Gadolinium-enhanced breast MRI may be considered in women who are postpartum and lactating at the time of diagnosis if the mammogram and/or ultrasound images are equivocal.

The American College of Radiology guidelines do not require that patients discontinue breastfeeding. MRI may be difficult to interpret in the lactating state because the increased enhancement from physiologic hypervascularity increases the background enhancement, where diffuse high-signal intensity on T2-weighted images can decrease efficacy. Prudence must be exercised in this setting to avoid unnecessary interventions to the lactating breast.

Biopsy

A clinically suspicious breast mass requires biopsy for definitive diagnosis, regardless of whether or not a woman is pregnant and despite negative mammographic or ultrasound findings. Core, vacuum-assisted, or excisional biopsies can be performed relatively safely during pregnancy, preferably under local anesthesia.

Ultrasound-guided core biopsy or vacuum-assisted biopsy is the preferred method and is a safe procedure regardless of gestational period. Either technique of biopsy can be used. Vacuum-assisted devices have a larger-gauge biopsy needle and lower false-negative rate. Reported complications from breast biopsy in the pregnant patient are similar to those in the nonpregnant patient and include infection, allergy to local anesthetic, hematoma, and milk fistula during pregnancy. In regard to formation of a milk fistula after core

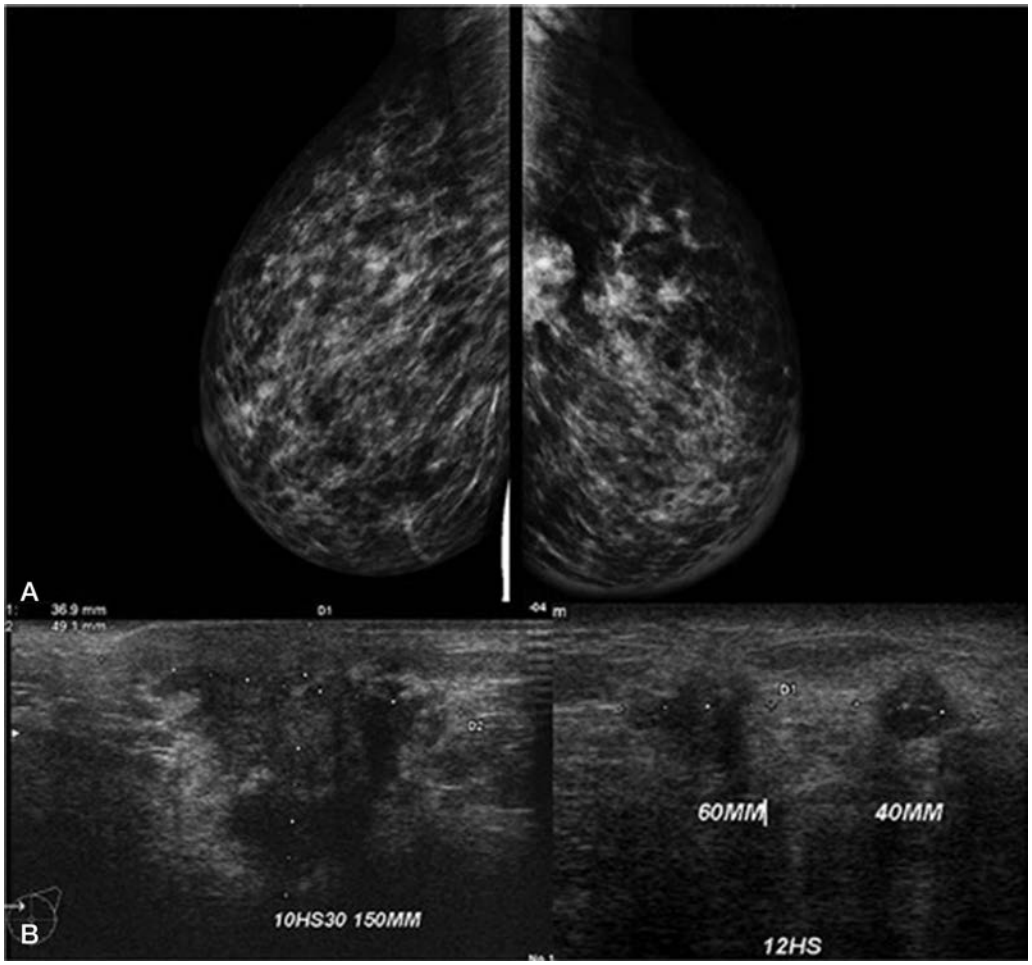

FIG. 3 Inflammatory breast cancer in a 32-year-old woman who is 1 month pregnant. Multifocal lesions in mammography **(A)** and ultrasound **(B)**. *(Courtesy Dr. Adriana Langer. From Alipour S, Omranipour R, et al.,* Diseases of the breast during pregnancy and lactation. Advances in Experimental Medicine and Biology, vol 1252. Springer; 2020.)

needle biopsy, the literature contains only sporadic case reports, which makes this a low to nonexistent risk. The risk may be higher in more centrally located lesions and in the setting of excisional biopsies, but it is a process that will resolve spontaneously.

After performing the biopsy, it is important to alert the pathologist that the biopsy is from a pregnant patient as histologic changes occur as a result of hormonal influences, such as epithelial proliferation in the lobular unit and an increased glandular vascularity as described. If there is radiographic and pathologic discordance, an excisional biopsy is then performed.

It is important to note that fine-needle aspiration (FNA) biopsy can also be considered, but it is suboptimal compared with core needle biopsy. Given the physiologic changes of the breast secondary to pregnancy, the cytologic analysis is challenging and will demonstrate increased cellularity and frequent mitosis, which can be physiologic from pregnancy and not secondary to an underlying malignancy.

Staging

It is important to limit the exposure to ionizing radiation in the pregnant patient. The most sensitive period for radiation-associated malformations is during organogenesis, at 8 weeks of gestation. CT scan, scintigraphy (bone scan), and PET scans are contraindicated throughout the pregnancy because of the high radiation exposure.

Staging workup is performed on those patients with clinical stage III (cT3N1 or any ≥ N2) or stage IV disease or symptoms suggestive of distant metastases. Workup consists of a chest x-ray with abdominal shielding, liver ultrasonography or noncontrast MRI for visceral organ evaluation, and noncontrast skeletal MRI if bone metastases are suspected. Bone is the most common metastatic site in breast cancer, and it is important to note that alkaline phosphatase increases in pregnancy so cannot be used as a marker for bony metastases. Diffusion-weighted whole-body MRI without gadolinium can be considered after the first trimester if metastatic disease is suspected. If brain metastasis is suspected, MRI is the most sensitive imaging technique.

The use of PET in pregnancy is very limited. Estimates of fetal radiation dose from ^{18}F fluorodeoxyglucose (^{18}F-FDG) are 6.29×10^{-3} to 2.46×10^{-2} mGy/MBq, where earlier bladder voiding reduced these doses by 25% to 45%; however, there is no evidence to support its use. The amounts of ^{18}F-FDG excreted in breast milk after a PET scan are low, and guidelines would suggest the only adjustments that a nursing mother should make after a PET scan are to avoid close contact with the infant for up to 12 hours.

HISTOLOGY OF BREAST CANCER IN PREGNANCY

There are no obvious differences in histologic types of breast cancer among those associated and not associated with pregnancy. Invasive ductal carcinoma, not otherwise specified (NOS) is the most prevalent type of tumor in pregnancy; representing 78% to 88% of cases. Invasive lobular carcinoma is reported with a very low frequency in some studies. Mucinous, medullary, and other types of carcinoma are also reported. Ductal carcinoma in pregnancy has a higher histologic grade, a more aggressive profile, and a more advanced stage at diagnosis: a larger tumor size, a higher frequency of nodal involvement, less frequent expression of estrogen receptors (ERs) and progesterone receptors (PRs), and a higher proportion of inflammatory breast cancer.

TREATMENT: BREAST CANCER IN PREGNANCY

There are still certain cultures and countries that recommend abortion when a woman is diagnosed with breast cancer during her pregnancy. Termination of pregnancy does not improve maternal prognosis or outcome. The conversation with these patients should focus on balancing the risks to the fetus from the cancer treatment with the risks to the mother from the cancer, which leads to alterations to standard treatment options and sequences that have not been shown to change the prognosis of these women.

The treatment of their cancer should adhere as much as possible to standard treatments for breast cancer in the nonpregnant patient. Surgery and chemotherapy are possible and safe during pregnancy and should be tailored based on anatomic stage, tumor biology, and the gestational age of the fetus to guide choices of treatment and sequence of treatment.

Managing the pregnant breast cancer patient should involve a multidisciplinary team including the breast surgeon, medical oncologist, radiation oncologist, radiologist, maternal fetal medicine specialist, anesthesiologist, obstetrician, neonatologist, and genetic counselor.

Genetic testing is indicated when a pregnant patient is diagnosed with breast cancer. Special surveillance tests, chemoprevention, and risk-reducing surgery would not be recommended for pregnant women found to carry pathogenic variants. These interventions can be considered postpartum. The probability of detecting a pathogenic *BRCA* variant in a young patient with a triple-negative breast cancer is approximately 20%.

SURGICAL CONSIDERATIONS

Surgery may be performed at any time during pregnancy in all trimesters, but the safest time to operate on a pregnant patient is in the second trimester (weeks 12–24). General anesthetics all cross the placenta but have not been reported to increase the risk of congenital anomalies. Spontaneous abortion has been reported in women undergoing surgery in the first and early second trimesters of pregnancy. Key tenets for a successful operation are avoiding maternal hypoxia or hypotension. The goal should be to maintain the mean arterial pressure (MAP) at 60 mm Hg, as this is the optimal MAP for uterine perfusion during surgery.

After 20 weeks' gestational age, the position of the patient should be in the left lateral tilt position for uterine displacement off the inferior vena cava. After 24 weeks, which is when the fetus is considered viable, intraoperative fetal monitoring is necessary. Maternal fetal medicine specialists should also be available and the neonatologist on standby should the patient start to labor during the operation. Figure 4 shows a pregnant patient positioned in the operating room with fetal monitoring after undergoing a mastectomy.

Mastectomy versus Breast Conservation

In the past, mastectomy was considered the standard surgical procedure for the local management of all pregnant patients with breast cancer. However, mastectomy is not mandatory at all stages of pregnancy. Breast conservation and mastectomy are options for these patients depending on the gestational age at diagnosis. Mastectomy can be performed in all trimesters. When considering breast-conserving surgery, timing for radiation therapy must be considered as radiation cannot be given during pregnancy. Therefore, mastectomy is the standard for local control in the first trimester. Suitability for breast-conserving surgery in the second and third trimesters is determined in the same way as for nonpregnant patients and considers tumor size, tumor location, and tumor–to–breast size ratio as well as adjuvant therapy.

Breast-conserving surgery is not recommended in the first trimester or early second trimester as this would cause a significant delay in the receipt of radiation and increase the risk of local recurrence. Breast conservation is an option in the second trimester if followed by adjuvant chemotherapy during the remainder of the pregnancy and then radiation therapy soon after delivery. In the third trimester, breast-conserving surgery can be performed and followed with postpartum radiation. Further, breast conservation can be performed preceding neoadjuvant chemotherapy, which

FIG. 4 Positioning and monitoring of the pregnant patient after mastectomy. *(From Amant F, Loibl S, Neven P, Van Calsteren K. Breast cancer in pregnancy.* Lancet. *2012;379:570–579.)*

would start during week 14. The patient can then receive adjuvant chemotherapy until the end of the pregnancy and postpartum radiation thereafter. This decision should be made in the context of a multidisciplinary team discussion. Figure 5 outlines the breast and axillary surgeries allowable by trimester of pregnancy.

Axillary Staging/Sentinel Lymph Node Biopsy

Historically, axillary lymph node dissection was recommended to all women diagnosed with breast cancer in pregnancy as data on the safety and efficacy of sentinel lymph node biopsy (SLNB) in the pregnant patient was lacking. Currently, there are sufficient data demonstrating that SLNB is safe and can be performed in all trimesters with the use of technetium-99. SLNB involves locoregional administration of relatively low injected radioactivity doses. There is rapid clearance of the negligible radioactivity in the body, with a substantial and stable uptake at the injection site, which is removed surgically shortly thereafter. Considering the radiopharmaceuticals and the amounts of activity typically used for SLNB in optimized protocols, the doses absorbed by the fetus are mostly less than 20 μGy. There is no need to perform an upfront axillary dissection for a clinically node-negative

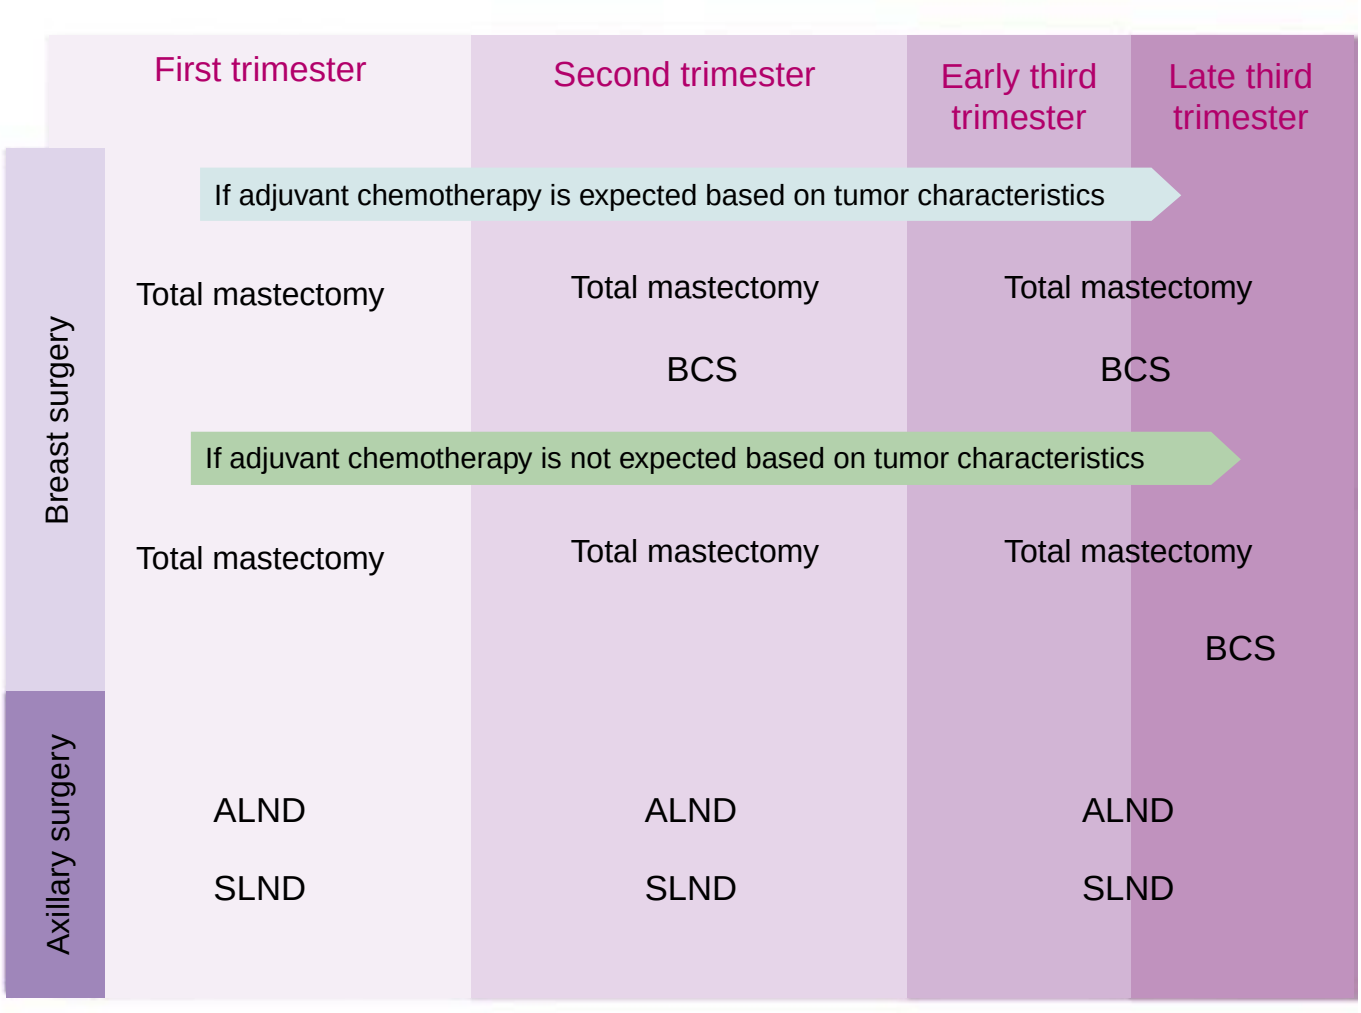

FIG. 5 Type of surgery of the breast and axilla for pregnancy-associated breast cancer in different trimesters; when two types of surgery are allowed, the choice depends on tumor characteristics and patient preference. Blue dye should not be used for sentinel lymph node dissection in pregnancy. ***ALND,*** Axillary lymph node dissection; ***BCS,*** breast-conserving surgery; ***SLND,*** sentinel lymph node dissection. *(From Omranipour R. Surgery for pregnancy-associated breast cancer. In Alipour S, Omranipour R, et al.,* Diseases of the breast during pregnancy and lactation. Advances in Experimental Medicine and Biology, vol 1252. Springer; 2020.)

axilla. Pregnant patients with breast cancer should be offered SLNB rather than axillary dissection whenever it is indicated according to general practice in the nonpregnant patient. Blue dye is currently contraindicated in pregnancy. Isosulfan blue causes anaphylaxis in 1% of patients, and methylene blue places the fetus at risk for methemoglobinemia. Further, the blue dyes have unknown teratogenicity.

Immediate Reconstruction

It is safe and feasible to reconstruct after mastectomy using tissue expanders. Studies have demonstrated an increase in operating room time and anesthesia, but no increase in maternal morbidity, obstetric complications, or adverse fetal outcome. Further, immediate reconstruction with tissue expanders may preserve reconstructive options for patients undergoing postmastectomy radiation (PMRT), especially in patients who would be poor candidates for an autologous flap in the future.

CHEMOTHERAPY IN PREGNANCY

The decision to administer chemotherapy to the pregnant breast cancer patient should follow the same guidelines as in nonpregnant patients, taking into account the gestational age and the overall treatment plan such as the timing of surgery and the need for radiotherapy. Chemotherapy can be administered in the adjuvant or neoadjuvant setting and should be administered after the first trimester. Chemotherapy is contraindicated in the first trimester because of the risk of fetal teratogenesis during weeks 4 to 12 but can be started as early as week 14. Chemotherapy has been shown to be safe in the second and third trimesters. Fluorouracil, cyclophosphamide, doxorubicin, and taxanes are all safe in pregnancy. Clinicians can use standard regimens used for nonpregnant patients. One of the most common regimens is doxorubicin-based (doxorubicin plus cyclophosphamide or doxorubicin plus cyclophosphamide and taxanes [paclitaxel weekly to every 3 weeks or docetaxel every 3 weeks]. There are other regimens described such as fluorouracil, epirubicin, and cyclophosphamide. Some investigators recommend weekly epirubicin treatment on the basis of fetal safety data, but this is not the standard treatment for breast cancer, and clinicians should not put maternal prognosis at risk to limit or reduce unproven fetal damage. The main advantage of weekly regimens during pregnancy is shorter nadir periods that might reduce the risk of complications when unexpected delivery occurs. Dose-dense regimens of doxorubicin with cyclophosphamide and taxane result in improved DFS and OS in hormone receptor–negative nonpregnant breast cancer patients. Hormone receptor–negative disease is more common in pregnancy, but the data on dose-dense chemotherapeutic regimens during pregnancy are scarce. Small studies have shown that there is no increased risk of maternal or fetal complications with the use of dose-dense regimens.

In regard to supporting the pregnant patient on chemotherapy, antiemetics (i.e., metoclopramide, ondansetron, granisetron, and prochlorperazine) are considered safe. Steroids are used before induction of chemotherapy and are safe in pregnancy, specifically methylprednisolone and hydrocortisone, which are extensively metabolized in the placenta and are therefore preferred. Further, growth factors used for white blood cells and red blood cells during chemotherapy are considered safe in pregnancy, specifically in the second and third trimesters.

Chemotherapy doses are similar to those in the nonpregnant patient and are based on body surface area and creatinine clearance. Doses should be adapted throughout the pregnancy, taking into account the weight changes. Gestational changes include an increase in heart rate and blood pressure, an increase in plasma volume and glomerular filtration rate, and hormonal changes in hepatic function. For doxorubicin, epirubicin, paclitaxel, and carboplatin, these changes result in a decrease in plasma drug exposure and peak plasma concentration. There is also an increase in distribution volume and drug clearance secondary to the physiologic changes during pregnancy. This raises doubt about the effectiveness of such regimens in this setting, but no direct relation exists between toxic tissue effects and prognosis. Further, studies have shown similar outcomes to nonpregnant women when controlling for stage and tumor characteristics and regimens received.

Chemotherapy is avoided after 35 weeks' gestational age or within 3 weeks of planned delivery. A 3-week interval should be left between the last cycle of chemotherapy and the delivery to avoid problems associated with myelosuppression (bleeding, infection, anemia) in the mother and baby and to avoid drug accumulation in the fetus. Further, the myelosuppression (i.e., pancytopenia, neutropenia) caused by the chemotherapeutic agents may increase the risk of sepsis complications at delivery. The placenta of these patients should be sent for evaluation as there are reports of placental metastasis, but none of fetal metastasis.

Treatments that are contraindicated during pregnancy are HER2-targeted therapy (risk of oligohydramnios resulting in pulmonary and renal insufficiency); methotrexate (teratogenic); tamoxifen (teratogenic causing craniofacial malformations, ambiguous genitalia, and fetal death); bisphosphonates (category C risk of maternal toxicity, fetal underdevelopment, embryolethality, hypocalcemia, and skeletal retardation); and radiation therapy.

If neoadjuvant chemotherapy is to be administered during pregnancy, the regimen is started at 14 weeks' gestation and is continued for a standard cycle as tolerated. At this point, the patient can decide between mastectomy or breast conservation, which is followed by postpartum radiation therapy.

Further, there have been several cases reporting radiation administered for breast cancer in pregnancy with low fetal doses and resulting in the delivery of healthy babies. Therefore, radiation might be considered in the first or early second trimester if the risk of delay or omission is believed to outweigh that of harming the fetus, but this is not the standard and should be discussed with the multidisciplinary team.

PEDIATRIC OUTCOMES AFTER MATERNAL CANCER DIAGNOSIS

The rate of congenital abnormalities in children exposed to chemotherapy is 3%, which is similar to the national average. Overall, the outcomes of the babies born to women with breast cancer during their pregnancy are favorable and comparable to those of women without breast cancer. But it is important to note that pregnant patients have a higher rate of preterm delivery (61.2% compared with 8% in the general population). Women treated for breast cancer during pregnancy also tend to have children of lower birth weight, but this normalizes over time. There have been no long-term health problems or cognitive developmental issues in children born to mothers that had breast cancer treatment during their pregnancy. If oncologically safe, the patient should be encouraged to carry the pregnancy to as close to term as possible.

Breastfeeding

Lactation from the treated breast is not contraindicated, but there may be reduced milk volume after breast-conserving surgery secondary to scar tissue. It is contraindicated for mothers to breastfeed while undergoing chemotherapy or radiotherapy.

KEY POINTS

- Ultrasound is the first-line imaging modality used.
- Surgery can safely be performed at any time during the pregnancy.
- The recommended method of sentinel node localization is with technetium-99 (99m-Tc sulfur colloid) alone.
- Radiation, trastuzumab, and tamoxifen are contraindicated and given only in the postpartum period.

- Chemotherapy is contraindicated in the first trimester. Anthracycline-based chemotherapy can be safely given in the second and third trimesters and should be stopped 3 to 4 weeks before delivery.
- Dosing of chemotherapy should be similar to that in the nonpregnant patient, based on body surface area.
- Prognosis in the pregnant breast cancer patient appears to be the same as in nonpregnant patients if standard therapy is given.

Ablative Techniques in the Treatment of Benign and Malignant Breast Disease

Marissa Vane, MD, MSc, and Armando E. Giuliano, MD, FACS, FRCSEd

Extending the trend toward less invasive treatment, ablative techniques for benign tumors and small breast cancers have continued to progress. Ablative treatments are all image-guided percutaneous techniques (using ultrasonography, mammography, magnetic resonance imaging [MRI], or computed tomography [CT]). Complete tumor ablation can be achieved using different types of energy instead of or in addition to immediate or delayed surgical excision. The goal of these ablative techniques is to reduce the complications, decrease morbidity, shorten hospitalization, and improve the cosmetic outcome and quality of life while not increasing recurrence rates. Ablation techniques include radiofrequency ablation (RFA), microwave, laser ablation, electromagnetic waves, cryoablation, and high-intensity focused ultrasound (HIFU).

RADIOFREQUENCY ABLATION

RFA is a widely used ablative technique for various solid tumors at different sites, including liver, lung, kidney, and bone. RFA uses low-frequency electromagnetic waves to generate heat and ablate these tumors. To perform RFA, a needle is inserted percutaneously within the tumor, usually with ultrasound guidance, but CT or MRI guidance may be used. A generator creates a high-frequency alternating current; in response, ions attempt to follow the changing direction, causing agitation and frictional heating. This results in destruction of the tumor tissue through thermal coagulation and protein denaturation (Fig. 1).

In most studies, RFA is followed by immediate or delayed surgical excision of the tumor. Izzo et al. performed one of the first feasibility studies that included 26 breast cancer patients with a mean tumor size of 1.8 cm (range, 0.7–3.0 cm). Complete tumor ablation was obtained in 96% (25 of 26) of the patients. Since then, multiple RFA studies have been performed with success rates varying from 77% to 100%. Only a few studies performed RFA without surgical excision. Oura et al. included 52 patients with a tumor size of 2 cm or less who underwent RFA alone. MRI after 1 to 3 months showed no evidence of residual disease. After a follow-up of 15 months, none of the patients developed locoregional or distant recurrences. Cosmetic outcome was reported excellent in 83%, good in 11%, and fair in 6% of the patients.

Excision RFA (eRFA) consists of surgical excision of the tumor followed by RFA. The aim is to decrease the rate of reexcisions after breast-conserving surgery, to improve locoregional recurrence rates by extending the margins, and ablating possible residual disease. Klimberg et al. performed a study in 100 patients undergoing breast-conserving surgery followed by eRFA in which biopsy showed at least 1 cm circumferential ablation around the resection cavity. Of these 100 patients, 78 had negative margins (>2 mm) and 22 had margins 2 mm or less, of which 3 were focally positive. Recurrence after 5 years of follow-up was seen in 3% of the patients treated with systemic hormonal therapy and in 10% without systemic hormonal therapy. Recently, results of the multicenter Radiofrequency Ablation After Breast Lumpectomy study were presented. A total of 267 T0 to T2 breast cancer patients treated with breast-conserving surgery followed by eRFA were included. Results showed a reexcision rate for positive margins of <5%. The rate of breast recurrence was 2.5% after 3 years of follow-up.

RFA appears to be limited to tumors with a maximum size of 2 cm. RFA treatment is not suitable for infiltrating lobular breast tumors, tumors with an extensive in situ component, and in patients treated with neoadjuvant systemic therapy. Complications from RFA are rare and generally mild, including skin or muscle burns and ecchymosis.

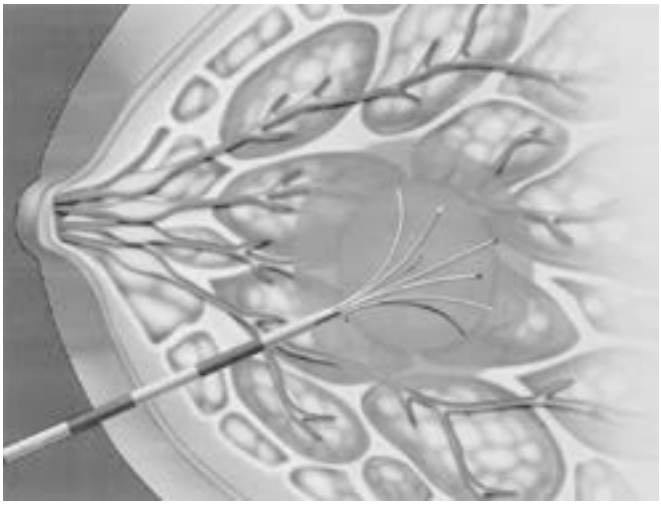

FIG. 1 Radiofrequency ablation showing star array probe with breast and surrounding frozen ablation zone. *(Courtesy RITA Medical Systems. From Simmons R. Ablative techniques in the treatment of benign and malignant breast disease.* J Am Coll Surg. *2003;197:334–338.)*

MICROWAVE ABLATION

Thermal ablation can also be performed with the use of microwaves. Microwave ablation (MWA) uses electromagnetic waves at frequencies of at least 900 mHz. Localized heat caused by water molecules moving within tissues results in tissue destruction. Tissues with high water content, such as breast tumors, are heated and damaged more rapidly compared with tissues with lower water content, such as normal breast tissue with surrounding fat, which may remain unharmed. To perform MWA, the breast must be compressed between two plates. The electric-field probe is inserted into the central portion of the tumor under ultrasound or CT guidance. A fiber-optic temperature probe is placed in the tumor to guide and adjust the temperature. Skin temperature probes are applied to the skin to monitor the temperature to avoid skin burns. A cooling system can be used to provide air cooling, decreasing the risk of thermal injury to the skin.

The first pilot study of MWA was performed by Gardner et al. to assess the feasibility and safety of this technique. MWA was performed in 10 breast cancer patients with a mean tumor size of 4.3 cm (range, 1.0–8.0 cm). A reduction in tumor size was seen in 60% (6 of 10) of the patients. Dooley et al. performed a small trial that randomized patients to breast-conserving surgery followed by MWA versus breast-conserving surgery alone. This study found that patients with early breast cancer treated with breast-conserving surgery and MWA had 0% (0 of 34) positive tumor margins compared with 9.8% (4 of 41) for those with breast-conserving surgery only. More recently, Zhou et al. showed that complete tumor ablation using contrasted enhanced ultrasound was seen in 90% (37 of 41) of patients treated with MWA.

CRYOABLATION

Cryoablation is the only ablative technique using cold instead of heat to create tissue necrosis. It is accomplished percutaneously guided by ultrasound, MRI, or CT. Cryoablation involves two phases: freezing and thawing. Liquid nitrogen is inserted into the probe and results in a local freezing reaction; thereafter, a second gas (i.e., helium) is released through the probe to arrest the freezing process, allowing thawing to occur (Fig. 2A). Tumor cells are destroyed through direct intracellular and indirect vasculature injury. Intracellular ice formation results in shearing and irreversible rupture of cell membranes. Extracellular formation occurs, creating a hypertonic environment. Water flows out of the cells resulting from osmosis, causing cellular dehydration and damage. When thawing occurs, water flows back into the cell, increasing intracellular volume and lysis occurs. Freezing and thawing is repeated. After at least two freeze-thaw cycles, an ice ball is created, which can be visualized with imaging. The tumor-ice ball remains in situ and is reabsorbed by the body (Fig. 2B).

Several studies have investigated the efficacy of cryotherapy in the treatment of fibroadenomas. The prospective Fibroadenoma Cryoablation Treatment Registry included 444 patients with fibroadenomas treated with cryotherapy. Two freeze-thaw cycles were used with a temperature of −160°C for the treatment of lesions with a median size of 1.8 cm. A reduction in size of 51% was seen after a follow-up of 6 months. Furthermore, palpability of the fibroadenomas reduced from 75% at pretreatment to 46% after 6 months and 35% after 12 months of follow-up. Recently, the role of cryoablation in the treatment for malignant breast tumors has been evaluated. The systematic review of Lanza et al. showed complete tumor ablation in 73% of included patients after a mean follow-up of 8 months. Cosmetic satisfaction was reached in 99% of the patients. In 2016, the American College of Surgeons Oncology Group undertook Z1072, a phase II trial exploring the effectiveness of cryoablation in the treatment of breast cancers, and published their results. Patients with a malignant tumor size less than 2 cm with less than 5% intraductal component were included. There was a complete tumor ablation in 76% (66/87) of patients. If multifocal tumors were excluded, the success rate increased up to 92% (80/87). The Freezing Instead of Resection of Small Breast Tumors trial is currently recruiting women with early-stage invasive breast cancer to investigate whether cryoablation can achieve complete tumor ablation and adequate local control without surgical excision.

Criteria for cryoablation include tumor size smaller than 2 cm, location at least 1 cm from the skin surface, and lack of an extensive in situ component (<25% of carcinoma in situ). Advantages of cryoablation are patients' comfort and treatment of larger lesions with sparing of normal breast tissue. Disadvantages are potential risk of thermal injury to the skin, losing staging information (e.g., tumor size and margin status), and timing of the sentinel lymph node biopsy.

HIGH-INTENSITY FOCUSED ULTRASOUND

HIFU is a complete noninvasive thermal-based ablative technique using transcutaneously focused ultrasonic waves (Fig. 3). The focused ultrasound waves cause rapid (1–2 seconds) temperature elevation within the targeted tissue up to 50°C to 95°C. This causes melting of the lipid bilayer of the cellular membrane and protein denaturation, leading to tissue necrosis, whereas tissues outside the targeted area are spared. Because of the small ($0.8 \times 0.2 \times 0.2$ mm^3) ablation zone, multiple overlapping sonifications are required to treat an entire lesion. Complete ablation can take up to 2 to 3 hours.

Peek et al. published a systematic review, including 9 HIFU studies and 167 breast cancer patients. No residual tumor after HIFU treatment was found in 46.2% (55 of 119) of the patients. The most reported complication was pain (40.1%), followed by edema (16.8%), skin burn (4.2%), and pectoralis major injury (3.6%). Symptomatic palpable fibroadenoma patients were included in a separate HIFU-fibroadenoma trial. Twenty of the included patients were treated with HIFU, whereas the other 20 underwent an ultrasound after 6 months (control group). Primary outcome was reduction in treatment time; secondary outcomes were reduction in volume on ultrasound after 12 months and the complication rate. Treatment time was reduced with 29.4% in circumferential ablation compared with whole lesion ablation. Reduction in volume was reported in 43.2% of the patients after 12 months of follow-up.

HIFU is a completely noninvasive ablative technique. Cosmetic outcome is very good because there is no scarring at skin entry site. Disadvantages are patient discomfort, general or spinal anesthesia, and prolonged treatment times.

INTERSTITIAL LASER

Laser interstitial thermotherapy (LITT) is a hyperthermic ablative technique. Laser fibers are percutaneously inserted into the tumor, whereas a second probe is placed to measure the temperature (Fig. 4). A refraction of laser light is produced at the tumor, producing heat and causing coagulation necrosis and protein denaturation, resulting in irreversible tissue destruction. The level of necrosis depends on the temperature and ablation time. Three types of lasers are available: carbon-dioxide, argon, and neodymium-doped yttrium aluminum garnet laser. The two latter lasers have the benefit of being able to treat larger volumes. Only a few studies have evaluated LITT followed by surgical excision. Dowlatshahi et al. performed a study in 54 breast cancer patients and showed complete tumor ablation of 70% in tumors with a mean diameter of 12 mm (range, 5–23 mm). Incomplete tumor ablation was attributed to technical issues, such as inadequate laser energy, patient motion, malfunctioning thermal probes and fluid pump, and suboptimal target visualization. LITT under MRI guidance showed a complete ablation in 76% of the tumors ranging from 1.8 to 4.0 cm. LITT performed in patients with fibroadenomas (n = 24) showed a reduction of 60% after 6 months of follow-up.

The advantage of LITT is that it has a photocoagulation effect that reduces bleeding during the procedure. Disadvantage is that tumors larger than 2 cm or tumor with extensive in situ component are not good candidates for laser therapy.

IRREVERSIBLE ELECTROPORATION

Irreversible electroporation is a nonthermal ablative technique that uses electrical fields to create permeable cell membranes and cause cell death. Electroporation occurs when short electric pulses (1000 V/cm field) are passed across the cell membranes, resulting in membrane permeabilization. This ablative technique only affects the cell membrane while sparing the extracellular matrix and other tissues (i.e., blood vessels). Permeabilization can be reversible or irreversible, depending on the number, duration, and time between electric pulses and electric field strength. Irreversible electroporation has been investigated for a short period and much of in vivo research involves animal models only. Disadvantages of this technique are the potential occurrence of cardiac arrhythmias and general anesthesia because the electric pulses cause muscle contractions.

SUMMARY

A meta-analysis showed that complete ablation rates of ablative techniques such as RFA, MWA, cryoablation, LITT, and HIFU vary and have been highest in patients undergoing RFA (87.1%), followed by MWA (83.2%), cryoablation (74.1%), laser ablation (52.2%), and HIFU (47.6%). Other important but less investigated outcomes are recurrence and complication rates. No local recurrences have been reported using MWA (0%). Other ablative techniques have small but measurable recurrence rates: cryoablation (1.4%), HIFU (2.9%), RFA

(3.1%), and laser ablation (10.7%). Complications occur in about 10% of patients. Most commonly seen were skin burns followed by pectoralis major muscle damage. MWA is associated with the highest posttreatment complication rate of 14.6%, followed by cryoablation (10.9%), RFA (10.5%), HIFU (6.5%), and laser ablation (6.3%). Excellent cosmetic outcome has been reported in patients treated with ablation. Cryoablation results in greater than 90% excellent cosmesis compared with 85.3% in patients treated with RFA and 59.3% in patients treated with HIFU. HIFU may ultimately have the best cosmetic outcome because this technique is completely noninvasive.

All ablative techniques show several benefits compared with breast-conserving surgery; however, larger multicenter randomized controlled trials are required to confirm the efficacy of ablation compared with resection. Current problems are the lack of a predictive tool for assessing complete tumor ablation, determination of accurate tumor size, information on the timing of axillary surgery, and adequate patient and tumor inclusion criteria. Ablative treatment techniques may be most suitable for patients with contraindications to operation or patients with a preference to avoid breast-conserving therapy. Furthermore, ablative treatment can only be used for small (T1) breast tumors (≤2 cm) 1 cm from the skin and pectoralis major, less than 25% carcinoma in situ component, and, most important, tumors must be visible using imaging modalities. In addition, many techniques result in a palpable mass, disturbing to patient and surgeon. Intraoperative RFA after surgical excision may become a means to avoid radiation after breast-conserving surgery for patients with favorable tumors.

Lymphatic Mapping and Sentinel Lymphadenectomy

Roi Weiser, MD, and V. Suzanne Klimberg, MD, PhD, MSHCT

INTRODUCTION

Axillary surgery has been a standard part of breast cancer treatment since the introduction of Halsted's radical mastectomy at the end of the nineteenth century. With it, for the first time, long-term survival and regional control were achieved for a growing number of patients. But this dramatic improvement in outcome came with the cost of significant side effects, including a lymphedema rate of up to 80%. Henceforth, reducing the rate of lymphedema, "the most dreaded complication of breast cancer treatment," has been a central motivation in the evolution of axillary surgery. In addition, screening has promoted early detection of breast cancer, producing a growing number of clinically node-negative patients, 60% of whom would have a pathologic negative axilla after excision. For them, axillary lymph node dissection (ALND) would come with the cost of side effects with no therapeutic advantage.

The concept of a reproducible pattern of tumor lymphatic spread has been utilized since the 1960s in parathyroid, penile, and testicular cancer as well as in melanoma surgery. With the use of blue dye and radiotracers for lymphatic mapping, the first node(s) in the chain of lymph nodes draining the anatomical location of a tumor, termed *sentinel lymph nodes* (SLNs), can be identified and examined. Negative findings would confirm with high probability the lack of further lymphatic and metastatic spread, obviating the need for further surgery or staging. These principles of sentinel lymph node biopsy (SLNB) have been utilized in breast cancer since the 1990s to identify clinically node-negative patients who have a high probability of a pathologically negative axilla and in whom a completion axillary lymph node dissection (cALND) would be redundant.

INDICATIONS FOR SENTINEL LYMPH NODE BIOPSY

Currently, SLNB is the standard of care for operable invasive breast cancer patients with T1–T2 (up to 5-cm) tumors with or without multicentricity and a clinically negative axilla (Box 1). This is true whether breast conservation or mastectomy are planned. Though data are more limited in these situations, many clinicians would extend these indications to tumors larger than 5 cm (T3), patients undergoing neoadjuvant chemotherapy with prechemotherapy-negative nodes, recurrent disease in the breast, and after ipsilateral breast surgery or radiation. However, ALND should be performed for T4 tumors and for patients with recurrent axillary disease or those who have had prior axillary surgery. Axillary surgery including SLNB can be forgone in a subset of ≥70-year-old patients with hormone receptor–positive, HER2-negative, clinically T1–T2, N0 disease who will be treated with endocrine therapy. Several studies have shown that omitting SLNB does not affect disease-free survival (DFS) or overall

BOX 1 Indications for SLNB in Operable Breast Cancer*

Indications for SLNB

T1/T2 (up to 5 cm) tumors, possibly T3 (>5 cm)
Clinically node-negative disease (cN0)
Female or male
Unicentric or multicentric disease
DCIS (Tis) when mastectomy is planned or when high-risk features exist
Possible after prior breast surgery
Possible after NACT
Limited clinically node-positive disease (cN1) after NACT with favorable response†

SLNB Not Recommended

T4 tumors and inflammatory breast cancer
Clinically positive axillary involvement without neoadjuvant chemotherapy or recurrent axillary disease
More than "limited" nodal involvement (several level I/II nodes, involvement beyond level I/II)
Prior axillary surgery
Pregnancy before week 30

*Based on ASCO Clinical Practice Guidelines. Lyman GH, Somerfield MR, Bosserman LD, et al. Sentinel lymph node biopsy for patients with early-stage breast cancer: American Society of Clinical Oncology Clinical Practice Guideline Update. *J Clin Oncol*. 2017;35:561–564.

†The meaning of a limited positive axilla is controversial. We recommend performing targeted axillary dissection (see text) when no more than one suspicious lymph node is present before NACT or when all suspicious lymph nodes were marked and are excised during targeted axillary dissection for evaluation.

ASCO, American Society of Clinical Oncology; *DCIS,* ductal carcinoma in-situ; *NACT,* neoadjuvant chemotherapy; *SLNB,* Sentinel lymph node biopsy.

survival (OS) in these patients while improving quality of life, and it is endorsed by the Society of Surgical Oncology (SSO) through the Choosing Wisely campaign (https://www.choosingwisely.org/societies/society-of-surgical-oncology/).

Another subgroup of patients that qualifies for SLNB includes patients with ductal carcinoma in-situ (DCIS) with high-risk features who have higher chances of invasive cancer on final pathology, including high-grade tumors, estrogen or progesterone receptor (ER/PR)-negative tumors, large-size tumors, and mass-forming tumors. SLNB would also be indicated for DCIS patients who are planned for a mastectomy, which would make a second-stage SLNB less feasible.

Patients with clinically node-negative disease with one to two positive SLNs who undergo breast conservation with postoperative whole-breast irradiation and systemic therapy can also be treated with SLNB alone, under ACOSOG Z0011 criteria. Similarly, patients with micrometastasis to their SLNs and those with one to three positive SLNs who will undergo nodal irradiation can have SLNB alone with equivalent oncologic results to patients who undergo cALND.

A more controversial group that could be considered eligible for SLNB and is being studied in an ongoing clinical trial are patients with palpable axillary involvement at presentation, who undergo neoadjuvant chemotherapy (NACT) with a complete clinical response. These patients would be considered eligible by most for a targeted axillary dissection (TAD) in which an SLNB is performed in addition to retrieval of the clipped positive node. This technique demonstrates very low false-negative (FN) rates. However, data as to the effect of TAD on local and systemic recurrence are not yet available, and an ongoing Alliance study is investigating whether it is safe to leave resistant disease behind.

Patients with T4 disease that ulcerates the skin or invades the chest wall, patients with inflammatory breast cancer, and those with more than limited axillary involvement would not be eligible for SLNB. Pregnancy is also a relative contraindication for SLNB. The use of blue dye has the risk of causing anaphylactic shock (<1% with isosulfan blue) and is discouraged during pregnancy because of fetal concerns. The injection of technetium (^{99m}Tc)-labeled sulfur colloid has been shown to cause minimal irradiation exposure to the fetus, though data are limited as to its safety and efficacy. Its use is not contraindicated during pregnancy, though it is discouraged by some before 30 weeks of gestation.

SLNB: TECHNIQUE

Before surgery begins, a tracer is injected into the breast that will allow identification of the SLN or nodes. The two main tracers used are a radiotracer and blue dye (isosulfan blue or methylene blue) or a combination of the two techniques. Several other tracers are available or under investigation, including indocyanine green (ICG) fluorescence mapping as well as magnetic tracers. The most commonly used radiotracer is ^{99m}Tc-labeled sulfur colloid. A 0.25 to 2.5 mCi dose in 0.4 to 4 mL is injected into the breast. During surgery, the radiotracer is identified in the SLN using an intraoperative gamma counter, such as the Neoprobe GDS. If injected a day before surgery, 2.5 mCi are injected. The blue dye most often used is 3 to 5 mL of isosulfan blue. Its main adverse reaction is a 2% rate of hypersensitivity with a <1% rate of anaphylaxis; therefore patients should be screened for makeup and tattoo allergies, which are associated with a higher risk of allergic reaction. When encountered, a hypersensitivity reaction should be treated with systemic antihistamines (e.g., Benadryl) and systemic steroids (e.g., hydrocortisone). Patent Blue V, an additional blue dye, can be similarly used. It also belongs to the triarylmethane dye group and has a strong cross-reactivity with isosulfan blue. Dilute methylene blue is a third option, but we personally prefer not to use it because of the danger of dermal necrosis on dermal injection as well as considerable drug interactions. It is also contraindicated in pregnancy and in patients with G6PD deficiency. Of note, with the use of blue dye, transient skin and urine discoloration are expected, and occasional skin tattooing occurs, especially when the dye is injected intradermally.

Several practical aspects of tracer injection have been raised since the advent of SLNB.

1. Preoperative versus intraoperative injection: The preoperative injection of a radiotracer at the nuclear medicine clinic is a painful procedure, with obvious scheduling and financial burden. Studies comparing preoperative to intraoperative injection have shown intraoperative injection to be as accurate, with a 96% to 99.8% detection rate. Costs have been shown to be over 7-fold lower. We therefore practice and advocate the use of intraoperative injection after induction of anesthesia and before prepping the patient. Nevertheless, preoperative injection with subsequent lymphoscintigraphy or SPECT-CT, which is useful in identifying the lymphatic basin in truncal melanoma, can prove advantageous in breast cancer patients who have had prior surgery that could have resulted in alternative lymphatic drainage.
2. Peritumoral, subareolar, dermal, or intratumoral injection: During the first multicenter trial involving 443 patients who underwent SLNB followed by ALND in which injection was done peritumorally, all 13 FN SLN cases were in patients with tumors located in the upper outer quadrant of the breast. Hypothesizing that the proximity of the injection site to the axilla caused the radiotracer's zone of diffusion to interfere with SLN identification led us to investigate the subareolar region as an alternative injection site. A multicenter prospective study including 3961 patients showed a 99.3% identification rate with subareolar injections versus 91.1% with peritumoral injections, with similar FN rates. Moreover, this technique can be safely used in cases with multifocal and multicentric tumors. Radiotracer can also be injected

dermally. In any case, one should avoid injection into the tumor or seroma/hematoma cavity.

3. Some surgeons massage the breast after injection of a tracer, especially after the injection of blue dye. Not much data exist on this subject. One study comparing 50 cases of 3 to 5 minutes of massage to no massage after peritumoral injection of Patent Blue V showed no difference in detection rate between techniques with higher rates of false negativity without massage. We do not practice routine massage after tracer injection.
4. Single or dual tracer: There have been conflicting reports as to the advantage of dual tracing, (blue dye in addition to a radioisotope) over the use of a radiotracer alone. Blue dye alone has been shown by some to have a comparable and by some an almost 10% poorer detection rate compared with a radiotracer alone. Some studies show no advantage to the addition of blue dye to a radioisotope, while others show an improvement in detection of 1.5% and an improvement in FN rate of <1%. Nevertheless, cases in which blue dye detected an SLN that the radiotracer did not are mostly cases in which no radioactivity was detected in the axilla by lymphoscintigraphy or during surgery. More experience with any technique results in a higher rate of detection and a lower FN rate. We recommend using only a radiotracer, injected intraoperatively to the subareolar region, and having the blue dye ready on the field. We consider dual tracing after neoadjuvant therapy, prior breast or axillary surgery, and in patients with a high BMI. If before the incision, no radioactivity is detected in the axilla, blue dye is injected to the breast for dual tracing. If we have a reading, we use the blue dye for axillary reverse mapping (ARM).
5. ARM is used during SLNB to identify the lymphatics draining the arm that cross the axilla. We inject 5 mL of isosulfan blue to subcutaneous tissue of the upper inner volar aspect of the ipsilateral arm and radioactivity and/or the tracer of your choice in the breast. This results in split mapping, differentiating lymph nodes draining the breast that should be excised as SNLs from those draining the extremity that should be preserved to prevent lymphedema. Blue arm lymphatics are detected in 29% to 47% of SLNB-only cases, with blue lymphatics juxtaposing the SLN in almost 8% of cases. This procedure allows to preserve these lymphatics and to identify transected arm lymphatics so they can be reapproximated or re-anastomosed. This procedure has been shown to reduce the rate of lymphedema in SLNB to less than 1%.
6. Dosages in bilateral cases: In bilateral cases, a double dose of Technetium can be injected. The dose of blue dye is divided between breasts.
7. Eventually the choice of technique, including location of injection, timing of injection, use of lymphoscintigraphy, and single or dual tracer use should be governed by the experience and level of comfort of the individual surgeon and the specifics of each case.

In the operating room, after induction of anesthesia, the patient is positioned supine with both arms extended to 90 degrees. We usually do not prep and drape the arm into the field for SLNB. Before incision, the gamma probe is used to evaluate the maximal reading around the injection site in the breast and then in the axilla, and the gamma probe is adjusted to separate the zone of diffusion from the SLN. Most often the point of maximal reading in the axilla is at the lateral aspect of the pectoralis muscle at an imaginary line connecting it with the inferior part of the hairline. The maximal point is marked. Then blue dye is injected in the volar aspect of the arm or the breast. At this time, we use the gamma probe to evaluate the internal mammary (IM) area, the neck, and the lower chest to detect possible extramammary SLNs. If one is detected, intraoperative ultrasonography is used for visualization, and if a node is visualized, it is excised (discussed later). If not visualized by ultrasound, it may be considered a false-positive read.

Before incision, for better visualization of the axilla and to reduce the interference of radioactivity from the injection site, the breast can be secured inferomedially with a 1050 adhesive drape. An incision is made close to the point of maximal reading, preferably inferior to the axillary hairline and in a natural skin crease. Care should be taken not to extend the incision anterior to the pectoralis muscle as it does not provide more exposure and gives a poor cosmetic result on the breast. One can create an incision that is parallel and posterior to the pectoralis muscle as well. In mastectomy cases, the SLNB can be performed through the mastectomy incision. Then dissection is carried down toward the two layers of axillary fascia, which are identified lateral to the pectoralis muscle and incised, "entering" the axillary space. As this point, axillary fat is apparent, and the gamma probe is used to redirect dissection in a line-of-sight technique, much like using a flashlight in a dark room to find a finite point. Retractors are placed in the direction of maximal reading and dissection continues. If blue dye has been used in the breast, attention is given to any blue lymphatics to be followed toward blue SLNs. Dissection should also follow these lymphatics proximally to ensure that a proximal SLN is not left behind. Some practice sharp dissection of axillary content, following or clipping apparent lymphatics in their way. Blunt dissection is best, separating the fat while preserving lymphatics, until the SLN is identified. It is held by Babcock forceps, while the surrounding fat is dissected free from the hilum, exposing the afferent and efferent lymphatics (Fig. 1). These are approximated by a clamp, and they are ligated together using an absorbable suture after removing the node, enabling lymphatic recanalization. The gamma probe is used at this point to detect further nodes, taking node(s) with 10% or more of the maximal SLN count. It is important to note that any suspicious node, by palpation or visualization, regardless of read or coloration, is regarded as an SLN and excised; replaced lymph nodes are less likely to take up the localizing agent. Ultrasound is a useful tool to evaluate indeterminate nodes, especially in obese patients as fatty nodes are often palpable. After no reads over 10% are identified, the cavity is irrigated, and hemostasis achieved. The axillary fascia is approximated using absorbable sutures, and the incision is closed.

In the majority of cases, ARM should be performed with SLNB. The technique of surgery does not change, apart from preserving the blue lymphatics and lymph nodes encountered during surgery. An exception to their preservation would be when an SLN by gamma probe reading is also a blue ARM node. In these cases, the blue SLN, called by some a *crossover node,* is resected as an SLN, and the lymphatics are reapproximated using an absorbable suture.

FIG. 1 Sentinel lymph node biopsy. The sentinel lymph node, identified with the gamma probe, can be seen held by Babcock forceps. Fat and a blue axillary reverse mapping node have been bluntly dissected away from it and preserved. Next, a clamp will be applied under the node to approximate its afferent and efferent lymphatics. It will be excised, and the lymphatics will be ligated.

The evaluation and excision of IM SLNs is not routinely recommended. Surgeons are usually unfamiliar with this procedure and fear its potential risks of bleeding and pneumothorax. Studies have shown IM nodes function as SLNs in 7% to 8% of cases, with higher rates of positive nodes, up to 40%, when axillary nodes have been found to be positive. It is rare for the IM node to contain metastasis without a positive axillary node. Nevertheless, in such cases of positive IM SLNs, staging as well as adjuvant treatment can be affected. We usually excise the IM SLN when it is detected by the gamma probe and visualized by intraoperative US. In these cases, an incision is made over the IM node, exposing the pectoralis. Then the muscle is bluntly divided along its fibers until the intercostal space is exposed. The intercostal muscles are further split along their fibers, exposing the intercostal space with the IM node, which is bluntly excised. Care should be taken not to use electrocautery, to avoid a pneumothorax.

TROUBLESHOOTING SLNB

We suggest a few troubleshooting algorithms for common problems one might encounter during SLNB. One of the more common problems, especially when starting to perform SLNBs, is not finding the SLN during surgery (Fig. 2). Preparing for such cases by identifying high-risk patients before surgery can be helpful, and one could consider preoperative lymphatic imaging or using dual tracing during surgery to better identify SLN location. During surgery either before or after incision, several techniques can be helpful in locating the SLN, including dermal instead of subcutaneous injection of the radiotracer and promoting tracer advancement by injection of sterile saline into the injection site and massaging the breast. One can also look for suspicious axillary nodes using ultrasound or palpation, and for extraaxillary SLNs using the gamma probe. If the SLN still cannot be found, the surgeon should assess the likelihood of lymphatic involvement and importance of axillary staging and decide whether performing axillary sampling or ALND is necessary at this point.

A second problem that can be encountered is continuous high reads in the axilla without being able to discern a specific SLN (Fig. 3). It is important that nuclear medicine use an unfiltered radioactive colloid as the filtered colloid advances easily beyond the SLN. Technical tips would be to make sure the probe is not pointed in the direction of the breast, fixing the breast away from the axilla and removing a superior-lateral tumor when peritumoral injections are performed. Dual tracing and removing palpable nodes or nodes that are suspicious on ultrasound examination can also help. Eventually, if five nodes have been removed, no further surgery is needed.

RESULTS OF SLNB AND LYMPHATIC MAPPING

SLNB in Node-Negative Patients

The largest multicenter randomized controlled trial (RCT), randomizing clinically node-negative patients to SLNB or ALND, was the NSABP B-32. It randomized 5611 women, 3989 of whom eventually

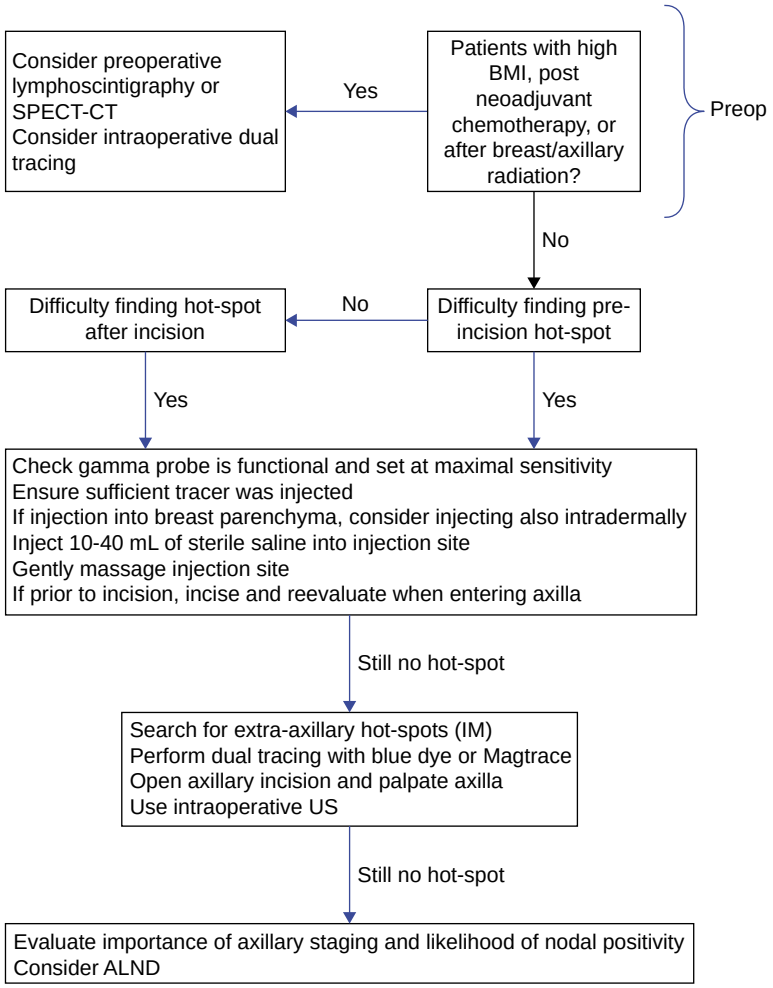

FIG. 2 Troubleshooting no uptake of radioactive tracer in axilla.

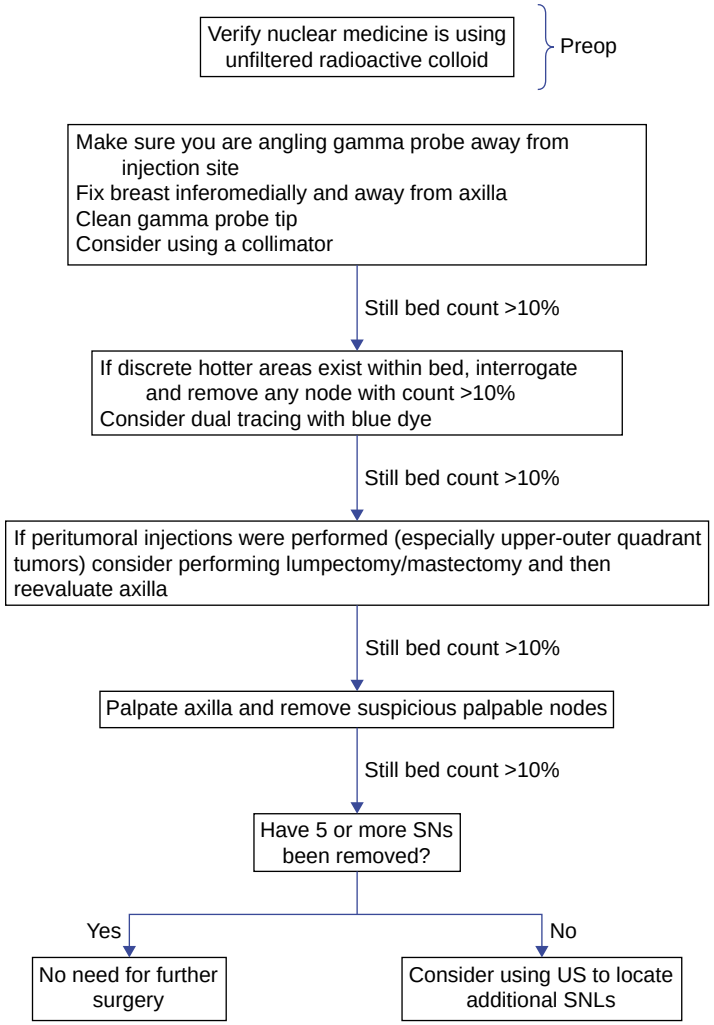

FIG. 3 Troubleshooting inability to achieve a <10% background or inability to identify sentinel lymph node resulting from high reads.

had negative SLNs, to cALND or no further surgery. The trial had a success rate of over 97% in identifying the SLN during SLNB, and it was able to show a reduction in lymphedema rate from 14% with ALND to 8% with SLNB. With these findings, it validated earlier findings from retrospective studies and smaller prospective studies that showed improvement in lymphedema rates from as high as 77% with ALND to single-digit rates with SLNB. Table 1 summarizes the findings of these studies.

Apart from the success in reducing the side effects of axillary surgery, SLNB was shown to be a good predictor of axillary status. The first multicenter trial, published in the *New England Journal of Medicine* in 1998, demonstrated an FN rate of 11.4%. Following studies have shown lower FN rates, with rates as low as 2.5%. Consequently, a detection rate of >95% and an FN rate of <5% are considered a good clinical result, and FN rates have been shown to decrease with surgeon experience. Regardless of the FN rate, this trial and others have demonstrated low or no axillary recurrence and similar survival rates with SLNB compared to ALND in these patients.

An additional advantage with SLNB is that a higher rate of positive lymph nodes is detected when SLNB is employed compared with ALND, with a 4-fold increase in the rate of detected micrometastasis or isolated tumor cells. This is made possible by the pathologists having to examine a limited amount of lymph nodes, allowing for 2-mm serial sectioning of each node, sometimes using immunohistochemistry as an adjunct. This proves the potential of SLNB, not only to safely reduce the rate of lymphedema, but to also more accurately stage the axilla.

Positive SLNs in Clinically Node-Negative Patients

After establishing the ability of SLNB to safely identify patients with both a clinically negative axilla and pathologically negative SLNs, additional subgroups of patients in whom SLNB alone would be sufficient were sought. Upon cALND of patients with a clinically negative axilla and a positive SLN, 40% to 50% of patients have no additional lymphatic involvement, exposing them to unnecessary morbidity. Several RCTs have been performed to identify such patients who could safely avoid cALND. They are summarized in Table 2.

The largest and practice-changing multicenter ACOSOG Z0011 randomized women with one or two positive SLNs and a T1 or T2 tumor, with cN0 disease, who underwent breast-conserving surgery and postoperative whole breast irradiation (WBR) and adjuvant

systemic therapy, to cALND (n = 445) or observation (n = 446). The study had low accrual, with only 47% of the targeted 1900 patients entered, as well as a low event rate. Nevertheless, it was able to show no significant difference between the groups in respect to 10-year locoregional recurrence (6.2% vs. 5.3%), DFS (78.2% vs. 80.2%) and OS (83.6 vs. 86.3%). In 27% of patients in the cALND group, additional positive lymph nodes were found, with nodal recurrence in either group being <1%. Many suggestions have been made to explain this result, the most probable one being the effect of tangential radiation. It is important to note that though survival and recurrence rates were comparable between the ALND and SLNB groups in the Z0011 trial, so were the 1-year objective lymphedema rates, with 11% of ALND patients versus 6% of SLNB patients having measurable lymphedema ($P = 0.0786$).

Other studies have examined replacing cALND with axillary radiation. These include the OTOSAR and AMAROS trials. Both included patients with T1 or T2 tumors (the OTOSAR limited tumor size to 3 cm). They both showed equivalent axillary recurrences of less than 2%, as well as equivalent DFS and OS. Most patients had one positive SLN (75%–78%), and in both trials over 80% of patients underwent breast conservation. Another subset of patients examined by RCTs was patients with micrometastases (≤2 mm) in their SLNs. The IBCSG 23-01 and AATRM trials examined patients with T1 or T2 tumors (the AATRM limited tumor size to 3.5 cm). Neither trial found a difference in DFS between patients who underwent cALND versus those who were only observed. Locoregional recurrence was also very low and similar between the groups, an interesting finding regarding that additional positive nodes upon cALND were found in 13% of patients in both trials. The IBCSG 23-01 reported an improvement in lymphedema rates in the radiation group of 4% versus 13% in the cALND group.

Population-based studies have shown that clinicians are extending Z0011 criteria as well as the criteria of the other RCTs and implementing them on patients who would not have qualified for the trials, including patients with T3 tumors, those with three or more positive SLNs or clinically positive nodes, and those who undergo mastectomy or do not undergo postoperative WBR or adjuvant systemic therapy. As far as mastectomy patients, who are not represented in the Z0011 and are poorly represented in the other RCTs, the omission of cALND is based mostly on extrapolation, rather than on direct data.

SLNB and TAD in Node-Positive Patients after Neoadjuvant Treatment

With the advent of modern chemotherapy regimens and HER2-directed therapy, the rate of pathologic complete response (pCR) of primary tumors and lymphatic metastases has increased considerably. This improvement in response prompted investigations into the use of SLNB to identify such patients who might not profit from an upfront ALND. Several such studies were conducted, including the ACOSOG Z1071, SENTINA, and SN FNAC, all of which showed SLNB to have FN rates well over 10% (Table 3). Of note, unlike SLNB in untreated patients, in these cases the residual positive lymph nodes left behind would contain potentially resistant disease, conceptually different than SLNB on untreated patients.

Upon subgroup analysis of the ACOSOG Z1071, when looking at patients in whom the clipped node was retrieved, the FN rate

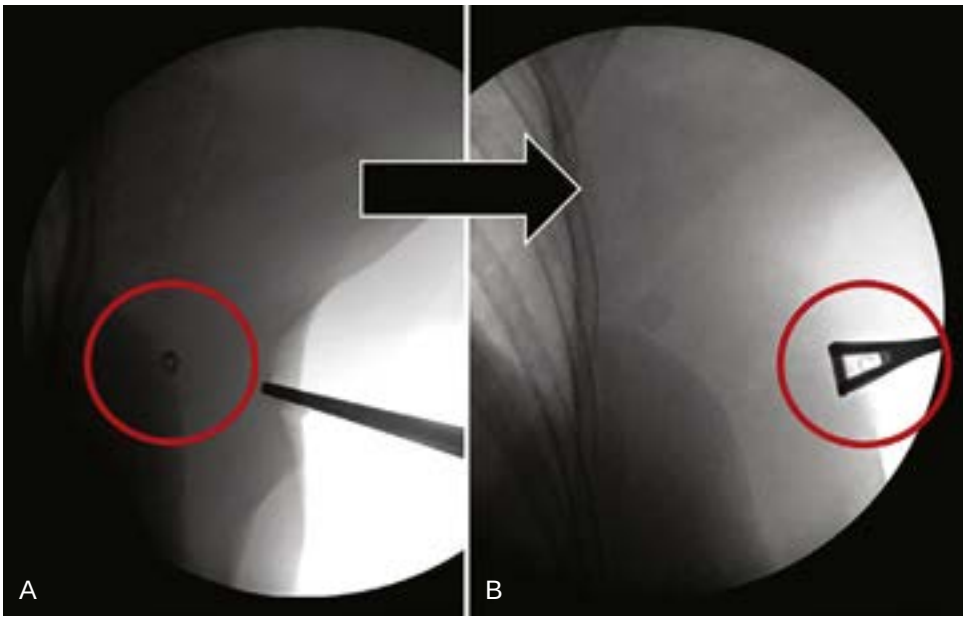

FIG. 4 Fluoroscopy-guided localization of a ring clip *(red circles)* in a left axillary lymph node. **(A)** Clamp pointing to and localizing the clip. **(B)** Babcock forceps grasping the clipped node.

decreased to 6.8%. Other trials have shown the proven positive clipped node to be other than the SLN in 24% of patients, with its retrieval lowering FN rates to 4.5%. This led to further investigation and the definition of TAD, as retrieval of the clipped node as well as performing SLNB, which showed an FN rate as low as 2.3% in the report by Caudle et al. Localizing the clipped node can be easily done using intraoperative fluoroscopy guidance (fluoroscopic intraoperative neoplasia and node detection [FIND]; Fig. 4). Other techniques for clip node localization that necessitate additional painful, time-consuming and costly procedures have been suggested, such as needle localizations, tattooing of the node, and placement of localization devices.

The Alliance 11202 is investigating the omission of cALND in patients with positive nodes upon TAD after NACT, randomizing them to cALND versus axillary radiation. Both arms will receive radiation to the infraclavicular, supraclavicular and IM nodes. The NSABP B-51 examines similar patients with negative nodes upon TAD after NACT. It omits cALND in all of these patients and randomizes them to adjuvant nodal basin radiation or no further treatment.

Axillary Reverse Mapping

Much like SLNB, mapping the lymphatic drainage of the breast, ARM maps the lymphatic drainage of the ipsilateral arm (Fig. 5). Both techniques have the same motivation of reducing lymphedema rate and other side effects of ALND, and both employ lymphatic mapping for more accurate and selective axillary surgery. In a large prospective phase II trial, ARM has been shown to reduce the lymphedema rate after ALND to 6.5% and after SLNB to 0.8%. Split mapping, with radioactivity in the breast and blue dye in the arm, allows for differentiation between lymphatics draining the breast and those draining the arm. It further allows to prioritize oncologic principles by excising crossover nodes—blue arm nodes that are found to be "hot." In addition, mapping the ARM lymphatics allows for identification and ligation of afferent and efferent transected lymphatics or for selective utilization of the LYMPHA (LYmphatic Microsurgical Preventive Healing Approach) procedure, both proven to reduce lymphedema rates.

There have been over 20 retrospective and prospective single-arm studies of the ARM procedure and 5 RCTs (Table 4). Patient

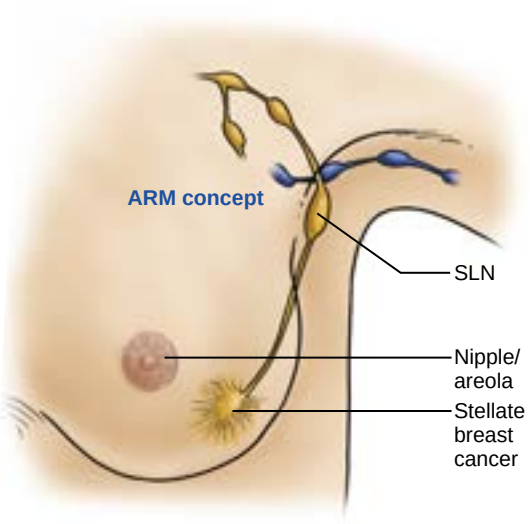

FIG. 5 Axillary reverse mapping (ARM) using split mapping, with lymphatics draining the breast and the sentinel lymph node in gold and the lymphatics and lymph nodes draining the arm in blue.

populations vary among trials in their burden of axillary disease (from N0 to N3 disease) and the surgery they undergo. The vast majority of trials show a significant reduction in lymphedema rate when utilizing ARM across all patient populations and surgical techniques. Moreover, the rate of positive ARM nodes is as low as 2.3%, with lower numbers seen with more limited axillary involvement. Furthermore, considering that many of the ARM trials did not follow protocol and did not inject a radiotracer into the breast, which would have allowed the identification of some of these nodes as crossover nodes to be resected, the actual rate of positive ARM nodes might be even lower. In addition, axillary recurrence rates with ARM are well below 1.5%, comparable with standard ALND. Currently recruiting is the Alliance A221702, a multicenter RCT examining the use of ARM.

CONCLUSION

Lymphatic mapping has made it possible to perform more accurate axillary surgery and reduce the side effects of ALND, mainly that of lymphedema. SLNB as well as the ARM procedure allow for patient-directed surgery, with more limited surgery for a growing number of indications and the identification and protection of the arm lymphatics. In addition, ligation of resected lymphatics and localization of clipped positive nodes after neoadjuvant treatment can help further reduce the rate of lymphedema. Clinical trials are ongoing to further advance axillary surgery and should be advocated among patients.

SURGICAL MANAGEMENT OF THE AXILLA

Genevieve Fasano, MD, Solange Bayard, MD, and Lisa Ann Newman, MD, MPH

OVERVIEW

There are two main indications for axillary surgery in breast cancer patients today: for staging/risk stratification and for therapeutic management of regional disease. Before the 1990s, both of these goals were achieved with a standard, anatomically defined axillary lymph node dissection (ALND). Although ALND provides excellent and durable axillary control (with axillary recurrences typically occurring in no more than 2%–3% of patients), this is achieved at the expense of significant morbidity including risks of ipsilateral upper extremity lymphedema (occurring in 10%–40% of patients); sensory loss in the upper, inner arm skin and posterior shoulder; and occasional patients will also suffer from shoulder dysfunction/stiffness. Advances in systemic therapy and radiation therapy (both of which can effectively control microscopic/clinically occult nodal

metastases) have resulted in deescalation of axillary surgery. The majority of breast cancer patients treated in affluent, westernized populations can avoid the morbidity of ALND by undergoing targeted, minimally invasive surgery with lymphatic mapping/sentinel lymph node biopsy (SLNB), and selected low-risk patients can avoid axillary surgery completely. Patients who have access to surgery but reside in medically underresourced low- and middle-income countries continue to require ALND as a basic component of their management.

Ongoing clinical research in multidisciplinary management of breast cancer is expected to further reduce the number of patients requiring therapeutic ALND. Improvements in screening results in earlier detection of breast cancer, when the axillary burden of disease is likely to be low-volume or nonexistent. For patients who present with more advanced, documented node-positive disease, advances in systemic therapy and the neoadjuvant treatment sequence can successfully downstage many, thereby averting the need for ALND. Patients who continue to routinely require an anatomically based ALND include those with high-risk disease such as inflammatory breast cancer; cases of residual nodal disease despite delivery of optimal neoadjuvant systemic therapy; and patients with clinically evident axillary nodal disease undergoing primary surgery because of a medical contraindication to receiving appropriate neoadjuvant systemic therapy.

SURGICAL APPROACHES TO AXILLARY LYMPH NODE DISSECTION

Review of the axillary anatomy and familiarity with operative techniques for the ALND remain important in contemporary surgical oncology. Although fewer patients need to undergo this procedure, those who do require a therapeutic ALND typically have more challenging anatomy because of prior SLNB dissection or because of regional nodal disease that has either recurred or resisted systemic therapy.

The axilla is divided into three levels defined by the pectoralis minor muscle—level I is inferolateral to the pectoralis minor, level II is posterior to the pectoralis minor, and level III is superomedial to the pectoralis minor. A conventional ALND for breast cancer patients involves resection of levels I and II with sparing of level III. The rationale for this anatomic focus is based on the facts that although an axillary "sampling" procedure limited to resection of level I alone will reduce frequency of lymphedema, it risks missing "skip metastases" that have gone directly to level II or III in 20% to 25% of patients, thereby understaging and/or undertreating up to one-fourth of patients. In contrast, skip metastases that have gone directly to level III, leaving levels I and II negative, occur in only 2% to 3% of cases. The lymphatic mapping/SLNB experience has validated these concepts as the SLN will usually reside in the level I fat pad, but in approximately 25% of patients it is located in level II, and only 2% of patients will have SLN(s) limited to level III of the axilla.

A standard level I and II ALND will typically yield 10 to 30 lymph nodes in this fat pad. Patients who have received neoadjuvant chemotherapy often have relatively fewer nodes because chemotherapy response and fibrosis can obliterate the architecture of discrete nodes. Mastectomy patients undergoing elliptical incisions that include resection of the nipple-areolar skin can usually undergo ALND through the mastectomy wound. A separate transverse axillary incision is usually necessary in patients undergoing lumpectomy surgery or in nipple-sparing mastectomy cases in which an inframammary fold incision or limited periareolar incision precludes adequate exposure of the axillary contents. After the skin incision is deepened through the subcutaneous fat, key elements of exposure include entry into the clavipectoral fascia; medial retraction of the pectoralis major/minor muscles; and lateral retraction of the latissimus dorsi muscle. The axillary fat pad between these anatomic boundaries must be cleared while ensuring protection of the axillary vein, the thoracodorsal bundle (which includes the nerve innervating the latissimus dorsi), the long thoracic nerve (which innervates the serratus anterior), and the medial/lateral pectoralis bundles (which innervate the pectoralis major and minor muscles). Damage to the thoracodorsal nerve can cause arm/shoulder weakness and dysfunction; long thoracic nerve disruption causes winging of the scapula; and transection of the pectoralis nerves can result in denervation atrophy of the pectoralis musculature. Approaches to the intercostobrachial nerves vary by surgeon; these cutaneous nerves traverse through the axillary specimen and are often routinely sacrificed in the ALND, thereby resulting in a loss of sensation in the skin of the underarm and posterior shoulder. Some surgeons attempt to preserve these nerves by dissecting them out of the axillary fat pad, but this approach is potentially associated with traumatic damage and postoperative neuropathic pain. A surgical drain is left at the end of the procedure and removed postoperatively when drainage is minimal.

There are two basic operative techniques that can be followed to optimize the safe performance of an anatomically defined ALND. One approach involves attention to the superior aspect of the dissection first, with entry into the clavipectoral fascia, exposure of the axillary vein, and dissection proceeding in an inferior direction as the axillary contents are retracted in a downward direction. With this approach, prompt identification of the lateral thoracic vein can be a helpful anatomic cue as this vein can be readily seen branching directly and perpendicularly from the axillary vein, running vertically through the axilla. The proximal aspect of the thoracodorsal bundle can typically be found running just posterior (and usually lateral) to the lateral thoracic vein. Once the thoracodorsal bundle has been identified, every effort must be made to preserve it intact, whereas the lateral thoracic vein can be ligated and sacrificed. As the axillary tissue is retracted inferiorly, the serratus anterior muscle at the medial aspect of the surgical field is inspected to identify the long thoracic nerve running vertically, and adjacent to this muscle. Although the pectoralis minor and major muscles are retracted medially, their neurovascular bundles will be found curving around the lateral muscle edges. Venous branches of these bundles running into the axillary tissue can be sacrificed, but the main nerves should be preserved intact.

An alternative operative approach to ALND involves proceeding through the dissection with an initial lateral and inferior dissection. This approach can be particularly useful in patients who have had prior SLN dissection, and it can be useful to identify the critical neurovascular structures before dissecting around the fat necrosis and fibrotic mass of the SLN surgical site. This operative approach involves identification of the vertically running edge of the inferior aspect of the latissimus dorsi muscle as a first step in the procedure. The axillary fat is reflected medially from this muscle, exposing the vertically running thoracodorsal bundle lying posterior to the axillary fat and anterior to the belly of the latissimus dorsi muscle. One or two venous branches can generally be found running horizontally from the thoracodorsal vein to the serratus anterior muscle, and the long thoracic nerve can invariably be identified running vertically into this intersection. The axillary fat pad is then retracted further superiorly, while maintaining consistent exposure of the long thoracic and thoracodorsal neurovascular bundles. The thoracodorsal vein will be traced proximally to its entry into the axillary vein, and at this point the dissection can be completed from the anterior/superior approach as described earlier.

SENTINEL LYMPH NODE BIOPSY: HISTORY

Lymphatic mapping and SLNB was introduced in the mid-1990s and rapidly replaced the ALND as an accurate technique for identifying node-negative breast cancer patients. The goal is to replicate the pathway taken by metastatic cells from the primary tumor in the breast, through the intramammary lymphatics, and then to identify the first few nodes likely to have accepted these metastases. Blue

dyes and/or technetium-labeled sulfur colloid injections into the breast are effective mapping agents that are readily taken up by the lymphatic system of the breast. Visual inspection identifies the blue-stained nodes, and use of an intraoperative gamma detector identifies the radioactive nodes. Early studies of lymphatic mapping involved peritumoral injections of these mapping agents, with concomitant ALND so the accuracy of the procedure could be defined. Within a few years, the completion ALND was abandoned in favor of a stand-alone SLNB for patients found to have no evidence of sentinel node metastases. Lymphatic mapping and SLNB became even more easily incorporated into clinical practice following the demonstration that the mapping agents can be injected into the subareolar tissue with comparable and accurate identification of the SLNs; this approach allows for standardization of the mapping regardless of tumor location or tumor size and supports lymphatic mapping/SLNB in patients with multifocal/multicentric disease. The embryologic development of the breast lymphatic system results in the majority of intramammary lymphatics draining through the subareolar plexus before reaching the axillary nodes. A single set of SLNs can therefore be expected to represent the primary lymphatic drainage of the entire breast.

Data generated from multiple large prospective studies conducted internationally have confirmed the safety of relying on a negative SLN to stage the axilla without increasing rates of axillary recurrence. In 2003, the Milan trial demonstrated that SLNB is a safe and accurate staging method for the axilla, with reduced morbidity in comparison with ALND. Of 516 patients with tumors clinically T2 or smaller, the accuracy of SLNB was 96.9% with a sensitivity of 91.2% and specificity of 100%. Patients in the SLNB cohort demonstrated less arm pain and improved arm mobility. The NSABP B32 trial was another phase 3 clinical trial, and it demonstrated equivalent overall survival, disease-free survival, and regional control between stage-stratified patients randomized to either SLNB with ALND or SLNB with ALND only if the SLNB was positive. The American College of Surgeons Oncology Group (ACOSOG) Z0010 study was not randomized, but it also validated the use of SLNB in early-stage breast cancer. This was a prospective study of 5119 patients with T1/T2 tumors and SLNs that were negative by H&E staining, all of whom underwent lumpectomy followed by adjuvant whole-breast radiotherapy. At median follow-up of 8.4 years, axillary recurrences occurred in fewer than 0.5% of patients. Risk factors for locoregional recurrence included tumor characteristics such as hormone-receptor negativity and lymphovascular invasion. The ALMANAC trial compared quality-of-life outcomes between patients with clinically node-negative disease undergoing SLNB versus those undergoing ALND. This trial showed that the relative risk of lymphedema and sensory loss was significantly lower in SLNB group as well as drain use, length of stay, and time to resumption of normal activities.

AVOIDING AXILLARY LYMPH NODE DISSECTION IN PATIENTS WITH SENTINEL NODE METASTASES

Decisions regarding systemic therapy in breast cancer are increasingly made on the basis of primary tumor features including tumor phenotype (based on estrogen receptor, progesterone receptor, and HER2/neu evaluation). Nodal status continues to play a role in risk stratification, but documentation of the full extent of nodal metastatic burden based on a complete ALND has become less relevant compared with the simple distinction of absence versus presence of axillary nodal disease. This premise was the basis for the ACOSOG Z0011 trial, which randomized lumpectomy patients with T1/T2 breast cancer and metastases in one or two SLNs to undergo completion ALND or no ALND, but all patients received adjuvant breast radiation and systemic therapy. This trial randomized 891 patients between May 1999 and December 2004, at which point the study was closed early because of sluggish accrual rates and anticipated failure to meet the targeted 1900 accrual goal. These patients nonetheless provided practice-changing data, confirming the safety of omitting completion ALND in selected patients with SLN metastases. The 10-year cumulative incidence of nodal recurrence was 0.5% for the ALND patients compared with 1.5% for the patients undergoing SLNB alone ($P = 0.28$). Overall survival rates have also been reported as equivalent for the two randomization arms.

Of note, however, the Z0011 trial pertains to patients with early-stage breast cancer undergoing lumpectomy and breast radiation. Questions persist regarding the optimal axillary management of mastectomy patients found to have SLN metastatic disease, as the precise findings from a completion ALND in these patients will influence decisions regarding postmastectomy radiation (PMRT). PMRT is considered standard of care management in cases of at lease four metastatic axillary nodes and it is considered in patients with one to three metastatic nodes. Decisions regarding PMRT carry heightened significance in the setting of patients undergoing immediate reconstruction as the radiation can potentially compromise the reconstruction appearance and infectious risks.

The IBCSG 23-01 and AATRM trials also randomized patients with SLN metastases to ALND versus no ALND, but both studies were limited to patients with micrometastatic axillary disease (metastatic focus no larger than 2 mm). Unlike the Z0011 trial, both of these studies included mastectomy patients, but more than 90% of the participants from each trial underwent breast-conserving surgery. The 5-year median follow-up from both studies demonstrated excellent outcomes, with fewer than 1% rates of axillary recurrence and 98% overall survival rates. These data have therefore served to establish the safety of omitting the completion ALND (as well as PMRT) among mastectomy patients found to have SLN micrometastatic disease.

The AMAROS (After Mapping of the Axilla: Radiotherapy or Surgery?) trial provided high-level, phase 3 evidence that regional radiation can replace ALND in women with SLN macrometastatic disease, regardless of whether mastectomy or lumpectomy has been performed. This study randomized 1425 women with SLN metastases to undergo ALND versus axillary radiation. At more than 6 years median follow-up, there were no statistically significant differences in axillary recurrences (0.54% vs. 1.03%, respectively) or overall survival (93.3% vs. 92.5%, respectively). The 5-year rates of symptomatic lymphedema, however, were twice as high in the ALND patients (23%) compared with the axillary radiation patients (11%). This study therefore documented lower morbidity from axillary radiation compared with ALND with comparable regional control of disease. These results, however, must be interpreted in the context of other studies and issues. First, the ACOSOG Z0011 study demonstrated that SLN biopsy alone (without axillary radiation) is adequate in breast-conserving surgery patients. Second, for mastectomy patients with SLN metastases, the decision to commit to axillary radiation/PMRT to avoid ALND requires acceptance of the possibility that completion ALND may have confirmed minimal-volume axillary disease, indicating that PMRT was not necessary. Multidisciplinary discussion of these mastectomy/reconstruction cases is especially important, with consideration of possible focused axillary radiation to avoid radiating the mastectomy flaps overlying the reconstruction. Table 1 summarizes the prospective randomized clinical trials involving management of breast cancer patients with SLN metastatic disease.

MANAGEMENT OF THE AXILLA IN PATIENTS RECEIVING NEOADJUVANT CHEMOTHERAPY

Early studies of lymphatic mapping and SLNB following the delivery of neoadjuvant chemotherapy began appearing in the literature by 2000. They usually involved patients undergoing completion ALND (similar to the early years evaluating SLNB in the setting of primary surgery) so identification as well as false-negative rates could be reported. Although many surgeons wanted their patients to reap the

benefits of neoadjuvant chemotherapy with regard to primary tumor downstaging and improved lumpectomy eligibility, several concerns remained regarding whether neoadjuvant chemotherapy would cause fibrosis of the intramammary lymphatics and compromise accuracy of the lymphatic mapping technology. Several meta-analyses evaluating this question demonstrated SLN identification rates of at least 90%. National Comprehensive Cancer Network (NCCN) guidelines ultimately included the recommendation that for patients presenting with clinically node-negative disease and receiving neoadjuvant chemotherapy, SLN biopsy can be performed at the time of breast surgery, and no additional axillary surgery is necessary if the SLN dissection is negative.

Many neoadjuvant chemotherapy patients are found to be node positive at the time of diagnosis by axillary staging with ultrasound- and sono-guided needle biopsy. Axillary management for these patients continues to evolve but is trending toward further deescalation of axillary surgery if the post-neoadjuvant chemotherapy SLN surgery indicates downstaging of the axilla.

The ACOSOG 1071 study was designed to specifically address the question of whether a post-neoadjuvant chemotherapy SLN biopsy is accurate in documenting axillary downstaging for women presenting with needle biopsy–proven node-positive disease. All 687 patients underwent SLN biopsy with completion ALND, and a disappointing 12.6% false-negative rate was reported, which exceeded the predefined 10% rate that would have been deemed acceptable. The Z1071 study as well as two other comparable prospective studies (the SENTINA and Canadian SN FNAC protocols) all demonstrated that the SLN false-negative rates could be reduced by using dual-agent (blue dye and isotope) mapping and by ensuring that at least two SLNs are identified/resected. The most convincing strategy for ensuring that the axilla is accurately staged following neoadjuvant chemotherapy involves performing a "targeted" SLN biopsy. This approach requires that the originally biopsied metastatic node have a clip inserted so this biopsied/clipped node is localized and resected along with the lymphatic mapping/SLN biopsy procedure following the delivery of the neoadjuvant chemotherapy. Data from the University of Texas MD Anderson Cancer Center as well as subset analysis from the Z1071 study demonstrated that this approach brought the SLN biopsy false-negative rate down to 1.4% and 6.7%, respectively.

Lymphatic Mapping and SLNB in Special Situations

Several scenarios require special consideration with regard to lymphatic mapping and SLN biopsy. These are discussed in the following sections.

Pregnancy

Phantom model studies have demonstrated negligible isotope exposure to the fetus following isotope injection into the breast for lymphatic mapping, but the NCCN continues to recommend counseling pregnant patients regarding the paucity of data regarding SLN biopsy in this setting. Blue dye injections are contraindicated during pregnancy.

Ductal Carcinoma in Situ

Patients with ductal carcinoma in situ (DCIS) undergoing mastectomy surgery should be offered a concomitant SLN biopsy for staging purposes in the event that an invasive cancer is identified in the mastectomy specimen. Once the breast has been removed, the opportunity to reliably perform lymphatic mapping via breast injection has been lost. For DCIS patients who are undergoing lumpectomy but the preoperative biopsy is thought to have understaged the extent of disease (e.g., DCIS associated with a spiculated mass on imaging), a concomitant SLN biopsy may be offered to reduce the chance of requiring a second surgical procedure for staging purposes.

Reoperative Axillary Surgery

Several studies have demonstrated that lymphatic mapping and SLN biopsy can be attempted in patients who have undergone prior axillary surgery either via ALND or SLN biopsy. However, these patients are more likely to have aberrant lymphatic drainage, and their SLNs may be located in the contralateral axilla or in the internal mammary nodal basin. Risk of this aberrant lymphatic drainage is higher after ipsilateral ALND and after ipsilateral locoregional radiation.

Situations in Which Axillary Staging Can Be Omitted

Older Patients with T1/HR-Positive/HER2-Negative Breast Cancer

The highest age-based incidence of breast cancer is in patients older than 70 years of age. Overall survival in this population is reduced because of comorbidities that limit life expectancy. Axillary staging guides systemic therapy but may provide limited benefit to older, frail patients who are unable to tolerate chemotherapy to comorbidities. Elderly patients are also more likely to have hormone receptor–positive disease for which endocrine therapy may be the only indicated adjuvant systemic therapy. These differences in clinical presentation and tumor biology, in addition to the desire to limit surgical extent in patients with comorbidities, underscore the rationale for questioning the utility of axillary staging in elderly women. The Society of Surgical Oncology therefore recommends not performing routine SLN biopsy for women older than 70 years of age with clinically node-negative, hormone receptor–positive breast cancer as SLNB does not affect locoregional control or mortality in this population. These recommendations are based on the IBCSG 10-93 trial that showed no differences in disease-free survival or overall survival in breast cancer patients 60 years of age and older with early-stage, clinically node-negative and hormone receptor–positive disease that were randomized to undergo lumpectomy with versus without axillary clearance.

DCIS Patients Undergoing Breast-Conserving Surgery

DCIS patients undergoing lumpectomy do not require routine axillary staging surgery with SLN biopsy. However, they must have meticulous evaluation of their surgical specimen. If invasive disease is identified, they should be advised to return to the operating room for lymphatic mapping/SLN biopsy to inform adjuvant systemic therapy recommendations.

THE NEXT FRONTIER IN DEESCALATION OF AXILLARY MANAGEMENT: ONGOING TRIALS OF AXILLARY MANAGEMENT AFTER NEOADJUVANT THERAPY

Ongoing clinical trials are now attempting to further clarify optimal management of node-positive breast cancer patients receiving neoadjuvant chemotherapy.

The Alliance Trial A11202 is a phase 3 randomized clinical trial designed to determine whether radiation is adequate for locoregional control of disease in patients who have residual axillary node involvement following neoadjuvant chemotherapy. This trial enrolls patients presenting clinical T1/T3 N1 disease. If the axilla is clinically negative after neoadjuvant chemotherapy is delivered, then a staging SLNB is performed. Patients with residual metastatic disease in the sentinel node(s) afterward are randomized to ether ALND with regional nodal irradiation or axillary radiotherapy with regional nodal irradiation. Patient accrual began in February 2014 and is expected to complete in January 2024. Survival and recurrence outcomes will be reported.

Additionally, the NSABP B-51/RTOG 1304 phase 3 randomized clinical trial is designed to investigate whether regional radiation can be omitted in patients whose axillary metastatic disease has been downstaged by neoadjuvant chemotherapy. This trial is therefore frequently referred to as the "Sister Study" to the Alliance 11202 trial. This trial is expected to complete patient accrual by August 2028.

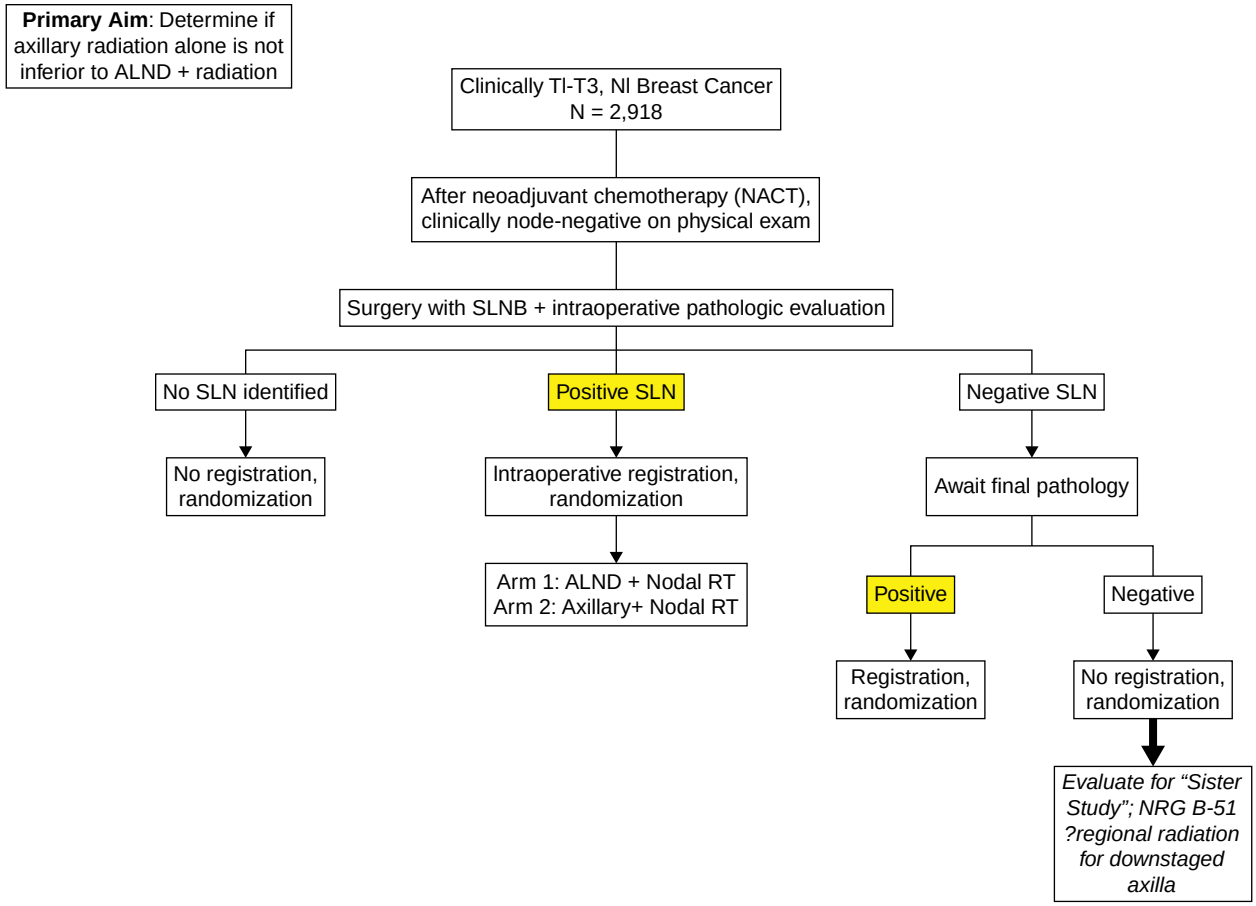

FIG. 1 Next frontier in deescalating axillary management: algorithm for the Alliance 11202 and NRG B-51 trials of patients presenting with node-positive breast cancer and receiving neoadjuvant chemotherapy.

Figure 1 demonstrates the management algorithm for these two studies exploring deescalation of axillary management in women presenting with node-positive disease following neoadjuvant chemotherapy.

SUMMARY

In summary, surgical management of the axilla remains a key element of adequate staging and subsequent guide to treatment decisions. Although management has changed significantly over the past few decades, the deescalation of axillary surgery to avoid ALND when possible has facilitated improved outcomes and reduced surgical morbidity of breast cancer surgery.

Inflammatory Breast Cancer

Jennifer K. Plichta, MD, MS, Xuanji Wang, MD, MS, and Laura H. Rosenberger, MD, MS

INTRODUCTION

Inflammatory breast cancer (IBC) is a rare presentation of locally advanced breast cancer. Although the incidence is 1% to 3%, IBC has a disproportionally dismal prognosis with a 5-year survival rate of 41% overall in the United States. IBC is a clinical diagnosis characterized by the hallmark presentation of skin edema, erythema, and peau d'orange. However, the diagnostic criteria includes erythema/edema that covers at least one-third of the breast and is acute in onset (within 6 months). It lacks unique histologic subtypes, molecular markers, and/or genetic signatures. Pathologically, IBC is defined by extensive tumor involvement and tumor emboli in dermal lymphatics, causing the quintessential skin findings. Radiologically, IBC lacks a central tumor in 50% of patients. At the time of diagnosis, 85% of patients have regional lymph node disease, and 30% have distant metastases. Even with the adjunct of chemotherapy and radiation, survival rates remain dismal.

WORKUP

For patients presenting with breast erythema (Figs. 1A and 2A), a standard history and physical examination should focus on duration of symptoms, exposures, and a bilateral breast and regional lymph node exam. Traditional risk factors for breast cancer, such

FIG. 1 A 59-year-old woman with inflammatory breast cancer, clinically T4d/N1/M0, ER+/PR+/HER2, who presented with erythema of the right breast **(A)**. Subsequent mammogram demonstrated skin thickening and developing global asymmetry with a prominent focal asymmetry at 9–10:00 measuring up to 6.1 × 6.1 cm **(B).** Follow-up ultrasound documented skin thickening measuring up to 0.8 cm and multiple hypoechoic irregular masses at 9:00 7 to 10 cm from the nipple, largest measuring 2.3 × 1.6 × 2.1 cm **(C).** Breast MRI demonstrated an irregular heterogeneously enhancing mass with microlobulated margins at 9–10:00 anterior depth measuring 2.7 × 2.1 × 2.2 cm; additional nonmass enhancement noted in the anterior upper outer quadrant measuring 9.2 × 9.4 cm; diffuse skin thickening; and multiple enlarged right axillary lymph nodes, largest measuring 5.7 × 3.6 × 3.0 cm **(D)**.

as family history, should also be assessed. The differential diagnosis for patients with erythema, edema, skin thickening, and/or peau d'orange (pitting or dimpling of skin) should include IBC as well as benign etiologies such as breast lymphedema, infectious sources causing mastitis, and inflammatory dermatologic conditions (e.g., dermatitis). The initial workup for patients with these clinical exam findings should include a bilateral diagnostic mammogram and targeted ultrasound of the affected breast. For patients with imaging findings suggestive of malignancy (BIRADS 4 or 5), core needle biopsy should be performed with or without a skin punch biopsy of the skin changes. Mammographic findings may include skin thickening, single or multiple breast masses, an asymmetry (see Fig. 1B–C), or it may be nonspecific (see Fig. 2B). For patients with negative, benign, or likely benign mammogram/ultrasound findings (BIRADS 1-3), additional workup may include a breast MRI and/or skin punch biopsy of the abnormal skin. Breast MRI is not routinely recommended if a diagnosis can be established by mammogram/ultrasound. However, breast MRI may also demonstrate skin thickening, single or multiple masses, nonmass enhancement, (see Fig. 1D) or it may be nonspecific.

When diagnosing IBC, it important to recognize that it is mainly a clinical diagnosis. Although a pathologic diagnosis of breast cancer is required, the remaining diagnostic criteria are clinical. The minimum criteria required for diagnosing IBC include: (1) rapid onset of breast erythema, edema, peau d'orange, and/or breast warmth with or without underlying mass; (2) duration of symptoms for no more than 6 months; and (3) erythema involving at least one-third of the breast. Once cancer has been confirmed histologically (typically by core needle biopsy of the breast), tumor grade and biomarkers (i.e., estrogen receptor [ER], progesterone receptor [PR], and human epidermal growth factor 2 [HER2]) should also be assessed. If a skin punch biopsy is performed of the skin changes (typically at least two biopsies from separate areas), tumor emboli in the dermal lymphatics (Fig. 3), along with the previous skin changes, are confirmatory of an IBC diagnosis but not required. Of note, tumor emboli in dermal lymphatics without the aforementioned skin changes are not sufficient alone for a diagnosis of IBC.

Patients with IBC are categorized as having clinical T4d disease, and thus, they have a minimum of stage III breast cancer. However, many patients with IBC are metastatic at diagnosis, and thus, systemic staging is recommended for all patients with IBC. Staging should include a CT with contrast of the chest, abdomen, and pelvis, and a bone scan or FDG-PET/CT. For premenopausal women, fertility counseling is also recommended before initiation of

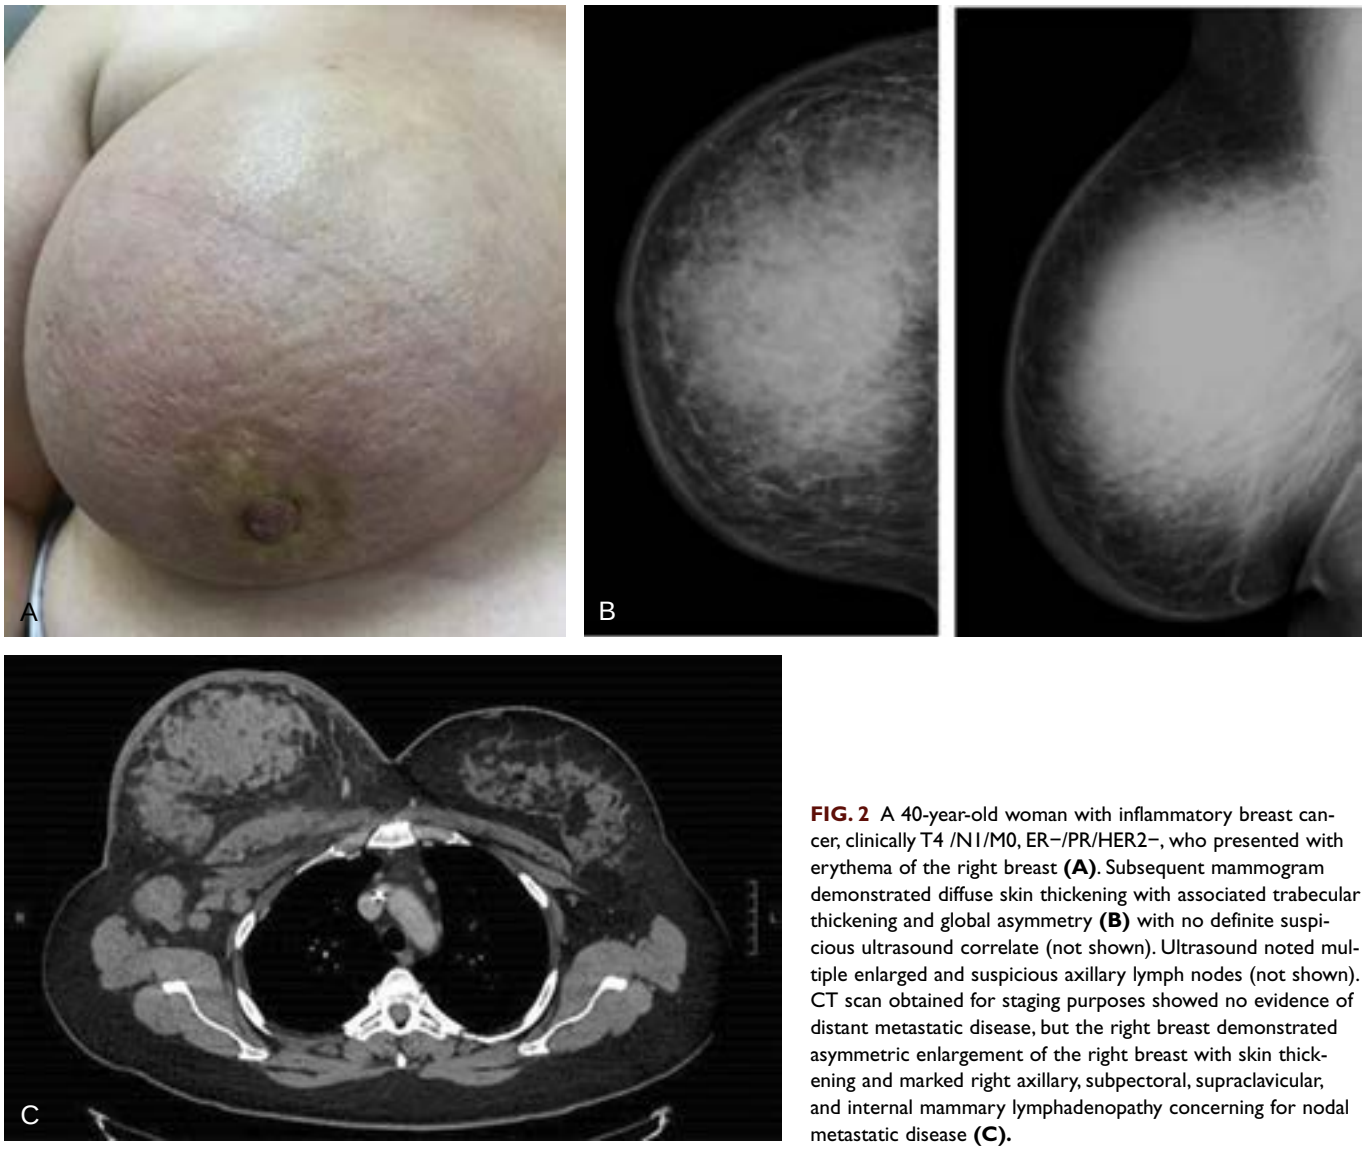

FIG. 2 A 40-year-old woman with inflammatory breast cancer, clinically T4 /N1/M0, ER−/PR/HER2−, who presented with erythema of the right breast **(A)**. Subsequent mammogram demonstrated diffuse skin thickening with associated trabecular thickening and global asymmetry **(B)** with no definite suspicious ultrasound correlate (not shown). Ultrasound noted multiple enlarged and suspicious axillary lymph nodes (not shown). CT scan obtained for staging purposes showed no evidence of distant metastatic disease, but the right breast demonstrated asymmetric enlargement of the right breast with skin thickening and marked right axillary, subpectoral, supraclavicular, and internal mammary lymphadenopathy concerning for nodal metastatic disease **(C).**

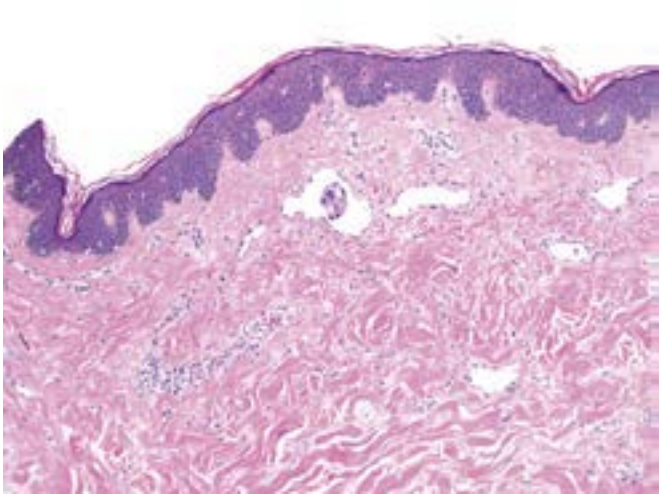

FIG. 3 Patient presented with breast erythema and edema, and skin punch biopsy of breast skin from this patient with inflammatory breast cancer demonstrated tumor emboli in the dermal lymphatics (original magnification, 40×; hematoxylin-eosin stain). *(Micrograph courtesy of Dr. Rex Bentley.)*

chemotherapy. Genetic testing should be considered for all appropriate patients at risk for hereditary breast cancer.

TREATMENT FOR NONMETASTATIC IBC

The standard treatment algorithm (Fig. 4) includes a combination of systemic therapy (chemotherapy, anti-HER2-targeted therapy, and/or endocrine therapy when appropriate) and local-regional management (surgery and radiation). Neoadjuvant chemotherapy with or without endocrine therapy improves overall survival. Patients who do not achieve meaningful clinical response or develop disease progression are typically offered additional systemic therapy and/or preoperative radiation therapy. The duration of the preoperative therapy varies based on the regimen given but may last up to 4 to 6 months. Following completion of neoadjuvant systemic therapy, repeat staging scans may be considered, particularly for those without a clear response. Those who have at least a partial response are offered a modified radical mastectomy (MRM) 4 weeks after completing systemic therapy. After allowing sufficient time to recover from surgery (typically 4–6 weeks), postmastectomy radiation is delivered to the chest wall and regional nodes (ipsilateral axilla, infraclavicular, supraclavicular, and internal mammary). A cumulative dose of 50 to 60 Gy is typically given over 4 to 6 weeks.

When selecting systemic therapies, neoadjuvant anthracycline and taxane-based chemotherapy regimens are preferred. For patients with HER2+ disease, HER2-targeted therapies are also recommended, including trastuzumab ± pertuzumab. Following surgery, the planned chemotherapy regimen should be completed (if not completed preoperatively), and endocrine therapy should be initiated, if ER+ and/or PR+. For patients with HER2+ disease, patients should complete up to 1 year of HER2-targeted therapy, which may be administered concurrently with radiation and endocrine therapy.

SURGICAL APPROACH TO IBC

Surgical management of the breast is intended to optimize local control in a clinical setting where there is extensive local disease in the form of lymphovascular invasion (cT4d). Standard surgical management of the breast in patients with IBC follows neoadjuvant chemotherapy and includes an obligatory MRM, which comprises a total mastectomy and ipsilateral level I/II axillary lymph node dissection (ALND; Box 1), regardless of response to neoadjuvant therapy. A level III dissection to the thoracic inlet may be pursued if there remains gross disease in the level II or level III space. Surgery is generally performed 4 weeks following completion of chemotherapy to allow immunologic recovery for optimal surgical healing. Although repeat systemic staging may be considered before surgery, it is not required. Repeat breast and/or axillary imaging is also not typically necessary.

Breast conserving surgery and sentinel lymph node biopsy are absolutely contraindicated for IBC due to the widespread local disease, most evident in the dermal lymphatics, which defines this unique disease entity. Although there are clinical scenarios in which a sentinel lymph node biopsy following neoadjuvant chemotherapy may adequately stage the axilla, IBC still requires a complete node dissection, even for those who were clinically node negative at the outset. Nipple-sparing and skin-sparing mastectomy, as well as immediate reconstruction, are relatively contraindicated as removal of the involved skin and radiation to the remaining skin are critical aspects of the treatment of the dermal involvement. Postsurgical complications or the added steps in the reconstruction process may cause a delay to radiation impacting local control and recurrence risk.

MODIFIED RADICAL MASTECTOMY

Total Mastectomy

Although most patients require general anesthesia for this procedure, a regional nerve block, such as a thoracic paravertebral nerve block, may be considered. Standard preoperative prophylactic antibiotics should be given, sequential compression devices should be placed on the bilateral lower extremities, and a urinary Foley catheter may be considered but is not required and should be removed at the end of the case, if placed. Once in the operating room, the patient is placed supine on the operating room table with ipsilateral arm extended and widely prepped. The planned skin incision includes a broad skin ellipse to encompass the nipple-areolar complex and as much of the remaining involved skin as possible. It is typically oriented in a transverse-oblique direction across the width of the breast to permit ease of axillary node dissection from within the mastectomy incision. Mastectomy flaps are raised in the avascular plane between breast parenchyma and subcutaneous fat, extending to the clavicle *superiorly*, the lateral border of the sternum *medially*, the rectus sheath/inframammary fold *inferiorly*, and to the anterior border of the latissimus muscle *laterally*. When dissecting in the superior-lateral aspect of the breast, care must be taken to include the axillary tail of Spence. Once all mastectomy planes have been carried down to the chest wall, attention is turned to the superior aspect of the breast, and the breast and underlying pectoralis fascia are excised from the pectoralis muscle. For the small bleeding vessels coming through the pectoralis muscle that are encountered during this aspect of the dissection, hemostasis may be achieved with electrocautery and/or clips. Medially, internal mammary perforators are identified in the intercostal spaces along the lateral edge of the sternum and controlled with clips or ties at their origin. At the lateral border of the pectoralis muscle, the breast may be completely dissected free from final attachments or the axillary tail left in continuity with the axillary tissue for progression to axillary node dissection, as described later. The breast should be oriented for pathologic assessment.

Axillary Lymph Node Dissection

Following excision of the breast from the chest wall, the ALND may be completed en bloc with the breast or performed separately following transection of the breast at the axillary tail. A standard axillary dissection for breast cancer includes levels I and II of the axilla, and it typically involves removal of at least 10 lymph nodes. The boundaries of this dissection include the axillary vein superiorly, the chest wall

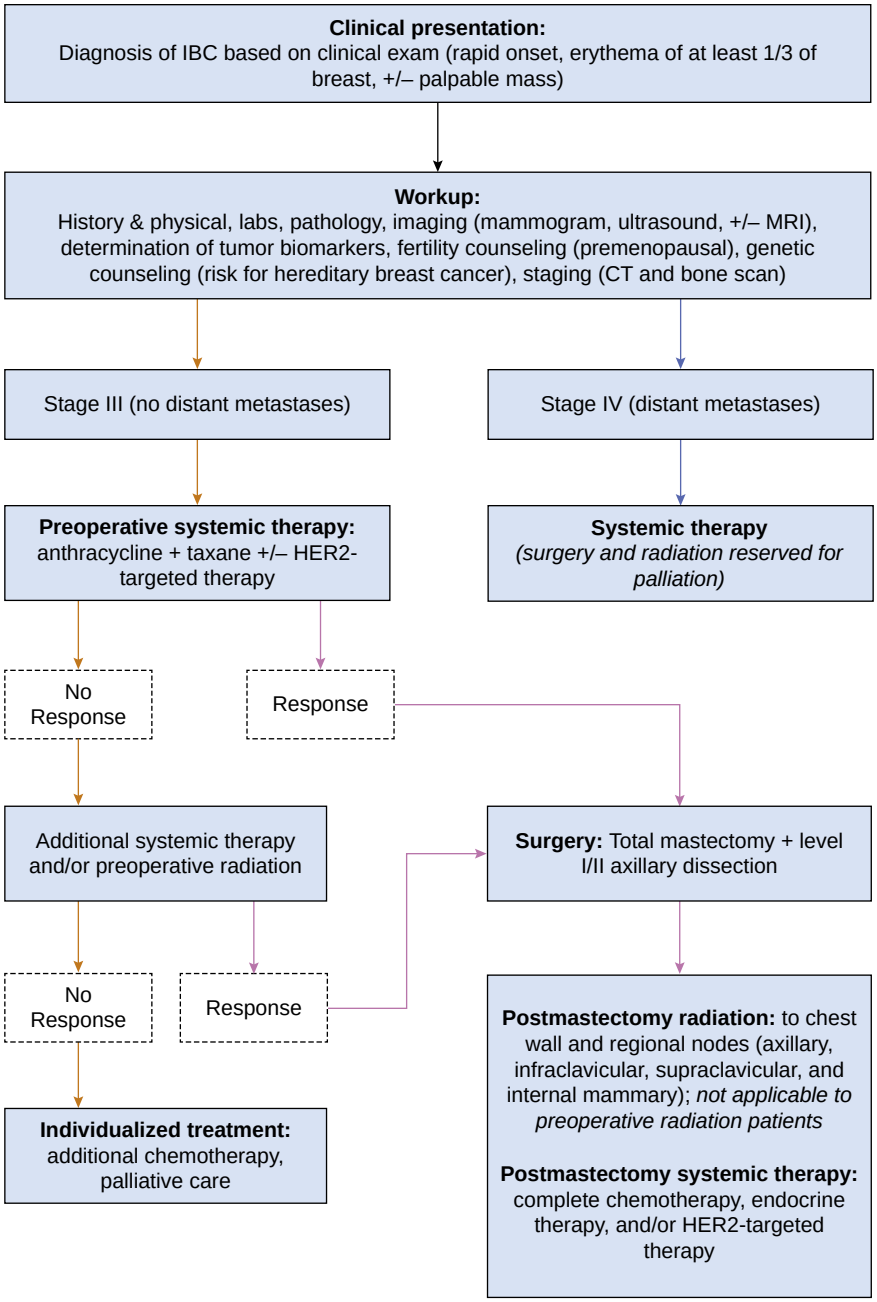

FIG. 4 The standard presentation, workup, and treatment algorithm for patients with inflammatory breast cancer *(IBC)*.

medially, the axillary skin laterally, the pectoralis muscle anteriorly, and the latissimus dorsi muscle posteriorly. Attention must also be given to identifying the thoracodorsal and long thoracic nerves (Fig. 5) to avoid injury.

To start the dissection, the clavipectoral fascia is incised at the lateral edge of the pectoralis major muscle inferiorly, and progression is made superiorly toward the apex of the axilla. The pectoralis muscles are progressively retracted superiorly and medially while mobilizing axillary fat and nodal tissue laterally. The medial pectoral neurovascular bundle may be identified at the entry to Rotter's space and either preserved or ligated based on palpable and/or suspected nodal involvement of Rotter's nodes. This approach may be continued superiorly along the pectoralis edge to identify the axillary vein *medially* in the apex of the axilla; however, *lateral* identification of the vein is preferred. The latissimus dorsi muscle is identified *inferiorly* and *laterally* in the axillary space, and the vertically oriented fibers are followed superiorly, progressing up the anterior surface of the latissimus. The axillary vein may be identified superiorly, as it crosses anterior to the latissimus muscle's tendinous band. This *lateral* approach to axillary vein identification is safest, with no critical structures laterally in the axilla, and permitting optimal control of the vein when encountered, as compared with the medial, apical aspect of the axilla.

The axillary vein is then dissected free of fatty and nodal tissue, anteriorly and inferiorly, with venous tributaries being clipped and divided as progression is made laterally to medially. The thoracodorsal neurovascular bundle is identified entering the axilla in a deep posterior position, usually in the center of the specimen, approximately halfway between chest wall and latissimus muscle. This is identified and protected, as injury causes weak arm/shoulder

BOX 1 Key Procedural Steps and Pitfalls for a Modified Radical Mastectomy

Key Operative Steps

Mastectomy

1. Plan the elliptical skin excision to encompass nipple-areolar complex, oriented transverse-obliquely to accommodate subsequent axillary node dissection
2. Raise avascular mastectomy flaps to the borders of the breast (clavicle *superiorly*, lateral sternal edge *medially*, rectus sheath/inframammary fold *inferiorly*, latissimus dorsi *laterally*)
3. Excise breast and underlying pectoralis fascia from the pectoralis major muscle

Axillary Lymph Node Dissection

1. Incise the clavipectoral fascia at the lateral border of the pectoralis muscles
2. Following the anterior surface of the latissimus muscle, identify the axillary vein as it crosses the tendinous portion superiorly
3. Dissect the fatty and nodal tissue from the inferior aspect of the axillary vein, managing small venous tributaries
4. Identify and protect the thoracodorsal neurovascular bundle in the center of the axillary space
5. Identify and protect the long thoracic nerve along the medial chest wall
6 Sweep axillary specimen inferiorly, dividing final attachments, including anterior thoracodorsal neurovascular branches

Potential Pitfalls

Mastectomy

1. Inadequate skin excision leaving excess tissue with residual dermal lymphatic disease
2. Excessive skin resection with tension on closure leading to dehiscence and delay to radiation
3. Failure to identify or control the internal mammary sternal perforators at sternal border

Axillary Lymph Node Dissection

1. Dissection around *medial* shelving edge of latissimus causing injury to thoracodorsal bundle at insertion site into latissimus muscle inferiorly in axilla
2. Dissection *superior* to axillary vein causing severe worsening of lymphedema risk
3. Dissection *medial* to long thoracic nerve, mobilizing nerve into axillary specimen
4. Failure to recognize a smaller caliber bifid axillary vein, and/or distinguish axillary vein, thoracodorsal vein, and anterior thoracoepigastric vein.

movements. A large anterior tributary to the axillary vein, often a large proximal vein, is the anterior thoracoepigastric vein that must be ligated, once certain distinction has been made from the thoracodorsal vein. The axillary specimen is then mobilized laterally, and the intercostobrachial nerve may be encountered as it runs medial to lateral across the surgical field to the upper inner aspect of the arm, as opposed to the vertically oriented thoracodorsal and long thoracic nerves. If possible, the intercostobrachial nerve should be preserved to limit some of the unavoidable sensory neuropathy that results from an ALND, although it is often sacrificed to allow for improved visualization of the axilla and easier mobilization of the axillary contents.

The long thoracic nerve is identified along the medial chest wall, coursing vertically along chest wall and entering inferiorly into the serratus anterior. This nerve is carefully protected against the chest wall, as injury may result in a winged scapula. When retracting laterally during this dissection, the long thoracic nerve may also be pulled laterally away from the chest wall, and thus, it may be occasionally identified by easing the lateral retractors when it is not readily visible.

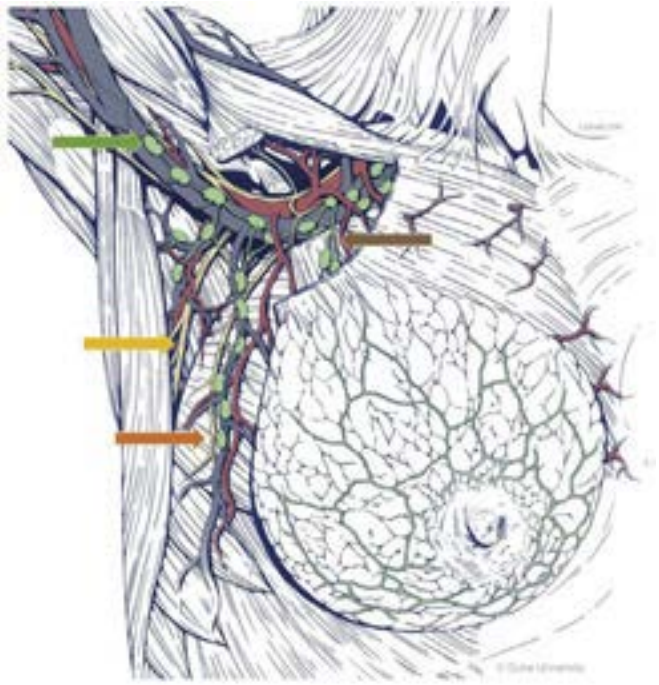

FIG. 5 Select key anatomic landmarks of the breast and axilla to consider when performing a modified radical mastectomy. *Green arrow* highlights the superior/anterior lymphatic chain overlying the axillary vein from the upper extremity. *Yellow arrow* highlights the thoracodorsal neurovascular bundle as it inserts into the medial aspect of the latissimus dorsi muscle. *Orange arrow* highlights the long thoracic nerve as it inserts into the serratus anterior muscle. *Brown arrow* highlights Rotter's nodes in Rotter's space between the pectoralis muscles. *(Illustrated by Megan Llewellyn, MSMI, CMI; copyright Duke University; with permission under a CC BY-ND 4.0 license.)*

The remaining axillary tissue is then dissected free in the apex of the axilla, connecting the cleared axillary vein to the chest wall, beneath the pectoralis minor muscle. The nodal specimen is mobilized inferiorly, and tissue between the thoracodorsal and long thoracic nerves are clamped, tied, and divided to be included within the specimen. A blunt sweep of this tissue clears the specimen from the latissimus and subscapularis floor of the axilla. The remaining anterior branches of the thoracodorsal neurovascular bundle are clipped and divided to free the specimen from its final attachments.

The specimen may be sent for intraoperative specimen radiograph to confirm any previously biopsied and clipped nodes are included within the specimen. The axilla should then be palpated for any residual adenopathy, paying particular attention to Rotter's space and level III of the axilla. If suspicious adenopathy is identified, attempt at resection should be undertaken. Once all specimens have been removed, it is prudent to verify that the thoracodorsal and long thoracic nerves remain intact by either visual verification and/or stimulation of the nerves. Following hemostasis, two closed suction drains are placed, one looped into the apex of the axilla and the other under the mastectomy flap. When reapproximating the wound edges, additional skin may need to be resected to allow for a tighter closure, and this skin should also be sent for pathologic evaluation. The mastectomy flaps are closed in layers with a deep interrupted dermal and a subcuticular skin closure. After dry dressings are placed, a binder or wrap may provide additional compression of the surgical site and help minimize drain output.

POSTOPERATIVE MANAGEMENT

Patients are generally admitted for 23-hour observation to monitor drain output and assess adequacy of pain control. Immediate normalization of the patient is recommended with early ambulation, oral fluid intake, regular diet, oral analgesia, and resuming all prior

medications. Intravenous antibiotics may be reasonably delivered during overnight observation but discontinued before discharge. The chest wall should be examined in the early postoperative period to ensure there is no hematoma, which is classically visible by sanguineous drain output, chest wall swelling, and/or mastectomy flap ecchymosis. Applying ice to the chest wall and/or axilla may improve pain control and help minimize residual oozing.

Drain output may be expectedly higher in volume as compared with a standard mastectomy, in light of breast edema, and surgical drains should remain in place until a threshold of volume has been reached and not a designated duration after surgery. The binder/wrap placed in the operating room should be continued until the drains are removed, even if the other surgical dressings are removed. Drains may be removed once the volume is below 30 mL per 24-hour period and are generally removed sequentially and not on the same day.

SPECIAL CONSIDERATIONS FOR SURGERY

Given the aggressive nature of the disease, few factors will alter the surgical approach for IBC—essentially all patients who undergo surgery should have a MRM. For patients with extensive skin involvement, attempts should be made to remove/treat as much of the involved skin as possible with surgery and/or radiation. For patients with extensive nodal involvement, surgical resection should include as many of the involved nodes as possible, including those in Rotter's space and level III, as applicable. For elderly patients, the surgical management should not be particularly altered based on age alone, but the patient's comorbidities may dictate additional preoperative and postoperative considerations, such as evaluation by other medical specialists for risk stratification and optimization before surgery or referring the patient for physical therapy after surgery. For pregnant patients, the surgical approach should also not be altered, but radiation therapy should be delayed until after delivery.

POTENTIAL SURGICAL COMPLICATIONS AND MANAGEMENT STRATEGIES

Early operative intervention is encouraged for a hematoma, as this is likely from an inadequately controlled internal mammary perforator, pectoralis muscle perforator, or axillary venous branches. Operative evacuation of a hematoma is beneficial to improve chest wall flap apposition and infection prevention from a retained hematoma. Postoperative cellulitis is often managed with oral antibiotics, while flap necrosis and incisional dehiscence may require additional surgical attention, although routine dressing changes (wet-to-dry) are often adequate. These fairly common complications should be identified and managed early to ensure timely initiation of adjuvant radiation.

If the drain output is unexpectedly high and white appearing shortly after surgery, the possibility of a chyle leak should be considered. Lymphatic fluid in the drain may appear more milklike than expected and sending the fluid for triglyceride assessment is diagnostic (often >110 mg/dL). Chyle leaks may be managed with continued drainage, a pressure dressing, and diet modification (low fat). If the chyle leak does not resolve, reexploration and ligation of the leak is recommended.

For patients with persistently elevated serous drain output after several weeks, it is often reasonable to remove the drains at 4 weeks if they are close to meeting the cutoff threshold. However, if the patient develops a seroma after drain removal, a percutaneous drain may be replaced by interventional radiology. Drain output should be strictly monitored, and a higher threshold may be used for drain removal. If a high drain output still persists or a chest wall seroma reaccumulates, sclerotherapy may be considered. This may be accomplished by instilling 95% to 99% ethanol into the drain (or seroma cavity after aspirating the seroma) and then reaspirating the ethanol after 10 to 20 minutes. Pressure dressings may also be helpful after sclerotherapy to help minimize the space for reaccumulation.

Unfortunately, chronic pain may develop in 20% to 30% of patients following MRM; this is termed *postmastectomy pain syndrome* (PMPS). This neuropathic pain may involve the chest wall, axilla, and/or upper arm, and it may be described as dull, burning, aching, numbness, and/or shooting or pricking pain. It may be exacerbated by movement, straining, overhead activity, and/or cold weather. Most women report that it is mild, but it may impact their quality of life. Risk factors for PMPS include ALND, radiation, younger age, minority race/ethnicity, and preexisting pain and/or psychologic disorders. Given that the etiology is unknown, treatment can be difficult, and collaborating with pain specialists may be considered.

The combination of ALND and radiation dramatically increases the risk of lymphedema, which may be as high as 40% in this population. The initial treatment strategy for lymphedema may include wearing a compression garment, exercise, physical therapy, massage, and/or decongestive therapy. Surgical treatments for lymphedema are still considered largely experimental.

Following axillary surgery, patients may also experience axillary web syndrome, which is also known as cording. This refers to a rope or cordlike texture that develops in the axilla just deep to the skin and may extend partially down the arm. The treatment for cording is exercise, physical therapy, massage therapy, hot compresses, and over-the-counter nonsteroidal antiinflammatory medications. Similarly, patients that develop shoulder stiffness following axillary surgery may also benefit from range of motion exercises and physical therapy.

OTHER CONSIDERATIONS

Once all therapies for IBC have been completed, ongoing surveillance should include a history and physical examination one to four times a year for 5 years, then annually, as well as annual mammography for the contralateral breast. However, systemic staging is not routinely recommended in the absence of clinical signs or symptoms of metastatic disease. Monitoring for lymphedema is prudent. All patients should be encouraged to maintain an active lifestyle, eat a healthy diet, limit alcohol intake, and maintain a healthy weight. Breast reconstruction may be considered after 2 to 5 years without signs of recurrence or distant disease, which often requires autologous tissue flap-based reconstruction.

For patients with a suspected recurrence, a biopsy is required for definitive diagnosis, and if confirmed, biomarkers should be repeated. Systemic staging is recommended, and goals of care should be discussed, particularly for those with distant disease. When an isolated chest wall or axillary recurrence is present, local therapy, including surgery, should be considered.

Ductal and Lobular Carcinoma in situ of the Breast

Lauren M. DeStefano, MD, and Kristine E. Calhoun, MD

Breast cancer is one of the most common types of cancers and is the second leading cause of death in women. Due to advances in screening, there has been an increase in the incidence of high-risk lesions and preinvasive cancers over recent years, with approximately 48,000 new cases of ductal carcinoma in situ (DCIS) diagnosed annually. Although DCIS and lobular carcinoma in situ (LCIS) sound similar, they are distinct entities with different treatments and prognoses. DCIS is a noninvasive, nonobligate precursor to invasive carcinoma that originates in the ducts of the breast. LCIS originates in the lobules of the breast and has been described as both a nonobligate precursor of breast carcinoma and a high-risk marker of developing a breast carcinoma in either breast. Due to these differences, LCIS was removed from the 8th edition of the AJCC staging system and is now considered lobular neoplasia.

DUCTAL CARCINOMA IN SITU

Diagnosis

DCIS is most often diagnosed on mammography as new or changing suspicious-appearing calcifications. As mammography screening increased in the 1980s and 1990s, the incidence of DCIS increased more than 11-fold (7 per 100,000 to 83 per 100,000). Today, mammographically detected DCIS accounts for 25% of all breast cancers. Rarely, DCIS can present as a palpable or mammographically detected mass. DCIS associated with Paget's disease can present as nipple discharge or changes.

Once an abnormality is noted on screening mammography, additional diagnostic views may be completed to further characterize the abnormality. Stereotactic, or mammographic-guided, core needle biopsy is typically performed next to obtain a tissue diagnosis and help guide the next steps in the patient's treatment. If the lesion is not amenable to stereotactic core needle biopsy, for example, due to proximity to skin, chest wall, or mammary implant, a surgical excisional biopsy can be performed for tissue diagnosis.

After a diagnosis of DCIS is made, many surgeons elect to obtain a preoperative breast MRI to aid in surgical planning. This is controversial, as it has not been proven to decrease positive margin rates but has increased the incidence of additional biopsies as well as the rate of mastectomies. Genetic counseling and testing should be offered preoperatively, especially to those under 60 or with a strong family history in first-degree relatives. Although some guidelines such as from the National Comprehensive Cancer Network (NCCN) offer criteria for those who should be offered testing, other guidelines, such as from The American Society of Breast Surgeons (ASBrS), state testing should be available for all patients with a personal history or diagnosis of a breast cancer.

Treatment

It is well established that a diagnosis of DCIS has an excellent prognosis; with a multimodality approach to treatment, including surgery, radiation therapy and endocrine therapy, survival rates for DCIS at 15 years are greater than 95%. It is also well established that local control and survival are similar after mastectomy as well as after breast conservation. Multiple randomized clinical trials from the National Surgical Adjuvant Breast and Bowel Project (NSABP) have examined outcomes of breast conservation. NSABP B-06 established equivalent long-term survival for breast conservation (lumpectomy plus radiation) compared with mastectomy for patients with invasive carcinoma. These results have been extrapolated for DCIS, although there was never a study specifically comparing mastectomy to breast conservation for DCIS. NSABP B-17 and B-24 focused on outcomes comparing treatment modalities within breast conservation. In B-17, breast tumor recurrences (IBTR) were compared among lumpectomy alone (LO) versus lumpectomy followed by radiation therapy (LRT). Long-term data demonstrated a 52% reduction in the risk of IBTR in the LRT group compared with the LO group.

Based on these data, the primary treatment of DCIS includes surgery: either breast conservation (lumpectomy plus/minus radiation) or mastectomy. Although there is no survival benefit for mastectomy, there are instances when mastectomy is recommended over breast conservation. Indications for mastectomy include extensive span of disease, multicentric disease, patients with contraindications to radiotherapy, or known pathogenic mutation. For those undergoing mastectomy, there are three types of mastectomies that one can offer their patient. A total mastectomy includes removal of the breast parenchyma, skin, and nipple-areolar complex. No reconstruction is typically offered with a total mastectomy; however, a flat aesthetic closure has gained popularity amongst these patients. A skin-spring mastectomy includes removal of the breast parenchyma along with the nipple-areolar complex, sparing enough skin to rebuild the breast mound. In a nipple-sparing mastectomy, only the breast parenchyma is removed, sparing the skin and nipple-areolar complex. For both a skin-sparing and nipple-sparing mastectomy, reconstruction can be immediate with placement of a tissue expander, mammary implant, or autologous tissue, or it can be delayed if there are concerns for flap integrity. There are no data suggesting one type of mastectomy is superior to another; however, it is important to evaluate the location of the lesion as well as proximity to the nipple-areolar complex when determining the type of mastectomy to offer one's patient.

For patients who opt for breast conservation, a lumpectomy, or segmental mastectomy, is the standard operation. Lumpectomies are often performed via preoperative localization, which can be with a wire placed preoperatively by breast imagers or with one of several newer wireless technologies to target the lesion for surgical excision, such as infrared reflectors (Scout devices), radioactive seeds, Mag seeds, or Tag devices. Large lumpectomies with preoperative bracketing utilizing multiple wires or devices can be performed by breast surgeons familiar with oncoplastic techniques or in conjunction with a plastic surgeon who performs oncoplastic techniques, allowing for breast conservation in patients previously deemed not candidates for breast conservation. These techniques employ volume rearrangement such as oncoplastic reduction mammoplasty or mastopexy, or involve volume replacement such as with a lateral intercostal perforator artery flap (LiCap).

In 2014, the Society of Surgical Oncology and the American Society for Radiation Oncology released updated consensus guidelines indicating that "no ink on tumor" is a safe margin for invasive carcinoma; however, since DCIS is typically not a mass but scattered calcifications, the margin guidelines for DCIS remain at 2 mm. Subsequent consensus guidelines reestablished the 2-mm margin as standard of care for DCIS. If a negative margin is unable to be achieved with a reexcision lumpectomy, a patient may be advised to proceed with a completion mastectomy with or without reconstruction.

Axillary lymph node sampling is not routinely performed during lumpectomy for DCIS; however, sampling in the form of axillary sentinel lymph node biopsy is recommended at time of mastectomy in the event of tumor upstaging to invasive carcinoma on final surgical pathology. Once the breast has been removed and breast lymphatics severed and destroyed, sentinel node mapping is not possible should invasive cancer be found, hence the need to do the mapping concurrent with the breast removal. Traditionally, a combination of radioactive sulfur along with a blue dye is used to identify the axillary sentinel lymph node at time of the mastectomy. Newer tracers have been developed to allow for a delayed sentinel lymph node procedure if final pathology yields an invasive carcinoma in the mastectomy specimen.

In NSABP B-24, the addition of tamoxifen (a selective estrogen receptor modulator) to breast conservation for estrogen receptor-positive (ER+) disease was examined. Long-term data demonstrated a 32% risk reduction of ipsilateral IBTR for breast conservation plus tamoxifen compared with placebo. Comparing across B-17 and B-24, ipsilateral IBTR were shown to have a 70% risk reduction for lumpectomy plus radiation and tamoxifen compared with LO. Furthermore, the addition of tamoxifen in B-24 demonstrated a 32% reduction in contralateral breast cancers. Although more than half of the IBTR were invasive, the use of radiotherapy or addition of tamoxifen was not associated with overall mortality reduction in either study. NSABP B-35 later examined the breast cancer-free interval of tamoxifen compared with anastrazole (an aromatase inhibitor) among postmenopausal women. Results demonstrated that anastrazole was superior to tamoxifen in postmenopausal women under age 60 and equivalent in women above the age of 60. These data lay the basis for endocrine therapy for patients with ER+ disease.

Although an operation is currently included in the standard of care in the treatment of DCIS, there are some who believe there is overtreatment for DCIS, particularly those that are low grade, small, and ER+. There are currently ongoing studies to evaluate the role of monitoring without surgical intervention. The COMET (US) and LORETTA (Japan) trials are phase III randomized trials currently underway to compare operative intervention versus monitoring and endocrine therapy for patients with low-risk DCIS. The LORIS (UK) and LORD (Europe) trials are examining the role of monitoring alone without endocrine therapy. These trials will be instrumental in determining if there are low-risk DCIS patients who can be safely treated without surgical intervention.

Surveillance

After completion of local control for DCIS (surgery plus/minus radiation), patients should begin surveillance. It is recommended that patients undergo interval history and physical examinations every 6 to 12 months for the first 5 years and then annually thereafter. Annual mammography should continue, with the first mammogram 6 to 12 months after completion of breast conservation therapy. Patients who were undergoing high-risk surveillance with annual MRIs in addition to their annual mammogram should continue their high-risk surveillance. Patients who have undergone mastectomy no longer require mammography or MRI and instead are monitored with a comprehensive chest wall examination every 6 to 12 months.

LOBULAR CARCINOMA IN SITU

Classifications

LCIS was first described in 1941 as a rare form of incidentally found noninvasive breast cancer. After much data looking at long-term outcomes, LCIS has been reclassified as lobular neoplasia to demonstrate the more indolent nature of this process. Histologically, LCIS is classified as classic (cLCIS), pleomorphic (pLCIS), and florid (fLCIS). cLCIS is more common in premenopausal women compared with pLCIS and fLCIS, which are more commonly diagnosed in postmenopausal women. pLCIS and fLCIS have been described as having behavior more similar to DCIS, so many treat these entities in a similar manner as DCIS. However, there is a paucity of data on long-term outcomes and recurrence risks after excision.

Diagnosis

Although DCIS is often mammographically detected and suspected during workup, LCIS is often incidentally found when a biopsy or procedure is performed for a different indication. The incidence of LCIS found in benign breast core needle biopsies is under 3.5%, and those found in reduction mammoplasty specimens is under 1.2%; however, the exact incidence is truly unknown given that most women are asymptomatic, and the lesions are mammographically occult. pLCIS and fLCIS can be associated with calcifications, and rarely a mass lesion, on mammography.

Treatment/Management

Recent studies have indicated that the upgrade rate of LCIS to an invasive carcinoma on surgical excision is less than 5% when there are no other lesions present that require excision and there is radiologic-pathologic concordance. Based on this, the American Society of Breast Surgeons (ASBrS) has released a consensus statement regarding the management of LCIS, wherein the society does not advocate for routine excision of LCIS in the previous scenario. However, since pLCIS and fLCIS have a higher upgrade rate (40%) compared with cLCIS (1%–4%), many advocate for excisional biopsy when these variants are seen on core needle biopsy. If cLCIS is found in a surgical specimen, margin status is irrelevant, unlike DCIS; however, the significance of margin status in pLCIS and fLCIS is relatively unknown and controversial. Because many believe these lesions behave more similarly to DCIS, these lesions are typically excised to negative margins, which can be challenging given their typically diffuse distribution within the breast.

Although the incidence of LCIS has increased over time while surgical intervention has decreased, survival has remained unchanged and is exceedingly high. Although the upstage rate of cLCIS is relatively low, the lifetime risk of developing an invasive carcinoma (either ipsilaterally or contralaterally) is upwards of 40% with an absolute risk of 1% to 2% per year. This is an increase compared with the general population of almost 10-fold. Due to this, many advocate for high-risk surveillance in this patient population. Management options for LCIS include annual breast MRIs in addition to annual mammography, chemoprevention, and even risk-reducing prophylactic bilateral mastectomies. Many trials have demonstrated a risk reduction in the development of breast carcinoma of greater than 50% with 5 years of endocrine therapy compared with placebo in patients with LCIS. The side effect profiles vary between SERMS, such as tamoxifen, and aromatase inhibitors, such as Anastrozole, and can range from postmenopausal-like symptoms and decreasing bone density to thromboembolism and endometrial carcinoma. The maximal risk reduction is seen with bilateral risk-reducing prophylactic mastectomies, which reduce the risk of a breast carcinoma by almost 95%. This is not routinely recommended but could be considered in those with additional risk factors or those who are unable to tolerate chemoprevention or high-risk surveillance.

Advances in Neoadjuvant and Adjuvant Therapy for Early-Stage Breast Cancer

Julia Tchou, MD, PhD, and Seye Adekeye, MD, PhD

Over the past several decades, the treatment for early-stage breast cancer (clinical stage I and II) has almost always begun with surgery followed by adjuvant systemic therapy and adjuvant radiotherapy when indicated. Several landmark studies (listed in Suggested Readings) published in the past several years, primarily between 2017 and 2019, have changed this conventional approach. In this chapter, we review the key factors and rationale affecting the surgeon's recommendation of surgery first vs. neoadjuvant chemotherapy (NAC) in patients with clinical stage I or II breast cancer. Finally, we have provided a treatment decision algorithm (Fig. 1) used at our institution for the treatment of early-stage breast cancer according to receptor status.

ROLE OF RECEPTOR STATUS IN DETERMINING TIMING OF CHEMOTHERAPY (NEOADJUVANT VS. ADJUVANT)

Breast cancer is a heterogeneous disease. Gene expression profile analyses have stratified breast cancer into several molecular subtypes, which can be approximated by the expression of three receptors, namely estrogen receptor (ER), progesterone receptor (PR), and the human epidermal growth factor-2 or HER-2/neu (HER2). For practicing surgeons who care for breast cancer patients, the decision for systemic therapy in the adjuvant setting (after surgery) or in the neoadjuvant (before surgery) setting is significantly influenced by the composition of the expression pattern of the three receptor subtypes. Therefore, it is critical to confirm the expression status of ER, PR, and HER2 protein before proceeding with tumor resection.

For practical reasons, molecular subtype is generally determined using standard histopathology assessment, i.e., immunohistochemistry. The tumor is then classified into three subtypes defined by their receptor status as: (1) ER+ and/or PR+, which is also often referred to as hormone receptor positive (HR+) and HER2- (HR+/HER2-); (2) HR- and HER2- also known as triple negative breast cancer (TNBC); and (3) (HR+ or HR-) and HER2+, or simply HER2+. Following subtype classification, tumor size (T) and nodal status (N) further direct local (surgery ± radiotherapy) and systemic treatment planning.

HR+/HER2- BREAST CANCER

For patients with HR+/HER2- breast cancer, the decision for NAC at our institution is often reserved for those with bulky lymphadenopathy or those with large tumors, e.g., tumors ≥T2 (≥5 cm). The purpose of NAC is to downstage disease in the axilla and/or breast to ease the axilla staging procedure and improve breast conservation success rate, respectively. For patients with smaller HR+/HER2– breast cancer (e.g., tumors <5 cm), especially in those with low axilla disease burden (≤cN1), surgery is often recommended first to allow for accurate pathologic staging of the axilla. Surgical management includes breast conservation versus mastectomy with sentinel lymph node biopsy for cN0 or axillary dissection for cN1 disease.

For those with pathologic node negative (pN0) disease, the use of the 21-gene recurrence score assay (Oncotype Dx) is now standard of care to help guide the recommendation of adjuvant chemotherapy. The 21-gene recurrence score assay yields a recurrence score ranging from 0 to 100 and stratifies risk of recurrence into two risk groups: low or high risk. For women age 50 or above, recurrence score ≤25 is considered low risk, while recurrence score of 26 or higher is high risk. For women <50 years old, recurrence score of 15 or lower is considered low risk. For those with low-risk recurrence score, endocrine therapy (e.g., tamoxifen, anastrozole, or other aromatase inhibitors) will be recommended for systemic therapy based on menopausal status. For those with high-risk recurrence score, systemic chemotherapy will be recommended followed by endocrine therapy. The typical systemic chemotherapy in this setting is composed of four cycles of two drugs often abbreviated as TC: Cyclophosphamide (Cytoxan) and Paclitaxel (taxol) or Docetaxel (Taxotere).

For those with ≤3 positive axilla nodes (pN1) disease, systemic adjuvant chemotherapy followed by endocrine therapy is standard of care in premenopausal women. For postmenopausal women, preliminary results from an ongoing study (RxPONDER Trial, NCT01272037) showed that chemotherapy followed by endocrine therapy may not improve survival beyond the benefits of endocrine therapy alone if their tumor recurrence score is ≤25. Subgroup analysis showed that the invasive disease-free survival (iDFS) 5-year rates were similar in postmenopausal women who received

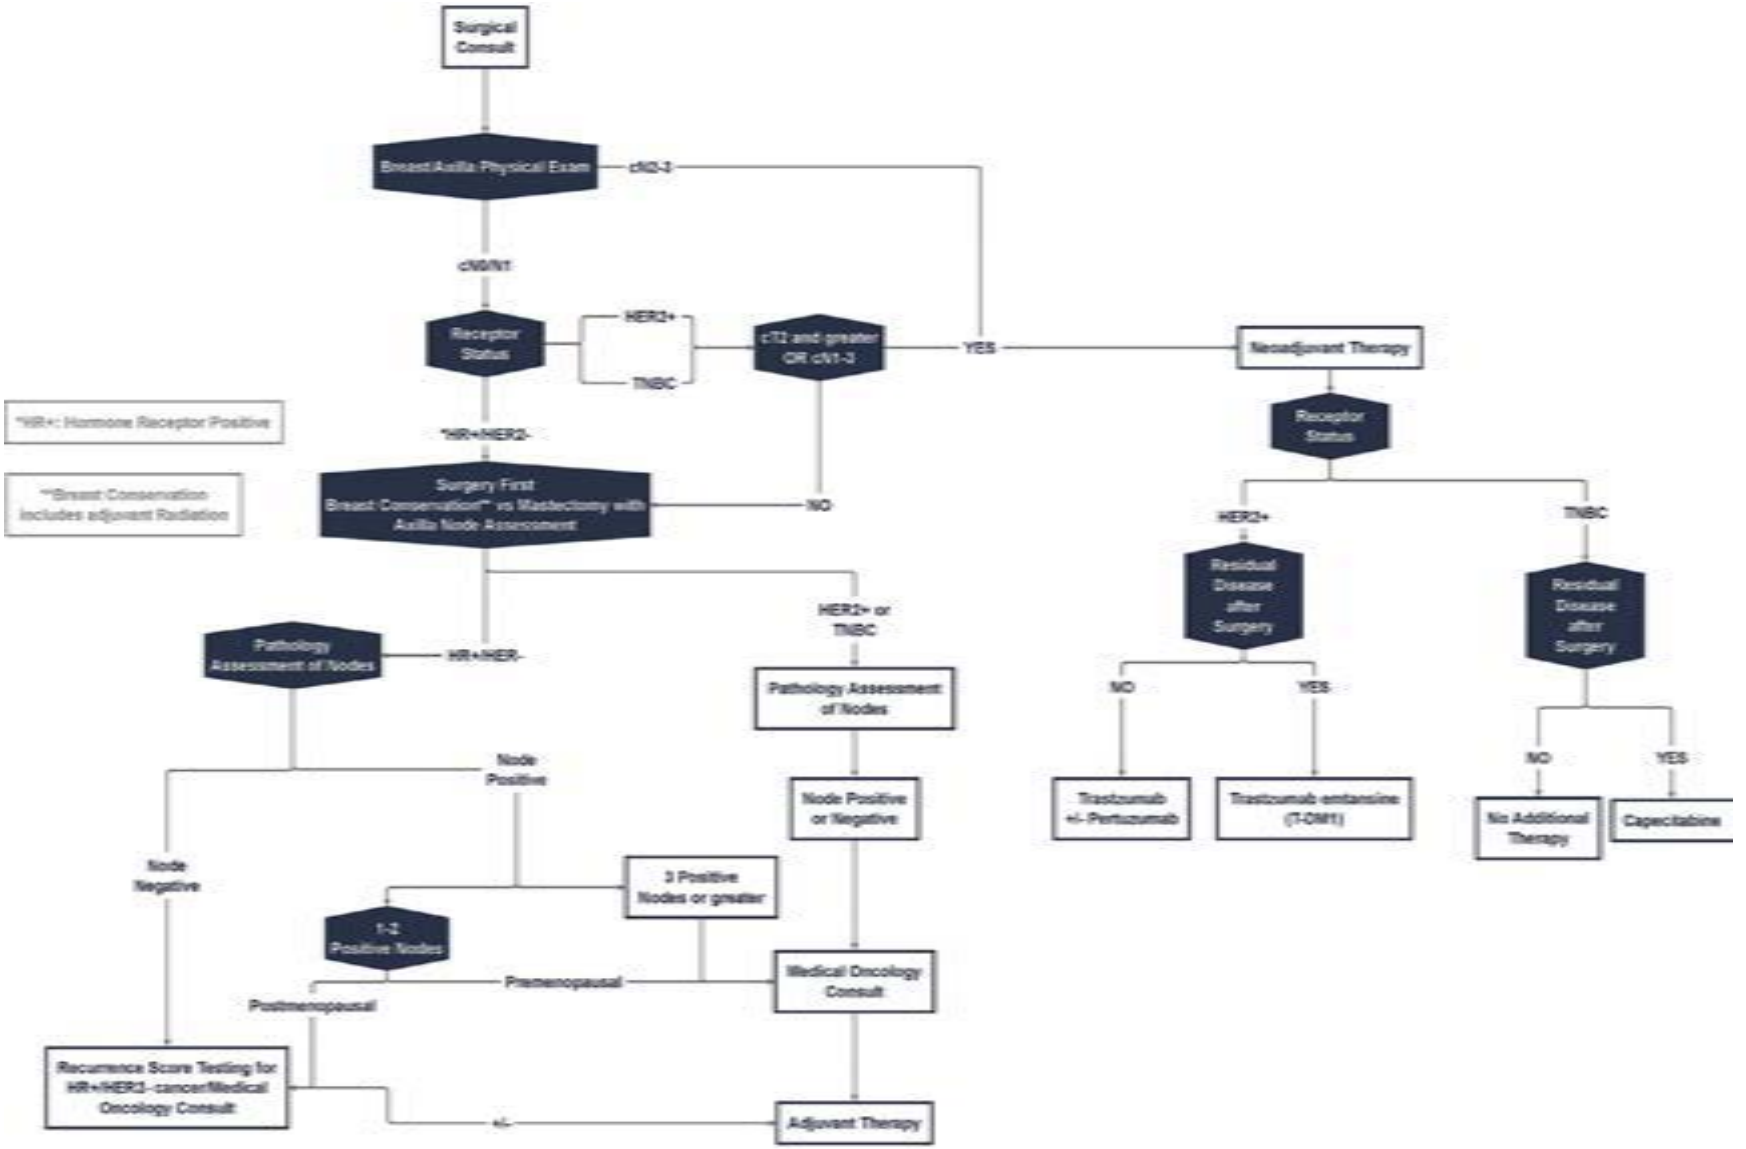

FIG. 1 Algorithm for the treatment of early-stage breast cancer according to receptor status.

chemotherapy plus endocrine therapy (91.9%) versus endocrine therapy alone (91.6%) ($P = 0.82$). In contrast, the iDFS 5-year rates in premenopausal who received chemotherapy plus endocrine therapy was 94.2% vs. 89% with endocrine therapy alone ($P = 0.0004$). The typical systemic chemotherapy regimen in women with node positive disease is generally comprised of three drugs: doxorubicin (Adriamycin), Cyclophosphamide (Cytoxan), and Paclitaxel (taxol) or Docetaxel (Taxotere).

Adjuvant radiation therapy is guided by the pathologic nodal staging information, which helps guide the decision for the inclusion of regional node (supraclavicular and internal mammary nodal basins) radiation field postlumpectomy or postmastectomy.

TRIPLE NEGATIVE BREAST CANCER

This breast cancer subtype comprises about 15% to 20% of all breast cancer subtypes. The aggressive tumor biology of TNBC renders this breast cancer subtype to be more sensitive to chemotherapy than the more common and indolent HR+/HER2- breast cancer subtype. The complete pathologic response (pCR) rate after NAC for TNBC is around 50%, whereas pCR rate in HR+/HER2− is only ∼15% to 20%. Therefore, NAC is often recommended to patients with larger tumors and axilla nodal involvement to improve the feasibility of breast conservation surgery.

The ability of NAC to downstage disease in the axilla may allow the patients to have a less invasive axilla staging procedure (e.g., targeted sentinel node axilla dissection), which involves the removal of the biopsy-proven clipped node along with 2 or 3 additional sentinel nodes rather than the conventional axilla node dissection. Removal of fewer axilla nodes may decrease the likelihood of lymphedema and other complications associated with axilla node dissection. The ability of NAC to downstage the extent of disease in the breast may improve the success rate of breast-conserving surgery by allowing the surgeon to excise a smaller volume of breast tissue, thus reducing the need for mastectomy.

The treatment paradigm of TNBC has changed in the past several years. NAC has become the standard of care in patients with early-stage TNBC with tumor size >2 cm regardless of axilla nodal status based on results of the CREATE-X study published in 2017. In this study, patients with either HR+/HER2− or TNBC were enrolled between 2007 and 2012 to receive NAC. Patients with residual tumor (n = 910; i.e., nonpathologic complete response) at the time of surgery were randomized to receive capecitabine plus standard postsurgical care therapy (n = 443) versus control (n = 444) who received standard postsurgical care therapy alone. Capecitabine is given daily orally twice a day on days 1 to 14 every 3 weeks for 6 or 8 cycles. Subgroup analysis showed that women with TNBC and tumor size >2, among other clinical variables, had significantly improved disease-free and overall survival with hazard ratio (HR) (95% CI) of 0.58 (0.39–0.87) and 0.52 (0.30–0.90), respectively. Of note, the HR for women with tumor size ≤2 cm was 0.65 (0.30–1.44), which was not statistically significant. Based on this study, NAC is recommended for women with tumor size ≥2 cm (cT2) regardless of nodal status. After NAC therapy and surgical management, the need for further adjuvant chemotherapy depends on the presence of residual disease in the surgical specimen. Adjuvant capecitabine comprising of 6 to 8 cycles is recommended for those with residual disease (nonpathologic complete response (non-pCR), while no additional systemic therapy is recommended for those with pathologic complete response (pCR). More recently, KEYNOTE-522 study demonstrated that immune checkpoint blockade therapy (pembrolizumab) in combination with chemotherapy in the neoadjuvant setting was shown to improve pCR rates and disease-free survival in women with ≥ T1c, node (+) or ≥ T2, any nodal status TNBC.

HER2+ BREAST CANCER SUBTYPE

The introduction of trastuzumab in the adjuvant setting has revolutionized the treatment of HER2+ breast cancer. Trastuzumab (Herceptin) binds to HER2 to elicit antibody-dependent cellular cytotoxicity (ADCC). Trastuzumab was approved for use in the adjuvant setting in the United States in 1998. The release of trial results of five major studies (Herceptin Adjuvant [HERA] Breast International Group [BIG] 01-01 trial, the Breast Cancer International Research Group [BCIRG] 006 trial, the National Surgical Adjuvant Breast and Bowel Project [NSABP] B-31 trial, the North Central Cancer Treatment Group [NCCTG] N9831 trial, and the Finnish FinHer trial in 2005) investigating the benefits of Trastuzumab in the adjuvant setting provided the basis for its use in clinical practice.

Since then, other HER2-directed monoclonal antibodies have been developed (e.g., pertuzumab), which inhibits the dimerization of the HER2 receptor. More recently, the NeoSphere trial, published in 2012, supported the use of dual HER2 blockade in the neoadjuvant setting, demonstrating that the addition of dual HER2-targeted NAC therapy (i.e., chemotherapy combined with pertuzumab and trastuzumab) significantly improved the rate of pCR for patients with nonmetastatic HER2+ invasive disease. Analysis of the cohort at 5 years revealed improved survival advantages for those who received dual HER2 blockade in the neoadjuvant setting. Therefore, based on the NeoSphere study, the combination of dual HER2-targeted therapy, trastuzumab and pertuzumab, is superior to single agent (trastuzumab alone) HER2-targeted therapy. This is not surprising as the combination of trastuzumab and pertuzumab are mechanistically synergistic in their tumor cell kill activities.

NAC is usually not recommended for patients who present with smaller breast tumors (<2 cm) and clinically negative axilla. For these patients with clinical stage I disease, surgery first is recommended followed by adjuvant systemic chemotherapy. The chemotherapy regimen is based on HER2-targeted therapy (comprising of either single [trastuzumab] or dual [trastuzumab and pertuzumab] HER2-targeting agent) plus various chemotherapy combinations that may include taxanes (docetaxel or paclitaxel), carboplatin, and/or doxorubicin.

NAC is generally recommended if tumor size is ≥2 cm (cT2) and/or axilla nodes are clinically positive. In the neoadjuvant setting, both the NOAH and TECHNO trials found that the pCR rate following addition of trastuzumab to NAC was improved. Patients with operable HER2+ breast cancer who had pCR were shown to have improved long-term outcomes (i.e., improved progression-free and overall survival). Similarly, results from the APT trial showed that early-stage, node-negative HER2+ patients had a 3-year DFS of 98% after treatment with weekly TH followed by 1 year of trastuzumab monotherapy. An updated report showed that DFS remained favorable at 93% after 7 years.

As in patients with TNBC or other subtypes, the presence of residual disease or non-pCR confers worse prognosis. In patients with pCR (i.e., no residual disease in the breast and axilla surgical specimens), adjuvant systemic therapy is composed of trastuzumab ± pertuzumab (the infusion is given every 21 days for a total of 1 year, up to 18 cycles). For those with residual disease, a recent phase III clinical trial, the KATHERINE study published in 2019, demonstrated that patients who received emtansine or DM-1, conjugated with trastuzumab, known as T-DM1, in the adjuvant setting, had significantly improved overall and disease-free survival compared with those who received standard of care adjuvant trastuzumab. Results from the KATHERINE study, much like those from the CREATE-X study, have been practice-changing for women with early-stage HER2+ breast cancer.

IMMUNOTHERAPY IN BREAST CANCER

Immune checkpoint blockade (ICB) therapy has revolutionized the treatment of a wide variety of malignancies, including melanoma and lung cancer. The success of ICB therapy has changed the treatment paradigm in oncology over the past several years; however, the idea to use the immune system to attack "invading" tumor cells isn't completely new. More than 100 years ago, surgeon William Coley boldly tested a new strategy for shrinking tumors: injecting a combination of pathogens and toxins directly into malignant masses. Clinicians and researchers now recognize Coley's eponymous "toxin" as an early

form of immunotherapy, a treatment that enhances the immune system's ability to recognize, attack, and kill tumor cells. In 2013, *Science* designated cancer immunotherapy as the breakthrough of the year. In 2018, James P. Allison and Tasuku Honjo received the Nobel Prize in Physiology and Medicine for their discovery of immune checkpoint receptors CTLA-4 and PD-1, respectively. This well-deserved recognition confirmed the pivotal role of immunotherapy as an effective cancer treatment strategy.

The objective response rate of ICB therapy as a single agent in patients with breast cancer has been poor. In patients with metastatic breast cancer who had been heavily treated before enrolling in a Phase 1b study (JAVELIN NCT01772004), the objective response rate (ORR) of avelumab (antiprogrammed death-ligand 1 [PD-L1]) was only 5.2% (confidence interval [CI], 1.1–14.4) in TNBC, 2.8% (CI 0.3, 9.7) in the hormone receptor-positive (HR+) subtype, and 0% (CI 0, 13.2) in HER2+ breast cancer. The response rate to pembrolizumab (antiprogrammed cell death protein 1 [PD-1]) was slightly better in patients who had tumors that expressed PD-L1. In the KEYNOTE-028 study, the ORR of pembrolizumab in patients with advanced or metastatic HR+ cancer was 12% (CI 2.5–31.2). Similarly, in the KEYNOTE-012 study, the ORR of pembrolizumab in patients with metastatic PD-L1+ TNBC was 18.5% (CI 6.3–38.1).

When combined with chemotherapy, the clinical benefit in patients with advanced or metastatic TNBC was significantly improved compared with chemotherapy alone in a recently published study in 2018 entitled "Impassion130 study: Atezolizumab (anti-PDL1) and Nab-paclitaxel in advanced TNBC". In this study, patients with advanced or metastatic TNBC were randomized to receive atezolizumab + protein-bound paclitaxel (nab-paclitaxel) or nab-paclitaxel alone (n = 451 per group) between June 2015 and May 2017. In the intention-to-treat analysis, the median overall survival was 21.3 months in the group that received atezolizumab plus nab-paclitaxel and 17.6 months in the group that received placebo plus nab-paclitaxel (hazard ratio for death, 0.84; 95% CI, 0.69–1.02; $P = 0.08$). Among patients with PD-L1–positive tumors, the median overall survival was 25.0 months and 15.5 months in the two treatment groups, respectively (hazard ratio, 0.62; 95% CI, 0.45–0.86). These results paved the way for the approval of atezolizumab by the FDA in March 2019 to be used in combination with protein-bound paclitaxel, for adults with unresectable, locally advanced, or metastatic TNBC whose tumors express PD-L1 (defined as PD-L1 stained tumor-infiltrating immune cells of any intensity covering ≥1% of the tumor area), as determined by an FDA-approved test. The role of immunotherapy in women with early-stage TNBC is less clear and under investigation (KEYNOTE-522 clinical trial NCT03036488). Recently published findings from this study showed that the combination of pembrolizumab with a platinum-based chemotherapy regimen led to an increased rate of pCR in early-stage TNBC compared with chemotherapy treatment alone. The implication of this finding is significant; however, whether clinical practice will be changed remains to be determined.

In summary, the role of immunotherapy in breast cancer continues to be defined. There are several ongoing trials studying the use of immunotherapy as an adjunct for treatment in the different breast cancer subtypes, and more options are expected to be discovered in the coming years.

SUMMARY

The decision for neoadjuvant or adjuvant chemotherapy in the treatment of patients with nonmetastatic breast cancer is heavily influenced by the tumor receptor status. The ability of NAC to downstage disease may drive the decision for NAC, but results from several clinical trials have further confirmed the clinical benefit of NAC, as a stratification tool, in patients with early-stage HER2+ or TNBC. The presence of residual disease after NAC, or non-pCR, now serves as a biomarker to identify patients to receive additional adjuvant therapy such as capecitabine or T-DM1 for those with TNBC or HER2+ disease, respectively. As immunotherapy for breast cancer continues to evolve, the use of immunotherapy in the neoadjuvant and adjuvant setting may become standard of care for some patients in the future.

Treatment Trends in Locally Recurrent and Metastatic Breast Cancer

Joy Zhou Done, MD, Pathik Aravind, MD, and Mehran Habibi, MD

BACKGROUND AND EPIDEMIOLOGY

Globally, breast cancer is the most common cause of cancer in women. Although overall survival has improved significantly over the last several decades, up to 20% of breast cancer survivors will experience a recurrence during their lifetime. Over the past three decades, rates of locoregional recurrence have declined thanks to improvements in therapeutic interventions as well as widespread adoption of surveillance programs. It is worth mentioning that recurrence rates of ductal carcinoma in situ (DCIS), which do not represent invasive breast cancer, have also decreased due to improvements in detection, surgical technique to obtain negative margins, and use of adjuvant hormone therapy. Recurrences of true breast cancers, when they do occur, are most common within the first 3 to 5 years after resection. Recurrences can occur locally (in the ipsilateral breast or chest wall of the original tumor), regionally (in axillary, supraclavicular, or internal mammary nodal basins), or distally (in lungs, bones, brain, and other organs). Local recurrences are most common, but about 40% of patients with recurrent disease

have both local and regional nodal recurrence. Rarely is there an isolated regional nodal recurrence. The presence of metastatic foci defines stage IV of disease, where 5-year survival rates range between 11-42% depending on the specific phenotype of breast cancer, with a median survival of 18 to 24 months. Despite widespread screening efforts in developed countries, roughly 15-20% of patients will present with metastatic disease.

DEFINING A BREAST CANCER RECURRENCE

Biomarker testing of hormone receptor and HER2 receptor statis is used to differentiate between recurrent disease and a new, primary tumor. Generally, recurrent tumors carry the same receptor phenotype as the primary tumor. However, in a small study in the 1990s, authors hypothesized that a loss of hormone receptor expression in recurrent tumors may explain why the tumors did not respond to endocrine therapy and recurred.Likewise, tumors that were initially HER2- may present as HER2+ when they recur.

Recurrence risk varies by intrinsic breast cancer subtypes, which are often divided into luminal A (ER or PR+ and *HER2*−), luminal B (ER or PR+ and *HER2*+), and triple negative breast cancer (TNBC). Yu et al. (2019) retrospectively observed that luminal A tumors have low risk for distant metastatic disease that persists in the long term, and that luminal B tumors have higher initial risk of distant metastatic disease, which decreases after the first 5 years following treatment. TNBCs have high recurrence risk compared with receptor-positive breast cancers and generally are more locally aggressive with higher grade pathologic features. When TNBCs recur, they tend to do so earlier than their receptor-positive counterparts. Basal subtypes, which include TNBCs as well as EGFR+ and HER2-overexpressing breast cancers, have a higher risk of recurrence even after chemotherapy and radiation. Despite these generalizations, Groenendijk et al. (2019) demonstrated that when subjected to an 80-gene signature assay, 13% of luminal-type tumors were reclassified as basal-type, with behavior and response to therapy similar to that of TNBCs. A possible explanation is the inability of conventional immunohistochemistry or in-situ hybridization techniques to distinguish between functional and nonfunctional estrogen receptor variants in some patients.

Following treatment, younger patients have a higher risk of recurrence compared with older women. Those with *BRCA1/2* mutations also bear a higher risk of recurrence compared with their *BRCA1/2*-negative counterparts. Recurrence risk is largely determined by tumor biology but can also be influenced by initial treatment modality. Following lumpectomy, risk of recurrence is higher in those found to have positive margins, positive lymph nodes, as well as those of younger age at diagnosis. Lack of adjuvant radiation therapy also increases risk of recurrence following lumpectomy. For those who underwent breast conservation therapy (BCT) consisting of lumpectomy followed by radiation therapy, risk of recurrence is predominantly dictated by tumor biology (with larger, higher-grade, and hormone receptor-negative tumors independently contributing to higher risk of recurrence).

Historically, patients who underwent BCT were found to have higher rates of local recurrence compared with those who underwent mastectomy alone, although contemporary data suggest that improvements in modern breast cancer therapies have reduced the local recurrence risk following BCT. For patients who underwent mastectomy, the risk of recurrence increases with increasing number of positive axillary lymph nodes and larger tumor size. Recurrences tend to occur earlier and involve more regional nodes, which is associated with worse outcomes and a higher incidence of distal metastases.

GENOMIC ASSAYS USED TO STRATIFY RECURRENCE RISK

Gene expression profiling assays can use tumor features to prognosticate the risk of locoregional recurrence. The Oncotype Dx 21-Gene Breast Recurrence Score measures the expression of 21 genes in early-stage ER+/HER2− breast cancers to predict whether an individual will benefit significantly from adjuvant chemotherapy (in addition to hormonal therapy. TAILORx trial, a phase III clinical trial investigating the benefit of chemotherapy in hormone receptor-positive, HER2−, axillary node-negative breast cancers, used the Oncotype Dx Breast Recurrence Score to assign a cancer recurrence risk score between 0 and 100 to tumors based on the gene expression profile. Those with low-risk tumors (0–10) received hormone therapy only, whereas those with high-risk scores (greater or equal to 26) underwent treatment with hormone therapy and chemotherapy. Those with intermediate scores (between 11 and 25) were randomized to either hormone therapy alone or combination therapy, and the study found no difference in 5-year invasive disease-free survival between the two groups. 5-year overall survival was similar in both groups. Additionally, those with low-risk score (0–10) had very low recurrence rates with hormone therapy alone, and those with high-risk scores had high distance recurrence rates (13%) despite combination therapy. The findings of the trial thus suggest that chemotherapy may be avoided in patients with recurrence scores between 0 and 10, patients older than age 50 with a recurrence score between 11 and 25, and patients under age 50 with a recurrence score between 11 and 15.

Similarly, MammaPrint uses a 70-gene assay to assess risk of recurrence and is validated for early-stage tumors under 5 cm in size with 0 to 3 positive lymph nodes. MammaPrint is used in decisions regarding withholding chemotherapy. The MINDACT trial sought to provide prospective evidence for using a genomic assay in addition to clinical risk assessment to identify patients who would benefit from adjuvant chemotherapy. The study found that for patients with high clinical risk but low genomic risk based on the MammaPrint assay, the use of adjuvant chemotherapy increased 5-year distant metastasis-free survival by only 1.5%, thus concluding that approximately 46% of patients with breast cancer who are clinically high risk may be able to avoid chemotherapy based on a low genomic risk as determined by the MammaPrint assay. Further analysis at a median of 8.7 years of follow-up later revealed a small distant metastasis-free survival benefit (5%) among the subset of women under age 50 who had received chemotherapy and confirmed the lack of a clinically substantial benefit for women over age 50. The effect modification of age is thought to be related to the ability ovarian suppression in those who receive chemotherapy.

EVALUATION AND MANAGEMENT OF RECURRENT DISEASE IN BREAST CANCER

The presence of symptoms such as a palpable lump, pain, or skin changes in a patient with a history of breast cancer should prompt further workup for a recurrence of disease, beginning with a focused history and physical exam that includes inspection and palpation of the breast(s), chest wall, and regional nodal basins. Approximately half of ipsilateral breast cancer recurrences have detectable findings on clinical exam. Palpable masses can be evaluated with ultrasound, diagnostic mammogram, and MRI. Following the history and clinical exam, the evaluation of a suspected breast cancer recurrence begins with staging imaging with CT scans of the chest, abdomen, and pelvis, and bone scans to identify bony metastases. MRI of the breasts is highly sensitive in detecting breast cancer and have a high negative predictive value and thus is most useful in those with a high pretest probability of breast cancer. In practice, this commonly translates into those with at least a 20% lifetime risk of developing a second primary breast cancer based on risk models that take family history heavily into account. Otherwise, breast MRI is not routinely used to screen for asymptomatic recurrence. Brain MRI with contrast is obtained if there is concern for central nervous system involvement, and spine MRI with contrast can evaluate complaints of back pain or concerns for spinal cord involvement. PET CT is most useful in situations

when standard staging MRI or CT are equivocal and can also be helpful in identifying regional lymph node recurrence and occult distant metastases. Suspicious lesions can be biopsied, and once a recurrence has been diagnosed, germline and somatic genetic testing is performed to identify targets for therapy. A treatment plan is formulated, and psychosocial assessment and support should be provided.

Generally, ipsilateral recurrences, when operable, are treated with repeat ("salvage") mastectomy. The challenges of performing salvage mastectomy after prior surgery and/or local radiation include compromised blood supply to the skin flap, the loss of typical tissue planes between subcutaneous fat and breast tissue, and the need for negative margins that may necessitate creation of large skin defects that cannot be closed primarily. In these situations, reconstruction may necessitate tissue flaps or a staged closure using an allograft and negative pressure wound therapy, followed by a skin graft. A history of prior radiation increases the risk of skin necrosis and poor wound healing. In the elderly or those with prohibitively high surgical risk, repeat lumpectomy with or without additional radiation therapy can be considered. The majority of ipsilateral recurrences present as "first-failure" events and usually are localized and resectable. They may present on routine surveillance mammogram, MRI, or on physical exam as skin changes, palpable masses, lymphadenopathy, or localized discomfort, usually within 5 cm of the original tumor bed.

The treatment approach of ipsilateral breast cancer recurrences depends on prior treatment history and the location of recurrence. The National Comprehensive Cancer Network (NCCN) classifies ipsilateral recurrences into three categories based on prior therapy: (1) recurrences that occur after (1) BCT, (2) after mastectomy and axillary lymph node dissection (ALND) only, and (3) after mastectomy and ALND and Radiation Therapy (RT). For patients who initially underwent BCT, a total mastectomy is recommended, with ALND if not previously performed at the index cancer operation. Repeat BCT with radiation therapy is not the standard of care. There is some evidence, however, that for recurrences in tumors that were initially treated with lumpectomy without radiation therapy, a completion mastectomy offers no survival benefit over BCT (lumpectomy with radiation therapy). If a mastectomy and ALND were initially performed, resection of the local recurrence and radiation therapy to the chest wall and regional LN basin is recommended. For those who underwent mastectomy, ALND, and prior RT, surgical resection of the recurrence is recommended when technically feasible. The CALOR trial, a prospective randomized study that used adjuvant chemotherapy after surgical excision of recurrent breast cancer, showed survival benefit and reduced risk of second treatment failure for patients with ER– recurrent tumors and no benefit in those with ER+ tumors (who received adjuvant endocrine therapy). When a tumor is diagnosed distant to the initial tumor, or when it presents more than 5 years after the initial tumor was treated, or when it is found to have discordant receptors, a new primary is suspected (rather than a recurrence of the initial tumor). In these cases, a sentinel lymph node biopsy (SLNB) can be attempted if an ALND had not been performed at the initial surgery. Lymphoscintigraphy can be used to aid in operative planning given anatomical changes in lymphatic drainage. If a SLNB cannot be performed, consideration should be given to performing an ALND.

RT is discouraged for those who previously received RT given the cumulative risk of tissue toxicity with repeated course of radiation.

More aggressive recurrences may invade underlying nerve, bone, or muscular structures, which can render them unresectable. Systemic therapy can be used with the goal of converting a nonresectable tumor into a resectable one.

AXILLARY LYMPH NODE DISSECTION IN RECURRENT DISEASE

Axillary lymph node status is one of the most important prognostic factors in breast cancer; traditionally, surgical management of breast cancer involves resection of the primary tumor followed by ALND. Over the years, SLNB has been demonstrated to be sufficient in ruling out axillary lymph node metastases, sparing patients from the morbidity associated with ALND. SLNB has now replaced ALND for the staging of clinically node-negative breast cancer patients, and routine ALND is not performed as the initial staging procedure in clinically node-negative patients. In patients who have positive axillary nodes by biopsy, ALND or SLNB are options depending on the planned surgery and extent of nodal disease. Those with 1 or 2 positive sentinel lymph nodes who are willing to undergo standard whole-breast irradiation and standard adjuvant systemic treatment following BCT may avoid ALND, based on evidence from the Z0011 and IBCSG 23-01 trials demonstrating similar disease-free survival, overall survival, and locoregional recurrence rates between ALND and SLNB-only treatment groups.

Nodal recurrences generally occur in the axillary nodes among patients who underwent a SLN resection; they may also recur in the contralateral axilla or in the interpectoral, internal mammary, and infraclavicular nodal basins due to altered lymphatic drainage following SLNB or axillary dissection. Repeat SLNB in patients with ipsilateral breast tumor recurrence (IBTR) after BCS with SLNB has been shown to be accurate with a false negative rate of less than 10% (Chang, 2020). If a prior ALND was performed at the index surgery, then surgery to resect the recurrent tumor is recommend and no further axillary dissection is warranted. Axillary nodal recurrences and chest wall recurrences are occasionally also amenable to repeat surgical resection. Adjuvant radiation is often utilized, and systemic therapy is employed based on the molecular characteristics of the tumor. Isolated axillary recurrence is rare, occurring in an estimated 1% to 3% of cases within the first 3 or 4 years after treatment (with a median interval of 2.2 years). The 5-year overall survival rate following isolated axillary LN recurrence is about 50%, with a mean survival of approximately 5 years. There are extremely limited data on the optimal management strategy in these patients, and options include completion ALND, isolated axillary lymph node excision, radiation therapy to the regional nodal basin, and systemic therapy. In a Canadian retrospective study examining factors affecting survival after isolated axillary LN recurrence (that is, no other local recurrence, regional recurrence, distant metastasis, or contralateral new breast primary), there was no difference in survival when comparing isolated axillary LN excision versus completion ALND. When comparing surgery alone versus radiation therapy alone versus both surgery and radiation, those treated with both surgery and radiation saw an overall survival benefit. Despite treatment, patients with isolated axillary recurrence had nearly a 50% incidence of distant metastases on subsequent follow-up. Of note, there is no prospective trial to date comparing a completion ALND with a targeted lymphadenectomy. Based on traditional treatment paradigms, the current standard of care is to perform a full ALND. In the setting of modern systemic chemotherapy, however, prospective studies should aim to investigate whether full ALND provides additional survival benefit beyond a targeted lymphadenectomy in the setting of an isolated axillary recurrence.

Current NCCN guidelines recommend surgical resection and RT when feasible. For recurrences in the supraclavicular or internal mammary nodal basins, RT is recommended when possible. When recurrences are not technically amenable to resection or when recurrence presents in the form of stage IV disease, the mainstays of treatment involve endocrine therapy or systemic treatment tailored to hormone and HER2 receptor status.

ROLE OF LOCOREGIONAL THERAPY IN METASTATIC DISEASE

IBTR predicts high likelihood of distant metastatic spread, and therefore systemic therapy remains the mainstay of care. Systemic therapy and palliative care have been the mainstay of therapy for stage IV disease, with locoregional therapy (LRT) generally offered

for palliative intent for symptom control. LRT refers to surgery for the primary tumor, local radiation therapy, or a combination of the two modalities. Hormone receptor–positive tumors also receive endocrine therapy, and HER2+ tumors also receive trastuzumab. The goal of these systemic therapies is to make inoperable tumors operable. A PET CT is obtained to assess for the presence of synchronous metastases, and a repeat scan obtained after a full course of adjuvant systemic therapy can help guide the appropriateness of reoperation. Palliative surgery is an option for those with persistent residual disease to address wound and bleeding complications secondary to locally advanced/destructive tumors.

The traditional belief is that once a cancer metastasizes, there is no therapeutic survival benefit to surgical resection of the primary tumor. However, there is evidence for survival benefit for patients who underwent resection of their primary tumor in stage IV disease. In particular, patients with early metastatic disease limited to bone, *HER*2+ disease, and a positive response to systemic therapy with a resectable primary tumor may benefit from LRT. The proposed mechanisms include (1) reduction of the tumor burden and propagation of clonal heterogeneity (implicated in development of resistance to therapy), (2) disruption of tumor cell movement between the primary tumor and metastatic sites, and (3) elimination of cancer stem cells (CSCs) and their tumor-promoting activities. Although a review of CSCs is beyond the scope of this chapter, CSCs are a subgroup of cells thought to be localized in the primary tumor that differentiate, self-renew, and maintain the tumor microenvironment, thus playing an important role in disease propagation. By depleting the CSC pool, resection of the primary tumor may disrupt the process of metastatic spread and remove a source for possible new metastases.

Animal models have also suggested that removal of the primary tumor reverses the tumor-induced immunosuppression that normally promotes metastatic spread. This effect is seen in early stages of metastatic disease, with little to no positive impact on survival in late stages. That there is a survival benefit for LRT even in metastatic disease suggests that surgical intervention should be considered in early metastatic disease. Khan et al. (2002) reported that most patients had a total mastectomy, but there was no survival benefit compared with patients who underwent partial mastectomy with clear margins achieved. Both partial and total mastectomy had improved survival compared with no surgery, and neither tumor size nor extent of nodal involvement was predictive of survival. Kommalapati et al. (2018) similarly demonstrated no survival difference between breast conserving therapy (partial mastectomy followed by radiation therapy) and total mastectomy in metastatic disease; however, the study also demonstrated worse survival in patients with severe/aggressive disease. Similarly, Wang et al. (2018, 2019) noted worse survival in stage IV patients with liver/lung metastases who underwent surgical resection of the primary tumor.

Several retrospective studies have aimed to identify which patients with metastatic disease benefit from LRT. Arciero et al. (2018) reported that among those who underwent surgical LRT, increased survival was seen in those who had hormone receptor-positive tumors, those who underwent radiation therapy, and those who had clear margins. The greatest increase in survival was seen in those who underwent both surgery and systemic therapy, but survival benefit was seen in those who underwent surgery regardless of systemic therapy. Lane et al. (2017) similarly noted the greatest survival benefit in ER+ patients who underwent surgery after systemic therapy to reduce the burden of disease, and surgery alone compared with systemic therapy alone was associated with improved survival. Importantly, the patients who underwent surgery before systemic therapy had worse survival, despite smaller primary tumor size and lesser degrees of lymph node involvement. Wu et al. (2017) demonstrated that well-differentiated, small tumors with low nodal burden had survival benefit across all breast cancer subtypes (regardless of receptor status). Thomas et al. (2016) found that tumors <2 cm had an additional survival improvement of 11 months after surgical resection of the primary tumor. Tan et al. (2016) found the greatest survival benefit in those who underwent joint primary and metastatic resection; they also noted that in hormone receptor-negative patients, primary and metastatic resection had no additional benefit compared with primary resection alone. Pons-Tostivint et al. (2019) showed that LRT conferred a survival benefit in those who had more than 1 year of controlled disease on their systemic regimens, even when there were more than 2 metastatic sites present. The group found no survival benefit of LRT for TNBC. Co et al. (2019) identified ER+ status as a positive prognostic factor.

