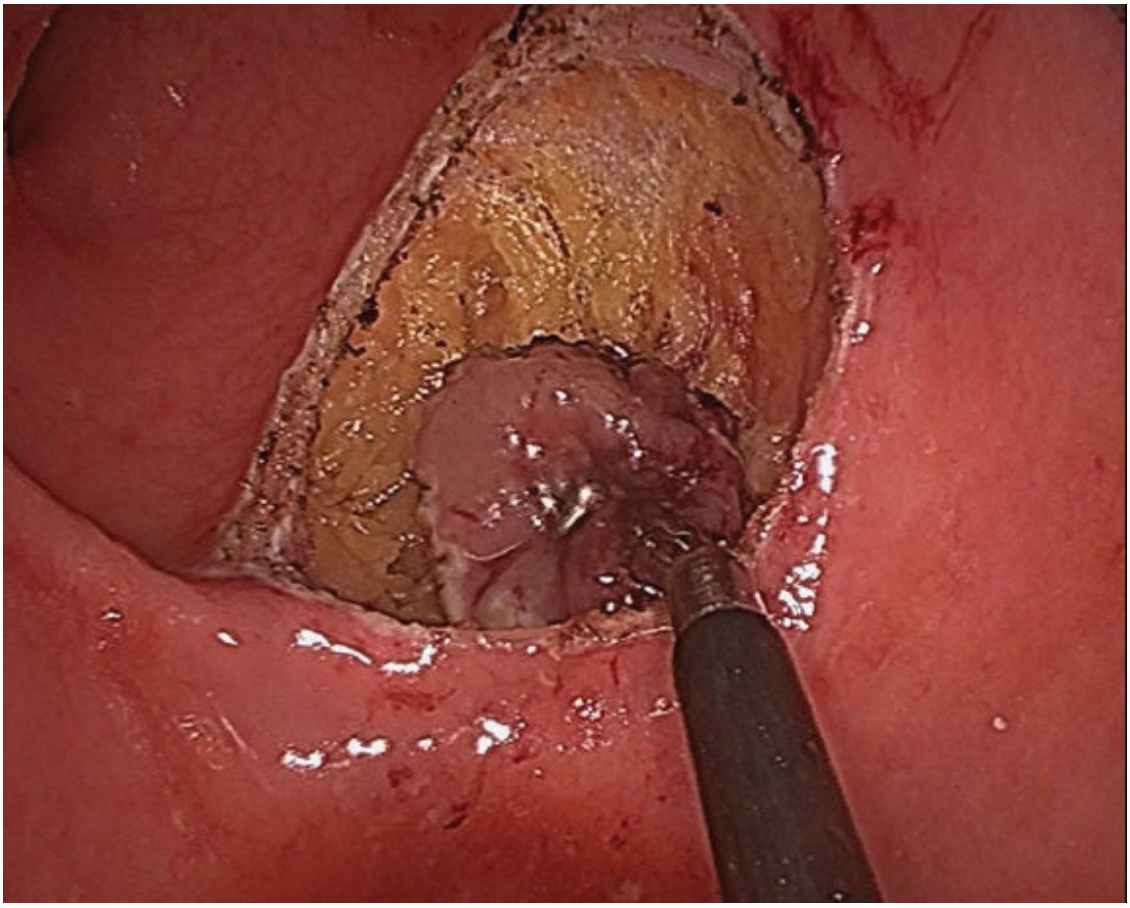

Figure 165.5. The operative picture shows the full thickness circumferential dissection of a malignant lesion with a 1-cm margin all around. Notice that the dissection is carried through the entire rectal bowel until the yellow fat of the perirectal tissues is reached. (Reproduced from Albo D, Mulholland MW. *Operative Techniques in Colon and Rectal Surgery*. Philadelphia, PA: Wolters Kluwer Health; 2015.)

After proper positioning, the rigid rectoscope is gently introduced with the aid of an obturator. The obturator is withdrawn and pneumorectum is established. When the lesion is visualized, the TEM rectoscope is secured via the Martin Arm to the operating table rail. Although this secures the platform, frequent subtle repositioning of the rectoscope is often necessary during local excision with TEM to maintain a clear view of the operative field.

Once the instruments are introduced and the target lesion identified, the operating surgeon works to perform an LE. The first and critical step in TEM local excision is to determine the excision margin by marking with cautery the perimeter of the lesion. An accepted negative margin is 1 cm for malignant lesions, and typically 5 mm for benign neoplasms. However,

most authors will accept any negative margin. Therefore, surgeons will not perform reexcision for lesion resected with a close but negative margin, and further intervention in this scenario is seldom necessary.

Because there can be uncertainty about whether or not a benign neoplasm harbors an invasive component, most experts believe that for lesions within the extra peritoneal rectum, a full thickness excision is required. For benign, typically small lesions that involve the intraperitoneal portion of the rectum whereby the morphologic appearance and preoperative biopsy do not suggest malignancy, then a partial thickness, submucosal excision can be performed to decrease the probability of peritoneal entry. If the peritoneum is inadvertently entered, the defect can be closed using the TEM suturing device. If the patient is appropriately positioned (such that abdominal access is practical), then a laparoscopic-assisted approach can also be performed to reapproximate the defect with a two-layered repair, although this is usually not necessary.

For early-stage T1 lesions in the upper one third of the rectum whereby peritoneal entry is likely and full thickness excision is mandatory, consideration for a low anterior resection rather than local excision with TEM should be given. This is especially true because morbidity from a minimally invasive anterior resection in this segment has significantly less morbidity than for resections of the lower portions of the rectum.

Circumferential adenomas that carpet the rectum are often resected as a mucosal sleeve preserving the underlying rectal muscle tube, utilizing the same technique described by Sir Alan Parks. TEM can be used to perform an anastomosis, but if the excision does not violate the peritoneal cavity and is confined to the subperitoneal rectum, it can be left open to granulate and heal by secondary intention.

The techniques for closure after excision with TEM typically utilize absorbable monofilament suture (such as 3-0 polydioxanone) in combination with silver clips secured to the suture to minimize the need to perform knot tying with TEM, which is arduous for even adept surgeons. Alternatively a self-locking suture can be used. As stated previously, closure of the surgical wound for any partial thickness defect or any subperitoneal full-thickness excision is not mandatory, and some authors do not routinely close these defects after TEM. It is strongly recommended by pathologists that the fresh specimen be pinned out and oriented prior to submission (Fig. 165.3). This greatly facilitates the accuracy of specimen interpretation. For defects that have been closed, and when a margin for a

malignant lesion is found to be positive, then most experts will reexcise the scar or consider rescue radical rectal excision. Thus, the specific margin that was positive is not relevant, as all margins will have become incorporated into the scar itself.

Transanal Endoscopic Operation (TEO)

TEO is a rigid, reusable advanced transanal platform similar to TEM and is indicated for LE of rectal neoplasms, which are 2 cm to 15 cm from the anal verge. This device, manufactured by Karl Storz-Endoskope (Tuttlingen, Germany), is available in three beveled shaft lengths—7.5 cm, 15 cm, and 20 cm. The outer diameter of TEO is the same as outer diameter of TEM and measures 40 mm. The optics for TEO relies on a forward-oblique telescopic 30-degree angled eyepiece, with diameter 5 mm. Like its analogue TEM, the TEO utilizes a stabilization arm, which affixes to the operating tableside rail to firmly secure the TEO scope and prevent movement once it has been inserted transanally. The working instruments (WEXNER Operating Instruments) consist of specialized 5-mm devices with unique distally curved design and specialized effector arm handles that are intended to facilitate operating within the narrow confines of the rectal lumen. The rigid platform is also intended to be used with a specialized CO_2 insufflation system (ENDOFLATOR 40 SCB), which provides a stable pneumorectum.

The technique of TEO is similar to that of TEM, and the two are considered analogues of one another although TEO does not offer true binocular vision or “steady-state” insufflation. An appropriate shaft length for the TEO scope is first selected based on the distance of the lesion from the anal verge, with long shaft (15 cm/20 cm) typically selected for proximal one-third rectal neoplasms. The patient is prepared as described previously, and the tumor is positioned dependently. The anus is gently dilated, and the shaft is then introduced with the aid of an obturator. Once the TEO scope is in place, it is secured to the operating table rail and connected to the video feed so that the image can be transmitted to an LCD monitor for viewing. An eyepiece is also available so that the surgeon can operate under direct vision without videoscopic assistance. The specialized instruments are then used to perform the LE in a manner similar to TEM.

Transanal Minimally Invasive Surgery (TAMIS)

TAMIS was developed in 2009 as a consequence of advancement in

laparoscopic surgery and was based on the need to provide surgeons who did not have access to TEM and TEO with the ability to perform advanced transanal surgery for the LE of rectal neoplasia. In the mid- to late 1990s, both surgeons and industry began looking at methods to improve laparoscopic abdominal access. Among the important refinements in laparoscopy was the ability to decrease instrument size to 5 mm without detracting from function, and thereby decreasing abdominal access trauma. Another important development occurred in 2004 when Anthony Kalloo and colleagues performed the first transgastric peritoneoscopy in a porcine model and soon afterward Rao and Reddy performed the first transgastric appendectomy in a human, heralding a new era in minimally invasive surgery. The advancements would lead to steering committees and working groups that would describe this next-step in minimally invasive surgery as Natural Orifice Trans luminal Endoscopic Surgery, or NOTES. Industry manufactures and surgeons then began to explore abdominal access with a different viewpoint. In particular, the concept of trans-umbilical access as a kind of “embryonic” or E-NOTES was born. In fact, one-wound trans-umbilical laparoscopy for appendectomy had been described as early as 1992 by MA Pelosi et al.; but, now with the impetus of E-NOTES, industry developed multi-channel laparoscopic ports that could essentially combine three or more 5-mm ports into a single platform. Introduced at the umbilicus, a multichannel, disposable port could be used to perform an appendectomy, cholecystectomy, and even colectomy with the specimen retrieved via an embryonic natural orifice. Today, fewer surgeons refer to single-port surgery as E-NOTES, and the same device can be used elsewhere in the abdomen with essentially the same cosmetic outcome. Interestingly, surgeons have not been successful in demonstrating a true advantage to single-port laparoscopy over conventional laparoscopy, and some argue that the rate of hernia formation for general surgical procedures may be higher than with conventional multi-port laparoscopy.

Notwithstanding, the development of the multichannel port and its availability led to colorectal surgeons pioneering its use as a platform for transanal access—an approach now known as TAMIS. Because of its versatility and availability, TAMIS has become an important method for accessing the rectum for LE. The platform does not require an upfront capital investment and relies on ordinary (reusable) laparoscopic equipment and standard CO_2 insufflation machines used in laparoscopy.

TAMIS is perhaps the best application for the multichannel single-port device. Ironically, however, this application was never intended by the original manufacturer design. As TAMIS became a practical and cost-effective alternative to the rigid platforms (TEO and TEM), manufactures have now begun to develop ports specific for this application. In the United States, there is one multichannel port that has been specifically designed and FDA-approved for advanced transanal surgery (GelPOINT Path, Transanal Access Platform, Applied Medical, Rancho Santa Margarita, CA, USA). Currently, the only other FDA-approved device for transanal access is the Single-Incision Laparoscopic Surgery PORT (SILS Port, Covidien, Minneapolis, MN, USA). This port was the original port used to perform the first TAMIS operations, when the technique was pioneered on June 30, 2009.

TAMIS Operating Room Setup

Patient preparation includes mechanical bowel prep and the administration of parenteral antibiotics less than 30 minutes preoperatively (our preference is single-dose ertapenem 1 g intravenously). Patients should be positioned dorsal lithotomy in candy-cane stirrups. This is preferred, regardless of the position of the lesion in the rectal wall. The operating room should be fitted with standard laparoscopic equipment, including light source, video monitor, and CO_2 insufflator. We strongly recommend general anesthesia with muscle paralysis to avoid collapse of the rectal wall, which often occurs with diaphragmatic excursion. Unlike TEM and TEO, which can be completed via a single-surgeon approach, TAMIS does require an experienced assistant to operate the camera and direct the visual field as the TAMIS surgeon operates.

TAMIS Surgical Technique

Either a single-incision laparoscopy surgery port (SILS Port, Covidien) or the GelPOINT Path (Applied Medical, Rancho Santa Margarita, CA, USA) (Fig. 165.6) is deployed into the anal canal with lubricant and gentle maneuvering. These ports are seated with the inner lip just above the anorectal ring. Once in place, three cannulas allow access to the rectum so that TAMIS can be performed. Using a standard laparoscopic tower, pneumorectum with high-flow cycled CO_2 is established with the pressure maximum set to 18 mm Hg. This is achieved via an insufflation-dedicated cannula. Alternatively, a valve less trocar system can be adapted to the

TAMIS platform using a specialized trocar and insufflation system (AirSeal ConMed, Inc. Milford, CT, USA). Such a system helps decrease smoke and keeps the operative field clear. Because the system can regulate pressure and CO_2 insufflation separately, the pneumorectum is more stable with less billowing of the rectal wall during LE.

The current TAMIS platforms allow admission of both 5-mm and 10-mm devices. Once the port is placed, standard laparoscopic instruments, including graspers, thermal energy devices, and needle drives, can be used to perform the procedure. A 5-mm 30- or 45-degree angled camera lens is inserted, and triangulation of the instrument facilitates the surgical dissection.

The first step with TAMIS for LE is to demarcate the perimeter of the lesion (Fig. 165.7), providing an appropriate negative margin. As with TEM and TEO, this is done using electro cautery to circumscribe the lesion. Simple short bursts of suction using a laparoscopic suction irrigator device maintain image clarity quite well. The specimen may be tented gently using a grasper and electro cautery on a spatula tip or needle tip allows for full-thickness excision. As with all advanced transanal platforms, the CO_2 insufflation provides a natural "pneumodissection," thereby clarifying the plan of dissection during LE.

Using this approach, TAMIS permits for margin-negative full-thickness local excision, and allows for a portion of the mesorectum to be removed with the specimen in the majority of cases (Fig. 165.8). Once the excision has been completed, the specimen can be retrieved by removing the SILS port, or by simply removing the lid of the GelPOINT Path platform. Depending on surgeon discretion, the specimen may be sent to pathology intraoperatively, so that clear margins can be established.

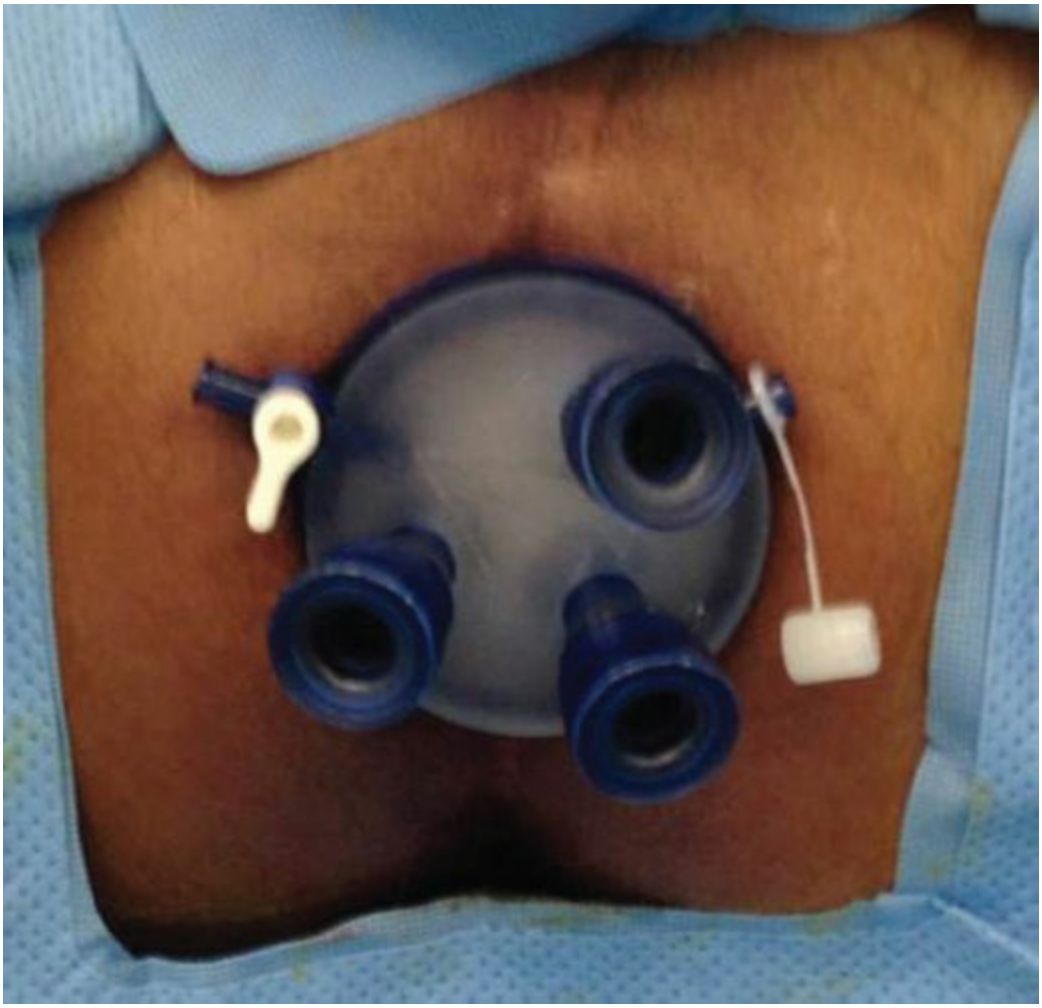

Figure 165.6. Transanal access device with cap and ports inserted into anal canal. (Reproduced from Albo D, Mulholland MW. *Operative Techniques in Colon and Rectal Surgery*. Philadelphia, PA: Wolters Kluwer Health; 2015.)

Next, the TAMIS platform is reintroduced and suturing of the rectal wall defect is performed, typically with absorbable suture. This is facilitated by gently bending a swaged needle to permit admission through one of the 5-mm cannulas or by using an available 10-mm cannula, which does not require skiing of the needle. Securing knots intraluminally is done with the help of standard laparoscopic knot pusher. Alternatively, automated suturing devices such as the EndoStitch (Covidien) or RD 180 (LSI Solutions) can be used to perform endoluminal suturing (Fig. 165.9). When coupled with Lapra-TY (Ethicon) or 5-mm TK (LIS Solutions), the suture can be secured without intraluminal knot tying. Generally, it is preferred to close the rectal wall defects after excision, and this should be done transversely (when feasible) to prevent luminal narrowing.

MANAGEMENT OF COMPLICATIONS

Operative complications of transanal local excision are not common, but have been reported to occur in 6% to 30% of cases. The most significant intraoperative complication of full-thickness LE in the proximal one third of the rectum is peritoneal entry. With TEM and TAMIS, the rate ranges from 0% to 9%, depending on the series. Peritoneal entry rates are biased by the level of the lesion and whether or not a full thickness excision was performed. For TAMIS, the mean peritoneal entry rate has been measured

at 1.025%.

Overall, this is a special complication specific to the use of advanced transanal platform (TEM/TEO/TAMIS) since the intraperitoneal rectum is not accessible by conventional TAE. Inadvertent peritoneal entry can be managed by performing a two-layered sutured repair, either using suturing techniques from below or in combination with laparoscopic assistance. Some authors prefer the abdominal approach to assess the degree of peritoneal entry and rule out collateral damage to surrounding viscera.

Except for instances in which the bowel has been irradiated, dehiscence of the surgical wound after layered repair is quite uncommon, although patients should be admitted and monitored for 24 hours or longer depending on clinical course. The primary symptom reported by patients with dehiscence of the surgical wound after LE is pain at the operative site.

Dehiscence of the rectal wall closure is most likely to result in patients who have received neoadjuvant external beam radiotherapy, for example, for patient who have a cPR after upfront chemoradiation. Under study protocol including ACOSOG Z6041 and the UK-TREC trial, stage I rectal cancer (uT2N0 lesions) was treated with upfront radiotherapy prior to local excision. In these instances, the rate of dehiscence is high, and typically occurs between 5 and 7 days postoperatively.

Some authors have described techniques to decrease the risk of wound dehiscence including postprocedure catheter drainage (using a Foley catheter in the rectum) and applying fibrin glue into the base of the excision site prior to sutured closure in an effort to minimize dead-space. Adjuvant antibiotics have also been used. All together, no proven benefit has been established for these approaches and benefit remains anecdotal. Wound dehiscence is most typically managed expectantly with hospital admission and pain control. Bowel rest, intravenous fluid hydration, and oral or intravenous analgesics are used. Reintervention is reserved for patients who develop systemic signs of infection or sepsis. Rarely, surgical debridement and diversion of the fecal stream are required.

Fistulization to the vagina after local excision of an anterior rectal neoplasm has been described in females. In males, it is difficult to injure the prostatic urethra and this is less of a concern with LE. However, more radical resection such as transanal TME using TAMIS, TEM, or TEO for rectal cancer can lead to injury of the preprostatic urethra when the dissection from below commences in the distal 3 cm of the rectum.

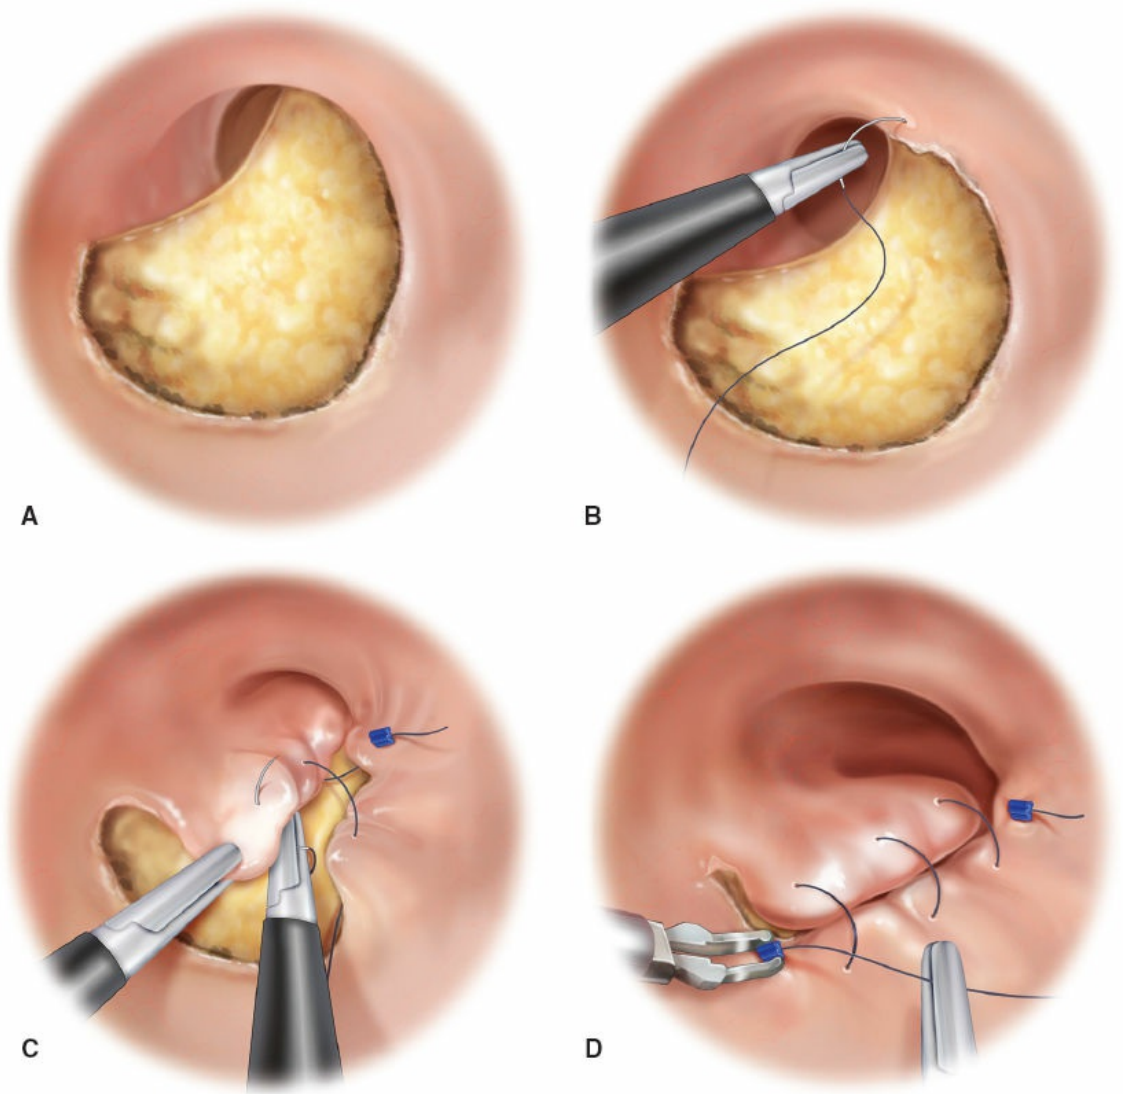

Figure 165.9. Suture repair is completed transversely from right to left (surgeon's dominant to nondominant side). The sutures are secured on both ends with Lapra-Tys. A single running suture or two to three shorter running sutures may be used. (**A–D**) demonstrate progression of suture repair. (Reproduced from Albo D, Mulholland MW. *Operative Techniques in Colon and Rectal Surgery*. Philadelphia, PA: Wolters Kluwer Health; 2015.)

Fistulization to the vagina after local excision is first managed expectantly with tap-water enemas with or without antibiotics (depending on whether or not there is a local septic process). Definitive treatment depends on the level of the fistula, with proximal fistulas approached transabdominally and often the fistula is taken down with an omental interposition placed in the recto-vaginal septum.

Lower-third fistulae are best managed via a local procedure, such as a transvaginal or transperineal flap repair. Patients who have received prior

radiotherapy to the pelvis or who are immunocompromised or otherwise deconditioned will require diversion of the fecal stream prior to planned repair of the fistula regardless of approach.

Other morbidity includes pneumodissection of tissue planes when an advanced transanal platform in utilized. This can lead to subcutaneous emphysema, particularly of scrotum; however, crepitation to the level of the neck has been observed. Patients are usually asymptomatic and no treatment in indicated. The symptoms resolve without further sequelae. Occasionally, pneumatic dissection with TAMIS/TEM/TEO can lead to retroperitoneal air and even “free” intraperitoneal air. If pneumoperitoneum is realized at the time of transanal surgery, diagnostic laparoscopy is indicated to exclude an occult rectal wall injury that violates the peritoneal cavity.

Bleeding can occur after LE regardless of the surgical approach used. Postoperative hemorrhage usually will result from submucosal arterial bleeding and has been reported to occur 1% to 10% of the time. Most often postoperative hemorrhage is managed expectantly; however, persistent hemorrhage mandates evaluation and most authors would recommend evacuation of retained rectal clot to prevent further bleeding.

Infection of the surgical site after local excision is infrequent. Pelvic CT imaging can help determine whether or not there is a drainable abscess, and if so this can be drained percutaneously. Adjuvant antibiotics with gram-negative and anaerobic coverage are indicated. Rarely, in the event of pelvic sepsis, debridement and diversion of the fecal stream can be performed. Other complications include rectal stenosis and long-term functional compromise when the rectum is narrowed from excision of a bulky lesion and whereby rectal compliance is diminished. Overall though, morbidity rates are low and significant complications rare.

CLINICAL OUTCOMES

In general, the clinical outcomes of local excision of rectal neoplasia are determined by the quality of the excision. The key measurable metrics in determining the quality of excision are the (a) completeness of the specimen (i.e., degree of fragmentation) and (b) the margin status. Most of the emphasis on high-quality excision is for invasive cancer and less emphasis is placed on excision quality for benign neoplasms. Overall, the adenoma recurrence rate following TEM ranges from 0% to 16%, and it has been demonstrated that the most likely predictor of adenoma

recurrence is inadequate excision with positive margins. Parks' TAE (in comparative studies with TEM) results in a higher margin positivity rate and increased specimen fragmentation. This is the likely reason for the higher local recurrence rate of adenomas observed with conventional Parks' TAE (32% TAE vs. 3% TEM, $p = 0.003$).

Data on TAMIS are limited as it is a relatively new modality for LE of rectal neoplasia. Pooled data from 390 TAMIS procedures performed during the first 4 years of clinical experience with this platform (2010 to 2013) revealed that the overall margin positivity rate was 4.36% and specimen fragmentation occurred 4.1% of the time, which is similar to results with TEM and TEO. Recurrence rates measured 2.7% with TAMIS (compared to 3% for TEM), although mean follow-up was limited to 7.1 months, and long-term data for TAMIS are not yet available.

There are increasing data to strongly suggest that the excision quality of the specimen is dependent on whether or not an advanced transanal platform is used, and this is most significant when local excision is being performed for rectal cancer with curative-intent. As early as 1996, Winde et al. demonstrated that patients with T1 rectal cancer who were randomized to standard anterior resection versus local excision with TEM had no difference in survival and cure rates. Meanwhile, a 2015 meta-analysis of local treatment for T1N0M0 rectal cancer demonstrated that while oncologic outcomes with TEM were similar to those with standard resection, local excision via conventional TAE demonstrated a significantly lower 5-year survival rate. Importantly, evidence-based medicine demonstrates that patients who undergo curative-intent local excision—via any transanal approach—and who develop a local recurrence have a much lower likelihood of ever being cured as neither reexcision of a luminal recurrence nor salvage anterior resection or even APR will result in an acceptable cure rate in this setting. In fact, not all recurrences are amenable to surgical intervention. Salvage surgery via SR is only feasible if, after LE, the excised lesion is of a more advanced T stage or demonstrates unfavorable histologic features (e.g., lymphovascular invasion, sm3, mucinous features). Patients who undergo immediate salvage surgery in this setting have been shown to have survival patterns predicted for their specific stage without diminished oncologic results.

FUNCTIONAL OUTCOMES

While the conventional, Parks' TAE has not been well studied in terms of functional outcomes, TEM and, more recently, TAMIS have been studied. The data on functional outcome with TEM appear to be conflicting, but most experts agree there is no proven adverse functional compromise after TEM. A series by Allaix ME et al. revealed that there was no adverse functional outcome in quality of life (QoL) after local excision at 12- and 60-month follow-up. The existing data on function after TEM do however reveal transient anal sphincter mechanism impairment; specifically decreased anorectal manometric resting pressures following TEM have been reported and this correlates with TEM operative time. Other measurable parameters such as pudendal nerve terminal motor latency, anorectal sensation, and rectal compliance were not altered by TEM. Continence was shown to be impaired by some, but not all, studies and the effect was noted to be transient. Dafnis et al. demonstrated impaired continence in 37% of patients after TEM, and this was shown to be independent of patient age or gender. This correlated with prolonged operative time. Cataldo et al. demonstrated that there was no significant change in patient anorectal function before and after the procedure based on the fecal incontinence severity index (FISI) and the fecal incontinence quality of life (FIQL) assessment tool.

The functional outcomes after TAMIS have also recently been studied. Schiphorst et al. examined 37 patients who underwent TAMIS for local excision of rectal neoplasia by a single-surgeon. With median 11-month follow-up, the functional outcomes based on the FISI assessment tool demonstrated that the majority of patients (88%) *improved* after TAMIS excision. This can most likely be attributed to the functional effects of a mass in the rectum and because, after excision, function returns to normal. Furthermore, TAMIS is typically performed with a soft, flexible multichannel port, and hence anorectal dysfunction from device insertion is probably nominal.

Verseveld et al. have prospectively studied patients undergoing TAMIS and the FISI and FIQL were used to assess anorectal function postoperatively. The data for $n = 24$ patients in the study revealed that FISI remained unaffected after TAMIS (9.8 vs. 7.3; $p = 0.26$) and FIQL preoperative versus postoperative scores were similar (3.8 vs. 3.9; $p = 0.15$). Overall FISI was either improved or the same after TAMIS in 11 out of 13 patients who had a preoperative abnormal FISI, and the authors concluded that improvement in function is probably attributed to tumor

removal. Data from most series on postoperative function after transanal surgery with TEM show similar results with either no change in functional outcome or improvement after excision.

Risk factors for dysfunction include distance from the anal verge. For example, LE for tumors near the anorectal ring has a relatively decreased incidence of functional impairment and lower postoperative FISI scores as well as incontinence (p = 0.01). In contrast, it has been shown that functional results are decreased when the lesions excised are more proximal (≥8 cm from the anal verge). One explanation for this may be that excision of more proximal lesions typically requires a longer operative time as it is a more challenging and complex operation than when excision is performed in the lower two thirds of the rectum.

Larger tumors—in particular, lesions ≥4 cm in diameter—that undergo LE result in an increased urgency primarily because the rectal volume and compliance are decreased upon excision and closure of the defect.

EDITOR'S COMMENT

The authors present an outstanding account of local excision of rectal tumors. The chapter opens with an elaborate description of history followed by a detailed account of various stages of technical evolution this operation has enjoyed over the last few decades. The authors close the chapter with a detailed technical discussion complemented by excellent descriptions of operative approach.

As described by the authors, transanal resection for rectal tumors has been in clinical practice for a long time. The technique underwent a surge in popularity roughly two decades ago when it transitioned from its steady, low level of clinical application to mainstream use. Perhaps, this sudden popularity and ensuing widespread adaption was attributable to the initial reports suggesting local control rates comparable to proctectomy complemented by the obvious benefits that the technique offered: low operative morbidity coupled with sphincter preservation in patients who would have otherwise received an abdominoperineal resection and a permanent stoma. In addition, the introduction of TEM was truly a game changer. With its enhanced visualization and increased reach, TEM helped to catapult this technique into popular use.

The widespread adaption of this technique lead to expansion of its indications from the treatment of low lying, mostly benign tumors to extirpation of mid, even upper rectal tumors. Not surprisingly, some surgeons went as far as routine employment of this approach for locally advanced rectal cancers. Like many new techniques in surgery, this newfound enthusiasm was soon to be dampened by emergence of multiple reports detailing suboptimal local oncologic control compared to total mesorectal excision, as eloquently described by the authors in this chapter. Consequently, most practices limited the use of transanal resection to benign polyps and selected cases of early T1 cancers. Another area where the technique remains valid is its use as a "full-thickness excisional biopsy" to help determine the need for a radical excision in cases where a large polyp is suspected to harbor a malignant component.

More recently, the interest has been revitalized by the emergence of literature attesting the effectiveness of chemoradiation in combination with local excision. Multiple large retrospective series and a recent prospective trial (Z6041) have indicated that the disadvantage of inferior local control—the major drawback of this technique—can be resolved by the addition of chemoradiation therapy.

These studies are fairly recent and long-term results are keenly awaited. A word of caution to the reader: While the early results of Z6041 trial show comparable local control to total mesorectal excision, the surgical and radiation-related side effects and complications were also observed at a very high rate prompting midstudy radiation dose adjustment. Furthermore, the investigators recently reported the functional outcomes of the trial; while there were no significant changes in Fecal Incontinence Severity Index, there were statistically significant reductions in Fecal Incontinence Quality of Life Scores (Lynn PB, Renfro LA, Carrero XW, et al. Anorectal function and quality of life in patients with early stage rectal cancer treated with chemoradiation and local excision. *Dis Colon Rectum* 2017;60(5):459–68).

The operative technique itself has gone through a remarkable evolution from its early stages entailing utilization of standard anal retractors with a limited reach of 5 to 6 cm from the anal verge to introduction of TEM and finally modern day TAMIS technique. TEM and TAMIS result in much better operative visualization and increase the operative reach allowing the surgeon to approach tumors in mid and upper rectum. Due to its low cost, universal availability and its compatibility with conventional laparoscopic equipment, TAMIS has mostly supplanted older techniques and is my preferred approach for transanal resection of rectal tumors.

As mentioned by the authors, the importance of Airseal insufflation system cannot be overstated. There is no doubt that the Airseal system results in dramatic reduction of the luminal bellowing effect resulting in significantly improved visualization and more importantly, a considerable reduction in operator frustration.

In my practice, conventional transanal resection remains relevant for very distal tumors, those located within 3 to 4 cm from anal verge. In my opinion these tumors are relatively inaccessible to TEM or TAMIS due to their proximity to anal verge making it very difficult to maintain airtight seal around the anus, a prerequisite for successful performance of video-assisted platforms.

I concur with the authors that all patients undergoing local excision, perhaps with the exception of very distal tumors, should undergo bowel prep. It is my practice to use oral antibiotic prep in addition to mechanical prep specially in cases where peritoneal entry is anticipated. I feel that the reduction in colonic bacterial burden with preoperative oral antibiotics assists in minimizing peritoneal contamination in case an inadvertent peritoneal entry during the course of the operation.

In terms of complications, I think it is imperative to mention the risk of luminal compromise and in some cases, complete luminal occlusion during rectal defect closure. This typically occurs during conventional transanal excision and in my opinion, is much less of a concern with video-assisted platforms (TEM and TAMIS). The limited visualization afforded by the standard anal retractors can lead to approximation of mucosal edges across the lumen. I have personally experienced this on two occasions, both of which were

during the early phase of my learning curve and involved extirpation of large tumors occupying substantial portion of rectal circumference. Fortunately, I was able to identify the luminal compromise in both cases as I routinely perform endoscopic evaluation of mucosal closure at the end of these operations. For this reason, I strongly recommend an endoscopic exam at the conclusion of all transanal resections as this complication can have disastrous consequences, assuring a return trip to the operating room.

Next, I would like to touch the topic of inadvertent peritoneal entry during the course of these operations. A breach of peritoneal cavity typically has dramatic appearance on imaging studies due to tracking of large amount of gas in the peritoneal and retroperitoneal spaces. While fairly ominous in its appearance, this outcome can be managed successfully with conservative therapy and reoperation is rarely necessary. My approach is to keep patients with inadvertent peritoneal entry in house for 2 to 3 days for close clinical observation. I also maintain these patients on broad-spectrum antibiotics for 10 to 14 days. While there is no evidence supporting empiric antibiotics therapy in this situation, I feel that it minimizes the risk of a postoperative abscess and provides me with much needed peace of mind.

Finally, in my experience postoperative bleeding is one of the most common complications after this procedure. The bleeding is typically associated with wound dehiscence. In the recent past, I have adapted what I call the “three-point suturing” technique. This technique incorporates a full-thickness edge of rectal wall on one side followed by a deep bite including the base of the defect and a third full-thickness bite through the edge of rectal wall on the opposite side. I feel that this approach results in complete obliteration of dead space minimizing the risk of hematoma formation, which typically leads to suture line dehiscence and resultant bleeding.

As indicated by the authors, sphincter dilation during the performance of TEM can result in poor sphincter function. Much of this sphincter trauma can be mitigated by the use of soft, pliable TAMIS port. Although there are limited data on functional outcomes after TAMIS in comparison to TEM, it is conceivable that the reduced amount of sphincter stretch during TAMIS will result in improved postoperative functional outcomes.

In my opinion, local excision is an optimal approach for benign tumors located in distal rectum; however, the use of this approach in malignant conditions remains controversial. Locally advanced (T3 or more) or lymph node positive tumors should be dealt with neoadjuvant chemoradiation followed by total mesorectal excision; local excision in these cases is not advisable. Early T1 tumors without poor prognostic features can be cautiously treated with local excision with a clear understanding that this approach may result in increased local recurrence rates and decreased survival. These facts underscore the importance of a detailed preoperative discussion with the patient to ensure a complete understanding of these risks on patient’s part. The issue of local excision of T2 tumors in combination with chemoradiation remains unsettled

until long-term data become available. We have to bear in mind that a total mesorectal excision alone is curative for T2 rectal cancers *without* the need for chemotherapy or radiation. The important question we need to ask ourselves is this: Are the benefits of local excision for T2 rectal cancer worth the side effects and reduction in quality of life seen with neoadjuvant chemoradiation therapy. I feel that this will remain an important philosophical question even after long-term data from prospective trials become available.

INCONTINENCE

Incontinence of feces is a demoralizing and psychologically devastating condition for the patient. It is far worse in terms of quality of life than incontinence of urine. So distressing is the condition that many patients afflicted by incontinence of feces never admit their problem to their families or closest medical attendants. Symptoms are therefore concealed, because patients feel ashamed that they are "dirty," with the inevitable consequence that they become social outcasts with loss of self-esteem, demoralization, and loss of confidence.

Fecal incontinence without awareness causing passive incontinence is the most distressing symptom, necessitating protective clothing and diapers. There is loss of anorectal sensation and motor function.

With urge incontinence, patients have to rush to the bathroom. Hence, sensory awareness is retained, but motor control is only capable of preventing involuntary defecation for a short time. These patients fear traveling or moving out of social circumstances in which a bathroom is not available. Urgency is a common symptom in patients with rectal disease, particularly proctitis or a narrowed rectum, as well as after obstetric trauma.

Soiling is caused by the inability of the anal canal to close completely. Sensation is preserved, and there is a gutter defect in the anal canal through which feces may seep.

Overflow incontinence is caused by fecal impaction. Liquid feces leak around a solid bolus of fecal material that occupies the entire lumen of the rectum. Overflow incontinence is often associated with the aging process; megacolon is associated with loss of sensory awareness in the rectum.

Clinical Presentation

Clinical presentation usually identifies the principal cause for incontinence. Women are affected far more commonly than men are,

because obstetric injury is the most common cause of incontinence requiring surgical treatment. Some patients become incontinent after operations on the anal canal or on the rectum and colon. A further group includes patients who sustain trauma to the perineum. Any patient presenting with fecal incontinence should be closely questioned to exclude underlying neurologic disorders, particularly demyelinating disease in the young and cauda equina lesions at all ages. There is also a group of patients with congenital disease who present with incontinence. In such patients, there is usually a history of surgical treatment in the neonatal period for anorectal agenesis, Hirschsprung disease, meningocele, or other congenital lesions affecting the cauda equina or anorectum. Finally, 70% of patients with a rectal prolapse are incontinent; hence, prolapse must be excluded in all patients with symptoms of incontinence.

Causes

Factors Responsible for Normal Continence

Normal continence depends on a number of correlated factors that, in principle, include a reservoir, an anorectal junction that opens and closes at will, and a closed anal canal at rest.

The rectal reservoir may be compromised in patients with inflammatory disease affecting the rectal mucosa and the wall of the rectum, as in ulcerative colitis and Crohn disease. The capacity of the rectal ampulla may be severely compromised in patients who have had previous radiation treatment or may have been surgically reduced in patients having ileoanal or coloanal anastomoses, particularly where no reservoir has been constructed. The voluntary control mechanism for opening and closing the anal canal consists of the pelvic diaphragm and puborectalis sling, particularly, as well as the striated external anal sphincter. These muscles may be damaged from trauma after obstructed vaginal deliveries. They may become neuropathic from prolonged second stage of labor, and they may be traumatized by the fetal head or if an episiotomy extends through the sphincters. The striated muscle may fail to function if there has been severe infection resulting in fibrosis around the sphincters or pelvic floor, or the external sphincters may have been divided during anal operations, particularly fistulotomy, or by perineal trauma.

The anal canal is normally closed at rest. This depends on the involuntary contraction of the circular smooth muscle around the anal canal and the integrity of unscarred anus. The internal sphincter is under

autonomic control mediated through nitric oxide. The smooth muscle itself may be damaged by previous surgery, such as hemorrhoidectomy, anal dilation, or sphincterotomy. It may become neuropathic from operations that interrupt the normal intermyenteric fibers innervating the internal sphincter, and it may be defective in patients in whom normal chemical transmitters no longer function, as, for instance, in Hirschsprung disease.

The anorectum cannot function normally if it does not receive afferent signals. Thus, patients with impairment of rectal or anal sensation have compromised continence. The sensory fibers of the pudendal nerve supply the anorectum, and this nerve may be damaged after obstetric trauma and in cauda equina lesions. Cerebral degeneration from any cause may result in impaired rectal evacuation and incontinence.

Causes of Incontinence

Obstetric trauma may result in disruption of the fibers of the puborectalis and pelvic floor, a neuropathic injury affecting the pudendal nerve, division of the internal or external anal sphincter, or fibrosis encasing the sphincters following sepsis or repeated operations. Patients may have impairment of rectal evacuation urgency, urge incontinence, soiling, and lack of flatus control.

Postoperative incontinence may be a result of damage to the internal or external anal sphincter after operations on the anus, such as hemorrhoidectomy, sphincterotomy, anal dilation, and anorectal fistula surgery. In some cases, the sphincter muscles may be divided. In others, a gutter deformity may develop in the anal canal, which prevents the anal canal from remaining closed at rest. Colorectal operations may also result in incontinence if they cause rectal strictures or fibrosis of the reservoir, which then is no longer compliant and is small in volume capacity. Incontinence may develop after transection of the low rectum or anal canal as a result of interruption of the intermyenteric autonomic nerve plexus. Thus, any operation on the colon and rectum, particularly if it involves a low anastomosis, may result in impaired continence.

Perineal trauma may result in damage to the sphincter, pelvic floor, anal canal, and rectum. There is often associated injury to the urethra, the bony pelvis, and the soft tissues of the buttocks.

Neurologic injury may involve upper motor neurons, which usually results in severe constipation, fecaloma, and soiling, or lower motor neurons, in which the anorectum is completely patulous and there is buttock anesthesia. More localized neurologic injury may involve the

pudendal nerve in patients who strain or in whom there has been a prolonged second stage of labor. Diffuse neurologic abnormality may occur in demyelinating disease and in the neurologic degenerative process seen in the acquired immunodeficiency syndrome.

Sepsis around the anal canal may result in skeletal muscle destruction and fibrosis. This cause of incontinence may occur when inefficient or delayed drainage of anorectal sepsis has occurred and in patients with severe localized inflammatory disease of the anal canal, as may occur in Crohn disease or in deep penetrating ulcers associated with the acquired immunodeficiency syndrome.

Congenital causes of incontinence may be anorectal agenesis, Hirschsprung disease, rectal reduplication, and anorectal dermoids, or the congenital abnormality may affect the neural tube, as in patients with meningomyelocele or its variants.

Diagnosis

Clinical Examination

Clinical examination identifies the principal cause of incontinence in most patients, but in certain instances specialized anorectal physiology is required for diagnosis and as a means of recommending whether surgical treatment is indicated.

Inspection of the perineum can identify scars from previous anal surgery, episiotomy, or obstetric injury. Often, a defect in the sphincter ring is apparent. The site of the anus should be noted. Anterior displacement suggests an ectopic anus (minor variant of anorectal agenesis). The presence of skin tags, fistulae, or the presence of patulous anus should be recorded. Inspection should then include examination during straining to exclude a rectal prolapse and to assess the degree of perineal descent and vaginal descent, cystocele, and rectocele.

Rectal examination should attempt to assess resting tone and the contractile activity of the external anal sphincter and the puborectalis. Rectal examination should also identify any defect in the sphincter and any gutter deformity, in addition to any palpable pathologic abnormality in the rectum.

Proctosigmoidoscopy should be performed to exclude proctitis, polyps, or any other colorectal pathology.

Specialized Diagnostic Techniques

Anal manometry provides data on the maximum resting anal canal pressure and the maximum pressure generated during a maximum squeeze effort (Fig. 166.1). Manometry also helps to identify the length of the high-pressure zone, and vector manometry may be used to clarify areas of reduced anal pressure, signifying localized defects. In some circumstances, ambulatory manometry may be necessary. An inflatable balloon should then be inserted into the rectum and anal manometry performed during balloon distention to determine the presence or absence of the rectoanal inhibitory reflex. This reflex may be absent in Hirschsprung disease and in some patients with incontinence. Distention of a rectal balloon is a simple method of crudely assessing rectal capacity and rectal sensation. However, for compliance measurements of the rectum, integrated changes in intrarectal pressure are recorded with incremental volumes in the rectal balloon. Anal sensation should be measured using the technique of anal mucosal electrosensitivity in the lower, mid, and upper anal canal.

Electromyography was formerly used for mapping the external anal sphincter in patients with sphincter defects and in assessing ectopic anus. However, the use of needle electrodes is painful and poorly tolerated by patients, particularly if there is scar tissue. Likewise, measurement of fiber density as an assessment of the degree of denervation may be performed by repeated sampling of the external sphincter and puborectalis by the use of concentric needle electrodes. For the same reason, patients find this investigation difficult to tolerate and are not particularly compliant. By contrast, conduction studies are less invasive and give an assessment of pudendal neuropathy. Pudendal nerve terminal motor latency measurements can be made by stimulating the pudendal nerve as it winds around the ischial tuberosity and recording the evoked contraction in the external sphincter after stimulation (Fig. 166.2). Conduction delays are associated with pudendal neuropathy, but there is considerable observer variation with this measurement and most units have abandoned this method of assessment because it is considered unreliable.

Ultrasound examination of the anal canal and rectum has superseded electromyography in the identification of sphincter defects. It is important to assess the length of any injury in the anal canal as well as its

circumferential extent and position. Anal ultrasonography can be used for dynamic assessment of contractility, as well as definition of anatomic defects (Fig. 166.3A,B), morphology, and pathologic conditions (e.g., abscess and fistula). Magnetic resonance imaging (MRI) of the anorectum may provide additional important information, particularly in injuries and disorders affecting the pelvis floor.

Many patients with fecal incontinence have some impairment of rectal evacuation. Thus, assessment of rectal emptying by isotopic techniques or during videoproctography is indicated for some patients. Videoproctography may also be needed to exclude coexisting abnormalities, such as intussusception, perineal descent, and rectocele, as well as to provide playback images to record pelvic floor movements during contraction and attempted defecation.

In general, patients with low resting anal pressures, a short high-pressure zone, gross perineal descent, anal anesthesia, gross prolongation of pudendal nerve terminal motor latency, and those with poor external sphincter contractility do badly after attempted reconstructive surgery. Thus, for such patients, counseling that there are alternative therapies other than conventional surgical reconstructions that are more likely to improve a patient's quality of life is needed.

Treatment

Conservative Therapy

Many patients with fecal incontinence have a history of diarrhea. Under these circumstances, particularly if the incontinence is relatively mild, control of the diarrhea may achieve sufficient improvement and further therapy becomes unnecessary. Use of codeine phosphate and loperamide can be important. In patients with rapid transit times, tablets or capsules may not be absorbed, but an elixir may be.

Diet and Anal Hygiene Methods

Many patients with bowel incontinence find that bowel control is poor on a vegetarian diet. Foods that produce gas, for example, onions, root vegetables, beans, and brassicas, should be avoided if the sufferer has flatus incontinence. Alcohol is generally poorly tolerated in incontinence patients. Diets rich in animal protein and starch often suit patients who suffer with bowel incontinence. Many patients find that the timing of meals is critical for work and social events.

For those whose principal problem is soiling, washing with water, the use of wipes to remove fecal debris when visiting the toilet to micturate avoids perianal excoriation and soreness from fecal staining.

Physiotherapy and Biofeedback

Unquestionably, some patients can no longer contract the sphincter and pelvic floor complex appropriately in response to rectal distention. Others seem incapable of sphincter and pelvic floor contraction on command and tend to strain during attempted voluntary contraction. Another group finds it difficult to contract the sphincter and pelvic floor after recent injury because of pain and psychological trauma. Such patients may be improved dramatically by a series of pelvic floor exercises, faradism, electrical stimulation of the sphincter muscles, and biofeedback retraining. Biofeedback involves an afferent stimulus as a learning process to trigger pelvic floor and sphincter contraction. Biofeedback retraining may produce dramatic improvement in patients who have problems in learning the technique. Biofeedback may also heighten rectal sensory awareness. However, biofeedback is dependent on cooperation by the patient and personality synthesis between the therapist and the patient. For motivated patients, this form of treatment is useful in minor forms of incontinence. It may also be helpful as a preoperative conditioning process so that the discipline can be reinforced postoperatively.

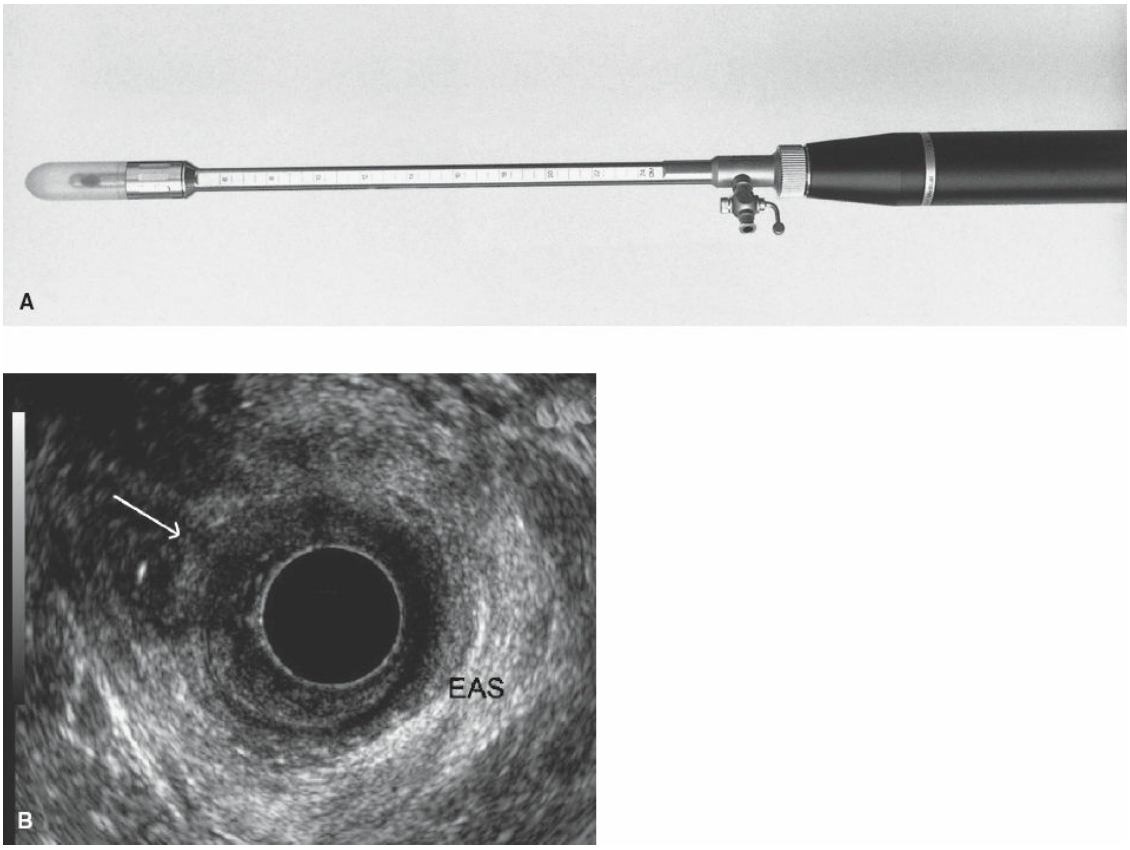

Figure 166.3. A and **B:** Anal ultrasound. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon.* 3rd ed. Philadelphia, PA: WB Saunders; 2008. Copyright © MRB Keighley MA MS FRCS.)

Keeping the Rectum Empty

Recognition that surgical treatments for bowel incontinence rarely fully control the symptoms of flatus incontinence, soiling, and may result in deterioration of rectal emptying, conservative measures to keep the rectum empty have assumed a much greater role for therapy during the last decade.

The simplest approach is the use of glycerin or bisacodyl suppositories, but these only empty the rectum. Small volume enemas achieve greater compliance than phosphate enema but are less effective in emptying the left colon. Enemas are used by many with a neuropathic anorectum so as to achieve regular evacuation while preventing fecal impaction.

Self-administered rectal washout is the logical extension of colostomy irrigation. It was pioneered in countries where availability and cost of stoma appliances were prohibitively expensive. The technique has now been accepted in colorectal units. Management of incontinence by washouts has become an extension of the role of the stoma therapists or

colorectal nurse specialists. It is curious that this simple measure has taken so long to become accepted as an alternative to a stoma and as an effective method of achieving predictable anal hygiene. Like colostomy irrigation, it requires a motivated patient who is psychologically able to accept the technique as an extension to normal toileting. There are now commercially available kits and nursing staff trained to teach and supervise rectal irrigation.

The principle is to teach patients to infuse a variable volume of fluid through a delivery system with an appropriate anal applicator so as to stimulate a series of mass left side colonic evacuations. As a consequence, the left colon is emptied of gas, liquid, and solid contents. If successful, patients may then feel clean for the rest of the day without the fear of urgency, soiling, or even flatus incontinence. The technique takes between 20 and 40 minutes at the beginning of the day and achieves almost complete continence for the rest of the day in over 80% of patients. Thus, in compliant poor outcome potential surgical patients, this procedure replaces the need for an operation with uncertain results and greatly improves patient's quality of life. Consequently, individuals who master self-administered rectal washouts are largely able to lead independent social lives, allowing a full range of physical exercise and return to the workplace.

Anterior Levatorplasty

Anterior levatorplasty is useful in patients with rectocele and in many patients requiring sphincter repair, in whom, there is also a deficiency of the perineal body and the anterior aspect of the pelvic floor. The patient is placed in the prone jackknife or lithotomy position. Liberal infiltration of the rectovaginal septum with a weak adrenaline solution and a local anesthetic is often advisable. A transverse incision is made across the perineum, between the rectum and the vagina, but in front of the anterior border of the anal sphincters. The external anal sphincter is identified posteriorly, and the entire rectovaginal septum is dissected free to the level of the pelvic peritoneum, where the rectum and the vagina move away from one another at the rectovaginal cul-de-sac. The posterior vaginal wall is then dissected from the levator muscles, so that the anterior limbs of the puborectalis can be easily identified. Repair involves approximating the anterior aspect of the puborectalis in the midline between the rectum and the vagina. In patients with an obstetric sphincter injury, the anterior aspect of the external anal sphincter is also plicated or repaired (Fig.

166.4).

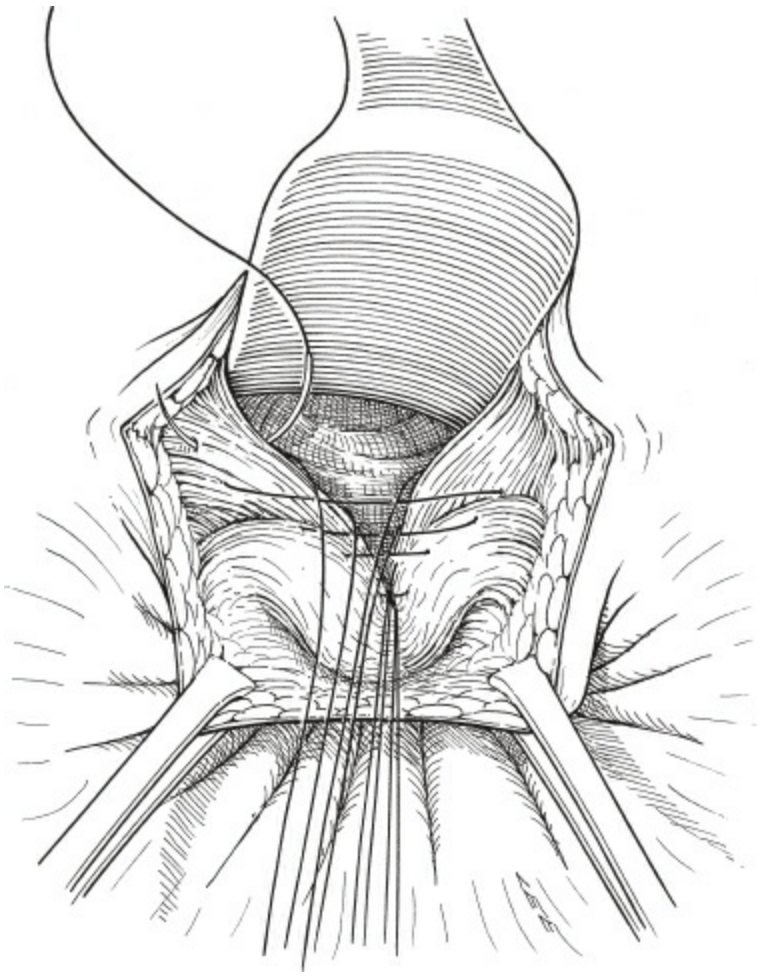

Figure 166.4. Anterior levatorplasty. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon.* 3rd ed. Philadelphia, PA: WB Saunders; 2008. Copyright © MRB Keighley MA MS FRCS.)

Sphincter Repair

Sphincter repair is indicated for patients with a localized defect in the external anal sphincter, provided the healthy sphincter is capable of vigorous contraction. The operation may be needed for postobstetric injury, division of the sphincter after fistula surgery, or traumatic injuries of the perineum. In each of these three situations, the specific method of repair may have to be modified according to the extent of damage.

The patient may be operated on in the prone jackknife or lithotomy position. Prior infiltration with a weak adrenaline solution and a local anesthetic is always advisable. In postobstetric sphincter injuries, a cruciate incision may be used to provide excellent access to the

rectovaginal septum, the perineal body, and the sphincters. The cruciate incision is usually closed as a Z-plasty, but there is a tendency for wounds to break down. Thus, a circumanal incision is preferred by most surgeons, leaving the center open for drainage (Fig. 166.5). For a defect after previous fistulotomy, a circumanal incision is usually more appropriate (Fig. 166.6). In traumatic perineal injuries, the incision depends on the precise site of the defect. The first task is to dissect the external anal sphincter on either side of the defect and preserve, where possible, the internal anal sphincter. Stay sutures are placed on either side of the sphincter defect, and the scar tissue is divided. In patients with postobstetric injuries, the entire rectovaginal septum is dissected free so that an anterior levatorplasty (Fig. 166.7) can be combined with sphincter repair. However, in the case of traumatic injury and defects after fistula operations, levatorplasty is rarely necessary unless one is dealing with an anterior deficiency. In patients with perineal trauma, it may be necessary to identify any defect that may be present in the anorectum as well as by MRI. In such cases, reconstitution of the anorectum by repair of its circular smooth-muscle fibers and mucosa may have to be combined with sphincter repair.

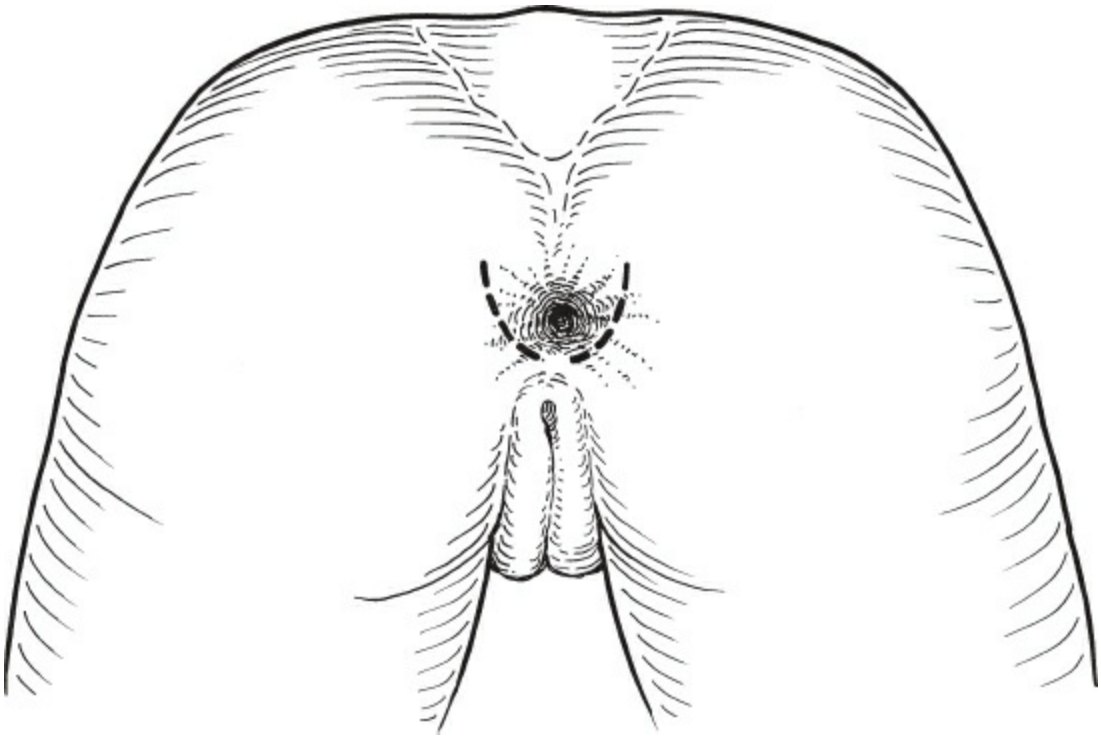

Figure 166.5. The incision for a conventional obstetric injury sphincter repair. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon.* 3rd ed. Philadelphia, PA: WB

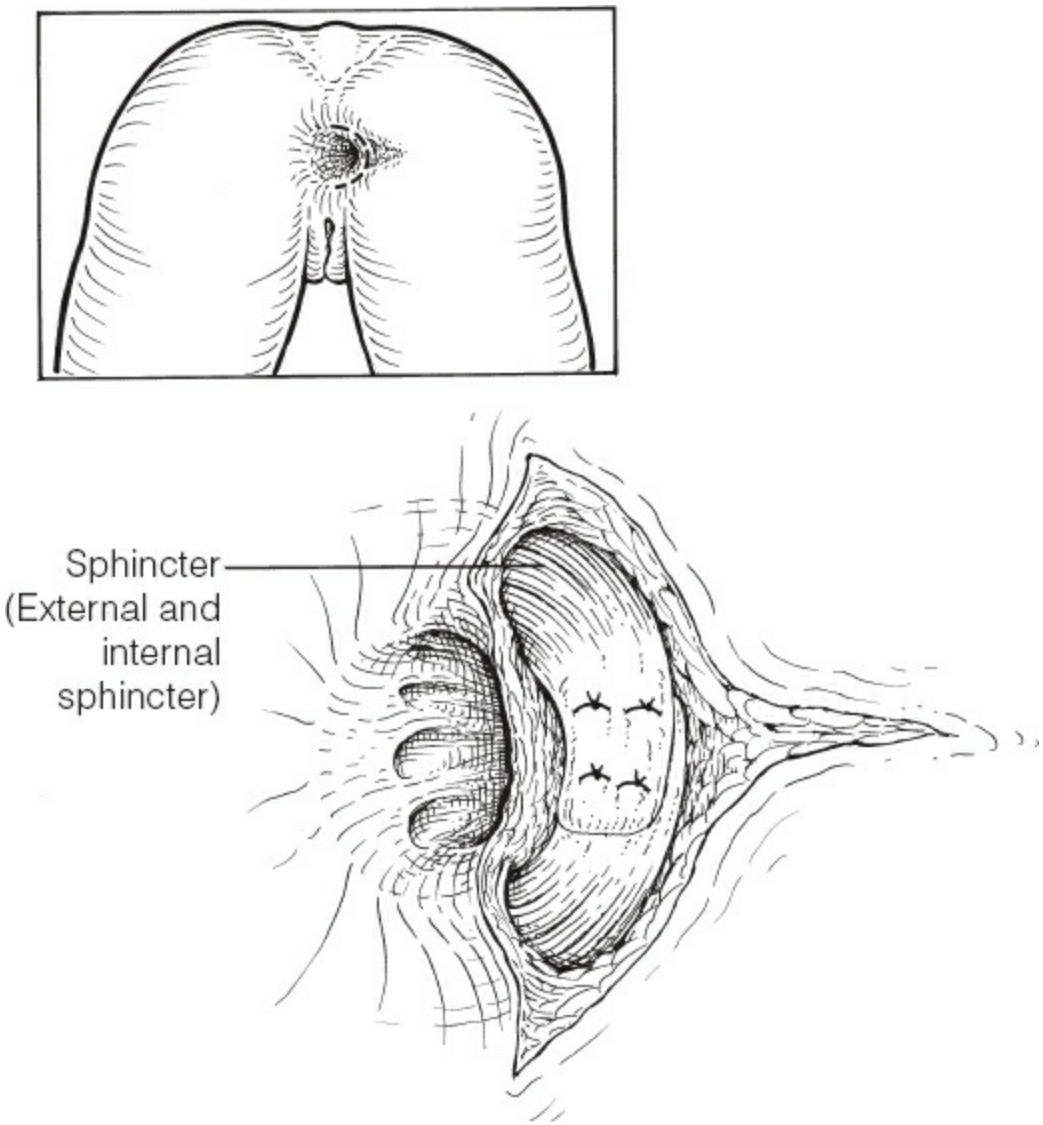

Figure 166.6. The incision for sphincter repair following fistula surgery. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon.* 3rd ed. Philadelphia, PA: WB Saunders; 2008. Copyright © MRB Keighley MA MS FRCS.)

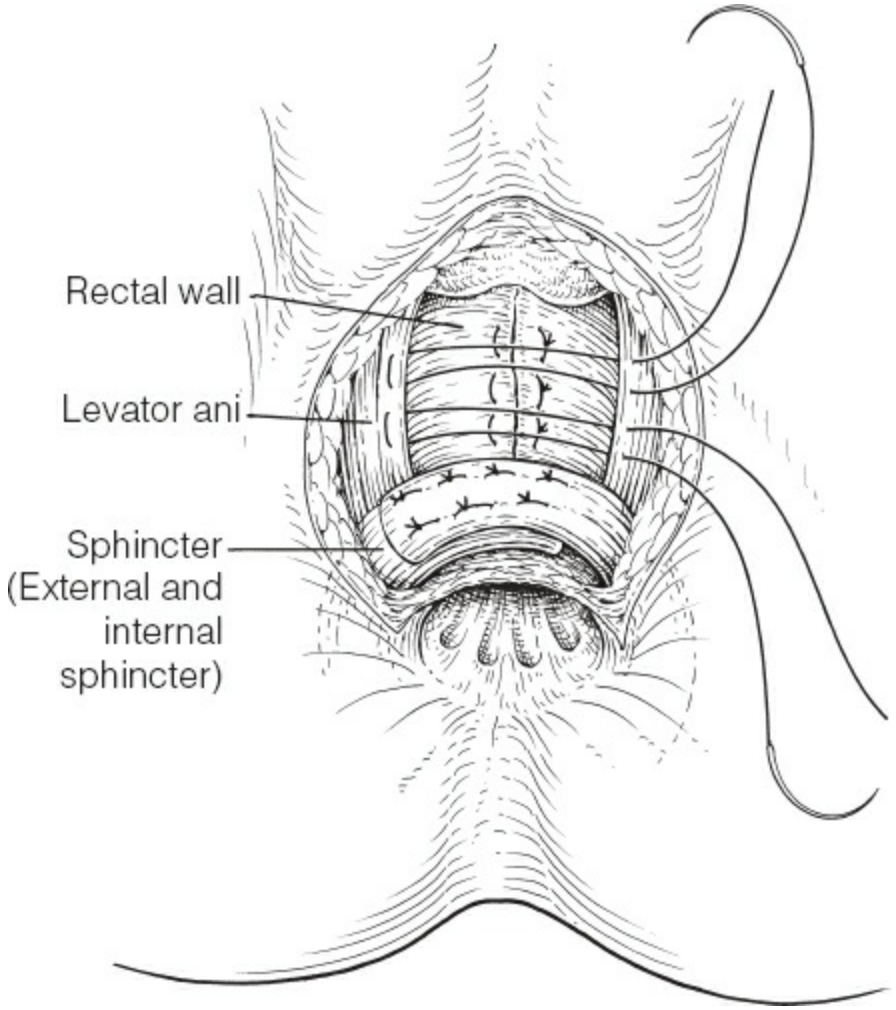

Figure 166.7. Sphincter repair. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon.* 3rd ed. Philadelphia, PA: WB Saunders; 2008. Copyright © MRB Keighley MA MS FRCS.)

Sphincter repair itself involves a flap-over technique that takes one half of the divided sphincter muscle under the other, which thereby tightens the sphincter and eliminates the defect. It is wise to use a closed suction drain if there has been any difficulty with hemostasis. If the patient has a large sphincter defect or a history of impaired rectal evacuation, or is at risk of sepsis, it would be wise to consider a temporary covering loop colostomy.

Postoperative complications include sepsis, hematoma, stenosis with impairment of rectal emptying, and breakdown of the repair, which can lead to a suprasphincteric fistula. Thus, it is essential that all patients are carefully counseled. It is also important to use perioperative antibiotic cover, mild laxatives, and ensure careful attention to local dressings and hygiene. Fecal impaction must be avoided. The short-term success rate of sphincter repair is ~75%, but there is deterioration in the quality of

continence with time. All the long-term evidences indicate that <50% of patients having a delayed sphincter repair are fully continent at 5 years. Nevertheless, the symptom of urgency is greatly improved and patients are usually more able to cope after a secondary sphincter repair provided there is good contractile activity in the remaining sphincter.

Sacral Nerve Stimulation

This treatment is now established as a successful treatment modality for fecal incontinence and impaired rectal evacuation and the 5 year results indicate that about 50% remain improved. Urgency is greatly reduced but soiling and flatus incontinence often persists despite treatment.

It is unclear how sacral nerve stimulation (SNS) achieves continence. It may also improve impaired rectal evacuation and has been applied for treatment of intractable constipation. It appears therefore to coordinate rectal evacuation and sphincteric contraction. Treatment was first explored in patients with an intact sphincter and pelvic floor who had features of pudendal neuropathy. Since then, it has been assessed in patients with a sphincter deficiency and poorly contracting muscle. Given the potential risks of sphincter repair, particularly sepsis and breakdown, SNS has an important role in patients with an anatomical defect in the sphincter ring.

A careful selection process is essential. Candidates for SNS must be psychologically stable and sufficiently intelligent to cope with programming the implanted stimulator. Patients are only offered treatment if temporary percutaneous SNS has been effective over 4 to 6 weeks. Usually, S4 on one side of the sacral foramina is stimulated. The implantable device is placed in a subcutaneous pocket; either the perineum or in the supra pubic region and connected to the stimulator electrodes, which is programmed according to clinical efficacy and manometry (Fig. 166.8). The implantable device is expensive. There may be battery failure, migration of leads, and problems with electrical connections requiring reoperation and careful surveillance.

So far, the 5-year results indicate that in carefully selected patients, quality of life and quality of continence are greatly improved in 60% to 80%; however, continence to gas and avoidance of soiling are frequently imperfect.

Nerve stimulation is usually switched off at night, which prolongs battery life. The stimulator is often used during physical exercise, which is normally associated with a greater risk of leakage.

Clearly, SNS has the potential for considerable therapeutic benefit and

the long-term results are at least as good as sphincter repair without the risks of anatomical reconstruction.

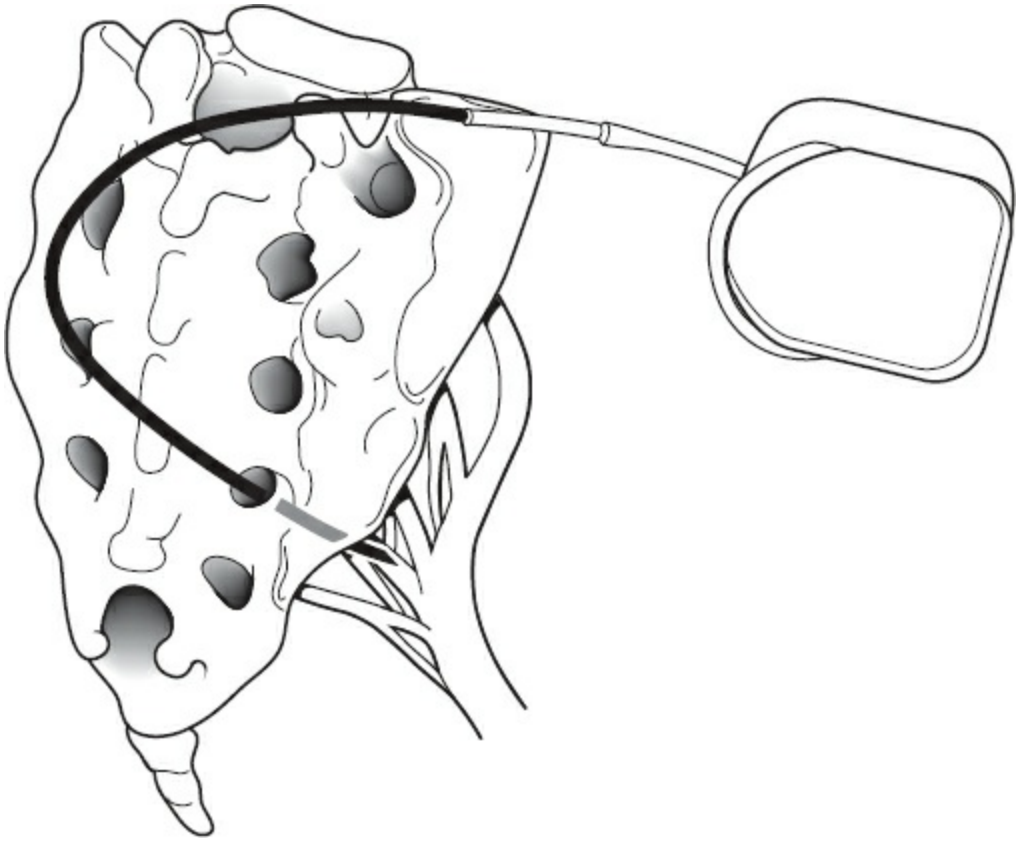

Figure 166.8. Sacral nerve stimulation (SNS). (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon.* 3rd ed. Philadelphia, PA: WB Saunders; 2008. Copyright © MRB Keighley MA MS FRCS.)

Posterior Tibial Nerve Stimulation

This is an alternative method of neuromodulation. It involves transcutaneous needle stimulation or percutaneous stimulation of the posterior tibial nerve. Usually six sessions of electrical stimulation is offered. Short-term improvement is achieved in about 50%, but sustained benefit is disappointing. The great advantage is that this is noninvasive and cheap.

Rerouting of Ectopic Anus

The patient is catheterized and placed in the prone jackknife or the lithotomy position. Previous infiltration with a weak adrenaline solution in a local anesthetic is advised around the ectopic anus. The external anal sphincter should have been identified preoperatively by electromyography

or MRI. A disk of skin is taken from the center of the defined external anal sphincter, and a plane of dissection is developed through the center of the sphincter ring. A gauze swab is placed in the future site of the anal canal.

The ectopic anus is then dissected from the back of the vagina or from the back of the prostate by use of a circumanal incision. The anus must be mobilized for at least 6 or 7 cm from the perineum above the levators before it is rerouted to its correct anatomic site. Stay sutures are placed on the lateral margins of the anus after it has been thoroughly mobilized, particularly anteriorly. The stay sutures are used to draw the anorectum through the center of the external anal sphincters to its correct anatomic position (Fig. 166.9). The mucosa is then sutured to the edges of the skin disk, and an anterior levatorplasty is performed to reconstitute the perineal body. The biggest hazard of rerouting the anal canal is fecal impaction. Many patients have chronic constipation and some impairment of evacuation. Thus, a regimen of postoperative laxatives is essential to achieve a satisfactory long-term outcome.

Gluteus Maximus Transposition

Gluteus maximus transposition may prove extremely useful for a few patients with sphincter failure, particularly if the sphincters and puborectalis are neuropathic. The concept of taking normally innervated muscle, particularly from a muscle that is usually used to assist continence, is an attractive concept. Bilateral oblique gluteal incisions are made to expose the superficial fibers of the gluteus maximus on either side of the anus. The neurovascular bundle to the superficial fibers of the gluteus maximus is identified. The muscle insertion into the femur or its origin from the ileum is detached. We prefer the former. Superficial fibers of the detached gluteus are then split. Subcutaneous tunnels are made anterior and posterior to the anus, so that the split muscle can be taken on either side of the anus and sutured to one another on the opposite side and to the opposite gluteus muscle itself (Fig. 166.10). Postoperative complications are hematoma and infection. Long-term results of this procedure are disappointing and most patients would now be offered SNS as first-line therapy.

Gracilis Muscle Transposition

Graciloplasty was introduced as a means of augmenting a damaged sphincter if the defect was too large to perform a sphincter repair. The unique properties of the gracilis muscle are that it is long, has a strong tendinous insertion to the tibia, is not required for locomotor function, and has a proximal neurovascular supply. Hence, by detaching the distal tendon, two thirds of the distal component of the muscle can be rerouted around the anus, and its tendon can be sutured to the opposite ischial tuberosity or to the sphincter if it is used for augmentation. The muscle may be rerouted clockwise or anticlockwise.

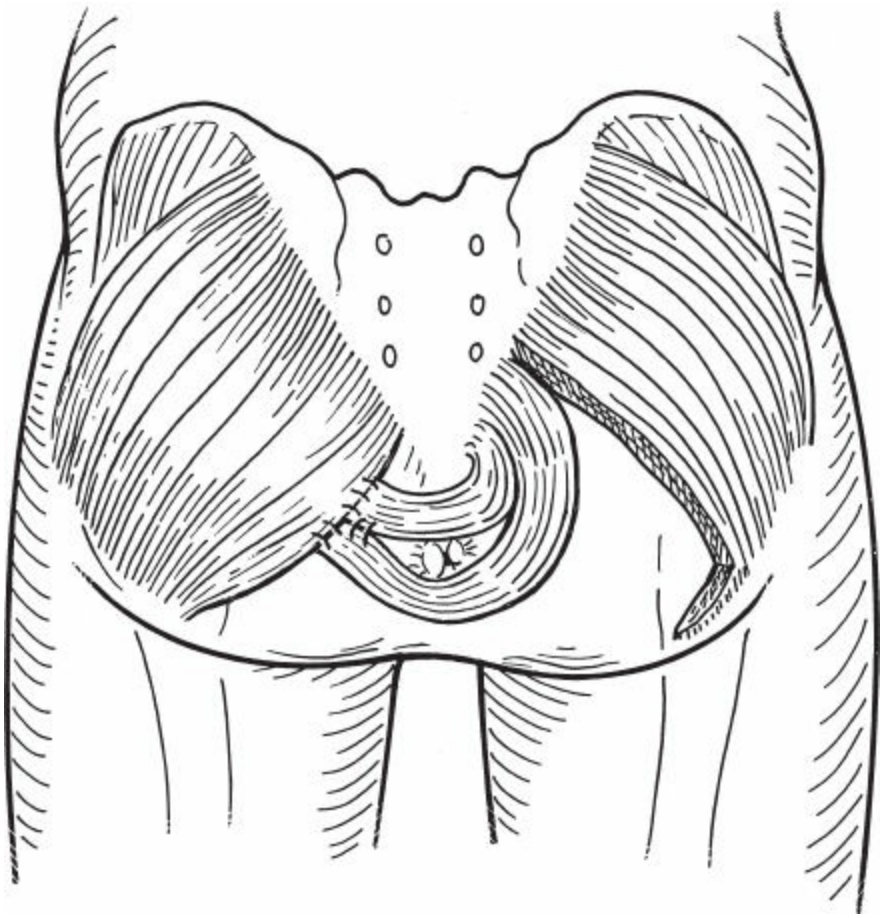

Figure 166.10. Gluteus maximus transposition. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon.* 3rd ed. Philadelphia, PA: WB Saunders; 2008. Copyright © MRB Keighley MA MS FRCS.)

The patient is placed in the lithotomy position with the legs in stirrups. The gracilis muscle is mobilized through a single longitudinal incision or through multiple small incisions over the muscle or laparoscopically, which improves cosmesis and reduces postoperative pain. We prefer a single longitudinal incision, because identification of the muscle can be difficult, and we do not think that morbidity is reduced by a series of small incisions. Tributaries of the long saphenous vein often require ligation. Great care must be taken to avoid injury to the saphenous nerve. The muscle is easily identified by its longitudinal muscle fibers, rounded belly, and long tendon. The tendon is detached from the medial border of the tibia as close to its insertion as possible. The distal two thirds of the muscle are delivered from its bed, but great care must be taken at the junction between the proximal third and the distal two thirds to identify the neurovascular bundle. The nerve is a branch of the anterior obturator nerve

lying on adductor brevis. The blood supply is more variable, but the principal artery is nearly always just distal to the nerve, which splits into two branches before it reaches the muscle. If separate distal arteries are identified, they must be ligated. An incision is made over the buttocks, and another over the ischial tuberosity on the opposite buttock (Fig. 166.11). It may be possible to develop subcutaneous tunnels around the anus without making further incisions, but sometimes, additional anterior or posterior access is necessary. If this is the case, the anterior and posterior anal raphe should be preserved. After subcutaneous tunnels around the anus are developed and meticulous hemostasis is achieved, gauze swabs are left in each before muscle transposition.

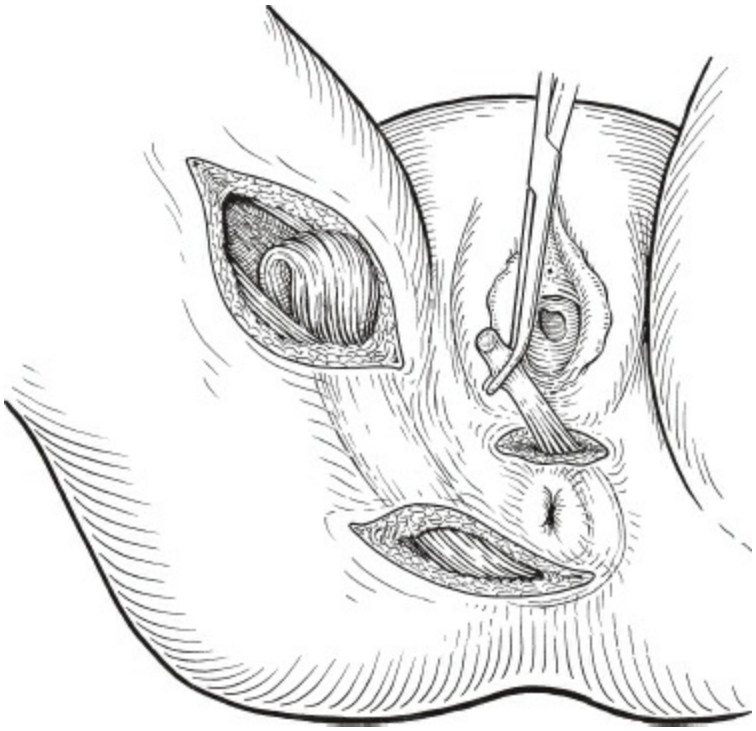

Figure 166.11. Unilateral graciloplasty. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon.* 3rd ed. Philadelphia, PA: WB Saunders; 2008. Copyright © MRB Keighley MA MS FRCS.)

We prefer to transpose the gracilis muscle by using an alpha loop, taking the muscle initially anterior to the anus around the right lateral margin of the anus underneath the posterior raphe and subsequently over itself, and then under the anterior raphe so that the tendon can be sutured to the opposite ischial tuberosity or in the case of augmentation into healthy sphincter muscle and the scar of the injury. It is crucial to obtain

secure apposition between the periosteum of the ischial tuberosity and the tendon, or the tendon and the sphincteric scar. We use three or four interrupted Prolene sutures on a heavy, round-bodied needle. The sutures are carefully positioned before they are tied. Closed suction drains are needed to evacuate hematoma, and the wounds are closed with Prolene sutures or staples.

A variant of unilateral nonstimulated graciloplasty is bilateral graciloplasty. This is a much more extensive operation, but the advantage is that a complete encircling sling of muscle, rather than tendon, is achieved around the anus, and each tendon is sutured to itself, thereby minimizing the consequences of local sepsis that causes disintegration of the sutures from the tendon to the ischial tuberosity (Fig. 166.12).

Complications of graciloplasty include pain, hematoma, infection, nerve injury, ischemic necrosis of tendon, and synergistic gangrene of the perineum. In view of these risks, some advocate a proximal colostomy until complete healing has been achieved.

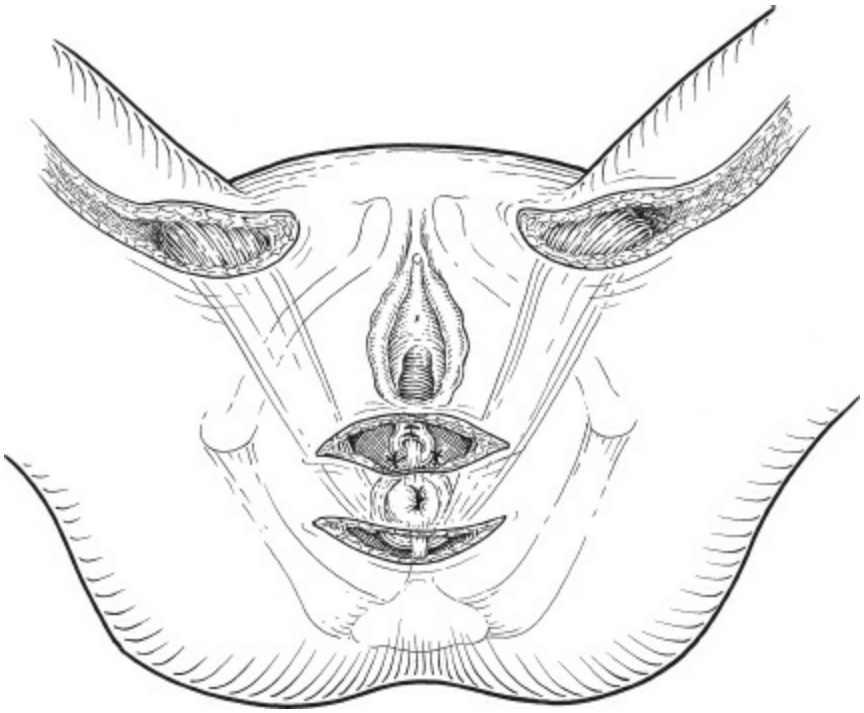

Figure 166.12. Bilateral graciloplasty. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon.* 3rd ed. Philadelphia, PA: WB Saunders; 2008. Copyright © MRB Keighley MA MS FRCS.)

Graciloplasty seems to be effective for patients who are incontinent from anorectal trauma and in patients with incontinence after previous

surgery for Hirschsprung disease. It has been far less effective for patients with fecal incontinence in whom all other simpler methods of treatment have failed.

Gracilis Neosphincter

The principle of the gracilis neosphincter is to convert the gracilis muscle from a fast-twitch to a slow-twitch, continuously active muscle. Constant electrical stimulation of the nerve to the gracilis or to the muscle fibers themselves can convert the fast-twitch muscle of locomotor function to a slow-twitch, constantly active sphincter. Constant electrical stimulation is achieved by leads placed on the muscle itself or on the nerve to the gracilis muscle after the muscle has been transposed. Electrical stimulation, as in SNS, is delivered through an implantable stimulator box placed in the subcutaneous tissues of the anterior abdominal wall or perineum from which leads deliver the electrical stimulus to one or two gracilis muscles (Fig. 166.13A,B). This operation can successfully replace a sphincter in 60% to 70% of patients but the device is expensive and there is high risk of infection and obstructed defecation. Furthermore, the battery life of the stimulator box is unknown. The operation must be selected only for patients who have a primary sphincter abnormality. Patients with incontinence often have coexisting impairment of rectal evacuation and impairment of anorectal sensation. Such patients are probably unsuitable for gracilis neosphincter unless some form of colonic irrigation is used. Currently, the three possible stages of the procedure are: (a) delivery of a proximal stoma (optional) and mobilization of the gracilis muscle in situ; (b) rerouting of the gracilis muscle and placement of stimulator leads on the nerve or muscle, which is attached to an implantable stimulator box; and (c) reprogramming of muscle over a period of 6 months to convert the muscle from fast to slow twitch. At the end of the 6-month reprogramming period, the stoma is closed (optional). Many surgeons now perform the operation as a single procedure without stoma and continence stimulation after 6 to 8 weeks, provided there are no complications.

ABS Implantable Artificial Bowel Sphincter

An implantable device has been used for many years for treatment of urinary incontinence. A device using the same principle is available for treatment of anal incontinence (Fig. 166.14). An inflatable cuff is placed around the anorectum through a single perineal or two paraanal incisions. The cuff is connected by a closed, water-filled system to a compliant reservoir placed in the retropubic space and is activated using a pump placed in the scrotum in the man or labia in the woman. Normally, the anorectal cuff is distended with fluid, which achieves continence. When there is a desire to defecate, the patient squeezes the pump that deflates the cuff to allow stool to pass. This device has been implanted under controlled audit in North America and Europe. There is a high risk of sepsis and extrusion of the implant in 20% to 40%. In those who achieve successful implantation continence of solids and liquids is achieved in 50% to 70%, but flatus incontinence and soiling usually persist.

Stoma Construction

For some patients, particularly the elderly and patients with severe neuropathy, the construction of a good stoma may be the best means of improving quality of life and restoring self-esteem to patients with fecal incontinence. However, with self-administered rectal washouts, the need to construct a stoma for bowel incontinence has fallen considerably. The best stoma is an end colostomy, which can be constructed laparoscopically or

through a small trephine in the abdominal wall. This stoma can be subsequently used for colostomy irrigation. Thus, patients are not necessarily committed to wearing a bag. Some patients with an improved quality of life following a colostomy eventually require rectal excision if they become incontinent of mucus from the defunctioned rectum.

For patients who are incontinent after extensive colorectal surgery, a loop ileostomy may be a better option than a colostomy. In a small number of patients, the option of a reservoir ileostomy should not be totally dismissed. Admittedly, this is an extensive operation, but patients do not have to wear an appliance. Furthermore, with stapling of the nipple valve, the proportion of patients requiring revision surgery after Kock reservoir ileostomy is not as high as it used to be. For more information on stoma appliances, see Chapter 141. Finally, in some patients, consideration should also be given to an appendicostomy for antegrade colonic irrigation (ACE) or a continent colostomy irrigation device to facilitate ACE. Such techniques are particularly appropriate when impaired rectal evacuation exists with the incontinence (Figs. 166.15 and 166.16).

RECTAL PROLAPSE

Chapters 145A and B contain an account of the functional considerations of rectal prolapse.

Clinical Presentation

Rectal prolapse is a complete rectal intussusception. The prolapse appears on the perineum as a circumferential swelling that bleeds or becomes ulcerated. In 70% of patients, there is a history of bowel incontinence. In 60% of patients presenting with rectal prolapse who are under 40 years of age, there is associated constipation.

Causes

Rectal prolapse, as a complete intussusception of the rectum, results in attenuation of the lateral ligaments of the rectum. There is often descent of the uterus associated with cystocele or rectocele. There is always a patulous anus and a weak pelvic floor associated with pudendal neuropathy. Rectal sensation is impaired because of the presence of the prolapse. Almost all patients with rectal prolapse give a history of discharge of mucus, which is commonly associated with pruritus ani.

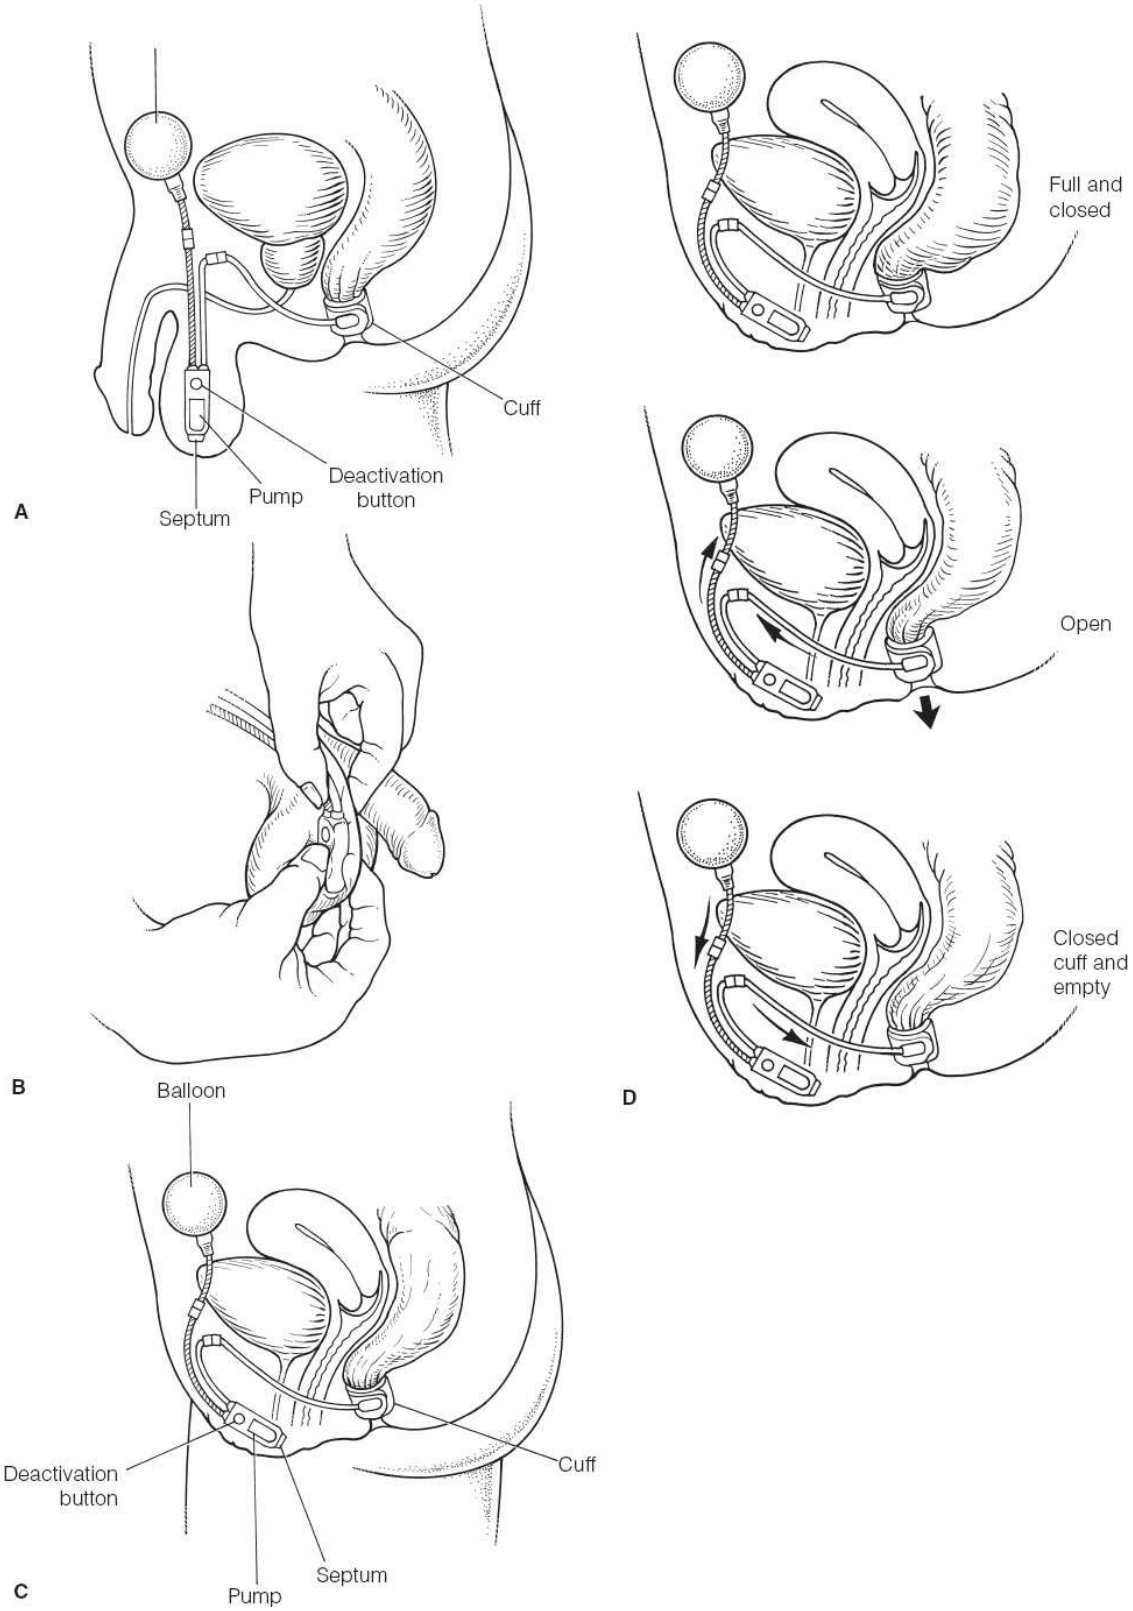

Figure 166.14. Artificial bowel sphincter. **A.** A cuff is placed around the anal canal. An inflatable pump control assembly is placed in the scrotum and the balloon reservoir under the symphysis pubis. **B.** The pump in males is placed in the scrotum. To open the cuff to defecate, the pump must be squeezed and

released several times. **C.** The same arrangement is used in women, but the pump is placed in the labia. **D.** When the cuff is closed, the stool stays in the rectum. When the pump is repeatedly squeezed (in the labia in women), the cuff opens, and the bowel can empty. Fluid then automatically returns to the cuff, which again closes around the anal canal. Appendicostomy for antegrade colonic enema. **A.** The mesoappendix is preserved. **B.** The appendix is relocated through the mesentery along the cecum in an antiperistaltic fashion. **C.** The appendix is laid within a submucosal space, its distal end is amputated, and this is then anastomosed to the cecum. **D.** The seromuscular layer is closed over the enterocecostomy without compromising the mesenteric vascular pedicle. The proximal end of the appendix is exteriorized. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon.* 3rd ed. Philadelphia, PA: WB Saunders; 2008. Copyright © MRB Keighley MA MS FRCS.)

Diagnosis

A rectal prolapse is usually obvious on clinical examination during straining, but some patients are too embarrassed to strain and deliver the

prolapse during clinical inspection. A patulous anus is a ubiquitous in prolapse. It is important during clinical examination to assess whether uterine descent, cystocele, enterocele, or rectocele exists and to assess the tone of the anal sphincters at rest and during maximum voluntary contraction. Videoproctography may be helpful, as may inspection of the perineum after defecation.

Treatment

The treatment of rectal prolapse depends on the functional abnormality. In most young patients with rectal prolapse, there is coexisting straining, impaired rectal evacuation, and delayed colonic transit. In such patients, we believe that an abdominal rectopexy is advisable, with a variable colonic resection above the rectopexy (Fig. 166.17). Usually this is performed laparoscopically. If impaired rectal evacuation is a major feature and the prolapse is small, anterior resection might be a better option. By contrast, for elderly patients with rectal prolapse and associated comorbidity, we believe that a perineal procedure is much more appropriate and favor perineal rectosigmoidectomy with synchronous repair of the pelvic floor (Fig. 166.18).

MEGABOWEL

Clinical Presentation

Megacolon or megarectum usually presents with severe constipation and soiling caused by a large fecaloma filling the rectum and around which liquid feces seep. Patients also frequently complain of abdominal discomfort and abdominal swelling, which is caused by gross fecal loading of the colon.

Causes

The cause of adult megacolon is not well understood. Some are almost

certainly cases of adult Hirschsprung disease, usually with a short segment of aganglionosis. However, the majority of cases are acquired and associated with long-standing constipation or neurologic disease (e.g., hydrocephalus, epilepsy, or cerebral birth trauma), or result from degenerative disorders affecting the autonomic nervous system, as in Chagas disease.

There are four anatomic varieties: megacolon alone, megarectum alone, megarectum and megasigmoid, and total megacolon with megarectum.

Diagnosis

Megacolon may be suspected solely on clinical grounds. A huge fecal mass may be felt arising from the pelvis. Rectal examination may reveal an enormous fecaloma in a cavernous rectum with a patulous anus.

Plain abdominal radiographs may demonstrate gross dilation of the transverse diameter of the rectum filled with solid fecal material. In other cases, the diagnosis is less obvious, and a barium enema examination may be necessary. However, preparation for barium enema can prove difficult. Sometimes, patients require hospital admission for manual evacuation and repeated enemas to disimpact the fecaloma from the rectosigmoid region.

For the same reasons, anorectal physiology can prove extremely difficult in these patients and is virtually useless unless the fecaloma is disimpacted. If the rectal obstruction can be removed, resting and squeeze anal canal pressures are usually low, and the rectoanal inhibitory reflex is usually absent. Rectal sensation is always impaired. Transit marker studies usually reveal some delay in colonic transit proximal to the dilated segment, but isotopic studies are much more useful in determining whether proximal colonic motility and transit are normal. Despite these theoretic considerations, the extent of resection is largely determined by the macroscopic appearance of the bowel at the time of laparotomy. The presence of normal ganglion cells in the anorectum may be verified by full-thickness rectal biopsy or anorectal myectomy. However, we would not advise anorectal myectomy in these patients, because it might compromise continence, and the histopathologic exclusion of Hirschsprung disease is really academic. In the presence of megarectum, these individuals do not have a normal lower rectum or upper anal canal, and full rectal excision is necessary.

Treatment

Conservative Therapy

There is no doubt that some forms of megarectum may be controlled by keeping the rectum empty. Thus, a manual evacuation and thorough colon catharsis with purgatives and repeated enemas can be justified at first. Thereafter, the aim of conservative treatment is to keep the rectum empty by use of stimulant suppositories, enemas, and mild laxatives. This policy may be satisfactory, provided that anal sphincter function is sufficiently preserved for patients to be able to retain the enema and suppositories. This approach also needs a good deal of compliance by the patient, but sometimes, in mild disease and in patients who understand that surgical treatment is a major undertaking, these measures are successful.

Surgical Treatment

For most patients, surgical treatment is the only way to overcome overflow incontinence. Unlike the surgical treatment for pediatric Hirschsprung disease, the aim of surgical resection in the adult is to remove the dilated, nonfunctioning colonic and rectal segments. In some patients wishing to avoid major surgical resections, loop ileostomy alone may be the best approach to therapy. For megacolon alone, subtotal colectomy and ileorectal anastomosis are indicated (Fig. 166.19). For patients with megarectum or megarectum and megasigmoid, excision of the dilated nonfunctioning segment is undertaken, and the normally innervated normal caliber proximal colon is preserved with coloanal anastomosis (Fig. 166.20). Hence, operations described for the treatment of Hirschsprung disease, such as the Duhamel procedure, are inappropriate for adult megarectum. Also, for technical reasons, the Duhamel procedure is rarely possible in these patients, because the rectum completely fills the pelvis. In the small proportion of patients with gross megarectum and megacolon, total excision of the large bowel and rectum is indicated; if anal sphincter function is adequate, ileopouch–anal anastomosis is indicated. One must admit, however, that there are some patients whose anal sphincter function is so badly compromised that no form of restorative resection is indicated. In such patients, proximal loop ileostomy alone may be used for treatment. If ablative surgery is indicated, conventional resection and a covering proximal stoma are advisable.

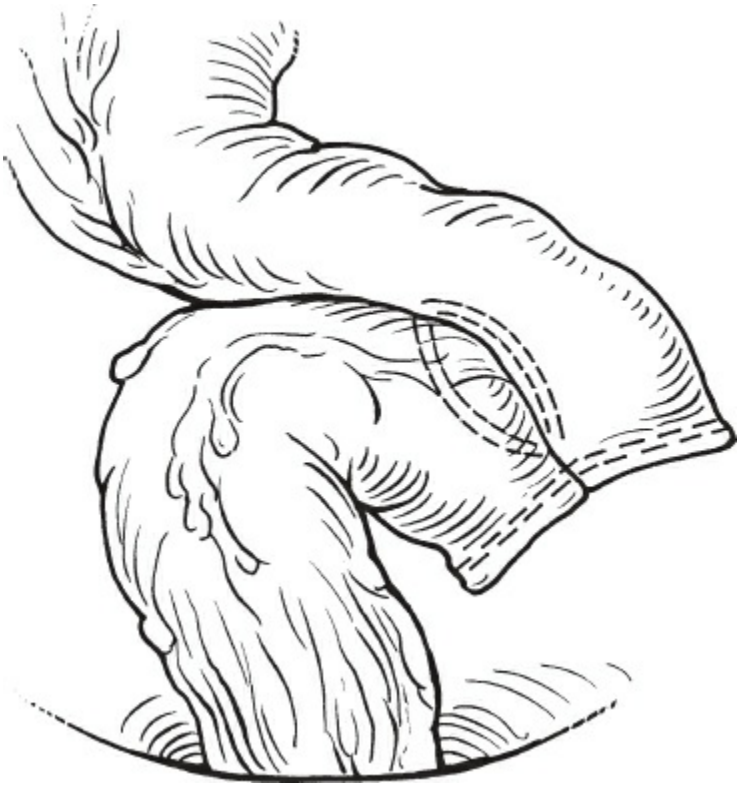

Figure 166.19. Subtotal colectomy and ileorectal anastomosis. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon.* 3rd ed. Philadelphia, PA: WB Saunders; 2008. Copyright © MRB Keighley MA MS FRCS.)

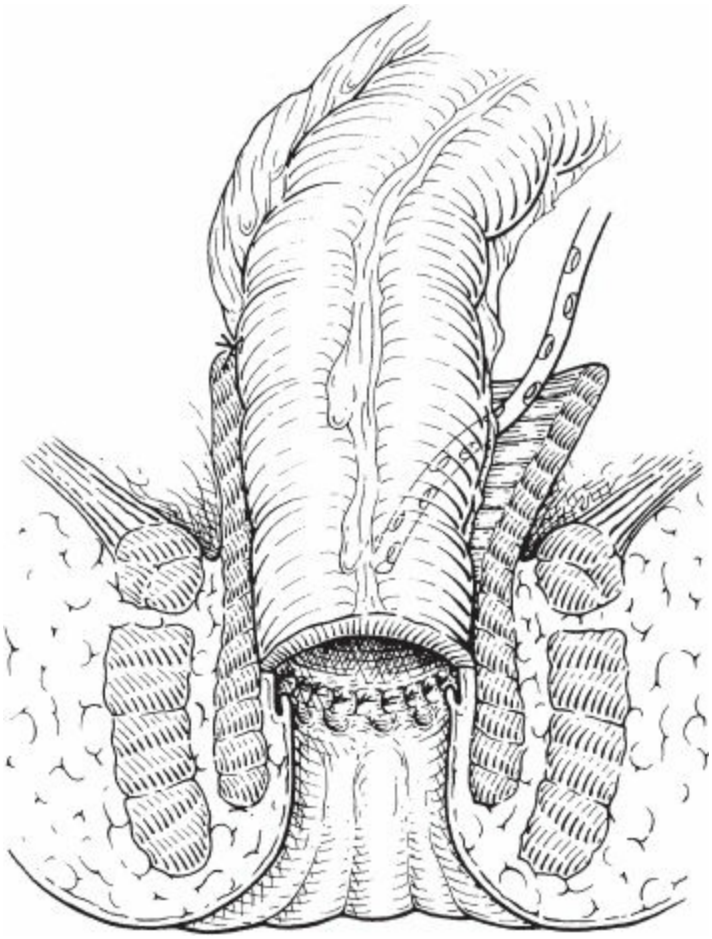

Figure 166.20. Coloanal anastomosis (hand sutured). (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon.* 3rd ed. Philadelphia, PA: WB Saunders; 2008. Copyright © MRB Keighley MA MS FRCS.)

There are certain specific surgical strategies that have to be considered in patients with adult megarectum. These strategies are described below.

1. Preoperative mechanical bowel preparation may not be possible or desirable. Manual evacuation of a huge fecaloma before a reconstructive surgical procedure may cause iatrogenic damage to the sphincter and pelvic floor. Hence, we do not attempt mechanical bowel preparation preoperatively. We milk the fecaloma from the anorectum during operation into the segment of bowel that is being resected.
2. Stapling procedures to perform a coloanal anastomosis are rarely possible in these patients. The dilated rectum imperceptibly continues downward into a dilated anus. Furthermore, the walls of the bowel are extremely thickened, which makes stapling transection almost impossible. Hence, for these patients, hand-sutured straight coloanal or ileoanal anastomosis is the only technique possible for restoring

intestinal continuity. We do not advise constructing a colonic pouch.

3. Hemorrhage is a real problem in these patients. The pararectal veins are enormously enlarged. Hence, meticulous hemostasis is necessary at operation, and intense vigilance is needed postoperatively to detect blood loss and to assess transfusion requirements. In view of the risk of blood loss, it is often wise to retain the lower third of the rectum so that it can be transected at a site that can be easily controlled from above by the abdominal surgeon. In this manner, the proximal colon can be delivered through the anal stump without the necessity of a mucosectomy and a sleeve coloanal anastomosis at the dentate line (see Chapter 154). The same technique may be used for ileoanal anastomosis with pouch construction. In these complex surgical procedures, a covering ileostomy is always desirable unless, of course, the dilated segment is confined to the colon, in which case an unprotected ileorectal anastomosis is an accepted option.

SLOW TRANSIT CONSTIPATION

Clinical Presentation

Slow transit constipation typically occurs in women between the ages of 20 and 35. There are often menstrual irregularities, which suggest abnormal ovulation and coexisting symptoms of nausea, backache, and abdominal distention. Many patients express evidence of psychological instability. Some may have a history of sexual abuse. Many patients are aggressive, and some are on psychotropic drugs for depressive illness. A few of these patients give a history of eating disorders. A few patients also experience intermittent diarrhea and constipation and exhibit features of the irritable bowel syndrome.

Causes

There are a variety of organic disorders that may be associated with slow transit constipation. Endocrine causes include hypothyroidism, glucagonoma, hypercalcemia, pheochromocytoma, hypopituitarism, and pregnancy. Metabolic causes include amyloidosis, diabetes, systemic sclerosis, hypokalemia, porphyria, and uremia.

A variety of underlying neurologic disorders may be associated with slow-transit constipation. They include demyelinating disease; neurologic ischemia; traumatic lesions of the brain and spinal cord, or tumors of the central nervous system; Parkinson disease; tabes dorsalis; autonomic

neuropathy; von Recklinghausen disease; and multiple endocrine tumors.

A number of drugs may be associated with delay in the transit of fecal material through the colon. They include all analgesics (particularly opiates), anticholinergics, compounds formulated with calcium or aluminum, iron compounds, anticonvulsants, antidepressants, antihistamines, barium, bismuth, drugs for the treatment of Parkinson disease, ganglion-blocking drugs, long-standing laxatives, muscle relaxants, and psychotropic drugs.

There is also a large group of psychogenic disorders associated with slow-transit constipation.

Diagnosis

Constipation can be subclassified functionally into delayed colonic transit and impaired rectal evacuation. In practice, many patients exhibit both forms of motility disorder.

The history of prolonged incapacitating constipation given by many patients may be unreliable. Therefore, a variety of simple screening tests are needed to determine whether there is a physical problem and to ascertain whether the problem is one of impaired colonic transit or a disturbance of rectal evacuation. It is also important for clinicians to recognize that many in this group of patients are unhappy, aggressive, and expect instant attention for a long-standing problem. These patients must be counseled and told that a series of investigations is essential to unravel the source of the problem.

First, patients should be given the opportunity to carefully explain their normal dietary habits and their fluid intake. Definition of terms is important, because there is enormous variation in the understanding of the word “constipation.” A careful drug history is essential. Some patients date the onset of symptoms to a previous operation; hysterectomy, oophorectomy, and other pelvic operations are predisposing factors to constipation. It is crucially important to exclude an eating disorder and to ascertain the patient’s normal toilet practice. Many patients spend hours straining.

A plain abdominal radiograph can help determine whether there is gross fecal loading in the colon. An inert marker study is also a useful method of screening for impaired colonic transit. However, it is not a sensitive test, and the results may vary markedly from week to week. Hence, the test may need to be repeated. The distribution of markers also gives some

indication of the possible site of colonic delay. However, therapy should not be based on marker studies alone. Simple assessment of rectal emptying may be achieved by inserting a known volume of a semisolid inert physical substance into the rectum and asking the patient to attempt evacuation under normal circumstances in the bathroom for a specified period. This simple technique may give a rough guide as to whether there is impairment of rectal evacuation. For a more detailed study, colonic transit should be assessed by using an isotopically labeled meal, and rectal evacuation should be studied after inserting an isotopically labeled paste into the rectum. Further important information can be obtained by videoproctography, which can help to define any morphologic abnormality in the anorectum and the degree of pelvic floor movement during attempted contraction and evacuation. Incomplete intussusception can also be demonstrated, along with evidence of rectocele, cystocele, or enterocele. Definition of these abnormalities may involve placing contrast material in the vagina, bladder, peritoneal cavity, or the small bowel. Videoproctography also helps define the efficiency of rectal evacuation and the degree of perineal descent. Electromyography of the puborectalis can indicate whether there is failure of relaxation of the puborectalis during attempted defecation, but the technique is painful and has generally been superseded by other methods. Preoperative assessment is not complete without a detailed psychological evaluation. Previous physical and psychological trauma should be explored. Eating disorders should be identified, and sexual disturbance should be gently investigated.

A few physical disorders must be excluded in the patient with long-standing constipation. These disorders are sigmoid volvulus, cecal volvulus, and pseudo-obstruction. In addition, patients with constipation may have a disturbance of motility affecting the whole of the gastrointestinal tract. Hence, gastric emptying and small bowel transit should also be studied. Surgical treatment should not be undertaken without these investigations.

Treatment

Conservative Measures

Many patients pressure the surgeon to undertake something immediately to relieve pain and distress. However, it is essential to ensure that patients have an adequate fluid intake and a balanced diet. Excessive intake of fiber may be contraindicated in these patients, because it aggravates abdominal

distention. If there is impaired rectal evacuation, simple measures, such as nonstimulant or stimulant suppositories, should be tried. Failing this, disposable enemas may provide a regular regimen of rectal evacuation. Patients should be told that laxatives are not necessarily harmful if they are used judiciously—a variety of prokinetic agents or cathartics should be tried as a way to alleviate symptoms. Patients must be told that symptoms of pain, nausea, abdominal distention, and backache cannot necessarily be relieved by control of constipation.

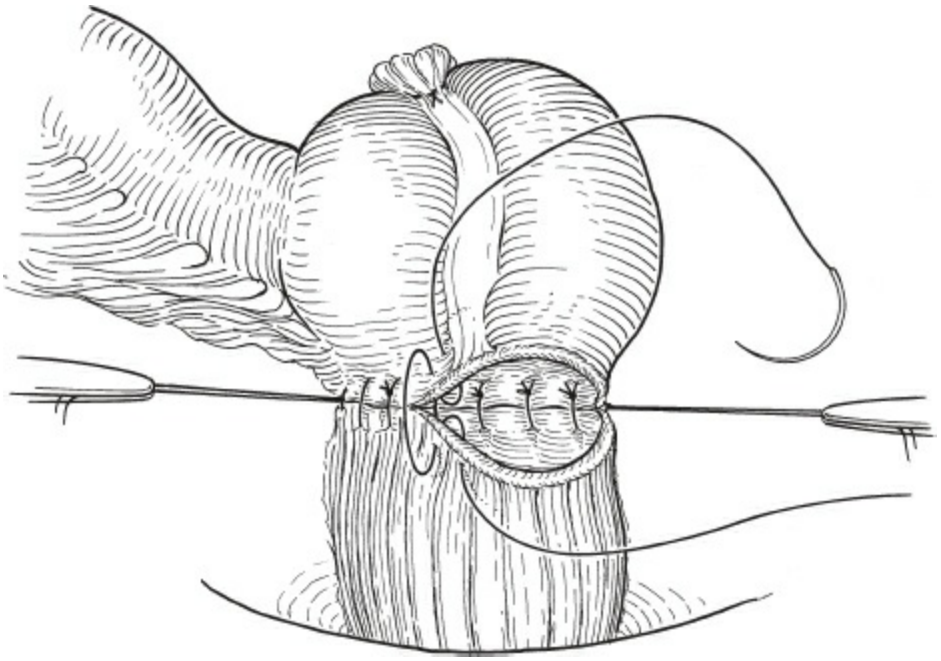

Figure 166.21. Colorectal anastomosis. (From Keighley MRB, Williams NS. *Surgery of the Anus, Rectum, and Colon.* 3rd ed. Philadelphia, PA: WB Saunders; 2008. Copyright © MRB Keighley MA MS FRCS.)

Biofeedback retraining may have a role, but it is usually directed to patients with outlet obstruction. Elderly patients with constipation may have fecal impaction; for these individuals, manual evacuation may be necessary.

Surgical Treatment

Surgical treatment of slow-transit constipation should never be undertaken lightly. Patients must be psychologically stable, and there must be a physical abnormality demonstrated on repeated investigation. All patients should be counseled about the possibility of having a stoma. In some patients, the construction of a stoma is a useful screening technique to see

whether an operation is likely to improve symptoms. They should be warned that the results of resection may be unpredictable and that colic, abdominal bloating, backache, and nausea may not be improved at all.

If surgical resection is contemplated, the optimal type of resection should be tailored according to the results of repeated physiologic studies. Segmental colectomy may have a role in patients with isolated segments of colonic inertia. However, the long-term results of segmental colectomy for slow-transit constipation are generally disappointing, because many patients continue to have infrequent bowel actions. If there is impairment of rectal evacuation and colonic transit, the primary abnormality may lie in the rectum, and for such patients, excision of the rectum and sigmoid with coloanal anastomosis may be the most appropriate treatment. However, for most patients, subtotal colectomy and ileorectal or cecorectal anastomosis (CRA) are the operations most commonly performed (Fig. 166.21). The results of resection are generally poor in patients with coexisting outlet obstruction; they are terrible if there is coexisting psychiatric disease. These operations are described elsewhere. In most patients, constipation is alleviated by either of these operations, but other abdominal symptoms usually persist. Furthermore, in 20% there is troublesome diarrhea, and a few develop incontinence. Subtotal colectomy relieves associated abdominal pain in <50% of patients and rarely influences abdominal distention or nausea. In our view, preoperative psychological assessment is absolutely essential for all these patients. A high index of psychological instability is almost always associated with a poor outcome. Hence, psychological evaluation has a predictive value in defining outcome in this difficult group of patients. There are some patients who would be better served by a stoma, a continent colonic conduit, or antegrade colostomy irrigation through an appendicostomy.

OUTLET OBSTRUCTION

Clinical Presentation

Some patients with constipation recognize that their problems are essentially caused by impairment of rectal evacuation. Many give a history of straining and the feeling that something obstructs the defecation process.

Causes

The onset of outlet obstruction may be precipitated by difficult vaginal delivery, particularly if there has been an assisted delivery or delay in the second stage of labor. Previous pelvic operations may be associated with outlet obstruction, and a long-standing history of straining is often elicited. Outlet obstruction may be secondary to solitary rectal ulcer, incomplete intussusception, enterocele, or rectocele, and may be associated with an anterior mucosal prolapse.

Diagnosis

Classically, diagnosis of outlet obstruction is made by electromyographic evidence of failure of the puborectalis to relax during attempted defecation. In many patients, the syndrome can be assumed from clinical examination, particularly if there is gross perineal descent, an anterior mucosal prolapse, or evidence of an incomplete intussusception on sigmoidoscopy.

Apart from electromyography, simple tests of rectal evacuation by use of physical agents, videoproctography, or isotopic studies help to define the syndrome. In many patients, the impairment of rectal evacuation is associated with secondary stasis of markers in the colon. In some patients, there is impairment of rectal sensation.

Treatment

Conservative Therapy

Simple conservative measures include the regular use of suppositories or enemas and biofeedback. The aim of biofeedback is to retrain the pelvic floor so that relaxation occurs during attempted defecation. The short-term results of biofeedback are often reported to be encouraging in 80% of patients, but long-term results are generally disappointing.

Surgical Treatment

Anorectal myectomy may be used to exclude Hirschsprung disease. It should not be considered a treatment, but in many patients (45% to 50%), improvement occurs afterward. Similarly, improvement has been reported in some patients after gentle anal dilation. However, care must be exercised in advising anorectal myectomy or anal dilation, because in a few patients impairment of continence may result.

Patients with a large rectocele and a history of having to press the vagina to achieve complete rectal evacuation deserve consideration for

repair. Repair of a rectocele may be performed through the perineum, the vagina, or the rectum and performing an anterior levatorplasty, as described in the section on incontinence. However, the results of rectocele repair, if the rectocele involves the entire rectovaginal septum, are often disappointing, with a high recurrence rate, continued symptoms, and dyspareunia. Thus, case selection is critical. An abdominal rectopexy with ventrosuspension of the vagina may be a better alternative. However, great care should be taken in selecting patients for repair of a rectocele and particularly rectopexy when used to treat nonprolapsing functional disease.

There was tremendous enthusiasm a few years ago for attempted correction of rectal intussusception by laparoscopic ventral mesh rectopexy (LVMR). Unquestionably, surgical treatment prevents the intussusception from continuing, but most patients do not report any improvement in their symptoms as a result; indeed, in many patients, symptoms are actually made worse by rectopexy. Similarly, there has been a vogue for correcting enteroceles by LVMR, but most of these patients strain and the habit is generally difficult to correct. Hence, the results of surgery for enterocele like rectocele are often disappointing. LVMR introduced in 2006 gained great popularity in Europe, but case selection was often not particularly rigorous and the long-term results were often very disappointing. The operation has virtually disappeared from the list of therapeutic options for functional disease owing to the lawsuits associated with chronic sepsis and mesh erosion into the rectum, vagina, and small bowel.

In a few patients with solitary rectal ulcer not improved by rectopexy, excision of the rectum and sigmoid with coloanal anastomosis may prove to be worthwhile, but these patients must be carefully selected.

Finally, there are a few patients whose symptoms are so intolerable that life for them is better with a stoma. Hence, there are also some patients in whom a trial of stoma construction alone might be justified.

EDITOR'S COMMENT

This chapter deals with functional disorders of the elimination of feces: either the inability to control it (incontinence) or having too much control as it were (constipation). Both fecal incontinence and constipation are high expense items in terms of health care dollars. Due to embarrassment, it is estimated that 70% of patients with fecal incontinence problems do not seek help or advice from any treating physician (Whitehead WE, Rao SS, Lowry A, et al. Treatment of fecal incontinence: state of the science summary for the National Institute of Diabetes and Digestive and Kidney Diseases workshop. *Am J Gastroenterol* 2015;110(1):138–46). Incontinence can make patients virtually homebound for fear of having an accident in public. Affected patients carry changes of clothes with them; they are uncomfortable in social situations and lack confidence in performing the most mundane tasks. In contrast, constipation is even more widespread, largely due to our Western diet. There is great variability in what is considered "normal." In the Rome III definition (http://www.romecriteria.org/assets/pdf/19_RomeIII_apA_885–898.pdf. Accessed January 16, 2016), constipation is defined as two or more of six criteria including (a) straining during at least 25% of defecations, (b) lumpy or hard stools in at least 25% of defecations, (c) a sensation of incomplete evacuation for at least 25% of defecations, (d) a sensation of anorectal obstruction/blockage for at least 25% of defecations, (e) facilitating manual maneuvers performed during at least 25% of defecations (e.g., digital evacuation and support of the pelvic floor), and lastly (f) fewer than three defecations per week. In my experience, many patients who have problems with certain types of outlet obstruction constipation (i.e., nonrelaxing puborectalis muscle) have a past history of having been a victim of sexual abuse. One presumes this severe psychological trauma to be a significant contributor to this condition. In evaluating the patient with a fecal incontinence, there is always the debate how much elaborate anorectal physiology testing really is necessary. The "educated finger" can determine a lot. During a digital exam, the physician can assess the resting tone, which roughly corresponds to that of the internal anal sphincter. Asking the patient to squeeze on the examining finger in the anal canal will allow the physician to assess the external anal sphincter tone. In a woman, placing one finger in the vagina and the other finger in the anal canal permits one to assess the thickness of the tissue between these structures (which represents the perineal body). Thinning of this structure suggests loss of external anal sphincter, most frequently seen due to obstetrical injury. In cases of recent traumatic obstetric injury, it is advisable to wait at least 6 months before proceeding with a definitive repair. Digital examination can also reveal the presence of a rectocele anteriorly within the rectum; this is a very common cause of constipation in women. Examination of the patient in the upright position while straining is important to in order to exclude rectal or

hemorrhoidal prolapse that can be a cause of fecal incontinence.

This chapter could easily also been referred to as the "bionic chapter" since it describes implantation of peripheral sacral nerve root stimulators or "pacemakers" to "pace" the S3 nerve root to improve fecal incontinence. It is no accident that Medtronic, the world's largest pacemaker manufacturer produces this device. The cost implication of technology is enormous. Beyond the initial implantation, long-term patient care, including programming and battery replacement can be very costly (McMullin CM, Jadav AM, Hanwell C, et al. Resource implications of running a sacral neuromodulation service: a 10-year experience. *Colorectal Dis* 2014;16(9):719–22; Hetzer FH, Bieler A, Hahnloser D, et al. Outcome and cost analysis of sacral nerve stimulation for faecal incontinence. *Br J Surg* 2006;93:1411–17). Depending on programming, the average battery life ranges from 3 to 5 years. The cost of the stimulator device alone (not including surgical and anesthesia fees, electrode costs, and other charges) is roughly $15,000!

Notwithstanding the above comments, sacral nerve stimulation appears to be a procedure that is almost too good to be true and long-term results seem to be durable (Altomare DF, Giuratrabocchetta S, Knowles CH, et al.; on behalf of the European SNS Outcome Study Group. Long-term outcomes of sacral nerve stimulation for faecal incontinence. *Br J Surg* 2015;102:407–15; Thaha MA, Abukar AA, Thin NN, et al. Sacral nerve stimulation for faecal incontinence and constipation in adults. *Cochrane Database Syst Rev* 2015;8:CD004464). The procedure is minimally invasive, and unlike sphincteroplasty or operations for incontinence, it results in no scarring to the anal sphincters. In addition to benefiting patients with conventional fecal incontinence due to obstetric injury, it appears that patients who have "atypical problems" such as those with fecal incontinence following pelvic radiation, imperforate anus, and perhaps even those who have low anterior resection syndrome may benefit from this procedure (Ramage L, Qiu S, Kontovounisios C, et al. A systematic review of sacral nerve stimulation for low anterior resection syndrome. *Colorectal Dis* 2015;17(9):762–71).

The issue of implantation of mesh prosthetics into the pelvis is one of tremendous debate. In 2008, the U.S. Food and Drug Administration (FDA) posted a public health notification on severe complications associated with transvaginal placement of mesh in the repair of pelvic organ prolapse and urinary incontinence and updated again in 2011 (http://www.fda.gov/MedicalDevices/Safety/AlertsandNotices/ucm262435.htm. Accessed January 16, 2016). The FDA received over 1,000 reports of adverse events from 2005 to 2007 and subsequently received nearly 3,000 additional reports of complications associated with surgical mesh devices used to repair pelvic organ prolapse. It was in this environment that colorectal surgeons increasingly performed laparoscopic anterior ventral mesh rectopexy for rectal prolapse. That debate continues. As is true for many minimal access procedures that are "newly developed," large series rapidly appeared in the literature

reporting outstanding results with often very short follow-up. This technique was used to treat a range of diagnoses from full-thickness rectal prolapse, to internal rectal Intussusception, to rectocele. In longer follow-up, the expected mesh complications are starting to be reported, although still with relatively low infrequency (Evans C, Stevenson AR, Sileri P, et al. A Multicenter Collaboration to Assess the Safety of Laparoscopic Ventral Rectopexy. *Dis Colon Rectum* 2015;58(8):799–807). These reports will undoubtedly increase with increased patient follow-up. In this report of 2,203 patients who had undergone this procedure at five centers in the United Kingdom over a 14-year period, the median length of follow-up for patients with synthetic mesh was 38 months (0 to 162 months) and 26 months (0 to 68 months) for patients with "biologic grafts." Surgeons must be leery of device and product manufacturers when they promote their products. While some of these products are worthy, the surgeon must use common sense and always keep the overall good of the patient foremost. The surgeon must carefully evaluate his or her patient and make sure a given procedure is unequivocally indicated for that patient before proceeding.

One final comment on the future; before one begins buying Medtronic stock, and hiring extra TSA personnel for the airports to help with all the implanted stimulators, there should be brief mention of the stem cell research being done on fecal incontinence (Raghavan S, Miyasaka EA, Gilmont RR, et al. Perianal implantation of bioengineered human internal anal sphincter constructs intrinsically innervated with human neural progenitor cells. *Surgery* 2014;155(4):668–74). There are promising animal experimental data that have been obtained using bioengineered internal anal sphincter constructs innervated with human neural progenitor cells. Obviously, such approaches are far from clinical application; however, "re-growing" an anal sphincter or using such technology to enforce weakened tissues seems likely to be preferable to using synthetic materials and power sources.

Susan Galandiuk

167 Groin Dissection

Kiran K. Turaga and Jonathan S. Zager

Groin dissection is a technique utilized in the management of lymph node metastases to the inguinofemoral and pelvic nodal basins. Involvement of the regional lymph nodes in these basins occurs commonly from lymphatic metastases from cutaneous malignancies such as melanoma, squamous cell, and Merkel cell carcinoma. Pelvic malignancies can also present with inguinal metastases especially when metastases occur along the external pudendal vessels (superficial and deep). The detection of adenocarcinoma in an inguinal lymph node must prompt thorough evaluation of the vaginal canal, the cervix, the endometrium, and the prostate. Squamous cancers and melanomas of the perineum can also present with lymph node metastases.

PATHOPHYSIOLOGY AND ANATOMY

The understanding of the development of lymphatic metastases significantly improved in 2001 after the discovery of tumor lymphangiogenesis that is distinct from angiogenesis. Malignant tumors can generate factors such as VEGF-C, VEGF-D, VEGF-A, and HGF (Hepatocyte growth factor) that foster lymphangiogenesis both on pre-existing lymphatic channels and at the draining "sentinel" lymph node. Remodeling of the lymphatic channels occurs with dilation of the channels, and with changes in the structure of the smooth muscle cells, which then leads to secondary lymph node metastases or distant metastases via the thoracic duct.

The anatomical location of the malignancy dictates its drainage to the corresponding inguinal nodal basin, although it can be quite varied due to extensive collaterals of the lymphatic channels. The development of the sentinel node biopsy technique enhanced the understanding of the anatomical drainage of extremity lesions. The femoral triangle is bounded by the inguinal ligament, the sartorius muscle, and the adductor magnus/pectineus muscles. The contents of the femoral triangle include the "superficial nodal basin," and the technique of removing the nodes in

this anatomical space is called a superficial node dissection or a femoral lymphadenectomy. Inclusion of the lower external oblique and inguinal canal lymph nodes is mandatory during such a dissection, and thus the term is appropriately coined as an inguinofemoral lymphadenectomy. Dissection of the lymph nodes along the external and internal iliac vessels (and obturator) is termed as a pelvic lymphadenectomy.

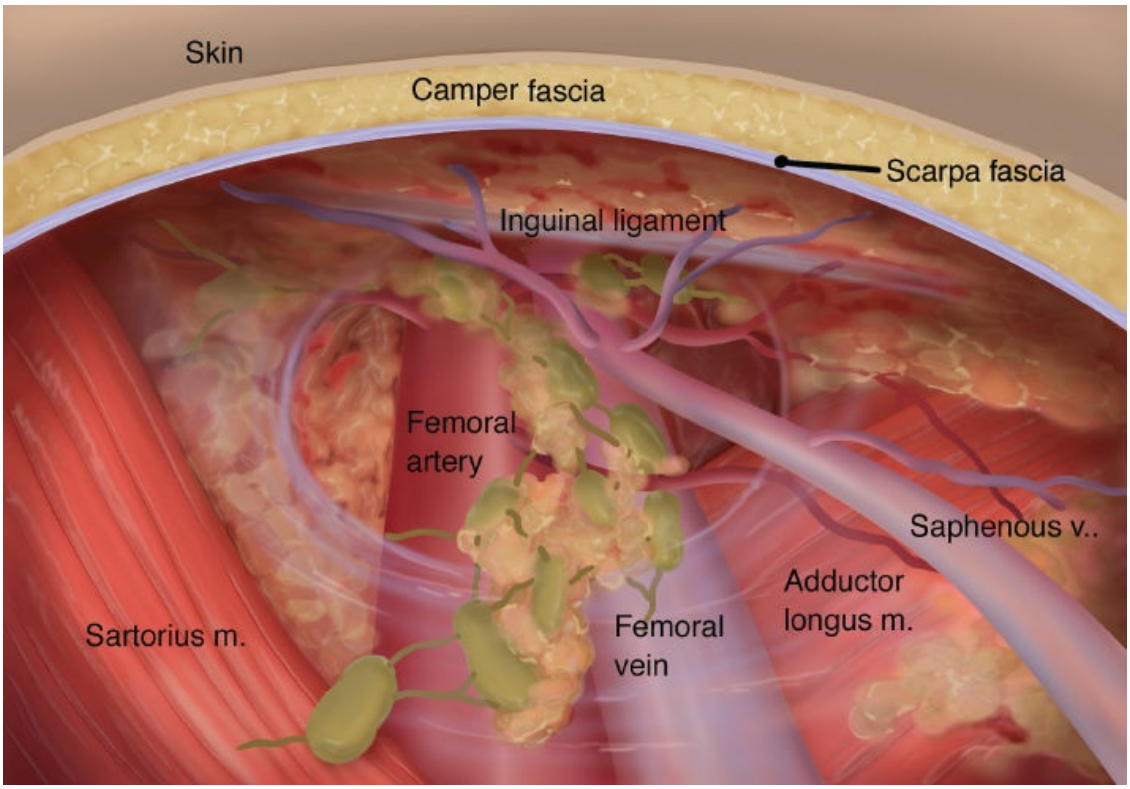

Figure 167.1. Cross-section of upper thigh showing skin, nodes, and saphenous vein.

The apex of the dissection is defined by the saphenous vein, along with the saphenous nerve (Fig. 167.1). Laterally the sartorius muscle defines the constant border as it arises from its origin on the anterior superior iliac spine. It is easy to injure the lateral femoral cutaneous nerve superficially during the lateral dissection. The motor and sensory branches of the femoral nerve are medial to the sartorius. The lateral femoral circumflex artery runs posterior to the femoral nerve and often given branches to the sartorius. Denervation and devascularization of the muscle can occur with an aggressive medial dissection. The femoral artery and vein have fewer anterior branches in the inferior aspect of the femoral triangle. Superiorly, the saphenous vein drains into the femoral vein after piercing through the fascia lata via the fossa ovalis. The superficial branches of the femoral

vessels at this level include the superficial circumflex, the superficial epigastric, and the superficial and deep external pudendal vessels. Posterior to the inguinal ligament as the femoral artery transitions to the external iliac artery, one must be aware of the deep circumflex branch that lies posterior and the inferior epigastric branch that lies medial. The external iliac artery has fewer branches in the true pelvis. The internal iliac artery divides into the anterior and posterior division. Relevant branches of the internal iliac artery that are encountered in the dissection include the obturator vessels from the anterior trunk, and the inferior vesical artery supplying the bladder that can be torn during dissection. The posterior trunk branches such as the superior gluteal artery have particular significance for collateral flow to the lower extremity. The dissection is considered complete as the bifurcation of the aorta common iliac artery is reached and care must be taken to protect the ureter that crosses anterior to the vessels.

CLINICAL PRESENTATION AND INDICATIONS

Nodal metastases can either be palpable or clinically occult, which are usually detected by either imaging or sentinel lymph node biopsy. In advanced cases, nodal disease can present with lymphedema (limb and scrotal), and with local ulceration and excoriation. Large lymph nodes can also predispose to ipsilateral venous thrombosis.

The indications for a radical groin dissection are discussed in Table 167.1. Recent randomized controlled trials in melanoma have failed to show a survival benefit with immediate completion node dissection in patients with intermediate thickness melanoma with SLN positive nodes compared to observation (MSLT-II trial). Similarly, patients with micrometastatic disease in the lymph nodes are also unlikely to draw survival benefit from lymphadenectomies (DECOG trial). The improved control of local recurrences must be balanced with the morbidity of the procedure.

Patients who have uncontrolled metastatic disease are not usually recommended nodal dissection. Palliation of nodal metastases with surgery or radiation may be warranted when patients present with pain, excoriation, or significant enlargement.

PREOPERATIVE PLANNING

Patients who may be considered as candidates for a radical groin

dissection must undergo a thorough tumor staging evaluation (cross-sectional imaging such as computed tomography [CT] scans or CT/Positron emission tomography [CT/PET] fusion scan and magnetic resonance imaging [MRI] or CT of the brain for those with metastatic melanoma) and in case of palpable nodes must include fine needle aspiration to confirm the diagnosis. Occasionally, contrast-enhanced cross-sectional imaging of the groin and pelvis with CT scan or an MRI might be essential to further delineate vascular anatomy (Fig. 167.2).

Once the decision to proceed with surgery has been made, one must optimize the patient for surgery, and the ACS-Risk calculator can be used as a tool to quantify perioperative risk. Preoperative fitting with 20- to 30-mm compression stockings is useful in the preoperative setting before significant lymphedema develops. Planning for resection of the primary site of disease and planning of the skin incision are essential at the preoperative visit.

Surgical Technique

An inguinofemoral node dissection can be performed under general or regional anesthesia. In the event of a pelvic lymphadenectomy, muscle relaxation is helpful and such cases are best done under general anesthetic. Preoperative antibiotics are usually administered, although these cases are clean cases with a low risk of postoperative wound infections, since the wound breakdown rates are high. Foley catheters are placed in patients undergoing pelvic lymphadenectomy to decompress the bladder and in cases that are anticipated to be long. The patient is placed supine, and the leg is usually abducted and externally rotated after supporting the heel with soft padding. Hair clipping of the pubic area is performed. The knee can be supported on a pillow or sterile towels depending on whether the entire extremity is included in the prep. Sequential compression devices are applied to both legs unless specifically precluded. Surgical prep is performed with standard prepping solutions containing chlorhexidine or iodophors. Scrubbing solutions of povidone iodine or chlorhexidine can be used in case of contaminated wounds or in the case of significant debris. Table to table prep is often helpful especially if manipulation of the thigh is necessary and the abdomen is prepped to the umbilicus. U-drapes are useful in maintaining a sterile field.

TABLE 167.1 Indications for Groin Dissection

Inguinofemoral Lymphadenectomy

Melanoma
- Clinically palpable lymph nodes with no extra-nodal metastatic disease
- Positive sentinel node with macrometastatic disease in patients with thick melanomas (not included in MSLT-II)
- Symptomatic nodal disease in the setting of controlled extra-nodal disease

Evolving indications
- Based on MSLT-II trial:
  - Nodal failure on observation of sentinel node positive disease
  - Inability to participate in frequent ultrasound nodal observation
- Incomplete assessment of nodal drainage due to lack of technology, or absence of sentinel node identification in a high-risk melanoma
- Positive SLN with micrometastatic disease do not need immediate completion dissection (DECOG trial)

Merkel cell carcinoma
- Clinically palpable lymph nodes with no extra-nodal metastatic disease
- Positive sentinel node
- Symptomatic nodal disease in the setting of controlled extra-nodal disease

Squamous cell carcinoma (skin and perineum)
- Clinically palpable lymph nodes with no extra-nodal metastatic disease
- Positive sentinel node
- Symptomatic nodal disease in the setting of controlled extra-nodal disease

Pelvic lymphadenectomy

Melanoma
- Enlarged (imaging) or biopsy proven external iliac/obturator lymph nodes without extra-nodal metastatic disease

Relative indications
- Involvement of >3 inguinal nodes, especially with extracapsular extension of disease
- Large (>3 cm) positive superficial inguinal nodes
- Pelvic sentinel lymph nodes (SLNs) identified on lymphoscintigraphy that were not sampled in the setting of positive superficial SLN

Merkel cell carcinoma/squamous cell carcinoma
- Enlarged (imaging) or biopsy proven external iliac/obturator lymph nodes without extra-nodal metastatic disease

Gynecological malignancies/anal cancer
- See associated chapters

Figure 167.2. Patient with enlarged necrotic metastatic melanoma to the left external iliac nodal chain requiring contrasted cross-sectional CT scan to define relationship to external iliac vessels.

The classic skin incision for the lymphadenectomy is planned in a longitudinal fashion incorporating the prior sentinel lymph node biopsy site. In the event of a pelvic lymphadenectomy, the incision is modified into a lazy S incision with termination 2 to 3 cm medial to the anterior superior iliac spine. Variants of the incision include a transverse incision along Langers lines in the suprainguinal crease (or infrainguinal crease, although the latter has been shown to have higher wound infection rates) or two separate incisions to avoid traversing the inguinal ligament. After a skin incision is made, it is carried down to the level of Scarpa fascia in the abdomen and the fascia lata in the thigh. Skin flaps are raised medially until the adductors, laterally until the sartorius, and superiorly about 4 cm above the inguinal ligament. Care must be taken in handling the skin flaps and maintaining a uniform thickness of the flaps. While an elliptical incision could avoid subsequent trimming of skin edges, our preference has been to trim the edges of the skin flaps at the end of the dissection. Self-retaining retractors such as long Adson-Beckman retractors are preferred over Weitlaner retractors. Gelpie’s have also been used by

others. Our preference has been to start laterally to expose the sartorius muscle. While modifications of the technique have been proposed to preserve the sartorius fascia, we routinely include the sartorius fascia in the dissection. The entire node bearing fatty tissue is swept medially. Superiorly above the inguinal ligament, branches of the superficial circumflex vessels are often encountered and must be ligated or appropriately coagulated to maintain hemostasis. At the inferior aspect of the femoral triangle, the saphenous vein is encountered and is a relative constant anatomical landmark during this operation. The saphenous vein is doubly ligated with 2-0 silk ties. Anterior tributaries of the vein and the posteromedial thigh tributary can be encountered and occasionally mistaken for the main saphenous trunk. The dissection is carried out medial to the sartorius muscle, and care is taken to preserve the branches of the femoral nerve. Patients are routinely not paralyzed during this operation in order to detect any twitching if thermal proximity occurs to the nerves. The specimen is elevated up off the adventitia of the femoral artery. At this point, we tend to dissect the medial aspect of the specimen elevating the nodal tissue of the adductor longus and adductor magnus muscles and the pectineus superiorly. The dissection is carried out in the infrainguinal space, and the specimen is made contiguous with the lateral specimen inferiorly. Dissection of the common femoral artery and vein is then undertaken, elevating the specimen off the adventitia of the vessels. Branches that are encountered are usually small and can be safely clipped or ligated. At this point, the superior aspect of the node dissection is performed. In this way, the dissection is performed in from the lateral medial and superior aspects until all dissections meet at the fossa ovalis. The fatty tissue under the skin flaps raised superior to the inguinal ligament is elevated off the external oblique fascia. The inguinal ligament is identified and preserved. Careful dissection can help preserve the ilioinguinal and hypogastric nerves, laterally. The nodal tissue is swept off the superficial ring and is made contiguous with the medial aspect of the specimen. Upon approaching the infrainguinal portion of the fatty nodal tissue, the superficial circumflex iliac, superficial epigastric, and the superficial external pudendal vessels are encountered and must be ligated. The nodal tissue is dissected off the femoral canal where Cloquet node is identified. This node may be sent off separately for evaluation in the event that a pelvic lymphadenectomy is contemplated. At this point, the dissection is centered around the fossa ovalis that is about 4 cm medial and

inferior to the pubic tubercle. The entire node packet is dissected away and is centered around the saphenous vein as it enters the femoral vein. The nodal packet around the junction must be dissected carefully and elevated up until the junction is clearly seen. The saphenous vein is ligated between clamps and is occasionally suture ligated if larger in size. Occasional use of a side biting vascular clamp may be necessary with primary suture closure of the defect with a 4-0 or 5-0 Prolene stitch. The specimen is oriented and handed of for further evaluation.

In the event that the dissection proceeds toward a pelvic lymphadenectomy, one must be prepared to use a self-retaining retractor such as a Bookwalter, Omni, or Thompson retractor system. The decision must be made whether a radical dissection that splits the inguinal ligament should be undertaken or two separate incisions would be used with a dissection of the inguinal ligament. While the former creates excellent exposure, the morbidity of splitting the ligament is not inconsequential with risk for hernias and weakness of the abdominal wall. To split the ligament, an incision is made in the external oblique fascia 4 cm medial to the anterior superior iliac spine and carried down until the ligament is divided medial to the femoral artery. On the other hand, a transverse incision is made 5 to 6 cm above the inguinal ligament and is carried through the external oblique fascia. The muscles are separated and the transversus abdominis muscle and transversalis fascia are carefully opened until the preperitoneal plane is reached. At this point, a blunt dissection of the retroperitoneal space usually affords a clear visualization of the pelvis as the peritoneum is swept away. Care must be taken not to avulse the inferior epigastric vessels and the lateral circumflex iliac vessels. The lateral circumflex vessels lie between the internal oblique and the transversus abdominis muscles and must be ligated. The bladder is the medial aspect of the dissection and this must be visualized and noted to be decompressed. Pelvic retractors are placed and a deep right angle blade is suitable to medially retract the bladder. Cord contents such as testicular vessels and the vas deferens are preserved in males while the round ligament can be divided in females. The inferior epigastrics may be ligated between silk ties if the dissection is restricted by the exposure reached. Cadaveric studies have demonstrated the presence of nodal metastases only in the medial aspect of the external iliac vessels and hence the dissection is started over the anterior aspect of the external iliac artery. The dissection is carried over the external iliac vein, and the space between the

bifurcation of the external and internal iliac artery is clearly dissected out. The obturator nerve is usually encountered in this space as a taut string like structure before it joins the obturator vessels to exit via the obturator foramen. While electrocautery dissection might be necessary, a significant portion of this dissection can be performed even with gentle sweeping motions of the peanut dissector. Clips for small branches might be used, although there are rarely any anterior branches of the vessels in the pelvis. The dissection over the adventitia of the external iliac artery is carried up to the bifurcation of the common iliac artery. The ureter is encountered along the dissection, and it is gently elevated away from the vessels. The internal iliac artery is rarely dissected out, although prominent branches of the anterior trunk including the inferior vesical artery and the obliterated umbilical artery may be encountered. The entire nodal packet is dissected and delivered with careful identification of the obturator and the iliac nodal chains separately. It is critical if a decision to not transect the inguinal ligament is made, that all nodal tissue behind the inguinal ligament be dissected away and made contiguous with the pelvic specimen.

At the completion of the pelvic lymphadenectomy, a drain is usually introduced in the pelvis via the lateral side. A 10/19-French drain is usually appropriate for collection of pelvic fluid in the perioperative phase. The internal oblique muscle is approximated using a 2-0 Vicryl running suture, and the external oblique is also closed with the same suture. In the event that the superficial ring was opened, it is recreated to ensure adequate space for the cord structures. Careful attention is placed to ensure that the drain is not trapped between the sutures that might prevent removal.

In the event that the inguinal ligament is divided, it is our practice to re-approximate it with 0-polyester suture in an interrupted fashion. It is our usual practice to rotate a sartorius flap over the exposed vessels. While this is not always necessary, the significantly high wound complication rate of an inguinal node dissection can lead to significant issues if the vessels are exposed. The sartorius muscle is dissected from its origin and is detached from the anterior superior iliac spine. If significant muscle fibers are present near the origin, we occasionally use a stapler to divide the muscle since it holds sutures more easily. A 4.5-mm leg length stapler is usually necessary for this division. Dissection of the sartorius is performed over the upper third to half of the muscle to ensure mobility to rotate over the

vessels. Care is taken to protect the medial vasculature and nerve fibers so as to prevent atrophy of the muscle. Sutures are then placed between the muscle and the inguinal ligament to close the femoral canal. The femoral canal is approximated with the lacunar ligament with a figure-of-eight stitch. Interrupted sutures are placed to approximate the divided sartorius to the adductors and pectineus medially, the inguinal ligament and femoral canal superiorly. Two 19-French drains are placed in the space and brought out through stab incisions inferiorly taking precautions to avoid skewering the saphenous vein. The skin edges are examined and trimmed back to healthy tissue. The deep dermis is closed with 2-0 or 3-0 Vicryl interrupted deep dermal sutures, and the skin is closed with 4-0 monocryl sutures. The drains are secured with nylon or similar sutures. Skin closures are often reinforced with dermabond- or cyanoacrylate-based adhesive dressings given their remarkable water resistance in a fairly moist area. Alternate dressings are acceptable and no superiority has been seen in any comparative studies.

TECHNICAL MODIFICATIONS

While several technical modifications exist outside of those discussed in the above section, the preservation of the saphenous vein, and/or the adductor and sartorius muscular fascia have been suggested to have lower morbidity. While the dissection is relatively similar, the former requires more bisection of the specimen to clearly examine the saphenofemoral junction. In the case of preservation of the muscular fascia, care must be taken to elevate the fascia lata off the femoral vessels to restore continuity of the specimen.

POSTOPERATIVE COURSE

In the case of the inguinofemoral lymphadenectomy, patients are watched overnight to ensure adequate pain control. The lower limb is elevated and could be wrapped with ACE wrap bandages to minimize swelling. Patients are typically discharged the next morning and brought back for early follow-up to check the wound site. Drains are typically removed when the output is <30 to 50 mL/24-hr period. When a pelvic lymphadenectomy is performed, we routinely remove the pelvic drain the next morning after the operation (12 to 24 hours later). If excessively high outputs (>200 mL) are noted, the drain is left in for an additional 24 hours. Some patients could develop an ileus and resumption of bowel function could take a few days.

For patients with reliable follow-up, early discharge is relatively safe even in the absence of bowel function. Voiding without a catheter needs to be confirmed prior to discharge.

Significant wound complications have been described for patients undergoing this operation. Flap necrosis/dehiscence has been reported in almost 19% to 26% of the patients. A significant wound infection rate has also been described of as high as 9%. Early and meticulous wound care is essential with early debridement of necrotic tissue. Use of vacuum-assisted closure devices may be necessary in some cases. Occasionally, reoperation to place a skin graft or flap assisted closure may be necessary. Prevention of lymphoceles and hematomas with meticulous dissection helps tremendously, although they still occur 5% to 27% of the time. In such a setting, early aspiration may be considered, although repeated aspirations could lead to infection of the lymphocele. In the case of aspiration or drain placement, it is essential to place the puncture site away from the main incision.

Lymphedema has been described in as many as 30% of patients undergoing a radical groin dissection. Early appropriate management with a compression stocking with 20- to 30-mm graded compression is highly effective in managing patients. Elevation of lower extremity during the early postoperative period and regular use of stockings during nonsleep hours for 6 months are generally adequate in managing lymphedema. Massage therapy and other lymphedema management therapy can be used in patients with persistent or long-standing edema. Body garments with compression are also available for those who develop abdominal wall edema. Scrotal edema can be managed with supportive undergarments. Microsurgical therapy for lymphedema has been shown by some proponents to be effective in controlling both scrotal and lower limb lymphedema, although this has been more commonly used in the upper extremity.

MINIMALLY INVASIVE LYMPHADENECTOMY

The technique of a minimally invasive lymphadenectomy has potential advantages in reducing the wound complications associated with a radical groin dissection. The technique is best suited to patients with low burden of disease and favorable anatomy. Below we describe the technique associated with a minimally invasive inguinofemoral and pelvic lymphadenectomy. While both are feasible procedures separately, it can be

logistically arduous to combine both procedures at the same time.

INGUINOFEMORAL LYMPHADENECTOMY

Patients with infrainguinal disease are placed in split leg position (Fig. 167.3). Foley catheter is optional especially if concern for a technically difficult dissection is anticipated. The femoral triangle is marked out including the space 5 cm above the inguinal ligament. The site of the previous sentinel lymph node biopsy site is usually included within the skin flaps of the dissection. The technique is performed using three ports of 10- to 12-mm diameter placed away from the femoral triangle. The inferior most port is placed inferior to the apex of the triangle by 3 to 4 cm, and the other ports are separated by around a hand breadth outside the triangle. The procedure is begun by making an incision to accommodate a balloon Hasson port. Dissection through the fascia lata is performed, and a combination of blunt and cautery dissection is performed to raise flaps for around 5 cm in the direction of the triangle. Teflon tip cautery is essential if flaps are being raised with thermal energy. Insufflation with a higher pressure (20 to 25 mm Hg) is initiated for the first 10 minutes followed by reduction in the pressure to 15 mm to reduce CO_2 crepitus. Using short 12-mm ports in the medial and lateral positions, dissection is carried out using ultrasonic shears and counter traction with a grasper/endoscopic kittner instrument. Skin flaps are raised endoscopically, while maintaining care to not create thermal burns. The pneumatic dissection facilitates dissection that makes this procedure expeditious. The dissection is carried out by identifying the saphenous vein and dissecting along the vein superiorly. After creating dissecting space, the sartorius fascia is incised ensuring that the medial aspect of the dissection is carefully performed. The ultrasonic shears does not lead to nerve stimulation similar to thermal energy and femoral nerve branches must be carefully preserved. The dissection is then carried out medially over the adductor and pectineus muscles and the fascia is elevated up. At the fossa ovalis, we dissect the saphenofemoral junction. The superficial circumflex, superficial external pudendal, and superficial epigastric branches are identified and divided using 10-mm clips. Care must be taken to ensure that subsequent division of the saphenofemoral junction is not impaired by the clips. Dissection above the inguinal ligament is performed later on in the dissection to reduce CO_2 insufflation of the abdominal wall. The saphenofemoral junction is dissected, and Cloquet node is identified and pulled into the specimen. The

junction is divided with a 45-mm vascular staple load. The specimen is then dissected off the femoral artery and vein, carefully re-establishing the subfascial plane with the femoral sheath. The hook electrocautery can be useful along with blunt dissection with the kittner device. Vasavasorum can occasionally lead to nuisance bleeding and must be controlled. Medial branches to the adductors and pectineus are controlled. Posterior dissection of the femoral vessels is not performed. The specimen is rolled inferiorly, and the distal proximal aspect of the saphenous vein is identified and divided with the stapler (Fig. 167.4). A specimen bag is introduced and the contents are placed within the bag and removed. The specimen is oriented and hemostasis is confirmed. One or two drains are placed through the medial and inferior incisions. Patients are discharged home either the same day or the next and are given a regular diet.

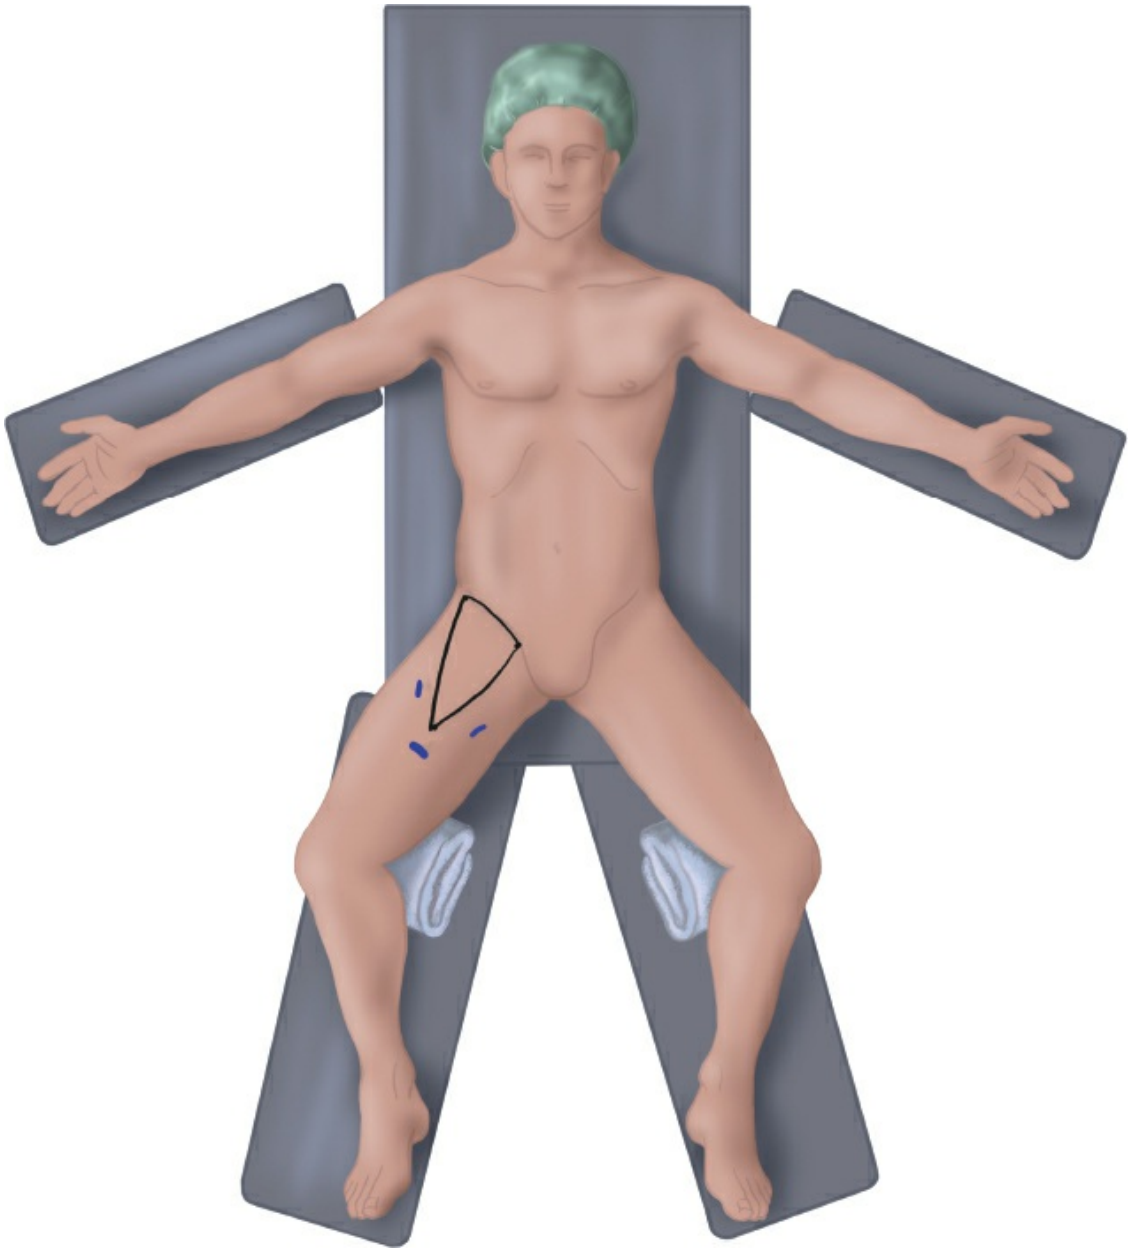

Figure 167.3. Patient is placed in split-leg position and femoral triangle is marked for a inguinofemoral lymphadenectomy.

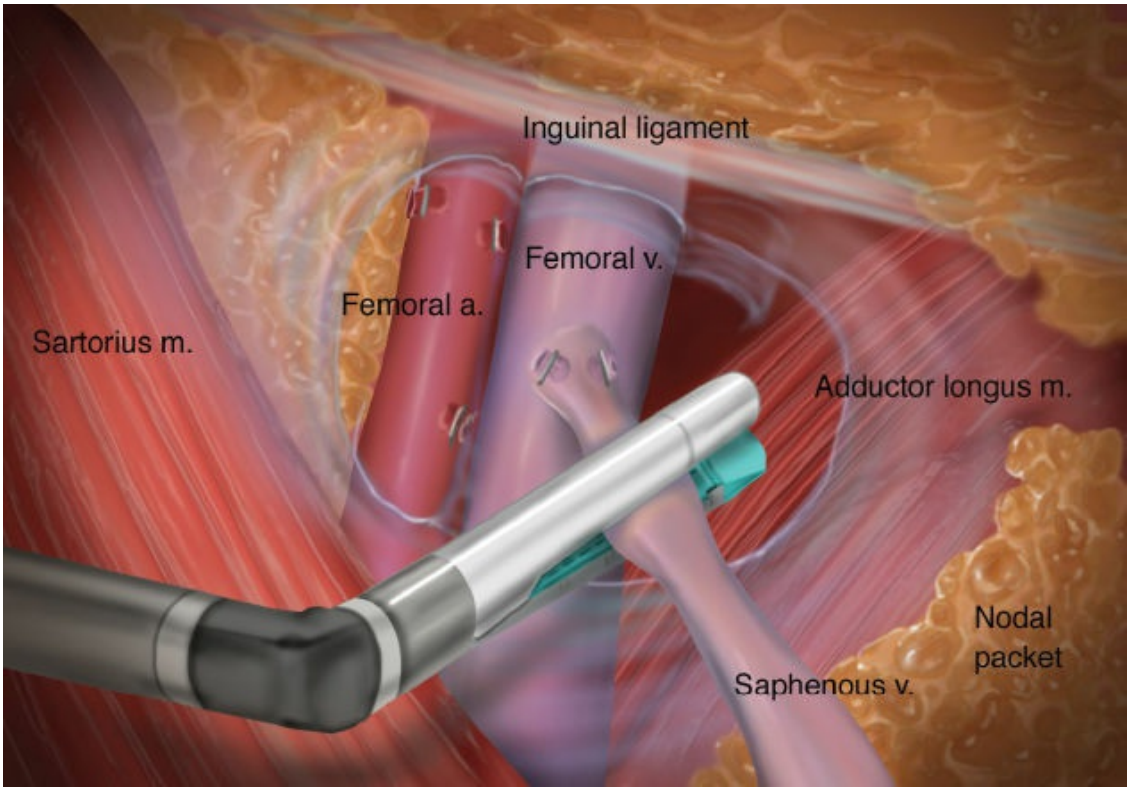

Figure 167.4. The surgical stapler dividing the distal proximal section of the saphenous vein.

ROBOTIC PELVIC LYMPHADENECTOMY

Techniques for a robotic pelvic lymphadenectomy are similar to those described in this book elsewhere (Chapter 163). While the anatomical principles of a laparoscopic and robotic pelvic lymph node dissection are similar, the setup of the patient and the port placement differ significantly. The utility of a minimally invasive pelvic lymphadenectomy is usually in the setting where a pelvic recurrence occurs after a prior inguinofemoral lymphadenectomy. Patients identified as candidates for robotic pelvic lymphadenectomy are adequately staged and imaged as discussed previously. Foley catheters are routinely placed. Patients are placed in split leg position. Pneumoperitoneum is usually created with a supraumbilical 12-mm port. Robotic ports must be spaced at least a hand breadth distance, and the ports are usually placed with two robotic ports on the contralateral side and one robotic and one assistant port on the ipsilateral side. The patient is placed in steep Trendelenburg position before docking the robot. Incising the peritoneum lateral to the medial umbilical ligament is usually accomplished as the first step. The monopolar scissors are usually in the ipsilateral port, and the Maryland bipolar and a grasping forceps such as a Cadiere or Prograsp are appropriate third arm graspers. The Cadiere allows

for potential manipulation of the bowel especially on the left side. The sigmoid colon attachments are taking down, and any adhesions are taken down to ensure a clear field. The peritoneum is incised anterior to the external iliac artery and carried over to the common iliac artery. The ureter is carefully dissected as it crosses the artery. Medially the nodal packet is swept between the external iliac vein and the internal iliac artery. The obturator nerve and vessels are encountered, and care must be taken to dissect with minimal thermal cautery. The nodal packet is usually swept up, and the pneumoperitoneum significantly facilitates dissection. The external iliac artery and vein are dissected carefully, closer to the inguinal ligament. While occasional branches need to be coagulated, it is rare to require significant clips/ties. The inferior epigastric artery is dissected and divided if necessary, and the dissection is made contiguous with the infrainguinal dissection if extensive scar tissue is not present. The node packet is placed in a specimen bag and extracted. The peritoneum can be reperitonealized with an absorbable suture, although this is not necessary. The port sites are closed. Patients are watched overnight for any events, and are typically discharged the next day after the operation.

Management of Complications of a Groin Dissection

Wound complications are the predominant class of complications that require close management. Aggressive debridement of necrotic wounds, early detection and treatment of cellulitis, and close monitoring of lymphoceles are essential in preserving flap integrity. Dusky flaps frequently require reoperative surgery. In the case of an open wound, vacuum-assisted closure devices are safe especially if a sartorius muscle flap transposition was done at the primary operation. If not, reoperative surgery is necessary if exposed vessels are present. Lymphedema must be managed aggressively in patients undergoing groin dissection. Early elevation of the limb is key. Wrapping the leg and ankle with ACE bandages has been utilized by some to reduce edema. Compression stockings and elevation play a key role in the management of edema. Avoiding long travel, excessive salt intake, and optimization of other causes of edema are essential. Lymphedema massage therapy is helpful for patients with intractable edema. Microsurgical options have also been explored for patients with life-limiting edema.

SUMMARY

Radical groin dissection is the standard of care for patients with palpable/clinically involved nodes in patients with melanoma and other cutaneous and perineal malignancies. The overarching goal is disease control, and there is limited evidence to suggest prolongation of length of life with a node dissection in a majority of disease sites. Immediate completion node dissection for patients with positive sentinel lymph nodes for patients with intermediate thickness melanoma or with micrometastatic disease is no longer the only standard of care when careful observation is feasible. The major morbidity of this operation includes lymphedema and wound complications that can be reduced with meticulous surgical technique, aggressive postoperative management of edema, and potentially minimally invasive strategies.

EDITOR'S COMMENT

Although less commonly performed today than in decades past, radical groin dissection remains a very important surgical procedure in the regional control of a number of cutaneous, gynecologic, and urologic malignancies. Indeed, prior to the advent of lymphatic mapping and sentinel lymph node (SLN) biopsy in the 1990s, it was routine for many patients with melanoma to undergo elective lymph node dissections even in the absence of clinically evident regional adenopathy. Of course, routine lymph node dissections only conferred a potential benefit to the 20% of patients who harbored metastatic disease in their nodes, while at the same time exposing all of the patients to the morbidity of the procedure. Don Morton revolutionized the staging of the regional nodal basin(s) with the sentinel lymph node biopsy technique for a whole host of malignancies with a propensity for nodal metastasis. He and his colleagues showed in the prospective Multicenter Selective Lymphadenectomy Trial (MSLT-1), randomizing patients with cutaneous melanoma to either SLN biopsy or nodal observation, that SLN status is the most significant predictor of survival. Although no overall survival benefit was observed for the entire cohort of 1,269 patients, subgroups of patients with intermediate thickness (1.2- to 3.5-mm) and thick (>3.5-mm) melanomas showed improved distant metastasis-free survival and melanoma-specific survival after SLN biopsy and completion lymphadenectomy compared with observation alone (Morton DL, Thompson JF, Cochran AJ, et al. Sentinel-node biopsy or nodal observation in melanoma. *N Engl J Med* 2006;355:1307–17; Morton DL, Thompson JF, Cochran AJ, et al. Final trial report of sentinel-node biopsy versus nodal observation in melanoma. *N Engl J Med* 2014;370:599–609). Even in the absence of an overall survival benefit, most would agree that the SLN biopsy procedure provides important staging information to estimate prognosis and to guide further treatment decisions, as well as to provide regional disease control. The question of greater

debate is the role of completion lymph node dissection in extending survival in patients with positive SLN biopsies and, importantly, in identifying which patients may be safely spared the morbidity of a radical lymph node dissection. This question is of such debate because only 20% or so of patients with one or more positive SLNs will have metastatic disease in one or more of the remaining nonsentinel lymph nodes (Pasquali S, Mocellin S, Mozzillo N, et al. Nonsentinel lymph node status in patients with cutaneous melanoma: results from a multi-institution prognostic study. *J Clin Oncol* 2014;32:935–41), bringing us back to the exact same problem we faced in the 1980s with performing morbid lymph node dissections on a significant percentage (80%, to be exact) of melanoma patients who could not hope to benefit from it. Thus, the MSLT-2 trial was launched to specifically address this question, the results of which were just published. In this trial, patients with sentinel node metastases were randomly assigned to immediate completion lymph node dissection or nodal observation with ultrasonography. Though the findings of this trial confirmed that immediate completion lymph node dissection increased the rate of regional disease control and provided valuable prognostic information, it did not lead to an improvement in survival, and the rate of lymphedema in the dissection group was significant at 24% (Faries MB, Thompson JF, Cochran AJ, et al. Completion dissection or observation for sentinel-node metastasis in melanoma. *N Engl J Med* 2017;376:2211–22). Therefore, the European Organisation for Research and Treatment of Cancer (EORTC) initiated a similar trial (EORTC 1208, or MINITUB), randomizing patients with minimal sentinel lymph node tumor burden to either completion node dissection or observation, but the results of this trial are not expected for at least another 3 to 5 years.

In the meantime, we do have prospective data from the DeCOG-SLT trial, which was organized by the German Dermatologic Cooperative Oncology Group. This was a multicenter, randomized, phase III trial comparing the survival of SLN biopsy positive melanoma patients with and without completion lymph node dissection. Although underpowered, the authors found no difference in any survival outcome in patients treated with completion lymph node dissection compared with those who were simply observed (Leiter U, Stadler R, Mauch C, et al. Complete lymph node dissection versus no dissection in patients with sentinel lymph node biopsy positive melanoma (DeCOG-SLT): a multicentre, randomised, phase 3 trial. *Lancet Oncol* 2016;17:757–67). The majority (66%) of patients in this study had a low tumor burden (micrometastases <1 mm in size) in the SLNs, and so the authors concluded that melanoma patients with micrometastatic disease in their SLNs should not undergo a completion radical lymph node dissection. These findings have been confirmed in many other retrospective cooperative group and single-center studies (van der Ploeg AP, van Akkooi C, Rutkowski R, et al. Prognosis in patients with sentinel node-positive melanoma without immediate completion lymph node dissection. *Br J Surg* 2012;99:1396–405; Satzger I, Meier A, Zapf A, et al. Is there a therapeutic benefit of complete lymph node dissection in

melanoma patients with low tumor burden in the sentinel node? *Melanoma Res* 2014;24:454–61).

Regardless of the potential benefits of radical groin dissection, a major drawback of this procedure is the undeniable fact that it can be quite morbid. Chang et al., in a prospective assessment of postoperative complications following radical groin dissection in 53 melanoma patients, identified a 30-day wound complication rate of 77.4% (Chang SB, Askew RL, Xing Y, et al. Prospective assessment of postoperative complications and associated costs following inguinal lymph node dissection (ILND) in melanoma patients. *Ann Surg Oncol* 2010;17:2764–72), and a body mass index >30 significantly increased the risk of wound complications. Stuiver et al. examined the outcomes of 145 patients undergoing a radical groin dissection for melanoma and found that one or more complications occurred in 72% of cases, including a wound infection in 45%, seroma formation in 37%, and skin flap necrosis and/or dehiscence in 26% (Stuiver MM, Westerduin E, Ter Meulen S, et al. Surgical wound complications after groin dissection in melanoma patients—a historical cohort study and risk factor analysis. *Eur J Surg Oncol* 2014;40:1284–90). These authors identified older age as the only predictor of complications. Notably, neither the type of skin incision (longitudinal vs. transverse vs. two transverse), sparing of the greater saphenous vein, removal of an ellipse of skin with the specimen, nor use of a sartorius muscle transposition flap influenced the risk of complications. In my practice, I prefer the longitudinal, lazy S-shaped incision described by the authors in this chapter, as well as the routine division of the greater saphenous vein and the trimming of the skin edges at the conclusion of the case prior to skin closure. I selectively harvest a sartorius muscle flap in those I deem at highest risk of a major wound complication (e.g., patients with obesity, diabetes, currently smoking), though admittedly, prospective, randomized data demonstrate that use of a sartorius muscle transposition flap does not in fact reduce the wound complication rate after radical groin dissection (Judson PL, Jonson AL, Paley PJ, et al. A prospective, randomized study analyzing sartorius transposition following inguinal-femoral lymphadenectomy. *Gynecol Oncol* 2004;95:226–30).

In order to minimize the significant morbidity associated with a radical groin dissection, many groups (including our own) have adopted minimally invasive techniques. The most common minimally invasive technique is the video endoscopic inguinal lymphadenectomy (VEIL), which the authors of this chapter so nicely describe. One of the first clinical applications of this technique dates back to 2003, when it was proposed for the treatment of inguinal lymph node metastases from squamous cell carcinoma of the penis (Bishoff JT, Basler JW, Teichman JM et al. Endoscopic subcutaneous modified inguinal lymph node dissection (ESMIL) for squamous cell carcinoma of the penis. *J Urology* 2003;169:78). Since then, at least 10 series of this minimally invasive technique have been described, most commonly for the treatment of metastatic melanoma (Sommariva A, Pasquali S, Rossi CR, et al. Video endoscopic inguinal

lymphadenectomy for lymph node metastasis from solid tumors. *Eur J Surg Oncol* 2015;41:274–81). VEIL has been shown to be safe and feasible, is associated with much lower rates of complications than its radical open counterpart, and, at least on short-term follow-up, appears to offer equivalent oncologic outcomes, with lymph node yields ranging between 7 and 16 nodes and locoregional recurrence rates of <10% (Delman KA, Kooby DA, Ogan K, et al. Feasibility of a novel approach to inguinal lymphadenectomy: minimally invasive groin dissection for melanoma. *Ann Surg Oncol* 2010;17:731; Master VA, Jafri SM, Moses KA, et al. Minimally invasive inguinal lymphadenectomy via endoscopic groin dissection: comprehensive assessment of immediate and long-term complications. *J Urol* 2012;188:1176–80; Sommariva A, Pasquali S, Rossi CR, et al. Video endoscopic inguinal lymphadenectomy for lymph node metastasis from solid tumors. *Eur J Surg Oncol* 2015;41:274–81). Not surprisingly, we are also starting to see reports of the salutary benefits of robot-assisted inguinal and pelvic lymph node dissections (Ahlawat R, Rakesh K, Gagan G, et al. Robot-assisted simultaneous bilateral radical inguinal lymphadenectomy along with robotic bilateral pelvic lymphadenectomy: a feasibility study. *J Laparoendosc Adv Surg Tech A* 2016;26:845–9), including one from the authors of this chapter (Dossett LA, Castner NB, Pow-Sang JM, et al. Robotic-assisted transperitoneal pelvic lymphadenectomy for metastatic melanoma: early outcomes compared with open pelvic lymphadenectomy. *J Am Coll Surg* 2016;222:702–9). Despite the higher costs of equipment and operating room time with the robotic approach, I suppose the cost savings conferred by the much lower rate of complications than that seen with the radical, open approach may justify its use.

John Mullen

168 Transanal Pull-Through for Hirschsprung Disease

Jacob C. Langer

ETIOLOGY AND PATHOPHYSIOLOGY

Hirschsprung disease is characterized by the absence of ganglion cells within the submucosal and myenteric plexuses in the distal bowel. The aganglionic bowel lacks peristalsis, which results in functional obstruction. The disease involves the rectum and part of the sigmoid colon in about 85% of cases, although the aganglionosis can extend through the entire colon (10%) and even through some or all of the small bowel in rare cases.

It is unknown why the ganglion cells are absent in the affected bowel, or why the aganglionic segment virtually always starts at the anus and extends to a variable distance proximally. It is known that the ganglion cells arise from the neural crest, and there is evidence that the neural crest cells fail to either complete their migration or fail to survive within the microenvironment of the aganglionic bowel. It is clear that Hirschsprung disease is not a single disease, but in fact is a common phenotype of a variety of genetic mutations and therefore likely a variety of etiologic mechanisms. The most common gene that has been identified is the RET proto-oncogene, but mutations in the endothelin family of genes as well as SOX-10, ZFHX1B, Phox2B, and the Hedgehog/Notch complex have been implicated as contributory to Hirschsprung disease. These mutations may cause early neuronal cell death, early maturation or differentiation of neural crest cells, or a hostile microenvironment for ganglion cell survival.

CLINICAL PRESENTATION

Hirschsprung disease involving the rectum or rectosigmoid is more common in males than females (4:1), but long-segment disease affects males and females with the same frequency. Associated congenital anomalies are seen in a significant number of patients. Hirschsprung disease may also be associated with chromosomal abnormalities (particularly trisomy 21) and a number of other syndromes, including a

number of neurocristopathies, congenital central hypoventilation syndrome, and multiple endocrine neoplasia type 2.

Diagnosis is suspected on clinical grounds in newborns and infants with distal intestinal obstruction or in older children with severe chronic constipation. Contrast enema usually shows a transition zone between the normal and aganglionic bowel (Fig. 168.1), although the contrast enema may be falsely negative in up to 10% of neonates with Hirschsprung disease. The diagnosis is confirmed based on a rectal biopsy showing aganglionosis, usually associated with histologic evidence of hypertrophic nerves and abnormal cholinesterase and calretinin staining. In neonates this is done using a suction device, and in older children a deeper biopsy must be done. In all cases, care must be taken to biopsy at least 1 to 2 cm above the dentate line, since there is a normal hypoganglionic region below that level.

SURGICAL MANAGEMENT

The treatment of Hirschsprung disease is surgical, and the principle of the operation is to remove the aganglionic colon and anastomose normally innervated bowel to the anus, while preserving anal sphincter function. The first such operation, described by Swenson in the late 1940s, involved complete rectal resection and primary end-to-end anastomosis just above the anal sphincter. Two additional operations were subsequently described and popularized. The Soave procedure involves a submucosal dissection with an endorectal pull-through, leaving a rectal muscular cuff, and the Duhamel operation brings the normal bowel through the avascular plane behind the aganglionic rectum, with a stapled anastomosis joining the two lumens.

Figure 168.1. Contrast enema demonstrating a typical transition zone between normal and aganglionic bowel at the rectosigmoid junction. The lateral view is the most effective for seeing the transition zone.

Because these children often presented with severe malnutrition or enterocolitis, a preliminary colostomy was usually done, followed by a pull-through procedure many months later. Earlier recognition and diagnosis of the disease led a number of surgeons in the 1980s to report single-stage pull-through procedures even in small infants. Over the past few decades, one-stage operations have become increasingly popular are considered to be safe, cost-effective, and the approach of choice for most children with Hirschsprung disease. A stoma is still considered to be appropriate in children with severe enterocolitis, very dilated proximal bowel, long-segment aganglionosis, or lack of adequate pathology support.

In the early 1990s, Georgeson described a minimal access approach, consisting of a laparoscopic biopsy to identify the transition zone,

laparoscopic mobilization of the rectum below the peritoneal reflection, a short endorectal mucosal dissection from below, and an anastomosis from below after prolapsing and excising the rectum. Laparoscopic approaches were subsequently described for the Duhamel and Swenson operations. The transanal Soave procedure represented a natural evolution from the laparoscopic operation, and initial series in children with Hirschsprung disease were published by de la Torre and by Langer in the late 1990s. The transanal approach has the principal benefit of avoiding the need for intra-abdominal mobilization of the rectum via either laparotomy or laparoscopy. Both the laparoscopic and transanal approaches are associated with less pain, shorter hospital stay, and a better cosmetic result than open surgery, but there have not been any studies comparing the laparoscopic to the transanal approach. However, the transanal pull-through can be done by any pediatric surgeon, including those without laparoscopic skills, and by pediatric surgeons in parts of the world where access to appropriately miniaturized laparoscopic equipment is limited.

PREOPERATIVE PLANNING AND PREPARATION

Infants with intestinal obstruction or enterocolitis should undergo rapid resuscitation with intravenous fluids, antibiotics, and a nasogastric tube. Early decompression of the colon using digital rectal stimulation and/or irrigations through a rectal tube is important to prevent and treat enterocolitis and to decrease the diameter of the colon. Children with associated abnormalities such as cardiac disease or congenital central hypoventilation syndrome must have these problems investigated and managed prior to definitive surgical repair. Once the child has been stabilized, surgery can be done semi-electively. While waiting for surgery most children can be fed breast milk or an elemental formula, in combination with rectal stimulations or irrigations, although some will require ongoing nasogastric decompression and parenteral nutrition.

The older child who presents with severe constipation and an extremely dilated colon may require weeks or months of irrigations to bring the colon to a more normal size prior to definitive surgery. Some children with particularly dilated or thickened proximal colon may require a colostomy to achieve adequate decompression.

IMPORTANT ANATOMICAL CONSIDERATIONS

There are three important anatomic structures or planes that must be

recognized during the safe and correct performance of a transanal pull-through. Firstly, the anorectal squamocolumnar junction (dentate or pectinate line) must be clearly identified, and the initial mucosal incision must be made high enough that the transitional epithelium is preserved. If this epithelium is damaged, sensation will be abnormal and continence will be impaired. Secondly, the relatively bloodless submucosal plane of the rectum permits the surgeon to avoid injury to the vagina or prostate during the initial dissection. Thirdly, the plane on the serosal surface of the rectum is also relatively bloodless, and the principle of staying in this plane will prevent injury to pelvic structures.

Since the basic principle of the operation is to bring normally innervated bowel to the anus, it is very important to ensure that the proposed pull-through bowel has normal ganglion cells, confirmed by frozen section. We prefer to do this prior to beginning the anal dissection using a small umbilical incision, although some surgeons prefer to use laparoscopy for this purpose. The advantage of the umbilical approach is that it can be done by any surgeon, anywhere in the world, regardless of ability or access to neonatal laparoscopy. The use of a preliminary biopsy does not change the outcome of the transanal pull-through in terms of time to feeds, amount of pain, or hospital stay. If the operation is to be done in one stage, the surgeon must have the assistance of an experienced pediatric pathologist in order to avoid error.

In children with a more proximal transition zone, the normal bowel may not reach the anus. In these cases a number of maneuvers can be done, including dividing the lateral attachments of the descending colon, taking down the splenic flexure, and dividing the mesenteric vessels proximally so that blood supply is maintained via the marginal vessels. These maneuvers can be done through a small umbilical incision or using laparoscopy.

SURGICAL TECHNIQUE

A single-shot caudal block should be placed both prior to beginning the operation and at the end of the procedure. All patients should receive antibiotic prophylaxis to cover gram-negative bacilli and colonic anaerobes. Preoperative bowel preparation usually fails because of the functional obstruction caused by the aganglionic segment, and results in abdominal distension and retention of fluid. Instead, the rectum and distal colon should be washed out on the table after induction of anesthesia. A

Foley catheter is not necessary in infants; the bladder can be emptied intermittently using a Coude maneuver instead.

The patient is placed into lithotomy position, and an umbilical incision is made. This can be either supra- or infraumbilical, and can be extended into an “omega” shape if necessary. A Hager dilator is placed through the anus to push the sigmoid colon toward the umbilical incision (Fig. 168.2A), where it can be easily grasped with a Babcock clamp. A full-thickness biopsy is done in order to optimize the pathologist’s accuracy. While awaiting the frozen section, the mesentery between the biopsy site and the peritoneal reflection is divided from proximal to distal, using bipolar electrocautery along the edge of the colon.

Once the frozen section has documented normal ganglion cells the surgeon moves to the bottom of the table for the perineal portion of the operation. A nasal speculum can be gently used to initially visualize the mucosa and the dentate line, without the need for stretching of the sphincter (Fig. 168.2B). A circumferential mucosal incision is made 0.5 to 1.0 cm above the dentate line, depending on the size of the child, ensuring that the transitional epithelium is protected from injury. Fine silk sutures are placed in the mucosal edge to provide traction, and the mucosa is then stripped from the underlying muscle for approximately 2 cm using a combination of electrocautery with a fine-tipped needle and blunt dissection (Fig. 168.2C). Once the mucosal dissection has been completed, the rectal muscle can be seen prolapsing down through the anus. The muscle is incised circumferentially, starting anteriorly and progressing circumferentially around both sides, permitting the dissection to continue proximally along the outside of the rectal wall (Fig. 168.2D). The vessels must be divided either by electrocautery or with ties just as they enter the bowel wall, to avoid injury to pelvic nerves and vessels, as well as to the prostate or vagina. It is also very important to avoid twisting of the bowel as the dissection progresses proximally. This can be accomplished by holding the rectum with a curved clamp, making sure that the orientation of the clamp does not change. It is also important that most of the dissection be done outside the anus without the need for retraction of the anal sphincter, which can result in long-term continence issues from sphincter injury.

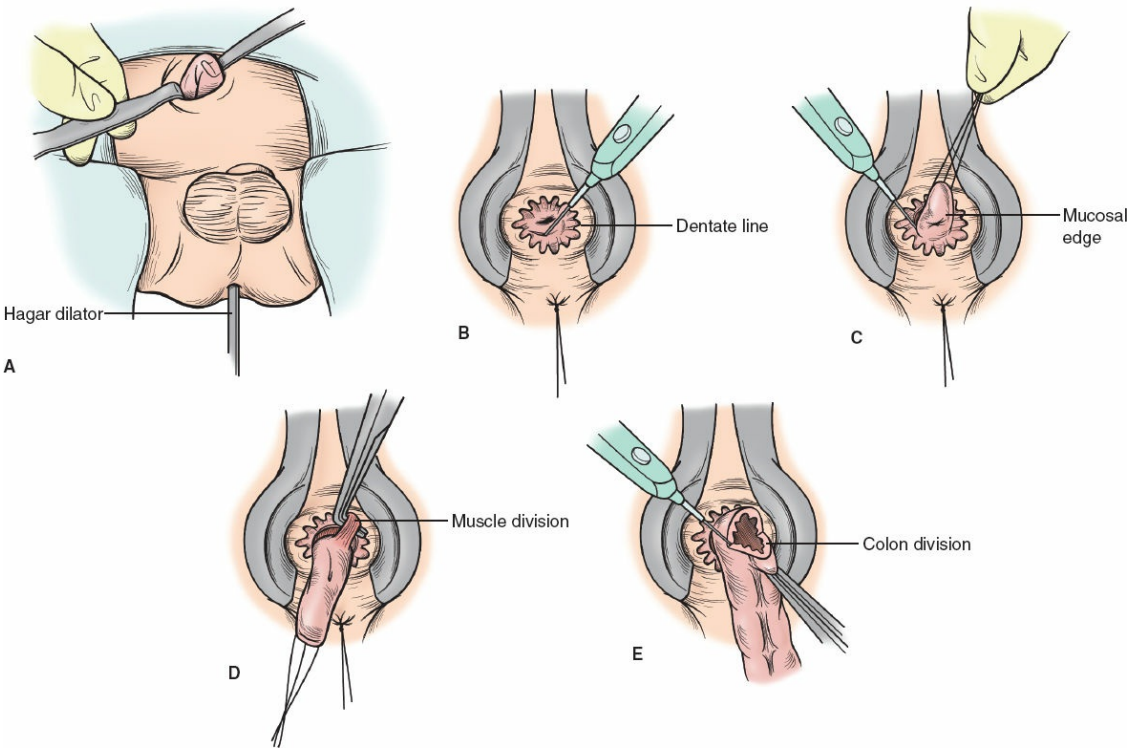

Figure 168.2. **A.** A Hagar dilator is passed through the anus to push the sigmoid colon up toward the incision, and the colon is biopsied until normal ganglion cells are identified on frozen section. **B.** The dentate line is clearly visualized and a mucosal incision is made 0.5 cm above the dentate line. **C.** Fine silk sutures are placed circumferentially along the mucosal edge and the mucosa is dissected off the underlying muscle for approximately 2 cm. **D.** The muscle is divided and the dissection is carried proximally on the rectal wall until the site of the normal biopsy is reached. **E.** The colon is divided and the anastomosis performed.

If the transition zone is proximal to the mid-sigmoid colon, additional mobilization must be done. The first step is division of the lateral attachments of the descending colon, which can be done bluntly using a finger through the umbilical incision. If there is still too much tension, the splenic flexure can be mobilized, and if necessary, the middle colic vessels can be divided, leaving a generous arcade of marginal vessels along the colon. Both maneuvers can be accomplished through the umbilical incision.

When the site of the biopsy that revealed normally innervated bowel has reached the anus, the colon is divided at least 2 cm above the transition zone, and the anastomosis is performed using 4-0 polyglycolic acid sutures (Fig. 168.2E). The stitches should include a generous bite of the pull-

through colon, as well as substantial bite of underlying muscle and a small bite of distal mucosa. As previously mentioned, the transitional epithelium must be spared in order to avoid postoperative pain and preserve normal continence.

When the anastomosis has been completed, the umbilical incision is closed, a second single-shot caudal block is placed, and the patient is awakened.

POSTOPERATIVE CARE

Feeding is started as soon as the child starts to pass stools, which is usually within the first 24 hours. For pain management, oral acetaminophen is usually sufficient, with narcotics reserved for those in whom the caudal block was ineffective. Most children can be discharged 24 to 48 hours after the operation. Because of the high incidence of perianal dermatitis due to frequent bowel movements and liquid discharge during the initial months after a transanal pull-through, immediate application of barrier creams to the perianal skin is imperative. The stool frequency usually decreases to a more normal rate over several months.

The patient is seen 1 to 2 weeks postoperatively, and the anastomosis is calibrated with a dilator or finger, depending on the size of the child. Although most surgeons then teach the parents to do daily dilatations at home, we prefer to see the child weekly for 6 weeks, calibrating the anastomosis each week and only recommending daily dilatations if there is evidence of anastomotic or cuff narrowing.

The most important and dangerous complication following a pull-through is enterocolitis, since it is the most common cause of death in children with Hirschsprung disease. The major signs and symptoms of enterocolitis include fever, abdominal distension, vomiting, diarrhea, and in the later stages, systemic sepsis. In the early stages it can be difficult to differentiate enterocolitis from gastroenteritis, but it is extremely important that both the parents and the community pediatrician who follows the patient be educated to recognize possible enterocolitis, and that the child is brought to medical attention early if any of those clinical features occur. It is better for a child to make an unnecessary trip to the emergency department with gastroenteritis than to delay and develop overwhelming sepsis from rapidly progressive enterocolitis.

COMPLICATIONS AND THEIR MANAGEMENT

Like with any operation on the intestinal tract, surgery for Hirschsprung disease may be complicated by bleeding, infection, injury to other organs or structures, and the risks of anesthesia. Children undergoing a staged repair with a preliminary stoma may experience stoma-specific complication such as stricture, retraction, prolapse, and skin breakdown.

Anastomotic complications, although uncommon, can be seen after any of the pull-through procedures. Anastomotic leaks, or subsequent anastomotic strictures, may occur due to inadequate blood supply or excessive tension of the pulled-through bowel. In addition, the normally innervated bowel may be twisted during the pull-through. Perianal excoriation is seen in up to 50% of children undergoing pull-through surgery, and tends to be more common in children with long-segment disease.

OUTCOMES

Although most children with Hirschsprung disease do well after pull-through surgery, a significant number will have problems that include ongoing obstructive symptoms, soiling, and enterocolitis. In most children these problems improve significantly or resolve by 5 years of age, and every child should therefore be followed on a regular basis until at least school age, or longer if they are continuing to have ongoing problems. It is extremely helpful for these children to have access to a nurse practitioner who is experienced with bowel management, as quality of life is enhanced by ongoing support.

Obstructive symptoms may take the form of abdominal distension, bloating, borborygmi, vomiting, or ongoing severe constipation. There are five major reasons for persistent obstructive symptoms: mechanical obstruction, recurrent or acquired aganglionosis, disordered motility in the proximal colon or small bowel, nonrelaxation of the internal anal sphincter, or stool-holding behavior. Effective management of persistent obstructive symptoms requires careful investigation to identify the underlying cause, followed by targeted intervention and close follow-up with ongoing support (Fig. 168.3).

Soiling after pull-through surgery is present in between 10% and 50% of children, depending on how it is defined. The three major causes of soiling are abnormal sphincter function, abnormal sensation, and “pseudo-incontinence,” which may be caused by severe constipation or hypermotility of the pulled-through proximal colon. Anorectal manometry

may be very helpful in identifying the underlying cause of soiling. Treatment is dependent on a clear understanding of the etiology of the problem, and may include dietary manipulation, stool softeners, stimulant laxatives, enemas, or in severe cases a colostomy.

Enterocolitis may occur both before and after surgical correction of Hirschsprung disease. Estimates of incidence range from 15% to 50%, depending on how it is defined. Most importantly, enterocolitis is the most common cause of death in children with Hirschsprung disease, so early recognition and treatment with bowel rest, colonic irrigation, and systemic antibiotic therapy is imperative.

Long-term outcome for children with Hirschsprung disease is usually excellent, even for those children who have issues with obstructive symptoms, soiling, or enterocolitis in the first few years postoperatively. Children with long-segment disease and those with trisomy 21 are more likely to have ongoing problems, but even these children will ultimately have an excellent quality of life in most cases.

EDITOR'S COMMENT

Dr. Langer discusses transanal pull-through for Hirschsprung disease in children and while many readers may think that this is only relevant for pediatric surgeons, knowledge of this subject is important for all general and colorectal surgeons.

Virtually every surgeon will in their career see the occasional adult patient with newly diagnosed Hirschsprung disease. These are almost always short-segment Hirschsprung's and are almost invariably patients with proactive parents such as mothers who are nurses, who have regularly given their children enemas or other vigorous bowel regimens to ensure that their children remained asymptomatic.

It is amazing how difficult treating an adult with Hirschsprung disease is with respect to obtaining a proper pathologic evaluation of colon biopsies for ganglia. In many institutions, this is done exclusively by the pediatric pathologists. I have had to send specimens from the "adult" hospital to a "pediatric" hospital pathologists for evaluation!

In the adult, operations that seem so simple in children are far more complicated. Years of disordered bowel function will frequently lead to extreme colonic dilatation, with size discrepancy as well as significant thickening of the colonic wall making handling and suturing of this tissue much more difficult. The colon wall in such patients is so thick and unwieldy that routine suturing and stapling is much more difficult than usual.

Knowledge of this subject is also important for the all abdominal surgeons since patients with Hirschsprung disease, who have undergone surgery when they were young, in many cases will have deteriorating bowel function as they age (Granström AL, Danielson J, Husberg B, et al. Adult outcomes after surgery for Hirschsprung's disease: Evaluation of bowel function and quality of life. *J Pediatr Surg* 2015;50(11):1865–9). This is manifest in multiple different ways including increased problems with fecal soiling, increased complaints of pruritus, and night-time incontinence, leading to increased referrals for evaluations for procedures to improve anal sphincter tone such as sacral nerve root stimulation and evaluations for colostomy construction. Some of these patients may be helped by conservative irrigating techniques such as using daily "colonic washout" therapy with a bulb syringe to cleanse their colons every morning so that they are not incontinent during the day. Other patients may wish to utilize an antegrade continence enema (ACE) procedure, whereby they perform colonic irrigation through a cutaneous appendicostomy in order to prevent fecal incontinence (Dolejs SC, Smith JK Jr, Sheplock J, et al. Contemporary short- and long-term outcomes in patients with unremitting constipation and fecal incontinence treated with an antegrade continence enema. *J Pediatr Surg* 2017;52(1):79–83).

In one report evaluating quality of life in patients who had undergone Hirschsprung surgery during childhood, continence was impaired as compared to controls, with a greater number of patients having continence problems for flatulence, having difficulty with respect to needing to strain, and requiring several defecations in order to completely empty (Granström AL, Danielson J, Husberg B, et al. Adult outcomes after surgery for Hirschsprung's disease: Evaluation of bowel function and quality of life. *J Pediatr Surg* 2015;50(11):1865–9). The general quality of life in patients was; however, said

to be comparable to that of controls. In another study, Rintala and colleagues showed that the functional outcome and quality of life in patients with Hirschsprung disease may deteriorate with increasing age and that constipation and fecal soiling are common late sequelae (Rintala RJ, Pakarinen MP. Long-term outcomes of Hirschsprung's disease. *Semin Pediatr Surg* 2012;21(4):336–43).

In a recent systematic review and meta-analysis, the transanal endorectal pull-through that Dr. Langer describes was found to be superior to the transabdominal approach with respect to time of operation, duration of hospital stay, and rate of postoperative constipation and incontinence (Chen Y, Nah SA, Laksmi NK, et al. Transanal endorectal pull-through versus transabdominal approach for Hirschsprung's disease: A systematic review and meta-analysis. *J Pediatr Surg* 2013;48(3):642–51). It may be that over time we will see fewer such problems as these procedures become more popular.

Managing the adult Hirschsprung patient can be difficult, that is the pediatric patient who has had surgery and has "outgrown" his pediatric health care providers. This class of patient is often "lost" in the transition of care between their pediatrician and an "adult" primary care physician or internist. Problems such as fecal incontinence are embarrassing, they are often not brought up or volunteered on behalf of the patient, and may therefore long go untreated.

Often, modification of the consistency of the bowel movement with something as simple as loperamide, for example, taking ½ tablet every day or every other day (1 mg/day) is all that is needed to improve continence. In other patients, adding an antispasmodic such as hyoscyamine may provide adequate symptom relief. Anecdotally, in selected patients, sacral nerve root stimulation may be useful for improving continence. Use of this technology has already been proposed as an aid in the initial management of such patients (Hasselbeck C, Reingruber B. Sacral nerve stimulation is a valuable diagnostic tool in the management of anorectal and pelvic malformations. *J Pediatr Surg* 2012;47(7):1466–71).

Hirschsprung disease is one of the entities that educated surgeons once upon a time thought they understood, but it has now been shown to be due to a variety of genetic mutations. More progress continues to be made as we learn about this disease and its associated enterocolitis.

169 Neonatal Enterocolitis and Short Bowel Syndrome

Brad W. Warner and Jacqueline M. Saito

Despite dramatic progress in the overall care of the premature infant, neonatal necrotizing enterocolitis (NEC) remains a significant cause of morbidity and mortality. The underlying cause of NEC has not yet been identified and is likely multifactorial. The pathophysiology of NEC and strategies to prevent development of NEC continue to be actively investigated. For infants who require surgical intervention, research efforts have focused on improving patient survival, minimizing intestinal loss, and assessing neurodevelopmental outcomes. Infants who require massive intestinal resection are at high risk for developing short bowel syndrome (SBS) and long-term dependence on parenteral nutrition (PN). SBS is characterized by insufficient intestinal absorptive capacity to sustain normal growth and development. The underlying cause of SBS may be acquired, as with NEC, or congenital. In conjunction with medical management, surgical intervention has an important role in the prevention and treatment of SBS complications.

NEONATAL NECROTIZING ENTEROCOLITIS

NEC is an acquired condition in which the intestine develops acute inflammation. The inflammation may affect the small intestine and/or colon in a focal, patchy, or extensive distribution, and may progress to necrosis and perforation. Risk factors for NEC include low birth weight and prematurity. Though NEC may affect full-term infants, approximately 90% of cases occur in infants born under 36 weeks' gestation. The estimated incidence of NEC ranges from 0.5 to 5 per 1,000 live births. Up to 7% of very low birth weight (VLBW) infants (birth weight <1,500 g) may develop NEC. Case fatality rates for NEC range from 12% to 30% and are higher among infants who require surgical intervention.

The pathophysiology of NEC has been the subject of intense investigation but remains incompletely understood. In retrospective studies

of NEC, the role of feeding practices (breast milk vs. formula, rate at which feedings are increased) has been examined. An infectious etiology has been suggested by clusters of NEC cases within neonatal intensive care units. Hypotension and hypoxia have been less strongly associated with NEC; however, comorbidities such as congenital heart disease, perinatal asphyxia, and respiratory distress are often present in term neonates who develop NEC. Experimental studies have explored the role of intestinal immaturity, abnormal intestinal microbe colonization, and immature regulation of intestinal circulation (Fig. 169.1). Features of the premature intestine that may confer susceptibility to NEC are abnormal or immature bowel motility, digestive capacity, epithelial barrier function, and immune function.

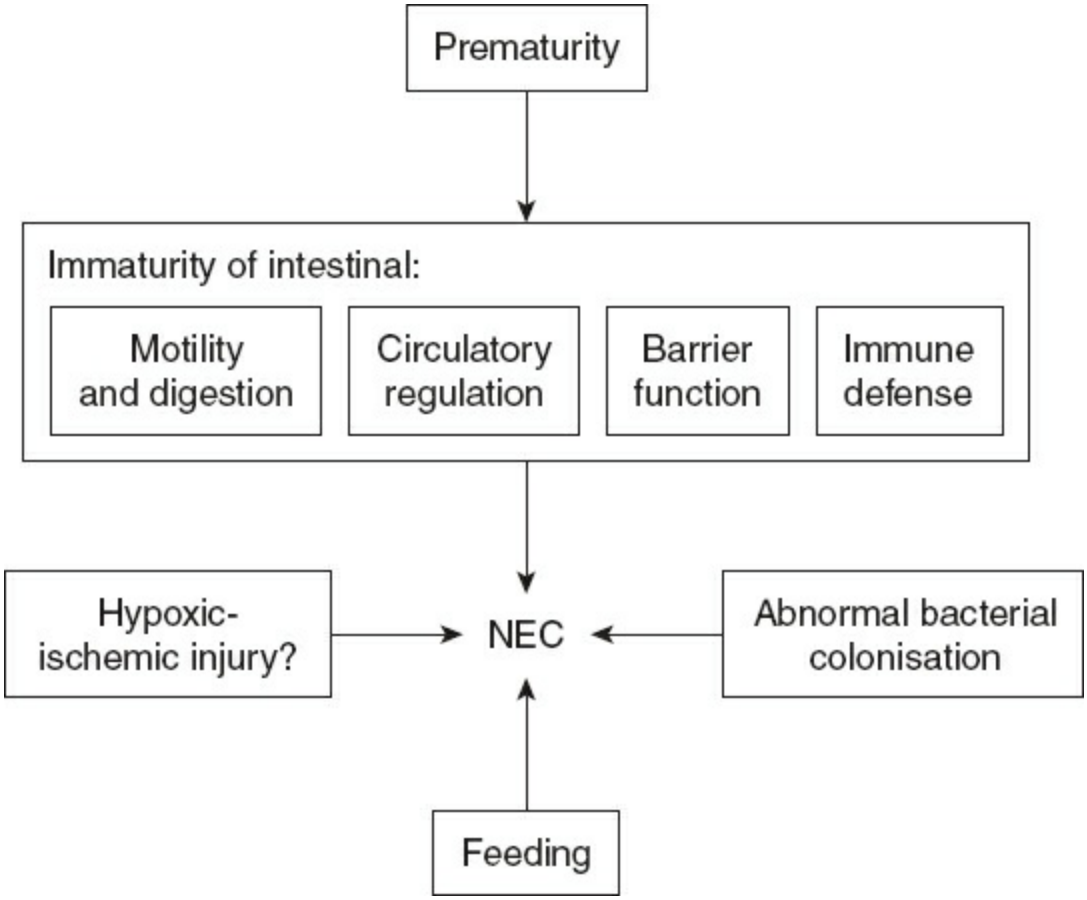

Figure 169.1. Pathophysiology of NEC. (Reprinted from Lin PW, Stoll BJ. Necrotising enterocolitis. *Lancet* 2006;368:1271–83. Copyright © 2006, with permission from Elsevier.)

Clinical Presentation and Diagnosis

The clinical presentation of NEC varies in severity and rapidity of onset.

Bell criteria for NEC categorize the signs and symptoms into suspected, definite, and severe disease (Table 169.1). Infants with NEC may have a combination of symptoms such as hypotension, temperature instability, feeding intolerance with emesis or increased gastric residuals, and bloody stool. Manifestations of NEC on physical examination are mottled skin, reflecting poor peripheral perfusion, abdominal distension, abdominal discoloration, and abdominal wall erythema and edema. Because of the thin abdominal wall in premature infants, dilated, edematous loops of intestine may be visible; leaked stool from intestinal perforation may cause a blue discoloration to the abdomen. Laboratory abnormalities are generally nonspecific and resemble those seen with neonatal sepsis, such as thrombocytopenia, leukocytosis or leukopenia, elevated C-reactive protein, metabolic acidosis, and respiratory acidosis, especially if ventilation is impaired by abdominal distension. The diagnosis of NEC is usually established with plain abdominal radiographs. Pneumatosis intestinalis, or air within the intestinal wall, and portal venous gas can be transient radiographic findings (Fig. 169.2A,B); therefore, intermittent radiographs are typically obtained when NEC is suspected. Other radiographic signs of NEC are persistent dilation of a specific bowel loop ("fixed loop"), and separation of bowel loops due to bowel wall edema. Free intraperitoneal air may be subtle on supine abdominal radiograph and can create a lucency over the liver (Fig. 169.2C), with a central longitudinal line from air adjacent to the falciform ligament; free air is typically more easily seen on left lateral decubitus or cross-table lateral views (Fig. 169.2D). Abdominal ultrasound may reveal complex ascites in the context of intestinal perforation, evidence of gas within the portal vessels, and bowel wall thickening.

TABLE 169.1 Bell Stages of Necrotizing Enterocolitis

	I. Suspected disease	II. Definite disease	III. Advanced disease
Systemic signs	Temperature instability, lethargy, apnea, bradycardia		Deterioration of vital signs, septic shock
Gastrointestinal signs	Poor feeding, ↑ gastric residuals, emesis, mild abdominal distension, occult blood in stools	Persistent occult or gross gastrointestinal bleeding, marked abdominal distension	
Abdominal radiographic findings	Distension with mild ileus	Marked intestinal distension, small bowel separation/edema, persistent bowel loops, pneumatosis intestinalis, portal venous gas	Pneumoperitoneum

Adapted from Bell MJ, Ternberg JL, Feigin RD, et al. Neonatal necrotizing enterocolitis: therapeutic decisions based upon clinical staging. *Ann Surg* 1978;187:1–7. Wolters Kluwer Health, Inc.

Treatment

Treatment of suspected and definite NEC includes bowel rest, nasogastric or orogastric decompression, broad-spectrum intravenous antibiotics, and resuscitation with intravenous fluids (Fig. 169.3). Pressor and ventilatory support is instituted as required by the infant's overall status. Unfortunately, premature infants who have respiratory distress syndrome often require abrupt escalation of ventilatory support with the onset of NEC. The optimal duration of bowel rest and antibiotics for treatment of NEC is not known. For infants who recover from NEC with medical treatment, the role of contrast studies of the intestine prior to feeding is also not well established.

Indications

The clearest indication for surgical intervention in NEC is evidence of intestinal perforation, typically diagnosed with plain abdominal radiograph showing free intraperitoneal air. Relative indications are progressive clinical deterioration, as reflected by worsening hypotension, metabolic acidosis, respiratory acidosis related to abdominal distension, or thrombocytopenia, and evidence of bowel obstruction or necrosis. On physical examination, patients may have focal abdominal wall erythema or abdominal wall discoloration indicative of segmental bowel necrosis or

loculated intestinal perforation. Fixed or persistent intestinal loop on plain abdominal radiographs may be indicative of bowel compromise.

Preoperative Planning

Consideration of patient comorbidities and stability is essential in the preoperative preparation of the infant with NEC. Even in the absence of NEC, the respiratory status of the premature neonate is often tenuous and can rapidly deteriorate. Increased oxygen and ventilatory requirements sometimes precede the clinical recognition of NEC. Tenuous respiratory status may render transport of a neonate to the operating room too risky and necessitate a bedside operation. In the face of massive intraperitoneal air, temporary decompression of the abdomen with a large-bore angiocatheter can significantly improve ventilation. Intravenous fluid resuscitation must be carefully administered, especially if a patent ductus arteriosus is present; overaggressive intravenous fluid administration may lead to worsened hypoxia, because of increased shunting through the pulmonary vascular bed. Anemia, thrombocytopenia, and coagulopathy necessitate the availability of appropriate blood products.

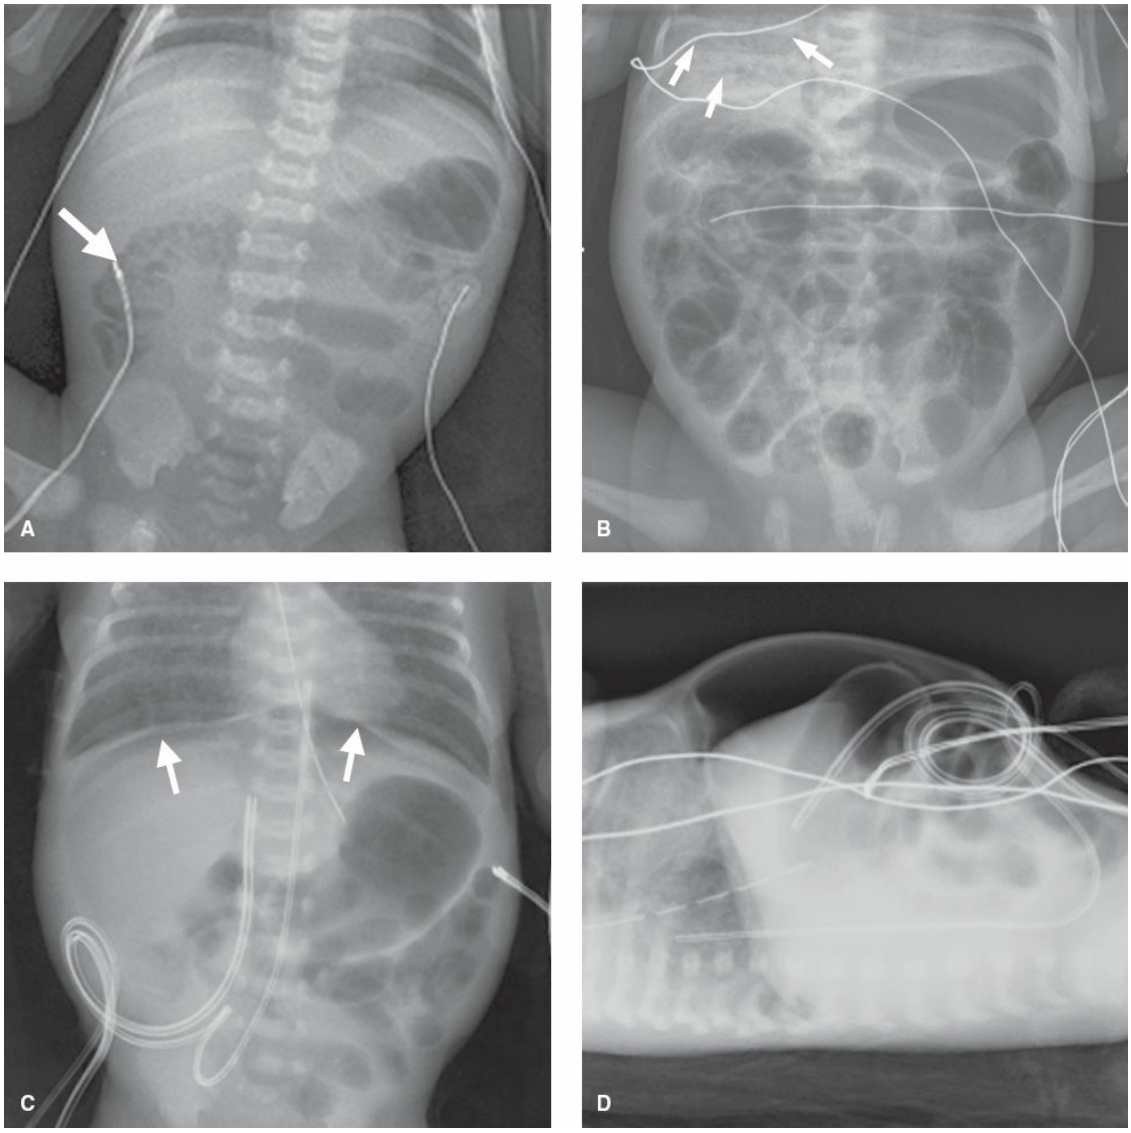

Figure 169.2. Findings associated with neonatal necrotizing enterocolitis on plain abdominal radiographs: (**A**) focal pneumatosis (*arrows*), (**B**) diffuse pneumatosis and portal venous gas (*arrows*), (**C**) free intraperitoneal air (supine) manifested as lucency over liver and under diaphragms (*arrows*), and (**D**) free intraperitoneal air (cross-table lateral view).

Often influenced by the gestational age, size, and stability of a patient, the choice of surgical procedure has been the subject of multiple studies. Laparotomy traditionally has been the mainstay for treatment of neonates with intestinal perforation. Peritoneal drainage was first described by Ein in 1977 in a series of five unstable neonates with intestinal perforation. In a follow-up report in 1980, 46% of patients survived, and 49% never required laparotomy. Over the past 30 years, mixed outcomes following peritoneal drainage or laparotomy have been reported from single

institutions; meta-analysis of these studies has shown that neonates treated with peritoneal drainage tend to be smaller and more premature. A prospective cohort study in 2006 through the National Institute of Child Health and Human Development (NICHD) Neonatal Network of extremely low birth weight (ELBW) infants (401 to 1,000 g) who developed NEC or isolated intestinal perforation reported 50% overall survival to discharge and a high rate of neurodevelopmental impairment at age 18 months (49% of survivors). Infants in the peritoneal drain group tended to have lower birth weight, were more premature, and had greater use of vasopressors, more severe hypotension, and higher ventilatory requirements. In addition, several infants in the peritoneal drain group were “too ill” for laparotomy. Unadjusted mortality was higher in the peritoneal drain group; with adjustment for confounders, the difference in mortality between infants treated with peritoneal drainage and laparotomy was diminished. In an effort to minimize selection bias, randomization to peritoneal drain or laparotomy was used in NECSTEPS, a multicenter trial of infants who developed intestinal perforation and weighed less than 1,500 g at birth; both peritoneal drain and laparotomy groups had similar 90-day mortality (35%), hospital length of stay, and need for total parenteral nutrition (TPN) at 90 days.

Surgical Technique

Peritoneal drain placement may be performed rapidly at the patient's bedside (Fig. 169.4). After administration of intravenous sedation, the abdomen is sterilely prepped and draped. Local anesthetic is infiltrated in the right lower abdomen. A small incision is made at a site that avoids the liver edge and bladder. The subcutaneous tissue and abdominal wall muscle are spread with a fine-tipped clamp, and the peritoneal cavity is entered bluntly as confirmed by release of air and feculent ascites. The peritoneal cavity may be lavaged with warmed saline through a large-bore angiocatheter. A quarter-inch plastic drain is advanced into the peritoneal cavity and secured to the skin. A second drain may be placed in the left

lower abdomen. After drainage ceases, the drain is gradually withdrawn. Clinical deterioration, bowel obstruction, and persistent fistula are among the indications for laparotomy following drain placement; up to two-thirds of patients treated with peritoneal drainage require subsequent laparotomy.

For infants undergoing laparotomy, minimizing surgical stress is a priority. Laparotomy, like peritoneal drainage, may be performed at the patient's bedside if transport to the operating room is too hazardous. Anesthetic considerations include availability of pressors and blood products to minimize hypotension, and maintenance of patient warmth. Performance of an expeditious operation to avoid hypothermia, limit blood loss, and avoid injury to the delicate premature liver is a key concern for the surgeon. Generally, a transverse incision is used for laparotomy in neonates, as the width of the abdomen generally exceeds the length. The incision may be placed above the umbilicus to leave room in the lower abdomen for potential ostomies. Because intravascular access may be limited, umbilical catheters may need to remain in place and should be avoided when making an abdominal incision.

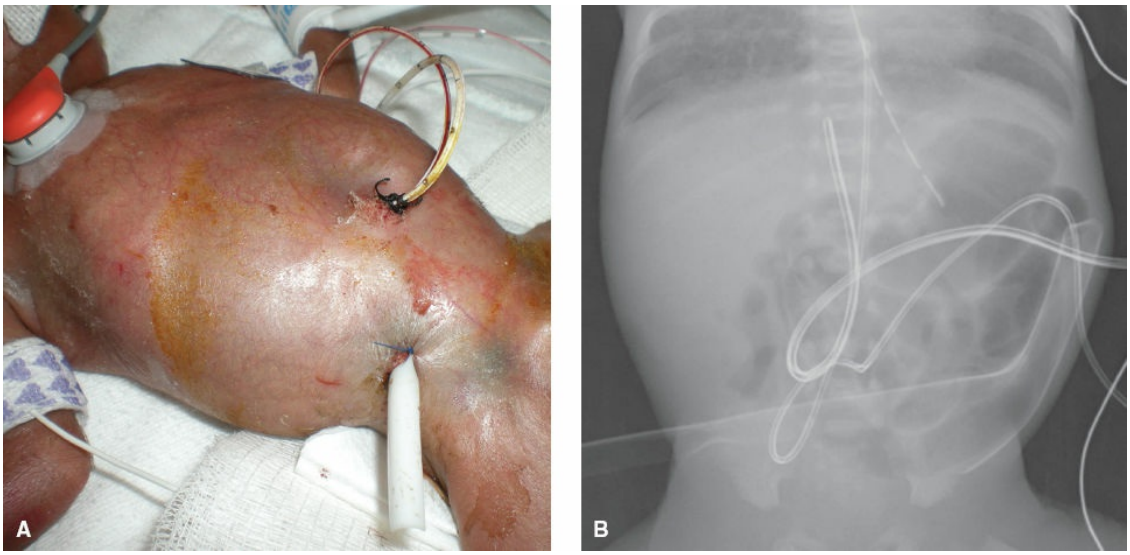

Figure 169.4. Peritoneal drain placement for intestinal perforation: (**A**) ELBW infant following peritoneal drain placement, with prominent bluish discoloration of the abdomen inferior to the drain, (**B**) peritoneal drain crosses the abdomen on abdominal radiograph.

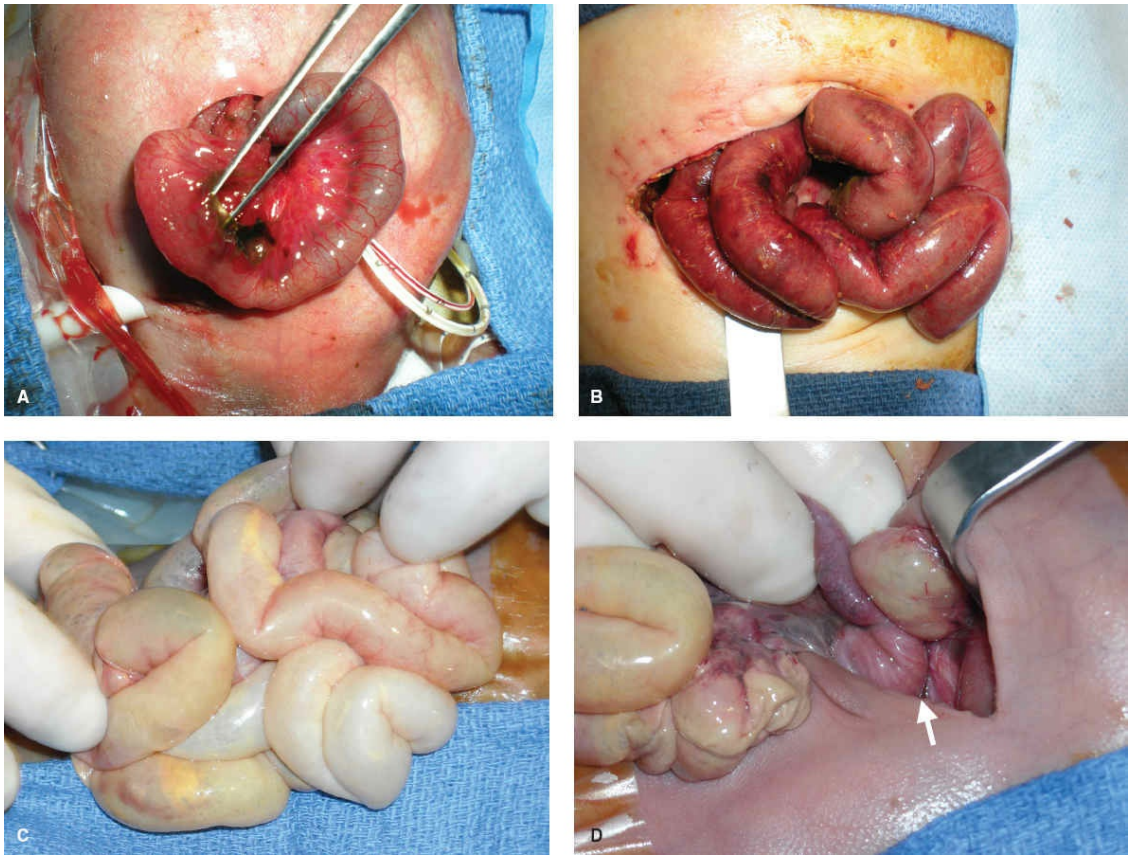

Figure 169.5. Findings during laparotomy for intestinal perforation: (**A**) isolated ileal perforation, (**B**) patchy/diffuse NEC, (**C**) extensive NEC, (**D**) extensive NEC with only viable duodenum (*arrow*).

In contrast to peritoneal drainage, laparotomy enables full assessment of the disease extent. Findings may range from isolated intestinal perforation, which typically occurs in the ileum and may represent a distinct disease process, to pan-intestinal necrosis (Fig. 169.5). For focal disease, options include repair (patch/imbricate), resection with anastomosis, and resection with ostomy. Ostomy creation is often selected because of concern for the additional time required for intestinal anastomosis and inadequate healing postoperatively. In patchy or extensive disease, a key priority is preservation of intestinal length to avoid SBS. Second-look laparotomy may be used for reassessment of intestine with marginal viability at the initial operation. If multiple intestinal resections are performed, anastomoses may be created distal to a protective ostomy and stented with a tube. Ostomy placement can be challenging due to the limited space on the premature infant's abdominal wall. For markedly edematous infants, the laparotomy incision may be left open, closed loosely with prosthetic mesh sewn to fascia, or closed at the

level of the skin only. When the skin is left open, the wound may be covered with a sterile dressing or wound vacuum. Following recovery from NEC, laparotomy may be required for intestinal obstruction from strictures (Fig. 169.6) or adhesions, or persistent drainage of stool from a peritoneal drain site.

Postoperative Management

Immediately following peritoneal drain placement or laparotomy, supportive care includes intravenous antibiotics, pressor support, ventilatory support, and transfusion of blood products as needed to correct anemia, thrombocytopenia, and coagulopathy. Patients are continued on intravenous fluids and PN, with initiation of feedings after recovery of bowel function and as permitted by patient stability. In the face of severe comorbidities associated with prematurity and extensive intestinal necrosis, an ethical discussion regarding continuation of aggressive care may be warranted. Ostomy closure is generally delayed to allow for infant growth, stabilization of hemodynamic and respiratory status, and maturation of intra-abdominal adhesions.

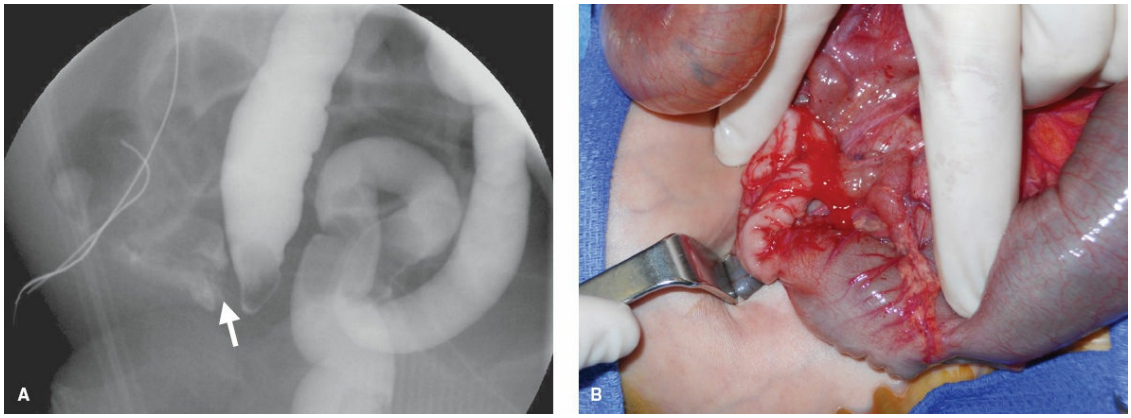

Figure 169.6. Stricture following episode of medically treated neonatal necrotizing enterocolitis: (**A**) contrast enema revealing ascending colon stricture with small amount of contrast within proximal colon (*arrow*), (**B**) intraoperative photograph of ascending colon stricture with proximal dilation of small bowel and colon.

Complications

The most concerning complication in the treatment of NEC is death. Mortality is high among infants with NEC who require surgical

intervention, with only 50% survival to hospital discharge. Early complications, such as intra-abdominal abscess, intestinal stricture formation, and intestinal obstruction, may occur with both peritoneal drain placement and laparotomy. Laparotomy wounds may develop superficial infection and fascial dehiscence. SBS and neurodevelopmental impairment are among the most extensively studied long-term outcomes. The length of residual intestine correlates with survival and ability to wean off of PN. For VLBW (<1,500 g birth weight) infants, meta-analysis has revealed increased risk of neurodevelopmental impairment among infants who had NEC compared with those without NEC, and among infants who had surgically treated NEC compared with those with medically treated NEC.

SHORT BOWEL SYNDROME

SBS occurs when intestinal mass is insufficient for enteral absorption of nutrients necessary to support normal growth and development. The diagnosis of SBS is based on intestinal function rather than absolute intestinal length. Individuals with SBS require support with PN chronically, though the minimum duration of PN administration is not uniformly defined in the SBS literature. The incidence of SBS is estimated as 1,200 per 100,000 live births. Common underlying causes of pediatric SBS are NEC, intestinal atresia (multiple or extensive), complicated gastroschisis (with bowel necrosis or atresia), volvulus associated with intestinal malrotation, and long-segment Hirschsprung disease. In the older child, traumatic injury, Crohn disease, and vascular thrombosis may lead to massive intestinal loss. The distribution of underlying etiologies for SBS varies geographically and may reflect differences in the aggressiveness with which extremely premature infants receive care. With the development of PN over 40 years ago, the survival of children with SBS markedly improved and is currently estimated at 73% to 89%.

Massive intestinal resection results in dramatic changes in intestinal morphology and function, both experimentally and clinically. The remaining intestine undergoes “bowel adaptation,” a process in which the bowel dilates and thickens macroscopically, and has increased villus height and surface area microscopically. In terms of function, the intestinal transit time slows, and enterocyte carrier capacity increases. Clinically, this results in the ability of SBS patients to gradually increase enteral absorption of nutrients and gradually decrease dependence on PN. Overall, small bowel length and patient age affect the ability to wean off of PN; the

presence of the ileocecal valve and underlying cause of SBS may also affect this process. Experimentally, specific nutrients such as long-chain fatty acids may enhance bowel adaptation. Strategies to increase bowel adaptation, such as administration of growth hormone, GLP-2 (glucagon-like peptide 2), and glutamine, have been explored with mixed results.

Treatment

When an infant or child is recognized to have shortened bowel length and potential for development of SBS, the focus of early treatment is bowel preservation and placement of a tunneled silastic central venous catheter in preparation for PN administration. If possible, ligation of major veins should be avoided during central venous catheter placement to preserve sites for future catheters. In the initial weeks to months following massive intestinal resection, the primary goal of medical therapy is to limit gastrointestinal losses of fluid, electrolytes, and nutrients. Treatment is multifaceted and includes proton pump inhibitors to minimize gastric hypersecretion, antimotility agents to slow intestinal transit, bile acid binders to decrease steatorrhea and bile salt diarrhea, and elemental formulas to minimize nutrient malabsorption. Despite its complex composition, breast milk contains growth factors that potentially enhance bowel adaptation and may be favored over elemental formula.

For patients with established SBS, placement of a gastrostomy and closure of ostomies may facilitate enteral tolerance. Tube feedings are often necessary for infants with oral aversion, and may help maximize enteral intake through administration of continuous and nocturnal tube feedings. In addition, infants and children may be adverse to drinking elemental formulas, which are not known for their taste. By maximizing intestinal length, ostomy closure has been associated with increased likelihood of weaning off of PN.

Complications of SBS

Care of the SBS patient must be intensive due to the range of potential complications. Many SBS complications directly result from absence of intestinal length. Early after intestinal resection, SBS patients are prone to fluid–electrolyte abnormalities; as bowel adaptation occurs, malabsorptive diarrhea tends to subside. However, SBS patients remain at risk for profound dehydration and electrolyte disturbances with acute conditions such as viral gastroenteritis and may temporarily require supplemental

intravenous fluids and bowel rest. Due to malabsorption, growth failure in weight and height are often chronic problems for SBS patients. Careful monitoring of growth is imperative, with provision of calories and nutrients in the form of PN and supplemental enteral nutrition when failure to thrive is detected. Depending on the absence of specific regions of intestine, SBS patients are susceptible to vitamin and micronutrient deficiencies, and may require supplementation of vitamin B12, zinc, iron, or fat-soluble vitamins (A, D, E, K). With bowel adaptation, the small intestine tends to progressively dilate and have slower motility. As a consequence, bacteria not normally present in the small intestine may overgrow and lead to inflammation; bacterial overgrowth can lead to decreased fluid and nutrient absorption and gaseous distension, which are manifested by watery diarrhea and cramping. Bacterial overgrowth is often diagnosed by clinical symptoms and treated with cycled oral antibiotics. Caused by fermentation of malabsorbed carbohydrate by colonic bacteria, D-lactic acidosis presents with weakness and mental status changes, such as confusion, slurred speech, and ataxia, and is treated with intravenous hydration and oral antibiotics. Over time, SBS patients may develop osteopenia due to a combination of vitamin D deficiency and calcium malabsorption. Oxaluria may occur when malabsorbed fat is metabolized by colonic bacteria and can lead to nephrolithiasis.

Parenteral nutrition-associated liver disease (PNALD) is a particularly vexing problem for the SBS patient. PNALD can progress from fibrosis to liver failure and has been among the primary causes of death in SBS. The pathophysiology of PNALD is not well established and may be related to patient and PN characteristics. Contributing factors include liver immaturity, as SBS patients born prematurely are at higher risk for PNALD, disruption of enterohepatic circulation of bile acids, the composition of PN, and recurrent sepsis. In terms of PN composition, excessive energy intake, specific amino acids and lipids, and disrupted glucose homeostasis are among the potential causes of PNALD. Recently, lipid composition and dose have been specifically implicated in PNALD development. Current parenteral lipid preparations in the United States are derived from soy and are primarily composed of omega-6 fatty acids that may be pro-inflammatory. Reversal of PNALD has been reported with use of a low dose (0.5 to 1 g/kg/d) of lipid derived from fish oil that is rich in omega-3 fatty acids. It remains unclear whether the beneficial effect seen with low-dose fish-oil lipid is related to reduced hepatic inflammation

from omega-3 fatty acids or lowered lipid dose itself.

While PN administration is required, the SBS patient is at risk for central venous catheter-associated complications. Sepsis, especially with Gram-negative bacteria and yeast, can be recurrent and severe. Like PNALD, catheter-associated sepsis is included among the most common causes of death in SBS patients. The chronic presence of an intravascular foreign body can lead to venous thrombosis, which can pose a challenge when ongoing central venous access is needed. Catheter breakage and occlusion are common complications of chronic central venous catheters; fortunately, central venous catheters can often be salvaged with repair kits and thrombolytic therapy.

Though it may sound trivial in comparison with liver disease and sepsis, skin breakdown can be a significant of source of misery for SBS patients. Skin breakdown often occurs with leakage of fluid around gastrostomy tubes or under ostomy appliances, or with profuse diarrhea. Desquamation can be extensive and painful; though skin breakdown can occur rapidly, healing of the affected skin can be a slow and challenging process. Prevention by monitoring the fit of gastrostomies and ostomy appliances and aggressive treatment of early skin breakdown with thick ointments are imperative; recognition and treatment of yeast rashes with topical ointment or powder are also important.

Bowel Lengthening Procedures

Intestinal dilation that occurs as part of bowel adaptation can be problematic when associated with bacterial overgrowth. Bowel tapering has been used to reduce stasis and enhance motility. However, removal of a portion of the intestine in a SBS patient is unappealing. Bowel lengthening procedures capitalize on the intestinal dilation seen with bowel adaptation to improve motility and preserve absorptive surface area while effectively increasing intestinal length. The primary indication for bowel lengthening procedures is persistent PN requirement despite bowel adaptation and maximal medical therapy. Bowel dilation of a minimum 4- to 5-cm diameter must be present and can be assessed with contrast studies. Two procedures are currently used for bowel lengthening. Longitudinal intestinal lengthening and tailoring (LILT) was described by Bianchi in animals in 1980 and in a series of patients in 1984. Kim reported serial transverse enteroplasty (STEP) in animals and cases in 2003. Both procedures effectively increase the intestinal surface area-to-

volume ratio, which may improve motility and absorption while decreasing bacterial overgrowth.

Surgical Technique

Both LILT and STEP are performed through a laparotomy incision. Because patients have typically undergone prior laparotomies, the operations often begin with extensive lysis of adhesions. Often called the Bianchi procedure, LILT involves longitudinal division of the bowel along a midline intervascular plane, which is made possible by separation of the mesenteric blood vessels into two leaves when entering onto the bowel wall (Fig. 169.7). After bluntly separating the mesenteric blood vessels adjacent to the dilated small intestine, the bowel is divided to form two smaller tubes or “hemi-loops” sewn by hand or using a GIA stapling device. Intestinal continuity is reestablished with isoperistaltic anastomoses in an S-shape or loop.

STEP alters the surface area-to-volume ratio of the dilated bowel by converting one large tube into a narrower zigzag (Fig. 169.8). The antimesenteric surface of the dilated small bowel is marked. The goal is to create a lumen that is uniformly 2 cm in diameter. A small mesenteric window is created adjacent to the small bowel at 2-cm intervals. Oriented perpendicular to the mesentery, a GIA stapler is applied partially across the bowel with 2 cm left uncut. Serial applications of the GIA are fired, separated by 2 cm on alternating sides. A stitch may be placed for reinforcement of the vertex of the staple firings. The increase in effective bowel length correlates with the degree of bowel dilation.

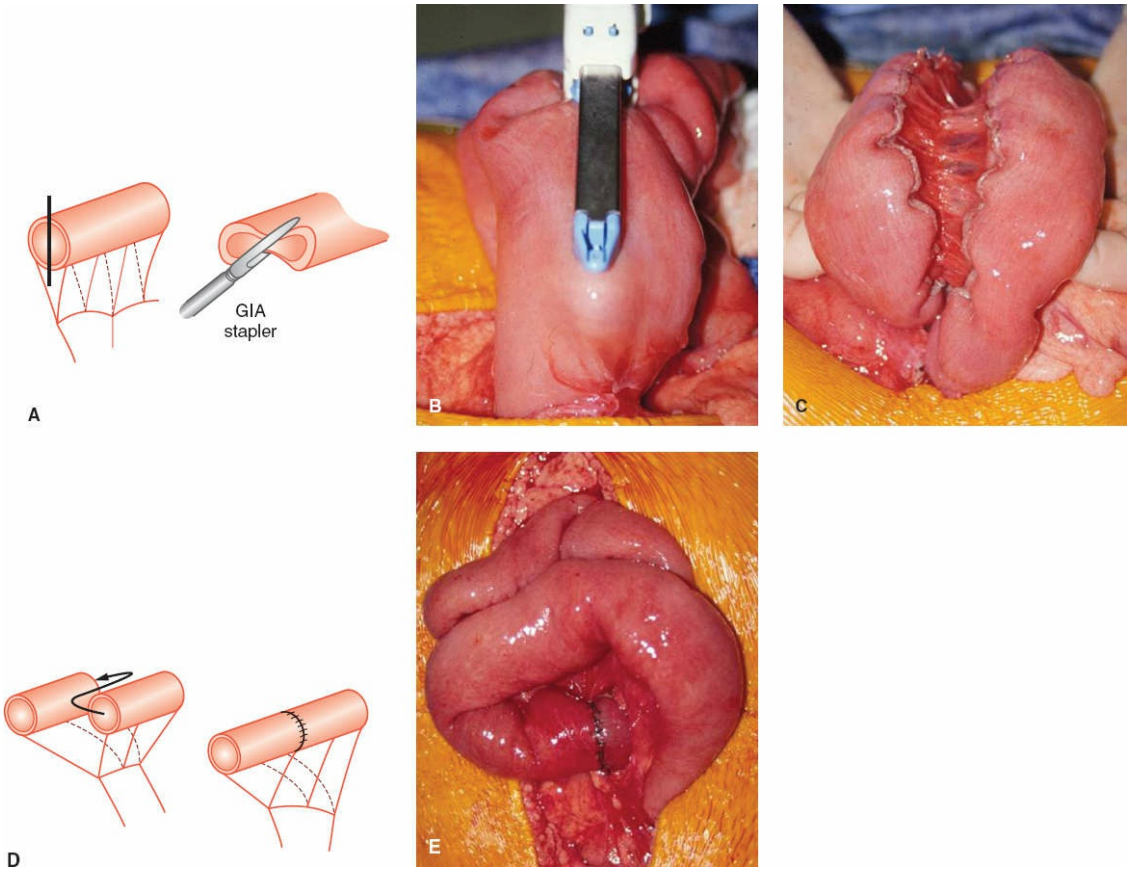

Figure 169.7. Longitudinal intestinal lengthening and tailoring, or Bianchi procedure: (**A**) intramesenteric plane developed adjacent to dilated small intestine; (**B**) GIA stapling device applied to oppose intramesenteric plane and antimesenteric border of dilated small intestine; (**C**) resulting small intestine hemiloops; (**D**) and (**E**) isoperistaltic anastomosis created between hemiloops.

Postoperative Management

Postoperatively, patients are supported with intravenous fluid and PN until bowel function resumes. Contrast studies may be obtained to confirm bowel patency and check for anastomotic or staple line leaks. Enteral feedings are gradually initiated. In terms of functional outcomes following bowel lengthening procedures, a trend toward more rapid weaning of PN following STEP compared with LILT has been reported.

Complications of Intestinal Lengthening

Anastomotic or staple line leak and intestinal obstruction have been reported as early complications for both LILT and STEP. Bowel necrosis may occur after LILT, likely due to damage to the mesentery during dissection prior to longitudinal division of the bowel. Late complications

include adhesive bowel obstruction, stricture, and recurrent bowel dilation. Recurrent bowel dilation may be treated with STEP following LILT or initial STEP. Interloop fistulas have been found following LILT.

Intestinal Transplant

For SBS patients who have severe complications related to dependence on PN, intestinal transplant offers some hope for a future free of PN. Indications for transplant referral include PNALD, thrombosis of major venous access (more than two of subclavian, jugular, or femoral veins), recurrent catheter-associated sepsis, and frequent severe dehydration or electrolyte losses caused by the underlying disease. Intestinal transplant may be performed alone, in combination with liver, or with other abdominal organs (multivisceral). Though refinement of immunosuppression is reducing the incidence of acute and chronic rejection, the current 5-year pediatric patient survival rate is approximately 55%. Survival may be influenced by the underlying cause of intestinal failure and may be better with volvulus as compared with other causes of pediatric SBS. Other complications seen in association with intestinal transplant are infections, posttransplant lymphoproliferative disease, and graft-versus-host disease. Limited availability of donor organs has also led to significant mortality in pediatric SBS patients while awaiting transplant.

EDITOR'S COMMENT

One of the most challenging situations in pediatric surgery remains the premature infant with neonatal enterocolitis or other bowel problems. Fortunately, there is now considerable expertise in the care of these tiny infants with a reasonable salvage. Nucci et al. (*J Gastrointest Surg* 2008;12:429–36) described the fate of 389 pediatric patients with a median age of 1 year (range from 1 day to 28.8 years). They described their effort as interdisciplinary, utilizing parenteral and enteral nutrition, surgical lengthening procedures, and finally intestinal transplantation. They found three features that were predictive of weaning from TPN:

1. Increased mean bowel length in patients with gastroschisis: 44 cm versus 23 cm (P <0.05).
2. In those patients with intestinal atresia, increase in bowel length 35 cm versus 20 cm (P <0.01).
3. A decrease in bilirubin to 6.1 versus 12.7 mg/dL in neonatal enterocolitis (P <0.05).

If the patients were able to wean from TPN, the average time of weaning was 2.5 years. Further, 95% of those who were weaned survived 5 years while only 52% of those who did not wean survived. In addition, in 25 patients who underwent bowel lengthening procedures, eight weaned from TPN without intestinal transplantation.

Another center dealing with relatively large numbers of these patients and using a total bilirubin of >2 mg/dL as a marker for liver disease was reported by Cowles et al. (*J Pediatr Surg* 2010;45:84–88). When the patients were admitted,

76 of the 93 reviewed retrospectively had a total bilirubin of >2.0 mg/dL indicating some intestinal failure-associated liver disease. Treatment between 2003 and 2009 consisted of cycling of parenteral nutrition, limiting lipid infusion, enteral stimulation, use of ursodeoxycholic acid, and finally surgical intervention "when necessary." The total bilirubin normalized in 57 of 76 children with elevated total bilirubin at the time of referral, but total bilirubin remained elevated in 19. Normalization of total bilirubin resulted in the mortality of 5.2%. Transplantation was required in 5.2%. When total bilirubin remained elevated, in about 19 children, mortality was 58% and transplantation occurred in 58%. Fish oil was not utilized in this group despite the fact that for at least 3 years in which these children were treated it could have been used as a desperate measure. The response to this paper was remarkably brief in the discussion period and the absence of commentary speaks volumes. In the discussion section of the paper, the question of Omegaven was raised. However, this product was possibly not available in all centers. It is possible but unclear that the 19 patients in this study who did not respond to treatment would have benefited from a fish oil-based lipid emulsion. The obvious question to me is why didn't the patients receive Omegaven? I find it difficult to believe that "Omegaven was too expensive" for the Morgan Stanley Children's Hospital. Transplants were not thought to be very expensive. The only reason I can think of as to why fish oil-based lipid emulsions were not used in the 19 children who did not normalize their bilirubin, most of whom died, is that the authors did not originate the therapy. This in my view, if it is true, is a disgrace and is one of the things in our current situation when attention is focused on the medical profession, which gives us a bad name. I could say more, but this is a book which may be read by polite company.

Gura et al. (*Pediatrics* 2008;121:e678–86) compared 18 patients with reversal of cholestasis who were given Omegavens with 21 historical controls with bilirubin >2.0 mg/dL who had intestinal failure-associated liver disease and had not received Omegaven. In the current group, there were two deaths without any liver transplantation, while in the historical control group, there were seven deaths and two patients requiring transplantation. The obvious question to the authors in what is a series of papers is why not do a randomized prospective trial? The authors state that this type of study would be difficult to conduct, because "some may consider it unethical to perform a study where children with preexistent parenteral nutrition liver injury could potentially be randomly assigned to a treatment group in which they would continue to receive a soybean oil-based parenteral lipid emulsion." I would argue that if this break with past practices is to be fully accepted, then one would have to design a trial in which patients with further deterioration on a soybean oil-based lipid emulsion would be entered provided there was a rescue provision. Failing this, there will still be children dying for all of the reasons given in the Cowles paper previously quoted, and that is not right.

An interesting paper reported by Malcolm et al. (*J Pediatr Surg*

2007;42:1811–5) in which dietary fat was added to 10 neonates with necrotizing enterocolitis or isolated intestinal perforations requiring temporary enterostomies. Paradoxically, administering dietary lipids decreased the excretion of ostomy output from 29.3% to 19.8% of dietary intake, a relative decrease of 32%. Daily weight gain increased from an average of 7.7 to 26.8 g/day (P <0.05). Patients with the greatest ostomy output benefitted the most. They report this result as a paradoxical effect and attribute it to "a jejunal and ileal brake," which has been well described and is associated with decreased bowel motility. Peptide YY has been implicated and follows a neurohormonal pathway. I have an alternative explanation based on some experience in patients who have had denudation of the bowel lining due to an ischemic event and believe that part of the beneficial effect may simply be increased number of calories enabling increased protein synthesis and enterocyte proliferation, resulting in a greater absorptive surface. It is likely that multiple beneficial effects are operant.

Despite the progress in salvaging low birth-weight preterm infants with surgical short bowel syndrome, Cole et al. (*Pediatrics* 2008;122:e573–82) reviewing a huge database of the National Institute of Child Health and Human Development Neonatal Research Network evaluated survivors at 18 to 22 months. Although the incidence of short bowel syndrome is less than 1%, necrotizing enterocolitis was the most common diagnosis associated with a short bowel syndrome. At the time of evaluation between 18 and 22 months, 33% still required tube feedings and 79% had been rehospitalized at some time in the course. Importantly, these infants had growth delay and smaller head circumference than those without neonatal enterocolitis. This is probably an outcome that needs to be examined because of the lifelong necessity for support.

Finally, in very low birth-weight infants with multiple perforations, Blejter et al. (*J Pediatr Surg* 2008;43:1358–60) report on using SILASTIC stents either inserted into perforations both proximally and distally or using an appendectomy site as an exit site, sparing a resection. While only two patients are reported, they are now at 3.5 and 2 years of age, respectively, eating without restriction and with "mild developmental delays." This latter point appears, unfortunately, to be the price paid for salvaging these tiny infants. It remains to be seen what the overall price for society is.

SECTION VIII

NONGASTROINTESTINAL TRANSABDOMINAL SURGERY

A THE SPLEEN

170 Laparoscopic Splenectomy

Charles E. Lucas and Anna M. Ledgerwood

DANGERS OF THE ASPLENIC STATE

The ancients considered the spleen essential for such diverse functions as laughter, humor, purification of the blood, and the maintenance of life. In contrast, many senior surgeons were taught that the spleen is a vestigial organ without function. These philosophical controversies had no clinical relevance until Riegner, in 1892, introduced the modern era of splenic surgery when he performed a successful splenectomy following a blunt injury. This 14-year-old construction worker fell from a scaffold and sustained a grade V splenic injury (Fig. 170.1) with fragments of the spleen lying free in the peritoneal cavity. This operation helped establish two principles. First, laparotomy with definitive control of bleeding, rather than extra-abdominal compression for refractory bleeding, leads to a better outcome; second, splenectomy is well tolerated, thus, laying to rest the ancient concept that the spleen was essential for life.

Early 20th century authors perpetuated the view that the spleen was without function. Pearce, in 1918, reported that 25% of animals undergoing splenectomy died from either peritonitis or pneumonitis; unfortunately, these deaths were considered unrelated to the asplenic state as reflected in his conclusion that these animals survived splenectomy with "relative impunity." Pearce also noted postsplenectomy eosinophilia and leukocytosis, of unknown significance. Shortly thereafter, Morris and Bullock documented the importance of the spleen as an immune organ. Asplenic rats, subjected to a *Pasteurella* bacterial challenge, did poorly when compared to their eusplenic controls suggesting immune incompetence. The surgical community, however, rejected these findings concluding that fears of infection after splenectomy were "poppycock"; thus, routine splenectomy for even the smallest of injuries became the

norm.

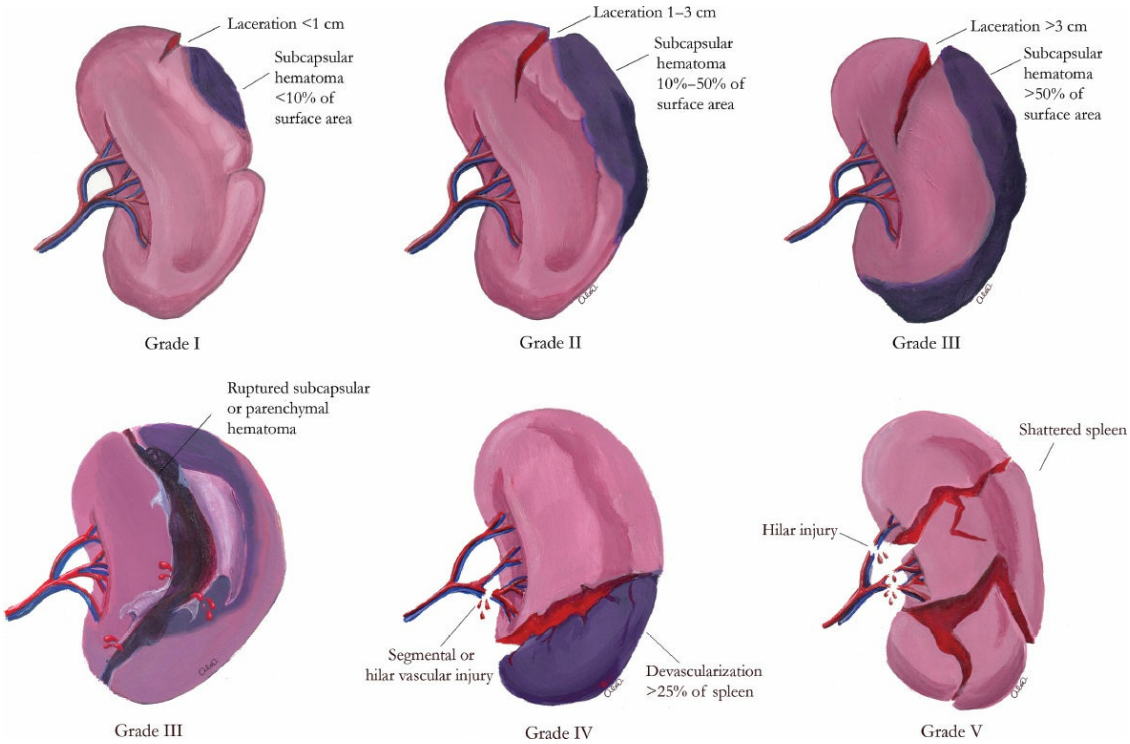

Figure 170.1. AAST grades of splenic injury.

The seed that gave rise to our current appreciation of splenic function was planted when King and Shumacker reported two deaths in five children, who died of an overwhelming postsplenectomy infection (OPSI) after splenectomy for spherocytosis. Smith, in 1957, reported the first death from OPSI following splenectomy in an injured patient without pre-existing comorbidities. Subsequent studies demonstrated that OPSI occurs in about 2% of children and 1% of adults without vaccination and frequently causes death. The common organisms responsible for OPSI are the gram-positive encapsulated bacteria, namely, *Pneumococcus*, *Meningococcus*, *Staphylococcus*, and *Streptococcus;* however, *Escherichia coli*, *Haemophilus influenza*, and other coliform organisms may lead to this syndrome. These findings led to a reassessment of splenic function.

SPLENIC FUNCTION

The spleen at birth is small and remains immature throughout the neonatal period; there are fewer lymphoid follicles and a relative absence of germ centers. Throughout childhood, the spleen slowly increases in size and reaches its maximal weight at puberty when it represents about 25% of the

total body lymphoid mass. Perfusion through the mature spleen facilitates leukocyte sequestration and the production of immunoglobulins, tuftsin, properdin, and antibodies to circulating antigens. This immunologic protection is mediated through the perifollicular lymphoid cells. The result is enhanced opsonization and phagocytosis of bacteria. The resultant enhancement of bacterial clearance is directed primarily toward the encapsulated gram-positive bacteria, but also affects gram-negative bacteria.

Immunologic efficiency correlates with the amount of spleen mass; animals with hemisplenectomy do far better than their asplenic controls, but not as well as eusplenic animals when subjected to a bacterial challenge. Furthermore, the volume of the spleen following partial splenectomy correlates directly with the antigenetic response. Thus, preservation of the maximal splenic tissue affords the best protection against OPSI. The intact spleen participates in the normal response to the polyvalent pneumococcal vaccine. Thus, vaccination is best administered before splenectomy.

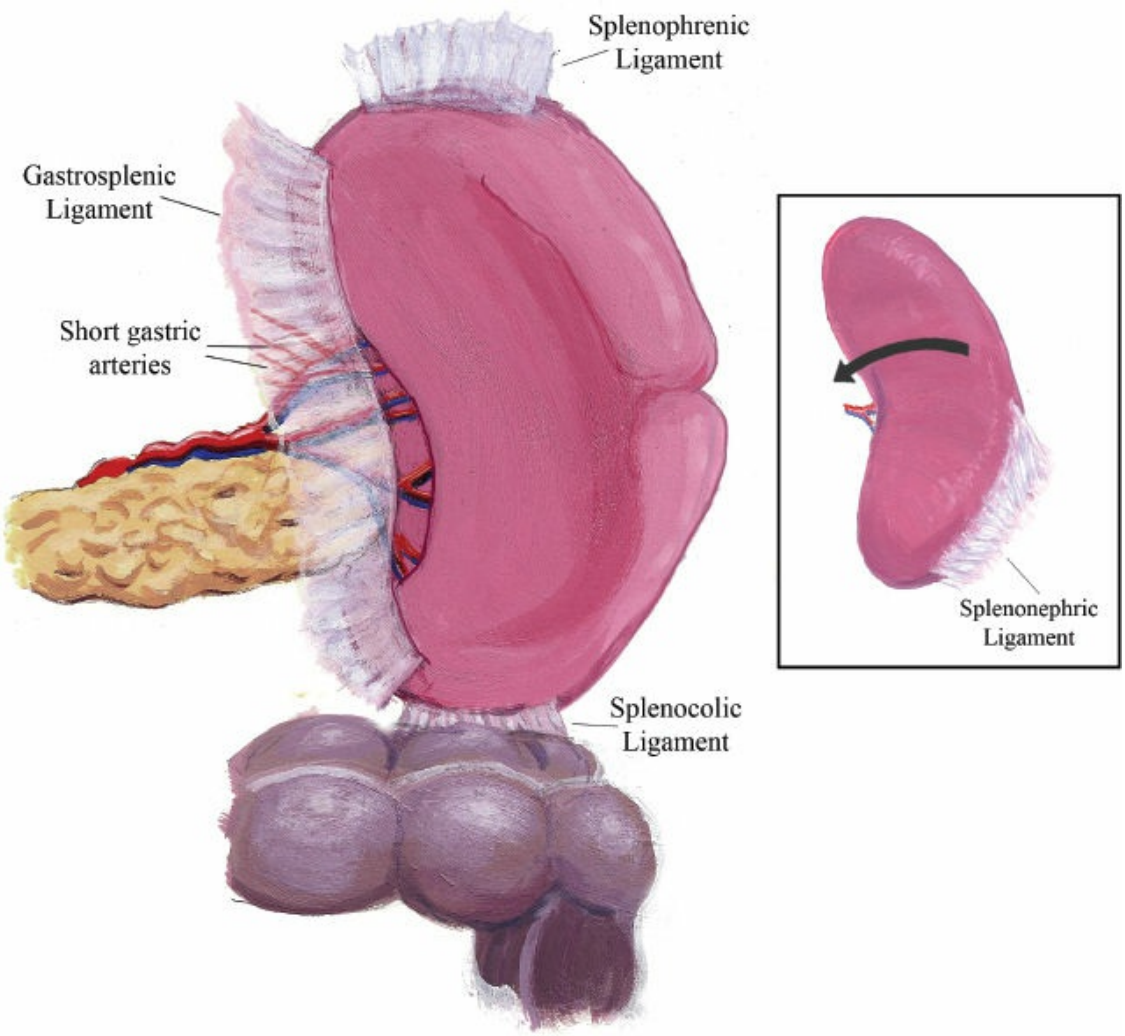

Figure 170.2. Splenic ligaments and attachments along with the splenic blood supply are shown. The gastrosplenic ligament contains the short gastric vessels that extend from the upper pole vessels and also contains the posterior gastric vessels that arise from the splenic vessels approximately 4 cm proximal to the splenic hilum. The splenocolic ligament always contains at least two small vessels, whereas the splenophrenic and splenorenal ligaments have no named vessels.

SPLENIC ANATOMY

The normal spleen is about 8 to 10 cm in longest dimension, weighs about 100 g, and lies high up in the left upper quadrant protected by the lower rib cage. The splenic hilum lies within 2 cm of the pancreatic tail and contains the branching vessels of the splenic artery and splenic vein. The superior branches of these vessels extend superiorly through the gastrosplenic ligament and attach, as the short gastric vessels, to the very proximal greater curvature of the stomach (Fig. 170.2). Other ligamentous

attachments include the superior and posterior splenophrenic ligament, the inferior splenocolic ligament, and the posterior splenonephric ligament (Fig. 170.2).

SURGICAL INCISIONS

Most injured patients undergo laparotomy in the supine position through a midline incision that gives rapid access to the peritoneal cavity and provides good visualization for all organs including the spleen. When operation is done for hemoperitoneum, rapid packing of the left upper quadrant allows one to sequentially identify any associated injuries that have a greater priority than the splenic injury. When patients with a small spleen require elective splenectomy, a left subcostal incision provides excellent exposure.

Infrequently, splenectomy is indicated in patients with myeloproliferative disease with extensive splenomegaly. The largest spleen removed by the authors weighed 26.5 kg. Massive splenomegaly requires wide exposure to all structures since bleeding from enlarged unnamed vessels can be lethal. A thoracoabdominal incision excising the eighth or ninth rib and extending medially to the linea alba allows safe exposure to the mammoth spleen. The diaphragm is divided to the hiatus. The vessels are huge with the splenocolic veins being 5 mm in diameter, the short gastric vessels 5 to 7 mm in diameter, and the splenic vein 3 to 4 cm in diameter. The wide exposure permits bloodless control of all named and unnamed vessels to prevent rapid lethal hemorrhage.

OPEN SPLENECTOMY

Once the peritoneal cavity is entered, typically through a midline incision, the actively bleeding spleen should be packed in order to obtain temporary hemostasis while full splenic exposure is accomplished. The lesser sac is entered through the greater omentum outside the arcades of the gastroepiploic vessels (Fig. 170.3). Using the nasogastric tube as a handle, one can retract the stomach anteriorly and medially, thus identifying the most proximal left gastroepiploic vessels and the short gastric vessels within the gastrosplenic ligament (Fig. 170.2). There usually are two or three short gastric vessels that are most safely controlled by ligature. As this dissection is carried superiorly along the greater curvature of the stomach, the proximal branches of the left gastroepiploic vessels may need to be divided; this facilitates the dissection near the apical fat pad and the

cardiophrenic ligament. Mobilization of the proximal stomach anteriorly and medially allows for one to visualize the short gastric vessels coming from the superior branches of the splenic artery before these branches enter into the superior segment of the spleen. Dissection of the apical fat pad helps expose and control the highest short gastric branches. Once these vessels are divided, one can see the posterior gastric artery that arises from the splenic artery and inserts on the posterior gastric wall about 2 cm medial to the short gastric vessels. Careful dissection of these vessels permits safe division and ligation. The splenic flexure of the colon is then mobilized. Typically, there will be two short vessels extending from the colonic mesentery to the inferior pole of the spleen. These are the same “aberrant” vessels that are notoriously avulsed from the splenic capsule when too much anterior and medial tension is placed on the omentum during gastric mobilization for truncal vagotomy. These vessels are always present; they should be identified and made hemostatic by coagulation or ligation prior to division.

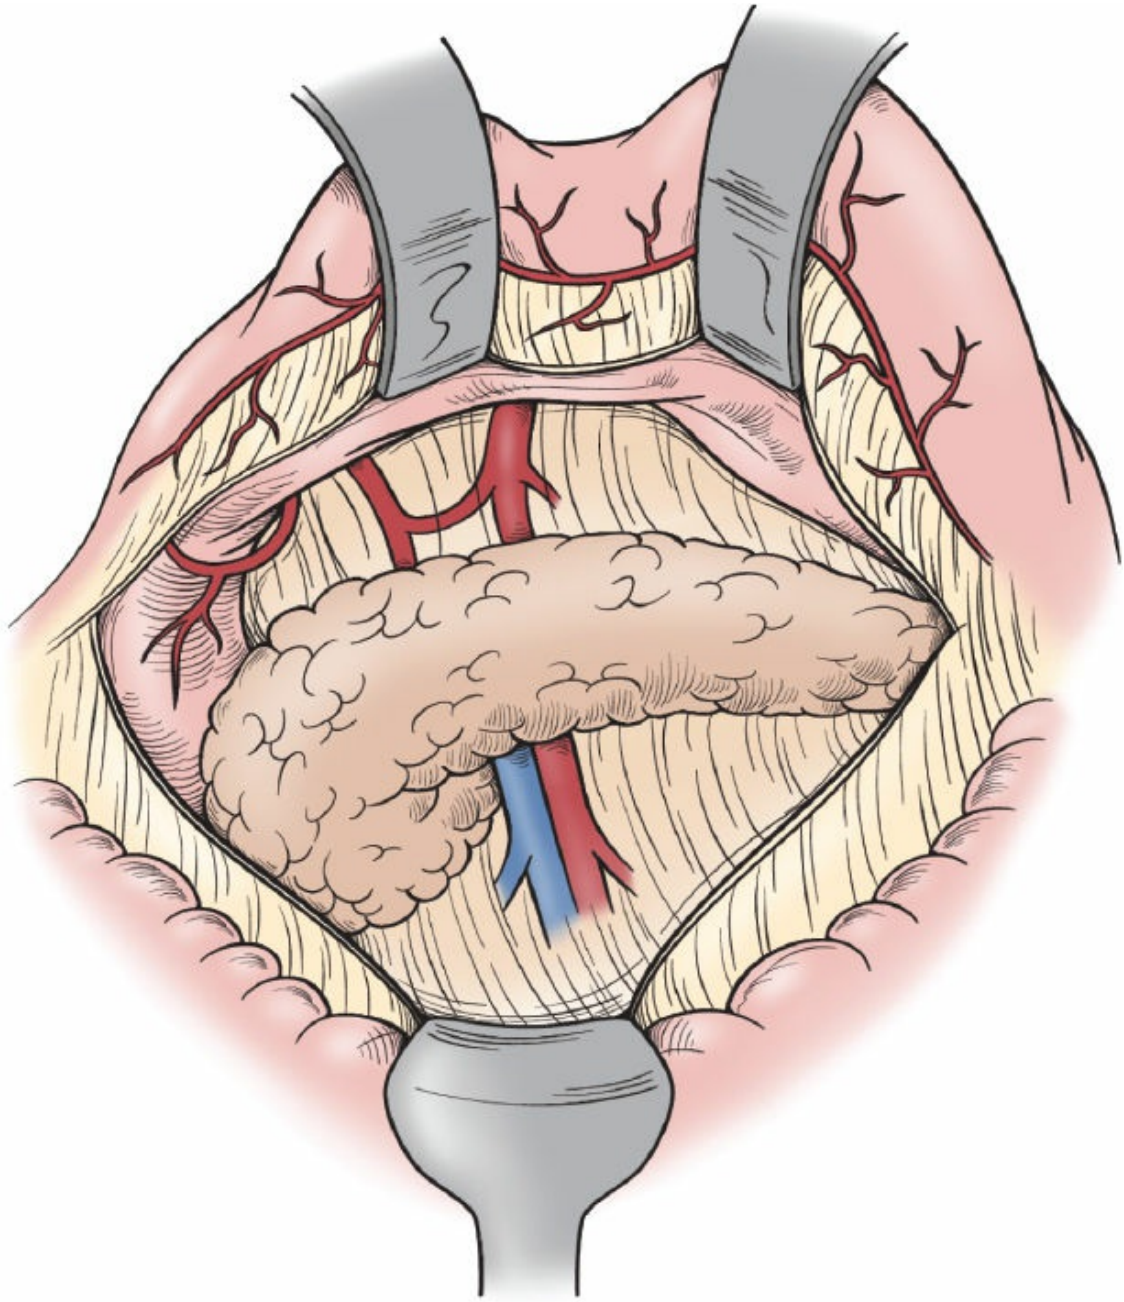

Figure 170.3. When splenic exposure is not hurried, access to the lesser sac is achieved through the greater omentum outside the arcades of the gastroepiploic vessels. Proximal dissection exposes short gastric vessels near the apical fat pad of the stomach, whereas lateral dissection exposes the splenic hilar vessels.

The spleen can then be detached from its “avascular” splenophrenic and splenonephric attachments (Fig. 170.2) remembering that small vessels are often present in these attachments; they can be controlled by electrocoagulation. Patients with portal hypertension may have extensive collaterals in this “avascular” plane, necessitating suture ligation or

ligature control. This can be achieved by dividing the ligamentous attachments approximately 2 cm from the spleen, between clamps and suture ligating each side. The spleen shares in the hyperdynamic portal hypertensive state, thereby making successful splenorrhaphy for trauma unlikely in cirrhotic patients. Such patients are served best by splenectomy. When bleeding occurs from the posterior ligamentous attachments, placement of packs posterior to the area of digital dissection controls bleeding and allows the operation to proceed as the spleen is mobilized. The plane posterior to both the spleen and the body and tail of the pancreas is then bluntly dissected, taking care to remain within this plane and not extend posteriorly, where one might injure the adrenal vessels or renal vessels. The pancreas with spleen is then gently pushed anteriorly and medially; one must never pull on the spleen in an effort to lift the pancreas (Fig. 170.4). When the injured spleen is actively bleeding, control of hemorrhage can be achieved by compressing the splenic hilum with the fingers and thumb of the left hand while the right hand is used to continue the anterior and medial mobilization of both the pancreatic body with tail and the spleen. Again, packs can be placed posteriorly in the plane that was previously occupied by these organs. This holds the spleen anteriorly and medially. When digital pressure does not control splenic bleeding, the operation likely will be hurried; this almost certainly will result in the patient requiring a total splenectomy. Therefore, this tedious and compulsive digital mobilization should be continued until the spleen has been fully delivered to the wound (Fig. 170.4).

One can then approach the branches of the splenic artery and splenic vein. When the pancreas has been fully mobilized anteriorly and medially, these vessels are more easily identified along the posterior aspect of the splenic hilum and can be individually divided and ligated. One should be careful in performing this dissection to avoid inadvertent clamping of the tail of the pancreas, which may result in subsequent pancreatitis or a pancreaticocutaneous fistula.

Prior to closing, one needs to check carefully for hemostasis. Placing a pack in the left upper quadrant allows one to assess the splenic flexure, the greater curvature of the stomach, and, finally, the tail of the pancreas. Once these areas have been confirmed to be hemostatic, the pack is removed and inspection of the posterior surface of the diaphragm is performed; oozing is controlled by electrocoagulation. Drains are not normally placed unless there is concern about refractory oozing or injury

to the tip of the pancreas.

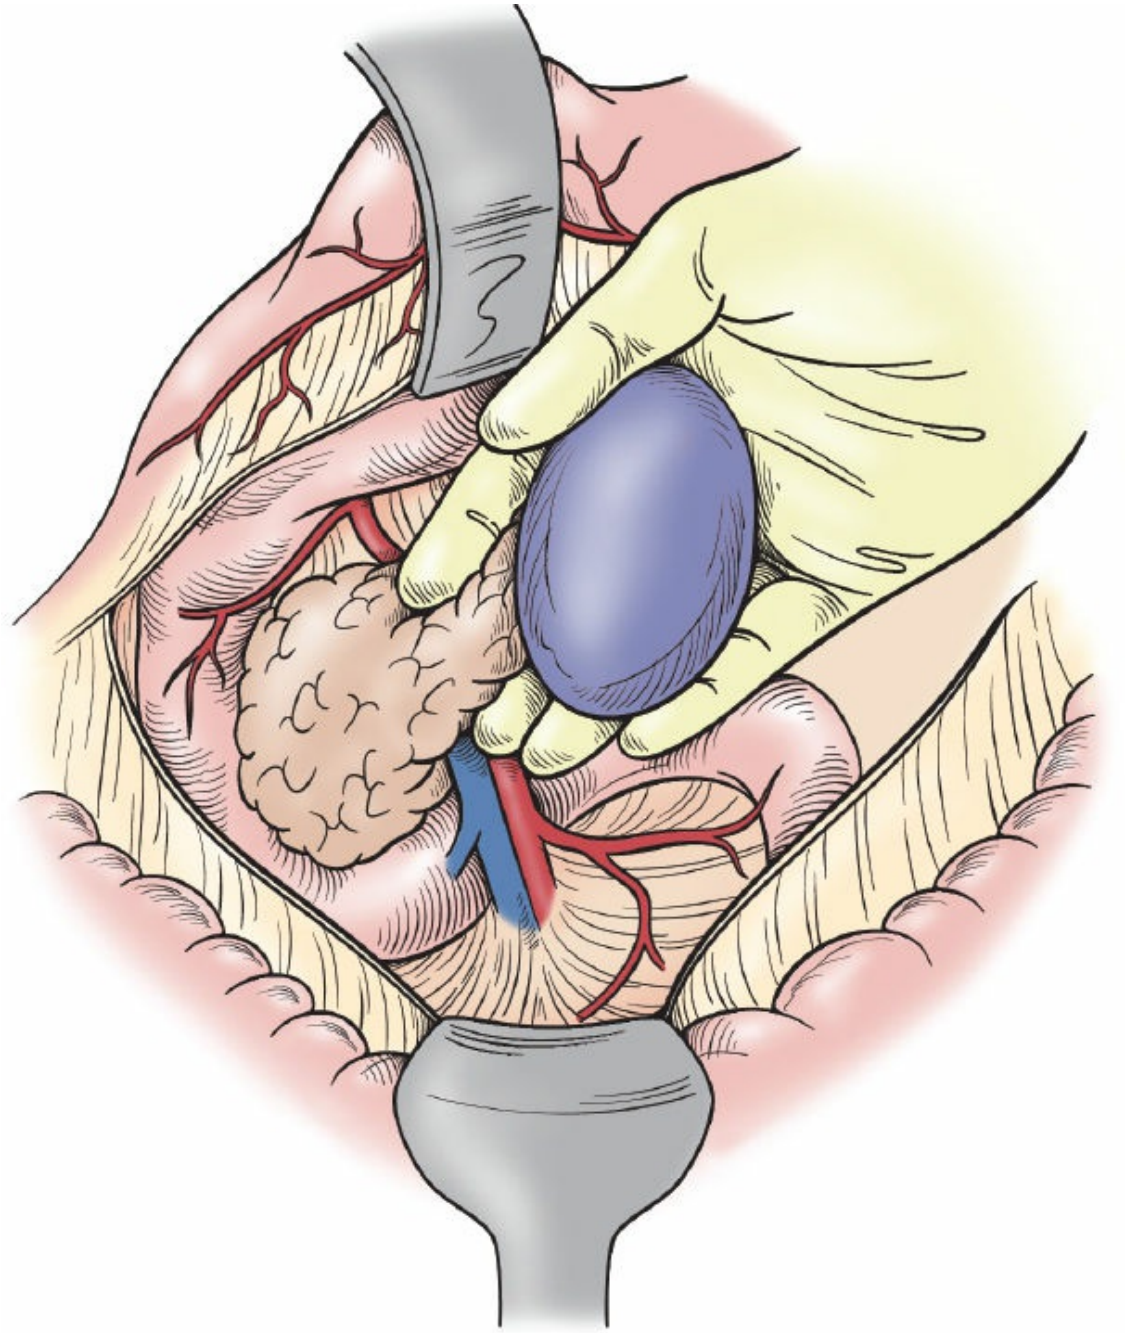

Figure 170.4. After dividing the posterior and lateral splenic attachments to the diaphragm, the plane posterior to the spleen and pancreas is digitally dissected so that the pancreas with spleen can be gently rotated anteriorly and medially. Pulling on the injured spleen will inevitably aggravate the injury, necessitating total splenectomy.

IMMUNE THROMBOCYTOPENIA PURPURA (ITP)

When the procedure is done for ITP, one enters the abdomen through a

midline incision and divides the greater omentum just outside the arcades of the gastroepiploic vessels. This permits access to the pancreas and exposure of the splenic artery as it courses along the superior posterior border of the pancreas. Ligation of this artery is recommended in patients with ITP in order to reduce splenic blood flow and continued platelet destruction. If intraoperative platelet replacement is planned, the transfusion should be delayed until the splenic artery is ligated or the splenic hilar branches are controlled. The remainder of the operation proceeds as above.

POSTOPERATIVE SPLENIC BLEEDING

When the patient has postoperative bleeding, rapid return to the operating room is the procedure of choice. Once the incision is reopened, the clots are removed from the left upper quadrant and packs are placed. One should then sequentially look for bleeding from the small vessels arising from the splenic flexure of the colon, from the gastrosplenic ligament, namely, the short gastric vessels and the posterior gastric vessels, and the left gastroepiploic vessels. Bleeding sites should be suture ligated. Inversion of the greater curvature of the stomach at this point with seromuscular sutures will prevent the development of a gastric fistula. Seldom is the bleeding coming from the branches of the pancreatic vessels that are inspected next. Any bleeding at this site is best controlled by suture ligature. Lastly, the left upper quadrant packs are removed one at a time to look for any oozing from the retroperitoneal tissues and the posterior surface of the diaphragm. Hemostasis here is best achieved by electrocoagulation.

LAPAROSCOPIC SPLENECTOMY

Schwaitzberg provides an excellent summary for the role of laparoscopic splenectomy. This procedure has become the procedure of choice for the performance of elective splenectomy in patients with both benign and malignant conditions. Common indications are ITP, spherocytosis with hemolytic anemia, various types of leukemia, and myeloproliferative disease without massive splenomegaly.

Patient positioning for laparoscopic splenectomy is vital and is surgeon-specific. Delaitre described the “hanged spleen” approach, based upon the same lateral approach advocated for laparoscopic adrenalectomy. The patient is placed in the right lateral decubitis position or semi-lateral

position (Fig. 170.5A,B) and the “kidney bar” of the operating table is raised, thus, flexing the operating table and increasing the distance from the lower rib cage to the iliac crest. When the lateral position is at approximately 80 degrees, there is greater freedom to move the laparoscopic instruments along the left costal margin. Three 12-mm trocars are placed underneath the left costal margin with the most lateral port being just medial and inferior to the tip of the 10th rib where the abdominal musculature is not excessively thick. Once inside the abdomen, the reverse Trendelenburg position allows the intra-abdominal viscera to hang by gravity away from the diaphragm and the spleen. With the patient placed in the lateral position, the stomach is mobilized by dividing the superior gastroepiploic vessels allowing the stomach to pull away from the spleen by gravity as the spleen remains attached to its retroperitoneal ligaments. A fourth more lateral trocar may be added after the splenic flexure has been mobilized. Schwaitzberg describes the sequential ligamentous mobilization using ultrasonic dissection and cautery to divide the splenocolic ligament, the gastrosplenic ligament, and the more proximal short gastric vessels. Division of these structures is made by clips, vascular staples, ultrasonic shears, or bipolar cautery. Once these ligamentous attachments have been divided, the splenic artery may be dissected and ligated prior to the splenic hilum after which the splenic hilar vessels are approached. Extra care is taken when accessing the splenic hilar vessels to avoid the potential hazard of ligating too close to the pancreas resulting in pancreatic injury and pancreaticocutaneous fistula. Adjusting the camera at this critical point of the operation will allow for the splenic hilar vessels to be divided near the splenic hilum, thus avoiding pancreatic injury. Once the spleen is completely freed, it is placed in an endobag and morselized with a crushing clamp prior to removal by way of the endobag.

Some laparoscopic surgeons prefer to have the patient in the supine position with the left chest and abdomen elevated by a folded sheet (Fig. 170.6). This may raise the patient’s left side approximately 35%. Gas insufflation is provided by way of a Veress needle that is placed inferior to the left rib cage in the anterior axillary line where a 12-mm port is inserted. A second 5-mm port is placed directly medial to port no. 1 in the midclavicular line; this port is used for the camera. A third 5-mm port is placed slightly superior in the midline and is used for most of the tissue dissection, tissue mobilization, and hemostasis with the ligature. A fourth

5-mm port is placed underneath the right rib cage at the midclavicular line and is used to grasp tissues that are being dissected. A fifth 5-mm port is placed at the right anterior axillary line and helps retract the liver away from the areas of dissection while the patient is in a reversed Trendelenburg position.

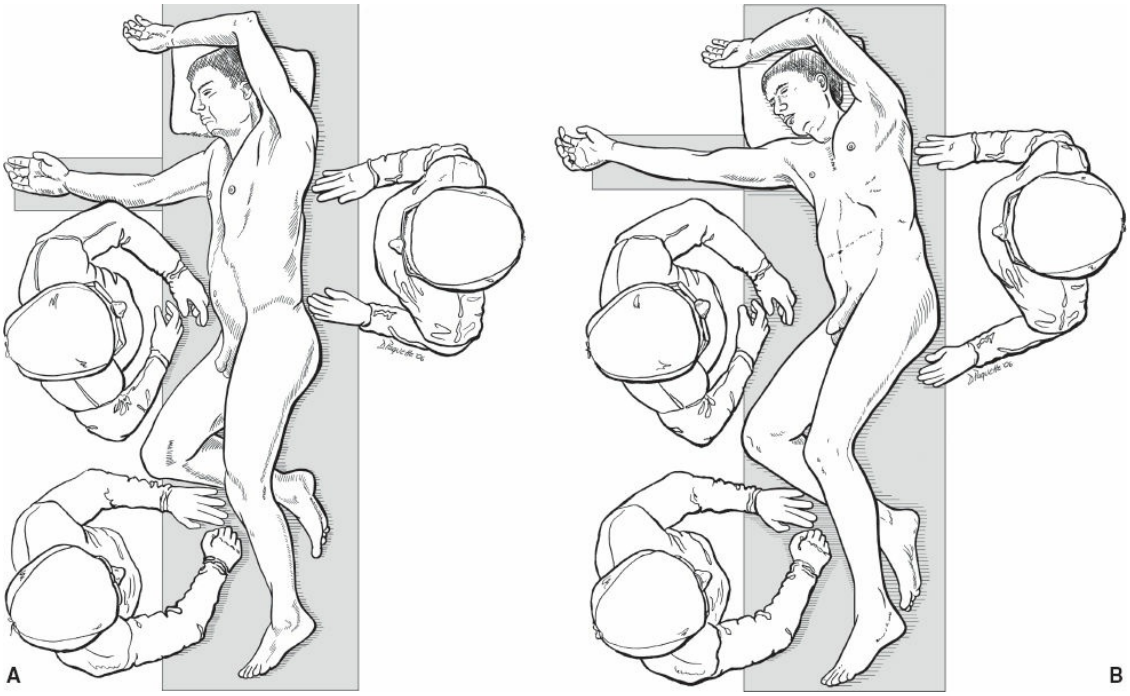

Figure 170.5. A. Demonstration of the lateral decubitus position. **B.** Demonstration of the semilateral decubitus position.

The sequential dissection includes division of the greater omentum peripheral to the gastroepiploic vessels, division of the short gastric vessels and the posterior gastric vessels, and division of phrenocolic ligament; this is typically achieved with electrocoagulation. The division of these vessels may be achieved by clips or vascular staples. Sometimes this may be accomplished by bipolar cautery. At this time, one needs to be sure that there is no accessory spleen and to identify the tail of the pancreas to make sure that there is no iatrogenic injury. The patient is placed in a reverse Trendelenburg position to facilitate division of phrenosplenic ligaments leaving, as the only remaining attachments, the vessels of the splenic hilum. These are taken down with a curved stapler that fires staples of 1-mm thickness in the closed position while the stapler is being gently pushed toward the spleen itself in order to avoid injury to the tail of the pancreas. The spleen is then placed in the endobag for morselization by a crushing clamp so that it can easily be extracted through the port site no. 1.

During the course of the dissection, there may be inadvertent bleeding; the surgeon should always be prepared to convert to an open procedure. The patient should understand, ahead of time that such conversion is potential and should be considered as an extension of a safe operation rather than a complication.

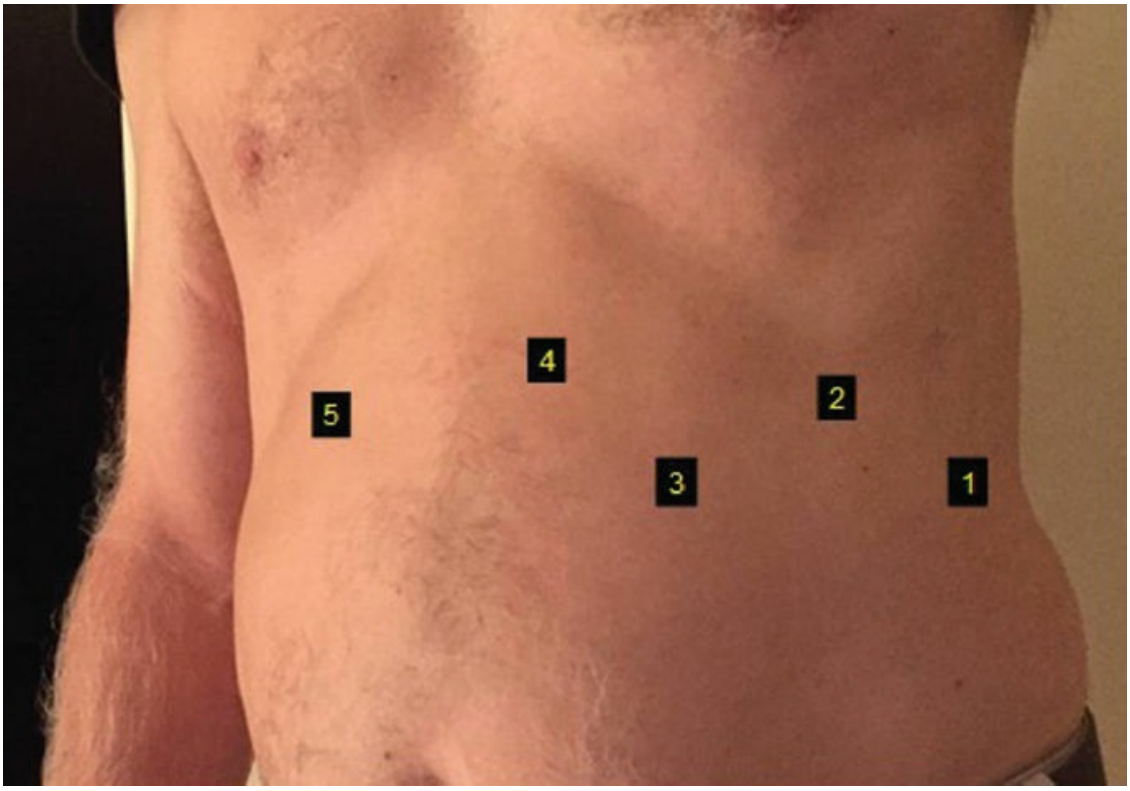

Figure 170.6. Port site 1 is used to insert the Veress needle followed by placement of a 12-mm port. The remaining ports are 5 mm with port site 2 used for the camera; port site 3 used for most of the tissue dissection, mobilization, and hemostasis; port site 4 used to grasp tissues that are being dissected, and port site 5 used to retract the liver away from the area of dissection. (Courtesy Dr. John D. Webber, Chief of MIS, Michael & Marian Ilitch Wayne State University Department of Surgery.)

The role of laparoscopic splenectomy in the injured patient has not been established. Most injured patients who require splenectomy have major injuries and have shown evidence of hemorrhage so that the added time to perform a laparoscopic splenectomy in the presence of active bleeding is potentially dangerous. The decision to convert from laparoscopic to open splenectomy, of course, will be based upon surgical experience. Otherwise, the potential for postoperative complications following laparoscopic splenectomy is similar to those seen following open

splenectomy.

LAPAROSCOPIC SPLENECTOMY WITH PORTAL HYPERTENSION

Portal hypertension due to liver cirrhosis is complicated by upper gastrointestinal bleeding from gastroesophageal varices. Some type of splanchnic devascularization procedure has been effective in controlling such varices. Part of this procedure includes splenectomy with or without devascularization of the gastroepiploic vessels along the greater curvature. Laparoscopic splenectomy in this setting has traditionally been considered contraindicated. With improved results of different treatments for portal hypertension from cirrhosis such as the use of interferon, laparoscopic splenectomy has gained in popularity. Depending upon the grade of cirrhosis and the clinical findings, splenectomy may be indicated with or without associated devascularization of the gastroepiploic vessels and may require a hand-assisted port site for patients with unusual splenomegaly.

Kawanaka recommends that the patient is placed with the left flank elevated about 60 degrees. A 12-mm port that is used for insufflation is placed to the left of the umbilicus following which three additional ports are placed in the epigastric area, the midclavicular line underneath the rib cage, and the left flank. When the spleen extends below the left subcostal margin, two additional ports are placed in the flank immediately below the lower pole of the spleen. When a hand-assisted splenectomy is planned, a 7-cm midline epigastric incision is used. This is routine when the spleen is unusually large. Based upon past experiences, Kawanaka and colleagues plan ahead of time for a hand-assisted laparoscopic splenectomy when the Child-Pugh score exceeds 9 and the preoperative splenic weight is thought to be greater than 1,000 g, or there appear to be large perisplenic collateral vessels on preoperative imaging.

The sequence of the splenic mobilization is similar to that described in patients without portal hypertension, but the increased vascularity of portal hypertension favors the use of a vessel-sealing device. Once all of the ligamentous tissues have been divided, the last step is to divide the hilar attachments from the tip of the pancreas. These attachments are taken down using the endoscopic vascular stapler with a 1-mm thickness in the closed position. Because of the rapid bleeding that may occur in patients with portal hypertension, conversion to open splenectomy is performed much more quickly than would be the case in patients without portal

hypertension.

OPERATIVE SPLENIC SALVAGE AFTER INJURY

Once the spleen became recognized as a vital link in the immune response to infection, operative attempts at splenic salvage became fashionable. A few far-sighted surgeons, however, practiced splenic salvage before their less prescient colleagues. Zikoff, in 1897, may have performed the first splenorrhaphy; Dretzka, in 1930, published the first splenorrhaphy performed on a child. This early report by Dretzka and the subsequent report by Morganstern and Shapiro highlight the technical factors involved with achieving successful splenorrhaphy, including a generous incision, proper exposure, and gentle manipulation.

SURGICAL TECHNIQUE

Splenorrhaphy

Once fully mobilized using the techniques described above, there are a variety of techniques for obtaining splenic hemostasis. For large deep injuries, the authors prefer the placement of 2-0 chronic sutures swedged on a 2-in, blunt tip needle; these are placed about 1 to 2 cm away from the torn margin and passed deep into the wound crevice; the suture exit tract should be a mirror image of the entrance placement (Fig. 170.7). Often, two of these sutures are placed sequentially so that the surgeon can tie one while the other suture is held by the assistant, with the exact tension to achieve gentle compression of the spleen without tearing the parenchyma or causing tissue necrosis. Equal tension on both sides of the crevice is best obtained with two-handed ties, with each hand being close to the splenic surface. Displays of virtuosity by immature residents using fancy one-handed ties should be discouraged; these cause uneven tension, which promotes parenchymal injury with additional bleeding. Once parenchymal apposition is achieved, most bleeding will rapidly subside; minor oozing through the needle holes is best treated by placing a dry sponge over the spleen and returning the spleen to the left upper quadrant for about 10 minutes while other organs are assessed. If hemostasis appears good when the pack or sponge is removed, the “no touch” technique applies; the surgeon should leave it alone.

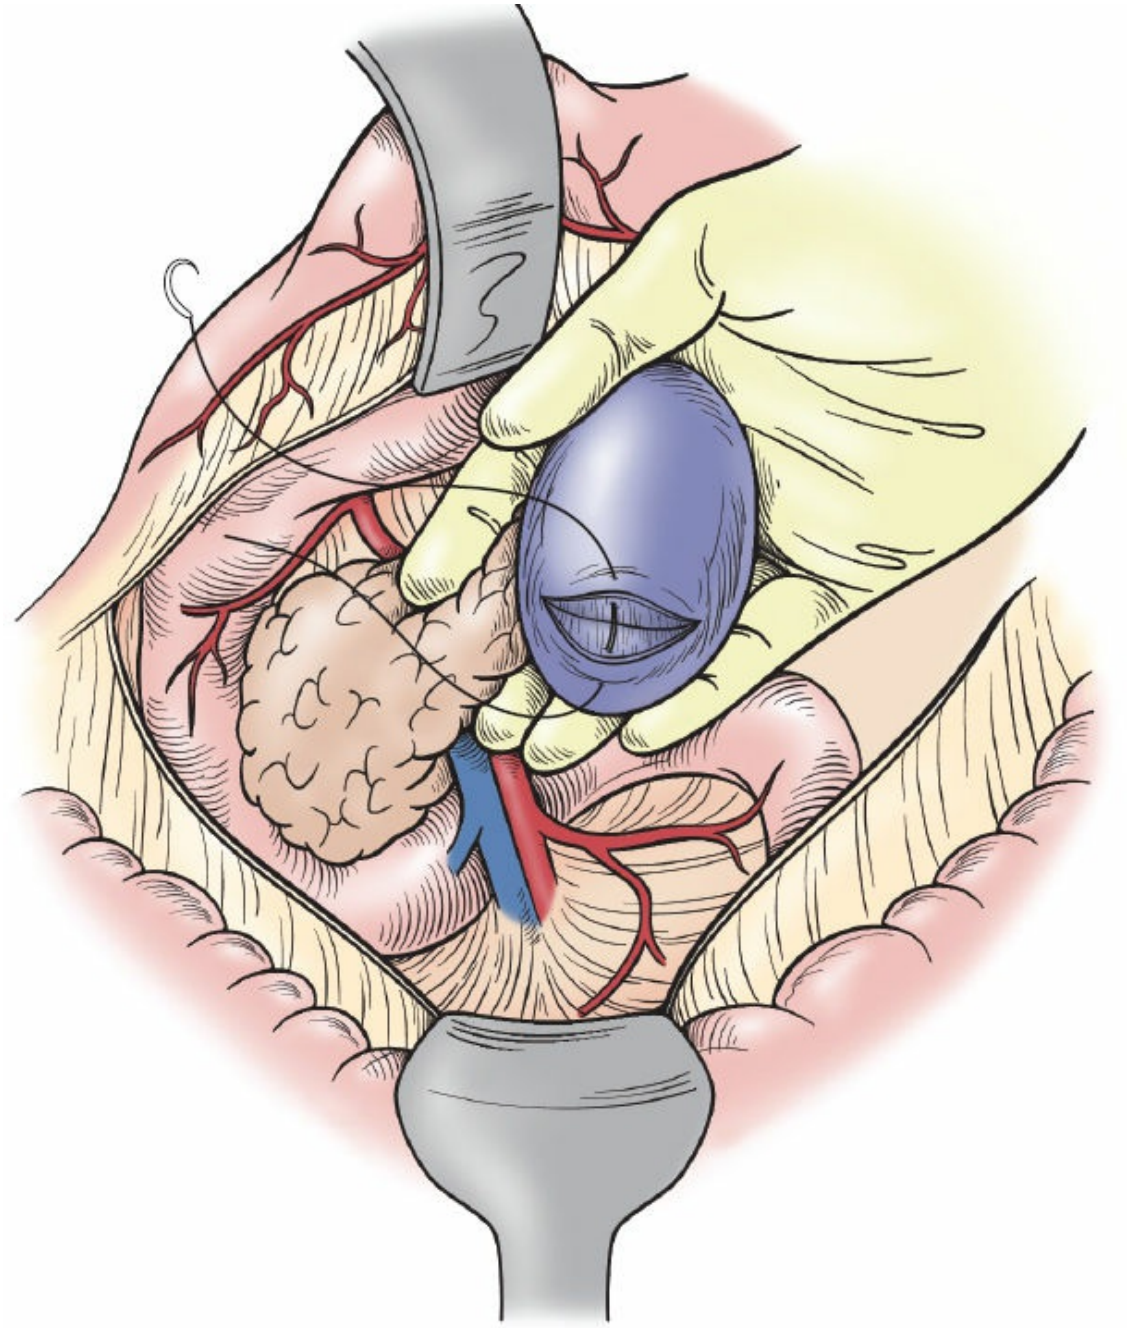

Figure 170.7. Deep splenic lacerations can be sutured with the blunt-tipped, swedged-on, 2-0 chromic (EAD21) suture, which is placed 1 to 2 cm away from the tear and passed deeply into the wound crevice. When two sutures are placed, one can be held at the desired apposition while the other is gently tied.

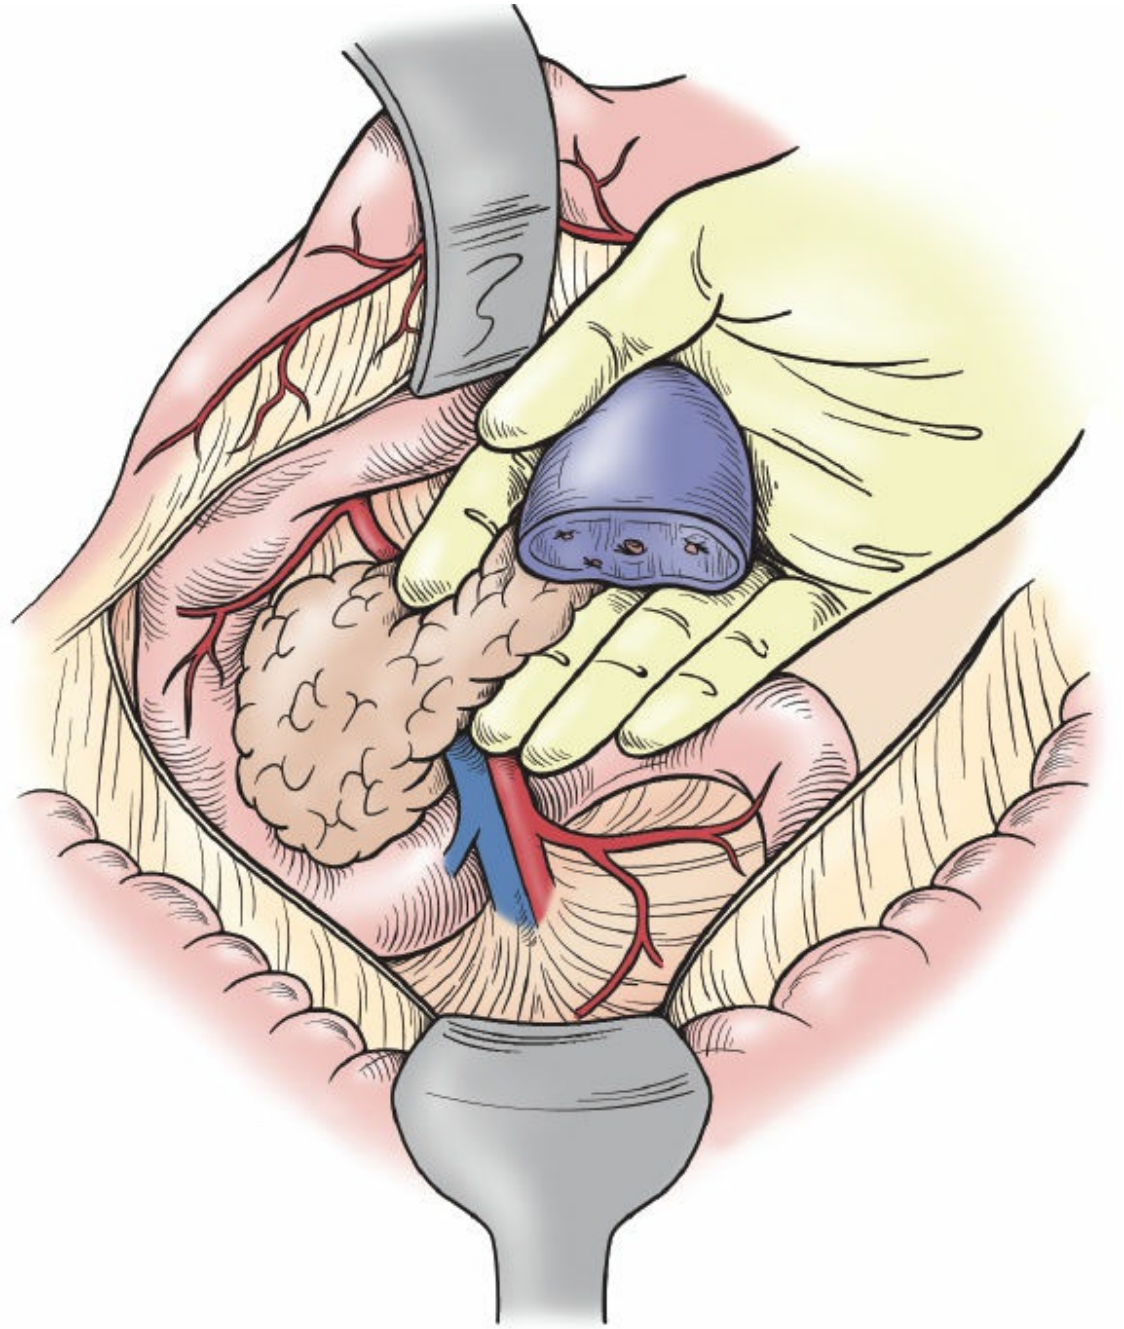

Figure 170.8. When performing partial splenectomy for major laceration or for ischemia caused by hilar segmental vessel disruption, the trabecular vessels may be made hemostatic by electrocoagulation or suture ligation. Carefully placed figure-of-eight sutures followed by gentle tying give good hemostasis without excessive injury to the adjacent parenchyma.

Partial Splenectomy

When performing a partial splenectomy for extensive injury to a splenic segment, or for segmental splenic ischemia distal to transected hilar segmental vessels, transverse intraparenchymal arteries may continue to

bleed. Sometimes these transverse spurting vessels can be made hemostatic by electrocoagulation applied to an occlusive clamp, whereas other bleeding vessels require suture ligatures (Fig. 170.8). The authors prefer to use a 4-0 silk suture placed in a figure-eight manner to best avoid tearing of the adjacent splenic tissue while getting hemostatic occlusion of an arterial pumper (Fig. 170.8). The same principles of gentleness apply when suturing the splenic parenchyma surrounding a spurting vessel; a two-handed tie with equal tension reduces the chance for added parenchymal injury.

Following partial splenectomy, the splenic capsule may be approximated, especially if the splenic crevice angles toward a central valley. This approximation should be done with fine parenchymal sutures, such as 4-0 silk, and they should be tied quite gently. Bleeding through the needle holes is best contained by placing a pack over the repair and returning the spleen to the left upper quadrant, as previously indicated. When the injury causes disruption of the hilar vessels, identification and ligation provide optimal hemostasis, whereas an obviously ischemic splenic segment, distal to the ligation, is best resected using the techniques described previously.

There are many adjuncts to successful splenorrhaphy. These include the use of a variety of hemostatic agents to augment the hemostatic effect afforded by temporary packs; the argon laser may be more effective than simple electrocoagulation for larger splenic tears; the use of stapling devices gives quicker control, but may cause ischemia or tearing; the placement of absorbable meshes around the badly injured spleen, which is then restored to the left upper quadrant and covered, may provide salvage of grade V injuries (Fig. 170.9). In general, the authors advocate simplicity in providing splenic preservation; when complicated techniques must be used, the surgeon must ask the question whether the added efforts are conducive to an enhanced risk-to-benefit ratio in the patient with ongoing bleeding.

Using these techniques, the success of operative splenic salvage is over 50%. The best results have been obtained in patients with blunt injury, although these techniques can be used for penetrating wounds. Attempts at operative splenic salvage are discouraged, however, in the unstable patient with active bleeding from the spleen and/or from other organs; the extra time required for splenic preservation will increase the need for blood transfusion and compromise the patient’s overall well-being.

Splenectomy With Splenic Replantation

Splenosis is a condition whereby patients with shattered spleens will sometimes develop islets of splenic growth following splenectomy when not all of the splenic fragments are identified and removed. Stimulated by this unusual event, the use of splenic preservation, by placing small fragments of splenic tissue within the folded omentum, has been promulgated. This “omental omelet” of multiple splenic fragments, measuring no more than 1 cm in size, may contain 50% of splenic parenchyma. This technique has often been used in patients requiring rapid splenectomy for bleeding after penetrating wounds. Large clinical series have demonstrated that these splenic segments remain viable and, later, will concentrate isotope. The clinical protection against OPSI afforded by this splenic omelet, however, has not lived up to expectations. Likewise, these patients with splenic replantation do not respond in the same way as do patients with splenic salvage in the normal position with maintained splenic blood flow or in patients without splenic injury. Maintenance of normal splenic perfusion is critical to successful clearance of circulating bacteria.

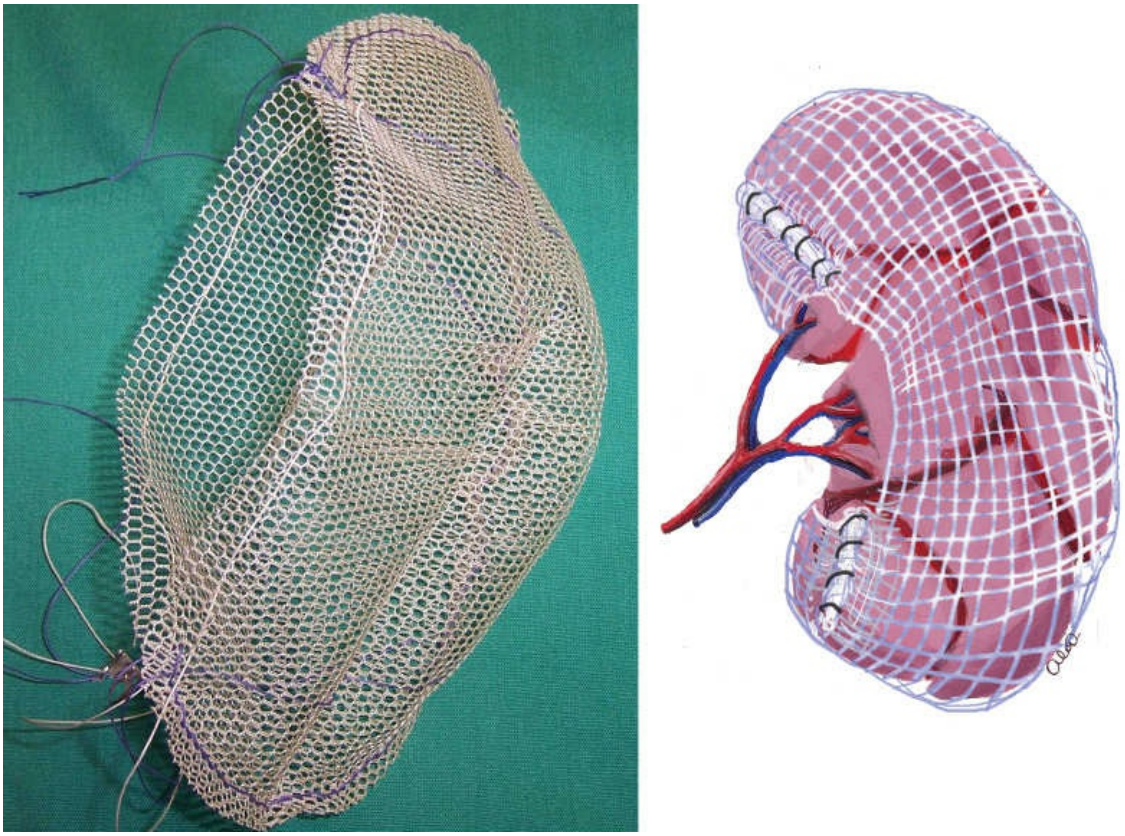

Figure 170.9. Type V splenic injuries may be salvaged by the placement of a custom devised mesh wrap around the injured

spleen, which is then returned to the left upper quadrant. Careful inspection of successful hemostasis is mandatory prior to closure.

The paradox of having a live splenic replant without the expected immunologic protection was studied in a canine model of splenic replantation over 18 months; the results of this study explain why the omental omelet does not provide full immunologic protection. The splenic omelets in this canine model uniformly survive and take up isotope but the histology of these surviving splenic fragments shows that the perifollicular lymphoid tissue is absent. This lymphoid tissue is thought, by most researchers, to be the source of the protective immune response. Based upon these animal studies and upon bad clinical experiences, the authors no longer recommend this technique.

Nonoperative Splenic Preservation After Injury

Billroth, in the 1870s, suggested that the injured spleen could be treated nonoperatively. He reported on a patient who sustained a lethal closed head injury and died on postinjury day 5; the autopsy revealed a splenic rupture, which had completely coagulated. Despite this early prophetic observation, nonoperative treatment of splenic injury, for all practical purposes, was avoided until the 1950s in children and the 1970s in adults. During the past 30 years, nonoperative splenic preservation has become the norm; successful observation in both children and adults approaches 90% after blunt injury. Success with this regimen correlates with a number of factors, with the grade of splenic injury (Table 170.1), and the presence of associated injuries requiring laparotomy being high on the list (Table 170.1). The high success rate of nonoperative treatment, likely, will create a generation of surgeons who are insecure with open splenectomy.

TABLE 170.1 Severity of Splenic Injury

Grade – Injury Description[a]
I. Small subcapsular hematoma (<10% surface area) Small laceration (<1 cm deep)
II. Medium subcapsular hematoma (10%–50% surface area) Intraparenchymal hematoma (<5 cm in diameter) Medium laceration (1–3 cm deep)
III. Large subcapsular hematoma (>50% surface area) Intraparenchymal hematoma (>5 cm in diameter) Expanding hematoma Large laceration (>3 cm deep or involving trabecular vessels)
IV. Laceration involving hilar vessels Devascularized >25% of spleen
V. Shattered spleen involving hilar vessels Total devascularization of spleen

[a]Condensed from Organ Injury Scaling Committee for the American Association for the Surgery of Trauma (1994 revision).

Many important advances in the successful nonoperative splenic preservation have been made in the past few years. The clinical presentation is now recognized as the single most important factor in deciding upon nonoperative therapy; patient age and grade of splenic injury are less important in the clinically stable patient. A vital clinical decision about aborting the nonoperative approach relates to the need for blood transfusion during the period of observation. When the patient requires more blood transfusions than would be predicted on the basis of associated injures, especially to bones, or when the patient with an isolated splenic injury requires any blood transfusion because the hemoglobin has drifted to below a critical range of 8 to 10 g/dL, the authors recommend immediate operative intervention for a recently ruptured spleen. Like any clinical decision, the risk-to-benefit ratio must be assessed and

comorbidities must be taken into consideration. As long as one does not endanger the patient with the risk of multiple blood transfusions, which could be avoided with splenectomy, the main complication of nonoperative therapy for splenic injury is the need to do a delayed exploration.

When nonoperative therapy fails and the patient requires exploration, the same principles of splenic preservation by the techniques described previously apply; the likelihood of successful operative splenic salvage, however, is much lower after unsuccessful observation. In retrospect, it appears that patients, who had injuries that could be successfully treated by splenorrhaphy or partial splenectomy, are now being successfully treated by nonoperative therapy. Thus, the 50% success rate for operative splenorrhaphy falls to about 10% when nonoperative management is used as the primary treatment mode.

One of the important subgroups, for patients being observed nonoperatively for splenic injury, includes those patients who have evidence of a splenic blush on computed tomography or active bleeding into the parasplenic hematoma. The stable patient with a splenic blush may benefit from angiography and embolization of the intrasplenic vessel. Tominaga and coworkers showed that immunologic function, as measured by immunoglobulins, C3 compliment, compliment factor B, and T cell function, was maintained after splenic embolization in comparison to eusplenic patients. In patients with active bleeding, embolization provides prompt cessation of bleeding, thereby precluding emergency operation. Cessation of active bleeding can be achieved in over 60% of patients. Splenic embolization, however, is not without risk. Even when the embolization is performed in one of the segmental branches, splenic infarction with significant and prolonged pain may result. Likewise, the patient with splenic infarction may develop the picture of sepsis and circulating cytokines, which is immediately relieved with splenectomy (Fig. 170.10). Shih and coworkers suggest that splenic embolization dysregulates the immune response and aggravates the cytokine response to peripheral mononuclear cells, which may increase susceptibility to infection.

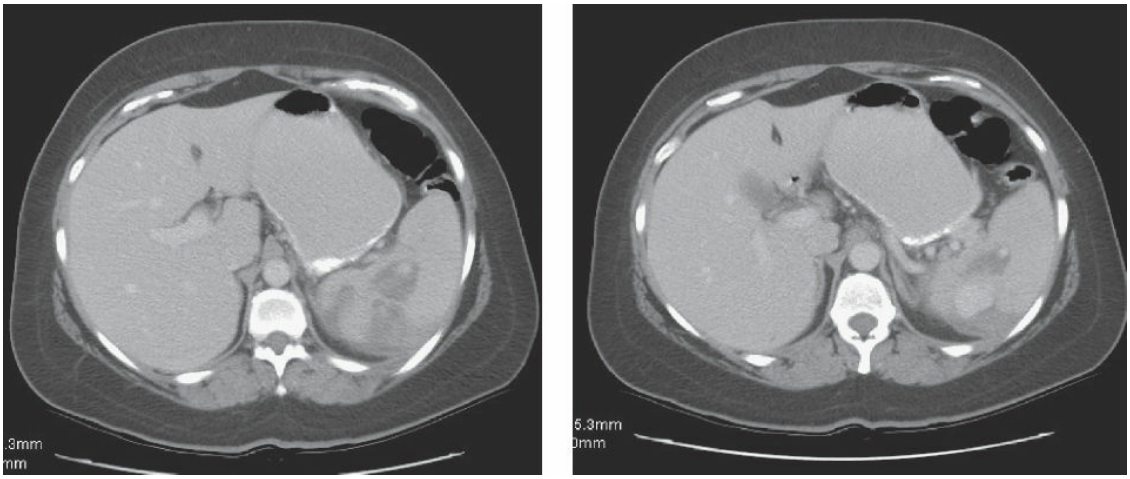

Figure 170.10. This 27-year-old woman driver was T-boned on the left side and presented with a type III splenic injury (**left**) with an intrasplenic pseudoaneurysm (**right**). She was transferred for splenic embolization that was successfully accomplished as an outpatient through a pole lower branch. Within 12 hours, she had diffuse aches and pain, fever, and malaise, which subsided immediately following splenectomy 7 days later. Histology showed necrosis around the false aneurysm. Consequently, the authors recommended observation for asymptomatic patients whose false aneurysm is totally intrasplenic.

Nonoperative Management and Anticoagulation

The pendulum has swung toward the widespread use of pharmacologic anticoagulation for venous thromboembolic (VTE) prophylaxis in all surgical patients, including patients with injury. Patients with defined intraparenchymal bleeds to solid organs such as the liver, spleen, and brain have initially been excluded from any anticoagulation regimen. The emphasis on initiating anticoagulation in all patients, however, has extended to patients with intraparenchymal hemorrhages that have remained stable for 24 to 48 hours; after this interval, VTE prophylaxis has been recommended. The urgency to initiate VTE prophylaxis is even greater in those patients with atrial fibrillation, a prior myocardial infarction, or a mechanical heart valve. The authors have seen rebleeding into solid viscera in patients with brain injury and splenic injury following initiation of VTE prophylaxis after 48 hours (Fig. 170.11). Njaastad and coworkers showed that the likelihood for a thromboembolic event was 0.6% in 3 weeks in patients without VTE prophylaxis in the presence of atrial fibrillation. The authors recommend that no VTE prophylaxis be administered in patients with intraparenchymal hemorrhage for the initial 3

weeks, by which time the hematoma and surrounding tissues will be in the third phase of wound healing.

Distal Pancreatectomy With Splenic Salvage

The use of splenic preservation while performing distal pancreatectomy for grade II or grade III pancreatic injury with ductal disruption to the left of the superior mesenteric vein was promulgated by Pachter (Fig. 170.12). The distal pancreatectomy is performed by ligating each branch of the splenic artery and splenic vein as they enter into the pancreas while, at the same time, protecting their terminal branches at the splenic hilum in order to protect splenic perfusion. This technique has subsequently been applied to localized pancreatic tumors that are benign, cystic in nature, or have low potential for malignancy, such as some of the papillary tumors. Most reports describe the open laparotomy technique.

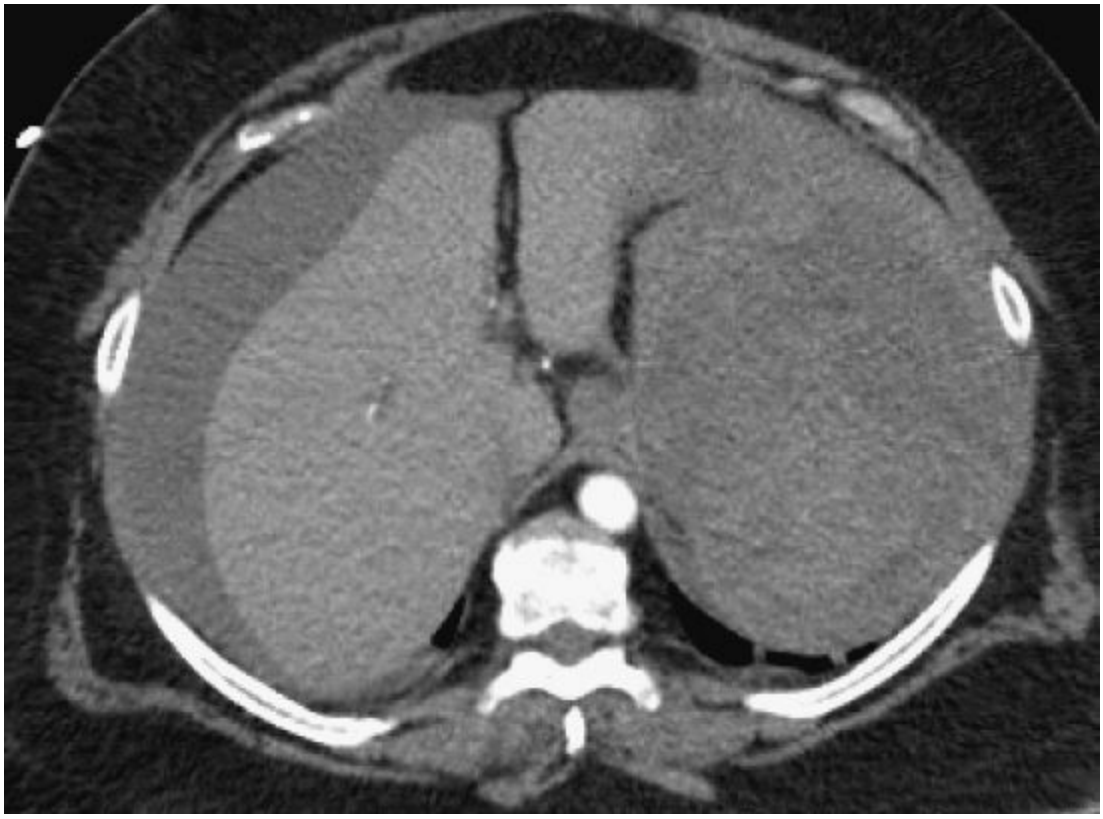

Figure 170.11. This middle-aged woman was restarted on her Coumadin for atrial fibrillation 2 days after sustaining a type II splenic injury. Five days later, she presented with an acute abdomen and hemoperitoneum necessitating emergency splenectomy. The authors recommend that reinstitution of anticoagulation be delayed for 3 weeks with nonoperative treatment of splenic injury.

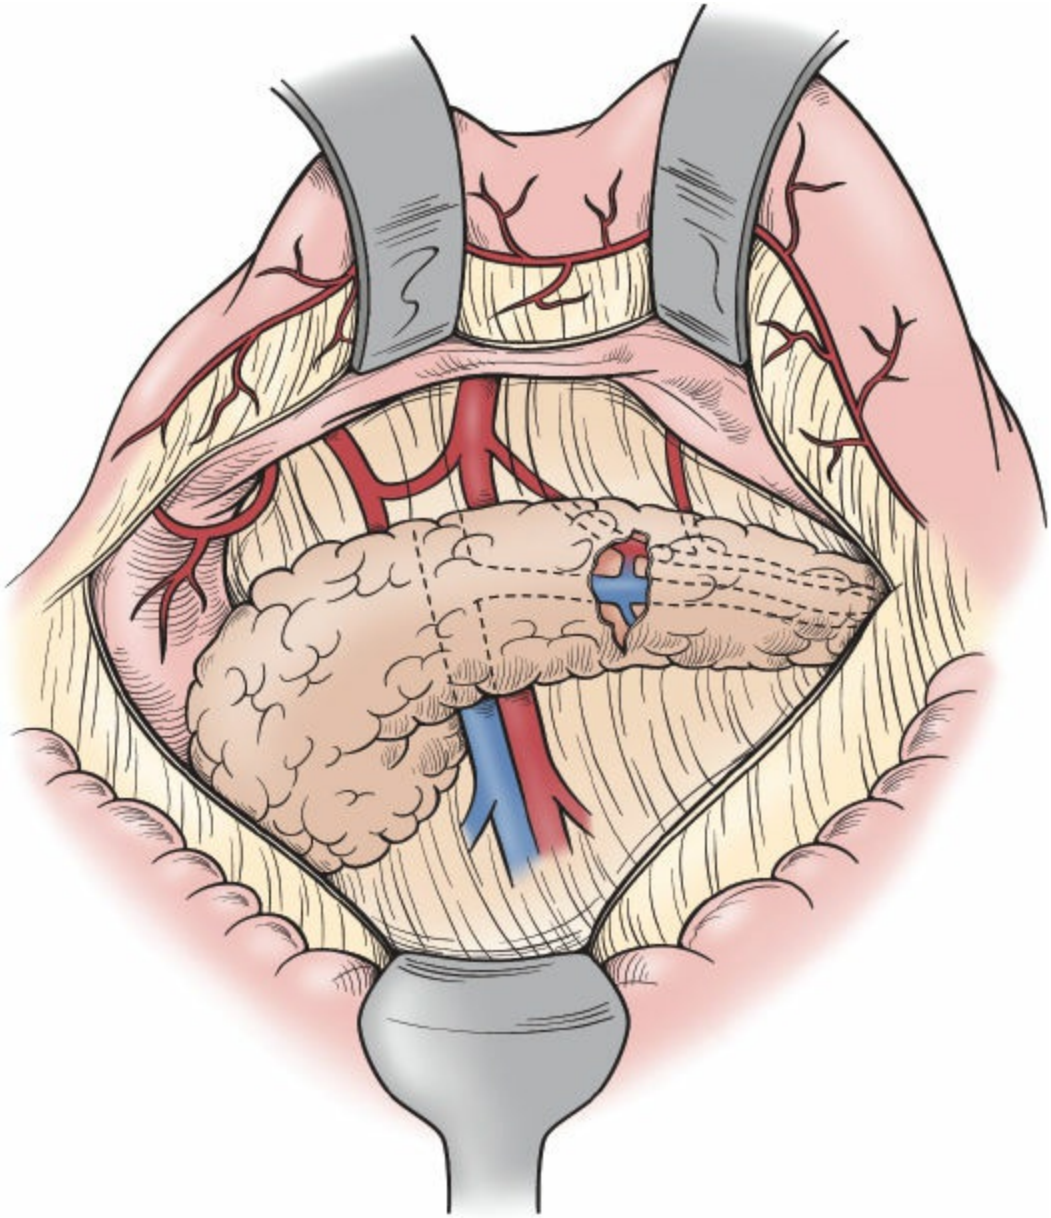

Figure 170.12. A grade II pancreatic injury, typical for what is seen after blunt trauma, is depicted. The pancreatic transection is to the left of the superior mesenteric vein and is associated with ductal disruption. The dot indicates the posterior gastric artery (PGA), which arises from the splenic artery approximately 3 to 4 cm proximal to the splenic hilum, and enters into the stomach posteriorly and slightly inferior to the short gastric vessels.

Access to the pancreas and spleen may be achieved through a midline incision, although the authors prefer a left subcostal incision, which may be extended as needed into the right subcostal area to give good exposure to all of the pancreas and the splenic hilum. The omentum is divided as described above, and the splenic flexure is mobilized to fully expose the

retroperitoneal tissues (Fig. 170.13). The posterior leaf of the lesser omentum attaches to the superior border of the pancreas. The anterior leaf of the transverse colon mesentery attaches to the inferior border of the pancreas. These attachments should be severed through the avascular plane, which is quite close to the pancreas. There will also be some avascular attachments between the posterior greater curvature of the stomach to the tail of the pancreas; these should also be divided close to the pancreas. The above techniques leave the pancreas fully exposed on the anterior, superior, and inferior surfaces.

The splenic vein and its branches should be approached first. This is best achieved by rotating or lifting the inferior border of the pancreas superiorly and anteriorly, thus exposing the posterior surface (Fig. 170.14). Careful dissection in this area will identify the short branches of the splenic vein as they enter into the pancreatic parenchyma (Fig. 170.14). These short veins should be carefully freed, divided, and ligated. Passing sutures around these vessels with the help of small right angle clamps helps minimize bleeding. This ligation can be achieved with fine 4-0 silk ties or with small hemoclips; the authors prefer the fine silk ties, which do not get caught by sponges, as may happen when staples come in proximity to fine mesh gauze. The sequential division of the venous branches is more easily accomplished by moving from the superior mesenteric venous area toward the inferior mesenteric vein and, finally, to the splenic hilum.

Once the hilum is identified, the small terminal arterial branches of the splenic artery can be identified and controlled in the same manner prior to moving from the splenic hilum back to the splenic artery as it descends from the celiac axis. Once all of these branches have been divided, while at the same time preserving the terminal branches of the splenic artery and vein within the hilum, the pancreas can be resected. The division of the pancreas should be at the point of transection in injured patients or to the right of the neoplastic lesion in patients with tumors or cysts (Fig. 170.15). The pancreatic division can be performed by electrocoagulation followed by suture ligation of small parenchymal vessels that exhibit refractory bleeding; the pancreatic duct, if it can be identified, should be suture ligated. The remaining pancreatic stump is then approximated with fine “capsular” sutures to decrease the likelihood of later bleeding or fistulization. Alternatively, the pancreatic resection can be accomplished in a “fish mouth” manner with the “mouth” being closed or apposed with interrupted 4-0 silk sutures. The authors have also been pleased with

resection and stump closure using the GIA stapler. Long-term data on complications of suture closure versus stapler closure of the pancreatic stump have not yet accrued. When this technique of splenic preservation is performed, the spleen does not have to be fully mobilized from its retroperitoneal attachments. When dissection is difficult, however, mobilization is recommended.

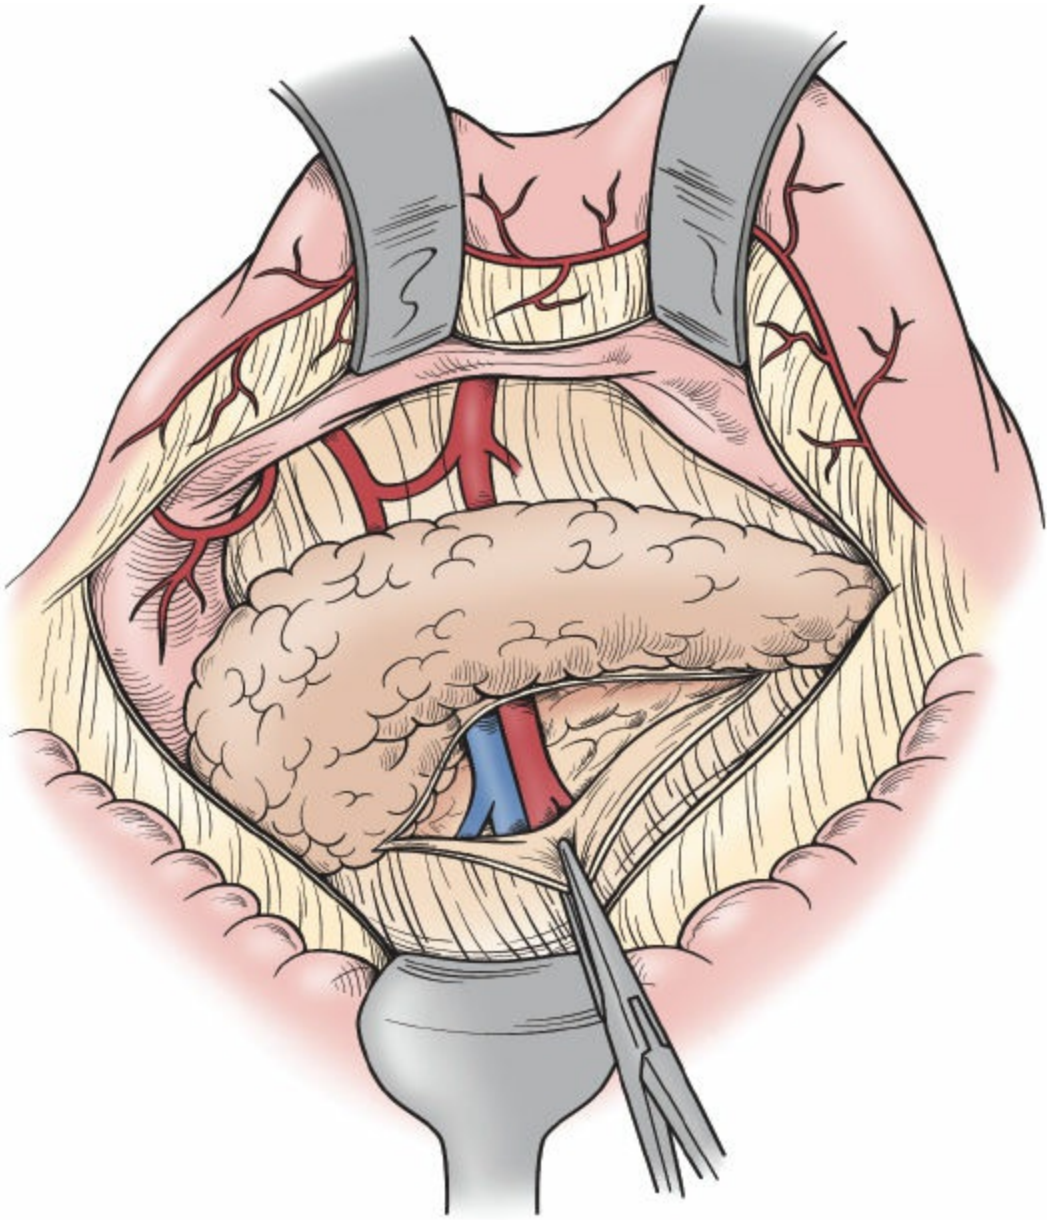

Figure 170.13. The anterior leaf of the transverse mesocolon inserts onto the inferior border of the pancreas. Division of this mesenteric leaf is best performed immediately adjacent to the pancreas, where there are no collateral vessels. This schematic highlights how the underlying mesenteric vessels are exposed after separation of this anterior leaf from the pancreas.

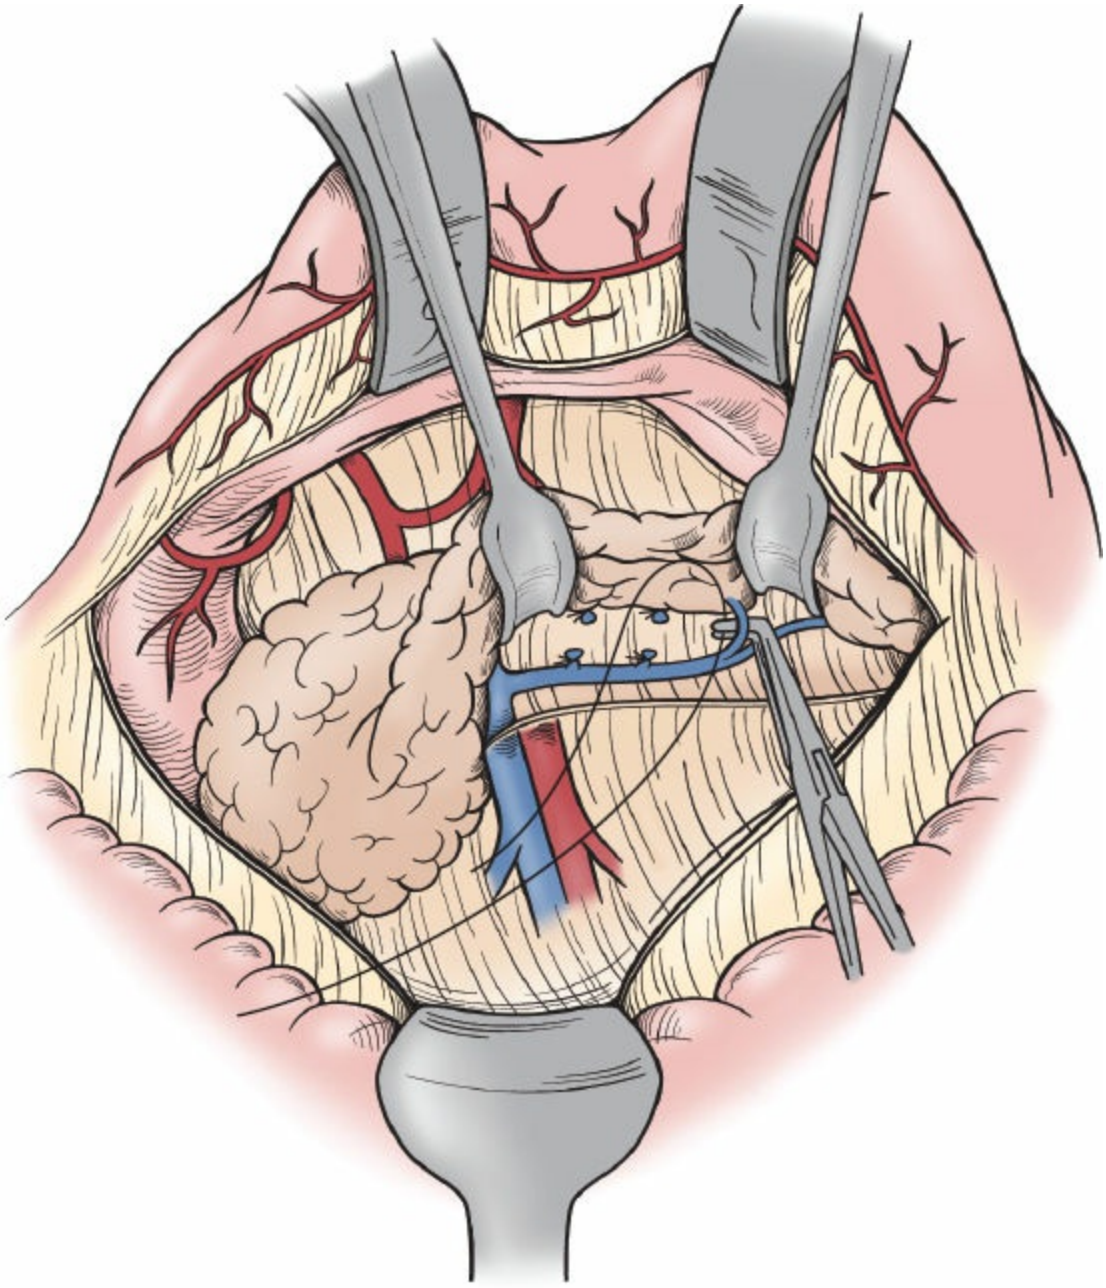

Figure 170.14. By gently rotating the inferior border of the pancreas anteriorly and superiorly, the splenic vein, with its branches into the pancreatic parenchyma, is identified. These branches, which are much shorter than those depicted in this schematic, are individually divided and hemostasis is obtained by means of small clips or ligatures.

Warshaw described an alternate technique for splenic preservation while doing distal pancreatectomy for small, localized neoplasms (Fig. 170.15). This consists of dividing the pancreas with the splenic artery and splenic vein at the site of pancreatic division, but preserving the splenic hilar branches so that perfusion of the spleen is maintained by means of

backflow through the short gastric vessels and the posterior gastric artery (Fig. 170.12). The short gastric vessels arise from the superior segmental branches of the splenic vessels and enter into the greater curvature of the stomach just below the apical fat pad. The posterior gastric artery arises from the splenic artery about 3 or 4 cm proximal to the splenic hilum and enters the posterior wall of the proximal stomach about 2 cm inferior and medial to the short gastric vessels (Fig. 170.12). When using this technique for splenic salvage, one has a better chance for maintaining retrograde flow to the spleen if both the short gastric vessels and the posterior gastric vessels are protected. One of the complications of this technique for splenic preservation is splenic infarction of the inferior pole, which was documented in the Warshaw report of distal pancreatectomy for small tumors and has been observed by the authors following distal pancreatectomy with splenic preservation after injury. When retrograde flow is insufficient, inferior pole splenic ischemia may result and lead to significant pain and possible abscess formation. When seen during operation, splenectomy is recommended.

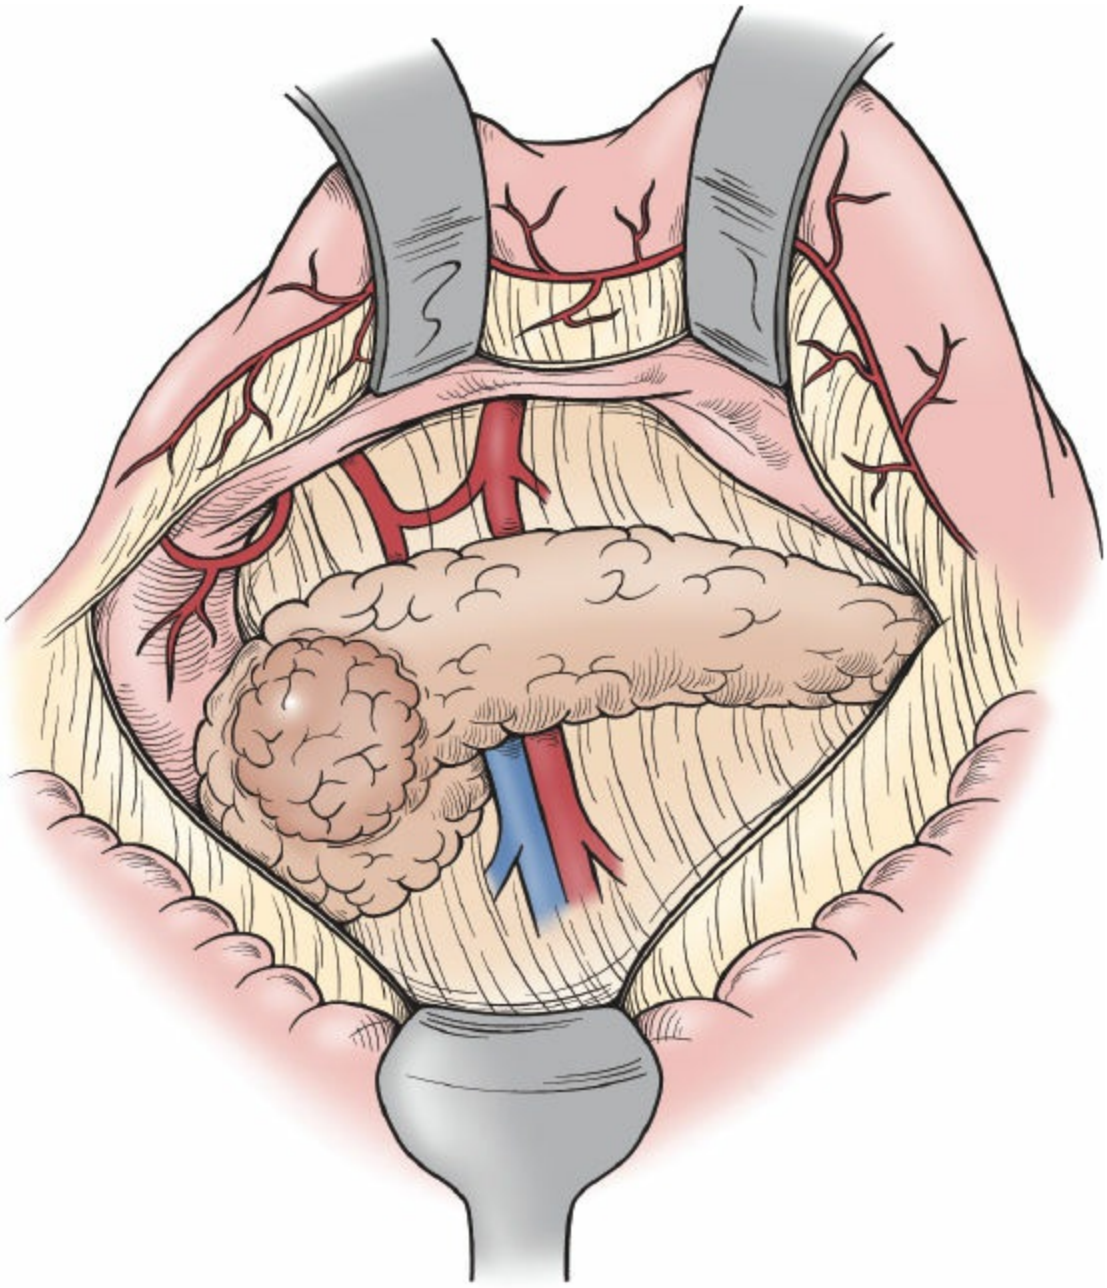

Figure 170.15. Patients with cystic neoplasms or atypical papillary masses at the neck of the pancreas may be treated by local resection of the neoplasm followed by closure of the duodenal segment of remaining pancreas and decompression of the distal pancreas into a Roux-en-Y jejunal limb.

Distal pancreatectomy with splenic preservation in patients with gunshot wounds or stab wounds involving the distal pancreas is more likely to be accomplished by the technique of dividing the splenic artery and splenic vein at the site of pancreatic injury, because ongoing bleeding or significant hematoma following penetrating wounds in this area is more common. Blunt rupture of the pancreas is seldom associated with major

bleeding, which compromises proper exposure. When splenic preservation with distal pancreatectomy is performed after penetrating injury, the surgeon must be sure that the patient is stable and that there is no persistent bleeding from other sites. The risk of spending extra time preserving the spleen in a patient with marginal stability or ongoing bleeding outweighs the risk of OPSI following rapid distal pancreatectomy with splenectomy. When splenectomy is needed, the administration of polyvalent vaccine is indicated; the authors no longer send the patients home on oral antibiotics.

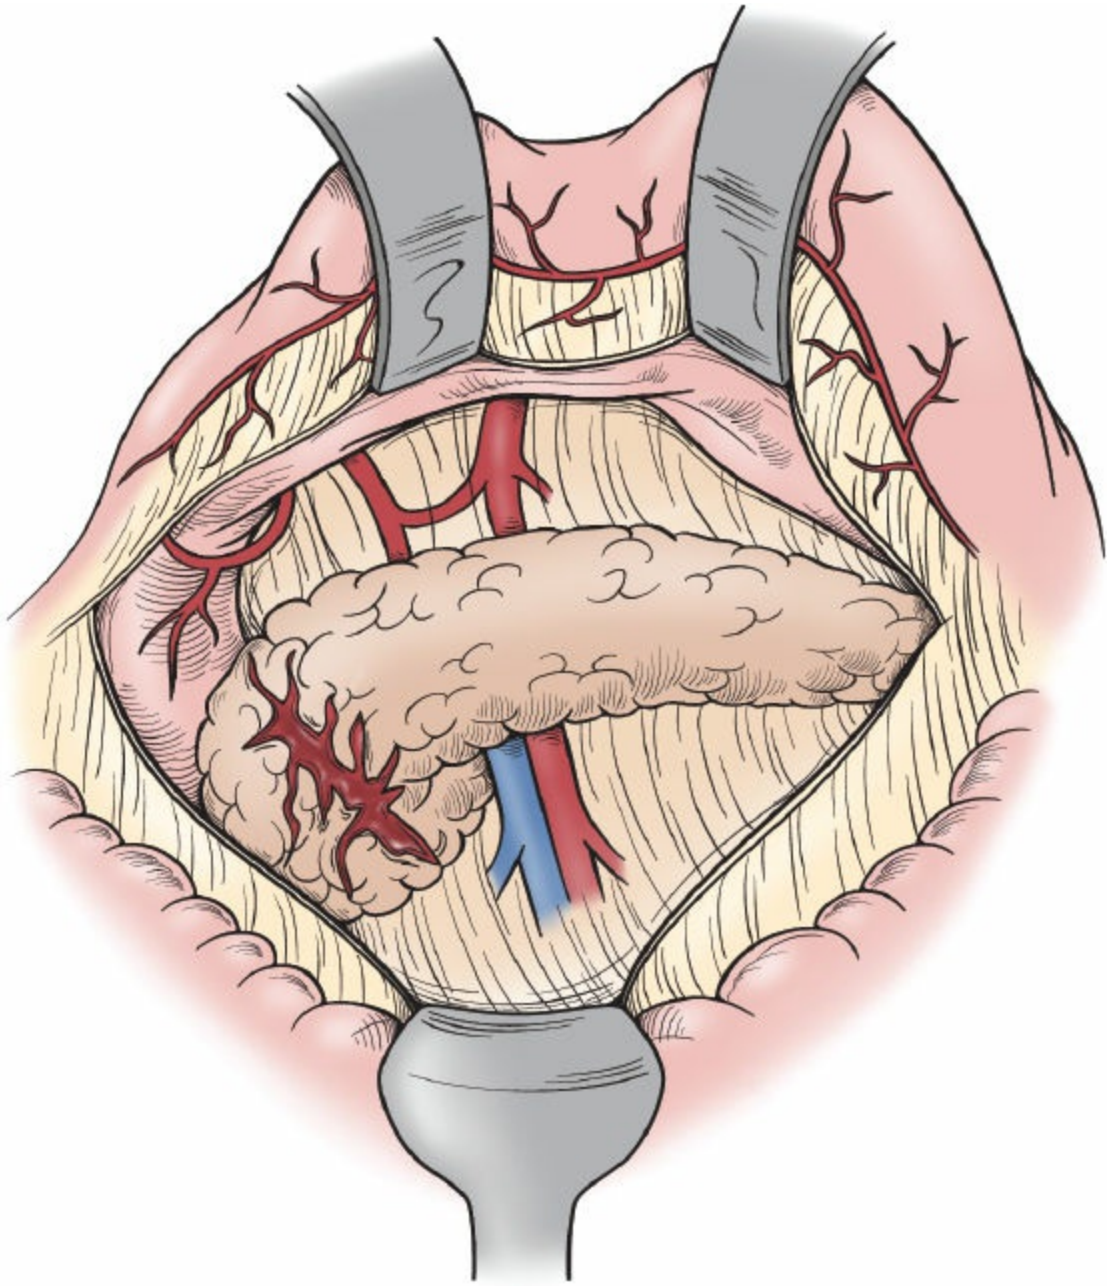

Figure 170.16. Patients with blunt abdominal injury may sustain a stellate fracture of the head of the pancreas in the vicinity of the intrapancreatic portion of the common bile duct. Patients with

large gunshot wounds to this area usually die on the operating table.

Treatment of Pancreatic Head Lesions/Tumors With Splenic Preservation

Some patients with blunt abdominal injury will present with a stellate laceration in the head of the pancreas, anterior to the intrapancreatic portion of the distal common bile duct (Fig. 170.16). Although superficial lacerations in this area after blunt injury can be treated with wide drainage, the deeper lesion requires careful assessment for complete transection and for involvement of the bile duct. When complete transection of the pancreatic head occurs, preservation of the lateral portion of the head of the pancreas, pancreatic neck, and the distal pancreas with spleen preservation can be achieved by creating a Roux-en-Y jejunal limb, which is then anastomosed to the distal pancreas in an end-to-end or, in the author's preference, an end-to-side pancreaticojejunostomy (Fig. 170.17). The residual pancreatic rim along the duodenal sweep is made hemostatic followed by "capsular" approximation (Fig. 170.17). When this injury occurs following a gunshot wound, the associated bleeding from injuries to adjacent vessels usually makes this approach impractical and unsafe. Some cystic tumors or benign pancreatic tumors lying between the superior mesenteric vein and the intrapancreatic portion of the bile duct can be treated in the same manner with local resection of the tumor, closure of the residual pancreas along the duodenal sweep, and Roux-en-Y pancreaticojejunostomy.

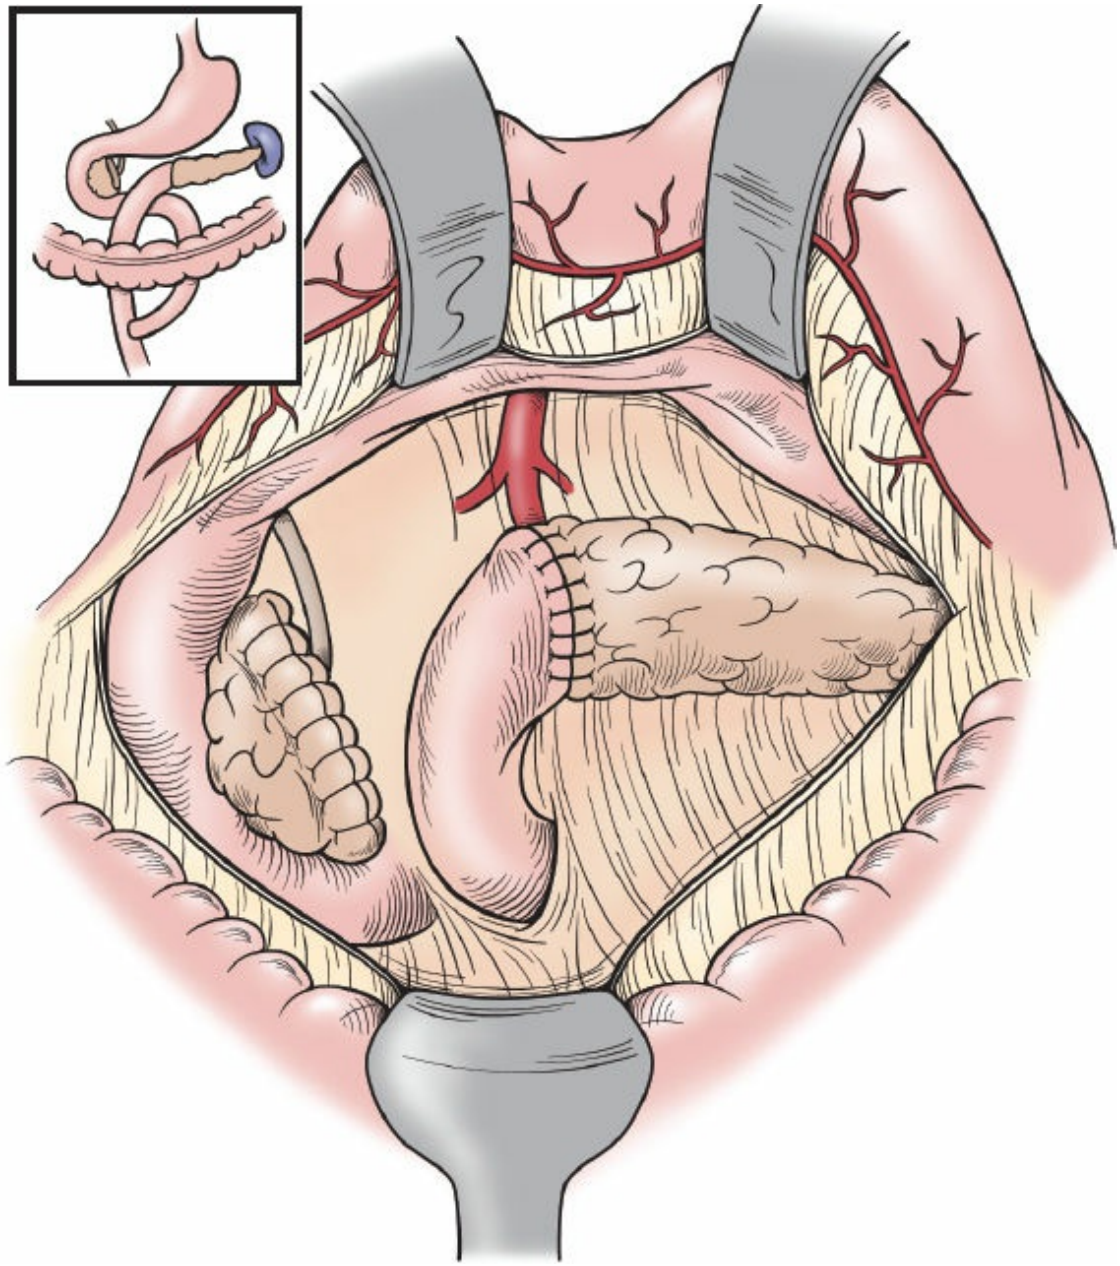

Figure 170.17. When extensive injury to the head of the pancreas occurs anterior and to the left of the intrapancreatic portion of the common bile duct, the transection can be completed and followed by end-to-side Roux-en-Y pancreaticojejunostomy and oversewing of the residual pancreatic remnant adjacent to the duodenum.

Laparoscopic Approach to Splenic Preservation

The rising trend toward laparoscopic surgery has expanded into the domain of splenic preservation. Removal of a benign pancreatic cyst with distal pancreatectomy and splenic preservation has been described utilizing a three-port technique. The laparoscopic approach follows the same steps

summarized previously with the open approach; each step is followed sequentially. The authors have no experience with this technique.

Distal pancreatectomy with splenic preservation has also been described in patients with pancreatitis requiring distal resection for ductal ectasia. This approach, however, must be scrutinized carefully; the authors have had extensive experience with surgery of the inflamed pancreas, which can be quite tedious. Dissection of the severely inflamed pancreas is most difficult using the open approach. The authors question the severity of pancreatitis that would need pancreatectomy in a setting where this could be safely accomplished laparoscopically. Furthermore, most patients with benign pancreatic ductal obstruction are best treated with Roux-en-Y pancreaticojejunostomy rather than distal pancreatectomy, thus preserving both endocrine and exocrine functions.

The use of the laparoscopic approach has also been used for the resection of simple splenic cysts, thus providing for splenic preservation. These are true cysts of the spleen. The results of these studies have not been uniformly good. These techniques can be facilitated by radiofrequency control of bleeding. The true role of such techniques needs to be determined by future experience.

EDITOR'S COMMENT

The authors have done a masterful job combining and integrating three previous chapters in the 6th edition of *Mastery of Surgery* that were devoted to splenic preservation and splenectomy. Therefore, the current chapter covers multiple topics including nonoperative management of the spleen for trauma, splenic preservation for traumatic injury to the spleen and pancreas, spleen preserving distal pancreatectomy for neoplasms, as well as open and minimally invasive splenectomy.

Clearly their experience with traumatic injury to the spleen is nearly unparalleled. As the authors point out, clinical presentation remains the single most important factor in deciding upon nonoperative therapy while patient age and grade of splenic injury are less important in the clinically stable patient. Successful nonoperative observation for splenic injury approaches 90% for in both children and adults. As the authors state, it is clear that patients who could be successfully treated by splenorrhapy or partial splenectomy are now being successfully treated by nonoperative therapy. As a consequence, many surgeons, including trauma and pediatric surgeons, will have limited experience and opportunities to practice splenorrhapy. In fact, in those patients failing nonoperative management of the spleen, the success rate of splenorrhapy falls

from about 50% to 10%. Since only the more extensive splenic injuries are requiring operative management, once operative management is embarked upon, only a small minority of patients will be appropriate for splenorrhapy.

Recent articles have commented on the lost art of splenorrhapy (Arbuthnot M, Onwubiko C, Mooney D. The lost art of the splenorrhaphy. *J Pediatr Surg* 2016;51(11):1881–4). Arbuthnot et al. reviewed a large pediatric national database of 9,567 children with splenic injury from 2004 to 2013. The vast majority of children were managed nonoperatively while 2.1% underwent a splenectomy and 0.8% underwent a splenorrhaphy. The average surgeon performed 0.6 splenectomies and 0.2 splenorrhaphies for trauma. It was calculated that if these rates remain constant over time, the average surgeon would perform 1.8 splenectomies and 0.6 splenorrhaphies for trauma over a 30-year surgical career. It was concluded that nonoperative management has resulted in a decrease in the experience level of the pediatric surgeons expected to perform an emergency splenectomy or splenorrhaphy when the unusual occasion arises. It is likely that similar trends have been witnessed for adult trauma patients with splenic injury.

Algorithm-based care for trauma patients including those with splenic injury has become standard practice and should be utilized to help guide trainees. Certainly, angiography for an arterial “blush” visualized on CT scan in the stable patient is approached with embolization in the vast majority of patients. In a review by Scarborough et al. of the American College of Surgeons Trauma Quality Improvement Program (TQIP) Participant Use Data Files from 2013 to 2014, nonoperative management was attempted in 1,489 (52.2%) of 2,746 patients who sustained grade IV or V blunt splenic injury (Scarborough JE, Ingraham AM, Liepert AE, et al. Nonoperative management is as effective as immediate splenectomy for adult patients with high-grade blunt splenic injury. *J Am Coll Surg* 2016;223(2):249–58). Propensity matching techniques resulted in a cohort of 758 immediate splenectomy (IS) and nonoperative management (NOM) patients who were well matched for all known patient- and injury-related variables. In-hospital mortality was not different between the IS and NOM patients (11.5% vs. 10.0%, $p = 0.33$). The rate of NOM failure in the sample was 20.1%. Independent predictors of failed NOM included the presence of a bleeding disorder, early blood transfusion requirement, and grade V injury. Splenic artery embolization was associated with a decreased risk of NOM failure. It was concluded that nonoperative management is as effective as IS for hemodynamically stable adult patients with grade IV or V blunt splenic injury. The delay in operative intervention that results from failed attempts at NOM does not adversely affect the outcomes of patients who ultimately require splenectomy.

Approaches to splenic preservation during distal pancreatectomy have evolved over time. As laparoscopic approaches have become more mainstream and with the improvement in instrumentation, visualization, and tissue sealing techniques, it is much easier to perform complicated dissection with

laparoscopy with excellent accuracy and minimal bleeding. Up to recently, there have been limited series that have described results with splenic preservation during laparoscopic distal pancreatectomy. However, Dal et al. have recently published a single institution series of 108 patients who underwent laparoscopic spleen preserving distal pancreatectomy (Dai MH, Shi N, Xing C, et al. Splenic preservation in laparoscopic distal pancreatectomy. *Br J Surg* 2016 Dec 22. doi: 10.1002/bjs.10434. [Epub ahead of print]). From 2004 to 2016, 126 had a planned laparoscopic spleen preserving distal pancreatectomy for which it was accomplished in 86% of patients. Tumor size was an independent risk factor for splenic vessel resection in planned splenic vessel preservation operations, and a cut-off value of 3 cm provided optimal diagnostic accuracy. After a median follow-up of 35.9 months, there were no clinically significant splenic infarctions and no patient developed gastrointestinal bleeding after laparoscopic spleen preserving distal pancreatectomy. These results emphasize the excellent results that can be achieved with careful surgical technique and patient selection.

Recently, surgeons have increased their experience with major pancreatic resection utilizing a robotic assisted platform. Those surgeons who have embraced the robotic approach to distal pancreatectomy have argued that increased visualization and better angulation of the robotic arms allow for increased opportunity for blood vessel control and spleen preservation. Nevertheless, published results to date are conflicting. Two recent metanalyses have compared laparoscopic spleen preserving distal pancreatectomy with robotic spleen preserving distal pancreatectomy. Zhou et al. reported a literature review of seven nonrandomized studies involving 568 patients (Zhou JY, Xin C, Mou YP, et al. Robotic versus laparoscopic distal pancreatectomy: a meta-analysis of short-term outcomes. *PLoS One* 2016;11(3):e0151189). Robotic-assisted distal pancreatectomy was associated with longer operating time, lower estimated blood loss, and a higher spleen-preservation rate. In contrast, Gavriilidis reported a literature review of nine nonrandomized trials evaluating 637 patients. Although conversion rates were only 9% for robotic spleen preserving distal pancreatectomy as compared to 20% for laparoscopic spleen preserving distal pancreatectomy, they concluded that there was no significant difference in the conversion rate and spleen preservation rate between laparoscopic spleen preserving distal pancreatectomy and robotic spleen preserving distal pancreatectomy (Gavriilidis P, Lim C, Menahem B, et al. Robotic versus laparoscopic distal pancreatectomy: the first meta-analysis. *HPB (Oxford)* 2016;18(7):567–74). There are no randomized controlled studies so far that have compared laparoscopic spleen preserving distal pancreatectomy and robotic spleen preserving distal pancreatectomy; therefore, selection bias is a real problem and these findings have to be interpreted with caution. It is clear that there are now increased options for minimally invasive distal pancreatectomy with spleen preservation and that it can be routinely and safely achieved with proper patient selection.

Drs. Lucas and Ledgerwood briefly describe the approach for laparoscopic

splenectomy advocated by Dr. Schwaitzberg in the 6th edition of *Mastery of Surgery* (Schwaitzberg SD. Laparoscopic splenectomy. In Fischer JE, ed. *Mastery of Surgery*. 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, Chapter 176) and by colleagues at Wayne State University (Fig. 170.6). Drs. Lucas and Ledgerwood indicate that patient positioning for laparoscopic splenectomy is vital and is surgeon-specific. All the approaches they describe involve some component of elevation of the left side of the patient either via the right lateral decubitis or semilateral position or via the supine position with the left chest and abdomen elevated by a folded sheet.

I have found that a laparoscopic splenectomy (with or without distal pancreatectomy) can be routinely accomplished with no elevation of the left side of the patient. This keeps patient positioning very simple and easily remembered by the trainees, anesthesiologist, and operating room staff. A footboard and a table that can obtain steep reverse Trendelenburg position are needed. The table can also be rotated to allow the spleen to tilt forward as necessary.

In almost all patients undergoing laparoscopic splenectomy, the dissection, blood vessel transection, and detachment of the spleen from the ligaments can be accomplished with one 12-mm and three 5-mm ports. An additional 5-mm incision for the nathanson liver retractor is needed in the subxiphoid location. Port placement is quite different than that demonstrated in Fig. 170.6 and depends on the size of the spleen. The larger the spleen, the better it will be to have the ports away from the left upper abdomen. An optiview direct entry 5-mm port is placed in the left paramedian position approximately at the level of the umbilicus. This is for the camera and will be held by the assistant. The assistant also will be utilizing a 5-mm port in the left mid to lower lateral abdomen. The operating surgeon will have a 12-mm port just to the right of midline and a 5-mm port in the right abdomen. The ports are all placed well away from the epigastrium except for the nathanson port. Following mobilization of the stomach and division of the short gastric vessels, the nathanson blade is utilized to retract the stomach and liver. The posterior gastric artery does not need to be routinely divided.

In large spleens, the splenic artery and vein are clearly identified as separate pedicles feeding the lower and upper poles of the spleen. The dissection of the splenic hilum proceeds from a caudal to cranial direction. The inferior attachments of the spleen are divided, and this helps provide access to the lower pole blood vessels. The lower pole vessels are encircled (a gastric band dissector can assist) and then they are stapled with an articulating stapler. Subsequently, the upper pole vessels are encircled and divided. Alternatively, if desired, the splenic artery can be identified and divided along the superior border of the pancreas in an attempt to reduce spleen size and make the hilum dissection safer. Following division of the hilar blood vessels, the superior and lateral attachments of the spleen are divided. The spleen is typically removed through a pfannenstiel or infraumbilical midline incision. Embolization of the

splenic artery prior to splenectomy in the presence of splenomegaly is not routinely done and typically reserved for massive spleens (i.e., >20 cm in maximal dimension).

B THE URINARY TRACT AND BLADDER

171 Anatomy of the Kidneys, Ureter, and Bladder

Jennifer M. McBride and Richard L. Drake

KIDNEYS

The kidneys are located in the retroperitoneal connective tissue of the posterior abdominal wall. They develop as pelvic organs that ascend to their final position in the abdomen. The kidneys are bean-shaped structures with a reddish-brown coloration and are approximately 11 to 12 cm long, 5.0 to 7.5 cm wide, and 2.5 to 3.0 cm thick. The left kidney is usually somewhat longer and narrower than the right kidney. Their location in the posterior abdominal wall is usually between the upper border of T-12 and L-2. However, the right kidney is usually slightly lower than the left kidney because of the presence of the liver.

Relationships and Fascias

The location of the kidneys against the posterior abdominal wall provides development of unique relationships with numerous other structures. Structures anterior to the right kidney are the suprarenal gland, the liver, the second part of the duodenum, the right colic flexure, and the small intestine (Fig. 171.1A). Structures posterior to the right kidney include the diaphragm; the costodiaphragmatic recess; the 12th rib; the psoas major muscle; the quadratus lumborum muscle; the transversus abdominis muscle; and the subcostal, iliohypogastric, and ilioinguinal nerves (Fig. 171.1B). Structures anterior to the left kidney include the suprarenal gland, the spleen, the stomach, the body (or tail) of the pancreas, the left colic flexure, and the small intestine (Fig. 171.1A). The listed structures lie directly against the fascias covering the kidney without any intervening

tissues except for the liver, the stomach, the spleen, and the small intestine, which are covered with peritoneum. The structures listed as posterior to the right kidney are also posterior to the left kidney, with the addition of the 11th rib because of the higher position of the left kidney (Fig. 171.1B). Thus, numerous structures must be considered in any surgical approach to the kidneys.

The fascias covering the kidneys are unique. Enclosing the renal parenchyma is a fibrous tissue called the *renal capsule.* This layer of tissue is lightly bound to the kidneys and can be removed easily except in certain disease processes. Immediately adjacent to the renal capsule is the perinephric (perirenal) layer of fat (Fig. 171.2). This layer covers the kidneys and the ureter and is called the *adipose capsule.* Continuing outward is a membranous condensation of the extraperitoneal connective tissue called the *renal (Gerota) fascia* (Fig. 171.2). This specialized membrane separates the perirenal fat from the adipose tissue covering the posterior abdominal wall and must be incised in any operation, whether an anterior or posterior approach is used. The renal fascia consists of anterior and posterior layers that surround the kidneys and the suprarenal gland, usually sending an intervening septum between the two structures. Moving laterally, the anterior and posterior layers may fuse and become continuous with the transversalis fascia. Medially, the posterior layer fuses with the fascia covering the psoas muscle, and the anterior layer may fuse with the sheaths of the blood vessels in the area or cross to the opposite side and fuse with the anterior layer from that side (Fig. 171.2). Superiorly, the anterior and posterior layers fuse after passing over the suprarenal gland and, inferiorly, the layers also fuse, except where the ureter passes through these tissues. Because of the opening around the ureter, infections around the kidneys may descend into the pelvis and vice versa. Finally, outside the renal fascia is the paranephric (pararenal) fat (Fig. 171.2). This is a layer of adipose tissue on the posterior abdominal wall and is usually in a posterolateral position.

Structure

The renal parenchyma consists of the outer cortex and the inner medulla (Fig. 171.3). The cortex is an outer, pale, continuous broad band of tissue. It is a dense, homogeneous tissue and consists of renal corpuscles and convoluted portions of renal tubules. The medulla is an inner layer of discontinuous tissue caused by the inward projections of cortical tissue

called the *renal columns.* The medulla is a darker brown than the cortex and is composed of the renal pyramids. The renal pyramids appear to have longitudinal striations, which extend into the cortex as medullary rays. Each pyramid contains the descending and ascending limbs of the renal tubules and the collecting tubules. The apex of each pyramid is called a *renal papilla*, and it projects into a minor calyx, which is a subdivision of the renal pelvis.

The medial margin of each kidney is occupied by the hilum. The hilum expands into a central cavity called the *renal sinus* and is the site of entrance or exit for blood vessels, lymphatics, and nerves. It transmits, from anterior to posterior, the renal vein, the anterior branch of the renal artery, the ureter, and the posterior branch of the renal artery. It also contains fat and the renal pelvis. The renal pelvis is the expanded upper end of the ureter. It divides into two or three major calyces that further subdivide into many minor calyces. Each minor calyx is indented by a renal papilla. The renal pelvis continues inferiorly and tapers to a narrow tube that becomes the ureter. The ureteropelvic junction is rather indefinite but is usually referred to as located opposite the lower pole of the kidneys.

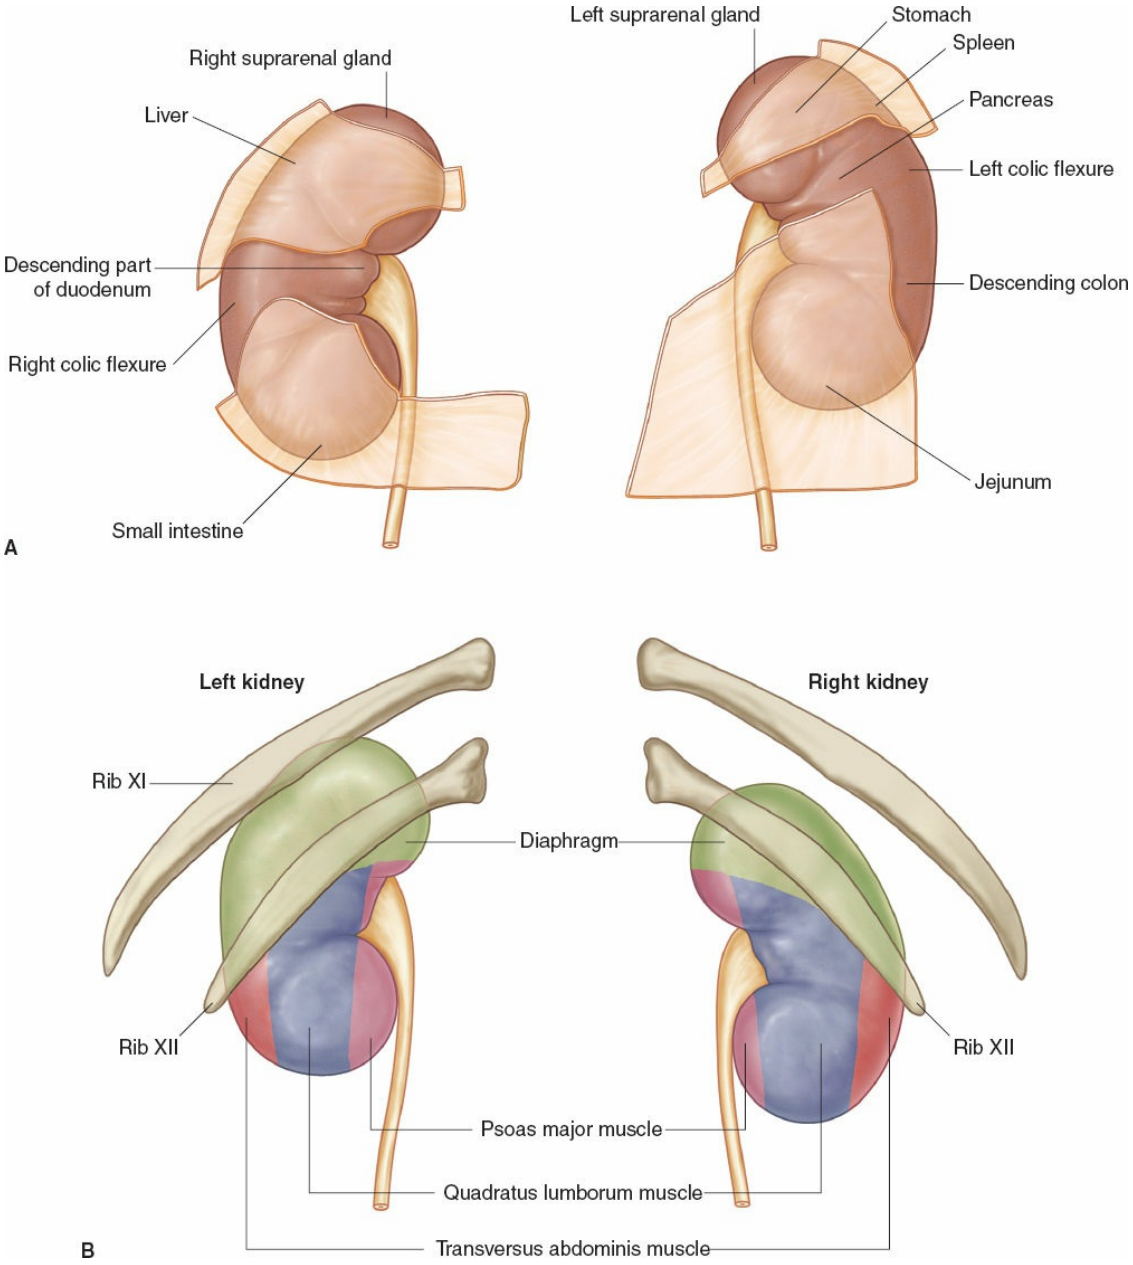

Figure 171.1. A. Anterior relations of the right and left kidneys. All the structures lie against the fascias covering the kidneys, except for the liver and the small intestine on the right and the stomach, the spleen, and the small intestine on the left, which are covered with peritoneum. **B.** Posterior relations of the right and left kidneys. (From Drake RL, Vogl W, Mitchell AWM. *Gray's Anatomy for Students*, 3rd ed. Philadelphia, PA: Churchill Livingstone [Elsevier], 2015, with permission.)

Vascular Supply and Lymphatics

The kidneys are supplied by the renal arteries, which arise from the lateral aspect of the aorta just inferior to the origin of the superior mesenteric

artery (usually between L-1 and L-2). On occasion, the right renal artery may arise a little higher than the left and has a unique pathway to the right kidney in that it passes posterior to the inferior vena cava as it crosses the posterior abdominal wall. As each renal artery approaches the renal pelvis, it divides into anterior and posterior branches that pass on either side of the renal pelvis and major calyces (Fig. 171.3). This provides a somewhat bloodless horizontal plane through the kidney because the anterior branch supplies the anterior half of the organ, and the posterior branch supplies the posterior half of the organ. Additional accessory renal arteries may be found entering the hilum or extrahilar regions. Generally, the accessory arteries do not anastomose with the major renal arteries and may arise from the aorta, the renal artery, or from a different vessel.

The venous drainage of the kidneys consists of anastomosing channels forming a single renal vein that exits at the hilum. Most tributaries of the renal vein pass anterior to the renal pelvis, but on occasion one may pass posterior to this structure. After exiting the hilum, the left renal vein passes anterior to the aorta and posterior to the superior mesenteric artery as it approaches the inferior vena cava. The right renal vein has a short, direct path to the inferior vena cava and enters this vessel at approximately the same level as the left renal vein.

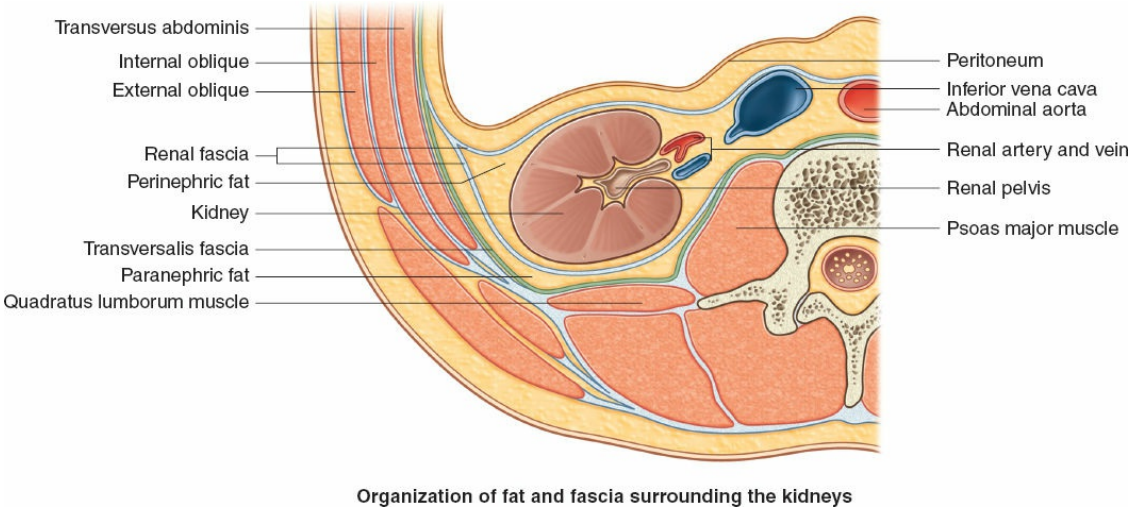

Figure 171.2. Transverse section showing the relation of the renal fascias to the right kidney. (From Drake RL, Vogl W, Mitchell AWM, et al. *Gray's Atlas of Anatomy,* 2nd ed. Philadelphia, PA: Churchill Livingstone [Elsevier], 2015, with permission.)

The lymphatic drainage of each kidney is to the lateral aortic or lumbar

nodes around the origin of the renal artery.

URETER

The ureters are muscular tubes that extend ~25 cm from the kidneys to the posterior surface of the bladder (Fig. 171.4). Each ureter has an upper expanded end called the *renal pelvis.* Of clinical relevance is the fact that three constrictions are present as the ureter descends from the kidney to the bladder. These constrictions occur at the ureteropelvic junction, where the ureter crosses the pelvic brim and where the ureter enters the bladder wall. In addition, obstruction of the ureter may be caused by stenosis of the ureteropelvic junction, compression of the ureter, a urinary calculus lodged anywhere along the ureter, or from abnormalities at the junction of the ureter with the bladder.

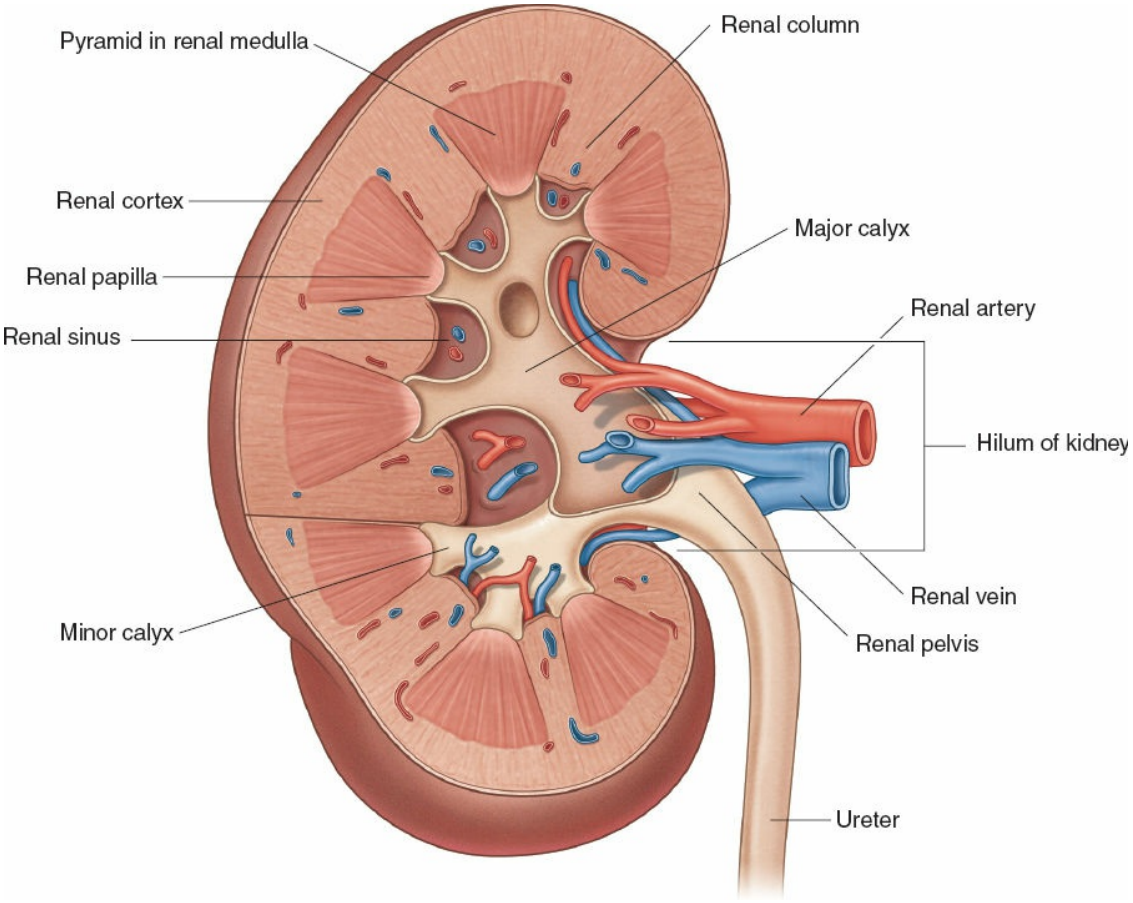

Figure 171.3. Longitudinal section showing the internal structure of the kidney, which consists of an outer cortex and inner medulla. Note that each renal pyramid ends as a renal papilla that projects into a minor calix. (From Drake RL, Vogl W, Mitchell AWM. *Gray's Anatomy for Students*, 3rd ed. Philadelphia, PA: Churchill Livingstone [Elsevier], 2015, with permission.)

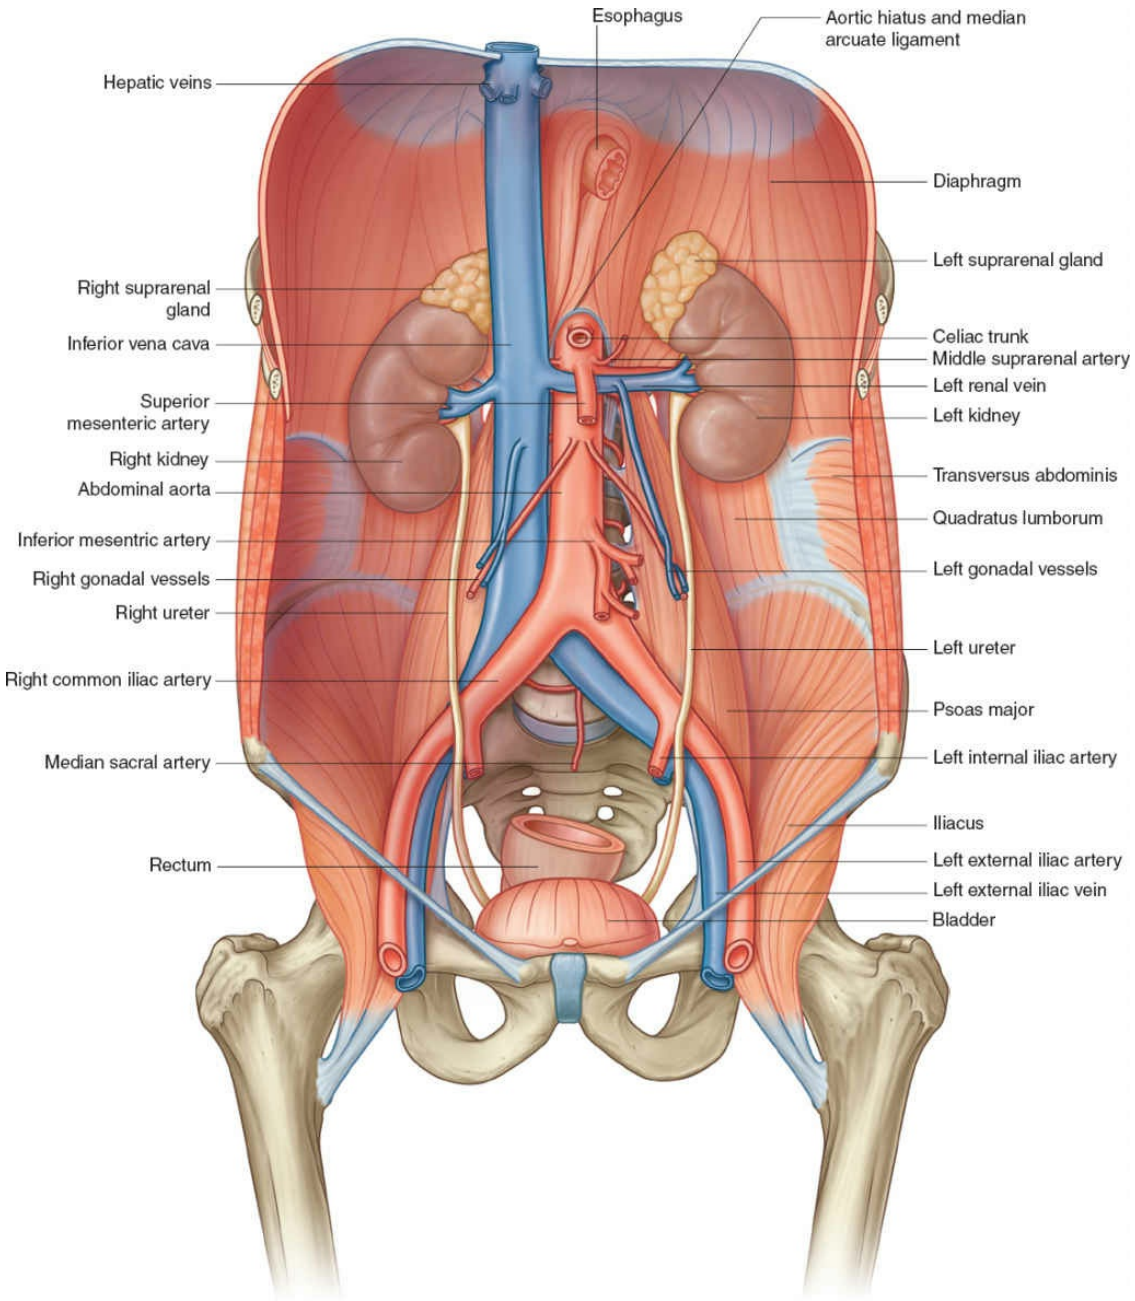

Figure 171.4. The path of the ureter as it passes down the posterior abdominal wall toward the bladder. (From Drake RL, Vogl W, Mitchell AWM, et al. *Gray's Atlas of Anatomy*, 2nd ed. Philadelphia, PA: Churchill Livingstone [Elsevier], 2015, with permission.)

Pathway

Inferior to the ureteropelvic junction, the ureter descends more or less vertically in the extraperitoneal connective tissue of the posterior abdominal wall on the psoas major muscles (Fig. 171.4). In this retroperitoneal position, the proximal portion of each ureter is lateral to the

testicular/ovarian vessels before being crossed by these vessels and continuing distally on their medial side.

The right ureter begins posterior to the descending (second) part of the duodenum and is crossed anteriorly by the right colic and ileocolic vessels. Because of its relationship to the ascending colon as the right ureter continues toward the pelvis, it can be injured when the ascending colon is being "mobilized."

The left ureter is crossed anteriorly by the left colic vessels. In addition, in this retroperitoneal position, the left ureter travels for a considerable distance along the lateral border of the inferior mesenteric vein. It should also be mentioned that as the left ureter nears the common iliac vessels, it lies lateral to the superior rectal (hemorrhoidal) artery. As the left ureter approaches the pelvic brim, it lies posterior to the sigmoid colon in the base of the sigmoid mesocolon. This is a unique relationship that exists only on the left side and is a location where an injury to the ureter can occur during a surgical case involving the sigmoid colon.

At the pelvic brim, the ureters cross the common iliac vessels, usually at the level of the bifurcation of these vessels into the external and internal iliacs (Fig. 171.4). They continue along the posterolateral pelvic wall medial to the internal iliac artery, obturator nerve, and the branches of the artery. From this point to their entrance into the bladder, the pathway is somewhat variable in man and woman. Each one is discussed here separately.

The Female Pathway

At the pelvic brim in the female, the ureters are closely related to the ovarian vessels (Fig. 171.5), a relationship that makes them vulnerable to injury during surgical procedures. The ureters cross the pelvic brim just medial to these vessels. During surgical procedures involving the ovaries, the ureters may be damaged when the ovarian vessels are secured. Continuing inferiorly, the ureters lie deep to the peritoneum and are located near the internal iliac vessels as they pass down the lateral pelvic wall. The ureters pass posterior to the ovaries and enter the uterosacral folds toward the floor of the pelvis. They continue in a medial and anterior direction in these folds along with numerous vessels and nerves. At the base of the broad ligament, the ureters are associated with the lateral cervical or cardinal ligament and pass inferior to the uterine artery as this vessel passes in a transverse direction toward the uterus (Fig. 171.5).

Crossing of the ureters by the uterine artery occurs just lateral to the uterus and is a possible site of surgical injury to the ureter. After crossing inferior to the uterine arteries, the ureters continue in their anterior and medial pathway, passing just lateral to the lateral fornix of the vagina before entering the posterolateral aspect of the bladder. This is another site of possible injury during surgical procedures. Because of these unique relationships to the female pelvic viscera, injuries to the ureter during surgical procedures are more common in females than in males.

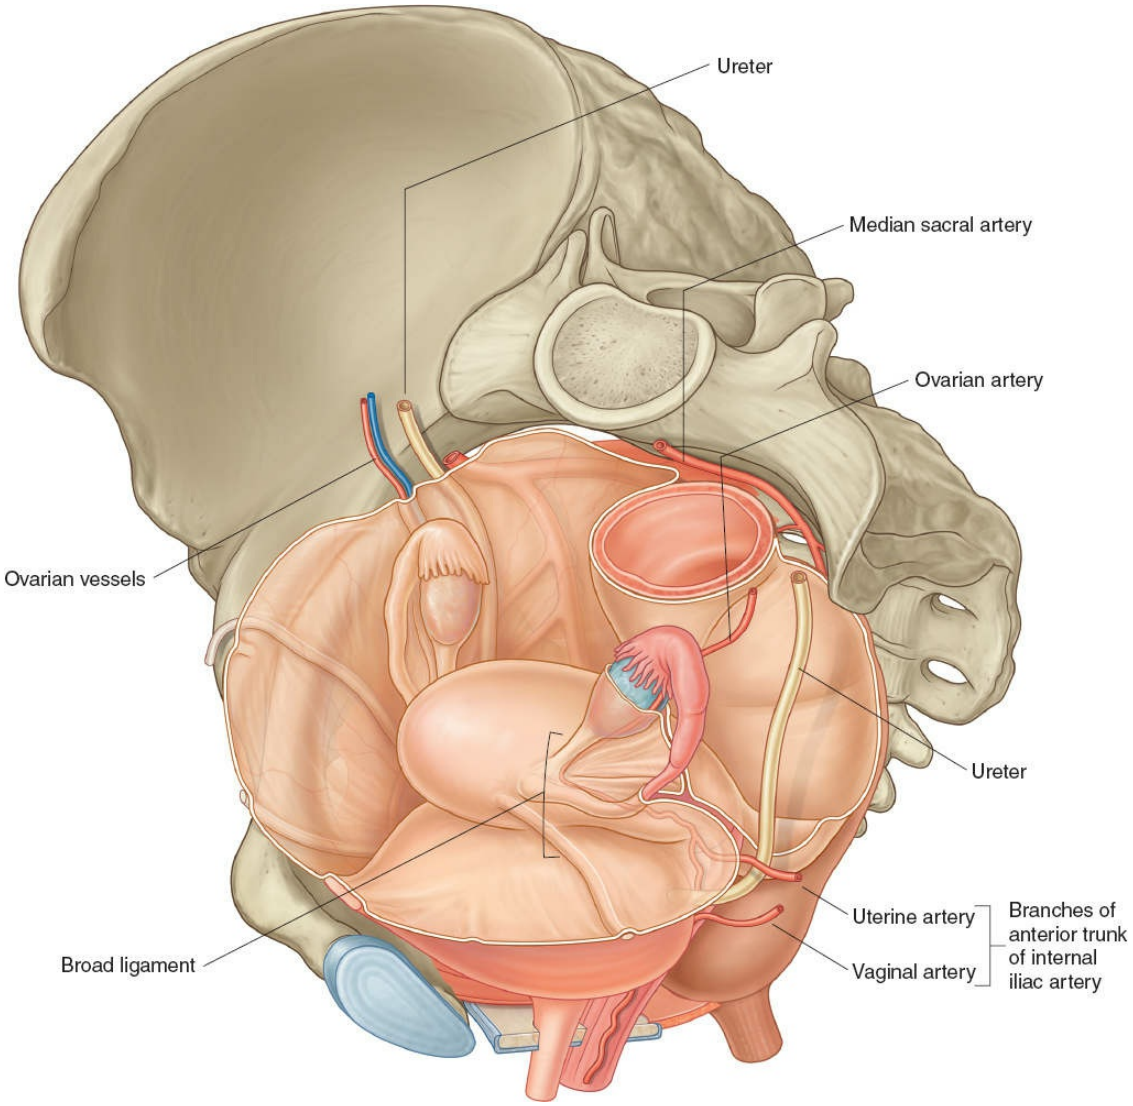

Figure 171.5. Superolateral view looking into the pelvis. As the ureters move toward the bladder, they are located inferior to the uterine artery as this vessel passes in a transverse direction to supply the uterus. (From Drake RL, Vogl W, Mitchell AWM. *Gray's Anatomy for Students*, 3rd ed. Philadelphia, PA: Churchill Livingstone [Elsevier], 2015, with permission.)

The Male Pathway

Near the pelvic brim in the male, the ureters and the testicular vessels separate and the testicular vessels follow the external iliac vessels. The ureters cross the pelvic brim and continue to descend in a slightly medial direction as they continue their intrapelvic course to the bladder (Fig. 171.6). As in the woman, they lie deep to the peritoneum and near the internal iliac arteries as they pass down the lateral pelvic wall. Toward the floor of the pelvis, the ureters enter the sacrogenital folds along with

several vessels and nerves. As they continue anteriorly and medially in these folds, the ureters pass inferior to the ductus deferens and anterior to the seminal vesicles before entering the posterolateral aspect of the bladder (Fig. 171.6). Because of the particular relationships to these two structures, the ureters are vulnerable to injury during surgical procedures in this region.

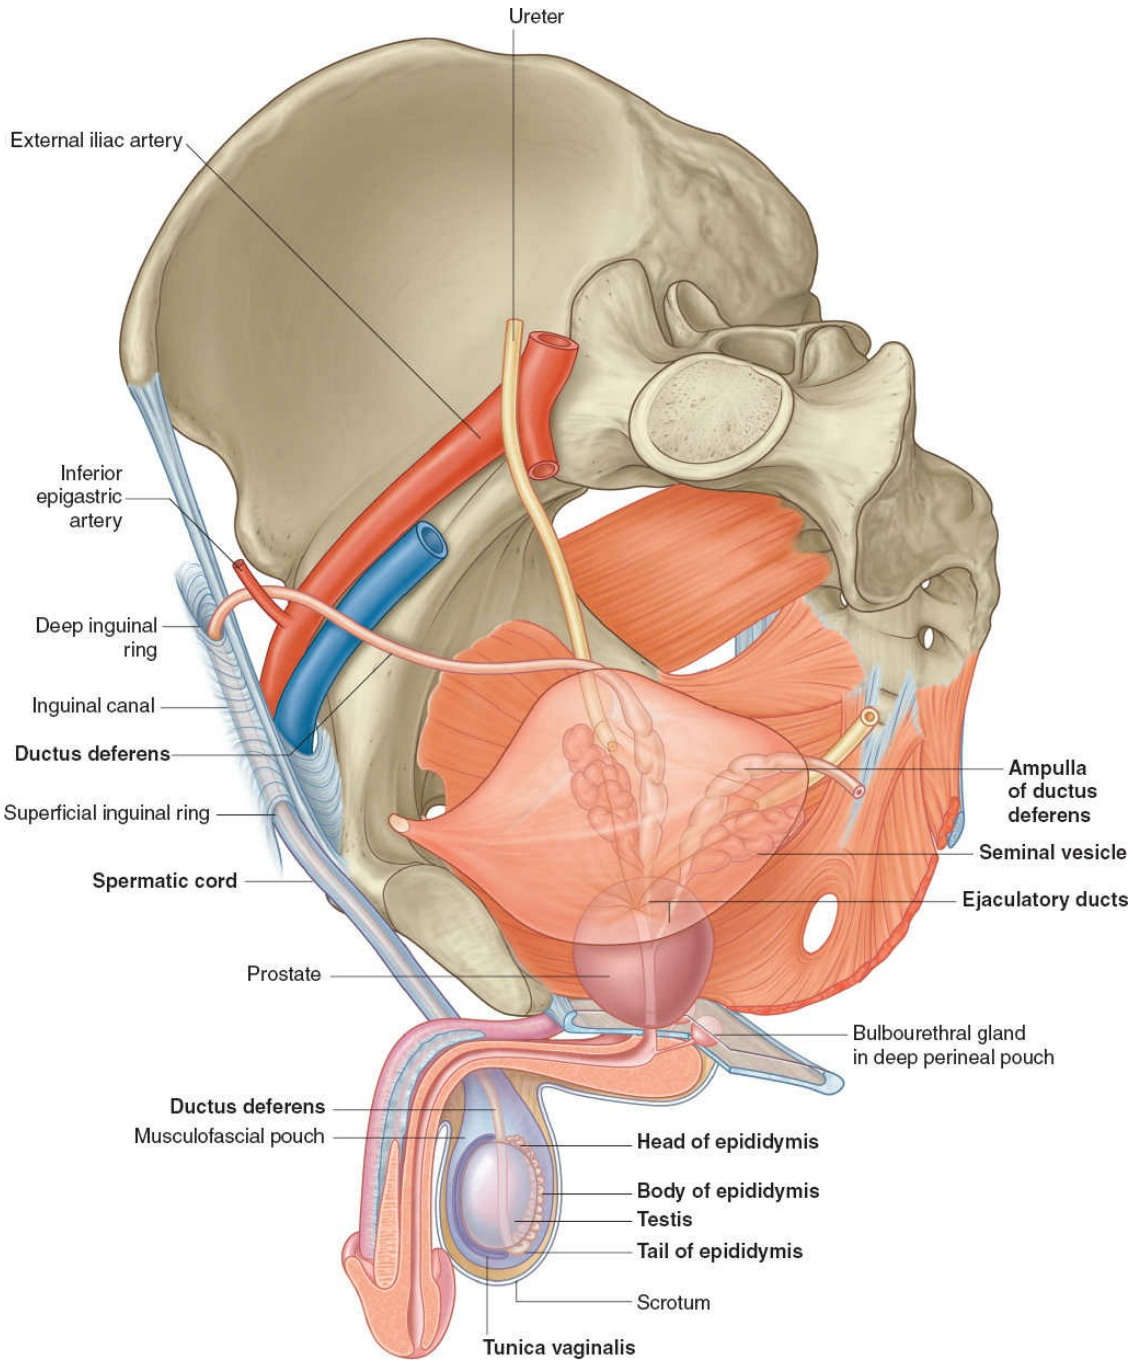

Figure 171.6. Superolateral view looking into the male pelvis showing the ureter passing inferior to the ductus deferens and anterior to the seminal vesicle before entering the posterolateral aspect of the bladder. (From Drake RL, Vogl W, Mitchell AWM. *Gray's Anatomy for Students*, 3rd ed. Philadelphia, PA: Churchill Livingstone [Elsevier], 2015, with permission.)

Vascular Supply and Lymphatics

The ureters receive arterial branches from adjacent vessels as they move toward the bladder (Fig. 171.7). The renal arteries supply the upper end,

and the middle portion may receive branches from the aorta, the testicular or ovarian arteries, and the iliac arteries. In the pelvis, the ureters are supplied by one or more arteries from branches of the internal iliac arteries. In all cases, arteries reaching the ureters divide into ascending and descending branches that form a longitudinal anastomosis.

Lymphatic drainage of the ureters follows a pattern similar to that of the arterial supply. Lymph from the upper portion of each ureter drains to the lateral aortic or lumbar nodes, from the middle portion drains to lymph nodes associated with the common iliac vessels, and from the inferior portion drains to lymph nodes associated with the external and internal iliac vessels.

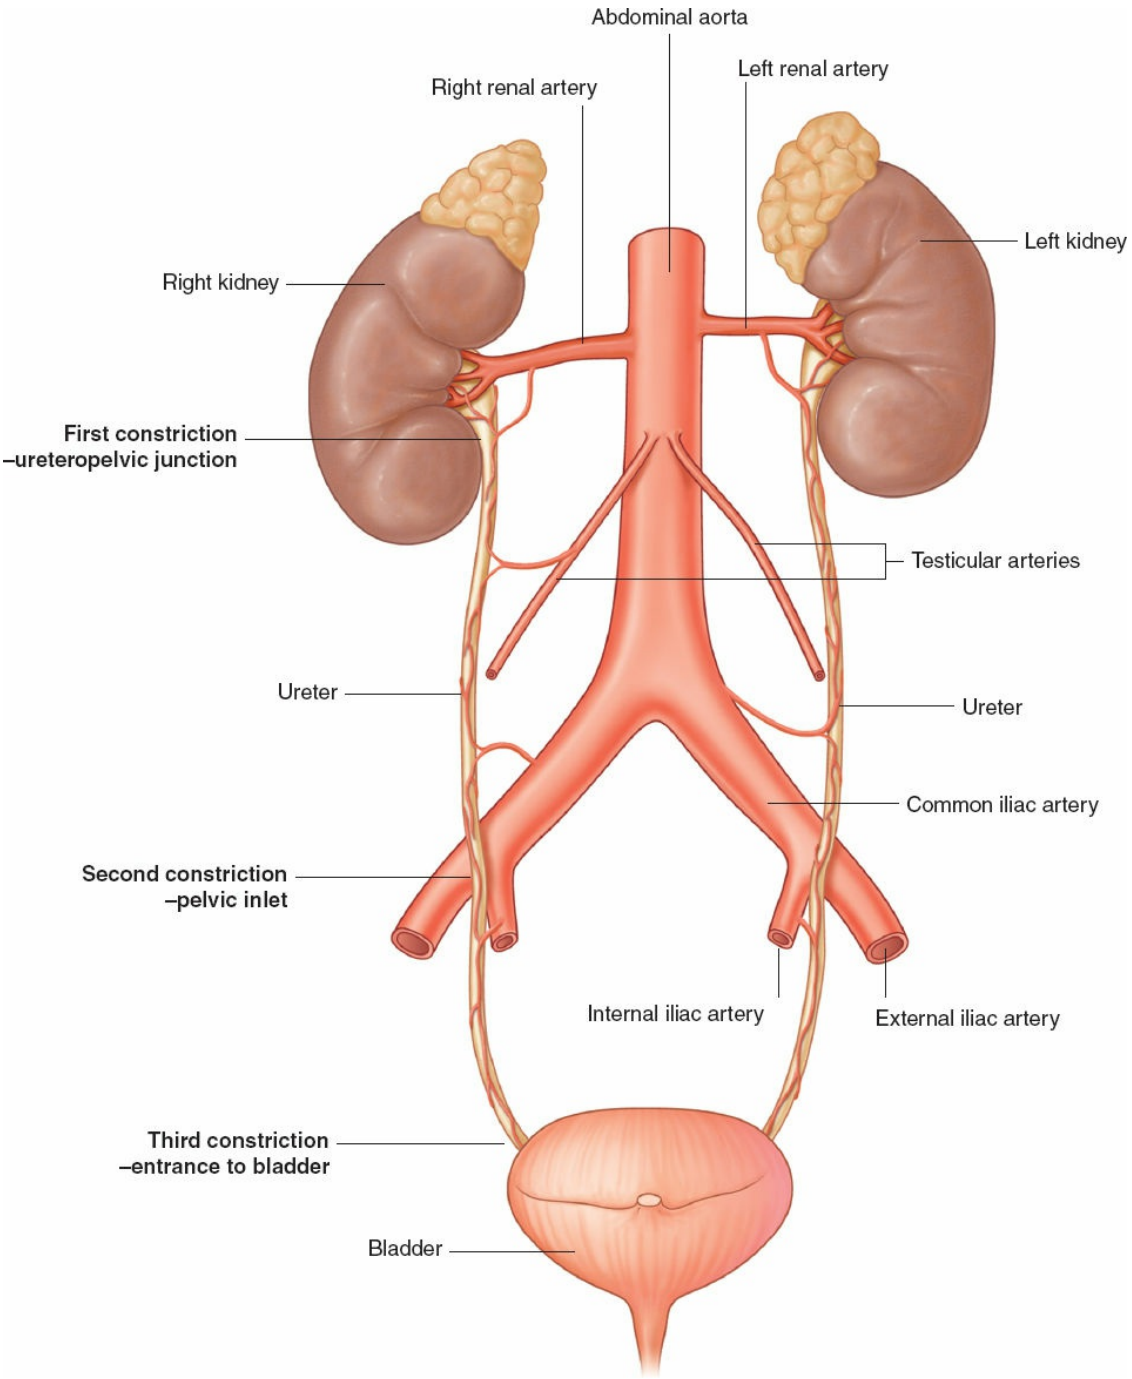

Figure 171.7. The ureter receives arterial branches from the renal, ovarian (testicular), and common iliac arteries. (From Drake RL, Vogl W, Mitchell AWM. *Gray's Anatomy for Students*, 3rd ed. Philadelphia, PA: Churchill Livingstone [Elsevier], 2015, with permission.)

BLADDER

The bladder is a musculomembranous sac located behind the pubic bones and the pubic symphysis. The empty bladder has a pyramidal shape with an apex, a base, and a superior and two inferolateral surfaces (Fig.

171.8A). It also has a neck that extends inferiorly. The empty bladder is within the pelvic cavity. As it fills, it rises above the pelvic brim, contacting the posterior surface of the anterior abdominal wall.

Structure

As mentioned, the bladder, when empty, has a pyramidal shape (Fig. 171.8A). The apex (or vertex) of the bladder points anteriorly and is connected to the umbilicus by the median umbilical ligament (a remnant of the allantois). The base (or fundus) of the bladder is the area between the two ureteric openings and the internal urethral orifice. It is triangular and points posteriorly. Internally, the smooth triangular area outlined by the three openings is called the *trigone* (Fig. 171.8B). This area is smooth compared with the rest of the internal surface of the bladder because here the mucous membrane is firmly bound to the underlying muscular coat.

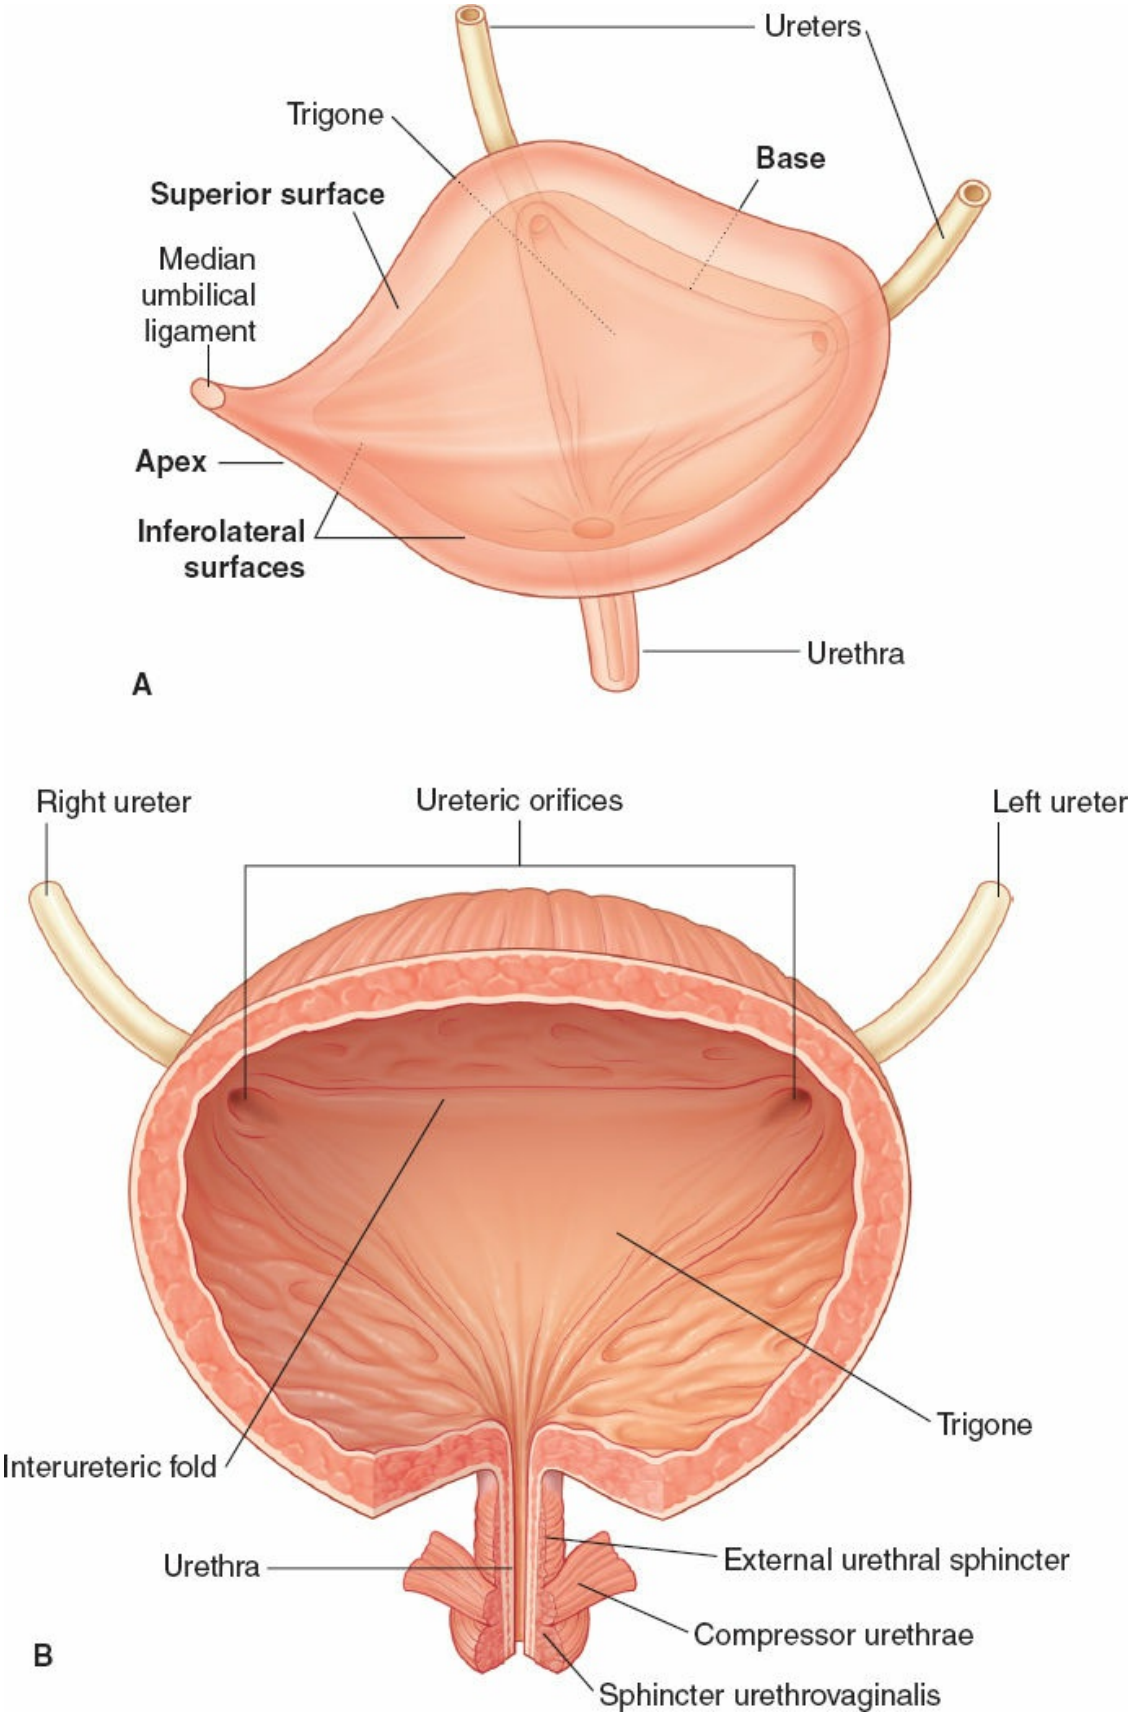

Figure 171.8. A. A superolateral view of the bladder. (From Drake RL, Vogl W, Mitchell AWM. *Gray's Anatomy for Students,* 3rd ed. Philadelphia: Churchill Livingstone [Elsevier], 2015, with

permission.) **B.** Internal view of the bladder. (From Drake RL, Vogl W, Mitchell AWM, et al. *Gray's Atlas of Anatomy*, 2nd ed. Philadelphia, PA: Churchill Livingstone [Elsevier], 2015, with permission.)