Despite numerous studies demonstrating a survival benefit of surgical resection, the evidence is limited by the dearth of high-quality prospective data. In the largest meta-analysis on the topic to date, LRT in stage IV disease was reported to reduce mortality by 31.8%, and surgery specifically was reported to reduce mortality by 36.2%. However, when only the prospective studies were included in the meta-analysis, the reported mortality benefit was only 19.2% in LRT compared with no LRT. Of these, Badwe (2015) demonstrated in a randomized control trial that LRT conferred no survival benefit and increased distant metastases, possibly due to tumor shedding/seeding during surgery. Fitzal (2007) reported significant worse survival following surgery for luminal A subtypes. In contrast, the third study by Soran (2018) reported a significant survival benefit for the LRT arm in patients with HR+, HER2− tumors with solitary bone metastases. Most recently, Khan (2020) demonstrated in a randomized control trial that there was no difference in survival in women with stage IV disease who underwent LRT. It also found no difference in quality-of-life measures in the LRT arm. Importantly, Cady (2008) performed a case-matched analysis of LRT in stage IV breast cancer and reported that case-selection bias accounted for all, if not most, of the apparent survival benefit in patients receiving LRT. Current NCCN guidelines cautiously recommend consideration of locoregional surgery in certain subsets of patients with stage IV breast cancer.

Preliminary results from a handful of more recent prospective studies are promising. Hotton (2021) comparing patients with stage IV breast cancer found that surgery within 12 months of diagnosis was associated with a longer overall survival and progression-free survival. Of note, patients undergoing surgery had fewer distant metastatic sites. Yu (2021) similarly demonstrated longer progression-free survival for those who underwent locoregional surgery, but a survival benefit only in patients whose metastases were limited to bone. Several other prospective trials evaluating the benefit of LRT are actively recruiting, with estimated study completion dates in the next 5 years.

The challenge remains to identify which subset of patients with stage IV disease benefit from LRT. Based on current evidence, LRT appears to provide benefit in those with hormone receptor positivity, younger age, and more indolent disease (as defined by both longer periods of progression-free survival on systemic therapy as well as fewer distant metastatic sites). Other questions include the optimal sequence and timing of LRT, as well as effects of delay of systemic therapy due to complications secondary to LRT. Additional investigation is needed to identify more specific subsets of patients who will likely benefit from LRT based on their clinicopathologic characteristics.

FUTURE QUESTIONS TO ANSWER

Ongoing prospective trials aim to further characterize the role for adjuvant treatments in recurrent and metastatic disease. The ongoing phase III clinical trial (NSABP B51/RTOG 1304) is examining the role of regional nodal radiation therapy after mastectomy for patients who achieve a pathologic complete response to neoadjuvant chemotherapy. The Alliance A001202 trial is a randomized clinical phase III trial comparing ALND to axillary radiation in those who

have positive sentinel lymph nodes after neoadjuvant chemotherapy. Early results from the ongoing OlympiA trial have demonstrated survival benefit of adjuvant treatment with PARP inhibitor olaparib after completion of multimodal therapy with surgery, radiation therapy, and chemotherapy in high-risk, *HER2*–, and *BRCA1/2*-mutated breast cancers.

RECONSTRUCTION IN ADVANCED AND RECURRENT DISEASE

For patients with localized breast cancer, breast reconstruction is a commonly offered and often preferred pathway of care. However, with regard to metastatic breast cancer, breast reconstruction as an option is not always offered to the patient.

The literature in the past has been split regarding reconstruction in the metastatic population. However, more recent literature has suggested increasing rates of reconstruction, from 5.2% in 2004 to 14.3% in 2013. Reconstruction rates were lower in patients with higher tumor (T) and nodal (N) stages, but this may have been due to lower rates of mastectomy among these patients. Some of the well-described barriers to reconstruction include the type of cancer center referred to, insurance coverage, and area of residence. Type and timing of reconstruction can be variable in patients with advanced disease.

The type of mastectomy is also pertinent to breast reconstruction. There has been no clear evidence that nipple-sparing mastectomies (NSM) are associated with a higher risk of locoregional recurrence compared with skin-sparing mastectomy (SSM), even in advanced disease. From a reconstruction standpoint, NSM is associated with significantly better aesthetic outcomes. Thus, in the absence of any clear contraindications, NSM may be considered in suitable patients.

In the case of recurrent breast cancer, the approach to reconstruction varies significantly based on recurrent tumor size and the extent of resection. In the most straightforward case, postlumpectomy recurrence may be treated with mastectomy and reconstruction. If the patient previously underwent radiation therapy, then autologous breast reconstruction is the preferred reconstructive path due to significantly increased risk of capsular contracture with implant-based reconstruction. In advanced cases, a complex staged

reconstruction may require initial skin grafting, followed by negative pressure wound therapy before final coverage with skin graft. Figures 1–8 depict a case of advanced recurrence involving skin that required such an approach. Another group of patients who may require salvage mastectomy are patients who report recurrence after breast reconstruction. Last but not least, little is known about breast reconstruction and quality of life, specifically in the population of patients with metastatic or advanced recurrent breast cancer. A greater understanding of quality of life considerations in this patient population can help guide patient-centered reconstructive plans.

Management of Male Breast Cancer

Austin D. Williams, MD, MSEd, Kaitlyn Kennard, MD, and Ned Z. Carp, MD

INTRODUCTION

Accounting for only about 1% of all breast cancers diagnosed in the United States, male breast cancer (MBC) is a relatively rare disease. Compared with the 1:8 lifetime risk for females, males have an approximately 1:1000 lifetime risk of developing breast cancer, though evidence suggests that, in recent decades, the incidence of MBC may be rising. While the United States documented an estimated 1970 new cases in 2010, there were 2620 new diagnoses in 2020.

Because there are no breast cancer screening algorithms for men, elucidating the risk factors for MBC has been a focus for clinical researchers attempting to identify men at higher risk for developing breast cancer. Advanced age, increased estrogen exposure (e.g., obesity, cirrhosis, Klinefelter syndrome), and history of radiation exposure all increase the risk of breast cancer. Importantly, about one in five men diagnosed with breast cancer has a family history of the disease, and, while most cases may be sporadic, the recent increase in genetic testing has identified several gene mutations linked to increased risk for MBC. An estimated 4% to 40% of MBC are associated with inherited mutations in the *BRCA1* or *BRCA2* genes, which are important in DNA repair and recombination. Specifically, male *BRCA1* carriers have a 1:100 chance of developing breast cancer, while those with *BRCA2* mutations have a 7:100 chance, corresponding to a relative risk of 12 and 42 times that of men with wild type genes, respectively. Mutations in *PALB2*, a gene coding for a chaperone protein in the BRCA protein complex, are encountered in approximately 1% of women with breast cancer but in 16% of men. Mutations in *CHEK2*, which codes for a cell cycle checkpoint peptide, have also recently been linked to an increased risk of MBC, but more work is needed to determine its true clinical implications.

The rarity of MBC has limited the development of comprehensive diagnostic and treatment algorithms specific to men, so clinicians extrapolate from randomized controlled trials performed in women. Several recent reviews of the protocols for breast cancer clinical trials have demonstrated that men have actively been excluded, though there appears to be an increased interest in recruiting men to ascertain the nuances in the clinicopathology and treatment of MBC. There is, however, evidence that MBC may be a distinct entity. Approximately 90% of MBC are estrogen receptor (ER) and progesterone receptor (PR) positive and HER2 negative, compared with approximately 70% of female breast cancers. Given the anatomic differences between the male and female breast, histologically MBC are much more likely to be ductal (~95%) rather than lobular in origin. Broad genomic analyses of MBC have revealed a different distribution of somatic mutations when compared with breast cancers in women, including amplification of the gene *EMSY*, a transcription repressor that interacts with *BRCA2*, which is found in 13% of female breast cancers but 35% of MBC. In contrast, other studies have demonstrated that the distribution of the recurrence score derived from the validated 21-gene expression assay is similar between men and women, bringing the clinical impact of the mutational analyses into question. Additional large cohort studies have demonstrated that, unlike in women, tumor grade is not associated with breast cancer outcomes in men, further strengthening the argument that MBC may have different tumor biology.

Because MBC is typically not screen-detected, men tend to have higher stage cancers at presentation than their female counterparts. In an analysis of the National Cancer Database (NCDB), 18.2% of men had clinical stage III or IV disease at the time of diagnosis compared with 10.2% of women (Table 1). These differences at presentation extend into long-term disparities in which 5-year survival for men was 77.6% and 86.4% for women, which persist even when analyzed stage-for-stage.

DIAGNOSIS

No guidelines for breast cancer screening currently exist, though recent work suggests a potential benefit of the development of a screening protocol for men with high risk. Therefore, the diagnosis of MBC is typically made after the self-palpation of a painless, unilateral, subareolar breast mass. Because 40% of MBCs present stage III or IV, signs of advanced disease, such as invasion into the skin or muscle and axillary adenopathy, may also prompt evaluation (Fig. 1).

The differential diagnosis of a breast mass in a male includes gynecomastia, which typically presents as bilateral breast enlargement with or without a mass. The masses that present in patients with gynecomastia tend to be firm and mobile, are more likely to be tender than those related to a malignancy, and may also be transient in nature. Aside from men who have a clear physiologic or pharmacologic etiology for their gynecomastia, malignancy cannot be ruled out with examination alone.

The workup of a breast mass in a male patient is similar to the workup in women and includes mammogram and ultrasound. If the mass appears benign, biopsy can be deferred, and the patient can be instructed to perform serial self-examinations, as the majority of the masses will resolve over time. Core needle biopsy is indicated if there are any concerning findings on imaging or in situations of high clinical suspicion for malignancy, with a localizing clip placed at the biopsy site. Pathologic analysis of the specimen should be compared with the imaging findings for concordance, and if radiographic-pathologic discordance is present, the patient should undergo excisional biopsy. ER, PR, and human epidermal growth factor 2 (HER2) assays should be performed on all biopsy specimens to aid in directed therapy.

Ultrasound of the axilla is indicated if any lymphadenopathy is present on physical examination, and fine needle or core biopsy should be performed of any abnormal lymph nodes. Institutional protocols vary based on whether a localizing clip should be placed in the biopsied lymph node for future targeted axillary dissection.

Finally, patients who present with locally advanced disease require a metastatic workup with either a CT scan of the chest,

TREATMENT

Preoperative Considerations

Discussion of MBC patients at a multidisciplinary tumor board and preoperative referral to medical oncology and radiation oncology provide patients the opportunity to review their treatment options and formulate a comprehensive plan. Referral to a plastic and reconstructive surgeon should also be considered to discuss options for simultaneous reconstruction during the index operation.

All MBC patients should be referred for genetic counseling and testing. Although not necessary to be completed preoperatively, a discussion should be held with the patient about whether the results of genetic testing will impact their decision making as related to the operative approach to treating their cancer. For example, in an analysis of the National Surgical Quality Improvement Project, 6.7% of MBC patients opted for contralateral prophylactic mastectomy, and, as in women, these decisions are likely impacted by the presence of a high-risk genetic mutation.

Although surgery is the mainstay of treatment for MBC, neoadjuvant chemotherapy (NAC), anti-HER2 therapy, or antihormonal therapy may be considered in those who present with advanced tumor or nodal stage. As in women, the goal of neoadjuvant therapy is to downstage the primary breast tumor or axilla to offer the patient breast conservation or sentinel lymphadenectomy (SLNB). The ultimate goal of NAC would be a complete pathologic response as these patients have the best oncologic outcome; however, this can only be achieved between 20% and 65% of the time depending on the tumor type and neoadjuvant regimen. There are very few data related to the use of neoadjuvant therapy for MBC in the literature, and guidelines for administration are extrapolated from those in female patients. Fewer male patients may benefit from neoadjuvant therapy given the smaller proportion of patients for whom breast conservation is an option, though recent data from the NCDB do demonstrate lower mastectomy rates for males with locally advanced cancers after NAC. One limitation of neoadjuvant therapy for MBC is that most tumors are hormone receptor positive, which is associated with the lowest pathologic complete response rate (15%–20%) when compared with other subtypes.

Operative Management

Mastectomy

Historically, men with breast cancer have undergone mastectomy more often than breast conserving surgery (BCS); however, breast conservation is increasingly being performed in men, and evolving data indicate safety and feasibility. Decisions about breast conservation versus mastectomy in men should be made according to similar criteria as for women.

The mastectomy is typically performed through a transversely oriented elliptical incision encompassing the nipple and areola. The incision width is dependent on the volume of breast tissue in the individual with a smaller incision used in patients with smaller breast mass. Skin flaps are raised sharply or with electrocautery and are typically thicker in men than women given the general distribution of breast parenchyma. In obese patients, flaps should become progressively thicker laterally to avoid a sharp "drop-off" deformity at the lateral margins. As in females, the breast is dissected off the underlying pectoralis major with removal of the pectoralis fascia. If muscle invasion of the tumor is identified intraoperatively, this adherent portion should be removed from the pectoralis muscle. Resection of the pectoralis major (radical mastectomy) is rarely needed in current treatment paradigms, but postmastectomy radiation therapy is indicated for all patients with muscle invasion. Although uncommonly used, reconstruction options should be made available to men undergoing mastectomy since cosmetic outcomes can be improved with the use of multiple strategies, including fat grafting and implants (Fig. 2).

Breast Conservation

Due to its low incidence, the safety and feasibility of BCS in MBC has been difficult to evaluate in a prospective manner, but reduced morbidity has been documented for men undergoing BCS when compared with mastectomy. As in female breast cancer, BCS should be avoided if the tumor is close to the nipple or encompassing a significant volume of the existing male breast as a cosmetic outcome may not be feasible. In contemporary studies, the rates of BCS are lower in men than women given the more commonly unfavorable tumor-to-breast ratio, but local recurrence and disease-free survival among those undergoing BCS is similar. Despite being an integral part of breast conservation, adjuvant radiation has been historically underused in MBC due to concerns regarding the use of tangential-field radiotherapy to the smaller male breast and the proximity of chest wall, heart, and lung. These concerns are negligible with the contemporary delivery of CT-guided treatment planning; therefore, adjuvant radiation should be offered to men undergoing partial mastectomy according to current breast conservation guidelines.

Axillary Management

Management of the axilla in MBC is comparable to that of female breast cancer. As with women, separate incisions for the breast and axilla often provide improved cosmesis in those undergoing mastectomy.

SLNB is appropriate for all operable invasive MBC with clinically negative axillary nodes (cT1-3N0). Rates of SLNB in men have historically lagged behind those for women, with only 18% of men in one cohort undergoing SLNB between 1990 and 2010, but rates have been increasing. There is controversy over the application of the results of the ACOSOG Z0011 trial to men with clinically

FIG. 2 Postoperative outcomes in men with breast cancer after breast conserving surgery **(A)**, modified radical mastectomy **(B)**, and modified radical mastectomy with reconstruction with fat grafting **(C)**.

node-negative disease. Further investigation is needed to clarify whether men with one or two positive sentinel lymph nodes benefit from completion axillary lymph node dissection (ALND), but patients with three or more positive sentinel nodes should undergo completion ALND.

For patients with clinically node-positive disease, a preoperative biopsy of concerning nodes can be performed, and if any nodes are found to contain metastatic carcinoma, an ALND is recommended. If carcinoma cannot be confirmed, we recommend a SLNB with patient understanding that a completion ALND may be warranted based on final pathology.

For patients who underwent NAC for locally advanced disease, we recommend axillary staging before initiation of chemotherapy with fine-needle or core biopsy rather than SLNB. Up to 40% of patients with positive axillary nodes will have a complete pathologic response in the nodal basin, though this varies by breast cancer subtype. Subsequent SLNB is then performed at the time of definitive surgery with the goal of obtaining three or more lymph nodes for evaluation. Targeted lymphadenectomy is used at some institutions if the positive lymph node was marked before neoadjuvant therapy. Patients with a positive sentinel node or those in whom three sentinel nodes cannot be identified require a completion ALND.

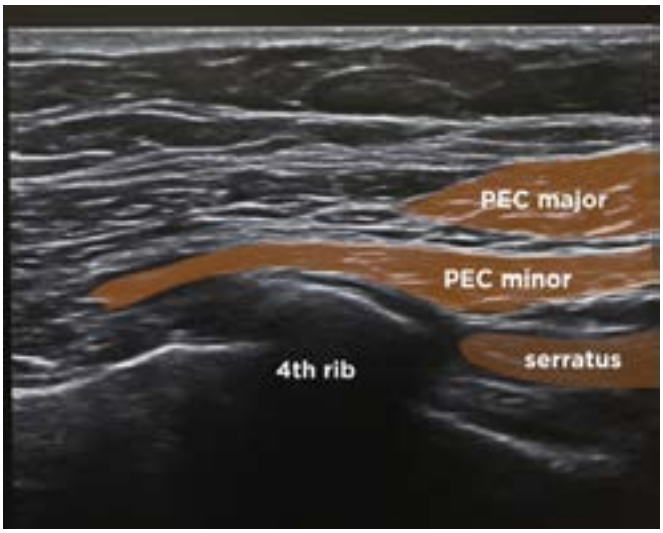

FIG. 3 Sonographic view of the muscle bellies of pectoralis major, pectoralis minor, and serratus anterior used to perform a PECS II block.

Analgesia

Pain control in the perioperative period is essential for patient satisfaction and improved recovery. A perioperative enhanced recovery after surgery protocol is recommended, several protocols for which exist. In most protocols, patients receive preoperative oral analgesics and pain modulators such as acetaminophen, celecoxib, and gabapentin. Before incision, a pectoralis II (PECSII) block can be used

as a regional block to mitigate the need for opioids in both BCS and mastectomy. To perform this block, a total of 20 cc of 0.25% bupivacaine is infiltrated between the muscle bellies of pectoralis major and pectoralis minor and between the pectoralis minor and serratus anterior under ultrasound guidance (Fig. 3).

Postoperative Considerations

Immediate postoperative care includes pain control, management of any drains, and routine wound care. Adjuvant radiation therapy and chemotherapy typically begin several weeks postoperatively for those in whom it is indicated.

The development of a contralateral breast cancer is much rarer among MBC survivors than for females, and there are no data to support the use of postoperative mammographic screening in men. However, MBC survivors should undergo lifelong routine follow-up with history and physical examination aimed at the early detection of local or distant recurrence. Survivorship programs specifically for men are sponsored by several national organizations and should be made available given the excellent prognosis for men who are diagnosed with early-stage disease.

A Surgeon's Practical Guide to Breast Imaging

Michael D. Grant, MD, and Ronald C. Jones, MD

This chapter serves as a surgeon's guide for the appropriate use of imaging modalities in the evaluation and management of a potential breast disorder. Due to widespread screening, more than half of breast lesions that require assessment are nonpalpable. Therefore, it is important for the clinician to be aware of the available tools to further diagnose and manage specific breast abnormalities. Likewise, the interaction of the surgeon with the radiologist is of paramount importance in optimally managing patients with breast disease. Selecting the appropriate application of these various imaging modalities is beneficial in efficiently and economically obtaining a diagnosis.

For the purposes of this review, mammography refers to either 2D digital or 3D digital breast tomosynthesis (DBT) methods unless otherwise specified. Sonography is performed with specialized high-resolution handheld equipment designed specifically for breast imaging. MRI is accomplished with IV contrast and specialized breast coils.

THE ABNORMAL SCREENING MAMMOGRAM

A screening mammogram may identify an abnormality that requires further diagnostic evaluation. The radiologist will then give a specific recommendation for a diagnostic workup requiring an order from a physician. Breast calcifications are common abnormalities, and although most are benign, they can also be one of the earliest signs of a developing cancer. Magnification views are necessary to further define the characteristics based on size (macro vs. micro), shape (round, punctate, irregular, rod-shaped, pleomorphic), distribution (focal, scattered, clustered, linear, segmental), and behavior (stable, new, developing) and serve as the basis to judge whether a biopsy will be required. Suspicious microcalcifications are consistently irregular, represent a change in comparison to prior studies, and occur in a clustered or ductal distribution. The next step is a percutaneous needle biopsy using a stereotactic-directed, vacuum-assisted device; if the target is not easily identified using this approach, localized excision may be recommended as an alternative procedure.

Screening mammograms may also reveal abnormal densities that are classified as masses, asymmetries, or architectural distortions. A mass is a three-dimensional space-occupying lesion (seen in two views) and categorized as round, oval, or irregular in shape. Further evaluation by sonogram is then used as a diagnostic study to determine if this is solid, cystic, or complex. A mammographic asymmetry is a density that is visualized in one or two views and is usually caused by superimposition of normal breast tissue. This is clarified by special spot compression or rolled views and, if persistent, may lead to a biopsy recommendation. Architectural distortions are caused by tethering or indenting of breast parenchyma. The etiologies can be benign or malignant, but additional evaluation by special mammographic views, tomosynthesis, sonography, or MRI is required for further characterization. For all of the previously discussed abnormalities, BIRADS category of 2 or 3 will need follow-up imaging in 6 to 12 months, whereas BIRADS category 4 or 5 requires a biopsy.

PALPABLE MASS

A palpable mass is a frequent presenting complaint, either self-discovered or found by a clinician during routine examination. In addition to a thorough physical examination, a diagnostic mammogram (age >30) and sonogram should be obtained. Due to limitations with dense breast tissue, a mammogram may not be necessary if the patient is <30 unless there are adverse features on sonography. If the mass is found to be purely cystic and asymptomatic, observation is appropriate and many will resolve spontaneously; if the patient is symptomatic (pain, concern), percutaneous aspiration is recommended. A complex lesion also requires aspiration under sonographic guidance to rule out the possibility of an intracystic mass that, if present, will need to be biopsied. A solid mass necessitates a

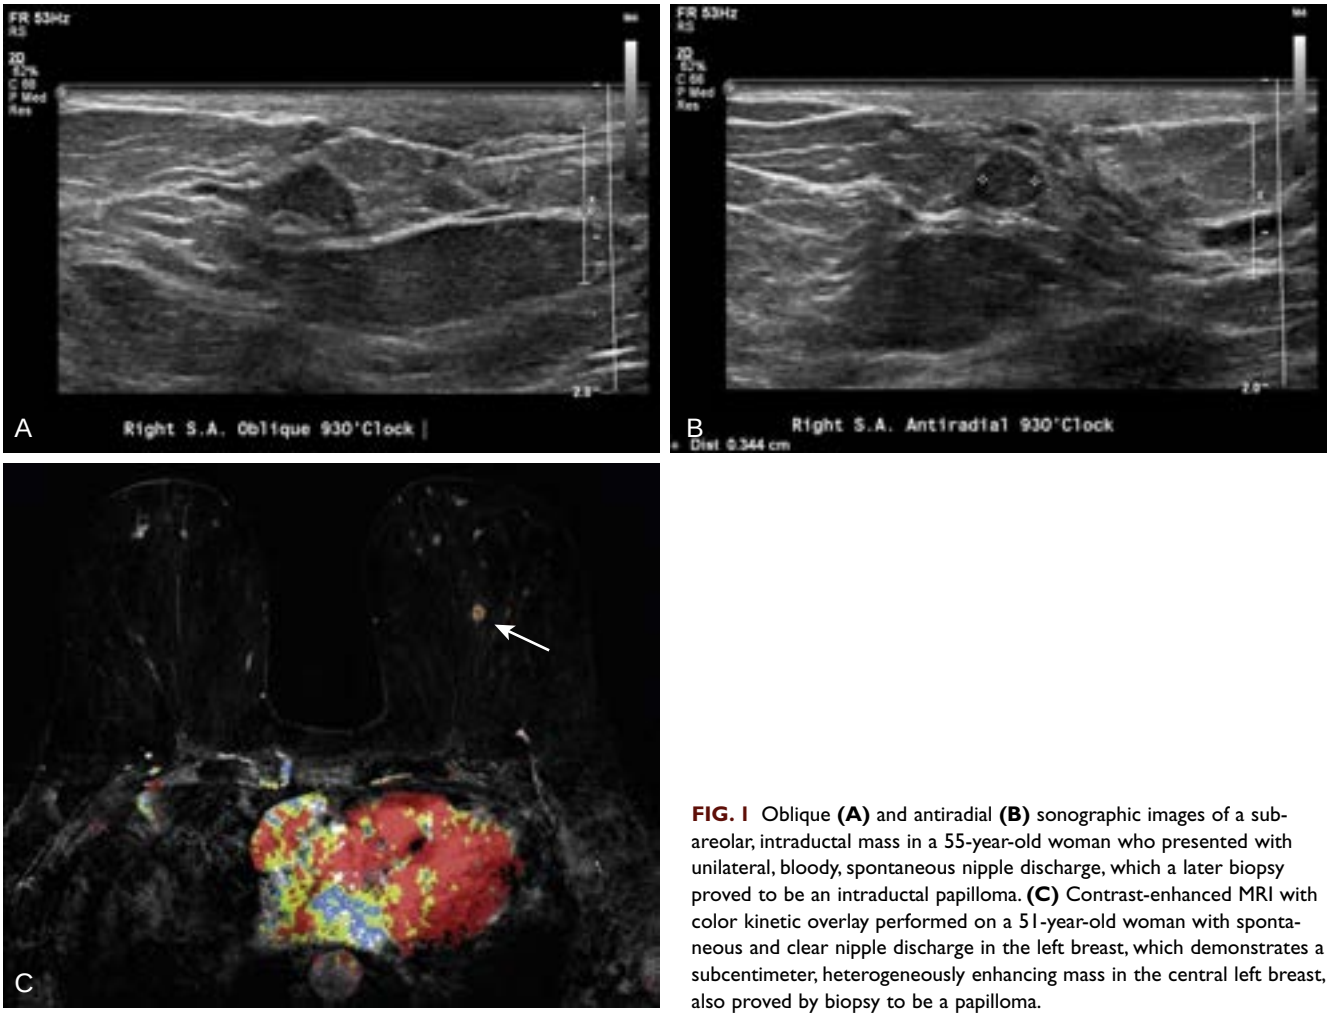

FIG. 1 Oblique **(A)** and antiradial **(B)** sonographic images of a subareolar, intraductal mass in a 55-year-old woman who presented with unilateral, bloody, spontaneous nipple discharge, which a later biopsy proved to be an intraductal papilloma. **(C)** Contrast-enhanced MRI with color kinetic overlay performed on a 51-year-old woman with spontaneous and clear nipple discharge in the left breast, which demonstrates a subcentimeter, heterogeneously enhancing mass in the central left breast, also proved by biopsy to be a papilloma.

tissue diagnosis either by fine-needle aspiration (FNA) or preferably core biopsy. If a biopsy is performed and the lesion is benign, a 6- to 12-month follow-up is recommended. Any lesion showing atypical features is further analyzed by excision. A diagnosis of malignancy calls for further multidisciplinary management. If neither the mammogram or sonogram is diagnostic, an attempt to obtain a tissue diagnosis should be entertained (core biopsy or excision).

NIPPLE DISCHARGE

Nipple discharge is the third most common complaint resulting in surgical and diagnostic radiologic evaluation. Most of the etiologies are benign and can be classified as physiologic or nonphysiologic. Physiologic nipple discharge is typically bilateral, spontaneous (not elicited), emanates from several duct openings, and is white, milky, yellow, or green in color. On the other hand, nonphysiologic discharge arises from a single duct opening and is usually unilateral, serous, or bloody. The radiologic evaluation should start with a diagnostic mammogram (age appropriate) in both circumstances. In the case of physiologic discharge, if the findings are negative, no additional radiology studies are necessary and a search for the underlying etiology should progress medically.

With nonphysiologic discharge, additional evaluation with directed subareolar sonography is also warranted (Fig. 1). If the mammogram and sonogram are negative, further evaluation with ductogram (galactography) or MRI should be considered.

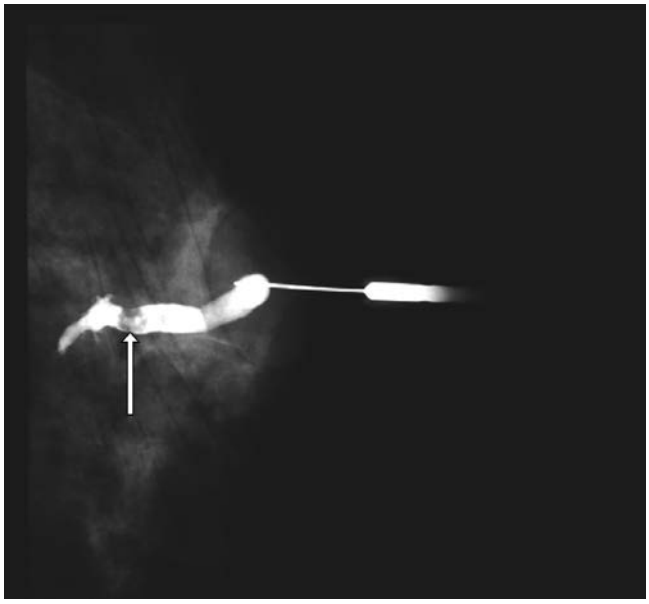

FIG. 2 Ductogram illustrating an intraductal filling defect *(arrow)* that proved to be a papilloma on subareolar resection. *(Courtesy Joe Spigel, MD, and Jean Wang, MD.)*

Ductography utilizes a thin cannula to access the duct in question and instilling a small amount of contrast material that opacifies the duct system for visualization on a mammogram. An abnormal study will identify a filling defect or abrupt truncation of the duct (Fig. 2). MRI can be used as an alternative to ductogram, identifying underlying pathology in 19% to 96% of cases where mammogram and sonogram are negative (see Fig. 1). Focal abnormalities discovered with any of these studies provides a target for obtaining a tissue

FIG. 3 **(A)** Axial MRI of an extracapsular rupture shows extravasated silicone, seen as a bulge in the axillary portion of the implant. The linguine sign is seen within the implant. **(B)** In a different patient, axial three-point Dixon MRI shows bilateral extracapsular rupture with the linguine sign and extravasated silicone in the lateral aspect of the implant *(arrow)*. **(C)** A more inferior slice on the axial three-point Dixon MRI shows the bilateral extracapsular rupture with extravasated silicone in the lateral aspects of the implants *(arrows)*. **(D)** Sagittal three-point Dixon MRI shows intracapsular and extracapsular rupture, with extravasated silicone anterior to the implant *(arrow)*. **(E)** Sagittal three-point Dixon MRI shows extravasated silicone far lateral to the implant within the breast tissue *(arrow)*. *(From Ikeda DM: Breast Imaging:* The Requisites*, 2nd edition. Philadelphia: Elsevier, 2011, Fig. 9.17.)*

diagnosis by image-directed needle biopsy or surgical subareolar excision.

The most common etiology is an intraductal papilloma (35%–48%), followed by duct ectasia (17%–36%), and then rarely malignancy (5%–20%). The risk of malignancy escalates with increasing age as well as the presence of a palpable mass. If all studies are negative and a spontaneous, nonphysiologic discharge is persistent, surgical biopsy by localized duct excision or subareolar resection can be considered.

An isolated nipple discharge in the male breast is very abnormal and requires diligent evaluation to rule out malignancy. Up to 9% of malignancy in males presents as a nipple discharge. Mammographic and sonographic evaluation should be performed followed by subareolar resection if the results are negative.

THE AUGMENTED BREAST

Surgeons are frequently consulted to diagnose breast abnormalities in patients with breast implants. These findings may or may not be related to a problem with the implant material, while the goal may also be to determine the presence or absence of implant rupture. Rupture of a saline implant is frequently diagnosed through physical exam alone since the patient will present with obvious asymmetry that spontaneously occurred. When the clinical exam is equivocal, mammography can be useful since the collapsed implant is easily visualized with routine imaging. In younger patients (<30), sonography is sensitive enough to detect a collapsed implant shell.

Silicone implant rupture may be more challenging to diagnose depending on whether it is intracapsular or extracapsular. If the rupture is intracapsular, it may not present with asymmetry on physical exam or routine mammographic imaging due to the low sensitivity for this entity (11%–69%). Sonography can be more helpful with a sensitivity of up to 75% but is more limited in diagnosing intracapsular ruptures where the accuracy is highly operator-dependent.

Extracapsular ruptures are frequently more easily diagnosed because of the classic "snowstorm" appearance of extracapsular silicone. MRI has the highest sensitivity (80%–90%) and specificity (90%–97%) but is expensive (Fig. 3). Finally, sonography is highly sensitive in determining the presence of periimplant fluid that is the common presentation of breast implant–associated anaplastic large cell lymphoma (BIA-ALCL), a rare T-cell lymphoma recently identified in association with textured implants.

LOCALIZATION

Preoperative localization is an integral component of surgical procedures to remove nonpalpable breast lesions. This is typically performed by a radiologist on the same day of surgery in an imaging center that may or may not be close to the surgical suite. The most common method is the percutaneous placement of one or more thin localization wires through or adjacent to the target area under a local anesthetic using mammographic, sonographic, or MRI guidance. This approach is accurate, effective, and relatively inexpensive assuming the expertise of the radiologist, cooperation of the awake patient, and scheduling logistics are all optimal. Disadvantages include inadvertent wire displacement, suboptimal wire placement, risk of vasovagal reactions of the patient during placement, and timing limitations when scheduling the surgical procedure. Some surgeons choose to perform their own localizations intraoperatively under sonographic guidance after induction of the patient's anesthetic; this is possible only if the target lesion can be adequately visualized sonographically.

As an alternative to wire placement, new technologies enable breast lesion localization before the day of surgery. These include radioactive seed localization, SAVI SCOUT, Magseed, and LOCalizer. Radioactive seed localization utilizes a weakly radioactive (I^{125}) seed that is placed percutaneously at the target area and then located intraoperatively using a handheld gamma probe. Although this localization procedure can be performed several days before surgery, the main disadvantage is difficulty of implementation due to stringent Nuclear Regulatory Council guidelines for handling of radioactive materials. The other devices are nonradioactive and use various technologies to detect percutaneously placed targets. LOCalizer utilizes a radiofrequency identifier tag (RFID) and a handheld detector for pinpointing the objective. Magseed is a tiny surgical steel marker that is placed up to 30 days before the surgical procedure and is located intraoperatively with a probelike sensor. The SAVI SCOUT apparatus is an implantable reflector paired with a radar detector. While these devices allow placement at a time other than the day of surgery, they are also expensive, require specialized equipment, and each have their own limitations. All of these techniques can also be applied to localization of clipped lymph nodes for targeted removal after preoperative chemotherapy treatment.

Genetic Counseling and Testing

Katherine deAngeli, MD, and Elisa Port, MD

The identification of the *BRCA* genes in the 1990s was a monumental step forward in the care of breast cancer patients. And while *BRCA1/2* are still the most important genes associated with increased risk of hereditary breast cancer, many other genes have been identified in the past 25 years. As more genes have been identified, genetic testing has become more extensive. The field changes quickly enough that many women who originally tested negative before 2014 are being offered repeat testing with contemporary panels.

IMPLICATIONS OF GENETIC TESTING

Genetic counseling must be done in conjunction with testing and includes discussing the implications for the patient and their family. The Genetic Information Nondiscrimination Act (GINA) was passed in 2008 to protect patients from discrimination in health insurance and employment opportunities based on their genetic results. However, it does not cover life insurance, disability insurance, or long-term care insurance.

For patients who wish to proceed with testing, the good news is that it has become much more affordable and accessible in the past several years. There are three possible outcomes of genetic testing: negative, positive pathogenic mutation, and variant of unknown significance (VUS). A VUS is a genetic variant that has been identified but not necessarily associated with a negative clinical result. As the field of genetics expands, many of these VUS results are reclassified. Fortunately, most are downgraded to a negative result. Patients who are found to have a VUS are encouraged to reach out every few years to see if their specific VUS has been reclassified.

Genetic testing also has potential implications for other family members, particularly when testing results reveal a pathogenic mutation. The decision to undergo testing and the disclosure of the positive result can be quite sensitive among family members who are estranged or have made different decisions about when to test or whether to test at all. These issues related to complex family dynamics and the ripple effect on other family members (siblings, parents, offspring, and even those more distant such as cousins) are best handled in the context of genetic counseling.

GENETIC COUNSELING

Counseling is done before and after testing. Pretest counseling involves discussing the implications, getting a detailed medical history, and developing a pedigree with at least three generations. Posttest counseling addresses the significance of the results for the patients and their family members. The lack of availability and accessibility of genetic counseling services has been cited as a barrier to implementing more widespread genetic testing. Some insurance companies even mandate genetic counseling as a prerequisite for determining eligibility for testing based on National Comprehensive Cancer Network (NCCN) criteria and reimbursement. There are some geographical locations in the United States where in-person genetic counseling is of quite limited availability due to lack of genetic counselors. At our institution, we partnered with a company that provides an explanatory video to assist with pretest counseling and then a genetic counselor to perform remote/telephone posttest counseling once the test results are available. This helps offload the volume of patients with negative results so our in-house genetic counselors can spend their time on complex families and positive results.

WHO SHOULD GET TESTED?

According to NCCN guidelines, patients with a new diagnosis of in situ or invasive breast cancer qualify for genetic testing if they are male, of Ashkenazi Jewish ancestry, diagnosed with triple negative breast cancer, diagnosed young (≤45), or diagnosed at any age with a first-degree relative with young or male breast, ovarian, pancreatic, or metastatic prostate cancer. Patients can also be tested without a diagnosis of breast cancer if they have a known mutation in their family or a first or second degree relative who qualifies for testing. The American Society of Breast Surgeons released a consensus statement in 2019 that recommended testing everyone with a diagnosis of breast cancer to increase the identification of patients with a clinically meaningful mutation who do not fall into strict NCCN guidelines.

WHO ARE WE MISSING?

Despite these guidelines, genetic testing is underutilized. At our own institution with resources for testing and several genetic counselors, we found that age over 45 and having no identifiable Ashkenazi Jewish heritage were both associated with a missed referral.

WHICH GENES ARE TESTED FOR?

Genetic testing can range from testing only for *BRCA1/2* to a panel of more than 77 different genes. Genetic counselors typically discuss how extensive of a panel to send during pretest counseling. A smaller panel can answer the immediate question of hereditary breast cancer risk. A larger panel can inform a patient's risk and screening recommendations for several other hereditary cancers. Some patients prefer to keep a narrow focus when undergoing genetic testing while others prefer to know as much information as possible.

To assess breast cancer risk, a commonly run panel is Ambry's *BRCA+*, which includes eight genes for breast cancer: *BRCA1, BRCA2, CHEK2, PALB2, ATM, CDH1, PTEN,* and *TP53*. All are tumor suppressor genes. *BRCA1/2, PALB2*, and *ATM* are involved in repair of double-stranded DNA breaks. A mutation in *CDH1* causes a loss in E-cadherin, a protein that allows cell adhesion and is associated with hereditary diffuse gastric cancer and lobular breast cancer specifically. Staining for E-cadherin is one of the ways pathologists differentiate lobular breast cancers, which stain negative, from ductal breast cancers, which stain positive. *CHEK2, PTEN,* and *TP53* are involved in regulation of cell division. There are several known mutations in *CHEK2*, but the most studied mutation increases breast cancer risk as the number of affected family members increases. *PTEN* is associated with Cowden's syndrome, and *TP53* is associated with Li Fraumeni syndrome.

In our practice, the smaller, eight-gene panel is run in the peridiagnostic period of a newly diagnosed breast cancer when the results of testing could affect plans for surgical management. Results typically take 10 to 12 days, which allows patients to proceed to surgery in a timely fashion without significant delay. However, the selection of a surgery date should allow enough time for discussion for those with a high likelihood of testing positive and for whom results would affect recommendations for management by the physician or desire for different operative management by the patient.

WHAT TO DO WITH A POSITIVE RESULT

Although most breast cancers are not associated with an identifiable gene, as discussed earlier, positive genetic results can drastically influence surgical management. For example, a patient with a small breast

cancer who originally planned on having a lumpectomy may choose a bilateral mastectomy instead if she learns she carries a *BRCA* mutation. A positive genetic result is also informative for any children the patient may have. We generally recommend that the children of someone with a mutation wait until they are 25 before getting tested because this is the age at which screening would likely begin.

For an asymptomatic patient who tests positive for a pathogenic mutation, we offer high-risk screening. This involves a yearly mammogram alternating with a yearly MRI so they are getting imaging every 6 months. In addition to imaging, they come for a yearly breast examination. It is important to explain that high-risk screening does not change a person's risk of getting breast cancer. We counsel our patients that the goal of high-risk screening is to identify breast cancer early when it is very treatable but is not in any way preventive of breast cancer development. In addition, identifying early breast cancer is a goal but not a guarantee. Interval cancers that are identified by physical examination between "normal" screening tests are notorious among the *BRCA*-positive population. In particular, estrogen receptor/progesterone receptor/Her2-neu negative cancers (also known as triple negative breast cancers) that make up approximately 75% of cancers developed by *BRCA1* carriers can be particularly aggressive and defy screening and even rigorous early detection regimens. The only way to substantially reduce risk is with surgery, specifically by removing the vast majority of the tissue at risk for developing the disease. Although bilateral mastectomy cannot completely prevent breast cancer, it can reduce a patient's risk of breast cancer to approximately 1%. Historical series of subcutaneous mastectomy have shown risk reduction of approximately 90%. However, more recent series show a risk reduction closer to 99%, most likely based on current techniques and commitment to removing all breast tissue.

For a patient who learns she has a pathogenic mutation peridiagnostically, the pathway involves treating the current breast cancer followed by high-risk screening postoperatively if she decides to have a lumpectomy or yearly physical examination if she decides to have a bilateral mastectomy.

WHO IS OFFERED RISK-REDUCING MASTECTOMY?

Current NCCN guidelines recommend offering risk-reducing mastectomy for asymptomatic patients with *BRCA1/2, PTEN*, and *TP53* mutations. For *BRCA* patients, it is important to refer them to gynecology to discuss bilateral salpingo-oophorectomy as well. Although there is excellent screening for breast cancer, there is not for ovarian cancer. Therefore, women with *BRCA* mutations are generally recommended to have their ovaries removed after they have completed childbearing and before age 40 to 45. When they are ready for their mastectomies, we make sure to have updated imaging, which is usually a bilateral mammogram and ultrasound or bilateral mammogram and MRI within the last 6 months.

WHAT ARE THE SURGICAL OPTIONS?

For patients who are undergoing risk-reducing mastectomy, nipple-sparing mastectomy with reconstruction is a safe option. The two incisions we most commonly use are an inframammary fold incision or a radial incision on the lateral breast. The best candidate for nipple-sparing mastectomy is someone with a smaller, nonpendulous breast where the nipple-areolar complex (NAC) is in anatomic position. This type of NAC has the most robust blood supply and thus the best chance of surviving. If a woman is not a nipple-sparing mastectomy candidate because her breasts are too large and pendulous, she may choose to have a breast reduction and lift in preparation for nipple-sparing mastectomy several months later. The delay of a two-stage mastectomy is acceptable in a prophylactic setting, whereas it would be inappropriate for a patient with breast cancer.

Contralateral Prophylactic Mastectomy

Thomas W. Smith Jr., MD, MS, and Swati A. Kulkarni, MD

Contralateral prophylactic mastectomy (CPM) is a surgical procedure that is most often performed when the unaffected breast is removed at the time of a therapeutic mastectomy for a unilateral cancer. The rates of CPM have continued to rise in recent years, largely driven by younger, average-risk women. Misconceptions about cancer risk, peace of mind, and interest in symmetry are among the primary reasons women opt for CPM. Importantly, the number of women who develop contralateral breast cancer has been decreasing in recent years, and there is little evidence that CPM improves survival. CPM should be discussed with women who have a high risk of contralateral breast cancer but should be discouraged in average-risk women (Fig. 1).

INDICATIONS FOR CONTRALATERAL PROPHYLACTIC MASTECTOMY

Pathogenic Variants in Breast Cancer Susceptibility Genes

Some genetic counselors and surgeons recommend a more tailored approach to genetic testing for breast cancer susceptibility genes based on age of diagnosis, family history of cancer, Ashkenazi Jewish decent, histology, and tumor biology. Others test all women with a newly diagnosed breast cancer. As a result, multigene panel testing is currently performed before surgical planning for a significant proportion of women with a newly diagnosed unilateral breast cancer.

Pathogenic variants in *BRCA1* and *BRCA2* carry increased risk of contralateral breast cancer after breast cancer diagnosis. *BRCA1* mutation carriers have a higher risk of contralateral breast cancer compared with *BRCA2* mutation carriers. The cumulative 10-year risk is 20% for *BRCA1* and 10% for *BRCA2*. Moreover, this cumulative risk increases with early age of primary cancer diagnosis. Women carrying a pathogenic variant of *BRCA1* or *BRCA2* under

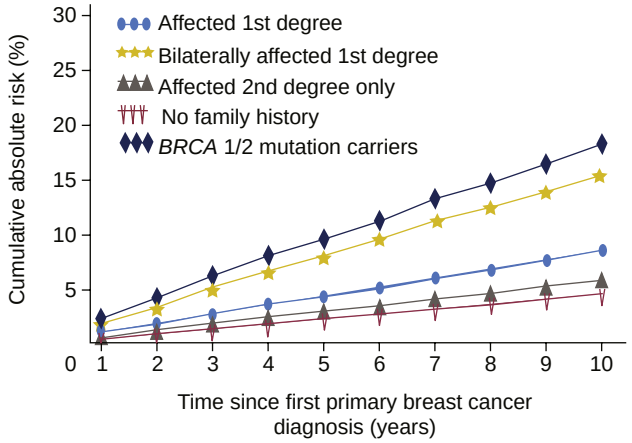

FIG. 1 Risk of contralateral breast cancer. *(Data from Reiner AS, John EM, Brooks JD, et al. Risk of asynchronous contralateral breast cancer in noncarriers of BRCA1 and BRCA2 mutations with a family history of breast cancer: a report from the Women's Environmental Cancer and Radiation Epidemiology Study. J Clin Oncol. 2013;31:433–443.)*

40 years of age have a 10-year cumulative risk of contralateral breast cancer of 25% compared with approximately 6% in noncarrier women of the same age demographic. Additional highly penetrant mutations associated with contralateral breast cancer, identified in multigene panel testing, include pathogenic variants in *TP53* (Li Fraumeni syndrome), *PTEN* (Cowden's syndrome), *CDH1* (associated with hereditary diffuse gastric cancer), and *PALB2*. The option of CPM should be discussed with these women to reduce their risk of developing contralateral breast cancer. There is insufficient data to recommend CPM to women with mutations of moderate penetrance genes such as *CHEK2*, *ATM*, *BARD1*, *STK11*, and *NF1*. These women can be managed with clinical breast exam, yearly screening mammography, and MRI.

Variant of Unknown Significance

A variant of unknown significance (VUS) is a mutation in a gene that has not yet been classified as pathogenic or benign because there is insufficient data on the cancer risk associated with the mutation. It is important to counsel patients on the significance of a VUS identified on panel testing. The vast majority of VUS that are identified are ultimately reclassified as benign; therefore, the presence of a VUS is not an indication for a CPM.

History of Chest Wall Radiation

Women diagnosed with Hodgkin's lymphoma as adolescents and young women treated with mantle field radiation have a 25% to 30% risk of developing breast cancer before the age of 50. Bilateral breast cancer is common in these women, with half of women presenting with synchronous breast cancer and about 20% of women presenting with metachronous breast cancer at 5 years. Because of the excess risk of contralateral breast cancer in Hodgkin's lymphoma survivors treated with mantle radiation, CPM should be discussed with those women who present with a unilateral breast cancer.

Family History

The Women's Environmental Cancer and Radiation Epidemiology (WECARE) study found a strong relationship between family history of breast cancer and risk of contralateral breast cancer. Women without a pathogenic variant (specifically in *BRCA1* and *BRCA2*) and a first-degree relative with breast cancer had a two times greater risk of contralateral breast cancer compared with women without family history of breast cancer. The risk of contralateral breast cancer varied depending on the degree of relationship to the women, with first-degree relatives imparting the highest risk of contralateral breast cancer (see Fig. 1). Polygenic Risk Scores are emerging as a clinical tool to further stratify risk in women with a strong family history without an identified pathogenic variant in breast cancer susceptibility genes. At present, there is no evidence to support the use of polygenic risk to recommend CPM.

Age

The WECARE study also demonstrated an increased risk of contralateral breast cancer with earlier age of diagnosis. In women less than 45 years old at time of initial breast cancer diagnosis, the risk of developing contralateral breast cancer is higher than women greater than 45 years of age. This elevated risk is likely due to the increased life span of the woman, presence of a known genetic predisposition, and a family history of breast cancer.

Average Risk Women with Sporadic Breast Cancer

For the average-risk woman with a newly diagnosed breast cancer, the risk of contralateral breast cancer is low, and it has been declining steadily since 1985. Overall, women diagnosed with unilateral stage I–III breast cancer from 1990 to 2015 in the Surveillance, Epidemiology, and End Results (SEER) database were found to have a 0.37% annual risk of contralateral breast cancer, with a 25-year risk estimated to be below 10%. This decline is due in large part to advances in adjuvant endocrine therapy for estrogen receptor (ER)+ women. Even in ER– patients, cytotoxic chemotherapy and targeted therapies such as trastuzumab have been shown to reduce contralateral breast cancer risk by 30% to 40%.

Male Breast Cancer

Overall, male breast cancer is exceedingly rare in the general population, occurring in approximately 1:1000 males. Even in men with a pathogenic variant in *BRCA2* or *BRCA1,* the cumulative lifetime risk of developing a primary breast cancer is only 5% to 10% and 1% to 5%, respectively. Of those men diagnosed with unilateral breast cancer, only 2% to 4% develop contralateral breast cancer, and even though the numbers are small, it appears to be independent of the presence of a pathogenic variant or family history. Therefore, CPM is not recommended in men diagnosed with unilateral breast cancer.

OUTCOMES OF CONTRALATERAL PROPHYLACTIC MASTECTOMY

Risk Reduction for Contralateral Cancer

CPM confers a 95% relative risk reduction for developing a new breast cancer for all women. This can be impactful for women who have a pathogenic variant such as *BRCA1* or *BRCA2* because they have a high risk of developing a contralateral breast cancer. However, for women with average risk, who may have a 3% to 4% risk of developing a contralateral breast cancer over 10 years, the absolute of CPM benefit is very low.

Survival

There is little evidence that CPM improves breast cancer specific survival. Retrospective studies demonstrating improved survival should be viewed cautiously as there is likely significant selection bias towards healthy patients. Survival is largely driven by the index cancer because most subsequent cancers are early-stage invasive cancers or ductal carcinoma in situ (DCIS) detected by increased

surveillance after breast cancer diagnosis. A Markov model was developed by Portschy et al. to reduce the effect of selection bias seen in retrospective studies. The model estimated that the benefit of CPM in women with early-stage breast cancer was less than 1% regardless of age, stage, or biomarker status.

Local and Distant Recurrence of the Index Cancer

Patients often cite the desire to reduce the risk of local recurrence and distant recurrence after breast cancer diagnosis as a reason to perform CPM. CPM does not prevent local recurrence or distant recurrence from the primary tumor. It is important to counsel patients that CPM only prevents the development of a new breast cancer in the contralateral breast.

SURGICAL RISKS ASSOCIATED WITH CONTRALATERAL PROPHYLACTIC MASTECTOMY

A number of single-institution, retrospective studies have reported an increased risk of complications and higher rates of planned and unanticipated reoperations in women undergoing CPM compared with women who undergo unilateral mastectomy. Because women undergoing CPM are more likely to have breast reconstruction, and reconstruction is associated with more postoperative complications, the question of whether the increased risk is due to the increased risk of having a CPM alone or the addition of breast reconstruction was addressed in two American College of Surgeons National Surgery Quality Improvement Program (NSQIP) database reviews. Osman et al. identified 4291 patients who had either a unilateral mastectomy or CPM without reconstruction from 2007 to 2010. The 30-day complication rate was 4.2% versus 7.6%. A second study by Silva et al. analyzed 20,501 patients undergoing unilateral and bilateral mastectomy with immediate reconstruction and found a statistically significant increase in return to operating room, overall rate of complications, hospital stays, and transfusion rates for bilateral mastectomy patients compared with patients undergoing a unilateral mastectomy with immediate reconstruction. Overall, CPM confers a 2-fold risk of complications compared with unilateral mastectomy. Significant complications could negatively affect the start of therapy for individual women with high-risk breast cancer. However, overall, CPM does not appear to significantly delay the onset of adjuvant therapy.

IMPACT ON QUALITY OF LIFE AND PATIENT SATISFACTION

Eighty to ninety percent of women were satisfied with their decision to undergo CPM at 10 to 20 years after procedure, and more than 90% would choose CPM again. Women who have undergone CPM are generally satisfied with the appearance of their breasts and they have reduced cancer worry. However, women do not appear to have an improvement in overall quality of life, and about 20% to 30% of women cited decreased satisfaction with body appearance and femininity. Moreover, CPM appears to impact the sexuality of younger women. This could be a result of the loss of sensation in the breast skin that occurs with mastectomy.

ALTERNATIVES TO CPM

Patients cite fear of contralateral breast cancer as an indication for CPM; however, there are alternative approaches to reducing risk. Improved radiographic screening has increased breast cancer detection rates with the onset of 3D digital breast tomosynthesis and contrast-enhanced breast MRI. Beyond improved screening, alternatives to surgical risk reduction for contralateral breast cancer include improvements in systemic therapies. Women with hormone receptor-positive breast cancers have increased options for preventative techniques with endocrine therapy. Multiple randomized controlled trials have shown that women with ER+ breast cancers can halve their risk of contralateral breast cancer by taking tamoxifen, a selective estrogen receptor modulator (SERM) or aromatase inhibitors for 5 years. More recently, for women concerned about the risk of side effects of tamoxifen, a recent study found that 5 mg PO daily was as effective at reducing risk of breast cancer as the standard dose (20 mg PO daily) but was associated with fewer side effects. There are also surgical alternatives to CPM. Many women believe the only way to achieve symmetry is through CPM. Those women may be eligible for symmetrizing surgery such as mastopexy, augmentation, or reduction mammoplasty. Alternative surgical approaches to achieving symmetry should be included in the discussion with women who request CPM for symmetry.

COST-EFFECTIVENESS OF CONTRALATERAL MASTECTOMY

Beyond the effects on the individual patient, what is the cost of performing CPM compared with continued surveillance of the contralateral breast? Patients treated with unilateral mastectomy have continued costs after surgical intervention, including regular physician visits, screening breast imaging (mammogram, ultrasound, and MRI), and potential diagnostic biopsies for imaging detected or palpated abnormalities. Model-based studies have been used to compare cost of CPM with surveillance of the contralateral breast. For average risk women with early-stage, node-negative breast cancer, the cost-effectiveness over a patient's lifetime is controversial within the literature; however, it has been shown to decrease with age. For women aged 45 years old and younger, the cost of surveillance over a lifetime was equal to the breast cancer-related treatment costs with CPM. However, it was shown that CPM offers increased quality adjusted life years (QALYS) compared with surveillance (one QALY equals 1 year spent in perfect health, other health states equal a fraction of a QALY). It was estimated that women aged 70 years and older have no cost benefit, financial or QALY, with CPM compared with surveillance. Although the exact difference of cost-effectiveness of CPM and surveillance is unknown for average risk women, for high-risk women (including *BRCA1* and *BRCA2* genetic mutations) CPM has been shown to offer significant cost-effectiveness with increased QALYS for women of all ages.

SURGICAL OPTIONS FOR CONTRALATERAL PROPHYLACTIC MASTECTOMY

Types of Mastectomies

Simple mastectomy is performed for those women who do not want to have reconstruction. It involves removing the nipple-areolar complex, excess skin, and underlying breast tissue with an elliptical skin incision. Care should be taken to align the linear scars from both breasts and to avoid dog ears on the lateral and medial aspects of the incision. Skin-sparing mastectomy involves resection of breast tissue and the nipple-areolar complex while preserving the majority of the overlying skin to create a skin envelope for immediate breast reconstruction. For those women who are eligible based on bra size and amount of ptosis, nipple-sparing mastectomy can be performed through an inframammary incision. Care must be taken to remove all breast tissue, especially in the axillary tail. Mastectomy can be carried out with electrocautery or with tumescence depending on surgeon preference. At this time, there is insufficient evidence that robotic mastectomy improved outcomes of mastectomy and these should only be performed as part of a clinical trial.

Axilla

A meta-analysis by Nagaraja et al. found that occult invasive disease in the contralateral breast was identified in 1.8% of cases, and the rate of sentinel node positivity was 1.2%. Therefore, staging of the

axilla with sentinel lymph node biopsy (SLNB) is not recommended with CPM when preoperative imaging does not identify any suspicious or indeterminant lesions due to the low occult malignancy rate and the potential for short- and long-term surgical complications such as seroma, hematoma, sensory changes in the skin, and lymphedema.

Breast Reconstruction

Patients interested in reconstruction after mastectomy can undergo implant-based reconstruction or autologous reconstruction. Implant-based reconstruction generally involves a shorter operative time and shorter hospital stay. Tissue expanders are often placed at the time of mastectomy followed by permanent implants after adequate expansion. Occasionally, direct to implant reconstruction can be performed. Autologous reconstruction can be performed in women with adequate abdominal fat for reconstruction using free flaps such as deep inferior epigastric perforator (DIEP) flap or rotational flaps such as transverse rectus abdominis muscle (TRAM). Operative time and hospital stay tend to be longer, and the patient will have an additional surgical incision in the abdomen, but autologous reconstruction generally results in more natural appearing and feeling breasts. More recently, nerve preservation and grafting has been incorporated to preserve sensation after mastectomy. Consultation with a reconstructive surgeon should be part of the decision process for CPM as the recommendation for autologous versus implant-based reconstruction can differ depending on whether the patient chooses a unilateral mastectomy or bilateral mastectomy.

SHARED DECISION MAKING AND PATIENT EDUCATION

The goal of surgical planning is to come to a shared decision from medical understanding leading to the best oncologic outcome. Patients view surgeons among the most important source of information about their care. Surgeons should take the opportunity to include a discussion of CPM as part of their consultation. It is important to understand why a patient is requesting a CPM. The most common reasons women choose CPM are cancer worry, wanting peace of mind, and cosmetic outcome. Many patients overestimate risk of contralateral breast cancer and the benefits of CPM. If there are misconceptions about their risk of contralateral breast cancer, survival advantage, and/or reduction in local and distant recurrence, the surgeon should address them with the patient and provide them with their absolute risk of breast cancer when possible. For patients with more advanced disease who are requesting CPM, it can be helpful to inform patients that their risk of recurrence from their known index cancer is higher than their risk of contralateral breast cancer. It is also important to remind patients that the systemic treatment they will take to treat their index cancer will also reduce the risk of contralateral breast cancer. The surgeon should then discuss the risks and benefits, including the risk of additional surgical complications and lengthy recovery compared with breast conservation versus the benefits the patient will receive from CPM. The use of decision aides for CPM may also be helpful for the patient to focus on why they are choosing CPM. Overall, it is important for the surgeon to provide the patients with adequate information and support, so that the patient can make an informed decision about CPM (Fig. 2; Table 1).

CONTRAINDICATIONS TO CONTRALATERAL PROPHYLACTIC MASTECTOMY

CPM is contraindicated in patients with advanced stage disease, including stage IIIB (T4 disease, inflammatory breast cancer), stage IIIC (N3 disease), and stage IV (metastatic disease) breast cancers because initiation of oncologic medical therapy is crucial in overall survival. No potential risk of contralateral breast cancer outweighs risk of advanced primary disease and risk of distance recurrence and death (see Fig. 1; Table 1). Furthermore, CPM is relatively contraindicated in patients with severe medical comorbidities increasing the morbidity and mortality of surgery, including cardiac, pulmonary, hepatic, and renal dysfunction. A multidisciplinary team discussion is paramount in balancing desire for CPM versus risk of a poor outcome for the patient.

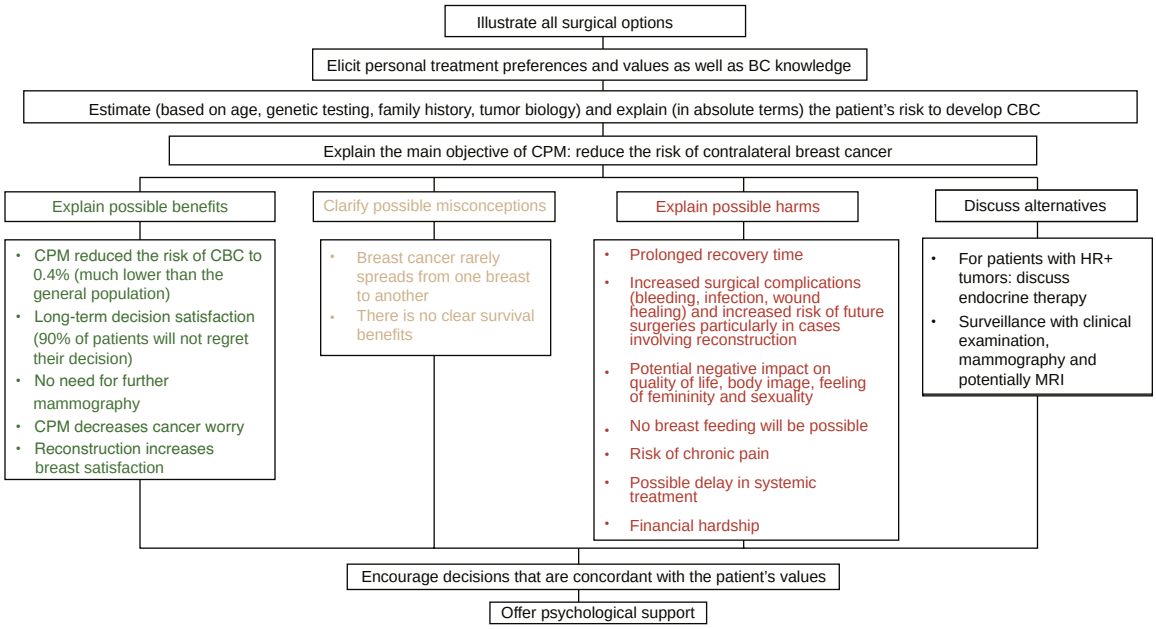

FIG. 2 Framework for a stepwise informed discussion with patients with sporadic unilateral breast cancer who are considering CPM. *BC*, Breast cancer; *CBC*, contralateral breast cancer; *CPM*, contralateral prophylactic mastectomy. *(From* Expert Rev Anticancer Ther. 2020;20:159–166.)

TABLE 1 Consensus Guidelines

	ASBrS	NCCN
CPM Discouraged	1. Average-risk women with unilateral breast cancer 2. Women with advanced index cancer (e.g., inflammatory breast cancer, T4 or N3 disease, stage IV disease) 3. Women at high risk for surgical complications (e.g., patients with comorbidities: obesity, smoker, diabetes) 4. Woman tested *BRCA* negative with a family of *BRCA*+ carriers 5. Male breast cancer, including *BRCA* carriers	
CPM Considered	1. Deleterious mutations of *BRCA1/2* 2. Greater than 25 % lifetime risk (Gail Model) of breast cancer primarily due to family history in the absence of deleterious mutations 3. History of mantle radiation (typically for Hodgkin lymphoma) before age 30 4. Gene carrier of non-*BRCA* gene (e.g., *CHEK-2, PALB2, p53, CDH1*).	Women with a known *BRCA1/2* pathogenic or likely pathogenic variant, typically between 35 and 40 years of age

ASBrS, American Society of Breast Surgeons; *NCCN*, National Comprehensive Cancer Network.

CONCLUSION

There are no absolute indications for CPM. It is an elective procedure that should only be discussed in a limited subgroup of women who have significant risk of developing contralateral breast cancer. For these women, the stage of the index cancer, patient age, medical comorbidities, and reconstructive options should be incorporated into the decision to undergo CPM. For the average-risk woman who requests a CPM, it is incumbent on the surgeon to understand the patient's motivations for CPM, educate the patient on the perceived versus actual risks and benefits of CPM, discuss alternative treatments, and discuss potential outcomes so the patient can make an informed decision about proceeding with CPM.

Margins: How to and How Big?

Patricia A. Cronin, MD, and Richard J. Gray, MD

Complete cancer resection with negative margins is the goal of any surgical oncologist. It is an important component of breast cancer surgery, with local recurrence rates significantly higher in patients with positive margins. One of the more difficult conversations to have with a patient postoperatively is informing her of the presence of a positive margin and advising that further surgery is required. However, in breast conserving surgery (BCS), taking margins that are wider than necessary does not improve local control and may significantly worsen cosmesis. The volume of resection is the biggest driver of poor cosmetic outcome. Therefore, the balance in BCS is achieving optimal margins to maximize local control while maintaining the best possible cosmetic outcome.

Achieving negative margins and an acceptable aesthetic outcome requires careful interpretation of imaging, wise patient selection, regimented operative technique, coordinated specimen handling and communication with pathologists, and multidisciplinary interpretation of the pathologic findings that incorporates the best evidence in the context of the individual patient.

PREOPERATIVE PLANNING

Imaging

Evaluation of the available breast imaging is invariably the first step in assessing a new diagnosis of breast cancer. A complete and adequate set of mammographic views of both breasts should be obtained. The surgeon should review the imaging personally, but we encourage review with the breast radiology team. This can be done directly or at a multidisciplinary conference where new cases are discussed. This multidisciplinary assessment ensures adequacy of the imaging to determine whether further views are required. Multidisciplinary review helps optimize any further evaluation such as biopsies to confirm extent of disease or evaluate additional ipsilateral or contralateral lesions. Review in conjunction with breast imaging colleagues helps all parties to better appreciate the location and extent of disease within the breast. One must confirm pathologic concordance of the biopsy or biopsies, whether the clip placement was accurate, and the sites and types of clips if multiple clips were placed for multiple biopsies. In planning for preoperative radiologic localization, direct discussion with the breast imager performing the localization is invaluable, especially with multiple lesions or lesions in need of bracketing techniques.

For patients with ductal carcinoma in situ (DCIS), mammographic imaging alone is typically sufficient to establish the extent of disease based on microcalcifications. For those with invasive disease, mammography with ultrasound is the standard assessment. The use of adjunct imaging such as MRI should not be routinely performed. MRI does not improve margin reexcision or local recurrence rates. It is associated with false positives, second look ultrasounds, additional biopsies, and recommendations for short interval imaging. It may overestimate the extent of disease, especially with postbiopsy change having the potential to confound the reviewer. Clarification and investigation of MRI findings may delay surgery and can increase patient anxiety. The use of preoperative MRI has been associated with increased mastectomy rates.

MRI use should be limited to cases with complex radiologic findings on mammography and ultrasound for which MRI can help clarify and troubleshoot. The most common situations in which we would request additional imaging include mismatch between the clinical and the radiology findings, mammographically dense breasts that make the extent of disease difficult to assess, and in many cases of invasive lobular carcinoma where extent of disease may be underappreciated by conventional imaging. In our practice, we commonly utilize contrast-enhanced digital mammography (CEDM) in these cases as an alternative to MRI. MRI is clearly indicated for mammographically occult primary tumors in patients presenting with metastatic axillary disease.

Patient Selection

Patient selection for BCS is an important part of margin management. Essentially this comes down to a decision that the patient desires BCS and the surgeon can achieve negative margins with a reasonable cosmetic result. There is no defined tumor size for which BCS should not be considered, rather the ratio between the expected volume of resection to the size of the breast must be considered. A larger breast may accommodate a large resection that would be unacceptable in a smaller breast. Resection of volumes over an estimated 20% of breast volume is likely to result in asymmetry. For patients who will benefit from systemic therapy, this should be considered in the preoperative setting if the tumor size is too large or borderline for BCS and the patient would like to achieve breast conservation. Oncoplastic techniques, such as a combined reduction mammoplasty with BCS, can also help facilitate resection of tumors that are large in relation to the total breast volume. The tumor bed of any resection done with oncoplastic reconstruction should be carefully marked with clips to facilitate reexcision should a positive margin be found on final pathology. BCS may be attempted for multifocal and/or extensive disease but these circumstances are associated with an increased risk of positive margins and BCS should be reserved for well-informed, motivated patients.

Preoperative Localization

Lesions that are clearly palpable do not require additional localization. One must be mindful of clinical assessment after core biopsy when postbiopsy inflammation or hematoma may give the impression of a palpable lesion that will not be evident later. When in doubt, perform preoperative localization. For impalpable lesions, we use radioactive seed localization with iodine-125 radioactive seeds (Fig. 1). Single seeds can be used in most straightforward cases. In cases of multifocal or extensive disease or a linear distribution of microcalcifications, one should not hesitate to localize with multiple seeds or bracketing seeds around the lesion(s). Other localization devices are now available that do not use radiation, such as magnetic seeds. Wire localization is still an excellent option, but it must be placed on the morning of surgery, which affects timing and perioperative logistics, and it can be potentially dislodged inadvertently.

OPERATIVE TECHNIQUE

On the day of surgery, the surgeon should review the preoperative imaging, biopsy results, and clinical findings. The surgeon should have a clear understanding of the biology of the target lesion, its estimated size, the position of the lesion, the location and appearance of all clips, and the method of localization. Preoperative imaging including the craniocaudal (CC) and mediolateral oblique (MLO) views should be displayed in the operating room for review throughout the case. Displaying and reviewing CEDM and/or MRI imaging, if obtained, can be also useful.

Breast Conserving Surgery

There are many approaches to incision placement in BCS. It comes down to a balance between allowing sufficient access for adequate tumor resection with negative margins and a good cosmetic result. One should keep in mind the possibility of having to return to the OR to reexcise margins and thus how your approach now may help or hinder you in the future. Incision placement away from the tumor means tunneling; it may give a more hidden scar but may limit your ability provide adequate resection at the first procedure and hinder access at any needed subsequent operation. We typically utilize periareolar incisions for central tumors. In the upper pole of the breast, a transverse or curvilinear incision over or just inferior to the targeted lesion works well. In the upper outer quadrant with large tumors, a radial incision can give an excellent cosmetic result and may also allow for access to the axilla for sentinel node biopsy. For upper inner quadrant lesions, one should try to avoid incisions in the decolletage that may be visible later and a periareolar incision, or a crescent or batwing mastopexy approach, can be employed. For tumors in the lower pole of the breast, radial incisions give good access, facilitate cavity closure, and heal well.

BCS is typically performed either with a single specimen maintaining circumferential margins of 5 to 10 mm or a close excision of the targeted lesion followed by separate shaves of the cavity margins. The latter technique is the approach we will describe here. Following incision, dissect down to a level just anterior to the tumor. From preoperative imaging, one should already understand if the

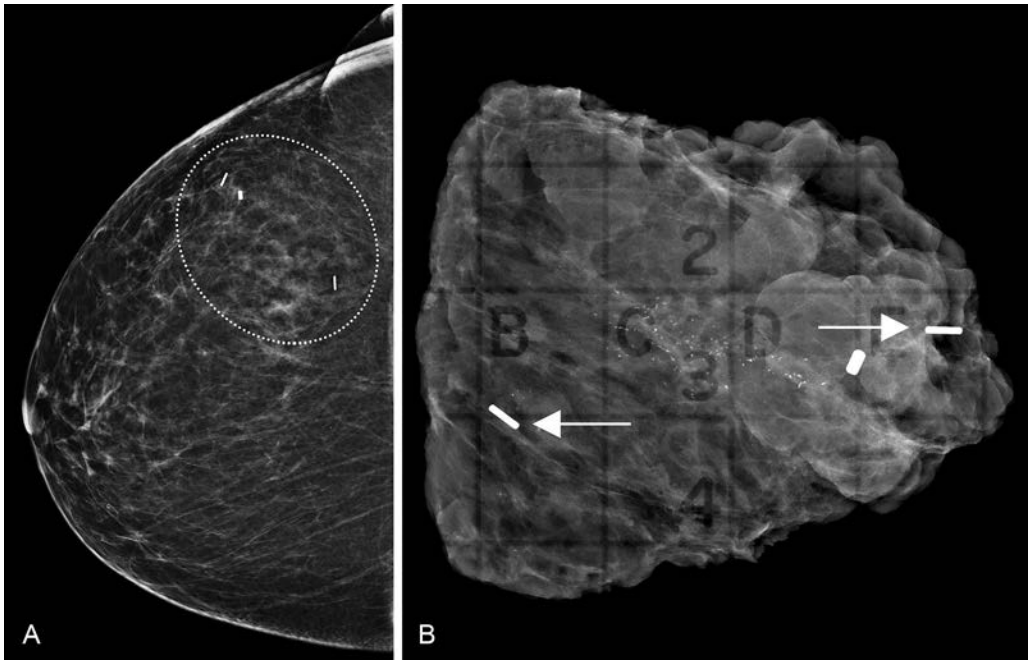

FIG.1 **A,** Localization mammogram demonstrating bracketing radioactive seeds demarcating an area of extensive ductal carcinoma in situ with the microcalcifications being targeted for resection. **B,** Specimen radiograph after resection demonstrating the bracketing radioactive seeds *(arrows),* microcalcifications and biopsy clip.

lesion is in the anterior, middle, or posterior depth. The localization technique then provides more precision during dissection through palpation, ultrasound, or position of the radiologic localization device. We utilize a measure of the gamma signal from the radioactive seed to determine distance from the seed and therefore the lesion. One must assure the gamma probe is directly aimed at the seed, not oblique to it, for accurate margin distance determination. One can then perform circumferential flaps at that depth anterior to the tumor. Aim to leave sufficient anterior margin on the main resection specimen while maintaining anterior tissue on the skin flaps to improve cosmesis. One need not routinely resect from the skin to the chest wall.

For palpable tumors, "hug" the tumor during the initial excision, using the nondominant index finger to feel as you go with frequent repositioning. Visual clues can also be evident with cicatrization of the tissues closer to the tumor. Many clinically impalpable lesions may be palpable intraoperatively when closer to them during dissection. For nonpalpable tumors with radioactive seed localization, continued measurements of gamma signal during dissection can maintain appropriate distance from the lesion. One should also use the preoperative imaging and the estimated size of the lesion to help guide the extent of resection.

The cavity is reviewed following resection of the main specimen. Five separate, uniformly 5- to 7-mm thick specimens are taken around the four radial margins and posteriorly. One should avoid creating any crevices on the true margin side that ink may penetrate and thus interfere with interpretation of the margin. A separate anterior margin can be taken if one is concerned about that margin on the main specimen or if the intraoperative pathologic assessment is that this margin is close or positive. If the main tumor is very close to or involves skin, then skin excision may be required. Incision placement should be planned preoperatively in the situation of superficial carcinomas to allow for this possibility and still minimize the effect on cosmesis. For invasive tumors found to be abutting or invading the underlying muscle, a portion of pectoralis or serratus may need to be taken to achieve negative margins.

Mastectomy

Even when performing a mastectomy, the surgeon should be mindful of the tumor location within the breast. If a skin paddle is excised, it may need to be adjusted to maximize the anterior margin. Areas of concern during dissection of the mastectomy flaps or posterior margin should be marked with ink and/or clips to make subsequent interoperative or reoperative reexcision more accurate should pathologic interrogation of the specimen reveal a close or positive margin. Such areas of concern should also be documented in the operative note with measurements from the nipple or other landmarks for future reference.

The anterior resection margin for nipple-sparing mastectomy (NSM) at the nipple is at the base of the nipple. It is not necessary to routinely core out the nipple as minimal duct tissue, if any, is present depending on the size of the nipple. The nipple margin is subjected to intraoperative frozen section. A positive margin may be improvable in patients with a substantial nipple by coring it out with an 11-blade scalpel. For most patients, a positive nipple margin will result in excision of the nipple, but the areola can be spared. In NSM cases with a lesion in proximity to the nipple on preoperative imaging, we recommend considering a lateral transverse incision to better accommodate possible nipple or nipple-areolar excision. An inframammary incision is an excellent approach for most patients to achieve the best cosmesis, but excising the nipple-areolar complex in these cases will result in two scars that may compromise the perfusion of the inferior mastectomy flap.

Borderline Lesions

Atypical ductal hyperplasia and classic lobular carcinoma in situ (LCIS) are lesions that are often excised for evaluation of the whole lesion due to the risk of upstaging to DCIS or invasive cancer. These lesions should be excised with narrow margins since they do not require a negative margin. Nonetheless, one should be mindful that if the lesion is upstaged the excision margins will become essential.

Thus, the specimen must still be carefully and accurately orientated for margin assessment. Cavity shaves need not be performed for these lesions unless for a specific intraoperative finding. Pleomorphic LCIS differs from the classic type and likely behaves more similarly to DCIS. Therefore, therapeutic excision with negative margins should be the goal of surgery for the vast majority of these patients.

SPECIMEN HANDLING AND PROCESSING

All specimens must be clearly oriented by the operating surgeon. Most use suture markings, clips, inks, or a combination of these. We place a long stitch in the center of the lateral margin, a short stitch on the superior margin, and a double stitch on the anterior margin of the main specimen. For cavity shave specimens, the new, true resection margin is marked with a medium clip for efficiency and further oriented on a piece of paper with written labels. More important than the method used is that orientation is done in a standardized fashion in one's practice and preferably at one's institution. This will minimize errors in labeling or interpretation by the pathology team.

Impalpable, localized lesions undergo specimen radiography. The specimen radiograph confirms retrieval of the seed(s) and the clip(s). It can also be useful to further assess the adequacy of margins, particularly for specimens containing microcalcifications. To better facilitate this assessment, the orientation of the specimen for the specimen radiograph should also be standardized. We place the specimen on the x-ray board with superior at 12 o'clock and lateral at 3 o'clock (for left-sided lesions) or 9 o'clock (for right-sided lesions). If the mass, calcifications, or the clip/seed are close to the edge of the specimen, this guides us in closer pathologic examination of that margin, a wider cavity shave margin at that site, or even a reexcision based on the imaging findings.

The main specimen and the five additional shave margins are brought to surgical pathology for processing and are assessed intraoperatively. As with orientation by surgeons, pathologists should have a standardized procedure for inking and processing specimens. In our practice, main specimens are inked with six colors, each standardized in designation of one of the six margins to be assessed. All specimens undergo gross pathologic examination and, depending on gross findings, tumor biology, and consultation with the surgeon, are subjected to targeted frozen section analysis. Although labor intensive and time consuming, targeted intraoperative frozen section further reduces the risk of reoperation for positive margins.

REEXCISION OF MARGINS BASED ON FINAL PATHOLOGY

When reoperation for margin reexcision is planned, it should be performed reasonably soon after the initial operation, especially when the cavity has been closed. The underlying mastopexy can then be taken down and the tumor bed reidentified. Then the face of the involved margin can be taken as a cavity shave and the new margin oriented. This should be performed similarly to what is described earlier for resecting cavity shave margins with intraoperative pathologic consultation.

For patients undergoing reexcision who had extensive microcalcifications, a postoperative mammogram should be performed to identify any residual calcifications that can be localized for the second operation to assure adequate resection of all disease. If a patient underwent an oncoplastic procedure, such as a reduction mammoplasty, reidentification of the tumor bed will rely on clips placed at the time of tumor resection. If identification of the site of needed reexcision cannot be done in a reliable fashion, mastectomy may be required to ensure the resection of all disease.

Breast Conserving Surgery for Invasive Cancer

We routinely follow the guidelines published in 2014 by the Society of Surgical Oncology (SSO) and the American Society of Radiation Oncology (ASTRO), which were subsequently endorsed by American Society of Clinical Oncology (ASCO) and the American Society of Breast Surgeons (ASBrS) and incorporated into the National Comprehensive Cancer Network clinical practice guidelines. For early-stage invasive breast cancer, no ink on tumor is a sufficient margin for women undergoing BCS with whole breast radiation. Achieving wider margins than no tumor on ink does not appear to reduce local recurrence rates. Of note, these guidelines do not apply to patients who plan to undergo no radiation or partial breast irradiation or patients who underwent neoadjuvant chemotherapy. The best practice for patients in these circumstances, as well as for all patients with close (<2 mm) final margins, is to undergo multidisciplinary review to impartially consider patient and tumor factors to finalize the decision on reexcision of margins. For some patients, a deviation from these general guidelines will be in their best interest, but a multidisciplinary review helps assure the best judgment for these exceptions. The decision to return to the operating room for margin reexcision should balance the risk of residual disease and local recurrence with the morbidity, cosmetic effect, and cost of reexcision.

Breast Conserving Surgery for Ductal Carcinoma In Situ

Likewise, we routinely follow the guidelines published in 2016 by SSO-ASTRO-ASCO regarding the optimal margins for pure DCIS lesions. DCIS has an excellent prognosis, but local recurrence rates are higher following BCS for DCIS lesions compared with invasive cancers, and half of all local recurrence events are invasive. The growth pattern of DCIS may be different, and the receipt of adjuvant therapies is less than that for invasive cancer. Thus, margins of at least 2 mm are associated with a reduced risk of local recurrence compared with narrower margins, and we routinely reexcise for margins less than this width. Margins greater than 2 mm do not significantly improve local control. This guideline does not apply to women who plan for to forego radiation. There are mixed data as to whether margins wider than 2 mm in that population would improve local control rates. Again, the best practice for patients with DCIS who plan to forego radiation, as well as for all DCIS patients with close (<3 mm) final margins, is to undergo multidisciplinary review to be sure to consider all patient and tumor factors. A 2-mm margin for DCIS is ideal, but the value of reexcision of a single focus of microscopic DCIS 1 mm from the margin in an octogenarian, for example, should be questioned.

Breast Conserving Surgery After Neoadjuvant Chemotherapy

The appropriate margin width for BCS after neoadjuvant chemotherapy is not known. Preoperative imaging is important to assess the pattern of tumor response. The effect of chemotherapy on primary tumors can differ with some tumors downsizing in a concentric fashion and others in a more "swiss cheese" pattern. This should be factored into assessment of appropriateness for BCS and preoperative planning. We routinely use a "no ink on tumor" criterion for the adequacy of margins in these circumstances since the National Surgical Adjuvant Breast and Bowel Project (NSABP) B18 and B27 trials used no ink on tumor as their margin definition with high local control rates and other published institutional data further support this criterion. But patients with close (<2 mm) margins should again undergo multidisciplinary review.

Mastectomy

Positive margins after mastectomy should be infrequent but can be challenging. There are no guidelines for what constitutes an adequate margin of excision for patients undergoing mastectomy, but positive margins are associated with increased recurrence risk, and many patients do not meet criteria for postmastectomy radiation. We

therefore ensure negative margins (no ink on tumor) for mastectomy patients and routinely perform reexcision for positive margins after multidisciplinary review. Reexcision is preferable to adjuvant radiation, which should be reserved for cases where the site of positive margin cannot be identified and improved.

Reoperation should be done early in the postoperative phase when the mastectomy cavity is more readily accessible with minimal dissection. Reoperation for positive mastectomy margins requires careful rereview of the original imaging; measurements from landmarks like the nipple in preoperative imaging, the operative report, and the pathology report; and the surgeon's recollection, and hopefully marking with clips, of the intraoperative findings. The surgeon should significantly overlap the targeted area of reexcision to allow for postoperative changes in orientation and the imprecision of such targeting. If a positive nipple margin is detected following NSM, then the nipple should be excised. The areola can be spared if desired. This should be planned in conjunction with the patient's reconstructive surgeon.

CONCLUSION

With modern management of breast cancer, local control rates are excellent. A better understanding of biology and use of systemic therapy have certainly played a role, but a robust, multidisciplinary approach to the primary tumor has been essential in these improvements. Surgeons should routinely reexcise for positive margins or for margins <2 mm when performing BCT for DCIS. But decisions to reoperate are best made with multidisciplinary review to dispassionately account for patient, tumor, and treatment characteristics, rather than margin width in isolation.

Breast Reconstruction Following Mastectomy: Considerations, Techniques, and Outcomes, Part 1

Salih Colakoglu, MD, and Gedge Rosson, MD

Breast cancer remains the most common cancer and the second most common cause of cancer death in women. In recent years, breast cancer incidence rates have increased by 0.5% per year, however; the death rate decreased by 1% per year. The Agency for Healthcare Research and Quality reported a significant increase in overall mastectomy rates and, in particular, bilateral mastectomies more than tripled in less than a decade. This can potentially be attributed to an increase in genetic screening and improved patient awareness of breast reconstruction options after mastectomy.

Although the demand for breast reconstruction continues to increase, and the beneficial effects of reconstruction on quality-of-life and self-esteem are now well established, as of 2017 fewer than half of all women who required a mastectomy were offered breast reconstruction surgery in the United States. Studies revealed that a breast surgeon's decision to refer a patient for reconstruction significantly affects whether the patient will receive breast reconstruction. Because many women are unaware of insurance coverage for breast reconstruction provided by federal law (The Women's Health and Cancer Rights Act) and do not know how to access to such procedures, breast surgeons assume a crucial role by providing patients with appropriate referrals.

PREOPERATIVE CONSIDERATIONS

Mitigating Preoperative Risks

Although reconstruction of a new breast is a powerful adjunct of breast cancer treatment, it is still an elective procedure. Therefore, an operative risk assessment should be made accordingly. Elevating large skin flaps, performing large incisions, and placing foreign bodies such as implants and acellular dermal matrices (ADMs) require an optimized healing environment for satisfactory results. Although radiation and chemotherapy treatments cannot always be avoided, surgeons should identify and optimize the modifiable risk factors to minimize the risk of complications.

Because there is no distinct anatomic plane between the breast tissue and the subcutaneous fat, a breast surgeon's desire to remove the entire breast tissue to minimize the risk of local recurrence frequently results in thin mastectomy skin flaps. Because the mastectomy skin flap relies on the subdermal plexus for the blood supply, a thin and large flap becomes vulnerable to ischemia. Additionally, surgical retraction– and reconstruction-related mechanical stresses can further diminish tissue perfusion.

Patients with microvascular disease have a very high risk for partial or total mastectomy skin necrosis. Active smoking status has a strong association with infection, delayed wound healing, and skin necrosis complications. An infected breast implant, partial or total loss of mastectomy skin flaps, or partial or total loss of donor site skin flaps after autologous breast reconstruction can result in poor cosmetic outcomes and months of delay in postmastectomy breast cancer treatment. Although there is no high-level evidence behind different smoking cessation protocols, many surgeons require their patients to stop smoking 6 to 12 weeks before and after surgery. If a patient fails urine nicotine test before surgery, a delayed breast reconstruction can always be offered in the future.

Poorly controlled diabetes, high BMI (especially over 35), and poor nutritional status can all cause delayed wound healing and skin

necrosis, which ultimately results in loss of breast reconstruction, whether it is implant or autologous based. The impact of such major complications on a cancer patient's emotional status and overall outcomes can be destructive; therefore, patient optimization should be a crucial part of the surgical decision-making process.

AESTHETIC CONSIDERATIONS

Unilateral versus Bilateral Reconstruction

Whether it is an autologous- or implant-based reconstruction, achieving symmetry with a natural breast on the contralateral side creates a challenge for the reconstructive surgeon. This usually requires some revision surgeries including both the reconstructed and the contralateral breast. Although both reconstruction types can give satisfactory results, when aging-related changes are considered, it is not surprising that studies show higher general and aesthetic satisfaction rates with autologous flaps for unilateral reconstruction. Nevertheless, studies show that long-term quality-of-life scores are the same for both unilateral and bilateral reconstruction.

Nipple-Sparing versus Simple Mastectomy

Studies have shown that when certain tumor characteristics criteria are met, nipple-sparing mastectomy can be a safe option with similar recurrence and survival outcomes compared with traditional mastectomy techniques. Although this encourages patients to preserve their nipples to improve cosmetic outcomes, this can only be a feasible option for patients with small to moderate breast tissue volume and with low-grade breast ptosis. When patients have high-grade ptosis, nipple-sparing procedures may not be possible. Patients should be informed about several types of nipple reconstruction techniques and/or three-dimensional nipple tattoos that can be performed as a last stage of reconstruction in the future.

Patients who undergo bilateral prophylactic mastectomy because of genetic predisposition can be offered a breast reduction or breast lift procedure to improve the nipple position on the chest wall 3 to 6 months before the mastectomy. In this fashion, a nipple-sparing mastectomy can then be utilized for satisfactory cosmetic outcomes for patients with high-grade breast ptosis and/or macromastia. Because these procedures can delay the mastectomy 3 to 6 months, they usually cannot be offered to patients with active cancer.

RADIATION THERAPY

Radiation therapy creates a significant challenge to breast reconstruction by increasing almost any surgical complication rate and adversely affecting cosmetic outcomes. Although radiation therapy requires an entire chapter to discuss, two main points should be highlighted for the purposes of this textbook. First, when there is planned radiation therapy after mastectomy or just a possibility of radiation therapy based on the final pathology results, an autologous flap-based reconstruction typically should be delayed. The well-vascularized abdominal skin and soft tissue should be preserved to replace the radiated, unhealthy tissue after the radiation therapy is completed. Studies show that the long-term results of autologous reconstruction are more favorable than implant-based reconstruction for the radiated breast.

TIMING OF RECONSTRUCTION

Immediate Reconstruction

In an appropriate setting, any type of breast reconstruction technique can be utilized at the same time as the mastectomy surgery. Because the breast pocket is preserved, the reconstructive surgeon can have better control while shaping the new breast, thus providing a more natural aesthetic outcome. Overall, patients require fewer surgical procedures and a shorter, cumulative hospital stay. Also, women who opt to undergo immediate reconstruction avoid the experience of a flat chest altogether. The viability of mastectomy skin flaps is a greater consideration in the immediate setting because of the risk of infection and skin necrosis, as mentioned previously.

Delayed Reconstruction

Delayed breast reconstruction offers the ability to deliver adjuvant therapies without compromising the reconstructed breast. Especially with autologous breast reconstruction, radiated breast skin and soft tissue can be exchanged with healthy tissue when the patient recovers from adverse effects of adjuvant therapy. Also, it was seen to be a reasonable option when patients were unsure about their wishes or when they were overwhelmed with the ongoing breast cancer treatment. Loss of the breast envelope and need of a larger skin paddle with autologous flap reconstruction are two main disadvantages of delayed reconstruction. Today, truly delayed reconstruction is usually performed when there is no plastic surgeon readily available at the time of mastectomy. In high-volume centers, delayed-immediate reconstruction is a variant that is becoming the standard of care because it has several emotional and cosmetic outcome advantages over truly delayed reconstruction.

Delayed-Immediate Reconstruction

The delayed-immediate paradigm aims to circumvent the problems associated with loss of the breast envelope encountered with immediate reconstruction and the risk of radiating a newly reconstructed breast with healthy autologous tissue. A temporizing tissue expander is placed at the time of mastectomy to maintain the skin envelope in case the patient needs adjuvant radiation therapy. If final pathology results mandate radiation therapy, the expander can be deflated to facilitate the treatment. Once radiation therapy is completed, if the envelope has contracted it can be reexpanded gently to accommodate an implant, or the expander can be removed and replaced with autologous tissue. The latter route is perhaps preferable because of the significant risks of both short- and long-term reconstructive failure with implant-based reconstructions in the irradiated breast.

RECONSTRUCTIVE TECHNIQUES (FIG. 1)

Oncologic Reconstruction

This method refers to performing a lumpectomy surgery by utilizing breast reduction techniques. A plastic surgeon helps the surgical oncologist design a resection pattern that will remove the breast pathology with necessary margins while leaving enough and appropriately distributed breast tissue behind for a cosmetically acceptable breast shape and volume. Because the majority of these patients will require adjuvant radiation therapy, patients should be informed adequately regarding complications related to delayed wound healing.

Implant Based Reconstruction

Two-Stage Reconstruction

This more traditional implant-based breast reconstruction technique involves placing an expander into a subpectoral or prepectoral pocket as the first stage. Around 3 weeks after surgery, the patient returns to the clinic, and the expansion process starts by injecting saline (usually 50–150 mL per visit) into the expander port. Once the desired volume is achieved, the patient is scheduled for the second stage, which involves exchange of the expander with an implant. Although this might be a time-consuming process with several office visits, it offers better control over breast position, size, and shape. Also, arguably a tissue expander puts less stretch on fresh mastectomy flaps during the first-stage surgery.

Whether to choose a subpectoral versus prepectoral plane is an ongoing debate in the field and requires shared decision making

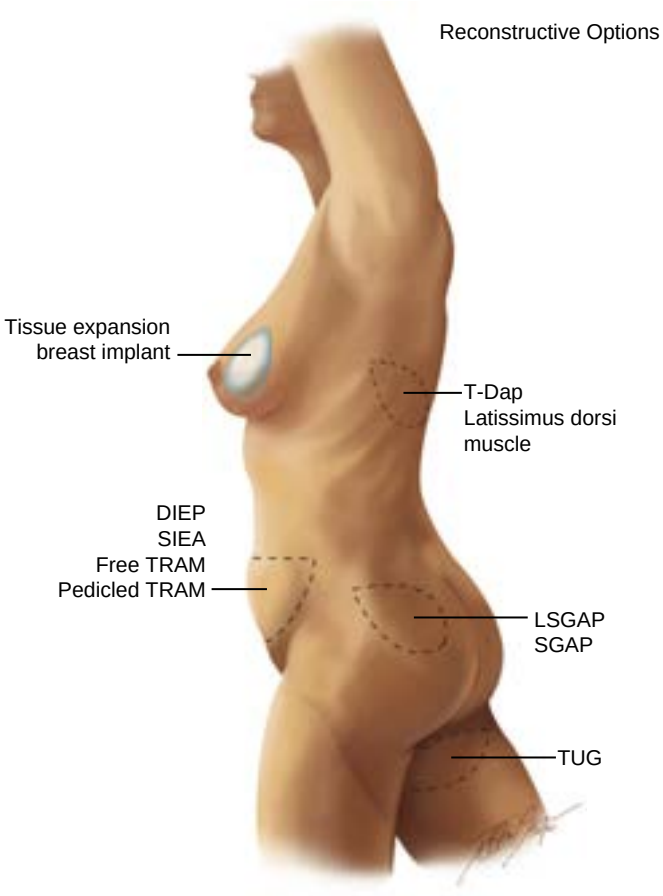

FIG. 1 Reconstructive options.

between the surgeon and patient with meticulous examination of the patient's skin and body habitus. For patients with thin mastectomy skin flaps, especially when there is concern for tissue viability, an additional muscle layer covering the expander can avoid exposure and potentially salvage the expander in case of tissue necrosis. Also, muscle coverage usually gives a smoother and more natural transition to implant on the superior pole. On the other hand, implants placed in the subpectoral plane usually create more discomfort during the expansion period given the increased muscle tension. Also, physically active women often complain about the animation deformity and displacement of implants superiorly with pectoralis muscle contraction. Because the subpectoral technique requires use of only a small piece of ADM (usually 8 × 16 cm) as a sling to cover the lower outer portion of the implant, it usually carries less seroma risk, with decreased cost compared with the prepectoral technique in which the entire anterior surface of the implant is covered with ADM. The prepectoral plane offers less discomfort during the expansion period but carries its own disadvantages. With mastectomy skin flap loss, expander salvage would be less likely, seroma formation can be problematic with extended drain stay, and a rippling deformity on the skin can result from inadequate soft tissue coverage over the implant. Revision surgeries with fat grafting can greatly mitigate these issues.

Single-Stage Reconstruction

Because the prepectoral plane precludes a tight inadequate submuscular space, a single-stage direct implant placement can be possible with this technique. Once again, because of mastectomy flap–related concerns, this is a less preferred technique, particularly for surgeons in a breast center where the oncologic surgeon creates these skin flaps. A small- to medium-size implant can be placed under thick and well-perfused mastectomy skin flaps after wrapping circumferentially with ADM. An indocyanine green angiogram can be utilized to assess viability of skin flaps before proceeding with implant placement.

Acellular Dermal Matrices

ADMs are cadaver-derived biologic sheets of dermis that support revascularization by ingrowth of blood vessels from adjacent tissues and, ultimately, integrate into the skin. Although there is controversy in the literature regarding their impact on increased infection and seroma formation rates, they are usually an essential part of implant-based breast reconstruction with acceptable risks.

COMPLICATIONS

Capsular Contracture

Capsules forming around the implants are normal physiologic responses to the insertion of foreign material in the body. Hematoma formation, radiation therapy, infection, subclinical bacterial contamination of the implant, implant rupture, and patient-related factors can all trigger an exaggerated physiologic response resulting in a firm, tight, and displaced breast pocket. This can create a wide spectrum of symptoms from mild firmness with palpation to chronic pain based on the severity of capsular contracture. A plastic surgeon may need to remove the entire capsule (capsulectomy) or revise it (capsulotomy). Sometimes a change in the tissue plane can create the most predictable and satisfying outcomes with complete resolution of the symptoms.

Infection

Implant infections usually arise in the subacute postoperative period (20–30 days), and patients commonly present with a red breast and a history of pyrexia or feeling generally unwell. Implant infections without systemic manifestation should be managed by oral antibiotics first, most commonly linezolid and high-dose ciprofloxacin. Signs of sepsis, recurrence of symptoms after completion of antibiotic course, or no improvement with initial antibiotics all warrant explantation of the implant. In exceptional circumstances, it might be possible to irrigate the breast pocket and place a new implant in the immediate setting, but reinfection rates are generally high, and patients must be counseled accordingly.

Implant Rupture

Implant rupture rates have been reported to be to be as high as 10% to 20% at 10 years after breast reconstruction. The US Food and Drug Administration (FDA) recommends performing the first ultrasound or magnetic resonance imaging (MRI) examination at 5 to 6 years postoperatively, and then every 2 to 3 years thereafter for asymptomatic patients. For symptomatic patients, an MRI is recommended at any time postoperatively.

Clinical signs of a ruptured saline implant are usually very clear, with significantly decreased breast volume and distortion in the breast shape on the affected side. However, a silicone implant rupture can be clinically asymptomatic, with minimal symmetry issues or physical examination findings.

Breast Implant-Associated Anaplastic Large Cell Lymphoma

Breast implant-associated anaplastic large cell lymphoma (BIA-ALCL) is a new form of T-cell, non-Hodgkin lymphoma arising within the capsule of breast implants and is currently thought to arise in relation to primarily textured implants. The true incidence is unknown, but current estimates range between 1 in 3187 to 30,000 women with textured implants. The etiology of BIA-ALCL remains elusive, but tonic activation of the immune system in relation to either subclinical infection or inflammation is considered as the

underlying drive for lymphomagenesis. Patients commonly present with late-onset seroma formation on the effected breast (on average 7 years after insertion). Needle-guided aspiration with cytologic evaluation for CD30-positive cells confirms the diagnosis. Capsulectomy alone is curative for disease confined to the capsule, but adjuvant therapies such as chemotherapy or monoclonal antibodies may be required for extracapsular spread.

AUTOLOGOUS RECONSTRUCTION

Although over 70% of breast reconstructions performed in the United States are implant based, free flap reconstruction has advanced significantly in the past two decades, and abdominal-based perforator flaps have become increasingly common in autologous breast reconstruction. Autologous reconstruction is commonly accepted as a preferred technique after radiation therapy because it exchanges the thin, discolored, and contracted skin and soft tissue with healthy tissue. The primary advantage of autologous reconstruction is absence of prosthetic device–related complications with more natural feel as they are made of vascularized tissue. Long recovery time, emotional and physical distress in case of flap loss, donor site morbidities, and wound healing–related problems are main disadvantages of autologous breast reconstruction. Although autologous reconstructions require a greater investment of time at the time of reconstruction, over a lifetime they can offer more favorable outcomes and incur less of a healthcare and economic burden than implant-based reconstructions, particularly in patients who underwent radiation therapy.

Abdominal Free Flaps

Replacing tissue loses is essential to achieve functionally and aesthetically pleasing outcomes; therefore, the ideal tissue for breast reconstruction is fat with or without skin (Fig. 2). Because of the availability and quality of the soft tissue with an acceptable postsurgical scar pattern, abdominal-based flaps are the most commonly used autologous tissues for breast reconstruction. In the past two decades, advancements in microsurgical skills have allowed reconstructive surgeons to raise the abdominal skin and the underlying fat tissue without damaging the rectus muscle as much as in previous techniques. Several studies reported superior donor site outcomes (less ventral hernia, abdominal bulging, and pain) and patient satisfaction rates with deep inferior epigastric artery perforator flaps (DIEPs) compared with the more conventional pedicled transverse rectus abdominis muscle (TRAM) flaps.

The skin of the abdomen is supplied by blood vessels that are originating from the deep epigastric artery and perforating through the rectus abdominis muscle and its fascia in a predictable manner. The skin and fat of the abdomen can be raised by dissecting these perforators with a varying degree of accompanying muscle and following the deep inferior epigastric artery to its origin at the external iliac artery. In the majority of patients, it is possible to raise this flap without sacrificing muscle because of the suitable trajectory and caliber of the perforators. Therefore, the donor site morbidity is minimized by preserving the musculature and its innervation. However, in some instances, the caliber of perforators is too small; therefore, some or all of the rectus muscle must be included to ensure adequate blood supply to the flap. Both sides of the abdomen can be harvested to reconstruct both breasts at the same time, or both sides can be used to reconstruct one breast where greater volume is required. Abdominal flaps can also be raised with cutaneous nerves that pierce the anterior rectus fascia to supply the overlying skin. These can be coapted to nerves at the recipient site with a view to restoring protective and proprioceptive sensation to the breast.

The incidence of abdominal bulge/hernia is reported to range from 1% to 3% for DIEP flaps to up to 20% with TRAM flaps. It is therefore recommended that where muscle is taken, a formal

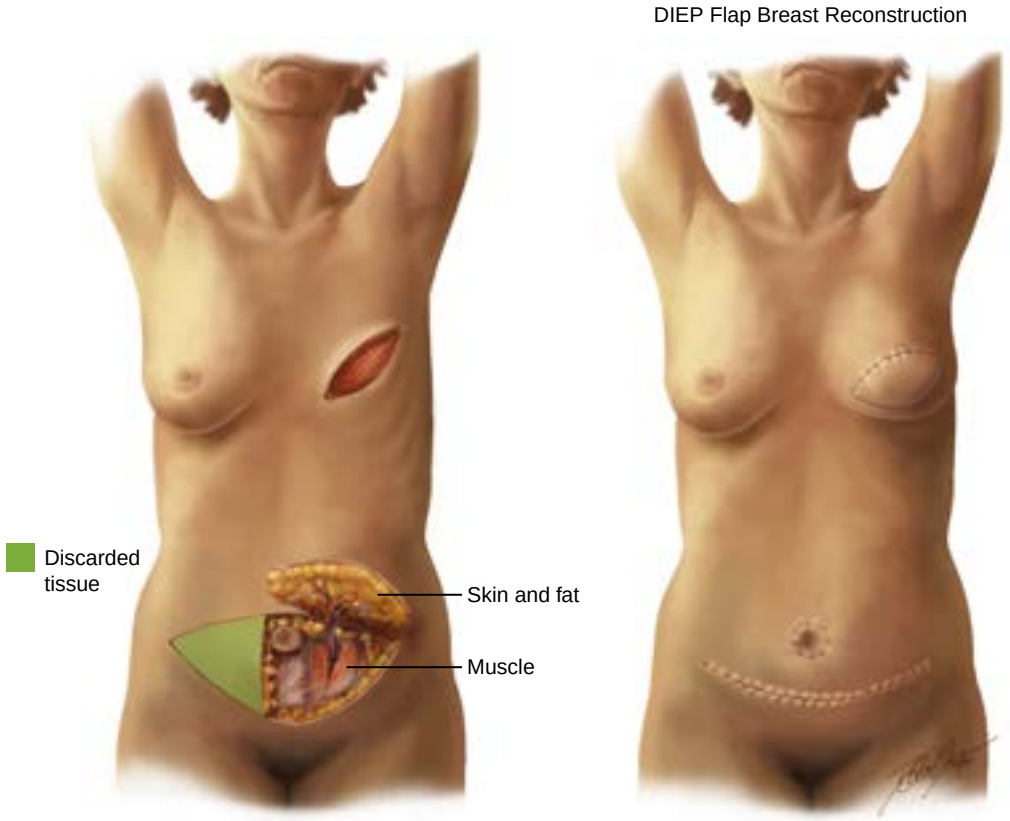

FIG. 2 Deep inferior epigastric artery perforator (DIEP) flap.

permanent mesh repair is performed to reduce this risk. The resultant donor site scar from an abdominal flap harvest is designed to stay as low as possible based on the perforator location seen on three-dimensional computed tomography angiogram or MRI angiogram and extends from hip to hip.

Before starting the ischemia time by clipping the vascular pedicle at the abdomen, the breast pocket should be prepared for flap inset, and the recipient vessels should be exposed and prepared for microsurgical anastomosis. The internal mammary artery and vein are the most common recipient vessels, and the preferred location for exposure is the second or third intercostal space (Fig. 3). Thoracodorsal vessels are the second most commonly used vessels in the axilla. Once the recipient vessels are ready for anastomosis, the ischemia time is started by clipping the deep inferior epigastric vessels as proximal as possible to obtain an adequate pedicle length. Venous anastomosis is usually performed first to avoid perfusing the flap without outflow, which might result in early congestion. For arterial anastomosis, 8-0 or 9-0 nylon sutures are usually placed in interrupted fashion. The flap is then inset loosely and carefully inside the breast pocket to avoid vessel kinking and congestion. The patient usually is transferred to a floor where hourly flap monitoring is available. Patients are usually discharged to home in 3 to 5 days.

Other Perforator Flaps

Gluteal soft tissue has been considered as a viable option when the abdominal donor site is not available because of inadequate tissue volume or damaged perforators caused by prior surgical procedures. Gluteal flaps like the superior gluteal artery perforator (SGAP) and the inferior gluteal artery perforator (IGAP) can sustain soft tissue with consistent vascular anatomy, good skin color match, and excellent thickness and texture of subcutaneous fat. However, difficult dissection of perforators, short pedicle length, and patient positioning–related problems make them less favorable choices compared with the new-generation perforator flaps such as the transverse upper gracilis (TUG) and profunda artery perforator (PAP) flaps in our practice.

The medial thigh is currently regarded as the second-line choice for autologous tissue. Thigh-based perforator flaps offer a discrete donor site scar in the groin crease. The TUG myocutaneous flap is based on perforating blood vessels traversing the gracilis muscle to supply the overlying skin. The profunda artery perforator flap is also raised from the medial thigh but sits posteriorly to the TUG flap. It is supplied by the perforating branches (second or third) of the profunda artery that pierce the adductor magnus posterior to the gracilis. The advantage of this over the TUG flap is that it usually offers a longer pedicle; however, both medial thigh flaps usually offer only a small amount of volume for transfer.

Pedicled Latissimus Dorsi Flap

The latissimus dorsi flap was more commonly used in the late 80s and 90s. It is raised based on the thoracodorsal vessels. A skin paddle can be designed transversely below the tip of the scapula so the scar can be hidden in the bra line when closed. This robust flap can be harvested in a short period because of its reliable anatomic landmarks. Although the latissimus flap rarely provides sufficient volume to reconstruct a breast, it becomes a viable option after failed microsurgical flaps. An implant can also be placed to increase the breast volume under the latissimus muscle at the anterior chest wall. The donor site can sometimes be problematic with prolonged seroma drainage. Also, studies suggest that there may be some degree of upper-limb/shoulder weakness, and up to 30% has been reported.

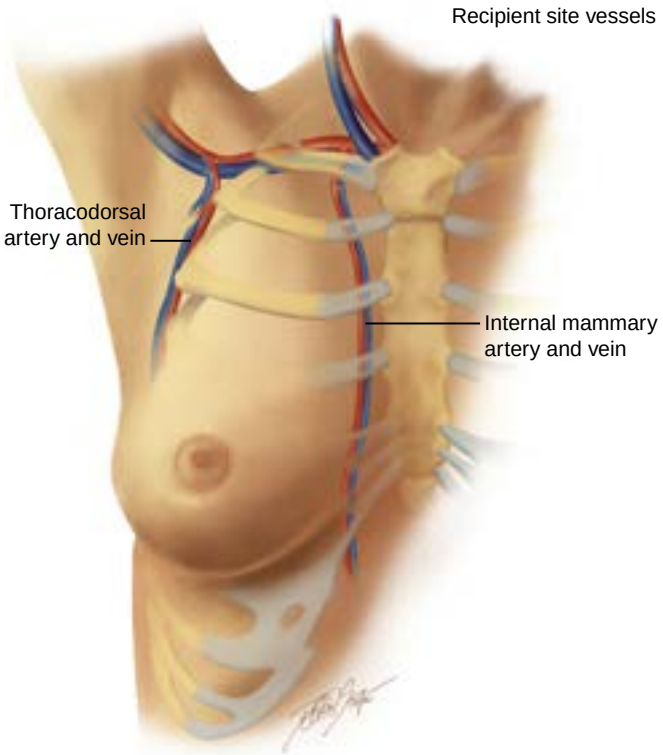

FIG. 3 Recipient vessel options.

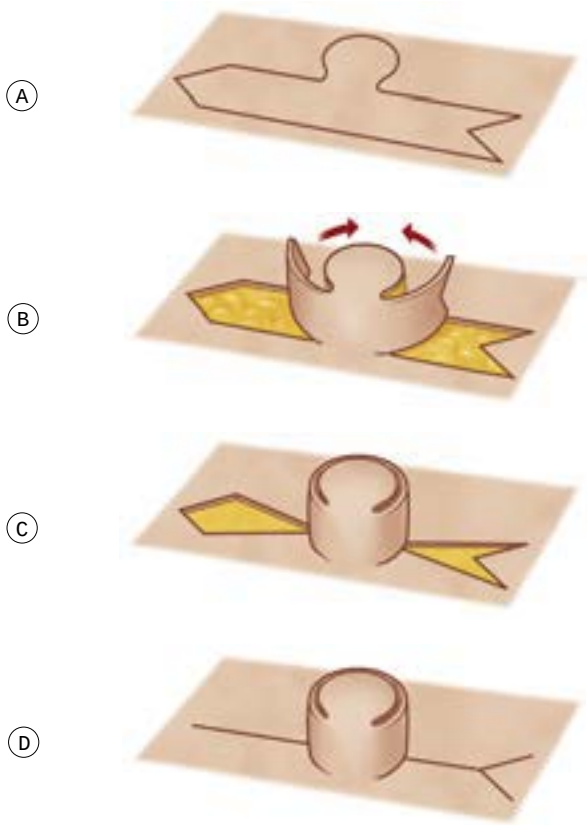

FIG. 4 Nipple reconstruction. *(From Neligan P. Plastic Surgery, 4th ed. Volume 5. Philadelphia: Elsevier; 2018.)*

REVISION SURGERIES

Fat Grafting/Lipofilling

A thin mastectomy skin flap that is inadequate to cover the underlying implant can give an unnatural appearance to the breast reconstruction with prominent implant borders, especially in the upper and medial poles. Also, patients with upper-pole deflation can require additional tissue to improve cosmesis. Liposuction of excessive fat from the abdomen, flank, and/or inner thighs can usually provide high-quality fat to improve these contour deformities. In a single stage, 100 to 150 cc of fat can be injected safely. Patients should be counseled that up to 30% to 40% of injected fat might disappear in time as a result of inadequate perfusion. Therefore, surgeons should consider multiple sessions to correct the deformities.

Nipple Reconstruction

Sparing the nipple during mastectomy may not be feasible, either because of tumor-related factors or advanced-grade breast ptosis. Patients should be counseled that there are variety of techniques available to create a new nipple as a final stage of breast reconstruction including local skin flaps, ADM-based reconstruction, or tattooing (Fig. 4).

BREAST CANCER SURVEILLANCE AFTER BREAST RECONSTRUCTION

Reconstruction with a variety of methods were found to be safe without any adverse effects on the incidence or time to detection of recurrent breast cancer. Mammogram and other imaging studies are usually not recommended to evaluate the reconstructed breast. However, patients and clinicians should continue routine examinations to detect locoregional metastasis on the chest wall, native breast skin, and regional lymph nodes.

Breast Reconstruction Following Mastectomy: Considerations, Techniques, and Outcomes, Part 2

Mark S. Burke, MD, and Dennis K. Schimpf, MD

INTRODUCTION

Breast reconstruction decreases psychological stress following extirpation of breast cancer and has been shown to not have a negative impact on cancer recurrence or survival. As a patient navigates the reconstructive process, there are many decisions to be made including the method and timing of breast reconstruction desired, which some patients find a source of additional stress on top of the cancer itself. The breast surgeon or general surgeon is often the patient's initial point of contact regarding reconstructive options, and it has been demonstrated that collaborative decision making, with medical professionals providing information regarding advantages and disadvantages of reconstructive options and patients expressing their desires for reconstruction and risk, helps patients move more smoothly through the reconstructive process. As such, it is imperative that the ablative surgeon have a sound grasp on potential reconstructive options and outcomes.

RECONSTRUCTIVE METHODS

Many different options for replenishment of lost breast volume due to mastectomy exist. Each has different advantages and disadvantages as well as ability to provide a satisfactory result both emotionally and physically for an individual patient (Table 1). Patients may have different goals for reconstruction including, but not limited to, complexity and length of the reconstructive process, tolerance to risk and potential complications, additional operative sites and scars, time in the hospital or off of work, and expectations for the final result. Additionally, patients have different comorbidities, body habitus, and potential need for breast radiation. It is important to understand all of the reconstructive options so the chosen reconstruction can be the one best suited to the patient's factors. While it is not unusual for a patient to tell their surgeon, "I just want whatever reconstruction is best!", one must understand that although there is not a *"best reconstruction,"* there may be a *"best reconstruction for this patient."*

Alloplastic Reconstruction

Alloplastic, or implant-based, reconstruction is the most common modality for breast reconstruction in the United States and is traditionally a two-stage reconstruction process. The first reconstructive procedure following mastectomy entails a tissue expander being placed in the breast pocket, either above or below the pectoralis major muscle, with or without the support of a scaffolding such as human acellular dermal matrix (ADM). The tissue expander is slowly filled with saline during serial outpatient office visits over several months to expand the remaining breast skin, which gives the patient the advantage of having some control over size and symmetry but results in an elongated timeline from start to finish. Following this, the tissue expander is removed, and a permanent implant is placed in the pocket created by the inflation of the tissue expander.

With the goal of circumventing the additional time and office visits required for traditional two-stage alloplastic reconstruction, single-stage implant-based reconstruction in which the patient goes "direct to implant" following mastectomy is becoming increasingly popular. With this technique, immediately following mastectomy, the reconstructive surgeon creates a pocket or "sling," typically with ADM, in which the permanent implant is secured to the pectoralis major muscle in the desired footprint of the breast. The native breast skin is then loosely draped over the implant, providing soft tissue coverage while the ADM scaffold supports the implant and prevents

TABLE 1 Comparison of Reconstructive Methods

	Reconstructive Method	Advantages	Disadvantages
Technique	**Expander-implant**	Smaller, low-risker operations/minimal down time; no donor site; more control of breast size	Requires foreign body; will need additional surgeries over time; poor radiation tolerance; longer time to completion; less patient satisfaction in obese
	Straight to implant	One stage to completion/minimal down time; lower-risk; no donor site	Requires foreign body; will need additional surgeries over time; poor radiation tolerance; requires careful patient selection
	Autologous	No foreign body; tolerates radiation well; behaves more like natural breast; higher patient satisfaction rates in obese	Donor site; longer, more complicated operations; more down time
	Hybrid	Very reliable (LMF); excellent implant protection/radiation tolerance; additional control of size/symmetry	Requires foreign body; donor site; more down time vs. IBR
Timing	**Immediate**	Improved psychosocial immediately after mastectomy; reduces overall number of surgeries/time to completion	Less time for patient decision-making; less time for patient optimization, surgeon coordination, increased postoperative complications compared with mastectomy alone
	Delayed	No delays to cancer extirpation; no additional complications to mastectomy	Worsened psychosocial immediately following mastectomy; issues with breast prosthesis
	Delayed-Immediate	Patient has breast(s) following immediately after mastectomy; simplifies initial reconstructive decision-making/scheduling	May cause unnecessary steps/delay to completion of reconstruction in some patients

IBR, Implant based reconstruction; *LMF*, latissimus myocutaneous flap.

excessive tension on the fresh mastectomy skin flaps. This method of reconstruction provides an immediate, one-stage reconstruction while avoiding the prolonged tissue-expansion process of the traditional two-stage technique.

Advantages to alloplastic reconstruction include the lack of a donor site from harvesting tissue as with autologous flaps and therefore a lack of pain, scars, or risk of complications anywhere except the breast(s) being reconstructed. The operation tends to be shorter and of lower risk with minimal to no time in the hospital and potentially less time off of work.

One of the biggest concerns with implant-based reconstruction is the prevention of infection. Maintaining sterility of the implants with sound surgical technique at the time of placement, healthy skin/soft tissue coverage with well-vascularized mastectomy flaps, and facilitation of good wound healing are vital to success when using a prosthetic device. Additionally, utilizing an implant-based reconstruction in a radiated breast field must be carefully considered, as alloplastic reconstructions that are radiated have a more than 4-fold risk of complications including infection, mastectomy skin flap necrosis, and capsular contracture compared with irradiated alloplastic reconstructions.

Breast Implant-Associated Anaplastic Large Cell Lymphoma

Breast Implant-Associated Anaplastic Large Cell Lymphoma (BIA-ALCL) is a non-Hodgkin T-cell lymphoma first described in 1997 and was recognized as a distinct disease associated with breast implants by the World Health Organization in 2016. As of the current literature, there have been 573 reported cases, all of which were associated with textured implants, regardless of whether they were saline- or silicone-filled. No cases have been reported in smooth implants. The risk for patients with exposure to textured breast implants is estimated at 33 per 1,000,000 in the United States. Theories of etiology include chronic inflammation and preexisting lymphoproliferative disorders. Patients may present 7 to 10 years after texture implant exposure with breast seroma, swelling, or pain around the implant, and one-third of patients have a palpable mass of the implant capsule. In rare cases, regional lymph node involvement has been reported. Diagnosis is usually derived via cytology from aspirating the periprosthetic seroma or from histologic examination of the capsule. Treatment in most cases is accomplished with implant removal and complete capsulectomy. In cases where there is significant capsule infiltration or residual disease left in the patient, adjuvant radiation should be considered. Chemotherapy is typically reserved for those cases with lymph node involvement (CHOP). This disease is rare, and typically patients tend to do very well with survival rates of 93% at 3 years and 89% at 5 years. For asymptomatic patients, even those with implants that are currently under worldwide recall, serial follow-up with history and physical is recommended rather than prophylactic removal of the implants.

Autologous

Purely autologous reconstruction utilizes the patient's own tissue to replace the breast volume lost to mastectomy without use of an implant. Autologous reconstruction provides a single-stage breast reconstruction in which the reconstructed breast is the patient's own *living* tissue. As opposed to implants, autologous tissue tends to feel more like breast tissue, will gain weight and lose weight with the patient, and be less likely to need additional revisions years after the reconstruction. Women undergoing autologous breast reconstruction have higher satisfaction with their reconstructed breast, as well

as increased psychosocial and sexual well-being years later when compared with alloplastic reconstruction.

Abdomen

The most common donor site for autologous breast reconstruction is the abdomen, where the epigastric arterial system supplies the flaps. This system consists of the superior and inferior epigastric vessels that run on the deep surface of the rectus abdominis muscles. The superior and inferior epigastric vessels are in continuity with each other via smaller "choke" vessels. The epigastric system also sends perforating vessels through the rectus abdominis muscle that helps supply the skin of the fat and abdomen. All abdominal-based breast reconstructions take advantage of this epigastric system.

The most traditional option in abdomen-based reconstruction is the *Transverse Rectus Abdominus Myocutaneous (TRAM)* flap that can be transferred either pedicled or via free tissue transfer. Both methods entail a flap design where a transverse ellipse is marked out on the lower abdominal skin with a height extending from just superior to the umbilicus to the lower abdomen several centimeters above the mons and spanning laterally from hip to hip, utilizing tissue similar to what would be removed in a cosmetic "tummy tuck" operation. The skin, fat, and entire rectus abdominis muscle is included with the TRAM flap and can be transferred in one of two manners. The simplest method of transfer is a *pedicled TRAM*, in which the inferior epigastric vessels are divided and a subcutaneous tunnel from the abdominal donor site up to the breast pocket is created through which the flap is transferred and supplied by the superior epigastric vessels. The second potential mode of transfer is to divide both the superior and inferior epigastric vessels and separate the flap completely, moving the tissue up to the breast pocket and reconnecting the flap's inferior epigastric vessels to recipient vessels near the breast (typically the internal mammary or thoracodorsal vessels) under microscopic magnification, known as a *free TRAM*. The advantage of TRAM flaps in general over other autologous options is their ease of harvest and reliability. Pedicled TRAMs do not require specialized equipment or microvascular surgical skills, while free TRAMs do. Free TRAMs, however, have a better blood supply because the inferior epigastric vessels supply the lower abdominal soft tissue directly, as opposed to depending on the superior epigastric that must travel through choke vessels. The problem with TRAM flaps compared with other autologous options from the abdomen are postoperative abdominal wall weakness, abdominal bulging, and potential need for permanent mesh for closure of the anterior rectus sheath.

The donor site problems with TRAM flaps described earlier, as well as the advancement of perforator flap dissection techniques, led abdominal-based breast reconstruction to evolve from the traditional TRAM flap to the *Deep Inferior Epigastric Artery Perforator (DIEP)* flap. This technique employs the same flap design as the TRAM flap described before, but rather than harvesting the entire rectus muscle to include *all* of the blood vessels perforating the rectus muscle from the epigastric vessels as with the TRAM, only the main one to three perforating vessels are identified during the dissection and preserved with the flap. The fascia of the anterior rectus sheath is opened vertically around the perforating vessels, exposing the rectus abdominis muscle and removing essentially no fascia. The rectus abdominis muscle is split along its fibers (with minimal division of muscle fibers) around the preserved perforating vessels to allow these perforators to be dissected down to the underlying inferior epigastric vessels. Through the split rectus abdominis muscle, the full length of the inferior epigastric vessels are dissected and included with the flap. The DIEP flap consists only of skin and fat without harvesting any of the rectus abdominis muscle or overlying fascia. It is then transferred to the breast where microvascular anastomoses and inset are carried out, similar to that described for a free TRAM flap earlier. At the abdominal donor site, the anterior rectus sheath is closed primarily with no need for synthetic mesh, even in cases of bilateral DIEP flap harvest. Because no muscle is harvested, the abdominal weakness and bulging following a TRAM is typically significantly reduced or avoided. The use of abdominal tissue in breast reconstruction leaves an acceptable scar on the lower abdomen, as well as excellent abdominal soft tissue contour that is actually sought after by some patients for cosmetic purposes. DIEP flaps have become the gold standard for autologous breast reconstruction.

Lower Extremity

In cases where an abdominal donor site is not possible (previous abdominoplasty, previous free flap from the abdomen, or a patient too thin to harvest adequate abdominal tissue for breast reconstruction), the use of the thigh is a second donor site option for autologous breast reconstruction. Options such as the *Transverse Upper Gracilis (TUG)* flap and the *Profunda Artery Perforator (PAP)* flap utilize the medial and posterior-medial skin and soft tissue of the upper thigh, respectively. Other lower extremity donor site options are *Superior Gluteal Artery Perforator (SGAP) and Inferior Gluteal Artery Perforator (IGAP)* flaps, which are harvested from the buttock.

Advantages to autologous reconstruction are that it provides a single-stage reconstruction with higher overall satisfaction rates than alloplastic techniques. The lack of a prosthetic implant significantly reduces the consequences of infection. Disadvantages are the requirement of a flap donor site with associated scarring, pain, and potential complications remote from the reconstructed breast. Additionally, autologous reconstruction requires longer, more complicated operations, in some cases requiring specialized microvascular skills as well as longer operative times, hospital stay, and time off of work.

Hybrid

Hybrid breast reconstruction refers to the use of both autologous tissue as well as some form of breast implant. The most common example of hybrid breast reconstruction is the use of a *latissimus dorsi myocutaneous* flap (LMF). In this technique, an elliptical skin paddle is designed over the latissimus muscle on the side of the breast to be reconstructed. The skin paddle is cut away from the surrounding skin but left in continuity with the underlying latissimus muscle. The surrounding skin is elevated off of the superficial surface of the latissimus muscle, and the entire muscle along with the attached skin paddle is mobilized all the way up to the humoral attachments of the muscle. Care is taken not to disrupt the thoracodorsal blood supply to the flap. A subcutaneous tunnel is then created along the axilla from the flap donor site in the back to the breast pocket, and the muscle and skin are simply passed through this tunnel to the breast. The donor site is closed primarily, and the flap is inset at the breast. As opposed to abdominal and thigh donor sites, there is typically a paucity of soft tissue associated with this flap that does not usually allow enough volume to reconstruct a breast, and as such an implant is typically used in addition to a latissimus flap breast reconstruction. A tissue expander may be positioned deep to the flap at the time of transfer, or a permanent implant may be placed immediately if there is enough tissue laxity. The latissimus flap is highly reliable with acceptable donor site morbidity. This is a reasonable first-line option for breast reconstruction, although it is becoming less popular in this regard, losing ground to pure implant-based and DIEP flap options. It is an outstanding choice to cover an implant and significantly reduce complications in a radiated breast for a patient who prefers an implant-based reconstruction or for salvage of a previously failed breast reconstruction. The only absolute contraindications for the use of this flap are previous harvest, the thoracodorsal vessels having been sacrificed from previous axillary dissection, or attempt at free tissue transfer where these vessels were used as recipients.

TIMING OF RECONSTRUCTION

Immediate

Immediate breast reconstruction typically requires coordination between the ablative surgeon and the reconstructive surgeon, with the breast surgery team performing the extirpative operation and the

reconstructive team following immediately in the same operative setting. This method allows the patient to wake up from cancer surgery with a completed, or at least in-process, reconstruction, and may help to alleviate some of the stress many patients have at the thought of waking up with no breast(s). Immediate reconstruction also reduces the total number of surgeries required and provides a faster time to completion of the reconstruction process.

There are some challenges to immediate reconstruction, however. First and foremost, the requirement of schedule coordination between the cancer surgeon and reconstructive surgeon can be an obstacle that leads to delays in a patient's cancer resection. For implant-based reconstruction, with its relatively short operative time and much lower rate or intraoperative problems and complications, this delay is typically minimal. For autologous reconstruction, especially in the setting of free tissue transfer, the need for large amounts of scheduled time on both the part of the reconstructive surgeon as well as the operating room team can cause further delays. Although these delays are typically minimized between experienced practices, they are a consideration. Additionally, reconstructive surgeons managing patients who are active smokers, or have medical issues that could otherwise be optimized such as poorly controlled diabetes or obesity, may feel more comfortable delaying a patient's reconstruction to give them the best chance for a successful result. Care must be taken not to compromise a patient's cancer care for the sake of the reconstruction. Additional considerations to immediate reconstruction are a longer operative time for the patient at the time of mastectomy, potentially a longer hospital stay, and increased risk for postoperative complications vs. mastectomy without immediate reconstruction. In some instances, a patient may have difficulty deciding what type of reconstruction they wish to undergo or feel confusion or pressure from family, friends, a spouse, other doctors, or society in general that they *must* have their breasts reconstructed. If patients are sure they wish to undergo reconstruction but are not certain which route they would like to pursue, the most reasonable option may be delayed or delayed-immediate reconstruction.

Delayed

Delaying the start of the reconstruction of the breast is an option for patients that conveys advantages and disadvantages, which are the inverse of immediate reconstruction. From the surgeon standpoint (both the ablative as well as the reconstructive), scheduling becomes less of a challenge, especially for longer autologous reconstructive plans. The breast surgeon is free to perform the cancer operation as soon as appropriate without the added concern of coordinating with the reconstructive surgeon. In turn, the reconstructive surgeon can do the same at a future date without delaying or impacting the patient's care. Additional benefits to delaying reconstruction include the opportunity for improvement of patient-related factors such as smoking cessation, weight loss, or improved control of medical issues such as diabetes before reconstruction, where these problems can have a detrimental effect on outcome. Delaying the reconstruction may also be an advantage for those patients who feel overwhelmed by all of the decisions required in planning their reconstruction and do not want to be burdened with these decisions while they are undergoing cancer treatment. Others do not feel overwhelmed but simply do not want the added surgery, visits to the reconstructive surgeon's office, or potential complications of reconstruction until their cancer treatment is further along or even complete. Reconstructive delay is also an advantage in many cases when a patient is likely to need adjuvant radiation treatment. Radiation in the setting of a purely implant-based reconstruction is a significant source of complications and reconstructive failure (see later). Even in the setting of a purely autologous reconstruction, radiating the flap can lead to changes to size, position, and feel of the reconstructed breast, which may have been improved or avoided if the reconstruction was performed after radiation.

Disadvantages to waiting for reconstruction are several as well. Many patients find the thought of waking up from mastectomy without any form of reconstruction disheartening or even completely unacceptable and may be better served with some form of immediate reconstruction. Additional skin and breast pocket space that may be available immediately at the time of mastectomy may have been resected by the breast surgeon to facilitate closure or lost to wound healing, making delayed reconstruction of the breast more difficult due to less space for the reconstructive volume and loss of tissue pliability. The number of overall planned surgeries the patient will require is also increased because the patient's initial surgery was not used as part of the reconstruction.

Delayed-Immediate

Delayed-immediate reconstruction is a method of reconstruction that attempts to take advantage of the advantages of both of the traditional *immediate* and *delayed* timing options. In this method, most reconstructive candidates have a tissue expander placed immediately at the time of mastectomy. This allows all patients to wake up from mastectomy with a reconstruction started, and because of the speed and simplicity of the reconstructive part of the process, there initially are few decisions to be made on the part of the patient. Also, coordination of the schedules between the breast surgeon and reconstructive surgeon becomes much less of an obstacle. After this, all reconstruction options are open to the patient: if they wish to continue with expander-implant reconstruction, expansion proceeds as normal, and the reconstructive process continues uninterrupted. If patients decide to have autologous reconstruction, the tissue expander preserves the breast pocket, and the reconstructive procedure can be scheduled electively without the concern of delaying the patient's cancer operation. If the patient turns out to require adjuvant radiation therapy, the tissue expander can be left in place and postradiation reconstructive plans can be made.

RISK MANAGEMENT CONSIDERATIONS

Smoking

Cigarette smoking increases the risk of postoperative complications in both alloplastic and autologous breast reconstruction. In implant-based reconstructions, smoking increases the risk of postoperative wound healing delay, mastectomy skin flap necrosis, and implant infection by 8-fold, and the risk of these complications increases exponentially when smoking is combined with obesity or breast radiation. For autologous reconstructions, smoking-related complications include both mastectomy and abdominal skin flap necrosis and hernias. The risk of smoking-related postoperative complications improves with each week of smoking cessation up to 6 weeks, and patients who quit smoking at least 4 weeks before surgery have similar complication rates to nonsmokers. Smoking cessation should be encouraged before attempt at breast reconstruction, and many surgeons refuse to perform breast reconstruction in active smokers.

Obesity

Obesity (defined as a BMI >30 kg/m^2) is a major risk factor for postoperative breast reconstruction complications such as wound healing issues, infection, seroma, and reconstructive failure. Implant complications increase with increasing BMI and jumps significantly with BMI over 35 kg/m^2. These complications are increased regardless of the reconstructive technique or timing. Additionally, obese women have greater operative time, anesthesia risk, length of hospital stay, and perioperative morbidity, with obese women being nearly twice as likely to require reoperation than nonobese. Although failure rates are elevated with both implant-based and autologous reconstruction in obese women, they are less elevated with autologous reconstruction. In addition to the higher complication rates, patient satisfaction

with their postoperative breasts is lower for obese women as well, especially with implant-based reconstruction. Immediate microsurgical autologous breast reconstruction has been shown to yield higher satisfaction rates.

Patient Age

With approximately 75% of breast cancer diagnoses made in patients older than 65 years old, use of age alone as exclusion criteria for reconstruction results in a substantial portion of mastectomy patients without the option of reconstruction. While some studies have revealed complications rates similar between young and elderly groups when comorbidities are controlled for, other research has suggested patients older than 65 years of age may be a risk factor for perioperative complications following expander/implant reconstruction but not for autologous breast reconstruction where no difference in complications rates were found between those over or under 65 years of age. While there is some conflicting data, the use of the 5-factor modified frailty index (mFI-5),which looks at functional status, diabetes, chronic obstructive pulmonary disease, congestive heart failure, and hypertension requiring medication, appears to have a stronger predictive ability for complications than age alone.

Radiation

Patients who have breast reconstructions complicated by breast radiation therapy have typically either failed breast conservation efforts and required subsequent mastectomy or required postmastectomy radiation therapy (PMRT), which may be performed either before or after the patient's reconstruction. The use of radiation increases complications for all forms of breast reconstruction, regardless of timing, but can be especially problematic with implant-based reconstructions where they elevate the risk of mastectomy skin necrosis, infection, seroma, and capsular contracture. When radiation is performed before implant-based reconstruction, reconstructive failure in this setting is reported at 14%, and complications overall at 36%. In cases where PMRT was delivered after implant reconstruction, reconstructive failure was 19% versus 3% for nonradiated patients. Risk of reconstructive loss was higher when a tissue expander was radiated vs. the permanent implant, but cosmesis was worse when radiation was delivered to the permanent implant. For patients who wish to have an implant-based reconstruction in the setting of radiation, hybrid options such as utilizing a latissimus dorsi myocutaneous flap to cover implant-based reconstructions should be considered. This option reduces implant infection and reconstructive failure by over 70%.

Autologous reconstructions fare much better in radiated fields than do implant-based reconstructions. Microvascular free flaps placed in a radiated field have been shown to have minor postoperative complications such as mastectomy skin loss or infections. They may also have higher intraoperative arterial complications requiring further arterial dissection and anastomotic revision but no increase in flap loss or fat necrosis. Additionally, these patients will not have radiation changes to the breast flap such as pigment changes or fibrosis of the skin and subcutaneous tissue. Autologous flaps placed before PMRT tolerate radiation very well and may have some increased fat necrosis but otherwise minimal increase in problems. Autologous breast reconstruction is considered by many to be the gold standard for reconstruction in a radiated field.

SUMMARY

Although more than 60% of patients choose to undergo some form of reconstruction following mastectomy, others do not feel the need to undergo reconstruction at all and others simply want to focus on dealing with their cancer treatment and not be distracted with the decisions, additional doctors, and potential complications that accompany breast reconstruction. Although all patients should be given the opportunity to understand their breast reconstruction options, a decision to forgo or delay the reconstructive part of the process should be supported.

All of our patient's concerns are valid and it is the job of the reconstructive surgeon to use the tools and techniques available to us to help fill our patients desires for breast reconstruction as best as possible, while being observant of their emotional needs as they go through this process.

Breast Implant-Associated Anaplastic Large Cell Lymphoma

Melissa S. Camp, MD, and Michele Ann Manahan, MD, MBA

INTRODUCTION

Breast implant–associated anaplastic large cell lymphoma (BIA-ALCL) was first reported in 1997, and it has emerged as a distinct type of T-cell lymphoma that develops in association with breast implants. The World Health Organization (WHO) initially categorized BIA-ALCL as a new class of lymphoma in 2016, and the National Comprehensive Cancer Network (NCCN) established the first set of evidence-based guidelines for the evaluation and management of BIA-ALCL the same year. Awareness of BIA-ALCL has gained traction over the last several years, resulting in an increased recognition and reporting of cases. This chapter will summarize the present knowledge regarding BIA-ALCL, review the current algorithm for diagnosis and treatment as published in the NCCN Guidelines version 1.2021 (last updated October 5, 2020), and address decision making regarding prophylactic management of patients who currently have breast implants.

SCOPE

BIA-ALCL is a rare peripheral T-cell lymphoma that most commonly arises in association with a current or prior textured breast implant. As of January 2020, the US Food and Drug Administration (FDA) has reported a total of 733 cases and 36 deaths from BIA-ALCL. BIA-ALCL can develop in association with breast implants that are placed for either aesthetic augmentation or reconstructive purposes and can occur with both saline and silicone implants. Implant manufacturer and shell type numbers associated with cases of BIA-ALCL are not currently evenly distributed.

EPIDEMIOLOGY

The actual incidence and prevalence of BIA-ALCL are challenging to ascertain due to multiple factors. Concerns exist regarding the accurate reporting of the overall prevalence of patients with implants, the level of detail recorded specifying the type of implant, the lack of robust implant and BIA-ALCL registries secondary to the voluntary nature of reporting, and the potential for underreporting due to lack of awareness of BIA-ALCL by providers and patients. Data collected over the years has estimated the risk of BIA-ALCL from 1 in 1 million (for all types of implants) to more recently as ranging from 1 in 3000 (for patients in Australia and New Zealand with textured implants) to 1 in 30,000 (for patients in the United States with textured implants).

Textured implants were initially developed with the premise that normal tissue growing into the textured surface would decrease capsular contracture, but it remains controversial as to whether the rate of capsular contracture is notably different for smooth versus textured implants. The classification system for implant surfaces ranges from grade 1 to grade 4 and is based on the surface area as well as the roughness of the surface, with 1 representing smooth implants and 4 representing the most textured surface. BIA-ALCL appears to be most associated with implants of grade 3 and 4 surfaces. It is postulated that the more highly textured surfaces allow for attachment of bacteria and development of a biofilm, stimulating a chronic inflammatory response and eventually leading to T-cell transformation and development of BIA-ALCL. Studies have examined the bacterial biofilms of breast implant capsules in patien' with BIA-ALCL as well as in patients with capsular contracture and have noted that gram-negative rods of the *Ralstonia* species are far more common in BIA-ALCL compared with *Staphylococcus* species in capsular contracture.

Given the rare nature of BIA-ALCL, the FDA recommends reporting of confirmed cases to the American Society of Plastic Surgeons BIA-ALCL Patient Registry and Outcomes for breast Implants and anaplastic large cell Lymphoma etiology and Epidemiology (PROFILE) registry, available at www.thepsf.org/PROFILE. Tracking of cases over time will hopefully allow for a more accurate assessment of the incidence and prevalence of BIA-ALCL.

PRESENTATION

The most typical clinical presentation of BIA-ALCL is a patient with a breast implant who develops a new fluid collection surrounding the breast implant or asymmetric breast swelling, occurring at least 1 year after the implant was placed and unexplained by other etiologies such as infection or recent trauma to the chest. The average length of time from implant placement to development of BIA-ALCL is 7 to 9 years. Far less commonly, BIA-ALCL can present as a palpable mass, lymphadenopathy in the regional lymph node basins (axillary, supraclavicular, or internal mammary), overlying skin changes such as a rash, or capsular contracture.

DIAGNOSIS AND WORKUP

For patients with breast implants presenting with a delayed fluid collection, asymmetric breast swelling, or less commonly a palpable mass, the initial step in diagnostic evaluation should be an ultrasound of the breast and ipsilateral axilla. Ultrasound can detect a fluid collection surrounding the implant, characterize a palpable mass (if present), and identify any lymphadenopathy. If ultrasound is inconclusive or indeterminant, then an MRI of the breast can be considered.

If a fluid collection is detected on ultrasound, aspiration of the fluid should be performed and the fluid sent for histopathologic evaluation. If there is any suspicion for potential infectious etiologies, a sample of fluid can also be sent for gram stain and culture. For the most accurate diagnosis of BIA-ALCL, at least 50 cc of fluid should be aspirated and sent for evaluation by cytology, immunohistochemistry, and flow cytometry. The specific tests to request include ALK (anaplastic lymphoma kinase), CD2, CD3, CD4, CD5, CD7, CD8, CD30, and CD45. BIA-ALCL is always ALK-negative and CD30-positive, and cytologic evaluation will demonstrate large anaplastic cells that express CD30. CD30 expression is nonspecific, however, and can be associated with other types of lymphoma as well as with benign inflammatory cells. BIA-ALCL will have a single clone of T cells present on flow cytometry. Correlation of the appropriate clinical context in conjunction with the cytology findings of large anaplastic cells that are ALK-negative and CD30-positive is necessary for the diagnosis of BIA-ALCL.

Patients with breast implants presenting with a breast mass on clinical examination or detected on imaging should undergo further evaluation with core needle biopsy of the mass. Pathologic evaluation should be performed using the biomarkers previously listed if there is clinical concern for BIA-ALCL, and other etiologies such as breast cancer should also be ruled out.

TREATMENT

Following histopathologic confirmation of a diagnosis of BIA-ALCL, a multidisciplinary treatment approach involving plastic surgery, surgical oncology, and medical oncology is recommended. Further imaging evaluation with a PET CT is indicated to evaluate for the

presence of any associated masses in the breast implant capsule, involvement of the chest wall, regional lymphadenopathy, and distant metastatic disease. For disease that is localized to the breast implant capsule and/or breast, the mainstay of treatment is complete surgical resection including the breast implant, total capsulectomy of the implant capsule, and resection of any masses associated with the breast implant capsule. Any suspicious regional lymph nodes should also be excised. The implant capsule, any fluid surrounding the implant, and any lymph nodes that are excised should be evaluated pathologically for complete staging of BIA-ALCL. For patients who have undergone complete surgical resection with no concern for residual disease, adjuvant therapies are not indicated. Close follow-up with clinical evaluation and examination every 3 to 6 months for 2 years, as well as consideration of annual systemic imaging with a CT scan of the chest/abdomen/pelvis or PET CT, is recommended.

If BIA-ALCL involves regional lymph nodes, or if complete surgical resection is not feasible and a portion of the capsule or residual disease remains, then adjuvant therapy is indicated. Radiation therapy can be utilized to treat local residual disease that is not amenable to surgical resection. Adjuvant systemic therapy is recommended for patients with node positive disease or in cases where radiation may not be possible to treat local residual disease. Systemic therapy is also indicated as first line treatment for patients with more advanced disease for whom surgical resection is not an option. Systemic therapy regimens that are utilized to treat BIA-ALCL include anthracycline-based regimens such as CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) or brentuximab vedotin (a CD30-targeted therapy) in combination with CHP (cyclophosphamide, doxorubicin, and prednisone).

Although the vast majority of cases of BIA-ALCL present with early-stage disease confined to a fluid collection surrounding the implant and/or involving the implant capsule, up to about 18% of cases can present with more advanced disease such as regional lymph node involvement or distant metastatic disease. As demonstrated by one study, patients with advanced BIA-ALCL were more likely to have a longer length of time from diagnosis to surgery and were less likely to have complete surgical resection compared with patients with early-stage disease.

With respect to prognosis, there are limited data regarding the overall survival for BIA-ALCL due to the rarity of the disease and the paucity of long-term follow-up. In one study of 87 patients with BIA-ALCL, the overall survival was reported as 94% at 3 years and 91% at 5 years. The ability to achieve complete surgical resection has been associated with improved overall survival and disease-free survival, as compared with incomplete surgical resection with or without adjuvant therapies. Locally recurrent BIA-ALCL is most commonly seen in patients who undergo incomplete surgical resection or partial capsulectomy.

For patients with bilateral breast implants, removal of the contralateral implant and capsule may be considered, as BIA-ALCL has been identified in the contralateral breast implant in approximately 4.6% of cases

STAGING

BIA-ALCL was initially staged according to the Ann Arbor Staging System for hematologic malignancies. Due to the behavior of BIA-ALCL being more in line with that of a solid tumor, the proposed staging system developed by Clemens et al. and included in the NCCN guidelines is based on American Joint Committee on Cancer TNM staging system. Tables 1 and 2 depict the TNM category descriptions and associated staging.

TABLE 1 Proposed TNM Category Descriptions for BIA-ALCL

TNM	Description	
T: Tumor extent	T1	Confined to effusion or a layer on luminal side of capsule
	T2	Early capsule infiltration
	T3	Cell aggregates or sheets infiltrating the capsule
	T4	Lymphoma infiltrates beyond the capsule
N: Lymph node	N0	No lymph node involvement
	N1	One regional lymph node involved
	N2	Multiple regional lymph nodes involved
M: Metastasis	M0	No distant spread
	M1	Spread to other organs or distant sites

TABLE 2 Proposed TNM Staging for BIA-ALCL

Stage Designation	Description
IA	T1 N0 M0
IB	T2 N0 M0
IC	T3 N0 M0
IIA	T4 N0 M0
IIB	T1-3 N1 M0
III	T4 N1-2 M0
IV	T any N any M1

FDA WARNINGS ON IMPLANTS

In response to concerns regarding the association between textured implants and BIA-ALCL, the FDA requested that Allergan recall Natrelle BIOCELL textured breast implants and tissue expanders in July 2019. The FDA's recommendation was based on the report of 481 out of 573 cases of BIA-ALCL worldwide being attributed to Allergan breast implants, resulting in a 6-fold higher risk of BIA-ALCL with Allergan textured implants compared with textured implants produced by other manufacturers. In addition, 12 of 13 deaths in patients with BIA-ALCL where the manufacturer of the implant was known had Allergan implants. The manufacturer was unknown for 20 additional deaths. Allergan complied with the FDA's request, and removed the specified Natrelle BIOCELL textured breast implants and tissue expanders from the worldwide market. BIOCELL is a unique textured surface that is found only in Allergan textured implants.

In the United States, textured implants represent approximately 10% of all breast implants. The FDA released labeling guidance for all breast implants (textured and smooth) in September 2020, with recommendations for a boxed warning stating that breast implants have been associated with BIA-ALCL, that BIA-ALCL occurs more commonly in patients with textured as opposed to smooth implants, and that deaths have occurred from BIA-ALCL. Moreover, the FDA recommends that breast implant information brochures provided to patients contain a decision checklist that indicates the risk of BIA-ALCL.

DECISION MAKING REGARDING PROPHYLACTIC MANAGEMENT

For patients who currently have breast implants (textured or smooth) and are asymptomatic, removal of implants as a precautionary measure is not recommended. Rising public awareness, discussion amongst medical professionals, and media coverage of BIA-ALCL have led to increasing inquiries regarding prevention of BIA-ALCL among patients, in educational forums, and during patient-physician encounters. Methods to potentially mitigate risk are frequently queried in the absence of any worrisome clinical symptoms and signs. Management of these concerns encompasses addressing patients' fears regarding potential development of BIA-ALCL in the future, rather than simply appropriately diagnosing and treating the disease if it occurs. Moreover, patient concerns related to BIA-ALCL are often intertwined with concerns regarding a constellation of symptoms commonly referred to as "breast implant illness." Literature in these areas is increasing, but consensus is not easily defined and controversy still exists.

Patients may request explantation, without replacement, of their breast implants. Recently, the number of implant explantation surgeries has been increasing (33% increase from 2018 to 2019, with more than 33,000 explantations performed in 2019). These surgeries can be associated with significant negative implications regarding chest aesthetics, and the true effect on risk mitigation is difficult to quantify. As a result, careful consideration of all options and thorough discussion with patients remains critical.

Patient-reported outcomes are integral to the justification of surgical decision making when considering explantation of implants for prophylactic reasons. Existing literature has demonstrated increased patient satisfaction and well-being following breast implant explantation in both symptomatic and worried patients. Studies have shown statistically significant subjective health improvement (in the realms of vitality, mental health, and body area satisfaction) and breast implant illness symptom resolution after explantation in patients experiencing preoperative concerns; with increased postoperative improvement associated with a greater magnitude of preoperative concern. Additionally, explantation regret has been minimal in several studies. The quality of the literature, however, is plagued by small sample sizes, complex and nebulous clinical scenarios, and questionable broad applicability of findings. Documented opportunities for psychological and physical improvement, or simply respect for patients' wishes, can justify explantation as a viable treatment option when considering the entire patient, rather than just the breast. Previously, Slavin and Goldwyn wrote, "Satisfying the needs in these patients emphasizes the importance and necessity of the surgeon taking the time to understand what the patient wants." Patient desire for removal of their implants may be an adequate sole justification for explantation.

SOFT TISSUE MANAGEMENT FOR PROPHYLAXIS

While en bloc capsulectomy is recommended for suspected or proven cases of BIA-ALCL, the appropriate management of the implant capsule in prophylactic explantation cases is less clear. Literature is lacking with respect to demonstrating clear benefits of prophylactic en bloc capsulectomy. Standard capsule management for implant revisions and removals includes capsulotomy as well as capsulectomy (partial, complete, or en bloc). Capsulectomy may decrease future risks related to any influence of proinflammatory substances, microbiomes, and genetics of capsules and periimplant tissues. Further confusion arises due to the fact that within the existing literature, "capsulectomy" may actually refer to "partial" capsulectomy, or total capsulectomy performed only in certain circumstances, with many authors accepting remnants of thin capsular tissue in surgical beds of asymptomatic patients.

Focusing solely on the physical results of surgery rather than on reduction of risk for future development of BIA-ALCL, capsulectomy may decrease risk for seromas, palpable or radiographic masses, and silicone retention; but it carries potential additional risks like increased operative time and expense, larger incisions, increased morbidity, pain, increased recovery time, risk of pneumothorax, and thinning of the soft tissue envelope. Potential contraindications to capsulectomy include thin capsules, thin overlying soft tissue of the breast/chest, a capsule that is densely adherent to chest wall structures, and use of the capsule for pocket management (such as lateral plication, inframammary fold revision, or symmastia correction). In reality, factors including characteristics of the implant (such as the composition of the implant contents and outer shell), size and shape of the implant pocket, thickness of the implant capsule, capsular contracture, silicone granulomas, calcification, implant rupture, infection, and carcinoma may affect decision making for any individual patient.

SUBSEQUENT RECONSTRUCTION

Reconstruction after BIA-ALCL is a realistic consideration if complete surgical ablation of the disease is achieved. While some authors have placed smooth implants following a diagnosis of BIA-ALCL, many patients and other authors would advocate for autologous tissue techniques such as mastopexy, fat grafting, and flaps. Patients who elect to undergo explantation of their implants for prophylactic reasons are also likely to look more favorably upon autologous methods of reconstruction.

Explicit patient counseling is recommended regarding the potential for undesirable postexplantation aesthetic results such as ptosis, nipple retraction, skin laxity, and hollow upper poles, as well as wide, deflated, "aged," and laterally displaced breasts. Studies have documented a wide spectrum of patient reactions to explantation, ranging from improvement to satisfaction to dissatisfaction and even feelings of mutilation. Various reconstruction techniques have not been reliably linked to any of these patient reported outcomes. There are many reported reconstruction methods with varied incisions, pedicles, flaps, and management of the implant pocket. The potential options for reconstruction will differ in patients who had implants placed for aesthetic augmentation versus patients who had implants placed for reconstruction following mastectomy. The quality and volume of the remaining soft tissue envelope, nipple and areola ptosis and size, implant size and position, and skin elasticity will all affect aesthetics of the postexplantation results and the available reconstruction options.

Insufficient breast tissue, poor quality skin, and history of radiation therapy are all factors that can make patients less ideal candidates for soft tissue redistribution techniques. Many patients with a history of implants will have the poorest quality tissue in the inferior pole, as a result of mechanical pressure and aging, particularly if the implants have been present for many years. This may make them poor candidates for many described autoaugmentation techniques. Volume can be reintroduced with autologous tissue transfer using distant flaps from donor sites such as the abdomen, but these procedures carry additional scar burdens. Literature has reported techniques for reintroduction of volume using other materials, such as acellular dermal matrix and fat grafting.

Regardless of the planned reconstruction method, timing of these techniques can be debatable. Immediate reconstruction when BIA-ALCL is suspected or proven has been performed, but should be considered only when preoperative workup and imaging demonstrate disease confined to the implant capsule. Otherwise, staging reconstruction 6 to 12 months later is likely prudent. In the setting of implant explantation solely for prophylactic purposes, reconstruction may be pursued in an immediate or delayed fashion based on anatomic considerations. In these situations, it is important to recognize that the scarring and uncontrolled contracture that can occur

in the absence of immediate reconstruction may be challenging to correct at the time of delayed reconstruction.

CONCLUSION

BIA-ALCL is a rare type of lymphoma most commonly associated with textured breast implants. The precise underlying etiology of BIA-ALCL is currently unknown, but it is hypothesized that the interaction between a bacterial biofilm and the textured implant surface may stimulate a chronic inflammatory response leading to transformation of T cells. Although the risk of developing BIA-ALCL is difficult to quantify, it is estimated to be 1 in 3000 to 1 in 30,000. Awareness on the part of patients and providers of the existence of BIA-ALCL and its presenting symptoms are key to early diagnosis and appropriate treatment.

In patients who present with a delayed fluid collection surrounding a breast implant, inclusion of BIA-ALCL in the differential diagnosis as well as appropriate histopathologic evaluation to confirm the diagnosis are essential. The vast majority of cases of BIA-ALCL are diagnosed at an early stage, and achieving complete surgical resection (removal of the implant, total capsulectomy of the breast implant capsule, and any masses associated with the implant capsule) portends an overall good prognosis. For patients who present with more advanced BIA-ALCL, systemic therapy is recommended, and radiation therapy may also be indicated. For patients who desire prophylactic explantation of their implants, a thorough discussion of the risks, benefits, spectrum of potential outcomes, and subsequent reconstruction options is essential.

Adrenal Incidentaloma

Whitney Sutton, MD, MHS, Shkala Karzai, MD, and Aarti Mathur, MD, PhD

An adrenal incidentaloma is defined as an adrenal mass identified on imaging performed for an indication other than suspected adrenal disease. With increasing utilization of cross-sectional imaging over the past several decades, 40% of adrenal masses are now discovered incidentally. It is estimated that 1% to 8% of adults have an adrenal incidentaloma, and the incidence increases with age.

The initial diagnostic evaluation of an adrenal incidentaloma must (1) assess the risk of malignancy and (2) determine whether it is hormonally active. Of the functional lesions, the most common is Cushing's syndrome followed by pheochromocytoma and aldosteronoma. Once the diagnosis is achieved, if surgery is indicated, the benefits and risks of surgery should be considered and the operative approach determined. Finally, postoperative or nonoperative surveillance must be established.

INITIAL EVALUATION

The initial evaluation of an adrenal incidentaloma consists of: (1) A comprehensive history and physical examination to elicit signs and symptoms of adrenal hormone excess and cancer history, (2) radiologic evaluation, and (3) biochemical evaluation to determine risk of malignancy and functionality (Fig. 1).

The most common signs and symptoms in patients with hypercortisolism include hypertension, obesity, and hyperglycemia/diabetes (Table 1). They can also present with osteoporosis, facial plethora, proximal muscle weakness, easy bruising, weight gain, cutaneous abdominal striae, buffalo hump, and moon facies. Signs and symptoms of catecholamine excess are present in over 60% of patients with a pheochromocytoma and include hypertension, episodes of severe headaches, palpitations, perspiration, anxiety, abdominal pain, and nausea or vomiting. Patients with hyperaldosteronism may present with a history of asymptomatic or symptomatic hypokalemia, refractory hypertension, or fluid retention. In assessing for primary malignancy or metastasis, a personal history of cancer, smoking history, or recent weight loss should be elucidated. Hirsutism or feminization may represent physical signs of sex hormone excess, which can accompany adrenocortical carcinoma. In addition to the aforementioned signs and symptoms, particular attention should paid to the patient's vitals signs as an elevated systolic and diastolic blood pressure and/or heart rate are consistent with hypercortisolism, hyperaldosteronism, and pheochromocytoma.

Radiographic Assessment

The primary goal of imaging studies is to evaluate for radiographic features that portend a higher risk of malignancy. Although CT is the most commonly used imaging modality, MRI is preferred in children, adolescents, and pregnant women (Figs. 2 and 3). A triple-phase CT scan with and without intravenous contrast including arterial-enhanced, venous-enhanced, and delayed images of the adrenal glands is ideal for initial radiographic assessment as this imaging modality is readily available and provides excellent anatomic guidance should patients require surgery. Several specific radiographic features on CT should be considered to assess for malignancy or need for surgical resection. These are discussed in the following sections.

Size

Adrenal mass size >4 cm has been associated with an increased risk for cancer across several studies. Prior studies have approximated a 2% risk of adrenocortical carcinoma in masses <4 cm, a 6% risk in masses measuring 4 to 6 cm, and a 25% risk in masses >6 cm. However, size must be considered along with additional radiographic features in determining the threshold for surgery. The majority of incidentalomas >6 cm should undergo adrenalectomy. Management of benign-appearing, nonfunctional incidentalomas 4 to 6 cm in size is controversial, and either adrenalectomy or active surveillance can be offered for the appropriately selected patient. Myelolipomas, for example, can present as large adrenal lesions, but they have distinct radiographic features and do not necessitate surgery at >6 cm unless the patient is symptomatic.

Computed Tomography Features

CT characteristics that differentiate lesions from one another include margins, shape, heterogeneity, attenuation, and washout. Typical benign features include distinct and smooth margins, round shape, and homogenous composition. Attenuation of <10 Hounsfield units (HU) without contrast and rapid (>60%) absolute washout on 15-minute delayed-phase images is characteristic of lipid-rich benign adenomas. In contrast, lipid-poor lesions, such as malignant tumors, have a density >10 HU without contrast. However, 20% to 30% of benign adenomas can be lipid poor. Contrast enhancement and percentage of contrast washout convey information related to the vascularity of lesions. Lesions with increased vascularity, such as malignant tumors, demonstrate strong arterial enhancement and absolute washout <60% on delayed-phase imaging. Further features suggestive of malignancy include large size, irregular borders, heterogenous composition, central necrosis, and local invasion into surrounding structures. Pheochromocytomas may be difficult to distinguish from malignant lesions on CT as both have a high density, enhance, and have <60% washout. Additionally, central necrosis and calcifications may be present in pheochromocytomas. Pheochromocytomas, however, do not have the same predilection for local invasion as adrenocortical carcinomas and are distinguished by biochemical testing. Myelolipomas are composed of mature adipose tissue and interspersed areas of myeloid tissue. These features provide a characteristic appearance on CT of a well-circumscribed mass with areas of higher attenuation intermixed with areas of predominantly

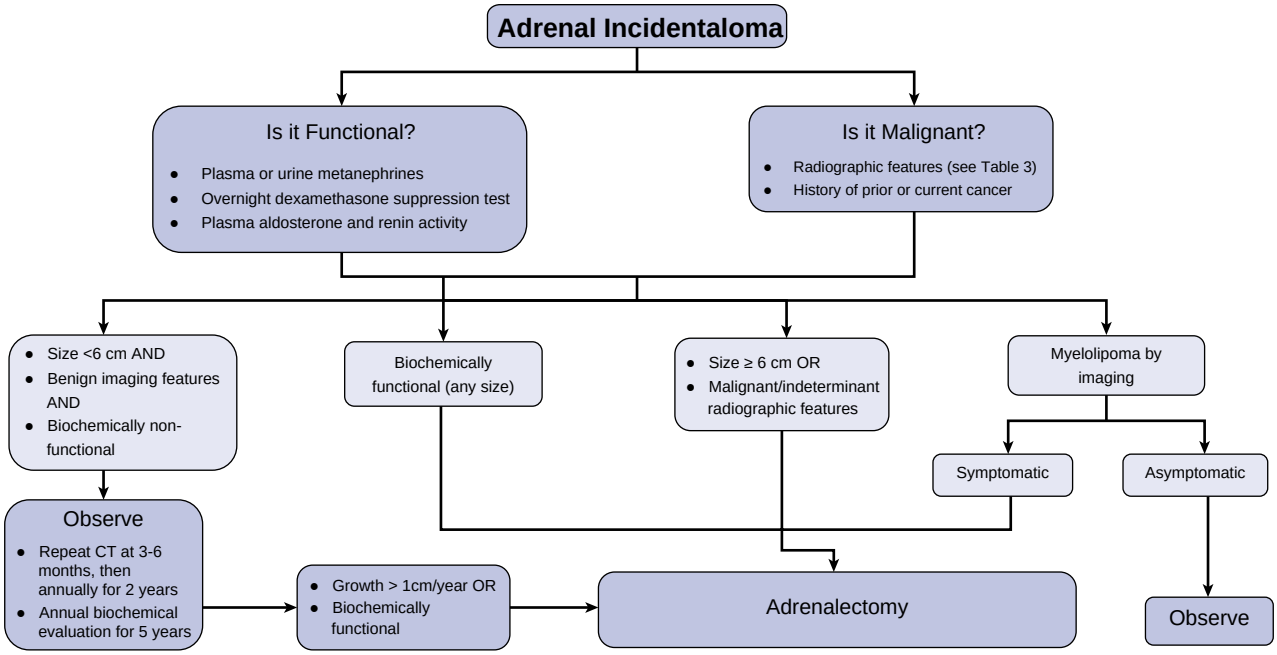

FIG. 1 Initial evaluation for a patient with an adrenal incidentaloma.

TABLE 1 Differential Diagnosis for an Adrenal Incidentaloma

	Nonfunctional	Functional
Benign	• Adenoma • Cyst • Ganglioneuroma • Hemangioma • Hemorrhage • Infection (tuberculosis, fungi) • Granulomatous disease (sarcoidosis) • Lymphangioma • Myelolipoma • Pheochromocytoma • Schwannoma	• Adenoma • Cushing's syndrome • Pheochromocytoma • Aldosteronoma • Micronodular or macronodular hyperplasia
Malignant	• Adrenocortical carcinoma • Metastatic cancer from a non-adrenal primary tumor (lung, renal cell, melanoma)	• Adrenocortical carcinoma • Pheochromocytoma

low attenuation, measuring −130 to −23 HU without contrast. Myelolipomas can be diagnosed on the basis of imaging alone.

Magnetic Resonance Imaging Features

MRI for evaluation of the adrenal glands includes contrast-enhanced and T1- and T2-weighted images of the entire abdomen. In-phase and out-of-phase images of the adrenal glands are also performed to evaluate the fat content of lesions. A loss of signal intensity on out-of-phase images indicates fatty composition, which is compatible with lipid-rich lesions such as adenoma or myelolipoma. A lack of signal drop in out-of-phase images is more suggestive of malignancy or pheochromocytoma. These dense lesions show high signal intensity in T2-weighted images on MRI. Large pheochromocytomas and cancers can demonstrate heterogenous signal intensity that is related to the cystic and necrotic degeneration that may accompany large lesions. A classic "light bulb" T2 signal can be found in 11% of pheochromocytomas. Similar to their appearance on CT, pheochromocytomas and malignant lesions will demonstrate strong contrast enhancement following injection of gadolinium. Myelolipomas appear hyperintense on T1-weighted images (macroscopic fat) with regions of hypointensity caused by the presence of interspersed marrow elements.

Molecular Imaging

[$^{123/131}$I] Metaiodobenzylguanidine (MIBG) scintigraphy, FDG-PET/CT, and DOTA-PET/CT are molecular imaging tests available for the evaluation of adrenal malignancies and neuroendocrine tumors. The clinical utility of molecular imaging includes staging of malignancies (PET/CT) and localization of pheochromocytomas (MIBG). FDG-PET/CT carries a sensitivity and specificity of 100% and 98%, respectively, in differentiation of malignant and benign lesions. FDG-PET/CT should be used in patients in whom a high clinical

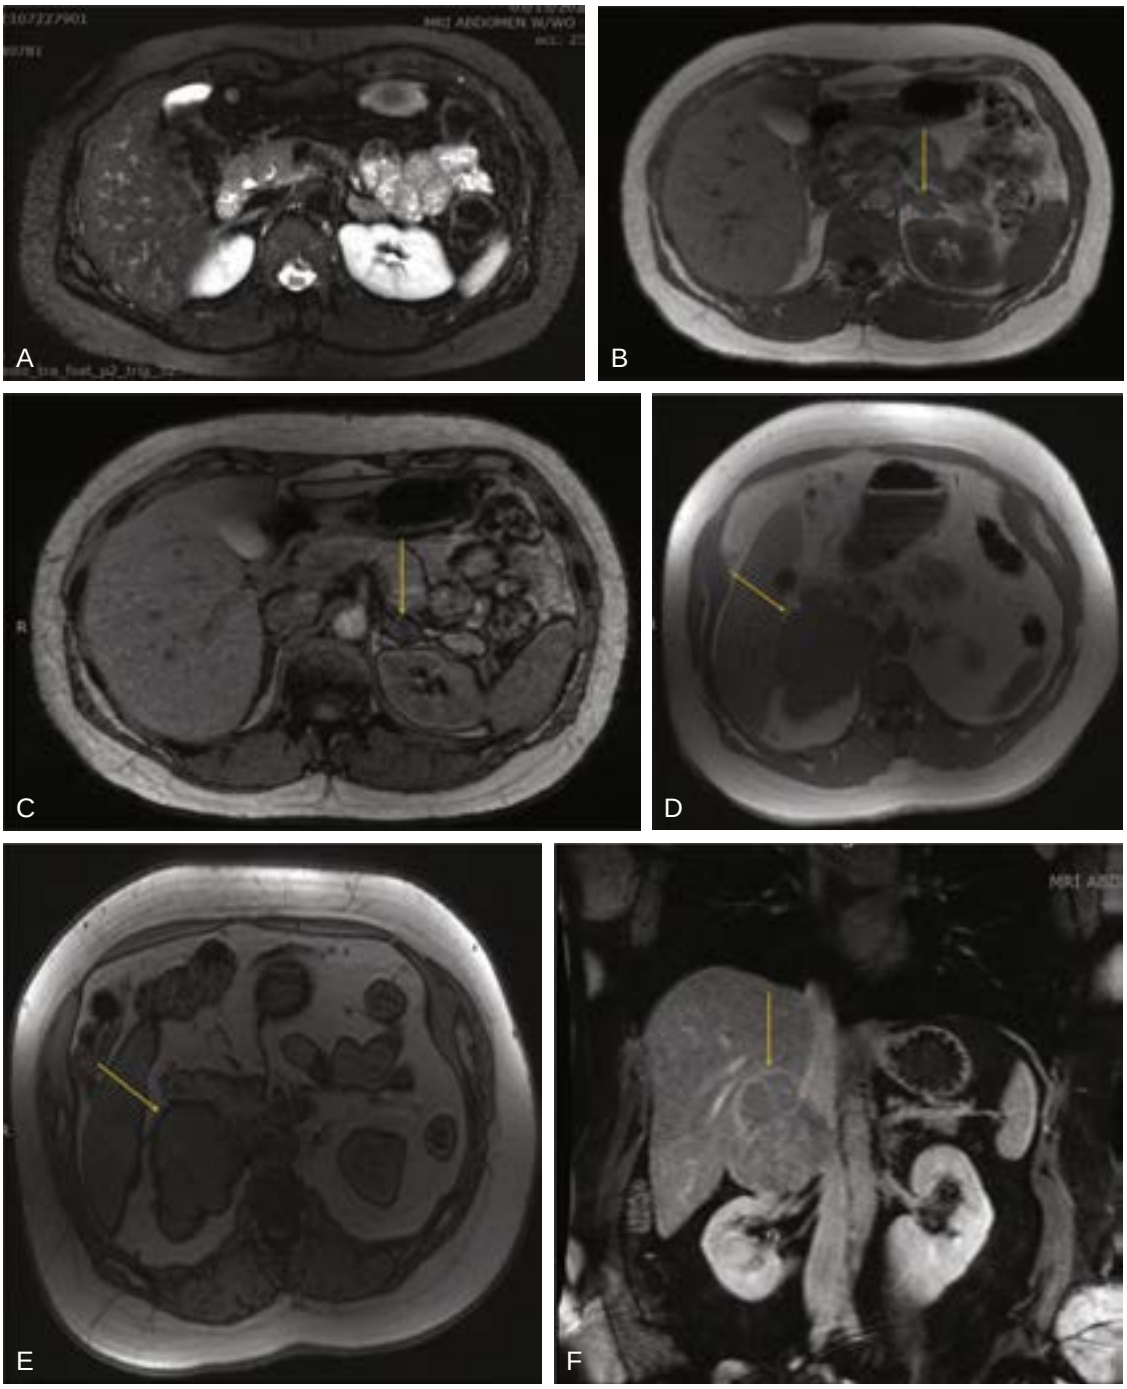

FIG. 2 In a patient with Cushing's syndrome secondary to a benign cortisol-producing adenoma, T2-weighted image **(A)** demonstrates an isointense appearance of the nodule. T1-weighted images demonstrate loss of signal intensity shifting from in-phase **(B)** to out-of-phase **(C). (D-F)** MR images in a patient with right adrenocortical carcinoma. Compared with in-phase imaging **(D)**, out-of-phase imaging **(E)** demonstrates no evidence of signal dropout to suggest that this lesion contains fat. Postcontrast MRI imaging **(F)** demonstrates heterogeneous enhancement. There is mass effect on the adjacent inferior vena cava without discrete infiltration of the inferior vena cava.

suspicion of metastatic adrenal cortical carcinoma or another primary cancer with suspected metastasis to the adrenal gland exists. In the setting of an adrenal incidentaloma, this includes patients with a synchronous malignancy, history of previous cancer, and patients with incidentaloma characteristics highly suggestive of adrenal cortical cancer. MIBG scintigraphy carries a sensitivity of 83% to 100% and a specificity of 95% to 100% for pheochromocytomas. MIBG is useful in the localization of paragangliomas, metastatic pheochromocytomas, and in clinical scenarios in which the diagnosis between a nonfunctional pheochromocytoma and malignancy remains uncertain. MIBG is particularly useful in patients with biochemical findings consistent with pheochromocytoma but without evidence of an adrenal lesion on CT. DOTA-PET, which uses a somatostatin receptor imaging agent, carries a sensitivity of 88% for pheochromocytoma, and it can be used in a similar context as MIBG scintigraphy.

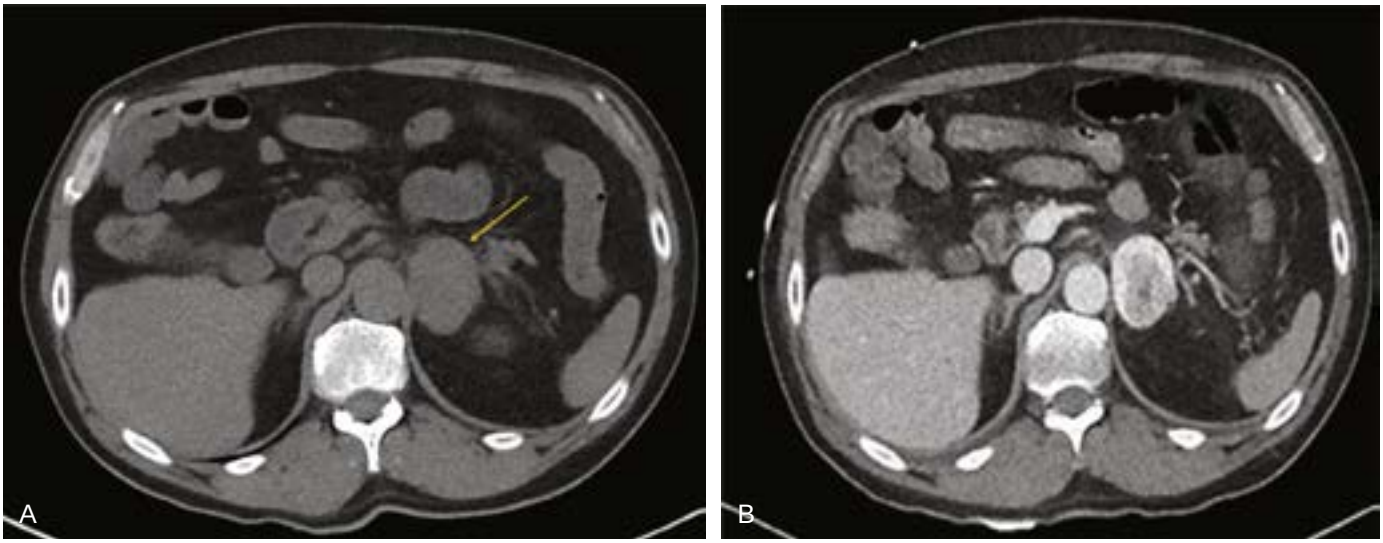

FIG. 3 Classic CT scan findings in a patient with a left pheochromocytoma. The left adrenal mass is well circumscribed; compared with the noncontrast image **(A),** it is heterogeneous and strongly enhances on arterial phase **(B)** with increased attenuation at the periphery, suggestive of a pheochromocytoma.

Fine-Needle Aspiration

There is limited utility in the use of fine-needle aspiration (FNA) biopsy of adrenal lesions, most importantly because it cannot differentiate between benign and malignant disease. If adrenocortical carcinoma is present, a biopsy can cause peritoneal seeding of tumor along the tumor tract. Finally, in the case of pheochromocytoma, adrenal biopsy can cause a physiologically catastrophic release of catecholamines. Unless there is a clinical concern for metastasis in which pathologic confirmation could affect therapy, biopsy should not be performed.

Assessment of Biochemical Functionality

The biochemical workup of adrenal incidentalomas is critical to assess for functionality, and ultimately for surgical decision making (Table 2). It is imperative to identify or rule out pheochromocytoma, cortisol hypersecretion, or primary hyperaldosteronism before an attempted resection of any adrenal mass as it affects perioperative management, guides subsequent medical therapies, and informs surveillance. Positive screening tests should be followed by confirmatory testing.

Screening for Hypercortisolism

All patients with an adrenal incidentaloma should be screened for autonomous cortisol secretion. Screening tests include a low-dose dexamethasone suppression test, midnight salivary cortisol × 2, or urine free cortisol × 2. A 1-mg dexamethasone suppression test involves administering 1 mg dexamethasone at 11:00 PM the night before and drawing blood between 8:00 AM and 9:00 AM the following morning for cortisol and dexamethasone levels. A cortisol level of >1.8 μg/dL is 90.4% to 100% sensitive and 51.8% to 100% specific for autonomous cortisol secretion. Dexamethasone levels are included to confirm proper administration. If results of the dexamethasone suppression test, 24-hour urine cortisol, or midnight salivary cortisol are abnormal, the patient can undergo further confirmatory testing with an adrenocorticotropic hormone (ACTH) level to differentiate ACTH-dependent versus ACTH-independent hypercortisolism. A suppressed ACTH level confirms the diagnosis of autonomous cortisol secretion from the adrenal gland. Although not a routine step in the diagnostic algorithm, low dehydroepiandrosterone sulfate (DHEA-S) concentrations caused by sustained negative feedback on the hypothalamus and pituitary gland can provide further support for the diagnosis.

Screening for Pheochromocytoma

Measurement of plasma free metanephrines (normetanephrines and metanephrines) is the most sensitive test tool to rule out pheochromocytoma. Several physiologic states and medications, such as hypertension, exercise, trauma, amphetamines, antidepressants, and β-blockers can elevate metanephrine levels, leading to false positives. However, they do not typically cause levels as high as two times to four times the laboratory upper normal limit, which are considered diagnostic. If plasma metanephrines are equivocal or mildly elevated, a diagnosis can be confirmed by 24-hour collection of fractionated metanephrines, which carry a higher specificity.

Screening for Hyperaldosteronism

Hyperaldosteronism is less commonly diagnosed from an adrenal incidentaloma, as aldosterone-secreting adenomas tend to be smaller. Concurrent diagnosis of hypertension must be present in patients with an adrenal incidentaloma. Only 9% to 37% of patients present with hypokalemia. Screening involves measurement of aldosterone and renin levels, and computation of the aldosterone-to-renin ratio (ARR). An ARR >20 in the absence of mineralocorticoid antagonists such as spironolactone encourages further investigation. The diagnosis of hyperaldosteronism can be confirmed with aldosterone suppression testing including a saline infusion test or a 24-hour urinary aldosterone test while the patient maintains a high-sodium diet. All mineralocorticoid antagonists should be stopped for at least 6 weeks before confirmatory testing. Once confirmed, surgical candidates older than 35 years of age who wish to pursue surgery must undergo adrenal venous sampling (AVS) to localize the hypersecreting gland. AVS can also be obtained routinely in all patients with hyperaldosteronism in the setting of an adrenal nodule.

Screening for Secretion of Sex Hormones

Screening for sex hormones should only be performed for patients with clinical signs or symptoms of virilization or feminization, or those with masses suspicious for adrenocortical carcinoma. Screening is performed by measuring plasma DHEA-S levels. For men exhibiting features of feminization, estradiol-17 can be measured.

TABLE 2 Biochemical Evaluation for Adrenal Incidentaloma*

	Screening Test	Confirmatory Test
Cushing's syndrome	1. Overnight 1-mg dexamethasone suppression test (AM cortisol ≥ 1.8 μg/dL) 2. 24-hour urine free cortisol (elevated) 3. Midnight salivary cortisol (elevated)	Random ACTH level (low/suppressed)
Pheochromocytoma	Plasma free metanephrines and normetanephrines (≥2–4 × upper limit of normal)	24-hour urine fractionated metanephrines and normetanephrines (≥2–4 × upper limit of normal)
Primary hyperaldosteronism	Serum aldosterone (PA) >15 and serum aldosterone-to-renin ratio (ARR) ≥ 20	Saline suppression test (PA ≥ 10 ng/dL) Salt load test (elevated aldosterone) **Adrenal vein sampling

*Levels in parentheses indicate a positive result indicative of a functional tumor.
**Adrenal vein sampling is used to lateralize an aldosteronoma.
ACTH, Adrenocorticotropic hormone.

Management

Treatment should be individualized according to the patient's comorbidities, preferences, and the clinical expertise available. Surgery is indicated for functional adrenal tumors and adrenocortical carcinoma in the absence of distant metastatic disease. Surgery may be indicated for indeterminate nodules and large, benign, or symptomatic tumors as well (Table 3).

Surgery

Adrenalectomy can be performed with an open or minimally invasive technique (laparoscopic versus robotic) and with either a transabdominal or retroperitoneal approach. Open surgery should be performed in cases of suspected adrenocortical carcinoma or large tumor size. An open approach for suspected adrenocortical carcinoma allows for optimal exposure of surrounding structures should the need arise for more extensive dissection or vascular reconstruction. For presumed benign lesions, minimally invasive techniques, such as laparoscopic or robotic, can be used and choice of technique is a matter of surgeon preference, as there is no additional benefit to robotic-assisted adrenalectomy. The adrenal glands can be approached transabdominally in the lateral decubitus position and retroperitoneoscopically in a modified prone position. A retroperitoneal approach can be particularly useful in patients with a history of multiple abdominal surgeries to avoid the risks of extensive adhesiolysis and in those who need a bilateral adrenalectomy.

Perioperative Management

All adrenalectomy patients should receive chemical deep venous thrombosis prophylaxis. Additionally, each type of functional tumor requires specific considerations in the perioperative period.

Patients with Cushing's syndrome must undergo optimization of blood pressure and glucose control. They may require stress doses of glucocorticoids well into the postoperative period resulting from adrenal insufficiency of the remaining contralateral gland. Preoperative antihypertensives and diabetic medications can slowly and judiciously be adjusted as the patient's blood pressure and glucose trend demand. Patients eventually may not require some or even all of their previous medications.

Patients with pheochromocytomas carry an elevated risk of catastrophic perioperative hemodynamic lability. These patients require preoperative nonselective alpha blockade with agents such as doxazosin or phenoxybenzamine to reduce the risk of a hypertensive crisis for approximately 2 weeks. After alpha blockade is established, beta blockade may be added for patients with tachycardia. Anesthesia plays a critical role in the care of patients intraoperatively; therefore excellent communication with the anesthesia team regarding vascular access, hemodynamic monitoring, and critical steps during surgery is key for optimal patient outcomes. All patients with a pheochromocytoma should be offered genetic testing to include *NF1, VHL, RET, SDHB,* and *SDHD* mutations. Genetic mutations have been reported in 19% of patients with apparently sporadic pheochromocytomas and a negative family history, and the prevalence is much higher in families with known syndromes. Postoperative hypotension may occur; it is transient and more often seen in those treated with phenoxybenzamine preoperatively because of its residual longer-acting alpha-blocking effects in the setting of sudden excess catecholamine withdrawal. Hypotension can be managed with

TABLE 3 Radiographic Characteristics Suggestive of Benign vs. Malignant Adrenal Masses

Characteristics	Likely Benign	Likely Malignant
Size	<4 cm	≥4 cm
Margins	Smooth	Irregular
Heterogeneity	Absent	Present
Rate of growth	<1 cm/year	≥1 cm/year
CT Density (HU)		
Unenhanced density	<10 HU	≥10 HU
Contrast-enhanced density	Low	High
Washout	>60%	<60%
Features on MRI		
T2-weighted intensity	Isointense/ hypointense	Hyperintense
Out-of-phase imaging	Loss of signal intensity	No change
FDG avidity on PET	No	Yes

fluid boluses and vasopressors should it persist despite adequate fluid resuscitation. Rebound hypoglycemia is rare but can occur immediately postoperatively due to preoperative suppression of alpha and beta pancreatic cell function from high catecholamine levels that are no longer present after adrenalectomy.

Patients with aldosteronomas should discontinue any potassium supplements and potassium-sparing diuretics, such as spironolactone, immediately postoperatively. Rebound hyperkalemia is a risk in the postoperative period. Potassium-containing crystalloid solutions and potassium repletion should be avoided. Similar to patients with hypercortisolism, preoperative antihypertensives can be resumed cautiously.

Special Cases

Patients with bilateral pheochromocytomas require bilateral adrenalectomy. The bilateral adrenal glands can be resected during the same anesthetic event. Because pheochromocytomas arise from the adrenal medulla, bilateral cortical-sparing adrenalectomy can be performed to minimize life-long adrenal insufficiency. Ideally, a remnant of adrenal cortical tissue around the adrenal vein should be spared. The management of patients with hypercortisolism is more controversial. Options include: bilateral adrenalectomy, AVS to identify and then excise the more biochemically active gland, or removal of the larger gland. The latter two options require close postoperative surveillance as hypercortisolism can recur requiring contralateral adrenalectomy. Patients with hyperaldosteronism caused by bilateral adrenal hyperplasia are not surgical candidates and should be managed medically.

Follow-up

Both nonoperative and postoperative patients require long-term surveillance, and management varies according to the type of adrenal lesion.

Postoperative Surveillance

After adrenalectomy for pheochromocytoma, patients require life-long follow-up as pheochromocytomas can recur. Surveillance entails annual history and physical examination with particular attention paid to blood pressure, heart rate, and resurgence of symptoms of catecholamine excess. Plasma metanephrines can be assessed periodically, and a rising trend should be evaluated further with cross-sectional imaging.