There are two additional internal structures. One is found in men and women, and the other is found only in men. In men and women, there is a ridge between the two ureteric openings called the *interureteric crest (fold)* (Fig. 171.8B). The second structure, observed in men only, is the uvula vesicae. This is a small swelling produced by bulging of the prostate's median lobe into the bladder at the inferior corner (apex) of the trigone, just above the internal urethral orifice.

The musculature in the wall of the bladder (tunica muscularis) is called the *detrusor muscle.* It consists of three layers of smooth-muscle fibers arranged as an outer longitudinal layer, a middle circular layer, and an inner longitudinal layer. At the neck of the bladder, the middle circular layer forms the sphincter vesicae muscle.

Relationships and Fascias

Peritoneum covers the bladder on its superior surface and is continuous anteriorly with the median and medial umbilical folds and with the parietal peritoneum of the supravesical fossa. Posteriorly, the peritoneal reflections differ between men and women. In the man, the peritoneum descends to the base of the bladder, lines the rectovesical pouch, and continues posterolaterally as the sacrogenital folds. In the woman, the peritoneum reflects onto the uterus without covering the base of the bladder and lines the shallow vesicouterine pouch.

Numerous structures are directly related to the bladder because of its location in the pelvic cavity. In the man, the neck of the bladder rests on the upper surface of the prostate (Fig. 171.9A). Anterior to the bladder are the pubic symphysis, the retropubic pad of fat, and the anterior abdominal wall. Posterior to the bladder are the rectovesical pouch, ductus deferens, seminal vesicles, rectovesical fascia, and the rectum (Fig. 171.6). Lateral to the bladder are the obturator internus muscle above and the levator ani muscle below. Superior to the bladder are the peritoneal cavity, coils of the ileum, and the sigmoid colon. Inferior to the bladder is the prostate. In the woman, the bladder lies at a lower level than it does in the man, and the neck of the bladder lies directly on the deep perineal pouch (Fig. 171.9B).

Anterior to the bladder are the pubic symphysis, the retropubic pad of fat, and the anterior abdominal wall. Posteriorly, the bladder is separated from the rectum by the vagina. Lateral to the bladder are the obturator internus muscle above and the levator ani muscle below. Superior to the bladder are the vesicouterine pouch of the peritoneal cavity and the body of the uterus. Inferior to the bladder is the deep perineal pouch.

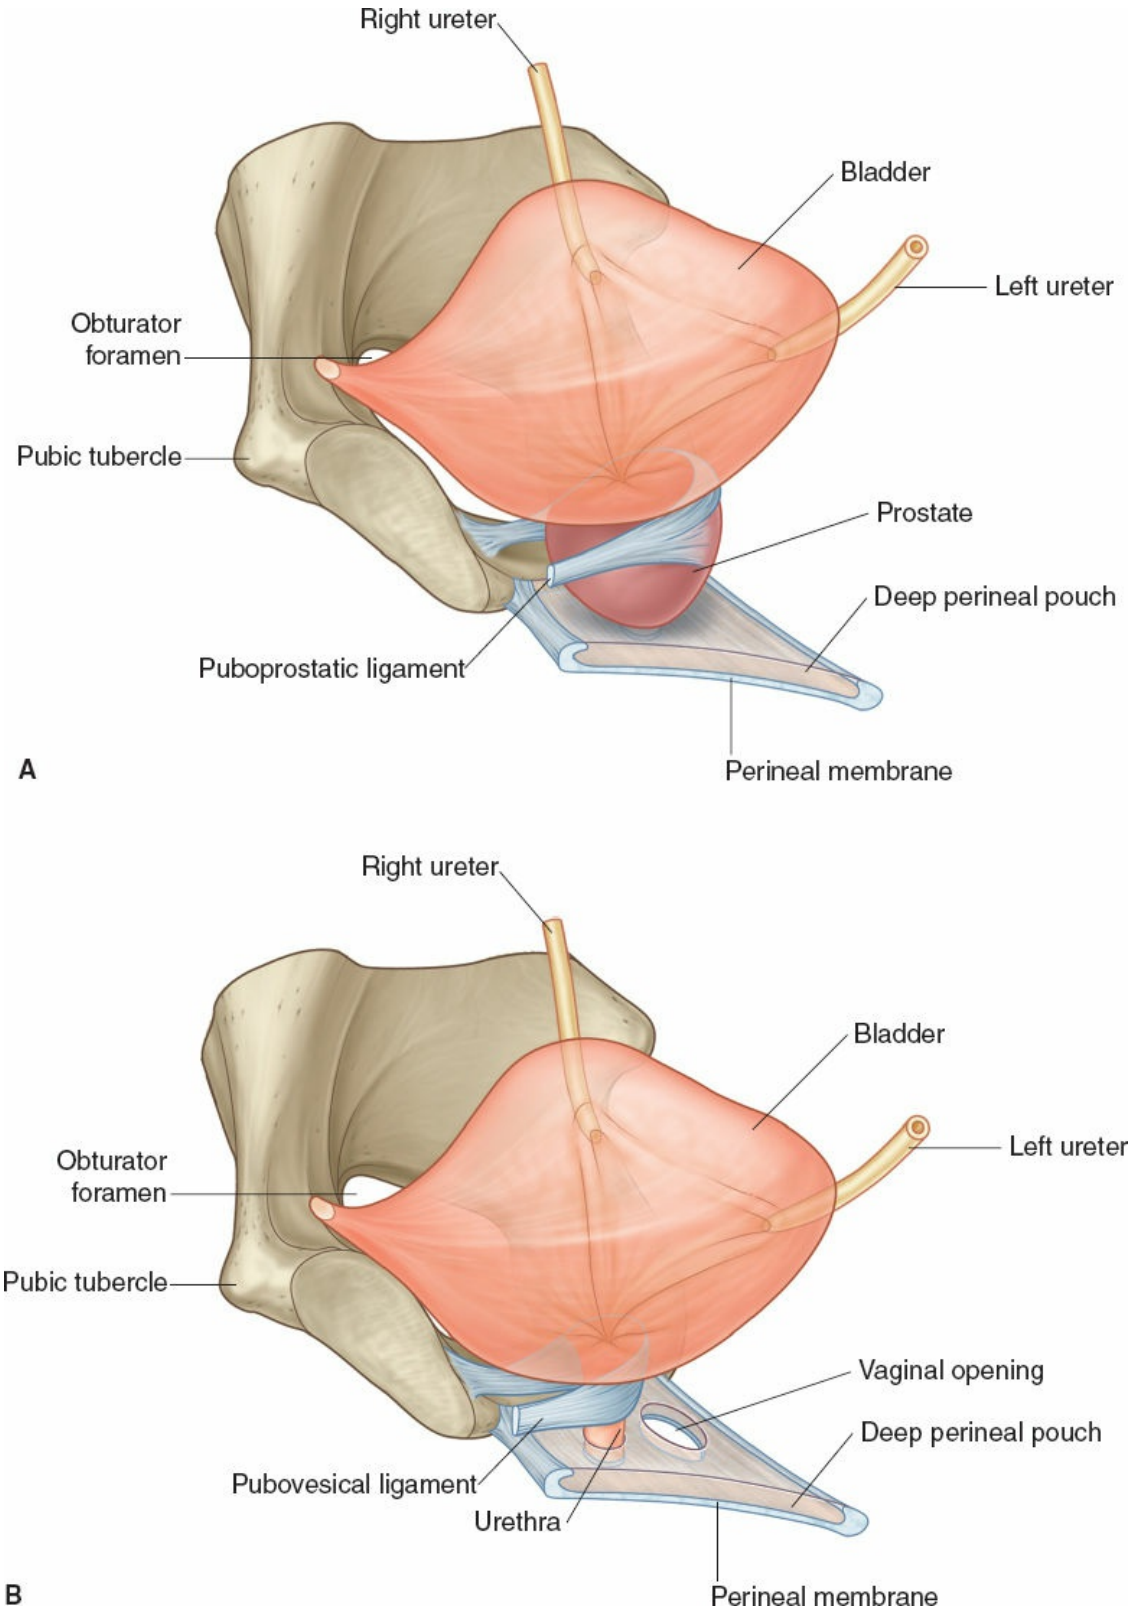

Figure 171.9. A. Puboprostatic ligaments supporting the bladder in the male. **B.** Pubovesical ligaments supporting the bladder in the female. (From Drake RL, Vogl W, Mitchell AWM, et al. *Gray's Atlas of Anatomy*, 2nd ed. Philadelphia, PA: Churchill Livingstone [Elsevier], 2015, with permission.)

The bladder is held in position by ligaments attached to the base of the bladder near the exit of the urethra and the apex of the bladder. In the man, because the prostate is attached to the bladder in this region, the ligaments pass between the prostate and pubic bone. These ligaments are called the *medial* and *lateral puboprostatic ligaments* (Fig. 171.9A). In the woman, the ligaments attach directly between the bladder and the pubic bone. These ligaments are called the *pubovesical ligaments* (Fig. 171.9B). The base of the bladder is also attached posteriorly to the sides of the rectum and the sacrum by the rectovesical ligaments in the man and by the uterovesical and uterosacral ligaments in the woman. Finally, the apex of the bladder is attached anteriorly by the median umbilical ligament, which is a fibrous cord extending from the bladder to the umbilicus.

Vascular Supply and Lymphatics

There are usually two, and sometimes three, arteries that supply the bladder. The superior vesical arteries are present in men and women. They arise from the paired umbilical arteries and are distributed to the apex and body of the bladder. The other constant arterial supply to the bladder is through the inferior vesical arteries. These arteries are variable in their origin and supply the inferolateral region of the anterior surface of the bladder. In the woman, a vaginal artery is usually identified as having a distribution pattern similar to that on the bladder. In men, a third artery has been described as supplying approximately one third of the posterior surface of the bladder. This artery is usually a branch of the artery of the ductus deferens. The venous drainage of the bladder is through a network of veins that drain down toward the neck of the bladder to form the vesical venous plexus. From this point, the plexus receives drainage from other nearby structures before draining laterally to the internal iliac vein. Lymphatic drainage is through lymph nodes associated with the common, internal, and external iliac arteries.

EDITOR'S COMMENT

The anatomies of the kidneys, ureter, and bladder are quite important not only because they are vital in urologic surgery, but also because we need to keep in mind that the lower GI tract, especially the sigmoid, retrosigmoid, and certainly the rectum wanders into the area, which is essential to know where you are and where you are not. The kidneys are less of a problem, except that they are retroperitoneal, and sometimes when one is dealing with great vessels or especially the lymph node dissections associated with malignancies of either lymphoma of the testis or the bladder, there is also alongside the great vessels things called kidneys. These have large vessels associated with them, which I think is fair to say that the average general surgical resident does not see much of. The renal vein can bleed, the right adrenal vein which is very short and connected directly to the inferior vena cava can bleed a lot, and some idea of where you are, especially when doing a right adrenalectomy, whether it is open and associated with the other side or laparoscopically, means that it behooves you to avoid injury or disruption of the short right adrenal vein, which goes directly into the vena cava. If you want to see bleeding, injuring that vessel and being careless in that area will show you bleeding.

Another area in which one needs to be careful is at the lateral border of the inferior mesenteric vein, and in other parts of these volumes you will see that there are a number of surgeons who believe that with carcinoma of the colon, the inferior mesenteric vein should be divided and taken near its origin. This is an area where the left ureter lies close to the inferior mesenteric vein as the author points out and needs to be protected. Further down, when one is doing a hysterectomy, the left ureter comes close to the ligaments behind the ureter, and if one gets careless while taking the posterior aspect of the ureter, one may run into the ureter and sever it. The left ureter is close to the base of the sigmoid mesocolon and crosses to the mesocolon on the way to the bladder. In the female, especially the left ureter is medial to the ovarian vessels as the author points out, and again the left ureter comes very close to the uterosacral ligaments while one is taking and dividing the uterosacral ligaments, especially on the left side. On the occasion when one has to take the uterine arteries up front and down near the base of the uterus for a uterine exenteration or else a hysterectomy in which the tumor grows adjacent to the base of the bladder, care must be utilized. The uterine arteries come close to the ureter as they come around and enter the bladder anteriorly. Less common point of injury are the vaginal corners when one is taking out the uterus, in which the ureters are slightly lateral to the lateral fornix, so some care is necessary.

In the male, the seminal vesicles need to be protected, especially when one is doing a total mesenteric excision (TME) of rectosigmoid cancer, which is responsible for the improvement in the survival of cancer of the rectum by ~15%; Professor Heald has been universally recognized for this work. As one

dissects down, it is important to stay within Denonvilliers fascia, which is a demarcation between the border of where the dissection is for carcinoma of the rectum and where one wanders into the area in which the ureters come close to the seminal vesicles and is necessary to protect the seminal vesicles, especially the base of seminal vesicles where they are adjacent to the prostate. The nerves of orgasm and sensation run at the base of seminal vesicles, and if one gets into bleeding in that area, which is not hard to do, suturing blindly or cauterizing blindly at the base of the seminal vesicles near the prostate will render the patient impotent.

It is particularly unfortunate that our medical schools think that it is much more important to learn about leprosy and genetics of some of the rarer diseases than to teach anatomy. It is true that surgery attracts in most schools a minimum of students who want to go into surgery. This does not negate the fact that what used to be a surgical anatomy course is the last time that these medical students and residents will hear anything about some of the things that are going to be important, and that is completely true of this particular chapter in which I suspect that more damage is done to the ureter, and also to seminal vesicles and prostates, resulting in impotence, making the male more miserable and being told that nothing can be done or nothing could be helped about preventing impotence. We now know that this is very important for our freshman surgeons, urologists, and so forth, to learn the anatomy of this area completely because it may help some people who otherwise might be miserable after certain operations.

172 Surgical Management of Nephrolithiasis

Brian H. Eisner

INTRODUCTION

Nephrolithiasis is a common cause of morbidity, including emergency department evaluation and procedural intervention; the lifetime prevalence of kidney stone disease in the United States is nearly 9%. Over the past 25 years, advances in minimally invasive and endoscopic techniques have significantly changed the management of patients with nephrolithiasis, bringing shockwave lithotripsy (SWL), ureteroscopy, and percutaneous nephrolithotomy (PCNL) to the forefront of management as the standards of care while open, laparoscopic, and robotic approaches are typically reserved for unique situations. Herein we review the current standards of care for minimally invasive treatment of nephrolithiasis.

PREOPERATIVE EVALUATION

Imaging Studies

The mainstays of imaging for renal and ureteral stones include plain abdominal radiography of the kidneys/ureters/bladder (KUB), renal ultrasonography, and computerized tomography (CT) scan. Ultrasonography is not associated with any ionizing radiation exposure to the patient, whereas KUB and CT both expose the patient to some degree of radiation, with CT being greater radiation exposure than KUB. KUB can be useful in the detection of renal and ureteral stones, as well as preoperative planning for intervention. The sensitivity of KUB for detection for nephrolithiasis has been reported to be 45% to 85% as the technique can be limited by bowel gas, extrarenal calcification, and high body mass index (BMI).

Renal ultrasonography is a useful tool to assess for hydronephrosis or ureteral obstruction, and also carries the advantage of not exposing patients to any ionizing radiation. Ultrasonography is highly sensitive for

the detection of hydronephrosis and also useful for the evaluation of renal stones, with sensitivity and specificity for renal stones at 24% to 81% and 82% to 100%, respectively. However, it is noteworthy that in many adult patients, the ureteropelvic junction and ureterovesical junction are visible on ultrasound whereas the proximal and distal ureter are not, so renal ultrasound alone often will not identify a ureteral stone though it will identify hydronephrosis. Studies have also questioned the accuracy of renal ultrasound in accurately estimating the size of renal and ureteral stones, which is of importance in guiding decision for observation versus intervention for renal and ureteral stones. Finally, a recent study noted that in the emergency department setting, ultrasonography is an excellent first-line imaging study for patients with suspected nephrolithiasis and may be comparable with CT in terms of identifying high-risk diagnoses and the risk of return emergency visits.

Noncontrast CT is considered the gold standard for evaluation of nephrolithiasis, with superior sensitivity and specificity to KUB and ultrasound. While CT does expose patients to greater amounts of radiation than KUB and ultrasound, in recent years, efforts to decrease the radiation dose of CT while maintaining its diagnostic accuracy have resulted in a significant reduction in radiation exposure. In addition, CT parameters including stone Hounsfield density, stone-to-skin distance (SSD), and renal infundibular anatomy predict outcomes of SWL and are not available by KUB or renal ultrasound. CT is recommended for all patients in whom PCNL is considered to identify potential for injury to retrorenal organs and risk of thoracic complications, and it is considered an option for clinicians who are deciding between ureteroscopy and SWL for a given patient.

Laboratory Studies and Antibiotic Prophylaxis

For elective management of ureteral or renal stones, demonstration of sterile urine or sterilization of the urine prior to intervention is the standard of care. It is recommended that patients undergo urinalysis prior to planned procedure, and if the urinalysis is suspicious for infection, then a urine culture should be obtained. In the absence of infection, the American Urological Association Best Practice Policy Statement on Urologic Surgery Antimicrobial Prophylaxis recommends the following: no antibiotics for SWL procedures and ≤24 hours of IV antibiotics for ureteroscopy and PCNL. Examples of appropriate antibiotics in these cases include first-/second-generation cephalosporin, ampicillin +

aminoglycoside, ampicillin/sulbactam. Though historically fluoroquinolones were used for antibiotic prophylaxis, issue with selection of resistant organisms and also for tendon rupture have raised concerns about the use of this class of antibiotics. Two recent studies have examined the effects of these antibiotic prophylaxis recommendations on postoperative infection rates after ureteroscopy and PCNL, respectively, and have confirmed the safety of this practice.

In patients who are at higher risk for infection after stone treatment (i.e., those with history of prior recurrent cystitis, pyelonephritis, or positive preoperative urine culture), the exact duration of antimicrobial prophylaxis and postoperative antimicrobial treatment has not been determined. Many clinicians will treat a positive preoperative urine culture for 5 to 7 days both prior to and after stone treatment with SWL, ureteroscopy, or PCNL. No specific guidelines exist on this topic. A previous study reported that 1 week of antibiotics prior to PCNL may be beneficial in patients with a positive urine culture in terms of reducing the risk of postoperative positive urine culture and systemic inflammatory response syndrome (SIRS) where as other studies have failed to confirm this finding.

With regard to laboratory studies, the American Society of Anesthesiologists recommends selective ordering of preoperative laboratory studies. Complete blood count with platelet count is recommended for those undergoing procedures where there is a significant risk of blood loss such (i.e., PCNL) or for patients with symptoms of anemia or thrombocytopenia. Serum electrolytes can be obtained selectively for patients with suspected renal insufficiency.

PATIENT AND TREATMENT SELECTION

Drainage of the Collecting System for Patient With Obstruction and Active/Acute Infection

Though much of stone treatment can be performed on an elective basis, for patients with obstruction of the urinary system due to a ureteral or renal stone and concomitant infection (i.e., fever, signs/symptoms of pyelonephritis, positive urinalysis/culture), emergent decompression of the collecting system is the standard of care. This can be performed either by cystoscopic placement of ureteral stent or by image-guided placement of a nephrostomy tube—each is an equally acceptable treatment. A recent study demonstrated that mortality decreased by over 50% for patients with

infection and obstruction in whom immediate decompression was performed compared to those who were treated with antibiotics and observation (8.8% mortality versus 19.2% mortality). It is also recommended that if purulent urine is encountered during ureteroscopy or PCNL, the procedure should be aborted, the collecting system should be drained with a stent or nephrostomy tube, and then the procedure can be completed in a second-stage several weeks later after treatment with culture-specific antibiotics.

Ureteral Stones

For the patient presenting with an obstructing ureteral stone (in the absence of infection and severe unremitting renal colic), observation can be offered for stones ≤10 mm in diameter. Spontaneous passage rate are largely determined by stone size, with passage rates for stones <10 mm from 30% to 90%; passage rates decrease with increasing stone diameter. The use of alpha blockers for medical expulsive therapy (MET) has been debated. In the early 2000s, MET was recommended and used as the standard of care after multiple reports showed that alpha blockers increased the spontaneous passage rate for ureteral stones, presumably by decreasing peristaltic contractions of the ureter. However, a recent multicenter study, the SUSPEND trial, has called the use of MET into question as this trial failed to show efficacy of this treatment. More recent examinations of data from dozens of trials of MET have demonstrated that MET is most efficacious for larger ureteral stones (i.e., those 5 to 10 mm) and for distal ureteral stones.

Repeat imaging is typically performed 4 to 6 weeks after the initial stone event to assess for interval stone passage, and for those in whom a ureteral stone and ureteral obstruction persists, intervention is recommended using a shared decision-making approach to select either SWL or ureteroscopy. It is also acceptable to perform intervention sooner than 4 to 6 weeks if the patient has recurrent bothersome symptoms such as renal colic and/or nausea/vomiting. It is paramount to ensure the resolution of ureteral obstruction either by visual confirmation of stone passage per urethra or by imaging studies—if the ureteral stone fails to pass (even in the case where colic has resolved), it should be removed using SWL or ureteroscopy due to the potential risks of renal ureteral stricture formation and/or renal damage secondary to long-term obstruction.

For ureteral stones which fail to pass, it is recommended that the patient and clinician participate in a shared decision-making approach to determine the optimal treatment. SWL is the less invasive of the two treatments, but is also associated with a lower stone-free rate for ureteral stones (SWL success rate = 72%, ureteroscopy success rate = 90%). The 2016 joint guidelines publication by the American Urological Association and the Endourological Society for the surgical management of stones advises that for patients who have a distal or mid ureteral stone which fails to pass, clinicians should offer ureteroscopy as first-line therapy due to its higher success rate and reserve SWL for patients who decline ureteroscopy. Of note, this is a significant update and change in recommendation from the previous guidelines published nearly a decade earlier which viewed SWL and ureteroscopy as equivalent first-line treatments for ureteral stones.

Though stone-free status can be accomplished in the majority of patients with ureteral stones by either observation (with or without MET), SWL, or ureteroscopy, there are cases in which these treatments may not be efficacious. These scenarios may include the following: altered genitourinary anatomy which does not allow for retrograde ureteroscopy (e.g., urinary diversion or neobladder, prostatomegaly) or stone impaction within the ureter resulting in a significant inflammatory response and edema of the urothelium which can cause difficulty visualizing the stone during ureteroscopy. For those patients, PCNL with antegrade ureteroscopy can be considered, in addition to laparoscopic or robotic surgery. Laparoscopic/robotic surgery is typically the final consideration if SWL, ureteroscopy, and PCNL have failed, but surgical outcomes with laparoscopic/robotic techniques demonstrate low morbidity and success rates above 90% for ureteral stone removal.

Renal Stones

Standards of care and guideline recommendations for the treatment of renal stones are dependent on several factors, including whether or not the stone is causing symptoms, whether the stone is likely to lead to a future symptomatic event, and stone size and location. Other factors which predict outcomes of surgical procedures (such as stone Hounsfield density, SSD, and renal anatomy) are useful in determining which patients are suitable candidates for SWL versus ureteroscopy or PCNL (covered later in this chapter).

For patients with asymptomatic renal caliceal stones, observation with surveillance may be offered. Periodic follow-up imaging to assess for stone growth is recommended. For patients with an asymptomatic renal stone diagnosed on imaging, 5-, 10-, and 15-year rates of a symptomatic stone episode are 30%, 45%, and 50%, respectively. Clinicians may take these episode rates and stone size into consideration when counseling/informing patients about the risks and benefits of observation for these stones.

Stone location plays a role in the decision for type of intervention for renal stones—in particular, stone location in the lower pole may influence treatment decisions. The lower pole of the kidney lies in a dependent position, which has been shown to decrease the efficacy of SWL—stones may fracture with the treatment but are difficult to expel due to their dependent position in the lower pole. In addition, to treat lower pole stones with ureteroscopy requires anatomy that will allow the ureteroscope to properly deflect to safely fracture the stone or place the stone into a basket and move it to a position in the kidney which is more favorable for treatment. A prospective-randomized study of SWL versus ureteroscopy for lower pole stones demonstrated 3-month stone-free rates of 35% and 50%, respectively, and a similarly designed study comparing SWL to PCNL demonstrated 3-month stone-free rates of 37% and 95%, respectively. It is important to note that with continued improvements in technology of flexible ureteroscopes, stone-free rates for flexible ureteroscopy for lower pole stones have improved significantly in the past 5 years with a recent large multicenter study reporting lower pole stone-free rates of 89% for stones <10 mm, 75% for stones 10 to 20 mm, and 23% for stones >20 mm.

For symptomatic lower pole renal stones, SWL or ureteroscopy may be offered for stones ≤10 mm in diameter. However, for lower pole stones >10 mm, ureteroscopy or PCNL are preferred due to the lower efficacy of SWL for lower pole stones of that size. Ureteroscopy is associated with lower stone-free rates and need for retreatment but also lower morbidity compared with PCNL. For symptomatic nonlower pole renal stones ≤20 mm in diameter, SWL and ureteroscopy are appropriate first-line options. Retreatment rate are lowest for PCNL and greatest for SWL. For symptomatic renal stones >20 mm, PCNL is the standard first-line treatment; ureteroscopy can be offered but patients must be counseled that ureteroscopy may require multiple procedures to render the patients stone

free. SWL is not recommended for symptomatic renal stones >20 mm.

SURGICAL INTERVENTIONS

Shockwave Lithotripsy Background

The first report of SWL by Chaussy and colleagues in 1980 signaled the beginning of the end of the era of open stone surgery. At that time, options for the treatment of ureteral and renal stones were limited to observation, open surgery, and chemolytic agents (for less common stones susceptible to chemolysis); SWL represented a truly minimally invasive technique to treat painful renal colic and/or obstructing stones which threatened the overall health of the kidneys. Over the past 35 years, SWL technology has evolved to include newer-generation and more portable machines, allowing for the widespread use of this technique. Though it competes with other minimally invasive techniques such as ureteroscopy and PCNL in the urologist's armamentarium for the treatment of stone disease, SWL accounted for just over 50% of all procedures in the United States for stone disease in 2005. More recent studies note that as stone-free rates for ureteroscopy improve with improvements in ureteroscope technology that ureteroscopy may overtake SWL as the most common procedure for stone disease in the near future.

Shockwave Lithotripsy Patient Factors

There are multiple patient factors which are associated with success rates for SWL. Stone composition is known to affect outcomes of SWL. From least successful to most successful treatment by SWL, stone composition is ranked as follows: cystine, struvite, brushite, calcium oxalate, uric acid. As stone composition is often unknown at the time of SWL (especially for first-time stone-formers), attention has shifted to imaging characteristics which define stone fragility; Hounsfield density has been shown to correlate with SWL success. Several studies have evaluated this relationship and determined that stones with Hounsfield densities greater than 900 to 1,000 Hounsfield units are associated with lower stone-free rates than those of lower Hounsfield densities. Patient body habitus, and more specifically SSD also predicts the success of SWL. Multiple studies have examined SWL stone-free rates in patients with varying SSD. SSD of ≤8 to 10 cm is associated with higher stone-free rates than higher SSDs.

SWL is contraindicated in patients who are pregnant. Though limited

data exist, concerns regarding the effects of shockwaves on fetal hearing and other fetal organs are largely unknown. Animal studies have demonstrated potential for fetal trauma due to SWL exposure. SWL is also contraindicated in patients taking anticoagulants or with uncorrected bleeding diathesis. Renal hematomas are a known complication of this procedure and occur in 1% of patients without bleeding diathesis—as such, the risk of significant hemorrhage for those with bleeding disorders or taking anticoagulants exceeds the benefits of SWL, especially since ureteroscopy is an alternative procedure which can be safely performed in this group of patients. One study demonstrated a 4-fold increased risk of postoperative perinephric hematoma for SWL patients who were taking aspirin or nonsteroidal anti-inflammatory drugs and use of more potent antiplatelet agents such as clopidogrel has been associated with hemorrhage requiring nephrectomy after SWL. Patients with untreated urinary tract infection or acute cystitis/pyelonephritis should not be treated with SWL until infection has been properly treated.

Shockwave Lithotripsy Technique

Shockwave Rate

SWL fractures stones by creating cavitation bubbles in the urine which fracture the stone upon contact. Several studies have demonstrated that there is an optimal range of shocks per minute to achieve the highest stone-free rates. In this instance, “faster is not always better.” At the highest shock wave rates, it is thought that the increased frequency of cavitation bubbles may actually cause the bubbles to interfere with one another, decreasing their effectiveness at fracturing the stone upon contact. A recent meta-analysis of nine randomized controlled trials (over 1,500 patients) noted that rates of 60 to 90 shocks per minute are equivalent in terms of postoperative stone-free rates, and that these rates are superior to 120 shocks per minute.

Renoprotective Protocols

SWL does cause a small amount of trauma to the kidney. While clinically significant bleeding or hemorrhage after SWL is rare, animal studies have demonstrated that focal kidney injury occurs after this procedure. While the majority of these injuries likely resolve, multiple SWL procedures for a given patient could create renal scarring over time. Several protection protocols which alter treatment parameters of the SWL machines have

been investigated in efforts to determine whether particular settings will decrease renal trauma due to SWL. Early animal studies demonstrated that giving 100 shocks at a lower power (18 kV) followed by a 3-minute pause, and then finishing treatment at the highest power (24 kV) up to 2,000 total shocks resulted in less renal damage than giving 2,000 consecutive shocks at the highest voltage (24 kV). More recent studies have noted that low voltage can be applied continuously for the first several hundred shocks and the pause can be omitted, while maintaining decreases in renal trauma compared with continuous SWL at the highest voltage level—that is, 500 shocks at low voltage followed by the remainder at high voltage without pause resulted in effective renoprotection.

Voltage Escalation

It is hypothesized that initial treatment with lower power shocks may "prime" the stone for more efficient fragmentation with escalation of shockwave power. A randomized controlled trial evaluated the use of escalating voltage doses during SWL versus performing the entire procedure at a higher power. In this study, the control group was treated at a higher power for a total of 3,000 shocks, while the experimental group was treated with a voltage escalation protocol, starting at lower power and increasing the power every 500 shocks for a total of 3,000 shocks. The control group demonstrated 72% stone-free rate compared with the voltage escalation of 96% stone-free rate at 8 weeks follow-up. The authors concluded that voltage escalation protocols result in more efficient stone fragmentation than standard high power protocols.

Strategies to Improve Stone-Free Rates After SWL

Pharmacotherapy is used to improve stone-free rates after SWL. Tamsulosin, a selective alpha blocker also used to facilitate expulsion of ureteral stones, has been evaluated in multiple trials, as have other medications such as calcium channel blockers and corticosteroids. These medications result in reduced expulsion time (i.e., quicker time to stone-free status or decrease in residual fragments) as well as decrease in incidence of postoperative colic and pain medication requirements. In addition to medications to facilitate stone passage, medications to prevent regrowth of stones have also been used successfully. Potassium citrate, which complexes with calcium in the urine to calcium oxalate stone formation has been used to decrease stone recurrence and improve stone-free rates. A randomized trial demonstrated that at 1-year follow-up, SWL

patients treated with potassium citrate demonstrated significantly fewer renal stones (and presumably residual stone fragments) than those treated with placebo—12.5% versus 44.5%. A final class of therapeutics, herbal remedies, has also been used effectively—*Phyllanthus niruri*, also called "chanca piedra," is an extract that comes from a tropical, coastal plant seen commonly in South America. This extract is thought to prevent crystal aggregation and has been associated with improvement in stone-free rates after SWL compared with placebo (93% versus 70.8%).

Percussion, diuresis, and inversion therapy has also been used to improve stone-free rates. This technique involves the patient bending 90 degrees with the waist parallel to the ground and the head directed toward the ground, most often accomplished by the patient lying on a bed or similar furniture. Prior to getting into this position (e.g., 30 to 60 minutes prior), the patient is often advised to drink 1 to 2 large glasses of fluid. Once in the inverted position, percussion (either by machine or by hand percussion by another individual) is applied to the patient's flank on the side of the stone for 5 to 15 minutes. While no universally accepted protocol exists, this is often done for 2 to 4 weeks after SWL treatment. Two randomized-controlled trials of diuresis, inversion, and mechanical percussion have been shown to significantly increase stone-free rates after SWL.

Complications of Shockwave Lithotripsy

Serious complications of SWL are rare, but can occur. Renal subcapsular hematoma occurrence is associated with the following risk factors: hypertension, diabetes, preoperative urinary tract infection, coronary artery disease, obesity, and age. Urinary tract infection occurs in about 2% to 4% of post-SWL cases and sepsis is a rare occurrence. Infection after SWL may be more related to the patient and stone (i.e., patient with history of recurrent cystitis/pyelonephritis; stone colonized with bacteria than the SWL treatment itself). Steinstrasse, from the German for "stone street" occurs 2% to 10% of the time after SWL and is defined as an accumulation of stones within the ureter. Often this can be managed conservatively but for unresolving steinstrasse or in patients who present with concomitant infection, decompression with stent or nephrostomy tube followed by definitive stone treatment is often necessary. The risk of steinstrasse is related to stone size—larger stones carry a far greater risk than smaller stones. Concerns have been raised about the risk of long-term development of diabetes mellitus and hypertension after the publication of a

retrospective review of 20 years' clinical experience with SWL from the Mayo Clinic, which demonstrated that patients undergoing SWL were more likely to develop diabetes and hypertension than those who underwent ureteroscopy for the treatment of stone disease. However, there have been a number of articles which dispute this finding. These potential complications are important to remember and perhaps should be taken into account for those who have undergone many SWL treatments or those who may already carry a diagnosis of diabetes mellitus and/or hypertension.

Ureteroscopy Technique

Gaining Access to the Ureter

Ureteroscopy is performed in the dorsal lithotomy position and with fluoroscopic guidance in the majority of cases. After positioning and sterile preparation of the penis or female introitus, the procedure generally begins with a cystoscopy and the passage of a guidewire into the ureteral orifice and into the renal pelvis or calyces, performed under fluoroscopic guidance. Various types of guidewires exist and generally fit into one of several categories. A standard 0.035- or 0.038- in PTFE-coated guidewire is cost-effective and useful for gaining access to the ureter—straightforward cases without significant ureteral obstruction or tortuous anatomy. Other commonly used guidewires include hybrid guidewires (which include a floppy, hydrophilic tip attached to a stiffer nitinol core), glidewires (entire guidewire is hydrophilic), and "superstiff" or "extra-stiff" which are useful for the introduction of dilators or access sheaths. Advantages of the hybrid wires are that the hydrophilic floppy tip often aids in bypassing ureteral obstruction or tortuous anatomy, but the stiff core still allows this wire to be used for the passage of a ureteroscope and sometimes the passage of ureteral access sheaths. In contrast, the glidewires, which are hydrophilic in their entirety, are excellent for bypassing obstruction or tortuous anatomy but are less commonly used as a "working wire" and more commonly used for difficult anatomy, then exchanged for a more suitable working wire such as a hybrid wire. Many urologists also advocate for placement of a second "safety wire," especially if the ureteroscopy is to treat pathology within the ureter (e.g., stone, tumor, stricture). The safety wire remains in position adjacent to the ureteroscope throughout the procedure—in the event of ureteral abrasion, ureteral trauma, or perforation of the ureter, the safety wire often still

allows for a ureteral stent to be placed at the end of the procedure, decreasing the risk of significant ureteral injury or need for nephrostomy tube placement for extremely difficult cases. If performing flexible ureteroscopy in the renal pelvis or kidney, the safety wire may not be as necessary or useful in preventing injury because the risk of ureteral injury should be decreased in these situations.

If the ureteral orifice is too narrow to accommodate the ureteroscope, a number of techniques exist to dilate the orifice to allow for passage of the ureteroscope. A common technique is balloon dilation—in general, a dilating balloon of short length (e.g., 4 cm) is introduced over the guidewire and inflated to 12 to 15 Fr. Other options for dilation of the ureteral orifice include sequential rigid dilators, dual-lumen catheters, or ureteral access sheaths. Whereas routine balloon dilation of the ureteral orifice was performed in the early experience with ureteroscopy in the 1990s, it is less commonly performed currently—the continued development of smaller and more ergonomic ureteroscopes over the past 2 decades has allowed for more frequent introduction of the ureteroscope into the ureteral orifice without the need for dilation of the ureteral orifice.

Ureteral access sheaths are commonly used for flexible ureteroscopy procedures and are most useful for the following indications: (1) large stone burden which requires basket extraction of multiple stone fragments from the upper ureter or kidney; (2) to decrease renal pelvis pressures and lower the risk of urosepsis for patients at risk for postoperative infection; and (3) for dilation and access to the ureter that is too narrow to accommodate the ureteroscope alone over a guidewire. A recent survey noted that over 50% of flexible ureteroscopy procedures worldwide are performed with a ureteral access sheath by routine. Ureteral access sheaths have been shown to cause trauma to the ureter, though significant long-term complications of ureteral abrasion such as ureteral stricture have not been reported, leading many to feel that these ureteral abrasions heal over ureteral stents placed at the end of the procedure.

Semi-Rigid and Flexible Ureteroscopy

The choice of ureteroscope is determined by the patient's anatomy and the location of the stone or pathology to be treated. Semi-rigid ureteroscopy is commonly performed for the distal ureter in all patients. It can be used for the proximal ureter in males, but sometimes the use of this instrument is limited by the length of the male genitourinary tract and the potential difficulty in advancing the semi-rigid ureteroscope proximal to the

sacroiliac joint where the iliac vessels cross anterior to the ureter in males. In females, however, semi-rigid ureteroscopy can be more regularly performed in the proximal ureter. For patients in whom the semi-rigid ureteroscope cannot be advanced up to the stone (regardless of gender), the flexible ureteroscope can be used.

Semi-rigid ureteroscopes range in size from 4.0 to 7.5 Fr and can be introduced into the ureteral orifice alongside a safety guidewire or over a guidewire with an additional safety wire in position. Of note, this diameter is a significant decrease from the semi-rigid ureteroscopes commonly used in the late 1990s and early 2000s, many of which were as large as 10 Fr and were much more difficult to atraumatically advance into the ureter and up to the target stone. As mentioned previously, if the ureteral orifice is too narrow to accommodate the semi-rigid ureteroscopes, dilation of the ureteral orifice is performed with a balloon or rigid dilator. For extremely narrow ureters, the surgeon may choose to place a ureteral stent to allow for passive dilation of the ureter and return several weeks later to perform ureteroscopy. In general, the ureteroscope is advanced alongside the guidewire up to the stone, and then lithotripsy (most commonly laser lithotripsy) is performed. Stones are either dusted into tiny fragments which are too small to basket and are expected to pass spontaneously or stones are fragmented into larger fragments and basket extracted. The advantages of the semi-rigid ureteroscope are ease of maneuverability (easier than flexible ureteroscopes), large working and irrigation channels which allow for the placement of larger laser fibers or combinations of laser fibers and baskets, durability, and visibility.

Flexible ureteroscopy is performed routinely for stones from the iliac vessels to the renal collecting system. Advances in size (i.e., smaller tip size), optics (digital imaging), and deflection over the past 20 years have revolutionized the practice of flexible ureteroscopy and moved this procedure to the forefront of options for the treatment of upper ureteral and renal stones <2.0 cm. The working channel of flexible ureteroscopes is typically 3.6 Fr and can accommodate a laser fiber for lithotripsy or a basket for stone manipulation or the fragment retrieval. The flexible ureteroscope is commonly passed up to the kidney either over a guidewire through its working channel or through a ureteral access sheath. In a similar fashion to semi-rigid ureteroscopy, the flexible ureteroscope is then advanced to the stone and lithotripsy and/or extraction is performed.

Ureteroscopic lithotripsy is most commonly performed using a

Holmium:YAG laser as the energy source. For semi-rigid ureteroscopes, laser fibers up to 400 μm are frequently used, whereas smaller fibers (i.e., 200 to 270 μm) are used for flexible ureteroscopy. For the flexible ureteroscopes, larger fibers are associated with decreased deflection capability and may also increase the risk of damaging the internal working channel. There are a wide range of potential laser settings and two commonly used techniques are “fragmentation with basketing” and “dusting.” Fragmentation with basket retrieval is typically a higher-power, lower-frequency setting of the laser (e.g., 1 to 2 J, 4 to 10 Hz); this typically results in fracture of the stone into larger fragments which may require basket extraction. In contrast, dusting is predicated on lower-power, high-frequency laser settings (e.g., 0.2 to 0.5 J, 20 to 80 Hz) and typically results in tiny particles which are likely to spontaneously pass and may not require basket retrieval. It is important to note that not all stones fracture in the same manner—some calculi may be more efficiently treated with fragmentation settings while for others, dusting may be preferable. A recent multicenter trial demonstrated similar efficacy in terms of procedure success of these two techniques. A recent survey study noted that the dusting technique is used in up to 65% to 75% of ureteroscopic procedures worldwide.

Postoperative Ureteral Stent

Ureteral stents are commonly placed in ureteroscopy in order to optimize drainage of the kidney and ureter which may be decreased due to ureteral edema after instrumentation. Absolute indications for stent placement include ureteral perforation or injury and infected upper urinary tract, while relative indications for stent placement include large stone burden, solitary kidney, edematous ureter, and bilateral ureteroscopy. Potential advantages of ureteral stent placement include decrease in postureteroscopy admissions for pain and dilation of the ureter which may allow stone fragments to pass easier after the procedure. For procedures in which a ureteral access sheath is used, many surgeons will use a ureteral stent due as ureteral edema is likely after this magnitude of ureteral dilation—in this setting, ureteral stenting has been demonstrated to decrease emergency department visits. However, ureteral stents are also associated with bothersome flank pain and bladder discomfort and have not been shown to decrease risk of ureteral stricture formation after ureteroscopy. Stent-related symptoms of flank discomfort, urinary frequency, and urgency have been successfully treated with alpha

blockers, anticholinergics, and nonsteroidal anti-inflammatory medications. The decision to leave a ureteral stent is surgeon-dependent, and multiple studies, including systematic reviews and meta-analyses have struggled to make firm recommendations due to heterogeneity of prior published studies on the topic.

Complications of Ureteroscopy

One of the more important principles of ureteroscopy and stone treatment in general is that if there is a high risk of injury to the ureter or collecting system associated with complete treatment of a stone, placement of a ureteral stent and return in several weeks for a second-stage procedure is an acceptable and prudent approach. In 2% to 8% of procedures, access to the ureter or the stone is difficult and stent placement with second-stage treatment is necessary. Rates of urinary tract infection and sepsis after ureteroscopy are reported at 2% to 4% each, and rates of ureteral stricture formation (which may require future ureteroscopic dilation/incision or reconstructive surgery) are 1% to 4%. Mucosal abrasion or minor ureteral perforation from the ureteroscope or ureteral access sheath may occur and will often require a stent postoperatively—however, as discussed prior, the association between these abrasions and downstream formation of ureteral stricture has not been established. Selective postoperative imaging with renal ultrasound is recommended for complicated procedures such as those with ureteral perforation or impacted ureteral stone due to risk of stricture in these patients.

Major ureteral injuries such as ureteral avulsion occur at very low rates (~0.2%) and are typically treated either with immediate reconstruction if possible or nephrostomy tube placement and delayed reconstruction.

Treatment of Pregnant Patients With Ureteral Stones

Pregnant patients with ureteral stones and renal colic may present a dilemma to the obstetrician and the urologist. Renal colic is a common cause of nonobstetric abdominal pain in pregnant women and may be associated with preterm labor. The first step in management of the pregnant patient with renal colic and urolithiasis is always conservative management—however, if this fails, drainage with a ureteral stent or nephrostomy versus ureteroscopy with definitive treatment should be considered. Whereas stent or nephrostomy tube placement may be a quicker procedure than ureteroscopy and require lower amounts of regional or general anesthesia, the risk of encrustation of stents or

nephrostomy tubes in the gravid patient is high, due to elevated levels of urine calcium. A recent multicenter study demonstrated the safety and feasibility of ureteroscopy for stone removal in pregnant patients without apparent increased risk of preterm labor compared with renal colic itself.

Percutaneous Nephrolithotomy

PCNL is the gold standard treatment for larger stones—renal stones >2.0 cm, branched/staghorn stones, lower pole renal stones >1.5 cm, as well as for patients in whom ureteroscopy may not be possible due to aberrant anatomy (i.e., urinary diversion, neobladder, significant prostatomegaly). The key to this procedure is percutaneous access to the kidney via needle puncture, using either ultrasound or fluoroscopic guidance. Typically a posterior facing calyx is desired and puncture directly through the "cup" of the calyx will minimize bleeding and also optimize access to the kidney. From its inception to present, PCNL has been commonly performed in the prone position, though over the past 2 decades, many have adopted a supine or modified supine/flank position for this procedure. Advantages of the prone over supine position may include reduced risk of injury to adjacent organs due to greater ability to vary the entry point and position of the puncture needle. Advantages of supine over prone position include elimination of need to reposition the patient, potential increased ability to perform flexible ureteroscopy, and decrease anesthetic risks for obese patients or others with respiratory compromise. No comparative studies have shown a definitive superiority of one position over the other—this is based largely on surgeon preference and experience.

Access to the collecting system is gained via percutaneous puncture, using either ultrasound or fluoroscopic guidance. Proponents of ultrasound guidance note that they have real-time control of the puncture and the ability to change direction guided by the ultrasound image. Ultrasound also allows for identification of retrorenal structures (i.e., spleen, liver, colon, pleura) and avoidance of injury. While retrorenal spleen, liver, or colon are uncommon, the consequences of injury can be great. Ultrasound-guided puncture also avoids exposure of the patient and operating room personnel to ionizing radiation. In contrast, fluoroscopy-guided puncture tends to be technically less challenging—a 2-dimensional image of a retrograde pyelogram (either performed with contrast injection or air injection of the kidney) is visualized on the monitor, various techniques exist to judge the depth of the puncture, and then the needle is advanced

into the kidney. Common techniques for fluoroscopic puncture include “triangulation” and “eye-of-the-needle” techniques. A modification of access techniques which is used by some includes endoscopic-guided access—in which a flexible ureteroscope is advanced to the desired calyx of entry and then the puncture needle is directly visualized entering the kidney; the wire can be grasped with a ureteroscopic basket and brought to the patient’s bladder or urethra with the flexible ureteroscope.

Once access to the collecting system has been achieved with the puncture needle, a variety of techniques exist to establish the percutaneous tract. An example of step-by-step technique is as follows, though significant variation of technique exists among surgeons: (1) puncture desired calyx under imaging +/− endoscopic guidance; (2) advance wire down the ureter into the bladder with assistance of torqueing catheter; (3) use coaxial dilator to dilate tract to 10 to 12 Fr and advance second wire (safety wire) down to the bladder (some may omit the introduction of safety wire); (4) radial dilation of PCNL tract with either sequential rigid dilators or single-step balloon dilator; (5) advance nephrostomy sheath over rigid or balloon dilator to proper position within the collecting system with imaging guidance; (6) remove dilator and leave guidewires and sheath in place; (7) introduce nephroscope into kidney and perform lithotripsy with stone disintegration and/or extraction; (8) survey collecting system and ureter with combination of imaging (ultrasonography, fluoroscopy with antegrade or retrograde pyelography, rigid or flexible nephroscopy and ureteroscopy); (9) consider placement of nephrostomy, stent, or omission of drainage tube.

In recent years, significant variation in nephrostomy tract/sheath sizes has been reported. Standard PCNL is performed via a 30-Fr nephrostomy sheath and typically a 24- to 26-Fr nephroscope. However, significant advances in technology have allowed for the miniaturization of the PCNL technique. Namely, the introduction of higher power lasers, the miniaturization of lithotripters, and improvements in nephroscopes now support mini PCNL, micro PCNL, and super-mini PCNL (with tract sizes ranging from 18 Fr to 5 Fr). Somewhat analogous to the debate of prone versus supine position for PCNL, proponents of each PCNL tract size have debated the merits of each. Smaller tract size may theoretically be less traumatic to the kidney, but also is associated with the necessity to create smaller stone fragments in order to extract through smaller sheaths. Surgeon preference and experience as well as surgeon comfort/ability with

flexible ureteroscopy (during or after PCNL) determines the choice of tract size.

Postoperative Drainage After PCNL

Historically, it was surgical dogma that a nephrostomy tube be left in the percutaneous tract(s) after PCNL to promote drainage and to tamponade the percutaneous tract to decrease the risk of postoperative hemorrhage. In addition, for those considering a "second-look PCNL"—that is, a second percutaneous procedure within 1 to 2 weeks of the first PCNL procedure for complex stones—an indwelling nephrostomy maintains access to the collecting system and may avoid additional punctures and tract dilations. However, within the past decade, many of the perceived advantages of the postoperative nephrostomy tube have been called into question. Multiple systematic reviews and meta-analyses have been performed and have reported that tubeless (i.e., placement of ureteral stent and omission of nephrostomy tube) and even "totally tubeless" (i.e., neither nephrostomy nor stent) are safe, feasible, and equally efficacious to standard PCNL with a postoperative nephrostomy tube in properly selected patients. Some advantages of tubeless approaches include decreased postoperative pain and decreased urinary leakage/extravasation after surgery. Also, studies have failed to demonstrate that leaving a nephrostomy tube in place actually reduces hemorrhage or need for transfusion compared with tubeless approaches. The decision whether to perform PCNL with a nephrostomy, a ureteral stent, or without either drainage device is largely surgeon dependent. However, many surgeons agree that for situations in which there is a large amount of urinary extravasation or renal pelvis injury, placing a nephrostomy tube and a ureteral stent concomitantly optimizes drainage and healing of such injuries.

Complications of PCNL

Though PCNL is the most complex procedure performed for urinary stone disease, major complications are uncommon. A recent multicenter international cooperative study of over 5,800 PCNL cases demonstrated that ~9% of complications were >Clavien class 2. Major complications which are seen after PCNL include the following: infection/sepsis; bleeding requiring transfusion or angioembolization; injury to retrorenal structures including spleen/liver/colon; and pleural injury resulting in pneumothorax, hydrothorax, or hemothorax. Significant postoperative bleeding is reported to occur in 0.5% to 5% of procedures and risk

increases with operative time and multiple punctures. Injury to surrounding organs is quite rare and preoperative evaluation of cross-sectional abdominal imaging may decrease the risk of these types of injuries. Pleural injury can often be managed conservatively, though occasionally a chest tube is required for drainage of fluid or blood or for re-expansion of the lung in situations of pneumothorax. This is most commonly associated with upper pole punctures.

Special Cases—Patients With Uncorrected Bleeding Diathesis

SWL is contraindicated in patients who are taking anticoagulants or those with uncorrected bleeding diathesis due to the increased risk of hemorrhage. On the other hand, ureteroscopy is considered safe and feasible in patients with coagulopathy and is commonly performed under these conditions. A meta-analysis of three studies of ureteroscopy in patients with coagulopathy demonstrated no major complications and a stone-free status of 87%. A more recent publication comparing 272 patients who underwent ureteroscopy and had associated coagulopathy versus >4,400 control patients noted an increased risk of hematuria, emergency visits, and unplanned return to the OR after ureteroscopy and a stone-free rate of 73%. More recently, surgeons have begun to study the safety of continuing aspirin during PCNL. Evaluating a cohort of patients who chronically take aspirin for a history of coronary artery disease, a recent study noted no significant increase in transfusion rates after PCNL for those who continued aspirin therapy compared with those who held aspirin for 1 week prior to PCNL.

TAKE HOME POINTS

The last 3 decades have witnessed the end of open surgery for urolithiasis. SWL, ureteroscopy, and PCNL have become the mainstays of intervention for stone disease. These treatments are safe and effective and with proper patient selection as described above, can be utilized to treat nearly all renal and ureteral calculi.

EDITOR'S COMMENT

In this chapter "*Surgical Management of Nephrolithiasis*," Brian Eisner nicely overviews the current minimally invasive treatment options for renal stones including the primary options of SWL, ureteroscopy (URS) with laser lithotripsy, and PCNL. Indeed, with the tools available today, the role of open surgical stone management has largely been relegated to historic interest.

In recent years, advances in surgical technology have come primarily in the realms of URS and PCNL, with SWL technology remaining stagnant. As Dr. Eisner highlighted in the text, the advances that have occurred with SWL have related to optimizing the outcomes with the current technology while at the same time attempting to reduce complications. The technology used for SWL has changed little in recent years. It is interesting that so many years after the instruction of SWL that it was realized that delivering the maximum number of shocks at the maximum power was not the optimal technique for SWL, but rather a "start low and go slow" approach is superior. Furthermore, by utilizing information from the preoperative CT imaging that is readily available on most patients, such as the density of the stone (measured in Hounsfield units) and the skin to stone distance, that patients can be more appropriately selected and counseled regarding the potential efficacy of the procedure (Bhojani N, Lingeman JE. Shockwave lithotripsy-new concepts and optimizing treatment parameters. *Urol Clin North Am* 2013;40(1):59–66).

An important aspect of SWL that does distinguish it from URS and PCNL to some degree, is that the majority of procedures can be performed without the placement of a ureteral stent. Indeed, the 2016 AUA Guidelines on Surgical Stone Disease do not recommend the placement of a ureteral stent for routine stones <15 mm in maximal diameter (Assimos D, Krambeck A, Miller NL, et al. Surgical management of stones: American urological association/endourological society guideline, PART I. *J Urol* 2016;196(4):1153–60). This can be an important consideration for patients as stent morbidity remains a major factor for both patients and clinicians alike and stent placement after URS remains a common practice (Muslumanoglu AY, Fuglsig S, Frattini A, et al. Risks and benefits of postoperative double-j stent placement after ureteroscopy: results from the clinical research office of endourological society ureteroscopy global study. *J Endourol* 2017;31(5):446–51). Patients who have previously tolerated stents poorly may be more inclined to select SWL over URS, even if the success rate may be slightly lower, knowing that a stent would not be placed. This highlights the importance of a shared decision-making approach with patients to consider all aspects of the

intervention.

Ureteroscopy, specifically flexible URS for the upper ureter and renal collecting system, is the area of surgical stone disease management that has garnered much interest over the past decade. As Dr. Eisner outlined in the chapter, with modern flexible endoscopes the entire renal collecting system can be accessed in most of the cases. With the advent of the holmium:YAG laser, and the small caliber flexible fibers that deliver the laser energy to the target stone, stones of all compositions can be fractured into small pieces. The ability to safely perform the procedure in patients on anticoagulation, as well as in the morbidly obese, gives the urologist a critical tool to treat these challenging patient populations. From a patient perspective, the lack of a surgical incision, the high fragmentation rate, and the outpatient nature of the procedure are highly appealing. However, there remain challenges with URS. The initial purchase cost of the flexible ureteroscopes are high and maintenance of these fragile instruments even higher. The durability of these endoscopes is poor with only 10 to 15 procedures on average performed before repair is needed (Knudsen B, Miyaoka R, Shah K, et al. Durability of the next-generation flexible fiberoptic ureteroscopes: a randomized prospective multi-institutional clinical trial. *Urology* 2010;75(3):534–8). Even with the advent of digital technology has failed to show an improvement in these figures (Shah K, Monga M, Knudsen B. Prospective randomized trial comparing 2 flexible digital ureteroscopes: ACMI/olympus invisio DUR-D and olympus URF-V. *Urology* 2015;85(6):1267–71). In addition to the cost of the endoscopes, the other equipment used during the procedure such as guidewires, stone baskets, laser fibers, and stents are primarily single use, with laser fibers being the exception where both single use and reusable options are available. This disposable equipment adds significantly to the cost of the procedure. Worldwide, health care costs are a growing concern and the high cost of the equipment used for these procedures will be a budgeting challenge in the future. When one factors in payment reform, such as bundled payments, having to justify each tool used will likely become a reality.

While PCNL has been an established treatment modality for many years, the technique has been continually refined to improve the success rate and decrease the morbidity (Duvdevani M, Razvi H, Sofer M, et al. Third prize: contemporary percutaneous nephrolithotripsy: 1585 procedures in 1338 consecutive patients. *J Endourol* 2007;21(8):824–9). It remains the treatment of choice for large stone >2 cm and for smaller stones in the lower pole (Assimos D, Krambeck A, Miller NL, et al. Surgical Management of Stones: American urological association/endourological society guideline, PART I. *J Urol* 2016;196(4):1153–60). This is due to the ability to efficiently clear large volumes of stones through a small incision in a rapid and safe manner. Refinements in percutaneous renal surgery have occurred in recent years. While data are limited, there is a trend toward using smaller tract sizes in an attempt to further reduce surgical morbidity. As Dr. Eisner discussed, there has been a

trend in PCNL to reduce the tract size from 30 Fr to a smaller size (<20 Fr) with the goal to reduce the morbidity of the procedure. However, with a reduction in tract size there are other trade-offs. The size of the fragments that can be removed are limited by the size of the tract. Therefore any reductions in the tract diameter require additional fragmentation of the stone prior to removal, thereby lengthening the procedure. In addition, the instruments used to fragment the stones are all smaller with a reduced tract size; again this can result in a decrease in efficiency and longer operative times. In the coming years it is likely that prospective studies evaluating tract size in a randomized fashion will help to determine which size is truly optimal.

Physicians, especially in the United States, have been actively challenged to reduce length of stay (LOS) for our patients. While SWL and URS are performed primarily as outpatient procedures, PCNL has historically been associated with an inpatient hospital admission. However, the LOS for PCNL has become shorter with many cases in tertiary care centers in the United States taking place as 23-hour observation stays. Others have taken this a step further and are now performing PCNL as a same-day outpatient procedure (Beiko D, Lee L. Outpatient tubeless percutaneous nephrolithotomy: the initial case series. *Can Urol Assoc J* 2010;4(4):E86–90). While these patients must be carefully selected, the feasibility of this approach has been clearly demonstrated and is a trend to observe in the coming decade.

Surgical management of stone disease has been well established in the minimally invasive era for some time now. Future refinements aimed at increasing stone-free rates, limiting morbidity, and reducing lengths of stay are likely to occur over the next decade. These improvements, however, will need to be balanced with cost containment as our health care systems come under increasing budgetary challenges in the years to come.

173 Operations on the Ureteropelvic Junction

Frank Hinman, Jr.

This Chapter can be accessed in the accompanying eBook edition (see inside front cover for access instructions).

As an alternative to open operation, consider endoscopic incision. If open surgery is indicated, the most adaptable technique is the Anderson–Hynes dismembered pyeloplasty. This method not only uniformly provides a funnel, but also allows resection of functionless portions of the pelvis and ureter. For selected cases, the YV-plasty and pelvic flap operations are excellent, whereas intubation techniques are reserved for cases in which more plastic methods are not possible.

ANDERSON–HYNES DISMEMBERED PYELOPLASTY

Expose the kidney through an anterior subcostal incision, taking care to stay out of the peritoneal cavity, or use a flank incision. In infants, the pelvis may be readily approached through a dorsal lumbotomy incision.

Open Gerota's fascia laterally to preserve the dorsal layer; its contained perinephric fat will be used later to cover the repair.

Dissect the ureter starting below the ureteropelvic junction, taking care not to interfere with the segmental blood supply to this area (Fig. 173.1). Place a small Penrose drain or vessel loop around the ureter.

After exposure of the ureteropelvic junction, decide on the type of operation. Ureteropelvic junction obstructions are usually from an anomalous insertion of the ureter, with or without stricture, from a stricture just below the ureteropelvic junction, or, in the upper ureter, from a stricture or a ureteral valve. Ask yourself: Is the ureter long enough to allow dismemberment and excision of the ureteropelvic junction? If so, a modified Anderson–Hynes pyeloplasty is suitable most often, although a Foley Y-plasty can work well with high insertions of the ureter. For a long dependent junction, the Culp or Scardino techniques may solve the

problem of having insufficient ureter for approximation.

Place a stay suture in the ureter at its junction with the pelvis (Fig. 173.2), divide the ureter obliquely, and spatulate it on its (less vascularized) lateral surface for a distance equal to the length of the proposed V-shaped flap.

With the pelvis full, map the proposed diamond-shaped incision with a skin-marking pen, angling the caudal triangle medially to form a V-flap (Fig. 173.3). Place stay sutures of 7-0 catgut at the angles of the diamond. Incise along one of the planned lines for a short distance with a no. 11 hooked blade. With Lahey or Potts scissors, cut the pelvis from the inside of one stay suture to the inside of the next (Fig. 173.4).

Insert an infant feeding tube of suitable size into the ureter to prevent a suture from catching the far wall (Fig. 173.5). Place one 5-0 or 6-0 synthetic absorbable suture adjacent to the apex of the V-shaped flap, inserted first from outside in, then out through the apex of the ureteral slit. Place a second suture 2 mm away from the first. Tie both sutures with four knots and cut the short ends.

Continue the first suture along the far side of the wall to the tip of the ureter as a continuous stitch, locked at every four or five bites (Fig. 173.6A). Do the same for the second suture on the near side. Be sure to irrigate the pelvis and calices free of clots.

Tie the two sutures together, cut one at the knot, and close the pelvic defect with the other (Fig. 173.6B). If the infant feeding tube is to remain as a stent, bring it out through the renal parenchyma.

Inject saline with a fine needle through the pelvic wall to test for watertightness and for patency of the anastomosis.

Insert a Penrose drain and fasten it by the long-suture technique to be sure it is near but not touching the anastomosis or the ureter below it (Fig. 173.7). Nephropexy stitches can be used to hold the kidney in place if it has been mobilized. Tack the two edges of Gerota fascia together around the kidney with fine plain catgut to isolate the kidney from the body wall and close the wound in layers.

FOLEY YV-PLASTY

This technique may be indicated for a high insertion of the ureter, especially when the pelvis has a box shape (Fig. 173.8A).

Draw the ureter cephalad with a Penrose drain and mark a long Y-shaped incision between stay sutures. Incise the pelvis between the stays

with a no. 11 hooked blade, and open it with Potts scissors. This forms a V with arms equal to the length of the ureteral incision (Fig. 173.8B). A nephrostomy tube may be placed, with or without a stent. Suture the apex of the flap to the apex of the ureteric incision with a 7-0 synthetic absorbable suture passed in through the apex of the V and out through the apex of the ureteral incision (Fig. 173.9A). Place interrupted sutures of 4-0 synthetic absorbable suture down both sides of the V to make a watertight anastomosis (Fig. 173.9B).

CULP-DEWEERD PELVIC FLAP PYELOPLASTY

This procedure may be used for long low defects with a dilated pelvis, for which a dismembered procedure would result in tension.

Make a spiral (Culp) flap running obliquely around the enlarged pelvis, and extend the incision down the ureter for a distance equal to the length of the flap (Fig. 173.10A). For the Scardino variation, run the incision vertically from the ureteropelvic junction.

Incise the flap and deflect it down with a stay suture (Fig. 173.10B). Suture the posterior edge of the flap to the lateral ureteral edge with a running 4-0 or 5-0 synthetic absorbable suture (Fig. 173.10C). Close the anterior edge of the flap and pelvis with similar sutures (Fig. 173.10D).

DAVIS INTUBATED URETEROTOMY

Intubated ureterotomy is reserved for very long scarred defects involving the ureteropelvic junction, but endoscopic incision is usually preferable.

Incise the pelvis with a no. 11 knife blade just above the ureteropelvic junction between two stay sutures. Open the ureter with Potts scissors, until normal caliber is reached (Fig. 173.11A). Insert a No. 8 French silicone double-J stent and a nephrostomy tube. Tack the edges of the defect loosely together with 5-0 synthetic absorbable sutures. Cover with omentum (Fig. 173.11B).

EDITOR'S COMMENT

Dr. Hinman has presented the classic operation of the Anderson–Hynes dismembered pyeloplasty. This operation appears to be the classic operation from which most of the pyeloplasties for strictures at the ureteropelvic junction are derived. The chapter herein describes the classic open technique. In the intervening interval since this operation was described, attention in urology

since Schuessler's introduction of laparoscopy in a number of urologic operations has increased. Endoscopic pyeloplasties have also been used. The success of the open procedure appears to be 90% or greater (O'Reilly et al., *Br J Urol* 2001;87:287; Brooks et al., *Urology* 1995;46:791). However, rigorous follow-up of endopyelotomy and balloon dilatation, which gained popularity in the early 1990s, have failed to reveal a similar success rate (Knudsen et al., *Urology* 2004;63:230). It is also true in most series that subsequent reconstruction of the ureteropelvic junction for failed primary pyeloplasty results in lower success rates (Inagaki, *Br J Urol Int* 2005;95(suppl 2):102).

Moon et al. (*Urology* 2006;67:932) reported 170 consecutive cases of laparoscopic pyeloplasty using the four-port extraperitoneal approach. The conversion rate was 0.6% with no conversions in the last 161 cases. Mean hospital stay was 3 days, not different than the open pyeloplasty; however, this was a report from the Basingstoke North Hampshire Hospital in the United Kingdom, in which lengths of stay generally tend to be longer. Success rate as measured by diuresis renography obtained 3, 12, 24, and 36 months after surgery and ureteroscopy performed when the renographic findings were equivocal or obstructive resulted in a success rate of 96%, with 12 complications including three major adverse events and one contained urinary leak. A right hemicolectomy for colonic injury was diagnosed 6 days postoperatively; port site bleeding was operated 12 hours postoperatively and one patient had a postoperative subendocardial myocardial infarction. In an earlier review, Inagaki (previously quoted 2005) reported 147 transperitoneal pyeloplasties between 1993 and 2000 in patients whose mean age was 36 years. The Anderson–Hynes dismembered pyeloplasty was performed in the majority (106) of patients, whereas YV-plasties and 28 Fenger pyeloplasties were used. Twenty-five patients had previously undergone a procedure. The success rate in the primary cases was 95% in patients followed for at least 2 years, with the longest being 84 months.

Ost et al. (*Urology* 2005;66(suppl 5A):47) reported 100 consecutive outpatients, of which 50 were operated on endoscopically and 50 laparoscopically and an additional 5 by endopyeloplasty. The average age was approximately 45 ± 16 years and the mean hospital stay was 2.5 days. Postoperative creatinines were unchanged in both groups. The criterion for success was an improvement in the half-life of diuretic renal scintigraphy of less than 12 minutes. Obstruction was a half-life of more than 20 minutes. Success rates were 92% for primary antegrade endopyeloplasty and 58% for secondary percutaneous antegrade endopyelotomy.

Laparoscopic pyeloplasty, using a transperitoneal three-port Anderson–Hynes pyeloplasty, was performed on patients averaging 38 ± 15 years of age. Again, there was no significant change in the postoperative creatinine level (1.1 → 1.0). Success rates included 100% for primary repair and 95%, 20 of 21, for secondary repair. It does seem as if a number of groups have mastered laparoscopic transperitoneal Anderson–Hynes pyeloplasty with excellent

results.

This can also be carried out in an infant younger than 4 months as reported from the Children's Hospital of Philadelphia by Kutikovia et al. (*J Urol* 2006;175:1477). Eight infants with a mean age of 4.5 months underwent transperitoneal laparoscopy pyeloplasty for ureteropelvic junction obstruction. A hospital stay was 1.2 days; the stent was removed 6 weeks postoperatively in all patients except one. Laparoscopic pyeloplasty in this young group resulted in 100% relief of obstruction.

Geavlete et al. (*J Endourol* 2006;20:179) reviewed 2,436 patients between 5 and 87 years of age who underwent retrograde ureteroscopy under video and fluoroscopic procedures. Upper urinary tract lithiasis was present in 2,041 cases. The mean complication rate was 5.9%; 95% of these 95 cases were operated on for ureteropelvic junction stenosis. It is difficult to tell exactly how many patients of the benign ureteropelvic junction stenosis group were successful, but it seems to be in the 80% or more range.

Taken altogether, it does appear as if the laparoscopic Anderson–Hynes dismembered pyeloplasty carried out transperitoneally seems to have evolved as the new ìgold standardî for the treatment for this disease.

J.E.F.

174 Radical Nephrectomy for Renal Cell Cancer

Elias S. Hyams and Mohamad Allaf

INTRODUCTION

Renal cell carcinoma (RCC) constitutes ~3% of adult malignancies and 90% to 95% of renal neoplasms. Rising utilization of abdominal imaging in the past 20 years has increased the rate of incidental diagnosis to >50%. Concurrently, there has been stage migration with a rising frequency of small tumors and localized disease at presentation. As such, nephron-sparing surgery (NSS) has been increasingly performed with the goal of preserving normal renal parenchyma and residual renal function without conceding oncologic outcomes. Although NSS has become the standard of care for treatment of most small renal masses, radical nephrectomy is still the treatment of choice for larger and/or central lesions. RCC overall remains a surgical disease given its resistance to chemotherapy and radiation, although immunotherapies have been shown to have modest survival benefit in the setting of metastatic disease.

In this chapter, we review the pathology, epidemiology, clinical presentation, and surgical management of RCC with a detailed review of the various operative approaches.

PATHOLOGY

RCCs are derived from renal tubular epithelial cells and have variable histologic subtypes. Differentiating between histologies provides useful information regarding prognosis, recurrence risk, familial associations, and possibly response to systemic therapies in the metastatic setting. Clear cell or “conventional” RCC is the most common subtype (70% to 80%) and is associated with loss of chromosome 3p. These tumors have a worse prognosis compared with the other main types of RCC (i.e., papillary, chromophobe). Clear cell RCC is associated with von Hippel Lindau (VHL) disease and hereditary clear cell RCC, but more frequently occurs sporadically. Clear cell disease responds better to immunotherapies should

they be necessary in the adjuvant setting; in particular, IL-2 only addresses clear cell RCC.

Papillary RCC (10% to 15%) is associated with trisomy of chromosomes 7 and 17, c-met gene mutations on chromosome 7, and loss of the Y chromosome. Papillary RCC can occur in hereditary syndromes as well ("hereditary papillary RCC") and is frequently bilateral and multifocal (up to 40%).

Chromophobe RCC (5%) may have a more indolent course than other RCC subtypes, and frequently presents at low stage and low grade. It has a close histologic resemblance to oncocytoma, which is a benign renal neoplasm. There can be difficulty differentiating chromophobe RCC from oncocytoma on percutaneous biopsy.

Additional subtypes of RCC are less common. These include collecting duct carcinoma, which is rare and aggressive and frequently presents with metastasis, and renal medullary carcinoma, which is associated with sickle cell trait and is extremely aggressive with a poor prognosis. Certain histologic characteristics of RCC are associated with more aggressive behavior, including sarcomatoid or spindle cell variants.

Grading of RCC is an important prognostic tool. Fuhrman nuclear grading (I to IV) is based on nuclear characteristics, including size, contour, and nucleoli. Higher grade is associated with a worse prognosis.

ETIOLOGY/GENETICS

Tobacco smoking is the most salient risk factor for RCC with an estimated doubling of risk of cancer. Numerous other potential environmental factors (e.g., phenacetin, heavy metals) have been investigated, but none has been definitively shown to be causative. Obesity and hypertension appear to be associated with the increased risk of RCC. Acquired cystic disease from chronic end-stage renal disease (ESRD) also increases the risk of RCC; the relative risk in ESRD patients may be up to 20 times higher than the general population.

RCC occurs in both sporadic and hereditary forms. Sporadic RCC is typically unilateral and unifocal, with 2% to 4% rate of bilateral disease. Hereditary forms are more commonly bilateral, and occur within several syndromes. VHL disease is an autosomal dominant disorder associated with a deletion of chromosome 3p, the VHL tumor suppressor gene. Renal cancer develops in 30% to 55% of patients with VHL. RCC is typically multifocal and bilateral; thus, there may be a greater imperative to perform

NSS in this population. Major clinical manifestations of VHL include clear cell carcinoma, hemangioblastomas of the central nervous system, retinal angiomas, and pheochromocytoma. Interestingly, deletion of the VHL gene is associated with both sporadic and familial forms of clear cell RCC.

Birt–Hogg–Dube syndrome is a hereditary cutaneous syndrome associated with development of fibrofolliculomas, lung cysts, pneumothorax, as well as bilateral multifocal oncocytoma and chromophobe RCC. This syndrome results from mutation of the BHD1 gene on chromosome 17.

Hereditary papillary RCC is an autosomal dominant disorder in which patients develop bilateral, multifocal papillary RCC; the specific type of tumor is considered Type 1 papillary RCC. Mutations in the c-met proto-oncogene on chromosome 7 are thought to be etiologic.

Familial leiomyomatosis and RCC result from mutation of the fumarate hydratase gene on chromosome 1. This leads to Type 2 papillary RCC as well as cutaneous leiomyomas and uterine leiomyomas. These RCC lesions tend to be more aggressive than other forms of familial RCC.

Tuberous sclerosis appears to be associated with RCC, although the underlying relationship is not well understood. Interestingly, there is not thought to be increased incidence of RCC in autosomal dominant polycystic kidney disease.

CLINICAL PRESENTATION

Symptoms of RCC when present may be related to bleeding, local growth, paraneoplastic syndromes, or metastasis. The classic “triad” of flank pain, gross hematuria, and a palpable flank mass is fortunately uncommon (10%) as it generally represents advanced disease. Findings suggestive of advanced disease include significant weight loss, bone pain, clinical lymphadenopathy, and poor performance status. Patients with local invasion may have pain from invasion of the abdominal wall, nerve roots, or paraspinous muscles.

Up to one third of patients with RCC have metastasis on initial presentation. Metastases usually involve more than one site, and occur by both hematogenous and lymphatic spread. Metastatic sites from most to least frequent include lung, bone, regional lymph nodes, liver, ipsilateral adrenal gland, contralateral kidney, and brain. Systemic abnormalities may represent metastatic disease and include elevated erythrocyte sedimentation rate; hypertension; anemia; cachexia; weight loss; fever;

abnormal liver function; and hypercalcemia, polycythemia, and neuropathy.

Importantly, these abnormalities may also be stigmata of a paraneoplastic syndrome, although metastatic disease should be rigorously excluded. Paraneoplastic syndromes develop in 20% to 30% of patients with RCC and result from ectopic hormone section. Substances that can be secreted include parathyroid-like substance (causing hypercalcemia), erythropoietin (polycythemia), renin (hypertension), gonadotropins, placental lactogen, enteroglucagon, insulin-like substances, prostaglandin A, and prolactin. Syndromes associated with these hormones typically reverse upon removal of the tumor; persistence is compatible with occult metastatic disease.

"Stauffer syndrome" is an idiopathic reversible hepatic dysfunction that occurs in up to 20% of patients with RCC. This syndrome manifests with increased alkaline phosphatase, indirect bilirubin, and altered international normalized ratio (INR). These abnormalities will reverse postoperatively in the setting of localized disease.

Venous insufficiency and thromboembolism may be consistent with tumor thrombus extending into the inferior vena cava (IVC), and may warrant an investigation for RCC. Concerning signs include lower extremity edema, pulmonary embolism, right-sided varicocele or persistent varicocele in the supine position, and dilated superficial abdominal veins.

DIAGNOSIS

Diagnosis of renal neoplasms is typically made on cross-sectional abdominal imaging. The gold standard exams for evaluation of a renal mass are contrast-enhanced computed tomography (CT) or magnetic resonance imaging (MRI). The differential diagnosis for a renal tumor may include RCC, benign neoplasm (e.g., angiomyolipoma [AML], oncocytoma, renal adenoma), abscess, lymphoma, metastasis from a separate primary lesion, pyelonephritis, renal cyst, renal infarction, and sarcoma or Wilms tumor.

Renal masses may be solid, cystic, or mixed. Solid masses may represent benign or malignant disease, thus contrast imaging is needed to detect "enhancement" that is generally compatible with malignancy. An increase in Hounsfield units of >10 to 15 from noncontrast to arterial phase is thought to be consistent with a malignant process. However, although ~80% of enhancing renal masses are histologically malignant

upon removal, 20% will be benign (e.g., oncocytoma, fat-poor AML). Patients should be appropriately counseled regarding this possibility.

Considerations on CT/MRI include the size and position of the tumor, the status of the adrenal glands and contralateral kidney, presence of lymphadenopathy, presence of visceral metastasis, and renal vein or IVC involvement. Nodes ≥2 cm are thought to be more likely malignant, whereas smaller nodes are typically inflammatory. Presence of tumor thrombus can be detected with high sensitivity with both multiplanar CT and MRI.

Cystic renal masses are typically categorized using the Bosniak system that applies to CT appearance. This system reflects the likelihood of malignancy, with increasing complexity (thickness/number of septations, solid and/or enhancing components) increasing the likelihood of RCC. Bosniak III–IV lesions are typically treated as carcinoma, II–IIF lesions are followed radiographically, and Bosniak I or "simple" cysts do not require follow-up. Calcifications are thought to be associated with malignancy but are not pathognomonic.

Renal ultrasound frequently detects incidental masses in the course of evaluation for flank or abdominal pain. Ultrasound may assist in characterizing a mass as solid versus cystic, and a cyst as simple versus complex; however, ultrasound has a poor sensitivity for malignancy compared with cross-sectional imaging. Ultrasound may be used as a screening study in patients with impaired renal function who cannot receive iodinated contrast or gadolinium.

Percutaneous biopsy of renal masses has become more common, particularly at tertiary centers, as pathologic accuracy has improved. Indeed, 20% to 30% of small renal masses will represent benign pathology and may not require treatment. However, while biopsy may be useful and impact clinical decision making, in many cases it will not change management and is not required. For instance, a negative result may not be trusted in a young healthy patient such that surgery will be performed regardless of biopsy result. Conversely, in an elderly, comorbid patient, a biopsy showing malignancy may not lead to surgical intervention based on concerns regarding procedural risks, and the tumor may be observed such that the biopsy was superfluous and potentially harmful. In addition, biopsy is known to underestimate tumor grade in a way that limits risk stratification. Scenarios in which biopsy should be performed include presence of a second malignancy and concern for renal metastasis,

suspicion for infection (abscess/phlegmon), or suspicion of lymphoma based on radiographic appearance of the mass (diffuse and infiltrating rather than encapsulated).

STAGING

The TNM staging system of the American Joint Committee on Cancer is most commonly used for RCC and had been validated to correspond with cancer-specific survival. See Table 174.1 for details of staging. Estimated 5-year disease-specific survival rates are 95% for T1 disease, 88% for T2, 59% for T3, and 20% for T4.

TABLE 174.1 American Joint Committee on Cancer (AJCC) TNM Staging System for RCC

T1a	Organ confined, ≤4 cm
T1b	Organ confined, 4 to 7 cm
T2a	Organ confined, 7 to 10 cm
T2b	Organ confined, >10 cm
T3a	Perinephric tissue, renal sinus, or renal vein
T3b	Vena cava below diaphragm
T3c	Vena cava above diaphragm or into wall of vena cava at any level
T4	Beyond Gerota's fascia or directly into adrenal gland
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastases in regional lymph node(s)
M0	No distant metastasis
M1	Distant metastasis

Stage	T	N	M
I	T1	N0	M0
II	T2	N0	M0
III	T1 or T2	N1	M0
	T3	N0 or N1	M0
IV	T4	Any N	M0
	Any T	Any N	M1

PREOPERATIVE EVALUATION

Preoperative evaluation for radical nephrectomy includes a complete history and physical exam. Comorbidities that might affect patient positioning or surgical approach (e.g., severe cardiopulmonary disease, kyphoscoliosis) should be assessed. The presence of chronic kidney disease (CKD) or comorbidities affecting risk of renal dysfunction (e.g., diabetes, hypertension) should be noted and factor into decision-making regarding partial versus radical nephrectomy. Prior abdominal or retroperitoneal surgery should be considered regarding the desired surgical approach. Family history of renal masses or genetic syndromes should be elicited. Assessment of patient performance status is critical if cytoreductive nephrectomy is being considered.

A complete metabolic panel including liver function tests is sent preoperatively. Serum calcium should be assessed to screen for bone metastasis or paraneoplastic syndrome. A complete blood count should be assessed to rule out polycythemia due to erythropoietin-producing tumors or lactoferrin-producing tumors with anemia. Glomerular filtration rate (GFR) should be calculated to stratify for risk of renal dysfunction postoperatively.

Operative planning based on CT or MRI is critical. The size and position of tumor are noted for radical nephrectomy to ensure Gerota's fascia is not violated near the tumor and to anticipate areas of gross inflammation, and for partial nephrectomy to plan the depth/extent of resection. Relationships of the tumor to the collecting system, renal sinus fat, and the renal hilum should be assessed. The number and position of renal arteries and veins should be noted. Involvement of the adrenal gland and other adjacent structures should be assessed, as should the presence and extent of renal vein or caval thrombus. The contralateral kidney should be examined for abnormalities.

Chest imaging is necessary preoperatively to rule out lung metastasis. A chest x-ray is an acceptable first-line test, and a chest CT can be performed if there are equivocal findings. A bone scan can be considered if there is bone pain, fracture, hypercalcemia, or elevated alkaline phosphatase. A head CT can be considered if there is an abnormal neurologic exam.

Preoperative infarction via angioembolization is rarely utilized, but can be useful for large tumors in patients with arterialized caval tumor thrombus or medial extension of the tumor that may prohibit early ligation of the renal artery. Infarction can also be used for palliation in the setting of severe bleeding.

TREATMENT

There are numerous management strategies for RCC, including radical nephrectomy (open vs. laparoscopic), partial nephrectomy (open vs. laparoscopic/robotic), ablation (percutaneous vs. laparoscopic), and active surveillance.

Radical Nephrectomy

Radical nephrectomy is indicated for large and/or complex renal tumors that are not candidates for NSS. This procedure entails removal of Gerota's fascia and its contents including kidney and perirenal fat. The adrenal gland is also present within Gerota's fascia; however, it is generally spared unless there is direct invasion or metastasis. Laparoscopic radical nephrectomy (LRN) is currently the standard of care based on equivalent long-term cancer control compared with open surgery, with hastened convalescence, and decreased postoperative pain. This procedure is typically performed transperitoneally but can be performed retroperitoneally as well. Hand-assisted LRN can be performed to decrease the learning curve of the procedure. There has been recent interest in further minimizing the invasiveness of nephrectomy through single-incision surgery, which has been shown to be safe and feasible in those with appropriately thin body habitus. Open radical nephrectomy (ORN) is rarely performed for localized kidney cancer, although it is the approach of choice in the presence of caval tumor thrombus because of superior exposure to the great vessels and the ability to mobilize the liver as necessary. ORN is performed if there is concern for local invasion, plan to resect visceral metastasis, or significant lymphadenopathy in the setting of cytoreduction.

We advocate sparing the ipsilateral adrenal gland during radical nephrectomy unless there is direct involvement or if there is an abnormality suggestive of metastasis. The adrenal should also be taken for upper pole lesions in which there is concern regarding surgical margins.

We do not routinely perform a regional lymphadenectomy with radical nephrectomy, as studies have shown that it does not appear to influence outcome. Indications for a nodal dissection include suspicious lymphadenopathy on preoperative imaging and/or concerning nodes detected intraoperatively.

Tumor thrombus extending into the renal vein or IVC occurs in 4% to 10% of patients. When there is isolated renal vein involvement, the vein

can be controlled beyond the edge of thrombus and standard radical nephrectomy performed. However, extension into the cava requires opening the cava for extraction of thrombus. Primary repair, patch grafting, or interposition grafting can be employed in conjunction with a vascular surgeon. Extension to the diaphragm and/or chest may require mobilization of the liver, venovenobypass, and/or cardiopulmonary bypass with circulatory arrest in conjunction with a cardiothoracic surgeon. Caval thrombus is associated with high perioperative risks and modest long-term survival rates; however, long-term survival can be achieved with radical surgery in up to 50% of the patients depending on patient selection. Important predictors of survival include tumor stage, grade, lymph node status, presence of distant metastasis, and presence of systemic symptoms at diagnosis.

When RCC presents with a single site of metastasis, radical nephrectomy and metastectomy are recommended for patients with good performance status as resection may provide a cancer-specific survival advantage. Recent reports have suggested that there is a survival advantage with resection of multiple metastases as well when technically feasible. If a metachronous single metastasis occurs, resection of that metastasis is performed. Radical nephrectomy in the setting of advanced and/or metastatic disease is performed for “cytoreduction” to be followed by systemic immunotherapy in conjunction with a medical oncologist. There is thought to be an immunologic benefit to removing the primary tumor; cytoreduction has been shown to confer advantages in terms of delayed progression and overall survival in selected patients with metastasic disease. Eastern Cooperative Oncology Group (ECOG) performance status 0–1 is an important selection criterion for pursuing this treatment approach. There are specific criteria described by Motzer and colleagues that help predict survival in patients with metastatic RCC, and may help with decision making regarding use of systemic therapy. There is active investigation of neoadjuvant immunotherapy in the setting of metastatic RCC, and recent prospective data have suggested a survival benefit of this approach in selected good-risk patients. Importantly, RCC is notoriously resistant to chemotherapy and hormonal therapy. Radiation therapy may be considered for palliation of bone and brain metastasis, but is not effective for treatment of the primary tumor.

Partial Nephrectomy

Partial nephrectomy is currently the standard of care for treatment of most small renal masses. Historically, partial nephrectomy has been used primarily for patients with imperative indications for renal preservation (e.g., solitary kidney, bilateral renal tumors, preexisting CKD, genetic tumor syndromes). However, it is presently recommended for all patients with T1a and T1b disease, when technically feasible, based on equivalent long-term oncologic outcomes of radical nephrectomy and decreased long-term risk of CKD. There is convincing evidence linking radical nephrectomy with CKD, particularly in patients with preexisting medical renal disease, as well as CKD with cardiovascular morbidity and mortality. As such, nephron preservation is highly prioritized in treatment of renal tumors to maximize overall survival. However, there has been an evolving debate on how far to push partial nephrectomy, as it is not appropriate for higher stage masses. The balance between nephron preservation and cancer eradication for more complex tumors, at present, requires a case by case evaluation. There has been one randomized trial (EORTC-GU trial 30904) comparing radical and partial nephrectomy, and unfortunately it underaccrued; however, it did demonstrate decreased overall survival among partial nephrectomy patients, which is counterintuitive. Further high-quality studies are needed to clarify the appropriate line for partial versus radical nephrectomy for larger and more complex tumors.

The desired approach to partial nephrectomy depends on surgeon experience, but in general a minimally invasive approach including laparoscopic and/or robotic surgery is preferred. Laparoscopic partial nephrectomy (LPN) by experienced surgeons has been shown to have long-term oncologic outcomes equivalent to open surgery, with decreased perioperative morbidity and hastened convalescence. Robotic techniques are analogous to traditional laparoscopy, and facilitate the suturing/reconstructive portion of the procedure. Indeed, improved dexterity, magnification, and surgeon ergonomics have applied naturally to tumor resection and renal reconstruction. Ultimately, however, nephron-preservation should be prioritized over a minimally invasive approach, given the long-term benefits of renal preservation that outweigh the short-term and cosmetic benefits of laparoscopy and robotics.

Partial nephrectomy, whether open or minimally invasive, generally requires temporary clamping of the renal artery during resection of the tumor to minimize blood loss and to allow visual assessment of the deep tumor margin. Clamping of the renal vein may also be performed,

although sometimes will cause back-bleeding and require release. Renal ischemia should be minimized to reduce the risk of acute kidney injury postoperatively and to ensure preservation of long-term renal function. Recent evidence has demonstrated that the safe duration of ischemia depends largely on nonmodifiable patient factors like preexisting renal dysfunction. For open partial nephrectomy (OPN), the kidney is cooled via ice slush prior to resection to prolong the safe duration of ischemia by slowing renal metabolism; this is called “cold ischemia.” Minimally invasive partial nephrectomy (MIPN) requires “warm” ischemia as there is not an opportunity to cool the kidney intracorporeally. It is typically thought that 30 minutes of warm ischemia will minimize the likelihood of long-term renal dysfunction, although shorter ischemia times are preferred. Cold ischemia is thought to prolong this safe duration for up to 4 hours. There has been recent debate regarding the importance of ischemia time and the role of selective ischemia or “off-clamp” partial nephrectomy. While it is beneficial as a general concept to limit renal ischemia, thresholds for significant or permanent renal injury are likely to vary by patient based on preexisting renal function and the presence of medical kidney disease. Studies have demonstrated that there may be a short-term benefit of selective artery clamping or off-clamp surgery; however, there are no rigorous intermediate or long-term data supporting this approach, and there is a short-term risk of bleeding that argues rather for an efficient resection during global renal ischemia.

Ablative Treatments

Ablative treatments have also been developed to treat small renal tumors in minimally invasive fashion. Cryotherapy and radiofrequency ablation (RFA) have been employed both percutaneously and laparoscopically to destroy a lesion while minimizing treatment morbidity and enabling preservation of the kidney. These approaches are typically used in older, comorbid patients, as retreatment rates are higher than for extirpative therapy, and long-term efficacy has only been demonstrated in selected patients.

Active Surveillance

Active surveillance has been increasingly utilized as a management strategy for patients with small renal masses and significant comorbidities that might compromise the safety of active intervention. Many small renal

masses (20% to 30%) will be benign, and additional malignant lesions will have indolent biology; in an older, sicker patient, it may be reasonable to observe a mass for growth as a proxy for its aggressiveness, with the thought that the risks of surgical intervention exceed the potential benefits. The typical threshold for “safe” observation of a renal mass is 3 cm. Most small renal neoplasms that are observed have slow growth (0.15 cm/yr), and incidence of metastasis in these observed populations is quite low. Ultimately, the decision to pursue active treatment versus surveillance requires a detailed conversation with the patient regarding the risks and benefits of alternative management strategies.

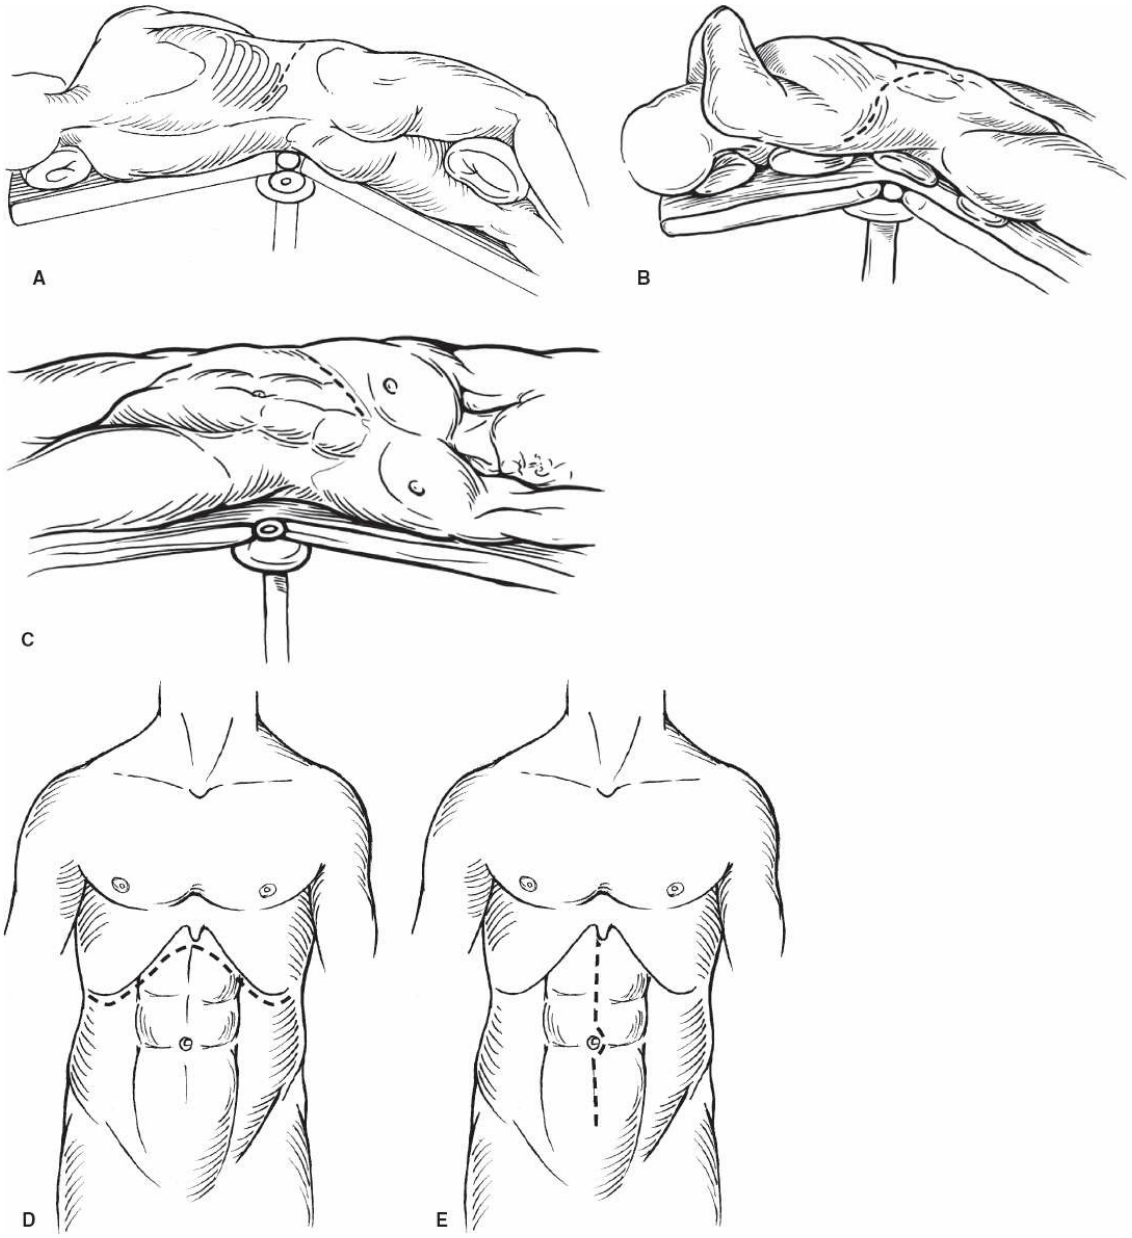

Figure 174.1. Types of incisions used in nephrectomy. **A.** Full flank (thoracoabdominal). **B.** Anterior thoracoabdominal. **C.** Subcostal. **D.** Chevron. **E.** Midline.

INCISIONS

Selection of the appropriate incision is critical to enable optimal exposure during open renal surgery. Factors influencing the type of incision include size and location of the tumor, body habitus of the patient, prior abdominal or retroperitoneal surgery, adjacent organ involvement, and/or the need for bilateral renal operations. The type of incision can globally be divided into the flank approach and the anterior approach (see Fig. 174.1).

Flank/Thoracoabdominal Approach

We favor the flank approach for open surgery as it enables an extraperitoneal dissection that avoids the abdominal viscera. The flank approach may be contraindicated in patients with severe cardiopulmonary disease or scoliosis based on positioning concerns. An incision is made from the interspace between the 10th and 11th ribs, and directed toward an area ~1 cm above the umbilicus (see Fig. 174.2). Incisions below the 11th rib may not enable adequate access to the renal hilum, adrenal gland, and upper pole of the kidney. A traditional flank incision involves positioning the patient perpendicular to the bed. The patient can also be positioned in a modified flank position to improve access to the central abdomen, or depending on surgeon preference. This entails placing the patient with the ipsilateral abdomen tilted up 45 degrees. The patient is carefully strapped to the table, and the table can be tilted in either direction as needed.

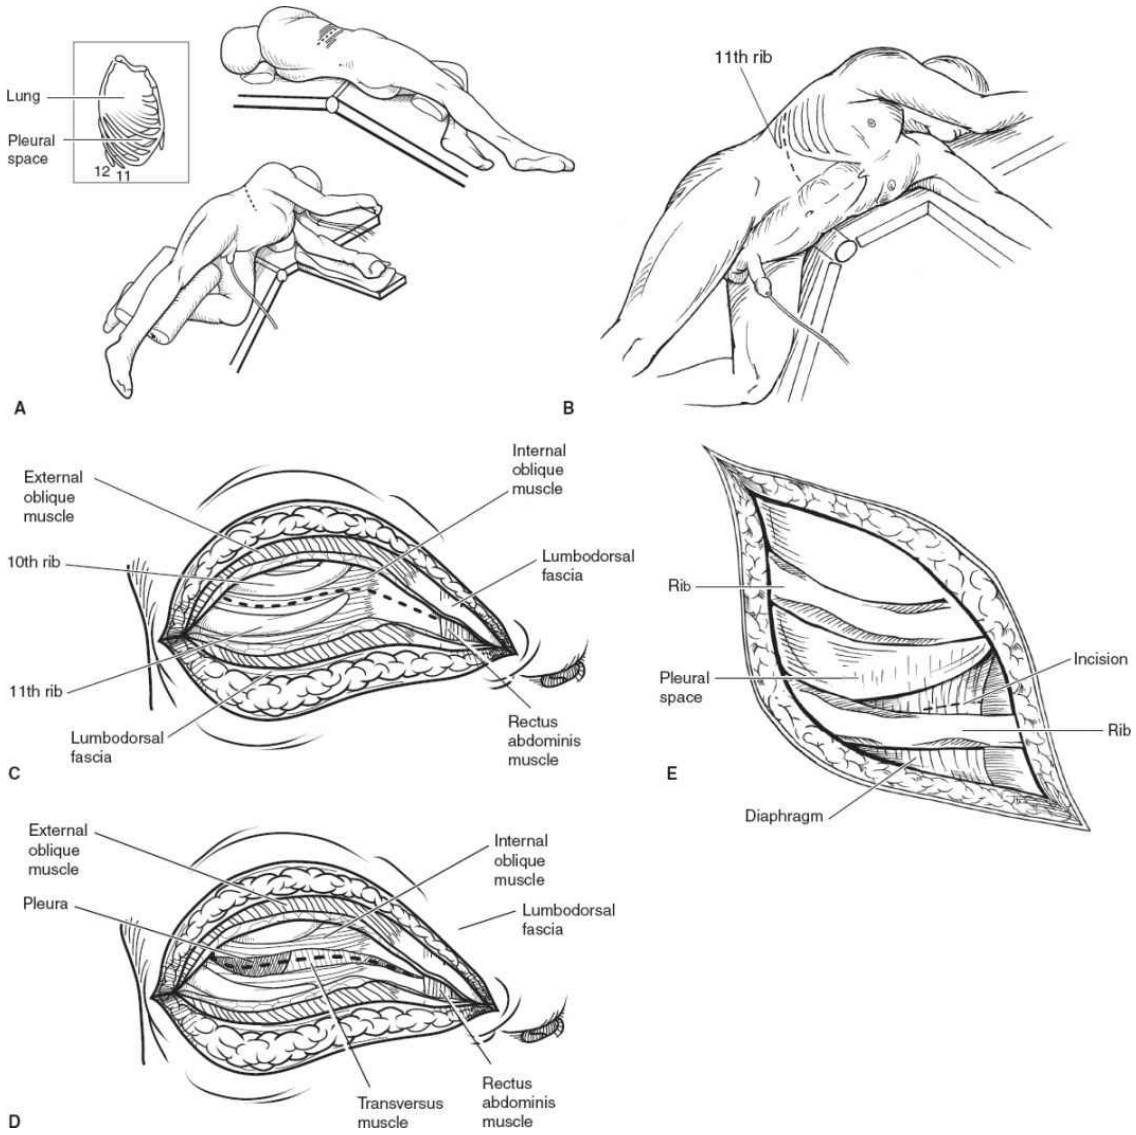

Figure 174.2. Steps for performing flank incision. **A.** Position of the patient for the flank approach. **B.** The incision is lined up between the 11th and 12th ribs, going from the midaxillary line to the edge of the rectus, and aimed at a position 1 cm above the umbilicus. **C,D.** The incision continues through the lumbodorsal fascia. **E.** The peritoneum is incised and the diaphragm cut about 5 to 10 cm with the liver cephalad and the colon covering the retroperitoneal kidney.

A thoracoabdominal incision is utilized for large upper pole masses or management of caval tumor thrombus on the right side. This incision may start as high as the eighth to ninth interspace and is directed toward the umbilicus. This incision enables excellent exposure of the upper pole and adrenal gland, as well as the suprarenal IVC. Frequently, the pleural space will be entered, which can be expeditiously closed at the end of the case with evacuation of pleural air.

For a flank incision, the patient should be positioned with the tip of the 12th rib over the kidney rest. An “axillary roll” is placed under the upper chest, though not in the axilla per se, to avoid direct compression of the axillary nerve and vessels. The legs are positioned with flexion of the lower leg to 90 degrees and straight extension of the upper leg, with careful padding. The contralateral arm can be tucked at the patient’s side, or extended perpendicular to the body on an arm board. The ipsilateral arm can be positioned in padded fashion over the patient’s chest above the xiphoid, or extended over the bed and secured within a padded armrest. The table is generally flexed and kidney rest is utilized to increase the space between the costal margin and iliac crest.

A flank incision is typically made starting in the 10th to 11th rib interspace and extending toward the supraumbilical abdomen to the edge of the rectus muscle. Incision of skin and subcutaneous tissue is performed through the latissimus dorsi and external oblique fascia and muscle, continuing through the internal oblique and transversus abdominus. Transversalis fascia is divided near the tip of the 11th rib with care to avoid entering the pleural cavity, if possible. The retroperitoneal space is then developed by blunt and sharp technique. Resection of the rib is sometimes needed to obtain the desired exposure. Care is made not to injure the intercostal neurovascular bundle that runs typically along the inferior border of the rib.

The pleural reflection typically crosses the ribs at the junction of the anterior and middle third of the ribs. The pleura may be released by incising fascial attachments to the diaphragm, or the lower diaphragmatic fibers can be detached from the posterior 11th and 12th ribs. Frequently, however, the pleural space is entered, which does not present a significant problem. Care should be taken to avoid injuring the lung; however, the diaphragm can generally be expeditiously repaired and air from the chest evacuated at the end of the case. When entering the chest, one should take care to anticipate the eventual closure and leave diaphragmatic tissue adequate for suturing on either side of one’s incision.

A flank incision can be used for either a retroperitoneal or intraperitoneal radical nephrectomy, depending on surgeon preference. The peritoneum may be violated during a retroperitoneal procedure, which is not problematic, as the bowel should just be carefully retracted. If the procedure is performed retroperitoneally, the peritoneal reflection should be identified on the underside of transversus abdominus and bluntly swept

medially, superiorly, and inferiorly with either a sponge stick or Kitner to develop the retroperitoneal space. Once this space is developed, or once the intraperitoneal cavity is entered depending on the approach, a self-retaining retractor is placed. The radical nephrectomy is then performed as discussed below.

At the conclusion of the nephrectomy, the table is taken out of flexion to reduce tension for closure. If the pleural cavity has been entered, the diaphragm can be closed in running fashion using nonabsorbable suture. Air and fluid from the chest can be evacuated using a red rubber catheter that is placed through the closure prior to knot tying. The open end of the catheter can be placed in a basin under water and several deep breaths are administered by anesthesia with the goal of releasing air from the pleural space. When bubbles are no longer seen under water, the catheter can be removed and the knot cinched down. Alternatively, a chest tube can be left in place; this can be inserted through a separate stab incision and attached to suction. The layers of the flank are then closed in stepwise fashion, typically with the transversus abdominus and internal oblique muscle/fascia closed in one layer, then the external oblique fascia closed as a second layer. The external oblique fascia constitutes the strength layer of the closure and should be closed securely with nonabsorbable or heavy absorbable suture to prevent flank hernias. If a partial nephrectomy has been performed, a Jackson-Pratt drain can be placed through a separate stab incision and secured to the skin.

Anterior Transabdominal Approach

Transabdominal approaches to nephrectomy include chevron or subcostal incisions. We do not prefer this approach for most tumors because they provide less optimal exposure to the adrenal gland and upper pole. We use these incisions primarily when a transperitoneal laparoscopic procedure requires conversion to open. A chevron incision can be considered if access to bilateral kidneys and renal hilar structures is desired, or for a left-sided tumor thrombus case. A midline or paramedian approach can be considered in thin patients and/or those with spinal deformities. Transabdominal approaches do enable exploration of the abdominal cavity for metastatic disease if that is a concern. Our preferred subcostal incision is made from the tip of the 11th rib anteriorly toward the xiphoid process, about 2 fingerbreadths below the costal margin (see Fig. 174.3). Dissection is performed through the layers of the anterior abdominal wall to the

peritoneum, which is sharply entered. A self-retaining retractor is placed for the nephrectomy.

OPEN RADICAL NEPHRECTOMY

As discussed above, radical nephrectomy is typically performed for larger and/or deeper renal masses for which NSS is not feasible. ORN is rarely performed as a first-line option, as LRN has become the standard of care based on equivalent cancer control and decreased postoperative morbidity. ORN may be performed if a laparoscopic procedure requires conversion, if there is significant prior abdominal surgery such that an open approach is preferred, if there is concern for involvement of adjacent structures (e.g., colon, pancreas, spleen), and/or in the presence of caval thrombus.

Radical nephrectomy traditionally has included all components within Gerota's fascia, including kidney, perirenal fat, and adrenal gland. As discussed above, however, the adrenal gland can be safely spared if there is no gross or radiographic involvement. Radical nephrectomy, by including perirenal fat, helps optimize cancer control for tumors that are T3 or greater. Performance of lymph node dissection depends on the presence of suspicious adenopathy, as discussed above.

For all patients undergoing nephrectomy, we recommend a bowel preparation that includes clear liquids starting the morning prior to surgery, and one bottle of magnesium citrate the evening prior to surgery. Even when performing a pure retroperitoneal operation, it is helpful to have the bowel decompressed, and there may be a need to work intraperitoneally. We recommend one perioperative dose of prophylactic antibiotics, typically a first-generation cephalosporin administered prior to incision. Use of subcutaneous heparin perioperatively can be considered based on patient habitus or history of thrombosis. Initially, the patient is brought to the operating room and bilateral compression stockings and sequential compression devices are placed on the lower extremities for deep venous thrombosis prophylaxis. General anesthesia is administered, and an endotracheal tube is placed to secure the airway during patient positioning. An orogastric tube is placed to ensure the stomach is completely decompressed. A Foley catheter is placed at the beginning of the case as well. The patient is then positioned on the table.

Retroperitoneal Approach

The retroperitoneal space is entered through a flank incision, and

developed by bluntly releasing the peritoneal reflection from the underside of the transversus abdominus muscle. This is done medially, superiorly, and inferiorly. A self-retaining retractor is placed. Care is taken to gently retract adjacent structures to provide exposure including, on the left side, the bowel and pancreas medially and the spleen superiorly, and on the right side, the bowel medially and the liver superiorly; see Figure 174.4 for anatomical relationships. The kidney is generally palpable at this time. Initially release of the lateral attachments of the kidney is performed using an instrument such as LigaSure (Covidien, Mansfield, MA). The ureter and gonadal vessels are identified running caudally from the kidney within its medial attachments. The plane posterior to the kidney is developed bluntly to separate the posterior surface of Gerota's fascia from the psoas muscle such that the kidney can be elevated (see Fig. 174.5). With advanced tumors, care must be taken during lateral and posterior dissection to avoid inadvertently injuring parasitic vessels, which can be well developed and cause significant bleeding.

The superior attachments of the kidney are taken including lienorenal ligaments on the left and hepatorenal ligaments on the right. The adrenal gland is released from the kidney by identifying a plane between the adrenal and kidney within Gerota's fascia, and releasing with a device like LigaSure or with use of clips (see Fig. 174.5). It is important to be cognizant of vital adjacent structures within the peritoneal cavity including the bowel that is vulnerable to thermal injury. Also the pancreas on the left side should be carefully identified and retracted with care.

We address the hilar structures last once the rest of the kidney has been dissected, in case hilar bleeding occurs such that urgent clamping and removal of the kidney are required. Dissection of the hilum is performed to isolate the vessels for control. It is important to dissect out the artery proximally so that multiple distal branches do not require separate control. Initially, sequential ligation of arterial structures is performed. The renal artery is dissected for sufficient length to accommodate suture ligation or vascular stapling. A posterior approach to the artery may be preferred for visibility. On the left side, extreme care should be taken to ensure the putative renal artery is running directly to the kidney, as the superior mesenteric artery can be inadvertently ligated. For hilar control, a vascular stapler can be used, either an EndoGIA with cutting capability or a TA that requires the surgeon to cut between the staple lines. If there is insufficient length to accommodate a stapler, as per the surgeon's preference, suture

ligation can be performed. Generally, large permanent (e.g., O silk) sutures are passed around the artery proximally and distally, and tied down. The proximal end should be double ligated, with another tie or a suture LigaSure. If the latter is preferred, the proximal end of the artery can be carefully clamped with a right angle clamp; the artery is divided and suture-ligated with 2-0 nonabsorbable suture. After release of the artery, the renal vein is ligated in similar fashion. The right renal vein is shorter, and there may have only modest length to the vena cava. On the left side, care should be taken regarding the takeoff of the adrenal, gonadal, and lumbar veins from the longer left renal vein. It is preferable to spare the adrenal vein if the adrenal is being spared. The gonadal vein can be left intact or ligated without sequelae. In addition, there may be a lumbar vein emanating posteriorly from the left renal vein that may require ligation for exposure of the artery, and that should not be inadvertently avulsed.

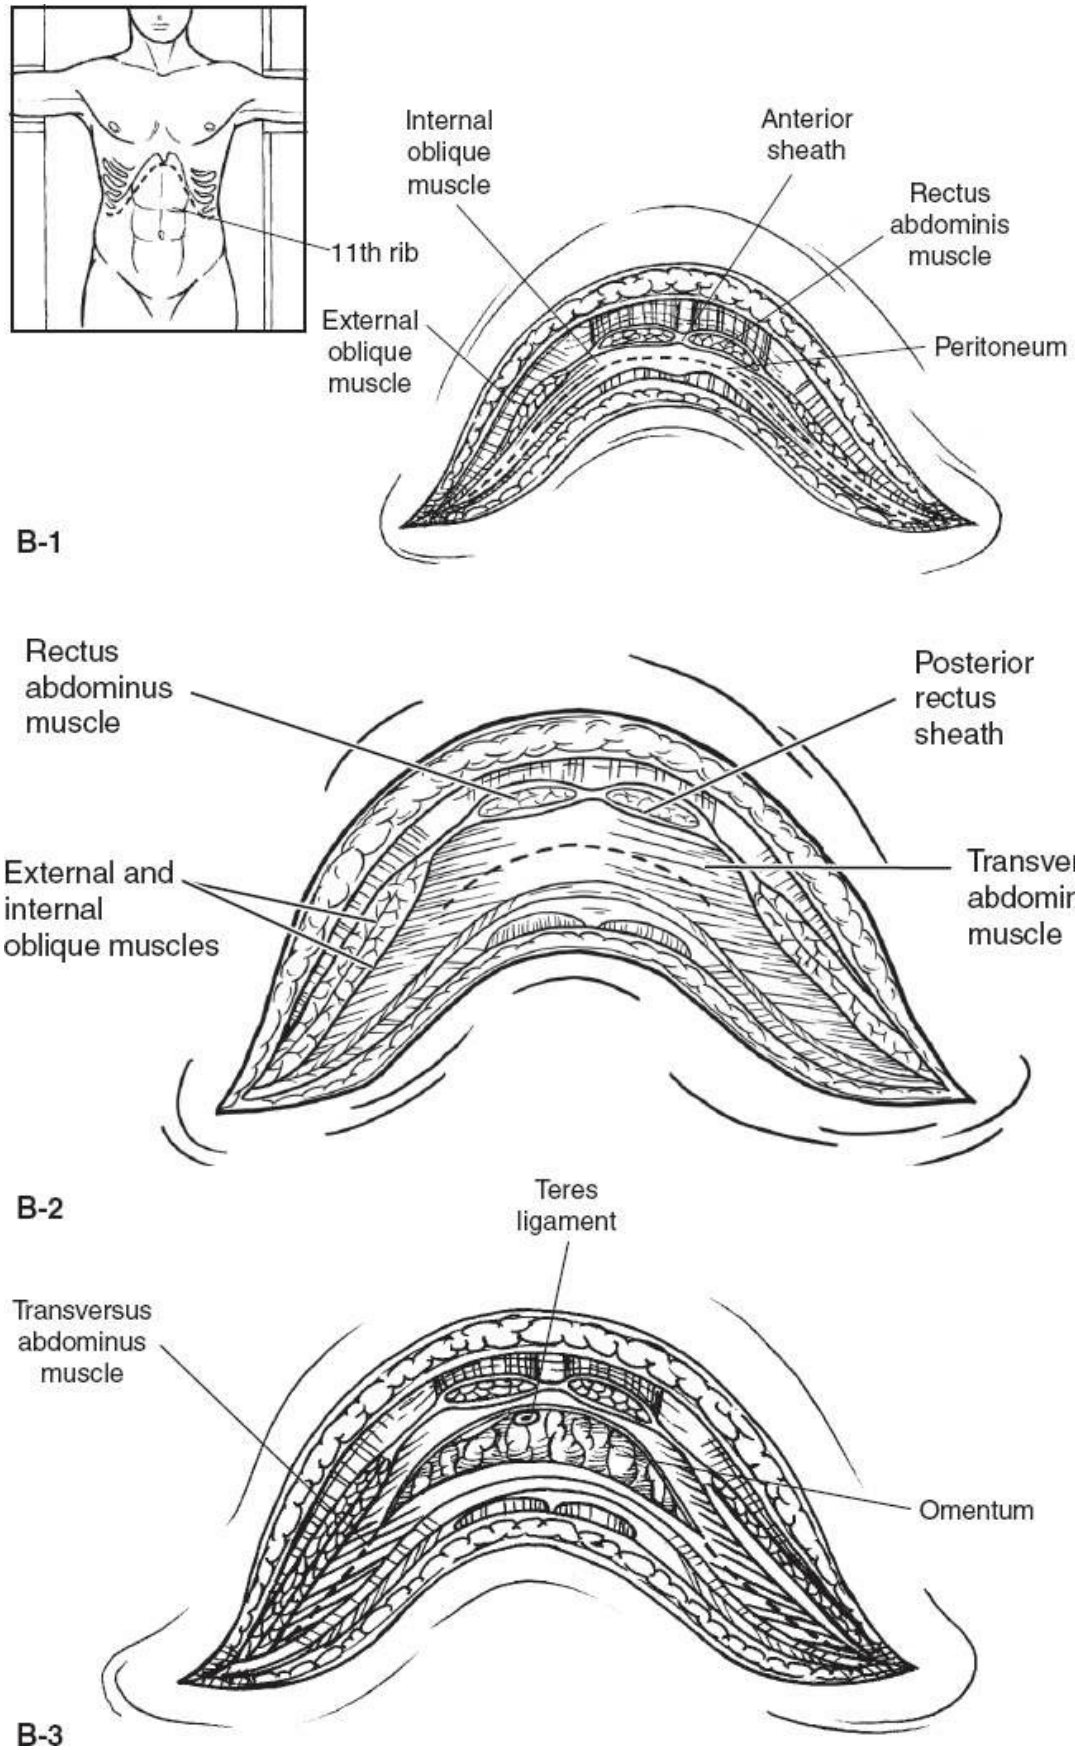

Figure 174.3. Incision using the chevron or subcostal approach. The incision begins at the tip of the ipsilateral 11th rib and

remains 2 fingerbreadths below the costal margin, extending medially to the midline near the xiphoid process.

Once the specimen is completely free, it is removed from the patient and sent as specimen. Lymph node dissection can be performed as indicated. If nodes are removed, it is critical that clipping of lymphatic channels be meticulously performed to minimize the risk of lymphatic leak. Meticulous hemostasis should be obtained. In particular, the integrity of hilar control should be evaluated, and the adrenal gland/bed inspected.

Transabdominal Approach

ORN can also be performed transabdominally or intraperitoneally. The initial steps of this procedure diverge from the retroperitoneal approach, although hilar control is performed with a similar technique. Upon entering the peritoneal cavity, a self-retaining retractor is placed. The white line of Toldt is incised to medialize the ascending or descending colon off of the anterior surface of Gerota's fascia depending on laterality (see Fig. 174.6). On the left side, the splenorenal ligament is incised to mobilize the spleen cephalad and medial from the upper pole. On the right side, the hepatic flexure is mobilized from the right upper pole. The colon mesentery should be carefully preserved. On the right side, the duodenum will typically be encountered overlying the hilum and should be carefully Kocherized. Use of cautery should be stringently avoided in the vicinity of the duodenum to avoid inadvertent thermal injury. On the left side, reflection of the colon should proceed with awareness of the pancreas and splenic vessels, which can ordinarily be avoided. Reflection of these structures should be relatively avascular based on ordinarily good tissue planes between the peritoneum and retroperitoneum. The remainder of the procedure occurs as stated above.

RADICAL NEPHRECTOMY WITH INFRAHEPATIC VENA CAVAL INVOLVEMENT

RCC may have venous extension from the renal vein to various levels in the IVC, and extend as high as the right atrium. Staging of IVC thrombus includes level I (adjacent to the ostium of the renal vein), II (extending to the lower aspect of the liver), III (involving the intrahepatic portion of the IVC but below the diaphragm), and IV (extending above the diaphragm). It is critical that patients have recent staging imaging by CT or MRI to

assess level of thrombus to inform the need for vascular and/or cardiothoracic surgical consultants. Thoracoabdominal incisions are preferred for right-sided tumors, whereas bilateral subcostal or a long midline incision can be utilized for left-sided tumors to enable exposure of the ipsilateral kidney as well as the IVC.

For management of tumor thrombus, ORN is initially performed as discussed above. The specimen is completely mobilized except for the renal vein in continuity with the cava; manipulation of the venous structures is minimized. The cava is widely exposed to provide full vascular control. If the thrombus extends partly into the vein, there may be sufficient margin to control the vein on the cava side with ties or a stapler. If this is not feasible, the cava may need to be side-clamped, and the vein with a cuff of cava resected. If there will be <50% decrease in circumferential diameter of the cava, the cava can be primarily repaired with 4-0 Prolene. If the thrombus extends cephalad into the cava, the cava will have to be opened with proximal and distal control, and a portion of the caval wall may require resection along with the specimen. Primary repair can again be performed if there is not significant narrowing (>50%), or patch graft repair with bovine pericardium or expanded polytetrafluoroethylene (ePTFE) can be performed. If thrombus extends further cephalad to the retrohepatic cava, further maneuvers are required including mobilization of the liver and ligation of retrohepatic venous branches. Venovenous bypass may be needed if test clamping of the cava above the thrombus leads to significant hypotension. Cardiopulmonary bypass and circulatory arrest may be needed for thoracic and intracardiac extension of tumor thrombus.

OPEN PARTIAL NEPHRECTOMY

OPN is performed for resection of renal lesions for which cold ischemia is desired in anticipation of longer clamp times, that is, for larger and/or deeper tumors, and/or in patients with an imperative indication for NSS, for example, solitary kidney, bilateral masses, preexisting renal dysfunction. In addition, OPN is performed when NSS is preferred, but there are not capabilities for a minimally invasive approach. The goal of partial nephrectomy is to remove the mass while sparing normal renal tissue. Unlike radical nephrectomy, in which Gerota’s fascia is left intact, partial nephrectomy requires entering Gerota’s fascia to identify the tumor itself. Typically a resection of tumor with a margin of at least several

millimeters of normal tissue is performed. However, in certain cases of well-circumscribed tumors, particularly deep tumors abutting the renal vessels, or in cases of multiple tumors, enucleation can be performed to minimize damage to vital adjacent structures and enable preservation of uninvolved kidney without obtaining a positive margin.

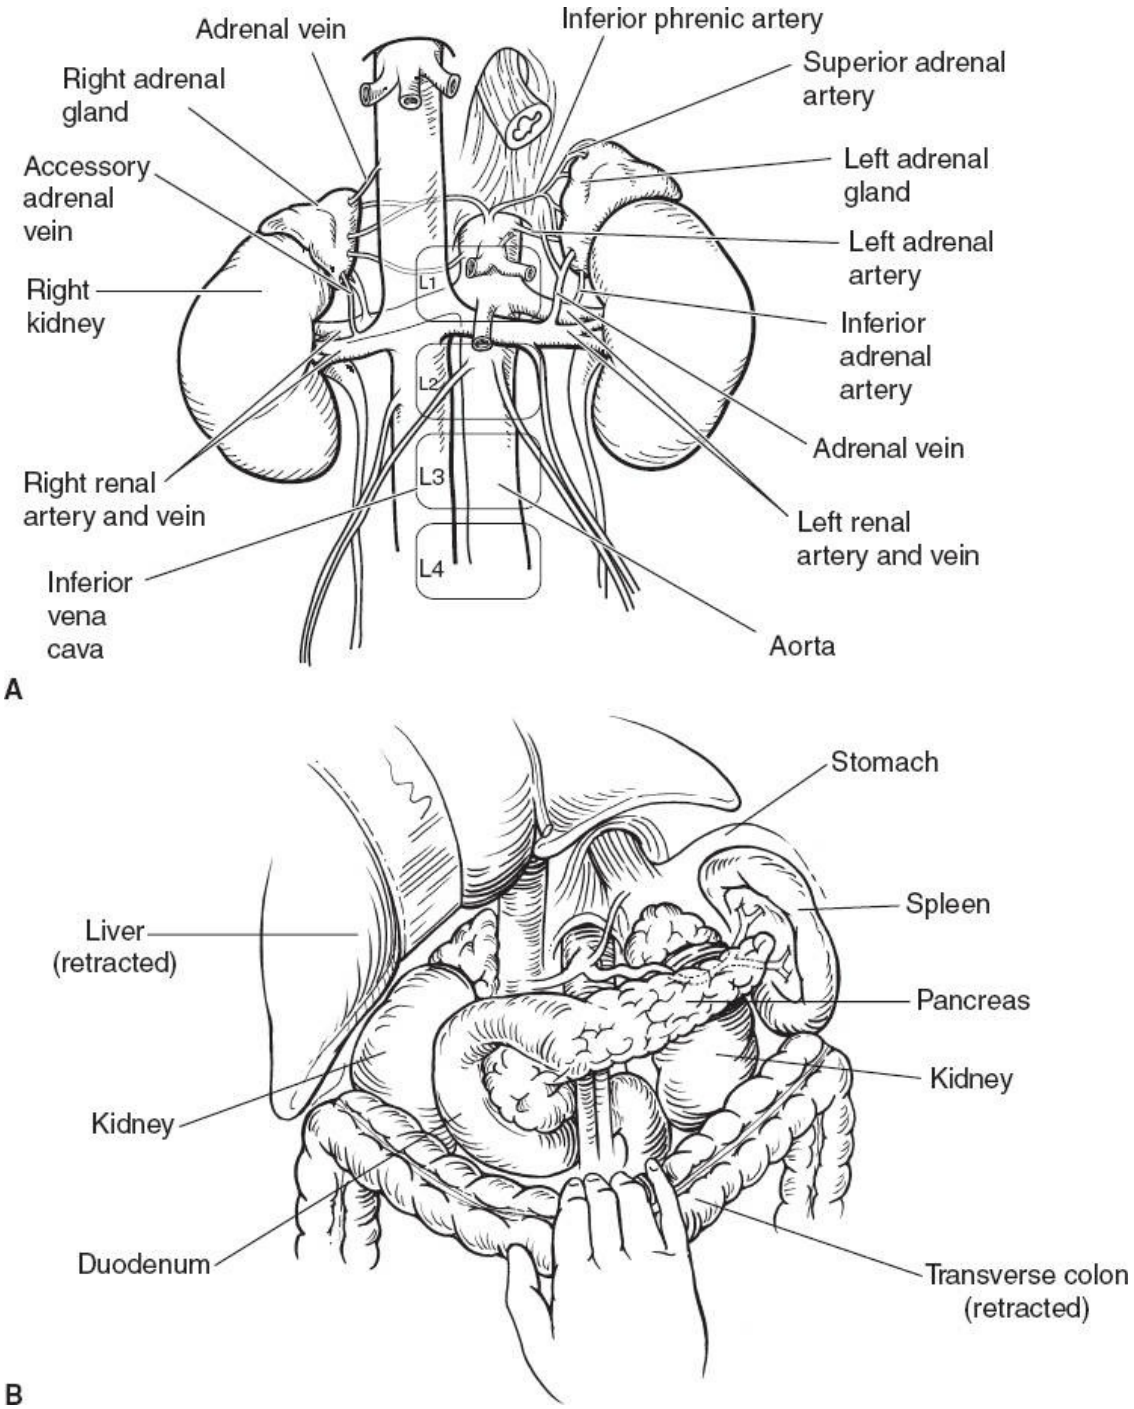

Figure 174.4. Anatomical relationships of kidney, adrenal glands, and associated organs.

For OPN, the kidney should be separated from adjacent structures in all directions to ensure ready access to the renal hilum. Gerota's fascia is entered away from the tumor itself, as perinephric fat overlying the tumor should be preserved to be sent as specimen. Intraoperative ultrasound is used to confirm the location, shape, and depth of tumor; for purely endophytic tumors, this may be the only means of tumor identification. The renal capsule is exposed circumferentially around the tumor leaving adequate space for a resection line and sutures to be used for renorrhaphy. The intended line of resection is superficially marked with cautery. Capsule should be left intact to ensure sutures used to repair the defect are held by strong tissue, as renal parenchyma itself may easily tear. The hilum is fully dissected to enable temporary clamping of the hilum. Accessory vessels should be sought, as a missed artery can cause significant bleeding during tumor resection. The renal vein should be exposed as well, as it can be clamped per surgeon preference. The vessels are marked with color-coded vessel loops, and each is doubly encircled with a loop so that gentle traction can compress the vessel. The ureter is marked with a vessel loop as well as the surgeon should always be keenly aware of the location of this structure to avoid inadvertent injury.

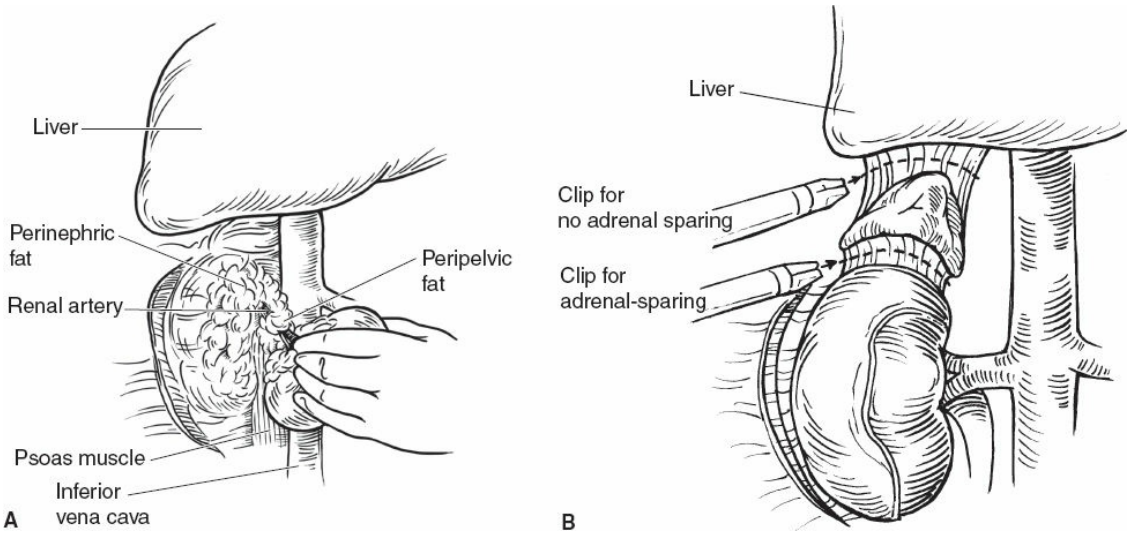

Figure 174.5. **A.** The kidney is lifted off the retroperitoneum; there is a fat plane between the peripelvic and perinephric fat. **B.** The attachments between the kidney and adrenal gland are dissected.

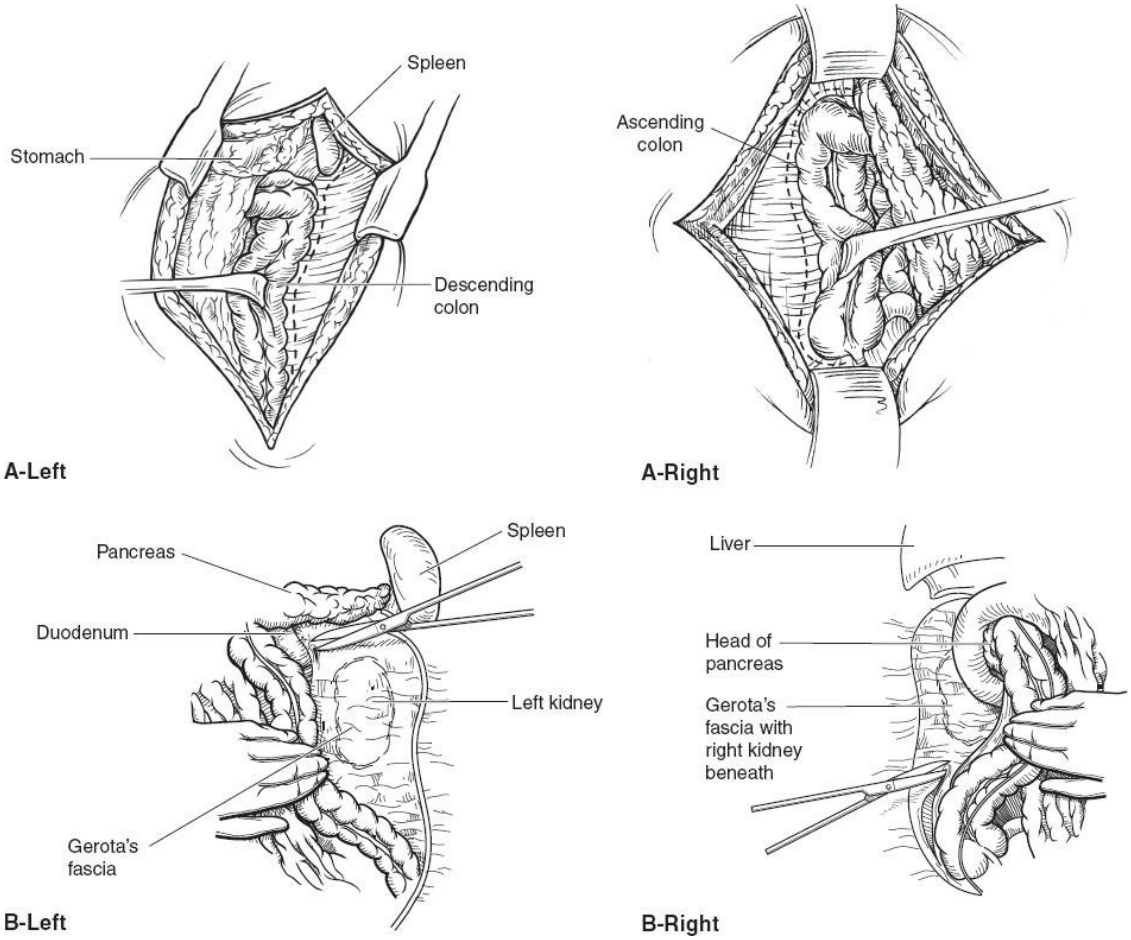

Figure 174.6. The colon is reflected medially to expose the right (**A**) or left (**B**) kidney and great vessels. When approaching the right kidney (**C**), the colon is reflected with the mesentery up off the Gerota's fascia. The colon is held at a right angle to Gerota's fascia and blunt dissection is used to separate the two. When approaching the left kidney (**D**), the mesocolon also separates off Gerota's fascia, leading down to the duodenum.

Prior to initiating renal ischemia, the patient is given 12.5 g of intravenous mannitol and 20 mg intravenous lasix for the purpose of minimizing reperfusion injury. Instruments and sutures for resection and renorrhaphy should be readily available prior to going on clamp. Then, bulldog clamps are placed on the renal artery and vein for occlusion. The kidney is "iced" by placing a bowel bag around the kidney; this is placed upside down, with the draw string pulled around the base, and the bottom cut out to allow exposure to the kidney. Chopped ice is placed in the bag and the kidney is cooled for at least 10 minutes. There are various techniques for tumor resection, but we prefer the use of a Metzenbaum scissors to incise the previously marked line of resection circumferentially.

Resection proceeds with a margin of at least 3 mm from the specimen. Cutting to renal sinus fat and/or collecting system may be necessary to ensure a negative deep margin. A Penfield dissector, or the handle of a scalpel blade, can be used for blunt dissection and/or enucleation per surgeon preference. Frazier tip suction can be used to evacuate backbleeding from the defect. When the specimen is removed, it is inspected to ensure there is a grossly negative margin. If there is concern for residual tumor, further resection and/or biopsy from the base of the defect can be performed. Routine frozen section analysis of a biopsy from the base can be done for patient reassurance but is not necessary.

The base of the defect is then examined, and discrete blood vessels and collecting system are oversewn. This is done in running or figure-of-eight fashion with absorbable suture such as 3-0 vicryl or chromic. High current electrocoagulation such as argon beam can be used along the cut surface to improve hemostasis. Then, closure of the defect is performed. This can be performed with horizontal mattress sutures placed 90 degrees to one another, with or without use of a bolster, typically with 2-0 vicryl suture. Bolsters are typically made from Surgicel (Ethicon, Somerville, NJ), which is oxidized cellulose to promote clotting. Our preferred technique is termed the “Weck sliding technique,” which emulates the laparoscopic approach. Individual sutures (2-0 vicryl) are placed across the defect in simple fashion, ensuring that a healthy bite of capsule is taken on either side for strength. These sutures are pre-made by the scrub nurse to have a Weck clip (Teleflex, Research Triangle Park, NC) on the side opposite the needle, with a knot at the end of the suture to prevent clip dislodgement. After the suture has been placed across the defect, a second Weck clip is placed on the needle side of the suture, and firmly but carefully slid down to the renal capsule, with sufficient tension for dimpling of the kidney but without tearing through. This Weck is secured with another Weck clip or a Lapra-Ty (Ethicon, Somerville, NJ) to prevent dislodgement. We feel that this technique allows for excellent closure of the defect in expeditious fashion.

After closure of the defect, the bulldog clamps are removed from the hilum. The venous clamp if present should be removed first. The arterial clamp is removed and the defect observed. Bleeding from the defect if mild can be observed as venous bleeding may stop from tamponade effect as the kidney fills. However, if there is substantial bleeding, additional bolster sutures can be placed. Repeat clamping should be avoided if

possible to minimize reperfusion injury; however, this can be performed if hemostasis cannot be readily obtained. With significant persistent bleeding, the initial renorrhaphy may need to be taken down and the defect inspected for an arterial vessel.

At this time, the vessel loops are removed and the ureter inspected to ensure its integrity. Perirenal fat can be secured over the defect for tissue coverage, if possible. Closure proceeds as discussed above. We routinely place a 10-mm Jackson-Pratt drain adjacent to the kidney through the skin through a separate stab incision, usually inferior to the wound.

"Clamp-less" partial nephrectomy can be performed as well for small exophytic tumors. Bleeding during resection can be profuse and can obscure the deep margin; thus, patients for clampless procedures should be carefully selected. Patients with preexisting CKD may be candidates for this procedure as the risk of ischemia may outweigh transient operative bleeding.

LAPAROSCOPIC RADICAL NEPHRECTOMY

Laparoscopy is the approach of choice for radical nephrectomy in most patients. LRN is typically performed transperitoneally; thus, the steps of surgery are quite similar to the transabdominal open approach described above. A retroperitoneal approach can also be utilized and will be discussed below. For the transperitoneal approach, the patient is positioned in a modified lateral position at ~30 to 45 degrees. He/she is carefully secured to the table with surgical tape as the table will be tilted for the majority of the operation. A Pfannenstiel or lower vertical midline incision (in men) is premarked on the abdomen for extraction.

Laparoscopic access is achieved by either Veress or Hassan techniques. The abdomen is insufflated to 15 mm Hg. Incisions are marked on the abdomen for camera and working ports. A camera port is placed periumbilically for patients with normal body habitus; however, for obese or large patients, we shift the camera port laterally and superiorly to where the "adjusted" umbilicus would be. Then 10- to 12-mm working ports are placed one hand's breath laterally and superiorly to the camera port. Optical access for the initial port is preferred in the cases of prior abdominal surgery. For right-sided cases, a 5-mm port will be placed subxiphoid for placement of a self-retaining liver retractor. We prefer placement of a locking grasper under the liver for anterior and superior retraction; this is secured superficially to the peritoneum overlying the

diaphragm in the right superolateral abdomen. An additional assistant port can be placed in the lower abdomen within the intended extraction incision. We prefer to use a 15-mm port for this assistant port, as a large specimen bag will be placed here for ultimate extraction. This may be less useful in larger patients for whom reach to the upper abdomen may not be feasible. The table is then maximally rotated toward the contralateral side of surgery to medialize the visceral contents.

A laparoscopic grasper (e.g., DeBakey's) is used in the left hand, and a monopolar shears in the right hand. We will exchange the shears for a simultaneous coagulation/cut device like the Harmonic scalpel (Ethicon, Somerville, NJ) or LigaSure. The line of Toldt is incised to a point just superior to the iliac vessels to release the colon and expose the anterior surface of Gerota's fascia. Importantly, the lateral attachments are preserved to enable lift of the kidney to expose the hilum later in the case. The spleno- or hepatorenal attachments are released to expose the upper pole of the left- and right-sided kidneys, respectively. On the right side, the duodenum is carefully Kocherized using athermal technique to reveal the renal vein; the tail of the pancreas is carefully reflected medially on the left side. The kidney is carefully lifted anteriorly and the medial lower pole attachments are assessed. The plane posterior to the kidney, above the psoas muscle, is bluntly entered. It is important, during this step, to identify the ureter and the gonadal vein to avoid inadvertent injury. The ureter and the gonadal vein on the left side are elevated anteriorly with the kidney to put the medial attachments and renal hilum on "stretch." This stretch is the most important facet of LRN as it allows safe and expeditious dissection of the hilum. The medial attachments are released to the level of the renal vein. On the left side, the insertion of the gonadal vein into the renal vein will be seen. In addition, on the left side there is typically a lumbar vein running posteriorly from the renal vein that prohibits full lift and exposure of the artery. This lumbar vessel requires dissection and control. Once the renal artery is identified, typically posterior to the vein, it is controlled and released with a vascular stapler. Accessory arteries can be sought and controlled depending on preoperative imaging and intraoperative inspection. When the artery has been controlled, the vein is taken with a vascular stapler as well. For adrenal sparing, Gerota's fascia is entered adjacent to the adrenal and it is released from the kidney. The remaining renal attachments are released, and the kidney is placed in a specimen bag. Reassessment of the hilar staple line and adrenal bed is

performed to ensure complete hemostasis.

Retroperitoneal LRN can also be performed, though less commonly. This approach is considered if there has been significant prior transperitoneal surgery, and the patient strongly desires a minimally invasive approach. Advantages of retroperitoneoscopy include rapid access to the renal hilum, as the renal artery can be rapidly identified. The major disadvantage of this approach is limited working space, which can make this procedure more challenging. For this approach, the patient is placed in full flank position. The tip of the 12th rib is identified and a 2- to 3-cm incision made at the tip of the rib. Dissection is performed through initial tissue layers, then a Kelly clamp is used to enter the retroperitoneal space. Finger dissection is performed to release the retroperitoneal fat and peritoneum off of transversus abdominus and quadratus lumborum. The retroperitoneal space is developed using a balloon insufflator. A camera port is placed in this initial access tract. Two additional 10-mm working ports are placed superomedially and superolaterally under vision. The peritoneum is bluntly reflected to increase working space, with care not to enter the peritoneal cavity, as this will result in loss of retroperitoneal insufflation. The psoas is identified as the initial landmark, and the kidney is elevated to expose the posterior hilum. The artery and the vein are controlled and the remainder of the kidney dissected. Extraction can be performed by extension of the initial incision or through a Gibson incision.

MINIMALLY INVASIVE PARTIAL NEPHRECTOMY

MIPN has been increasingly performed in an era in which both minimally invasive techniques and NSS have been prioritized. LPN has been the traditional minimally invasive approach to NSS; however, the technical challenges of intracorporeal suturing have been a major impediment to dissemination of this technique. Robotic assistance using the DaVinci system (Intuitive, Sunnyvale, CA) has recently been applied to LPN, and has provided substantial benefits regarding ergonomics and suturing dexterity.

MIPN is typically performed transperitoneally but can be performed retroperitoneally, akin to LRN as discussed above. The steps of surgery are initially equivalent to LRN, with reflection of the colon, release of adjacent structures, and exposure of Gerota’s fascia. The ureter and gonadal vessels are identified and the kidney lifted anteriorly. The hilum is dissected but preserved for clamping. Warm ischemia is used for MIPN as

there is no reliable method of cooling the kidney intracorporeally. Gerota's fascia is entered away from the tumor, and exposure of the kidney surface circumferentially around the tumor is performed. Laparoscopic ultrasound is used for confirming tumor location and depth, akin to the open approach. The resection line is marked with cautery, and the hilum is clamped using laparoscopic bulldogs. Resection is performed with cold shears. The tumor is placed to the side, and a biopsy can be taken from the base of the defect. Discrete large vessels and collecting system are oversewn laparoscopically or robotically. Suturing can be done in figure-of-eight fashion, or by running a suture through the defect. We use 3-0 vicryl suture for this purpose. Argon beam can be used to cauterize the raw resection edges within the defect. Then, parenchymal sutures are placed in simple fashion across the defect with care to include generous capsule for strength. The Weck sliding technique as described above is utilized. A bolster is optional but may be used for wider defects. After closure of the defect, the hilar clamps are released (vein first) and the renorrhaphy is observed. Mild bleeding will typically cease with tamponade effect, but persistent or brisk bleeding may require additional sutures placed across the defect. Similar to open surgery, the need for reclamping is rare. A drain is placed equivalently to the open procedure.

POSTOPERATIVE MANAGEMENT

Patients are treated on an inpatient basis following nephrectomy. Immediately postoperatively, the orogastric tube is removed. If patients are hemodynamically stable, complete blood count (CBC) and basic metabolic panel (BMP) are checked the morning of postoperative day (POD) 1; bloodwork can be sent postoperatively depending on clinical concern. Early ambulation is encouraged. Use of minimally invasive approaches shortens hospitalization to 1 to 2 days for LRN patients, and ~2 days for MIPN patients. Open surgical patients have variable hospitalization times depending on postoperative pain, but average length of stay is 3 to 4 days. Diet is initiated with sips of clear liquids on the evening of surgery, and is advanced as tolerated. Patients with flank incisions have more postoperative pain and may have issues with splinting and atelectasis. Incentive spirometry, early ambulation, and effective pain management are critical to minimize pulmonary complications in these patients.

For radical nephrectomy patients, the Foley catheter is typically removed on POD 1 and/or when the patient is ambulating well. For

patients undergoing partial nephrectomy, the Foley catheter is generally left in place for 2 days. On the morning of POD 2, the Foley is removed and output from the perirenal drain is observed. If output is low (<30 cc/shift), it may be pulled. However, if the output increases with removal of the Foley and/or there is >30 cc drainage/shift, the fluid should be sent for creatinine assessment. If it is equal to serum creatinine, there is no urinary leak and it may be removed; if fluid creatinine is elevated, it should be left in place until the leak seals.

LONG-TERM FOLLOW-UP

Postoperative surveillance following nephrectomy depends primarily on final pathology, specifically tumor stage. There are variable recommendations for timing of surveillance, but we generally follow the protocol recommended by the National Comprehensive Cancer Network (NCCN Web site). Timing of follow-up exams is based pathologic stage. Patients have interval history and physical exams, abdominal imaging (CT or MRI), chest imaging (chest x-ray), and bloodwork including liver function tests and BMP. Development of CKD warrants referral to a nephrologist for counseling.

COMPLICATIONS

Intraoperative Complications

Bleeding may be encountered during nephrectomy from various sources. Venous bleeding, in particular, generally resolves with manual pressure, even from the renal vein or vena cava. During laparoscopic nephrectomy, increasing the abdominal insufflation pressure to 20 mm Hg and holding manual pressure, often with an intracorporeal “lap pad,” may be effective. The sites prone to venous bleeding include the entry of lumbar veins into the posterolateral vena cava, where the right gonadal vein enters the cava on the anterolateral surface, where a lumbar vein often enters the left renal vein posteriorly, and the short right renal vein from the cava that can avulse without care. Large tumors with parasitic vessels may be at increased risk for bleeding during dissection, and these vessels should be carefully identified and controlled. In addition, the adrenal gland is typically friable and can ooze during dissection; this will typically resolve with pressure as well. Arterial bleeding requires identification of the cut vessel and clip or suture control. If a vascular injury requires suturing, 4-0

or 5-0 Prolene suture can be used. An Allis clamp or Satinsky clamp can be used to oppose edges of the vascular defect to enable suturing. There should be a low threshold to involve a vascular surgeon in larger vessel repair.

Bowel injuries are rare and typically are avoided with constant awareness of the location of the bowel. Athermal technique should always be used for bowel mobilization. Mobilization of the duodenum on the right side, in particular, should be performed carefully as duodenal injuries can be devastating. Sharp injuries to bowel should be repaired via suture imbrications with silk suture. Thermal injuries if recognized should be similarly oversewn.

Injury to the spleen or liver can occur typically from avulsion of renal attachments. Delicate manipulation of these structures during release is critical to avoid injury. Management of these injuries, if minor, includes pressure and coagulation (e.g., argon beam). For more significant splenic injuries, splenectomy may be necessary. Also, the pancreas should be identified and treated with extreme care during nephrectomy; gentle manipulation is needed to avoid postoperative pancreatitis or pancreatic leak.

Diaphragmatic and/or pleural injuries can be encountered during nephrectomy. The chest may be deliberately entered during open surgery, and should be evacuated and closed by the methods described above. This avoids significant postoperative pneumothorax. If a diaphragmatic injury occurs laparoscopically, this can be repaired via laparoscopic suturing. If there is concern for pleural injury and pneumothorax, a small chest tube can be placed, or an angiocatheter is placed in the lateral chest and attached to intravenous tubing that is placed in a basin under water. Deep breaths are delivered by anesthesia and the air evacuated as detected by bubbles in the water. The angiocatheter is subsequently removed.

Postoperative Complications

There are some postoperative complications unique to partial nephrectomy that deserve mention. Delayed bleeding can occur based on pseudoaneurysm or arteriovenous fistula formation. This can occur from several days to several months postoperatively, and can be associated with precipitous bleeding. There is frequent fistulous formation to the connecting system and severe gross hematuria. The gold standard for both diagnosis and treatment of these vascular lesions is angioembolization,

which should be promptly performed if there is a high index of suspicion.

Urine leak can also occur after partial nephrectomy. The perirenal drain will frequently have increased output, and will have an elevated fluid creatinine level. For modest elevations of fluid creatinine, the drain can be left in place for an additional 1 to 2 weeks, then removed if there is resolution of leak based on fluid creatinine levels. An abdominal imaging study (e.g., CT) should be obtained to ensure there is no undrained perirenal urinoma, and as well as no distal obstruction within the ureter from a blood clot. A CT with intravenous contrast and delayed images is diagnostic of ongoing urine leak. More substantial urine leaks require placement of a ureteral stent to maximize antegrade drainage and decrease intrarenal pressure; a Foley catheter should be replaced in these patients as well to avoid vesicoureteral reflux. When healing is confirmed (e.g., via repeat CT w/delayed images, or retrograde pyelogram), the drain and stent can be removed.

If the patient presents at a delayed interval from partial nephrectomy with a symptomatic perirenal collection, urinoma should be considered and a percutaneous drain should be placed. A drain should be placed immediately if there is a suspicion for an infected collection based on clinical signs and symptoms. Collections adjacent to the kidney following nephrectomy may also be hematoma or lymphocele, particularly in the setting of concomitant lymphadenectomy with nephrectomy. Lymphocele is generally managed with percutaneous drainage and a medium chain triglyceride diet.

In addition, patients may have acute elevations of creatinine following radical or partial nephrectomy. In radical nephrectomy patients, this requires careful trending and possibly involvement of a nephrologist. Following partial nephrectomy, a rising creatinine +/− flank pain may be indicative of ureteral obstruction from clot, and a renal ultrasound or CT should be performed to rule out hydronephrosis.

EDITOR'S COMMENT

Kidney cancer is among the 10 most frequently diagnosed cancers in the United States with an estimated incidence of more than 62,000 new cases in 2016 (Siegel RL, Miller KD, Jemal A. Cancer statistics, 2016. *CA Cancer J Clin* 2016;66(1):7–30). The overall 5-year survival rate for kidney cancer is 74%, decreasing to 53% among patients with locoregional disease and 8% among patients with metastatic disease. Interestingly, this survival demonstrates a temporal trend with survival increasing from 57% in 1987−1989 to 74% in 2006−2012 (Li P, Wong YN, Armstrong K, et al. Survival among patients with advanced renal cell carcinoma in the pretargeted versus targeted therapy eras. *Cancer Med* 2016;5(2):169–181). Many suggest that this improvement in clinical outcomes is attributable in part to a higher proportion of indolent and low-stage tumors identified using enhanced early-detection techniques. The role of surgery in these patients cannot be understated as the evolution of treatment options has accompanied this differing presentation of RCC.

Perhaps the most notable change in the treatment of kidney cancer is the shift from open radical nephrectomy with its attendant morbidities to minimally invasive alternatives shown to reduce or avoid these inherent negative consequences. Drs. Hyams and Allaf have done an outstanding job of reviewing the role of radical nephrectomy in this patient population. I would like to take the opportunity to expound on two key points related to the surgical management of kidney cancer. First, I will evaluate the role of lymphadenectomy in this patient population. I will then discuss the surgical management of metastatic disease.

Although regional lymphadenectomy is a cornerstone of surgical oncology, its role in the management of kidney cancer is limited owing to the disease's potential for hematogenous and lymphatogenous spread. Lymphatic drainage of the kidney tumors can be divided into anterior, posterior, and intravascular drainage relative to their position to the renal vein. Lymphadenectomy is accepted for 4% to 5% of cases with clinically positive disease (Capitanio U, Jeldres C, Patard JJ, et al. Stage-specific effect of nodal metastases on survival in patients with non-metastatic renal cell carcinoma. *BJU Int* 2009;103(1):33–7); however, the advent of imaging technology and the subsequent discovery of smaller tumors have resulted in the investigation of sentinel lymph node biopsy for the identification and removal of microscopic disease. A reasonable extension of this work would include evaluation of the role of sentinel lymph node biopsy in the management of small renal cancers.

Approximately 30% of patients with RCC present with metastatic disease. A recent analysis by the Surveillance, Epidemiology, and End Results Program (SEER) database revealed that only 35% of patients diagnosed with advanced renal cell cancer between 2000 and 2013 underwent nephrectomy as their initial therapy; therefore, the role of surgery on the management of metastatic disease

is of utmost importance. Current factors to be considered prior to cytoreductive nephrectomy include histology, performance status, symptoms form disease, burden of metastatic disease, Memorial Sloan Kettering Cancer Center Risk Criteria, and the risk of surgical complications (Vaishampayan UN. The role of nephrectomy for kidney cancer in the era of targeted and immune therapies. *Am Soc Clin Oncol Educ Book* 2016;35:e16–20).

Hormonal therapy and cytotoxic chemotherapy have little to no activity in metastatic renal cell cancer while immunotherapeutic approaches with interferon-α and high-dose interleukin-2 have response rates of 12% and 23%, respectively. Two randomized trials have shown that patients who underwent cytoreductive nephrectomy followed by interferon-α experienced longer overall survivals relative to patients treated with interferon alone (Flanigan RC, Yonover PM. The role of radical nephrectomy in metastatic renal cell carcinoma. *Semin Urol Oncol* 2001;19(2):98–102; Mickisch GH, Garin A, van Poppel H, et al. Radical nephrectomy plus interferon-alfa-based immunotherapy compared with interferon alfa alone in metastatic renal-cell carcinoma: a randomised trial. *Lancet* 2001;358(9286):966–70). This difference might be attributable to an improvement in host immune reaction as clinically spontaneous regressions have been observed in patients after cytoreductive nephrectomy (Dadian G, Riches PG, Henderson DC, et al. Immunological parameters in peripheral blood of patients with renal cell carcinoma before and after nephrectomy. *Br J Urol* 1994;74(1):15–22; Uzzo RG, Clark PE, Rayman P, et al. Alterations in NFkappaB activation in T lymphocytes of patients with renal cell carcinoma. *J Natl Cancer Inst* 1999;91(8):718–21). The emergence of immune checkpoint inhibitors for the treatment of renal cell cancer invites continued study of cytoreductive nephrectomy prior to the initiation of these potent immunoodulators.

The current era of targeted therapy for metastatic renal cell cancer has raised very interesting issues regarding the role of cytoreductive nephrectomies in this cohort of patients treated with antiangiogenic agents as well as mTor and tyrosine kinase inhibitors. Two retrospective studies reported improved overall survival in patients treated with cytoreductive nephrectomies prior to the initiation of targeted systemic therapy (Choueiri TK, Xie W, Kollmannsberger C, et al. The impact of cytoreductive nephrectomy on survival of patients with metastatic renal cell carcinoma receiving vascular endothelial growth factor targeted therapy. *J Urol* 2011;185(1):60–6; Heng DY, Wells JC, Rini BI, et al. Cytoreductive nephrectomy in patients with synchronous metastases from renal cell carcinoma: results from the international metastatic renal cell carcinoma database consortium. *Eur Urol* 2014;66(4):704–10). However, these trials have well-recognized selection biases favoring systemic therapy alone in poor-risk patients. Two large, prospective trials are underway to consider the role of cytoreductive nephrectomy for patients being treated with targeted therapy. Patients in the CARMENA trial will be randomized to sunitinib versus sunitinib following cytoreductive nephrectomy. The SURTIME trial will evaluate

patients randomized to sunitinib followed by nephrectomy versus sunitinib alone (Vaishampayan UN. The role of nephrectomy for kidney cancer in the era of targeted and Immune therapies. *Am Soc Clin Oncol Educ Book* 2016;35:e16–20). These trials will hopefully provide insight into the potential synergy between cytoreductive nephrectomy and systemic therapy.

175 Radical Cystectomy and Orthotopic Urinary Diversion for Bladder Cancer

Eila C. Skinner and Siamak Daneshmand

INTRODUCTION

In the United States, urothelial carcinoma of the bladder is the second most common malignancy of the genitourinary tract, and the second most common cause of death of all genitourinary tumors. In the United States and the European Union, bladder cancer (BCa) accounts for approximately 180,000 new cancer diagnoses and >50,000 deaths annually. Approximately 75% of patients with primary urothelial carcinoma of the bladder present with tumors confined to the superficial mucosa. These tumors carry a high risk of recurrence but low risk of progression to invasive or metastatic disease, especially if low grade. Nonmuscle invasive tumors are initially managed with transurethral endoscopic resection and in some cases administration of intravesical therapy. However, 20% to 40% of all patients will either present with or develop a high-grade, invasive tumor of the bladder. If left untreated, the majority of patients with muscle invasive bladder cancer will die of the disease within 2 years of diagnosis. Radical cystectomy is considered the most effective therapy for patients with high-grade, muscle invasive bladder and patients with nonmuscle invasive cancers at high risk of progression that are not controlled with intravesical therapies.

Invasive bladder tumors tend to progressively invade through muscularis propria into the perivesical fat, and then into contiguous pelvic organs, with an increasing incidence of lymph node involvement at each level. While distant metastases can appear in the absence of deep invasion, in most patients nodal involvement precedes distant metastatic disease, and the latter can be prevented by cystectomy when the tumor is organ-confined.

With improvements over the past several decades in medical, surgical, and anesthetic techniques, the morbidity and mortality associated with

radical cystectomy have dramatically decreased. Prior to 1970, the perioperative mortality rate of cystectomy was nearly 20%. This has significantly diminished to 2% to 3% in contemporary series. However, postoperative complications are still common with this surgery, even in expert hands, and this has not really been impacted by adoption of minimally invasive techniques. Several studies have shown that morbidity, mortality, and cost are all less for both surgeons and hospitals with higher case volumes.

In addition to the potential for cure, a properly performed radical cystectomy with pelvic lymphadenectomy provides optimal local control of the tumor, with <10% pelvic recurrence for patients with node-negative disease. Local symptoms can be extremely debilitating for patients, with bleeding, urinary frequency, pain, and obstruction. These may stimulate consideration of palliative cystectomy even in patients with metastatic disease.

The Bricker ileal conduit (or urostomy) has been the most popular form of urinary diversion since it was described in the 1950s, and today accounts for 85% to 90% of diversions in patients undergoing cystectomy in the United States. However, many patients are unwilling to accept a permanent stoma, and reconstruction with an orthotopic ileal neobladder urinary diversion has provided an attractive alternative. This may allow both patients and surgeons to consider this surgery earlier in the disease process when it has the best chance of cure. Orthotopic reconstruction eliminates the need for a cutaneous stoma or urostomy appliance, and in most cases the need for intermittent catheterization. In our experience, many if not most patients will choose this option when presented with the pros and cons of each type of diversion.

There are two randomized trials underway to try to clarify the relative benefit of a more extended dissection. Based on nonrandomized studies suggesting improved outcomes with a more extended dissection, we have advocated performing a lymph node dissection with the proximal boundary above the aortic bifurcation at the level of the inferior mesenteric artery and extending laterally to the genitofemoral nerve (lateral limits of dissection), and distally to the lymph node of Cloquet, including a thorough dissection of the obturator, internal iliac, and presacral nodes.

This chapter will detail the perioperative management, surgical technique, and clinical results and outcomes of radical cystectomy and orthotopic ileal neobladder.

ANATOMY

The empty bladder is roughly triangular in shape, with only the top covered by peritoneum. It lies within the true pelvis, and the extraperitoneal space around the sides is known as the space of Retzius. The detrusor muscle of the bladder is closely covered by the perivesical fat, which can be removed only with some difficulty. In both males and females, the anterior bladder lies free of any attachments to the abdominal wall except through the urachal remnant (median ligament), which extends up to the umbilical scar in the midline. Deep in the pelvis the endopelvic fascia reflects from the pelvic floor up onto the prostate and bladder. A consolidation of this fascia, the puboprostatic ligament, fixes the prostatic apex to the undersurface of the pubic bone. Levator muscle fibers also attach to the prostatic apex. A similar but less well-developed ligament extends between the proximal urethra and pubic bone in the female. In the male, the bladder and prostate are essentially fused at the bladder neck, with the transitional mucosal lining of the bladder extending into the prostatic and bulbar urethra without interruption. Posteriorly, the peritoneal reflection behind the bladder and prostate (Pouch of Douglas) extends down as a fusion fascia between the prostate and rectum (Denonvillier's fascia). Dissection in the plane behind this fascia (Denonvillier's space) allows safe separation of the seminal vesicles and prostate from the rectum. In the female, the bladder lies on the anterior surface of the uterine cervix, with the peritoneal fold between the two generally not extending all the way down to the vagina. The bladder is quite densely adherent to the anterior vaginal wall, requiring sharp dissection to separate the two structures.

The blood supply to the bladder arises from the internal iliac artery and vein, including the superior and inferior vesicle branches. The superior vesicle artery and vein course over the top of the ureter as it enters the detrusor muscle. The inferior vesicle artery arises more inferiorly off of the internal iliac trunk, and with the superior vesicle vessels forms the lateral pedicle. The anterior trunk of the internal iliac artery terminates in the internal pudendal artery. In the male, the inferior vesicle artery supplies the prostate and bladder neck area. In the female, the uterine artery arises off of the superior vesicle artery and courses over the ureter toward the uterus and cervix. There are additional branches from the middle rectal artery and vein that course around the rectum (and vagina in the female) and supply the bladder neck area and form the posterior pedicle. A major

venous plexus courses along the lateral bladder in both males and females and can be a source of significant bleeding during cystectomy. A second venous plexus courses anteriorly over the urethra (the dorsal venous complex).

The neurovascular bundle in the male carries parasympathetic fibers along with small vessels from the hypogastric plexus toward the penis, coursing along the groove between the posterior prostate and the rectum. Preservation of this bundle during cystectomy is required if erectile function is to be preserved. A similar bundle courses along the lateral vagina in the female, although the role of these nerves in preserving continence or sexual function is somewhat controversial. The main nerve supply to the external urethral sphincter in both males and females appears to course within the levator muscle fibers in the pelvic floor lateral and anterior to the urethra.

The lymphatic drainage of the bladder follows the primary vessels, coursing to the obturator, internal iliac, and common iliac chains. However, additional drainage includes the external iliacs and presacral nodes. The drainage appears to be bilateral in most cases. From the pelvic nodes, drainage continues up along the periaortic and pericaval chains. There is no single identifiable sentinal node for bladder cancer. Node mapping studies have suggested that the primary landing site is in the internal iliac and obturator areas, but solitary positive nodes can often occur in the external iliac chain and occasionally in the presacral and common iliac areas as well and very rarely in the paracaval and para-aortic areas.

There are few congenital anomalies of bladder formation. However, some vascular variations that are important include the presence of accessory obturator arteries and veins arising from the external iliac vessels in up to 40% of patients, and accessory pudendal vessels in males, which may be important in preservation of potency. In addition, conditions such as bladder diverticula and prior pelvic surgery or radiation, or a prior renal transplant can impact the ease of dissection. Renal anomalies such as horseshoe kidney, duplicated ureters, and others must be recognized as well.

CLINICAL PRESENTATION

The vast majority of patients with bladder cancer present with gross painless hematuria. Any patient over age 40 with hematuria should have

evaluation for bladder cancer. Other presenting symptoms may include irritative symptoms (frequency, urgency, incontinence) that are often misdiagnosed as a urinary tract infection, sometimes delaying diagnosis for months. Symptoms of extravesical involvement include flank pain (from upper tract obstruction), bone pain, cough or hemoptysis, or weight loss.

Smoking is the most significant known risk factor for bladder cancer. Often, patients have quit smoking many years before the diagnosis; however, the risk declines only slightly over decades. Up to 30% of men and 50% of women with this disease have never smoked. Other environmental exposures such as industrial chemicals and dyes have also been identified as etiologic agents.

DIAGNOSIS

The evaluation of hematuria is very standardized and should include upper tract imaging (generally a CT scan of the abdomen and pelvis with intravenous [IV] contrast) as well as flexible or rigid cystoscopy. Ultrasound and noncontrast CT scans have poor sensitivity for detection of both bladder cancer and small renal masses. The ideal CT scan evaluation should include a noncontrast scan followed by an IV contrast scan including the delayed excretion phase (often called a CT urogram or CT IVP). In patients with contrast allergy or poor renal function, the upper tracts may be evaluated with ultrasound combined with retrograde pyelography or MRI with gadolinium.

Currently available imaging tests have poor sensitivity for small bladder tumors, so cystoscopy is required, usually performed in the doctor’s office with a flexible or rigid cystoscope under local anesthesia. Papillary tumors are very easily identified on cystoscopy. Carcinoma in situ (CIS) is a flat lesion in the bladder, which has a very aggressive natural history. It may be difficult to identify with cystoscopy, although a patchy, slightly raised erythematous area may be visible. Urinary cytology is nearly always positive in the presence of CIS, and this test is an important adjunct to the initial cystoscopy. However, cytology can be normal in the presence of low-grade and even high-grade bladder cancers, so it is not useful alone as a screening test. A number of other urinary tests are also currently available to diagnose bladder cancer. There are protein-based tests (NMP22 and BTAStat), immunohistochemical tests (UroVysion FISH and Immunocyt), as well as RNA-based tests (CxBladder), and a number of

others are under development. So far no single or combination of urinary markers has been proven to be sensitive and specific enough to replace cystoscopy in the initial evaluation of hematuria or for follow-up of patients with a history of cancer.

Once a bladder tumor is visualized, the next step is transurethral resection of the bladder tumor (TURBT) to establish histology and grade as well as depth of invasion. A bimanual examination should also be performed under anesthesia during that resection since a palpable mass is highly predictive of extravesical extension. This is important for clinical staging (Table 175.1) and for planning the surgical approach for patients with invasive tumors. For patients with low-grade papillary tumors, no further metastatic workup is necessary. However, patients with high-grade or invasive lesions require a full staging evaluation including a CT scan of the chest, abdomen, and pelvis along with a bone scan. Recently, FDG PET/CT scans have been used for staging, with conflicting data regarding any advantage over standard CT. There is considerable increased cost and radiation exposure with PET scans. However, in patients at high risk of metastases there may be a benefit to identifying occult metastases prior to surgery.

TABLE 175.1 AJCC TNM Staging System for Urothelial Carcinoma of the Bladder

a. 2009 AJCC TNM staging (7th edition AJCC Manual)

Ta		Mucosa only
Tis		Carcinoma in situ
T1		Lamina propria invasion
T2		Muscularis propria invasion
	T2a	<0.5 thickness of detrusor muscle
	T2b	>0.5 thickness of detrusor muscle
T3		Into perivesical fat (clinically palpable mass on bimanual exam)
	T3a	Microscopic invasion only
	T3b	Macroscopic invasion
T4		Invading surrounding organs
	T4a	Into prostate, uterus, ovaries
	T4b	Into pelvic sidewall (fixed mass or invasion of sidewall on imaging)
N	Nx	No nodes sampled
	N1	Single positive node in pelvis
	N2	Multiple positive nodes in pelvis
	N3	Positive node above common iliac bifurcation
M	Mx	No metastatic evaluation
	M0	No metastatic disease
	M1	Distant metastases present

TABLE 175.2 Discrepancy Between Clinical and Pathologic Staging in Patients Undergoing Cystectomy by Clinical Stage

Clinical Stage	Pathologic Stage (%)					
	<pT2	pT2	pT3	pT4	Understaged	Overstaged
Ta, Tis	78	11	3	8	na	22%
T1	59	22	13	6	na	41%
T2	25	29	37	8	25%	45%
T3	18	13	46	23	23%	31%
T4	29	9	10	54	48%	na

Despite recent advances in radiographic imaging techniques, inaccuracy in clinical staging of the primary bladder tumor is very common. Patients with hydronephrosis, a palpable mass on bimanual examination, lymphovascular invasion or variant histology such as neuroendocrine, micropapillary or sarcomatoid variants, or with clear extravesical extension on preoperative imaging are highly likely to have disease in the perivesical fat or positive nodes on final pathology. Table 175.2 shows the discrepancy between clinical and final pathologic stages for a contemporary group of patients undergoing cystectomy.

TREATMENT AND INDICATIONS FOR CYSTECTOMY

The treatment of bladder cancer should be adjusted for the risk of the tumor recurrence or progression. In general smaller, low-grade, Ta lesions are treated successfully with endoscopic transurethral resection alone. Guidelines are available from the European Association of Urology (EAU), the American Urological Association (AUA), and the National Comprehensive Cancer Network (NCCN) to guide optimal therapy for each patient situation. A single dose of intravesical chemotherapy (with mitomycin C or other agent) may be instilled immediately following transurethral resection and has been shown to reduce early recurrence of noninvasive tumors. Repeat resection is recommended for patients with lamina propria invasion or high-volume high-grade disease to ensure that muscle invasive tumor has not been missed.

Patients with high-grade tumors, especially with lamina propria invasion or CIS, are at significant risk of recurrence and progression to muscle-invasive disease. Intravesical immunotherapy with BCG (Bacillus Calmette-Guerin, a live attenuated strain of *Mycobacterium tuberculosis*) has been the most effective to reduce both recurrence and progression for these patients. Six weekly instillations are administered, with ongoing maintenance therapy for the highest-risk patients. BCG is contraindicated in most patients on immunosuppression or those with prior severe

reactions to it. Intravesical chemotherapy with mitomycin C, epirubicin, gemcitabine, and other agents has been effective to reduce recurrence (but not progression) for patients with intermediate risk tumors if BCG is contraindicated or has not been effective. Newer agents and delivery technologies are under development to try to enhance effectiveness of intravesical therapy.

The long-term risk of progression to muscle-invasive disease for patients with high-risk tumors treated with intravesical therapy may be as high as 50%. For this reason, cystectomy may be a reasonable option for the younger, healthy patients with high-grade T1 tumors, especially with known risk factors for progression such as large tumors, associated CIS, lymphovascular invasion, variant histology, or deep lamina propria invasion. If a patient has persistent or recurrent disease after intravesical therapy, cystectomy is most effective if applied before the patient develops a muscle-invasive tumor. Delaying cystectomy until muscle invasive disease has developed results in inferior survival when compared to patients undergoing cystectomy for initial high-grade T2 disease.

Any patient with localized muscle-invasive disease should be considered for cystectomy, with or without systemic neoadjuvant chemotherapy. Patients who are not reasonable surgical candidates or who refuse surgery may be treated with external beam radiation therapy with concomitant systemic chemotherapy. Although radiation therapy is popular in many other parts of the world, it has been much less often used in the United States as primary local therapy for bladder cancer. The advantages of cystectomy over radiation therapy include the ability to obtain accurate pathologic staging, better local tumor control, and better long-term disease-free rates. Randomized trials comparing cystectomy to chemoradiation have not been performed, but nonrandomized comparisons suggest similar overall survival rates. Salvage cystectomy is feasible after failure of local radiation therapy, but it is technically challenging, has higher complication rates, and is generally less amenable to efforts for nerve-sparing and orthotopic neobladder reconstruction.

Many patients with aggressive bladder cancers are very elderly with significant comorbidities. These cancers will usually progress to metastasis and death within 2 years of diagnosis, causing significant misery from bleeding, pain, and obstruction from the local bladder tumor if the bladder is not removed. Therefore, an elderly patient who is believed to have at least a 2-year life expectancy and is likely to survive the surgery should be

considered for cystectomy regardless of his or her chronologic age.

Surgery alone achieves long-term cure in approximately 50% to 70% of patients with invasive bladder cancer. Pathologic stage is the strongest predictor for survival. A number of other factors have been shown to be prognostic indicators, including age and gender, the presence of lymphovascular invasion, and genetic markers in the tumor such as p53 tumor suppressor gene mutation. Cystectomy is rarely recommended in the treatment of low-grade disease unless there is extremely bulky disease and a concerted effort at endoscopic management has failed. Cancer-free patients will occasionally require cystectomy because of severe bladder dysfunction resulting from intravesical therapy or pelvic radiation therapy. Patients with metastatic urothelial cancer with an intact bladder occasionally require palliative cystectomy to manage severe bleeding, pain, or urinary obstruction.

There is strong evidence supporting the use of neoadjuvant cisplatin combination chemotherapy prior to cystectomy in patients who have muscle invasive disease and reasonable renal and cardiac function. Studies have shown a 5% overall survival advantage for patients receiving chemotherapy in addition to surgery compared to surgery alone. Probably similar advantage is obtained with postoperative adjuvant therapy, although this is much more difficult to deliver in patients who are recovering from surgery, and randomized studies in adjuvant therapy have been difficult to complete.

Therefore, a consultation with a medical oncologist to discuss neoadjuvant chemotherapy should be strongly considered for any patient with muscle-invasive disease prior to cystectomy. Patients with a palpable pelvic mass on bimanual exam, hydronephrosis, lymphovascular invasion, or apparent extravesical disease on CT scan should nearly always receive cisplatin-based neoadjuvant therapy (if they have adequate renal function) since they are unlikely to have organ-confined disease at surgery. In addition, patients with variant histologic patterns including the presence of neuroendocrine differentiation or micropapillary pattern should also be considered for initial chemotherapy given the high rates of upstaging at cystectomy. Patients who have not received preoperative chemotherapy and have extravesical or node-positive disease on final pathology may be considered for adjuvant chemotherapy, usually begun 6 to 8 weeks following surgery. Perioperative radiation is not routinely used, although the role for postoperative pelvic radiation in patients with high-risk

pathologic features is being evaluated in a cooperative group clinical trial.

CHOICE OF URINARY DIVERSION

There are three primary options for urinary diversion following cystectomy: ileal or colon conduit, orthotopic neobladder, or continent cutaneous diversion. Cutaneous ureterostomy has been advocated in some countries but has been traditionally associated with an unacceptably high rate of stenosis at the skin requiring indwelling catheters. Orthotopic urinary diversion is offered to nearly all patients undergoing cystectomy in our practice unless they have a specific contraindication (Table 175.3), regardless of age. The advantages and disadvantages of each form of diversion are discussed in an attempt to help the patient make a choice that fits his or her own priorities and lifestyle. Every form of diversion has an impact on the patient's quality of life and carries a risk of specific complications, and there is no strong evidence that the overall quality of life is better for patients with one diversion or another. Table 175.4 shows a simplified list of pros and cons of each diversion that is useful in helping patients make decisions about which to choose.

TABLE 175.3 Contraindications for Orthotopic Diversion

Absolute Contraindications:

Renal insufficiency (estimated creatinine clearance of <40)

Cancer invading the anterior vagina and/or proximal urethra in women

Cancer at the prostatic apex or proximal urethra in men

Incompetent external urethral sphincter or severe urethral stricture disease

Inadequate available bowel

Relative Contraindications:

Severe comorbidities requiring very short operative time

Cancer involving the prostatic urethra (especially with stromal invasion)

Significant stress incontinence in women

Locally extensive disease at surgery (stage T4)

Rectal injury at surgery

Prior prostate or bladder radiation

Continent diversion in the hands of an experienced surgical team does not increase hospital stay or early postoperative complications compared to ileal conduit. Orthotopic diversion has the specific advantage of allowing the most “natural” form of voiding without the need for an appliance. Over 80% of patients achieve daytime continence with time, and approximately half of them are consistently dry at night. In men, advanced age appears to delay the achievement of continence but does not otherwise affect outcome. Elderly women do appear to have a higher risk of permanent incontinence compared to younger women. Patients sometimes need to do self-catheterization (more often in women than in men), so any patient considering an orthotopic neobladder should be willing and able to perform this. Late complications such as stones and anastomotic strictures can generally be managed with endoscopic techniques.

Renal Function

One of the most important contraindications for continent neobladder reconstruction is compromised renal function. In patients with compromised renal function, hyperchloremic metabolic acidosis can develop along with worsening dehydration, uremia, nausea, and bone loss due to reabsorption of electrolytes and loss of bicarbonate. There is general consensus that an estimated creatinine clearance (eGFR) of >40 mL/min is recommended for patients considering continent diversion.

There is no evidence that orthotopic diversion leads to progressive renal dysfunction in patients with normal renal function prior to surgery.

Risk of Urethral Recurrence

In men who have undergone cystectomy and orthotopic diversion, the presence of prostatic urethral involvement with urothelial carcinoma increases the risk of late urethral recurrence. In our series of almost 800 male patients, the risk of urethral recurrence at 5 years was 5% for patients without any prostatic involvement compared to 11% with any involvement. The risk went up to 18% for patients with invasion of tumor into the prostatic stroma (stage pT4a). Thus, in a patient with prostatic urethral involvement documented preoperatively, the decision whether or not to perform an orthotopic diversion must be made with this risk in mind. Preoperative biopsy of a normal appearing prostatic urethra is not mandatory as we routinely perform a frozen section of the apical urethral margin at surgery to determine eligibility for orthotopic reconstruction.

TABLE 175.4 Pros and Cons of Each Type of Diversion for Shared Decision-Making

Diversion Type	Advantages	Disadvantages
Ileal conduit	Simple, quick, familiar to all surgeons	Problems with appliance Peristomal hernia Skin problems
Orthotopic neobladder	Allows normal voiding Relatively simple, quick	Incontinence Retention Need to void at night to stay dry
Continent cutaneous diversion	No initial incontinence Usually can sleep through the night	Most difficult to construct Difficulty catheterizing Leakage from stoma
Common to all diversions	Preserve renal function	Risk of infection Stones in kidney or pouch Ureteroileal stricture Metabolic derangements

For women, the risk of urethral involvement is primarily driven by tumor location. Tumors located at the bladder neck or associated with palpable invasion into the anterior vaginal wall are associated with a high risk of urethral involvement. In all cases, we depend on the negative frozen section of the proximal urethral margin at the time of surgery to make a decision to proceed with orthotopic diversion.

Locally Advanced Disease

Many urologists are hesitant to perform continent orthotopic diversion in patients with locally extensive disease. This is based on two factors: (a) concern about the possible impact of local recurrence on the neobladder itself, and (b) a belief that these patients are doomed to suffer distant recurrence and have a shortened life expectancy and will not benefit from the neobladder. However, in our series of over 2,000 patients undergoing cystectomy, <7% of patients suffered a local recurrence with a median follow-up of over 10 years. Patients who do develop a pelvic recurrence rarely have problems with direct tumor invasion into the reservoir causing symptoms. Thus, this form of diversion appears to be an option even with locally extensive disease, especially if one can achieve a grossly negative margin.

Effect of Prior Radiation Therapy

It is not uncommon for patients with invasive bladder cancer to have a history of prior radiation therapy for other pelvic malignancies. We reported on 184 patients who underwent cystectomy following prior

radiation from 1983 to 2008, 48 of whom underwent neobladder reconstruction and 35 a continent cutaneous diversion. Early complications were more common than in nonirradiated patients, and increased by age. Requirement for artificial sphincter and urethral strictures were also both more common in irradiated patients undergoing neobladder reconstruction. Others have reported similar results with small series of patients. These are highly selected patients, and intraoperative assessment is crucial to determine the health of the urethral tissue and the advisability of performing an orthotopic diversion. High-dose prostate irradiation seems to be particularly damaging to the external sphincter compared to other types of radiation.

PREOPERATIVE PLANNING

Patients undergoing cystectomy often have significant comorbidities, especially heart and lung dysfunction related to smoking. Preoperative optimization is crucial in making this a safe operation. Most patients are evaluated by a cardiologist, usually with provocative cardiac testing (stress tests) and pulmonary function testing when indicated to assist in perioperative management.

Education for the patient and family is a key component of preoperative preparation. We are fortunate to have a dedicated enterostomal therapist on our team who meets with each patient preoperatively to go over expectations for the perioperative period. He or she also marks the patient for a possible ileal conduit diversion in case that should become necessary during the surgery. We also have a set of written instructions that patients receive, which describes the usual perioperative course, management of catheters and drains, Kegel exercise techniques, and techniques for self-catheterization.

Enhanced recovery after surgery (ERAS) techniques have been applied to cystectomy patients in recent years to shorten hospital stay and minimize gastrointestinal complications that have been a common problem with this surgery. Six double-blind randomized controlled trials in colorectal surgery and cystectomy patients have shown that a mechanical or antibiotic bowel prep is not necessary and may be detrimental. In addition to avoiding the bowel prep, minimizing fasting periods before surgery and addition of a liquid bolus with high carbohydrate fluid 2 hours before surgery have decreased preoperative dehydration. These techniques along with postoperative management (described below) have resulted in a

significant decrease in gastrointestinal complications and shorter hospital stay.

Minimally Invasive Surgical Approaches to Cystectomy and Ileal Neobladder

In recent years, laparoscopic and robot-assisted laparoscopic techniques have been applied to radical cystectomy, with somewhat mixed results. Completing a thorough extended pelvic lymphadenectomy using these techniques is challenging and can be very time-consuming. Nearly all surgeons doing laparoscopic or robotic cystectomies now perform an extracorporeal ileal conduit or neobladder through a small suprapubic incision to facilitate the bowel work.

Most reports of minimally invasive cystectomies show a decreased blood loss compared to open series, and a few have shown shorter hospital stay. A recent randomized trial showed lower blood loss but significantly longer surgery for robotic approach, with no difference in hospital stay, complications, or recovery. Another group of experienced robotic surgeons who were trained and committed to performing an extended lymphadenectomy found very similar complication rates and hospital stay to our open series. Techniques for intracorporal construction of the diversion have been developed and are being applied but have been limited to a few very experienced surgeons. Thus, the advantage of the extended operative time and increased cost associated with use of the robot is still unclear.

RADICAL CYSTECTOMY AND EXTENDED LYMPHADENECTOMY: SURGICAL TECHNIQUE IN THE MALE AND FEMALE PATIENTS

Patient Positioning

The patient is placed in the supine position with table extended at the patient's waist to open the pelvis (Fig. 175.1). In the female patient, the modified frog leg or lithotomy position is used to allow access to the vagina. All pressure points are well padded. Slight reverse Trendelenburg position levels the abdomen parallel with the floor and helps to keep the small-bowel contents in the epigastrium. In the female patient, the vagina is fully prepped along with the abdomen, and in both genders the Foley catheter is placed after draping to afford surgeon access to it during the

case.

Incision

A vertical midline incision is made extending from the pubic symphysis to the umbilicus or slightly above in an obese patient. After opening into the peritoneum, the urachal remnant (median umbilical ligament) is divided just below the umbilicus, and kept attached to the bladder (Fig. 175.2). This maneuver prevents early entry into a high-riding bladder and ensures complete removal of all bladder tissue. The rectus fascia should be opened all the way down to the pubic bone to afford optimal view of the deep pelvis.

Abdominal Exploration

A careful systematic intra-abdominal exploration is performed to determine the extent of disease and to evaluate for any hepatic metastases or gross retroperitoneal lymphadenopathy. The abdominal viscera are palpated to detect any concomitant unrelated disease. Adhesions should be incised and freed if present.

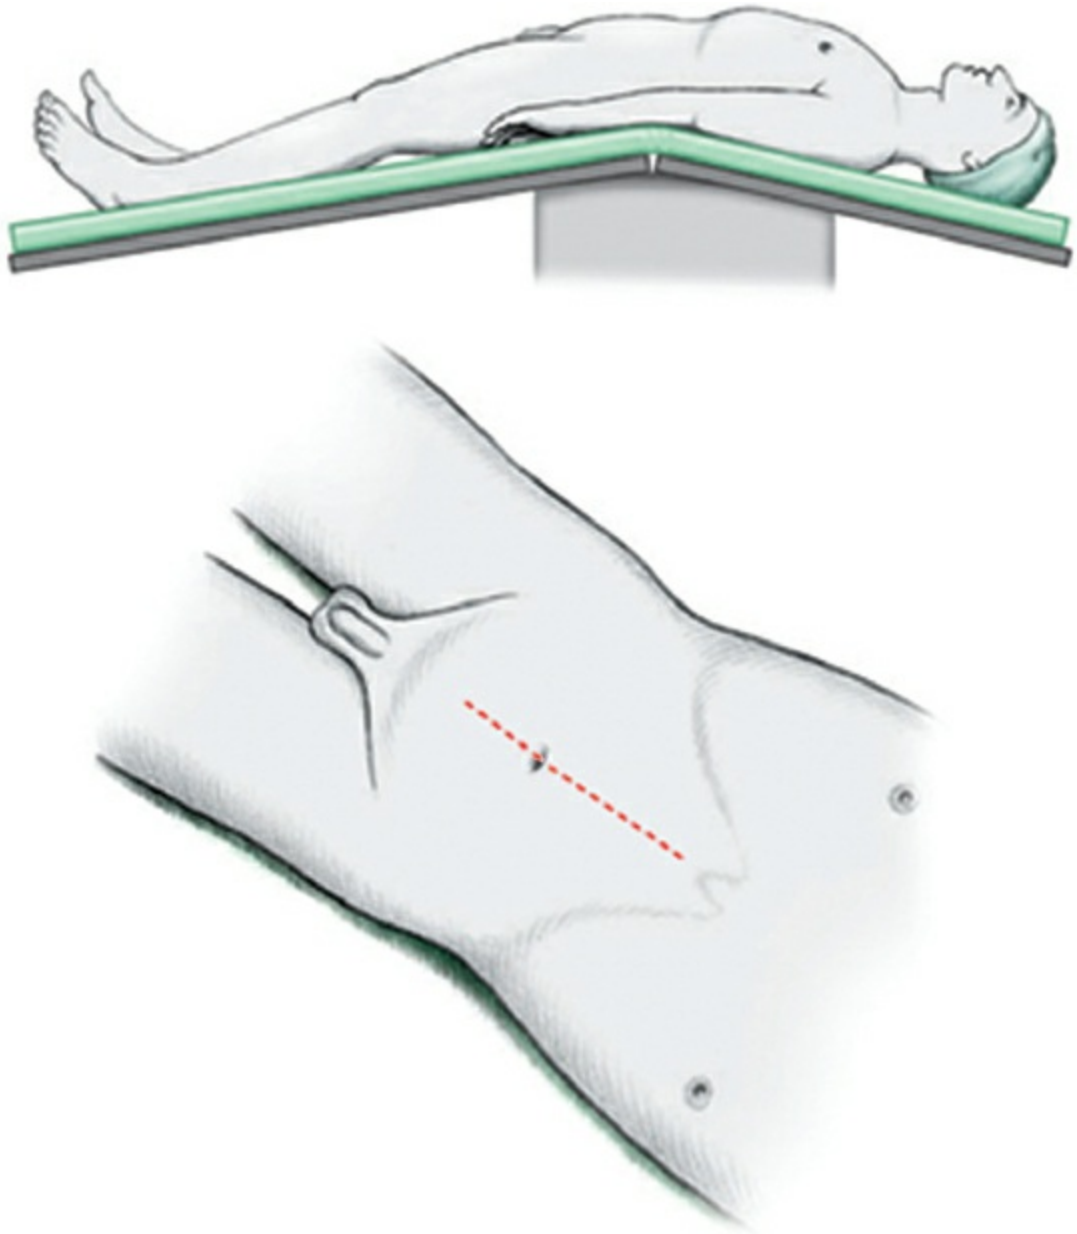

Figure 175.1. Proper patient positioning for cystectomy. Note that the iliac crest is located at the break of the table. Incision usually does not need to extend above the umbilicus except in very obese patients. (From Stein JP, Skinner DG. Surgical atlas-radical cystectomy. *Br J Urol Int* 2004;94:197. Figure 175.2. Wide excision of the urachal remnant en bloc with the cystectomy specimen. (From Stein JP, Skinner DG. Surgical atlas-radical cystectomy. *Br J Urol Int* 2004;94:197. Copyright © 2004 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

Bowel Mobilization

The bowels are mobilized starting with the right (ascending) colon. The posterior peritoneum may be opened along the white line of Toldt lateral to the cecum to facilitate packing. That is carried around the ileocecal area and then across toward the aorta. The cecum and small bowel mesentery

are elevated off of Gerota's fascia to allow access to the proximal portion of the node dissection (Fig. 175.3).

The peritoneum lateral to the sigmoid colon is then incised. The spermatic cord is swept off the side of the colon mesentery and the left ureter identified crossing the common iliac artery. A window is made in the mesentery of the sigmoid colon over the left common iliac vein and is opened up to the level of the inferior mesenteric artery and down behind the rectum. This provides access to the presacral nodes and is later used to bring the left ureter to the right side of the pelvis (Fig. 175.4). Care should be taken to dissect along the base of the mesentery and avoid injury to the inferior mesenteric artery and blood supply to the sigmoid colon.

A self-retaining retractor is placed, and the right colon and small bowel are carefully packed into the epigastrium under moist lap pads. The descending and sigmoid colon are not packed and are left free. The lap pads are used as sheets tucked below and above the bowel contents to keep them out of the pelvis. A wide retractor is placed with gentle traction cephalad. Another retractor is used to keep the sigmoid to the left side, and body wall retractors are used laterally. We use an Omnitrac self-retaining retractor system that gives maximum flexibility without impeding manual access into the pelvis.

Ureteral Dissection

The ureters are most easily identified in the retroperitoneum over the common iliac vessels. They are dissected into the deep pelvis (several centimeters beyond the iliac vessels) and divided between two large hemoclips. A section of the proximal cut ureteral segment (distal to the proximal hemoclip) is then sent for frozen section analysis to ensure the absence of CIS or overt tumor. The ureter is then mobilized cephalad and tucked under Gerota's fascia to prevent inadvertent injury. Alternatively the ureters may be left intact until the node dissection is complete. Leaving the proximal hemoclip on the divided ureter during the exenteration allows for hydrostatic ureteral dilation and facilitates the ureteroenteric anastomosis. In females, the infundibulopelvic ligament is ligated and divided after identification of the ureters.

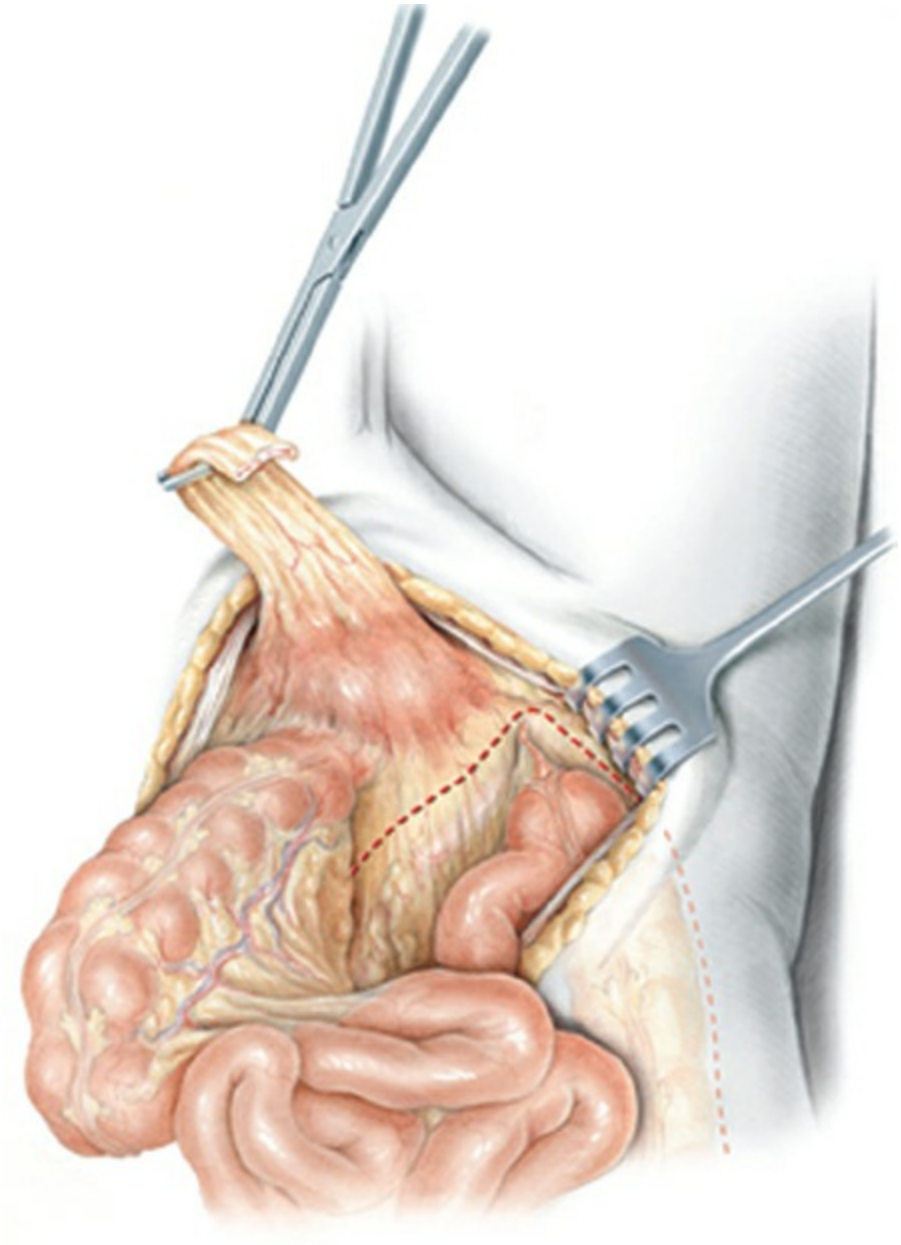

Figure 175.3. View of the pelvis from overhead. Note that the ascending colon and peritoneal attachments of the small-bowel mesentery (*dotted line*) are mobilized up to the level of the duodenum. This lateral mobilization is optional but can allow the bowel to be packed in the epigastrium. The medial dissection exposes the retroperitoneum over the distal aorta and vena cava. Figure 175.4. View of the pelvis from overhead. The sigmoid mesentery is mobilized off the sacral promontory, common iliac vessels, and distal aorta up to the origin of the inferior mesenteric artery. (From Stein JP, Skinner DG. Surgical atlas-radical cystectomy. *Br J Urol Int* 2004;94:197. Copyright © 2004 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

Distal Retroperitoneal and Pelvic Lymphadenectomy

The lymph node dissection is initiated at the inferior mesenteric artery (superior limits of dissection) and extends laterally over the inferior vena cava and aorta to the genitofemoral nerve bilaterally, representing the lateral limits of dissection. Clips are applied distally and proximally to

decrease lymph leak. Distally, the lymph node dissection extends to the lymph node of Cloquet medially (just medial to the external iliac vein on Cooper's ligament) and the circumflex iliac vein crossing the eternal iliac artery. Frequently, small anterior tributary veins originate from the vena cava just above the bifurcation, which should be clipped and divided. We routinely remove the nodes in individual packets identified by location.

All fibroareolar and lymphatic tissues are dissected off the distal aorta and vena cava, and the common iliac vessels are skeletonized. There is often a lateral psoas branch arising from the distal common iliac artery and vein that must be ligated (Fig. 175.5). After cleaning off the left common iliac vein below the aortic bifurcation, the dissection continues over the sacral promontory into the deep pelvis. Care is taken to control small arterial and venous branches coursing along the anterior surface of the sacrum. The tissue is cleaned off the sacral promontory down into the sacral fossa.

Once the proximal portion of the lymph node dissection is completed, the peritoneum is divided lateral to the bladder, dividing the vas deferens (or round ligament in a female). The tissue surrounding the external iliac vessels medial to the genitofemoral nerve is all dissected off, leaving the vessels free of any fat. The genitofemoral nerve is occasionally injured or intentionally taken if involved with adenopathy—the only consequence is some numbness on the anterior thigh. The lymph node of Cloquet is dissected out of the corner medial to the external iliac vein on Cooper's ligament, and the distal lymphatics clipped. An accessory obturator vein or artery is ligated (present in up to 40% of patients). The dissection continues up to the takeoff of the internal iliac artery.

At this point, a finger is passed lateral to the external iliac vein to free it from the sidewall, and a small gauze sponge may be passed lateral to the vessels along the psoas and pelvic sidewall to clean all the tissue off the sidewall of the obturator fossa (Fig. 175.6). This sponge is passed from along the common iliac bifurcation down caudally and posteriorly. Vein retractor is then placed on the medial side of the external iliac vein and the gauze retrieved inferiorly (Fig. 175.7). This maneuver facilitates identification of the obturator nerve deep to the external iliac vein. The obturator nerve is carefully dissected free from all lymphatics (Fig. 175.8). The obturator lymph node packet is then swept medially toward the sidewall of the bladder, ligating small tributary vessels and lymphatics from the pelvic sidewall, and removed.

Ligation of the Lateral Vascular Pedicle to the Bladder

Following dissection of the obturator fossa, the lateral vascular pedicle to the bladder is isolated and divided. The ureters may be divided at this point if not done previously, and the proximal ends tucked away. Fingers on the left hand are passed medial and lateral to the internal iliac artery to isolate

the pedicle. The pedicle can be ligated with a tissue sealant device, hemoclips, or suture ties (Fig. 175.9). The superior vesical artery is individually ligated and divided relatively easily. The remaining anterior branches of the lateral pedicle are then isolated and divided. Care is taken to stay anterior to the internal iliac vein, which is just deep to the pedicle.

Male Dissection

Following division of the lateral pedicles, the bladder specimen is retracted anteriorly and the sigmoid retracted superiorly exposing the cul-de-sac (pouch of Douglas). The peritoneum is incised from lateral to the rectum behind the ureteral stump across the cul-de-sac to the contralateral side (Fig. 175.10). The peritoneal incision should be made just to the rectal side of the reflection. This allows dissection posterior to Denonvillier's fascia, which arises as a fusion fascia of anterior and posterior peritoneal reflections, extending caudally to the urogenital diaphragm (Fig. 175.11). This important anatomic boundary in the male separates the prostate and seminal vesicles from the rectum. The plane between the rectum and the posterior sheath of Denonvillier's (Denonvillier space) can usually be developed using primarily blunt dissection down to the apex of the prostate.

Once the plane behind the prostate has been developed, the rectum is swept off laterally to free it from the vessels coursing around the rectum toward the bladder (posterior pedicle). This is best done by sweeping laterally with pressure against the prostate, taking care not to perforate the rectal wall (Fig. 175.12). Incision of the endopelvic fascia on either side of the prostatic apex can facilitate the apical dissection, taking care to avoid injury to the dorsal venous complex anteriorly or the area of the urethral sphincter medially. Once the pedicle is clearly separated from the rectal wall, it may be divided with clips or a tissue sealant device.