Patients undergoing adrenalectomy for Cushing's syndrome require short-term glucocorticoid supplementation until normal function of the hypothalamic-pituitary-adrenal (HPA) axis is restored. In the first year after surgery, they should be followed closely by an endocrinologist as they may require frequent medication adjustments because of weight loss, lower blood pressure, and lower glucose levels. Cushing's syndrome may recur, especially in patients status post–unilateral adrenalectomy in the setting of bilateral nodules, and these patients should continue to have routine long-term follow-up with particular attention paid to resurgence of hyperglycemia, worsening hypertension, and weight gain. Patients undergoing bilateral adrenalectomy will require life-long physiologic glucocorticoid supplementation as well as education regarding stress doses during illness, injury, and so on.

After adrenalectomy for hyperaldosteronism, it may take several weeks or months before patients can be weaned off some or all of their antihypertensive agents. In some cases, especially if hyperaldosteronism went unrecognized for a prolonged period causing permanent renal changes, patients will remain hypertensive and continue to require all preoperative antihypertensives. Patients should continue to be seen and evaluated by a clinician to address these potential changes.

Standardized guidelines for surveillance after resection of adrenocortical carcinoma do not exist; however, patients require close life-long follow up to monitor for local and metastatic recurrences. Physical examinations, hormonal studies, and CT of the chest and abdomen should be performed every 3 months, which can be increased to every 6 months after a few years. Surveillance can be extended to every 1 to 2 years after a 5-year disease-free interval.

Nonoperative Management

Observation with repeat imaging and biochemical testing is an acceptable alternative for patients with indeterminate, nonfunctional nodules with low suspicion of adrenocortical carcinoma. Repeat imaging should be performed at 3 months, 6 months, and then annually for 1 to 2 years. Biochemical testing should be repeated annually for up to 5 years. Should the tumor grow more than 1 cm or become hormonally active, adrenalectomy is indicated.

Management of Adrenal Cortical Tumors

Mark A. Eckardt, MD, Jennifer B. Ogilvie, MD, and Nita Ahuja, MD, MBA

INTRODUCTION

The adrenal cortex is the main source of corticosteroid hormone synthesis, producing both mineralocorticoids and glucocorticoids. These hormones help regulate inflammation, stress response, metabolism, catabolism, as well as electrolyte and water balance, depending on the anatomic adrenal layer from which the hormone is produced. Tumors arising from the zona glomerulosa, zona fasciculata, or zona reticularis can produce increased levels of hormones from the involved layer (functional), or they may be hormonally inactive (nonfunctional). Although they are important in the discussion of surgical management of adrenal tumors, tumors arising from the adrenal medulla (pheochromocytoma and neuroblastoma) are discussed elsewhere.

The prevalence of adrenal cortical tumors has been reported at about 2% (ranging 1% to 9%) in autopsy studies, with higher prevalence noted in the older population. Because of the increased use of diagnostic imaging over the past 3 decades in conjunction with advances in each imaging modality, the prevalence of adrenal tumors on computed tomography (CT) imaging has been reported at 4% to 10%. The majority of these tumors are found incidentally.

Less than 2% of adrenal tumors are found to be adrenocortical carcinomas (ACCs); however, despite the rarity of this malignancy (annual incidence of 1 to 2 per 1 million), the diagnosis of ACC carries a 5-year disease-specific survival (DSS) of approximately 50%. Therefore prompt identification and treatment are critical in these patients.

PREOPERATIVE EVALUATION FOR THE SURGEON

The initial workup of a patient with an adrenal tumor includes a detailed personal history (including a history of malignancy to evaluate for recurrent primary or metastatic disease to the adrenal glands) and a physical examination. A careful family history is important to identify potential underlying genetic syndromes that would require further investigation (multiple endocrine neoplasia, familial paraganglioma syndrome, von Hippel-Lindau disease, neurofibromatosis type 1, Carney complex, Li Fraumeni syndrome). The history should focus on the signs and symptoms that may also help identify the specific adrenal hormone(s) being overproduced. A complete biochemical assessment should be performed to evaluate for elevated adrenal hormone levels (Table 1). For adrenal cortical tumors, it is helpful to always send for serum aldosterone, renin, ACTH, and dehydroepiandrosterone sulfate (DHEAS) as well as perform an overnight low-dose dexamethasone suppression test.

Approximately 10% to 15% of adrenal cortical tumors secrete excess hormone and are considered functional adrenal cortical tumors. These are typically referred for adrenalectomy and can be

TABLE 1 Biochemical Workup of Adrenal Cortical Tumors

Biochemical Abnormality	Layer	Syndrome	Symptoms	Screening Test	Indications For Further Evaluation
Hyperaldosteronism	Zona glomerulosa	Conn's syndrome	Hypertension, weight gain, edema, muscle cramping, weakness, temporary paralysis, headaches, polyuria, polydipsia	**Plasma aldosterone, plasma renin activity**	Plasma aldosterone to renin activity ratio > 20
Hypercortisolism	Zona fasciculata	Cushing's syndrome	Hypertension, weight redistribution (central obesity, "buffalo hump," "moon face"), diabetes, bruising, fatigue, abdominal striae, proximal muscle weakness, hirsutism, amenorrhea, impotence, depression	**ACTH, overnight low-dose (1-mg) dexamethasone suppression test**	Serum cortisol > 1.8 mcg/dL with suppressed ACTH
Increased sex hormones	Zona reticularis	Virilization/feminization	Hirsutism, menstrual irregularities, precocious puberty, postmenopausal bleeding, feminization (gynecomastia, testicular atrophy)	**DHEA-S,** +/–androstenedione, 17-hydroxyprogesterone, testosterone (total and free) for women, estradiol for men and postmenopausal women	Abnormally elevated levels with associated clinical symptoms

ACTH, Adrenocorticotropic hormone; *DHEA-S*, dehydroepiandrosterone-sulfate.
Bolded studies indicate recommended minimum during biochemical workup.

identified via the clinical symptoms and screening tests listed in Table 1. Nonfunctional tumors with indeterminate initial imaging should have additional adrenal-specific imaging including adrenal protocol computed tomography (CT) with timed contrast and multiphase scanning, magnetic resonance imaging (MRI), and/or fluorodeoxyglucose positron emission tomography (FDG-PET). These imaging modalities can help differentiate between benign adrenal tumors that can be observed and suspicious or malignant tumors that should be resected. (Table 2)

Percutaneous fine-needle aspiration (FNA) is not routinely recommended in the preoperative workup of adrenal tumors. Biochemical and imaging findings, in addition to personal/family history and physical examination, are sufficient to make a diagnosis in most cases. Additionally, FNA cytology cannot reliably differentiate a benign adrenal adenoma from adrenal cortical carcinoma (ACC). Finally, adrenal biopsy is associated with multiple risks including malignant seeding of the FNA tract, adrenal hemorrhage that may complicate subsequent adrenalectomy, damage to surrounding organs and vessels, and hypertensive crisis in patients with undiagnosed pheochromocytoma.

There are rare instances in which FNA can be useful, such as for patients in whom surgery is not recommended but a tissue diagnosis will help guide appropriate treatment. For example, tissue diagnosis by FNA may be helpful in the workup of metastatic disease from a non-adrenal primary tumor, an unresectable adrenocortical carcinoma, or for patients who are poor surgical candidates because of multiple medical comorbidities.

In patients with a history of nonadrenal malignancy and a new adrenal lesion, FNA may be useful in determining cell type of origin.

TABLE 2 Differences in Imaging Characteristics of Adrenal Cortical Tumors

Characteristic	Benign	Indeterminant
Size	< 4 cm	> 4–6 cm
Growth	< 3 mm/year	> 5 mm/year
Noncontrast CT (Hounsfield units)	< 10	> 10
Percentage washout on CT (if homogeneous)	> 50%–60%	< 50%–60%
MRI chemical shift	> 50%	< 50%
Internal attenuation	Homogeneous	Heterogeneous
Calcification	Absent	Present
Necrosis	Absent	Present
Borders	Regular	Irregular
Invasion of adjacent structures	Absent	Present
Intravascular tumor thrombus	Absent	Present
Lymphadenopathy	Absent	Present
FDG PET CT: Tumor SUV	< 3.4	> 3.4
FDG PET CT: Tumor/liver SUV ratio	< 1.45	> 1.45

CT, Computed tomography; *MRI*, magnetic resonance imaging; *FDG PET*, fluorodeoxyglucose positron emission tomography; *SUV*, standardized uptake value.

However, if the adrenal lesion is the only evident site of metastasis and clinical suspicion is high, adrenalectomy may be performed without adding the risks associated with FNA. Despite the adrenal glands being the fourth most common location for metastatic disease, a series of studies showed that, on average, greater than 50% (range 9%–76%) of adrenal masses found in these patients are benign adrenal adenomas.

INDICATIONS FOR SURGICAL INTERVENTION

Adrenalectomy is recommended if biochemical evaluation and imaging characteristics are consistent with a hormonally active and/or potentially malignant adrenal lesion, and the patient is a reasonable candidate for surgery (Fig. 1). Patients with functional or suspicious-appearing lesions who are not operative candidates may be managed with observation or medical management.

Although tumor size (>4 or 6 cm) has in the past determined the threshold for adrenal surgery in nonfunctional adrenal lesions, imaging characteristics are also necessary to consider in a complete evaluation. Washout of contrast of >50% to 60% on CT or a loss of signal on out-of-phase images on MRI can reliably identify benign adrenal adenomas. The rate of growth in solid adrenal lesions is another important determinant used to help identify benign and malignant tumors; a growth rate of less than 3 mm/year is consistent with an adenoma, compared with malignant tumors that characteristically grow more than 5 mm/year (see Table 2). Previous size criteria that guided surgical resection for adrenal tumors 6 cm and greater were determined given the greater risk of a malignancy with larger tumors: > 6 cm carries a 22% risk of malignancy, 4.1 to 6 cm carries a 6% risk of malignancy, and ≤ 4 cm has approximately 2% or less risk of malignancy. On the other hand, benign adrenal masses like myelolipomas and simple adrenal cysts have characteristic imaging features, can grow to large sizes, remain asymptomatic, and do not need to be resected. Benign-appearing tumors can be observed with repeat scans in 3 to 6 months and then annually. Biochemical testing should be repeated annually for 5 years to monitor for any changes in hormonal activity.

Functional Cortical Tumors

Functional adrenal tumors, especially in patients with worsening symptoms, should undergo adrenalectomy to remove the source of excess hormone production. The rate of malignant transformation of functional tumors is unknown, with only a few case reports identifying this rare situation.

Nonfunctional Cortical Adenomas

Nonfunctional, stable, benign-appearing adenomas do not need surgical resection. Nonfunctional adenomas that are continually growing or with indeterminant radiographic features should be reevaluated for resection with the surveillance schedule mentioned previously. (Fig. 2A; see Table 2). It is important to note that adenomas are not thought to be premalignant lesions and do not seem to have the potential for malignant transformation.

Adrenocortical Carcinoma

Complete surgical resection is the only potential curative treatment for ACC. It is typically recommended to be done via an open approach, regardless of size and functional status. As further explained later in this chapter, this is done via en-bloc open resection for a decreased rate of recurrence compared with the laparoscopic approach (see Fig. 2B).

Isolated Adrenal Metastases

Lung cancer, breast cancer, melanoma, gastrointestinal malignancies, and renal cell carcinoma are the most common primary malignancies

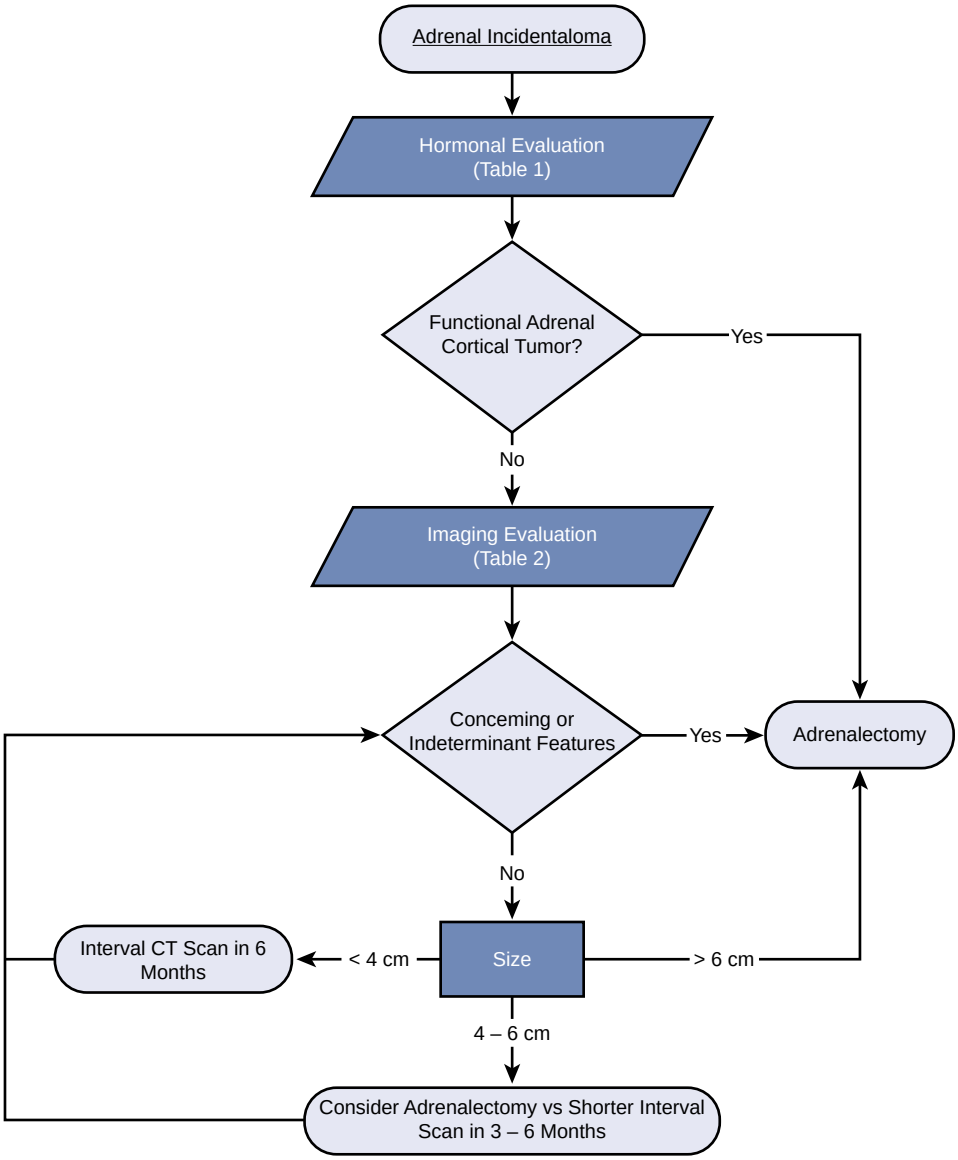

FIG. 1 Adrenal incidentaloma workup and general management algorithm.

that metastasize to the adrenal glands. Approximately 50% of these tumors metastasize to bilateral adrenal glands. Isolated adrenal metastases should be surgically resected in appropriate patients if feasible and can be done so safely via a laparoscopic approach unless characteristics of more aggressive disease are present (e.g., lymphadenopathy, invasion into surrounding organs or vessels), at which time open adrenalectomy is recommended.

IMMEDIATE PERIOPERATIVE MANAGEMENT AND CONSIDERATIONS

There have been very few studies looking at neoadjuvant systemic therapy for ACC, and although they have suggested a potential benefit in patients with borderline resectable ACC, the studies were not randomized controlled trials, and they lacked power; therefore there is no clear consensus on neoadjuvant therapy from the various society guidelines.

It is critical to avoid capsular rupture when handling an ACC as they have a high propensity to seed the entire field, increasing local recurrence rates. For large or invasive ACCs that involve the inferior vena cava (IVC), liver, diaphragm, spleen, or kidneys, a multidisciplinary team approach at a regional center where there is adequate expertise should be considered, and resection should be planned in conjunction with hepatic, vascular, and/or cardiothoracic surgeons as needed. For tumors with extensive IVC involvement, vascular bypass, IVC resection and repair or replacement may be necessary.

SURGICAL APPROACH

Choosing Minimally Invasive versus Open Adrenalectomy

Determining the optimal surgical approach for adrenalectomy should be done on a case-by-case basis, and certain factors may lead to choosing one approach over the other (Table 3). In general, although minimally invasive laparoscopic and retroperitoneoscopic approaches have replaced traditional open adrenalectomy for most presumed benign adrenal tumors, the debate over open versus minimally invasive surgery for ACC continues to evolve. The American

FIG. 2 Adrenal cortical lesions on CT imaging can appear **(A)** benign, hypodense compared with normal adrenal tissue, and generally contained to the adrenal gland, or **(B)** malignant, with areas of hyperintensity and invasion into surrounding structures (such as the liver and retrohepatic inferior vena cava in this example). *(**A** from Mazzaglia PJ. Radiographic evaluation of nonfunctioning adrenal neoplasms. Surg Clin North Am. 2014;94:625–642; **B** from Chagpar R, Siperstein AE, Berber E. Adrenocortical cancer update. Surg Clin North Am. 2014;94:669–687.)*

Association of Clinical Endocrinologists and the American Association of Endocrine Surgeons currently recommend open adrenalectomy for ACC, regardless of size, per their most recent guidelines (published in 2009). The National Comprehensive Cancer Network (NCCN) agrees with these recommendations in their guidelines (Version 1.2021 for Neuroendocrine and Adrenal Tumors), yet also acknowledges that depending on individual surgeon expertise and tumor characteristics, a minimally invasive approach may be used for small tumors, with a plan for converting to an open procedure if local invasion is noted. This indicates that despite their recommendation for open resection of ACC, there is still debate within the guidelines. In contrast, the European Society of Endocrine Surgeons recommends that laparoscopic adrenalectomy may be attempted for stage I or II ACCs < 10 cm.

Benign adrenal masses, both functional and nonfunctional, can be safely approached using a minimally invasive approach, barring any intraoperative concern for malignancy, at which point the procedure should be converted to open. Benign tumors 10 cm or greater can pose technical challenges to minimally invasive resection; however, tumor size alone is not an absolute contraindication to a minimally invasive approach.

Open Right Adrenalectomy

The patient is placed in the supine position with a wedge or bump to elevate and separate the pelvis from the costal margin on the right side. The initial steps involve making a long right subcostal or bilateral subcostal incision and then examining the peritoneal cavity to assess for distant metastases, lymph node involvement, and fixation of the mass to the surrounding tissues. The liver is mobilized by dividing the falciform and right lateral triangular ligaments, allowing for retraction of the liver upward. The hepatic flexure of the colon is mobilized by dividing the lateral gastrocolic ligament and exposing the IVC via the Kocher maneuver. Upon entering the Gerota fascia along the IVC, the adrenal gland can now be examined (Fig. 3). If the adrenal mass does not involve the upper pole of the kidney, the Gerota fascia is opened, and all perinephric fat below the adrenal gland is mobilized upward with the adrenal gland en-bloc to ensure an adequate margin. If invasion into the kidney or renal vessels is found, continuation of the mobilization with en-bloc partial or total resection of the right kidney as needed to ensure capsule integrity and minimize the chance of tumor spillage. If there is IVC invasion, the IVC must be secured superiorly under the diaphragm at the crus as well as distally to the right renal vein inferiorly. If there is invasion into the liver, a limited right hepatectomy may be performed, typically using a multidisciplinary approach. The superior dissection can extend up to the diaphragm, and the inferior dissection should include all perinephric fat over the superior pole of the kidney to ensure an adequate margin. The medial dissection is done very delicately as it is just anterior to the vena cava, and the right adrenal vein is very fragile. The medial attachments are then mobilized and ligated with the right adrenal vein being last, including all fatty tissue medial to the gland and lateral to the IVC. If bleeding does occur after ligation of the right adrenal vein, the surgeon can obtain proximal and distal control of the vena cava and repair the stump primarily via suture ligation.

Open Left Adrenalectomy

The patient is positioned in the same way as described earlier for the open right adrenalectomy resection, with a bump/wedge placed under the left side. A left-sided or bilateral subcostal incision is

TABLE 3 Advantages of Operative Approaches for Adrenal Cortical Tumors

Adrenalectomy	Open	Laparoscopic	Retroperitoneoscopic	Robotic	Single-Port
Advantages	Tactile feedback	Familiar anatomic orientation to open approach	Avoids peritoneal cavity	Increased dexterity	Excellent cosmesis
	Better exposure	Decreased postoperative pain	Shorter distance of dissection	Three-dimensional depth perception	Similar results to laparoscopic
	Decreased local recurrence of ACC with en bloc resection	Decreased hospital stay	Can do bilateral without patient repositioning	Good for obese patients	
	Appropriate for any tumor size	Better cosmesis	Prior abdominal surgery does not hinder this approach	Appropriate for larger tumors (even in RP given dexterity)	
	Can utilize a single midline incision for bilateral adrenalectomy	Shorter operative time compared with robotic/single-port			
	Quicker management if catastrophic injury occurs	Appropriate for larger tumors			
	No CO_2 insufflation for preload-dependent patients	Good for obese patients			
	Good for obese patients				
Disadvantages	Larger incision	Risk of iatrogenic injury to intraabdominal organs	Requires increased insufflation pressure to maintain exposure	Increased cost	Learning curve
	Increased postoperative pain	Increased manipulation of additional organs	Restricted exposure to retroperitoneum	Longer operative time	
	Increased hospital stay	Difficult in patients with prior abdominal surgery	Difficult in obese patients		
	Increased risk for hernia	Requires patient repositioning for bilateral adrenalectomy	Difficult with larger tumors		
	Risk of iatrogenic injury to intraabdominal organs		Patient must tolerate prone positioning		
	Difficult in patients with prior abdominal surgery				

ACC, Adrenocortical carcinoma; *CO_2,* carbon dioxide; *RP,* retroperitoneum.

made, and the abdomen is examined in similar fashion. The gastrocolic ligament is divided to mobilize the splenic flexure of the colon distally. The spleen and tail of the pancreas are mobilized medially to expose the kidney and adrenal gland (see Fig. 3). For tumors that surround or invade the splenic vessels, a simultaneous splenectomy is performed, dividing the splenic artery at the upper border of the pancreas and the individual gastrosplenic arteries, while preserving the vessels along the greater curvature of the stomach. The tail of the pancreas is usually preserved unless directly invaded. If the left kidney is involved with the adrenal tumor, the kidney is mobilized from lateral to medial from the lower pole and removed en-bloc with the adrenal tumor.

If there is no invasion into surrounding structures, in contrast with a right adrenalectomy, the left adrenal vein is ligated as an earlier step along with the inferior adrenal arteries, to aid in mobilization of the adrenal gland. The superior and inferior arteries are controlled and ligated, and the adrenal gland is dissected along with all surrounding perinephric fat off the superior pole of the kidney to ensure adequate margins.

Open Posterior Adrenalectomy

The patient is placed in the prone position with the patient's arms lifted over his or her head. An incision is made over the 12th rib, and the rib is resected for exposure. The peritoneum is swept inferiorly and laterally, and the retroperitoneal organs are identified and mobilized, with the kidney being retracted inferiorly. The adrenal gland is identified medially and superior to the renal hilum, and adrenalectomy is completed in a similar fashion to the anterior approach. Open posterior adrenalectomy can be complicated by subcostal nerve injury and lumbar hernias.

Open Thoracoabdominal Adrenalectomy

The patient is placed in the supine position, with the upper torso rotated laterally approximately 45 degrees with the help of a bump. The incision is made in either the 8th or 9th intercostal space, and the diaphragm is divided peripherally near the costal margin to avoid injury to the phrenic nerve and to allow for easy reconstruction at the end of the case. Once the abdominal cavity is opened, the adrenal glands are exposed and ultimately resected in the same manner as the anterior approach (Fig. 4).

At the end of the case, the diaphragm should be repaired with interrupted nonabsorbable sutures in a figure-of-8 fashion, and a chest tube is placed to water seal.

Laparoscopic Transabdominal versus Retroperitoneoscopic Adrenalectomy

Patient anatomy, past surgical history, underlying pathology, and the surgeon's expertise should be considered when determining the appropriate minimally invasive surgical approach to adrenalectomy. A summary of such considerations can be found in Table 3. For instance, patients who have had extensive abdominal surgery or require bilateral adrenalectomy will likely benefit from a retroperitoneoscopic approach as this approach avoids the peritoneal cavity and does not require repositioning for bilateral procedures, whereas patients with tumors > 6 cm may benefit from a transabdominal laparoscopic approach given the larger working area. Patients with high body mass index (BMI) or extensive retroperitoneal fat (both are particularly difficult in male patients) may be better suited for the laparoscopic approach.

Laparoscopic Right Transabdominal Adrenalectomy

The patient is placed in the left lateral decubitus position, with the bed flexed just above the waist and the kidney rest elevated, to allow for maximum exposure to the flank. The patient is secured in place with a beanbag, and the right arm is supported on an upper arm rest. A gel roll is placed under the left axilla, and the head is supported.

Four ports are typically used for the right-sided approach (Fig. 5A). The most medial port, placed in the epigastric/subxiphoid

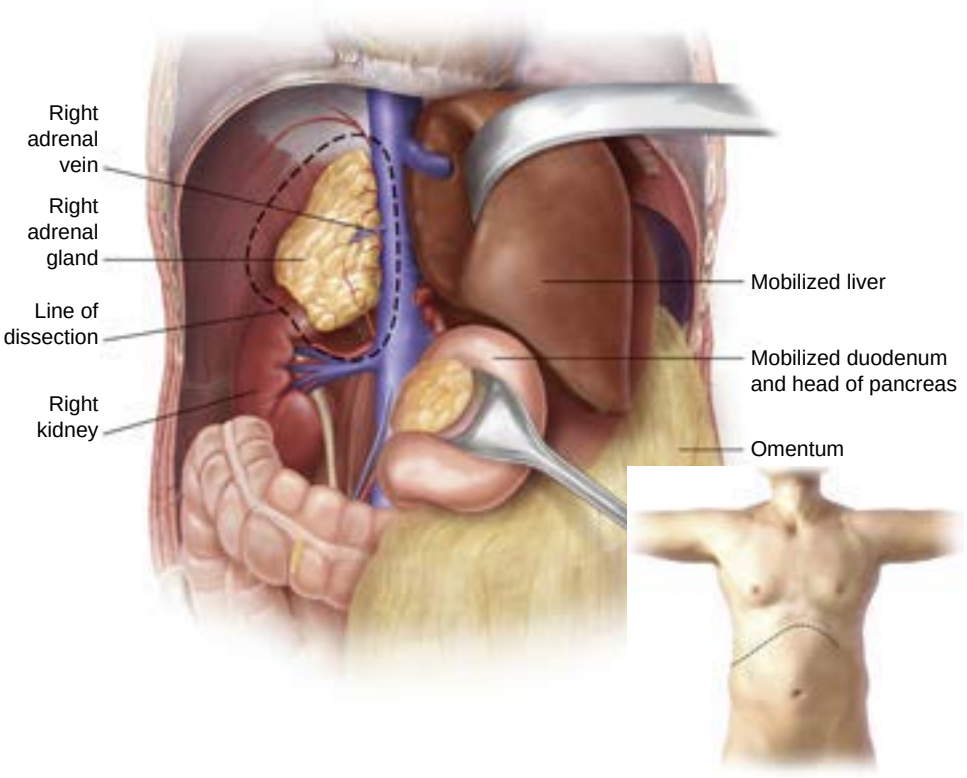

FIG. 3 Exposure of the right and left adrenal glands via an open abdominal approach.

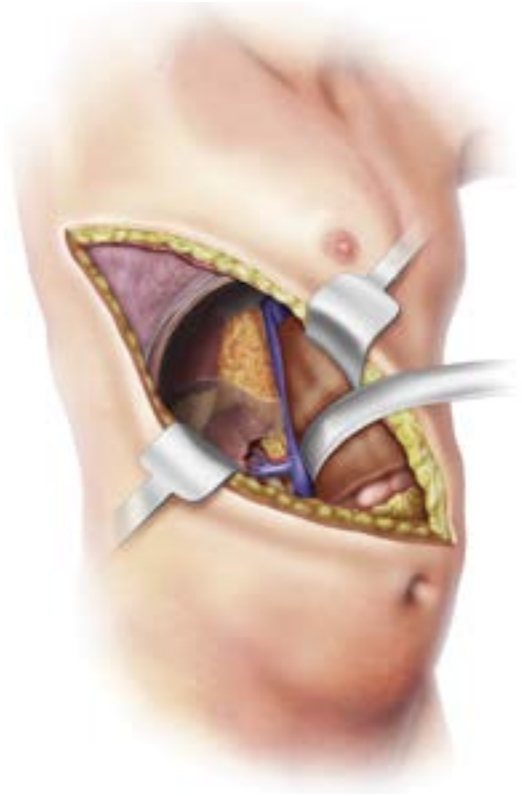

FIG. 4 Exposure of the right adrenal gland via a thoracoabdominal approach.

region, is used to retract the liver superiorly. The two other working ports are placed approximately 6 to 10 cm apart along the subcostal margin, with the most lateral in the midaxillary line, to allow for the unobstructed use of the instruments. The final port, for the camera, is placed in the right upper quadrant. These locations should be marked before insufflation as a guide, but after placing the first port (the camera port via an open technique) and insufflating the abdomen to 15 mm Hg with CO_2, the other ports should be placed under direct visualization. Before placing the most lateral port, the surgeon should examine the hepatic flexure to determine if mobilization is needed (rare). The liver is mobilized by dividing the right triangular ligament, and use of a liver triangular retractor (or fan retractor) through the medial subxiphoid port aids in retracting the liver superiorly and medially. The use of a harmonic scalpel or hook electrocautery allows the opening of the retroperitoneal fascia between the inferior edge of the liver and the superior margin of the adrenal gland. It is helpful to work from medial to lateral and avoid the adrenal vein at the superomedial aspect of the gland. At this point, the surgeon should look for and carefully divide any accessory veins between the adrenal and liver or IVC. In general, for any rotation or movement of the adrenal gland, blunt instruments like a closed grasper or laparoscopic peanut should be used, or, alternatively, grasp the periadrenal fat to avoid disrupting the adrenal capsule. Next, mobilization is performed along the medial edge of the adrenal gland to open the Gerota fascia in a longitudinal fashion from inferior to superior and identify the lateral edge of the IVC. The perinephric fat is dissected off while leaving a small layer on the adrenal gland for margin. The surgeon continues to carefully develop the space between the kidney, adrenal gland, and IVC while working superiorly toward the adrenal vein. The adrenal vein is divided using a harmonic scalpel or clips. The harmonic scalpel is then used to dissect the inferior aspect of the adrenal gland off the superior pole of the kidney, while dividing the small inferior adrenal arteries. At this point, attention is paid to

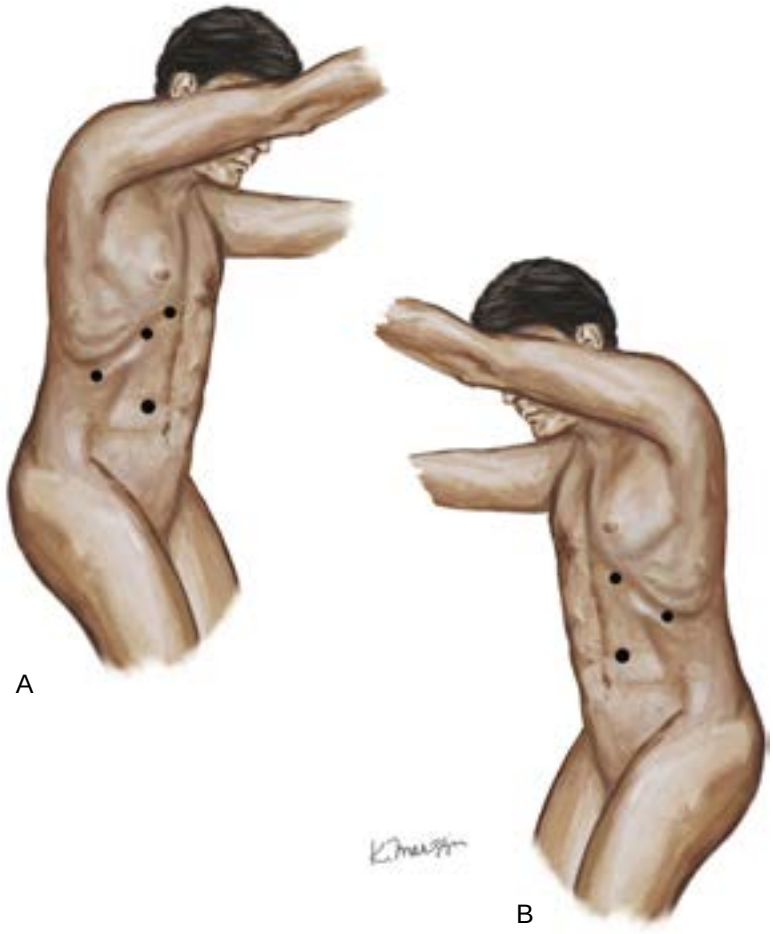

FIG. 5 Patient positioning and port placement for **(A)** right-sided and **(B)** left-sided laparoscopic transabdominal adrenalectomies. Although not indicated in the figure, the subxiphoid port can be used in a left-sided approach to aid with retraction of the spleen and tail of the pancreas. *(Netter illustration from www.netterimages.com. Copyright Elsevier Inc. All rights reserved.)*

protect any accessory renal artery branches. The dissection continues to remove all periadrenal fat with the gland, working from a medial to lateral fashion until the adrenal gland is taken off the diaphragm posteriorly and laterally. The adrenal gland can then be removed in a retrieval bag via the camera port. The port site can be enlarged to remove the tumor in an intact fashion, and then all port sites are closed in the normal fashion.

Laparoscopic Left Transabdominal Adrenalectomy

The patient is positioned and port placements are mirrored to those of a laparoscopic right transabdominal adrenalectomy, with the only difference being that the subxiphoid port can be used if needed to rotate the spleen (see Fig. 5B). The splenocolic ligaments are divided, and the splenic flexure is mobilized while retracting the colon inferiorly. The spleen is then mobilized along its lateral aspect from an inferior to superior dissection, continuing all the way superiorly to the fundus of the stomach. The spleen is then retracted medially with the tail of the pancreas.

The Gerota fascia is then opened medially to identify the kidney and the adrenal gland. The dissection then continues along the superomedial edge of the adrenal gland, sweeping the gland off the diaphragm posteriorly. The phrenic vein is identified and traced down from the diaphragm to the left adrenal vein and then to the location where the left adrenal vein enters the left renal vein. The adrenal vein is then ligated and divided using a harmonic scalpel or clips. The adrenal gland is elevated superiorly, and the small inferior adrenal arteries are then divided while mobilizing all periadrenal fat off the superior medial aspect of the kidney while working from a medial to lateral fashion. The superior attachments are then divided, and the adrenal gland is removed using a retrieval bag placed through the camera port. This port site may be enlarged as necessary to remove the gland intact, and the ports can then be closed in the normal fashion.

Posterior Right Retroperitoneoscopic Adrenalectomy

The patient is placed in the prone position with the abdomen resting in an open rectangular support, and the hips and knees flexed and supported at 90 degrees (Fig. 6). The retroperitoneal space is accessed via a 1.5-cm incision just under the tip of the 12th rib using sharp and blunt dissection. With a finger inserted into the retroperitoneum and lifting up on the 11th rib, a 5-mm trocar is placed just below the tip of the 11th rib. CO_2 insufflation to 20 to 25 mm Hg is initiated through a blunt trocar with an inflatable balloon. A 10-mm trocar is then placed medially under direct vision to avoid the subcostal nerve, about halfway between the spine and the initial incision. The retroperitoneum is then examined with a 30-degree camera, and the area is bluntly dissected to expose the diaphragm, spine, and top of the kidney. Next, the adrenal gland is mobilized inferiorly first, elevating it superiorly away from the kidney. Definitive identification of the vena cava is critical as the pressure from the insufflation may likely cause compression of this structure. The inferior adrenal arteries are divided along the IVC, working clockwise or lateral to medial, from 3:00 to 9:00 superiorly toward the adrenal vein at the superomedial border. Once the adrenal vein is divided, the remainder of the adrenal attachments are dissected free.

Throughout the dissection, be careful not to enter the peritoneal cavity as the hole will lead to loss of pneumoretroperitoneum and exposure. The adrenal gland is extracted through the central incision using a retrieval bag, and the ports are closed in the normal fashion.

Posterior Left Retroperitoneoscopic Adrenalectomy

A similar approach is taken for a left retroperitoneoscopic adrenalectomy. Here, the adrenal gland is often anterior and medial to the superior pole of the kidney, requiring more extensive mobilization of the superior pole to expose it. Dissection of the adrenal gland is again approached from its inferior aspect, working counterclockwise or lateral to medial, from 9:00 to 3:00, to expose the adrenal vein medially. The superior attachments are removed last, and the adrenal gland is extracted as described earlier.

Newer Techniques

Single-Port Adrenalectomy

The single-port approach is a newer technique that has been gaining more traction over the past decade. The initial studies comparing the single-port and the traditional laparoscopic approaches showed no significant difference in complications, but significantly increased operative times, decreased hospital stay, and decreased postoperative pain. However, newer studies have since shown that with continued refinement, all variables showed no significant differences between the two techniques, proving that a single-port adrenalectomy is a

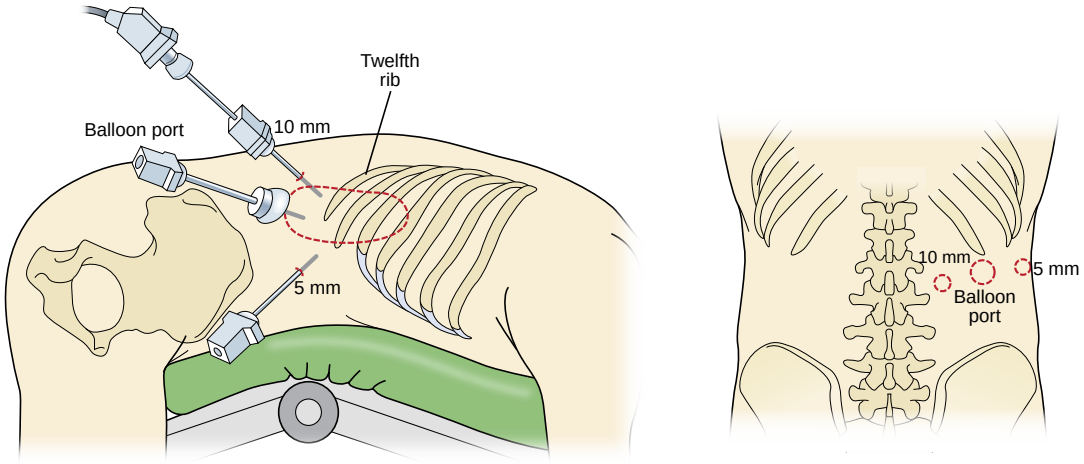

FIG. 6 Patient positioning and port-site placement for a posterior retroperitoneoscopic adrenalectomy. The port sites are mirrored for left- and right-sided adrenalectomies.

feasible option in the skilled surgeon that results in a single incision with excellent cosmesis.

This approach can be done in either a transabdominal or retroperitoneal fashion. A transabdominal approach utilizes a 2- to 3-cm periumbilical incision, a specialty multiport device, and extra-long instruments to reach the adrenal glands. A right-sided adrenalectomy may also utilize an additional 2-mm needlescopic port for liver retraction.

This technique is essentially the same as the retroperitoneoscopic approach; however, a 2- to 3-cm incision below the 12th rib is used in conjunction with a specialty multiport device allowing for a total of three ports. The space is then insufflated to 30 mm Hg, and using a blunt dissector and a LigaSure, the remainder of the operation is similar as noted earlier. The difficulty with this approach is the minimal maneuverability caused by the smaller retroperitoneal space and the close location of the ports to fit into the single 2- to 3-cm incision. An extended mobilization of the upper pole of the kidney may be required compared with the standard retroperitoneoscopic approach.

Studies have shown that this is a safe and feasible approach when done by an experienced surgeon; however, there is no significant advantage in outcomes compared with the standard laparoscopic approaches other than cosmesis.

Robotic Adrenalectomy

A computer-assisted surgical device (robot) can be used in both minimally invasive transabdominal and retroperitoneal approaches. Since the first robotic adrenalectomy was described in 2001, perioperative outcomes and average length of hospitalization are decreased compared with open adrenalectomy and are comparable to laparoscopic adrenalectomy—albeit at an increased cost. Meta-analyses have shown that there are no differences in intraoperative and postoperative morbidity and mortality between the robotic and laparoscopic approaches. Operative times are increased in the robotic approach but appear to decrease as a surgeon's experience moves past the learning curve. Conversely, multiple studies have shown that robotic adrenalectomies actually have shorter operative times in patients with tumors > 6 cm. The main advantages of the robotic approach are the added dexterity in a small working space and the three-dimensional visualization of the operative field.

In placing the robotic trocars, special consideration is needed to avoid having the robotic arms hit each other throughout the case. The optical trocar is inserted first 2 cm beneath the costal margin at the anterior axillary line under direct visualization, and the abdomen is then insufflated. Two 8-mm trocars are placed a few centimeters away, equidistant, on either side of the optical trocar and 2 cm below the costal margin. For a left adrenalectomy, a single 5-mm trocar is placed a few centimeters medial to the most medial robotic trocar for the bedside assistant to utilize, yet still along the same line connecting the other ports to facilitate a fast and easy conversion to an open procedure if needed. For a right adrenalectomy, the same 5-mm port is placed medially, but an additional 10-mm port can be placed inferiorly along between the mid and anterior axillary lines to utilize a fan liver retractor. The robot is then docked, approaching the patient from behind and over his or her shoulder. The reminder of the procedure is performed similar to the laparoscopic approach described earlier.

SPECIAL CONSIDERATIONS

Genetics

As discussed previously, obtaining a family history is crucial in helping to identify a genetic link to adrenocortical tumors. ACCs, for example, are thought to be hereditary in 50% of cases. Some genetic mutations driving sporadic ACC are also found as the driving mutation for some familial tumor syndromes that are characterized by including ACC such as Li Fraumeni syndrome (*TP53* mutation), Beckwith-Wiedemann syndrome (*IGF2* mutation), and Gardner syndrome (*APC* mutation). Mutations in the tumor suppressor gene *ARMC5* have identified families with an autosomal dominant inheritance type of Cushing's syndrome (primary bilateral macronodular adrenal hyperplasia), and activating mutations in *GNAS1* caused adrenocortical tumors in infants with McCune-Albright syndrome via elevated cAMP signaling. While most benign cortisol-producing tumors are related to elevated cAMP signaling, the drug mitotane has been found to inhibit basal and cAMP-induced cortisol secretion in ACC. Additional genetic syndromes that were associated with adrenal neoplasia or hyperplasia include Carney complex *(PRKAR1A)* and MEN 1 *(Menin)* (Table 4). If any of these mutations are identified, further workup is indicated with a referral to the appropriate specialty.

POSTOPERATIVE CONSIDERATIONS

Cortisol-secreting tumors are often associated with diabetes, and blood glucose levels must be monitored closely in the perioperative setting. ACCs commonly secrete cortisol; therefore, like other cortisol-secreting tumors, resection can be associated with perioperative and postoperative adrenal insufficiency (e.g., hypotension, tachycardia, hypoxia, fever). Patients with cortisol-producing tumors often require perioperative stress-dose steroids with a long postoperative taper often managed in conjunction with endocrinology. Additionally, cortisol-producing ACCs have been shown in several studies to be an independent risk factor for poorer prognosis compared with non–cortisol-producing ACCs, and these patients should be closely monitored.

Patients with aldosteronomas are usually managed with different types of hypertension medications such as calcium channel blockers (nifedipine), mineralocorticoid antagonists (spironolactone), ACE inhibitors (lisinopril), and/or angiotensin receptor blockers (losartan). These must be weaned off so as to not cause hypotension in the postoperative period. Spironolactone should be started preoperatively for blood pressure control as it also gives an idea as to the estimated blood pressure the patient will obtain postoperatively. Patients are also generally on potassium supplementation before surgery, and this should be stopped immediately preoperatively.

It is important to note the final pathology for ACC not only to ensure that a complete oncologic resection was achieved, but also to identify the Ki67 Labeling Index (Ki67 LI) status of the tumor. Of all clinicopathologic variables, the Ki67 LI status is the most important prognostic factor in regard to recurrence and survival—even in patients with a complete oncologic resection. Ki67 is a proliferation marker identified in an ACC sample by immunohistochemistry, and tumors that have a lower percent of Ki67 staining (<10%) have decreased risk of recurrence and increased survival compared with patients with higher levels of Ki67. Therefore patients with an ACC that has ≥10% of its cells staining of Ki67, despite an R0 resection, may need additional adjuvant therapies.

Adjuvant Treatment for Adrenocortical Carcinoma

After resection of an ACC, adjuvant treatment with mitotane and/or external-beam radiation therapy may be utilized to potentially improve cure rates and increase survival in high-risk patients for local recurrence. Chemotherapy treatment, with or without mitotane, has not been well studied for treating ACC in the adjuvant setting; however, a cisplatin-based regimen has been suggested with mitotane treatment for high-risk patients. The European Society of Endocrinology and the European Network for the Study of Adrenal Tumors (ENS@T) recommend the use of adjuvant mitotane in high-risk patients. Retrospective studies have differed on their results as to if adjuvant mitotane improves overall survival; however, multiple prospective randomized clinical trials are currently in process looking at mitotane with or without additional chemotherapeutic agents in the adjuvant setting, and their results will be crucial for this fatal disease.

TABLE 4 Genetic Syndromes Associated with Adrenal Cortical Tumors

Condition	Gene	Adrenal Disease	Associated Nonadrenal Disease	Important Next Steps
Beckwith-Wiedemann syndrome	*IGF2*	ACC, adrenal hyperfunction, and hyperplasia	Embryonal tumors, macroglossia, omphalocele, renal abnormalities, visceromegaly/hemihypertrophy	Genetic testing
Carney complex	*PRKAR1A*	Primary pigmented nodular adrenocortical disease	Heart and skin myxomas, skin hyperpigmentation	Cardiac evaluation
Gardner syndrome	*APC*	Adrenal adenomas	Desmoid tumors, epidermoid cysts, fibromas, gastrointestinal polyps, lipomas, osteomas, periampullary carcinoma, thyroid cancer	Annual thyroid evaluation, colonic screening, genetic testing, family history
Li Fraumeni syndrome	*TP53*	ACC	Breast cancer, leukemia, sarcoma	Family history, genetic testing, associated cancer screening
McCune-Albright syndrome	*GNAS1*	Bilateral adrenal hyperplasia, Cushing's syndrome	Fibrous dysplasia, skin hyperpigmentation (near midline)	Endocrinology consult, orthopedic consult
Multiple endocrine neoplasia, type 1	*Menin*	Adrenal adenomas, ACC	Pituitary tumors (prolactinomas, growth hormone–secreting), pancreatic tumors (gastrinomas, insulinomas), parathyroid tumors	Endocrinology and endocrine surgery consults
Primary bilateral macronodular adrenal hyperplasia	*ARMC5*	Hyperplasia, Cushing's syndrome	—	Endocrinology and endocrine surgery consults

ACC, Adrenocortical carcinoma.

Management of Pheochromocytoma

Wilson M. Alobuia, MD, MS, and Electron Kebebew, MD

BACKGROUND

Pheochromocytomas and paragangliomas (PPGLs) are rare tumors that arise from chromaffin cells, and they have the potential to produce, accumulate, and/or secrete catecholamines (epinephrine, norepinephrine, dopamine) and metabolites of catecholamines. Approximately 80% to 85% of these tumors arise from the adrenal medulla and are referred to as *pheochromocytomas*. Conversely, paragangliomas make up the remaining 15% to 20% of chromaffin neoplasms that arise from outside the adrenal gland, but along the path of the embryologic neural crest cells as they migrate in the autonomic ganglia. Because of the cranial, vagal, trunk, and sacral locations of the neural crest cells, patients can develop paraganglioma anywhere from the skull base to the perineum. The incidence of PPGL is about 2 to 8 cases per 1 million, with a prevalence between 1 in 2500 and 1 in 6500. The prevalence is higher between the third and fifth decades of life and among patients with hypertension (0.1%–0.6% in adults and 2%–4.5% in the pediatric population). Although the overall prevalence is low, the incidence and prevalence of PPGL

reported at the time of autopsy is higher (about 0.05%–0.1%), which suggests that a good proportion of PPGLs go undiagnosed, and these patients are at risk of premature death resulting from cardiovascular and metabolic complications associated with a functional PPGL. Patients with a functional PPGL may have cardiovascular and metabolic complications such as hypertension, myocarditis, cardiomyopathy, arrhythmias, impaired glucose tolerance, and diabetes. With the increasing use of imaging studies, adrenal incidentalomas are increasingly being discovered. Approximately 10% of all PPGLs are discovered incidentally on imaging performed for other reasons. Recent advancements in genetics and whole-genome sequencing have revealed that about one-third of patients with pheochromocytomas and one-half of patients with paragangliomas have a genetic predisposition to developing these tumors. Although once described as "the rule of 10s tumor" with 10% of tumors described as being familial, bilateral, multiple, extraadrenal, malignant, and in pediatric populations, it is now recognized that the rate of these clinical characteristics is associated with the specific genetic background of PPGL. This information has become particularly important in the workup and management of patients diagnosed with PPGL because knowledge of genetic mutation status has been associated with increased overall disease-free survival and optimal treatment and surveillance. Patients with a genetic predisposition to PPGL have an increased likelihood of developing multiple, bilateral adrenal and/or extraadrenal tumors. This information is essential in determining the optimal surgical treatment for such patients because the preoperative identification of these genes has been shown to affect the surgical approach and the extent of adrenalectomy. For example, patients diagnosed with PPGL who are found to have a mutation in *RET, NF1,* or *VHL* have a low risk of metastatic disease and are therefore good candidates for cortical-sparing adrenalectomy, especially if the tumor is small (<2–3 cm) and there is no family history of metastatic disease. On the other hand, patients with a mutation in the *SDHB, FH,* or *MAX* genes and a large primary tumor are at a much higher risk of metastatic disease and may therefore be better treated with a total adrenalectomy and regional lymphadectomy. Similarly, improvements in functional imaging and tumor localizing studies have made it easier to accurately define the extent of disease in patients with PPGL and has important implications in preoperative and intraoperative decision making.

In this chapter, we highlight the important clinical features, diagnostic tests, syndromic features and susceptibility genes, imaging studies, and key perioperative measures that are essential for the optimal surgical management of patients with PPGL.

CLINICAL PRESENTATION

Some patients with functional PPGL tumors may have a triad of symptoms: paroxysmal headaches, excessive sweating, and palpitations. These symptoms may be provoked by a variety of stimuli including postural changes, exercise, anxiety, trauma, pain, or certain medications. Hypertension among PPGL patients can be sustained, or it can be paroxysmal, with occasional orthostatic hypotension and hypertensive episodes occurring daily, weekly, or even every few months. Patients may also experience other symptoms such as warmth, pallor, tremors, paresthesia, weight loss, anxiety and fear of death, vision changes, dyspnea, chest pain, abdominal pain, nausea, vomiting, and grand mal seizures. Patients who present with these symptoms as well as asymptomatic patients with an incidental finding of an adrenal mass with or without hypertension, those who experience hypertensive episodes during surgery or anesthesia without a previous diagnosis of pheochromocytoma, and those with a genetic predisposition or history of PPGL should all undergo screening for PPGL.

Patients with hereditary forms of PPGL commonly have a familial history, multiple and bilateral lesions, younger age at presentation, and extraadrenal disease. However, patients with apparently sporadic PPGL can have an inherited predisposition in nearly one-third of cases. Von Hippel-Lindau (VHL) syndrome, multiple endocrine neoplasia type 2 (MEN2), neurofibromatosis type 1 (NF1), and familial paraganglioma/pheochromocytoma syndrome (caused by mutations in succinate dehydrogenase A *[SDHA],* B *[SDHB],* C *[SDHC],* D *[SDHD]* and AF2 *[SDHAF2]* subunits) account for most hereditary PPGL syndromes. Over 15 genes with germline or somatic mutations have been implicated in hereditary PPGL with varying likelihood of disease susceptibility (Table 1), so all patients diagnosed with PPGL

TABLE 1 Clinical Features of Genetic Syndromes or Mutations Associated with Pheochromocytomas and Paragangliomas*

Gene	SDHD	SDHC	SDHB	SDHA	SDHAF2	VHL	RET	NF1	TMEM127	MAX	HIF2α†	PHD1†	PHD2†	FH

*Patients who have bilateral or multiple pheochromocytomas/paragangliomas, extra-adrenal paragangliomas, younger than 40 years of age at presentation, or with a family history pheochromocytoma/paraganglioma should undergo genetic testing for *SDHx*, *VHL* and *RET*. Patients with a history of any of the tumors present in MEN2 (medullary thyroid cancer, hyperparathyroidism) and VHL (central nervous system and retinal hemangioblastomas, renal cell carcinoma and cysts, pancreatic tumors and cysts, and epididymal cystadenomas) should also undergo genetic testing.

†Occur as a somatic mutation (or mosaic) and have been associated with polycythemia and require aggressive hydration perioperatively, and most of these patients are on aspirin therapy. Patients with *HIF2α* mutation are also at risk of developing neuroendocrine tumors such as somatostatinomas.

should have genetic counseling and testing. This information is also extremely important to enable the physician to identify syndromic disease (other diseases that may be present), for screening and surveillance of the patient and other at-risk family members, and for surgeons to select the optimal management strategy, surgical approach, and treatment (Table 2).

DIAGNOSIS

Biochemical Testing

Patients with a suspected catecholamine-secreting tumor should undergo biochemical testing. Confirmation of the presence of pheochromocytoma and functional paraganglioma with biochemical

TABLE 2 Inherited Pheochromocytoma/Paraganglioma Syndrome*

Syndrome	Susceptibility Genes	Clinical Features	Surgical Management Considerations
Carney-Stratakis syndrome	*SDHB, SDHC, SDHD*	Dyad of PPGL and GISTs, with risk of RCC	Patients with large tumors and SDHB mutation have a high risk of malignant tumors, so consider open resection and prophylactic lymphadenectomy.
Hereditary PPGL syndrome	*SDHA, SDHB, SDHC, SDHD, SDHAF2*	Most common germline mutations found in hereditary PPGL *SDHB* related with higher morbidity and mortality and higher risk of malignancy GISTs, renal cell carcinoma, pituitary adenomas	Patients with large tumors and SDHB mutation have a high risk of malignant tumors, so consider open resection and prophylactic lymphadenectomy.
HIF-related PPGL	*HIF2α/EPAS1*	PPGL, polycythemia	High-risk for multiple tumors that should be localized preoperatively to avoid persistent disease
MAX-related PPGL	*MAX*	PPGL, renal cell carcinoma, renal oncocytoma	High-risk of malignant tumors; should consider open resection for large tumors and include prophylactic lymphadenectomy
MEN2A/B	*RET*	Recurrent and bilateral PPGL with a relatively low risk of malignancy Pheochromocytoma >>> Paraganglioma • Mutation in codons 918, 833, 634 on exons 16 and 11 associated with ~50% risk of pheochromocytoma • Mutation in codons 609, 611, 618, 620 in exon 10 associated with ~20% risk of pheochromocytoma • Mutation in codons 804 and 891 in exons 13-15 associated with ~5% risk of pheochromocytoma	Consider partial adrenalectomy to avoid need for steroid replacement as low risk of malignant tumors
TMEM-related PPGL	*TMEM127*	Pheochromocytoma > Paraganglioma RCC	
VHL	*VHL*	Pheochromocytoma > Paraganglioma Low risk of malignancy Clear-cell renal cell carcinoma, pancreatic islet cell tumors, lymphatic sac tumors, hemangioblastoma of the kidney, pancreas, cerebellum and retina	Consider partial adrenalectomy to avoid need for steroid replacement as low risk of malignant tumors.
Von Recklinghausen's disease	*NF1*	Relatively later age of presentation Pheochromocytoma > Paraganglioma Neurofibromas, dermal café-au-lait spots, Lisch nodules, bone dysplasia, skinfold freckling, optic gliomas	Consider partial adrenalectomy to avoid need for steroid replacement as low risk of malignant tumors.

*Mutations in the following genes have also been described, but are either very rare, have not been well-studied, or have not been associated with any known genetic syndromes: *FH, SLC25A11, GOT2, MDH2, PHD2, KIF1β, MERTK, MET,* and *H3F3A*.

GIST, Gastrointestinal stromal tumor; *HIF,* hypoxia-inducible factor; *MEN,* multiple endocrine neoplasia; *PPGL,* pheochromocytoma/paraganglioma; *RCC,* renal cell carcinoma; *VHL,* von Hippel-Lindau.

testing is then followed by imaging studies to localize the tumor. The initial biochemical screening tests include 24-hour urinary fractionated metanephrine and normetanephrine as well as plasma-free fractionated metanephrine and normetanephrine. The sensitivities and specificities of these biochemical tests are dependent on the cutoff value used (> two- to fourfold of the upper limit of normal) and whether the patient has a hereditary predisposition for pheochromocytoma. In patients with a hereditary predisposition for pheochromocytoma, plasma metanephrine testing should be used for screening because it has an overall higher sensitivity compared with 24-hour urinary fractionated testing. However, its specificity is lower, and it is associated with a false-positive rate as high as 10%. Plasma metanephrine should therefore be drawn in the supine position and after an overnight fast to reduce the likelihood of false-positive results resulting from increased levels caused by upright posture, caffeine use, or nicotine use. In patients with borderline elevation in metanephrine and normetanephrine levels, checking chromogranin A and urinary-fractionated metanephrine levels in combination or performing a clonidine suppression test have also been proposed to reduce the likelihood of false-positive results. In addition to many food products, several medications, including acetaminophen, labetalol, sotalol, alpha-methyldopa, tricycle antidepressants, buspirone, phenoxybenzamine, monoamine oxidase inhibitors (MAOIs), sympathomimetics, sulphasalazine, and levodopa, can also cause falsely elevated levels of plasma and urinary metanephrine and normetanephrine. Paragangliomas (by virtue of their extraadrenal location) do not secrete epinephrine because of the lack of phenylethanolamine *N*-methyltransferase (PNMT), except when located in the organ of Zuckerkandl.

Imaging

Once biochemical evidence of PPGL is confirmed, the precise location of the tumor(s) must be identified. Computed tomography (CT) and magnetic resonance imaging (MRI) are the most commonly used imaging modalities (Fig. 1). Pheochromocytomas are better visualized on adrenal protocol CT scans that use thin-cut and timed

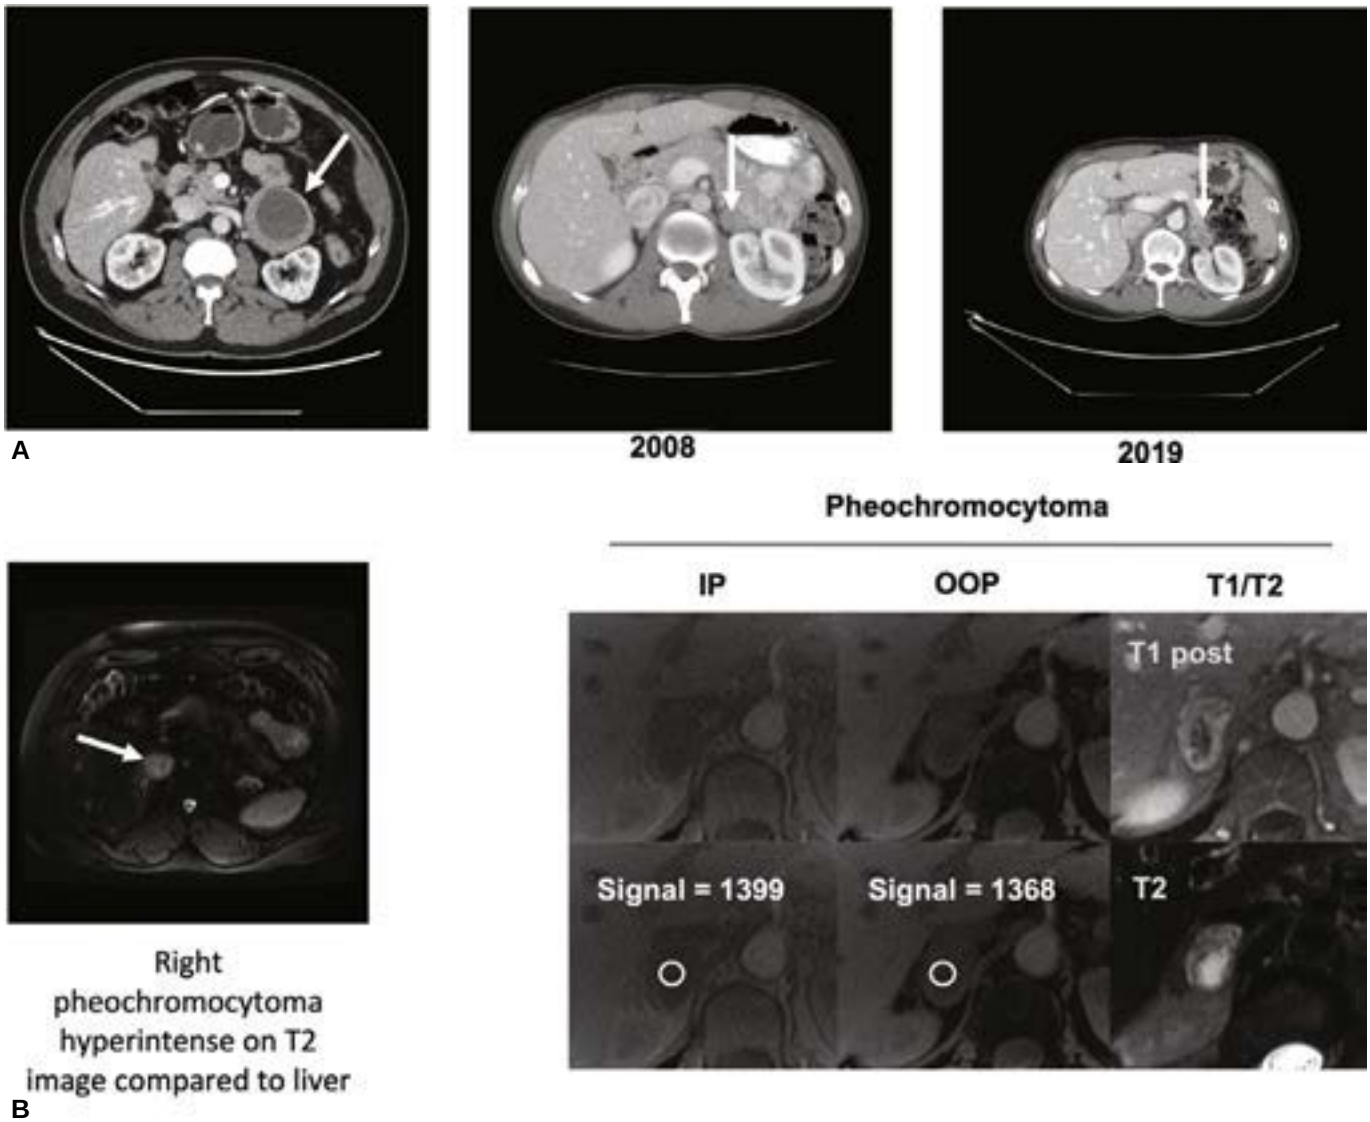

FIG. 1 Anatomic imaging of pheochromocytoma. **(A)** CT scan of the abdomen with intravenous contrast shows a left sided pheochromocytoma that has a central area of necrosis and peripheral enhancement *(left panel, arrow showing mass)*. CT scan of the abdomen in a patient who was found to have an adrenal incidentaloma in 2019 *(right panel, arrow showing mass)* with biochemical testing showing elevated normetanephrine and metanephrine. The tumor is a heterogenous mass, but there was no change in tumor size when compared with an older CT scan in the same patient done in 2008 *(middle panel, arrow showing mass)*. **(B)** MRI of the abdomen on fat-suppressed T2-weighted image shows right-sided pheochromocytoma that is hyperintense *(left panel, arrow showing mass)*. MRI showing a right adrenal pheochromocytoma in phase (IP), out of phase (OOP), and on T1 and T2 *(right panel)*.

intravenous (IV) contrast images to evaluate for tumor enhancement and washout. CT has excellent sensitivity (ranging from 90%–100%) for the detection of both PPGLs. CT findings consistent with a pheochromocytoma include Hounsfield units (HUs) greater than 10 and vigorous tumor enhancement in the early contrast phase, with less than 60% of washout in the venous phase (see Fig. 1A). On noncontrast CT scans, pheochromocytomas commonly have HUs in the range of 40 to 50. PPGLs on CT scan may appear homogenous or heterogeneous, necrotic with some calcification, solid, or cystic. Smaller tumors tend to be more homogenous, while larger tumors are typically more heterogenous and more likely to have necrotic, calcified, and cystic components. CT scans of the neck, chest, abdomen, and pelvis, with and without contrast, should be performed to exclude extraadrenal paragangliomas, using a section thickness of 2 to 2.5 mm in the neck and 5 mm through the chest, abdomen, and pelvis, especially in high-risk patients: young patients (< 40 years) and patients with germline *SDHx* mutations or a family history of PPGLs (see Table 1).

MRI is the imaging test of choice in pediatric and pregnant or lactating patients. Other patient groups that benefit from this modality include patients with documented allergies to CT contrast agents and patients who refuse radiation exposure. Because of their increased vascularity and high water content, PPGLs may have a pathognomonic high signal intensity on T2-weighted MRI (see Fig. 1B). However, this is not always the case, and PPGLs can appear homogenous with intermediate intensity, diffusely heterogeneous with swirl-like areas of high and low signal intensity, and heterogeneous with multiple pockets of high signal intensity (cystic lesions) (see Fig. 1B). MRI has a higher sensitivity for the detection of extraadrenal paraganglioma compared with CT scans, with some studies reporting a sensitivity as high as 100% with MRI.

Although anatomic imaging modalities like CT and MRI have excellent sensitivity, they have very poor specificity. Functional imaging studies, such as nuclear scintigraphy with ^{123}I-metaiodobenzylguanidine (MIBG), ^{18}F-fluorodeoxyglucose (FDG), ^{18}F-3,4-dihydroxyphenylalanine (DOPA), ^{18}F-fluorodopamine (FDA), and ^{68}Ga-DOTA (DOTATATE, DOTATOC, DOTANOC) peptide positron emission tomography (PET)/CT, can be helpful in localizing previously undetected tumors on CT/MRI and for identifying additional tumor sites (Figs. 2 and 3). For ruling out metastatic disease and localizing the primary tumor, ^{18}F-FDG PET/CT and ^{68}Ga-DOTA peptide PET/CT are most accurate (see Figs. 2 and 3). ^{123}I-MIBG scanning is not as sensitive as the other functional imaging modalities and should only be used when planning radiotherapy with ^{131}I-MIBG for patients with metastatic disease.Table 3 summarizes the anatomic and functional imaging studies that can be used to localize PPGLs, with their advantages and disadvantages, and the clinical settings in which their use can facilitate the selection of the optimal surgical management strategy.

PREOPERATIVE MANAGEMENT

The preoperative management of patients with PPGL should focus on the optimization of blood pressure and treatment for tachyarrhythmias. Hypertension and elevated levels of circulating catecholamines predispose patients with PPGL to compromised cardiovascular function, which is commonly manifested as a tachyarrhythmia. These patients may have concomitant, long-standing hypertension, which predisposes them to cardiomyopathy and aseptic myocarditis. A preoperative cardiac evaluation is therefore prudent, regardless of blood pressure levels, to assess cardiac function, optimize perioperative management, and risk-stratify patients for perioperative cardiovascular events.

Preoperative antihypertensive medications to reduce the risk of intraoperative hemodynamic instability are required for all patients with catecholamine-producing PPGLs. Alpha-adrenergic antagonists are usually the first agents of choice because of their ability to lower blood pressure, reverse volume depletion, and reduce peripheral vascular resistance. Patients who are normotensive should be started on alpha blockade to counter any potential activity from dormant tumors that may release catecholamines during intraoperative tumor manipulation. Adrenergic blockade should start 7 to

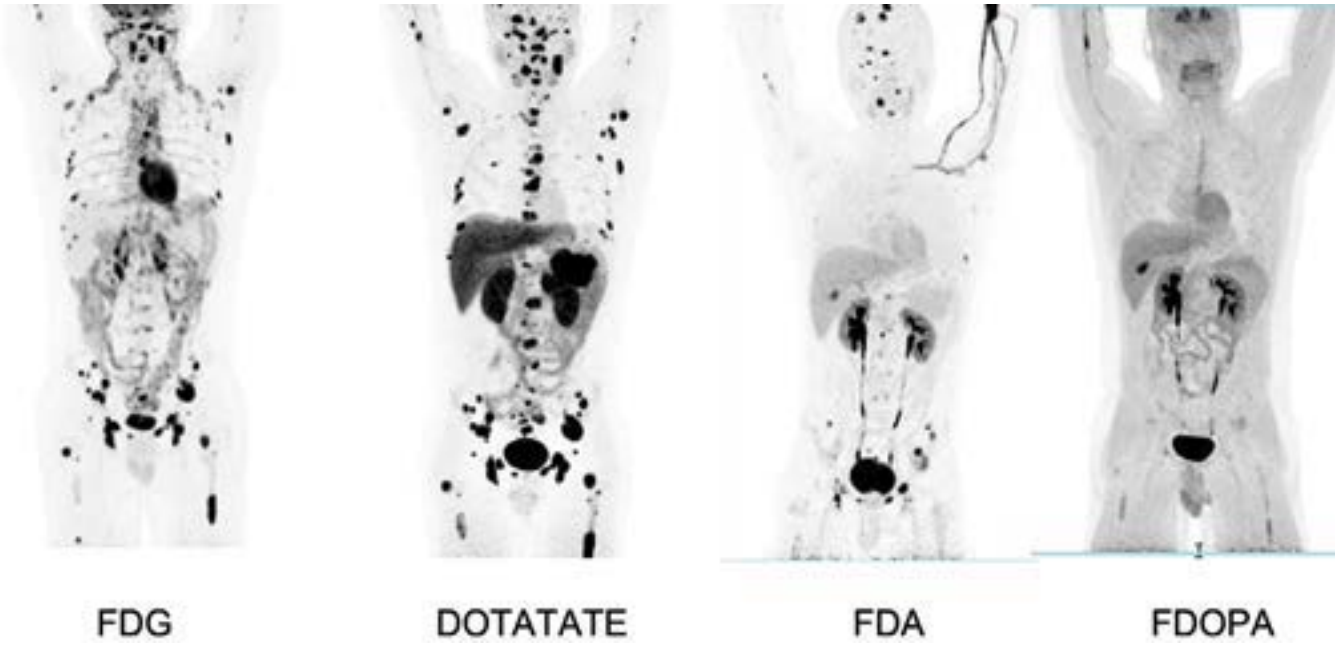

FIG. 2 Functional imaging in a patient with metastatic and recurrent pheochromocytoma. ^{18}F-fluorodeoxyglucose (FDG), ^{68}Ga-DOTATATE, ^{18}F-fluorodopamine (FDA), and ^{18}F-3,4-dihydroxyphenylalanine (FDOPA). The DOTATATE imaging shows the greatest number of metastatic lesions followed by FDG and FDA, and none is seen on FDOPA.

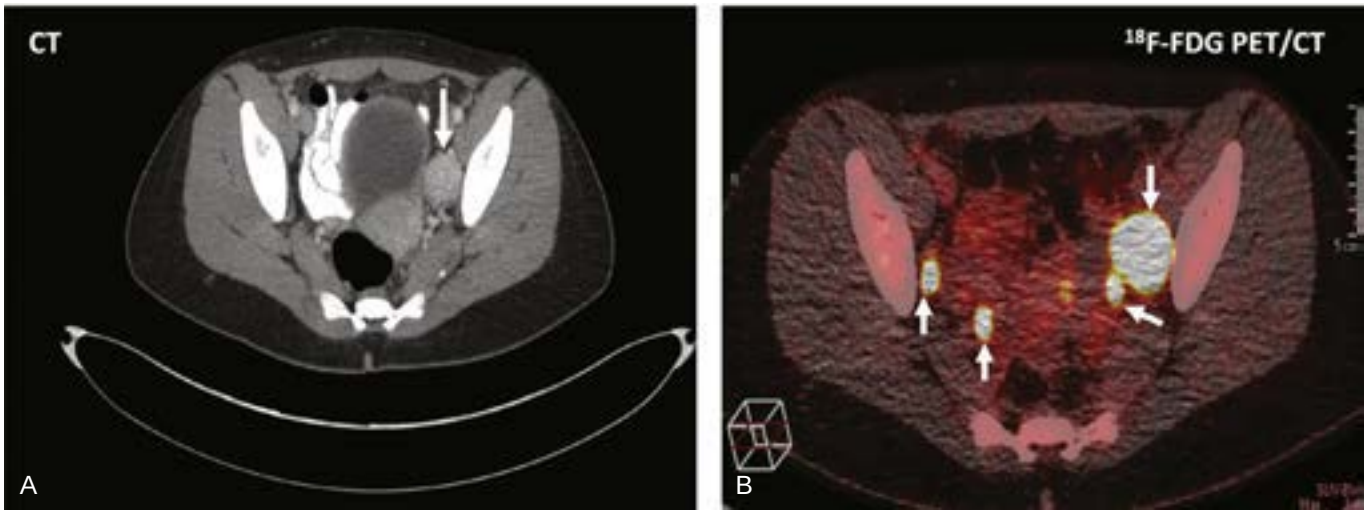

FIG. 3 CT scan **(A)** and ^{18}F-fluorodeoxyglucose (FDG) PET/CT scan **(B)** in a 16-year-old girl with a left functional paraganglioma. CT scan showed only the left paraganglioma *(arrow)*, but ^{18}F-FDG showed additional tumor adjacent to the mass *(arrows)* and on the right side of the pelvis.

TABLE 3 Anatomic and Functional Imaging Studies Used to Localize Pheochromocytomas and Paragangliomas

Imaging Modality	MRI	CT	^{18}F-FDG	^{68}Ga-DOTA Peptide	^{18}F-FDA	^{18}F-DOPA	MIBG
Advantages	Anatomic detail	Anatomic detail	Widely available, preferred functional imaging test	Most sensitive functional imaging study for all sites of disease, potential for therapy with avid disease	Sensitive functional imaging for primary tumor (except skull base and neck)	Most sensitive functional imaging study for skull base and neck paragangliomas	Potential for therapy if disease avid tumor is not resectable
Disadvantages	Lower specificity	Lower specificity	Lower sensitivity and higher false-positive rate compared with other functional imaging studies	Not widely available	Not widely available	Not widely available	Lower sensitivity than other functioning imaging studies
Best clinical setting to use imaging studies	Initial localization of tumor	Initial localization of tumor	Rule out metastatic disease or multiple primary	Rule out metastatic disease or multiple primary; SDHx mutation carriers; when planning treatment with peptide receptor radionuclide therapy	Rule out metastatic disease or multiple primary	Patients with primary skull base and neck paragangliomas; multiple and metastatic disease	When planning treatment with ^{131}I-MIBG

14 days preoperatively to normalize blood volume, blood pressure, and heart rate. We normally initially place patients on phenoxybenzamine (10 mg twice a day). Other alternative agents include a selective alpha antagonist such as doxazosin (2 mg once a day), prazosin (2 mg twice a day), or terazosin (2 mg once a day). The goal should be to achieve a preoperative blood pressure of 130/80 mm Hg or less while sitting and approximately 100 mm Hg while standing. If the patient continues to have high blood pressure, the dose is increased in increments of 10 to 20 mg every 2 to 3 days. In addition, medications are titrated for a heart rate of about 60 to 70 beats per minute (bpm) while sitting and 70 to 80 bpm while standing.

Many patients with PPGL have chronic vasoconstriction secondary to high levels of catecholamines. Preoperative normalization of blood volume reduces the risk of hypotension during or after removal of the tumor. A high-salt diet 3 days after initiation of alpha blockade and 1 to 2 L of normal saline starting the evening before surgery can normalize intravascular volume and reduce the risk of hypotension after removal of the tumor. With appropriate alpha-adrenergic blockade, patients may experience tachyarrhythmias. A beta blocker should be added to control the heart rate 2 to 3 days after initiation of alpha blockade. Most importantly, a beta blocker should never be used in the absence of adequate alpha blockade. The utilization of a beta blocker without alpha blockade leads to unopposed alpha-adrenergic catecholamine stimulation, which will exacerbate vasoconstriction. Beta-selective drugs such as atenolol or metoprolol are started for a target heart rate of 60 to 80 bpm. Labetalol, a nonselective beta blocker, should not be used as first-line therapy because the beta effect is seven times more potent than the alpha effect. For patients with persistent hypertension despite optimal alpha and beta blockade, a calcium channel blocker (30 to 90 mg of nifedipine a day) or metyrosine (1 to 4 grams a day) may be used, although it is important to note that metyrosine has very significant side effects including sedation, fatigue, sexual dysfunction, extrapyramidal symptoms, headache, diarrhea, nausea, and vomiting. Its use should therefore be limited to patients with refractory hypertension and not as a first-line agent.

A diagnosis of PPGL during pregnancy is associated with significant rates of maternal mortality (up to 40%) and fetal mortality (over 50%), resulting largely from the challenges related to preoperative management. Alpha-adrenergic antagonists should be initiated immediately at the time of diagnosis, and plans should be made for an elective third-trimester caesarean delivery. Vaginal delivery is contraindicated in patients with PPGL because of the potential for catastrophic, massive catecholamine release during labor and at the time of delivery. Overall, a combined adrenalectomy at the time of caesarean section versus early postpartum resection is generally preferred. Tumor removal should be avoided during the first trimester because of the high risk of miscarriage. However, adrenalectomy in the second trimester has been reported and may be considered if necessary.

INTRAOPERATIVE CONSIDERATIONS

Successful intraoperative management of PPGL requires collaborative preparation and good communication between the surgery and anesthesiology teams. Despite being adequately blocked by preoperative adrenergic blockade, patients with PPGL may still have hypertensive crises or tachyarrhythmias during manipulation of the tumor. Therefore intraarterial monitoring is required and appropriate venous access, including a central venous catheter for monitoring the volume status, is imperative. Patients may have fluctuations in blood pressure during the operation, so multiple vasoactive medications should be premixed and ready to be administered in anticipation of these labile blood pressures. Hypertensive episodes can be treated with esmolol (500 μg/kg over 1 minute loading dose, followed by a 4-minute maintenance infusion of 50 μg/kg/min) or sodium nitroprusside (0.5 to 3 μg/kg/min), which reduces cardiac preload. Excellent communication between the surgeon and anesthesiology team is required just before ligation of the adrenal vein because this maneuver can lead to abrupt hypotension, which should initially be treated with crystalloids. Once adequate volume resuscitation has been achieved, treatment of persistent hypotension with vasopressors such as norepinephrine, phenylephrine, or vasopressin can be initiated.

OPERATIVE TECHNIQUE

Options for the surgical approach in the resection of PPGL include open and minimally invasive approaches (laparoscopic, robotic), which can all be performed using either a transabdominal or retroperitoneal approach. Minimally invasive surgery for the removal of PPGL is the procedure of choice in most cases and has been shown to be associated with significant advantages compared with open resection: decreased blood loss, decreased blood transfusion requirement, shorter intensive care unit and postoperative hospitalization, decreased analgesic requirements, and faster return to normal patient activity. Furthermore, minimally invasive approaches are associated with fewer catecholamine surges during tumor manipulation and therefore fewer episodes of blood pressure lability. A direct open approach is typically reserved for larger, locally advanced or malignant tumors. Conversion to an open procedure may also be required because of intraoperative suspicion of malignancy or metastatic disease. Robotic-assisted removal of PPGL is also safe and feasible, but it does not appear to afford any significant advantages over laparoscopic resection using either the transabdominal or retroperitoneal approach, especially in light of its higher financial cost.

The surgical approach and extent of resection for pheochromocytoma we use depends on (1) whether the tumor is unilateral or bilateral, (2) whether there are any additional paragangliomas or possible sites of metastatic disease, (3) tumor size, (4) patient body habitus and body mass index, (5) whether the tumor is sporadic or familial relative to the risk of malignancy, and (6) the risk of developing metachronous pheochromocytoma in the contralateral and remnant adrenal gland. We most commonly use a transabdominal laparoscopic approach in patients who have unilateral adrenal tumors and sporadic disease and those who have no evidence of extraadrenal tumors. In patients with bilateral tumors and familial disease with a low risk of malignant pheochromocytoma, such as the MEN2 or VHL syndromes, we perform a cortical-sparing adrenalectomy using a transabdominal or retroperitoneal laparoscopic approach. When patients have unilateral or recurrent tumors, possible site(s) of lymph node metastasis/local invasion, and an *SDHB* germline mutation, we perform a total adrenalectomy and retroperitoneal lymph node dissection with an open approach. Even when the tumor is large, we usually begin the operation using a laparoscopic approach until we encounter evidence of local invasion or features suspicious for malignancy. We believe that a complete resection is most important and, whatever the surgical approach, there should be no fracturing of the tumor or violating the tumor capsule, as there have been reports of pheochromocytomatosis with evidence of higher rates of peritoneal implants, locoregional recurrence, and metastatic disease among patients who underwent laparoscopic resection. For this reason, clinical guidelines recommend open resection for large tumors (>6 cm) and locally invasive PPGLs. Minimally invasive approaches may be used, however, for small, noninvasive paragangliomas in safe and favorable locations.

Transabdominal Laparoscopic Adrenalectomy and Paraganglioma Resection

Transabdominal laparoscopic adrenalectomy is the most common laparoscopic approach used by most surgeons. The main advantage of this approach is a larger working space than that afforded by the retroperitoneal approach. The procedure is performed by placing the patient in the lateral decubitus position, with the operating table flexed. An incision is made one fingerbreadth below the costal margin in the midclavicular line. We use a 0-degree videoscope to enter the peritoneal cavity under direct visualization. Then we use a 30-degree videoscope to place additional trocars and for the dissection. The tumor should not be manipulated, or manipulation should be kept to a minimum, until the venous drainage is divided, as severe hypertension can result otherwise. Clear communication with the anesthesia team is important to anticipate and treat hemodynamic instability during manipulation of the tumor and division of the adrenal vein. The key steps and intraoperative images of a transabdominal laparoscopic adrenalectomy (right and left) are summarized in Figure 4.

For a right adrenalectomy, we use four trocars, from the mid-clavicular line to the mid-axillary line, with a distance of

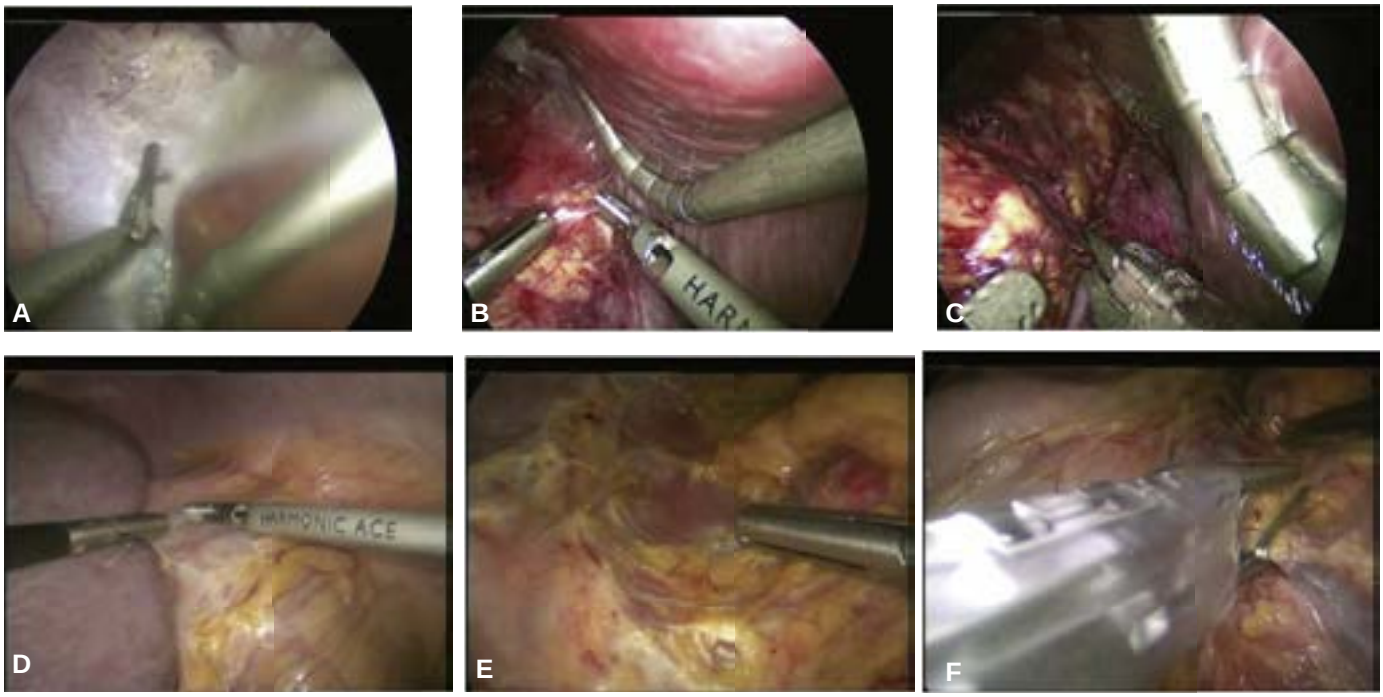

FIG. 4 Key steps in right lateral laparoscopic adrenalectomy. On the right side, **(A)** the triangular ligament is divided to mobilize the right lobe of the liver medially; **(B)** the adrenal gland and tumor are dissected from the top down along the medial edge after opening Gerota's fascia; **(C)** the adrenal arteries (usually small) and the adrenal vein are encountered and the vein is clipped and divided. Adrenal pheochromocytoma may have multiple parasitic vessels. The inferior limb of the gland is carefully dissected free from the renal hilum and the renal vessels. The gland is then mobilized free from the kidney and retroperitoneal fat. The adrenal gland is placed in a bag and removed without morselization. On the left side, **(D)** the splenic flexure of the colon is mobilized free, as well as the lateral attachments of the spleen along the avascular space; **(E)** Gerota's fascia is divided superior and medial to the adrenal gland and the dissection continued inferior; **(F)** often the inferior phrenic vein is identified along the medial aspect of the adrenal gland and can be traced down to the adrenal vein. The vein is clipped and divided. The inferior limb of the gland is carefully dissected free from the renal hilum and the renal vessels. The gland is then mobilized free from the kidney and retroperitoneal fat. The adrenal gland is removed in a bag.

approximately two fingerbreadths between the trocars. The initial dissection consists of dividing the triangular ligament of the liver to mobilize the right lobe of the liver medially and expose the right adrenal gland. Once this has been completed, a fan, paddle, or snake retractor is placed on the right lobe of the liver to maintain the working space. The dissection from the triangular ligament is extended down inferiorly, dividing the peritoneum and Gerota's fascia along the liver down to the infrahepatic inferior vena cava. Commonly, the adrenal vein is encountered during this top-down dissection and is circumferentially dissected, clipped, and divided. Any accessory veins and the three adrenal arteries, which are usually more prominent in patients with pheochromocytoma, are divided by an energy device along this medial dissection. The inferior pole of the gland is then mobilized free from the renal hilum, taking care not to injure the renal artery and vein. The attachment to the superior pole of the kidney and posterior musculature is then divided, and the dissection is extended up to the diaphragm, removing the periadrenal fat along with the gland. We usually detach the attachment to the diaphragm last as it keeps the adrenal gland in place, allowing good visualization of the adrenal hilum and inferior limb of the gland.

For a left adrenalectomy, we usually use three trocars because the spleen and the tail of the pancreas are retracted by gravity. The first subcostal trocar is placed in the midclavicular line at the Palmer point, and the lateral two are placed approximately two fingerbreadths apart and one fingerbreadth from the costal margin. The lateral attachment of the spleen (approximately 1 cm from the lateral edge of the spleen) and the splenic flexure of the colon are released up to the diaphragm until visualization of the cardia of the stomach. This dissection allows the spleen and the tail of the pancreas to be retracted medially by gravity. At the medial aspect, the adrenal gland is dissected top-down along with the periadrenal fat and the adrenal arteries divided with an energy device. Often the inferior phrenic vein is encountered during this medial dissection and can be traced to the left adrenal vein. The adrenal vein is then clipped and divided above the renal vein into which it drains. The inferior pole is carefully dissected free from the renal hilum without injury to the renal vein and artery, and then free from the superior pole of the kidney and from the posterior musculature.

Posterior Retroperitoneal Adrenalectomy

We commonly use the posterior retroperitoneal approach in patients who require bilateral total or partial adrenalectomy and in patients who have undergone previous abdominal operations and have significant intraabdominal adhesions. The key steps of a posterior retroperitoneal adrenalectomy (left and right), including intraoperative images, are outlined in Figure 5. Once there is adequate general anesthesia and intravenous and intraarterial lines are placed and secured, the patient is placed in the prone jackknife position. The hips and knees are flexed at 90 degrees, and all pressure points are padded. Cushions are used to support the hips and lower chest, allowing the anterior abdominal wall to hang unconstrained between

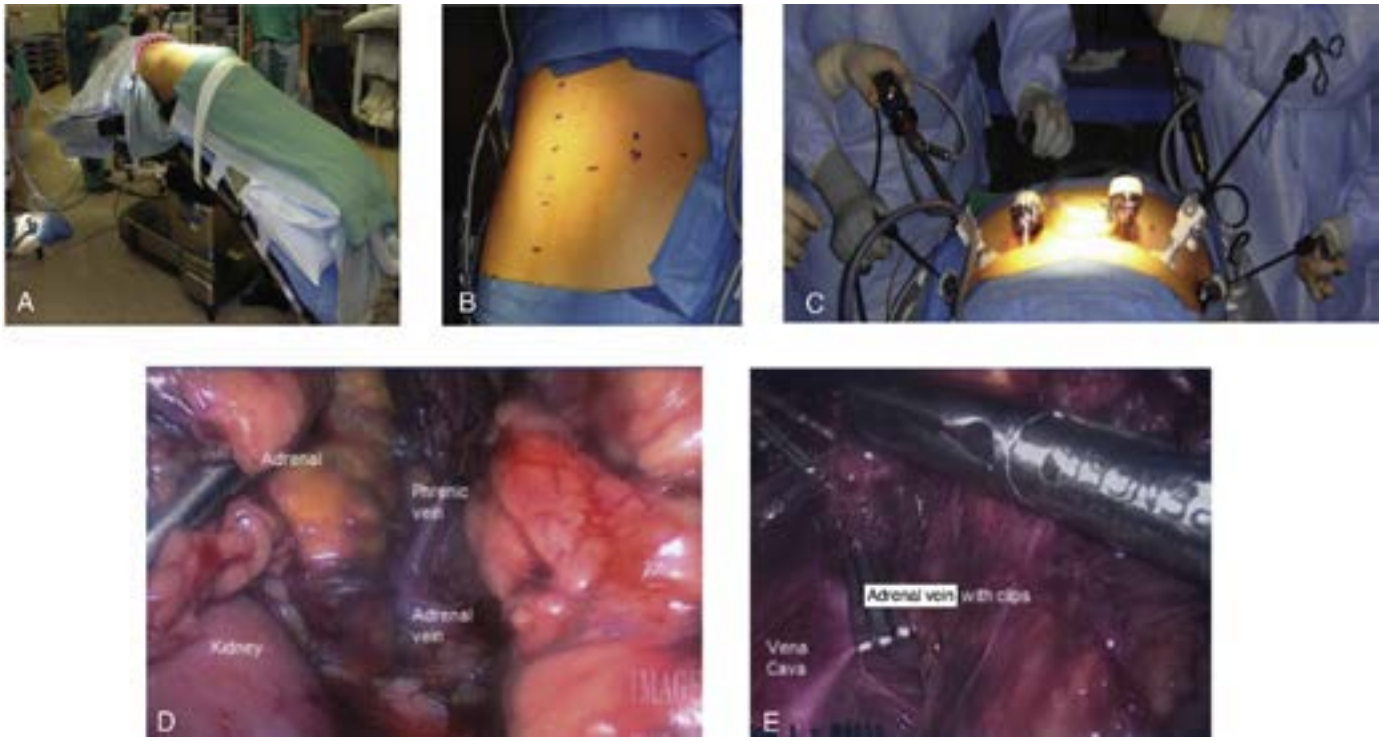

FIG. 5 Retroperitoneal approach for adrenalectomy. **(A–C)** Patient positioning and trocar placement. **(A)** Patient is supported in a modified prone jackknife position. **(B)** Port sites are marked using the 12th rib as a landmark. **(C)** Operative image of simultaneous bilateral adrenalectomy. **(D)** Left adrenal tumor is retracted to expose adrenal vein. **(E)** Operative field after blunt dissection of the retroperitoneal fat down with visualization of the adrenal vein.

the cushions. This helps to expand the retroperitoneal space. The tip of the 12th rib is palpated, and a 1.5-cm transverse incision is made below the tip of the rib and extended into and through the posterior musculature and fascia to enter the retroperitoneum. A working space is initially created by blunt digital separation of the retroperitoneal fat. A lateral 5-mm trocar is inserted 4 to 5 cm from the initial incision, beneath the 11th rib, under finger guidance. Next, a medial 10-mm trocar is inserted 4 to 5 cm medially from the initial incision. Finally, a 10-mm, blunt-tip trocar with an inflatable balloon is inserted and secured in the initial incision, followed by insufflation with carbon dioxide. The pressure should be maintained around 20 mm Hg. The retroperitoneal fat is pushed down and away medially from the posterior musculature and diaphragm. The retroperitoneal fat and the adrenal gland are dissected free from the diaphragm superiorly. The superior pole of the kidney is retracted, and the adrenal gland is mobilized free medially and inferiorly: on the right side, the adrenal vein is identified during this dissection draining into the inferior vena cava; on the left side, it is identified medially and inferiorly along with the phrenic vein in most cases. Once the adrenal vein is clipped and divided, the gland, along with the retroperitoneal fat, is lifted and retracted laterally and superiorly to divide the remaining small vessels and attachments. Hemostasis should be checked after the carbon dioxide pressure is reduced.

Laparoscopic Cortex-Sparing Adrenalectomy

In patients who have MEN2 and VHL and who also have bilateral pheochromocytomas, there is an opportunity to perform cortex-sparing adrenalectomy to avoid the need for long-term steroid replacement and the risk of an Addisonian crisis if a bilateral total adrenalectomy were to be performed. Furthermore, patients with MEN2 and VHL who have unilateral pheochromocytoma may also need to have cortical-sparing adrenalectomy because of the risk of developing a contralateral pheochromocytoma, which would require an adrenalectomy. Laparoscopic cortex-sparing adrenalectomy can be performed in a similar fashion to laparoscopic adrenalectomy in terms of port placement and mobilization of surrounding organs. Intraoperative ultrasound is beneficial in identifying smaller tumors and helping the surgeon identify the margins of resection. The adrenal gland parenchyma can be transected using electrocautery or Harmonic and LigaSure scissors. The remnant adrenal gland is left in situ and not dissected. This is critical, especially if the adrenal vein cannot be spared to maintain adequate blood flow and drainage of the remnant adrenal gland.

Open Adrenalectomy

We use an open adrenalectomy approach in patients who may have malignant tumors, a diagnosis based on a sufficiently large tumor size, the presence of local invasion, or presentation with locoregional recurrence—and for those who have a positive germline *SDHB* mutation or other less-common susceptibility gene mutations, such as *FH* and *HIF2α,* which are associated with a high rate of metastatic disease. We use a subcostal incision for our open adrenalectomies, but a thoracoabdominal incision may be necessary in patients with large, locally invasive tumors. In addition to resecting the primary tumors or site of recurrent disease, we routinely perform a prophylactic retroperitoneal locoregional lymph node dissection. There are several key steps in an open right adrenalectomy for malignant or potentially malignant PPGLs. An extended Kocher maneuver is essential for adequate exposure and to allow vascular control of the infrahepatic inferior vena cava (Fig. 6). The triangular ligament should be routinely divided, and the right lobe of the liver should be fully mobilized medially. When resecting locally invasive tumors, it is essential to gain vascular control over the suprahepatic and infrahepatic inferior vena cava before dissecting the tumor free from the vena cava or dissecting the right adrenal vein. Depending on the extent of local disease, adjacent organs may need to be

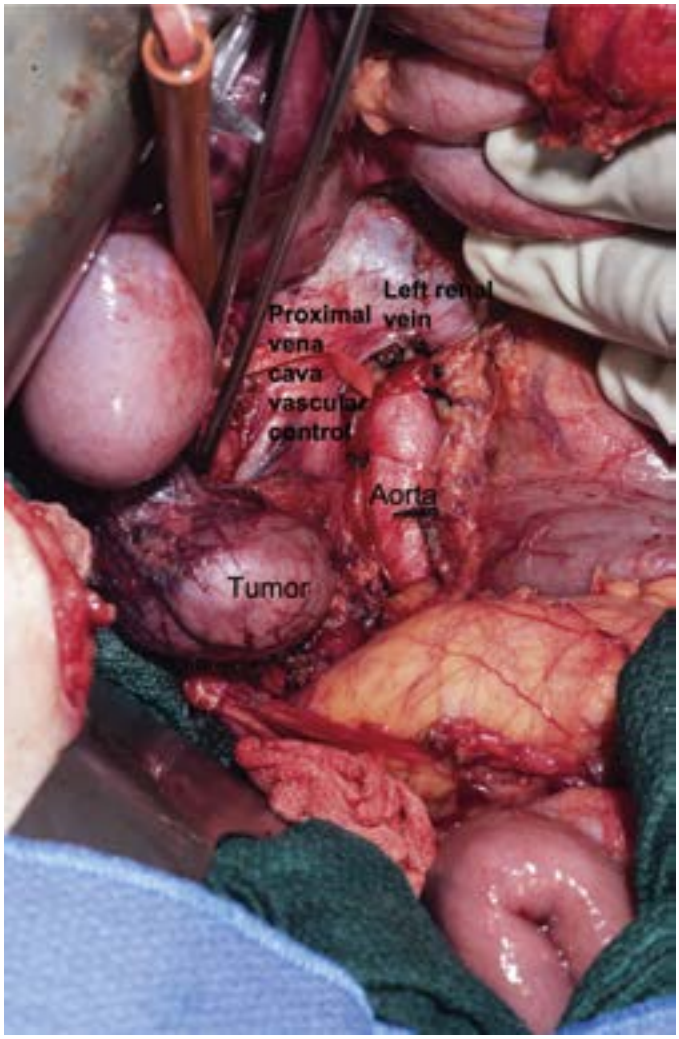

FIG. 6 Open resection of a right infrarenal pericaval paraganglioma after extended Kocher maneuver and proximal vena cava control.

resected (nephrectomy/nonanatomic liver resection/right hepatic lobectomy). For a left open adrenalectomy, division of the gastrocolic ligament and mobilization of the pancreas may be necessary if an en bloc resection of the tail of the pancreas and spleen is planned. If not, the left adrenal gland is exposed by medial rotation of the spleen, pancreas, and left colon. Vascular control of the renal vessels is important for a right or a left open adrenalectomy when removing a locally invasive tumor. For negative margins, a cuff of the posterior musculature or diaphragm, or a full-thickness resection of the diaphragm may be necessary and should be reconstructed primarily or with a Gore-Tex patch graft and an angled chest tube left above the diaphragm. Although it is rare for a patient to require such aggressive surgical treatment for locally advanced PPGLs, most patients who have cardiovascular complications associated with their tumors benefit from such an approach to functioning tumors, especially when an R0 or R1 resection can be performed.

POSTOPERATIVE MANAGEMENT

Postoperatively, patients should be monitored for blood pressure fluctuations in the intensive care unit or a step-down unit for the first 24 hours. Patients may have hypotension caused by the continued effects of alpha-adrenergic blockade or withdrawal of catecholamine and metabolites, and they may require vigorous infusion of intravenous fluids. There have been reports of hypoglycemia caused by rebound secretion of insulin after removal of a pheochromocytoma; therefore blood sugars should be monitored. Plasma metanephrine levels should be evaluated at 6 weeks and at 6 months to confirm the patient's biochemical response.

MALIGNANT PHEOCHROMOCYTOMA AND PARAGANGLIOMA

Currently, there are no histologic, biochemical, or molecular markers that can differentiate patients with benign and malignant PPGLs in the absence of locoregional invasion, distant metastasis, or lymph node metastasis. A metastatic PPGL may be present at the initial time of diagnosis or (commonly) become evident within 5 years of diagnosis. However, there are reports in the literature of recurrences up to 42 years after pheochromocytoma resection, which emphasizes the importance of annual biochemical screening in both sporadic and hereditary PPGLs and imaging surveillance in patients without a functional tumor. Features that have been associated with metastatic PPGLs include a tumor size greater than 5 cm and germline *SDHB* gene mutation.

In patients with metastatic PPGLs, surgical resection of recurrent or metastatic disease is the best treatment option. This is especially true in patients for whom an R0 or R1 resection can be achieved. However, some patients who have widely metastatic disease with elevated catecholamine and metabolites may still benefit from cytoreductive surgery to palliate symptoms or control cardiovascular events associated with the presence of excess catecholamine and their metabolites. The prognosis of patients with metastatic PPGLs is variable, with some patients developing stable disease and others developing rapidly progressive disease, including debilitating symptoms and difficult-to-control cardiovascular complications from the presence of excess catecholamines and metabolites. Overall, the median survival for patients with malignant PPGLs is 7 years, with less than 50% of patients surviving past 5 years.

Patients with unresectable disease may benefit from cytotoxic chemotherapy, such as treatment with a combination of cyclophosphamide, vincristine, and dacarbazine or ^{131}I-MIBG therapy. Unfortunately, only two-thirds of metastases are avid upon MIBG scanning, which can limit the efficacy of this therapy. Up to two-thirds of patients can have an objective response, with complete response, partial response, or stable disease with ^{131}I-MIBG therapy. PPGLs have been localized using newer imaging modalities such as ^{68}Ga-DOTA peptide PET/CT, which shows superior metastatic disease detection rates compared with other anatomic and functional imaging studies. For tumors that are ^{68}Ga-DOTA peptide–avid, peptide receptor radionuclide therapy with ^{177}Lu or ^{90}Y may result in a partial or complete response and symptomatic relief and is currently being studied in clinical trials.

SUMMARY

PPGLs are rare tumors that can occur throughout the body, and they are associated with an increasingly recognized number of genetic mutations. Initial diagnosis of functional PPGLs is by biochemical testing with 24-hour urinary or plasma metanephrines, followed by tumor localization with CT/MRI. Functional imaging studies with ^{18}F-fluorodeoxyglucose (FDG) and ^{68}Ga-DOTA peptide PET/CT are helpful for the evaluation of additional primary tumors and metastatic disease. Genetic testing should be performed in all patients with PPGL. Surgical management of PPGL requires close collaboration and communication with the anesthesiologist. Preoperative alpha blockade and beta blockade is imperative to optimize blood pressure, treat tachyarrhythmia, and restore normal circulating blood volume. Surgical removal is the mainstay of treatment and can be performed via minimally invasive or open approaches with excellent results.

Management of Thyroid Nodules

Quan-Yang Duh, MD, and Sarah S. Sims, MD

INTRODUCTION

There has been a substantial increase in the detection of thyroid nodules and thyroid cancer over the past decades in the United States and other countries, which is attributed to the availability of neck ultrasound. However, deaths from thyroid cancer have remained rare yet relatively constant. Due to increased detection, not accompanied by increased mortality, some are concerned about the overtreatment of thyroid nodules and cancer, and this controversy has been popularized in the mainstream media. It is very important to risk-stratify patients with thyroid nodules to avoid the morbidities of overtreatment that can substantially affect quality of life, while still providing appropriate treatment to achieve optimal outcomes.

Thyroid nodules are very common, affecting as many as half of the population by age 50. Most thyroid nodules are asymptomatic and identified incidentally from imaging studies. Some patients have a palpable neck mass or goiter. The vast majority of thyroid nodules are not cancerous. The rate of cancer, however, is higher in patients with risk factors such as exposure to ionizing radiation at a young age or having a first-degree relative with thyroid cancer. In contrast, thyroid nodules causing hyperthyroidism are rarely cancerous. Patients with suppressed thyroid-stimulating hormone (TSH) (hyperthyroid) and a thyroid nodule are usually first evaluated by scintigraphy to establish the diagnosis (e.g., solitary or multiple hyperfunctioning nodules [Plummer's disease] or hypofunctioning nodules in Graves' disease).

ULTRASONOGRAPHY

Ultrasonography is safe and the most efficient first-line evaluation for thyroid nodules. Multiple large cohort studies have identified ultrasound characteristics of thyroid nodules that are associated with risk of cancer. The high-risk characteristics include nodules that are large, hypoechoic, contain microcalcifications, have irregular borders, or are taller than they are wide. Ultrasound characteristics associated with a low risk of thyroid cancer include nodules with more cystic components and those that have clear borders or are spongiform. Ultrasound characteristics help to stratify the risk of thyroid cancer and are used to determine when fine-needle aspiration (FNA) biopsy is indicated. The 2015 American Thyroid Association guidelines recommend FNA for thyroid nodules larger than 1 to 2 cm depending on their ultrasound characteristics: 1 cm for those classified at highest risk by ultrasound and 2 cm for those classified at the lowest risk (Fig. 1). The American College of Radiology has developed the Thyroid Imaging Reporting and Data Systems (TI-RADS) to provide a point scale option to "quantify" the level of risk for each nodule in addition to guidance for size threshold of when to biopsy based on TI-RADS score (Fig. 2).

NONULTRASOUND THYROID INCIDENTALOMAS

Occasionally, thyroid nodules are found on imaging modalities other than ultrasound, such as computed tomography scans and magnetic resonance imaging. These still should be investigated by ultrasound, and further workup should proceed accordingly. Hypermetabolic thyroid nodules incidentally found on fluorodeoxyglucose-positron emission tomography (PET) scan are at higher risk for cancer, thus FNA is recommended at the lower threshold of more than 1 cm.

OTHER TESTS IN EVALUATION OF THYROID NODULES

Serum levels of thyroglobulin are useful in the follow-up of patients with differentiated thyroid cancer but not in the diagnosis of whether a thyroid nodule is cancerous, because serum thyroglobulin can be elevated in many patients with benign thyroid disease. Although serum calcitonin measurement has been advocated in some European countries as a screening test for medullary thyroid cancer in patients with thyroid nodules, it is not done routinely in the United States. Furthermore, of studies showing that calcitonin screening is helpful, most used pentagastrin stimulation, which is not available in the United States or Canada. Without a known risk factor for medullary thyroid cancer (such as a family history or other manifestation of multiple endocrine neoplasia type 2), routine measurement of serum calcitonin has a low yield, a high false-positive risk, and is not cost effective.

SIZE OF THYROID NODULE

Current guidelines generally recommend further evaluation only for thyroid nodules larger than 1 cm. Nodules smaller than 1 cm in patients with previous radiation exposure, family history of thyroid cancer, or other high-risk clinical findings, such as hoarseness or rapid growth, and those associated with lateral lymphadenopathy may warrant biopsy. Evaluation of multinodular goiters follows similar criteria for biopsy as for solitary thyroid nodules. Rapidly growing goiters or those causing compressive symptoms, such as dysphagia, dysphonia, or dyspnea, have independent indications for thyroidectomy and may not need biopsy unless the results will change the operative plan.

BIOPSY

FNA biopsy can be done by palpation, but ultrasound-guided biopsy is associated with fewer nondiagnostic aspirates. To address variability in the reporting of FNA results for thyroid nodules, the National Cancer Institute developed the *Bethesda Classification* of thyroid cytopathology in 2009, which was updated in 2017. In this system, there are six categories that represent a spectrum for the risk of thyroid cancer. Category I is nondiagnostic, and categories II and VI are benign and malignant, respectively. Benign FNA cytology (category II) has a malignancy rate of up to 3%. A small subset of thyroid nodules with very high-risk ultrasound characteristics will likely have a

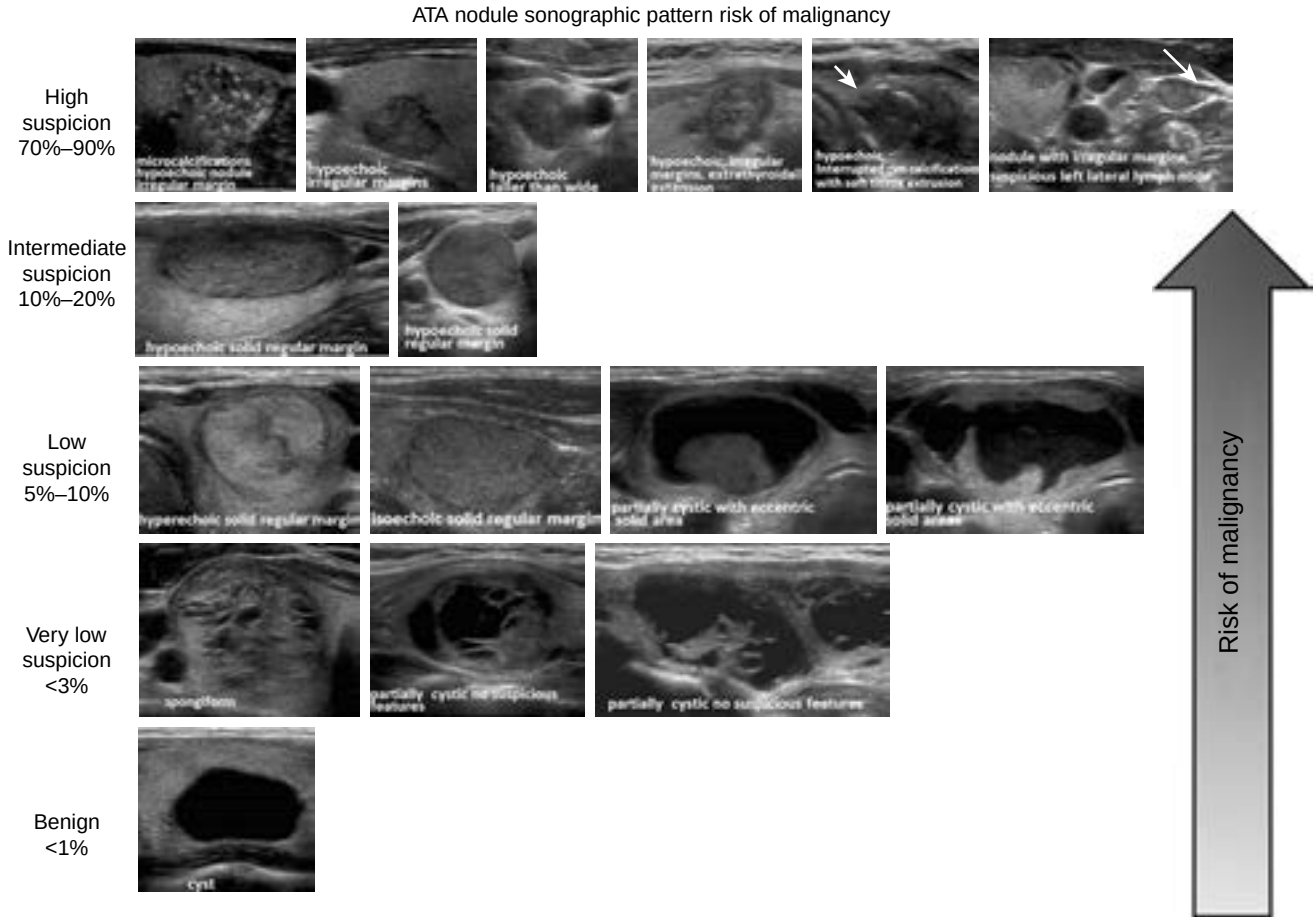

FIG. 1 American Thyroid Association (ATA) nodule sonographic pattern risk of malignancy. *(From Haugen BR, Alexander EK, Bible KC, et al. 2015 American Thyroid Association Management Guidelines for Adult Patients with Thyroid Nodules and Differentiated Thyroid Cancer. Thyroid. 2015;14:26, Fig. 2.)*

much higher risk of malignancy even with a benign FNA cytology. Malignant biopsies (category VI) have an accuracy rate of 97% to 99%. Categories III through V nodules have a spectrum of risk that varies by center and depends also on the malignancy rates of the population ("pretest probability"). Category III nodules include nodule with atypia of undetermined significance (AUS) and follicular lesion of undetermined significance (FLUS). Category IV nodules include follicular neoplasm (FN)/suspicious for follicular neoplasm. Hurthle cell neoplasms are included in this category. Category V nodules are those suspicious for malignancy. The reported rates of cancer in these categories are 10% to 30% for AUS/FLUS, 25% to 40% for FN, and 50% to 75% for suspicious for malignancy lesions (Table 1).

Noninvasive Follicular Thyroid Neoplasm with Papillary-Like Nuclear Features (NIFT-P)

Since the release of the 2015 American Thyroid Association Guidelines, an additional pathologic classification for some thyroid nodules has been created. Noninvasive follicular thyroid neoplasm with papillary-like nuclear features (NIFT-P) represents a subset of thyroid nodules with almost no risk of metastatic spread and is therefore no longer considered a malignancy. The diagnosis requires a complete histopathologic review of the entire nodular capsule to ensure no capsular invasion. NIFT-P is indistinguishable from other follicular lesions on FNA, and therefore surgical removal is required to differentiate these lesions from well-differentiated thyroid cancers. As it is no longer considered malignant, Table 1 demonstrates probabilities of malignancy that are lower because a subset of tumors previously defined as malignant are now considered benign.

INDETERMINATE NODULES

For patients with benign or malignant nodules, there is usually a clear treatment plan. For FNA cytology of indeterminate nodules, Bethesda categories III and IV, the decision for operation versus observation is more complex because of the uncertainty for risk of malignancy. Over the past decade, there has been an explosion of research into molecular analysis of these thyroid nodules with indeterminate cytology. Knowing when and whether to use which molecular tests and how to interpret their results has become an important prerequisite for a modern thyroid surgeon.

MOLECULAR TESTING

Molecular testing may be used for patients with indeterminate nodules to help with the decision to operate (or to perform a more aggressive operation) or to observe. It is important to know that molecular testing may not give a simple yes or no answer but usually returns a probability for risk of cancer for the nodule tested.

MUTATIONAL ANALYSIS

ThyroSeq v3

ThyroSeq is a molecular test for indeterminate thyroid nodules based on molecular alterations in cell DNA and RNA. Since its initial introduction in 2007, it has evolved from a 7-gene panel to the most recent ThyroSeq v3 genomic classifier which was launched in 2017 and uses sequencing technology to analyze 112 genes to test for mutations,

insertions and deletions, gene fusions, gene expression alterations, and copy number alterations (important for Hurthle cell and follicular carcinomas). A ThyroSeq v3 result provides the clinical team with the genetic alterations, if present, and the respective probability of cancer based on that combination of alterations. The frequency of negative test result in ThyroSeq v3 for Bethesda III/IV nodules is above 60% (benign call rate), and residual cancer risk in these test-negative nodules is approximately 3%, which allows some patients with indeterminate nodules to safely avoid surgery with a negative ThyroSeq v3 result.

Afirma Genomic Sequencing Classifier (GSC)

Afirma Genomic Expression Classifier (GEC) used a microarray measurement of messenger RNA expression of 167 genes in indeterminate nodules to give further guidance on management. It had a great negative predictive value (NPV) of up to 95%; however, it has been replaced by Afirma GSC due to its lower positive predictive value (PPV) of around 38% and specificity of 50%, limiting use in positively predicting malignancy. Afirma GSC evaluates nuclear and mitochondrial RNA transcriptome gene expression, RNA sequencing, and genomic copy number analysis. It has a benign call rate of around 76% and specificity of 94%. This has reduced the number of unnecessary surgeries as compared to Afirma GEC.

SURGICAL MANAGEMENT

Although surgery is not the main focus of this chapter, it is obvious that diagnostic testing for thyroid nodules have significant implications for thyroid surgery. Current guidelines have trended toward more conservative surgery (lobectomy instead of total thyroidectomy with no routine central neck dissection) for smaller, low-risk thyroid cancers. If a diagnostic lobectomy is the definitive treatment for low-risk small cancer, preoperative confirmation of thyroid cancer may not be as important. When determining the extent of surgery such as a thyroid lobectomy versus total thyroidectomy, the probability the nodule is cancer, the type of mutation or cancer the nodule has, and the probability that the cancer would progress should all be considered. Other indications for surgery can include thyroid nodules that are symptomatic or causing local symptoms, including substernal goiters or substernal nodules. In addition, hyperfunctioning nodules can be an indication for resection instead of treatment with radioiodine treatment.

MANAGEMENT OF BENIGN NODULES WITH RADIOFREQUENCY ABLATION

Thyroid radiofrequency ablation (RFA) is an emerging technique that is used to treat benign thyroid nodules without surgery. RFA uses alternating electric current to agitate tissue ions with results in heat production and coagulation necrosis of the tissue. This results in progressive volume reduction over time, 50% reduction within the first few months and 85% reduction beyond 6 months. For appropriately selected patients with nodules showing benign characteristics on imaging, aspiration cytology confirmed benign, and who desire volume shrinkage of their thyroid nodule for symptomatic or cosmetic reasons, this is a newly adopted technique that shows promise. Following RFA, patients require surveillance with ultrasound. On follow-up, if the nodule grows or has other sonographic changes, or if the patient becomes symptomatic, FNA or lobectomy can be offered.

CONCLUSION

As more thyroid nodules are being found, it is important for a thyroid surgeon to have a clear algorithm for their evaluation. Ultrasound is the primary imaging test for a thyroid nodule. Size and ultrasound characteristics are used to determine the need for FNA. Cytology should be reported based on Bethesda classification, which stratifies the risk of cancer. Advances in molecular testing can be useful for surgical decision in patients with Bethesda III and IV indeterminate nodules. Clinical judgment remains paramount in deciding when to use these tests and how to interpret them.

Nontoxic Goiter

Matthew A. Nehs, MD, and Gerard M. Doherty, MD

OVERVIEW

Goiter is a nonspecific term referring to any enlargement of the thyroid gland. However, in common use, it mainly denotes benign causes of thyroid enlargement, such as toxic multinodular goiter, diffuse toxic goiter (Graves' disease), or nontoxic multinodular goiter. Though malignant enlargement of the thyroid gland can technically be considered a goiter, it is usually referred to as a *mass* or *nodule*.

Nontoxic goiter is a benign condition, even though some specimens may contain small incidental cancers (up to 20% contain microcarcinomas). The predominant decision-making process is based on the benign enlargement and resulting symptoms (e.g., dysphagia, dyspnea, or neck pressure). In some areas of the world, nontoxic goiters are endemic due to iodine deficiency, though public health efforts have reduced this somewhat.

PATHOGENESIS

A nontoxic multinodular goiter is defined as an enlargement of the thyroid gland containing follicles that are morphologically and functionally altered. The pathogenesis is multifactorial and can include

iodine deficiency, goitrogens such as bamboo shoots, maize, and sweet potatoes, genetic factors, and dyshormonogenesis. A family history of nontoxic goiter could implicate the environment, diet, or dyshormonogenesis as causes. Aside from severe iodine deficiency, the cause in an individual is typically not evident nor does it often influence management.

CLINICAL FEATURES

Nontoxic goiters may remain asymptomatic, or they may give rise to compressive features such as dyspnea, dysphagia, or venous congestion/discomfort with certain movements. A change in the voice can occur from direct pressure on the larynx or from stretching of the laryngeal nerves. Direct effects on the nerve causing paresis of the ipsilateral vocal fold are uncommon from benign goiter, as nerve paresis is much more commonly associated with malignant infiltration of the nerve. Sudden changes in the goiter, as from hemorrhage into a nodule, can cause transient, intermittent, or permanent hoarseness. Thyroidectomy can often assuage voice changes due to direct pressure on the larynx, but the benefits for more uncommon changes due to effects on the nerve are inconsistent.

On physical examination, the size of the gland, the features of diffuse enlargement or nodularity, tracheal deviation, and extension of the gland below the sternum or clavicular heads or high up into the neck near the angle of the mandible are all important for treatment planning. Many large goiters are not palpable by physical examination, particularly if they have a predominant substernal or posterior component (Fig. 1). Associated lymphadenopathy should raise suspicion of malignancy.

EVALUATION

Thyroid-stimulating hormone (TSH), free T4, and T3 levels should be assessed to identify subclinical or overt thyrotoxicosis, hypothyroidism, or a euthyroid state. Fine-needle aspiration should be performed with ultrasound guidance for any suspicious thyroid nodule. Ultrasound features that raise the risk of malignancy include hypoechogenicity, microcalcifications, hypervascularity, and solid components of complex (cystic and solid) nodules, as well as regional lymphadenopathy.

Plain chest films can demonstrate tracheal deviation, retrotracheal and retrosternal extension, airway compression, and gross calcifications. However, cross-sectional imaging such as CT or MR is more informative for these findings. In particular, evaluating the extent of airway compression, the precise geometry of goiter position in the chest, and any associated lymphadenopathy that might indicate a clinically significant malignant component is much more effective with CT or MR.

Radioiodine scans, pulmonary function tests, flow volume loops, and barium swallow studies may each be useful in specific situations but are not typically necessary in the era of accurate cross-sectional imaging.

Preoperative assessment of vocal fold movement should be considered for each patient. Deliberate voice assessment is mandatory,

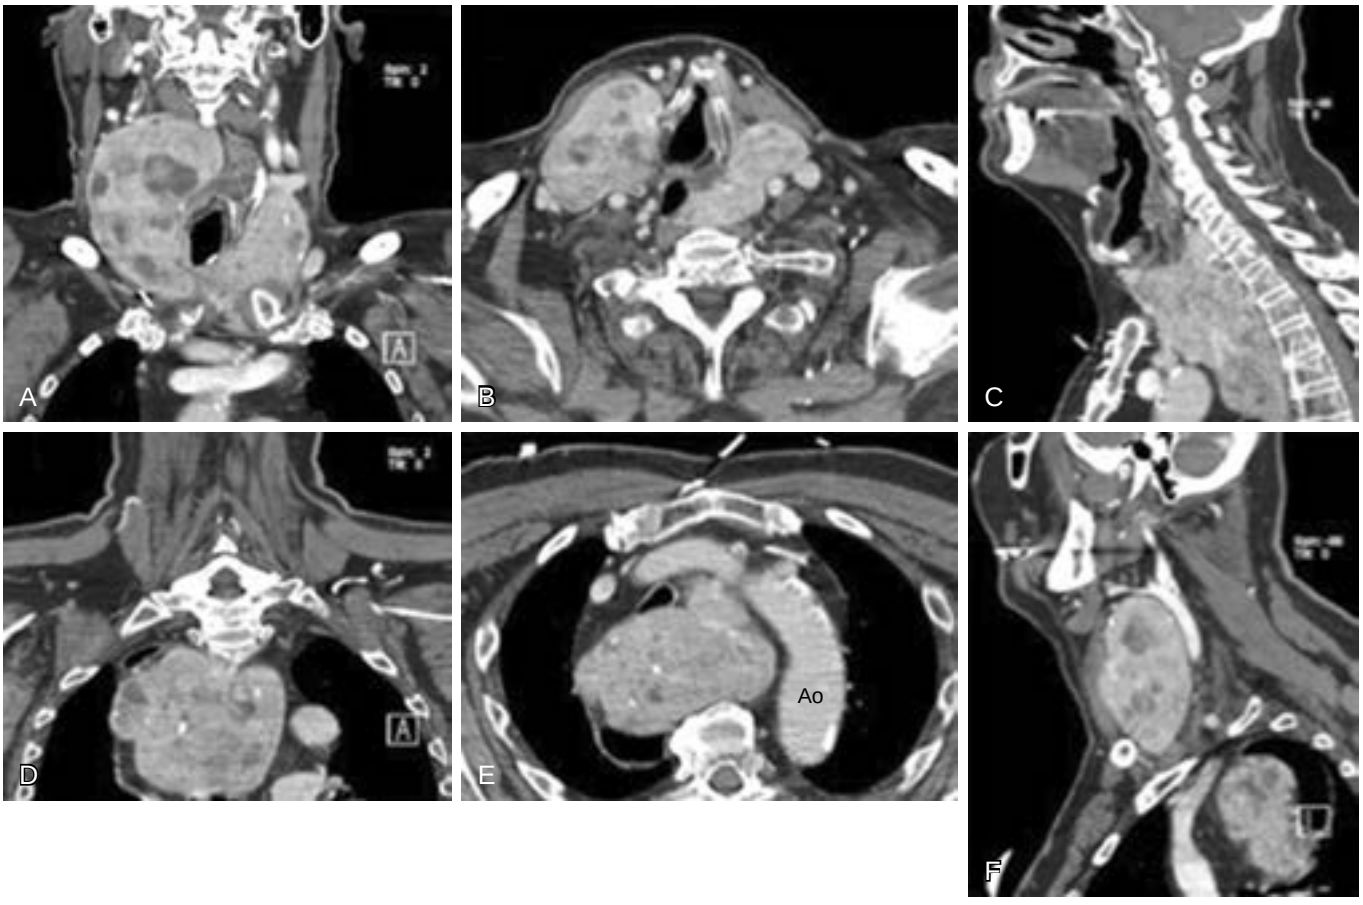

FIG. 1 An 82-year-old man with a palpable right thyroid mass. Cross-sectional imaging revealed a heterogeneous bilateral massive nontoxic multinodular goiter **(A, B)** with a retrosternal left thyroid lobe **(C, D)**. **(E)** Note that the retrosternal component is below the arch of the aorta (Ao) and has grown along the prevertebral fascia. **(F)** The right upper pole has displaced the course of the right common carotid artery. This patient required manubriotomy to deliver the mediastinal component of the gland safely.

and fiber-optic laryngoscopy should be considered for patients with any voice alteration or any prior neck or chest operation that places the vagus or recurrent laryngeal nerves (RLN) at risk of having been injured. It is important to assess for inspiratory stridor, which can be associated with severe narrowing of the tracheal lumen (Fig. 2), and cross-sectional imaging is critical in this situation.

INDICATIONS FOR TREATMENT

Nontoxic goiter that causes local discomfort, such as tightness or a choking sensation, especially with certain movements, or that has caused mechanical partial obstruction of the upper aerodigestive tree should be considered for treatment. Substantial extension of the goiter into the chest, even in the absence of symptoms, should be considered a relative indication for treatment, as further enlargement of the thoracic component can lead to the need for a more disruptive operation to resect it in the future. Cosmesis alone is rarely an isolated concern or indication for therapy because most patients with goiter of sufficient size to be bothersome also have other associated symptoms.

TREATMENT MODALITIES

TSH-suppression therapy with thyroxine has little role in the management of an established goiter. Prospective trials have failed to demonstrate a benefit for management of multinodular goiter. The side effects of TSH-suppression, including bone density loss and atrial arrhythmias, negate the theoretical value, particularly in elderly patients for whom nonoperative therapy might be most attractive.

Radioiodine administration can cause goiter size reduction of 40% to 60% within 2 years, decreasing compressive symptoms. Complications include radiation thyroiditis and hypothyroidism, as well as a temporary enlargement of the gland, which may be important in some clinical situations. Recent experience with the use of exogenous TSH administration to increase the efficiency of radioiodine administration in goiters with limited iodine uptake shows some improvement over radioiodine alone. These approaches may be useful for patients who have comorbidities that affect the safety of operative management, but those same comorbidities must be considered if the patient may become temporarily hyperthyroid from treatment or as the time course of correction of the local pressure symptoms of the goiter is extended. Percutaneous ablation of thyroid tissue shows promise but is currently mainly used for large benign nodules rather than for ablating larger volumes of tissue such as diffuse goiter.

Surgical management is the mainstay of treatment for symptomatic, nontoxic goiter and is generally well-tolerated even in patients with limited physiologic reserve. The operation should typically be a bilateral procedure, removing all, or nearly all, of both thyroid lobes, in addition to any substernal extension. The operation is nearly always limited to a cervical incision, with median sternotomy or posterolateral thoracotomy being necessary only very rarely in previously unoperated patients. In experienced centers, complication rates are low (<2%) with techniques that include careful hemostasis and liberal parathyroid autotransplantation. For patients with significant airway compression or deviation, securing the airway can be the most critical part of the operation and may require conscious fiber-optic intubation under topical anesthesia to begin the procedure.

The thyroid gland should be exposed by a sufficient incision; though many thyroid operations can be done through very limited incisions, the geometry of the large multinodular goiter often requires a long incision to safely expose and remove the gland. Subplatysmal flaps improve the exposure of the limits of the gland, especially superiorly for glands with upper poles that extend high in the neck. The strap muscles can be separated in the midline or divided near the upper pole, as necessary, to expose the thyroid gland. In almost all cases, division of the sternothyroid muscle at the thyroid cartilage is sufficient for this exposure, but the sternohyoid can be divided as well if necessary. The larger the cervical portion of the gland, especially the upper poles, the more likely it is that transverse division of the sternohyoid and sternothyroid muscles will be helpful.

We find it helpful to divide the isthmus early in the case, as this provides a useful anterior landmark, particularly in cases where tracheal deviation distorts the typical course of the trachea and larynx. We then begin the dissection on the side of the larger lobe if the goiter is asymmetric. This ensures that the patient will have the most benefit in case the procedure has to be confined to a unilateral procedure (e.g., intraoperative RLN injury).

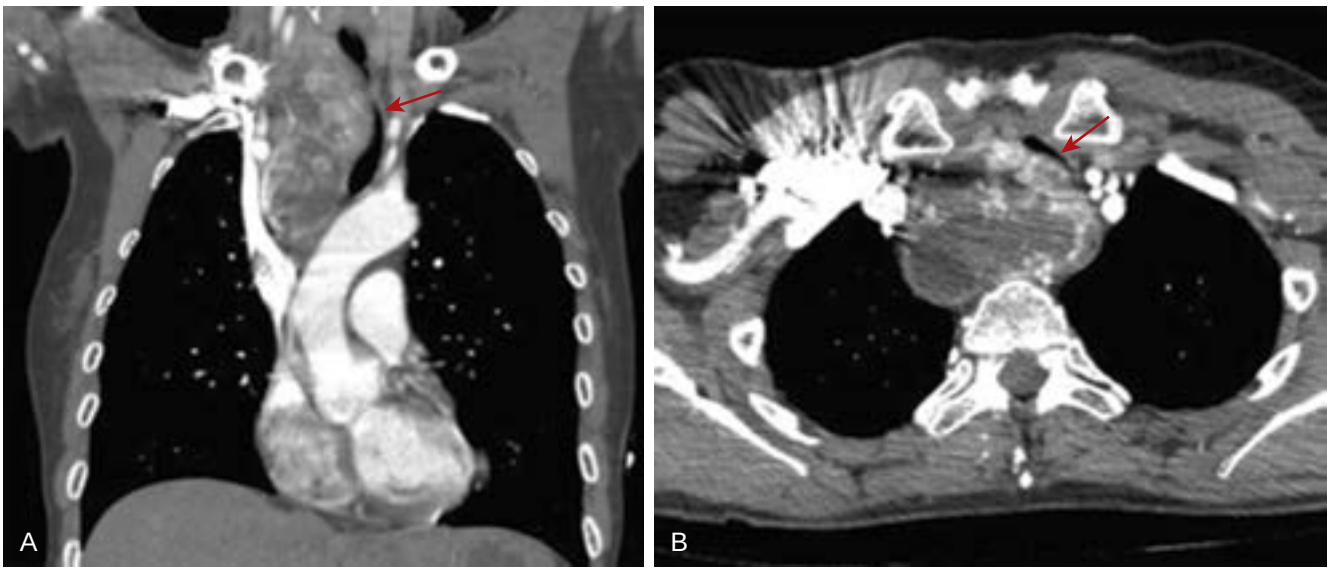

FIG. 2 A 68-year-old woman with an incidental goiter found during workup for dyspnea. On physical examination, the patient had no evidence of a palpable thyroid mass, but she had mild inspiratory stridor. A CT scan revealed a large right-sided substernal thyroid with tracheal deviation to the left **(A)** as well as severe narrowing of the lumen of the trachea **(B)**.

The upper pole of the gland is isolated by first separating the lateral aspect of the upper portion of the thyroid gland from the carotid sheath. If recurrent nerve monitoring is used, then the sheath is opened and the vagus nerve stimulated to establish baseline electromyography (EMG) function. The plane between the larynx and the upper pole of the thyroid gland is then opened, exposing the superior thyroid artery. The external branch of the superior laryngeal nerve (EBSLN) can be identified during some operations by direct inspection or by nerve monitor stimulation, keeping in mind that many EBSLNs run in an intramuscular course. Positive confirmation of the nerve can be determined by seeing a symmetric wave in both the anterior and posterior segments of the ipsilateral cricothyroid muscle in response to nerve stimulation. However, in any case, the delicate fascia over the cricothyroid muscle should be kept intact as the nerve is deep to this. As the plane is followed superiorly, the EBSLN should stay medial and superior to the upper pole of the thyroid and its vessels. The upper pole vessels can then be divided safely using any number of hemostatic strategies, including ligatures, clips, and powered dissection tools. The branches of the superior thyroid artery should be individually controlled immediately adjacent to the thyroid parenchyma to minimize the risk to the EBSLN.

Once the upper pole is fully mobilized, the thyroid is partially rotated anteriorly and medially to continue dissecting the lateral portion of the thyroid gland. The middle thyroid vein, if present, is divided and the thyroid separated from the carotid sheath along its entire extent. The dissection can then be carried posteriorly into the paratracheal space. The ability to rotate the thyroid gland may be limited by a large substernal component. The decision of whether to proceed with the dissection of the tracheoesophageal groove, RLN, and parathyroid glands (our preference), or whether to dissect the substernal portion of the goiter to create the necessary mobility, is dictated by the geometry of the particular patient and goiter. A large substernal component with a narrow thoracic inlet can create venous congestion of the goiter and significant hemorrhage from the capsular veins of the gland. Delivery of the substernal component (either transcervically or by manubriotomy) will often relieve this congestion and allow a more hemostatic dissection.

The tracheoesophageal groove is dissected to identify the RLN. We try to identify the RLN as low in the neck as possible, as this is the area where the nerve is least tethered to surrounding structures and least likely to be stretched during dissection and identification. The nerve is identified by its appearance, anatomic course, and by stimulation if nerve monitoring is used; however, stimulation alone is not sufficient to identify the RLN. In particular, the absence of an EMG signal does not prove that a stimulated structure is not the RLN. Although intraoperative nerve monitoring is used by many experienced thyroid surgeons as an intraoperative adjunct, large trials have failed to show a benefit to patients as measured by RLN injury rates. The use of intraoperative nerve monitoring is a reasonable adjunct at the discretion of the surgeon but is not a required standard of care.

Once the recurrent nerve is identified, it can be separated from the posterior aspect of the thyroid gland, and the intrathoracic portion of the thyroid gland can be safely delivered into the wound. The arterial supply to the thyroid goiter comes entirely from branches in the neck; there is no intrathoracic arterial supply to be concerned with (with the exception of the rare thyroid ima, which can arise from the innominate artery or the aorta). The main risk, then, is traction on the RLN as the substernal or paraesophageal intrathoracic portion of the goiter is delivered into the cervical wound by blunt dissection and gentle traction.

An important note of caution: in posteriorly displaced goiters with a component that extends inferiorly along the esophagus, especially on the right, the RLN may pass anterior to some portion of the goiter and may appear to be buried within the thyroid parenchyma as it has been trapped between nodules. This configuration makes the RLN especially vulnerable to stretch injury if this possibility is not recognized and anticipated early in the dissection.

Once the nerve is identified and the inferior portion of the thyroid gland mobilized, the RLN is traced up to its insertion into the larynx under the inferior border of the cricopharyngeus muscle. The small branches of the inferior thyroid artery are divided along the parenchymal surface of the gland with the RLN always in view and protected. The parathyroid glands typically become evident during this portion of the dissection. Their blood supply from the inferior thyroid artery should be preserved if possible. If not, then the glands should be removed and grafted into the sternocleidomastoid muscle. As the dissection approaches the insertion of the RLN into the larynx, the RLN becomes progressively more fixed by surrounding tissues, including branches of the inferior thyroid artery, the fascial attachments of the thyroid gland to the trachea, and the insertion itself. Great care is necessary to safely dissect the thyroid gland away from the RLN without directly injuring or stretching the RLN. Once the RLN is fully separated from the thyroid gland, the final attachments of the thyroid gland to the trachea can be divided. If intraoperative nerve monitoring was used, then the EMG signal with vagus nerve stimulation should be assessed at the completion of the dissection.

The process is then repeated on the opposite side. If there has been difficulty with the dissection on the initial side, then the contralateral procedure may be modified to reduce the risk of complications. For example, if the RLN lost function as documented by intraoperative nerve monitoring, then the contralateral RLN dissection may be modified to leave the RLN segment near the laryngeal insertion undisturbed by leaving a portion of the thyroid lobe in place at that position.

Devitalized parathyroid tissue should be cut into small (1–2 mm) pieces and grafted into small pockets in the sternocleidomastoid muscle. It is best to close each pocket with a suture to hold the graft in place while it develops a blood supply over the ensuing 6 to 12 weeks. It is not necessary to attempt to mark the site with permanent sutures or clips because subsequent reoperation to remove these remnants is extremely rare and best guided by ultrasound if necessary.

Meticulous hemostasis is important, as bleeding in the confined space of the neck can compromise breathing. The strap muscles are reapproximated in some fashion, depending upon how they were opened or divided, but the closure should not be occlusive. We routinely leave a large gap at the inferior aspect of the strap muscles to allow decompression if a postoperative hematoma should occur. The platysma muscle is reapproximated to align the skin edges and remove tension from the wound. The skin is closed according to the preference of the surgeon; one popular preference is to approximate the skin edges with a running 3-0 polypropylene pull-out subcuticular suture, followed by skin glue. The suture is removed after the glue is dry (about 2 minutes). This provides a cosmetic closure that requires no further attention until after the glue peels away at about postoperative day 14.

POSTOPERATIVE CARE

In our practice, patients remain hospitalized overnight after removal of a nontoxic goiter to manage their limited pain and monitor them for neck hematoma or hypocalcemia. All patients are managed with oral calcium supplements (calcium citrate 950 mg PO QID) and Rocaltrol 0.25 mcg PO daily beginning immediately after the operation. If they are symptomatic with numbness or tingling, or if their calcium on the morning after surgery is below 8 mg/dL, then the dose is doubled. If their symptoms persist, either before or after discharge, or if there is special concern about the immediate parathyroid function (for example, if two or more parathyroid glands were grafted), then we will consider keeping the patient for further observation or facilitating calcium lab draws within a few days of discharge.

Postoperative voice assessment is mandatory in all patients. Most patients have some immediate voice changes, but these nearly all resolve within 2 weeks of operation. Laryngoscopy to document vocal cord motion should be performed for all patients with significant voice changes that persist beyond 2 weeks and for all patients

who have a change in their intraoperative nerve monitoring findings during the procedure if that adjunct has been used. While some have advocated for more broad use of laryngoscopy preoperatively and postoperatively, there is no evidence that this changes patient outcomes, and so most experienced surgeons focus this effort in a more selective way.

Management of Thyroiditis

Christopher R. McHenry, MD

INTRODUCTION

Thyroiditis refers to inflammation in the thyroid gland that consists of a diverse group of conditions (Box 1) with variable clinical manifestations, which can include neck pain that can radiate to the jaw, chest, or ear; neck tenderness; symptomatic or asymptomatic goiter; subclinical or overt hypothyroidism or hyperthyroidism (Boxes 2 and 3); and rarely fever and chills. Patients with a large goiter may have compressive symptoms including dysphagia, dyspnea, cough, choking, hoarseness, and voice change. Patients with thyroiditis may rarely complain of ear pain.

Thyroiditis can be classified based on whether or not neck pain and tenderness are principal presenting manifestations (Box 4). Patients with subacute thyroiditis, acute suppurative thyroiditis and trauma, or radioiodine-induced thyroiditis have neck pain and tenderness, often occurring in association with thyroid dysfunction. Patients with Hashimoto thyroiditis, painless thyroiditis, and Reidel thyroiditis typically present with a goiter with or without thyroid dysfunction, and neck pain and tenderness are characteristically absent.

The treatment of thyroiditis is dependent on whether or not there are symptoms, thyromegaly, thyroid dysfunction, and/or concern for malignancy. The goal is to achieve a euthyroid state, which in most patients occurs spontaneously and results in resolution of symptoms of hypothyroidism and hyperthyroidism. Thyroid surgery has a role for specific indications (Box 5).

BOX 1 Clinical Variants of Thyroiditis

- Hashimoto thyroiditis (chronic autoimmune thyroiditis, lymphocytic thyroiditis)
- Reidel thyroiditis
- Subacute thyroiditis (granulomatous thyroiditis, De Quervain's thyroiditis)
- Suppurative thyroiditis
- Painless thyroiditis (postpartum thyroiditis, lymphocytic thyroiditis with spontaneously resolving hyperthyroidism)
- Drug-induced thyroiditis
- Radiation-induced thyroiditis

BOX 2 Symptoms of Hypothyroidism

Fatigue
Weight gain
Constipation
Dry skin
Cold intolerance
Muscle cramps
Decreased libido
Menstrual irregularity
Hair loss
Poor exercise tolerance
Depression

BOX 3 Symptoms of Thyrotoxicosis

Increased appetite
Weight loss
Palpitations
Tremor
Heat intolerance
Diaphoresis
Insomnia
Thinning of the hair and hair loss
Anxiety
Irritability
Increased frequency of bowel movements
Menstrual irregularities
Infertility

BOX 4 Thyroiditis Classified Based on the Presence or Absence of Neck Pain and Tenderness

Thyroiditis Manifesting With Neck Pain and Tenderness

- Subacute thyroiditis
- Acute suppurative thyroiditis
- Radioiodine induced thyroiditis
- Traumatic thyroiditis

Thyroiditis Manifesting Without Neck Pain and Tenderness

- Hashimoto thyroiditis
- Painless thyroiditis including postpartum thyroiditis
- Reidel thyroiditis
- Drug-induced thyroiditis

BOX 5 Indications for Surgery

- Associated thyroid nodule and/or suspicion of malignancy
- Thyromegaly with mass effect on the trachea or compressive symptoms
- Hashimoto thyroiditis and persistent autoimmune-related symptoms despite adequate thyroid hormone replacement
- Definitive diagnosis of Reidel thyroiditis and exclusion of anaplastic thyroid cancer
- Suppurative thyroiditis refractory to antibiotic therapy and percutaneous abscess drainage
- Thyrotoxicity refractory to medical therapy in patients with subacute thyroiditis or amiodarone-induced thyrotoxicosis

HASHIMOTO THYROIDITIS

Hashimoto thyroiditis, also known as *chronic autoimmune thyroiditis* or *lymphocytic thyroiditis*, is a T-cell–mediated, chronic autoimmune disease of unknown etiology that progresses to thyroid failure with hypothyroidism in approximately 20% of patients. It is the most prevalent autoimmune disease in the United States and worldwide. It is also the most common cause for diffuse goiter and hypothyroidism in the United States, as opposed to worldwide where iodine deficiency still remains the most common cause for goiter. In iodine-replete populations, the prevalence of hypothyroidism is 1% to 2%, and Hashimoto thyroiditis is the cause in approximately 85% of patients.

Hashimoto thyroiditis tends to cluster in families and can occur in association with Graves' disease and other autoimmune diseases. In general, there are two primary types of Hashimoto thyroiditis, an atrophic form and a goitrogenic form. There is also a fibrosing variant of Hashimoto thyroiditis (Fig. 1), which can sometimes be difficult to distinguish from Reidel thyroiditis.

Hashimoto thyroiditis is associated with elevated antithyroid peroxidase (TPO) antibody (also known as *antimicrosomal antibody*), antithyroglobulin antibody, and inflammatory cytokines. Hashimoto thyroiditis is a common cause for hypothyroidism and less commonly thyrotoxicosis, known as Hashitoxicosis. It is characterized by lymphocytic infiltration of the thyroid gland, lymphoid follicle formation with germinal centers, atrophy of the thyroid parenchyma, fibrosis, and Hurthle cell metaplasia. There may also be associated Hurthle cell nodules.

Patients may present with symptoms of hypothyroidism or hyperthyroidism (see Boxes 2 and 3), which normally resolve with treatment that reestablishes a euthyroid state. They may also present with globus sensation and experience profound fatigue, muscle and joint pain, poor sleep quality, and dry mouth and eyes, which may not resolve with thyroid hormone replacement therapy. Persistent symptoms, despite adequate replacement thyroid hormone therapy, are thought to be autoimmune-related.

FIG. 1 Fibrosing variant of Hashimoto thyroiditis.

Patients with Hashimoto thyroiditis may also present with thyromegaly (Fig. 2), which may cause mass effect in the neck, compressing adjacent structures and causing dyspnea, cough, dysphagia, choking, and hoarseness. Patients may also have neck pain, but this is not typical. The thyroid gland is diffusely firm and may be tender on exam. The thyroid gland is heterogenous in appearance on ultrasound exam (Fig. 3).

Patients with Hashimoto thyroiditis have Hurthle cell metaplasia and may have associated thyroid nodules. Most nodules are benign Hurthle cell nodules. Fine-needle aspiration biopsy (FNAB) reveals follicular epithelial cells, colloid, lymphocytes, and Hurthle cells that are classified as benign (Bethesda category II). FNAB may also reveal a predominance of Hurthle cells, which are cytologically classified either as atypia of undetermined significance (Bethesda category III) or Hurthle cell neoplasm (Bethesda category IV). Hashimoto thyroiditis is also a cause of false-positive FNAB in patients with thyroid nodules interpreted as suspicious for papillary thyroid cancer (Bethesda V). Patients with Hashimoto thyroiditis are known to have a higher incidence of thyroid lymphoma than the general population.

The treatment of Hashimoto thyroiditis is variable. Asymptomatic, euthyroid patients require no treatment. Patients with hypothyroidism are treated with thyroid hormone replacement. Patients are started on a dose of levothyroxine based on weight using a 1.6 ug/kg initial dosage estimate. The dose is adjusted to achieve a normal serum thyrotropin (TSH) level. Surgery is rarely necessary. Indications for surgery include a thyroid nodule with an indeterminate or malignant FNAB (Bethesda III–VI), unilateral or bilateral thyromegaly with mass effect on the trachea or compressive symptoms, and persistent symptoms despite adequate thyroid hormone replacement therapy.

The decision to proceed with thyroid lobectomy and isthmusectomy or total thyroidectomy is based on risk factors for cancer and the extent of the disease, which is determined by physical examination, ultrasound examination, and intraoperative evaluation. Patients with disease limited to one lobe can be treated with lobectomy and isthmusectomy. Most patients are treated with total thyroidectomy.

When thyroidectomy is recommended for persistent symptoms despite adequate thyroid hormone replacement therapy, a total thyroidectomy is performed. Total thyroidectomy removes the target antigens that generate the immunologic response in Hashimoto thyroiditis. Total thyroidectomy is associated with a decrease in the systemic inflammatory response and a reduction in serum antithyroid peroxidase antibody titers and proinflammatory cytokines. The Norwegian Trial on Surgery for Hashimoto Disease, a prospective, randomized clinical trial comparing total thyroidectomy to thyroid hormone therapy alone for persistent symptoms despite adequate thyroid hormone replacement, demonstrated improved health-related quality of life and fatigue and normalization of anti-TPO antibody titers in patients with histologically verified Hashimoto thyroiditis treated surgically compared with no significant change in the control group.

At operation, it is not unusual to have enlarged reactive lymph nodes in the central compartment of the neck. A firm nodule and enlarged lymph nodes associated with Hashimoto thyroiditis can mimic thyroid cancer. Excision of a lymph node and frozen section examination is always an option to exclude metastatic thyroid cancer. The diffusely firm thyroid gland with its associated inflammation in patients with Hashimoto thyroiditis make the thyroid gland difficult to retract anteriorly and medially and can potentially lead to excessive traction on the recurrent laryngeal nerve and paresis. Intraoperative nerve monitoring may be used to help identify transient loss of function related to traction on the recurrent laryngeal nerve.

PAINLESS THYROIDITIS

Painless thyroiditis is also known as silent thyroiditis or lymphocytic thyroiditis with spontaneously resolving hyperthyroidism. Painless thyroiditis is a variant of Hashimoto thyroiditis and is thought to occur as a result of autoimmune-mediated follicular cell destruction. Patients may have a personal or family history of other autoimmune diseases. Postpartum thyroiditis is a specific type of painless thyroiditis that occurs within 1 year of parturition or a spontaneous or induced abortion. It may occur in up to 10% of pregnancies.

FIG. 2 Diffuse goiter removed from a patient with Hashimoto thyroiditis causing compressive symptoms.

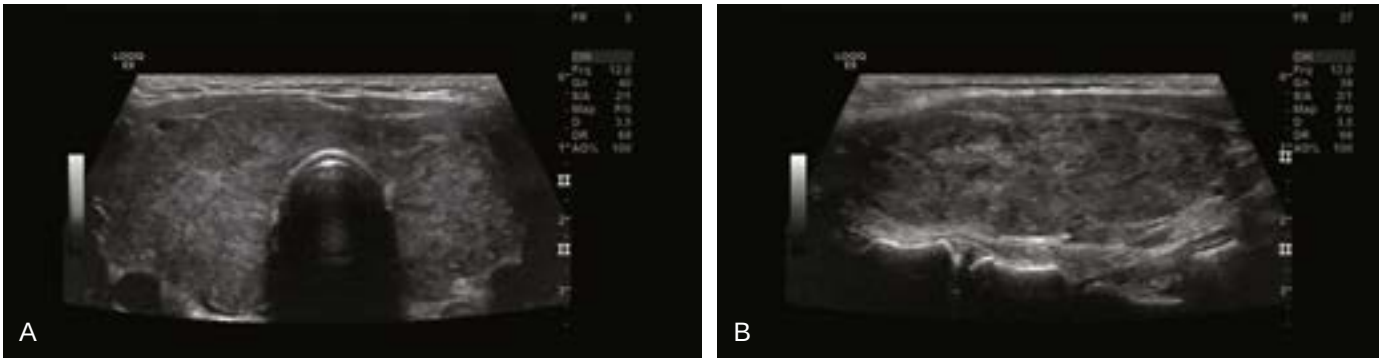

FIG. 3 Diffuse heterogeneity of the thyroid gland characteristic of Hashimoto thyroiditis. **(A)** Transverse view of the trachea and right and left lobes and isthmus of the thyroid gland. **(B)** Sagittal view of the left lobe of the thyroid gland.

However, it may not always be clinically evident and is diagnosed as a result of a low serum TSH level found on routine monitoring of thyroid function tests. Recurrences may occur with subsequent pregnancies.

Painless thyroiditis is characterized by transient thyrotoxicosis resulting from follicular cell destruction and release of thyroid hormone. Patients usually present with symptoms of thyrotoxicosis and diffuse, nontender, firm thyroid enlargement. This may be followed by symptoms of hypothyroidism. The thyrotoxic phase is transient and lasts for 1 to 3 months until thyroid hormone stores have been depleted. It is followed by a euthyroid phase lasting a few months and then a hypothyroid phase that can last up to a year. Most patients recover with normal thyroid function within 12 to 18 months after onset of symptoms, but permanent hypothyroidism may occur in 20% of patients.

During the thyrotoxic phase, patients have an elevated free T4 level and a suppressed TSH level. They may also have an elevated free T3 level. The free T4 and free T3 levels correspond to the normal proportion found in the thyroid gland. The suppressed TSH level inhibits thyroid hormone synthesis. Antithyroglobulin and anti-TPO antibodies are elevated. Radioiodine uptake by the thyroid gland is low, and ultrasound of the neck reveals diffuse hypoechogenicity. Thyroid-stimulating immunoglobulins are negative, distinguishing painless thyroiditis from Graves' disease. During the hypothyroid phase, serum TSH may be elevated and free T4 level normal or low.

Management of patients with painless thyroiditis includes serial monitoring of thyroid function tests as patients may be thyrotoxic, euthyroid, or hypothyroid during the progression of the disease, and some patients will develop permanent hypothyroidism. Many patients are asymptomatic and require no therapy at all because thyroid dysfunction is mild and transient. During the thyrotoxic phase, patients with symptoms of excess sympathetic nervous system activity, such as palpitations, tremor, and diaphoresis, can be treated with a beta-receptor blocking agent. Antithyroid drugs and radioiodine therapy are not effective because the thyrotoxicosis is due to the release of thyroid hormone from damaged follicular cells with suppression of iodine uptake by the thyroid gland and not from increased thyroid hormone synthesis. Levothyroxine can be started during the hypothyroid phase for patients with symptoms or when TSH levels are greater than 10 uIU/mL and may be required lifelong for patients who develop permanent hypothyroidism. Recurrence is common, and patients are followed with a yearly screening serum TSH level.

DRUG-INDUCED THYROIDITIS

Thyroiditis has been reported as a side effect of certain drugs (Box 6). Drug-induced thyroiditis is most often a variant of painless thyroiditis, with follicular cell destruction and thyrotoxicosis secondary to release of free T4 and free T3. This is often followed by transient or persistent hypothyroidism. Many of these drugs can also have additional effects on the thyroid gland.

BOX 6 Drugs That Can Induce Thyroiditis

Interferon alpha
Interleukin-2
Tyrosine kinase inhibitors (sunitinib, vandetanib)
Lithium
Immune checkpoint inhibitors (ipilimumab, nivolumab, pembrolizumab, atezolizumab)
Amiodarone

Before initiation of these drugs, a baseline screening serum TSH level should be obtained and serial monitoring should occur during use of the drug. An abnormal serum TSH level should trigger measurement of free T4 and free T3 levels. Consideration should also be given to measurement of antimicrosomal and antithyroglobulin antibodies. Discontinuation or dosage reduction of the drug is usually not necessary. In most circumstances, however, discontinuation of the offending agent results in return of normal thyroid function. A beta-receptor blocking agent can be used for treatment of thyrotoxicosis symptoms if necessary. Hypothyroidism is managed with thyroid hormone replacement.

Interferon alpha, a recombinant cytokine, was used primarily for treatment of chronic hepatitis C infection. It has also been used for treatment of leukemia, lymphoma, Kaposi's sarcoma, and other malignancies. Interferon alpha can cause both thyrotoxicosis and hypothyroidism. Anti-TPO and antithyroglobulin antibodies are measured before initiation of interferon alpha. Patients with high antithyroid antibodies are at higher risk of developing thyroid dysfunction.

Painless thyroiditis occurs in approximately 2% of patients on interleukin-2, an immunotherapeutic agent often used in combination with other anticancer immunotherapy and chemotherapy to treat metastatic renal cell cancer and melanoma. Sunitinib, vandetanib, and other tyrosine kinase inhibitors can cause hypothyroidism in 50% to 70% of patients. In addition to follicular cell destruction from autoimmune thyroiditis, tyrosine kinase inhibitors also inhibit iodine uptake by the thyroid gland.

Persistent hypothyroidism is also common in patients on other agents. Lithium can cause painless thyroiditis with follicular cell destruction; however, hypothyroidism is most commonly related to inhibition of c-AMP, which results in decreased thyroid hormone synthesis. Immune checkpoint inhibitors, agents targeting the cytotoxic T lymphocyte-associated antigen 4 (CTLA-4), and the programmed cell death 1(PD-1) receptor used to treat patients with melanoma and other malignancies are associated with autoimmune-related adverse events in many patients, and endocrinopathies occur in approximately 10% of patients. In addition to painless

thyroiditis, immune checkpoint inhibitors may also cause hypophysitis resulting in hypothyroidism secondary to reduced TSH synthesis by the anterior pituitary. Patients have a decreased FT4 level with a decreased TSH level. Other pituitary hormones are also decreased.

Amiodarone, an antiarrhythmic agent, has a molecular structure similar to T4 and T3, and one-third of its molecular weight is made up of iodine. It is also highly lipid soluble. Amiodarone, because of its large iodine content, is a cause for iodine-induced increase in thyroid hormone synthesis that occurs more often in patients with a multinodular goiter (Type I amiodarone-induced thyrotoxicosis). More commonly, however, amiodarone has a direct toxic effect on the follicular cells of the thyroid gland causing thyroiditis and follicular cell destruction, release of thyroid hormone stores, and thyrotoxicosis (Type II amiodarone-induced thyrotoxicosis). Patients with preexisting Hashimoto thyroiditis are more likely to develop subsequent hypothyroidism, which usually resolves with discontinuation of amiodarone but can be permanent.

Amiodarone can be discontinued and another antiarrhythmic agent started. However, because of its high lipid solubility, the plasma levels of amiodarone decrease very slowly. Type I amiodarone-induced thyrotoxicosis usually responds to thioamide drug therapy, although high doses are more often required. Glucocorticoids are the mainstay of therapy for Type II amiodarone-induced thyrotoxicosis. Total thyroidectomy is indicated for patients with amiodarone-induced thyrotoxicosis refractory to medical therapy.

SUBACUTE (DE QUERVAIN) THYROIDITIS

Subacute thyroiditis, also known as De Quervain thyroiditis, granulomatous thyroiditis, giant cell thyroiditis, and painful thyroiditis, is a transient self-limited inflammatory disease of the thyroid gland, which is thought to be precipitated by a viral upper respiratory infection. Subacute thyroiditis has been described as an extrapulmonary manifestation of SARS-CoV-2 infection. It is an important entity for surgeons to be aware of because the signs and symptoms are similar to acute suppurative thyroiditis.

The inflammatory process in the thyroid gland results in damage to the follicular epithelial cells and proteolysis of thyroglobulin. This results in release of stored thyroid hormone into the circulation causing thyrotoxicosis, which persists until all of the thyroglobulin stores are depleted. Increases in circulating T4 and T3 suppress TSH secretion from the anterior pituitary, inhibiting thyroid hormone synthesis and euthyroidism followed by hypothyroidism ensues. As the inflammatory process resolves, the follicular epithelial cells regenerate and thyroid hormone synthesis resumes leading to complete recovery and a euthyroid state.

Subacute thyroiditis is usually a clinical diagnosis. Patients present with severe neck pain, which often radiates to the jaw, upper chest, and ear. They may also have symptoms of thyrotoxicosis. On examination, they have asymmetric or diffuse thyroid enlargement with significant neck tenderness. At the onset of the disease process, laboratory evaluation reveals a suppressed TSH, an increased free T4 and T3 level, and an increased erythrocyte sedimentation rate and C-reactive protein. Serum anti-TPO and antithyroglobulin antibodies are usually undetectable. Subacute thyroiditis is distinguished from other causes of thyrotoxicosis with iodine-123 imaging that demonstrates low uptake (less than 3%).

Rarely, ultrasound or FNAB may have a role in distinguishing subacute thyroiditis from suppurative thyroiditis, hemorrhage into a thyroid nodule, thyroid cancer, or thyroid lymphoma. Ultrasound exam can exclude nodular disease and abscess, and Doppler sonography shows decreased flow in contrast to Graves' disease, which is characterized by increased flow. Characteristic fine needle biopsy findings in patients with subacute thyroiditis are multinucleated giant cells, granulomas, and mononuclear cell infiltration.

Thyroid function tests will change with time as patients experience predictable changes in thyroid function, initially presenting with thyrotoxicosis, followed by euthyroidism, hypothyroidism, and eventual complete recovery of normal thyroid function in most patients in 3 or 4 months. Long-term hypothyroidism requiring thyroid hormone replacement therapy may occur in 5% to 15% of patients.

Subacute thyroiditis is treated with an antiinflammatory agent. Aspirin or a nonsteroidal antiinflammatory agent is used for most patients. Patients with severe pain or pain refractory to antiinflammatory agents are treated with glucocorticoids. A beta-receptor blocking agent may be used for treatment of symptoms of thyrotoxicosis. Thyroid hormone replacement therapy may be necessary for symptomatic patients during the hypothyroid phase and is necessary for patients who develop long-term hypothyroidism.

REIDEL THYROIDITIS

Reidel thyroiditis is a rare disease characterized by chronic inflammation, dense fibrous tissue infiltration, and follicular cell destruction of the thyroid gland that may also affect surrounding structures in the neck. It is most often an insidious disease with a good prognosis, but it can be rapidly progressive. Patients present with compressive symptoms such as dyspnea, dysphagia, hoarseness, and stridor and have an enlarged, "rock hard", fixed thyroid gland on exam. Patients may present with Horner syndrome secondary to involvement of the sympathetic trunk. Most patients have hypothyroidism and, less commonly, hypoparathyroidism secondary to parathyroid gland involvement. Retroperitoneal, mediastinal and orbital fibrosis, primary sclerosing cholangitis, and Hashimoto thyroiditis may occur in association with Reidel thyroiditis.

Anti-TPO antibodies are positive in most patients with Reidel thyroiditis. Ultrasound of the neck reveals a diffusely hypoechoic and hypovascular thyroid gland with ill-defined borders; on computed tomography (CT), the thyroid gland is hypodense without enhancement after administration of intravenous contrast. CT of the neck is valuable for assessment of involvement of the surrounding structures in the neck including encasement of the carotid artery, mass effect on the trachea and esophagus, and involvement of the neck musculature.

It is important to distinguish Reidel thyroiditis from anaplastic thyroid cancer, thyroid lymphoma, and sarcoma of the thyroid gland. FNAB may show spindle cells and fragments of fibrous tissue but is most often nondiagnostic (Bethesda I), and it cannot reliably exclude anaplastic thyroid cancer. A definitive diagnosis of Reidel thyroiditis usually requires an incisional biopsy, which demonstrates dense fibrous tissue, occlusive phlebitis, and an eosinophilic infiltrate. Giant cells, granulomas, and malignant cells are absent.

The mainstay of treatment of Reidel thyroiditis is glucocorticoid therapy; however, the response to therapy is variable. Early in the disease process when chronic inflammation predominates and fibrous tissue replacement is less prominent, patients may experience a reduction in the size of the thyroid gland and dramatic improvement in symptoms. Late in the disease, when fibrous tissue replacement predominates, there may be no response to glucocorticoids.

Tamoxifen, a selective estrogen receptor modulator, used alone or in combination with glucocorticoids may decrease the size of the thyroid gland in patients with Reidel thyroiditis. The therapeutic effect of tamoxifen on the thyroid gland is thought to be mediated by induction of tumor growth factor beta, a potent growth inhibitor. Alternative therapies have been used in patients without response to glucocorticoids and tamoxifen including mycophenolate mofetil, rituximab, azathioprine, and radiation.

Surgical intervention is usually limited to incisional biopsy for making a definitive diagnosis of Reidel thyroiditis and rarely thyroid resection or tracheostomy to relieve obstruction. The loss of the normal tissue planes related to the chronic inflammation and extrathyroidal fibrosis makes surgery difficult and increases the risk of complications. Thyroid isthmusectomy is the preferred operation to relieve mass effect on the trachea and minimize complications.

ACUTE SUPPURATIVE THYROIDITIS

Acute suppurative thyroiditis is a potentially life-threatening infection of the thyroid gland with a 5% to 10% mortality rate. Infection may extend into the deep spaces of the neck and mediastinum and are a cause for necrotizing soft infection, laryngeal and pharyngeal edema, and septicemia. Infection of the thyroid gland is rare. Factors that may protect the thyroid gland from infection include a high iodine content, rich blood supply and lymphatic drainage, and a thick capsule.

Acute suppurative thyroiditis may occur as a result of direct extension of infection from the pyriform sinus, a thyroglossal duct cyst, or the tonsils; hematogenous spread of infection; traumatic injury; or a complication from a locally invasive esophageal cancer or an esophageal perforation. A pyriform sinus fistula is the most common cause for acute suppurative thyroiditis in children and young adults. In older adults, acute suppurative thyroiditis occurs more often in elderly, immunocompromised, and debilitated patients.

Patients present with neck pain, which often makes it difficult to distinguish from subacute thyroiditis. It may also be difficult to distinguish from anaplastic thyroid cancer, which may present with neck pain and tenderness as a result of rapid growth and necrosis mimicking acute suppurative thyroiditis. Patients with acute suppurative thyroiditis may have dysphagia, odynophagia, and symptoms of thyrotoxicosis. On examination, they appear acutely ill with fever and chills, asymmetric thyroid enlargement, neck tenderness, and erythema. Patients have leukocytosis and may also have thyrotoxicosis with a suppressed serum TSH level and increased free T4 and free T3 levels. Serial thyroid function tests are recommended to detect release of thyroid hormones related to the destruction of thyroid follicles. Ultrasound or CT of the neck with contrast is obtained to help establish a diagnosis and identify an abscess that will need to be drained.

Fine needle aspiration may also help establish a definitive diagnosis of acute suppurative thyroiditis and exclude other causes. Cytologic evaluation reveals follicular epithelial cells, with or without colloid, acute inflammatory cells, and bacteria. Needle aspiration is also important for obtaining material for gram stain, culture, and antibiotic sensitivity testing. This should also include fungal and acid-fast bacteria culture. The most common pathogens are Streptococcus and Staphylococcus species. Other pathogens include *Pneumocystis carinii, Coccidioides* species, *Aspergillus*, and *Mycobacterium tuberculosis*. Mortality is highest in patients with fungal infections.

Management of patients with acute suppurative thyroiditis consists of obtaining blood cultures, administration of empiric broad-spectrum antibiotics, and abscess drainage. Once a specific organism is identified, the antibiotics are adjusted accordingly. In the absence of an abscess, patients may respond to antibiotic therapy alone. Patients who do not respond to antibiotic therapy and abscess drainage should undergo open surgical drainage or thyroidectomy.

After abscess resolution, imaging with a barium swallow or a CT of the neck with oral and intravenous contrast should be performed to assess for a pyriform sinus fistula. A trumpet maneuver may help to enhance visualization of a pyriform sinus fistula on CT. The trumpet maneuver is performed by having a patient blow into a catheter that is attached to a syringe to inflate the syringe. Pyriform sinus fistulae develop from remnants of the third and fourth branchial pouches, which typically form a tract to the left lobe of the thyroid gland. Resection or obliteration of a pyriform sinus fistula may be best accomplished after treatment of infection and resolution of acute inflammation. Flexible fiberoptic laryngoscopy may be helpful in identifying an internal opening of a pyriform sinus tract and for endoscopic cauterization and potentially eliminating the need for resection.

RADIOIODINE–INDUCED THYROIDITIS

Thyroiditis is a rare complication of radioiodine therapy for Graves' disease, occurring in less than 1% of patients. It usually manifests with neck pain and tenderness within the first 10 days following radioiodine administration and may cause acute exacerbation of thyrotoxicosis that is transient. It occurs because of direct radioiodine–induced follicular cell necrosis and destruction. Neck pain and tenderness can be treated with a nonsteroidal antiinflammatory agent or prednisone.

SARS-COV-2–INDUCED THYROIDITIS

Infection with the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has been associated with an increased frequency of thyrotoxicosis secondary to inflammatory thyroiditis with follicular cell destruction and transient thyrotoxicosis. It has been associated with atrial fibrillation and thromboembolic complications. The thyroiditis is thought to be correlated with SARS-CoV-2–induced increase in proinflammatory cytokines, specifically interleukin-6 and tumor necrosis alpha. Subacute thyroiditis and Hashimoto thyroiditis have also been described in rare patients with COVID-19.

Management of Hyperthyroidism

Jina Kim, MD, and Julie Ann Sosa, MD, MA

INITIAL EVALUATION

Hyperthyroidism refers to a state of inappropriate high hormone production by the thyroid gland and can be overt or subclinical. Patients with overt hyperthyroidism often present with classic symptoms such as weight loss, heat intolerance, palpitations, tremors, and anxiety (Table 1). Physical examination often will reveal a goiter, and they will have low serum TSH with high T3 and T4. On the other hand, patients with subclinical hyperthyroidism generally endorse minimal or limited symptoms; their T3 and T4 may be normal despite a suppressed TSH.

In patients with suspected hyperthyroidism, serum TSH should be measured first, because it has the highest sensitivity and specificity in the diagnosis of thyroid dysfunction. If the TSH is low, serum T3 and T4 levels (free or total) should be obtained to differentiate

TABLE 1 Signs and Symptoms Associated with Thyrotoxicosis

	Signs	Symptoms
General	Weight loss	Increased appetite; heat intolerance; sweating
Cardiovascular	Tachycardia, hypertension, arrhythmia (atrial fibrillation)	Palpitations
Pulmonary	Tachypnea	Dyspnea
Gastrointestinal		Diarrhea, nausea, vomiting
Reproductive	Changes in menstrual cycle	
Ocular	Proptosis, eyelid retraction, periorbital edema	Diplopia, blurry vision, retro-orbital pain, irritated eyes
Dermatologic	Warm and moist ("clammy") skin	
Neuromuscular	Tremors, hyperactivity, hyperreflexia	Nervousness, anxiety, fatigue, weakness, disturbed sleep, poor concentration

between subclinical and overt hyperthyroidism. The ratio of total T3 to total T4 also can be useful in determining the cause of thyrotoxicosis, because T3 will be more elevated in hyperthyroidism, whereas T4 is more elevated in thyrotoxicosis caused by thyroiditis.

Once the diagnosis is established, the cause should be determined. Current American Thyroid Association (ATA) guidelines recommend the following diagnostic strategies, depending on available expertise and resources: measurement of thyrotropin receptor antibodies (TRAb), determination of radioactive iodine (RAI) uptake, or measurement of thyroidal blood flow on ultrasonography (Fig. 1). Elevated TRAb levels are diagnostic for Graves' disease, an autoimmune disease caused by antibodies to the TSH receptor. Normal TRAb levels are suggestive of toxic multinodular goiter or toxic adenoma. An iodine 123 (123-I) scan will demonstrate different patterns of uptake in Graves' disease vs. toxic nodule(s) (Fig. 2). Thyroid ultrasonography should be performed in conjunction with TRAb measurement if nonfunctioning or hypofunctioning nodules are identified on 123-I scans or if a thyroid nodule is noted on physical examination. The evaluation of a cold thyroid nodule with fine-needle aspiration (FNA) biopsy should be guided by existing guidelines for the management of thyroid nodules in euthyroid individuals; thyroid nodules that are functional on radioiodine uptake scans do not need FNA as these are rarely malignant.

Based on the initial evaluation, patients with hyperthyroidism may be ultimately diagnosed with thyroiditis, Graves' disease, toxic multinodular goiter, or toxic adenoma. This chapter focuses on the medical and surgical management of the latter three diagnoses. Selection of the appropriate treatment modality not only depends on the patient's diagnosis and comorbidities but also the patient's preference (Tables 2 and 3). In the end, the patient should make an informed treatment decision in consultation with their medical and surgical teams, as there are different risks and benefits for each option.

MEDICAL MANAGEMENT OF HYPERTHYROIDISM

Although the long-term management of hyperthyroidism can take many routes, initial treatment should be focused on controlling the signs and symptoms of hyperthyroidism. The initial management of patients with symptomatic thyrotoxicosis should include β-adrenergic blockade, particularly in elderly patients and patients with resting heart rates greater than 90 beats/min or coexistent cardiovascular disease. These include a nonselective β-adrenergic receptor blocker such as propranolol (10–40 mg, 3–4 times a day) or those with relative β-1 selectivity, such as atenolol (25–100 mg, 1–2 times daily) or metoprolol (25–50 mg, 2–3 times daily). β-blockers are generally contraindicated in patients with asthma, given that there is insufficient β-1 selectivity at the recommended doses, and they also should be used cautiously in patients with congestive heart failure, bradyarrhythmias, and Raynaud's disease. For patients who do not tolerate β-adrenergic agents, calcium channel blockers have been shown to provide effective rate control.

Antithyroid Medications

Thionamides such as methimazole (MMI) and propylthiouracil (PTU) inhibit thyroid hormone synthesis to control hyperthyroidism, but they are not curative. MMI and PTU are available in the United States, and carbimazole (which is completely metabolized to MMI) is a third option in some countries. These medications can be used as primary treatment for Graves' disease or as a temporizing measure before RAI or thyroidectomy. If thionamides are used, MMI is favored over PTU due to the black box warning added to PTU in 2010, which is described in more detail later.

Thionamides can be used as primary treatment for Graves' disease. In Europe, Latin America, and Japan, there has been greater physician preference for antithyroid medications as first-line therapy. Patients should be treated for 12 to 18 months because results of a randomized clinical trial demonstrated that remission rates are not improved after more than 18 months of treatment. After completion of initial therapy, the medication can be tapered or discontinued among patients where TRAb levels have normalized, based on the clinical symptoms. Remission is defined as biochemical euthyroidism more than 12 months after discontinuation of therapy. Relapse rates are 20% to 30% over 3 to 5 years of follow-up. In patients who relapse, definitive therapy with RAI or thyroidectomy should be considered.

Major adverse effects of thionamides include agranulocytosis, vasculitis, and hepatotoxicity. MMI-induced hepatotoxicity is usually cholestatic, whereas PTU can cause hepatocellular injury and lead to fulminant hepatic failure. In 2010, the Food and Drug Administration added a black box warning to PTU due to reports of associated liver injury and even liver failure. Based on adverse event reports and published case reports, PTU was found to carry a higher risk of liver injury in children, leading to recommendations that PTU be stopped in favor of alternate therapies for children with hyperthyroidism. Now, PTU is used in rare clinical scenarios such as thyroid storm and the first trimester of pregnancy (due to the teratogenic risk of MMI).

In addition to liver injury, PTU at any dose is more likely to cause agranulocytosis than low doses of MMI. If a patient using a thionamide develops fever and/or sore throat, the medication should be discontinued and a complete blood count obtained. The diagnosis is established if the absolute neutrophil count is less than 500/μL in the

appropriate clinical scenario. Treatment includes discontinuation of the drug, collection of blood and urine cultures, and admission for intravenous broad-spectrum antibiotics. In severe cases, granulocyte colony stimulating factor can be used as adjunctive treatment.

In contrast to patients with hyperthyroidism secondary to Graves' disease, not all patients with toxic thyroid nodules will require pretreatment with antithyroid medications. Current ATA guidelines recommend that any patient at increased risk of complications related to a persistent hyperthyroid state, such as geriatric patients and patients with cardiovascular disease, be pretreated with antithyroidal medications with consideration of β-blockade. However, younger and middle-aged patients may only require β-blockade for symptomatic hyperthyroidism related to toxic nodules.

Adjunctive Therapies

Patients with severe hyperthyroidism or an adverse reaction to thionamides may benefit from alternative medical treatment. Glucocorticoids can be used to inhibit peripheral T4 to T3 conversion; they have been used to treat thyroid storm. Cholestyramine, when given with MMI, can also help lower serum T3/T4 faster than MMI alone. Other infrequently used medications include lithium and rituximab, although utility is limited by associated adverse effects.

Radioactive Iodine Therapy

In the United States, RAI has been the preferred modality of treatment for Graves' disease. In a 2011 survey of clinical endocrinologists,

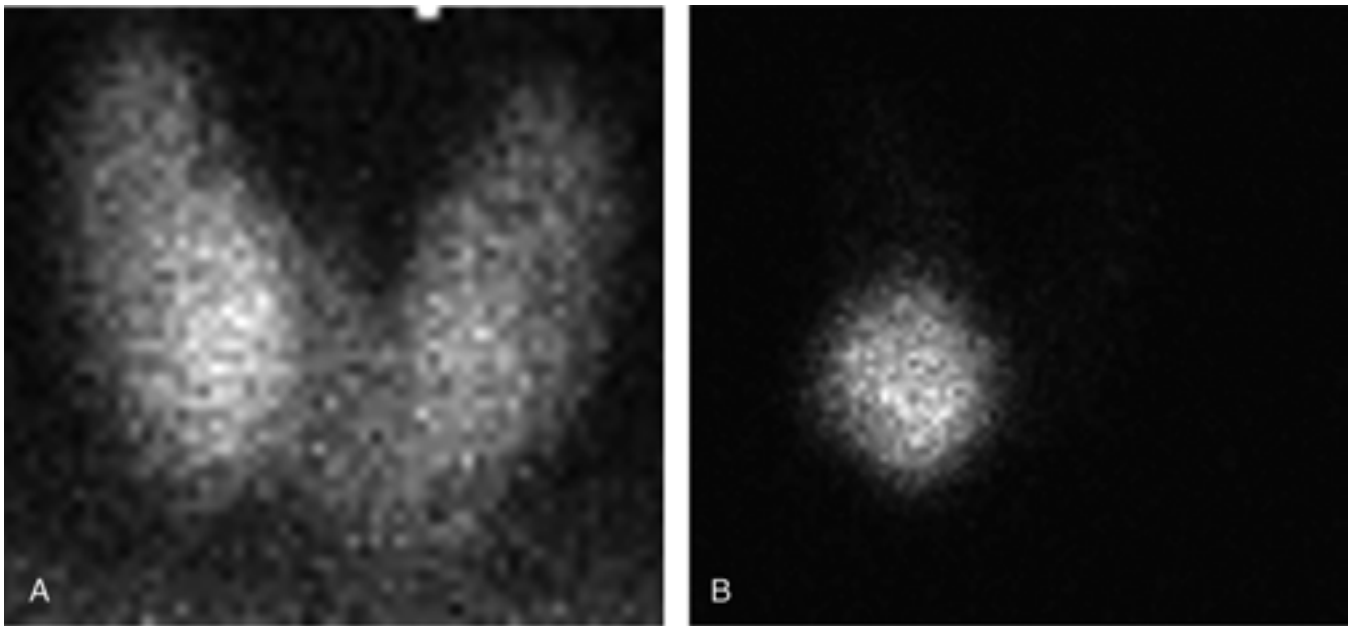

FIG. 2 Iodine 123 thyroid scan can demonstrate different patterns of radioactive iodine uptake in hyperthyroid patients. Diffuse, elevated uptake is consistent with Graves' disease **(A),** while uptake in a single nodule is consistent with toxic adenoma **(B)**.

TABLE 2 Clinical Situations That Favor a Particular Modality as Treatment for Graves' Hyperthyroidism

Clinical Situations	RAI	ATD	Surgery

nearly 60% of respondents practicing in North America preferred RAI as primary treatment. The goal of RAI therapy is to render the patient hypothyroid; RAI is incorporated into thyroid hormone, causing ionizing damage to thyroid follicular cells and destruction of the gland. RAI treatment can cause a transient exacerbation of hyperthyroidism; therefore, consideration should be given to initiation of antithyroid medication and for β-adrenergic blockade in symptom-free patients who may be at risk of complications from worsening thyrotoxicosis, such as the elderly or patients with cardiopulmonary comorbidities. Antithyroid medications should be stopped 2 to 3 days before RAI therapy and restarted 3 days later, which allows for RAI incorporation into the thyroid. Most patients will develop hypothyroidism 2 to 3 months after a single dose of 12 to 15 mCi of RAI. Patients should have repeat assessment of TSH, total T3, and free T4 in 1 to 2 months after therapy; biochemical monitoring should occur every 4 to 6 weeks for 6 months or until the patient is hypothyroid and stable on thyroid hormone replacement. Consideration for repeat therapy should not be considered for at least 6 months after initial treatment.

RAI is contraindicated in pregnant or lactating women, those with coexisting thyroid cancer or suspicion of thyroid cancer, and those unable to comply with radiation safety guidelines. Assuming a RAI dose of 10 to 15 mCi, radiation safety precautions include sleeping alone for 3 to 6 days (15–18 days in the case of a pregnant partner) and keeping a distance of 3 feet from adults and 6 feet from pregnant women and children during the day. RAI also should be used with caution among women planning a pregnancy within the first 4 to 6 months after treatment.

The presence of active moderate or severe Graves' orbitopathy also is a contraindication to RAI due to the risk of worsening eye disease. Total thyroidectomy should be the preferred treatment for these patients. Studies have shown thyroidectomy to be associated with stable or improved Graves' orbitopathy. If patients have absent or mild eye disease, RAI, antithyroidal medications, or thyroidectomy are all equally acceptable. Patients with mild Graves' orbitopathy may benefit from corticosteroid prophylaxis if they opt for RAI. Other side effects of RAI include transient worsening of thyrotoxicosis, risks of secondary malignancy, and potential anterior neck pain from radiation thyroiditis, sialadenitis, and dry mouth.

RAI should also be considered with caution in children and young adults with hyperthyroidism due to the risk of secondary malignancy. Since the early 1900s, experiences with physicians exposed to ionizing radiation and Japanese survivors of the atomic bombings have raised a concern of secondary malignancy with RAI. While the exact relationship between RAI and risk of secondary malignancy remains equivocal, a recent cohort study of 180,805 US and UK patients treated for hyperthyroidism found a positive association between greater organ-absorbed doses of RAI and risk of solid cancer death.

SURGICAL MANAGEMENT OF HYPERTHYROIDISM

Surgical management will require total or near-total thyroidectomy for patients with Graves' disease or toxic multinodular goiter and thyroid lobectomy for those with a toxic adenoma. Compared with medical treatments, surgery can achieve rapid correction of the hyperthyroid state and avoid potential long-term sequelae of RAI. These benefits may be most attractive to children and young adults with hyperthyroidism in whom the risk of secondary malignancy from RAI is most significant. Also, patients with local compression symptoms related to a large goiter or concurrent concern for thyroid malignancy may prefer surgery.

Surgery as First-Line Treatment for Graves' Disease

Despite the safety and effectiveness of antithyroid medications and RAI for the long-term treatment of hyperthyroidism secondary to Graves' disease, there may be circumstances that warrant a clinical preference for surgery. Of all preoperative diagnoses that may warrant thyroid surgery, Graves' disease has been associated with the highest risk of hypoparathyroidism and recurrent laryngeal nerve injury. Therefore, thyroidectomy for Graves' disease should be considered with appropriate preoperative preparation and an experienced, high-volume surgeon. Indications for surgical management of Graves' disease include women planning a pregnancy in less than 6 months, patients with other indications for thyroidectomy (presence of large thyroid nodules >4 cm, large goiters with compressive symptoms, suspected or known thyroid malignancy, or concurrent primary hyperparathyroidism requiring parathyroidectomy), and persistent disease despite previous treatment with antithyroid medications or RAI. Also, as mentioned previously, surgery should be the preferred treatment for patients with moderate to severe Graves'

orbitopathy. Surgery is relatively contraindicated in patients who have comorbidities that can shorten their life expectancy or increase the risk of perioperative morbidity, such as severe cardiopulmonary disease or advanced cancer.

Both surgery and RAI aim to render the patient hypothyroid. As recommended by the ATA, surgery should involve total thyroidectomy or near-total thyroidectomy. In a systematic review of published literature between 2001 and 2011, total thyroidectomy was associated with the lowest rate of persistent or recurrent hyperthyroidism. Persistent or recurrent hyperthyroidism was present in 0.3% of patients after total thyroidectomy, compared with 21% of patients who received a single dose of RAI or 10% of patients after subtotal thyroidectomy.

Patients with Graves' disease and associated cardiovascular morbidity also may benefit from total thyroidectomy. In a retrospective comparative cohort study of a Finnish registry, patients treated with RAI had a higher risk of mortality related to cardiovascular disease, hospitalization for cardiovascular disease, and atrial fibrillation compared with those who received thyroidectomy. However, treatment with RAI that resulted in hypothyroidism was not associated with increased cardiovascular comorbidity compared with thyroidectomy. Similarly, in a single institution retrospective US study, patients who underwent total thyroidectomy had higher rates of cardiac arrhythmia resolution than those treated with RAI.

Preoperative Management

Ideally, patients should be euthyroid before undergoing thyroidectomy for hyperthyroidism to minimize the risk of general anesthesia. In hyperthyroid patients, associated cardiovascular comorbidity may cause perioperative hemodynamic instability and require additional anesthetic to manage blood pressure and heart rate. Also, induction of anesthesia may be slower and require higher concentrations of inhaled anesthetics due to higher cardiac output in hyperthyroid patients. Lastly, thyroid storm is a rare perioperative complication that has been reported to occur during surgery and in the immediate postoperative period for hyperthyroid patients, although the incidence is low in patients who receive antithyroid medications.

Specifically for Graves' disease, in addition to thionamides and β-adrenergic blockade, guidelines from both the ATA and the American Association of Endocrine Surgeons (AAES) recommend consideration of potassium iodide-containing compounds in the immediate preoperative period. Potassium iodide (50 mg iodide/drop; 1–2 drops 3 times daily) or Lugol's solution (5% elemental iodine and 10% potassium iodide, 8 mg iodide/drop; 5–7 drops 3 times daily) should be administered for 7 to 10 days before surgery. Potassium iodide-containing compounds inhibit iodine organification in the thyroid to diminish thyroid hormone synthesis and inhibit hormone secretion. In a Turkish prospective clinical trial comparing preoperative treatment with or without Lugol's solution, thyroid mean blood flow and intraoperative blood loss were lower in those treated with Lugol's. However, other studies have shown that use of potassium iodide does not influence immediate postoperative outcomes such as hypoparathyroidism, vocal cord paresis, and hematoma formation. Of note, while the current ATA guidelines recommend using potassium iodide preoperatively for Graves', they discourage use of potassium iodide for toxic nodular disease due to the risk of exacerbating hyperthyroidism.

To optimize post-thyroidectomy outcomes, clinical guidelines from both the AAES and ATA recommend that calcium and 25-hydroxyvitamin D levels be repleted or supplemented preoperatively. One study found that patients treated with oral calcium carbonate 1 g three times daily for 2 weeks before surgery had lower rates of biochemical and symptomatic hypocalcemia. Although not limited to hyperthyroid patients, prospective trials have shown that adding vitamin D supplementation to oral calcium preoperatively is associated with a reduced risk of post-thyroidectomy hypocalcemia. The 2016 ATA guidelines for hyperthyroidism also recommend preoperative calcitriol supplementation in patients at increased risk of hypoparathyroidism, which would include those with Graves' disease or history of Roux-en-Y gastric bypass.

Extent of Surgery

Current ATA guidelines recommend near-total or total thyroidectomy be performed by a high-volume surgeon if surgery is chosen as primary therapy for Graves' disease or toxic multinodular goiter. For toxic adenomas, an ipsilateral thyroid lobectomy can be performed as long as there is no contralateral thyroid lesion that would compel total thyroidectomy.

Total thyroidectomy has been shown to be superior to subtotal thyroidectomy for surgical treatment of Graves' disease and toxic multinodular goiter. Subtotal thyroidectomy preserves a remnant of the thyroid to preserve both the integrity of the recurrent laryngeal nerve as it enters the cricothyroid muscle and the blood supply to the superior parathyroid gland. Subtotal thyroidectomy can be performed in two ways: as a bilateral subtotal (leaving a small amount of thyroid tissue on each side) or as a Hartley-Dunhill procedure (unilateral total lobectomy with contralateral subtotal lobectomy). However, leaving a remnant of thyroid increases the risk of persistent or recurrent hyperthyroidism. In a randomized clinical trial of Graves' disease patients, 9% of patients who underwent subtotal thyroidectomy developed recurrent hyperthyroidism within the 5-year follow-up period compared with 0% of total thyroidectomy patients. There was no difference in rates of transient or permanent hypoparathyroidism or recurrent laryngeal nerve injury. A 2014 systematic review of total thyroidectomy vs. subtotal thyroidectomy for Graves' disease also found that subtotal thyroidectomy was associated with higher risk of recurrent hyperthyroidism. Similarly, for toxic multinodular goiter, a 2015 systematic review of total thyroidectomy vs. subtotal thyroidectomy showed that goiter recurrence was lower with total thyroidectomy, but there was no significant difference in incidence of permanent nerve injury or permanent hypoparathyroidism.

Technical Considerations of Thyroidectomy

Thyroidectomy for hyperthyroidism can be challenging because of the hypervascularity of the gland. A recent US retrospective study of over 200,000 patients undergoing total thyroidectomy found that patients with Graves' disease had higher rates of hypocalcemia and hematoma requiring reoperation compared with patients with multinodular goiter or thyroid cancer. From a technical perspective, hypervascularity of the thyroid in Graves' disease makes identification of the parathyroid glands and recurrent laryngeal nerves more difficult. A few technical aspects that should be considered during thyroidectomy include the following:

1. Although cosmesis is important, particularly for patients with benign disease, the emphasis should be on safe visualization of key structures. Therefore, the incision length should be made with careful consideration of gland size and the expected hypervascularity of the gland.
2. It is often helpful to ligate the superior thyroid vessels first; these are often engorged in patients with hyperthyroidism, and early ligation can facilitate mobilization of the superior pole of the thyroid. This can be done with silk ties or with vessel-sealing devices, but one should be mindful that the maximum vessel size for many devices is 7 mm.
3. The recurrent laryngeal nerve typically lies within the tracheoesophageal groove. Its course can be more variable on the right, and it can lie anterior or posterior to the inferior thyroid artery. In rare cases, a nonrecurrent laryngeal nerve can be present and is typically associated with aberrant subclavian artery anatomy on the right side. If a CT scan of the neck and/or chest is available, aberrant vascular anatomy may raise suspicion for a nonrecurrent laryngeal nerve.

4. Blood supply to both the superior and inferior parathyroid glands is typically derived from the inferior thyroid artery. The inferior parathyroid glands can be more variable in location, and dissection close to the thyroid gland provides the safest plane to avoid inadvertent devascularization of the parathyroid glands.

Intraoperative recurrent laryngeal nerve monitoring is increasingly used during thyroidectomy, although visualization of the nerve remains the gold standard. During surgery, the vocal fold response to nerve stimulation can be measured by an electrode system incorporated in the endotracheal tube, which is positioned at the level of the vocal cords. Auditory or visual electromyographic signals can be obtained from the vagus or recurrent laryngeal nerve by intermittent stimulation using a handheld probe during thyroidectomy and at the time of visualization of the nerve or when dissection is occurring close to the nerve, depending on the system used. Changes in the pattern of the signals may hint at possible nerve irritation and dysfunction. Routine use of intraoperative nerve monitoring has not been shown to decrease rates of recurrent laryngeal nerve injury, and if a surgeon chooses to incorporate it into their practice, routine use allows for familiarity with the system and ability to troubleshoot the technology by all who are involved in the surgical procedure, including the surgeons, anesthesiologists, and nurses.

In current times, technical considerations in thyroidectomy may also include discussion of newer remote access approaches and percutaneous techniques. Remote access approaches such as transoral and bilateral axillary breast approach have been introduced as techniques to perform thyroidectomy while avoiding a cutaneous scar. Transoral endoscopic thyroidectomy vestibular approach, which approaches the thyroid via the oral cavity, has been shown to be a feasible procedure for Graves' disease, although these data derive from a single high-volume center, and operative times were significantly longer compared with open thyroidectomy. For toxic adenomas, physicians have reported successfully applying thermal ablation techniques such as radiofrequency ablation and high-intensity focused ultrasound to render patients euthyroid. These newer techniques currently are only performed at select institutions and require further study before consideration of widespread adoption.

Postoperative Management

After total thyroidectomy for either Graves' disease or a toxic multinodular goiter, thionamides and potassium iodide-containing preparations should be discontinued, while β-blockade can be tapered in patients for whom they are used solely for management of symptoms of hyperthyroidism (rather than preexisting hypertension). Thyroid hormone replacement should be initiated at a dose appropriate to the patient's weight (typically 0.8 μg/lb or 1.5–1.7 μg/kg) and age (typically lower doses in the elderly). TSH levels should be measured 6 to 8 weeks after surgery and then every 1 to 2 months until levels are stable, followed by annual assessment. After lobectomy for a toxic thyroid nodule, TSH and free T4 levels should be obtained 4 to 6 weeks after surgery; thyroid hormone supplementation should be started if there is a persistent rise in TSH levels. Long-term thyroid hormone supplementation may be required in 15% to 20% of patients after thyroid lobectomy.

Complications of Thyroidectomy

The most common complications of thyroidectomy include transient or permanent recurrent laryngeal nerve injury and postoperative hypocalcemia/hypoparathyroidism. Both are uncommon (1%–2% in the hands of experienced thyroid surgeons) but can have a significant effect on the patient's quality of life. Patients who elect to undergo thyroidectomy should have a preoperative voice evaluation, based on any subjective voice changes perceived by the patient and the surgeon's objective assessment of voice quality. Formal vocal cord evaluation should be obtained for any patient with subjective findings of voice change and any patient with previous anterior neck surgery (e.g., parathyroidectomy, thyroidectomy, carotid endarterectomy, or cervical fusion via the anterior approach) or mediastinal/thoracic surgery that places the vagus nerve at risk. Evaluation can include indirect or direct laryngoscopy, videostroboscopy, or transcutaneous vocal cord ultrasonography. Recurrent laryngeal nerve injury can be transient or permanent; subjective changes in voice quality should prompt referral to a voice specialist for evaluation and management.

During total thyroidectomy, manipulation, devascularization, or unintentional resection of the parathyroid glands can result in transient or permanent hypoparathyroidism and associated hypocalcemia. To prevent development of symptomatic hypocalcemia after total thyroidectomy, management options include routine oral calcium supplementation or selective supplementation based on serum calcium or parathyroid hormone levels. Especially in patients with hyperthyroidism, hungry bone syndrome can occur after total thyroidectomy. Hungry bone syndrome is a phenomenon related to the high bone turnover associated with hyperthyroidism; after total thyroidectomy, hyperthyroid patients can experience severe or prolonged hypocalcemia despite normal levels of parathyroid hormone. Other serum electrolyte abnormalities seen with hungry bone syndrome include low phosphate, low magnesium, and high potassium.

SPECIAL CONSIDERATIONS

Thyroid Storm

Thyroid storm (thyrotoxic crisis) is a rare condition that occurs in 1% to 5% of patients admitted to a hospital for thyrotoxicosis and is associated with a high (up to 25%) risk of death. Development of thyroid storm is not dependent on serum TSH levels, and the pathogenesis is not well understood. It can be triggered by cessation of antithyroid medications, acute illness, trauma, or stress. Thyroid storm also can be precipitated by manipulation of the thyroid during surgery, particularly in patients who are not biochemically euthyroid before surgery. The diagnosis is clinical, and in 1993, Burch and Wartofsky introduced a scoring system to assess the severity of the crisis based on temperature, central nervous system manifestations, gastrointestinal-hepatic dysfunction, cardiovascular dysfunction, and any precipitating factors. Treatment of thyroid storm is supportive, and a multidisciplinary approach to management, including definitive therapy with RAI or thyroidectomy, is recommended.

Graves' Disease in Children

Graves' disease is the most common cause of hyperthyroidism in children. Although thionamides, RAI, and thyroidectomy all remain treatment options for children, the choice of initial treatment depends on the patient's age, clinical status, and patient/parent values. If surgery is chosen, the availability of a high-volume thyroid or pediatric surgeon is particularly critical, given the possibility of lifelong hypoparathyroidism or recurrent laryngeal nerve injury. If antithyroid medications are chosen, MMI therapy for 1 to 2 years is considered appropriate initial management, although it is important to recognize that most pediatric patients will not have durable remission on medication alone. MMI should be used and PTU avoided because of the risk of hepatotoxicity.

In patients who are not in remission after initial MMI therapy, consideration for RAI or surgery should be given. The goal of RAI therapy is to induce hypothyroidism in a single treatment, either as an estimated or fixed dose. Smaller doses aimed at euthyroidism result in higher rates of persistent/recurrent hyperthyroidism and exposure of residual thyroid tissue to multiple doses of radiation that may lead to increased risk to the development of thyroid neoplasms. Long-term studies have not yet shown a definitively increased risk of thyroid or nonthyroid malignancies. A 2019 study of US and UK patients with hyperthyroidism found that higher estimated organ-absorbed doses of RAI was associated with higher risk of solid

cancer mortality. Given this theoretical risk, RAI therapy is generally avoided in children younger than 5 years. The European Thyroid Association guidelines recommend thyroidectomy as primary treatment in childhood and consideration of RAI in postpubertal children.

The ATA guidelines prefer surgery for pediatric patients younger than 5 years, those with large thyroid glands >80 g (in which response to RAI may be poor), and those noncompliant or unresponsive to antithyroid medications. Total or near-total thyroidectomy should be performed. Particularly in pediatric patients, access to a high-volume thyroid surgeon is critically important. Multiple analyses of US hospital discharge data have shown that children undergoing thyroid surgery are at higher risk of complications, but outcomes are optimized when surgeries are performed by high-volume surgeons. Current ATA guidelines also strongly recommend total thyroidectomy performed by a high-volume surgeon if surgery is elected for children with Graves' disease.

Graves' Disease in Pregnancy

The diagnosis of hyperthyroidism in pregnancy is challenging because normal pregnancy can alter thyroid function testing. The diagnosis is made with serum TSH values and either total T3 and T4 levels, but reference ranges should increase to 1.5 times above that of the nonpregnant range by the second/third trimester or be trimester-specific. If overt hyperthyroidism is diagnosed during pregnancy, treatment with antithyroid medications should be initiated. PTU should be used during the first trimester, given the teratogenic effects associated with MMI, including aplasia cutis, choanal/esophageal and other intestinal atresias, abdominal wall abnormalities (e.g., omphalocele), and eye, heart, and urinary tract malformations. PTU-associated birth defects have been reported but appear to be less severe than those related to use of MMI. MMI can be used after the first trimester. RAI therapy is contraindicated during pregnancy.

Surgery as definitive therapy should be considered by patients interested in starting families and who require high doses of antithyroid medications for euthyroidism, making spontaneous remission less likely. Surgery for patients diagnosed during pregnancy should be reserved only for those patients for whom medical management is not successful or those who have a contraindication to antithyroid medications. If performed, surgery during the first and third trimesters should be avoided, given the risks for fetal development and preterm labor, respectively.

Amiodarone-Induced Thyrotoxicosis

Amiodarone is an iodine-rich antiarrhythmic drug that can result in amiodarone-induced thyrotoxicosis (AIT) or amiodarone-induced hypothyroidism in 15% to 20% of patients. AIT may develop at any point during amiodarone treatment, even several months after cessation, secondary to its long half-life (up to 100 days) and storage in fat tissues within the body. There are two forms of AIT, although both forms may occur in a single patient: type 1 develops in patients with underlying thyroid disease (iodine-induced hyperthyroidism), and type 2 develops in patients without underlying thyroid disease (destructive thyroiditis). Thyroid ultrasonography is helpful because it identifies the presence of thyroid nodules and the vascularity of the gland; type 1 AIT is associated with increased vascularity and multinodular goiter, whereas type 2 AIT is characterized by absent vascularity. RAI uptake scans can also be useful, as uptake is very low in patients with type 2 AIT but may be normal or high in type 1 AIT.

For patients with type 1 AIT, the preferred treatment strategy is medical (thionamides), although spontaneous remission is unlikely because of the high levels of iodine present. Therefore, higher doses of thionamides may be needed, and definitive therapy with surgery may be required, particularly given the risks of ongoing thyrotoxicosis in patients with underlying cardiac disease. Type 2 AIT may be self-limited, given that the destructive thyroiditis is caused by the amiodarone. It is best treated with glucocorticoids, at an initial dose of 0.5 to 0.7 mg/kg per day, with an initial course of 3 months. RAI is not feasible in patients with either type of AIT because of the high iodine levels in the thyroid.

Surgical Management of Thyroid Cancer

Yinin Hu, MD, and John A. Olson Jr., MD, PhD

Surgery is a mainstay of thyroid cancer treatment. This chapter summarizes broad categories of thyroid cancer, the basics of staging, and surgical decision making. Surgical anatomy and technical considerations in thyroidectomy and cervical lymph node dissection (CLND) will be addressed.

BACKGROUND

Thyroid nodules are extremely common; roughly half of all adults will develop one or more thyroid nodules during their lifetime. In nonsurgical series, around 5% of thyroid nodules harbor malignancy. However, the incidence of small, asymptomatic thyroid cancers is growing as a result of expansion in diagnostic imaging. By autopsy reports, the prevalence of thyroid cancers is over 10%.

Treatment is broadly dictated by classification into three major categories: differentiated epithelial, undifferentiated (anaplastic), and medullary. Thyroid lymphoma is rarely approached surgically and will not be discussed. Within differentiated epithelial cancers

are papillary carcinomas, follicular carcinomas, and Hürthle cell cancers. Papillary thyroid cancer (PTC) is the most common subtype, accounting for 80% of all thyroid cancers. When localized to the gland, it carries an excellent prognosis (>95% survival at 10 years). Although greater than a third of patients harbor microscopic or macroscopic cervical lymph node metastases, the clinical significance of microscopic lymph node disease is unclear. Follicular thyroid cancer (FTC) accounts for 10% of all thyroid cancers and is more prevalent in the setting of iodine deficiency. Although FTC's natural history remains favorable, it has a higher risk for distant hematogenous spread and disease-specific mortality than PTC. Nodal metastases are comparatively uncommon, at around 10%. Initially considered a subcategory of FTC, Hürthle cell carcinoma is now recognized as a distinct entity. It carries a poorer prognosis than FTC, a higher proclivity for lymph node metastases, and a lower affinity for radioiodine uptake.

In stark contrast with its differentiated counterparts, anaplastic thyroid cancer (ATC) is extremely aggressive, often presents at an advanced stage, and is almost universally fatal. Although it is hypothesized that ATCs arise from more differentiated predecessors because of late, dedifferentiating driver mutations, the exact pathogenesis is unproven. More than 90% of patients present with regional or distant metastases—most commonly to the lung, bone, and/or brain. Mass effect is common, and resection usually serves a palliative—rather than curative—role. The 1-year survival is in the range of 20%. Only in the rare instances that ATC is diagnosed without extrathyroidal extension is the likelihood of long-term survival >75%.

Medullary thyroid cancer (MTC) arises from parafollicular C cells. Well-known for secreting the calcium regulator hormone calcitonin, C cells also secrete to varying degrees adrenocorticotropic hormone, carcinoembryonic antigen, and chromogranin, all of which may occasionally serve as useful tumor markers. Nonelevated calcitonin is usually a marker of dedifferentiation and an aggressive disease course. Prevalence of lymph node metastases is high, ranging from 15% in T1 disease to over 90% in T4 disease. Roughly half of patients with sporadic MTC present with stage III or IV disease, for which 10-year survival is 70% and 20%, respectively. One in four MTCs are hereditary, with germline mutations in the protooncogene *RET* being most commonly identified. Indeed, 50% of sporadic MTCs carry a somatic mutation in *RET*. The natural history of any given MTC is deducible by identifying the specific mutation within *RET*, with M918T and A883F—driver mutations for the MEN2B syndrome—associated with aggressive biology and disease course.

DIAGNOSIS AND STAGING

Thyroid cancers usually present in one of two ways: (1) as a clinically-palpable thyroid nodule, or (2) as an incidental lesion discovered through imaging for an unrelated condition. Following a focused history and physical examination, the basic workup for a new thyroid nodule must include, at minimum, thyroid hormone functional testing and neck ultrasonography. Sonographic suspicion for malignancy is commonly scored using the TI-RADS criteria, and lesions with high-risk features—solid nature, irregular margins, taller-than-wide shape, rim calcifications, or extrathyroidal extension—are recommended for fine needle aspiration (FNA). Cytopathology is then categorized by the Bethesda system into benign (malignancy risk 0%–3%), atypia of undetermined significance or follicular lesion of undetermined significance (5%–15%), follicular neoplasm or suspicious for follicular neoplasm (15%–30%), suspicious for malignancy (60%–75%), or malignant (97%–99%). Results of atypia or follicular neoplasm may prompt repeat FNA, diagnostic lobectomy, or assessment for molecular biomarkers predictive of malignancy to further define the risk window.

Once a diagnosis of thyroid cancer is confirmed, all patients should undergo staging ultrasonography (also known as *lymph node mapping*) of the central and lateral cervical lymph node compartments. For larger tumors and those with extrathyroidal extension, cross-sectional imaging with noncontrast CT or MRI can more accurately assess extent of disease. In advanced cases or those presenting with voice or swallowing complaints, vocal cord mobility should be assessed using ultrasound examination or fiberoptic laryngoscopy. Routine preoperative assessment of thyroglobulin or antithyroglobulin does not affect management and is not indicated. For differentiated epithelial thyroid cancers, cross-sectional imaging to assess for distant metastases is not indicated before resection. Because of a high likelihood of disseminated disease, staging for newly diagnosed ATC should routinely include CT of the chest, abdomen, and pelvis and whole-body FDG PET/CT. Further, any acquired ATC tissue sample should be submitted for DNA testing for actionable mutations.

In patients with newly-diagnosed MTC, basal serum calcitonin and carcinoembryonic antigen provide insight into disease burden. Most patients with calcitonin <20 pg/mL have thyroid-only disease, with 20% to 30% harboring cervical node metastases. Conversely, calcitonin >100 may be indicative of stage IV disease with low likelihood of surgical cure. However, primary resection may be indicated, even in the setting of distant disease because of the highly variable prognosis of stage IV MTC. In addition to cervical ultrasonography, screening for germline mutations in *RET* and concurrent pheochromocytoma should precede thyroid resection given the association of these tumors in the MEN2 syndromes. National Comprehensive Cancer Network (NCCN) guidelines stipulate that patients with a basal calcitonin >400 pg/mL or elevated carcinoembryonic antigen should be considered for cross-sectional staging with ^{68}Ga DOTATATE PET/CT. An alternative staging regimen includes CT of the neck and chest, a triphasic liver CT, and a bone scan. This approach is reflective of MTC's predilection to metastasize to cervical lymph nodes, lungs, liver, and bone.

OVERVIEW OF SURGICAL MANAGEMENT

For patients with differentiated epithelial thyroid cancer, treatment strategies range from active surveillance to total thyroidectomy with adjuvant radioactive iodine (RAI). Papillary thyroid cancers <1 cm in size are categorized as papillary thyroid microcarcinomas (PTMCs). Following resection, disease-specific mortality in this subgroup is <1%, with <5% of patients developing locoregional recurrence. Over two-thirds of patients who develop recurrence harbor mutations in *BRAF*. Most PTMCs are asymptomatic and discovered incidentally following thyroid resection for unrelated pathology. In the uncommon situation that a PTMC is diagnosed *in situ* through needle biopsy, the American Thyroid Association (ATA) recommends either partial thyroidectomy or active surveillance. The safety of active surveillance is supported by several large prospective series from Japan that indicate 10-year primary tumor growth rate of <10%, with lymph node spread in <4%. Overall, 15% of patients on active surveillance undergo resection at 5 years. Although limited by shorter follow-up and smaller numbers of patients studied, Western series have shown similarly low rates of primary tumor progression and metastatic spread. Active surveillance is not recommended for PTMCs located posteriorly in the thyroid gland near the trachea or recurrent laryngeal nerve (RLN), high-grade pathology, or for tumors harboring a *BRAF* mutation. Younger age is also associated with higher rates of primary tumor growth.

For most differentiated thyroid cancers between 1 and 4 cm in size, the ATA recommends thyroid lobectomy or total thyroidectomy. Long-term oncologic outcomes comparing lobectomy versus total thyroidectomy have been assessed by analysis of administrative and clinical databases, rather than prospective trials. Data from the National Cancer Database and Surveillance, Epidemiology, and End Results database indicate equivalent overall survival. Locoregional recurrence after lobectomy for low-risk thyroid cancer is <4%. There are several advantages to thyroid lobectomy. Roughly two-thirds of patients who undergo lobectomy do not require long-term thyroid hormone supplementation. Although complication rates in experienced hands is usually less than 1%, total thyroidectomy is associated with a twofold

higher rate of postoperative hemorrhage, twofold higher rate of permanent RLN injury, and threefold higher rate of persistent hypocalcemia. Less than 10% of patients who appropriately undergo lobectomy will require completion thyroidectomy in the future. Indications include upstaging to high-risk disease, locoregional recurrence, or the development/progression of contralateral nodules. The ATA lists the following indications for up-front total thyroidectomy: size >4 cm, extrathyroidal extension, lymphadenopathy, and need for postoperative RAI. Total thyroidectomy may also be considered for patients with contralateral nodules, prior neck irradiation, preexisting hypothyroidism, and extensive family history of thyroid cancer.

Risk factors for lymph node metastasis in differentiated epithelial thyroid cancer include age <45 years, tumor size >1 cm, multifocality, extrathyroidal extension, lymphovascular invasion, and *BRAF* V600E mutation. However, the prognostic significance of microscopic lymph node metastases is uncertain. As such, there is no role for prophylactic *lateral* cervical lymphadenectomy for clinically node-negative disease. Prophylactic *central* neck dissection (CND) may be considered for patients with tumor size >4 cm, extrathyroidal extension, or if lymph node status will impact recommendations for adjuvant RAI. In most cases, *therapeutic* neck dissection of the central and lateral cervical node basins is indicated for clinically evident lymph node metastases. Even in the setting of low-volume distant metastases, therapeutic neck dissection can reduce macroscopic disease burden, thereby improving the efficacy of high-dose RAI ablation.

Unlike papillary and follicular thyroid cancers, the natural history of sporadic MTC is dictated by stage, while that of hereditary MTC is determined by mutation status. Lymph node metastases, categorized as stage III disease, is present in 10% to 15% of patients with a T1 primary tumor (≤2 cm), and in >90% of patients with a T4 primary tumor (extrathyroidal extension). Lymph node micrometastasis is prognostic for sporadic MTC: 10-year survival of stage I and II cancer is >90%, while that of stage III cancer is roughly 70%. Thus all surgically suitable patients with bilateral and unilateral MTC >1 cm and many patients with unilateral MTC <1 cm should undergo a total thyroidectomy and CND. Management of the clinically negative lateral neck is controversial. More than two-thirds of patients with basal calcitonin >30 pg/mL possess ipsilateral lateral cervical node metastases. Thus some advocate prophylactic ipsilateral modified radical neck dissection (MRND) among these patients. On the other hand, for patients without central neck nodal disease, the likelihood of lateral lymph node metastases is <10%. Thus it is also reasonable to perform a two-stage operation, with total thyroidectomy and central neck nodal dissection in the first operation. Node-positive patients may then be considered for ipsilateral MRND. Although patients with basal calcitonin >100 have a >75% likelihood of *bilateral* cervical node metastases, these patients are also at high risk for synchronous distant metastases, and thus the therapeutic benefit of bilateral MRND may be limited.

The majority of patients with ATC are not surgically curable. The American Joint Committee on Cancer categorizes all ATC as stage IV, regardless of extent of disease. Stage IVa patients—those without extrathyroidal extension—are potentially curable, with a 1-year survival rate of 75%. However, >90% of patients present with stage IVb (extrathyroidal extension) or IVc (distant metastases) disease, and 1-year survival among these patients is well below 25%. Standard treatment for the uncommon stage IVa patient with resectable disease is total thyroidectomy and CND followed by adjuvant radiation with or without concurrent chemotherapy (typically doxorubicin). More than half present with esophageal and/or tracheal invasion, and en bloc resection of adjacent structures should be anticipated for patients with gross stage IVb disease. Although systemic agents can induce objective response in some patients (particularly BRAF/MEK inhibition for *BRAF* V600E–mutant tumors), none have shown consistent impact on survival. Nevertheless, neoadjuvant chemoradiation may be indicated for locally advanced disease without distant spread. Because most patients die of distant metastases within 2 to 5 months, there is no compelling evidence that an R0 resection is superior to R1. Further, because ATC typically does not exhibit radioactive iodine uptake, there is no reason to aggressively "debulk" locoregional disease with the hope of enriching systemic therapy. Many patients with ATC present with unilateral vocal cord palsy resulting from involvement of the RLN. In these patients, a subtotal thyroidectomy may be favored to preserve the contralateral nerve. Palliation is a key goal for stages IVb and IVc ATC. Palliative care and hospice care should be consulted early, and focusing on airway protection with tracheal stenting or tracheostomy in the setting of stage IVb unresectable or IVc disease may be indicated to improve quality of life.

TOTAL THYROIDECTOMY

Anatomy

Proficiency with thyroidectomy begins with an intimate knowledge of surgical anatomy. The thyroid gland is situated anterior to the cricoid cartilage and inferior to the thyroid cartilage. The superior pole on each side may extend several centimeters superiorly, and a surgeon-performed ultrasound can optimize placement of the transverse neck incision. The two lobes of the thyroid gland are joined at the midline by the thyroid isthmus. In one of four patients, the congenital thyroglossal duct remnant retains thyroid tissue, which takes the form of a midline pyramidal lobe extending cephalad. From superficial to deep, the major tissue layers overlying the thyroid include dermis, platysma, the sternohyoid muscle and superior belly of the omohyoid muscle, the sternothyroid muscle, and pretracheal fascia. Each lobe of the thyroid gland is fed by two named arteries (superior and inferior) and drained by three named veins (superior, middle, and inferior). However, inferior venous drainage is often via a plexus of veins rather than a single dominant vessel.

Two named nerves are near each thyroid lobe. The external branch of the superior laryngeal nerve (EBSLN), which innervates the cricothyroid and controls high-pitch voice projection, lies close to the superior thyroid artery. It travels from cephalad to caudad lateral to the vascular pedicle, crossing the superior thyroid artery in a medial direction to enter the cricothyroid. The anatomic relationship between the EBSLN and the superior pole of the thyroid gland is described using the Cernea classification. Type 1 nerves cross more than 1 cm above the superior pole of the thyroid gland, type 2A nerves cross within 1 cm above the superior pole, and type 2B nerves cross below the superior border of the superior pole (Fig. 1).

The recurrent laryngeal nerve (RLN) on the left descends from the vagus nerve, loops around the arch of the aorta, and ascends in the tracheoesophageal groove, ultimately innervating the remaining intrinsic laryngeal muscles. On the right, the RLN loops around the subclavian artery and ascends more laterally than its left-side counterpart, a few millimeters away from the tracheoesophageal groove. It is prudent to establish normal carotid artery anatomy on the right using ultrasound or cross-sectional imaging in the preoperative setting. A carotid artery that originates directly from the aortic arch (rather than the innominate artery) indicates an aberrant, retroesophageal right subclavian artery with an associated *non*-recurrent inferior laryngeal nerve. The prevalence of this anatomy is roughly 0.5%, and in such cases the nerve lies in a near-transverse trajectory behind the thyroid gland (Fig. 2).

Classically, two parathyroid glands (superior and inferior) lie posterior to the thyroid gland on each side. However, innumerable variations in gland number and position have been reported. Superior glands generally lie posterior to the plane of the RLN, while inferior glands lie anterior to this plane. Superior glands are more anatomically predictable, with the right and left superior parathyroid glands on average lying within 2 to 5 mm of the nerve. Inferior glands are more variable, lying on average 7 to 10 mm away from the nerve (Fig. 3). Ectopic parathyroid glands are reported in 15% of patients. Common ectopic locations include retroesophageal,

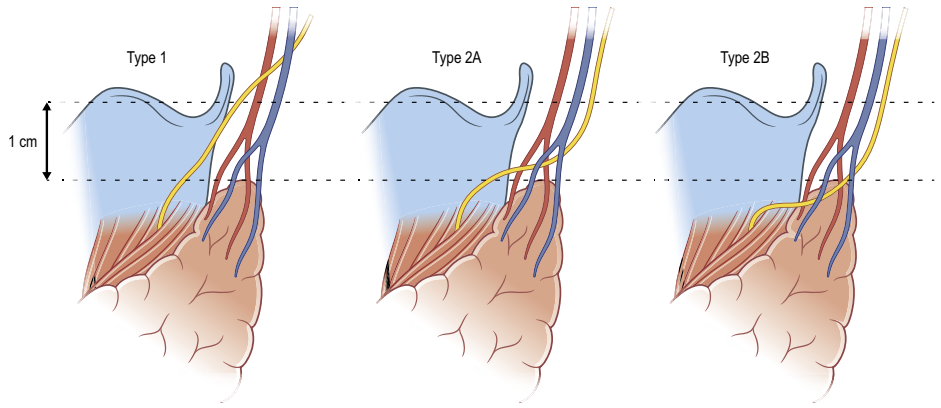

FIG. 1 Cernea classification of the external branch of the superior laryngeal nerve. A type 1 nerve crosses greater than 1 cm above the superior pole of the thyroid. A type 2A nerve crosses within 1 cm of the superior pole. A type 2B nerve crosses below the border of the superior pole. Type 2A and 2B nerves are more prone to injury during superior pole mobilization. *(From Brennan P, Standring S,* Wiseman S: Gray's Surgical Anatomy. *Philadelphia: Elsevier; 2020.)*

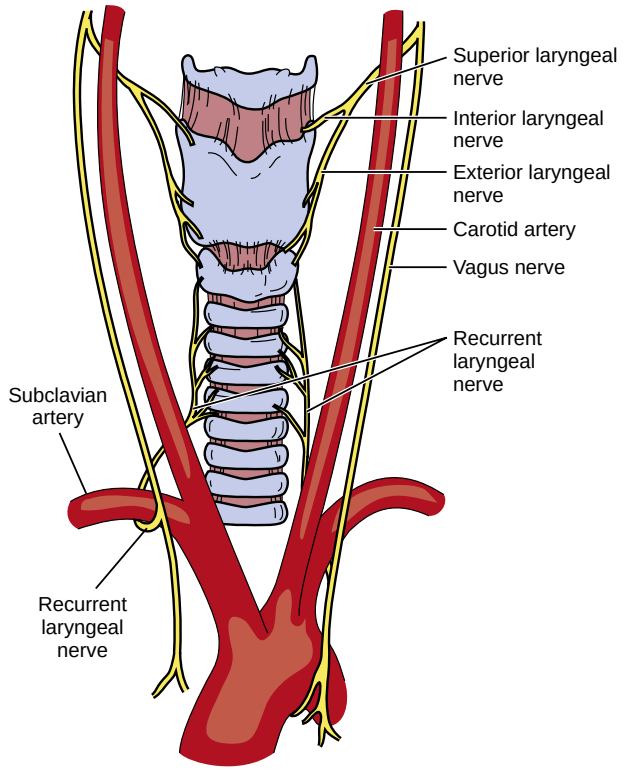

FIG. 2 Anatomy of the recurrent laryngeal nerves. The right nerve takes a more oblique course posterior to the thyroid gland than the left nerve. *(From Phillips N, Hornacky A.* Berry & Kohn's Operating Room Technique. *14th ed. Philadelphia: Elsevier; 2021: F41.14.)*

intrathyroidal, or along the carotid sheath. Inferior glands are also frequently located within the thyro-thymic ligament or even in the mediastinum. Although knowledge of ectopic positions is key to successful parathyroidectomy, parathyroid tissue in these locations seems protective from unintended resection or devascularization during thyroidectomy. Importantly, up to 25% of superior parathyroid glands derive blood supply from the superior thyroid artery rather than the inferior thyroid artery, placing them at risk for devascularization if the superior thyroid artery is ligated and divided away from the upper pole thyroid tissue.

Technique Overview

The fundamental technique of thyroidectomy has not changed in decades. Addition of ultrasonic and bipolar energy devices has reduced operative time but has not changed the broad steps of resection. Minimally invasive approaches such as transaxillary and transoral thyroidectomy offer cosmetic advantages. In this section, a classic open thyroidectomy will be described, along with tenets that facilitate exposure and safe dissection.

Exposure

The patient is positioned supine, with the head raised roughly 15 degrees and the neck extended by way of a posterior shoulder roll. Excessive extension is uncomfortable postoperatively, while inadequate extension crowds the surgical field. A collar incision is made along Langer's lines or within an existing neck crease, typically 2 to 3 cm above the clavicular heads. The incision is carried through the platysma, and the subplatysmal flaps are raised inferiorly to the clavicular heads and superiorly to the thyroid cartilage through a combination of sharp and blunt dissection. The strap muscles are lifted off the thyroid capsule at midline and separated from the thyroid capsule posteriorly along avascular planes. The middle thyroid vein is then exposed and ligated between the thyroid and internal jugular vein (IJV). For very large or firm glands, it may be helpful to transect the sternothyroid muscle either medially or entirely for added lateral exposure. In these cases, the muscle should be divided high, near the insertion into the thyroid cartilage, as innervation from the ansa cervicalis (which may be exposed by laterally retracting the SCM) enters inferiorly. The ansa cervicalis should be preserved along its length in the unlikely event it is needed for reconstruction of the recurrent laryngeal nerve if divided intentionally or unintentionally during the thyroidectomy.

Retraction and Mobilization

We usually begin the thyroidectomy by isolating draining veins of the isthmus and pyramidal lobe. If a lobectomy is planned, early division of the isthmus can facilitate mobilization and delivery of the gland through small (<4 cm) incisions. Development of the isthmus is then followed by dissection of the superior pole of the diseased lobe, which is approached first by developing the avascular cricothyroid space (space of Reeve) between the superior pole and cricothyroid muscle. The superior thyroid artery is isolated

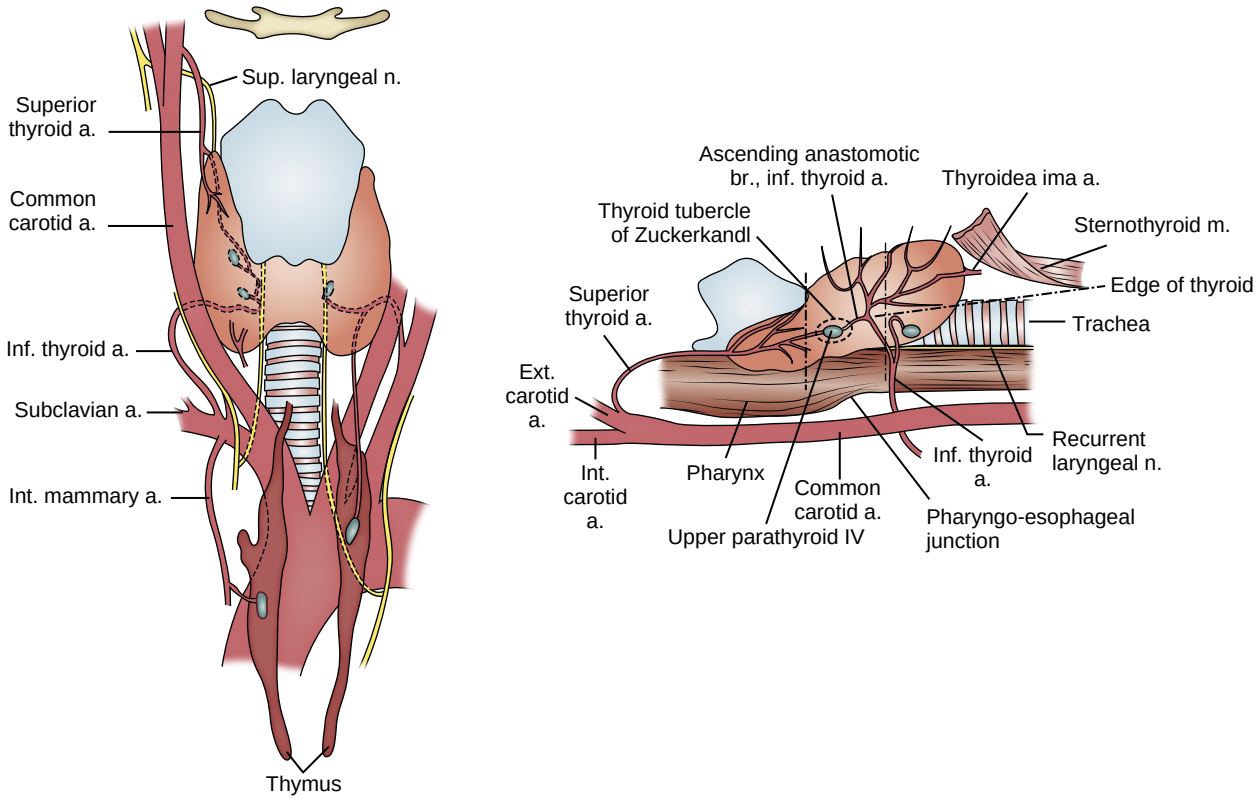

FIG. 3 Parathyroid anatomy. Most common locations for parathyroid glands are along the tracheoesophageal groove, close to the recurrent laryngeal nerves. Ectopic locations include retroesophageal, intrathyroidal, or along the carotid sheath. Inferior glands are also frequently located within the thyro-thymic ligament or even in the mediastinum. *(From Kaplan EL. Thyroid and parathyroid. In Schwartz SI, ed.* Principles of Surgery. *5th ed. New York: McGraw-Hill; 1989: 1613–1685.)*

through blunt, closed-tip dissection. Excessive spreading will cause bleeding and obscure visualization. The EBSLN should be identified (either visually or with the aid of a nerve monitor) before superior pedicle ligation, and the pedicle should be divided as close to the gland as possible to minimize the risk of nerve injury. At this point, the inferior pole can be retracted superiorly, exposing the inferior thyroid vein branches. These are ligated close to the thyroid gland, as straying deep and lateral to the inferior pole risks injury to the recurrent laryngeal nerve and devascularization and removal of the lower parathyroid gland.

Preservation of Parathyroid Glands

With the venous drainage divided, the thyroid lobe is rotated medially and elevated out of the surgical field. Maneuvers for gland retraction include manual retraction, hemostatic clamps, Allis clamps, suction catheter, or Kittner sponge. If clamps are used, repositioning should be limited as repeated gland trauma can cause fracture or bleeding. Medial retraction exposes the tracheoesophageal groove and the carotid sheath. This is a convenient time to test RLN functional integrity by stimulating the vagus nerve. Posterior dissection reveals the inferior thyroid artery and recurrent laryngeal nerve. This posterior exposure also reveals the parathyroid glands in their standard positions. In 80% of cases, both the superior and inferior parathyroid glands are supplied by branches of the inferior thyroid artery. In the remaining cases, the superior gland is supplied by a branch of the superior thyroid artery. Identification of the glands on one side facilitates dissection on the contralateral side, as symmetry in gland position is present in 80% of superior glands and 70% of inferior glands. Dissection immediately along the thyroid capsule to individually divide the tertiary branches of the inferior thyroid artery usually preserves parathyroid blood flow. For parathyroid glands located within the thyroid capsule, the capsule may be entered focally to liberate the gland. This usually preserves the gland's vascular pedicle. The decision to do so must account for the position of the malignant nodule. If the cancer is close to an intrathyroidal parathyroid gland, that gland is removed en bloc with the thyroid gland. Truncal ligation of the inferior thyroid artery without identification and preservation of the parathyroid glands is discouraged; doing so significantly increases the probability of postoperative hypocalcemia due to hypoparathyroidism. If a parathyroid gland is clearly devascularized or unintentionally explanted, it should be preserved in iced saline until the end of the operation (<120 minutes), at which point it is sharply divided into 1- to 3-mm pieces. One or more avascular pockets are then developed in the SCM, and the piecemeal parathyroid tissue is reimplanted. A permanent suture may be placed to mark the implanted location. Hemorrhage must be avoided, as a muscle pocket hematoma prevents parathyroid revascularization.

Preservation of the Recurrent Laryngeal Nerve

From the mediastinum, the course of the RLN is typically anterior or lateral to the tracheoesophageal groove. The right nerve, which is positioned more laterally in the chest than the left, has a more oblique course. As the nerve ascends, dozens of anatomic variations between the RLN and inferior thyroid artery have been described. The most common scenario places the nerve deep to the inferior thyroid artery. However, the nerve can also be found anterior to or coursing between the branches of the artery. Nerves located anterior to the inferior thyroid artery are at particularly high risk of injury as they are drawn

anteriorly with medial retraction of the thyroid lobe. Anatomic variations are more common on the right. In the vast majority of cases, the nerve courses within a few millimeters of the artery and the ligament of Berry before diving deep to the cricothyroid muscle to enter the larynx. At its terminus, the nerve often divides into abductor and adductor branches, and this branching may occur significantly proximal to the cricothyroid muscle, such that two RLNs may be identified within the surgical field. The three most common locations for inadvertent nerve injury are posterior to the inferior pole of the thyroid gland, at the intersection with the inferior thyroid artery, and behind the ligament of Berry. The RLN is also vulnerable to pinching behind the ligament of Berry during medial retraction of the thyroid gland at late stages of the thyroidectomy before dividing the ligament. To safely isolate the nerve, it is prudent to spread perpendicular to the nerve axis through the fatty and nodal tissue posterior to the thyroid gland to initially expose the nerve. Once identified, the nerve is exposed by using a blunt hemostatic clamp with the tip upward to separate the nerve from superficial structures along its course. This protects the nerve and facilitates the safe division of the ligament of Berry. Frequently, cephalad nerve exposure will encounter a posterior, thickened projection of thyroid tissue called the *tubercle of Zuckerkandl.* This projection must be mobilized laterally and lifted anteromedially to expose the nerve course within a fissure between the tubercle and remaining thyroid gland. In cases anticipated to require adjuvant RAI ablation, these maneuvers not only preserve the RLN but also maximize the completeness of thyroidectomy. Although direct visualization of the nerve is advantageous during dissection of the tubercle and the ligament of Berry, we seldomly expose the entire nerve throughout its course in the tracheoesophageal groove during thyroidectomy for benign disease. We do routinely do so during thyroidectomy for cancer when pathologic adenopathy is present and when performing elective CND.

Intraoperative Neuromonitoring

Intraoperative neuromonitoring (IONM) has expanded in popularity over the past 15 years as a useful adjunct that facilitates identification of the RLN. In part because of the low incidence of permanent RLN injury (<0.5% in most series), nearly all studies—randomized and retrospective alike—have been underpowered to show a difference in nerve injury rate. The most common approach to IONM involves a receiving electrode on the endotracheal tube to sense vocal cord signaling and a grounding electrode on the skin. Not surprisingly, effectiveness of IONM is contingent on optimal endotracheal tube positioning and other factors that influence circuit completeness. For this reason, while the negative predictive value of IONM to rule out nerve injury approaches 100%, positive predictive value (i.e., the rate of true nerve injury upon signal loss) is <50% in most large series. Thus an experienced thyroid surgeon who chooses to routinely implement IONM must be familiar with troubleshooting and verification techniques. Even in experienced hands, IONM has not been shown to *prevent* nerve injury but may facilitate nerve identification and alter surgical decision making if injury is suspected. This is particularly true for the reoperative neck, large nodules, and immunogenic goiters. We do not use the monitor to "find" the nerve, rather, we routinely use nerve monitoring during thyroidectomy to confirm visual assignment and map the RLN branching pattern, ensure preservation of signal while retracting the gland at the ligament of Berry, and to reinforce visual identification of the entire nerve during central neck dissection. Our practice is to confirm signal at the vagus and tracheoesophageal groove at the beginning, intermittently throughout, and at the end of the procedure.

Closure

There is no role for routine drainage following thyroidectomy, nor is there compelling evidence for routine placement of synthetic hemostatic agents. Thorough irrigation and meticulous hemostasis are vital. The Valsalva maneuver can assist in inspecting the surgical field for sources of hemorrhage. The strap muscles are reapproximated in the midline using absorbable suture, leaving at least a 1-cm gap at the inferior aspect to prevent fluid or blood accumulation that might compress the trachea. The platysma is similarly approximated with absorbable suture, and skin is closed in a subcuticular layer. Techniques aimed at improving cosmesis vary across institution and may include: (1) not reapproximating the platysma, (2) using a permanent subcuticular suture that is removed in the early postoperative setting, (3) injecting a dilute steroid solution in the subcutaneous layer, and (4) routine prescription of a topical scar-reducing agent.

SELECTIVE CERVICAL LYMPH NODE DISSECTION

Although differentiated epithelial thyroid cancers carry an overall excellent prognosis, over 30% of patients harbor lymph node metastases. Clinically evident synchronous or metachronous nodal disease is common and is generally treated with therapeutic node dissection. Unlike thyroidectomy, compartment-oriented selective CLND can be approached in many ways, all of which require intimate and detailed knowledge of cervical anatomy. Regardless of the specific surgical approach, meticulous technique with attention to staying in native tissue planes is a requirement for safe and thorough lateral neck dissection.

Anatomy

Boundaries of the lateral cervical node stations dictate a thorough CLND. For thyroid cancer, most draining lymph nodes are located in stations IIa and III to V, the boundaries of which are listed in Figure 4. Anatomic descriptions of the vital structures within each station will be described in the following sections.

Technique Overview

Exposure

From the aforementioned position for a total thyroidectomy, the patient's head is turned away gently from the side of dissection while maintaining neck extension. Excessive turning or extension is unnecessary and heightens the risk of postoperative pain. Two types of

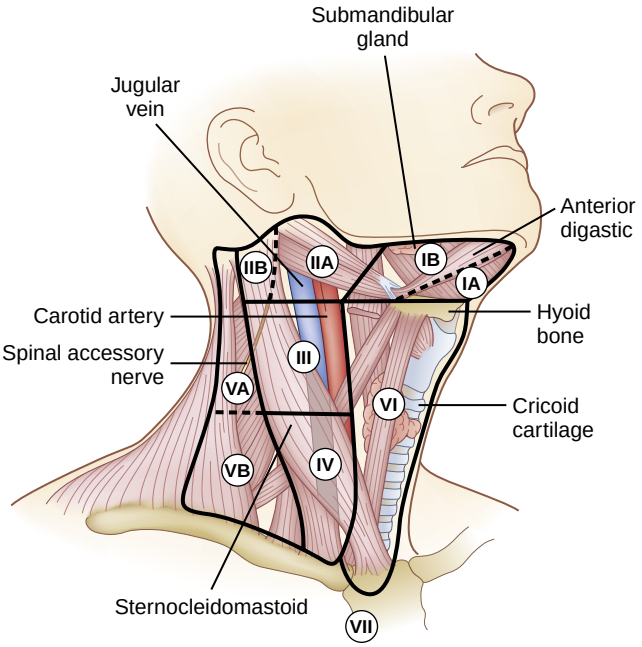

FIG. 4 Boundaries of cervical lymph node compartments. *(From Townsend, et al.* Sabiston Textbook of Surgery: The Biological Basis of Modern Surgical Practice. *21st ed.; Philadelphia: Elsevier; 2022: F37.3.)*

incisions are commonly used. First, a traditional collar incision may be extended superiorly along the anterior border of the SCM to form a "hockey stick" configuration. We find this incision infrequently needed and prefer to usually extend the thyroidectomy collar incision posterolaterally along Langer's lines into level V. This approach yields superior cosmetic results but requires a more extensive subplatysmal flap elevation for adequate cephalad exposure. If needed, a second parallel incision can be made in a higher skin crease to allow exposure to level II cervical nodes, which still yields a cosmetically better result than the hockey stick incision. The subplatysmal flap should be developed from the clavicle inferiorly up to two fingerbreadths from the body of the mandible. Here great care must be taken to avoid the marginal mandibular branch of the facial nerve that courses superficial to the submandibular gland and can be seen at the superior extent of the field. Care should be taken to preserve the nerve as injury results in an asymmetric smile. Flap mobilization over the lateral SCM will expose the greater auricular nerve, which provides sensory innervation to the skin overlying the parotid and external ear and should be preserved. The spinal accessory can be identified at Erb's point located 1 cm superior, lateral, and deep to the greater auricular nerve (Fig. 5). Beneath the submandibular gland is located a packet of lymph nodes overlying the facial vein and its neighboring branches. This packet is mobilized from these veins and submitted separately from the remaining node packet. Medial to the SCM, the IJV is identified and dissected on its lateral extent until the spinal accessory nerve is identified and defines the upper extent of the node dissection.

Lateral Mobilization

We take an extrafascial approach to en bloc dissection of lateral cervical nodes. This is accomplished by first lifting the medial investing fascia off the SCM near its anterior border. Branch vessels between the fascia and the muscle are divided by bipolar cautery. At the superior aspect of this mobilization, along the anterior edge of the SCM, lies the spinal accessory nerve (CN XI). A neurostimulator can elicit trapezius contraction to verify nerve anatomy. Blunt dissection along either side of the nerve will allow circumferential mobilization and elevation. The anterior fascia overlying CN XI should be left in situ, as this contains the nerve's microcirculation. With the nerve separated from the node packet, the fascial layer surrounding the packet is retracted medially from behind the SCM while the muscle is elevated and retracted laterally. The superior extent of this mobilization is the posterior belly of the digastric muscle, beyond which is level IB. The node packet and overlying fascia can be followed deep and posteriorly to pull level V nodal tissue anteromedially into the surgical field. Separating the fascia from the deep border of the SCM will expose the omohyoid muscle belly, delineating the border between levels III and IV. This muscle may be divided for exposure.

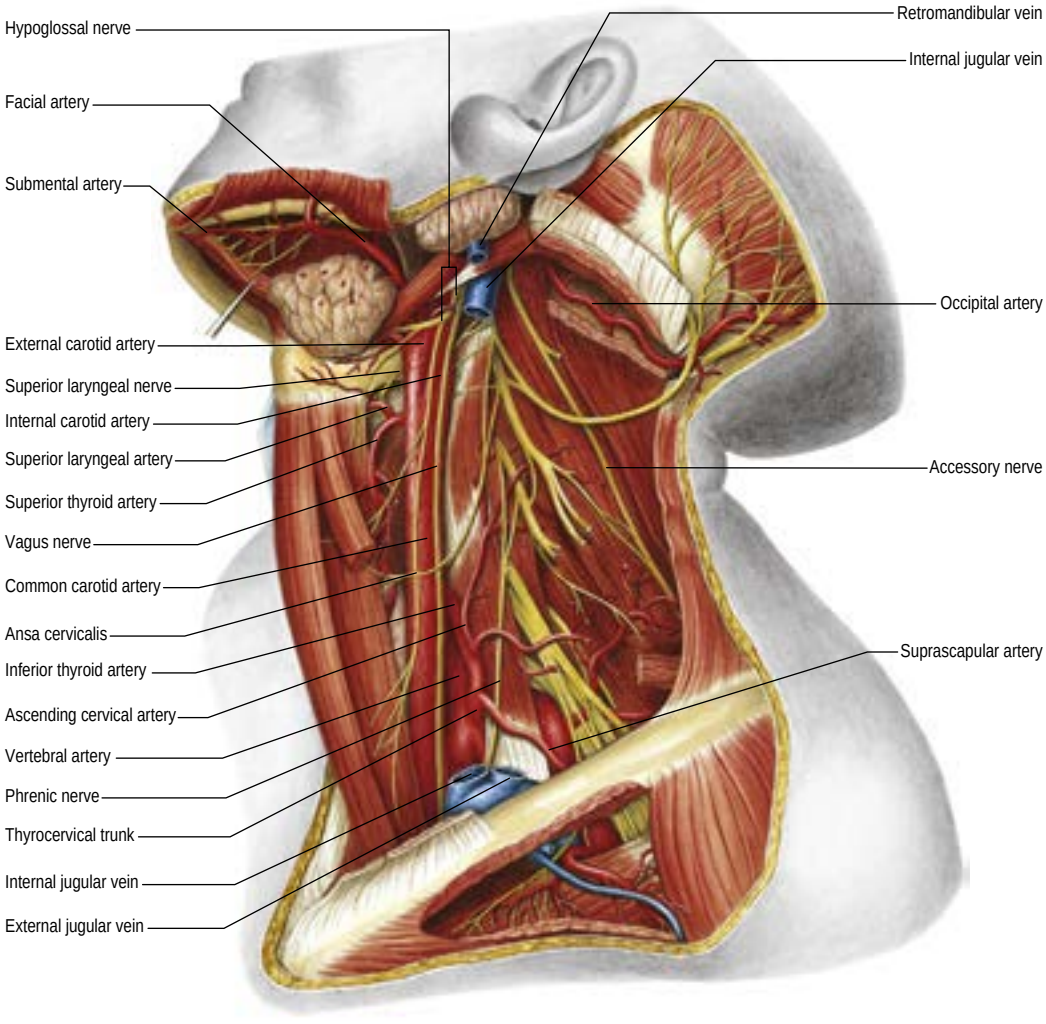

FIG. 5 **Lateral neck neurovascular anatomy.** *(From Waschke J, Paulsen F, eds.* Sobotta Atlas of Human Anatomy. *15th ed. Philadelphia: Elsevier; 2013.)*

The angle of dissection is then altered toward the floor, dividing the fascial plane and ultimately exposing the scalene fascia. At the correct depth, the cervical plexus is exposed. Nodal tissue between the plexus rootlets is mobilized and lifted off of the scalene fascia. Along this floor of dissection, the phrenic nerve travels lateral to the IJV.

Inferior Mobilization

At the inferior aspect of the deep dissection, the transverse cervical artery is encountered and preserved. On the left, the thoracic duct and lymphatic drainage from the head and neck converge near the level of the transverse cervical artery. It is customary to avoid sharp or cautery dissection at this level and instead mobilize the inferior aspect with suture tie ligation to minimize risk of lymphatic or thoracic duct leak.

Medial Mobilization

With the nodal tissue fully mobilized inferiorly and laterally, the packet is retracted medially, exposing its posteromedial attachments to the IJV. The fascia is incised over the IJV, and the vein is retracted laterally while the node packet is elevated off the IJV just anterior to the vein. Mobilization along the IJV will encounter the facial vein superiorly, which may be preserved or ligated as necessary. Once the medial edge of the IJV is fully dissected away from the node packet, the fascia investing the node packet is incised to release it from the carotid sheath. This dissection approach respects the fascial planes of the carotid sheath and does not expose the vagus nerve for potential injury. Finally, the node packet in its entirety is retracted laterally, demonstrating its remaining medial attachments to the strap muscles. The strap muscles are separated from the node packet superiorly to the hyoid bone and inferiorly to the clavicle. This anterior plane is then joined to the posterior dissection to fully separate the node packet along its medial edge. If the level IIA dissection is incomplete, this node packet can be retracted inferiorly to facilitate separation from the posterior belly of the digastric muscle. Dissection deep to the digastric muscle is unnecessary and places the hypoglossal nerve at risk of injury.

Closure

It is our practice to routinely place one drain along the dissection bed behind the SCM, lying along the inferior lymphatic-rich tissues. A second drain is occasionally placed in the central neck if an extensive central and mediastinal node dissection is performed. Special attention is paid to the level IV area behind the clavicle to ensure that no thoracic duct leak is present, reflected by excessive lymph fluid. If present, tissues are re-ligated and fibrin glue or similar can be placed. Platysma is approximated with interrupted absorbable suture, and the skin is closed in a subcuticular fashion. Surgical drains in the lateral neck are typically removed as an outpatient, depending on quality and quantity of output.

Primary Hyperparathyroidism

Shkala Karzai, MD, and Jason D. Prescott, MD, PhD

BACKGROUND

Normocalcemia is critical to physiologic function, and adaptive feedback mechanisms have thus evolved to maintain normal body calcium levels. The most specific of these is mediated by the parathyroid glands, which are four small (20–40 mg) organs situated in the neck, adjacent to the thyroid gland (Fig. 1). The function of these glands is to actively maintain normocalcemia by producing parathyroid hormone, an 84–amino acid polypeptide that acts to increase body calcium levels. Under normal circumstances, parathyroid hormone production and thus parathyroid gland activity is actively titrated to blood calcium concentration.

The most common pathology involving the parathyroid glands is primary hyperparathyroidism, which is characterized by adenomatous, hyperplastic, or, rarely, malignant parathyroid gland growth, with concomitant loss of gland regulatory control. This results in chronic blood parathyroid hormone level elevation and, consequently, hypercalcemia, both of which can disrupt normal physiologic function and produce end organ damage.

DIAGNOSIS

The diagnosis of primary hyperparathyroidism is biochemical, depending on coincident frank or inappropriately elevated blood calcium and parathyroid hormone levels. Although parathyroid imaging plays an important role in preoperative planning and intraoperative decision making, imaging is not used to establish diagnosis. Physical examination may reveal an associated neck mass, especially in cases of parathyroid carcinoma, although neck inspection/palpation is unremarkable in the majority of cases. It is critical to distinguish primary hyperparathyroidism (intrinsic parathyroid dysfunction) from secondary hyperparathyroidism (physiologic blood parathyroid hormone elevation) (Box 1). This distinction is not always straightforward, as associated biochemical testing may be equivocal. Physiologically, blood calcium and parathyroid hormone levels are inversely related, with low blood calcium levels inducing compensatory blood parathyroid hormone level elevation (secondary hyperparathyroidism) and vice versa. Apart from some cases of renal failure–related disease, secondary hyperparathyroidism should be managed medically. Relative loss of this inverted relationship, however, represents primary disease (Table 1). Testing the 24-hour urine calcium level may also reveal hypercalciuria, although normal urine calcium levels do not rule out primary hyperparathyroidism. In contrast, hypocalciuria (24-hour urine calcium levels <100 mg) in the context of normal dietary calcium intake is suggestive of familial hypercalcemic hypocalciuria (FHH), an autosomal dominant condition that does not require surgery.

Indications for Surgery

Parathyroidectomy is the standard of care for management of primary hyperparathyroidism, although not all patients require definitive management. As such, well-established guidelines based on the presence of associated signs and symptoms as well as the potential

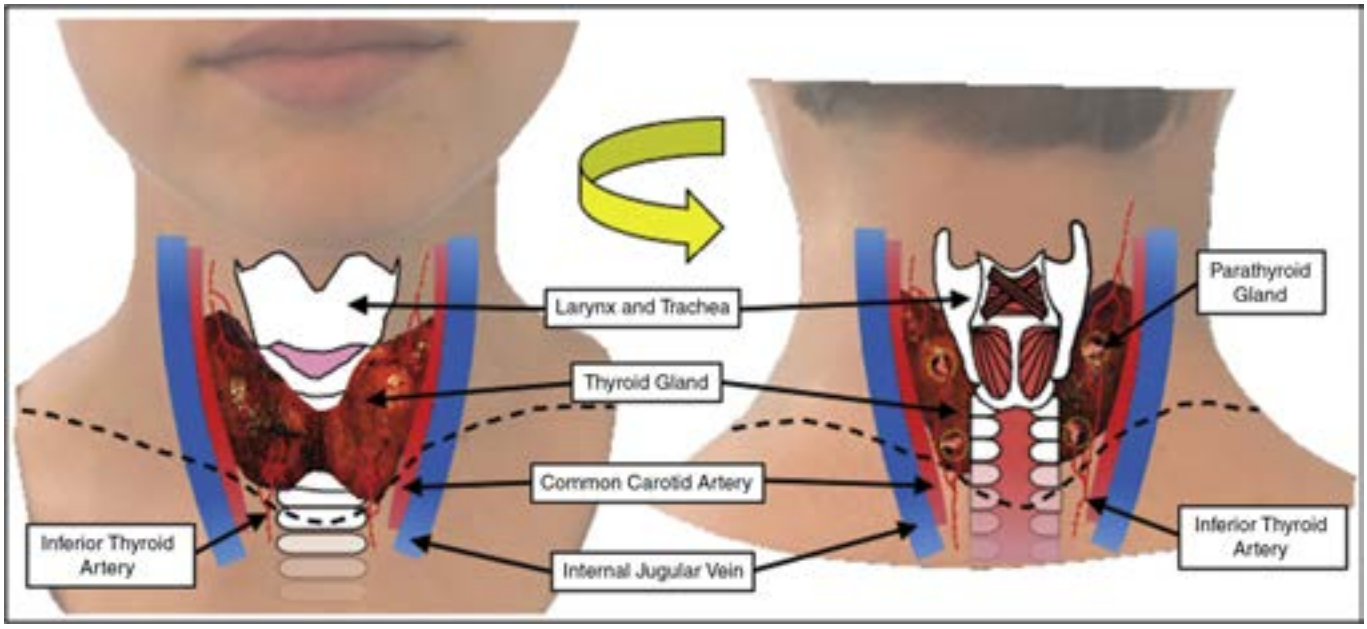

FIG. 1 Normal parathyroid gland localization. The normal anatomic location of the thyroid gland is shown, anterior *(left)* and posterior *(right)*, with associated laryngeal and major vascular structures included, respectively. The four parathyroid glands are shown *(dashed yellow circles)* in their most typical locations, situated adjacent to the posterior surface of the thyroid gland. It is important to note that parathyroid gland localization may be highly variable. The *dashed black line* indicates the position of the clavicle and sternal notch.

BOX 1 Indications for Parathyroidectomy Among Asymptomatic Patients

Estimated glomerular filtration rate <60 mL/minute
Hypercalciuria (24-hour urine calcium level >400 mg)
Nephrolithiasis
Osteoporosis, fragility fracture
Vertebral compression fracture
Blood total calcium level >1 mg/mL above the normal high range value
Age <50 years
Inability to participate in serial follow-up monitoring
Patient preference for surgical management

*Modified from the 2013 Fourth International Workshop on Asymptomatic Primary Hyperparathyroidism Guidelines (see Bilezikian JP, Brandi ML, Eastell R, et al. Guidelines for the management of asymptomatic primary hyperparathyroidism: summary statement from the Fourth International Workshop. *J Clin Endocrinol Metab.* 2014;99[10]:3561–3569).

sequalae of chronic hypercalcemia have been developed (see Box 1). Symptoms of hyperparathyroidism are divided into neurocognitive, musculoskeletal, and gastrointestinal categories and include memory deficits, difficulty concentrating, muscle and joint pain, abdominal pain, heartburn, depressed mood, irritability, and fatigue. Signs of hyperparathyroidism include osteoporosis, pathologic fractures, hypertension, insomnia, nephrolithiasis, kidney dysfunction, constipation, urinary frequency, and pancreatitis. These signs and symptoms are nonspecific, however, and not all patients with this diagnosis develop signs and/or symptoms. Moreover, the severity of signs and symptoms, if present, varies among patients and may not be related to the degree of hypercalcemia/hyperparathyroidism. For these reasons, alternative etiologies for potentially associated signs and symptoms should be carefully considered.

Patients having symptoms attributable to primary hyperparathyroidism should be offered parathyroidectomy as these symptoms usually improve following surgery. Parathyroidectomy is also indicated among asymptomatic patients if any of the following are identified: renal dysfunction (estimated glomerular filtration rate <60 mL/minute), hypercalciuria, nephrolithiasis, osteoporosis, vertebral fracture, blood total calcium >1 mg/mL above the normal high range value, age <50 years, inability to participate in regular follow-up, and patient preference for surgical management (see Box 1). Otherwise, serial monitoring for development of surgical indications is reasonable. Medical intervention for primary hyperparathyroidism, including treatment with calcium-sensing receptor agonists such as cinacalcet (Sensipar), should be reserved for patients who are not operative candidates as current medical interventions are inferior to parathyroidectomy. Parathyroidectomy is curative in up to 98% of primary hyperparathyroidism patients.

Preoperative Considerations

Preoperative planning plays a critical role in successful parathyroidectomy. In particular, localization imaging to identify causative gland(s) facilitates focused surgical exploration, minimizing operative time and the extent of neck exploration, and thus associated complication risk. All preoperative imaging studies should be reviewed collaboratively by the operating surgeon and interpreting radiologist as this facilitates anatomic correlation during surgery. In addition, preoperative assessment for concomitant surgical thyroid disease is critical, as such disease should be addressed at the time of parathyroidectomy. Finally, careful preoperative assessment for an underlying syndromic etiology (e.g., MEN1, MEN2A, jaw tumor syndrome, familial primary hyperparathyroidism) is critical as such syndromic disease requires additional workup for concomitant diagnoses potentially affecting management (in particular, coexistent pheochromocytoma and/or medullary thyroid cancer in cases of MEN2A.) In such cases, appropriate preoperative workup is greatly facilitated by an experienced endocrinologist and/or

TABLE 1 Approximate Biochemical Features of Hyperparathyroidism Subtypes

Blood Total Calcium (Normal 8.5–10.5 mg/dL)	Parathyroid Hormone	25-OH Vitamin D	Diagnosis
>10.5 mg/dL	Elevated or unsuppressed	Normal	Primary hyperparathyroidism
10–10.5 mg/dL	Elevated or unsuppressed	Normal	Probable primary hyperparathyroidism (normocalcemic or normohormonal)
9.5–10 mg/dL	Elevated	Normal	Possible normocalcemic primary hyperparathyroidism
9–9.5 mg/dL	Elevated	Normal or low	Probable secondary hyperparathyroidism
<9 mg/dL	Elevated	Normal or low	Secondary hyperparathyroidism

medical geneticist. We therefore strongly encourage a multidisciplinary approach to parathyroid disease management.

Preoperative Imaging

Neck Ultrasound

All patients for whom parathyroidectomy is planned should undergo formal neck ultrasonography (Fig. 2). Ultrasound is ~80% sensitive for single parathyroid adenoma identification. Sensitivity is dependent on the skill and experience of the operator, however, and decreases for multigland disease. Disease localization also depends on the anatomic domain involved, as ultrasound cannot visualize parathyroid glands located posterior to bony structures, such the clavicles, or air-filled structures, such as the trachea. Parathyroid adenomas generally appear solid, homogenous, hypoechoic, smooth, and, in contrast with cervical lymph nodes, tend to demonstrate internal vascularity when imaged using color Doppler ultrasound. Any thyroid nodules identified by preoperative ultrasound should be categorized using primary malignancy risk criteria (e.g., those established by the Thyroid Imaging Reporting and Data System [TI-RADS] or the American Thyroid Association), and fine-needle aspiration should be performed if indicated. Patients diagnosed with coexistent surgical thyroid disease should undergo thyroid surgery at the time of parathyroidectomy.

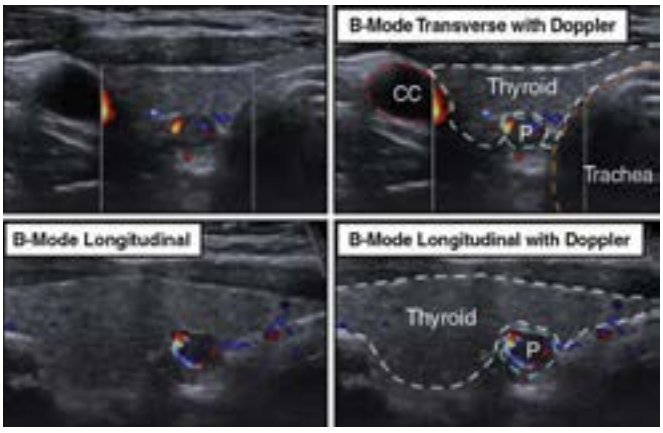

FIG. 2 Thyroid/parathyroid B-mode ultrasound with Doppler enhancement. Transverse *(top row)* and longitudinal *(bottom row)* images are shown. An enlarged parathyroid gland *(P, dashed blue line)* is shown abutting the posterior thyroid surface *(dashed white line)* in the tracheoesophageal groove. The *dashed orange line* shows the trachea. *CC,* Common carotid artery.

Nuclear Scintigraphy/Sestamibi Scanning

Nuclear scintigraphy for parathyroid gland localization is performed with intravenous (IV) technetium-99m (Tc-99m) sestamibi radiotracer (Fig. 3). Both parathyroid and thyroid tissue absorb this tracer, although tracer washout for the thyroid is more rapid than for parathyroid tissue. Thus sequential timed imaging for persistent radiotracer retention (representing parathyroid tissue) is necessary. This includes immediate (5-minute) and delayed (2- to 4-hour) planar imaging, relative to the time of Tc-99m administration. Single photon emission computed tomography (SPECT) imaging can be performed concurrently to allow superimposition of anatomic structures, thus improving localization sensitivity. The sensitivity of nuclear scintigraphic disease localization is similar to that of neck ultrasound. In particular, this modality may be useful in identifying ectopic parathyroid adenomas inaccessible by ultrasound, including ectopic mediastinal/chest and high cervical disease. The quality of nuclear scintigraphy is highly variable, depending on precise image acquisition timing relative to radiotracer administration and on the experience of the interpreting radiologist.

Four-Dimensional Computed Tomography

Four-dimensional computed tomography (4D CT) involves fine-cut four-phase scanning of the neck and upper chest (including noncontrast, arterial, venous, and delayed/washout series in the axial, coronal, and sagittal orientations; Fig. 4). 4D CT is the most sensitive (90%) modality for parathyroid localization and is particularly useful in cases of failed prior exploration or recurrent disease. CT also provides superior anatomic structural information, defining peri-parathyroidal structures, including the thyroid gland, trachea/larynx, esophagus, ipsilateral common carotid artery, ipsilateral internal jugular vein, clavicles, and lung apices. Parathyroid adenomas frequently show early arterial contrast enhancement and early

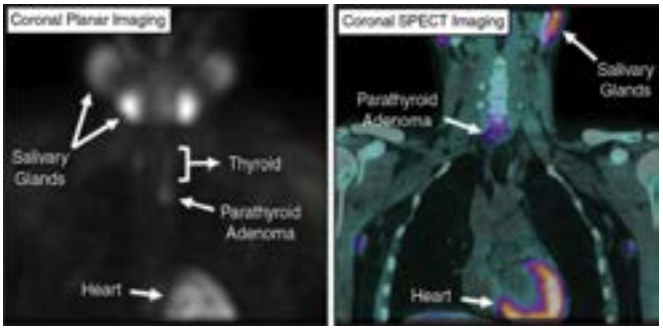

FIG. 3 Nuclear scintigraphy for parathyroid disease localization. Planar *(left)* and SPECT *(right)* examples are shown, each representing a different case. Artifactual tracer uptake is prototypically seen in the salivary glands and heart, as shown.

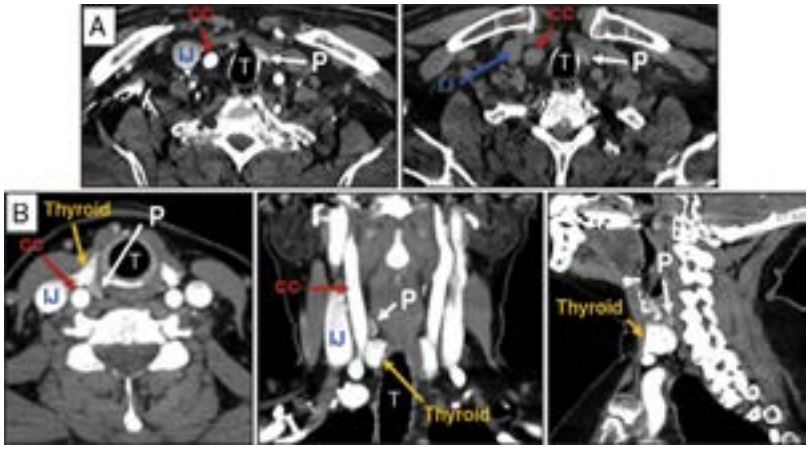

FIG. 4 Four-dimensional CT scan for parathyroid disease localization. Axial arterial and noncontrast images are shown for case A *(top)*. Axial, coronal, and sagittal washout images are shown for case B *(bottom)*. *White arrows* indicate enlarged parathyroid glands *(P)*. The common carotid artery *(CC)*, internal jugular vein *(IJ)*, and trachea *(T)* are shown, where relevant.

contrast washout during the venous phase. On unenhanced images, parathyroid glands appear hypodense relative to the thyroid gland. Despite these imaging features, enlarged parathyroid glands may be difficult to distinguish from benign cervical lymph nodes, which are common and may localize similarly. A small arterial branch of the inferior thyroid artery (see Fig. 1) may be seen supplying a parathyroid adenoma, helping to distinguish a parathyroid gland from a lymph node.

Other Imaging Modalities

Magnetic resonance imaging (MRI), selective venous blood parathyroid hormone level sampling/catheter angiography, and image-guided fine-needle aspiration biopsy with parathyroid hormone washout are additional options for preoperative parathyroid disease localization. In general, these modalities are less sensitive, more expensive, more invasive, and/or require special expertise relative to the first-line studies discussed previously.

We recommend preoperative neck ultrasound and 4D CT scanning for all primary hyperparathyroidism patients planning surgery as we have found this imaging combination to be most predictive of parathyroid disease localization, especially for single gland disease. We have abandoned routine preoperative nuclear scintigraphy-SPECT scanning as progressive improvement in 4D CT scanning protocols has allowed more sensitive and accurate disease localization. We limit MRI, catheter angiography/venous sampling, and image-guided fine-needle aspiration biopsy to special circumstances, including pregnancy (MRI), and to cases for which first-line localization modalities have failed.

PARATHYROIDECTOMY

Surgical Approach

Parathyroidectomy should be performed using as small an incision as possible, generally 3 cm or less (especially if single gland disease is expected). General or regional anesthesia (cervical nerve block) may be employed. Regional anesthesia affords faster recovery in the immediate postoperative period and thus shorter time to hospital discharge as well as improved postoperative nausea. These features reduce overall associated cost and promote efficient clinical workflow. Drawbacks include the need for an experienced anesthesiology team and the potential need for intraprocedural conversion to general anesthesia if unexpected disease complexity/multigland disease, airway concerns, and/or intraoperative patient intolerance is encountered. In addition, traditional technology for intraoperative recurrent laryngeal nerve monitoring cannot be used in the context of regional anesthesia as the associated monitoring circuit requires a specialized endotracheal tube electrode. Given these factors, with particular emphasis on regular use of real-time intraoperative recurrent laryngeal nerve monitoring and our experience of relatively high multigland disease rates (~35%), we use general anesthesia whenever possible. Long- and intermediate-acting neuromuscular blockers/paralytics commonly used for general anesthesia (e.g., rocuronium, vecuronium) must be avoided as such agents will interfere with recurrent laryngeal nerve monitoring. Induction doses of short-acting neuromuscular blockers like succinylcholine (paralytic effect 4–6 minutes) may be used during intubation without such interference. Parathyroidectomy is a "clean" surgery (does not access inherently unsterile body compartments); thus perioperative antibiotic administration is contraindicated. Whenever possible, preoperative therapeutic dose anticoagulation and antiplatelet therapy should be suspended preoperatively to minimize the potential risk of postoperative expanding neck hematoma.

The overwhelming majority of expert parathyroid surgeons use intraoperative blood parathyroid hormone level testing to guide intraoperative decision making, and this testing is standard for all parathyroid surgeries performed by our group. Following anesthesia induction, large-bore intravenous access may be established for blood sample acquisition. Alternatively, samples may be obtained from the surgical field, most commonly from the internal or external jugular veins or from accessible individual peripheral veins (we usually prefer superficial foot veins). A baseline blood parathyroid hormone level should be obtained preoperatively on the day of surgery. The arms are then tucked to facilitate operative field access, and the patient is positioned in the semi-Fowler position. The patient's head is then gently extended by placing a shoulder roll behind the neck, assuming this maneuver is not precluded by concomitant cervical spine disease. Wide sterile skin prepping is then performed to include the upper chest, the bilateral anterior and lateral neck, and the chin, mandibles, and earlobes. Sterile drapes are placed, leaving these anatomic zones visible during surgery (Fig. 5A).

A transverse Kocher incision is then made in the anterior neck. To facilitate favorable cosmetic outcomes, this incision should be as small as possible, should lie within a preexisting skin crease, and should be symmetric and made as inferiorly as possible (to blend with the natural neck irregularity created by the clavicles and be readily hidden by clothing). The superficial subcutaneous tissues, including the platysma, are then divided using electrocautery, and subplatysmal flaps are raised. The superior flap is dissected to the level of the cricoid cartilage, and the inferior flap is raised to the

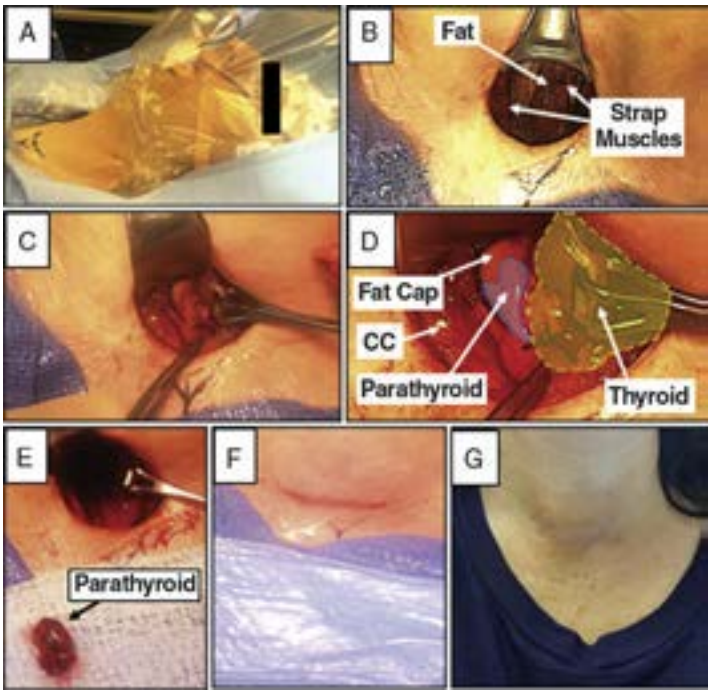

FIG. 5 Parathyroidectomy operative sequence. **(A)** Pre-incision positioning following sterile prepping and draping. **(B)** Operative field view following subplatysmal flap creation. The longitudinally coursing strap muscles are shown (the sternohyoid anteriorly), with interposed fat between these muscles in the midline, anterior to the underlying thyroid gland. (**C** and **D)** Magnified view of tracheoesophageal groove exploration. The strap muscle is retracted laterally to expose the right thyroid lobe *(area outlined in yellow),* which is retracted medially using a Babcock clamp. This exposes the posterior adjacent parathyroid adenoma *(area outlined in blue)* and associated fat cap, which are rotated anteromedially with the right thyroid lobe. The right recurrent laryngeal nerve is not visualized. **(E)** Resected parathyroid adenoma. **(F)**Closed incision. **(G)** Healed incision 17 days postoperatively.

level of the sternal notch. The associated external jugular veins are generally preserved during flap creation, although these may be ligated if significant bleeding is encountered. The midline raphe between the exposed strap muscles (coursing longitudinally, Fig. 5B) is then incised, and the strap muscle ipsilateral to the expected causative gland is dissected from the underlying thyroid lobe. This allows lateral retraction of the strap muscle and sequential thyroid lobe exposure. Associated thyroidal blood supply should be ligated mechanically and/or with vessel-sealing technology to minimize the risk of postoperative bleeding. The dissection plane should be maintained at the thyroid capsule to facilitate identification and preservation of normal parathyroid tissue and the ipsilateral recurrent laryngeal nerve. As dissection proceeds, the thyroid gland is rotated medially and anteriorly using a finger or an atraumatic clamp (Fig. 5C, D), which allows progressive exposure of the tracheoesophageal groove.

The tracheoesophageal groove is then carefully explored. All dissected tissue is carefully assessed for the presence of the recurrent laryngeal nerve and for normal parathyroid tissue, both of which must be assiduously preserved. A detailed understanding of this anatomy is thus critical. Once identified, the enlarged parathyroid gland (Fig. 5C, D) is carefully dissected away from the surrounding tissue. This dissection should be performed at the level of the parathyroid capsule, with care taken to identify the recurrent laryngeal nerve, which may be in close proximity to the enlarged gland. The surgeon should also avoid damaging the abnormal parathyroid gland capsule as this may result in spillage of parathyroid cells into the operative field, with subsequent implantation and recurrence (parathyromatosis). We also request routine intraoperative specimen frozen-section analysis to verify specimen tissue identity and gland enlargement by weight.

Following excision of a single enlarged parathyroid gland (Fig. 5E), we pause our dissection for intraoperative blood parathyroid hormone level testing (although deferring such testing in favor of exploring the remaining parathyroid glands remains an alternative option if preoperative localization imaging is negative or if four-gland disease is anticipated). This intraoperative testing uses sequential decrement in blood parathyroid hormone level to estimate probability of surgical cure on the basis of in vivo parathyroid hormone metabolism kinetics (blood hormone half-life 3–5 minutes). In our practice, we use a modified version of the standard Miami criteria to estimate surgical cure on the basis of intraoperative blood parathyroid hormone level testing. Specifically, this involves blood sampling before incision on the day of surgery ("baseline"), at the time of abnormal gland excision ("time zero"), and 10 minutes, 20 minutes and 30 minutes later. We have found surgical cure rates to be near 100% when: (1) intraoperative blood parathyroid hormone levels fall by at least 50% relative to the baseline or time zero value (whichever is higher) at 10 minutes following abnormal gland excision and (2) the remaining parathyroid gland function is suppressed (blood parathyroid hormone trends down to <35 pg/mL). Failure to meet these criteria indicates additional parathyroid disease, and exploration is consequently continued, with repeat intraoperative blood testing performed sequentially following each subsequent enlarged parathyroid gland excision. Normal parathyroid glands identified during sequential dissection should be left in situ on their native vascular pedicles. If the identity of a parathyroid gland is unclear, a small fragment of this tissue may be sharpy resected (with care taken to avoid compromising the gland's blood supply) for intraoperative frozen-section analysis.

When four-gland disease is encountered or expected (as in familial forms of primary hyperparathyroidism), subtotal parathyroidectomy or total parathyroidectomy with autotransplantation should be performed. Subtotal parathyroidectomy involves resecting all but a normal volume of viable parathyroid tissue, which is left in situ on the tissue's native vascular pedicle. Associated bilateral neck

exploration may require a longer surgical incision, although we are often able to accomplish this using the same incision length planned for single-gland disease. After resecting three enlarged parathyroid glands, we place a large titanium hemoclip across the width of the remaining unresected enlarged gland, leaving a normal volume of parathyroid tissue proximal to the clip on an intact vascular pedicle. The tissue distal to the clip is then sharply resected, leaving the clip, a normal volume of parathyroid tissue, and the associated vascular supply intact. We prefer subtotal parathyroidectomy to total parathyroidectomy with autotransplantation, as parathyroid tissue left in situ is more likely to be viable when supplied by its native vascular pedicle, which translates into lower rates of postoperative permanent hypoparathyroidism.

When performing a total parathyroidectomy with autotransplantation, we transplant into the anterior surface of the ipsilateral sternocleidomastoid muscle as this area is readily accessed via the existing cervical incision. In addition, we have not experienced increased technical difficulty or complication rates when reaccessing this site in the rare circumstance of associated disease recurrence. Autotransplantation into the nondominant brachioradialis muscle is an alternative option, although this requires creating a separate operative field. Autotransplantation involves resecting an approximately normal volume of parathyroid tissue, confirmed by frozen-section analysis, and then sharply mincing this tissue into a fine slurry (1- to 2-mm fragments). The ipsilateral sternocleidomastoid muscle is then exposed, and three to four pockets are bluntly dissected into the anterior muscle surface. Equal volumes of parathyroid slurry are then passed into each muscle pocket, which are then closed using nonabsorbable suture. The suture ends are left long to facilitate future reoperative localization, when needed. Autotransplanted parathyroid tissue will survive initially via imbibition but will eventually recruit an independent blood supply. Autotransplanted tissue will not produce adequate parathyroid hormone for the first 2 to 12 weeks postoperatively, and aggressive supplementation with calcium and activated vitamin D such as calcitriol (Rocaltrol) will generally be required to avoid symptomatic hypocalcemia. In some cases, this may require postoperative hospitalization for intravenous calcium gluconate infusion.

Rarely, intraoperative parathyroid hormone levels will not decrease adequately following excision of all identified enlarged glands. This scenario indicates additional disease, representing either unidentified ectopic causative gland(s) or hyperfunctional supernumerary gland(s). Under this circumstance, a thorough sequential bilateral neck exploration is indicated, including exploration of the carotid sheaths, exploration of the paraesophageal and retroesophageal tissues, and, because ectopic parathyroid tissue commonly localizes to the thymus, bilateral transcervical thymectomy. Except in cases of supernumerary disease, laterality will be apparent if both parathyroid glands on the contralateral side have been identified. Otherwise, direct comparison of blood intact parathyroid hormone levels from each internal jugular vein may facilitate lateralization. Finally, intraoperative failure to identify all but one parathyroid gland, despite thorough bilateral neck exploration, may indicate intrathyroidal localization of the remaining abnormal gland. This may be misidentified as a thyroid nodule by preoperative ultrasonography. In this case, we perform a thyroid lobectomy on the side for which the remaining parathyroid gland has not been identified. For this reason, the potential need for thymectomy and/or thyroid lobectomy should be discussed preoperatively with all patients.

Failure of blood parathyroid hormone levels to decrease appropriately is uncommon. When this occurs, however, additional exploration is unlikely to be fruitful. In such cases, we stop our operation, with the understanding that future attempts at disease localization, followed by reoperation, will be necessary. Sternotomy and/or thoracotomy are not indicated without clear preoperative mediastinal disease localization.

Parathyroid carcinoma is a rare cause of primary hyperparathyroidism and is generally associated with very high preoperative blood parathyroid hormone and calcium levels. Intraoperatively, the causative gland is hard/firm in consistency and may be fixed to adjacent tissues, especially the ipsilateral thyroid lobe. Treatment requires en bloc resection of the tumor with neighboring associated tissues, including the ipsilateral thyroid lobe, as well as ipsilateral comprehensive central neck dissection. Preservation of the parathyroid tumor capsule is of paramount importance during dissection as tumor capsule violation may allow seeding of liberated cancer cells in the surgical field, with subsequent development of incurable parathyromatosis.

The operation concludes with careful wound bed inspection for hemostasis, which must be verified to minimize the potential for development of postoperative expanding neck hematoma. Hemostatic agents may be applied for this purpose as well (we coat the operative field with a small volume of fibrinogen-thrombin sealant). Identified normal parathyroid glands should also be assessed for viability. The recurrent laryngeal nerve(s), if identified, should be evaluated for anatomic integrity and, if nerve monitoring is used, for functionality. The strap muscles are then closed vertically, with subsequent transverse closure of the platysma, using absorbable 3-0 suture. The skin is then closured with a 4-0 running absorbable monofilament suture (see Fig. 5F). Care should be taken to appose the dermal edges of the incision to maximize the chance of good cosmetic healing (see Fig. 5G).

Intraoperative Adjuncts and Alternative Surgical Approaches

Recurrent Laryngeal Nerve Monitoring

The recurrent laryngeal nerve on each side of the neck courses in the immediate vicinity of the ipsilateral parathyroid glands, and these nerves are often encountered during parathyroidectomy. Because each nerve innervates all but one of the ipsilateral intrinsic laryngeal muscles, inadvertent injury to these delicate structures results in ipsilateral vocal cord paresis. Depending on the position of the paralyzed cord, associated morbidity may be asymptomatic or may be significant, including hoarseness, subjective shortness of breath, thin liquid aspiration, and, in cases of bilateral nerve injury, possible airway compromise requiring emergent tracheostomy. Recurrent laryngeal nerve monitoring allows real-time intraoperative assessment of nerve function, which translates into improved recognition of nerve injury. This may, in turn, facilitate intraoperative decision making, especially if exploration of the side contralateral to known nerve dysfunction is entertained. In addition, this technology can facilitate intraoperative nerve identification, thus theoretically diminishing nerve injury risk. Specialized equipment (including an endotracheal tube electrode) and surgeon expertise are required for intraoperative nerve monitoring, however. Use of this technology therefore requires general anesthesia and incurs both additional cost and operative complexity.

Gamma Probe–Facilitated Intraoperative Parathyroid Disease Localization

As is the case for preoperative parathyroid disease localization by nuclear scintigraphy, technetium (^{99}TC) sestamibi may also be employed for intraoperative identification of hyperfunctional parathyroid glands. Specifically, a handheld radioisotope (gamma) probe can be used during surgery to guide intraoperative parathyroid exploration following preoperative ^{99}TC sestamibi injection. This technique has largely been abandoned, however, as the associated specificity is often confounded by background signal originating from normal thyroid tissue, which also absorbs technetium.

Parathyroid Autofluorescence Detection

Parathyroid tissue is known to produce autofluorescence when exposed to excitation wavelengths in the near-infrared range. This has led to recent development of technology for detection of this autofluorescence, with one potential application being improvement in

identification of hyperfunctional parathyroid glands during parathyroidectomy. Intraoperative autofluorescence detection necessitates specialized equipment, however, and currently requires operative exposure, or near exposure, of the autofluorescing gland(s). For these reasons, this new technology has not yet demonstrated incremental value during parathyroid surgery relative to traditional disease localization strategies, and it has not been generally adopted by expert parathyroid surgeons.

Alternative Surgical Approaches to the Parathyroid Glands

In the context of ongoing interest in surgical technology/technique development and the relative importance of optimal postoperative cosmesis (complete avoidance of a surgical scar) for some patients, surgical approaches to parathyroidectomy that avoid a neck incision have been developed. These include transaxillo-breast, postauricular (facelift), and, most recently, transoral vestibular parathyroidectomy approaches, all of which allow complete avoidance of a neck scar. In general, these techniques do not afford the same potential for neck exploration inherent to the traditional approach and thus should be limited to cases of well-localized single-gland disease. In addition, these techniques are associated with potential complications not otherwise encountered during parathyroidectomy, including brachial plexus (transaxillo-breast), marginal mandibular nerve (facelift), and mental nerve (transoral) injuries. For these reasons, alternative approach parathyroid surgery should be reserved for patients who are highly motivated to avoid a neck incision scar and should be performed by surgeons with experience in one or more of these techniques.

OPERATIVE COMPLICATIONS

Significant complications associated with parathyroid surgery include recurrent laryngeal nerve injury, described earlier, permanent hypoparathyroidism, and expanding neck hematoma. Overall, risk is related to extent of neck exploration, with complication rates of approximately 4% for bilateral neck surgery and between 1% and 3% for focused/unilateral exploration. Permanent hypoparathyroidism and airway compromise potentially requiring emergent tracheostomy are only associated with bilateral neck exploration as these morbidities require injury to bilateral structures (all four parathyroid glands or both recurrent laryngeal nerves, respectively).

Recurrent laryngeal nerve dysfunction and associated symptoms related to nerve compression, traction, or minor thermal injury are usually self-limited, with spontaneous nerve recovery usually within 6 months of surgery. Vocal fold paresis resulting from recurrent laryngeal nerve transection is permanent, however, and cannot be restored by nerve reconstruction (although end-to-end nerve reconstruction should be performed whenever possible to minimize subsequent laryngeal muscle atrophy). Formal laryngeal evaluation should be performed postoperatively if the recurrent laryngeal nerve is injured or if injury is suspected.

Temporary hypoparathyroidism is common after parathyroidectomy (20%–30% of cases) as resumption of normal synthetic function by remaining normal parathyroid tissue may take several days. In contrast, inadvertent damage to or resection of all parathyroid tissue or a failed autotransplantation following total parathyroidectomy results in permanent hypoparathyroidism. Related signs and symptoms include perioral and/or distal extremity paresthesias and muscle spasms/cramps. Tetany and/or seizures may occur in cases of severe hypocalcemia, usually in the context of severe permanent hypoparathyroidism. Blood calcium levels should be assessed if symptoms develop, and oral calcium carbonate supplementation should be titrated to improve associated symptoms/blood calcium levels. Calcium citrate should be used in cases of previous gastric surgery or low stomach acidity as calcium carbonate is not readily absorbed in this context. Vitamin D plays a crucial role in calcium homeostasis and is required for normal intestinal calcium absorption. Supplementation with oral vitamin D should be initiated in combination with calcium supplementation if blood levels are low. Intravenous calcium gluconate is required if severe hypocalcemia is encountered (blood total calcium <7 mg/dL).

Postoperative expanding neck hematoma is a rare but serious complication of parathyroid surgery. This is generally characterized by rapid neck swelling followed by tachypnea, anxiety, and progressive airway compromise. Any evidence of expanding neck hematoma postoperatively should be interpreted as a surgical emergency. This should prompt immediate opening of the surgical wound at the bedside/in the emergency department for clot evacuation followed by surgical wound bed exploration for hemostasis in the operating room.

POSTOPERATIVE CONSIDERATIONS

We assess blood parathyroid hormone, total calcium levels, and vitamin D levels during the routine postoperative office visit, usually 2 to 4 weeks following surgery. The blood parathyroid hormone levels may be mildly elevated at this time in the context of normal or low normal blood total calcium levels. This is almost always the result of vitamin D deficiency and relative postoperative hypocalcemia, and it resolves with oral vitamin D and calcium supplementation. We reassess these blood values again at 6 months postsurgery to verify surgical cure. Recurrent primary hyperparathyroidism will develop in up to 2% of these patients, and for this reason, blood total calcium levels should be assessed annually.

Persistent and Recurrent Hyperparathyroidism

Aditya S. Shirali, MD, and Nancy D. Perrier, MD

Persistent hyperparathyroidism (HPT) is defined by elevation of serum calcium (and parathyroid hormone [PTH] in the event of eucalcemic hyperparathyroidism) within 6 months after parathyroidectomy. Recurrent hyperparathyroidism is defined as the existence of eucalcemia at 6 months and then the development of hypercalcemia and/or elevated PTH afterward. This chapter will address management in the reoperative setting. The etiology of persistent and recurrent HPT, diagnosis and surgical indications for reoperation, preoperative evaluation, and surgical techniques will be discussed.

ETIOLOGY

Persistent HPT occurs at a rate of 1% to 6% and recurrent HPT from 2.5% to 15%. The most common causes of persistent disease are a missed gland or unrecognized multigland disease. Other less common causes include incomplete resection (i.e., a dumbbell-shaped gland), implantation of disease from a ruptured parathyroid cyst (parathyromatosis), or parathyroid carcinoma (Fig. 1). In cases of a missed gland, it is not uncommon to have removal of a gland, albeit not the autonomous hyperactive gland. Anatomically, missed hyperfunctional glands are most commonly located deep in the tracheoesophageal groove or posterior to the thyroid gland tethered within the capsule. Glands deep within the tracheoesophageal groove are superior glands that fall from a vascular pedicle lateral to the recurrent laryngeal nerve (RLN). On a more rare occasion, superior glands can be located in the retropharyngeal space. Alternatively, large inferior glands may fall into the thymus or superior mediastinum. Inferior glands can be undescended and in the high submandibular region or even within the thyroid parenchyma. Because most missed abnormal parathyroid glands, however, are found in the usual anatomic locations, the surgeon should have a thorough knowledge and understanding of the anatomy and embryology of the cervical and mediastinal regions.

The most common cause of recurrent HPT is multigland disease. Multigland disease may occur sporadically or in patients with familial disease, such as Multiple Endocrine Neoplasia (MEN) Types 1, 2A, and 4. Recognizing familial disease preoperatively informs the correct operation, which is not single gland removal, and management of future endocrinopathies.

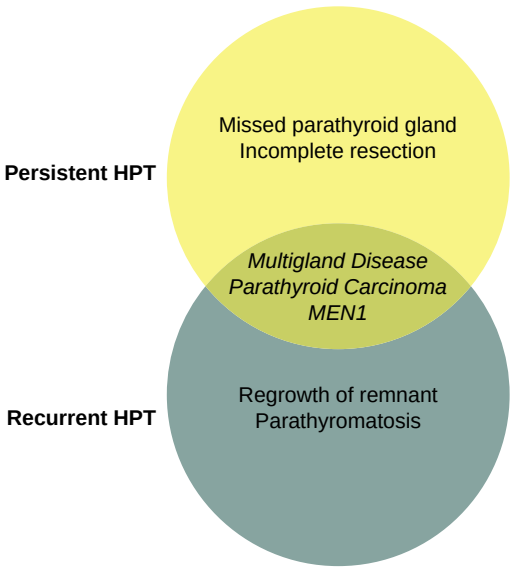

FIG. 1 Causes of persistent and recurrent hyperparathyroidism (HPT). Patients with suspected multigland disease or parathyroid carcinoma may present with either persistent or recurrent hyperparathyroidism. *MEN1*, Multiple endocrine neoplasia, type 1.

DIAGNOSIS AND INDICATIONS FOR REOPERATIVE PARATHYROIDECTOMY

The evaluation of suspected persistent or recurrent HPT is initiated with confirming the biochemical diagnosis of HPT with serum calcium, PTH, 25-hydroxy vitamin D, creatinine, and phosphorus. Hypercalcemia with a concomitant inappropriately elevated PTH confirms the diagnosis. Eucalcemia with only elevated PTH may be due to hungry bone syndrome, vitamin D deficiency, or renal failure. It is imperative to rule these out as potential confounders. In addition, thiazide diuretics, sarcoidosis, hypercortisolism, multiple myeloma, and other causes of hypercalcemia should be reconsidered when an elevation in PTH is not identified. A 24-hour urinary calcium level measurement also should be performed to exclude familial hypocalciuric hypercalcemia (FHH) to avoid unnecessary reoperation. A young patient should raise the suspicion of MEN syndromes and familial endocrinopathies, such as familial isolated HPT, and one should have a low threshold for referral to genetic counseling in the reoperative setting.

The decision to reoperate should consider the risks and benefits, symptoms and disease severity, the etiology of persistent or recurrent disease, and the likelihood of achieving cure and relief of the patient's symptoms. In general, reoperative parathyroidectomy should be considered for patients with a failed initial operation, for symptomatic HPT patients, and those with progressive decline in end organ disease (i.e., osteoporosis or worsening kidney function).

EVALUATION

After the diagnosis of persistent or recurrent HPT is rendered, the most important next step is determination of single or multigland disease. This can be deciphered through a thorough review of biochemical trends and prior operative and pathology reports.

Review of prior pathology reports is the most important aspect of care. Gross and histologic review of all tissue removed, number of specimens, degree of hypercellularity, size and weight of the glands, and the presence of thyroid parenchyma, lymph nodes, and fat should be performed. Preferably, or if there is any uncertainty about the histopathologic diagnosis, the slides from the initial operation should be reviewed. Next, operative reports should be meticulously read to determine the number of glands visualized and the reported appearance and number of glands presumed to have been resected. Deciphering whether clips were placed or biopsies performed and the identification of the RLN are critical. Correlating the operative reports with pathologic confirmation of hypercellular parathyroid tissue is critical to discern single-gland versus multigland disease. For example, a pathology report that shows no evidence of hypercellular parathyroid tissue in the resected specimen(s) is more likely to suggest missed single-gland disease than the operation that involved resection of two parathyroid glands found to be hypercellular upon histologic review.

Once the reoperative surgeon has a better understanding of the cause of persistent or recurrent HPT, repeat localization studies

should be performed. For reoperative parathyroidectomy for a suspected missed single gland, a minimum of two concordant imaging studies is required for proper operative planning. This allows for planning of a directed and targeted operation. Cervical ultrasonography, technetium (^{99}Tc) sestamibi-single photon emission computed tomography/computed tomography (sestamibi-SPECT/CT), and four-dimensional multidetector computed tomography (4D-CT) are the preferred initial imaging modalities for reoperative cases. Growing evidence in Europe has identified ^{11}C-choline and ^{18}F-fluorocholine positron emission tomography (PET)/CT as attractive second-line imaging studies for localization.

The most important aspect of imaging is that the surgeon understands the techniques and strengths and weaknesses of each study at their institution. Although nuclear medicine and anatomic cross-sectional imaging can be combined, having a well-synchronized team of collaborating radiologists and nuclear medicine experts working together is the most important aspect of care. In addition, interpretation of negative studies can be as helpful as positive studies. For example, if a missed gland is in the thymus, one would expect the ultrasound to be negative because that modality cannot adequately visualize behind the sternum.

For suspected multigland disease requiring reoperation, we do not routinely advocate for multiple imaging modalities in patients because a bilateral approach is warranted, and intraoperative inspection should identify enlarged glands. Nuclear medicine studies are not reliable in multigland disease because radiotracer uptake may not be seen in all hyperfunctioning glands. Furthermore, asymmetric enlargement of glands is common in multigland disease, and anatomic imaging is frequently less sensitive in identifying small glands and thus adds little benefit to operative planning.

LOCALIZATION STUDIES

A review of several common localization studies follows:

Ultrasonography plays a key role because of its cost effectiveness and added benefit of identifying any concomitant thyroid pathology. Imaging from the submandibular region cephalad to the clavicles caudally is completed with Doppler imaging to assess the vascularity of any suspicious lesions and inform the surgeon of the location of the vascular pedicle. A fine-needle aspiration (FNA) biopsy of a suspicious lesion, whether extra- or intrathyroidal, can be obtained at the time of ultrasound and sent for both cytologic confirmation and PTH biochemical assay. Cytologic assessment of intrathyroidal parathyroid lesions may inaccurately be read as indeterminate follicular lesions, highlighting the importance of the PTH biochemical assay to cytologic interpretation. The combination of cytologic and biochemical confirmation improves the accuracy of ultrasonography alone from 65% to more than 80% and the sensitivity from 75% to 90%.

4D-CT is a powerful modality for identifying missed parathyroid glands, especially those in undescended positions (Fig. 2). The

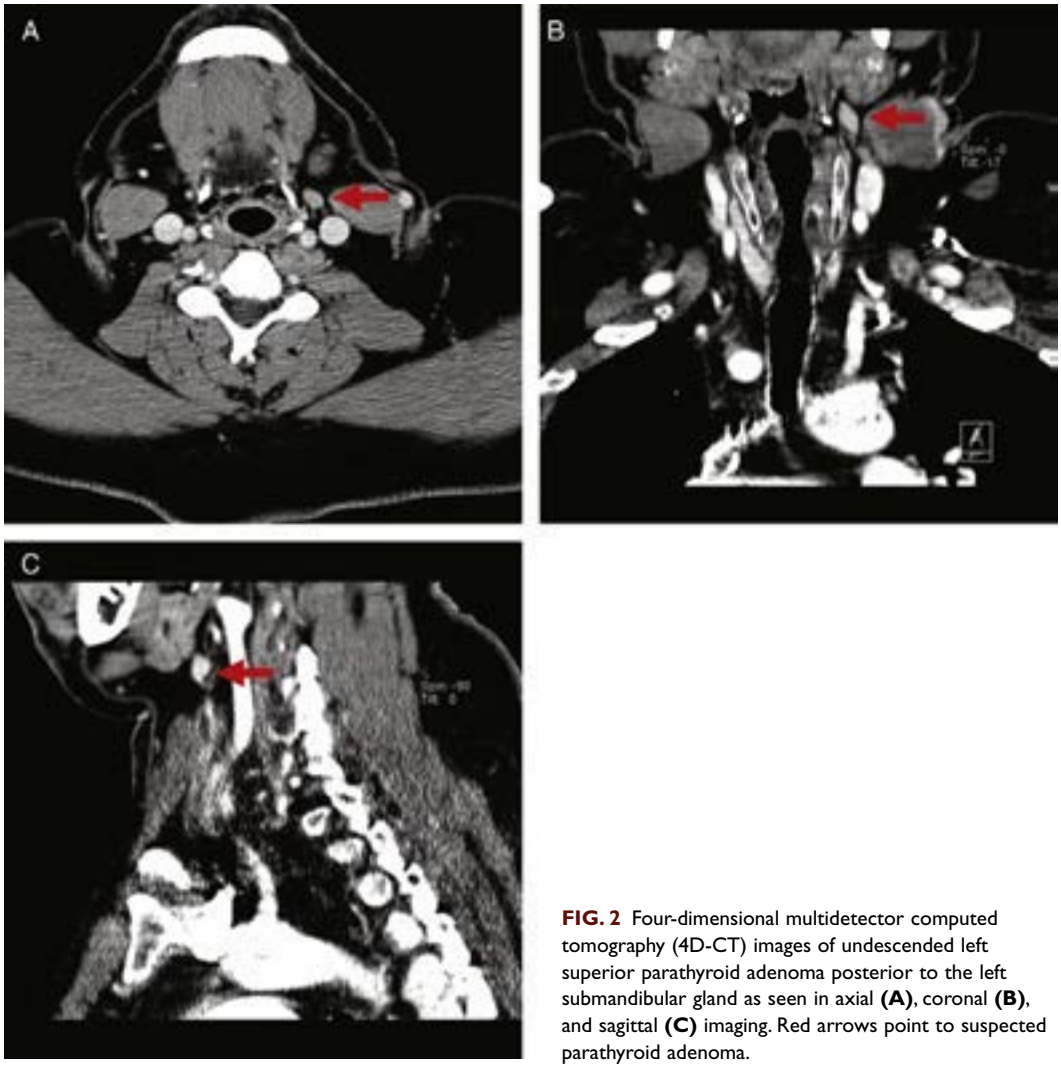

FIG. 2 Four-dimensional multidetector computed tomography (4D-CT) images of undescended left superior parathyroid adenoma posterior to the left submandibular gland as seen in axial **(A)**, coronal **(B)**, and sagittal **(C)** imaging. Red arrows point to suspected parathyroid adenoma.

study should include multiple views from the jaw to the aortic arch and with arterial and delayed enhancement phases. 4D-CT allows visualization of differences in perfusion characteristics between hyperfunctioning parathyroid glands (i.e., rapid uptake and quick washout) and normal parathyroid glands and other structures in the neck. This single study provides both anatomic information and a correlation for function (perfusion). 4D-CT has a sensitivity of over 90% in identifying single-gland disease initially with recent studies showing a sensitivity greater than 75% in recurrent or persistent HPT compared with less than 50% for sestamibi and ultrasound alone. Having experienced radiologists engaged and using common terminology in these interpretations is pivotal to the success of the reoperative parathyroid surgeon.

The use of ^{11}C-choline and ^{18}F-fluorocholine PET/CT, previously used for detection of recurrent prostate cancer, has shown promise in providing parathyroid adenoma localization. The study combines the use of these specific radiotracer injections and PET from the skull base to the upper thighs with dedicated arterial-enhanced CT of the neck to provide the true functional component missing in 4D-CT imaging. Several small studies have shown sensitivity and specificity for parathyroid localization greater than 90%. One recent study by Christakis et al. examined its use in persistent/recurrent primary hyperparathyroidism (PHPT) with negative first-line localization studies and identified cure in 58% of patients. Further studies examining its utility in persistent/recurrent PHPT are necessary.

Historically, invasive methods to differentiate laterality based on the discrepancy of PTH drawn from the cervical veins were previously a modality of discussion. In the era of enhanced imaging, this practice has gone out of favor. It serves as mere lateralization, is less specific, and fails to provide sufficient information for directed resections. Selective venous sampling (SVS) involves catheterization of the internal jugular and multiple veins in the neck and mediastinum. We do not advocate routine use of this invasive study due to alteration of the venous drainage pattern from previous neck operations or thyroid lobectomy that may obscure localization, high risk of technical failure, and rare operative complications (such as bleeding, infection, pseudoaneurysm, and arteriovenous fistula). More importantly, the use of new imaging modalities, such as PET/CT with ^{11}C-choline or ^{18}F-fluorocholine, and FNA of suspicious targets with PTH aspirate, may actually be more specific.

PLANNING AND RISK ASSESSMENT

After diagnosis of persistent or recurrent HPT, appropriate indications for surgery are met, the etiology of persistent or recurrent HPT is identified, and localization is attempted by preoperative imaging, the surgeon must next consider the patient's functional status, comorbidities, any sequelae of previous neck operations, and anesthetic risks when weighing the risks and benefits of reoperative parathyroidectomy (Fig. 3; Box 1). Compared with initial surgery, reoperative surgery is associated with more operative complications due to scarring and fibrosis from the previous operation as well as potential devascularization and inadvertent removal of remaining parathyroid glands.

Preoperative planning for a reoperation should involve reviewing previous operative imaging, operative reports, and pathology reports. Surgeons should identify whether a unilateral or bilateral exploration was performed, the location and number of parathyroid glands that were identified, whether biopsies or clips were placed by suspicious parathyroid glands, and whether resection of the thyrothymic tract was performed. Furthermore, the operative report should be reviewed for concerning thyroid pathology, such as Hashimoto's thyroiditis or multinodular goiter, that may further complicate the dissection and/or necessitate concomitant thyroidectomy.

Reoperations are associated with a greater incidence of vocal cord paralysis, with a RLN injury rate of approximately 2% to 15% (compared with 0.5% to 1% in initial operations). The patient should be considered to undergo videostroboscopy to assess function of their vocal cords and the RLN integrity before consideration for reoperation. Unilateral RLN paralysis may already be present yet unnoticed, especially if the length of time between the initial operation and recurrence has been extensive. This information may influence use of intraoperative adjuncts. If there is a documented unilateral RLN injury, the risks and benefits of reoperation on the contralateral side must be considered and the implications of possible bilateral RLN palsy should be explicitly discussed with the patient.

The surgeon must have a clear understanding of the viability of the remaining parathyroid glands. Prior knowledge of which parathyroid glands were explored, and thus potentially devascularized, and which glands were biopsied and/or clipped will help the surgeon develop a strategy to prevent postoperative hypoparathyroidism, which may be permanent in 10% to 16% of patients. This is especially important in patients undergoing subtotal parathyroidectomy, as leaving a devascularized remnant will place the patient at high risk for permanent hypoparathyroidism. If the suspected diseased gland is the only viable parathyroid gland, autotransplantation should be considered. Patients should be counseled about the risks of future repeat hyperfunction of autotransplanted tissue and need for future debulking of the autograft. Patients must also be counseled about the risk for aparathyroidism, particularly in the setting of previous four-gland exploration with resection or devascularization of multiple glands. The exact number of functioning parathyroid glands is impossible to know preoperatively, and thus the surgeon should always keep immediate or delayed autotransplantation in their armamentarium during reoperative parathyroidectomy.

Cryopreservation involves removing confirmed parathyroid tissue from the neck at the time of surgery, dicing of tissue to increase surface area, preservation with Tis-U-Sol solution, and freezing at −80°C for later autotransplantation. Cryopreservation of parathyroid tissue is a tedious process that requires adequate planning and appropriate storage techniques for the possibility, but low probability, of future autotransplantation. Furthermore, this practice may have legal and ethical ramifications involving the storage, destruction, or use of tissue for research purposes. In addition, there is a significant cost to processing and storage of cryopreserved tissue. Most institutions have abandoned the practice of routine cryopreservation as the utilization of cryopreserved tissue is low and delayed autografts were found to be functional in only 50% to 60% of patients. In contrast, the success rate for fresh parathyroid autografts has been reported to exceed 80%. For this reason, in patients who have already had multiple glands removed, autotransplantation at the time of gland removal is an ideal option. Transplantation into the ipsilateral pectoralis major muscle (already in the surgical field and without overlying fat) or the nondominant brachioradialis muscle at the time of reoperative surgery are both good options. These sites are preferred over the sternocleidomastoid to avoid reoperative neck surgery in the event the patient experiences persistent or recurrent disease due to the autotransplanted tissue. The brachioradialis position also affords future discernment of the source of PTH because comparative venous samples can be obtained in each arm, denoting large gradients from systemic versus local production.

Intrathyroidal and retroesophageal parathyroid glands are rarely encountered. However, patients found with these lesions may require thyroid lobectomy or retroesophageal dissection, respectively. Patients should be counseled regarding the potential development of hypothyroidism, especially in the setting of preexisting Hashimoto's thyroiditis, and requirement of lifelong thyroid supplementation. Patients requiring retroesophageal dissection in a reoperative field should be counseled regarding risks of postoperative dysphagia and the small, but present, risk of esophageal injury and leak.

BOX 1 Indications for Reoperative Parathyroidectomy in Persistent or Recurrent PHPT

- Worsening hypercalcemia refractory of medical management
- Worsening bone mass
- Ongoing nephrolithiasis
- Progressive renal dysfunction
- Associated neuromuscular and neurocognitive symptoms

OPERATIVE TECHNIQUE

Reoperation for persistent or recurrent HPT can be hindered significantly by fibrosis, loss of normal anatomic planes, and anatomic modifications that resulted from the initial operation. Thus, the endocrine surgeon must have a clear operative plan to avoid risks of hypoparathyroidism or injury to the RLN and surrounding structures. The surgeon must use their understanding of the etiology of disease (i.e., missed single-gland disease versus multigland disease), preoperative localization studies, prior operative reports, and documentation of vocal cord mobility to guide decision making. If parathyroid carcinoma is suspected, a metastatic workup for distant disease should be obtained before operative intervention and the operative plan should include en bloc resection with ipsilateral thyroid lobectomy. If parathyromatosis is the cause, the surgeon should expect multiple implants of tissue in the prior cervical region. Intraoperative ultrasound can help to localize and guide complete resection, which can be tedious as the parathyroid tissue implants into muscle and fat.

Critical to the technical success of reoperative parathyroidectomy for benign etiology is a thorough knowledge of the embryology and anatomy of parathyroid disease. This knowledge combined with preoperative localization studies and descriptions of parathyroid location in previous operative reports can help guide operative approach. A nomenclature system proposed by Perrier and colleagues (2009) classifies parathyroid glands as types A through G, with the recent

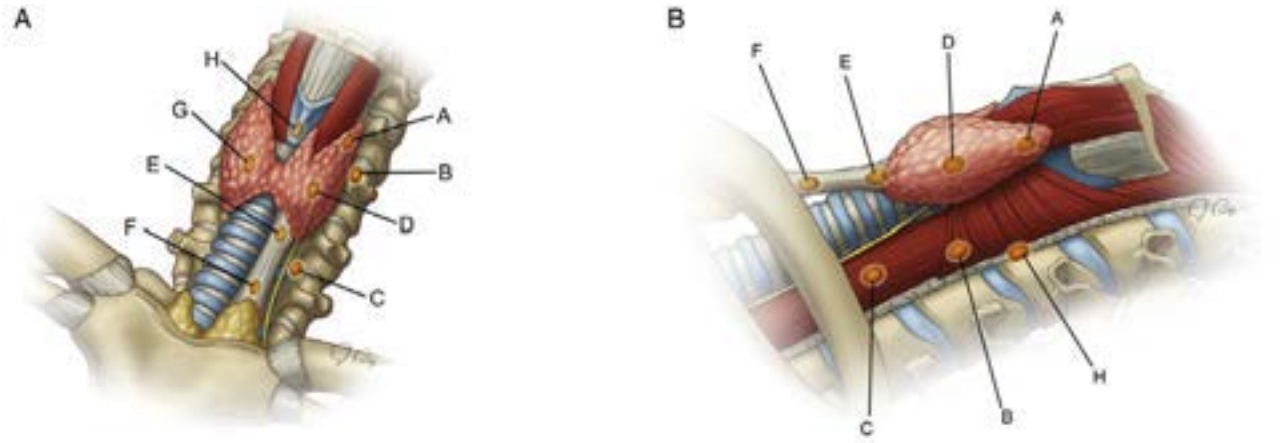

FIG. 4 The position of type A to H glands in the nomenclature system of Perrier and colleagues. Types A, B, C, and H glands are superior glands, and types E, F, and G glands are inferior glands. Type D glands may be either superior or inferior glands with determination made intraoperatively based on the location of the vascular pedicle in relation to the recurrent laryngeal nerve. Illustrations of coronal **(A)** and sagittal **(B)** views.

addition of type H glands in the retroesophageal position (Fig. 4). This nomenclature system emphasizes the anterior-posterior location of enlarged parathyroid glands in relation to the thyroid parenchyma, trachea, and esophagus. Types A, B, and C represent superior parathyroid glands that are usually found on a vascular pedicle that is lateral and posterior to the RLN; when adenomatous, these glands may fall posterior to the thyroid tissue (A) or into the tracheoesophageal groove (B and C). Glands that are derived embryologically from the inferior pedicle are classified as type E or F glands; the pedicles of these glands are medial and slightly more anterior to the RLN. Type D glands are found overlying the RLN. Types G and H are infrequently encountered and are found either intrathyroidal or posterior to the esophagus in the midline, respectively. A thorough understanding of these positions in relation to adequate localization may help the parathyroid surgeon determine an operative approach.

The focused lateral approach is a good option for missed single-gland disease (adenomas) located in a superior or posterior position, or A, B, C, D, or H types of Perrier's nomenclature. This approach is an excellent option in reoperative cases to avoid scar tissue in the central compartment of the neck if the initial operation used a central approach. A 2- to 3-cm horizontal incision is made at the level of the adenoma, extending from the midline to the anterior border of the sternocleidomastoid muscle. The plane between the sternocleidomastoid and the strap muscles is entered with blunt dissection, the carotid sheath is visualized and carefully retracted laterally, while the thyroid lobe and the strap muscles are retracted medially (Fig. 5), exposing posterior to the thyroid, the tracheoesophageal groove and the retroesophageal position.

The focused central anterior approach is ideal for missed single inferior parathyroid glands (types E, F, and G) that may require excision of the thyrothymic tract or thyroid lobectomy. This approach, which requires a cervical collar incision, involves separation (not division) of the strap muscles in the median raphe and a midline-initiated approach. It has obvious disadvantages if previously used in the initial operation but nevertheless provides a direct route to inferior parathyroid glands without having to "cross" the RLN. Furthermore, this approach is ideally suited for patients with suspected multigland disease who require bilateral cervical exploration and subtotal parathyroidectomy. These patients, in particular, are at risk for hypoparathyroidism given concern for devascularization during their initial operation. Every effort should be made to avoid aggressive dissection, clip application, and biopsy of normal-appearing glands to prevent inadvertent devascularization.

Most parathyroid glands located in the superior mediastinum can be removed via a transcervical approach by gentle manipulation and retraction of the ipsilateral thymic tissue with the help of digital dissection and the use of a right-angle instrument. In rare cases in which the parathyroid gland is located inferiorly in the mediastinum, the use of video-assisted thoracoscopy in combination with a thoracic surgical colleague can prevent the need for a sternotomy to excise the gland. This procedure should only be performed in the presence of concordant preoperative localization studies.

In patients undergoing reoperative parathyroidectomy with concern for devascularization of multiple glands, consideration should be made for immediate autotransplantation into the ipsilateral pectoralis major muscle. We prefer to use the pectoralis major muscle just inferior to the clavicle as a site for autotransplantation in patients without a familial endocrinopathy. Patients with familial endocrinopathies may undergo autotransplantation in the nondominant brachioradialis muscle to help guide localization of recurrence by laboratory assessment. Creating a single pocket in the region immediately below the clavicle where there is the least amount of subcutaneous fat allows for easy access (Fig. 6). The area is on the surgical field and, if contained with a clip, the pocket can be opened on the morning after the operation and tissue easily evacuated after confirmation of detectable and robust PTH, confirming viable tissue elsewhere. This is an easy but important "insurance policy" to prevent against aparathyroidism. If on the morning after the operation the PTH is undetectable, suggestive of no viable intact parathyroid tissue, the autotransplanted tissue can be left in place to grow and vascularize. It usually requires 4 to 6 months for the tissue to be robust enough for detectable PTH to become apparent on blood draws and for the patient to be weaned from calcium supplementation.

The following operative adjuncts may be used in the reoperative setting:

1. **Intraoperative Neurophysiological Monitoring**
   Intraoperative neurophysiologic monitoring (IONM) in reoperative parathyroid surgery may be useful to confirm nerve function during dissection in the event of contralateral nerve injury confirmed by videostroboscopy. Surgeons must be well-versed in the use of IONM before its use for this indication to avoid false positives or negatives that may result in further unnecessary dissection.
2. **Intraoperative PTH Aspirate**
   Frozen section analysis is always used to confirm the identity of abnormal removed parathyroid glands before cessation of

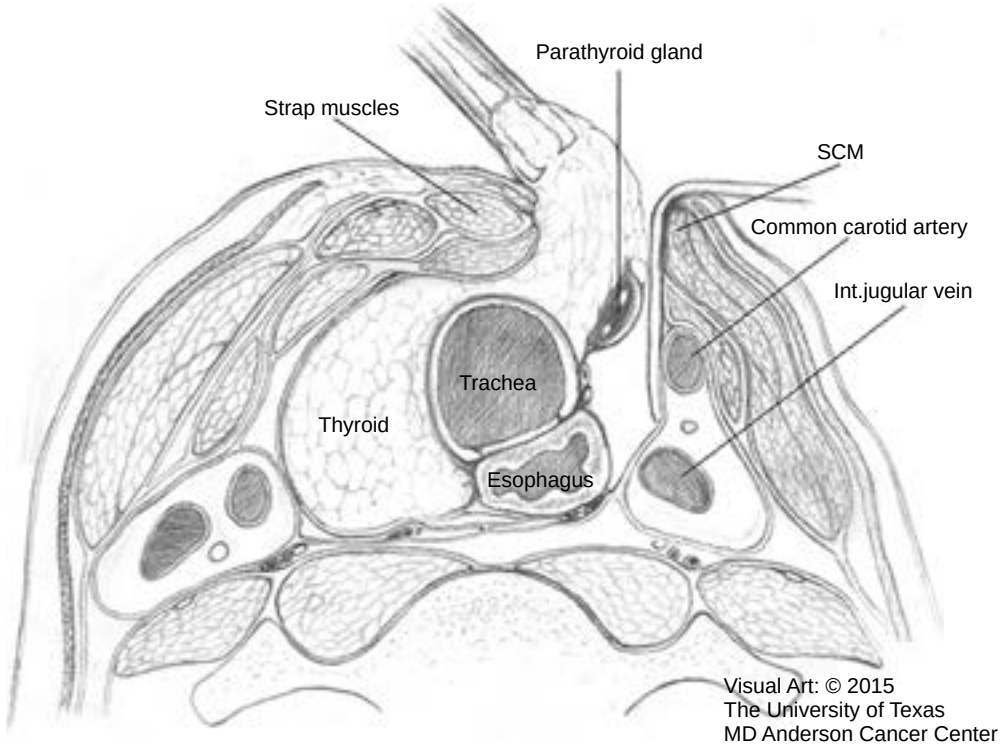

FIG. 5 Cross-sectional drawing of the cervical region undergoing a focused lateral approach. Dissection is performed lateral to the strap muscles for a minimally invasive parathyroidectomy. Retracting the thyroid lobe superiorly and medially allows the identification of a left type A gland attached to the undersurface of the left thyroid parenchyma. *Int. jugular vein*, internal jugular vein; *SCM*, sternocleidomastoid muscle.

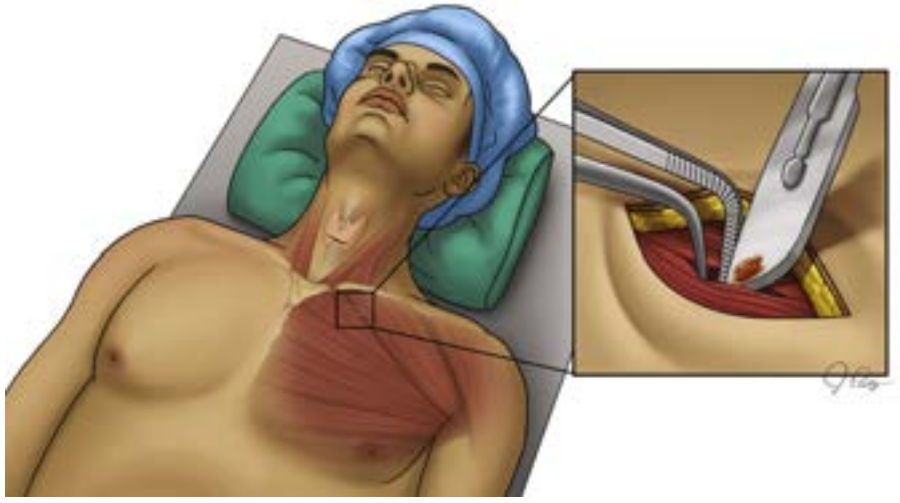

FIG. 6 Illustration of pectoralis major muscle autotransplantation. The transplanted gland is placed in a small pocket of the pectoralis major muscle through a mini-incision.

surgery. In addition to histologic confirmation, direct aspiration of the suspected gland may be useful for biochemical confirmation. PTH values greater than the upper limit of normal (1900 pg/mL with the Roche assay) confirm that the tissue is of parathyroid origin, although this does not confirm cellularity; hence aspiration of the gland for PTH measurement can be a useful tool to complement histologic evaluation.

3. **Intraoperative Ultrasonography**
Intraoperative ultrasonography can facilitate incision placement in patients with ectopic glands. After the patient is anesthetized and in position, an on-the-table ultrasonographic examination is performed to identify and confirm the location of the gland.

POSTOPERATIVE MANAGEMENT

The postoperative management for reoperative parathyroidectomy is similar to that of initial parathyroidectomy. In general, serum calcium and PTH levels are obtained on the evening of the procedure and the morning of the first postoperative day to detect hypocalcemia. A detectable PTH level ensures viability of residual parathyroid gland function. In our practice, prophylactic calcium supplementation is not routinely performed. Oral calcium and vitamin D supplementation is given in the presence of clinical symptoms of hypocalcemia, if the serum calcium levels falls below 7.5 mg/dL, or the PTH level falls below 5 pg/mL. If the serum calcium level is lower than 7.0 mg/dL, we administer intravenous calcium gluconate and bridge to oral supplementation of calcium and possible calcitriol until calcium levels have normalized. Interpretation of the biochemistry along with the clinical status of the patient should drive the decisions regarding hospital discharge. Before discharge, patients are thoroughly educated regarding signs and symptoms of hypocalcemia and are sent home with appropriate calcium supplementation, if indicated.

Patients who undergo pectoralis muscle autotransplantation, as discussed earlier, will undergo removal of the autograft in the event of a detectable and normal PTH on postoperative day one. Patients who undergo brachioradialis autotransplantation should be educated regarding future venous blood draws for assessment of PTH and should undergo bilateral venous blood draws to determine function of the autograft.

After discharge, the patient returns for laboratory analysis including serum calcium and PTH at 2 weeks postoperatively and again at 6 months postoperatively to ensure cure. If the indication for surgery was osteopenia or osteoporosis, a repeat bone mineral density study is obtained 18 months following successful cure. Given the reoperative nature, patients are thoroughly educated and screened for potential voice changes and referred for videostroboscopy if there is any concern for RLN palsy.

CONCLUSION

Reoperative parathyroidectomy is complex. Before considering reoperative surgery, the surgeon must determine the etiology of persistent or recurrent HPT and indications for reoperation, and then must weigh these against the risks of reoperation. The focused lateral approach offers an attractive operative strategy for missed single-gland disease to avoid a previous scarred cervical incision. Patients with missed multigland disease require safe subtotal parathyroidectomy with creation of a healthy viable remnant.

Surgical Management of Secondary and Tertiary Hyperparathyroidism

Zeyad T. Sahli, MD, and Martha A. Zeiger, MD

INTRODUCTION

Hyperparathyroidism (HPT) is defined as the hypersecretion of parathyroid hormone (PTH) from one or more parathyroid glands. This results in an imbalance in serum calcium levels that are maintained through a regulatory axis consisting of the parathyroid glands, PTH, membrane calcium receptors, kidneys, the gastrointestinal tract, and bone. **Secondary HPT** is defined as a compensatory increase in PTH secretion due to a nonparathyroid cause of calcium dysregulation and **hypocalcemia** (Box 1). This occurs most commonly or "secondary" to chronic kidney disease (CKD) with up to 90% of renal failure patients developing the disease by the time hemodialysis is required. Secondary HPT can also be caused by decreased calcium intake, decreased calcium absorption, renal calcium losses, or secondary to phosphate replacement therapy in bone metabolism disorders. Decreased calcium absorption can be due to vitamin D deficiency or gastrointestinal malabsorption due to chronic pancreatitis, small bowel disease, or malabsorption-dependent bariatric surgery. Other causes include long-term lithium therapy and bone metabolism disorders.

Tertiary HPT refers to the autonomous hypersecretion of PTH after successful correction of the primary reason for secondary HPT (e.g., CKD). Up to 30% of renal transplant recipients with secondary HPT are at risk of developing tertiary HPT. In contrast to secondary HPT, the patients are **hypercalcemic**.

PATHOPHYSIOLOGY

Secondary HPT develops after chronic parathyroid gland stimulation from hypocalcemia, hyperphosphatemia, and reduced renal production of 1,25-dehydroxy vitamin D. This constellation of factors results in PTH hypersecretion and parathyroid cell proliferation among all four glands. The pathophysiology of secondary HPT due to CKD is summarized in Figure 1. CKD patients have been shown to have an increase in fibroblast growth factor 23 (FGF23) due to hyperphosphatemia. FGF23, secreted by osteocytes, and alpha Klotho, its obligate coreceptor, induce phosphaturia and inhibit renal production of 1,25-dehydroxy vitamin D. Moreover, CKD patients also exhibit decreased expression of calcium-sensing receptor (CaSR) in parathyroid cells as well as bone resistance to PTH due to diminished expression of the PTH receptor in osteoblasts. In turn, these events lead to hypocalcemia and resulting stimulation of the parathyroid glands. When left untreated, changes such as decreased extracellular calcium-sensing and monoclonal expansion of parathyroid cells may cause further derangement in calcium metabolism, leading to tertiary HPT.

Classically, tertiary HPT develops among end-stage renal disease (ESRD) patients with chronic secondary HPT after renal transplantation. Within 1 year of successful renal transplantation, PTH hypersecretion, hypercalcemia, and hypophosphatemia will resolve in the majority of patients with secondary HPT. In tertiary HPT, the hypertrophied parathyroid glands will continue to autonomously hypersecrete PTH resulting in hypercalcemia, even after correction of the primary disorder.

BOX 1 Signs and Symptoms of Hyperparathyroidism

- Fatigue/mental status changes
- Renal calculi
- Proximal muscle pain
- Bone pain
  - Due to osteitis fibrosa cystica, mainly affecting weight-bearing joints including hips, knees, ankles, and lower back
- Joint pain
  - Joint inflammation due to periarticular calcium deposits
- Bone fracture
  - Atraumatic fractures or nonhealing of fractures
- Pruritus
- Calciphylaxis
  - Results in expanding, painful, cutaneous, purpuric lesions that cause tissue calcification and ischemic necrosis, which lead to dry gangrene if untreated

CLINICAL PRESENTATION

Physicians should maintain a high level of suspicion for the diagnosis of HPT when evaluating patients with renal failure (see Box 1). Patient symptoms include fatigue, changes in mental status, nephrolithiasis, proximal muscle pain, skeletal abnormalities, bone and joint pain, pathologic fractures, pruritis, and calciphylaxis. Skeletal abnormalities and bone pain are due to renal osteodystrophy, hyperphosphatemia, and hypercalcemia. More severe symptoms due to HPT occur at PTH levels greater than 1000 pg/mL. Calciphylaxis or calcific uremic arteriolopathy, wherein calcium accumulates in small vessels of fat and skin, can be found in patients with renal failure involving subcutaneous vascular calcification and cutaneous necrosis (Fig. 2). This sign is indicative of severe HPT and its often-fatal sequelae. Parathyroidectomy (PTX) should be offered as it can enhance wound healing.

DIAGNOSIS

The diagnosis of secondary and tertiary HPT is made biochemically (Table 1). Because the vast majority of CKD patients have some degree of HPT, there is no unique presentation for secondary HPT, and most diagnoses are made during routine laboratory testing to monitor CKD patients. Serum levels of PTH, calcium, phosphorus, and 25-hydroxyvitamin D should be measured. Patients with secondary HPT exhibit low to normal calcium levels and elevated PTH. Serum phosphorus level is dependent on the secondary HPT etiology. CKD patients will tend to have hyperphosphatemia, whereas patients with secondary HPT due to vitamin D deficiency will have hypophosphatemia. Levels of bone metabolic markers, including total alkaline phosphatase and osteocalcin, will be elevated. Unlike secondary HPT associated with hypocalcemia, in addition to hypercalcemia, patients with tertiary HPT also exhibit hypophosphatemia.

MEDICAL MANAGEMENT

Although no global consensus for treatment has been established, the Kidney Disease Improving Global Outcomes (KDIGO) Chronic Kidney Disease Mineral Bone Disease (CKD-MBD) guideline is considered the leading resource for the treatment of secondary and tertiary HPT in the United States. Medical management is the mainstay of mild secondary HPT, whereas tertiary HPT is treated surgically. Primarily, calcium and vitamin D or vitamin D analogues supplementation can be used to slow the progression of secondary HPT until the patient can undergo a renal transplant. Other treatment options include calcimimetics and phosphate binders. Currently, there are two FDA-approved calcimimetics: cinacalcet and etelcalcetide.

Approved by the FDA in March 2004, cinacalcet is an oral calcimimetic that functions by allosteric activation of the calcium-sensing surface receptor expressed by parathyroid gland chief

Calcium	Low to normal	Elevated
PTH	Elevated	Elevated
Serum Phosphorus	Elevated	Elevated
Vitamin D	Low	Low to normal

cells, resulting in reduced PTH production. The randomized trial Evaluation of Cinacalcet Hydrochloride Therapy to Lower Cardiovascular Events (EVOLVE) found that CKD patients treated with cinacalcet were less likely to develop severe progression of secondary HPT, although cinacalcet did not reduce the risk of all-cause and cardiovascular mortality. Cinacalcet treatment has also been reported to be associated with a significant reduction in the risk of needing PTX, fracture, and cardiovascular hospitalization compared with placebo. Moreover, its long-term effect on patients or allograft survival appears to be safe and effective for the treatment of post-transplant HPT, though no randomized clinical trials examining this have been performed.

In 2017, the FDA approved etelcalcetide, an intravenous calcimimetic, for the management of secondary HPT in hemodialysis patients. Etelcalcetide is administered intravenously three times per week at the end of each dialysis session. A double-blind, randomized clinical phase III trial by Block et al. found that etelcalcetide was superior to cinacalcet in achieving a more than 30% reduction in mean predialysis PTH concentrations. Further studies are needed to evaluate the effect of etelcalcetide on the progression of HPT and need for surgery.

PARATHYROIDECTOMY

Despite the initial medical management of secondary HPT, PTX is required in approximately 20% of patients after 3 to 10 years of dialysis and up to 40% after 20 years. The goals of parathyroid surgery include the immediate reduction in PTH levels, long-term symptomatic relief, and end organ improvement. Due to the lack of randomized clinical trial data, indications for and timing of PTX vary greatly among experts.

ANATOMY

A thorough understanding of the anatomy is essential to safely perform the surgery (Fig. 3). The four parathyroid glands descend from the third and fourth pharyngeal pouches. The two inferior parathyroid glands and thymus originate from the third pharyngeal pouch, while the two superior parathyroid glands originate from the fourth pharyngeal pouch. Due to the longer descent of the inferior parathyroid glands, their anatomical location is more variable compared with the superior parathyroid glands. It should be noted that the inferior parathyroid glands lie ventral to the recurrent laryngeal nerve (RLN), while the superior glands lie dorsal to the RLN (Fig. 4). The four glands are vascularized by the left and right inferior thyroid arteries. There are usually four parathyroid glands. However, it has been reported that 1% to 3% of patients have only three identifiable glands, and 2% to 13% of individuals have supernumerary parathyroid glands. Parathyroid glands are yellow-brown, flat, and oval-shaped tissue that normally weigh approximately 30 to 35 mg each.

INDICATIONS FOR SURGERY

Secondary HPT

Recommendations regarding the guidelines for PTX in secondary HPT patients differ geographically and lack a clear consensus. As a general rule, all symptomatic HPT patients or those who failed medical management should be considered surgical candidates (Box 2). The National Kidney Foundation recommends PTX in patients with a PTH greater than 800 pg/mL associated with hypercalcemia and/or hyperphosphatemia refractory to medical therapy as an indication for surgery. However, the Kidney Disease: Improving Global Outcomes Group recommends a PTH target threshold for treatment nine times above the upper limit of normal for the PTH assay (585 pg/mL).

Among asymptomatic patients, consensus among experts regarding indications for PTX is also inconsistent. PTX patient selection must be individualized based on age, comorbidities, and risk-benefit evaluation. Younger patients (<65 years) with little comorbidity are more likely to tolerate surgery and benefit over the long term. The benefits of PTX have been documented in observational studies and

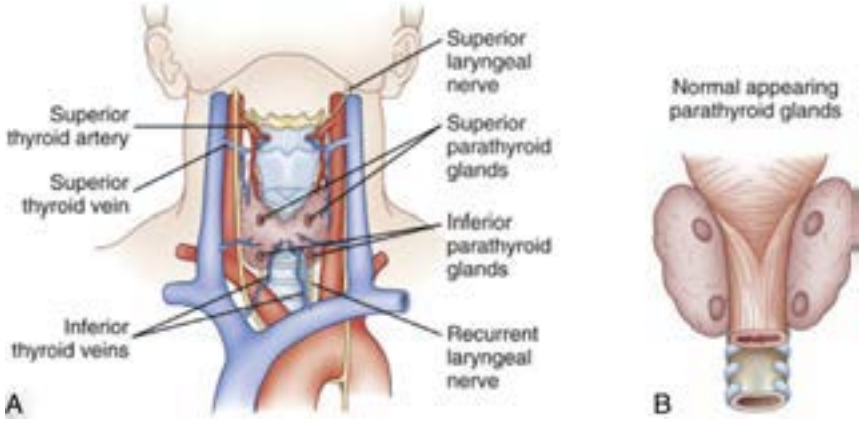

FIG. 3 Anatomy of parathyroid glands. *(From Miller FR, Netterville JL. Surgical management of thyroid and parathyroid disorders.* Med Clin North Am. *1999;83[1]:247, Fig. 1.)*

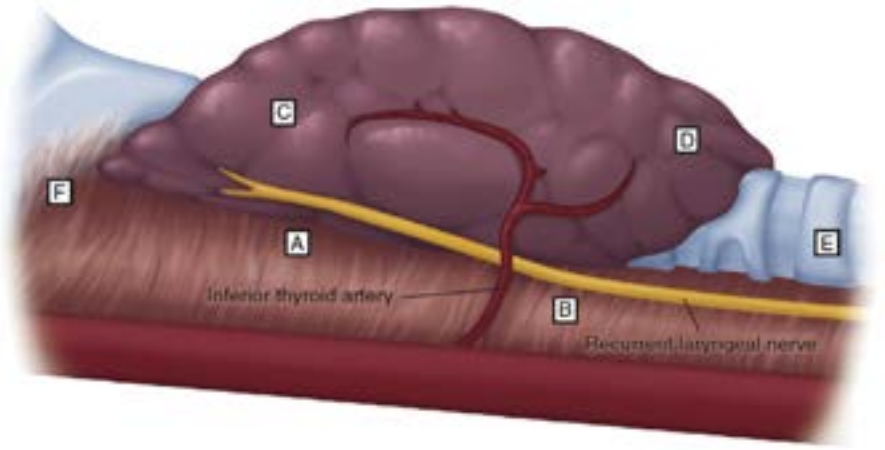

FIG. 4 Location of parathyroid glands. *A,* The superior glands are most frequently located superior to crossing point of the inferior thyroid artery and recurrent laryngeal nerve (RLN) and dorsal to the RLN. *B,* The inferior parathyroid gland most frequently is located inferior to the artery-nerve crossing point and lies ventral relative to the RLN. *(From Tominaga, Y.* Surgery of the Thyroid and Parathyroid Glands, *3rd ed, Philadephia: Elsevier; 2021.)*

include a reduction of 10% to 37% in mortality, 33% to 41% in cardiovascular risk, and 32% in fracture risk, as well as improvements in peripheral arterial disease, quality of life, erythropoietin-resistant anemia, nutritional status, and humoral and cellular immunity.

Tertiary HPT

Despite the potentially high incidence of tertiary HPT, PTX is performed in less than 10% of renal transplant recipients who harbor this disorder after 1 year of surgery but should be considered the standard of care and recommended to all. Indications for surgical management among patients with tertiary HPT include those who are symptomatic, have persistent or severe hypercalcemia, or osteoporosis (see Box 2).

PREOPERATIVE MANAGEMENT

Patient risk assessment and counseling is recommended before operative management for the selection of appropriate surgical candidates. Risk assessment is especially important among ESRD patients who may have comorbidities, such as coronary artery disease, heart failure, myocardial infarction, hypertension, stroke, anemia, uremic coagulopathy, pulmonary disease, and general debility, which may prevent safe surgery. Moreover, patients with calciphylaxis may develop unique complications including peripheral vascular disease and wound sepsis, potentially requiring revascularization procedures or wound debridement, respectively. When scheduling surgery, the surgeon should coordinate with the patient's nephrologist or dialysis center to arrange for dialysis one day before surgery and to avoid unnecessary delay on the day of surgery caused by conditions such as hyperkalemia. Although renal transplant patients are commonly healthier than patients with ESRD, their immune system is medically suppressed, which may increase the risk of postoperative complications.

Despite the involvement of all four parathyroid glands in secondary and tertiary HPT, the authors still recommend preoperative localization studies to localize ectopic glands. The importance of preoperative imaging among secondary/tertiary HPT patients is highlighted because 32% of recurrent or persistent cases are due to supernumerary glands. We recommend the use of ^{99}Tc-Sestamibi scans or 4D scans. Similar to any patient undergoing parathyroid surgery, a thyroid ultrasound should also be performed to exclude any concerning thyroid nodules. There is, however, a lack of consensus among experts for the use of preoperative localization imaging before initial surgery in patients with secondary or tertiary HPT. Opponents of preoperative imaging have argued that preoperative imaging is not sensitive in localizing ectopic glands and that imaging

BOX 2 Adult Parathyroidectomy Indications for Secondary versus Tertiary HPT

Secondary HPT Indications

- Calciphylaxis
- Patient preference
- Medical observation not possible
- Symptoms due to hyperparathyroidism
- Failure of maximal medical management with:
  - Hypercalcemia
  - Hypercalcuria
  - PTH >800 pg/mL
  - Hyperphosphatemia (with calcium × phosphorus >70)

Tertiary HPT

- Severe hypercalcemia (serum calcium >12.5 mg/dL)
- Persistent hypercalcemia
  - Serum calcium >10.2 mg/dL more than 3 months after surgery
- Osteoporosis
- Symptomatic hyperparathyroidism

will not change operative management since a bilateral exploration is warranted. On the other hand, advocates of preoperative imaging argue that ultrasound examination may identify concurrent abnormalities in the thyroid gland that may require further evaluation or simultaneous surgical management. Furthermore, preoperative imaging may localize an ectopic gland within the chest that may require a different surgical approach.

Before reoperation, vocal cord visualization should be performed by laryngoscopy among patients with a history of thyroidectomy, PTX, carotid endarterectomy, or cervical spine surgery to exclude prior RLN injury. In secondary or tertiary HPT patients undergoing reexploration, preoperative imaging is strongly recommended among experts.

EXTENT OF SURGERY

Surgical options for secondary and tertiary HPT patients include sub- or near-total PTX and total PTX with or without heterotopic autotransplantation. Subtotal PTX is the resection of three (or more, if supernumerary glands are present) glands and subtotal resection of a fourth gland, with preservation of a viable, histologically confirmed remnant, approximately the size of a normal gland. A total PTX with a heterotopic autotransplantation removes all parathyroid glands, including supernumerary if present, that can be identified and autotransplants a small portion of a gland to a new, nonanatomic site such as the neck, chest, or forearm.

Published literature regarding the recommended extent of surgery in both secondary and tertiary HPT is inconsistent. For this reason, the decision regarding extent of surgery is largely dependent on surgeon preference in addition to several other factors, including whether the surgery is primary or reoperative and whether the patient has an existing or planned renal transplant. The extent of surgery should be weighed according to the advantages and disadvantages of each procedure. A 2019 meta-analysis of 3656 patients comparing subtotal PTX with total PTX with autotransplantation found no significant differences between symptomatic improvement, hypocalcemia rate, persistence rate, time to recurrence, recurrence rate, and reoperation rate. Significantly longer operative time and patient length of stay (LOS) were observed in patients who underwent total PTX with autotransplantation compared with those who underwent subtotal PTX. However, patients with a relative contraindication for future neck surgery due to prior history of repeated neck surgery, known RLN injury, or significant medical comorbidities should undergo a total PTX with autotransplantation to facilitate access to the gland in case of recurrent HPT.

Total PTX without autotransplantation has been reported to prevent recurrence more effectively than with autotransplantation. However, it also has the highest risk of hypoparathyroidism postoperatively among the three procedures. Patients anticipating a kidney transplant should avoid undergoing total PTX without autotransplantation.

Targeted PTX is not commonly performed among patients with secondary or tertiary HPT but can be considered in patients with recurrent HPT or in post–renal-transplant patients with single or double adenomas, reported in up to 29% among post–renal-transplant patients. However, this may be associated with an increased risk of recurrence. Currently, debate exists regarding the need for a prophylactic thymectomy. Thymectomy should be performed, however, during the search for a missing inferior parathyroid gland or supernumerary glands.

SURGICAL TECHNIQUE

The common steps of these procedures are detailed in Box 3 and Figure 2. General anesthesia is used for most patients undergoing PTX with bilateral neck exploration. However, local or regional anesthesia has also been described in patients deemed too high risk for general anesthesia. The RLN should be identified and preserved during the entire course of the procedure. After identification of the parathyroid glands, care should be taken to avoid biopsy, capsular rupture, or fragmentation of the glands to prevent parathyromatosis.

If the surgeon fails to identify four parathyroid glands on bilateral exploration, then a search for the missing gland is warranted. Ectopic parathyroid glands are shown in Figure 3 and can be found in the tracheoesophageal groove, retroesophageal, paratracheal, carotid sheath, intrathyroidal, mediastinal, and thymus. All suspected parathyroid glands resected should be confirmed on frozen section.

Intraoperative PTH Monitoring

The PTH half-life in patients with normal renal function is 2.2 minutes, whereas that of ESRD patients is 6.6 minutes. Due to the partial

BOX 3 Parathyroidectomy Steps

1. The patient is placed in a supine position with the neck hyperextended by placing a head ring under the patient's head. Potential sites of auto transplantation should be exposed and prepped.
2. A standard Kocher incision measuring 3 to 5 cm should be made through skin and platysma.
3. Superior and inferior flaps should be created in usual fashion to thyroid cartilage superiorly, sternal notch inferiorly.
4. Strap muscles are divided longitudinally in the midline and retracted.
5. All four parathyroid glands should be exposed after a bilateral neck exploration.
6. If four parathyroid glands cannot be identified, then a search for the ectopic gland is warranted in the tracheoesophageal groove, retroesophageal, undescended paratracheal, carotid sheath, intrathyroidal, mediastinal, or thymus.
7. If indicated, create an autograft to implant in neck, chest, or forearm.

renal metabolism of PTH, an intraoperative PTH monitoring protocol, such as the Miami criteria in cases of primary HPT, to confirm treatment has not been established in patients with secondary or tertiary HPT. Despite this, intraoperative PTH level measurements are commonly used. Multiple studies in the literature have used various time periods, PTH thresholds, or PTH level decline from baseline to predict cure in these patients. A lack of consensus remains regarding how to monitor PTH intraoperatively, but its use has been shown to be beneficial. These include a recommended range of decline of 50% to 90% at anywhere between 10 to 30 minutes after PTX as a reliable predictor of postoperative cure.

Creating a Parathyroid Remnant

During subtotal PTX, the parathyroid remnant should be created before resection of other glands to monitor its viability throughout the operation. The parathyroid remnant should be approximately 50 to 100 mg and preferably an inferior parathyroid gland remnant. This would leave the remnant in a relatively easily accessible position and away from the RLN should the patient require reoperation. Marking the remnant with a titanium clip or nonabsorbable suture facilitates its localization in the event of a reoperation.

Creating an Autograft

The process of creating an autograft is described in Box 4. A recent technique includes injecting a suspension of parathyroid tissue fragments into a muscle with a syringe. There is no consensus regarding the optimal site for grafting. Potential autotransplantation sites include the neck, chest, or forearm subcutaneously or intramuscularly. Implantation and resection of subcutaneous parathyroid autografts is simpler to perform than intramuscular procedures. Regardless of implantation sites, parathyroid fragments often infiltrate surrounding tissues, which may make resection of all foci challenging. In cases of recurrent HPT among patients with a history of total PTX with autotransplantation, the surgeon must have a high level of suspicion about the presence of an additional cervical gland, complicating the picture of recurrent HPT.

We recommend implanting the autograft in the nondominant forearm brachioradialis muscle or subcutaneously due to its relatively easy access under local anesthesia for reexploration. We also recommend that the implanted arm not have an arteriovenous fistula. Furthermore, determination of autograft function can be performed by differential PTH measurements. A twofold increase in PTH from a sample drawn above the autograft compared with measurement in the contralateral arm denotes a hyperfunctioning autograft. Patients with a forearm autograft may require several reoperations to completely remove autografts from the forearm because of regrowth causing recurrent HPT. For this reason, during reexploration procedures, it may be appropriate to excise all visible autograft tissue.

The sternocleidomastoid muscle is another convenient location for autotransplantation as it is within the operative field. A third possible location for autotransplantation is in the middle to lower third of the presternal area subcutaneously. The autograft can be easily located and excised under local anesthesia in the event of a recurrence. Autografts are rarely placed intramuscularly in the chest.

BOX 4 Creation of a Parathyroid Autograft

1. Resected parathyroid tissue is preserved in cold saline until transplantation.
2. Use frozen section to confirm parathyroid tissue.
3. Using a scalpel, divide a portion of the excised parathyroid gland into a total of 10 to 20 pieces measuring approximately 1 to 2 mm. The aim is to implant approximately 50 to 100 mg of parathyroid tissue.
4. Insert one or separate pockets subcutaneously or intramuscularly in the neck, chest, or forearm.
5. Mark the autograft site with nonabsorbable silk suture and a hemoclip to facilitate localizing site in case of recurrent HPT.

Cryopreservation

Cryopreservation of parathyroid tissue is available in less than 30% of healthcare centers. When possible, cryopreservation of parathyroid tissue in patients undergoing subtotal or total PTX is recommended in patients at higher risk of hypo-PTH. However, the low utilization combined with the high associated costs of storing cryopreserved tissue for later use has raised concerns regarding the cost effectiveness of the procedure. The cryopreserved tissue can be used for delayed autotransplantation in case of parathyroid remnant ischemic necrosis or autograft failure. Variable success rates have been reported ranging from 17% to 83%. The duration of cryopreservation has been reported to be a significant indicator of graft failure, with preservation beyond 22 months failing to yield a functional autograft.

POSTOPERATIVE MANAGEMENT AND COMPLICATIONS

ESRD patients have a 17% unplanned admission rate. Half of those readmitted are due to postoperative hypocalcemia and hungry bone syndrome—the hyperdynamic reabsorption of calcium into bones. Moreover, PTX patients experience a 39% higher hospitalization rate in the first year after surgery compared with the prior year. In addition, 5% to 20% of patients experience persistent disease, which is defined as hypercalcemia or PTH level above the recommended target range according to CKD stage after PTX. ESRD patients are at high risk for transient postoperative hypocalcemia due to delayed autograft or remnant function. For this reason, protocols must be in place to prevent postoperative hypocalcemia including administration of calcitriol as well as oral calcium, or intravenous calcium gluconate during the immediate postoperative period, and oral medication when discharged home.

Patients typically do not require pain medications stronger than acetaminophen. Patients may resume dialysis after surgery in the hospital; however, the minimum amount of heparin should be used during the first few dialysis sessions to minimize the risk of neck hematoma.

After hospital discharge, patients should be followed up with a baseline laboratory profile of serum and ionized calcium, magnesium, and serum PTH at 1 to 4 weeks after surgery and vitamin D levels at 3 and 6 months. Long-term follow-up, with serum calcium and serum PTH measurements at least annually, is important to monitor for potential persistent or recurrent HPT.

SUMMARY

Surgical management of secondary and tertiary HPT is complex due to the lack of specific guideline consensus. From 2015 to 2018, the incidence and prevalence of ESRD increased 3.19% and 0.93% annually, respectively. This is due to a decline in mortality rate among these patients according to the United States Renal Data System. During this time period, patients with a severe HPT (PTH >600 pg/mL) increased from 21.8% to 28.0%. For these reasons, it is important to understand how to effectively manage these patients. A well-developed prospective multiinstitutional randomized controlled clinical trial comparing the three procedures (subtotal *versus* total with autotransplantation *versus* total without autotransplantation) is needed.

Subtotal PTX and total PTX with autotransplantation are acceptable surgical approaches. Total PTX without autotransplantation should be used only in select patients due to its high risk for permanent hypoparathyroidism. However, all three procedures are effective at treating HPT and its associated metabolic disturbances. The creation of multidisciplinary consensus guidelines is needed regarding the ideal surgical management of these patients.

Metabolic Changes Following Bariatric Surgery

Patrick Crosby, MD, Thomas H. Magnuson, MD, and Michael A. Schweitzer, MD

METABOLIC CONSEQUENCES OF OBESITY

Morbid obesity is a syndrome resulting from an excess accumulation of body fat that has been shown in multiple studies to be severely detrimental to overall health. There are numerous ways to define obesity, each with benefits and limitations. Body mass index (BMI), which is calculated by dividing a person's weight in kilograms by the square of the height in meters (kg/m^2), is the most commonly used measurement of obesity, especially in the world of medicine and biostatistics. It is easy to calculate and a reproducible and accurate population-level indicator. A BMI of more than 30 kg/m^2 indicates obesity. The main limitation of BMI, however, is that it does not differentiate between fat and lean muscle mass. A world-class athlete, who would otherwise be considered fit, could be classified as overweight or obese. An alternative method to avoid this is defining obesity according to the percentage of body fat: more than 32% in women and 25% in men. The problem is that body fat calculations require specialized measurements or devices such as calipers or body composition, making them less reproducible, especially in unskilled hands. More importantly, neither of these two methods addresses the regional distribution of fat or weight, which is critical because the metabolic consequences of obesity are determined by both the amount and distribution of body fat. Central or visceral obesity (also referred to as android or abdominal obesity) is more common in men and is associated with increased risk of insulin resistance, hyperlipidemia, hypertension, cardiovascular disease (CVD), and stroke. Visceral fat is a highly active endocrine organ, which may lead to a chronic inflammatory state caused in part by the release of free fatty acids and cytokines from this adipose tissue. The gynecoid pattern of obesity, on the other hand, is characterized by an excess accumulation of subcutaneous fat in the hips and thighs, typically seen in women. Gynecoid obesity is less frequently associated with adverse metabolic effects. The importance of central obesity is again highlighted in populations who, despite relatively low BMI, have high levels of visceral obesity (e.g., Asians) and are prone to adverse effects of obesity at a lower BMI. A simple measurement of waist circumference or waist-to-hip ratio can address visceral obesity but does not accurately address height and fat content. A waist circumference of more than 35 in. in women or 40 in. in men indicates higher risk of metabolic syndrome and obesity-related comorbidities, and a waist–hip ratio above 0.85 for females or 0.90 for males can be used to classify obesity.

The current global obesity epidemic is a well-documented and worsening public health crisis. According to the CDC, US obesity prevalence was 42.4% in 2017 to 2018. From 1999 to 2000 through 2017 to 2018, US obesity prevalence increased from 30.5% to 42.4%. During the same time, the prevalence of severe obesity increased from 4.7% to 9.2%. Similar rates are described in several western countries The World Health Organization indicates that, in 2016, more than 1.9 billion adults were overweight (39% of the world population). Of these, more than 650 million (13%) were obese. Worldwide obesity has nearly tripled between 1975 and 2016, and now most of the world's population live in countries where overweight and obesity kills more people than underweight. The obesity epidemic also extends to children as 39 million children under the age of 5 were overweight or obese in 2020. With all the health consequences that come with obesity, it has quickly become a significant public health crisis worldwide.

Adipose tissue was initially thought to be a quiescent storage medium for excess calories. However, recent studies have shown it to be metabolically and hormonally active. In severe obesity, excess lipid accumulates in adipocytes, hepatocytes, and muscle cells. Excess accumulation of nutrients, especially fat, within these cells leads to increased secretion of adipocyte-derived peptides (e.g., leptin, adiponectin, resistin) and cytokines (e.g., tumor necrosis factor-a [TNF-a], interleukin-6 [IL-6]), collectively referred to as adipokines. The paracrine and endocrine actions of these adipokines contribute to a state of chronic low-grade inflammation, which in turn interferes with many physiologic cellular processes (e.g., insulin signaling) and leads to the metabolic derangements seen in obesity (e.g., insulin resistance and type 2 diabetes mellitus [T2D]). Our center has conducted the first studies showing the relevance of C1q/TNF-Related Protein (CTRP) family, a family of novel adipokines, in humans as it relates to obesity, metabolic syndrome, insulin resistance, and T2D.

The obesity-induced inflammatory state adversely affects organ systems in the body and contributes to a shortened life expectancy. Each 5-unit increase in BMI is associated with a 30% increase in all-cause mortality, with BMIs of more than 40 associated with a reduced life expectancy of 8 to 10 years, similar to that of regular cigarette smoking. Obesity is characterized by poor quality of life, with increased risk of many life-threatening conditions including cancers, heart disease, T2D, hypertension, stroke, gastroesophageal reflux disease (GERD), hyperlipidemia, and sleep apnea. The prevalence of these comorbidities often increases with the severity of obesity (Table 1). This is most evident with T2D. At age 18 years, women with a BMI of 30 to 35 have a 54.6% lifetime risk of development of diabetes, which is increased to 74.4% for those with BMI of more than 35.

Although modest weight loss (5%–10% excess weight) can lead to reductions in the risk of these chronic diseases, nonsurgical weight loss is often unsuccessful or short-lived in 90% to 95% of patients. As a result, bariatric surgery (weight loss surgery) has become the standard of care in the treatment of medically complicated or severe obesity.

METABOLIC IMPROVEMENTS AFTER WEIGHT LOSS SURGERY

Weight Loss

The term excess body weight loss (EWL), calculated by subtracting ideal body weight from current weight, is commonly used to describe weight loss. Not surprisingly, the degree of EWL varies between procedures. At 2 years postprocedure, mean EWL is 70% to 80% for biliopancreatic diversion (BPD) with or without a duodenal switch, 60% to 70% for Roux-en-Y gastric bypass (RYGB), 50% to 60% for sleeve gastrectomy (SG), and 40% to 45% for laparoscopic adjustable gastric banding (LAGB). In general, procedures with higher EWL are also associated with increased short-term and long-term complications. The balance between the desired weight loss and surgical risk influences both the patient and surgeon when deciding upon the optimal procedure.

The mechanisms underlying postprocedure weight loss are multifactorial and vary by procedure. There is no single mechanism that explains the change but instead a combination of them. The proposed mechanisms have been summarized in Table 2. Some of them are still controversial and being studied. Of critical importance are long-term changes in hunger signals and food preference after surgery. In contrast, nonsurgical weight loss leads to increased hunger and reduced energy expenditure, which presumably contributes to the ultimate failure of dieting in achieving long-term weight reduction. Weight loss surgery prevents such physiologic responses and maintains hunger control despite limited calorie intake.

Long-term follow-up studies such as the Swedish Obesity Study show significant long-term weight loss in surgical patients compared with control subjects, with up to 20 years of follow-up. The durability of postsurgical weight loss is a concern for patients and clinicians. The definition of successful weight loss after bariatric surgery varies depending on the procedure; for RYGB, success often is described as losing and maintaining 50% or more EWL. Most patients regain some weight after reaching their nadir weight, with pathologic weight regain (>20% of the maximal weight loss) reported in 15% to 20% of patients. This observation highlights the fact that bariatric surgery is not a replacement for long-term lifestyle changes,

TABLE 1 Risks of Cardiovascular and Metabolic Disorders Associated with Obesity

Life expectancy	30% increase in mortality rate for each 5-unit increase in BMI. At BMI >40, life expectancy is reduced by 8 years.
Cardiovascular disease	There is a 9% increase in cardiovascular mortality with each unit increase in BMI. A BMI >25 increases the risk of CVD by 32%. A BMI >30 increases the risk of CVD by 81%.
Hypertension	Fivefold risk of hypertension in obesity. 85% of patients with hypertension have a BMI >25.
Stroke	A BMI >25 increases the risk of stroke by 22%. A BMI >30 increases the risk of stroke by 64%.
Type 2 diabetes	Men with BMIs of 30 or higher have a sevenfold higher risk of developing type 2 diabetes. Women with BMIs of 30 or higher have a twelvefold higher risk. At BMI >35, patients have a 74% lifetime risk of type 2 diabetes.
Cancer	There is a confirmed direct association between obesity and cancers of the breast, colon and rectum, endometrium, esophagus, kidney, ovary, and pancreas.

TABLE 2 Proposed Mechanisms for Weight Loss After Bariatric Procedures

Caloric restriction	Immediate effect in RYGB and SG due to anatomical changes. In the perioperative period of bariatric surgeries, the caloric intake is dramatically reduced to 200–300 kcal/day.
Malabsorption	Although a degree of this occurs after BPD, little malabsorption is seen after LAGB, SG, or RYGB as measured with stool calorimetry and nitrogen balance.
Decreased hunger signals	This is true for all bariatric procedures secondary to neuroendocrine changes. There is an altered hormonal expression (leptin, ghrelin, GLP-1, PYY, etc.) along the gut-brain axis after surgery that decreases hunger signals.
Vagus nerve stimulation	Vagal nerve endings sense the increased gastric distention and nutrients in the Roux limb leading to activation of anorexigenic mechanisms.
Increased energy expenditure	There is controversial evidence on this matter, and no definite conclusions on the role of energy expenditure can be drawn at this time.
Changes in food preference	Several studies have shown the predilection for lower-fat foods after RYGB. Options to explain such behaviors include postoperative enhanced taste acuity and altered craves for food.
Changes in gut microbiota	Animal studies show a potential role for the gut microbiome in obesity and diabetes. Definitive human data are currently lacking, but this is an area of significant scientific interest.

which are needed to help maintain weight loss. A commitment to changes in diet and exercise are critical for long-term success. The importance of such lifestyle changes and the need for regular (at least annual) postoperative follow-up with the bariatric team should be emphasized with patients before surgery.

Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD) is a spectrum of clinical disease that ranges from simple accumulation of liver fat (steatosis) with resultant inflammation to nonalcoholic steatohepatitis (NASH), eventually leading to fibrosis and cirrhosis. Hepatic steatosis and NASH, markers of central adiposity, are thought to be important in the pathogenesis of obesity-related metabolic disorders, often referred to as the metabolic syndrome (visceral adiposity, insulin resistance, hyperinsulinemia, hypertension, and hyperlipidemia). NASH is now a leading cause of cirrhosis in the United States and thus one of the main indications for liver transplantation. In patients undergoing bariatric surgery, the prevalence of simple steatosis may be greater than 95%, NASH is often reported from 20% to 30% (prospective data from our center shows a prevalence of NASH of 54.5%), and fibrosis between 10% and 14%. Therefore, the improvement and sometimes resolution of NAFLD is a significant endpoint for bariatric surgery.

Bariatric surgery leads to a near-universal improvement in the severity of hepatic steatosis with most studies reporting more than 75% of patients with no evidence of steatosis after weight loss. Yung Lee et al performed a systematic review and meta-analysis to determine the overall effects of bariatric surgery on histologic features of NAFLD (steatosis, inflammation, ballooning degeneration, and fibrosis). They analyzed data from 32 cohort studies (15 retrospective, 17 prospective cohort studies, no randomized controlled studies) including 3,093 biopsy specimens. Bariatric surgery resulted in biopsy-confirmed resolution of steatosis in 66% of patients, inflammation in 50%, ballooning degeneration in 76%, and fibrosis in 40%. Other studies show that overall RYGB has greater improvement in liver disease compared with primarily restrictive procedures such as SG.

Lipid Profiles

Dyslipidemia is seen in up to 50% of patients who undergo bariatric surgery. The STAMPEDE trial 5-year outcome data, comparing intensive medical therapy to RYGB and SG, showed that the decrease from baseline in triglyceride levels (−39.8 mg/dL for RYGB and −29.4 mg/dL for SG; $P = 0.03/0.04$) and the increase from baseline in high-density lipoprotein (HDL) cholesterol levels (+31.9 mg/dL for RYGB and +29.6 mg/dL for SG; $P = 0.012/0.016$) were significantly greater at 5 years after RYGB and SG than after intensive medical therapy. By contrast, no significant change in low-density lipoprotein levels was observed among the three study groups. Overall, RYGB has a greater effect than primarily restrictive procedures, and significant changes in lipid profiles can be seen as early as 1-month postoperation.

Hypertension

Hypertension (HTN) is common in obese individuals and is increasingly prevalent in patients with increasing BMI. In the normal weight population (BMI <25), HTN is present in 15% to 20% of the population, rising to 30% to 40% in the obese population (BMI >30). When compared with normal-weight controls, the odds ratio for HTN is 1.7 for BMI 25 to 29.9 kg/m^2, 2.6 for BMI 30 to 34.9 kg/m^2, 3.7 for BMI 35 to 39.9 kg/m^2, and 4.8 for BMI 40 kg/m^2 or more. Furthermore, a 10 kg (22 lb) higher body weight is associated with 3.0 mm Hg higher systolic and 2.3 mm Hg higher diastolic blood pressure.

The mechanism that links obesity with HTN is not fully understood. It is thought to involve a combination of enhanced renal reabsorption of sodium (possibly resulting from insulin resistance), expansion of intravascular volume, activation of the renin-angiotensin-aldosterone system, activation of the sympathetic nervous system, and release of angiotensinogen from adipose tissue. The chronically increased intraabdominal pressure seen with central obesity has been shown to significantly upregulate the hormonal output of the renin-angiotensin-aldosterone system and may play an important role in obesity-induced hypertension. Weight loss has been shown to be associated with a reduction in vascular resistance, total blood volume, and cardiac output, an improvement in insulin resistance, a reduction in sympathetic nervous system activity, and suppression of the activity of the renin-angiotensin-aldosterone system.

HTN is seen in up to 50% of patients who undergo bariatric surgery. Of these, 50% to 60% have remission, and 60% to 70% show improvement after bariatric surgery. One study of patients undergoing RYGB versus intensive medical therapy showed that the rate of hypertension remission was 49% for the surgical group versus 23% for the medical therapy group. BPD has also been shown to resolve hypertension in 60% to 80% of patients.

Cardiovascular Risk and Mortality

CVD remains the leading cause of mortality in the United States. The Framingham Heart Study (FHS) is a long-running prospective cohort study, initiated in 1948, that has contributed to our understanding of obesity, its associated diseases, and to how these conditions relate to overall and cardiovascular-related mortality. These long-term data show a relative risk for CVD of 1.38 in obesity compared with normal weight. The FHS was also used to create the Framingham Risk Score (FRS), which combines several parameters and allows one to calculate an individual's risk of having a cardiovascular event. Bariatric surgery has been shown to reduce the FRS and the 10-year risk of a cardiac event by 40%. Serum and laboratory risk predictors, such as C-reactive protein (CRP), have also been shown to decline after surgery by about 60%.

At 10 years, the Swedish Obesity Study showed a 23.7% unadjusted (30.7% adjusted) overall reduction in overall mortality in well-matched patients who underwent weight-loss surgery when compared with those who did not. Another propensity score-matched cohort study from Canada, including 2638 patients with previous ischemic heart disease or heart failure who received bariatric surgery, showed a significant difference in the incidence of major cardiovascular events when compared with the control population (11.5% vs. 19.6%—adjusted hazard ratio 0.58 [95% CI, 0.48–0.71]; P <0.001).

Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) is a common endocrine disorder of unknown etiology characterized by menstrual abnormalities with hyperandrogenism. It is a common cause of infertility in women, especially in severe obesity. Up to 50% of those with PCOS are overweight or obese, and the phenotypic severity of PCOS is reported to correlate with the severity of insulin resistance and to worsen with increased weight. A meta-analysis of 13 studies involving 2130 female patients who underwent bariatric surgery gathered evidence of the effects of bariatric surgery on PCOS. Out of all the patients, 45.6% had PCOS before their operation. At 12-month follow-up after surgery, only 6.8% of the patient still had PCOS. A total of 56.2% of the patients had irregular menstrual cycles; 12 months after their surgical procedure, only 7.7% still had this irregularity. Before surgery, 67% of the patients had hirsutism. At 12-month follow-up, the incidence of hirsutism had decreased to 38.6% and to 32% at the study end. Furthermore, the incidence of preoperative infertility was 18.2%, which significantly decreased to 4.3% at the study end.

Fertility

The mechanism by which obesity leads to decreased fertility in women is multifactorial and complex. Excess adipose tissue leads to increased aromatization of androgens to estrogen, as well as an overproduction of leptin. Furthermore, insulin resistance and

hyperinsulinemia, resulting from obesity, lead to hyperandrogenemia, which in part leads to a decrease in sex hormone-binding globulin (SHBG), growth hormone (GH), and insulin-like growth factor binding proteins (IGFBP). All these changes affect the neuroregulation of the hypothalamic-pituitary-gonadal axis leading to impaired ovulatory function and thus reproductive health. When it comes to men, obesity leads to decreased levels of testosterone. This together with the decreased levels of SHBG and increased levels of estrogen (also seen in women) leads to reduced sperm counts and subfertility. Other hormones involved in the regulation of Sertoli cell function and spermatogenesis, such as FSH/LH ratios and inhibin B, have also all been observed to be decreased in males with increased BMI.

One study in Canada included 783 women after bariatric surgery, 251 of which had postoperative pregnancies. Of patients who were unable to become pregnant preoperatively, 47.0% were successful postoperatively. Ninety out of 109 women (82.6%) reported an appropriate weight gain (9.1 ± 5.9 kg) during postoperative pregnancies. The incidence of fetal macrosomia decreased from 34.8% to 7.7%, with a concomitant increase in normal-weight babies from 62.1% to 82.7%.

Several studies have also examined the effects of bariatric surgery on pregnancy complications compared with matched controlled subjects. Collectively, they suggest that the risk of gestational diabetes and large-for-gestational-age infants during pregnancy are decreased after bariatric surgery. Although preterm birth, stillbirth, and congenital malformations were not impacted, the risk of small-for-gestational-age babies appears to be increased after bariatric surgery. Other recent studies suggest that surgical weight loss before pregnancy has the potential to reduce the risk of obesity and metabolic risk factors in offspring by epigenetic mechanisms involving DNA methylation.

Type 2 Diabetes

The metabolic changes after bariatric surgery associated with glucose homeostasis have been one of the most studied overall. Diabetes is a significant public health problem worldwide, with persistently increasing prevalence. Over the last 25 years, the prevalence of diabetes has doubled in the United States and multiplied by three to five times in India, Indonesia, China, Korea, and Thailand. In 2014, 8.5% of adults worldwide aged 18 years and older had diabetes. Between 2000 and 2016, there was a 5% increase in premature mortality from diabetes with more than 1.5 million deaths in total attributed directly to diabetes. It represents a substantial economic burden as reflected by diabetes and obesity consuming 14% and 5.7% of the total US health expenditure, respectively. Unfortunately, new pharmacologic therapies like glucagon-like-peptide-1 (GLP-1) analogs and dipeptyl-peptidase IV inhibitors have been disappointing in the morbidly obese, and many diabetic patients on maximal medical therapy fail to reach the therapeutic goal of HbA1c <7% set by the American Diabetes Association. For this reason, bariatric surgery has quickly been pushed to the forefront when it comes to the treatment of diabetes in obese patients.

Improvements in glycemic control after gastrointestinal surgery were originally reported in the 1960s. This was followed by studies showing the durable effect of bariatric surgery in improving glucose homeostasis in T2D patients as early as 1995. Since then, several meta-analyses have confirmed that all bariatric procedures lead to significant improvements in glucose control and diabetes remission, although success does vary among the different surgeries (Table 3).

Naturally, the next step was comparing bariatric surgery to intensive medical therapy. By 2021, most studies conclude that bariatric surgery leads to better glycemic control and diabetes remission when compared with intensive medical therapy in obese patients. The Swedish Obese Subjects data shows that, of the patients who underwent bariatric surgery with T2D at baseline, 72% were in remission at 2 years postoperation compared with 21% in the medical treatment group. At 10 years, this decreased to 36% in the surgery group and 13% in the control group. Additionally, bariatric surgery reduced the risk of developing T2D by 96%, 84%, and 78% after 2, 10, and 15 years, respectively, when compared with medical management. The recently published 5-year STAMPEDE trial, which compared rates of diabetes remission (defined as HbA1c <6%) after intensive medical therapy versus RYGB and SG, showed similar results with a 29% remission rate in the RYGP group and 23% in the SG group, compared with only 5% in the medical therapy group. Another large cohort of more than 400 patients who had RYGB, showed that the remission rate after 12 years of follow-up (with a 90% follow-up rate) was 51%.

These data have prompted many diabetes societies to alter their treatment guidelines for the management of diabetes. They now recommend bariatric surgery as an early treatment of eligible patients who have T2D and a BMI ≥35 kg/m^2, or with a BMI between 30 and 35 kg/m^2 when diabetes cannot be adequately controlled by an optimal medical regimen, especially in the presence of other major CVD risk factors.

The exact mechanisms by which bariatric surgery leads to improved glucose homeostasis in diabetic patients is an area that has received significant scientific attention lately. Initially, it was thought that such a profound response was the result of caloric restriction and weight loss. However, it is now known that there are several mechanisms behind this change, with gastrointestinal hormones leading the way (Table 4).

METABOLIC SURGERY AND FUTURE DIRECTIONS

Low BMI Metabolic Surgery

The current National Institute of Health (NIH) consensus statement in agreement with the Diabetes Surgery Summit II recommends bariatric surgery in patients with a BMI of more than 40 kg/m^2; a BMI of more than 35 kg/m^2 with concomitant comorbidities like diabetes, coronary artery disease, or sleep apnea; or a BMI between 30 and 35 kg/m^2 when T2D cannot be adequately controlled by an optimal medical regimen. Unfortunately, despite the consensus and current existing data, surgery is still rarely used in the lower BMI patient group (30–35) and is not covered by most insurance providers in the United States. With the increasing prevalence of T2D, the slow progress in finding new effective medical therapies, and the significant rate of diabetes remission and safety of bariatric surgery, there should be a progressively strong push to encourage surgical intervention in patients with diabetes to 30 kg/m^2 or even lower.

TABLE 3 Weight Changes and Metabolic Improvements After Bariatric Procedures

	TBWL (%)	Hypertriglyceridemia Remission	Hypertension Remission	Type 2 Diabetes Remission
RYGB	30%–35%	90%–95%	40%–70%	70%–80%
SG	20%–25%	50%–60%	30%–60%	50%–70%
LAGB	10%–15%	60%–70%	20%–30%	30%–40%

TABLE 4 Proposed Mechanisms of Antidiabetic Effect of RYGB

Caloric restriction and weight loss	Unlikely to be a major mechanism. Improvement if glucose homeostasis typically begins within days of surgery before significant weight loss.
Malabsorption	There is no clear evidence that RYGB leads to enough nutrient malabsorption to account for the improvement of diabetes as early as postoperative day 2.
Hindgut hypothesis and changes in incretin levels (GLP-1)	Rapid delivery of nutrients to the distal small bowel stimulates L cells leading to increase GLP-1 secretion. Increased GLP-1 levels enhance glucose-stimulated insulin secretion and improve insulin sensitivity and beta-cell proliferation and function.
Foregut hypothesis	Rat models have shown that isolating the duodenum and proximal jejunum results in a decreased release of an unknown anti-incretin leading to improved glucose homeostasis. Ghrelin secretion is also reduced.
Intestinal adaptation	The alimentary limb undergoes compensatory hyperplasia and hypertrophy, with increased expression of glucose transporters and thus glucose absorption into the epithelial cells. There is a reprogramming of intestinal metabolism to use this glucose to support tissue growth.
Changes in circulating bile acids	Human and rodent studies have shown increased levels of circulating bile acids (reduced in diabetic patients) after RYGB. Bile acids have been linked to receptor signaling on incretin-secreting L-cells.

One of the main issues in the matter is that currently there is no clear consensus on the best surgical procedure for this patient group. In a randomized study from Taiwan, including diabetic patients with BMI from 25 to 34, RYGB was shown to be more effective than SG in achieving diabetes remission, with a 93% remission compared with 47%. Importantly, the mean postoperative BMI was 22.8 for RYGB and 24.4 for SG, showing that these lower BMI patients did not lose excessive weight following surgery. Unfortunately, more studies need to be performed for a final consensus on which bariatric surgery to recommend.

Adolescent Bariatric and Metabolic Surgery

The use of BMI as a measure for childhood obesity is more problematic than its use in adults because of the additional complications of growth patterns, age, and sex in a growing child. Special BMI growth charts have been devised to correct for these variables and are used when assessing the pediatric population. These define the BMI range of 85th to 94th percentile as overweight, and 95th percentile or higher as obese. This has been further clarified by the American Academy of Pediatrics who proposes a BMI of 30 to 32 kg/m^2 for youths 10 to 12 years old and 34 kg/m^2 for youths 14 to 16 years old as the 99th percentile. The Bogalusa Heart Study showed that 84% of children with a BMI in the 95th to 98th percentile had a BMI greater than 30 kg/m^2 as adults, showing that childhood BMI was strongly associated with adult BMI in this BMI range.

Childhood obesity has more than doubled in children and quadrupled in adolescents in the past 30 years. The percentage of obesity in children aged 6 to 11 years in the United States increased from 7% in 1980 to 21.2% in 2018. Similarly, the percentage of obesity in adolescents aged 12 to 19 years increased from 5% to 21% over the same period. Several studies have shown that childhood obesity is strongly associated with adult obesity, as well as a higher incidence of risk factors for CVD, such as high cholesterol or hypertension. In a population-based sample of 5- to 17-year-olds, 70% of obese youth had at least one risk factor for CVD. Current estimates predict a decrease in life expectancy in obese adolescents of 5 to 20 years depending on additional risk factors such as race and sex.