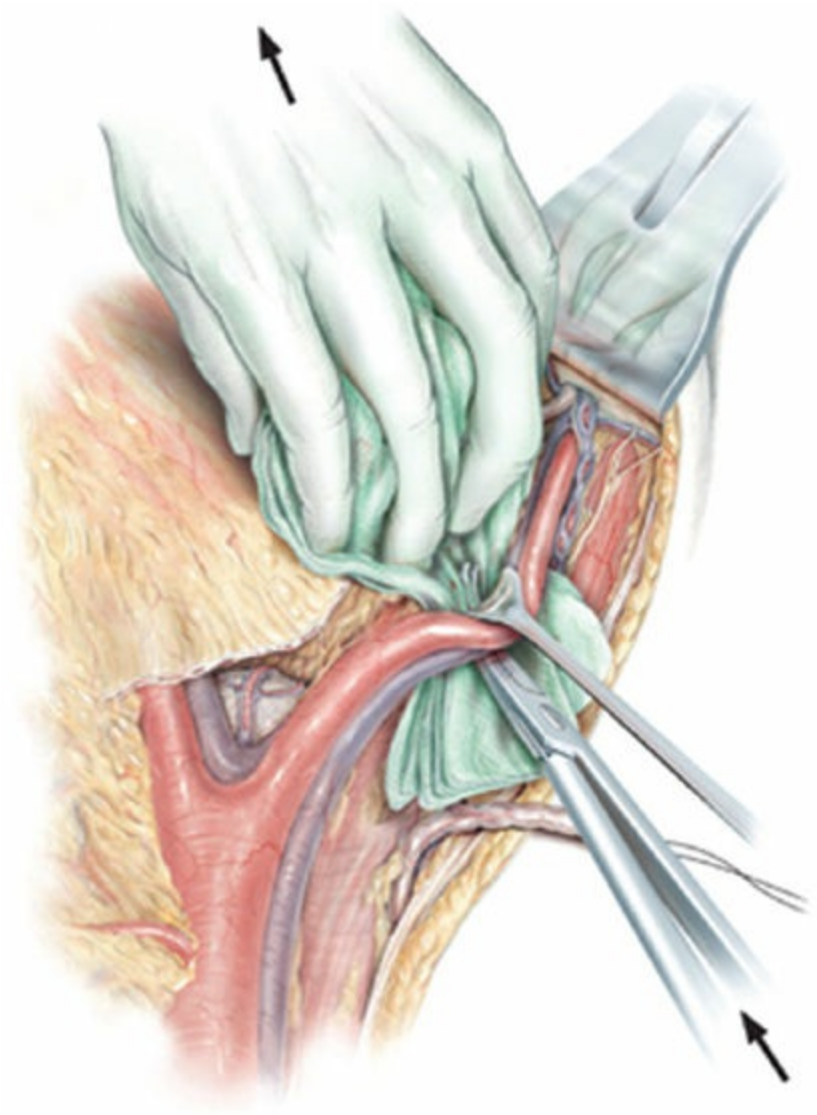

Figure 175.7. Technique of withdrawing the gauze sponge with the left hand. This will clean off the sidewall of the obturator fossa, sweeping all fibroareolar and lymphatic tissue toward the bladder and exposing the obturator nerve. (From Stein JP, Skinner DG. Surgical atlas-radical cystectomy. *Br J Urol Int* 2004;94:197. Copyright © 2004 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

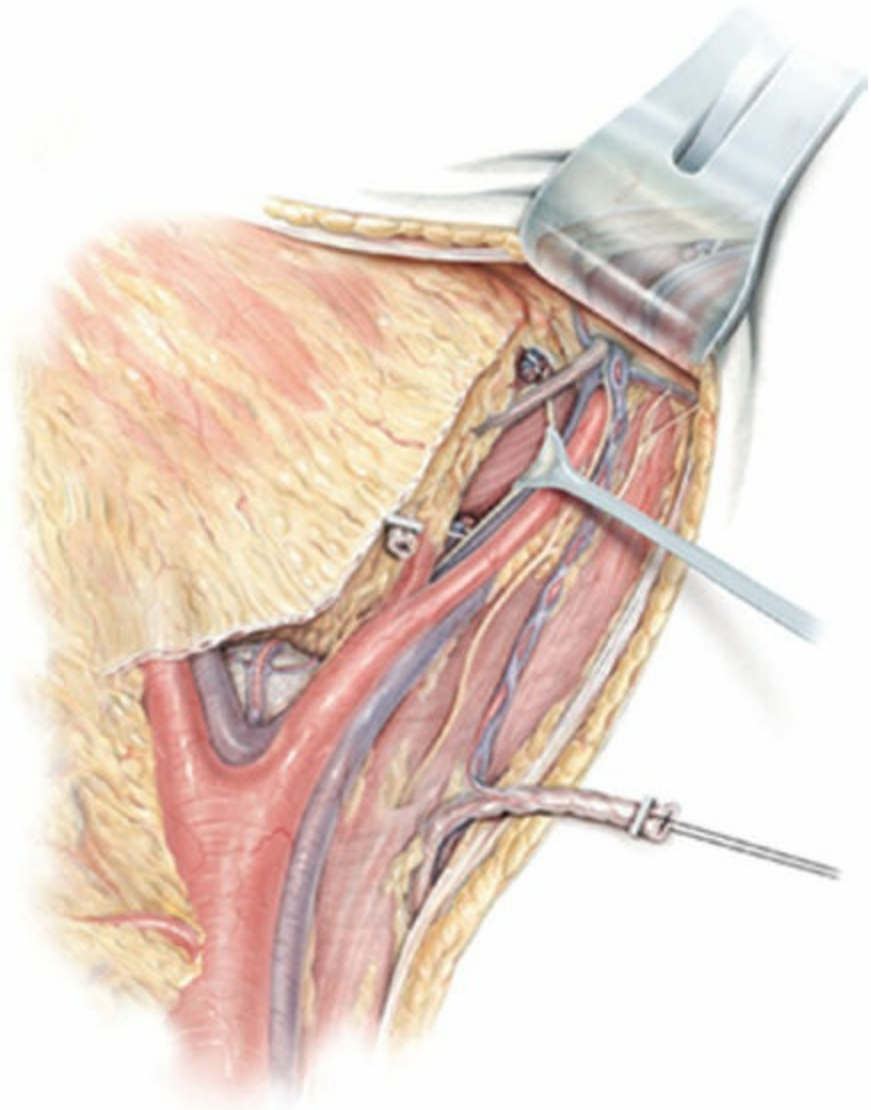

Figure 175.8. The obturator nerve passes deep to the external iliac vein. Here the nerve is retracted with the external iliac vessels. (From Stein JP, Skinner DG. Surgical atlas-radical cystectomy. *Br J Urol Int* 2004;94:197. Copyright © 2004 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

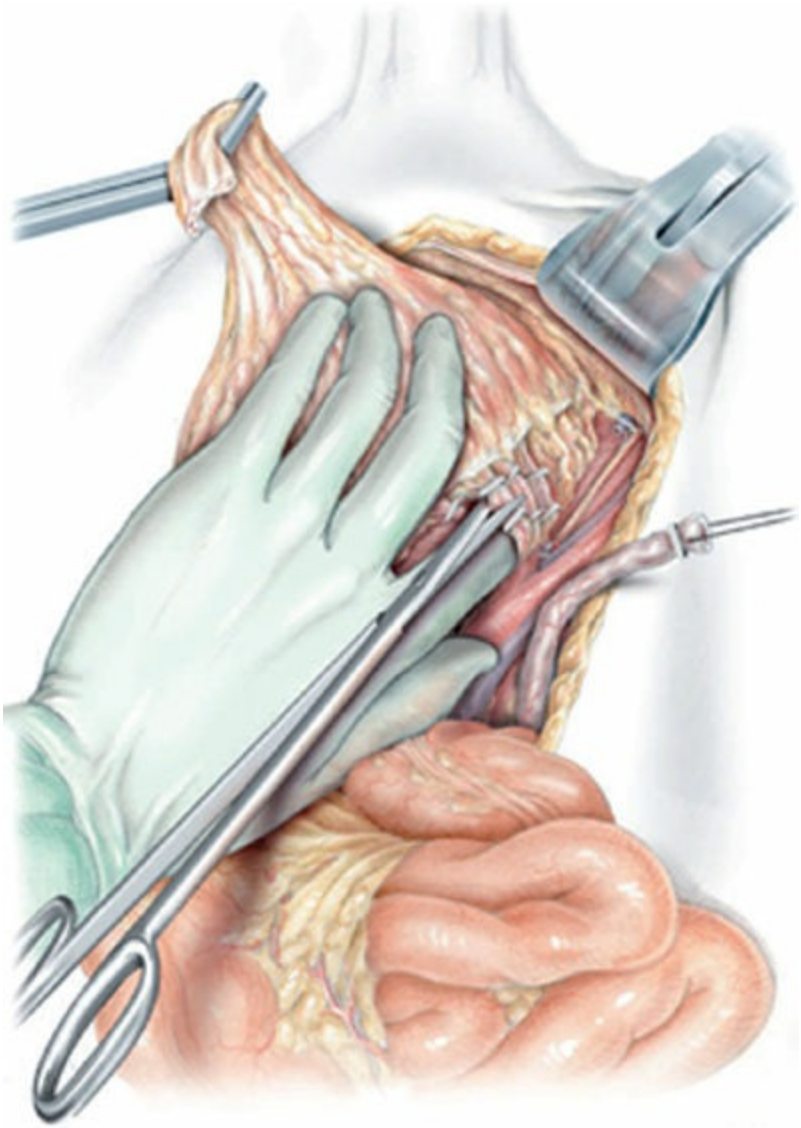

Figure 175.9. The left hand is used to define the right lateral pedicle, extending from the bladder to the hypogastric artery. This vascular pedicle is divided down to the endopelvic fascia. Firm traction with the left hand helps define the vascular pedicle, allows direct visualization, and protects the rectum from injury. (From Stein JP, Skinner DG. Surgical atlas-radical cystectomy. *Br J Urol Int* 2004;94:197. Copyright © 2004 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

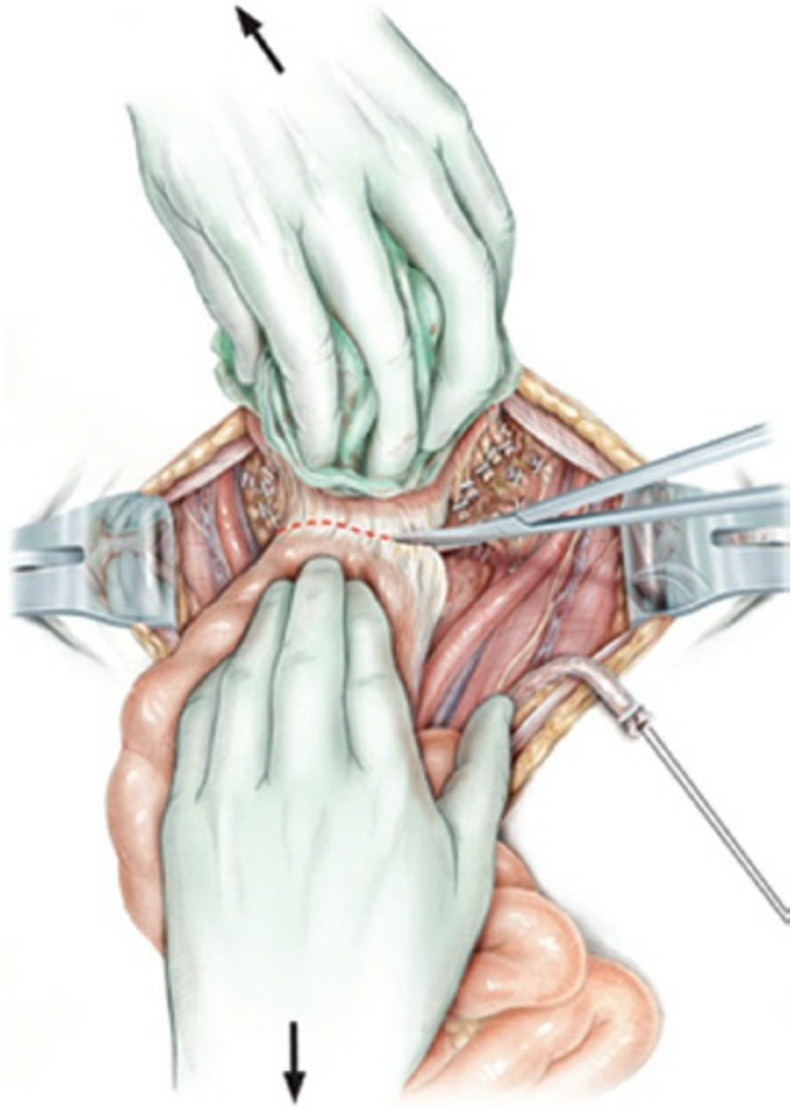

Figure 175.10. The peritoneum is incised across the rectum into the cul-de-sac and carried anteriorly over the rectum to join the opposite side. The incision is made slightly to the rectal side in the center so the plane behind Denonvillier's fascia can be developed safely. (From Stein JP, Skinner DG. Surgical atlas-radical cystectomy. *Br J Urol Int* 2004;94:197. Copyright © 2004 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

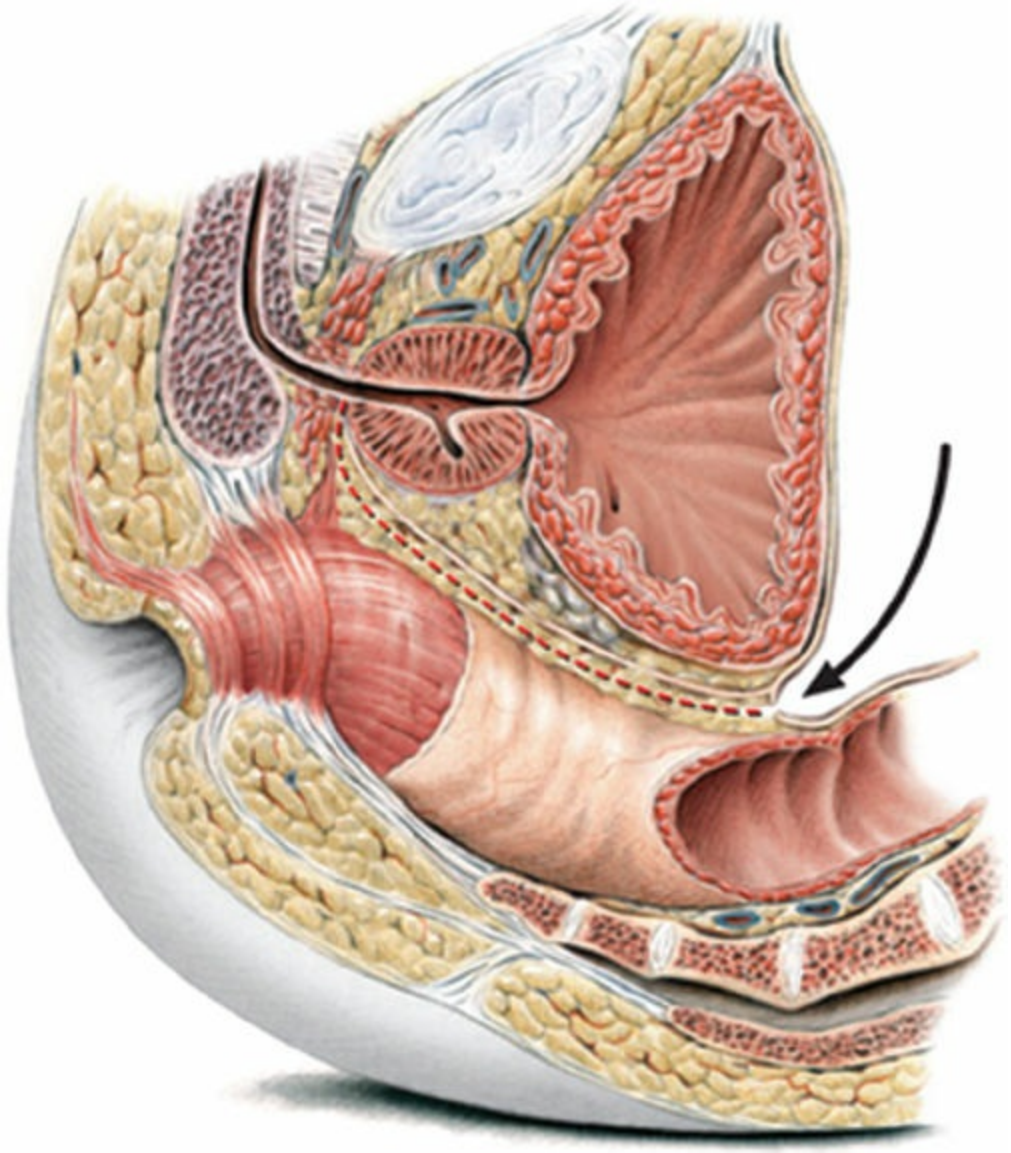

Figure 175.11. The formation of Denonvillier's fascia, derived from a fusion of the anterior and posterior peritoneal reflections. Denonvillier's space lies behind the fascia. (From Stein JP, Skinner DG. Surgical atlas-radical cystectomy. *Br J Urol Int* 2004;94:197. Copyright © 2004 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

If the dissection in Denonvillier's space is not easily performed bluntly, it should be taken down with careful sharp dissection under direct vision. This is often required near the prostate apex. In patients with prior high-dose pelvic radiation, sharp dissection is nearly always required. If a rectotomy occurs, a two- or three-layer closure is recommended after removing the specimen. A diverting proximal colostomy is not routinely required unless gross contamination occurs, or if the patient has received previous pelvic radiation therapy. If orthotopic diversion or vaginal

reconstruction is planned, an omental interposition is recommended to prevent fistula.

If a nerve sparing approach is to be used, the neurovascular bundle must be dropped off the side of the prostate before dividing the posterior pedicles. Then care must be taken not to extend the division of this pedicle too far posteriorly. This dissection may be carried out from apex to base of the prostate as in the classic Walsh approach to radical prostatectomy, ultimately connecting up to meet the dissection from above.

Once the cystectomy specimen is completely freed and mobile posteriorly, attention is then directed anteriorly to the urethra. The fat around the anterior prostate apex is teased off and the superficial dorsal vein is identified, ligated, and divided. The incision in the endopelvic fascia is completed and the levator muscle fibers are carefully swept off the lateral and apical portions of the prostate with gentle dissection to preserve the tissue around the urethral sphincter. The puboprostatic ligaments are identified and divided just beneath the pubis. Care should be taken to avoid any extensive dissection in this region. The puboprostatic ligaments need only to be incised enough to allow for a proper apical dissection of the prostate.

There are a number of ways to ligate the dorsal complex. We avoid staples and clips that can work their way into the urethral anastomosis. A suture may be passed on a needle or passer, and the distal DVC is ligated and divided just outside the apex of the prostate. If any bleeding occurs from the transected venous complex, it is oversewn superficially with an absorbable (2-0 polyglycolic acid) suture (Fig. 175.13). Deep suture bites should be avoided because of potential damage to rhabdosphincter.

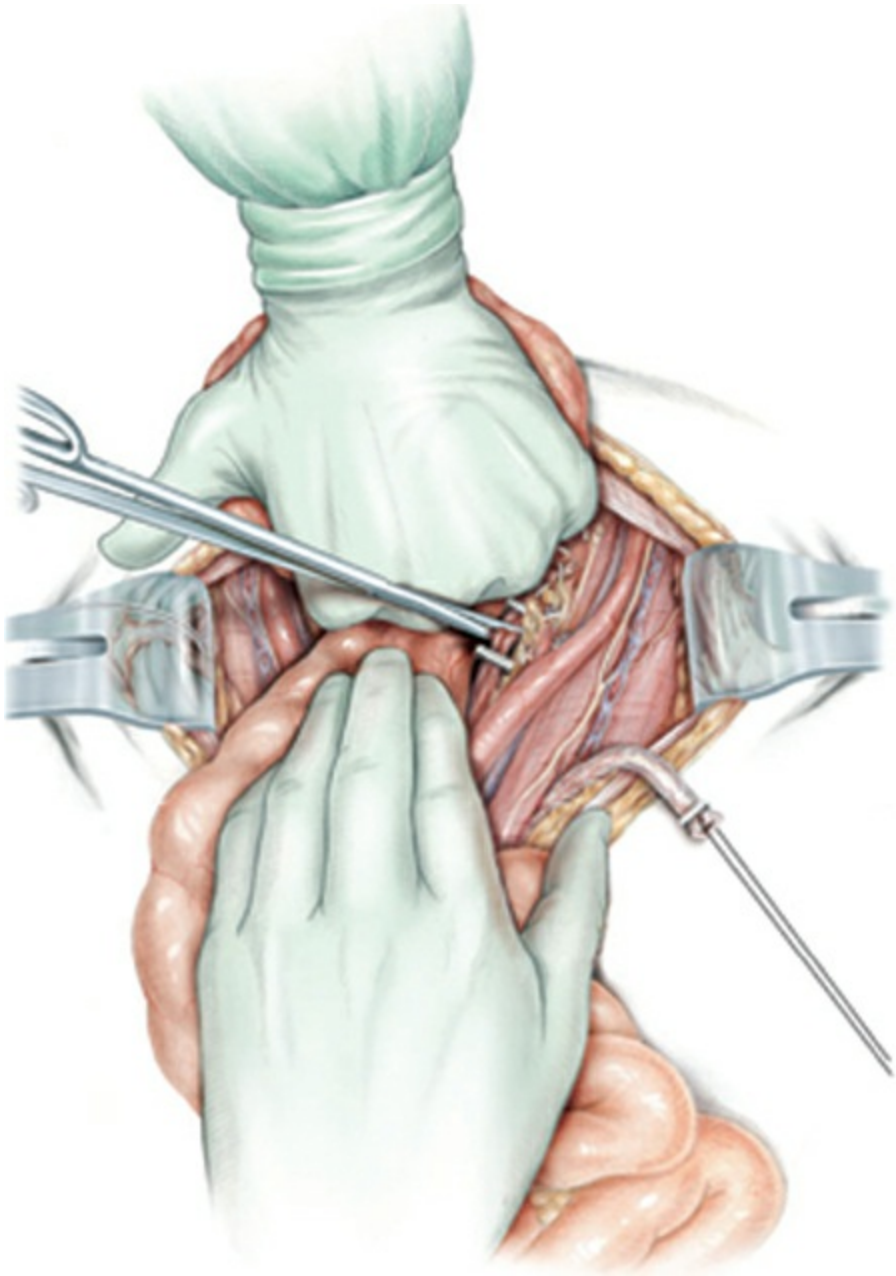

Figure 175.12. After the peritoneum of the cul-de-sac has been incised, the anterior rectal wall can be swept off the posterior surface of the Denonvillier's fascia. This effectively defines the posterior pedicle that extends from the bladder to the lateral aspect of the rectum on either side. (From Stein JP, Skinner DG. Surgical atlas-radical cystectomy. *Br J Urol Int* 2004;94:197. Copyright © 2004 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

After the complex has been ligated and divided, the anterior urethra is exposed. The urethra is then incised 270 degrees just beyond the apex of the prostate. Six 2-0 polyglycolic acid sutures are placed in the anterior

urethra, carefully incorporating only the mucosa and submucosa of the striated urethral sphincter muscle anteriorly. Following this, two posterior urethral sutures are placed, incorporating the rectourethralis muscle or the caudal extent of Denonvillier's fascia. The posterior urethra can then be divided and the specimen removed after dividing the Foley catheter between clamps in order to prevent spillage of any bladder contents. Frozen section analysis of the distal urethral margin of the cystectomy specimen is then performed in order to exclude tumor involvement.

Female Dissection

In the female patient when a hysterectomy is planned, the apex of the vagina (posterior fornix) identified and opened behind the cervix. The vagina is then circumscribed anteriorly with the cervix attached to the cystectomy specimen (Fig. 175.14). We prefer to spare the anterior vaginal wall if orthotopic diversion is planned and an adequate margin can be maintained. This decreases the risk of pouch-vaginal fistula and may be important in maintaining the neurovascular bundle that runs along the lateral vaginal wall, which may contribute to continence, sexual function, and efficient emptying.

The plane between the bladder and vagina is carefully developed using sharp dissection right on the anterior vaginal wall. Bleeding is controlled with cautery. The dissection is continued down to the bladder neck, identified by the Foley catheter balloon (Fig. 175.15). The posterior pedicle is mobilized by dissecting along the anterolateral vaginal wall and dividing the pedicle alongside the vagina with the tissue sealing device. There is a complex of veins around the urethra and bladder neck that can cause significant bleeding.

If there is concern about an adequate surgical margin at the posterior or base of the bladder, then a strip of the anterior vaginal wall should be removed en bloc with the bladder specimen. Although neobladder may be considered in this situation, the risk of vesicovaginal fistula is increased. An omental flap is critical in this case after water tight closure of the vagina.

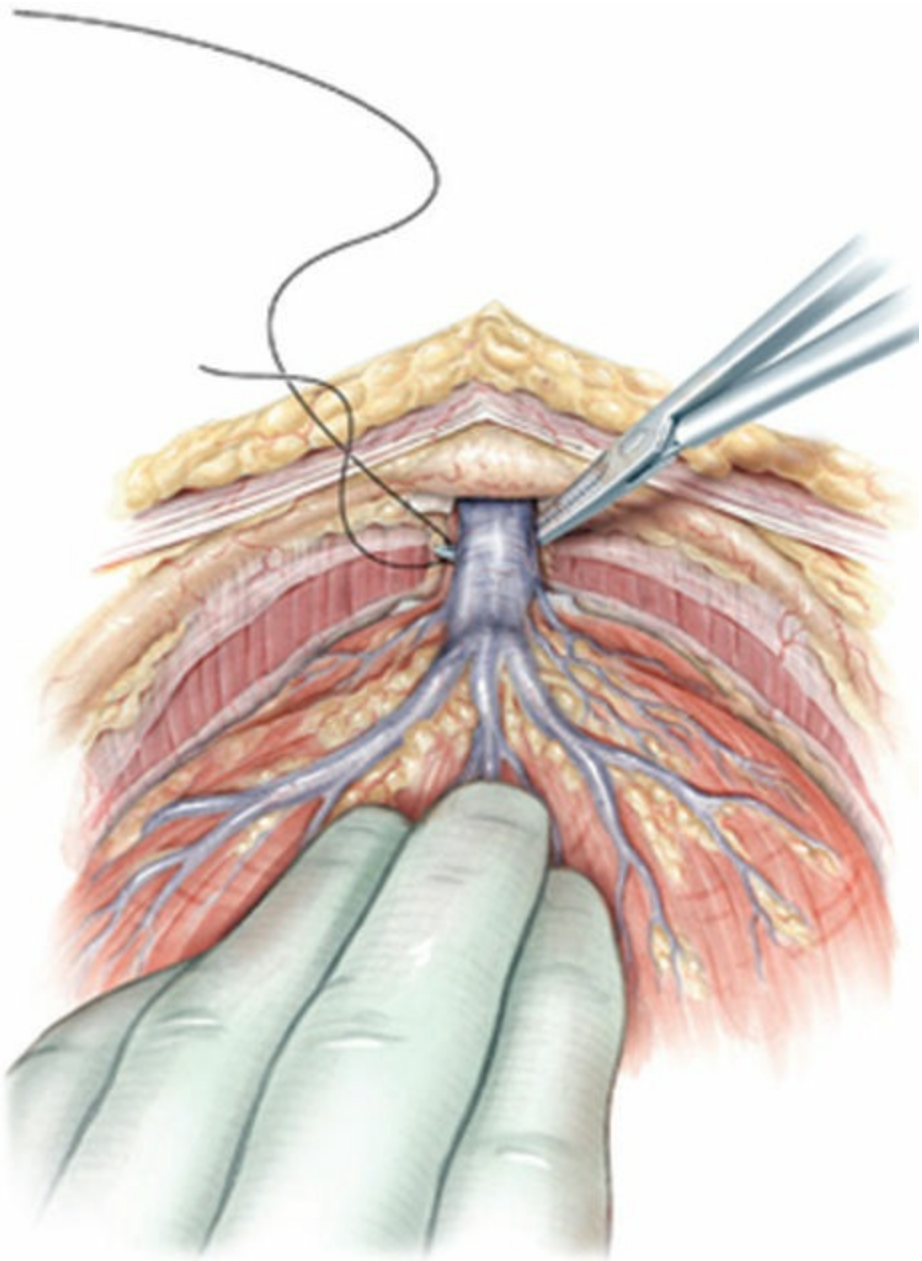

Figure 175.13. Controlling the dorsal venous plexus. One may pass an angled clamp beneath the dorsal vein complex anterior to the urethra to pass a free suture, or alternatively pass a suture on a large needle in the same plane, to ligate venous complex. Figure 175.14. Developing the posterior pedicles in women. The posterior vagina is incised at the apex on the posterior fornix behind the cervix. This incision is carried anteriorly along the lateral and anterior vaginal wall, circumferentially around the cervix. (From Stein JP, Skinner DG. Surgical atlas-radical cystectomy. *Br J Urol Int* 2004;94:197. Copyright © 2004 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

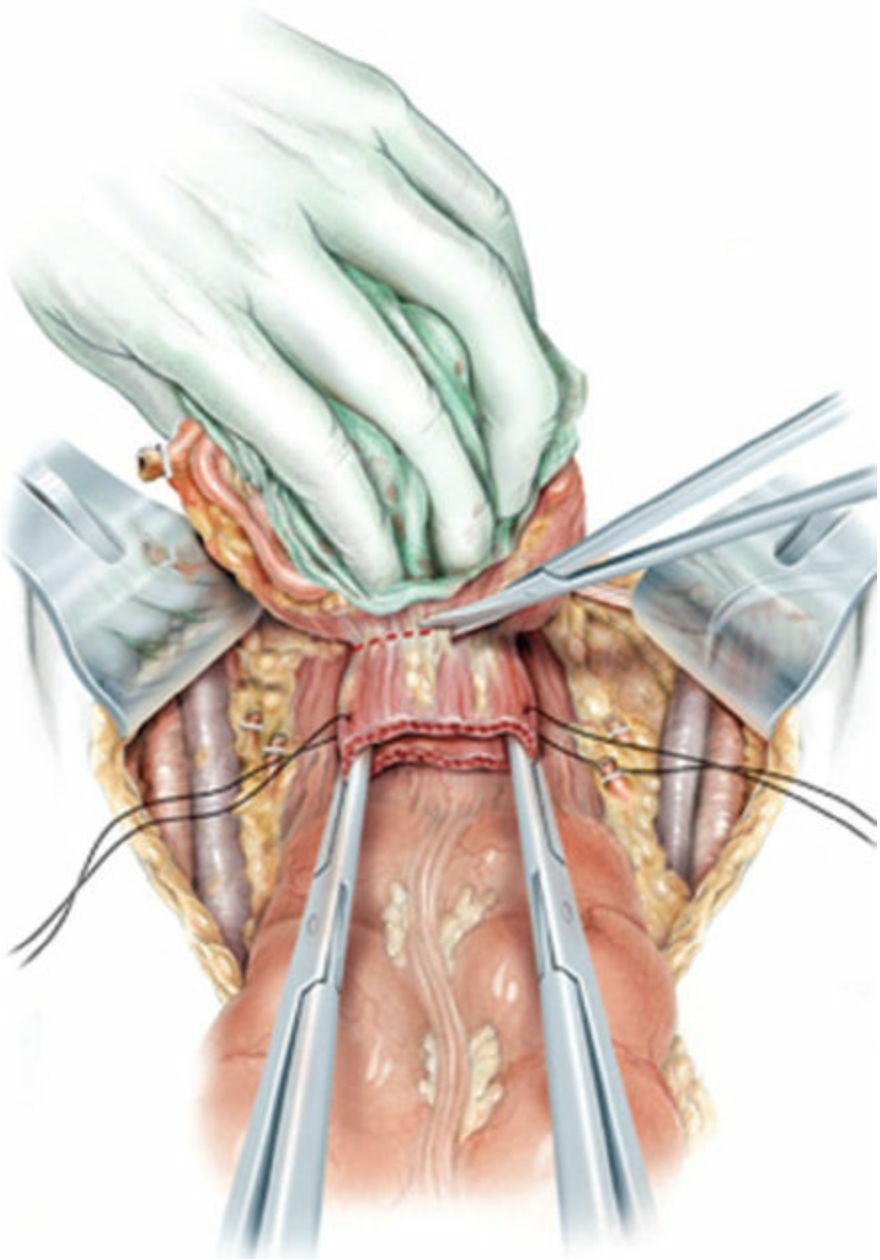

Figure 175.15. The anterolateral vaginal wall is grasped with a curved Kocher clamp, which allows for countertraction, and sharp dissection is used to separate the anterior vaginal wall and the bladder. Care must be taken not to enter the posterior bladder, which may be quite thin. (From Stein JP, Skinner DG. Surgical atlas-radical cystectomy. *Br J Urol Int* 2004;94:197. Copyright © 2004 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

There has been recent interest in preserving the uterus in selected women with low-stage bladder cancer away from the posterior wall who are at very low risk of cervical or uterine invasion. In these patients, the infundibulopelvic and round ligaments are preserved. The uterine artery is

isolated and preserved during dissection of the lateral pedicle. An incision in the peritoneum is made anterior to the cervix behind the bladder and the plane between the vagina and bladder developed in an identical manner. Care must be taken to avoid dissecting immediately lateral to the cervix where troublesome bleeding will be encountered. The ureteral stumps must be passed under the uterine artery prior to dividing the posterior pedicles anterolateral to the vagina.

Once the specimen has been dissected down to the bladder neck, the fat above the endopelvic fascia anterior to the bladder is gently cleaned off and the Foley balloon is used as a guide to identify the junction between the bladder and urethra. It may be helpful to put 20 cc into the balloon during this portion. It is important that no dissection be performed below the endopelvic fascia. This prevents injury to the rhabdosphincter region and corresponding innervation, which is critical in maintaining the continence mechanism. The planned incision in the proximal urethra just distal to the bladder neck is marked with a suture or light cautery. The Foley is removed and a clamp placed across the bladder neck to avoid spill. The urethra is divided sharply, avoiding cautery. It is not necessary to place urethral sutures at this time because they are easily placed later once the frozen section is confirmed to be negative.

After careful water-tight closure of the vaginal apex, we routinely mobilize an omental flap and tack it down to the anterior perivaginal tissue on either side of the urethral stump (Figs. 175.16 and 175.17). If a hysterectomy is performed, we also routine do a sacrocolpopexy with mesh attaching the vaginal apex to the sacral promontory to maintain better posterior support of the vagina in the normal anatomic angle.

ORTHOTOPIC LOWER URINARY TRACT RECONSTRUCTION

The Need to Prevent Reflux

Reflux has been recognized as causing renal damage in children, especially in the face of infection. However, it is unclear if the same problems arise in adults. Medium to long-term results with a refluxing type of reservoir such as the Studer pouch show that normal renal function and preserved upper tract anatomy are possible in the majority of patients. Early experience with the Kock ileal neobladder, which included an intussuscepted nipple antireflux valve, showed that the valve mechanism

could be a source of upper tract obstruction, sometimes developing after 10 years or more. The T-pouch was developed by Stein and Skinner in a modification of a pouch designed by Ghoneim to attempt to avoid the risk of late stenosis while maintaining an antireflux system. However, occasional late stenosis of this system has also been observed. A randomized study with over 400 patients comparing the Studer and T-pouch constructions at the University of Southern California (USC) showed no difference in renal function at 3 years but an increased risk of diversion-related procedures in the patients who had a T-pouch.

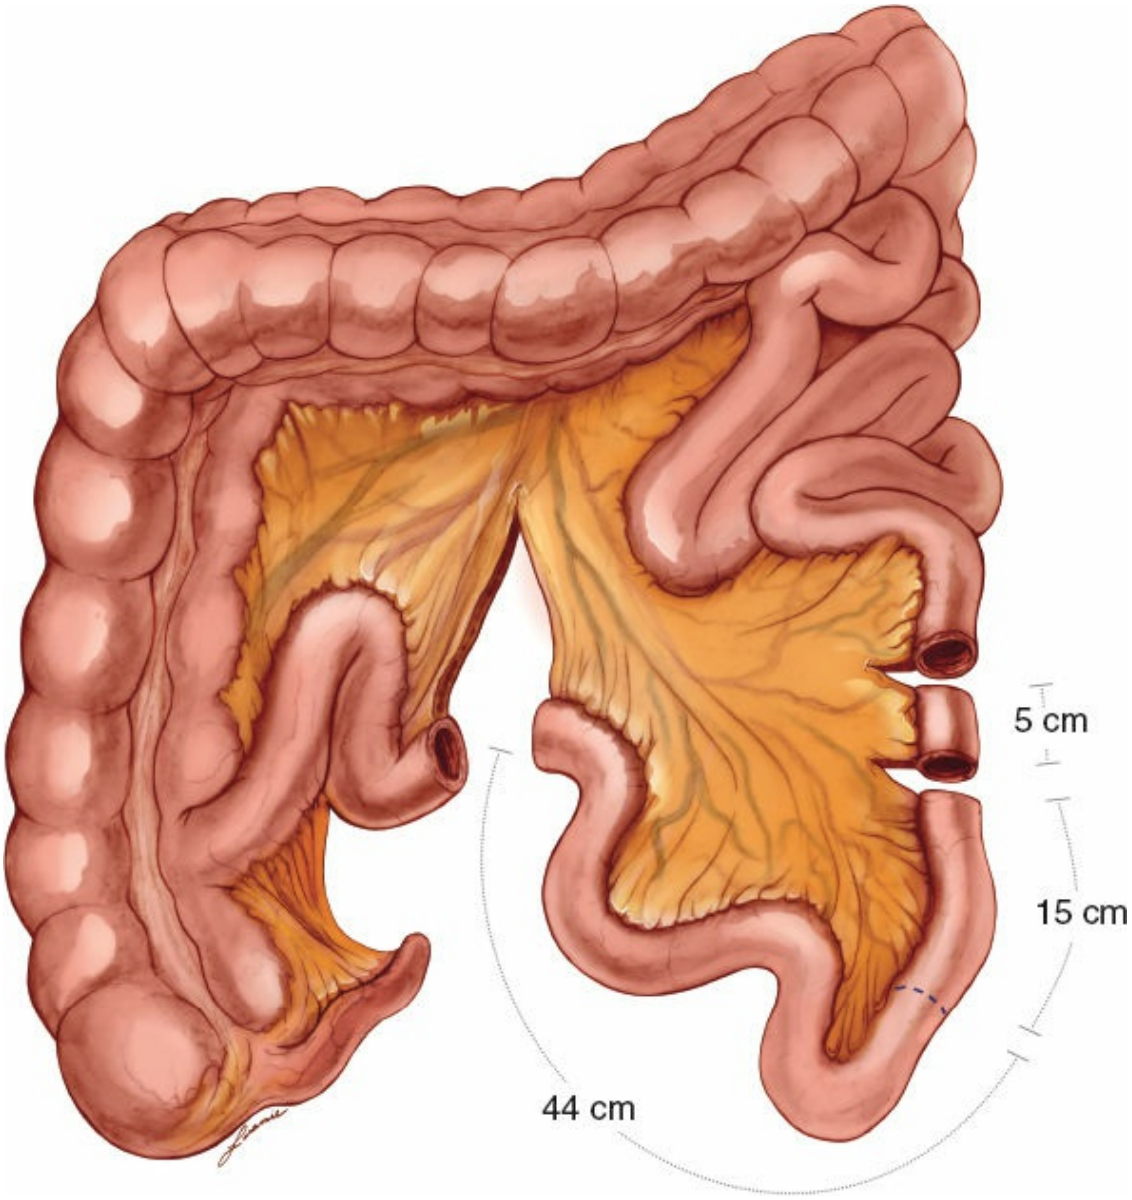

Figure 175.18. Segments of terminal ileum for construction of the orthotopic Studer pouch ileal neobladder. The distal mesenteric division is made between the ileocolic and terminal branches of the superior mesenteric artery, which extends into the avascular plane of the mesentery. In addition, a small window of mesentery and a 5-cm segment of proximal small bowel are discarded to allow mobility to the pouch and small bowel anastomosis. This avoids deep incision into the mesentery proximally, which could compromise the blood supply to the pouch.

We describe here the technique for the modified Studer pouch (without an antireflux mechanism), which is currently the most popular form of ileal neobladder reconstruction in the United States. However, we will also describe how to construct an extra-serosal tunnel antireflux mechanism (T-

pouch) for cases in which prevention of reflux is believed to be beneficial.

SURGICAL TECHNIQUE

The Studer Ileal Neobladder

The terminal portion of the ileum is used to construct the Studer pouch. The distal mesenteric division is made along the avascular plane of Treves between the ileocolic artery and terminal branches of the superior mesenteric artery. This division extends deep into the avascular portion of the mesentery, which is essential for adequate mobility of the reservoir. The proximal mesenteric division, however, is short and provides a broad vascular blood supply to the reservoir. In addition, a small window of mesentery and 5 cm of small bowel proximal to the overall ileal segment are discarded, ensuring mobility to the pouch and small-bowel anastomosis. The bowel segments are divided using the GIA stapler in its most proximal and distal aspect (Fig. 175.18).

The reservoir is created from 44 cm of distal ileum with each limb of the "U" measuring 22 cm, and a proximal 12-cm segment of ileum used as the afferent limb. If ureteral length is short or compromised, a longer afferent ileal segment may be used. The proximal end of the isolated afferent ileal segment is closed with a running Parker-Kerr suture of 3-0 chromic and an imbricating layer of interrupted 3-0 silk sutures. A standard small bowel anastomosis is performed to reestablish bowel continuity, and the mesenteric trap is closed.

The isolated 44-cm ileal segment is then laid out in an inverted "U" configuration, with the apex of the "U" lying caudally and a suture marking a point between the two 22-cm adjacent segments of ileum. It is important to discard the staple line at this point to prevent stone formation in the pouch. Starting at the apex of the "U," the bowel is then opened about 2 cm away from the mesentery using electrocautery and carried upward to the afferent limb (Fig. 175.19). The previously incised ileal mucosa is then oversewn with two layers of a running 3-0 polyglycolic acid suture starting at the apex and running upward to the afferent limb. Once the ostium of the afferent limb is reached, the running suture is tied (Fig. 175.20).

T-Pouch Modification

The technique is modified for construction of an antirefluxing afferent

limb in the T-pouch. The ileum is divided between the proximal afferent ileal segment and the 44-cm segment, and the antireflux mechanism is created by anchoring the distal 3 to 4 cm of the 15-cm afferent ileal segment into the serosal-lined ileal trough formed by the base of the two adjacent 22-cm ileal segments. Mesenteric windows of Deaver are opened between the vascular arcades on the T-limb. A series of 3-0 silk sutures are then used to approximate the serosa of the two adjacent 22-cm ileal segments at the base of the "U" with the sutures being passed through the previously opened windows of Deaver to anchor the afferent limb (Fig. 175.21). The anterior portion of the afferent limb is tapered over a 30-Fr catheter. When the incision in the "U" limb of reservoir reaches the level of the afferent ostium, it is extended directly lateral to the antimesenteric border of the ileum and carried upward (cephalad) to the base of the ileal segment. This incision provides wide flaps of ileum that is brought over the tapered afferent ileal segment and sutured in two layers to create the antireflux mechanism in a flap-valve technique (Fig. 175.22A). An interrupted mucosa-to-mucosa anastomosis is then performed between the ostium of the afferent ileal limb and the incised intestinal ileal flaps with 3-0 polyglycolic acid sutures (Fig. 175.22B). The rest of the neobladder is constructed in the same fashion as the Studer pouch.

For both techniques, the reservoir is closed by folding it in half in the opposite direction to which it was opened (Fig. 175.20). This effectively creates a low-pressure, high-capacity urinary reservoir. The anterior wall is closed with a two-layer 3-0 polyglycolic acid suture that is watertight (Fig. 175.23). This anterior suture line is stopped prior to the end of the (patient) right side to allow insertion of an index finger. This is the most mobile and dependent portion of the reservoir and will later be anastomosed to the urethra (Fig. 175.24). Alternatively, a new hole of 8 to 10 mm can be created in the most caudal part of the reservoir.

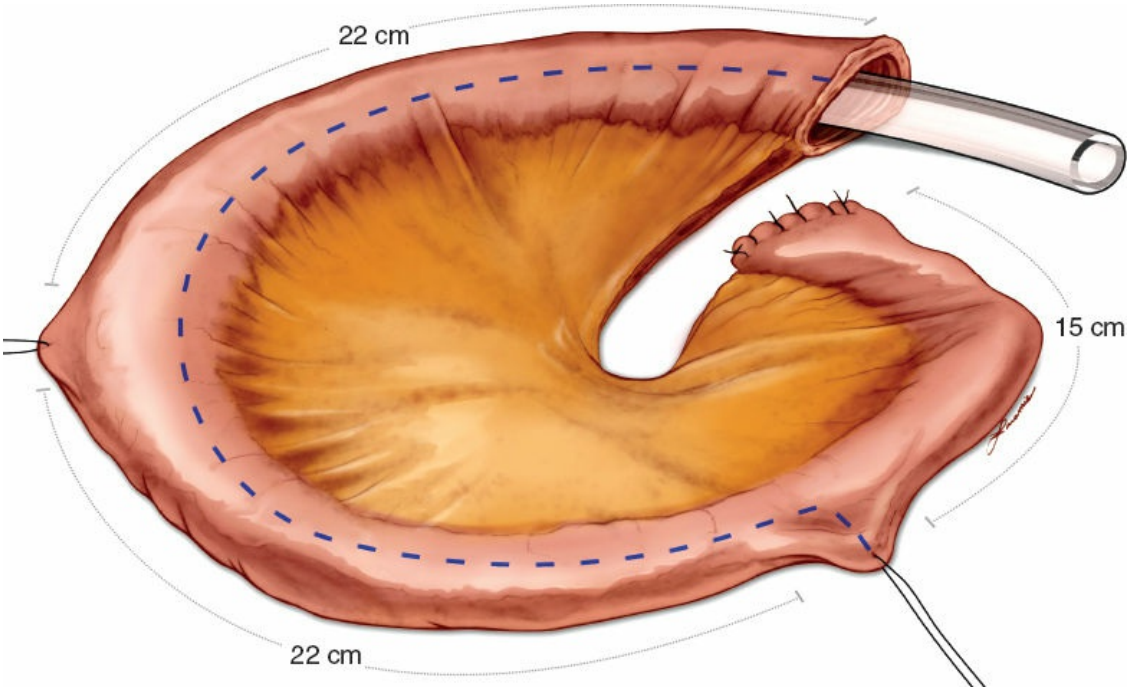

Figure 175.19. The reservoir is constructed from two 22-cm ileal segments (placed in an inverted "U" configuration). A proximal 12- to 15-cm segment of ileum forms the afferent limb. The two 22-cm ileal segments are opened along the medial mesentery.

Once the pouch has been closed, each ureter is spatulated and a standard bilateral end-to-side ureteroileal anastomosis is performed using interrupted 4-0 polyglycolic acid suture (Fig. 175.24, inset). These anastomoses are stented with 8-Fr infant feeding tubes or 7-Fr urinary diversion stents, which are directed from the ipsilateral renal pelvis (kidney) across the ureteroileal anastomosis through the afferent limb into the reservoir. A 24-Fr hematuria catheter is placed per urethra to provide adequate drainage of the reservoir, and the ureteral stents are secured to the end of the urethral catheter with a 3-0 nylon suture. This facilitates removal of the stents at 3 weeks along with the urethral catheter. A tension-free mucosa-to-mucosa urethral anastomosis is performed using the previously placed urethral sutures (Fig. 175.25). Lifting the sigmoid out of the pelvis provides space to bring the pouch down to the urethra. The pouch is irrigated to check that all suture lines are water-tight. A drain is placed and the abdomen is closed.

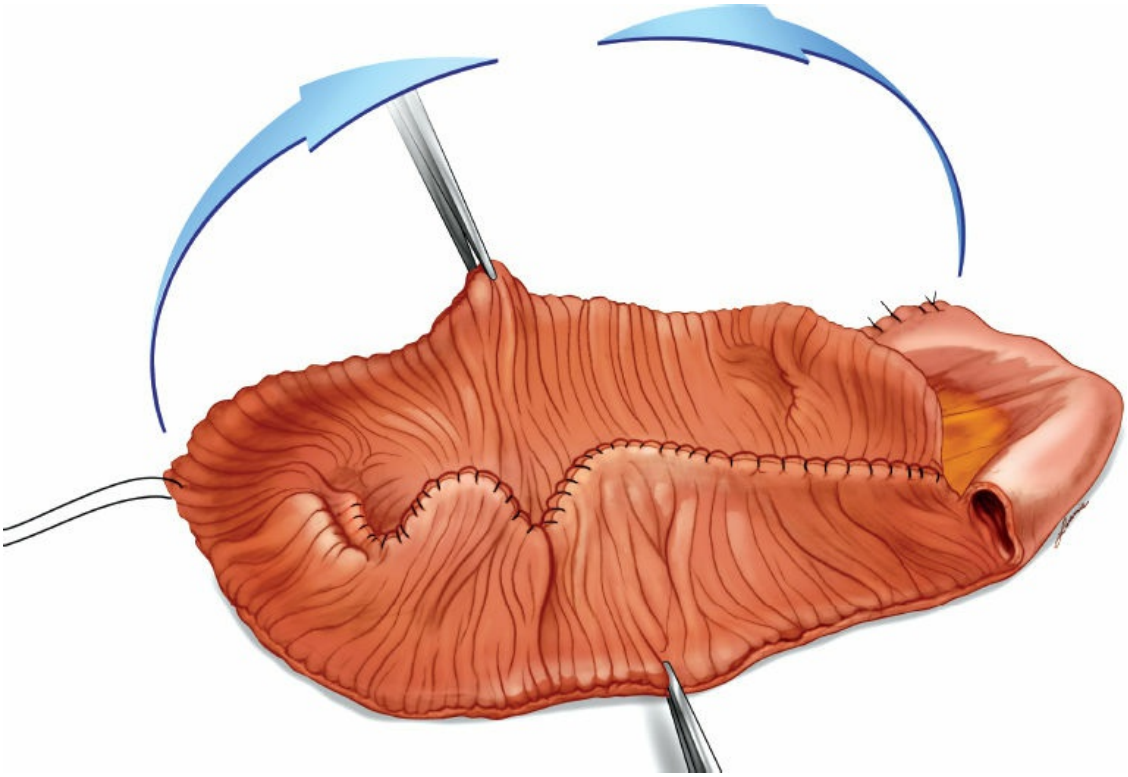

Figure 175.20. The two 22-cm segments are joined with a running 3-0 polyglycolic acid suture starting at the apex and running upward to the afferent limb. A second layer may be used for security. The reservoir is then closed by folding it in half in the opposite direction to which it was opened and that suture line closed in a similar fashion.

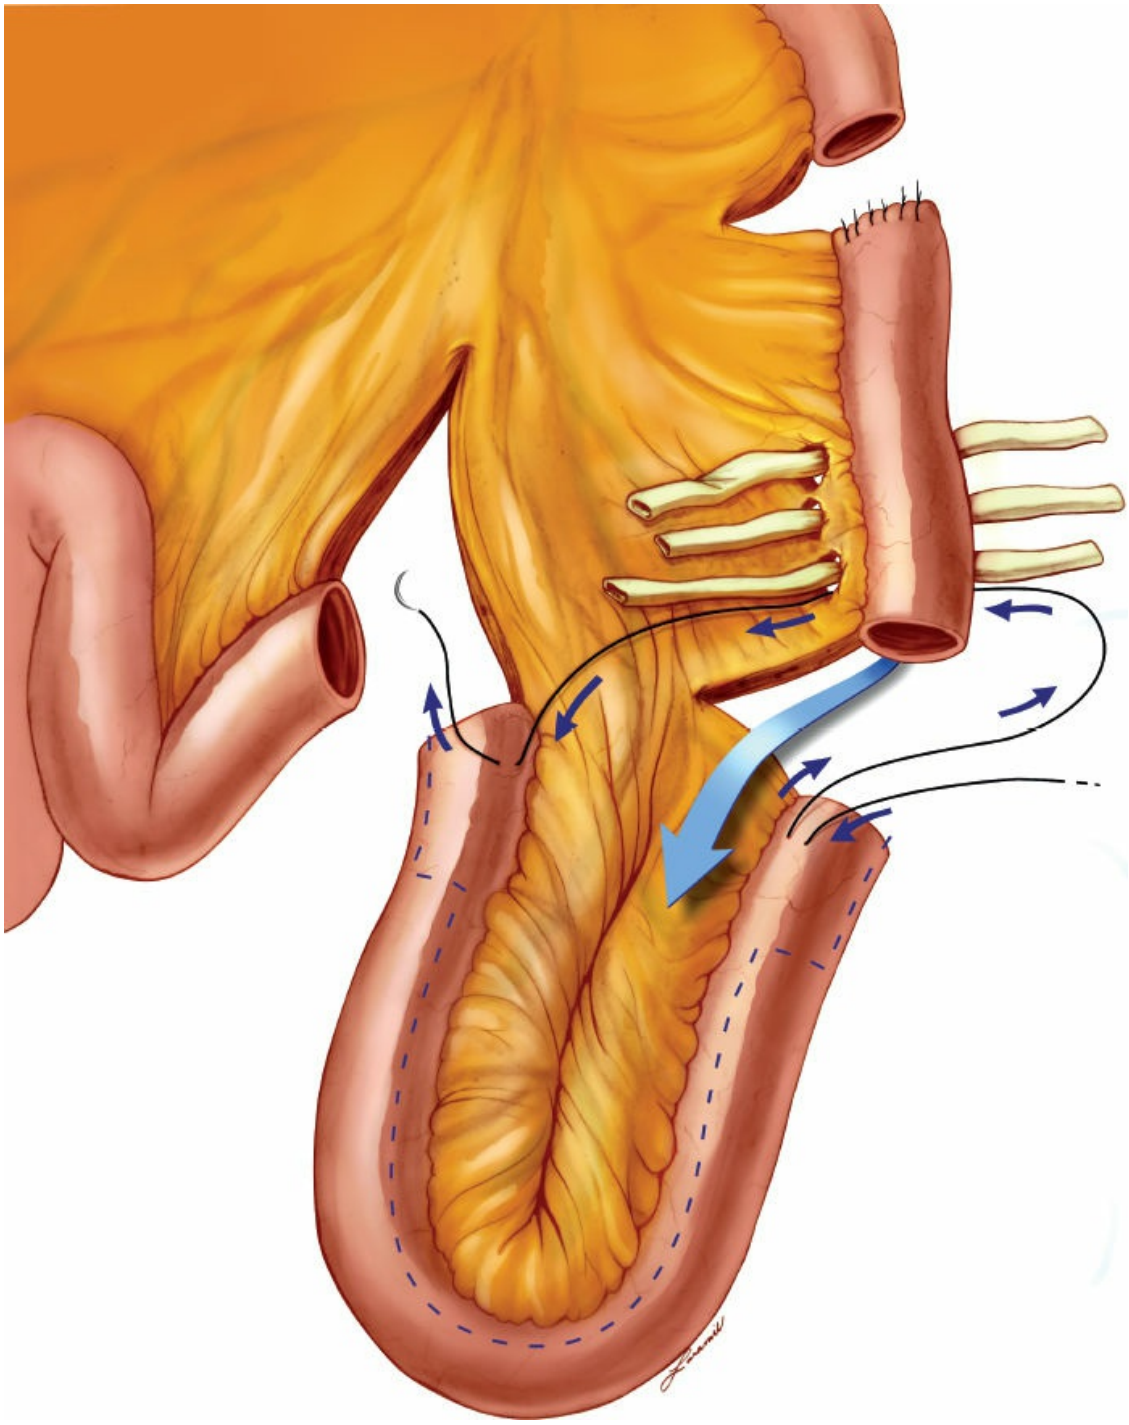

Figure 175.21. Construction of the antireflux mechanism in the T-pouch. The ileum is divided between the proximal afferent ileal segment and the 44-cm segment. The dotted line depicts the incision line on the U limbs. Mesenteric windows of Deaver are opened between the vascular arcades adjacent to the serosa of the separated afferent limb. Placement of small Penrose drains through each mesenteric window helps facilitate passage of sutures. The distal 3 to 4 cm of the afferent ileal segment is anchored into a serosal-lined ileal trough formed by the base of the two adjacent 22-cm ileal segments, using 3-0 silk sutures.

POSTOPERATIVE MANAGEMENT

A clinical care pathway is used to manage these patients postoperatively with a team approach. The ERAS protocol includes patient education, no bowel prep, no postoperative nasogastric (NG) tube, minimization of narcotics, judicial use of perioperative IV fluids, and the use of a μ-opioid antagonist (alvimopan) to decrease ileus related to narcotics. At USC, the ERAS protocol reduced postoperative hospital stay from a median of 8 to 4 days without an increase in readmissions or complications. The primary benefit is from a significant decrease in postoperative ileus and other bowel complications (Table 175.5).

Most patients do not require ICU management unless they have serious cardiac or pulmonary disease. Prophylaxis against deep vein thrombosis is important, using subcutaneous heparin or fractionated heparin compounds as well as leg squeezers. Anticoagulation with low molecular weight heparin should be continued for at least 4 weeks after surgery as supported by large randomized clinical trials of patients undergoing pelvic cancer surgery. Alvimopan is begun on the AM of surgery and continuing for up to 7 days or until discharge. Early feeding has been demonstrated to be safe and to improve recovery of bowel function. Sips of liquids (including high-carbohydrate, high-protein fluids) are started early on the evening of surgery if tolerated. On POD 1, patients are started on a regular diet (tailored for postoperative surgical patients) provided the patient has no nausea, vomiting, or abdominal distention, regardless of gas passage or bowel movement. Laxatives are used as needed. If the patient is not tolerating oral food by POD 6 or 7 and there is no bowel activity, parenteral nutrition is considered.

We manage catheters and drains using a 24-Fr hematuria urethral catheter to which the ureteral stents are secured so that they can all be removed together at 3 weeks from surgery. The drain is also left in the entire 3 weeks to allow for drainage in the event of a urinary leak from the pouch as it heals. We irrigate the Foley catheter every 4 to 6 hours in the hospital to prevent mucous plugs and teach the patient and family to do so at least three to four times daily after discharge. Patients without major complications are generally discharged 4 to 5 days postoperatively.

COMPLICATIONS

Early Complications

Early postoperative complications are common, occurring in >50% of patients, with major complications occurring in ~15%, and postoperative mortality rates of 2% to 4% in most modern series. The most common causes of complications include gastrointestinal problems (although ileus has markedly decreased with current management), cardiovascular and pulmonary complications, hemorrhage, infections, thrombotic events, and problems related to the urinary diversion (Table 175.5). Many studies have shown that the overall incidence of early complications, mortality, and hospital stay are not increased with continent diversion compared to ileal conduit.

Urine leaks are fairly common in continent diversion because of the long suture lines. However, the majority will resolve with observation alone with proper management of catheters and drains. An undrained leak is best treated with an attempt at percutaneous drainage and/or bilateral nephrostomy tube placement rather than open surgical repair, which can be extremely difficult during the first few weeks after the initial surgery. Similarly a pelvic abscess or leak from the bowel anastomosis whenever possible is managed with percutaneous drainage and bowel rest rather than reoperation. In our experience, 5% of patients require some sort of percutaneous drain or nephrostomy tube placement during the early postoperative period to manage these problems. Early operative intervention is rare, primarily used to treat either severe hemorrhage or a dense early bowel obstruction that fails to resolve with conservative management.

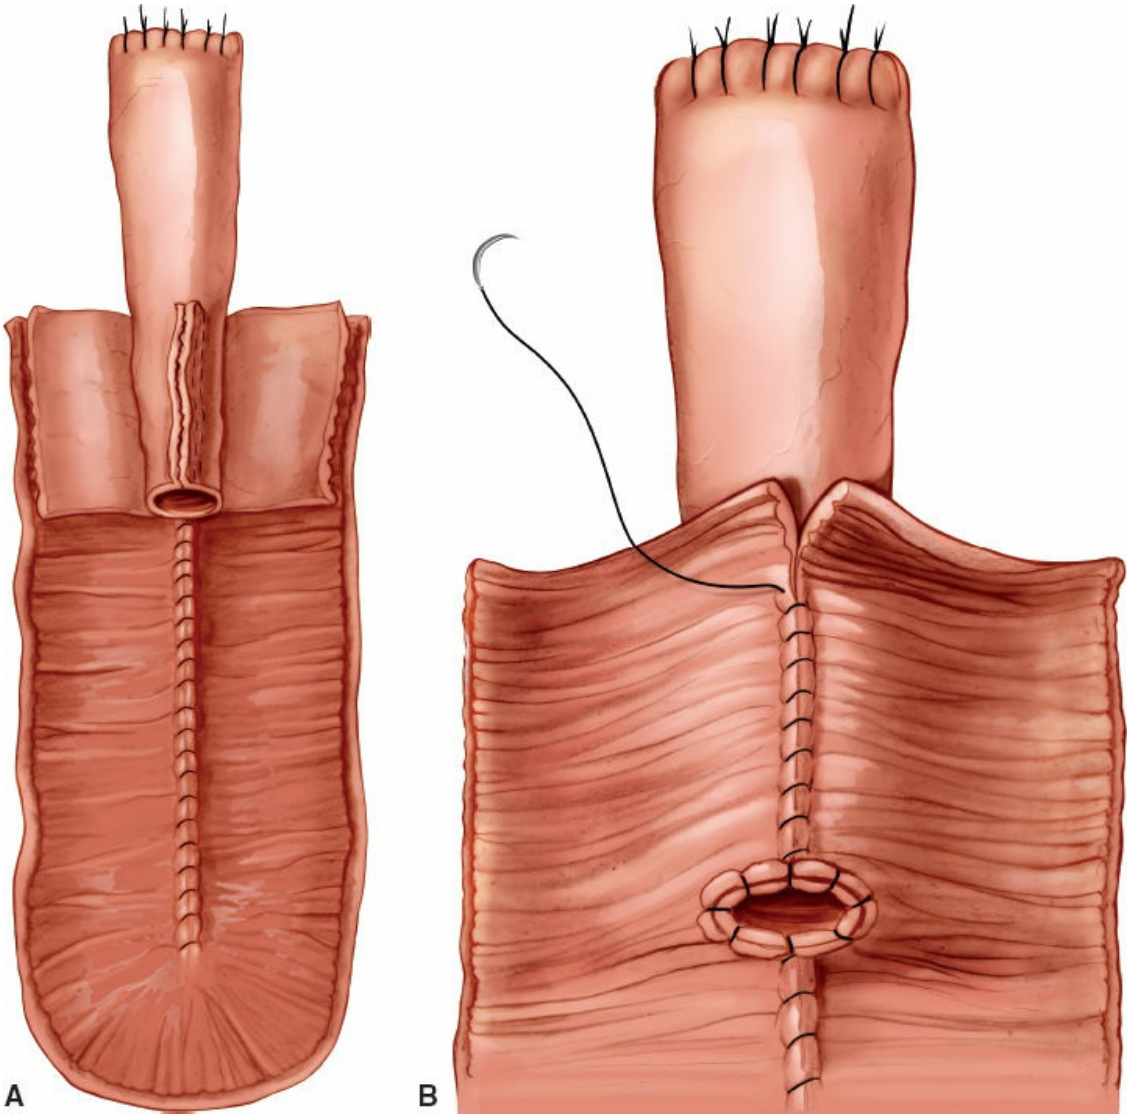

Figure 175.22. Construction of the antireflux mechanism in the T-pouch. **A.** The previously anchored distal 3- to 4-cm afferent ileal segment may be tapered over a 30-Fr catheter or may be left intact. The pouch is then opened creating wide flaps of ileum at the level of the tunnel. The flaps are brought over the tapered distal afferent ileal segment to form the antireflux mechanism in a flap-valve technique. **B.** The ostium of the afferent segment is matured into the reservoir using interrupted 3-0 polyglycolic acid suture.

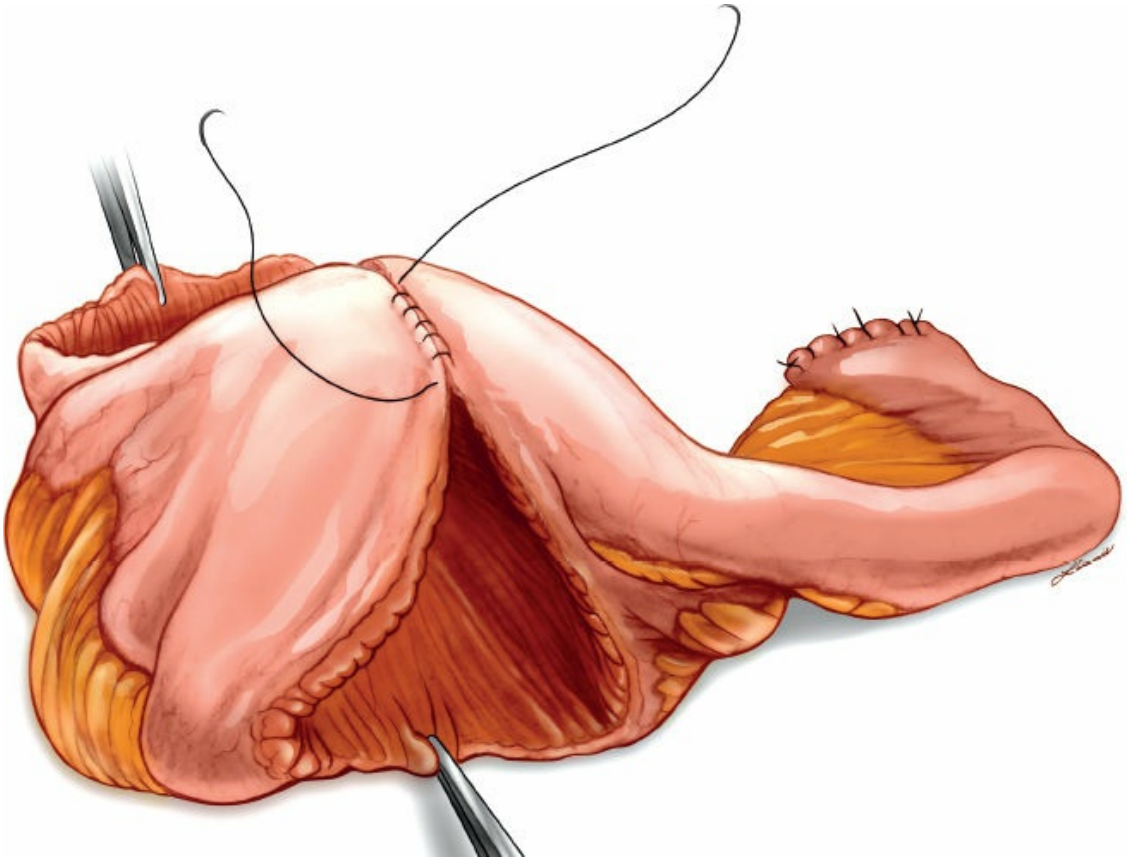

Figure 175.23. Once the reservoir is folded in half, the anterior wall is closed with a two-layer 3-0 polyglycolic acid suture that is watertight. Note that the anterior suture line is stopped just short of the (patient) right side to allow insertion of an index finger, which will ultimately be attached to the urethra. Alternatively the suture line may be closed completely and a separate small opening made for the urethral anastomosis.

Another common cause of early readmission to the hospital after discharge is dehydration, often associated with the development of nausea or vomiting or diarrhea. The neobladder tends to excrete water and counteract normal urinary concentrating ability in the face of dehydration. This can result in the rapid development of dehydration, especially in elderly patients and those with baseline renal insufficiency. Support with IV fluids in the first few weeks is all that is typically required for this self-limiting problem. Finally, febrile urinary tract infections are also common due to the required prolonged catheter drainage. The ideal method to prevent such infections has not been determined, although long-term antibiotics do not seem to be able to prevent such complications.

Late Complications

The primary late complications of orthotopic neobladders include recurrent urinary tract infections, pouch stones, uretero-ileal stricture, vesico-urethral stricture (rare), metabolic complications, and incontinence. All of these problems except incontinence can be managed initially with endoscopic techniques.

Many neobladder patients will have urine that is chronically colonized with bacteria, especially if they have to self-catheterize regularly. We make an initial attempt to eradicate the bacteria, but long-term antibiotics will only result in resistant organisms. Patients with recurrent febrile urinary tract infections or pyelonephritis should be evaluated to rule out incomplete emptying, ureteral obstruction, or stones.

Pouch perforation is a rare but potentially life-threatening complication. We are aware of at least two deaths due to pouch perforation that was unrecognized when the patient was admitted to an outside hospital. Acute abdominal pain in a patient with any form of continent diversion should be evaluated with a CT cystogram, and a perforation should be generally managed with open exploration and repair.

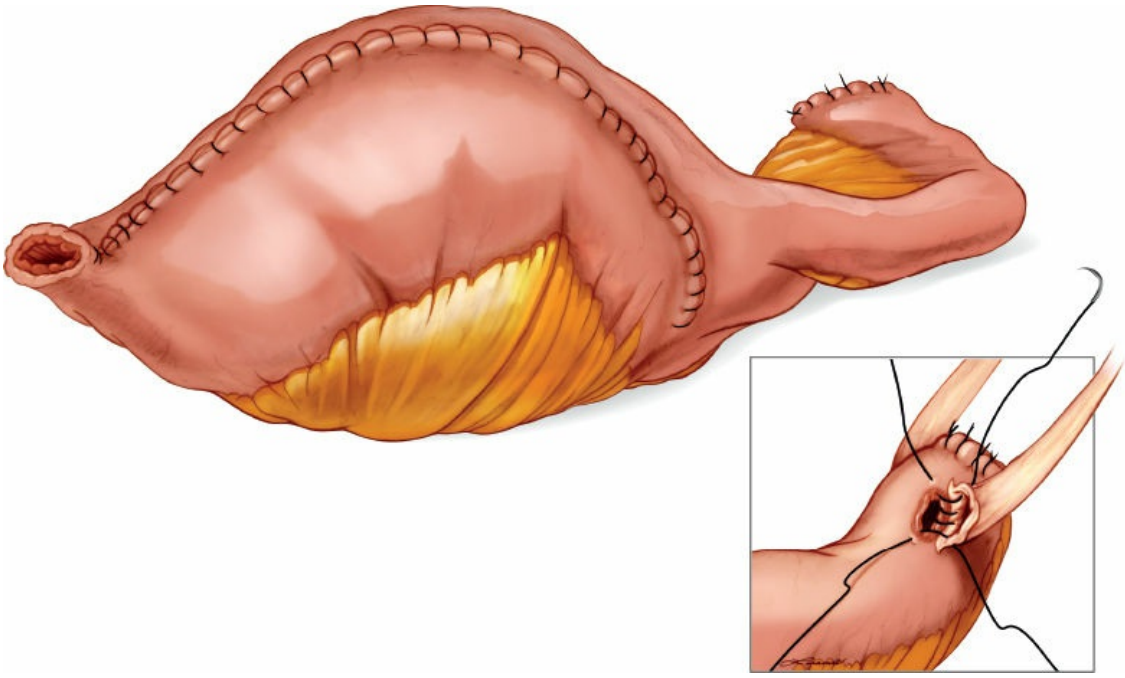

Figure 175.24. Each ureter is spatulated and a standard bilateral end-to-side ureteroileal anastomosis is performed using interrupted 4-0 polyglycolic acid suture. The ureters are stented with either stents that can be tied to the foley catheter or brought out through the pouch to the skin.

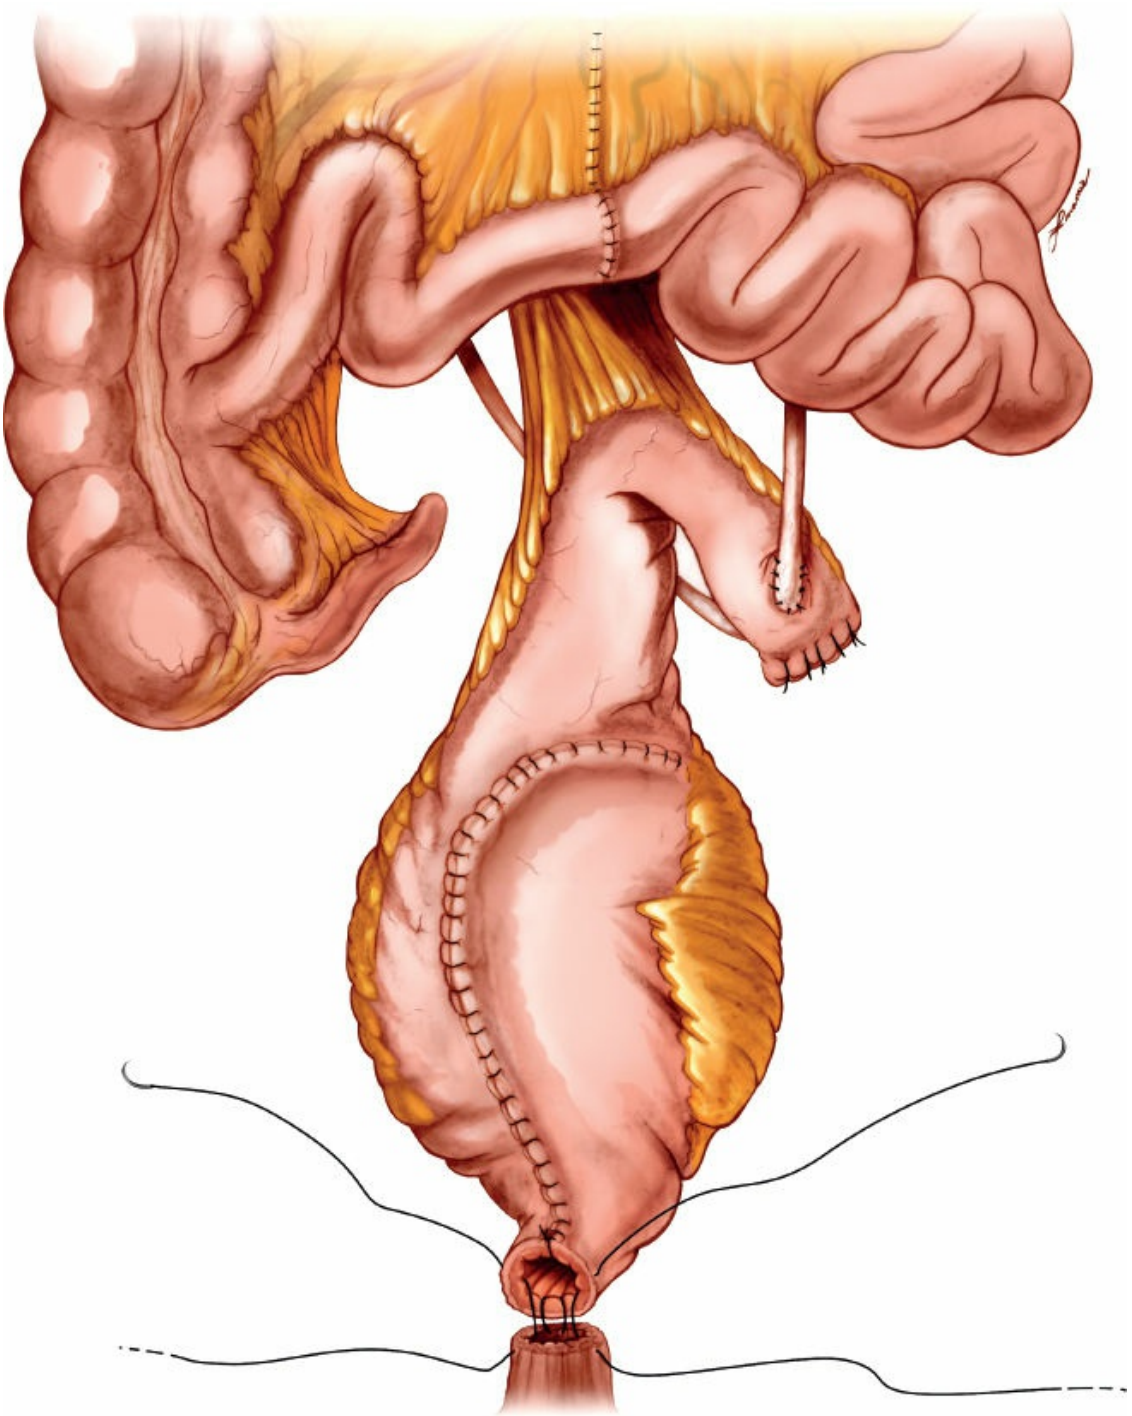

Figure 175.25. The most mobile and dependent portion of the reservoir will be anastomosed to the urethra using the previously placed urethral sutures.

Metabolic problems may develop in patients with continent diversion. The most common is vitamin B_{12} deficiency due to the use of the distal ileal segment. We check serum B_{12} levels annually in all patients and add intramuscular or sublingual supplements when serum levels drop below normal. Diarrhea occasionally may be a long-term problem due to the loss

of bile absorption from the distal ileum. Treatment with oral cholestyramine will usually control this. Patients with chronic renal insufficiency can also lose significant bicarbonate and develop hyperchloremic acidosis. This complication is rarely seen in patients with a creatinine clearance above 40 mL/min. It is treated with chronic sodium bicarbonate or sodium citrate supplementation.

Stones may occur in the neobladder or upper tracts and may be a source of continued infection, obstruction or bleeding. Obstruction of the uretero-ileal anastomosis is usually due to fibrosis and scar, although the possibility of tumor recurrence should be entertained. Urethro-ileal anastomotic strictures are extremely rare probably at least in part due to the excellent blood supply of the pouch and the urethral stump. Endoscopic management is usually possible, although not universally successful. Obstruction of an antireflux valve mechanism may present with silent renal failure with bilateral hydronephrosis. This can also be managed endoscopically in most cases.

Long-term follow-up of patients with continent diversion initially is driven by surveillance for cancer recurrence. After that risk has passed (3 to 5 years), the patient should continue to have periodic upper tract imaging (e.g., annual ultrasound and KUB or CT scans) along with serum chemistries and B_{12} levels. Urinary cytology is also useful to diagnose upper tract or urethral recurrence.

OUTCOME

Cancer Cure

The recurrence-free survival in a series of 1,488 patients treated at USC from 1980 to 2005 was 68% and 66% at 5 and 10 years. Overall survival was 66% and 43% at 5 and 10 years (Table 175.6). Most deaths occurring within the first 3 years following radical cystectomy are due to bladder cancer recurrence. With continued follow-up (after 3 years), most deaths in this elderly group of patients are primarily related to other diseases. Recurrence-free survival has not improved over this time. Although adjuvant chemotherapy was given to patients with extravesical extension, fewer than 50% were able to receive it in this series. In recent years, neoadjuvant chemotherapy has been provided to all patients with muscle-invasive disease who have acceptable renal function, which may provide some improvement over these numbers.

TABLE 175.5 90-Day Complications by Category, ER Visits and Readmissions With ERAS Protocol Compared to Historic Controls

Complication	ERAS%	Control%	p Value

The median time to any recurrence was 12 months, with 86% of all patients developing their recurrence with the first 3 years postoperatively. Distant recurrence was the most common finding, observed in 75% of those suffering a recurrence. The overall local recurrence rate in our series using this standardized surgical approach with a thorough extended lymphadenectomy was only 7%. Median time to distant recurrence was 12 months and local recurrence 18 months.

The pathologic stage of the primary bladder tumor and the presence of lymph node metastases are the most important survival determinants in patients undergoing cystectomy for bladder cancer (Table 175.6). Patients may be categorized into organ-confined (pT0, pTa to pT2b, N0), extravesical (pT3, pT4, N0), and node-positive subgroups (any T stage, N1-N2) that allow for simplified risk stratification. The incidence of lymph node tumor increases with increasing primary bladder tumor stage (Table 175.7). Other pathologic predictors of recurrence following cystectomy include lymphovascular invasion (in node-negative patients), and a number of genetic alterations and protein tumor markers. Most of these have not been studied in a prospective manner.

Although patients with positive lymph nodes are at very high risk of recurrence, nearly one third of these patients in our series were alive at 5 years, and 23% were alive without recurrence at 10 years. The prognosis in patients with lymph node-positive disease can be stratified by the number of lymph nodes involved (tumor burden), and by the p stage of the primary bladder tumor. Patients with fewer than five positive nodes and with

organ-confined bladder tumors had a significant improved recurrence-free survival compared to those with nonorgan-confined disease or more than five positive nodes. The concept of lymph node density (defined as the total number of positive lymph nodes divided by the total number of lymph nodes removed) accounts for the extent of the lymph node dissection (number of lymph nodes removed) and the tumor burden (number of positive lymph nodes) and was previously shown to have independent prognostic value. In a recent update, submission of the nodes in 13 separate packets significantly increased the total lymph node yield, but did not result in a significant increase in the number of positive nodes or a consecutive nodal stage shift. In this study, lymph node density was not an independent predictor of recurrence. For patients with positive nodes, the level of the highest positive lymph node (above or below the common iliac bifurcation) was a predictor of recurrence, as was receipt of adjuvant chemotherapy.

TABLE 175.8 Day and Nighttime Continence Results With Ileal Neobladders

Author and Pouch Type	Number of Patients	Daytime Continence (%)	Nighttime Continence (%)	Requiring Catheterization (%)
Elmajian 1996 Kock reservoir	295	87	86	8
Hautmann 1999 ileal neobladder	363	96	95	6
Stein 2004 T-pouch	209	87	72	25
Studer 1996 Studer pouch	200	90	80	0.5
Ali-el-Dein 2008 ileal neobladder (females)	192	92	72	16
Stein 2009 (females)		77	66	63% (39% catheterize regularly)

Continence

There is no consensus on the definition of continence or the measures used to describe it in patients undergoing orthotopic reconstruction. Continence can be influenced by a number of factors, including patient age, gender, prior radiation therapy, diabetes, and the segment of bowel used for the reservoir as well as factors such as how often the patient wakes to void at night. However, in spite of this variability, there is remarkable consistency in the rates of continence described in series using ileum for the neobladder (Table 175.8). Most patients undergoing orthotopic diversion experience improving daytime continence over the first 3 to 6 months, with continued improvement out to 12 months and beyond.

From 2000 to 2014, a total of 1,545 patients underwent open radical cystectomy at USC. Orthotopic ileal neobladder was constructed in 1,057

(68%) patients, of whom 892 (84%) were male. A total of 345 pad usage questionnaires have been collected prospectively from 161 male patients from 2012 to 2014 of whom 58% reported daytime continence within 3 months of surgery. By 12 to 18 months postoperatively, daytime continence had increased to 89%. Nighttime continence increased from 25% at 3 months to 52% by 18 to 36 months. Reporting of combined daytime and nighttime continence increased from 25% within 3 months postoperatively to 50% by 18 to 36 months (Fig. 175.26). As the functional capacity of the neobladder increases and mucosal changes occur over time, there is less absorption of electrolytes from the surface and less of a nocturnal diuretic effect caused by the electrolyte shifts. Physical therapy with biofeedback focused on the pelvic floor muscles may help some patients attain initial continence. Patients should be encouraged to wait until the second year to pursue any surgical treatment such as a sling or artificial sphincter device.

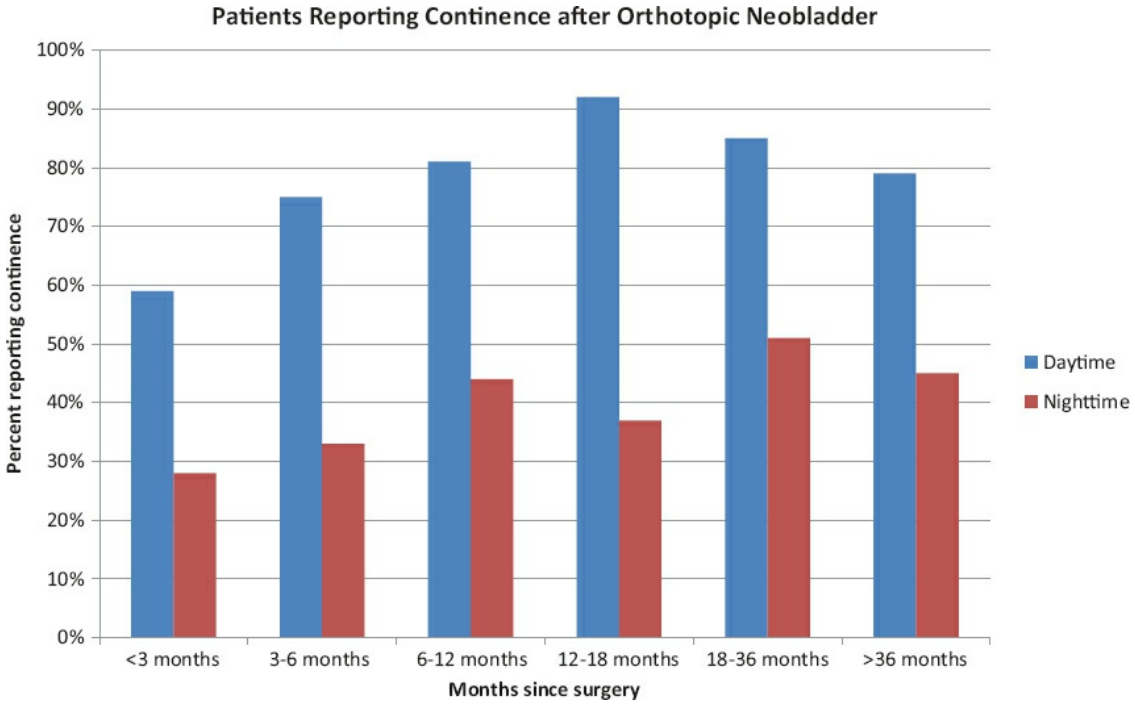

Figure 175.26. Reports of continence on a patient-reported questionnaire filled out prospectively by 161 male patients at various times after undergoing cystectomy and ileal neobladder.

Urinary Retention

Failure to empty or urinary retention has been reported in a wide range of patients undergoing orthotopic reconstruction at various centers, and is

more common in women than in men. Self-catheterization was reported in 13% of men in the 161 patients participating in the questionnaire study described above. Median time from surgery to starting catheterization was 15.8 months (1.2 to 63.7 months). A similar study of 56 female patients using patient-reported questionnaires found similar continence rates as in male patients, but as many as 62% used intermittent catheterization at least occasionally. Patients with incomplete emptying may present with acute retention but more often present with recurrent infections or the new onset of overflow incontinence. The retention may also be discovered on routine follow-up with a distended reservoir on imaging or on postvoid residual check. The development of retention is often a late event, so the reported rates are very much influenced by the length of follow-up of the series.

CONCLUSIONS

The clinical results and outcomes following radical cystectomy and extended pelvic lymph node dissection demonstrate good survival, with excellent local recurrence rates for high-grade, invasive bladder cancer. Details of the surgical technique including surgeon experience, the extent of lymphadenectomy, and the dissection around the proximal urethra have all been shown to impact outcomes of the surgery in terms of both cancer cure and functional outcomes.

These results provide sound data and a standard to which other forms of therapy for invasive bladder cancer can be compared. Furthermore, improvements in orthotopic urinary diversion have allowed us to offer this type of diversion to most men and women undergoing radical cystectomy. Continence rates following orthotopic diversion are good and provide patients a more natural voiding pattern per urethra.

In conclusion, a properly performed radical cystectomy with an extended lymphadenectomy provides the best survival rates, with the lowest reported local recurrence rates for high-grade invasive bladder cancer. The surgical technique is critical to optimize the best clinical and technical outcomes in patients with this procedure. Advances in lower urinary tract reconstruction provide a reasonable alternative for patients undergoing cystectomy.

EDITOR'S COMMENT

The operation of radical cystectomy and urinary diversion has evolved in many facets over the last two decades leading to a safer and possibly more curative operation with significant improvements in quality of life for some patients. In large part, these improvements in care are the result of a greater understanding of the anatomy of the operation, emphasizing the importance of not only quantity but quality of lymphadenectomy, refinement in continent urinary reservoir design, and postsurgical recovery pathways that shorten hospital stay. The authors of this chapter very nicely outline these points by sharing their extensive experience with this operation. Nevertheless radical cystectomy remains a highly complex surgical procedure and outcomes are influenced by surgical volume, hospital setting, and extent of postresidency training leading to the argument for centralization of radical cystectomy care at centers of experience.

Several recent publications from experienced centers demonstrate that at least 70% of patients experience some form of complication following radical cystectomy, mostly Clavien–Dindo grades 1 and 2, however 15% to 20% of patients experience Clavien–Dindo grades 3 to 5 complications. The negative impact of complications on quality of life, cost to the health care system, and inability to provide adjuvant cancer therapies in a timely manner have all been reported and provide a sobering reminder of the challenges to a patient of undergoing a radical cystectomy. Unfortunately the initial enthusiasm of minimally invasive surgical techniques to reduce complications, including robot-assisted radical cystectomy, has been tempered by several reports, including recently reported randomized clinical trials that demonstrate no improvement in complication rate, length of hospital stay, or hospital readmissions with these techniques.

A recent focus on enhanced recovery after surgery (ERAS) pathways is favorably impacting complication rates after radical cystectomy by reducing bowel-related complications, mostly ileus, leading to earlier hospital discharge. Importantly earlier hospital discharge is not leading to higher readmission rates or number of emergency room visits. Most ERAS protocols focus on precystectomy patient education, (usually with an enterostomal therapist), avoiding a bowel preparation, not placing a postoperative nasogastric tube, early feeding, nonnarcotic pain management, and the use of cholinergic and mu-receptor opioid antagonists. As a result of these changes infectious complications have become the most common complication of radical cystectomy and it is imperative that more attention is focused on how to reduce

this problem.

The chapter provides a very nice detailed description of the operation and important aspects of pelvic anatomy as it pertains to improving oncologic and quality-of-life outcomes following radical cystectomy and orthotopic ileal neobladder. Multiple reports demonstrate that performing a lymphadenectomy at radical cystectomy reduces the rate of positive soft tissue surgical margins and improves overall cure rates from the disease, including curing some patients with metastatic disease to the regional lymph nodes. However, there is a lack of consensus as to how extensive of a lymph node dissection needs to be performed to provide the most oncologic benefit (i.e., bifurcation of the common iliac artery [standard dissection] vs. bifurcation of the aorta [extended dissection]). The authors of the chapter describe a lymph node dissection whose proximal extent is the inferior mesenteric artery (super-extended dissection) and is more extensive than what is done by most surgeons who treat this disease. Fortunately two randomized trials have recently met accrual and closed in the United States and Germany that will provide higher-quality evidence of how different templates of lymphadenectomy affect cancer outcomes and the results of these studies are highly anticipated. Nevertheless it is clear that a lymphadenectomy is an important aspect of the radical cystectomy operation and should be done in all patients.

Preservation of erectile function in a man is challenging for any pelvic operation due to damage to the neurogenic mechanism and possibly the vasculogenic mechanism responsible for erections. The chapter outlines the anatomy of the pelvic plexus and neurovascular bundles responsible for erections that course alongside the tip of the seminal vesicles and in close continuity to the prostate fascia and urethra. Knowing the anatomy of these structures is important for potency-sparing surgery but even with concerted surgical effort to preserve the neurovascular bundles at the time of radical cystectomy the literature is limited both in number and the quality of the studies that measure erectile function after radical cystectomy. Therefore, it is not uncommon that men who desire erectile function after radical cystectomy often require penile injection therapy with vasculogenic agents or surgical placement of an inflatable penile prosthesis. Reports from France suggest that in highly selected younger patients in whom oncologic outcome is unlikely to be compromised that prostate/seminal vesicle–sparing surgery, including preserving only the prostate capsule or the apex of the prostate, leads to high potency rates after radical cystectomy by not disrupting the neurovascular bundles. This approach is somewhat controversial because of cancer recurrence risk but is worthy of discussion in very highly selected individuals.

The number of individuals in the US population who are choosing orthotopic ileal neobladder construction as opposed to an external appliance or urostomy is less than 20% however the number is slowly growing. Quality-of-life studies published to date demonstrate that there is no difference in various health-related domains between patients who choose an ostomy or an orthotopic

neobladder. This may be more a reflection of properly educating and managing patient expectations for a given urinary diversion. Importantly it can take up to 18 months to achieve daytime continence and 36 months to achieve nighttime continence for a neobladder. It is fair to assume that only 50% of men will achieve total day and nighttime continence but up to 85% will remain dry during the day and nighttime leakage is more the norm than the exception. Age and other patient factors, including body mass index, seem to impact neobladder function and continence and this can change over time. The authors of the chapter have a wealth of experience with orthotopic neobladders and have attempted to modify neobladder design to improve functionality and tested the concepts in a clinical trial design. They recently published a randomized trial that demonstrated that creating antireflux mechanisms versus a refluxing orthotopic ileal neobladder does not improve renal function at 3 years follow-up but antireflux mechanisms were associated with more urinary diversion–related procedures to correct problems. Needless to say the outcomes of an orthotopic neobladder are influenced by meticulous attention to detail and surgical experience and this type of procedure should be centralized to centers specializing in bladder cancer care.

Initially orthotopic neobladder construction was limited to male patients because of heightened concern that preserving the urethra in women would increase local cancer recurrence rates as well as increase the risk of urethral cancer recurrences. This has not proven to be the case. There are now multiple reports in the literature of large series of women following radical cystectomy and orthotopic ileal neobladder demonstrating equivalent oncologic efficacy to men with low rates of urethral cancer recurrence. Importantly a frozen section margin of the urethra submitted at the time of surgery to rule out the presence of cancer is the most predictive factor of later developing a urethral recurrence and should be sent on all cases. A urethral margin identifying the presence of cancer on frozen section is a contraindication to neobladder construction in both women and men. Detailed study of the neural innervation of the female urethra has led to modifications of the technique of radical cystectomy in an attempt to improve functional outcomes of an orthotopic neobladder in women and minimize damage to the branches of the pudendal nerve. Unlike men urinary retention or neobladder emptying failure is much more common than incontinence in women resulting in the need to perform clean intermittent catheterization (CIC) to empty the neobladder. Over the short term up to 20% of women develop neobladder emptying failure and require routine CIC but over time this number increases and as many as 60% of women will require some degree of CIC, including once or several times per day. Nevertheless most women when questioned have little regret from their choice of desiring and choosing an orthotopic neobladder. Again this may be a function of properly educating patients when they are making treatment decisions and managing expectations.

176 Laparoscopic Pelvic and Retroperitoneal Lymph Node Dissection

Ornob P. Roy and Louis R. Kavoussi

Regional lymphadenectomy is utilized for staging and treatment in a variety of urologic malignancies. Pelvic lymph node dissection (PLND) is performed in prostate, bladder, penile, and posterior urethral carcinoma. Retroperitoneal lymph node dissection (RPLND) is employed in the management of metastatic germ cell tumors. In an effort to minimize the morbidity of lymph node dissection, laparoscopic and robotic-assisted techniques have been applied to these operations.

LAPAROSCOPIC PELIC LYMPHADENECTOMY

Indications

Prostate cancer is the most common noncutaneous malignancy in men. In 2012, approximately 177,000 men were diagnosed and over 27,000 died from the disease within the United States. Patients with clinically localized disease may undergo active surveillance or primary therapy with either extirpative surgery or radiation treatment. Removal of the prostate gland may be performed via an open (perineal or retropubic) or laparoscopic (conventional or robotic-assisted) approach. Radiation therapy may be delivered by external beam or placement of interstitial implants.

No randomized studies have demonstrated a survival advantage for local therapy in patients with metastatic disease. Unfortunately, no radiologic technique exists to accurately detect lymph node metastases. Both computed tomography (CT) and magnetic resonance imaging (MRI) rely on size-based criteria to diagnose node-positive disease, resulting in sensitivities of approximately 30%. Other diagnostic modalities such as fine needle aspiration and immunoscintigraphy are also unreliable. Pelvic lymphadenectomy remains the most accurate means of detecting lymph node involvement (LNI).

In 1991 Schuessler reported the first series of patients undergoing laparoscopic pelvic lymph node dissection (LPLND) for prostate cancer. Subsequent studies demonstrated the equivalence of LPLND to open node dissection with regard to nodal yield and complication rates. Multiple series found LPLND to be associated with decreased blood loss, analgesic use, length of hospital stay, and duration of convalescence compared with open PLND.

Following its introduction, LPLND became the most commonly performed laparoscopic urologic procedure. However, its role has steadily declined following widespread utilization of prostate-specific antigen (PSA) screening, which resulted in a dramatic stage migration in favor of organ-confined disease. At present, only 5% of individuals are found to have node-positive disease at the time of diagnosis. In addition, multiple nomograms to predict LNI have been developed that are based upon routinely available parameters (clinical stage, PSA level, and histologic Gleason score), which have further obviated the need for staging lymphadenectomy. Based upon these clinical parameters, patients can be classified as having low-risk (clinical stage ≤T2a, PSA <10 ng/mL, and Gleason Score ≤6), moderate-risk (clinical stage T2b, or PSA 10–20 ng/mL, or Gleason Score 7), and high-risk disease (clinical stage ≥T2c, or PSA >20 ng/mL, or Gleason Score ≥8).

Low-risk patients do not require PLND because their risk of metastatic disease is less than 2%. Moderate- and high-risk patients should undergo node dissection at the time of either open or robotic-assisted laparoscopic radical prostatectomy. At present, indications for LPLND (conventional or robotic-assisted) include moderate- and high-risk patients intending to undergo perineal prostatectomy or radiotherapy. In addition, LPLND should be contemplated in high-risk patients being considered for open retropubic prostatectomy in order to spare them the morbidity of a lower midline incision should their nodes prove to be positive.

LPLND has been applied to other genitourinary malignancies. For bladder cancer there is essentially no role for LPLND independent of cystectomy. However, multiple reports of laparoscopic radical cystectomy with extended pelvic lymph node dissection (ePLND) have been published. The majority of these cases were robotic-assisted. Long-term functional and oncologic outcomes are encouraging, and there is evidence for oncologic benefit via increased cancer-specific survival for localized bladder cancer.

Penile squamous cell carcinoma most often metastasizes to the inguinal followed by pelvic lymph nodes. Patients with high-risk disease (tumors invading past the subepithelial connective tissue) should undergo inguinal lymph node dissection for both staging and therapeutic purposes. However, LPLND should be considered in patients with suspicious pelvic lymph nodes on imaging because inguinal lymphadenectomy provides no oncologic benefit to patients with positive pelvic nodes. In this setting, LPLND potentially spares patients the morbidity of radical inguinal node dissection, which includes chronic lymphedema and perioperative wound infections in 25% and 10% of cases, respectively.

Carcinoma of the posterior urethra is a rare, but aggressive urologic malignancy. Treatment involves cystourethrectomy with pelvic node dissection. In women, en bloc removal of the urethra, bladder, uterus, adnexa, and anterior vaginal wall is required. In many instances, resection of the pubic symphysis and inferior pubic rami are also necessary. Patients with node-positive disease have an exceptionally poor prognosis despite aggressive surgical management. Therefore, staging LPLND may spare patients with LNI the considerable morbidity of anterior pelvic exenteration.

Preoperative Planning

For patients at high-risk of lymphatic metastases, radiographic studies, such as CT of the abdomen and pelvis, should be obtained before surgery to detect gross nodal disease. If feasible, percutaneous biopsy in patients with adenopathy should be considered because it may preclude the need for surgical intervention. Bone scans are reserved for patients with prostate cancer who have a PSA ≥20 ng/mL and for individuals with prostate or bladder cancer who have an elevated alkaline phosphatase and/or bone pain suspicious for metastatic disease.

Patients who are scheduled to undergo concurrent prostatectomy or cystectomy should receive a mechanical bowel prep. A full bowel prep may be helpful in patients who are expected to have extensive intra-abdominal adhesions. A type and screen for blood products is appropriate in most cases.

A single dose of a first-generation Cephalosporin or Clindamycin should be given prior to starting the case. If the node dissection is to be done along with a prostatectomy or cystectomy, then either a first- or second-generation Cephalosporin should be used and continued for less

than 24 hours. Alternatively, an Aminoglycoside plus Clindamycin can be used.

Positioning and Setup

General anesthesia is used. Nitrous oxide is avoided given the risk of bowel distention. An orogastric tube and Foley catheter are placed to decompress the stomach and bladder. The genitalia are wrapped with a compressive dressing to prevent tracking of carbon dioxide (CO_2) into the penis and scrotum.

The patient is placed in the supine position with both arms secured at the side (Fig. 176.1). Patients undergoing robotic-assisted LPLND are placed in the low lithotomy position. This position is also utilized for patients undergoing concurrent prostatectomy or cystectomy. All pressure points are adequately padded to prevent compression injury. Extended time in the lithotomy position places the peroneal nerve at increased risk of injury due to its superficial location as it passes around the head of the fibula. Peroneal neuropraxia results in a foot drop.

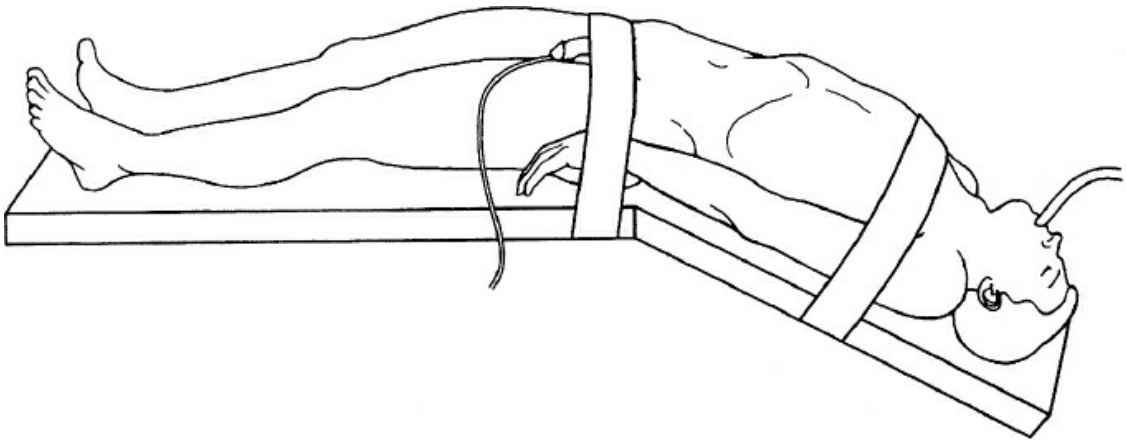

Figure 176.1. The patient is positioned supine, and, after trocar placement, the table is flexed to move the bowel out of the pelvis. A bladder catheter and orogastric tube are placed. The patient is secured to permit maximal table rotation.

The positioning of the surgical team is represented in Figure 176.2. The anesthesiologist is at the head of the table. The operating surgeon is on the contralateral side of the table from the lymph node packet to be excised. The assistant is opposite the surgeon while the scrub nurse and Mayo stand are placed adjacent and superior to the operating surgeon. The video equipment is placed at the foot of the table such that the surgeon is facing

the same direction as he or she is operating. In robotic-assisted cases the Da Vinci patient-side cart (Intuitive Surgical, Sunnyvale, CA) is docked between the patient's legs. The surgeon is located at the console and the assistant at the patient's right side. The ports placed the same except for the suprapubic 12-mm assist port, which is instead placed 2 cm cephalad and medial to the anterior superior iliac spine on the right.

Port Placement

The abdomen is entered using either a Veress needle or the Hasson technique at the base of the umbilicus. If the Veress needle is employed, the surgeon's hand or towel clamps are used to elevate the abdominal wall away from the viscera. Proper needle placement is confirmed by observing a low intra-abdominal pressure during initiation of pneumoperitoneum and by the saline "drop test." Insufflation is continued until an intra-abdominal pressure of 20 mm Hg is achieved, which is decreased to 15 mm Hg once the trocars have been placed.

A 1-cm incision is made at the umbilicus. A hemostat is used to separate the subcutaneous fat down to the fascia. A laparoscope with a 0-degree camera lens is placed within a 10-mm Visiport (U.S. Surgical, Norwalk, CT) or Optiview (Ethicon Endosurgical, Cincinnati, OH) incising visual obturator. The camera is focused on the tip of the obturator. The camera and trocar are advanced into the peritoneal cavity under direct vision. After removal of the obturator, a 30-degree lens is placed through the umbilical trocar. The abdominal cavity is inspected to rule out viscus or vascular injury. The abdominal wall is transilluminated with the laparoscope to identify blood vessels that may be injured, in particular the inferior epigastric vessels, during placement of the remaining ports under direct visualization.

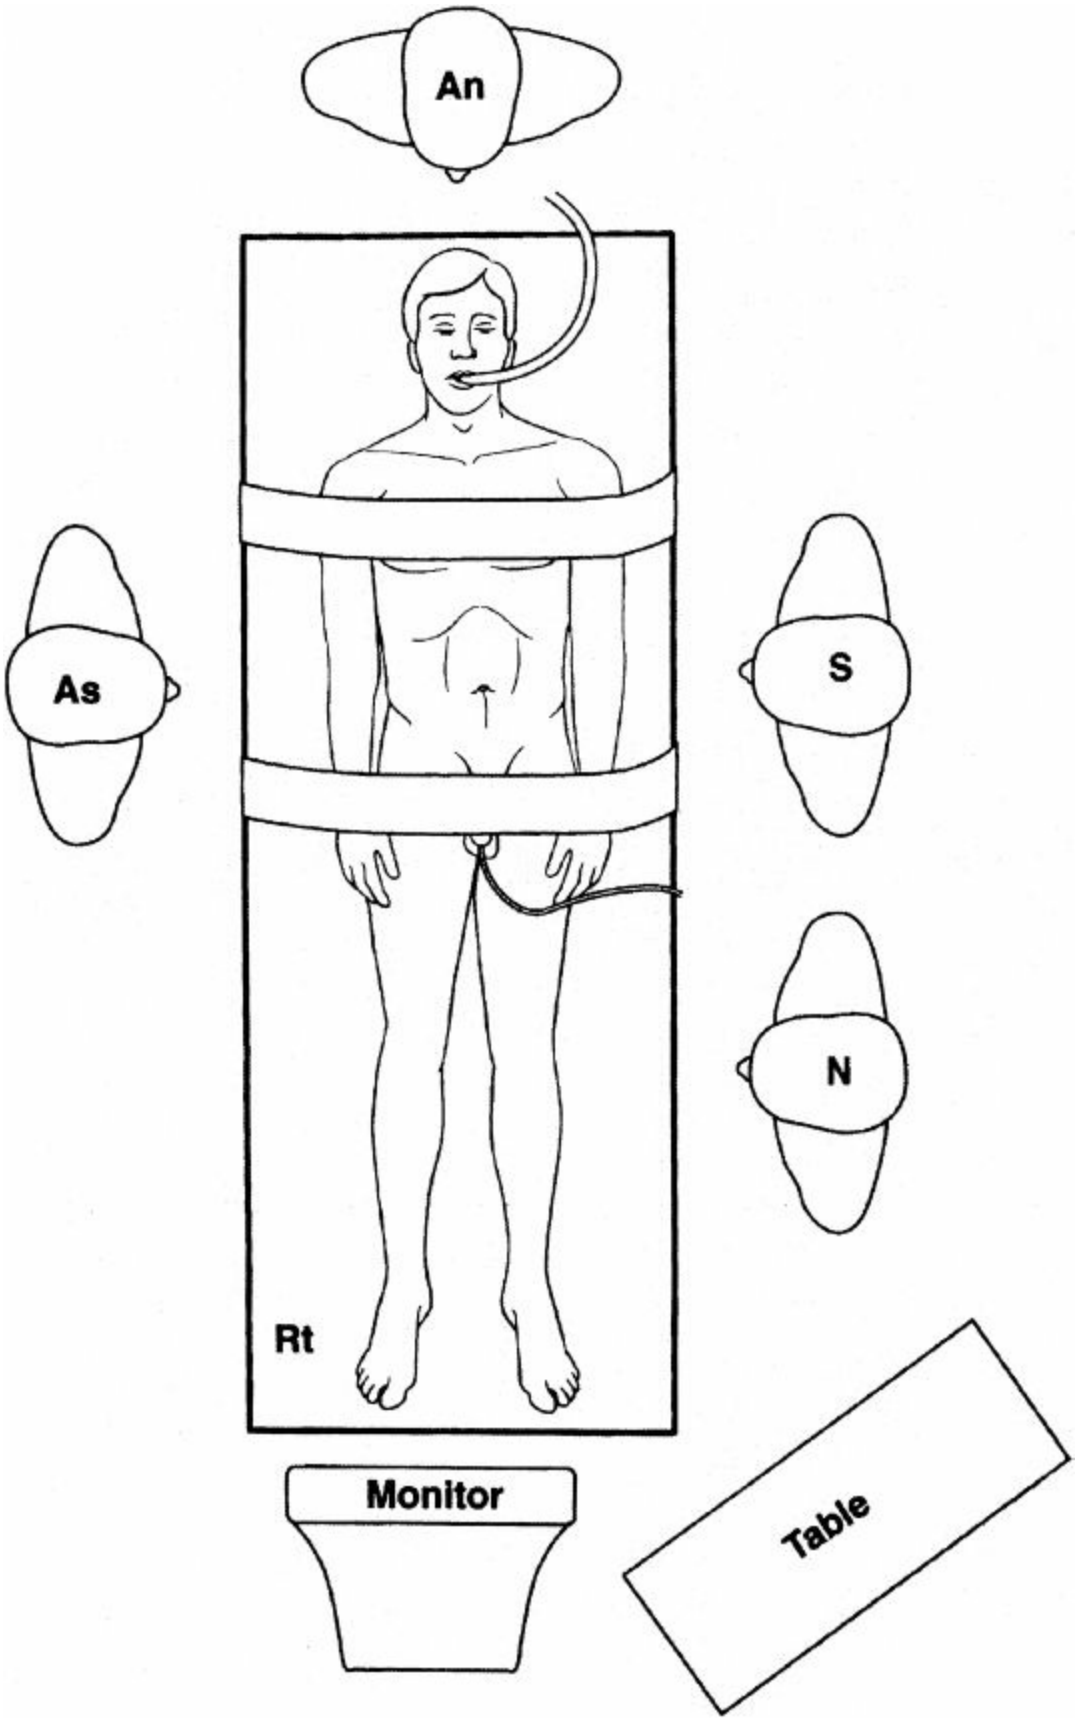

Figure 176.2. Surgical team is positioned as depicted for laparoscopic pelvic lymph node dissection. An, anesthesiologist; As, assistant surgeon; N, scrub technician or nurse; S, surgeon.

The typical port site pattern is illustrated in Figure 176.3A. A "diamond" configuration is most commonly used. The camera is usually situated at the umbilical port. A trocar is placed approximately four fingerbreadths above the pubic bone along the midline. The lateral trocars are placed one third of the way from the umbilicus to the anterior superior iliac spine on each side. In obese patients, a "fan" configuration facilitates retraction and dissection (Fig. 176.3B). For the nonumbilical ports, any combination of 5-mm and 10-mm ports is acceptable, depending on the surgeon's preference. The port site pattern for patients undergoing concurrent radical prostatectomy or cystectomy is typically different and is outside the scope of this chapter. Following port placement, the patient is then placed in the Trendelenburg position, which aides in keeping the intestines out of the pelvis during the dissection.

Surgical Technique

Pertinent anatomic landmarks for pelvic lymphadenectomy are illustrated in Figure 176.4. The node dissection template varies by indication. The anatomical boundaries for patients with moderate- and high-risk prostate cancer undergoing standard template dissection include the pubic bone distally, the bifurcation of the common iliac vessels proximally, the external iliac vein anteriorly, the obturator nerve posteriorly, the medial umbilical ligament medially, and the pelvic sidewall laterally.

Although controversial, several recently published observational series support a potential survival advantage for patients undergoing lymphadenectomy in the setting of limited nodal burden. These data, combined with studies showing up to half of nodal metastases occur within the internal iliac nodes, which would be missed by the standard template dissection, have led some urologists to advocate for an ePLND in patients with high-risk prostate cancer. The limits of the extended lymphadenectomy include the pubic bone distally, the bifurcation of the common iliac vessels proximally, the genitofemoral nerve anterolaterally, the internal iliac artery posteriorly, the medial umbilical ligament medially, and the pelvic sidewall laterally.

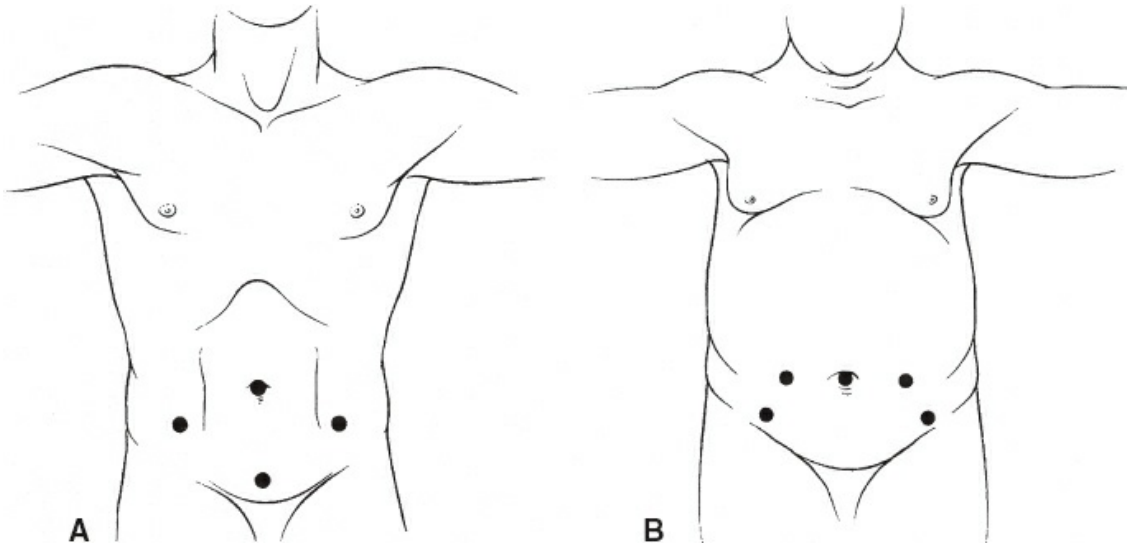

Figure 176.3. A. “Diamond” configuration for laparoscopic pelvic lymph node dissection port placement. **B.** “Fan” configuration for port placement in obese patient.

The importance of an extended node dissection in patients undergoing radical cystectomy for urothelial cell carcinoma (UCC) of the bladder is well established. The limits of the ePLND for bladder cancer are the same as for prostate cancer except the dissection is carried up to the aortic bifurcation cranially. The optimal extent of dissection for patients with penile or posterior urethral carcinoma has not been defined. However, most reports have utilized the standard prostate cancer dissection template.

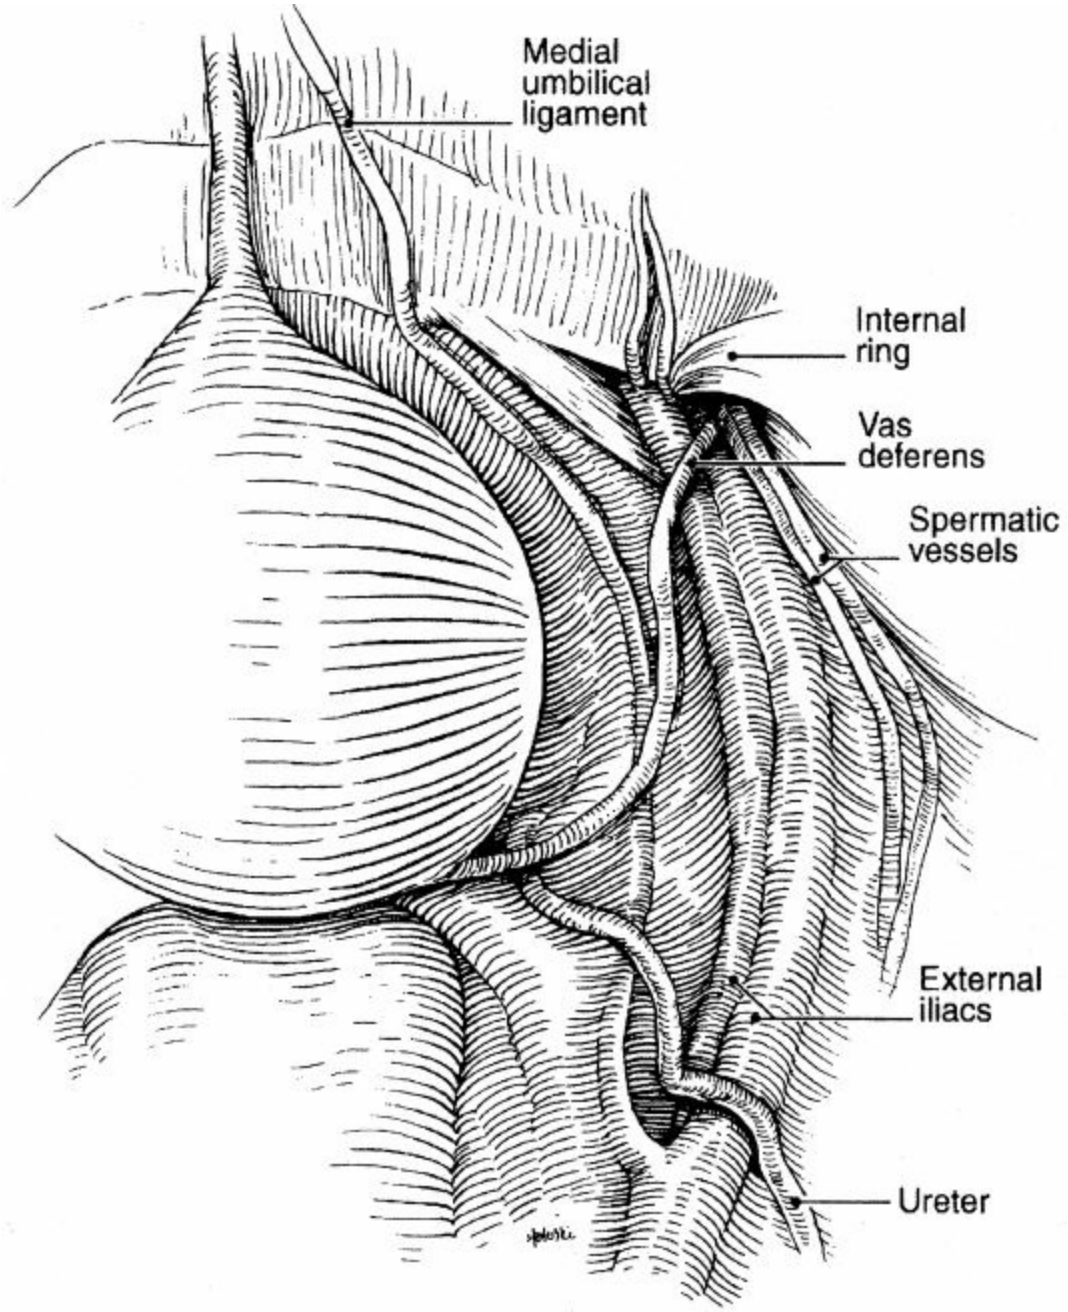

Figure 176.4. Anatomic landmarks for laparoscopic pelvic lymph node dissection.

After placing the trocars, a longitudinal incision is made in the peritoneum lateral to the medial umbilical ligament (Fig. 176.5). This extends from the pubic symphysis to just proximal to the iliac vessels. On the left side, it is quite common to encounter adhesions to the sigmoid colon that need to be incised first. For patients undergoing concurrent prostatectomy or cystectomy, the node dissection may be completed before or after the extirpative portion of the case, depending on surgeon preference.

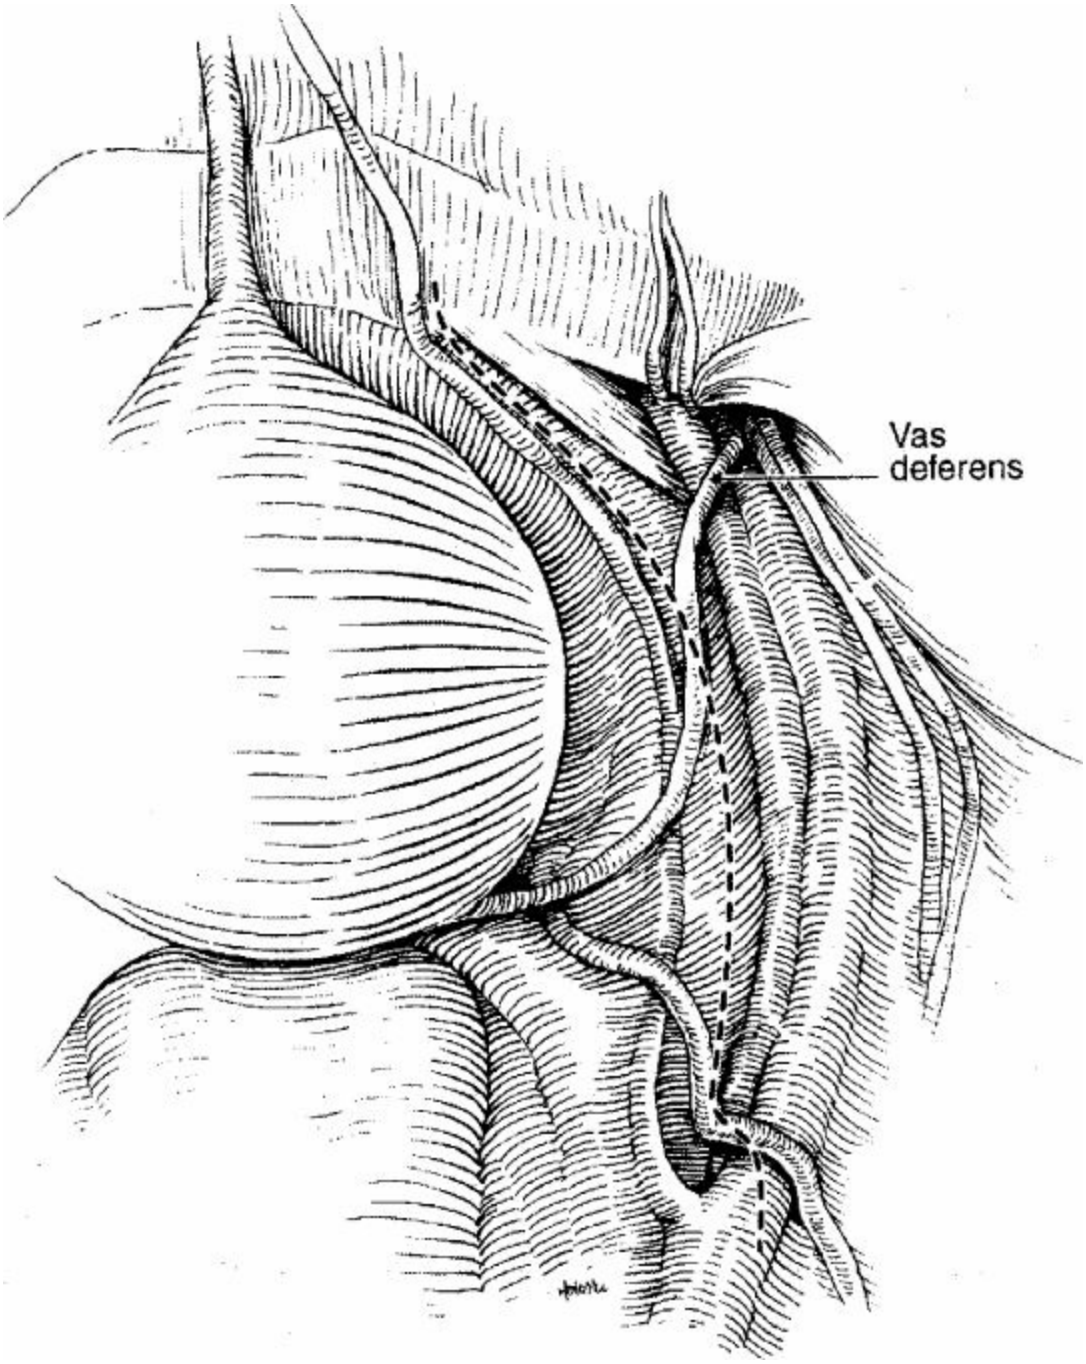

Figure 176.5. An incision is made lateral to the medial umbilical ligament. This is extended from the pubic bone to the bifurcation of the common iliac vessels.

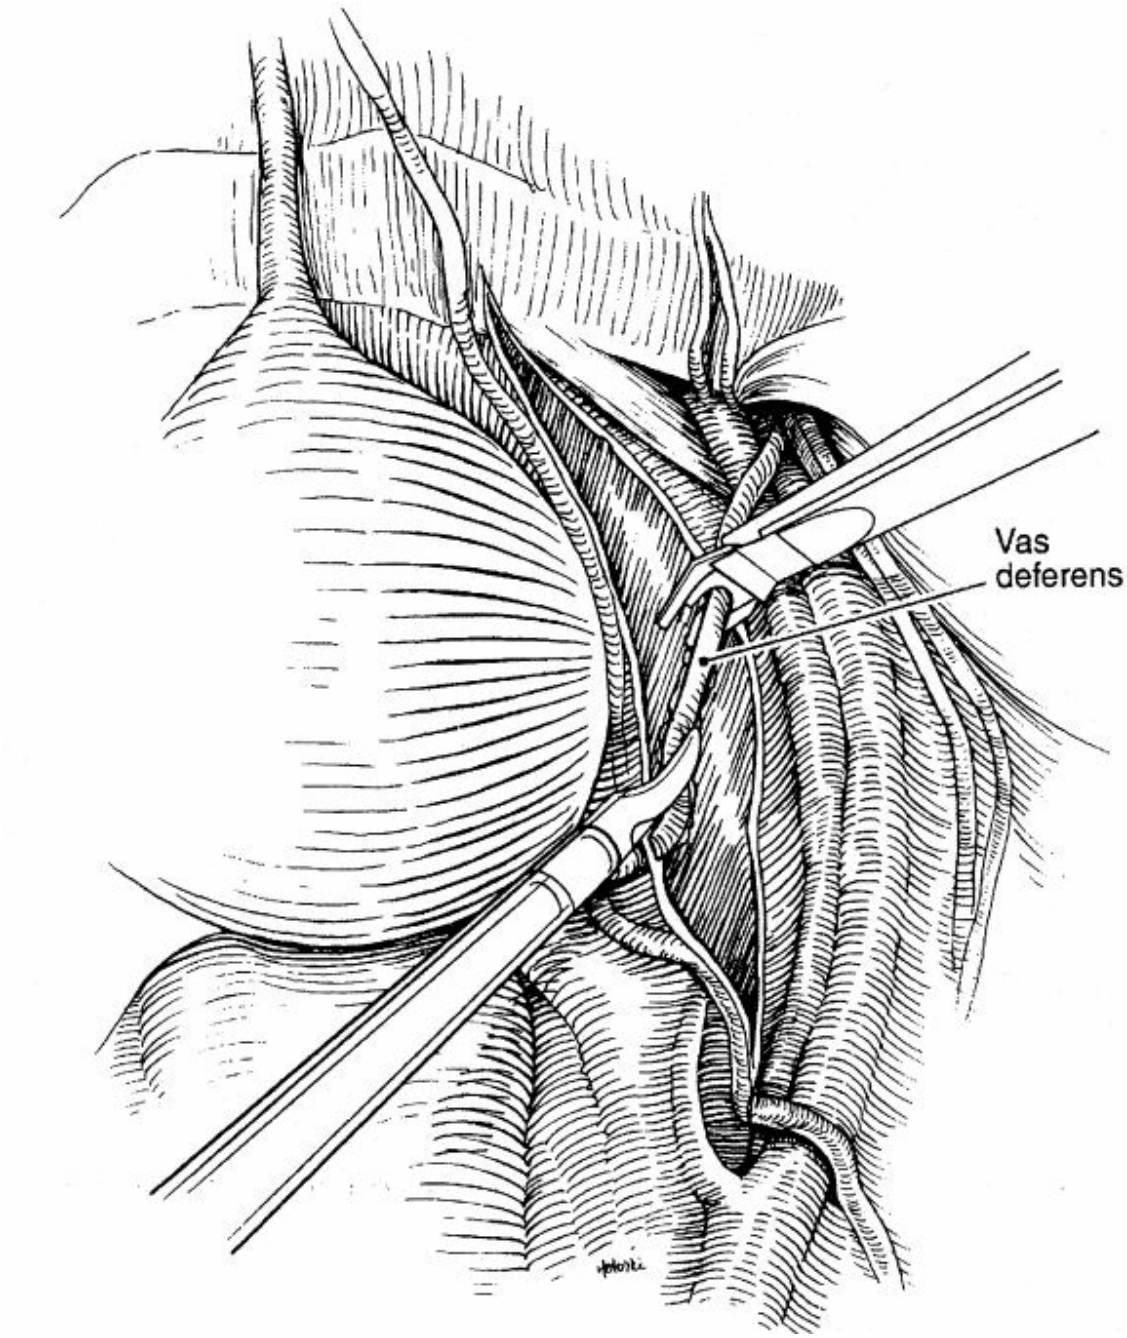

Figure 176.6. The vas deferens is identified, ligated, and divided.

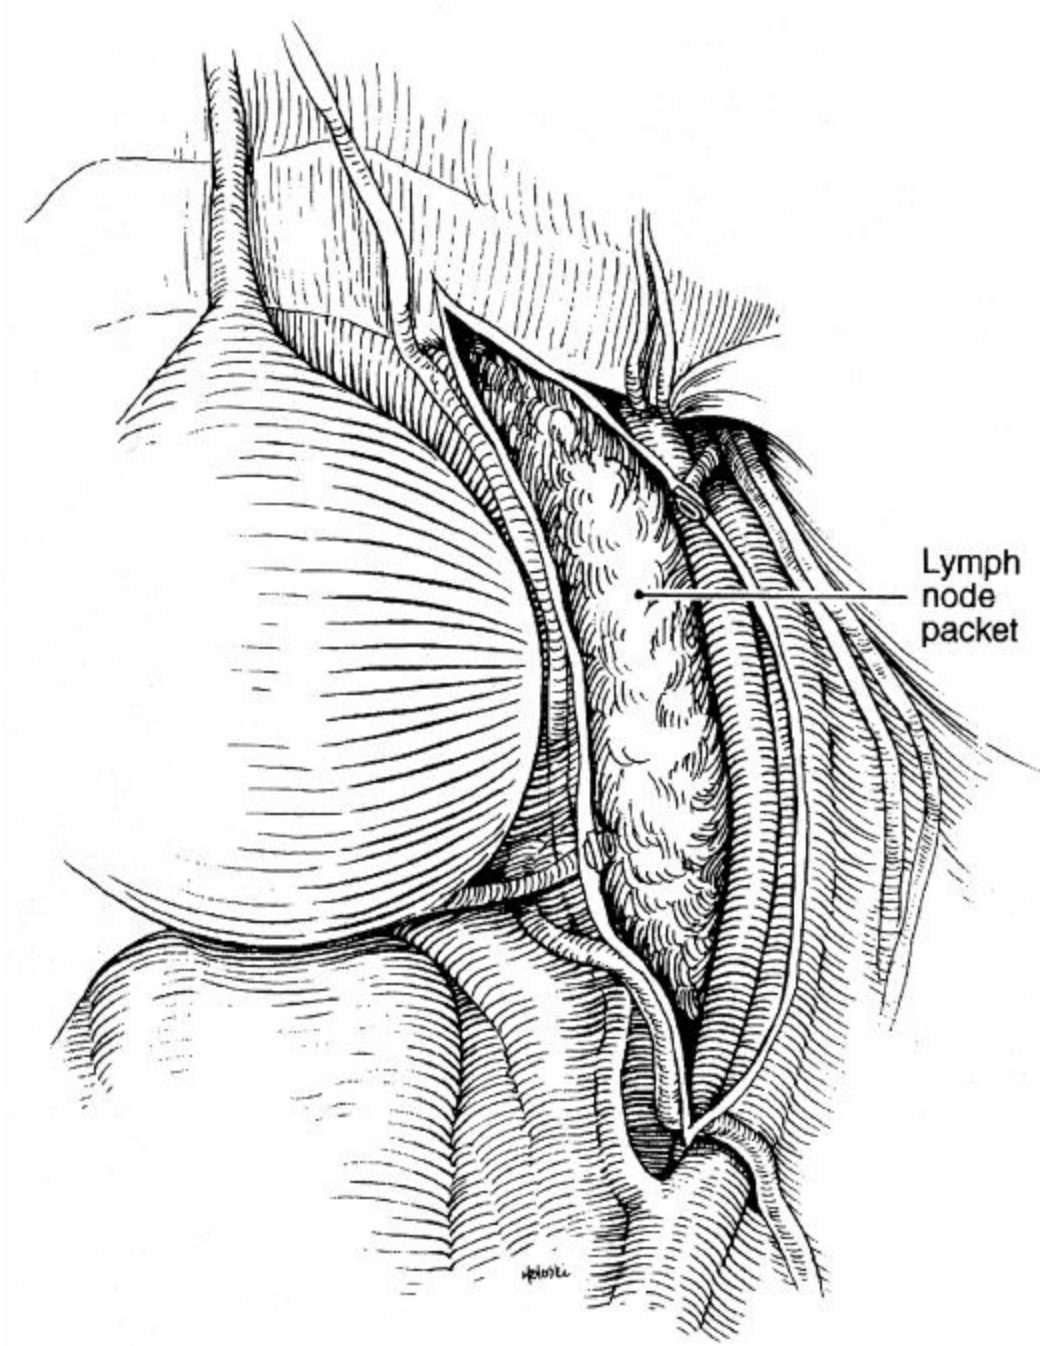

Figure 176.7. The lateral edge of the lymph node packet is developed. The medial edge of the iliac vein and the nodal tissue are identified.

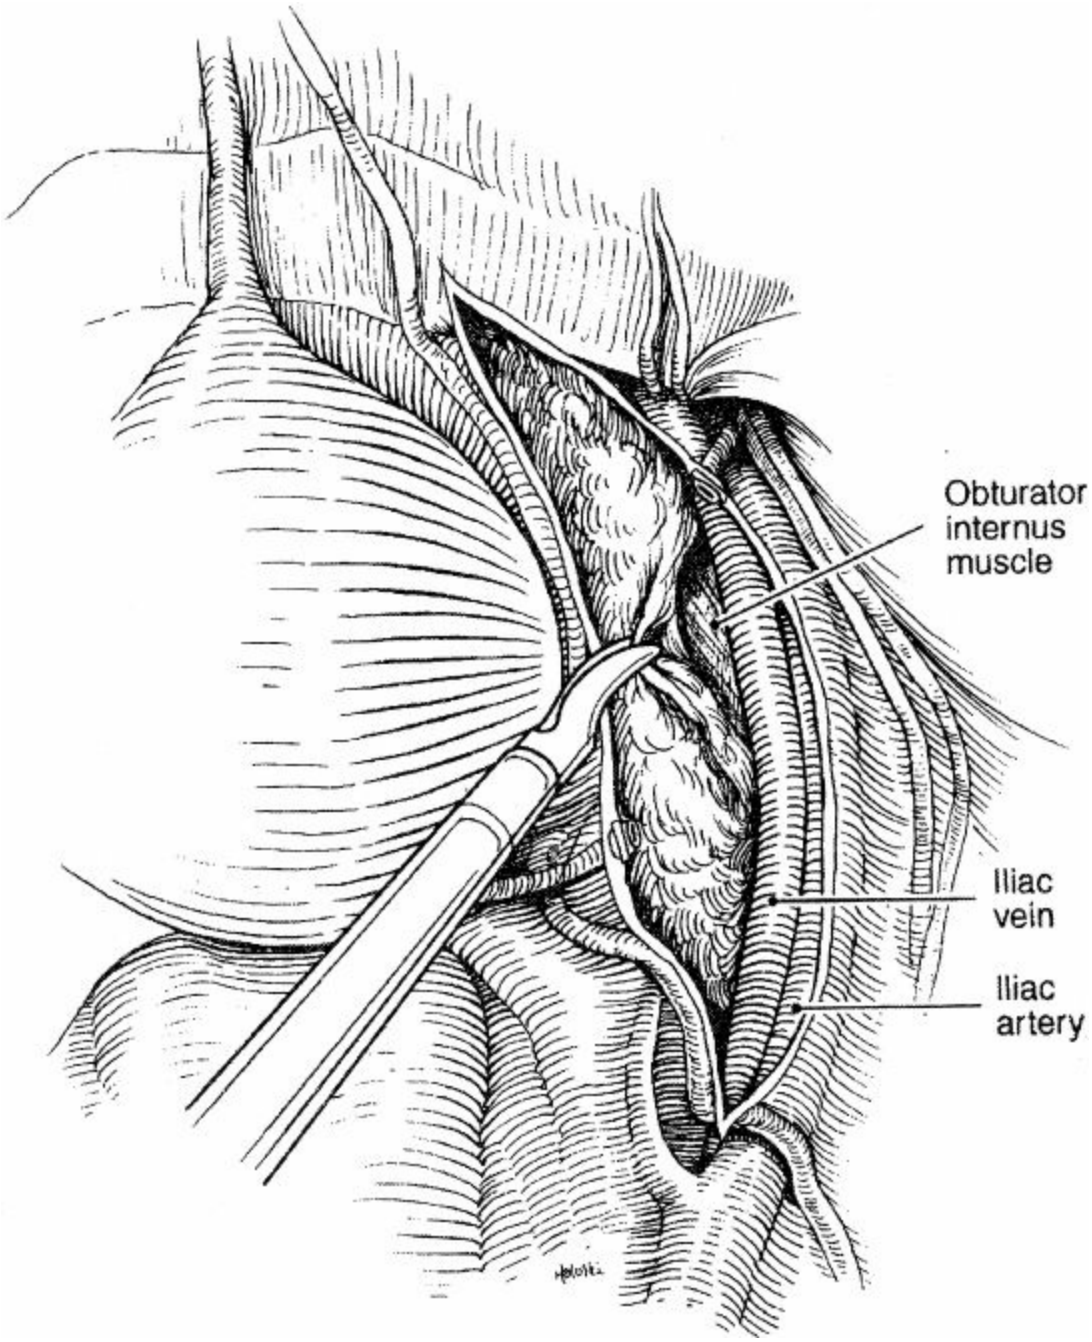

Figure 176.8. The nodal packet is dissected off the obturator internus muscle, and the dissection proceeds proximally toward the junctions of the medial umbilical ligament and the bifurcation of the iliac vessels.

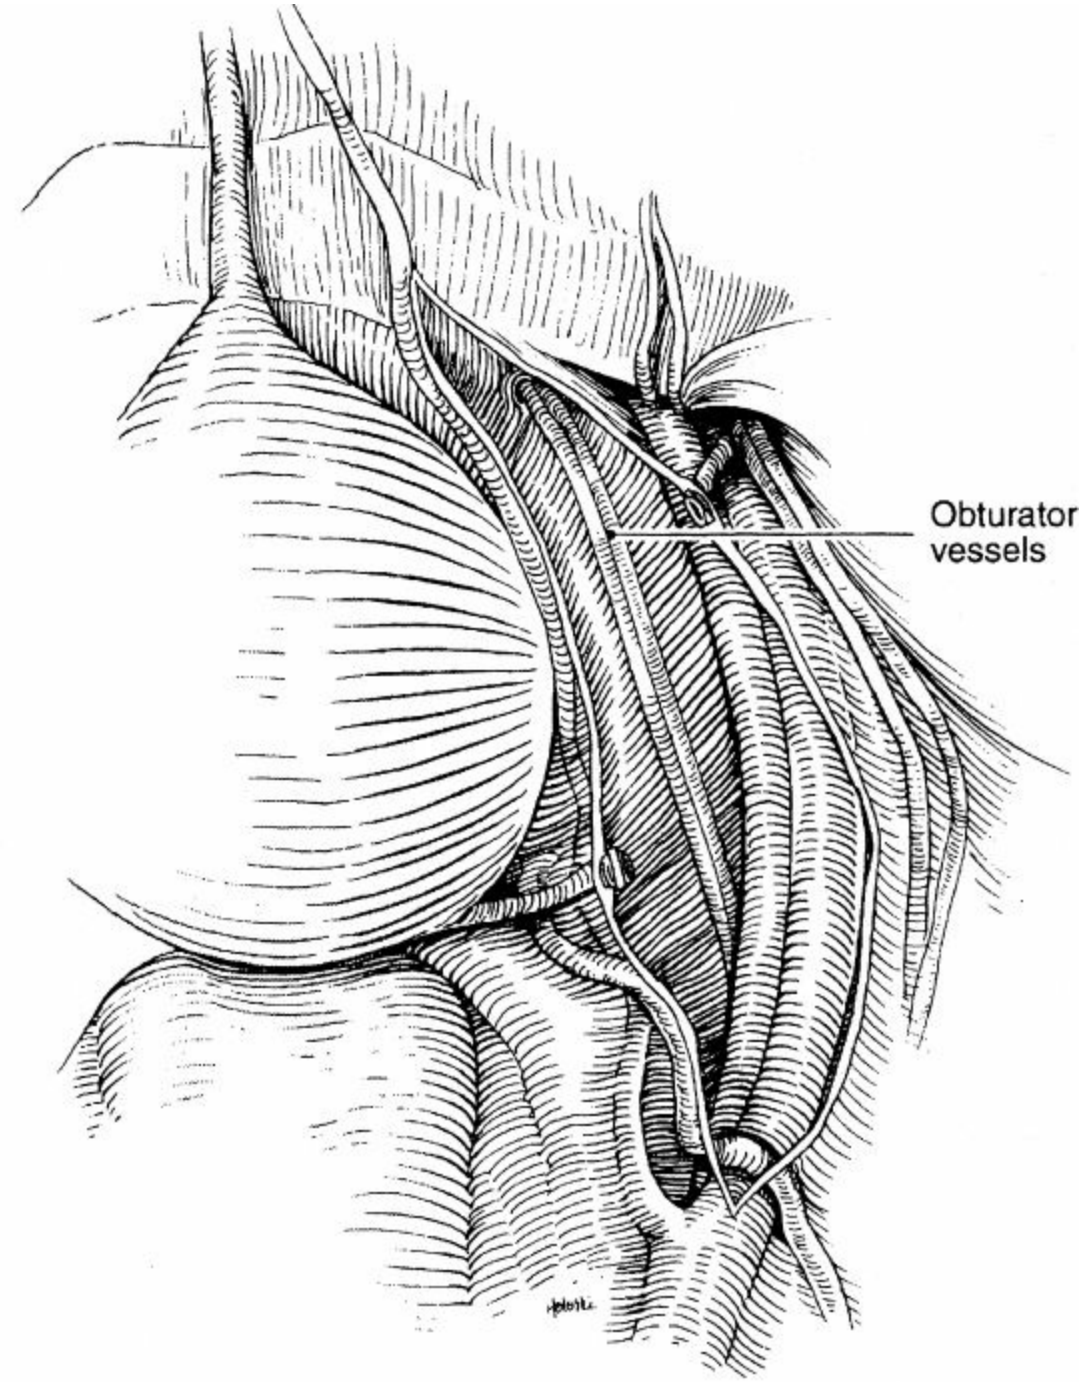

Figure 176.9. With the lymphatic tissue dissected free, the obturator nerve vessels should be visible.

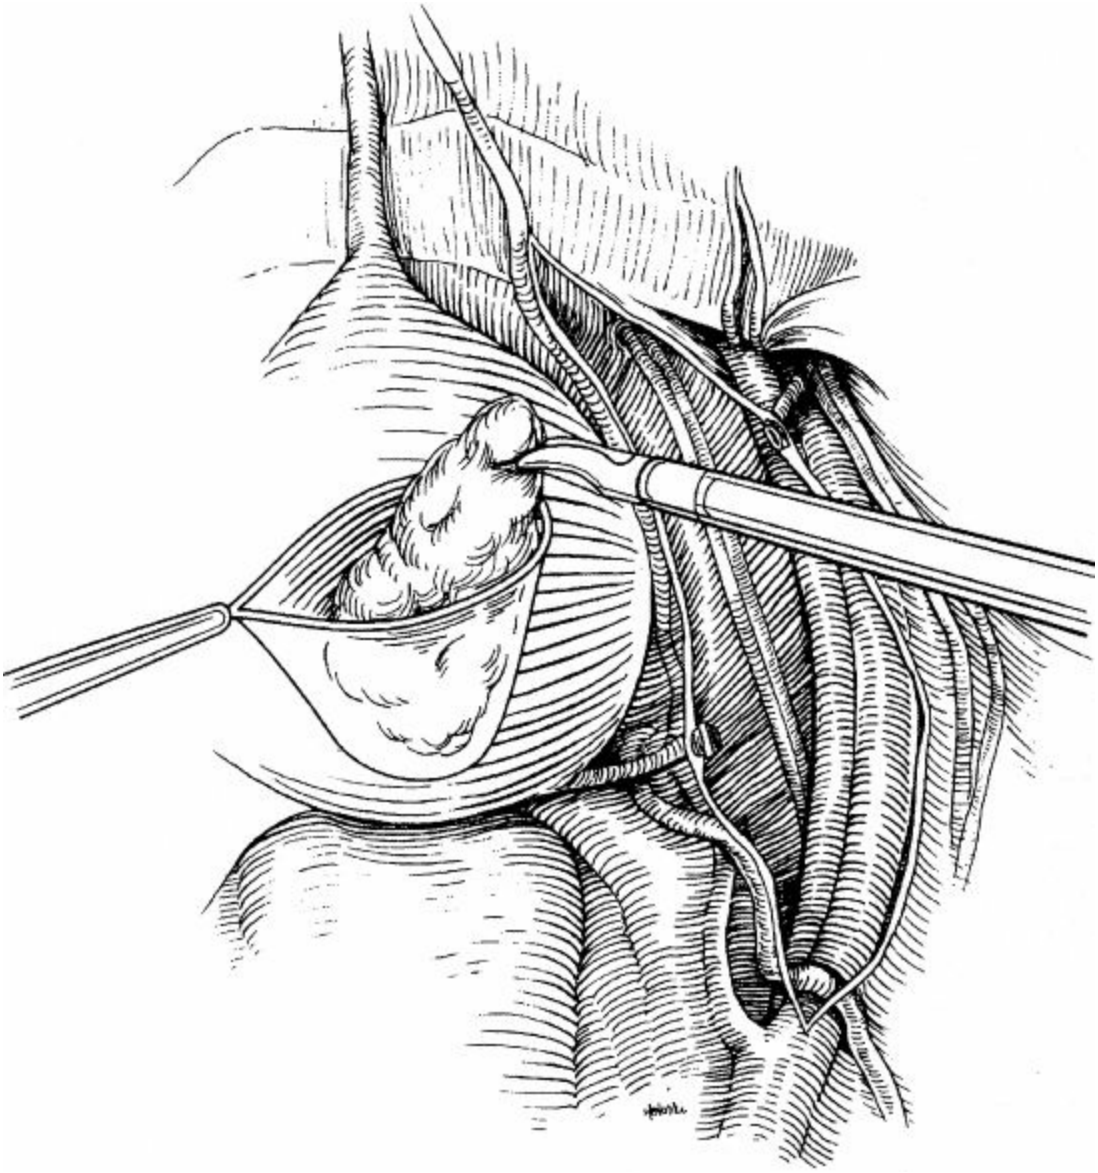

Figure 176.10. The lymphatic tissue is extracted. Depending on specimen size, it can be extracted with an Endocatch bag.

Once the peritoneum is opened, the vas deferens is identified and divided (Fig. 176.6). Next, the medial edge of the external iliac vein is identified and, by retracting the nodal tissue medially, the nodes are freed from the pubic bone to the bifurcation of the common iliac vessels (Fig. 176.7). This defines the lateral border of the nodal packet. The nodal packet is then dissected free posteriorly from the obturator internus muscle. The dissection proceeds proximally toward the junction of the medial umbilical ligament and the bifurcation of the iliac vessels (Fig. 176.8). This maneuver exposes the obturator nerve and vessels (Fig. 176.9). Care must be taken to avoid injury to the ureter, which lies medial at this point.

The medial boundary of dissection is defined by retracting the umbilical ligament medially while pulling the nodal packet laterally. Blunt dissection is usually sufficient to free the nodal tissue along this plane. Distal attachments beneath the pubis are clipped and transected. The entire packet is pulled cranially, and the remaining attachments located at the junction of the medial umbilical ligament and the internal iliac artery are clipped and divided. The specimen can then be extracted using an Endocatch bag (U.S. Surgical, Norwalk, CT) or a laparoscopic spoon forceps (Fig. 176.10). The contralateral side is addressed in a similar fashion.

The extended dissection for prostate cancer begins with the external iliac packet. The adventitia overlying the external iliac vein is divided distally near the superior pubic ramus. The nodal tissue is then retracted medially, and the dissection is carried proximally to the bifurcation of the common iliac vessels. The fibroalveolar tissue just medial to the genitofemoral nerve is divided, and the packet is swept off of the psoas muscle. Clips are usually required along the proximal and distal extents of dissection. The obturator packet is then dissected, as previously described. Dissection of the internal iliac nodal packet is then performed. If not readily apparent after removal of the external iliac and obturator nodal tissue, the origin of the internal iliac artery is identified by tracing the medial umbilical ligament to its origin. The dissection is continued from the origin of the internal iliac vessels down to the floor of the pelvis. Care is taken not to damage the obturator nerve or avulse the obturator vessels. This completes the extended node dissection for patients with prostate cancer (Fig. 176.11). In patients undergoing a radical cystectomy, the dissection is carried up the common iliac vessels to the aortic bifurcation.

The prostatectomy or cystectomy portion of the case is then performed, if indicated, or if not done prior to the node dissection. Upon completion, the pressure within the abdomen is reduced to 5 mm Hg to evaluate for occult sources of bleeding. Hemostasis is achieved using electrocautery, surgical clips (metal or polymer), and hemostatic agents. A final survey of the peritoneal cavity is performed to check for visceral injury. If utilized, the robotic patient-side cart is undocked. The ports are then removed under direct visualization to rule out the onset of abdominal wall bleeding. Closure of the fascia is not required for 5-mm port sites but is for 10/12-mm ports to prevent hernia formation. The fascia may be repaired extracorporeally following evacuation of the pneumoperitoneum or

laparoscopically with the Carter-Thomason (Inlet Medical, Eden Prairie, MN) or Endoclose (U.S. Surgical, Norwalk, CT) devices. Before securing the last trocar site, an effort is made to expel all CO_2 from the peritoneum. The port site skin incisions are closed with absorbable sutures in a subcuticular fashion or with skin glue.

Postoperative Management

For patients undergoing LPLND alone, the orogastric tube is removed at the end of the procedure. The Foley catheter is discontinued when the patient is ambulatory. Oral intake is begun the evening of surgery. The length of hospitalization is usually less than 24 hours. Patients undergoing laparoscopic prostatectomy with PLND are typically discharged on postoperative day 1 with the Foley in place for 7 to 10 days. Laparoscopic cystectomy patients have a longer length of stay primarily due to the urinary diversion portion of the case.

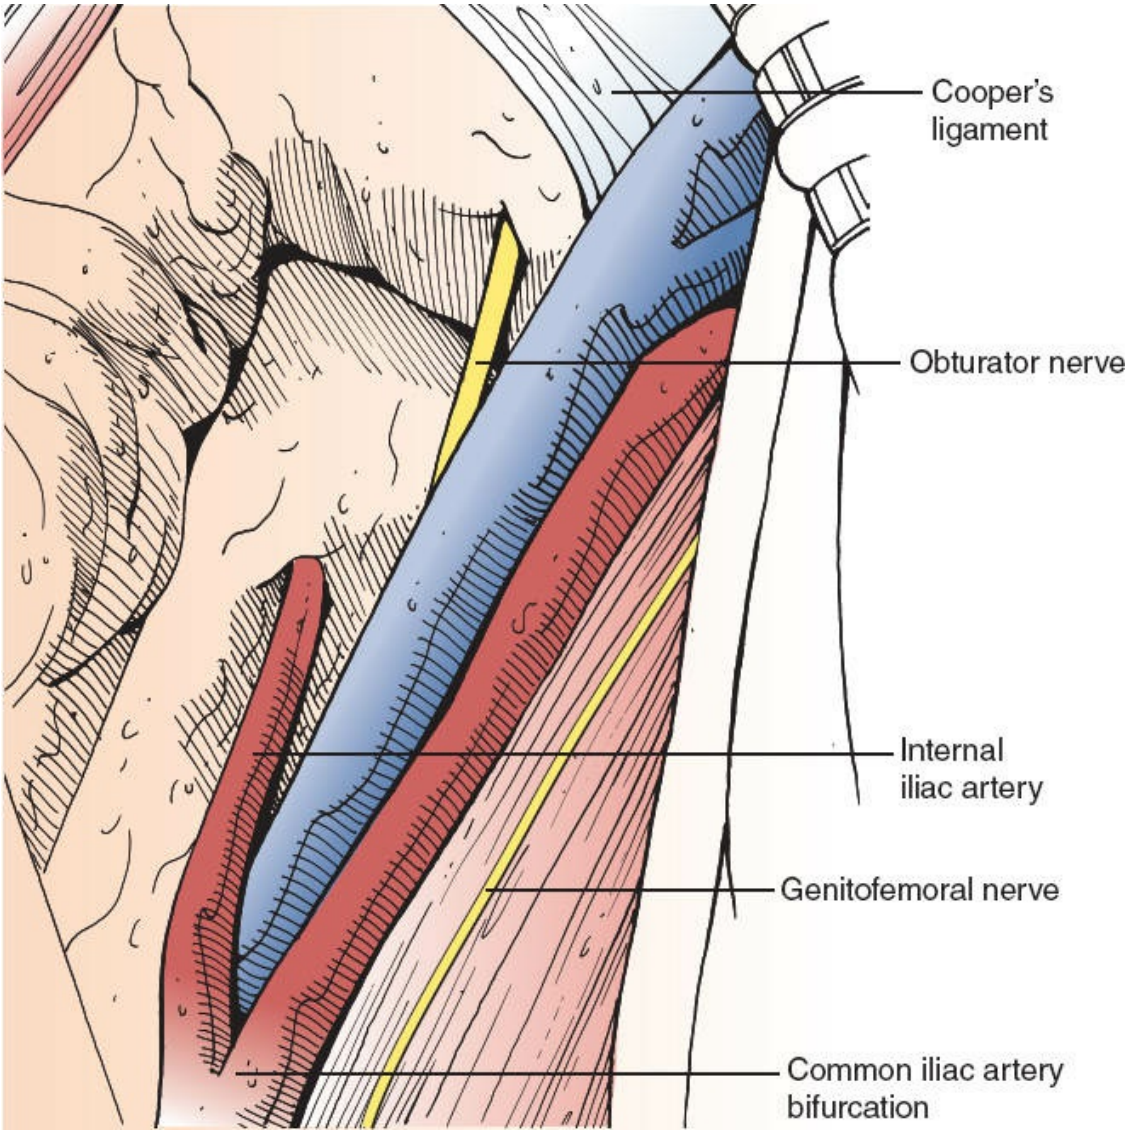

Figure 176.11. Completed extended pelvic lymph node dissection.

Complications

General complications of LPLND are similar to those seen in all laparoscopic cases and include ileus, deep vein thrombosis, and urinary retention. Vascular injuries can occur during trocar placement or nodal dissection. Most commonly, the inferior epigastric vessels are injured during lateral trocar placement. The external iliac and obturator vessels can also be injured during nodal dissection. Despite the close proximity of these vessels, vascular injury is rare, occurring in approximately 2% to 3% of cases.

Care must be taken to identify and avoid clipping or transecting the obturator nerve. Injury results in the inability of the patient to adduct the

thighs. Injury to the ureter, especially during extended dissections, is also possible. Meticulous hemostasis and attention to anatomical relationships help in the identification of these structures, thereby minimizing the risk of injury.

Viscus injuries are also rare; most of these are bowel and bladder injuries. These injuries can occur during trocar placement or dissection. Decompression by orogastric tubes or Foley catheters can minimize the potential for these injuries. Injuries that are recognized intraoperatively should be repaired promptly. Unrecognized bowel injuries often present 2 to 7 days postoperatively with a low-grade fever, persistent ileus with mild distention, possible leukopenia, and notable trocar site pain. A low index of suspicion must be maintained at all times resulting in prompt imaging of the abdomen and pelvis with subsequent surgical repair if a bowel injury is found.

Lymphocele formation is a complication of both open and laparoscopic PLND. Some studies suggest that this complication is more common with extended dissections. The transperitoneal approach may decrease its incidence. Lymphocele management includes open, percutaneous, or laparoscopic drainage.

The overall complication rate for LPLND varies from 3% to 33% depending upon series, with a mean of approximately 15%. This rate is comparable to open series. Reported complications following ePLND have also varied in the literature, ranging from 4% to 36%. An overall complication rate of 20% is not unexpected, which once again is roughly equivalent to open series. The vast majority of complications are minor and require no intervention.

RPLND is utilized in patients with metastatic germ cell tumors, select gynecologic malignancies, and sarcomas of the cord. Retroperitoneal node dissections are also utilized for select patients with transitional cell carcinoma of the upper tract and renal cell carcinoma (RCC). Laparoscopic techniques have been applied to these operations to minimize morbidity.

LAPAROSCOPIC RETROPERITONEAL LYMPHADENECTOMY

The most common application of laparoscopic retroperitoneal lymph node dissection (LRPLND) is in the treatment of select patients with testicular cancer. Testicular cancer is the most common solid malignancy in men

aged 15 to 35. Fortunately, with advances in chemotherapy, radiotherapy, and surgery, significantly improved survival is seen with all stages of this disease. Sensitive biomarkers (e.g., β-human chorionic gonadotropin, α-fetoprotein) and modern axial radiologic imaging have improved staging, allowing for tailored treatment.

Surgery has multiple roles in the treatment of testicular cancer. Radical orchiectomy is the only modality that currently can reliably control the primary growth of the tumor. It also establishes the histologic diagnosis and along with biomarkers, and radiographic imaging, aids in creating individual treatment algorithms.

Testis cancer spreads in a predictable fashion to the retroperitoneal lymph nodes. The patterns of distribution of lymph node metastasis have allowed for the creation of modified templates that preserve the sympathetic nerves that are responsible for normal antegrade ejaculation (Figs. 176.12 and 176.13). RPLND in select patients can give valuable staging information, which dictates further therapy. In addition, RPLND can be therapeutic, particularly those with residual retroperitoneal tissue following chemotherapy.

The classification of testicular cancer can be broadly divided into germ cell or non-germ cell tumors. The germ cell tumors are further subclassified into seminomatous and nonseminomatous germ cell tumors. Further treatment is guided by appropriate staging and the knowledge that most of these tumors initially spread to the retroperitoneal lymph nodes (Figure 176.13). For low-stage disease, strict surveillance protocols, single-agent primary chemotherapy, and primary radiation therapy to the retroperitoneum are widely utilized. Higher-stage seminoma is approached with multi-agent chemotherapy.

The treatment options for stage I nonseminomatous germ cell testicular tumors (NSGCTs) include surveillance, primary chemotherapy, and RPLND. Most patients are cured regardless of which initial option is chosen. Therefore, individual factors, cost, and associated morbidity are important in making individual decisions.

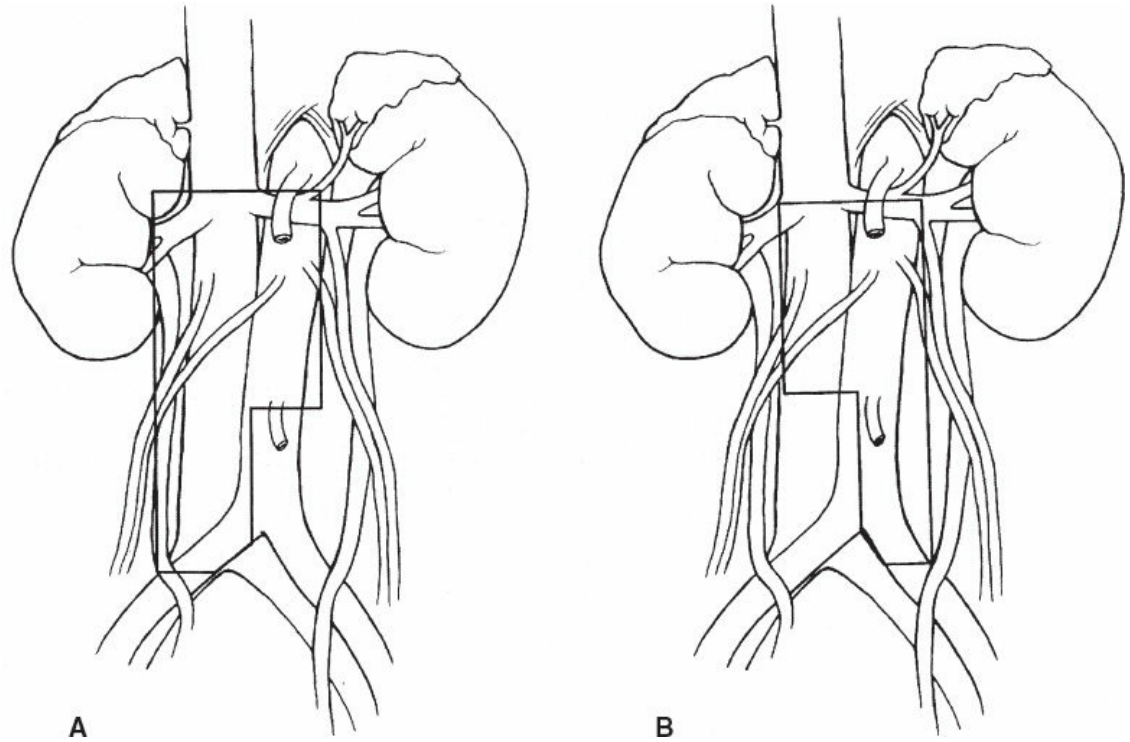

Figure 176.12. **A.** Modified template for right retroperitoneal lymph node dissection. The template is defined by the left renal vein superiorly, the ureter laterally, the bifurcation of the common iliac vessels inferiorly, and the vena cava medially. **B.** Modified template for left retroperitoneal lymph node dissection. The limits of dissection are the left renal vein superiorly, the ureter laterally, the bifurcation of the common iliac vessels inferiorly, and the vena cava medially.

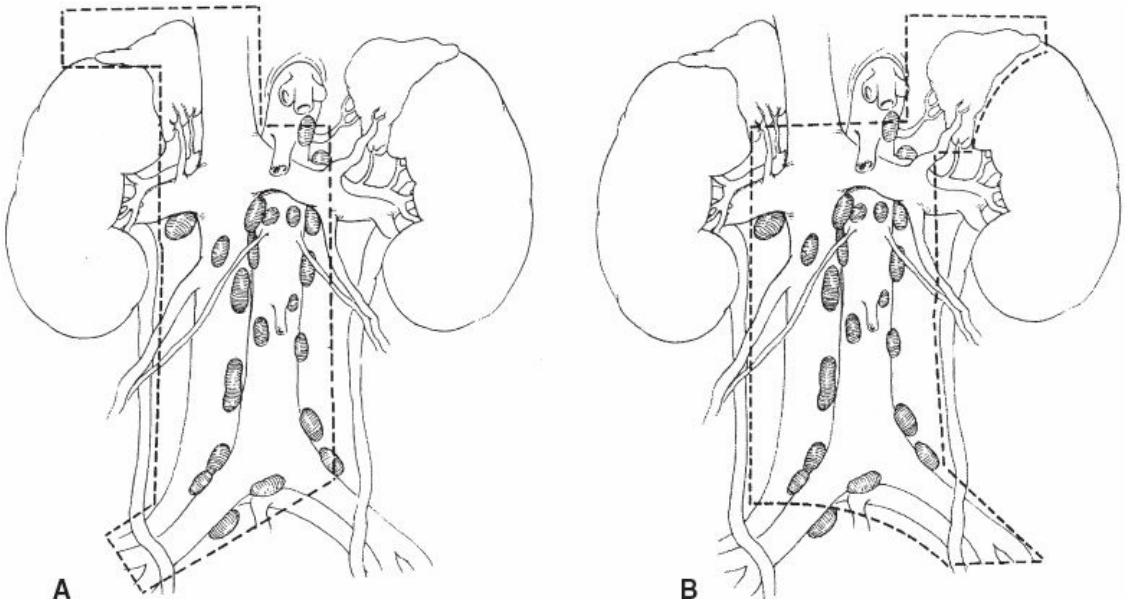

Figure 176.13. **A.** The limit for a bilateral right-sided retroperitoneal lymph node dissection for residual disease after

chemotherapy. **B.** The limit for a bilateral left-sided retroperitoneal lymph node dissection for residual disease after chemotherapy.

RPLND may ultimately overtreat 70% of patients, because these clinical stage I patients have pathologically negative nodes. It is also associated with potential complications as well as a significant incision and postoperative course. However, fertility can be preserved in the majority (75%) of patients. Also, RPLND can be utilized to remove residual retroperitoneal masses following chemotherapy.

In an effort to further decrease the morbidity associated with open RPLND, LRPLND was developed. During laparoscopic surgery, magnification provided by the endoscope can facilitate identification. The application of laparoscopic techniques to this procedure results in a shorter hospital stay, quicker convalescence, less postoperative pain, and improved cosmesis over the traditional open approach. Recent meta-analysis suggests rates of staging accuracy and long-term outcome similar to open RPLND. These meta-analyses also indicate that although operating room times are longer for LRPLND (204 minutes) when compared to open RPLND (186 minutes), length of hospital stay, postoperative analgesic requirements, and complication rates favor LRPLND.

Retroperitoneal lymphadenectomy has more recently been advocated for UCC. RPLND may provide prognostic information in upper tract UCC at the time of nephroureterectomy. Further study is required for RPLND in UCC patients before establishing its utility. The template for lymph node resection in the above scenarios would be similar to that for NSGCT, namely a modified unilateral template for upper tract UCC.

The role of RPLND in RCC is also unclear. Recent literature has suggested that removal of lymph nodes at the time of nephrectomy does not result in a significant increase in complications. Potential benefits include removal of the 10% of clinically undetected local LNI and providing more accurate staging for adjuvant systemic therapies. It does seem that only patients with clinical stage T2 or higher would benefit from RPLND in RCC, because of the very low rates of retroperitoneal lymph node metastasis in patients with lower stage disease. No established template has been agreed upon for lymph node resection due to the variability of renal lymphatic drainage; however, the perihilar nodes would comprise the minimum nodal packet.

Because of the lack of consensus for RPLND in UCC and RCC, in the

following sections we will discuss its role only in testicular cancer.

Indications

RPLND can be used for both staging and treatment of retroperitoneal disease. Suggested utility is most in patients with NSGCT with Stage I and Stage IIa disease and select, low-volume Stage IIb disease. Currently there is no convincing indication to perform RPLND in cases of pure seminoma, although nontemplated resection of residual masses after chemotherapy is supported.

In RPLND, all nodal tissue within the template is excised, including retroaortic and retrocaval tissue. Identification of those patients with pathologically negative nodes avoids the unnecessary morbidity associated with chemotherapy. These individuals still need to be followed, as 10% may develop extraretroperitoneal recurrences. Patients found to have positive nodes at the time of RPLND are subsequently offered observation or chemotherapy. With observation roughly 15% to 30% of individuals with low volume disease will develop recurrent disease, with the most common extraretroperitoneal site in the chest, and require further treatment. If large volume disease is found, more than 80% of individuals will have recurrence, again usually in the chest.

RPLND also has a role in the management of residual disease after chemotherapy. Of resected residual masses after chemotherapy, approximately 50% will have necrosis, 35% will contain teratoma, and 15% will harbor viable tumor. The inability to reliably differentiate tumor from necrosis nonoperatively and the risk of malignant transformation of teratoma to adenocarcinoma or sarcoma usually calls for surgical removal of residual disease. Chemotherapy obliterates the natural tissue planes, increasing the morbidity associated with open and laparoscopic RPLND.

Contraindications for primary RPLND include presence of extranodal metastatic disease or active peritoneal or abdominal wall infection. Patients with excessive bulky adenopathy or bleeding diathesis may best be approached with an open dissection. As mentioned previously, care should also be taken when approaching patients who have had previous chemotherapy. Dense scar tissue that forms in the retroperitoneum after chemotherapy can make dissection difficult. As such, these patients are at increased risk of vascular injury. Conversion to open surgery during a laparoscopic dissection is thus more likely in these cases, and patients should be counseled with respect to this possibility.

Preoperative Planning

Before undergoing RPLND, the patient should have a complete metastatic evaluation, including abdominal CT, chest CT, or chest radiograph; liver function tests; and bone scan as indicated. Serum markers for testis cancer, such as α-fetoprotein, β-human chorionic gonadotropin, and lactate dehydrogenase, should be obtained. Persistent elevation of these markers following orchiectomy indicates the presence of metastatic disease, which usually requires chemotherapy. Preoperative sperm banking should be discussed.

A mechanical bowel preparation is helpful. In postchemotherapy patients and cases where dense adhesions are anticipated (history of multiple abdominal surgeries), a full bowel prep may be indicated. Antibiotic coverage with a first-generation cephalosporin is given.

Blood should be sent for type and screen. Postchemotherapy patients should be typed and cross-matched for at least two units of packed red blood cells owing to the increased risk of vascular injury. For laparoscopic cases, a laparotomy tray should be readily available in the event that open conversion is required.

In patients who have undergone prior chemotherapy, several precautions need to be taken. Bleomycin-induced pulmonary fibrosis puts patients at risk for postoperative adult respiratory distress syndrome (ARDS). As such, screening pulmonary function studies should be obtained along with a baseline arterial blood gas. Patients should be well hydrated preoperatively; however, fluid replacement intraoperatively should be judiciously administered, as large volumes of fluid can increase the risk of developing postoperative ARDS.

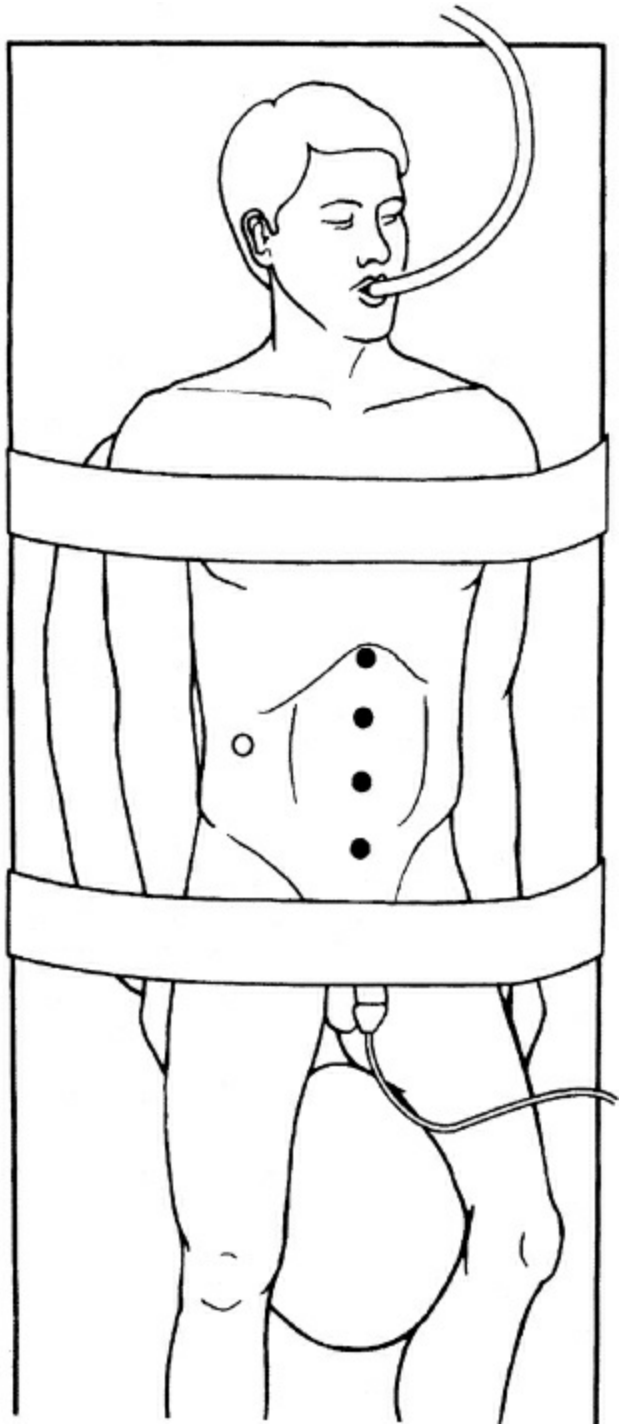

Figure 176.14. Patient and trocar positioning for right laparoscopic retroperitoneal lymph node dissection. The patient is placed in the modified flank position and secured such that the table can be maximally rotated. A bladder catheter and orogastric tube are placed. Four 10-mm ports are placed in the midline (*black circles*). A fifth port is placed in select situations (*open circle*).

Platinum-based regimens can also result in renal toxicity. As such, care

should be taken to avoid additional nephrotoxic agents in the postoperative period. Myelosuppression is also a side effect of chemotherapy regimens. This is self-limited, but adequate time (~5 weeks) should pass after chemotherapy before offering surgical intervention.

Laparoscopic Positioning and Setup

After induction of general anesthesia, an oral gastric tube and Foley catheter are placed. The patient is placed supine with both arms tucked (Fig. 176.14) and sequential compression devices on the lower limbs. The chest, shoulders, and hips are immobilized with heavy cloth tape to permit maximal table rotation during the procedure. For modified template resections, a gel roll or "bump" can be placed underneath the ipsilateral side to facilitate exposure of the retroperitoneum without extreme rolling of the operating table. The patient is prepped from the xyphoid process to the upper thighs bilaterally.

The surgical team is positioned around the operating table, as depicted in Figure 176.15. The surgeon and surgical assistant stand on the contralateral side of the table to the side of pathology. At times, a second assistant is necessary to assist in retraction. This individual would stand across the table from the surgeon with the scrub nurse. A video monitor is placed directly across the operating table from the surgeon and also from the scrub nurse and/or assistant on the contralateral side.

Port Placement

The placement of the Veress needle and initial umbilical trocar is described earlier in this chapter with reference to LPLND. Four 10-mm midline abdominal ports are used. The ports are equally spaced from 2 to 4 cm inferior to the xiphoid process to 4 cm above the pubic symphysis, and as such, the umbilicus may not always be incorporated into one of the port sites. On occasion a 5-mm lateral port is required to help in dissection of the spermatic cord (Fig. 176.14). The table is placed in slight Trendelenburg position and tilted toward the surgeon to allow bowel to fall away from the operative field. For the dissection, a paddle retractor is placed in the lowermost port. This is used to retract the bowel medially for the bulk of the dissection.

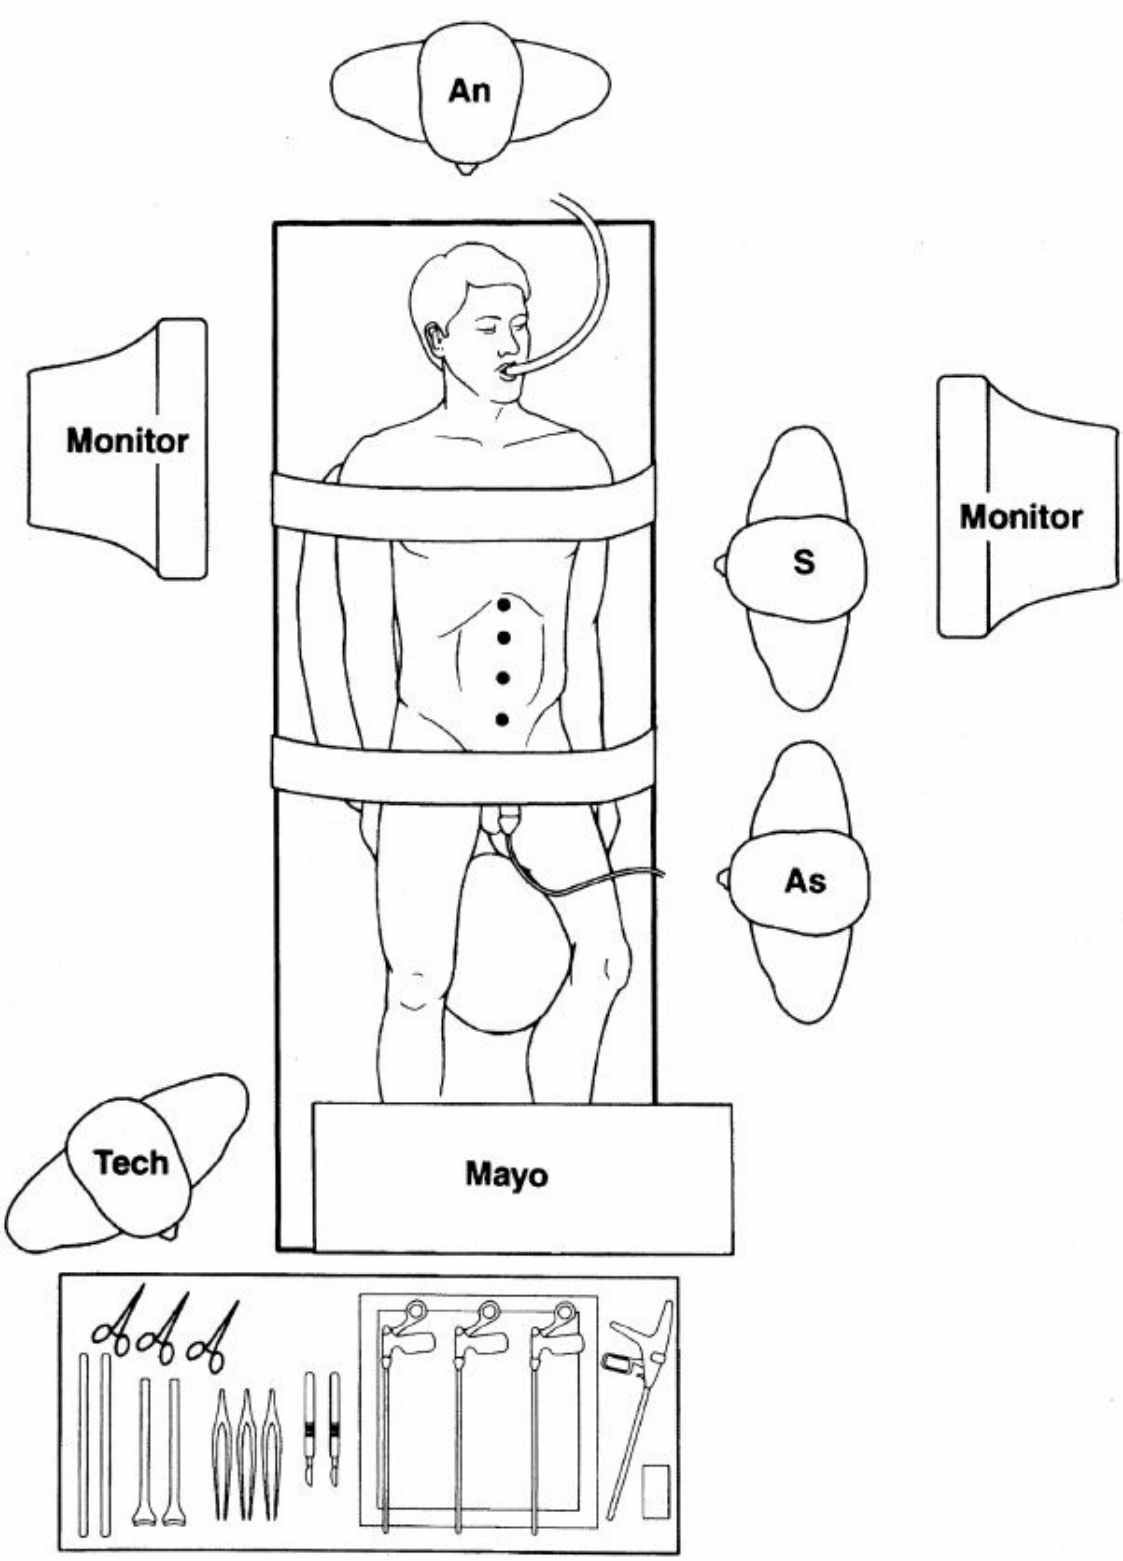

Figure 176.15. The surgical team positioning for right-sided laparoscopic retroperitoneal lymph node dissection is depicted. An, anesthesiologist; As, assistant surgeon; S, surgeon; Tech, scrub nurse or technician.

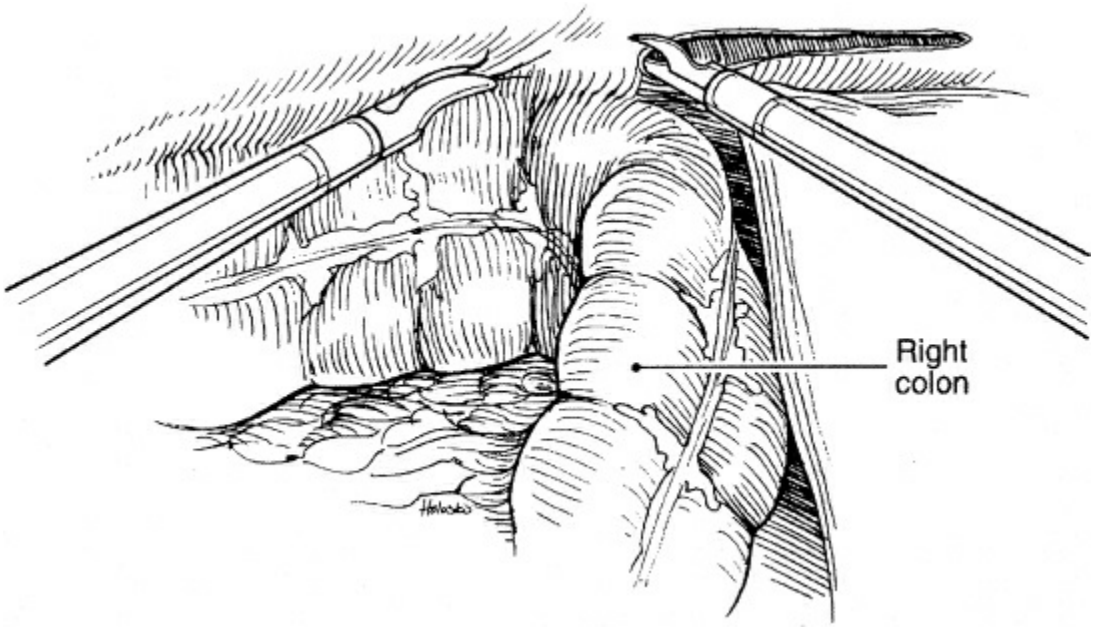

Figure 176.16. Incision of the line of Toldt from the hepatic flexure down to the medial umbilical ligament.

Surgical Technique for Right-Sided Tumor

A modified template is used for dissection. The lateral margin is the right ureter, the superior limit is the level of the renal vein, and the inferior margin is the bifurcation of the right common iliac vessels (Fig. 176.12A). Dissection around the vena cava including intra-aortic tissue is performed superior to the inferior mesenteric artery (IMA). Tissue is taken anterior to the aorta to its left lateral border. Below the IMA, the dissection is limited.

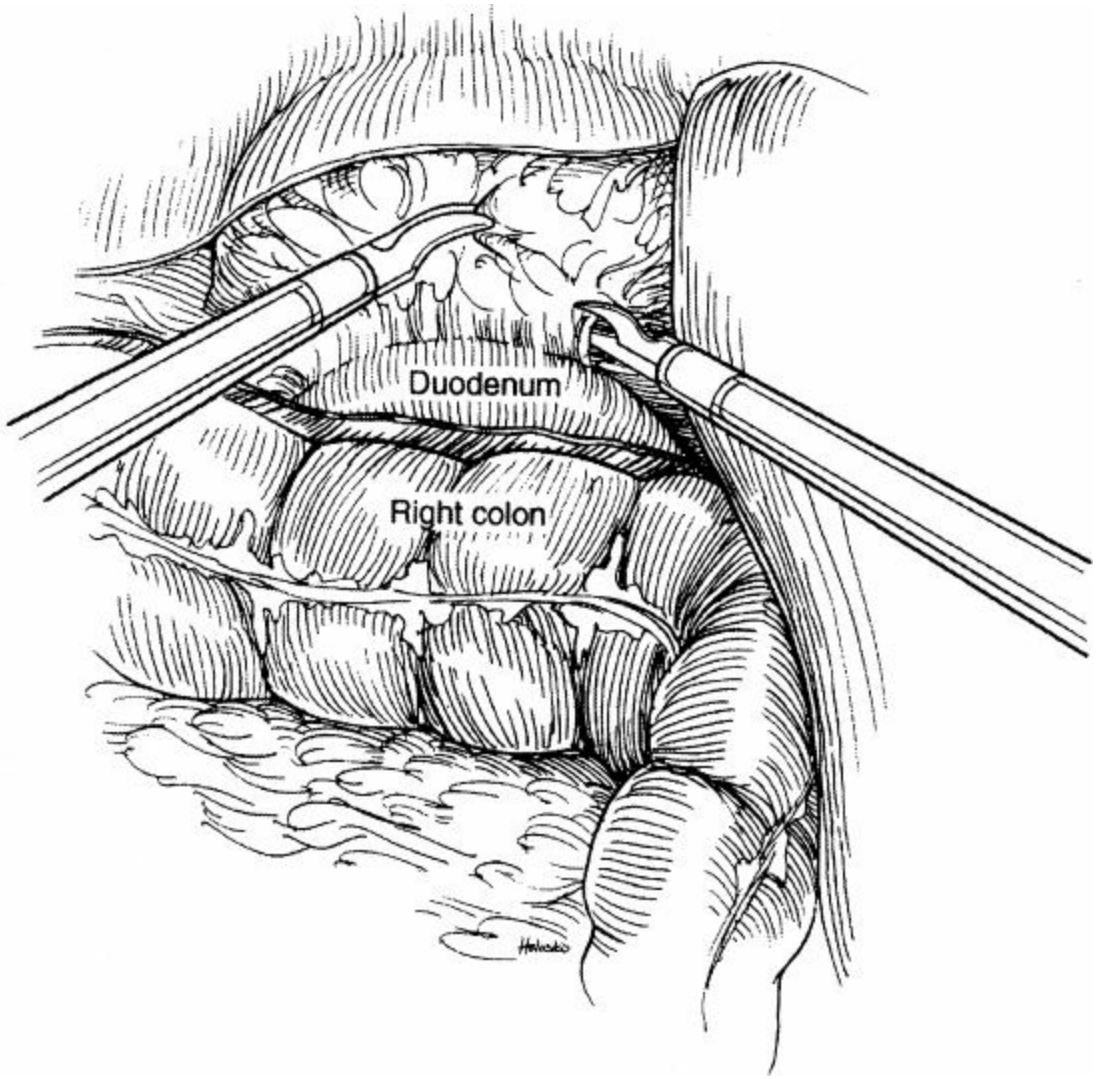

Figure 176.17. With medial retraction of the right colon, the second portion of the duodenum is exposed. The Kocher maneuver is performed to mobilize the duodenum, thereby exposing the great vessels.

The first step is to incise the line of Toldt from the hepatic flexure down to the medial umbilical ligament (Fig. 176.16). This is accomplished by colonic retraction and sharp dissection with the endoscopic scissors or advanced electrosurgical device. Electrocautery can be applied to small vessels as indicated. Lateral to medial sweeping motion with the irrigator aspirator can be used to bluntly dissect the colon medially. Colorenal and hepatorenal ligaments and attachments can be divided sharply to expose the duodenum. The Kocher maneuver is performed to mobilize the duodenum, thereby exposing the great vessels (Fig. 176.17).

After reflecting the colon medially, the spermatic cord and internal inguinal ring are identified. The peritoneum is incised sharply along the

spermatic cord to the level of the common iliac bifurcation, connecting to the peritoneal incision used to reflect the colon. The spermatic cord is dissected free as it crosses over the ureter and followed to the vas deferens, which is clipped and transected. The dissection proceeds distally through the inguinal ring until the permanent ligature placed on the cord at the time of radical orchiectomy is identified (Fig. 176.18). Care must be taken not to injure the external iliac or inferior epigastric vessels at this point.

Once the cord is freed, the dissection proceeds proximally toward the insertion of the gonadal vein into the vena cava and to where the gonadal artery crosses over to the aorta (Fig. 176.19). By placing gentle traction on the cord, it may be dissected off of Gerota's fascia laterally. As one moves cranially, care must be taken not to avulse the origin of the gonadal vessels. The gonadal vein helps identify the vena cava. It is clipped at its origin. The artery is followed medially to identify the aorta, where it is also ligated and divided. The cord is extracted in an entrapment sac bag to prevent loss of specimen or potential port site seeding.

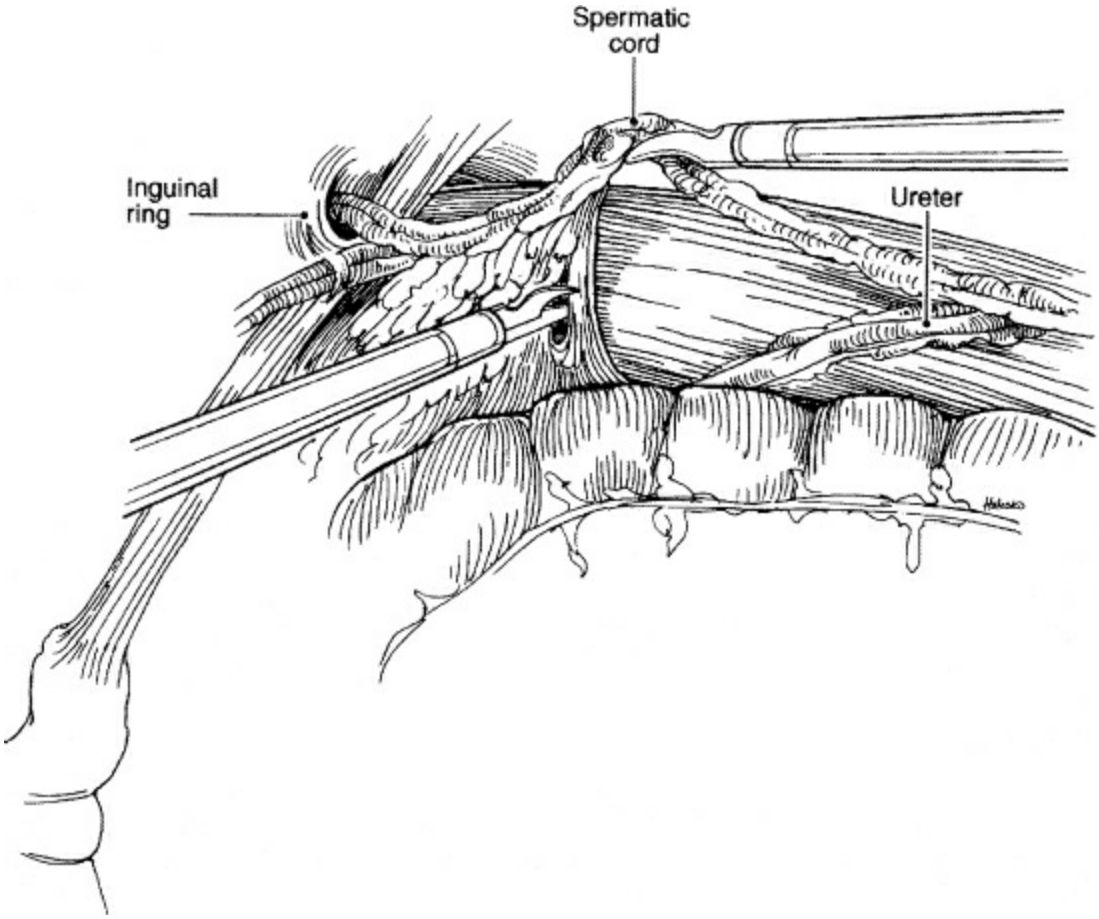

Figure 176.18. The spermatic cord is dissected free as it crosses over the ureter. Distally, the dissection proceeds through the

inguinal ring until the permanent ligature placed on the cord at the time of radical orchiectomy is identified.

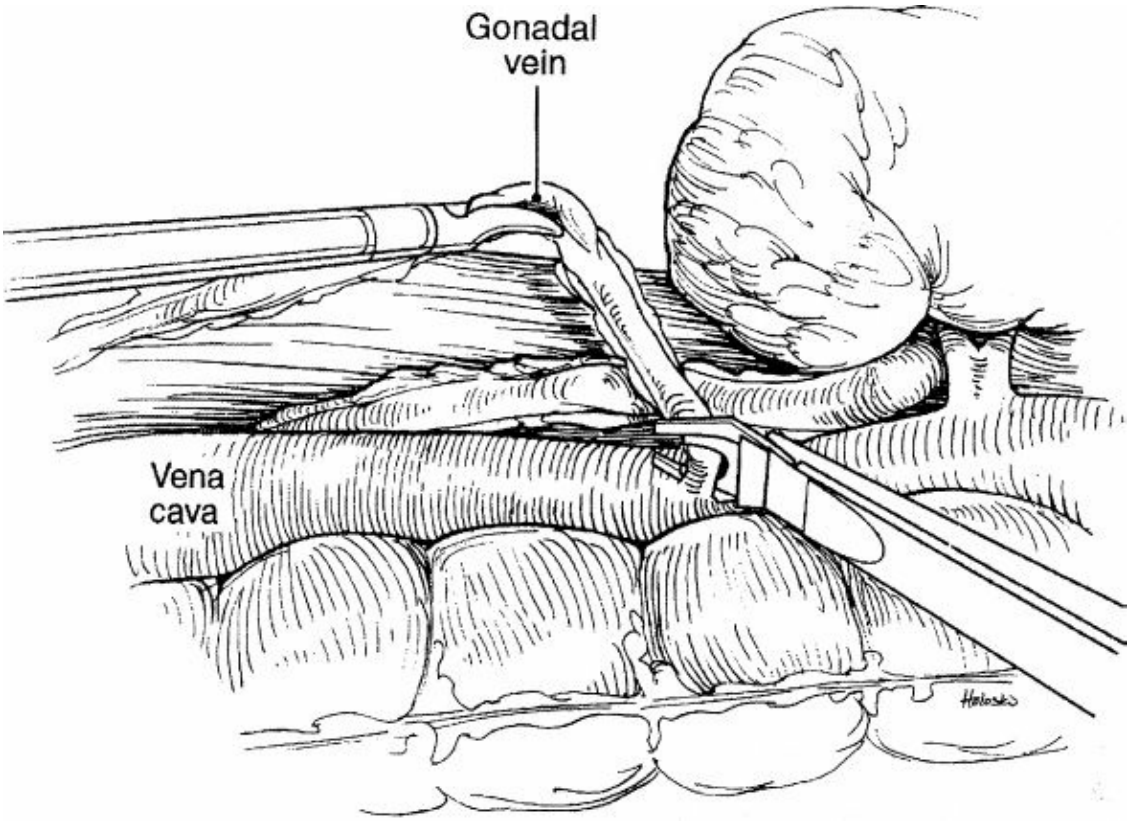

Figure 176.19. Once the cord is freed, dissection proceeds proximally toward the insertion of the gonadal vein into the vena cava and to where the gonadal artery crosses over to the aorta. The gonadal artery and vein are divided.

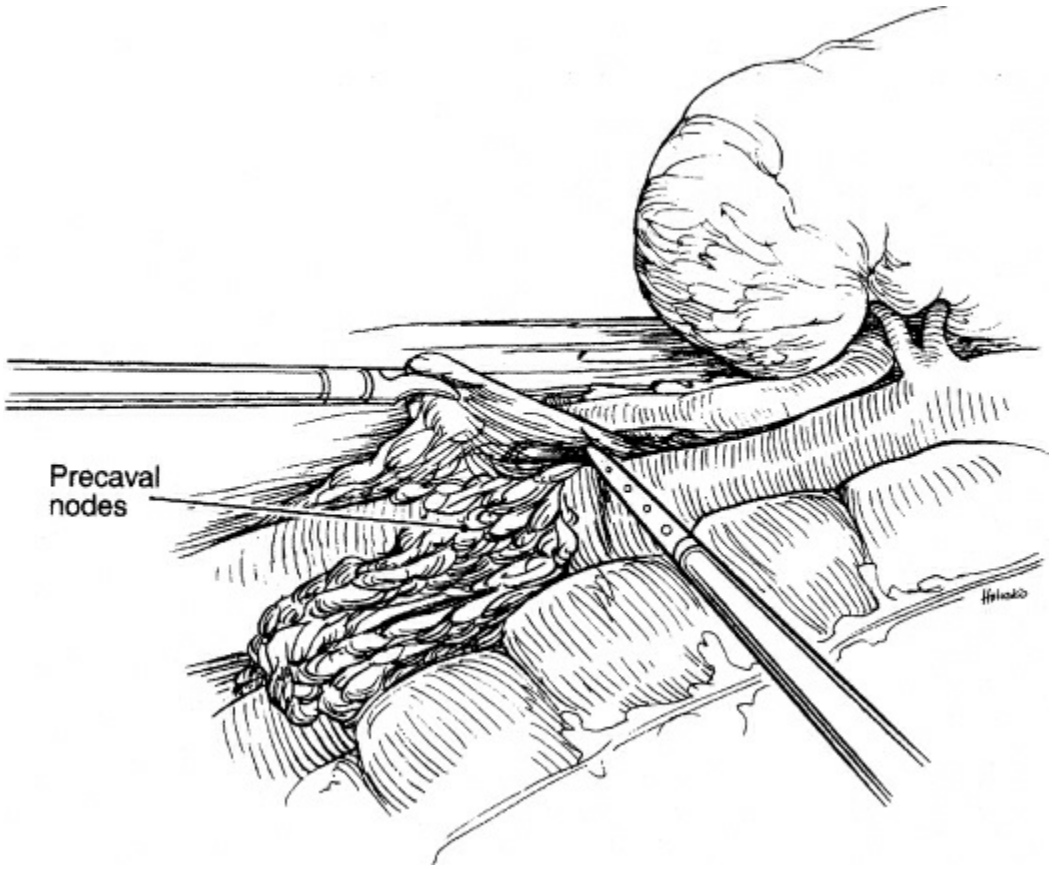

Figure 176.20. The adventitia overlying the vena cava is then divided from the bifurcation of the common iliac vessels to the level of the renal vein. Using blunt and sharp dissection, the lymphatic tissue is reflected laterally toward the ureter.

Beginning at the origin of the gonadal vein, the adventitia overlying the vena cava is then divided to the bifurcation of the common iliac vessels caudally and then cephalad up to the superior level of the renal vein. Using blunt and sharp dissection, the lymphatic tissue is reflected laterally toward the ureter (Fig. 176.20). The ureter is gently retracted laterally as the packet is swept medially. A vessel loop placed around the ureter and closed with a clip is a useful tool to prevent crush injury to the ureter during its retraction. The ureter is traced distally to where it crosses the iliac vessels. At this location, the lymphatic tissue anterior to the artery and vein is clipped and transected. The nodal tissue is swept superiorly. Lateral dissection continues to identify and spare the sympathetic trunk branches, which can be identified lateral and posterior to the vena cava as they course anteromedially toward the hypogastric plexus. Cautery should be avoided during dissection of the sympathetic chain and nerves.

The left border of the iliac aorta is now identified by carefully observing for pulsation and sweeping the sucker onto the lateral surface.

Lymphatic tissue is ligated and the anterior nodal tissue is swept medially. Care is taken to identify branches of the aorta, including the IMA and left renal artery. In some cases, it may be necessary to take the IMA. The medial border of the aorta is identified and tissue continued to be swept medially to join the tissue swept medially from the vena cava. The aorta is followed medially and posteriorly until the fascia of the anterior spinous ligament is identified. Of note, lumbar arteries and veins need to be ligated with clips as they come off the great vessels and again as they enter the vertebral foramen. Care must be taken at the superior aspect of dissection to avoid injuring or inadvertently clipping the right renal artery. In addition, up to 20% of renal units are associated with accessory renal arteries that should be identified and avoided. Beware of retroaortic renal veins and accessory renal arteries, these can be easily confused with lumbar vessels.

The tissue is swept under the vena cava and the vena cava is gently retracted anteriorly. It is important to identify and divide lumbar vessels that tether the vena cava or interfere with the extraction of lymphatic tissue (Fig. 176.21). The tissue is now in continuity with the previously dissected lateral nodal tissue. After dissecting the lateral packet free, final proximal and distal lymphatics are clipped, and the nodal tissue is extracted in an entrapment sac.

Surgical Technique for Left-Sided Tumor

The limits of the dissection are the left renal vein superiorly, the ureter laterally, the bifurcation of the common iliac vessels inferiorly, and the vena cava medially (Fig. 176.12B). The limits of dissection with respect to the IMA are illustrated in Figure 176.12B.

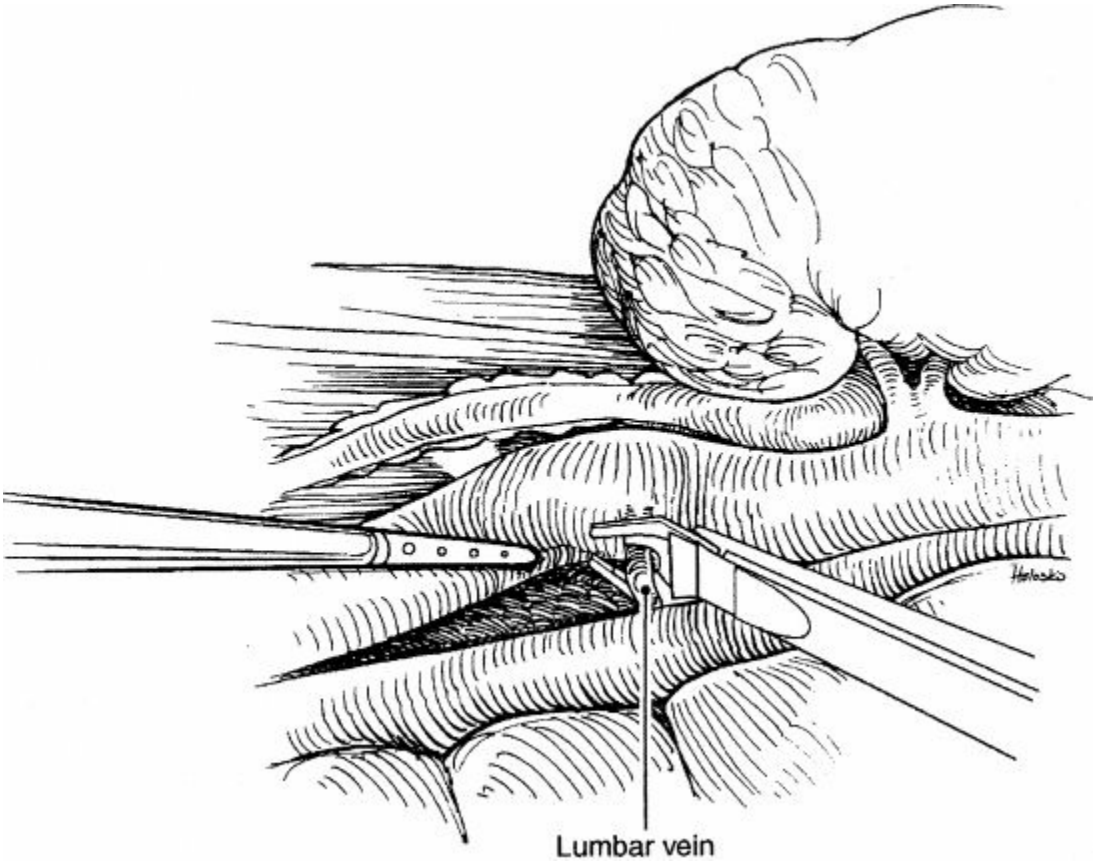

Figure 176.21. It is important to identify and divide lumbar vessels that tether the vena cava or interfere with the extraction of lymphatic tissue.

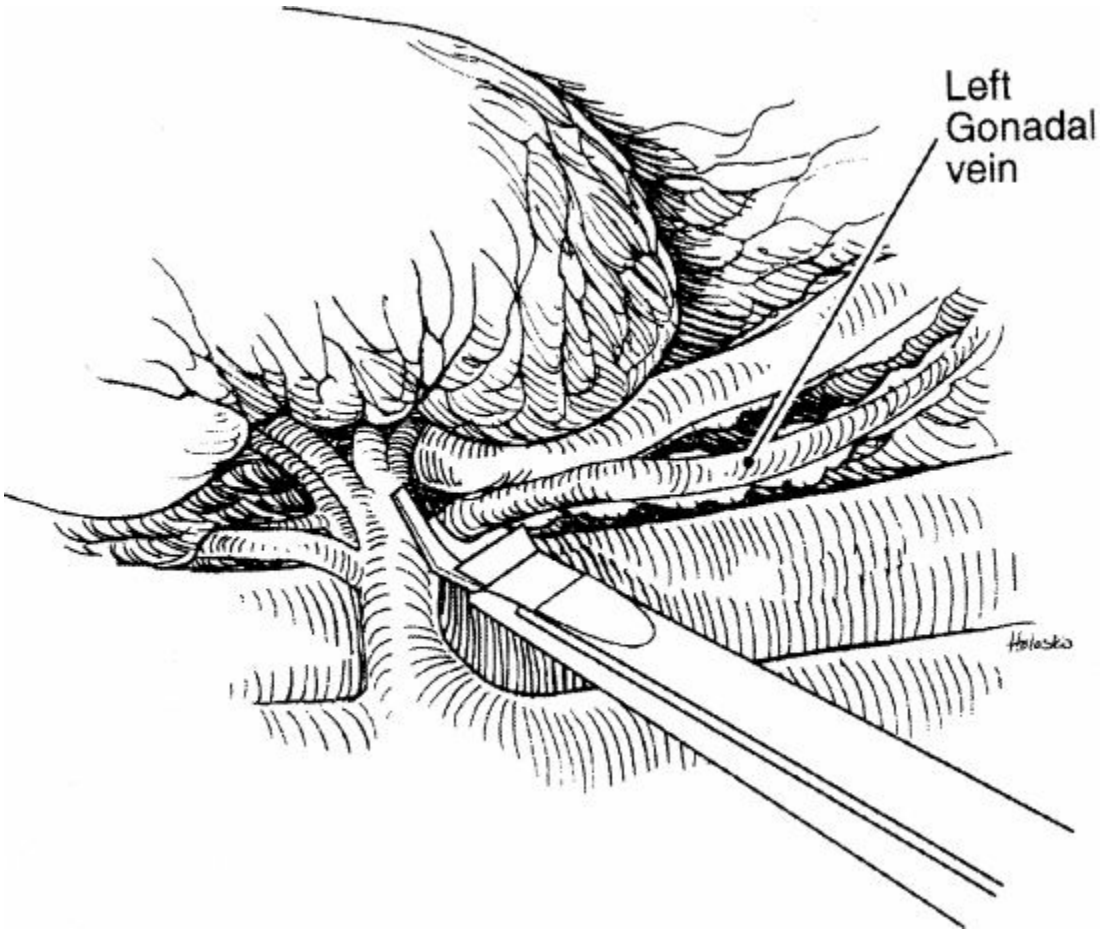

Figure 176.22. The left gonadal vein is dissected up to its origin from the left vein.

Once again, dissection starts with incision of the line of Toldt. Sharp and blunt dissection is used to mobilize the colon medially from the splenic flexure down to the bifurcation of the common iliac vessels. Splenophrenic attachments are divided to assist in exposure of the renal hilum.

After the colon and spleen are mobilized, the internal inguinal ring and spermatic cord are identified, and dissection of the cord proceeds as described previously for right-sided tumor. In this case, however, the gonadal vein is dissected up to its origin in the left renal vein (Fig. 176.22).

With the identification of the ureter and aorta, dissection of the para-aortic lymphatic packet can proceed. The adventitia overlying the aorta is divided, and then the lymphatic tissue is reflected laterally toward the ureter (Fig. 176.23). Dissection proceeds inferiorly to the IMA, where it is shifted to the left side down to where the ureter crosses the iliac vessels. As for the right dissection, branches from the sympathetic chain can be

identified lateral and anterior to the aorta. Sharp and blunt dissection combined with the judicious use of surgical clips is used to free up the nodal tissue (Fig. 176.24). Although advanced surgical sealing devices can be used to divide lymphatics, we prefer the use of metal clips due to the lack of convincing literature on the durability of sealing energy only in prevention of lymphatic leak. The lymphatic tissue in the interaortocaval area is then dissected from the level of the renal vein down to the IMA in the same manner described for right-sided tumor. The tissue overlying the vena cava is split and rolled medially. It is necessary to retract the inferior vena cava to the right and ligate lumbar branches to facilitate total nodal dissection. Lumbar arteries are taken to identify the anterior spinous ligament, and the aorta is gently retracted anteriorly to sweep the interaortal package posteriorly to join the previously freed lateral tissue. Again, it is important to identify and avoid injuring the renal arteries during this dissection.

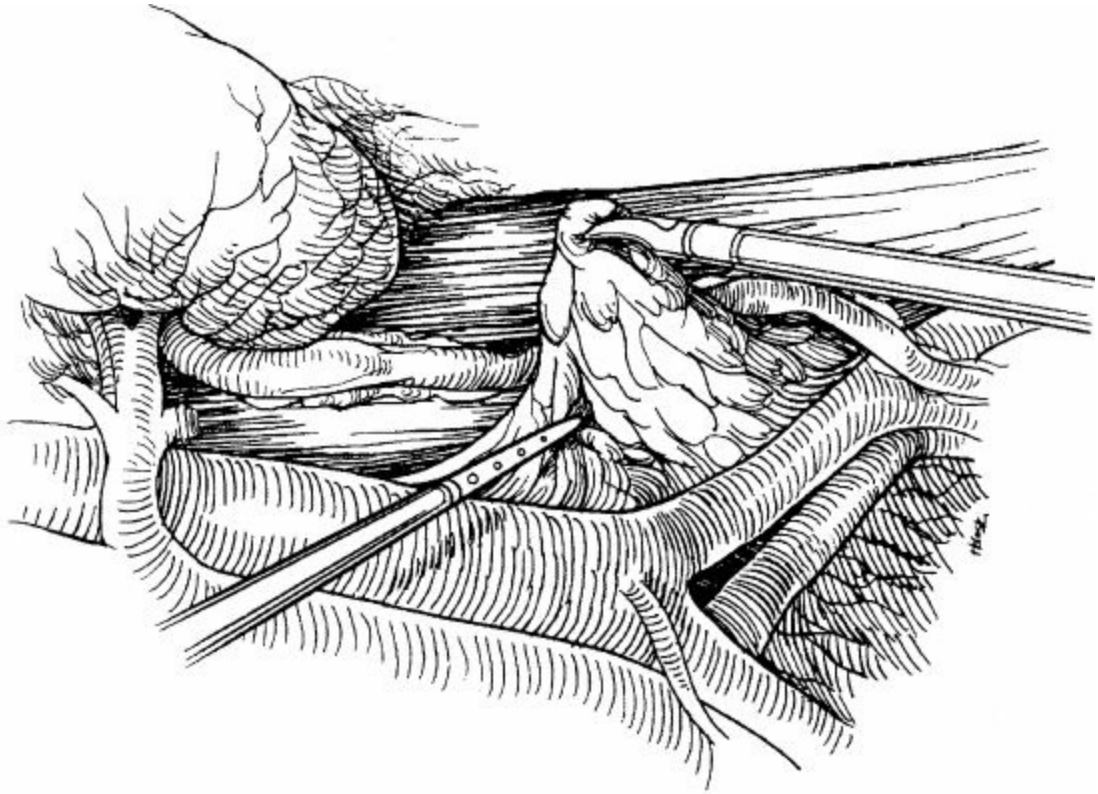

Figure 176.23. The adventitia overlying the aorta is divided, and then the lymphatic tissue is reflected laterally toward the ureter. Dissection proceeds inferiorly to the inferior mesenteric artery. All of the lymphatic tissue between the aorta and ureter is removed.

After completing the dissection, gas pressure is lowered, and the

operative site is inspected for hemostasis. Hemostatic and fibrin-based sealing products can be applied to small areas of venous ooze, but convincing literature does not exist to support improved complication rates. Trocar sites are sequentially closed, as described in the technique section for LPLND.

ROBOTIC-ASSISTED LAPAROSCOPIC RETROPERITONEAL LYMPHADENECTOMY

The indications, pre-operative preparation, post-operative care, and complications are similar to LRPLND. Although surgical literature evaluating feasibility and outcomes of robotic RPLND is currently limited, it has proven the technique to be successfully reproducible across oncologic surgical centers. Operative times with robotic RPLND for surgeons experienced with robotic procedures are similar to an experienced laparoscopist.

For a modified template robotic-assisted LRPLND, the robot is docked from behind the side of the patient in modified ipsilateral flank positioning, similar to LRPLND. Using traditional Hasson or Veress technique with a 12-mm camera port, peritoneal access is obtained with the patient's abdomen flat relative to the floor achieved by rolling the operating table. The bedside assistant is placed on the contralateral side of the template, facing the patient. Figure 176.25 demonstrates the port placement for right-sided modified template robot-assisted LRPLND. The black circles represent the three robotic assistant arm ports (8 mm), the white umbilical port as the robotic camera port (12 mm), and the white right upper quadrant port as a 12-mm assistant port or application of clips and additional retraction. The right upper quadrant robotic port, or "fourth arm port" may be substituted by a second non-robotic 5- or 12-mm port (concentric circles) placed midway between the camera and right-arm robotic ports and 7- to 10-mm laterally toward the contralateral side. Useful robotic instruments include electrosurgical scissors and hook; fine dissecting forceps; and grasping forceps along with traditional laparoscopic retractors, suction irrigator, and clip appliers.

The initial portion of the operation, including the incision of the line of Toldt, mobilization of the colon, and excision of spermatic cord stump may be best performed using traditional laparoscopic instruments prior to docking the robot. This is because of the improved mobility over a large space provided by traditional laparoscopy. For the remainder of the

operation, robotic instruments are used to perform the steps and operative techniques as described above for LRPLND. With more modern surgical robotic systems, improved mobility from decreased arm-clashing may allow the entire procedure to be performed with the robot docked to the patient.

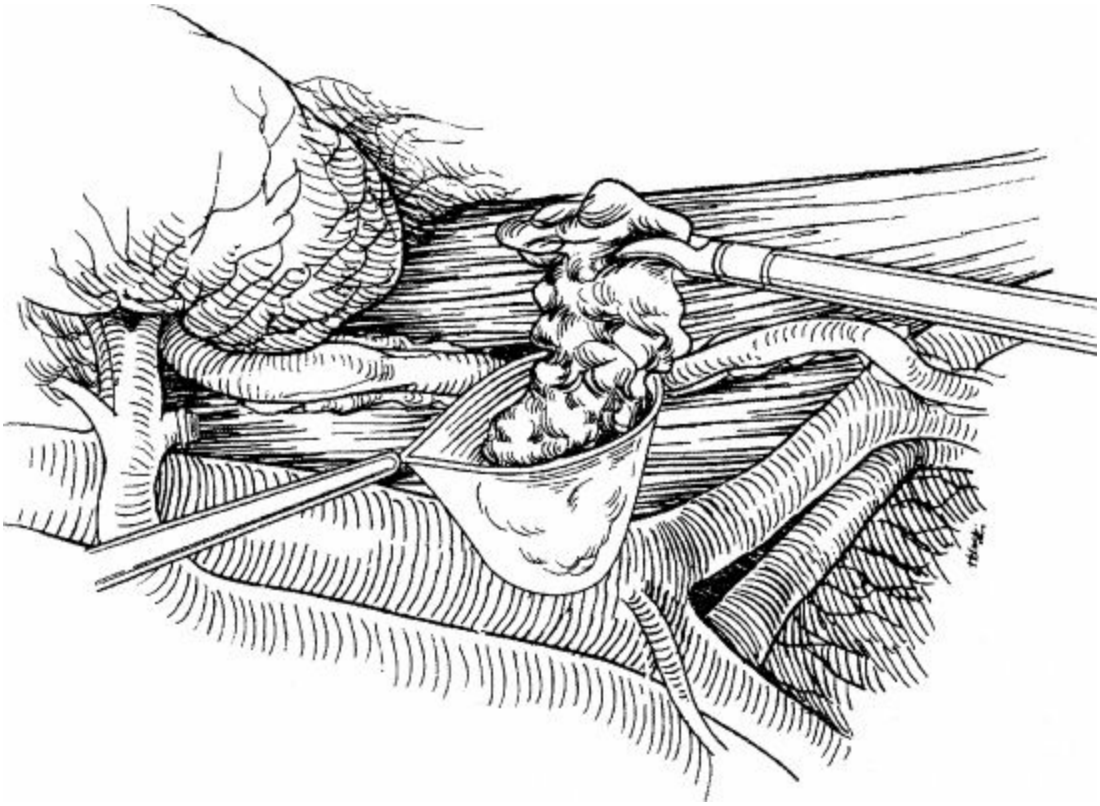

Figure 176.24. The specimen is placed within an Endocatch bag and removed.

Conclusion of Procedure

At the end of the procedure, care is taken to search for hemostasis and any unrecognized injuries. If pooled lymph is seen, an effort needs to be made to locate and occlude the open lymphatic channel. Bowel viability is assessed as it is replaced in the anatomic position. The fascia and skin are closed in a standard fashion.

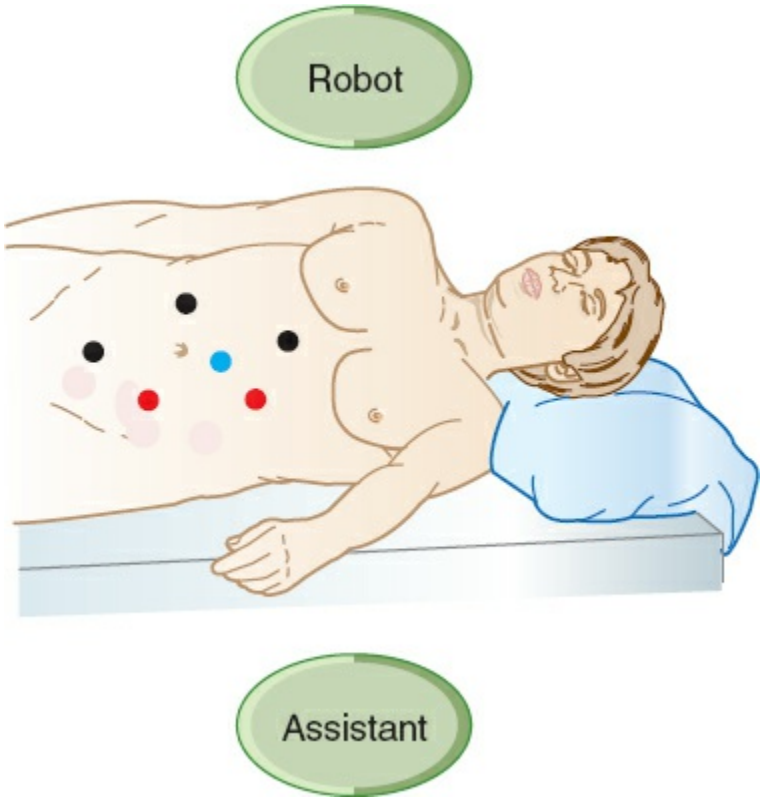

Figure 176.25. Port placement for robotic-assisted modified right template LRPLND in modified flank position. *Black circles* represent robotic ports, *red circles* represent assistant ports, and *blue circle* is camera.

Postoperative Management

The orogastric tube is removed at the end of the procedure. The Foley catheter can be removed when the patient is ambulatory, and diet should be advanced as tolerated. A typical hospital stay is 1 to 2 days with resumption of normal activity as tolerated (usually 2 to 3 weeks).

Complications

Several complications have been reported with LRPLND. The most serious complication reported during LRPLND is hemorrhage. Common areas of potential vascular injury include tributaries of the vena cava and aorta (gonadal branch, lumbar branches, and so on). Minor injuries to the great vessels may be repaired with 5-0 vascular sutures. Major vascular injuries are rare, but may require synthetic grafting and/or removal of a portion of the vessel.

Initial experience with hemorrhage during LRPLND often necessitated open conversion and occasional blood transfusion. More recently

advancements in instrumentation and suturing techniques have decreased the rates of conversion to between 1% and 5%. In cases of venous bleeding, compression with a laparoscopically placed gauze pad for 5 to 10 minutes can abate most bleeding. We have managed bleeding of avulsed lumbar and gonadal veins successfully in this manner. Adjunct hemostatic agents such as gelatin matrix (FloSeal Matrix Hemostatic Sealant, Fusion Medical Technologies, Fremont, CA) or oxidized cellulose (Surgicel, Ethicon, Inc., Piscataway, NJ) should also be available. Large injuries can be sutured or clipped. Torn vessels from the aorta usually require suture ligation as stumps are short for clip placement. Vascular injury is increased in patients who have had chemotherapy.

Lymphocele formation can present postoperatively with persistent flank pain or hydronephrosis from ureteral compression. As with open surgery, this can be avoided with generous clipping of lymphatic channels. Insufficient evidence exists to advocate the use of only advanced bipolar surgical sealing devices in the prevention of lymphatic leak in the setting of RPLND. Lymphocele formation can be managed with percutaneous drainage or laparoscopic marsupialization.

Chylous ascites occurs in 2% to 3% of cases and results from failure to ligate the cisterna chyli. Patients may present in the early postoperative period with abdominal distention, prolonged ileus, pleural effusion, or chylous leakage from the incision. The diagnosis is confirmed with abdominal ultrasound and paracentesis. Patients are initially treated with a low-fat diet, medium-chain triglycerides, diuretics, and, if necessary, hyperalimentation. If conservative management fails, rexploration or lymphangiography may be used to control the leak. When all measures fail, peritoneovenous shunting may be necessary. Asymptomatic lymphoceles may be observed. Aspiration under CT guidance is recommended if there is associated infection, hydronephrosis, or bowel obstruction.

Retrograde ejaculation is less common with nerve-sparing techniques. This complication occurs in less than 5% of patients with nerve-sparing techniques in modern series. Ureteral stricture is another late complication and is also rare (<5%).

Bowel injury can occur during trocar placement or surgical dissection. Unrecognized bowel injuries can result in significant postoperative morbidity or mortality. In suspected patients, CT scan can be used to diagnose these injuries. If bowel injury is identified, prompt surgical

exploration is warranted.

Persistent ileus should raise the suspicion of a retroperitoneal process such as hematoma, pancreatitis, or urinary extravasation. Small bowel obstructions should initially be treated conservatively with nasogastric decompression. Persistent obstruction or associated toxicity may require exploration. Bowel obstruction is rare if the mesentery was carefully closed.

To minimize the risk of atelectasis and pneumonia, all patients should undergo aggressive pulmonary toilet. Pulmonary fibrosis is a potential risk in patients with previous bleomycin chemotherapy. Judicious use of intraoperative fluids and avoiding high concentrations of inspired oxygen help prevent this serious complication.

Other described rare complications include pulmonary embolus, myonecrosis, and leg paresthesia. Port-site metastasis is specific to LRPLND. Fortunately, it is exceedingly rare (0.3%).

SUMMARY

1. Lymphadenectomy has a diagnostic and, in some instances, a therapeutic role in prostate, bladder, penile, urethral, and testicular malignancies.
2. The primary application of lymphadenectomy has been in staging and treatment of patients with low-stage nonseminomatous germ cell tumors of the testis and in the staging of moderate- and high-risk prostate cancer.
3. With the advent of prostate-specific antigen testing, nomograms have been developed to predict nodal status. As such, fewer patients require an isolated pelvic lymphadenectomy.
4. Open RPLND has been the “gold standard” of surgical management of testes cancer. With advances in instrumentation and optics, equivalent dissection has been achieved with the laparoscopic approach by experienced laparoscopists. Robotic-assisted RPLND is feasible, but advantages over traditional laparoscopy have yet to be defined.

EDITOR'S COMMENT

The staging and management of regional lymph node basins provide the cornerstone for the surgical management of cancer. Regional lymphadenectomy for urologic malignancies has evolved significantly since its original description in the 16th century by Henri Le Dran (Sakorafas GH, Safioleas M. Breast cancer surgery: an historical narrative. Part II. 18th and 19th centuries. *Eur J Cancer Care [Engl]* 2010;19(1):6–29). As with other malignancies, evaluation of regional lymph node basins is based upon Halsted theory that cells from primary tumors spread in an orderly manner along the lymphatic chain to adjacent lymph nodes. Dr. Kavoussi has provided us with an excellent overview of pelvic and retroperitoneal lymphadenectomy, and their work provides the opportunity for robust discussion of the roles of these procedures in the treatment of urologic malignancies.

LeDran first noted that breast cancer that had spread to axillary lymph nodes resulted in much poorer outcomes than localized tumors. Stephen Paget published the definitive article on metastasis, espousing his "seed and soil hypothesis" in 1889 (Sakorafas GH, Safioleas M. Breast cancer surgery: an

historical narrative. Part II. 18th and 19th centuries. *Eur J Cancer Care [Engl]* 2010;19(1):6–29). Isaiah Fidler spent many years studying metastasis, first demonstrating that it is a nonrandom process and later demonstrating the varying metastatic potential of cancer cells. With several decades of research on the genetic basis of cancer, scientists are just beginning to understand the molecular biology of metastasis (Fidler IJ, Kripke ML. The challenge of targeting metastasis. *Cancer Metastasis Rev* 2015;34(4):635–41). It is this understanding of cancer metastases that provides a backdrop for the discussion of lymphadenectomy for urologic malignancies.

The management of the pelvic lymph nodes in patients with prostate cancer has been the topic of significant discussion. Normograms divide patients into low, medium, and high risk for lymph node metastases. Those with low-risk disease should be spared lymphadenectomy, while individuals with medium and high risk should be offered it. Understanding the surgical treatment of prostate cancer relies on clear delineation of lymphatic drainage patterns of the prostate. Lymph from the prostate drains via one of three routes, either draining to internal iliac lymph nodes, to external iliac lymph nodes and thus forming a paravesical plexus, or travelling posteriorly to sacral lymph nodes. The drainage patterns allow for the categorization of pelvic lymph node dissections into standard and extended pelvic lymphadenectomy. An extended pelvic lymph node dissection (ePLND) reaches from the bifurcation of the common iliac artery superiorly to the femoral canal inferiorly; posteriorly, the obturator nerve, obturator vessels, and internal iliac artery are skeletonized. The standard pelvic lymph node dissection does not include removal of the internal iliac artery node. A recent study noted a 14% complication rate with standard PLND compared with a 35% rate in patients who underwent an extended procedure; however, most PLND complications are minor (Rousseau B, Doucet L, Perrouin Verbe MA. Comparison of the morbidity between limited andextended pelvic lymphadenectomy during laparoscopic radical prostatectomy. *Prog Urol.* 2014;24(2):114–20).

Standard PLND has always been preferred to the ePLND in the United States because of the low rates of advanced disease at presentation. Offering an ePLND in low-risk patients is unlikely to slow disease progression or improve cancer-specific survival in this patient population (DiMarco DS, Zincke H, Sebo TJ, et al. The extentof lymphadenectomy for pTXNO prostate cancer does not affect prostate canceroutcome in the prostate specific antigen era. *J Urol* 2005;173(4):1121–5). Proponents of the ePLND contend that there is improved therapeutic benefit to identification and removal of lymph nodes with micrometastatic disease; however, these patients will have improved outcomes compared with clinically node-positive patients and thereby improving the overall outcomes of patients undergoing ePLND. There are no clear data to suggest that ePLND improves survival for all patients with prostate cancer; thus, a prospective randomized trial is required to definitively answer this question. The completion of such a trial is highly unlikely given the decline in

the numbers of PLNDs performed in the United States (Allaf ME, Partin AW, Carter HB. The importance of pelvic lymph node dissectionin men with clinically localized prostate cancer. *Rev Urol* 2006 Summer;8(3):112–9).

The authors did not include a discussion of sentinel lymph node biopsy (SLNB) for urologic cancers. Given that this procedure is increasingly used in the management of penile cancer since its original description by Cabanas nearly 40 years ago, I feel it worthwhile to review the current data on its use. (Cabanas, 1977) Lam et al. recently evaluated 500 inguinal lymph node basins in patients with squamous cell carcinoma of the penis. They found a 94% sensitivity in patients in which SLNB and ultrasound were utilized compared with a 91% sensitivity in patients in whom blue dye and gamma probe guided SLNB (Lam. 2013). Later work by Djajadiningrat et al. found a statistically significant difference in 5-year cancer-specific survival in cohorts before and after the SLNB era (82% vs. 91%, $p = 0.021$) (Djajadiningrant, 2014). These findings suggest that the identification and resection of microscopic disease led to superior outcomes relative to the resection of palpable nodes.

The authors provide an outstanding review of retroperitoneal lymph node dissection (RPLND) with specific attention given to the management of testicular cancer. I believe that a historical perspective will make its consideration complete. Although RPLND was first described by the English surgeon Bland-Sutton in the early 1900s for the treatment of nonseminomatous germ cell tumors, the extent of lymphatic drainage including the suprahilar and contralateral regions was not delineated until the advent of lymphoscintigraphy in the 1960s (Busch FM, Sayegh ES, Chenault OW. Some uses of lymphangiography in the management of testicular tumors. *J Urol* 1965;93:490–5). The ensuing modification of RPLND to include bilateral retroperitoneal dissection combined with suprahilar dissection and division of the lumbar arteries and veins to allow access to the lymphatic tissue dorsal to the great vessels led to numerous complications, including ejaculatory dysfunction. Subsequent improvements in RPLND were focused on targeting the dissection template to avoid injuring the sympathetic plexus, thereby improving ejaculatory function. Richie et al. reported that the primary landing site for regional metastasis for stage I testicular cancer was located well above the aortic bifurcation. They therefore limited their distal dissection to the ipsilateral level of the inferior mesenteric artery, resulting in a relapse rate comparable to that associated with standard bilateral RPLND and an antegrade ejaculation rate of 95% (Richie JP. Clinical stage 1 testicular cancer: the role of modifiedretroperitoneal lymphadenectomy. *J Urol* 1990;144(5):1160–3). Similarly, Donohue et al. dissected only the node-bearing tissue around the postganglionic sympathetic fibers in a procedure that is currently referred to as the nerve-sparing RPLND. This group reported a 98% antegrade ejaculation rate with cure rates comparable to those who underwent classic RPLND (Donohue JP, Thornhill JA, Foster RS, et al. Retroperitoneal lymphadenectomy for clinical stage A testis cancer (1965 to 1989): modifications of technique and

impact on ejaculation. *J Urol* 1993;149(2):237–43).

As with most surgical procedures, minimally invasive approaches to RPLND have undergone numerous refinements. Rukstalis and Chodak presented a case report on laparoscopic retroperitoneal lymph node dissection (L-RPLND) in 1992 (Rukstalis DB, Chodak GW. Laparoscopic retroperitoneal lymph node dissection ina patient with stage 1 testicular carcinoma. *J Urol* 1992;148(6):1907–9; discussion 1909–10). Janetschek et al. consequently reported on 76 patients who underwent L-RPLND for stage I disease in 2000. At a 4-year median follow-up, antegrade ejaculation rate was 99%, while retroperitoneal recurrence rate was very low at 1.3%. We look forward to further refinements, including widespread utilization of robotic RPLND (Janetschek G, Hobisch A, Peschel R, et al. Laparoscopic retroperitoneal lymph node dissection for clinical stage I nonseminomatous testicular carcinoma: long-term outcome. *J Urol* 2000;163(6):1793–6).

177 Robot-Assisted Radical Prostatectomy

Ahmed A. Hussein and Khurshid A. Guru

INTRODUCTION

Prostate cancer is the third leading cause of cancer death among American men, and is the commonest non-skin malignancy. Radical prostatectomy is an established treatment modality for localized prostate cancer and is superior to observation in terms of survival. In the past decade, robot-assisted radical prostatectomy (RARP) has gained much popularity among patients and urologists, with more than 80% of all radical prostatectomies performed in the United States are performed with robot assistance. In this chapter, we will shed light on important anatomical and surgical considerations for RARP, with special emphasis on the surgical technique.

ANATOMICAL CONSIDERATIONS

Sound knowledge of the surgical anatomy of the prostate is the key to optimize cancer control and functional outcomes after radical prostatectomy. The main outcomes of radical prostatectomy have been classically reported as "trifecta," comprising the likelihood of urinary continence, potency, and cancer control biochemical recurrence-free survival rates following surgery. Key anatomical considerations to achieve the trifecta will be discussed in this section with special emphasis on the anatomy of the dorsal venous complex (DVC), the location and course of the neurovascular bundles (NVB), and the anatomy of the bladder neck and pelvic floor. With advances in minimally invasive approaches and incorporation of RARP into the surgical armamentarium, the current expectations of patients who desire surgical treatment for prostate cancer are much higher and extend beyond the classic trifecta, and the newer concept of "pentafecta" was introduced. In addition to the factors included in the trifecta, pentafecta also includes negative surgical margin and absence of complications.

The DVC overlies the urethral sphincter covering up to one third of the

cross-sectional urethral sphincter surface area laterally at the apex of the prostate and 5 mm distal to the apex. Therefore, during DVC control especially with transverse en bloc ligation of the DVC extending beyond its lateral limits, a considerable portion of the sphincter tissue might be included, which may adversely affect postoperative continence. To avoid this problem, selective dissection and ligation of the DVC is strongly recommended to minimize sphincter injury as possible.

The most frequent origin of *prostate arteries* is from the internal pudendal artery. The artery then courses obliquely toward the posteroinferior aspect of the bladder and provides several inferior vesical arteries. It terminates in two main pedicles while providing numerous branches to the prostate. The posterior pedicle surrounds the seminal vesicles (SVs) and the vas deferens near the prostate base. The anterior pedicle runs along the lateral border of the prostate to the prostate apex and continues as anterior capsular prostate branch. These arteries may be responsible for ancillary penile blood flow. Therefore, preserving them during radical prostatectomy may help postoperative erectile function and help maintain penile integrity and length. *The inferior hypogastric (pelvic) plexus* is responsible for erection, ejaculation, and urinary continence. It lies within a fibrofatty tissue between the bladder and the rectum. The pelvic plexus and the erectile nerves are at risk during standard pelvic lymph node dissection (pLND) dissection, especially in the area of the internal iliac artery and toward the bladder wall. An inverse relation between erectile function and more extended lymph node dissection and higher lymph node yield has been previously demonstrated.

Several dissection planes have been proposed for *NVB preservation.* One of the most commonly utilized classifications comprise intrafascial, interfascial, and extrafascial dissection planes. Intrafascial dissection follows a plane on the pseudocapsule of the prostate (internal to the prostatic fascia), allowing preservation of the whole NVB. Interfascial dissection occurs within the periprostatic fascia and includes incremental nerve sparing with wider resection. The extrafascial dissection occurs lateral to the levator ani fascia with complete removal of the NVB. Patient selection for NVB preservation on one or both sides depends on patient and cancer site and extent.

Pelvic floor musculature plays an important role in postoperative urinary continence. The anteromedial part of levator ani muscle close to the urethral sphincter, also known as puboperinealis muscle, contracts and

pulls the urethra and prostate forward and upward, resulting in closure of the urethra. The nerve supplying runs on the levator ani surface just lateral to the fascial tendinous arch and may be injured during incision of the endopelvic fascia. Preserving the *bladder neck* is another key component for postoperative urinary continence. It is formed by several structures, including detrusor muscle near the bladder outlet, the internal urethral sphincter in addition to the adjacent proximal prostatic tissue. Although controversial, bladder neck-sparing techniques aim at preserving this area aiming at improving postoperative continence. The external urethral sphincter is located distal to the apex of the prostate, close to the puboperinealis muscle. However, with considerable variation of the shape of the prostate at the apex, parts of the urethral sphincter can be found inside the prostate, making preservation of the entire length of the urethral sphincter difficult. Based on this observation, full-length preservation of the urethral sphincter by dissecting the distinct striated and smooth muscle part of the sphincter from inside the prostate has been proposed for early recovery of postoperative continence.

INDICATIONS AND CONTRAINDICATIONS

Radical prostatectomy may be performed in patients with clinically localized prostate cancer and estimated life expectancy of at least 10 years. It may be also performed in the salvage setting in patients experiencing biochemical recurrence after external beam radiation therapy (EBRT). However, in the salvage setting, the risks of incontinence, bladder neck contracture, and erectile dysfunction are higher and with variable cancer-specific survival. Therefore, salvage prostatectomy should only be performed by highly experienced surgeons.

The decision to proceed with pLND should be guided by the probability of lymph node metastasis. The National Comprehensive Cancer Network Guidelines recommend a cut-off of ≥2% based on the Memorial Sloan Kettering Cancer Center Nomogram. This nomogram utilizes pretreatment PSA, clinical stage, and the Gleason score.

PREOPERATIVE PLANNING

This includes risk stratification and patient counseling about the different available therapeutic strategies, as well as the use of different nomograms to estimate the probabilities of extracapsular extension, SV involvement, lymph node metastasis, positive soft tissue surgical margins, and oncologic

outcomes. A crucial part of preoperative planning is to decide on the possibility and laterality of NVB preservation, as well as to perform pLND or not. The ability of multiparametric magnetic resonance imaging (MRI) to detect extracapsular extension can also guide decision making for nerve-sparing surgery. Patients should be also carefully counseled about the pros and cons of each treatment option and possible consequences on survival and health-related quality-of-life outcomes.

SURGICAL TECHNIQUE

Positioning and Port Placement

The patient is positioned in the Trendelenburg position to provide more working space by displacing the intestinal loops upwards. The abdomen is insufflated using the Veress needle or Hassan technique. After placing the camera port, all ports are placed under direct vision. A standard 6-port transperitoneal approach is used

Complying with the principles of modular training, we recommend deconstructing RARP into seven key steps. The same steps have been developed and validated by a panel of 12 experienced robotic surgeons who created the Prostatectomy Assessment and Competency Evaluation scoring for RARP. This divides the procedure into measurable portions, facilitates learning, and allows structured feedback to trainees that guides training activities.

Bladder Drop and Opening of the Space of Retzius

The bladder is identified and dissected proximally from the anterior abdominal wall lateral to the medial umbilical ligament. Care must be undertaken to avoid injury to the external iliac vein. Dissection of the bladder from the pubic bone distally is then performed opening the prevesical space (of Retzius). Care must be taken to avoid injury of the obturator nerve or vessels, or the lateral pelvic wall.

Defattening of the Prostate

Using the bipolar grasper and the hook monopolar cautery, the periprostatic fat overlying the anterior aspect of the prostate and endopelvic fascia is gently removed till the prostate-vesical junction and the endopelvic fascia are clearly identified. The superficial DVC and puboprostatic ligaments are encountered. We prefer to defer DVC control

with apical dissection to avoid excessive bleeding obscuring the field. The endopelvic fascia is opened and levator muscle fibers are bluntly sweeped laterally and separated from the prostate.

Bladder Neck Dissection

Accurate determination of the correct plane between the bladder neck and the base of the prostate is a key factor to achieve a satisfactory bladder neck. However, this plane is not always obvious. Manipulation of the urethral catheter can help defining the prostato-urethral junction, especially in the presence of a large median lobe. Division of the prostate-urethral junction can be done using the monopolar hook cautery to minimize bleeding. Once the anterior part of prostato-urethral junction is divided and the bladder is opened, the ureteric orifices should be clearly identified. The tip of the urethral catheter can be held up with the fourth arm. Division of the posterior wall of the junction is then ensued. If a median lobe is present, the mucosa along the posterior edge of the lobe is divided and the median lobe mobilized away from the bladder and along with the remainder of the prostate. Adequate and proportionate thickness of the bladder neck should be achieved without entering into the prostate.

Dissection of the Seminal Vesicles and Posterior Anatomical Plane

After complete division of the bladder neck, the SVs can be grasped and dissected. The right SV is grasped with the fourth arm toward the anterior abdominal wall to facilitate exposure and further dissection. The vas is then identified and divided, followed by the SV pedicles. Judicious use of cautery should be exercised to avoid thermal injury of the NVB. The same steps are repeated on the left side. After complete dissection of both SVs, they are both grasped by the fourth arm and retracted toward the anterior abdominal wall. Blunt dissection of the posterior aspect prostate from the anterior layer of Denonvillier fascia is then carried out. Care must be taken to avoid entry into the base of the prostate or into the rectum.

Preservation of the Neurovascular Bundle

Preservation of the NVB should be preoperatively planned depending on the stage, grade, and site of the tumor in the prostate. We use hydrodissection to further define the fascial planes. The NVB is dissected

in a blunt fashion from the anterolateral aspect of the prostate. Care should be exercised to avoid NVB injury or entering the wrong plane. The use of electrocautery should be minimized to avoid thermal injury to the NVB. Once the NVB are dissected, Hem-o lock clips are placed to control the vascular pedicles to the prostate near its base. If nerve sparing was not planned, then a wider dissection of the pedicles is performed to ensure oncologic control and avoid positive soft tissue surgical margins.

Apical Dissection, Control of the Dorsal Venous Complex, and Urethral Transection

The pneumoperitoneum pressure is increased to 15 mm Hg. The DVC is cut with cold scissors and dissection is completed until the urethral is clearly visualized. Maximum urethral length preservation is crucial for adequate urethrovesical anastomosis. Again, manipulation of the Foley catheter can help identifying the prostatic apex. The anterior wall of the urethra is divided with the cold scissors till the Foley is visualized. The Foley is then held up toward the abdominal wall, and cutting the posterior wall is then performed. The pneumoperitoneum is lowered again to 12 mm Hg, and the DVC is then sutured with a 3-0 V-loc suture. The freed prostate is placed in the endobag and moved to the upper abdomen to allow for urethra-vesical anastomosis.

Urethro-Vesical Anastomosis

The “Rocco” stitch (reapproximation of the Denonvilliers fascia) prior to anastomosis of the bladder to the urethral stump has been advocated to improve postoperative continence. One or more figure-of-eight absorbable sutures are placed vertically between the proximal and distal lips of Denonvilliers’ fascia (just posterior to the urethral stump).

The anastomosis starts by constructing the posterior wall first. Two 3-0 v-lock sutures are used, starting at 6 o’clock position with one running to the right and the other to the left. The needle is passed through the posterior bladder wall first (outside-in), then through the urethra (inside-out). The two running sutures are continued anteriorly with mucosa-to-mucosa approximation over a 22-Fr silicone catheter till the 12 o’clock position. The anastomosis should be watertight and not under tension. Irrigation of saline through the Foley can be performed to ensure adequacy of the anastomosis.

Pelvic Lymph Node Dissection

Extended pLND should be performed. It involves dissection of all the lymphatic tissue between the external iliac vein anteriorly, the pelvic side wall laterally, the pelvic floor posteriorly, Cooper ligament caudally, the internal iliac artery cranially, and the bladder wall medially. This template has been associated with better staging, and potentially improved survival due to elimination of micrometastatic foci. Judicious use of cautery is exercised control and seal the lymphatic channels while avoiding vascular injury. The dissected nodal tissue is placed in an endobag and can be extracted through extension of one of the ports incision.

OUTCOMES

Compared with observation, there is level I evidence supporting the benefit of surgery in terms of disease-specific and overall survival, as well as the risk of local progression and metastasis at 13 and 23 years, especially for younger men (65 years or younger). Outcomes also depend on the presence of adverse prognosticators, including PSA >10 ng/mL, cT2b or higher, Gleason score 9 or 10, higher number of positive cores on biopsy, and over 50% of core involvement.

Comparative effectiveness between surgery and irradiation for clinically localized prostate cancer is not straightforward. This may be related to the long natural history of the disease, various definitions of what constitutes recurrence, and the difference in impact and time course of different treatments on cancerous cells (effects on PSA and PSA kinetics, and the definitions of biochemical recurrence). The data suggest that EBRT is comparable to radical prostatectomy, with some benefit for surgery over radiotherapy for higher-risk patients. EBRT avoids complications associated with surgery and anesthesia, including bleeding, blood transfusion, myocardial and pulmonary complications. In contrast to surgery, urinary control and erectile function are better on the short term, but they tend to worsen with time. There is also a low but definite risk of protracted symptoms from radiation proctitis. In cases of recurrence or biochemical failure, salvage prostatectomy is a morbid procedure with high rate of complications and variable success.

RARP offers adequate oncologic control that is equivalent to its open counterpart, and is superior in terms of shorter hospital stay, less blood loss, and fewer blood transfusions. Other studies suggested some benefit in terms of 1-year urinary continence and recovery of erectile function. There

was no significant difference in terms of complications, readmissions, or positive soft tissue surgical margins rates.

EDITOR'S COMMENT

Radical prostatectomy can be a curative procedure in many cases of prostate cancer. As noted by Dr. Hussein and Dr. Khurshid in their excellent summary of the robotic-assisted radical prostatectomy (RARP) technique, this approach now accounts for over 80% of the cancer-related prostatectomies performed in the United States.

For those new to the robotic approach to radical prostatectomy, the basic intraoperative principles of the surgical removal of the prostate performed using robotic assistance are not new or revolutionary. A robotic prostatectomy replicates the prostate removal of an open radical retropubic prostatectomy. Further, RARP is technically a laparoscopic procedure. RARP can be more formally defined as a robotic-assisted laparoscopic prostatectomy or RALP. These authors and others prefer to use the term robot-assisted radical prostatectomy or RARP.

With the advent of laparoscopic urologic surgery in the early 1990s, the initial focus was on pelvic lymphadenectomy and renal surgery (Gomella LG, Strup SE. History of laparoscopy: urology's perspective. *J Endourol* 1993;7(1):1–5). Interest grew quickly into exploring other potential urologic applications of this minimally invasive technique. While still practiced by a few artisans, the purely laparoscopic approach to the prostate was and remains a challenging procedure due to the location of the prostate, deep within the pelvis, and the technical challenges associated with the suturing necessary for the bladder neck and urethral reconstruction. The ability of the robotic technology introduced around 2000 improved the laparoscopic visualization of the pelvic structures using stereoscopic lens systems, and the articulation of the robotic instrumentation greatly improved the ability to suture using a laparoscopic approach (Menon M, Hemal AK, VIP Team, et al. Vattikuti Institute prostatectomy: a technique of robotic radical prostatectomy: experience in more than 1000 cases. *J Endourol* 2004;18(7):611–9).

The surgical anatomy, physiology of urinary continence, and the principles of nerve sparing have been nicely reviewed by the authors of this chapter. These advances are not directly attributable to the robotic radical prostatectomy but

were refined in association with the renaissance in the open radical prostatectomy that took place in the early 1980s and widely attributed to Dr. Patrick Walsh (Walsh PC. How surgical innovation reduced death and suffering from prostate cancer. *J Craniofac Surg* 2013;24(1):49–50). All of these surgical principles based on the open radical prostatectomy that have evolved over the last 40 years are now being applied to the robotic approach.

As there are alternative approaches to open radical prostatectomy such as the retropubic and perineal techniques, there are also alternative approaches to robotically assisted radical prostatectomy. The authors of this chapter discuss the much more common transperitoneal RARP (tRARP). Also described in the literature is the extraperitoneal robot-assisted radical prostatectomy (eRARP), a less commonly employed robotic prostatectomy technique. Several recent papers have highlighted the outcomes and safety of eRARP in comparison to tRARP (Semerjian A, Pavolvich CP. Extraperitoneal robot-assisted radical prostatectomy: indications, technique and outcomes. *Curr Urol Rep* 2017;18(6):42). The data suggest the two, eRARP and tRARP, are fairly similar in terms of outcomes. In addition, eRARP may be preferred in certain circumstances, such as if concomitant repair of inguinal hernia is being considered.

As noted by Dr. Hussein and Dr. Khurshid, expectations of patients who undergo surgical treatment for prostate cancer may be unrealistically high in our technologically advanced world. Open radical prostatectomy can be associated with increased blood loss and slightly longer hospital stay. The assumptions that a robotic procedure is minimally invasive, allows a more rapid discharge from the hospital are reasonable. However, patients also often assume that RARP is not associated with complications. These men must be counseled in an objective preoperative discussion. Overall, the risks of radical prostatectomy that are most feared, impotence and incontinence, are similar with either the robotic or open approaches (Healy KA, Gomella LG. Retropubic, laparoscopic, or robotic radical prostatectomy: is there any real difference? *Semin Oncol* 2013;40(3):286–96). Selected papers may highlight superior outcomes in favor of one type of procedure over the other; however, the literature is fairly split.

Dr. Hussein and Dr. Khurshid are objective in terms of noting the long-term oncologic control of the robotic versus open radical prostatectomy based on available data. Advocates of the robotic technique also must recognize the increased cost of using robotic technology. It is not appropriate for a low-volume facility to justify the high costs of the robotic operating room technologies now approaching the 2 million-dollar mark for the newest robotic platforms. Further, in addition to annual maintenance contracts, the costs of robotic arm instruments that lock out after typically 10 uses, whether they are still functional or not, also increase the costs of the RARP. These cost increases due to robotic technology vary widely but are generally $2,000 higher for robotic prostatectomy compared with open; when including the fixed cost of the robot, the difference can be increased to $4,800 (Lowrance WT, Parekh DJ. The

rapid uptake of robotic prostatectomy and its collateral effects. *Cancer* 2012;118(1):4–7). The increased cost is often justified by the more rapid hospital discharge and decreased transfusion rate associated with RARP. It should be recognized that all of this cost data may be institution specific.

While RARP has become the most common surgical approach to radical prostatectomy in the United States, the open surgical approach to radical prostatectomy remains a very relevant and important procedure. Some men with localized prostate cancer may not be suitable candidates for a robotically assisted radical prostatectomy. Further, the more specialized and costly robotic technology may not be readily available to patients in all locales.

The patients who may not be ideal candidates for RARP or who do not have access to a robotically trained urologic surgeon or appropriate robotically equipped facility may be better served with an open surgical approach. Although Dr. Hussein and Dr. Khurshid discussed the oncologic indications and contraindications, there are some relative contraindications and limitations of RALP described in the literature and based on the commentators personal experience as an open prostatectomy practitioner (Menon M, Hemal AK, VIP. Vattikuti Institute prostatectomy: a technique of robotic radical prostatectomy: experience in more than 1000 cases. *J Endourol* 2004;18(7):611–9; Huang AC, Kowalczyk KJ, Hevelone ND, et al. The impact of prostate size, median lobe, and prior benign prostatic hyperplasia intervention on robot-assisted laparoscopic prostatectomy: technique and outcomes. *Eur Urol* 2011;59(4):595–603). While some of these may also present challenges to standard open radical prostatectomy surgery, many are more easily managed using open techniques.

- Obesity (BMI >30 kg/m^2): This may distort anatomy and create instrumentation challenges. These men may also present anesthesia-related difficulty tolerating the steep Trendelenburg position required when performing RARP.
- Some patients with pre-existing medical conditions may not be able to tolerate the effects of CO_2 insufflation on hemodynamics, oxygen levels, and acid–base levels.
- Prior abdominal surgery with extensive adhesions or with a history of ruptured viscera or peritonitis.
- Prior mesh hernia repair and orthopedic hip or pelvic surgery can obliterate the prevesical space and make landmarks for lymphadenectomy anatomy difficult to identify.
- Previous pelvic or prostate radiation can be difficult for any radical prostatectomy approach.
- Large volume prostate (>80 to 100 g) with large median or lateral lobes or a very narrow pelvis.

Robotic radical prostatectomy has become the norm for most men undergoing cancer-related prostate removal in the United States. In the not too

distant past, young urologic surgeons who had a keen interest in becoming skilled as robotically assisted surgeons required a post-residency fellowship in order to develop their operative skills. Today, most urology training programs have incorporated robotic surgical exposure into their residency programs and most urologic oncologists employing robotic radical prostatectomy in their armamentarium. However, fewer trainees are leaving residency with the experience needed to operate in the pelvis and perform radical prostatectomy using time-tested open techniques. Robot-assisted radical prostatectomy will continue to evolve and improve as the technology and long-term experience grow. Regardless of these advances, there will continue to be a group of men who should be considered for potentially curative radical prostatectomy but may not be suitable candidates for the robotic approach. These men should be offered alternative standard surgical approaches such as open prostatectomy.

Leonard G. Gomella

178 The Undescended Testis

Courtney Shepard, Kate H. Kraft, and David A. Bloom

ETIOLOGY AND PATHOPHYSIOLOGY

Cryptorchidism is one of the common disorders of pediatric urology, with 1% to 4% of full-term and up to 45% of preterm male neonates having a diagnosis of undescended testis at birth. Testicular descent is now better understood but as a complex part of human development, it requires further investigation.

During the 5th week of gestation, primordial germ cells migrate from the yolk sac and differentiate into gonocytes. In both sexes, the arrival of primordial germ cells in the area of future gonads signals the existing cells of the mesonephros and adjacent coelomic epithelium to proliferate and form a pair of genital ridges medial to the developing mesonephros. In the 6th week, the cells of the genital ridge invade the mesenchyme in the region of future gonads to form the primitive sex cords, which will support the development of germ cells. Under the influence of the SRY (Sex-determining Region of the Y chromosome), cells in the primitive sex cords of males begin to differentiate into Sertoli cells around the 7th week. During the 9th and 10th weeks, Leydig cells differentiate from mesenchymal cells of the genital ridge also in response to SRY. Leydig cells will produce testosterone and Insulin-like 3 ($INSL_3$), thought to be the key hormones required for testicular descent.

Swelling of the gubernaculum is critical in the enlargement of the inguinal canal, allowing testicular passage. The gubernaculum is unattached distally during and following transinguinal passage of the testis, and then it gradually settles into the scrotum, which has formed from the labioscrotal folds. Most testes have situated into a scrotal position after week 27. Studies in rodent models have shown that gubernacular development and testicular descent are most likely driven by $INSL_3$ and androgen signaling pathways. Similar studies have also provided evidence that the genitofemoral nerve may play a role in guiding testicular descent via stimulating development of the gubernaculum (Box 178.1).

CLINICAL PRESENTATION

The definition of an undescended testis is the absence of one or both testes in a normal scrotal position. Most cases are unilateral (60% to 70%). Cryptorchid testes are distinguished by whether they are palpable (75% to 80%) or nonpalpable (20% to 25%) on examination. The patient should be examined in a supine and the inguinal canal compressed manually from the anterior superior iliac spine toward the scrotum, allowing the testis to be palpated by the examiner's opposite hand. If the testis can be brought into the scrotum, it should be released to determine whether it remains in a scrotal position. If not, then this suggests an ectopic or incompletely descended testis. A retractile testis can be manually positioned into the scrotum and will remain there upon release, at least for a few seconds. A palpable undescended testis may lie anywhere within the inguinal canal toward the scrotum along the line of normal descent, or may be found in an ectopic location, such as the superficial inguinal pouch or in a perirenal, femoral, penile, perineal, or contralateral scrotal position.

Box 178.1 Five Major Phases of Testicular Descent in the Human Male

Phase 1: The caudal mesonephros contacts the gubernaculum at the internal inguinal ring (5 weeks).

Phase 2: The genitofemoral nerve becomes associated with the gubernaculum and processus vaginalis (7 weeks). The gubernaculum continues to grow while the processus vaginalis deepens. The cremaster fibers extend into the gubernaculum (8 to 10 weeks gestation).

Phase 3: The testis grows while the müllerian ducts and mesonephros regress (10 to 12 weeks). The testis contacts the gubernaculum, which begins its swelling phase (12 to 14 weeks).

Phase 4: Gubernaculum swelling, development of the cremaster muscle, and migration of the processus vaginalis widen the inguinal canal (14 to 20 weeks).

Phase 5: The subcutaneous attachment of the gubernaculum releases, and the testis begins its passage through the inguinal canal (20 to 28 weeks). Up until the time of birth, the gubernaculum continues to regress while the testis descends caudally into the scrotum (7th month and beyond).

Testes may be nonpalpable due to an intra-abdominal location (25% to 50%); atrophy of the testis before birth, otherwise known as a “vanishing” testis (15% to 40%); or in an extra-abdominal location but difficult to palpate due to obesity, lack of patient cooperation on examination, or small testicular size (10% to 30%). Ultrasonography has proven unreliable in determining testis position, and MRI requires sedation in younger children and is rarely necessary in managing undescended testes. Examination under anesthesia followed by diagnostic laparoscopy for nonpalpable undescended testes is the gold standard according to the American Urological Association Guidelines on Cryptorchidism.

INDICATIONS AND PREOPERATIVE PLANNING

If a patient has a testis that has not descended by 6 months (corrected for gestational age), he should undergo surgical correction by a specialist within the next year. Medical treatment with hormone therapy is not recommended given the lack of evidence for long-term efficacy. Orchiopexy before 18 months of age may maximize future fertility potential as histologic examination of cryptorchid testes has shown that testes that remain undescended are associated with progressive loss of germ cells.

Boys with a history of cryptorchidism are at increased risk of testicular germ cell tumor. The relative risk of malignant transformation in an undescended testis is 2.5 to 8 overall and 2 to 3 in boys undergoing prepubertal orchiopexy. Every attempt should be made to perform orchiopexy as soon as possible given that these data suggest the risk of malignancy increases with deferred orchiopexy. While the overall increased risk of testicular cancer is not eliminated by orchiopexy, bringing the testis into the scrotum facilitates testicular examination, the mainstay of testicular cancer screening.

Undescended testes may be more mobile within the tunical vaginalis, predisposing them to increased risk of testicular torsion. Approximately 70% or more boys with undescended testes will have a patent processus vaginalis (inguinal hernia) on the ipsilateral side, so the surgeon should mobilize and ligate the processus vaginalis to achieve herniorrhaphy. In adolescents or young adults with unilateral cryptorchidism who have not yet undergone orchiopexy, orchiectomy should be considered given the malignancy risk.

Informed consent for orchiopexy should consider the risks including

bleeding, infection, testis atrophy, possibility of a staged procedure, revision if the testis does not remain in a scrotal position, and injury to the vas deferens.

SURGICAL TECHNIQUE

Inguinal Orchiopexy

Inguinal orchiopexy is the standard treatment for undescended testes within or distal to the inguinal canal. After the induction of anesthesia, a scrotal examination should be performed to confirm the location of both testes. A caudal block may be given at this time. A transverse incision is then made approximately one third the distance between the pubic tubercle and anterior superior iliac spine (Fig. 178.1). Dissection is taken down to scarpa's fascia, taking care to avoid injury to an ectopic testis residing beneath it in the superficial inguinal pouch. Blunt dissection is used to expose the three key landmarks of the external oblique fascia, the shelving edge of the inguinal ligament, and the external ring. The external oblique fascia of the inguinal canal is opened sharply, avoiding injury to the ilioinguinal nerve (Fig. 178.2). The spermatic cord is identified within the canal and freed of the cremasteric and spermatic fascial attachments. The cord is further isolated distally to the testis and the gubernaculum is identified. After confirming its identity by visualizing an indentation of the skin of the point of maximal gubernacular fixation when tugging on it, the gubernaculum is transected with electrocautery (Fig. 178.3).

Figure 178.1. Inguinal incision above and lateral to the external inguinal ring one third of the distance from the pubic tubercle to the anterior superior iliac spine. Scrotal incision is made along Langer lines in the mid-scrotum.

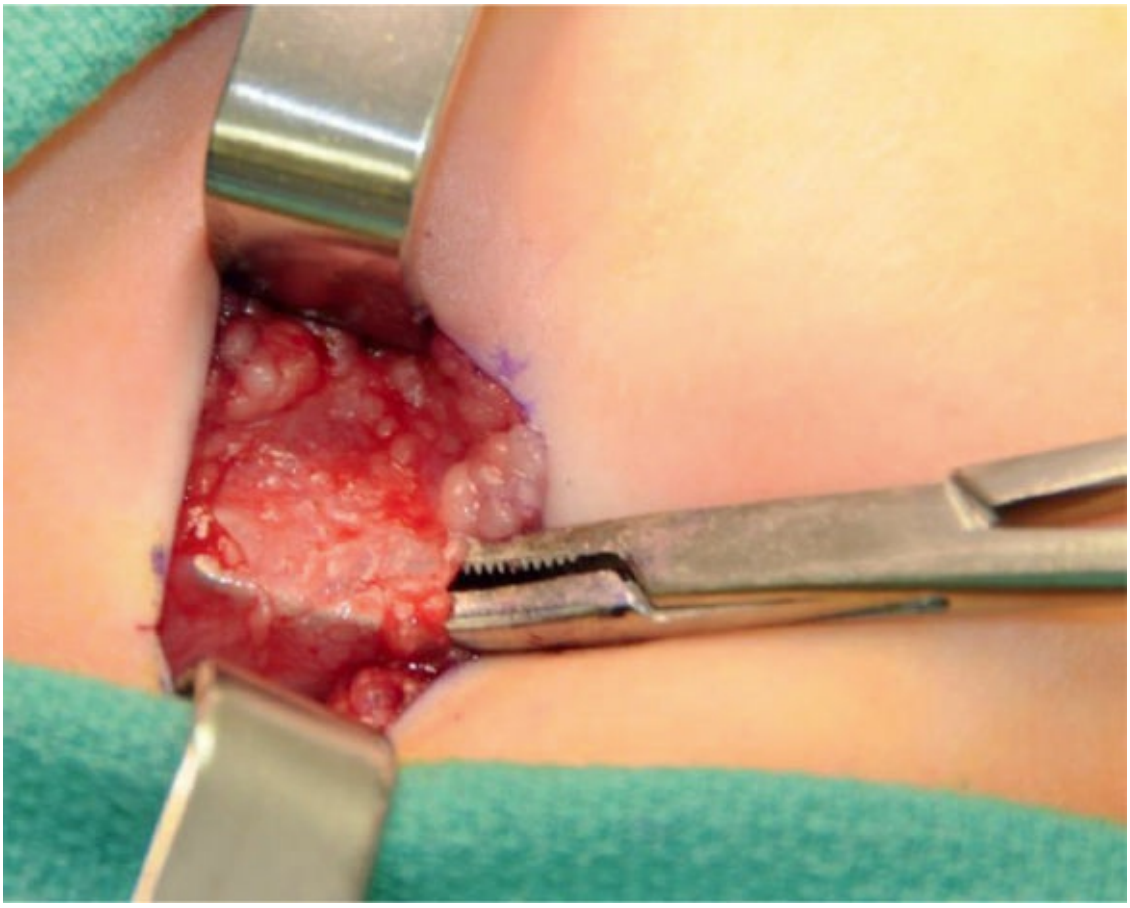

Figure 178.2. The external spermatic ring can be opened in a retrograde or antegrade fashion taking care to avoid injury to the spermatic cord, ilioinguinal nerve, and testis.

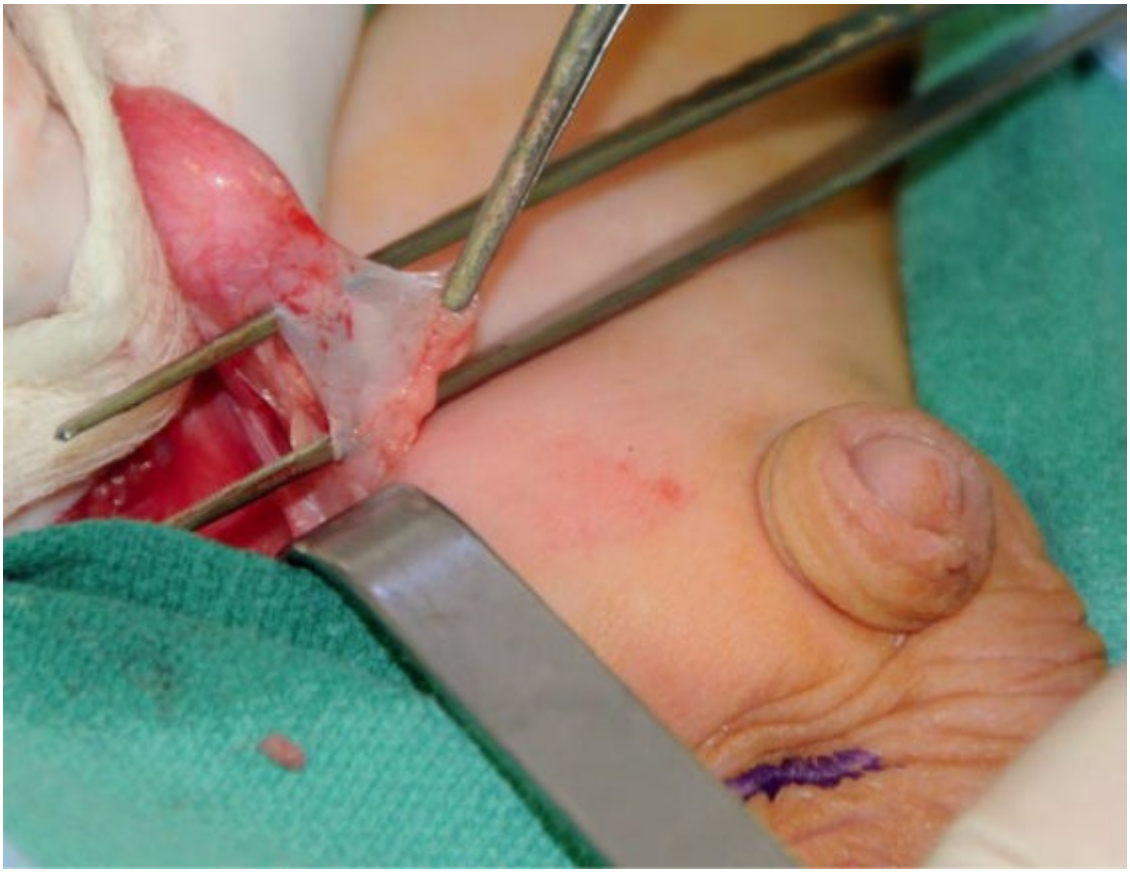

Figure 178.3. The thin white filmy gubernaculum is identified distal to the testis. The superior aspect of the scrotum can be seen tenting inward at the ectopic gubernacular attachment. Care is taken to identify a long looping vas and the ilioinguinal nerve to transection of the gubernaculum.

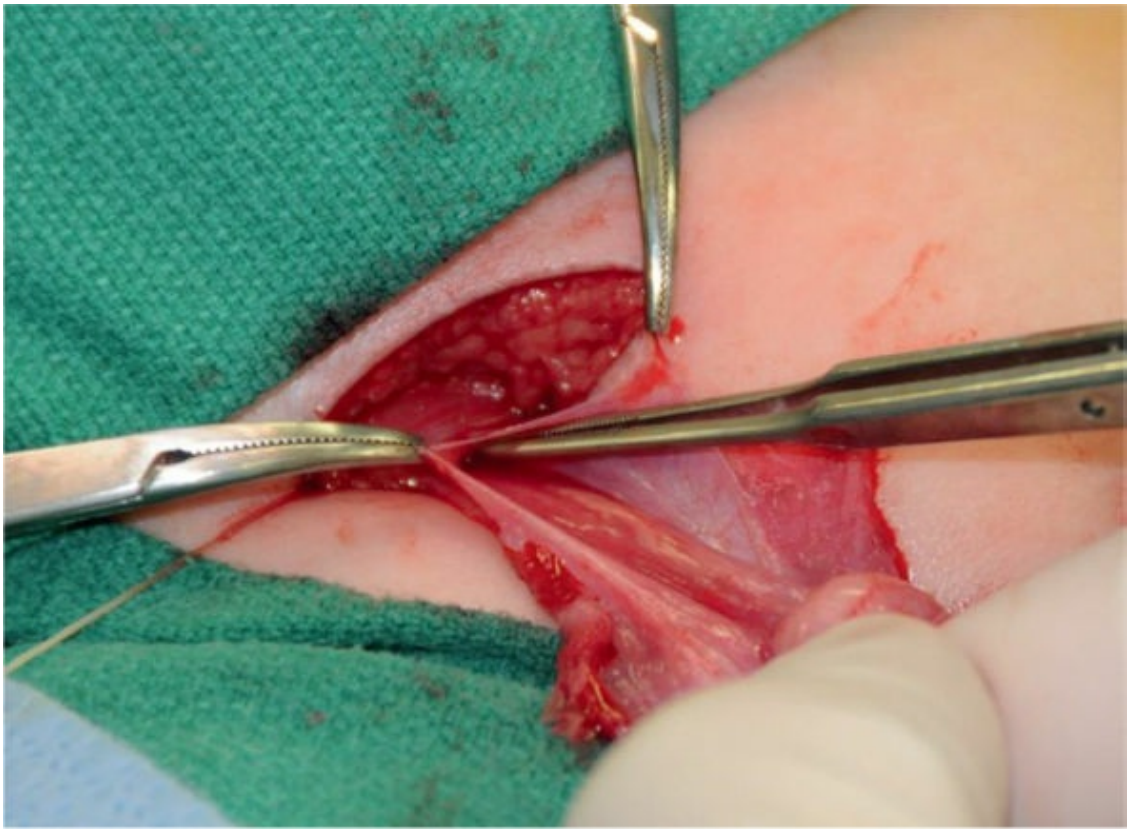

Figure 178.4. The patent processus vaginalis is identified. It may be mobilized away from the spermatic cord by opening the hernia sac and peeling it off the cord or peeling the sac intact off the cord, based on the surgeon's preference. In this example, it is opened.

Most undescended testes are associated with a patent processus vaginalis, so this hernia sac must be carefully freed from the spermatic cord and high ligated. It is helpful to remember that the sac usually forms a "C" or saddle configuration draping over the vas deferens and testicular vessels. The tunica vaginalis surrounding the testis is opened and testicular and epididymal appendages are transected. The tunica vaginalis is then examined to identify a patent processus vaginalis. Based on the patient's anatomy and surgeon's preference, herniorraphy may be performed either by keeping the sac intact while freeing it from the cord or by opening the sac to dissect it off the cord structures (Fig. 178.4). Using either method, the hernia sac is isolated from the spermatic cord to the level of the internal ring where the peritoneal reflection can be identified (Fig. 178.5). The patent processus is divided at this level and the proximal stump double ligated (Fig. 178.6).

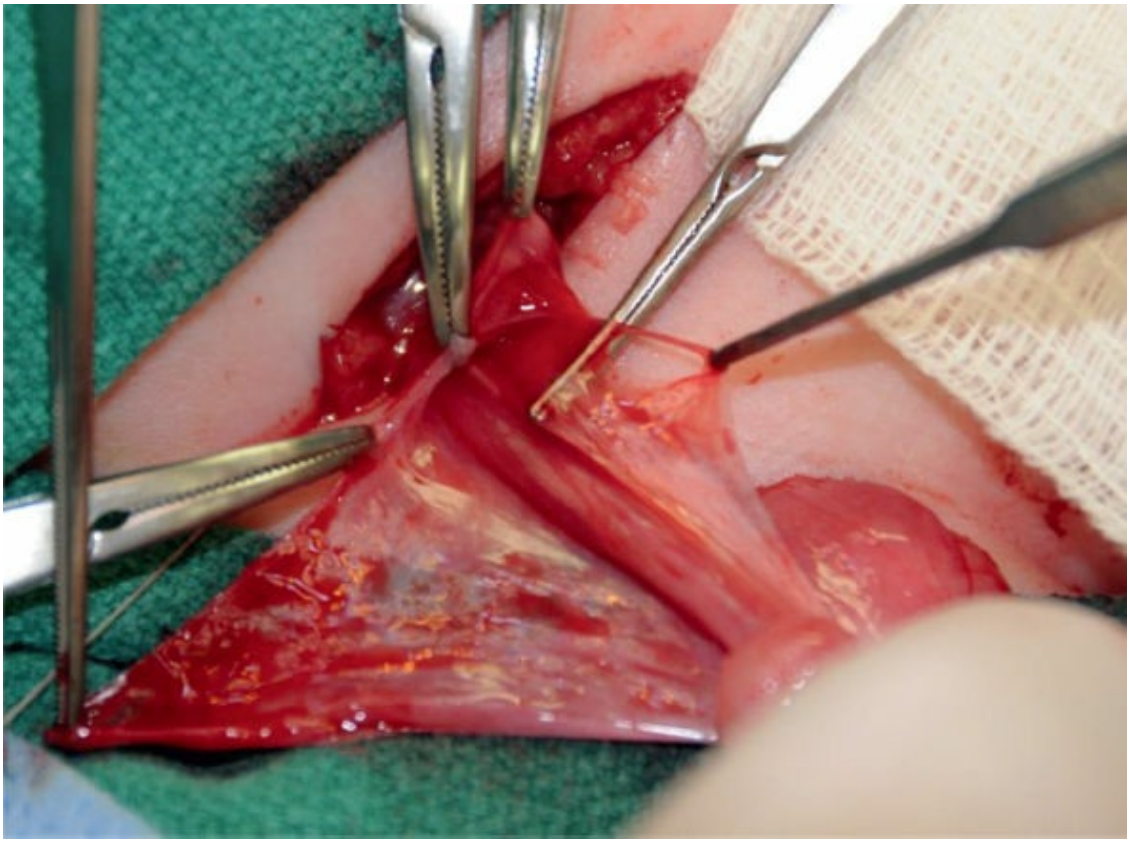

Figure 178.5. The processus vaginalis is carefully separated from the spermatic cord, making sure to mobilize the entire hernia sac while protecting the vas deferens and spermatic vessels.

Next, adequate length on the spermatic cord is established by freeing the cord from any remaining cremasteric fibers and the lateral spermatic fascia. On rare occasions, the above steps fail to achieve adequate length and additional procedures may be required. Prentiss et al. created a more medial pathway by passing the testis under the epigastric vessels. Hutcheson et al. suggested thorough dissection of the internal spermatic fascia from the cord will usually gain necessary length, but the inguinal canal may be further opened to expose the retropeitoneum and the vas deferens and testicular vessels can be freed from the endoabdomial fascia up to their origins. If further length is necessary, the testicular artery can be ligated for a one- or two-stage Fowler–Stephens procedure.

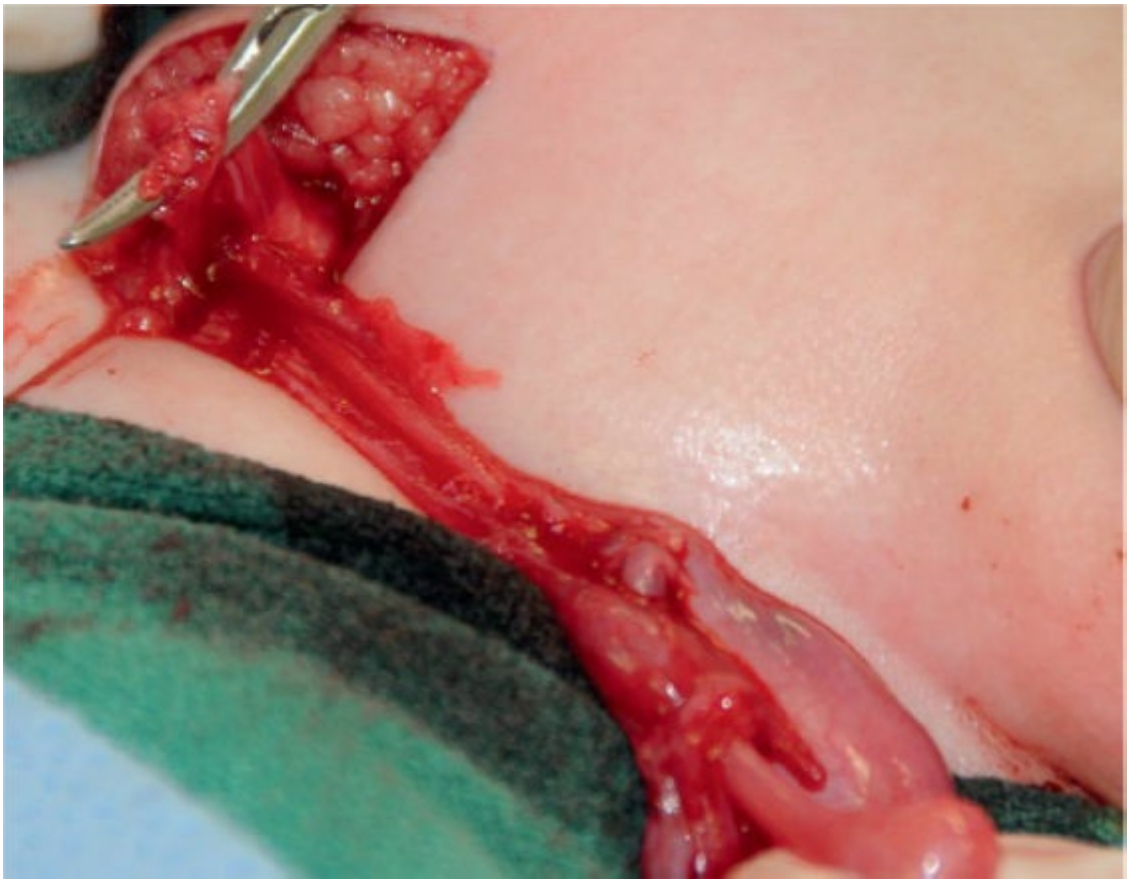

Figure 178.6. The processus vaginalis is mobilized off the cord up to the internal spermatic ring and the peritoneal reflection. It is then suture ligated and allowed to fall back into the retroperitoneal space.

Figure 178.7. The testis is brought down to the scrotum along the path of usual descent, making sure to not cause any iatrogenic twisting of the spermatic vessels. A scrotal pouch is created and the testis secured within it.

Finally, a scrotal pouch is created by passing a finger along the path of testicular descent down into the ipsilateral hemiscrotum where a small incision is made along Langer lines and a subcutaneous pouch is created. The dartos is then opened over a finger, and stay sutures are placed in the dartos aperture and deep in the most dependent portion of the scrotum to act as a pseudo-gubernaculum. A clamp is then passed up from the scrotal incision into the inguinal region over the finger. The testis is grasped by the tunica vaginalis after confirming the correct orientation of the spermatic cord and is brought out through the scrotal incision (Fig. 178.7). The position of the testis and cord is checked again to confirm there is no iatrogenic torsion. The stay sutures are then passed through the paratesticular aspects of the tunica vaginalis of the testis and tied. The testis is dunked into its pouch, and the scrotum is closed with interrupted

buried sutures. Prior to closing the external oblique fascia, a long acting local anethestic can be injected around the ilioinguinal nerve and under the skin if no caudal block was placed. The external oblique fascia is then closed with interrupted sutures taking care not to injure the ilioinguinal nerve or to strangulate the spermatic cord. Scarpa's fascia is reapproximated, and the skin is closed with a running subcuticular suture and skin glue is applied to both the inguinal and scrotal incisions.

Scrotal Orchiopexy

Orchiopexy performed through a single scrotal incision, initially described by Bianchi and Squire, has gained popularity in recent years for its cosmetic appearance, short operative time, and minimal postoperative pain. However, appropriate patient selection is imperative for success.

Once general anesthesia is induced, an examination is performed to determine if the affected testis can be manipulated down into the superior scrotum. If it reaches, an attempt can be made to proceed with a scrotal orchiopexy. Otherwise, inguinal orchiopexy should be performed. The incision is made along the crease between the hemiscrotum and inguinal skin (superior lateral border of the ispilateral hemiscrotum), although an incision along the median raphe has also been described. The testis is grasped and mobilized until it can be brought through the incision. The gubernaculum is usually then transected, although it has been argued that this step is not necessary. The spermatic cord is then mobilized up to the external ring by dividing the attached cremasteric fibers. The use of a Deavor or similar retractor can be helpful at this point for visualization. The processus vaginalis is isolated from the spermatic cord. If it is noted to contain fluid or can be cannulated, this usually implies that it remains patent. It is ligated high in the inguinal canal, similar to the traditional inguinal approach. The remaining lateral spermatic fascial attachments are transected. At this point, the testis should be evaluated for any residual tension. If any tension remains, the external ring and canal may be opened to facilitate further dissection. However, if this still does not gain adequate length, a traditional inguinal incision should be made and inguinal orchiopexy performed. If the testis does reach and remains in the dependent scrotum, it can then be secured in a scrotal pouch and the incision.

Laparoscopic Diagnosis

Laparoscopic evaluation has become the standard approach to a nonpalpable testis, allowing for the identification of an abdominal testis, proof of absence, or facilitation of treatment.

The anesthetized patient should be fully relaxed, and an orogastric tube may empty the stomach. The bladder is drained. A small periumbilical incision is made and the camera port is inserted using the Hasson technique or Veress needle. The abdomen is inflated with care to avoid over-inflation. The camera is then inserted and the abdomen inspected for any entry injury. If needed, the patient may be placed in Trendelenburg position to allow the bowel to fall away from the pelvis. First, the unaffected side is examined to confirm that both the vas deferens and testicular vessels pass through a closed internal ring. The affected side is then examined. The testis usually lies anywhere along its path of embryologic descent between the ipsilateral kidney and inguinal canal. It is imperative to identify the testicular vessels, which may be normal caliber if associated with a testis or atretic if associated with an absent or atrophied testis. However, the vas deferens in rare cases may not unite with the testis, and therefore identification of a blind-ending vas deferens alone is not diagnostic of testicular atresia. Alternatively, the vas deferens may enter the inguinal canal, turn, and exit the canal to meet an abdominal testis in the case of a long-looping vas. The surgeon needs to be cognizant of this possibility during dissection to avoid injury to the vas and its collaterals. If, however, no testicular vessels are identified, the rare circumstance of an ectopic testis and the possibility of an absent kidney should be considered. Ultimately the spermatic vessels are the key to diagnosis: proof of an absent testis are blind-ending spermatic vessels.

Laparoscopic Orchiopexy

Management is based on laparoscopic findings. If testicular vessels and vas deferens enter the inguinal ring, groin exploration is performed and standard orchiopexy is performed if a satisfactory testis is found. If blind-ending vessels are identified, the authors recommend scrotal orchiopexy of the contralateral testis to decrease the risk of torsion in the solitary testis, a catastrophic event. However, because of the very low but nonetheless real potential of injury of the testis during orchiopexy, this is controversial and should be discussed with the parents. In the case of an intra-abdominal testicular nubbin, the authors recommend removal to prevent the risk of malignant transformation, although others argue it can be safely left due to

the low incidence of this.

If a satisfactory intra-abdominal testis is found, it may be brought down into the scrotum in a single or stage procedure depending on the length of the testicular vessels. A 3-mm port is placed in each side of the lower abdomen. In the case of a one-stage laparoscopic procedure, the entire length of the vas deferens is identified so that a long-looping vas is not missed. The gubernaculum is circumferentially dissected and transected using electrocautery. Remaining attachments are used as a handle for manipulating the testis. The peritoneum is incised lateral to the testicular vessels and caudal to the vas deferens. The peritoneum may be carefully freed from the underlying vessels to gain further length, ensuring to preserve a triangle of intact peritoneum distally between the vessels and vas due to the collateral vessels in this area. The cord and testis are also freed from any attachments dorsally. At this point, the surgeon must determine if the testis can be brought down into the scrotum in one or two phases. The gubernaculum is grasped and the testis brought across the midline to the contralateral external ring and inguinal canal. If it reaches this far, it will likely reach the ipsilateral scrotum in one step. An incision is made in the ipsilateral scrotum and a subcutaneous pouch is bluntly developed. A laparoscopic grasper is then advanced from the ipsilateral working port either through the inguinal canal provided adequate spermatic cord length or a new path is created medial to the epigastric vessels (laparoscopic Prentiss maneuver). The grasper is brought out of the scrotal incision and a 3- or 5-mm trocar is backloaded over this. A laparoscopic grasper is then inserted through this scrotal trocar and follows the initial grasper into the abdomen. The testis is then grasped by the gubernacular remnant and pulled out of the scrotum. The cord is inspected laparoscopically and the orientation of the testis is also checked to ensure there is no torsion. The testis is then fixed in the dartos pouch and the scrotal skin closed. After checking for hemostasis, the abdomen is deflated, trocars removed, and fascia and skin closed.

If the testis does not reach into the scrotum, further careful mobilization may be performed or a Fowler–Stephens procedure can be performed. The testicular artery is clipped or suture ligated. In a one-step Fowler–Stephens procedure, the spermatic vessels are occluded for 5 minutes. If the testis seems to remain viable based on the visual appearance, the vessels may then be ligated and transected and the testicle brought down into the scrotum. In the two-step procedure, the spermatic vessels are clipped and

the procedure is terminated. Six months later, after collateral blood supply is better established, the procedure is completed by transecting the testicular artery proximal to the area of ligation, freeing the testicle further from its attachments, and bringing it into the scrotum as described above.

Postoperative Care

Orchiopexy is usually performed as an outpatient procedure unless there are significant comorbidities. Pain is controlled with weight-dosed narcotic pain medication, tylenol, and/or motrin. Caregivers are counseled that the child should avoid any straddle activities such as bike riding for a few weeks, although car seats are safe. Patients are usually seen in 1 to 2 months to ensure adequate recovery and good testicular position. Often patients then follow up again in approximately 1 year to ensure the testis remains orthotopic. Patients return again prior to puberty for counseling on testicular self-exams due to their increased risk of testicular malignancy.

COMPLICATIONS

Complications such as bleeding or scrotal hematoma, hydrocele, or local wound infection are rare, but can usually be managed conservatively unless there is concern for active bleeding or if the hydrocele is large. Division of the vas deferens can be managed with immediate microsurgical repair or delayed repair performed after puberty. Testicular ascent is managed by reoperative orchiopexy.

OUTCOMES

The success of orchiopexy, defined as a normal sized testis in the dependant scrotal position, varies by initial location of the testes and the procedure performed. The lower the testis, the higher the success. Inguinal orchiopexy has a reported 89% to 99% success rate, one-stage Fowler–Stephens orchiopexy has a 63% to 67% success rate, and two-stage Fowler–Stephens orchiopexy has a 67% to 89% success rate.

All patients with cryptorchidism are at increased risk for subfertility, but subfertility is more likely (up to 55%) with bilateral cryptorchidism. Nonetheless, orchiopexy decreases the risk. Later malignancy is possible for both the cryptorchid and the contralateral descended testes in these patients, although the relative risk is substantially less if orchiopexy is performed prior to puberty versus after puberty (2.23 vs. 5.4).

EDITOR'S COMMENT

As the authors note, the undescended testicle is one of the most common genitourinary anomalies encountered by the pediatric, general, or urologic surgeon. With a better understanding of the physiologic consequences of delayed repair—increased risk for infertility and malignancy—treatment guidelines established by national societies have recommended evaluation by 6 months of age and definitive repair by 18 months (Kolon TF, Herndon, A, Baker LA, et al. Evaluation and treatment of cryptochidism: AUA guideline. *Journal of Urology* 2014;192(2):337–45). Unfortunately, adherence to these guidelines remains inconsistent (Kokorowski PJ, Routh JC, Graham DA, et al. Variations in timing of surgery among boys who underwent orchidopexy for cryptorchidism. *Pediatrics* 2010;126(3):e576–82) and as a result many infants are referred late.

The authors present an excellent summary of how they perform an orchiopexy. One additional step we use to gain additional length on the vas and the blood vessels is blunt dissection of the peritoneum off these retroperitoneal structures. The blunt dissection can be achieved by elevating the hernia sac superiorly with the cord structures on gentle tension inferiorly creating a space into which a corner of a moist unfolded Raytec gauze sponge can be inserted and with gentle packing, bluntly free the peritoneal attachments from the cord structures. We have found that this dissection can result in up to a half centimeter of length allowing the testicle to reach further the scrotum. As the authors note, transposition of the structures under the epigastric vessels is an additional step that can be helpful in patients with a short cord but repair of the inguinal floor will then become necessary.

As the authors nicely describe, laparoscopy for undescended testicle is an integral part of the diagnostic and treatment regimen. If the testicle cannot be palpated in the inguinal canal, laparoscopy is warranted to determine the testicle's location. In some patients no testicle is found and it is presumed that in utero torsion occurred. These patients once they have completed puberty should for cosmetic purposes have a prosthetic testicle placed in the scrotum. When the testicle is found within the abdomen, the key is to determine whether the testicle can be delivered to the scrotum. If using a laparoscopic grasper, the testicle can be delivered through the deep ring into the inguinal canal such that it is palpable, it is likely that a standard orchiopexy can be performed. If this cannot be achieved, we proceed with a Fowler–Stephens two-stage procedure. Of note, one additional approach for an intra-abdominal testicle is testicular autotransplantation. This procedure is done in conjunction with plastic surgeons where the artery and vein of the testicle is carefully dissected from within the retroperitoneum such that adequate length is obtained. The testicle is completely freed and placed in a subdartos pocket with the vessels extending up the inguinal canal where they are then anastomosed to inferior epigastric artery and vein using microsurgery (Bukowski TP, Wacksman J, Billmire DA, et al. Testicular autotransplantation: A 17 year review of an effective approach to the management of the intra-abdominal Testis. *Journal of Urology* 1995;154(2):558–61).

179 Surgical Management of Wilms Tumor

Gwen M. Grimsby and Michael L. Ritchey

ETIOLOGY AND PATHOPHYSIOLOGY

Wilms tumor, or nephroblastoma, is an embryonal tumor that develops from remnants of immature kidney. It is the most common renal tumor of childhood constituting approximately 6.3% of all cancers and 95% of all renal cancers in children under the age of 15 in the United States. The average annual age-adjusted incidence is 8.0 per million or approximately 500 new cases in the United States per year. The incidence is highest among children under 2 years of age, in females, and African Americans. Although greater than 80% of cases are diagnosed before 5 years of age, with a median age of 3.5 years, older children and occasionally even adults can be affected. Synchronous bilateral Wilms tumor occurs in 4% to 6% of cases and these patients are diagnosed at a younger age.

Approximately 10% of children with Wilms tumor have a congenital anomaly or an associated overgrowth or nonovergrowth syndrome. Familial cases account for 1% to 12% of Wilms tumor. The overgrowth syndrome Beckwith–Wiedemann (BWS) is characterized by macroglossia, visceromegaly, and an omphalocele. Other overgrowth syndromes include Simpson–Golabi–Behmel syndrome, Perlman syndrome (macrocephaly, macrosomia, visceromegaly, dysmorphic facial features), and Sotos syndrome (cerebral gigantism). Nonovergrowth syndromes include isolated aniridia, trisomy 18, WAGR syndrome (Wilms tumor, aniridia, genitourinary malformations, mental retardation), Bloom syndrome (short stature, micrognathism, café-au-lait spots), and Denys–Drash syndrome (male pseudohermaphroditism, mesangial renal sclerosis). Isolated genitourinary anomalies found in children with Wilms tumor include hypospadias, cryptorchidism, and renal fusion.

Screening with serial renal ultrasounds has been recommended in children at high risk for development of Wilms tumor. Review of most studies suggests 3 to 4 months is the appropriate screening interval.

Tumors detected by screening will generally be a lower stage. Early detection can provide an opportunity for nephron sparing surgery, since these children are at an increased risk for bilateral disease. It is recommended that screening be performed when a condition has a Wilms tumor incidence of greater than 5%. Ultrasound surveillance should continue to 7 years of age in patients with BWS, Simpson–Golabi–Behmel, hemihypertrophy, and familial Wilms. Screening has also been recommended in children in infants under 12 months of age found to have nephrogenic rests (NRs) in the resected kidney.

NRs are foci of primitive metanephric tissue that are found in 1% of postmortem infant kidneys. Because NRs are found in up to 44% of kidneys removed for Wilms tumor and nearly 100% of patients with bilateral Wilms tumors, these tissues are thought to represent precursor lesions in children genetically predisposed to Wilms tumor. NRs are categorized as either perilobar or intralobar based on their anatomical location within the kidney. Perilobar NRs are observed in kidneys harboring Wilms tumors with WT2 deletions, whereas intralobar NRs are more often observed in those with WT1-associated tumors. The presence of multiple NRs in the nontumoral portion of a Wilms tumor kidney has been shown to be a risk factor for development of metachronous tumor in the contralateral kidney.

A number of genes have been identified that play a role in the development of Wilms tumor (Table 179.1). The *WT1* gene is located on chromosome 11p13 and encodes a zinc-finger transcriptional factor that serves both tumor-suppressive and developmental regulatory functions. The incidence of WT1 mutations in patients with nonsyndromal Wilms tumor is 2%. Mutations in the *WT2* gene, located at the chromosome 11p15 locus, have also been associated with Wilms tumor and loss of heterozygosity (LOH) at this locus is associated with BWS. Aniridia, found in 1.1% of Wilms tumor patients, is caused by an abnormality of the *PAX6* gene located adjacent to the *WT1* gene. Another tumor suppressor gene, *WTX*, is targeted by somatic mutations in up to 30% of cases of Wilms tumor. Finally, LOH at chromosome 16q or 1p occurs in up to 20% of Wilms tumors and has been shown to be associated with an increased risk for tumor relapse and mortality. More recently, 1q gain has been identified in up to 30% of Wilms tumors and has been associated with decreased event-free survival (EFS).

TABLE 179.1 Syndromes and Genes Associated With Wilms Tumor

Syndrome	Genes	Locus	Wilms Tumor Risk
WAGR	WT1	11p13	50%
Denys-Drash	WT1	11p13	50%
Frasier	WT1	11p13	5–10%
Beckwith—Wiedemann	WT2	IGF2, H19, p57, Klp2	5–10%
Familial Wilms tumor	FWT1	17q21	30%
	FWT2	19q13	
Perlman	Unknown		>20%
Mosaic variegated aneuploidy	BUB1B	15q15	>20%
Fanconi anemia D1	BRCA2	13q12.3	>20%
Simpson-Golabi-Behmel	GPC3	Xq26	10% (in males)
Li-Fraumeni	p53	17p13	Low
Neurofibromatosis	NF1	17q11	Low
Sotos	NSD1	5q35	Low
Trisomy 18	Unknown	18	Low
Bloom	BLM	15q26	Low

Wilms tumor usually compresses the adjacent normal renal parenchyma to form a pseudocapsule composed of compacted, atrophic renal tissues which can be helpful to distinguish Wilms tumor from NRs and other renal tumors. Most Wilms tumors are unicentric, but 12% are multicentric unilateral tumors. Extrarenal Wilms tumor arising in the retroperitoneum and elsewhere are rare and are thought to arise from displaced metanephric elements or mesonephric remnants. Histologically, “classic” Wilms tumor is characterized by islands of compact undifferentiated blastema and epithelial differentiation in the form of embryonic tubules, rosettes, and glomeruloid structures separated by a significant stromal component. The unfavorable histologic feature of anaplasia is associated with resistance to chemotherapy and has been demonstrated to carry a poor prognosis even when the tumor is confined to the kidney.

CLINICAL PRESENTATION

More than 90% of children with Wilms tumor are diagnosed when an asymptomatic abdominal mass is discovered incidentally by a family member or physician. The mass is usually quite large relative to the size of the child and is not necessarily confined to one side of the abdomen. Approximately 20% of children have hematuria at diagnosis and in these patients it is important to rule out invasion of tumor into the collecting system. Hypertension will be present in 25% of children and may be

secondary to elevated plasma renin levels. Other symptoms may include fever, anorexia, and weight loss in 10% of patients. Rarely children may present with acute abdominal pain from tumor rupture into the peritoneal cavity or bleeding within the tumor.

A firm, palpable mass is usually evident on physical examination. A persistent varicocele in the supine position or hepatomegaly may be reflective of inferior vena caval (IVC) obstruction from tumor thrombus. Atrial thrombus can result in hypertension or congestive heart failure. During the physical examination, it is also important to assess for signs of associated Wilms tumor syndromes such as aniridia, hemihypertrophy, and other genitourinary anomalies.

PREOPERATIVE PLANNING

Emergent operation is not necessary unless there is evidence of active bleeding or tumor rupture. Thus, a thorough preoperative work up with appropriate laboratory and imaging studies is recommended before proceeding with surgical resection. An abdominal ultrasound can differentiate between solid and cystic masses and Doppler ultrasonography of the renal vein and IVC can evaluate for the presence of tumor thrombus. All patients should undergo either CT of the abdomen and pelvis with oral and intravenous contrast or MRI of the abdomen and pelvis with gadolinium. These imaging modalities allow for improved preoperative planning by evaluating for extrarenal spread of disease, the relationship of the tumor to adjacent visceral structures, and the presence of synchronous tumors in the contralateral kidney. Preoperative chest CT with or without contrast is performed to rule out pulmonary disease as the lung is the most common location of distant metastasis. Positron emission tomography (PET) has not been shown to have any advantages over conventional imaging modalities in preoperative assessment of Wilms tumor and is not routinely recommended.

It is important to remember that a precise histologic diagnosis cannot be obtained on preoperative imaging studies and all solid renal tumors of childhood have some common radiographic features including renal cell carcinoma. In the SIOP-9 study, 5.4% of patients who underwent preoperative chemotherapy for Wilms tumor prior to diagnostic biopsy were found to have renal malignancies other than Wilms tumor or a benign renal condition upon nephrectomy.

Preoperative laboratory evaluation should include a complete blood

count, liver enzymes, and serum electrolytes, including blood urea nitrogen, creatinine, and calcium. Acquired von Willebrand disease has been noted in 8% of newly diagnosed patients with Wilms tumor and thus prothrombin time and partial thromboplastin time should be obtained. Patients with prolonged coagulation studies can have this defect corrected preoperatively with the administration of 1-desamino-8-D-arginine-vasopressin (DDAVP).

TREATMENT

Tumor histology and stage have long been recognized as the most important determinants of prognosis in patients with Wilms tumor. Favorable histology tumors have a better prognosis. As noted above, tumors with unfavorable features such as anaplasia, portends a much poorer prognosis. Not all Wilms tumors have a triphasic pattern, but present only biphasic or even monomorphous patterns. Wilms tumors with predominantly epithelial differentiation have a low degree of aggressiveness and the majority are stage I tumors. However, these tumors may be more resistant to therapy if they present as advanced stage disease.

Primary radical nephrectomy is recommended for the majority of children with unilateral Wilms tumor diagnosed in North America. However, many children worldwide are treated with preoperative chemotherapy usually according to protocols developed by the International Society of Pediatric Oncology (SIOP). The relative proportions of histologic subtypes of Wilms tumor differ following preoperative chemotherapy when compared to those reported following primary surgical resection. Stromal and epithelial predominant tumors are found more often after chemotherapy. These histologic subtypes may demonstrate a poor clinical response to therapy but have an excellent prognosis if the tumor is completely excised. The proportion of blastemal predominant tumors is decreased after chemotherapy, indicating some response of this tumor type to the preoperative chemotherapy. However, patients with blastemal predominant tumors after chemotherapy have a high rate of relapse. Tumor progression during therapy occurred in 5% of patients enrolled in SIOP 93–01. These patients were documented to have decreased overall survival. The SIOP group uses the response of the tumor to chemotherapy to stratify patients for treatment.

Staging of Wilms tumor is based on various intraoperative and pathologic findings. The COG staging system is listed in Table 179.2.

Accurate staging of disease allows treatment results to be evaluated and enables universal comparisons of outcomes. Examination for extension through the capsule, residual disease, vascular involvement and lymph node involvement are essential to properly assess the extent of the tumor at presentation. Tumor invasion of the renal sinus is the first sign of spread outside the kidney in stage II tumors. Penetration through the renal capsule is the next most common finding of extrarenal spread. Any tumor spill results in a stage III designation and is associated with an increased risk for local tumor recurrence. It is important to remember that the surgeon has responsibility for complete tumor removal and avoidance of tumor spill. For NWTS-5, the distribution by stage for patients with favorable histology tumors was stage I, 24.9%; stage II, 29.9%; stage III, 30.6%; and stage IV, 14.5%.

TABLE 179.2 Children's Oncology Group Staging System

Stage	Characteristics
I (45%)	The tumor is limited to the kidney and completely excised. The renal capsule is intact and the tumor was not ruptured prior to removal. There is no residual tumor. The vessels of the renal sinus are not involved.
II (20%)	The tumor extends beyond the kidney, but is completely excised. There is regional extension of the tumor (i.e., penetration of the renal capsule, extensive invasion of the renal sinus). Extrarenal vessels may contain tumor thrombus or be infiltrated by tumor. Lymph nodes do not contain cancer.
III (20%)	Residual nonhematogenous tumor confined to the abdomen: lymph node involvement, tumor spillage either before or during surgery, peritoneal implants, tumor beyond surgical margin either grossly or microscopically, or tumor not completely removed.
IV (10%)	Hematogenous metastases (lung, liver, bone, brain, etc.) or lymph node metastases outside the abdominopelvic region are present.
V (5%)	Bilateral renal involvement at diagnosis

For decades, tumor histology and stage were used to guide adjuvant therapies after surgery. All clinical trials for children with Wilms tumor strive to tailor treatment to individual risks for tumor recurrence and reduce the overall morbidity of treatment and reduce treatment related side effects. Recent clinical trials have also incorporated biologic markers (LOH 1p and 16q) into risk stratification. Future trials may also include other markers, for example, gain of 1q. Treatment recommendations for the most recent COG studies are listed in Table 179.3.

The first generation of COG studies (2006 to 2013) grouped patients by risk for recurrence (very low, low, standard, and high). Children with stage I or II FHWT and LOH of 1p and 16q were treated with vincristine (VCR), dactinomycin (AMD), and doxorubicin (DOX) without radiotherapy. Patients with stage III FHWT disease without LOH of 1p and 16q were treated with VCR, AMD, and DOX and irradiation of the flank or abdomen. A response-based approach was explored for management of children with pulmonary metastases. Those with resolution of the pulmonary lesions on chest CT after 6 weeks of chemotherapy were continued on treatment with VCR, AMD, and DOX. Patients who did not have resolution of the pulmonary lesions by week 6 received more intensive chemotherapy and pulmonary irradiation. Children with stage I to III focal anaplastic histology Wilms tumor (AHWT) and stage I diffuse AHWT were treated with AMD, VCR, DOX, and abdominal irradiation. Children less than 2 years of age with stage I FH tumors weighing less than 550 g were defined as very low risk Wilms tumors (VLRWT). These children do not receive chemotherapy after nephrectomy.

TABLE 179.3 Recommended Therapy on Children's Oncology Group Protocols

Stage/Histology	Risk Group	Radiotherapy	Chemotherapy
Stage I FHWT <2 yr, <550 g	Very low	None	None
Stage 1 FHWT, >2 yr or >550g	Low	None	Regimen EE-4A
Stage II FHWT	Low	None	Regimen EE-4A
Stage I or II FHWT and LOH 1p, 16q	Standard	None	Regimen DD-4A
Stage III FHWT, no LOH 1p, 16q	Standard	Yes	Regimen DD-4A
Stage I–III focal AHWT	High	Yes	Regimen DD-4A
Stage I diffuse AHWT	High	Yes	Regimen DD-4A
Stage III or IV FHWT and LOH 1p, 16q	High	Yes	Regimen M
Stage IV FHWT pulmonary metastases			
Lesions resected at diagnosis	High	Yes	Regimen DD-4A
Lesions resolve after 6 weeks chemo	Standard	None	Regimen DD-4A
Lesions persist after 6 weeks chemo	High	Yes	Regimen M
Stage IV FHWT nonpulmonary metastases	High	Yes	Regimen M
Stage II or III diffuse AHWT	High	Yes	Regimen UH-1
Stage IV diffuse AHWT (no measurable disease)	High	Yes	Regimen UH-1
Stage IV focal AHWT	High	Yes	Regimen UH-1
Stage I CCSK	High	None	Regimen I
Stage II or III CCSK	High	Yes	Regimen I
Stage IV CCSK	High	Yes	Regimen UH-1
Stage I–III MRT	High	Yes	Regimen UH-1
Stage IV MRT	High	Yes	Regimen UH-2
Stage IV AHWT (measurable disease)	High	Yes	Regimen UH-2
Stage V FHWT (disease ≤ stage II)	Bilateral	+/–	Regimen EE4A
Stage V FHWT (disease ≥ stage III)	Bilateral	+/–	Regimen DD4a
Stage V AHWT	Bilateral	+/–	Regimen I

Regimen EE-4A: Pulse-intensive AMD plus VCR (18 weeks)
Regimen DD-4A: Pulse-intensive AMD, VCR, and DOX (24 weeks)
Regimen M: VCR, AMD, DOX, alternating with CYCLO and ETOP (24 weeks)
Regimen UH-1: CYCLO, carboplatin, ETOP alternating with VCR, DOX, CYCLO (30 weeks)
Regimen I: VCR, DOX, CYCLO alternating with CYCLO, ETOP (24 weeks)
Regimen UH-2: VCR, DOX, CYCLO alternating with CYCLO, carboplatin, ETOP and VCR, irinotecan (30 weeks)

FHWT, favorable-histology Wilms tumor; LOH, loss of heterozygosity; AHWT, anaplastic-histology Wilms tumor; CCSK, clear cell sarcoma of the kidney; MRT, malignant rhabdoid tumor of the kidney; AMD, dactinomycin; VCR, vincristine; DOX, doxorubicin; CYCLO, cyclophosphamide; ETOP, etoposide.

Children with bilateral Wilms tumors should not undergo initial radical nephrectomy. These patients receive preoperative chemotherapy with the goal of shrinking the tumors and allowing more patients to be treated with renal sparing surgery. The goal is to preserve renal function and decrease the risk of renal failure which approaches 15% at 15 years posttreatment for patients with bilateral tumors. After 6 weeks of VCR, AMD, and DOX, tumor response is evaluated with computed tomography (CT) or magnetic resonance imaging (MRI). Tumors amenable to renal-sparing procedures can proceed with surgery and if there has not been a good response to chemotherapy, biopsy of the tumor(s) is recommended. Open biopsies are recommended because they are more accurate than percutaneous needle biopsies when assessing for anaplasia. Bilateral biopsies are also recommended as anaplasia can be discordant between the two kidneys. Failure to achieve a reduction in tumor volume may be due to tumor

differentiation. Additional chemotherapy is then given, but all patients should undergo surgical resection within 12 weeks of starting therapy.

The SIOP advocates preoperative chemotherapy for patients with Wilms tumor regardless of the extent of disease. The driving force behind this approach is that preoperative chemotherapy can produce dramatic reduction in the size of the primary tumor, thus facilitating surgical excision. SIOP trials have demonstrated that the incidence of tumor rupture is lower after preoperative chemotherapy. There is concern that patients who are staged by imaging studies alone are at risk for understaging. However, the SIOP group has used the response of the tumor to chemotherapy to guide treatment decisions. Overall survival is similar for similarly staged patients treated with COG and SIOP protocols.

COG studies primarily use preoperative chemotherapy for children with bilateral tumors, those with IVC tumor thrombus extending above the hepatic veins and inoperable tumors. The latter decision should not be based on preoperative imaging studies that may overestimate local tumor extension. If the tumor is found to be unresectable at surgery, it is considered stage III. Repeat imaging is performed after 6 weeks of chemotherapy. Experience in SIOP has shown that the majority of reduction in tumor volume occurs in the first 4 weeks of therapy. After there has been adequate shrinkage of the tumor, definitive resection can generally be completed. A clinically good response (by imaging) is usually associated with a pathologically good response in terms of regressive histologic changes. The converse is not always true. Stromal and epithelial predominant tumors are found more often after preoperative chemotherapy. These histologic subtypes may demonstrate a poor clinical response to therapy, but have an excellent prognosis if the tumor is completely excised. Patients with progressive disease during preoperative chemotherapy have a poor prognosis and these patients will require treatment with a more intensive chemotherapeutic regimen.

SURGICAL TECHNIQUE

The initial therapy for most children with Wilms tumor is radical nephrectomy and the surgeon is responsible for determining the extent of tumor. Accurate staging is essential for the subsequent determination of the need for adjuvant radiation and chemotherapy. The recommended surgical approach is through a transperitoneal, transabdominal incision which allows for inspection and exploration of the abdominal cavity. The

peritoneal cavity is inspected to assess for any evidence of tumor rupture of peritoneal implants. Formal exploration of the contralateral kidney is not recommended if preoperative CT or MRI does not demonstrate bilateral lesions. In the case of a contralateral solitary peripheral renal lesion less than 1 cm in diameter, the contralateral lesion can be completely excised at diagnosis followed by a unilateral radical nephrectomy. A margin of normal renal tissue should be removed with the lesion in case the lesion is a Wilms tumor rather than an NR.

The patient should be placed in a supine position with mild flexion of the lumbar spine to facilitate the exposure of retroperitoneal structures. The incision should be made approximately 2 fingerbreadths above the umbilicus beginning in the midaxillary line on the side of the tumor (Fig. 179.1). The incision can be extended across the midline depending on the size of the tumor and amount of exposure needed. The incision may also be extended into a thoracoabdominal approach by continuing through the bed of the 9th or 10th rib, if necessary. The muscle layers are sequentially divided and the peritoneal cavity entered and assessed for evidence of tumor rupture and peritoneal implants. An assessment of tumor extent should be performed by palpation of the IVC and inspection for regional lymphadenopathy, perinephric extension, and tumor mobility.

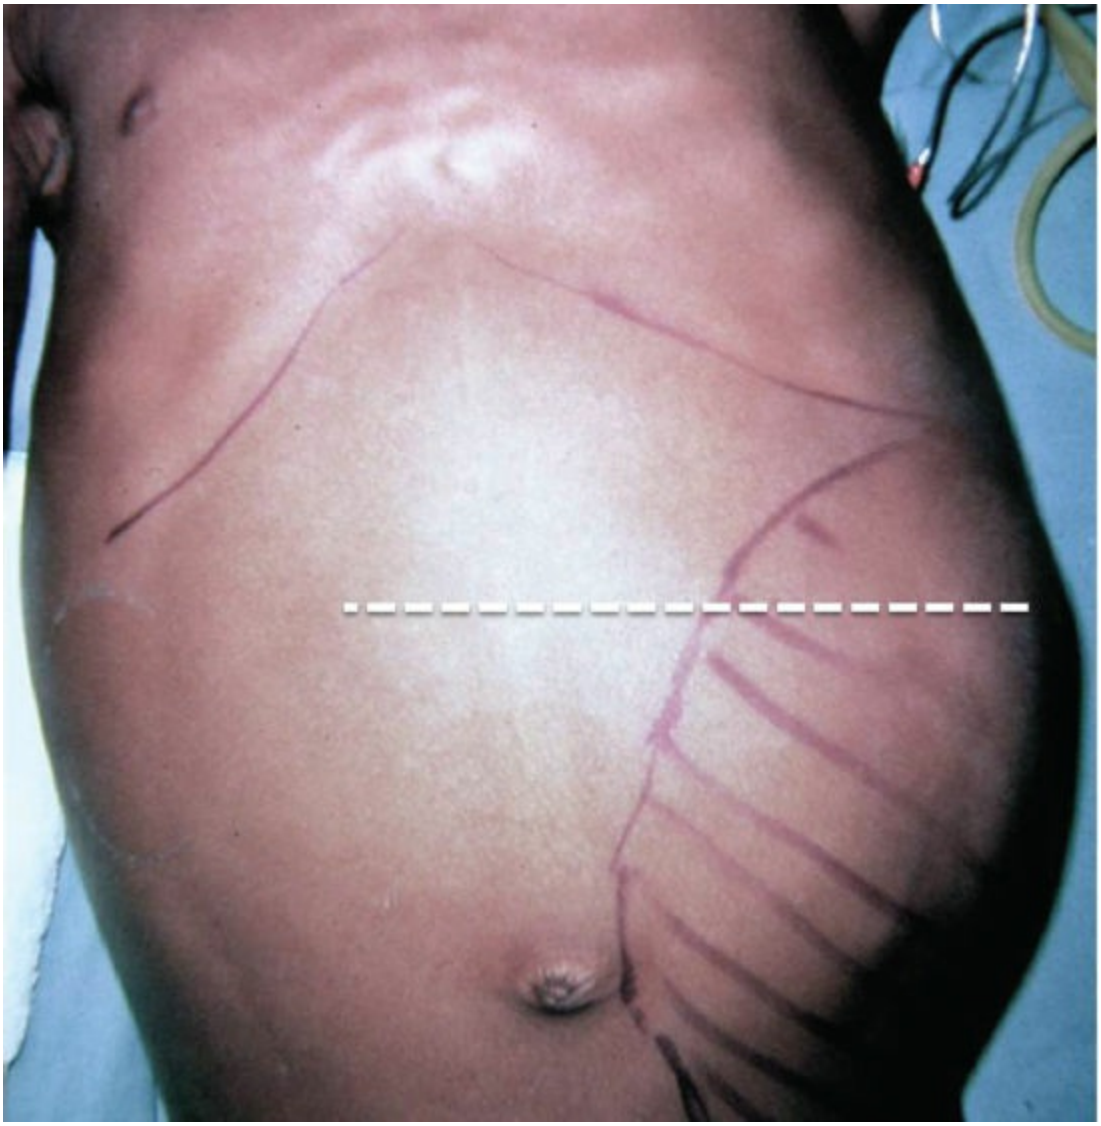

Figure 179.1. Abdominal incision for resection of Wilms tumor.

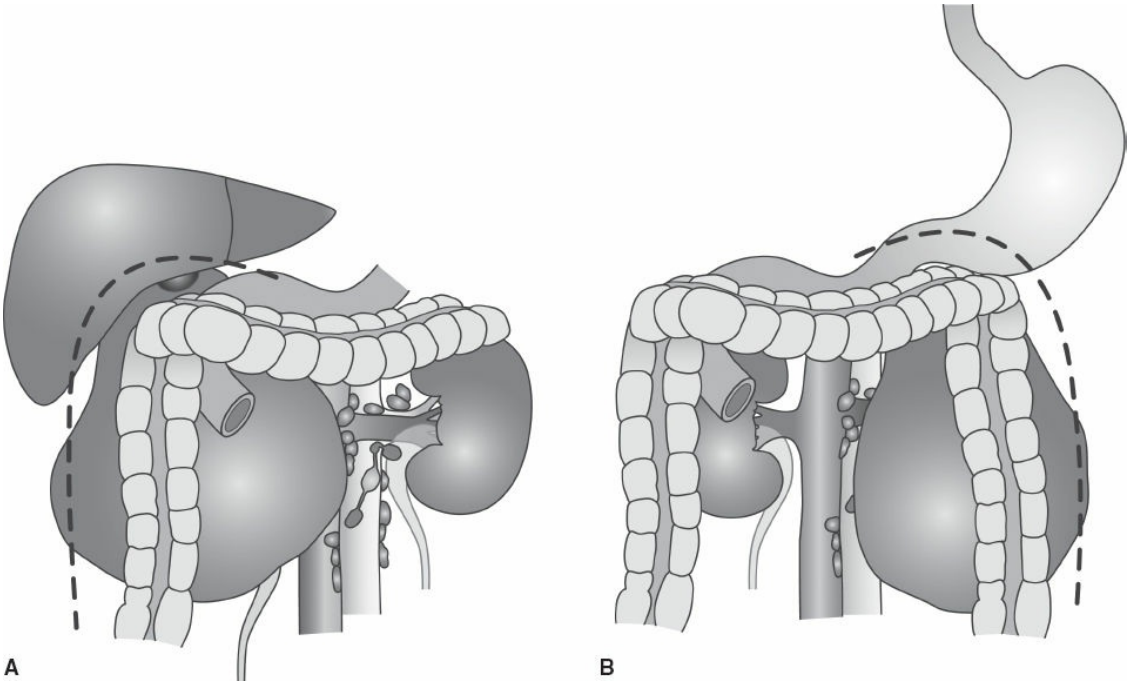

Figure 179.2. Line of dissection for mobilization of the colon to expose the kidney and associated tumor (**A, B**).

Following exploration of the abdominal cavity, the white line of Toldt should be incised and colon reflected medially. The colonic mesentery can then be mobilized, being careful to preserve the colonic vessels that may be draped over the tumor. In some cases, the mesentery may need to be sacrificed to avoid entering the tumor and causing tumor spillage. The colon can then be retracted medially to expose the renal hilum (Fig. 179.2). For right-sided tumors, the posterior peritoneum can be incised up to the base of the mesentery to allow for reflection of the entire colon and small bowel to provide improved exposure of the retroperitoneal vessels.

Early ligation of the renal vessels before manipulation of the tumor is ideal to decrease the theoretical risk of tumor dissemination. After identification, the renal vessels can be individually encircled with vessel loops. Prior to ligation of the renal hilum, the renal vein and IVC should be carefully palpated for the presence of tumor thrombus. However, as large tumors can significantly distort vascular anatomy, it is more important to carefully identify the contralateral renal vessels, superior mesenteric artery or other major vessels prior to ligation of the renal hilum to avoid injury to these structures. The renal vessels can then be doubled ligated and divided, generally taking the renal artery prior to the renal vein in order to avoid distention of the vein, which may dislodge the ligature.

If the renal vein is short or there is tumor extension beyond the renal

vein, a Satinsky clamp can be placed on the IVC just proximal to the insertion of the renal vein. The tumor thrombus should be gently milked back prior to placement of the clamp. The renal vein can then be divided and the venous stump over sewn with continuous 5-0 Prolene in two layers.

If tumor thrombus is present in the IVC, additional surgical exposure is warranted as both proximal and distal vascular control is necessary. For minimal thrombus extension below the level of the hepatic veins, the inferior edge of the liver can be retracted to expose the infrahepatic vena cava. If the tumor thrombus extends more cephalad, mobilization of the liver is required. Division of the triangular and coronary ligaments of the liver allows for rotation and exposure of the retrohepatic vena cava. Additional exposure can also be gained by dividing the lesser hepatic veins. The contralateral renal vein and infrarenal IVC should then be controlled with vessel loops. The IVC is then vertically incised just medial to the entrance of the renal vein. If the thrombus is free floating, it can be manually extracted (Fig. 179.3). If the thrombus is adherent to the wall of the IVC, a Fogarty or Foley balloon catheter can be passed beyond the level of the hepatic veins, inflated, and pulled inferiorly to displace the adherent thrombus into the cavotomy. The IVC should then be allowed to fill by releasing the vessel loops on the distal cava and contralateral renal vein to displace any air from within the IVC prior to closure. The cavotomy can then be clamped with a Satinsky clamp and oversewn with a continuous 5-0 Prolene suture. In rare instances, tumor thrombus invades the wall of the IVC, precluding thrombectomy necessitating partial resection of the IVC.

Patients with IVC extension above the level of the hepatic veins or atrial thrombus remain a difficult surgical challenge. Pretreatment with chemotherapy is recommended in these cases to decrease surgical morbidity. If this fails to shrink the thrombus or if a primary surgical approach is chosen, the procedure may require cardiopulmonary bypass and benefit from a combined abdominothoracic approach with a pediatric cardiothoracic surgeon. Suprahepatic or atrial involvement is best approached through a median sternotomy and performed in conjunction with a subcostal or a midline abdominal incision for nephrectomy.

After the renal vessels are controlled, a dissection plane can be established outside of Gerota fascia with sharp and blunt dissection. Perforating vessels may be quite large and should be ligated individually.

Use of a ligasure can be very helpful for some of these very vascular tumors. Gentle manipulation of the tumor should be emphasized as Wilms tumors are very soft and may easily rupture. Any tumor spill leads to a stage III designation due to the increased risk for local tumor recurrence. It is not necessary to remove the adrenal gland with the specimen if there is no evidence of direct involvement with tumor.

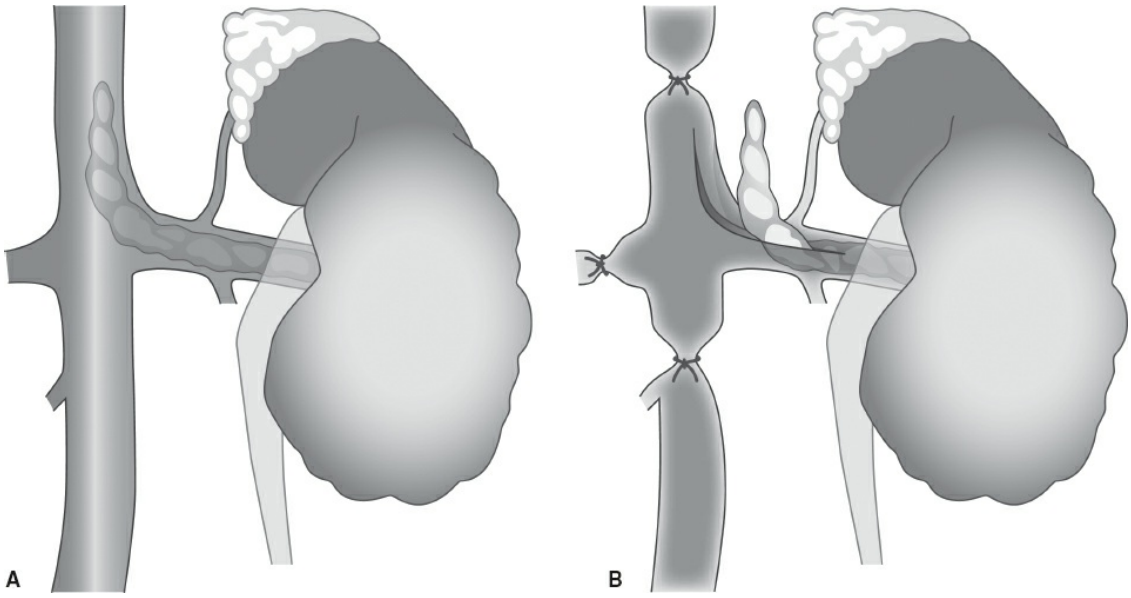

Figure 179.3. Removal of an intravenous tumor thrombus in continuity with the tumor and affected kidney (**A, B**).

Nephroblastomas often compress and adhere to adjacent structures without frank invasion. The gross appearance of the tumor at the time of surgery can be misleading in interpreting tumor extent, and in the majority of cases tumor invasion is not confirmed when adjacent visceral organs are removed. There may be circumstances, however, when removal of other organs is justified. In a patient known to have extracapsular extension, resection of a small portion of liver or tail of the pancreas to avoid leaving residual tumor, for example, may eliminate the need for radiation therapy and allow a reduction in the amount of chemotherapy. Even if the tumor is confined to the kidney, en bloc resection of nonessential structures may also prevent violation of the tumor capsule and obviate tumor rupture or spill. Therefore, it is a tradeoff between the added surgical morbidity of en bloc resection versus a potential reduction in long-term complications of adjuvant treatment if this can be limited by complete tumor removal. In prior reviews, one factor associated with an increased rate of complications was en bloc resection of other visceral organs. If the tumor

is found to be unresectable, biopsy of the tumor can be followed by chemotherapy and/or radiation therapy.

Lymph node sampling is critically important for tumor staging, despite the absence of abnormal nodes on preoperative imaging, or upon gross inspection during operative exploration. Lack of lymph nodes sampling has been identified as a risk factor for local tumor recurrence, likely due to understaging and undertreatment. A prior review of lymph node sampling by the NWTSG demonstrated a false-negative rate of 31% and a false-positive rate of 18% based on preoperative and intraoperative assessment. Unfortunately, there is currently a fairly high incidence of inadequate intraoperative staging, primarily due to failure to sample lymph nodes. In a review of NWTS-4 and -5 patients, 12.5% of patients did not have lymph node sampling performed. The likelihood of having a positive lymph node was greater if more than seven lymph nodes were sampled, but EFS was not improved with removing more lymph nodes. Lymph nodes in the pericaval (right-sided tumors) and periaortic region (left-sided tumors) should be removed and submitted for histologic evaluation. Hilar lymph nodes are often removed with the nephrectomy specimen. However, all suspicious lymph nodes should be biopsied. Failure to sample lymph nodes will mandate increased therapy due to incomplete staging.

The ureter should be palpated to rule out intraureteral tumor extension before it is divided as distally as possible. There is increased suspicion of ureteral extension in children with hematuria and poor visualization of the kidney on preoperative imaging. After extraction of the intact tumor, the wound should be copiously irrigated and hemostasis assessed. Drains are not routinely placed unless a portion of the pancreas or liver has been resected. The displaced colon should be replaced in the tumor bed and abdominal wall closed in the standard fashion.

There have been several reports of laparoscopic nephrectomy for Wilms tumor. This is usually done in conjunction with preoperative chemotherapy and is likely more feasible after the tumor is reduced in size. Experience with open nephrectomy after chemotherapy has shown that these tumors are less prone to tumor spillage. Although prechemotherapy laparoscopic nephrectomy has been reported many more cases will need to be performed to determine if there is an increased risk of tumor spillage, residual disease or surgical complications.

At the time of definitive surgery for bilateral tumors, partial nephrectomy or wedge excision of the tumor is preferred, but only if

complete removal of the tumor can be achieved. The kidney with the lower tumor burden should be addressed first. If complete excision of tumor can be performed leaving a viable functioning kidney, then surgery of the contralateral kidney with more extensive tumor involvement is undertaken. Enucleation of the tumor may be considered in lieu of a formal partial nephrectomy. This may be considered for large centrally located tumors where removal of a margin of renal tissue would compromise the vascular supply to the kidney. Even when very large bilateral masses remain after initial chemotherapy, a high percentage of children can be successfully managed with renal-sparing surgery. As it is easy to underestimate the amount of renal parenchyma that can be salvaged due to compression by the tumor, renal-sparing surgery should be entertained in all patients. Fortunately, bilateral nephrectomies and dialysis are rarely required when the tumors fail to respond to radiation and chemotherapy.

As most Wilms tumors are too large at diagnosis to allow partial nephrectomy, renal sparing surgery has been traditionally used only in patients with bilateral tumors. However, COG is now studying the role of renal sparing surgery for select patients with unilateral tumors. Patients eligible for renal sparing surgery include those with a solitary kidney, a predisposition syndrome where tumors are found at a smaller size, and patients with an increased risk for developing renal failure. After preoperative chemotherapy, partial nephrectomy can be performed in 10% to 15% of patients.

Distant metastases are found in 10% to 12% of patients with Wilms tumor at diagnosis. The lungs are the most common primary site for hematogenous metastases accounting or 80% of cases. Fortunately, the overall survival for patients with favorable histology tumors and metastases at diagnosis is very good. The recent COG study employed a response-based approach for patients with pulmonary metastases. Patients with lung metastases were initially treated with regimen DD-4A. Those children documented to have complete disappearance of the lung metastases (or who had excision of residual nodules that did not contain viable tumor) at the week 6 re-evaluation were considered “rapid responders.” These patients were treated with chemotherapy alone avoiding pulmonary irradiation. Patients that did not have complete resolution of pulmonary nodules were then treated with more intensive chemotherapy and received whole lung irradiation. Patients who had all pulmonary metastases resected at diagnosis (and therefore have no residual

disease available for response monitoring) continued treatment with DD-4A but received whole lung irradiation.

It is strongly recommended that, if there is any doubt about the nature of metastatic lesions, all lesions be biopsied since as many as one third of small (<1 cm) pulmonary lesions may not be metastatic tumor. COG defines pulmonary metastases as detectable lesions of any size which are thought to represent metastases. It is the responsibility of the treating physician to ultimately determine the nature of small metastatic lesions.

Any suspicious site in the abdomen or liver should also be biopsied or resected at exploration to determine the nature of the mass as it will affect tumor stage and therapy. If residual intra-abdominal metastatic disease remains at week 12 of chemotherapy, it should be resected if complete resection is feasible. If complete resection is not feasible, then residual disease should be reassessed for feasibility of resection at the completion of therapy.

POSTOPERATIVE MANAGEMENT

Appropriate postoperative pain management should be obtained with intravenous narcotics, an epidural catheter, or a combination of the two. Intravenous antibiotics are continued for 24 hours postoperatively. A Foley catheter may be left in place until the patient is ambulatory. A nasogastric tube may be used in anticipation of postoperative ileus. Postoperative fluid management is generally routine as the remaining kidney quickly adapts to clear extra fluids.

Approximately 15% to 20% of patients with favorable-histology Wilms tumor and 50% of patients with anaplastic or postchemotherapy blastemal type Wilms tumor develop recurrent tumor. The vast majority of recurrences occur within 2 years of initial diagnosis, with the most frequent sites being pulmonary, tumor bed, and liver. Imaging surveillance after treatment of the primary tumor is recommended to detect tumor recurrence. COG studies advocate for periodic chest CT and either CT or MR of the abdomen. However, some have begun to question the value of these studies and whether they will detect relapse early enough to improve survival. Many patients will present with clinical symptoms related to relapse before imaging detection. Omitting even the pelvic portion of the abdominal CT can significantly reduce the radiation exposure without compromising detection of relapse. Patients with bilateral Wilms tumor need more frequent and longer monitoring after surgery. Local recurrence

can occur many years after the initial renal sparing surgery. These patients are also at greater risk for new renal tumors due to the high prevalence of NRs.

A uniform approach for the treatment of tumor relapse was used in NWTS-5. Patients with relapsed Wilms tumor may be divided into risk groups according to overall survival rates after salvage therapy. Children with nonanaplastic Wilms tumor who relapse after therapy with only VCR and/or AMD are considered standard risk. The survival rates for these patients are in the 70% to 80% range. Patients with nonanaplastic Wilms tumor who relapse after therapy with three or more agents are called high risk and have survival rates in the 40% to 50% range. Patients with unfavorable histology patients who relapse with metastatic disease have a grave prognosis. This very high-risk group includes recurrent anaplastic or blastemal-type Wilms tumor and have survival rates in the 10% range.

The Childhood Cancer Survivor Study group has reported on very late mortality in 5-year survivors of childhood tumor, and found that the leading cause of death was recurrence of the original tumor. The incidence of late tumor recurrence is, however, lower for Wilms tumor patients than for other solid tumors. An international study or more than 13,000 patients found a 0.5% recurrence beyond 5 years. Tumor recurrence in the contralateral kidney was identified in 15 of the 70 patients and 87% of these patients were alive without evidence of disease. This is compared to a 45% survival for those patients with recurrence in other sites.

COMPLICATIONS AND THEIR MANAGEMENT

Removing a large renal tumor in a small child is associated with some morbidity. NWTS-4 patients undergoing primary radical nephrectomy had an 11% incidence of surgical complications. Factors associated with an increased risk for surgical complications include higher tumor stage, tumor size >10 cm, incorrect preoperative diagnosis, thoracoabdominal incision, intracaval tumor extension, and resection of other visceral organs. A mortality rate of 0.5% related to surgical complications was reported from NWTS-3. However, a higher intraoperative mortality rate of 1.5% has been reported from other centers.

The most common intraoperative complication is bleeding. Iatrogenic injury to the aorta and its major vessels may occur as large tumors can distort the anatomy and the great vessels can easily be mistaken for the renal vessels. Mesenteric vessels may also be adherent to the renal hilum.

Vascular injury can be avoided with proper surgical exposure and identification of the aorta, IVC, superior mesenteric artery, celiac axis, and contralateral renal vessels. The renal artery should be carefully traced and seen entering the kidney prior to ligation. Operative repair of significant vascular injury should be undertaken immediately. As tumor thrombus can break off and embolize during the course of nephrectomy, unexplained intraoperative hypotension or cardiac arrest should raise concern for unrecognized vena caval or intracardiac extension of tumor.

Following surgery, the most common complication is small bowel obstruction (SBO) which occurs in 5% of patients. The majority of SBOs occur within the first 100 days after surgery and are usually due to bowel adhesions or intussusception. Factors associated with increased risk of SBO include intravascular tumor extension, resection of other organs, preoperative tumor rupture, residual disease, stage III, and possibly tumor spill. Surgical techniques thought to reduce the incidence of SBO include gentle handling of the bowel, maintaining a moist serosal surface of the bowel, and avoiding foreign materials on the bowel.

Disruption or obstruction of lymphatic drainage can lead to chylous ascites. Increased abdominal girth and poor feeding should lead to the suspicion of chylous ascites. Diagnosis is confirmed by evaluation of the white milky fluid obtained during paracentesis or exploratory laparotomy which will reveal a high triglyceride content 2 to 8 times as great as plasma, specific gravity greater than serum, and protein content >3 g/dL. The initial management should be conservative with total parenteral nutrition or a medium chain triglyceride diet. Small lymphatic leaks usually resolve with conservative management but occasionally chylous ascites may require surgical intervention, such as direct ligation of leaking lymphatic channels or placement of peritoneovenous shunt. Avoiding extended lymphadenectomy may help prevent the formation of chylous ascites and intraoperatively care should be taken to ligate any disrupted lymphatics.

Preoperative chemotherapy may influence surgical complication rates by producing tumor shrinkage. The United Kingdom Children’s Cancer Study Group (UKCCSG) compared the complication rate for patients undergoing immediate nephrectomy versus delayed nephrectomy after 6 weeks of chemotherapy and found significantly fewer complications in those undergoing delayed nephrectomy (1% vs. 5.8%). They also noted a much higher rate of tumor rupture/spill in those undergoing immediate

nephrectomy (14.6% vs. 0%).

Numerous organ systems are subject to the late sequelae of anticancer therapy and clinicians must be aware of the spectrum of problems that face children as they grow into adulthood. Gonadal radiation can produce hypogonadism and temporary azoospermia in boys. The severity of damage is dependent on the radiation dose. Leydig cells are more radio resistant than germ cells, but higher doses of radiation can produce damage resulting in inadequate production of testosterone and delayed sexual maturation. A 12% incidence of ovarian failure was found in girls receiving abdominal XRT. Abdominal XRT also increases the risk for adverse pregnancy outcomes. An increased incidence of second malignant neoplasms has been noted in children treated for Wilms tumor. There is a 1% cumulative incidence at ten years post diagnosis and a rising incidence thereafter. One of the greatest risk factors is prior irradiation, and most tumors occur in the radiation field.

The development of renal failure is of concern for Wilms tumor patients. Fortunately, the incidence of renal failure following nephrectomy for most children with unilateral Wilms tumor is low, 0.6% at 20 years posttreatment. The risk of renal failure is higher for patients with genitourinary anomalies, DDS and WAGR. This is due to mutation of WT1 which is necessary for normal renal development. Patients with bilateral Wilms tumor are also at increased risk for development of renal failure, which approaches 15%, at 15 years posttreatment. The most common cause of renal failure in these children is the need for bilateral nephrectomy for persistent or recurrent tumor in the remaining kidney after initial nephrectomy. For this reason, every effort should be made to perform renal sparing surgery in these children to preserve as much functioning renal tissue as possible.

OUTCOMES

Despite advances in chemotherapy protocols and radiation techniques, a high quality surgical operation remains paramount in the treatment of Wilms tumor. According to the SEER registry, the relative 5-year survival rate for children with Wilms tumor under the age of 15 has improved from 73.1% in 1975 to 93.6% in 2002. This improvement in survival is a testament to the systematic approach from which multimodal therapy has evolved. The overall goal in treatment of Wilms tumor is to maximize outcomes while limiting the intensity of therapy as the late effects of

chemotherapy and radiation can be significant. Clinical trials continue to refine treatment regimens to improve survival, in particular for higher-risk populations with unfavorable histology. Continued support of the pediatric cooperative groups that study Wilms tumor is essential.

NWTS-5 found that children less than two years of age with stage I FHWT weighing less than 550 g (VLRWT) who did not receive chemotherapy after nephrectomy had a 5-year EFS of 84% compared with 97% for those who underwent postoperative AMD and VCR. However, the 5-year OS was equivalent between the two groups at 98% and 99%, respectively ($p = .70$). Thus, there is a tradeoff between more intensive therapy and the potential long-term sequelae required for the 16% of children who relapse versus the avoidance of any postoperative chemotherapy in the majority. NTWS-5 also found that both WT1 and LOH for chromosome 16q and 1p were significantly associated with relapse in VLRWT patients. Finally, NTWS-5 found that stage I patients with anaplastic tumors treated with AMD and VCR had a low 4-year EFS of 69.5% and a new intensified chemotherapy regimen used for patients with Stage II-IV diffuse anaplasia did not result in an improved survival.

SIOP 93–01 evaluated a reduction in postoperative chemotherapy for patients with stage I intermediate risk and anaplastic Wilms tumor. Patients were randomized to receive either 4 or 18 weeks of postoperative AMD and VCR. Two year EFS was 91.4% after 4 weeks and 88.8% after 18 weeks of chemotherapy demonstrating that survival can be maintained while shortening the duration of postnephrectomy therapy. Patients with stage II or III with low or intermediate risk histology received 4 weeks of AMD and VCR before surgery. Postoperative chemotherapy consisted of AMD, VCR and epirubicin/doxorubicin for 27 weeks. Flank or whole abdomen irradiation was given for stage III. With a median follow-up of 8 years, 5-year EFS was 90% and OS 95%. Patients with blastemal type histology had a worse prognosis with 62% EFS at 5 years. These patients comprised only 10% of patients but contributed to one third of the relapses and deaths.

SIOP also found that for stage II or stage III intermediate risk histology Wilms tumor there was no significant disadvantage in removing doxorubicin from postoperative chemotherapy. Thus, SIOP now recommends 6 months only of VCR and AMD rather than a three-drug regimen including doxorubicin which will significantly reduce the number of children receiving this cardiotoxic drug.

EDITOR'S COMMENT

Renal tumors are among the most common of pediatric cancers. The histologic subtypes of pediatric renal tumors include the benign lesion mesoblastic nephroma and the malignant lesion Wilms tumor, clear-cell sarcoma, malignant rhabdoid and renal cell carcinoma (RCC) with Wilms tumor by far the most common. The treatment strategy for a patient diagnosed with a pediatric renal

tumor requires multidisciplinary coordinated care involving oncologists, pediatric surgeons, and radiation therapists achieving overall outcomes of greater than 90% long-term survival. The authors present an excellent overview of Wilms tumor management.

The current treatment paradigms for pediatric renal tumors were established through a series of cooperative group studies that began over 40 years ago and serve as the template by which a multi-institutional cooperative group can advance pediatric cancer treatment. The National Wilms tumor study group trials (NWTS 1–5) that transitioned to the Children's Oncology Group (COG) driven AREN series prospectively determined how to optimize outcomes while minimizing attendant morbidity (O'Leary M, Krailo M, Anderson JR, et al. Progress in childhood cancer: 50 years of research collaboration, a report from the Children's Oncology Group. *Semin Oncol* 2008;35(5):484–93; Dome JS, Fernandez CV, Mullen EA, et al. Children's Oncology Group's 2013 blueprint for research: renal tumors. *Pediat Blood Cancer* 2013;60(6):994–1000). The approach was to risk adapt treatment reducing therapy intensity in cohorts with good outcomes and intensifying therapy in cohorts with poor outcomes. The first meeting of the Wilms' Tumor Integrated Study Group was held in May 1968 at Babies Hospital in New York with the NWTS-1 study opening soon thereafter. Five NWTS trials were conducted before the study group evolved into the Renal Committee of the Children's Oncology Group which has subsequently conducted multiple AREN studies. In total, over 11,000 pediatric patients with renal tumors have participated in these trials and are captured in the NWTS and COG patient registries. A comprehensive summary of the contributions that these trials accomplished is beyond the scope of this commentary; however, examples of its risk-adapted approach can be summarized in the treatment of stage I Wilms tumor whose outcome is favorable versus those with stage II or III Wilms tumor in which outcomes were more challenging. In children with a stage I tumor, treatment moved from a combination of resection at diagnosis, a long course of chemo, and a moderate dose of radiation to resection at diagnosis, a 4-month course of chemotherapy given in an efficient manner requiring shorter hospitalization and no radiation. In contrast, children with stage II–III tumors, resected at diagnosis saw treatment intensity increases from one-drug to three-drug treatment (vincristine, actinomycin, and doxorubicin) accompanied by radiation therapy of moderate intensity. As the biologic understanding of Wilms tumor pathogenesis evolved, the trials tested that biologic understanding in study questions as demonstrated in NWTS-5, where the molecular markers' loss of heterozygosity on chromosomes 1p and 16q were found to be adverse factors in favorable histology Wilms tumor requiring higher-intensity chemotherapy. The current COG AREN series of studies has established a risk stratification schema in which the risk of relapse (very low, low, intermediate, and high), based on stage and molecular characteristics determine the type and length of therapy. In addition to improving treatment strategies for the varying types of renal tumor

patients, the capture of patients allowed long-term monitoring resulting in late effects studies. Late effects studies determined the impact of nephrectomy, exposure to chemotherapy and abdominal irradiation in Wilms tumor survivors with the knowledge gained altering subsequent studies. Additionally, the paradigms developed in these studies influenced the current late effects follow-up programs integral to the care of every current pediatric oncology patient found at all pediatric oncology programs. Beyond direct clinical treatment regimens, the cooperative group studies had an impact on pathologic definitions as it was during the 40-year effort the concentration of patients allowed study pathologists to review a large number of specimens including the uncommon histologic subtypes clear-cell sarcoma and rhabdoid tumors such that precise definitions of the characteristics of the varying pediatric renal malignancies were established. The NWTS and AREN series of trials have had an immense impact on child health and serve as the template for the development of cooperative group trials that continue to this day.

While the NWTS trials were underway in North America, the Societe Internationale Oncologique de Pediatrique (SIOP) group in Europe developed a markedly different approach. In contrast to the COG approach where resection at diagnosis was favored, the SIOP studies demonstrated the effectiveness in which a child with a renal mass is treated with chemotherapy first with planned resection after several cycles of treatment. The basis by which this approach evolved was the observation of increased surgical morbidity (and in the past mortality) in patients who underwent resection at diagnosis, a factor that could be attenuated by preoperative chemotherapy. The major limitation of the SIOP approach is the potential for misdiagnosis of the uncommon histologic subtypes resulting in overtreatment if the tumor is benign (i.e., mesoblastic nephroma) or under-treatment if the tumor is a more aggressive malignant subtype (i.e., clear-cell sarcoma/rhabdoid tumor). Otherwise, outcomes were similar to those experienced in North America. As a result, in current treatment protocols the two approaches are used in a complimentary fashion.

Wilms tumors are thought to be derived from nephrogenic rests, embryonic remnants from the developing kidney representing microscopic malformations/dysplasias. Although rests are best known as precursor lesion for tumorigenesis, most rests involute and are of no clinical significance. As the authors note, there are two types of rests, peri- and intralobar with differing molecular etiologies. Perilobar rests occur in overgrowth syndromes while intralobar rests are associated with deletions or mutations of the tumor suppressor WT1. The presence of rests dictates the need for close monitoring, especially in high-risk populations (overgrowth syndromes or in the contralateral kidney of an afflicted patient). Here again was a benefit of the NWTS studies as analysis of the registry allowed the generation of evidence-based recommendations for surveillance duration (Beckwith JB. Nephrogenic rests and the pathogenesis of Wilms tumor: developmental and clinical considerations. *Am J Med Genet* 1998;79(4):268–73).

As the authors note, the current COG treatment protocols are risk adapted with treatment regimens shown in Table 179.3. The treatment regimens utilize resection, chemotherapy, and radiation therapy with the intensity of chemotherapy and radiation dosage adjusted according to the risk profile. Complete resection with appropriate staging remains the most critical intervention required to achieve long-term cure. The surgical principles of resection are nicely illustrated in the chapter. As risk profiles for relapse have been better defined, it has become apparent that some children can be cured with surgery alone. Two analyses focused on the very low-risk cohort (resected at diagnosis, small tumor, favorable histology i.e., no anaplasia, negative lymph nodes—NWTS-5 and AREN 0532 trials) have demonstrated the efficacy of surgery alone where over 80% of patients will have event-free survival without adjuvant chemotherapy. In those who relapse, rescue can be achieved with standard intensity chemotherapy achieving 98% overall survival (NWTS-5—Shamberger RC, Anderson JR, Breslow NE, et al. Long-term outcomes for infants with very low risk Wilms tumor treated with surgery alone in National Wilms Tumor Study-5. *Ann Surg* 2010;251(3):555–8; AREN 0532–Fernandez CV, Perlman EJ, Mullen EA, et al. Clinical outcome and biological predictors of relapse after nephrectomy only for very low-risk Wilms tumor: A Report From Children's Oncology Group AREN0532. *Ann Surg* 2017;265(4):835–40). Proper staging is critical as regional lymph nodes must be sampled appropriately to ensure no extrarenal spread which would dictate the need for adjuvant chemotherapy and radiation.

An interesting aspect of the biology of a Wilms tumor can be seen in the management and outcome of tumors that have invaded contiguous organs to the kidney (liver, duodenum on the right, tail of the pancreas on the left) or present with intravascular tumor thrombus. Despite the intuitive assumption that tumors such as these would have more aggressive biologic features therefore require more intense treatment, if local control can be obtained by en bloc resection or complete tumor thrombectomy at the time of diagnosis, intensity of treatment is not escalated. If the treating team elects not to offer resection at diagnosis and perform a biopsy, then the patient is by definition stage III and will be treated with three-drug chemotherapy and abdominal radiation.

Intravascular venous tumor thrombus provides an interesting technical challenge as resection may require complete control of the IVC and its tributaries. Careful analysis of preoperative imaging to determine if tumor thrombus is present is critical for appropriate operative planning (Shamberger RC, Ritchey ML, Haase GM, et al. Intravascular extension of Wilms tumor. *Ann Surg* 2001;234(1):116–21). If by cross-sectional imaging, venous involvement is not clear ultrasound can be helpful. As the authors note, if tumor thrombus remains below the hepatic veins, resection can be completed in the abdomen without the requirement of cardiopulmonary bypass such that resection at diagnosis should be considered. Should the tumor extend into the right atrium, neoadjuvant chemotherapy is warranted as the tumor thrombus

may decrease in size shrinking below the hepatic veins. If right atrial tumor thrombus persists, then cardiopulmonary bypass with hypothermic circulatory arrest is required. In this circumstance, to avoid bleeding during and after the anticoagulation that will be required during bypass and arrest, nearly all of the dissection in the abdomen should be completed (mobilization of the renal tumor, dividing arterial inflow and the retrohepatic IVC dissection) leaving a completely free renal tumor ready to be removed except for its attachment via the vein containing tumor thrombus. The chest can then be opened, the patient heparinized and bypass initiated followed by cooling and circulatory arrest. Both the right atrium and the IVC extending from the renal vein superiorly are opened and the tumor thrombus removed—often in fragments. Once resection is complete, the atriotomy and cavotomy are closed followed by reinstitution of bypass and warming. Postoperatively, careful intensive care unit monitoring is warranted as intravascular volume status will be a complicated combination of post pump physiologic changes altered by a complex abdominal procedure with accompanying fluid shifts. In the Shamberger et al. review of the NWTS registry focused on this population of patients, they found that in the 165 patients who had intravascular extension of disease, neoadjuvant chemotherapy facilitated resection by decreasing the extent of the tumor thrombus including a small subset that went from requiring cardiopulmonary bypass to an abdominal procedure alone. Interestingly, the frequency of complications was similar if resection was attempted at diagnosis when compared to those who received neoadjuvant chemotherapy. Overall survival was similar when comparing those with intravascular extension to no intravascular disease highlighting the counterintuitive observation that vascular involvement does not mandate the need for a more aggressive chemotherapy and radiation treatment.

Patients with stage V, bilateral disease—about 5% of the cohort—provide an interesting treatment challenge as the goal is a high cure rate while maintaining long-term renal function. Renal/nephron sparing is advocated as should bilateral nephrectomy be necessary, renal transplantation with all of the attendant morbidity of life-long immunosuppression will be required. In these patients, biopsy, neoadjuvant chemotherapy followed by partial nephrectomy is the currently recommended treatment paradigm although adherence to that strategy is not uniform. In an analysis of the NWTS-4 experience of 188 patients with bilateral disease, preservation of renal parenchyma was possible in many patients after initial preoperative chemotherapy; however, 87 kidneys in 83 patients were managed with primary resection (encompassing, nephrectomy, partial nephrectomy, and enucleation of the tumor). The incidence of end-stage renal disease was 13%. Relapse or progression of disease occurred in 54 children. The 8-year event-free survival if tumor had favorable histology was 74%, and overall survival was 89%; whereas the event-free survival with unfavorable histology was 40% and overall survival was 45% (Hamilton TE, Ritchey ML, Haase GM, et al. The management of synchronous bilateral Wilms tumor: a report from the National Wilms Tumor Study Group. *Ann Surg*

2011;253(5):1004–109). A more recent single-institution experience reporting on the efficacy of a nephron-sparing approach demonstrated a more favorable outcome (Davidoff AM, Interiano RB, Wynn L, et al. Overall survival and renal function of patients with synchronous bilateral Wilms tumor undergoing surgery at a single institution. *Ann Surg* 2015;262(4):570–6). In the study from St Jude's, overall survival in a 42-patient cohort in which all but three underwent bilateral nephron-sparing surgery was 85.7% (mean follow-up, 4.1 years). Of the 6 patients who died, 5 had diffuse anaplastic histology—a high-risk feature. No patient developed end-stage renal disease. The current AREN 0534 trial focused on bilateral disease and has nearly completed enrollment with study results to be released soon thereafter. Although nephron-sparing surgery is the goal, survival is still paramount as renal transplantation after bilateral nephrectomy is successful.

Clear-cell sarcoma of the kidney is uncommon and in contrast to Wilms tumor is characterized by a distinct pattern of recurrence and metastasis most commonly to the bone. Treatment regimens are when compared stage for stage with Wilms tumor, more intense but as a result have improved survival to reasonable outcomes (Gooskens SL, Furtwängler R, Vujanic GM, et al. Clear cell sarcoma of the kidney: a review. *Eur J Cancer* 2012;48(14):2219–26). In the Gooskens et al. review of the literature, he notes that therapy for CCSK is approaching the maximum tolerated intensity of traditional cytotoxic agents therefore further improvement of outcome will likely depend on more targeted therapy based on specific molecular/genetic aberrations. In this case, the cooperative group construct will need to expand to an international level as the frequency of clear-cell sarcomas are rare enough that current constructs are inadequate. This effort has been initiated by members of the COG Renal committee and their SIOP colleagues.

Rhabdoid tumors of the kidney are even more uncommon but are the most aggressive of the histologic subtypes. As a result, afflicted patients have the worst of outcomes often presenting with metastatic disease to the lung and brain. In the NWTS registry, there were a total of 142 patients who had rhabdoid tumors (Tomlinson GE, Breslow NE, Dome J, et al. Rhabdoid tumor of the kidney in the National Wilms' Tumor Study: age at diagnosis as a prognostic factor. *J Clin Oncol* 2005;23(30):7641–5). Age at diagnosis was a highly significant prognostic factor for survival where infants less than 6 months had a dismal prognosis (9% 4-year OS), while, older children had a slightly better outcomes (40% 4-year OS)—still markedly worse than a Wilms tumor patient. A CNS lesion was also a highly negative predictor as no patient who has brain metastases survived. A better understanding of the molecular basis of these tumors is required such that treatment strategies can be optimized.

RCC is also uncommon in the pediatric population but should it arise, are usually found in the adolescent population. In a recent study by Geller et al. analyzing the cohort enrolled in the COG AREN03B2 bio-repository, the characteristics of adolescent and pediatric RCC was reported (Geller JI, Ehrlich

PF, Cost NG, et al. Characterization of adolescent and pediatric renal cell carcinoma: A report from the Children's Oncology Group study AREN03B2. *Cancer* 2015;121(14):2457–64). There were 120 out of 3,250 patients who had a unilateral RCC with a median age of 12.9 years. Histologic review classified these as translocation morphology (56 patients), papillary (20 patients), renal medullary carcinoma (13 patients), chromophobe (4 patients), oncocytoma (1 patient), conventional clear cell (1 patient), and RCC not otherwise specified (25 patients). Lymph node disease was common and present even when there were small primary tumors. Radical nephrectomy was performed in 73% of the patients with surgical staging including lymph node sampling critical. With current treatment regimens, patients with RCC can be managed effectively as the overall 10-year survival of pediatric RCC patients was 70% (Zhuge Y, Cheung MC, Yang R, et al. Pediatric non-Wilms renal tumors: subtypes, survival, and prognostic indicators. *J Surg Res* 2010;163:257–63).

The surgeon involved in the care of pediatric renal tumors must be well versed in all the histologic subtypes and aware of the nuanced treatment regimens that have evolved for this diverse set of patients. Significant progress in the management of pediatric renal tumors has over the last 40 years been achieved; however, there are still many opportunities to improve outcomes. Future studies are being developed by COG and SIOP that will evaluate therapy adjustments based on novel biomarkers with new treatment regimens that incorporate biologic therapies for the high-risk population (Dome JS, Fernandez CV, Mullen EA, et al. Children's Oncology Group's 2013 blueprint for research: renal tumors. *Pediatr Blood Cancer* 2013;60(6):994–1000).

180 Genitourinary Tract Trauma

Jack W. McAninch and Viraj Master

INTRODUCTION

The genitourinary system, encompassing the kidney, ureter, bladder, urethra, and external genitalia, is commonly injured in both blunt and penetrating trauma. Approximately 10% of all traumatic injuries seen in the emergency department involve some element of the genitourinary tract, from obvious genital skin injuries to subtle renal injuries. Early, thorough assessment allows for accurate staging, which then guides treatment and is essential in preventing serious complications. In this chapter, an evidence-based approach to diagnosis and management has been used. A detailed analysis of all genitourinary trauma articles published worldwide between 1966 and 2002 was conducted by an invited panel of surgeons (and chaired by J.W. McAninch), with subspecialty interests in traumatic and reconstructive urology, which was convened by the World Health Organization at the 2003 Stockholm Société Internationale d'Urologie meeting. Each paper from the primary literature was analyzed according to its numerical level of evidence classification, from randomized prospective clinical trials to case reports. Consensus papers were written on trauma to each genitourinary organ. As the editor of *BJU International* wrote (in a preface to the ureteral trauma consensus paper), "This is quite a unique document, of interest to all urologists, not only as a consensus of how this condition should be managed, but also as a model of how to review publications." The principles embedded in these documents have been codified into a series of guidelines, both from the American Urological Association, presented in 2014, and the European Association of Urology, from 2005. Evidence-supported diagnostic algorithms for adult blunt injury and pediatric blunt injury are shown in Figures 180.1 and 180.2, respectively. Penetrating abdominal trauma, especially gunshot wounds, will certainly be evaluated in the operating room. Treatment and further diagnostic algorithms for injuries to specific areas of the genitourinary tract are presented later in the chapter.

RENAL TRAUMA

The kidney is the genitourinary organ most commonly injured due to external trauma, found in approximately 5% of abdominal trauma cases. Advances in staging techniques resulting from increased use of computed tomography (CT) scanning and increased awareness based on outcomes research of the kidney's capacity for healing have permitted the vast majority of these injuries to be successfully managed nonoperatively by the surgical consultant. Nonetheless, certain severely injured kidneys are best managed by exploration and reconstruction, with nephrectomy reserved for life-threatening hemorrhage or kidneys that have been injured beyond repair. Ultimately, the objective of managing these patients is to prevent significant hemorrhage and retain enough functioning nephron mass to avoid end-stage kidney failure. A secondary goal is to avoid complications specifically attributable to the traumatized kidney.

Staging of Renal Injuries

Approximately 90% of renal injuries result from blunt trauma—usually falls from great heights, motor vehicle accidents, and violent assaults. Most of these injuries are minor and rarely require surgical exploration. At San Francisco General Hospital, only 2% of all bluntly injured kidneys required exploration or repair. Pediatric kidneys as well as congenitally abnormal kidneys (cystic kidneys, hydronephrotic kidneys) are more susceptible to major injury secondary to blunt mechanisms. Although only 10% of renal injuries result from penetrating trauma, up to 55% of these injuries will require exploration or repair. This is usually due to a more severe renal injury, associated intra-abdominal injuries, incomplete preoperative radiographic staging, or a combination of these factors.

The American Association for the Surgery of Trauma (AAST) has created a renal organ injury scale that correlates with patient outcomes and allows appropriate and selective management to be undertaken (Table 180.1). The renal injury classification is one of the few classification schemes that has been prospectively validated and found to correlate directly with need for surgical intervention. Grade 1 injuries include subcapsular hematomas and renal contusions (Fig. 180.3). Grade 2 injuries involve small lacerations into the renal cortex. Grade 3 injuries extend through the corticomedullary junction. Grade 4 injuries consist of either injury into the collecting system or renal vascular injuries such as main renal artery or vein injury with contained hemorrhage, or segmental vessel

injury. Grade 5 injuries include kidneys with pedicle avulsion off the great vessels, as well as completely shattered kidneys.

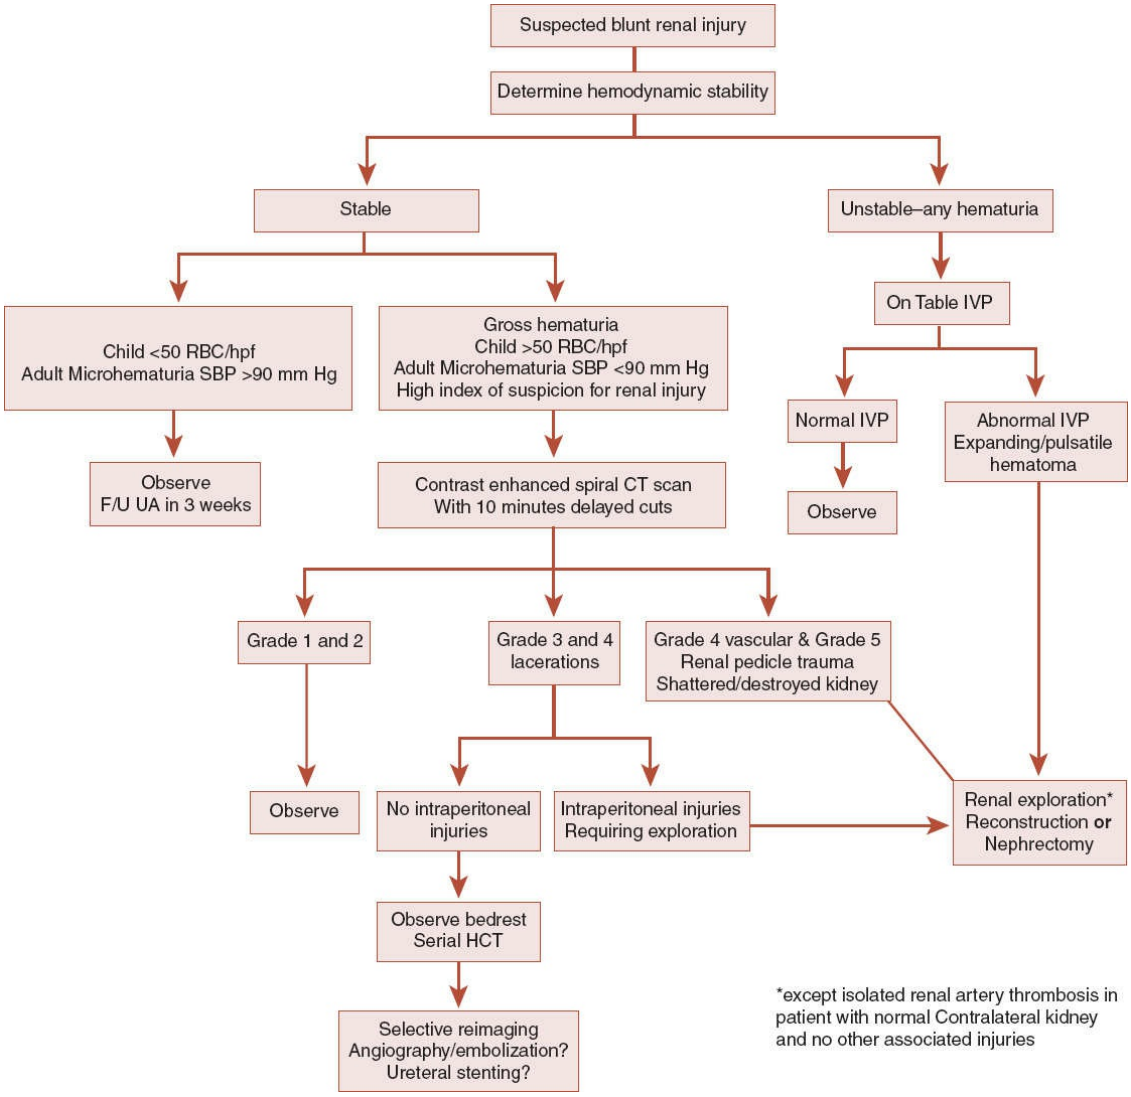

Figure 180.1. Algorithm for staging blunt trauma in adults. CT, computed tomography; HPF, high-power field; IVP, intravenous pyelogram; RBC, red blood cell; SBP, systolic blood pressure. (Adapted from Santucci RA, Wessels H, Bartsch G, et al. Evaluation and management of renal injuries: consensus statement of the Renal Trauma Subcommittee. *BJU Int* 2004;93:937.)

Clinical staging begins with history and physical examination, including the determination of whether the patient has been in shock as well as assessment for presence of hematuria. Based on these criteria, a subset of patients likely to have significant renal injury may be identified. This subset may then undergo radiographic staging in order to completely stage the injury and determine whether operative management is indicated (Figs. 180.4 and 180.5).

History should focus on the mechanism of trauma (blunt [Fig. 180.4] or

penetrating [Fig. 180.5]), as well as presence of significant deceleration, which should raise suspicion for significant renal injury. In penetrating trauma, knowledge of type of bullet (high vs. low velocity) or knife used in the assault may assist in prediction of degree of renal injury. On physical examination, the presence of shock (defined as systolic blood pressure <90 mm Hg) should be recorded. The lowest recorded systolic blood pressure is critical in determining the need for radiographic imaging in adult blunt renal trauma. Clearly, a patient in shock who cannot be resuscitated may require urgent laparotomy, thus bypassing radiographic staging of suspected renal injury, and will require intraoperative staging. The abdomen, flank, and back should be carefully examined. Flank tenderness or ecchymosis as well as lower rib fractures may indicate underlying renal injury. In penetrating trauma, entry and exit wounds may be a helpful indicator that the kidney has been injured.

TABLE 180.1 American Association for the Surgery of Trauma Organ Injury Severity Scale for Renal Trauma

Grade	Injury	Description
I	Contusion	Microscopic or gross hematuria, urologic studies normal
	Hematoma	Subcapsular, nonexpanding without parenchymal laceration
II	Hematoma	Nonexpanding perirenal hematoma confined to renal retroperitoneum
	Laceration	<1 cm parenchymal depth of renal cortex without urinary extravasation
III	Laceration	>1 cm depth of renal cortex without collecting system rupture or urinary extravasation
IV	Laceration	Parenchymal laceration extending through the renal cortex, medulla, and collecting system (meaning extravasation)
	Vascular	Main renal artery or vein injury with contained hemorrhage
V	Laceration	Completely shattered kidney
	Vascular	Avulsion of renal hilum, which devascularizes kidney

Note that the injury scale is advanced one grade for bilateral injuries up to grade III. For more information, go to www.aast.org/injury/injury.html

Hematuria is the most common sign of penetrating and blunt renal trauma. However, importantly, the presence of hematuria and degree of hematuria do not correlate consistently with the degree of renal injury. This is particularly true in penetrating injuries, where a significant percentage of patients with significant renal injuries may have no hematuria. It is imperative that the first voided or catheterized specimen be analyzed, because hematuria may clear rapidly. Either dipstick or microscopic analysis may be performed.

Radiographic Staging

Using the clinical information outlined above, the indications for radiographic imaging may be tailored to detecting patients with a significant chance of having a major renal laceration (AAST Grades 3 to 5). Based on our experience at San Francisco General Hospital, we

recommend imaging the following categories of patients, although it must be emphasized that clinical judgment continues to be paramount:

1. Penetrating trauma: Abdomen, flank, or back injury with ANY degree of hematuria, particularly when the course of the missile appears to involve the kidney or ureter.
2. Blunt trauma with either gross (visible) hematuria or shock (defined as any recorded systolic blood pressure <90 mm Hg): Patients having sustained blunt trauma with microhematuria only can safely avoid renal imaging.
3. Blunt trauma in the setting of significant deceleration injury, for example, falls from heights or motor vehicle accidents: This mechanism of injury has been associated with a higher incidence of ureteropelvic junction disruption as well as renovascular trauma.
4. Pediatric penetrating injury or blunt trauma with microhematuria >20 red blood cells (RBCs) per high-power field (HPF): There is increasing evidence that the adult imaging criteria outlined above will identify the majority of significant renal lacerations in children, but this remains controversial. The surgeon should continue to maintain a low threshold for renal imaging in the pediatric population.

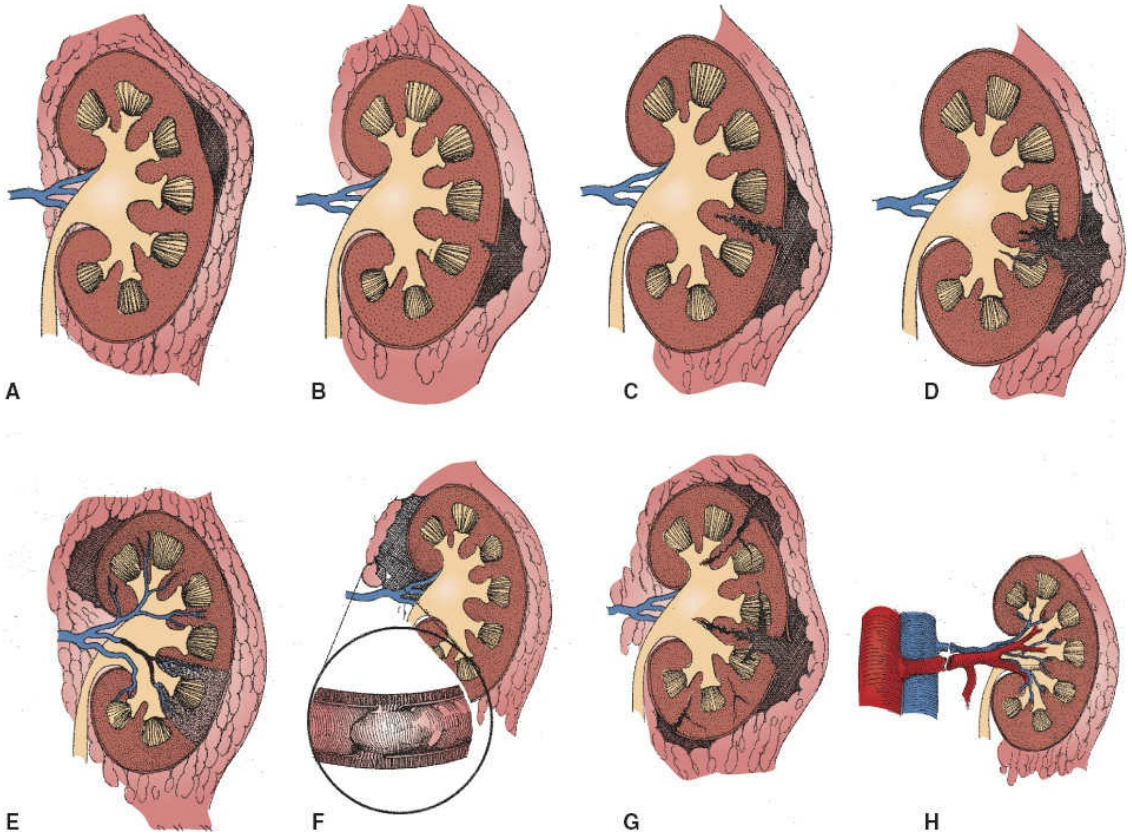

Figure 180.3. Renal injury classification. Renal injuries are

classified by the American Association for the Society of Trauma Organ Injury Scale. Grades 1 and 2 are considered minor renal injuries, only rarely requiring intervention, while grades 3, 4, and 5 are considered major renal injuries. **A.** Grade 1 is contusion or contained subcapsular hematoma without parenchymal laceration. **B.** Grade 2 is a nonexpanding, confined perirenal hematoma or cortical laceration less than 1 cm deep without urinary extravasation. **C.** Grade 3 is a parenchymal laceration extending greater than 1 cm into the cortex, but without urinary extravasation. **D.** Grade 4 can be parenchymal or vascular injury. Parenchymal grade 4 injuries are those with a laceration extending through the corticomedullary junction and into the collecting system. A segmental vessel may also be lacerated. **E.** Grade 4 vascular injury consists of a segmental renal artery thrombosis without a parenchymal laceration. Renal arteries are end-arteries and the area of parenchyma subtended by the injured segmental artery will be ischemic. **F.** Grade 5 injuries are multiple and consist of shattered kidneys, pedicle avulsion, or main renal artery thrombosis. These are life-threatening by nature. Main renal artery thrombosis is generally due to intimal disruption with resultant thrombosis, which can be observed in the close-up of the figure. **G.** Grade 5 injury can also be a "shattered" kidney, consisting of multiple major lacerations. **H.** Avulsion of the main renal artery and/or main renal vein is also a grade 5 injury. (Adapted from Nash PA, Carroll PR. Staging of renal trauma. In: McAninch JW, ed. *Traumatic and Reconstructive Urology*. Philadelphia, PA: WB Saunders; 1996.)

Contrast-enhanced CT scanning has replaced intravenous pyelography (IVP) as the imaging modality of choice in renal trauma patients. CT is noninvasive and offers rapid and accurate detection of renal injuries, as well as associated injuries to other organs. CT defines depth and extent of lacerations, a functioning contralateral kidney, the presence of associated hematoma, and contrast extravasation, which suggests injury through the collecting system, as well as any devitalized renal parenchyma. Consideration must be given to each of these factors when deciding upon a treatment plan.

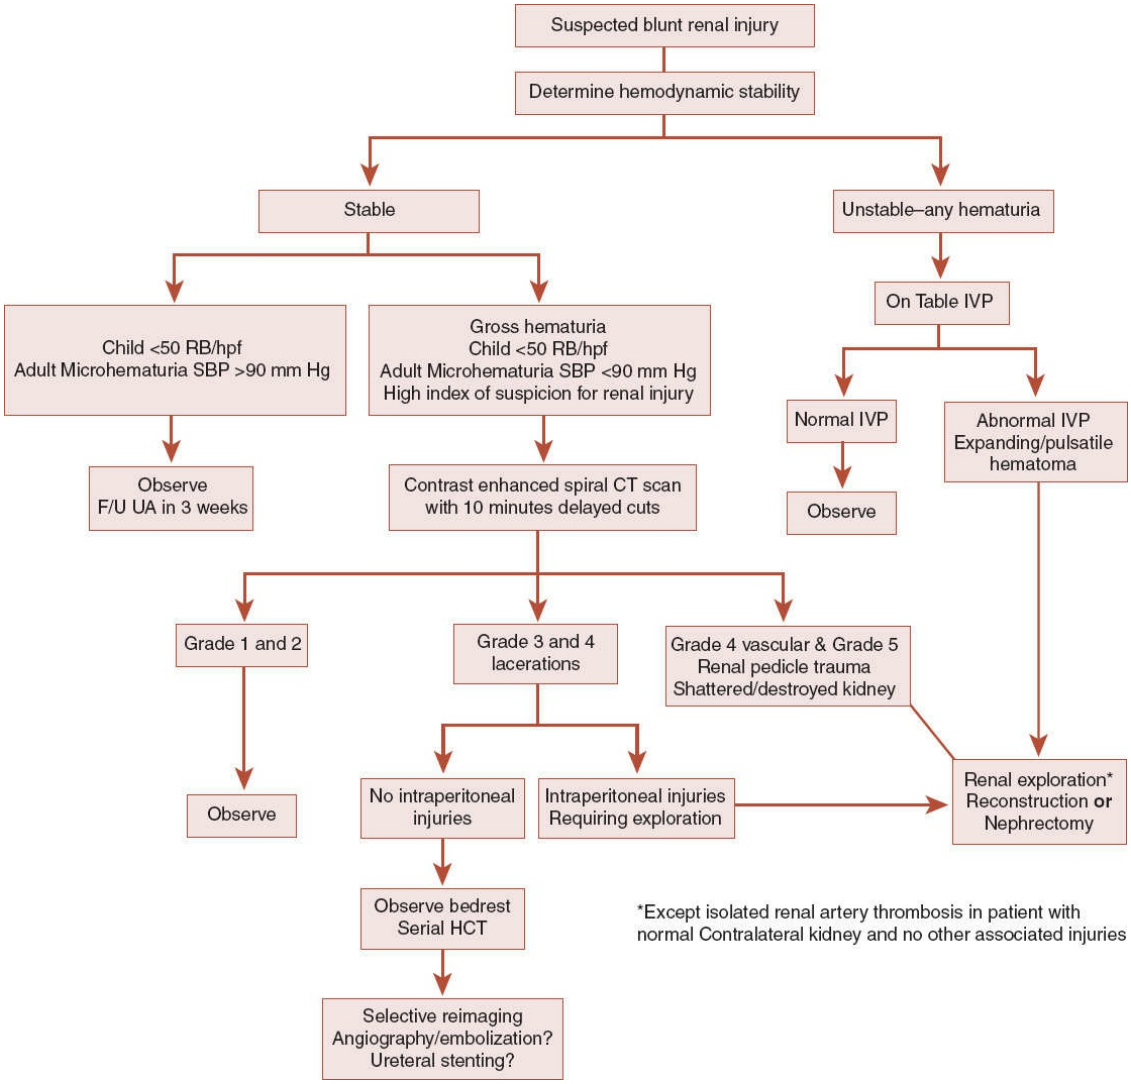

Figure 180.4. Suspected blunt renal trauma algorithm. CT, computed tomography; HCT, hematocrit; HPF, high-power field; IVP, intravenous pyelogram; RBC, red blood cell; SBP, systolic blood pressure. (Adapted from Santucci RA, Wessels H, Bartsch G, et al. Evaluation and management of renal injuries: consensus statement of the Renal Trauma Subcommittee. *BJU Int* 2004;93:937.)

Helical (or spiral) CT scanning has been supplanting traditional CT scanning because of its speed in the trauma setting. The patient may pass through the scanner in a few minutes. This has limited use in fully staging renal injuries, because contrast may not have reached the renal calyces or renal pelvis before the images are obtained. Significant collecting system injuries may thus be missed. We routinely obtain a set of delayed images at 10 minutes in order to visualize the entirety of the collecting system down through the bladder. If this is not possible, a plain abdominal

radiograph (kidney-ureter-bladder [KUB]) at this time may add complementary information to the CT scan. While CT may accurately demonstrate parenchymal lacerations, it has limited use in staging renovascular injuries. A renal vein laceration may be suspected by the finding of hematoma medial to the renal hilum. Adjunctive radiographic imaging techniques include renal ultrasound, nuclear scintigraphy, magnetic resonance imaging (MRI), and retrograde pyelography. None of these is recommended as a first-line study in the acute setting.

INDICATIONS FOR SURGICAL EXPLORATION

The vast majority of renal injuries are contusions or minor lacerations, and may thus be managed nonoperatively if adequately staged. Appropriate radiographic staging has also permitted selective nonoperative management of major lacerations in both blunt and penetrating trauma (Figs. 180.4 and 180.5). In a recent series of grade 4 lacerations at San Francisco General Hospital, 22% were successfully managed nonoperatively. Penetrating injuries more commonly require laparotomy because of associated injuries or hemodynamic instability. In our experience, however, 55% of stab wounds and 24% of gunshot wounds are successfully managed expectantly through the use of careful selection and complete clinical and radiographic staging. If expectant management is selected in the setting of a major renal laceration, close monitoring with serial hematocrit measurements and liberal use of repeat imaging, especially at 36 to 48 hours, is indicated.

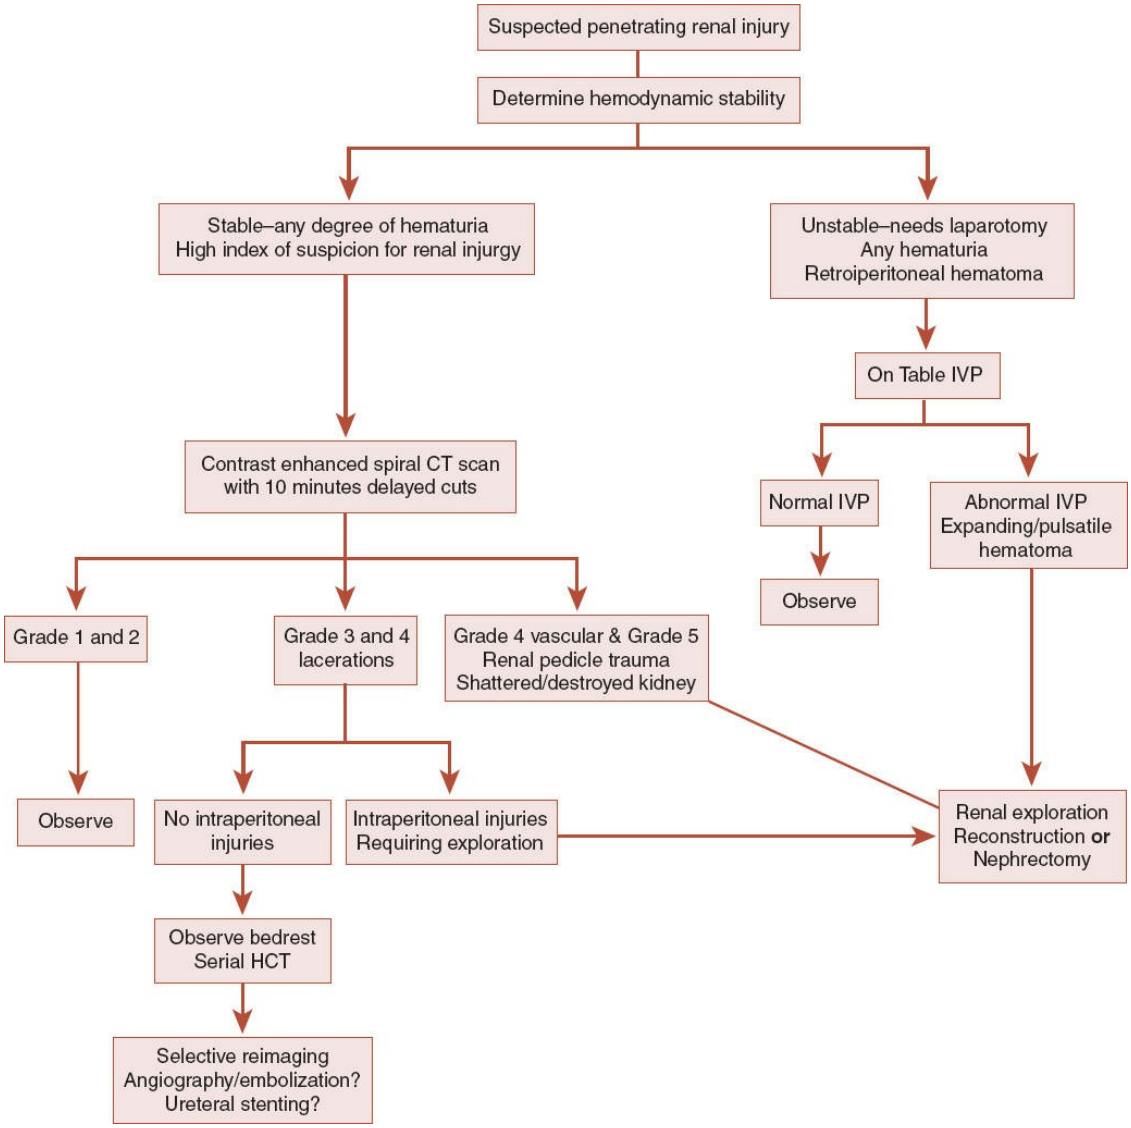

Figure 180.5. Suspected penetrating renal trauma algorithm. CT, computed tomography; HCT, hematocrit; IVP, intravenous pyelogram. (Adapted from Santucci RA, Wessels H, Bartsch G, et al. Evaluation and management of renal injuries: consensus statement of the Renal Trauma Subcommittee. *BJU Int* 2004;93:937.)

The only absolute indications for surgical exploration in renal trauma are persistent, life-threatening hemorrhage believed to be from renal injury, renal pedicle avulsion, and expanding, pulsatile, or uncontained retroperitoneal hematoma. These patients often present in severe shock, and it is thus rare for these patients to have undergone radiographic staging prior to emergency laparotomy. In the setting of renal pedicle avulsion or a severely shattered kidney, reconstruction may be impossible, and nephrectomy may be lifesaving.

Relative indications for renal exploration include incomplete staging, devitalized renal parenchyma, vascular injury, and urinary extravasation. In a hemodynamically unstable patient, radiographic assessment is not possible prior to laparotomy, and there may be an unexpected retroperitoneal hematoma found at the time of laparotomy in the trauma patient. At this time, if the patient's clinical condition permits, a single abdominal plain film taken 10 minutes after the bolus administration of 2 mL/kg of intravenous contrast, delivered as a bolus, in a normotensive patient is quite helpful. This is known as a "one-shot" IVP. This film is most helpful for confirming the presence of a normally functioning contralateral kidney and may possibly help to diagnose the injury in the affected renal unit. In addition, all patients with penetrating trauma and incomplete preoperative staging and a retroperitoneal hematoma require exploration. Although the one-shot IVP may be indeterminate, a recent study found that it successfully obviated renal exploration in 32% of patients in whom it was required. Furthermore, this approach has not been found to increase the rate of unnecessary nephrectomy. The initial laparotomy is the optimal time for any required renal reconstruction. Delayed exploration has resulted in nephrectomy rates as high as 50%.

PARENCHYMAL INJURY

Significant amounts of devitalized renal parenchyma are often best managed by early surgical debridement. Expectant management of patients with devitalized fragments and associated intra-abdominal injury may lead to a higher rate of abscess and infected urinoma formation as well as delayed bleeding. Immediate exploration in this setting reduced the posttrauma complication rate from 82% to 23%. This result suggests that major renal lacerations with devitalized fragments and associated intra-abdominal injuries should be immediately repaired, particularly if a laparotomy is already planned by the trauma surgeon. Additionally, patients with a major devitalized fragment associated with urinary extravasation and a significant hematoma are ultimately best treated by early exploration and reconstruction, even without concomitant intraperitoneal injury. However, the nonoperative approach in this situation may be more prudent for the surgeon who rarely undertakes renal exploration in the trauma setting, as the chance of unnecessary nephrectomy is increased.

Urinary extravasation signifies collecting system violation secondary to

a major renal laceration, but does not specifically mandate surgical repair. The collecting system may be violated at a fornix, at a minor or major calyx, or even through the renal pelvis and ureteropelvic junction (UPJ). While the majority of lacerations into fornices and minor calyces will seal spontaneously, larger degrees of extravasation may leak for a prolonged period and are less likely to resolve spontaneously. Serial CT scans are mandatory in the management of these patients. The first scan should be obtained at approximately 36 to 48 hours postinjury in order to rule out the development of significant new complications. Intervention is indicated in the setting of sepsis, ongoing leakage, or significant urinoma formation. In these cases, placement of an indwelling ureteral stent or even a nephrostomy tube may speed resolution of extravasation. Lacerations of the renal pelvis usually do not resolve spontaneously, and should be surgically repaired. Similarly, UPJ avulsion mandates surgical repair. These unusual injuries are more commonly found in the setting of deceleration injury or in children, but may also take place in adults with an undiagnosed congenital anomaly such as UPJ obstruction. CT findings that suggest UPJ avulsion include nonvisualization of the ipsilateral ureter and medial extravasation of contrast material. When a kidney injured by a gunshot wound shows continued extravasation at the time of the first repeat CT scan, the surgeon should also maintain a low threshold for repair. These injuries are often associated with significant devitalized parenchyma secondary to blast effect, especially when a high-velocity missile has been used, and are unlikely to heal spontaneously.

VASCULAR INJURY

Major injury to the main renal artery or vein usually requires operative management. These patients have higher rates of complications, renal loss, and mortality when compared to those with nonvascular renal injuries. CT findings consistent with main renal artery injury include lack of renal enhancement or abrupt cutoff of an enhancing artery. Segmental arterial injuries typically appear as wedge-shaped infarcts with the apex facing the renal hilum. Injuries to the main renal vein typically appear as central or large hematomas that may displace the kidney anteriorly. Vascular injuries typically occur secondary to deceleration trauma causing the disruption of the inelastic intimal layer with subsequent irreversible parenchymal ischemia and infarction.

Despite the ongoing advances in trauma care, successful renal salvage

after major renovascular injury only occurs in 25% to 35% of cases, at best. Time to reperfusion is the major factor in determining the ultimate outcome. Renal function is significantly impaired following 3 hours of total and 6 hours of partial ischemia. Despite technically successful repair, late hypertension occurs in approximately 50% of renal arterial injuries managed nonoperatively, compared to 57% that were revascularized. Renal arterial repair should be reserved for solitary kidneys, for bilaterally injured kidneys, and in the rare situation of detection within 6 hours of injury. Endovascular stenting may have a limited role, as maintaining patency requires anticoagulation, which is rarely possible in the traumatically injured patient. If detection of renal artery thrombosis is delayed and laparotomy is otherwise indicated, nephrectomy should be performed at that time. Otherwise, the kidney may be allowed to atrophy, with delayed nephrectomy performed if hypertension develops.

RENAL EXPLORATION AND RECONSTRUCTION

Proximal Vascular Control

Primary goals for exploration/reconstruction include control of renal hemorrhage, preservation of maximal parenchyma, and reduction of potential complications attributable to the injured kidney. Historically, renal exploration in the trauma setting usually resulted in total nephrectomy. Using a refined approach to proximal vascular control and a meticulous approach to reconstruction, it is possible to salvage the vast majority of injured kidneys requiring surgical exploration.

The reason behind unplanned nephrectomy in the trauma setting is uncontrolled hemorrhage. We therefore routinely obtain proximal vascular control prior to opening the retroperitoneal hematoma. While temporary vascular occlusion is rarely necessary (approximately 17% of renal explorations at our institution), there is no accurate method of determining which kidneys will require this maneuver during the subsequent reconstruction. Those who have presented series suggesting pedicle control can be safely obtained if necessary following the release of the perinephric hematoma have reported nephrectomy rates approximately three times higher than those with early vascular control.

The traumatized kidney should be explored through a midline transperitoneal incision extending from the xiphoid process to the pubic symphysis. Except in cases of renal pedicle avulsion, all associated intra-abdominal injuries (spleen, liver, pancreas, small and large intestine)

should be addressed before renal exploration, thus allowing Gerota fascia to maintain its natural tamponade effect on the hematoma.

The approach to the injured kidney begins with proximal vascular control. A Bookwalter self-retaining retractor should be used if available. The transverse colon is wrapped in moist laparotomy sponges and placed on the chest (Fig. 180.6A). The small intestine is placed in a bowel bag and retracted superiorly and to the right. This exposes the root of the mesentery and the ligament of Treitz and the underlying great vessels. The retroperitoneal incision is made over the aorta superior to the inferior mesenteric artery and extending up to the ligament of Treitz (Fig. 180.6B). If a large retroperitoneal hematoma obviates easy palpation of the aorta at the level of the ligament of Treitz, the incision may be made medial to the inferior mesenteric vein. This vein is an important guide, running a few centimeters left of the aorta. It is easily identifiable, even in the presence of a large hematoma. Dissection should be carried superiorly along the anterior wall of the aorta until the left renal vein is identified crossing anterior to it. This vessel is encircled but not occluded with a vessel loop, allowing for retraction. The encircled left renal vein serves as a guide to the remaining renal vessels, each of which is then encircled in vessel loops. These vessels are all left unoccluded unless heavy bleeding is encountered during the renal dissection. In our experience, most bleeding is successfully controlled with manual compression alone. Temporary renal vascular occlusion should be kept below 30 minutes to minimize warm ischemic damage. After vascular control has been successfully achieved, the injured kidney may be exposed by mobilizing the ipsilateral colon along the white line of Toldt and reflecting it medially. Gerota fascia is then incised along the lateral aspect of the kidney in order to completely expose the kidney. Care should be taken to maintain the integrity of the renal capsule as the kidney is mobilized in order to decrease hemorrhage and preserve the capsule for later closure.

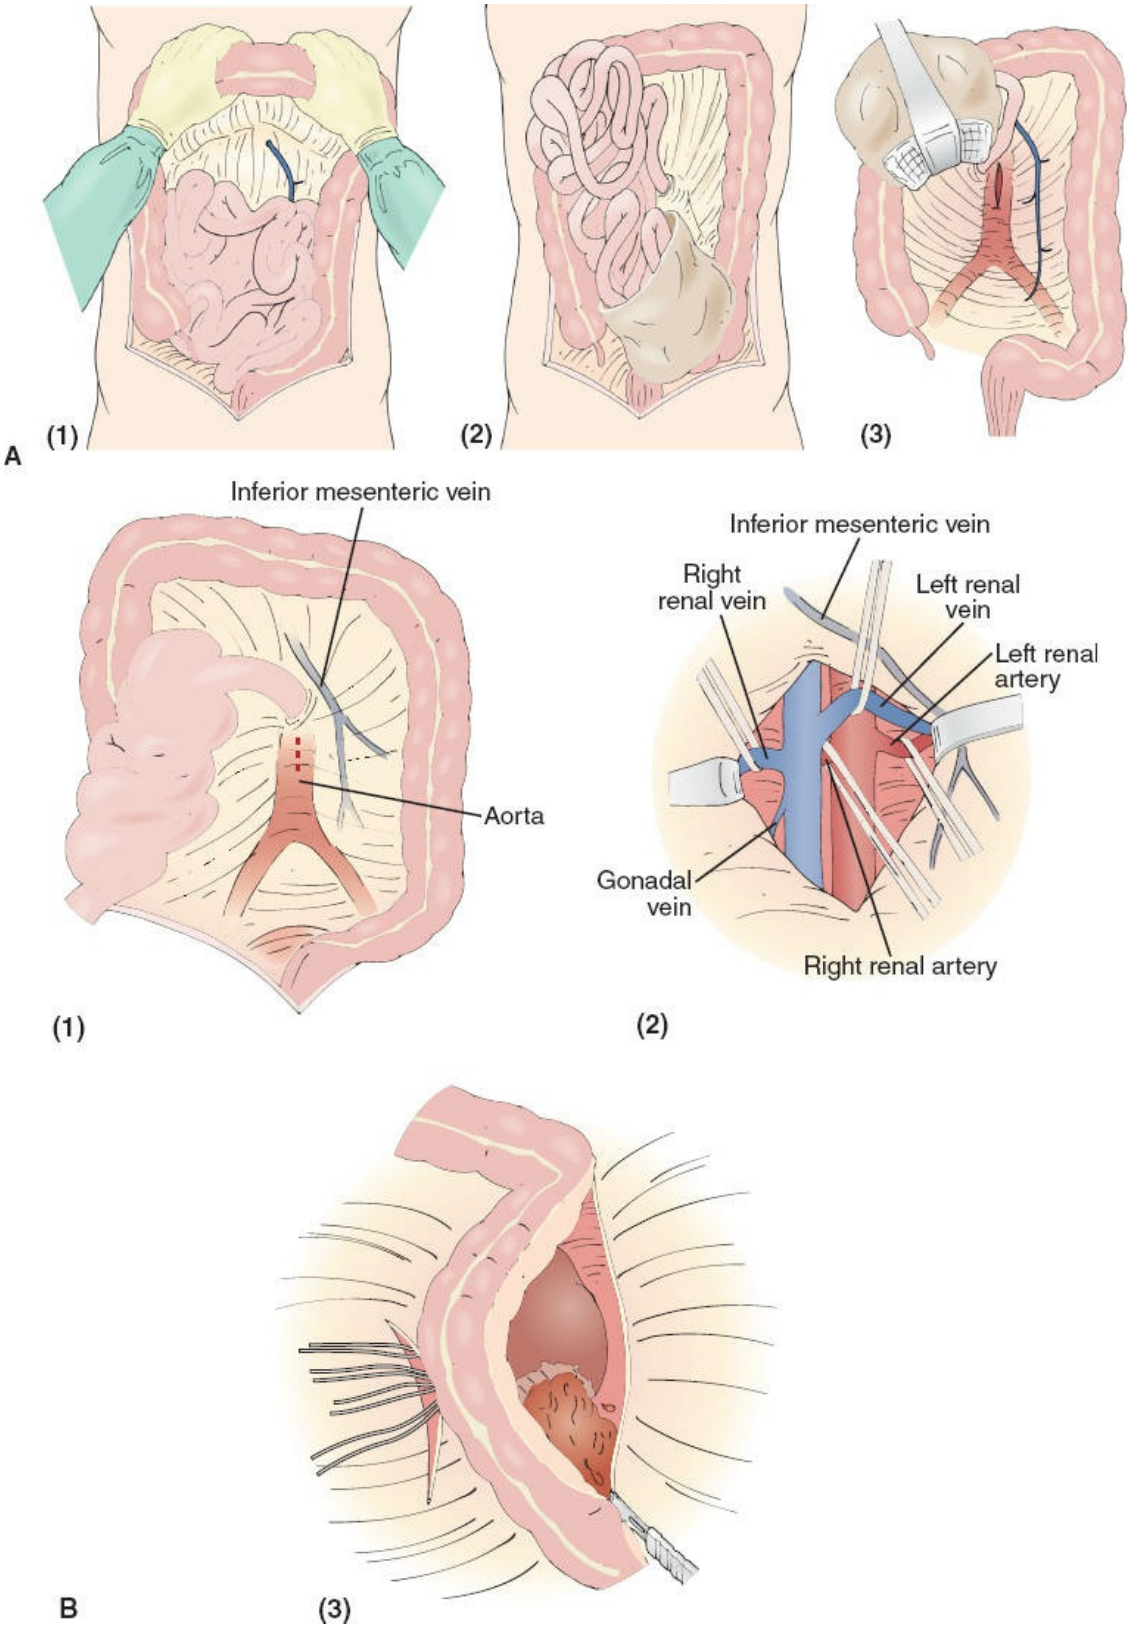

Figure 180.6. A. Optimal exposure for proximal vascular control. **(1)** A midline laparotomy, extending from xiphoid to pubis, should be made, if it has not already been made by the trauma surgeons. It is important to ensure especially that the superior extent of the incision is as high up as possible. The first

maneuver is to place the transverse colon onto the chest. **(2)** The small bowel is reflected out of the body toward the right nipple. **(3)** Small bowel contents are placed into a bowel bag or covered in moist laparotomy pads. The root of the small bowel mesentery should be visible, allowing for excellent visualization of the posterior peritoneal incision overlying the aorta from the ligament of Treitz to the aortic bifurcation. (From Brandes SB, McAninch JW. Surgical exposure and repair of the traumatized kidney. *Atlas Urol Clin North Am* 1998;6(2):32.) **B.** Surgical approach to the renal vessels and kidney. The overlying principle is that of proximal vascular control. **(1)** The posterior peritoneum is incised over the aorta medial to the inferior mesenteric vein. **(2)** The renal vessels are isolated with vessel loops to secure, but not occlude, the vessels. This should be done in the following order: left renal vein, left renal artery, right renal vein, right renal artery. **(3)** After the renal vessels are secured, an incision is made in the posterior peritoneum lateral to the colon, exposing the kidney. (From McAninch JW. Surgery for renal trauma. In: Novick AC, Pontes ES, Streem SB, eds. *Stewart's Operative Urology*. 2nd ed. Baltimore, MD: Williams & Wilkins; 1989:235.)

Principles of Reconstruction

The general principles that are applicable to all renal reconstructions include the following: (a) broad exposure of the entire kidney; (b) temporary vascular occlusion for bleeding not arrested by manual compression of the parenchyma; (c) sharp debridement of nonviable parenchyma; (d) meticulous hemostasis; (e) watertight collecting system closure; (f) primary reapproximation of the parenchymal edges (renorrhaphy) or coverage of the parenchymal defect; (g) omental interposition flap placement to separate reconstructed kidney from surrounding pancreatic, colonic, or vascular injuries; and (h) retroperitoneal drain placement.

The kidney should be débrided sharply back to viable, bleeding parenchyma. Approximately 30% of one normally functioning kidney is required to avoid dialysis, which may serve as a guide in determining whether renal salvage should be undertaken. Major polar injuries are best managed with partial nephrectomy, while lacerations to the midkidney should undergo renorrhaphy. Hemostasis is performed by individually suture-ligating arterial vessels with 4-0 chromic sutures. We then place hemostatic agents such as thrombin-soaked Gelfoam bolsters or FloSeal

between the cut parenchymal edges. The collecting system is then inspected for obvious tears. Injection of 2 to 3 mL of methylene blue into the renal pelvis (using a 27-gauge needle) may demonstrate these openings more clearly. They are then oversewn with running 4-0 chromic suture. A stent is placed only in cases of significant renal pelvis or ureteral injuries, but not in simple calyceal injuries. In a deep, slit-like parenchymal laceration from a knife or sword, the thin parenchymal defect will not permit easy access to the collecting system, and we rely on closure of the overlying parenchyma to seal the collecting system.

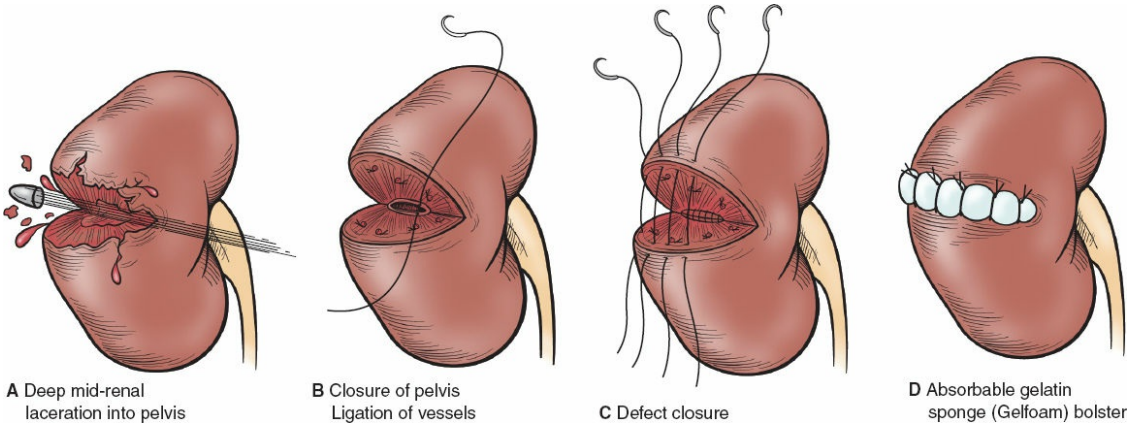

Figure 180.7. Renorrhapy technique. **A.** A deep midrenal laceration is depicted, with collecting system entry. **B.** Sharp debridement is carried out to viable tissue edges. Following this, the collecting system is closed with absorbable suture and discrete end-arteries are suture-ligated. **C.** Interrupted polyglactin (e.g., Vicryl) 2-0 sutures are placed into the renal capsule. After these are placed, thrombin-soaked absorbable gelatin sponges such as Gelfoam are placed as bolsters into the defect. **D.** The parenchyma is approximated by tying the capsular sutures loosely so that they do not rip through the capsule. (From McAninch JW. Surgery for renal trauma. In: Novick AC, Pontes ES, Streem SB, eds. *Stewart's Operative Urology*. 2nd ed. Baltimore, MD: Williams & Wilkins; 1989:238.)

If the renal capsule is intact and viable, it should be used to close the parenchymal defect primarily without tension. If the capsule has been destroyed or the defect is too large to close primarily without causing ischemia, an omental flap can be used. The omentum is guided through the paracolic gutter to reach the kidney, and sutured to the defect. If omentum is not available, the defect may be covered with perinephric fat or a peritoneal free graft; however, these are less desirable options. In the case

of a shattered kidney or multiple deep lacerations, the kidney may be placed in an envelope of Vicryl mesh to stabilize the repair.

Following reconstruction involving the collecting system, a Penrose drain is placed adjacent to the kidney and connected to a urostomy bag to drain any leak if necessary. Alternatively, a closed system drain such as a Jackson-Pratt drain may be used, but the bulb should not be placed on suction, as this negative pressure promotes prolonged urinary drainage. These drains are typically removed after 48 to 72 hours unless output is high, in which case the drainage creatinine should be measured. If the creatinine value suggests a urine leak, the drain is left in place for a more prolonged period. Placement of an indwelling ureteral stent may help to expedite sealing of a persistent urine leak.

Specific Techniques

Renorrhaphy is appropriate for lacerations involving the interpolar aspect of the kidney or polar lacerations with a limited amount of devitalized tissue (Fig. 180.7). This technique employs all the principles outlined above. Following debridement and hemostasis, the collecting system is closed. The residual wedge-shaped defect is then closed over an absorbable thrombin-soaked Gelfoam bolster. Omental flaps are used in cases of large parenchymal defects. In order to identify the site of the repair on subsequent imaging studies, we place titanium surgical clips on the sutures, which approximate the capsular edges.

Extensive damage to the upper or lower renal poles usually requires partial nephrectomy (Fig. 180.8). The capsule should be dissected off the fractured parenchyma for use in defect coverage. Following hemostasis and collecting system closure as outlined above, the defect may be covered by capsule (if available) or alternatively by an omental pedicle flap as shown in the illustration.

VASCULAR INJURY AND REPAIR

Unlike parenchymal lacerations, renovascular injuries are frequently irreparable, and may result in nephrectomy. Proximal vascular control is particularly critical in these cases. Injury to the main renal vein typically results in significant hemorrhage and may require ligation. If reconstruction is feasible, the partially lacerated vein may be repaired with 5-0 Prolene suture following appropriate vascular clamping. Injuries to segmental veins may be safely ligated because of the extensive renal

venous collateral circulation.

As previously mentioned, the ultimate outcome of attempted renal arterial reconstruction is time-dependent. Segmental arterial injuries may be safely ligated, with fewer complications arising from the subsequently devascularized renal parenchyma. Alternatively, a partially lacerated segmental artery may be repaired with 5-0 or 6-0 Prolene suture.

In cases of main renal artery injury, the type of repair indicated relates to the extent and mechanism of injury. Penetrating injuries with incomplete transection may be primarily repaired using 5-0 Prolene sutures. Blunt injuries typically require thrombectomy and debridement of the damaged arterial segment. Ideally, a primary tension-free reanastomosis of the injured artery should be undertaken. If this is not feasible, we recommend an interposition vascular graft. While technically feasible, ex vivo renal reconstruction and autotransplantation into the iliac fossa is rarely indicated in the critically injured patient with multiple associated injuries.

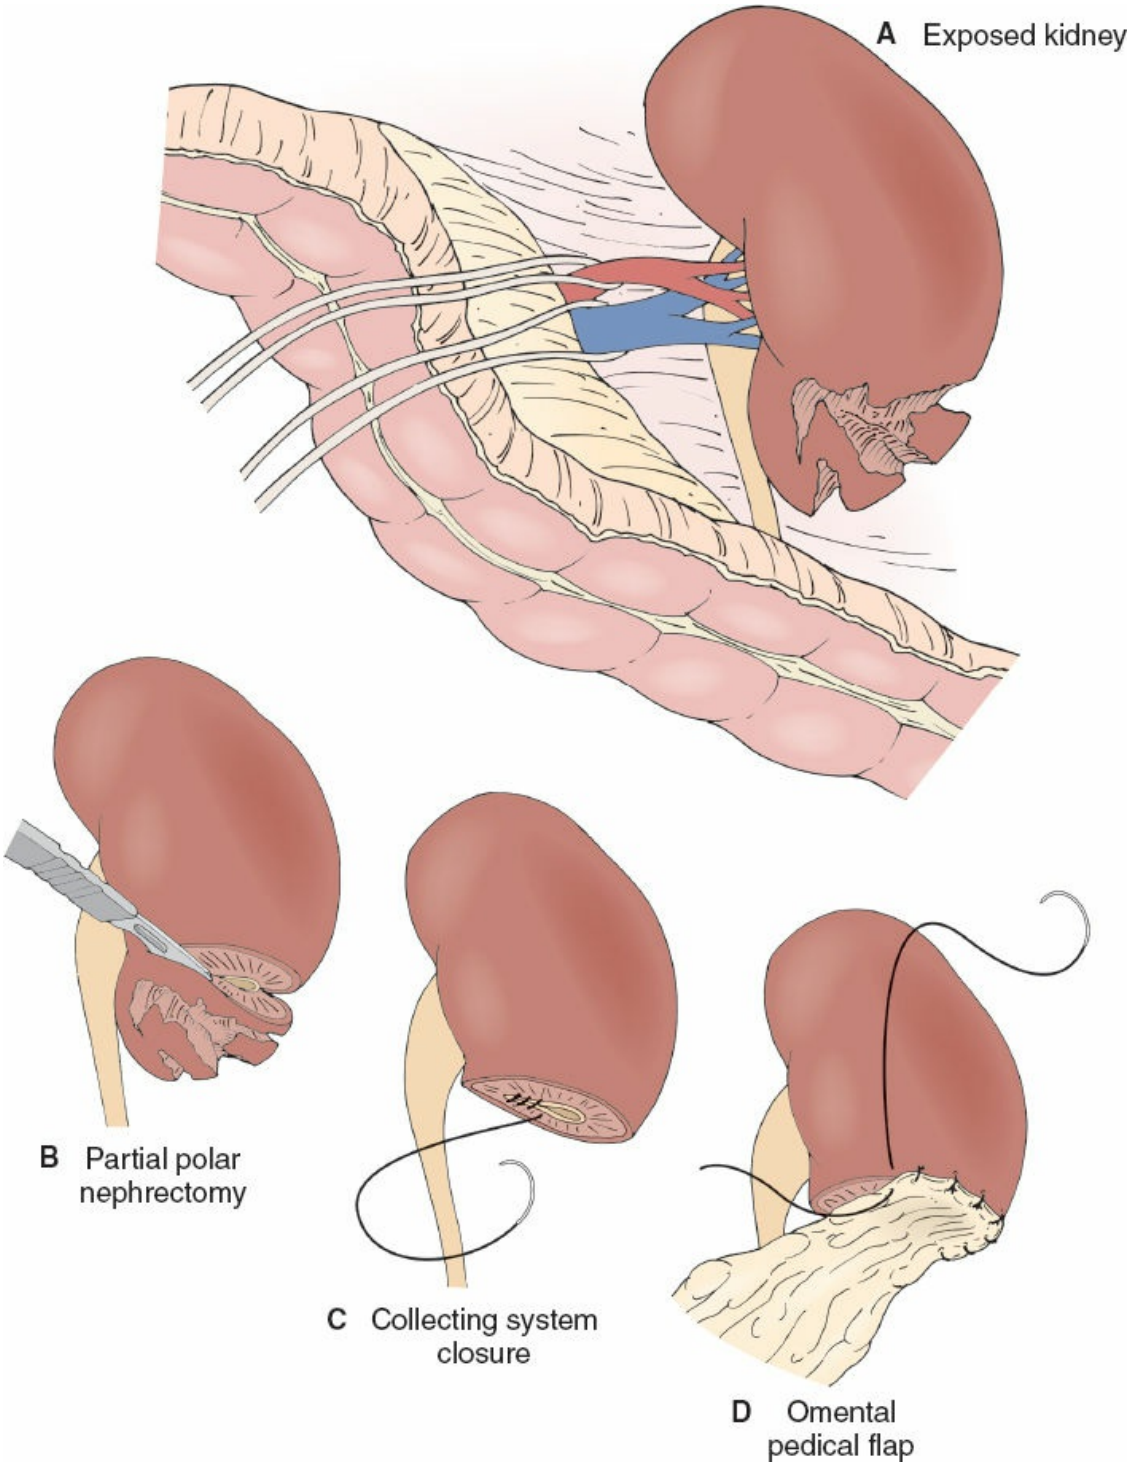

Figure 180.8. Partial nephrectomy technique. **A.** The kidney is totally mobilized to completely assess for injury. The ureter is carefully inspected. **B.** The nonviable renal tissue is sharply removed. Hemostasis is obtained with manual compression of the kidney during this maneuver. **C.** The collecting system is closed with absorbable suture and discrete end-arteries are oversewn. **D.** Defect coverage is done with omentum, or, alternatively, with residual capsule if it was preserved. (From McAninch JW. Surgery for renal trauma. In: Novick AC, Pontes

ES, Streem SB, eds. *Stewart's Operative Urology*. 2nd ed. Baltimore, MD: Williams & Wilkins; 1989:237.)

POSTOPERATIVE CARE AND COMPLICATIONS

A urethral catheter should be maintained until the patient is hemodynamically stable and mobile enough to void. The patient should be kept on bedrest until gross hematuria clears. We recommend obtaining an abdominal CT scan and radionuclide renal scan (DMSA scan) at approximately 3 months to quantify the function of the injured/reconstructed kidney. In our series of traumatically injured and subsequently reconstructed kidneys, the average differential renal function of the repaired kidney was 39%, corresponding to two thirds of one kidney.

The reported complication rate following renal injury ranges from 3% to 20%. Complication rates increase proportionately with increasing grade of injury and appear to be higher in kidneys managed nonoperatively. Our complication rate is approximately 10%. We have observed that the complication rate (attributable specifically to the kidney) for grade 4 injuries was similar for nonoperative and operative management, 5% and 4%, respectively. This is likely due to our higher rate of renal exploration (78% of grade 4 injuries) than other series, as well as our patient selection for nonoperative management. Complications may be divided into early (within 1 month) and late complications. Early complications include urinomas, delayed bleeding, urinary fistulae, abscesses, and hypertension. Late complications include hydronephrosis and renin-mediated hypertension (Fig. 180.9). Urinomas are the most common complication, and are usually successfully managed by endoscopic stenting and/or percutaneous drainage. Delayed bleeding typically occurs within 1 to 2 weeks of injury, and is more commonly associated with stab wounds. Angiography and selective embolization is both diagnostic and therapeutic in this case.

USE OF INTERVENTIONAL RADIOLOGY TECHNIQUES IN RENAL TRAUMA

Angioembolization

There is an increasing utilization of angioembolization in the management of bleeding in the traumatically injured population, but mostly in the form

of case reports and limited case series. This is most commonly done for embolization of pelvic vessel bleeding, rather than solid abdominal organs. The kidney, however, is well suited to angioembolization for bleeding after injury, mostly because the arteries and arterial branches supplying each part of the kidney are end-arteries. Prospective studies are needed to judge the long-term efficacy of this technique.

Endovascular Stents

For renal arterial thrombus without arterial avulsion, it occasionally may be feasible and safe to deploy an endovascular stent to restore arterial inflow, and there have been a few case reports describing this technique. However, many times patients have other visceral injuries such as splenic or hepatic injuries, preventing the use of anticoagulants, which would be required in the case of an endovascular stent. It is possible that new drug-eluting stents that are used in cardiac endovascular stenting may avoid this problem.

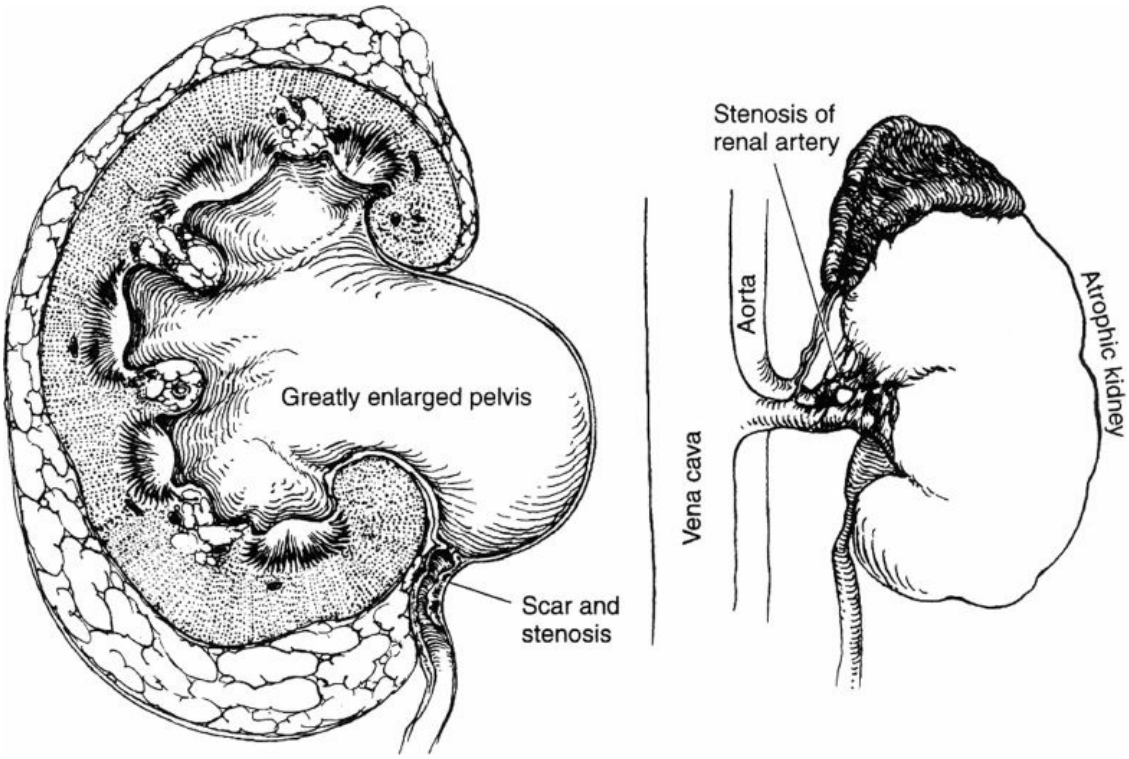

Figure 180.9. Late complications of renal injury. **Left:** Ureteropelvic stenosis with hydronephrosis secondary to fibrosis from extravasation of blood and urine. **Right:** Atrophy of kidney caused by injury (stenosis) of arterial blood supply.

COMPLICATIONS OF RENAL INJURIES

Hypertension may be seen in the setting of untreated arterial thrombosis and devitalized parenchyma. This has been documented in approximately 0.2% of cases. Posttraumatic hypertension is mediated by the renin–angiotensin system, and delayed nephrectomy is indicated in this setting if medical management fails. Arteriovenous fistula may present with hemorrhage, hypertension, or high-outpsut cardiac failure following a stab wound. Arteriography and fistula embolization usually characterize and treat the fistula successfully. Long-term follow-up is critical to check for development of hypertension, which may develop slowly.