Although studies are limited, current data suggests that bariatric surgery is at least as safe in adolescents as it is in adults, having similar success in both weight reduction and resolution of metabolic derangement. The Teen-Longitudinal Assessment of Bariatric Surgery (Teen-LABS) study is the largest ongoing observational cohort study of youth undergoing metabolic and bariatric surgery to date. There were 242 patients (12–28 years of age) enrolled at five US centers (2007–2011) undergoing RYGB (n = 161), VSG (n = 67), or LAGB (n = 14). Although the study is still underway, the RYGB and SG groups experienced a mean weight reduction of 27% and resolution of comorbidities at 3 years, including T2D (95%), hypertension (74%), and dyslipidemia (66%), with a reduction of overall prevalence of multiple concurrent CVD risk factors. The FABS-5+, another important study with the longest-term follow-up data in adolescents to date, showed that, after RYGB, adolescents demonstrated a 29% reduction in BMI and significant improvements in blood pressure, dyslipidemia, and T2D at 8 years. Despite all these data, there is hesitancy on the part of pediatricians and pediatric specialists to consider surgery, even for adolescents with life-threatening comorbidities; of polled pediatricians, half of the respondents would not refer their patients for bariatric surgery before 18 years of age.

Alternative Surgical Procedures

Research of the mechanisms for the antidiabetic effects of current bariatric procedures is of particular interest because it also leads to the opportunity of developing less invasive interventions. As explained earlier, the isolation of the duodenum and proximal bowel from nutrient exposure and early exposure of distal bowel and ileum to undigested food are thought to be critical to the metabolic success of bariatric surgical procedures. New surgical procedures such as duodenal-jejunal bypass and ileal interposition with or without SG may offer less invasive options for metabolic surgery targets, especially in patients with low BMI. These procedures, however, are still complex and not without risk, and it is still not clear whether they offer any major advantages in terms of long-term effectiveness and safety over RYGB or SG. More studies are required at the time.

Endosurgical Options and Devices

An area of heavy development at this time, in part, because it is the least invasive option, is endoscopically delivered gastrointestinal manipulation. The goal of these endoscopic procedures is to replicate the metabolic or weight loss success of bariatric surgery without an abdominal incision, making for a less invasive procedure. These options range from implantable neurostimulators to modify vagal or gastric tone, to barrier devices that stent through the proximal bowel and block nutrient contact or intragastric balloons designed for gastric volume restriction and increased satiety. The efficacy of these minimally invasive options needs to be further studied, but endoscopic procedures will, most likely, be an ongoing target for development in the near future.

Cardiovascular Disease Risk Reduction After Bariatric Surgery

Robert C. Ross, MD, Vance L. Albaugh, MD, PhD, and Philip R. Schauer, MD

Despite significant advances in medical and surgical treatment over the past several decades, cardiovascular disease (CVD) persists as the leading cause of morbidity and mortality in the United States. The Centers for Disease Control and Prevention estimates that 49.2% of adults 20 years of age and older are affected by CVD, which includes coronary artery disease, heart failure, cardiomyopathy, hypertension, and stroke. Although the mortality rate resulting from the different CVD entities vary, collectively these entities are responsible for more deaths than cancer and trauma. The American Heart Association lists CVD as the most common underlying cause of death in the United States, outpacing cancer and chronic lower respiratory disease combined, and it remains the leading cause of death globally. Coronary heart disease is the most common (42.1%) cause of CVD-related death, followed by stroke (17%), hypertension (11%), and heart failure (9.6%).

In addition to morbidity and mortality, CVD places significant economic costs on the community and utilizes substantial resources within the healthcare system. From 2016 to 2017, CVD cost the United States an estimated $363.4 billion per year. The Healthcare Cost and Utilization Project found that CVD was associated with 11.6% of 30-day hospital readmissions in 2018. CVD is among the leading conditions filed for disability in the United States. The American Heart Association has projected a $1.1 trillion price tag for treatment of CVD by 2035.

Obesity, diabetes mellitus, and multiple additional risk factors leading to CVD are well established. Controlling these risk factors accounts for up to 75% of the possible reduction in CVD mortality in highly developed countries. Obesity, particularly central obesity, is an independent risk factor. This chapter will explore the relationship between central obesity and CVD and will discuss the effect of bariatric and metabolic surgery on CVD risk factors and outcomes.

CARDIOVASCULAR DISEASE RISK FACTORS

Overview

CVD risk factors can be divided into traditional modifiable, traditional nonmodifiable, and nontraditional (Table 1). Population-based studies have revealed that most CVD results from modifiable risk factors such as poor diet, low level of physical activity, and tobacco smoking. Other modifiable risk factors include high systolic blood pressure, triglyceride cholesterol levels, fasting plasma glucose levels, and body mass index (BMI). Approximately half (47.3%) of the United States adult population has hypertension, just one of the many risk factors for CVD. Black patients experience higher BMI, hemoglobin A1c, and systolic blood pressure on average than white patients, but have lower average total cholesterol and are less likely to be current smokers.

Traditional nonmodifiable risk factors for CVD are increasing age, sex, race, and family history of premature coronary heart disease. Males are at higher risk of CVD. Black patients are at a higher 10-year risk for CVD than their white or Hispanic counterparts when adjusting for age, sex, and social determinants of health.

Metabolic Syndrome

Metabolic syndrome, formerly known as *syndrome X,* comprises a group of conditions that lead to CVD and type 2 diabetes mellitus (T2DM). The International Diabetes Federation (IDF) defines metabolic syndrome by the presence of central obesity plus ≥2 metabolic risk factors, including increased blood pressure, high triglyceride levels, elevated fasting plasma glucose, and low high-density lipoprotein (HDL) cholesterol (Table 2). The National Cholesterol Education Program (NCEP) Adult Treatment Panel III (ATP III) uses the presence of any three of the aforementioned five factors to define metabolic syndrome (Table 3). The prevalence of metabolic

CHD, Coronary heart disease; *HDL,* high-density lipoprotein; *LDL,* low-density lipoprotein.

TABLE 2 International Diabetes Federation Criteria for Metabolic Syndrome

Central obesity* or BMI ≥30 kg/m² plus presence or treatment of two of the following:	
1. Raised triglycerides	≥150 mg/dL (1.7 mmol/L)
2. Reduced HDL cholesterol	<40 mg/dL (1.03 mmol/L) in males <50 mg/dL (1.29 mmol/L) in females
3. Raised blood pressure	Systolic BP ≥130 mm Hg or diastolic BP ≥85 mm Hg
4. Raised fasting plasma glucose	≥100 mg/dL (5.6 mmol/L)** or previous diagnosis of type 2 diabetes

*If BMI is >30 kg/m², central obesity can be assumed, and waist circumference does not need to be measured.
**If positive, an oral glucose tolerance test is strongly recommended but is not required for diagnosis.*BP,* Blood pressure; *HDL,* high-density lipoprotein.

TABLE 3 Diagnostic Criteria for the Metabolic Syndrome as Defined by the National Cholesterol Education Program Adult Treatment Panel III

Having or on treatment for three or more of the following:	
1. Abdominal obesity	Waist circumference ≥40 inches (102 cm) in males; ≥35 inches (88 cm) in females
2. Hypertriglyceridemia	≥150 mg/dL (≥1.7 mmol/L)
3. Low HDL cholesterol	<40 mg/dL (1.03 mmol/L) in males; <50 mg/dL (1.29 mmol/L) in females
4. Systemic hypertension	≥130/85 mm Hg
5. Elevated fasting plasma glucose	≥100 mg/dL (≥5.5 mmol/L)

HDL, high-density lipoprotein.

syndrome in the United States is estimated to be 34.7%. This number increases with age, affecting only 19.5% of individuals between 20 and 39 years of age and 48.6% of those ≥60 years of age. Metabolic syndrome substantially increases the risk for CVD (RR 1.78, 95% CI 1.58–2.00). Furthermore, all-cause mortality is higher in patients with CVD in the presence of metabolic syndrome (RR 1.58, 95% CI 1.39–1.78). Each additional component of metabolic syndrome that a patient exhibits further increases their risk of major cardiovascular events (RR 1.22, 95% CI 1.09–1.36).

Diabetes Mellitus

Diabetes mellitus is an endocrine disorder in which blood glucose level is dysregulated and is subclassified by the pathogenesis of this dysregulation. In the United States, 1 in 10 individuals has diabetes, and T2DM accounts for more than 90% of these diagnoses. In T2DM, insulin resistance in bodily tissue causes abnormal glucose levels despite continued pancreatic insulin production. Despite previously being considered an adult-onset disease, there has been a concerning increase in the number of youths 10 to 19 years of age diagnosed with T2DM, almost doubling from 0.34 per 1000 youths in 2001 to 0.67 per 1000 in 2017. T2DM is associated with microvascular and macrovascular pathology that increases risk of CVD. Data from the National Health Interview Survey has shown that patients with diabetes have higher CVD-related and all-cause mortality when compared with patients without diabetes.

Obesity

Central obesity is determined by the measurement of the waist circumference and is sex- and ethnic group–specific. Patients with a BMI ≥30 kg/m² are assumed to have central obesity and do not require waist circumference measurement. The prevalence of obesity in US adults increased from 30.5% in 1999 to 2000 to 42.4% in 2017 to 2018. Severe obesity, or BMI ≥40 kg/m², increased from 4.7% to 9.2% over the same period.

Obesity is associated with many other risk factors for CVD (Table 4) and independently increases lifetime risk for CVD, T2DM, hypertension, sleep apnea, and venous thromboembolism. Obesity has been shown to increase all-cause mortality (HR 1.18, 95% CI 1.12–1.25). BMI has an overall *J*-shaped relationship with all causes

TABLE 4 Cardiovascular Conditions Associated with Obesity

- Structural heart changes and congestive heart failure
- Atrial fibrillation
- Sudden cardiac death
- Stroke

of mortality, with the lowest risk of mortality from most causes between BMI of 21 to 25 kg/m^2. Every 5 kg/m^2 increase in BMI >25 equates to a higher hazard ratio (HR) for mortality and decreased life expectancy. Overweight, obesity, and extreme obesity have an HR of 1.07 (95% CI 0.91–1.26), 1.41 (95% CI 1.16–1.73), and 2.46 (95% CI 1.91–3.16), respectively.

Effect of Weight Loss on Risk for Cardiovascular Disease

Lifestyle-Induced Weight Loss

Weight loss in patients with obesity has been linked to reduced risk of developing CVD. Intentional weight loss improves systolic blood pressure, triglyceride levels, and fasting blood glucose. Lifestyle-induced weight loss has been the target of multiple studies. The Look AHEAD trial, one of the largest randomized controlled trials on lifestyle-induced weight loss, aimed to test the long-term health effects of intensive lifestyle interventions versus standard support and education in patients with both T2DM and overweight/obesity. Patients who lost 5% to 10% of their excess body weight had improved CVD risk factors, including BMI, blood pressure, HDL, and triglycerides (Table 5). Although the Intensive Lifestyle Intervention group was able to achieve significant weight loss of 8.5% at 1 year compared with 0.6% in the support and education group, they had significant weight regain and at year 8 had lost 4.7% and 2.1% of excess body weight, respectively. The two groups had no significant difference in CVD morbidity or mortality, the study's original primary outcome, or in cognitive function or cancer rates.

TABLE 5 Mean Changes in Weight and Risk Factors for Cardiovascular Disease in the Intensive Lifestyle Intervention and Diabetes Support and Education Groups and the Difference Between Groups*

Measure	DSE	ILI	Between-Group Mean Difference	*P*-value

Drug-Induced Weight Loss

Pharmaceutical interventions to target weight loss are on the rise. Multiple drugs developed over the past several decades have had limited use as a result of cardiovascular and neurologic adverse effects, leading to a limited number of medications approved by the US Food and Drug Administration (FDA) for chronic weight management. Orlistat, approved in 2007, is a lipase inhibitor and works by preventing around 30% of dietary fat from being absorbed. Mean body weight loss with orlistat ranges from 4.6% to 10.2%, with average weight regain of 32.5% of initial weight loss. Phentermine/topiramate, a combination of sympathomimetic and antiepileptic medications approved in 2012, has demonstrated 9.3% to 10.5% weight loss over 2 years. Naltrexone/bupropion, a combination of an opioid antagonist and a dopamine/norepinephrine reuptake inhibitor, was approved in 2014. The drug is associated with a variable 3.7% to 8.1% weight loss and has been shown to transiently increase blood pressure, although with no significant difference in cardiovascular events.

Liraglutide is a glucose-like peptide-1 (GLP-1) receptor agonist daily injection that was approved in 2014. It has shown 4.9% to 7.4% mean reductions in body weight in obese patients without diabetes. It has been shown to decrease CVD risk in patients with diabetes, but this reduced risk has not been shown to be weight dependent. Lorcaserin, a serotonin receptor activator initially approved in 2012, has recently been withdrawn as a result of concerns for adverse events including increased occurrence of cancer.

A once-weekly injection with semaglutide 2.4 mg has demonstrated significant weight reduction improvement over prior weight-loss medications. In a double-blind, randomized controlled trial of 1961 obese adults (or BMI ≥27 with obesity-related comorbid conditions), semaglutide demonstrated a 12.4% body weight loss over placebo at 68 weeks. Follow-up studies will help determine whether this weight loss is sustainable longer-term, but initial data are promising. Additional studies on the combination of surgical and medical weight loss may shed light on the optimal strategy to decrease CVD risk in overweight and obese populations.

Metabolic and Bariatric Surgery: Overview of Common Procedures

Metabolic and bariatric surgery is the most effective intervention for significant and sustained weight loss. The common bariatric procedures—sleeve gastrectomy, gastric bypass, gastric banding, and biliopancreatic diversion or duodenal switch—are illustrated in Figure 1. These procedures differ in their effects on the magnitude and durability of weight loss as well as the degree of metabolic disease resolution (Table 6). The benefit of metabolic and bariatric surgery for reduction of cardiovascular risk and metabolic disease has been repeatedly demonstrated in longitudinal studies. This benefit has also been translated to improved quality of life and overall survival, although randomized controlled trials assessing cardiovascular outcome have yet to be conducted. Bariatric and metabolic surgery is believed to improve cardiovascular risk profile primarily through weight loss and possibly through additional mechanisms such as reduced inflammation. The safety of metabolic and bariatric procedures has been well established and has improved with advances in laparoscopic surgery. The risk profiles differ between types of bariatric and metabolic surgery and should be discussed with the patient during the informed consent process (Table 7).

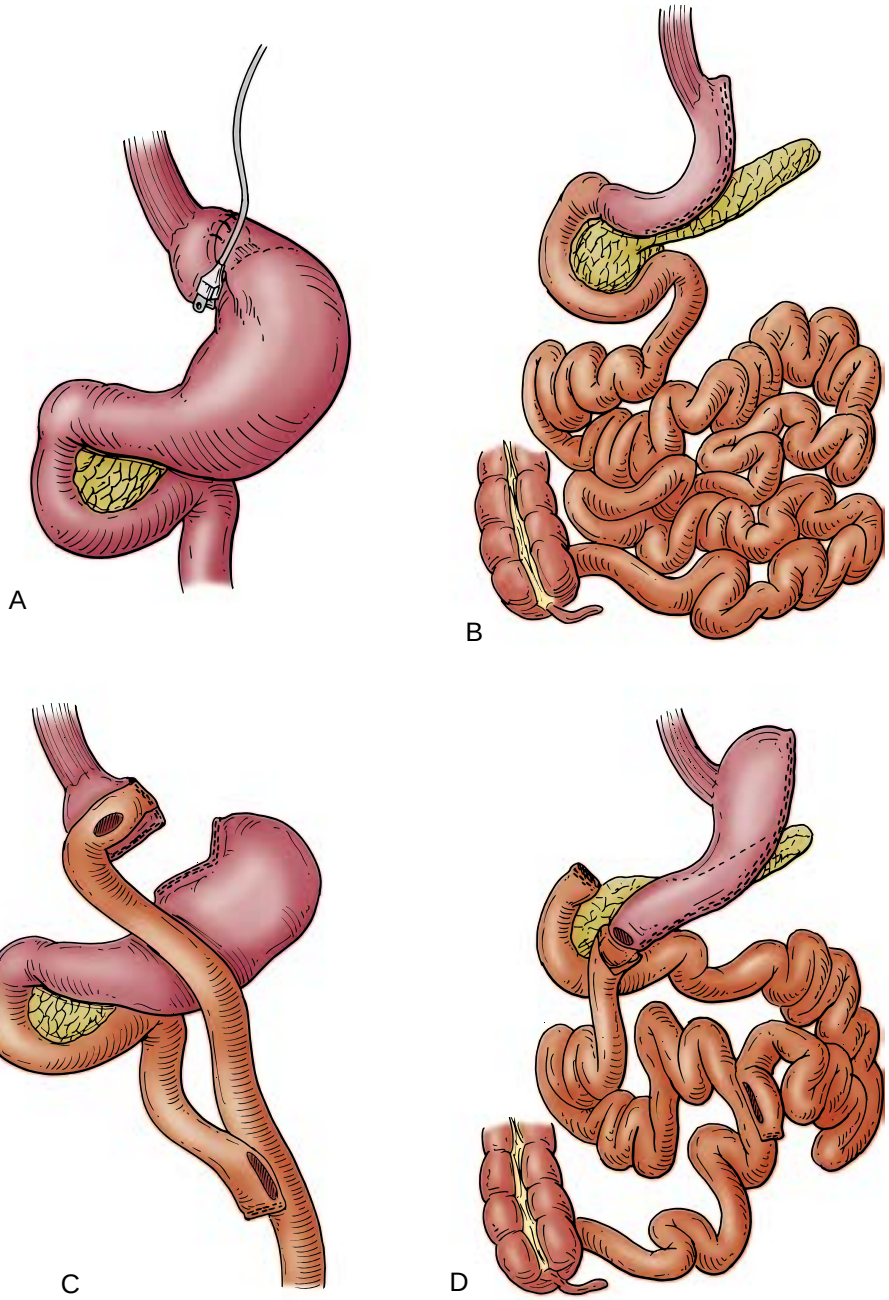

FIG. 1 Commonly performed bariatric procedures. **(A)** Adjustable gastric banding. **(B)** Sleeve gastrectomy. **(C)** Roux-en-Y gastric bypass. **(D)** Biliopancreatic diversion (illustrated with duodenal switch).

Effect of Bariatric Surgery on Cardiovascular Disease Risk Factors

Surgically induced weight loss and associated blood pressure improvement contribute significantly to decreasing CVD risk. Independent of weight loss, bariatric surgery reduces CVD risk by improving glucose and lipid metabolism and reducing systemic inflammation.

Glycemic Control

Bariatric surgery has been known as the most effective therapy to improve insulin resistance and T2DM since the landmark paper by Pories et al. described the durable effect on diabetes control and the safety of bariatric surgery in 1995. Multiple studies have since confirmed the therapeutic effect of the various bariatric procedures in patients with prediabetes and T2DM.

The mechanisms for postoperative improvement in diabetes and glucose metabolism remain an active area of research. Clinically, however, improved glycemic control is evident within days after surgery when the amount of weight loss is insufficient to explain the observed improvement. Schauer et al. reported that 30% of patients who were on oral hypoglycemic agents exhibited immediate postoperative independence from these medications after RYGB. Prolonged remission of diabetes after bariatric surgery has also been described. In a study published by Pories et al, 83% of 146 patients with non–insulin-dependent diabetes mellitus maintained normal blood glucose and HbA1c after RYGB. A randomized controlled

trial by Mingrone et al. comparing metabolic surgery to conventional medical therapy on T2DM demonstrated an 82% remission rate in surgical patients at 2 years. At 10-year follow-up, the surgical arm maintained a 37.5% remission rate compared with 5.5% in the medical therapy arm.

Long-term durability of remission of T2DM has been shown in the Swedish Obese Subjects (SOS) project, a nonrandomized, matched, prospective observational study that enrolled more than 4000 obese patients and followed them over time. This study showed reversal of diabetes in 72.3% of the surgical group as compared with just 16.4% of the control group at 2 years of follow-up (OR 40.5, 95% CI 21.0–78.2; $P < 0.001$). Weight gain after surgery was associated with a relapse of diabetes. At 10 years, 50% of those patients who had previous T2DM remission had relapsed. At 15 years, diabetes remission rates had decreased to 30% in the surgical group, which was still a substantial improvement over 6.5% in the control group (OR 6.3, 95% CI 2.1–18.9; $P < 0.001$). Although bariatric surgery has been associated with hypoglycemic events in patients without diabetes, patients with baseline diabetes were at no increased risk of hypoglycemic episodes after undergoing bariatric surgery.

Meta-analyses of smaller randomized controlled trials have supported the durability of diabetes remission after bariatric surgery. A 2021 meta-analysis by Carmona et al. reviewed the results of 11 primary trials with a minimum of 5-year follow up. The analysis compared the efficacy of different bariatric surgeries and medical treatment on T2DM remission in patients with T2DM and BMI ≥25 kg/m^2. Compared with standard medical treatment, laparoscopic one anastomosis gastric bypass (RR 0.14, 95% CI 0.04–0.49), duodenal switch (RR 0.17, 95% CI 0.05–0.55), RYGB (RR 0.21, 95% CI 0.07–0.63), and vertical sleeve gastrectomy (VSG) (RR 0.26, 95% CI 0.08–0.79) were all significantly more likely to result in full diabetes remission at 5 years.

Randomized controlled trials, as shown earlier, have begun to provide the strongest evidence for the superiority of bariatric and metabolic surgery to medical therapy alone in improving glycemic control and diabetes remission. Initial results from the Surgical Therapy And Medications Potentially Eradicate Diabetes Efficiently (STAMPEDE) trial were released in 2012. This randomized controlled trial enrolled 150 patients with T2DM (mean HbA1c 9.2%) into intensive medical therapy versus RYGB or VSG plus medical therapy. This 1-year follow-up showed an HbA1c <6% in 42% in the RYGB group, 37% in the VSG group, and 12% in the medical therapy alone group. In 2017, the group published 5-year follow-up results with HbA1c <6% in 22.4% in the RYGB group, 16.9% in the VSG group, and none in the medical therapy alone group. In 2022, Kirwan et al. reported data on 316 patients with T2DM previously enrolled in the STAMPEDE trial and three other ongoing trials (TRIABETES, SLIMM-T2D, and CROSSROADS) to further understand diabetes remission and bariatric surgery. The 3-year data from 160 patients assigned to bariatric surgery were compared with 76 patients assigned to medical and lifestyle therapy. Remission of T2DM (defined as HbA1c ≤6.5% for 3 months without glucose-lowering therapy) at 3-year follow-up was achieved in 37.5% of the surgical group and only 2.6% of the medical/lifestyle treatment group ($P < 0.001$). HbA1c decreased by an average of 1.9 (± 2.0) in the surgery group versus only 0.1 (± 2.0) in the medical/lifestyle group ($P < 0.001$). The decrease in fasting plasma glucose and BMI was also greater in the surgical group.

Another randomized controlled trial by Mingrone et al. reported their initial 2-year follow-up data on bariatric surgery versus medical therapy in patients with T2DM >5 years and BMI ≥35 kg/m^2 in 2012. Diabetes remission was defined as fasting plasma glucose <5.55 mmol/L and HbA1c <6.5% without glucose-lowering medications. Two operations, RYGB and biliopancreatic diversion (BPD), were grouped separately. Diabetes remission at 2 years was 95% in the BPD group, 75% in the RYGB group, and did not occur in any patients in the medical therapy alone group. Post hoc analysis showed that preoperative BMI and postoperative weight loss were not predictive of the degree of improvement in glycemic control in surgical groups. The 5-year follow-up showed a continued 63% remission of T2DM in the BPD group and 37% in the RYGB group,

TABLE 7 Postoperative Complications Associated with Bariatric Procedures

	Complications	
Procedure	**Early Postoperative Period (<30 Days)**	**Late**
RYGB	Anastomotic leak with peritonitis Abdominal abscess Pulmonary embolism Bleeding Pulmonary complications Acute distal gastric dilation Roux limb obstruction Wound infection	Stomal stenosis Marginal ulcer Dumping syndrome Intestinal obstruction Internal hernia Incisional hernia Cholecystitis Vitamin and mineral deficiencies Weight regain Hypoglycemia
BPD ± DS	Same as RYGB	Same as laparoscopic RYGB with the following being more common in the BPD procedure than in RYGB if aggressive prophylactic measures are not followed postoperatively: Anemia Protein-calorie malnutrition Vitamin B_{12} deficiency Hypocalcemia Osteoporosis Fat-soluble vitamin deficiency Night blindness
SG	Staple line leak Abscess Hemorrhage Sleeve stricture Wound infection	Intractable nausea +/– vomiting Reflux symptoms Gastric dilation Weight-loss failure Weight regain
AGB	Hemorrhage Wound infection Food intolerance Reflux Nausea +/– vomiting Band migration Wound infection	Reflux symptoms Erosive esophagitis Esophageal dilation Pouch enlargement Band migration Gastric prolapse Vomiting Tubing-related problems Reservoir leakage Band erosion Weight-loss failure Lower average weight loss

with none of the medical therapy patients achieving remission. In 2021, the group published 10-year follow-up data demonstrating continued efficacy of surgery on T2DM. Remission rates were 50% for the BPD group and 25% for the RYGB group. The only participant in the medical therapy group who achieved remission at 10 years did so after crossover to undergo bariatric surgery.

Bariatric surgery for patients with T2DM has been widely considered an acceptable therapy in patients with BMI ≥35 kg/m^2; surgical treatment of class 1 obesity (BMI 30–35 kg/m^2) and lower has been controversial. In 2011, the IDF recognized the role of bariatric surgery in the treatment of class 1 obesity patients whose diabetes cannot be adequately controlled by optimal medical regimens, especially in the presence of other major CVD risk factors. Since 2017, the American Diabetes Association has recommended bariatric surgery in class 1 obesity for patients unable to achieve adequate HbA1c with medical therapy. The American Society for Metabolic and Bariatric surgery (ASMBS) currently recommends bariatric surgery as a safe option for patients with BMI ≥30 kg/m^2 who have not been able to achieve durable weight and comorbidity control with nonsurgical methods.

Lipid Metabolism

Bariatric surgery improves dyslipidemia, a significant component of CVD risk characterized by low HDL cholesterol, hypertriglyceridemia, and elevated LDL cholesterol. In 2021, Liu et al. reported the results of a meta-analysis of 35 randomized controlled trials evaluating the effect of bariatric surgery versus medical therapy on dyslipidemia. Bariatric surgery was found to significantly reduce total cholesterol, triglycerides, and LDL cholesterol and increase

HDL cholesterol. These changes were seen more often after procedures with malabsorptive components, such as RYGB and BPD. A meta-analysis of bariatric surgery outcomes the same year by Lee et al. compared resolution of dyslipidemia between sleeve gastrectomy and RYGB, the two most common bariatric surgical procedures. RYGB was found to result in resolution more often than sleeve gastrectomy at 1 year (RR 0.58, 95% CI 0.46–0.73, $P < 0.001$) and at 5 years (RR 0.68, 95% CI 0.46–0.99, $P = 0.04$).

Inflammatory State

Adipose tissue, once considered an inert energy storage tissue, has been appreciated as an endocrine organ since the early 2000s. It produces an array of adipokines with inflammatory and immune functions, and researchers have begun to describe how bariatric surgery alters these important factors. Chronic systemic inflammation, often seen in central obesity, causes endothelial dysfunction and accelerates atherosclerosis, leading to increased CVD risk.

A 2019 meta-analysis of 116 studies aimed to describe the effect of bariatric surgery on inflammatory markers. C-reactive protein, a key acute-phase reactant of inflammation, was shown to decrease by 5.30 mg/L (95% CI −5.46 to −5.15, $P < 0.001$). IL-6, a proinflammatory cytokine in blood vessels, also produced by adipocytes, was found to decrease by 0.58 pg/mL (95% CI −0.64 to −0.53, $P < 0.001$). Tumor necrosis factor alpha (TNFα), which is involved in vasodilation, leukocyte adhesion to epithelium, blood coagulation, and oxidative stress, was found to decrease by 0.20 pg/mL (95% CI −0.39 to −0.02, $P = 0.031$). A study of 40 patients with significant weight regain after bariatric surgery showed lower levels of IL-6 than their matched counterparts who had not undergone surgery, suggesting that these patients may have maintained decreased levels of IL-6, even after regaining weight. Bariatric surgery may have lasting effects not related to weight-loss maintenance that reduce CVD risk.

Effect of Bariatric Surgery on Cardiovascular Disease and Mortality

Multiple observational studies have shown bariatric surgery to be a safe procedure associated with a reduction in overall mortality (Table 8). In a retrospective case control study in 2004, the McGill Bariatric Cohort Study was among the first to report the association of reduced mortality with excess weight loss. Comparing over 1000 patients who underwent bariatric surgery to over 5700 control patients with normal BMI, they showed that a 67% excess weight loss at 5 years decreased risk of overall mortality by 89%. More recently in 2021, Syn et al. reported a meta-analysis involving 174,772 patients showing that metabolic and bariatric surgery was associated with an increased median life expectancy of 6.1 years (95% CI 5.2–6.9) when compared with usual medical treatment.

Although initial studies focused on improved CVD risk profile and overall mortality after bariatric surgery, newer studies have shed light on the translation of risk-profile improvement to a decrease in CVD morbidity and mortality. The SOS study is the longest running prospective study of bariatric surgery outcomes to date. The SOS study compares 2007 obese individuals (BMI ≥34 kg/m^2 in men; BMI ≥38 kg/m^2 in women) who underwent bariatric surgery (gastric bypass 13.2%, gastric banding 18.7%, or vertical banded gastroplasty 68.1%), 2040 well-matched controls, and 1135 participants in a reference population. Mortality within 90 days of surgery was 0.2%, and 2.9% of patients in the surgical group required repeat surgery. A recent update in 2020 of over 20-year follow-up reported 22.8% mortality in the surgical group and 26.4% mortality in the control group (HR 0.77, 95% CI 0.68–0.87, $P < 0.001$). CVD-specific mortality was also reported with an HR of 0.70 (95% CI 0.57–0.85). The median life expectancy in bariatric surgery patients was 5.5 years shorter than the general population reference group, but 3 years longer than the nonsurgical control group. CVD incidence after controlling for risk profile at baseline was significantly lower in the surgical group

(HR 0.70, 95% CI 0.57–0.85). Compared with controls, the adjusted HR of bariatric surgery for myocardial infarction was 0.51 (95% CI 0.33–0.79), for heart failure was 0.52 (95% CI 0.31–0.88), and for stroke was 0.45 (95% CI 0.24–0.84). Despite significant improvement in cardiovascular outcomes over controls, when compared with the reference population group, HR for CVD-related mortality in the surgical group was 2.64 (95% CI 1.78–3.91). Bariatric surgery mitigates cardiovascular morbidity and mortality in obese patients, but this risk is still elevated compared with that of the general population (Fig. 2). Benefits of bariatric surgery were even when analyzed by subgroups of BMI and cardiovascular risk factors, suggesting limited usefulness of these factors in estimating potential benefits to patients.

In patients with obesity and T2DM who are at significant risk of CVD, bariatric surgery has been associated with significantly lower risk of major adverse cardiovascular events (MACE) when compared with usual care. A retrospective cohort study of patients with diabetes and obesity in the Cleveland Clinic Health System matched 2287 patients who underwent metabolic surgery 1:5 with nonsurgical controls. Cumulative incidence of MACE at 8 years was 30.8% in the surgical group and 47.7% in the nonsurgical group (absolute 8-year risk difference 16.9% [95% CI 13.1–20.4], $P < 0.001$) (Fig. 3).

Nonalcoholic steatohepatitis (NASH), a form of hepatic injury resulting from metabolic syndrome, is strongly linked to CVD. Previously, no therapy was shown to reduce the risk of MACE in these patients. The Surgical Procedures and Long-term Effectiveness in NASH Disease and Obesity Risk (SPLENDOR) study, a prospective controlled cohort study, has revealed that patients with NASH who undergo bariatric surgery are at significantly reduced risk of developing MACE. This study included 650 patients who underwent bariatric surgery and 508 patients in the control group. The 10-year cumulative incidence of MACE was 8.5% in the surgical group and 15.7% in the control group (adjusted absolute risk difference: 13.9% (95% CI 5.9–21.9).

Recent insight to the role of bariatric surgery in obese patients who already have CVD has come from a retrospective cohort based on database information in Ontario, Canada. In 2021, Doumouras et al. reported on MACE in 2638 patients with previous ischemic heart disease or heart failure (1319 bariatric surgery patients and

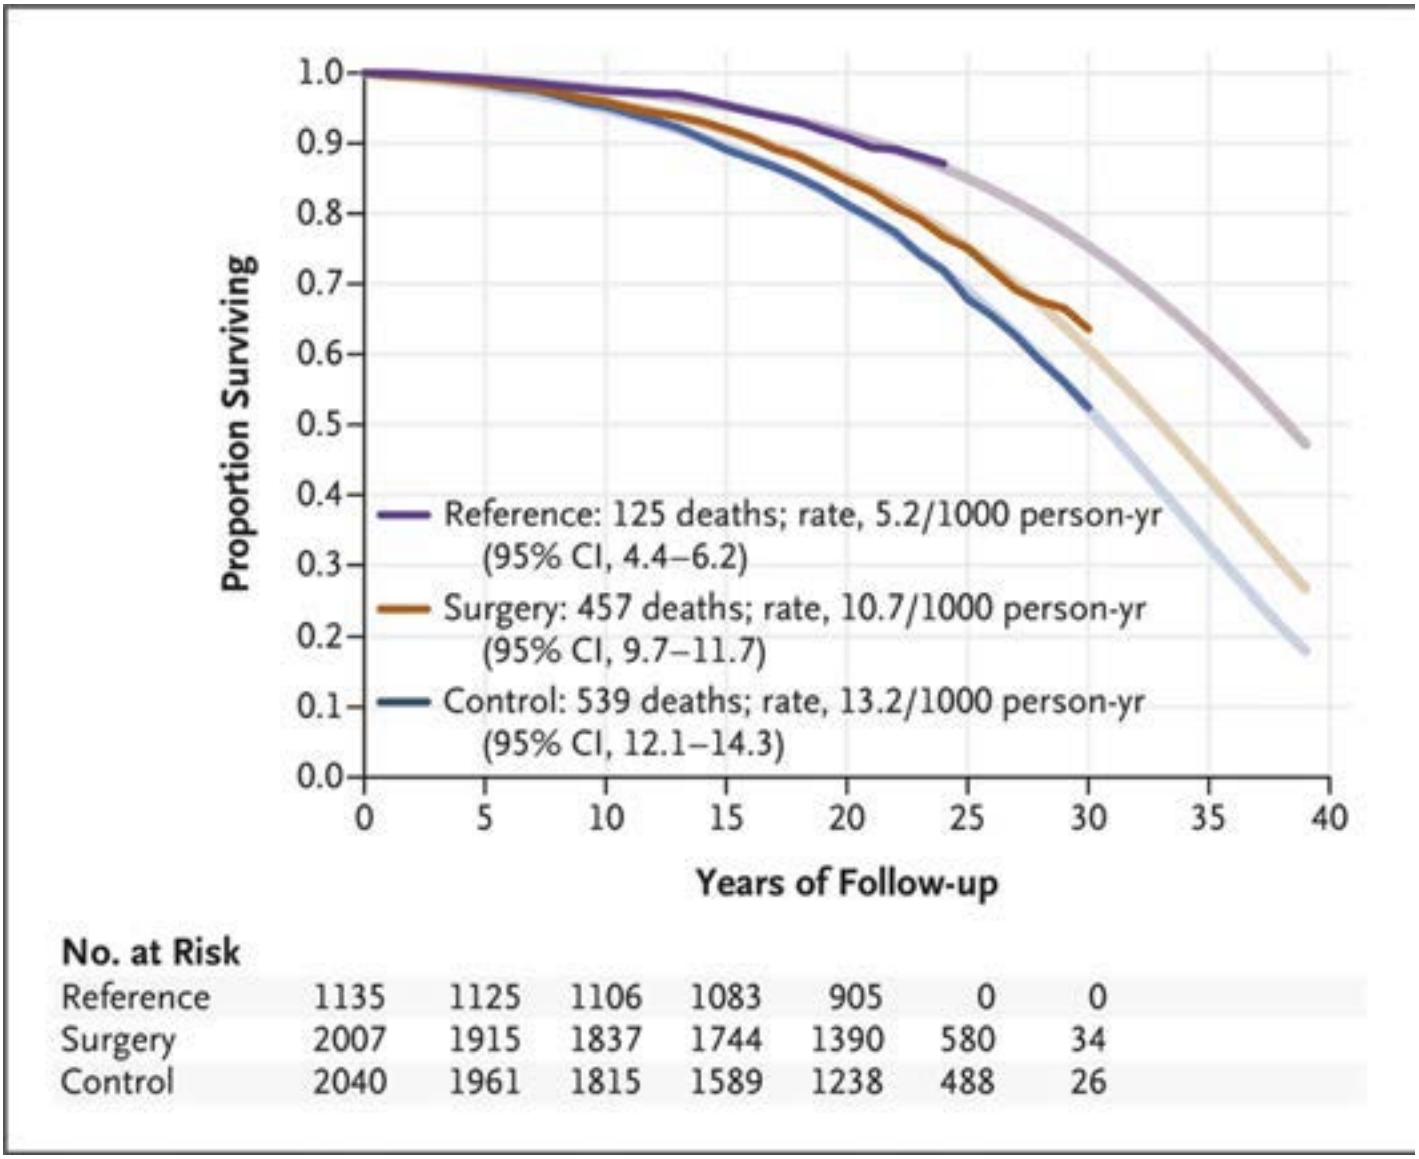

FIG. 2 Survival in the surgery and control groups and in the reference cohort. *(From Carlsson LMS, Sjöholm K, Jacobson P, et al. Life Expectancy after Bariatric Surgery in the Swedish Obese Subjects Study.* N Engl J Med. *2020;383[16]:1535–1543.)*

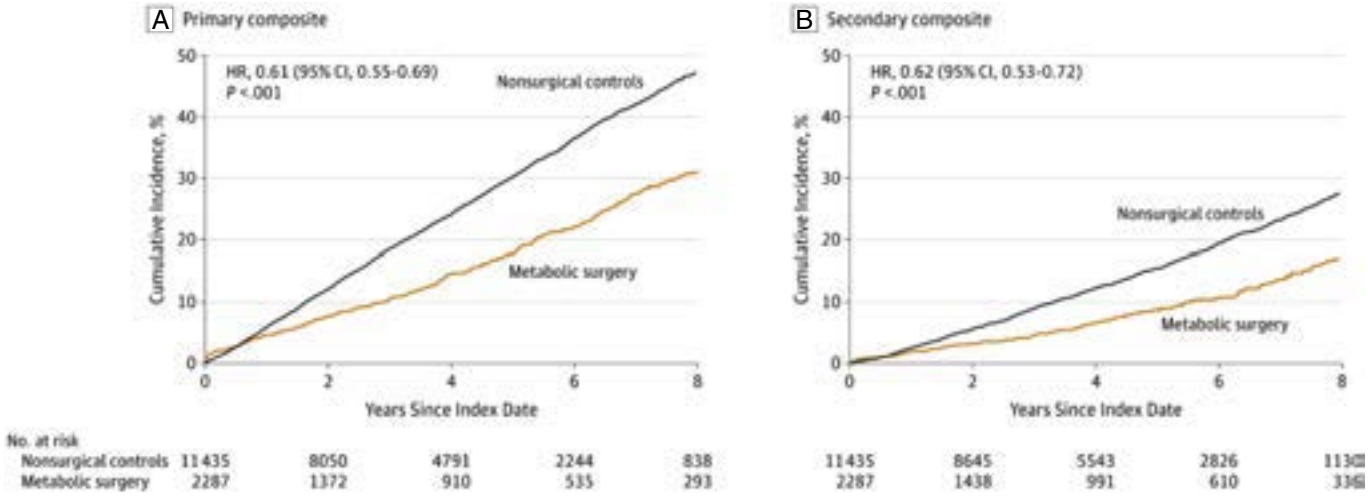

FIG. 3 Eight-year cumulative incidence estimates for two composite end points. The primary end point was the incidence of extended major adverse cardiovascular events (MACE; composite of 6 outcomes), defined as first occurrence of coronary artery events, cerebrovascular events, heart failure, atrial fibrillation, nephropathy, and all-cause mortality, recording the first occurrence after the index date as the event date. The secondary composite end points included the three-component MACE (all-cause mortality, myocardial infarction, and ischemic stroke), recording the first occurrence after the index date as the event date. For both end points, the median observation time was 4.0 years (interquartile range [IQR] 2.1–6.1) for nonsurgical patients and 3.3 years (IQR 1.2–6.3) for surgical patients. *HR,* Hazard ratio. *(From Aminian A, Zajichek A, Arterburn DE, et al. Association of metabolic surgery with major adverse cardiovascular outcomes in patients with type 2 diabetes and obesity. JAMA. 2019;322[13]:1271–1282.)*

1319 matched controls) at a median follow-up of 4.6 years. MACE occurred in 11.5% of the surgery group and in 19.6% of the control group (adjusted HR 0.58 [95% CI 0.48–0.71]). Cardiovascular mortality in the surgical group was significantly lower, with an HR of 0.35 (95% CI 0.15–0.80).

Bariatric surgery may decrease CVD risk through direct end-organ effects on the heart. A recent study of echocardiographic changes in ventricular systolic function in patients with obesity who underwent bariatric surgery showed that patients with heart failure before surgery had a significant improvement in left ventricular ejection fraction (LVEF) from 38.79% ± 13.26 preoperatively to 48.47% ± 14.57% ($P = 0.039$) 18 months after surgery. There was no significant change in LVEF in patients without prior heart failure.

CONCLUSION

The pandemics of obesity, diabetes, and CVD have a multifaceted impact on both individuals and societies. The surgeon's role in reversing and mitigating the damage of these pandemics cannot be understated as research into advancing bariatric therapies and understanding mechanisms of bariatric surgery continues. Bariatric and metabolic surgery is no longer simply beneficial in weight loss but is proving to have remarkable metabolic and cardiovascular effects in the short and long term, and its safety profile continues to improve. National and international societies have begun to understand the potential role of bariatric surgery in patients with any level of obesity and poorly controlled T2DM, especially in the presence of other CVD risk factors. Results of large-scale systematic reviews and important long-term prospective studies, like the SOS study, all point to the important role of bariatric surgery in improving cardiovascular risk profile and decreasing long-term cardiovascular morbidity and mortality in patients with obesity. However, many clinicians and investigators alike argue that clear and convincing evidence of cardiovascular risk reduction after bariatric surgery remains elusive until such time that a well-conducted randomized controlled trial provides definitive supporting evidence. Regardless of the reality of conducting such a definitive trial, surgeons and scientists will continue to find innovative ways to study and serve patients with obesity and CVD.

Nonmelanoma Skin Cancers

Nicholas Calotta, MD, Paul N. Manson, MD, and Anthony Tufaro, MD, DDS

Common nonmelanoma skin cancers (NMSCs) include basal cell carcinoma (BCC) and squamous cell carcinoma (SCC). The common forms of skin cancer arise, respectively, from the upper layers (epidermis) of the skin:

- Basal cell: arises from the basal layer of the epidermis
- Squamous cell: arises from the superficial layer of the epidermis
- Melanoma: arises from the basal pigmented cells of the epidermis

Surgeons are often called upon to evaluate cutaneous lesions and malignancy. This chapter reviews cutaneous nonmelanoma malignancies and provides suggestions for evaluation, planning, and treatment.

BACKGROUND

NMSCs are the most common human malignancies, occurring more frequently than all other solid tumors combined. There are over 80 different NMSCs. The most common of these tumors are BCC and SCC, although several other types exist and will be discussed briefly. The frequency of these cancers is such that almost everyone living in the United States to 80 years of age will have one; as the life span increases, these malignancies become more common as the effects of sun exposure and other causative factors become more important. These are as follows:

- Reduction of protective factors in the atmosphere
- Reduction with aging in previously very effective local skin immune mechanisms responsible for tumor surveillance
- Increased sun exposure and the general reduction of immunity with progressive aging

These factors and the constantly increasing life span keep the incidence of these common malignancies increasing rapidly. Progress in the past 40 years has produced vast improvements in the classification, diagnosis, and treatment of NMSCs. Accurately identifying lesions early in their course allows classification and directed differential treatment for improved outcomes. Not infrequently, patients ignore their initial lesions, permitting development of large tumors. Disfigurement may result as not only skin tissue structures are involved but also muscle, nerves, cartilage, and bone.

Recent figures indicate that the annual cost of treating basal and squamous cell cutaneous cancer in the United States will exceed over $8.1 billion dollars. Although most of these skin lesions have a rather benign behavior as far as cancers are concerned, certain more aggressive subtypes must be identified and treated differently with wider excisions, margin evaluation, possible sentinel lymph node biopsies, and continued periodic observation for regional and distant metastatic spread. Specifically, these subtypes need complete negative peripheral and deep margin confirmation before reconstruction and, subsequently, consideration for frequent postoperative observation. Less commonly, some of these patients will need radiation and medical oncologic treatment, in addition to surgery. Although cutaneous SCC is curable with local excision for the most part, tumor recurrence, metastasis, morbidity, and even disease-specific death does occur. It is estimated that 5600 to 12,600 US patients with cutaneous SCC will develop nodal metastasis, and 4000 to 8800 will die from the disease. Although few surgeons would recognize it initially, these numbers of disease-specific death are similar to deaths from melanoma, leukemia, non-Hodgkin's lymphoma, and renal and bladder cancers.

RISK FACTORS AND PRECURSOR LESIONS

Risk factors for BCC and SCC include a number of carcinogens. The most agreed on is sunlight. Cumulative exposure to sun, especially tropical sun without protection, in fair-skinned individuals who burn rather than tan, is the most generally discussed and accepted risk. Tumors are more common on sun-exposed surfaces such as the face, scalp, and neck. Sun lamp or ultraviolet light treatment for psoriasis is a risk factor for squamous cell skin cancers. Microtrauma to the skin contributes to the etiology of basal cell skin cancers. Radiation exposure, such as historically commonly delivered for acne in teenagers, also predisposes to skin cancer and thyroid cancer.

Because sun exposure has been implicated in the predisposition to these lesions, there has been considerable attention to programs aimed toward preventing excess exposure, especially sunburns. Two guides to this prevention are "Safe Sun Guidelines" and "Skin Protection from Ultraviolet Light Exposure" (available from the Skin Cancer Foundation). The exact effectiveness of prophylaxis is not known but is under extensive study. Sun-protective clothing is also offered.

Genetics and hereditary conditions such as basal cell nevus syndrome predispose to the development of hundreds of multiple cutaneous basal cell skin cancers. Northern Europeans, such as those of Irish and English heritage, also seem more prone to the development of skin cancer. Mutations in the *RIS* and *DOS* oncogenes have been implicated as well as the sonic hedgehog-signaling pathway for basal cell skin cancer. The *PTCH* (patched) gene on chromosome 9Q has been suggested in the genesis of these lesions.

A very significant factor in the development of NMSC is associated with the advances in solid organ transplantation and the medical immunosuppression management for the maintenance of those organs. This progress has rendered longer life spans for these

FIG. 1 Cutaneous malignancies in organ transplant recipients are common and can behave more aggressively than in a similar, immunocompetent patient. This patient, who had a history of kidney transplantation, presented with two large, rapidly growing cutaneous tumors.

patients but is associated with a high risk of NMSC development as well as poor disease prognosis. We have also seen an increase of immunomodulating drugs for many medical conditions such as IBD, rheumatoid arthritis, and several others.

Fifty percent to 70% of OTR patients are affected by NMSC, and posttransplant BCC risk linearly increases, whereas SCC incidence rises exponentially (Fig. 1). This is reflected in the switch from a usual 4:1 ratio of BCC to SCC. SCC is the predominant OTR NMSC observed (although BCC is still highly prevalent). Merkel cell carcinoma occurs in OTRs at 5 to 10 times greater rates compared with the general population. Functional immunosuppression via HIV, lymphoma, and leukemia is a risk factor for NMSC and portends poor disease prognosis.

INITIAL EVALUATION OF SUSPECTED CUTANEOUS MALIGNANCY

Clinical Evaluation

History and physical examination remain the mainstay of initial diagnostic workup in cases of suspected cutaneous malignancy, noting identification of relevant risk factors, especially as they relate to prior carcinogen exposure, genetic cancer syndromes, or immunosuppression. A generalized skin and physical examination must include several key elements: (1) comprehensive skin evaluation of the surrounding area; (2) for lesions in the head and neck region, suspicion should be raised for those in the hair-bearing scalp or behind the ears. A complete regional examination of the skin and lymph nodes, and a complete, careful skin examination is performed because of the frequency of additional lesions. Attention should be directed particularly to sun-exposed skin sites. Patients with BCC and SCC are at increased risk for developing melanoma as well as additional NMSCs.

The clinical appearance of lesions such as squamous cell and basal cell are characteristic. They include color change, nodularity, and ulceration. Scaling and telangiectasia are frequent. Generally, the skin is reddened and thickened. Flaking or keratoses may be present, and both types of lesions frequently demonstrate surrounding premalignant lesions, such as keratoses. Frequently, squamous cells arise in areas of actinic keratoses, known *precursor lesions*.

The physical examination and evaluation of BCCs and SCCs first includes an analysis of tumor location and size. The tumor should be characterized by its apparent appearance as a particular skin cancer type. This evaluation should map the borders of the tumor, the entire local and regional area, and examine local lymph nodes. The lesion is classified as primary, recurrent, or one with less common features. The general health of the patient may dictate treatment considerations. Certain locations have been known to predispose to recurrence (such as fusion planes, which are areas where the primitive parts of the face come together in the fetus) in head and neck BCC, the areas of the nasal labial fold, and the groove between the nose and the cheeks. Certain areas such as the ear, mucosal surfaces, genitalia, and lip, tend to produce squamous cell skin cancers that possess a greater capacity for metastasis (Table 1). The "mask area" of the face has been known to have deeper skin cancers that are prone to incomplete resection and therefore have a higher risk for recurrence or persistence. Those lesions greater than 2 cm in diameter or more than 2 mm in thickness present more risk of persistence and recurrence than do smaller lesions.

In general, all lesions that have higher risk should have surgical complete margin assessment, preferably at the time of resection. Enlarged nodes must be carefully documented and warrant further diagnostic workup. Contrast-enhanced CT or MRI can be used for evaluation of clinically suspicious lymphadenopathy. Soft tissue disease including nerve invasion is best discerned by the use of MRI. Bone or cartilage invasion is best evaluated with CT. Ultrasound-guided fine-needle aspiration biopsy can be used to evaluate suspicious lymphadenopathy.

BASAL CELL CARCINOMA

BCC is the most common malignancy observed in adults. There are at least 5.5 million new BCC cases diagnosed each year in the United States alone; the risk of developing a BCC is more than 20% over the course of an entire lifetime, and its incidence more than 4 times that of SCC. The predominant risk factor for the development of BCC is ultraviolet light exposure, primarily UVB. The strength of

TABLE 1 High-Risk Clinical NMSC Parameters That Predict Incomplete Excision and/or Metastasis per the National Comprehensive Committee on Cancer

Anatomic location
- Mask areas of the face ≥6 mm are considered high risk
  - Central face: nose, lips
  - Eyelids, eyebrows, and periorbital skin
  - Ear, preauricular, and postauricular skin including postauricular sulcus
  - Temple
  - Genitalia
  - Hands, feet
- Nonmask areas of the face, head, and neck ≥10 mm
  - Cheeks
  - Forehead
  - Neck
  - Scalp
- Tumor size ≥2 cm on the trunk or extremities

Immunosuppression: seemingly low-risk tumors can be aggressive and metastatic
- Organ transplant recipients, particularly kidney and heart
- HIV
- Lymphoma and leukemia
- Long-term immunosuppression

Recurrence or chronic conditions
- Chronic inflammation (such as burn scar or other chronic wounds for SCC only)
- Prior radiation therapy

the causal relationship is not as clear as in the case of SCC. UV light induces inflammation of the skin that clinically results in visible erythema. On the molecular level, prostaglandin synthesis is markedly increased through the induction of cyclo-oxygenase-2 (COX-2). COX-2 is induced by inflammation. COX-2 inhibitors markedly decrease the incidence of cutaneous SCC and BCC. Other important risk factors include individuals with fairer skin, freckling, or blonde or red hair coloring. Genetic syndromes such as basal cell nevus syndrome and xeroderma pigmentosum are less common but strong risk factors. Finally, a history of immunosuppression, especially in the context of solid organ transplantation, poses a substantial risk for the development of BCC.

BCC is a mostly indolent entity from the perspective of metastatic or mortality risk. Untreated BCC is most concerning for local tissue destruction as opposed to systemic involvement or death. As a result, the goal of treatment is complete elimination of the primary lesion, sparing of as much healthy tissue as is reasonably achievable. Surgery is typically the preferred treatment and will be discussed in detail later. Less commonly, in circumstances such as very large tumors, cosmetically challenging areas, patients who cannot tolerate surgery, or for palliative treatment of BCC, radiotherapy can be employed with an expected success rate of 90% or more. The problem arises with identification of recurrence in the irradiated bed. There is no pathologic margin status to review and no specimen for microstaging. Medical therapies with topical 5-fluorouracil (5FU), topical imiquimod cream, and intralesional injection of interferon-α-2b have been studied and show some success. More recently, the novel hedgehog pathway inhibitor, vismodegib, has become an option for treatment of challenging or metastatic disease.

The majority (80%) of BCCs will manifest as lesions of the sun-exposed areas of the head and neck. Although it is tempting to treat the subtypes of BCC as superfluous minutiae, knowledge of the different pathologic entities that exist under the umbrella of BCC is essential to prognostication and appropriate treatment.

The most common subtype of BCC is the nodular type, comprising about 50% of all BCC tumors. This entity often presents with a shiny, pearly papule or nodule with a smooth surface and surrounding telangiectasias. Over time, lesions enlarge, ulcerate, and develop a more prominent rolled edge. The most likely location is the face, but other hair-bearing skin areas can also develop nodular BCC; non–hair bearing areas rarely develop these lesions.

Superficial BCC is the second most common, accounting for approximately 20% of all BCC tumors. Masses of this type are most often well-circumscribed, erythematous, and either truly flat macules/patches versus thin papules/plaques. An atrophic quality with associated hypopigmentation is common.

Nonaggressive subtypes of basal cell skin cancers include the keratotic, infundibulocystic, and nodular types and superficial types. Primary lesions in this group may generally be managed with 5-mm resection margins. It is very unusual for BCCs to exhibit lymph node or systemic metastasis. Lesions that do exhibit these aggressive traits have frequently been neglected, previously radiated, or multiply recurrent lesions.

Aggressive subtypes possessing more risk have more aggressive growth. These include the micronodular, infiltrative, sclerosing, morpheaform, and desmoplastic types and "basosquamous" carcinoma.

Some basal cells are pigmented and are easily confused with melanoma by appearance. The difference is often only established pathologically. Micronodular, infiltrative, and sclerosing tumors are notorious for a subclinical component that spreads laterally, leading to a high recurrence rate compared with other BCC subtypes. The final two subtypes worthy of a brief discussion are the basosquamous and morpheaform BCCs. The basosquamous family of tumors exhibit the worst features of BCC and SCC, most notably with tendencies for aggressive local growth, recurrence despite treatment, and metastasis in nearly 10% of cases. Morpheaform lesions have an indurated quality that is usually light pink to white in color with ill-defined borders and areas of regression. Aggressive local tissue destruction is the rule as opposed to the exception.

Basal Cell Nevus Syndrome

Basal cell nevus or Gorlin syndrome or nevoid BCC syndrome is an inherited disorder that presents with multiple cutaneous basal cells, multiple odontogenic keratocysts of the jaws, musculoskeletal and neurologic abnormalities, and pitting of the palmar and plantar surfaces of the skin. The disease is autosomal dominant. The lesions behave as basal cell skin cancers and are usually managed with surgical excision.

Usually, patients will have hundreds of basal cell skin cancers over the course of their lifetime, and many eventually succumb to the disease as sheer numbers overwhelm treatment. Topical chemotherapy agents have been used in an attempt to eradicate early superficial nonfacial basal cells, but surgical excisions are the treatment of choice.

SQUAMOUS CELL CARCINOMA

SCC of the skin is the second most common malignancy, with more than 3.3 million new cases diagnosed per year in the United States alone. Similar to BCC, cumulative UV radiation exposure is considered the strongest risk factor for the development of SCC. In addition to the mentioned risk factors for BCC, which also augment risk for SCC, tobacco smoking, human papillomavirus infection, and chronic/nonhealing wounds are other notable risk factors for SCC. There are many histologic features of these tumors that can affect prognosis (Table 2). Originally, squamous cell skin cancers were divided into several grades; however most pathologists presently feel that two general groups of behavior, can be identified for squamous cell cancers: (1) well-differentiated lesions and (2) moderately differentiated, poorly differentiated, and undifferentiated lesions.

Although the prognosis within the latter groups becomes dramatically worse in the poor and undifferentiated categories (which, like melanomas, are capable of in-transit, lymphatic, and systemic metastasis) the tendency is to treat these high-risk lesions with wider and deeper resection margins. Sentinel lymph node biopsies in the latter group may be considered if the lesion is greater than 2 cm area or greater than 2 mm thickness (Fig. 2). Histologic confirmation of negative peripheral and deep margins before defect closure or flap reconstruction must be routinely accomplished.

SCC carries a risk of metastasis (about 5%) in patients with less differentiated lesions and in certain anatomic areas, such as the lip and genital region. The frequency is also increased for immunoincompetent individuals, who tend to have less differentiated lesions. The mainstay of treatment for most lesions is surgical excision.

Radiotherapy has a role in the treatment of BCC for patients who are poor surgical candidates, those receiving palliative treatment, or those in whom the sheer volume or anatomy of the surgical resection would challenge appearance or function. Of course, radiation is used in the adjuvant setting for patients with aggressive disease and or metastasis to regional nodal beds. There is a subset of SCC lesions that manifest with perineural invasion (as evidenced by the

TABLE 2 High-Risk Histologic Features of Squamous Cell Carcinoma

- Differentiation (moderate or poor)
- Perineural involvement
- Desmoplasia or desmoplastic
- Adenoid, adenosquamous
- Tumor thickness/level of invasion ≥6 mm or involvement of subcutaneous fat
- Lymphovascular involvement

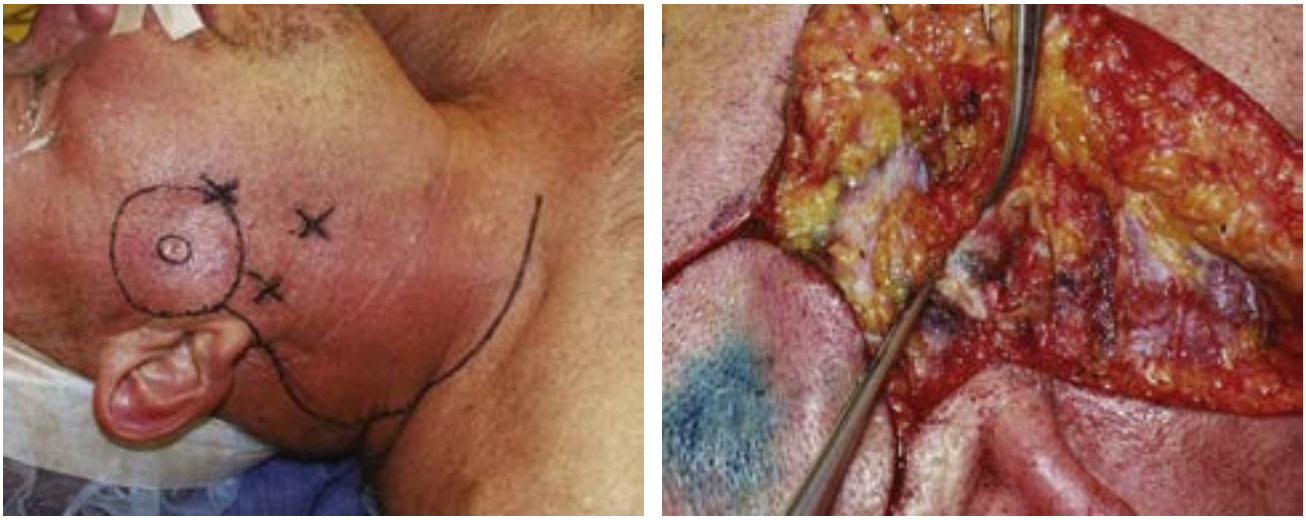

FIG. 2 Sentinel lymph node biopsy has a limited, though important, role in prognostication for squamous cell carcinoma. Particularly high-risk lesions can prompt evaluation of the sentinel node. In this patient with a high-risk lesion, the sentinel lymph node can be seen as the blue tinged tissue at the tip of the instrument, indicating a positive node.

development of neuropathic symptoms or on pathology). These lesions are at higher risk when named rather than unnamed nerves are involved, and contrast MRI will assist in defining the extent of involvement.

Any discussion of SCC requires mentioning important precancerous lesions and in situ malignancies that are both direct precursors to the frankly malignant lesions of SCC. Actinic keratoses are exceedingly common and represent disordered keratinocyte growth that is limited to the epidermis. The growth occurs as a direct result of photodamage, which explains the predilection for the head, neck, upper trunk, and extremities. Although the morphology of these lesions can be quite variable, they classically present as a rough erythematous papule with prominent white to yellow scaling. Associated tenderness portends a higher probability of associated squamous carcinoma.

Keratoacanthoma Squamous Cell Variant

Keratoacanthomas comprise a group of cutaneous neoplasms that share many features of SCC but are unique enough to merit individual discussion at a genetic level. Keratoacanthoma lesions may double in size quite rapidly. The more rapidly growing lesions should be removed for diagnosis as soon as feasible because most of these lesions are malignant. Keratoacanthomas most often manifest as a solitary lesion that grows rapidly over several weeks into a sharply circumscribed nodule with a cratered, keratotic core. The lesions are characteristically sensitive or painful when touched, and sensory nerve symptoms such as numbness, pain, burning, and paresthesia are concerning and should raise suspicion of SCC. Motor nerve involvement is much less frequent and occurs in extensive or deeply penetrating lesions that exhibit paralysis, weakness, or double vision, placing treatment of the tumor in a high-risk category. A contrast MRI is the best modality to document major nerve invasion.

Most lesions occur on the head and neck or in sun-exposed areas of the extremities. Occasionally, the lesion will spontaneously resolve over several months, leaving behind an inconspicuous atrophic scar. Because 95% of these lesions will continue to grow and not involute, creating a much larger lesion which is difficult to treat, it is our recommendation to excise them as growth is frequently alarmingly rapid (doubling every few weeks), and complete removal is always more challenging when larger. They should be treated identically to SCC as even pathologic differentiation from the benign variant is difficult. Recently, syndromes of elderly individuals with multiple keratoacanthoma squamous cells have occurred (frequently on the legs in severely sun-damaged skin), coming back frequently, even in resected squamous cell cancer scars, challenging treatment. Some have postulated a viral etiology. Injections of 5FU have been utilized with success in some patients, especially when multiple lesions appear almost simultaneously in elderly patients or if patients are not good candidates for operative resection.

Subtypes of squamous cell variants, such as the adenoid cystic type or adenosquamous carcinoma, are tumors whose more aggressive behavior characteristics increase the risk of incomplete resection, recurrence, and metastasis.

Desmoplastic cutaneous squamous cell carcinoma has a higher risk of recurrence as a result of incomplete resection because of subtle deeper extensions along fascial planes with failure to achieve clear margins. Some have suggested that invasion of a tumor into the fat or invasion deep enough to penetrate lymphatics constitutes more potential for recurrence and metastasis, as is known with melanoma.

Squamous Cell Carcinoma in Situ

Squamous cell carcinoma in situ represents full-thickness atypia of the upper skin layer (epidermis). Because the lesions are noninvasive, they are treated by simple complete excision because metastasis is not possible. As a pathologic entity, SCC in situ involves the abutment of neoplastic cells onto the epidermis but not into the dermis. Clinically, these lesions resemble eczema or psoriasis and have a characteristic pink to red color with scaling and sharply demarcated borders. Patients who have had development of SCC from SCC in situ are thought to have a roughly twofold to threefold higher chance of metastasis, especially in cases of mucosal, lip, or perineal SCC in situ. Topical chemotherapy agents such as 5FU, imiquimod, or cryotherapy can be utilized for SCC in situ; however, excision with margin confirmation is preferred for recurrence, persistence, or previous treatment failures. It is difficult to predict the cure rate of these treatments because they are not predicated on complete biopsies, and follow-up is generally incomplete and lacking biopsy proof of eradication. Immune modulators can also be offered for extensive disease or for patients who are not candidates for surgical treatment, and success has been described with vismodegib.

Certain precursor lesions, such as actinic keratoses, are precancerous. Actinic keratoses are red, crusty lesions that weep and

sometimes develop cutaneous horn proliferation or thick layers of flaky skin. They have an incidence of in-situ and invasive squamous cell skin cancer development of at least 10% (0.1%/year); therefore, treatment of these lesions with liquid nitrogen, a topical chemotherapy, or excision seems reasonable. However, recurrence should be a marker for progression to SCC and should be treated accordingly. Actinic keratoses may regress and reappear. SCC may be preceded by SCC in situ. Two syndromes are Bowen's disease and Paget's disease, which are types of SCC in situ that affect the breast and perineal areas and may progress to invasive SCC.

Bowen's Disease

Bowen's disease is an erythematous, plaquelike lesion that represents a low-grade, slow-growing intraepithelial variant of SCC. Essentially, the growth of this tumor is intraepidermal, and its history and progression are similar to other intradermal carcinomas such as erythroplasia of Queyrat or Paget's squamous cell disease. It is a less common malignancy that appears as a circumscribed, red or pink patch that can weep and present a scaly appearance. Many lesions occur on the trunk, lower extremities, and genitalia, but the lesions can involve the head and neck region. The progression of the lesion is slow and limited and extends normally over years. Invasive SCC can arise in these lesions, and if so, metastasis is possible. Excision to clear the margins with an initial 5-mm margin is recommended, and Mohs excisions with margin evaluation are favored. Larger lesions may require flap coverage or skin grafting. In the head and neck, cosmetically sensitive flap reconstructive techniques are preferred when primary closure is not possible.

SURGICAL EVALUATION AND TREATMENT

Biopsy

The gold standard in diagnosis of cutaneous lesions is full-thickness skin biopsy to at least the reticular dermis (infiltrative histology, deeper penetration, higher-risk lesions). Pathologic information that results from this biopsy depth includes lesion type, differentiation, histology, histopathologic subtype (for SCC and BCC), ulceration, perineural involvement, vascular involvement, degree of differentiation (SCC), tumor depth (SCC), and tumor thickness (SCC). A shave biopsy of a squamous cell skin cancer will frequently be read as SCC in situ and not confirm any invasive component.

Recall that SCCs with poorly or undifferentiated histologic characteristics and those greater than 2 cm in area or more than 2 mm thick (tumor can invade lymph vessels in the dermis) are at higher risk for infiltrative spread and lymph node involvement. Based on the histologic confirmation of aggressive characteristics, a sentinel lymph node examination or more aggressive resection may be considered. Clinically enlarged nodes should be evaluated with an ultrasound-guided fine-needle aspiration biopsy. The use of the ultrasound guidance allows for a more accurate biopsy, focusing on the most suspicious area of the node based on vascularity and echo texture. This process will help avoid the problem of false-negative biopsies.

RISK PROGNOSTICATION

Appropriate management of NMSC depends on formulating an appropriate risk estimate. A small, slowly growing SCC found in an immunocompetent patient is an entirely different entity than a large, rapidly growing, painful SCC located in the amputation stump of an immunocompromised patient. The workup and treatment for these lesions would be different and is influenced by the risk stratification of a lesion. This includes advanced imaging or diagnostic procedures, different surgical margins, need for lymph node biopsy, consideration for referral to medical or radiation oncology, and follow-up (see Table 1).

Area L: trunk, extremities; Area M: cheeks, forehead, neck, scalp; Area H: "mask areas" of face (central face, eyelids, eyebrows, periorbital, nose, lips, chin, mandible, preauricular and postauricular skin/sulci, ear, temple), genitalia, hands, and feet.

SURGICAL MANAGEMENT OF NONMELANOMA SKIN CANCER

Once a diagnosis is made, (either clinical diagnosis with a high degree of certainty or pathologic diagnosis), a surgical plan may be formulated. All surgical plans have a few commonalities, including expected margins, plan for margin evaluation and amount of resection desired, and type of wound closure or reconstruction.

Markings and Margin Considerations

A systematic approach to marking begins with first tracing the extent of the lesion itself. In straightforward cases, there will be stark differentiation between the abnormal tissue and the normal tissue with an obvious border. Commonly, confounding factors such as marginal erythema, telangiectasias, or dyspigmentation may add confusion in determining which areas of skin constitute the lesion.

Next, an uninvolved segment of tissue is added: the *surgical margin.* There are published and widely circulated national guidelines for resection margins for both BCC and SCC that are confirmed by high-level clinical data from expert national group consensus. Our practice is to follow recommendations from the National Comprehensive Cancer Network (NCCN) in the United States listed in Table 3, which are intelligent, comprehensive, and pragmatic.

Evaluation of Margins and Confirmation of Negative Margins

Marginal evaluation is the most critical aspect of tumor extirpation. An operation that removes some tumor but not all introduces the morbidity of surgery without the benefit of cure. With this in mind, surgeons must be well equipped to fully understand that both all peripheral and deep margins are evaluated. Guidelines exist for peripheral margin distance, as listed earlier, but deep margins are often determined by the surgeon's decision making or, in the case of Mohs micrographic surgery, real-time pathologic evaluation.

Techniques for rapid or intraoperative evaluation of margins include frozen-section assessment and Mohs micrographic surgery. Frozen-section assessment is done by laboratory-based pathologists and considers representative "breadloaf" or interval margin samples. The Mohs technique produces an immediate determination of the full length of the cutaneous margin as well as the deep margin. In

TABLE 3 Recommendations from the National Comprehensive Cancer Network

Tumor Type and Risk	Recommended Margin
Local, low-risk SCC	4–6 mm
Local, high-risk SCC	10–15 mm
Local, low-risk BCC	4 mm
Local, high-risk BCC	3 mm followed by 3 mm if first margin positive; consider Mohs surgery
Dermatofibrosarcoma protuberans	3–5 cm and down to investing fascia; consider Mohs surgery
Merkel cell carcinoma	1–2 cm; include sentinel node biopsy

BCC, Basal cell carcinoma; *SCC*, squamous cell carcinoma.

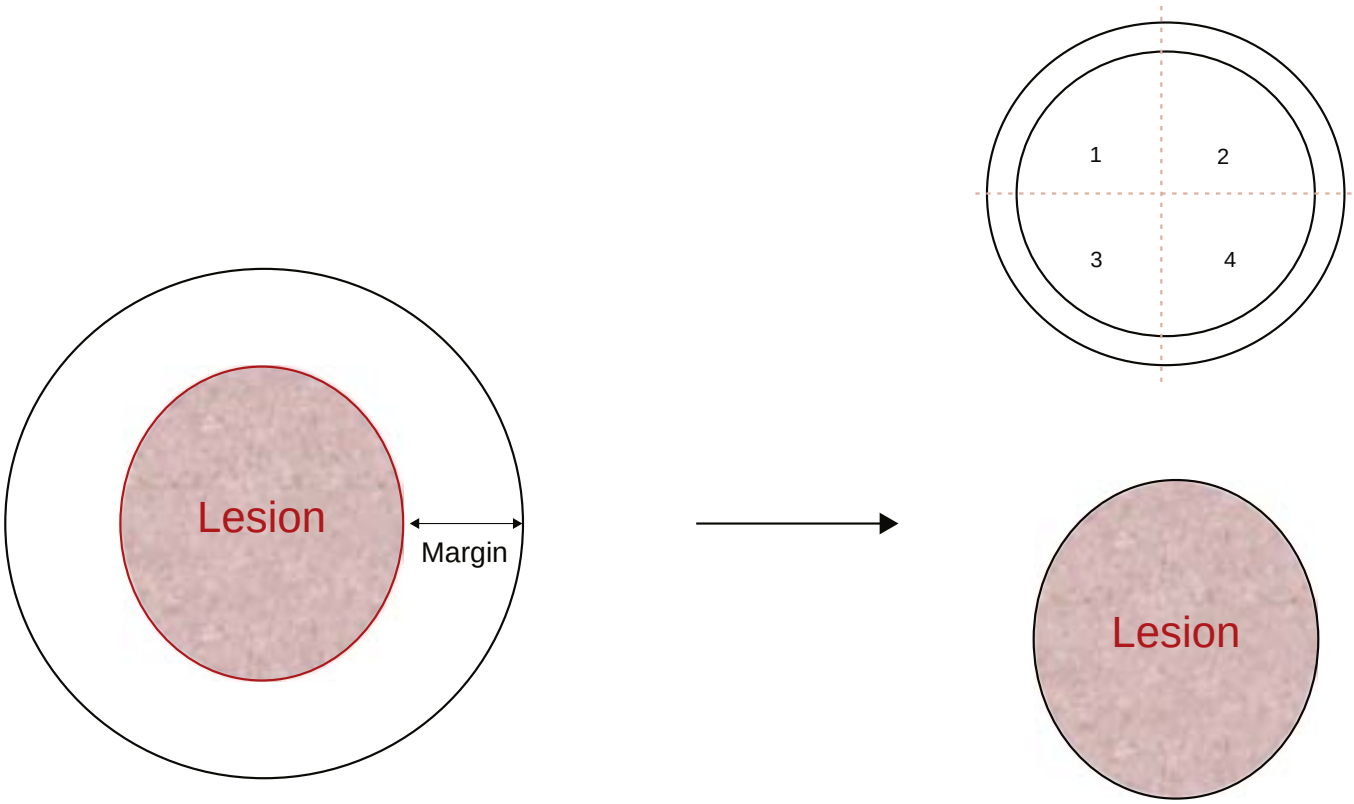

FIG. 3 The authors' preferred method of excisional biopsy and margin evaluation. The appropriate margin should be measured, and this annulus of tissue is excised. It is recommended to section this into four pieces, which can each be viewed by the pathologists as a linear specimen; it is important to make note of which segments came from which portion of the wound. The lesion itself is then sent as well as its own specimen for pathologic review.

either case, the surgeon may request permanent sectioning when unclear. In the case of equivocal margin status, the wound should be temporized with allograft or dressings until final permanent margins are available.

An alternative approach to rapid margin evaluation is to excise a thin rim of tissue from all quadrants at the estimated periphery of the lesion. Each skin section from each quadrant is then labeled and sent individually for analysis guaranteeing identification, and each thin defect is closed primarily (Fig. 3).

The situation of a patient being referred for reconstruction following resection by an outside physician is worth a brief discussion. One course of action is re-resection of a thin margin around the initial resection bed, regardless of the outside pathology report, which serves to even and square the edge, trim a contaminated or devascularized edge, and provide an additional clean margin for further pathologic confirmation. It has been our experience that the rate of residual tumor identified on such secondary marginal examinations may reach 10%.

Considerations for Enlarged Lymph Nodes

If an enlarged node is identified or the lesion is high risk, lymph node sampling is suggested. Sentinel node biopsy or fine-needle aspiration biopsy with ultrasound guidance would be the first options for nodal interrogation. If these modalities are not available, directed, open biopsy may be considered. The author prefers at least consideration of sentinel node evaluation in poorly differentiated or undifferentiated high-risk squamous cell skin cancer; however, the benefit of routine lymph node evaluation in less differentiated squamous cell cancers has *not* been proven. In the event of nodal disease, surgical resection or consultation with medical and radiation oncology should proceed. Many institutions have multidisciplinary conferences in which these discussions occur weekly.

NONSURGICAL MANAGEMENT OF NONMELANOMA SKIN CANCER

Surgical excision is most often the preferred therapy for cutaneous nonmelanoma malignancies. There are a small number of patients who are not candidates for surgery. The most common reason for this is substantial medical morbidity that limits the safe administration of anesthesia. Other patients are resolutely against surgical excision for a variety of reasons. Finally, certain lesions may not be well treated with surgery, such as diffuse lesions of Bowen's disease or those in anatomically sensitive areas that are functional and difficult to reconstruct.

Also, it must be understood that small, noninvasive in situ and precancerous lesions may be treated very effectively with nonsurgical modalities.

Imiquimod is a topical immunomodulator that now provides two different formulations (1% and 3%) that are approved by the US Food and Drug Administration (FDA) for precancerous actinic keratosis, actinic cheilitis, and small truncal superficial BCC lesions; dosing frequency and duration depends on the indication and formulation. Imiquimod functions by inducing local antitumoral cytokines that produce a striking inflammatory breakdown of areas involving superficial BCC and precancerous actinic keratoses. Erosions can be quite extensive depending on the treated area; erosions are predisposed to infection and may require antibiotic treatment during imiquimod therapy. It is important to note that many practitioners

now use imiquimod for off-label, non–FDA-approved uses, such as low-risk BCC (other than superficial) histology or anatomic sites other than the trunk (such as the face).

Liquid nitrogen is very effective for precancerous actinic keratoses and low-risk BCC. Actinic keratoses can be treated with a few seconds of exposure, while BCC requires successive rounds of tissue freezing.

5FU is topical chemotherapy, a derivative of the deoxyribonucleic acid uracil, that intercalates into DNA; rapidly dividing cells (such as NMSC and precancerous actinic keratosis) take up more 5FU, inducing necrosis. Similar to imiquimod, it can cause extensive erosions, and superinfection is common. 5FU has generally fallen out of favor because it is mutagenic on normal tissue and predisposes treated patients to cancer, which makes it a less appealing option compared to nonmutagenic imiquimod.

Electrodessication and curettage effectively treats truncal or extremity low-risk BCC, whereby the tumor is aggressively debulked with a curette, and then a broad-tipped curette tip is used under the electrodessication setting to ablate the bed of the tumor. This is repeated two additional times. Advantages are that it is quick, simple, has a good cure rate, and has favorable healing (a small circular white scar). Disadvantages include wound care required sometimes for weeks, which may be inconvenient if a patient does not have anybody assisting them at home.

Radiation as Primary or Adjunctive Treatment

Radiation therapy in cases of primary straightforward NMSC of the basal or squamous type can often produce good cure rates (90%) and excellent cosmetic results. Multiple treatments are required over a period of weeks, and there is no confirmation of negative margins, nor is there complete examination of the histology of the lesion to confirm complete histologic characteristics. The authors have found that many elderly patients with lesions of the lower extremities do not do well in terms of cure or residual symptoms following radiation treatment. Young patients in whom there is risk of further radiation-induced malignancy are generally treated with surgery. The use of radiation as a primary treatment modality will often preclude its further use as an adjuvant modality in the same area, thus limiting the possibility of using radiation for the management of recurrence or new disease.

Radiation therapy has also been utilized as adjunctive treatment in patients in whom the margins are histologically but not clinically positive or for perineural involvement or where the danger of intralymphatic spread into adjacent skin is high. Patients who have extracapsular extension, referred to as *soft tissue disease,* of tumor are also candidates for postoperative radiation. Patients with more than two positive nodes will be considered for adjuvant radiation to the nodal basin.

CONSIDERATIONS FOR METASTATIC DISEASE

Treatment of metastatic disease often employs medical oncologic or radiotherapy. Some encouraging results have been obtained with immune modulators, such as vismodegib. Patients with disease remaining following radiation may be candidates for vismodegib, a hedgehog pathway inhibitor. This drug has shown some efficacy in the management of metastatic and inoperable BCC.

Although several chemotherapeutic agents have been described in case studies or small patient cohorts, only one randomized controlled trial (RCT) has been conducted, demonstrating a 34% overall response rate for a cisplatin-based regimen. EGFR inhibitors evaluated for use in cutaneous SCC by RCTs include cetuximab, panitumumab, and gefitinib; response rates ranged from 15% to 31%. Inhibitors of the immune checkpoint programmed death-1 (PD-1) have yielded promising outcomes in advanced cutaneous SCC. The PD-1 inhibitor cemiplimab recently received FDA approval for use in advanced cutaneous SCC. Despite these advances, the preferred regimen for systemic treatment of cutaneous SCC remains unclear, particularly in immunocompromised populations.

Long-Term Follow-up of Basal Cell and Squamous Cell Skin Cancers

All patients with BCC and SCC, especially those with high-risk lesions, should have a complete skin examination periodically with special attention to the area of origin, where recurrence, either locally or regionally, is likely. Although most recurrences of lesions develop within a 2-year period, rarely a tumor will recur after 5 to 10 years.

Nonaggressive skin cancer types will recur in about 50% of lesions with positive histologic margins. One-third to one-half of patients having a basal or squamous cell skin cancer will develop a second primary lesion within the next 5 to 10 years. Follow-up schedules should be tailored to the particular severity and extent of disease and to the risk of recurrence.

OTHER MALIGNANT CUTANEOUS ENTITIES

There are dozens of cutaneous malignancies that do not arise from keratinocytes, all of which are substantially less common than BCC and SCC. There is a handful worthy of a brief mention, but we encourage interested readers to pursue further reading in a cutaneous oncology text.

Merkle Cell Carcinoma

Merkle cell carcinoma is a rare neuroendocrine skin cancer with about 1600 cases diagnosed in the United States annually. It is characterized by rapid growth and very aggressive behavior. A firm, intradermal, red nodule rapidly progresses to ulceration. Recently, some lesions have been traced to a polyomavirus infection, and the disease is more frequent in patients receiving immunosuppression. The disease progresses rapidly by intravascular and lymphatic spread. Therefore, initial positron emission tomography (PET) imaging should evaluate the possibility of regional and distant spread. Prognosis is often predicted by positive regional lymph nodes, which occur in 25% to 30% of N0 patients (no clinical evidence of nodal disease). The disease often tends to be undertreated by limited surgical resections; thus, local failure is common (up to one-third of patients). Local control may be improved by larger resection margins that often generate the need for skin grafting. The current NCCN guidelines recommend excision with a 1- to 2-cm margin down to fascia or periosteum (level III evidence). The creation of surgical wide margins must be balanced with the potential morbidity of this surgery. For instance, would it be appropriate to resect upper and lower eyelids for a Merkel cell carcinoma of the lateral cheek? The rate of local recurrence, even in the face of wide local excision, ranges from 25% to 40%. Sentinel node biopsies are routinely recommended.

Periodic follow-up with local, regional, and systemic monitoring is recommended. Although most recurrences occur in the first 2 to 3 years, survival is best predicted by the presence of nodal and distant disease. The behavior of Merkle cell cancer is usually more aggressive than significant invasive melanomas, and in fact, the mortality exceeds that of melanoma. The histologic diagnosis is confirmed by performing immunohistochemical staining (IHC). Because of the frequency of local failure in treatment when surgical margins are compromised, some have recommended postoperative radiation therapy for the primary tumor, draining lymphatics, and regional lymph node basins. The added value of this treatment when surgical margins are generous, negative sentinel lymph node biopsy is obtained, and PET scans are negative has not been established. Adjuvant chemotherapy for regional disease has also been recommended (positive regional node disease) in addition to surgery, but its value is unproven. The diagnosis of Merkle cell cancer portends a high risk

of local, regional, and distant recurrence. The 5-year disease-specific survival ranges from 60% to 87% for local disease, 39% to 62% for nodal disease, and 20% for distant metastatic disease. The median time to recurrence is 7 to 9 months, with 80% to 90% of recurrences occurring within the first 2 years. The draining nodal basin is the most common site for recurrence. Because of the high recurrence rates, patients should be evaluated every 3 to 4 months for the first 2 years following treatment.

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans (DFSP) is a rare intermediate-grade soft tissue sarcoma that usually features indolent irregular, trabecular, and infiltrative growth with projections a far distance from the primary tumor. The final diagnosis is often delayed because of the innocuous appearance of the initial tumor. This will often lead to inadequate resection and recurrence. Approximately 85% to 90% of DFSPs are low grade; the remainder contain a high-grade sarcomatous component (which is usually a fibrosarcoma, designated DFSP-FS) and are considered to be intermediate-grade sarcomas.

The age range of affected individuals is usually between 20 and 50 years of age. Most lesions are located on the trunk or proximal extremities, with the head and neck area affected less commonly. Some patients provide a causal history of trauma; however, the relationship has not been proven. The lesion is slowly growing as a rule (and for practical purposes does not metastasize); however, it has a strong tendency for local fascial extension along tissue planes in small, thin fingers, that defy clinical and pathologic perception. Standard surgical excisions without Mohs pathology have yielded up to a 60% recurrence rate, generating the recommendation that 3- to 4-cm clinical margins or better Mohs surgery be utilized.

The DFSP presents clinically as a painless, firm, red to brown or purple plaque. It can demonstrate soft areas or protrusions. This indolent presentation is often enough to prevent early diagnosis because of its benign nature. The diagnosis can prove difficult, and differentiating it from other fibrotic skin processes can require special stains. Negative biopsies in one area should not be reassuring but should prompt more biopsies and/or complete excision of a suspicious lesion. Immunostaining with CD-34 factor, XIIIA metallothionines, tenascin, and stromelysin-3 are helpful in making the diagnosis. The lesion is frequently misdiagnosed both clinically and pathologically and underestimated surgically.

Treatment

Treatment for DFSP is surgical excision with wide margins, and up to 3 to 4 cm have been recommended. Currently, Mohs micrographic surgery is the surgical method of choice, which has reduced recurrence rates to about 2%. Regional lymph node biopsies are *not* indicated because the incidence of metastatic spread is so low, probably 1%. Although adjuvant radiation has been recommended following standard surgical treatment, the value of supplemental radiation in patients who have widely negative surgical margins has not been established.

Cutaneous T-Cell Lymphoma

Lymphomas may present as cutaneous lesions and include mycosis fungoides and Sezary syndrome, which are cancers originating from T4-helper cells. These are rarer tumors that appear as a reddish patch, plaque, or lump. They are sometimes oozing or have a "psoriatic" appearance. Itching is a prominent clinical symptom. Because of its benign appearance, diagnosis is commonly delayed because it overlaps in appearance with many other cutaneous dermatologic conditions. Some patients progress to frank systemic lymphoma over time, and 5-year survival rates of the skin lesion itself vary from 50% to 100% and often relate to the development of another internal serious blood neoplasm.

Therapy varies from medication such as Rituxan to excision, chemotherapy agents, or topical radiation, such as skin electron-beam therapy. In some cases, surgery provides control of local symptoms and apparent cure for limited lesions.

Angiosarcoma

This rare and aggressive vascular tumor of the skin generally occurs as a rapidly enlarging nodule or plaque, sometimes simulating a bruise. In-transit metastasis occurs quickly, and initial presentation with satellite nodules is not uncommon. There is a predilection for occurrence in the head and neck area and in the elderly. In one series, the mean age was 70 years and seemed to favor male patients. Aggressive treatment is indicated with 3- to 5-cm margins, frequently requiring flap or skin graft reconstruction. Sentinel lymph node biopsy is recommended. Local and systemic recurrence is the routine because of the tendency for in-transit metastasis, and the prognosis is quite limited, with 20% survival. These statistics and the proven aggressive behavior of this tumor have generated the recommendation that radiotherapy and chemotherapy accompany the planned surgery. Despite these additions, the prognosis remains largely unaffected by additions to the surgical treatment proposed.

Adnexal Tumors of the Skin

Adnexal tumors occur from skin appendages such as eccrine, apocrine, and sebaceous glands as well as hair follicles. Some occur from fibrous or neural tissues. Sebaceous carcinomas usually present as a slightly reddened nodule whose diagnosis is dependent on biopsy. The prognosis varies with the aggressiveness of the lesion, and wide excision with 2-cm margins to the fascia are recommended. Although some practitioners perform sentinel lymph node evaluations in more aggressive lesions, the value of these interventions remains to be proven.

NMSCs vary in severity from the relatively common and benign varieties to very aggressive and frequently lethal lesions. Treatment favors surgical resection, predicated on accurate diagnosis and classification, with the aggressiveness of treatment based on good pathologic definition of the lesion type and proper margins.

Acknowledgment

The authors wish to express their appreciation for the contributions of the panels who created the NCCN guidelines, which form an excellent and carefully considered basis for the recommendations for diagnosis and treatment of these lesions that are summarized in this chapter. The authors recommend these guidelines in the strongest terms for those wishing further information and clarification as they serve as a yearly, up-to-date summary of current recommendations for diagnosis, evaluation, and treatment.

Management of Cutaneous Melanoma

Nicholas Calotta, MD, Paul N. Manson, MD, and Anthony Tufaro, MD, DDS

Melanoma is a malignant neoplasm that arises from melanocytes, most often as a cutaneous lesion, but primary tumors also arise in other tissues where neural elements penetrate. Although melanoma accounts for approximately 5% of all cutaneous malignancies, it is the deadliest form of skin cancer, responsible for greater than 90% of deaths. It is the third most common malignancy responsible for death, and its rate of increase is much higher than for other common cancers except breast cancer. Melanoma is the ninth most common malignancy.

Ninety percent of cases present with local or regional disease, for which the primary treatment is surgical and potentially curative. Current surgical approaches have reduced disease extent and morbidity compared with historical techniques but have equivalent or superior effectiveness.

Melanoma is a rare disease, with an incidence of 22.1 per 100,000. Melanoma misdiagnosis accounts for more pathology and dermatology malpractice claims than any other cancer except breast cancer.

Prognostic factors relate to thickness, location, ulceration, and the presence of lymphatic and nodal disease. It may spread unpredictably to any organ. Melanoma also has a proclivity for arising in middle-aged adults compared with other cutaneous malignancies, which tend to appear in later life.

Given the substantial risk for morbidity and mortality, a thorough understanding of diagnosis, initial management, and subsequent follow-up care is important for surgeons who encounter melanoma in practice. Although there is an increasing trend toward nonsurgical treatment of melanoma in this era of advancing immunotherapy and targeted molecular therapy, we believe that identification by inspection and surgical tumor extirpation remains the backbone of comprehensive initial melanoma care. Thankfully, for the great majority of affected individuals, this is all that is necessary.

EPIDEMIOLOGY AND RISK FACTORS

There has been an alarming increase in the incidence of melanoma since the 1950s, especially in young Caucasian women. At that time, the incidence was approximately 1 per 100,000 in the adult population in the United States. Compare this to recent estimates reporting the incidence to be closer to 40 per 100,000 for the same population. This makes melanoma one of the fastest-growing neoplasms. Experts argue whether this is the result of heredity, environment (sun), or overdiagnosis.

Risk Factors

Substantial time and resources have been invested in identifying risk factors for the development of melanoma. From a patient-level perspective, relevant risk factors are lightly pigmented skin, red hair color, and an inability to tan/tendency to sunburn easily (Fitzpatrick types I and II; Fig. 1). Environmental factors include cumulative dose of ultraviolet (UV) radiation (either from chronic sun exposure or intense intermittent sun exposure), use of UV tanning beds, and immunosuppression. Important precursor lesions are dysplastic nevi. Finally, recent research has highlighted the important role that genetics play; numerous single-gene mutations have been implicated along with the classically associated DNA repair conditions such as xeroderma pigmentosum. Oncogenesis is thought to be based on gain-of-function mutations in oncogenes and loss-of-function mutations in suppressor genes. Two-thirds of the risk generation is felt to come from UV light exposure (natural or man made), and reduction of UV exposure, particularly sunburns, results in decreased frequency. The sun-drenched head and neck contains 9% of the body surface but accounts for 30% of melanoma cases. Whereas keratinocytes subjected to UV damage undergo programmed cell death, melanoma cells survive this insult and may change their characteristics toward malignant behavior.

Precursor Lesions

Important precursor lesions exist in melanoma in 30% of cases, some of which impart different risks for the subsequent development of malignancy. Currently the bulk of melanoma is felt to arise de novo. Acquired

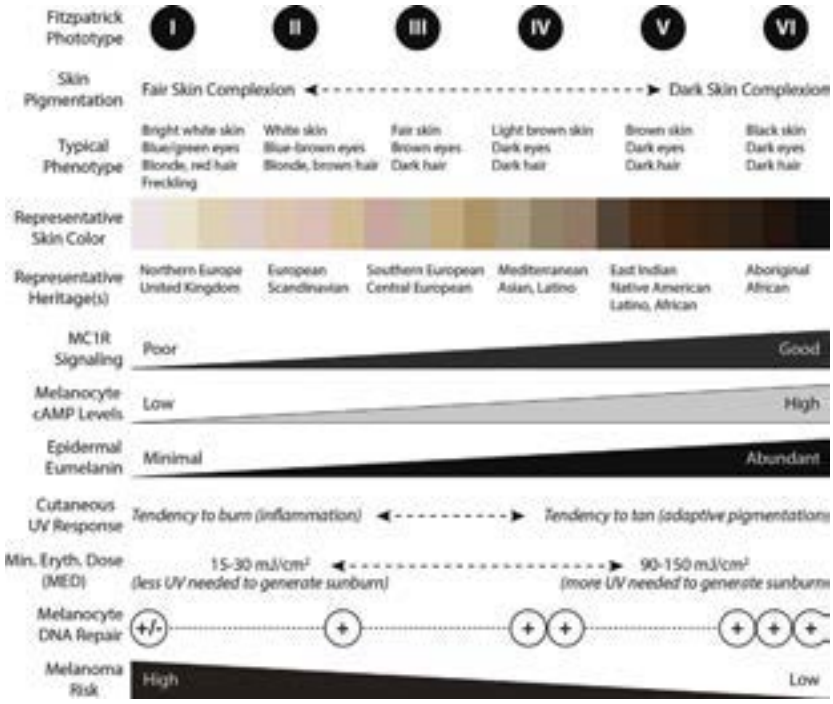

FIG. 1 Fitzpatrick skin types.

melanocytic nevi are considered the most closely related pathologic entities to melanoma; development of >100 acquired melanocytic nevi imparts a tenfold increase in risk for developing melanoma. Atypical melanocytic nevi (AMN) have both sporadic and dominant forms, as the development of >5 atypical melanocytic nevi carries a fivefold increase in risk for melanoma (Fig. 2). Finally, solar lentigines, when found in groups, are responsible for a fourfold increase in melanoma risk. Other risk groups include FAMMM (familial atypical multiple mole syndrome), AMS (atypical mole syndrome), DNS (dysplastic nevus syndrome), congenital nevi, and cellular blue nevi; all increase the frequency of malignancy. Elder in 1985 extended the theory of *nevus-melanoma transition,* postulating dysplastic nevi as a precursor to sporadic melanoma. Dysplastic nevi exist in 2% to 8% of the population.

MELANOMA, CLINICALLY AND PATHOLOGICALLY, DOES NOT HAVE SOLID DIAGNOSTIC CRITERIA

The plain fact, accounting for the challenge and difficulty of the diagnosis both clinically and pathologically, is that there are no ubiquitously agreed-upon criteria by which to make the diagnosis. Seventy percent of melanomas detected are now less than 1 mm, and many of these smaller lesions are in a diagnostic gray zone. Pathologists are increasingly evaluating lesions in a diagnostic "overlap" zone in which penalties exist for underdiagnosis but not overdiagnosis. Recently, in order to prove that a part of the increased frequency of melanoma is generated by overdiagnosis, a group of pathologists were asked to re-read their own slides from 20 years ago, and there was a significant increase (60%) in diagnoses of melanoma versus benign/dysplastic nevi. The conclusion is that a portion of the increased frequency of melanoma is physician generated by threat of litigation for "underdiagnosis." This fact would also account for some of the increased survival.

There are two forms of melanin produced by melanocytes: the black/brown pigment eumelanin, and the red/yellow pigment pheomelanin. The ratio of these compounds produces skin color, rather than the absolute number of melanocytes. Eumelanin is a better UV shield, whereas pheomelanin is less protective and has a higher DNA damage in response to sunlight.

MELANOMA CLASSIFICATION

Melanoma is an umbrella term that encompasses a collection of heterogenous neoplastic lesions arising from melanocytes. Understanding the major differences among these entities is paramount to providing appropriate surgical care. The heterogeneity of forms makes clinical and histologic diagnosis difficult. Melanomas of the skin start from the basal layer of pigment cells. They first grow horizontally or radially within the epidermis. In this stage, they are at first *melanoma in situ* (see Fig. 2) and are not invasive. This stage may be long or short. They then may change their surface antigens and cytogenetic profiles to develop a vertical growth phase. Steps in the process may be rapid or slow. As melanoma invades the mid-dermis, it reaches the area where blood vessels and lymphatics are present, and metastasis is then possible, either into the adjacent skin (in transit metastasis) or regionally and distally through lymph or blood.

Superficial Spreading Melanoma

This is the most common subtype of melanoma, accounting for approximately 75% of all cases (Fig. 3). Although the risk of any individual nevus progressing to melanoma is very low, nevi that progress to malignant transformation manifest as superficial spreading lesions most often. They have first a radial and then a vertical growth phase; 30% begin in a preexisting nevus, but the majority arise de novo.

FIG. 2 Dysplastic nevi (possible premelanomas). **(A)** Deeply pigmented dysplastic nevus. **(B)** Severe dysplastic nevus with some changes similar to melanoma; it looked like melanoma clinically, but it was a dysplastic nevus pathologically. **(C)** Melanoma in situ; early malignant melanoma is easily confused with benign lesions.

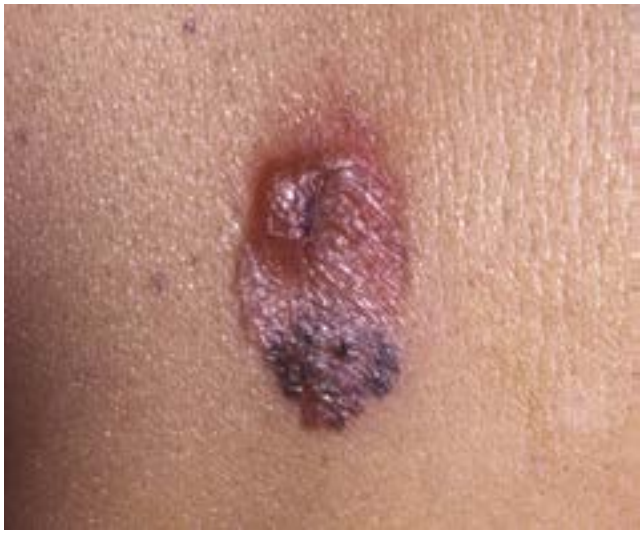

FIG. 3 Superficial spreading melanoma. Combinations of red, blue, and brown pigment are seen. A nodule is developing from one area, indicating that a vertical growth phase is arising contemporaneously with the horizontal or radial growth phase.

The majority of superficial spreading melanomas are observed on the trunk and extremities. Classically, these lesions develop with the widely known *ABCDE* characteristics: asymmetric shape, irregular borders, uneven/multiple colors, diameter in excess of 6 mm (though 50% of diagnosed lesions are now smaller than that threshold), and unpredictable evolution in time. Because smaller lesions are frequent, this criterion should now be modified. A very common history provided by the patient will be a period of slowly progressive expansion in a radial direction followed by comparatively rapid vertical growth, usually causing a papule or nodule. These changes relate to growth limited to the epidermis followed by invasion more deeply into the dermis. Partial regression with corresponding loss of pigment, interval pale and atrophic areas, are also common.

Nodular Melanoma

The second most common subtype of melanoma is the nodular melanoma, identified in 15% to 30% of all melanoma cases (Fig. 4). The physical manifestation of nodular melanomas can be variable, making clinical diagnosis challenging. The *ABCDE* criteria are less applicable because nodular tumors may be symmetric or asymmetric; pink, red, blue, black, and nonpigmented lesions are all well described; the tumor often appears as an isolated nodule or papule without an ensuing increase in size, and the timeline for growth is variable. Much of this clinical variability arises from the pathologic behavior of the tumor, namely that it lacks a superficial-radial phase and instead tends to grow almost exclusively in a vertical fashion. Much like an iceberg, the majority of the neoplasm often exists beneath the visible surface of the skin. A high index of suspicion is required to pursue further workup and accurately identify this tumor. Nodular melanoma is often diagnosed at a later stage than other subtypes of melanoma.

Lentigo Maligna Melanoma

Lentigo maligna melanoma is the third most common form of melanoma (10%–15%) and the subtype most strongly linked to chronic UV irradiation (Fig. 5). As a result, these lesions are almost exclusively identified in older adults in areas of chronic sun exposure, such as the distal extremities and the head and neck region. The clinical examination classically features a variably pigmented patch in the setting of notable photodamage. Radial growth is often slowly progressive, leading to highly irregular borders and substantial pigment variations. Lentigo maligna melanomas are notorious for exerting a

FIG. 4 Nodular melanoma. This is a dark, heavily pigmented lesion with rapid growth. Two examples are shown: lip **(A)** and back **(B).**

field effect in which surrounding dermis has suffered the cumulative mutagenic effects of chronic UV irradiation. This allows the primary tumor to infest its vulnerable surroundings with foci of malignant cells, termed *skip lesions.* Incisional biopsy specimens may fail to identify malignant cells surrounding the clinically obvious melanoma, placing patients at higher risk for recurrence, reoperation, or advanced disease. Negative margins at the time of definitive surgical excision may also be difficult to interpret as a result of the skip lesions/regression frequent in lentigo maligna melanoma.

Acral Lentiginous Melanoma

Acral lentiginous melanoma is an uncommon manifestation of melanoma, accounting for less than 5% of cases (Fig. 6). However, these lesions tend to make up a higher proportion of all melanoma cases in dark-skinned populations. Arising in the skin of the palms and soles or intimately within the nail structure, a high degree of suspicion is required for accurate and timely diagnosis. The usual presentation is similar to other melanoma subtypes; usual features include an asymmetric, brown to black macule with variable coloring and irregular borders. With regard to lesions of the nail bed itself, melanoma can be very difficult to distinguish from posttraumatic changes or benign nevi (Fig. 7). A guideline to help identify candidates for biopsy includes subungual lesions in fair-skinned patients, darkly pigmented lesions, irregularly pigmented lesions, those wider than 3 mm, or lesions that extend beyond the nail plate either into the hyponychium, paronychium, or eponychium (Hutchinson sign).

Amelanotic Melanoma

The majority of melanomas are pigmented in some manner, facilitating their detection. However, melanoma without any evidence of

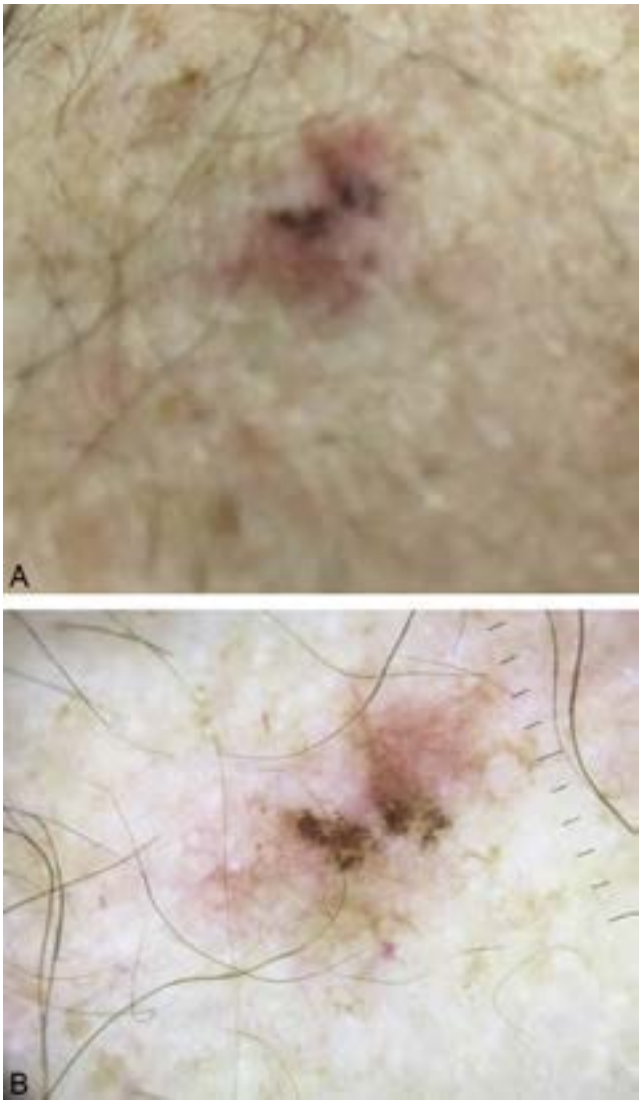

FIG. 5 Lentigo maligna melanoma. **(A)** Variegated colors of red, brown, and black with considerable pigment variation and multiple areas of regression are shown. **(B)** The same lesion under magnification clearly demonstrates areas of central and peripheral irregular regression.

FIG. 6 Acral melanoma. Two variations are shown: nodular **(A)** and flat **(B).**

pigmentation is also possible (Fig. 8). These lesions appear similar to a squamous cell carcinoma or a wart, and they may be red or occasionally pale. There should thus be a low threshold to biopsy unidentified lesions. Repeat observation of lesions in this category will reduce diagnostic errors, and clinicians should not hesitate to perform a full-thickness skin biopsy recognizing the atypical appearance of 10% of the subset of all melanomas. Odd lesion colors or the lack of pigment have no impact on prognosis.

Desmoplastic Melanoma

Desmoplastic melanoma is a particularly notable variant as this lesion poses substantial risk for destructively aggressive local growth and recurrence as a result of inadequate resection (Fig. 9). Because it has many of the appearances of a keratosis, the lesion is easily missed. The most frequent clinical manifestation of desmoplastic melanoma is a flesh colored plaque in sun-bathed skin, though red, pink, brown, or black lesions are possible. Exact identification of desmoplastic type is exclusively a histologic diagnosis. Identification and classification require full-thickness tissue sampling as the superficial layers of the lesion are classically nondiagnostic or vaguely resemble

FIG. 7 Nail bed melanoma. This lesion seems to extend beyond the nail bed into the perionychium.

fibrosis, cutaneous lesions, or even scars. Some feel that, because of the depth of the lesion, traditional depth-based staging may overestimate the seriousness of the tumor; this melanoma variant seems less likely to metastasize to nodes or beyond, and it is usually discovered at a later stage. **(Warning: Fully 10% of melanomas are not easily identifiable by their presenting color or clinical appearance characteristics. Adequate biopsy remains the single confirmation of pathologic type. Remember that pathologic identification may also be challenging.)**

Clear Cell Sarcoma

Clear cell sarcoma is a very rare tumor that recently has been identified as a molecular relative of melanoma. Most clear cell sarcomas arise from tendon sheaths and fascial aponeuroses, especially in the lower extremities; the trunk is the second most common site for tumor growth. Clinically, the lesion is almost always noted to be a tender flesh- or gray-colored mass that ranges in size from one to several centimeters. A hallmark is intimacy with underlying tendon or aponeurotic structures. Metastasis is common, and prognosis is poor.

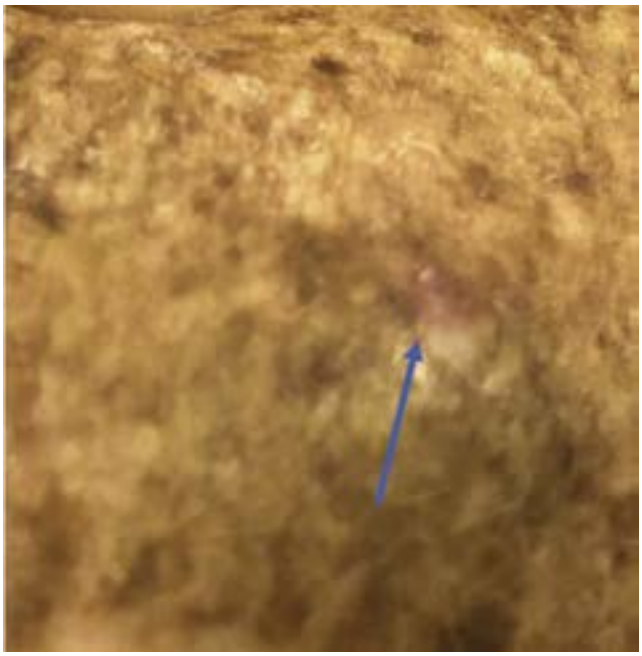

FIG. 8 Amelanotic melanoma. The appearance of these lesions may easily be confused with a benign lesion. The *arrow* indicates the subtle lesion.

FIG. 9 Desmoplastic melanoma. This lesion was interpreted by the screening dermatologist as a severe keratosis.

Mucosal Melanoma

The family of mucosal melanomas comprises a diverse group of tumors characterized by their anatomic locations and their unique genetic signatures. These tumors develop in the mucosa of the mouth, nasopharynx, larynx, and anogenital regions along the junction of epithelial morphologies. Clinical examination usually discloses a pigmented, sessile, or slightly raised mass, though as many as 40% may be amelanotic. As with several other variants, a low threshold to perform biopsies characterizes a prudent approach.

STAGING AND PROGNOSIS

The staging of melanoma is based on the American Joint Committee on Cancer (AJCC) staging system, which was most recently updated to the eighth edition and considers tumor size, node status, and metastases. We have provided the citation for the most updated AJCC system and encourage readers to review this. Specifically, T status is driven by tumor size and the presence or absence of ulceration. The N status characterizes both clinically apparent and clinically occult nodal metastases and non-nodal local spread. Finally, M status is determined by the anatomic site of distant spread and the serum lactate dehydrogenase level. Melanoma staging is vital for providing accurate prognosis.

Prognosis determination proceeds directly from staging. Four tumor features have been specifically repeatedly associated most closely with prognostic outcomes:

1. Primary tumor thickness
2. Presence of ulceration in the primary lesion
3. Mitotic rate of tumor cells
4. Presence of microscopic metastasis on analysis of resected lymph nodes

Survival varies from >95% at 10 years for promptly treated stage 1 tumors to <20% for metastatic stage 4 disease. These figures may be changing, however, in the era of advanced immunotherapies and targeted molecular therapies.

INITIAL WORKUP

Lesion History and Characteristics

A detailed history and physical examination are both very important in the initial encounter for a patient presenting with suspected melanoma. Specific historical elements that should be collected include risk factors for melanoma (see earlier) and family history of cutaneous malignancies. Questions pertaining to the lesion should include time course (including possible precursor lesions present at birth or in development thereafter), circumstances surrounding lesion development (e.g., in a preexisting nevus, following trauma), associated dermatologic symptoms such as itching or burning, and the presence of constitutional symptoms, ulceration, or bleeding.

Total Body Skin Examination

A total body skin examination is a must, especially if there are numerous melanocytic nevi or clinically atypical appearing nevi. It is very frequent that additional melanomas or melanoma precursor lesions will be discovered. Some dermatology experts utilize dermoscopy (examination with a magnified light device) in screening for atypical nevi.

Examination of Regional Nodes

Particular attention should be paid to the examination of local/regional lymph nodes. Clinically palpable nodes must be further evaluated, as one-half of the clinically palpable nodes are positive, and one-half are negative for melanoma involvement, emphasizing the importance of ultrasound or sentinel lymph node biopsy (SLNB).

Laboratory Examinations

Routine laboratory and imaging studies were formerly a cornerstone of preoperative workup in cases of suspected melanoma. Recent meta-analyses have determined that the diagnostic utility of these measures is minimal. Up-to-date recommendations from several national societies, both in the United States and elsewhere, do not include these evaluations for asymptomatic patients. For patients with concerning pathology or signs or symptoms of metastatic disease on presentation, targeted workup (e.g., head imaging for a patient with headaches and suspected central nervous metastasis) should be pursued and may be performed in coordination with a medical oncologist or other specialist.

BIOPSY

Excisional biopsy is the cornerstone of diagnosis in cases of suspected melanoma. The recommended technique is excisional biopsy with 1- to 2-mm margins, followed by straight-line closure with minimal undermining. If needed, closure with allograft skin or negative-pressure therapy devices are lesser options while awaiting final pathology. All samples should be appropriately oriented and sent for pathologic review. Ideally, a pathologist with specific expertise in the review of melanocytic neoplasms is identified for consultation.

Excisional biopsy is considered ideal because it allows for an accurate assessment of tumor architecture, including Breslow depth, mitotic rate, invasive characteristics, and identification of the deepest areas for classification. This method further reduces the error of a sampling bias that may occur with melanoma arising in a previously benign nevus or in cases of Lentigo maligna melanoma. An extremely important principle of biopsy technique is orientation of the incision. The surgeon's mindset should be that all suspicious lesions are malignant until proven otherwise, implying that wider resection may eventually be needed. The subsequent resection, therefore, must necessarily remove the scar of the biopsy incision plus the appropriate margins, which is best accomplished when the biopsy excision has been properly planned with the possibility of later excision in mind. On extremities especially, careful planning of the initial biopsy incision is crucial for facilitating tissue salvage in a radical future operation. Therefore, virtually all extremity incisions should be oriented longitudinally and within the relaxed skin tension lines (RSTLs) in a proximal-to-distal fashion, and not transversely (medial to lateral), as depicted in Figure 10. Some favor making the long ellipse of the skin excision parallel to the direction proximally of presumed lymphatic drainage to have a chance of capturing more lymphatics in the long axis of the excision.

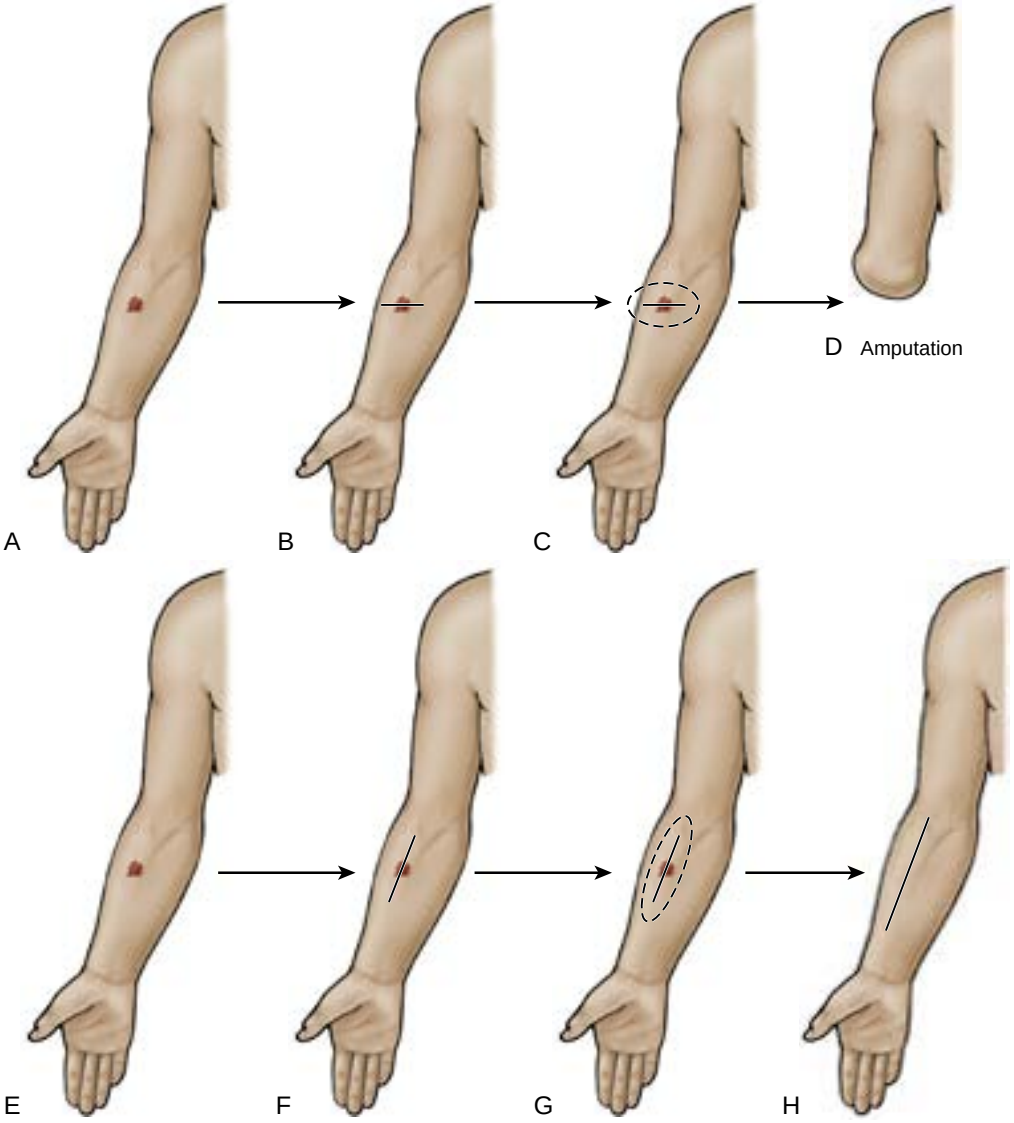

FIG. 10 **(A)** A suspected melanoma on the volar forearm. **(B)** A hypothetical transversely oriented incision for excisional biopsy, with a resulting straight-line scar in medial-lateral fashion. **(C)** The *dashed ellipse* represents standard excisional margins after pathologic review confirms melanoma. Note that standard margins fall outside the width of the extremity. **(D)** There are no margins that can be taken in such a fashion as to provide adequate oncologic treatment to preserve limb salvage. Thus, amputation is the only surgical option at this juncture. **(E)** The same suspected melanoma on the volar forearm. **(F)** A hypothetical longitudinally oriented incision for excisional biopsy, with a resulting straight-line scar of exact dimension as in **(B),** but instead in proximal-distal fashion. **(G)** The dashed ellipse again represents standard excisional margins after confirmed melanoma and is the exact dimension of the ellipse portrayed in **(C). (H)** Result of re-excision of confirmed melanoma with appropriate margin, though this situation clearly permits an anatomic solution consistent with maximum limb function and preservation.

If excisional biopsy is not a feasible option, full-thickness skin punch biopsy is the next best modality. Shave biopsy is discouraged because it does not permit conclusive review of tumor depth, which all too frequently cannot be accurately assessed once scar tissue from the shave biopsy is present. The biopsy process itself almost always obscures future attempts at depth determination. *Saucerization* is a partial-thickness skin sampling and is also discouraged.

Relevant Information Provided by Biopsy

Biopsy reports must include several crucial pieces of information: pathologic diagnosis (ultimately, the pathologist must confirm the suspected clinical diagnosis or provide an alternative diagnosis); tumor thickness (otherwise known as *Breslow depth*) must also be measured accurately to the nearest 0.1 mm; presence or absence of ulceration; the positive or negative status of both the deep and peripheral margins; and the mitotic rate of the lesion. Additional information includes any histologic subtyping presence or absence of vascular, lymph, or nerve invasion character of the inflammatory infiltrate and the presence or absence of microscopic satellite lesions. Immunohistochemical staining techniques also provide further characterization of tumors, but as yet are not of consequence to surgical planning. The Clarke level may also be mentioned, but please note that the Clarke level is clinically inconsequential in modern practice. Instead, the Breslow depth is used.

SURGICAL MANAGEMENT OF PRIMARY CUTANEOUS MELANOMA

Tumor Extirpation

Surgical excision is the principal treatment for cutaneous melanoma. There has been a trend away from radical excisions with very wide margins and extensive lymphadenectomy to conservative excisions with targeted lymphatic tissue removal. Results from important randomized, controlled trials have shed light on critical questions pertaining to surgical care, but many important components of surgical resection are still practiced based on traditional surgical experience.

The purpose of surgical excision is to provide complete excision of the lesion and its immediate surrounding area to provide durable, recurrence-free survival in the local area. Removal of tissue adequate to ensure elimination of the primary tumor, surrounding nests of malignant cells (microsatellites), and even closely situated second primary tumors is the major goal. Currently, there is a strong desire to avoid debilitating or disfiguring wide resections, large wounds that may necessitate advanced reconstructive techniques, or wounds of such size or location as to predispose to an unnecessarily high risk of surgical site infection, or cause disability. A number of high-quality, multicenter, randomized, controlled trials have evaluated the optimal margins for surgical excision and concluded that exceptionally wide margins offer no benefit in either survival or in local recurrence. Tumor thickness is the predominant factor that dictates the appropriate margin.

The recommended guidelines for surgical margins are shown in Table 1. It is crucial to point out that *margins* represent the distance from the scars of prior excisions and/or biopsies of the lesion or from the edges of any residual tissue that appears to be involved. In other words, if a punch biopsy is performed and there is residual pigmented tissue as well as a thin halo of erythematous tissue around the lesion that appears suspicious, the proper margins should be measured from the edge of the suspicious erythema, not just the pigmented lesion itself.

TABLE 1 American Joint Committee on Cancer Guidelines for Margins of Excision in Cases of Primary Cutaneous Melanoma

Tumor Thickness (mm)	Excision Margin (cm)
In situ	0.5–1.0
<1	1
1–2	2*
2–4	2
>4	2†

*For tumors in areas in which 2-cm margins would introduce substantial functional or aesthetic morbidity, 1-cm margins can be considered.
†Individual microscopic tumor characteristics, satellites, and tumor location should be considered, as "wider margins" have a degree of variability.

Optimal Deep Margins

Despite robust evidence supporting cutaneous margin dimensions when removing melanoma, there is relatively little published on the optimal deep margin. Thus, by tradition, the deep margin is typically through one extra tissue layer of clear uninvolved tissue (frequently to or less commonly including the muscle fascia or deep fascia). Although some surgeons resect fascia, many only resect this layer if the tumor appears to be closely invading the tissue layer above the fascia.

We do not recommend frozen/rapid section analysis of melanoma samples. Although skill can be obtained in the analysis of melanoma samples with stains made for nonpigmented basal cells or squamous cells, there is an error rate with rapid techniques both for margins and depth assessment of tumors. The techniques associated with frozen-section processing have been shown to introduce errors of up to 0.4 mm in the measurement of tumor depth. Surgeons should base their final judgment recommendations exclusively on final pathology measurements in fully stained specimens.

The role of Mohs micrographic surgery is unproven for invasive melanoma but seems valuable in challenging (repetitively positive) margin cases to provide temporary margin assessment. It is useful in those (less frequent) cases of melanoma in situ where the microscopic extent of the lesion exceeds the visible dimensions of the lesion. This assessment, using tissue stains developed for basal cell and squamous cell, is 75% accurate on the immediate Mohs stains for those who practice. Provisional analysis must be confirmed with standard pathologic processing before any reconstruction is accomplished. Less commonly, melanoma in situ is still present on permanent stains after clear temporary margins with Mohs surgery, but it has not been recognized. Society-level recommendations state that Mohs micrographic surgery can be considered for melanoma in situ or lentigo maligna melanoma for cases in which conventional margins may be disfiguring or disabling (e.g., the face) in order to limit extensive excisions. Definitive outcomes in these cases are not currently available.

The exact role of immunostains for margin assessment has not been confirmed. They may highlight extensive disease whose relevance for a particular patient may justify thought before extensive deforming resection is accomplished to clear an immunostain margin.

Our experience has shown that Mohs micrographic surgical excisions of melanoma in situ have a 25% rate of positive permanent margins on follow-up with regular hematoxylin and eosin (H&E) stains, so permanent sections should always be employed for confirmation of rapid margins by Mohs surgery or frozen sections. Reconstruction must be deferred awaiting permanent negative margins.

Management of Regional Lymph Nodes

Historically, patients with all but thin melanoma were treated with early, elective complete lymphadenectomy because experience demonstrated that cutaneous melanoma had a proclivity for nodal

and distant metastasis. The passage of time demonstrated that this approach introduced substantial morbidity without measurable reduction in regional or distant metastasis or improved survival for thin tumors. Two techniques have accurately predicted which patients are at risk for nodal and systemic disease: (1) specimen risk analysis outlined earlier with histologic examination and (2) analysis of the sentinel lymph node biopsy or ultrasound biopsy of the nodal basin. The evolution from routine widespread complete lymphadenectomy to targeted sentinel lymph node biopsy permit both approaches to have differing and sequential roles in the surgical management of regional lymphatic areas. Nodes that have a length-to-depth ratio of less than 2, a hypoechoic center, absent hilar vessels, or focal nodularity with increased vascularity are suspicious for tumor involvement.

Physical examination of regional nodes alone is unable to confirm 50% of those with clinically positive nodes, and similarly 20% of patients with clinically negative nodes have or will have microscopic involvement. Metastasis to regional nodes or into the bloodstream occurs when the melanoma reaches the mid-dermis, where blood vessels and lymphatics are present.

Most patients with regional lymph node metastasis on sentinel lymph node biopsy can select nodal observation, ultrasound observation, or completion nodal dissection, as approximately three-fourths of patients with positive sentinel nodes have one to two positive nodes.

MANAGEMENT OF PATIENTS WITHOUT CLINICALLY SUSPICIOUS OR CLINICALLY POSITIVE NODES

Staging of regional lymph nodes may be accomplished with SLNB or with ultrasound-guided sampling for regional lymphatic mapping-sampling, fine-needle biopsy, or excisional biopsy; one or several lymph nodes may be identified for lymphatic mapping.

The sentinel lymph node biopsy is much more commonly indicated than complete lymphadenectomy; the technique has a low false-negative rate, is very important for determining prognosis, and is a basis for surgical or adjuvant therapy or for clinical trials. When nonsentinel nodes in the basin are positive (11%), the prognosis for systemic spread is increased.

At a theoretical level, the sentinel node concept depends on proof that a given area of skin will reliably drain first into one single or perhaps several closely associated nodes within the larger lymph node basin. Sampling the sentinel nodes can thus provide an accurate pathologic examination of the relevant nodes in the basin, assuming that lymphatic fluid from the affected skin patch does indeed pass through the sentinel nodes before encountering the other nodes in the basin. Initially the accuracy of the technique was 75%, but with time and practice the accuracy now approaches 94%. Studies have shown variability in lymphatic drainage over time, and some sites drain to several node basins simultaneously. Some studies have demonstrated that the positive node may not be the node with the highest count, and node excision should define all nodes within 80% to 90% of the highest node sampled. The false-negative rate is 11%, and currently the procedure has a negative predictive value of 97%.

Survival is poorer in patients with thicker primary tumors, ulceration of the primary tumor, or involvement of nonsentinel nodes. SLNB is performed in thick melanomas more for purposes of regional disease control, adjuvant therapy, or investigational drug treatment.

Complications from sentinel lymph node biopsy are much less common than from complete lymphadenectomy; most recent high-quality studies show the rate of surgical site occurrences (e.g., seroma, wound infection, dehiscence) for sentinel lymph node biopsy to be 4% to 10% and for complete lymphadenectomy to be 25% to 40%. Complete lymphadenectomy also carries a substantially higher risk of extremity lymphedema, whereas lymphedema is rare after removal of one or two nodes (less than 1%) and probably reflects prior deficient lymphatics on a congenital or infectious basis. Extremity complications include lymphedema (sentinel node vs. completion lymphadenectomy) (0.7% vs. 12%), wound infection (1% vs. 7%), hematoma and seroma (2% vs. 6%), and sensory nerve injury (0.2% vs. 1.8%). Shoulder dysfunction occurs after axillary dissection, and arm delayed wound healing (16%). Lymphedema (32% overall in complete node removals) is more frequent with inguinal dissections, which have 8% and 51% complication rates for SNLB versus complete inguinal dissections.

The indications for sentinel lymph node biopsy have grown in recent years. Their rationale is to determine prognosis, to select patients who may benefit from lymphadenectomy or additional adjuvant therapy, or to select patients who may benefit from clinical trials. Current recommendations are to perform sentinel lymph node biopsy in all patients with clinically uninvolved nodes and melanoma ≥1 mm in thickness or those with melanoma <0.8 to 1 mm in thickness but with high-risk features (e.g., ulceration, >2 mitoses/mm^2, histologic evidence of lymphovascular invasion). The status of the sentinel node has been shown to have a profound effect on prognosis. The findings on sentinel lymph node biopsy may significantly change a patient's stage for a given T status. Patients with a positive sentinel lymph node biopsy are equally likely to have metastases elsewhere in the nodal basin or at distant sites. Moreover, the role of completion lymphadenectomy after positive sentinel lymph node biopsy has been called into more question considering the prevalence of systemic disease when multiple positive lymph nodes are found.

To perform the sentinel lymph node biopsy, a radioactive tracer, technetium-99 sulfur colloid is injected preoperatively into the dermis at the location of the suspicious skin lesion or directly into the scar from the prior excisional biopsy. It is of vital importance to ensure that the injection is done into the dermis because the subcutaneous tissue has a much less predictable lymphatic drainage pattern than the dermis. Radioactivity is then sensed with a scintillation counter as early as 15 minutes after injection of the radiotracer solution and for as many as 6 hours afterward. Simultaneously, a blue dye (isosulfan blue) may also be injected intradermally into the skin lesion in surgery. The dye will also transit via the lymphatics and help visually mark the involved lymphatic vessels and nodes with blue staining. Scintigraphy counts further direct the surgeon to the appropriate lymph nodes in the basin. An appropriately placed skin incision is made, and the combination of blue dye marking and radioactivity counts obtained via intraoperative probe identify the relevant sentinel node or nodes for excision. We inject the lesion with the radiotracer and dye and then perform the sentinel lymph node biopsy *before* the wide local excision of the lesion or biopsy scar. Some feel that more radical biopsy excisions of the original lesion may change the location of the draining node to a different and inappropriate node for consideration. Node harvest should continue until the count falls below 10% to 20% of that in the highest sentinel node.

In intermediate-thickness melanomas (1.2–3.5 mm), sentinel lymph node biopsy followed by regional lymph node dissection had a potential survival advantage (MSLT I) of up to 23% over those having delayed lymph node dissections when late lymphatic metastases (85% immediate survival vs 62% in delayed node dissection survival). With thicker melanomas, the survival statistics were 71% survival with early node dissections versus 64% observation. Thus, this study indicates there is the possibility of decreased nodal recurrence, decreased distant metastasis, and death with early complete node dissection.

More recent studies (MSLT II) have not shown a significant survival difference at 3 years, but they do show better local control of the appearance of new tumor deposits. This included a 69% decrease in local recurrence, 5% better survival at 3 years, and better disease control (92% vs. 77%). Long-term studies are awaited to highlight and further confirm survival differences.

In thick melanomas (>3.5 mm), these figures in MSLT 1 are 64% survival with immediate node dissection versus 48% in delayed-node dissection survival, with 17% of patients in the delayed group having

lymph nodes appear with an average presentation time of 19 months. Thick melanoma sentinel node biopsies had an average 9% relapse rate over time following the original lymph node sampling, where the initial positive rate was 33% and with follow-up reached 42% for delayed presentation of nodes in the sentinel basin.

NONSURGICAL MANAGEMENT OF LOW-VOLUME INVOLVEMENT IN SENTINEL LYMPH NODES

Low-volume involvement of a lymph node is infrequently accompanied by additional lymph node involvement in the node basin. The number, size, and character of lymph node tumor deposits yields a further classification of sentinel node involvement which predicts safe observation alone for minimal disease. Seventy percent of positive sentinel lymph nodes have single node involvement, and many have peripheral (less threatening location) as compared with central deposits, which indicate early lesions. Thus, many are observing these patients with serial ultrasound examinations of the remainder of the lymph node basin, doing delayed lymph node biopsies or delayed node dissection when indicated for late appearing and nonsentinel nodes. When the largest area in the involved lymph node is less than 0.1 mm, there is a 9% chance of further involvement; when the area is 0.1 to 1.0 mm, there is a 16% chance, and when it is greater than 1.0 mm, there is a 25% chance. One large study showed a sentinel lymph node biopsy group had a 4% late recurrence in the original lymph node basin. After thorough review of the original samples, 80% of those with late positive nodes could be identified in retrospect in the original slides. Immunostains increase detection accuracy of positive nodes as they are able to detect 1 in 100,000 cells versus 1 in 10,000 cells with H&E. Complex staging systems are offered for types and character of lymph node involvement, and observation and immunotherapy are now offered more widely versus completion lymph node dissection. In several studies, long-term disease-free 10-year survival occurred in a retrospective subset of 20% to 40% of intermediate-thickness melanoma patients after regional lymph node dissection.

MANAGEMENT OF PATIENTS WITH CLINICALLY SUSPICIOUS OR POSITIVE NODES

For patients with clinically suspicious nodes on physical examination, biopsy is still indicated. Only 50% of these are positive. Most often, ultrasound-guided fine-needle or core biopsy is appropriate, convenient, and 90% accurate. Once the pathologic diagnosis of nodal metastasis is made, complete lymph node dissection (preferred) versus frequent observation are considered to accurately characterize the patient's N status and manage regional disease. In summary, sentinel lymph node biopsy is not routinely performed for lesions less than 1 mm thick in the absence of aggressive histologic characteristics, but it is considered "therapeutic" for lesions 1 to 4 mm thick and "prognostic" for lesions greater than 4 mm thick. Early positive sentinel lymph node evaluations in intermediate-thickness melanoma occur with a 16% to 20% frequency, with 4% demonstrating late positivity after SLNB. In patients who did not undergo SLNB, late follow-up demonstrates appearance of positive nodes in 17% in intermediate-thickness melanoma, usually at around 20 months. In those who had SLNB and regional lymph node dissection, there was often a small but distinct survival advantage of 10% to 20% in both local control and survival; however, recent short-term studies have indicated that early survival statistics are identical. Lymph node metastases were found in 33% of patients with thick melanomas (>3.5 mm), and a further 9% had an additional late appearance of node metastases over time.

In 2% to 5% of patients, no clear sentinel node can be found; if no sentinel node can be identified, planned completion lymphadenectomy demonstrates 1% to 2% positive nonsentinel nodes. Curiously, late node dissections when interval follow-up demonstrates late appearance of further positive nodes have fewer complications (5% vs. 25% as compared with early lymphadenectomy).

Deep lymph node dissections (e.g., pelvis) may occasionally be individually considered based on the original pathology, despite their increased difficulty and morbidity.

MANAGEMENT OF RECURRENT MELANOMA

The management of recurrent melanoma becomes much more complicated than the relatively straightforward approach to the patient with primary cutaneous melanoma. Recurrence can be at the location of the initial lesion, along the dominant lymphatic pathway (termed *in-transit metastasis*), or in the draining lymph node basin. Accurate identification of the nature of recurrence is important for prognosis. Treatment options have become quite diverse in the past decade, with surgical resection now accompanied by systemic immunotherapy. Radiotherapy, various forms of isolated limb perfusion, intralesional injections, and topical medications are considered infrequently in some situations. These choices are generally managed by institutional tumor boards.

Tumor extirpation for recurrences still has the goal of achieving clear margins (foundational approach) as more than 20% of patients with locoregional recurrence survive and may even achieve a cure after such an operation. Unfortunately, unlike in the case of primary melanoma, there are little data available to guide appropriate margins for repeat excision or the consequences of residual microscopic disease foci within resection margins. The need for reconstructive operations after oncologic resection is also more common in cases of recurrent melanoma, which adds further complexity to surgical planning. Thus, patients with recurrent melanoma are usually managed under the care of a multidisciplinary team in the context of an institutional tumor board.

IMMUNOTHERAPY AND TARGETED THERAPY

There are 100,000 cases of melanoma per year in the United States with 9000 deaths. Distant metastases have a short-term survival rate of 26%, with metastasis the leading cause of melanoma death. In the past 10 years, melanoma has gone from one of the least responsive tumors to therapy (dacarbazine 20% response and little survival benefit, and interleukin 2 (IL-2), very toxic with few responses but occasional treatment victories) to one of the most responsive, with the lethality of advanced disease decreasing in the past 10 years. Immunotherapy has gone from a 10% response rate with a small survival benefit to a 56% response rate to multiple checkpoint drug therapy and 20% of patients requiring no further treatment in limited 10-year follow-up. Hence this turns the patient's problem in to a chronic disease, thanks to the long-term memory of the immune system. Although toxic effects increase with drug combinations, dose delays, glucocorticoids, and antitumor necrosis factor antibodies have decreased symptoms.

Melanoma is an immunologic malignancy with increased incidence in immunocompromised patients, evidence of lymphocyte infiltration, and recognition of melanoma antigens by tumor-infiltrating T lymphocytes. Melanoma tumors have high immunogenicity, and current immunotherapy is focused on counterregulatory mechanisms of the immune response. Immunotherapy also has immune-related adverse events. Melanoma cells are first in a stage of "equilibration" in metastasis, with a variable period of dormancy followed by escape to active metastatic cells with immunogenetic or non-immunogenic mutated or nonmutated melanoma cells. Anti–programmed cell death 1 (PD1) inhibitors have recently been employed for metastatic disease and have shown promise (nivolumab or pembrolizumab) as has targeted therapy versus BRAF V600 with dabrafenib or trametinib.

Since 2010, significant advances in the treatment of metastatic melanoma have occurred, and now also in adjuvant settings with high recurrence risk. These advances have led to immunotherapy with anti–PD-1 (pembrolizumab and nivolumab) and anti–CTLA-4 (ipilimumab) antibodies. These therapies have yielded up to 52% treatment improvement with significant survival in follow-up for 3 to 5 years.

Forty percent of melanomas harbor the *V600BRAF* mutation, leading to activation of the MAPK signaling pathway. Dual inhibition of this pathway with BRAF and MEK inhibitors has a rapid response rate with good effectiveness, but the survival benefit is short-lived because of the rapid development of resistance. Follow-up in these cases with traditional immunotherapy with PD-1 or targeted therapy has accomplished significant long-term results. A plateau effect in overall survival occurs, with most responders remaining in remission after treatment in limited 5-year follow-up in which response varies from 25% for single-drug trials to 52% for multiple drug trials, and 34% to 39% for targeted therapy. Other treatment regimens, such as the oncolytic viruses, may also have benefit in metastatic disease. These encouraging results are providing hope to the multitude of patients who face the grim diagnosis of metastatic melanoma.

Management of Soft Tissue Sarcomas

Adam S. Levin, MD, and Carol D. Morris, MD, MS

INTRODUCTION

Soft tissue sarcomas (STSs) represent a rare group of malignancies of mesenchymal origin. In the United States, there are approximately 13,000 new STS diagnoses per year, resulting in over 5000 deaths. Given the wide variety of mesenchymal tissues, including fat, muscle, connective tissues, and blood vessels, among others, these can be further subclassified into more than 50 recognized histologic subtypes, largely based on the tissue to which it most closely resembles.

The majority of soft tissue sarcomas present in adults and become more prevalent with increasing age. The incidence has slowly increased in the United States in recent decades, with an overall incidence of about 2 per 100,000, increasing to about 8 per 100,000 in patients over the age of 80 years (Figs. 1 and 2). However, although they are less commonly seen in the pediatric/adolescent population, soft tissue sarcomas are the third most common solid malignancy found in this age group, accounting for approximately 15% of all pediatric cancers.

There is a slight male predominance, though some histologic subtypes exhibit a small female predilection. Although nearly one-half of all sarcomas present in the extremities, they may arise in any anatomic region with connective tissue. The abdomen, pelvis, and retroperitoneum are common locations as well. Ultimately, these malignancies represent a broad family of diagnoses, with highly variable demographics, anatomic localizations, clinical presentations, imaging appearance, histopathologic findings, treatment considerations, and prognoses.

This chapter aims to outline general, anatomic-specific, and histopathology-specific considerations in the treatment of soft tissue sarcomas. The exception would be gastrointestinal stromal tumors (GISTs). The majority of soft tissue sarcomas require a multidisciplinary approach including surgery, radiation, and chemotherapy, alone or in combination. Treatment paradigms in the context of disease-specific considerations will be discussed in detail.

ETIOLOGY

The majority of soft tissue sarcomas arise without a clear inciting cause. Often, patients will relate a history of prior trauma to the site, though such events more likely reflect the initial identification of the mass rather than a true causative factor. There are, however, environmental exposures and predisposing conditions that appear to have close associations.

Radiation

Radiation exposure, either therapeutic or environmental, is perhaps the most recognized etiologic factor for soft tissue sarcoma development. This is most commonly associated with undifferentiated pleomorphic sarcomas, though several other histopathologic subtypes have been identified as well. Radiation may account for up to 5% of all soft tissue sarcoma diagnoses, despite being evident in less than 1% of exposed adults. Incidence appears to be higher in children, though this may be related to the underlying diagnoses being treated. Although some have suggested a higher risk of sarcomagenesis in patients exposed to orthovoltage radiation, more modern megavoltage radiation therapy has a clear association as well.

By definition, radiation-associated sarcomas must be histologically distinct from the original diagnosis and arise within the radiated field no sooner than 3 years postradiation. Sarcomas may develop at any point following 3 years, with an average latency of about 11 years. Radiation-associated sarcomas tend to follow an aggressive clinical course, and their management may be further limited by prior therapies.

Other Causative Factors

Angiosarcomas are closely associated with chronic lymphedema, or Stewart-Treves syndrome. Chemical exposures, such as Thorotrast, vinyl chloride, and arsenic, have been linked with hepatic angiosarcoma. Additional exposures to agents such as herbicides and defoliants have been associated as well. Exposure to chlorinated dioxins,

such as that in Agent Orange, has also been implicated without clearly established causation.

Predisposing Genetic Conditions

Some heritable and sporadic genetic mutations and cellular alterations demonstrate a clear association with soft tissue sarcomas. Li Fraumeni syndrome, related to *p53* mutations, is implicated in numerous malignancies including bone and soft tissue sarcomas. Neurofibromatosis type 1, with mutations in *NF1,* carries an approximately 15% lifetime risk of developing a malignant peripheral nerve sheath tumor. Overall, nearly half of all malignant peripheral nerve sheath tumors are in patients with *NF1* mutations. Similarly, desmoid tumors are closely associated with Gardner's syndrome. As discussed later, some histopathologic subtypes of soft tissue sarcoma exhibit characteristic chromosomal rearrangements within the involved tumor cells, including the Ewing family of tumors, synovial sarcoma, clear cell sarcoma, among others.

DIAGNOSTIC EVALUATION

Although the diagnosis may be glaringly evident in some patients, the differentiation between benign and malignant soft tissue neoplasms can often be challenging. With careful attention to history, clinical examination, and imaging findings, the diagnosis of soft tissue sarcoma can often be reasonably suspected (Figs. 3–13).

Pain

The majority of soft tissue tumors, benign or malignant, are not painful. A painful soft tissue mass is typically an indication of nerve involvement or compression, bone invasion, or vascular etiology. Most commonly, a soft tissue mass localized to the nerve will be a schwannoma or neurofibroma. In patients with NF1, increasing pain within a neurofibroma may prompt evaluation for transformation into a malignant peripheral nerve sheath tumor (MPNST). As previously noted, nearly half of MPNSTs develop in patients without

neurofibromatosis. Less commonly, other soft tissue sarcoma subtypes may present as an intraneural neoplasm, with synovial sarcoma being the most common.

In the absence of a primary neural neoplasm, soft tissue masses may compress directly on nerves or blood vessels, resulting in pain as well. These may be insidious in onset, though often are associated with a positive Tinel sign. Alternatively, some soft tissue masses may erode into the underlying bone, leading to either discomfort from periosteal inflammation or potentially even a pathologic fracture from external compression. Although not common, sarcomas may elicit a robust surrounding inflammatory response that may be associated with pain.

Size

The size of the mass may be misleading regarding its local aggressiveness. Some benign conditions, such as desmoid-type fibromatosis or benign lipomatous neoplasms, may grow to be quite large. Similarly, high-grade sarcomas may initially present as small masses. Although an index of suspicion may be appropriate under many circumstances,

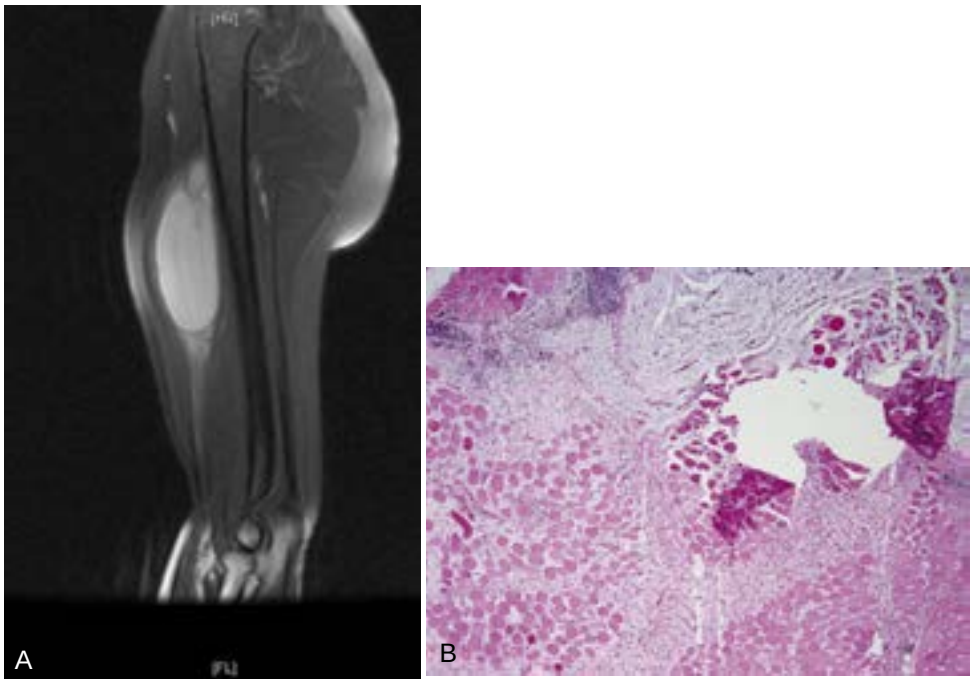

FIG. 6 Myxofibrosarcoma commonly presents on the superficial aspect of the fascia, typically with a wide peritumoral reactive zone extending along fascial planes **(A).** Histopathologically, this may demonstrate microscopic extension between muscle fibers **(B).**

lesions greater than 5 cm should prompt evaluation and consideration that it may represent a soft tissue sarcoma.

Depth

In the extremities, more than two-thirds of soft tissue sarcomas are deep to the investing fascia of muscle. Although not pathognomonic, a mass greater than 5 cm that is deep to the fascia draws increased suspicion that this may represent a malignancy. Dermatofibrosarcoma protuberans and myxofibrosarcoma, however, are two exceptions as soft tissue sarcomas that most commonly present superficial to the deep fascia. Perhaps as a result of their superficial location, dermatofibrosarcoma protuberans and myxofibrosarcoma lend themselves to misdiagnosis or mistreatment, with providers presuming that they are benign conditions such as ganglion cysts or lipomas. Since superficial cysts and lipomas tend to be soft and commonly transilluminate on clinical examination, the lack of such findings should prompt advanced imaging to further characterize.

Mobility

At least in the extremity, most benign soft tissue masses are largely mobile on clinical palpation, whereas malignant tumors are typically fixed to the surrounding soft tissues. A firm mass that is relatively immobile should raise the suspicion for malignancy.

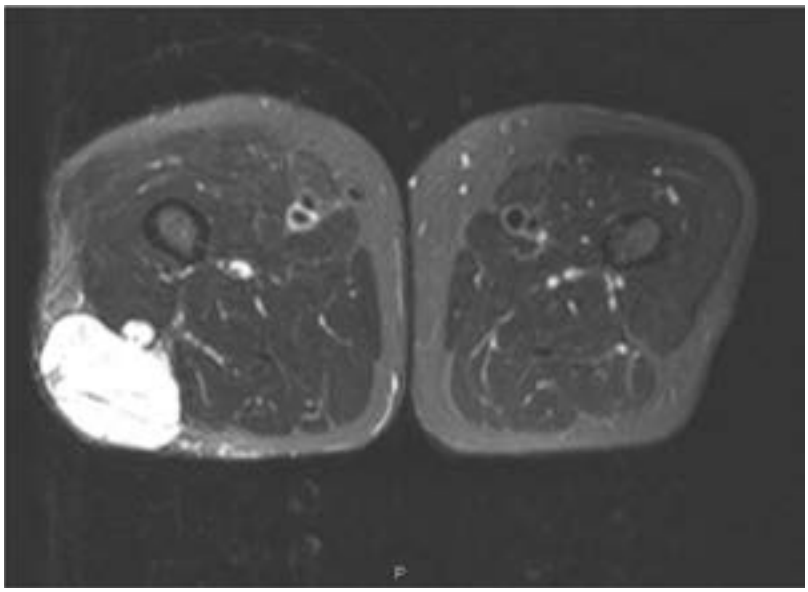

FIG. 9 Dermatofibrosarcoma protuberans (DFSP) is associated with a t(17;22) translocation. Because of its typical superficial location, it is often initially mistaken for a benign process and commonly identified after an unplanned surgical excision.

Growth

In light of their malignant nature, most soft tissue sarcomas will demonstrate progressive growth over time. Although this is overwhelmingly true, low-grade soft tissue sarcomas may sometimes grow at a very slow rate. In addition, some high-grade sarcomas, including synovial sarcoma and clear cell sarcoma as prime examples, may be notoriously slow growing over a prolonged period before rapid growth. These entities, in particular, may present a diagnostic challenge as there indolent growth pattern may lull the patient and provider into a false sense of security regarding its nature.

Imaging Characteristics

As relatively inexpensive and widely available imaging tests, radiographs may be the initial imaging study to suggest a neoplasm, though most soft tissue masses are not easily identified on radiographs. In some cases, a soft tissue shadow may be evident. Dystrophic calcifications may be seen in extraskeletal osteosarcoma and about 30% of synovial sarcomas. Radiographs can also be helpful in patients with mechanical pain and suspected bone involvement. However, for the majority of patients, plain radiographs provide little value in the diagnosis and management of soft tissue sarcomas.

Contrast-enhanced CT is highly effective in the evaluation of abdominal or retroperitoneal sarcomas. In the extremities, however, MRI is overwhelmingly the most useful imaging modality for workup of a soft tissue mass. This is commonly performed with both T1 and fat-saturated T2 sequences, and both with and without gadolinium enhancement. The overall MR appearance may be highly variable, though it often will demonstrate isointensity to muscle on T1-weighted images and high signal on T2-weighted or fluid-sensitive sequences. A heterogeneously enhancing soft tissue mass, particularly deep to the fascia, is highly suspicious for representing a

soft tissue sarcoma. Cross-sectional imaging of the primary tumor is key to finding the extensive tumor involvement, including the depth of invasion and its anatomic relationship with neurovascular or other important structures.

Other imaging modalities, including ultrasound, PET/CT, and bone scan, are typically of little value in the initial evaluation of a soft tissue mass. In some histopathologic subtypes, particularly those with high rates of nodal metastasis, a PET/CT may be indicated as part of systemic staging.

Biopsy

In the vast majority of soft tissue masses suspicious for STS, a biopsy should be performed before definitive management including surgical excision. As a result of advances in pathologic interpretation of small amounts of tissue, core needle biopsy is usually sufficient for diagnostic purposes. Reviewing the images with the interventional radiologist will aid in maximizing the yield of diagnostic tissue. For extremity tumors, biopsies should be performed along a limb salvage incision minimizing cross-compartment contamination. Although abdominal and retroperitoneal tumors may present unique considerations, biopsy is still recommended before surgical manipulation. In certain instances, neoadjuvant treatment may be indicated. Open biopsies are typically reserved for when needle biopsy fails to provide a diagnosis. Finally, a small number of tumors may be indicated for primary wide excision in which an undiagnosed mass is taken out with intended negative margins. The indications for primary wide excision are narrow and require considerable expertise to navigate.

Regardless of whether performing an incisional biopsy or core needle biopsy, the anticipated extensive or limb salvage incision should be mapped out. In the extremities, the extensile approach for soft tissue masses will typically be longitudinal, rather than transverse or in line with skin creases. Ideally, the biopsy tract should be along or immediately adjacent to the anticipated extensile incision. This allows for the biopsy tract to be excised with the mass at the time of definitive surgical excision. Some controversy exists as to whether a needle biopsy tract requires excision as the risk of local recurrence along the needle tract is relatively low for most histopathologic subtypes, especially if radiation is incorporated in the local treatment plan.

At the time of biopsy, a direct approach should be used, preferably limiting potential contamination to a limited amount of noncritical structures. Whether performed as an incisional or needle biopsy, avoidance of critical neurovascular structures will limit contamination when planning for further local control management. A primary advantage of core needle biopsy over open incisional biopsy is the ability to target a specific area within the mass. This is particularly helpful in masses with suspected heterogenous grade (e.g., dedifferentiated liposarcoma) or necrotic regions.

For incisional biopsies of extremity tumors, an ideal approach would avoid dissection of neurovascular structures altogether. Strict oncologic surgical principles, with limited surgical incision lengths, avoidance of multiple muscle compartments, and separation of instruments contaminated by tumor, can greatly limit potential complications including further contamination of the surrounding soft tissues. Care should be taken for meticulous hemostasis to avoid a postoperative hematoma, which could iatrogenically spread tumor cells. At the time of biopsy, initial evaluation with frozen section may be helpful to ensure diagnostic quality tissue. Although the differentiation between neoplastic and infectious conditions can often be highly suspected on preoperative workup, these are not mutually exclusive. As such, a culture of every biopsy and a biopsy of every culture is often recommended.

Staging

The American Joint Committee on Cancer (AJCC) has a prognostic staging system specific for soft tissue sarcomas. This is based on the tumor histologic grade, tumor size, and the presence of nodal or visceral metastatic disease. Although the depth of the tumor relative to the fascia was once considered prognostically relevant, the most recent iteration of the AJCC staging manual (eighth edition) reflects the current literature, suggesting that tumor depth is not a significant factor in patient survival.

Histologic grading of soft tissue sarcomas is based on tumor differentiation, mitotic count, and spontaneous tumor necrosis. For other entities, such as myxoid/round cell liposarcoma, tumor grading may be based on the percent of round cells. Otherwise, tumors are most commonly graded on the three-tiered scale of the French Federation of Cancer Centers Sarcoma Group (FNCLCC): low grade (grade 1), intermediate grade (grade 2), or high grade (grade 3). Commonly, intermediate-grade tumors are treated similar to high-grade sarcomas.

Although the AJCC system is the most useful for prognostication in soft tissue sarcoma, the Musculoskeletal Tumor Society (MSTS) has developed a surgical staging system to help conceptualize extremity surgical excision. Similar to the AJCC, this system is based on tumor grade and the presence or absence of metastases, but instead of using size as a factor, the MSTS system further characterizes by whether the tumor is contained within a single anatomic compartment.

In light of the numerous histopathologic variant as well as other prognostic factors that are not included in the AJCC or MSTS staging systems (e.g., age, anatomic location, histologic subtype), these systems have intrinsic limitations. Precision medicine tools such as nomograms are prognostic calculators based on multiple patient and tumor variables. Several STS nomograms have been developed to aid clinicians in stratifying patients into more graded and hopefully meaningful risk tiers. Further, as our understanding of molecular/genetic and other cytologic factors continues to expand and novel targeted therapies are developed, our ability to prognosticate for specific tumor continues to improve.

As noted, the AJCC staging system considers nodal and visceral metastases. As part of routine staging for extremity soft tissue sarcomas, chest imaging is routinely included for routine staging and long-term surveillance. Patients with abdominal, pelvic, and retroperitoneal sarcomas would also typically include CT imaging of the abdomen and pelvis.

Nodal metastases are infrequent and have been reported to occur in 2.6% to 5.3% of extremity soft tissue sarcomas. There is some suggestion that this rate may be higher among patients with visceral and retroperitoneal tumors. Some histologic subtypes, however, exhibit higher rates of lymph node involvement, namely the CARE diagnoses: *c*lear cell sarcoma, *a*ngiosarcoma, *r*habdomyosarcoma, *e*pithelioid sarcoma, and *E*wing's sarcoma. Nodal metastasis rates across these particular diagnoses range from 12% to 55% in some series. Although synovial sarcoma has often been included in this group, more recent evidence suggests that synovial sarcoma does not portend an increased risk of nodal metastasis. In patients who present with these conditions, particularly the small round blue cell tumors (rhabdomyosarcoma and Ewing's sarcoma), consideration may be given for PET/CT as part of staging. Otherwise, PET/CT is rarely indicated as part of the diagnostic restaging workup for soft tissue sarcoma. Although controversy exists regarding the role of sentinel lymph node biopsy, the current literature is not conclusive as to a clear benefit, even in those histologic subtypes recognized to have higher rates of nodal involvement.

TREATMENT

Soft tissue sarcomas are best treated by a multidisciplinary team. The primary teams include surgery, radiation oncology, and medical oncology. Unique clinical scenarios may draw on the expertise of other subspecialties such as interventional radiology or palliative care.

Surgical Management

The cornerstone of treatment of nearly all soft tissue sarcomas is surgical excision. A landmark randomized control trial in the early 1980s by Rosenberg et al. evaluated oncologic outcomes following amputation versus limb-sparing surgery in 43 adult patients with high-grade soft tissue sarcoma of the extremity. Although there was suggestion of increased rate of local recurrence with limb salvage, there was no difference in disease-free survival or overall survival, laying the foundation for limb-sparing oncologic resections. Today, at experienced centers, more than 95% of extremity soft tissue sarcomas are managed with limb-sparing surgery.

Enneking and colleagues described a conceptual framework regarding surgical margins. Intralesional procedures involve incising into the tumor. In sarcoma surgery, this is essentially limited to incisional biopsies. Marginal excisions describe an en bloc mass excision that either abuts the tumor pseudocapsule or dissects through the peritumoral inflammatory zone. Wide surgical margins, the treatment of choice for STS, describes an en bloc excision with a rim of normal tissue entirely surrounding the tumor. In the Enneking description, radical excisions are limited to those that excised the entire involved compartment. Although, at the time of that description, radical resections were utilized for sarcomas without an effective adjuvant, excision of the entire compartment is rarely utilized in modern sarcoma management.

It is well recognized that the peritumoral inflammation, known as the "reactive zone," may contain microscopic deposits of malignant cells. This is perhaps best recognized in myxofibrosarcomas, which typically have a broad extension of peritumoral inflammation along fascial planes. Researchers have demonstrated neoplastic cells within the reactive zone of soft tissue sarcomas up to 4 cm from the grossly identified mass. As such, excision of the peritumoral inflammation together with the soft tissue sarcoma, with wide surgical margins through normal tissue planes, remains the ideal surgical management. Preoperative radiation therapy may help in decreasing cell viability within the reactive zone, though it may challenge the ability to distinguish between radiation-associated inflammation and the peritumoral reactive zone.

Several investigators have attempted to define margin adequacy both quantitively and qualitatively. For example, the Japanese Orthopedic Association advocated that biologically robust barriers such as fascia, periosteum, joint capsule, or epineurium can adequately substitute for centimeters of adipose tissue. Despite the clinical utility of these types of efforts, significant ambiguity remains on the concept of margins.

Reflecting the concept of wide surgical margins, the AJCC classification indicates R0 excisions as having no microscopic tumor cells exist at the excision margin. This is typically the goal for sarcoma excisions. More recently, consideration has been given to a goal of R0 +1 mm as being a target. With effective local adjuvant treatment, planned margins of less than 1 mm on critical structures like nerves and vessels did not demonstrate an increase in local recurrence at 10 years, though unplanned positive margins have markedly increased rates of local recurrence. For extremity tumors abutting a long bone, the periosteum may act as an excellent margin. In the absence of osseous erosion or invasion, data out of the MD Anderson Cancer Center suggest that resection of bone may not be necessary.

Ultimately, while considering the extent of surgical margins around a soft tissue sarcoma, one must weigh potential functional considerations against the risk of local recurrence. Low-grade sarcomas and those with a low risk of local recurrence following preoperative radiation may be appropriate for careful dissection, aiming to preserve critical neurovascular elements when feasible. However, for sarcomas that either originate from (e.g., leiomyosarcoma, MPNST) or encase critical vascular or neural structures, strong consideration should be given to excision of those elements with the soft tissue mass, with subsequent vascular bypass or nerve/tendon transfers. If the anticipated function of the limb after adequate oncologic resection is not superior to that of an amputation, limb-sparing surgery would no longer be favored.

Despite extensive data regarding the role of operative margins as it relates to local recurrence, there is no clear data to suggest that this translates to disease-specific or overall survival. Nonetheless, careful attention to margin status is integral to standard sarcoma care. Intraoperative frozen-section margin analysis, particularly of any abnormal-appearing tissue, may guide intraoperative decision making. For patients who have previously undergone either an unplanned excision or had positive margins on prior excision, a wide re-excision of the surgical bed may be appropriate. This may result in large soft tissue defects, and these patients may have an increased need for advanced soft tissue reconstructions. In circumstances with highly infiltrative tumors as well as those with prior unplanned excisions, consideration is given to a staged approach, awaiting final histopathologic margin assessment before soft tissue reconstruction.

Considerations Specific to Retroperitoneal Sarcomas

Approximately 15% of all soft tissue sarcomas present in the retroperitoneum. The nature of the retroperitoneum may lead to delayed recognition of soft tissue sarcomas until they reach a large size, at which point nonspecific symptoms such as early satiety, constipation, or abdominal discomfort may exist. In larger masses, a sarcoma may become palpable, though many remain asymptomatic and are identified incidentally on imaging.

The majority of retroperitoneal soft tissue sarcomas may be identified on CT of the abdomen and pelvis. The most common sarcomas in this location include liposarcomas and leiomyosarcomas, each of which have some characteristic imaging features on CT to assist in formulating a differential diagnosis. However, with the exception of well-differentiated/dedifferentiated liposarcoma, imaging alone is rarely diagnostic.

In this regard, a detailed history and careful clinical examination together with CT of the abdomen and pelvis can help point to a diagnosis. Typically, a staging CT of the chest is indicated. Although biomarkers for soft tissue sarcoma are not of current clinical utility, laboratory testing for a lactate dehydrogenase (LDH), alpha-fetoprotein, human chorionic gonadotropin (hCG), and CA-125 may help in screening for alternative diagnoses. PET/CT is rarely indicated.

Although MRI is the mainstay for evaluation of extremity soft tissue masses, its utility over CT in the retroperitoneum is less well defined. Ultimately, although imaging may be highly suggestive, nearly all retroperitoneal masses are appropriate for biopsy to ensure a correct diagnosis before treatment. This is most commonly performed with core needle biopsy under image guidance. Although biopsy tract recurrences are rare, transrectal and transvaginal approaches should be avoided.

Unlike extremity soft tissue sarcomas, for which local recurrence has not been clearly associated with disease-specific or overall survival, locoregional recurrence in retroperitoneal sarcomas is more closely associated with mortality. Local control can often be difficult, and even low-grade tumors such as well-differentiated liposarcomas can lead to mortality related to local recurrence. As such, the initial surgical management is of utmost importance to ensure the best chance at cure.

Given the location, retroperitoneal sarcomas may encase or displace vital organs or major vessels. A clear understanding of involved structures as well as those abutting the tumor is critical in determining an optimal operating room plan. The anatomic boundaries of the retroperitoneum typically involve the gastrointestinal structures such as the colon, pancreas, stomach, or liver anteriorly. The posterior extent is typically bordered by the kidney and/or iliopsoas, though it often includes the diaphragm. Medially, these tumors may frequently abut the aorta and/or vena cava, and the decision about whether to resect otherwise uninvolved viscera is often related to the safe dissection of the feeding vessels.

Because of challenges of visualization adjacent to vessels and viscera, vascular or organ excision may be necessary, even in the absence of direct tumor involvement. Variability exists in recommendations regarding the extent of excision appropriate in the retroperitoneum, though aggressive adjacent visceral resection has not demonstrated clear improvement in local control beyond that obtained with gross total resection. However, although more than 90% of planned primary excisions for retroperitoneal sarcomas will demonstrate grossly negative margins, up to 20% prove to have R1 resection margins on final pathology. In this regard, there is still considerable disagreement regarding the benefits of removing adjacent uninvolved anatomic structures when a planned R1 marginal excision is necessary on other structures such as the aorta.

Although there may be a role for a more extensive surgical excision involving viscera, particularly a primary presentation, careful consideration of the risk of local or distant recurrence based on anatomy and tumor biology must be weighed. In patients with planned ipsilateral nephrectomy, a renal scan may routinely be performed to ensure adequate function of the contralateral kidney. There is no clear role for a macroscopically positive excision in sarcoma surgery, even in the case of locally recurrent disease. Therefore, tumor "debulking" surgery or morcellation is usually worse than nonoperative management.

Radiation Therapy

Radiation therapy has been shown to decrease the risk of local recurrence for high-grade extremity soft tissue sarcomas in a randomized controlled trial. In high-grade extremity sarcomas measuring greater than 5 cm, especially those with anticipated close margins, infiltrative borders, deep anatomic locations, and radiosensitive histopathology, strong consideration should be given for radiation therapy. The benefit of radiation therapy is less clear in the retroperitoneum, however. Colocalization of the tumor around radiosensitive anatomic structures may limit its utility in some patients. A recent randomized controlled trial comparing preoperative radiation and surgery for retroperitoneal sarcomas to those receiving surgery alone demonstrated no improvement in recurrence-free survival and increased adverse events in those receiving preoperative radiation. As a result, although this may be considered on an individualized basis, preoperative radiation is not routinely utilized for retroperitoneal sarcomas.

For extremity soft tissue sarcomas, although radiation therapy may reduce the rate of local recurrence from about 25% to less than 10%, there is no clear impact on distant recurrence or overall survival. An improvement in local recurrence has been demonstrated in some studies for low-grade extremity soft tissue sarcomas as well, though one must carefully weigh the risks of radiation against the risks of local recurrence. For small (<5 cm), superficial, and noninfiltrative extremity sarcomas that can be adequately excised with wide margins, the benefit of radiation therapy remains less clear.

The timing of radiation has been investigated in various study designs. Radiation can be given preoperatively, intraoperatively, or postoperatively. Preoperative and postoperative radiation demonstrate equal efficacy for decreasing local recurrence. Typical doses range from 50 Gy preoperative to 66 Gy postoperative. Further, although preoperative radiation includes the tumor and the surrounding reactive zone, postoperative radiation involves a larger field to include the operative bed. The resulting smaller field and smaller dose when given preoperatively can decrease the long-term side effects of stiffness, contractures, edema, and myofibrosis when compared with postoperative radiation, resulting in greater impairment of physical function scores in the long term. Late toxicity, particularly fibrosis and stiffness, appears to correlate with the size of the radiation field.

The primary risk of preoperative radiation is an increased risk of wound complications. The best data suggest a doubling of postoperative wound complications, from 17% with postoperative radiation to 35% with preoperative radiation. With advances in surgical techniques and increased attention to wound management following radiation, this may be decreased in more recent analyses. Following radiation, patients typically require some time for skin inflammation to decrease before operative intervention. However, by approximately 6 weeks, the skin becomes more fibrotic and less elastic. An optimal window between 3 and 6 weeks following radiation was demonstrated to have the lowest risk of postoperative wound complications.

At the completion of radiation therapy, differentiating the perioperative inflammation of the reactive zone from the inflammation from radiation may be challenging. When feasible, excision of the entire area of peritumoral inflammation, even in the setting of preoperative radiation, is preferred. For patients treated with preoperative radiation, a postoperative boost of radiation does not appear to improve local recurrence rates, including patients with positive surgical resection margins. As such, paramount importance of surgical resection margin status remains.

Chemotherapy

Even in the setting of adequate local control, up to 50% of patients with high-grade extremity soft tissue sarcomas may develop evidence of distant metastases. The most recent (eighth) edition of the AJCC staging system for soft tissue sarcomas recognizes the prognostic significance of tumor size, further stratifying large tumors as >5 cm, >10 cm, and >15 cm. For patients at the highest risk of metastases (large, high-grade tumors), cytotoxic chemotherapy is often offered. The most commonly utilized active agents are doxorubicin and ifosfamide.

The true benefit of chemotherapy for management of STS remains unclear. Randomized trails have failed to demonstrate a clear benefit for chemotherapy. Institution-specific and histologic specific trials have demonstrated more variable results. Myxoid liposarcoma, synovial sarcoma, epithelioid sarcoma, leiomyosarcoma, and malignant peripheral nerve sheath tumors, in particular, are histopathologic subtypes for which systemic therapy may often be indicated in the neoadjuvant setting. Although there are conflicting results from individual trials, meta-analyses suggest an absolute risk reduction for overall survival of 11% with systemic chemotherapy for high-grade soft tissue sarcomas. Results may be somewhat higher in extremity primary locations. However, the risks and benefits must be weighed on an individual basis.

The timing and sequence of radiation, surgery, and chemotherapy is not standardized. Both sequential and interdigitated approaches have been reported with similar survival outcomes. Given the complexity of decision making and care coordination, these patients are usually best served by multidisciplinary tumor boards.

HISTOLOGY-SPECIFIC CONSIDERATIONS

Well-Differentiated Liposarcoma/Atypical Lipomatous Tumors

Atypical lipomatous tumors (ALTs) and well-differentiated liposarcomas (WDLSs) are histopathologically identical tumors. They each carry the *MDM* amplification and have similar imaging features. Although these entities do not demonstrate metastatic potential, they do have a high rate of local recurrence. Those identified in the extremities are classified as ALTs, whereas those in the retroperitoneum are classified as WDLSs. This nomenclature is somewhat reflective of the risk of the tumor itself. In the extremity, with a manageable risk of local recurrence and without metastatic potential, excision can be marginal, recognizing the potential for late local recurrence.

However, in the retroperitoneum, these are given a sarcoma diagnosis because of the risk of local recurrence around vital organs and increased associated mortality. In light of these anatomic

considerations, wide resection margins may be more challenging but also carry increased prognostic significance. Further, ALTs/WDLSs carry a risk of transformation to dedifferentiated liposarcoma.

Myxoid Liposarcoma

Unlike most other subtypes of soft tissue sarcoma, the histologic grade of myxoid liposarcoma is determined not by its pleomorphism or histopathologic aggressiveness, but rather by the percentage of round cells within the neoplasm. Tumors with a greater than 5% round cell component are considered high grade. In addition to the differences in histologic grading, myxoid liposarcomas demonstrate an atypical pattern of metastatic spread. Although the risk of pulmonary metastases remains, myxoid liposarcomas have a high predilection for extrapulmonary spread, namely to areas of high lipomatous content (e.g., bone marrow, retroperitoneal fat). MRI has shown to be most sensitive for identifying metastatic sites, with studies suggesting routine MRI of the spine as part of staging for this entity. Consideration may be given as well for whole-body MRI versus PET/CT to identify alternative sites of metastatic spread. High-grade myxoid liposarcomas appear to be particularly responsive to radiation therapy as well as systemic therapy, suggesting a potential role for neoadjuvant treatment.

Leiomyosarcoma

Leiomyosarcomas differentiate down a smooth muscle pathway such as seen in the uterus or vasculature. As such, these are commonly identified in the retroperitoneum. Differentiating a uterine leiomyosarcoma from the more common uterine leiomyoma may be challenging on preoperative imaging in some cases, suggesting a role for biopsy when the diagnosis is uncertain.

Extremity locations typically originate from venous structures and may demonstrate intramural or intravascular extension, with or without deep venous thrombosis. With wide surgical margins, local recurrence rates may be less than 5%, so preoperative radiation may be used more judiciously. However, distant recurrence rates remain high (up to 30%), indicating a potentially increased role for systemic therapy. Female patients with extremity leiomyosarcoma should undergo pelvic imaging to rule out a uterine primary site.

Synovial Sarcoma

Synovial sarcoma is the most common soft tissue sarcoma of the foot. On imaging, synovial sarcoma may demonstrate dystrophic calcifications in up to one-third of patients, which may help in the diagnosis. These may show a very slow initial growth kinetic, which may be confused for an indolent or benign process over several years, potentially delaying the diagnosis. This high-grade, translocation-associated sarcoma (t(X;18) SYT-SSX) may be seen in a younger age population than most other soft tissue sarcomas, including children and adolescents. In addition, synovial sarcomas have shown to be relatively chemosensitive to doxorubicin-ifosfamide–based therapy, and they may be considered for neoadjuvant therapy.

Epithelioid Sarcoma

Epithelioid sarcomas are the most common soft tissue sarcoma in the hand. Similar to synovial sarcoma, these may have a younger age demographic than most other soft tissue sarcomas. Histologic markers for cytokeratins and epithelial membrane antigen (EMA) may be confused for carcinomas. Epithelioid sarcomas commonly present as small, superficial soft tissue masses, which may ulcerate through the skin. Local satellite nodules may be seen in the surrounding soft tissues. In addition, a high rate of nodal metastasis (20%) suggests a potential role for PET/CT. The role for routine sentinel lymph node biopsy remains unclear for this diagnosis.

Malignant Peripheral Nerve Sheath Tumors

Up to 50% of malignant peripheral nerve sheath tumors (MPNSTs) may be seen in the setting of neurofibromatosis type 1 (NF-1). These typically high-grade malignancies originate either from peripheral nerves or from neurofibromas. These have a high rate of local or distant recurrence. Differentiation of the MPNST from surrounding neurofibroma may be challenging at the time of surgery in many cases, though functional MRI techniques and FDG-PET have been demonstrated to be discriminating in this regard.

Myxofibrosarcoma

Whereas most extremity soft tissue sarcomas present deep to the investing fascia, myxofibrosarcomas most commonly present on the superficial aspect of the fascia. These masses tend to infiltrate along fascial planes, often manifesting by a large area of peritumoral edema. This peritumoral "reactive zone" has been shown to harbor malignant cells along the entire area of enhancement, which can be quite sizable in some instances. Perhaps myxofibrosarcoma is associated with high rates of local recurrence because of this infiltrative nature.

Particular attention to margin status, excising the entire area of peritumoral inflammation with wide margins, is key for adequate local control. Fortunately, this entity tends to be relatively radiosensitive, and consideration may be given for preoperative radiation. The large area of superficial resection may often necessitate advanced soft tissue closure or flaps. Some advocate for a staged approach, with local wound care until final histopathologic margins can be confirmed, before performing soft tissue coverage procedures.

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans (DFSP) represents another soft tissue sarcoma subtype that typically presents in the superficial soft tissues. Similar to myxofibrosarcomas, they tend to be quite infiltrative. Because of their superficial location and often indolent initial growth pattern, DFSPs often present to the sarcoma surgeon following an unplanned initial excision. In light of their infiltrative nature, local recurrence rates may be high. As such, microscopic margin status is of paramount importance. Similar to myxofibrosarcomas, a staged reconstructive approach may be considered.

These tumors are often low grade and are therefore not typically indicated for radiation therapy or chemotherapy. However, up to 10% may demonstrate fibrosarcomatous dedifferentiation, suggesting a more aggressive biologic behavior.

SUMMARY

Soft tissue sarcomas represent a wide variety of malignancies of mesenchymal origin, involving nearly all anatomic sites. Reflecting the range of underlying histopathologic entities, a carefully considered clinical approach is necessary. In extremity locations, limb-sparing surgical excision is typically achieved. A multidisciplinary approach among the surgical team, medical oncology team, and radiation oncology team is critical. In addition to wide surgical excision, most high-grade sarcomas may be treated with radiation therapy to improve local control. Careful consideration of the potential role of systemic chemotherapy and/or immunotherapy may be given on an individualized basis. Ultimately, a thorough understanding of this family of diseases and the unique attributes of each individual entity affords the best clinical results.

Management of Solitary Neck Mass

Christopher A. Maroun, MD, and Peter S. Vosler, MD, PhD

GENERAL PRINCIPLES

The neck is composed of a complex anatomic infrastructure that includes a rich lymphovascular supply and an intricate compartmentalization of various structures and tissues. Neck masses thus result from multiple etiologies, and the most crucial aspect of management of a solitary neck mass is obtaining a diagnosis. This requires consideration of the holistic view of the patient in conjunction with thorough knowledge of the anatomy of the neck. Proper workup includes a thorough history, focused physical examination, and an appropriate choice of ancillary studies to narrow the differential diagnosis (Fig. 1). Patient characteristics such as age and gender provide clues directing investigation of the diagnosis; however, the increasing incidence of human papilloma virus (HPV)-related head and neck cancer in younger patients warrants a critical evaluation of every neck mass to rule out malignancy. The purpose of this chapter is to provide a comprehensive overview of the workup and management of neck masses in the context of the complex anatomy of the neck for optimal treatment.

ANATOMIC CONSIDERATIONS

Understanding of the compartments and drainage pathways of the neck provide clues regarding the cause of the mass, and it is also important to consider when planning procedural intervention. Classically, the neck is divided into an anterior and posterior triangle by the sternocleidomastoid (SCM) muscle (Fig. 2A). These triangles can be further subdivided into occipital and supraclavicular triangles posteriorly, and submandibular, carotid, and muscular triangles anteriorly. Clinically, the Memorial Sloan-Kettering system, which denotes levels of the neck according to both radiographic and surgical anatomic boundaries, is used (Fig. 2B). If a neck mass is suspicious for a metastatic focus of malignancy, knowledge of the nodal basins of the neck and their associated primary sites helps guide both physical examination as well as subsequent testing.

A thorough knowledge of neck anatomy is vital for making a clinical diagnosis and avoiding procedural complications. In particular, the topography of the neck can be useful for assigning a location to a mass during physical examination, as well as for estimating the distance from vital structures. Palpable landmarks in the midline of the neck include the *hyoid bone* superiorly, followed by the *thyroid cartilage notch*, the *cricoid cartilage*, and the *sternal notch* moving inferiorly. These normal landmarks may be difficult to appreciate in a patient with excess subcutaneous tissue, and conversely may be mistaken as pathologic, by both patients and physicians, in a patient with minimal subcutaneous tissue. A prominent carotid bulb is also occasionally mistaken for a mass; its pulsatile nature provides reassurance of normal anatomy. Other structures that may be mistaken for pathology include the superior horns of the thyroid cartilage, the greater cornu of the hyoid bone, the transverse processes of C1, and a prominent submandibular gland.

One should be familiar with the proximity of a neck mass to the number of critical structures found within the different neck compartments. Most of these structures lie deep to the platysma muscle, which serves as a good landmark during dissection. The external jugular vein and the great auricular nerve, which provides sensation to the external ear, lie more superficially and are found within the same layer as the platysma deep to the superficial cervical fascia. Caution should be taken when attempting to excise masses found in level I, as the marginal mandibular branch of the facial nerve can be found superficial to the fascia of the submandibular gland. Injury to the marginal mandibular branch can result in weakness of the depressors of the lower lip, resulting in an asymmetric smile and, in severe cases, can lead to oral incompetence. Other nerves that lie deeper but are at risk of damage in this area include the lingual nerve, which provides sensation and taste to the anterior two-thirds of the tongue, and the hypoglossal nerve, which provides motor innervation to the intrinsic muscles of the tongue. The accessory nerve, which provides innervation to the trapezius and SCM muscles, is at risk when dissecting within level II and level V. Dissection within level IV can lead to a chyle leak due to injury of the thoracic duct. The midline overlying the trachea is generally safe for dissection; however, just lateral to midline within the tracheoesophageal groove lies the recurrent laryngeal nerve, which provides innervation to all the muscles of the

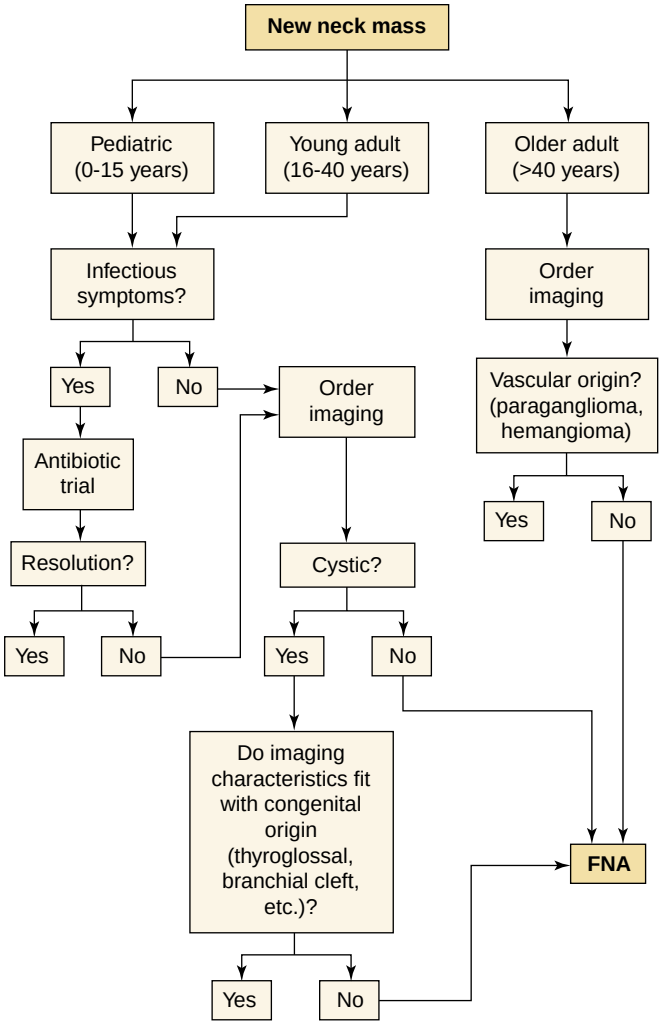

FIG. 1 Diagnostic algorithm for a new neck mass. The distinction made based on age of 40 years should be taken as a general guideline to be adjusted based on clinical evaluation and not as an absolute rule. *FNA*, Fine-needle aspiration. *(Modified from Flint PW, Haughey BH, Lund VJ, et al. editors:* Cummings Otolaryngology: Head & Neck Surgery. *5th ed. Philadelphia: Elsevier; 2010.)*

larynx except for the cricothyroid muscle. Damage to the recurrent laryngeal nerve can lead to vocal cord paresis, and bilateral injury can result in airway compromise due to an inability to adequately abduct the vocal cords.

DIFFERENTIAL DIAGNOSIS

Solitary neck masses can arise due to various causes: *neoplastic* (both benign and malignant), *congenital*, *infectious*, *traumatic*, and manifestations of *systemic* disease (Fig. 3). Age of the patient is a useful factor in guiding the differential diagnosis. In children, the most common cause of a solitary neck mass is cervical lymphadenitis. Congenital neck masses, such as branchial cleft cysts and thyroglossal duct cysts, are the second most common type. Most neck masses in children are benign, yet malignant tumors such as lymphoma, rhabdomyosarcoma, and neuroblastoma may manifest themselves as a solitary neck mass. In contrast, a neck mass in an adult, regardless of age and history of smoking and alcohol consumption, should be considered a malignancy until proven otherwise. This is especially true given the rising incidence of HPV-related head and neck cancer in recent decades.