URETERAL INJURY

Staging

The physical findings associated with ureteral injuries are nonspecific. Unless the surgeon maintains a high index of suspicion, the diagnosis may go unnoticed, with subsequent renal loss. Any patient who sustains a penetrating injury to the flank or abdomen is at risk for ureteral injury and warrants further evaluation (Fig. 180.10). There is a dearth of prospective data concerning management of ureteral injury. Ureteral trauma accounts for less than 1% of all urologic trauma. Iatrogenic trauma is the leading cause of ureteral injuries. Preoperative stent placement does not prevent injuries, but may assist in the identification of an injury. The vast majority of complications, including renal loss, occur when the diagnosis of ureteral injury is delayed. Diagnostic tests are often specific but not sensitive. The false-negative rate of hematuria is approximately 30%. IVP, but not a “one-shot” (single-view) IVP, is accurate at diagnosing injury. Abnormal IVP findings warrant further investigation (i.e., ureteral dilation or deviation, incomplete visualization of the entire ureter, delayed or no visualization of the renal unit, and urinary extravasation). In the modern era, most patients are imaged with CT scans, which must be performed with the delayed phase, which is at 10 minutes; otherwise, only parenchymal abnormalities will be noted. Thirty to forty-five percent of patients with ureteral injury do not have any degree of hematuria, a consistent finding seen in multiple reports. Most external ureteral injuries occur from gunshot wounds, and if a high-caliber bullet is used, a missile path even close to the ureter can cause significant delayed tissue destruction. Therefore, all periureteral gunshot wounds and associated

retroperitoneal hematomas, if noted during trauma laparotomy, should be explored. Visual ureteral inspection with or without intravenous or intraureteral dye injection is reliable. Ureteral injuries from blunt trauma are rare. They usually occur in children during rapid deceleration, causing excessive hyperextension and disruption at the UPJ. Most traumatically injured patients are usually polytraumatized and have associated multiple organ injuries (liver, spleen, and skeletal system).

Principles of Reconstruction

Prompt treatment of ureteral injuries is required to prevent significant patient morbidity in terms of the development of persistent low-grade fevers, flank and lower quadrant pain, and paralytic ileus, which are all due to urinoma development. Occasionally patients can develop ureterovaginal (usually after gynecologic procedures) or ureterocutaneous fistulae. Proximal urinary drainage via a percutaneous nephrostomy tube may be required if the injury is recognized only in a delayed fashion, or if the injured patient has other significant complications that make immediate reconstruction impossible. The important principles underlying all ureteral repairs are to achieve tissue debridement to viable tissue and a tension-free, spatulated, water-tight repair that is stented and drained via a retroperitoneal drain. If there are simultaneous bowel, pancreatic, or vascular injuries, it may be prudent to isolate the repair with omentum. Stents are important in this repair as they maintain a ureter with a constant caliber during early healing, prevent extravasation, and provide a conduit for urine during healing. They should be left in place for 8 weeks and can be removed using endoscopy and local anesthesia.

Techniques of Reconstruction

The ureter can be conveniently divided into thirds when considering different types of repair: lower, mid, and upper ureter. Injuries to the lower ureter can usually be managed with a reimplantation of the proximal end of the ureter directly into the bladder, as the bladder is mobile enough to be brought to the ureter for lower ureteral injuries. Ureteral reimplantation should be done in an antirefluxing fashion whenever possible (Fig. 180.11) in order to prevent long-term kidney infection and damage. Reimplantation is usually done with the bladder fixed to the psoas muscle, termed a “psoas hitch” (Fig. 180.12), with nonabsorbable sutures in order to prevent tension on the anastomosis. However, if the ureter has been ligated but not

transected during a pelvic surgical procedure, a primary ureteroureterostomy may be performed. Finally, a transureteroureterostomy (Fig. 180.13) can be used in lower ureteral injuries when there is significant scarring and pelvic infection, which may be preferable as the ureteral anastomosis is far from any ongoing pathologic processes.

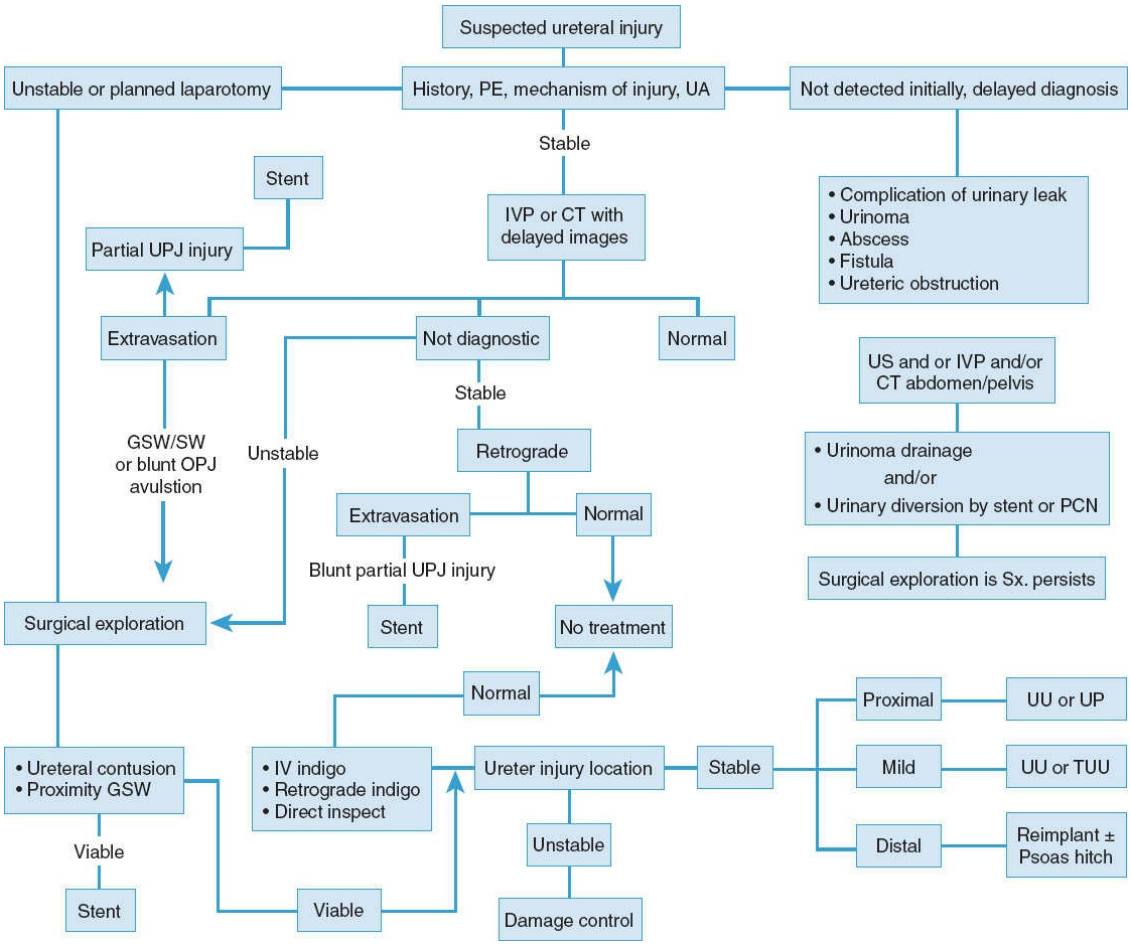

Figure 180.10. Suspected ureteral injury algorithm. CT, computed tomography; GSW, gunshot wound; IVP, intravenous pyelogram; PCN, percutaneous nephrostomy; PE, pulmonary embolism; SW, stab wound; TUU, transuretero-ureterostomy; UA, urine analysis; UP, ureteropyleostomy; UPJ, ureteropelvic junction; US, ultrasound; UU, uretero-ureterostomy. (Adapted from Brandes S, Coburn M, Armenakas N, et al. Diagnosis and management of ureteric injury: an evidence-based analysis. *BJU Int* 2004;94:277.)

Midureteral injuries comprise the majority of injuries from external violence. This injury is best managed with either a primary ureteroureterostomy (Fig. 180.14) or a transureteroureterostomy. The

ureter will usually need to be mobilized distally in order to provide sufficient length. It is critical to avoid devascularizing the ureter, as this will guarantee failure of the repair. Leaving a generous amount of periureteral fat surrounding the ureter may assist in preserving vascularity. Occasionally, the kidney will need to be mobilized downward and fixed with permanent suture to provide ureteral length.

Upper ureteral injuries are best managed with primary ureteroureterostomy. If there is extensive ureteral loss, then a segment of ileum can be harvested to provide a ureteral replacement. Rarely, autotransplantation of the kidney can be performed. This is not advised in the trauma situation as it adds to the length of time on the operating table.

Bladder Trauma

Bladder trauma occurs generally from external forces, but may also be due to iatrogenic/instrumentation-related trauma. A high index of suspicion needs to be maintained in intoxicated individuals with a full bladder who sustain even mild trauma and complain of abdominal pain, as they may have sustained a bladder rupture. Fifteen percent of all pelvic fractures are associated with concomitant bladder or urethral injury, but, conversely, 90% of bladder ruptures are associated with pelvic fractures. Data for management guidelines of bladder trauma are primarily from retrospective analysis (Fig. 180.15). Physical examination is vital, especially a vaginal speculum examination in women, as vaginal lacerations or traumatic communication between the bladder and vagina may occur, which can lead to disastrous results if missed. Gross hematuria is the cardinal sign of a bladder rupture (>95%). Static and CT cystograms are both effective at diagnosing bladder injury, but must be performed with an appropriate amount of contrast (350 to 400 mL). Ultrasound is not effective for diagnosis of rupture. Passive bladder filling is unacceptable and the injury may be missed, even on CT scan. Serious complications, including death, may ensue with a delayed diagnosis. Intraperitoneal lacerations should all be surgically repaired. Extraperitoneal perforations can generally be managed with a catheter providing urinary drainage. However, repair of extraperitoneal perforations should be performed if other surgical services are operating on the patient; if there is a suspicion of bladder neck, vaginal, or rectal injury; if there is a failure of the catheter to provide adequate drainage; or if bleeding is causing catheter malfunction. The catheter can generally be removed on the 10th postoperative day, but a

cystogram should be performed as less than or equal to 15% of bladders may not be healed. With the increasing utilization of laparoscopic technology for more complex surgery, there appears to be a trend of increased iatrogenic bladder injury.

Principles of Reconstruction

If the bladder is the only organ to be repaired, a lower midline abdominal incision should be made. The bladder should be approached in the midline to avoid pelvic hematomas, which are usually lateral. Entering the hematoma is not advisable as release of tamponade can result in significant bleeding and the hematoma itself can then be infected with urine.

For extraperitoneal ruptures, the bladder is opened in the midline and repaired intravesically, usually in two layers with 2-0 and 3-0 chromic or polyglycolic acid sutures. If the bladder neck is lacerated, careful attention should be paid to the repair; the patient will suffer from incontinence if not repaired. In female patients, a careful vaginal exam must be done to examine for the presence of lacerations, which should be repaired. If indicated, a peritoneotomy can be made at the end of the procedure to assess for the presence of bloody intra-abdominal fluid. Drainage via either a suprapubic tube or a urethral catheter is acceptable.

Intraperitoneal bladder ruptures should be repaired via a transperitoneal approach using a lower midline incision. All other bladder sidewall defects should be closed. The peritoneum should be closed over the area of injury, and the wall of the bladder itself should be closed in two or three layers. All urinary fluid should be removed from the peritoneum prior to closure. If a suprapubic tube is used for drainage, care should be taken that the suprapubic cystotomy is in the extraperitoneal position.

Urethral Trauma

Injuries to the urethra can be classified as either anterior or posterior urethral injuries. The posterior urethra is the most proximal portion of the urethra and begins at the bladder neck and continues through the prostate. This is referred to as the prostatic urethra, which then continues as the membranous urethra, which passes through the levator muscles and is surrounded only by the striated urethral sphincter. The prostatic and membranous urethras are together termed the posterior urethra. The anterior urethra is the remaining urethra, which continues to the urethral meatus, is surrounded by the corpus spongiosum and glans penis, and consists of the bulbar urethra and the pendulous urethra. Figure 180.16 shows an evidence-based algorithm for diagnosis and treatment of urethral injuries.

Anterior Urethral (Straddle) Injuries

Anterior urethral injuries are distinctly rare, encompassing at most 10% of urethral injuries. These injuries are most commonly caused by a blunt straddle-type injury, where the bulbar urethra is crushed upward against the pubic rami. Penetrating trauma to this region (stab or gunshot injury) is rarely encountered. Patients may present with blood per meatus or inability to void, or an expanding scrotal hematoma, which may contain extravasated urine. Retrograde urethrography is mandatory to diagnose this injury.

Because of the rarity of these injuries, management algorithms have been based upon small series. Most anterior urethral disruptions can be managed with immediate repair consisting of minimal debridement followed by tension-free, spatulated anastomotic repair. Other options include catheter alignment followed by delayed repair, or suprapubic urinary diversion followed by delayed repair. The latter option may lead to the best outcomes in the setting of shotgun blasts or high-velocity projectiles, as the true extent of devitalized tissue injury may only declare itself over time.

Posterior Urethral Injuries

The vast majority of membranous urethral injuries occur in association with a pelvic fracture, and more specifically with bilateral pubic rami fractures. The prostate is anchored behind the pubic rami via the puboprostatic (pubourethral) ligaments. When a deforming force fractures the pubic ramus and distracts the bony fragment superiorly and posteriorly, the resulting displacement will tear through the membranous urethra, typically at the point of departure of the bulbous urethra. The membranous urethra may rarely be injured by bullets or other projectiles. Thus, the physician encountering patients with pelvic trauma must maintain a high index of suspicion for urethral injury.

Appropriate early recognition and treatment of prostatomembranous urethral disruption significantly reduce long-term morbidity. Although these patients have often suffered critical orthopedic, vascular, and visceral injury, it is often the sequelae of the urethral injury (incontinence, erectile dysfunction) that cause the most morbidity after all the other injuries have healed.

Clinically, these patients present with blood at the meatus, inability to void, and a palpably full bladder. The prostate has been described as “high riding,” but this sign is unreliable, as a normal (nondisplaced) prostate may

be impalpable secondary to the surrounding pelvic hematoma. A perineal hematoma may or may not be present. Finding any of these signs warrants a retrograde urethrogram. An attempt at catheter placement in this setting prior to urethrography may have serious consequences if the urethra has been disrupted.

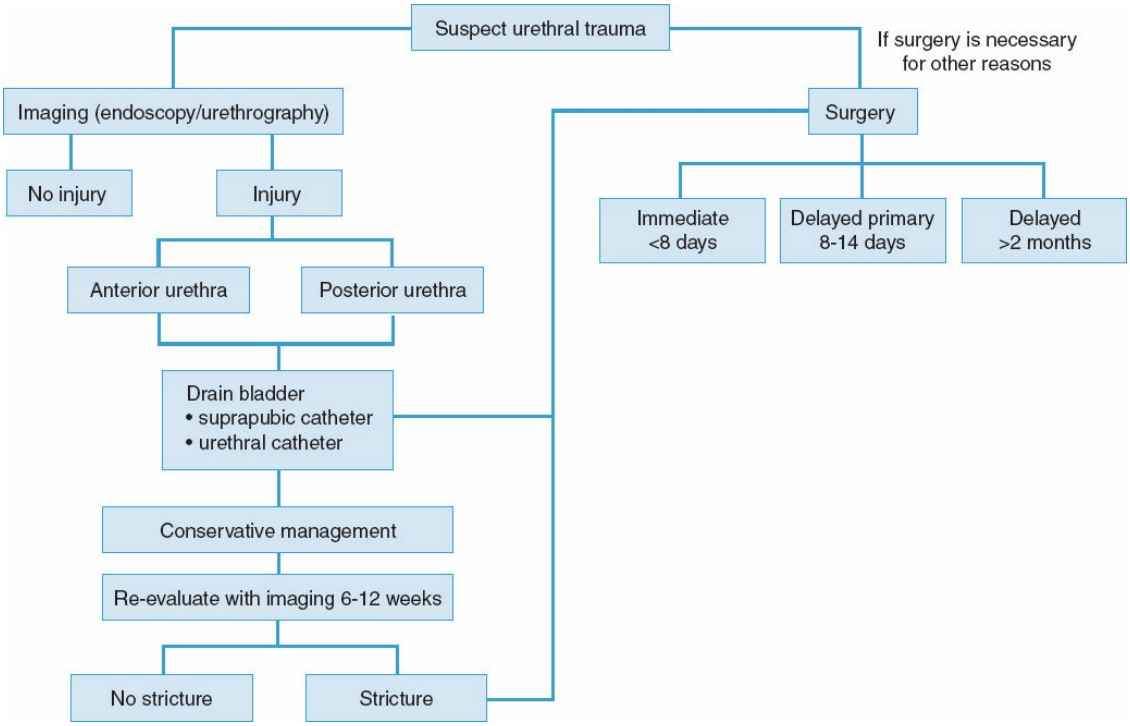

Figure 180.16. Urethral injury algorithm. (Adapted from Chapple C, Barbagli G, Jordan G. Consensus statement on urethral trauma. *BJU Int* 2004;93:1195.)

The findings on retrograde urethrography (RUG) dictate subsequent management steps. It is important to highlight that oblique/lateral decubitus views are necessary to adequately visualize the bulbous and membranous urethra. A normal RUG rules out significant urethral injury, and a Foley may then be placed for urinary drainage. Placement of the catheter in this setting should be immediately followed by a cystogram to rule out an associated bladder or bladder neck laceration.

If the RUG demonstrates extravasation of contrast at the level of the membranous urethra with or without bladder filling, a prostatomembranous urethral disruption is present. Initial and early management of these injuries remains a controversial topic. Current treatment options include suprapubic catheter placement alone followed by delayed reconstruction between 3 and 12 months, suprapubic catheter

placement followed by endoscopic placement of an aligning catheter (to bring the severed ends of the urethra into alignment), and urethral reconstruction in the early postinjury period. We advocate immediate suprapubic cystotomy followed by a delayed urethral reconstruction, as this method of management results in the best long-term success rate of urethral patency. Park and McAninch studied 78 patients with straddle injury–related bulbar urethral injuries. Patients who underwent primary realignment required more complex flap or graft urethroplasties. Success was 95% at a mean follow-up of 25 months. Recurrent strictures occurred in four men who were successfully managed by direct-vision internal urethrotomy.

Regardless of the management option chosen, the first priority is achievement of urinary drainage—typically with a suprapubic catheter. If the patient is stable and the surgeon has adequate expertise and equipment, an attempt to place an aligning catheter may follow. Endoscopic realignment does not appear to increase complications if properly performed, and may simplify a later posterior urethral reconstruction by bringing the urethral ends into alignment. However, most patients managed with aligning catheters will heal with a urethral stricture requiring operation at a later date.

Delayed primary sutured coaptation of the urethra (typically within a few days of the initial injury) is rarely employed in the United States, but this approach has gained enthusiasm in parts of Europe. This approach involves exploration of a maturing pelvic hematoma and placement of sutures into the prostatic apex and severed urethral margins. The long-term results in terms of restricture, continence, and erectile function have yet to be reported, but theoretic concerns exist regarding further injury to cavernous nerves and sphincter muscle fibers in this setting.

Open placement of a suprapubic catheter is indicated in a setting where bladder inspection and repair are planned, for example, in the case of a bladder neck laceration. A suprapubic catheter may also be placed at the time of concomitant orthopedic plating of the anterior pubic arch. Another absolute indication for open suprapubic catheter placement is in the case of simultaneous rectal or vascular injury. In these complicated cases, irrigation and drain placement are warranted, but no attempt to expose or repair the urethral disruption should be made at the time of the acute injury.

Delayed reconstruction may be undertaken between 3 and 12 months,

assuming that the patient has healed from other nonurethral injuries. It is beyond the scope of this chapter to outline technical aspects of posterior urethral reconstruction, but certain key points deserve mention. The vast majority of prostatomembranous urethral disruptions may be successfully repaired via a perineal approach in a single stage. Following excision of all the scar tissue separating the two urethral ends, the urethra is adequately mobilized to allow a tension-free anastomosis. Endoscopic techniques that attempt reconstruction by coring through the scar to bridge the defect ("cut to the light" procedures) between the two ends may have unacceptably high failure rates. Because of the complexity of this type of reconstructive surgery and the relative paucity of patients requiring it, it is best undertaken in referral centers where urologists have developed special expertise in this area.

External Genital Trauma

External genital trauma is relatively uncommon, but may be increasing in terms of proportional incidence, especially due to penetrating injury in war situations, because of the improvements in body armor, which decreases injury to the thorax and abdomen. There are multiple prospective studies concerning genital trauma, and different treatment approaches are described below. It is critical to remember that mismanagement of these injuries may result in significant physical and psychological consequences, which are often difficult to predict at the time of injury.

Testicular Trauma

Traumatic injuries to the testes and scrotum may result from either blunt or penetrating insults. The relative mobility of the testes usually allows it to swing away from crushing forces. The fibrous tunica albuginea usually protects the delicate seminiferous tubules within from further trauma. However, a significant deforming force may cause rupture of the tunica, clinically known as testicular fracture. Scrotal contusions that do not rupture the tunica but nonetheless produce significant hematomas within the wall of the scrotum may be clinically difficult to distinguish from a fractured testicle.

Although once believed to be rare, the risk of testicular rupture following major blunt scrotal trauma may be as high as 50%. The most common causes are assault and sports-related injuries, but testicular trauma may be self-inflicted in the unusual transsexual patient. Penetrating

trauma secondary to gunshot wounds is uncommon, but may rarely be self-inflicted from a loaded firearm misplaced in a pants pocket. Penetrating injury is more likely to require testicular exploration.

Clinical findings are often nonspecific, but usually include significant pain and a swollen, ecchymotic scrotum. Because of rapid expansion of the scrotal hematoma, it is often difficult to appreciate the testicular contour on physical examination. A history of forceful trauma should raise suspicion for testicular rupture. In penetrating trauma, associated injuries to the penis, perineum, and femoral vessels should be considered and ruled out.

While scrotal imaging may serve as a useful adjunct to physical examination in suspected testis trauma, the definitive diagnosis of testis rupture is made surgically. It is thus most appropriate to explore a grossly abnormal scrotum without ultrasonography when the index of suspicion is high. Scrotal ultrasonography is the most sensitive imaging method for detecting intrascrotal injury, with a positive predictive value of 78%. Heterogeneity of the testicle echotexture is diagnostic of a testicular rupture. Discontinuity of the tunica albuginea is insensitive, being visualized only 17% to 20% of the time.

Early scrotal exploration and repair of testicular rupture result in the highest testis salvage rate. Observation of the traumatized testis results in higher orchiectomy rates, and also significantly increases the patient's disability period. Nonoperative management is usually complicated by infection, testicular atrophy, or necrosis and is not advised.

The operative approach via a midline scrotal incision permits full exposure of both testes and spermatic cords, as needed. Large scrotal hematomas are then evacuated. All necrotic testicular parenchyma is débrided, and the tear in the tunica albuginea is closed. Penetrating injury through the spermatic cord is more likely to result in orchiectomy at the time of exploration. Typically, a Penrose drain may be left in place if hemostasis is in question. Testicular salvage is possible in most cases, and spermatogenesis and endocrine function (testosterone production) are thus preserved.

Testicular amputation injuries are fortunately uncommon, and are usually self-inflicted by the psychotic patient. Unlike the penis, the testes do not tolerate prolonged periods of warm ischemia. Testicular replantation is thus reserved for cases of bilateral amputation or amputation of a solitary testis. This involves microsurgical reanastomosis

of the testicular artery, vasovasostomy, and reapproximation of two or three of the spermatic veins. The overlying amputated skin is not vascularized by the deep structures, and thus is usually not replantable. The ideal coverage of the replanted testis is via primary scrotal closure with remaining scrotal skin.

PENILE TRAUMA

Penile Fracture

A fractured penis implies disruption of the tunica albuginea surrounding the corpora cavernosa. Penile fractures are most commonly caused by excessive sudden angulation of the erect penis against the pubic symphysis during vaginal intercourse. This injury may also be self-inflicted by abrupt bending of the erect penis during masturbation. The classic history involves the scenario described above, with patients usually reporting a popping sound as the tunica tears, followed by pain, swelling, and rapid detumescence. The laceration is classically found on the pendulous part of the penis, but more proximal tears have been reported. There is frequently a delay in presentation to the hospital, presumably secondary to patient embarrassment.

Physical examination typically reveals a swollen, ecchymotic penis, classically described as an “eggplant penis,” because of the discoloration and enlargement caused by the hematoma. The fracture line in the tunica is often palpable. There is often a clot lying over or near the fracture site, which corresponds to the cavernosal rupture site. Urethral injury is associated with penile fracture in 20% of cases. Retrograde urethrography should be performed to rule out suspected injury, particularly in the presence of hematuria, inability to void, or blood at the urethral meatus. Physical examination and history are diagnostic and radiologic studies such as cavernosography or ultrasound, which is diagnostic when read by experienced physicians, should be reserved for unclear cases of penile fracture.

Immediate exploration and surgical repair of penile fracture are warranted. Nonoperative management has no place in the management of this injury, as severe penile curvature, abscess, missed urethral injury, and fibrosis will likely ensue. The penis is explored via a circumcising incision, and the entire length of the corporal bodies and urethra are inspected. The corporal laceration is closed with absorbable sutures. If an associated urethral injury is present, it is repaired over a catheter. Patients

who undergo this type of expedient repair have a low complication rate and usually avoid disabling and disfiguring penile curvature in the postoperative period.

Penile Amputation

Penile amputation is a very rare entity, arising largely from self-mutilation in the hands of a psychotic patient. It may also be caused by violent assault or as a devastating complication of circumcision. Most psychotic patients respond well to psychiatric rehabilitation, and the vast majority will not attempt to repeat amputation. Expeditious penile replantation is thus the treatment of choice. Replantation is best accomplished using microvascular techniques, if available.

The penis is remarkably resistant to cold ischemia, and successful replantation has been accomplished up to 24 hours postamputation. The penis should be preserved in a saline-soaked gauze and placed within a sterile plastic bag. This bag is then immersed in ice slush, which increases ischemic tolerance of the amputated segment.

Microsurgical replantation of the amputated penis involves two-layer closure of the urethra over a catheter in order to stabilize the remainder of the repair. The tunica albuginea of the corporal bodies is reapproximated in a watertight fashion. At least one dorsal artery and the dorsal vein should be reapproximated. Dorsal nerve repair through the epineurium is also warranted, if possible. These patients should be diverted with a suprapubic catheter. If microsurgical techniques are not available, the penis may be replanted using macroscopic techniques, whereby only the urethra and the corporal bodies are reapproximated. The incidence of skin loss and urethral stricture is significantly higher using the latter technique. Remarkably, return of partial or complete erectile function has been reported in many cases in the months following replantation.

Penetrating Penile Injury

Penile gunshot and penetrating injuries are uncommon outside of a wartime setting. Eight percent of these patients will have injuries to adjacent organs, which require evaluation. The urethra is injured in approximately 50% of cases, and thus RUG should be performed prior to exploration, if possible. Most of these injuries may be débrided and repaired primarily with a good functional outcome. The exception is in the case of a close-range shotgun injury, where massive and diffuse tissue

destruction is present. These should be débrided and allowed to declare themselves in terms of the extent of injury. They may then be repaired in a staged fashion.

Corporal injuries should be closed with buried absorbable suture. Associated urethral injury should be closed primarily in a watertight fashion over a Foley catheter. A more superficial laceration that is superficial to Buck fascia may be débrided and closed primarily.

Skin Loss to Genitals

Historically, genital skin avulsion resulted from accidental entanglement of clothing and underlying skin in farm or rotary machinery. Currently, these injuries arise more commonly secondary to motorcycle or bicycle deceleration trauma, whereby the genital skin is avulsed as the rider is thrown forward. The most common cause for genital skin loss overall is in the setting of necrotizing genital gangrene (Fournier gangrene), where necrotic genital skin is débrided acutely.

Genital skin usually avulses along a loose, avascular plane, which usually spares the deeper structures. On the penis, it will dissect superficial to Buck fascia, while the scrotal skin usually dissects superficially to the external spermatic fascia. The testes, spermatic cords, urethra, and corporal bodies are thus usually left intact.

Because of the tremendous elasticity of genital skin, the scrotum may usually be closed primarily, even when as much as 60% of the skin surface area has been lost. If primary closure is not possible, the testes and cords are left exposed and dressed during the perioperative period with moist saline gauze dressings. If the wound is clean at this point, split-thickness skin grafts (STSGs) may be applied. If the wounds are contaminated, the testes are placed in subcutaneous thigh pouches for delayed scrotal reconstruction with STSGs or local thigh flaps. Thigh pouches protect the testes well and ease subsequent reconstructive efforts. Testes that are left exposed for a prolonged period develop a thick fibrous peel that impedes graft take. In contrast, thigh pouches prevent the formation of this fibrous covering.

Scrotal reconstruction with meshed STSGs taken from the thigh or buttock usually provides an aesthetically pleasing outcome. The grafts ultimately assume a dependent rugate appearance that mimics the native scrotum. The donor site usually re-epithelializes with minimal complication. Local thigh flaps may also be used, but this may be more

labor-intensive and the ultimate cosmetic outcome is not optimal compared to STSGs.

In the case of avulsed penile shaft skin, STSG reconstruction also provides an excellent result. Meshed grafts should be avoided on the penis because of their tendency toward contracture and a worse cosmetic appearance associated with the meshing. It is important to excise any remaining subcoronal skin prior to grafting, as this residual skin may have impaired lymphatic drainage and lead to circumferential lymphedema.

Genital Burn Injuries

Genital burn injuries may be caused by thermal, electrical, or chemical energy sources. Thermal burns of the genitalia are usually associated with more extensive burns of adjacent tissues. Initial treatment should include aggressive fluid resuscitation and evaluation of depth and extent of the burn. A Foley catheter should be placed early in the resuscitation period unless the urethra is obviously involved in the burn. In this case, suprapubic catheter placement is advised.

Most genital thermal burns are first or second degree, and will usually heal with local wound care and rarely require debridement. Conversely, third-degree genital burns of the penis or scrotum require prompt debridement of nonviable tissue, followed by STSG reconstruction as previously described. This approach may decrease infection rates and ultimately prevent formation of a genital burn scar, which usually results when third-degree burns are managed conservatively. Chemical burns are managed with initial flushing of burned surfaces with copious amounts of sterile water. The injury is then managed as outlined for thermal burns.

Electrical burns to the genitalia may be particularly devastating because tissue destruction is often far deeper and more extensive than the visible surface burn indicates. Evaluation should thus include cystoscopy, vaginal speculum examination, and sigmoidoscopy to rule out associated pelvic organ damage. Electrical burns may cause extensive muscle necrosis and consequent myoglobinuria and hemoglobinuria, both of which lead to renal insufficiency. Electrical burns may require repeat debridement before skin graft or myocutaneous flap reconstruction may be undertaken.

CONCLUSIONS

The genitourinary system is involved in approximately 10% of traumatically injured patients. The recommendations presented in this

review are based on an experience in managing over 3,000 renal trauma patients during more than 30 years at San Francisco General Hospital and, most importantly, on an evidence-based international consensus conference on genitourinary trauma, and incorporated into both 2014 US and 2005 European guidelines for urotrauma. Treatment algorithms presented here are based on this experience; the development and ongoing refinement of these treatment algorithms provide validated guidelines for the surgeon who is called upon to manage urologic trauma.

EDITOR'S COMMENT

The authors provide a concise and comprehensive overview of the key urinary tract injuries requiring immediate evaluation and management. The commentary

is based on evidence-based reviews, including the SIU Consensus Conference on Genitourinary Trauma, and more recently the European Association of Urology, and most recently the American Urological Association (AUA) guidelines. It should be noted that there are differences in recommendations from the different guidelines, and the AUA guidelines from 2014 represent the most up-to-date evidence review. Examples of differences include those around indications for imaging after renal trauma. For example, the question of significant deceleration is raised by the authors. Different guidelines have different suggested algorithms, but whether a deceleration is defined as a fall from a great height or a motor vehicle collision is not specifically clear. Similarly, the authors use the terms shock and systolic blood pressure less than 90 mL of mercury interchangeably; this can create some confusion. Shock is a clinical scenario associated with hypoperfusion of organs that may or may not be present with a systolic blood pressure of 90 mL of mercury. The imaging criteria represent a clinical prediction rule, and the blood pressure less than 90 mL of mercury is used as a point in favor of imaging. The authors appropriately note that a patient in hemodynamic hemorrhagic shock should not undergo radiographic imaging but instead requires some form of operative intervention.

Pediatric natal injuries are difficult because of the lower number of publications and the lower propensity for children to exhibit shock; thus, variable definitions or indications for imaging exist. In blunt trauma cases, the authors point to greater than 20 RBCs per high power field as a criterion. Until we have a definitive consensus statement or guideline, each institution should consistently apply its own criteria. Whether this is 30 or 50 RBCs per high power field or simply following the adult criteria, all of these relate to blunt trauma. For pediatric penetrating injury, the same criteria as for adults are relevant, namely any degree of hematuria. The authors describe a set of 10-minute delayed images in order to visualize the collecting system down through the bladder. This is now part of the AUA guidelines. Of note, sometimes if there is a renal contusion or hypoperfusion for other reasons, the entire upper urinary tract may not be visualized at 10 minutes. In such cases, in the absence of significant perinephric or periureteral low-density fluid, it is reasonable to defer additional attempts at imaging specific segments of the ureter. Certainly, uretopelvic junction injuries should be excluded. This is most commonly done by seeing contrast distal to the UPJ.

The additional pieces of CT that reflect new thinking about imaging include the identification of intravascular contrast extravasation and the distance or thickness of the hematoma. These criteria, which have been validated by a number of series from Japan, Parkland, and Harborview Medical Center, identify high-risk patients at greater likelihood of bleeding.

A trend toward nonoperative management for high-grade renal injuries persists, and the number of patients successfully managed nonoperatively with grade 4 renal lacerations is certainly higher than 22% in most contemporary series. The vast majority of blunt trauma patients, in excess of 90%, require

surgical intervention at most trauma centers. One reason for this is that it is no longer routine practice to explore devitalized renal parenchymal fragments or urinary extravasation. The most expert renal surgeon may be able to preserve and repair such injuries, but in the majority of the country, such injuries may, when explored, lead to nephrectomy.

The authors describe nonoperative management of urinary extravasation. This is the rule with forniceal ruptures and major lacerations. Although no longer mandatory guidelines do recommend a follow-up CT scanning in the post injury period for these patients. Others recommend expectant management and intervention for symptomatic urinoma. Such symptoms may include fever, flank pain, hydronephrosis, and the like.

Renovascular injuries remain challenging because arterial injuries have a high rate of renal loss. Endovascular stenting, described by the authors as having a limited role, should probably be considered experimental and performed under institutional protocols. An important consideration is whether anticoagulation is necessary, and the risks this poses to patients with other solid organ injuries.

Renal reconstruction after injury is well described in this chapter, and following the classic steps of vascular isolation and exploration described can lead to high rates of renal salvage. Increasing use of angioembolization in solid organ injury is an advance that is likely to lead to increased renal salvage rates. However, this important adjunct should not be overused. There is a trend nationally to embolize intravascular contrast extravasation regardless of hemodynamic status. The patient with a small perinephric hematoma and isolated intravascular contrast extravasation (ICE) may not have a significant bleeding event, and embolization may not be necessary. Clinical parameters and injury severity assessment represent opportunities for further enhancement of care pathways.

Ureteral injuries are best repaired in the immediate post-injury period. After several days, urinary extravasation and urinoma formation may lead to significant inflammation that makes reconstruction difficult; thus, when injury identification is delayed, damage control approaches may be appropriate. These include ligation of the ureter, nephrostomy tube drainage, and delayed reconstruction. This is particularly important in the context of delayed presentation of ureteral injury where there may be infection on top of obstruction and urinoma formation. Ureteroureterostomy and ureteroneocystostomy are the mainstay of treatment of upper and lower ureteral injuries, respectively. The transureteroureterostomy puts the contralateral ureter at risk and should be reserved for cases in which the ipsilateral ureteral injuries associated with major vascular or bladder injuries are compromised. In contrast to the authors, this commentator prefers a refluxing ureteral reimplantation. For the vast majority of adults with normal lower urinary tract, such a repair is sufficient and reduces the risk of subsequent obstruction. Lastly, the concept of acutely using ileal ureter or autotransplantation in the setting of a severe ureteral

injury is not advisable. Again, damage control principles are appropriate here. Such more extensive procedures require more additional planning, lengthy operative time, and should not be imposed on the severely injured trauma patient. Bladder injuries should be repaired if there is a potential for adjacent organ injury that would otherwise go unrecognized; very large defects that will not close spontaneously; the presence of contamination, foreign bodies, boney fragments, missiles, or the like; and inability to drain the urinary tract. Thus, penetrating injuries generally require exploration. However, if a penetrating injury could be assessed and all the criteria given above were met, it could be treated in many cases similar to an extraperitoneal bladder rupture.

Bladder ruptures can be managed nonoperatively with great success.

When operative exploration is required, most extraperotineal ruptures are related to pelvic fracture, sit in the anterior bladder wall region, and are easily accessible and visible through a lower abdominal incision. Thus, the bladder does not routinely need to be opened. Instead, the injuries can be identified and closed. Current cystography is generally sufficient to identify additional injuries.

Urethral injury identification relies on retrograde urethrogram, which is clearly recommended in AUA guidelines. As with all injuries of the urethra, in pelvic fracture urethral injury immediate bladder drainage is the top priority. This is generally with a superpubic cystotomy placed either pericutaneously or open. For anterior urethral injuries related to straddle, the crush injury is focal and short and generally a realigning catheter is not required nor will it prevent stricture formation. Conversely, in the posterior urethra, after pelvic fracture urethral injury, an aligning catheter is associated with a lower rate of stricture. A significant minority of patients up to 22% to 35% depending on series will not need subsequent urethroplasty after early urethral realignment. However, heroic attempts at realignment, whether on day 1 or day 5, are to be condemned. If the realignment is attempted, it should be carried out in the environment of the operating room where appropriate equipment, staff support, and patient supervision can be ensured. Attempts at realignment from below with flexible endoscopes retrogradely placed will not be sufficient for many pelvic fracture urethral injuries.

External genitalia trauma can, when repaired surgically in the immediate postoperative period, preserve function and cosmesis with a high degree of success. Ultrasonography is a useful adjunct for both penile and testicular injuries. Its improved accuracy relates to the higher resolution of images, and the ability to visualize the tunic albuginea, the testis, and penis and determine whether there are breaks in its continuity. The sections on genital skin loss and amputation reflect current principles.

181 Supravesical Urinary Diversion

Kristin Chrouser and Badrinath R. Konety

INTRODUCTION

Supravesical diversion involves the external diversion of the urine stream without use of the bladder. While percutaneous nephrostomy offers a short-term alternative to operative diversion, problems with frequent tube changes, dislodged tubes, infection, and external appliances make surgical diversion the preferred method in those needing long-term supravesical diversion. This chapter focuses on surgical supravesical diversion. Except in the case of cutaneous pyelostomy or ureterostomy, supravesical diversion employs intestinal segments to bridge the gap between the ureters and the skin. Types of supravesical diversion may generally be categorized as continent and noncontinent. Noncontinent diversions involve a wide stoma and an external appliance to collect the urine (urostomy bag). Heterotopic continent diversions utilize a catheterizable stoma on the abdominal wall to empty an intraabdominal neobladder or "pouch," whereas orthotopic continent diversions create a pelvic neobladder that is anastomosed to the urethra.

INDICATIONS

The most common indication for supravesical diversion is following radical cystectomy for cancer of the bladder. Other indications include refractory ureteral or urethral obstruction and urinary fistula: these are often less amenable to repair when the etiology is radiation damage. Radiation cystitis, interstitial cystitis, or hemorrhagic cystitis not responsive to more conservative therapy can also be managed with supravesical diversion as a last resort. Additionally, supravesical diversion may be considered in the management of poorly compliant, high-pressure neurogenic bladders when bladder augmentation cystoplasty is not an option.

PREOPERATIVE PLANNING

Patients should be appropriately selected to ensure they are medically fit for major surgery. Coexistent bowel pathology including inflammatory bowel disease, history of abdominal radiation, or previous bowel resection should factor into selection of the appropriate intestinal segment for diversion.

Patient considerations specific to the choice of the type of urinary diversion include visual, cognitive, neuromotor, and renal function as well as the level of available social support. As continent neobladders can lead to electrolyte disturbances, they should be avoided in patients with renal impairment. When considering a continent diversion, one must take into account the patient's neuromotor status and dexterity along with the availability of other caregivers to assist with care of the diversion. Although many patient void spontaneously, some suffer from incomplete emptying or mucous plugging after an orthotopic neobladder, and the ability to catheterize or irrigate the neobladder is important. Patients need to be aware that nighttime leakage is not uncommon after orthotopic neobladder. A heterotopic neobladder (or "pouch") with a catheterizable abdominal stoma also requires the ability to physically catheterize and the cognitive faculties to comply with a regular catheterization schedule. When the ability to catheterize or electrolyte disturbances are a concern, a noncontinent diversion is preferable.

All patients should be seen by a stoma therapist prior to surgery for an upright abdominal examination to determine the optimal placement of the abdominal stoma relative to their pannus. The patient's hand function will also be taken into account in choosing the best location. Even patients who desire a neobladder should be marked for an incontinent stoma as there are rare situations in which the mesentery is too short for the ileum to reach the pelvis without tension, thus preventing construction of an orthotopic diversion.

If a urinary diversion is being contemplated in a patient with a ureteral stricture, it is important to delineate the length and location of the stricture before surgery. As an indwelling stent may mask the true extent of disease, preoperative nephrostomy tube placement and ureteral stent removal are recommended. An antegrade ureterogram several weeks later or in the operating room at the time of reconstruction will best identify the extent of stricture and the appropriate level for ureteral transection. A stent-free period of at least 2 weeks also allows ureteral inflammation associated with the stent to improve prior to reconstruction. In such patients,

intraoperative identification of the ureters is often more difficult due to periureteral scarring from chronic inflammation, so antegrade ureteral catheters may be placed down to the site of obstruction on the day of diversion if needed.

It is always advisable to remove the bladder when performing supravesical diversion, even in the absence of bladder malignancy. Diversion of the urine stream away from an intact bladder too frequently results in pyocystis, a condition of retained mucous and desquamated bladder epithelial cells complicated by infection. Pyocystis is managed by bladder drainage and/or cystectomy. A controversial management alternative in women is to create an iatrogenic fistula into the vagina, which allows for bladder drainage without catheterization. However, removal of the bladder prevents pyocystis altogether and is preferred when performing supravesical diversions. In men, the prostate should also be removed except in rare circumstances where natural fertility is still desired.

SURGICAL TECHNIQUE

Noncontinent Diversions

Cutaneous Ureterostomy

Although cutaneous loop ureterostomy or pyelostomy can be performed as a *temporary* diversion to manage infants with severe hydroureteronephrosis in anticipation of future reimplant, this technique is rarely utilized in adults. Due to the high rate of stomal stenosis, cutaneous end ureterostomy is rarely employed as a *permanent* diversion for adults in the modern era. In adults, the degree of ureteral mobilization that is required in order to bring them to the skin results in devascularization and stenosis in approximately 60%. The small caliber ureter may also be predisposed to stomal stenosis. However, in the rare patient with multiple comorbidities and very dilated ureters, there may still be a role for permanent cutaneous ureterostomy. In order to avoid two stomas, it is customary to perform a “double-barrel” ureterostomy where both ureters exit the skin together. Stomal stenosis may be minimized by eversion of the ureters into a rosebud and by incorporating a V-shaped skin flap into each of the two ureters in the ureterostomy.

Ileal Conduit

Originally pioneered by Bricker in 1950, the ileal conduit is the most

commonly performed type of supravesical urinary diversion. Like other ureterointestinal diversions, ureteral devascularization and the risk of stomal stenosis are minimized because the intestine is brought to the ureters rather than mobilizing the ureters to the skin. Contraindications include short bowel, radiation enteritis, and Crohn disease. After transection, holding sutures are placed on the ureters and a 15- to 20-cm segment of terminal ileum is selected for the conduit. Vitamin B_{12} and folate malabsorption is minimized by selecting a segment 15 to 20 cm proximal to the ileocecal valve. Good blood supply to the ileal segment may be confirmed by palpation or visually with backlighting of the mesentery. After identifying an adequate vascular pedicle, the segment of ileum can be marked with sutures on the bowel. Since the conduit can rotate on its pedicle during the procedure, some choose to tag the proximal and distal ends with different colored suture (e.g., “silk to stoma”). This ensures correct isoperistaltic orientation of the conduit is maintained. The relatively avascular portions of the mesentery adjacent to the proximal and distal ends of the conduit are then divided using ligatures or electrocautery to create windows running at right angles to the selected segment of bowel. The segment of ileum is excised from the rest of the bowel, usually with a gastrointestinal anastomosis (GIA) stapler. The ileal segment is dropped toward the pelvis and the remaining bowel is brought back into continuity above it with either a two-layer sutured end-to-end anastomosis or a stapled side-to-side anastomosis (often using a combination of GIA and straight “TA” staplers). The mesenteric defect is closed with either running or interrupted suture to prevent internal hernias. Due to the risk of urinary stones forming on the staple line, some prefer to exclude the staple line from the proximal (“butt”) end of the conduit using absorbable suture in a horizontal mattress. One can open the distal/cutaneous end of the conduit at this time and irrigate the interior to flush out any remaining enteric contents.

Since most urostomies exit the right side of the abdomen, a window is created either beneath or (carefully) through the sigmoid mesentery to allow passage of the left ureter into the right retroperitoneum in front of the sacral promontory. It is important to do this under direct vision if possible in order to avoid injuring the presacral veins, as controlling bleeding from these veins is difficult. The tunnel should be wide enough to prevent kinking of the ureter and care must be taken to avoid twisting of the ureter. The ureter is brought underneath using the previously placed

holding suture. It cannot be overemphasized that ureteral mobilization should be kept to a minimum and the intestinal segment should be brought to the retroperitoneum rather than bringing the ureters into the peritoneal cavity. When anastomosing the ureters to the intestinal segment, one may elect a tunneled or a refluxing reimplantation. Longitudinal studies have shown the risk of renal dysfunction from obstruction in a tunneled reimplant may outweigh the risk of renal dysfunction from reflux and infection in a nontunneled, refluxing reimplant. Most opt for a refluxing reimplant in the modern era. Refluxing reimplants may be accomplished in the fashion of Bricker or Wallace.

The Bricker ureterointestinal anastomosis involves separately anastomosing the two ureters to the bowel in an end-to-side manner (Fig. 181.1). A small enterotomy is made on the posterior aspect of the proximal end of the ileal conduit. We find it easiest if a seromuscular suture is used to hold up on the intestine and the enterotomy made with scissors just below this. The bleeding from the mucosal edges makes visualization difficult but cautery should be avoided in order to preserve blood supply at the anastomosis site. Some place mucosal eversion stitches, with fine absorbable suture—these control bleeding nicely and make identification of the mucosa during the anastomosis straightforward. Others avoid extra sutures in order to minimize inflammation that may lead to subsequent scarring. Some advocate a shield shaped ileotomy for ease of suturing and to minimize the risk of ureteroileal anastomotic strictures. The ureter is spatulated and a running or interrupted mucosa-to-mucosa anastomosis is performed with fine absorbable monofilament suture such as 5-0 polydioxanone (PDS) (Fig. 181.1). After one side of the ureteroenteric anastomosis is completed, a “single J” ureteral stent is placed. The coiled end of the stent is placed through the open ureter up to the kidney over a guidewire, about 15 to 20 cm. The stent will eventually pass from the renal pelvis, down the ureter, across the anastomosis, through the conduit and out into the appliance. Correct placement can be confirmed with a postoperative plain film of the abdomen. A clear Yankaur suction can be used to negotiate the stent through the conduit or a long Schnidt clamp can be passed from the cutaneous end of the conduit up to the anastomosis to grasp the straight end of the stent and bring it out. A rapidly absorbable suture is used to secure the stent to the distal bowel near the stoma which helps prevent accidental dislodgement. The second half of the ureter is then closed and the same process is repeated on the other side.

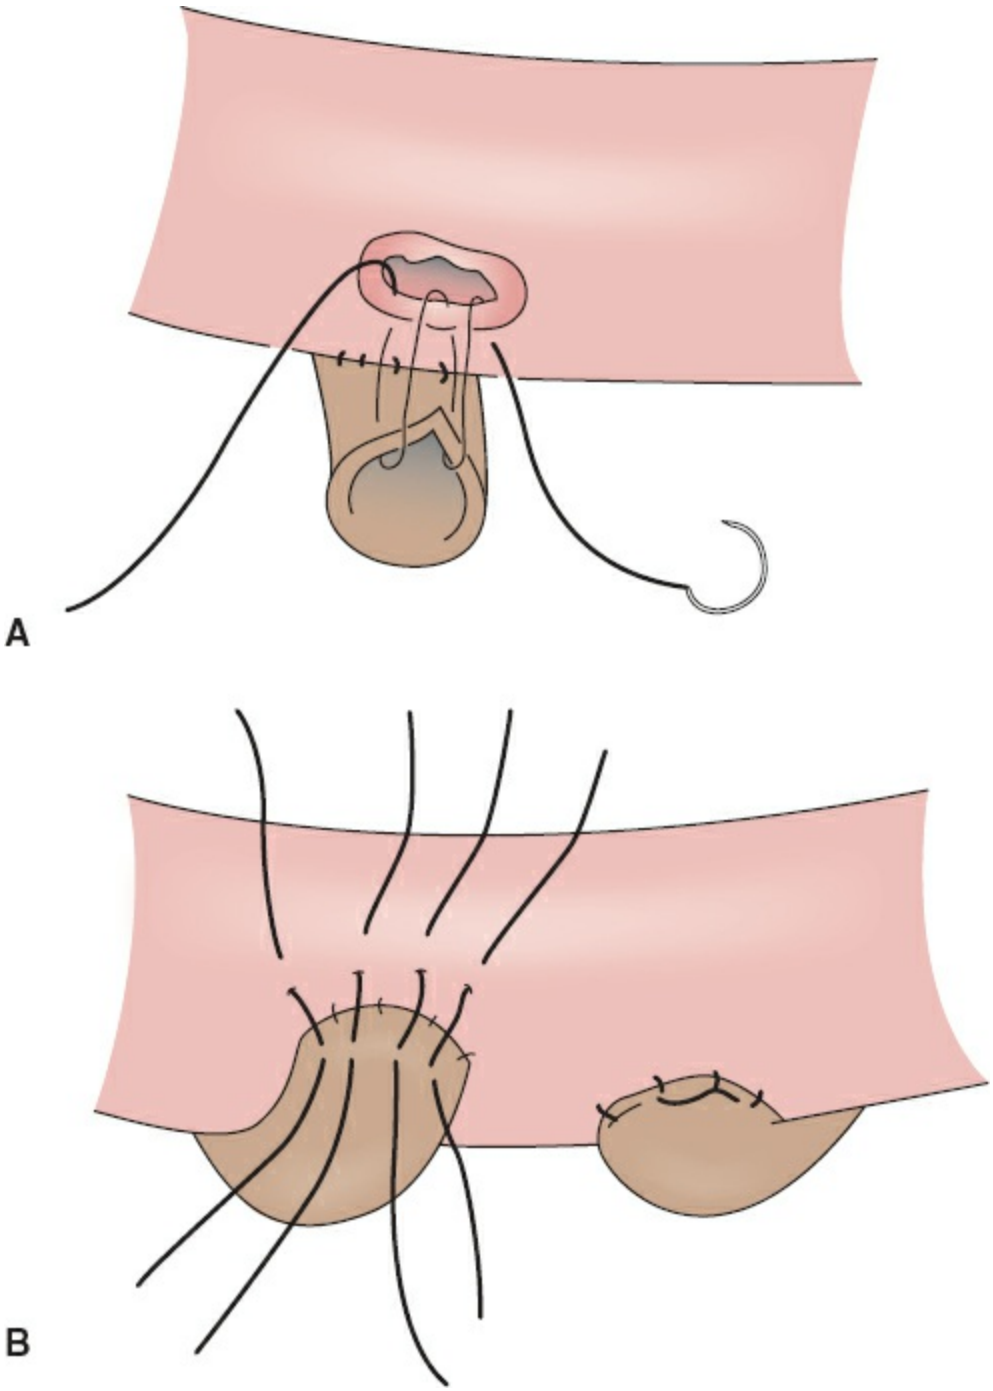

Figure 181.1. Bricker ureterointestinal anastomosis. **A.** An end-to-side mucosa-to-mucosa anastomosis is performed separately between each spatulated ureter and the intestine using fine absorbable suture. **B.** Some elect to further reinforce the anastomosis by creating a second layer closure of serosa to serosa.

In a Wallace ureterointestinal anastomosis, the staple line is trimmed off the proximal end of the conduit and the entire proximal lumen of the conduit is utilized for the anastomosis. The ureters are spatulated and then

sewn together side-to-side in a running or interrupted fashion with fine absorbable suture such as 5-0 PDS (Fig. 181.2). This is followed by an end-to-end anastomosis of the "double-barrel" ureters to the open proximal ("butt") end of a loop of intestine (Fig. 181.2). This can be accomplished using three different orientations as shown in Figure 181.2B–D. We prefer to sew the joined apical ends (proximal spatulation) of the ureters to the bowel first (Fig. 181.2B) as this can be the most difficult portion of the anastomosis. The remaining ureteral walls and distal ends of the joined ureters can then be sewn to the bowel. Ureteral stents are placed before completing the anastomosis, as previously described. The Wallace anastomosis makes it easier to endoscopically access the ureters postoperatively if there is a need for upper tract evaluation or stone removal. The principal concern regarding the Wallace anastomosis is that obstruction of the terminal portion of one ureter, due to stenosis, stone, or recurrent tumor, may obstruct both ureters, resulting in critical renal impairment. In addition, if a ureteric or renal pelvic tumor should develop in one renal moiety, it would be harder to separately dissect out the corresponding ureter at the time of a nephroureterectomy.

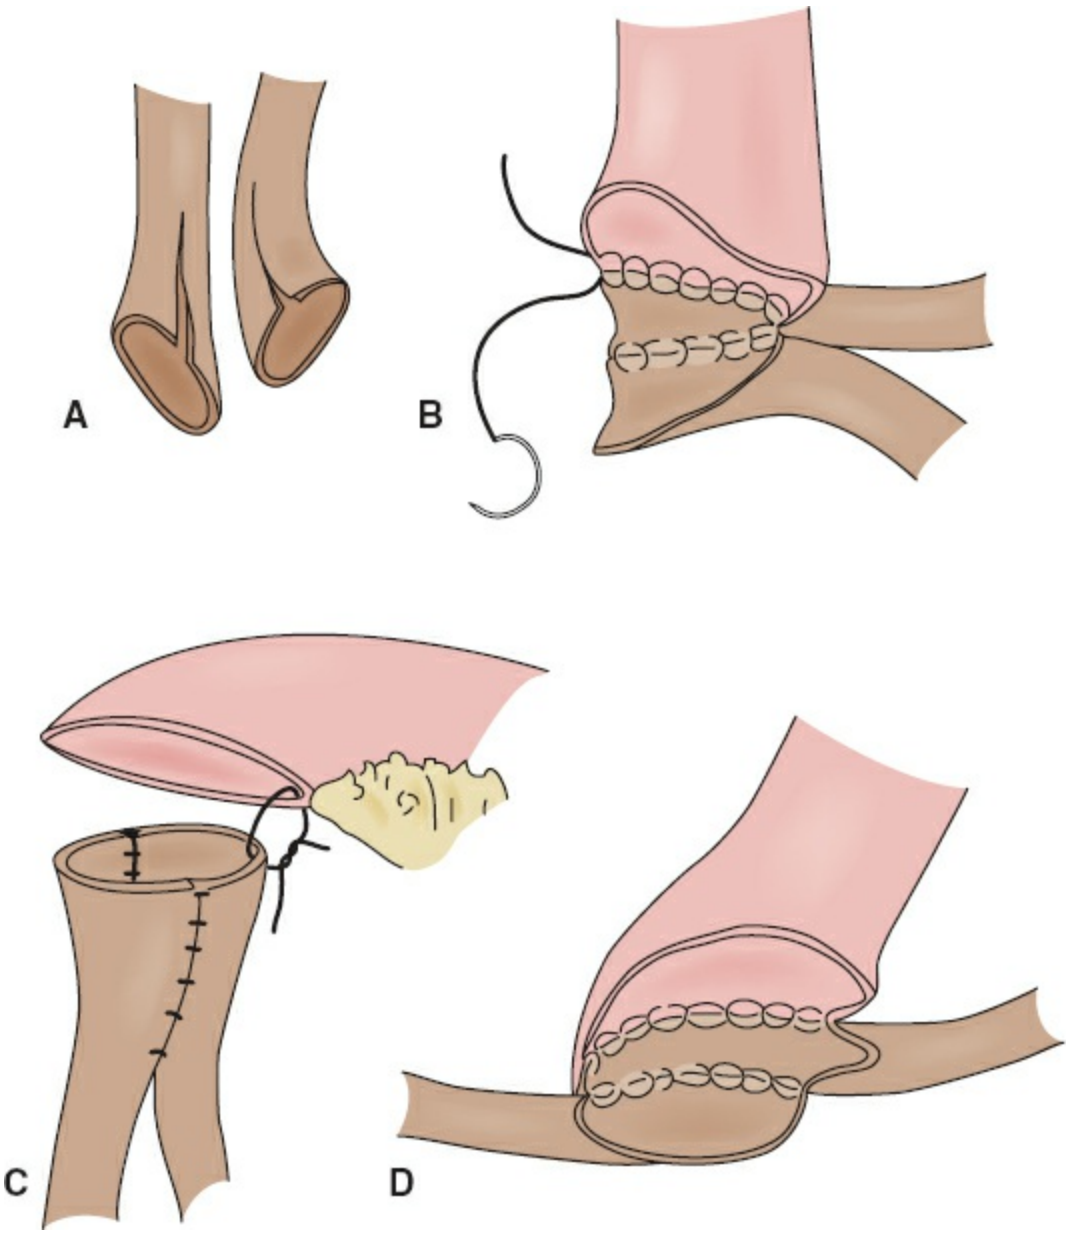

Figure 181.2. A. Common to all techniques is that the ureters are spatulated. There are three methods of Wallace ureterointestinal anastomosis (**B–D**). **B.** Medial walls of ureters are anastomosed in a side-to-side fashion. Then the joined ureters are sewn end-to-side to the bowel. **C.** The medial and lateral walls of ureters are both anastomosed in a side-to-side fashion. Then the joined ureters are sewn end-to-end to the bowel. **D:** The medial wall of one ureter is anastomosed to the lateral wall of the other ureter such that they are side-to-side but directed opposite each other. Then the joined ureters are sewn side to end to the bowel.

A disk of skin is excised from the urostomy site that was marked preoperatively by the stoma therapist. The underlying column of fat is removed down to the rectus fascia. A cruciate incision is made in the

anterior rectus fascia and the rectus muscles separated bluntly with a Kelly clamp. A fasciotomy is then made in the posterior sheath. The fascial defect should accept two fingers. Then, 2-0 or 3-0 absorbable sutures are placed in the outer portions of the cruciate incision with the needles left on. A Babcock clamp is used to grasp the conduit and stents, bringing them gently through the abdominal wall until 5 to 6 cm of bowel is visible. The serosa of the conduit is then anchored to the fascia using the previously placed 2-0 or 3-0 sutures, passing the needles parallel to the ileal blood supply. The conduit should be placed so that the mesentery is oriented superiorly and it should not be under tension. Bricker originally described a stoma that was flush with the skin. Brooke advocated use of the everted “rosebud” stoma, which helps prevent stomal stenosis, urine leaking around the appliance, and minimizes urinary skin irritation by ensuring that the effluent urine drips directly into the bag. This eversion is achieved with three or four 3-0 absorbable sutures passed from the skin to the serosa of the conduit and then through the most distal edge of the conduit (Fig. 181.3), taking care to avoid injury to the mesentery. When tying these down, to encourage eversion, a Babcock clamp can be used to grasp the inner mucosa and pull up from the luminal side or a blunt right angle can be placed on the serosal surface of the conduit near each suture and used to ensure adequate outward intussusception of the bowel circumferentially. The conduit is then matured with interrupted absorbable stitches from the skin to the serosal edge of the conduit. The proximal (internal) end of the conduit is anchored by sewing the cut edge of posterior peritoneum over it with three to five interrupted nonabsorbable sutures. This secures the conduit at both ends and prevents volvulus and internal hernias while retroperitonealizing the conduit which can contain potential urine leaks.

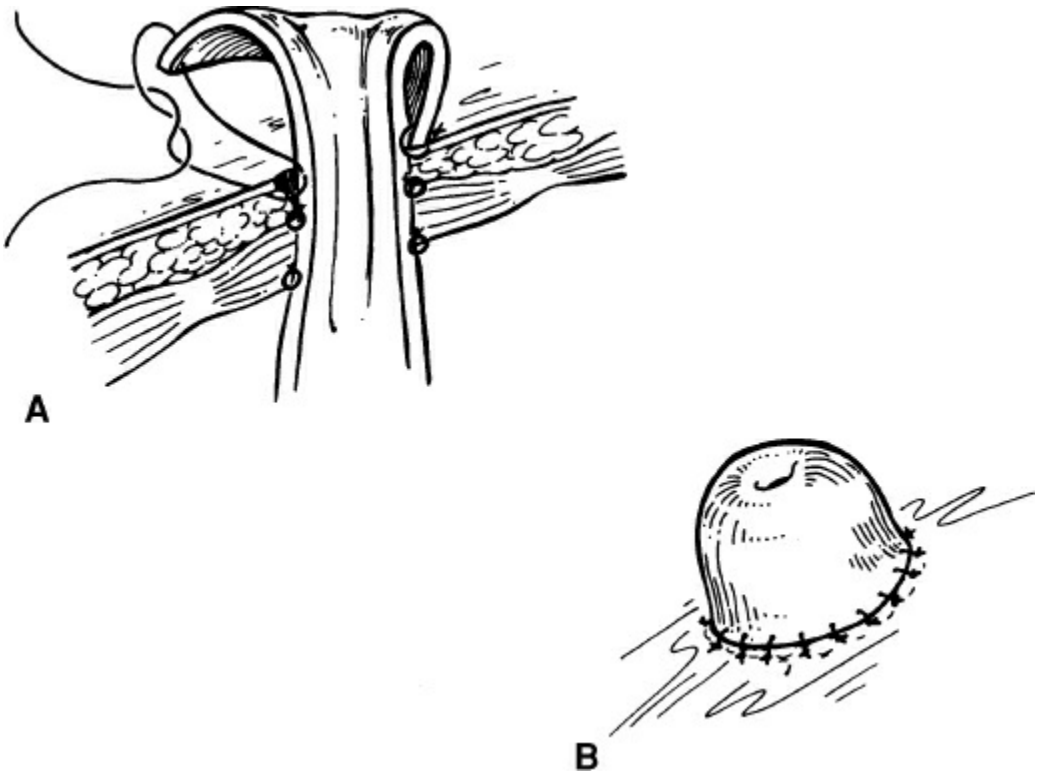

Figure 181.3. Maturation of the urinary conduit in the fashion of Brooke. **A.** The conduit is sutured at the fascia level to prevent parastomal herniation. A separate layer of suture should incorporate the skin, the serosa, and the muscularis of the conduit at the level of the skin and at the edge of the conduit. **B.** Rosebud stoma after maturation.

An alternative to the previously described terminal stomas is a Turnbull loop stoma (Fig. 181.4). This may reduce stomal stenosis because blood supply to the stoma is not compromised as it is with the terminal Bricker stoma. The Turnbull stoma is also advantageous in the obese patient with thick or short mesentery in whom it can be difficult for the distal edge of the conduit to reach the abdominal wall without tension to fashion a Bricker stoma. A shortcoming of the Turnbull stoma is its higher risk of parastomal hernia due to the necessarily larger fascial defect. Both ends of the conduit are left intact and then a loop of the conduit is brought through the fascial defect and secured as in the Bricker technique described previously. The antimesenteric side is opened and the bowel edge is matured to the deep portion of the loop just above the fascia and then to the skin, as for the Brooke modification of the Bricker stoma. One can opt to pass a red rubber catheter or a loop colostomy rod through a window in the mesentery below the loop and suture it to the skin in order to prevent recession of the stoma. If desired, it can be left in place for the immediate

postoperative period. Because the edema that sometimes occurs postoperatively can cause this catheter to erode the skin, an alternative is to simply suture the catheter to itself off the abdominal wall to complete a circle. It can be removed about 2 weeks post operatively.

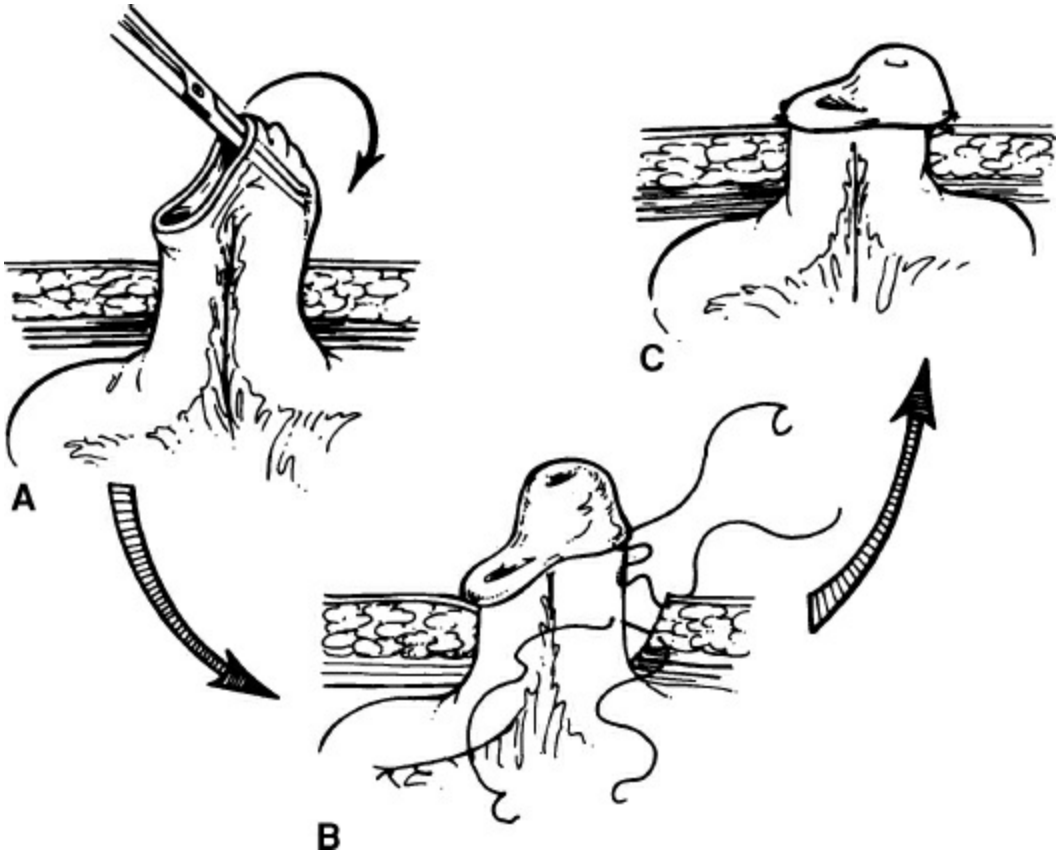

Figure 181.4. Turnbull loop stoma. **A.** The distal end of the conduit is left intact. A loop of conduit is pull above the level of the skin. The loop should protrude 3 to 4 cm and be secured to the fascia. The loop is opened over the antimesenteric side. **B.** The stoma is maturated with interrupted sutures, including the skin, the seromuscular layer of the conduit, and the edge of the mucosa. **C.** Stoma after maturation.

Colon Conduit

The ileal conduit is familiar to most urologists. However, one should be prepared to perform a colon conduit in select patients. When total pelvic exenteration is performed, the sigmoid colon conduit is advantageous since it avoids the potential complications associated with a bowel anastomosis. A transverse colon conduit is essential in cases of long segment ureteral stricture or radiation ureteritis/enteritis.

After identifying an adequate pedicle, the necessary length of sigmoid

colon is selected for the conduit. It should be noted that in some older patients the sigmoid colon can be redundant due to long-standing constipation. Unlike the ileal conduit, it is not necessary to pass the left ureter across to the right side. Once the sigmoid colon mesentery is mobilized, the two ureters can be brought toward the midline or the colon can be stretched across the retroperitoneum. Anastomotic techniques are as described below for the transverse colon conduit. Because the transverse colon and its middle colic artery originate in the upper abdomen, this segment can be anastomosed to the upper one third of the ureter or even directly to the renal pelvis if needed (Fig. 181.5). The transverse colon has the added advantage of being out of the pelvic radiation field whereas the ileum may be affected by radiation enteritis. The combination of unirradiated bowel and unirradiated ureters and the absence of ureteral mobilization optimizes success in the high-risk radiation patient.

Figure 181.5. Loopogram of a transverse colon conduit. X-ray demonstrates the utility of the transverse colon in reaching the upper ureters and renal pelvis. Also shown is how long a segment of transverse colon is required to traverse the retroperitoneum and reach the skin.

When constructing a transverse colon conduit, it is frequently necessary to extend the abdominal incision to the xiphoid in order to adequately mobilize the hepatic and splenic flexures of the colon. The middle colic artery that supplies the transverse colon is easy to identify. The entire transverse colon is isolated and divided as described above for the ileal

conduit. While the segment will seem long, the length is necessary in order to reach both upper ureters, as minimal ureteral mobilization will be performed and the left ureter won't be brought to the right side as for the ileal conduit. Depending on the preference of the surgeon, the transverse colon conduit can be left in an intraperitoneal location or placed on the posterior peritoneum. If intraperitoneal, the colon is brought back into continuity superior to the colon conduit, as described for the ileal conduit. The ureters are brought up through windows in the left and right colonic mesentery, careful to avoid injury to the inferior mesenteric vein on the left side. Small enterotomies are made in the portion of the colon adjacent to each ureter. We avoid the tenia coli when performing refluxing anastomosis, given the thickness of this colonic band of muscle. The ureteroileal anastomoses are then performed, stents are placed, and the stoma is matured as described for the ileal conduit previously.

Because intraperitoneal placement of the transverse colon conduit can be difficult in a patient with (a) very short ureters or a planned anastomosis to the renal pelvis, (b) a thick fatty poorly mobile colonic mesentery, or (c) an edematous mesentery after a long operation, we frequently employ an alternative approach, which involves placing the conduit on the posterior peritoneum. In this case, the bowel is brought back into continuity inferior to the conduit and the conduit is stretched across the posterior peritoneum from kidney to kidney. The upper ureters or renal pelvis can then be anastomosed to the conduit as described above. Regardless of the approach, bringing the stents through the terminal stoma end of the conduit can be difficult due to the long length of the colon conduit, relative to an ileal conduit. This sometimes requires using a flexible cystoscope to pass a wire first or making a small colotomy midway through the conduit to help guide the stents through with a long clamp.

Continent Diversions

Options for continent diversions include rectal diversion, relying on the anal sphincter for continence, orthotopic neobladders, relying on the external urinary sphincter for continence, and heterotopic pouches, relying on a tunneled catheterizable segment for continence.

Continent diversions work best when fashioned as a pouch rather than a tube. Initially, continent diversions used nondetubularized segments of intestine such as the ureterosigmoidostomy or the Camey pouch. However, currently all pouches rely on a detubularized segment of bowel refashioned

in a spherical shape in order to minimize pressure and metabolic complications. Low-pressure reservoirs aid in protecting the kidneys from high pressures as well as maintaining continence. In heterotopic pouches, continence is achieved by creating an antireflux valve as well as by creating a narrow catheterizable segment. The likelihood of leakage through the catheterizable segment is reduced more rapidly by narrowing the tube than by lengthening it. Because long catheterizable segments increase the risk of catheterization problems, a shorter catheterizable segment is preferred (10 to 12 cm). In orthotopic neobladders, continence is aided by preservation of the voluntary sphincter, and in rectal pouches by the anal sphincter. Many of the surgical principles are common to continent and noncontinent diversion, including bowel isolation and reanastomosis as well as refluxing ureterointestinal anastomosis. These have been reviewed in detail in the previous section and are not repeated here. Unique aspects of continent diversion are covered in detail.

Rectal Diversion

Ureterosigmoidostomy

Due to the significant complications associated with this technique it is only briefly described, primarily for historical interest. It is rarely used given concerns regarding increased risk of secondary malignancy (adenocarcinoma), chronic pyelonephritis with renal impairment, and electrolyte disturbances. Some argue, however, that there is still a role for this diversion in the frail or elderly because it can be accomplished quickly and without a bowel anastomosis. This technique essentially combines the urinary and fecal streams, leading to chronic diarrhea that can impact quality of life. It also requires an intact rectal sphincter in order to maintain fecal continence. In summary, the left ureter is brought anteriorly through the sigmoid mesentery and the ureters are anastomosed into the rectum. The anastomosis should always be tunneled; this can be done extracolonically or transcolonically and the techniques parallel those of extra/intravesical reimplant commonly done in pediatric urology for vesicoureteral reflux. The Leadbetter/Clarke technique for extracolonic reimplant involves creating a submucosal tunnel in the anterior colonic tenia and performing a mucosa-to-mucosa anastomosis at the distal end of the tunnel (Fig. 181.6).

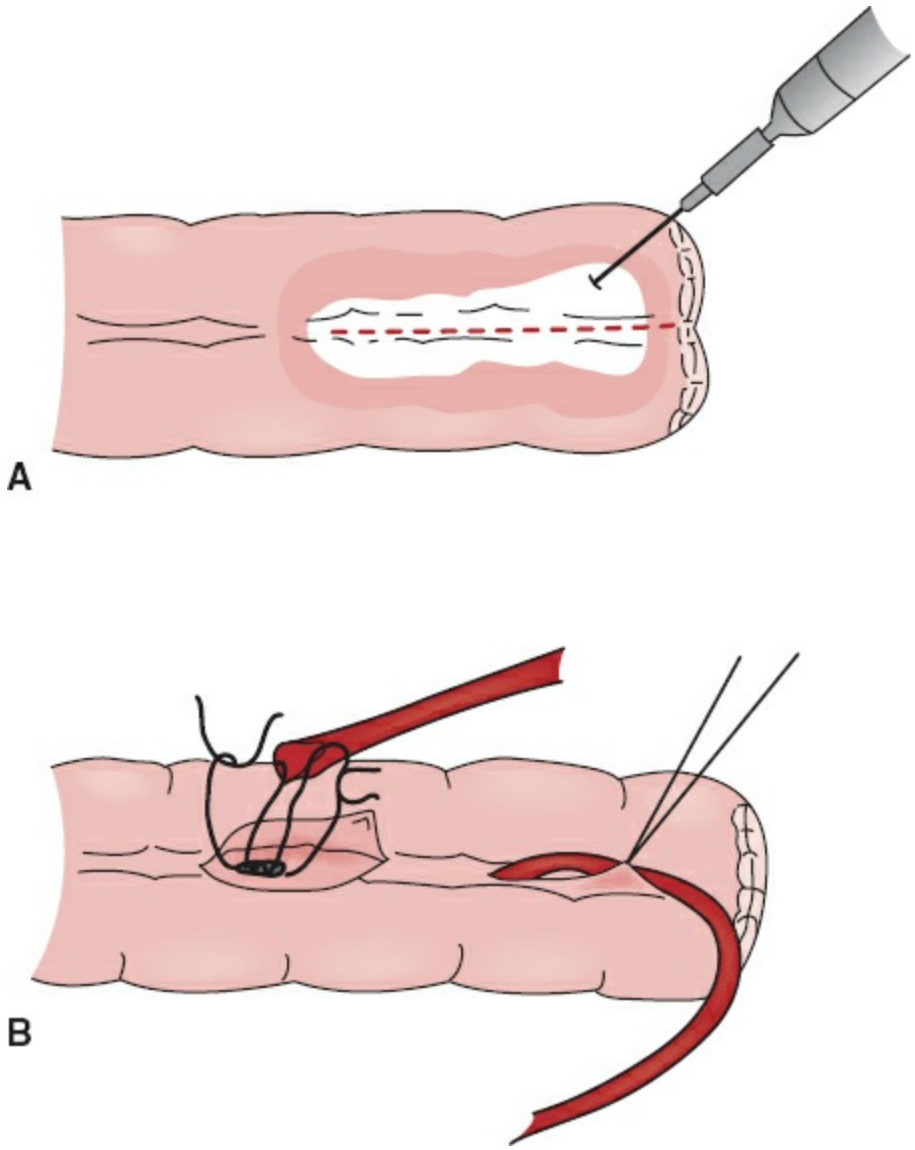

Figure 181.6. Extracolonic ureterocolonic anastomosis in the fashion of Leadbetter and Clarke. **A.** Hydrodissection may aid in the separation of the muscle from the mucosa. The tenia is incised longitudinally. **B.** The muscle is then broadly and meticulously separated from the underlying mucosa. This creates a trough in which one buries the ureters. A mucosal opening is created at one end and the spatulated ureter is anastomosed to the mucosa. The tenia is then closed over the ureter.

Complications including adenocarcinoma and hyperchloremic hypokalemic metabolic acidosis are particularly high with rectal diversions. Metabolic acidosis can be relieved acutely with a rectal tube and managed chronically with oral sodium bicarbonate supplementation.

Rectal Pouches

Rectal pouches were introduced in order to minimize peristaltic pressure in the rectal diversion and thus minimize incontinence, pyelonephritis, and renal stones. Either a U-shaped (Mainz II) or S-shaped pouch can be created by opening and refashioning the rectosigmoid colon. The ureters are tunneled posteriorly and then anastomosed to colonic mucosa via an anterior colotomy (Goodwin technique). Rectal pouches are sometimes utilized in developing countries for urinary diversion after severe obstetric trauma with destruction of the bladder and urinary sphincter. Incontinent diversion in these settings is not only socially unacceptable but external collection appliances are often unavailable or too expensive. Unreliable catheter supplies preclude the use of catheterizable pouches. Given their limited options, many women with severe fistulae are willing to accept the risks associated with a Mainz II pouch in order to achieve continence. However, in the developed world, rectal pouches have generally been abandoned in favor of orthotopic neobladders and heterotopic pouches.

Heterotopic Continent Diversion

Heterotopic pouches utilize a detubularized intestine to create a low-pressure reservoir. Urine is evacuated from the pouch by intermittent catheterization through a continent cutaneous stoma. The various approaches use different segments of intestine for the pouch, different reconfigurations of the intestinal pouch, different segments of intestine for the catheterizable segment, various methods of tapering the catheterizable segment, and a variety of ways of creating a continence valve. The following description of methods is by no means exhaustive.

Right Colon Pouches

Right colon pouches include the Indiana pouch, the Florida pouch, the Miami pouch, and the Penn pouch. The first three utilize tapered ileum for a catheterizable channel whereas the Penn pouch uses an appendiceal Mitrofanoff. The Indiana, Florida, and Miami pouches differ slightly in the amount of colon utilized and in the techniques used for buttressing the ileocecal value to maintain continence. To create an Indiana pouch, the right colon is isolated and divided distally at the junction of the blood supply from the right colic and middle colic arteries. About 10 cm of terminal ileum is isolated (Fig. 181.7). An ileocolonic anastomosis is performed to reestablish continuity of the bowel. If the appendix is present, then an appendectomy is performed. The colon is detubularized over along the antimesenteric border. A refluxing mucosa-to-mucosa

ureterocolonic anastomosis is performed from the inside of the bowel after delivering the ureters through a small posterior colotomy. Alternatively, the ureteral anastomosis can be accomplished in the fashion of Bricker with sutures placed from the serosal side of the bowel (see above). The ileocecal junction is buttressed to maintain continence, using interrupted seromuscular Lembert permanent sutures in two rows (Indiana), opposing Lembert sutures on each side of the terminal ileum (Florida), or two purse-string sutures 1 cm apart placed in the most distal ileum (Miami) (Fig. 181.8A–C). The remaining proximal 6 to 7 cm of ileum is tapered with GIA stapler over 12 to 14F catheter along its antimesenteric border and the excess is excised (Fig. 181.8D). Alternatively, some surgeons use either Lemberts or staples along the entire efferent limb (Fig. 181.7B). We also slightly intussuscept the terminal ileum by burying the final 2 cm inside the cecum with two permanent Lembert sutures in the cecum. It is helpful to perform ileal imbrication with the colon open in order to observe the tightening of the ileocecal valve and confirm easy catheterization. The colon is then closed in a clamshell fashion or the posterior plate is reconstructed in a U-shaped fashion and then the anterior wall is closed. In the end, the two approaches produce a similar final configuration. A large cystostomy catheter and 12F or 14F stomal catheter are left for 3 to 4 weeks and externalized ureteral stents are left for 1 to 3 weeks, at the discretion of the surgeon.

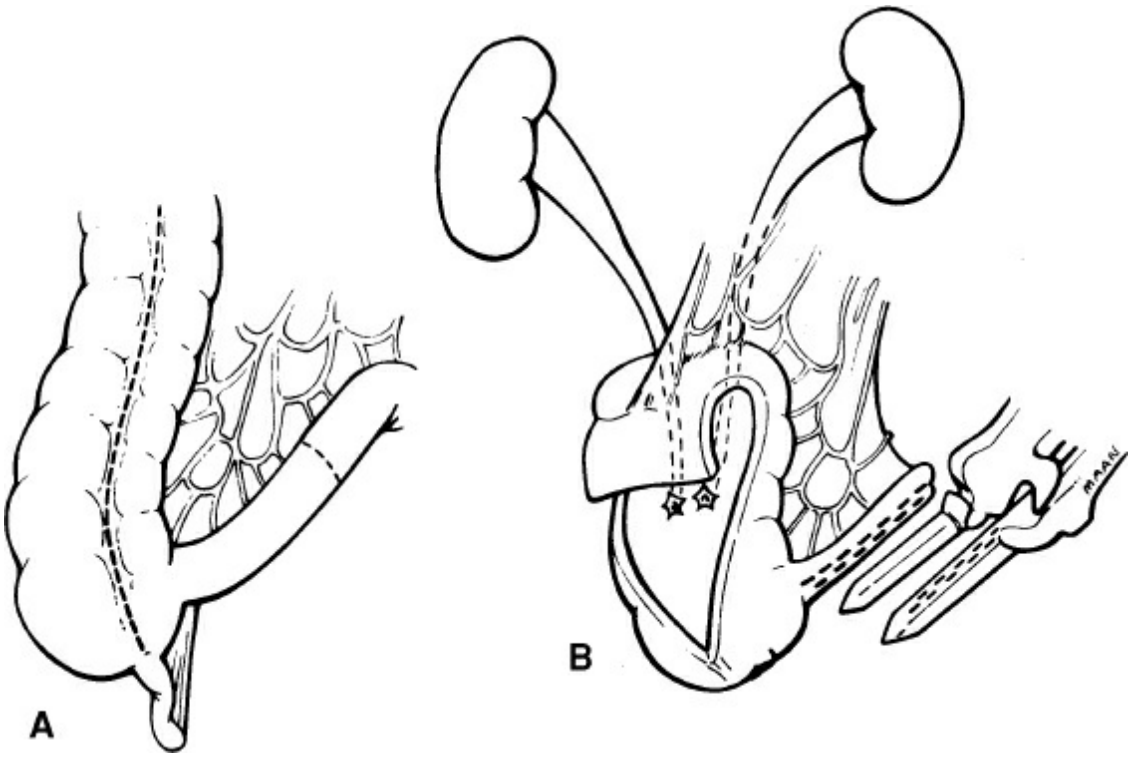

Figure 181.7. Indiana pouch creation. **A.** The right colon is divided at the hepatic flexure. The ileum is divided 10 cm from the ileocecal valve. **B.** The colon is detubularized and closed in a spherical fashion. The ileum is tapered for the efferent limb which can be done with all staples (as shown here) or a combination of Lembert sutures and staples (see Fig. 181.8A).

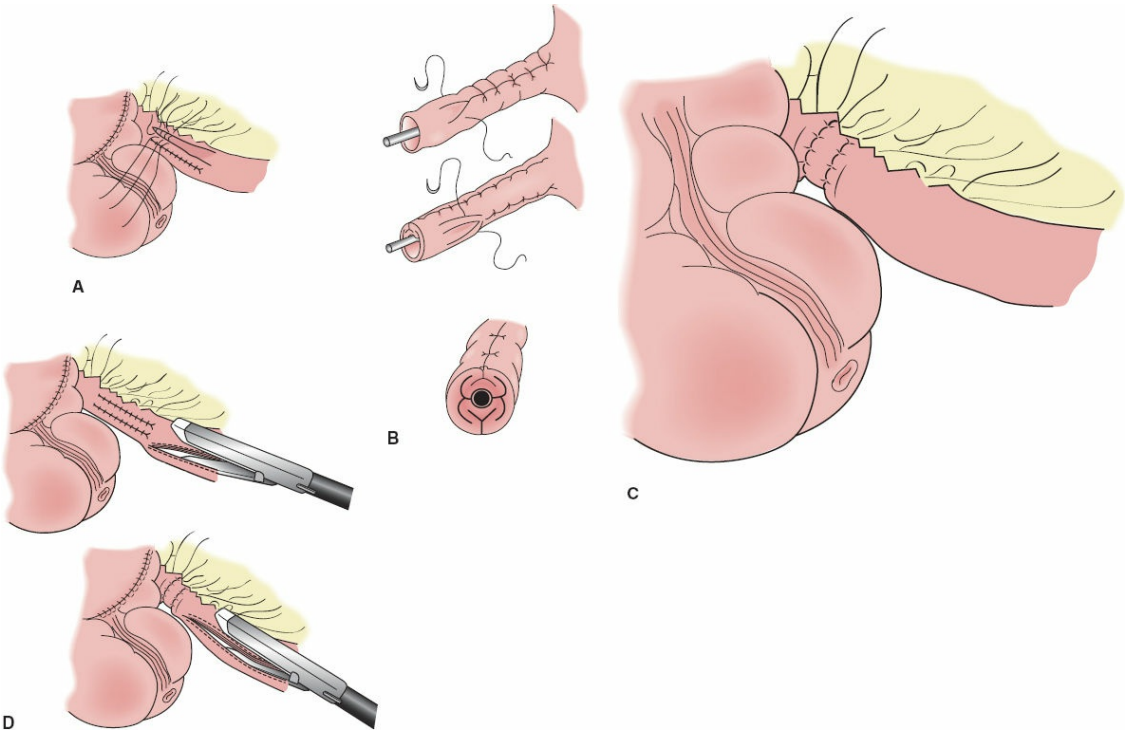

Figure 181.8. Options (A-C) for buttressing distal ileum **A.** Distal ileum can be imbricated using 2 rows of Lembert sutures over a catheter (Indiana). **B.** Opposing Lembert sutures on each side of the terminal ileum (Florida). **C.** Two purse-string sutures 1 cm apart placed in the most distal ileum near the IC valve (Miami). **D.** After buttressing, the proximal 6 to 7 cm of ileum is then tapered over catheter with GIA stapler.

With the Penn pouch, similar techniques are used for right colon isolation and reconfiguration. An ileocolonic anastomosis is performed and the ileocecal valve is closed on the cecal side. A Mitrofanoff procedure is then performed. This can be done by dividing the appendix at its insertion into the colon and by inverting or, more simply, by leaving the appendix in situ and burying it in a 3- to 4-cm tunnel created in the anterior tenia, similar to the technique used in the Malone anterior continence enema procedure (ACE-Malone).

With any of these approaches, the efferent limb is then brought through

a finger-sized defect in the rectus fascia and skin. It can be helpful to anchor the anterior aspect of the pouch to the posterior rectus sheath for two reasons. First, it prevents the pouch from moving, which can alter the catheterization angle. Second, should a percutaneous procedure such as cystostomy tube placement or percutaneous stone removal be necessary, the pouch can be punctured without injury to the intervening bowel. We prefer to perform these fixation sutures on either side of the temporary cystostomy tube that we place intraoperatively.

Ileal Pouches

Three general types of ileal pouches have been described: the Kock pouch, the ileocecal Mainz pouch, and the various orthotopic pouch configurations (described later), which can be used in a heterotopic location with the application of a Monti or Mitrofanoff catheterizable channel. The Kock pouch is rarely performed in the modern era due to its complexity and high rate of complications. It is not described further in this text.

The ileocecal Mainz pouch combines the distal ileum and cecum in a pouch with a separate ileal segment for a catheterizable channel while preserving the ileocecal valve for continence (Fig. 181.9). One isolates 10 to 15 cm of cecum and the right colon, two 10- to 15-cm segments of the distal ileum, and a 20- to 25-cm segment of ileum just proximal to that. The cecal segment and two 10- to 15-cm ileal segments are detubularized and sewn side to side in an “S” configuration to form the posterior plate of the pouch, taking care to preserve the ileocecal valve. The other ileal segment serves as the efferent limb. It is separated from its mesentery for 6 to 8 cm and intussuscepted into the posterior plate of the pouch. The intussusception is stabilized with two passes of a noncutting stapler. The stabilized segment is then passed through the ileocecal valve and stabilized again with the stapler. The pouch is closed and the efferent limb is brought out through the rectus fascia and skin.

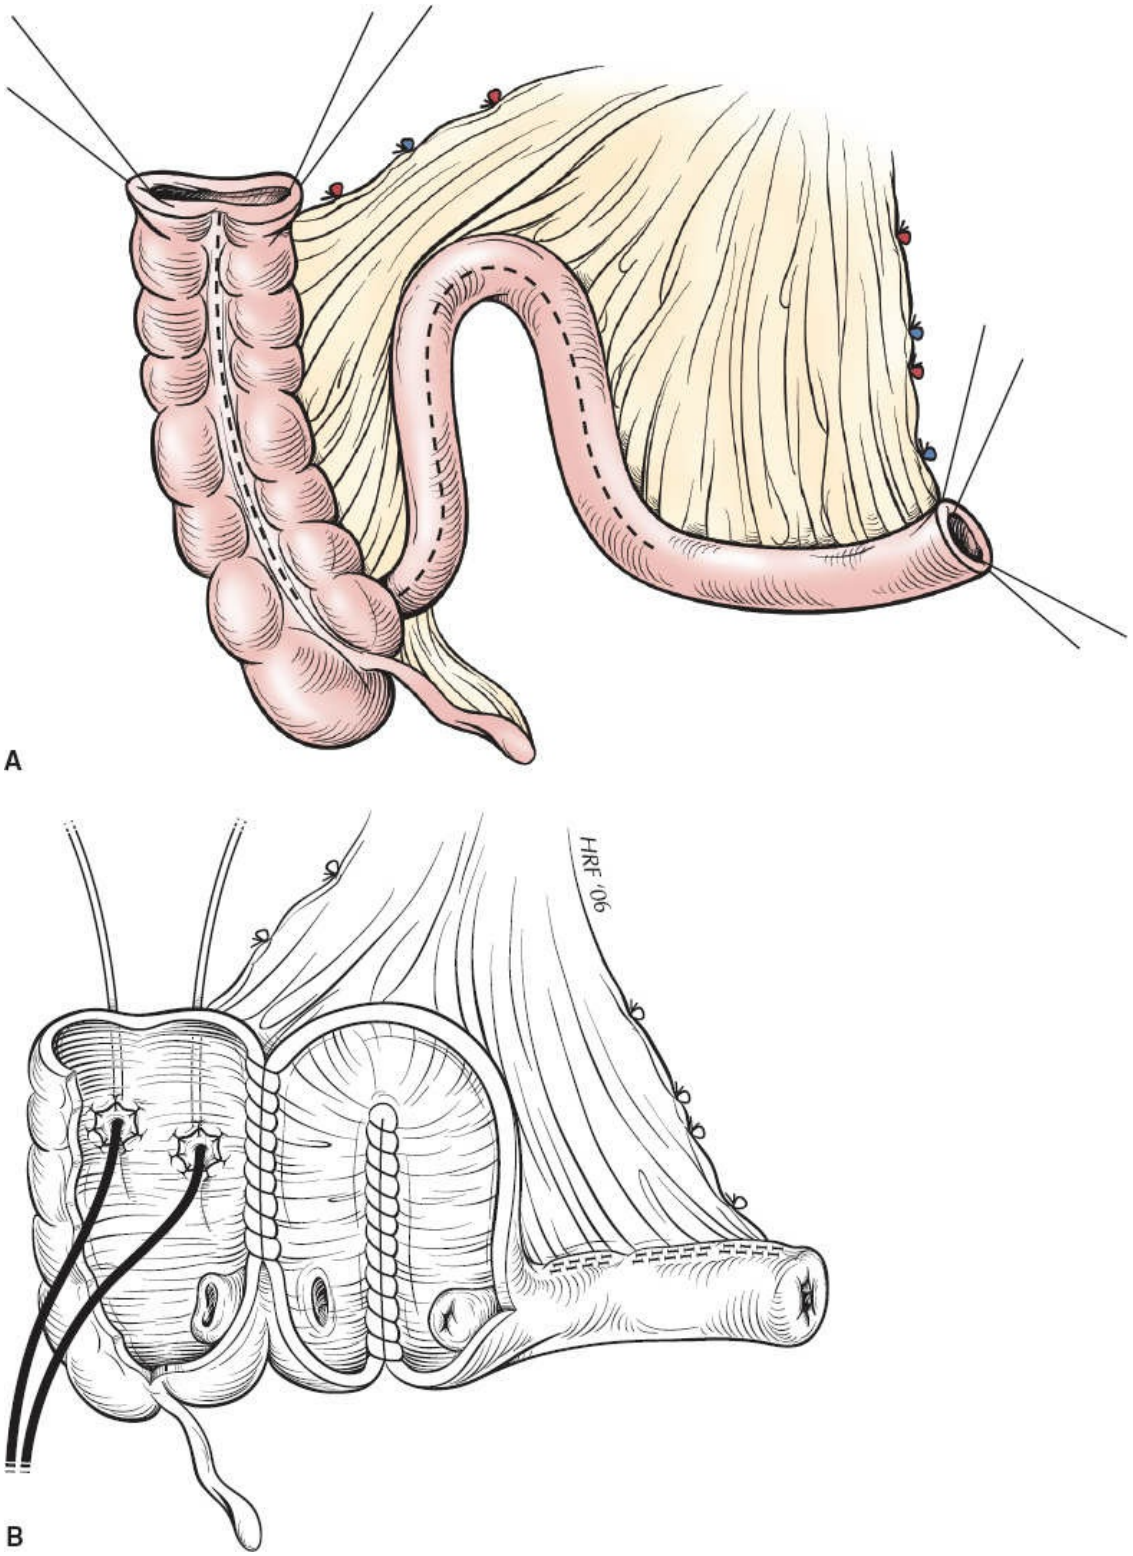

Figure 181.9. Mainz pouch. **A.** The pouch is created from 10 to 15 cm of detubularized ascending colon and 20 to 25 cm of detubularized terminal ileum folded in an S-shape. Another more proximal 10-cm segment of ileum is not detubularized. **B.** The proximal nondetubularized ileum is intussuscepted into the pouch and through the preserved ileocecal valve. This double intussusception is secured with staples.

Any ileal pouch can serve as a heterotopic reservoir, including those originally intended as orthotopic pouches. However, without an ileocecal valve to serve as a continent catheterizable segment, one must rely on a tunneled appendix or ileum. When using the ileum as the catheterizable channel, one minimizes the amount of bowel that must be resected by using the Monti technique rather than by simply tapering a long segment of ileum (Fig. 181.10). In this manner, 2 cm of ileum is harvested and opened lengthwise. The bowel is then closed transversely such that the mucosal folds are oriented along the length of the channel. The closure is done over a 12F or 14F catheter with absorbable sutures. In adults, in order to achieve enough narrowing of the channel over the catheter we often find it necessary to imbricate a second layer of closure in a Lembert fashion. Because this layer will be extraluminal, we use permanent sutures. Because the bowel is opened closer to the mesentery on one side, the mesentery will attach closer to one end of the catheterizable channel. This allows the surgeon some flexibility in putting the shorter end through the pouch and freeing up the longer end to traverse to the skin, or vice versa. Submucosal tunneling into the pouch is done as originally described by Mitrofanoff, which is similar to that described by Leadbetter and Clarke for extracolonic ureteral implantation. The serosa and muscularis are elevated over a distance of 3 cm and the catheterizable segment laid in the trough. A small hole is created in the end of the bowel mucosa and a mucosa-to-mucosa anastomosis performed between the catheterizable segment and the pouch. The Monti technique yields a channel that is about 6 cm in length. When longer segments are required, one can use a spiral Monti or double Monti. In the double Monti, two Monti segments are sewn end to end. In the spiral Monti described by Casale, a 4-cm ileal segment is detubularized on one side of the mesentery for half the length of the bowel, the incision is brought across the bowel to the opposite mesentery, and the remainder of the bowel is opened along that mesentery. When the bowel is closed longitudinally, the reconfiguration is in a spiral (Fig. 181.11).

Orthotopic Neobladders

The original orthotopic diversion was the Camey procedure, using a nondetubularized ileal segment. This has been abandoned due to high rates of incontinence and loss of renal function from high reservoir pressures. Current approaches share the concept of detubularized and reconfigured ileum, with continence achieved by the preserved external urinary sphincter. Some surgeons leave a temporary suprapubic catheter and a

urethral catheter, others just a urethral catheter. In our experience, including the larger suprapubic catheter allows for better irrigation of mucus than the single 16F urethral catheter. However, when no suprapubic catheter was left in place we obtain good results by using a 24F hematuria catheter as the urethral catheter. Regardless which method of postoperative drainage is chosen, scheduled catheter irrigation helps clear mucous and prevent obstruction. Ureters are typically reimplanted in a refluxing manner. Some surgeons externalize “single J” ureteral catheters through the skin and drain them to an external pouch until removal. Others tie “double J” stents to the urethral catheter, allowing them to be removed with the urethral catheter at 3 weeks postoperatively. While “double J” stents may at first appear to minimize morbidity, we have experienced increased pyelonephritis in the postoperative period in the setting of prolonged stenting, potentially due to reflux from bladder irrigation. Thus, we prefer to externalize the stents by passing them out through a stab incision on the pouch and the anterior abdominal wall and allowing them to drain into a stoma bag postoperatively. They can be removed within a week, while the urethral catheter is left for 3 weeks and removed after a cystogram demonstrates no evidence of leak.

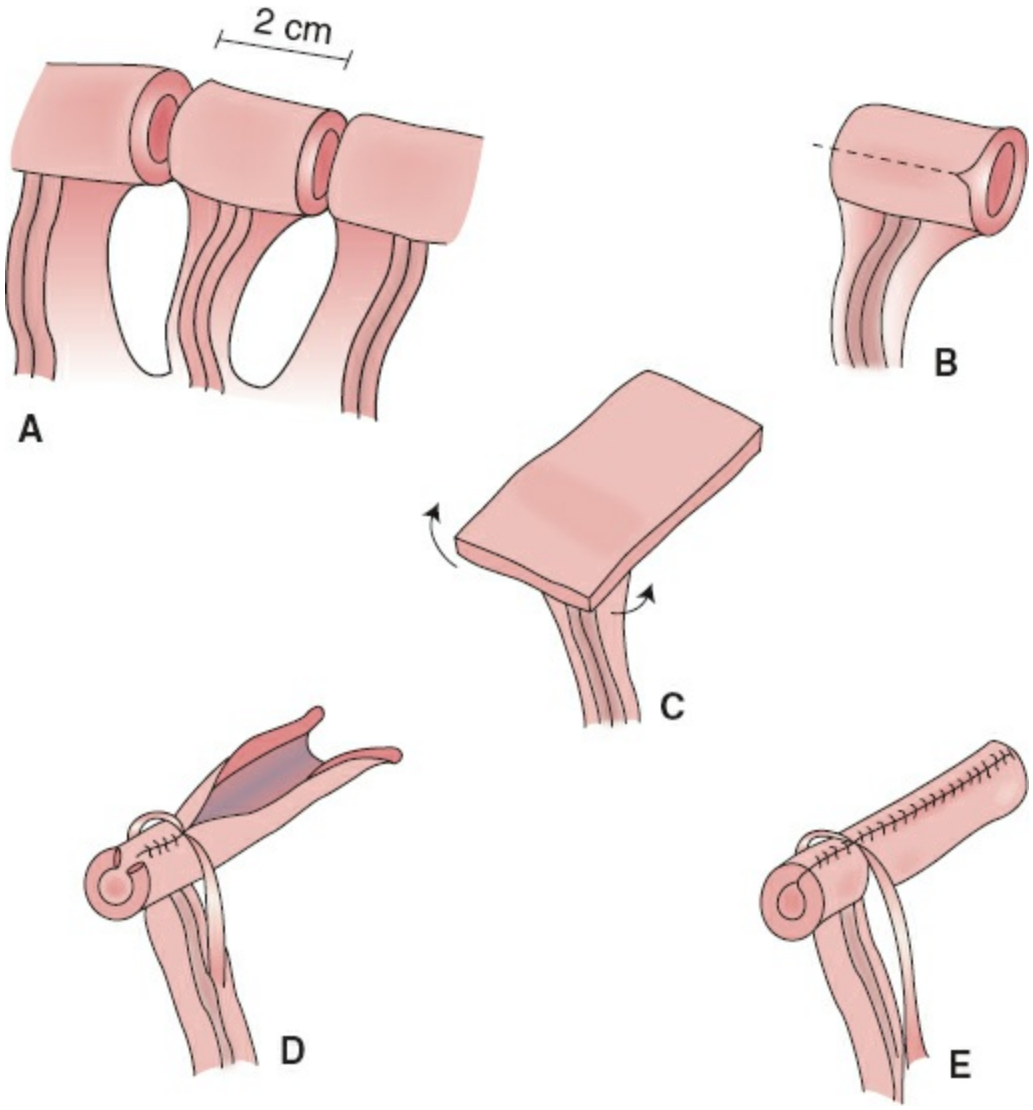

Figure 181.10. Monti catheterizable channel. **A.** A 2-cm segment of ileum is isolated. **B.** The segment is detubularized closer to one side of the mesentery than the other. **C.** The segment is retubularized perpendicular to its original configuration. **D,E.** A mucosa-to-mucosa anastomosis is performed over a 12F to 14F catheter.

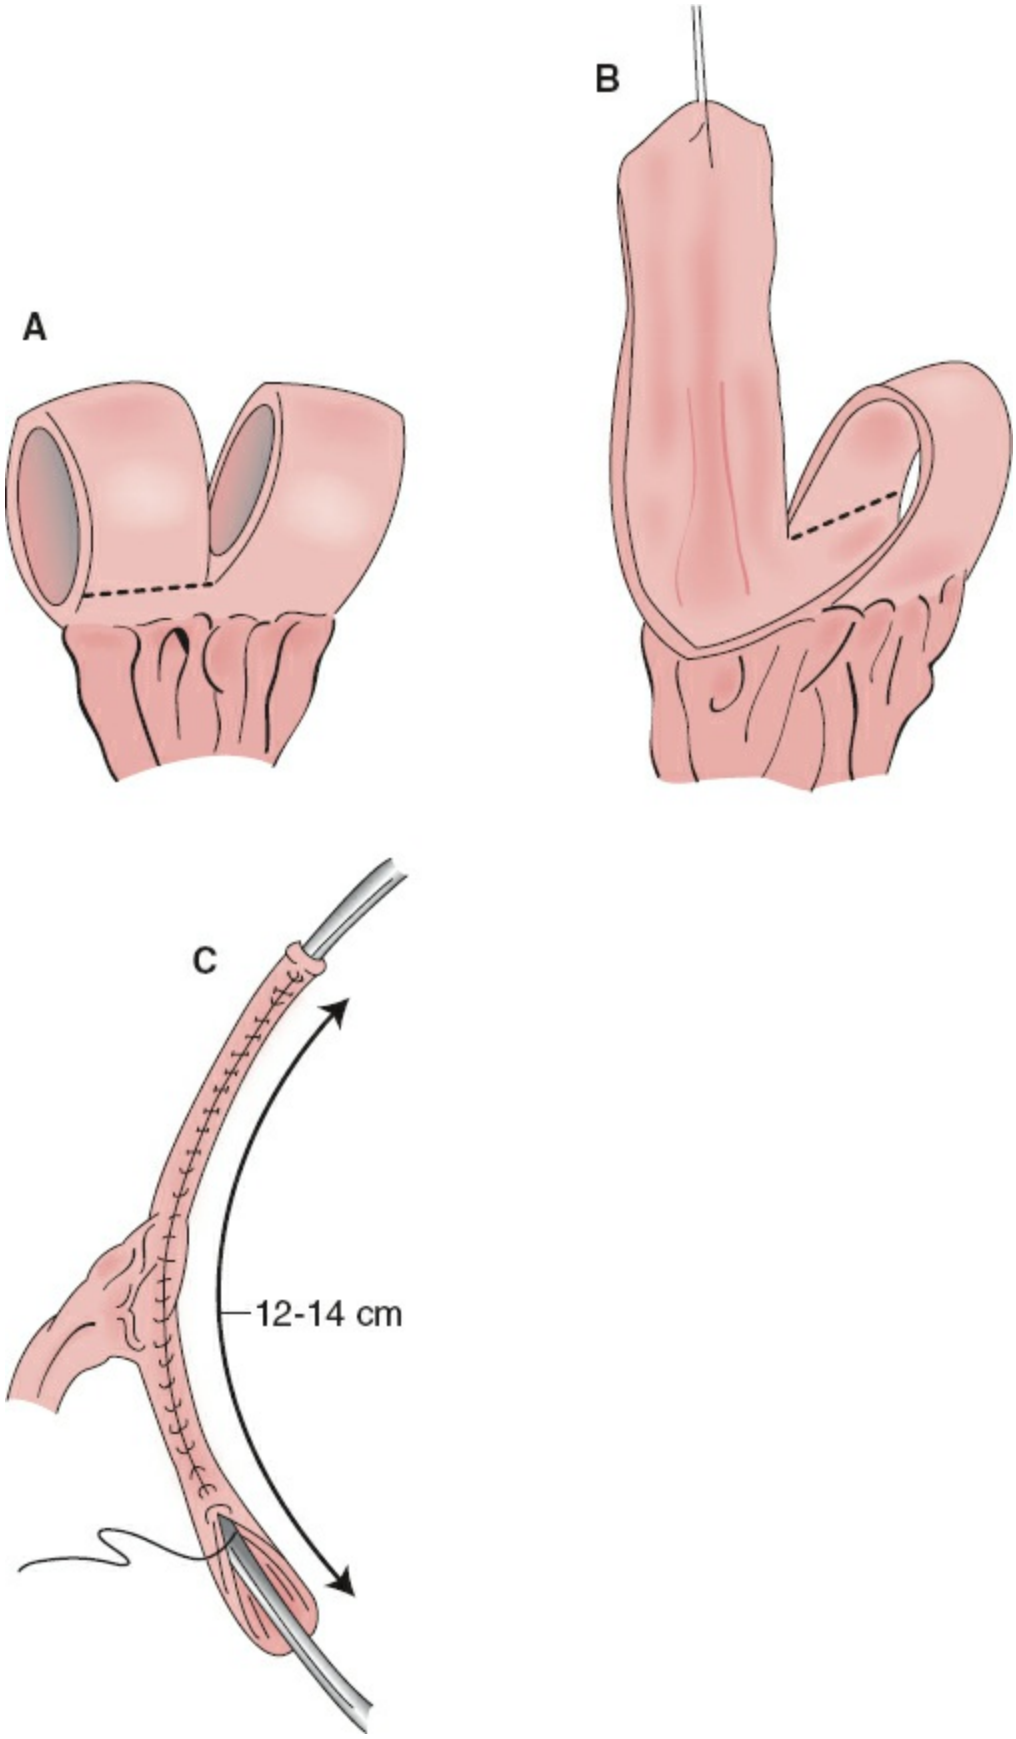

Figure 181.11. Spiral Monti in the fashion of Casale. **A,B.** A 4-cm segment of ileum is isolated and an S-shaped detubularizing

incision is made such that one half of the bowel is opened along one side of the mesentery and the other half is opened along the other side. **C.** The resulting long strip of bowel is then closed over a 12F to 14F catheter.

Voiding is achieved by Valsalva and simultaneous voluntary sphincter relaxation. Daytime continence is better than nighttime continence due to relaxation of the voluntary sphincter during sleep. Both types of incontinence improve over time, with only a minority continuing to experience these issues at 1 year postoperatively. Initial problems with urinary retention, especially in women, have been improved by fixing the pouch to the anterior abdominal wall to avoid kinking of the urethra.

Studer Neobladder

The Studer neobladder is the simplest to perform of the orthotopic diversions. It is essentially a "J" pouch with the upper limb of the "J" serving as the afferent limb for ureteral reimplantation. A 60-cm segment of ileum is isolated 15 to 25 cm from the ileocecal valve (Fig. 181.12). The distal 40 cm is detubularized and the posterior plate reconstructed in a "U" fashion using running absorbable suture (typically 3-0), then the upper and lower halves are closed to each other in a clamshell fashion, forming a sphere. The upper 20 cm is left intact, allowing this segment to reach the mid ureters. The ureters are sewn to the conduit in the fashion of Bricker. This afferent limb may offer several advantages. First, the peristaltic waves help minimize reflux. Second, it allows the surgeon to resect the ureters above the iliac vessels. As the internal iliac blood supply to the ureters is interrupted during cystectomy the distal ureters are relatively devascularized, relying on blood flow from the upper and mid ureter. By anastomosing the mid ureter to the afferent limb, the "chimney" of the Studer neobladder minimizes distal ischemia and may thus minimize ureterointestinal anastomotic strictures. The most dependent portion of the pouch is opened and the mucosa everted for anastomosis to the urethral stump with 2-0 or 3-0 absorbable sutures. Initial pouch volumes are lower than with other pouches—about 150 mL—but this increases over time to about 500 mL.

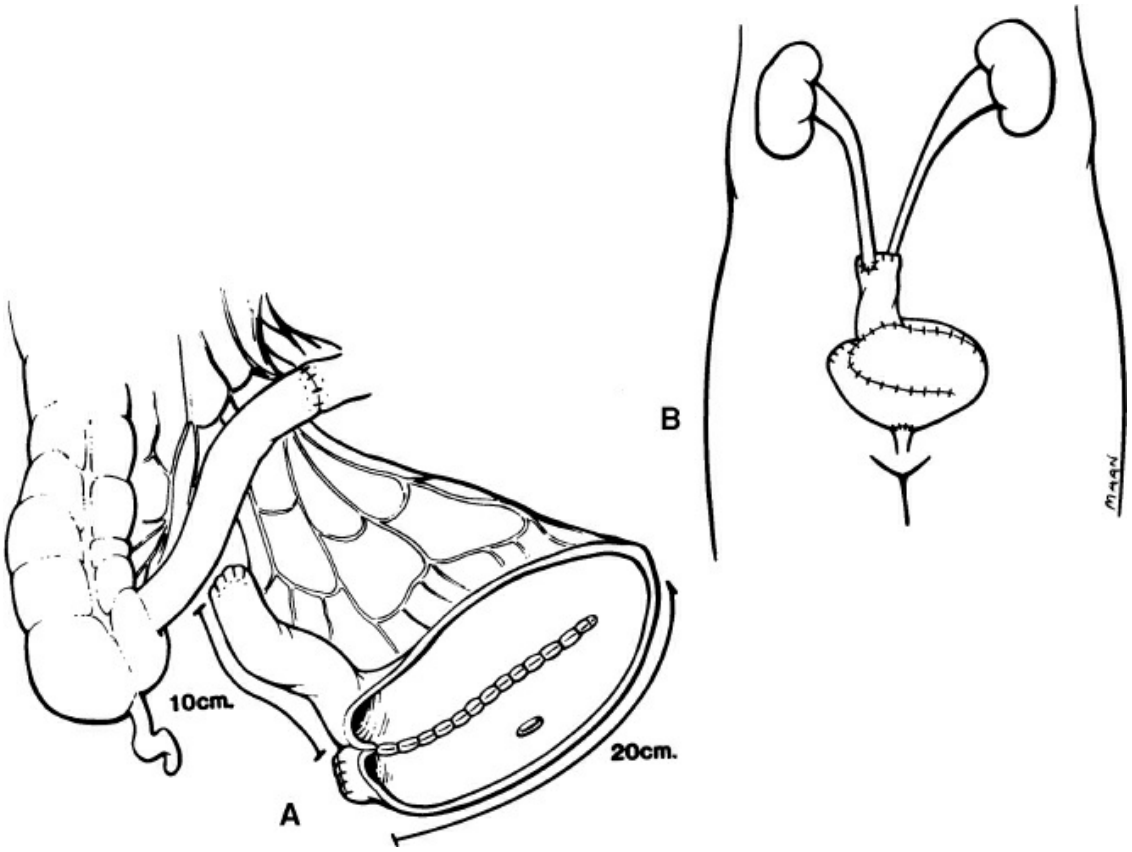

Figure 181.12. Studer neobladder. **A.** A U-shaped pouch is created from 40 cm of ileum while sparing the terminal 15 cm. Another proximal 15-cm segment of ileum acts as the “chimney” into which the ureters are reimplanted. **B.** The bottom of the pouch is closed, but not before the most dependent portion is brought down and anastomosed to the urethra.

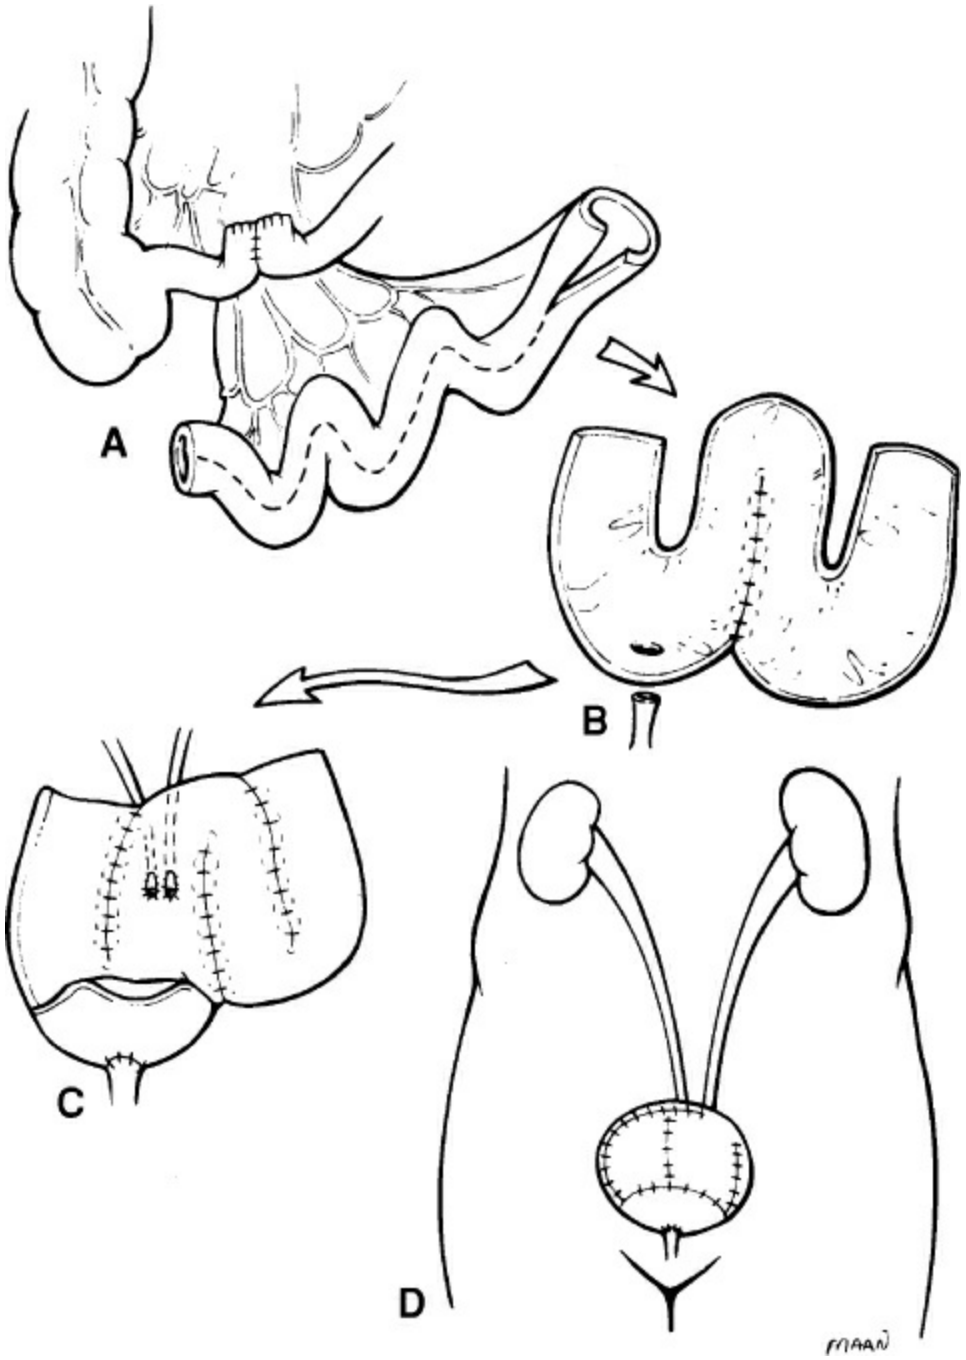

Figure 181.13. Hautmann neobladder. **A.** The pouch is created from a 60- to 80-cm segment of ileum, sparing the terminal 15 cm. **B.** The bowel is detubularized along its antimesenteric border and fashioned into a “W” shape. A larger flap between the first and second limb is allowed to create a wider plate for anastomosis to the urethral stump. **C.** The ureters are reimplanted into the second and third limbs. **D.** The pouch is then folded over to close on itself. A Studer modification includes an afferent nondetubularized limb onto which a Bricker anastomosis of the ureters is performed.

Hautmann Neobladder

The Hautmann neobladder is an ileal reservoir that uses 60 to 80 cm of ileum with the back plate fashioned in a "W" (Fig. 181.13), thus achieving higher initial volumes compared with the Studer pouch. Classically, the ureters were brought through the posterior wall of the neobladder and the anastomosis was done from the inside. Alternatively, a Studer modification can be performed by creating a chimney into which the ureters are anastomosed. This technique also differs from the Studer approach in that the segment to be used for the urethral anastomosis is chosen before opening the bowel. The line one follows when opening the bowel should be deviated away from the antimesenteric line toward the anterior mesentery in the area of the planned urethral anastomosis. This creates a posteriorly based "U" flap, which can be fashioned into a tube and makes the anastomosis easier to perform.

Mainz Neobladder

The Mainz neobladder is created in a fashion similar to the Mainz heterotopic pouch, using 10 to 15 cm of cecum and right colon and two 10- to 15-cm segments of ileum (Fig. 181.14). The posterior plate is constructed in an "S" fashion using the three limbs. The urethral anastomosis is performed and then the anterior wall is closed.

POSTOPERATIVE MANAGEMENT

Cystectomy and urinary diversion are a highly complex operation and operative times may exceed 8 hours in some cases. Blood loss is minimized with current techniques but can still reach 1,000 mL or more. Patients with bladder cancer or radiation cystitis are frequently elderly and may possess multiple comorbidities, increasing their risk of postsurgical complications. For all these reasons, careful postoperative care is essential to a successful outcome. Care pathways have led to earlier discharge and helped minimize complications.

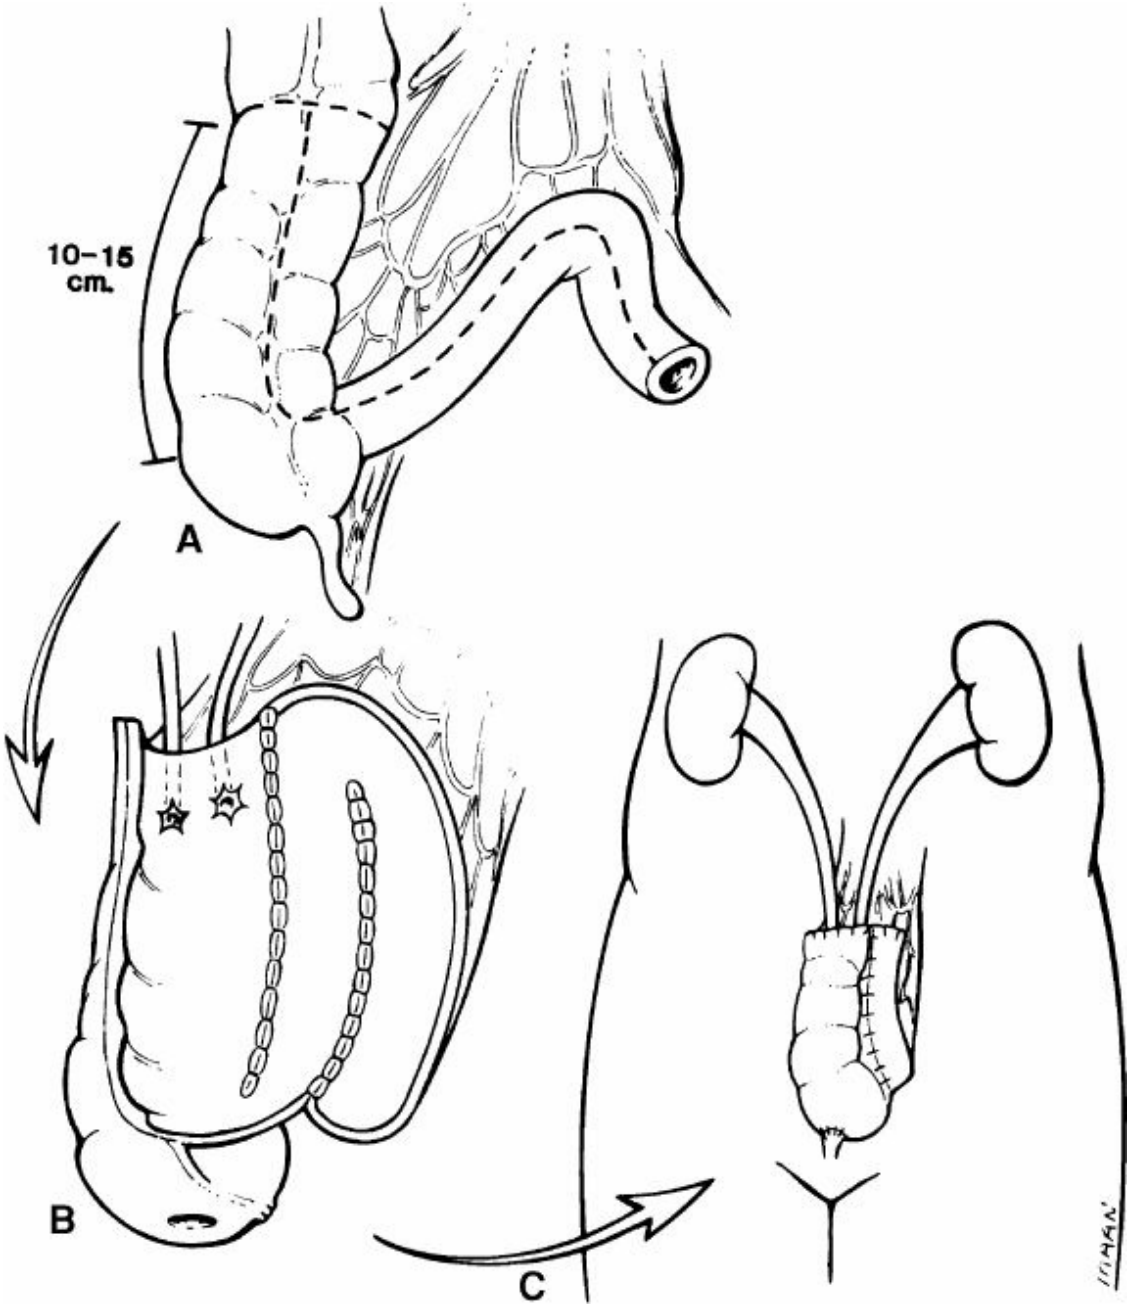

Figure 181.14. Mainz neobladder. **A.** Ten to fifteen centimeters of cecum and ascending colon with 20 to 30 cm of ileum is isolated. **B.** The entire segment is detubularized along its antimesenteric border, and a broad posterior plate is created by suturing the opposing edges to create a W. Tunneled ureterocolonic anastomoses are performed. **C.** A buttonhole incision is created at the base of the cecal portion for the ureterointestinal anastomosis. The neobladder is closed by folding the lateral limbs anteriorly and suturing in a continuous fashion.

If a bowel anastomosis is performed, many opt to leave a nasogastric

tube. Others choose to omit the nasogastric tube based on a meta-analysis of randomized trials that showed no change in return to bowel function but an increase in pulmonary complications with a nasogastric tube. Some surgeons use metoclopramide to help stimulate bowel activity, although evidence of efficacy in the postoperative period is mixed. Ulcer prophylaxis is important. Early feeding may help advance the date of discharge. Deep venous thrombosis prophylaxis is important; many patients undergoing cystectomy are at high risk of thrombosis and anticoagulation therapy in addition to sequential compression devices and frequent ambulation play a role in prevention.

COMPLICATIONS

Perioperative mortality occurs in 2% of cystectomy patients. Over a third to almost 50% of cystectomy patients develop minor complications and about 10% suffer major complications in the acute postoperative period; some of these are related to urinary diversion but most are not. As the focus of this chapter is urinary diversion, not cystectomy, we will focus on complications directly related to urinary diversion. About 5% will develop bowel obstruction and 1% to 2% an enteric anastomotic leak. About 1% to 3% will develop a urine leak from the pouch or ureteroenteric anastomosis and <1% will develop acute stomal problems such as stenosis or necrosis.

In contrast, many of the long-term complications are diversion related. Ureterointestinal anastomotic stricture occurs in 7% to 14%. Minimal mobilization of the ureter and careful mucosa-to-mucosa anastomosis are important. Diarrhea is not uncommon and can impact quality of life. Serious metabolic complications occur rarely and are due to reabsorption of solutes from the urine. Risk is higher in continent than in noncontinent diversions. Almost all reservoirs today utilize the ileum and/or the colon; hyperchloremic metabolic acidosis can result from absorption of ammonium chloride in exchange for excretion of carbonic acid. Most patients have only minor electrolyte abnormalities, but clinically significant changes requiring bicarbonate supplementation occur in about 10% of continent pouches. Upper tract stones can occur in >30% of patients when followed for more than a decade. The risk is related to oxalate malabsorption, serum metabolic acidosis from urine reabsorption, and chronic infection with urea-splitting bacteria. Pouch stones occur due to mucous retention from inadequate emptying or staples/mesh/permanent suture inside the pouch. These can generally be managed transurethrally in

the case of the orthotopic pouch or percutaneously in heterotopic pouches. Revision of the catheterizable channel for stomal stenosis or false passage is required in about one quarter of patients followed long term. Parastomal hernias occur in up to 20% of patients; success rates with repair are disappointing though recent techniques of open transabdominal repair using mesh to buttress the fascial defect have yielded better results. Successful resolution frequently requires contralateral relocation of the stoma.

CONCLUSIONS

Surgical supravesical urinary diversion provides an alternative to a natural bladder function by providing drainage of urine from the kidneys using intestinal segments. Urinary diversion is technically challenging surgery associated with both short- and long-term complications. The variety of approaches, all with different risk/benefit profiles, suggests that there is no "ideal" diversion. Thoughtful patient selection, meticulous attention to intraoperative technique, and careful long-term monitoring are essential for ensuring good outcomes in patients with urinary diversions.

EDITOR'S COMMENT

The authors have written an excellent chapter with very detailed diagrams of the operative procedures. Supravesical urinary diversion is employed in patients in the most dire of straits, that is, in patients having bladder cancer, bladder dysfunction, severe congenital abnormalities, major procedures, complications of radical procedures, and often with the causative or complicating factor of radiation field effects. Choosing the right procedure for the right patient depends not only on the causative factor but also coexisting disease, mental faculties, and social support. It seems to me much of what applies for the colorectal surgeon and diversion of the fecal stream applies to urinary diversion. Types of continent pouches include the Kock, J, W and the S pouches including the Mainz pouch and most commonly the Studer pouch. According to the 2007 WHO consensus conference, the frequency of ileal neobladder diversion after radical cystectomy performed in centers of excellence was approximately 50%. Incontinent diversion includes placement of the ostomy as well as maturation of the loop or everted conduit in the fashion of Brooke all being a preoperative consideration. Continent cutaneous diversion is only offered in a few specialized centers in the United States in patients undergoing cystectomy due to the high complication rate and need for revision in 10% to 20% of patients. Many patients are willing to accept this risk in order to avoid wearing an ostomy appliance (Skinner E. Continent cutaneous diversion. *Curr Opin Urol* 2015;25:555–61).

Although not reviewed in this chapter, the number of robotic urinary diversion surgeries is increasing worldwide (Chopra S, Abreu AL, Gill IS. Robotic urinary diversion: the range of options. *Curr Opin Urol* 2016;26(1):107–13). The first robotic case reported was in 2003. However, according to the International Robotic Cystectomy Consortium the percentage of patients undergoing robotic surgery for neobladder reconstruction is less than 10%. Fahmy et al. (Fahmy O, Asri K, Schwentner C, et al. Current status of robotic assisted radical cystectomy with intracorporeal ileal neobladder for bladder cancer. *J Surg Oncol* 2015;112(4):427–9) have systematically reviewed the current status of robotic assisted radical cystectomy with intracorporeal ileal neobladder for bladder cancer. After excluding ineligible studies, they found

three case series and five case reports with a total number of 203 reported cases of which 114 neobladders were intracorporeally fashioned. A majority of complications with the procedure are not with the radical excision of the bladder but with 17.2% of the patients developing diversion-related complications. Although robotic intracorporeal neobladder reconstruction is in its starting phase, initial perioperative results seem to be comparable to open series. The International Robotic Cystectomy Consortium reported with a median follow-up of 9 months that the major complication rate was 20% for robotic-performed intracorporeal diversion compared to 32% with extracorporeal performed diversion. There has been an increasing use of robotics but more so for radical cystectomy than making an intracorporeal neobladder because of the technical difficulty and doubling of the operative time to do so. Some surgeons perform the cystectomy robotically and then form the ileal pouch extracorporeally. Although some advantage is obtained with shortening the length of the operation and decreased nerve damage with this approach, the patient still has the disadvantages of increased postoperative pain, hernias, and ileus from the celiotomy. As always, randomized studies are forthcoming to confirm noninferiority of robotic techniques.

With new approaches come new procedures. Dal Moro and Zattoni have developed a novel robotic intracorporeal orthotopic ileal neobladder, the so-called “Ves.Pa.” procedure and in a systematic manner in a robotic pelvic model confirmed the feasibility of the technique and simplified the technique. In general, developing procedures and working to improve the technical aspects of the procedure is a particular advantage of robotics. Clinical studies are needed to confirm this technique (Perletti G, Magri V. Re: Shoskes et al: The Urinary Microbiome Differs Significantly Between Patients With Chronic Prostatitis/Chronic Pelvic Pain Syndrome and Controls as Well as Between Patients With Different Clinical Phenotypes. *Urology* 2016 Aug;94:315–6.).

Complications with long-term follow-up are detailed in this chapter and as nicely put are best avoided by working with unirradiated bowel and ureters and minimizing ureter mobilization. Something not mentioned that is detailed in a recent study by Raup et al. (Dal Moro F, Zattoni F. Ves.Pa.-Designing a Novel Robotic Intracorporeal Orthotopic Ileal Neobladder. *Urology* 2016 May;91:99–103. doi: 10.1016/j.urology.2016.02.008. Epub 2016 Feb 18.) is use of botulinum toxin type A injection in the treatment of continent catheterizable ileal-colic urinary diversion muscularis overactivity and may be a good option for the long-term treatment of contracted continent catheterizable diversions. Another nice nonoperative procedure detailed using a flexible ureteroscopic treatment and laser lithotripsy for the removal of a frequent complication of pouches—a large urinary stone (Wilhelm K, Frankenschmidt A, Miernik A. Analgesia-free flexible ureteroscopic treatment and laser lithotripsy for removal of a large urinary stone: a case report *J Med Case Rep* 2015;9:225).

Ongoing trials are looking at quality of life issues comparing continent and incontinent diversion. Robotics has little effect on QOL but may assist in the

postoperative management as it is affected by often by the advanced age of the patient and poor functional status as well as the ill-effects of concomitantly administered adjuvant therapies (Ahmadi H, Lee CT. Health-related quality of life with urinary diversion. *Curr Opin Urol* 2015;25(6):562–9). The reduction in ostomies seems the most effective way to improve patients' quality of life.

V. Suzanne Klimberg

C GYNECOLOGIC SURGERY

182 Cesarean Delivery

Thomas R. Moore

BACKGROUND

Definition and History

The origin of the term *cesarean* is unclear, but the legend of Julius Caesar's "cesarean" birth is unlikely to be true. In those ancient times, cesarean delivery was universally fatal, and Caesar's mother was known to have lived for many years after his birth. The term may have derived from the Latin words *caedere* (to cut), and *caesons* (the term for children delivered by cesarean), or from the Roman law known as *Lex Cesare*, which mandated postmortem delivery so the mother and infant could be buried separately. The term "cesarean section" is redundant, derived from the Latin words *caedere* and *secare*, which both mean "to cut."

The evolution of the current surgical technique is of interest. Maternal mortality rates for cesarean birth prior to the 20th century approached 100% owing to the almost universal uterine sepsis that followed. Consequently, very few cesareans were performed. Cesarean delivery was combined with hysterectomy in the late 19th century in an effort to reduce infection and thus prevent maternal death. Although one innovation (the "Porro" technique) involved suturing the edges of the uterine incision to the abdominal wall, allowing the lochia to drain externally significantly reduced postpartum sepsis and death; it was not until well into the 20th century that advances in surgical suture material, aseptic technique, anesthetic advances, the low-transverse incision, and antibiotics improved the safety of cesarean delivery. As a result, cesarean delivery rates in the United States increased from 4.5% of all deliveries in 1965 to 16.5% in 1980 to 24.5% in 1988 to 32% in 2015. Cesarean rates still vary widely with geographic area and type of hospital (i.e., teaching vs. nonteaching). Currently, over 1 million cesarean deliveries are performed annually in the

United States alone, making it the most common surgical procedure performed on women today.

INDICATIONS

Cesarean delivery may be indicated for fetal and/or maternal reasons, such as failure to progress in labor, fetal malpresentation, placenta previa, nonreassuring fetal monitoring (category II or III by the American College of Obstetricians and Gynecologists [ACOG] guidelines), suspected macrosomia (>5,000 g or 4,500 g if diabetic), active infections like herpes simplex virus or high viral load HIV, vertical uterine incisions from previous deliveries, and certain fetal anomalies such as severe fetal hydrocephalus or fetal neck masses. The majority of cesareans are still primary with repeat cesarean as an indication for 37.5% of all cesarean births. A currently controversial topic is the "cesarean-on-demand"—elective, patient-choice cesarean birth. There are data suggesting less urinary incontinence and pelvic organ prolapse after elective cesarean, but the slightly increased morbidity and mortality associated with surgical delivery make the risk/benefit ratio for elective cesarean difficult to quantify. There is currently no standard recommendation regarding patient-choice cesarean. ACOG states, "Given the balance of risks and benefits, the Committee on Obstetric Practice believes that in the absence of maternal or fetal indications for cesarean delivery, a plan for vaginal delivery is safe and appropriate and should be recommended to patients" (ACOG Committee Opinion on Cesarean Delivery on Maternal Request 2013).

RISKS

Currently, cesarean delivery has an overall low maternal mortality and morbidity but is still significantly elevated over vaginal delivery. The current cesarean mortality rate in the risk of death for cesarean sections is 13 per 100,000 and for vaginal birth 3.5 per 100,000 in the developed world. Maternal morbidities associated with cesarean birth depend on the indication for surgical delivery, but include increased risk of endomyometritis (up to 20%); wound infections; increased blood loss; need for transfusion (up to 7%); thromboembolic events; anesthetic complications; and surgical complications with damage to bowel, bladder, and major pelvic blood vessels. Morbidity is highest in emergency cesarean birth, especially after prolonged labor and/or ruptured

membranes.

SUBSEQUENT OUTCOMES

Long-term morbidities commonly attributed to cesarean delivery include uterine scar dehiscence or rupture, fetal demise and expulsion from a uterine scar, placenta previa with or without accreta, increased surgical complications from adhesions, bowel obstruction, bladder injury, and increased blood loss during future surgery. Uterine rupture occurs in subsequent pregnancy <1% if a low-transverse uterine incision was done, and up to 12% if a prior vertical classical uterine incision was performed. Uterine rupture may be an asymptomatic uterine "window" with minimal consequences or may be a catastrophic expulsion of the fetus into the abdomen with subsequent fetal demise. If risk factors such as a previous classical uterine incision, extensive myomectomy, or more than two previous low-transverse uterine incisions are present, repeat cesarean delivery prior to the onset of labor is usually recommended. Alternatively, there is a 70% likelihood of successful vaginal delivery with labor following a single prior cesarean delivery via a low transverse incision. If a vaginal birth after cesarean delivery (VBAC) is considered, an appropriate support team of anesthesiologist, nurse, and pediatrician must be available in case an immediate abdominal delivery during labor is necessary. Women undergoing VBAC must be properly informed about the potential risks/benefits of vaginal versus repeat cesarean delivery, and this should be documented in written consent.

PREOPERATIVE PLANNING

Anesthesia

Choice of anesthesia is determined by the clinical situation and maternal/fetal indications for delivery. The options for anesthesia are spinal, epidural, combined spinal epidural, general anesthesia, and local anesthesia alone (least common). Regional anesthesia is most commonly used for planned cesarean deliveries or nonurgent cases. Epidural anesthesia may be used if already in place for labor analgesia and if time allows for dosing to an adequate level. Slow epidural anesthesia may be indicated in cases where general or spinal anesthesia is contraindicated. One example is a maternal cardiac disorder (i.e., pulmonary or aortic stenosis) where avoiding rapid decreases in systemic vascular resistance is

important. There are significant risks of general anesthesia in the laboring parturient. Gastric emptying is slowed and significant changes in maternal physiology make airways more difficult during gestation. Antacids or histamine-2 blockers are given regardless of gastric contents in all cases prior to surgery. Local anesthesia has been used alone, but should be reserved for the rare case where no anesthesiologist is available, immediate delivery is required, and patient consent has been obtained.

Patient Preparation

The patient is generally positioned supine with leftward uterine displacement (i.e., a wedge under the right hip) to reduce aortocaval compression. Surgical site preparation with betadine or a surgical scrub or paint such as chlorhexidine (CHG) or parachlorometaxylenol (PCMX) is typically recommended. If alcohol-based paints are used, it is important to allow them to dry completely because they are potentially flammable. A Foley catheter is placed in the bladder to allow decompression during surgery and urine measurement for management of intraoperative fluids. Clipping the pubic hair is usually done just prior to surgery in the operating room (OR) because shaving the previous evening may increase the risk of postoperative infection. Prophylactic antibiotics are generally recommended for all cesareans. Common practice in the United States is the use of a cephalosporin (in nonallergic patients) up to 30 minutes before skin incision to reduce the incidence of postpartum endometritis without adversely affecting neonatal outcomes. Ancef, 1 g, or 2 g if the body mass index (BMI) is >30, is a cost-effective choice. There is some evidence that providing extended coverage with azithromycin may further reduce the risk in some patient populations.

SURGICAL TECHNIQUE

Abdominal Incision

Three types of skin incisions are commonly used: Pfannenstiel, Maylard, or midline vertical (Fig. 182.1). In addition, there are three described modifications of the low-transverse incision—Joel–Cohen, Misgav–Ladach, and Pelosi. The choice of incision is based on the urgency of the procedure, presence or knowledge of prior scars/adhesions and presence of other pelvic pathology, and physician preference. The most common is the Pfannenstiel incision, also widely used in gynecologic surgery. The

Pfannenstiel is a transverse incision made in a curvilinear fashion, typically 12 to 15 cm in length (depending on fetal size) beginning 2 cm above the pubic symphysis in the midline and extending toward the iliac crests; the superficial epigastric vessels should be avoided, ligated, or cauterized to prevent excessive bleeding in the subcutaneous space. The fascia is then incised with the knife or cautery and extended laterally as well. Kocher clamps are then used to elevate the fascia and dissect bluntly or sharply the rectus muscles from the undersurface of the fascia. All perforating bleeding vessels should be controlled as this dissection occurs. The underlying rectus muscles are then separated in the midline, and the peritoneum is divided in the midline and retracted laterally. Inspection and palpation of the peritoneum is important at this point, as previous surgery or obstructed labor may affect the bowel or bladder location underlying the peritoneum. Care should be taken to avoid these structures. The peritoneal opening is then extended and the bladder retractor is placed inferiorly. The bladder flap is created by incising the peritoneal reflection over the lower uterine segment usually with Metzenbaum scissors. The vesicouterine space is then created with blunt dissection. The bladder is retracted out of the operating field and an appropriate-sized Richardson retractor is used for exposure in the upper portion of the incision (Fig. 182.2).

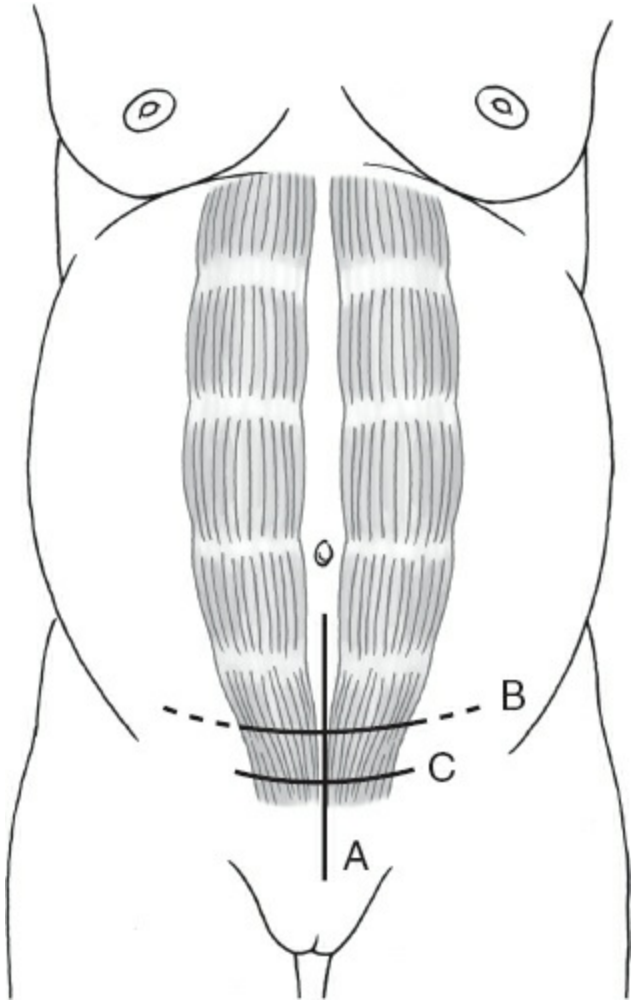

Figure 182.1. The obstetrician most commonly uses one of three abdominal incisions: midline (**A**), Maylard (**B**), and Pfannenstiel (**C**). *Dashed lines* indicate possible extension.

A Maylard incision may be used if significant scarring is suspected, or in a severely obese parturient to avoid making the abdominal incision in or under the panniculus. The Maylard incision is made 3 to 4 cm above the pubic symphysis and is extended in a transverse fashion. The superficial epigastric vessels may need to be ligated and the fascia is extended laterally with scissors or cautery. The rectus muscles are then elevated and incised approximately two thirds on each side with ligation of the deep inferior epigastric vessels located under the outer third of the rectus muscles. The rectus muscles can be incised by cautery (preferred) or sharp dissection.

A vertical skin incision is used if extreme speed is essential for delivery, if pelvic pathology such as ovarian tumor is suspected, if extensive adhesions were noted in a previous operative note, or if a

vertical scar already exists. Other indications include coagulopathies or the need for perioperative anticoagulation in order to reduce the risks of subfascial or wound hematomas. Some authors suspect that vertical incisions are more prone to herniation, poor wound healing, and increased pain postoperatively, but there are multiple confounding factors associated with these observations. The midline vertical incision avoids dissection of the rectus muscles completely. A midline incision is made just above the pubic symphysis and is extended midway to the umbilicus. This is followed by dissection of the subcutaneous layers and then incision of the fascia. Once the midline separation of the rectus muscles is identified, the rectus muscles are separated, the rest of the fascia incision is extended, and the peritoneum is entered sharply. The rest of the delivery proceeds as described below.

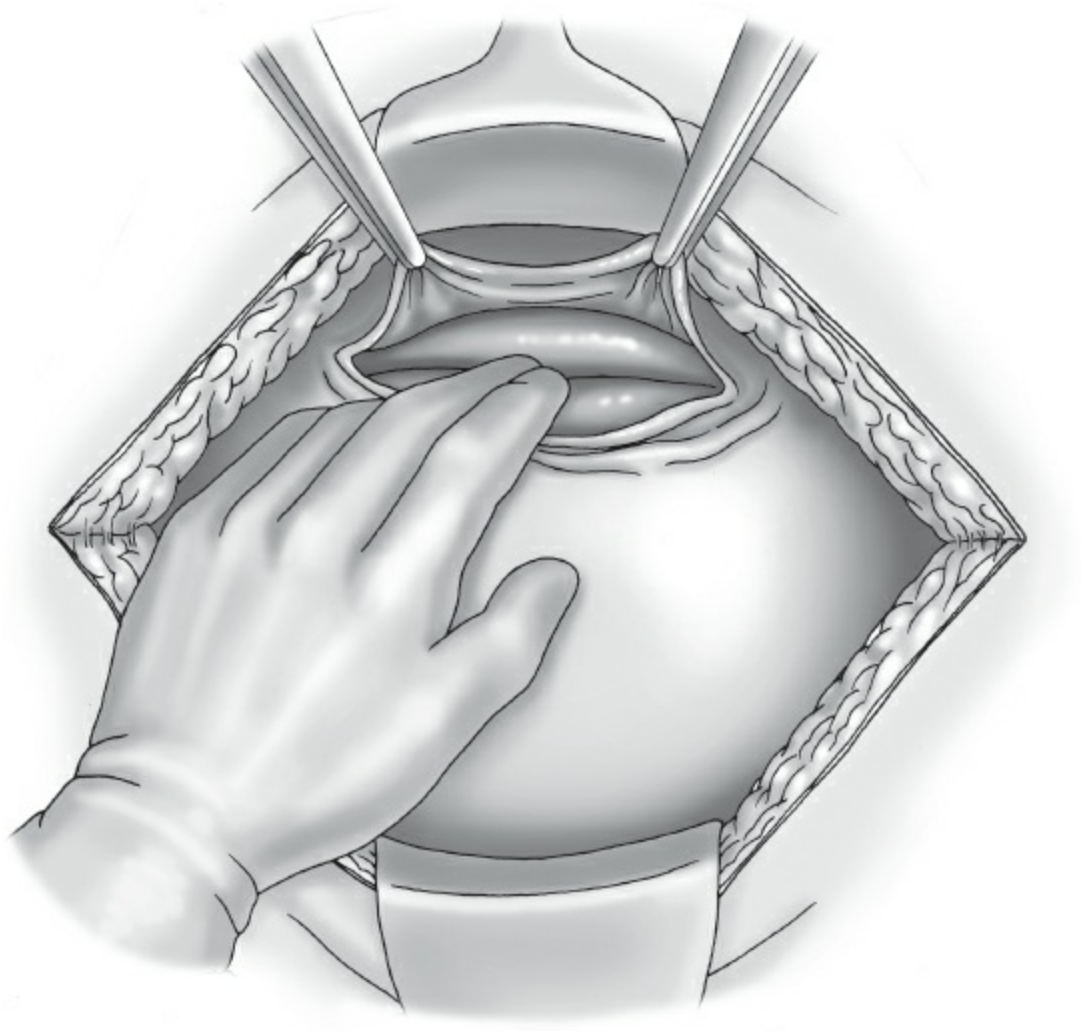

Figure 182.2. The bladder flap is created with the surgeon's index finger and forefinger as the potential space between the bladder and uterus is developed.

There are three described modifications of the low-transverse incision. The Joel–Cohen technique begins with a straight transverse incision slightly higher than a Pfannenstiel, 3 to 4 cm above the symphysis just below the level of the iliac spines. The subcutaneous fat is incised sharply in the middle of the incision and the fascia is also opened to a width of ~3 to 4 cm. The fascial incision is extended either by manual stretch or by inserting scissors into the fascial opening and pushing laterally toward the iliac spines. The rectus muscles are manually separated and the peritoneum entered digitally. The incision is stretched, a bladder flap created, and the myometrium opened in the midline and bluntly extended transversely. The uterus is closed with interrupted sutures. The Misgav–Ladach modification involves abdominal entry using a Joel–Cohen technique; however, the placenta is removed manually, the uterus exteriorized and then closed in a running, locked fashion in one layer. The fascia is closed with a running stitch and the skin with mattress sutures. Peritoneal closure is omitted. In the Pelosi modification, entry is via a Pfannenstiel incision with electrocautery used to divide the subcutaneous and fascial layers. The rectus are separated and the peritoneum entered bluntly with fingers and the incision stretched. No bladder flap is created and the uterus is entered similarly. Oxytocin is administered and the placenta is delivered spontaneously followed by uterine massage. The uterus is closed with a running locked 0-chromic and the peritoneum is not closed. The fascia is closed with a running synthetic absorbable suture and the subcutaneous layer is closed with interrupted 3-0 absorbable sutures if it is deep.

These techniques have been compared in a number of instances to treat randomized trials. These trials have also been subjected to meta-analysis. In general, the Joel–Cohen–based techniques are associated with reduced blood loss and operative times. There also appears to be a reduced time for return of bowel function, less pain, and fever and shorter incision to delivery times. However, these trials do not assess the potential for serious morbidity or long-term outcomes.

Uterine Incision

The uterine incision types are shown in Figure 182.3. The type of uterine incision most commonly used is a Kerr incision (low-transverse), but other choices are Krönig (low-vertical), classical, T, or J incision. Low-transverse incisions are made in the thin area of the lower uterine segment and heal much better than an incision that extends into the contractile or

upper portion of the myometrium. A low-transverse incision is made 1 to 2 cm above the bladder attachment to the uterus. A scalpel should be used to score the uterus in the midline taking care to avoid the fetus, especially if the membranes are ruptured or in emergency deliveries. To avoid fetal injury, one can elevate the myometrium with an Allis clamp or enter bluntly with a Mayo clamp or finger. Extension of the incision can be made with bandage scissors or blunt dissection. If using scissors, the surgeon's fingers should be placed underneath the uterine tissue to prevent unintentional injury to the fetus. Blunt extension is usually preferred because it is associated with less intraoperative blood loss and need for fewer transfusions postoperatively while avoiding the risk of sharp injury to the fetus. Furthermore, blunt manual extension of the low-transverse uterine incision by cephalad–caudad (vertical) stretching has been associated with less uterine vessel injury.

Indications for a classical uterine incision include, but are not limited to, anterior placenta previa, transverse back-down fetal lie, anatomic considerations such as fibroids or extensive vessels in the lower uterine segment, poorly developed lower uterine segment, or previous scarring that limits access to the lower segment. A low-vertical incision can first be made 1 to 2 cm above the bladder and then extended with bandage scissors to allow delivery. If adequate space is not achieved in the lower segment, the incision can be extended superiorly into a classical incision. The J or T incision is an extension when a transverse uterine segment does not allow delivery and must be extended either laterally (J) or in the midline (T) (Fig. 182.3). If any incision extends into the thicker uterine segment, patients should be counseled to avoid labor in the future due to increased risks of uterine rupture in these circumstances.

Delivery of Infant and Placenta

After the uterine incision is made, all retractors should be removed and the table lowered to allow adequate maneuvers for delivery. The surgeon's hand should be placed below the fetal presenting part, and if deeply engaged in the pelvis, the fetal part should be lifted up to the incision. If the vertex is presenting, the head may be flexed and then delivered with gentle external fundal pressure once elevated to the level of the incision. Delivery of the body should occur as usual followed by clamping and cutting of the umbilical cord on the surgical field. Bulb or catheter suctioning of meconium on the surgical field is no longere recommended.

A pediatrician, advanced practice nurse, or anesthesiologist may be present for resuscitation in cases of fetal compromise. A segment of umbilical cord may also be obtained if needed for cord gas analysis. Cord blood collection should only be done after this segment of cord is obtained.

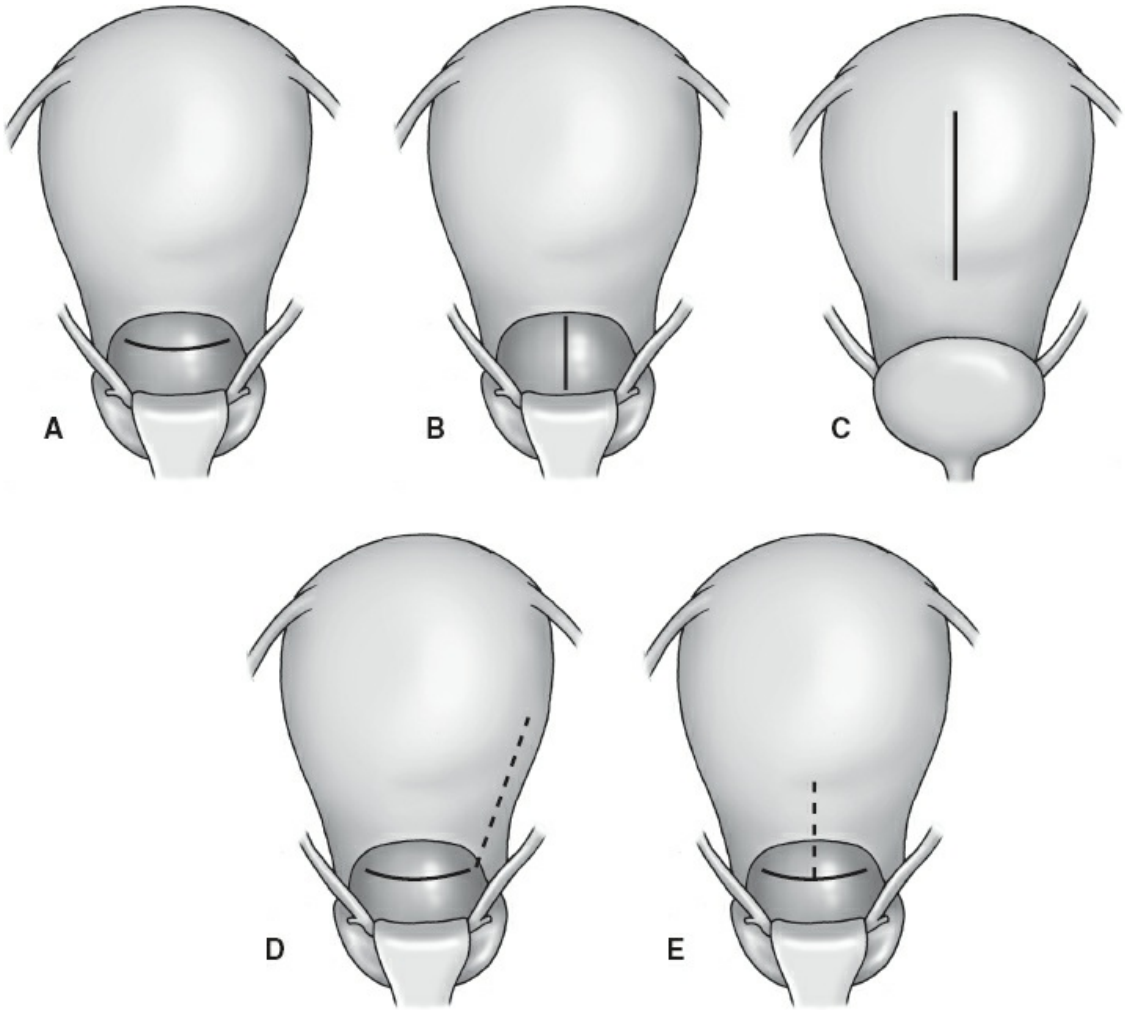

Figure 182.3. Uterine incisions for cesarean delivery. **A.** Low-transverse incision. The bladder is retracted downward, and the incision is made in the lower uterine segment, curving gently upward. If the lower segment is poorly developed, the incision can also curve sharply upward at each end to avoid extending into the ascending branches of the uterine arteries. **B.** Low-vertical incision. The incision is made vertically in the lower uterine segment after reflecting the bladder, avoiding extension into the bladder below. If more room is needed, the incision can be extended upward into the upper uterine segment. **C.** Classic incision. The incision is entirely within the upper uterine segment and can be at the level shown or in the fundus. **D.** J incision. If more room is needed when an initial transverse incision has been made, either end of the incision can be extended upward into the

upper uterine segment and parallel to the ascending branch of the uterine artery. **E.** T incision. More room can be obtained in a transverse incision by an upward midline extension into the upper uterine segment.

Special maneuvers may be necessary for delivery of the preterm infant or multiple gestations. Care should be taken to ensure a large enough uterine incision, especially in the preterm infant. With breech presentation, head entrapment may occur if the incision is too small. This can often be relieved by extending the incision or with uterine relaxation by administering sublingual nitroglycerin. By leaving the membranes intact, en caul delivery of the intact conceptus may reduce trauma in extremely premature infants. The infant in cephalic presentation with occiput posterior (OP) position or deep engagement of the vertex with molding and caput formation can present special difficulties in elevating the fetal head through the uterine incision. With OP positions, it is usually helpful to attempt to rotate the occiput to the anterior and then deliver the head by extension. Alternatively, if the vertex can be maneuvered to a transverse position, forceps can be used to bring the head through the incision. Vacuum devices may also be used, but neither should be used routinely due to the risks of fetal injury. With deep impaction of the vertex, attempts to dislodge the head vaginally before incision can reduce the force needed during surgery and an assistant applying manual pressure from below can also be beneficial. Banking of umbilical cord blood to harvest stem cells has become a common practice, although its efficacy in treatment of pediatric cancers is controversial. Many cord blood storage companies provide patients with kits for collection if notified in advance. The benefits of banked cord blood use for pediatric bone marrow transplantation are not fully known, and the likelihood of use in the routine obstetric patient is low (1:1,000 to 1:200,000).

The placenta should be spontaneously delivered with gentle massage of the uterine fundus and gentle cord traction as this method has been shown to reduce postpartum febrile morbidity. Manual placental removal increases the risk of postpartum endometritis and maternal/fetal hemorrhage. If the placenta cannot be removed spontaneously or if hemorrhage ensues, manual removal may be achieved by the surgeon’s hand creating a plane between the placenta and the uterine wall. After delivery of the placenta, the uterus should be wiped clean of all residual debris using dry surgical gauze. Vigorous curettage should be reserved for

persistently adherent placental cotyledons since this may increase the potential for intrauterine adhesions and theoretically abnormal placentation in the future.

Uterine Closure and Control of Hemorrhage

After delivery of the placenta, there is typically significant blood flow (~1 L/min) from the uterine wound edges as well as the denuded interior uterine surface, which continues until several uterine contractions have reduced uterine dimensions and the cesarean wound edges have been sutured. Hemorrhage should be controlled by rapid surgical closure of the uterine incision as well as stimulation of uterine contractions with intravenous oxytocin infusion. Uterine incision closure can be accomplished by various means, and to date there is substantial variation in technique from hospital to hospital and regions of the world. Most surgeons prefer uterine exteriorization prior to surgical repair to enhance visibility and possibly decreased blood loss, but this may be accompanied by increased patient discomfort. There is no increased risk of infection, and effective anesthesia usually prevents significant discomfort. Occasionally, severe scarring, obesity, or patient discomfort prevents exteriorization. Pennington or Allis clamps can be used to grasp the edges of the incision for control of hemorrhage and identify the hysterotomy during surgical repair. Suture material should be an absorbable material such as Vicryl, polyglycolic dermal suture (PDS), or Maxon (preferably size 0 or 1-0). Blunt needles have been shown to reduce the incidence of glove perforation and presumably needle stick injury (often unrecognized), although this may come at the expense of decreased surgeon satisfaction. If any extensions are identified, these should be closed first with a locking suture working toward the initial incision and then incorporated into the primary closure. The Kerr or Krönig uterine incision closure can be done by a single or double layer starting at one end of the incision and proceeding to the other end with locking sutures ~1 cm apart and 1 cm of tissue on each side. Some surgeons avoid incorporating the endometrium into the incision to theoretically prevent future development of adenomyosis, but little data exist to support this practice and some studies would discourage it. The repair should ensure hemostasis, especially at the edges of the incision as this is the most likely area for bleeding postoperatively. A classical incision should be closed in multiple layers as the uterine wall is much thicker and multiple layers are required to

reapproximate the tissue hemostatically (usually three layers: deep running locked, unlocked imbricating, and superficial unlocked serosal).

The benefit or risk of singleversus double-layer closure of a low-transverse uterine incision is controversial. Many authors feel double layers may decrease the risk of future uterine dehiscence or rupture (and thus theoretically accreta), but the data are confounded by lack of uniformity of suture material, technique, and definition of uterine dehiscence. Uterine dehiscence is also of such rare occurrence that it is difficult to study in a prospective fashion. Despite this, the most recent Cochrane review to address this issue would suggest a two-layer closure in patients who plan future pregnancies or labors. Single-layer closure may cause less necrosis of tissue, decreased surgical time, and fewer sutures to control bleeding. If double-layer closure is done, it may be with a second imbricating suture incorporating 1 cm of tissue above and below the uterine incision in a vertical or horizontal (Lembert) fashion (Fig. 182.4). Most surgeons no longer reattach the bladder flap to the lower uterine segment because theoretically there is less risk of scarring of the bladder high on the uterus (decreasing the risk of bladder injury in future surgery), less risk of hematoma or abscess in the potential closed-off space, and less operative time. Ovaries and fallopian tubes should be inspected prior to return of the uterus to the abdominal space (if exteriorization was done). There may be an exaggerated decidual reaction on the surface of the ovaries, and the fallopian tubes may appear very engorged. If ovarian pathology is suspected preoperatively or intraoperatively, consultation should be expedited so that removal can occur after cesarean delivery. Ovarian corpus luteum cysts need not be excised. Mature teratomas, large hydatid cysts of Morgagni, and suspected ovarian carcinoma should be removed.

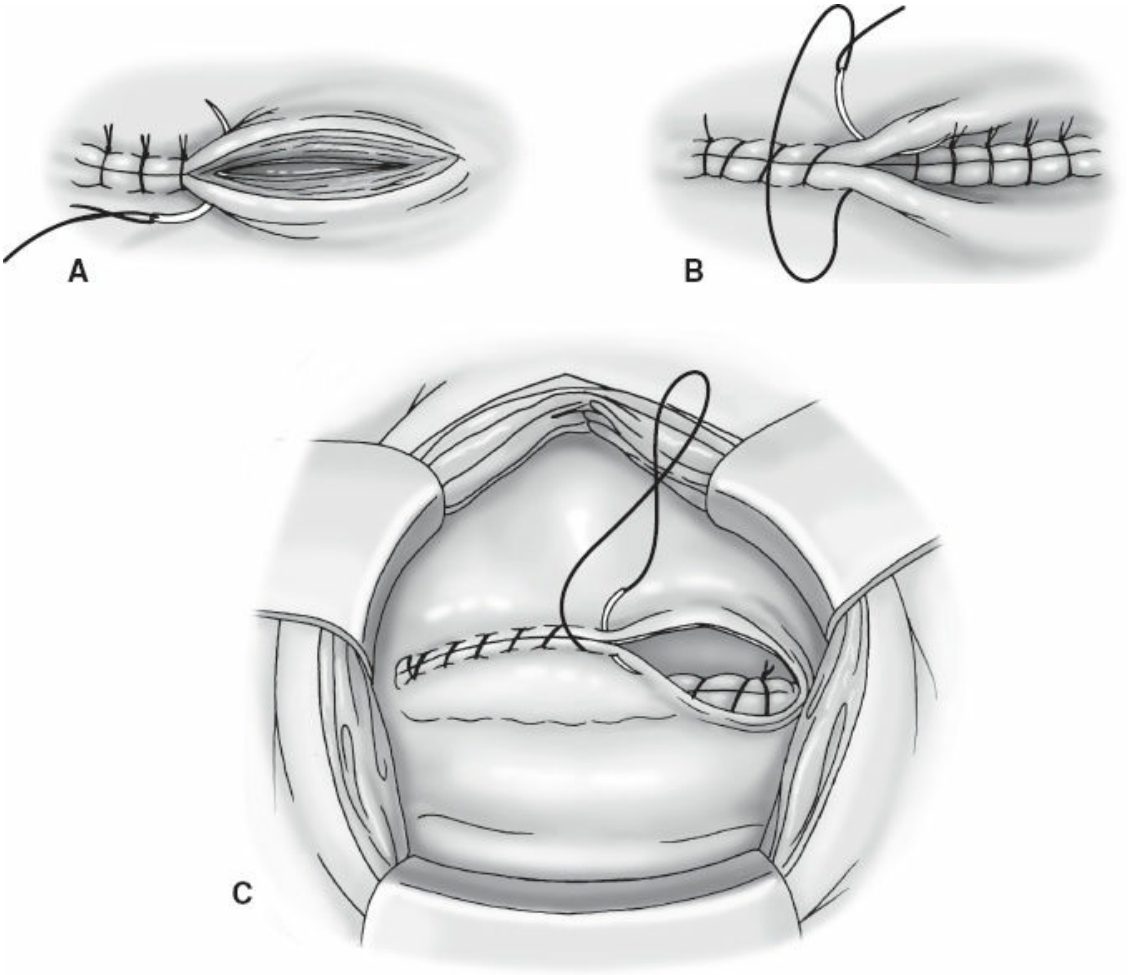

Figure 182.4. Closure of a low-transverse incision. **A.** The first layer can be interrupted or continuous. **B.** A second inverted layer can be created by using a continuous Lembert or Cushing stitch, but is really needed only when apposition is unsatisfactory after application of the first layer. **C.** The bladder peritoneum is reattached to the uterine peritoneum with fine suture.

If a patient has preoperatively consented to permanent sterilization, this may be performed after the uterine incision is closed. A modified Pomeroy method is commonly used. A midisthmic portion of fallopian tube is grasped with a Babcock clamp, a 3-cm portion is doubly ligated with two free ties of 0 or 1-plain catgut, and this segment is removed with Metzenbaum scissors. Alternatively, the Parkland method employs piercing the mesosalpinx, passing two free ties and separately ligating the tube in two places before excising the intervening segment. The removed portions of fallopian tube must be sent to pathology to confirm that a complete cross-section of tube was removed. Sterilization failures due to unintended ligation of the round ligament have been reported. In general,

myomectomy or major uterine surgery should be avoided at the time of cesarean due to the potential for severe blood loss (with the possible exception of a pedunculated fibroid).

The uterus should then be replaced inside the abdomen with care not to disrupt any sutures. If inadequate space is found, the broad ligament vessels should be drained by holding up the uterus in the midline with care to alleviate pressure on the vascular sides and then gently rotating the uterus to allow for easy replacement. Care must be taken to avoid disrupting sutures placed at the site of tubal ligation. Clots of blood and excess amniotic fluid should be removed from the peritoneal gutters prior to abdominal wall closure. Irrigation has not been shown to be of benefit. A careful inspection of all areas, including the bladder, should be done to assess hemostasis. If blood is noted in the Foley catheter, retrograde bladder filling via a three-way catheter can be done with methylene blue or sterile milk to assess for leakage of urine. If a laceration of the dome of the bladder is detected, repair should be performed with a double-layer closure of delayed absorbable suture. Urogynecologic or urologic consultation should be obtained if bladder laceration appears to involve the trigone or ureters.

If hemorrhage is not controlled primarily by uterine incision closure or uterine tone continues to be inadequate with ongoing blood loss during surgery, additional measures must be taken. Increased concentrations of oxytocin may be given intravenously (up to 40 units per liter), but should not be administered as a rapid bolus because hypotension and water intoxication can occur. If uterine tone cannot be achieved by oxytocin, other uterotonics such as Methergine (methylergonovine 0.2 mg IM), Hemabate (15-methyl prostaglandin F2α 250 μg IM), or Cytotec (misoprostol 800 μg per rectum) can be given. The first two are administered intramuscularly *not* intravenously, and Cytotec is given as rectally as suppositories. There are certain contraindications to giving Hemabate, such as asthma, and to giving Methergine, such as hypertension or preeclampsia. Occasionally there is excessive bleeding in the placental bed, and this can be controlled locally with sewing the vessels prior to uterine incision closure. In cases where abnormal placentation or incomplete removal of the placenta is seen or suspected, as in placenta accreta, additional and rapid surgical steps must be taken as peripartum hysterectomy is likely going to be required. In the case where accreta was suspected preoperatively, additional surgical assistance can be requested

from an oncologist or general surgeon.

The mainstay of surgical management for uncontrolled intrapartum hemorrhage remains hysterectomy, but in a gravida with a strong desire for future childbearing the surgeon must try to salvage the uterus. Blood and blood products must be readily available, and the surgeon must be skilled in performing alternative procedures to preserve the uterus. Surgical alternatives to hysterectomy include bilateral vertical uterine artery ligation (O'Leary stitch), bilateral utero-ovarian vessel ligation, B-Lynch suture, or hypogastric artery ligation. The O'Leary stitch is accomplished with a single suture of 0 or 1-0 absorbable material placed in the uterus 2 cm medial to the uterine artery with the needle driven either anterior to posterior or posterior to anterior at the level of the uterine incision (Fig. 182.5). It is often helpful for the surgeon to manually distract the large uterine veins laterally as the needle pierces the broad ligament to avoid tearing the veins as well as to protect posterior structures such as the bowel or the adnexa. It is also important to include at least 1 to 2 cm of myometrium medial to the uterine artery to provide sturdy tissue with which to compress the vessel. Once the stitch has been placed, the posterior broad ligament should be inspected to ensure no adjacent structures have been injured. If this is not successful, then bilateral utero-ovarian vessels may be ligated but with caution that if bleeding continues, each stepwise procedure increases blood loss and the potential for disseminated intravascular coagulation (DIC). Most surgeons would next attempt the B-Lynch suture if atony is the cause of hemorrhage (Fig. 182.6). A large absorbable suture is placed bilaterally in the lower uterine segment and looped over the fundus in an attempt to physically compress the uterus.

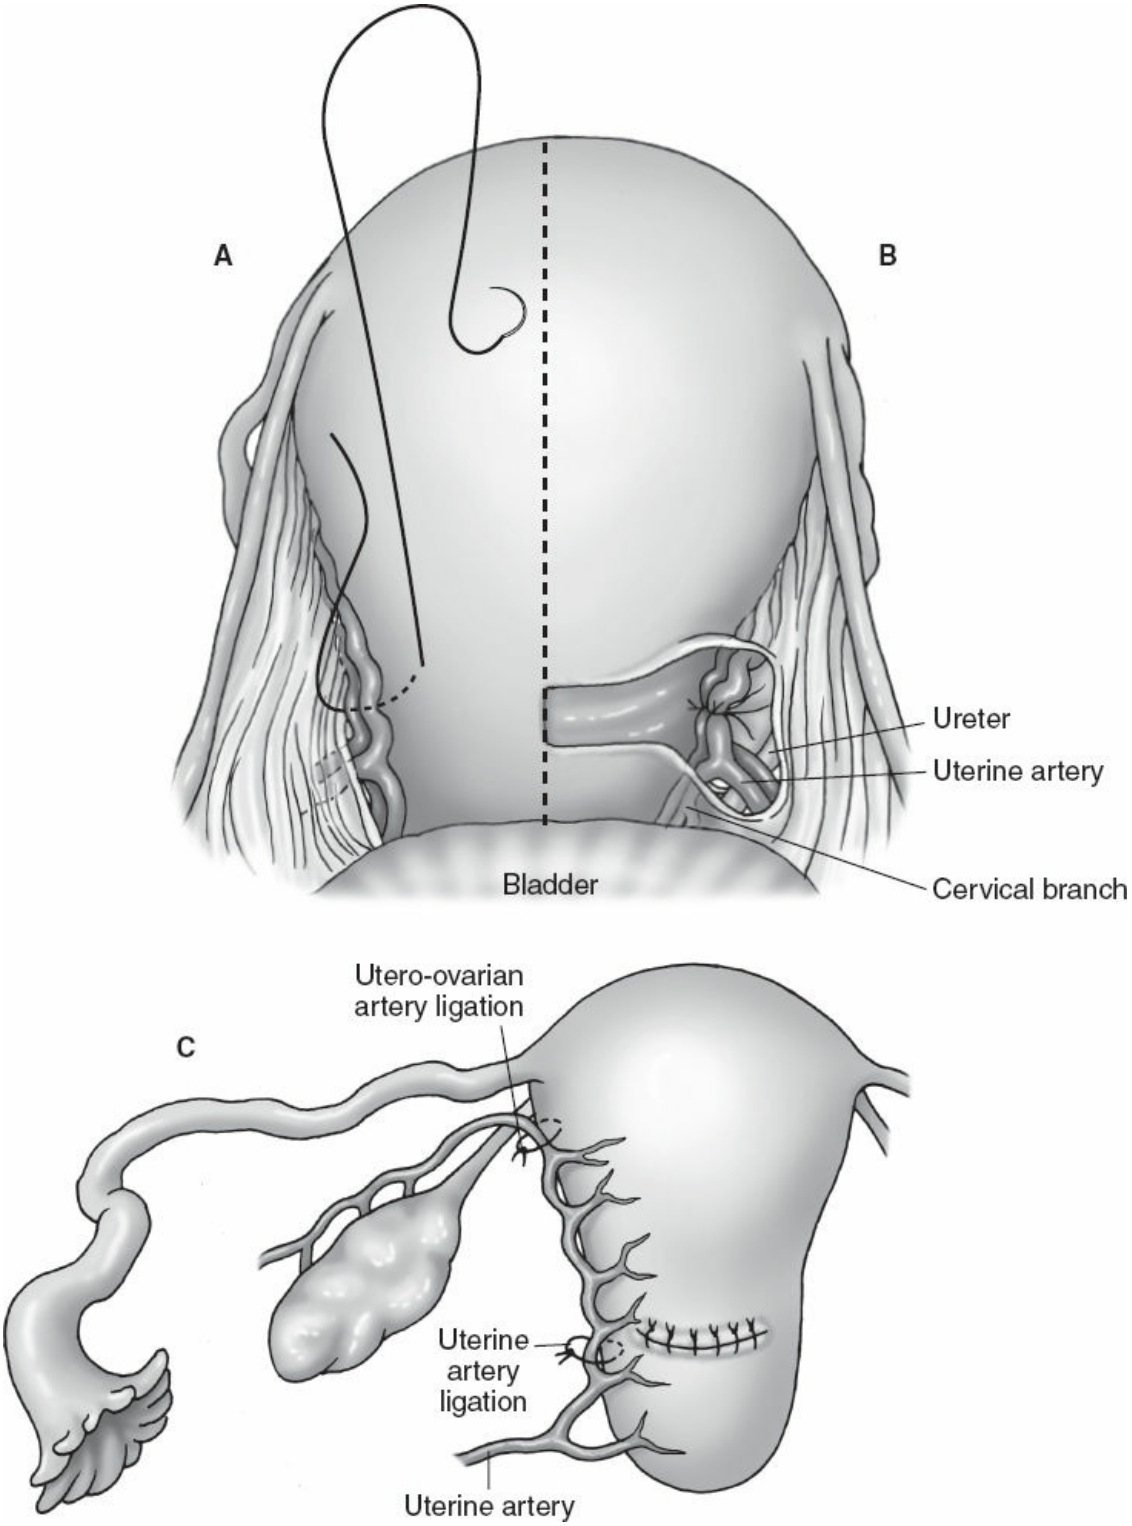

Figure 182.5. Ligation of the uterine artery. **A,B.** This anterior view of the uterus demonstrates the placement of a suture around the ascending branch of the uterine artery and vein. Note that 2 to 3 cm of myometrium medial to the vessels has been included in the ligature. The vessels are not divided. **C.** View of the sutured uterus.

An alternative to the B-Lynch suture is placement of the Bakri Balloon. This device is placed into the lower uterine segment and expanded with 300 to 500 mL saline fluid to provide internal compression of the myometrium and left in place for 24 to 48 hours while monitoring closely for recurrent uterine bleeding that will be evident in the vaginal effluent.

The last resort prior to hysterectomy in a stable but bleeding patient is hypogastric artery ligation. The procedure is begun by pulling the uterus over the symphysis and opening the retroperitoneal space. The iliac bifurcation is identified and the internal iliac traced 2 to 3 cm downstream to avoid the posterior division of the artery. The anterior division of the artery is doubly ligated with a nonabsorbable suture; the vessel is not divided. Between 25% and 60% of patients require additional procedures. Serious morbidities include accidental ligation of the external iliac artery, leading to necrosis of an extremity, laceration of the pelvic vessels, ureteral injury, and retroperitoneal hematomas (Fig. 182.7). Scant evidence exists that this procedure is efficacious, and most practitioners are not familiar enough with the anatomy to perform this quickly or safely.

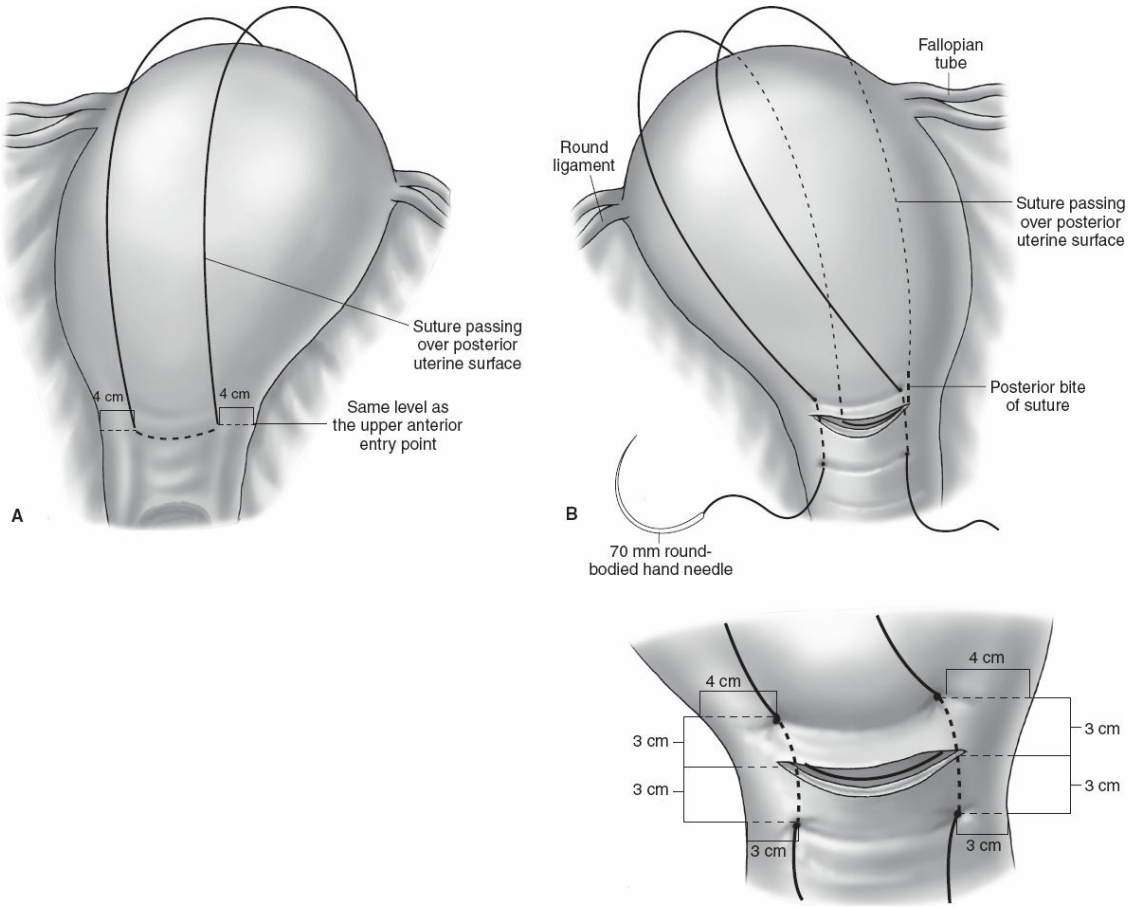

Figure 182.6. A. The B-Lynch technique. **B.** The B-Lynch suture technique for postpartum hemorrhage.

Postpartum or intrapartum hysterectomy is a procedure that must be done in cases of intractable bleeding, hemorrhage, or placenta accreta. The procedure itself is more complicated than the usual hysterectomy as the postpartum uterus is very large, the anatomy and location of routine landmarks (i.e., the ureter, uterine vessels, and the bladder) can be confusing, and the patient may be unstable in many circumstances with ongoing blood loss and DIC. Surgical removal of the uterus must be done with appropriate blood product replacement, adequate anesthesia, and patient consent, if feasible. Supracervical hysterectomy is sufficient to stop the bleeding in most cases. Prior to surgical closure, all efforts must be made to correct coagulation defects and to avoid postoperative bleeding and the need for reexploration.

Abdominal Wall Closure

Multiple studies have failed to demonstrate clear benefit of parietal peritoneal closure. Many studies show decreased operative times, pain and

fever without differences in wound infection, and postpartum endometritis or adhesions. However, other studies have shown decreased adhesions. Some surgeons reapproximate the rectus in the midline with one or two mattress sutures or close the peritoneum to allow more ease in future surgical cases. Because data as to the benefit of these procedures are lacking, the surgeon may individualize technique based on preference or patient anatomy.

All sites should be inspected for bleeding, including the underside of the rectus muscles, the fascia, and the subcutaneous space. The fascia is closed using an absorbable 0 Dexon or 0 Vicryl in a running fashion 1 cm apart and incorporating 1 cm of tissue width starting at the lateral corners and continuing toward the midline in a transverse incision. Hernias are more likely at the corners in Pfannenstiel or Maylard incisions, and therefore care should be taken to incorporate both layers of the fascia. Tissue necrosis occurs more easily here than on the uterus, so care must be taken not to make the sutures too close or too tight. A vertical incision may need to be closed with a delayed absorbable suture such as 0 PDS. A large needle with looped suture allows for extra strength and avoids the need to place knots at the inferior and superior ends of the closure; each strand from the superior suture can be tied to its counterpart from the inferior suture. This continuous layer can be either a full-thickness closure excluding skin and subcutaneous fat or a running Smead–Jones technique consisting of alternating wide full-thickness bites with fascia-only bites.

If the subcutaneous tissue is >2 cm in depth, closure of the subcutaneous tissue with a 2-0 Vicryl or 3-0 plain suture is appropriate. Data suggest a decreased risk of wound disruption and incidence of seroma without differences in hematoma or wound infection. The value of irrigation of this layer has not been proved, and drains have not been shown to be of benefit. The skin may be closed with a subcuticular dermal suture of 4-0 Vicryl/Monocryl or staples. Staples are most commonly used because their use decreases operating time, but the data regarding patient satisfaction and postoperative pain are conflicting. If increased risk of postoperative infection or bleeding is anticipated, a staple closure may be preferable, because it allows easier opening of only a portion of the incision. The patient’s abdomen should be cleaned of the preoperative solution and a sterile bandage applied for 24 hours postoperatively. The uterus should be massaged prior to leaving the OR to ensure that uterine tone is adequate and to prevent further clots from accumulating in the

lower uterine segment as these may distend the uterus and prevent adequate uterine contractility.

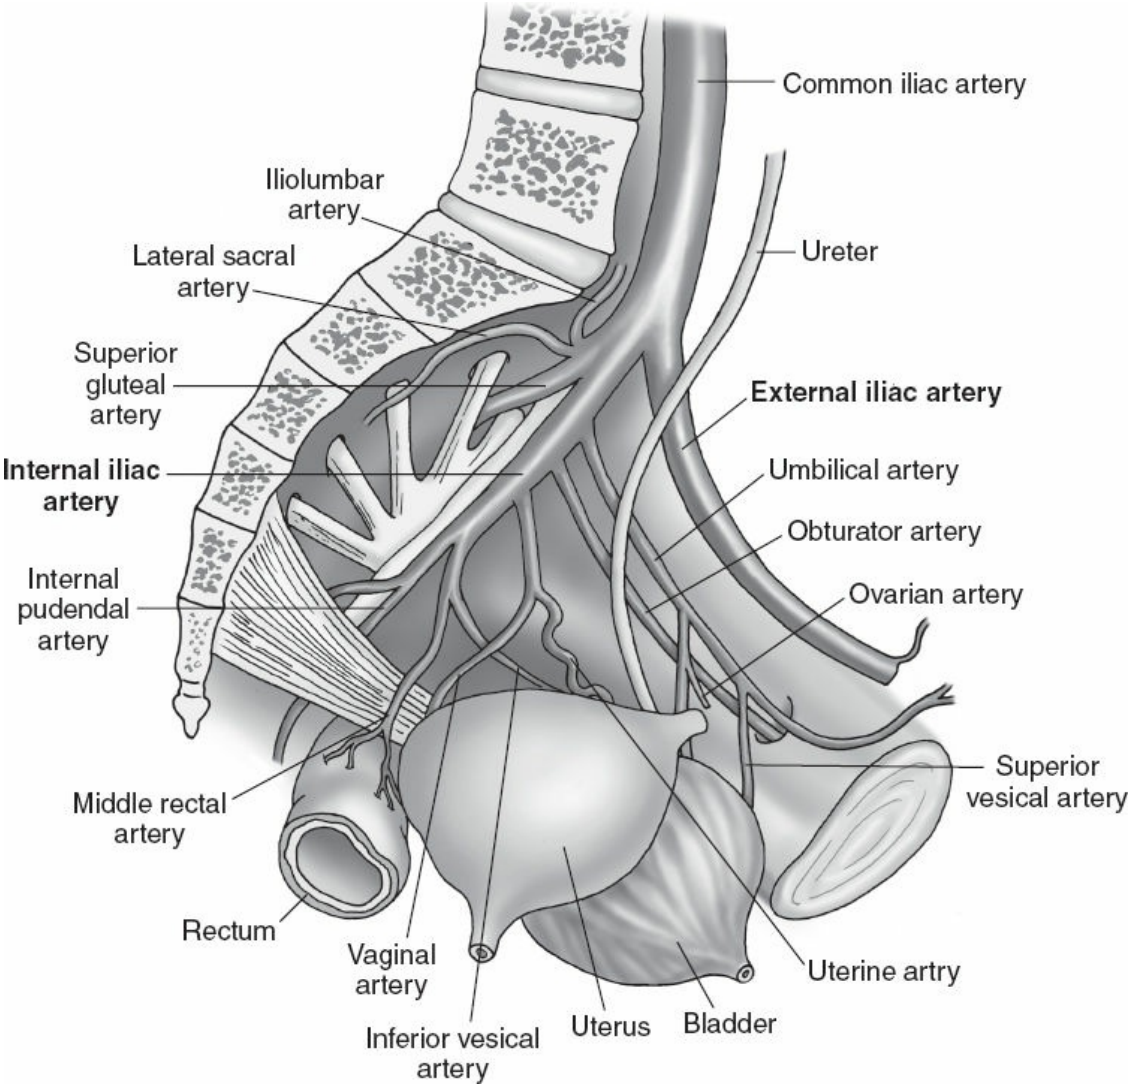

Figure 182.7. The internal iliac (hypogastric artery).

Postoperative pain management should be in the form of continued epidural anesthesia, long-acting morphine given through the epidural or spinal anesthetic, and/or intravenous medications, such as Toradol and/or narcotics.

POSTOPERATIVE MANAGEMENT

Volume Status

Recovery from cesarean delivery is usually uncomplicated as most parturients are healthy preoperatively. Patients may require 125 mL or greater of physiologic intravenous fluids per hour until oral intake is

established. Indications for cesarean delivery must be taken into consideration when assessing fluid status and urine output. Routine hematocrits are not performed unless blood loss was greater than anticipated or medical risk factors are present, such as preeclampsia, fever, low urine output, pulmonary edema, or renal or cardiac disease. However, a hemogram on postoperative day 1 may help identify patients in whom intraoperative losses were greater than expected. The most common cause of fluid imbalance postpartum is an underestimation of blood loss from surgery. As such, it is wise to attempt to quantitate the blood loss in the OR. This can be done by routinely noting the volume of fluid in the suction canister, minus the estimated volume of amniotic fluid and irrigation, plus the estimated volume in saturated lap sponges. Postoperative bleeding and complications can occur in even the most routine cases, and careful evaluation of the postoperative patient should be done if signs of hypovolemia are present. Transfusion of blood is recommended in patients with symptomatic anemia and ongoing blood loss such as postpartum hemorrhage.

Intravenous fluids should be discontinued as soon as oral intake is established, usually within 24 hours postoperatively. There are many studies supporting early feeding after most cesareans without awaiting flatus. If cesarean delivery involved bowel surgery or bowel injury, immediate oral intake is not offered. Ambulation is encouraged within 12 to 24 hours to decrease risk of postoperative thrombosis. Foley catheters are removed in ~12 to 18 hours in most patients without intraoperative bladder complications. Patients who are immobilized in an intensive care unit or who are unable to ambulate postoperatively require deep venous thrombosis prophylaxis in the form of pneumatic boot compression or subcutaneous heparin. Given the increased risk of venous thromboembolism in postoperative pregnant women, it would seem prudent to employ compression stockings routinely after a cesarean and add subcutaneous heparin for patients with additional risk factors such as obesity, history of thrombosis, or thrombophilia

Pain

Many patients receive long-acting morphine in an epidural or spinal catheter at the time of surgery. This allows for excellent pain relief for the first 24 hours in most cases. Additional nonnarcotic medications such as Toradol (ketorolac) can be given to these patients. Care must be taken if

any additional narcotics are used because the delayed absorption of long-acting morphine derivatives is variable and can lead to respiratory suppression. If spinal morphine is not used, patient-controlled analgesia (PCA) or intramuscular narcotics can be used until the patient tolerates oral intake. Pain medication is typically needed for 1 to 2 weeks postoperatively.

Infection

Postpartum febrile morbidity is common after cesarean delivery (3% to 35%), especially if the procedure was performed after rupture of membranes or labor. Ideally, prophylactic antibiotics are given in these cases, but this does not completely eliminate the occurrence of postpartum endometritis or pulmonary complications. The diagnosis of postpartum endometritis is clinical, based on fever above 100.4°F, fundal tenderness, foul-smelling discharge, and absence of alternative infections (i.e., wound infection, mastitis, or pneumonia). Treatment includes broad-spectrum intravenous antibiotics such as clindamycin and gentamicin or Zosyn until the patient is afebrile for 24 to 48 hours. If fever persists 24 to 48 hours after initiation of therapy, imaging studies, pelvic ultrasound, and computed tomography scans are recommended to evaluate for other fever sources such as hematomas, abscess collections, or thrombosis. If wound infection is apparent, wound exploration and culture may be necessary.

Postpartum Follow-Up

It is important to discuss with the patient before discharge her emotions and her understanding of the indication for cesarean delivery. There are wide variations in patient reaction after cesarean birth, including feelings of inadequacy, disappointment, and depression. In addition, if a trial of labor is contraindicated in the future due to a vertical uterine incision, it is prudent to educate the patient about this recommendation for future pregnancy. Patients are usually discharged 3 to 4 days after delivery (third-party payers in the United States will usually pay up to 4 days for uncomplicated care). This time allows for patient recovery while learning how to care for a newborn and ensuring that breast-feeding is well established. Pain medication is usually a combination of narcotic analgesia (oxycodone or codeine) and ibuprofen unless there are allergies or contraindications. Most patients no longer need medications by 2 weeks after delivery. Routine activity is encouraged, although heavy lifting, tub

baths, and vaginal penetration are avoided for at least 6 weeks. Driving is not recommended until the patient is no longer taking pain medications and minimal pain is present, usually about 2 weeks. Bleeding may normally persist for up to 6 weeks, with heavier bleeding noted with increased activity. Breast-feeding may alter this pattern with lighter bleeding but may also decrease vaginal lubrication, and the patient should be counseled that breast-feeding alone is not an adequate birth control option. Birth control should be reviewed and encouraged in all women not intending immediate conception after delivery since the timing of the first ovulation is unpredictable. Fever or incisional drainage should prompt immediate contact with a medical provider. Follow-up appointments may include a 2-week incisional check and 6-week postpartum examination. Additional follow-up may be necessary if any complications arise. Cesarean delivery requires careful postoperative follow-up even though the majority of patients have an uneventful recovery.

SUMMARY OF RECOMMENDATIONS

Suggested by good-quality data:

1. Administer antibiotics before skin incision
2. Bluntly extend the uterine incision
3. Undertake spontaneous delivery of the placenta
4. Close subcutaneous tissue if the depth is >2 cm

Surgeon preference:

1. Exteriorization of the uterus for closure
2. Irrigation of the peritoneal cavity
3. Staples versus suturing for skin closure

Conflict/controversy:

1. Extended spectrum antibiotic prophylaxis (azithromycin)
2. Creation of the bladder flap
3. Singleversus double-layer uterine closure
4. Parietal peritoneal closure

EDITOR'S COMMENT

Childbirth is the most dangerous thing that most women will do in their lifetime. Approximately 50% of maternal deaths are linked to surgery and 16% are associated with surgical site infection. So it is no wonder that both patient and physician are determined to find safer ways to have a good outcome and a healthy live birth. In our very litigious society who can blame anyone for opting for what appears to be the safest surgery. In 1985, a meeting of the World Health Organization (WHO) states that cesarean section (CS) rates higher than 15% were not medically justified (World Health Organization. Appropriate technology for birth. *Lancet* 1986;2:436–7). Despite this "ideal" number of 15% most countries exceed this rate. Souza and colleagues have developed a global reference for projected CS rates at differing health facilities (Souza JP, Betra AP, Dumont A, et al. A global reference for caesarean section rates (C-Model): a multicountry cross-sectional study. *BJOB* 2016;123(3):427–36). The authors used data from over 10 million women giving birth from 43 countries to develop a mathematical model to generate expected CS rates. Using maternal

characteristics their model can give a customized reference rate for CS for individual women and facilities and is available on line. (*www.who.int/reproductivehealth/publications/maternal_perinatal_health/c-model/en/*)

The calculator requires data on parity, previous c-section, multiple pregnancy, provider-initiated childbirth (spontaneous or induced), presentation (cephalic, breech, transverse), maternal age, organ dysfuntion or ICU admission, and complications (placenta praevia, abruption placentae, chronic hypertension, preeclampsia, renal disease, HIV. However, the authors admonish that there is no substitute for clinical judgment. However, note that twinned pregnancies have been shown in randomized trials to have different outcomes whether by CS or vaginal birth (Hutton EK, Hannah ME, Ross S, et al. Maternal outcomes at 3 months after planned caesarean section versus planned vaginal birth for twin pregnancies in the Twin Birth Study: a randomized controlled trial. *BJOG* 2015;122(12):1653–62). More than twin multiple pregnancy may be a different story. Most controversial is cesarean section delivery by maternal request (CDMR). This is performed at the request of the parturient and without any medical contraindication to vaginal delivery. Rates range from 2.6% to 26.8% and as indicated by the authors rates seem to be increasing. The Committee on Obstetric Practice strongly recommends a vaginal delivery in the absence of maternal or fetal indications and especially in women who desire multiple children (American College of Obstetrics and Gynecology: American College of Obstetrics and Gynecology committee opinion no. 559: Cesarean section delivery by maternal request. *Obstet Gynecol* 2013;121(4):904–7). It would seem the only way to stop such practice is for insurance companies not to pay for it.

Once you have had a cesarean section dependent on how the first cesarean section was performed your odds of a vaginal birth are low but as the authors suggest it should be done at full term as an elective repeat CS at 37 weeks has a higher risk of neonatal morbidity and mortality. (Ganchimeg T, Nagata C, Vogel JP, et al. Optimal timing of delivery among low-risk women with prior caesarean section: A secondary analysis of the WHO multicountry survey on maternal and new born health. *PLoS One* 2016;11(2):e014909). About one third of preterm births require special attention (Souza RT, Cecatti JG, Passini R, et al, The burden of provider-initiated preterm birth and associated factors: evidence from the Brazilian multicenter study on preterm birth (EMIP). *PLoS One* 2016;11(2):e0148244).

Perhaps the most interesting and by some controversial is the banking of the baby's cord blood which contains stem cells. Stem cells can be collected at birth and stored. The cells are cryopreserved. Umbilical cord tissue can also be saved and contains different stem cells than that of the cord blood. Stem cells from cord blood are immature (unlike those from a bone marrow harvest) and are easier to match with the recipient and less likely to be rejected. Like many institutions, we have a public cord blood bank and it is available for anyone

who needs stem cells. About one third of minorities (African Americans and Hispanics) have a difficult time finding stem cell matches and receive cord blood stem cells. Method of delivery does not impact this choice.

It would seem that everyone agrees that there are too many cesarean sections but as of yet no one has a plan on how assure diminution of unnecessary cesarean sections and especially cesarean sections by maternal request.

V. Suzanne Klimberg

183 Abdominal Hysterectomy

Mitchel S. Hoffman, Celso Silva, and Aileen Caceres

INTRODUCTION

Hysterectomy is the most common major gynecologic procedure performed in women in the United States; approximately 600,000 women undergo the operation each year. Since hysterectomy is a common surgical procedure among women, its trends and routes become important to evaluate through time. The peak year for hysterectomies for benign indications was in the 1970s, with more than 700,000 procedures performed. New medical technologies and therapies became available to gynecologists and, as a result, hysterectomy rates decreased in the 1980s.

Approximately one third of women 65 years of age have had a hysterectomy with the number of operations varying by year, geographic location, age, and race. The highest hysterectomy rates are in the South and the lowest in the Northeast. This rate difference is 2.5-fold. The highest rate occurs in the 40 to 50 years age group.

There are basically three routes for a hysterectomy: laparotomy, vaginal, and laparoscopic. Even though the American College of Obstetrics and Gynecology (ACOG) and the American Association of Gynecologic Laparoscopists (AAGL) have both published consensus statements regarding the benefits of a minimally invasive approach, the majority of hysterectomies are still performed via laparotomy. Following the introduction of the robotic surgical platform for gynecologic procedures in 2005, the impact of robotic-assisted surgery has also been examined regarding its effect on the mode of access for hysterectomy. For benign cases from 2007 to 2010, the proportion of hysterectomies performed with robotic assistance increased from 0.5% to 9.5%.

The choice of the surgical route of hysterectomy may be complex depending upon the clinical scenario. Clinical factors, a surgeons training and experience, safety, the facility and availability of equipment, and cost-effectiveness are all considerations. Women with very large uteri or complex pelvic pathology generally require a laparotomy. For benign disease, vaginal hysterectomy is the least invasive route and is preferred

whenever anatomic conditions make this feasible. The vaginal and laparoscopic routes for hysterectomy are associated with less postoperative infection, lower estimated blood loss, shorter hospital stay, and faster recovery than abdominal hysterectomy. Although recent data have shown an increase in rates of minimally invasive hysterectomy, in the United States the abdominal route is chosen in over 60% of cases.

Ultimately, the surgeon must decide upon the route of hysterectomy based upon his or her capabilities and the clinical factors associated with the individual patient.

INDICATIONS

About 85% of hysterectomies are performed as treatment of myomata, endometriosis, endometrial hyperplasia, cancer, or prolapse. Hysterectomy is occasionally required (often emergently) for the management of an obstetric complication (such as placenta accreta). Prolapse generally includes loss of support of the vagina and requires concomitant surgical correction. Cancer operations frequently involve extended surgical procedures such as lymph node dissection. Of the above indications, uterine myomata is the most frequent. Myomas are more common in African-American women, who have a higher incidence of having an abdominal hysterectomy. Symptoms usually reported by women with these diseases are abnormal bleeding, chronic pelvic pain, abdominal mass, abnormal Papanicolaou (Pap) test, or pressure in the vagina. Except for the diagnosis or suspicion of cancer, surgery should not generally be the first approach to therapy. Effective medical therapy exists for many of the benign diseases like myomas, endometriosis, and endometrial hyperplasia. Examples of these medical therapeutic agents are gonadotropin-releasing hormone agonists to establish early reversible medical castration for myomas and endometriosis, antiprogestins (RU486) for myomas, androgens (danazol) for endometriosis, and progestins for endometrial hyperplasia. Less extensive surgery is also available for these conditions such as myomectomy, laparoscopic excision and/or ablation of endometriosis, dilation curettage for endometrial hyperplasia, endometrial ablation or progestin-type intrauterine devices for menorrhagia, and pelvic arterial embolization for myomata.

SURGICAL TECHNIQUE

A Foley catheter is inserted into the bladder before surgery. This reduces

the size of the bladder and helps prevents incidental bladder damage when entering the lower abdomen and when taking the bladder off the lower uterine segment and cervix. Entry into the abdomen is usually by either a lower abdominal midline incision or by a transverse (e.g., Pfannenstiel) incision. The Pfannenstiel incision provides more limited exposure and its main advantage is cosmetic. In the presence of complicated pathology, a midline or true transverse incision will provide better exposure.

Once the abdomen has been entered, an exploration is performed. A self-retaining (e.g., Bookwalter) retractor is placed. Assuming the pathology is found to be limited to the pelvis, the bowel is then packed into the upper abdomen. Adhesions need to be divided prior to packing. In many cases, it is helpful to mobilize the sigmoid colon and cecum so that they are packed back as well. The retractor secures the packs and gives good visualization of the pelvic structures. The uterus is grasped and held with long clamps (e.g., Kelley) placed snugly along the lateral sides of the fundus. These clamps are used for traction on the uterus and control of back-bleeding. Traction on the uterus and counter traction on the surrounding soft tissues are important surgical principles to safe and efficient performance of a hysterectomy.

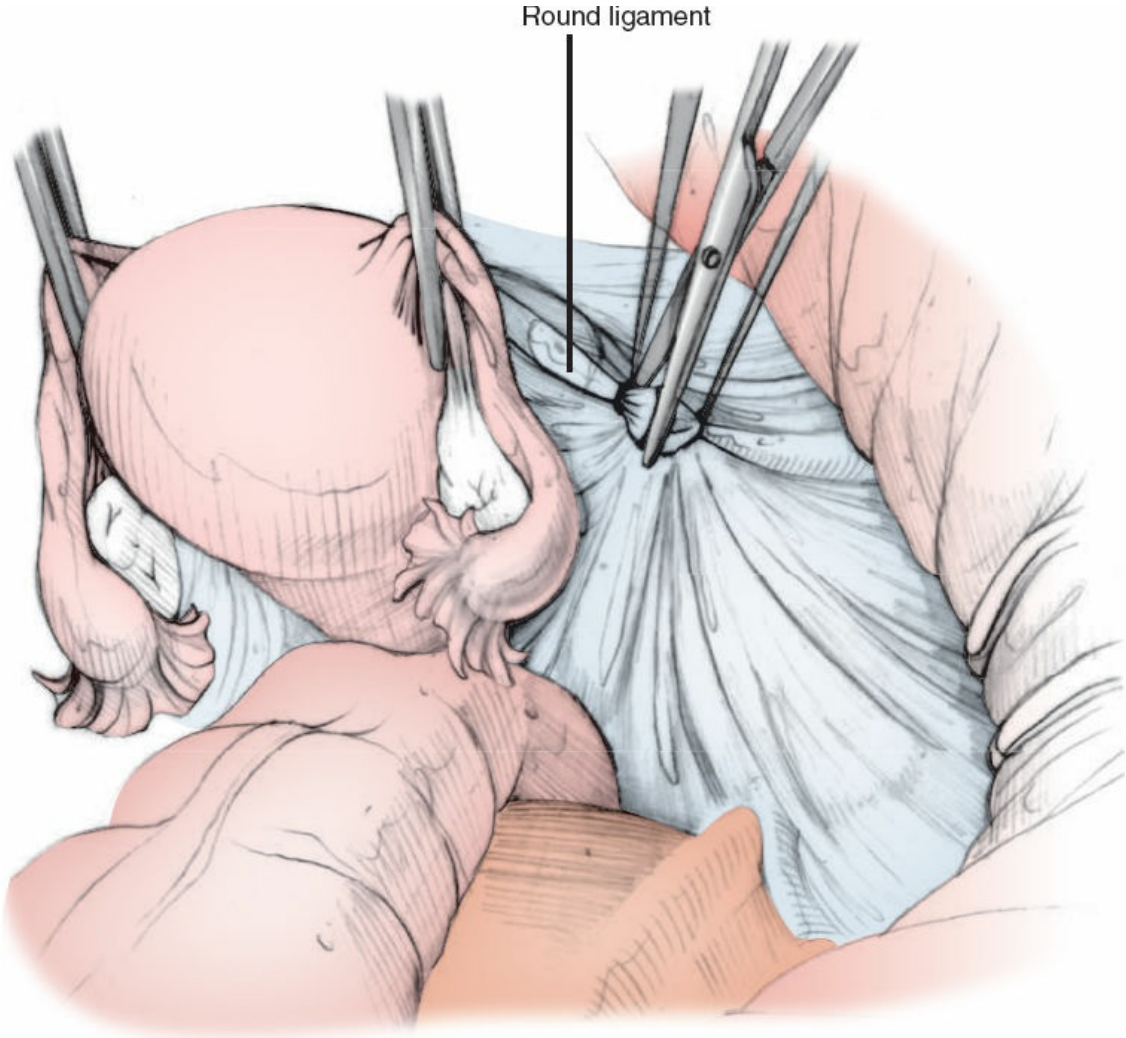

Figure 183.1. Uterus is held and upward traction is exerted with Kocher clamps during the hysterectomy. The right round ligament is doubly ligated and transected as the first step. This opens the retroperitoneal space.

The initial uterine incisions on each slide should begin at the round ligaments. These are elevated and divided hemostatically with cautery lateral to the uteroovarian vascular anastomoses (Fig. 183.1). One small artery (Sampson artery) runs under this ligament. The external iliac vessels are in close proximity. Division of the round ligament lateral to the uteroovarian vascular anastomosis avoids hemorrhage and facilitates isolation of the upper vascular pedicle. The pelvic peritoneum can then be opened laterally, caudal, and cephalad to the round ligament. This peritoneal incision is carried from each side completely across the front of the uterus at the vesicle uterine fold. The surgeon can then partially open the pararectal space. This will allow visualization of the iliac vessels on the lateral pelvic wall and the ureter on the medial peritoneal fold. A

decision about retaining or removing the ovaries should be discussed with the patient prior to surgery. In general, if the ovaries are normal and the woman is premenopausal, it is recommended that they be retained. Removal of ovaries in younger women will reduce their estrogen and androgen hormone levels and is not routinely done unless there is obvious gross ovarian pathology, a strong family history of ovarian cancer (or known genetic predisposition), or a disease process where ovarian hormones either aggravate the disease or may in fact harbor the disease, such as with endometriosis or chronic pelvic infection.

If the ovaries are to be removed, then the infundibulopelvic ligaments are identified safely away from the ureters and hemostatically divided (Fig. 183.2; sutures, staples, or a bipolar energy device). There are many large vessels in these ligaments and particular attention is required. If the ovaries are to be preserved, then the uteroovarian pedicles (uteroovarian ligament, fallopian tube and vascular anastomosis) are hemostatically divided in a similar manner (Fig. 183.3). These ligaments should be divided as close to the uterus as possible to reduce ovarian blood flow disruption.

The bladder is then separated from the cervix, generally in a largely avascular plane. If there are any adherent areas, these must be sharply dissected against or within the stroma of the cervix in order to prevent bladder injury. This is commonly a problem in women who have previously had a cesarean section. If bladder damage is suspected at any time during the operation, the bladder should be back filled with a sterile colored solution, which will quickly identify a cystotomy. Mobilization of the bladder continues just beyond the cervix so that the cervicovaginal junction can be safely transected. Mobilization also exposes the attachments of the paracervical ligaments so that they may also be safely clamped. This creates a “U” shaped region of ***u***rinary tract—containing soft tissue that is to be protected.

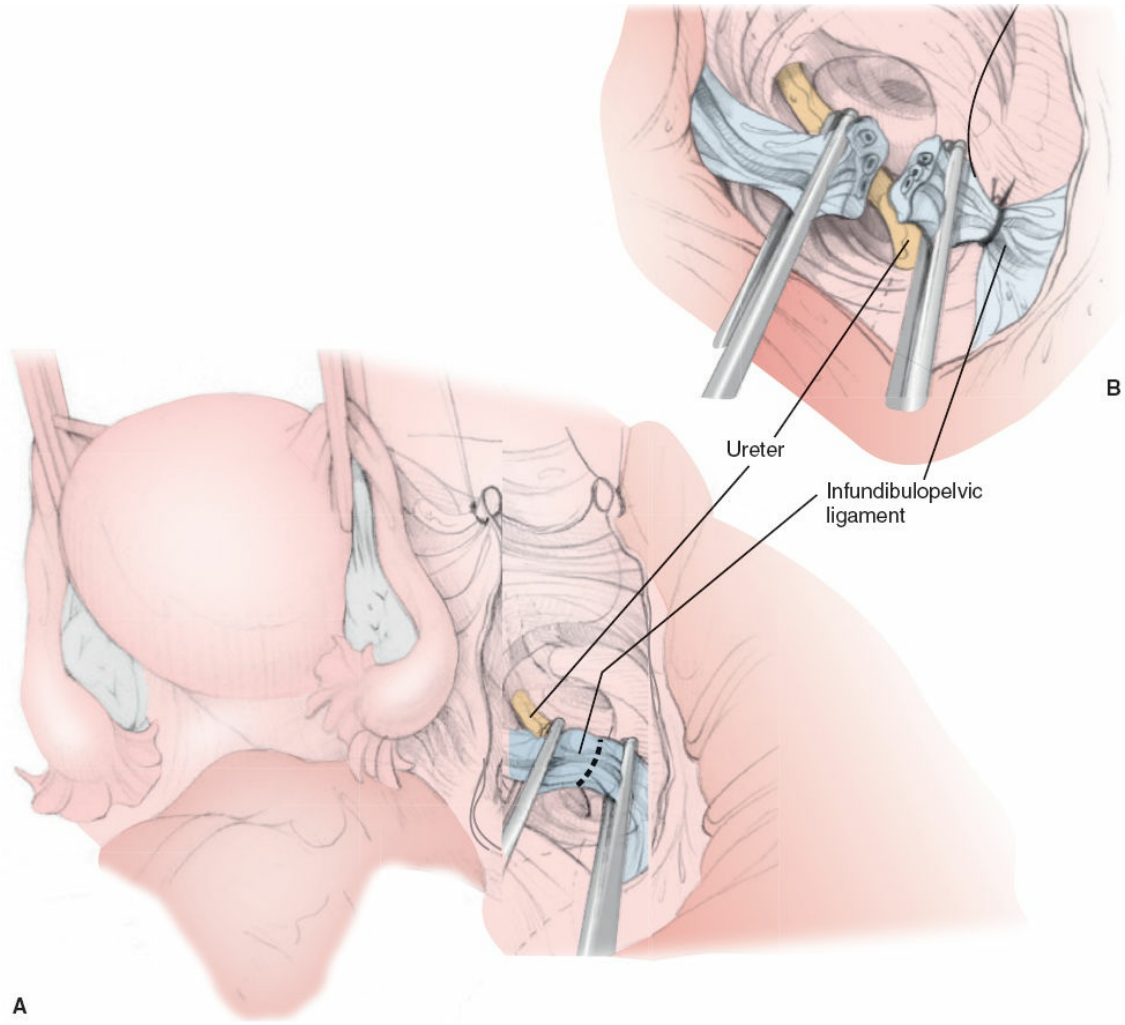

Figure 183.2. The infundibulopelvic ligaments are identified, clamped, cut, and sutured if the ovaries are to be removed. Care is taken to avoid the ureter.

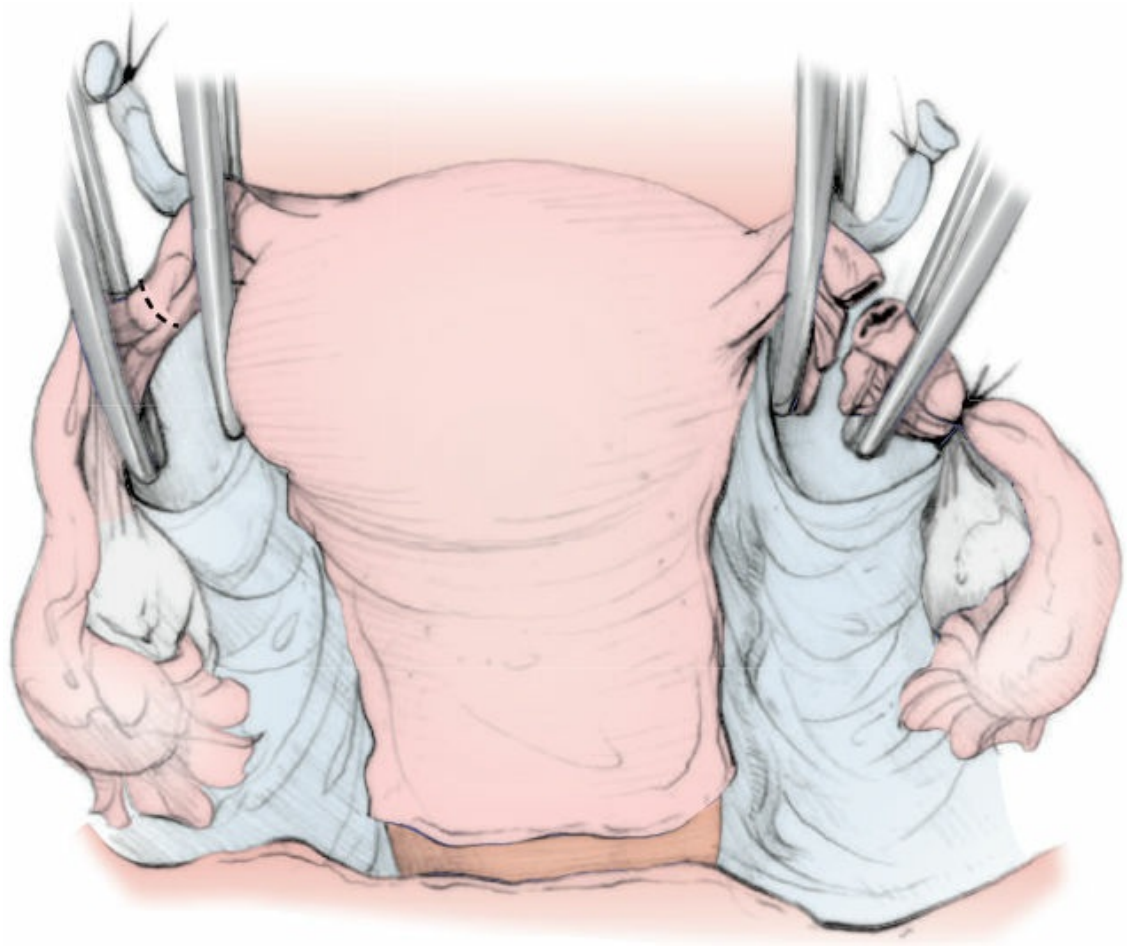

Figure 183.3. The uteroovarian ligaments are clamped, cut, and sutured when the ovaries are to be preserved.

The posterior leaf of the broad ligament is then partially divided toward the posterior cul-de-sac in order to better isolate the ascending uterine arterial branches and move the ureter further from the operative field. Starting with these ascending uterine vessels, hemostatic division then includes the paracervical (cardinal and uterosacral) ligaments (Fig. 183.4). The length of these ligaments varies depending on the uterine size and cervical length. Because the ureter passes approximately 1.5 cm lateral to the uterus and under the uterine artery, it is important to keep the line of dissection applied close to the uterus. When using a clamp-cut-stich method, it is useful to utilize heavy pedicle clamps to manage these somewhat thick fibrovascular tissues (Fig. 183.5).

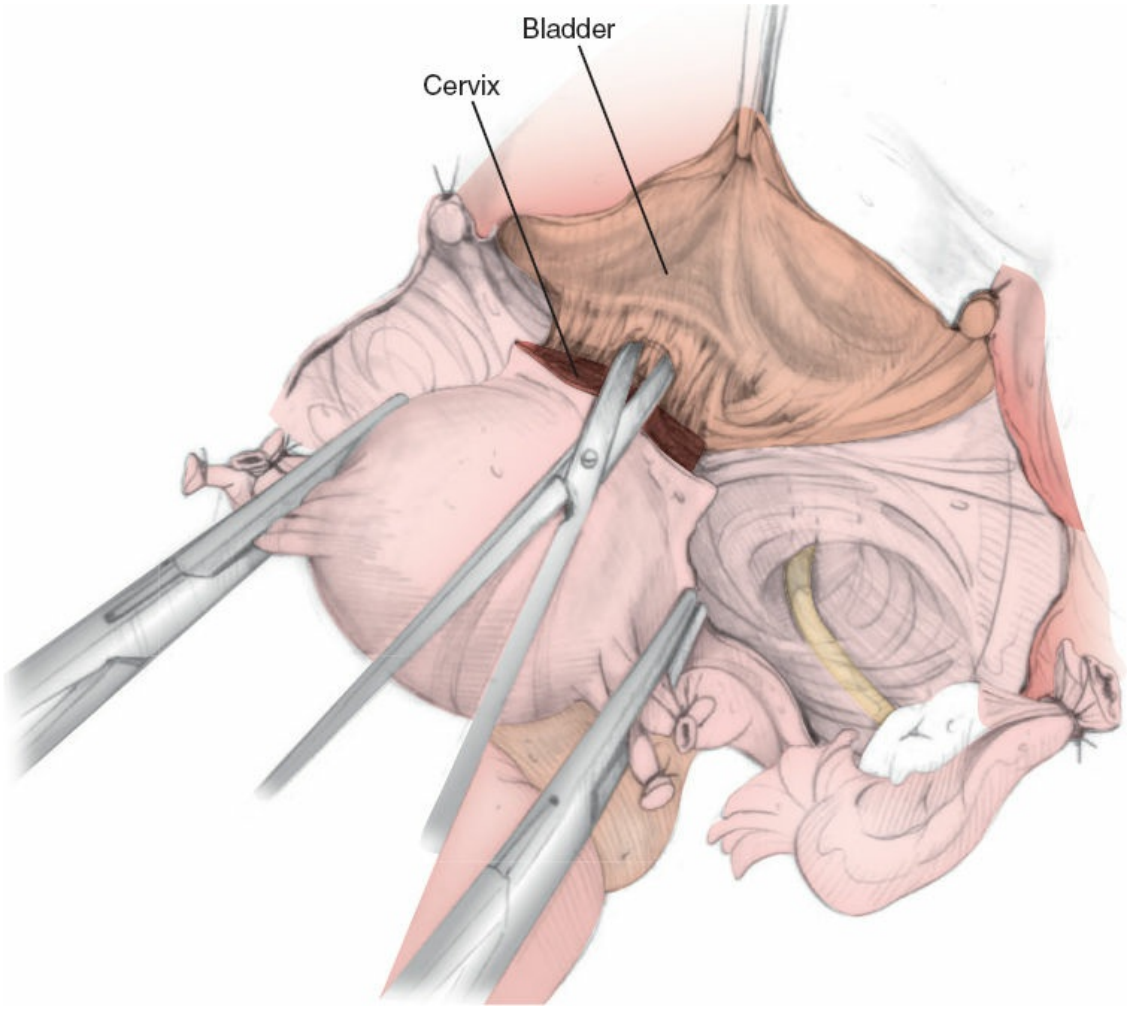

Figure 183.4. The vesicouterine peritoneum is incised and the bladder is dissected away from the cervix.

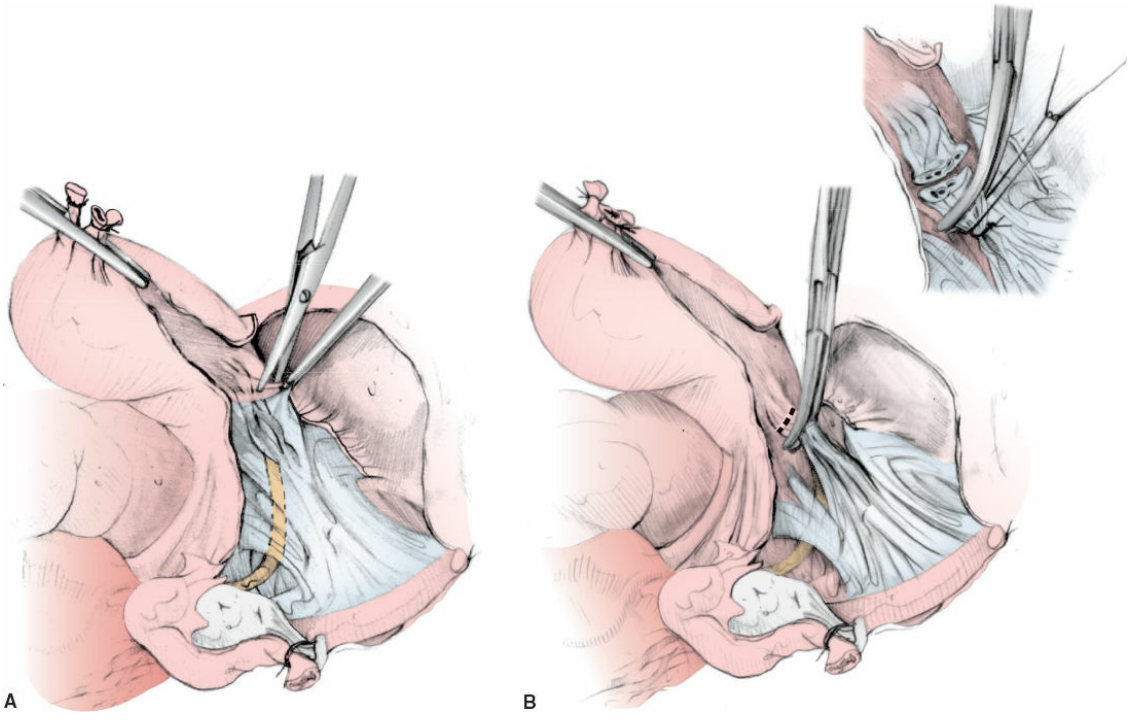

Figure 183.5. The uterine vessels are clamped close to the uterus above the uterine lower segment. These pedicles are clamped, cut, and sutured bilaterally. Staying close to the uterus and well above the cervix avoids damage to the ureters.

The hysterectomy can be done with complete removal of the cervix, which is the usual procedure or the cervix can be left in place (subtotal hysterectomy, Fig. 183.6). If the latter procedure is selected, cervical disease should have been excluded with a normal preoperative pelvic examination and Pap test. Retaining the cervix may be elected in some patients in order to reduce operative time or preclude urinary tract and/or rectal injury in cases of severe adherence. In some cases of advanced ovarian cancer, the cervix is retained to prevent cancer growth into the vagina and/or leakage of ascites. When the cervix is left, the endocervical canal should be excised or cauterized to prevent later bleeding from retained endometrium.

When the cervix is to be removed with the uterus, the end of the cervix can be palpated and a bulge can usually be seen at this area of the vaginal apex. The surgeon should attempt to ensure isolation of the cervicovaginal junction from the lateral vascular attachments. At this point, the vagina may simply be transected from the cervix, clamped and cut at each angle, or stalpled (absorbable). Inspection of the uterus will determine if the entire cervix is in the operative specimen. The vaginal cuff can be grasped with clamps (e.g., Allis, Kocher) including both the vaginal mucosa and submucosa. The cut edge will have small blood vessels, but the main arterial supply is at 3 and 9 o'clock as ascending branches of the internal iliac arteries. These lateral vaginal "angles" require particular attention to hemostasis. The vaginal cuff is usually closed with absorbable suture (Fig. 183.7) but may be left open, with the cut edge made hemostatic by a running locking suture. If the vaginal cuff is left open, the peritoneum should be used to cover the opening in order to prevent bowel herniation into the vagina. An occasional advantage of leaving the cuff open is that pelvic drains can be placed if there has been infection or excessive bleeding, and pelvic collections of fluid postoperatively can be easily drained if they occur. Oncology follow-up may also be facilitated.

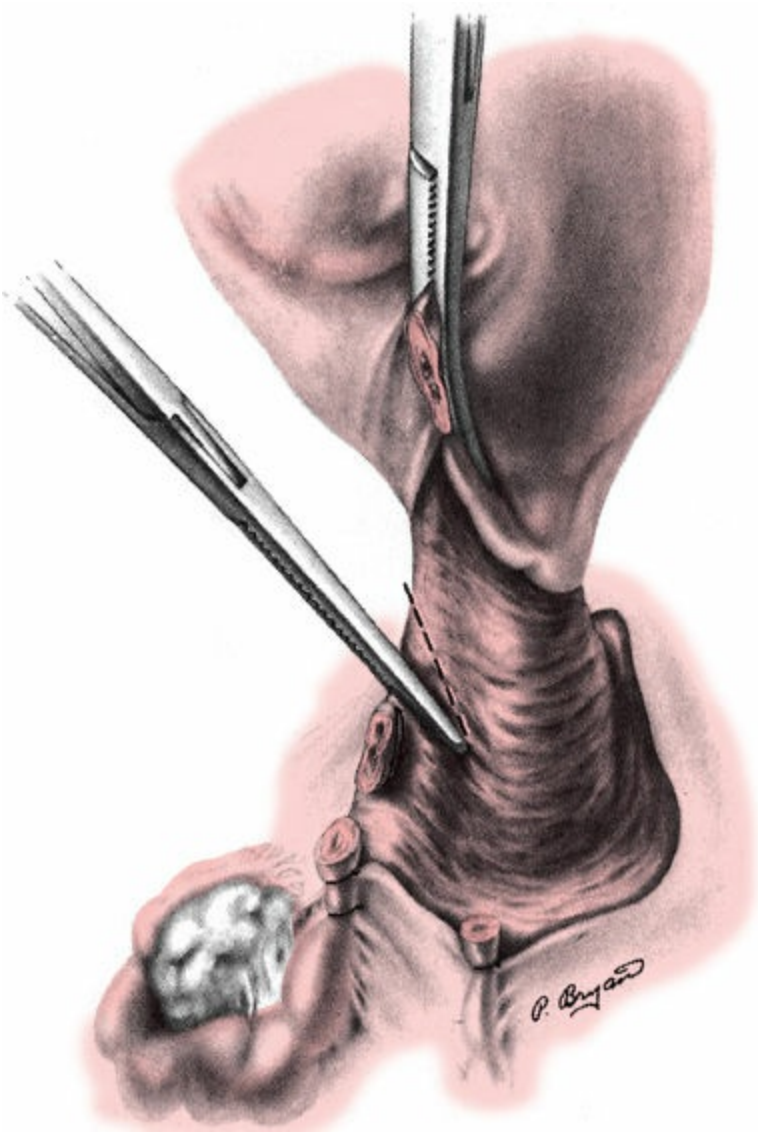

Figure 183.6. Hemostatic division then includes the paracervical (cardinal and uterosacral) ligaments. The clamps are maintained tightly against the cervix and within the “U” shaped region of mobilized soft tissue that contains the urinary tract.

After removal of the specimen, the pelvis should be inspected and hemostasis ensured. If the ovaries are retained, the ovarian ligaments may be sutured to the round ligament stumps to prevent them from falling into the cul-de-sac and producing pain and dyspareunia (Fig. 183.8). This also facilitates later removal if needed. There is no need to reperitonealize the entire pelvic surgical area except if the vaginal cuff is left open.

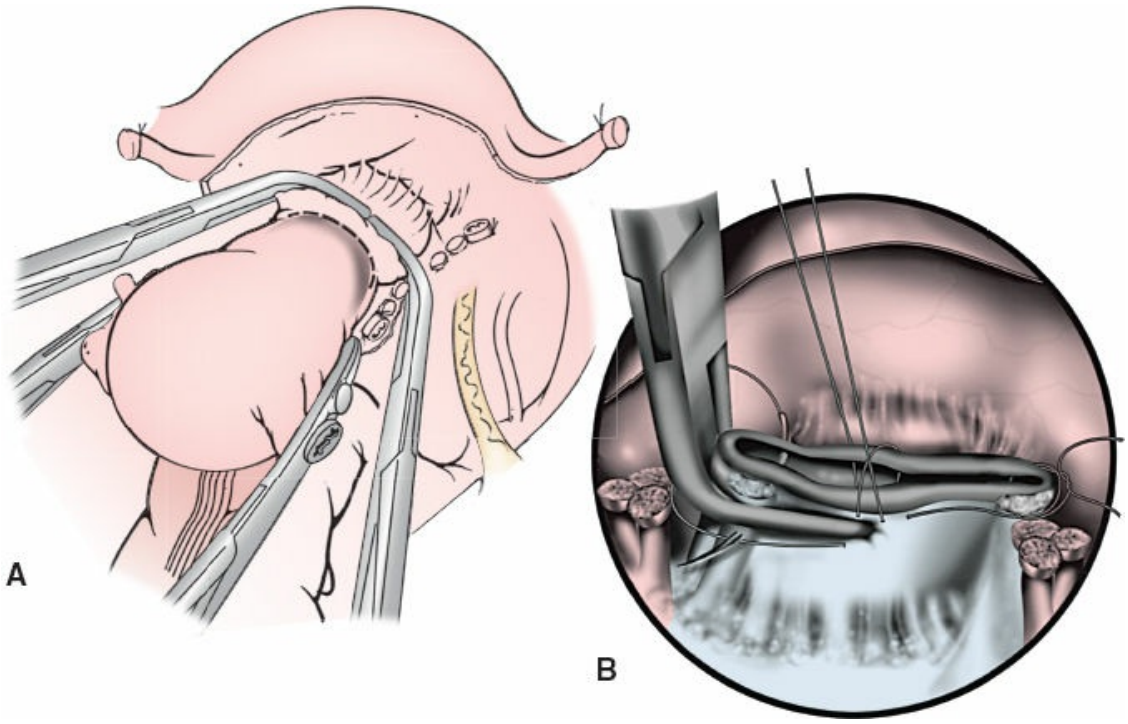

Figure 183.7. In the total hysterectomy the vagina is clamped below the cervix, cut, and sutured.

POSTOPERATIVE CARE

Postoperative care is essentially the same as that for any similar abdominal operation. The vagina and surrounding tissues are past the acute healing process by 6 to 8 weeks. During this time, patients are counseled to avoid immersion in water placement of anything into the vagina (i.e., intercourse, douching). A pelvic exam is done 6 to 8 weeks postoperatively to assess healing and the advisability of returning to sexual activity.

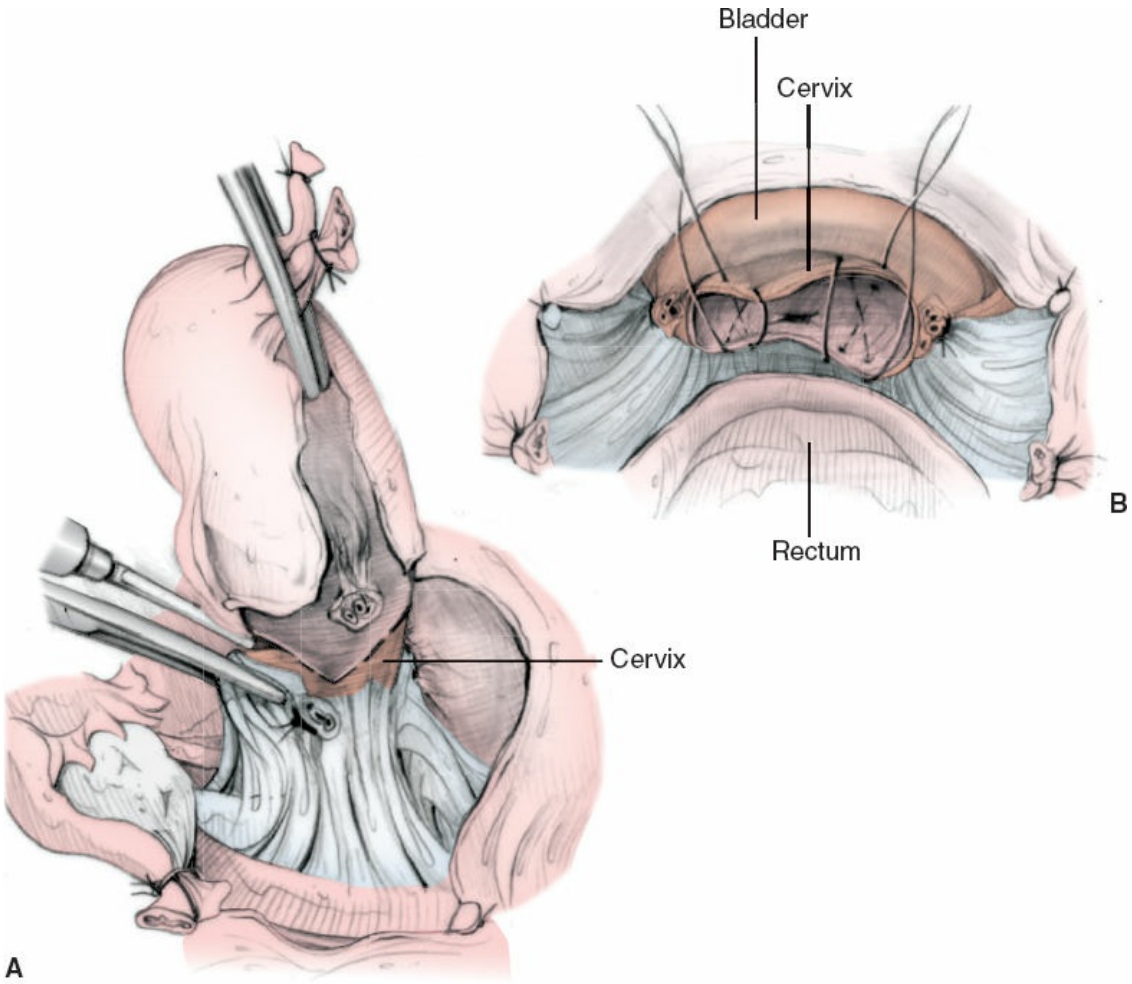

Figure 183.8. In the subtotal hysterectomy the surgeon cuts across the cervix and leaves the cervical stump in place. The cervical stump cut surface is sutured to obtain hemostasis.

When the ovaries have been removed in a premenopausal woman, acute estrogen withdrawal symptoms (vasomotor, mood swings, irritability) may need to be addressed with replacement. Related lifetime health care issues require an acute and long-term plan.

COMPLICATIONS AND THEIR MANAGEMENT

An abdominal hysterectomy has the usual surgical risks of bleeding and infection. For most procedures, the anticipated blood loss should not be excessive, and usually is no more than 500 mL. The major sites for postoperative infection will be the vaginal cuff, the wound, the urinary tract (as a result of the catheter), and the lungs. Total hysterectomy is a clean-contaminated operation and the use of short-term prophylactic antibiotics has been shown to significantly reduce the occurrence of pelvic and abdominal wound infection.

Intraoperative Complications

The majority of complications that occur with abdominal hysterectomy are common to laparotomies in general and especially to pelvic surgery in women. Structures that are occasionally injured during hysterectomy include the bladder, ureter, intestine, and lumbosacral nerves (Table 183.1). In addition, the pelvis is a highly vascular region with significant potential for hemorrhage. Postoperatively, occult injury to a viscus may become evident in the form of a vaginal fistula. Nerve injury is usually noted in the early postoperative period. Care should be taken with self-retaining retractors, especially in thin women where the lateral blades may impinge upon the femoral nerve as it exits from the caudal–lateral aspect of the psoas muscle. Postoperative infection specific to hysterectomy takes the form of a vaginal cuff cellulitis or abscess.

TABLE 183.1 Intraoperative Complications of Hysterectomy

Complication	Incidence (%)
Bladder injury	0.5
Ureteral injury	<0.2
Bowel injury	<0.5
Postoperative hemorrhage	1

The pelvic ureter and the bladder have an intimate anatomic relationship with the uterus. Through knowledge of these relationships, injury is avoided by appropriate traction and counter traction, isolation of the gonadal vessels from the ureters before ligation, careful dissection of the bladder from the cervix and anterior vaginal fornix, and placing clamps and sutures (or energy device) tightly against the cervix to avoid the lateral soft tissue where the ureters course. When there is significant pathologic distortion or inflammation of the pelvic organs, the anatomic relationships are less reliable, predisposing to urologic injury. Other factors that predispose to urologic injury during hysterectomy are intraoperative hemorrhage and poor exposure. Adnexal pathology, especially with fixation in the posterior lateral pelvis and inflammation involving the lateral pelvic peritoneum (especially if also retroperitoneal), makes isolation of the gonadal vessels difficult. Opening the retroperitoneum

above the pathologic process allows the surgeon to identify the ureter and trace it down. Injury of the ureter occasionally occurs at this level and management can be a challenge due to a potentially compromised distal ureteral segment. More commonly, the ureter is injured along its course through the paracervical tissues and is best managed with a ureteroneocystostomy. Less significant ureteral injuries may be managed by simple deligation, with or without stenting. If concern exists about ligating or transecting the ureter, verification of patency can be done with cystoscopy.

The urinary bladder is more likely to be injured during hysterectomy when inflammation or prior surgery (e.g., cesarean section) has obliterated the plane between the bladder and cervix. In such circumstances, leaving some cervical tissue on the bladder is usually the best approach. An inadvertent cystostomy should not be closed until the hysterectomy is completed; this facilitates a more appropriate path of dissection and avoids later tension on the cystotomy closure. When a cystotomy occurs near the vaginal fornix, it is close to the trigone. If there is concern about the integrity of the bladder or unexplained significant hematuria during the operation, then 100 to 200 mL of a dilute dye solution can be backfilled into the bladder to see if peritoneal leakage occurs.

The segment of intestine most commonly injured during the actual hysterectomy is the rectosigmoid colon. Several pathologic conditions (pelvic inflammatory disease, diverticulitis, ovarian cancer, endometriosis) may obliterate the posterior cul-de-sac, resulting in dense adherence of the rectosigmoid colon to the posterior aspect of the uterus. As with the bladder, sharp dissection leaving a small amount of uterus on the colon works well. For women with locally advanced ovarian cancer and in selected cases of severe endometriosis and diverticulitis, en-bloc hysterectomy with rectosigmoid colectomy is indicated.

The uterus, as would be expected from its function, is a highly vascular organ. Along its entire length, anastomosing branches of the gonadal and internal iliac vessels supply and drain the uterus. These numerous vessels run within the lateral uterine attachments, and it is not practical to isolate them. Rather, hemorrhage is avoided by careful attention to clamping, dividing, and ligating these ligaments (or utilizing an appropriate energy device in a similar manor). It is especially important to keep the clamps or energy device tight against the uterus and avoid large spaces between pedicles. This is made more difficult in the presence of significant

pathologic distortion (e.g., large lower uterine segment leiomyomata, adnexa densely adherent to the posterior broad ligament as seen with pelvic inflammatory disease or endometriosis) and with poor exposure (e.g., markedly obese patient). When hemorrhage is encountered, rather than attempting prompt and secure hemostasis, it is usually best to proceed with the hysterectomy in a careful but expeditious manner. Continued bleeding is usually from the more caudal blood supply and hemostasis occurs as this is ligated. When a large myomatous uterus interferes with distal exposure, it is best to ligate the gonadal and uterine vessels and then perform a supracervical hysterectomy. Occasionally, doing myomectomies improves exposure and thus facilitates hysterectomy. With greatly improved exposure, removal of the cervix becomes practical. Clamping or ligating bleeding from divided paracervical tissues endangers the ureter. One can carefully grasp the bleeding site with an Allis clamp, gently apply traction to the midline away from the ureter, and then carefully place a suture ligature. Cystoscopic assessment of ureteral patency is advisable in such cases.

Postoperative Complications

A significant though occult injury of the bladder becomes manifest as urinary leakage through the vaginal cuff. Depending on the mechanism of injury, this may be immediate or delayed, but will usually present within the first 10 days after surgery. The diagnosis is readily made by placing dilute methylene blue solution through a Foley catheter while observing for leakage through the vaginal cuff.

Unrecognized injury of a ureter may also present postoperatively with leakage of urine through the vaginal cuff. However, the patient may develop ureteral obstruction without leakage, and this is frequently asymptomatic. If concern arises immediately after the surgery, a simple test is to measure the blood creatinine level. One ligated ureter will raise the creatinine about 0.8 mg/dL for 2 days. The diagnosis is confirmed with intravenous pyelography.

Postoperatively, serous fluid or blood may accumulate at the operative site (above the vaginal cuff, between the bladder, and rectosigmoid colon). This collection is contaminated by bacteria from the vagina and occasionally develops into an abscess. Important risk factors for postoperative vaginal cuff cellulitis or abscess include prolonged surgery and excessive blood loss. Prophylactic antibiotics have dramatically

reduced the risk of this complication. Patients who develop an abscess present up to several weeks postoperatively with fever and lower pelvic discomfort. Drainage can usually be accomplished through the vaginal cuff although image-guided drainage may be preferred or required.

Absent anticoagulation, significant postoperative bleeding will usually manifest within the first 24 hours. Along with the usual signs of hemorrhage, the patient may develop vaginal bleeding, high drain output, or increasing abdominal distention. The usual source is a branch of the internal iliac system, often from the vaginal cuff itself. Management options include careful observation with transfusion as deemed necessary, reoperation (sometimes transvaginal cuff sutures work), or percutaneous arterial embolization after arteriography.

As with any abdominal operation, postoperative small bowel obstruction may develop. The site of obstruction is usually the ileum adherent to the operative site (pelvis) or abdominal wound. At the completion of hysterectomy, placement of the sigmoid colon and cecum over the raw pelvis and the omentum between the intestines and abdominal wound may help prevent this complication.

During abdominal hysterectomy, a component of the lumbosacral plexus may be damaged. Femoral neuropathy is by far the most common. The usual mechanism is thought to be ischemia or neuropraxia as a result of prolonged compression by a self-retaining retractor. Patients at risk are those who are thin, have poorly developed rectus abdominus muscles, have diabetes, and have a low transverse abdominal incision. The patient reports weakness (usually unilateral) of the leg, often stating that her knee “gives out” upon ambulation. Neurologic examination confirms the diagnosis. Management includes neurologic consultation and physical therapy. It must be emphasized that careful restricted ambulation under the guidance of a physical therapist is important to prevent a fall. Prevention of this injury is based on proper retractor placement to avoid compression of the nerve as it traverses and exits the psoas muscle.

Other postoperative complications may occur, including deep vein thrombosis (DVT), pulmonary embolism, wound dehiscence, and bowel herniation through the vaginal apex. Women who are at high risk for any of these complications may need specific prophylactic measures. For example, women who have had a DVT during pregnancy or during estrogen treatment are at risk of having a congenital coagulation disorder. If any of the thrombophilic tests are positive, then prophylactic

anticoagulation is recommended. Women with a postoperative serosanguineous wound discharge may have occult wound disruption and dehiscence and appropriate wound review is necessary.

SUMMARY

Abdominal hysterectomy is a very common surgical procedure, used as a definitive treatment modality for many gynecologic diseases after more conservative therapies have failed. Preoperatively, decisions about removal of the cervix or ovaries must be made with all concerned. With properly performed techniques, there are few complications expected.

EDITOR'S COMMENT

Drs. Hoffman, Silva, and Cecero have written a nice review of the indications, techniques, and potential complications associated with abdominal hysterectomy. As they point out correctly, despite consensus statements from several gynecologic societies regarding the benefits of a minimally invasive approach, the majority of hysterectomies are performed via laparotomy. A multicenter, prospective, randomized clinical trial comparing laparoscopic to open total hysterectomy evaluated 760 women with early stage endometrial cancer. The main study end points for this analysis were surgical adverse events, hospital length of stay, conversion from laparoscopy to laparotomy, including 753 patients who completed at least 6 weeks of follow-up. The incidence of intraoperative adverse events was comparable in either group. The incidence of serious adverse events (14.3% in Total Abdominal Hysterectomy [TAH], 8.2% in Total Laparoscopic Hysterectomy [TLH], $p = 0.007$) was significantly higher in the TAH group compared to the TLH group. Mean operating time was 132 and 107 minutes, and median length of hospital stay was 2 and 5 days in the TLH and TAH group, respectively ($p < 0.0001$). The authors of this trial conclude that compared to TAH, TLH is associated with a significantly decreased risk of major surgical adverse events, and that a laparoscopic surgical approach to early stage endometrial cancer is safe.

A recent Cochrane Database Systematic Review on the surgical approach to hysterectomy for benign gynecologic disease assessed four approaches including abdominal (open) hysterectomy, vaginal hysterectomy, laparoscopic hysterectomy, and robotic-assisted hysterectomy. A total of 47 studies with

more than 5,000 women were included. The authors concluded that among women undergoing hysterectomy for benign disease, vaginal hysterectomy appears to be superior to laparoscopic and abdominal hysterectomy as it is associated with faster return to normal activities. Where vaginal hysterectomy is not possible, the authors found that laparoscopic hysterectomy has some advantages over abdominal hysterectomy (including more rapid recovery, fewer febrile episodes, and fewer wound or abdominal wall infections), but these are offset by a longer operating time. Based on their analysis, the authors felt that robotic hysterectomy should either be abandoned or further evaluated since there is a lack of evidence of any benefit over conventional laparoscopic hysterectomy. The authors of this review do acknowledge that the observed benefits and hazards seem to be dependent on surgical expertise, and this may influence the decision with regard to the optimal approach.

Given the above findings, it is difficult to determine exactly why such a low percentage of overall abdominal hysterectomies are performed with a minimally invasive approach. This likely has something to do with the technical complexity of laparoscopic hysterectomy and the fact that laparoscopic skills are not derivative from open surgical skills. All gynecologists learn how to do an open abdominal hysterectomy in training, yet smaller portions are exposed to laparoscopy to a degree where they are completely comfortable with this approach. The robotic surgical platform may help ease the transition from open to a minimally invasive approach for surgeons who lack extensive laparoscopic experience. A recent review of the Premier Research Database including 289,875 hysterectomies at 156 US hospitals from 2005 to 2010 revealed that open abdominal cases decreased from 60% to 33%, while minimally invasive approaches increased from 40% to 67%. Much of the growth in minimally invasive hysterectomy was using a robotic approach, suggesting that the robotic platform facilitated the conversion of cases from open to minimally invasive—much like was observed in prostatectomy. Interestingly, in this particular study, the authors found that robotic operative times and complication rates decreased with increasing surgeon experience despite increased case complexity.

There is a growing body of literature examining the cost of a robotic approach to hysterectomy when compared to the alternatives. A systematic review and cost analysis on robotic assisted hysterectomy in benign and malignant conditions examined data from two health technology assessments: 1 systematic review and 16 original articles. In malignant conditions, less blood loss, fewer complications, and a shorter hospital stay were considered the main advantages of robot-assisted surgery. There were no significant differences between the techniques regarding oncological outcomes. When compared to laparoscopic hysterectomy, the main benefit of robot-assistance was a shorter learning curve associated with fewer conversions; but the length of robotic operation was often longer. In benign conditions, no clinically significant differences were reported and vaginal hysterectomy was considered the optimal choice when feasible. According to Finnish data, the costs of robot-assisted

hysterectomies were 1.5 to 3 times higher than the costs of conventional techniques. In benign conditions, the difference in cost was highest. Because of expensive disposable supplies, unit costs were high regardless of the annual number of robotic operations, suggesting that economical effectiveness cannot be markedly improved by increasing the volume of robotic surgery. The AAGL released a position statement of robotic surgery in 2013 that concludes "Robotic-assisted laparoscopic surgery should not replace conventional laparoscopic or vaginal procedures for women who could otherwise undergo conventional laparoscopic or vaginal surgery for benign gynecologic diseases." This is based on their findings that robotic-assisted laparoscopic surgery in gynecology is associated with similar clinical outcomes when compared to conventional laparoscopy, but with longer associated operating room time and costs.

Another recent controversy in the domain of minimally invasive hysterectomy revolves around the method of specimen extraction. When the uterus is removed through small incisions and a minimally invasive approach, the specimen usually cannot be retrieved through one of these incisions without significantly enlarging the incision. Devices known as morcellators have been used to facilitate specimen removal. It is difficult to determine if a presumed myoma is actually a uterine sarcoma (0.28%) or a leiomyosarcoma (0.2%) prior to removal. If an electronic morcellator is used during tumor removal and the lesion was actually a sarcoma, intrapelvic and intraabdominal dissemination and a poorer prognosis can result. Because of these concerns, in April of 2014 the Food and Drug Administration (FDA) issued a warning statement with regard to the use of power morcellators in hysterectomy.

"If laparoscopic power morcellation is performed in women with unsuspected uterine sarcoma, there is a risk that the procedure will spread the cancerous tissue within the abdomen and pelvis, significantly worsening the patient's likelihood of long-term survival. For this reason, and because there is no reliable method for predicting whether a woman with fibroids may have a uterine sarcoma, the FDA discourages the use of laparoscopic power morcellation during hysterectomy or myomectomy for uterine fibroids."

There is some controversy about the actual risks of disseminating an unsuspected sarcoma with a minimally invasive hysterectomy, but several studies have clearly demonstrated that following the FDA warning, the proportion of minimally invasive hysterectomies and myomectomies (relative to the total number of open procedures) has significantly decreased.

Overall, this is a very nice review of a topic that many general surgeons know little about. The technical descriptions and discussion with regard to potential complications are of value to anyone who performs pelvic surgery.

184 Radical Hysterectomy

Jonathan Boone and Warner Huh

INTRODUCTION

Radical hysterectomy with bilateral pelvic lymphadenectomy is considered the standard of care for the surgical management of early-stage cervical cancer. Wertheim developed the modern technique for radical hysterectomy in the early 20th century, and in the 1940s Meigs added routine pelvic lymphadenectomy to the procedure, thereby increasing its curative potential. Radical hysterectomy can now be performed with low rates of complications as modern surgical techniques and advances in anesthesia, transfusion, and antibiotics allow the operation to be performed with morbidity rates approaching 1%. As a result, radical hysterectomy and bilateral pelvic lymphadenectomy are an alternative to radiation for the definitive treatment of patients with FIGO stage IA, IB, and IIA cervical cancer.

A randomized study has shown that radical hysterectomy and radiation both result in 5-year survival rates of 85% in early cervical cancer. Therefore, the choice of treatment for a given patient is based on other considerations. Radical surgery has a number of potential advantages over radiation. It allows preservation of ovarian function. It also allows better preservation of sexual function relative to radiation. It is associated with fewer long-term complications than radiation, particularly with respect to chronic diarrhea and hematuria, tenesmus, small bowel obstruction, and urinary tract and bowel fistulas. Radical hysterectomy does have the disadvantage that it is not as widely applicable as radiation. Poor surgical candidates, such as those with numerous comorbidities or morbid obesity, may be better candidates for radiation therapy. Radical hysterectomy is also associated with more acute complications compared to radiation, such as infection, thromboembolism, and ureteral injury.

Radical hysterectomy differs from an extrafascial (or simple) hysterectomy in that the tissues surrounding the cervix are removed along with the uterus and cervix. This includes the cardinal ligaments, uterosacral ligaments, and upper vagina. While this additionally resected

tissue does not appear very impressive in the final specimen, the additional work necessary to remove them is considerable. During the operation, more time is spent in mobilizing the surrounding structures, namely the bladder, ureters, and rectum, than in removing the specimen. Pelvic lymphadenectomy, while not an essential part of radical hysterectomy, is almost always performed in conjunction with radical hysterectomy when treating cervical cancer. The final result of radical hysterectomy and pelvic lymphadenectomy is a classic Halstedian operation, with radical resection of the primary tumor and resection of the draining lymph nodes.

Early cervical cancer is by far the most common indication for radical hysterectomy and pelvic lymphadenectomy. However, this operation can be considered in patients with stage II endometrial cancers with gross cervical involvement. Small, centrally recurrent cervical cancers occurring after previous treatment with radiation therapy can also be treated with radical hysterectomy, although this is controversial as many surgeons feel these patients have a better chance of long-term survival with pelvic exenteration.

The number of women undergoing traditional radical hysterectomy has declined in recent years. In patients with stage IA1 cervical cancer, the standard operation is now an extrafascial hysterectomy without pelvic lymph node dissection. Studies have shown <1% risk of parametrial involvement or lymph node metastasis with survival rates approaching 99%. By performing an extrafascial hysterectomy in these patients, there is significantly less morbidity with the same curative potential. Patients with stage IB2 and IIA cancer warrant a careful physical examination to determine whether an adequate surgical margin can be achieved. CT, PET/CT and/or MRI imaging is commonly used to assess surgical resectability. Five-year survival rates for women with stage IB and IIA cervical cancer are similar regardless of whether they are treated with radical surgery or primary radiation therapy with radiosensitizing chemotherapy (chemoradiation). A prospective study found that 84% of patients with stage IB disease received postoperative radiation therapy even after radical hysterectomy, and these patients had over twice the morbidity of those who received radiation only. The increased morbidity experienced by patient receiving surgery followed by radiotherapy includes grade 2 and 3 complications like hydroureteronephrosis, chronic neurogenic bladder, cystitis, incontinence, and lower extremity edema. With similar survival rates regardless of treatment, a high likelihood of

receiving postoperative adjuvant radiation, and less morbidity with primary chemoradiation, many surgeons now treat women with stage IB2 and IIA disease with primary chemoradiation.

In an effort to reduce the radicality of this surgery, the modified radical hysterectomy was developed. A randomized clinical trial demonstrated that modified radical hysterectomy is associated with less morbidity and similar rates of cure in patients with stage IB and IIA cervical cancer. One limitation of this study was the high rate of adjuvant radiation, which may have negated the effects of any differences in surgical technique between the treatment arms. While some do not recommend modified radical hysterectomies, it is an accepted surgical treatment for stage IA2 or small (1 to 2 cm tumors) stage IB1 cervical cancers. It can also be performed in patients with cervical cancer who have small volume residual disease after primary chemoradiation or in those with endometrial cancer that have evidence of disease in the lower uterine segment, small volume disease at the level of the cervix, and a positive endocervical curettage.

With advances in surgical technology, minimally invasive traditional and robotic-assisted radical laparoscopic hysterectomies are commonly accepted alternatives to the open, abdominal approach. A systematic review and meta-analysis found a lower estimated blood loss, less febrile morbidity, shorter hospital stays, and fewer wound complications with robotic radical hysterectomies when compared to the open alternative. The traditional laparoscopic radical hysterectomy shows similar intraoperative and short-term postoperative outcomes to robotic radical hysterectomy, so surgeons have a choice between the two minimally invasive approaches. Since the robotic approach is seen by many surgeons as technically less challenging with shorter operative times, it is often the minimally invasive technique of choice.

Although radical hysterectomy is intended to be definitive treatment for early cervical cancer, some patients are at significant risk of recurrence with surgery alone and benefit from adjuvant therapy. Patients with positive pelvic or para-aortic lymph nodes, parametrial involvement, and positive surgical margins should be offered pelvic radiation with concurrent platinum-based chemotherapy. Adjuvant therapy may also be considered for other high-risk patients such as those with large tumors, deep stromal invasion, or lymphovascular space invasion, although the data supporting treatment of these patients are not as definitive. The management of patients with large (stage IB2) cervical tumors continues to

be controversial, with some surgeons favoring a primary surgical approach with or without adjuvant chemoradiation and others favoring chemoradiation alone. This question is currently being addressed by a randomized clinical trial.

Based on the current evidence, radical hysterectomy is indicated for stage IA2, IB1, and select stage 1B2 cervical cancers. In the United States, the procedure is rarely used for stage IIA disease. The purpose of this chapter is to describe the different types of radical hysterectomy and the robotic radical hysterectomy in detail, highlighting important points that allow these inherently difficult operations to be performed with success. Radical trachelectomy is a minimally invasive option for the treatment of stage I cervical cancer intent on sparing fertility without compromising the chance for cure; however, this is beyond the scope of this chapter.

STEPS

General anesthesia is induced. A single dose of antibiotic administered before incision is usually sufficient for prophylaxis, although a repeat dose may be given if the operation exceeds 4 hours or estimated blood loss is greater than 1500 mL. Pneumatic compression stockings (mechanical), a single injection of a prophylactic dose of unfractionated heparin or low molecular weight heparin (chemical), or the combination of both chemical and mechanical prophylaxis may be used for thromboembolism prophylaxis.

The patient is placed in dorsal lithotomy position. Examination under anesthesia is performed to exclude the presence of disease beyond the cervix and upper vagina. Rectal examination is particularly important in order to exclude disease extension into the cardinal ligaments. Cystoscopy and proctosigmoidoscopy may also be performed at the discretion of the surgeon to exclude disease extension into the bladder or rectum; however, with contemporary imaging techniques, this is less frequently utilized. Any findings suspicious for disease extension beyond the cervix and upper vagina should prompt abandonment of the operation in favor of radiation therapy.

A Foley catheter is placed. A vertical midline or low transverse incision may be used. Two transverse incisions, the Maylard and Cherney, provide excellent pelvic exposure. A vertical incision is preferable when the surgeon plans to sample the para-aortic lymph nodes. Once inside the peritoneal cavity, the abdomen and pelvis are thoroughly explored

manually and visually. Any evidence of metastatic disease should prompt abandonment of the procedure if confirmed histologically. Particular attention is paid to the area around the cervix, including the posterior cervix and cul-de-sac. A formal para-aortic lymph node sampling, while favored by some surgeons, is associated with low yield and is therefore not standard.

RADICAL HYSTERECTOMY

A Bookwalter or similar self-retaining retractor may be placed to expose the pelvis. Femoral neuropathy is a risk of using such retractors, but this risk can almost be eliminated by ensuring that there is room between the bottoms of the blades and the psoas muscles. The bowel is displaced cephalad using moist laparotomy packs. The uterus is grasped with Kocher or Kelly clamps on each cornu so that cephalad tension can be placed on the uterus. The round ligaments are suture-ligated and divided. Absorbable suture, commonly 0-Vicryl or no. 1-Chromic, is used throughout the operation. The broad ligaments are opened in a cephalad and caudad direction lateral to the gonadal vessels, and the ureters are identified along the medial leaves of the broad ligament (Fig. 184.1). They are most readily identified as they enter the true pelvis and cross over the bifurcation of the common iliac arteries.

The pararectal and paravesical spaces are then developed. These are avascular potential spaces that allow the peritoneum over the pelvic sidewall to be mobilized safely, thus exposing the pelvic sidewall vessels and the course of the ureters. The pararectal space is bounded by the external and internal iliac vessels laterally, the ureter medially, and the cardinal ligament anteriorly. Using either a single finger or a dissecting instrument, the common iliac artery bifurcation is identified and the space just medial to this is opened, resulting in displacement of the ureter medially. Care is taken to ensure that the dissection remains medial to the internal iliac artery. The dissection follows the hollow of the sacrum caudad and curves slightly medially toward the rectum. The space may be opened to the level of the levator plate.

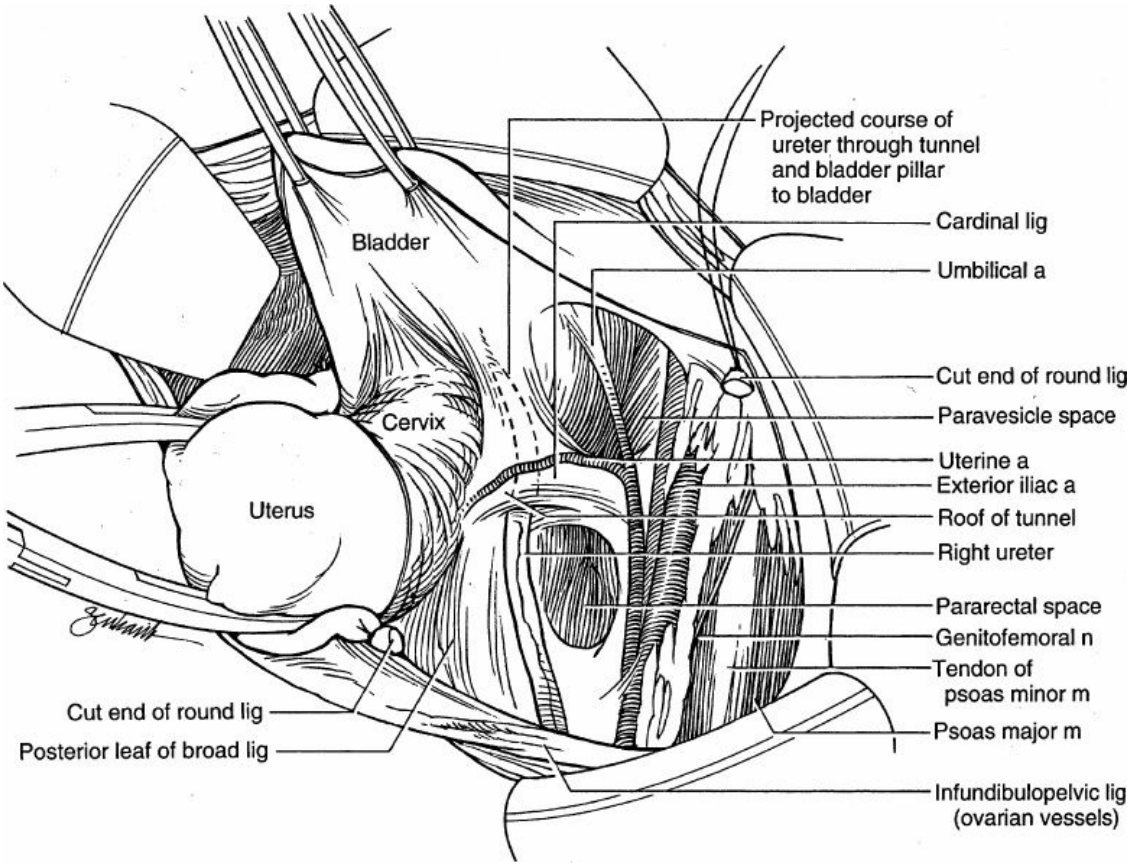

Figure 184.1. The paravesical and pararectal spaces are developed. The cardinal ligaments are assessed for tumor extension. The uterine artery is ligated at its origin from the internal iliac artery.

The paravesical space is bounded by the external iliac vessels laterally, the bladder and superior vesical artery medially, and the cardinal ligament posteriorly. Again using either a finger or a dissecting instrument, the space just medial to the most distal aspect of the external iliac vein is developed, displacing the bladder medially. The space is followed medially and caudad along the pubic symphysis toward the levator plate. Once the space is open, the superior vesical artery is readily apparent as it enters the lateral dome of the bladder. Care must be taken to avoid bleeding in the prevesical space just medial to the paravesical space.

Now the surgeon must make the final assessments for resectability prior to completing the planned operation. The vesicouterine fold of peritoneum is incised and the bladder is dissected down the anterior cervix and upper vagina in an avascular plane. This is best accomplished with sharp dissection or electrocautery to minimize bleeding and trauma to the bladder. Any tumor extension through the anterior cervix will be evident at this point. Such a finding indicates unresectability. The cardinal ligaments

are then palpated with two fingers: one in the paravesical space and another in the pararectal space. This “web” of tissue comprises the condensation of fibrovascular tissue lateral to the cervix constituting the cardinal ligament (the term *parametrium* is often used synonymously). Any palpable disease in the cardinal ligaments also indicates unresectability. Finally, the pelvic lymph nodes are assessed, and any grossly suspicious nodes are sent for frozen section. Most surgeons abandon the radical hysterectomy if grossly positive lymph nodes are encountered. There is evidence that debulking such nodes prior to closing improves the chances for cure so removal of grossly positive nodes should be considered if the surgeon determines resection is feasible.

If the adnexa are to be removed, the gonadal vessels are now isolated above the ureters and ligated. To isolate the gonadal vessels after the broad ligament has been separated, the medial leaf of the broad ligament is transilluminated or two fingers are placed under the gonadal vessels to confirm an avascular plane in that portion of the broad ligament. If the ureter is not visualized in the medial leaf of the broad ligament, it can be palpated by placing the thumb and index finger on either side of that leaf of the broad ligament to palpate for the classic “snap” produced from dragging your fingers across it. An incision is then made in the avascular plane of the broad ligament sharply or with cautery. Clamps are placed across the gonadal vessels that are suture ligated after cutting between the clamps. In order to improve visualization for the remainder of the procedure, removal of the fallopian tubes and ovaries can be performed. Advance the clamp on each uterine cornu across the utero-ovarian pedicle and cut laterally to the clamp so that the fallopian tubes and ovaries can be separated from the uterus.

If the adnexa are to be conserved, the utero-ovarian pedicles are isolated and ligated. The same window is made in an avascular plane of the medial leaf of the broad ligament. The clamp adjacent to the uterus is advanced across the utero-ovarian ligament and a second clamp is placed across the proximal utero-ovarian ligament. Cut between the two clamps and suture ligate the proximal and distal ends of the utero-ovarian ligament.

Some surgeons now proceed with pelvic lymphadenectomy, the rationale being that the finding of microscopically positive pelvic lymph nodes would result in abandonment of the operation. However, the yield is low if the nodes are grossly normal, and the technique of intraoperative

frozen section is inaccurate and cumbersome. Furthermore, many surgeons would complete the radical hysterectomy with microscopically positive pelvic nodes and recommend adjuvant chemoradiation afterwards. This approach may allow for improved sexual function compared with radiation alone, as the latter necessarily includes a very high dose of vaginal brachytherapy. We generally perform the pelvic lymphadenectomy before radical hysterectomy.

Two of the more difficult parts of the procedure are the dissections of the uterine artery and the ureter. The cardinal ligament is dissected down to the uterine artery, which is then ligated at its origin from the internal iliac artery (Fig. 184.2). The uterine artery is reflected above the ureter. The ureteral dissection then commences. The ureter is dissected off the peritoneum near the uterosacral ligament, taking care to preserve its surrounding adventitial blood supply. A small wavy vessel is often seen adjacent to the ureter and should be preserved. The ureter is then freed of its peritoneal attachments. This is facilitated by cephalad traction on the uterus and posterior traction on the ureter's adventitia. The ureter should not be handled directly. The "tunnel," through which the ureter courses lateral and anterior to the cervix, is then dissected, freeing the ureter (Fig. 184.2). It is crucial that the dissecting instrument remain in close proximity to the ureter in order to avoid significant bleeding that can ensue and obscure the field. The instrument is best placed just superolateral to the ureter. Once a pedicle is established, it may be ligated directly or after transection between clamps. The latter method is facilitated by specialized clamps developed by Casey.

The last part of the tunnel is composed of the bladder pillars, which are fibrovascular attachments of the bladder to the lateral aspects of the cervix. The pillars are exposed initially with the bladder dissection. Further anterior dissection of the pillars can facilitate the ureteral dissection, but care must be taken to avoid injuring the numerous small vessels within. The ureteral dissection is completed to the insertion into the bladder (Fig. 184.3). The surgeon must be careful to end the tunnel dissection once the bladder is reached, as the ureterovesical junction is not always obvious. The ureter, having been unroofed from its tunnel, is now dissected out of its cardinal ligament bed completely.

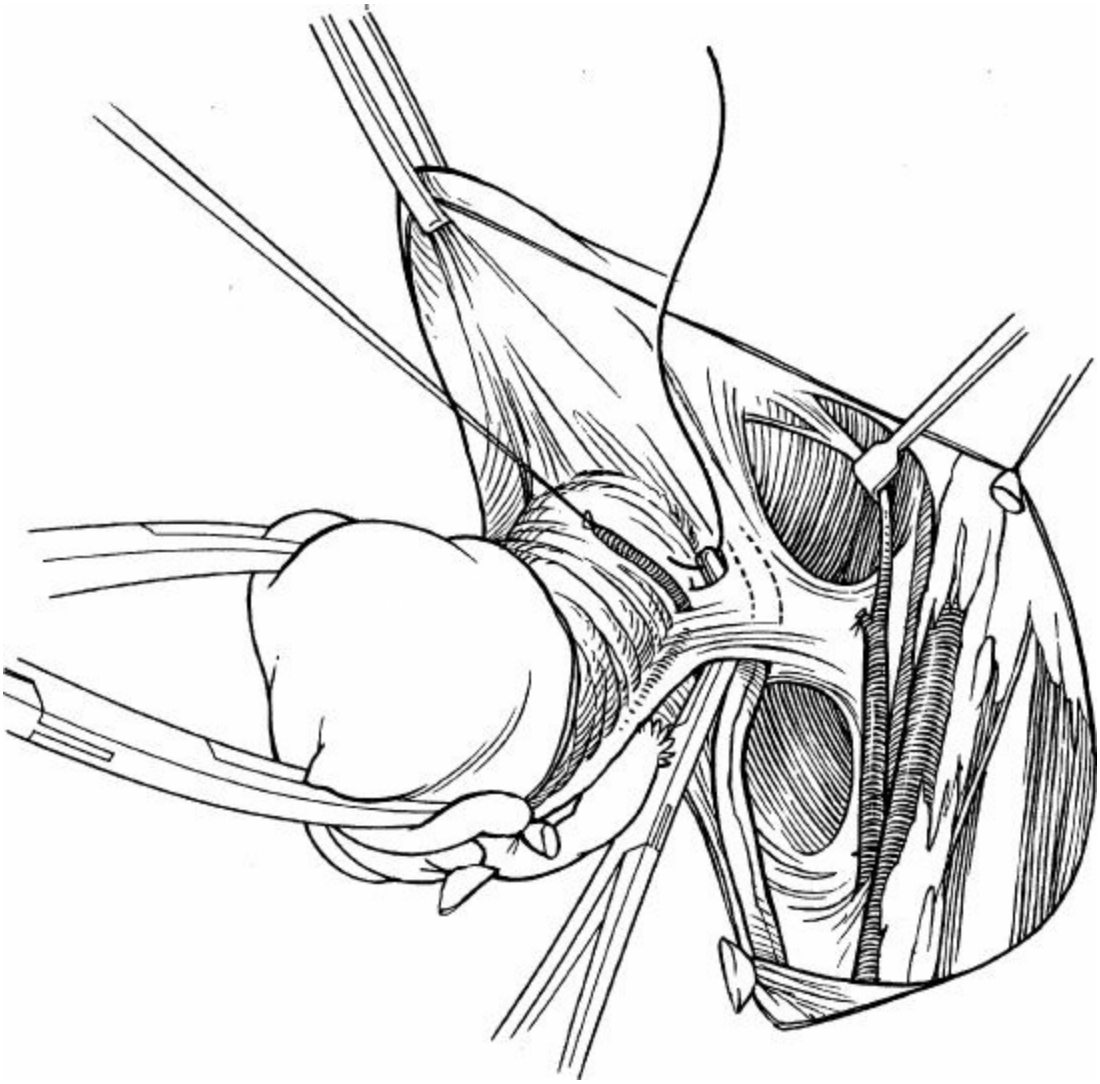

Figure 184.2. The ureteral tunnel is dissected. The ligated uterine artery is reflected above the ureter.

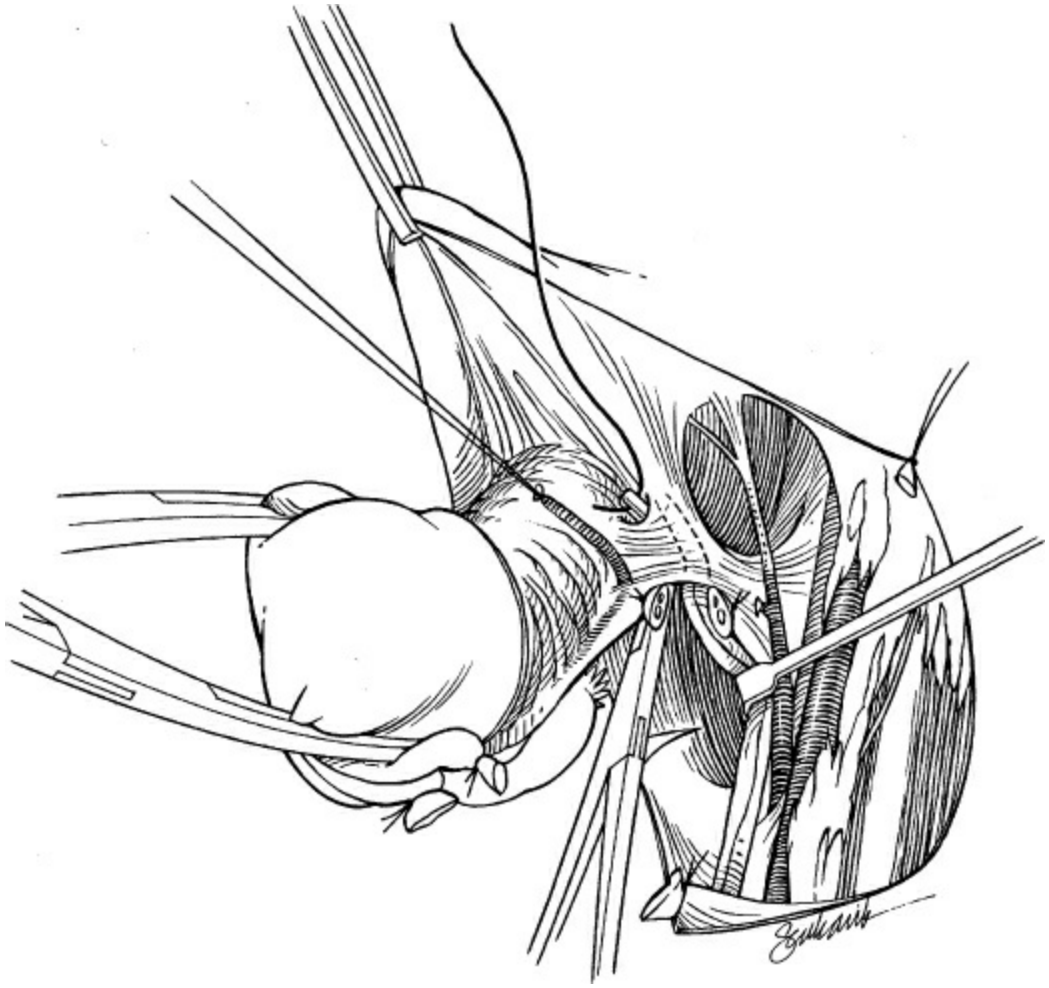

Figure 184.3. The last part of the tunnel is dissected and the ureter is completely freed to its insertion into the bladder.

The posterior dissection is then addressed (Fig. 184.4). The rectovaginal fold of peritoneum is incised, taking care to avoid the ureters. The incision crosses both uterosacral ligaments and the upper cul-de-sac. The rectum is dissected down the posterior vagina in an avascular plane. This can often be accomplished with gentle blunt dissection, with care taken to avoid direct pressure on the rectum. Excessive force can result in unintentional entry into the posterior vaginal wall, which is quite thin. The uterosacral ligaments are cleared of the rectum. Some bleeding from the rectal pillars may ensue, but this is generally not problematic.

The specimen is now removed. It is helpful to palpate the cervix to ensure an adequate margin of vagina. The uterosacral ligaments are taken with clamps, cut, and suture-ligated at roughly their midpoints, taking care to avoid the rectum (Fig. 184.5). The cardinal ligaments are similarly divided near the pelvic sidewalls, taking care to retract the ureters laterally (Figs. 184.6 and 184.7). The vagina is clamped below the cervix and the

specimen is removed. The vaginal margin may now be assessed. A 1 to 2 cm margin of vagina is generally adequate, but a larger margin should be obtained if there is disease extension to the upper vagina. The vaginal margin commonly appears smaller in the removed specimen than it does in vivo. The vaginal cuff is closed with transfixion sutures at the angles and figure-of-eight sutures in between (Fig. 184.8).

If the adnexa have been conserved, they are sometimes transposed out of the pelvis into the lower abdomen in case radiation is necessary postoperatively. This procedure results in preservation of ovarian function in about 50% of patients needing pelvic radiation. The adnexa are mobilized on their vascular pedicles and tacked to the lower paracolic gutter peritoneum with nonabsorbable suture.

At this point, the bladder, rectum, and ureters are inspected for injury. All structures should appear intact and well vascularized. The ureters should be peristalsing freely and of normal caliber. If there is any question of an injury, further evaluation is performed. The bladder may be assessed by distension with methylene blue or sterile milk through the Foley catheter. The ureters may be assessed by intravenous injection of indigo carmine and visualization of urine emanating from the ureteral orifices, preferably via cystoscopy or alternatively via cystotomy at the dome of the bladder. Absence of dye extravasation into the pelvis should also be confirmed. Although rarely necessary, the rectum may be evaluated by insufflation via proctosigmoidoscopy after filling the pelvis with fluid. If an injury is identified, appropriate repairs are performed.

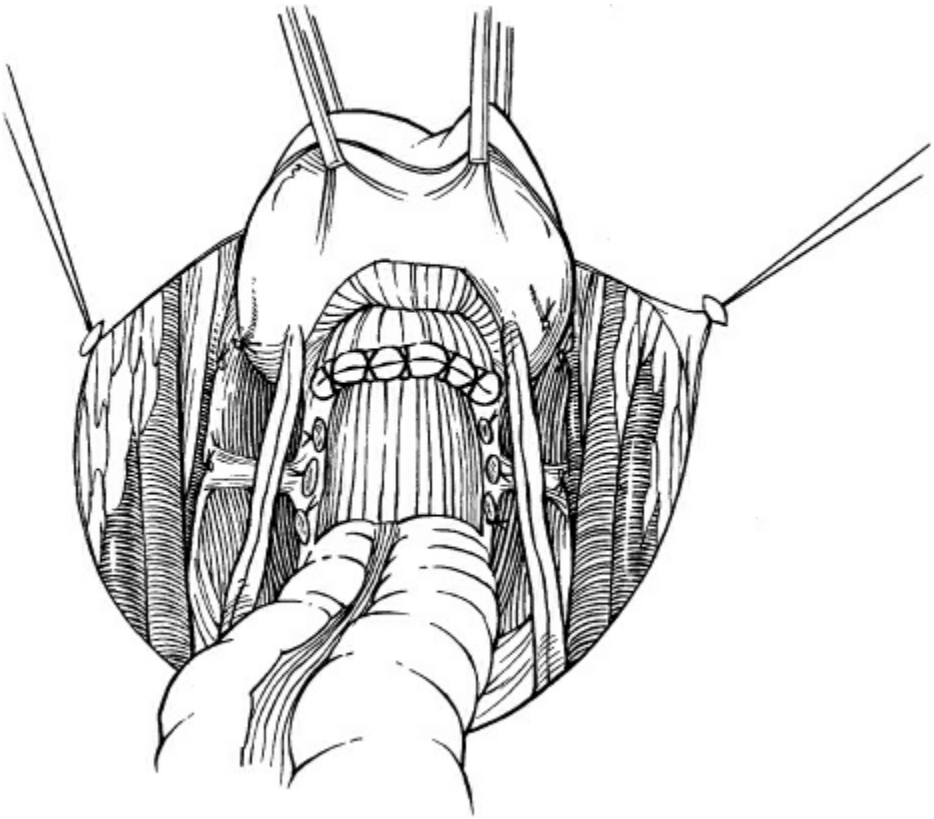

Figure 184.8. The vaginal cuff is closed with suture.

PELVIC LYMPHADENECTOMY

Pelvic lymphadenectomy is almost always performed in conjunction with radical hysterectomy for cervical cancer. Complete removal of the pelvic nodes rather than sampling is the goal. The operation is accomplished with sharp dissection or electrocautery, and hemoclips are often used for hemostasis and possibly to decrease the risk of lymphocysts.

The peritoneum is opened from the mid-common iliac artery to the deep circumflex iliac vein (Fig. 184.9). These landmarks constitute the cephalad and caudad limits of the dissection, respectively. A self-retaining retractor is used to expose the pelvic sidewall and retract the ureter medially. The dissection begins just medial to the genitofemoral nerve, which courses lateral and parallel to the external iliac artery. The lymph node–bearing tissues are mobilized medially off the external iliac artery and vein (Fig. 184.10). The obturator fossa is entered just below the external iliac vein. The surgeon should be aware of a possible accessory obturator vein off the external iliac vein, present in about 10% of patients (Fig. 184.11). This branch may be ligated to facilitate exposure of the obturator fossa. The dissection is carried under the external iliac vein toward the pelvic sidewall to the psoas muscle, separating the node bundle from the vein

completely. A vein retractor may be carefully used to retract the external iliac vein for exposure. The external iliac nodes may be taken separately or in continuity with the obturator nodes. The obturator nodes are then mobilized off the obturator nerve, which courses in the middle of the obturator fossa. It is important to avoid injury to this nerve, as it is vital for adduction of the lower extremity. Care should be taken to remove all lymph nodes above the nerve, including those in the genu between the external and internal iliac vessels and in the most distal aspect of the obturator fossa just proximal to obturator foramen. The lymph node bundle can often be grasped and pulled medially while sweeping it off the obturator nerve and internal iliac vessels with fine scissors. This allows the obturator nodes to be removed, often as a single specimen, without cutting any tissue, thereby minimizing bleeding and the risk of obturator nerve injury. There may be a few obturator lymph nodes below the nerve, but significant bleeding can be encountered in this space so it is generally not recommended to remove this nodal tissue. The distal common iliac nodes are then removed just lateral to the common iliac artery. Particular care is taken on the right, where the right common iliac vein is lateral to the artery. Once the dissection is completed, the genitofemoral nerve, obturator nerve, superior vesical artery, and ureter should all be clearly visible and uninjured. It is not necessary to place drains or close the peritoneum. These steps have not been found to decrease lymphocyst formation. Hemostasis is confirmed. The fascia is closed with a continuous permanent or delayed absorbable suture.

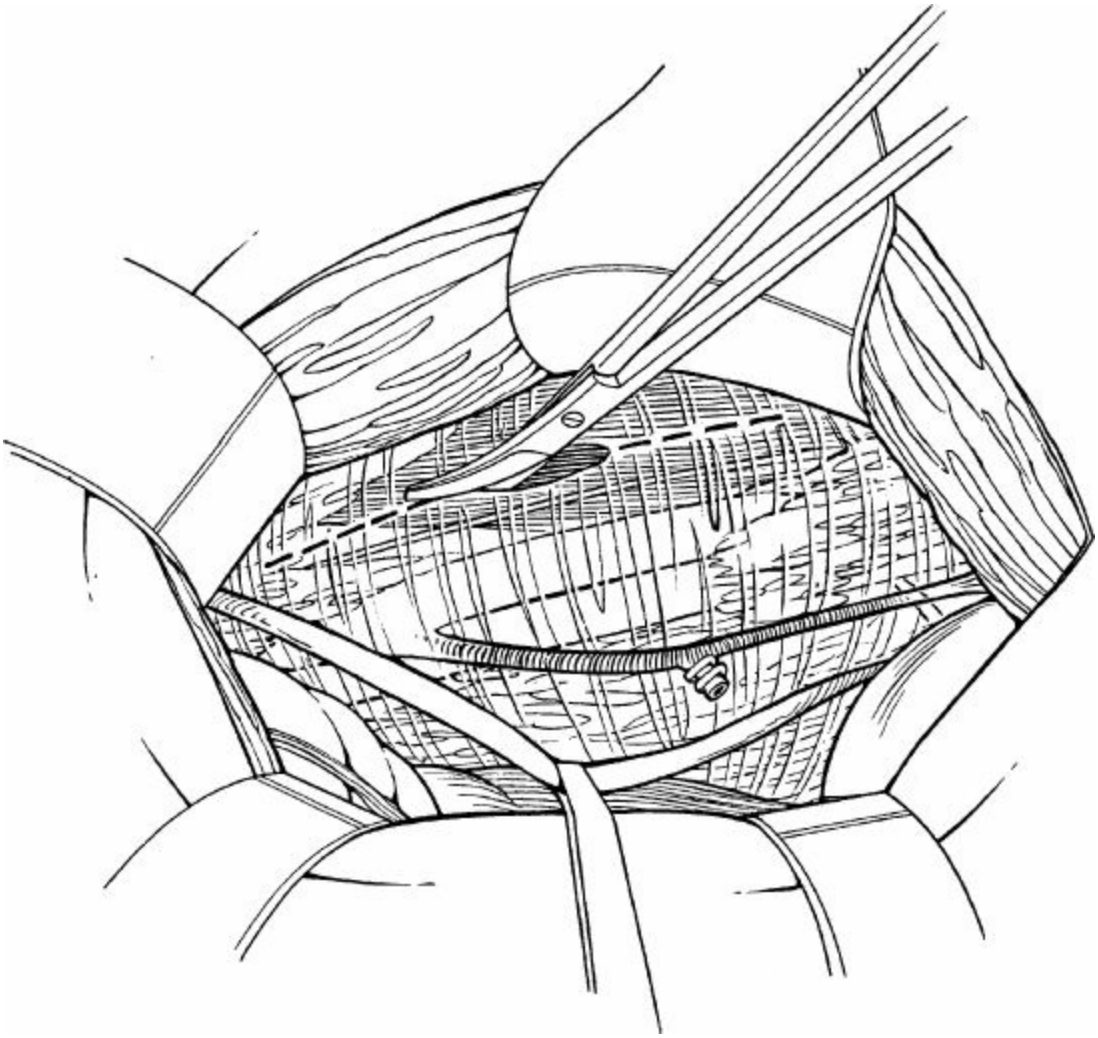

Figure 184.9. The peritoneum over the pelvic sidewall is opened over the external iliac artery.

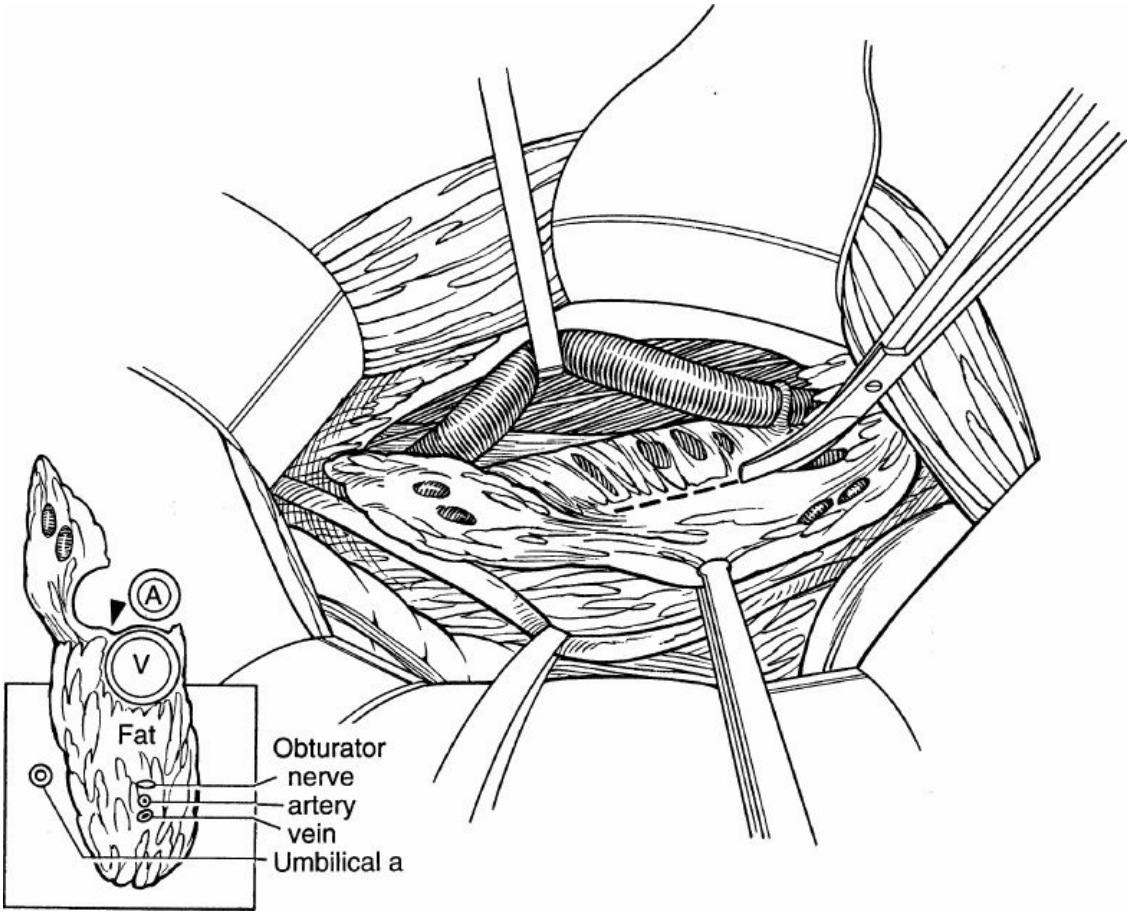

Figure 184.10. The lymph node–bearing tissues are mobilized medially off the external iliac vessels. The obturator space is entered just below the external iliac vein.

CLASSIFICATION OF RADICAL HYSTERECTOMY

The Querleu and Morrow classification of radical hysterectomy was adopted in 2008 in an effort to provide more descriptive, standardize anatomic terminology when defining the different types of radical hysterectomy. There are four different types of radical hysterectomy that differ based on the extent of lateral resection of tissue and to some degree the amount of vaginal tissue removed.

Type A: Extrafascial Hysterectomy

This resection is essentially a simple, extrafascial hysterectomy performed for early, stage IA1 cervical caner. The goal of a type A radical hysterectomy is to remove the cervix in its entirety. It can be performed abdominally, laparoscopically, traditional or robotic-assisted, or vaginally. A complete pelvic lymphadenectomy is generally not performed in conjunction with a type A hysterectomy. The paracervical tissue is

transected between the ureter and the cervix. The vesicouterine and uterosacral ligaments are transected at the cervix, and the vagina is resected at a minimal distance from the cervix, usually <10 mm.

Type B: Modified Radical Hysterectomy

Modified radical hysterectomy differs from radical hysterectomy only in the amount of paracervical tissue that is taken. Although the indications for modified radical hysterectomy are somewhat controversial, many surgeons feel it is the procedure of choice for patients with small tumors (1 to 2 cm) confined to the cervix. Modified radical hysterectomy offers the potential advantages of shorter operating times, less blood loss, and decreased overall morbidity, includin g bladder dysfunction. It can be performed through an abdominal incision or laparoscopically, either traditional or robotic-assisted. As with radical hysterectomy, a complete pelvic lymphadenectomy is almost always performed in conjunction with modified radical hysterectomy.

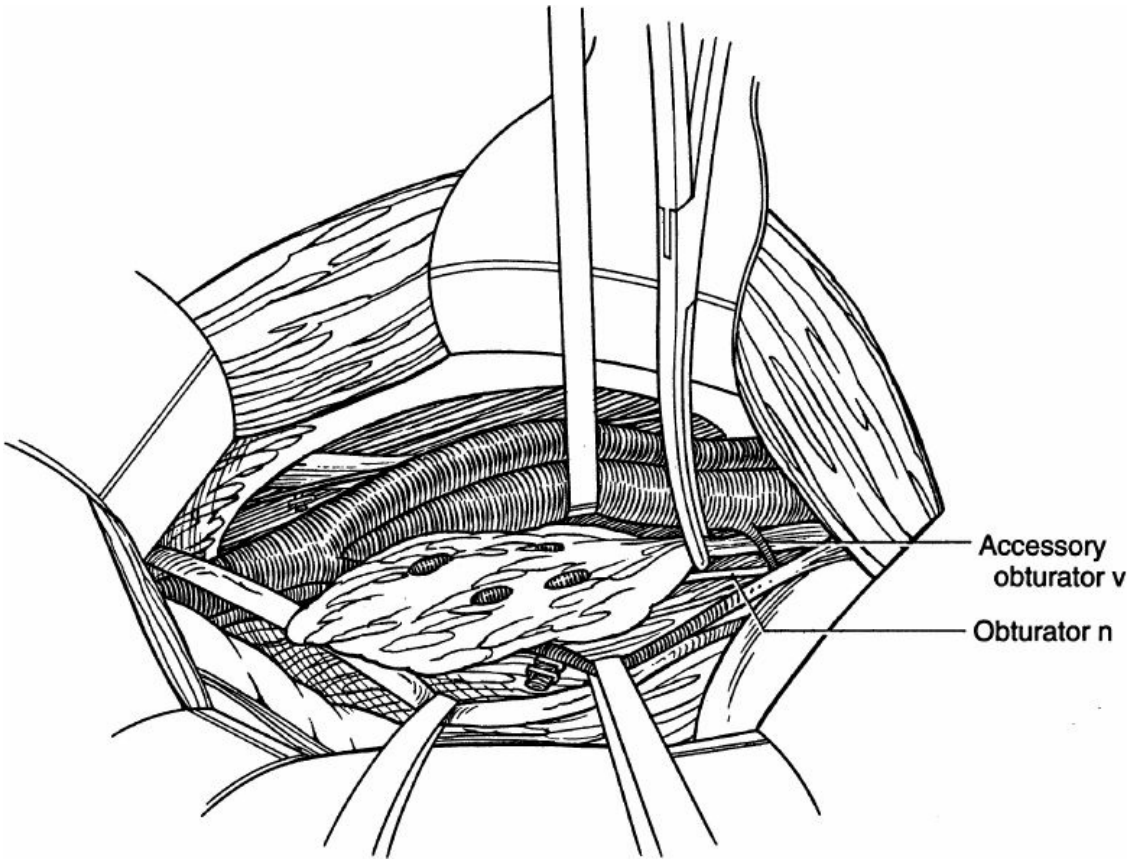

Figure 184.11. The obturator nodes above the obturator nerve are removed.

There are only a few important technical differences compared to radical hysterectomy. The uterine artery is ligated over the ureteral tunnel rather than at its origin (Fig. 184.12). Once the tunnel is unroofed, the ureter is only partially mobilized from its tunnel bed, enough that the paracervical tissue and cardinal ligament medial to the tunnel may be taken with the specimen (Fig. 184.13). The vesicouterine ligament is transected between the bladder and the cervix, and the uterosacral ligaments are ligated between the rectum and the cervix. A small vaginal margin is taken at least 10 mm from the cervix.

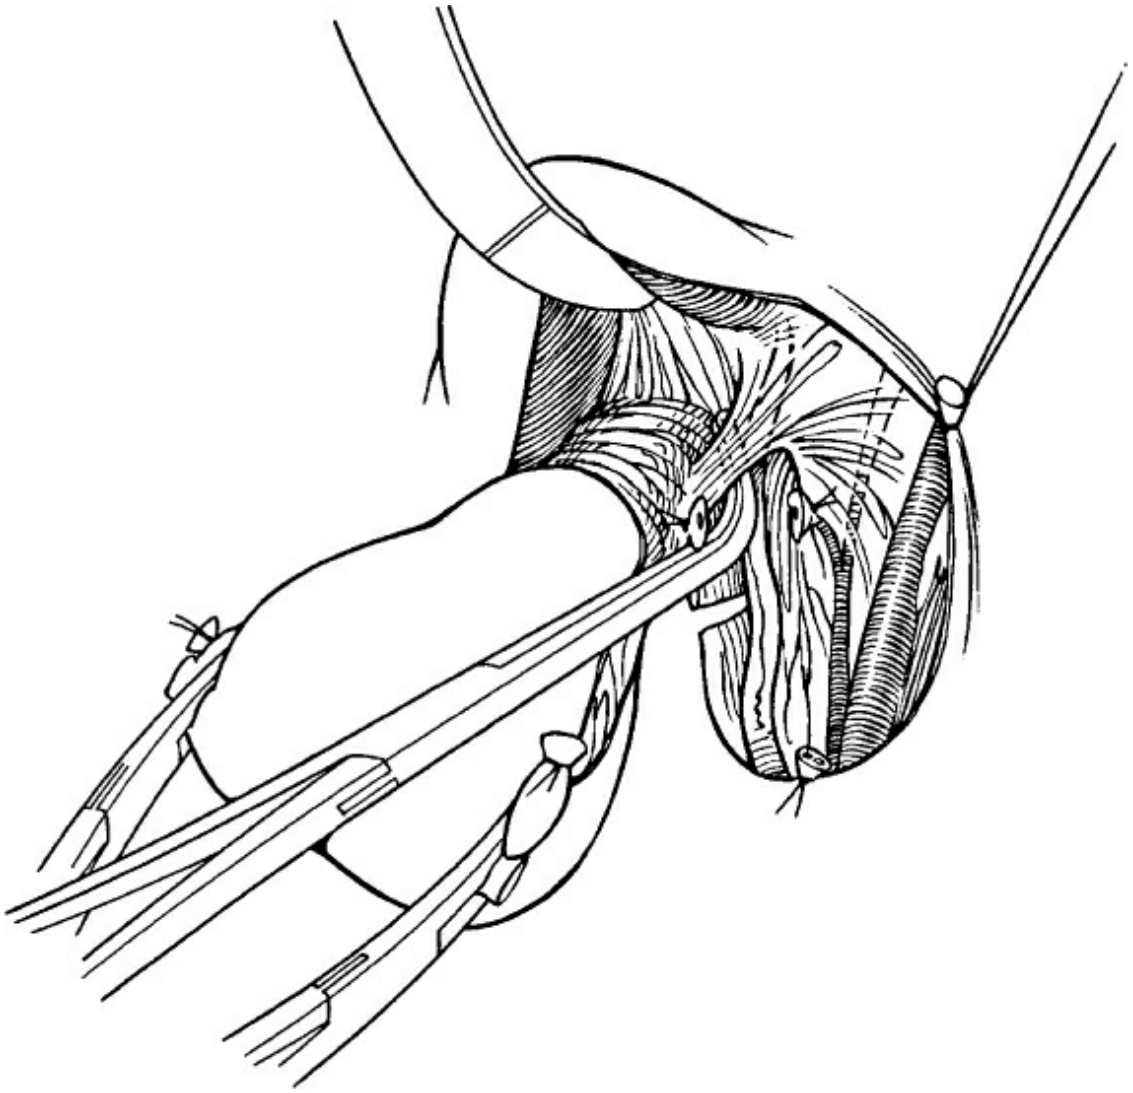

Figure 184.12. The uterine artery is ligated at the level of the ureter.

Type C: Radical Hysterectomy

The type C radical hysterectomy is the traditional radical hysterectomy as

described above in detail. There is a greater degree of tissue removed and, unlike types A and B where the autonomic nerves are not threatened, patients are at risk of autonomic nerve dysfunction. Just as with a modified radical hysterectomy, radical hysterectomy can be performed abdominally or laparoscopically, either traditional or robotic-assisted. If done abdominally, the incision may be altered from a Pfannenstiel to a Maylard of Cherney's incision depending on the patient's body habitus to provide better exposure. The laparoscopic approach does result in less blood loss, less pain, shorter hospital stays, and shorter recovery times.

The ureter is completely mobilized down to the bladder, the paracervical tissue is transected at the junction with the internal iliac artery and vein, the vesicouterine and uterosacral ligaments are transected at the bladder and rectum respectively, and the vaginal is transected 15 to 20 mm from the cervix or the tumor if it extends onto the vagina.

Common postoperative complaints from patients who have undergone a radical hysterectomy include urinary retention, difficulty voiding, and, to a lesser extent, rectal dysfunction. These symptoms are due to the disruption of the hypogastric plexus and splanchnic nerves that contains the sympathetic and parasympathetic nerves supplying the bladder and rectum. Nerve-sparing radical hysterectomies were developed to reduced patients' bladder and rectal dysfunction. While there are no large studies, that clearly show benefit of the nerve-sparing procedure, smaller studies have demonstrated smaller post-void residuals and rates of bladder dysfunction similar to that of the type B modified radical hysterectomy in women undergoing a nerve-sparing type C radical hysterectomy.

In order to perform a nerve-sparing radical hysterectomy, the sacrouterine space must be developed so that the hypogastric nerve can be separated from the uterosacral ligament, the posterior leaf of the broad ligament, and the ureter. The paracervical tissue is isolated down to the deep uterine vein for inclusion into the specimen then dissected away from the hypogastric nerve. The uterine branches of the inferior hypogastric plexus should be isolated and transected in order to be included into the specimen. The uterosacral, rectouterine, and rectovaginal ligaments can then be transected just medial to the inferior hypogastric plexus. Lastly, and most importantly, careful attention should be paid to isolating the bladder branches of the hypogastric plexus in order to avoid including them in transection of the vesicouterine ligament.

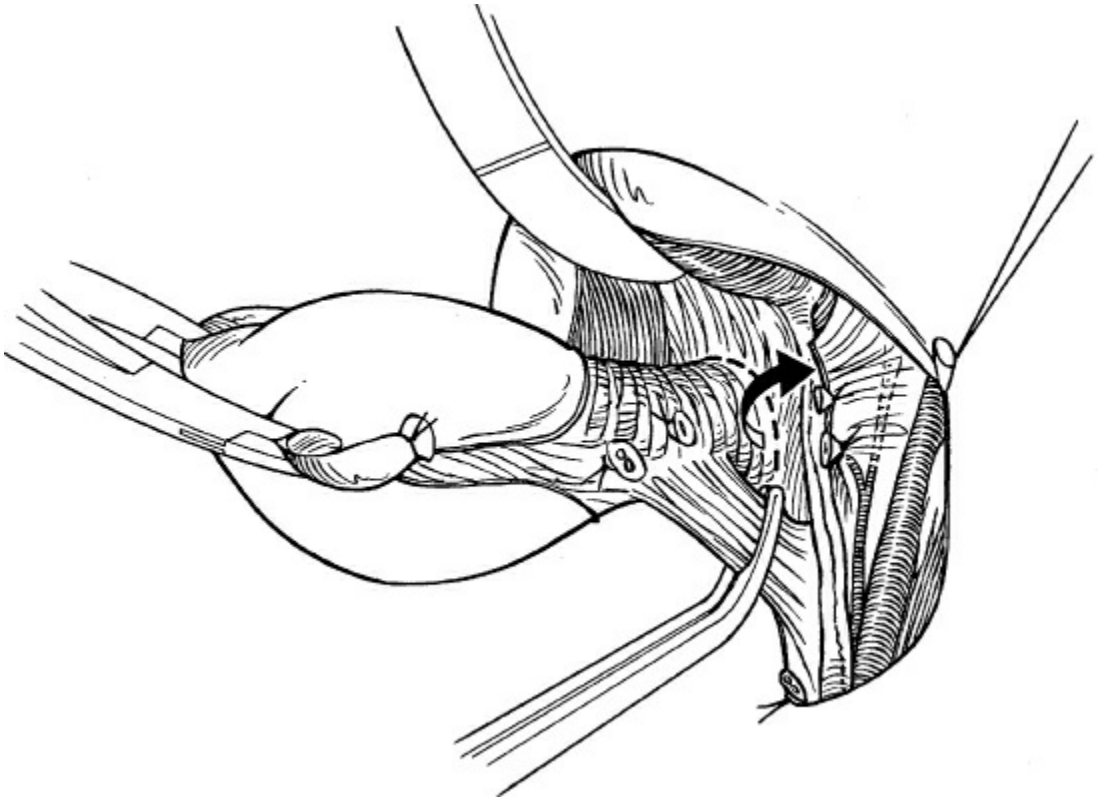

Figure 184.13. The ureter is partially mobilized laterally, enough to take an adequate amount of cardinal ligament.

Type D: Extended Radical Hysterectomy

With advances in chemosensitization and radiation therapy, type D hysterectomies are rarely performed for locally advanced tumors because of the likelihood of needing adjuvant radiation therapy and increased risk of bladder dysfunction and fistula formation compared to types B and C radical hysterectomies. To be considered an extended radical hysterectomy, all of the paracervical tissue extending to the pelvic sidewall, including the hypogastric vessels, is removed with the specimen. Approximately, three fourths of the vagina is also resected.

ROBOTIC-ASSISTED RADICAL HYSTERECTOMY

The patient is placed in dorsal, lithotomy position. Examination under anesthesia is performed to exclude the presence of disease beyond the cervix and upper vagina. A Foley catheter is placed as well as either an orogastric or nasogastric tube to decompress the stomach. The cervix is dilated in order to place a uterine manipulator, the VCare uterine manipulator (CONMED, Utica, NY) for example. Five ports are placed across the abdomen with the midline, camera port being placed roughly 20

cm superior to the pubic symphysis and above the umbilicus. There are different ways to place the remaining ports, but a diamond pattern is commonly used with each port about 8 to 10 cm apart and the lateral ports as far lateral on the patient's abdomen as possible (Fig. 184.14). The patient is then placed in the Trendelenburg position, and the robot is docked.

The procedure begins in the same manner as the abdominal radical hysterectomy with the ligation of the round ligament, separation of the medial and lateral leafs of the broad ligament, and development of pararectal and paravesical spaces with electrocautery after identification of the ureters. This is repeated on the opposite side. The uterine artery and vein are identified and ligated at their origin from the internal iliac vessels. Attention is then paid to developing the bladder flap by incising the peritoneum along the vesicouterine reflection and then dividing the vesicouterine ligament to mobilize the bladder inferiorly enough to ensure an adequate vaginal margin. A window is then made in the medial leaf of the broad ligament superior to the ureter so that the infundibulopelvic ligaments can be transected bilaterally. The rectovaginal septum is opened by incising the peritoneum with electrocautery. The tissue between the rectum and vagina is cut to expose the uterosacral ligaments that are then transected. Monopolar scissors are used to incise the vagina on top of the uterine manipulator removing the upper vagina with an adequate margin. The vaginal cuff is then sutured closed in a running, nonlocking fashion with a 0-Vicryl, 0-PDS, or 0-V-LOC (Medtronic, Minneapolis, MN) stitch.

POSTOPERATIVE MANAGEMENT

Patients are advised to ambulate immediately to minimize pulmonary and thromboembolic complications. Diet may be advanced as tolerated with patients usually tolerating a regular diet on the evening of surgery after a robotic-assisted radical hysterectomy. Evidence of bowel function is not a prerequisite to this. Oral pain medications are started as soon as the patient is tolerating oral intake. The urinary catheter is left in place during the immediate postoperative course due to anticipated voiding dysfunction. Using this approach, most patients may be discharged within 3 days following surgery.

Figure 184.14. Port placement for a robotic radical hysterectomy. C, camera; A, accessory; 1, right arm (monopolar scissors); 2, left arm (fenestrated bipolar forceps); 3, fourth arm (fenestrated ProGrasp forceps).

Traditionally, the Foley catheter was left in place for roughly 7 days; however, Foley removal can be done as early as postoperative day 1 in the case of a robotic radical hysterectomy or on postoperative day 3 or 4 for an open abdominal procedure. If the patient is unable to void, then the Foley catheter is replaced. Some patients require catheter drainage for 3 weeks or more, most require only a week. This will depend to some extent on the radicality of the operation. We typically use a Foley catheter and have a home visiting nurse remove it a week after surgery. We have found that patients rarely need to return for catheter replacement due to voiding difficulties.

INTRAOPERATIVE COMPLICATIONS

The most common intraoperative complication is blood loss. The literature indicates that average blood loss ranges from 500 to 1500 mL and up to two thirds of women receive a transfusion. Blood loss is probably dependent on patient selection and surgeon experience. The most problematic bleeding typically occurs during the ureteral dissection. Surgeons who exercise particular caution here are often rewarded with minimal blood loss and a clear surgical field. The ureter is surrounded by small, easily injured blood vessels as it courses through its tunnel into the bladder trigone. Once bleeding occurs, it can be difficult to control since the ureter is in close proximity. Often the only way to stop the bleeding is to hurriedly complete the ureteral dissection, a circumstance that places the ureter at risk of injury. Transfusion is often necessary, but should be avoided if possible due to concerns, although unproven, that this can adversely affect prognosis.

Operative injury is another major concern, occurring in about 2% of cases. The most common sites of injury are the ureter, bladder, nerves, major vessels, and rectum. Ureteral injuries are slightly more common, although not significantly increased, after robotic radical hysterectomies particularly because of electrocautery injury due to the close proximity of the monopolar scissors to the ureter during dissection of the ureteral tunnel. Sequelae of the most common injuries, to the ureter and bladder, include sepsis, fistula, loss of renal function, and reoperation. Injury can also delay or proscribe adjuvant therapy. Maintenance of a clear surgical field, gentle tissue handling, and careful dissection of surgical planes will minimize, though not eliminate, operative injury. The single most important determinant of outcome after operative injury is whether the injury is detected intraoperatively. Therefore, whenever an injury is suspected, careful evaluation as described above should be performed before closure of the abdomen.

POSTOPERATIVE COMPLICATIONS

Both short- and long-term complications are not uncommon following radical hysterectomy. The most common immediate complications are wound infection, thromboembolism, and ileus. Voiding dysfunction is expected and is therefore arguably not a complication. Likewise, febrile morbidity, although common, is of concern only insofar as it may be indicative of something more serious. In the immediate postoperative

period, the surgeon should be particularly attuned to signs or symptoms suggestive of thromboembolism, and should have a low threshold for evaluating patients with imaging studies. Timely diagnosis of this potentially fatal complication can be lifesaving.

Far less common but perhaps more dreaded, urinary tract fistula should be considered if a patient complains of watery vaginal discharge. Physical examination, testing with dye and tampons, and imaging studies such as contrast-enhanced computed tomography (CT) are diagnostic. A common first step is to instill the bladder with methylene blue after inserting a tampon in the vagina. Absence of dye on the tampon excludes a vesicovaginal fistula. Next, indigo carmine is injected intravenously. Further absence of dye on the tampon excludes a ureterovaginal fistula. It is important to recognize that a positive bladder dye test is diagnostic of vesicovaginal fistula but does not exclude a concomitant ureterovaginal fistula. Further evaluation, usually with cystoscopy and retrograde ureterography or CT urogram, is necessary. Prompt recognition of a fistula can decrease associated morbidity and in some cases even allow immediate reoperation and repair.

Ureteral obstruction after radical hysterectomy may be caused by direct operative injury or adhesions. Potential signs and symptoms include unexplained fever, flank pain, and prolonged ileus. Ureteral obstruction can occasionally be subclinical and come to light only upon discovery of a nonfunctioning kidney. Unilateral ureteral obstruction classically does not cause an elevation in creatinine, but a Mayo Clinic study showed that most patients do in fact experience a modest, transient creatinine elevation in the first 2 postoperative days. Unilateral obstruction is not associated with a change in urine output, but of course bilateral obstruction can result in anuria. Ureteral obstruction can be diagnosed by renal ultrasound or CT. The primary concerns in management are preservation of renal function, control of any urine leak (e.g., urinoma), and ultimately repair. The obstructed ureter may be stented either retrograde or antegrade, or a percutaneous nephrostomy may be placed. Just as with fistula, prompt recognition of ureteral obstruction may allow immediate reoperation if clinically indicated.

Potential delayed complications include lymphocysts, lymphedema, sexual dysfunction, and bowel obstruction. Symptomatic lymphocysts are rare now that most surgeons do not close the pelvic sidewall peritoneum. Chronic lymphedema is surprisingly uncommon after pelvic

lymphadenectomy in unirradiated patients but can be problematic in patients treated with radiation. Patients often experience some change in sexual function after radical hysterectomy, but severe dyspareunia as a result of a shortened vagina is not common with modern surgical techniques. As stated already, a vaginal margin of 1 to 2 cm is all that is necessary in most patients. Certainly patients receiving radiation rather than radical surgery are at higher risk of this complication. In addition, postoperative adjuvant radiation probably increases the risk of sexual dysfunction beyond that of surgery alone. If the ovaries are removed, this can result in dyspareunia from decreased vaginal lubrication, but this problem is readily corrected with estrogen, either topical or systemic. Estrogen use is not associated with cervical cancer risk and is not contraindicated in cervical cancer patients. Small bowel obstruction occurring after radical hysterectomy is usually caused by adhesions, although recurrence must always be considered. The risk of obstruction is increased in irradiated patients.

EDITOR’S COMMENT

The incidence of cervical cancer in the United States and the rest of the developed world has dramatically decreased due to the introduction of the Papanicolaou (Pap) smear, and the incidence should decline even further with the recent introduction of vaccines for the human papilloma virus (HPV). In 2016, it is estimated that there will be nearly 13,000 new cases of cervical cancer and an estimated 4,120 deaths due to this disease in the United States, and more than one third of these cases will be diagnosed in women of reproductive age (Siegel RL, Miller KD, Jemal A. Cancer statistics, 2016. *CA Cancer J Clin* 2016;66:7–30). In contrast, the global burden of this disease is much more dramatic, particularly in the developing world, where cervical cancer is the third most common cause of cancer death for women (Torre LA, Siegel RL, Ward EM, et al. Global Cancer Incidence and Mortality Rates and Trends–An Update. *Cancer Epidemiol Biomarkers Prev* 2016;25:16–27). Squamous cell histologies comprise greater than 85% of cervical cancers, with

adenocarcinomas (which are also HPV-related) being the second most common histology. The spread of cervical cancer is predictable, first involving the vagina and parametria, then spreading to the pelvic and para-aortic lymph nodes, and lastly spreading hematogenously to distant sites, at which point the disease is considered incurable.

Cervical cancer is staged clinically, and at its earliest stage (IA1), the vast majority of women are cured with conservative surgical procedures, such as excision of the transformation zone by electrosurgery (LLETZ or LEEP) or laser or cold knife cone excisional biopsy. The rationale for the more radical treatment of stage IA2 disease or greater is the increasing risk of lymph node metastases. For stage IA1 disease, the risk of nodal metastasis is extremely low (<1%), whereas for stage IA2 disease, defined as a depth of tumor invasion of 3 to 5 mm and horizontal spread of <7 mm, the risk of nodal metastasis rises to 5% to 7% (Roque DR, Wysham WZ, Soper JT. The surgical management of cervical cancer: an overview and literature review. *Obstet Gynecol Surv* 2014;69:426–41). For stage IB disease, the risk of regional nodal metastasis ranges from ~5% for tumors <2 cm in size to greater than 35% for tumors >4 cm in size. Thus, for stage IA2 and IB disease, more aggressive treatment with either radical hysterectomy (RH) and bilateral pelvic lymph node dissection (LND) or chemoradiation therapy is offered, and the 5-year survival rates with either of these strategies have exceeded 85%. However, RH with bilateral pelvic LND, as beautifully described and illustrated by Dr. Boone and Dr. Huh in this chapter, may be associated with significant long-term morbidities, such as urinary and bowel dysfunction, sexual dysfunction, and lymphedema, all of which can dramatically affect the quality of life of the many long-term survivors of this disease (Reade CJ, Eiriksson LR, Covens A. Surgery for early stage cervical cancer: how radical should it be? *Gynecol Oncol* 2013;131:222–30). Furthermore, RH obviously renders infertile the many reproductive age women affected by this disease. Therefore, there has been much interest in defining which women with early stage cervical cancer can safely undergo less radical, fertility-sparing surgery.

Radical trachelectomy has been an option for certain women with stage IA2 or IB1 cancers who wish to retain their fertility, though it should not be regarded as a particularly “conservative” option, as long-term morbidity associated with autonomic dysfunction after this procedure can be similar to that seen with RH (Ramirez PT, Pareja R, Rendón GJ, et al. Management of low-risk early-stage cervical cancer: should conization, simple trachelectomy, or simple hysterectomy replace radical surgery as the new standard of care? *Gynecol Oncol* 2014;132:254–9). Furthermore, the nerve-sparing radical hysterectomy (NSRH), increasingly done either laparoscopically or robotically, is felt to reduce long-term morbidity by providing a means to preserve the hypogastric nerves as they course through the uterosacral ligaments as well as the splanchnic nerves as they course through the paracervix. Though NSRH has similar oncologic efficacy, fewer postoperative complications, and a lower

likelihood of bladder dysfunction compared to RH, there are few data to support the assertion that NSRH confers better postoperative anorectal and sexual function than RH (Long Y, Yao DS, Pan XW, et al. Clinical efficacy and safety of nerve-sparing radical hysterectomy for cervical cancer: a systematic review and meta-analysis. *PLOS One* 2014;9:e94116).

Other conservative management strategies for early stage cervical cancer are the subject of three ongoing prospective studies. The Simple Hysterectomy and Pelvic node dissection in Early-stage low risk cervical cancer (SHAPE) trial is an international, multicenter, phase III, randomized trial comparing RH and pelvic LND to simple hysterectomy and pelvic LND (Plante M. The SHAPE Trial 2013;NCT016589309. ClinicalTrials.gov). Women with stage IA2 to IB1 disease are eligible. The study's primary outcome is to determine whether simple hysterectomy is safe and associated with less morbidity than RH and to investigate whether there is a difference in overall survival between the two groups. Secondary outcomes include relapse-free survival rates, rates of parametrial and pelvic lymph node involvement, cost-effectiveness, and patient-related quality of life outcomes. This study opened in 2014 and seeks to enroll more than 700 women.

The second study investigating the safety and feasibility of conservative surgery for stage IA2 and IB1 cervical cancer is the ConCerv trial, which is an international, multicenter trial (Schmeler KM, Frumovitz M, Ramirez PT. Conservative management of early stage cervical cancer: is there a role for less radical surgery? *Gynecol Oncol* 2011;120:321–5). The conservative surgical options in this trial include either cone biopsy or simple hysterectomy with pelvic LND, and the choice is guided by the woman's plans for future fertility. The primary outcome measure of this study is the safety and feasibility of performing cone biopsy or simple hysterectomy with pelvic LND. Secondary outcomes include toxicity and quality of life compared to historically matched patients undergoing RH.

The third study, GOG 278, is a prospective, randomized, phase III trial which seeks to evaluate the physical function and quality of life of patients before and after conservative surgery (either cone biopsy or simple hysterectomy with pelvic LND) for stage IA1 disease with lymphovascular space invasion up to stage IB1 disease, including a tumor size up to 2 cm (NCT01649089. ClinicalTrials.gov). The primary outcomes are to assess bladder, bowel, and sexual function as well as the incidence of lymphedema after conservative surgery.

Another approach to limit the morbidity of RH and pelvic LND for cervical cancer is to try to identify those women at low risk of regional lymph node metastases such that they may avoid unnecessary pelvic LND and its possible sequelae, principally lymphedema. Sentinel lymph node (SLN) mapping and biopsy, which has been successfully used to stage the regional nodal basin in patients with breast cancer or melanoma for more than two decades, is currently being studied prospectively for its feasibility in the surgical management of

early stage cervical cancer. The SENTICOL study evaluated the use of preoperative lymphoscintigraphy and SLN biopsy in women with stage IA1 to IB1 disease, and all patients went on to have bilateral pelvic LND after the SLNs were excised (Lécuru F, Mathevet P, Querleu D, et al. Bilateral negative sentinel nodes accurately predict absence of lymph node metastasis in early cervical cancer: results of the SENTICOL study. *J Clin Oncol* 2011;29:1686–91; Bats AS, Frati A, Mathevet P, et al. Contribution of lymphoscintigraphy to intraoperative sentinel lymph node detection in early cervical cancer: analysis of the prospective multicenter SENTICOL cohort. *Gynecol Oncol* 2015;137:264–9). The SLN detection rate on preoperative lymphoscintigraphy was 87.8%, and the intraoperative detection of the SLN using blue dye in addition to radioactive colloid was 97.8%. Interestingly, lymphoscintigraphy enabled the detection of lymphatic drainage to aberrant lymph nodes, as more than 10% of patients were discovered to have SLNs in the para-aortic region rather than within the pelvis. SLNs were identified in 95% of patients overall and were detected bilaterally in 76% of patients. The sensitivity of SLN biopsy for the detection of lymph node metastasis was 92%, and the negative predictive value of SLN biopsy was 98.2%. This study and others have confirmed that the SLN biopsy technique is feasible for patients with early stage cervical cancer and suggest that less radical surgery is safe in selected patients. Future studies will need to validate these findings in order for SLN biopsy to become the standard of care for the staging of the regional nodal basin in cervical cancer.

Lastly, several groups are investigating the utility of high-quality radiologic imaging to identify regional lymph node metastases preoperatively and to guide treatment in women with cervical cancer. Conventional imaging with CT and magnetic resonance imaging (MRI) scans has a low sensitivity for the detection of lymph node metastases (Choi HJ, Ju W, Myung SK, et al. Diagnostic performance of computer tomography, magnetic resonance imaging, and positron emission tomography or positron emission tomography/computer tomography for detection of metastatic lymph nodes in patients with cervical cancer: meta-analysis. *Cancer Sci* 2010;101:1471–9). Preoperative imaging with positron emission tomography (PET-CT) has been proposed as the optimal method for identifying metastases to the regional nodes, as unlike CT and MRI, PET-CT does not rely on lymph node size to differentiate between normal and metastatic nodes, and it has reasonably good sensitivity (75% to 86%) and specificity (92% to 97%) for the detection of metastatic nodes, at least in patients with more advanced stage cervical cancer (Rose PG, Adler LP, Rodriguez M, et al. Positron emission tomography for evaluating para-aortic nodal metastasis in locally advanced cervical cancer before surgical staging: a surgicopathologic study. *J Clin Oncol* 1999;17:41–5). The sensitivity of PET-CT in patients with earlier stage disease has in general been more variable and not quite as good, such that PET-CT may not be accurate enough to obviate the need for more invasive surgical staging of the regional nodes in many women with cervical cancer.

185 Surgical Management of Ovarian Carcinoma

Kara Long Roche, Arlan F. Fuller, Jr., and Dennis S. Chi

INTRODUCTION: THE PATHOGENESIS OF EPITHELIAL OVARIAN TUMORS

In the United States, ovarian cancer is the leading cause of death from a gynecologic malignancy, and its incidence rises steeply with increasing age after menopause. The lethality of this disease is in part due to the fact that the majority of patients present with advanced-stage disease, a result of early peritoneal dissemination and an absence of symptoms associated with early-stage disease. Risk factors include age, early menarche, late menopause, nulliparity, and most importantly, family history.

Only approximately a third of patients will be diagnosed with early-stage disease, and in many of these cases, the finding of an adnexal mass is incidental. It is not uncommon for these women to be asymptomatic; however, symptoms such as pelvic discomfort, bloating, urinary symptoms, dyspareunia, or changes in bowel habits may be subtle indicators of early-stage disease. Unfortunately, most women do not experience symptoms until the disease is advanced. Symptoms of advanced-stage disease can include abdominal distention, discomfort, nausea, vomiting, early satiety, increased abdominal girth, changes in bowel habits (diarrhea, constipation, changes in stool caliber), and/or shortness of breath. Any of these symptoms and/or the presence of a suspicious adnexal mass necessitate prompt evaluation and referral to a gynecologic oncologist, especially if the patient is postmenopausal, has a history of breast cancer, or has a family history of breast or ovarian cancer.

Experts in ovarian cancer pathogenesis have suggested a two-tiered system based on molecular and morphologic determinants. Type I ovarian cancers are generally low grade, indolent, and diagnosed at an early stage. These include endometrioid carcinoma, low-grade serous carcinoma, clear cell carcinoma, and mucinous carcinoma. Mutations in *KRAS*, *BRAF*, *ERBB2*, *PTEN*, *PIK3CA*, *ARID1A*, and microsatellite instability are

common in type I tumors. Type II ovarian cancers, in contrast, are high grade, clinically aggressive, and commonly diagnosed at an advanced stage. High-grade serous carcinoma, carcinosarcoma, and undifferentiated carcinoma are examples of type II tumors. Defects in the homologous recombination repair pathway such as deleterious mutations in *BRCA1* or *BRCA2* are associated with these cancers. Chromosomal disruption and, moreover, mutations in TP53 are extremely common.

Type I Tumors

Endometrioid carcinomas of the ovary commonly present at an early stage and are generally accepted to have their origin in the endometrium or from endometriotic implants. They account for approximately 10% of all invasive ovarian cancers and have an overall favorable prognosis. In addition to loss of mismatch repair proteins (MLS1, MSH2, MSH6, and PMS2), endometrioid ovarian carcinomas may carry other mutations, such as PTEN, ARID1A, CTNNB1, and PP2R1A. In many cases, a concurrent endometrioid carcinoma will be identified in the endometrium, and it remains a challenge for the pathologist to identify the lesion as either a synchronous or metastatic lesion. Synchronous tumors generally occur in young women and are characterized by a low-grade endometrial lesion with no/limited myometrial invasion and no lymphovascular invasion with a concurrent low-grade ovarian lesion. Synchronous tumors are also generally large and unilateral, with an expansile invasion pattern, and associated with endometriosis or an endometrioid borderline tumor.

Clear cell carcinomas are also commonly associated with endometriosis. These tumors also generally present at a low stage and account for approximately 10% of invasive ovarian cancers in the United States. Atypical endometriosis has been identified as a possible precursor lesion to ovarian clear cell carcinoma. They can be associated with loss of expression of mismatch repair proteins (MLS1, MSH2, MSH6, and PMS2) as well as mutations in ARID1A, PIK3CA, and PPP2R1A.

The predisposition for both clear cell carcinomas and endometrioid carcinomas to be multifocal and arising in endometriosis also accounts for the problem of local recurrence in pelvic peritoneum. Presumably, many cases of pelvic recurrence represent a field effect with new cancers arising in residual pelvic endometriosis. The long-term management of epithelial carcinoma arising in endometriosis represents an indication for postoperative pelvic radiation therapy in order to achieve a durable

prolonged remission. It is particularly notable that even after successful primary treatment of endometrioid or clear cell carcinoma arising in endometriosis, second primary tumors may represent a substantial proportion of what is otherwise thought to be “recurrent” carcinoma. This is particularly important for the surgeon to recognize that late recurrence of ovarian carcinoma should be considered as a potential second primary and may well represent isolated disease that can be successfully treated with surgery and potentially adjunctive chemotherapy. Future molecular characterization will better delineate this distinction in the development of second primary lesions.

Low-grade mucinous carcinomas of the ovary account for only 2% to 4% of all invasive ovarian cancers and may arise from one of two origins; as is characteristic of the mucinous borderline tumors, these may be either müllerian or an intestinal subtype. The most commonly encountered mutation is KRAS, which is identified in up to 75% of mucinous ovarian cancers. In non-KRAS mutated tumors, it is common to see overexpression of HER2, although these two mutations have also been found to coexist. It is crucial to rule out metastases from gastrointestinal sources, and as such, part of the abdominal exploration of patients with mucinous ovarian tumors should include the evaluation and removal of the appendix. For reasons yet to be determined, there may be isolated and very bulky metastasis to the contralateral ovary from the appendix without evidence of intervening disease in the ipsilateral ovary or uterus. These low-grade mucinous tumors of the appendix and ovary are often the precursor to the development of pseudomyxoma peritonei.

Low-grade serous ovarian cancers, recently accepted as a distinct entity from high-grade serous ovarian cancer, account for only 2% of all ovarian cancers. While traditionally these tumors are thought to arise in a stepwise fashion (from cystadenoma to borderline serous tumor to micropapillary borderline tumors to invasive low-grade serous carcinoma), recent evidence suggests that they may have a fallopian tube origin related to endosalpingiosis. Unlike the rest of type I tumors, low-grade serous carcinomas tend to present at an advanced stage and respond poorly to cytotoxic chemotherapy. The majority are both estrogen and progesterone receptor positive, and KRAS and BRAF mutations are found in 60% to 70% of cases.

Type II Tumors

High-grade serous carcinomas account for 70% of all ovarian cancers. They are the most common and one of the most lethal ovarian malignancies. Almost all high-grade serous ovarian carcinomas are associated with a TP53 mutation, which leads to the accumulation of DNA damage and chromosomal instability. The most commonly associated germline abnormalities are mutations in BRCA1 and BRCA2; however, mutations in BRIP1, RAD51C, RAD51D, and other mutations, recently have been associated with an increased risk of developing the disease.

In recent decades, the fimbriated end of the fallopian tube has been implicated in the pathogenesis of high-grade serous epithelial ovarian cancer. This is in contrast to the previous theory that epithelial ovarian cancer was derived from the overlying serosal surface of the ovary and related to incessant ovulation. While this theory was accepted for many years, there were major “gaps” to its full acceptability, such as a lack of an identified precursor lesion. Some of the most convincing evidence supporting this theory comes from the identification of serous tubal intraepithelial carcinoma (STIC), thought to be the precursor to high-grade serous cancer. STIC lesions are characterized by noninvasive cytologically malignant tubal epithelium. In women with BRCA mutations undergoing risk-reducing salpingo-oophorectomy, STIC lesions have been identified in approximately 5% to 15% of cases. Moreover, in women with BRCA mutations and high-grade serous carcinoma, STIC lesions are identified in the fallopian tubes in up to 80% of cases. While more is known about the association between BRCA positivity and the risk of STIC lesions, it is important to note that STIC lesions have also been identified in up to 60% to 75% of cases of sporadic high-grade serous carcinoma. Additional evidence comes from the lineage continuity of TP53 mutations in high-grade serous carcinoma and the accompanying STIC lesions. TP53 mutations lead to an overabundance of nonfunctional P53, which when found in the epithelium of fallopian tubes is referred to as a “P53 signature.”

Ovarian carcinosarcoma is a rare, clinically aggressive subtype accounting for only 1% to 4% of all ovarian malignancies. The most commonly accepted theory of pathogenesis is that the carcinomatous and sarcomatous elements represent a single neoplastic process. This is supported by both clonality studies and genomic analysis. P53 overexpression is common and appears to be associated with an overall worse prognosis.

PATTERNS OF METASTATIC DISEASE

While the current staging system (Table 185.1) follows a logical order of progression—from ovarian-confined disease, to pelvic and then abdominal-confined disease, to distant metastases—the natural history of the disease is likely quite different, with transperitoneal dissemination occurring very early in the disease course. This is particularly relevant for high-grade serous carcinomas, in which exfoliated tumor cells, likely from the distal fallopian tube, typically first implant in the paracolic gutters and on the right hemidiaphragm. The negative pressure associated with respiratory movement of the diaphragm over the liver creates a clockwise flow of peritoneal fluid, possibly explaining the predominance of disease in the right upper versus left upper quadrant (LUQ) (Fig. 185.1). Several typical patterns of spread are identified with more advanced disease; some patients may present with disease solely in the omentum, some with "oligo" metastatic disease (bulky metastases, fewer in number, usually in the omentum and on peritoneal surfaces), and some with miliary carcinomatosis.

TABLE 185.1 The FIGO Staging System for Ovarian Carcinoma

IA	Tumor limited to one ovary, capsule intact, no tumor on surface, negative washings
IB	Tumor involves both ovaries, otherwise like IA
IC	Tumor limited to one or both ovaries
IC1	Surgical spill
IC2	Capsule rupture before surgery or tumor on ovarian surface
IC3	Malignant cells in ascites or peritoneal washings
IIA	Extension and/or implant on uterus and/or fallopian tubes
IIB	Extension to other pelvic intraperitoneal tissues
IIIA	Positive retroperitoneal lymph nodes and/or microscopic disease beyond the pelvis
IIIA1	Positive retroperitoneal lymph nodes only
IIIA(i)	*Metastasis ≤ 10 mm*
IIIA(ii)	*Metastasis > 10 mm*
IIIA2	Microscopic, extrapelvic (above the brim), peritoneal involvement ± positive retroperitoneal lymph nodes
IIIB	Macroscopic, extrapelvic, peritoneal metastasis ≤2 cm ± positive retroperitoneal lymph nodes. Includes extension to the capsule of the spleen
IIIC	Macroscopic, extrapelvic, peritoneal metastasis >2 cm ± positive retroperitoneal lymph nodes. Includes extension to the capsule of the spleen
IVA	Pleural effusion with positive cytology
IVB	Hepatic and/or splenic parenchymal metastasis, metastasis to extra-abdominal organs (including inguinal lymph nodes and lymph nodes outside the abdominal cavity

Prat and FIGO Committee on Gynecologic Oncology. FIGO's staging classification for cancer of the ovary, fallopian tube, and peritoneum: abridged republication. *J Gynecol Oncol* 2015;26(2):87–9.

Patients with high-grade primary ovarian tumors clinically confined to the ovary may have evidence of occult regional spread to the pelvic nodes, as well as to para-aortic nodes at the origin of the gonadal arteries. These lymph node metastases may be the only site of metastatic disease. Patients with predominately lymph node metastases in the absence of transperitoneal spread actually have a better prognosis than patients with negative nodes and intraperitoneal disease. The pattern of lymph node metastasis in patients with stage III (abdominal spread) ovarian cancer and any nodal metastasis is such that the majority of patients will have both pelvic and para-aortic nodal disease, while a minority will have either pelvic or para-aortic disease. Patients with peritoneal carcinomatosis with disease not extensively involving the ovary have a lower incidence of nodal metastases for the same extent of intra-abdominal disease.

Each of these patterns has implications for the surgeon as it affects the resectability of disease and intraoperative planning of the sequence of tumor resection. Because stage II disease is relatively uncommon in light of what we understand about peritoneal spread, its occurrence is typically associated with bulky, low-grade tumors and direct rectosigmoid invasion. The association of endometrioid carcinoma and endometriosis accounts for a number of these patients, who, by definition, have local peritoneal involvement, arising in pelvic endometriosis. The locally invasive nature of this tumor is also consistent with the two-tiered approach, with “Type I” lesions less likely to be associated with extrapelvic metastatic disease. This locally advanced disease can be treated successfully with en bloc resection of the ovarian or peritoneal neoplasm, the uterus, pelvic peritoneum, or rectosigmoid colon. In similar manner, as noted above, the pattern of ovarian cancer spread to lymph nodes exclusively appears to carry a better prognosis, as the absence of associated peritoneal metastases seems to reduce the risk of peritoneal recurrence.

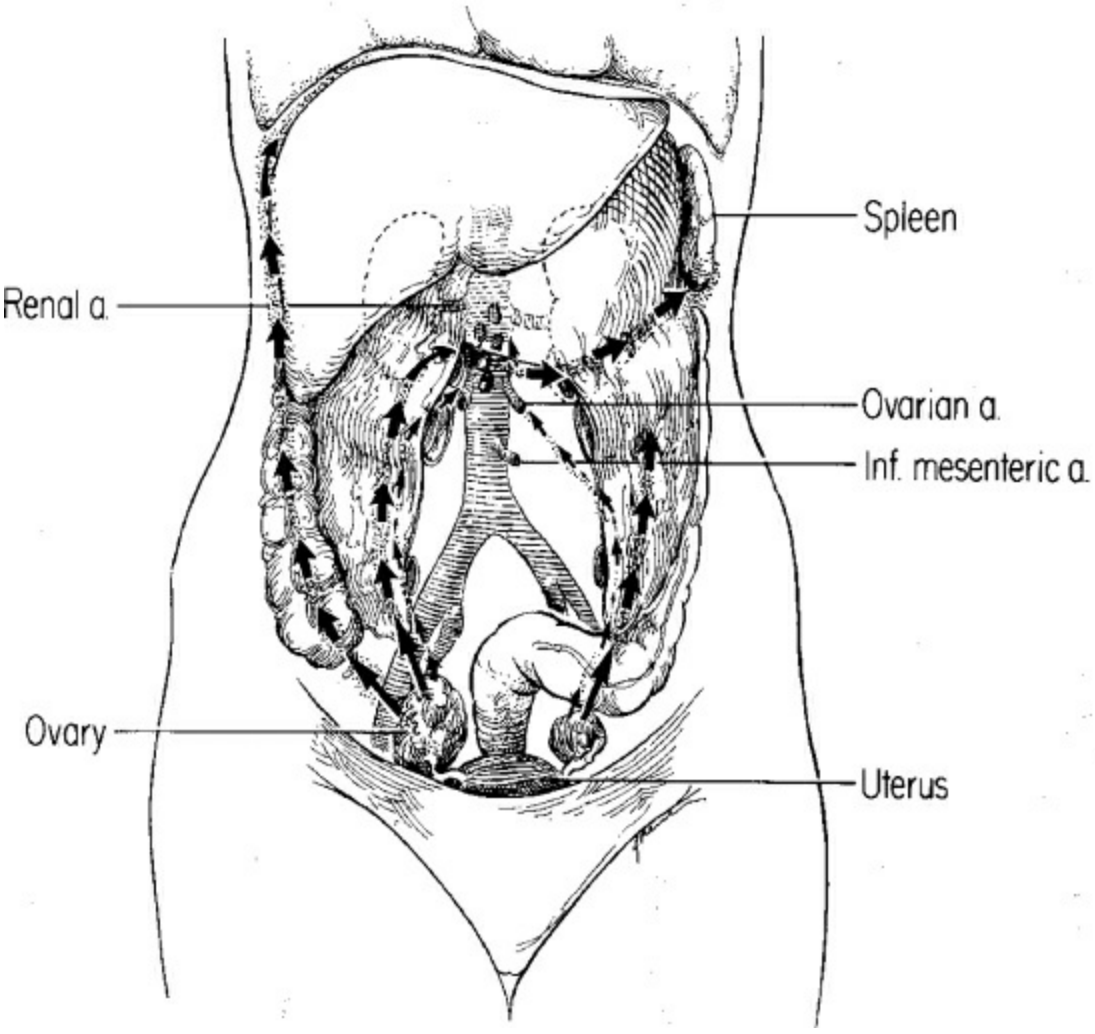

Figure 185.1. The pattern of intraperitoneal dissemination of ovarian cancer (Scully).

The clinical presentation at the time of diagnosis also may reflect the distribution of tumor, the tumor grade, and by inference, the patient's prognosis. Patients presenting with a typical picture of abdominal distention and symptoms of bowel obstruction most commonly have fairly extensive peritoneal carcinomatosis. On the contrary, patients with the largest pelvic masses often have compressive symptoms secondary to tumor bulk without extensive invasion or metastasis; hence, in the absence of invasion, the tumor has sufficient time to grow to a large size. Some patients with surgical stage IV disease actually have an excellent prognosis, if they present solely with distant nodal metastases. The surgeon should not be dissuaded from consideration of a surgical approach to this disease in that setting, although it may be preferable to consider video-assisted thoracoscopic surgery to rule out bulky pleural disease prior to proceeding with laparotomy and debulking.

Screening

There is no effective screening test for ovarian cancer. Various techniques and serologic assays have been evaluated, including review of symptomatology, physical exam, pelvic sonography, and serum tumor markers, without evidence of significant stage shift or decrease in mortality. There is currently no recommendation for routine screening in the average-risk woman. This is in large part related to the relatively high false-positive testing with serum CA125 and pelvic ultrasound, which result in a high rate of potentially unnecessary invasive procedures.

Multiple large prospective studies have not demonstrated a benefit to routine screening for ovarian cancer. In the UK Collaborative Trial of Ovarian Cancer Screening (UKCTOCS) study, more than 200,000 postmenopausal women were randomized to one of three arms: multimodal screening, transvaginal ultrasound screening, or no screening. The multimodal arm, which consisted of serum CA125 testing incorporated into a risk algorithm, was designed to assess change over time. While a reduction in mortality was identified in subgroup analyses of the multimodal arm, this was not significant in the primary analysis, and further evidence supporting a benefit to screening is needed before it can be recommended. In women at increased risk for ovarian cancer, such as

those with a BRCA1 or 2 mutation, screening with twice yearly transvaginal ultrasound and serum CA125 is reasonable; however, studies have failed to show a substantial benefit, even in this cohort.

Risk-Reducing Surgery in High-Risk Women

Family history is the most significant risk factor for the development of ovarian cancer. Hereditary breast and ovarian cancer syndrome (HBOC) is an inherited condition associated with an increased lifetime risk of developing breast and ovarian cancer. HBOC is most commonly associated with mutations in the BRCA1 and BRCA2 genes. The risk of ovarian cancer is 39% to 46% with a BRCA1 mutation and 10% to 27% with a BRCA2 mutation. As there is no effective screening test for ovarian cancer, risk-reducing salpingo-oophorectomy (RRSO) is recommended as the gold standard for prevention. There are strong data supporting this approach, which has been demonstrated to result in a 75% to 96% decrease in ovarian cancer risk, as well as a 50% decrease in breast cancer risk. Despite this dramatic decrease in risk, in women with BRCA mutations, RRSO is recommended by age 40 or when childbearing is complete; however, the timing of surgery can be individualized to an extent considering the patient's specific mutation and goals of care. Other mutations, such as those associated with Lynch syndrome, *MLH1*, *MSH2*, *MSH6*, and *PMS2*, as well as *BRIP1*, *PALB2*, *RAD51C*, *RAD51D*, and *BARD1*, have also been associated with an increased risk of ovarian cancer, and RRSO is recommended after thorough counseling.

Risk-reducing salpingo-oophorectomy is ideally performed in a minimally invasive fashion and should include peritoneal washings, as well as a thorough inspection of the peritoneal cavity. Specimens should be designated as "prophylactic," and pathologic assessment should utilize the SEE-FIM ("sectioning and extensively examining the fimbriated end") technique. As the origin of high-grade serous carcinoma is increasingly understood to be the fallopian tube, bilateral salpingectomy with delayed oophorectomy has been suggested as a risk-reducing option, avoiding the additional morbidity of premature surgical menopause. The efficacy of this technique has not yet been demonstrated, and therefore, it is not recommended outside the setting of a clinical trial.

Approach to the Adnexal Mass

Adnexal masses can generally be classified as physiologic, inflammatory,

or neoplastic. The goal of the clinician should be to address symptoms and assess the risk of malignancy in the setting of the patient's age, menopausal status, and genetic risk. Studies have consistently shown that patients with ovarian cancer who receive their initial surgical care from a gynecologic oncologist have improved outcomes; therefore, a thorough and efficient workup followed by appropriate referral is imperative.

A prompt evaluation is needed when a suspicious adnexal mass is present, or when advanced ovarian cancer is suspected based on patient symptoms or imaging. Workup should include a careful history and physical exam, including breast, gynecologic, and rectal exam. All screening, including colonoscopy, mammography, and cervical cytology, should be up to date. If a pelvic mass is palpated on bimanual exam, the size, mobility, and extent of disease (i.e., sidewall and rectal involvement) should be noted. If a rectal mass is palpated, consider a flexible sigmoidoscopy to evaluate the lesion, even if the patient is up to date on screening colonoscopy. The abdomen should be assessed for the presence of ascites and the lungs examined for the presence of effusions.

Imaging studies may include transvaginal ultrasonography (TVUS), computed tomography (CT) scans of the abdomen and pelvis, pelvic magnetic resonance imaging (MRI), and positron emission tomography (PET) scans. TVUS can evaluate the internal architecture of the ovary, assess the status of the contralateral ovary, and identify any evidence of metastatic disease, including ascites. MRI can serve as an adjunct to TVUS to further characterize a complex lesion, especially with the assistance of a radiologist experienced in gynecologic MRI. Evidence of a large, solid component may indicate occult malignancy, unless the mass has characteristics of an ovarian fibroma. The presence of a complex adnexal mass, pelvic tumor, lymphadenopathy, or peritoneal carcinomatosis suggests the diagnosis of advanced ovarian cancer. If advanced disease is suspected or if the patient has shortness of breath, imaging should also include a chest CT, which can identify pleural disease, effusions, and enlarged mediastinal lymph nodes.

Tests for serum tumor markers, especially CA125, may be helpful in confirming the diagnosis of ovarian cancer or indicating the need for evaluation of other possible primary malignancies. While in the postmenopausal patient, CA125, CEA, and CA19–9 are the most useful, in the young woman with a suspicious mass, LDH, AFP, inhibin, and HCG can be integral in the diagnosis of a nonepithelial ovarian malignancy. In

the setting of carcinomatosis, a CA125 to CEA ratio of 25:1 or greater supports a gynecologic etiology. Routine preoperative testing should also include a basic metabolic panel, complete blood count, coagulation studies, liver function tests, and serum albumin.

Ultimately, surgical pathology is required for the definitive diagnosis of ovarian cancer. If the preoperative suspicion for ovarian malignancy is high, the surgical procedure should be performed by, or in conjunction with, a gynecologic oncologist. Prior to surgical intervention, a thorough preoperative assessment should be performed in order to ensure that the patient is a suitable candidate for a potentially lengthy and extensive surgical procedure. During the preoperative consent discussion, the patient should be informed of the potential need for extensive surgery (laparotomy, if laparoscopy is planned), for blood transfusion, or for the creation of a temporary or permanent ostomy. If there is a question of tumor resectability, it is reasonable to consider a diagnostic laparoscopy as the initial step. In women of childbearing age, it is crucial to discuss the patient's desire for future fertility prior to any surgical intervention and plan accordingly.

There are fewer contraindications to a minimally invasive approach, especially if patients are consented for a possible conversion to laparotomy. In a young woman with apparent benign disease, a laparoscopic ovarian cystectomy with preservation of the integrity of the majority of ovarian tissue would be the appropriate conservative course of action. Ideally, the cyst should be removed and placed intact into a laparoscopic bag for removal. Typically, one will find residual ovarian tissue to be preserved along the ovarian vessels, though occasionally, tumors of very large size do not demonstrate any recognizable residual normal ovarian cortex. In postmenopausal women, in whom the risk of occult malignancy is greater and the value of preservation of one ovary is lesser, the appropriate course of action is to perform an oophorectomy rather than an ovarian cystectomy, particularly if there is any suspicious appearance to the ovarian mass. Generally, any major degree of fixation of the ovarian neoplasm in the absence of obvious endometriosis should both raise the suspicion of malignancy and increase the likelihood of cyst rupture at the time of laparoscopic intervention.

Clinically Early-Stage Disease

An intraoperative frozen section should be performed on any complex adnexal mass to determine the need for further surgical staging. Patients

with apparent early invasive cancer diagnosed at the time of laparoscopy or laparotomy require the same intensive staging procedure (Table 185.1) irrespective of the route of access. In the absence of overt metastatic disease, a minimally invasive approach to surgical staging, either laparoscopically or with a robotic-assisted laparoscopic approach, can be considered. The surgeon should be prepared to carry out a definitive staging and carefully examine (but not necessarily biopsy) the contralateral ovary as well, particularly if fertility-sparing management is warranted.

Intraoperatively, the peritoneal surfaces in all 4 quadrants should be carefully examined. In cases where disease is grossly limited to the ovary, it is important that the specimen be removed intact to avoid spillage of tumor into the abdomen. Frozen section can be utilized to confirm malignancy and gynecologic origin and to assist in planning the remainder of the procedure. Surgical staging of ovarian cancer includes peritoneal cytology, total hysterectomy, bilateral salpingo-oophorectomy, omentectomy, pelvic and para-aortic lymphadenectomy (up to the level of the renal vessels), peritoneal biopsies from anterior/posterior cul-de-sac, pelvic sidewalls, paracolic gutters, and bilateral diaphragms. In the absence of any other sites of extra-ovarian spread, a complete systematic node dissection is necessary to completely evaluate the risk of metastasis, as well as to remove residual disease. If there is histologic evidence of metastatic intraperitoneal disease, then sampling of nodes and only removal of all enlarged nodes may be sufficient, although this is somewhat controversial. The upper abdomen, including the omentum in the LUQ, the liver surface, and both diaphragms, should be carefully examined. It is particularly important to evaluate the posterior aspect of the diaphragm behind the liver, as well as the inferior aspect of the liver at the foramen of Winslow. In select cases, fertility preservation is reasonable, with conservation of the uterus and/or the contralateral ovary.

A systematic and thorough approach should be taken during surgical staging, as incomplete staging can lead to the underestimation of disease and, subsequently, undertreatment. This comprehensive assessment is necessary for the accurate assessment of risk for recurrence and determination of the appropriate adjuvant chemotherapy regimen. Essentially, all patients with high-grade serous ovarian carcinoma, even those confined to the ovary, are candidates for chemotherapy. At the present time, adjuvant chemotherapy has no role in the treatment of well-differentiated early invasive epithelial malignancies confined to the ovary

with no surface involvement. The data regarding grade 2 tumors do not clearly indicate a benefit for adjuvant chemotherapy, and only with grade 3, stage IA tumors, as well as for more advanced lesions, is there a role for adjuvant treatment. As the success with pregnancy following chemotherapy of other malignancies is well supported in the literature, it is reasonable to consider this possibility in carcinoma of the ovary as well. Patients with stage IA, G3, and all with unilateral stage IC disease should receive adjuvant platinum and taxane-based chemotherapy along with the preservation of a normal contralateral ovary. Patients with stage IB disease or more advanced disease with contralateral ovarian involvement may require bilateral oophorectomy. A careful deliberation with the patient and her family and clearly defined informed consent is critical to this course.

Fertility Preserving Surgery

In women of childbearing age who desire future fertility, conservation of the uterus and nonaffected ovary can be considered. In patients with suspicious bilateral lesions or evidence of extraovarian disease, preoperative consultation with a reproductive endocrinologist (REI) to discuss options for oocyte or embryo cryopreservation or other techniques to protect ovarian reserve is recommended. Intraoperatively, if a malignancy is suspected in a young and otherwise healthy woman, it is far more prudent to perform a two-step procedure after a definitive pathologic diagnosis than to proceed with a surgical resection that renders her infertile. One can go back at a later date when the patient is fully informed, has had the opportunity for REI consultation, and better prepared to undergo major surgery. Completion surgery with removal of the adnexa and uterus should be strongly considered when childbearing is no longer desired.

Ovarian Borderline Tumors

In contrast to invasive epithelial carcinomas of the ovary, conservative surgical management of ovarian tumors of borderline malignancy should be considered the rule for young women, rather than the exception. Faced with an ovarian neoplasm with surface excrescences and implants within the peritoneal cavity and omentum, if the histologic diagnosis suggests an ovarian tumor of borderline malignancy, one should still consider preservation of reproductive potential, even if the excision of all of one ovary and part of another might be required for removal of apparent malignant disease. The difficulty in distinguishing between invasive

tumors and tumors of borderline malignancy on frozen section evaluation, particularly with limited sampling of bulky tumors, is the basis for the general recommendation that *one should never ablate reproductive function in a young woman of childbearing age on the basis of frozen section alone.*

Controversial issues related to the surgical care of a patient with a borderline ovarian tumor include:

- Cystectomy versus oophorectomy in the management of the primary tumor, particularly as many tumors will only be definitively diagnosed by histopathology after laparoscopic ovarian cystectomy.
- The need to biopsy the opposite, often normal-appearing, ovary; one must balance the yield from the procedure versus the risk of infertility, which is usually already an issue by that time.
- The need to fulfill the requirements of FIGO staging, with pelvic and para-aortic node dissection in particular, when no definitive therapy is usually recommended for patients with nodal "metastases" that may actually represent mullerian inclusions and not metastases from a noninvasive lesion.

Management of patients with peritoneal implants also presents a difficult problem. Implants may be noninvasive, desmoplastic, or invasive. Each carries a different prognosis and prudent management demands adequate sampling of a substantial proportion, if not all, of the lesions identified. Complete removal of all macroscopic lesions *should* be the goal —both to excise the tumor itself and also to ensure that a more aggressive metastatic lesion is not missed. Only a small proportion of women with borderline tumors will have invasive implants and present a risk of recurrence and death. Monitoring of the typical patient with noninvasive implants requires regular pelvic examinations and CA125 monitoring for the first year. After that time, progressively longer follow-up intervals would be appropriate. Routine CT scans in the absence of symptoms or a rising CA125 level, even for nonserous tumors, would not appear to be indicated.

Chemotherapy for these patients with borderline tumors and advanced or recurrent disease is unlikely to produce any dramatic and sustained responses, because of the low-grade nature of these tumors, their functional similarity to the corresponding normal tissue, and the low growth fraction assayed in vitro.

The Management of Advanced Disease

Standard management of advanced ovarian cancer consists of a combination of debulking surgery and systemic platinum-based chemotherapy. While this combination of modalities has remained the same, the timing of these interventions as well as the radicality with which they are employed has evolved dramatically over the past two decades. The timing of surgical intervention, specifically the role of primary debulking surgery versus the utilization of neoadjuvant chemotherapy followed by an interval debulking procedure, continues to be an area of active research and much controversy. In all of these cases, however, there is little debate regarding the fact that volume of visible residual disease after debulking surgery is one of the strongest prognostic factors in advanced ovarian cancer.

Defining Optimal

At the time of diagnosis, ovarian carcinoma presents with the greatest tumor burden of any solid tumor; a kilogram or more of tumor may be distributed in the pelvis and upper abdomen, along with several liters of ascites. It is distinct from the majority of other solid tumors, in which there is no role for surgery in the setting of advanced disseminated peritoneal disease. Although the epithelial ovarian tumors are considered quite responsive to primary chemotherapy, with response rates in the 80% to 90% range in untreated individuals, the dominant variable predictive of long-term survival is the amount of residual disease present at the conclusion of the initial surgical procedure. The validity of less than total excision in the presence of obvious metastatic disease appears to violate basic tenets of surgical oncology and has often been questioned. Nonetheless, it has been subjected to careful scrutiny over the last three decades and has been consistently documented as the dominant prognostic factor in studies of patient survival, whether treatment involves chemotherapy or radiation therapy. Essentially every clinical study has documented that the extent of residual disease even outweighs surgical stage in its prognostic importance. The theoretical explanation employed to support this observation is that surgical cytoreduction removes bulky tumor that is either constitutively drug-resistant, or one that is resistant because of poor drug penetration into a large tumor mass. In addition to this effect, reduction from a 5-cm tumor mass to a 0.5-mm tumor mass represents a seven log tumor cell reduction, from 10^{11} cells to 10^{4} cells,

decreasing the amount of chemotherapy needed for tumor control based on first-order kinetics of cell kill. This threshold effect may further be explained in theory by the elimination of cells that carry extreme drug resistance.

The concept of maximal cytoreductive effort dates back to work done in the 1970s. Griffiths, in an NCI monograph, demonstrated that patients with bulky intra-abdominal spread of ovarian cancer who underwent extensive cytoreduction to minimal residual disease had the same median survival time as those patients who had the same amount of minimal residual disease but did not require extensive surgical cytoreduction. They demonstrated an inversely proportional relationship between tumor burden after surgery and survival. In this study, 102 patients with stage II and III disease were examined, and results showed that those with no residual disease had the best outcomes compared with those with >1.5-cm residual disease in whom surgery conferred no measurable benefit.

Over time, the concept of "optimal" has evolved. The results of Gynecologic Oncology Group (GOG) study 52, which were published in 1989 by Omura et al., support an "optimal" cut-off of 1-cm residual disease. This definition has become an established standard in many subsequent studies and has been corroborated by many, including Chi et al. in 2001 in a study of prognostic factors in patients with advanced ovarian cancer undergoing upfront surgical debulking. This study, which included 282 women with stage III/IV disease undergoing primary debulking, identified age, ascites, and volume of residual disease as significant prognostic factors.

Since that time, it has been clearly demonstrated in both prospective and retrospective studies that less residual disease after primary surgery continues to be the most important modifiable prognostic factor. A meta-analysis published by Bristow et al. in 2002 included nearly 7,000 patients from 81 studies treated with surgery and chemotherapy during the platinum era. They determined that each incremental decrease in the volume of residual disease below 1 cm translated into improved patient survival. Similar studies from the Mayo Clinic and Memorial Sloan Kettering Cancer Center by Aletti and Chi, respectively, have demonstrated similar results—most notably that the best survival outcomes reliably fall within the cohort of patients with no gross residual disease following primary debulking surgery (Fig. 185.2). Patients who underwent complete cytoreduction had a 5-year survival rate in excess of 75%, while

patients who had macroscopic residual disease of <1 cm in size had an approximate 30% survival rate, and patients with residual disease >1 cm but <2 cm had only a 15% 5-year survival rate. These data all support the concept that complete resection of all visible disease should be the goal of debulking surgery for advanced ovarian cancer.

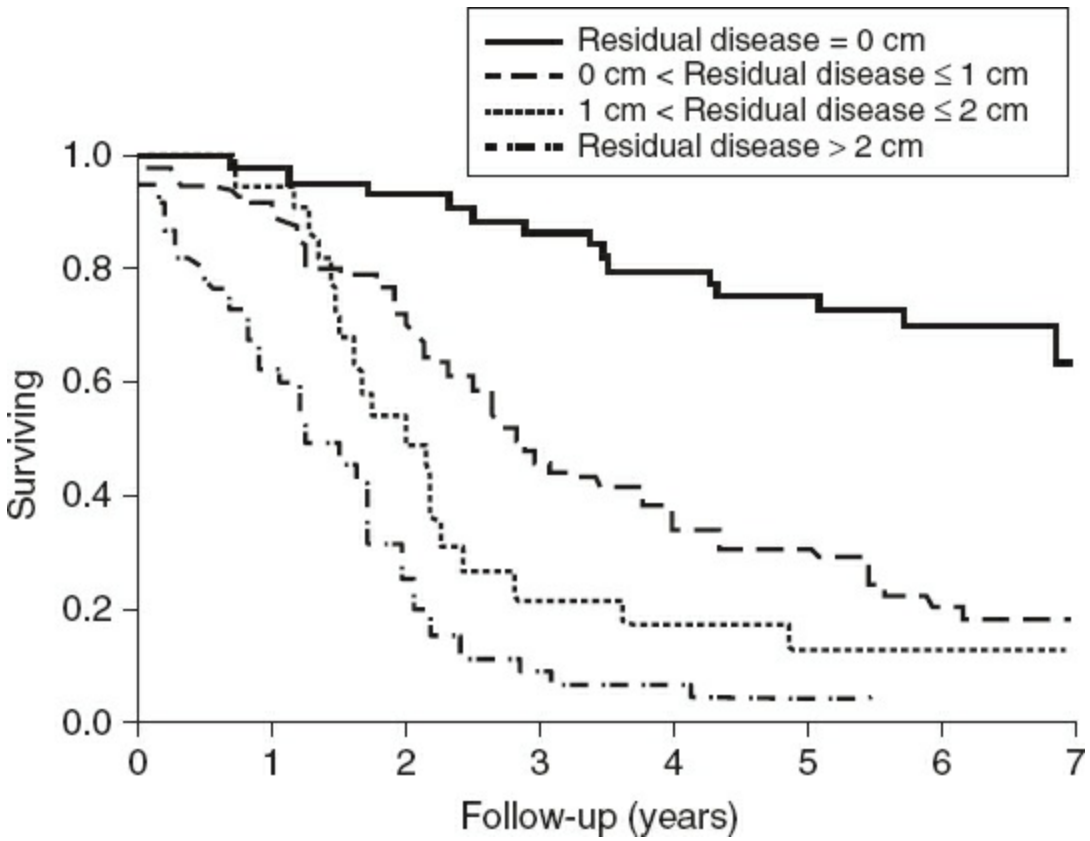

Figure 185.2. Survival curves for patients by the extent of residual disease after primary surgical therapy. (Aletti GD, Dowdy SC, Gostout BS, et al. Aggressive surgical effort and improved survival in advanced-stage ovarian cancer. *Obstet Gynecol* 2006;107:77–85.)

Expanding the Scope of Debulking Surgery

Historically, debulking surgery for ovarian cancer consisted of a hysterectomy, salpingo-oophorectomy, and omentectomy. However, as evidence supporting volume of residual disease as the most influential modifiable prognostic factors accumulated, a change in surgical paradigm occurred, with the routine incorporation of radical upper abdominal and thoracic procedures into debulking surgery. The addition of procedures such as diaphragm resection, liver resections, splenectomy, distal pancreatectomy, cholecystectomy, and portal lymphadenectomy has been

reported in one single institution study to have increased rates of optimal primary debulking from 46% to 80% and complete gross resection rates from 11% to 27%. In this cohort, both progression-free and overall survival were significantly higher than those of similar patients treated in a less-extensive surgical era. While the adoption of more radical and comprehensive debulking surgery results in a higher rate of perioperative morbidity, the survival outcomes remain improved, supporting this approach. In order to facilitate this, there is a clear role for the collaboration of gynecologic oncologists and general surgeons experienced in gastrointestinal and, particularly, hepatobiliary surgery.

In the modern era, ovarian cancer resectability is contingent upon the distribution of disease, the skill of the surgeon, and the patient's ability to undergo a major operation. Rarely is the pelvis the site of residual disease after incomplete cytoreduction. Common sites of surgical failure are the root of the small bowel mesentery, nodal disease above the celiac axis involving the lesser curve of stomach and the left lobe of liver, and perihepatic disease on the right as well as peripancreatic disease involving the C-loop of the duodenum. Although there may be an element of patient selection for surgical exploration, the proportion of patients who undergo "adequate" debulking surgery should be in the 80% to 90% range; approximately half of these patients should have no gross residual disease. Bristow has demonstrated that institutions with a high frequency of optimal cytoreduction also have improved survival when compared with institutions that do not have such a level of surgical success. Further documentation of the positive effect of the aptitude of the gynecologic oncologist also comes from the Mayo Clinic (Table 185.2), where, in another paper, they documented that Mayo surgeons performing radical surgery in >50% of patients had a patient median survival more than double that of their counterparts who performed radical surgery in <50% of patients.

Timing of Surgery

Primary Debulking

Primary debulking surgery, when feasible, should be the first line of treatment for advanced ovarian cancer. In a postmenopausal woman with carcinomatosis and ascites, ovarian cancer should be at the top of the differential diagnosis. If the diagnosis of ovarian cancer is supported by tumor markers, then preoperative biopsy is not necessary prior to

proceeding with debulking surgery. Intraoperative frozen section can be used to confirm a gynecologic origin.

Preoperative evaluation should include a discussion of intraperitoneal therapy. In a randomized prospective trial, the GOG demonstrated a 16-month improvement in median overall survival time (66 vs. 50 months) in patients who had undergone optimal (<1.0-cm residual disease) surgical cytoreduction followed by intraperitoneal chemotherapy with cis-platinum and paclitaxel compared with patients who underwent similar chemotherapy via an intravenous route. This improvement in survival occurred despite both toxic and mechanical complications of intraperitoneal chemotherapy that prevented 58% of patients assigned to this therapy from completing the planned six cycles of treatment. The current clinical challenges are to optimize the delivery of this therapy and, in particular, to minimize catheter complications that prevent completion of treatment.

TABLE 185.2 Impact of the Surgeon

Correlation between two subgroups of surgeons (the ones who perform radical procedures in >50% vs. <50% of patients) and residual disease in patients with IIIC ovarian cancer ($N = 194$) ($P = 0.008$; Pearson χ^2)

Surgeons	RD = 0 Macro	RD < 1 cm	RD = 1–2 cm	RD > 2 cm	Median Survival
Radical surgery in <50% of the patients	23.72	39.10	11.54	25.64	2.53 yrs
Radical surgery in >50% of the patients	23.68	63.16	10.53	2.63	5.9 yrs

RD, residual disease.
The last column represents the median survivals ($P = 0.04$; log rank test).
Aletti GD, Gostout BS, Podratz KC, et al. Ovarian cancer surgical resectability: relative impact of disease, patient status, and surgeon. *Gyn Oncol* 2006;100:33–7.

For patients with advanced ovarian cancer (stages IIIC and IV), National Cancer Database information demonstrates an increased primary surgical rate (vs. neoadjuvant chemotherapy) and an improved overall survival outcome for hospitals with a higher case volume (>21 cases/year) in comparison to hospitals with intermediate (9 to 20) or low (<9) case volumes. This volume effect has also been identified extensively in Europe.

Interval Debulking

In patients medically unfit for surgery or those deemed to have unresectable disease, either based on preoperative imaging or intraoperative assessment at the time of laparoscopy or debulking attempt, neoadjuvant chemotherapy can be utilized and a subsequent interval debulking performed. A retrospective study of 576 women with advanced ovarian cancer from four tertiary care centers identified a "high risk" group of patients in whom the risks of radical debulking appeared to outweigh the benefits. This group, composed of women aged 75 years or older, with poor performance status (American Society of Anesthesiologists score 3 or more) or poor nutritional status (preoperative albumin <3.0 g/dL), and a high tumor dissemination or stage IV disease, should be considered for neoadjuvant chemotherapy.

The role of neoadjuvant chemotherapy versus upfront primary debulking was examined in two recent multicenter randomized trials, both of which showed no significant difference in progression-free or overall survival. Specifically, a noninferiority study conducted by the EORTC of 632 eligible patients with stage IIIC or IV disease showed that neoadjuvant chemotherapy followed by interval debulking was not inferior to primary debulking surgery, with median overall survivals of 30 months and 29 months, respectively. Importantly, complete gross resection of disease at the time of debulking was identified as the single most important prognostic factor.

While these multicenter randomized trials show no significant difference in outcomes between neoadjuvant chemotherapy and primary debulking, the rates of optimal resection achieved in patients undergoing primary debulking were comparably lower than those of other published experiences and are the subject of ongoing critique. More importantly, the median survivals reported in these randomized trials when compared to other single-institution experiences are markedly decreased, and therefore, further studies are needed to validate this approach in other clinical settings.

TABLE 185.3 Recommendations for Secondary Cytoreduction Based on Disease-Free Interval, the Number of Recurrent Sites, and Evidence of Carcinomatosis

DFI	Single Site	Multiple Sites: No Carcinomatosis	Carcinomatosis
6–12 mo	Offer SC	Consider SC	No SC
12–30 mo	Offer SC	Offer SC	Consider SC
>30 mo	Offer SC	Offer SC	Offer SC

DFI, disease-free interval; mo, months; SC, secondary cytoreduction.
Chi DS, McCaughty K, Diaz JP. Guidelines and selection criteria for secondary cytoreductive surgery in patients with recurrent, platinum-sensitive epithelial ovarian carcinoma. *Cancer* 2006;106(9):1933–9.

Surgery for Recurrent Disease

There is convincing evidence that subsequent cytoreduction (secondary, tertiary, etc.) may offer additional survival benefit for a select group of patients. In 2006, Chi et al. published criteria for the consideration of secondary cytoreduction (Table 185.3), specifically disease-free interval, platinum sensitivity, number of sites of disease, and the presence or absence of carcinomatosis. The longer the disease-free interval from prior chemotherapy, the greater the likelihood that complete surgical resection will be associated with prolonged survival, particularly if there has been limited prior exposure to cytotoxic chemotherapy.

Eisenkop and colleagues reported their experience with 106 patients experiencing disease recurrence more than 6 months after completion of chemotherapy. They examined both the probability of successful cytoreduction and the survival after diagnosis of recurrence. In multivariate analysis, the size of the largest residual tumor mass, preoperative chemotherapy with "salvage" chemotherapy, and preoperative performance status influenced the likelihood of success in surgical cytoreduction to minimal residual disease. In univariate analysis, site of disease in the pelvis, a solitary site of recurrence, an asymptomatic state, and the absence of physical findings all influenced cytoreductive success, as might be expected, given that these variables all reflect the preoperative extent of disease. The overall survival was influenced by the disease-free interval prior to surgical resection. With a disease-free interval of 6 to 12 months as the baseline for comparison, the 13- to 36-month interval was associated with a risk ratio for recurrence of 0.16. With a disease-free interval of >3 years, the risk ratio for recurrence dropped to 0.08. It is of note in this study that 83% of patients did not have ascites at the time of recurrence, suggesting a strong selection bias. In further support of this contention, the median survival from the time of recurrence

in the group without preoperative “salvage” chemotherapy was 47 months from the time of diagnosis of recurrence.

In 2011, Bristow et al. published the results of a meta-analysis of 40 studies including 2,019 patients who had undergone surgical treatment for recurrent ovarian cancer (Fig. 185.3). The only significant clinical variable associated with postrecurrence survival was the proportion of patients undergoing complete resection of disease. Specifically, each 10% increase in proportion of patients undergoing complete resection resulted in a 3-month increase in median survival time.

Given the progressive development of drug resistance in this group of ovarian cancer patients treated with chemotherapy, it is not surprising that the outcome of secondary cytoreduction is even more dependent on the surgeon’s ability to completely remove all residual disease, if possible (Fig. 185.4). In patients with a limited number of sites of recurrent disease, the most vigorous attempt at complete cytoreduction is certainly warranted. In patients with multiple sites of “oligo” metastatic disease, again, an aggressive approach to resection of all disease is a prerequisite to success. For patients with recurrent disease, predictive factors for success include limited extent of disease, particularly isolated nodal disease, limited primary surgery, and prolonged time to recurrence (>24 months). In highly select cases with limited sites of disease, a minimally invasive approach is reasonable.

Preoperative Preparation

When the patient is referred with the clinical picture of ascites, abdominal pain, and distention with a palpable pelvic mass, the preoperative diagnosis of ovarian carcinoma is typically one of exclusion. What one seeks to exclude, therefore, are those lesions for which surgical exploration will not be beneficial. Attention to the patient’s history of upper gastrointestinal symptoms may help to exclude those patients with occult gastric cancer. Should there be any question, upper gastrointestinal endoscopy will be a useful adjunct to the abdominal and pelvic CT scan that is part of routine preoperative evaluation. CT scanning has particular value preoperatively in identifying occult liver metastases or extensive retroperitoneal invasion above the celiac axis by tumor that might require collaboration with a hepatobiliary surgeon in the approach to primary debulking surgery. The CT scan may also exclude a clinically occult primary pancreatic neoplasm with intra-abdominal metastases.

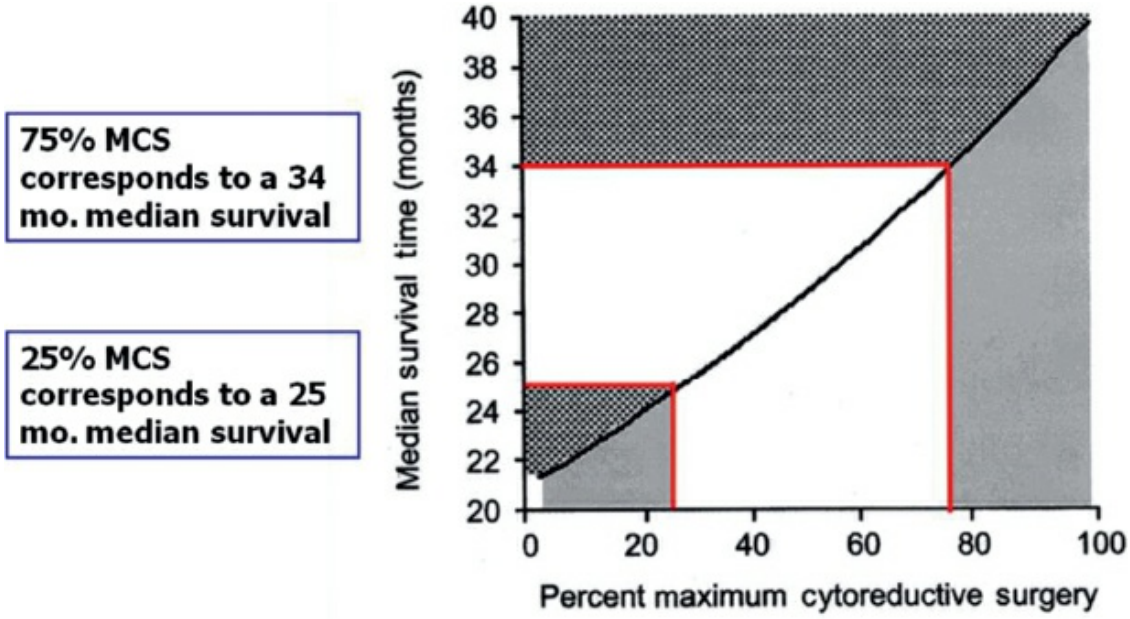

Figure 185.3. Greater success at achieving maximum cytoreductive surgery (MCS) is associated with longer median survival. (Bristow RE, Tomacruz RS, Armstrong DK, et al. Survival effect of maximal cytoreductive surgery for advanced ovarian carcinoma during the platinum era: a meta-analysis. *J Clin Oncol* 2002;20:1248–59.)

Preoperative physical examination is important in the identification of the extent of pelvic disease in so far as one can best identify infiltration of the pelvic sidewall or invasion of the very low rectovaginal septum that may present challenges to primary surgical resection with low anterior anastomosis. Although this extent of disease in the pelvis is not a contraindication to extensive debulking surgery, it certainly requires experience in en bloc resection of the intraperitoneal pelvic viscera, as will be described below. In the event that one encounters a positive stool test for occult blood, colonoscopy will be useful in the identification of a primary colonic tumor; however, surgical intervention with colonic resection is still necessary. On rare occasions when there is a considerable anterior extent of the pelvic tumor and the question of extrinsic bladder involvement, cystoscopy can exclude the rare patient with unresectable disease invading the bladder trigone. Except for overt obstruction of one or both ureters, there is little indication for preoperative ureteral catheterization. The typical lesion associated with ureteral obstruction will be a bulky intraperitoneal tumor with penetration through the peritoneum at the level of the uterine vessels. This is a common presentation of carcinoma arising in endometriosis involving the pelvic peritoneum.

Occasionally, bulky nodal metastases may also cause extrinsic compression; direct invasion of the pelvic ureter is much less common. Preoperative ureteral decompression may reduce the risk of trauma to that dilated ureter. One should not have to rely upon a ureteral catheter for the identification of the pelvic ureter: if the ureter is uninvolved by tumor, it is easily palpable; but if it is encased in tumor, a ureteral catheter provides little reassurance, as it is rarely palpable.

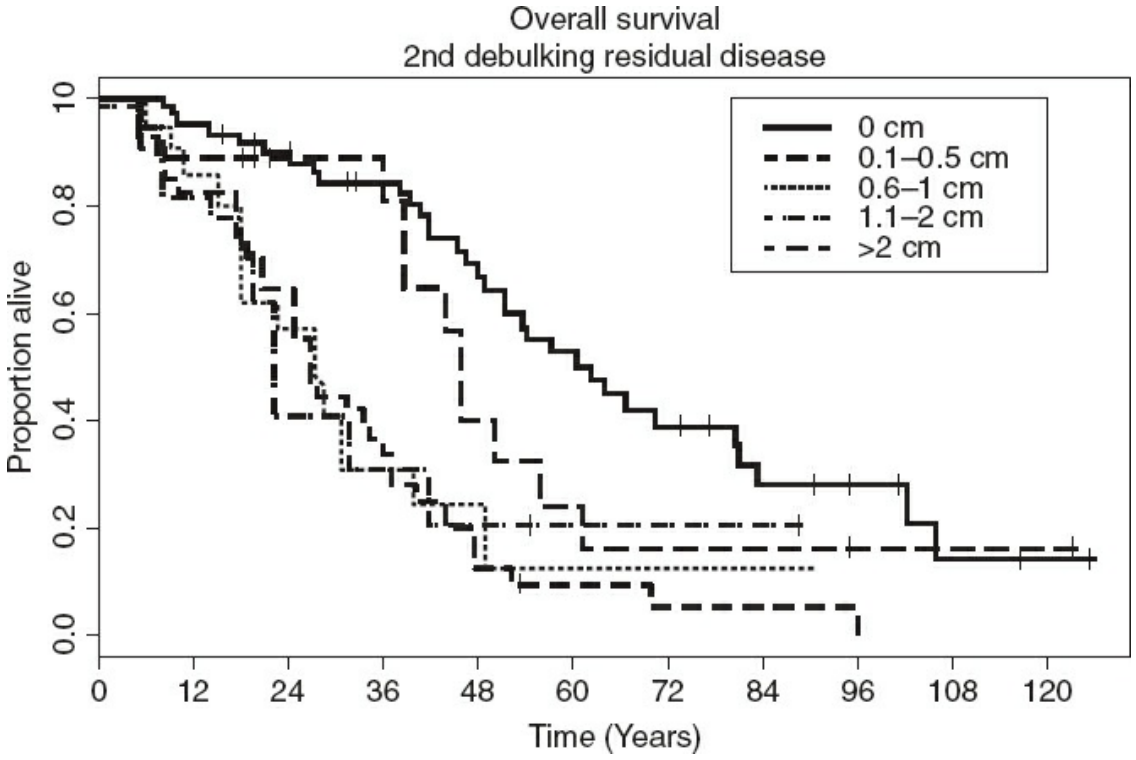

Figure 185.4. Overall Survival based on residual disease after secondary cytoreduction. (Chi DS, McCaughty K, Diaz JP. Guidelines and selection criteria for secondary cytoreductive surgery in patients with recurrent, platinum-sensitive epithelial ovarian carcinoma. *Cancer* 2006;106(9):1933–9.)

The preoperative preparation of the patient should include a forthright discussion of the diagnosis and management, with specific attention to the technique and importance of removing all gross residual tumor. Informed consent should specifically address the importance of complete surgical cytoreduction and the risks associated with this surgical procedure, including those associated with gastrointestinal resection, omentectomy, and retroperitoneal node dissection. As one evaluates the medical status of the patient preoperatively, it is important to identify the occasional patient with ascites secondary to liver disease associated with an elevated portal

venous pressure. Other conditions that can mimic advanced ovarian cancer include severe right heart failure and peritoneal tuberculosis; in both conditions, surgical exploration for a pelvic mass may be relatively contraindicated. Congestive heart failure, severe liver disease, and peritoneal tuberculosis are associated with an elevated CA125 in the absence of malignancy. Such findings may lead to exploration for benign ovarian disease in a patient with substantial medical contraindications to laparotomy.

Clear cell and endometrioid carcinoma of the ovary are associated with a hypercoagulable state; patients with ovarian cancer may present with deep venous thrombosis and pulmonary emboli as the initial sign of their disease. As is true with patients with symptomatic pleural effusions, one or two cycles of neoadjuvant chemotherapy along with anticoagulation using low molecular weight heparin will be beneficial for improvement in cardiopulmonary function with resolution of embolic disease. Typically, the patient will also have an inferior vena cava (IVC) filter placed prior to debulking surgery, unless thrombosis also involved the upper extremities.

The development of enhanced recovery pathways has heightened awareness of the importance of perioperative care and its association with complications. Skin preparation, bowel preparation, perioperative antibiotics, normothermia, euvolemia, and postoperative pain management and pulomonary care are all “bundled” to optimize patient outcomes. Recommendations for routine preoperative bowel prep have been changing and now consist of preoperative antibiotic bowel preparation with or without mechanical bowel preparation. As the extent of incision for the comprehensive surgery involves ultimately the extension of the incision from pubis to xiphoid, the use of preoperative epidural anesthesia is an attractive adjunct and, when properly performed, the source of considerable postoperative comfort for the patient.

Intraoperative Care

The anesthesia team should ensure adequate vascular access and have blood products available for transfusion should they be required. Sequential compression devices should be in place prior to the initiation of anesthesia and preoperative prophylactic heparin administered subcutaneously, unless contraindicated, for venous thromboembolism (VTE) prevention.

The patient should be placed in the dorsal lithotomy position, in which both hips are abducted with knees flexed, allowing for a thorough exam

under anesthesia and optimal access for a rectosigmoid resection and anastomosis, if needed. This position also facilitates improved access to the upper abdomen for an additional surgeon, when needed. A sterile Foley catheter should be placed when the patient is completely prepped and draped. In this manner, one has access to the catheter in order to fill or empty the bladder, as needed, to facilitate the anterior pelvic dissection. Should cystoscopy be necessary intraoperatively, this may be performed quite easily without additional preparation.

Determining Resectability

Assessment of tumor burden and resectability should always be the first step after entry into the abdomen, prior to any organ resections. This can be accomplished via diagnostic laparoscopy or through a reasonable vertical midline incision. After ascites, if present, is drained, all 4 quadrants should be evaluated, with special attention to the serosa and mesentery of the bowel. Once the decision to proceed with debulking is made, a generous vertical midline incision (from pubis to xiphoid) and placement of a fixed, self-retaining retractor (such as a Bookwalter or Omni) are recommended.

The extent of resection required to clear all visible disease is highly dependent on tumor volume and distribution. Other factors, such as patient performance status, patient preferences, surgeon ability, availability of consultants and resources, and judgment, all influence the decision to proceed with debulking. Clear contraindications to debulking include massive involvement of the root of the small bowel mesentery or extensive small bowel serosal disease. While total gastrectomy and total colectomy are technically feasible procedures, the need for these procedures generally represents an indication for neoadjuvant chemotherapy if identified laparoscopically or the need for aborting primary debulking surgery if laparotomy is underway.

Similarly, extensive resection of the small bowel that would compromise long-term bowel function should be avoided, unless of course that bowel appears obstructed or nonfunctioning due to disease infiltration. Ideally, the determination that disease is unresectable will be made prior to any major resections to limit the chance of postoperative morbidity and facilitate the quick initiation of neoadjuvant chemotherapy. As it is frequently the most challenging portion of the case, we recommend starting the resection in the upper abdomen. The following sections review procedures commonly required during extensive cytoreductive surgery

(CRS).

Omentectomy

The omentum is a frequent site of ovarian cancer metastases or tumor "caking." An infracolic omentectomy is occasionally sufficient; however, in cases in which tumor is present in the gastrocolic omentum, a supracolic omentectomy is also required. Mobilization of the hepatic and splenic flexures with resection of adjacent tumor-bearing paracolic peritoneum is necessary when omental disease is extensive (Fig. 185.5). Omental tumor often extends to the splenic hilum and can mimic splenic disease on preoperative imaging. While mobilizing the splenic flexure, care must be taken to avoid excess traction on the omentum, which can cause tears and bleeding from the splenic capsule.

If the transverse colon can be easily mobilized from the underside of the omental mass, that should be done next. If the tumor invades the transverse colon, it usually does so in the midportion of the transverse colon. The most prudent approach is to leave that dissection for last and begin working laterally to medially, freeing up the omentum from the paracolic gutters and mobilizing the ascending and descending colon at the hepatic and splenic flexures, respectively. This allows for the mobilization of both lateral aspects of the omentum from the peritoneal surface to which it may be fixed by tumor. Mobilization and resection of the omentum are ideally performed with a vessel-sealing device, such as the Ligasure, to allow for efficient dissection with excellent hemostasis. The omentum is initially mobilized along the duodenum, and then it is divided from the greater curve of the stomach using the Ligasure, entering the lesser sac just to the left of midline, and dividing the vessels while working toward the previously opened paracolic gutters. Then with the omentum remaining attached only to the transverse colon, one can dissect laterally to medially, mobilizing the omental mass from the mesocolon and from the bowel wall. If there is no plane, it may be necessary to resect the omentum and transverse colon en bloc. At the transverse colon, the mesocolon and middle colic artery should be preserved in order to maintain an adequate blood supply to the colon (Fig. 185.6). One may choose to delay the transection of the bowel until the end of the procedure to broaden options for the reconstruction of the gastrointestinal tract. Resection of a large omental cake may improve exposure to other areas of the abdomen, specifically the small and large bowel centrally, and is therefore a common first step during CRS. One can then proceed by evaluating the paracolic

gutters and subdiaphragmatic spaces, as well as the liver surface, stomach, and splenic capsule.

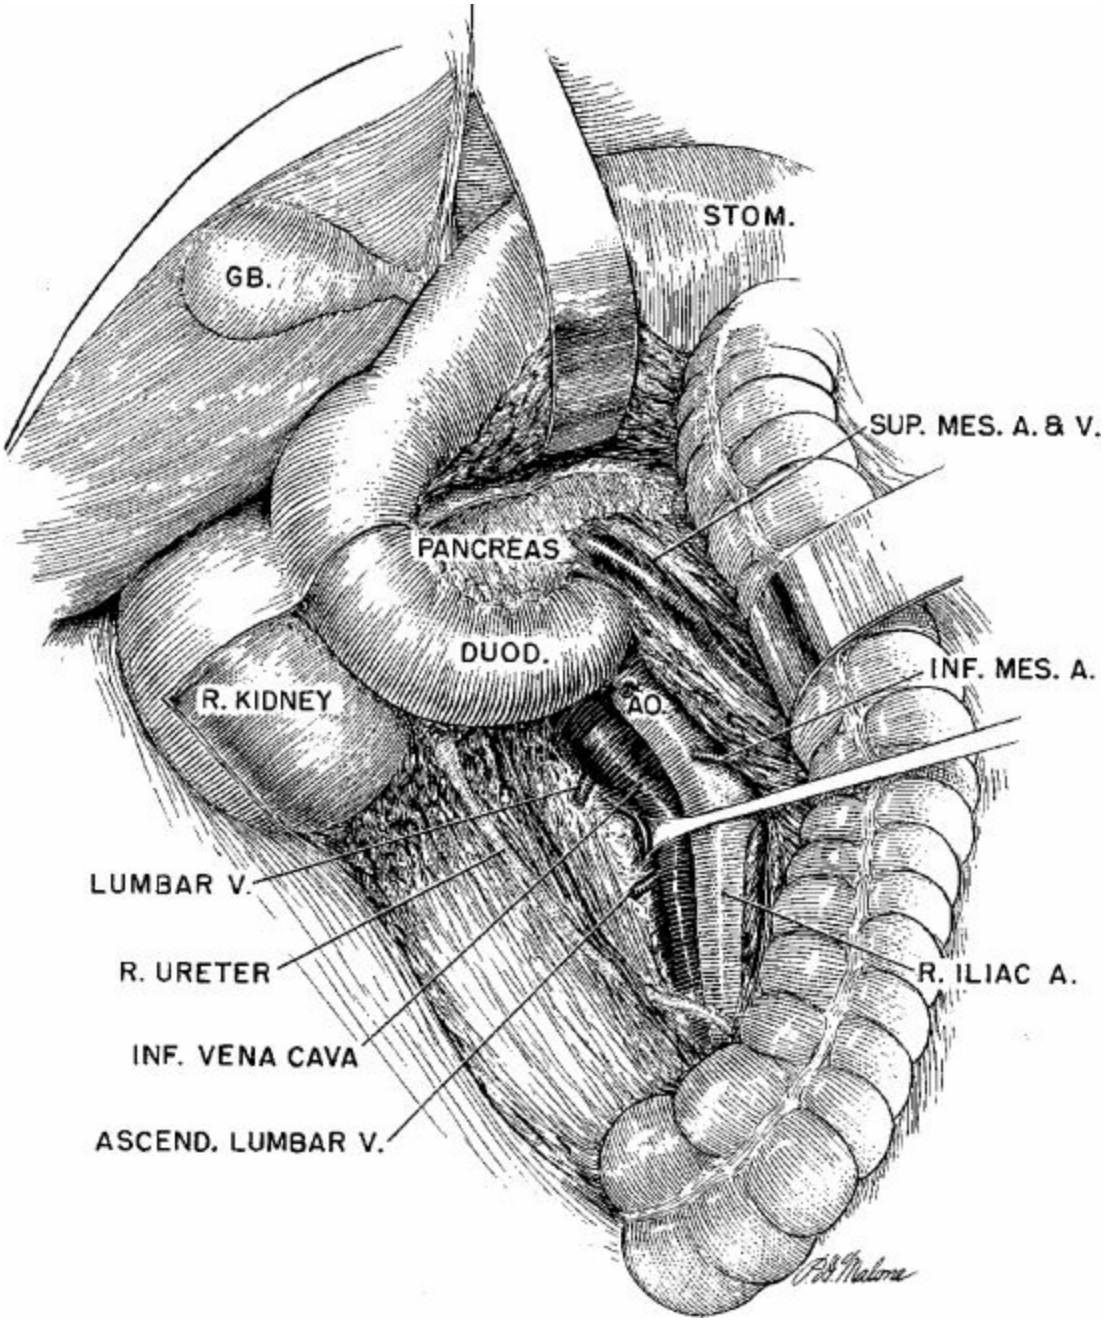

Figure 185.5. Exposure of the right para-aortic nodes by medial mobilization of the hepatic flexure and lesser sac. (From Edwards EA, Malone PD, MacArthur JD. *Operative Anatomy of the Abdomen and Pelvis*. Philadelphia, PA: Lea and Febiger; 1975.)

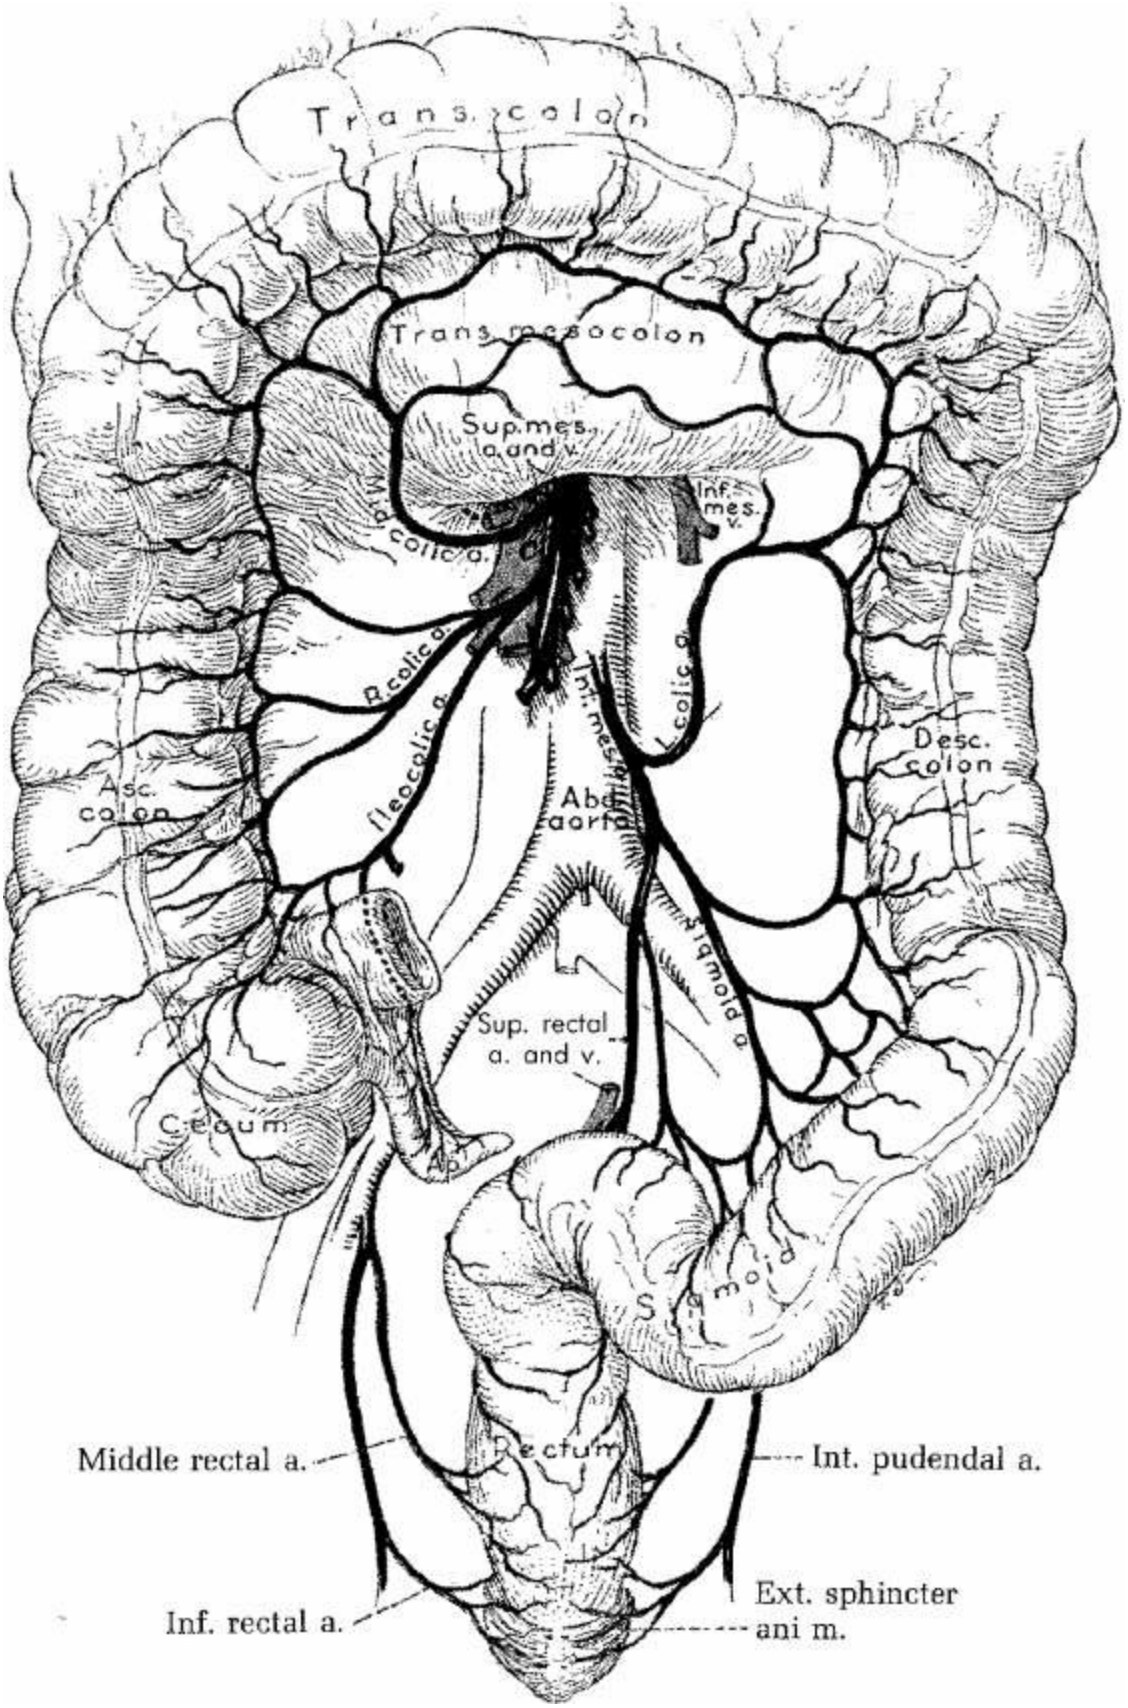

Figure 185.6. Vascular anatomy of the colon. (From Edwards EA, Malone PD, MacArthur JD. *Operative Anatomy of the Abdomen and Pelvis*. Philadelphia, PA: Lea and Febiger; 1975.)

Right Upper Quadrant (RUQ)

The right upper quadrant (RUQ) is a frequent site of metastatic disease in advanced ovarian cancer, partially due to the clockwise flow of peritoneal fluid in the abdominal cavity. The liver (surface and/or parenchyma), the right diaphragm, the peritoneum overlying Gerota fascia and Morrison pouch, the gallbladder, and the porta hepatis are all potential sites of tumor infiltration. While it can present a challenge, tumor involvement of these sites is not a contraindication to optimal or complete CRS (Fig. 185.7).

Liver mobilization is an important first step in adequately evaluating and treating right diaphragm disease, without which the extent of tumor involvement can be significantly underestimated. Tumor not easily visualized on first assessment may be present cephalad to the liver in the subphrenic space, as well as in the subhepatic space. The patient should be positioned in reverse Trendelenburg in the "RUQ up" position. The xiphoid can be resected in order to maximize exposure through the vertical midline incision. The Bookwalter retractor is placed obliquely above the right costal margin, retracting this structure upward. The falciform ligament should be identified and the free edge containing the round ligament (remnant of the umbilical vein) divided and tagged to assist in gentle downward traction on the liver. The falciform's attachment to the anterior abdominal wall should be separated in a cephalad fashion using electrocautery until the layers of the peritoneum split laterally to form the right and left coronary ligaments. During this dissection, we recommend staying adjacent to the liver surface. Dissection should then continue along the right coronary ligament, taking extreme care to identify and avoid the right hepatic vein and inferior vena cava. At this point in the dissection, a combination of medial and lateral approaches is frequently necessary, depending on the disease volume and distribution. The lateral triangular ligament can be divided and the dissection continued medially until the bare posterior surface of the liver is exposed. The liver mobilization will be complete once the right posterior coronary ligament is completely free. Gentle medial traction on the liver will expose the right diaphragm as well as the peritoneum overlying Gerota fascia and Morrison pouch. Metastatic disease typically consists of diffuse peritoneal implants that do not penetrate through and are easily removed with the subjacent peritoneum extending to the foramen of Winslow. With division of the lateral peritoneal attachments of the liver, one can retract the organ medially and excise or fulgurate the posterior peritoneal tumor.

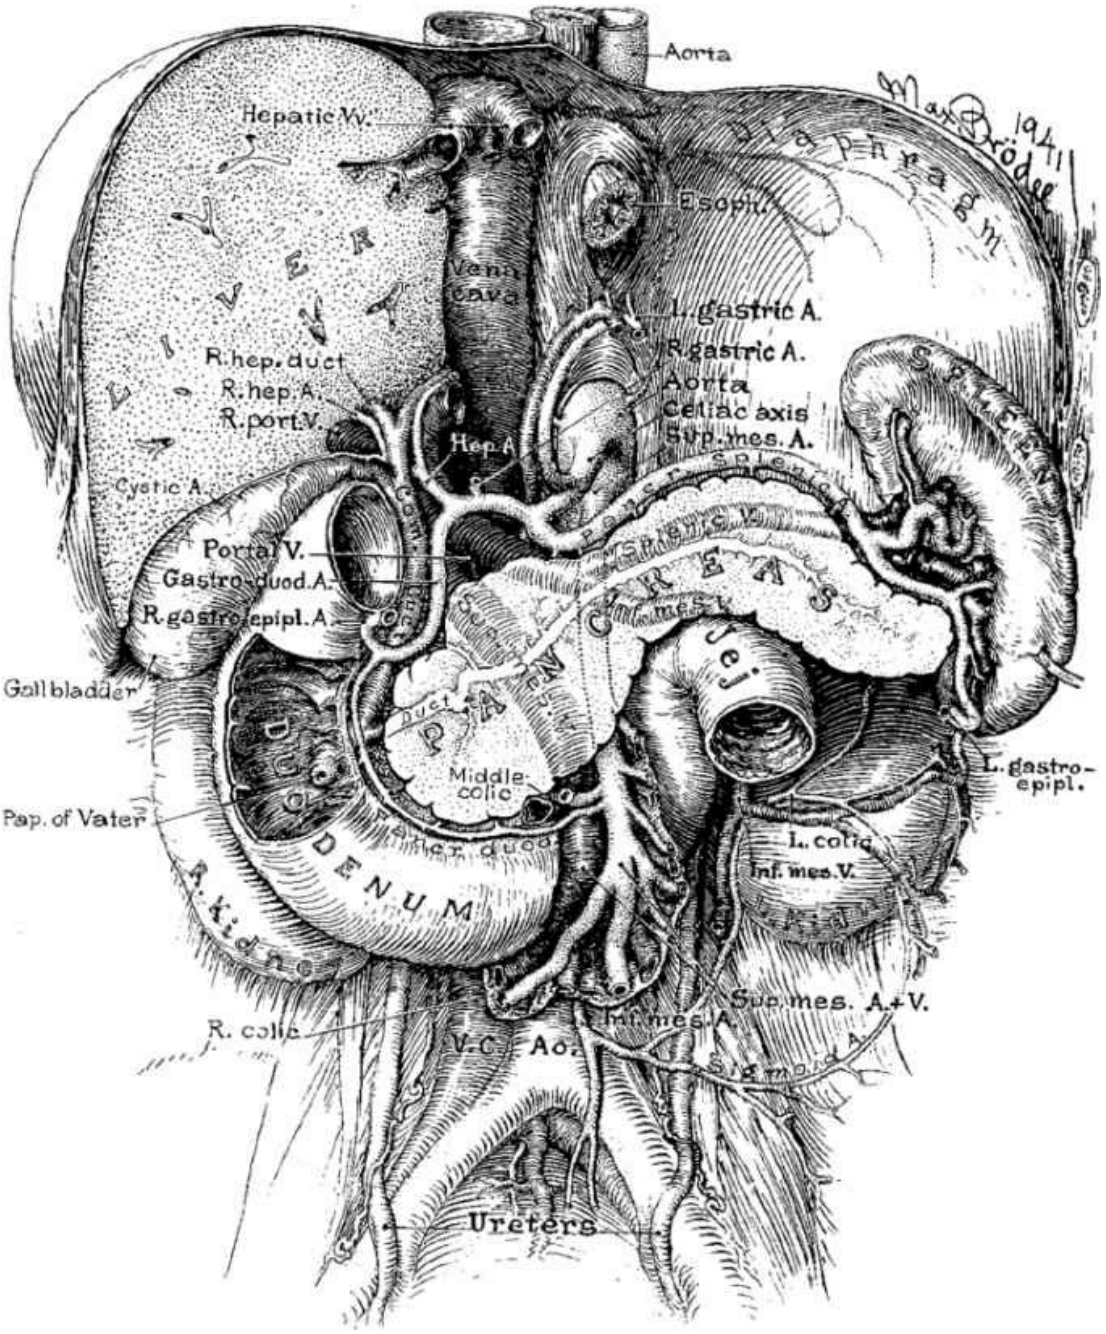

Figure 185.7. Visceral anatomy of the upper lesser sac and foramen of Winslow. In the right upper quadrant, peritoneal disease predominates in the foramen, in the retrohepatic area on the diaphragm, over the right adrenal and in the paracolic gutter. Extensive nodal involvement in the suprarenal area often involves the pancreas and indicates lack of resectability. (From Edwards EA, Malone PD, MacArthur JD. *Operative Anatomy of the Abdomen and Pelvis*. Philadelphia, PA: Lea and Febiger; 1975.)

Right diaphragm peritonectomy and resection. Tumor implants can be

superficially present on the peritoneum of the diaphragm or deeply invasive into the muscle. Once areas of disease are identified, the peritoneum at the level of the costal margin can be incised using electrocautery. The peritoneal edge can be grasped using Allis clamps and the dissection away from the underlying muscle continued posteriorly. Similar to liver mobilization, a combination of a medial and lateral approach is often necessary to achieve optimal results. A combination of blunt dissection (using a sponge stick) and electrocautery can be used as gentle downward traction is placed on the peritoneal edge to free it from the underlying muscle of the diaphragm. While this technique works very well for superficial implants, in areas where the tumor is deeply infiltrative (or at the central tendon of the diaphragm), dissection may become more difficult and may necessitate utilization of more electrocautery, sharp dissection, or ablative techniques such as argon beam coagulation. A vessel-sealing device may also be useful in controlling small bleeding vessels. Once the diaphragm peritoneum is resected, the muscle of the diaphragm should be carefully inspected for defects that can be repaired primarily using delayed-absorbable figure-of-eight sutures. Tumor that has invaded through the peritoneum and into the underlying muscle may require full-thickness resection of the diaphragm. In addition to the right hepatic artery, the right phrenic nerve can be injured if the resection extends medially. Anesthesia personnel should be notified of impending pneumothorax as the pleural cavity is entered. The involved diaphragm can be resected using electrocautery, a vessel-sealing device, or an endo-GIA stapler. Once the disease is resected, often the diaphragm can be closed using permanent sutures (1-0 polypropylene) in either an interrupted, figure-of-eight, or running fashion. A synthetic tissue can be utilized to repair larger defects and secured with a running permanent suture. After closing the diaphragm, air, blood, and fluid should be evacuated from the pleural space using either a red rubber catheter or chest tube placement. In addition to evacuating the acute pneumo/hemothorax, the chest tube can be used to drain postoperative pleural effusions, which are common after extensive diaphragm peritonectomies.

Liver wedge resection is commonly required in the setting of superficial parenchymal liver metastases and is often performed in conjunction with a hepatobiliary surgical consultant. Superficial liver disease frequently can be ablated using the argon beam coagulator (ABC) or other device such as the Cavitron ultrasonic surgical aspirator (CUSA).

Left Upper Quadrant (LUQ)

While metastatic ovarian cancer is less commonly found in the LUQ, a thorough assessment is needed to evaluate for the presence of disease. In order to gain exposure and appropriately identify all disease, entry into the lesser sac (by incising the posterior leaf of the omentum) is recommended. By reflecting the stomach and omentum anteriorly and medially, the spleen, pancreas, celiac axis, and porta hepatis can be accessed (Fig. 185.8).

Left diaphragm peritonectomy and resection. The approach to the left diaphragm is similar to the approach to the right side (as described above). It is best performed after mobilization of the liver. If tumor involvement is excessive, the left diaphragm can be removed en bloc with other structures in the LUQ such as the spleen and distal pancreas.

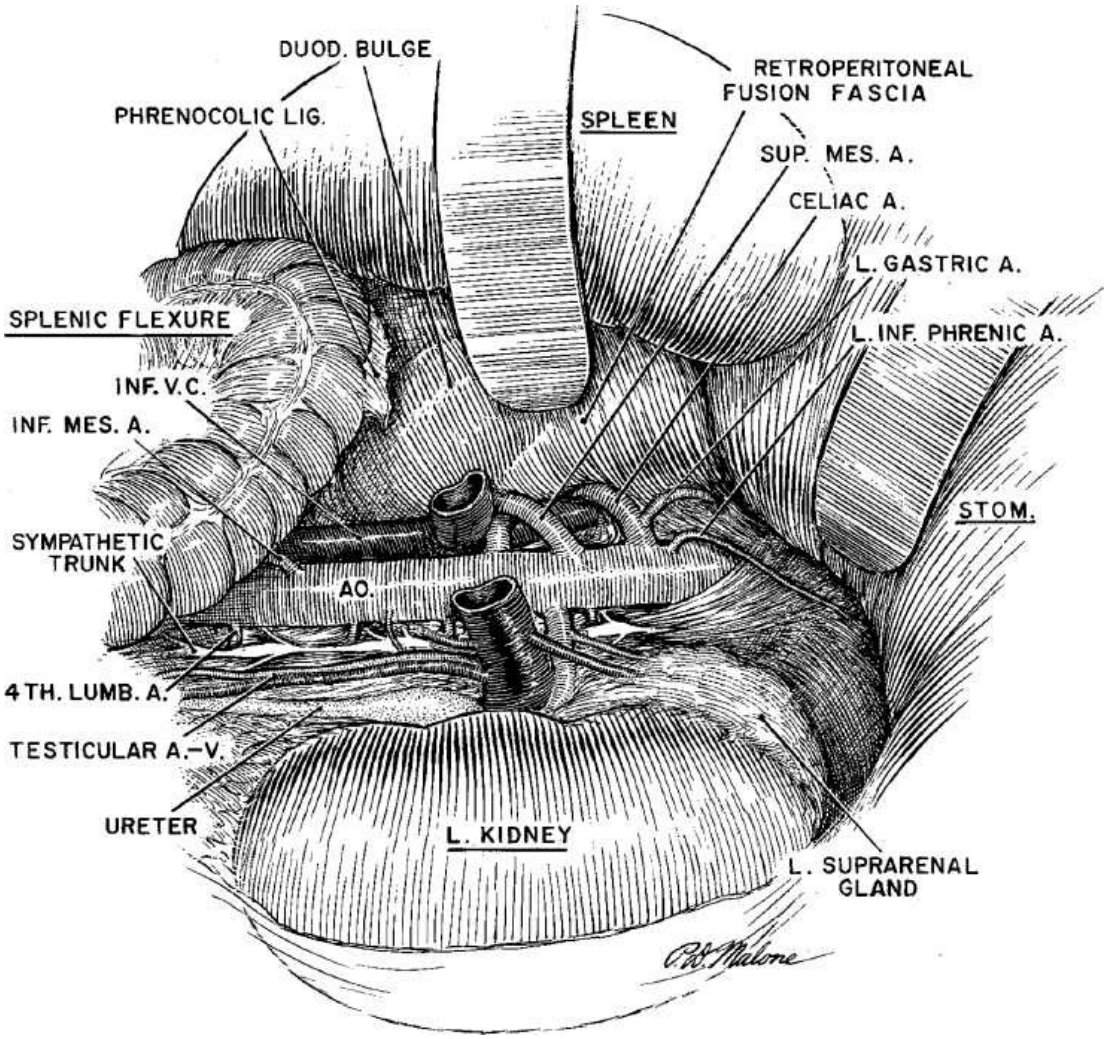

Figure 185.8. Exposure of the celiac axis and left para-aortic nodes by mobilization of the left upper quadrant contents. (From Edwards EA, Malone PD, MacArthur JD. *Operative Anatomy of*

the Abdomen and Pelvis. Philadelphia, PA: Lea and Febiger; 1975.)

Splenectomy is required in approximately 10% of cases due to either superficial or parenchymal tumor involvement. Splenectomy can be performed via an anterior or posterior approach; however, in the presence of tumor, a combination of the two approaches is generally the most efficient and safe. The patient should be placed in the "LUQ up" position, and the retractors should be adjusted accordingly. After entry into the lesser sac and retraction of the stomach medially, the gastrosplenic ligaments and short gastric vessels can be divided (taking care not to injure the posterior wall of the stomach). The spleen can be gently lifted and the distal pancreas examined. After incising the splenorenal ligaments, the splenic artery can be identified, isolated, and doubly ligated using permanent sutures or a surgical stapler with a vascular load. After the vasculature is secured, all remaining attachments, including the inferior splenocolic ligaments, the posterior and lateral lienorenal ligaments, and the splenophrenic ligaments, can be divided. If there is extensive omental tumor infiltration, it may be best to start with the posterior approach (and transection of the lateral attachments). All vascular pedicles should be inspected thoroughly after completion of the procedure, as any unsecured vessel in this region can result in significant postoperative hemorrhaging.