DIAGNOSTIC EVALUATION

History

A thorough history should be obtained. Timing and evolution of the mass is important in determining the etiology. It is useful to delineate how and whether the patient first noticed the mass, as occasionally the mass itself will be preceded by other symptoms such as pain. Alternatively, the patient may not have noticed an asymptomatic mass and rather was referred due to an incidental finding on physical examination or imaging. Pain attributed to the mass itself is often not revealing on its own; however, throat pain and referred otalgia may be suggestive of a primary process in the oropharynx, hypopharynx, or larynx. Changes in size, appearance, and overlying skin changes including erythema, bleeding, and drainage are important to determine, as well as a recent history of trauma. Associated symptoms that may include epistaxis, nasal obstruction, hearing loss, dysphagia, dysphonia, dyspnea, and hemoptysis should always be evaluated. When present, they prompt a higher suspicion for malignancy. Systemic symptoms including fever, night sweats, weight loss, and symptoms of hyper- or hypothyroidism are also important to obtain. The evaluating physician should inquire about a personal or family history of head and neck cancer, as well as a history of radiation to the head and neck. Other medical comorbidities that may place patients at risk of contracting atypical infections include a history of immunodeficiency, diabetes mellitus, or autoimmune disease. Immunosuppression can also increase the risk for malignancy. Social factors such as a history of tobacco, alcohol, and marijuana consumption along with a sexual history should be obtained as further risk factors for malignancy. A history of sexually transmitted infections or multiple sex partners may increase the risk of developing an HPV-related oropharyngeal malignancy. Travel and occupational history can be important in some cases, where exposure to asbestos, saw dust, and other inhaled chemicals may increase the risk of malignancy or atypical infection. History of surgery to the head and neck area is important when considering operative intervention as prior surgery can change the surgical anatomy and place important anatomic structures at increased risk during dissection, secondary to fibrosis and the obfuscation of dissection planes. Anticoagulants and antiplatelet medications should be asked about because these may need to be stopped before and after surgery. A history of adverse reactions to general anesthesia or a history of difficult intubation is also important to consider when taking a patient to the operating suite. Prior interventions, including treatment with antibiotics, biopsies, and surgery should be elicited during any evaluation. A mass persistent through antibiotic treatment may represent an underlying anatomic abnormality or malignancy.

A rapidly growing tender mass in a pediatric patient most often represents cervical lymphadenitis. A mass that has been present for a while and periodically grows and shrinks or repeatedly becomes infected may suggest a congenital mass such as a branchial cleft or thyroglossal duct cyst. A history of trauma may suggest a hematoma or seroma. A slowly growing nontender mass may represent an atypical infection in a pediatric patient or a metastatic lymph node in an adult. This, accompanied with a progressive history of hoarseness, may suggest the presence of a laryngeal malignancy. Unilateral nasal obstruction may indicate a sinonasal malignancy. Unilateral hearing loss may represent an obstructive mass of the ear canal, a middle ear effusion secondary to a nasopharyngeal mass blocking the eustachian tube, or a tumor compressing the auditory nerve. A history of fevers, night sweats, and weight loss may be suggestive of lymphoma.

Physical Examination

A good physical examination includes the general appearance of the patient. A patient appearing cachectic or ill increases the suspicion for malignancy. Increased work of breathing as well as hoarseness can point toward a laryngeal primary process that may manifest as a metastatic neck mass. Evaluation of the mass itself should include an estimate of the size, shape, mobility, fluctuance, depth, and location. A

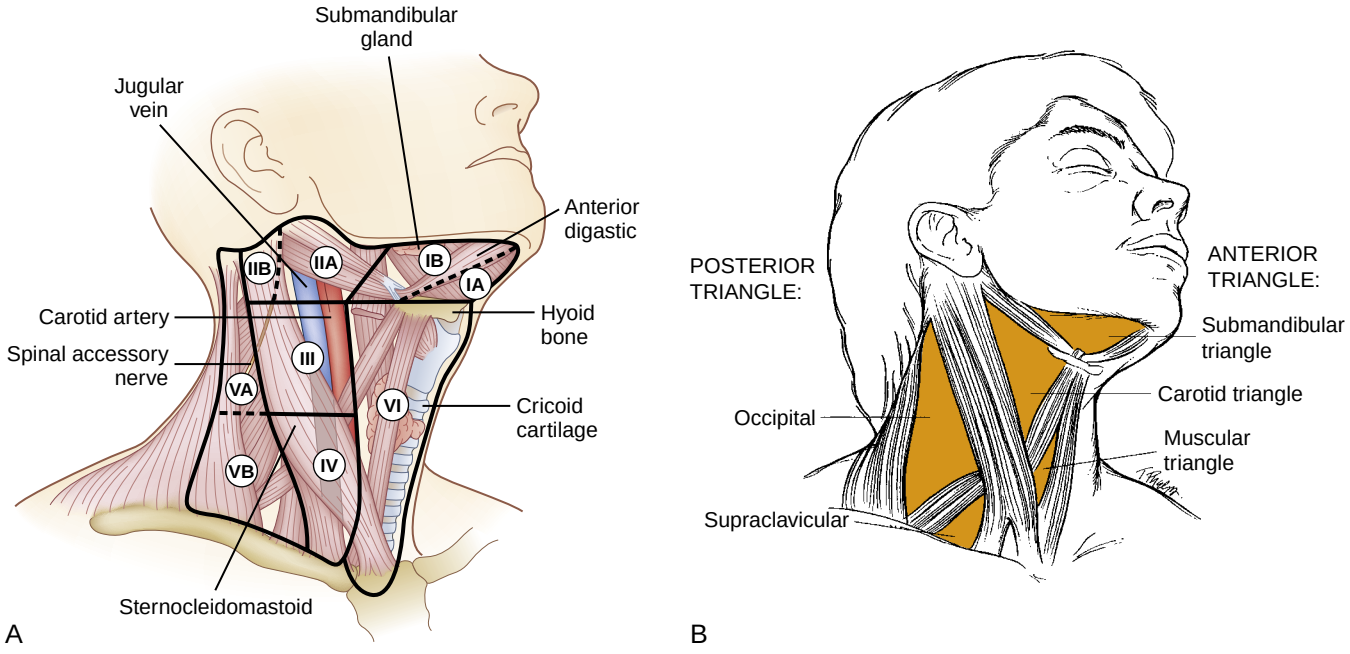

FIG. 2 Compartments of the neck. **(A)** Numbered lymph node levels of the neck. Boundaries are given in Table 1. Criteria exist to define these levels radiographically and surgically. **(B)** Anterior and posterior triangles of the neck, divided by the sternocleidomastoid muscle. The anterior triangle is further subdivided into the carotid, submandibular, submental, and muscular triangles; the posterior belly of the omohyoid divides the posterior triangle into occipital and supraclavicular triangles. TABLE 1 Cervical Lymph Node Groups and Associated Primary Sites of Metastasis

Level	Lymph Node Group	Boundaries				Primary Sites of Metastasis
		Superior	Inferior	Anteromedial	Posterolateral	
IA, IB (subdivided by anterior belly of digastric)	Submental, submandibular, prevascular, and retrovascular facial nodes	Mandible	Hyoid	Midline	Stylohyoid	Skin, lip, oral cavity, submandibular gland, parotid gland, paranasal sinuses
IIA, IIB (subdivided by spinal accessory nerve)	Upper jugular nodes	Skull base	Inferior border of hyoid/ carotid bifurcation	Stylohyoid	Posterior border of SCM	Parotid, oral cavity, oropharynx, larynx, hypopharynx, nasopharynx, thyroid
III	Middle jugular nodes	Inferior border of hyoid/ carotid bifurcation	Inferior border of cricoid/ omohyoid muscle	Sternohyoid	Posterior border of SCM	Oral cavity, oropharynx, hypopharynx, larynx, thyroid, cervical esophagus
IV	Lower jugular nodes	Inferior border of cricoid/ omohyoid	Clavicle	Sternohyoid	Posterior border of SCM	Oropharynx, hypopharynx, larynx, thyroid, cervical esophagus, Virchow's node (lung or abdominal malignancy)
VA, VB (subdivided by plane of inferior border of cricoid)	Posterior triangle nodes	Junction of SCM and trapezius	Clavicle	Posterior border of SCM	Anterior border of trapezius	Nasopharynx, skin including scalp, thyroid, infraclavicular primary
VI	Prelaryngeal, pretracheal, and paratracheal nodes (central compartment)	Hyoid bone	Sternum	Midline	Carotid sheath	Thyroid, larynx, hypopharynx, cervical esophagus
VII	Variably defined	Substernal extension of level VI to level of the innominate artery				-

superficial mass is more likely to be benign, such as a lipoma or epidermal inclusion cyst. The location of the mass should be described in relation to other anatomic structures (i.e., at the level of the hyoid bone or just inferior to the cricoid) as well as by cervical level. This provides a standard nomenclature to convey findings to other providers and is useful for identifying the source of the primary disease process.

A complete head and neck examination should be performed during the initial evaluation. This includes a thorough examination of the skin, including the scalp, which can reveal discrete lesions or more global evidence of sun damage. An otoscopic examination of the ears evaluates for lesions of the external auditory canal. A unilateral effusion in an adult should prompt endoscopic evaluation of the eustachian tube opening to rule out a primary nasopharyngeal malignancy. Anterior rhinoscopy should be performed to evaluate for lesions of the nasal vestibule, and in the absence of rhinologic complaints, is often sufficient for evaluation of the neck mass.

Examination of the oral cavity should include bimanual palpation as well as evaluation of all subsites of the oral cavity including the oral tongue, floor of mouth, the gingiva, and the teeth. Periodontal disease is important to note as this can lead to cervical lymphadenopathy. Dentures, if present, should be removed to examine the underlying mucosa. Clear saliva should be able to be expressed from the Stenson's (parotid) and Wharton's (submandibular) duct openings via gentle massage of the glands. If sialadenitis is suspected, purulence or turbid saliva may be expressed; obstructive stones may also be palpated. Mandibular and palatal tori are benign bony outgrowths that are commonly seen on examination and are unrelated to the presence of a neck mass.

The oropharynx is examined next. The soft palate is evaluated for lesions and symmetric elevation. Examination of the palatine tonsils may reveal asymmetry, which may warrant consideration of biopsy in a patient whose presentation is concerning for malignancy. A laryngeal mirror may be used; however, it is now standard to perform flexible fiberoptic nasopharyngoscopy to examine the mucosal surfaces of the base of tongue, the vallecula, the epiglottis, arytenoid cartilages, piriform sinuses, and the glottis. The vocal folds should be assessed for masses, lesions, and symmetric motion. Examination of the neck should include palpation of all nodal basins. Examination of the thyroid should include bimanual palpation, as well as observation of movement of any potential thyroid masses with swallowing. Palpation of the sternal notch may reveal substernal extension. A thorough cranial nerve examination should be performed on every patient, and knowledge of the anatomic trajectory of different cranial nerves can help locate a primary lesion when there is a deficit. Facial nerve weakness may suggest a parotid neoplasm, whereas asymmetric soft palate elevation or tongue protrusion may be caused by a skull base lesion.

Other examination findings that are specific to particular disease processes include movement of a midline mass with protrusion of the tongue, which may suggest the presence of a thyroglossal duct cyst. Branchial cleft cysts, in contrast, lie lateral to midline and may be associated with a fistula. First branchial cleft cysts are found inferior to the auricle and may communicate with the external auditory canal or be associated with the facial nerve. Second branchial cleft cysts are the most common branchial cleft cyst. They are found on the anterior border of the SCM and may communicate with the tonsillar fossae. Third branchial cleft cysts are also found on the anterior border of the SCM but lie lower in the neck and may communicate with the piriform sinus.

Office-Based Endoscopy

Office-based endoscopy is an important tool in the evaluation of the solitary neck mass. When the history or physical examination suggests the possibility of mucosal malignancy, the use of flexible laryngopharyngoscopy allows the physician to evaluate all mucosal surfaces of the upper aerodigestive tract. Risk factors such as alcohol, tobacco use, and repetitive trauma/inflammation can lead to genetic and molecular changes throughout the aerodigestive tract in a process termed *field cancerization*, increasing the risk of malignant transformation and presence of multiple synchronous primary tumors. Mucosal changes or concerning lesions seen on endoscopy may warrant an in-office or intraoperative biopsy depending on the location. Flexible laryngopharyngoscopy provides better visualization than the laryngeal mirror examination and can be used to evaluate the nasal passages, nasopharynx, eustachian tube openings, base of tongue, vallecula, piriform sinuses, postcricoid region, epiglottis, arytenoids, and false and true vocal folds; in some patients, even the subglottic region may be visualized.

Laboratory Testing

Laboratory testing in most cases is of limited utility in the evaluation of the solitary neck mass. In cases where infection is suspected, a complete blood count can be obtained to evaluate for leukocytosis. Additionally, an erythrocyte sedimentation rate or a C-reactive protein level can be useful for tracking degree of inflammation over time. In cases of a thyroid nodule, a thyroid-stimulating hormone level can be helpful for determining if the nodule is metabolically active. Other more specific laboratory tests may be ordered on a case-by-case basis.

Imaging

In many cases, imaging is essential in the evaluation of the neck mass. In cases where the history and physical examination suggests an acute process, such as a reactive lymphadenitis, it may be appropriate to treat empirically and follow up the response before obtaining imaging. However, in most other cases, imaging is warranted and can provide valuable information regarding the location and possible etiology of the mass.

While historically radiographs were often utilized, advancement in imaging technology has made radiographs of the head and neck of limited utility. Computed tomography (CT) of the neck is now often the imaging study of choice in the evaluation of the neck mass (Fig. 4). A contrast enhanced scan is warranted in almost all cases if the patient does not have a contraindication, such as renal dysfunction or an iodinated contrast allergy. CT of the neck is useful not only for evaluation of the mass and its relationship to surrounding structures, but it also may reveal the location of a primary malignancy if the neck mass is suspected to be metastatic to a lymph node. A rim-enhancing lesion can suggest an infectious process/abscess, whereas more uniform uptake of contrast may suggest a vascular malformation. Cystic-appearing lesions on CT, especially in an adult, should be biopsied to rule out malignancy. In an adult with a smoking history where malignancy is suspected, a CT of the chest may also be obtained concurrently to screen for lung cancer or metastatic disease. In cases where a CT scan is contraindicated, magnetic resonance imaging (MRI) may also be used. MRI provides better resolution of soft tissue structures and, in some cases, can be more useful than a CT scan, especially if a primary salivary mass or nerve invasion is suspected. MRI may also be more desirable if the suspected mass is related to a glomus tumor, carotid body tumor, or schwannoma. Angiography may be indicated if a primary vascular lesion is suspected, or if preoperative embolization may be required.

The positron emission tomography (PET/CT) scan has become a useful adjunct in recent years; however, it is often not indicated as a first-line imaging study for the evaluation of a neck mass. It can be useful to evaluate for distant metastasis or identification of the location of unknown primary malignancies manifesting as a metastatic lymph node. It should be noted that some tissues within the head and neck are inherently more metabolically active than others, which can lead to a false positive result. Specifically, the palatine and lingual tonsils, as well as some salivary tissue, can have increased avidity on PET/CT as a normal variation.

A bedside alternative to these imaging modalities is the point-of-care ultrasound (POCUS), which is gaining more popularity in the clinic setting. Ultrasound has the advantage of ease of use in clinic, and it can be combined with a fine-needle aspiration (FNA) or core needle biopsy to expeditiously obtain tissue for pathology during the initial patient encounter. Ultrasound assesses the consistency of the mass (solid versus cystic), size, vascularity with Doppler, and concerning features for malignancy such as microcalcifications in thyroid cancer. Nevertheless, the sonographic images obtained are often operator-dependent, and formal training is needed to perform and interpret them appropriately.

Pathology

Ultimately, definitive diagnosis is contingent on obtaining tissue for pathologic analysis. Indications for biopsy may include failure of empiric treatment or suspicion for malignancy. Depending on the location of the mass, patient tolerance, and comfort level of the physician, a biopsy may be obtained in clinic or the operating suite. Although easily palpable masses may be biopsied based on feel alone, the use of ultrasound in clinic has facilitated and expedited the process of obtaining tissue for pathologic evaluation. Ultrasound may be combined with either FNA or core needle biopsy (Fig. 5).

FNA is a minimally invasive method that has become a standard of care for diagnosis of most neck masses, as it has the lowest procedural risk compared with other biopsy methods. FNA samples may be sent for cytology or culture and can therefore be useful for diagnosis of both neoplastic and infectious processes. If an abscess, seroma, or hematoma is suspected, needle aspiration of the mass can be both diagnostic and therapeutic. Should surgery be needed at a later date, FNA does not alter the surgical anatomy, result in significant fibrosis, or spread the tumor through the needle tract. Although FNA is most commonly used for biopsies in the head and neck, tissue architecture cannot be evaluated from FNA alone, which in certain situations may lead to inconclusive results. A core biopsy may be indicated for evaluation of some malignancies, such as follicular thyroid cancer, lymphoma, and sarcomas where more tissue may be required. It is important to note that for the evaluation of lymphoma, specimens are sent in saline to the pathology lab, as flow cytometry used for characterization of lymphoma cannot be performed on formalin-fixed specimens.

FNA can be performed in the clinic under manual or preferably under ultrasound guidance. Local anesthetic is generally recommended since multiple passes are often required. A 20-gauge needle on a 10-mL syringe with short IV tubing is sufficient to perform the procedure by aspiration. An alternative method is to use a 25-gauge needle on a 10-mL syringe using capillary technique. If using manual guidance, the mass should be fixated using the thumb and forefinger

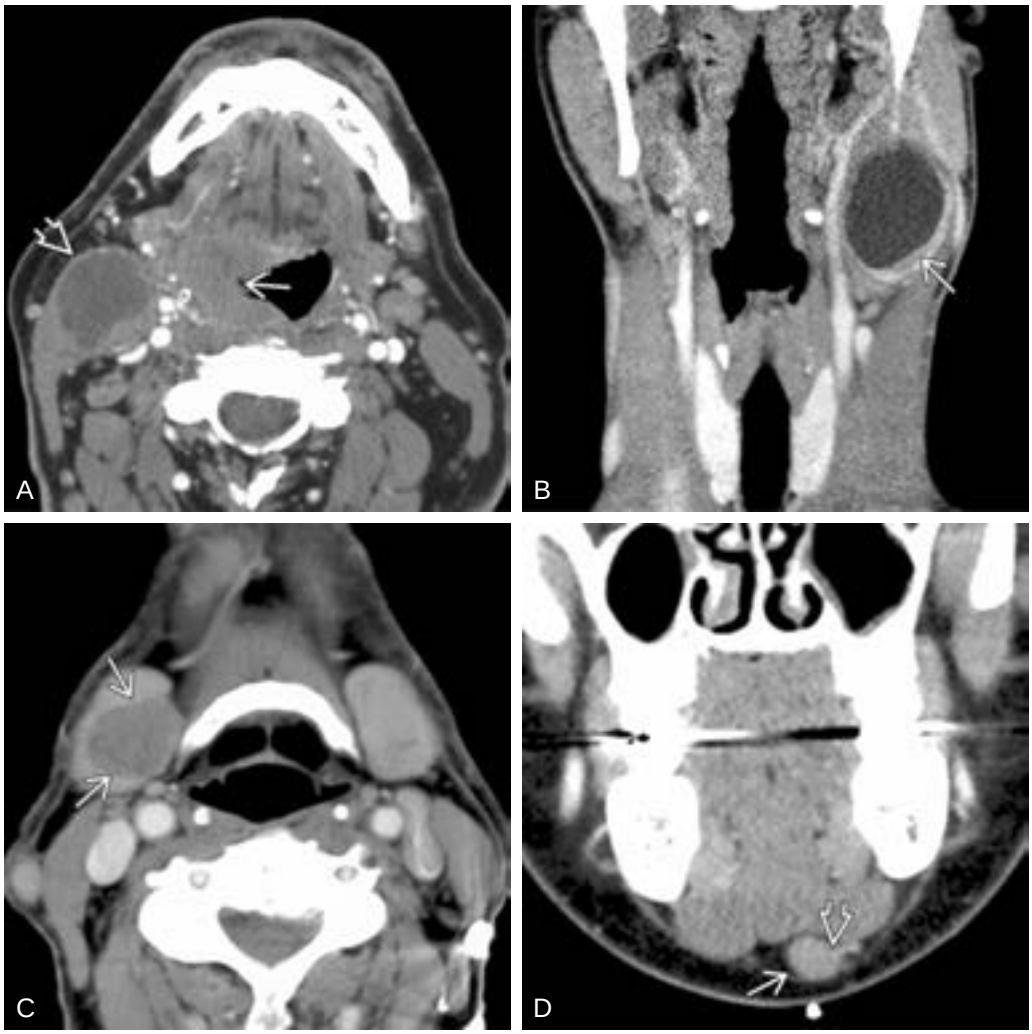

FIG. 4 Imaging characteristics of different neck masses on computed tomography. **(A)** Cystic metastatic lymph node with central necrosis in level IIA *(left arrow)*, with primary tumor found in the right oropharynx *(right arrow)*.**(B)** Coronal CT demonstrating a second branchial cleft cyst, anterior to the SCM and lateral to the carotid sheath. **(C)** Hypodense, well-defined mass enlarging the right submandibular gland, found to be a pleomorphic adenoma on histology. **(D)** Benign-appearing ovoid level IA node representing reactive adenopathy in a teenager. (**A,** *Nodal squamous cell carcinoma;* **B,** *2nd Branchial cleft cyst;* **C,** *Submandibular gland benign mixed tumor;* **D,** *Reactive lymph nodes. to stabilize it for entry with the needle. If using ultrasound guidance, centering the mass on the probe while following the needle's trajectory in the long or short axis improves visualization and success of the biopsy. Constant negative pressure should be applied during entry toward the mass, and multiple passes should be made through the mass while aspirating. If a lesion is cystic, the wall should be targeted to increase the diagnostic yield. The obtained sample should then be placed in a conical tube with cytology preservative or onto a slide and fixed with either formalin or ethanol and sent for cytopathologic examination.

Excisional biopsy should generally be performed as a last resort when other methods for obtaining tissue have failed. Excisional biopsy, depending on the location in the neck, poses increased risk to nearby anatomic structures, can lead to unfavorable scarring, and places the patient at risk related to general anesthesia when performed in the operating room.

Nasopharyngeal carcinoma is often associated with Epstein-Barr virus (EBV); therefore, any nasopharyngeal mass or a metastatic node in the setting of a nasopharyngeal mass should be tested for EBV. In the head and neck, HPV-related tumors most commonly grow from the lymphoepithelial crypts within the oropharynx, with the tonsil being the most common site followed by the base of tongue. HPV testing is most commonly performed via p16 immunohistochemistry staining, which is highly sensitive for HPV-related malignancy. However, it should be noted that p16 is not specific to oropharyngeal tumors and may also be related to a cutaneous primary. HPV in situ hybridization (ISH) is a far more specific laboratory test that can confirm the presence of HPV within the tumor cells and therefore has had increasing utility in the evaluation of a metastatic lymph node.

MANAGEMENT

Definitive management of the solitary neck mass may include observation, empiric treatment with antibiotics, or operative management. In the pediatric patient, management is often geared toward preventing recurrence of a benign or infectious process, while in the adult patient, management often involves ruling out malignancy.

Thyroglossal duct cysts are found in the midline and can be located anywhere along the thyroglossal tract remnant, from the base of the tongue to the thyroid. They are often noticed after they become infected; however, they may also be asymptomatic. They are often diagnosed at a young age but may not present until later in life. Treatment is classically by excision via the Sistrunk procedure, which involves removing the cyst along with its tract and the central portion of the hyoid bone. This method has been shown to decrease the rate of recurrence. Branchial cleft cysts may present in a variety of locations in the lateral compartments of the neck. Similar to thyroglossal duct cysts, they may become repeatedly infected, and this is often when they are diagnosed. Treatment is by surgical excision, as simple incision and drainage of an infected cyst will almost certainly result in recurrence. In cases where the cyst is associated with a fistulous tract, the tract should be obliterated or excised to prevent recurrence. Care should be taken to evaluate a suspected branchial

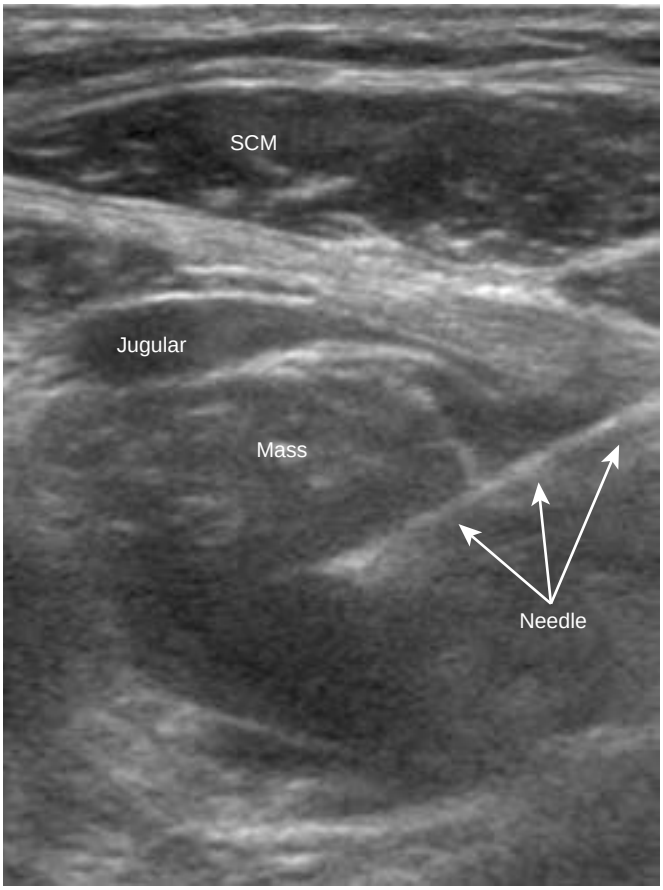

FIG. 5 Ultrasound-guided fine-needle aspiration biopsy of a neck mass lying posterior to the jugular vein. This biopsy was performed with a 22-gauge needle and confirmed metastatic papillary thyroid cancer. *SCM*, Sternocleidomastoid muscle.

cleft cyst for a metastatic cystic node in an adult as HPV-related cancers often manifest with an isolated neck mass.

Cervical lymphadenitis or a neck abscess can be treated with empiric antibiotics depending on the size, location, and associated symptoms. The immune status of the patient and other comorbidities may also play a role in the aggressiveness of treatment. Lesions not responding to antibiotics may require obtaining a culture and then directing antibiotic coverage appropriately. Atypical infections may require consultation with an infectious disease specialist to determine the appropriate antibiotic and duration of treatment. A deep neck abscess, depending on the size and location, may sometimes require more urgent operative intervention. Infection in the submandibular space may progress to Ludwig's angina, where floor of mouth swelling can cause prolapse of the tongue and rapid upper airway obstruction. A particularly large abscess in the parapharyngeal or retropharyngeal space can similarly narrow the airway. The retropharyngeal space communicates with the mediastinum, and infections in this area can lead to a life-threatening mediastinitis. Incision and drainage of a neck abscess alone is appropriate if there is no concern for an underlying congenital lesion or other anatomic abnormality. Should a neck abscess be related to IV drug use, one should take caution so as not to encounter any retained needles to avoid needlestick injury. Drainage of neck abscesses that are odontogenic in origin should always include removal of the involved tooth, either during the same procedure or shortly after abscess drainage.

Benign lesions may often be observed if they are asymptomatic, not rapidly growing, or not causing a cosmetic concern for the patient. Otherwise, the treatment of choice is most often surgical excision. Lipomas have a negligible risk for malignant transformation and may often be observed for years without significant change. They are often very superficial, mobile masses, and their removal generally poses a low risk of complications. Pleomorphic adenomas, however, are benign salivary gland tumors that have about a 1% risk of malignant transformation, termed *carcinoma ex pleomorphic adenoma*, and surgical excision is highly recommended. They are most commonly found in the superficial lobe of the parotid gland, followed by the submandibular gland. Care should be taken not to penetrate the tumor capsule during excision, as this can cause seeding of tumor throughout the surgical bed, resulting in increased risk for recurrence, along with the risk of a recurrent *carcinoma ex pleomorphic adenoma*. Thyroid nodules are best evaluated initially by ultrasound. The Thyroid Imaging Reporting and Data System (TIRADS) score can be used to evaluate for risk of malignancy and determine whether an FNA is warranted. Routine ultrasonographic surveillance may be warranted instead. If FNA is positive for malignancy, treatment with partial or total thyroidectomy with or without neck dissection may be indicated.

If a neck mass is found to be malignant, it most often represents metastasis from a primary tumor elsewhere in the head or neck. Effort should be made to find the primary tumor, and this search should be guided by the history, physical examination, and imaging when appropriate. Once a primary tumor is identified, it should be staged to determine the appropriate course of treatment. For squamous cell carcinoma (SCC) of the head and neck, a staging CT of the chest at minimum should be obtained. Treatment of the primary site may consist of single or multimodality therapy, including surgery, radiation, or chemotherapy. If surgery is pursued, depending on the location of the tumor and size of the expected defect, reconstruction for tissue coverage may be required. Treatment of the neck may include radiotherapy or modified radical neck dissection. The levels to be included are dictated by the primary tumor site and clinical involvement. Tumors that cross the midline often require bilateral neck dissection, and tumors in the base of tongue and hypopharynx have a much higher rate of bilateral nodal metastasis secondary to the rich lymphatic network in these anatomic sites. A multidisciplinary team should be involved in the management of head and neck cancer, and referrals should be made as appropriate to speech and language pathology, nutrition, medical oncology, and radiation oncology.

Almost 90% of patients with a metastatic SCC to the neck will have a primary tumor identified on physical examination, flexible laryngoscopy, or imaging. However, a number of patients will have no identifiable primary at initial evaluation. These patients should be taken to the operating room for examination under anesthesia and a comprehensive evaluation of the aerodigestive tract, including the nasopharynx, oropharynx, hypopharynx, and larynx. If a primary tumor still cannot be identified, ipsilateral or bilateral tonsillectomy may be performed and can reveal a primary tumor in approximately 40% of cases. Lingual tonsillectomy can also be considered. If the metastatic node is low in the neck, in levels IV or V, suspicion for an infraclavicular primary should also be raised and evaluation should include esophagoscopy, bronchoscopy, and imaging of the chest, abdomen, and pelvis.

Surgical Infections of The Hand

Visakha Suresh, MD, and Jaimie T. Shores, MD

BACKGROUND

Hand infections can be secondary to a wide variety of pathogens, and proper management is important to prevent long-term sequelae that can compromise functionality. Complications from these infections can result in severe disabilities, ranging from joint stiffness and contracture to amputation. Although most infections do not necessitate immediate surgical intervention, it is imperative to understand the unique pathophysiology and relevant anatomy that differentiates serious infections requiring emergent treatment from less urgent diagnoses.

GENERAL PRINCIPLES

Initial management depends on a thorough patient history that elucidates the following: mechanism of injury (laceration, bite wound, puncture by and/or retained foreign body, etc.), the duration of symptoms, inciting or alleviating factors (increased pain with ranging of a specific joint, etc.), patient occupation, and any contributing medical comorbidities. Significant medical diagnoses such as diabetes, immunocompromised state, or recent intravenous drug usage may be indicative of infections by atypical or otherwise nonvirulent pathogens. Certain mechanisms of injury or risk factors are associated with specific pathogens: *Pasteurella multocida* with dog/cat bites, *Eikenella* with human bites, *Herpes simplex virus* in dentists and dental hygienists, and *Vibrio vulnificus* in fishermen or wounds exposed to salt or brackish water.

EXAMINATION

Initial visual inspection of the bilateral hands must be performed after removal of any dressings/bandages, jewelry, or clothing. Note the skin color, size, shape, and position of the hand and fingers at rest. Examine the skin of the hand and fingers for any lacerations, wounds, or punctures. Assess the motion of the hand and fingers at each joint (carpometacarpal, metacarpal, proximal and distal interphalangeal [DIP]); any limitations or aberrations between the affected and unaffected limb may provide clues regarding the underlying functional integrity of the joint or other soft tissue components. Examination of the hand using a handheld Doppler may also be performed if there is concern for vascular compromise due to a possible concomitant injury. Sensory examination should be performed before infiltration of local anesthetic.

TESTS AND IMAGING

Laboratory testing should include a complete blood count and electrolyte panel. Erythrocyte sedimentation rate and C-reactive protein may be helpful in cases of suspected osteomyelitis or septic arthritis. Cultures and gram stain may be useful in abscesses or deep space infections to help tailor antibiotic regimens; however, these studies are less useful in patients with chronic wounds. Consider sending cultures for atypical bacteria, mycobacteria, fungi, and viruses in high-risk patients (active chemotherapy, chronic immunosuppression, active or latent HIV infection). Standard three-view x-rays of the affected hand (posterior-anterior, lateral, and oblique) should be performed (with all jewelry and dressings removed) to rule out subcutaneous air, retained foreign body, or fractures. Arthrocentesis should be performed if septic arthritis is high on the differential Computed tomography is indicated in patients with multiple fractures or if there is concern for vascular injury or deep space infection. Magnetic resonance imaging is the gold standard for evaluation of osteomyelitis.

TREATMENT

Initial treatment for most hand infections includes antibiotics, immobilization, and elevation. Elevation is especially important in patients with significant edema and pain, and can be achieved with either pillows placed under the affected extremity or by using a soft, padded, vertical arm sling. If the patient is hemodynamically stable, antibiotics may be delayed until cultures have been obtained. Bedside procedures may be performed to remove accessible foreign bodies, lance superficial abscesses, or clean grossly contaminated wounds. These procedures may be performed after infiltration of local anesthetic with or without epinephrine.

If there is no clinical improvement after the first 48 hours, it is highly unlikely that a prolonged course of antibiotic will suffice. In the setting of infection, local vessels are often inflamed and thrombosed, compromising circulation and reducing the efficacy of intravenous antibiotics. The hand also has numerous compartments and closed spaces in which walled-off abscesses can form; these are not amenable to IV antibiotics alone.

Patients with delayed presentations (>48 hours), rapidly progressive symptoms, or deep abscess formation as seen on imaging studies are candidates for operative intervention. Due to the unique anatomy and functional requirements of the hand, placement of surgical incisions is of utmost importance; poorly placed incisions may lead to inadequate visualization of anatomic compartments or, in the long term, scarring and contracture formation that compromises range of motion.

Thorough irrigation and debridement of any obviously nonviable tissue must be performed. Afterward, the wound may require closed or open postoperative drainage. If a tourniquet is used, the arm should be elevated and direct pressure applied to the brachial artery for 1 minute before inflation. This minimizes the risk of systemic bacterial infection. Intraoperative cultures should be acquired and the hand splinted postoperatively for at least 3 days.

MINOR INFECTIONS

Cellulitis

Cellulitis is an infection of dermis and subcutaneous tissue and may be associated with lymphangitis. The most common infecting organisms are *Staphylococcus* and group A *Streptococcus*, with the former being more common (more than 80% of cases). Cellulitis may also be the cutaneous representation of a deeper infection or abscess. Patients may cite a recent history of abrasion, puncture wound, or concern for retained foreign body.

Symptoms

Patients often present with erythema, warmth, swelling, and local adenopathy. Localized swelling may result in moderate to severe discomfort on palpation of the affected digit or region of the hand or with active/passive ranging of the joint. A thorough history is necessary to establish the chronicity of the infection.

Treatment

Initial management involves hand immobilization, elevation, and antibiotics. The area of erythema and swelling should be demarcated with a surgical skin marker to establish the progression/regression of the infection after beginning treatment. If a foreign body or underlying abscess is present, this should be removed or drained.

The affected extremity should not be used for venipunctures so as to avoid more proximal seeding of the limb. Patients with more minor cases of cellulitis may be treated as an outpatient. However, patients with worsening cellulitis or purulence, minimal response to antibiotics, or high-risk medical comorbidities may require inpatient treatment with IV antibiotics. Given the high prevalence of *Staphylococcus* infections, penicillins or first-generation cephalosporins are often used as first-line therapy; patients with penicillin allergies may be prescribed clindamycin or a fluoroquinolone. Vancomycin should be considered if there are patient-specific risk factors for methicillin-resistant *Staphylococcus aureus*.

Paronychia

The fingernail is defined by four boundaries: the two lateral paronychia, the proximal eponychium, and the distal hyponychium. An infection along the lateral folds of the fingernail's paronychia is one of the most common infections of the hand. An infection along the eponychium is classified as an eponychia. These nailfold infections are often caused by bacteria that are inoculated into the soft tissue; common etiologies include nail biting or hang nails. Patients may also present with a recent history of manicures or penetrating trauma to the region. Common organisms include *Staphylococcus* and oral anaerobes.

Symptoms

Patients may initially present with erythema and swelling at the site of the original infection, which then may spread to involve the adjacent nailfold. Without treatment, the infection may progress to increased fluctuance, pain, and eventually spontaneous drainage. Severe infections may progress to ascending cellulitis of the affected digit and hand.

Treatment

In early paronychia with only erythema and swelling, patients may be treated with oral antibiotics, soaks in warm soapy water (three times a day, for 10–15 minutes), and gentle splint immobilization. Patients should be counseled to avoid fingernail biting.

In cases with palpable fluctuance, surgical drainage is necessary. Cultures should be collected at the time of the decompression. The finger should be anesthetized with a digital block. To control any bleeding, a finger tourniquet may be applied using a Penrose drain or a cut finger of a glove that is rolled down to the base of the affected finger. Once the patient endorses numbness, a large-bore needle (18G) or a Freer elevator may be inserted under the nailfold to separate the nailfold from the underlying nail bed (Fig. 1). If using a needle, the bevel side should be pointed down to avoid unintentionally cutting the nailfold. Once the abscess is identified, the needle or a small blade should be utilized to make an incision away from the nail bed to decompress the abscess while avoiding injury to the underlying nail bed. If a single incision does not adequately expose the involved tissues, another parallel incision may be made to allow the eponychial fold to be reflected above the nail plate.

If the abscess is found to be under the nail plate itself, a portion of the nail plate can be elevated off the nail bed using a Freer elevator and cut with a small sharp scissors or scalpel.

The wound should then be dressed with a 0.25-inch iodoform ribbon gauze, nonadherent dressing (such as Xeroform or Telfa), and then gently wrapped. These dressings should be changed two or three times a day, and the finger should be soaked in warm, soapy soaks for 10 to 15 minutes. Oral antibiotics (with activity against *Staphylococcus*) should be prescribed for 5 days, and the patient should follow up in clinic in 1 week.

Chronic paronychia is characterized by an indurated and rounded eponychium and can lead to thickening of the nail plate. These are often seen in patients with chronic exposure to irritants or frequent water immersion (such as dishwashers, swimmers, etc.). Treatment of this problem is by marsupialization of the eponychial fold.

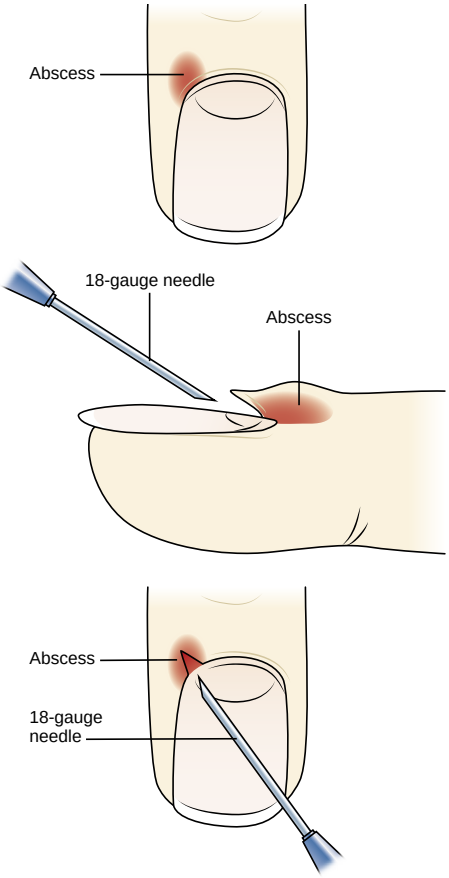

FIG. 1 Paronychia drainage. A large-bore intravenous needle (19- or 18-gauge) is inserted beneath the nailfold with the bevel side down and gently passed back and forth to lift the nailfold off the nail plate. This action allows for localization and puncturing of the abscess. The location of the abscess is noted. The needle is removed and turned 90 degrees. Using the sharp beveled edge as a knife, the nailfold is incised directly over the abscess to allow for drainage.

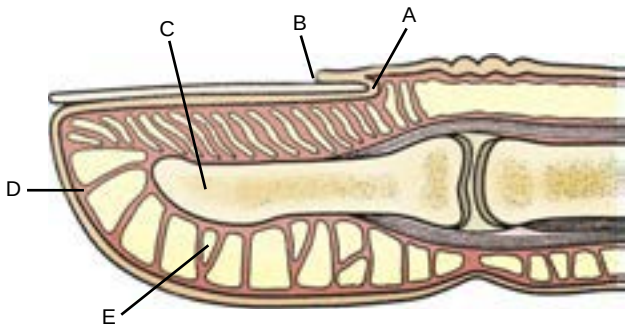

FIG. 2 Anatomy of the distal fingertip. Note the compartments formed by the vertical septae. *A,* Nail root; *B,* eponychium; *C,* distal phalanx; *D,* septum; *E,* finger pulp.

Felon

A felon is a subcutaneous abscess of the distal finger/thumb pulp. Note that not all abscesses of the distal fingertip are felons: superficial infections that only involve the skin are known as apical infections. Notably, a felon extends into the many compartments created by vertical fibers extending from the distal phalangeal periosteum into the epidermis (Fig. 2). Patients may describe a history of penetrating

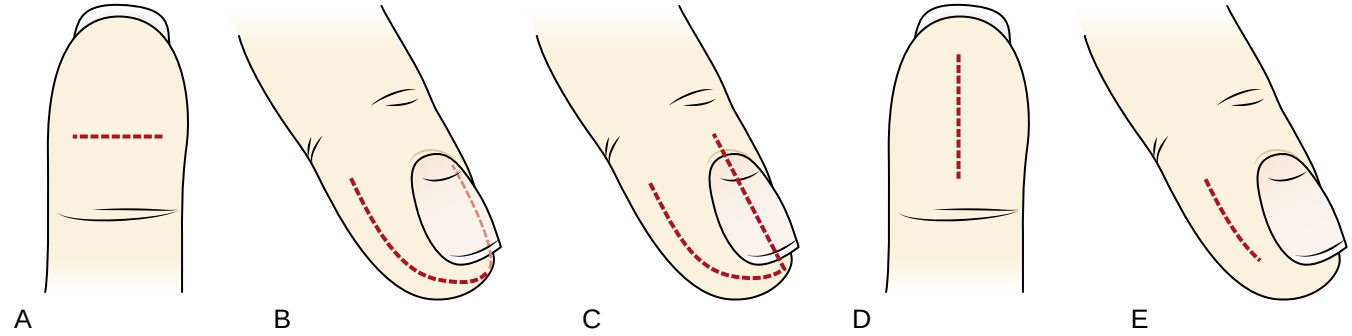

FIG. 3 Incisions used for draining felons. **(A)** Transverse palmar incision. **(B)** Fish-mouth incision; note the incision goes to the other side of the finger. **(C)** Hockey-stick, or J-incision. The two preferred incisions are **(D)** the longitudinal palmar incision and **(E)** unilateral longitudinal incision.

trauma or small cut. Diabetic patients who regularly use fingersticks for monitoring blood glucose levels are also at risk. Although *S. aureus* is the most common organisms, gram-negative rods and polymicrobial infections may be seen in immunocompromised or high-risk patients. Felons may progress to localized tissue necrosis, osteomyelitis of the distal phalanx, and septic arthritis of the DIP joint.

Symptoms

Patients often present with a rapid onset of pain, erythema, and significant swelling of the entire pulp of a fingertip. They may endorse a history of a localized injury or retained foreign body (such as a splinter). In severe cases with underlying cellulitis or septic arthritis, there may be some swelling that extends to the DIP crease.

Treatment

Oral antibiotics, warm soapy soaks, and elevation may be used in mild cases with minimal palpable fluctuance. However, fluctuance of the pulp or failure to improve with oral antibiotic treatment are indications for drainage. There are several locations for surgical incisions (Fig. 3). The midline of the fingertip in dorsal-volar axis contains several key anatomic structures that should be protected, namely the digital neurovascular bundle, flexor tendons, nail matrix, and the DIP joint space. After digital block and finger tourniquet application, a unilateral longitudinal incision is made (preferably on the side opposite the pinching surface of the finger but should be placed on the side where the patient reports maximal tenderness). A small mosquito clamp or Crile hemostat may be used to define the abscess cavity gently and bluntly without violating too much of the surrounding finger pulp. Afterward, the abscess cavity should be thoroughly drained and irrigated, and cultures should be obtained. The wound should be packed and changed two to three times a day with warm soapy soaks; patients should be prescribed a first-generation cephalosporin or clindamycin (if allergic to penicillin).

MAJOR INFECTIONS

Pyogenic Flexor Tenosynovitis

Pyogenic flexor tenosynovitis (FTS) is an infection within the flexor tendon sheath, between the visceral and parietal layers of the tenosynovium. This synovial sheath begins at the distal metacarpal neck, just proximal to the first annular pulley, and ends at the insertion of the flexor digitorum profundus on the distal phalanx. Of note, the flexor sheaths of the thumb and small fingers are continuous with the radial and ulnar bursae, respectively; thus, infections in these fingers can spread into these spaces if left untreated. Common causative organisms include *S. aureus* and group A *Streptococcus*. In immunocompromised patients or patients with a history of IV drug abuse, gram negatives and polymicrobial infections should be strongly considered.

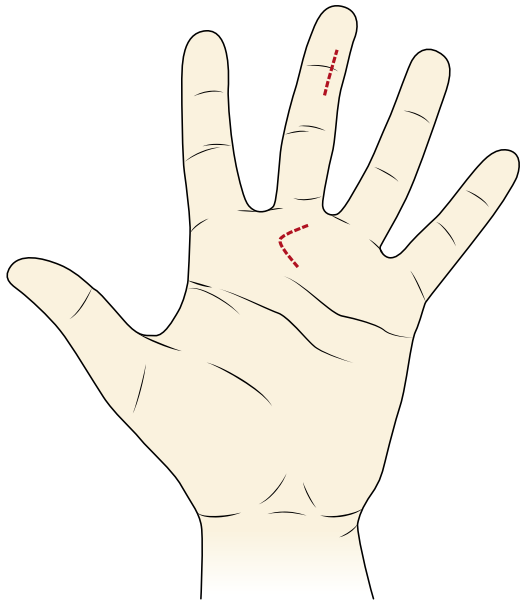

FIG. 4 Limited technique for draining pyogenic flexor tenosynovitis. The proximal incision is located over the A1 pulley. The second incision is made over the A5 pulley in the midaxial location.

Symptoms

Many patients will present with a history of penetrating injury. The most distinguishing features seen in a case of true flexor tenosynovitis include the four Kanavel signs: (1) marked, symmetrical swelling of the finger(s), resulting in a "sausage-like" shape; (2) fixed flexed posturing of the affected finger(s); (3) pain on passive extension of the involved finger(s); and (4) excruciating tenderness to palpation along the course of the flexor tendon sheath.

Treatment

Suspicions for flexor tenosynovitis necessitates immediate surgical intervention, along with initiation of broad-spectrum antibiotics.

Surgical drainage may be performed through a two-incision, limited exposure technique (Fig. 4). First, a proximal incision over the A1 pulley is made, which overlies the metacarpophalangeal joint of the affected finger. After dissecting down to the A1 pulley, the proximal half is incised, and a soft angiocatheter (16 or 18G) or pediatric feeding tube (5Fr) should gently be threaded into the underlying space. Cultures may be collected at this time. A second, midaxial incision should be made over the A5 pulley, overlying the distal phalanx, just distal to the DIP joint. The angiocatheter should then be sutured in place and the tendon sheath should be gently irrigated with 500 cc of normal saline. This second incision should serve as the

point of egress for the saline, and this should be noted during irrigation. If no fluid is seen, the angiocatheter should be repositioned. Afterward, the hand is loosely dressed, immobilized in a splint, and elevated. Irrigation may be continued for 48 hours. Afterward, the dressing may be removed and hand therapy may be initiated.

A more extensive and open debridement may be necessary in more severe cases, i.e., in immunocompromised patients or in the setting of frank purulence within the tendon sheath. A midaxial or volar zigzag (Bruner) incision (tracking between the joint creases) may be made at the cruciate pulleys with possible extension into the palm. The inflamed synovium should be visible and can be excised without damaging the delicate flexor pulley system and set for culture. The incisions are then closed loosely over an indwelling catheter for irrigation.

Infections of the Deep Spaces of the Hand

The hand is characterized by unique septae and investing fascia that anchors various soft tissues within well-delineated spaces. It is important to understand the borders and contents of these spaces to adequately treat them. There are six potential spaces (Fig. 5): five in the hand (the thenar, midpalmar, hypothenar, interdigital, and dorsal subaponeurotic spaces) and one in the volar (palmar) forearm (space of Parona). Common organisms are *S. aureus* and *Streptococcus* species. Common etiologies include penetrating trauma, retained foreign body, or contiguous spread from a subcutaneous abscess, flexor tenosynovitis, or from an adjacent deep space infection. Infections in any of these spaces necessitate surgical intervention with irrigation and packing.

Thenar Space

The borders of the thenar space are as follows: the interosseous muscles and the fascia of the adductor pollicis longus as the dorsal border; the tendon sheath of the index finger and the volar fascia as the volar border; the oblique fascial septum as the ulnar border; and the convergence of the adductor pollicis tendon and fascia at the thumb proximal phalanx as the radial border.

Symptoms

Patients will present with severe pain with both passive and active motion of the thumb; the thenar region will be extremely swollen. The thumb may be fixed in an abducted position due to swelling and/or a growing volume of purulence in this space.

Treatment

Surgical drainage is necessary for infections of the thenar space. Cultures should be obtained at the time of irrigation and drainage. A longitudinal volar incision is designed parallel to the thenar crease (Fig. 6). The palmar cutaneous branch and the recurrent branches of the median nerve are located in the subcutaneous and the deeper planes at the distal edge of the transverse carpal ligament, respectively, and must be protected when making the volar incision. Blunt dissection is performed carefully between the first and second metacarpal to decompress this space. The dorsal space between the adductor pollicis and the first dorsal interosseous muscle can also be accessed through this incision by extending it over the distal edge of the adductor.

A 1 to 2 cm longitudinal dorsal incision is designed over the most prominent dorsal aspect of the infection. However, the edge of the first webspace should not be included in the incision as this increases the risk of scar formation and possible webspace contracture. Dissection should be continued between the adductor pollicis and the first dorsal interosseous muscle, and the space thoroughly debrided. Note that a dorsal incision alone will not suffice for adequate irrigation of the thenar space.

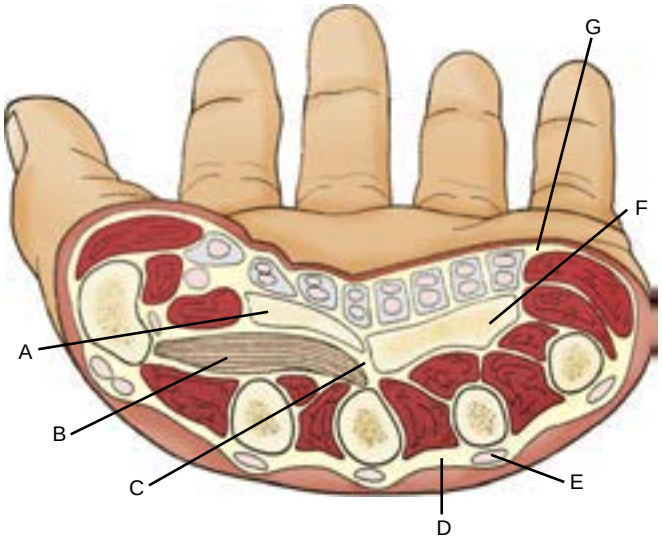

FIG. 5 Anatomy of the hand, cross-sectional view. The deep spaces are demonstrated: thenar space, midpalmar space, hypothenar space, and the dorsal subaponeurotic space. The interdigital webspace and the space of Parona are not shown. *A,* Thenar space; *B,* adductor pollicis muscle; *C,* midpalmar septum; *D,* dorsal subaponeurotic space; *E,* extensor tendon surrounded by dorsal aponeurosis; *F,* midpalmar space; *G,* palmar aponeurosis.

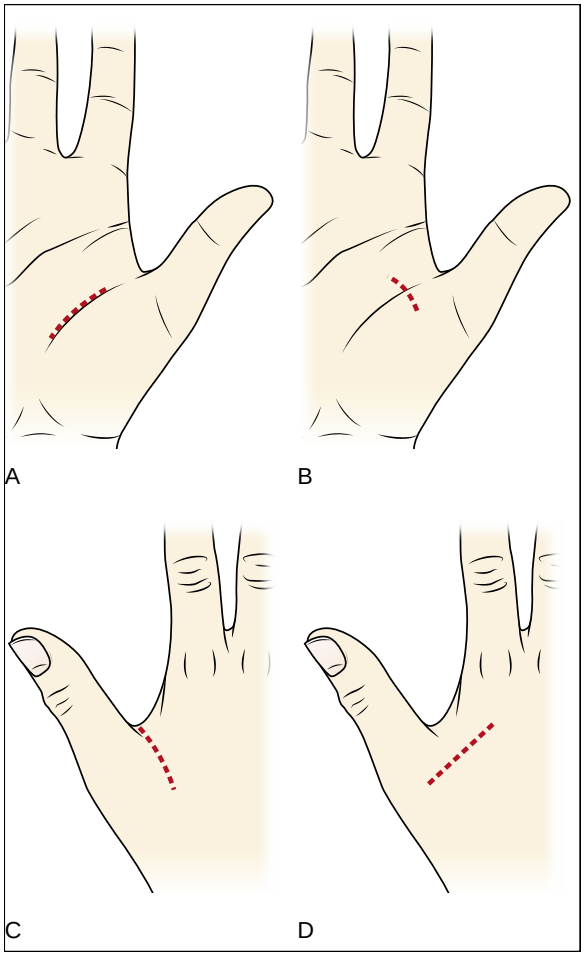

FIG. 6 Thenar space infection. **(A)** The palmar longitudinal incision is made parallel to or in the thenar crease. This is preferred over the palmar transverse incision **(B)**, dorsal incision, longitudinal incision **(C)**, and the transverse incision **(D)**.

Midpalmar Space

The midpalmar space lies between the hypothenar and thenar eminences. The borders are as follows: the fascia of the second and third volar interosseous muscles and periosteum of the third through fifth metacarpals as the dorsal border; the flexor sheaths of the long, ring, and small fingers and the palmar aponeurosis as the volar borders; the oblique septum as the radial border; and the hypothenar septum as the ulnar border.

Symptoms

Patients may present with paradoxical dorsal swelling of the hand due to the thick vertical fibrous septae of the palm that does not allow for much volar expansion. Fluctuance and erythema may be noted in the palm with loss of the typical concavity of the palm.

Treatment

Surgical drainage is the gold standard of treatment. A transverse, longitudinal, or combination incision may be used (Fig. 7). For example, the transverse incision can be designed either parallel or within the distal palmar flexion crease. The flexor tendons of the ring finger may be used as a guide for dissection, as deep dissection should be continued longitudinally on either side of the tendon to decompress the abscess. The oblique incision can be made proximal from the distal palmar flexion crease and extends along the long finger metacarpal, before stopping at the edge of the hypothenar muscles. Careful blunt dissection is performed until the midpalmar space is entered. Cultures should be collected and the abscess thoroughly irrigated and packed.

Hypothenar Space

Infections of this potential space between the fascia and muscle of the hypothenar eminence are rare. The borders are defined by the periosteum of the fifth metacarpal dorsally and the palmar fascia and fascia of the superficial hypothenar muscles volarly.

Symptoms

Patients present with erythema, swelling, and pain to palpation of the hypothenar space.

Treatment

A 3 cm volar incision should be made in line with the ulnar border of the ring finger, just proximal to the midpalmar crease toward the wrist flexion crease (Fig. 8). An ulnar incision may also be used instead, designed at the junction between the glabrous and dorsal skin of the hand. Most notably, blunt dissection in this area should proceed carefully to avoid injury to the ulnar artery and nerve contained within Guyon's canal.

Interdigital Webspace

The borders of this potential space are defined by the dorsal hand fascia and skin, the extensor mechanism, and metacarpophalangeal joint/capsule radially and ulnarly. These infections are often called "collar-button" abscesses. Patients may have a history of fissures within the skin of the webspace that put them at risk for infection.

Symptoms

Patients present with dorsal swelling due to the fibrous volar fascial attachments into the volar skin. Tenderness and fluctuance may be present as well. If the abscess is primarily volar, the fingers may be abducted.

Treatment

Surgical drainage and initiation of antibiotics are necessary for complete treatment of these abscesses. Incisions for surgical drainage must be carefully designed to prevent webspace contracture while also allowing for adequate exposure of the space (Fig. 9). A volar zigzag (Bruner) incision is placed between the metacarpal from the metacarpophalangeal joint to the base of the involved webspace.

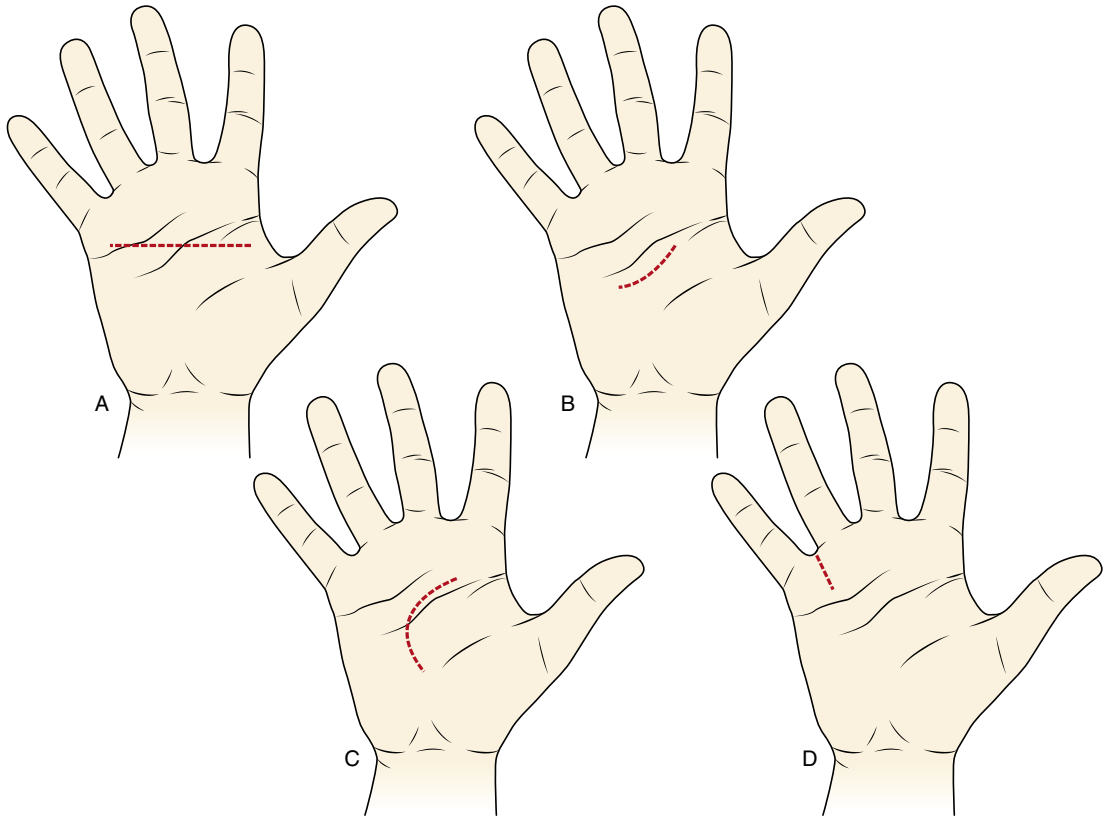

FIG. 7 Incisions used for draining midpalmar space infections. **(A)** Transverse incision. **(B)** Longitudinal or oblique incision. **(C)** Combined transverse and longitudinal incision. **(D)** Approach through the third lumbrical.

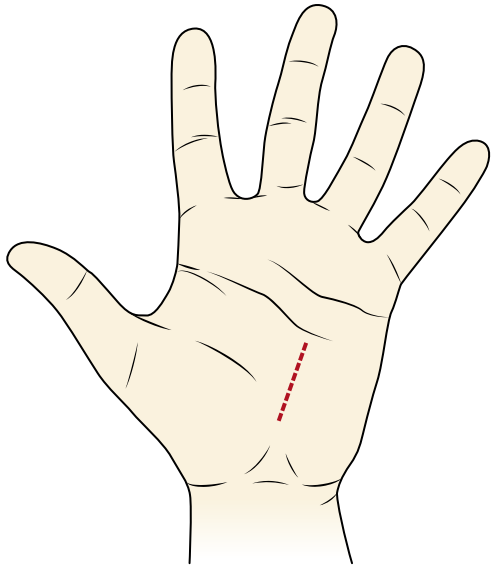

FIG. 8 Longitudinal incision for drainage of a hypothenar space is placed along the axis of the ring finger metacarpal in the proximal palm.

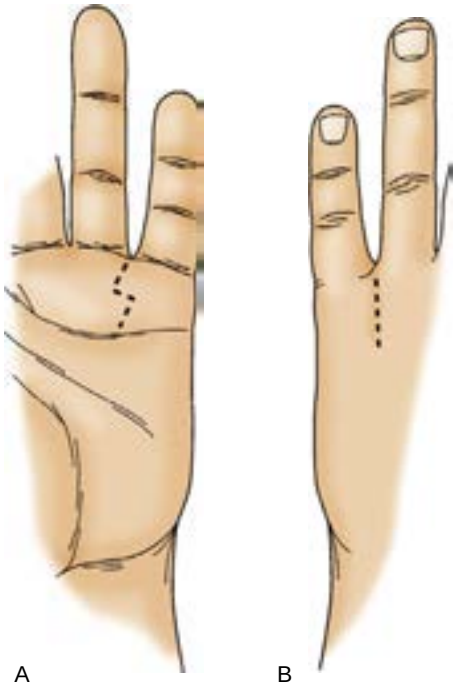

FIG. 9 Incisions for an interdigital webspace infection. Zigzag palmar incision **(A)** and dorsal longitudinal incision **(B)**.

Care must be taken to prevent injury to the neurovascular structures as they enter the affected fingers. A dorsal incision should also be made to thoroughly decompress and irrigate the space. Cultures should be collected, and the wound should be packed.

Dorsal Subaponeurotic Space

This is also another potential space on the dorsum of the hand deep to the extensor tendons and superficial to the interosseous muscle fascia and metacarpal periosteum.

Symptoms

The dorsal hand will be swollen, erythematous, and warm, similar to cellulitis. Fluctuance may also be present. Finger extension may be limited due to pain.

Treatment

In small abscesses, a single longitudinal incision over the most prominent aspect of the abscess may be used. In more diffuse infection, two dorsal longitudinal incisions over the second and fourth metacarpals can be made (Fig. 10). Incisions should be made in the fascia along the margin of the extensor tendon.

Space of Parona

Dorsal to the flexor digitorum profundus and volar to the pronator quadratus, the space of Parona is volarly located and continuous with the radial and ulnar bursae and the midpalmar space. Thus, infections in any of these other spaces may spread into the space of Parona. Untreated, advanced cases of flexor tenosynovitis may also result in infections in this area.

Symptoms

Patients present with erythema, tenderness, and potential fluctuance in the distal volar (palmar) forearm, with pain with active and passive flexion of the fingers.

Treatment

A longitudinal incision along the ulnar border of the palmaris longus should be designed, extending from the wrist flexion crease to the distal third of the forearm. The median nerve and tendons should be gently retracted radially to expose the space of Parona. Consider decompressing the midpalmar space as previously described, as infections from this area can spread into the space of Parona.

OTHER INFECTIONS

Animal and Human Bites

Bite injuries to the hand can result in significant morbidity if not treated in a timely manner; notably, the pathogens found in human bites are more virulent than that of animal bites. These "fight bite"

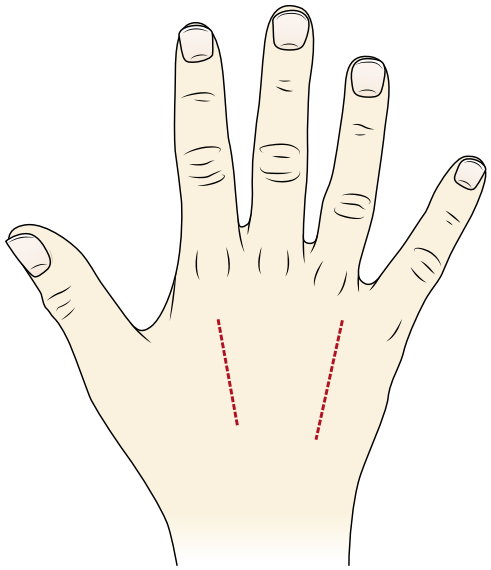

FIG. 10 Locations of the two dorsal incisions for draining a subaponeurotic space infection.

wounds are sometimes concomitant with other injuries, such as tendon lacerations and fractures. Human bites on any aspect of the hand or fingers have a high risk of infection and necessitate intraoperative exploration. If involving a joint, the wound should be extended to allow for complete arthrotomy, debridement of any devitalized tissue, and collection of multiple tissue cultures before thorough irrigation. Afterward, the hand should be splinted and elevated and intravenous antibiotics (typically a third-generation cephalosporin or gentamicin and a penicillinase-resistant penicillin) should be initiated.

Of the most common animal bites, dog bites are less likely to get infected but may be associated with significant soft tissue injury and/or fractures depending on the size of the animal; over half of all cat bites, on the other hand, get infected. It is imperative to take a thorough history including the rabies vaccination status of the animal. Cultures will show a mixed population of pathogens ranging from *S. aureus*, *Pasteurella multocida,* and *Streptococcus viridians* species. These wounds require thorough irrigation, local wound care, and IV ampicillin or oral Augmentin (for patients with penicillin allergies, antibiotic regimen may include fluoroquinolone and clindamycin).

Septic Arthritis

Infection of the interphalangeal and metacarpophalangeal joints of the fingers is rare. Incidence of septic arthritis of the wrist varies in the literature from 5% to 22% but is often associated with comorbid conditions such as immunosuppressed state, chronic renal disease, intravenous drug use, and diabetes. Although penetrating trauma is the most common cause, other mechanisms include hematogenous spread or contiguous spread from a local infection. Common pathogens include *S. aureus* and *Streptococcus*; *Eikenella* is a possibility if a human bite is present, whereas *Pasteurella multocida* should be considered in the setting of a cat or dog bite. Timely diagnosis is key to preventing destruction of articular cartilage that can then compromise the joint.

Symptoms

The patient may present with generalized symptoms such as low-grade fever, malaise, chills, and associated pain, erythema, and swelling in the involved joint. Active or passive motion of the joint will result in significant pain.

Treatment

Arthrocentesis is necessary to confirm the diagnosis. Samples should be sent for both cell counts, Gram stain, and microscopy to rule out other noninfective etiologies such as gout or pseudogout. Radiographs should be obtained; however, in acute infections, they will likely be normal. In chronic or severe cases, signs of osteomyelitis may be present. Septic arthritis is a surgical emergency; irrigation and drainage of the joint is the gold standard for treatment.

As with any surgical intervention on the hand, careful placement of incisions is key to prevent long-term complications. On the wrist, a longitudinal incision between the third and fourth dorsal compartments is preferred. For the metacarpophalangeal joints, a dorsal midline incision is made, and the extensor hood is then incised to exposed the joint. Damage to the sagittal bands, which originate from the volar plate and intermetacarpal ligament at the metacarpal neck and serve to stabilize the extensor tendon, must be avoided when exposing the joint. For the proximal interphalangeal joints, a midaxial incision from the DIP joint to the webspace should be designed. This will then avoid injury to the central slip; the accessory collateral ligaments and transverse retinacular ligaments are then incised to expose the joint. After cultures are obtained, the joint space should be copiously irrigated with normal saline (3–6 L), and any devitalized tissue should be debrided. Intravenous antibiotics are tailored according to surgical cultures and eventually transitioned to an oral regimen.

NECROTIZING INFECTIONS

Necrotizing fasciitis of the upper extremity is a true surgical emergency that necessitates immediate intervention to prevent further dissemination. Complications include amputations, septic shock, multisystem organ failure, and death. Patients may present with erythema, swelling, and significant pain; however, systemic symptoms such as hypotension, tachycardia, and altered mental status as well as soft tissue changes, such as skin sloughing/blistering or crepitus, differentiate this diagnosis from what is seen in more minor infections such as cellulitis. Subcutaneous air may be seen on plain films. Intravenous antibiotics and fluid resuscitation should be initiated immediately as the patient is transferred to the operating room for debridement. Infected tissues are superficial to the fascia, and grayish discharge ("dishwater drainage") may be seen intraoperatively. Multiple debridements may be needed before the infection is eradicated. Broad-spectrum antibiotics (such a multidrug regimen including vancomycin and piperacillin/tazobactam) should be continued until cultures are finalized.

SUMMARY

Hand infections need to be diagnosed accurately and in a timely manner to avoid long-term sequelae. A thorough understanding of anatomy and pathophysiology is necessary to treat these conditions effectively.

Nerve Injury and Repair

Christopher Frost, MD, and Gedge D. Rosson, MD

During the past 50 years, mainly due to the development of microsurgical techniques, surgeons have been routinely repairing severed peripheral nerves. This has paralleled the advances in microvascular reconstruction and digital replantation. Performance of nerve repair requires meticulous microsurgical technique and the use of both the science and art of peripheral nerve surgery. Furthermore, nerve repair is often an exercise in delayed gratification because many injuries can take months or even years to recover after repair.

BASIC ANATOMY

Nerve anatomy and physiology is fundamental to peripheral nerve surgery and guides the diagnosis of nerve injury. The basic subunit

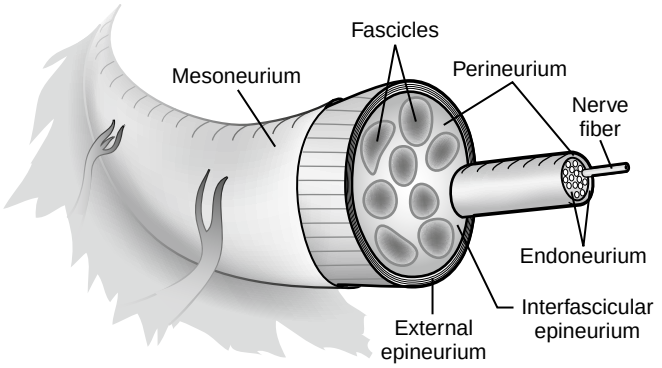

FIG. 1 Anatomy of a peripheral nerve.

of the peripheral nerve is the axon. These axons are surrounded by endoneurium and grouped into fascicles. Each fascicle is encapsulated by a perineurium, and groups of fascicles are in turn surrounded by an interfascicular epineurium. Each peripheral nerve is comprised of a group of fascicles surrounded by an external epineurium. Finally, the nerve sheath is contained within a mesoneurium, which both allows for nerve gliding during normal range of motion and contains the segmental blood supply to the nerve (Fig. 1).

FASCICULAR TOPOGRAPHY

When performing peripheral nerve surgery, it is important that proximal motor and sensory axons connect to their corresponding distal fascicles. More proximally there can be significant intermingling between sensory and motor axons with plexus formation in the nerve trunks proximally. As the nerves travel more distally, motor and sensory axons more clearly develop into distinct fascicles. This can have important clinical consequences after nerve repair. For example, repairing facial nerve injuries within the temporal bone often leads to improper connections between proximal and distal nerves. This can lead to a significant amount of disabling synkinesis and dyskinesis secondary to the lack of distinct fascicular architecture in the proximal facial nerve trunk. This is opposed to repairs distal within the face because these fascicles are organized into clear branches and errant innervation is less likely to occur.

PATHOPHYSIOLOGY

A clear understanding of the mechanism of injury, zone of injury, and degree of nerve injury is critical for successful management. Based on the mechanism of injury, lesions can be classified as open (laceration) or closed (overstretching, blunt, compressive trauma). Gunshot wounds behave like closed injuries typically because nerve injury is more likely due to blast effect rather than transection. Initial zone of injury can vary widely depending on the mechanism of injury. Sharp injury such as a scalpel blade produces a small zone of injury. More blunt mechanism such as a table saw, on the other hand, can produce a very wide zone of injury. The zone of injury can be difficult to determine on initial exploration if there is evidence of blunt trauma, crush, or nerve avulsion.

The degree of injury can be classified using several different systems (Table 1). The Seddon's classification divides injuries into neurapraxia, axonotmesis, and neurotmesis based on the anatomic nerve component that is damaged. The Sunderland classification I to V is based on the degree of injury and expected recovery. Mackinnon and Dellon added a VI degree to this system (combined nerve injury).

Focal or segmental demyelination with preservation of axon continuity is termed *neurapraxia* (Sunderland class I). In this case, functional recovery is expected to occur spontaneously as the myelin heals. This recovery occurs over a period of hours or days up to 6 weeks. No surgical intervention is required in this case. Radial nerve compression ("Saturday night palsy") with resulting wrist drop that spontaneously recovers is one common example.

Axonal injury with preservation of the endo and epineural sheath is known as axonotmesis (Sunderland class II–IV). In this case, the axon will die back to the nearest node of Ranvier. After initial stabilization, the axon will begin to form multiple "growth cones" and regrow at a rate of 1 mm/day or 1 inch/month through the distal endoneurial tubes. The axons distal to the injury site undergo Wallerian degeneration whereby myelin and cellular debris are phagocytosed and the axon replaced. Axonotmesis can result in a range from complete recovery to minimal or no recovery. Degree of recovery is dependent on the degree of damage to the surrounding structures (endoneurium, perineurium, and epineurium) and the resulting scar tissue. If the surrounding tissues remain intact, the axons will usually reach the distal endoneurial tubes and spontaneous recovery will occur (Sunderland class II–III). On the other hand, if the sprouting axons are unable to reach the distal endoneurium, then a neuroma in continuity will develop, and no spontaneous recovery will occur (Sunderland class IV).

Finally, complete transection of all neural structures is termed *neurotmesis* (Sunderland class V). Spontaneous recovery in this case is not expected. Surgical intervention is required in all cases of neurotmesis and in cases of axonotmesis where regenerating axons are unable to regenerate successfully through the distal endoneurium.

Importantly, the distal axon in all cases of nerve injury will have viable axons that can transmit electrical signals for between 72 and 96 hours after injury. After this time period, the distal axons will

TABLE 1 Classification and Expected Recovery of Nerve Injuries

Classifications		Nerve Component Injured					Expected Recovery		
Seddon	Sunderland Degree (Modified)	Myelin	Axon	Endoneurium	Perineurium	Epineurium	Extent	Rate	Surgery Indicated
Neurapraxia	First	X					Complete	Fast	No
Axonotmesis	Second	X	X				Good	Slow	Not usually
	Third	X	X	X			Variable	Slow	Variable
	Fourth	X	X	X	X		None	None	Yes
Neurotmesis	Fifth	X	X	X	X	X	None	None	Yes
	Sixth	Combination of injury					Variable	Variable	Variable

X, Injury.

irreversibly degrade and undergo Wallerian degeneration. In cases where it is critical to stimulate distal motor branches during repair such as in facial nerve injury, patients should be brought to the operating room within 72 hours of initial injury. Nerve repair between inappropriate proximal and distal motor fascicles can lead to synkinesis and dyskinesis.

After muscles lose innervation, they begin to degenerate from both disuse atrophy and denervation atrophy. Motor endplates within the muscle will irreversibly degenerate after 12 months and will be gone by 18 to 24 months. After this point, the muscle cannot be reinnervated, creating a relative deadline for recovery of motor function at 1 year after injury. On the other hand, sensory end organs do not undergo degeneration and reports have been made of successful sensory reinnervation many years after initial injury (Table 2).

TIMING

Optimal surgical timing is essential for successful nerve repair. Closed injuries should be approached differently from open injuries. Early recognition and treatment of nerves unlikely to recover spontaneously is key, and "time is muscle" remains a fundamental concept. Surgical timing can be summarized by the *3+1 rule* (Table 3), with early repair occurring within 3 days, subacute repair at 3 weeks, delayed repair at 3 to 6 months, and late repair after 1 year.

Early repair, occurring within 3 days after the injury or at presentation if evaluated after 3 days, is indicated in cases of suspected transection with sharp injuries. In this case, any neural deficits are likely to represent nerve transection (neurotmesis or Sunderland class V–VI) and will require surgical intervention. It is also indicated in situations with vascular (e.g., hematoma, pseudoaneurysm) or bony injuries causing acute nerve compression, especially if they occur in the vicinity of a closed compartment. If a neurologic examination worsens acutely under close observation, the nerve damage potentially can be reversed or reduced by immediate surgical intervention.

Subacute repair, occurring around 3 weeks after injury, is advocated by some for blunt or ragged transections (e.g., by propeller blades or chainsaw), but others still treat these injuries acutely. These injuries clearly represent neurotmesis and surgical intervention is

TABLE 2 Treatment Options and Indications for Repair of Nerve Injuries

Options	Indications
Observation	Recovering nerve injury Partial nerve injury
Neurolysis	Neuroma-in-continuity with positive NAP
Direct repair	Laceration Short gap after resection of a neuroma-in-continuity with negative NAP
Nerve graft	Laceration with retracted stumps (delayed repair) Larger gap after resection of a neuroma-in-continuity with negative NAP Direct repair without tension not possible
Nerve conduits (autogenous or synthetic)	Short gaps (<3 cm) of small diameter, usually sensory nerves (e.g., digital nerves)
Nerve transfer	Avulsions (brachial plexus avulsion) Specific cases of nerve injury for which nerve transfer may lead to a more rapid and reliable recovery (i.e., because of proximity to end organ) than proximal nerve grafting Innervation of free functioning muscle transfers
Direct neurotization	Under investigation for direct muscle reinnervation after severe trauma
Nerve reimplantation	Under investigation
Tendon or muscle transfers	Delayed (>1 year) for improvement of function
Bony or joint procedures	Delayed (>1 year) for improvement of function
Amputation	Rarely indicated; sometimes desired by patients

NAP, Nerve action potential.

TABLE 3 3+1 Rule for Timing of Nerve Repair

Timing	Time	Injury Type	Injury Classification
Early	3 days	Sharp laceration or transection Acute nerve compression resulting from vascular (e.g., hematoma, pseudoaneurysm) or bony injuries Acute neurologic worsening under close observation	Neurotmesis
Subacute	3 weeks	Blunt transection Ragged transection	Neurotmesis
Delayed	3 months	Lesions-in-continuity (nonpenetrating injuries such as stretch injuries, contusive injuries, gunshot wounds)	Axonotmesis
Late	>1 year	Salvage procedures	Neurotmesis or axonotmesis

required. Blunt injury can cause a large and unpredictable zone of injury, however. Delaying repair for a few weeks allows Wallerian degeneration to begin occurring, better defining the zone of injury. At the time of repair, the nerve endings can be resected back to healthy tissue. This would be difficult to evaluate if the injured nerves were explored immediately after the injury.

In contrast, advocates for earlier surgery feel that surgery is easier and more practical at an earlier time, especially if done at the same time that surgical intervention is performed by another team, such as a general, vascular, or orthopedic surgical team. Furthermore, the additional technical challenges of dealing with scarring can be avoided. For example, if a patient with a fracture and associated nerve palsy is being examined by an orthopedist, it would be reasonable to explore the nerve at the same time. If the nerve is found to be in continuity but nonfunctional, observation for several months is indicated. Note that because Wallerian degeneration does not occur until 72 to 96 hours after injury, intraoperative electrophysiologic testing would not be reliable or helpful in predicting recovery or acutely determining the grade of injury. If the nerve is found to be ruptured, some would repair it at the same time. Others would perform the surgery at a second stage, when the zone of injury can be better defined; nerve ends are tacked down under tension so they do not retract, using radiopaque clips or suture so that they can be identified easily. At a later time, a subacute nerve repair can be done.

Delayed repair, occurring approximately 3 months but up to 6 months after injury, is indicated for lesions-in-continuity, such as the majority of stretch injuries, contusive injuries, and gunshot wounds. In these cases, it is difficult to predict with certainty which path the nerve injury will follow from those described previously and whether the injury will recover spontaneously or require surgical repair. Nonoperative treatment can be continued in patients with early signs of spontaneous recovery or in partial lesions. Note that 90% of nerves that recover do so within 4 months. Surgery is indicated when there has been no evidence of clinical or electrical recovery after this period of observation. In these cases, the delay also will allow lesions-in-continuity to be evaluated during surgery with nerve action potential (NAP) testing to distinguish between recovering lesions (Sunderland class II–III) and nonrecovering (Sunderland class IV) lesions that require repair.

Late surgery, occurring more than 1 year after injury, may be considered a salvage procedure in patients who are seen in a delayed fashion or in those who either have not recovered or have recovered incompletely after spontaneous recovery or previous nerve surgery. Nerve repair and reconstruction typically does not work well after this period, which can be considered as short as 9 months by some surgeons because of permanent changes at the muscular level. The one exception might be distal nerve transfers (those performed close to the end organ), which can be performed in select cases even up to 18 months after injury. However, reconstructive options addressing muscles, tendons, bones, and joints may be useful.

TREATMENT FOR NERVE INJURY

The management and surgical treatment of nerve injury involves the application of general principles that are relevant to all nerve surgeries and of specific nerve repair techniques particular to each situation.

GENERAL PRINCIPLES

Preoperative Assessment

The optimal approach to nerve injury assessment includes a detailed history of the mechanism of injury and the onset of the deficit; a physical examination (neurologic, vascular, and musculoskeletal examination); and electrodiagnostic studies, such as electromyelography and nerve conduction studies. These three pillars (history, physical examination, and electrodiagnostic studies) help the clinician to determine the extent and severity of the nerve injury. Additionally, imaging studies (radiography, ultrasonography, computed tomography, magnetic resonance imaging and neurography, or myelography) can further enlighten the clinical scenario and the operative planning. Specifically, high-resolution (3 Tesla) magnetic resonance neurography (MRN) has been increasingly used to better define the anatomy of injured nerves. MRN provides a substantial benefit for the evaluation of large proximal nerve elements such as the brachial plexus, the lumbosacral plexus, the sciatic nerve in the pelvis, and other nerves that follow deep or complex courses, where electrodiagnostic studies are difficult to use. The clinician must also remember to use sensory and motor function grading scales, which will facilitate follow-up and assessment of the results of interventions (including observation).

Key Operative Principles

At surgery, the steps taken to expose the injured nerve before the nerve repair itself are important. Knowledge of the anatomy is crucial, especially when scarring from the injury is expected and likely will distort the anatomy. Adequate exposure should be planned, including the possibility of harvesting nerve grafts. Dissection usually is done between two muscle groups parallel to the long axis of the nerve. Ideally, a normal segment of the nerve is identified first, both proximally and distally, before dissection is carried toward the injured segment. If the injured segment is near a compression site, such as the median nerve near the carpal tunnel, then the site of compression should be released at this time. For practical purposes, there are two possibilities: the identification of a neuroma-in-continuity or nerve stumps.

If there is a neuroma-in-continuity, intraoperative NAP recordings can be performed to assess the degree of injury (recovery or no recovery) (Fig. 2). These are helpful because gross inspection or palpation of a neuroma-in-continuity does not predict histology, recovery, or outcomes. Furthermore, NAP can determine recovery across a short segment of nerve (i.e., proximal and distal to an injury) before recovery can be seen by physical examination or conventional electromyogram. When a NAP is present across a lesion, the lesion should not be resected because the outcome generally will be better with neurolysis alone. If a NAP is absent across a lesion,

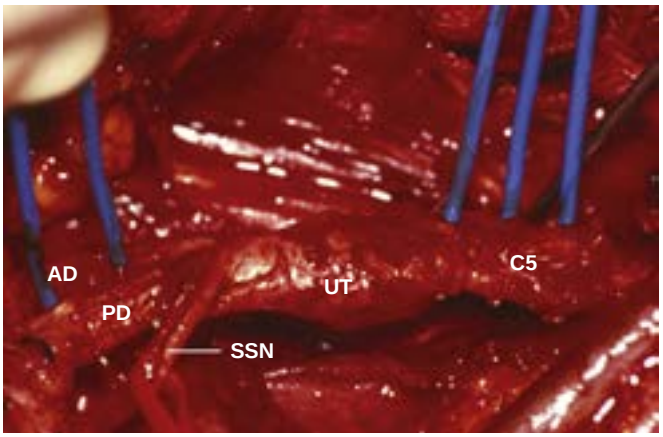

FIG. 2 Intraoperative photograph showing a nerve action potential (NAP) being recorded. The NAP is tested across a neuroma-in-continuity of the upper trunk *(UT)* of the brachial plexus. The C5 spinal nerve, the UT, the anterior *(AD)* and posterior *(PD)* divisions of the UT, and the suprascapular nerve *(SSN)* are seen. The C6 spinal nerve contributing to the UT is not seen in this view. The stimulating electrode (three prongs) is seen proximal to the neuroma-in-continuity; the recording electrode (two prongs) is seen distal to it.

the outcomes are generally poor if the lesion is left intact; therefore, surgical repair is indicated.

If two nerve ends suggestive of a rupture or transection are identified or if a nerve end suspicious for an avulsion is found, a nerve repair or reconstruction is indicated. The use of NAP recordings still can be helpful in these situations and can allow identification of the proximal location at which nerve grafting can be performed. Some use NAP in brachial plexus avulsion injuries to define preganglionic responses. Others use other techniques, including somatosensory-evoked potential and motor-evoked potential, to assess whether the proximal nerve stump is intact and can be used for reinnervation.

For the nerve repair, microsurgical techniques, which involve the use of micro instruments and of a microscope or magnifying loupes, should be used. The nerve ends on both sides should be prepared by removing sharply the neuroma and scar tissue, until normal fascicular structures are obtained. The nerve stumps should be sliced proximally and distally (like slicing a loaf of bread) until a healthy fascicular pattern is visualized. This is called *les yeux d'escargot* (snail's eyes). This pattern of healthy fascicles protruding from the cut nerve endings is due to the pressure within the endoneurium. The fascicles that protrude past the cut nerve ending should be divided further until all of the fascicles lie flush with the epineurial sheath. This is critical so that the fascicles do not overlap once the epineurium is sutured. Optimal microsurgical technique will cause minimal surgical trauma and permit an end-to-end repair or interpositional grafting; it is further recommended that 8-0, 9-0, or 10-0 sutures be used, and using the fewest number of sutures to approximate the nerve accurately is preferred. The repair must be without tension to obtain good results. Fibrin glue may be used to reinforce the suture line, but other methods involve the use of fibrin glue alone or with a variety of nerve conduits (entubulation).

If repair of a motor nerve is planned (and it is within 72 hours of the original injury), it is critical to remember that a tourniquet applied longer than 30 minutes can cause ischemia of the distal nerve, and intraoperative nerve stimulation will no longer be possible. Thus, the initial dissection must be well planned, focused, and directed to ensure that there is enough time to dissect the injured distal nerve and apply stimulation for 30 minutes afterward.

TECHNIQUES FOR NERVE SURGERY

Neurolysis

Neurolysis, defined as releasing scar tissue surrounding the injured nerve, is indicated when a neuroma-in-continuity with intact NAP conduction is found. In general, external neurolysis, which is completed during the nerve exposition, is sufficient. In select instances, some advocate limited internal neurolysis or removal of the scar tissue between the various nerve fascicles.

Direct Repair

Direct nerve repair is the end-to-end suture of nerve stumps. It is indicated when a short nerve gap exists, either from a sharply transected nerve—such as a cut from glass, a knife, or a razor—or after removing a focal neuroma-in-continuity that did not conduct a NAP. Direct repair is the preferred method of nerve repair whenever possible, assuming that the damaged segment of the nerve has been resected and that the sutures are without tension. This method allows direct delivery of proximal axons to the distal stump via a single suture line. It also usually permits fascicular alignment, which increases matching between motor and sensory axons and their targets.

For primary nerve repair, an epineurial repair is usually the most predictable (Figs. 3, 4, and 5). The external epineurial vessels can be arranged to ensure that the fascicles are appropriately aligned. Additionally, to facilitate restoration of fascicular orientation, it is important to be familiar with the serial cross-sectional fascicular topography, fascicular stimulation, histochemical stains, and gross fascicular matching. Often, only two or three interrupted sutures are necessary to align and coapt the nerve endings. It is critical at this stage to ensure that there is no overlapping of the fascicles (Fig. 6). The fascicles should just be gently coapted within the epineurium. It is also important to make sure that the needle passes only through the epineurium and does not catch a portion of one of the fascicles because this can lead to a small intraneural neuroma, and the fascicle will not heal properly.

FIG. 3 Nerve segment trimmed until healthy fascicles are encountered in a stepwise manner. In this case a neuroma is resected from the proximal nerve end.

Occasionally, it is appropriate to perform fascicular or grouped fascicular repairs. In a large nerve where the fascicles are easily identifiable, it may be possible to suture the internal epineurium between the fascicles with a few small, interrupted nylon sutures and then perform the epineurial repair. Some researchers have reported that grouped fascicular repair results in more intraneural scarring, so most peripheral nerve surgeons continue to use the epineurial repair. When performing nerve repairs, it is important to understand the difference between the fascicular topography in the proximal nerve trunk and the fascicular topography in the distal nerve (Fig. 7). Most nerves have a significant intermingling of sensory and motor fibers with plexus formation proximally, whereas more distally they usually become groups of sensory or motor fibers. This partially explains why more distal nerve repairs have better long-term functional outcomes.

If a small nerve gap is present, several methods can be used to reduce the gap and achieve a direct repair. Commonly used methods include nerve mobilization; nerve transposition, as with the ulnar and radial nerves; and joint positioning, such as repair and immobilization of a joint in some degree of flexion with gradual postoperative extension beginning at about 3 weeks. In some cases, bone shortening, as with comminuted fracture, may offer an opportunity for decreasing a nerve gap.

Nerve Graft

Nerve graft repair is performed when nerve stumps on either side of a gap cannot be opposed for a direct end-to-end repair without tension. Often this technique is necessary for neuromas-in-continuity of moderate or longer lengths with unrecordable (negative) NAP or for transected nerves with retracted stumps, which occurs when the initial surgery is delayed.

The most frequent source of nerve graft is the sural nerve (Fig. 8). However, the medial or lateral antebrachial cutaneous nerves, superficial sensory radial nerve, superficial peroneal nerve, distal posterior interosseous nerve, great auricular nerve, and cervical plexus nerves

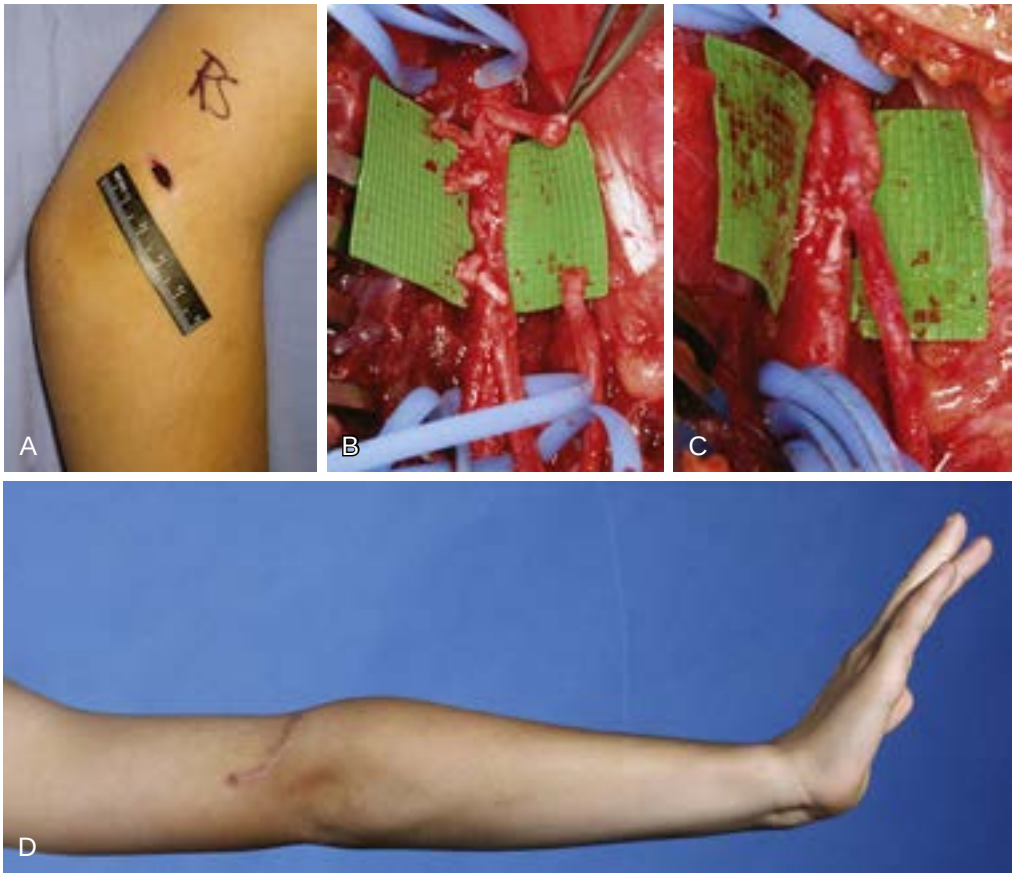

FIG. 4 Patient with a partial laceration of the radial nerve treated at presentation 1 week after injury. **(A)** The open knife-entry wound is seen in the right arm, slightly proximal to the elbow, near the interval between the brachioradialis and triceps. The knife blade had penetrated the arm to a depth of approximately 5 cm (2 inches). The patient had no thumb extension, partial weakness of the finger extensors and wrist extensors, and decreased sensation in the dorsum of the hand. **(B)** At exploration, the radial nerve was found to be partially lacerated at its bifurcation into the deep and superficial radial nerve. The complete laceration of the superficial (sensory) radial nerve is seen, as is the partial injury to multiple fascicles of the deep (motor) branch of the radial nerve. **(C)** Direct repair of the superficial sensory radial nerve and the fascicles of the deep branch of the radial nerve are shown; a 9-0 suture was used to perform this repair. **(D)** After 6 months, the patient had already regained good finger and wrist extension (Medical Research Council [MRC] grade 4). Thumb extension (the most distal motor target) improved to MRC grade 3, although the patient still had sensory abnormality in the dorsum of the hand.

are alternatives. The nerve graft should be sutured into place in a reversed fashion from its usual anatomic course (i.e., the more distal end of the nerve graft should be sutured to the proximal end of the nerve gap being repaired, and the proximal end of the nerve graft should be sutured to the distal end of the nerve gap). This ensures that axons will not be lost through small side branches in the nerve graft as the axons grow through the graft. When the diameter of the nerve at the site of repair is much larger than the diameter of the nerve graft, grouped fascicular repair may be used (Fig. 9). The disadvantage of nerve grafting is related to the minor sequelae associated with donor morbidity from the nerve harvest, such as expected permanent sensory loss and small chance of neuropathic pain.

The graft length is calculated by measuring the nerve gap and adding 10% to account for some desiccation of the graft and to avoid tension. One graft or several "cable" grafts are placed to maximize the surface area at the repair sites and to prevent mismatch. Interposed grafts may be sutured individually at both ends or may be glued together and then sutured as a single unit.

Vascularized nerve grafts have been advocated by some to improve the speed and quality of regeneration compared with standard, nonvascularized nerve grafts; however, this practice is controversial. Autogenous or synthetic conduits may be used for short gaps (<3 cm) of small diameter, usually sensory nerves (e.g., digital nerves). Using a nerve conduit requires an entubulation technique. The nerve conduit must be the correct diameter to accommodate the nerve and should be approximately 10 mm longer than the nerve gap. The entubulation technique involves placing the proximal nerve ending 5 mm within one end of the nerve tube and the distal nerve ending 5 mm within the distal end of the nerve tube, with horizontal mattress sutures tied on the outside of the nerve conduit.

Nerve Allografts

Decellularized grafts, which are devoid of all cellular material including Schwann cells, are increasingly used in nerve repair. These grafts are comprised of extracellular matrix, which provides a scaffold for axonal regeneration. Despite the lack of living Schwann cells, several smaller studies have reported good results with decellularized grafts. There are several additional randomized control trials with ongoing enrollment, and more data are required to fully evaluate their use and indication.

Nerve transplants have been reported, although specific indications are still evolving. The primary theoretical advantage of cadaveric donor nerve grafts is the presence of Schwann cells, which could aid in regeneration. However, their immunogenicity precludes their use in clinical practice. The use of nerve allografts almost always requires associated immunosuppressive therapies, without which graft rejection occurs.

FIG. 5 Patient with a spinal accessory nerve injury after a right retrosigmoid craniotomy for removal of a vestibular schwannoma. **(A)** Surgical incision used for the resection of the right vestibular schwannoma. After surgery, the patient developed prominent scapular winging, atrophy of the right trapezius muscle, and significant difficulty in abducting the right arm. Electromyography 3 months after surgery confirmed a right spinal accessory neuropathy affecting the motor branch to the trapezius (normal sternocleidomastoid) without evidence of reinnervation. **(B)** At exploration soon thereafter, the great auricular nerve (at the right of the nerve stump) and the greater occipital nerve (blue vasoloop) were identified. The proximal and distal stumps (clipped to a green background) of the spinal accessory nerve were found within the scar of the prior surgical exposure. **(C)** To achieve a direct repair, the two nerve stumps were mobilized proximally and distally. **(D)** A direct end-to-end repair was performed using an 8-0 suture. **(E)** The patient regained excellent function, scapular stability, and range of motion, shown here at 15 months after the repair.

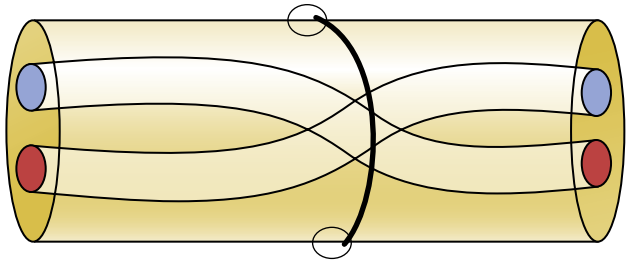

FIG. 7 Proximal nerve fascicles should be aligned to their corresponding distal fascicle. Mismatch between proximal and distal fascicles can lead to errant innervation of inappropriate distal targets and lead to synkinesis or dyskinesis.

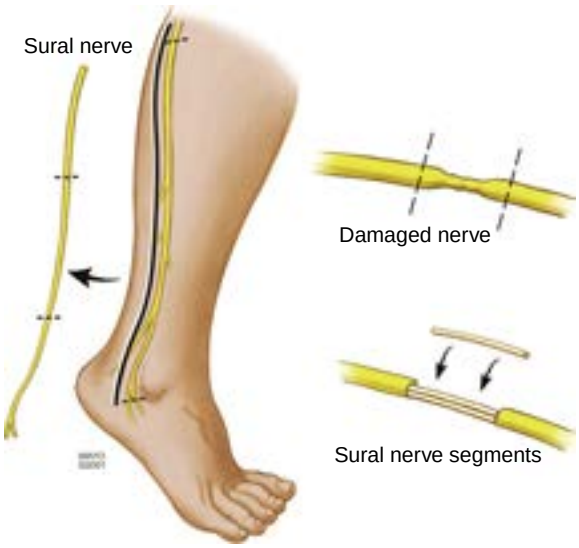

FIG. 8 The sural nerve is the most common source of nerve graft. A purely sensory nerve, it supplies sensation to a small area of the dorsolateral aspect of the foot. The sural nerve is up to 40 cm long in each leg; nerve grafts may be harvested bilaterally, and sural nerve segments are used to bridge the nerve gap.

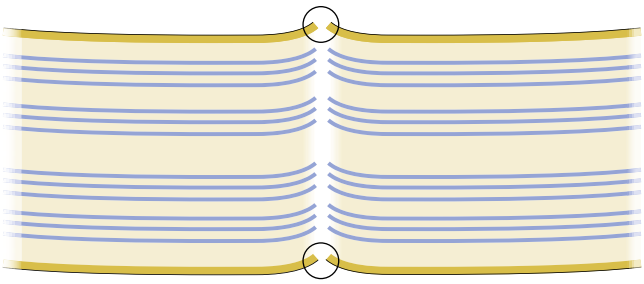

FIG. 6 Nerve ends should be trimmed to remove scarred tissue and reach healthy-appearing fascicles in a stepwise fashion. Nerve fascicles should be trimmed flush with the epineurium. Microsuture of the epineurium is performed with 8-0, 9-0, or 10-0 suture and should be done carefully to prevent bunching of the ends or inadvertent suturing through a fascicle. General topography can be aligned by examining blood vessels along the epineurium.

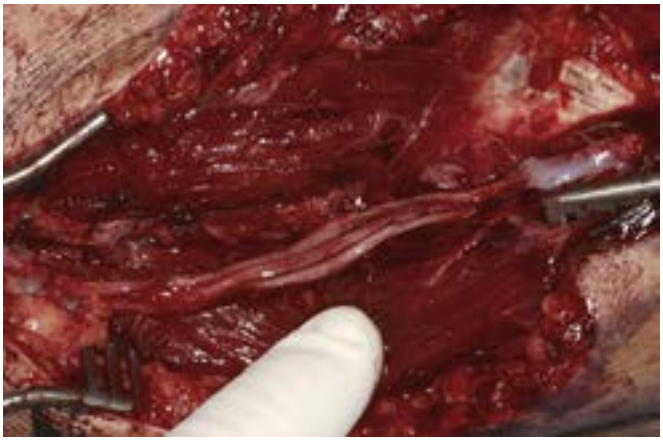

FIG. 9 Intraoperative image of three sural nerve segments bridging a radial nerve gap in the distal arm after a humeral fracture.

Nerve Transfers

Nerve transfer refers to the procedure of transecting an expendable working nerve, branch, or fascicle in the vicinity of an injured nerve to coapt it to the nonfunctioning nerve. The main advantages of nerve transfers are better proximity to the end organ (which in turn decreases the time to reinnervation) and the fact that distal nerves contain a larger number of relatively "pure" (motor or sensory) axons (i.e., because nerve transfers involve the distal components of the nerve, at this level the axons are either motor or sensory).

When nerve transfer is indicated, outcomes are improved because this can be performed more distally and closer to the muscles in question than other repair techniques. For example, an upper trunk brachial plexus injury would result in a loss of flexion of the elbow. If the lower trunk is intact, redundant fascicles of the ulnar nerve to the flexor carpi ulnaris muscle or from the median nerve going to superficial flexor muscles can be transferred to either the brachialis or the biceps motor nerve (Fig. 10). This will result in faster reinnervation of the muscles than if a repair of the upper trunk of the brachial plexus was performed because it would take many months for the axons to grow all the way down into the arm. Based on the expected time to reinnervation, the benefits of nerve transfers versus nerve grafts should be carefully evaluated for each clinical scenario. A variety of nerve transfer procedures have been described both for reconstruction of sensory and motor defects. Most surgeons advocate distal nerve transfers closer to the end organ as opposed to proximal nerve grafting farther from the end organ (Table 4).

Muscle and Tendon Transfer and Bone and Joint Procedures

These various procedures usually are performed in a delayed fashion, sometimes more than a year after the injury. Muscle or tendon transfer is the transfer of a muscle or tendon that is working and is expendable to achieve a new function. This technique, similar to nerve transfer, requires a functional expendable innervated muscle in the vicinity. Examples of reliable tendon transfers include opponensplasty, anticlaw procedure, thumb adductorplasty, flexor to extensor transfers, elbow flexorplasty, transfers for shoulder external rotation, antiwing (scapular) transfers, transfers for pronation, and extensor to flexor transfers. An alternative is the transfer of a free functioning muscle, such as the gracilis muscle from the lower extremity, which can be transferred at a late stage for elbow flexion or finger flexion. This requires the presence of an arterial and venous supply, as well as a functioning nerve to reinnervate the muscle. Bone and joint procedures, such as osteotomies and arthrodesis, also may improve function. Shoulder fusion may be an option for patients with brachial plexus palsy and refractory instability with pain.

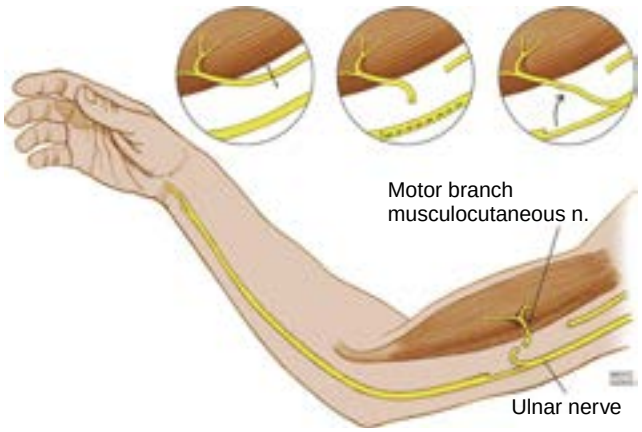

FIG. 10 Intraplexal nerve transfer technique (Oberlin procedure) used for the repair of injury to the brachial plexus or musculocutaneous nerve leading to loss of biceps motor function. To perform this transfer, the ulnar nerve function must be preserved. At the level of the middle or proximal third of the arm, a functioning ulnar nerve fascicle is used to reinnervate the biceps motor branch originating from the musculocutaneous nerve. In general, ulnar motor function is preserved (deficit in <1%), but the patient may experience transient sensory changes in the distribution of the ulnar nerve. A case series using this technique reports that 85% of patients recovered good elbow flexion after surgery.

EXPECTED OUTCOMES FROM REPAIR AND RECONSTRUCTION

Outcomes after nerve injury and repair are variable owing to a multitude of underlying factors. The best outcomes are achieved when spontaneous neural recovery occurs (i.e., when surgery is not indicated). Other factors influencing the recovery of nerve repair and reconstruction include the following:

Patient age: The younger the patient, the better the recovery because of inherent physiologic factors related to regeneration, limb length, and capacity for cortical reorganization and reeducation.

Level of injury: Distal injuries fare better because of the shorter distance to the end organ.

Type of nerve injured: Pure nerves fare better than mixed nerves because there is less chance of fascicular mismatch.

Specific nerve involved: Radial nerve recovers better than median nerve, which recovers better than ulnar nerve; nerves C5 and C6 and those of the upper trunk recover better than nerves C8 and T1 and those of the lower trunk; and tibial nerve recovers better than peroneal nerve.

Mechanism of injury: Lacerations have better outcomes than low-velocity gunshot injuries, which in turn have better outcomes than high-velocity gunshot injuries; transections have better outcomes than crush or avulsion injuries; and stretch injuries generally have better outcomes than ruptures, which fare better than avulsions. These variations in outcomes are related to the zone of injury and associated soft tissue and vascular damage.

Timing of repair and reconstruction: The earlier the better; outcomes are typically best before 6 months, but they depend on the size of the gap, the status of the end plate, and the status of the alpha motor neurons.

Type of repair or reconstruction: Patients in whom exploratory surgery is indicated, but in whom only neurolysis is performed because of a positive NAP, generally have favorable outcomes. Patients in whom direct end-to-end nerve repair can be performed generally have better outcomes than patients who undergo conventional interpositional nerve grafting. Improved techniques with nerve transfers, especially distal nerve transfers, have improved outcomes in peripheral nerve surgery in recent years. Direct nerve transfers have better outcomes than nerve transfers with interpositional grafts.

WHO SHOULD OPERATE

By extrapolation based on data related to other surgical techniques, it seems reasonable to expect improved outcomes in centers performing high-volume practice. Timely referral to centers specializing in evaluation and management of nerve injuries is important and should be considered.

TABLE 4 Common Motor Nerve Transfers of Upper Extremity

Motor Deficit	Recipient Nerve(s)	Donor Nerve(s)
Elbow flexion	Biceps, brachialis branches of MCN	Ulnar nerve fascicle to FCU Median nerve fascicle to FDS/PL/FCR
Elbow flexion	MCN	Medial pectoral nerve branches
Elbow flexion	MCN	Thoracodorsal nerve
Elbow flexion	MCN	Distal accessory nerve
Elbow flexion	MCN	Intercostal nerves
Shoulder abduction/external rotation	Suprascapular nerve	Accessory nerve (distal end-to-end or end-to-side with neurectomy and proximal crush injury)[a] Pectoral fascicle of C7, middle trunk
Shoulder abduction	Axillary nerve	Medial triceps branch
Shoulder abduction	Axillary nerve	Medial pectoral nerve
Shoulder abduction	Axillary nerve	Thoracodorsal nerve
Shoulder abduction	Axillary nerve	Intercostal nerves
Scapular winging/instability	Long thoracic nerve	Thoracodorsal nerve[b]
Scapular winging/instability	Long thoracic nerve	Pectoral fascicle of C7, middle trunk[b]
Scapular winging/instability	Long thoracic nerve	Intercostal nerves
Intrinsic hand	Deep motor branch/fascicle of ulnar nerve	Distal AIN
Pronation	Pronator teres branches of median nerve	ECRB branch of radial nerve FDS or FCR/palmaris longus branch of median nerve
Wrist, finger extension	ECRB, PIN branches of radial nerve	FDS, FCR/PL branches of median nerve[a]
Finger flexion	AIN branch of median nerve	Brachialis branch of MCN ECRB, supinator branches of radial nerve
Elbow extension	Triceps branch of radial nerve	FCU fascicle of ulnar nerve ECRL fascicle of radial nerve
Elbow extension	Triceps branch of radial nerve	Intercostal nerves

Donor nerves are listed in order of preference.
AIN, Anterior interosseous nerve; *ECRB*, extensor carpi radialis brevis; *ECRL*, extensor carpi radialis longus; *FCR*, flexor carpi radialis; *FCU*, flexor carpi ulnaris; *FDS*, flexor digitorum superficialis; *MCN*, musculocutaneous nerve; *PIN*, posterior interosseous nerve; *PL*, palmaris longus.
[a]With TP to ECRB transfer.
[b]When combined, these transfers give the most rapid recovery of long thoracic function as a double-level nerve transfer.

SUMMARY

The treatment and management of nerve injuries require thorough knowledge of anatomy, of the nerve injury process, and of the available repair and reconstructive options. They also require specific microsurgical skills in the context of a multidisciplinary team able to address the peripheral nerves and associated muscles, tendons, and joint problems, as well as concomitant injuries to the central nervous system (spinal cord and brain) and other systems.

Necrotizing Skin and Soft Tissue Infections

Philip J. Wasicek, MD, and Arthur J. Nam, MD, MS

INTRODUCTION

Necrotizing skin and soft tissue infections (NSTIs), more colloquially referred to as "flesh-eating bacteria," represent a variety of rapidly progressive disease processes that requires prompt identification and aggressive surgical debridement and broad-spectrum antibiotic therapy. Although uncommon, with an incidence of 4 to 15.5 per 100,000 person-years, NSTIs are associated with high rates of morbidity and mortality due to aggressive bacterial infection of soft tissue, deep spaces, and/or muscle that result in tissue necrosis.

PATHOPHYSIOLOGY

NSTIs typically occur via microbial invasion of the subcutaneous tissues. Traumatic injury breaching skin or mucosal integrity, as well as surgery (including intestinal, urologic, and obstetric/gynecologic procedures) are risk factors for the development of NSTIs. Additional important risk factors include immunosuppression, age/frailty, peripheral vascular disease, obesity, and diabetes mellitus. Importantly, however, NSTIs can occur among otherwise healthy patients with no clear etiology of infection.

Once infection has been established, causative organisms may produce endotoxins and exotoxins resulting in obliterative endarteritis, thrombosis, and necrosis of blood vessels leading to further tissue necrosis. Consequently, compromised blood flow limits the effectiveness of intravenous antibiotic therapy. NSTIs frequently spread along fascial or subcutaneous planes where perfusion is less (compared with muscle). This allows for rapid progression of the infection despite potentially limited skin changes/manifestations. Furthermore, hematogenous spread of infection along with remote release of toxins and cytokines result in sepsis, multiorgan system failure, and death.

From a microbiologic standpoint, NSTIs are mainly distinguished by whether the infection is polymicrobial (type I) or monomicrobial (type II). Type I NSTIs are frequently seen in those with comorbidities and in the elderly. Gram-positive cocci, gram-negative rods, and anaerobes are the most frequent isolates including group A *Streptococcus*, *Staphylococcus aureus*, *Escherichia coli*, and clostridial species. Type II infections, in contrast to type I infections, are more indiscriminate and may affect any age group regardless of comorbidities. Type II NSTIs are frequently caused by group A *Streptococcus* or *Staphylococcus* aureus. A new and distinct type III NSTI has been proposed for *Vibrio* vulnificus and *Aeromonas* hydrophila, following exposure of seawater to wounds, but this has not reached widespread acceptance.

DIAGNOSIS

Early diagnosis and treatment of an NSTI is critical and a major factor determining outcome. NSTIs most commonly affect the extremities or perineum but can also originate from the trunk and head/neck. Additionally, noncontiguous multifocal NSTIs have been reported in the literature but are exceedingly rare.

A high index of suspicion must be maintained as NSTIs are uncommon and can present with a wide array of symptoms that are frequently nonspecific and may be confused with cellulitis. Pain out of proportion to examination (which may progress to tissues becoming insensate as the tissue dies), erythematous changes, blistering, fluctuance, and swelling/induration are frequently seen. A globally toxic-appearing patient (e.g., fever, tachycardia, diaphoresis), rapid progression of skin changes including necrotic skin and ecchymotic bullae, as well as crepitus are potential clues to distinguish NSTI.

As the disease course progresses, laboratory derangements are frequently seen. The Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) score (Table 1) can help predict the likelihood of NSTI based on white blood cell count, creatinine, hemoglobin, sodium glucose, and C-reactive protein levels. Importantly, a low LRINEC score does not exclude or rule out NSTI.

Imaging including x-ray and computed tomography may assist in identifying crepitus as well as better defining the extent of disease, but it is not an essential part of establishing the diagnosis. In fact, obtaining imaging after concern for NSTI has been raised may lead to worse outcomes secondary to delaying treatment including operative intervention.

Once sufficient clinical suspicion has been established, emergent operative exploration is warranted to establish the diagnosis. This may be performed at the bedside using local anesthesia or in the operating room. Exploration must include the underlying subcutaneous tissues and fascial planes. NSTIs frequently demonstrate turbid/greyish (dishwater) foul-smelling fluid, subcutaneous tissue that bleeds minimally/not at all, as well as tissue that is easily bluntly dissected from the fascia. A negative exploration rate in cases for suspected NSTI has been reported as high has 21%; however, some cases with initial negative explorations subsequently progressed to NSTI.

TREATMENT

Once definitive diagnosis has been established, further surgical debridement must be performed (Figs. 1 to 3). Source control is imperative, frequently resulting in extensive resection of soft tissue. Debridement should be performed until healthy tissue is encountered at the wound margins. Large, extensive wounds and soft tissue defects will result that are frequently much greater than initially evident skin changes. Amputations may be indicated during the initial or subsequent operative trips secondary to extensive resection of entire muscle groups or resections rendering limbs nonfunctional. Temporary dressings should be placed with plans for short interval reassessment as additional debridement can frequently be indicated.

In conjunction with surgical debridement, broad-spectrum antibiotics should be initiated. Cultures in the operating room should be

obtained and antibiotic regimen tailored once speciation and susceptibilities are available. Initially, however, broad coverage including gram-positive cocci, gram-negative rods, and anaerobes are recommended. Common regimens include a carbapenem (imipenem, meropenem, or ertapenem) or piperacillin-tazobactam, in addition to an antibiotic with activity against methicillin-resistant *Staphylococcus aureus* (vancomycin or daptomycin). Clindamycin should also be added as it has been shown to decrease expression and production of virulence factors and exotoxins from group A *Streptococcus*.

Adjuvant therapy with intravenous immunoglobulin (IVIG) may be beneficial in those with *Streptococcal* NSTI with associated toxic shock syndrome. IVIG is thought to neutralize *Streptococcal* superantigens and enhance bacterial clearance.

The utility of hyperbaric oxygen in treatment (HBOT) of NSTI remains unclear secondary to a lack of high-quality evidence but may result in improved mortality and limb salvage. Importantly, the use of HBOT should be postponed until source control has been achieved and the patient stabilized.

Patients diagnosed with NSTI should continue their care postdebridement in the intensive care unit. These patients are often profoundly critically ill and require substantial ongoing resuscitation. Any clinical deterioration should prompt earlier return to the operating room to assess for inadequate source control.

Many patients require serial operative trips to acquire source control, and then additional subsequent operative trips to appropriately perform wound care followed by potential reconstruction. Vacuum-assisted closure dressings are frequently implemented to encourage wound healing and granulation, as well as having a practical advantage with regard to wound care type and frequency. Some wounds, in particular perineal wounds, are quite extensive, and wound care becomes problematic with regards to fecal contamination. Once the patient has stabilized, a diverting loop colostomy may be indicated. Perineal and scrotal involvement may necessitate transposition of the testes into pockets of the medial thighs. Surgical castration is rarely necessary. Further reconstruction with skin grafting, rotational flaps, or free tissue transfer may be warranted, and involvement/comanagement with plastic surgery is advised.

CONCLUSION

NSTIs represent a rapidly progressive and highly morbid disease process with a multitude of presentations. A high index of suspicion combined with early diagnosis and prompt aggressive treatment (primarily surgical source control, as well as intravenous antibiotics) are the cornerstones of successful outcomes.

Management of Spontaneous and Secondary Pneumothorax

Cameron D. Wright, MD

PNEUMOTHORAX

Spontaneous pneumothorax is described as a pneumothorax that occurs in the absence of trauma or significant lung disease. Secondary pneumothorax occurs in the setting of significant underlying lung disease, which predisposes the patient to a pneumothorax. Air in the pleural space typically occurs because of a communication between the lung or the tracheobronchial tree, although it can also occur due to trauma, a significant esophageal rupture, or most rarely a gas-producing organism. As a result of a pneumothorax, there is a decrease in vital capacity of the lung and potentially a decrease in the PaO_2 depending upon the degree of pneumothorax. In young healthy people, this is typically very well-tolerated, but in patients with underlying cardiopulmonary disease, it can be quite physiologically significant. The time required to absorb all gases and the pneumothorax is thought to vary between 1% and 5% in 24 hours. The rate of resorption depends upon most importantly the gas present. Oxygen is absorbed about 60 times faster than nitrogen, whereas carbon dioxide is absorbed about 20 times faster than oxygen. This principal underlies the rationale for temporary administration of supplemental oxygen to patients with a pneumothorax to hasten resorption of the pneumothorax.

Primary Spontaneous Pneumothorax

Spontaneous pneumothorax is more common in men than in women. The classic characteristic profile is a young, tall, thin man in the second to fourth decade of life. The incidence is approximately 10 per 100,000 population in men and 3 per 100,000 and women. Cigarette smoking also increases the risk of a spontaneous pneumothorax approximately 10- to 20-fold, and the risk increases with the number of cigarettes smoked. The etiology of spontaneous pneumothorax is thought to be rupture of a subpleural bleb and are typically found at CT imaging or surgery in about 80% of patients (Fig. 1). The rate of recurrence after a primary spontaneous pneumothorax is about 25% and is usually within the first or second year after the first episode. The rate of recurrence does increase after each subsequent pneumothorax. Commonly quoted risks are 50% to 60% after the second pneumothorax and even higher after the third. Although the majority of patients have small blebs bilaterally, the risk of contralateral pneumothorax is typically quite low, around 10%.

Secondary Pneumothorax

Secondary pneumothorax occurs in patients with underlying lung disease, and this can cause more serious physiologic embarrassment of the patient. The incidence is fairly similar to primary spontaneous pneumothorax. Importantly, however, patients are typically 15 to 20 years older than patients with primary spontaneous pneumothorax largely due to a large number of patients with emphysema (Fig. 2). The risk of recurrence of a pneumothorax with underlying disease is higher than in spontaneous pneumothorax. A large number of potential lung diseases are associated with secondary spontaneous pneumothorax, but of course the most common is chronic obstructive pulmonary disease (Box 1). Although death is extremely rare with primary spontaneous pneumothorax, it is not uncommon for patients with secondary pneumothorax to die because of the underlying significant lung disease. Cystic fibrosis is probably the next most common cause of secondary pneumothorax, typically represents advanced disease, and is a marker of poor prognosis.

CLINICAL PRESENTATION

The most common symptom with a pneumothorax is localized sharp pleuritic chest pain, which is usually sudden in onset. This can be associated with dyspnea. Occasionally, a dry cough is present, and patients are rarely asymptomatic. Spontaneous pneumothorax typically occurs in the absence of any significant strenuous exercise or maneuvers that would increase airway pressures. Small to moderate pneumothoraces are typically not identified on physical examination by auscultation. Decreased breath sounds and percussion hyperresonance are occasionally present and can be confused with emphysema. Rarely, subcutaneous emphysema will be palpable in the neck or chest wall. Typically vital signs are normal, but tachycardia may be present in part due to anxiety; severe tachycardia and hypotension and tracheal deviation suggest a tension pneumothorax. If arterial blood gases are done, they may show mild hypoxemia and hypocarbia from hyperventilation.

IMAGING

Typically, a patient with a clinical presentation that suggests a pneumothorax has a chest x-ray performed that will demonstrate a pneumothorax and allow estimation of the severity (Fig. 3). If an initial inspiratory film is negative and the clinical suspicion is high, an expiratory film can be done. Of course, gas tends to collect at the apex with erect posture, whereas supine patients have gas collect anteriorly and the air may be harder to see if the amount is small.

FIG. 1 An apical bleb encountered at a video-assisted thoracoscopic exploration in a patient with a recurrent spontaneous pneumothorax.

FIG. 2 Axial CT scan of a patient with emphysema (*left arrow*) demonstrating a large bleb protruding from the right upper lobe and displacing the mediastinum *(right arrow)*.

Pleural lines need to be carefully sought for, and artifacts need to be excluded such as the edge of the scapula, a skin fold, or clothing. Although there are nomograms to estimate the size of a pneumothorax, most clinicians make a rough guess based on the amount of air in the apex and laterally. A tension pneumothorax is suggested by shift of the mediastinum away from the pneumothorax, depression of the diaphragm, and expansion of the rib spaces.

Lung ultrasound is increasingly being used in the emergency room department for rapid diagnosis of a pneumothorax. It is obviously user dependent. Although most commonly used in trauma patients, it is also useful in patients with spontaneous or secondary pneumothorax. In an experienced user's hands, lung ultrasound is more sensitive than a chest x-ray. Normal lung ultrasound findings including lung sliding with breathing and a granular pattern of aerated lung under the hyperechoic plural line in M mode (Video 1 and Fig. 4). A pneumothorax is detected by the absence of lung sliding and the loss of the granular pattern in the lung under the pleural line in M mode (Video 2 and Fig. 5).

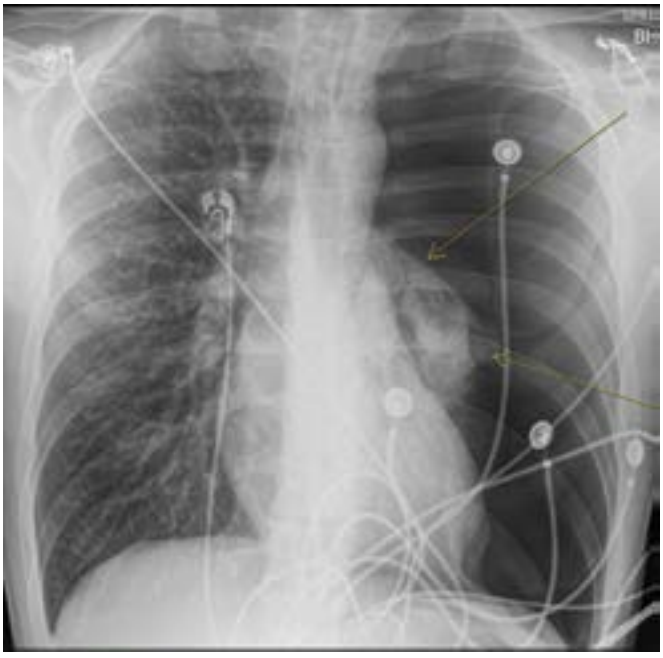

FIG. 3 Chest x-ray demonstrates a large left pneumothorax with complete collapse of the lung and evidence of mild tension with shift of the mediastinum and slight depression of the diaphragm in a patient with a spontaneous pneumothorax.

Computed Tomography

CT scans are now commonly performed in the emergency department when evaluating patients with pneumothoraces. Any underlying lung pathology will be quickly identified, and blebs typically at the apex of the upper lobes can be readily identified. It is not uncommon for a CT scan to identify a pneumothorax that was not seen on a plain chest x-ray, especially in the supine patient. CT scans are most

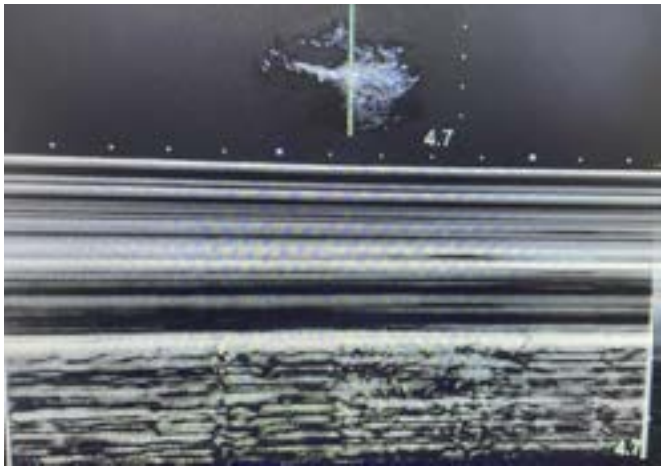

FIG. 4 Normal lung in M mode ultrasound. The small image at top illustrates the sample line along which the movement of tissues is recorded and displayed below. The chest wall demonstrates a series of horizontal lines. The white hyperechoic line is the pleura, and the aerated lung is somewhat granular below.

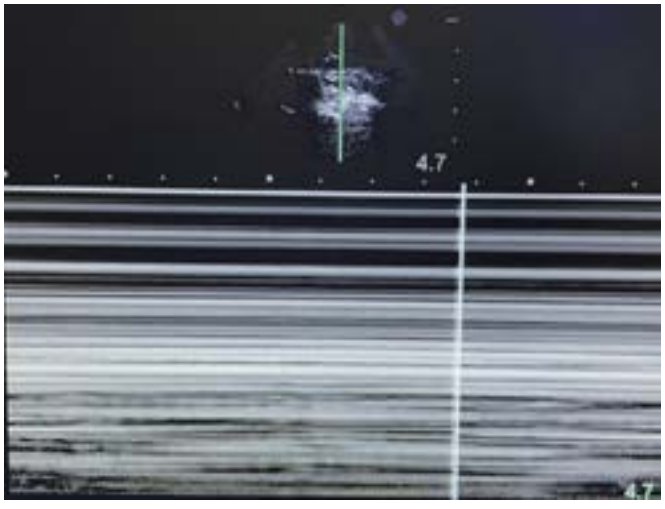

FIG. 5 Pneumothorax in M mode. The separation of the visceral and parietal pleura results in the loss of granular pattern of normal lung. A series of horizontal lines under the pleura are seen instead, also known as the "bar code" sign.

helpful in patients with secondary pneumothoraxes where there is a loculated pneumothorax from areas of pleural symphysis that make it extremely challenging to place non–image-guided catheters to drain the pneumothorax and reexpand the lung.

MANAGEMENT OF PNEUMOTHORAX

Although treatment of a pneumothorax is seemingly simple (i.e., placement of a drainage catheter), there are nuances to the management. Factors that weigh into treatment include the size of the pneumothorax, the timing of the presentation of the pneumothorax, the symptoms of the patient, whether it is a primary spontaneous or secondary pneumothorax, and the social aspects of the patient.

Observation

Although observation is rarely used in patients with secondary pneumothorax, occasionally healthy patients with spontaneous pneumothorax can be observed as an outpatient or with a brief stay in the emergency room observation area. Patients have to be reliable, have good social support, and be relatively close to an emergency room to be safely observed as an outpatient. The most important aspect of this management is that the patient has a history of a period of self-observation at home where the pain and dyspnea happened perhaps one to several days ago before presenting to the emergency department with a small, now relatively asymptomatic pneumothorax. They have already undergone a period of observation. And clinically it appears that the small leak from the lung has sealed since the pneumothorax has remained small. These patients, if reliable, can be sent home from the emergency department and be seen within the next day or two in the physician's office for a follow-up x-ray. Obviously if they develop a symptomatic pneumothorax, they are instructed to immediately return to the emergency room for treatment.

Aspiration

Aspiration is a controversial management strategy for a spontaneous pneumothorax. It is essentially never done with secondary pneumothorax. Aspiration does require a period of observation for at least several hours in the emergency department with repeat x-rays before discharge and thus does tie up resources in busy emergency rooms. It is most appropriate for patients who really want to avoid hospital admission with placement of a drainage catheter and again are reliable, well-supported patients. It is helpful if there has been at least some period of the patient tolerating the symptoms of pneumothorax before presentation to the emergency room, which presumably suggests that the air leak has sealed. A chest x-ray should confirm a sizable collection of air in the apex of the chest such that introduction of the intravenous catheter does not injure the anterior surface of the lung when inserted. Typically a 16-gauge or 18-gauge intravenous catheter is inserted after local anesthesia is used in the second interspace costal space anteriorly with a three-way stopcock and a large syringe. The metal inner needle cannula is removed as soon as air is aspirated to avoid injury to the underlying lung. Air is then aspirated through the plastic cannula until no further air can be aspirated. The patient is then observed for a period of several hours and a repeat x-ray done. If there is no recurrence, the patient is discharged again with a follow-up x-ray in 1 to 2 days and instructions to return immediately to the emergency room if symptoms recur. The patient should be seen in the office in a few days.

Tube Drainage

The classic treatment of the pneumothorax has been the surgical placement of the tube thoracostomy catheter. This is typically done as a bedside procedure with a thoracostomy tray for instrumentation. It can be a painful procedure, and often it is helpful to provide mild sedation with intravenous narcotics and/or benzodiazepines. The typical placement location recognizes that the chest wall muscle configuration allows placement through the least muscle possible below the axilla, between the anterior and posterior axillary lines, which mark the pectoralis muscle anteriorly and the latissimus muscle posteriorly. Typically, the tube is then placed through slips of the serratus muscle, which is thinner.

The area is widely prepped and draped in a sterile fashion. Typically 1% Xylocaine plain local anesthesia is used. Knowledge of the intercostal bundle and its relationship to the undersurface of the rib is important to avoid injury to the intercostal artery or vein. Accordingly, the pleural space is entered on top of the rib, which minimizes the chance of injury to these vessels that lie at the bottom of each rib. After a skin wheal is made, a small transverse incision is made that is at least as large as the catheter that is going to be placed. Additional local anesthesia is then given through this incision to the underlying soft tissue, the rib, and the interspace that is going to be used. The rib is then palpated with a finger to ensure that the surgeon is placing the

instrument just on top of the underlying rib. The rib is then palpated with a surgical clamp, typically a Kelly clamp, and once the top of the rib is found, controlled pressure on the clamp is used to enter the pleural space. The clamp is then spread to widen the passageway before the tube is placed. Thereafter, a clamp is used to squeeze and narrow the end of the chest tube; this is placed into the pleural space, and an attempt is made to thread the catheter apically. A technique of ballottement is often used to facilitate placement in the apex as the chest tube can hang up on the fissure of the lung, an osteophyte, or a rib. The surgeon should have a rough indication as to how far the tube should be inserted to reach the apex and should attempt to insert it to that distance. The tube is then connected to a pleural drainage device. The tube is then secured with heavy sutures to prevent dislodgment, and a dry sterile dressing is applied. Vaseline gauze is not used as that can promote infection. Typically, the tube is placed to suction if the pneumothorax was small, but with large pneumothorax it is often helpful to place it to waterseal for a period of time to allow slower lung expansion and avoid the phenomenon of reexpansion pulmonary edema, which is rarely seen. The reexpansion of a significantly shrunken lung often leads to paroxysms of coughing and pain, which the surgeon needs to talk the patient through. The coughing goes away once the lung is totally reexpanded. A chest x-ray is then performed to confirm the position of the chest tube and that the evacuation of the pneumothorax was appropriate. The patient is then monitored for air leakage, and subsequent chest x-rays are done as clinically appropriate. There are some chest tube insertion kits that come with a trocar insertion device. Care must be used when using a trocar technique to avoid inadvertent injury to the heart or lung. These are safe if there is a large pneumothorax and a significant air gap between the lung edge and ribs. If there is any pleural symphysis at the insertion point, lung injury will occur. Alternatively, there are some chest tube insertion kits that have a plastic insertion device that hooks onto the tip of the chest tube and can facilitate chest tube placement with much less possibility of damage to the lung.

In recent years, the numbers of tube thoracostomies have fallen off as the insertion of much smaller catheters that use the Seldinger technique have become very popular (Fig. 6). These catheters were first used many years ago by our interventional radiology colleagues and now have been widely used in emergency rooms, intensive care units, and at the bedside for less invasive chest drainage. The catheters themselves typically have a pigtail shape at the end once the insertion stylette is removed. These catheters are softer and smaller than typical chest tubes and cause less patient discomfort. As long as there is a significant pneumothorax, they are easy to insert. The disadvantage of these catheters is that they have very small diameter, are more easily kinked, and the small holes within the chest can become clogged with serum or blood. Furthermore, if there is a very large air leak, they may not be large enough to adequately evacuate the pleural space. However for most patients with a spontaneous pneumothorax, they are more than adequate.

The insertion technique mirrors that of open tube thoracostomy. A sterile field is created, local anesthesia is used, and the needle for the local anesthesia is aspirated for air once it enters the pleural space to confirm a pneumothorax is present, which is amenable to pigtail catheter placement. A guidewire is then passed through the needle, which has a soft flexible tip. A stiff dilator is then typically passed over the wire to slightly widen the insertion site, and then the dilator is carefully removed leaving the wire in place. Thereafter, the catheter is threaded onto the guidewire and advanced into the chest toward the apex. The catheter is then secured with a suture, a dry sterile dressing is applied, and the catheter is attached to a pleural drainage system. The catheter generally should be placed in a similar position as a tube thoracostomy. In men with relatively thin chest walls and an apical pneumothorax, they may be placed in the second intercostal space anteriorly in the midclavicular line. In general, we do not utilize this access point for a woman as it can cause unsightly scarring to the breast area.

The use of these small, less invasive pigtail catheters has led to an increased treatment of spontaneous pneumothorax in appropriate patients as an outpatient. The catheters can be hooked up to a Heimlich valve, a very small drainage collection receptacle that also has a one-way valve, or a small portable complete pleural drainage system that can be attached to a shoulder strap. The patients can then be discharged from the emergency room and seen in the office for follow-up in a couple of days at which time air leaks have usually sealed. An x-ray should have confirmed that the pneumothorax has resolved after pigtail placement, and obviously the patient must be carefully selected so they can safely manage such a device at home.

FIG. 6 Chest x-ray demonstrates a well-placed apical left pigtail chest tube catheter to reexpand the lung after a spontaneous pneumothorax.

Chemical Pleurodesis

The goal of the pleurodesis is to cause significant adhesions between the visceral and parietal pleura to obliterate the pleural space. This can seal an ongoing air leak or prevent future pneumothoraxes if the area of pleural symphysis is where a ruptured bleb occurs. Chemical pleurodesis is uncommonly performed for first-time spontaneous pneumothoraces. Chemical pleurodesis is typically performed for recurrent, difficult to control pneumothoraces, especially after a previous operative intervention. Bedside pleurodesis is much more commonly performed with secondary pneumothoraces to avoid operative intervention in patients at high risk for an operative procedure. Typically, a doxycycline solution (500 mg to 1 g) or a sterile talc slurry (4–5 g) is used for bedside pleurodesis. Talc is more effective than doxycycline at creating a pleural symphysis, but there are some concerns about using talc in young people with a spontaneous pneumothorax. Previous versions of talc were not guaranteed to be asbestos-free raising concern for late mesothelioma. However current versions of FDA-approved talc are asbestos-free. In addition, the symphysis caused by talc is usually quite strong, and if the patient was ever to need another thoracic operation, it makes that subsequent operation much more difficult because of the severe adhesions. Obviously, this is a relatively uncommon scenario. Pleurodesis with either these agents typically cause a fair degree of pleuritic chest pain, and the patient should be cautioned about this and pain medicine

made available for patient comfort. For pleurodesis to work, obviously there should be relatively complete apposition of the visceral and parietal pleura such that adhesions can form. If the patient has an ongoing air leak, the chest tube drainage system should not be clamped to allow pleurodesis to occur as this could lead to a tension pneumothorax. Typically, after sterilely prepping the drainage system tubing close to the chest tube insertion point, a needle is passed obliquely through the tubing such that it will seal quickly when the needle is removed. A large syringe is then used to inject the sclerosing solution, the needle is withdrawn, and then a clear plastic self-adherent dressing is placed over the insertion point to make sure that is sealed. If the patient has no air leak, the chest tube can be clamped to allow the solution to remain in the chest for 1 to 2 hours. If the patient has an ongoing air leak, the chest tube drainage tubing system can be hooked around an IV pole such that the solution remains in the chest once the injection is complete. There are rare cases of ARDS after talc is used related to both a very small particle size as well as doses over 5 g. For that reason, the typical adult dose is 4 to 5 g of talc. The chest drainage system is then placed on suction, typically for 1 to 2 days at a minimum, to ensure maximum pleural apposition to obtain the best possible pleurodesis.

Video-Assisted Thoracic Surgery

The advent of minimally invasive surgery for the chest, video-assisted thoracic surgery (VATS), has lowered the threshold for operative intervention for a pneumothorax. The indications for operative intervention are not particularly firm. The clearest indication for operative therapy is a recurrent pneumothorax, a patient with a first-time spontaneous pneumothorax with an ongoing air leak after 2 to 3 days, or the rare patient with a bilateral pneumothorax. Other indications include patients who present with a tension pneumothorax; patients with an identified large bleb; or patients with lifestyle issues such as pilots, scuba divers, or people who travel to areas without access to good medical care. Some patients elect to have operative intervention during the first hospital admission given the recurrence rate, which approaches about one-third, to reduce the chance of a recurrence.

VATS is typically performed under general anesthesia with three small incisions: one for the camera and the other ports for a stapler and forceps. It is, however, possible to do VATS under local anesthesia with sedation in thin, appropriately selected, compliant patients. In addition, uniportal VATS is certainly possible with a slightly larger main incision with this relatively simple surgical procedure. The lung is carefully explored, concentrating on the apex of the upper lobe and the tip of the superior segment of the lower lobe, which is where most blebs occur. Blebs are then typically stapled off with an endoscopic stapler. Most surgeons perform some sort of mechanical pleurodesis with a small gauze sponge, an electrocautery scratchpad, or with an energy device such as an argon beam coagulator. Alternatively, for high-risk patients, an apical pleurectomy is sometimes done, which is the most effective operative pleurodesis technique. However, this comes at the cost of longer operative times, increased risk of bleeding, and a slight risk of injury to adjacent structures such as the intercostal bundle or the stellate ganglion. A drainage catheter is placed after the procedure, and most patients can be discharged in 1 or 2 days. In patients with severe chronic obstructive pulmonary disease (COPD) who are being operated on, there can be significant leakage from the poor-quality lung at the staple line; these can be reinforced with commercially available buttressed staple loads or sealed with commercially available lung sealants. Talc pleurodesis is often used in patients with a secondary pneumothorax secondary to COPD to minimize the chance of recurrence.

Management of Primary Chest Wall Tumors

Whitney A. Davidson, MD, Lauren Antognoli, MD, and Avedis Meneshian, MD

OVERVIEW

A chest wall mass may represent any one of a broad spectrum of entities including benign or malignant primary chest wall tumors; locally invasive tumors originating from the lungs, pleura, mediastinum, or breast; metastatic lesions; and non-neoplastic (infectious or inflammatory) lesions. Of these, primary chest wall tumors, whether benign or malignant, are the least common; they comprise only 5% of all thoracic neoplasms. This creates a diagnostic challenge for surgeons as more commonly seen metastatic lesions must be ruled out. Primary chest wall tumors are best classified according to their tissue of origin and are further subdivided as either benign or bearing malignant potential. In this chapter, we review the most common primary chest wall tumors and focus on surgical management options, including chest wall resection and reconstruction. A list of benign and malignant primary chest wall tumors is provided in Box 1.

DIAGNOSIS

The vast majority of patients with primary chest wall tumors present with a painless, enlarging mass. Other patients who are entirely asymptomatic may have a primary chest wall tumor detected with thoracic imaging studies performed for unrelated indications. Pain in a patient with a primary chest wall tumor likely represents bony erosion or involvement of adjacent nerves, and it is often a harbinger of malignant tumor behavior. Workup includes a history and physical examination, with attention directed to a history of other malignancies, radiation exposure (therapeutic or environmental), and overt signs of infection or inflammation on physical examination.

A plain film chest radiograph may reveal a soft tissue or bony abnormality. Contrast-enhanced thoracic CT can help delineate the extent of bony, soft tissue, pleural, lung, or mediastinal involvement and can also exclude nodal or pulmonary metastatic disease. Contrast-enhanced MRI can help delineate vascular or

nerve involvement. A freely mobile mass less than 2 cm in size can generally be excised with clear margins, with both diagnostic and therapeutic intent. In contrast, larger lesions or those that are fixed to the underlying bone or soft tissue should undergo core needle biopsy or open incisional biopsy before definitive resection. Care must be taken to plan these biopsies with a subsequent curative resection in mind, with incisions placed appropriately so as not to preclude subsequent complete resection as indicated. Tissue diagnosis before surgical resection can help exclude infectious or inflammatory lesions for which resection may not be indicated, and it may allow for neoadjuvant radiation or chemotherapy, when appropriate, if the lesion is malignant.

CHEST WALL NEOPLASMS

Benign Bony and Cartilaginous Tumors

Fibrous Dysplasia

The most common benign bony tumor of the chest wall, fibrous dysplasia represents a lesion in which normal marrow and cancellous bone is replaced with a fibrous stroma (Fig. 1). It typically presents as a painless mass of the rib, commonly located posteriorly or laterally on the chest wall. Radiographic findings are variable but often include a central ground-glass appearance with punctate calcifications and peripheral cortical thinning. These tumors most commonly present as a solitary lesion in otherwise healthy individuals 20 to 30 years of age. They can, however, be multiple and are associated with McCune-Albright syndrome, which includes cutaneous manifestations and endocrine abnormalities in the context of short stature and precocious puberty. Surgical therapy is only indicated if the diagnosis is in doubt or if the lesion is symptomatic. In such cases, limited partial rib resection is the definitive treatment.

Osteochondroma

A benign bony lesion that typically presents in the third decade of life, an osteochondroma classically involves the costochondral junction. This lesion can present either as a small, palpable, painless mass or can grow to a larger size when unnoticed within the chest cavity. Punctate central calcifications with a mineralized hyaline cartilage are characteristic radiologic findings of osteochondroma. Observation with serial imaging is appropriate when lesions are small and asymptomatic. Symptomatic or enlarging lesions can be resected with local excision. Although malignant degeneration is rare (less than 1% of patients), resection should be considered if cartilage thickness exceeds 2 cm; malignant transformation to chondrosarcoma or osteosarcoma has been reported.

Chondroma

Chondromas are benign cartilaginous tumors that originate from the medullary cavity. They are more commonly found anteriorly in the rib and have no gender predilection. They present either as a painless mass or an incidentally documented lesion on imaging. On chest radiograph, chondromas are characteristically osteolytic lesions with well-defined sclerotic margins. On CT or MRI, punctate calcifications and cortical scalloping may be seen. These benign lesions are often difficult to differentiate from low-grade chondrosarcomas (both radiographically and histologically) and therefore should be resected with wide local excision.

Malignant Bony and Cartilaginous Tumors

Chondrosarcomas

Chondrosarcomas are the most common primary malignant chest wall tumor (Fig. 2). They occur most frequently in the fourth to seventh decades of life and are slightly more common in men than in women. They are typically located anteriorly and involve either the costochondral junction or the sternum. On imaging, irregular margins and bony destruction are typical. Early-stage lesions can retain a thickened cortical cap, whereas more advanced tumors progress to complete cortical destruction and an associated soft tissue mass. Suspected benign chondromas in which the cortical cap thickens over time may be in the process of malignant degeneration into chondrosarcoma. All suspected chondrosarcomas should undergo wide local excision; they often require chest wall reconstruction. Poor prognostic factors include hypercellularity, cytologic atypia, high mitotic index, and larger tumor size. High-grade tumors have a 75% chance of distant spread at the time of diagnosis. Because these tumors respond poorly to chemotherapy or radiation, complete surgical excision is the primary treatment modality. Studies demonstrate

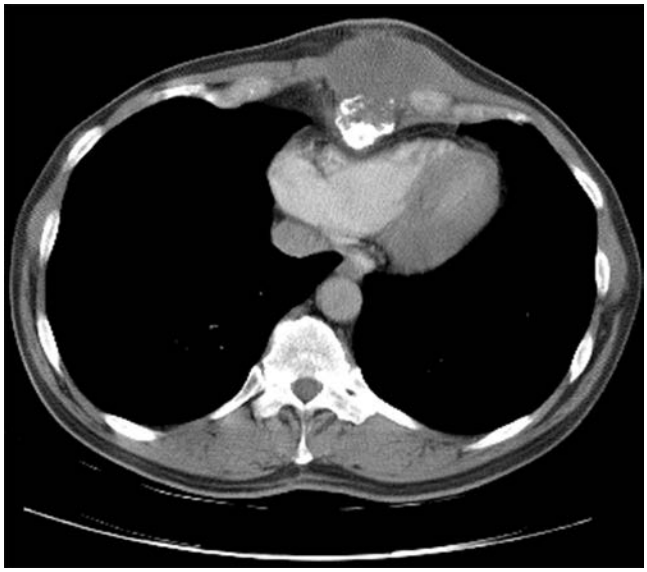

FIG. 2 Chest CT demonstrating a chondrosarcoma of the lower sternum and xyphoid.

that inadequate resection margins in chondrosarcoma are associated with significantly higher local recurrence and lower overall survival.

Osteosarcomas

Osteosarcomas of the chest wall have a bimodal presentation, with most cases occurring at puberty but with a secondary peak after 40 years of age. They present as a rapidly expanding mass and arise from the rib, scapula, or clavicle. Environmental factors (fluoride exposure, farmworkers) and genetic predisposition (young age at puberty, familial history, retinoblastoma, Li Fraumeni syndrome) increase the lifetime risk of development of osteosarcoma. Radiographic findings include bony destruction with an associated large, heterogeneous mass composed of necrotic tumor and hemorrhage and often punctate calcification. Because distant metastasis (typically to the lung) is common and good systemic options for therapy exist, complete staging with PET/CT imaging and biopsy for tissue confirmation is indicated for suspected osteosarcoma. Induction chemotherapy followed by surgical resection (wide local excision with reconstruction as needed) is the treatment of choice for localized disease. Overall 5-year survival rates have increased to 60% when the osteosarcoma is localized but remains below 30% in patients with distant metastases.

Ewing Sarcomas and Askin Tumors

Ewing sarcomas and primitive neuroectodermal tumors (PNETs), also known as Askin tumors, are malignant, small, round cell tumors with genetic translocation between chromosomes 11 and 12. They typically occur in children and young adults and are almost exclusively seen in Caucasians. Around 15% of Ewing sarcomas and up to 5% of PNETs arise in the chest wall and can involve a single rib, clavicle, or the scapula, in descending frequency. They often present as a painful enlarging chest mass with constitutional symptoms that include fever, weight loss, and generalized malaise. Associated pleural effusions are also common. Radiographic findings include a large, noncalcified mass with bony destruction. As with osteosarcomas, systemic disease at diagnosis is frequent and staging with PET/CT and consideration of neoadjuvant systemic therapy followed by complete surgical resection and chest wall reconstruction is warranted. Postoperative radiation should be reserved for a margin-positive resection. Bilateral whole-lung irradiation may be used in the adjuvant setting to increase event-free survival in patients with documented pulmonary metastases. Overall 5-year survival rates for Ewing sarcoma can approach 70%, whereas for PNETs, long-term survival remains about 30%.

Solitary Plasmacytomas

Plasmacytomas tend to occur in men in their 60s and 70s and present with pain, typically without a palpable mass. Imaging documents a punched-out osteolytic lesion of the bone. The role of surgery in these patients is generally limited to obtaining tissue for histologic diagnosis. After tissue diagnosis is confirmed, local therapy with radiation is indicated. Up to two-thirds of patients will develop systemic involvement with multiple myeloma, which carries a 5-year survival rate around 35%. However, solitary plasmacytomas that are successfully irradiated and do not progress to systemic multiple myeloma have an excellent long-term prognosis, with over 90% 5-year survival. Surgical resection as local therapy for isolated disease can be indicated for patients in whom radiation therapy is not an option.

Benign Soft Tissue Tumors

Lipomas

Chest wall lipomas are typically larger and deeper than those soft tissue lipomas found in other anatomic locations. They are rarely symptomatic. Imaging reveals a homogenous mass consistent with mature fatty tissue. Resection is only indicated for symptomatic or enlarging lesions or for suspicion of a low-grade liposarcoma.

Fibromas (Desmoid Tumors) and Fibromatosis

Desmoid tumors arise from fibroblasts deep within the chest wall musculature and often occur in patients in their teenage years to early 30s. They present as a slowly growing, sometimes painful mass, often in the context of prior trauma or prior thoracotomy; they are also sometimes seen in the context of systemic fibromatosis (Gardner syndrome). Complete surgical resection with wide margins (up to 4 cm if possible) with chest wall reconstruction is the optimal therapy. Local recurrence rates are quite high; adjuvant radiation therapy can be used both prophylactically and in the context of microscopically positive margins. Recurrence rates for margin-positive disease remain as high as 90%, even with radiation therapy.

Hemangiomas

Hemangiomas of the chest wall are benign proliferations of blood vessels that form in the context of muscle, rib, or subcutaneous tissues. They are most typically seen in children, and MRI or ultrasound can be used to confirm the diagnosis. Resection is only indicated if symptoms develop; bleeding, ulceration, and (rarely) heart failure from arteriovenous malformation and shunting (cavernous hemangiomas) can occur. In these cases, local excision is curative, with chest wall reconstruction reserved for larger lesions.

Benign Peripheral Nerve Sheath Tumors

Chest wall schwannomas are encapsulated tumors that develop from intercostal nerves or thoracic spinal nerve roots. They are typically asymptomatic and identified incidentally during thoracic imaging. CT and/or MRI are usually sufficient for diagnosis and, in asymptomatic cases, serial imaging and observation suffice. Needle biopsy can be confirmatory in cases of diagnostic uncertainty. Resection is reserved for symptomatic or enlarging lesions and may require contiguous chest wall or vertebral body resection and reconstruction.

Malignant Soft Tissue Tumors

Malignant Fibrous Histiocytomas

Malignant fibrous histiocytoma (MFH) has a bimodal distribution at diagnosis, with peaks at 20 to 30 years of age and 50 to 60 years of age, with the latter being more prevalent. These tumors rarely arise

from the chest wall; when they do, they are generally associated with prior radiation exposure. Imaging reveals a heterogeneous mass with irregular borders; bony involvement is rare. A well-planned needle biopsy for tissue diagnosis is indicated for MFH with induction chemotherapy followed by surgical resection and reconstruction being the therapy of choice. Postoperative radiation can be reserved for margin-positive disease. Even with complete resection and systemic therapy, metastatic disease is common, and 5-year survival remains less than 50%.

Synovial Sarcomas

These malignant tumors rarely present as a primary chest wall malignancy, and the thoracic surgeon is more typically involved with the management of oligometastatic lung involvement from systemic disease. Nevertheless, primary synovial cell sarcomas of the chest wall can occur, typically in early adulthood. Imaging generally reveals a mass with heterogeneous foci resulting from necrosis or hemorrhage within cystic components, with about one-half of the tumors showing calcification. Treatment includes complete surgical resection, with chemotherapy or radiotherapy being utilized in either the neoadjuvant or adjuvant setting. Five-year survival remains around 50%, irrespective of the timing of chemoradiotherapy.

Rhabdomyosarcomas

Rare in adults, rhabdomyosarcomas are the second most common malignant primary chest wall tumor in children. As the vast majority of cases present with distant metastases, complete staging should be undertaken to determine which patients are candidates for primary site resection. Staging in children can include CT scan of the thorax, abdominal ultrasound, and bone scan, although PET/CT scans are being used increasingly in the pediatric population. Tissue confirmation is important because, when resectable, these aggressive tumors are treated with induction chemoradiation followed by wide local excision with chest wall reconstruction. Sometimes adjuvant chemotherapy or radiation are also indicated. Survival remains poor with surgical resection alone; however, trimodal therapy has resulted in a significant improvement in 5-year survival, with rates as high as 75% in patients without documented metastatic disease at the time of diagnosis.

SURGICAL TREATMENT OF CHEST WALL TUMORS

Chest Wall Resection

Surgical resection remains the mainstay of therapy for primary chest wall tumors, whether benign or malignant. Benign lesions should be resected to microscopically negative margins. Many malignant chest wall lesions have high recurrence rates; therefore, aggressive wide local excision with chest wall reconstruction as indicated is recommended. The general guidelines for planning surgical resection of primary chest wall tumors are as follows. Primary malignant tumors of the chest wall should be resected with a 4-cm margin. This margin has been shown to afford better long-term survival. Tumors arising from adjacent structures (most commonly lung cancers) should be resected to include the involved rib as well as the rib above and below the area of invasion. Metastatic lesions can generally be resected to microscopically clear margins, but only in carefully selected patients in whom the solitary chest wall metastasis is thought to be the only site of systemic disease.

Adequate oncologic resection is critical in the management of chest wall tumors, so surgical resection should not be compromised because of concern for the resulting skeletal defect. However, this means that initial planning for resection must also include a plan for reconstruction of the resulting defect to restore function and optimize cosmesis. Surgical planning for resection should begin at the time of original tissue diagnosis, with care taken to place biopsy incisions in areas that can be subsequently incorporated into wide local excisions. Therefore, involvement of the surgeon in planning therapy for these patients and collaboration with plastic and reconstructive surgeons as needed should occur early in the treatment course.

Chest Wall Reconstruction

The thorax is a rigid structure that protects the underlying viscera, supports the upper extremities and shoulder girdle, and allows for ventilation. Anatomic defects in the bony framework of the chest may result in exposure of vital structures to the external environment or alteration of chest wall mechanics that lead to subsequent paradoxical chest wall motion and ventilatory impairment. Large defects may result in lung herniation, contraction of the resected hemithorax, or scapular entrapment. The goals of reconstruction are to mitigate these alterations of the chest wall and the potential complications, while maintaining optimal cosmesis. More specifically, the primary goals of chest wall reconstruction are to restore chest wall rigidity and integrity to protect intrathoracic organs and maintain proper pulmonary mechanics, while minimizing deformity of anatomic chest wall structure and overlying soft tissues. No formal guidelines exist for skeletal reconstruction after chest wall resection, thus rendering surgical judgment essential. A multidisciplinary approach involving thoracic and plastic surgery teams as appropriate is crucial in obtaining optimal functional and aesthetic outcomes.

General Principles of Chest Wall Reconstruction

When planning chest wall reconstruction, the surgeon must take into account defect location, size, local tissue condition, and patient comorbidities. See Table 1 for an overview of the following general principles for chest wall reconstruction after tumor resection. Anterior and lateral defects of two consecutive ribs with a resultant defect less than 5 cm in size are generally well tolerated with no functional consequence. Anterior resections of the first to third ribs may be especially well tolerated without reconstruction because of support provided by the overlying pectoralis muscles. When more than three adjacent ribs in the anterolateral location are resected or the resulting defect is 5 cm or greater, the possibility of paradoxical chest wall motion and its associated complications arises, suggesting that reconstruction is necessary. This is especially true for anterolateral defects and full-thickness defects. Posterior defects can often tolerate up to twice the size of anterior and lateral defects because of overlying scapular support and back musculature, and they may be left without skeletal reconstruction if the defect is less than 10 cm in diameter. If the posterior rib defect encompasses the fourth, fifth, or sixth ribs, special attention must be paid to the location of the scapular tip because it may become entrapped within the chest wall.

TABLE 1 General Principles for Chest Wall Reconstruction

Characteristics of Chest Wall Defect	Reconstructive Principle
1–2 consecutive ribs and/or defects <5 cm	No specific reconstruction is required Cover with autologous tissue alone
≥3 ribs and/or defects >5 cm	Require chest wall stabilization with semirigid and/or rigid material
Apicoposterior defect (up to 10 cm) entirely beneath scapula	May not require reconstruction (scapula may prevent lung herniation)
Posterior resection involving fourth, fifth, or sixth rib(s)	Consider notching inferior rib, removing tip of scapula, or covering defect with mesh to prevent painful/dysfunctional entrapment of scapula

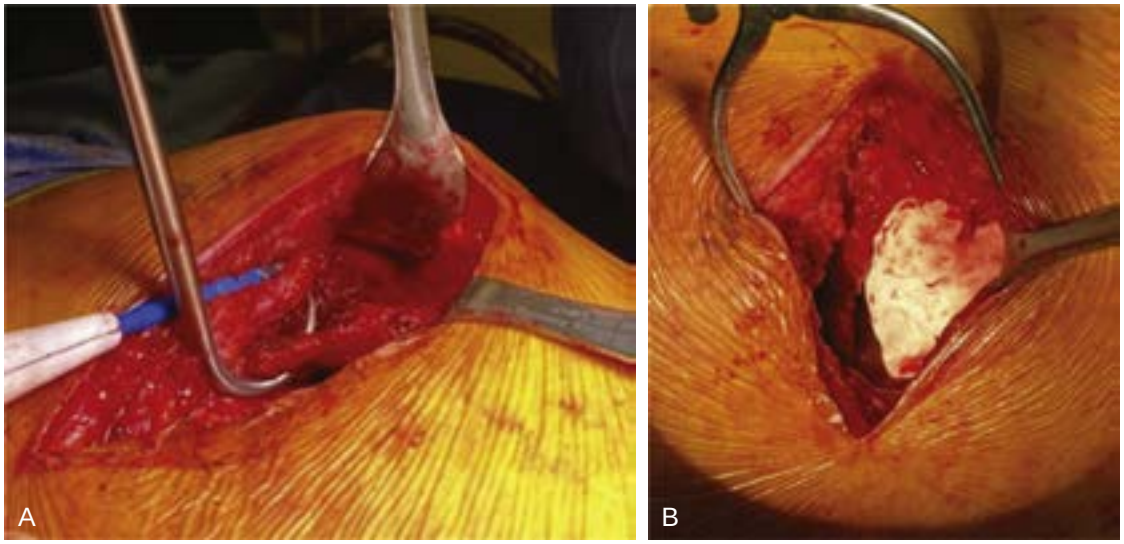

FIG. 3 A 64-year-old woman with a history of intermittent right scapular entrapment following prior chest wall resection. The surgical team used a bone hook to isolate the tip of the scapula and then resected the inferior component to prevent further impingement **(A).** Part of the fifth rib was also resected as this was identified as the rib causing entrapment on dynamic intraoperative manipulation of the shoulder. To prevent future impingement of the remaining scapula, the defect was covered by circumferentially securing polytetrafluoroethylene (PTFE) over the chest wall beneath the serratus anterior with interrupted 2-0 Prolene sutures **(B).**

In these cases, we recommend covering the defect with mesh (e.g., acellular dermal matrix [ADM], polytetrafluoroethylene [PTFE]) to prevent the scapular tip from entering the chest wall. Resection of the scapular tip and/or notching ribs adjacent to the scapular tip are also options to prevent entrapment (Fig. 3).

The author's practice is to reconstruct defects 4 cm or greater in size if pulmonary function is borderline, thus minimizing the chance of postoperative pulmonary insufficiency in these patients with marginal reserve. In patients who have dense underlying adhesions or pulmonary scarring from prior radiation or surgery, the authors may choose not to reconstruct defects larger than 5 cm as ventilation may not be affected. Tolerance for defect size also increases in the setting of infection as graft infection may develop. Finally, complete soft tissue coverage is imperative in all cases and varies greatly depending on defect size and location.

Options for Chest Wall Reconstruction

After the decision has been made to perform skeletal stabilization, a suitable graft option must be selected for both the bony defect and the overlying soft tissue coverage. The ideal materials for skeletal reconstruction provide strength and stability with acceptable cosmesis. Options for chest wall reconstruction include autogenous reconstruction (e.g., bone, fascia), bioprosthetic mesh (e.g., ADM), and synthetic materials (e.g., metals, plastics, synthetic mesh). The choice of which material to use depends on defect size, shape, and location; availability and cost of materials; patient comorbidities and pulmonary status; and surgeon preference.

Very large chest wall resections leading to severe skeletal destabilization requiring reconstruction with primarily rigid materials is quite uncommon. Synthetic rigid materials such as polymethylmethacrylate (PMMA) have largely fallen out of favor as they can cause significant pain and excessive chest wall rigidity, so they should be used judiciously in reconstruction. Semirigid materials such as ADM or PTFE are widely used for chest wall reconstruction as they provide initial stability until scar tissue envelops the materials over time, ultimately providing durable rigidity while allowing flexibility for chest wall movement. Semirigid materials can also be used in conjunction with rigid materials such as titanium struts to provide more stability in very large defects. PTFE is watertight and causes minimal foreign-body reaction, but it cannot be used in the setting of acute infection. One benefit of using ADM in chest wall reconstruction is its ability to withstand postoperative infections. Unlike infection involving synthetic mesh, ADM-adjacent infection can often be treated conservatively with antibiotics and ultimately salvaged. This is accomplished oftentimes with percutaneous drainage of the fluid collection, debridement of infected tissues, antibiotics, negative pressure wound therapy, and local wound care without ADM removal.

Again, complete soft tissue coverage is imperative regardless of defect size. Smaller defects may be closed primarily or covered by skin grafts or simple local advancement flaps (Table 2). Larger defects require coverage by more robust and richly vascularized autologous flaps such as pedicled myocutaneous flaps or free flaps to minimize the risk of graft exposure and infection. The latissimus dorsi flap is considered the workhorse in chest wall reconstruction as it has a robust blood supply and can cover the majority of the ipsilateral chest wall. Some patients with especially large defects may benefit from a combination of flaps, usually latissimus dorsi, pectoralis major, and/or omental flaps. Omental flaps lack musculocutaneous coverage but are an excellent option for eliminating dead space, and they can be used to cover intrathoracic structures or chest wall prostheses. Omental flaps are ideally passed into the thorax through a cruciate incision in the right hemidiaphragm, where the liver can help prevent herniation through the defect. Because the omentum is largely composed of fat, the size of the omental flap depends greatly on the patient's body habitus and may not be an option in malnourished or very thin individuals. Omental flaps can easily reach most areas of the thorax, but they require some sort of definitive soft tissue coverage. Patients who have undergone chest wall radiation may not be candidates for latissimus dorsi or pectoralis flaps if that tissue has been heavily irradiated because there is an increased risk of poor wound healing of both the donor site and flap as well as concern for decreased flap vascularity. Free flaps such as anterior lateral thigh (ATL), deep inferior epigastric perforator (DIEP), or tensor fascia lata (TFL) flaps are reserved for such patients in whom local flap options are not possible or have failed. While free flaps can provide excellent soft tissue coverage in these more complicated patients, one

TABLE 2 Flaps Used to Cover Thoracic Soft Tissue Defects After Chest Wall Resection

Type of Flap	Arterial Supply	Location of Defect
Latissimus dorsi	*Primary:* thoracodorsal *Secondary/turnover flap:* perforating vessels from posterior intercostal vessels/thoracolumbar perforators	Lateral, posterior, and anterior
Pectoralis major	*Primary:* thoracoacromial *Secondary/turnover flap:* internal mammary perforators	Anterior
Serratus anterior	Subscapular artery	Anterolateral Intrathoracic coverage
Rectus abdominis	Deep superior or inferior epigastric	Anterior (e.g., midline, lower sternum)
External oblique	Deep circumflex iliac, posterior intercostals	Anterior
Omentum	Gastroepiploic	Anterior and midline Intrathoracic coverage (no myocutaneous coverage)

must consider the need for a microvascular surgeon, more intensive postoperative surveillance, and donor site morbidity.

Surgical Technique for Chest Wall Reconstruction

The authors' preference is to use ADM or PTFE for chest wall reconstruction in conjunction with local rotational or pedicled myocutaneous flaps for soft tissue coverage of defects as needed. The authors' greatest clinical experience with ADM for chest wall reconstruction has been with AlloDerm (Lifecell Corporation, Bridgewater, NJ). Based on the estimated size of the defect during surgery before resection, we request that the AlloDerm be brought to the operating room for rehydration, which can take on average 30 to 60 minutes. We generally prefer the extra-thick, non–cross-linked graft to provide better skeletal support, although this observation is based on anecdotal evidence, and objective data do not currently exist. Graft selection is based on the defect, and multiple grafts may be sutured together for additional coverage.

After skeletal resection is complete, rib margins are blunted to avoid sharp injury to the graft or underlying viscera. Thorough inspection for hemostasis is performed, and the wound is irrigated with copious saline solution. ADM is then sized to the defect and prepared for inset. The authors generally do not prestretch the ADM more than 10% to 15% as the goal for graft placement is to maintain a taut and drumlike tension across the defect to prevent redundancy and leaking. During ADM sizing, it is essential to account for patient positioning. Most surgical approaches for chest wall resection are with the patient in the lateral decubitus position with maximal table flexion to increase interspace distance for chest entry. Thus, it is imperative to restore the operating table to a neutral position during determination of graft size to reduce the chance of inadequate tension. The AlloDerm matrix has two distinct surfaces, and the proper orientation of the allograft before insertion is important for optimal tissue integration. The authors use a heavy nonabsorbable suture with a cutting ½-circle 4-mm needle for graft implantation. This suture allows for ease of passage through the dense dermal graft and facilitates bone penetration when necessary. Single interrupted sutures for secondary support are placed in four quadrants and at any area where there is pleating or a tighter seal is desired. A combination of running or interrupted sutures is then placed circumferentially. Suture is passed through fascia when available or directly through the adjacent rib when fascia is not in proximity, and the superficial portion of the tissue flap is secured to the ADM to obliterate the dead space.

After implantation, the graft is thoroughly irrigated and tested for leakage by insufflating the underlying lung after submersion of the graft in saline solution. Once the ADM has been placed to provide the structural support, soft tissue coverage is generally achieved with a muscle flap to allow for cellular infiltration, vascularization, and tissue ingrowth. The authors then place a 28Fr chest tube in a posteroapical position through the interspace ideally two rib spaces below where the ADM is secured. The pleural tube is managed as for any standard lung resection. To help prevent seroma formation, at least two 19Fr closed-suction drains are placed to close the subcutaneous dead space below the tissue flap and ADM. The drains remain in place until the patient has been ambulating for 24 to 48 hours and once the drain output is less than 30 cc over 24 hours.

SUMMARY

Primary chest wall tumors are rare. When therapy is indicated, surgical resection remains the primary modality of treatment, alone or in combination with chemotherapy or radiation, in the neoadjuvant or adjuvant setting. Margin negative resection affords the best chance of cure. Careful planning and collaboration are critical to ensure outstanding oncologic outcomes with optimal functional and cosmetic results after reconstruction.

Mediastinal Masses

Hamza Khan, MD, Wasay Nizam, MBBS, and Malcolm V. Brock, MD

APPROACH TO A PATIENT WITH A MEDIASTINAL MASS

Mediastinal masses include a variety of entities—both benign and malignant—and are relatively uncommon. These masses should be considered when evaluating for signs and symptoms such as dyspnea, dysphagia, or head and neck swelling caused by compression of the trachea, esophagus, or great vessels, respectively. They should also be considered in the evaluation of general systemic symptoms such as fever, fatigue, or immunosuppression that may result from associated paraneoplastic syndromes. Mediastinal masses are often diagnosed incidentally on imaging performed for unrelated reasons. Laboratory studies such as alpha-fetoprotein (AFP), lactate dehydrogenase (LDH), or beta human chorionic gonadotrophin (B-HCG) play an important role in diagnosis. CT scans of the neck and chest provide valuable information regarding the location of the tumor, size, relationship to surrounding structures, and other characteristics important in narrowing the differential diagnosis. Core-needle biopsy is preferred where tissue histopathology is required for accurate diagnosis. In cases where the risk of tumor seeding is high, a surgical resection is often performed instead of biopsy. High volume centers are now minimally invasively resecting these masses using procedures such as video-assisted thoracoscopic surgery (VATS) or robot-assisted thoracoscopic surgery (RATS) over traditional open approaches.

ANTERIOR MEDIASTINAL MASSES

Of all mediastinal masses, 50% or more lie within the anterior mediastinum. The most common among these are commonly referred to as the "four T's" or "terrible T's"; namely thymic tumors, thyroid masses, "terrible" lymphoma, and teratoma (germ cell tumor). Approximately 60% of all anterior mediastinal masses are malignant, and most of these are symptomatic at presentation.

Thymic Tumors

Lesions of the thymus account for the majority of anterior mediastinal masses. These range from well-differentiated lesions such as thymoma to more menacing conditions such as invasive thymic carcinoma. Of these, thymomas are the most common entity with a similar incidence in both genders. The usual presenting complaints include the presence of a cough, chest pain, or shortness of breath that results from locoregional compressive effects. Additionally, patients may present with generalized systemic complaints due to associated paraneoplastic disorders. Up to 50% of the patients with thymoma can develop myasthenia gravis (MG), whereas 15% of the patients with MG have any underlying thymoma. Patients with MG and thymoma present with ptosis, fatigue, dysphagia, and less advanced thymic disease possibly because symptoms lead to earlier diagnosis. Other paraneoplastic disorders include myositis, acquired neuromyotonia, and Morvan's syndrome. In certain instances, hematologic disturbances may also be encountered. Red cell aplasia may be seen in 5% to 15% of the patients and immunodeficiency from white cell aplasia and hypogammaglobulinemia in less than 5% of the patients—both disorders more common in older females.

A CT scan with IV contrast is the imaging modality of choice for thymic lesions (Fig. 1). Tumors with well-circumscribed, smooth margins favor the presence of a thymoma. In the context of a typical clinical presentation, these radiographic findings may be sufficient to proceed with surgical resection, as preoperative biopsies carry the risk of tumor seeding and do not provide further diagnostic utility. In contrast, thymic carcinoma can be distinguished by the presence of an infiltrating mass, with central necrosis and irregular borders. In this setting, a biopsy may be considered to establish the malignant nature and to allow adequate staging and options for neoadjuvant treatment. Ideally, fine-needle aspiration (FNA) should be avoided since it lacks the architectural platform necessary to distinguish thymoma from lymphoma. In cases of diagnostic uncertainty, other imaging modalities like MRI can prove as useful adjuncts. For example, when differentiating thymoma from thymic hyperplasia, the latter will have a smooth and symmetric morphology with the presence of adipose tissue.

The eighth edition of the American Joint Committee on Cancer (AJCC) TNM Staging system now incorporates TNM staging for tumors of the thymus. This classification is dependent upon the invasion of the primary tumor and its dissemination. This new system, therefore, supersedes the Masaoka staging system that is still widely used and upon which many existing treatment guidelines are based. Prognosis for thymoma depends on the presence of invasion and the resectability of the mass. For patients where R0 (complete) resection is achievable, surgery is recommended. These patients with early-stage disease who undergo a complete resection can achieve a 5-year survival rate as high as 100%. Careful preoperative planning is needed for patients with MG that includes medical treatment with anticholinesterase or plasmapheresis preoperatively and avoids the use of neuromuscular blocking agents for anesthesia. For patients with tumor invasion into critical structures (great vessels, heart, or trachea) or metastatic disease, a combination of neoadjuvant chemotherapy or radiotherapy, radical resection, and postoperative chemoradiotherapy is indicated. Chemotherapy regimens are typically cisplatin-based; however, they are currently still poorly defined so treatments are individualized for patients or given as part of a clinical trial. Small-scale studies have shown response rates to neoadjuvant therapy in 70% to 100% of patients who have partially resectable tumors. For patients with thymic carcinomas who have a poor response to neoadjuvant chemotherapy, pembrolizumab, an immune checkpoint inhibitor, or sunitinib, a tyrosine kinase inhibitor, can be considered. In patients who develop recurrent disease, if localized, repeat surgical resection with adjuvant therapy for curative intent is advocated. Posttreatment surveillance is recommended with CT scanning performed annually for 10 years.

Thyroid and Parathyroid

Mediastinal goiters can either be an inferior extension of cervical thyroid tissue through the thoracic inlet or a proliferation of native ectopic thyroid tissue present within the mediastinum. For a goiter to be termed substernal, 50% or more of the mass should lie inferior to the thoracic inlet. For it to be called "aberrant," the thyroid tissue in the mediastinum must have no connection with its cervical counterpart and should not share its blood supply. Even though 15% of mediastinal masses can be thyroid lesions, only 2% or less of these goiters are substernally aberrant. Large masses can cause obstructive symptoms like dyspnea or dysphagia from compression of the esophagus or trachea. Often, these masses grow slowly over time, but hemorrhage into a nodule often precipitates an acute presentation such as compression of a vital structure such as the trachea. Other symptoms include chronic coughing, a choking sensation, sleep apnea, and nerve paralysis depending upon the location and size of the mass. Surgical resection is the gold standard treatment for such patients. Radioactive iodine ablation carries with it the risk of acute inflammation leading to worsening

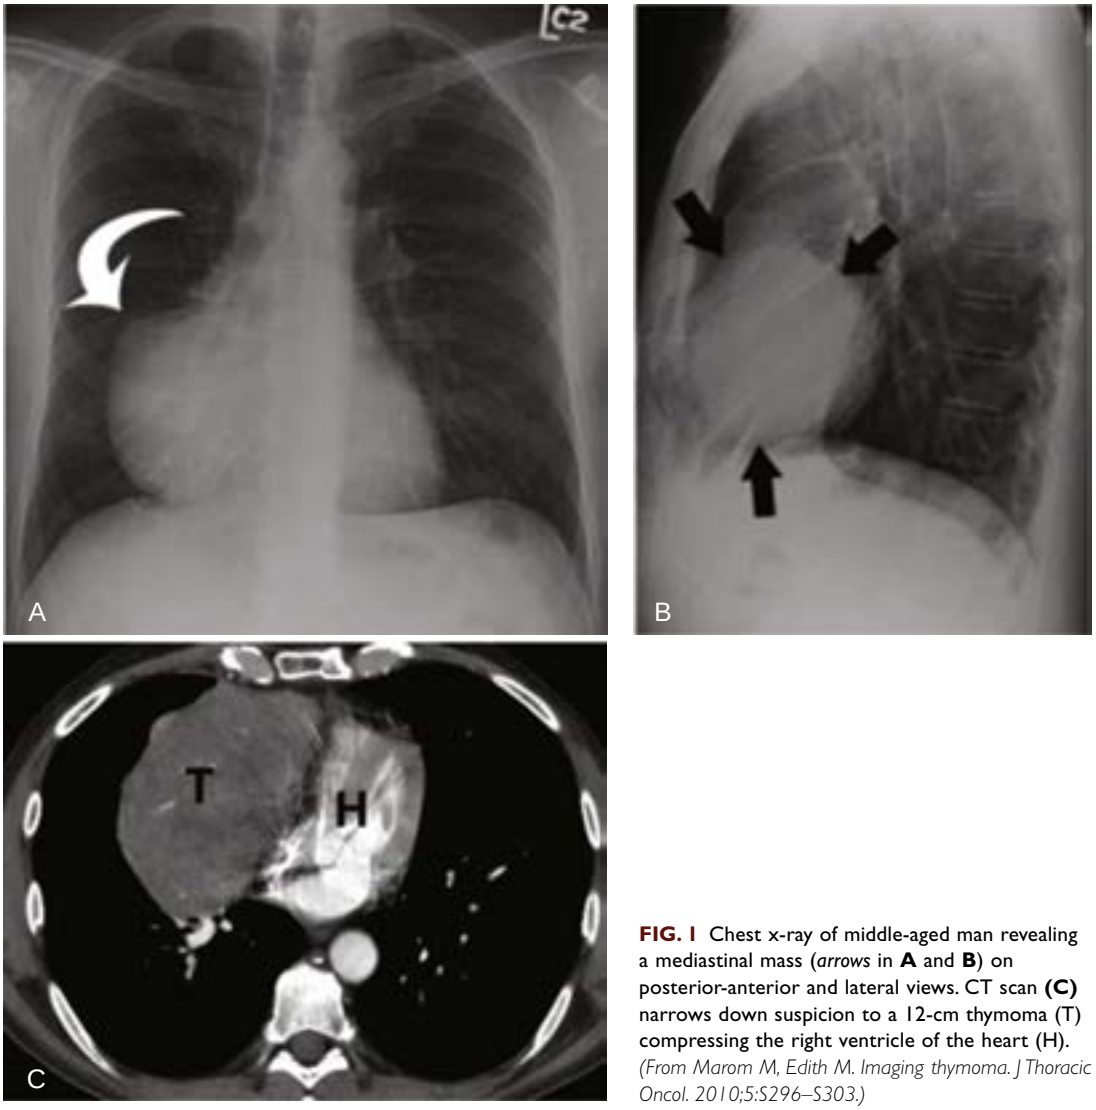

FIG. 1 Chest x-ray of middle-aged man revealing a mediastinal mass (*arrows* in **A** and **B**) on posterior-anterior and lateral views. CT scan **(C)** narrows down suspicion to a 12-cm thymoma (T) compressing the right ventricle of the heart (H). *(From Marom M, Edith M. Imaging thymoma. J Thoracic Oncol. 2010;5:S296–S303.)*

compression and is reserved for nonsurgical candidates only. Preoperative planning includes measuring a thyroid-stimulating hormone (TSH) level to ensure adequate medical management of hyperthyroidism. Laryngeal examination and imaging are also warranted to determine if any compromised function is solely from the mediastinal thyroid tissue. Surgical resection can be safely performed transcervically via a low collar neck incision in most cases (Fig. 2). Under certain circumstances where lesions are deeper or involve multiple mediastinal compartments, a partial or complete sternotomy is required for complete resection. Minimally invasive approaches including VATS are increasingly being employed at high volume centers. Postoperatively, patients who undergo total thyroidectomy require lifelong levothyroxine.

Parathyroid adenomas are rare causes of mediastinal masses but nonetheless important given their shared embryologic origin with the thymus. Up to 20% of patients with hyperparathyroidism can have mediastinal parathyroid adenomas. It is important to realize that a mediastinal parathyroid is a frequent cause of failure to localize the parathyroid during surgery. Typically, the inferior parathyroid glands descend along the thyrothymic tract, or a fifth parathyroid gland is found in the mediastinum. Patients present with symptoms of hypercalcemia—abdominal pain, kidney stones, polyuria, constipation, altered mentation, bone-related complications, or with an incidental finding on CT scan (stones, bones, groans, thrones, and psychic overtones). Accurate preoperative localization can be achieved with CT/Sestamibi fusion scan with up to 90% sensitivity (Figs. 3 and 4). Surgical resection via transcervical approach can be achieved in most cases; however, tumors present deep within the thorax require either a sternotomy or VATS.