Distal pancreatectomy. Pancreatic involvement by metastatic ovarian cancer usually occurs in the setting of extensive omental involvement (when the disease extends beyond the splenic hilum); in such cases, distal pancreatectomy is generally performed in conjunction with splenectomy. After the gastrosplenic and short gastric vessels are divided, the peritoneum overlying the inferior border of the pancreas is incised proximal to the area of tumor infiltration. After the splenic vessels are secured, the distal pancreas can be transected using a TA or GIA stapler and reinforced using a 2-0 permanent running suture. Similarly, if the pancreatic tail is injured during splenectomy, the defect can be reinforced with a continuous layer of 2-0 or 3-0 sutures. Recognition of injury and proper reinforcement of the transected edge/injured area are crucial to reduce the incidence of postoperative complications, such as pancreatic leak, the development of a pseudocyst, and pancreatitis. During this procedure, it is also important to avoid injury to the underlying inferior mesenteric vein. The placement of a drain in the splenic bed can facilitate monitoring of pancreatic leak and should be continued until minimal

output is noted and the patient can tolerate a regular diet.

Pelvis

While some women require a simple total hysterectomy and bilateral salpingo-oophorectomy to achieve optimal cytoreduction, many will have a large conglomerate mass obliterating the pelvis that will require a more complicated dissection. This frequently can be accomplished by performing a modified posterior exenteration (MPE), which entails an en bloc resection of the uterus, adnexa, rectosigmoid colon, and pelvic peritoneum. This en bloc resection is best accomplished using a retroperitoneal approach, which allows for easier access, exposure, and safer resection of tumor and pelvic viscera (Fig. 185.9A,B).

At the start of the procedure, the pelvic sidewalls should be opened using lateral peritoneal incisions, and the ureters and pelvic vasculature should be identified (Fig. 185.10). The left lateral peritoneal incision can be extended cephalad along the white line of Toldt to mobilize the descending colon. The ureters should be isolated and tagged with vessel loops and the infundibulopelvic ligaments identified and divided high. The pararectal and paravesical spaces should be developed and the ureters skeletonized from the pelvic brim to the tunnel of Wertheim. The peritoneum can be incised anteriorly and the involved bladder peritoneum dissected free from the underlying bladder muscularis. The vesicouterine space can be developed in the standard fashion. Occasionally, this dissection is limited by tumor infiltration into the bladder, which may necessitate full-thickness bladder resection. Bladder defects can be repaired primarily; however, care must be taken to avoid the trigone and bilateral ureteral insertions.

The uterine vessels should be secured and divided laterally at their origin from the hypogastric arteries. After unroofing the ureter from the bladder pillars, the ureters can be reflected laterally away from the specimen using the vessel loops for gentle traction. The bladder is then dissected off of the vagina approximately 2 to 3 cm distal to the cervicovaginal junction. At this point, a vaginal probe or sponge stick can be inserted into the vagina to assist in the anterior colpotomy, which ideally should be 1 to 2 cm distal to the cervicovaginal junction. The colpotomy is then extended laterally with Heaney clamps (or a vessel-sealing device) and the vaginal angles are secured using figure-of-eight sutures. The rectovaginal septum can then be safely entered by incising the posterior vaginal wall **(**Fig. 185.11).

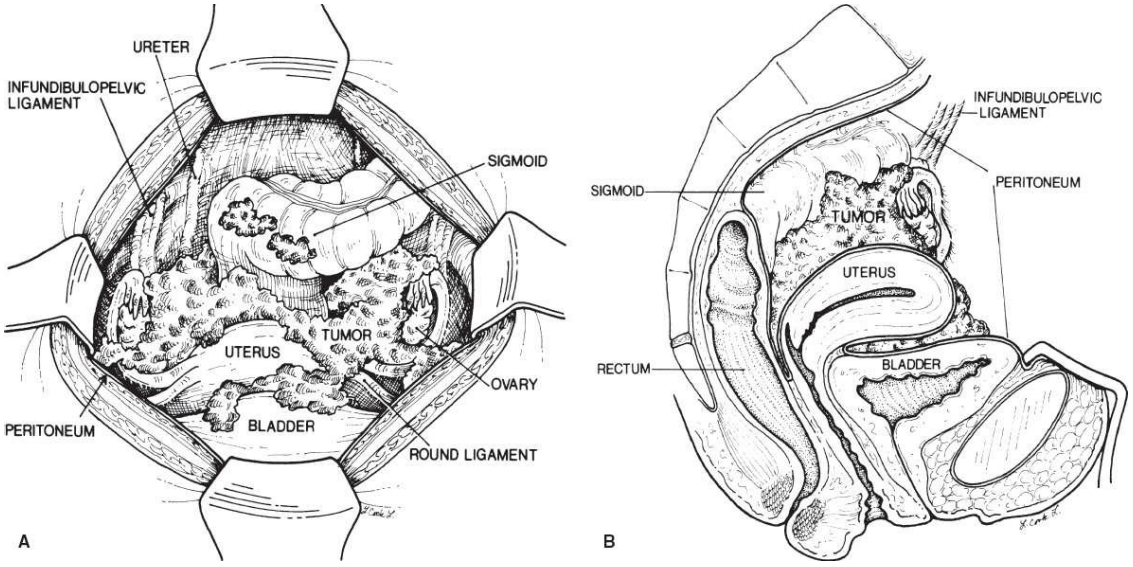

Figure 185.9. A. Anterior view of the pelvis at the time of initial abdominal exploration. **B.** Sagittal view of the pelvic cavity. The tumor obliterates all intraperitoneal tissue planes to the level of the cul-de-sac.

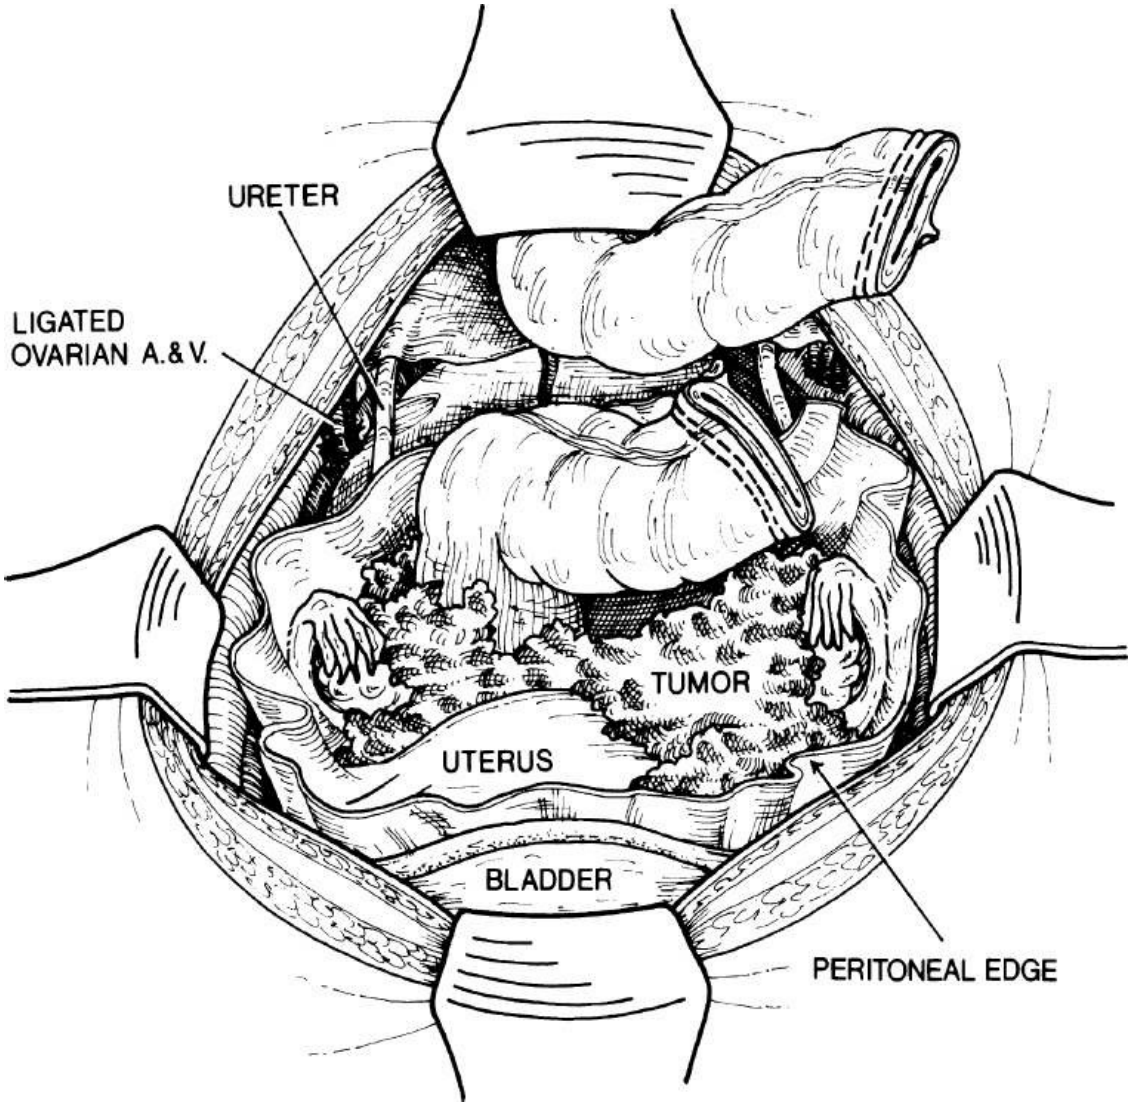

Figure 185.10. The pelvic dissection is started at the pelvic side walls, freeing the ureters laterally and dissecting the peritoneum from the bladder muscularis. The infundibulopelvic ligaments are ligated above the pelvic brand after identification of the ureters.

Depending on the degree of tumor involvement, the decision can be made to proceed with either a type 1 procedure (resection of the pelvic peritoneum including the peritoneum of the posterior cul-de-sac) or a type 2 procedure (resection of the rectosigmoid colon en bloc with the uterus and adnexa). If the decision is made to proceed with a type 2 resection, the rectosigmoid colon can be transected using a GIA stapler 2 to 3 cm proximal to the affected colon. The sigmoid mesentery and presacral peritoneum can then be incised and transected perpendicular to the long axis of the sigmoid and the superior rectal vessels identified, ligated, and divided (Fig. 185.12A,B). During mobilization of the left colon, care should be taken to preserve the left colic artery in order to maintain an

adequate blood supply to the descending colon. The rectum can then be dissected off of the presacral fascia after the development of the pararectal space using a combination of blunt dissection and electrocautery. Once the dissection is carried distal to the area of tumor infiltration, the specimen can be lifted ventrally and the mesorectal fat cleared from the site of transection. After reconfirming the location of the ureters and pelvic vessels, a TA stapler can be used to transect the rectum 2 to 3 cm distal to the area involved by tumor (Fig. 185.13). The rectum then can be anastomosed using an end-to-end stapling technique with a circular EEA stapler, with care to ensure that the anastomotic site is tension free, hemostatic, and secure, and has an adequate lumen and blood supply (Fig. 185.14). The integrity of the staple line is assessed by examination of the two rings of large bowel removed in the stapling device and by insufflating air into the rectum with a bulb syringe after filling the pelvis with warm saline, looking for bubbles issuing from a potential defect in the anastomosis. If there are any concerns regarding the integrity or perfusion of the anastomosis, a diverting loop ileostomy should be considered.

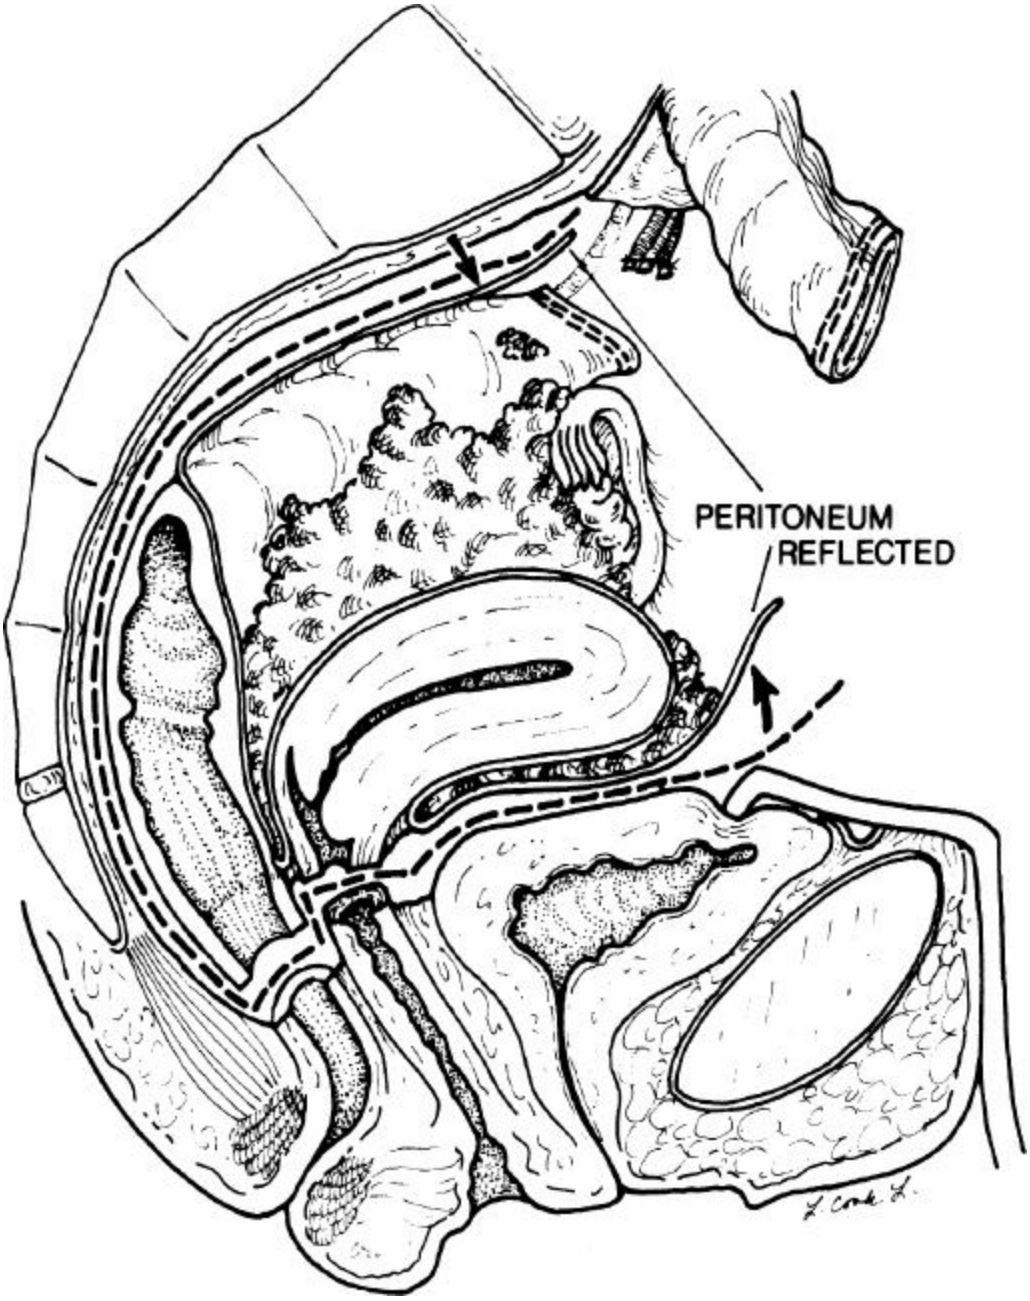

Figure 185.11. The *dashed line* indicates the plane of pelvic dissection. Beginning anteriorly, the peritoneum is dissected from the bladder. The hysterectomy is performed after lateral mobilization of the ureters and prior to its transection from the vagina, the rectovaginal space is bluntly developed.

Bowel Resection

It is important during the course of a debulking procedure to ascertain the degree of bowel resection required to ensure that adequate bowel remains for reconstruction and sufficient function. Approximately 35% of patients will require colon resection and 5% will require small bowel resection to achieve optimal cytoreduction. In addition to the rectosigmoid resection

(described above), patients may require a transverse colectomy, an ileocecal resection, an extended right or left hemicolectomy, or a small bowel resection. Proper mobilization of the colon is a crucial first step of a safe resection. The peritoneum overlying the paracolic gutters should be incised along the white line of Toldt and the colon reflected medially. The splenic flexure, hepatic flexure, and transverse colon can be further mobilized by transecting the gastrocolic ligaments and opening the lesser sac. The inferior mesenteric vein can be ligated and transected inferior to the pancreas to allow for greater descent of the mesentery. In general, the bowel can be transected using a GIA stapler, with care to maintain a adequate blood supply, and a tension-free, stapled, side-to-side or end-to-end anastomosis can be performed.

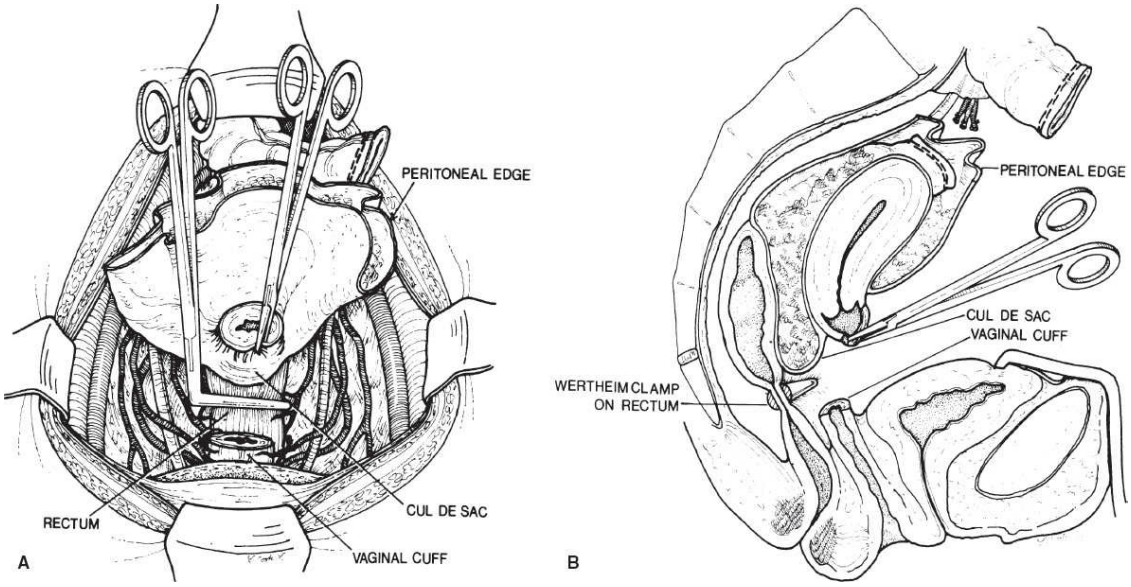

Figure 185.12. A. The entire peritoneal envelope including the anterior and posterior cul-de-sac with the cervix is retracted anteriorly so as to expose and skeletonize the upper rectum. **B.** The lateral view demonstrates the anterior and posterior exposure of the upper rectum levels facilitates transection of the upper rectum and removal of the specimen. Note that the Wertheim clamp is placed above the point of resection.

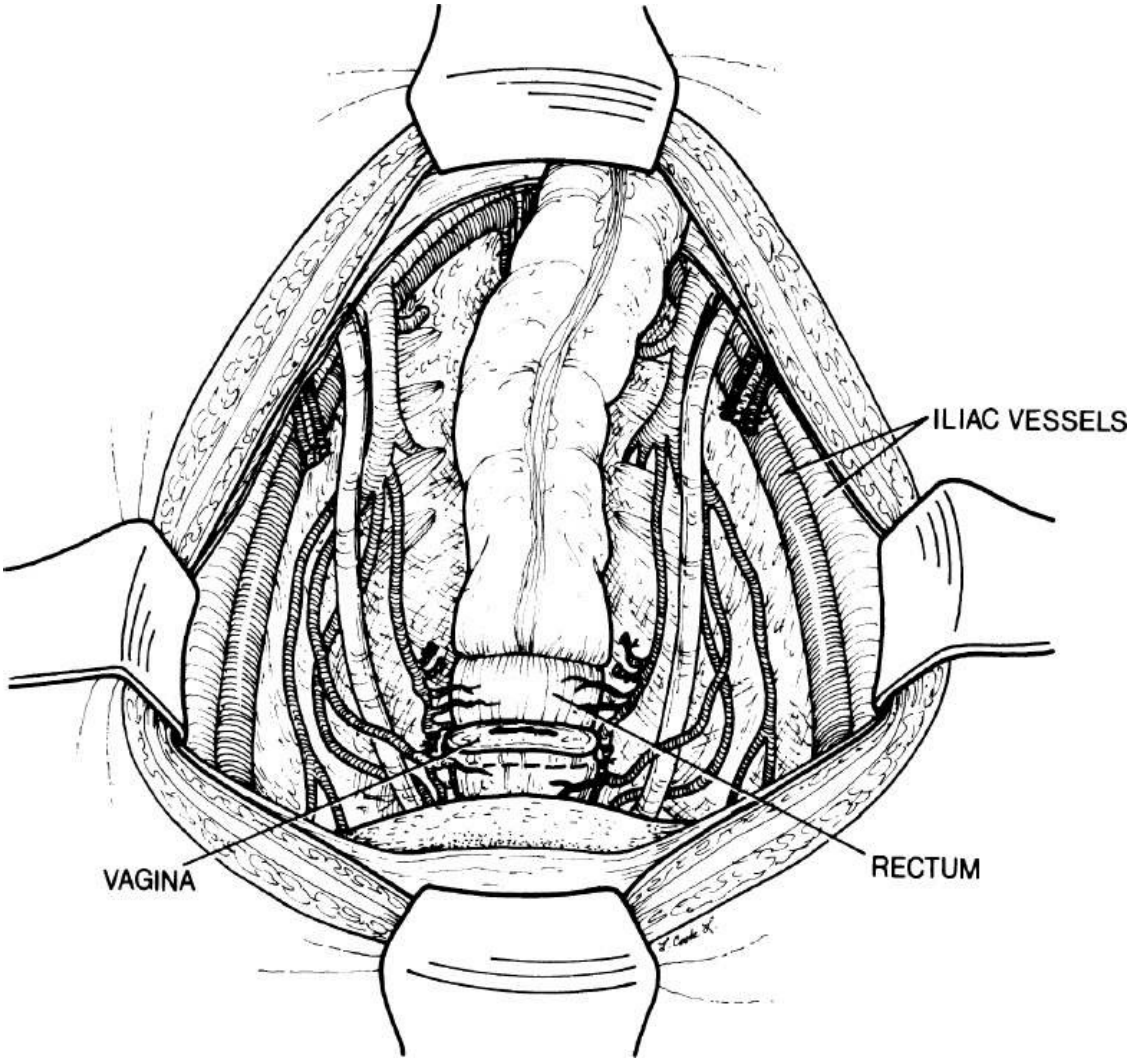

Figure 185.13. Anterior view of the pelvis at the procedures completion. All pelvic peritoneum, associated tumor, lymph nodes, and the intrapelvic peritoneal organs have been removed.

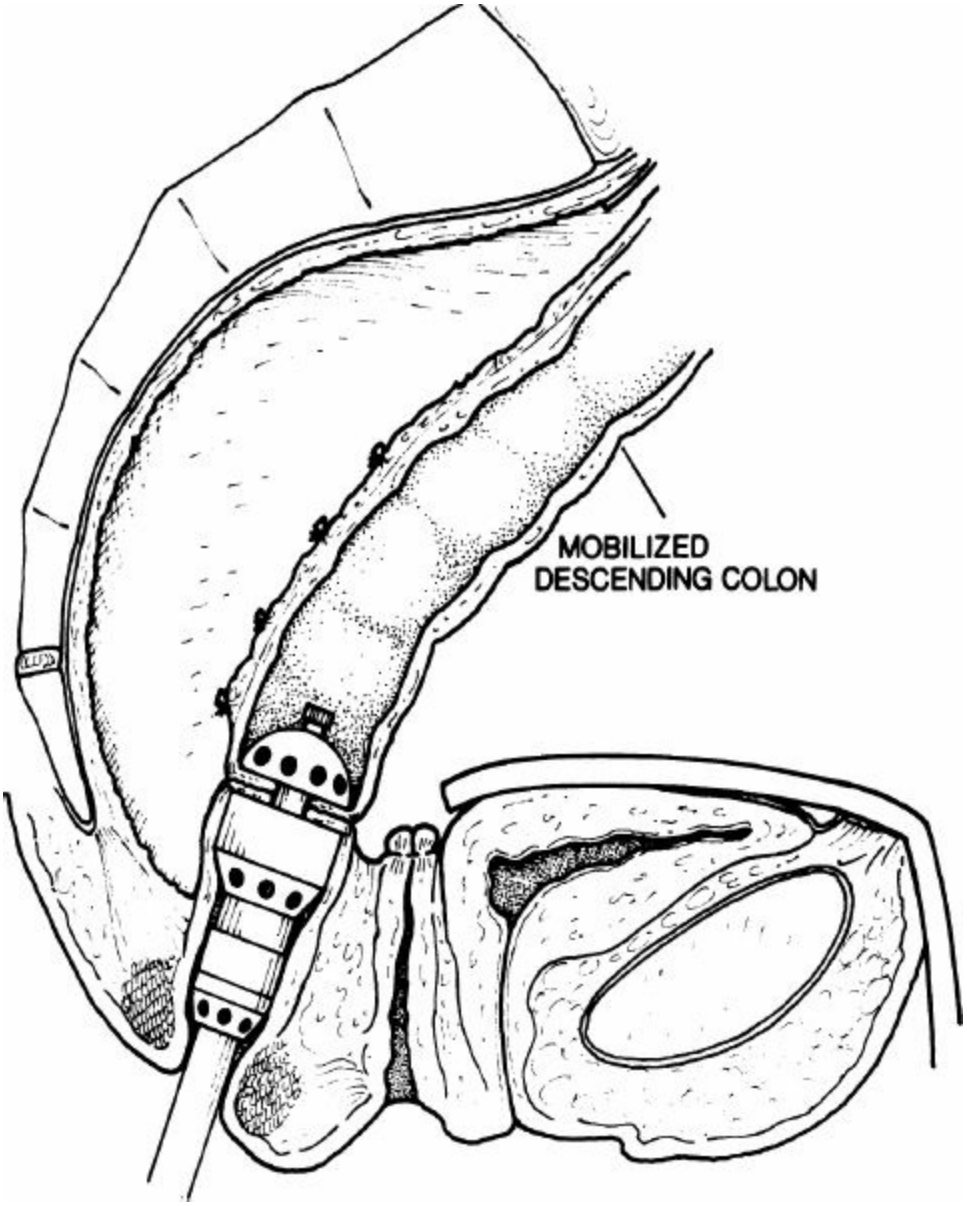

Figure 185.14. The distal end of the rectosigmoid is transected and stapled below the tumor; bowel continuity is restored using an EEA stapling device.

Rarely, one is faced with bulky tumor affecting virtually all of the left colon to the mid portion of the transverse colon. In this case, the appropriate maneuver is to derotate the ascending colon, allow the cecum to move cephalad into the midabdomen, and bring the proximal transverse colon down to a transanal anastomosis with the residual rectosigmoid colon.

Lymphadenectomy

In patients with grossly advanced disease (stage IIIC or IV), we recommend routine removal of any enlarged or grossly abnormal lymph

nodes in the pelvis, abdomen, or chest. If there is extensive adenopathy, then it is prudent to mobilize the root of the small bowel mesentery medially over the aorta and vena cava and reflect the entire small bowel and ascending colon into the upper abdomen. This provides exposure and permits excellent access to the entire infrarenal vasculature. On the right side, it is possible to elevate the cecum and descending colon as well as the root of the distal small bowel in a cephalic direction to expose the vena cava, right side of the aorta, and left renal vein. Again the nodes are dissected from a caudal to cephalic direction to the level of the origin of the right gonadal vessels. In patients with extensive, bulky para-aortic nodal disease, it is not unusual to find nodal metastases in the aortocaval sulcus, posterior to the vena cava, and posterior to the aorta on the left. On the right side, one can first mobilize the hepatic flexure and then perform a Kocher maneuver to improve access to the upper infrahepatic IVC. One can also explore the right side of the aorta through the lesser sac (Fig. 185.15).

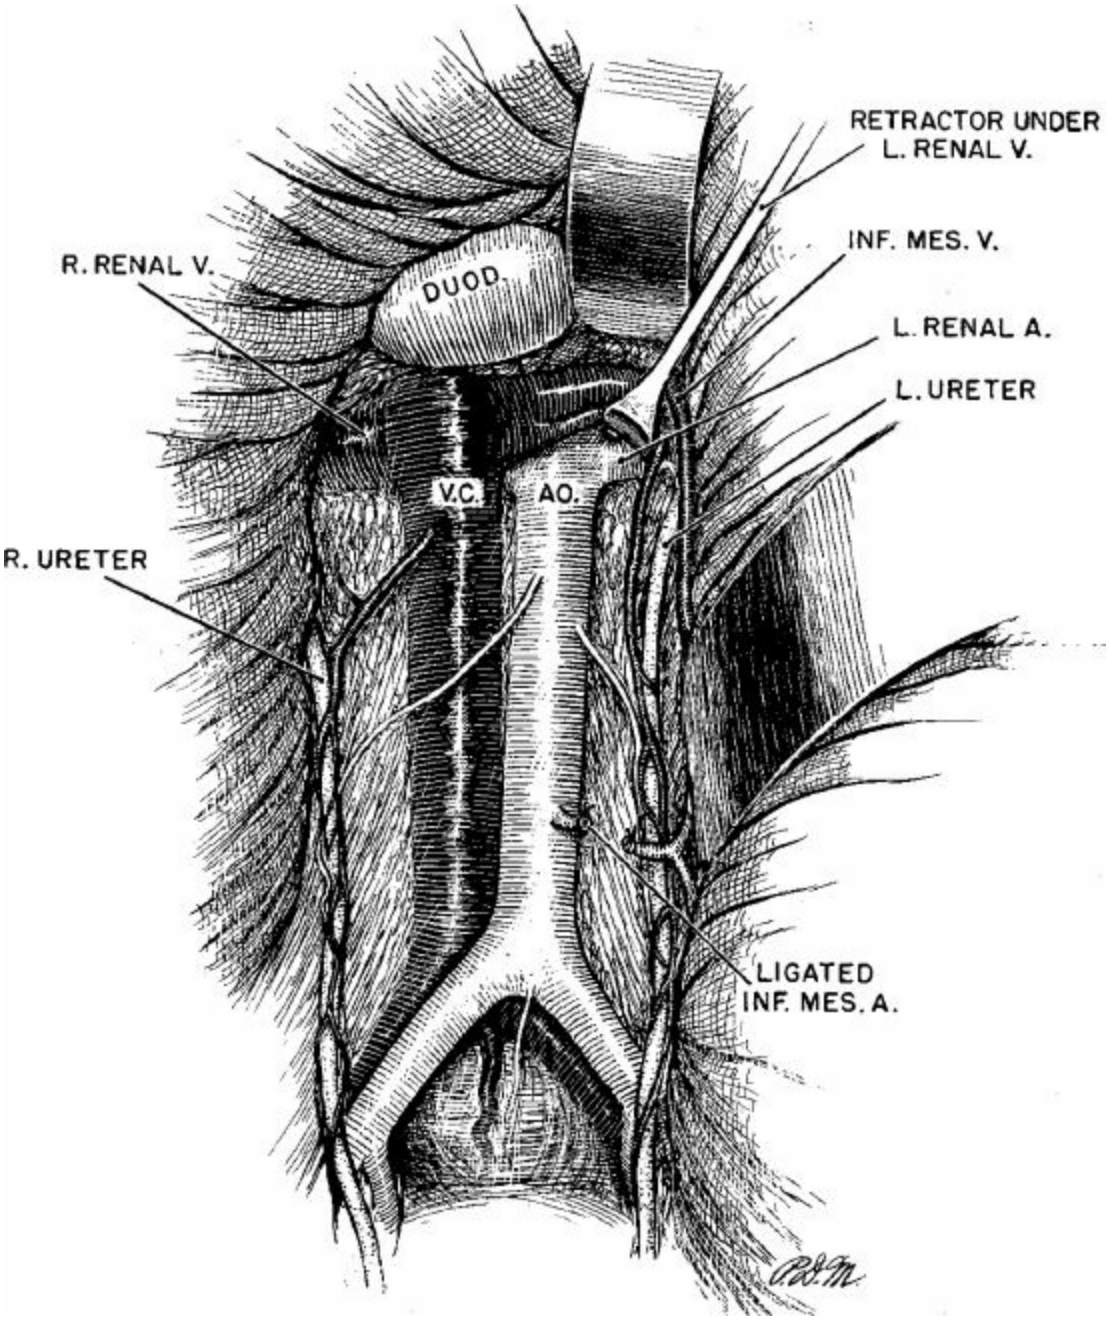

Figure 185.15. Exposure of the right para-aortic area is facilitated by cephalic reflection of the cecum. *Note that the right ureter normally lies immediately adjacent to the inferior vena cava. In this dissection, the sigmoid and descending colon had been resected, along with the inferior mesenteric artery.* (From Edwards EA, Malone PD, MacArthur JD. *Operative Anatomy of the Abdomen and Pelvis*. Philadelphia, PA: Lea and Febiger; 1975.)

Exposure of the left para-aortic nodes is facilitated by medial mobilization of the descending colon and associated left ureter. In patients in whom nodal metastases extend above the left renal vein, medial

reflection of the descending colon from the splenic flexure down may not provide sufficient exposure. In this case, one can mobilize the spleen and pancreas medially to expose the nodes about the celiac axis and superior mesenteric artery on the left (Fig. 185.8). Mobilization of the left kidney on its pedicle will similarly give access to the upper retroaortic area. The dissection of bulky nodes along the left side of aorta from its bifurcation up to the left kidney (and sometimes behind its pedicle) often results in a functional equivalent of a left lumbar sympathectomy. It is not unusual to be told postoperatively of concern for the vascular compromise of a cool right foot when what one is truly seeing is an abnormally well-perfused warm left foot secondary to sympathectomy. If there is more extensive disease in the suprarenal retroperitoneum, reflection of the LUQ contents, including the spleen, will provide optimal access to the celiac axis and posterior left diaphragm.

Mediastinal lymphadenectomy has been shown to be feasible and safe and frequently can be accomplished through the abdominal incision (with the assistance of a cardiothoracic surgeon if needed). In patients without evidence of advanced disease, a full staging lymphadenectomy should be performed up to the level of the renal vessels. The utility of removing normal appearing lymph nodes in the setting of grossly advanced disease is unknown and left to the discretion of the operating surgeon. In a prospective European trial for advanced ovarian cancer, there was no difference in overall survival between patients having selective removal of enlarged pelvic and abdominal lymph nodes and those having complete pelvic and para-aortic lymphadenectomy. Clearly however, it is important to remove any macroscopically enlarged lymph nodes, if they represent the largest site of residual disease.

Placement of an Intraperitoneal Catheter

If optimal cytoreduction is achieved, the placement of an intraperitoneal catheter should be routinely performed for infusion of adjuvant chemotherapy. If there are doubts intraoperatively about the patient’s candidacy for intraperitoneal chemotherapy, we recommend proceeding with placement, as removal can be safely performed under local anesthesia in the clinic. Options include the 9.6-Fr vascular catheter versus a 14-Fr fenestrated catheter and intraperitoneal reservoir.

Ideal placement is in the midclavicular line in the RUQ or LUQ over the distal ribs. A 4-cm transverse incision is made and carried down to the fascia, at which point blunt dissection can be used to make a pocket to

accommodate the reservoir of the port. A long, fine-tipped clamp can be used to create a tunnel from the incision into the mid abdomen (under direct visualization while elevating the abdominal wall). This clamp can be used to grasp the catheter tubing and pull it back through the incision. The tubing should be trimmed, and the reservoir attached as directed by the manufacturer. The port should then be flushed with heparinized saline, and each component examined for patency and leaks. Delayed absorbable sutures can be used to secure the reservoir to the fascia. Finally, the incision can be closed in layers.

Closure

Women with advanced ovarian cancer have been shown to be at high risk for the development of incisional hernias, especially if they go on to receive intraperitoneal chemotherapy. Abdominal closure should be performed with a continuous running delayed absorbable monofilament suture (we recommend No. 1 looped polydioxanone) with a suture length to wound length ratio of at least 4:1. Randomized data suggest that sutures should be placed 5 to 8 mm from the fascial edge to decrease the amount of tissue necrosis. Subcutaneous tissue should be copiously irrigated and closed after hemostasis is assured.

Postoperative Complications

Complications after extensive CRS are extremely common, and the prompt identification of these complications is an important aspect of postoperative care. Single-center data quantified the mortality rate after debulking surgery in advanced ovarian cancer between 1.4% and 2.5%, which compares favorably to population-based studies, with a mean mortality rate of 3.7%. Risk factors for higher mortality in these studies are age, performance status, and comorbidities, as well as emergency treatment compared to patients who were treated electively.

Because of the length and extent of surgical effort, many patients will require intensive care unit (ICU) admission for postoperative fluid management and supportive care. Malnutrition, ascites, and comorbidities should all be considered high-risk features for needing postoperative ICU care. The following list highlights some of the most commonly experienced complications following CRS, in addition to some clinical pearls regarding their diagnosis and management.

Infectious Complications

On physical exam in the first several weeks after surgery, patients should be monitored closely for fever, elevated white blood cell count, and abnormalities in pulse or blood pressure.

Wound infection

- Cellulitis frequently resolves with antibiotic treatment alone; however, we recommend opening surgical wounds to facilitate the drainage of underlying collections in the setting of cellulitis that persists despite appropriate antibiotic therapy, purulent drainage, or fluctuance on exam. Twice daily wet-to-dry dressing changes can be utilized until the infection resolves, at which point a wound vacuum system can be placed to expedite healing.

Hospital-acquired pneumonia

Intra-abdominal or peritoneal abscess

- Should be considered in the setting of unexplained leukocytosis, fever, prolonged ileus, or failure to spontaneously diurese by postoperative day 7. Most abscesses can be managed with intravenous antibiotics and interventional radiology drainage.

Peritonitis/Sepsis

- If peritoneal signs or sepsis is suspected, workup should include CT scan with contrast to identify any possible areas of bowel injury or anastomotic compromise.

Hematologic Complications

Bleeding/Coagulopathy

- Usually occurs within 24 to 48 hours of surgery. Monitoring of vital signs, blood counts, and coagulation profiles should allow for prompt identification. If aggressive transfusion of blood products fails to stabilize the patient and resolve coagulopathy in a timely fashion, prompt reoperation may be necessary. If there are any postoperative concerns about hemodynamic stability, patients should be observed and managed in an ICU setting.

Venous thromboembolism (VTE)

- Patients undergoing surgery for advanced ovarian cancer are at extremely high risk for VTE. Acute shortness of breath, hypoxia, unexplained tachycardia, or lower extremity tenderness/edema (especially if unilateral) should prompt a workup. We recommend that all patients receive postoperative prophylactic anticoagulation therapy after CRS (unless significant concerns exist regarding active bleeding or coagulopathy). Consideration should be given to provide the patient

with an extended course (4 to 6 weeks) of anticoagulants at discharge.

Cardiovascular Complications

Intravascular depletion and third spacing

- Extremely common in women with advanced ovarian cancer, especially in the setting of large-volume ascites. To assess renal perfusion, urine output should be monitored closely with a Foley catheter and serum creatinine tests. Most patients will begin to spontaneously diurese within 3 to 4 days after surgery. In our experience, failure to diurese within 7 days postoperatively may indicate an infectious or other significant intra-abdominal process.

Respiratory Complications

Pneumothorax

- All patients undergoing diaphragm resection/peritonectomy should have a chest x-ray in the recovery room to assess for pneumothorax. If sudden symptoms of dyspnea or hypoxia occur at any time postoperatively, a workup should include a repeat chest x-ray.

Pleural effusions

- The development of pleural effusions after liver mobilization and diaphragm peritonectomy/resection is extremely common, especially in patients with ascites. Routine chest x-ray can be used to diagnose and follow postoperative pleural effusions. If a symptomatic effusion develops, patients may benefit from thoracentesis or the placement of a chest tube or drainage catheter. If a chest tube was placed intraoperatively, the output should be followed closely. We recommend continuing chest tube drainage until output is <200 cc per day on straight drainage alone.

Gastrointestinal Complications

Ileus/Obstruction

- Postoperative ileus is extremely common, especially in patients who require bowel resection or extensive mobilization of the bowel. While we generally encourage early postoperative refeeding, the initial step in the management of postoperative nausea and vomiting should be bowel rest. In the majority of cases, postoperative ileus will resolve with bowel rest and nasogastric decompression. In our experience, limiting narcotics and fluid overload can also decrease the incidence, severity, and duration of ileus. Similarly, small bowel obstruction in the acute

postoperative setting will frequently resolve with conservative management (bowel rest and nasogastric decompression). However, surgical management may be required if these conservative measures fail. Parenteral nutrition should be considered in patients who require >5 to 7 days of bowel rest postoperatively.

Anastomotic leak

- In the setting of peritonitis, sepsis, drainage of enteric contents from surgical drains or incisions, unexplained fever, or persistent leukocytosis, a CT scan should be obtained to evaluate all sites of anastomosis. In unstable or septic patients, prompt reoperation is generally required. In stable patients without evidence of sepsis or peritonitis, anastomotic leaks may be amenable to nonsurgical management with drainage, intravenous antibiotics, and in some cases, endoscopic stent placement or repair.

Pancreatic leak/Pancreatitis

- In patients who underwent splenectomy or distal pancreatectomy, fever, nausea/vomiting, or unexplained leukocytosis may indicate a pancreatic leak. If a surgical drain was left in the LUQ, monitoring of daily output and drain amylase may assist in the early identification of a leak (if drain amylase >3× serum amylase). In addition to bowel rest and drainage, somatostatin can be used to manage a postoperative pancreatic leak.

EDITOR'S COMMENT

Readers of *Mastery of Surgery* may question the relevance or usefulness of a chapter on ovarian cancer for a general or abdominal surgeon; however, this is an important topic in which to stay current, simply because this is a commonly encountered abdominal cancer and the fifth most common cause of cancer death in women in developed countries (Siegel RL, Miller KD, Jemal A. Cancer statistics, 2017. *CA Cancer J Clin* 2017;67(1):7–30). Metastatic ovarian cancer can also be a source of large bowel obstruction, and as the authors discuss, bowel resection due to direct involvement by ovarian cancer can be necessary in up to 35% of patients (see also Chapter 143 "Large Bowel Obstruction"). Because of its different treatment and sensitivity to chemotherapy, it is important that all abdominal surgeons be aware of this and appropriately treat this cancer when it is incidentally encountered at laparotomy. In addition, the general abdominal or colon and rectal surgeon may be asked to assist the gynecologic or gynecologic oncologic surgeon in operations involving such cancers, and should for this reason also have a basic familiarity with this

cancer's behavior and treatment. In one study, rectosigmoid resections were the most frequently performed colorectal intervention performed during operations for gynecologic malignancy (Bedirli A, Mentes BB, Onan A, et al. Colorectal intervention as part of surgery for patients with gynaecological malignancy. *Colorectal Dis* 20057(3):228–31).

Gynecologic oncology is one of the true remaining "generalist" fields where the surgeon still "does it all." In other words, the gynecologic surgeon evaluates his or her patient preoperatively, performs the staging and surgery, and also administers the systemic or intraperitoneal chemotherapy. This is one of the true bastions for the all-encompassing physician-surgeon who has total charge of his patient! There are many laudable aspects to this type of care in terms of continuity of the doctor–patient relationship—the knowledge of exactly where the cancer was and knowing where a recurrence is likely to occur, and a willingness to reoperate if needed. These facets of care are not always present when surgery and follow-up adjuvant therapy are performed by different physicians, as is often the case with other types of cancers.

Ovarian cancer often has a poor prognosis primarily because only one third of patients have reasonably localized disease when the cancer is diagnosed. Its silent nature has been a clinical problem and recognized for nearly one hundred years. Despite extensive research on this subject, still many false positives exist with CA-125 as well as abdominal ultrasound. Simply stated, presently there are *inadequate* biomarkers for screening for ovarian cancer. The abdominal or colon and rectal surgeon should be alert to family history that may indicate an increased risk of ovarian cancer such as in patients with Lynch syndrome that may be on the order of 10% in MSH2 mutation carriers (Nakamura K, Banno K, Yanokura M, et al. Features of ovarian cancer in Lynch syndrome (Review). *Mol Clin Oncol* 2014;2(6):909–16). In addition, when operating upon postmenopausal women with colorectal cancer, the patient should always be asked regarding the option of oophorectomy. Although the incidence of colorectal metastatic disease to the ovaries is low, one study suggested a survival benefit (Young-Fadok TM, Wolff BG, Nivatvongs S, et al. Prophylactic oophorectomy in colorectal carcinoma: preliminary results of a randomized, prospective trial. *Dis Colon Rectum* 1998;41(3):277–83; discussion 283–5). Elective oophorectomy in such patients is a relatively quick and low-risk procedure.

A classic situation likely to confront a general surgeon who has just discovered unexpected ovarian cancer with limited metastasis at the time of a laparotomy to address suspected appendicitis or diverticulitis, or some other common abdominal illness. Although the operation is one that is conducted for suspected alimentary tract disease, seldom there will have been any preoperative studies except a chest x-ray. The authors in this text stress the importance of considering fertility preserving procedures—here the important item is, of course, whether the general or abdominal surgeon **is aware of them**! Obviously, nothing can be done once the ovaries have been removed. More

often than not, there will *not* be a gynecologic oncologist available for consultation at the time of an often urgent operation. Therefore, one needs to deal thoughtfully and carefully with the family, hopefully including the spouse as to what are the best options. It is always best to note the extent of the disease, obtain a tissue diagnosis if possible (omental or peritoneal implants), peritoneal cytology, and carefully examine the abdomen for any other disease. This should include the pelvis, omentum, upper abdomen, liver surfaces, diaphragms, and both left and right paracolic gutters.

One of the most difficult situations a surgeon will encounter is that of a patient with a recurrent ovarian carcinoma and malignant bowel obstruction. These are often the most challenging patients for which to care. There is currently a paucity of data particularly with respect to quality of life to guide treatment of these patients as to which is the best therapy. Colonic stenting has been shown to be associated with both low technical and clinical success in this particular group of patients (Trompetas V, Saunders M, Gossage J, et al. Shortcomings in colonic stenting to palliate large bowel obstruction from extracolonic malignancies. *Int J Colorectal Dis* 2010;25(7):851–4). A Cochran analysis comparing medical versus surgical palliation for bowel obstruction due to ovarian cancer found low-quality evidence and only one study met inclusion criteria (Kucukmetin A, Naik R, Galaal K, et al. Palliative surgery versus medical management for bowel obstruction in ovarian cancer. *Cochrane Database Syst Rev* 2010;7:CD007792. doi: 10.1002/14651858.CD007792.pub2). Weak evidence supported surgical management. Barton suggested that the absence of an abdominal pelvic mass, ascites, multiple levels obstruction, and weight-loss exceeding 9 kg could be used to help select cases for surgical palliation (Kolomainen DF, Barton DP. Surgical management of bowel obstruction in gynaecological malignancies. *Curr Opin Support Palliat Care* 2011;5(1):55–9). As with many things in surgery, clinical judgment remains the key to selecting which patients benefit most from surgery. Given the limited patient prognosis in this setting, a consult with family and palliative care physicians is indicated, and frank discussions with family regarding the high risk of postoperative complications is warranted.

Dionysios K. Veronikis

CYSTOCELE

The biggest imitator of anterior complex, combined vaginal segment defects is a cystocele. Genital prolapse and especially the anterior vaginal segment remains one of the most challenging aspects of reconstructive pelvic surgery. Anterior segment prolapse, the cystocele, is due to inadequate support and/or insufficient stabilization at rest or during increases in intra-abdominal pressure. Paravaginal defects refer to disturbances in the attachment of the anterior sulcus of the vagina to a connective tissue "bridge" attaching the anterior sulcus to the arcus tendineus fascia pelvis. The paravaginal defect clinically presents as a cystocele due to a lateral separation of the vaginal wall attachments from the lateral pelvic sidewall(s). According to Bayden and Walker, such a detachment should be suspected when the anterior vaginal wall is relaxed. If there is no elevation of the anterior vaginal wall when the patient squeezes the pelvic musculature, the connective tissue and vascular supports of the anterior vaginal wall may have been detached from the arcus tendineus fascia pelvis. The lateral vaginal wall is not attached directly to the arcus tendineus fascia pelvis; instead, the anterior vaginal sulcus is attached to the arcus tendineus fascia pelvis by a meshwork of intervening connective tissue—a connective tissue "bridge." This intervening connective tissue may be subject to various strains and stretching and partial or complete avulsion. This type of strain is more common in parous patients as a consequence of trauma during labor and delivery and perhaps can also be attenuated, stretched, or avulsed with pull of massive genital prolapse, even in the nulliparous woman.

In 1905, Ernest W. Hey Groves published a paper entitled "bridge." He stated in this manuscript that "If we regard the cystocele as a hernia, whose radical cure we have to undertake, it is not surprising that methods which depend for their success upon the fixation of so distensible a structure as

the vaginal wall should lead to failure." He explained that "vaginal cystocele exists under two conditions, that in which it only forms part of a uterine descent, and that in which it forms a distinct hernia or pouch, pushing the vagina before it, but leaving the uterus in a normal position." He further described the levator ani muscle complex, the "bridge" of the pelvis fascia, and its insertion. Although the description of his operative repair is not completely clear, he described the following: "A transverse incision is made from one labium majus to the other, about 3 cm behind the urethral orifice. The incision divides the whole thickness of the vagina…The margins of the levatores ani muscles are then sought for and defined in either angle of the wound. It will be found that they can easily be brought into apposition with little or no tension."

The first description of lateral cystocele repair incorporating the arcus tendineus fascia pelvis into the cystocele repair was by George R. White in 1909. White performed this repair on 19 patients over a 3-year period, as he stated always in connection with some other plastic operation.

White's classic paper described a surgical procedure that was designed to correct cystocele—a radical cure—by attaching the lateral vaginal sulci to the arcus tendineus fascia pelvis. One has to wonder what is meant by the term "bridge" because it could conceivably include as much a displacement cystocele from lateral detachment as a displacement cystocele from an apical prolapse. White's 1909 paper did not receive much attention, and he again reported his views in 1912. Interestingly, based on cadaver dissections, White wrote, "The easiest and simplest way to accomplish this is to incise the peritoneum at the side of the bladder, push the bladder aside until the white line comes into view, and then by the aid of an assistant's finger in the vagina, suture the anterior lateral side of the vagina to the white line of the pelvic fascia." Almost 50 years later, in 1961, John Christopher Burch, in performing a Marshall–Marchetti–Krantz operation, was unable to secure the sutures to the periosteum and concomitantly noticed the intravaginal finger elevating the vaginal wall to the "bridge"—the arcus tendineus fascia pelvis. After seven successful procedures he felt that the Cooper ligament was a stronger attachment point. The paravaginal defect and its repair as we know it today were redescribed by Richardson through an abdominal retropubic exposure instead of the original transvaginal approach used by White.

CYSTOCELE AND THE PARAVAGINAL DEFECT

Cystocele is a consequence of trauma/damage to the vagina, to the apical vaginal supports, to the lateral vaginal attachments, or to the vaginal wall itself. In examining and evaluating the anterior vaginal wall one must have in mind that there are several distinct types of cystoceles and each may contribute partially or totally to anterior segment defects. All of the existing combinations must be recognized and corrected if surgical treatment is to be effective and durable.

Cystocele has been described according to whether it is anterior to the interureteric ridge (anterior cystocele) or posterior to it (posterior cystocele). Anterior cystocele is synonymous with urethrocele, in which straining or Valsalva efforts result in downward bulging or rotational descent of the urethra with or without a demonstrable tendency of the bladder to "bridge" behind the vesicourethral junction. The distal third of the vaginal wall and attachments underlie and support the urethra. This rotational descent of the vesicourethral junction may be of varying degrees and is often associated with urinary incontinence. Pathologic dilation of the midurethra and/or distal urethra (true urethrocele) is quite uncommon. A true cystocele therefore does not include the distal vagina. Similarly, in patients with an intact cervix and uterus, the cervix occupies the upper third or so of the anterior vaginal wall. The length of the anterior vaginal wall plus the length of the cervix roughly equals the length of the posterior vaginal wall. Thus, a distention cystocele is between the bladder neck and cervix. A distention cystocele (Fig. 186.1) is almost without exception the result of an overstretching of the vaginal wall beyond its ability to recover/involute after vaginal delivery, or the consequence of the atrophic changes of aging upon the intrinsic structural components of the vaginal wall with or without earlier damage. Rugal folds once visible on the anterior vaginal epithelium diminish with aging and may disappear as the physiologic/pathologic changes behind the squamous epithelium and within the vaginal wall deep to the squamous epithelium progress. These processes allow the anterior vagina and bladder to "bridge" into the vaginal lumen. In a true distention cystocele the lateral attachments of the vagina are well supported. The transverse topographic length from vaginal sidewall to vaginal sidewall is increased. Therefore, almost without exception the true distention cystocele is the result of attenuation of the anterior vaginal wall. The vagina is an organ that responds to physiologic forces as well as pathologically with the same response, that is, by stretching.

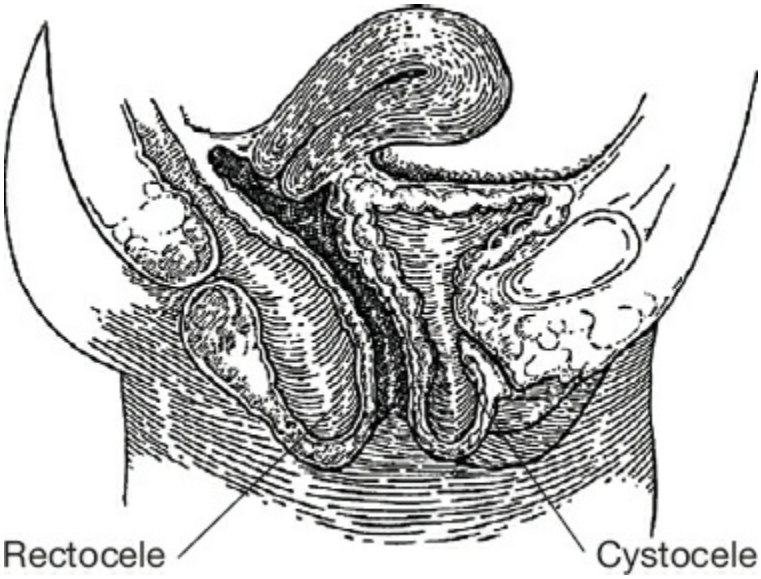

Figure 186.1. Sagittal section showing distention cystocele and rectocele. Note that the vaginal vault and uterus are at a normal position within the pelvis.

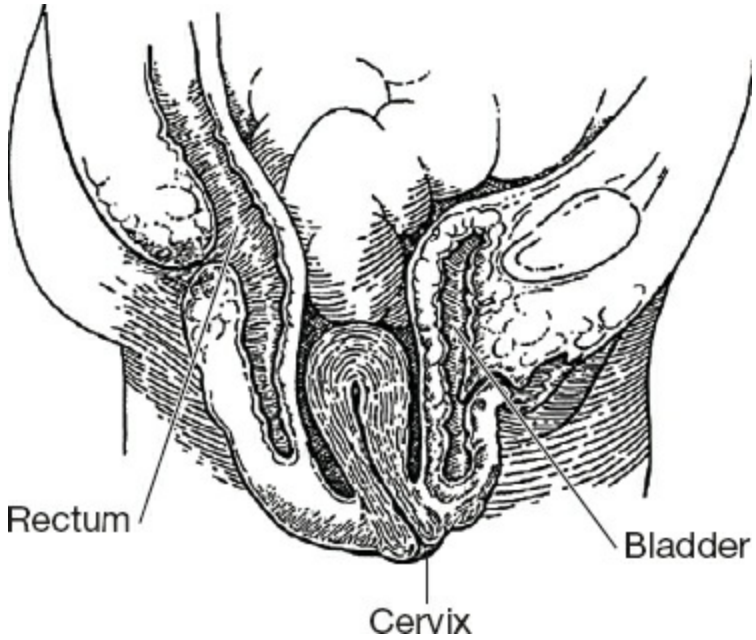

Figure 186.2. Sagittal section showing displacement cystocele, the result of a massive eversion of the vaginal apex and uterus. This represents a procidentia. Note the position of the small bowel entering the pelvic inlet.

Lateral displacement cystocele (Fig. 186.2) is the result of pathologic elongation or detachment of the lateral vaginal attachments and support of the vagina. Etiologically, this is quite different from distention cystocele caused by connective tissue damage to the normal vaginal wall. The

anterior vaginal segment also has superior attachments to the cervix. Thus, the tissues supporting both the vagina and cervix are component parts of the cardinal ligaments and function as an anatomic unit. Displacement of one component is often followed by similar displacement of the other. Posthysterectomy eversion or prolapse of the upper vagina may also present as displacement cystocele by creating a "bridge." If the upper vaginal segment does not descend, there cannot be a telescoping effect or an apical displacement cystocele. In its pure form, the displacement cystocele represents an eversion of the vagina with relatively well-preserved rugal folds. The loss of support of the lateral vaginal attachments can be unilateral or bilateral.

Preserved rugae with descent of the anterior vaginal wall suggests a defect of the connective tissue structures that support the vagina and urethra bilaterally at the lateral pelvic wall along the arcus tendineus fascia pelvis. This type of anterior segment defect is a displacement cystocele as is a cystocele from an upper vaginal vault prolapse. Descent of the upper vagina halfway between the ischial spines and hymen may easily be corrected by a surgical procedure directed only at the vaginal apex. Clinically, when the sulci disappear partially or completely, a paravaginal defect is coexistent. When one is evaluating the anterior segment, it is essential to determine whether the vaginal vault is partially or completely prolapsed, adding to the magnitude of a displacement cystocele. In addition, with the vaginal vault replaced one must consider the extent of distention cystocele as well as the extent of "bridge" displacement cystocele by the vault prolapse. Any coexistent paravaginal defects are then and only then evaluated. To reposition the vaginal vault to the ischial spines with a ring forceps and label it a pure lateral displacement cystocele is an error in diagnosis. Yet, often our residents, referring colleagues, and patients call a posthysterectomy vault prolapse a "bridge" cystocele! Hence, the biggest imitator of a cystocele in a posthysterectomy patient is an apical vaginal segment prolapse.

It is essential that the surgical gynecologist contemplating surgical repair of anterior segment defects take into consideration that "bridge" forms of individual anterior segment defects rarely occur. As a general rule, anticipate a combination, that is, a "bridge" of the above types of defects.

DIFFERENTIAL DIAGNOSIS OF ANTERIOR SEGMENT

DEFECTS

Examination of the patient with genital prolapse is facilitated by forceful Valsalva maneuver, especially in the standing position, in order to delineate defective vaginal sites that manifest themselves better under stress as well as the extent and magnitude of all defects. However, paravaginal defects are best evaluated in the lithotomy position initially at rest and then with forceful Valsalva maneuver to fully visualize descent of the anterior vaginal wall. Subsequent evaluation must analyze the site or sites of defects with repositioning of the sulci, as well as all other pelvic support defects if durable and long-term support of the anterior segment is to be obtained.

The importance of the damage caused by each component of the anterior vaginal segment may be noticeable at different levels within the anterior vaginal depth. Therefore, where are paravaginal defects along the vaginal depth? If we topographically divide the anterior vaginal segment into thirds, the paravaginal defects are in the middle third of the vagina. DeLancey examined vaginal support in cadavers that had previously undergone hysterectomy as well as cadavers with the uterus in place in order to study the relationship of vaginal support to uterine support, and vaginal support following hysterectomy. The structures that supported the vagina were divided into three levels corresponding to different areas of support: levels I, II, and III. Although these three levels of vaginal support are continuous, surgically we repair each of these three areas with different operations. We can almost select a surgical procedure and place it in one of these three levels.

One approach in evaluating patients with genital prolapse is for the initial assessment to be focused on the apical supports of the vagina. Descent of the vaginal apex or cervix suggests loss of connective tissue support between the vagina and the parametria, a level I defect. An undiagnosed partial vault prolapse may be spuriously treated surgically as a cystocele due to the telescoping effect of the anterior vaginal segment (from loss of apical support) in patients who have undergone hysterectomy. This apical defect is very frequently associated with a midline defect of the vaginal wall (distention cystocele).

The literature in reconstructive pelvic surgery has not clearly stated the incidence and coassociation of paravaginal defects in patients with primary and recurrent prolapse. Richardson reported that about 85% of the cystoceles with descent of the anterior vaginal segment in his patients and

more than 95% of the cystourethroceles with stress incontinence were caused by a paravaginal defect. Therefore, 95% of his patients were treated with paravaginal defect repair.

Topographically dividing the anterior vagina into thirds permits evaluation of four distinct areas. This provides a useful paradigm that focuses on the defects and the surgical treatment that can be applied to their repair. As stated by DeLancey, these three levels of vaginal support are continuous with one another and therefore interdependent. The midvagina, level II, relies on a well-supported upper vagina (level I) to prevent an apical displacement cystocele due to a telescoping effect of the anterior vaginal wall. As long as support of the upper vagina (level I) is intact, a “bridge” or anterior segment defect is a support defect at level II. Surgical correction of level I may be performed vaginally by unilateral or bilateral sacrospinous colpopexy—the Mayo-McCall culdoplasty—or an abdominal sacrocolpopexy. On the other hand, level III corresponds to the region of the vagina that extends 2 cm from the introitus to 3 cm above the hymenal ring and is fused with the surrounding structures. This is the area of the bladder neck—the urethrocele. In patients with total prolapse of the anterior vaginal wall and apex, urinary continence may be achieved by a “bridge” effect of the urethra. Reducing the cystocele and restoring the anatomic relationships of the anterior vaginal segment unmasks urinary incontinence.

Thus, the midportion of the anterior vaginal segment, level II, requires careful clinical evaluation because this is the site of both the midline distention cystocele and the lateral displacement cystocele (paravaginal defect). Therefore, a true cystocele develops because of midline damage to the anterior vaginal wall and/or to the lateral connective tissue supports of the bladder and arcus tendineus fascia pelvis. Attenuation and breaks in the connective tissue and/or the muscularis of the anterior vaginal wall within level II results in descent of the anterior vaginal wall into the vaginal canal as a space-occupying mass, that is, the cystocele. Since the distance from the left arcus tendineus fascia pelvis to the right arcus tendineus fascia pelvis is a fixed distance, any increase in the transverse anterior vaginal wall dimension along the length of level II will cause the anterior vaginal wall to bulge into the vaginal canal. Hence, an analogy can be drawn with respect to two fixed points such as clothesline poles and the clothesline between them.

Therefore, the diagnosis of a paravaginal defect requires the vaginal

apex, level I, to be repositioned in its normal anatomic position or at the site where reconstructive surgery will place it; then and only then should level II be evaluated. Preoperatively repositioning the vaginal apex in patients with significant vault prolapse will avoid spuriously diagnosing an apical prolapse as a cystocele or as a paravaginal defect. Repositioning the vaginal apex is the initial step in correctly identifying the cause of level II defects and the complex nature of the pelvic floor defects. Huddleston evaluated patients with magnetic resonance imaging (MRI) preoperatively and then 4 to 30 days postoperatively after surgically correcting the paravaginal defects. This study very effectively identified the paravaginal defects preoperatively and the persistent uncorrected vault prolapse and level I defects postoperatively. The identification of the level I defects in the immediate postoperative MRI scans underscores the need to evaluate level II defects after level I has been repositioned, and if a level I defect exists it ought to be repaired.

Let us consider preoperative evaluation of a patient with an unreduced posthysterectomy vault prolapse to the level of the hymenal ring. The ring forceps may be utilized to reposition the sulci and elevate the vagina to the ischial spines. The vault prolapse and possible paravaginal defect is reduced and disappears as the most dependent portion of the vaginal apex is taken to the level of the ischial spines by the tip of the defect analyzer and as the sulci are elevated in the midvagina to the lateral pelvic sidewall, respectively. These findings may spuriously be diagnosed as a complete bilateral paravaginal defect. Alternatively, if the same patient was evaluated by initially reducing the apex of the prolapse with a disarticulated speculum, a sponge stick, or preferably a Scopette (rectal swab), this would immediately identify the vault prolapse as a level I defect. Then, with the vaginal apex repositioned, a lateral defect at level II may be evaluated by repositioning the sulci with the Baden vaginal defect analyzer or a curved ring forceps at rest and during Valsalva. When the vaginal apex is restored, the displacement cystocele from the apical prolapse is also noted, and any remaining cystocele is due to a midline defect. In clinical practice, the magnitude of pelvic floor genital prolapse will undoubtedly yield variations in the severity of anterior segment defects, that is, cystoceles. Multiple anterior segment site defects, “bridge” with midline distention, paravaginal defect, and apical descent components require meticulous preoperative evaluation.

SYMPTOMS

The most common symptom of a displacement, distention cystocele, and paravaginal defect is an unwanted protruding bulge of anterior vaginal wall that is worse with the effects of gravity when the patient is standing or straining. There is a feeling of pelvic fullness and of "bridge." Urinary incontinence may be a coexistent, troublesome symptom in patients with cystocele. Under normal conditions, the pelvic organs are constantly exposed to increasing intra-abdominal pressure and maintain their anatomic relationships. Increases in intra-abdominal pressure, as from coughing, sneezing, or changing position, and the intrapelvic relationship of the urethra to the posterior aspect of the pubic symphysis cause abnormal rotational descent of the bladder neck and flattening of the posterior urethrovesical angle if a relatively greater portion of the intra-abdominal pressure is transmitted primarily to the bladder, resulting in momentary but troublesome urinary incontinence. This is called *urinary stress incontinence*.

On the other hand, with large cystoceles a "bridge" may occur at the bladder neck, preventing urine loss with coughing and effective evacuation during micturition. When hypotonia of the bladder develops in such instances, normal detrusor tone is compromised, and excess urine from the incompletely emptied bladder may flow over into the urethra, a condition described as *overflow incontinence*. This may also leave a large volume of residual urine that may become stagnant and easily infected, giving rise to chronic cystitis.

In such cases, after colporrhaphy, the "bridge" effect is removed as the bladder base and vagina are repositioned. If there is insufficient urethral sphincter tone to maintain an intraurethral pressure greater than intravesical pressure under these circumstances, occult urinary incontinence may be unmasked, which has also been called *iatrogenic urinary incontinence*. For this reason, if one is performing an anterior colporrhaphy, preoperative testing with the cystocele reduced, provocative coughing with a full bladder, and preoperative urodynamic evaluation are essential, even in the absence of preliminary urinary stress incontinence symptoms.

ANATOMIC SUPPORTS OF THE VAGINA, BLADDER, AND URETHRA

The urethra penetrates the urogenital diaphragm, and condensations of the latter may be found alongside the urethra continuous with the urogenital diaphragm and extending anteriorly to the back of the pubis. These have various names, such as *pubourethral ligament*, *puboprostatic ligaments of the female*, and *triangular ligament.* However, they differ from the standard ligamentous anatomic descriptions in that they include elements of smooth and striated muscle and therefore are capable of expansion and contraction. This constitutes the upper suspensory system that helps to hold the urethra in place. The lateral sulcus of the vagina beneath the urethra and bladder is attached by a connective tissue bridge to the arcus tendineus of the pelvic diaphragm, which runs along the back of the pubis, takes origin from the medial surface of the obturator internus muscle, and is, in fact, the origin of the levator ani muscles. The attachments of the anterior vaginal wall thus support the vagina, urethra, and bladder, which the wall covers. It is clear that the urethra and vesicourethral junction are thus suspended from above by the urogenital diaphragm and supported from below by the anterior vaginal wall and lateral vaginal attachment, anatomic systems that are relatively distinct from one another (Fig. 186.3). It is possible for any of these systems to be damaged with resultant site-specific cystocele. The vesicovaginal space is a natural plane of cleavage between the wall of the vagina and the wall of the bladder and constitutes a potentially useful surgical space (Fig. 186.3). It is avascular in nature and extends from the vaginal vault to the vesicourethral junction and to the bladder pillars laterally. The vesicovaginal space permits independent function of the bladder and vagina. When this space has been lost as a consequence of laceration, fibrosis from infection, or the trauma of an operation, the ability for independent function of bladder and vagina is compromised. Subsequent bladder filling and distention as well as any bladder and vagina movement must thenceforth always occur simultaneously rather than independently. A similarly separate space between the vagina and rectum serving an analogous purpose is known as the *rectovaginal space*, whose dimensions and surgical usefulness as it pertains to posterior colporrhaphy are described later.

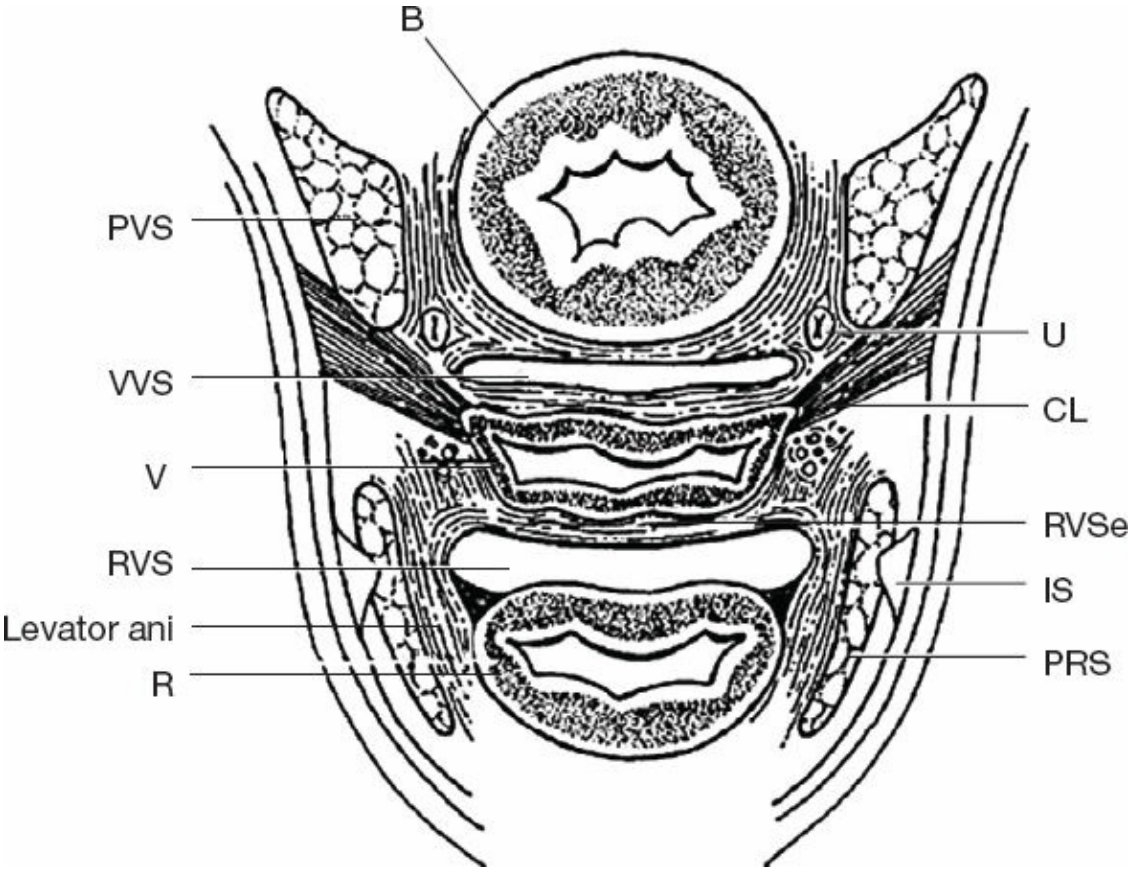

Figure 186.3. Coronal section showing the supports of the vagina and the connective tissue planes and spaces. The bladder (*B*) is separated from the vagina (*V*) by the vesicovaginal space (*VVS*) and is supported from the sidewall of the pelvis by the cardinal ligament (*CL*). This tissue is attached to the levator ani along the pelvic sidewalls as shown. The rectum (*R*) is separated from the vagina by the rectovaginal space (*RVS*) and the rectovaginal septum (*RVSe*). Note the location of the ureter (*U*) in the bladder pillar, the paravesical spaces (*PVS*), and the pararectal spaces (*PRS*). The ischial spine (*IS*) is found in the lateral wall of the paravesical space.

FINDINGS ON PHYSICAL EXAMINATION

The patient should be examined initially while in the lithotomy position, having been instructed not to empty the bladder before pelvic examination. The examination begins with the patient supine and at rest, then voluntarily squeezing the levator ani muscles to determine the extent to which this elevates the anterior sulcus and the bladder, and then voluntarily straining or bearing down. The examiner must evaluate all of the anterior vaginal wall segments for possible defects. While the patient is straining, careful note should be made of any coincident descent of the

vaginal vault with or without the cervix, indicating the presence or absence of any displacement of the vagina and bladder, as described earlier. The rugae and character of the vaginal wall should be carefully noted as an estimate of its estrogen status. If the patient is postmenopausal and no contraindications exist, appropriate oral and vaginal estrogen replacement should be instituted. Any suburethral tenderness should be identified, and nodularity that might suggest a urethral diverticulum should be investigated. The patient should be asked to cough and any spontaneous leakage of urine noted with the structures in the presenting state, and then the patient should be repositioned in the anticipated postsurgical reconstructive position. If no leakage has occurred, the latter is repeated with the patient standing. Additional maneuvers consist of depressing the perineum, thereby stretching the levator ani, after which the patient is asked to cough again. Regardless of the event of urine loss, an estimate of urine volume at that examination time should be obtained by transurethral catheter or by ultrasound, and a concomitant urine specimen should be submitted for culture.

The patient should again be asked to stand, and the previously described examination repeated with specific emphasis on any eversion of the vaginal vault, enterocele, rectocele, and perineal defect.

PLANNING A SURGICAL REPAIR

Because it is impossible to make a patient feel better by operating on something that is asymptomatic to begin with, the goals of surgical therapy must be clear. These are (a) relief of symptoms, (b) restoration of structures to normal, and (c) restoration of function to normal. However, when a patient is to undergo a pelvic reconstructive operation for other indications, such as symptomatic prolapse of the uterus, a rectocele, or an enterocele, any cystocele, even one that is asymptomatic, should be repaired. Other than that, there is no indication for operating on an asymptomatic cystocele, except a demonstrated and sustained progression from year to year with additional areas of developing prolapse and symptoms. Conversely, when a patient demonstrates coincident weakness of the posterior vaginal wall or perineum, or both, a posterior colporrhaphy and perineorrhaphy as needed to help support the anterior vaginal wall and aid the long-term effectiveness of anterior colporrhaphy may be necessary. When there is an obvious coincident prolapse of the vaginal vault or uterus, or both, vaginal hysterectomy and vaginal vault fixation must be

addressed to achieve the best long-term reconstructive result. The surgical reconstructive procedures should embrace techniques that are exacting and meet the specific needs of a particular patient. The hallmark of vaginal surgery is the development of vaginal wall flaps, using avascular planes between organs to reduce blood loss and minimize tissue trauma as well as to gain access to potential pelvic spaces that provide exposure and facilitate the operative procedure. This surgical exposure permits an array of repairs of the underlying structures and organs as well as the vagina, including excision of damaged and overdistended vaginal wall, excision of enterocele, repair of cystocele and rectocele, repositioning of the vagina over the levator plate, and reconstructing the perineum and introitus. It is this exposure and flap generation that bridges plastic surgery with gynecologic reconstructive surgery.

When the vagina is used for surgical exposure during vaginal reconstructive surgery, the goal is to reconstruct a functional, pain-free, pliable, distensible, and well-supported structure. Vaginal reconstructive surgery requires the development of flaps, essentially full-thickness vaginal wall advancement flaps. The anterior and posterior vaginal walls are mobilized by careful dissection within the vesicovaginal and rectovaginal spaces, avoiding splitting the vaginal wall. The amount of full-thickness vaginal wall that is removed from the herniated damaged areas, the overall dimensions of the vaginal caliber and length, and the reconstruction of the perineum and introital aperture are often guided by the indications for surgery and the surgical judgment of the surgeon, which must also take into account repair of all defective vaginal sites. By far, the most frequent defect is that occurring in the midline structures (i.e., the urethra and anterior vaginal wall), so that most of the reconstructive surgical repair is concentrated in the midline. A systematic method for evaluating all the sites of damage is essential to surgical success. The goal of reconstructive surgery is to restore more normal anatomy, restore function, and relieve the symptoms. The massively everted vagina constitutes a completely decompensated vaginal organ with multiple defects in the midline at the vaginal apex/vault of the vagina as well as laterally. It is, in essence, a massive pelvic floor hernia composed of the bladder, small bowel, rectum, vagina, and, at times, the sigmoid colon.

When all of the areas of pelvic floor prolapse and anterior vaginal segment damage have been identified and evaluated, the surgeon must correlate the observations with the patient’s symptoms. Also, any other

laboratory tests that may further explain any additional causes of urinary incontinence, such as detrusor dysfunction or other factors, must be figured into the surgical plan, and attempts must be made to correct these before a surgical repair of cystocele is undertaken.

SURGICAL TECHNIQUE

The surgical technique of full-length anterior colporrhaphy described below presumes that the vaginal vault is located at or has been surgically replaced to a normal depth and that there is no coincident paravaginal defect. If any apical or lateral defects exist, performing only an anterior colporrhaphy will result in a foreshortened and narrow vaginal canal that will create a new symptom during coitus—dyspareunia.

A distention cystocele as seen topographically is shown in Figure 186.4, and a sagittal section of a distention cystocele with rotational descent of the bladder neck is shown in Figure 186.5. Traction on the tenacula applied to the anterior and posterior aspects of the cervix brings the cystocele and cervix to the introitus and just outside the vagina. To avoid splitting the anterior vaginal wall and to facilitate dissection within the vesicovaginal space, Allis clamps are applied to the full thickness of the anterior vaginal wall overlying the cystocele, and the full thickness of the anterior vaginal wall is incised directly into the vesicovaginal space (Fig. 186.6). A depth of dissection away from the vesicovaginal space toward the vaginal epithelium splits the fibromuscular wall of the vagina. The dissection is performed with scissors, and the incision is carried to the anterior margin of the vesicovaginal space. The scissors dissection is continued to the distal urethral segment, creating a plane between the urethra and the vagina, which are normally fused one to another. This incision is continued to within 1 cm of the external urethral meatus (Fig. 186.7). The connective tissue capsule of the bladder is separated from the underside of the full thickness of the vagina with the scissors by sharp and blunt dissection (Fig. 186.8). This dissection mobilizes the bladder and urethra to the full lateral extent of the cystocele, at times as far as the medial margin of the pubis. The pubourethral ligamentous portion of the urogenital diaphragm should be noted and their attachments preserved.

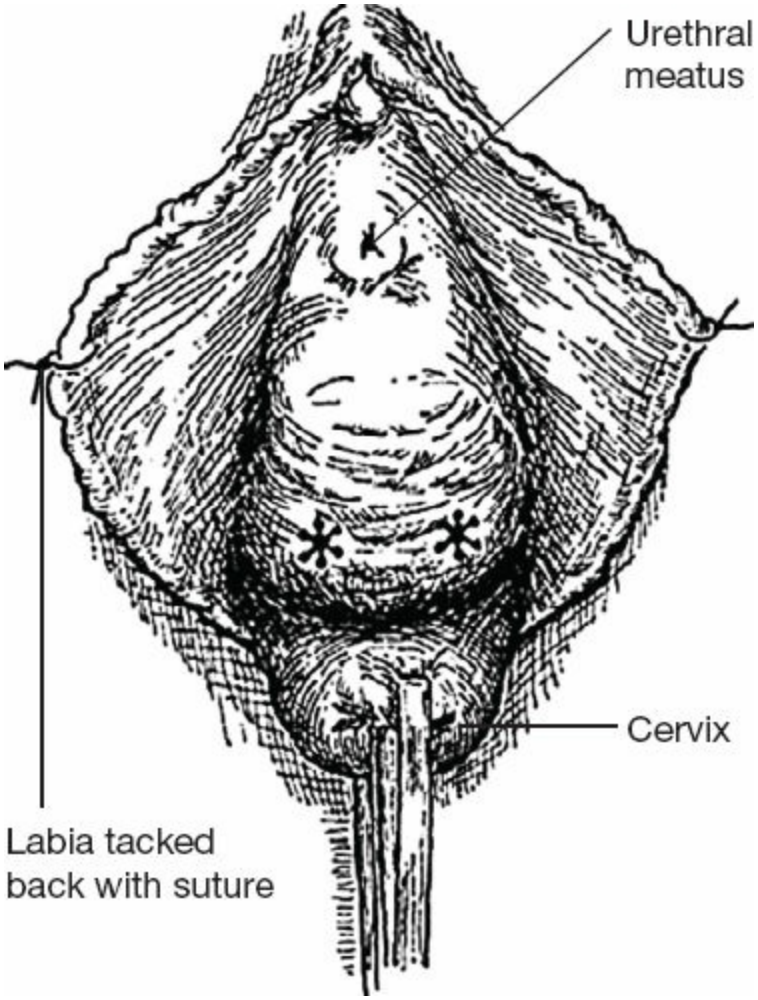

Figure 186.4. A distention cystocele. *Asterisks* identify the site at which Allis clamps are placed before the anterior vaginal wall is opened. (Redrawn from Nichols D, Randall C, eds. *Vaginal Surgery*, 4th ed. Baltimore, MD: Williams & Wilkins, 1996.)

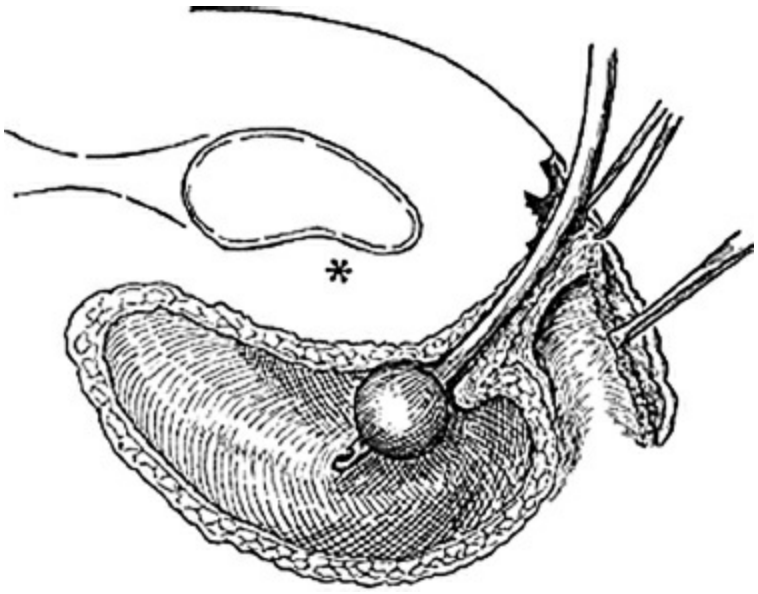

Figure 186.5. Sagittal section of a distention cystocele with rotational descent of the bladder neck in the absence of urethral funneling. Note the relationship of the inflated bulb on the Foley catheter and the *asterisk.* The asterisk is at the position of the normal urethral axis at the junction of the lower third with the upper two thirds of the back of the pubis. (Redrawn from Nichols D, Randall C, eds. *Vaginal Surgery*, 4th ed. Baltimore, MD: Williams & Wilkins, 1996.)

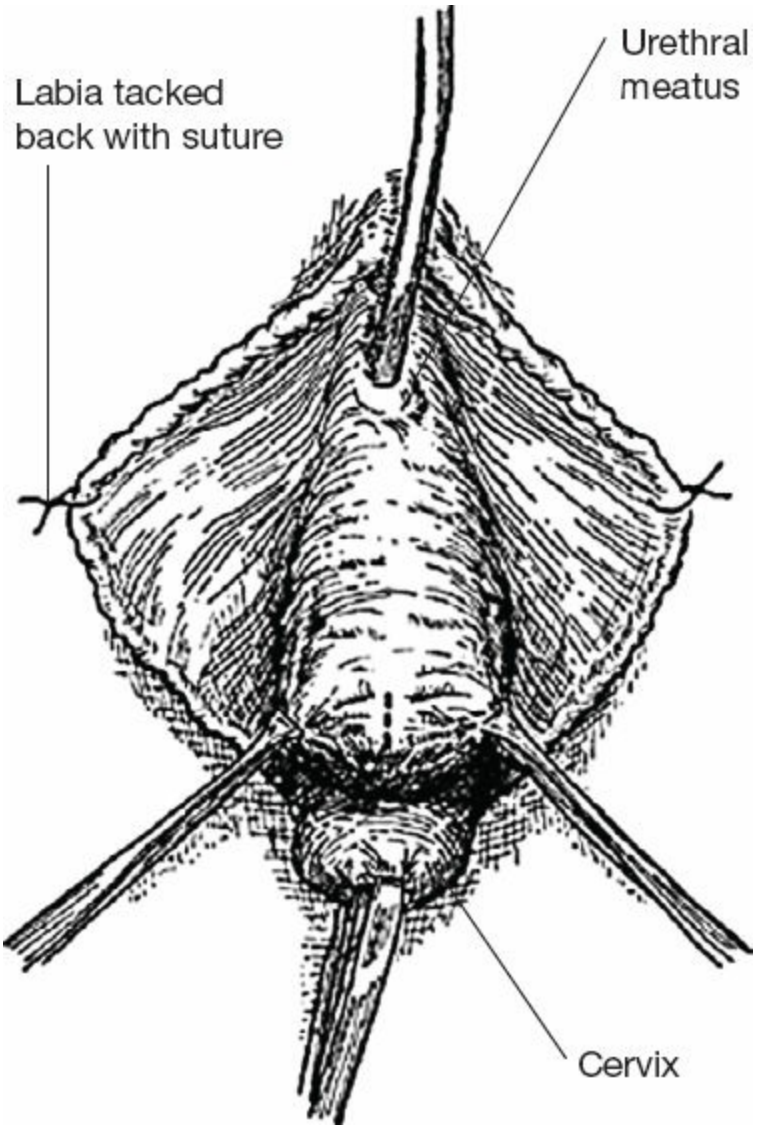

Figure 186.6. Allis clamps grasp the full thickness of the anterior vaginal wall, which is incised at the site of the *dotted line.* (Redrawn from Nichols D, Randall C, eds. *Vaginal Surgery*, 4th ed. Baltimore, MD: Williams & Wilkins, 1996.)

Funneling of the urethra with its consequent vesicalization (Fig. 186.9) should be reduced by one or more Kelly-type sutures of long-lasting

synthetic absorbable or nonabsorbable material. If the patient has urethral funneling as the sole departure from normal, reduction of this funneling by Kelly-type sutures may be all that is required. This may be seen in certain patients with urinary stress incontinence, but without urethral hypermobility.

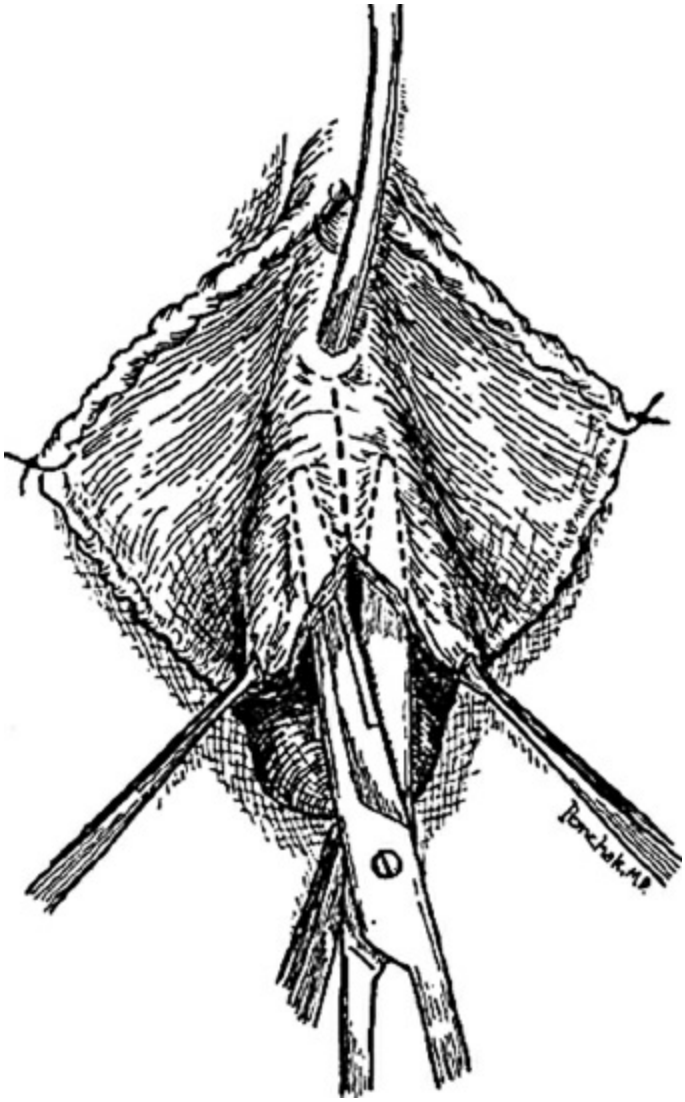

Figure 186.7. The incision in the anterior vaginal wall is carried cranially within the vesicovaginal space as indicated by the dotted line to within 1 cm of the external urethral meatus. (Redrawn from Nichols D, Randall C, eds. *Vaginal Surgery*, 4th ed. Baltimore, MD: Williams & Wilkins, 1996.)

If, on the other hand, there is coincident funneling and rotational descent of the vesicourethral junction, Kelly-type stitches and posterior pubourethral ligament plication can be used as shown (Fig. 186.10). The ultimate goal is that the funneling be reduced and the vesicourethral

junction be restored to its normal position (Fig. 186.11). After the funneling is corrected, the surgeon palpates the inflated bulb of the Foley catheter. This identifies the limits of the urethra and bladder neck. A baby Kocher clamp is applied to the paraurethral connective tissue lateral to the catheter, and the ratchet is closed with only one click. Traction is exerted posteriorly, and if the Kocher clamp has been correctly applied, the tissue condensation of the urogenital diaphragm (i.e., the pubourethral ligament on the patient's right) is captured, and traction actually moves the patient to a minor degree on the table (Fig. 186.12), because the pubourethral ligaments are firmly attached to the posterior aspect of the pubic symphysis (Fig. 186.13). If this movement is not demonstrated, then the clamp has been applied in the wrong place, the pubourethral ligament has been compromised by the dissection, or, possibly, the ligament of this particular patient has no useful surgical integrity.

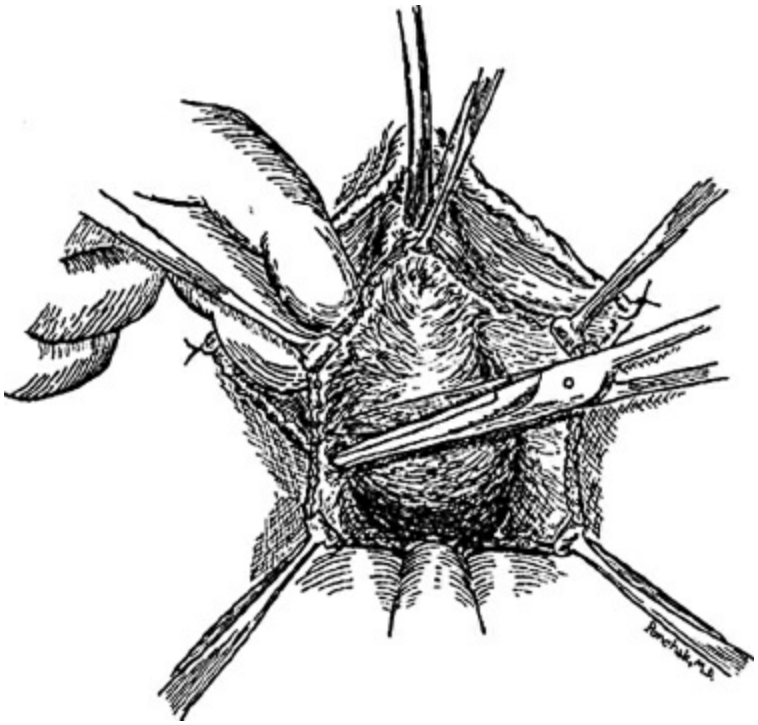

Figure 186.8. The vagina is separated from the bladder by sharp dissection, first on one side and then on the other. (Redrawn from Nichols D, Randall C, eds. *Vaginal Surgery*, 4th ed. Baltimore, MD: Williams & Wilkins, 1996.)

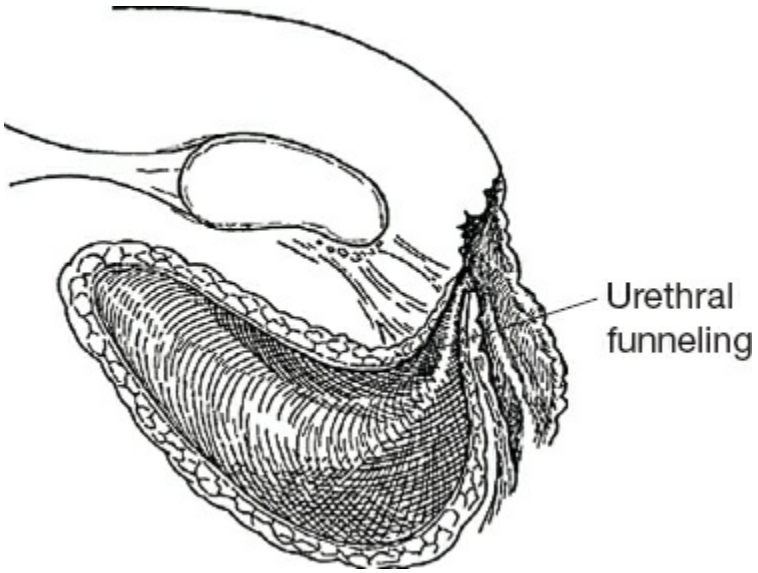

Figure 186.9. Coincident urethral funneling, rotational descent of the vesicourethral junction with elongation of the pubourethral ligament portion of the urogenital diaphragm, and some posterior cystocele. (Redrawn from Nichols D, Randall C, eds. *Vaginal Surgery*, 4th ed. Baltimore, MD: Williams & Wilkins, 1996.)

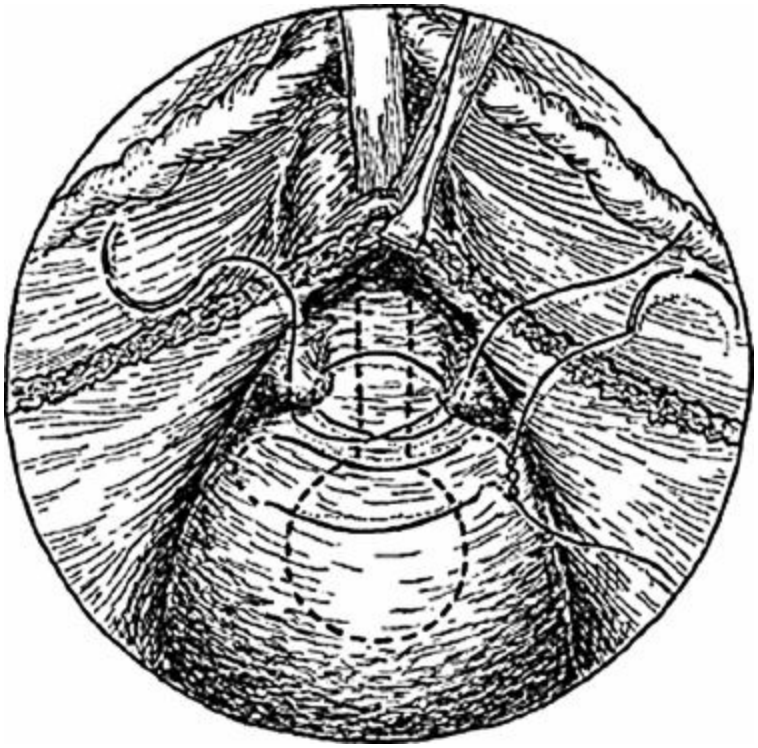

Figure 186.10. At the level of the bladder neck, just above the Foley bulb, a Kelly-type urethral plication stitch has been placed to correct coincident urethral funneling. A posterior pubourethral ligament plication suture has been placed to elevate and correct the urethral hypermobility. (Redrawn from Nichols D, Randall C, eds. *Vaginal Surgery*, 4th ed. Baltimore, MD: Williams & Wilkins,

1996.)

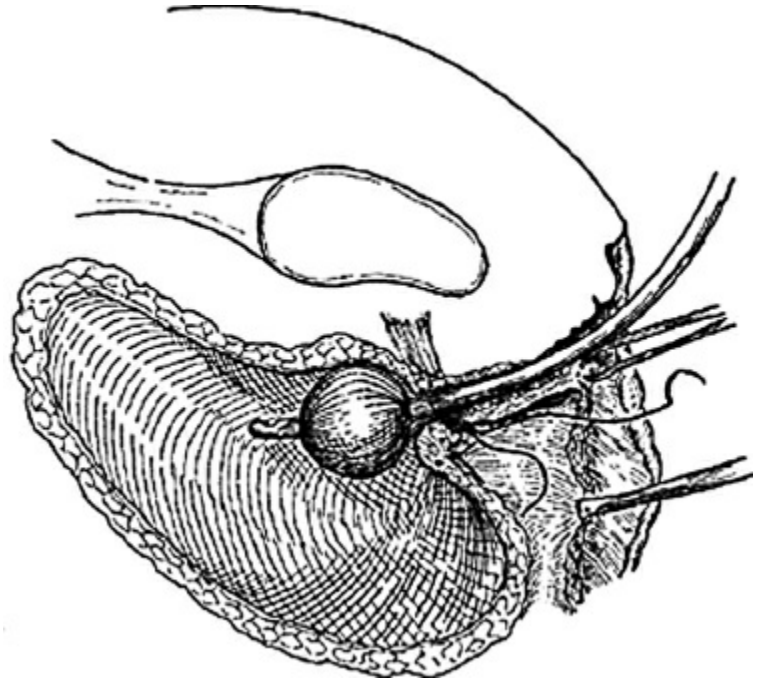

Figure 186.11. Sagittal view showing the effect of plication of the pubourethral ligaments and urogenital diaphragm beneath the vesicourethral junction and the correction of the urethral funneling by a separate Kelly stitch, proximal to the Foley bulb, which has been tied. (Redrawn from Nichols D, Randall C, eds. *Vaginal Surgery*, 4th ed. Baltimore, MD: Williams & Wilkins, 1996.)

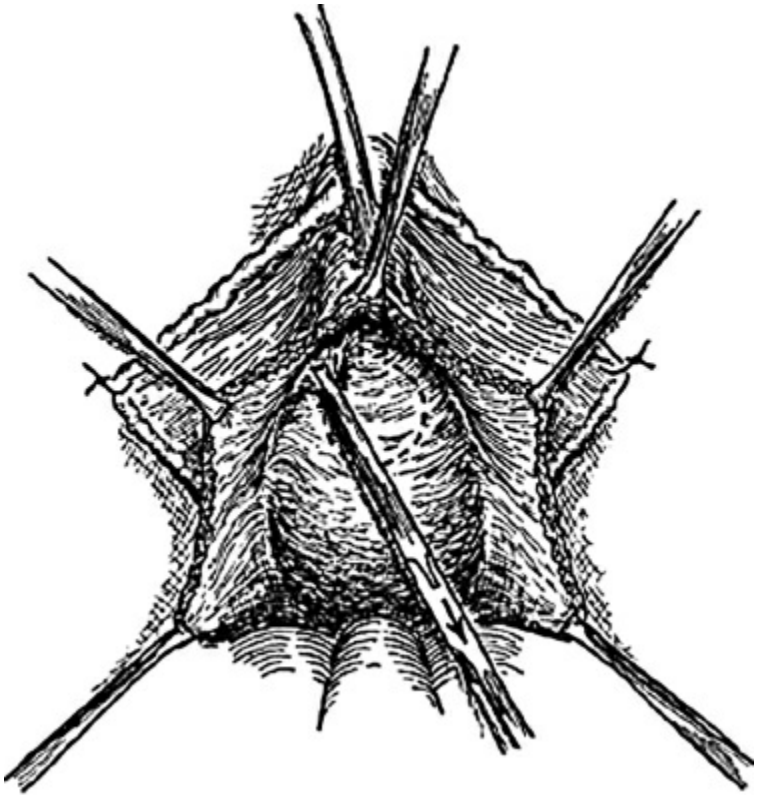

Figure 186.12. The *dotted line* indicates the position of the inflated bulb on a transurethral Foley catheter. The tissues lateral to the bulb are grasped in a Kocher hemostat, and gentle traction is made in the direction indicated by the *arrow* on the Kocher. If this hemostat is properly placed, it should actually move the patient a small bit on the operating table. This tissue represents a condensation of the tissues of the urogenital diaphragm lateral to the point at which it is penetrated by the urethra. These tissues are continuous with those of the pubourethral ligaments. (Redrawn from Nichols D, Randall C, eds. *Vaginal Surgery*, 4th ed. Baltimore, MD: Williams & Wilkins, 1996.)

Another Kocher clamp is applied similarly in the same position on the patient's left, and these tissues are brought together beneath the vesicourethral junction using a synthetic but absorbable suture (e.g., 00 polydioxanone type or polyglycolic acid type). These stitches are placed in such a way that the vaginal ends of these ligaments are plicated beneath the vesicourethral junction (Figs. 186.14 to 186.16). When these sutures have been tied, there is a prompt elevation of the vesicourethral junction, the goal of which is a point marking the junction of the lower third and the upper two thirds of the back of the pubis (Fig. 186.17). The free end of the pubourethral ligament stitch is now sewn to the undersurface of the vagina, re-establishing the fusion between the vagina and urethra that was present

preoperatively. If one suture has not been sufficient to accomplish this goal, a second one may be placed lateral to the first.

The posterior cystocele is then repaired. The connective tissue capsule of the bladder is sewn with one or more layers of interrupted mattress sutures, sufficient to restore it to a normal dimension (Fig. 186.18). If a sling urethropexy is indicated, it is placed before closing the anterior vaginal wall and brought to the skin surface above the pubic symphysis for securing later in the operation.

Similarly, if a coincident distention cystocele and paravaginal defect (Fig. 186.19), lateral detachment of the vagina, is present, then the time to repair this defect is before placing the sling. As described by White, the dissection is carried laterally between the bladder and vagina to the pelvic sidewall on one or both sides as indicated. The intent is to fix with permanent interrupted sutures the lateral vaginal sulcus and the arcus tendineus. Once the dissection is carried sufficiently laterally, the paravaginal space is identified by retracting the bladder medially. This permits palpation of the ischial spine, which serves as the most cephalad point of dissection (Fig. 186.20), and the arcus tendineus is visualized or palpated laterally as it traverses the pelvic sidewall from ischial spine to pubic symphysis. The paravaginal space is developed and enlarged (Fig. 186.21). A series of 00 nonabsorbable braided doubly armed sutures are placed directly into the obturator fascia at the site of the arcus tendineus. The first suture is placed lateral at the level of the ischial spine, and subsequent sutures are placed toward the vesicourethral junction (Figs. 186.22 and 186.23). When all of the sutures (one or both sides) are in place, they are individually sewn to the underside of the full thickness of the vaginal wall at the site of the sulcus (Fig. 186.24) and then tied (Fig. 186.25). The vaginal sulcus is brought to the site of the arcus tendineus on the obturator fascia. Then, all the stitches and the free ends are cut, and the knots are buried beneath the vaginal wall. After these sutures have been tied (Fig. 186.26), any redundant anterior vaginal wall is trimmed (Fig. 186.27), and the remaining vagina is approximated in a running subcuticular suture of polyglycolic acid (Fig. 186.28). The anatomic reconstruction and repair are surveyed to ensure that the desired result has been obtained and that all defects have been corrected (Fig. 186.29).

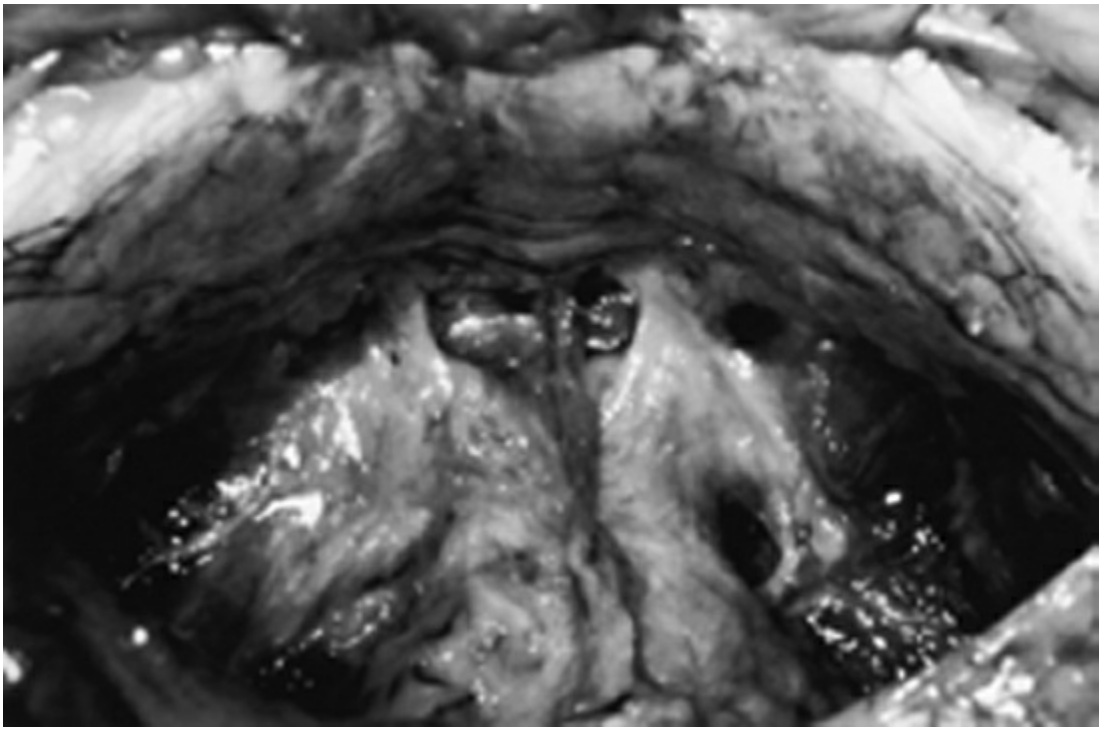

Figure 186.13. The abdominal wall has been opened and the view looking down into the space of Retzius has been developed. Notice the thick, whitish fiber-like condensation of the “bridge” of the urogenital diaphragm along either side of the urethra and extending to the lateral walls of its proximal portion. These are the posterior pubourethral ligaments that are mobilized vaginally and plicated suburethrally. (Photograph courtesy of Dr. Michael Aronson.)

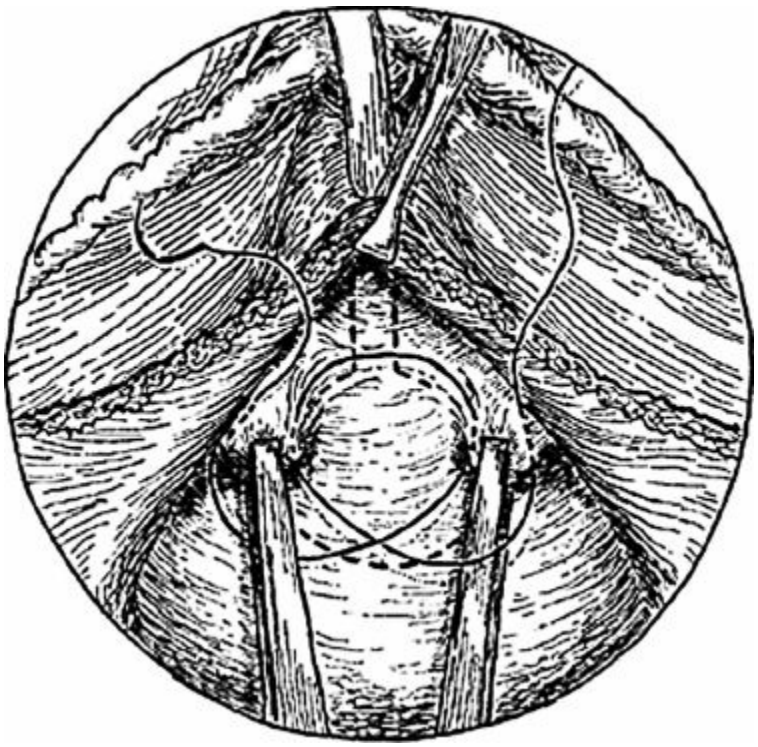

Figure 186.14. A stitch has been placed in a far–near, near–far manner through the tissues of the urogenital diaphragm grasped by the tips of the Kocher hemostats. The *dotted line* indicates the palpable position of the Foley catheter and its bulb. (Redrawn from Nichols D, Randall C, eds. *Vaginal Surgery*, 4th ed. Baltimore, MD: Williams & Wilkins, 1996.)

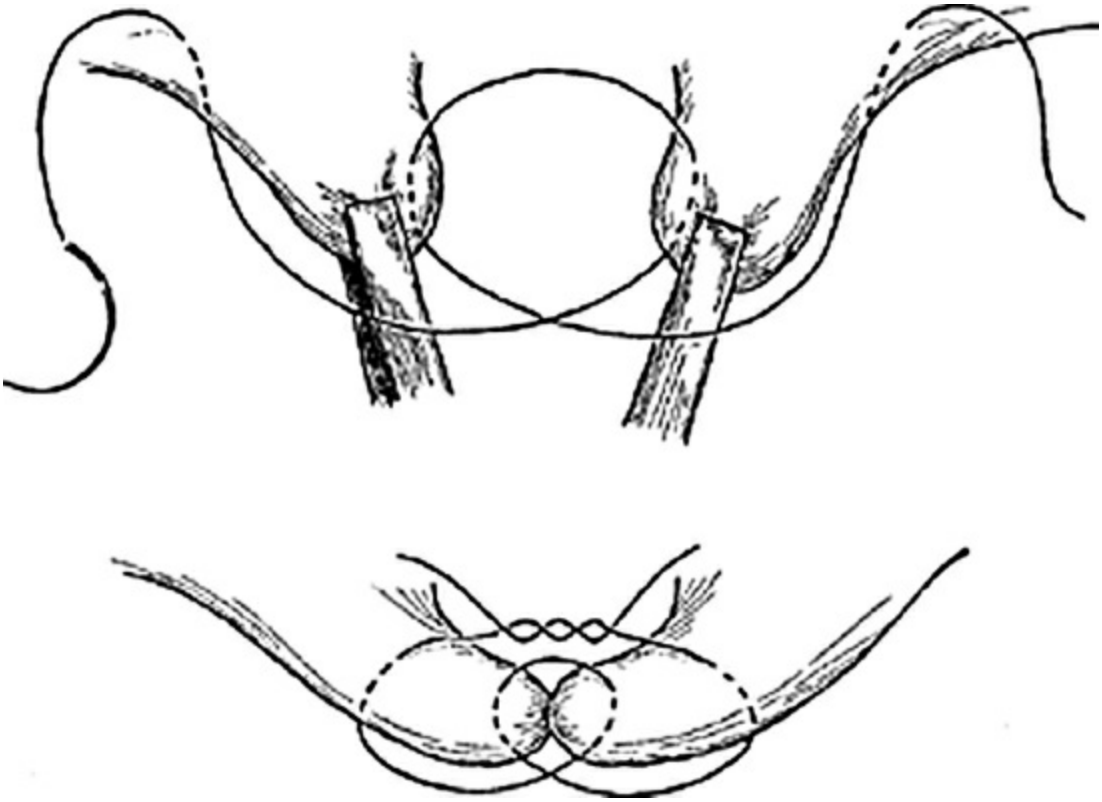

Figure 186.15. Placement of a far–near, near–far suture is shown. The effect of tying this suture (*bottom*) is to bring the tissues of the urogenital diaphragm together beneath the vesicourethral junction. (Redrawn from Nichols D, Randall C, eds. *Vaginal Surgery*, 4th ed. Baltimore, MD: Williams & Wilkins, 1996.)

POSTOPERATIVE MANAGEMENT

Some edema of the tissues is to be expected for several days postoperatively, and for this reason the Foley catheter is left indwelling and is usually removed the morning of the second postoperative day. On this morning, an appropriate antibacterial agent, such as nitrofurantoin or trimethoprim–sulfamethoxazole, is begun, because the mere presence of an indwelling catheter for this length of time predisposes to ascending bacterial colonization. The urethral walls contain many alpha-adrenergic

receptors, stimulation of which by surgical manipulation or by pain induces urethral spasm and, in conjunction with edema, may inhibit the resumption of postoperative voiding. Spasm can usually be blocked in most instances by the administration of a single dose of an alpha-adrenergic receptor blocker such as phenoxybenzamine, a 10-mg dose given by mouth at the time the catheter is removed and repeated as necessary 6 hours later. Prazosin, 1 mg three times a day, is an alternative.

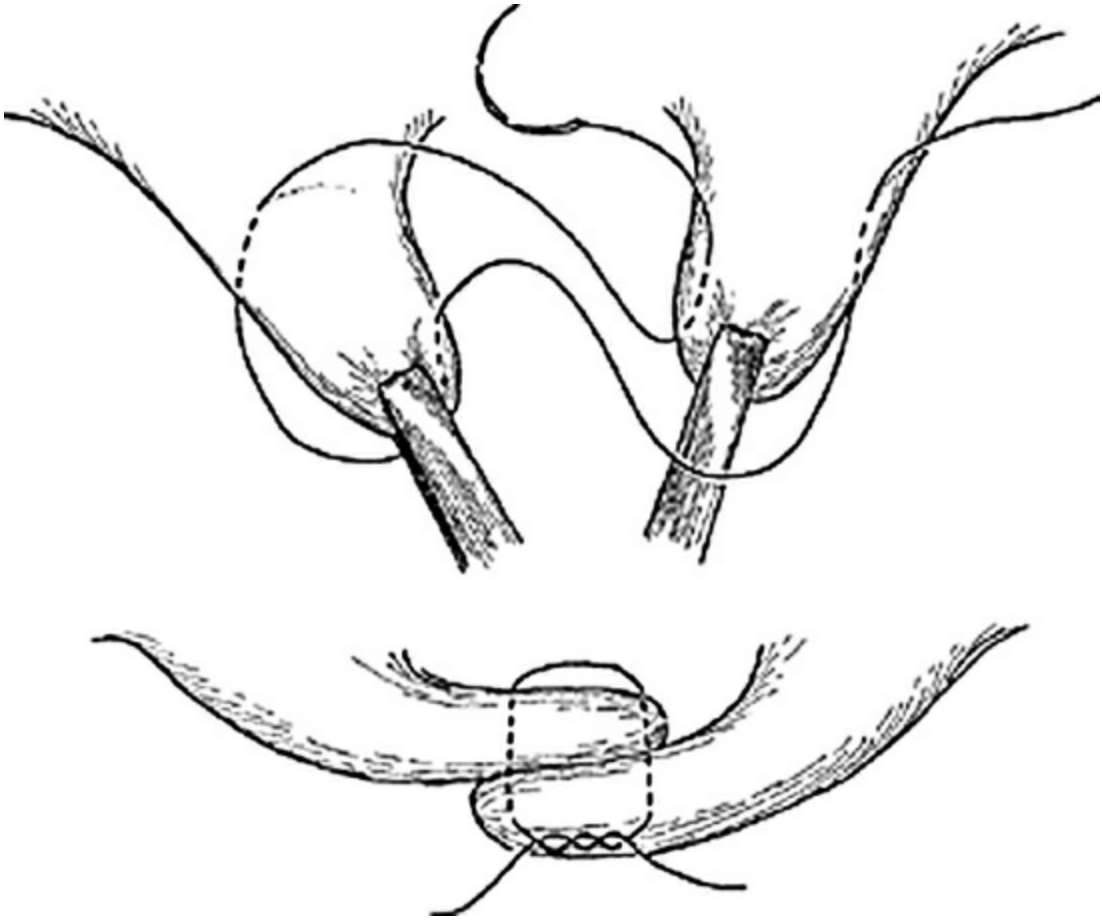

Figure 186.16. Alternative suture placement for bringing together markedly elongated tissues of the urogenital diaphragm. This placement, when tied, overlaps one of the tissue condensations with the other (*bottom*), further shortening this tissue. (Redrawn from Nichols D, Randall C, eds. *Vaginal Surgery*, 4th ed. Baltimore, MD: Williams & Wilkins, 1996.)

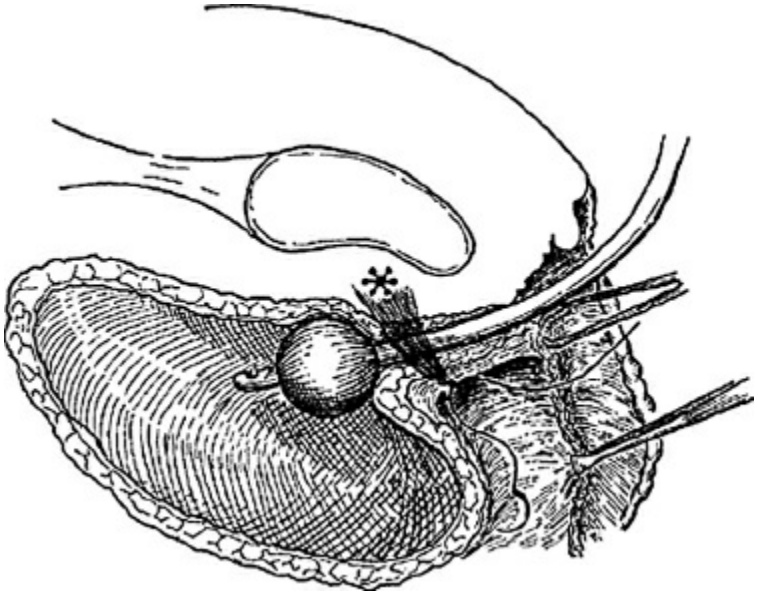

Figure 186.17. The effect of tying the urogenital diaphragm–pubourethral ligament plication stitches. The vesicourethral junction has been restored to its normal position at the junction of the lower third of the upper two thirds of the back of the pubis, the site indicated by the *asterisk.* (Redrawn from Nichols D, Randall C, eds. *Vaginal Surgery*, 4th ed. Baltimore, MD: Williams & Wilkins, 1996.)

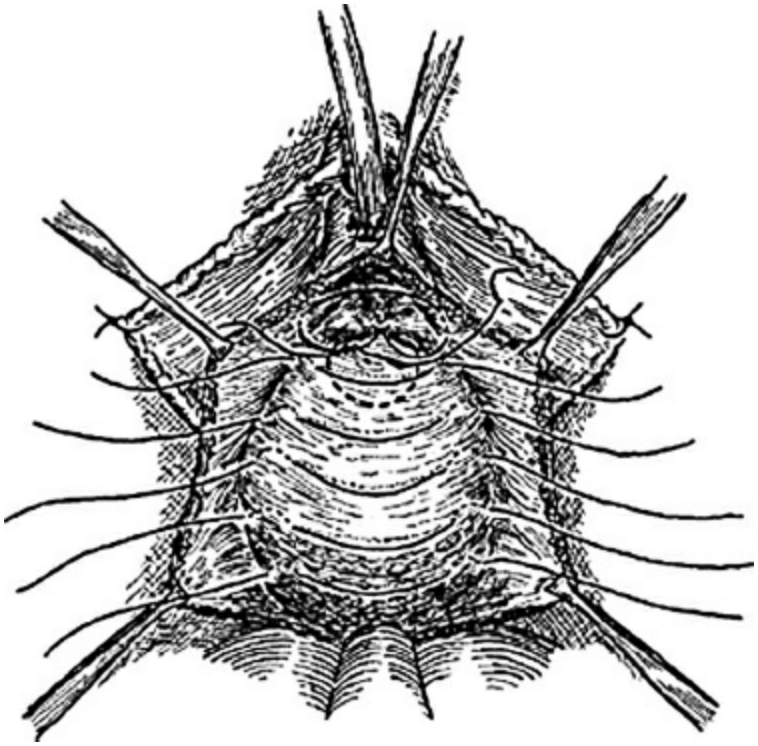

Figure 186.18. The pubourethral plication stitch has been tied, and a second bite is taken to the undersurface of the anterior vaginal wall, which, when tied, re-establishes the fusion that was

initially present in this area. Interrupted mattress sutures are placed in the connective tissue capsule of the bladder to reduce the size of the cystocele. (Redrawn from Nichols D, Randall C, eds. *Vaginal Surgery*, 4th ed. Baltimore, MD: Williams & Wilkins, 1996.)

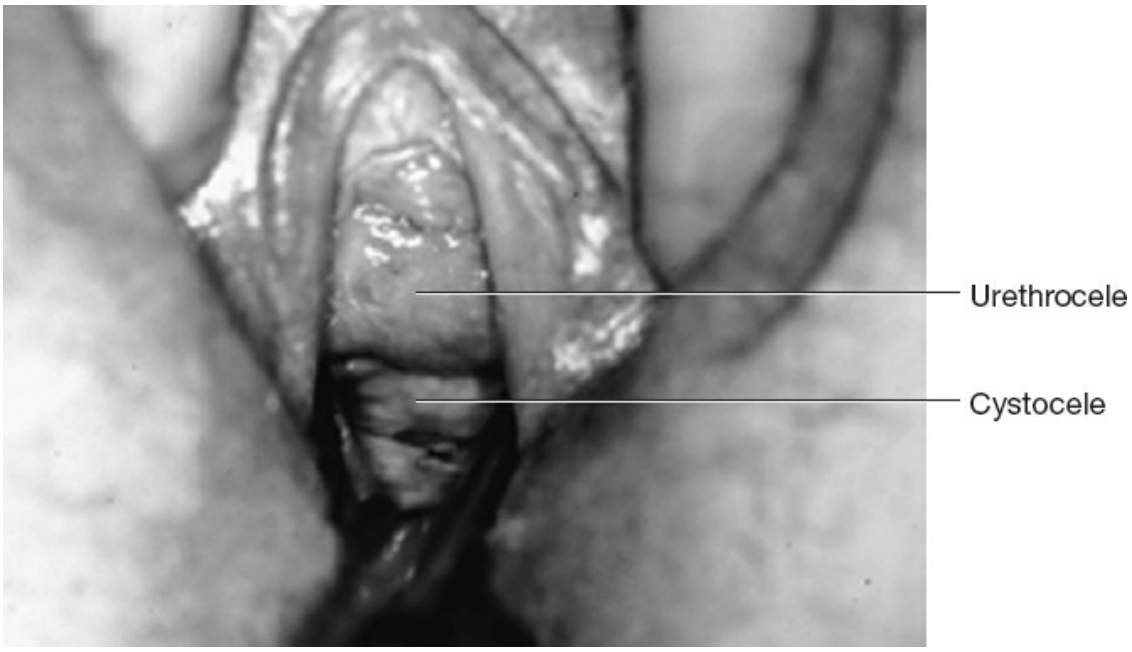

Figure 186.19. Vaginal view of a midline displacement cystocele, urethrocele, and altered urethral axis. Also evident are bilateral paravaginal defects, repositioned with a ring forceps apically to the ischial spines and laterally to the arcus tendineus, in an effort to produce the desired anatomic postsurgical relationships.

Nursing personnel should be instructed to catheterize the patient as necessary if the patient is unable to void and a suprapubic catheter has not been placed. In most instances, the patient voids effectively and comfortably, and can be discharged from the hospital the morning of the third postoperative day. If the patient is unable to void effectively and unable to learn self-catheterization, and if no suprapubic tube has been placed, a 16-Fr silicone-coated Foley catheter can be inserted transurethrally with a terminal plug as used with suprapubic tubes to be released by the patient intermittently. The patient is instructed to release the clamp as necessary to empty the bladder. Once placed, the catheter should be left in place for 7 to 10 days after discharge. The catheter is removed in the office after filling the bladder to a symptomatic volume, and the patient is asked to void. On the rare occasion that the patient is unable to void, the catheter can be reinserted for 1 week or, alternatively,

the patient can be reinstructed in the technique of self-catheterization using flexible plastic and disposable Mentor female urethral catheters. Self-catheterization should be continued as necessary until the bladder is emptying adequately. Some surgeons routinely use suprapubic cystostomy as a means of resting the bladder postoperatively, but we have not found this to be necessary.

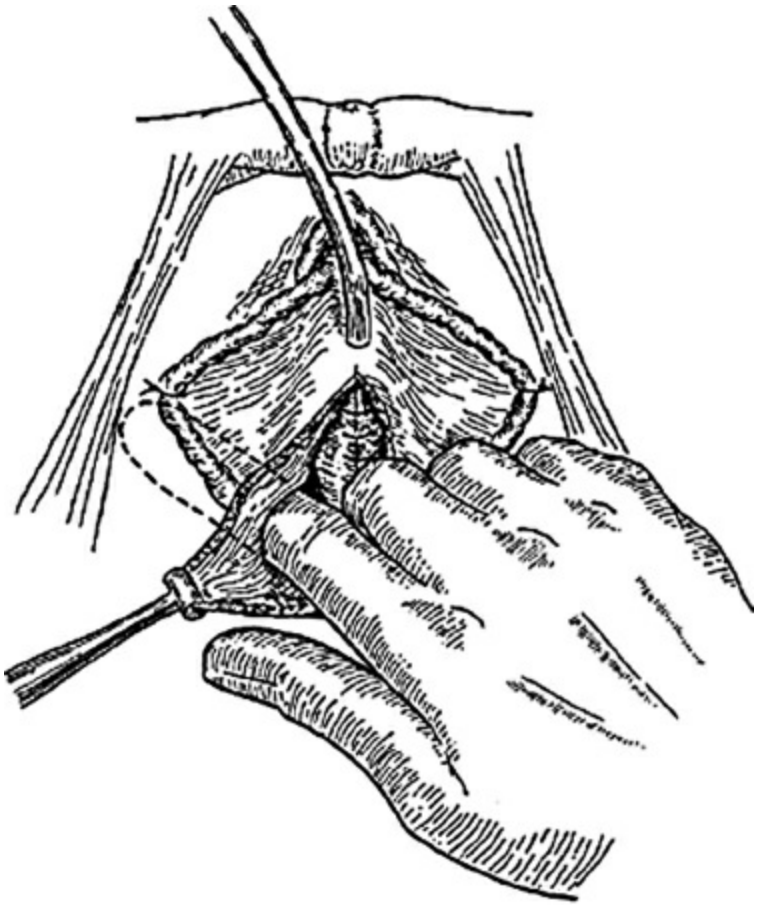

Figure 186.20. The sharp dissection has been carried laterally beneath the vaginal wall and has proceeded to develop the paravaginal space and expose the arcus tendineus fascia of the pelvis on the surface of the obturator internus. The position of the ischial spine and arcus tendineus are confirmed visually and by palpation.

Figure 186.21. Vaginal view of left paravaginal space. The Foley catheter is at the 12 o'clock position, the bladder is being retracted medially, the right paravaginal space is completely developed, and exposure is created for suture placement through the arcus tendineus fascia pelvis. Note the retropubic adipose tissue and the extent to which these spaces can be developed.

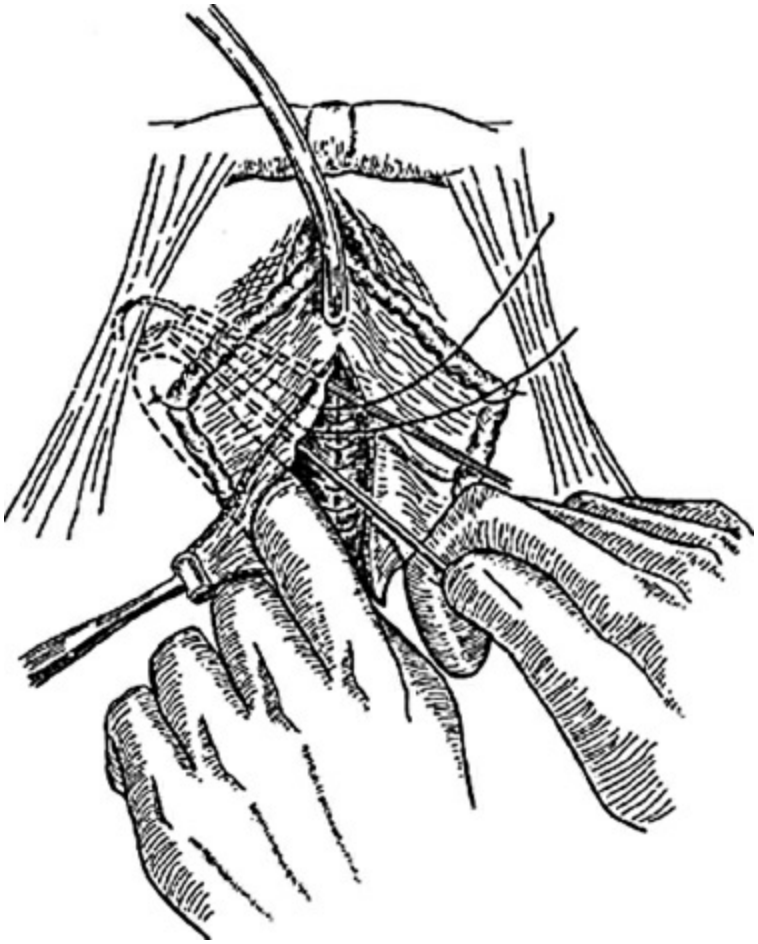

Figure 186.22. A Deschamps ligature carrier, or needle driver with doubly armed sutures, may be used to pass a series of nonabsorbable sutures through the arcus tendineus fascia of the pelvis.

Figure 186.23. Vaginal view of sutures placed through the left arcus tendineus fascia along a trajectory from the ischial spine to the pubic symphysis. The midline cystocele has not yet been repaired. Note thickness of the unsplit anterior vaginal wall.

Figure 186.24. When a Deschamps ligature carrier is used to pass the sutures through the arcus tendineus, a Mayo needle transfers each stitch to the underside of the anterior vaginal wall at the site of the vaginal sulcus. When tied and the freed ends cut, the knots are buried beneath the anterior vaginal wall. Any excess vaginal wall is trimmed, and the vaginal incision is closed from side to side by a running subcuticular suture.

In addition to surgical therapy, one should use certain nonsurgical adjunctive methods of treatment, including not only appropriate estrogen replacement, but also a course of perineal resistive exercises if the patient is able to contract the pelvic floor muscles, as opposed to repeated Valsalva maneuvers. Pelvic floor exercises consist of isometric contractions of the pubococcygeus, 20 repetitions, six times a day. Coincident detrusor hyperactivity related to excess caffeine consumption can be aided by restricting coffee, tea, cola drinks, and chocolate. In addition, bladder drills supplemented by use of anticholinergics such as oxybutynin, 2.5 mg two or three times per day, can be instituted. Newer time-release technology has been applied to oxybutynin, reducing the dry mouth and other anticholinergic side effects, permitting higher relative doses in a once-per-day delivery system.

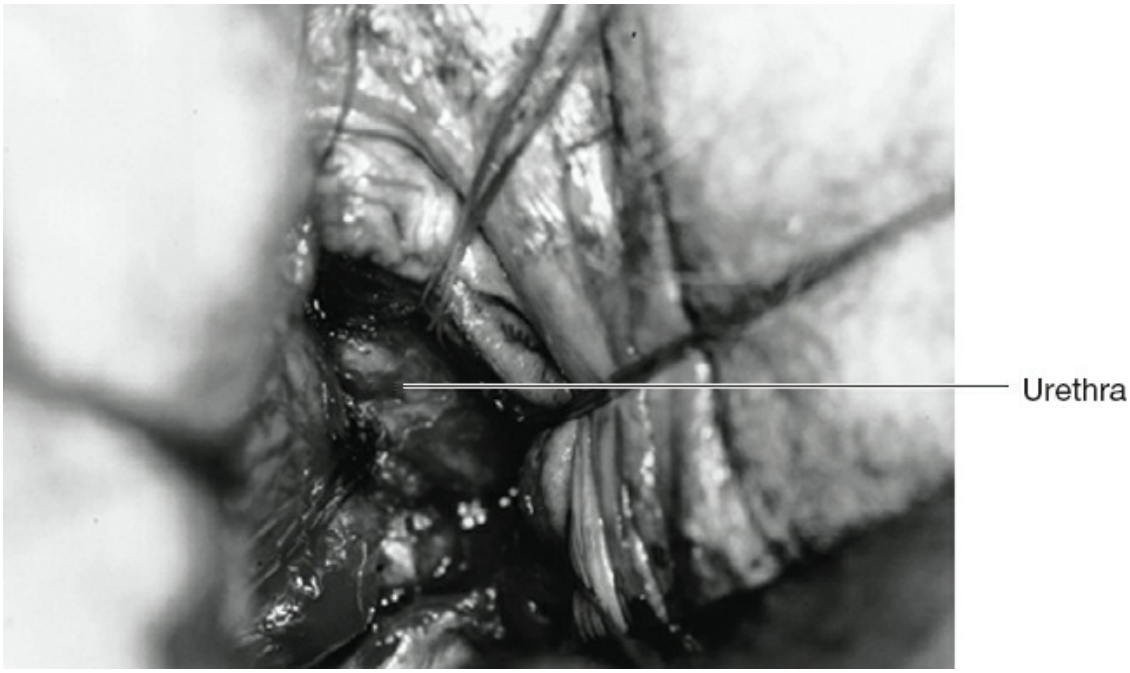

Figure 186.25. Vaginal view of repaired left paravaginal defect and reconstructed left sulcus. Urethra is at the 12 o'clock position.

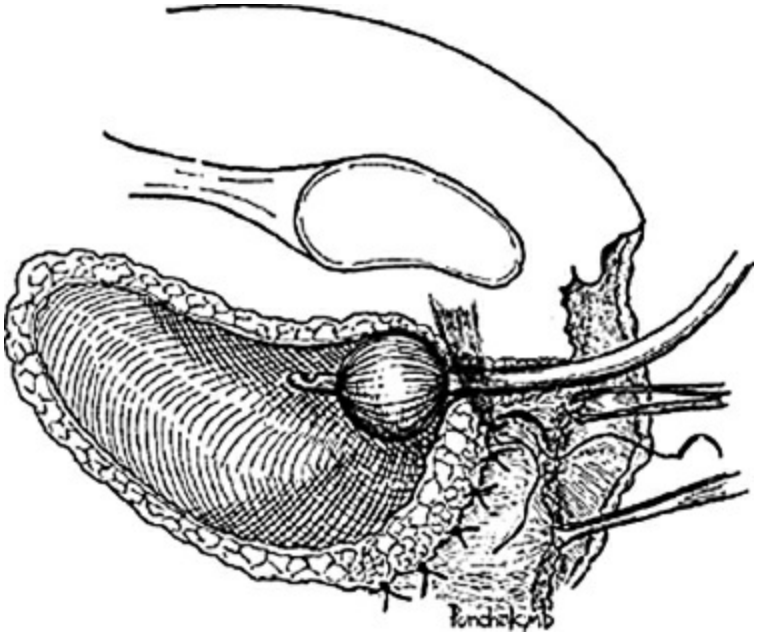

Figure 186.26. Sagittal view showing the effects of pubourethral ligament–urogenital diaphragm plication and anterior colporrhaphy. The urethra is once again in a normal relationship to the back of the pubis, and the cystocele is reduced. Excess anterior vaginal wall has not yet been trimmed. (Redrawn from Nichols D, Randall C, eds. *Vaginal Surgery*, 4th ed. Baltimore, MD: Williams & Wilkins, 1996.)

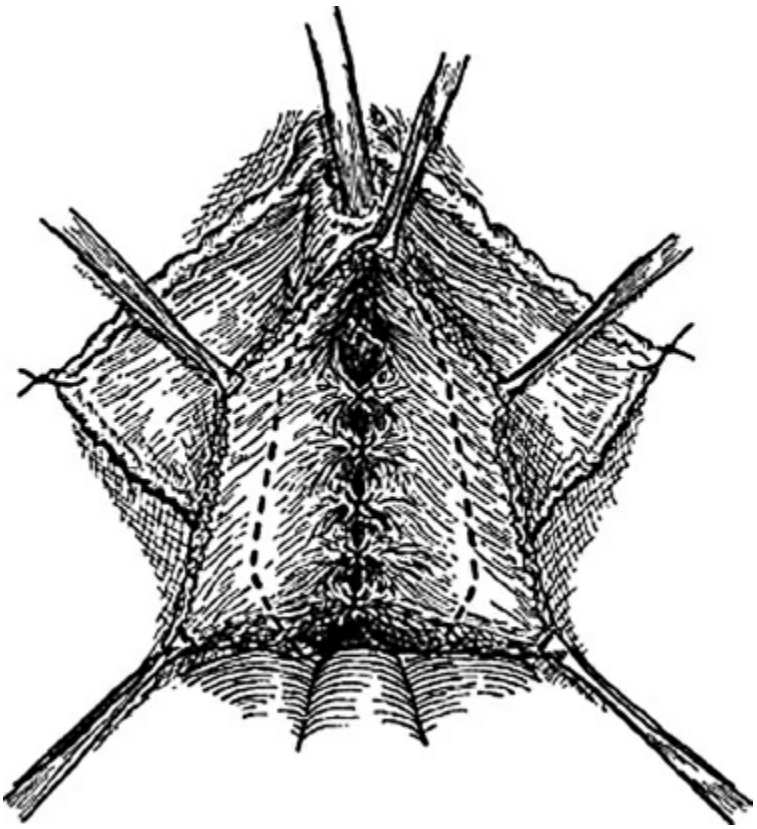

Figure 186.27. Stitches in the connective tissue capsule of the bladder and bladder pillars have been tied. The full thickness of the excess anterior vaginal wall to be excised is indicated by the *dotted lines.* (Redrawn from Nichols D, Randall C, eds. *Vaginal Surgery*, 4th ed. Baltimore, MD: Williams & Wilkins, 1996.)

RECTOCELE ON PERINEAL RELAXATION

Rectocele and perineal defects are separate and distinct lesions occurring in entirely different structures, although frequently these defects coexist. A rectocele is a defect in the posterior vaginal wall that permits the rectum to herniate into the vagina. It may occur with or without a perineal defect and may be seen low within the vagina, at its midpoint, in the upper vagina, or in any combination. Rectocele is more common in multiparous patients, and is, in fact, the most frequent weakness of the pelvis and its supporting tissue. It may be the consequence of various causes, as is a cystocele. It may be caused by damage to the posterior vaginal wall consequent to overdistention during labor and delivery (distention rectocele; see Fig. 186.1), or it may be seen when the posterior vaginal wall follows the descent of the vaginal vault with or without the cervix and uterus (displacement rectocele; see Fig. 186.2). Some women have a combination of distention and displacement, with or without a perineal defect.

Rectocele is often coincident with a widened genital hiatus, with increased distance between the medial borders of the pubococcygeus as a consequence of multiparity.

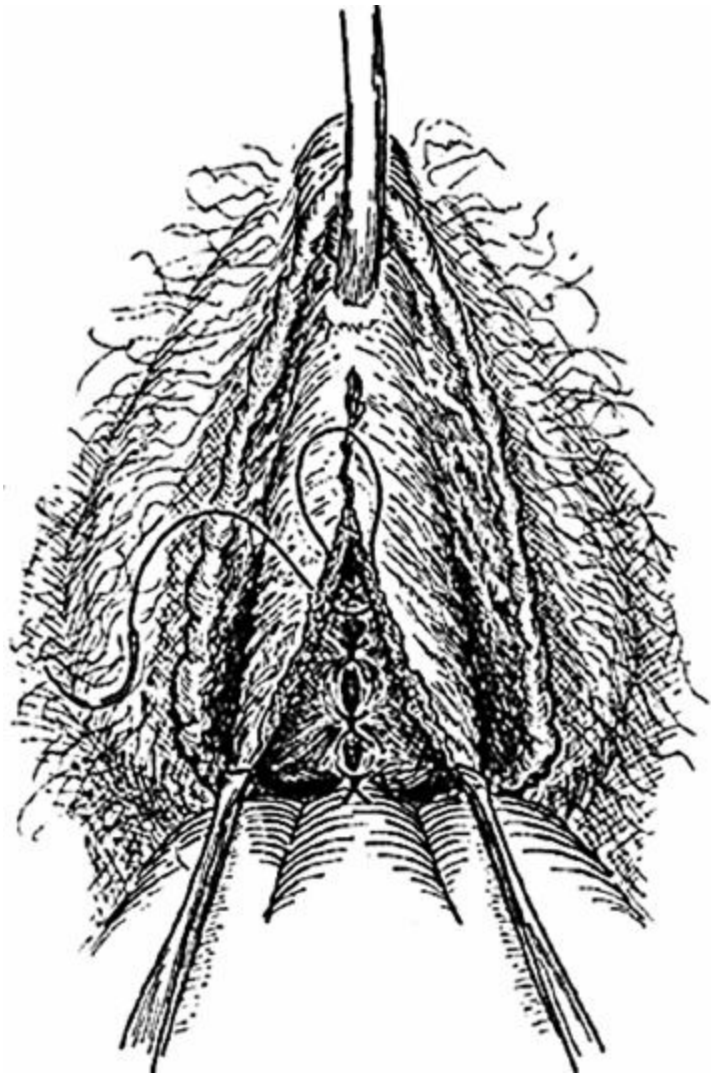

Figure 186.28. Excess anterior vaginal wall has been trimmed and the full thickness of anterior vaginal wall is being approximated from one side to the other with a running subcuticular suture. (Redrawn from Nichols D, Randall C, eds. *Vaginal Surgery*, 4th ed. Baltimore, MD: Williams & Wilkins, 1996.)

Figure 186.29. Vaginal view of reconstructed anterior vaginal wall. The midline distention cystocele and the paravaginal defects have been repaired. The urethral axis has been restored without a sling urethropexy, which, if indicated, could have added to surgical reconstruction.

The perineal body is a pyramidal fibroelastic structure found in the midline between the rectum and the vagina on a line between the ischial tuberosities. Its tone thickness and composition vary in different individuals. It serves as the central attachment point of various muscles, the superficial and deep transverse muscles of the perineum, the bulbocavernosus, the external anal sphincter, and some fibers of the levator ani. Chronic lacerations and relaxation of the perineum cause an enlarged genital hiatus and loss of support to the urethra and anterior vaginal wall.

SYMPTOMS

Many rectoceles are asymptomatic. Symptoms generally related to a rectocele are a feeling of incomplete emptying of the rectum or an aching sensation after bowel movements, or both. Patients quickly learn to “bridge” the herniated rectal area by pushing with several fingers against the posterior vaginal wall during bowel movements to eliminate symptoms

(the need to strain and facilitate bowel movements, often interpreted by the patient as constipation). However, constipation, per se, is not a significant symptom of rectocele but is more the consequence of a disorder of bowel function predicated on poor bowel habits with frequent coexistence of dehydration. Although many women with rectocele experience constipation, many women who are constipated have no rectocele. Repair of a rectocele, therefore, likely only corrects conditions that are associated with a rectocele, and is not curative for constipation in most instances. Symptoms of perineal relaxation are virtually nonexistent, except perhaps shortly after the defect occurs, when the previously asymptomatic patient notices that retaining a tampon for the absorption of menstrual flow is no longer possible.

ANATOMIC CONSIDERATIONS

Depending on the cause of the rectocele, the defect may occur in the lower, middle, or upper vagina, or in any combination of these locations. The rectum bears an intimate relation to the pelvic diaphragm that supports it. The surgeon must always be cognizant that the pubococcygei, in their passage from the back of the pubis to the coccyx, cross the sides of the rectum and fuse effectively posterior to the rectum but not anteriorly. This fusion behind the rectum that extends to the coccyx is termed the *levator plate*, and it is on the integrity of this levator plate that the pelvic support of the internal genitalia is dependent.

During late fetal life, the base of the peritoneal cavity, or posterior *cul-de-sac*, extends all the way to the perineal body. Soon afterward, this deep *cul-de-sac* fuses up to the level of the cervix and to the underside of the layers of the posterior vaginal wall. This fused peritoneum (the fascia of Denonvilliers) forms the anterior margin of the rectovaginal space and is referred to as the *rectovaginal septum.* The rectovaginal septum (fascia of Denonvilliers) is the superior border of the avascular, potential rectovaginal space between the anterior rectal wall and the posterior vaginal wall (Fig. 186.3). The rectovaginal space allows each organ to function with a degree of independence from each other. Recognizing and identifying the rectovaginal space is important for effective reconstruction of the posterior vaginal wall. As mentioned previously with respect to the anterior vaginal wall, splitting the posterior vaginal wall is surgically possible. In addition, if the embryologic fusion of the peritoneal layer is incomplete (the fascia of Denonvilliers), particularly at its cranial end,

there may be a deepening of the *cul-de-sac*, which is the origin of a congenital enterocele—a peritoneum-lined sac separating the vagina from the rectum to various depths. This congenital enterocele weakens the thickness of the upper posterior vaginal wall by its splitting of the peritoneal fusion layer (i.e., the fascia of Denonvilliers), providing one causal basis for a high rectocele. For this reason, a high rectocele is sought coincident with a congenital enterocele, and vice versa. An enterocele suspected preoperatively must incite a surgical search, and it should be deliberately and separately repaired. Almost invariably, when the fascia of Denonvilliers is identified, the enterocele is inferior to the fascia of Denonvilliers and above the rectum. If any doubt exists, or if the enterocele continues to be elusive, cephalad dissection in this space following the fascia of Denonvilliers results in entry into the *cul-de-sac*, and the search for the enterocele can be terminated.

It is important to bear in mind a three-dimensional concept in which the perineal body essentially is considered a pyramid, with its base at the bottom. The base is beneath and parallel to the perineal skin, and the anterior, lateral, and posterior surfaces all converge superiorly to the most inferior limit of the rectovaginal space, at which point they attach to the anterior layer of the fascia of Denonvilliers. The avascular potential space known as the *rectovaginal space* normally permits the rectum and vagina to function independently. When the rectovaginal space has been obliterated due to infection, laceration, trauma, or iatrogenic surgical reconstruction, this important independent function may be lost, with some significant consequences for the patient, such as constipation.

FINDINGS ON PHYSICAL EXAMINATION

Because the pelvic diaphragm (the levator ani and its various divisions) is a voluntary muscle, it is best evaluated when the patient is awake. Because the diaphragm is effectively paralyzed by anesthesia, it is relaxed in the operating room, and therefore any weaknesses, as well as those of a rectocele, are best appreciated by examination of the patient while unanesthetized, retaining the ability to contract the pelvic muscles voluntarily, as described previously.

The physical examination of an unanesthetized patient should be performed initially in the lithotomy position and then standing. In the latter position, the examiner can clearly identify and note for correction of any descent of the vaginal vault, prolapse of the uterus, cystocele, rectocele,

and enterocele. The estrogen effect on the vaginal wall should be noted. The patient should be asked to voluntarily contract the pubococcygei so that their integrity, function, and effectiveness can be adequately assessed. The surgeon should determine the condition of the levator plate posterior to the rectum and whether it is horizontal, remembering that the empty rectum normally rests on the horizontally oriented levator plate. This determines the characteristic horizontal axis of the rectum and the upper vagina. The surgeon should note whether the patient is able to contract the external anal sphincter voluntarily and effectively. With a finger in the rectum and in the vagina, the surgeon should carefully note the integrity of the perineum and perineal body at rest and when the patient is voluntarily contracting the pelvic muscles. The finger in the rectum should carefully identify whether a pocket of rectal wall is herniating into the vagina, into which the examining finger can be introduced. This pocket essentially functions as an effective stool trap and accounts for the patient's inability to completely empty the rectum, thereby necessitating the digital "bridge" and, at times, expression of rectal contents. If constipation is a complaint and hardened stool is noted, a stool softener should be given, along with instruction in proper dietary habits, before surgical correction.

The operator should also note carefully the position of the patient's perineum and anus in relation to the most dependent portion of the buttocks and the ischial tuberosities. A descending perineum or "bridge" in which the anus is the most dependent portion of the patient's perineum, strongly suggests detachment of the external anal sphincter from the perineal body. The same finding may be noted coincident with a defect of the levator ani because of an intrinsic weakness of the muscle or as the result of inadequate innervation. If a defect of the levator ani exists, regardless of the cause, straining during defecation may in effect produce elongation and funneling, the anus descending to an even more dependent position, with resulting constipation and a decrease in the diameter of the stool. As a consequence, the harder the patient strains, the narrower the stool becomes, and it is then more difficult to expel stool and effect a satisfactory bowel movement. The surgical procedure of retrorectal levatorplasty may correct this condition and is performed through an incision posterior to the rectum with attachment of the separated levators to each other posterior to the rectum.

SURGICAL PRINCIPLES

Rectocele repair, posterior colporrhaphy, and perineorrhaphy are separate and distinct operations. Each corrects a specific defect. Some patients require a perineorrhaphy, some require a posterior colporrhaphy, and some require both operations.

The goals of posterior colporrhaphy and perineorrhaphy are relief of symptoms, restoration of anatomy to normal, and restoration of function to normal. Indicated estrogen replacement therapy contributes to the success of the surgical procedure, as does correction of dietary causes of constipation. It is axiomatic in posterior colporrhaphy that the dissection and repair extend to a point cranial to the upper limit of the rectocele. It is therefore essential that the latter be determined preoperatively during examination of the unanesthetized patient.

It is important for the surgeon to remember that the pubococcygei come together behind the rectum and not between the rectum and the vagina. Thus, the so-called bridges, which deliberately interposed the bellies of the pubococcygei between the vagina and rectum, are not anatomic, and, when tightly tied, may form a bridge of tender fibrous tissue between the vagina and rectum that may be the source of future pain with resultant dyspareunia and apareunia, as well as chronic pain in the levator ani. More properly placed side-to-side stitches that reconstitute the perineal body draw the fascia of the pubococcygei, and, thus, the lateral muscles to which the fascia is attached, to the upper lateral sides of the long perineal body, and in doing so effectively restore a normal genital hiatus.

TECHNIQUE OF POSTERIOR COLPORRHAPHY AND PERINEORRHAPHY

In the following technical section, we describe a surgical procedure suited to a patient who would benefit from posterior colporrhaphy and perineorrhaphy. Although a rectocele may be the symptomatic defect, and the perineal defect is asymptomatic, the following techniques are useful in correcting these defects as well as in providing additional support to the anterior vaginal wall, thereby improving the long-term results of the anterior colporrhaphy.

The standard transverse incision for perineorrhaphy provides limited and incomplete exposure of the inferior surface of the base of the perineal body. Closure of the incision runs the risk of creating the formation of a ridge-like “bridge” with the possibility of associated dyspareunia. Rectocele and associated perineal widening are shown in Figure 186.30. A

V-shaped incision made through the skin of the perineum overlying the inferior margin of the perineal body and carried to the hymenal margin provides exposure and permits closure in the longitudinal axis. The width of the incision is determined by the degree to which the diameter of the subsequent vaginal outlet will be narrowed; that is, the incision is wider in a patient in whom there is to be considerable narrowing and is narrower in a patient, usually an older woman, in whom the degree of narrowing is to be considerably less.

The incisions are carried into the full thickness of the wall of the posterior vagina. The perineal skin is carefully dissected from the perineum and the rectum (Fig. 186.31) through the scar tissue from the patient's previous deliveries until the operator has identified the lower margin of the rectovaginal space. This is the upper margin of the perineal body, and the dissection is continued to the weakened fibromuscular wall of the vagina, which is carefully separated from the surrounding scar tissue searching for the fascia of Denonvilliers. Continued sharp dissection using the scissors extends the limits of the dissection laterally to the margins of the rectovaginal space (Fig. 186.32). The limit of dissection should be carried as high as necessary cranial to the highest point of the rectocele (Fig. 186.33). Any enterocele sac should be identified, opened, and, after high ligation of its neck with permanent suture, excised. Any necessary colpopexy should be accomplished to restore the depth and position of the vaginal vault.

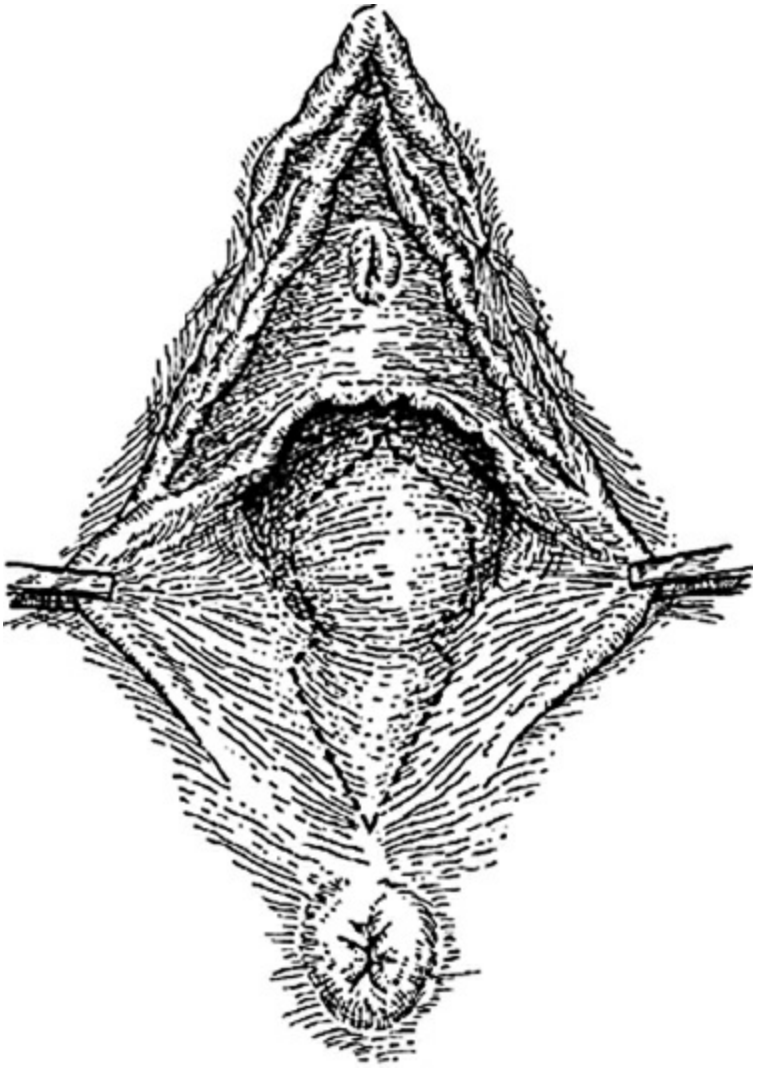

Figure 186.30. A rectocele and perineal defect. The site of the V-shaped incision in the perineum is noted by the *dotted line*, as is the site of incision in the posterior vaginal wall.

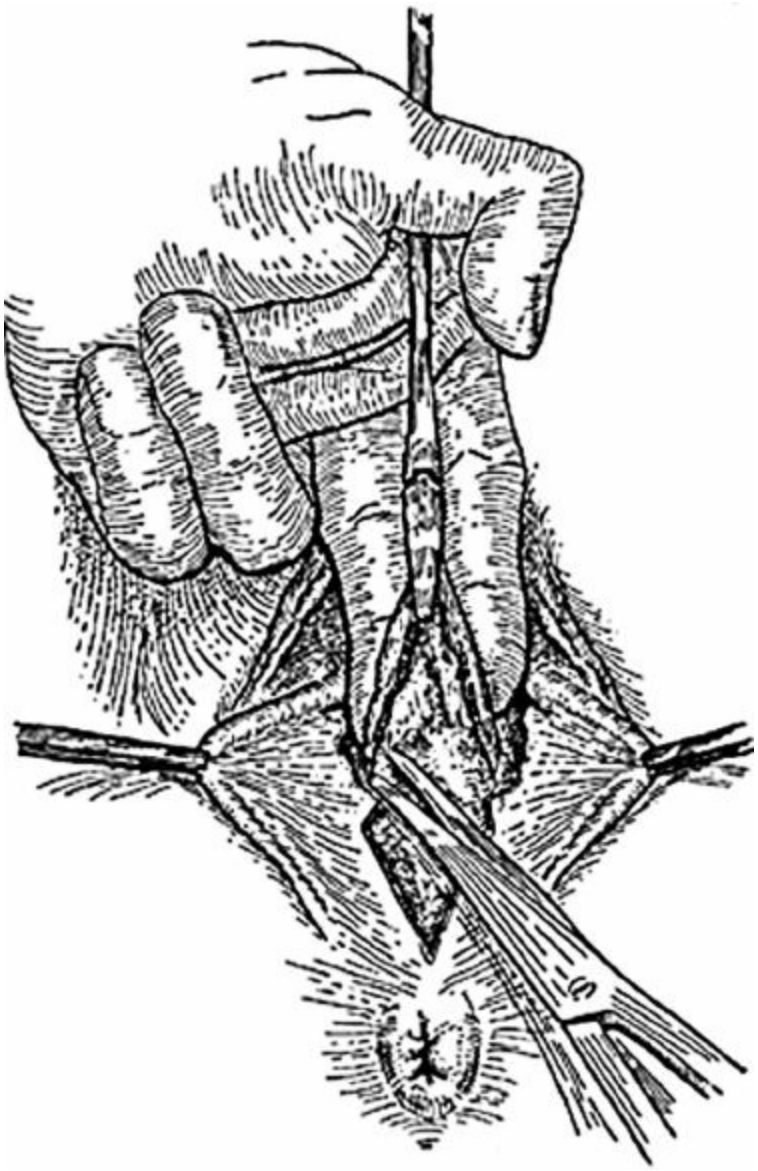

Figure 186.31. The incision has been made, and the skin of the perineum and of the posterior vaginal wall is being separated from the underlying connective tissue.

Ballooning of the anterior rectal wall can be reduced by plication with a running polyglycolic acid. A series of horizontal mattress sutures of polyglycolic acid suture (Fig. 186.34) that includes fibers of the deep transverse perineal muscles as well as perirectal fascia are placed but not tied. After each stitch is placed, the ends are crossed before they are tied, and the operator should check carefully for any bridge or ridge that may be present. If a bridge or ridge is found, the stitch is removed before it is tied and replaced with one positioned closer to the rectum, lessening the chance for postoperative dyspareunia. The posterior vaginal wall is then approximated by a running subcuticular suture embracing the full

thickness of the fibromuscular layer and the fascia of Denonvilliers, which is fused to the undersurface of the posterior vaginal wall (Fig. 186.35). Every effort is made to reconstruct the perineal body with the normal anatomic components. However, if no other usable tissues to reconstruct the perineum are found, stitches are placed in the levator muscles (Fig. 186.36). Detachment of the perineal body from the capsule of the external anal sphincter can be repaired by a figure-of-eight stitch (Fig. 186.37).

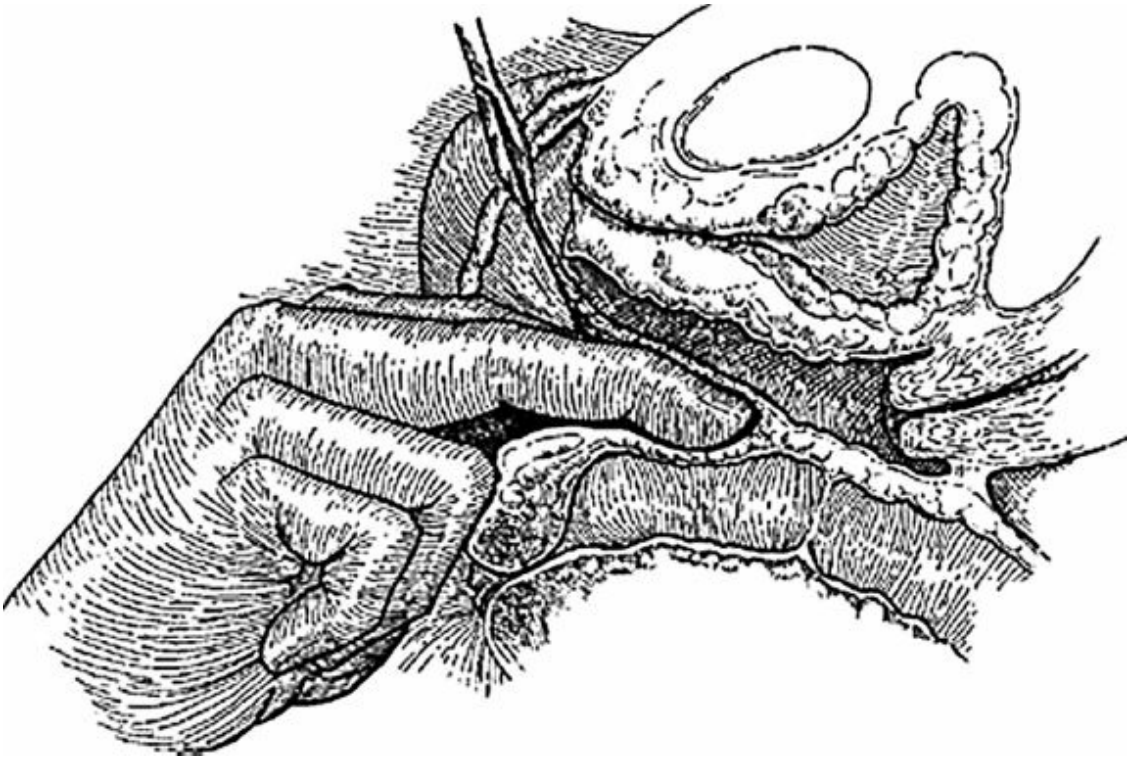

Figure 186.32. Entry has been gained into the rectovaginal space. The surgeon's finger identifies the most cranial point of the rectocele, and the dissection is taken to a point cranial to the defect.

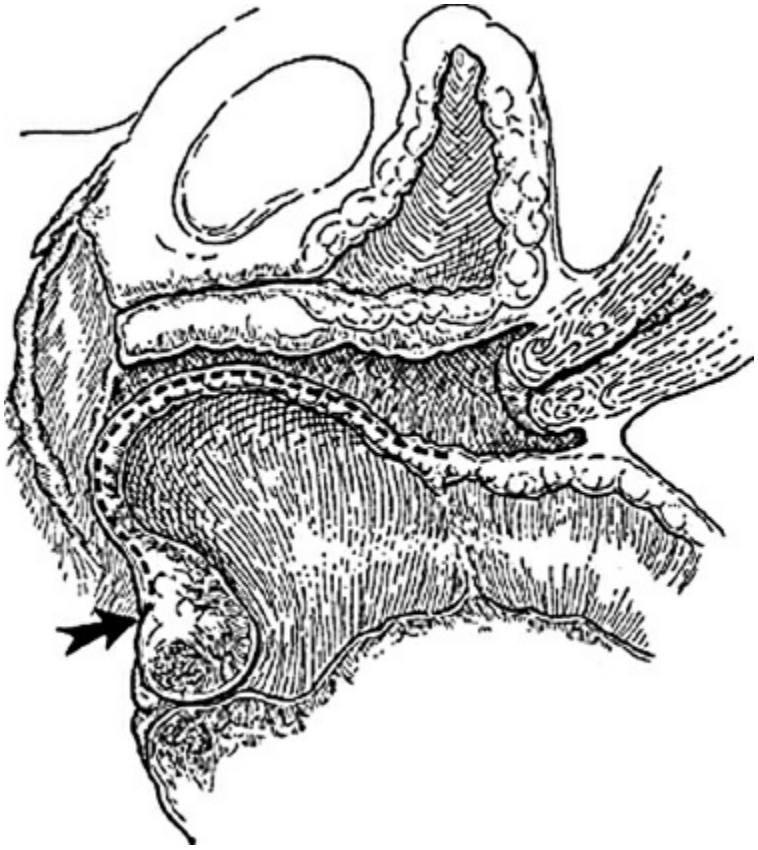

Figure 186.33. The incision is begun at the site indicated by the *arrow*; the extent of dissection is noted by the *dotted line.* The dissection must extend to a point cranial to the rectocele, which may at times extend along the entire length of the posterior vaginal wall.

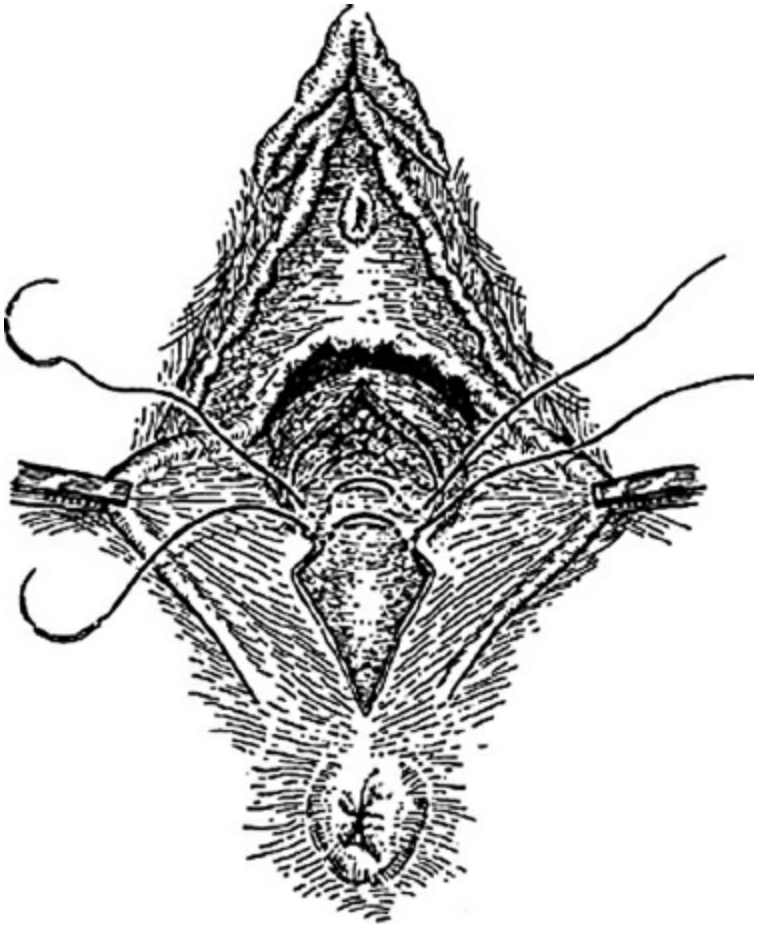

Figure 186.34. The perineum is reconstructed by plicating the transverse perineal muscles and pararectal connective tissues with interrupted mattress sutures in the midline.

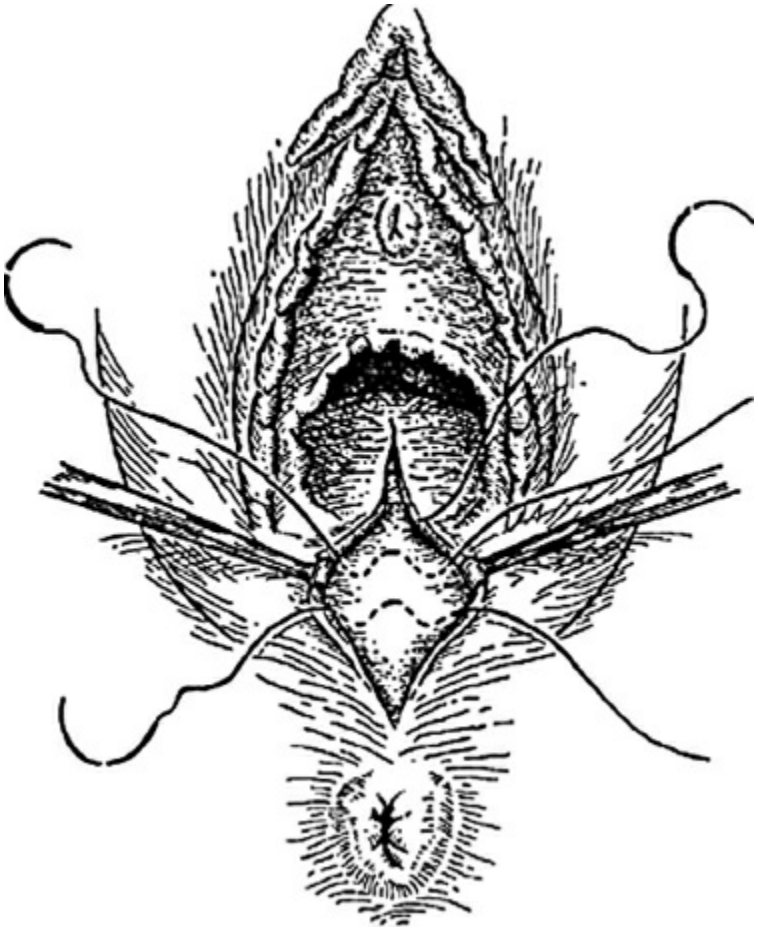

Figure 186.35. The posterior vaginal wall is reapproximated by a running subcuticular suture, and the perineal body is re-formed by placing interrupted mattress sutures.

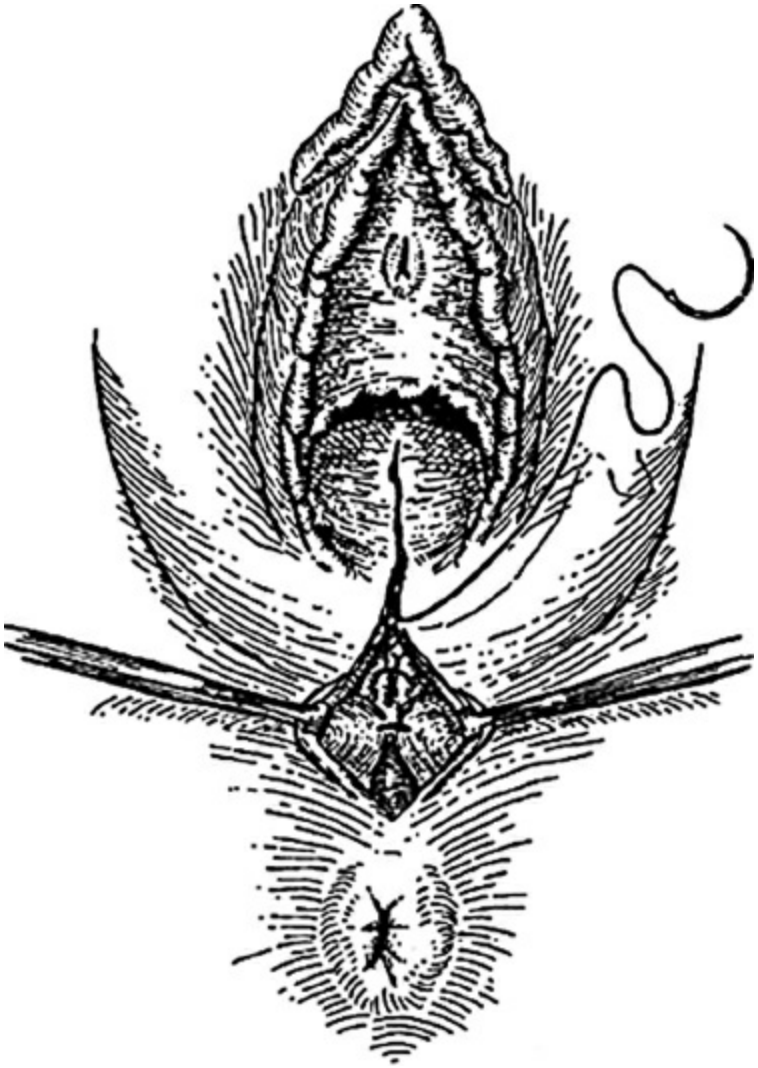

Figure 186.36. If perineal soft tissue is absent, the perineal body can be built up from stitches taken in the fascia of the pubococcygeus.

Horizontal mattress stitches of long-lasting absorbable suture are used to approximate the fascia and connective tissue medial to the levator muscles (Fig. 186.38). Direct levator stitches are unnecessary in most instances and are unanatomic, because the vaginal and perineal closure stitches bring the tissues to which they are attached closer together, appropriately restoring the narrowness of the genital hiatus (Fig. 186.39). The restorative stitches of the perineal body are now tied and the perineal skin closed with a continuation of the running subcuticular suture in much the way one might close a midline episiotomy.

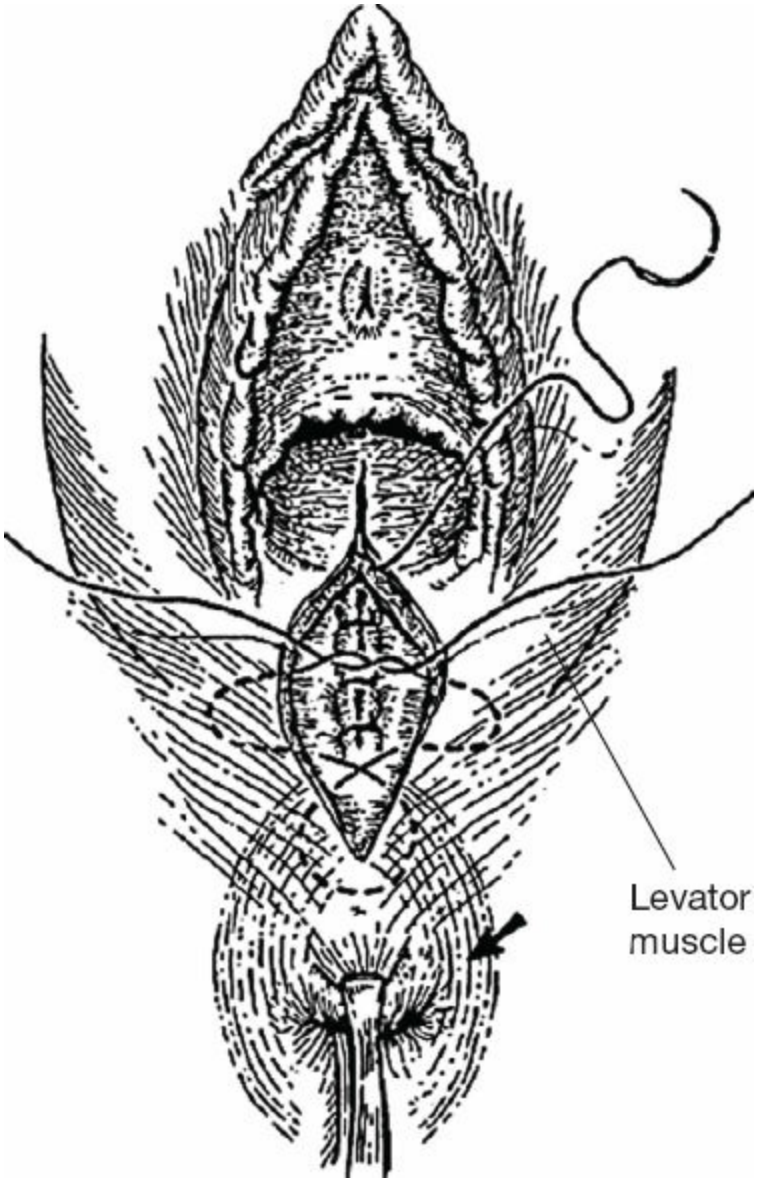

Figure 186.37. Attachment of the perineal body to the connective tissue capsule of the external anal sphincter (*arrow*) can be restored by a figure-of-eight stitch.

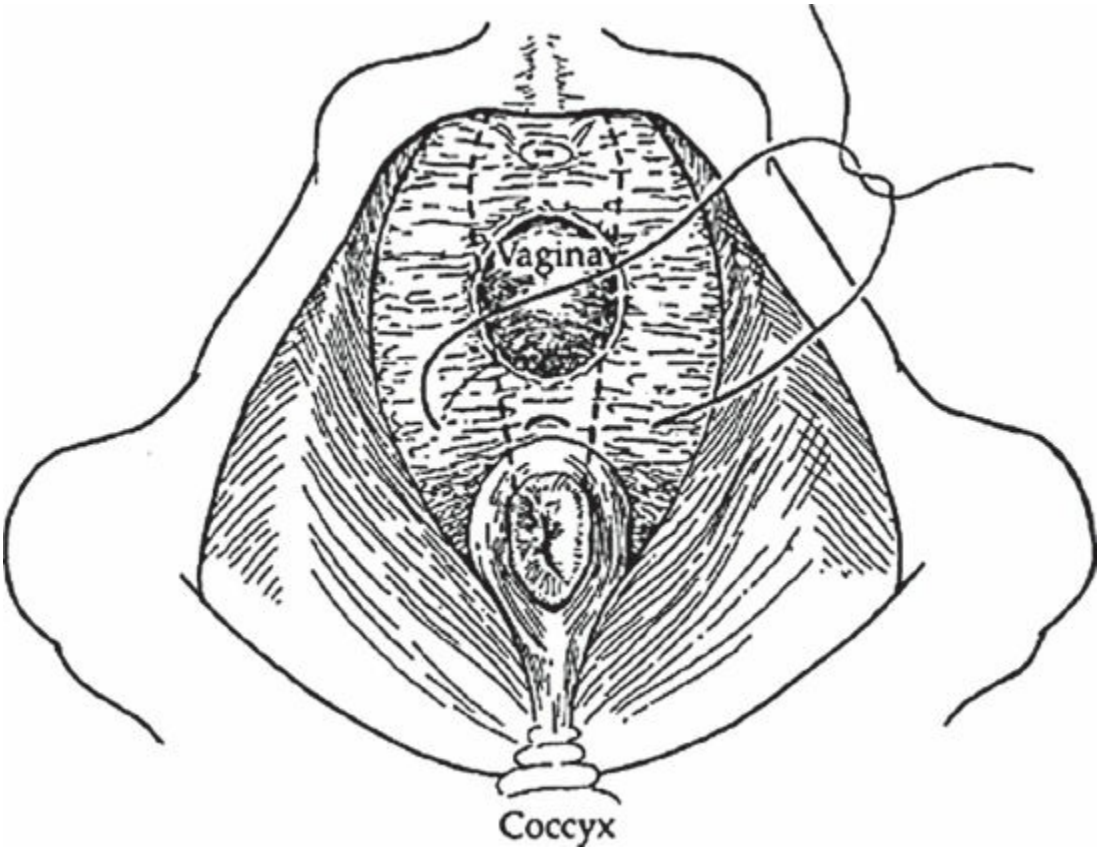

Figure 186.38. Schematic showing the widened genital hiatus between the bellies of the pubococcygei. The normal position of the medial border of the pubococcygei is indicated by the *dotted line.* A perineal body plication stitch has been placed in the connective tissue medial to the pubococcygei.

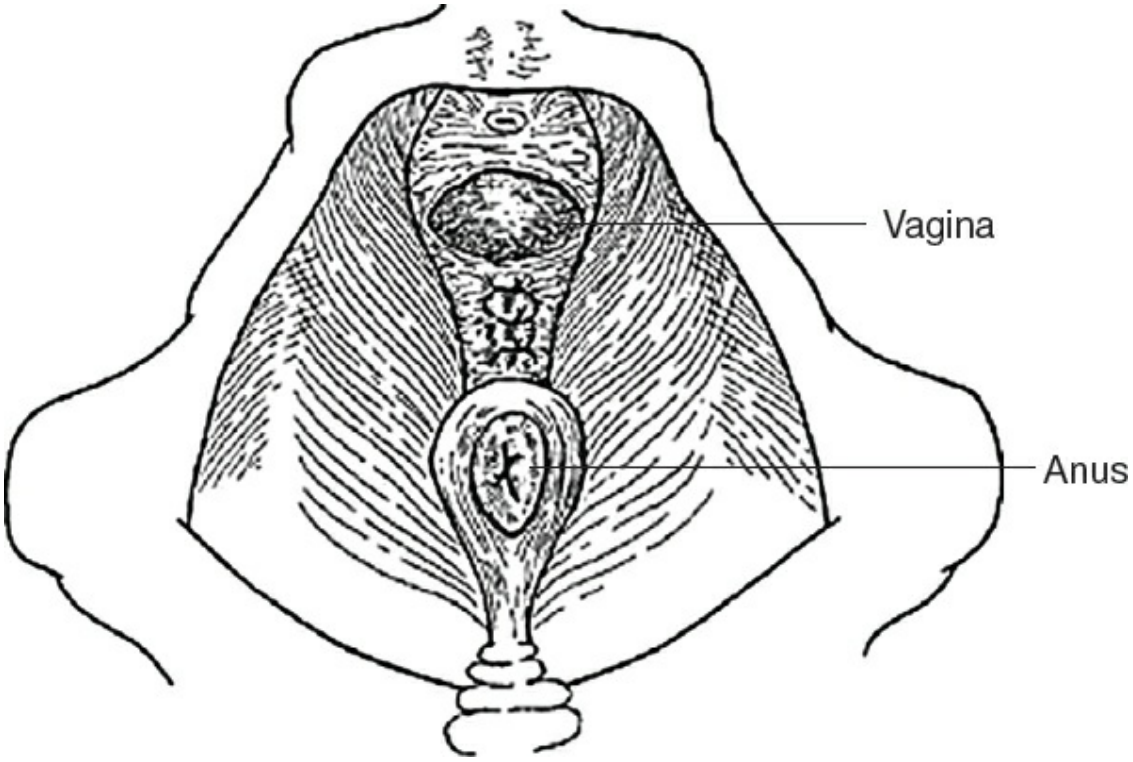

Figure 186.39. Several perineal plication stitches have been placed and tied. Note the narrowing effect on the genital hiatus to a more normal relationship with the vagina.

At the conclusion of the procedure, a gentle rectal examination is performed to confirm the integrity of the rectum and the absence of any suture penetration, as well as to correct the defect that had been determined preoperatively. If, at the conclusion of the procedure, it is evident that the desired goals of surgical treatment have not been met or that the vagina or introitus has been made overly constrictive, narrow, or stenotic, these observations should be addressed by appropriate additional surgical steps while the patient remains anesthetized. These may range from the placement of vaginal relaxing incisions at the 3 and 9 o'clock positions of the vagina to appropriate perineotomy, or to removal of any previously unidentified ridges or bridges in the subepithelial tissue. These conditions are far more easily corrected at this time than postoperatively.

POSTOPERATIVE MANAGEMENT

The rectum is a much more sensitive organ than the bladder. The perirectal tissues are tender postoperatively until the edema and swelling have dissipated and healing is complete. It is important that the patient take stool softeners for 2 months, with laxatives as necessary, to avoid

unnecessary straining at stool. Inquiries should be made as to the patient's bowel habits, appropriate dietary hydration, and restoration of normal bowel function.

EDITOR'S COMMENT

Dr. Veronikis has masterfully described the techniques of anterior and posterior colporrhaphy. The clinical entities repaired by these procedures are often not recognized by the general surgeon. Due to the increasing age of our population, all physicians are likely to encounter women with symptoms due to such disorders. Prompt recognition of these problems will earn the physician the

patient's gratitude.

Rectoceles are a common cause of constipation in women, frequently leading to an extensive and negative workup by gastroenterologists and other physicians. A careful history and simple physical examination can often lead to a rapid diagnosis. Rectoceles are often the consequence of vaginal delivery and increasing age. The most common presentation, as is brought out in the chapter, is often a feeling of incomplete evacuation, that is, the patient feels as if they need to defecate; however, they feel as if they cannot completely expel their bowel movement.

Within this chapter, the author carefully outlines the techniques of both anterior and posterior colporrhaphy. General surgeons, particularly those practicing in the United States, should be aware of the significant legal actions that have taken place following some of these procedures. The United States Food and Drug Administration issued a warning regarding the significant complications experienced by patients following use of surgical mesh following transvaginal repair of pelvic organ prolapse, stating that serious complications were "not rare" (https://www.fda.gov/MedicalDevices/Safety/AlertsandNotices/ucm262435.htm). As with all surgery, with attention to detail, careful diagnosis, proper patient selection, and selection of the proper operation, good results are achieved. A recent American College of Surgeons National Surgical Quality Improvement database study examining 6,849 patients undergoing transvaginal cystocele repair found that over 82.5% of patients underwent native tissue repair (Theofanides MC, Onyeji I, Matulay J, et al. Safety of mesh for vaginal cystocele repair: analysis of national patient characteristics and complications. *J Urol* 2017;198(3):632–7). A higher postoperative morbidity was seen in the remaining patients who underwent mesh repair, but this was low in both groups. A recent systematic review aimed at identifying risk factors for mesh erosion after female reconstructive surgery found that patients who were younger, those who had greater parity, those who were smokers, those who were diabetics, those in whom a concomitant hysterectomy was performed, those who were premenopausal or receiving estrogen replacement therapy, and those who had their surgery performed by a junior as opposed to a senior surgeon were at higher risk for mesh erosion (Deng T, Liao B, Luo D, et al. Risk factors for mesh erosion after female pelvic floor reconstructive surgery: a systematic review and meta-analysis. *BJU Int* 2016;117(2):323–43). In yet another 2016 systematic review comparing the use of biologic graft and synthetic mesh in transvaginal prolapse repair, the authors found that synthetic mesh repair of anterior wall prolapse improved outcomes compared with native tissue repair (Schimpf MO, Abed H, Sanses T, et al.; Society of Gynecologic Surgeons Systematic Review Group. Graft and mesh use in transvaginal prolapse repair: a systematic review. *Obstet Gynecol* 2016;128(1):81–91). In this study, however, up to 36% mesh erosion was observed. The rate of reoperation for this was however low. In the 2016 Cochrane review of "Surgery for Women with

Anterior Compartment Prolapse," there is a more guarded recommendation stating that "current evidence does not support the use of mesh repair compared with native tissue repair for anterior compartment prolapse owing to increased morbidity" (Maher C, Feiner B, Baessler K, et al. Surgery for women with anterior compartment prolapse. *Cochrane Database Syst Rev* 2016;11:CD004014). The authors cite the availability of newer lightweight meshes which have not, however, been assessed in randomized controlled trials.

In my community, fewer and fewer general gynecologists are willing to undertake anterior and posterior colporrhaphy and more of these patients are being referred to pelvic floor specialists. Rectoceles can also be treated in a transrectal manner (often performed by colon and rectal surgeons) with an anterior rectal mucosectomy and suture plication of the anterior rectal wall. This accomplishes a similar repair, as the gynecologist is performing from the transvaginal route. It is, however, very important to obtain a detailed history of symptoms from patients, as pelvic floor problems often do not occur in isolation, that is, women who have problems with defecation also may have problems with urinary incontinence. In a woman with an associated cystocele, it makes sense to repair both the anterior and posterior problems at the same time, that is, by a transvaginal approach.

Susan Galandiuk

D SURGERY OF THE HERNIA

187 Surgical Anatomy of the Hernial Rings

Petros Mirilas and Lee J. Skandalakis

Hernia, in general, is defined as the proptosis of tissue or viscus through an opening (ring). It follows that the surgeon must understand the boundaries of the ring, the content of the hernia, and at which surgico-anatomical layer this hernia occurs and the other implicated surgico-anatomical layers. Therefore, mastery of the layers of the abdominal wall, anterolateral and posterolateral, is a prerequisite for understanding and repairing hernias.

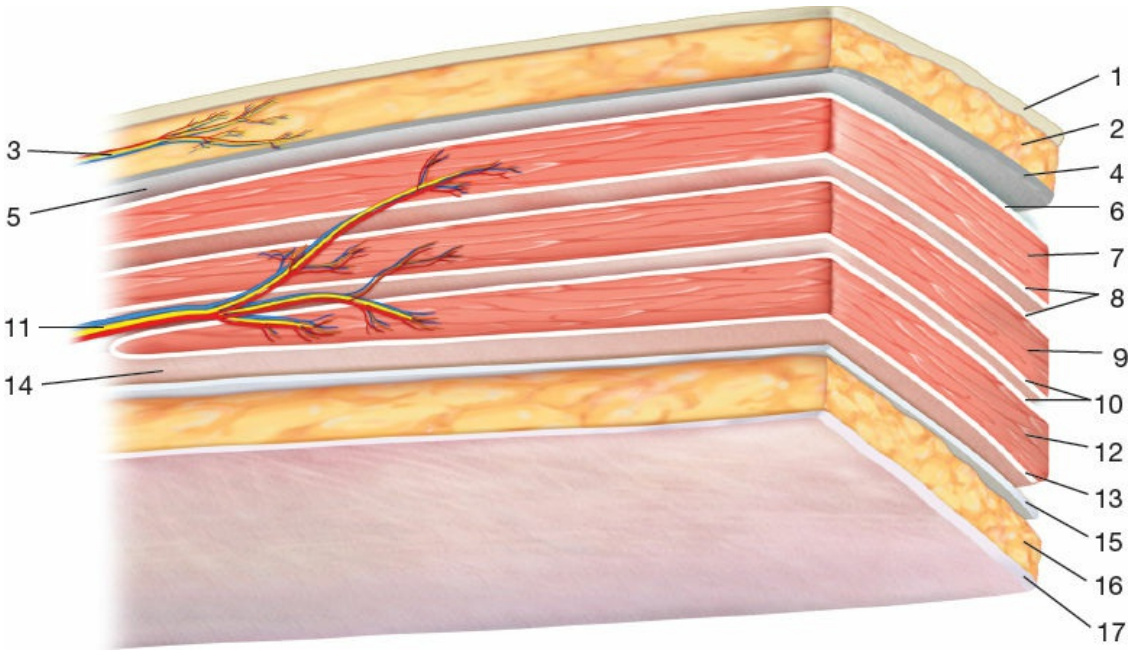

Figure 187.1. Schematic representation of the layers of the anterolateral abdominal wall. 1, skin; 2, fatty layer of superficial fascia (Camper fascia); 3, neurovascular supply of superficial fascia; 4, membranous layer of superficial fascia (Scarpa fascia); 5, space with areolar tissue; 6, deep fascia (outer investing fascia of external oblique muscle); 7, external oblique muscle; 8, inner

investing fascia of external oblique muscle and outer investing fascia of internal oblique muscle (they fuse; here presented separately for didactic reasons); 9, internal oblique muscle; 10, inner investing fascia of internal oblique muscle and outer investing fascia of trnasversus abdominis muscle (they fuse; here presented separately); 11, neurovascular bundle of abdominal muscles (between internal oblique and transversus abdominis muscles); 12, transversus abdominis muscle; 13, transversalis fascia (the inner investing fascia of the transversus muscle); 14, parietal compartment of preperitoneal space; 15, membranous layer of preperitoneal tissue; 16, preperitoneal fat in the visceral compartment of preperitoneal tissue; 17, peritonmeum.

LAYERS OF THE ANTEROLATERAL ABDOMINAL WALL

The structure of the anterolateral abdominal wall is diagrammatically presented in Figure 187.1. Under the skin, the superficial fascia comprises a fatty layer (Camper fascia) and a membranous layer (Scarpa fascia). In the upper abdominal wall, above the umbilicus, the Scarpa fascia is not easily discriminated and separated from the deep fascia, which invests the muscles. Advancing toward the inguinal region, the deeper part of the fatty layer becomes more membranous. Some report that Scarpa fascia becomes multilayered; however, Scarpa fascia is a single, dense, strong layer, distinct from the more superficial fatty layer. Scarpa fascia is always identified during opening of the abdominal wall and always sutured independently during closure. Scarpa fascia is attached on the inguinal ligament, and is fastened to the fascia lata of the thigh at a distance of one finger breadth below the inguinal ligament. Scarpa fascia is attached to the linea alba, and continues in the perineum as the membranous layer of the superficial perineal fascia. It continues in the scrotum, where it is replaced by the dartos (enriched by muscle).

The superficial fascia harbors its neurovascular supply in the fatty layer. Lateral and anterior cutaneous branches of thorocoabdominal and subcostal nerves supply the superficial fascia. The arteries are cutaneous branches of the superficial epigastric and superficial circumflex artery. The superficial veins (superficial epigastric, etc.) below the umbilicus empty in the saphenous vein, while cephalad into the lateral thoracic vein that goes into the axillary vein.

Between Scarpa fascia and muscles, there is an areolar layer, which permits the movement of the whole superficial fascia, fatty, and

membranous layers. The muscles are arranged in three layers—the external oblique, internal oblique, and transversus abdominis muscles. Each muscle is enveloped by an investing fascia. Thus, in the outer surface there is an investing fascia of the external oblique, called deep fascia. The investing fasciae between muscle layers fuse, while the internal surface of the transversus muscle is covered by the investing fascia that takes its name, the transversalis fascia.

The transversalis fascia has been the subject of misunderstanding. Classically, it is described to be continuous with the diaphragmatic, parietal pelvic, and with the transversalis fascia of the contralateral side. Thus, the transversalis fascia, although in truth is the inner investing fascia of the transversalis muscle, is asked to continue behind the rectus sheath where the transversalis muscle is absent or to stay behind as the posterior wall of the inguinal canal at the moment the transversalis muscle arches over the spermatic cord to find the conjoined tendon (together with the internal oblique). In order to solve this inaccuracy, in the past, writers including us suggested that the transversalis fascia has two layers—an anterior lamina and a posterior lamina. The anterior layer was said to be attached to the muscle as should an investing fascia do. The posterior (inner) was deeper, in the extraperitoneal tissue. The truth, however, is that the inner layer of the transversalis fascia is a condensation fascia, part of the extraperitoneal tissue.

The three layers of muscles are fed by the thoracoabdominal vessels and nerves. The neurovascular bundles, which merit attention during operation, are found between the second and third muscular layer, i.e., between the internal oblique and the transversus muscle (Fig. 187.1).

Deep to the investing fascia of the transversus muscle (transversalis fascia), and exterior to the peritoneum is the extraperitoneal space, which is named preperitoneal when referring to the anteriolateral abdominal wall. The structure of this space is almost a mirror image of the superficial fascia: there is a membranous layer of the preperitoneal space and an inner fatty layer (Fig. 187.1). This structure is most evident in the lower abdominal wall pelvic wall; in order to accommodate movement and expansion of extraperitoneal organs (e.g., urinary bladder), there is an aggregation of extraperitoneal fascia to fill in spaces and to ensheath and support these organs. The membranous layer of the extraperitoneal tissue is considered to be a condensation fascia and divides the extraperitoneal space into two planes—a parietal and a visceral. The contents of these

planes are discussed in association with the secondary internal inguinal ring in the inguinal hernia section.

EPIGASTRIC HERNIA

Epigastric hernia is known also as hernia of the linea alba. It is also referred to as a ventral hernia, but this term describes any hernia that can develop in the abdominal wall, even incisional hernias. In the epigastric hernia, the hernial ring is composed entirely of fibers of the linea alba. It may lie anywhere between the xiphoid process and the umbilicus (Fig. 187.2). It is likely that herniation is the result of enlargement of the spaces existing between decussating tendinous fibers of the rectus sheath at the linea alba, especially at sites of passage of neurovascular bundles.

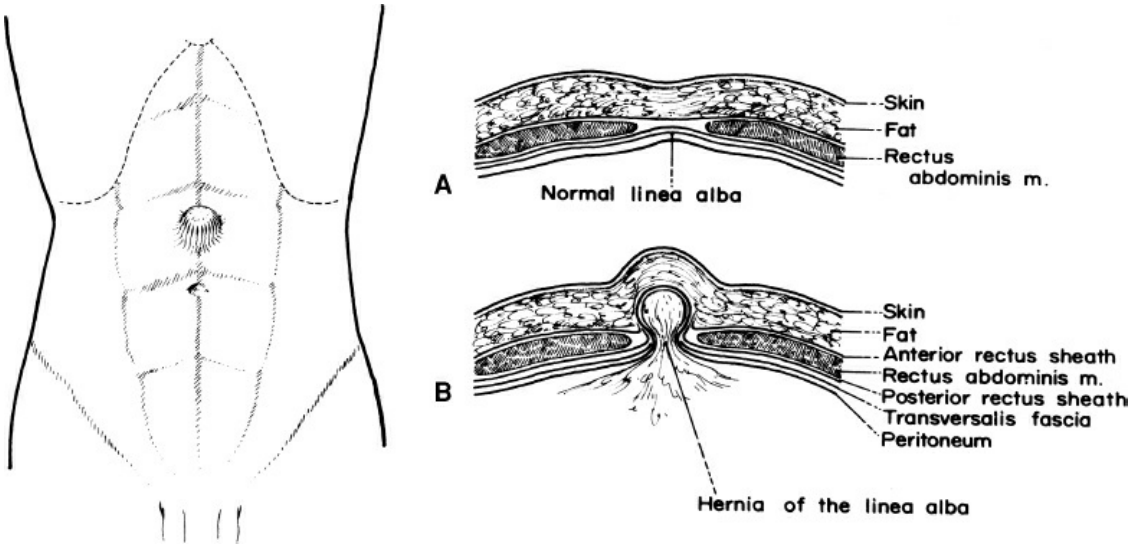

Figure 187.2. Epigastric hernia. **A.** Transverse section of the normal body wall above the umbilicus. **B.** Herniation through the linea alba above the umbilicus. (From Skandalakis JE, Gray SW, Akin JT Jr. The surgical anatomy of hernial rings. *Surg Clin North Am* 1974;54:1227, with permission.)

The medial edge of one or both rectus muscles may form the lateral border of the hernial ring. If the defect is >1.5 cm, the lateral border of the hernial ring may be formed not only by the anterior and posterior laminae of the rectus sheath, but also by the lateral edge of the muscle between.

A sac may be present at the site of weakness, or there may be a protrusion of preperitoneal fat without a sac. When incarceration occurs, the ring may be enlarged surgically by superior or inferior incision of the linea alba. Occasionally, but rarely, a lateral incision of the anterior lamina

of the rectus sheath may be necessary.

The epigastric hernia should be distinguished from the diastasis recti, i.e., the separation of the recti muscles (>2 fingertips), which is due to stretching of the linea alba. This condition usually affects infants, children, and pregnant women. This is not a true hernia and there is no ring, but can lead to epigastric or umbilical hernia as a complication.

UMBILICAL HERNIA

At the umbilicus, the layers of the abdominal wall fuse. Thus, in the mature organism the skin remains attached to the deep fascia despite the accumulation of subcutaneous fat and produces the depressed scar.

In the embryon, the umbilical ring is the exit and entrance point of the major vessels connecting to the maternal circulation (umbilical arteries and umbilical vein) and the entrance for the urachus. At the opening of the umbilicus attaches the umbilical cord that carries the two umbilical arteries and the umbilical vein; the covering of the umbilical cord is continuous with the skin. The round ligament of the liver is the continuation of the umbilical vein that becomes obliterated. This ligament arises from the inferior margin of the umbilical ring and passes superiorly to continue in the falciform ligament of the liver. At the umbilical ring there are more structures-remnants of embryonic entities: the two medial umbilical ligaments representing the two obliterated umbilical arteries, and the median umbilical ligament, which is the obliterated urachus (Fig. 187.3).

Often, in the preperitoneal tissue, between the peritoneum and the umbilical vessels, develops a fibrous lamina, the umbilical fascia (Fig. 187.4). The fibers of this fascia run transversally, and its upper and lower borders are not very distinct. The umbilical fascia is at the same layer with the membranous layer of the preperitoneal tissue and most likely is a condensation of the latter. Some authors consider the umbilical fascia as a thickening of the transversalis fascia (the inner layer), which is here renamed as membranous fascia of the extraperitoneal tissue. The round ligament of the liver is found external to the umbilical fascia (Fig. 187.5).

In most cases, the round ligament of the liver crosses over the umbilical ring (Fig. 187.6A). There are cases where the round ligament splits and attaches to the superior margin of the umbilical ring (Fig. 187.6B). Beneath the umbilical ring, the “floor” consists of umbilical fascia and peritoneum; preperitoneal tissue is minimal at the umbilicus. The umbilical fascia may undercover the floor of the umbilical ring entirely (Fig.

187.6C) or partially, i.e., in the superior portion (Fig. 187.6D) or the inferior portion (Fig. 187.6E); or the umbilical fascia may exist but does not lie under the ring (Fig. 187.6E).

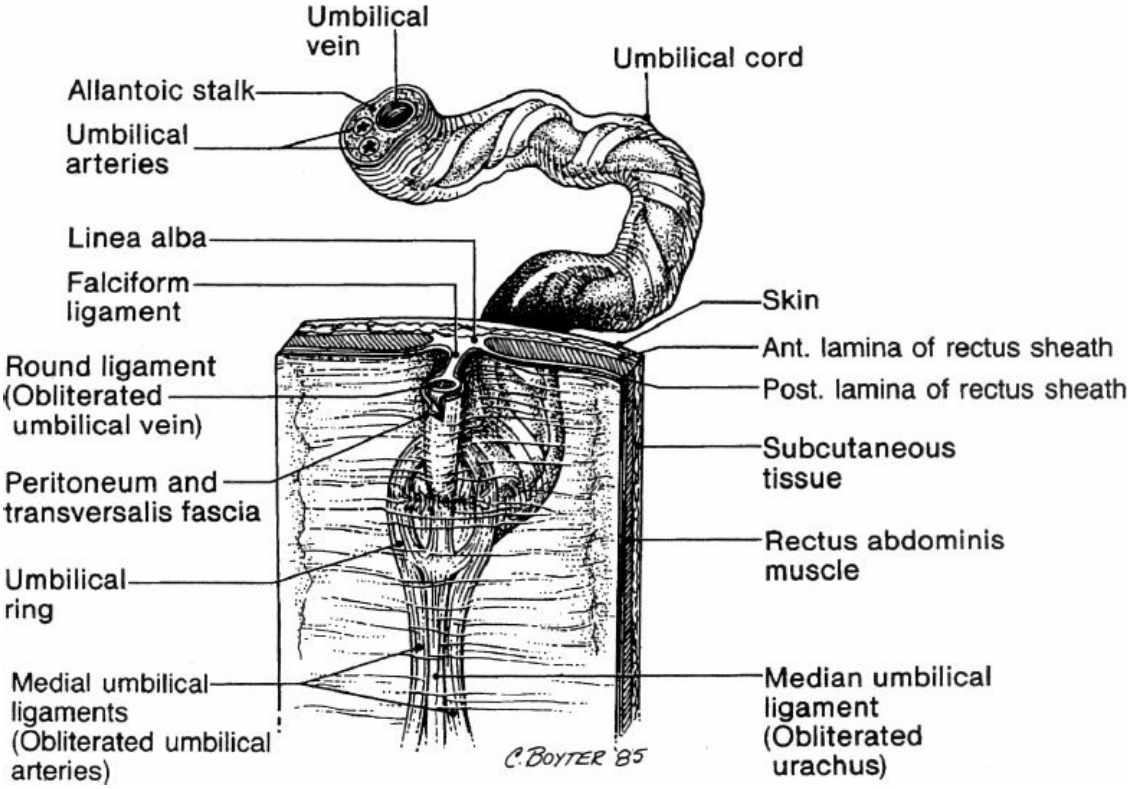

Figure 187.3. Posterior surface of the anterior abdominal wall of a newborn infant. The umbilical cord is still attached. The medial umbilical ligaments (obliterated umbilical arteries) and the median umbilical ligament (obliterated urachus) participate in the formation of the umbilical ring. The round ligament (obliterated umbilical vein) arises from the inferior margin of the ring and passes into the falciform ligament. (From Skandalakis JE, Gray SW, Mansberger AR Jr, et al. *Hernia: Surgical Anatomy and Technique.* New York: McGraw-Hill; 1989.)

The round ligament and the umbilical fascia offer support to the umbilical area. In case the round ligament bifurcates and is not attached to the lower semicircle of the umbilical ring, herniation is easier. If, in addition the umbilical fascia is absent, then the umbilical region is unsupported, and a “direct” hernia may occur through the ring (see arrow in Fig. 187.6B,F). If the umbilical fascia covers only partially the ring, then an “indirect” hernia may descend or ascend into the ring (see arrow in Fig. 187.6D,E). If the umbilical fascia is absent, the umbilical ring is unsupported and prone to hernia (see arrow in Fig. 187.6F,G).

The umbilical hernia is the minor of the congenital anomalies of the umbilical ring. The anomaly is essentially an enlarged umbilical ring, and the sac is covered by all layers, i.e., peritoneum, membranous layer of preperitoneal tissue (the previously called transversalis fascia) (Fig. 187.7). The umbilical fascia is not a covering of the sac; this fascia is considered to belong only to the floor of the umbilical ring and the absence of the fascia or the partial covering of the ring as a reason for the hernia. The hernial sac is usually tightly adherent to the umbilical skin.