Lymphoma

Lymphomas are broadly classified as Hodgkin's and non-Hodgkin's and comprise up to 25% of the masses in the anterior mediastinum. Primary mediastinal B-cell lymphoma (PMBL) and nodular sclerosing Hodgkin's lymphoma (HL) are the most common subtypes. Patients commonly present with B-type symptoms—fatigue, low-grade fevers, weight loss, and night sweats—or with compression effects on the surrounding structures (Fig. 5). CT/MR imaging

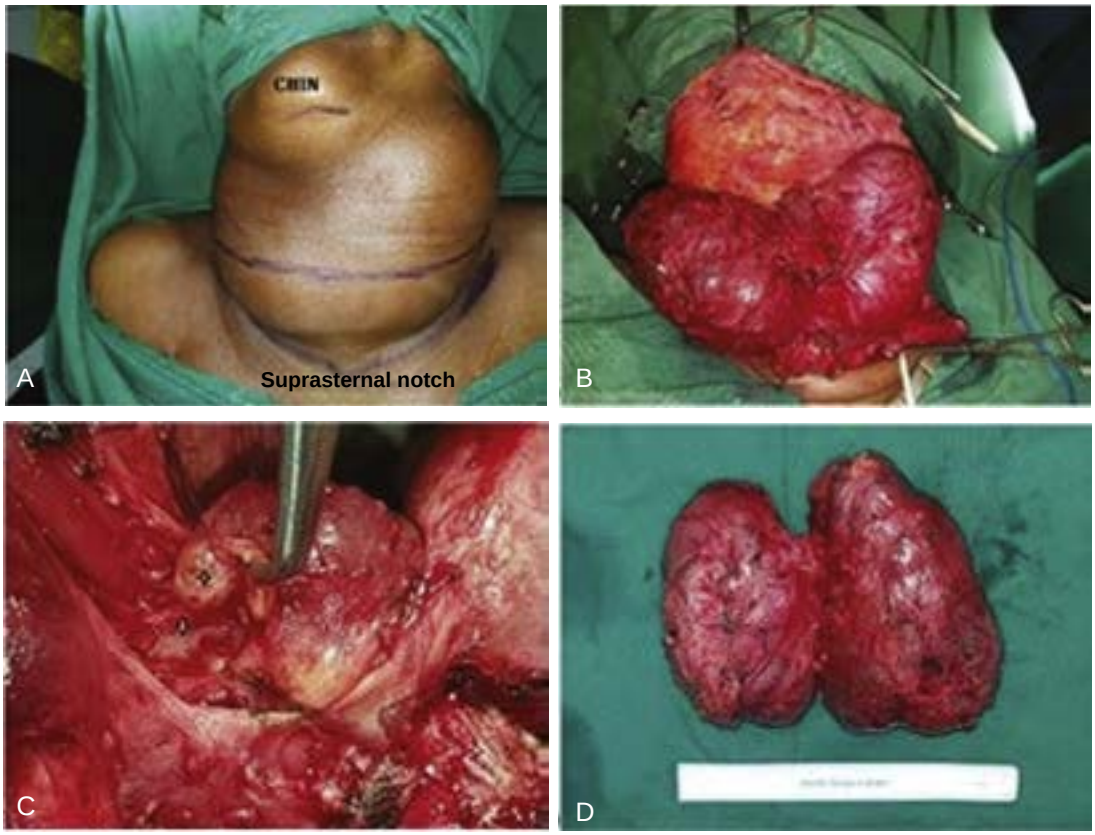

FIG. 2 **(A)** Large neck swelling measuring 10 cm in the longest dimension. **(B).** Horizontal neck incision extending bilaterally to the mastoid tips with exposure of the thyroid gland along with the mass. Enlarged pyramidal lobe of thyroid extending into the pre-cervical space **(C)** and gross specimen after removal **(D).** Pathologic diagnosis later confirmed toxic multinodular goiter. *(From Alaguvelsamy S, Sujeethra S, et al. Giant toxic multinodular goiter with dyspnea: A case report.* Int J Surg Case Rep. *2020;73:190–195.)*

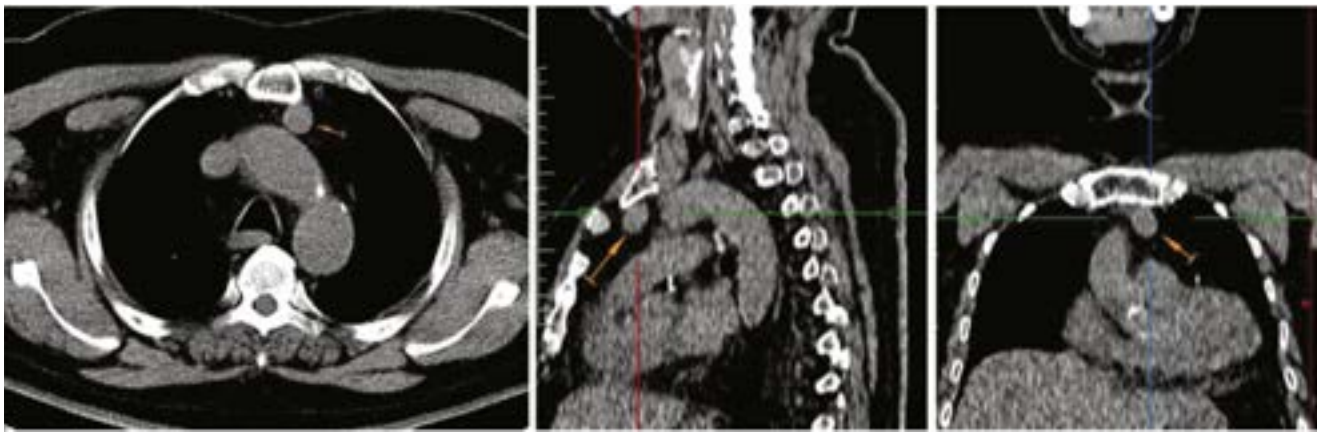

FIG. 3 CT scans show a well-defined circular mass (orange arrows) in the anterior mediastinum posterior to the manubrium of the sternum and anterior to the aortic arch that measures 1.7 × 1.7 × 2.8 cm. *(From Khalaf SH, Sarwani, AA, George SM, et al. Primary hyperparathyroidism caused by an ectopic parathyroid adenoma in an uncommon location: a case report.* J Taibah Univ Med Sci. *2021;16:782–787.)*

often reveals enlarged mediastinal lymph nodes along with vascular encasement and a pleural/pericardial effusion (Fig. 6). However, a formal diagnosis requires a core needle biopsy to evaluate the structural composition of the tissue in addition to flow cytometric analysis. Given the success of chemotherapy, the role of the surgeon in this instance is limited to the occasional need for a surgical biopsy for adequate tissue specimen. Management is primarily based on chemotherapy followed by consolidation radiotherapy. Such treatment regimens risk tumor lysis syndrome, and hence close monitoring of potassium, phosphate and uric acid is employed. Functional imaging

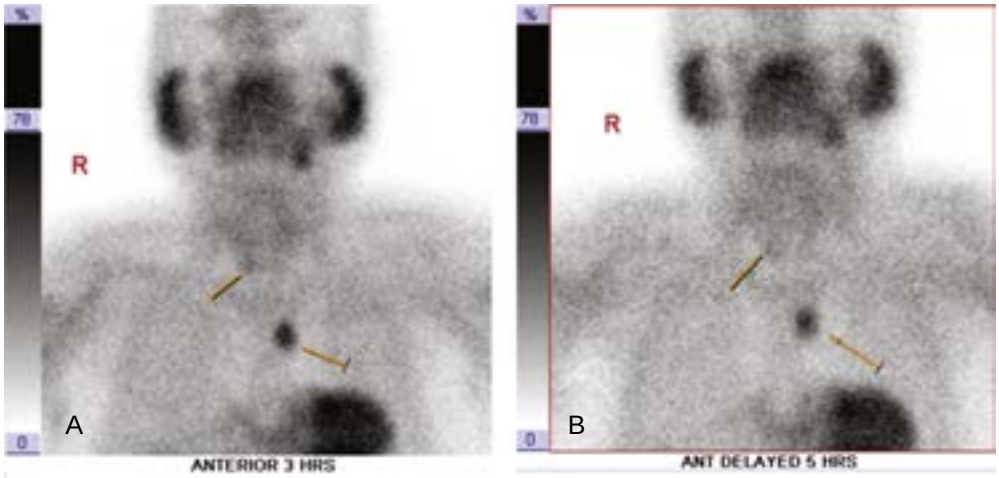

FIG. 4 Parathyroid sestamibi scan showing a MIBI-avid focus on 3 hr **(A)** and 5 hr **(B)** images (inferior left, *orange arrow*). Also seen is a faint focus corresponding to the location of the right lower pole of the thyroid (superior right, *orange arrow*). Pathology later confirmed a diagnosis of a parathyroid adenoma of the left paraaortic mediastinal mass. *(From Khalaf SH, Sarwani, AA, George SM, et al. Primary hyperparathyroidism caused by an ectopic parathyroid adenoma in an uncommon location: a case report.* J Taibah Univ Med Sci. *2021;16:782–787.)*

modalities such as PET-CT may be utilized for long-term disease monitoring and to assess for possible recurrence.

Germ Cell Tumors

Mediastinal germ cell tumors (GCTs) are believed to originate from embryonic germ cells as a result of failed migration or from primordial thymic cells. Among the three subtypes—teratoma, seminoma, and nonseminoma—teratomas are the most common. A careful physical examination of the testicles along with an ultrasonographic workup is important to exclude a potential metastatic lesion arising from a testicular source. Diagnostic workup includes imaging of the chest, serologic markers, and most importantly, a tissue biopsy.

Teratoma

Mature teratomas are benign tumors containing two or more of the embryonic layers: endoderm, mesoderm, or ectoderm. They are the most common GCT of the mediastinum comprising up to 60% of all masses with an equal prevalence in both genders. Teratomas mostly present incidentally, although they can also come to attention from symptoms of obstruction on surrounding structures. Imaging reveals a heterogenous calcified cystic mass containing fat, fluid, or bone (Fig. 7). Gross appearance is that of a tan-brown cystic structure (Fig. 8). These tumors are often resistant to chemotherapy and radiotherapy, and therefore surgical resection is the mainstay of treatment. The surgical approach (sternotomy vs. thoracotomy or VATS) depends on the location and size of the tumor. Postresection recurrence rates are low with an excellent prognosis.

Seminoma

Mediastinal seminoma is a slow-growing mass; however, metastasis may be present in up to 70% of the patients. The majority are symptomatic with chest pain being the most common symptom. These tumors account for one-third of all mediastinal GCTs and are mostly seen in males during the second to fourth decade of life. Diagnosis requires CT imaging, tissue biopsy, and a testicular examination to rule out the gonads as a potential primary source. On serology, AFP is found to be negative, and B-HCG is mildly elevated. Surgical management is limited to occasional biopsy when the diagnosis is uncertain. Chemotherapy based on cisplatin, etoposide, and bleomycin is the standard of care. Radiation therapy (RT) is used only in cases where contraindications to chemotherapy exist because of mediastinal toxicity concerns like constrictive pericarditis or valvular disease. Overall, seminomas have an excellent prognosis, with treatment offering 90% survival at 5 years. Often patients, regardless of systemic treatment, are found to have residual masses that are mostly necrotic tissue and can be followed if small in size.

Nonseminoma

Nonseminomatous GCTs, like their counterparts, occur in young to middle-aged males. However, unlike seminomas, these lesions are more aggressive and present with an invasive mass in addition to elevated levels of both AFP and B-HCG. Imaging reveals a heterogeneous mass in the anterior mediastinum. At some institutions, if the presentation is pathognomonic—young male with symptoms of obstruction/invasion, typical imaging, and elevated markers—chemotherapy may even be started without a definitive histologic evaluation. Systemic therapy typically consists of cisplatin-based chemotherapy. In patients with limited pulmonary reserve, bleomycin is avoided due to the risk of pulmonary toxicity. Posttreatment, surgical resection of any residual mass is recommended due to the high likelihood of malignancy. Often these masses invade surrounding structures like the pericardium, pulmonary parenchyma, or phrenic nerve, thereby necessitating an en-bloc resection to achieve complete disease control. Compared with teratomas and seminomas, the prognosis for mediastinal nonseminomatous GCTs is comparatively worse: a 40% to 45% survival rate in 5 years. Serial monitoring of serologic tumor markers is employed for long-term surveillance.

MIDDLE MEDIASTINAL MASSES

Castleman's Disease

This lymphoproliferative disorder, also known as Angiofollicular lymph node hyperplasia, primarily affects the young and has increased risk in immunocompromised patients. Though the precise etiology is unknown, an association with HHV-8 has been postulated. Castleman's disease (CD) can occur in any lymph node location but is most commonly found in the mediastinum and is asymptomatic on evaluation. CT scan shows lymphadenopathy with or without an associated mass and postcontrast enhancement. Diagnosis is confirmed on histopathology. For unicentric CD, complete surgical resection is the definitive treatment. For multicentric disease, a multimodal approach including radiation and immunotherapy is employed.

Mediastinal Cysts

Cystic masses in the middle mediastinum are typically bronchogenic cysts that, along with esophageal cysts, are known as *foregut duplication cysts* (Figs. 9 and 10). Less common middle mediastinal masses are pericardial and neuroenteric cysts. All can present secondary to symptoms of compression or obstruction. CT imaging reveals the cysts as smooth-walled soft tissue density that are nonenhancing. The CT also identifies the structure associated with the cystic lesions. Other imaging modalities, like MRI and EBUS, are employed when CT imaging is unequivocal. Management depends on the type of cyst and presentation; if symptomatic, surgical resection is indicated. Biopsy of the cyst is generally avoided to prevent the risk of secondary infection. Some types of cysts, like bronchogenic cysts, also have the potential for malignant degeneration, and excision is recommended in patients with low operative risk.

Mediastinal Lymphadenopathy

The most common mass arising in the middle mediastinum is an enlarged lymph node. Among the variable causes—malignant, infectious, or inflammatory—malignancy is the most prevalent. Advanced lung cancer may spread to the subcarinal or paratracheal lymph nodes. For patients presenting with a cough, polyarthralgia and

Pathology later confirmed the initial suspicion of a bronchogenic cyst. *(From Eldib OS, Abdelmeged S. Surgical management of mediastinal cysts.* J Egyptian Soc Cardiothorac Surg. *2016;24:58–64.)*

hypercalcemia, along with mediastinal lymph node enlargement (sarcoidosis) become important in the differential diagnosis. Histoplasmosis, coccidiomycosis, and other infectious agents are also common causes for lymphadenopathy in the middle mediastinum depending on the specific location. While serology may aid in the diagnosis, pathologic evaluation remains the gold standard for diagnosis. EBUS, cervical mediastinoscopy, or CT-guided tissue biopsy are amongst the many options for obtaining the pathologic specimen.

POSTERIOR MEDIASTINAL MASSES

Schwannomas and Neurofibromas

Most posterior mediastinal tumors are neurogenic in nature and arise from either the peripheral nerves or sympathetic and parasympathetic ganglia. The most common posterior mediastinal tumor, Schwannoma, arises from the Schwann cells that form the nerve sheath. With equal predominance in both genders, these tumors are mostly asymptomatic but can present with compression effects and paralysis. CT scan reveals a well-circumscribed mass with focal calcifications. Surgical resection is curative. Similarly, neurofibromas are also nerve sheath tumors that present in the second or third decade of life. They are associated with neurofibromatosis type-1 especially when multiple tumors are present. Both of these tumors have malignant variants that are highly aggressive and often present with unremitting symptoms as well as distant metastasis.

Ganglion and Paraganglion Cell Tumors

Ganglion cell tumors arise from the sympathetic ganglion cells. Their benign subtype, ganglioneuroma, is due to their embryonic neural crest cell origin. They can occur anywhere along the sympathetic chain. Arising mostly before the second decade, these tumors are asymptomatic unless large enough to cause compressive symptoms which then requires surgical resection (Fig. 11). Their malignant counterparts, ganglioneuroblastoma and neuroblastoma, are highly aggressive and more commonly encountered in the pediatric population. Biochemical workup can show elevated levels of catecholamine metabolites, VMA, and HMA. WDHA (watery diarrhea, hypokalemia, and achlorhydria) as well as Cushing's syndrome have been described in such patients. Postoperative treatment involves adjuvant systemic or RT.

Paraganglion cell tumors give rise to mediastinal pheochromocytomas that can secrete catecholamines resulting in the classic symptoms of hypertension, headache, tremors, and diaphoresis. Only 10% of pheochromocytomas are extraadrenal. Diagnosis is confirmed with plasma and/or urinary metanephrines and catecholamines.

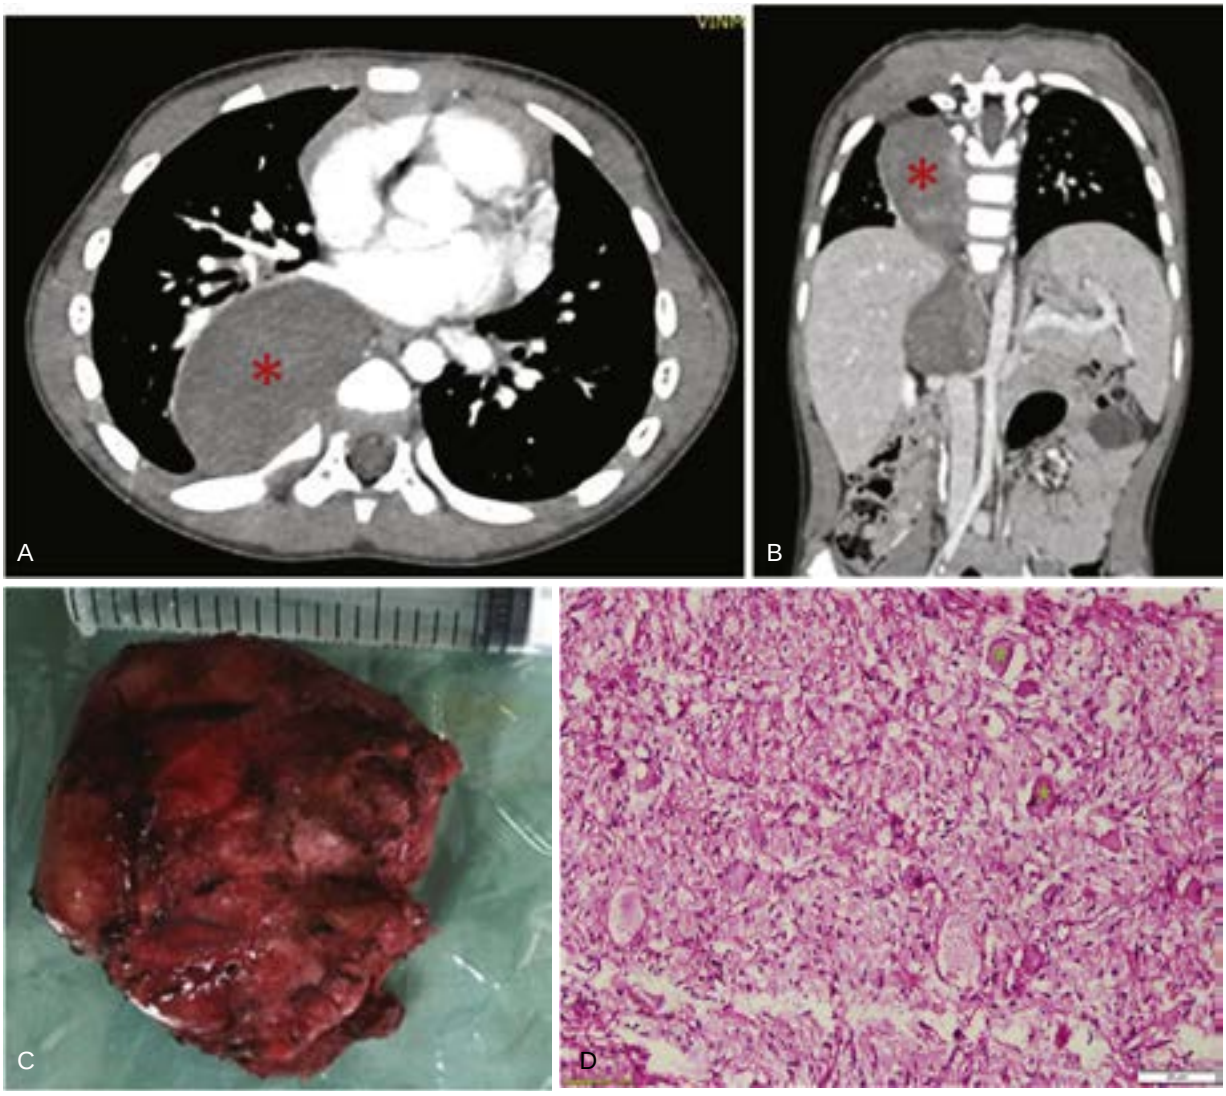

FIG. 11 **(A, B)** CT scans of 8 × 6 cm mass in the right posterior mediastinum *(asterisk)*. **(C)** Gross specimen after resection. **(D)** Microscopic image after hematoxylin-eosin stain showing mature ganglion cells *(green stars)* and Schwann cells characteristic of ganglioneuroma. *(From Son BBB, Nguyen TKH, Rodriguez-Galindo C. Ganglioneuroma of mediastinum and adrenal gland.* J Pediatr Surg Case Rep. *2020;61:101628.)*

MIBG scanning can aid in localizing the disease if a CT scan is nondiagnostic. Preoperative alpha- and beta-blockade are imperative before surgical resection to prevent intraoperative sympathetic crises.

SURGICAL APPROACHES

Biopsy vs. Surgery

Routine biopsies of mediastinal masses are avoided. This is primarily due to the risk of spreading disease as well as the cost and morbidity of an additional procedure. In cases where the lesion appears to be well encapsulated and imaging is classic for masses like teratoma, thymoma, or cysts, surgical resection is considered first-line. However, with our improved understanding of induction therapy and advanced biopsy techniques, many physicians are now opting for pathologic confirmation when lymphoma or thymic carcinoma is suspected so that appropriate neoadjuvant treatment can be offered first.

When selecting the operative approach, optimal exposure is key since the most important prognostic indicator is complete resection. It is not uncommon to resect adjacent serosal membranes, lung parenchyma, and even great vessels to achieve en bloc resection of the tumor mass. Preoperative planning for patients with mediastinal masses hence includes consultation with a pulmonologist in a multidisciplinary setting to optimize the patient's condition a priori and determine if their respiratory reserve allows pulmonary resection.

Anterior Mediastinotomy

Chamberlain procedure—anterior parasternal mediastinotomy—allows good exposure and the ability to obtain adequate biopsy specimens from the anterior mediastinum as well as the aortopulmonary window. The operation can be performed as an outpatient procedure and does not require single-lung ventilation. A small incision is made over the second costal cartilage on the side of interest followed by dissection of the pectoralis and resection of the chondral cartilage if needed (Fig. 12). The posterior perichondrium is then incised, and the tumor mass is accessed.

Median Sternotomy

A full median sternotomy provides the most ideal exposure to masses in the anterior mediastinum; most commonly, it is used for a thymoma. Combined with an anterior thoracotomy, access is enhanced to all critical structures including the anterior pericardium, great vessels, phrenic, and laryngeal nerves. An upper sternal split may be performed if access is only required in the superior compartment. However, this approach has not been proven to give better patient outcomes. The incision for the median sternotomy extends from below the jugular notch to the xiphisternal junction. Mobilization of the thymus begins caudally, dissecting the attached mediastinal fat, and continues cranially in the neck to the superior poles. Small vessels are clipped, and care is taken to stay clear of the phrenic nerves. In cases where invasion of the great vessels is encountered, access in the groin is obtained for possible cardiopulmonary bypass.

Transcervical Approach

This approach is used in a minority of the cases where resection of parathyroid adenomas, goiter, or thymic resection is needed. There has been a recent resurgence of interest in using the transcervical approach for resection of thymomas given early operative recovery and same-day return to home for the majority of patients. To expose the thymic gland, a 5-cm curvilinear incision is made above the jugular notch followed by creating subplatysmal flaps and separating strap muscles in the midline. The superior poles of the thymus are mobilized first using blunt dissection that is then carried down as far as possible. The use of a Cooper retractor to elevate the sternum opens up a sizeable space and allows appropriate visualization (Fig. 13). Patients must have good cervical spine extension for this procedure. Although this procedure avoids the morbidity of a sternotomy, conclusive evidence is not available yet of oncologic outcomes, and the judgment of the surgeon prevails.

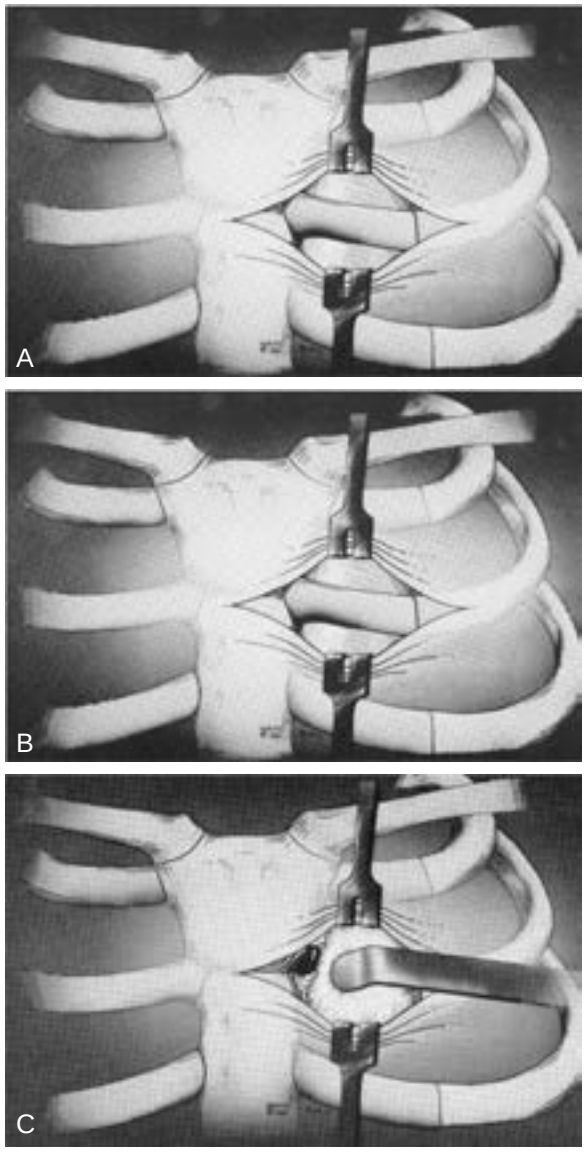

FIG. 12 Surgical technique of anterior mediastinotomy. Incision is made over the second costal cartilage on the left **(A)** after which the costal cartilage is resected, and pleura exposed **(B)** and underlying mass dissected for resection **(C)**. *(From Ravipati NB, Mclemore EC, Schlinkert RT, Argueta R. Anterior mediastinotomy for parathyroidectomy.* Am J Surg. *2008;195:799–802.)*

Thoracotomy

Thoracotomy readily provides access to the middle and posterior compartments of the mediastinum. Combined with unilateral or bilateral thoracosternotomy (clamshell incision), not even bulky anterior masses extending into the pleura are out of reach. A clamshell incision involves creating an incision in the fourth intercostal space from one midaxillary line to the other connected via a transverse sternotomy and provides excellent exposure.

Minimally Invasive Approaches

VATS and RATS are gaining popularity for selected mediastinal masses including benign tumors, thymomas, and cysts (Fig. 14). In experienced hands, they offer improved visualization, decreased postoperative pain, and earlier recovery than an open procedure. Caution is advised however when invasive malignancies are encountered as the risk of leaving microscopic disease behind or

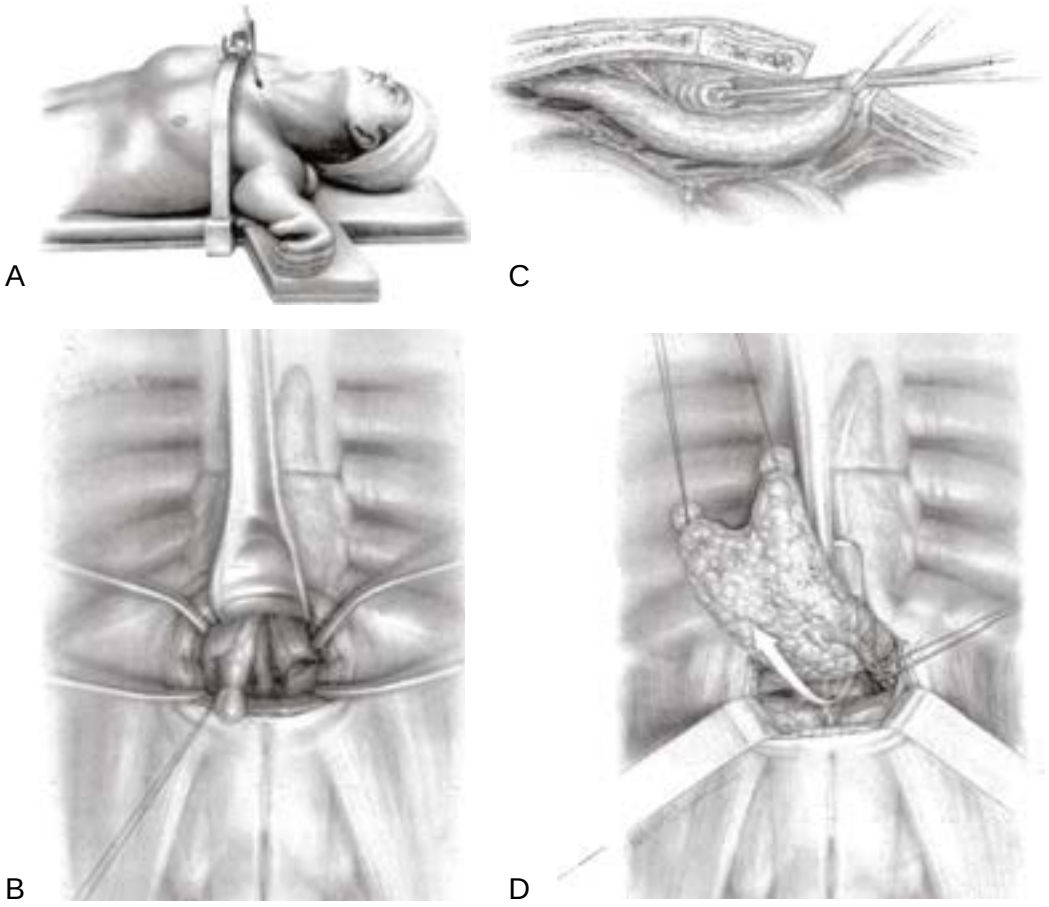

FIG. 13 **(A)** Patient is positioned supine on a surgical bed with an inflatable pillow under the shoulders for elevation and hyperextension of the neck. A transverse incision is made 2 cm above the sternal notch for a transcervical thymectomy. A sternal retractor is later used at the inferior edge for adequate visualization in the mediastinum. In some instances, the patient is nearly lifted off the bed. **(B)** Surgeon's view from the cranial end after early dissection. A silk tie on the thymus helps with retraction. **(C)** Blunt dissection using a sponge stick for creating a substernal plane. Silk ties help with gentle cephalad retraction. **(D)** Thymus after further dissection has been carried into the mediastinum. *(From Meyers BF. Transcervical thymectomy.* Op Tech Thorac Cardiovasc Surg. *2001;6:201–208.)*

FIG. 14 Single site video-assisted thoracoscopic surgery **(A).** Prior chest tube site that is enlarged for insertion of GelPoint Mini that can accommodate three trocars – two 5 mm and one 12 mm **(B)**. Wedge resection of right apical blebs using endoGIA stapler **(C).** *(From Won TM, Munoz A, Sacks MA, et al. port-site malignancy increases. Other circumstances advocating for thoracotomy include active infection in a cyst or tumor size larger than 6 cm. Accordingly, when obtaining informed consent for VATS from patients, it is prudent also to discuss thoracotomy as an option.

Primary Tumors of the Thymus

Joshua E. Preiss, MD, and Douglas E. Wood, MD, FRCSEd

INTRODUCTION

Primary tumors of the thymus are rare, with approximately 1.5 cases per million worldwide. Although uncommon, they represent the most frequent tumors found in the anterior mediastinum in adults. *Primary thymic tumors* are often referred to as *thymic epithelial neoplasms*. Both terms describe the main types of malignancies that arise from the epithelial elements of the thymus, which include thymoma, thymic carcinoma, and neuroendocrine tumors of the thymus (NETTs). These thymic malignancies have distinct histopathologies and natural histories but are grouped by similar classification and staging systems. These diseases are in contrast to benign tumors of the anterior mediastinum or malignancies of nonthymic origin, including thymic cysts, thymic hyperplasia, retrosternal goiter, lymphoma, and germ cell tumors. There is a strong association of thymomas with myasthenia gravis and other autoimmune diseases. Long-term outcomes for thymomas are good, with 5-year survival rates approaching 95%. Thymic carcinomas have a higher propensity for local invasion and metastasis, with 5-year survival rates approximately 55%. The mainstay of treatment for primary tumors of the thymus is complete surgical resection, which relies on thorough preoperative diagnostic imaging and staging to determine resectability. Neoadjuvant systemic therapy followed by surgery can be considered for large or marginally resectable tumors, and chemotherapy with radiation can be utilized for potentially unresectable and residual/recurrent disease, respectively.

CLINICAL PRESENTATION

The majority of anterior mediastinal masses are discovered incidentally on imaging in patients who are otherwise asymptomatic. Patients who do present with symptoms can display effects from local tumor invasion or associated paraneoplastic disorders. Locally advanced tumors can cause mass effect with associated cough, dyspnea, chest pain, or superior vena cava syndrome. Invasion of intercostal, phrenic, or recurrent laryngeal nerves can also contribute to symptoms. Thymomas have a more indolent course compared with the rapid onset of symptoms seen in patients with other mediastinal masses, such as lymphoma or germ cell tumors. Compared with thymomas, thymic carcinomas have higher rates of local invasion and therefore symptoms at time of presentation. Additionally, thymic carcinomas can frequently present with associated pleural or pericardial effusions. Thymomas mainly occur in adults, while thymic carcinomas can occur over a wide range of ages. Thymic tumors affect males and females equally, and the majority are thought to be idiopathic.

Paraneoplastic syndromes are more commonly associated with thymomas, with the most common being myasthenia gravis. Up to 50% of patients with thymomas have myasthenia gravis, whereas approximately 20% of patients diagnosed with myasthenia gravis will have an associated thymoma. (Note that, for this reason, a chest CT is a necessary part of the evaluation during a new diagnosis of myasthenia. Conversely, imaging that demonstrates a probable thymoma requires eliciting possible symptoms of myasthenia.) Additional autoimmune disorders associated with thymomas include red cell aplasia and hypogammaglobulinemia. Thymic carcinomas are rarely associated with these autoimmune conditions. The most common NETTs are carcinoid tumors, which can be associated with Cushing's syndrome and multiple endocrine neoplasia type 1 (MEN1).

Laboratory testing is less critical in the diagnosis of thymic tumors compared with clinical signs and imaging. When myasthenia gravis is suspected, antiacetylcholine receptor antibody levels should be obtained. When narrowing the differential for anterior mediastinal masses, individualized testing may include complete blood count, LDH, alpha-fetoprotein, serum beta-HCG, and thyroid function studies.

IMAGING

Diagnosis of thymic tumors relies on thorough radiologic assessment of the mediastinum and chest. Computed tomography (CT) scan with intravenous (IV) contrast is recommended as the initial study to evaluate a mediastinal mass. Patients referred with noncontrast CT scans should obtain further imaging with IV contrast to assess enhancement of the mass and its relationship to vascular structures. Small thymic neoplasms are most often found in the normal anatomic thymic bed located in the cephalad portion of the substernal area, bounded by the innominate vein superiorly and the phrenic nerves laterally. Early stage thymomas are most often homogenous discrete masses, within the thymus with smooth, rounded borders (Figs. 1 and 2).

Both thymic carcinomas and invasive thymomas can have indistinct borders between contiguous mediastinal structures as well as internal heterogeneity representing necrosis, hemorrhage, or calcifications (Fig. 3). It is these presentations, where diagnosis and resectability are uncertain, where tissue diagnosis is important. Thymomas can be locally invasive but rarely metastasize to lymph nodes. In contrast, thymic carcinomas are aggressive tumors that frequently metastasize to regional lymph nodes. Although more common with thymic carcinomas, both can exhibit direct invasion of the lung, pericardium, innominate vein, great vessels, and phrenic nerves with associated hemidiaphragm elevation. Additional findings of more

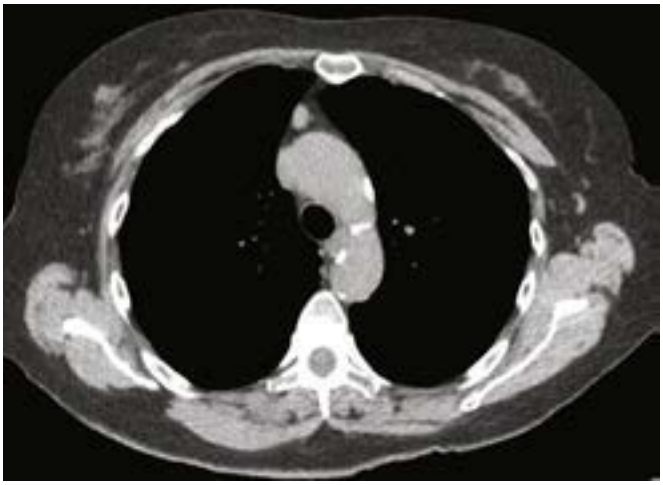

FIG. 1 A small, well-circumscribed stage I thymoma located just anterior to the aorta.

FIG. 2 A moderate size homogenous thymoma abutting the pericardium and right pleural space.

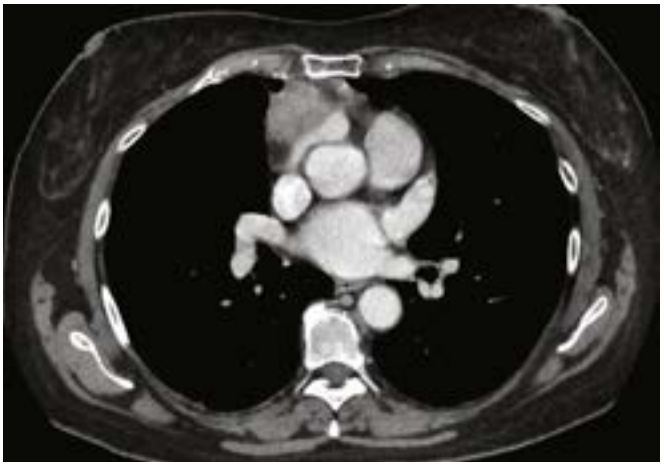

FIG. 3 A heterogenous, poorly defined anterior mediastinal mass representing a locally advanced thymic carcinoma with invasion into the pericardium.

aggressive disease include pleural implants or "drop metastases," pericardial effusions, and pleural effusions.

Magnetic resonance imaging (MRI) with thymic protocols are also frequently used in the evaluation of thymic tumors. MRI is recommended for patients with contraindications to obtaining contrast-enhanced CT, including renal dysfunction or contrast allergy. Thymic MRI can increase diagnostic specificity to distinguish thymic cysts from thymic neoplasms. Use of chemical shift sequence can aid in differentiating thymic hyperplasia from a thymic malignancy. Compared with CT, MRI can improve differentiation of tissue planes when there is concern for chest wall or vascular invasion. The role of positron emission tomography (PET) imaging is less clearly defined. PET can be utilized for determining whether extrathoracic metastases are present, especially for thymic carcinoma. PET is less useful for differentiation of thymic masses themselves, as avidity can be seen in normal thymic tissue as well as benign and malignant lesions.

TISSUE DIAGNOSIS

Anterior mediastinal masses have the classic differential of lymphoma, thymoma, teratoma, and substernal thyroid. Careful review of the radiologic characteristics and patient demographics, symptoms, and signs are usually diagnostic. Lymphomas rarely present as an isolated and discrete mediastinal mass; very large infiltrating tumors and those with associated lymphadenopathy elsewhere are those likely to be lymphoma (or unresectable thymic carcinoma) and warrant biopsy. Thyroid masses generally demonstrate continuity with the cervical thyroid and teratoma has a characteristic pattern of heterogeneous fat, calcifications, and soft tissue density. A well-circumscribed mass in the thymic bed without associated lymphadenopathy is highly likely to be a thymoma and usually does not need tissue confirmation before resection.

Pretreatment tissue diagnosis is not generally necessary, or advisable, for resectable masses in the anterior mediastinum that are likely to be thymoma. They do not change the indication for surgery and, depending on biopsy technique, may run the risk of tumor seeding in the mediastinum, biopsy tract, or pleural space. Bulky tumors and those that are infiltrating and appear unresectable do require tissue diagnosis to differentiate between lymphoma, thymic carcinoma, or an aggressive locally advanced thymoma. Usually a CT-guided core needle biopsy is feasible and has a high likelihood of being diagnostic. However, sometimes a surgical biopsy is needed. If a thymic neoplasm is in the differential, it is critically important to avoid a transpleural approach for surgical biopsy as this runs a very real potential of seeding the pleural space and converting a localized tumor to stage IV disease. Therefore, video-assisted thoracic surgery (VATS) or transpleural robotic approaches are contraindicated for biopsy in most cases. The most direct and safest approach for surgical biopsy is usually an anterior mediastinotomy or Chamberlain procedure.

HISTOLOGIC CLASSIFICATION

Historically, thymic epithelial tumors have been pathologically classified in three groups: thymomas without cellular atypia, atypical thymomas with cellular atypia or well-differentiated thymic carcinomas, and thymic carcinomas that are not well-differentiated and with aggressive features. NETTs were often a subgroup of thymic carcinoma, despite differing histology and behavior. It is also important to note that thymomas have different natural histories than thymic carcinomas and are not "advanced thymomas." The World Health Organization (WHO) proposed a histologic classification system in 1999 that was further refined in 2015. This system is the most widely used for pathologic differentiation between thymomas, thymic carcinomas, and NETTs. The WHO system provides the histologic diagnostic criteria for thymomas (Table 1) as well as the pathologic variants of thymic carcinoma (Table 2), with the most common being squamous cell carcinoma. The progression through the classification

TABLE 1 World Health Organization Histologic Classification of Thymomas

Thymoma Subtype	Obligatory Criteria
Type A	Occurrence of bland, spindle shaped epithelial cells, paucity or absence of T cells
Atypical type A variant	Criteria of type A thymoma; in addition: comedo-type tumor necrosis, increased mitotic count, nuclear crowding
Type AB	Occurrence of bland, spindle shaped epithelial cells, abundance of T cells focally or throughout tumor
Type B1	Thymus-like architecture and cytology: abundance of immature T cells, areas of medullary differentiation, paucity of polygonal or dendritic epithelial cells without clustering
Type B2	Increased numbers of single or clustered polygonal or dendritic epithelial cells intermingled with abundant T cells
Type B3	Sheets of polygonal slightly to moderately atypical epithelial cells, absent or rare intercellular bridges, paucity, or absence of intermingled T cells
Micronodular thymoma	Nodules of bland spindle or oval epithelial cells surrounded by an epithelial cell-free lymphoid stroma
Metaplastic thymoma	Biphasic tumor composed of solid areas of epithelial cells in a background of bland-looking spindle cells; absence of T cells

Adapted from Marx A, Chan JK, Coindre JM, et al. The 2015 World Health Organization Classification of Tumors of the Thymus: Continuity and Changes. *J Thorac Oncol.* 2015;10:1383–1395.

system correlates with increasing invasiveness and worse prognosis, but there is often poor inter-reader reliability among pathologists in clinical practice and multiple cell types represented on final pathology. Prognosis is better determined by complete surgical resection and tumor stage.

STAGING

Multiple staging systems for thymic tumors have been proposed over the past decades. The most widely adopted is the Masaoka-Koga staging system (Table 3), which incorporates degree of tumor invasion and presence of metastases in staging both thymomas and thymic carcinomas. This system has been validated with mortality data from multiple studies, with 5-year survival rates for stage I disease up to 95% and rates for stage IVb disease less than 50%. More recently, the International Association for the Study of Lung Cancer (IASLC) and the International Thymic Malignancy Interest Group (ITMIG) proposed a TNM classification for the staging of thymomas and thymic carcinomas, which was subsequently incorporated into the eighth edition of the American Joint Committee on Cancer (AJCC) staging manual.

TABLE 2 World Health Organization Thymic Carcinoma Subtypes (Type C)

Thymic Carcinoma
Squamous cell carcinoma
Basaloid carcinoma
Mucoepidermoid carcinoma
Lymphoepithelioma-like carcinoma
Clear cell carcinoma
Sarcomatoid carcinoma
Adenocarcinomas
- Papillary adenocarcinoma
- Thymic carcinoma with adenoid cystic carcinoma-like features
- Mucinous adenocarcinoma

NUT carcinoma
Undifferentiated carcinoma
Other rare thymic carcinomas
- Adenosquamous carcinoma
- Hepatoid carcinoma

PRINCIPLES OF SURGERY

The treatment of primary tumors of the thymus should be led by a thoracic surgery team with experience in caring for patients with thymic malignancies. The most effective treatment for thymic malignancies is complete surgical resection, which requires careful review of preoperative imaging by the thoracic surgeon to determine resectability. The main goal of surgery is a complete (R0) resection, as this has been shown to have a greater impact on prognosis than either preoperative stage or WHO histologic classification. Complete surgical resection necessitates total thymectomy, removal of all mediastinal fat, and en bloc resection of tumor with contiguous and noncontiguous disease. The standard borders of resection are bound by the phrenic nerves bilaterally, the sternum anteriorly, the

TABLE 3 Masaoka-Koga Staging System

Masaoka Stage	Diagnostic Criteria
I	Macroscopically encapsulated without microscopic capsular invasion
II	A: Microscopic transcapsular invasion B: Macroscopic invasion into surrounding fatty tissue or grossly adherent to but not through mediastinal pleura or pericardium
III	Macroscopic invasion into neighboring organs – pericardium, great vessels, lung A: Without invasion of great vessels B: With invasion of great vessels
IV	A: Pleural or pericardial dissemination B: Lymphogenous or hematogenous metastasis

pericardium posteriorly, the cervical thymic horns superiorly, and the diaphragm inferiorly. Removal of direct tumor invasion into adjacent tissues, including lung, pleura, pericardium, phrenic nerve, innominate vein, and other vascular structures, may be required to obtain R0 resection. Of course, preservation of the phrenic nerves is important for long-term pulmonary function. Sometimes it is possible to carefully skeletonize the phrenic nerve away from an adjacent mass, but occasionally it may be necessary to sacrifice one phrenic nerve that is invaded by tumor. Bilateral phrenic nerve resection is contraindicated due to its severe effect on respiratory function. In areas where there are close margins, surgical clips should be placed to guide potential adjuvant radiation therapy. Additionally, the specimen should be carefully marked and oriented after removal to assist the pathologist in determination of margins. The surgeon should avoid violation of the tumor capsule or overhandling the specimen to prevent dispersion of tumor cells and propagation of drop metastases. This should also include protection of the edges of the tumor extraction incision from exposure to tumor cells. The pleural surfaces should be examined for evidence of noncontiguous pleural-based disease, with resection of theses metastases if discovered. Mediastinal lymph nodes should be evaluated when resecting thymic carcinomas or NETTs, but this is not routinely necessary for thymomas as they rarely metastasize to lymph nodes. For patients with thymomas and associated myasthenia gravis, preoperative medical optimization is necessary to reduce the risk of postoperative myasthenic crisis or complication.

TRANS-STERNAL THYMECTOMY

Midline sternotomy is the gold standard surgical approach for resection of thymic malignancies. The incision provides adequate exposure to the lower neck and bilateral pleural spaces that can aid in performing an oncologically sound surgery in most cases. Additional transsternal approaches have been utilized depending on the degree of tumor invasion and planned extent of resection, including clamshell thoracotomy and combined sternotomy with anterolateral thoracotomy. Anesthesia placement of a double-lumen endotracheal tube allows single lung ventilation as needed to improve visualization of the pleural spaces. For a midline sternotomy, the patient is positioned supine, both arms tucked at sides, with a shoulder roll to improve exposure of the lower neck structures. Skin incision is made from sternal notch to xiphoid process, and dissection is carried down to the midline of the sternal periosteum. Sternotomy is performed with sternal saw. Standard sternal spreader provides adequate exposure of the anterior mediastinum. Internal mammary retractors can also be used for additional exposure to the pleural spaces. The pleura should be opened on both sides to expose the bilateral phrenic nerves and assess for pleural metastases. Dissection of the thymus and mediastinal fat is typically performed caudad to cephalad, beginning at the cardiophrenic angles near the diaphragm. All mediastinal fat should be removed to the level of the phrenic nerves bilaterally. Bipolar cautery can be used near the phrenic nerves to limit thermal spread and potential nerve injury. As the dissection continues cephalad, feeding vessels from the internal mammary vessels can be sequentially ligated and divided. Stapled wedge resections of involved lung tissue may be required for en bloc tumor removal. The thymus is reflected upward off of the pericardium, which can be resected with the specimen if there is noted tumor involvement. The cephalad portion of the dissection involves ligation of thymic branches from the innominate vein, gentle retraction of the specimen to deliver the superior poles of the thymus from the cervical space, and division of the thyrothymic ligament with associated feeding vessels. Ligation of the innominate vein can be considered in cases of gross tumor involvement. Direct invasion of the superior vena cava may require partial resection with repair or bypass grafting. Standard chest tube drains are placed in the pleural spaces and anterior mediastinum. The majority of patients are able to be extubated in the operating room and do not require intensive care unit monitoring. Drainage tubes are typically removed on postop days 1 or 2, and patients can be discharged in the following days with standard sternal precautions.

MINIMALLY INVASIVE RESECTION

Thoracic surgery as a whole has seen a broadening use of minimally invasive techniques, including video-assisted thoracoscopic surgery (VATS) and robotic-assisted thoracoscopic surgery (RATS). These techniques have been adopted for the elective resection of benign thymus for management of myasthenia gravis. The role of minimally invasive surgery (MIS) for resection of thymic malignancies is more controversial. There are no prospective randomized control trials comparing minimally invasive resection to open resection of thymic tumors. Retrospective studies have highlighted potential for MIS thymectomy to reduce hospital stay, blood loss, and postoperative pain with reports of similar rates of R0 resection compared with open surgery. These studies are limited by lack of long-term follow-up data. Given the indolent nature of thymic malignancies, long-term data are needed to determine the oncologic completeness of minimally invasive approaches to thymic tumors. The routine use of MIS for thymic malignancies is not currently recommended. In the United States, approximately 25% of thymic tumors are resected using VATS or RATS. If MIS is used for a thymic tumor, it must follow all principles of thymic surgery as highlighted previously, including a complete dissection of the thymic bed for ultimate goal of R0 resection. In general, we believe that minimally invasive resection should be reserved for small (<3 cm), well-encapsulated tumors.

Minimally invasive thymic tumor resection can be performed from either side of the chest, and laterality is dictated by preoperative imaging. Often, the thymic tumor favors one side of the mediastinum, and surgical access can be obtained on the ipsilateral side of the tumor. For tumors that are midline, right chest access is frequently favored as there is less interference with the heart and better exposure of the superior vena cava and innominate vein. The patient should have a double lumen endotracheal tube placed for single lung ventilation on the contralateral side of surgical access. The patient is positioned with a large roll under the operative side to achieve a partial lateral decubitus position. Prepping of both sides of the chest can allow camera access to the nonoperative side of dissection to aid in visualization of the contralateral phrenic nerve if needed. Typically, three ports are placed that triangulate the anterior mediastinum, one camera port and two operative ports. Exact port locations are patient dependent but are placed approximately in the 3rd intercostal space in the midaxillary line, the 5th intercostal space in the anterior-axillary line, and the 7th intercostal space in the midclavicular line. Carbon dioxide insufflation can be used to increase visualization and maneuverability in the chest. The operation can be carried out in a similar fashion as the open technique, starting with dissection of mediastinal fat off of the diaphragm. The ipsilateral phrenic nerve should be identified early and carefully protected throughout the dissection. The thymus and adipose tissue should be skeletonized off of the superior vena cava with dissection proceeding cephalad to the junction of the brachiocephalic vein. An energy device can be used to ligate feeding vessels. The specimen is elevated en bloc off the pericardium. The thymic horns are delivered down from the neck and divided. The specimen should be placed in a retrieval bag to prevent dissemination of tumor cells. A chest drainage tube is typically left in the pleural space with subsequent removal postoperative day 1. Patients typically can be discharged the day after their surgery.

SYSTEMIC THERAPY

Neoadjuvant chemotherapy can be considered for locally advanced thymic malignancies when resectability is uncertain. Repeat imaging is recommended following completion of induction therapy. Patients with ipsilateral pleural metastasis or solitary metastasis can also be evaluated for induction therapy vs upfront surgery. Adjuvant

chemotherapy is often indicated for thymic carcinomas with microscopic residual tumor (R1 resection) or thymomas with macroscopic residual tumor (R2 resection) on final pathology. Definitive chemotherapy or chemoradiotherapy is indicated for patients with unresectable disease and chemotherapy alone for patients with evidence of extrathoracic metastases. Chemotherapy response rates are variable for thymic malignancies. Platinum-based chemotherapy regimens remain first-line systemic therapy for thymic tumors. There is an evolving role for targeted therapies in the treatment of thymic malignancies, though these drugs are often considered second-line therapy at this time.

RADIATION THERAPY

Thymic tumors are largely radiosensitive. All patients with positive microscopic or macroscopic margins after surgical resection should be evaluated for adjuvant radiation therapy. It is critical for surgeons to mark areas of close margins with clips at time of resection to help guide postoperative radiation planning if needed. Neoadjuvant radiation is rarely indicated for thymic tumors, as this limits potential postresection radiation options in patients that have focal positive margins who can otherwise benefit from more directed postoperative radiation treatment. Adjuvant radiation for completely resected thymic tumors is more controversial but can be considered for advanced stage tumors or thymic carcinomas with aggressive features. Frequently recurrences occur in the pleural space, so the benefit from postoperative mediastinal radiation after R0 resection in these patients is less clear. Locally advanced unresectable thymic tumors should be considered for definitive radiation in combination with chemotherapy.

SURVEILLANCE AND RECURRENCE

Locoregional recurrence rates after complete surgical resection of thymic epithelial tumors range from approximately 5% for stage I tumors up to approximately 50% for stage III tumors. Given the indolent nature of these tumors, it is important to maintain thorough postoperative surveillance. This can be especially critical for thymomas, as they often exhibit slower growth with potential for later recurrences. Patients are typically followed with postoperative surveillance CT chest with contrast every 6 months for 2 years, then annually for 5 years for thymic carcinomas, and annually for 10 years for thymomas. Fortunately, complete surgical resection of recurrences is often feasible, and prognosis for these patients approach similar survival rates as compared with R0 resections at time of index operation.

Management of Tracheal Stenosis

Andrea L. Axtell, MD, MPH, Douglas J. Mathisen, MD, and Ashok Muniappan, MD

INTRODUCTION

Tracheal stenosis is the most common postintubation injury to the trachea and is usually the result of endotracheal tube cuff ischemic necrosis of the underlying trachea or tracheostomy stomal injury. Injury at the stomal level can lead to side-to-side contraction and an "A"-shaped stenosis sparing the membranous wall. Tracheostomy can have a combined stenosis with stomal and cuff injury. Other causes of benign tracheal stenosis are trauma, inflammatory, and idiopathic. Tracheal infections and several collagen vascular disorders may result in chronic inflammation with secondary tracheal stenosis. Prolonged oral intubation, high tracheostomy, or erosion of tracheostomy through the cricoid cartilage may result in subglottic stenosis. Idiopathic tracheal stenosis occurs most commonly in women and is characterized by a circumferential fibrotic stenosis in the subglottic larynx and upper trachea. Patients with tracheal stenosis have signs and symptoms of upper airway obstruction: dyspnea on exertion, cough, wheezing, stridor, and obstructive pneumonia. The presentation of tracheal stenosis is often confused with adult-onset asthma; therefore, steroid therapy is often initiated before the correct diagnosis is ascertained.

INDICATIONS FOR TRACHEAL RESECTION

In general, any patient who has airway stenosis as a result of tracheal injury should be considered for a tracheal resection and reconstruction. Absolute contraindications are few and include a nonconstructible airway (usually due to an excessive length of damaged airway), severe comorbidities, or a prolonged need for mechanical ventilation. Relative contraindications include a history of radiation to the trachea, which limits tracheal mobility and impairs microvascular blood supply, active trachea mucosal inflammation, and active steroid therapy. Steroids should be weaned before tracheal reconstruction because they play no role in the amelioration of postintubation stenosis and interfere with healing of the tracheal anastomosis. Purulent, copious secretions are a relative contraindication. If necessary, tracheal dilation can be performed until inflammation subsides and steroids are discontinued. Surgery should be delayed 2 to 4 weeks after discontinuation of steroids. Other diagnoses such as relapsing polychondritis, scleroderma, polyarteritis, sarcoid, and granulomatosis with polyangiitis should be excluded.

PREOPERATIVE ASSESSMENT

Before tracheal resection and reconstruction is undertaken, the definitive diagnosis of the underlying pathology of the airway must be established. A preoperative assessment should include a history and physical, radiologic imaging, and bronchoscopy. Soft tissue radiographs of the neck can demonstrate the location of a subglottic/upper tracheal lesion, its linear extent, extratracheal involvement, and the amount of normal trachea. However, high resolution

computed axial tomography with 3D reconstruction has become the preferred method of imaging and allows measurements of the length and configuration of tracheal stenosis as well as its relationship to surrounding structures and thickness of tracheal walls (Fig. 1).

Bronchoscopy is invaluable in determining the extent of airway disease and the quality of the mucosa. The initial evaluation is best performed in the operating room with a rigid bronchoscope carefully inserted through the vocal cords just proximal to the point of stenosis. The rigid bronchoscope can then be used to measure the length of a stenotic segment of trachea, as well as assess the mucosa for inflammatory changes and granulation tissue (Fig. 2). Crucial to the management of tracheal stenosis is the ability to control the airway. Control of the airway is best accomplished in the operating room with an assortment of rigid bronchoscopes. Attempting to pass a large rigid bronchoscope beyond a tight inflammatory stricture is usually difficult and can result in tracheal rupture or total airway obstruction from bleeding and edema. Graduated rigid bronchoscopes (pediatric to adult) are preferred to dilate postintubation strictures serially. Balloon dilators are used by some but not preferred by us. Racemic epinephrine and steroids are often administered for 24 to 48 hours to minimize postdilatation edema. Caution should be exercised using flexible bronchoscopy in the outpatient setting when tracheal stenosis is suspected.

A complete morphologic and functional assessment of the larynx including voice and swallowing function can also be obtained preoperatively. This provides a baseline assessment of functional impairment and can be useful for tracking and comparing important functional outcomes postoperatively. A complete assessment includes transnasal video laryngoscopy, a flexible endoscopic evaluation of swallowing (FEES), and voice assessment, which can be assessed via a perceptual voice sound scaling, voice range profile, or Goettingen hoarseness diagram. Patient-based questionnaires are also increasingly used to determine voice quality and swallowing function and may include the Voice Handicap Index (VHI) or Dysphagia Handicap Index (DHI).

ANESTHESIA AND AIRWAY MANAGEMENT

Anesthesia for tracheal resection is best administered as total intravenous anesthesia (TIVA). This process provides satisfactory anesthesia and muscle relaxation before intubation, decouples ventilation and the delivery of anesthesia, and avoids environmental contamination of volatile anesthetics during the case. It also blunts airway reflexes, and its effects wear off quickly at the completion of the operation. Remifentanil and propofol are delivered by infusion and are excellent agents commonly used with TIVA, which has supplanted deep inhalation anesthetic techniques except in the case of critical stenosis when spontaneous ventilation must be preserved. This technique requires patience and time to reach the desired level of anesthesia. A laryngeal mask is placed, and the airway can be evaluated with a flexible bronchoscope and a pulmonary balloon can be used to dilate the airway. TIVA allows for a smoother, much more controlled emergence from anesthesia.

The surgeon should be available with an array of rigid bronchoscopes during induction of anesthesia to control the airway. A stricture less than 6 mm in diameter is dilated under direct vision with rigid pediatric bronchoscopes. It is not necessary to dilate a stricture beyond this diameter to accommodate a 5- or 5.5-mm endotracheal tube to avoid tearing or perforating the airway. If the stricture is more than 6 mm, a small endotracheal tube (5.5 mm) may be placed through the lesion. If the tracheal stenosis is located in the subglottic area, the lesion usually

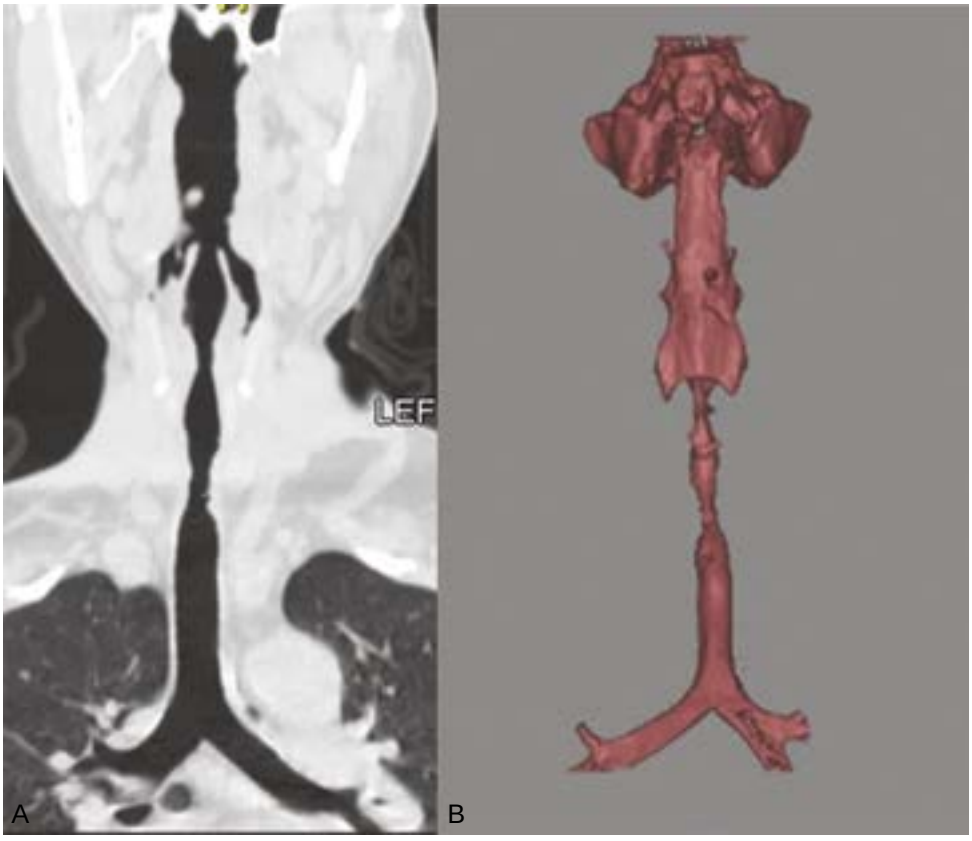

FIG. 1 Computed tomography **(A)** with 3D reconstruction **(B)** of a patient with tracheal stenosis.

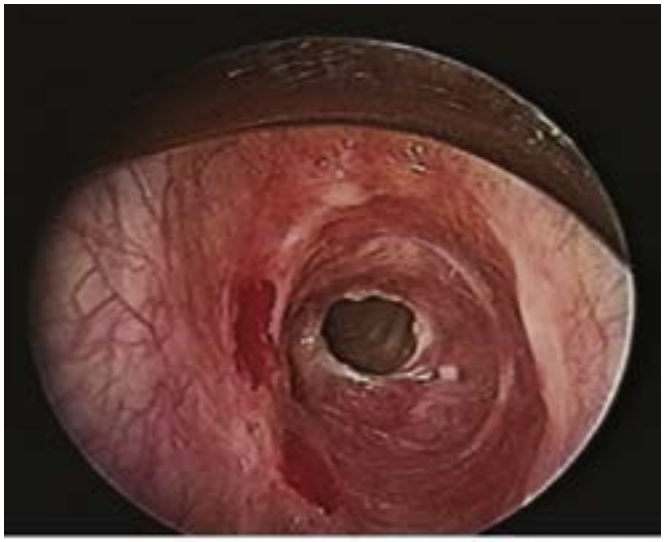

FIG. 2 Typical bronchoscopic appearance of an idiopathic subglottic tracheal stenosis.

requires dilation to allow passage of a small endotracheal tube. During resection of the trachea, the airway is divided, and the distal end of the trachea can be directly intubated with an armored, flexible endotracheal tube (Tovell tube). Sterile connecting tubes are passed off the surgical field to the anesthesiologist. The Tovell tube can be intermittently removed for brief periods of apnea to allow careful and precise placement of sutures. This technique allows ventilation during reconstruction of the trachea. Before completion of the tracheal anastomosis, the oral endotracheal tube is retrieved from the proximal trachea and passed distal to the suture line. Ideally, the patient should be extubated and breathe spontaneously at the conclusion of the operative procedure. This requires close coordination between surgeon and anesthesiologist. It is not desirable to have even a low-pressure cuff in close contact with the anastomosis for any period of time. If the patient does require intubation after surgery, a small, uncuffed endotracheal tube is preferred. The tube should be removed within 24 to 48 hours. If the airway is still a concern, a small tracheostomy should be placed two rings below the anastomosis. The innominate artery and tracheal anastomosis should be separated by a strap muscle flap carefully sutured to the trachea.

SURGICAL TECHNIQHE FOR TRACHEAL RESECTION

The patient is placed supine on the operating table with a roll or inflatable bag underneath the shoulders to extend the neck. A cervical or upper cervicomediastinal approach is used for benign strictures of the trachea at any level. The trachea is explored through a collar incision, which may encompass an existing tracheal stoma (Fig. 3A). Skin flaps are raised with platysma to the cricoid cartilage superiorly and the sternal notch inferiorly. The medial margins of the strap muscles are elevated, and the anterior surface of the trachea is bluntly exposed from the sternal notch to the carina. The thyroid isthmus is divided, dissected from the trachea, and retracted laterally with sutures. It is essential to keep the dissection absolutely close to the trachea to avoid injury to the recurrent laryngeal nerves, esophagus, and back wall of the innominate artery. If the innominate artery is adherent to the trachea and requires dissection, a strap muscle flap should be interposed between the artery and tracheal anastomosis at the completion of reconstruction. For lesions that are too far below the sternum to be accessible through a collar incision, the exposure can be increased by making a T incision in which the vertical arm extends downward to a point 1 cm below the sternal angle. The manubrium is divided to that point and separated with a pediatric chest spreader (Fig. 3B). No additional useful exposure is obtained by full median sternotomy because the carina lies at the level of the angle of Louis and the great vessels

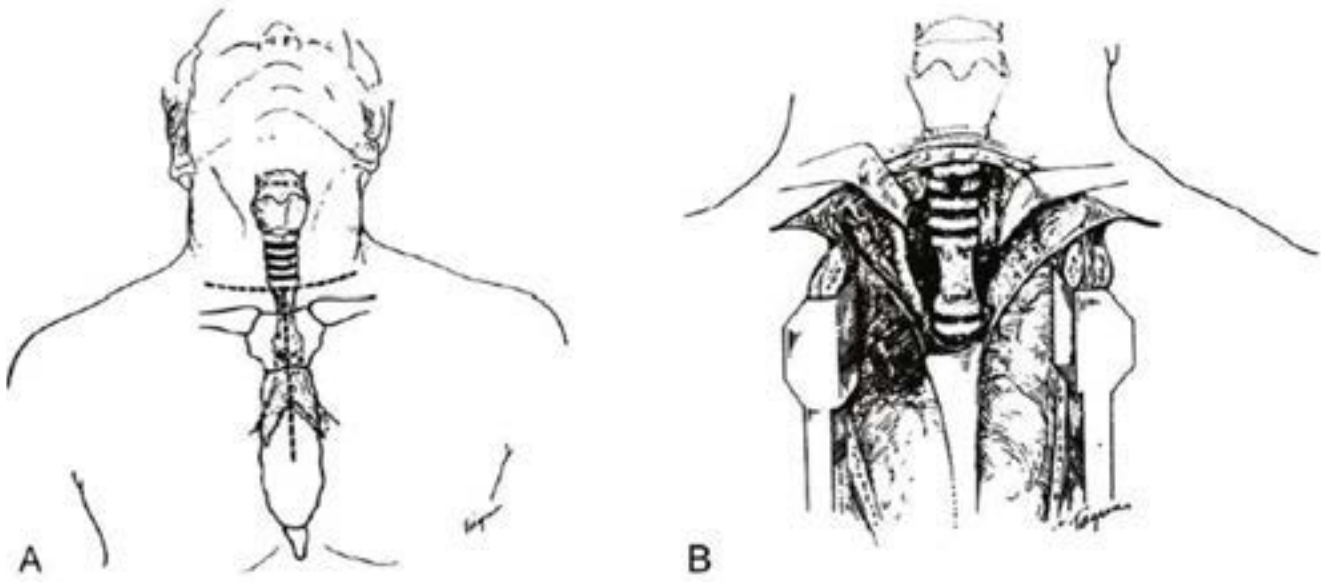

FIG. 3 Tracheal resection and reconstruction for postintubation stenosis. **(A)** A collar incision provides access for many upper tracheal lesions. For a wider access to the upper thoracic inlet and the mediastinum, a partial sternotomy is performed. Usually the incision is not carried more than 1 or 2 cm below the angle of Louis. This provides exposure even for the supracranial benign stenosis. **(B)** Partial sternotomy with retraction of innominate vein and artery without their exposure. The pretracheal plane is dissected only. Circumferential dissection is performed only just below the lesion. *(From Mathisen DJ. Curr Probl Surg. 1998;35:453.)*

obstruct access from an anterior approach. The upper sternal division provides access to the lower trachea. The innominate vein, which lies anterior and caudal to the dissection, is not divided. The innominate artery is dissected away from the trachea without exposing the wall of the artery. The anterior carina and the right and left tracheobronchial angles can be exposed as needed.

In cases of tracheal stenosis, the dissection is made meticulously along the lateral borders of the involved trachea and posteriorly approximately 1 cm below the lesion. If it is difficult to identify the level of the lesion, intraoperative bronchoscopy can help to localize the lesion. After carefully pulling the endotracheal tube back under bronchoscopic control, the position of the bronchoscope light is identified at the upper and then the lower end of the lesion while an assistant inserts a 25-gauge needle through the tracheal wall for precise localization. These levels are marked with fine sutures. Dissection close to the tracheal wall avoids injury to the recurrent laryngeal nerves, which lie in the tracheoesophageal groove on either side. This is particularly important if the stenosis lies just below the cricoid cartilage because the recurrent laryngeal nerves enter the larynx just medial to the inferior cornua of the thyroid cartilages. As the trachea is dissected circumferentially, great care must be taken to avoid perforation of the esophagus or the membranous wall of the trachea posteriorly. After the circumferential dissection of the trachea is completed, a tape is passed beneath the trachea for traction on the airway.

Before the division of the trachea, sterile anesthesia equipment is assembled on the field, and sterile corrugated tubing is passed off the table to the anesthetist. Lateral traction sutures of 2–0 Vicryl (Ethicon, Somerville, NJ) are placed on either side of the trachea in the midlateral position approximately 1 cm below the anticipated level of transection. These sutures pass vertically through the full thickness of the tracheal wall and around one ring. The trachea is opened anteriorly just distal to the lesion, staying close to the lesion if it is a benign stricture. Healthy cartilage should be present at the cut edge of the trachea. Transection of the trachea is generally above the ring, but it is acceptable to make the incision in the cartilage. When the airway is open, intermittent suctioning prevents seepage of blood into the distal airway. After transection, an assistant holds tension on the two lateral traction sutures and holds the flexible armored Tovell tube in the distal trachea. This maneuver draws the distal trachea and the ventilating tube away from the dissection. Circumferential dissection of the remaining proximal and distal trachea is limited to no more than 1 cm to protect the segmental blood supply, which enters laterally. Devascularization of healthy trachea that will be anastomosed invites possible necrosis and anastomotic dehiscence.

To test the ease with which the tracheal ends can be brought together, the anesthesiologist flexes the patient's neck, and the surgeons draw on the crossed proximal and distal traction sutures, bringing the tracheal ends together. The surgeon should be able to judge whether the tension is excessive. The length of trachea that may be safely removed should be determined before division of the trachea. The feasibility of resection is based on radiologic and bronchoscopic examinations made before the operation. The length of trachea that can be safely removed is influenced by the patient's age and body habitus, by the anatomy of the trachea, and by previous treatments. It is wise to open the trachea conservatively into slightly damaged trachea and resect conservatively, checking by approximation to be certain the airway will come together. After it has been demonstrated that the tracheal ends will come together without excessive tension, the neck is extended again. The first anastomotic suture (4–0 coated Vicryl) is placed in the posterior midline with the knots on the outside. These sutures pass vertically through the full thickness of the tracheal wall and around one ring (Fig. 4A). The sutures are carefully clipped to the drapes. The next suture is placed anterior to this and clipped to the drapes just caudad to the previous one. The sutures are placed serially until a point is reached at the midlateral tracheal traction suture (Fig. 4B). The same placement of

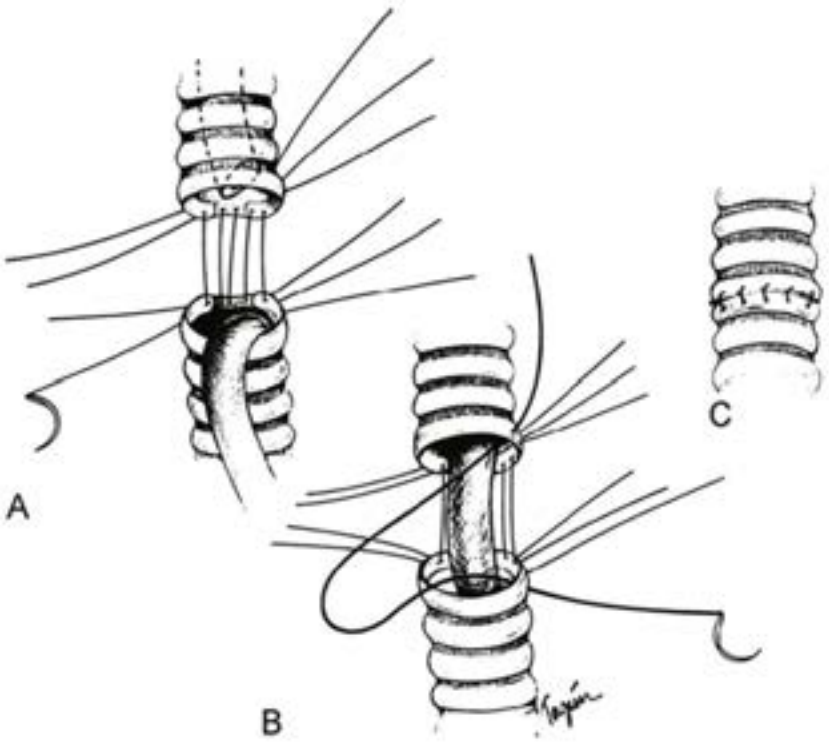

FIG. 4 Tracheal anastomosis. **(A)** Sutures are placed individually beginning in the midline posteriorly and ranging anteriorly on either side. **(B)** After the sutures are placed on either side up to the level of the midlateral traction sutures, the anterior sutures are then placed. Frequently, the endotracheal tube is not advanced from above until after all the sutures are placed. **(C)** The neck is placed in the flexed position, and the lateral traction sutures are tied on either side (not shown) to remove tension from the anastomotic sutures. After this, anastomotic sutures are tied from anterior to posterior on either side. The completed anastomosis is airtight. *(From Mathisen DJ.* Curr Probl Surg. *1998;35:453.)*

sutures is now carried out on the opposite side, from the posterior midline to the midlateral traction suture. Serial sutures are similarly placed anteriorly, proceeding from the lateral traction sutures to the midline. The sutures are placed through the cartilage approximately 4 mm from the cut edge of the trachea and 4 mm apart. When all the sutures are placed, the oral endotracheal tube is advanced from above until the tip is visible in the wound. The distal trachea is suctioned, and the endotracheal tube is advanced further, resuming ventilation through the original oral endotracheal tube. Care must be taken not to entangle the endotracheal tube in the anastomotic sutures. The patient's head is firmly supported on blankets in flexion. The crossed lateral traction sutures are pulled together on either side and tied with surgeon's knots opposing the tracheal ends.

The anterior anastomotic sutures are tied first without tension, and the ends are cut after each suture is tied. The assistant then rotates the trachea by carefully drawing medially on the traction sutures on the surgeon's side of the table. The surgeon ties the suture just behind the lateral traction suture and ties sutures in the direction of the posterior midline. This same technique is repeated on the opposite side (Fig. 4C). The cut traction sutures are left in place to guard against tension on the anastomotic sutures. The integrity of the anastomosis is checked by deflating the cuff and hearing a rush of air around the tube (confirms an adequate lumen), submerging the wound in saline solution, covering the mouth and nose, and insufflating to pressures between 20 and 30 cm H_2O. All anastomoses must be airtight, and a patient should not leave the operating room with an air leak. A leak must be repaired, even if it means taking the anastomosis down and redoing it again. The sternohyoid muscle or the thyroid isthmus is then used to cover all suture lines. This serves as a buttress, an adjunct to healing, and a barrier to superficial wound infections. If there is any concern regarding dissection of the innominate artery, a pedicled strap muscle should be interposed between the innominate artery and the trachea. Flat suction drains are placed in the pretracheal and substernal spaces, and the strap muscles are approximated in the midline. After the incision is closed, a heavy suture is placed through the submental skin crease beneath the chin and through the presternal skin. This suture is tied with the patient's neck in moderate flexion to prevent sudden hyperextension of the neck in the first week after the operation. Hyperflexion of the neck can result in ischemia to the spinal cord and quadriplegia and should be avoided.

If it is determined after neck flexion that excessive anastomotic tension exists, maneuvers should be performed to reduce tension. The most helpful maneuver for the upper and midtrachea is the Montgomery suprahyoid release. This can be performed by exposing the hyoid through a small horizontal incision just over the hyoid. The muscles inserting on the superior aspect of the hyoid between the lesser cornu are divided. The hyoid bone is divided just lateral to the lesser cornu on both sides. This release maneuver usually gives between 1 and 2 cm of additional mobility of the trachea.

After tracheal resection, patients are usually extubated in the operating room. If the airway is not satisfactory at this point, it is not likely to improve later unless the problem is caused by laryngeal edema. A small endotracheal tube with the cuff deflated can be left in place for 24 to 48 hours while the laryngeal edema resolves. The patient should be given 24 to 48 hours of steroids (Decadron, 4 mg intravenously every 6 hours), diuretics, fluid restriction, and have their head elevated in bed to reduce edema. We prefer to return to the operating room at the end of 48 hours and extubate the patient under anesthesia. If there is still a problem, a small tracheostomy tube is placed two rings below the anastomosis. A pedicled strap muscle flap should be employed to cover the anastomosis if not already performed. If doubt exists about the need for a protective tracheostomy, a "minitracheostomy" is useful to allow access of a more permanent tube. The minitracheostomy (5 mm lumen) allows suctioning and oxygen but is not a stable long-term solution. If the airway is determined to be stable, the minitracheostomy can be removed under bronchoscopic guidance at 7 days when the anastomosis is checked.

COMPLICATIONS OF TRACHEAL SURGERY

Complications after tracheal surgery are similar regardless of the problem for which resection and reconstruction is performed. Avoiding anastomotic tension and devascularization are the keys to minimizing complications. In general, resections greater than 4 cm should include additional maneuvers to avoid anastomotic tension. Standard techniques include dissection of the pretracheal plane, neck flexion, traction sutures, and suprahyoid laryngeal release in extreme cases.

One of the most common complications in the immediate postoperative period is edema, especially after subglottic resection. Edema generally manifests after 24 to 72 hours and is the most likely culprit for reduced airflow in the first few days after surgery if an adequate airway was demonstrated in the operating room. Separation and secretions are other explanations that must be considered. Edema is treated as previously described. Heliox can be used if shortness of breath is symptomatic.

If an air leak develops postoperatively, as manifested by subcutaneous emphysema, this could be a harbinger of separation and is a surgical emergency. The patient should be immediately returned to the operating room and the airway secured. In cases of separation, repair is unlikely and tracheostomy or a T-tube should be used to secure the airway. Local muscles can be used to buttress the tracheostomy or T-tube. If the airway is stable and the subcutaneous air is minimal, then CT imaging may be helpful in the initial assessment. Either way, the patient should undergo bronchoscopy to assess the competency of the airway. If a dehiscence is found, then surgical exploration and securing of the airway with a tracheostomy or T-tube is preferable. If the airway is secure and only a small leak from a suture or a small area of necrosis is identified, then attempted local repair buttressed by muscles utilizing suction to press the flaps securely in the damaged area is oftentimes successful. Alternatively, hyperbaric oxygen therapy (HBOT) has been used to enhance angiogenesis, improve wound healing, enhance reepithelialization, and avoid reoperation. Its use is predicated on a stable airway.

The most in-depth analysis of complications after tracheal surgery was reported by Wright and colleagues in patients with postintubation stenosis. The most common nonanastomotic complications are presented in Table 1. Of 392 patients treated between 1993 and 2017 in this series, only 3 (0.8%) died. The etiology of these deaths were pulmonary embolism, respiratory failure, and death after heart transplantation. Overall morbidity was 33%. There were no instances of postoperative tracheovascular fistula. Reintubation was required in 19 patients and usually represented an underlying anastomotic problem or inadequate airway due to structural issues or edema. Of the patients who required reintubation, 63% eventually had a good or satisfactory outcome, failure occurred in 26% (5 of 19), and death occurred in 10% (2 of 19). Voice changes occurred in 17 out of 392 patients. These changes reflected either vocal cord paresis (8 patients) or paralysis (9 patients).

Anastomotic complications are presented in Table 2. The most common complications were edema in 56 patients (14%) and granulation tissue formation in 70 (18%). Dehiscence or necrosis occurred in 16 patients (4%), with 10 patients having both. Wound infections occurred in 15 patients, all associated with necrosis or dehiscence. Risk factors for anastomotic complications include diabetes, resections greater than 4 cm, prior tracheostomy, age less than 17, and reoperations.

More recently, the use of HBOT has been studied as an intervention to enhance wound healing and avoid reoperation, tracheostomy, or T-tube placement in patients with anastomotic complications after tracheal resection and reconstruction. HBOT is the administration of 100% oxygen at pressures greater than 1 atm and is thought to promote wound healing by increasing angiogenesis and collagen synthesis. In a recent series published by Tapias and colleagues, patients with varying degrees of failed anastomotic healing, from cartilage necrosis to mild

separation identified by bronchoscopy, were treated with HBOT. A total of 23 patients underwent a median of 9.5 HBOT sessions that were administered in 90-minute intervals in a hyperbaric chamber pressurized to 2 atm with 100% oxygen over a median course of 8 days. In addition, patients were treated with broad-spectrum IV antibiotics, tobramycin nebulizers, and Heliox as clinically indicated. The airway anastomosis healed in 20 of 23 (87%) patients. Overall, a satisfactory long-term airway outcome was achieved in 19 (83%) patients. Four patients failed and required reoperation. Complications were minor and included inner ear discomfort and temporary blurry vision.

RESULTS

The results of tracheal resection and reconstruction have proven to be quite successful. In a series spanning from 1993 to 2017, a total of 392 patients underwent tracheal resection and reconstruction for postintubation stenosis, 45 of which were done for restenosis after an initial attempt at repair (Table 3). The amount of trachea resected ranged from 1 to 7.75 cm with a median length of 3 cm. Laryngeal release was performed in 3.8% of cases and 99% of the anastomoses were covered with a vascularized tissue buttress. Results were good (defined as an anatomically intact airway in a functionally normal patient) or satisfactory (defined as patients able to perform normal activities but with abnormalities such as stress with exercise, a paralyzed vocal cord, or

TABLE 3 Postintubation Tracheal Stenosis — MGH Experience 1993–2017

bronchoscopic evidence of narrowing) in 365 (93%) patients. Patients who underwent a primary tracheal resection and reconstruction had a good/satisfactory outcome in 96% of cases compared with 84% of patients who underwent a laryngotracheal resection. There were 24 failures (6%) and 3 deaths (0.8%).

The effect of additional treatments on outcomes can be seen in Table 4. Patients who had a prior tracheostomy that was removed before surgery had a good or satisfactory outcome in 96% of cases compared with 85% of patients who had a tracheostomy present at the time of surgery. At the conclusion of surgery, 27 patients required a protective tracheostomy, of which a good or satisfactory outcome was achieved in 74%. In contrast, 24 patients left the operating room without a tracheostomy but later required an emergent tracheostomy early in their postoperative course. In these patients, a good or satisfactory outcome was only achieved in 38%, 54% failed, and 8% died. Prior T-tube and stents also led to worse outcomes, whereas prior dilations and laser treatments did not have a significant effect on outcomes. In patients who underwent a reoperation, 91% had a good or satisfactory outcome and 9% failed. Additional prognostic factors are presented in Table 5. Multivariable analysis

indicated that laryngotracheal resections and tracheostomy at the time of surgery led to the worst results. Age, sex, a history of diabetes mellitus, and the use of a hyoid release did not influence outcomes. Low-dose steroids were needed at the time of surgery in 34 patients despite attempts to wean them off. Good or satisfactory results were achieved in 91% ($P = 0.458$) of patients still receiving steroids at the time of surgery.

Long-term results after laryngotracheal resection and reconstruction have also proven to be successful. Nauta and colleagues reported a series of 43 patients who underwent laryngotracheal resection for benign subglottic stenosis. At a mean of 53 months of follow-up, 95% of patients had late surgical success. Functional questionnaires were also administered, and overall, patients reported a significant improvement in dyspnea during rest and exercise. Swallowing was unchanged before and after surgery, voice impairment was absent to moderate in 88%, and 85% of patients reported an improvement in quality of life.

Management of Acquired Esophageal Respiratory Tract Fistula

James T. Nawalaniec, MD, and Christopher R. Morse, MD

OVERVIEW

A tracheoesophageal fistula (TEF) is a pathologic communication between the respiratory tract and esophagus. These fistulas develop in the setting of benign or malignant conditions. In adults, benign fistulas are most commonly acquired as a result of prolonged endotracheal intubation in mechanically ventilated patients and are typically managed with surgery. Malignant fistulas are challenging to manage, and a conservative approach directed at patient palliation remains the mainstay of therapy. This chapter reviews the cause, clinical manifestation, diagnostic approach, and surgical management of acquired TEF.

PATHOGENESIS

An acquired TEF is caused by tissue necrosis and breakdown of the respiratory tract and esophagus, which results in a pathologic communication between the two structures. They are most commonly located in the upper one-third of the esophagus, where the membranous wall of the trachea lies adjacent to the esophagus. Any TEF can be broadly classified as either benign or malignant. The latter is the most common cause of acquired TEF, and esophageal carcinoma, particularly squamous cell carcinoma, is responsible for the majority of cases. Other causes include direct invasion by bronchogenic or thyroid carcinoma or, more rarely, mediastinal lymphoma. In addition, radiation therapy, often necessitated by these malignancies, poses an increased risk for TEF. Benign TEF can be subclassified as iatrogenic, infectious, or traumatic based on the cause.

Iatrogenic

The most common cause of benign TEF is prolonged mechanical ventilation. The inflated cuff of an endotracheal tube presses against a hard esophageal tube, usually a nasogastric tube or temperature probe, which leads to pressure necrosis at the posterior membranous tracheal wall and anterior esophagus. Over time, there is full thickness necrosis, resulting in a pathologic connection between the trachea and esophagus. The risk of developing a TEF is increased in patients with impaired wound healing, such as the immunocompromised, those on corticosteroids, or those with poorly controlled diabetes. Because these connections develop insidiously, gross contamination of the mediastinum is not common. Other iatrogenic causes of TEF include injuries sustained during procedures, such as intubation, tracheostomy tube placement, and esophageal or airway surgery. For example, postsurgical anastomotic leak or devascularization of the trachea from close bilateral paratracheal dissection potentiates the risk for TEF, as does dilation of benign esophageal strictures or surgical anastomoses of the trachea or esophagus. Moreover, stenting of the trachea or esophagus can result in erosion or injury, especially if placement or extraction of the stent is difficult or traumatic.

Infectious

Infectious TEF is most seen with pathogens that cause granulomatous inflammation, including histoplasmosis and tuberculosis. These infections are both more common and more severe in patients with immunodeficiency syndromes, including human immunodeficiency virus.

Traumatic

A TEF can be acquired as a result of a traumatic process, such as foreign body impaction and erosion, ingestion of caustic agents, or penetrating or blunt trauma to the neck. Unlike most iatrogenic TEF, traumatic TEF develops acutely, which often leads to gross contamination of the mediastinum. It is important to recognize that, in cases of polytrauma, the diagnosis of TEF may be delayed during the treatment of other life-threatening injuries. As is discussed in this chapter, the surgical management of traumatic TEF may therefore follow an alternate algorithm.

CLINICAL FEATURES

Despite the broad spectrum of causes, the clinical features of acquired TEF in adults are similar and represent the sequelae of an abnormal connection between the upper respiratory and gastrointestinal tracts. Patients generally present with chronic cough, often exacerbated by oral intake with expectoration of food. Secondary to recurrent aspiration across the TEF, they often develop recurrent bronchopulmonary infections, which may manifest as hemoptysis, fevers, or frank and life-threatening pneumonia or mediastinitis; the latter is more likely in an acutely acquired TEF. Notably, TEF caused by malignancy often becomes apparent after chemotherapy or radiotherapy treatment of the primary tumor.

In the mechanically ventilated patient, signs suggestive of TEF include inadequate return of tidal volumes, often in the setting of gastric abdominal distension on physical examination or a large gastric bubble on abdominal imaging. Additional clues include increased secretions, aspiration of tube feeds from the airway on manual suction, difficulty maintaining seal with the cuff of the endotracheal tube, or persistent sepsis, pneumonia, or pulmonary infiltrates not attributable to other causes.

DIAGNOSIS

In patients with suspected TEF, diagnostic workup begins with chest radiography. This may reveal sequelae of a TEF, including aspiration pneumonitis or a dilated stomach and distal esophagus in patients on positive pressure ventilation. In patients with recurrent aspiration, swallow evaluation may be beneficial to rule out oropharyngeal dysphagia as a cause. Small fistulas (<1 cm) are difficult to diagnose and are best detected with barium swallow using dilute barium (Fig. 1). Large fistulas are best diagnosed with bronchoscopy and esophagoscopy. Bronchoscopy is essential to locate the fistula and to perform a mucosal survey. Rigid bronchoscopy allows for complete inspection of the airway, including careful measurements such as fistula size and distance between the fistula and the vocal cords proximally, as well as the carina distally. Bronchoscopy also provides the opportunity for biopsy if malignancy is suspected and cultures to guide antibiotic therapy, if necessary. Although esophagoscopy is less reliable in the diagnosis of TEF, it can be used in conjunction with bronchoscopy to instill air and methylene blue to define the anatomy, particularly for small fistulas. Further imaging with modalities such as computed tomography scanning is not necessary or helpful in benign disease, but it is useful in TEF secondary to a suspected or confirmed malignant process.

TREATMENT

Preop Care

The treatment of acquired TEF begins with preoperative planning and patient optimization. Preoperative chest radiography, barium swallow, bronchoscopy, and esophagoscopy must be reviewed to determine the anatomy of the fistula, which will guide surgical exposure. Patients with pulmonary sepsis as a result of chronic airway contamination from aspiration of enteric contents should be adequately treated with antibiotics and stabilized before surgery. In situations where mechanical ventilation can be weaned, it is paramount to delay surgery until ventilation can be definitively ceased to minimize postoperative manipulation and positive pressure within the reconstructed trachea. In patients who are intubated, it is important to advance the endotracheal tube below the level of the fistula and inflate the cuff to prevent further contamination. Nutrition should be optimized with enteral feeding via a jejunostomy tube with a venting gastrostomy tube. Nasogastric and orogastric tubes should be avoided to minimize further esophageal trauma. Lastly, preoperative coordination with an experienced team of anesthesiologists familiar with the challenges of induction and intraoperative ventilation during tracheal resections is paramount.

Some centers advocate for placement of esophageal or airway stents as a temporizing measure against ongoing complications of the TEF. Although stents may help reduce ongoing aspiration through the fistula, they do carry the risk of increasing the size of the defect, sometimes to an extent where operative repair becomes infeasible. For benign TEF, we prefer to avoid stents and instead use distal intubation with a cuffed tracheostomy tube below the airway defect. We also place a venting gastrostomy tube with a feeding jejunostomy tube. This strategy protects the distal airways from ongoing aspiration and should reduce gastric aspiration with the gastrostomy tube open to gravity. The jejunostomy tube is utilized for enteral feeding.

Operative Management

Benign TEF is managed primarily with surgery. For more proximal TEF, the patient is placed supine with the head extended as far as possible. Exposure is achieved via an anterior collar incision, encompassing

FIG. 1 Barium contrast esophagram showing fistulous communication between the esophagus and airway.

the tracheostomy stoma, if present (Fig. 2). Subplatysmal flaps are raised, the strap muscles are separated at the midline, and the thyroid isthmus is divided. Alternatively, a left cervical incision along the anterior border of the sternocleidomastoid can be used. Importantly, both approaches may be extended to include a sternotomy for exposure of the distal trachea and for proximal control of the great vessels.

For more distal TEF or bronchoesophageal fistulas, a right posterolateral thoracotomy through the fourth or fifth interspace provides adequate exposure. Conservative surgical management includes two stages: initial tracheal resection and reconstruction with esophageal diversion via cervical esophagostomy, followed by delayed primary esophageal reconstruction. This approach may be appropriate for patients with traumatic TEF, where the degree of local contamination, loss of viable tissue, or other traumatic injuries may preclude a single stage repair. When feasible, a single-stage repair is advisable because it avoids neck reoperation, as well as loss of esophageal length during the takedown of the cervical esophagostomy. Principles of single-stage surgical repair as originally described by Hermes Grillo include complete dissection and division of the fistula with tracheal transection to expose the esophagus, a two-layer esophageal closure, reanastomosis of the trachea, and buttressing of the repair with a pedicled tissue flap. There are several technical considerations in each of these steps.

First, during the exposure and dissection of the fistula, the trachea often requires segmental resection with distal tracheal intubation. This is especially true for TEF acquired from prolonged intubation given the circumferential damage sustained from the endotracheal tube cuff. Segmental resection of the trachea then provides excellent exposure to the esophagus (Fig. 3). During dissection of the esophagus, care must be taken to avoid damage to the recurrent laryngeal nerves that lie within the tracheoesophageal groove on either side. The nerves may be found cranial or caudal to the fistula, and identification can be challenging from local inflammation and scarring.

Second, once identified and divided, the esophagus is closed over a nasogastric tube to avoid narrowing the lumen. We advocate for a two-layer closure with interrupted nonabsorbable sutures: an inner layer to approximate and invert the esophageal mucosa, with an outer layer of approximated esophageal musculature to cover the inner repair (Fig. 4). It is important to debride the esophageal defect to healthy tissue to ensure the integrity of this primary repair.

Third, during tracheal repair, we recommend placing stay sutures (2-0 Vicryl) in the tracheal rings cranial and caudal to the transection, at the 3 o'clock and 9 o'clock positions in both rings. This reduces tension for the tracheal anastomosis, which is accomplished with interrupted absorbable sutures (4-0 Vicryl) placed circumferentially around the trachea, every 5 mm, with the knots tied outside of the lumen of the trachea. This minimizes the formation of postoperative granulomas at the suture line (Fig. 5). Once the sutures are in place, the neck is flexed to reduce tension, the stay sutures are tied first, followed by the finer sutures placed circumferentially, proceeding anteriorly to posteriorly.

Fourth, in cases of long-segment tracheal damage and resection where simple neck flexion does not allow for primary repair, the trachea may be repaired over a T-tube. Alternatively, experienced surgeons may perform a variety of release maneuvers, including a suprahyoid laryngeal release, right pulmonary hilar mobilization, or pericardial release.

Last, the use of a pedicled muscle flap to buttress both the esophageal repair and tracheal reconstruction is paramount to prevent recurrence of the TEF from the abutting suture lines. An infrahyoid muscle, typically the sternohyoid, is of adequate length and size to be secured to the repair with interrupted nonabsorbable sutures (Fig. 6). At the conclusion of the repair, a subcutaneous drain is placed before the incision is closed. The nasogastric tube is gently removed from the esophagus and a "guardian suture" is placed from the chin to the sternal angle to maintain neck flexion at approximately 30 degrees. The patient is extubated to prevent prolonged positive pressure ventilation within the reconstructed trachea. In situations where mechanical ventilation is necessary after surgery, a tracheostomy tube may be placed at least two tracheal rings below the level of the repair.

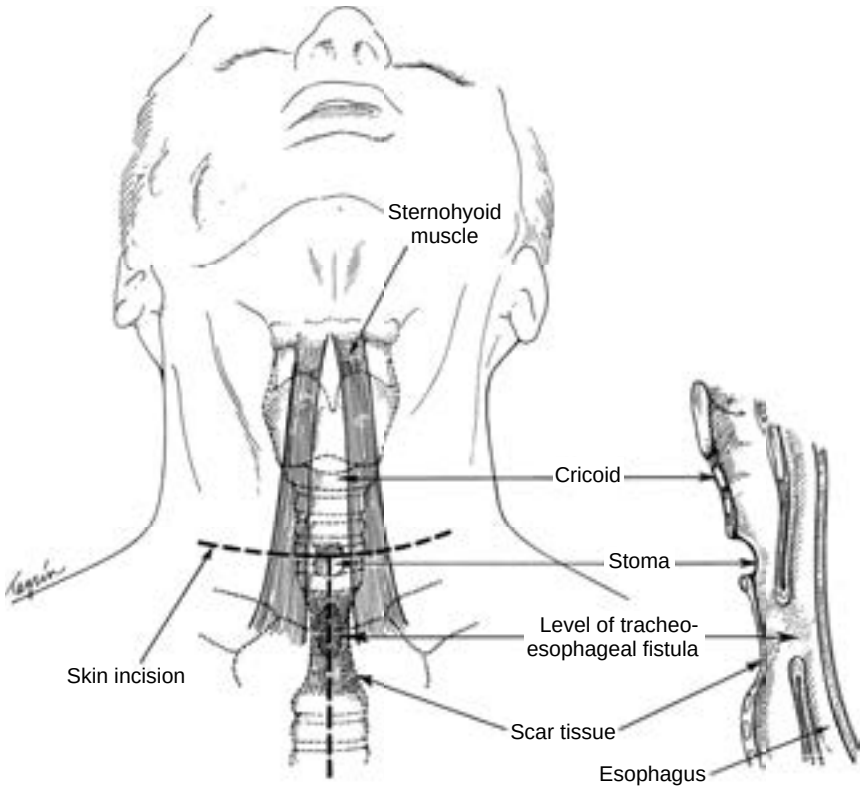

FIG. 2 Surgical exposure for repair of tracheoesophageal fistula. Both a transverse anterior collar incision incorporating a tracheotomy or left cervical incision provides necessary exposure. Additional exposure for distal fistulas can be exposed with division of the manubrium.

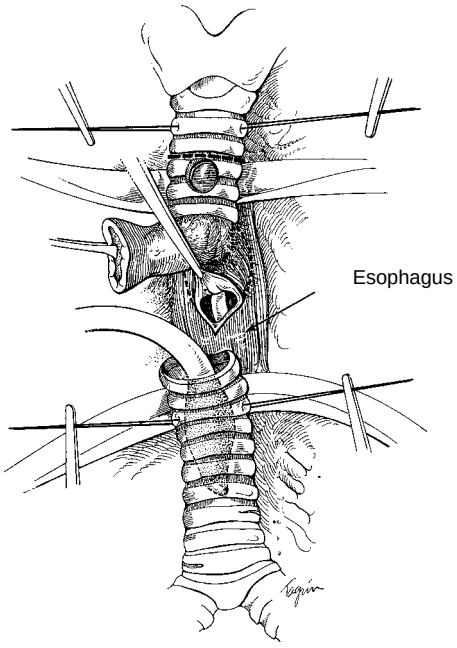

FIG. 3 Tracheal resection. Esophageal exposure after segmental tracheal resection in cases of acquired postintubation tracheoesophageal fistula.

Extensive TEF

For very large TEF, operative solutions may be limited or even infeasible. This usually occurs when the airway defect is so large (typically >5 cm) that it precludes segmental tracheal resection and primary anastomosis. For these complex defects, bioprosthetic grafts are emerging as a solution for operative repair. In this scenario, operative resection of the fistula and primary esophageal repair may still be pursued, with use of aortic homograft or acellular dermal matrix to cover the airway defect. A vascularized flap should still be used to buttress the repair. There have been several reports of successful bioprosthetic patching for large airway defects in TEF. Although primary repair of the airway is preferred when feasible, bioprosthetic grafts are emerging as a useful alternative to primary repair for giant TEF. Management of a large esophageal defect can involve primary repair as mentioned earlier or resection and reconstruction either at the time of the primary airway repair or at a later interval.

Postop Management

Postoperative care is focused on pain and nausea control to prevent cough or emesis. The patient is maintained nil per os; nutrition is provided via preoperative enteral access or parenteral nutrition. The patient returns to the operating room 7 days after surgery for bronchoscopic surveillance of the tracheal reconstruction, at which time the guardian suture is removed. A barium swallow is also performed to confirm the integrity of the esophageal repair before initiating a liquid diet.

Malignant TEF Management

While patients with malignant TEF have very poor prognosis, usually less than 10 weeks' survival in most series, aspiration pneumonia from the TEF can lead to more rapid demise. The management of malignant TEF is thus focused on palliation. Surgery, in many of these cases, is not within the initial oncologic principles of management. Furthermore, these patients are often significantly deconditioned and malnourished as a result of their disease burden, systemic chemotherapy, and local radiation. For these reasons, outcomes from radical and palliative surgery to address malignant TEF result in significant rates of morbidity and mortality.

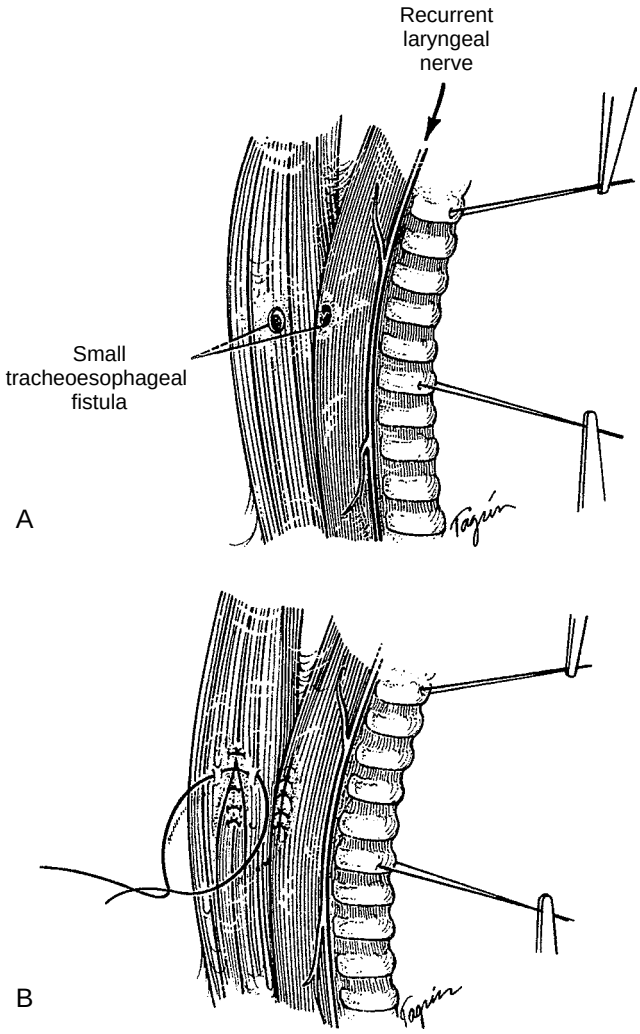

FIG. 4 Esophageal repair. **(A)** Lateral cervical approach to a small proximal tracheoesophageal fistula. **(B)** The esophageal defect is repaired in a two-layer fashion with interrupted sutures. The defect in the membranous wall of the trachea is repaired with a single layer of interrupted sutures.

In cases of incurable disease, airway and esophageal stenting has emerged as a viable option to achieve palliation. Either an individual or a combination of stents is placed across the fistula to prevent further spillage of enteric contents across it. This minimizes pulmonary contamination and alleviates the symptoms of chronic aspiration and pulmonary sepsis. The principals of preoperative planning in benign TEF also apply to patients with malignant disease. Preoperative imaging, including barium swallow, should be obtained to determine the anatomy and level of the fistula. Pulmonary sepsis should be treated with antibiotics, mechanical ventilation should be weaned as allowed, and nutrition should be optimized. Most malignant TEF may be sealed using a self-expanding covered or partially covered metal or plastic esophageal stents. These stents are typically placed under general anesthesia, using direct endoscopic guidance with the assistance of bedside fluoroscopy.

In some cases, tracheal stents may also be needed and should be placed under bronchoscopic vision before the esophageal stent. This technique decreases the incidence of tracheal narrowing from initial esophageal stenting. For fistulas located at or above the cricopharyngeus, the placement of a stent is not recommended because a

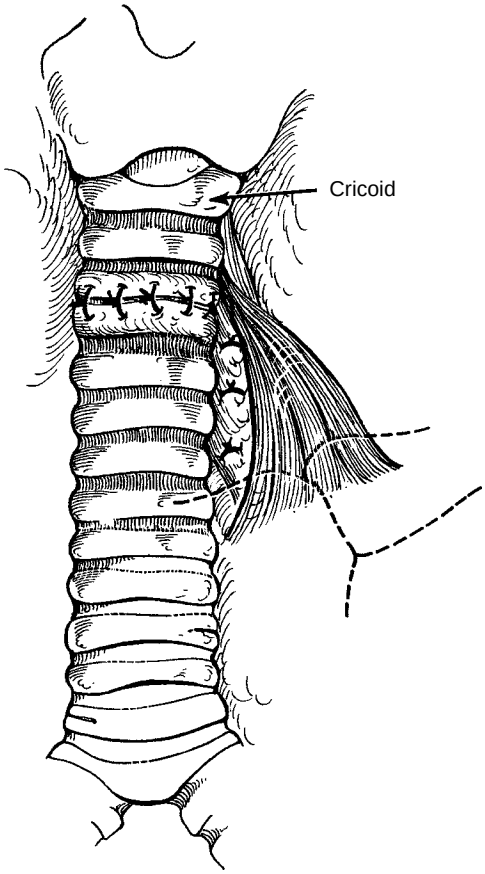

FIG. 5 Tracheal reconstruction. Placement of interrupted nonabsorbable sutures for tracheal reconstruction.

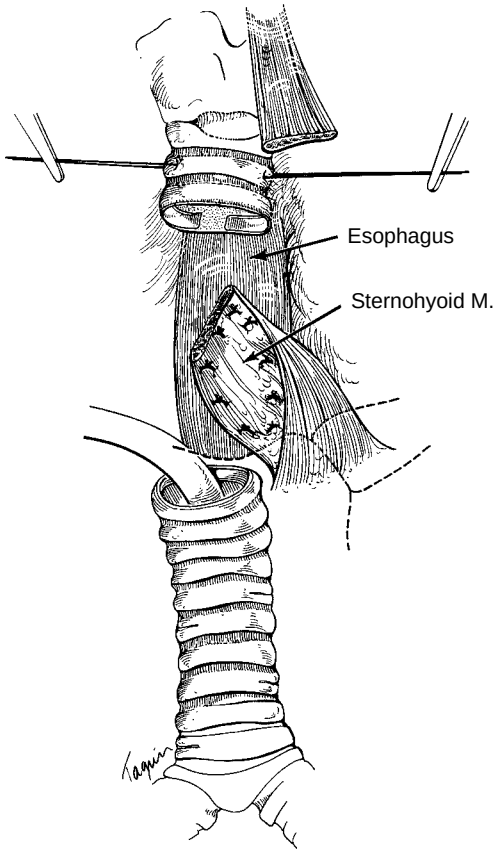

FIG. 6 Placement of pedicled infrahyoid strap muscle in between tracheal and esophageal suture lines to buttress repair and prevent fistula recurrence.

foreign body in the pharynx or larynx results in significant patient discomfort and the inability to swallow. In such cases, a definitive tracheostomy tube with inflatable cuff to protect the distal airways may be placed. Likewise, fistulas to the lobar or segmental bronchi are difficult to seal via bronchial stenting because there is a lack of healthy tissue proximally and distally. Typically treated with an esophageal stent alone, these peripheral fistulas may also be managed with the addition of a tracheobronchial stent.

Success rates of 80% to 100% have been reported with self-expanding stents to seal malignant TEF. Although well tolerated, patients should be counseled on the complications of esophageal and airway stenting, which can be minor to devastating. These include bleeding, migration, erosion, and further progression of the fistula, leak, and occlusion.

OUTCOMES

Surgical treatment of benign TEF results in successful fistula closure and is associated with minimal morbidity and mortality. In the largest recent series reporting the outcomes of a cervical approach to primarily postintubation TEF repair, successful fistula closure occurred in 95% of patients. Approximately 83% of patients resume oral feeding, and 72% are free from a tracheostomy or T-tube. Postoperative complications include fistula recurrence, pneumonia, wound infection, and postoperative tracheal stenosis. Death after TEF repair is rare. Patient survival in malignant TEF is poor regardless of supportive care, stent placement, or aggressive surgical treatment. Life expectancy is on the order of weeks to months. However, self-expanding stents have successfully palliated symptoms of dysphagia and chronic aspiration for patients with malignant TEF.

SUMMARY

Most benign acquired TEF are amenable to surgical repair. We emphasize the importance of a comprehensive preoperative evaluation to determine the anatomy of the fistula and optimize respiratory status and nutrition. A single-stage repair with division of the fistula, two-layer esophageal closure, tension-free tracheal resection and reconstruction, and buttressing of the repair with a pedicled interposition tissue flap has yielded excellent results. Malignant TEF are challenging to manage but are primarily treated nonoperatively with the use of self-expanding stents to maximize patient palliation.

Repair of Pectus Excavatum

Jennine H. Weller, MD, PhD, and Isam W. Nasr, MD

INTRODUCTION

Pectus excavatum (PE), also known as *funnel chest*, is the most common pediatric chest wall deformity, occurring in approximately 1 in 400 to 1000 children. Patients with PE present with progressive posterior displacement of the sternum and costal cartilage (Fig. 1). Although the pathophysiology is incompletely understood, PE is likely due to abnormal costal cartilage development and has an association with connective tissue disorders including Marfan and Ehlers Danlos. No genetic markers have yet been identified for PE, but there is a familial association in 40% of patients, and PE is three times more common in male as compared to female patients.

Pectus excavatum can be detected in young children, but the deformity becomes more pronounced during the pubertal growth spurt. The typical patient is a tall, thin adolescent with poor posture, scoliosis, and an anterior chest wall deformity. Pectus excavatum is frequently asymmetric and is more common on the right hemithorax. There is a wide spectrum of disease severity, ranging from asymptomatic to severe cardiac compression and cardiopulmonary compromise. Most patients report no PE symptoms at rest but experience exercise intolerance with associated pain or shortness of breath. Pectus excavatum also impacts psychosocial development, and children with PE often report self-consciousness, body-image distress, and impaired quality of life.

EVALUATION OF PECTUS EXCAVATUM

When assessing a patient for PE, it is important to ascertain the severity of the deformity, assess cardiopulmonary function, and when indicated, perform preoperative planning including metal allergy testing as well as patient and family education.

FIG. 1 Pectus excavatum. *(From Janes S. Encyclopedia of Respiratory Medicine, 2nd edition. Elsevier, 2021.)*

Disease Severity

Most surgeons rely on the Haller index to assess severity based on a noncontrast chest CT scan. The Haller index divides the transverse chest diameter by the anteroposterior chest diameter measured at the deepest point of the deformity (Fig. 2). Generally, a Haller index of 3.25 or greater is an indication for operative repair. However, studies suggest the Haller index may underestimate PE severity. A correction index, which measures the percentage of sternal depression on cross-sectional imaging, may better estimate PE severity. A correction index 28% or higher is considered significant. Chest CT scans can also assess for signs of atelectasis, asymmetry, or sternal torsion that may provide evidence of impaired function and inform operative strategies. An MRI can be used to minimize chest radiation, although the ribs and sternum are not visualized as clearly as on CT. Alternatively, caliper measures correlate well with CT findings. Calipers measure the external distance between the posterior midline chest and three anterior points: the deepest point of the deformity and each of the bilateral pectus ridges. Regardless of the method used to assess PE severity, we also recommend obtaining photographic documentation of the deformity in the medical records.

Cardiopulmonary Evaluation

Surgeons should assess the cardiopulmonary function of patients with PE using pulmonary function tests (PFTs), electrocardiogram (ECG), and transthoracic echocardiogram (TTE). On PFTs, patients with severe PE typically have a mild or moderate restrictive pattern at rest, but O_2 pulse and VO_2 max significantly decrease during exercise due to restricted diastolic filling. A preoperative ECG and TTE may reveal mitral valve prolapse in up to 65% of patients with PE. Patients with more severe disease may also have right ventricular compression or decreased stroke volume, which are correctable with PE repair.

Indications for Surgery and Operative Timing

Spontaneous resolution of PE is rare, thus operative repair to recontour the chest wall is the primary correction for PE deformities. Operative repair of PE is relatively safe and improves physical symptoms and psychological distress. Patients should be offered an operation if they have severe deformities with a Haller index ≥3.25 or a correction index ≥28%. Other operative indications include symptomatic disease, such as abnormal PFT or TTE findings, reported exercise intolerance, or evidence of impaired quality of life or psychosocial distress caused by the deformity. So long as a patient can tolerate general anesthesia, there are no absolute contraindications to surgery. However, most insurance policies require documented evidence of significant PE symptoms or impaired cardiopulmonary function to recognize the procedure as noncosmetic and cover the repair.

Whenever possible, it is important to plan surgery during the adolescent growth spurt to minimize complications of recurrence or asphyxiating chondrodystrophy. The latter was historically seen in children who underwent open PE repairs around four years of age and developed arrested growth of the thoracic cavity, likely due to iatrogenic damage of costochondral growth plates. For this reason, open PE repairs are contraindicated before the pubertal growth spurt. Prepubescent patients with mild or moderate disease should be referred to an exercise and posture program to minimize disease progression and should be followed annually. If a prepubescent patient has a severe deformity or disease progression, they should then undergo formal PE evaluation, including chest CT, PFTs, and TTE.

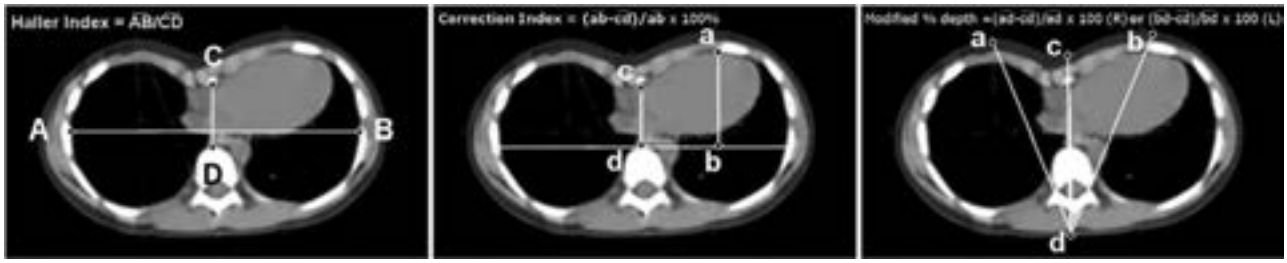

FIG. 2 Measurement of pectus excavatum severity using the Haller index *(left)*, correction index *(center)*, and modified percent depth *(right)*. The modified percent depth can be accurately measured with calipers. *(Snyder CW, Farach SM, Litz CN, et al. The modified percent depth: Another step toward quantifying severity of pectus excavatum without cross-sectional imaging.* J Pediatr Surg. *2017;52:1098–1101.)*

Other Preoperative Considerations

Approximately 1 in 10 patients with pectus excavatum have or will develop an allergy to metal alloys in the stainless-steel bars used for PE repairs. We recommend screening all patients for a personal or family history of metal allergies, and those with a positive history should get metal patch skin testing. For patients with documented metal allergies, the surgeon can order a customized titanium bar. Titanium bars are not routinely used because they are less malleable, harder to remove, and four times more expensive as they are shaped in the factory based on a patient's CT or MRI scan.

In the preoperative setting, it is also important to counsel patients on pectus exercises and expected postoperative recovery. Before surgery, the surgeon should encourage patients to do deep breathing exercises using an incentive spirometer or by breath-holding 10 to 15 seconds after inspiration, back and chest stretches, and aerobic exercise such as running, soccer, basketball, or swimming. These exercises help expand lung volume and should continue postoperatively to maximize the success of the repair. Recovery expectations should be discussed preoperatively as pain management is the major driver of postoperative hospital length of stay (LOS).

Finally, at our institution, we have initiated a preoperative pain management pathway. Three days before surgery, we recommend patients initiate 300 mg of gabapentin nightly as well as 8.5 g of MiraLAX twice daily. In the preoperative setting, patients are also given oral gabapentin, acetaminophen, tizanidine, and bisacodyl, as well as an intravenous ketamine infusion. We have found that this regimen helps minimize postoperative pain and hospital LOS for patients.

OPERATIVE REPAIR

There are two primary operative repairs for pectus excavatum, the open Ravitch procedure and the Nuss procedure or minimally invasive repair of PE (MIRPE). Most surgeons use the MIRPE as it reduces complications and improves cosmetic outcomes. Other techniques, such as the use of a vacuum bell device to lift the sternum, have shown some promise for smaller deformities in single center studies but are not widely adopted. Use of the Magnetic Mini-Mover, which uses magnetic attraction between an implanted sternal magnet and an external chest wall brace, was hindered by recurrence and device breakage in a pilot study.

Minimally Invasive Repair

First performed in 1987 by Nuss, the MIRPE places a substernal convex bar that, over a 2- to 4-year period, remodels the sternum and deformed cartilage (Fig. 3). The MIRPE has three key steps: substernal tunneling, placing the bar, and securing the bar to the surrounding ribs. The addition of thoracoscopy has modified the original Nuss operation to improve safe dissection of the substernal plane and allow for bar fixation with pericostal suturing and bar stabilizers.

We begin the MIRPE by positioning the patient supine with arms abducted and elbows slightly flexed. Before incision, the surgeon locates the horizontal position for the bar by marking the deepest point of the PE deformity or, if this is inferior to the sternum, marking the inferior edge of the sternum. We also recommend marking the pectus ridge at the horizontal level of the bar placement. When using a stainless-steel bar, the bar length is then measured so that it is 1 inch shorter (2.5 cm) than the distance between the midaxillary lines at the planned bar location. The surgeon should bend the bar to the desired chest wall shape, leaving a 2 to 4 cm flat section in the middle. This bar-shaping step is unnecessary if the patient requires a titanium bar due to a metal allergy as the bar is already preshaped. Most deformities only require one bar. However, we recommend considering placing a second bar if the deformity is complex or asymmetric, and if the patient is older than 30 years, has a connective tissue disorder, or has recurrence of their deformity.

After preparing the bar, a midaxillary incision is placed two intercostal spaces below the planned level of the bar placement. A 5-mm trocar is inserted and a 5-mm 30-degree thoracoscope is used to visualize the internal anatomy and confirm that it matches the external anatomy. We typically place the trocar on the right side with the plan to tunnel an introducer from right to left. Symmetric 4 cm incisions are then made laterally at the horizontal level of the planned bar placement. If the surgeon plans to perform cryoablation for pain management, this is now done through these lateral incisions. For the cryoablation procedure, the surgeon visualizes the intercostal nerves on the posterolateral chest wall. A cryoprobe is inserted into the thoracic cavity through the lateral incision, cooled to −60°C, and carefully applied bilaterally for 2 minutes to each posterolateral intercostal nerve between T3-T7, which is typically two levels above and two levels below the site of the incision.

After the cryoablation procedure is completed, the surgeon should raise skin flaps through the lateral incisions to the marked pectus ridge. Under direct visualization via skin retraction and thoracoscopy, a Lorenz introducer is gently pushed into the thoracic cavity through the intercostal space underlying the marked pectus ridge. Keeping the introducer tip always in view and facing away from the mediastinum, the surgeon should carefully dissect the pleura and pericardium off the sternum to create a substernal tunnel. We recommend always dissecting with a gentle, anterior to posterior motion before advancing the introducer to avoid mediastinal injury. This dissection can also be made safer with sternal elevation using a Rultract Skyhook Retractor through a subxiphoid incision.

Once the introducer reaches the contralateral pectus ridge, the surgeon gently pushes the introducer through the intercostal space into the contralateral subcutaneous tunnel. At this point, the introducer spans the chest wall, entering through one lateral chest wall incision and exiting the through the other. The surgeon and assistant should repeatedly lift on each side of the externalized introducer to elevate the sternum and begin the chest wall remodeling. This can help minimize postoperative pain or future bar displacement. An umbilical tape is attached to the introducer tip and threaded through the chest as the introducer is slowly removed. The umbilical tape is then attached to the bar. The bar should be positioned with the

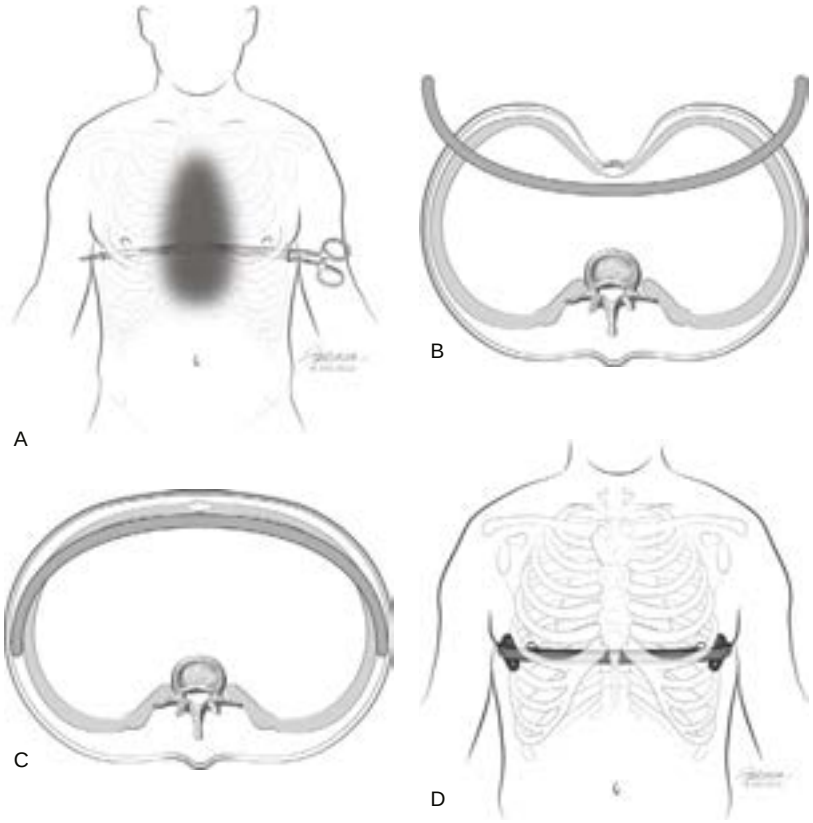

FIG. 3 Minimally invasive pectus excavatum repair. **(A)** Long clamp passing posterior to the sternum through bilateral intercostal incisions. **(B)** Initial orientation of bar after passage through chest. **(C)** Position of bar after flipping. **(D)** Bar stabilizers in position. *(Courtesy Johns Hopkins University illustrations, Jennifer E. Fairman, MA, MPS, CMI, FAMI.)*

convex side facing posteriorly and then pulled through the retrosternal tunnel by slowly pulling the umbilical tape through the chest cavity. If needed, anterior sternal retraction and direct thoracoscopic visualization aids bar placement across the mediastinum. Once the bar is in place, it is flipped 180 degrees using bar flippers so that the convex side faces anteriorly and elevates the sternum, correcting the PE deformity. The bar should be bent as needed so that it loosely fits against the lateral chest wall. This helps reduce pain and prevents the bar from eroding or adhering to the ribs.

The final step of the operation is to secure the bar to the chest wall bilaterally to prevent postoperative bar displacement. Typically, the surgeon applies a bar stabilizer on one side of the chest and uses pericostal sutures on the other side. We usually place the bar stabilizer under and perpendicular to the pectus bar on the left side. The bar is then secured to the stabilizer and underlying rib using nonabsorbable suture such as FiberWire or No. 3 surgical steel wire. The stabilizer is also secured to the chest wall fascia in multiple places using heavy absorbable suture such as 0 Vicryl. If two bars are required, the stabilizers should be placed on opposite sides. On the contralateral side to the bar stabilizer, the surgeon can use an EndoClose needle or Carter-Thomason port closure system under thoracoscopic visualization to place heavy absorbable suture, such as 0 or 1 polydioxanone (PDS), in a figure of eight around the underlying rib. It is important to place pericostal sutures in at least two locations and surrounding two or more separate ribs to prevent bar rotation. Once the bar is secured bilaterally, we ensure hemostasis in the pleural cavity, remove the thoracoscope, evacuate residual air, and close all incisions.

Open Repair

The open PE repair, as modified from the technique Ravitch described in 1949, involves excision of defective costal cartilage and placement of a metal strut for sternal support (Fig. 4). This procedure is a reasonable alternative to the MIRPE for older patients and is the preferred method to treat rare chondromanubrial deformities. The open procedure and MIRPE have comparable long-term outcomes, but a recent meta-analysis suggests that MIRPE results in shorter operations and less intraoperative blood loss.

The open procedure begins with a transverse inframammary incision. The surgeon should raise skin and pectoral muscle flaps to expose the costochondral junctions of ribs 3-8. After incising the anterior perichondrium, the surgeon carefully resects 1 to 2 cm of deformed cartilage, taking care to not devascularize the perichondrium. The xiphoid is mobilized and then pleural and pericardial attachments are dissected off the posterior sternum. The surgeon should make a wedge-shaped osteotomy at the sternal angle to correct the sternal depression. Formation of a retrosternal tunnel allows the surgeon to place a metal strut behind the sternum and to secure it to the bilateral periosteum with heavy nonabsorbable sutures. Alternatives to the metal strut include fixation of a retrosternal wire to an external brace or use of Marlex Mesh. Leaving retrosternal and subcutaneous drains, the pectoral flaps are reapproximated and the skin incision closed. Drains should remain in place for 2 to 3 days and the strut left in place for 1 year.

POSTOPERATIVE MANAGEMENT

Pain Management

Pain management is the primary postoperative concern for patients after a PE repair and drives postoperative hospital LOS. Most surgeons utilize multimodal pain management, combining IV analgesics, epidural catheters, intercostal nerve blocks, oral pain medications, and intercostal cryoablation. At our institution, we use a pain management pathway modeled after the ERAS pathway. This includes immediate initiation of patient-controlled anesthesia (PCA), ketamine infusion, Valium, and a bowel regimen postoperatively. We transition from the

FIG. 4 Open repair of pectus excavatum. **(A)** Following a transverse inframammary incision and bilateral elevation of the pectoralis major muscles, costal cartilages are freed circumferentially from the perichondrium and divided at the junctions with the sternum and with the ribs. **(B)** A cuneiform osteotomy allows the sternum to rise to a level position. **(C)** An Adkins strut in place maintains elevation. *(Courtesy Johns Hopkins University illustrations, Jennifer E. Fairman, MA, MPS, CMI, FAMI.)*

PCA to oral opioids, ibuprofen, acetaminophen, and gabapentin on postoperative day one, discontinue all IV analgesia by postoperative day two, and discharge on postoperative day two or three once medically cleared.

Cryoablation techniques are relatively new but are gaining popularity as they shorten hospital LOS and minimize opioid requirements. Intercostal nerve cryoablation is typically performed before Nuss bar placement and can utilize the same incision sites as the planned MIS repair. Cryoablation freezes the intercostal nerve axons and limits nerve signal conduction for months postoperatively. This provides effective analgesia and can reduce postoperative hospital LOS to as little as one day. Complications of cryoablation are rare, although long-term nerve damage has been reported.

Upon hospital discharge after a PE repair, patients should expect to continue oral opioids for 2 to 3 days as needed and acetaminophen, ibuprofen, and gabapentin for at least 1 week. It is also important to counsel patients about the small risk of experiencing chronic pain while the bar remains in place.

Physical Therapy Guidelines

Postoperative physical therapy is crucial to the success of a PE repair. For the first 8 weeks postoperatively, we recommend a 10-pound weight restriction. During this time, patients should avoid twisting, shoulder rotation, or movement that causes a pinching or pulling chest sensation. They can initiate other range of motion exercises including daily stretching, core-strengthening exercises, and aerobic activities by week three. We recommend jogging, swimming, or stationary biking. After 8 weeks, patients can slowly increase their weightlifting and aerobic exercise to preoperative levels. Except for full contact sports and sports that involve significant trunk rotation, such as baseball or golfing, we remove all other movement restrictions by postoperative week 12.

EARLY COMPLICATIONS

Postoperative complications for open or MIRPE repairs are relatively rare, occurring in 4% of patients. The most common complication is postoperative pneumothorax, while the most serious complication is mediastinal injury.

Approximately 4% of patients will develop a pneumothorax postoperatively. Small bilateral pneumothoraces are common and can be managed expectantly. A larger pneumothorax is usually a result of air introduced during the thoracoscopy rather than lung parenchymal injury and may require a thoracostomy tube if symptomatic. Therefore, it is important to ensure that all air is evacuated from the pleural cavity before closing incisions. We recommend obtaining a routine chest radiograph in the immediate postoperative period to assess for a pneumothorax.

Although extremely rare, technical errors during dissection of the substernal plane can result in life-threatening myocardial or lung parenchymal injuries. This is more common with the MIRPE repair as compared with the open repair. Surgeons should minimize the risk of this complication by directly visualizing the substernal dissection and keeping the tip of the introducer in view at all times during the dissection.

Other postoperative complications after a PE repair are relatively rare and include suture site infection (2%), pneumonia (1%), and pleural or pericardial effusions (1%–3.5%). Complication rates are not associated with the severity or asymmetry of a deformity but are reduced with surgeon operative experience.

LATE COMPLICATIONS

The most common late postoperative complication is bar displacement, which occurs in approximately 1.5% to 4% of patients. Bar displacement can range from mild lateral sliding of the bar to complete detachment from the lateral chest wall or flipping of the bar. Surgeons have reduced the incidence of bar displacement down from 15% by using lateral stabilizers and pericostal suturing. Minor displacement can be managed expectantly, but significant or symptomatic displacement, such as bar flip, should undergo urgent reoperation.

The use of allergy testing and titanium bar placement has reduced allergy complications, which occur in less than 1% of patients. In extremely rare circumstances the implanted bar triggers an allergic reaction and pericarditis. Most patients with metal allergies are medically managed and do not require bar excision. Another rare complication of a PE repair is overcorrection of the deformity. Overcorrection occurs in 1% to 3% of patients and is typically managed nonoperatively.

OUTCOMES

Outcomes of both open and MIRPE repairs are favorable with improvement in cosmesis, cardiopulmonary function, and quality of life. Symptomatic patients will frequently have immediate improvement in cardiac function and increased stroke volume. Pulmonary function will also improve more gradually and usually requires physical rehabilitation. It is extremely important for patients to participate in aerobic exercises, such as running or swimming, and deep breathing exercises to optimize lung expansion after their PE repair.

Reversal

We recommend removing the bar 2 to 3 years after placement. Removing the bar prematurely increases the risk of PE recurrence while delaying removal can increase the difficulty of the removal

procedure. The optimal timing of bar removal is individualized based on a patient's growth, activity level, and pulmonary function as assessed postoperatively at 6 months and then annually. For example, younger patients can tolerate the bar for 3 to 4 years while teenagers with rapid pubertal growth spurts may need only 2 years.

For bar removal, the patient undergoes general anesthesia, and the lateral incision sites from the bar placement procedure are reopened. The pericostal sutures and bar stabilizer are removed. The surgeon should then mobilize the lateral portions of the bar, pull them through the overlying skin incision, and straighten their ends. If there is osseous growth of the rib over the bar, a rongeur or hammer and chisel can help with bar mobilization. Slightly rotating the bar can also help free the bar but should be coordinated with the anesthesiology team as it can cause arrythmias. Once the bar is fully mobilized, the surgeon grasps it with a Kocher clamp and then slowly slides the bar out of the chest. Sternal elevation and thoracoscopy can aid difficult bar removal.

Vascular complications from bar removal are rare but serious. There have been case reports of life-threatening hemorrhage from laceration of the pulmonary vessels or erosion of the bar into the aorta, internal mammary artery, or sternum.

Recurrence

Recurrence of PE is defined as chest well depression after bar removal. Patients are at increased risk for recurrence if they have the bar removed prematurely, have a severe deformity, or are repaired as adults, when the chest wall is less compliant. Additionally, some young children who require operative repair will redevelop their PE during their pubertal growth spurt. Historical rates of recurrence were as high as 37%, but surgeons have lowered this rate to 1.4% with the use of stabilizers and pericostal sutures. Postoperative deep breathing exercises also improve chest wall mobility and reduce the risk of recurrence. Most patients with recurrence can be repaired with a repeat MIRPE, but surgeons should consider an open approach for patients with severe deformities or with abnormal sternocostal cartilage growth.

Open Repair of Abdominal Aortic Aneurysms

Erin E. McIntosh, MD, and Richard P. Cambria, MD

Abdominal aortic aneurysm (AAA) affects 15% of men over age 65 and accounts for up to 15,000 deaths annually in the United States. Average yearly growth is about 3 mm, though more rapid growth tends to occur in patients with risk factors such as active smoking, uncontrolled hypertension, and significant chronic obstructive pulmonary disease (COPD). Data published from multiple trials have shown that AAA should be repaired at a diameter of 5.5 cm in men and 5 cm in women, as the annual risk of rupture increases dramatically when the aneurysm sac enlarges beyond these values, and, once rupture occurs, mortality is extremely high. Current preventive medicine practices focus on screening high-risk patients for AAA and modifying risk factors, so as to decrease aneurysm sac growth and minimize rupture risk.

It is said that the overall incidence of AAA is declining. This is, in turn, felt to be related to better risk factor control—specifically improved control of hypertension and decreasing use of tobacco. As expected, there has been a resultant overall decrease in AAA repair among the Medicare population. The total number of AAA repairs in the Medicare population declined by 26% over the course of a decade, from 31,582 in 2003 to 23,421 in 2013. More specifically, the number of open AAA repairs declined by 76% during this same time period, 20,533 in 2003 to 4916 in 2013. While the total number of endovascular aneurysm repairs (EVARs) increased concurrently throughout most of the period from 2003 to 2011, they also declined a total of 15% from 2011 to 2013. Despite this, rupture of an AAA is associated with a mortality rate up to 90% and ranks 15th among the leading causes of death in North America.

Progress has been made in the early detection of AAA, as screening programs among at-risk individuals are both supported and reimbursed by insurance payors. Recommendations for screening of AAA have focused on those patients with well-appreciated risk factors of smoking, male sex, family history of aortic aneurysm, hypertension, and COPD. The latter has been amply demonstrated as a significant risk factor for aneurysm expansion and rupture. While male sex has been a well-established risk factor for AAA, more recent data suggest that the prevalence of AAA in females, especially in the setting of active smoking and positive family history, is higher than previously expected. Moreover, when the disease occurs in females, it appears to be more lethal, characterized by more extensive aneurysms, with rupture occurring at smaller sizes.

AAAs are frequently discovered as an incidental finding on imaging studies directed at other pathologies. While sequential surveillance of AAA with ultrasound is convenient and cost effective, both the precise measurement of aneurysm diameter and treatment planning, when indicated, are best determined by contrast-enhanced fine cut computed tomography angiography (CTA). As to the mode of surgical repair, it is estimated that up to 80% of elective AAA repairs are performed with endovascular technology. However, it has been our observation that operative misadventures and/or failed repair with EVAR are strongly correlated with attempts to push stent graft repair in anatomic circumstances where a considerable risk of failure exists both in the short and long term. It is certainly true that all sorts of endovascular mayhem, sometimes referred to as *chimneys, snorkels,* and even *physician-modified grafts*, has been attempted to extend endovascular repair into anatomically inappropriate circumstances. Such patients, with the proviso that they are appropriate open surgical candidates, are best treated with open surgical repair. Given the efficacy of EVAR for appropriate infrarenal lesions, open surgical repair is the technique of choice for more complex AAAs. It is our belief that there will always be a role for open surgical repair with its demonstrated durability and safety in the appropriate hands. Obviously, younger patients may prefer definitive open surgical repair and defer the perceived nuisance and/or safety considerations in lifelong radiographic surveillance. Herein we outline the principles for safe and effective open repair of AAAs.

PREOPERATIVE EVALUATION AND PLANNING FOR OPEN REPAIR

Although it is certainly true that the operative insult of open repair is substantially greater than EVAR, clinical decision making must include an assessment of life expectancy, as well as the ability to recover from a major (or minor) operation. As an example, patients with chronic or end-stage renal disease have such poor overall survival that elective repair is seldom indicated. In our practice, the overwhelming majority of AAA patients whose anatomy is amenable to stent graft repair are treated with EVAR. When the best technical option for treating the aneurysm is open surgery, risk stratification for a major operation is certainly indicated. This includes assessment of cardiac, pulmonary, renal function reserve, and perhaps most importantly, the extant functional status of the patient. Although surgeons have always appreciated that a given patient's strength and functional status is likely the most important variable in predicting complete recovery, there now exists objective criteria and scoring parameters to quantify same. Various scoring systems have been used to evaluate a patient's functional status and/or frailty to inform the decision to operate. Certain data demonstrate that preoperative functional dependency is an independent risk factor for mortality after major open surgery, including open AAA repair and EVAR. Although frailty may be more difficult than functional status to assess, data suggests that frailty is also a predictor of mortality and complications after major vascular surgical interventions.

A pertinent history will usually suffice to quantify the patient's pulmonary reserve, but pulmonary function studies may be added or desirable in the circumstance of clinically evident COPD. There is no defined threshold for a degree of COPD that would preclude open repair; it is worth emphasizing that there is a linear correlation between the degree of COPD and the risk of aneurysm rupture. Anecdotally in the years before the availability of EVAR, we have performed open aneurysm repair on patients with oxygen-dependent COPD (generally through a flank approach) and have had such patients do well. We insist that patients be free of tobacco for a month before open operation. A current serum creatinine level and GFR calculation is an important consideration, especially in patients who will require a suprarenal clamp and/or renal artery reconstruction. Converting a patient with CKD to dialysis-dependent renal failure with either open or endovascular repair is clearly a devastating complication and a death sentence for the patient. It is commonplace to encounter patients with complex AAA who have either a single functioning kidney or flow-limiting renal vascular occlusive disease. Such factors will figure prominently in operative planning as reviewed later.

The long and extensively studied history of objective parameters of cardiac risk stratification began in 1976 with the description by Boucher et al. of the dipyridamole thallium nuclear stress test to predict and prevent postoperative cardiac ischemic complications or cardiac-related death. Over the past 40 years, multiple clinical and imaging parameters have been utilized for cardiac risk stratification, and American Heart Association (AHA) guidelines advise when to apply nuclear stress testing and/or cardiac catheterization in the preoperative assessment of patients about to undergo open AAA repair. There also exists Level 1 evidence that aggressive detection and treatment of coronary artery disease before open vascular surgery produces no better outcome than optimal medical management of associated coronary artery disease. Our approach is generally consistent with the AHA guidelines and begins with a careful clinical history relative to known or previously treated coronary artery disease and the patient's exercise tolerance with respect to precipitating symptoms of exertional dyspnea or chest pain. Irrespective of seemingly benign clinical risk stratification, we maintain a low threshold to obtain cardiac functional studies (nuclear stress testing) especially in elderly patients or those with other factors such as arthritis, which might limit functional capacity. It is to be emphasized that such stress testing is not simplistically considered as "positive or negative." Rather, such functional cardiac studies are to be considered in a quantitative fashion, and if ischemic potential is identified, cardiology consultation is certainly indicated for a further discussion about the desirability for cardiac catheterization and especially to ensure optimization of an antiischemic medical regimen. In current practice, it is uncommon to go to the extent of cardiac catheterization and/or coronary angioplasty/stenting to prepare a patient for open aneurysm repair.

GENERAL PRINCIPLES OF OPEN REPAIR AND OPERATIVE PLANNING

Regardless of the various technical approaches for open repair or the proximal extent of the aneurysm, certain principles apply to ensure good results. With respect to aneurysm extent, a juxta- or pararenal aneurysm is one wherein there is insufficient neck length to permit infrarenal cross-clamp application and proximal anastomosis. A suprarenal aneurysm involves one or both renal arteries arising directly from the aneurysm and, of course, implies that separate renal artery reconstruction might be needed. A type 4 thoracoabdominal aneurysm, or total abdominal aneurysm, is one where the aneurysm extends to or slightly above the level of the celiac axis. First, a careful and precise operative plan, dictated by high-quality, fine-cut CTA imaging, is a sine qua non. The analogy to deriving a precise plan for endovascular repair extends also to open surgery. The extent of proximal and distal repair, location of suture lines and proximal cross-clamp application, and the desirability (or lack thereof) of concomitant renal/visceral artery repair are all determined by review of the preoperative CT scan. The site of proximal cross-clamp application is selected not only to allow complete resection of the aneurysm, but also specifically to avoid aortic wall fracture and/or atheromatous embolization; such information is dictated by the CTA and not by "feeling for a soft spot." We routinely use soft-jawed clamps, which have less potential for tearing a diseased aorta.

Successful open repair relies on the principles of an expeditious and bloodless operation with minimization of cross-clamp times and blood turnover. Broad surgical exposure, which absolutely requires fixed self-retaining retractor systems, is essential. Although it has been recognized throughout the history of aortic surgery that minimal blood turnover and cross-clamp times are strongly correlated with success, less emphasis has been given to performing an expeditious operation. Patients are best served with a perfect 4-hour operation, as opposed to a perfect 8-hour operation. In the era of cardiac risk stratification evolution, we performed a retrospective study of variables predictive of significant cardiopulmonary complications. The one independent variable that significantly predicted such complications was an operation that exceeded 5 hours in length. Related to this is a practical consideration to keep the repair simple in extent. To that end, we have a strong preference for tube graft reconstruction, and it is entirely appropriate to ignore minor degrees of iliac occlusive and/or aneurysmal disease. We conducted a long-term follow-up study, which indicated that subsequent iliac aneurysm repair was uncommon after tube graft reconstruction for AAA.

A vital consideration in successful open repair is the selection or determination of surgical approach best suited to a particular patient and particular aneurysm extent (Box 1). Over time, the majority of open AAA repairs were performed with a midline transperitoneal approach, familiar to the majority of vascular surgeons as an extension of their general surgery training and experience. Two variables have somewhat changed the paradigm over the past 25 years. First, master aortic surgeon, Dr. Melvin Williams at Johns Hopkins, reintroduced the advantages and facility of a left flank approach for abdominal aneurysm surgery in the 1990s; this method was originally described by Charles Rob of Rochester. Second, with the successful application of endovascular repair for most infrarenal aneurysms, open surgical repair has essentially become the preferred technique of more complicated AAAs, involving at least part of the visceral aortic segment. Related to that consideration, a surgical approach that enables continuous exposure of the entire visceral aortic segment is the preferred operation for most, if not all, such

BOX 1 Considerations for Different Surgical Approaches

Transperitoneal Approach

- Redo aortic surgery
- Explant of infected aortic graft
- Repair aortoenteric fistula
- Distal right renal artery reconstruction
- Bilateral transaortic renal endarterectomy

Left Flank Retroperitoneal Approach

- Decreased risk of prolonged ileus
- Proximal aortic lesions
- Ease of exposure for repair of complex lesions
- Exposure of large AAAs
- Hostile abdomen
- Horseshoe kidney
- Abdominal wall stoma
- Morbid obesity

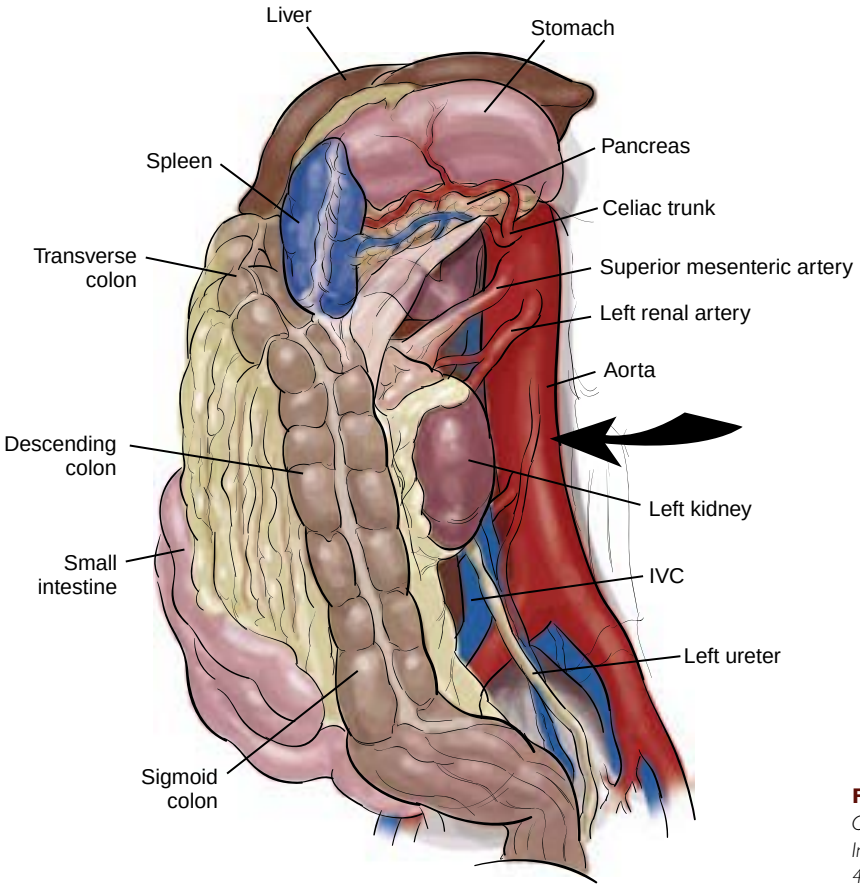

FIG. 1 **Left-sided medial visceral rotation.** *(From Aylwin C, Jenkins M. Abdominal Aortic Trauma, Iliac and Visceral Vessel Injuries. In Rasmussen TE, Tai NRM:* Rich's Vascular Trauma, *4th Edition, Philadelphia: Elsevier; 2022, 212–225.)*

complex aortic lesions. Note that we refer to this method collectively as a "left flank approach," as it has been our observation that there is much confusion about what is referred to as a "left retroperitoneal approach." The latter can, in fact, be performed at a variety of levels with respect to the intercostal spaces and is dictated by the proximal extent of the aneurysm and, importantly, patient body habitus. In addition to these considerations, vascular surgeons are familiar with other considerations that might dictate a left flank approach, such as a hostile abdomen, abdominal wall stoma, horseshoe kidney, and obesity. The evidence base with respect to the advantages of a left retroperitoneal approach would indicate that the only objective benefit is less disturbance of gastrointestinal function; while this is indeed true, it does not consider the facility of a left flank approach for more complex abdominal aneurysms, as previously noted. We have performed a strictly extraperitoneal approach by resection of a portion of the 11th rib and reflecting the peritoneal envelope right and medially. Again, dependent on body habitus, this method can afford adequate exposure for a pararenal aneurysm but has definite limitations for more proximal lesions. Accordingly, an 8th or 9th interspace thoracoabdominal incision with division of the solid portion of the costal margin has become our preferred approach for most aneurysms that require open operation in contemporary practice. It has also been our observation that the "morbidity" of such thoracoabdominal incisions is unfounded myth, as if entering the pleural cavity and partly dividing the left hemidiaphragm well away from the phrenic nerve is some major escalation of operative insult for the patient. While it is possible to keep the abdominal portion of such an incision entirely extraperitoneal, this is neither necessary nor desirable, as it is time consuming and bloody to peel the peritoneum off the undersurface of the left hemidiaphragm. For most aneurysm cases, the left-sided medial visceral rotation includes sweeping the left kidney out of its bed. Alternatively, in circumstances such as a retroaortic left renal vein or when this same incision is used for visceral segment endarterectomy or antegrade mesenteric bypass, the left kidney is left in situ (Fig. 1).

TECHNICAL DETAILS OF OPERATION

Midline Transperitoneal Approach and Its Variations

While our preference is for a left flank approach for the majority of complex abdominal aneurysms, as stated above, it is certainly true that the midline anterior approach is adequate for the majority of pararenal aneurysms, again after consideration of the patient's body habitus. We do not agree that a midline anterior approach is mandatory for some of the specific considerations that have previously been championed, such as a patient who requires reconstruction of the right renal artery or a right common iliac level anastomosis. Indeed, with appropriate patient positioning an aortobifemoral distal reconstruction can be performed in conjunction with a left flank approach. When the surgeon selects a midline anterior approach, familiarity with the variations and extensions of this operative incision is mandatory for the safe conduct of operation. These extensions include, in order of increasing application, wide mobilization of the left renal vein by ligation and division of its branches, extending proximal exposure by performance of a right-sided medial visceral rotation maneuver, and supraceliac clamp application through the lesser sac. The technique of midline transperitoneal exposure of the aorta follows a series of routinely performed steps in the following order: (1) mobilization of the entire omentum, transverse colon, and its mesentery superiorly, (2) division of the ligament of Treitz, (3) ligation and division of the inferior mesenteric vein and the peritoneum on the caudal border of the pancreas, which will allow superior retraction of the pancreas, and (4) evisceration of the small bowel

onto the right upper abdomen (although this step can be omitted in some patients in favor of simply packing the small bowel in the right side of the abdomen before placing the self-retaining retractor). We eschew division of the left renal vein because this maneuver entails at least transient left kidney dysfunction. Furthermore, after ligation of the adrenal, gonadal, and left renal lumbar vein, the left renal vein can be broadly mobilized and retracted superiorly or inferiorly to gain adequate exposure. We nearly always surround the aorta with an umbilical tape to ensure that the cross-clamp provides secure control.

Perhaps the only circumstance where we plan supraceliac clamp application from a midline transperitoneal approach is redo aortic surgery for graft infection and/or aortoenteric fistula. However, this cross-clamp scheme can be life-saving in the circumstance of operative misadventure in elective surgery or proximal control in the setting of ruptured AAA. Not only is this maneuver inconvenient in terms of working on both sides of the transverse mesocolon, but it can be quite difficult in mesomorphic individuals. The important technical steps of this maneuver are division of the ligament tethering the left lobe of the liver, entering the lesser sac, ensuring the orientation of the esophagus with an indwelling nasogastric tube, and dissecting off the fleshy portion of the diaphragmatic crura, which of course lies anterior to the aorta at this point. The surgeon works cephalad to the point where the median arcuate ligament crosses the aorta anteriorly. When a cross-clamp is applied at this level, the surgeon should endeavor to move it to a more distal location once the pararenal aorta is totally dissected out and secured.

The right-sided medial visceral rotation maneuver to extend exposure of the pararenal aorta and lower visceral aortic segment is not often utilized and is likely unfamiliar to many vascular surgeons. If this maneuver is needed, the patient would have been better served by a left flank approach. However, this maneuver can be life-saving in the circumstance of intraoperative complications or can greatly facilitate a graft reconstruction of the right renal artery. The technical steps of this maneuver involve extending the midline posterior peritoneal incision around the right paracolic gutter and, thus, mobilizing the entire right colon in continuity with the duodenum. This shifts the axis of orientation of the superior mesenteric artery (SMA) and the root of the mesentery from a 45-degree angle toward the right lower quadrant to a 90-degree angle where all of the abdominal viscera are now reflected and eviscerated onto the patient's chest. Sharp dissection of the neurosplanchnic tissue at the origin of the SMA, sometimes supplemented by sharp incision of the anchoring tendons of the diaphragmatic crura on either side of the aorta, will permit clamp application at or even cephalad to the SMA. This exposure can be utilized for combined aortic graft replacement in conjunction with bilateral transaortic renal endarterectomy.

Left Flank Approach

For the treatment of complex AAAs, as opposed to extent 1-3 TAAA, an 8th or 9th interspace thoracoabdominal incision will typically suffice. As previously noted, this is our strong preference for most lesions, although the retroperitoneal, extrapleural approach with partial resection of the 11th rib will suffice in patients of appropriate body habitus and pararenal aneurysm. The differentiating feature between the two incisions is division of the solid portion of the costal margin with partial lateral division of some of the left hemidiaphragm. Thereafter, the technical steps of operation are identical.

The patient is positioned in a right lateral decubitus position, but it is unnecessary and undesirable to have most of the chest in full lateral position. The hips are then rotated such that they are nearly flat, especially if an aortobifemoral reconstruction is contemplated. The incision extends about halfway posterior on the incident rib and posterior shingling, or division of the rib, is unnecessary. The costal margin is divided, and the internal mammary vessel secured. At this point, the left hemidiaphragm is divided laterally and posteriorly for a distance of about 6 inches, and this easily preserves phrenic innervation to the left hemidiaphragm. Now, the self-retaining retractor system is placed, and the field is set up in a totally infradiaphragmatic orientation. The left-sided medial visceral rotation maneuver is carried out by elevating the left kidney out of its bed after incising Gerota's fascia. Inferiorly, the left ureter is identified, swept medially, and protected with laparotomy pads when blades of the self-retaining retractor system are placed upon it. Fracture of the splenic capsule is commonplace, and there should be no hesitation to remove the spleen.

As the field is set up, the left kidney and the entire viscera are packed away to the right side of the abdominal cavity without the need for evisceration. The next step in the procedure is to identify the left renal artery, coursing just cephalad to the left renal lumbar vein, which is divided. The left renal artery is now dissected back to its aortic origin; in circumstances of very large aneurysms, it is common to find that the left renal artery origin is tucked at or even under the median arcuate ligament as it courses from the anterior aspect of the aorta to insert posteriorly on the bony elements. A right angle clamp is placed under the median arcuate ligament, which is then divided with the Bovie apparatus beginning the exposure of the visceral aortic segment. The left crus of the diaphragm is divided until the posterior mediastinum is encountered. Now, dissecting medially, the origins of the visceral vessels are circumferentially dissected out and the supraceliac aorta is encircled with a vessel tape (Fig. 2). Deliberately discerning the origin of the right renal artery is usually possible in pararenal or even suprarenal aneurysms; this is not advisable in the case of extent four thoracoabdominal aneurysms. Such complete dissection of the visceral aortic segment may be a necessity depending on the proximal extent of the aneurysm.

From the left renal artery origin, the posterolateral aspect of the aneurysm neck and the aneurysm is dissected free of retroperitoneal tissue, and ligation and division of the inferior mesenteric artery may be desirable to facilitate exposure of the aortic bifurcation. The iliac arteries are not circumferentially dissected and are nearly always controlled with intraluminal balloons. The proximal cross-clamp location, as dictated by preoperative imaging studies, can be supraceliac, between the celiac and SMA, or above one or both renal arteries. Sometimes an immediately infrarenal neck can be severely angulated in the case of large aneurysms and the surgeon may encounter a circumstance where an infrarenal clamp will not suffice. If the left renal artery originates from aneurysmal tissue, which requires resection or harbors a tight ostial stenosis, a side-arm left aortorenal bypass is performed with such a graft constructed before cross-clamp application. Installation of 4°C renal preservation solution directly into the renal arteries is used when a suprarenal or supravisceral clamp is applied. After cross-clamp application and

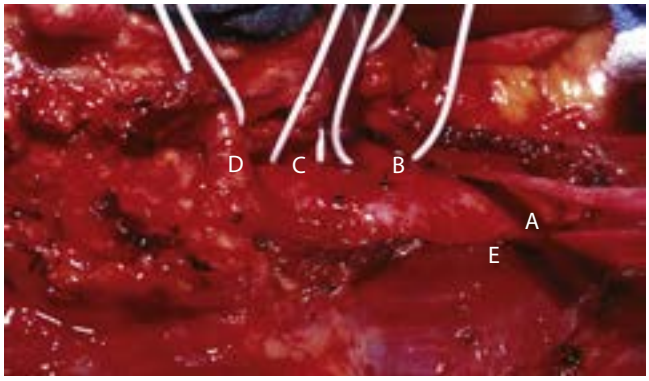

FIG. 2 Exposure of the visceral aortic segment with umbilical tape encircling the lower descending thoracic aorta *(A)*, white vessel loops around the celiac *(B)*, SMA *(C)*, and left renal artery with the left kidney rotated anteromedially *(D)*. Also visible is the left crus of the diaphragm, which is incised to facilitate exposure of the posterior mediastinum, allowing dissection of the visceral aortic branches *(E)*.

opening of the aneurysm, 12 French Foley balloon catheters are used to control iliac back-bleeding and the lumbar vessels are oversewn. The management of the proximal aortic cuff will vary with individual patient anatomy.

In circumstances where the graft can be sewn to an infrarenal aortic cuff, we strongly prefer circumferential division of the aorta for a more precise performance of the proximal anastomosis. However, when the aneurysm extends more proximally and the aortic cuff aortotomy becomes more beveled, the posterior wall of the aorta is left intact and the caudal border of the right renal artery ostium becomes the starting point for an oblique anastomosis, the posterior wall of which is performed in Creech fashion. In circumstances of significant ostial stenoses of the right renal artery or SMA, concomitant button eversion endarterectomy or, more preferably, direct ostial balloon expandable stenting is performed (Fig. 3). This adjunct can also be used at the ostium of the right renal artery if there is any question that the suture line has compromised same. The surgeon's goal should be to complete the proximal anastomosis with a clamp time of 20 to 30 minutes, and with renal cold preservation, major postoperative disturbance of renal function should be rare. Following completion of this proximal anastomosis, left renal artery reconstruction is completed in circumstances where the anatomy dictates. Polytetrafluoroethylene (PTFE) graft is preferred for this reconstruction for ease of handling, as opposed to attempting a Carrel button reimplantation. This left aortorenal graft does need to be carefully planned both in terms of length and orientation from the main aortic graft to prevent kinking and occlusion of the reconstruction when the left kidney is returned to its anatomic position. As previously noted, the distal reconstruction is almost always to the aortic bifurcation, although individual iliac anastomoses can certainly be performed through this approach if necessary. Similarly, tunneling for an aortobifemoral graft is accomplished without difficulty by extending the abdominal incision more inferiorly and rotating the operating table to the left.

SPECIAL CONSIDERATIONS IN OPEN REPAIR OF RUPTURED AAA

As in elective repair, vital information is gleaned from the preoperative CT scan with respect to the important considerations of the potential for endovascular repair versus the need for open operation. Clearly, factors such as the operating room environment and experience of the surgeon will also strongly influence this decision. Presuming that the patient will be treated with open operation, the same algorithm of which surgical approach to apply and the likely site of proximal aortic cross-clamp application must be decided. Also influencing this decision is the topography of rupture as displayed on the CT scan. If, for example, the retroperitoneal hematoma is inferior and/or on the right side of the abdomen, a left flank approach can be utilized with the expectation that rapid proximal aortic control

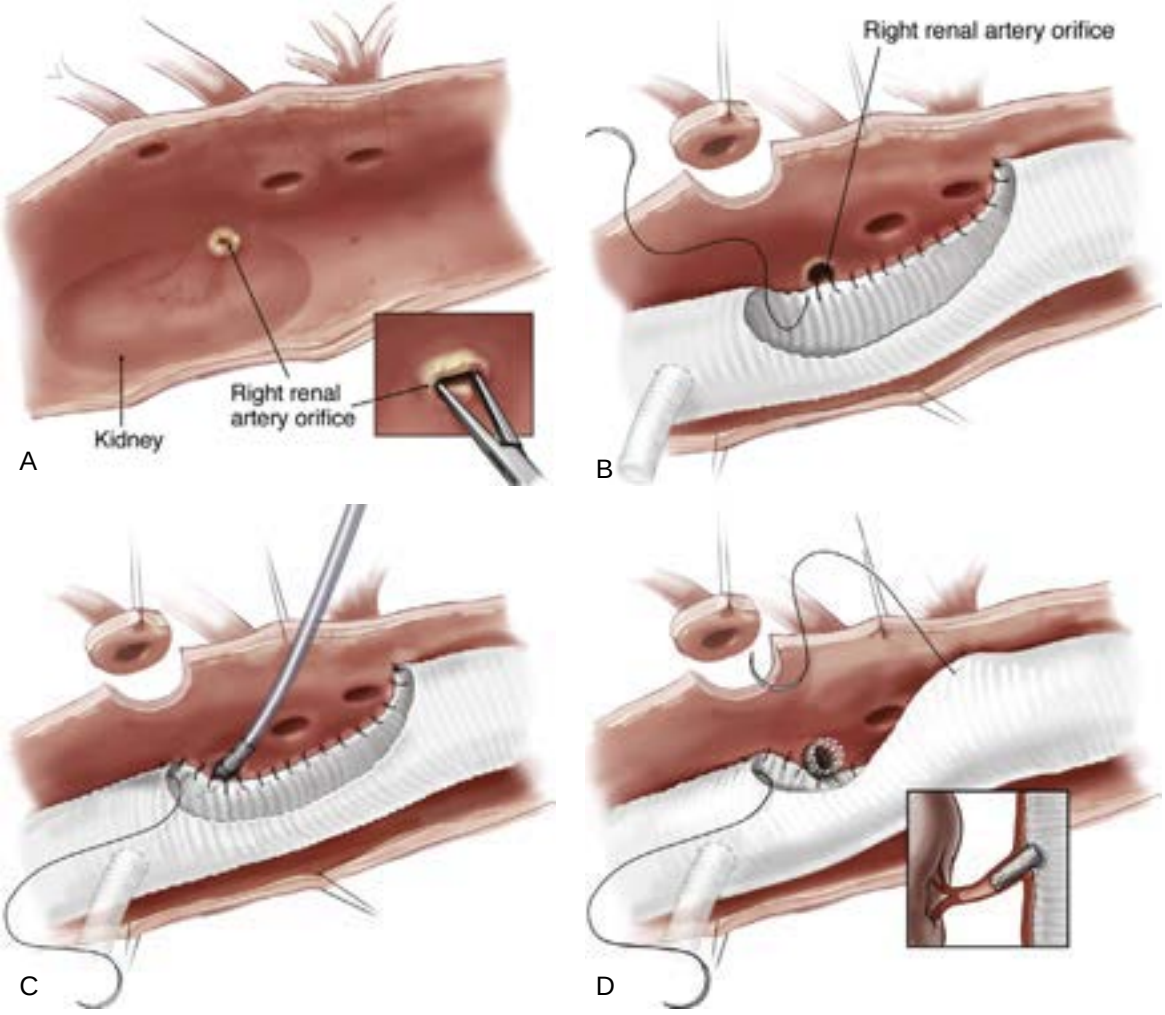

FIG. 3 Direct ostial balloon expandable stenting of the right renal artery in circumstances of significant ostial stenoses of the right renal artery (or SMA). *(From Patel R, Conrad MF, Paruchuri V, Kwolek CJ, Cambria RP. Balloon expandable stents facilitate right renal artery reconstruction during complex open aortic aneurysm repair.* J Vasc Surg. *2010;51:310–315.)*

in clean surgical planes can be anticipated. Alternatively, if the CT scan displays rupture or hematoma along the course where a left flank approach would proceed, the disaster of entering the rupture before proximal control can occur. In this situation, the patient is best served by a more proximal thoracoabdominal incision to facilitate supradiaphragmatic aortic control of the lower descending aorta. That being said, and depending on the clinical condition of the patient, most vascular surgeons would assume that the most rapid control would be that achieved with a midline transperitoneal approach, and we agree with this if the aneurysm is infrarenal or pararenal in extent. Dissecting the supraceliac aorta, as previously detailed, is a very useful adjunct in the clinical circumstance of a ruptured aneurysm being treated through a midline transperitoneal approach. Irrespective of the actual site of rupture, the retroperitoneal hematoma frequently surrounds the aneurysm neck and sets the stage for potential injury of the left renal vein in the hurried attempt to obtain proximal control. Blunt dissection in the hematoma of the aortic neck can be a helpful adjunct to ascertain a position for cross-clamp application. If hemorrhage occurs, the supraceliac clamp can be applied until the aneurysm neck and pararenal aorta are dissected out in the hopes of repositioning the clamp below the visceral vessels. We do not administer heparin in circumstances of ruptured aneurysms. However, after the iliac arteries are balloon-occluded with Foley catheters, regional heparin can be used to fill the iliac vessels and prevent thrombosis. Blood and fresh-frozen plasma must be administered concomitantly, and diffuse coagulopathy can be anticipated with either prolonged operation, excessive blood loss, or long cross-clamp times. Every attempt should be made to complete a tube graft type of reconstruction, yet adequate lower extremity circulation must be verified. If hemostasis in the retroperitoneum is not secure, packing of the abdomen with an anticipated return to the operating room within 24 to 48 hours after correction of coagulopathy is a very reasonable approach. In addition, this affords the surgeon the opportunity for a second look for left colon ischemia, which occurs frequently after treatment of ruptured AAA.

TREATMENT OUTCOMES WITH OPEN AAA REPAIR

The widespread commercial availability of fenestrated stent grafts has made a minimally invasive endovascular approach to complex AAA repair possible. As previously mentioned, while the degree of surgical insult is certainly greater with an open repair versus an endovascular one, the outcomes with open repair of complex AAA are such that we prefer this approach in select patients. Predictors of perioperative mortality in all patients undergoing AAA repair include CAD and the amount of intraoperative blood transfusion required. Predictors of cardiac complications include preoperative CHF, COPD, renal insufficiency, and intraoperative blood transfusion. COPD, the amount of intraoperative blood transfusion, and preoperative creatinine are also predictive of both renal and respiratory complications after AAA repair. The data available within the Vascular Study Group of New England (VSGNE) show that the long-term survival of the patients who underwent open repair of complex AAA from 2003 to 2011 was 91% at 1 year and 71% at 5 years, which was not significantly different from the long-term survival of patients undergoing routine open infrarenal AAA repair.

Data from a recently published multicenter, randomized trial showed that long-term survival was similar among patients who underwent endovascular repair and those who underwent open repair. While there was a difference in survival advantage seen early with endovascular repair, a late survival advantage was seen with open repair, and ultimately no difference was observed after 8 years postoperatively.

While endovascular technology continues to advance, long-term durability and/or device-specific complication rates are not yet fully elucidated. There is, therefore, a continued role for open surgical repair of AAA in a select patient population with anatomy that is not amenable to endovascular techniques.

Endovascular Treatment of Abdominal Aortic Aneurysms

Richard P. Cambria, MD, and Scott G. Prushik, MD

Abdominal aortic aneurysm (AAA) is defined as a 50% increase in diameter of a given blood vessel compared with the baseline diameter. There is a strong male predominance, with a male-to-female ratio of 6:1. AAA is fairly common, affecting 15% of men over age 65 and accounting for approximately 15,000 deaths annually in the United States. The average rate of growth of an AAA is approximately 3 mm/yr. Smoking increases the average annual growth by 20% and also increases the risk of rupture twofold. Multiple trials have established that an AAA should be repaired once it reaches a threshold of 5.5 cm in men and 5 cm in women.

Endovascular aneurysm repair (EVAR) was first performed in 1990 by Juan Parodi in Buenos Aires. The first EVAR was performed using a stainless steel bare-metal stent sutured to a Dacron graft, which was then mounted on a large angioplasty balloon and crimped inside a large sheath. The graft was then inserted and deployed through an open exposure in the common femoral artery. This successful first procedure paved the way for the current era of EVAR.

In the 30 years since EVAR was first introduced, the techniques and devices have been refined and improved. In 2003 EVAR surpassed open aneurysm repair as the preferred method, and currently approximately 80% of AAAs are repaired using an endovascular technique. EVAR has been shown to have a lower perioperative mortality rate, shorter hospital length of stay, and lower rates of early complications.

Several randomized controlled trials have compared endovascular and open aneurysm repair. These include the EVAR 1 trial, the DREAM trial, and the OVER trial. The results of the 3 trials are consistent and lead to similar conclusions. First, EVAR has lower periprocedural and 30-day morbidity and mortality rates compared with open aneurysm repair. Second, the short-term survival advantage of EVAR diminishes with time, and there are equal mortality rates between the techniques at 2 years and beyond. Finally, EVAR

is associated with higher long-term device-related complications as compared with open aneurysm repair. Therefore, the planning, accuracy of deployment, and long-term follow-up with imaging are important in achieving a good long-term result.

PREOPERATIVE PLANNING

Precise preoperative planning is essential for short- and long-term outcomes after EVAR. Procedural success depends on several factors: adequate iliofemoral access for device delivery, adequate proximal seal zone below the renal arteries, adequate distal seal between the graft limbs and the iliac arteries, and adequate length of overlap between components of the graft. To assess the patient's anatomy before the procedure, a computed tomography (CT) angiogram with fine cuts (<2.5 mm) is a necessity. The axial, coronal, and sagittal images should be reviewed, along with three-dimensional (3D) reconstructions to perform precise measurements. There are several commercially available third-party software programs that can be used to create these reconstructed images. These programs include Terarecon, M2S, 3mensio, and Intellix. These reconstructions show detailed images of the aortic lumen, branches, and aortic wall. The software can be used to generate a centerline through the aorta into both external iliac arteries, allowing for precise measurement of the distances between branch vessels to make an accurate plan in terms of the type and size of device. The length of the main body and corresponding iliac limbs are dictated by these careful centerline measurements performed using 3D reconstructions. The CT angiogram is also used to carefully inspect the aortic neck morphology in terms of calcification, mural thrombus, and diameter. It is also important to carefully assess the iliofemoral access to safely introduce and deploy the endovascular device.

ASSESSING ACCESS VESSELS

Current endovascular technology requires bilateral access for device delivery, with the most common site of entry being the common femoral arteries. It is important to assess the iliofemoral vessels for patency, diameter, calcification, thrombus, and tortuosity. If there is significant common femoral disease, an endarterectomy may be required to facilitate placement of the delivery sheath. Luminal diameter should be carefully measured to ensure that it is sufficient for placement of the device sheath safely. Iliac stenosis can be managed with angioplasty before device sheath placement. Patients with small external iliac vessels may require the creation of an iliac conduit through a retroperitoneal incision using a 10-mm Dacron graft on the distal common iliac artery. Alternatively, an endoconduit can be performed by placing a 10-mm covered stent graft followed by angioplasty. Tortuous iliac arteries are generally straightened with the use of a stiff guidewire; however, severe tortuosity may preclude safe delivery of the device.

PROXIMAL AORTIC SEAL

Achieving appropriate proximal seal between the endovascular device and the aorta depends on adequate apposition between the graft and nonaneurysmal aorta. The minimum length required for adequate seal varies between 10 and 15 mm depending on the device (Table 1). Adequate seal is assessed by measuring the aortic diameter below the level of the lowest renal artery and in 5-mm increments caudally to assess for a conical neck. The seal zone should be assessed for angulation relative to the adjacent aorta, calcification, and mural thrombus. It is important to perform these measurements in centerline, perpendicular to the wall of the aorta to ensure adequate graft sizing. If measurements are made on axial CT angiography without taking into account the centerline, the aortic neck diameter can be overestimated, leading to oversizing of the endograft and fabric infolding, resulting in possible type Ia endoleak. The proximal endograft is then oversized approximately 10% to 20% relative to the diameter of the aortic and the seal zone.

DISTAL ILIAC AND JUNCTIONAL SEAL

A nonaneurysmal distal seal zone is required in the common iliac artery for adequate distal fixation. The current devices require either 10 or 15 mm of length for adequate seal. If the common iliac artery is aneurysmal and adequate seal cannot be achieved, the graft may be landed in the external iliac artery. If the graft is sealing in the external iliac artery, the internal iliac artery must be embolized either before or as part of the aneurysm repair to prevent endoleak. In patients for whom it is important to preserve blood flow to one or both of the internal iliac arteries, Gore offers a commercially available iliac branch endograft that places a second bifurcated component into the external and internal iliac arteries to preserve pelvic flow. Iliac artery diameter measurements should be taken perpendicular to the wall of the artery, again taking advantage of the 3D reconstruction software and using the centerline measurement. Iliac limbs should be oversized between 10% and 20% just as in the proximal aortic fixation. Junctional seal should be maximized between components, generally about 3 cm of overlap, depending on the device. Once the device is placed, angioplasty should be performed on the overlap zone to prevent type III endoleak.

PATIENT SELECTION

As mentioned previously, the major selection criteria for EVAR are anatomic factors that can be used to predict outcomes. These include the diameter of the aortic neck, the length of the neck, angulation, and the distal iliac seal zone. There are currently 6 commercially available endovascular aneurysm devices that are approved by the Food and Drug Administration in the United States (Fig. 1). These current devices recommend a neck length between 10 and 15 mm and angulation between 45 and 60 degrees. One exception to the neck angulation is the Aorfix device, which allows for neck angulation up to 90 degrees. Generally, neck diameters up to 32 mm can be accommodated by current grafts.

Adherence to the instructions for use is vital to good short- and long-term outcomes. In general, vascular surgeons have had low rates of adherence to the instructions for use. It has been shown that nonadherence leads to a higher rate of endoleak and corresponding AAA sac diameter growth at 5 years. This puts patients at risk for rupture and requires a higher intervention rate. Therefore, patients who have anatomy that is not suitable for endovascular repair should be offered open surgical repair or fenestrated EVAR.

PROCEDURAL STEPS

Arterial Access

Open Femoral Access

Either a vertical or oblique skin incision is made overlying the common femoral pulse just below the inguinal ligament. The vertical incision includes the advantage of getting additional exposure to the iliac and femoral vessels if necessary; however, the oblique incision is favored by many surgeons due to a lower incidence of wound complications. The common femoral artery is dissected distal to the inguinal ligament and controlled with vessel loops. An 18-gauge access needle is then inserted into a disease-free portion of the artery, and a 0.035 starter wire is advanced into the proximal aorta. A short 6Fr sheath is placed over the wire and into the common femoral artery. A stiff wire, either an Amplatz or Lunderquist wire, is inserted into the descending thoracic aorta. A pigtail catheter with multiple 1-cm markers is introduced on the contralateral side in place just above the renal arteries. The patient is then systemically heparinized.

Percutaneous Femoral Access

Percutaneous access for EVAR has increased in popularity over the past 10 years. This approach has the advantage of shorter procedure time, less postoperative pain, and decreased risk of wound complications. Disadvantages of this approach include increased hospital

TABLE 1 Characteristics of Currently Available Endovascular Devices

Device	Graft /Stent Material	Treatable Aortic Neck Diameter (mm)	Main Body Diameter (mm)	Delivery System Size Main Body/Limb (Fr)	IFU Neck Length/Angle	Iliac Treatment Diameter (mm)	Distal Iliac Fixation Length (mm)	Proximal Fixation	Design Features
Excluder	ePTFE/ Nitinol	19–32	23–35	16–20/12–15	≥15 mm and ≤60 degrees	8–25	≥10	Infrarenal	Repositionable proximal delivery system to achieve accurate proximal landing zone
Zenith Flex	Woven polyester/ stainless steel	18–32	22–36	21/14–16	≥15 mm and ≤60 degrees	7.5–20	>10	Suprarenal	Partial proximal repositioning; shortened Z-stents inhibit kinking
Endurant II	Woven polyester/ nitinol	19–32	23–36	18/14–16	≥10 mm and ≤60 degrees or ≥15 mm and ≤75 degrees	8–25	≥15	Suprarenal	Approved for treatment of 10 mm proximal aortic neck
AFX	ePTFE/ cobalt chromium alloy	18–32	25–34	19/9	≥15 mm and ≤60 degrees	10–23	≥15	Infrarenal or Suprarenal	Unibody device provides anatomic fixation on aortic bifurcation

costs and occasional urgent conversion to open access and arterial repair. We recommend routine use of ultrasound guidance with percutaneous access to help identify an area on the anterior wall of the common femoral artery that is free of atherosclerotic plaque. A small transverse stab incision is made with an 11 blade just below the probe. The tract is then dilated above the artery using blunt dissection with a hemostat. A micropuncture needle is then inserted into the common femoral artery under ultrasound guidance, followed by the micropuncture wire and sheath. At this point arteriography is performed to ensure adequate positioning of the arterial access in the common femoral artery before upsizing the sheath. If satisfied with the access site, a 0.035 guidewire is placed, followed by a 6Fr sheath. Next, the sheath is removed, the Perclose Proglide is placed over the wire, and the wire is removed. The first Proglide is deployed in the 10 o'clock position, and the sutures are clamped with a straight snap. The 0.035 wire is replaced, the Proglide is removed, and manual pressure is held while the next Proglide device is placed over the wire. The wire is again removed, and the sutures are deployed in the 2 o'clock position. The sutures are then clamped with a curved snap and the wire is again replaced. After the Proglide is removed, manual pressure is held, and an 8Fr sheath is placed for hemostasis. This is repeated on the contralateral side. The patient is then systemically heparinized. On the ipsilateral side, the wire is exchanged for either an Amplatz or a Lunderquist wire to facilitate the placement of a large sheath. A marker pigtail catheter is placed just above the renal arteries on the contralateral side.

Device Deployment

We will describe the steps here for the deployment of a bifurcated modular graft because this is the most commonly used device. After bilateral open or percutaneous femoral access is performed, a floppy Glidewire is placed into the proximal thoracic aorta and exchanged over a catheter for a stiff wire, either Amplatz or Lunderquist. It is important always to visualize the tip of the stiff wire in the aortic arch to minimize inadvertent placement in the arch vessels, increasing the risk of stroke. A pigtail catheter is then placed through the contralateral side and placed just above the level of the renal arteries

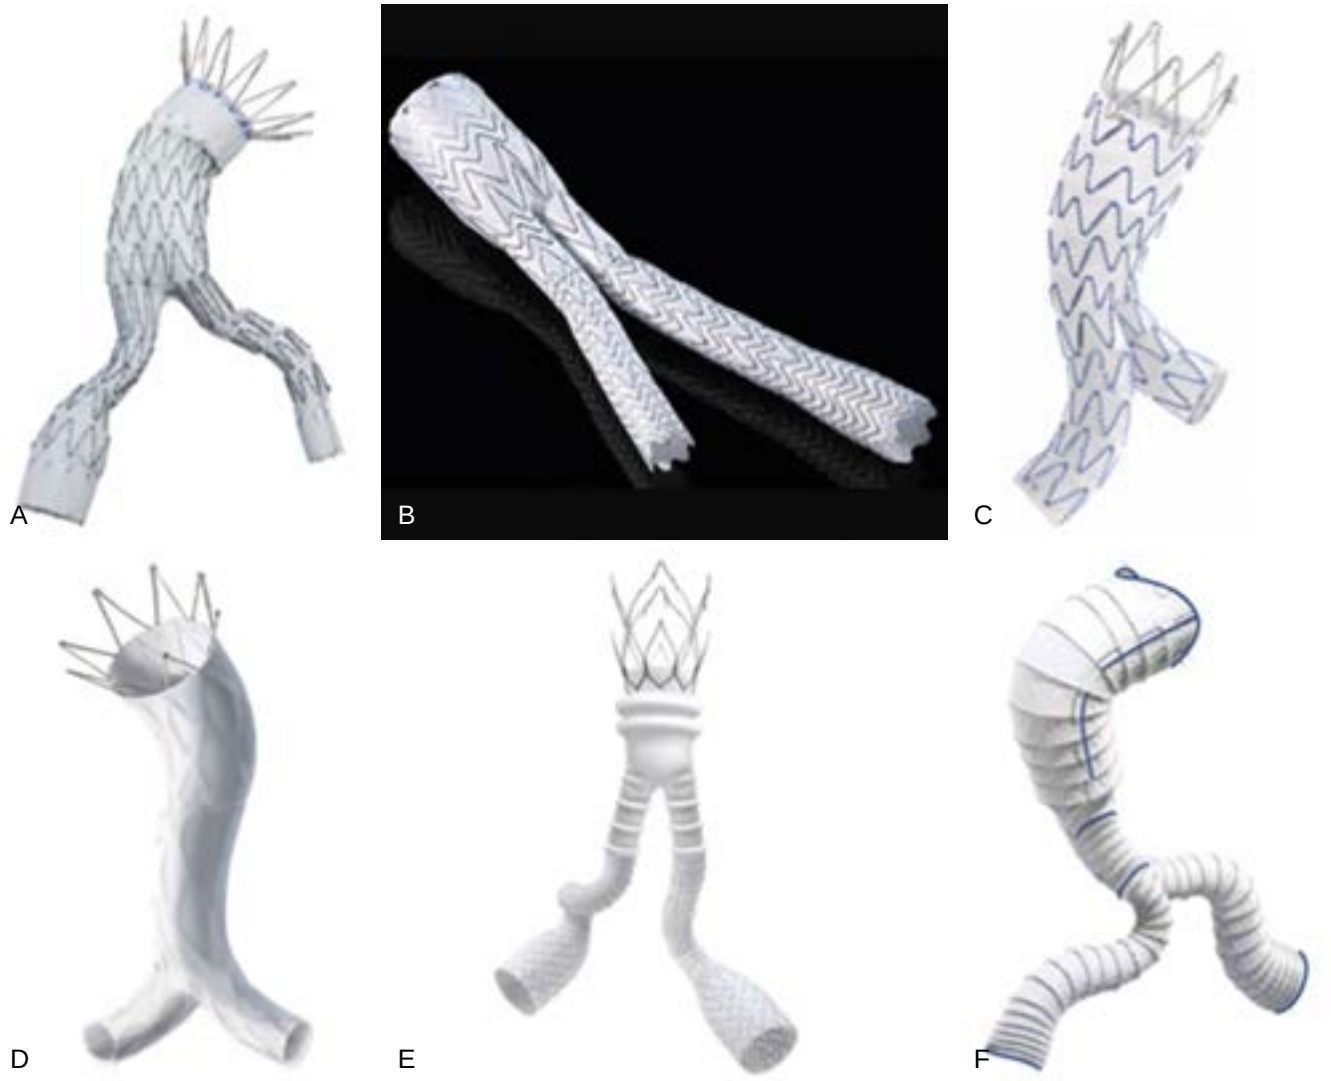

FIG. 1 Commercially available endografts. **(A)** Cook Zenith Flex. **(B)** Gore Excluder. **(C)** Medtronic Endurant II. **(D)** Endologix AFX. **(E)** Endologix Ovation. **(F)** Lombard Aorfix. *(From Brinster CJ, Sternbergh WC. Endovascular aneurysm repair techniques. In: Sidawy AN, Perler BA, eds.* Rutherford's Vascular Surgery and Endovascular Therapy. *9th ed. Philadelphia: Elsevier, 2019.)*

generally at about the L1 vertebral body. If there is a question about iliac occlusive disease or about the length of main body needed, an angiogram can be obtained now to make length measurements. However, usually, the main body is inserted through the ipsilateral side in the undeployed position, and angiography is performed to confirm the position of the renal arteries.

To properly deploy the main body, the contralateral gate should be oriented under fluoroscopy before insertion. The orientation should be confirmed as the device is being advanced to avoid the gait opening in a difficult position to cannulate. Once the undeployed graft is placed in the pararenal aorta, angiography is performed to confirm the position of the lowest renal artery, which is then marked on the screen. Initial deployment should begin about 1 cm above the renal arteries, and, as the graft is deployed, it is slowly pulled down below the lowest renal artery. After the proximal landing zone is established, the deployment continues until the contralateral gate is open. At this point, the bare-metal suprarenal stent is deployed for the devices that have it.

The next step is cannulation of the contralateral gate. This is generally performed using a Glidewire and catheter. It is important to confirm that the wire indeed has passed through the contralateral gate. This can be done by either placing a pigtail into the main body to ensure that it spins easily because it will be constrained behind the graft if not through the gate or by inflating an angioplasty balloon at the level of the contralateral gate and spinning the gantry to confirm its position within the gait. Once this is done, a stiff wire is placed, and the gantry is moved to 20-degree left anterior oblique for the right common iliac artery or right anterior oblique for the left common iliac artery. Angiography is then performed using the marker catheter to measure the length from the distal graft to the iliac bifurcation. The appropriate limb is then inserted with the least minimal overlap between device components and landed just above the takeoff of the internal iliac artery. At this point, the ipsilateral limb is fully deployed, and, if necessary and depending on the device, an ipsilateral iliac limb extension is advanced and deployed in a similar manner to the contralateral limb.

Once the graft is fully deployed, a compliant balloon may be used for gentle angioplasty of the aortic neck, device overlap zones, and distal seal. It is important not to be overly aggressive with angioplasty so as not to cause proximal aortic or iliac artery rupture. After this, completion angiography is performed. The angiographic catheter is placed in the pararenal aorta, and the following should be carefully

inspected on the angiogram: patency of the renal and internal iliac arteries, position of the proximal seal zone, flow through the graft and iliac arteries bilaterally, and inspection for endoleak.

Once the surgeon is satisfied with the result, femoral closure is performed. If open access was performed, the wires and sheaths are removed, the arteries are clamped, and repair is performed transversely with 5-0 Prolene suture. If percutaneous access was used, the sheath is removed, while leaving the wires in place to maintain access, and the Proglide device sutures are cinched down. Once adequate hemostasis is obtained, the wires can be safely removed.

Follow-up

Patients return to the office for follow-up at 1 month after surgery, at which time a CT angiography of the abdomen and pelvis is performed, which serves as the baseline study. Repeat CT angiography is performed at 1 year after surgery. Presence or absence of endoleak and aortic sac regression are determined by CT angiography, and follow-up is performed annually. Patients with shrinking aneurysm sacs and no evidence of endoleak can be safely managed with yearly duplex ultrasound scanning. Patients with enlarging sacs or endoleaks are best monitored with yearly CT angiography.

COMPLICATIONS

Endoleak

Endoleak is defined as persistent blood flow in the aneurysm sac after EVAR. This results in continued pressurization of the aneurysm sac, which places the patient at continued risk of aneurysm growth and ultimately rupture. Endoleaks can be classified in to one of five categories (Fig. 2), which help to determine the best course of treatment.

Type I Endoleak

Type I endoleak (Fig. 3) occurs as a result of an incomplete seal at either the proximal aortic sealing zone (Type Ia) or the distal iliac seal zone (Type Ib). This results in continued pressurization of the aneurysm sac, leading to sac growth. Type I endoleak is generally encountered at the time of stent graft placement or shortly thereafter, although it can be encountered at any time. Because this pressurization and aneurysm growth leads to continued risk of rupture, treatment of type I endoleak is mandatory. Proximal, Type Ia endoleak can be treated with angioplasty with a compliant balloon, proximal extension cuff if there is adequate length below the renal arteries, placement of a Palmaz stent, or with the use of the Aptus Endovascular Repair System. Treatment of type Ib endoleak can be done by deploying an iliac limb extension with embolization of the internal iliac artery as necessary.

Type II Endoleak

Type II endoleak (Fig. 4) is defined as persistent sac filling from back-bleeding side branches such as the inferior mesenteric artery, lumbar arteries, or middle sacral artery. Type II endoleak is relatively common and seen in between 10% and 20% of patients on CT angiogram after EVAR. Generally, there is a benign course with as many as 80% spontaneously resolving within 6 to 12 months of stent graft placement. It has been shown in multiple studies that the risk of aneurysm rupture due to type II endoleak is small. Therefore, treatment is only performed if there is documented sac enlargement. Treatment is generally performed through endovascular means using coil embolization or Onyx Liquid Embolic System (ethylene-vinyl alcohol copolymer). This embolization can be performed through a transarterial approach via the superior mesenteric artery or internal iliac arteries. It can also be performed from the iliac arteries and directly accessing the aneurysm sac from behind the iliac limb. If transarterial embolization is unsuccessful embolization can be attempted via either a translumbar or transcaval approach. If embolization is unsuccessful by all means and the sac continues to grow operative intervention can be performed by explant of the graft and open repair or direct ligation of back-bleeding vessels.

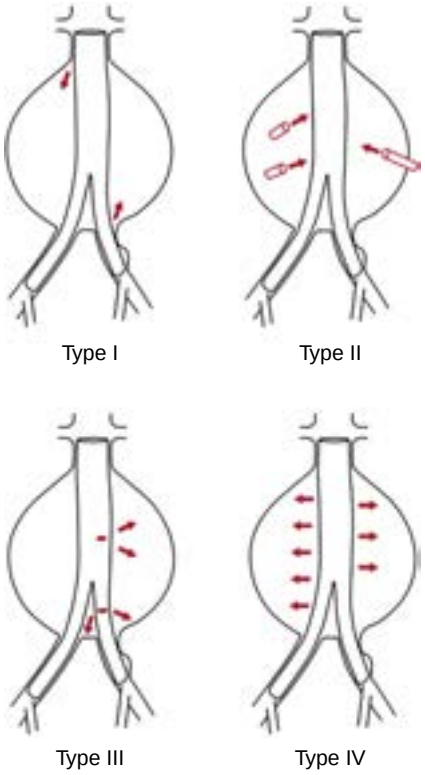

FIG. 2 Type I to IV endoleaks. Type I endoleak originates from an incomplete seal at the proximal (type Ia) and distal (type Ib) seal zones of the endograft. Type II endoleak results from back-bleeding from patent branch vessels of the abdominal aorta including the inferior mesenteric artery and lumbar arteries. Type III endoleak originates from tears in the graft fabric and from junctional leaks between graft components. Type IV endoleak results from porosity in the graft fabric.

FIG. 3 Type Ia (proximal) endoleak originating from the superior seal zone of an endograft.

Type III Endoleak

A type III endoleak (Fig. 5) occurs when there is a tear in the fabric of the graft or flow between separate components of the graft. This

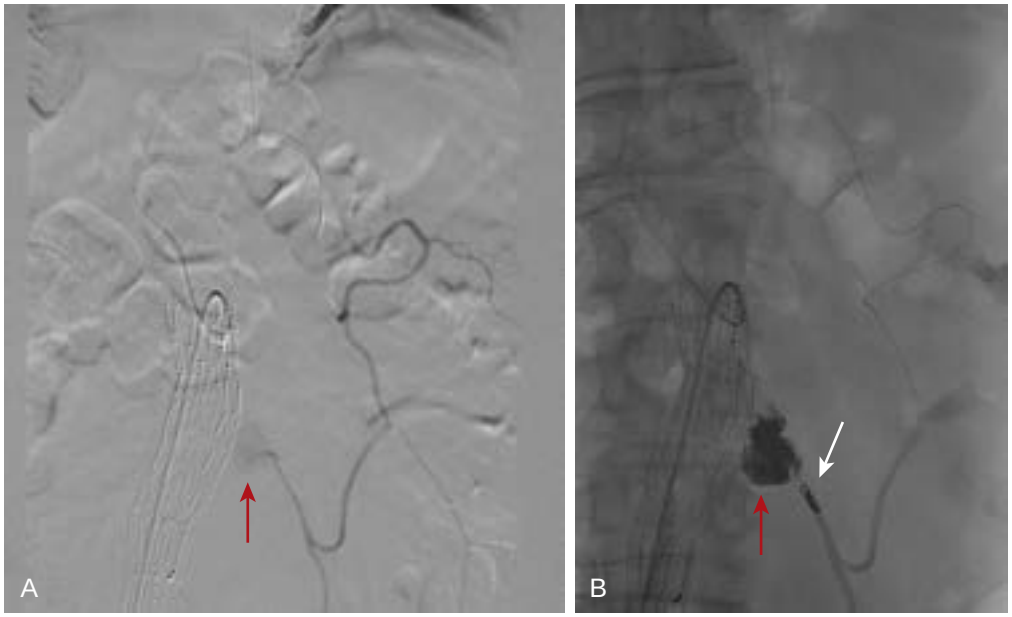

FIG. 4 Type II endoleak from the inferior mesenteric artery. **(A)** Angiography performed via selective catheter placement in the superior mesenteric artery demonstrates a blush at the ostium of the inferior mesenteric artery *(red arrow)* feeding an enlarging abdominal aortic aneurysm sac. **(B)** Coil embolization of the endoleak with Onyx glue *(red arrow)* and coil embolization *(white arrow)* of the inferior mesenteric artery.

leads to continued pressurization and sac enlargement increasing the risk of rupture as in type I endoleak. Therefore, treatment of type III endoleak is again mandatory. Treatment involves placement of a cuff or a new limb to bridge the gap between separated components. Treatment may require relining the graft with a new stent graft, which is generally performed using an aorto uni-iliac device along with a femoral-femoral bypass and coil embolization of the contralateral common iliac artery.

Type IV Endoleak

Type IV endoleak is related to flow through the graft due to the porosity of the fabric. It is rare to encounter this type of endoleak with the current generation of stent grafts. Typically, no treatment is necessary, and the endoleak resolves as the graft interstices thrombose.

Type V Endoleak

This type of endoleak is referred to as *endotension* and is defined as sac enlargement without an identifiable endoleak on imaging studies. There are several proposed theories behind type V endoleak. One theory is that the flow into the aneurysm sac is so slow that it cannot be detected with current imaging techniques. Another theory postulates that pressure is transmitted across thrombus in the aneurysm sac maintaining sac pressure. Regardless of the mechanism, continued sac pressurization leads to ongoing risk of rupture. Close follow-up is recommended to determine the rate of growth and the necessity of repair. Repair is performed through relining with a new graft or with explant and open repair.

Graft Limb Occlusion

Occlusion of one graft limb occurs in about 3% of patients and usually occurs in the first 6 months after EVAR. It is more common with aortoiliac occlusive disease, a small distal aorta, or tortuous iliac arteries. It was more common in stent grafts with unsupported limbs; however, in the current generation of stent grafts, with supported limbs, lower limb occlusion rates have been noted. Most patients with limb occlusion present with buttock, thigh, or calf claudication. Rest pain or acute limb ischemia occur but are less common. Several approaches have been used to treat limb thrombosis including thrombolysis, angioplasty, and stent placement to straighten out kinks. Open surgical approaches include femoral-femoral bypass, axillary-femoral bypass, axillary-bifemoral bypass, or surgical thrombectomy.

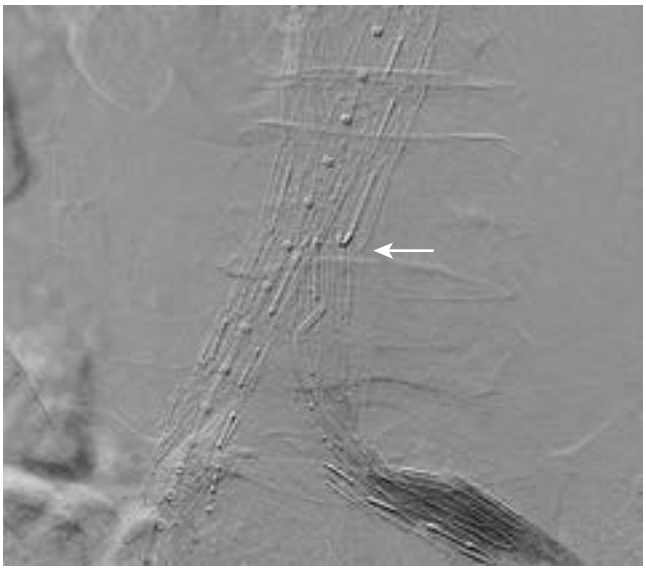

FIG. 5 Type III endoleak from separation of the limb from the main body of the graft *(arrow)*.

Ischemic Complications

Ischemic complications after EVAR stem from one of several mechanisms, including direct vessel occlusion, atheroembolization during manipulation and device deployment, and inadequate collateralization of the mesenteric and pelvic circulation. Pelvic ischemia can present as buttock claudication, buttock necrosis, spinal cord ischemia, colon ischemia, and erectile dysfunction. Pelvic ischemia can occur frequently after EVAR, especially sexual dysfunction and buttock claudication, which should be discussed with the patient

during the consent process. It generally occurs after embolization of one or both internal iliac arteries for the treatment of common iliac artery aneurysm. Buttock claudication can occur in more than 50% of patients with unilateral internal iliac artery embolization and more than 60% with bilateral internal iliac artery embolization. Erectile dysfunction occurs in 17% of patients with unilateral internal iliac artery embolization and 24% with bilateral embolization. Although the incidence of buttock claudication is relatively high, approximately two-thirds of patients report resolution of symptoms within 1 year of EVAR. Although mesenteric ischemia has a high mortality rate after aneurysm repair, it is seen in less than 2% of endovascular procedures. Spinal cord ischemia is an extremely rare event after endovascular AAA repair and has been reported in less than 0.5% of cases.

Renal Artery Occlusion

Renal artery occlusion either occurs from coverage of the origin of the artery by the graft or through embolization. Upward movement of the graft after deployment is uncommon. Usually, renal artery coverage is a complication that occurs as a result of deploying the graft too high, either from misjudging the location of the fabric relative to the radiopaque markers on the graft or due to parallax if there is improper gantry position. If coverage is detected on the completion angiogram, attempts should be made to salvage the kidney. If there is some flow identified over the top of the graft, this can usually be accomplished by placing a stent into the renal artery orifice, which is easiest from a left brachial approach. If the renal artery cannot be visualized and a wire cannot pass, it is sometimes possible to pull the graft down slightly to make a small channel for the wire. This can be accomplished with gentle traction downward with a compliant balloon inflated in the main body or with a wire snared up and over, "flossing" the graft to allow for traction. If all of these techniques fail, open splenorenal or hepatorenal bypass may be necessary. Embolization to the renal arteries can present with early or delayed renal insufficiency. This is especially true when there is thrombus in the aortic neck and a graft with suprarenal fixation is used.

Management of Ruptured Abdominal Aortic Aneurysms

David P. Stonko, MD, MS, and Caitlin W. Hicks, MD, MS

INTRODUCTION

Ruptured abdominal aortic aneurysm (rAAA) is a surgical emergency associated with high morbidity and mortality. Time to diagnosis, appropriate referral, and expeditious time to operation are crucial to achieving favorable outcomes. However, early detection and prevention provide the best treatment.

Risk factors for aortic rupture include smoking, which is the greatest risk factor for development of AAA, size, rapid growth, tenderness, chronic obstructive pulmonary disease, family history, peripheral artery disease, genetic predilection, and female sex. Although female sex is associated with an increased risk of rupture compared with male sex, females are less likely to have an AAA than men. Males 50 years of age and older who have smoked more than 100 cigarettes in their lifetime have a high rate of AAA and should be screened with a one-time abdominal ultrasound examination, which is reimbursed by Medicare.

Not all AAAs will be detected early, and some will progress to rupture. Historically rAAA has been associated with in-hospital mortality as high as 40% to 50%. Despite advances in critical care, transfer protocols, and centralization of care, this figure was stable across numerous studies for over 40 years. However, in 1994 the first endovascular aortic aneurysm repair (EVAR) for rupture was performed, which over the last 20 years has resulted in a paradigm shift toward endovascular management of rAAA. Since the introduction of EVAR, studies have shown an improvement in rAAA in-hospital mortality, with current estimates as low as 20%. Despite this encouraging improvement, there has been no proven mortality benefit for EVAR versus open repair for a rAAA in the long term.

PRESENTATION, DIAGNOSIS, AND INITIAL MANAGEMENT

Most AAAs are fusiform and are usually not associated with pain or other symptoms before rupture. The onset of abdominal or back pain portends impending or ongoing rupture, and these patients should be regarded as such, especially in the setting of a known AAA. Classically, patients with rAAA also present with a pulsatile abdominal mass and shock physiology including hypotension and tachycardia. However, most patients with rAAA do not actually present with the complete triad of signs and symptoms, and a high clinical suspicion of aortic pathology is necessary.

Several broadly held misconceptions exist about the diagnosis and natural history of rAAA. In the absence of other pathology, patients with rAAA will likely have a normal lower extremity pulse examination, may or may not have an abdominal bruit or thrill, and, though mortality for rAAA is high, death may not occur immediately as the rupture is often contained initially by the retroperitoneum (RP). The rAAA may take several hours to evolve to uncontained rupture and death.

The initial evaluation of a patient with a suspected rAAA should follow the typical airway, breathing, and circulation (ABC) protocol. Immediate management should focus on obtaining adequate venous and arterial access, cardiac monitoring, laboratory analysis including type and screen, and blood product preparation. As discussed in detail later, patients with rAAA should not be intubated until they are in the operating room, and the focus should be on initial blood pressure and heart rate control (SBP < 120, HR < 80) to reduce circulatory impulse

and slow the progression of rupture. If the patient is hypertensive, impulse control should be established with a short-acting agent such as esmolol or labetalol. This is particularly important in patients with a contained rupture. Fluid and vasopressor support should be limited to maintain impulse control, prevent further rupture or aortic tearing, and limit additional blood loss. This is contrary to the treatment of most patients presenting with hypotension, but it is critical in the management of rAAA. Once aortic control is obtained in the operating room, the transfusion strategy can be augmented as described later.

In practice, patients presenting with abdominal or back pain and vital sign changes will usually undergo computed tomography angiography (CTA) for diagnosis. Given the efficiency of CTA in the modern era, cross-sectional imaging should be obtained whenever possible to facilitate endovascular operative planning for treatment of rAAA and rule out other pathology. Many other conditions would likely be on the differential for patients presenting with rAAA, including perforated viscus, gastric or small bowel ulcer, hepatobiliary pathology, cardiac pathology, nephrolithiasis, pancreatitis, and other vascular etiologies such as aortic dissection. Prior studies have shown that CTA does not delay time to the operating room and can determine anatomic suitability for EVAR (Box 1). Conventional transabdominal ultrasound, although useful for screening AAA, is not sensitive for rupture and does not provide the anatomic information necessary to provide objective measurements to determine anatomic suitability for EVAR.

Time to hemorrhage control and aortic balloon occlusion is of the utmost importance when treating a patient with rAAA. No other vascular pathology carries the same consequences of delay. If the diagnosis is made and the facility can provide definitive management, then they should proceed accordingly. However, if the facility is unable to provide definitive care, then transfer should be arranged expeditiously. Prior studies have shown that transfer of patients with rAAA from smaller hospitals to those with aortic centers did not increase mortality and possibly improved it. This pattern held, even when the same surgeons were performing the procedure across both hospitals. If the patient is to be transferred, initial critical care management as described earlier should be started in parallel. CT imaging can also be transferred electronically to support preparation on the part of the receiving institution, surgical team, and operating room staff.

ENDOVASCULAR VERSUS OPEN REPAIR

Four large randomized clinical trials comparing EVAR versus open rAAA repair have been conducted to date: NOTTINGHAM, IMPROVE, ECAR, and AJAX. None of these trials demonstrated a survival advantage for EVAR over open surgery in the long term, though EVAR has been shown to have lower in-hospital morbidity and mortality. EVAR, however, has been associated with a higher rate of postoperative abdominal compartment syndrome (ACS) than open rAAA repair, likely because the hematoma from the rupture is not evacuated (discussed later).

Because of the improved in-hospital mortality and lower morbidity associated with EVAR, many centers have adopted an EVAR-first strategy for the treatment of rAAA patients. Typical anatomic requirements can be assessed with preoperative CTA. If the aneurysm neck is too short or too angulated for EVAR (see Box 1), then open repair may be necessary. In addition, if renal perfusion cannot be maintained with an endovascular approach, then open repair should be used. It is not appropriate to sacrifice the renal arteries to perform EVAR and thereby commit the patient to hemodialysis. The fluid shifts after EVAR related to the hemorrhage and resuscitation are substantial, and rAAA outcomes in hemodialysis patients are poor.

There are currently several devices approved by the US Food and Drug Administration for endovascular repair of an infrarenal AAA. Data and outcomes measures on each of these devices vary, but approximately 50% to 75% of all rAAAs are anatomically amenable to EVAR. It is possible to use EVAR outside the officially approved Instructions for Use (IFU). This technique may temporize rAAA patients who are poor candidates for open rAAA repair, but the long-term outcomes of an off-IFU EVAR application are marginal. In the future, as more sophisticated devices covering larger anatomic variability become available, the number of patients who will be anatomically suitable for EVAR is expected to increase.

BOX 1 Typical Anatomic Requirements for EVAR for Ruptured AAA

- Aortic neck diameter less than 32 mm
- Aortic neck angulation less than 60 degrees
- Limited aortic thrombus and calcification (relative)
- Parallel wall and undilated aortic neck length at least 15 mm below the lowest renal artery
- Appropriate-size iliac arteries without excessive tortuosity or occlusion, and at least a 10-mm seal zone

TECHNIQUE

Operating Room Preparation and Retrograde Balloon Occlusion of the Aorta

Regardless of whether an endovascular or open repair approach is planned, the initial operative management of a patient with rAAA is the same. The patient should be prepped and draped widely, including the bilateral groins and abdomen at a minimum. In general, all preparation of the patient, including intravenous access, arterial lines, and sterile preparation, should be performed before induction of anesthesia. This is important because for patients at the extent of their physiologic reserve, loss of preload with induction can result in cardiovascular collapse. Close discussion with anesthesia about the patient's hemodynamic status and the surgical plan is important.

Once adequate access is obtained, balloon occlusion of the aorta should be established. Local anesthesia should be used when possible for this step to allow for aortic control before induction of general anesthesia. Percutaneous common femoral artery (CFA) access should be obtained using ultrasound guidance, followed by stiff wire placement into the thoracic aorta, a 12Fr sheath, and an occlusion balloon. Pre-placement of closure devices may be done at this time or at the end of the case depending on patient stability, body habitus, and other clinical factors.

Occasionally, iliac vessel access may be difficult. The goal is to build a stable platform for sheath placement. The iliac arteries can be navigated with a guidewire followed by a straight or angle-tipped catheter and then exchanged for a stiff wire once aortic cannulation is obtained. The stiff wire will often straighten tortuous iliac arteries, making placement of a large-bore sheath more feasible. The goal of access and sheath placement is to maneuver the sheath through the iliac arteries without creating a dissection or other injury. For patients with extensive atherosclerotic disease, the iliac may need to be stented after straightening (crack and pave), allowing the graft to seal within the stent.

Once sheath access is obtained, the aortic occlusion balloon should be rapidly introduced to a level just proximal to the rupture. This allows for hemodynamic stabilization by both occluding flow into the rupture and increasing afterload. Once the balloon is up, progression toward definitive EVAR or open repair can follow.

Endovascular Repair

Once the aortic occlusion balloon is in place, diagnostic imaging can be obtained to identify the takeoff of the renal arteries. The next step in EVAR repair is deployment of the main body of the stent graft. After obtaining contralateral access, there are two main approaches to this: (1) fully deploy the main body; deflate the aortic occlusion

balloon and insert it into the stent graft; and then reinflate it at the proximal edge of the stent graft to maintain hemodynamic control during gate cannulation or (2) deploy the main body; remove the balloon; and then proceed with gate cannulation in the usual fashion because there is often sufficient seal with the main body in place. Gate cannulation can be the most time-consuming step of the case. It is important to have all necessary wires and catheters available nearby to avoid delays. Once the main body is deployed and the gate is cannulated, one may proceed with managing the distal segments. Here, either an aortouniiliac with femoral-femoral bypass or a bi-iliac stent graft may be used. The distal landing zone of the stent should be beyond the involved portion of the aneurysm but also beyond any substantially diseased portion of the iliac arteries. This will commonly be to the takeoff of the internal iliac artery, but it may need to be extended in certain circumstances, as discussed later.

The AJAX randomized clinical trial used aortouniiliac grafts for the management of EVAR. An aortouniiliac graft, when compared with the more standard bi-iliac stent graft, has the advantage of an easier learning curve and rapid hemorrhage control because contralateral gate cannulation is not necessary. However, the aortouniiliac configuration adds time for the femoral-femoral bypass and is associated with an increased surgical infection risk because of the need for open bilateral femoral artery exposure and presence of a prosthetic bypass graft. If attempting to place a bifurcated stent graft and gate cannulation is not possible, the bifurcated device can be converted to an aortouniiliac configuration in which the contralateral common iliac artery (CIA) is embolized and a femoral-femoral bypass is subsequently performed. Bilateral groin cutdowns and tunnelling are more likely to require general anesthesia, and this consideration may affect operative planning; however, a transition to general anesthesia after hemorrhage control is obtained is possible and may be necessary for other reasons, such as tenuous respiratory status and the need for large-volume resuscitation.

Once the EVAR is deployed in its entirety, gentle balloon angioplasty is used at the distal fixation zones and all areas of device component overlap. Proximal angioplasty should be performed with caution as it can cause recurrent rupture in the setting of a fragile aorta. A postdeployment angiogram should then be performed to assess for endoleak. Special attention should be paid for type 1 endoleaks, which should be addressed before leaving the operating room. For type 1a endoleaks, it may be necessary to perform a gentle balloon angioplasty of the proximal seal zone. If the endoleak persists, deployment of aortic cuffs or endoanchors to create an adequate proximal seal may be necessary. For rAAAs with a type 1a endoleak, no more than two attempts at ballooning the proximal seal zone should be made. In the event of a rupture with ballooning or manipulation, the balloon should be immediately advanced above the site of rupture and reinflated, with conversion to open repair to follow. In cases in which a proximal extension will violate the renal or visceral arteries, a chimney or snorkel technique to maintain renovisceral perfusion may be used. For type 1b endoleaks, it may be necessary to sacrifice the hypogastric artery to get a good seal distally. In these cases, the hypogastric artery should be coiled before covering to prevent the formation of a type 2 endoleak. Ideally, the patient would have at least one hypogastric artery preserved at the end of the case to maintain pelvic perfusion. For type 3 endoleaks, balloon angioplasty of the overlapping graft components should be performed. Type 2 endoleaks are less critical to address and can usually be followed with serial imaging to assess whether they result in aortic sac enlargement long-term.

No patient with a rAAA should leave the operating room with a type 1 endoleak. If a type 1a or 1b endoleak persists despite the maneuvers described, conversion to open repair may be necessary. Conversion is required in 1% to 2% of cases in most series but confers a significant in-hospital mortality disadvantage compared with successful EVAR.

At the end of the case following successful EVAR deployment, it is important to maintain a high index of suspicion for iliac artery injury. Iliac artery injuries are more common in emergent EVAR compared with elective EVAR, and they are more frequent in women compared with men because of the relatively smaller diameter of the iliac arteries. Often an iliac artery injury is masked throughout the case because the large sheaths tamponade it. Therefore, an exchange-length stiff wire should be maintained across access to both iliac arteries as the sheaths are removed. Ideally, the dilators are reinserted into the sheaths before removal to facilitate easy replacement if necessary. The sheaths should be removed one at a time, and attention should be paid to confirm no hemodynamic changes or bleeding before removing the wire. If an iliac injury is suspected, the sheath should be reinserted over the maintained wire on the offending side to provide tamponade, and a stent graft should ultimately be placed to cover the injury.

Consideration should be given to prophylactic exploratory laparotomy for decompression to avoid ACS following EVAR, as discussed later. EVAR has higher rates of ACS than open rAAA repair, likely because intraperitoneal or RP decompression is not routinely performed. Prophylactic exploratory laparotomy is particularly important in patients with intraperitoneal free rupture, regardless of repair approach. If the hematoma is limited to the RP, this may not be needed unless there are signs of femoral nerve compression.

There are variable practice patterns for heparin dosing and reversal during endovascular repair of rAAA. These range from no anticoagulation at all, to using heparin only after aortic control, to giving heparin at a half dose. At our institution, we administer heparin after the aortic occlusion balloon is placed. Heparin is initially dosed at approximately 80 units/kg to maintain an activated clotting time (ACT) >250 until case completion using point-of-care ACT measurements in the operating room.

Open Repair

The two main approaches to open rAAA repair are the transperitoneal (TP) or RP approaches. In general, the initial operative steps via both exposures are similar. If the aortic occlusion balloon is working well, the general principle is to get distal control first and then obtain supraceliac aortic control. However, if the aortic occlusion balloon is not working well, proximal (supraceliac) aortic control should be obtained before obtaining distal control. Once both proximal and distal control are achieved, the renal arteries are dissected, and the proximal clamp is moved down to the infrarenal or suprarenal position, depending on aneurysm anatomy.

If the RP approach for open rAAA repair is chosen, then a bump or sandbag should be placed underneath the left flank to allow the left chest to rest at 60 degrees and the pelvis at 45 degrees. A curvilinear incision is made extending from the left tenth intercostal space (plus or minus one depending on the level of the patient's renal arteries) down to the midpoint between the umbilicus and the pubis. The abdominal wall muscles are divided sequentially down to the peritoneum. Entry into the peritoneum is avoided. As the RP is entered, a hematoma will likely be encountered. The peritoneal contents are reflected to the patient's right side in a progressive fashion to expose the left psoas muscle and the aorta. Once the aorta is visible, a retractor is set in place. Assuming the aortic occlusion balloon is working well, both common iliac arteries should be dissected circumferentially for a short course, taking care not to injure the common iliac veins in the process. Obtaining bilateral common iliac artery control allows for aortic repair using either a straight tube or a bifurcated graft, depending on the patient and aneurysm anatomy.

Once distal control is obtained, supraceliac aortic control can then be obtained by moving proximally along the aorta to the level of the left crus. From here, the left crus can be partially divided, and an aortic cross-clamp can be placed. Following placement of the cross-clamp, the aortic occlusion balloon should be deflated.

Once both proximal and distal controls are obtained, the renal arteries should be identified and dissected. The aortic cross-clamp

should then be moved to the lowest level possible that still allows for proximal control. For most AAAs, this will be just above or just below the renal arteries. Prolonged placement of a supraceliac clamp should be avoided whenever possible as this is associated with substantially higher morbidity and mortality because of visceral ischemia. Once the proximal clamp location is revised and both the proximal and distal clamps are in place, the aortic sac can then be opened, and the aorta can be repaired in usual standard fashion.

Figure 1 represents the post–open repair of the ruptured juxtarenal AAA shown in Figure 2 at 30 days postoperatively. This was completed via the RP approach.

If the TP approach for open rAAA repair is chosen, the patient should be prepped and draped widely in the supine position. A generous laparotomy from xiphoid to pubis should be created. Distal and proximal control is sequentially obtained in the order discussed earlier.

FIG. 1 Postoperative CT scans with IV contrast, arterial phase images, from 30 days after open rAAA repair. **(A)** Representative axial cut demonstrating open rAAA repair and sequela of prior rupture. **(B)** Representative sagittal cut of the same repair. There is no sign of ongoing hemorrhage and the repair is intact.

FIG. 2 CT scans with intravenous contrast, arterial phase images. **(A)** Representative axial cut demonstrating a 10.4-cm rAAA with signs of rupture, including a large left retroperitoneal hematoma. **(B)** Representative sagittal cut of the same rAAA, demonstrating a nearly 90-degree neck angulation that precludes the use of endovascular aneurysm repair.

To expose the infrarenal aorta from the TP approach, the transverse colon is lifted cephalad, and the small bowel is swept to the right. The peritoneum is incised, and the ligament of Treitz is taken down to allow for full mobilization of the duodenum to the right. This maneuver exposes the anterior surface of the infrarenal aorta. From here, the aorta can be traced distally to the bifurcation, allowing for rapid identification and control of the bilateral common iliac arteries.

Supraceliac control can be obtained quickly from the TP approach by mobilizing the left lateral lobe of the liver, retracting the liver to the patient's right, and incising the gastrohepatic ligament. If not already done, the esophagus should be intubated with a nasogastric

or orogastric tube, identified, and retracted to the left. The right crus is then divided to expose the supraceliac aorta. From here, a clamp is placed on the supraceliac aorta, and the occlusion balloon is deflated and removed. Once the renal arteries are visualized, the proximal clamp should be moved distally as quickly as possible to perfuse the viscera. Finally, the sac is opened, and repair continues in standard fashion.

As with EVAR, heparinization protocols for open repair of rAAA vary by institution. We usually obtain proximal and distal aortic control and then administer heparin at a dose of 80 units/kg to maintain an ACT >250 during the remainder of the case, similar to EVAR.

Regardless of whether the RP or TP approach is used, one important intraoperative consideration is whether the inferior mesenteric artery (IMA) will be re-implanted. The watershed area of the IMA, which primarily affects the sigmoid colon, is teleologically affected by hypotension and ligation. Although there are no prospective clinical trials defining precisely when to re-implant the IMA, generally, if there is weak back-bleeding from the IMA, the patient has a history of prior colon surgery without intact collaterals, or the sigmoid colon appears ischemic, then re-implantation should be pursued. Figure 3 depicts an open repair with IMA re-implantation.

Another consideration during aortic cross-clamping and dissection in open rAAA repair is the avoidance of major venous injury. Aortocaval fistula also presents a serious challenge. This should be suspected if, when a controlled aortic aneurysm sac is entered, brisk dark bleeding is found from the right-side wall of the aneurysm sac. Sponge sticks on the inferior vena cava can help temporize this, and the aortocaval fistula should be repaired using large bites of nonabsorbable suture through the inside of the aortic wall.

COMPLICATIONS

Complication rates are substantially higher for rAAA repair compared with elective repair. The estimated major complication rates for open and endovascular rAAA repair are 50% to 80% and 40% to 60%, respectively. The most common major systemic complications include acute kidney injury (40%–75%), respiratory failure (40%), myocardial infarction (25%) and sepsis (15%).

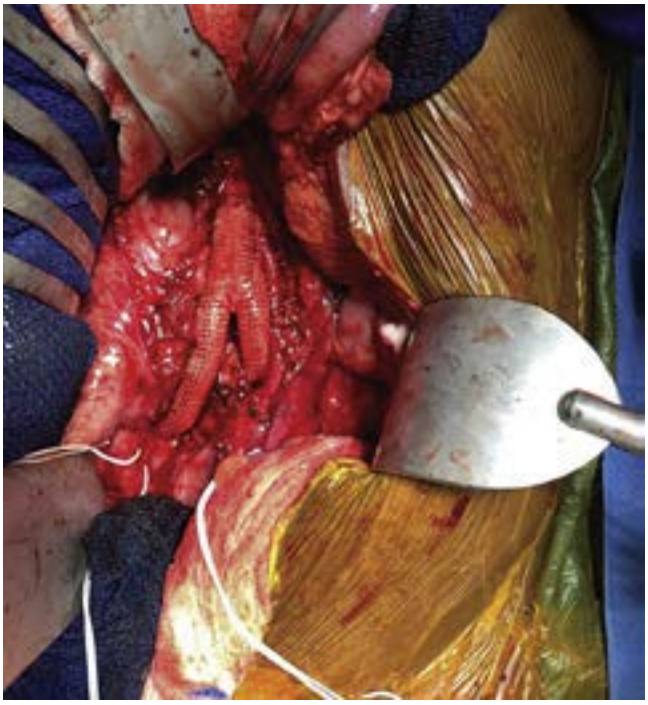

FIG. 3 Intraoperative image of open ruptured abdominal aortic aneurysm repair with inferior mesenteric artery re-implantation performed because of concern for sigmoid colon ischemia.

Bowel ischemia or ischemic colitis is six times more common after rAAA repair compared with patients who undergo elective surgery for AAA without rupture. This is partly a result of patient age, which tends to be higher for patients presenting with rupture, and ligation or coverage of the IMA in the setting of rupture with concomitant hypotension and shock. Hypotension alone is enough to cause bowel ischemia in some patients, and iatrogenic occlusion of the hypogastric artery during rAAA repair can exacerbate the effect. A high index of suspicion is required to diagnose bowel ischemia after rAAA repair. Large loose bowel movements immediately after surgery, bloody bowel movements, and persistent postoperative leukocytosis should all raise suspicion for ischemia. In any patient with suspected bowel ischemia, the initial diagnostic modality of choice is a flexible sigmoidoscopy. Subsequent management depends on the severity of the ischemia. Mild or moderate ischemia is treated with bowel rest, broad-spectrum intravenous antibiotics, and serial abdominal examinations. Severe ischemia (or mild ischemia with progression of symptoms despite optimal medical management) requires a return to the operating room for an exploratory laparotomy and likely bowel resection.

Abdominal compartment syndrome (ACS) also increases morbidity and mortality of rAAA and occurs when relaxed bladder pressure is sustained greater than 20 mm Hg and is associated with organ dysfunction. Increasing intraabdominal pressure and rising plateau or driving pressures may be useful adjuncts for making an early diagnosis. ACS has been linked to massive transfusion, coagulopathy, and use of an aortic occlusion balloon. It is more common after EVAR than open rAAA repair, occurring in up to approximately 20% of EVAR and 10% of open rAAA repair patients. The higher risk of ACS after EVAR is usually the result of an unevacuated intraperitoneal hematoma coupled with large resuscitative volumes leading to visceral and interstitial edema. Together, this impairs venous return and increases renal dysfunction.

ACS is also possible after open rAAA repair. This can be related to an unevacuated intraperitoneal hematoma if the RP approach was used and/or large resuscitative volumes leading to visceral and interstitial edema similar to post-EVAR ACS. If an intraperitoneal hematoma is present and the RP approach is used, the peritoneum should be incised at the end of the case to evacuate the peritoneum. Alternatively, once the RP incision is closed, a separate laparotomy may be performed. The TP approach has a built-in laparotomy that allows for easier evacuation, assessment of abdominal wall laxity, and the possibility of leaving the patient open temporarily without an additional incision. As discussed earlier, RP hematomas are fundamentally different than intraperitoneal hematomas as they are part of a separate compartment. They may, however, cause femoral nerve compression, which also requires evacuation associated with symptoms.

Access complications occur in approximately 15% to 25% of EVARs and can be dealt with via a myriad open and endovascular techniques. As discussed earlier, diseased or tortuous iliac arteries may be difficult to navigate, and intraoperative injury may require iliac stent placement after the large-bore sheaths are removed. Maintaining wire access, replacing the dilator in the sheath before removal, and being prepared with stents in several sizes can help avoid catastrophe. Acute thrombosis or occlusion of an EVAR limb or the native iliac arteries should raise suspicion for a kinked or stenotic graft limb or an undetected iliac injury such as a dissection. Depending on the etiology of the problem, this can usually be treated with femoral cutdown and embolectomy, femoral-femoral bypass, or extension of the iliac stent graft.

Acute kidney injury and renal failure are also common complications of rAAA repair, occurring in 40% to 75% of cases, and are associated with ACS. Acute kidney injury is related to preoperative systemic hypotension coupled with proximal aortic cross-clamping, both of which cause renal hypoperfusion. The risk of acute kidney injury can be reduced by decreasing the proximal aortic cross-clamp (and/or

balloon occlusion) time, and transfusing to maintain a hemoglobin above 8 g/dL throughout the case. Contrast agents used in EVAR may also contribute to acute kidney injury, but the magnitude of this impact is not well known. As many as 23% of patients presenting with rAAA who survive surgery will require hemodialysis in the early postoperative period, but this is usually (>90%) temporary as long as the renal artery origins are preserved during the repair. Renal failure, however, is an independent risk factor for all-cause 10-year mortality.

FOLLOW-UP

In the long term, complications of EVAR include endoleaks, device migration, limb occlusion, and recurrent rupture. Current guidelines recommend that patients who undergo treatment with EVAR be surveilled at 1 month, 6 months, and 12 months postoperatively with a CTA, however the 6-month CTA can be eliminated if the 1-month scan is not concerning for endoleak or other pathology. If there is no evidence of endoleak, sac enlargement, or stent graft disruption on the 12-month CTA, ongoing surveillance with annual duplex ultrasound examination is reasonable. If future ultrasound examinations are suspicious for endoleak or sac enlargement, then further evaluation with CTA should be pursued. Patients treated with open rAAA repair should undergo a baseline CT within 12 months of the initial repair. Both open and EVAR patients should also undergo CTA every 5 years following repair to detect noncontiguous aortic disease.

CONCLUSION

Ruptured abdominal aortic aneurysm is one of the most serious anatomic diseases encountered by surgeons. Despite improvements in screening algorithms, surveillance protocols, multidisciplinary aortic care centers, and critical care, morbidity and mortality associated with rAAA remain high. Early diagnosis is key, and a high threshold of suspicion and broad differential diagnosis in older adult patients with a history of smoking who present with abdominal pain is necessary. Once the diagnosis of rAAA is made, time to aortic occlusion and definitive repair is of the utmost importance. If necessary, patients should be expediently transferred to a facility with capabilities for both open and definitive endovascular repair. Although large clinical trials have not yielded a long-term mortality benefit for EVAR over open rAAA repair, most institutions are moving toward EVAR-first protocols when anatomically possible because of the lower in-hospital morbidity and mortality associated with EVAR compared with open repair. Expanded use of new endovascular techniques and devices may provide an avenue for improvements in long-term survival and complications in the future.

Management of Abdominal Aortic Aneurysm with Concomitant Nonvascular Abdominal Pathology

James K. Elsey, MD

GENERAL CONSIDERATIONS

Abdominal aortic aneurysm (AAA) is a relatively common, potentially life-threatening condition with an overall reported incidence of 5 to 10 cases per 100,000, with complications such as dissection and rupture leading to 15,000 deaths annually.

Associated AAA risk factors such as age, smoking, hypertension, and atherosclerosis not only increase the risk of aortic pathology but are also associated with nonvascular issues such as biliary tract, associated malignancies, and congenital and inflammatory conditions. The nearly universal application of high-resolution scanning in the workup of the AAA patient has shown that coincident nonvascular pathology is not a rare situation, with reported incidences between 7% and 29%.

The management of this complex clinical dilemma still remains controversial and a matter of debate due to the low number of reported patients and the obvious inability to conduct randomized studies. The danger of increased hemodynamic stress as well as the theoretical risk of graft infection remain the main arguments against combined procedures. Alternatively, the postlaparotomy AAA rupture rate of 3% to 10% with sizable aneurysms, as well as the potential of progression of coincident malignant disease, must be taken into consideration with any staged procedure.

Although open aortic aneurysm repair still has a place in appropriate patients, endovascular aneurysm repair (EVAR) is rapidly replacing it as the preferred method in the management of the aneurysm patient. This endovascular method has many potential advantages in the treatment of patients with concomitant disease including

decreased physiologic stress, lack of peritoneal cavity derangement, as well as the ability to shorten the time between staged procedures.

An appropriate and organized approach to these complex patients is to divide the discussion of possible treatment paradigms between the emergent and elective clinical situation.

ELECTIVE AORTIC ANEURYSM WITH ASYMPTOMATIC ABDOMINAL DISEASE

As previously stated, with the almost universal application of high-resolution scanning in the workup of elective AAA patients, the discovery of concomitant nonvascular abdominal pathology is increasingly common. The most common findings reported in the literature include cholelithiasis, gastrointestinal (GI) and genitourinary (GU) malignancies, solid organ tumors, Meckel's diverticulum, and abnormalities of the appendix.

CHOLELITHIASIS

Cholelithiasis is a common disorder occurring in approximately 10% to 15% of the general population. This is mainly a benign entity with only 2% to 3% of patients in the general population becoming symptomatic and, of those, only 3% to 5% develop complicated disease. Interestingly, the incidence of cholelithiasis seems to be higher in the AAA patient with reported rates of 13% to 20%.

The reported incidence of postoperative cholecystitis following open aneurysm repair has been reported to be 0.3% to 18%, but of note, another particular advantage of EVAR is that this rate does not seem to be increased following endovascular repair (0.2%–1.6%). The historic bias toward simultaneous surgery in these patients came out of the fear of postoperative biliary complications and predated the endovascular, laparoscopic, endoscopic, and interventional era. The obvious concern with the combined procedures emanate from the opening of the biliary tract with a known culture positive rate of 14% and risk of subsequent graft infection. As stated, new less-invasive treatment modalities in the management of biliary and aneurysm disease have led to a general consensus away from simultaneous surgery in these patients. Postoperative symptomatic cholelithiasis as well as choledocholithiasis can now be adequately and safely managed with new modalities without the need for another laparotomy.

GASTROINTESTINAL MALIGNANCIES

In the population presenting with an AAA, the concomitant presence of GI pathology is not uncommon with reported rates of 8% to 14%. Colorectal cancer is the most commonly associated lesion with occurrence rates as high as 2%.

When faced with this complex dilemma, the surgeon must choose between a staged or combined procedure. An aneurysm-first procedure obviates the postlaparotomy rupture risk; however, it can significantly delay the treatment of a neoplastic lesion leading to upstaging as well as potential complications such as obstruction, bleeding, and perforation. Conversely, a combined procedure exposes the patient to increased hemodynamic stress as well as the potential of graft infection with rates reported by Oriel as high as 2%.

Time-honored surgical principles direct the surgeon to treat the most pressing condition first. In the patient with a colorectal cancer-threatening complication and an asymptomatic AAA, the colectomy should be done first followed by aneurysm repair in 4 to 6 weeks, preferably by EVAR or retroperitoneal technique. Conversely, in the patient with a larger aneurysm (>5 cm) and a tumor unlikely to obstruct, the aneurysm should be treated first. In the unusual case where the patient presents with concomitant life-threatening GI and aneurysmal disease, a combined procedure is a reasonable consideration. In the conduct of this complex undertaking, meticulous surgical technique is mandatory avoiding inordinate blood loss, prolonged operative times, and graft contamination. Adequate broad-spectrum antibiotics are essential. The aneurysm repair should be done first, preferably with the use of autogenous, cryopreserved, or antibiotic impregnated grafts as well as the consideration of IMA implantation in cases of rectosigmoid pathology. Adequate coverage of the graft is essential with the possible use of an omental pedicle. The bowel resection follows, beginning with adequate packing and isolation of the periaortic retroperitoneum using antibiotic-soaked laparotomy pads. Finally, serious consideration of the liberal use of the Hartman's procedure should be entertained, especially when there are concerns of collateral colonic blood supply.

The rapid evolution and widespread application of EVAR provides many advantages in this complex subset of patients, including lower physiologic stress as well as significantly reduced delay between staged procedures. Currently, in the properly selected patient who is an endovascular candidate, consensus leans toward a staged EVAR first, followed relatively quickly (12–14 days) by GI resection. In preparing for the EVAR as the first procedure, particularly where subsequent left or sigmoid colon resection is anticipated, it is essential to assess the adequacy of the colonic blood supply as the procedure requires coverage of the IMA. In a patient with a patent IMA and inadequate SMA/IMA collateral support, open aneurysm repair with IMA implantation, either staged or combined, may be the best option.

Renal Cancer

The coincident occurrence of aneurysms and renal cancer (0.1%–3%) is increasingly reported with the current use of high-resolution scanning. As with GI malignancies, the management should be guided by AAA size, location of the cancer, and the extent of the malignant disease.

A simultaneous approach to both lesions has been reported to have acceptable results and obviates the complication of postlaparotomy aneurysm rupture as well as tumor growth. As the upper urinary tract is usually sterile, the risk of subsequent graft infection is extremely low. Renal failure is the most common complication, and thus it is important to assess preoperative renal function, the need for suprarenal aortic clamping, and overall technical difficulties that may lead to increased blood loss in the combined procedure. In cases where conditions may lead to significant renal insult, a staged procedure may be more appropriate allowing time for renal recovery between the next operation.

When performing a combined operation, patients with a left renal lesion should be approached retroperitoneally if possible, and right-sided lesions will need a midline procedure. There have been several recent reports in the literature discussing the use of a hybrid simultaneous approach combining laparoscopic nephrectomy and EVAR with good results in well-selected patients. In the patient where a staged approach is most appropriate, EVAR followed by a laparoscopic or open nephrectomy is the most reasonable treatment.

Bladder Cancer

Although minimal data exist on the coexistence of bladder cancer and aneurysm disease, Grego reported an incidence of nearly 3% in his series of patients. Although several series have reported excellent clinical outcomes with simultaneous procedures, it must be remembered that the lower GU tract is frequently not sterile and such an approach is accompanied by the practical risk of aortic graft infection. As this risk is substantially mitigated by EVAR, along with a reduction in physiologic insult, a staged EVAR as the first approach is the best option in appropriately selected patients.

Prostate Cancer

Prostate cancer and aortic aneurysms occur in the same population of older men, with some studies reporting a 100-times incidence of aneurysms in patients with prostate cancer. Although several less-invasive therapies exist in the management of prostate cancer that simplify the treatment algorithm in the patient with combined disease,

radical prostatectomy remains the mainstay therapy at the current time. As in the management of bladder cancer, combined surgery series have reported acceptable results with the previously described risks remaining. Given this, the application of mainstream, less-invasive treatments such as EVAR and robotic procedures in a staged or hybrid combined approach seems to provide a more reasonable strategy despite the paucity of data.

Solid Organ Tumors

Many reports exist documenting the successful resection of solid organ lesions at the time of aneurysm repair. Given the sterility of the lesions, synchronous treatment is reasonable assuming the patient can tolerate the physiologic insult. Despite this, in the endovascular candidate, a staged EVAR-first approach is the most reasonable course in management.

Appendix and Meckel's Diverticulum

Due to the associated risk of aortic graft infection and their mostly benign natural history, incidental appendectomy or Meckel's resection are inappropriate in asymptomatic patients during open aneurysm repair. In such patients found to have chronic inflammation or an uncomplicated tumor, many authors also feel a staged approach with laparoscopic resection following aneurysm repair is the safest therapy with a very low risk of second laparotomy. In the most unusual case of acute or complicated GI disease, a staged approach with intestinal resection preceding aneurysm repair should be undertaken once the peritoneal inflammation is resolved. However, if one is dealing with simultaneous life-threatening clinical entities during open surgery, a combined repair is probably the only option employing all of the risk-mitigating tools used with the combined colorectal operation. In the endovascular candidate faced with simultaneous life-threatening lesions, a combined hybrid approach of EVAR and laparoscopic resection is probably the best strategy.

EMERGENT AAA REPAIR AND CONCOMITANT DISEASE

Ruptured AAA is a catastrophic clinical event with high operative mortality (30%–50%) even with expedient and expert management. Whether the procedure is open or EVAR, the patient suffers significant physiologic insult often leading to cardiac, renal, hepatic, and mesenteric ischemia, and activation of a significant inflammatory response, often leading to multiple system organ failure (MSOF) and periodic abdominal compartment problems. The addition of another procedure to this process is imprudent and ill-advised. In the rare circumstance in which the patient has another coexistent, intraabdominal, life-threatening process, a simultaneous procedure may have to be considered with significant increased mortality. The patient with a symptomatic aortic aneurysm is, by definition, unstable and in the process of developing rupture. The same decision calculus applies in these patients as stated in the rupture patient.

Emergent Laparotomy for Abdominal Pathology with Incidental AAA

Consistent with previous statements, the immediate life-threatening process should be treated first followed by a staged aneurysm repair, preferably EVAR, in patients with concerning large aneurysms after recovering from the first procedure. In the very rare case when the intraabdominal emergency is met with an aneurysm mandating immediate repair in a patient not a candidate for an endovascular approach, a combined procedure must be considered.

In the patient explored for the presumed acute abdomen with negative findings except a sizable AAA, it is reasonable to assume that the aneurysm is symptomatic, and intraoperative vascular surgical consultation should be obtained.

Elective Laparotomy for Abdominal Pathology with an Incidental Asymptomatic AAA

As stated previously, in the modern-day workup for abdominal disease, the surprise discovery of an incidental AAA is extremely rare. However, when confronted with this situation, it is best to proceed with the planned abdominal procedure. In patients with large aneurysms (>5 cm), staged repair should follow as soon as reasonably possible.

SUMMARY

1. Avoid synchronous surgery if possible.
2. Treat the most life-threatening procedure first.
3. Emergent AAA repair takes priority over any type of intraabdominal disease.
4. Incidental sizable aneurysms (>5 cm) found during laparotomy for nonvascular disease should be treated as early as possible in the post-op period, preferably by EVAR.
5. Nonemergent nonvascular pathology found during AAA repair should be managed later in a staged manner.
6. In the unusual case where both the AAA and the intraabdominal pathology present as synchronous life-threatening issues, a combined procedure must be entertained. During the conduct of this risky procedure, meticulous surgical technique applying all known graft infection-mitigating strategies should be applied
7. In the conduct of the staged or synchronous procedure, one should enlist the least physiologically taxing and minimally invasive procedures, including EVAR and laparoscopic and robotic technologies.

Management of Thoracic and Thoracoabdominal Aortic Aneurysms

Yasaman Kavousi, MD, and James H. Black III, MD

INTRODUCTION

Descending thoracic aortic aneurysms (DTAAs) and thoracoabdominal aortic aneurysms (TAAAs) are uncommon when compared with isolated infrarenal abdominal aortic aneurysms (AAAs), accounting for only 2% to 5% of all aortic aneurysms. DTAAs are defined as those that involve the thoracic aorta between the origin of the left subclavian artery (LSA) and the diaphragmatic hiatus, whereas TAAAs can involve varying degrees of the visceral aortic segment along with the thoracic and infrarenal aorta. TAAAs are classified by anatomical definitions as devised by Dr. Stanley Crawford (Fig. 1).

Although pathologies of the abdominal aorta are commonly degenerative in nature, those affecting the thoracic and visceral aorta include a more diverse range of predisposing conditions, such as connective tissue disorders (Marfan syndrome, Loeys-Dietz syndrome, etc.), dissections, aortitis, and trauma. Open repair of DTAA and TAAAs, first described in 1952 by Bahnson and later simplified by Dr. Crawford, was initially plagued by increased morbidity and mortality rates as a result of renovisceral and spinal cord complications. Although adjuncts have been developed to decrease the incidence of these devastating complications at high-volume centers, these aneurysms continue to pose technical challenges to cardiac and vascular surgeons. The advent of thoracic endovascular aortic repair (TEVAR) has further diminished the morbidity associated with surgical repair. TEVAR is a well-established modality for the treatment of degenerative aneurysms of the thoracic aorta and traumatic transections; however, its utilization in patients with connective tissue disorders and for both acute and chronic dissections continue to be the subject of ongoing study. Endovascular repair of TAAA is now performed across the world using branched and fenestrated devices, although these devices remain under clinical trials in the United States.

INDICATIONS FOR SURGERY

In a study on the natural history of thoracic aneurysms, a 30% 5-year rupture risk was observed when aneurysm size exceeded 6 cm. Rupture risk was negligible in aneurysms less than 5 cm and equivalent to morbidity risk of surgical repair at the 5- to 6-cm range. Given these findings, ≥6 cm has been accepted as the size threshold to consider elective repair in acceptable risk patients for TAAA patients and >5.5 cm for isolated TAA. As aneurysms of the thoracic aorta become larger, they also begin to expand at more accelerated rates. This increased expansion has been found to correlate with higher rupture rates. As such, patients presenting with aneurysm growth rates ≥10 mm per year should also be considered for surgical repair. Additional risk factors for rupture have been identified and include increasing patient age, female gender, chronic pain, history of chronic obstructive pulmonary disease (COPD), compression of surrounding structures, and development of a dissection within a degenerative aneurysm. Chronic type B aortic dissections and presence of connective tissue disorders have been found to be independent risk factors for rupture proclivity at smaller aneurysm sizes. In these settings, the size threshold to consider surgical repair is reduced to 5 cm. Furthermore, these populations tend to present at younger ages compared with patients with degenerative aneurysms, potentially resulting in better comorbidity profiles and decreased operative risk.

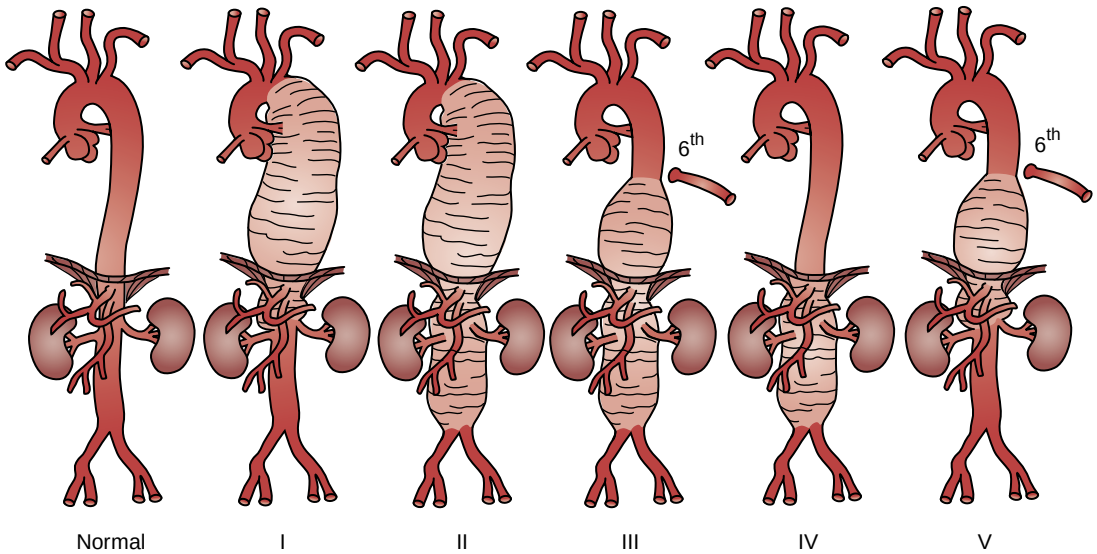

FIG. 1 Crawford classification of thoracoabdominal aortic aneurysms, types I-V. Type I, distal from origin of left subclavian artery to above renal arteries. Type II, distal from the left subclavian artery to the infrarenal aorta. Type III, from the sixth intercostal space to the infrarenal aorta. Type IV, from the 13th intercostal space to the aortic bifurcation. Type V, below the sixth intercostal space to the renal arteries. *(From Cronenwett JL, Johnston KW.* Rutherford's Vascular Surgery, *7th Edition, Philadelphia: Elsevier; 2010, Figure 131-8).*

PATIENT SELECTION AND PREOPERATIVE RISK ASSESSMENT

The approach and extent of operative repair required for DTAA and TAAAs varies greatly depending on the Crawford classification; however, consistent themes exist regarding clinical variables that influence both overall morbidity and ischemic spinal cord injury (SCI). Each patient's associated comorbid conditions, particularly those affecting cardiac, renal, and pulmonary function, require an accurate assessment to appropriately steer operative decision making. Aortic aneurysms are considered markers of coronary atherosclerotic disease, and because a majority of patients possess additional atherosclerotic risk factors, preoperative cardiac testing is mandatory in the elective setting. Echocardiography, either transthoracic or transesophageal, should be utilized to rule out valvular or ventricular dysfunction that may result in hemodynamic compromise from increased cardiac afterload following aortic cross-clamping. Additionally, nuclear stress testing can identify major areas of myocardium potentially at risk for significant ischemia. In patients with abnormal noninvasive workup, further evaluation via cardiac catheterization should be considered as both a definitive diagnostic and potentially therapeutic intervention. Nonreversible ischemic cardiomyopathy resulting in significantly decreased left ventricular function generally precludes open surgical repair.

A baseline serum creatinine is commonly used to assess renal function. If renal dysfunction is noted by elevated serum creatinine levels, patients may benefit from preoperative renal revascularization via percutaneous stenting, or by surgical bypass or endarterectomy at the time of aneurysm repair. Up to 15% of TAAA patients present with significant renal insufficiency, defined as a serum creatinine ≥1.8 mg/dL, and this has been shown to correlate with perioperative renal failure and mortality. Patients with renal insufficiency requiring extensive repairs, especially those with type II, type III, or type V TAAAs, have relative contraindications to open repair given the strong correlation with poor outcomes in these populations. Indeed, acute renal failure can have devastating effects on many other systems, such as fluid overload and electrolyte disturbances promoting malignant arrhythmias. Whether or not endovascular approaches to TAAA can reduce the burden of acute kidney injury (AKI) versus open repair remains unanswered. The requisite need for contrast-enhanced CT angiography after complex endovascular repair is a relative contraindication for such technology, as the patient cannot have proper imaging to determine presence of endoleak.

Patients with aneurysms involving large portions of the thoracic aorta, DTAAs, and type I–III TAAAs should undergo preoperative pulmonary function tests. These patients often require single-lung ventilation and, without the necessary pulmonary reserve, may not tolerate such technique. An FEV1 of >1.0 L or a PCO_2 of <45 mm Hg generally represents appropriate pulmonary function to accept single-lung ventilation. Patients who fail to meet these criteria should undergo aggressive medical therapy with subsequent reevaluation or evaluation for possible endovascular repair. Patient age in and of itself is not a contraindication to open repair; however, overall functional status should be evaluated as part of the preoperative risk assessment. Previous series have shown that the elderly with appropriate functional status have acceptable perioperative morbidity and mortality rates. Patients with overall fragility should probably not be offered open surgical repair, although they may be candidates for endovascular repair or hybrid procedures depending on their anatomy.

Along with the previous physiologic assessments, patients being considered for endovascular repairs have independent anatomical criteria that must be assessed. High quality imaging is necessary to ensure that there are appropriate proximal and distal seal zones to prevent endoleaks that may result in late aneurysm rupture. Patients with thoracic aneurysms may have extreme tortuosity of the aorta that prohibits the delivery and accurate placement of a stent-graft. For branched and fenestrated repair of TAAA, ostial disease of the renal and visceral vessels can complicate cannulation for stent graft placement. Likewise, TAAA also commonly requires larger diameter devices compared with isolated infrarenal AAA, making femoral and iliac artery access evaluation a priority. Patients with diffuse iliofemoral disease may not allow for passage of the larger sheaths necessary to deliver the stent-graft. Inadequate evaluation of the iliofemoral access can result in disastrous complications resulting from iliac artery disruption or avulsion. The presence of difficult access can be circumvented by utilizing iliac conduits, which are further described later in the chapter.

Standard central venous access and invasive hemodynamic monitoring should be employed for all cases, including the use of pulmonary artery catheter placement when indicated. Double-lumen intubation is often necessary to provide single-lung ventilation for aneurysms with extensive thoracic components. Systemic hypothermia can be avoided by using fluid warmers along with passive external warming after completion of aortic reconstruction. Washed red blood cells (Cell-Saver) and transfusion of banked packed red blood cells (PRBC) and fresh-frozen plasma (FFP) should be applied liberally as opposed to large volume crystalloid infusions. Given the extensive nature of the reconstructions and long graft surfaces, platelet consumption is common, and platelets should be administered to prevent significant thrombocytopenia.

STRATEGIES FOR THORACIC AND THORACOABDOMINAL AORTIC RECONSTRUCTION

Two surgical techniques that are commonly utilized to repair DTAA and TAAAs are the "clamp-and-sew" technique versus the use of distal aortic perfusion through a left heart bypass (LHB) circuit. Each technique has been found to be efficacious and is often surgeon- and center-dependent. Both techniques are often paired with other adjuncts to decrease complications related to spinal cord, visceral, and renal ischemia. Operative technique variations and ongoing research have been centered on preventing the dreaded complications of renal failure and SCI. The judicious application of adjuncts for organ protection have been supported by the literature and include cerebrospinal fluid (CSF) drainage, intercostal revascularization, renal hypothermic perfusion, and distal aortic perfusion.

Organ Protection Adjuncts

SCI following DTAA or TAAA repair is the most feared morbid complication after DTAA and TAAA reconstruction. Placement of spinal drains to allow CSF drainage has been the best studied and widely accepted strategy employed to prevent paraplegia following thoracic aortic surgery. Early studies suggested that proximal aortic cross-clamping results in elevated CSF pressures that may compromise perfusion of the spinal cord. Preoperative placement of drainage catheters to allow efflux of CSF during the perioperative period functions to preserve spinal cord circulation. In a randomized trial comparing type I and II TAAAs with and without CSF drainage, paraplegia rates were reduced from 13.0% to 2.6% with the utilization of CSF drainage. Both patient populations had similar aortic cross-clamp times, LHB use, and intercostal artery revascularizations. An 80% overall risk reduction of postoperative SCI complications was observed with CSF drainage in patients undergoing type I and II TAAA repair in this series. Our institution favors the use of CSF drainage in conjunction with monitoring of motor-evoked potentials (MEP) and distal aortic perfusion via LHB. In patients felt to be at increased risk of paraplegia, digital subtracted angiography (DSA) of the thoracic aorta may be performed preoperatively to identify the artery of Adamkiewicz for revascularization if mandated by intraoperative findings. MEPs are monitored during aortic cross-clamping,

and the decision to revascularize intercostal arteries is made based on the loss of MEPs, clinical inspection of patent intercostals, or as dictated by preoperative DSA imaging of the artery of Adamkiewicz. Other adjuncts include epidural cooling to decrease neuronal energy requirement and continuous infusion of naloxone as a free radical scavenger and inhibitor of excitatory amino acids.

Cold renal perfusion has been well established as an adjunct to minimize ischemic injury to the kidneys during open TAAA repair. Perfusion catheters are placed into the renal orifices, and cold renal preservation fluid is used to flush the kidneys followed by continuous infusion. At our institution, we use 1-L bags of normal saline with 500 mg of methylprednisolone added and then placed on ice. Preservation of renal function is paramount to successful outcomes, as evident from a study that found postoperative renal failure to result in an eightfold increase in mortality risk ([OR 7.8]; 95% CI, 3.4–17.9; P <0.01).

Operative Technique

A double lumen endotracheal tube is often necessary for single lung ventilation for patients with type I-III TAAA to facilitate exposure to the thoracic aorta and inferior pulmonary vein for partial LHB. In patients with type IV TAAA, LHB is not often necessary and the chest not opened widely enough to require single lung ventilation. For all patients with DTAA and TAAA, the patient is positioned in a modified right lateral decubitus position, with the left chest rolled upward between 70 to 90 degrees and the pelvis rotated only approximately 30 degrees. The patient is placed on an adjustable beanbag to support the position and an axillary roll is placed to protect the brachial plexus. The rib spaces are then identified and counted to mark the proper intercostal space for the necessary exposure (Fig. 2). The patient is then widely prepped and draped to include the left chest, left flank, and both groins.

The Johns Hopkins approach employs a thoraco-retroperitoneal approach to all TAAA repairs to minimize the convective fluid and temperature losses incurred by an open peritoneum. The transversalis muscle is identified at the costal margin and the fibers are split

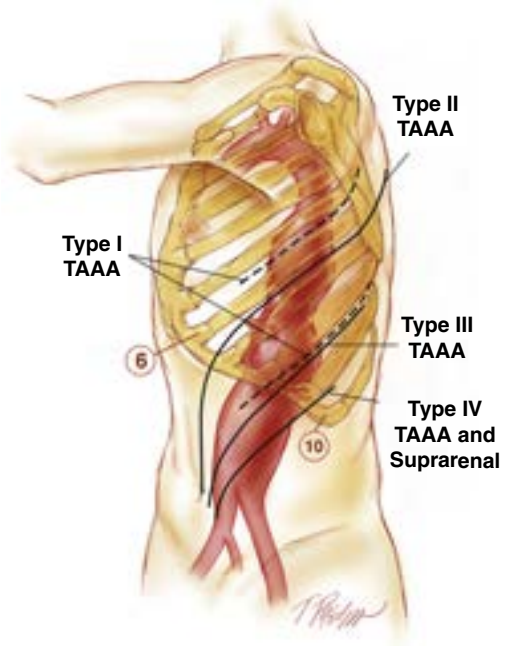

FIG. 2 Incisions based on patient anatomy and aneurysm classification. For type I thoracoabdominal aortic aneurysm (TAAA) repair, two separate thoracotomies are made through a single skin incision.

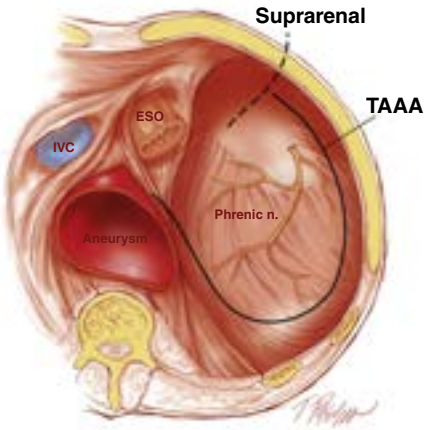

FIG. 3 For TAAA repair, the diaphragm is taken down in a circumferential fashion to avoid injury to the phrenic nerve branches and allow normal diaphragm function postoperatively. In patients with suprarenal abdominal aortic aneurysms in which the DTA does not require exposure, a partial division of the diaphragm can be used as part of left flank approach.

to identify the peritoneal sac. This is then bluntly swept medially out of the left retroperitoneal space. The anterior abdominal wall is then divided with electrocautery to the distal extent of the incision. Blunt mobilization of the retroperitoneum is continued medially to expose the left psoas muscle, where the left common iliac artery is often identified. The left ureter is commonly then found on the back of the peritoneal sac and at this point a static self-retaining retraction system is placed. Of note, for type I TAAA, we recommend the use of two separate thoracotomies at the 5th and 8th interspace, through a single skin incision, as depicted in Figure 2. This allows for sufficient exposure to the proximal DTA while also allowing diaphragm mobilization and identification of visceral branches for distal clamp location. The left renal artery is then identified to further guide the remainder of the visceral dissection. A prominent left lumbar vein is normally encountered coursing along the left aorta as it empties into the left renal vein. This structure can be ligated and divided to allow for safe medial retraction of the left kidney. The diaphragm can be mobilized in a circumferential fashion to further expose the DTA and suprarenal aorta (Fig. 3). We do not endorse radial division of the diaphragm as this sacrifices branches of the phrenic nerve that may predispose to pulmonary complications postoperatively. Once the left kidney and retroperitoneum have been completely mobilized, they can be safely retracted to provide complete exposure to the thoracic and abdominal aorta. For type I and II TAAA and proximal DTAA, the left vagus nerve is identified crossing the distal aortic arch and giving rise to the left recurrent laryngeal nerve as it courses around the arch at the ligamentum arteriosum. If the anatomy dictates a proximal clamp between the left common carotid artery and LSA, the ligamentum arteriosum is usually ligated and divided.

If LHB is to be utilized for distal aortic perfusion for type I–III TAAAs, the left inferior pulmonary ligament is taken down to expose the left inferior pulmonary vein. A purse-string 4-0 polypropylene suture is then placed, before sharply performing a venotomy to place a 24 Fr venous cannula. An 8-mm Dacron graft is then sewn in an end-to-side fashion onto the left common femoral or left iliac artery to avoid leg ischemia from direct cannulation that may confound MEP monitoring. Distal aortic perfusion is then initiated along with moderate hypothermia at 32°C to 34°C. Sequential aortic cross-clamping is then utilized to isolate the proximal DTA while the proximal anastomosis is performed, followed by the lower thoracic aorta if intercostal revascularization via an inclusion patch

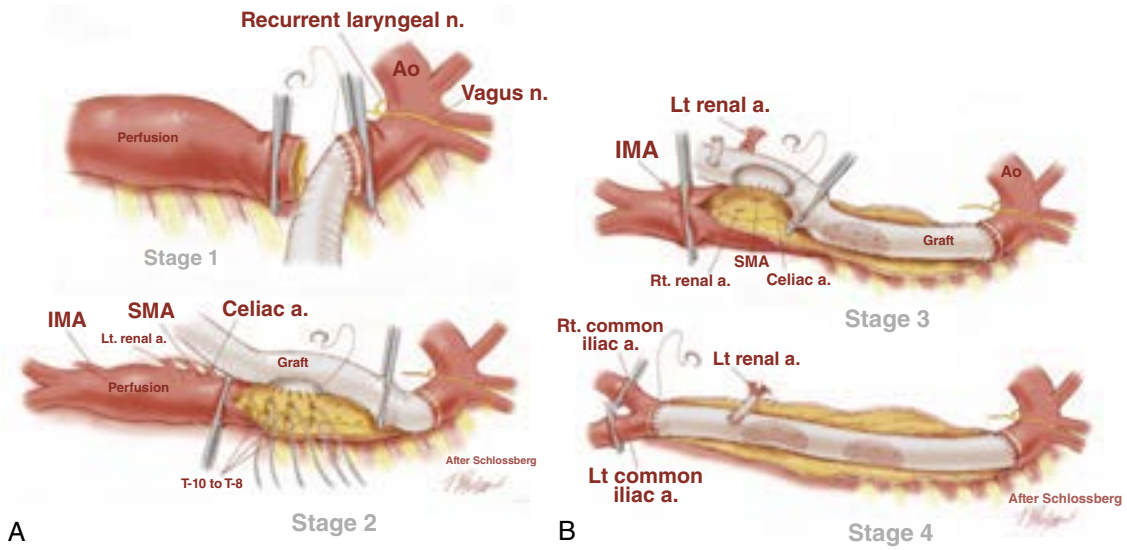

FIG. 4 **(A)** To minimize the risk of end-organ ischemic complications, we advocate for distal aortic perfusion and sequential aortic cross-clamping. The first stage includes proximal aortic cross-clamping with a distal clamp on the DTA to allow for completion of the proximal anastomosis. Next, the graft is clamped while a supraceliac clamp is placed distally to allow for either intercostal reimplantation or ligation. Balloon occluders can be placed to temporarily control intercostal arteries to be reimplanted. **(B)** The next clamp is placed on the infrarenal aorta to allow for reconstruction of the visceral segment. This is accomplished with either a Crawford visceral inclusion patch to revascularize the right renal, superior mesenteric, and celiac arteries; or, in the case of patients with connective tissue disorders, with separate bypass grafts to each vessel to reduce the risk of patch aneurysms in the follow-up period. Finally, clamps are placed on bilateral common iliac arteries for the distal anastomosis and reimplantation of the left renal artery. We prefer aortorenal bypass to a Carrel patch so as not to cause thinning of the artery or kinking if a renal endarterectomy is necessary. *IMA,* Inferior mesenteric artery; *SMA,* superior mesenteric artery.

anastomosis is to be done, then the abdominal aorta during visceral revascularization, and finally the iliac vessels for the distal anastomosis (Fig. 4). Before placing the initial cross-clamp, it should be emphasized to the anesthesia team to maintain lower systolic blood pressures to avoid complications from the increased afterload created from the aortic cross-clamp. Our institution strives to maintain bypass circuit flows of 2.0 to 3.5 L/minute to provide 60 to 80 mm Hg for distal pressures. Once the visceral reconstruction has begun, the rewarming process is started.

For the aortic reconstruction, after appropriate exposure and proximal and distal control, the aorta is entered posterior to the left renal artery and the aortotomy extended as necessary. Figure 4 demonstrates the sequence of steps utilized to perform the aortic reconstruction for a type II TAAA. Depending on the type of DTAA or TAAA and the anatomy of the patient, the sequence of clamping and anastomotic sites can be modified. During the visceral revascularization, cold renal perfusion is maintained as described earlier. The patient body temperature should be monitored during cold renal perfusion to avoid excessive hypothermia that can result in heart arrhythmias or poor myocardial performance. We advocate for left aortorenal bypass versus direct Carrel patch of the left renal artery as this prevents thinning of the artery and potential for kinking if a renal endarterectomy is to be performed. Furthermore, the left renal bypass graft can be constructed onto the main conduit before cross-clamping to avoid unnecessary additional renal ischemia. The distal anastomosis is then completed at the appropriate level based on the patient's anatomy. The aneurysm sac should be closed over the reconstruction if possible. The retractors are then released and the retroperitoneal contents returned to their appropriate position.

The thoracoabdominal incision closure is then started with the purpose to secure the chest wall and abdominal musculature to promote return to baseline function. A large axiom drain is routinely placed in the left retroperitoneal space that can be brought through the abdominal wall. The diaphragm is then reconstructed with interrupted figure-of-eight 0-silk sutures. The final several centimeters of the lateral diaphragm can be closed following the chest closure and can be done from the abdomen. For type I–III TAAAs, pleural chest tubes are placed to drain any effusions resulting from the chest dissection and proximal suture line. The rib interspaces are reapproximated using #2 looped absorbable sutures, and any residual cartilaginous joint at the costal margin is excised to provide stabilization and prevent overriding of the adjacent ribs. The chest and abdominal musculature is then closed in multiple layers along with the subcutaneous tissues and skin.

Outcomes

Postoperative outcomes following DTAA and TAAA repair are dependent upon the level of disease. Patients with DTAA are more prone to neurologic complications, whereas those undergoing TAAA repair are more susceptible to renal failure. As mentioned before, the evolution of adjuncts for end organ protection has made a considerable impact on patient mortality and significant morbidity. Likewise, the acuity at the time of patient presentation also affects patient outcomes, as those who present with need for emergent repair have a higher incidence of morbidity and mortality.

A review of our experience with 300 patients undergoing open TAAA repair or open DTAA demonstrated a perioperative mortality rate of 7.5%. Furthermore, our rate for SCI was only 2.5% with the judicious use of LHB for distal aortic perfusion, moderate hypothermia, CFS drainage, and selective use of intercostal revascularization based on MEP monitoring. Acute renal failure, using the definition of many clinical series that is more than double the baseline creatinine or an absolute value >3.0 mg/dL, occurred in 12.5% of patients with dialysis dependence in only 2% to 3%. However, in most of this subset of patients, they returned to their baseline renal function over the course of their follow-up. These findings are comparable to and have been replicated by other large-volume studies at centers of excellence.

Postoperative renal function is most affected in those patients whose aneurysm pathology require prolonged renal ischemia, such as type II–IV TAAA. The strongest predictor for postoperative renal failure is preoperative renal insufficiency, especially in those patients with a glomerular filtration rate <40 mL/min. While the utilization of cold renal perfusion and other adjuncts has led to a decrease in the incidence of postoperative renal failure, it has not been quite as a profound resolution as seen with SCI. Other measures to improve postoperative renal function have included sequential clamping to reduce renal ischemia time and fenoldopam infusions. Despite these maneuvers, most studies have found anywhere between 2% to 9% of patients require hemodialysis for postoperative renal failure. Following 2286 open TAAA repairs, Coselli et al. observed that hemodialysis was needed in 5.6% of all patients, with the incidence increasing to 8.3% in those with type II TAAA. Postoperative renal failure has repeatedly been observed to be a predictor of perioperative mortality. Patients who develop postoperative renal failure have been found to have a tenfold increase in risk of mortality.

ENDOVASCULAR MANAGEMENT OF DTAA AND TAAA

TEVAR has emerged as the preferred treatment of descending thoracic aortic pathologies as an alternative to the significant morbidity and mortality associated with traditional open repair. TEVAR offers decreased operative risk by minimizing aortic manipulation, hemodynamic shifts resulting from large volume hemorrhage, and complications associated with LHB. Open thoracic repair is indicated for patients with aneurysm or dissection secondary to connective tissue disorders, wherein these disorders were exclusion criteria, so the safety and efficacy of TEVAR has not been proven. Endovascular repair of TAAA is performed under clinical trials in the United States using branched and fenestrated technology (FBEVAR), but the results are encouraging as centers develop experience and expertise in device selection and placement.

Preoperative Planning

High-resolution imaging is imperative for all patients being considered for TEVAR and FBEVAR. The tortuous nature of the thoracoabdominal aorta and potential for involvement of the distal aortic arch mandate precise preoperative planning to prevent immediate treatment failures. Computed tomography angiography (CTA) is the most commonly used diagnostic test for patients with suspected aortic pathology. Of the many benefits of CTA, perhaps most important are the multiple reconstructions that can be created from the original images vital for preoperative planning. A classification system has been created to better define proximal seal zones based on anatomic landmarks (Fig. 5). The distal seal zone is typically proximal to the celiac axis for TEVAR, but FBEVAR will extend to the distal aorta or iliac vessels.

The location of the proximal seal zone dictates the potential need for additional interventions. Pathologies involving the proximal DTA or distal arch may require coverage of the LSA. The most recent literature suggests that patients undergoing LSA coverage have improved outcomes with preservation of flow to the LSA. This can be done either in a staged approach with a carotid-subclavian bypass or transposition, or at the time of TEVAR with creation of a fenestration to the LSA. Patients who mandate preservation of flow to the LSA include prior left internal mammary-coronary bypass, dominant left vertebral artery, incomplete circle of Willis, and presence of a functioning left upper extremity arteriovenous fistula or graft. Another critical element of preoperative planning is evaluation of the access vessels for delivery of the device, particularly the iliofemoral system. Although the evolution of devices has resulted in lower profile delivery systems, absence of appropriate access is a contraindication to TEVAR. An alternative to circumvent poor access vessels is to create an iliac or aortic conduit. Inadequate access vessel evaluation can lead to catastrophic consequences, including dissection, perforation, or frank rupture, which can result in patient mortality.

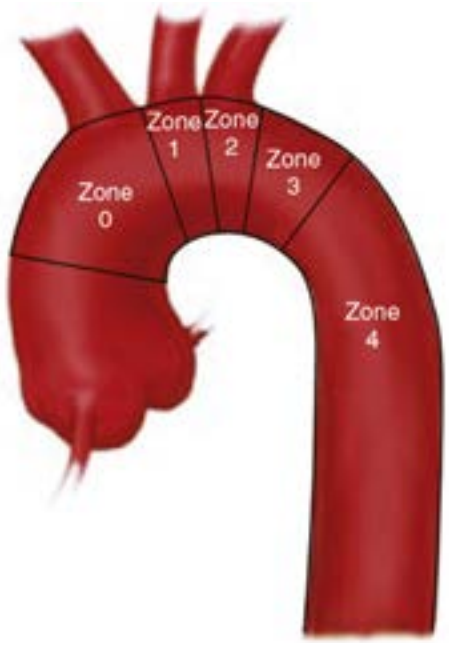

FIG. 5 Depiction of the proximal seal zones depending on patient anatomy. Patients with proximal seal zones between zones 0 to 2 often require debranching procedures to preserve cerebral and upper extremity perfusion. In patients requiring zone 2 proximal seal zone, we recommend staged left subclavian artery (SCA) revascularization for elective cases.

Operative Technique

In our Johns Hopkins approach to TEVAR and BFEVAR, we advocate for preoperative placement of a lumbar drain for CSF drainage to reduce the risk of paraplegia, as well as LSA revascularization. CSF drainage is particularly important in cases where coverage of the entire thoracic aorta is planned or the patient has previously undergone prior AAA repair. We recommend the drain be placed preoperatively as rapid placement of a lumber drain after the onset of neurologic deficit is not practical in most settings. Furthermore, it has been our experience that a limited time frame of 1 to 2 hours exists to initiate CSF drainage before irreversible ischemia to the spinal cord occurs. As such, delaying CSF drainage until the completion of the procedure and reversal of general anesthesia may place the patient at unnecessary risk. Additionally, the LSA should not be covered by the stent graft in the absence of a first-stage revascularization. For elective procedures, it is our practice to admit patients in advance of TEVAR to undergo either LSA-carotid transposition or bypass. While our preference is for LSA transposition, LSA-carotid bypass may be necessary for situations unsuitable for transposition, such as prohibitive distance between the LSA and left carotid or an early takeoff of the left vertebral artery just distal to the LSA origin. Following a recovery period of 2 or 3 days, they return to the operating room for TEVAR during the same hospitalization.

The patient is placed in a supine position, and bilateral groins and abdomen are prepped and draped. General anesthetic is commonly utilized in these patients; however, the advent of percutaneous closure devices has resulted in the possibly of local anesthetic and

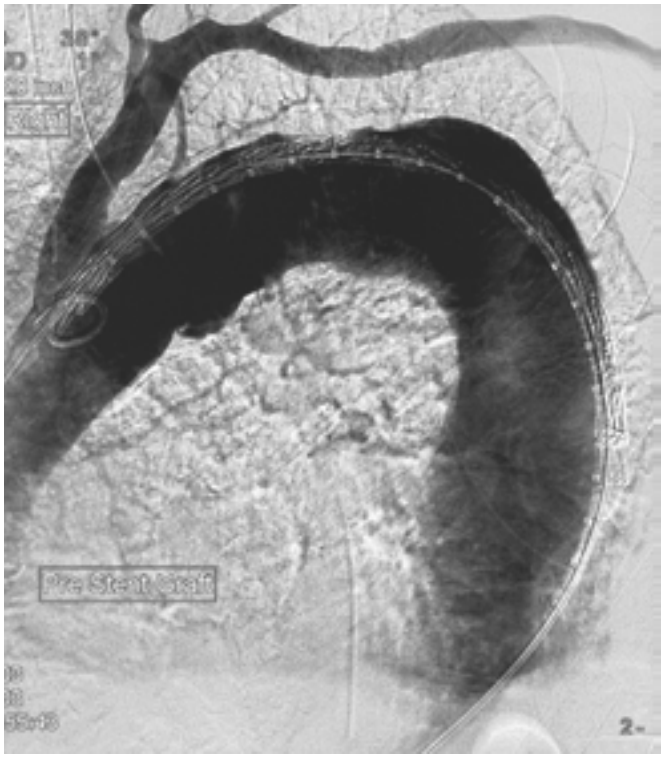

FIG. 6 During TEVAR, thoracic aortography is used to confirm the device is appropriately positioned in the proximal DTA before device deployment. In this angiogram, the undeployed device is located directly under the left subclavian artery origin.

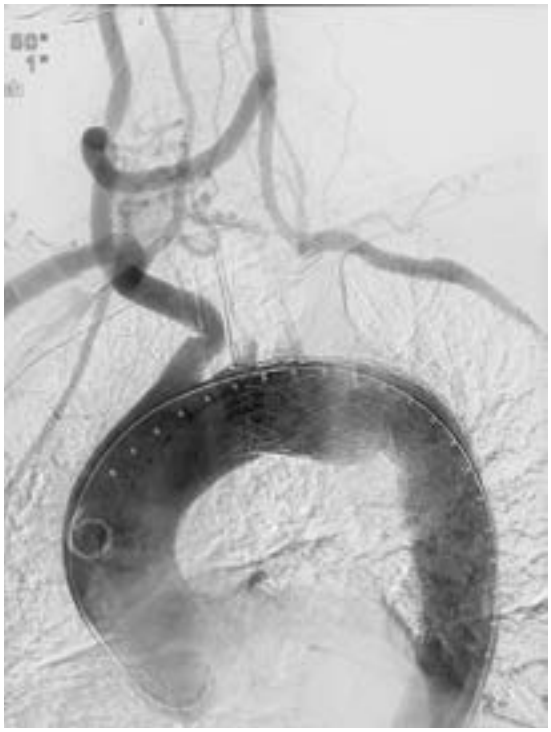

FIG. 7 Completion angiography is used to confirm stent graft placement and exclusion of the aneurysm sac. In this case, due to involvement of the aortic arch in the aneurysm pathology, a zone 1 proximal seal was required. The completion angiogram demonstrates patency of the preoperative debranching with a carotid-carotid bypass and left carotid-subclavian transposition.

moderate sedation for patients felt to be a prohibitive risk for general anesthesia based on cardiopulmonary comorbidities. Another option for high-risk patients includes epidural anesthesia.

Following the surgical exposure of the CFA for delivery of the device, the patient is systemically heparinized. An angiographic pigtail catheter is then introduced over a guidewire through the 5Fr sheath and into the thoracic aorta. The device is then introduced through the exposed CFA over a stiff wire to the approximate position of the pathology. Aortic arch or thoracic aorta angiography is then performed utilizing DSA to delineate the aortic anatomy and determine the appropriate positioning of the stent graft (Fig. 6). Following deployment of the stent graft, a large-diameter compliant balloon can be utilized for improved fixation of the stent graft to the aortic wall at the proximal and distal landing zones or at sites of overlap if multiple devices are deployed (Fig. 7).

It is critical to monitor the withdrawal of the access sheath while concurrently monitoring the patient's hemodynamics to evaluate for any signs of access vessel disruption. If there are any indications of iatrogenic access injury manifest usually abrupt hypotension with sheath removal, the sheath can be reinserted over the stiff wire to obturate the injury. In instances where the sheath cannot be replaced, the large-diameter compliant balloon can be placed proximal to the site of injury to occlude the aorta and provide vascular control. Depending on the degree of vessel injury, repair options include a flank incision to access the retroperitoneum for reconstruction of the vessel in cases of frank disruption versus endovascular covered stent placement for less severe injuries.

BFEVAR usually requires additional transaxillary access for insertion of stent grafts through the branches or fenestrations of the aortic device and antegrade into the visceral and renal vessels. Operator skill and experience in transaxillary access and direct cannulation of the aortic branch vessels is critical. Tortuosity of the target vessels, angulation cephalad of the target, or ostial disease can greatly complicate stable cannulation of the vessels to allow delivery of the bridging stents from the FBEVAR aortic device into the target vessel.

Outcomes

The application of endovascular therapies for pathologies of the thoracic aorta was pioneered by Dake et al. in 1994. Their initial series of 13 patients undergoing TEVAR demonstrated 100% technical success in the absence of mortality and paraplegia. This initial report was followed by the first long-term outcomes as part of the midterm follow-up results of the Gore TAG trial. The trial compared 191 patients undergoing TEVAR for DTAA to 94 patients who received traditional, open surgical repair. Their findings demonstrated that patients undergoing TEVAR had decreased rates of aneurysm-related mortality (2.8% vs. 11.7%, $P = 0.008$) but similar rate of all-cause mortality (68% vs. 67%, $P = 0.433$) at 5-year follow-up. TEVAR was also associated with lower rates of major adverse events during the first postoperative year (42% vs. 77%, $P < 0.001$). However, 3.6% of TEVAR patients were subjected to secondary interventions, and 21% were found to have endoleaks or persistent communication between the previously sealed aorta and the aneurysm sac. During the follow-up period, there were no reported ruptures or stent graft collapse, and only one incidence of significant stent graft migration. Trials utilizing additional devices have since been performed and again were found to be at least comparable to, if not superior to, open surgical repair (Table 1). Walsh et al. published a meta-analysis

TABLE 1 Summary of Outcomes Among the Three Multicenter Regulatory Trials Comparing TEVAR to Open Surgical Repair

	Gore TAG	Cook TX2	Medtronic Talent	Open Repair	Johns Hopkins Hospital
Patients	140	160	195	353	90
Mean age (yr)	71	72	70	68	67
Mortality	1.5%	1.9%	2.1%	7.1%	3.3%
SCI (paraplegia/paraparesis)	2.8%	5.6%	8.7%	13.0%	1%
Stroke	3.5%	2.5%	3.6%	6.7%	1%
1-year reinterventions	2.1%	4.4%	10.7%	3.7%	–
Aneurysm-related survival	83%	91.6%	83.9%	82%	–

of 17 studies and found significant reductions in mortality and major neurologic complication rates when comparing TEVAR to open surgical repair. Although prospective, randomized trials comparing TEVAR to open surgical repair are lacking, most mid- and long-term follow-up data suggest that TEVAR is superior to traditional open surgical repair in regard to perioperative mortality and SCI. TEVAR is particularly of benefit in patients felt to be unfit for open surgical repair due to preexisting comorbidities or baseline functional status.

Endovascular repair of TAAA was first described by Chuter et al. at University of California, San Francisco, in 2001. Since then, there have been advances made in endovascular technique including snorkel, sandwich, surgeon-modified endografts, and fenestrated and branched endografts (Figs. 8 and 9). These techniques have allowed for the treatment of high-risk patients with complex anatomy. The US Food and Drug Administration first approved the use of fenestrated endografts (FEVAR) in 2012 for juxtarenal AAAs. During the last 2 decades, endovascular repair of TAAA has shifted from physician modified stent grafts to manufactured off-the-shelf and custom-made endografts. Various nonrandomized studies looking at the outcomes of endovascular versus open repair of TAAA, have demonstrated lower morbidity, shorter length of stay in the hospital, and improved aneurysm related mortality (Table 2).

Management of Acute Aortic Dissections

Karen M. Kim, MD, MS, and Thomas E. MacGillivray, MD

Acute aortic dissection is the most common catastrophe of the human aorta. With a reported incidence of 3 out of 100,000 patients each year, aortic dissection is a deadly disease with an early mortality of 1% to 2% per hour. Without appropriate treatment, the 2-week mortality of aortic dissections involving the ascending aorta is approximately 90%. Although the presentation may be classic, symptoms can be nonspecific and can occur in patients with no evident risk factors. Misdiagnosis leading to even a slight delay in treatment is associated with increased mortality; therefore, proper diagnosis and expeditious therapy are essential for improved survival. Patients with aortic dissections require lifelong medical management and surveillance with regular imaging to monitor for aneurysmal degeneration or complications that can occur after open or endovascular repair of aortic dissection.

PRESENTATION AND DIAGNOSIS

Aortic dissection results from a sudden intimal disruption that leads to the pressurized propagation of blood flow through a "false lumen" within the media of the aorta. Circulatory collapse and death can occur within seconds due to aortic rupture, frequently misdiagnosed as a massive myocardial infarction. The classic presentation is sudden, severe, "10/10," "tearing," or "ripping" chest pain radiating to the back between the scapulae. Occasionally, patients will present with little or no pain. Afflicted patients often appear listless and possess a sense of impending doom.

Preferential blood flow in the false lumen, as opposed to the "true lumen," can disrupt and occlude branching vessels of the aorta, resulting in decreased blood flow to an organ ("malperfusion") and even end-organ ischemia with pathophysiologic compromise

("malperfusion syndrome"). A new neurologic deficit or a pulseless extremity can distract the unsuspecting clinician. Electrocardiogram (ECG) changes or a new diastolic murmur can occur from retrograde dissection into the coronary arteries or the aortic valve resulting in myocardial ischemia or congestive heart failure. Acute paralysis, abdominal pain, renal insufficiency, and syncope are all well-recognized atypical presentations of acute dissection. Difficult-to-control hypertension can be a risk factor as well as a presenting sign in patients with aortic dissection. Hypotension and shock are concerning signs of tamponade, cardiac dysfunction, or ongoing hemorrhage. A high index of suspicion for aortic dissection is imperative for any patient with asymmetric pulses or differential blood pressures in the extremities.

High-resolution contrast-enhanced computed tomographic angiography (CTA) has replaced conventional aortography as the gold standard diagnostic study to confirm or exclude the diagnosis of acute aortic dissection. CTA has a diagnostic sensitivity and specificity of 90% to 100% and is readily available in most hospitals. False positive diagnoses can occur due to artifactual lines resulting from mistiming of contrast boluses or inappropriate gating with the cardiac cycle. Although scans limited to the thoracic aorta can confirm the diagnosis, it is recommended to scan the entire aorta and iliofemoral vessels to assess for subclinical malperfusion and to assist in planning the surgical or endovascular intervention.

Transesophageal echocardiography (TEE) can be a valuable tool to diagnose and manage patients with acute aortic dissection. Although TEE does require special expertise, it can rapidly assess for tamponade, valvular dysfunction, and cardiac wall motion abnormalities, particularly in the hemodynamically unstable patient transported directly to the operating room. Magnetic resonance imaging (MRI), conventional aortography, and coronary angiography have a very limited role in the acute management of aortic dissection patients.

Historically, "acute" dissections are those present for 14 days or less, whereas "chronic" dissections describe those present for greater than 2 weeks. Recently, the nomenclature has been modified to include "hyperacute" (<24 hours), "acute" (between 24 hours and 14 days), "subacute" (15–90 days), and "chronic" (>90 days) phases based on time from the initial presentation.

Intramural hematoma (IMH) comprises approximately 10% to 20% of patients who present with the clinical picture of acute aortic dissection. It consists of hemorrhage within the media of the aortic wall, usually without identifiable intimal disruption. Radiographically, IMH appears as a high-attenuation crescentic or circumferential thickening of the aorta on noncontrast imaging, with absence of blood flow through a false lumen on contrast imaging (sometimes inappropriately referred to as dissection with thrombosed false lumen). IMH may result from a microscopic intimal tear, hemorrhage of the vasa vasorum, or a penetrating aortic ulcer. Although it is a matter of discussion and debate, acute IMH is usually managed similarly to acute aortic dissection.

CLASSIFICATION

Acute aortic dissection can manifest in several different anatomic patterns that have different therapeutic and prognostic implications. The two main classification schemes in use worldwide to describe aortic dissection are the DeBakey and Stanford systems (Fig. 1). The DeBakey system categorizes the dissection based on the origin of the intimal tear and the extent of the dissection. Aortic dissections involving the ascending, arch, and descending aorta are DeBakey type I. Dissections confined only to the ascending aorta are DeBakey type II. Aortic dissections that originate and propagate distal to the left subclavian artery are DeBakey type III, with IIIa limited to the descending thoracic aorta and IIIb extending below the diaphragm.

The Stanford classification system divides dissections into two categories: those that involve the ascending aorta (Stanford type A, or DeBakey types I and II) and those that involve the descending thoracic aorta (Stanford type B, or DeBakey type III), regardless of the site of primary intimal tear. The aortic arch is not straightforwardly addressed in the Stanford classification, and dissections involving this area are sometimes referred to as type B (by North American surgical consensus, described later) or as "non-A-non-B" (by European surgical consensus).

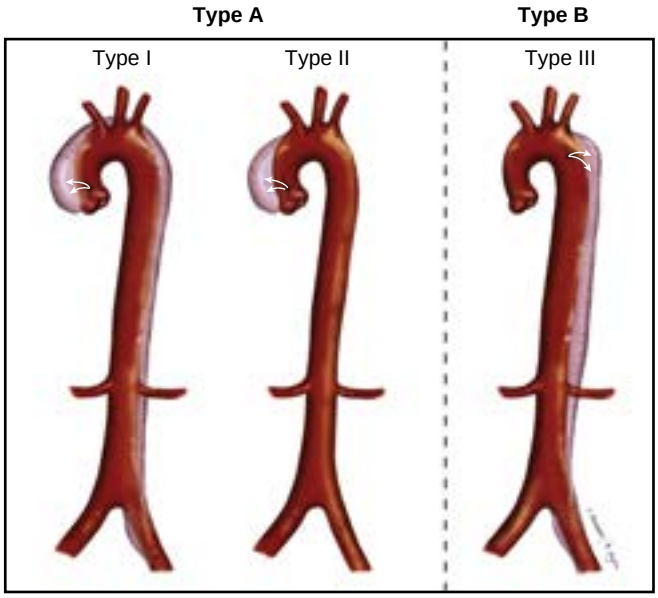

FIG. 1 Anatomy and classification of aortic dissection: DeBakey and Stanford systems. **DeBakey Classification**: Type I dissection originates in the ascending aorta and extends at least to the aortic arch and typically to the descending aorta (and beyond). Type II dissection only in the ascending aorta. Type III dissection originates in the descending aorta, usually just distal to the left subclavian artery, and extends distally. **Stanford Classification**: Type A dissection involves the ascending aorta (with or without extension into the descending aorta). Type B dissection does not involve the ascending aorta (includes arch dissection) *(From Braverman AC, Thompson R, Sanchez L. Diseases of the aorta. In: Bonow RO, Mann DL, Zipes DP, Libby P, eds.* Braunwald's Heart Disease. *9th ed. Philadelphia: Elsevier. 2012.)*

Recently, the Society of Thoracic Surgeons (STS) and the Society of Vascular Surgeons (SVS) created a new classification system that combines the "A" and "B" of the Stanford classification with endovascular aortic zones to communicate, in greater detail, anatomic features of the dissection that may affect planning for endovascular therapies. In the SVS/STS classification system, type A dissections encompass those with an intimal tear in the ascending aorta and proximal arch including the innominate artery ostium (zone 0), and type B dissections encompass those with an intimal tear in any portion of the aorta distal to that (zones 1 and beyond). In this system, dissections involving the arch are more clearly defined. Type I dissections (as in the letter "I," not the Roman numeral) are those with an unidentified intimal tear. For type A and I dissections, the distal extent of the dissection (d) by endovascular zone is denoted with a subscript (e.g., type A_d or I_d). For type B dissections, both the proximal extent (p) and the distal extent (d) by endovascular zone are denoted with subscripts (e.g., type $B_{p,d}$) (Fig. 2). For example, a type B dissection with an entry tear just beyond the left subclavian artery with retrograde extension of the false lumen to the origin of the left common carotid artery (i.e., zone 1) and antegrade extension to the renal arteries (i.e., zone 8) would be denoted as type $B_{1,8}$.

Acute type B dissections are further classified as "complicated," "uncomplicated," or "high risk" (Box 1). Complicated type B dissections include approximately 20% of patients with rupture or

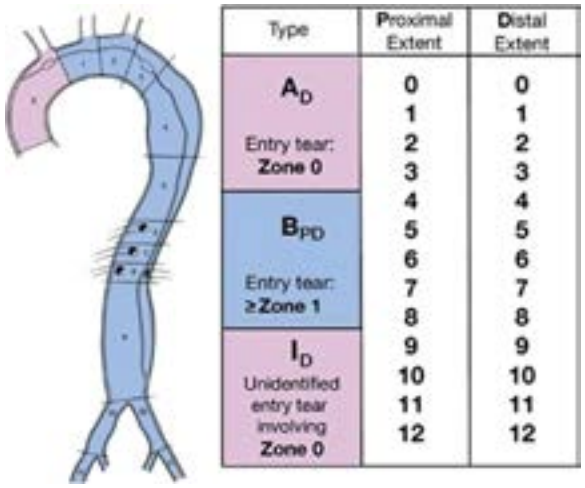

FIG. 2 STS/SVS aortic dissection classification system. *(Modified from Lombardi JV, Hughes GC, Appoo JJ, et al., Society for Vascular Surgery (SVS) and Society of Thoracic Surgeons (STS) reporting standards for type B aortic dissections.* Ann Thorac Surg. *2020;109:959–981.)*

BOX 1 Characterization of "Uncomplicated," "High Risk," and "Complicated" Aortic Dissections

Uncomplicated

No rupture
No malperfusion
No high-risk features

High risk

Refractory pain
Refractory hypertension
Bloody pleural effusion
Aortic diameter >40 mm
Radiographic only malperfusion
Entry tear: lesser curve location
False lumen diameter >22 mm

Complicated

Rupture
Malperfusion

Modified from Lombardi JV, Hughes GC, Appoo JJ, et al. Society for Vascular Surgery (SVS) and Society of Thoracic Surgeons (STS) reporting standards for type B aortic dissections. *Ann Thorac Surg.* 2020;109:959–981.

malperfusion syndrome for whom open surgical or endovascular therapy is indicated. Uncomplicated type B dissections are effectively managed with optimal medical therapy, while patients who have acute type B dissections with high-risk features may benefit from endovascular therapy to reduce short- and long-term morbidity and mortality.

MANAGEMENT

Initial Management

Once the diagnosis of acute aortic dissection, whether type A or type B, is suspected, invasive hemodynamic monitoring and aggressive antiimpulse therapy should be instituted without delay. A radial arterial monitoring cannula should be placed in the upper extremity with the best pulse and blood pressure, as a limb with a barely palpable pulse or lower blood pressure may indicate malperfusion. Intravenous β-blockade should be the medication of first choice to decrease the aortic dP/dT by titrating the infusion to a goal heart rate of 60 to 70 beats per minute and a systolic blood pressure of 100 to 120 mm Hg. Once adequate beta-blockade is achieved, vasodilators (nitroprusside, nicardipine, clevidipine, etc.) can be added to further control hypertension. Initial blood pressure control with vasodilators like nitroprusside or hydralazine should be avoided. Although vasodilators will lower the blood pressure, they can increase the dP/dT and shear forces in the aorta, thereby increasing the risk of rupture. Acute type A dissection patients with a diastolic murmur or TEE evidence of significant aortic valve regurgitation should not be managed with β-blockers because of the high risk of exacerbating congestive heart failure.

Acute aortic dissection can be a very dynamic disease with a rapidly evolving clinical course. Patients diagnosed with hyperacute/acute type A aortic dissection should be emergently transferred to a cardiac surgical center for immediate surgical repair. Unnecessary testing or optimizing medical therapy should not be allowed to delay definitive surgical repair. Even patients with coronary, cerebral, visceral, renal, and/or extremity malperfusion should be managed with central aortic reconstruction as a first step, which will frequently correct the malperfusion syndrome. Recently, some centers have had success with initial endovascular stabilization of visceral malperfusion syndromes before surgical repair of the ascending aorta due to the high risk of mortality in this group of patients. Nonoperative management, though it carries high risk of mortality, may be appropriate when faced with very high-risk patients, especially those with advanced coronary, pulmonary, and renal disease.

Management of Acute Type A Dissections

Acute Stanford type A dissections account for greater than 60% of all dissections and are surgical emergencies requiring immediate operation. The goal of surgical therapy for acute type A aortic dissection is to prevent imminent death from aortic rupture (causing exsanguination or tamponade), acute aortic insufficiency, or malperfusion of the coronary, cerebral, and systemic circulations. The principal technique to accomplish these goals is to resect the primary intimal tear in the ascending aorta by replacing the ascending aorta with a tube interposition graft, thus reestablishing blood flow in the true lumen of the aorta. Resuspension of the aortic valve is often needed to reestablish competence of the aortic valve after retrograde extension of the dissection has disrupted one or more of the aortic valve commissures.

Invasive arterial and central venous pressure monitoring are helpful for the induction and conduct of general anesthesia. Temperature monitoring of the nasopharynx, central venous or pulmonary arterial blood, and bladder can ensure uniform perfusion and cooling. TEE, EEG, and cerebral oximetry are useful adjuncts for monitoring.

As cardiopulmonary bypass is required for ascending aortic replacement, the surgeon must determine the site of arterial cannulation and perfusion. Although historically the common femoral artery was the most common approach for arterial cannulation given its size, easy accessibility, and surgeons' familiarity, recent studies have shown that the right axillary or innominate artery, via an 8 or 10 mm Dacron graft anastomosed end-to-side to the artery, is a preferred site for arterial perfusion to avoid retrograde embolic events and to facilitate the use of antegrade cerebral perfusion during circulatory arrest. Some experienced surgeons advocate the use of direct central ascending aortic cannulation with the use of TEE guidance—a potentially challenging approach but one that can be lifesaving in the management of an unstable patient.

Through a median sternotomy, the heart and ascending aorta are readily exposed. The right atrium is easily cannulated for venous drainage to initiate cardiopulmonary bypass. Most aortic surgeons

utilize a period of hypothermic circulatory arrest to perform an open distal aortic anastomosis. During cooling, it is imperative that the surgical, anesthesia, and perfusion teams monitor the patient to ensure uniform perfusion and cooling. Occasionally, cannulation strategies must be altered to manage malperfusion during cardiopulmonary bypass. In situations involving aortic insufficiency and/or coronary malperfusion, the surgeon should be prepared to vent the left ventricle on bypass, cross-clamp the aorta, and meticulously protect the myocardium with retrograde coronary sinus and possibly direct antegrade coronary ostial cardioplegia strategies.

Although there is considerable debate about the optimal temperature for hypothermia and circulatory arrest, the authors achieve moderate hypothermia (temperature between 24°C–27°C) in the nasopharynx before turning off the circulation to the body while employing antegrade or retrograde cerebral perfusion. With the patient in Trendelenburg position, the entire ascending aorta from the sinotubular junction up to the innominate artery, with a bevel including the lesser curve of the aortic arch, is resected. The aortic tissues are extremely fragile, and they should be delicately handled. Without an aortic cross clamp, the aortic arch can be inspected for complex intimal disruptions and to confirm that the brachiocephalic branches are intact and arising from the true lumen. All three layers of the proximal aortic arch are then reconstructed, thereby obliterating the false lumen, which will then allow blood flow through the true lumen once central perfusion is reestablished. Some surgeons reconstitute the aortic wall between two Teflon felt strips and anastomose a Dacron graft to the aortic-felt sandwich (Fig. 3A). The authors prefer to insert a piece of Teflon felt into the false lumen (Fig. 4A) and to then sew the Dacron graft to the reconstituted aorta, buttressed with a strip of Dacron around the adventitia. The authors avoid the use of glues during these operations. Although glues allow for easier tissue handling, they can be destructive to the aorta and promote late pseudoaneurysm formation.

With the distal anastomosis completed, the aortic arch is de-aired, the proximal end of the graft is clamped, and cardiopulmonary bypass is resumed through the Dacron graft to promote true lumen flow (Fig. 3B, C). Generally, aortic arch replacement is not routinely necessary for managing most patients with acute type A aortic dissection. Arch replacement increases the complexity and length of the procedure, which can add to the already high-risk operation. Situations when the aortic arch should be considered for replacement in acute dissection patients include complex intimal disruptions in the arch, arch aneurysms larger than 5 cm, or genetically triggered thoracic aortic diseases (e.g., Marfan, Loeys-Dietz, Ehlers Danlos). Arch replacements should be performed with the use of selective antegrade or retrograde cerebral perfusion, which has been demonstrated to improve outcomes. For patients with large intimal disruptions in the distal arch or proximal descending aorta, antegrade deployment under direct vision of a stent graft, or "frozen elephant trunk" (Fig. 5), can stabilize the distal aorta and reduce the need for early reintervention or can address distal malperfusion.

During rewarming, the aortic root, aortic valve, and proximal ascending aorta are assessed for reconstruction or replacement. The false lumen may extend retrograde into the aortic root but without intimal tear in the sinus segment; in this case, the aortic root can be reconstructed using a "neo-media" technique by obliterating the false lumen with Teflon felt (Fig. 4B,C). Attention is required in patients who present with aortic regurgitation and in those who have complex aortic root dissections approaching the coronary ostia. Aortic regurgitation is the most common cardiac complication associated with acute type A dissection. There are three possible dissection-related mechanisms that can contribute to aortic regurgitation. Acute dilation of the sinotubular junction and root caused by the expanding false lumen can result in incomplete coaptation of the valve cusps. The dissection can also extend into the aortic root, disrupting the commissural posts resulting in prolapse of the valve cusps. Additionally, an aortic flap can itself prolapse through the valve in diastole preventing appropriate valve function. In most patients, the sinotubular junction can be reconstructed, the aortic valve commissures resuspended, and the aortic valve preserved. Situations when composite aortic root replacement with coronary button reimplantation should be considered include patients with aneurysms of the aortic root exceeding 5 cm, complex aortic valve pathology, dissection approaching the coronary ostia, and genetically triggered thoracic aortic diseases. Valve-sparing aortic root replacement should be reserved for highly experienced aortic surgeons in this setting.

Surgical Results with Acute Type A Dissections

According to the International Registry of Acute Aortic Dissection (IRAD) database, the overall surgical mortality of acute type A aortic dissection is 18%. In unstable patients (e.g., preoperative presence of tamponade, shock, congestive heart failure, stroke, coma, myocardial ischemia/infarction, acute renal failure, or mesenteric ischemia), the surgical mortality is greater than 30%. Postoperatively, aortic dissection patients are at risk for coagulopathic bleeding requiring transfusions and reexploration. Transient neurologic dysfunction, stroke, renal insufficiency, acute lung injury, new malperfusion syndromes, multiorgan system failure, and refractory hypertension are some of the possible early postoperative complications requiring intensive care and prolonged hospital care of these complicated patients. There is variability of outcomes reported from different centers, but the fact remains that acute type A aortic dissection is a highly lethal condition which, even when appropriately managed, has a high risk of morbidity and mortality.

Management of Acute Type B Dissections

Historically, the results of open surgical therapy for acute type B dissection had been associated with a higher mortality than with medical therapy. Currently, optimal medical therapy using antiimpulse medications remains the preferred treatment for patients with uncomplicated type B dissection. Approximately 20% of patients with acute type B dissections are complicated by rupture or malperfusion and have a high risk of death without intervention. Thoracic endovascular aortic repair (TEVAR) with stent grafts has largely replaced open surgery for patients with complicated type B aortic dissection with improved early outcomes. Open surgical repair is reserved for those patients with unsuitable anatomy for TEVAR and for those with genetically triggered aortic diseases. Whether TEVAR of uncomplicated type B dissection with high-risk features proves to be superior to medical management remains to be proven. There are reports that TEVAR improves aortic remodeling over time, which may translate to decreased aortic complications and improved long-term survival.

Thoracic endovascular repair addresses rupture or malperfusion by covering the primary intimal tear and possible large reentry tear(s) in the descending thoracic aorta, thereby restoring blood flow to the true lumen of the aorta and its major branches. Coverage is usually extended from the caudal aspect of the left subclavian artery (LSA) (zone 3) to just proximal to the celiac artery (zone 5) and may extend proximally into zone 2 if the intimal tear is close to or involves the LSA. If TEVAR does not need to be performed emergently, revascularization of the LSA with carotid-subclavian bypass or subclavian-carotid transposition can decrease the risk of vertebrobasilar stroke, left arm ischemia, and paralysis.

TEVAR is most often performed via iliofemoral access, with open exposure or ultrasound and fluoroscopy-guided percutaneous access of the common femoral artery. Systemic heparin is administered to achieve ACT >250 sec. After advancement of a J-wire into the ascending aorta, intravascular ultrasound (IVUS) is used to confirm true lumen access along the entire extent of the wire. IVUS is also helpful in noting the origins of the LSA and celiac axis, a compressed true lumen, and dissection extending into branch vessels. The soft wire is then exchanged for a stiff Lunderquist

wire, and a large sheath is advanced into the abdominal aorta. The appropriately sized device is delivered through the sheath, a pigtail catheter is advanced alongside the stent graft (whether through the sheath or from contralateral femoral access), and thoracic aortography in left-anterior-oblique (LAO) projection is performed to delineate the origin of the LSA. The device is positioned with the proximal extent in the desired endovascular zone (zone 2 if coverage of the LSA is planned, zone 3 if not), and with ventilation held, the device is deployed. The delivery system is removed, and subsequent devices are advanced and deployed in similar manner until the desired extent of coverage is achieved. Completion aortography is performed to confirm patency of branch vessels and absence of proximal, distal, and overlap endoleaks. IVUS can be used as well to examine patency of branch vessels and to confirm the absence of retrograde type A dissection. The sheath is removed and the arteriotomy repaired primarily or with percutaneous closure devices. In the early postoperative period after TEVAR, when spinal cord perfusion is vulnerable, the mean arterial pressure should be kept at 80 to 90 mm Hg to decrease risk of paralysis or paraparesis. Once the risk of spinal cord ischemia has abated, lifelong blood pressure control is necessary to reduce long-term morbidity and mortality. Other early complications include stroke, bleeding from major vascular complication, and stent-induced new entry (SINE) tears, while late complications include endoleaks, aneurysmal degeneration of treated or untreated aorta, and infection.

The 5-year survival of patients with chronic type B aortic dissection is 60% to 80%, with many of these patients succumbing from aneurysmal degeneration and rupture.

Carotid Endarterectomy

Bruce A. Perler, MD, MBA

Stroke is one of the most important healthcare problems in the United States and throughout the Western world in terms of mortality, morbidity, and cost. Nearly 800,000 new strokes occur each year in the United States, and it is the fifth leading cause of death and the most frequent cause of long-term disability in this country. More than 80% of strokes are ischemic, and atherosclerosis of the extracranial carotid arteries is the most common preventable cause of ischemic stroke. It is therefore not surprising that carotid endarterectomy (CEA) has been the most frequently performed open vascular surgical operation in the United States.

CLINICAL PRESENTATION

In formulating a treatment plan for the patient with carotid artery disease, the two most critical issues have been the patient's clinical status and the degree of stenosis in the internal carotid arteries. Today, however, especially among patients with asymptomatic disease, we are recognizing that the composition of the plaque is predictive of future ischemic events and therefore is a relevant consideration in selecting patients for CEA. The vast majority of individuals with significant carotid artery disease are completely asymptomatic, and most are identified by the presence of a bruit in the neck. Although the cervical bruit is the only physical finding suggestive of carotid artery disease, it cannot be overemphasized that it is an insensitive and very nonspecific finding. Among individuals with a cervical bruit, no more than 30% to 50% will be found to have a clinically significant stenosis in the ipsilateral internal carotid artery (ICA). Conversely, among individuals with

high-grade carotid stenoses, a bruit will be found in no more than 20% to 50% on the affected side.

A minority of patients with significant carotid artery disease may be identified after presenting with a transient ischemic attack (TIA). A TIA is defined as an abrupt interruption of focal neurologic function, and usually with very rapid resolution. Symptoms consistent with a TIA include weakness, paralysis, numbness or paresthesias of an arm and/or leg on one side of the body (hemiparesis or hemianesthesia), difficulty speaking or finding words (aphasia or dysphasia), or acute loss of vision in one eye or a part of the eye (amaurosis fugax). An exceedingly uncommon but important manifestation of a TIA is the so called *limb-shaking TIA,* which typically occurs in individuals with very severe or pre-occlusive stenoses or those with carotid occlusions and are often confused with seizures. The average duration of a TIA is about 14 minutes, but most last less than 5 minutes, and more than 80% resolve within 2 hours. In other words, if symptoms have lasted longer than 2 hours, it is likely that the patient is in the process of evolving a completed stroke. To be considered a TIA, the symptoms must completely resolve within 24 hours. Formerly, if symptoms lasted longer than 24 hours but resolved within 48 hours, the presentation was considered a *reversible ischemic neurologic deficit* (RIND), although this terminology is falling out of favor. Finally, if symptoms persist and if there is evidence of an infarct on cerebral imaging, the patient has manifested a stroke. It should be noted that several recent large population-based studies have demonstrated that no more than 10% to 35% of individuals who suffered an ischemic stroke actually experienced a recognized TIA before the stroke occurred. Crescendo TIAs refers to a clinical scenario in which the patient is experiencing repeated neurologic events, often at increased frequency, with complete symptomatic resolution between attacks. A *stroke-in-evolution* refers to patients who manifest ongoing symptoms that often worsen over a short period, ultimately culminating in a completed stroke.

The differentiation of patients into the proper clinical class is critical because the risk of subsequent stroke and thus the threshold for and risk of CEA one would be willing to accept will depend on the clinical status. For example, among asymptomatic patients with a significant internal carotid stenosis, the risk of stroke over the next 5 years is approximately 10% to 15%, although recent improvements in medical management may have reduced the incidence somewhat. On the other hand, among patients who have experienced a TIA, the incidence of stroke is approximately 25% within the first year, and most of those strokes occur early, within the first few weeks or months after the TIA with a decreasing incidence over time. The 5-year incidence of stroke among individuals who have experienced a TIA is 35% to 45%. Finally, among individuals who have experienced an ischemic stroke secondary to carotid artery disease, the 5-year stroke incidence is roughly 50%, and nearly 50% of those second strokes may be fatal.

Imaging Studies

Carotid duplex ultrasound has emerged as the diagnostic modality of choice for evaluating patients with suspected carotid disease. Duplex evaluation provides both anatomic B-mode ultrasound imaging information about the composition of the plaque and degree of stenosis, as well as an assessment of flow velocities (spectral analysis) that allows one to more precisely predict the degree of stenosis in the carotid arteries. In the hands of experienced sonographers, it is more than 90% accurate in depicting significant carotid stenoses when compared with contrast angiography. As noted earlier, among patients with asymptomatic ICA stenoses, it is not only the severity of the stenosis but also the character of the plaque that should influence the decision to perform a CEA; specifically, plaque that appears echolucent on imaging may have a higher risk of subsequent ischemic events than more echogenic plaque. Duplex ultrasound is more sensitive than contrast angiography in identifying the potentially vulnerable or unstable carotid plaque and therefore the patient who will most benefit from performance of CEA.

When further anatomic information is required, for example in assessing a potentially high bifurcation or unusual lesion or when previous duplex scans provide conflicting information, magnetic resonance angiography (MRA) or computed tomography arteriography (CTA) may be obtained. On occasion, MRA may overestimate the degree of stenosis. CTA can provide more anatomic information than MRA, but it does require contrast administration.

In light of its invasiveness, risks, and costs, contrast arteriography is very infrequently performed today before CEA. In addition to its role in carotid artery stenting, it might play a role if there are ongoing concerns about the underlying anatomy such as a high carotid bifurcation, before reoperative CEA, to assess vertebrobasilar insufficiency, or to identify possible intracerebral arterial disease.

In the symptomatic patient, computed tomography (CT) or magnetic resonance imaging (MRI) should be obtained to assess for cerebral infarction and its extent. MRI is more accurate in the early hours after a stroke. Previous studies have demonstrated that as many as 10% of asymptomatic patients and 30% of patients who have experienced TIAs will have evidence of cerebral infarctions on CT or MRI studies. The presence of so-called "silent strokes" on imaging is associated with an increased risk of subsequent stroke among patients with clinically asymptomatic carotid stenoses.

INDICATIONS FOR CEA

The indications for CEA have been established by level 1 evidence derived from several randomized prospective clinical trials (Table 1). The North American Symptomatic Carotid Endarterectomy Trial (NASCET) demonstrated a clear benefit of CEA plus best medical management compared with best medical management alone for symptomatic patients with high-grade (70%–99%) carotid stenoses. The same year, the European Carotid Surgery Trial (ECST) demonstrated a similar but smaller benefit in symptomatic patients with 70% to 99% stenoses. Analysis of a second cohort of symptomatic patients with moderate (50%–69%) stenoses in the NASCET trial demonstrated a smaller but statistically significant benefit as well. Therefore, CEA is indicated in acceptable operative risk symptomatic patients with a > 50% ICA stenosis. One exception are symptomatic patients with a < 50% stenosis caused by a carotid web. This is a condition seen primarily in relatively young women, and it is felt to be a variant of fibromuscular disease. They have been found to develop thrombi behind the intimal web, which then embolize to the brain and cause recurrent strokes. Antiplatelet therapy has been much less effective than in arteriosclerotic disease, and CEA has resolved these episodes (Fig. 1).

The Asymptomatic Carotid Atherosclerosis Study (ACAS) demonstrated a significant benefit of CEA plus best medical management compared with best medical management alone for patients

TABLE 1 Carotid Endarterectomy: Randomized Trials

Trial	Indication	CVA/Death	Risk Reduction	*P*
NASCET	Sx: > 70%	5.8%	16.5%/2 years	< 0.001

with asymptomatic stenoses of 60% to 99%. These findings have been confirmed in the Asymptomatic Carotid Surgery Trial (ACST) in Europe.

The most recent published clinical practice guidelines of the Society for Vascular Surgery recommend CEA and optimal medical therapy for patients with symptomatic disease (stroke or TIA) and a ≥ 50% internal carotid stenosis, and state that CEA should be "considered" for asymptomatic patients with a ≥ 70% internal carotid stenosis, assuming the patient has a reasonable life expectancy (3–5 years) and that the operation can be performed with a stroke/death rate of < 3%. These recommendations mirror earlier guidelines from the American Heart Association (AHA). Specifically, the AHA recommends CEA for patients who have experienced a TIA or stroke within 6 months and ipsilateral 70% to 99% internal carotid stenoses if the surgeon has a perioperative stroke/death rate of ≤ 6%. For symptomatic patients with a 50% to 69% ipsilateral internal carotid stenosis, CEA is recommended after consideration of patient-specific factors such as age, comorbidity, and severity of symptoms. For asymptomatic patients, the AHA recommends CEA for patients with a 60% to 99% stenosis if the surgeon's perioperative stroke/death rate is ≤ 3%.

Despite this level 1 evidence, the role of CEA in the management of patients with asymptomatic carotid disease has been recently challenged. This argument is predicated upon the observation that the natural history of asymptomatic carotid disease in contemporary practice is better than what was observed in the medically managed patients in the randomized trials because of recent improvements in medical management and especially the use of statins. However, it is also true that the outcome of CEA today is superior to what was observed in the trials as well, in part because of the same improvements in medical management and especially statins (see later). Therefore, the author believes that there is no conclusive evidence to dismiss the findings of the ACAS and ACST investigations, and the recommendations for CEA in the currently published guidelines remain appropriate. The ongoing CREST-2 trial is designed to address this issue.

CEA: OPERATIVE TECHNIQUE

Anesthesia

CEA may be performed under general anesthesia, regional anesthesia with deep or superficial cervical block, and even pure local anesthesia. Although early reports suggested a reduced length of stay associated with CEA performed under regional anesthesia, comparable lengths of stay are routinely documented today among patients who undergo operations under general anesthesia. The majority of studies comparing the two techniques have reported improved perioperative cardiac stability with regional anesthesia, but this does not necessarily result in a reduced incidence of myocardial infarction. Disadvantages of regional anesthesia include potential patient discomfort or anxiety, risk of seizure or allergic reaction, anxiety for the operating surgeon, and compromise of technique.

Patient Positioning

Careful positioning of the patient is important to ensure patient comfort and adequate operative exposure. Positioning begins with placing a roll behind the scapula to achieve some extension of the neck. A padded ring is placed under the head to prevent neck injury from hyperextension. If general anesthesia is employed, the endotracheal tube should be taped to the corner of the mouth opposite to the surgical field. If local or regional anesthesia is used, a Mayo stand is placed over the patient's head to suspend the surgical drapes away from the patient's face to prevent sensations of claustrophobia.

Skin Incision

The standard incision used is a longitudinal incision parallel to the medial border of the sternocleidomastoid muscle. The upper portion of the incision is angled posterior to the earlobe if cephalad exposure above the angle of the jaw is required. An alternative incision is to place the incision transversely in an appropriately located skin crease, usually 1 to 2 cm inferior to the angle of the jaw (Fig. 2). This incision provides excellent postoperative cosmesis. However, if the transverse incision is made in a suboptimal location, it may be more difficult to obtain more cephalad and/or caudal exposure in the wound.

Operative Exposure

Meticulous surgical technique is paramount to a successful operation. Manipulation of the carotid artery should be minimized as intraoperative embolization can result from careless handling. The dissection is begun by dividing the platysma and mobilizing the medial border of the sternocleidomastoid muscle. The external jugular vein lies deep to the platysma and should be sought out in this plane to avoid injury or in the event it is needed for patching. It is

FIG. 2 **Longitudinal and transverse carotid incisions.** *(From Sidawy AN, Perler BA, eds. Rutherford's Textbook of Vascular Surgery & Endovascular Therapy. Elsevier; 2019.)*

more commonly encountered with an oblique skin crease incision than with a longitudinal incision. The other structure located at this level is the greater auricular nerve; injury to this nerve leads to numbness of the earlobe. The carotid sheath is entered, and the medial border of the internal jugular vein is dissected. The facial vein is identified crossing medially in the base of the wound and divided; sometimes it has an early bifurcation or trifurcation, and multiple branches need to be ligated. The internal jugular vein is then retracted laterally. The vagus nerve is identified at this point in the carotid sheath, usually located posteriorly between the internal jugular vein and the carotid artery, although in a minority of patients it may lie anteriorly. The common carotid artery (CCA) is controlled circumferentially with an umbilical tape and Rummel tourniquet if a shunt is to be used. At this point, the ansa cervicalis nerve should be identified; it usually lies medial to the distal CCA. Identifying this nerve facilitates safe dissection of the carotid bifurcation and avoids injury to the hypoglossal nerve that crosses medially from a superior to inferior location. The superior thyroid artery is identified coming off the medial border of the carotid bifurcation or proximal external carotid artery (ECA) and is controlled with a tie or vessel loop. The ECA and ICA are encircled with vessel loops, making certain to control the latter beyond the disease process. During the dissection of the carotid bifurcation and its branches, one should avoid dissecting in the crotch of the carotid bifurcation to avoid injuring the carotid body because this can result in hemodynamic instability and troublesome bleeding. If hemodynamic instability results, the carotid body can be injected gently with 1% lidocaine.

Before clamping, the patient is administered 70 to 100 units/kg of heparin, and it is allowed to circulate for 3 minutes. The ICA is clamped first to prevent embolization that can result when the CCA or ECA is clamped. Care should be taken to make sure the ICA is clamped on a normal portion of the artery distal to the plaque.

If local anesthesia or intraoperative electroencephalography (EEG) is employed for selective shunting, a test clamp on the distal ICA should be applied for at least 3 minutes to check for changes in the neurologic examination or EEG pattern. If such changes occur, the artery should be unclamped to allow for reperfusion before reclamping and opening the carotid bifurcation. This is because opening the bifurcation and placing a shunt may take 2 to 3 minutes and should not be performed while the brain is already ischemic. However, unclamping the ICA introduces the potential for embolization from a disrupted plaque.

If carotid stump pressure is to be measured, clamps are placed on the CCA and ECA, and a needle connected to a pressure line is placed into the distal CCA artery below the carotid bifurcation. A stump pressure > 50 mm Hg is generally indicative of adequate perfusion, but this is not foolproof. Clamping the CCA and placing the needle into the artery does introduce the potential for embolization.

Conventional Endarterectomy

The conventional technique for CEA consists of a vertical arteriotomy and today, closure with a patch angioplasty. The arteriotomy is begun in the CCA and continued through the carotid bifurcation into the ICA. One should avoid making the incision too close to the flow divider at the ECA origin because this can distort the anatomy and make the closure more difficult. If a shunt is used, it is first placed in the distal ICA and back bled before the proximal end is placed into the CCA. Two commonly used shunts are the Pruitt-Inahara and the Javid shunts. A third shunt, preferred by the author, is a simple vinyl tube. Because this shunt lies entirely within the artery, it allows the surgeon to almost completely finish closing the arteriotomy before the shunt is removed. Its small diameter allows atraumatic placement in even small ICAs, while its short length offers less resistance to blood flow such that physiologic flow in the ICA is maintained (Fig. 3).

The endarterectomy is begun in the CCA in the plane between the media and the adventitia. The proximal endpoint in the distal

FIG. 3 Exposure of the common, internal, and external carotid arteries with the author's shunt within the vessel. *(From Sidawy AN and Perler BA, eds. Rutherford's Textbook of Vascular Surgery & Endovascular Therapy. Elsevier; 2019.)*

CCA is established, and the plaque is trimmed at that location in a beveled manner. The endarterectomy is continued into the orifice of the ECA, first with a Freer elevator and then with a fine clamp that is passed up into the external carotid artery in the plane of the endarterectomy. The vessel loop on the ECA is released transiently while the plaque is everted from within the ECA. The endpoint of the plaque is inspected: an ideal endpoint has a gradually tapering, feathered endpoint.

The endarterectomy is then continued up into the ICA. A technically perfect endpoint in the ICA is absolutely critical to avoid perioperative stroke and recurrent stenosis. It is virtually always possible to achieve a satisfactory endpoint in the ICA, although this may require special maneuvers to expose the distal ICA with extension of the arteriotomy to facilitate extraction of a long endarterectomy specimen. Tacking sutures at the distal endpoint should be avoided unless absolutely necessary; these are associated with increased perioperative stroke and are indicative of a problematic endpoint. The endarterectomy should be terminated in normal ICA with a gradual, tapered transition to normal intima (Fig. 4). This is best accomplished by pulling the plaque transversely away from the

FIG. 4 Typical carotid endarterectomy plaque. Note the tapered endpoints from the internal and external carotid arteries.

artery with lateral traction. One should avoid pulling out or down on the plaque, which is more likely to result in a step-off that can be difficult to correct.

The preponderance of evidence indicates that the arteriotomy should be closed with a patch. A variety of patch materials are available for use, including autologous vein, polytetrafluoroethylene (PTFE), woven polyester (Dacron), and bovine pericardium. The author prefers Dacron and running 6-0 polypropylene suture. The vessels are bled, and then the endarterectomy site is vigorously irrigated with heparinized saline and inspected again for debris or intimal flaps before the arteriotomy is finally closed. The clamp on the ICA is briefly released to fill the vessel with blood. It is then replaced while the clamps on the CCA and ECA are released so any remaining air or debris will be flushed up the territory of the ECA rather than the ICA. At this point, the ICA clamp is removed.

Eversion Endarterectomy

Eversion endarterectomy represents an excellent alternative technique. The ICA is amputated obliquely at the carotid bifurcation, and the adventitia is rolled back until normal intima is encountered at the distal endpoint. Residual plaque in the common and/or external carotid arteries is endarterectomized, and the ICA is reanastomosed to the CCA with 6-0 polypropylene suture. The advantages of this technique are that the anastomosis can be performed rapidly and is not prone to restenosis; therefore, patching is not required. The disadvantages are that a more extensive dissection is sometimes necessary to mobilize the vessels during the eversion, the procedure does not lend itself readily to shunting (although shunting is not precluded by this technique), and it can be difficult to visualize the endpoint in the ICA after the plaque has been removed; the artery tends to retract as soon as the plaque pulls away from the adventitia, and it can be difficult to expose and reinspect this area of the artery (Fig. 5).

Eversion carotid endarterectomy illustrated: tips and tricks of the procedure.* Surg Rounds. *2006;29(8):382–389.)*

Cerebral Protection and Monitoring

One of the longstanding debated issues related to the performance of CEA concerns the use of intravascular shunts: the routine nonuse of shunts, selective use of shunts, and routine use of shunts. The simplest way to perform CEA is to just clamp the carotid bifurcation and perform CEA without a shunt, and there are published series that document excellent results of CEA without shunts. However, all of these studies demonstrate at least a small incidence of stroke, and the etiology of the stroke is intraoperative cerebral ischemia during carotid artery clamping in at least some cases.

Alternatively, some routinely shunt in all cases of CEA, and excellent results have been reported in several large series. However, all of these studies document an incidence of stroke, and the cause of the stroke was attributed to technical problems related to the use of the shunt in some of these cases.

A third option is to shunt selectively. Several techniques have been utilized to identify the patient who truly needs a shunt. In the patient who is under general anesthesia, these include intraoperative measurement of carotid "stump pressure" after the common and external carotid arteries have been clamped, intraoperative neurologic monitoring of the patient's EEG or somatosensory evoked potentials (SSEP), measurement of middle cerebral artery (MCA) flow by transcranial Doppler (TCD) ultrasound, and monitoring of cerebral oximetry. The most accurate method is to perform CEA under regional anesthesia whereby the selection of patients for shunting is based on alterations in the neurologic examination that develop after the carotid artery is clamped.

Completion Studies

Although there are several potential etiologies of perioperative stroke among patients who undergo CEA, a preventable cause is thromboembolism or carotid artery thrombosis resulting from technical imperfection in the carotid artery repair. To minimize this risk, intraoperative completion studies have been utilized including continuous wave Doppler ultrasound, duplex ultrasound, and intraoperative angiography.

Continuous wave Doppler analysis is a purely qualitative method by which an experienced operator can identify areas of stenosis by the high pitch associated with a stenosis. However, it is insensitive to small intimal flaps or more subtle stenoses, and it is quite operator dependent. Duplex ultrasound is a much more sensitive tool that provides detailed anatomic imaging and real-time physiologic information regarding blood flow through the carotid vessels, and it is the author's preference. However, although the ICA endpoint should be directly visualized before closing the arteriotomy, the CCA clamp site is a relatively blind spot. Duplex examination allows one to rule out unsuspected plaque injury, which can then be repaired before completing the arteriotomy closure (Fig. 6). The data yielded from duplex examination are somewhat operator dependent, and there can be technical limitations with placing the Doppler probe in the wound to achieve an adequate examination. Intraoperative angiography has been considered the "gold standard" of completion studies.

BOX 1 Options to Facilitate High Carotid Exposure

Nasotracheal intubation
Division of posterior belly of digastric muscle
Resection of styloid process
Anterior subluxation of mandible
Vertical osteotomy ramus of mandible

EXPOSURE FOR HIGH LESIONS

There are several methods to gain additional cephalad exposure of the high carotid bifurcation (Box 1). The easiest of these, and the initial approach, is to start the operation with nasotracheal intubation. With the patient's mouth closed, the vertical ramus of the mandible is displaced anteriorly 1 to 2 cm compared with when the mouth is open with an oral endotracheal tube. The additional few millimeters of distal ICA exposure afforded by this maneuver will often be the difference in achieving a suitable endarterectomy endpoint in the distal ICA. The next step to enhance distal exposure is to divide the posterior belly of the digastric muscle. This muscle takes the same diagonal course through the wound as the hypoglossal nerve, but it is located superficial to the nerve. Therefore, this nerve should be carefully identified and protected before the muscle is divided. Two other nerves that can be injured high in the neck are the spinal accessory nerve, which enters the tendinous portion of the sternocleidomastoid muscle, usually in the upper third of the muscle, and the glossopharyngeal nerve, which lies deep to the digastric muscle.

The next maneuver that can be extremely effective at gaining cephalad exposure is resection of the styloid process. The insertions of the muscles on the styloid process are excised, and it is carefully resected with a rongeur. This maneuver will permit exposure of the ICA all the way to the skull base.

There are two other options for improving distal exposure of the high bifurcation, both of which require preoperative planning and coordination with the oral or plastic surgeon. Anterior subluxation of the mandible requires placing the mandible in temporary intermaxillary fixation. An even more aggressive approach utilizes a complete vertical osteotomy through the vertical ramus of the mandible, with separation of the mandible to expose the ICA.

PERIOPERATIVE MEDICAL MANAGEMENT

In addition to risk factor control, the patient should be on an antiplatelet mediation (aspirin or clopidogrel) at the time of the CEA. Furthermore, there is compelling evidence that all patients undergoing CEA should be on a statin medication. In the author's series of nearly 1600 CEAs, the 30-day rate of stroke and death was significantly lower among patients taking a statin medication at the time of operation compared with nonusers. Specifically, in multivariate analysis, there was a threefold reduction in stroke and a fivefold reduction in mortality at 30 days among patients undergoing CEA while on statin medications. The perioperative benefits of statins have now been confirmed in multiple other published studies. There was also a trend toward a lower rate of perioperative myocardial infarction among statin users. The author prefers a continuous infusion of low-molecular-weight dextran for the first 24 hours postoperatively or until hospital discharge. Antiplatelet and statin therapy should be continued long-term in the CEA patient.

RESULTS

Perioperative mortality has become exceedingly uncommon following CEA, averaging < 1%, and generally around 0.5% today. Cardiac disease is the most common cause. The incidence of perioperative stroke ranges from 1% to 5% in contemporary practice and correlates directly with the clinical indication for operation. The perioperative stroke incidence should be no more than 1% to 2% among asymptomatic patients and ranges from 2% to 6% among symptomatic patients.

Carotid artery disease is an excellent marker for underlying coronary artery disease, and perioperative myocardial infarction occurs in 2% to 4% of patients in practice today. Systemic blood pressure instability is seen in at least 60% of patients following CEA and generally resolves within 4 to 8 hours in most patients, although it often requires close hemodynamic monitoring and aggressive pharmacologic treatment. The incidence of postoperative bleeding requiring reexploration is 1% to 4%. Wound infections are extremely uncommon following CEA and have been reported in < 1% of cases.

One of the most frequent complications of CEA is cranial nerve injury. This relates to the anatomic location of these nerves with respect to the carotid arteries. The incidence ranges from 5% to 17% in reported series (Table 2). The majority of these injuries result from traction or minor trauma, and they are quite transitory, often resolving in a few days or weeks.

Recurrent Carotid Stenosis

The incidence of a recurrent stenosis has been estimated to range from 5% to 22% of patients in several published institutional series, although only approximately 3% of these lesions were symptomatic. Within the first 36 months after CEA, recurrent stenosis usually results from intimal hyperplasia. Evidence from serial duplex evaluations suggests that at least some of these lesions regress with time, and in part, this may be responsible for some variability in

TABLE 2 Incidence of Cranial Nerve Injury

Nerve	Incidence (%)
Hypoglossal	4.4–17.5
Recurrent laryngeal	1.5–15
Superior laryngeal	1.8–4.5
Marginal mandibular	1.1–3.1
Glossopharyngeal	0.2–1.5
Spinal accessory	<1.0

the reported rates of recurrent stenosis. An occasional "recurrent" stenosis in fact represents residual arteriosclerotic disease after the endarterectomy. Lesions that develop more than a few years after CEA usually result from progressive or new arteriosclerotic disease. Recurrent stenoses develop more frequently in women, in patients who continue to smoke, and in hypercholesterolemic, diabetic, and hypertensive individuals. It has also been suggested that intraoperative injury secondary to arterial clamping, the placement of an intraluminal shunt, or the placement of tacking sutures within the vessel may also predispose to early myointimal hyperplasia lesions. As noted earlier, there is compelling evidence that closure of the arteriotomy with a patch will reduce the incidence of recurrent stenosis, although the optimal patch material remains to be identified.

Reoperative CEA

Reoperative CEA presents additional challenges with the dissection and reconstruction that can increase the risk compared with a primary procedure, but excellent results can be achieved in this situation with careful planning and technique. There are no prospective randomized trials to support repeat CEA, but most available evidence supports treating symptomatic and very-high-grade asymptomatic recurrent stenoses.

Management of Recurrent Carotid Artery Stenosis

Sarah E. Deery, MD, MPH, and Ying Wei Lum, MD

INTRODUCTION

Carotid endarterectomy (CEA) is the gold standard treatment for high-grade symptomatic and asymptomatic carotid artery stenosis and reduces the risk of stroke and death compared with best medical therapy. It is a safe and durable procedure with minimal morbidity and mortality when performed by qualified practitioners on appropriate surgical candidates. Carotid artery stenting (CAS), including transfemoral carotid artery stenting (TF-CAS) and transcarotid artery revascularization (TCAR), has been introduced as an alternative to CEA, particularly in high-risk patients. Following both CEA and CAS, carotid artery surveillance imaging shows that a minority of patients will develop a recurrent narrowing of the carotid artery at or adjacent to the site of revascularization. A luminal diameter narrowing of 50% or greater on duplex ultrasonography, corresponding to a 75% or greater stenosis in the cross-sectional area, is the most commonly used criteria to define carotid restenosis. Restenosis after carotid revascularization has been reported to range from 5% to 20%, depending on the definition used to characterize restenosis and the duration of follow-up. This chapter aims to discuss the risk factors, pathogenesis, morbidity, and management of carotid artery restenosis.

INCIDENCE AND PRESENTATION OF RECURRENT CAROTID STENOSIS

The incidence of recurrent carotid stenosis following CEA varies widely in the literature based on the method and time interval of surveillance. Follow-up prospective data collection from the Asymptomatic Carotid Atherosclerosis Study (ACAS) using Doppler ultrasound surveillance has shown an incidence of recurrent carotid stenosis post-CEA of 4.1% in the early postoperative period (<3 months), 7.6% from 3 to 18 months, and 1.9% from 18 to 60 months. Data from other studies have also shown that the average rates of recurrent carotid stenosis after CEA can be estimated to be 10% at 1 year, 3% in 2 years, 2% after 3 years, and 1% after 5 years.

Recurrent stenosis after CAS, or in-stent restenosis (ISR) also has an incidence ranging from 5% to 20%. Although ISR puts patients at increased risk of cerebrovascular events, the neointimal hyperplastic reaction seems to be associated with a reduced risk of distal embolization as compared with the initial native lesion. Several clinical trials have looked into the risk of stroke secondary to ISR. The Carotid and Vertebral Artery Transluminal Angioplasty Study (CAVATAS)

showed an increased risk of stroke at 5 years in patients who develop severe (>70%) carotid artery ISR. The Carotid Revascularization Endarterectomy versus Stenting Trial (CREST) also showed similar results, with more than 70% ISR after CAS placing patients at increased risk of stroke. However, multiple other studies including the Stent Protected Angioplasty versus Carotid Endarterectomy Trial (SPACE) showed that there was no associated increased risk of cerebrovascular ischemia in patients who develop ISR at 2 years.

Most patients with restenosis are asymptomatic, and recurrent stenosis is discovered on routine postoperative surveillance following carotid revascularization. However, between 8% and 25% of patients present with symptomatic neurologic events (i.e., transient ischemic attack or stroke). The rate of asymptomatic restenosis in patients that are lost to follow-up is of course unknown. While the vast majority of restenosis is identified in asymptomatic patients, recurrent carotid post-CEA does increase the risk of cerebrovascular ischemia secondary to flow obstruction and thromboembolism. The risk of ipsilateral stroke after CEA is at its highest within the first 2 years after the operation, and the risk decreases over time after 2 years. This can be explained by the relatively higher incidence of recurrent carotid restenosis during that time frame, which increases the risk of ipsilateral stroke. In fact, up to 50% of ipsilateral symptomatic strokes can be attributed to recurrent carotid stenosis after CEA. Not surprisingly, as the incidence of recurrent carotid stenosis decreases over time, so does the risk of developing symptomatic ipsilateral stroke beyond 2 years postoperatively.

RISK FACTORS FOR RECURRENT CAROTID STENOSIS

Several risk factors have been associated with recurrent carotid stenosis after CEA, namely those associated with native carotid artery disease and other atherosclerotic conditions, including continued smoking, diabetes, hypertension, hyperlipidemia, and end-stage renal disease (Box 1). Technical considerations also impact risk for recurrent carotid stenosis. The carotid artery can be reconstructed by primary closure or with patch angioplasty. There is clear and overwhelming evidence showing the superiority of patch angioplasty over primary closure in reducing the rate of recurrent stenosis. ACAS showed a restenosis rate of 4.6% with patch angioplasty versus 16.9% with primary closure. CREST showed a similar reduction in restenosis but no difference in stroke rate. A Cochrane systematic review of 2335 carotid endarterectomies in 2187 patients showed a 59% reduction in carotid restenosis and 27% reduction in serious adverse events. Some surgeons preferentially use the eversion endarterectomy technique when performing CEA, during which the internal carotid artery is transected at the level of the carotid bulb and the distal segment of the internal carotid artery is everted and the plaque peeled away, leaving the endarterectomy bed behind. The Eversion Carotid Endarterectomy versus the Standard Trial compared restenosis rates between standard CEA with patch angioplasty and the eversion technique and showed similar rates in both techniques. In light of overwhelming evidence from multiple studies in factor of conventional CEA with patch angioplasty or eversion endarterectomy over primary closure alone, the Society for Vascular Surgery (SVS) recommends these techniques over standard endarterectomy with primary closure in their Clinical Practice Guidelines.

BOX 1 Risk Factors Associated with Recurrent Carotid Stenosis After Carotid Endarterectomy

- Female sex
- Smoking
- Diabetes
- Hypertension
- Hyperlipidemia
- End-stage renal disease
- Primary closure of carotid artery without patch angioplasty
- Small internal carotid artery diameter
- Previous ipsilateral carotid surgery

BOX 2 Risk Factors Associated with In-Stent Restenosis After Carotid Stenting

- Female sex
- Smoking
- Diabetes
- Hypertension
- Hyperlipidemia
- End-stage renal disease
- Residual stenosis after index procedure
- Use of balloon expandable stents
- Stent subexpansion
- Deployment of multiple stents

ISR after CAS has been attributed to the same risk factors for atherosclerosis as for recurrent stenosis after CEA (Box 2). Technical factors related to ISR include residual stenosis on completion angiography, use of a balloon expandable stent, stent subexpansion, and the deployment of multiple stents. Carotid stents come in two main categories: open-cell stent and closed-cell stent. Open-cell stents are designed to keep adjacent segments of the stent detached from one another. This design allows for better conformational change and adaptability to the vessel anatomy, but with less plaque coverage and more tissue prolapse. Closed-cell stents, on the other hand, are designed with a higher density of interconnections due to more bridging of the adjacent segments. Closed-cell stents offer more plaque coverage but have reduced conformability and apposition to the vessel wall. No long-term study, up to now, has shown a difference in restenosis rate between the two styles of stents.

PATHOGENESIS OF RECURRENT CAROTID STENOSIS

Very early restenosis following CEA is often secondary to an incomplete endarterectomy or technical defect from surgery. Iatrogenic injuries to the blood vessels (i.e., trauma from forceps, vascular clamps, and intravascular shunts) can lead to immediate restenosis or thrombosis, but can also speed up the focal reactive process and increase later development of restenosis. Improper surgical techniques can also contribute to recurrent stenosis (i.e., residual atheroma postendarterectomy, myointimal flap, patch irregularities, and irregular bends and kinks to the blood vessel after reconstruction), particularly in the early postoperative period.

Intimal hyperplasia from a hyperplastic reaction in the endarterectomy bed is the primary cause of recurrent carotid stenosis occurring between 30 days and 2 years after CEA. After 2 years, luminal narrowing is secondary to progressive atherosclerosis, which occurs throughout the artery and is not necessarily confined to the endarterectomy bed. Interestingly, patients who undergo CEA for asymptomatic carotid stenosis have been observed to have a higher risk of developing carotid restenosis at 1 year compared with patients who undergo CEA for symptomatic disease (i.e., TIA). This observation can be explained by the difference in atherosclerotic plaque content in asymptomatic compared with symptomatic patients. Asymptomatic patients tend to have stable plaques that have low macrophage levels, small or absent lipid core, and low levels of matrix metalloproteinase. On the other hand, inflamed plaques with high levels of macrophages, leukocytes, and lipid-rich cores have high levels of matrix metalloproteinase activity, which leads to expansive remodeling of the media and adventitia and less restenosis.

TABLE I Different Patterns of Carotid In-Stent Restenosis

Type	Description and Characteristics of ISR Lesion
I (Focal end-stent group)	Lesions are ≤10 mm long and are positioned at the proximal or distal margin (but not both) of the stent. Lesions ≤10 mm long at both ends of the stent are defined as type I, multifocal end-stent.
II (Focal intra-stent group)	Lesions are ≤10 mm long and are confined to within the stent(s) without extending outside the margins. Two or more discrete lesions ≤10 mm long located within the stent are defined as type II, multifocal intra-stent.
III (Diffuse intra-stent group)	Lesions are >10 mm long and are confined to within the stent(s) without extending outside the margins.
IV (Diffuse proliferative group)	Lesions are >10 mm long and extend beyond the margin(s) of the stent(s).
V (Occlusion group)	Lesions have no prograde flow and no lumen is identified.

ISR, In-stent restenosis.

ISR after CAS likely results from neointimal hyperplasia caused by chronic inflammation secondary to endothelial dysfunction and traumatic irritation of the intima. It occurs within 2 years of the index procedure. Following 2 years, recurrent stenosis after CAS is also likely a de novo atherosclerotic lesion. Interestingly, patients who develop recurrent carotid stenosis after CEA have a higher risk of developing ISR if their restenosis is treated with carotid artery balloon angioplasty or stenting, suggesting that some patients have an above-average aggressive hyperplastic response and unfavorable biology that places them at higher risk to develop early restenosis. Carotid ISR is often detected on surveillance duplex ultrasonography and is categorized in a classification pattern that is similar to the one used for the coronary circulation. There are five types of ISR summarized in Table 1 and Figure 1. Notably, type I lesions (focal end-stent) are the most common after CAS and can occur at both the proximal and distal aspect of the stent. Type IV (diffuse proliferative) lesions are often found in patients with diabetes and are associated with subsequent stent failure requiring reintervention.

SURVEILLANCE FOR RECURRENT CAROTID STENOSIS

After Carotid Endarterectomy

It is crucial to have a methodical and timely surveillance imaging schedule after carotid revascularization to assess for ipsilateral restenosis and contralateral progression of preexisting stenosis. In fact, the progression of contralateral stenosis is more common than ipsilateral recurrent stenosis. Duplex ultrasonography is the imaging modality of choice for surveillance after CEA because it is noninvasive, cost effective, and has a sensitivity of 91% and specificity of 87% for detecting a 50% restenosis of the carotid artery. In its best practice guidelines, the SVS recommends surveillance imaging within 30 days postoperatively following CEA. The SVS guidelines also recommend continued surveillance in patients with 50% or greater ipsilateral restenosis or contralateral stenosis, in those who underwent primary closure of the artery after endarterectomy, and in patients with high-risk factors for atherosclerotic disease progression. However, there is no consensus on the timeline and the frequency of surveillance beyond the postoperative period, and this has been the subject of many debates. Because patients are more likely to develop an ipsilateral restenosis within the 2 years after CEA, it is essential to have more frequent duplex surveillance throughout that period. Most patients who develop atherosclerotic disease of the carotid artery have underlying risk factors such as smoking, diabetes, hyperlipidemia, and hypertension that inherently places them in the high-risk patient category. In our practice, we surveil our patients at the 1-month, 6-month, and 1-year marks postoperatively after CEA. The subsequent surveillance schedule is then tailored to the patient's specific needs depending on their risk factors and the data from previous studies about the progression of their disease.

After Carotid Artery Stenting

Surveillance for ISR in patients who underwent CAS is particularly important because the rate of developing restenosis after CAS is higher than after CEA, albeit most ISR are mild to moderate and require no intervention, and only a minority of patients will develop high-grade ISR that will require reintervention. Unlike restenosis after CEA, ISR after CAS can develop many years after the index procedure. A timely surveillance schedule is important to identify hemodynamically significant lesions that need reintervention; however, there is no consensus on the time intervals and duration of surveillance after the procedure. As with CEA, the imaging modality of choice for surveillance after CAS is duplex ultrasonography. Other modalities such as computed tomographic angiography and magnetic resonance angiography can also be used to detect ISR but may overestimate the degree of ISR and may be skewed by stent artifact. Whenever a hemodynamically significant ISR is suspected on noninvasive imaging, it is best to assess the suspected lesion with digital subtraction angiography to get a more accurate estimate of the degree of restenosis.

In our practice, patients who undergo both TF-CAS and TCAR are surveilled in a similar fashion as our patients who undergo CEA. We obtain a duplex ultrasound at the 1-month, 6-month, and 1-year marks. Subsequent surveillance is then tailored according to duplex findings and whether or not there is any progression of disease. It is important to note that the velocity criteria for duplex surveillance post-CAS are different from the velocity criteria used for surveillance post-CEA as the stent itself impacts velocities. A summary of the velocities and corresponding degrees of restenosis post-CEA versus CAS adopted by our vascular laboratory is shown in Table 2. The goal of duplex surveillance imaging is to identify patients who are at risk for hemodynamically significant (>70%–80%) restenosis that may result in a cerebrovascular event if not detected and intervened with in a timely fashion. Patients found to have less than 20% stenosis do not need a rigorous surveillance schedule. Those who have 20% to 50% stenosis need closer surveillance because there are limited data available on the natural progression of such lesions. Patients with 50% to 70% restenosis need duplex surveillance every 6 months to monitor the disease progression into the severe ISR category. When 70% to 80% restenosis is identified, patients should undergo additional axial imaging or the gold standard digital subtraction angiography for intervention planning.

MANAGEMENT OF RECURRENT STENOSIS AFTER CAROTID ENDARTERECTOMY

In the ACAS and NASCET trials, patients who underwent CEA were concurrently treated with best medical therapy. The results

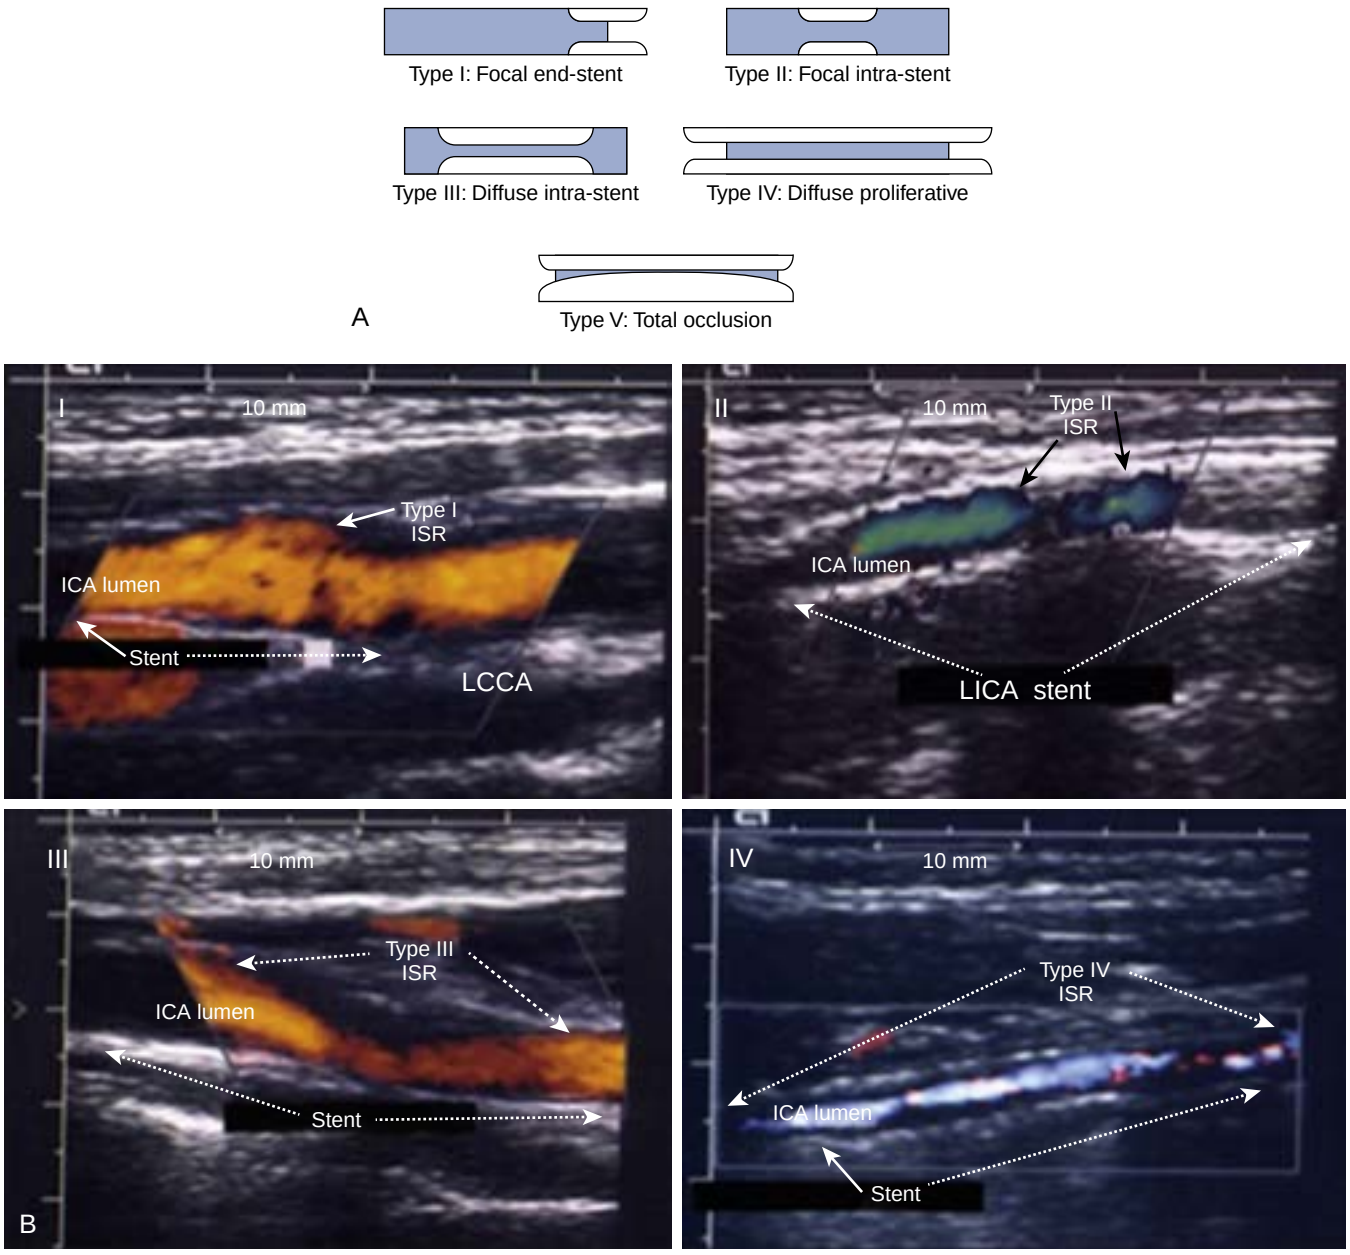

FIG. 1 **(A)** Types I to V carotid in-stent restenosis *(ISR)*. **(B)** Representative B-mode ultrasound images of ISR correspond to types I to IV of post–carotid angioplasty and stenting ISR. *ICA*, Internal carotid artery; *LCCA*, left common carotid artery; *LICA*, left internal carotid artery. *(Modified from Lal BK, et al. Patterns of in-stent restenosis after carotid artery stenting: classification and implications for long-term outcome. J Vasc Surg. 2007;46:833–840.)*

established by these trials reflect the combination of CEA and best medical management. Therefore, it is imperative that all patients be placed on an antiplatelet agent and statin and that their modifiable risk factors are reduced or controlled post-CEA to reduce their risk of recurrent carotid stenosis. Despite best medical management post-CEA, a subset of patients will still develop high-grade restenosis requiring surgical intervention. Reoperative CEA has a higher morbidity rate compared with primary CEA with a periprocedural stroke rate of 7% and a high rate of cranial nerve injury at 19% (compared with ~1% following CEA in a non-reoperative neck).

Symptomatic patients after CEA need a reoperation if their degree of restenosis is 50% or greater. The decision to operate on asymptomatic patients is more complex and requires weighing the risk of operative morbidity against the morbidity of stroke with medical management alone. To justify a reoperation in the asymptomatic population, the benefits of the operation must outweigh the risks of the operation (i.e., stroke, myocardial infarction, cranial nerve injury) and the risks of stroke with medical management alone. The SVS and European Society for Vascular Surgery (ESVS) recommend against a reoperation when the combined stroke and death rate exceeds 6% for patients with symptomatic carotid restenosis and 3% for those with asymptomatic carotid stenosis. In our practice, we initially treat asymptomatic carotid restenosis medically with antiplatelet therapy and high-intensity statin. Surgical intervention is considered in patients who progress to high-grade restenosis despite maximal medical management.

Reoperative CEA is a high-risk operation, and no specific technique has been described to offer superior results over another. Some of the techniques described include endarterectomy alone, patch angioplasty alone without endarterectomy (the patch can be saphenous vein, bovine pericardium, Dacron, or polytetrafluoroethylene [PTFE]), endarterectomy with patch angioplasty, and resection of

TABLE 2 Duplex Ultrasonography Velocity Criteria to Establish the Presence of Recurrent Carotid Stenosis in the Native Carotid Artery Postcarotid Endarterectomy Compared with Established Velocity Criteria to Establish the Presence of In-stent Restenosis After Carotid Artery Stenting

Degree of Stenosis (%)	Native Carotid Artery	Stented Carotid Artery
0–19	PSV <130 cm/s	PSV <150 cm/s and ICA/CCA ratio <2.15
20–49	PSV 130–189 cm/s	PSV 150–219 cm/s
50–79	PSV 190–249 cm/s and EDV <120 cm/s	PSV 220–339 cm/s and ICA/CCA ratio ≥2.7
80–99	PSV ≥250 cm/s and EDV ≥120 cm/s, or ICA/CCA ratio ≥3.2	PSV ≥340 cm/s and ICA/CCA ratio ≥4.5

EDV, End-diastolic velocity; *ICA/CCA*, internal carotid artery/common carotid artery; *PSV*, peak systolic velocity.

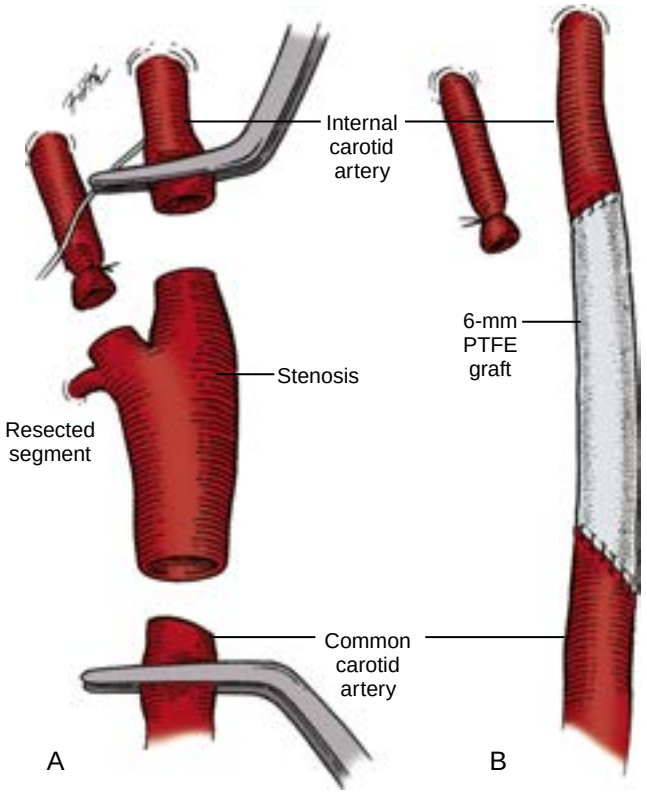

FIG. 2 (A) Resection of a diseased segment of the common and internal carotid arteries with ligation of the external carotid artery. **(B)** Placement of an interposition graft for revascularization of the internal carotid artery circulation, in this case using polytetrafluoroethylene *(PTFE)*. Reversed saphenous vein graft or Dacron additionally may be utilized. This is our preferred technique for management of tertiary recurrent carotid stenosis and for management of recurrent in-stent stenosis when endovascular options are not technically feasible.

the artery with interposition graft (saphenous vein, Dacron, or PTFE; Fig. 2). If performing reoperative CEA in our practice, we attempt excising the previous patch, repeat an endarterectomy, and replace the old patch with Dacron or bovine pericardium. If the repeat endarterectomy is technically not feasible or leaves the artery severely compromised, our approach is to resect the artery and perform an interposition repair with translocated reversed greater saphenous vein graft preferentially. In patients who do not have suitable veins, we use PTFE for an interposition conduit. In patients who develop recurrent stenosis for the second time after a reoperation, we follow a similar algorithm to a first-time restenosis. However, for tertiary carotid interventions, we prefer resection of the involved segment of the artery with interposition graft reconstruction.

An alternative to reoperative CEA is CAS as the first-line management for secondary carotid intervention to avoid dissection in a reoperative field. Older series comparing TF-CAS and CEA for restenosis suggest that neither procedure is associated with superior outcomes. However, TCAR has been developed as an alternative to traditional transfemoral CAS, avoiding the higher risk of periprocedural stroke associated with aortic arch manipulation by wires, catheters, and sheaths. The method of embolic protection utilized is dynamic flow reversal via an external shunt placed between the long introducer sheath in the common carotid artery and a shorter introducer sheath in the femoral vein, containing a filter to capture any debris. Additionally, flow reversal is established before any lesion manipulation, therefore adding an additional area of potential protection over TF-CAS with filter-type embolic protection devices. TCAR was previously indicated only for symptomatic patients with ≥50% stenosis and asymptomatic patients with ≥80% stenosis who were considered high-risk for CEA by the Centers for Medicare and Medicaid Services (CMS), but recently TCAR has been approved for use in standard-risk patients. These medical and anatomic risk factors (Box 3) notably include restenosis after prior CEA, thus automatically making all restenosis patients high-risk for CEA and thus candidates for TCAR even prior to the approval for use in standard-risk patients.

Recent data from the SVS Vascular Quality Initiative TCAR Surveillance Project show higher rates of perioperative stroke and death with TF-CAS compared with TCAR, whereas rates of stroke and death with TCAR were comparable to CEA. Most recently, a series from the Vascular Quality Initiative compared outcomes with reoperative CEA, TF-CAS, and TCAR for restenosis after CEA and found significantly lower odds of in-hospital stroke and transient ischemia attack with TCAR as compared with both redo-CEA and TF-CAS. Given this, and the added potential benefit of being able to avoid reoperative neck surgery with its associated risk, TCAR has become the preferred first-line treatment option in our practice for restenosis after CEA in patients with suitable anatomy.

MANAGEMENT OF RECURRENT STENOSIS AFTER CAROTID ARTERY STENTING

The management of ISR after CAS is a subject of many debates, especially for the asymptomatic patient population. There are no prospective trials that have established time-tested practice guidelines for the management of ISR after CAS. The consensus among most surgeons is that patients who are symptomatic and have an ISR of 50% or more require a reintervention. Patients who are asymptomatic with high-grade ISR of 70% to 80% or more on surveillance duplex should be considered on a case-by-case basis, taking into account the anatomy of their stenotic lesions and their perioperative risk of stroke and death.

Endovascular techniques described to treat ISR after CAS include balloon angioplasty alone, repeat CAS alone, or a combination of repeat carotid artery stent with balloon angioplasty. Balloon angioplasty can be achieved by using a regular angioplasty balloon, a drug-coated balloon, or a cutting balloon. Repeat stenting can be done

BOX 3 CMS Definitions of High Surgical Risk

Physiologic High Risk

- Age ≥ 75
- Congestive heart failure
- Left ventricular ejection fraction ≤ 35%
- Two or more diseased coronary arteries with ≥ 70% stenosis
- Unstable angina
- Myocardial infarction within 6 weeks
- Abnormal stress test
- Need for open heart surgery
- Need for major surgery (including vascular)
- Uncontrolled diabetes
- Severe pulmonary disease
- History of liver failure with elevated prothrombin time

Anatomic High Risk

- Prior head/neck surgery or irradiation
- Spinal immobility
- At risk for wound infection
- Restenosis post-CEA
- Tracheostomy or tracheostoma
- Surgically inaccessible lesion
- Laryngeal palsy, laryngectomy, and/or permanent contralateral cranial nerve injury
- Contralateral carotid artery occlusion
- Severe tandem lesions
- Bilateral carotid artery stenosis requiring treatment
- Dissection

with either a drug-eluting or a regular stent. There are no prospective data that have established one technique to be superior to another. However, because ISR is caused by intimal hyperplasia, some surgeons favor the use of balloon angioplasty with a cutting balloon over regular balloon angioplasty alone because of the reduced rate of recurrent stenosis of 4.2% with a cutting balloon as compared with 15% to 23% with a regular balloon. Figure 3 shows an example of a type II carotid artery ISR treated with angioplasty and stenting that showed improvement on both the completion digital subtraction angiography study and noninvasive duplex study one month postoperatively. Repeat endovascular intervention can be performed via transfemoral access or transcarotid access (TCAR) and should be conducted using embolic protection.

Open surgical techniques (i.e., CEA or carotid artery bypass/interposition grafting with translocated and reversed great saphenous vein, PTFE, or Dacron) can also be used for management of ISR after CAS, especially in cases where there is primary stent thrombosis (Fig. 4), technical failure during stent deployment, heavily calcified lesions that precluded optimal stent apposition to the vessel wall resulting in an inadequate technical result, and preocclusive lesions that cannot be traversed using endovascular methods. The risks of open CEA should also be considered, as some patients who underwent CAS did so as they were at high risk for traditional open surgery, and these risk factors are likely still present. A recent meta-analysis comparing redo CAS (without distinguishing between TF-CAS and TCAR) and CEA for ISR found no differences in perioperative stroke/death, event-free restenosis, or cranial nerve injury. In our practice, we prefer to manage ISR after CAS using angioplasty and/or repeat stenting if the lesion is anatomically amenable to endovascular intervention. We previously reserved open repair for cases where the

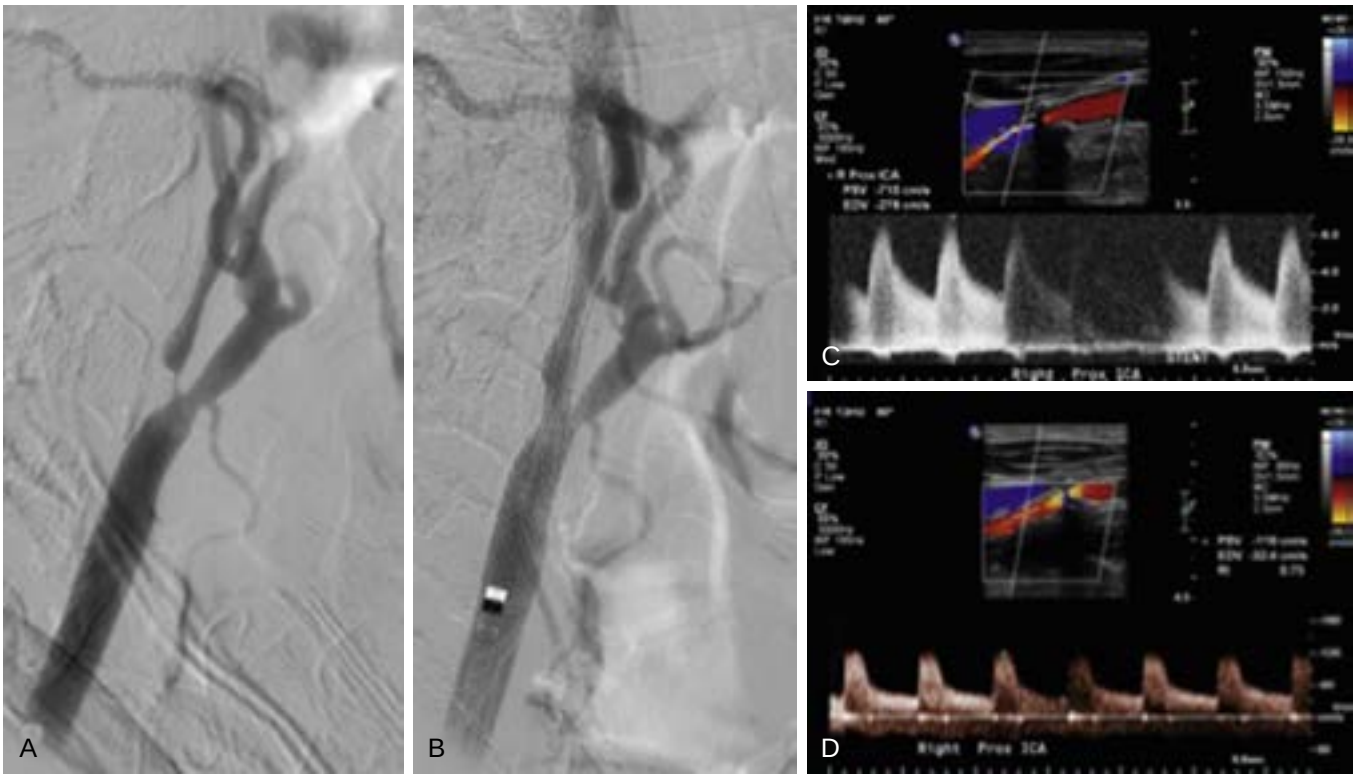

FIG. 3 Focal carotid in-stent restenosis (ISR) in a 78-year-old man with high-grade asymptomatic ISR 6 years after initial carotid angioplasty and stenting. **(A)** Carotid angiography demonstrated a string sign of the proximal internal carotid artery (ICA) with approximately 99% stenosis. **(B)** This restenosis was managed with carotid angioplasty with embolic protection followed by placement of a self-expanding 7 × 30 mm stent. Postprocedural angiogram is demonstrated. **(C)** Preoperative duplex ultrasound demonstrated severe ISR with peak systolic velocity (PSV) of 710, end-diastolic velocity (EDV) of 279, and ICA/common carotid artery (CCA) ratio of 12.2. **(D)** Duplex ultrasound obtained 1 month postoperatively demonstrated PSV of 128, EDV of 33, and ICA/CCA ratio of 2.5.

FIG. 4 Primary stent thrombosis following TCAR, managed with resection of the common and internal carotid arteries and ligation of the chronically occluded external carotid artery, with placement of an interposition graft using Dacron.

patient had a type III or severely calcified aortic arch or excessively tortuous, severely calcified, and/or long-segment stenosis of the internal and/or common carotid artery; however, these patients are often now candidates for TCAR. In patients who do undergo open conversion, we preferentially attempt stent removal with endarterectomy and patch angioplasty and reserve carotid bypass or interposition graft for cases where an endarterectomy endpoint cannot be safely achieved without compromising the integrity of the vessel wall proximal or distal to the endarterectomy bed.

SUMMARY

Symptomatic and asymptomatic carotid artery stenosis are routinely treated with either CEA or CAS. The majority of patients have excellent long-term results. However, a small subset of patients has an aggressive disease biology and tends to develop severe intimal hyperplasia leading to recurrent stenosis of the carotid artery after both CEA and CAS. Routinely scheduled surveillance duplex ultrasonography is the best imaging modality to detect these lesions, such that timely intervention can be offered to the patients to prevent cerebrovascular events. Symptomatic patients who are found to have 50% or greater stenosis on duplex or asymptomatic patients with 70% to 80% or greater stenosis after both CEA and CAS are candidates for reintervention. The procedure of choice for a secondary intervention depends on the patient's functional status, comorbidities, and anatomy of the tandem lesion. All patients should be on maximal medical treatment with an antiplatelet agent and a statin.

Balloon Angioplasty and Stents in Carotid Artery Occlusive Disease

Danon E. Garrido, MD, Rishi A. Roy, MD, and Charles S. O'Mara, MD, MBA

BACKGROUND

Nearly 800,000 people suffer a stroke each year in the United States, making it the third leading cause of death in people 65 years of age and older and the leading overall cause of serious, long-term disability. The total cost nationally for stroke-related illnesses is approximately $34 billion per year. The majority of strokes (about 87%) are ischemic in nature. Of those, an estimated 20% to 30% are related to an atheroembolic or thrombotic event caused by carotid occlusive disease.

With the advent of endovascular interventions for other arterial occlusive lesions, carotid artery balloon angioplasty and stenting (CAS) was advocated as an alternative to carotid endarterectomy (CEA) for treatment of carotid atherosclerosis. Although both CAS and CEA can be performed using local anesthesia with similar operative and hospitalization times, CAS offers the advantage of percutaneous groin arterial access and, in the case of transcarotid artery revascularization (TCAR), low risk of postoperative pain, cranial nerve injury, wound infection, and neck hematoma.

In 2010, the Carotid Revascularization Endarterectomy vs. Stenting Trial (CREST 1) compared the outcomes of CAS with those of CEA for patients with symptomatic or asymptomatic extracranial carotid stenosis. The trial demonstrated the relative safety of CAS in both symptomatic and asymptomatic patients. However, the data

showed a periprocedural stroke rate for CAS of 4%, with the highest risk for periprocedural stroke being among patients of advanced age (more than 70 years) and with recent (within 2 weeks) neurologic ischemic symptoms. In the CEA arm, the stroke rate was 2.3%. Myocardial infarction (MI) was noted to be more frequent with CEA than with patients undergoing CAS (2.3% vs. 1.1%). However, these are numbers that should be interpreted in light of the fact that patients with a stroke complication were documented to have a worse quality of life than those who had MI.

Interpretation of the results of CREST 1 have been intensely debated and influenced by biases for or against CAS or CEA. Stenting enthusiasts argue that statistical similarity in the primary composite endpoint establishes equipoise for the procedures. In contrast, others question the inclusion of MI as a component of the primary endpoint for procedures that have stroke prevention as their principal objective. They argue for the use of only stroke and death as more appropriate composite endpoints, which significantly favors endarterectomy in CREST 1.

Suffice it to say, CREST 1 has produced valuable level I data comparing CAS with CEA, but the trial did not fulfill the expectation by some of proving undeniably that CAS is better than or even equal to CEA. The CREST 2 trial consists of two independent multicenter, randomized controlled trials of carotid revascularization and intensive medical management versus intensive medical management alone in patients with asymptomatic high-grade carotid stenosis. One trial randomizes patients in a 1:1 ratio to endarterectomy versus no endarterectomy, and another randomizes patients in a 1:1 ratio to carotid stenting with embolic protection versus no stenting. Modern medical management is uniform for all randomized treatment groups and is centrally directed. We are anticipating the results of this trial.

TCAR provides a less-invasive option than CEA and can match the stroke hazard of CEA in standard-risk populations based on the pivotal Safety and Efficacy Study for Reverse Flow Used During Carotid Artery Stenting Procedure (ROADSTER). The ROADSTER study of high-risk patients undergoing TCAR achieved a 30-day stroke rate of 1.4%, the lowest to date for any prospective trial of endovascular carotid intervention.

BOX 1 Indications for Carotid Stenting According to CMS

- Patients who are at high risk for CEA and who also have symptomatic carotid artery stenosis ≥70%
- Patients who are at high risk for CEA and have symptomatic carotid artery stenosis between 50% and 70%
- Patients who are at high risk for CEA and have asymptomatic carotid artery stenosis ≥80%

TCAR is covered by CMS for "High Risk" patients who meet one of the following criteria: greater than 8% stenosis or symptomatic stenosis greater than 50%.

To receive reimbursement for TCAR, the surgeon or hospital must be part of either the ROADSTER (II) trial or VQI registry.

NOTE: Medicare coverage is limited to patients having these indications and to procedures performed using FDA-approved carotid artery stenting systems and embolic protection devices.

BOX 2 Patients at High Risk for CEA According to CMS

1. Congestive heart failure (CHF) class III/IV
2. Left ventricular ejection fraction (LVEF) <30%
3. Unstable angina
4. Contralateral carotid occlusion
5. Recent myocardial infarction (MI)
6. Previous CEA with recurrent stenosis
7. Prior radiation treatment to the neck
8. Other conditions used to determine patients at high risk for CEA in the prior carotid artery stenting trials and studies, such as ARCHER, CABERNET, SAPPHIRE, BEACH, and MAVERIC II

PREPROCEDURAL CONSIDERATIONS

Preprocedural assessment includes a complete history focused on cardiovascular elements, on symptoms of neurologic or ocular ischemic events related to the carotid circulation, and a history of neck interventions as well as history of neck radiation for the treatment of malignancies. A thorough physical examination with an emphasis on palpation of pulses, auscultation for bruits, and complete neurologic assessment is of utmost importance. The decision about advising for or against CAS is influenced by current Centers for Medicare and Medicaid Services (CMS) guidelines regarding indications for the procedure. These guidelines are listed in Boxes 1 and 2.

Preprocedural imaging should include carotid duplex scan, computed tomographic angiography, and magnetic resonance imaging and angiography (MRI/MRA). These imaging modalities give important information about the presence and hemodynamic significance of carotid occlusive disease, the condition of the brain parenchyma, the presence of additional intracranial or extracranial vascular anomalies (e.g., saccular aneurysms, vascular malformations), and the anatomy of the aortic arch.

Before CAS, patients should begin dual antiplatelet therapy. The authors' regimen consists of clopidogrel 75 mg daily and aspirin 81 mg daily beginning 3 to 5 days before the procedure. In emergency circumstances, when antiplatelet therapy has not been started before the procedure, we use a loading regimen of clopidogrel 600 mg and aspirin 325 mg given at the time of the intervention. In addition, for patients who have been taking antiplatelet therapy on a chronic basis, we typically give a smaller loading dose of clopidogrel 150 to 300 mg immediately after the intervention. If oral administration is not possible, clopidogrel can be given via nasogastric tube; aspirin can be given similarly or per rectum (300 or 600 mg per rectum).

Traditionally, CAS has been performed via a percutaneous transfemoral arterial approach. Assessment of the iliofemoral arterial system along with evaluation of the arch anatomy via computed tomography angiography (CTA) will determine the suitability of this access as a successful platform to deliver the treatment. The presence of an easily palpable femoral pulse strongly suggests that femoral access is suitable. On the contrary, the absence of a femoral pulse should trigger exploring other access options. The presence of a type III or bovine aortic arch, of severe arch atheroma, significant common carotid tortuosity, the presence of significant occlusive disease, as well as prior aortic or cervical arterial procedures complicate the use of the femoral arteries as the access vessel and can potentially increase the risk of cerebral embolization.

The use of TCAR with flow reversal has gained popularity and is now a standard option in most practices. This approach not only facilitates the delivery of the stent under challenging arch and common carotid artery (CCA) anatomy, it adds the benefit of cerebral protection before attempt at crossing the carotid lesion.

TRANSFEMORAL APPROACH FOR CAROTID ANGIOPLASTY

Provided that the patient has suitable aortoiliac and aortic arch anatomy, the transfemoral approach is usually chosen. The patient is placed supine on the angio-table. Topographic fluoroscopic

evaluation of the chest and the neck is performed before prepping to identify objects such as lines, leads, or other previously inserted devices that would interfere with imaging. The range of motion of the C-arm is also evaluated to make sure that it will rotate freely and away from other equipment in the procedural room.

Invasive blood pressure monitoring is obtained. We perform this procedure under strict local anesthesia at the groin access site to afford patient comfort while also being able to assess neurologic function during the procedure. At certain times during CAS, the patient is asked to intermittently squeeze a sound-making device held in the contralateral hand for motor function and to count verbally to assess cognitive function.

To facilitate accurate entry, the chosen femoral artery is accessed under ultrasound guidance with a micropuncture needle that is subsequently exchanged over a microwire for a micropuncture sheath using the Seldinger technique. An arteriogram should be performed through the micropuncture sheath. Inadequacies of the access, if any, should be managed before continuing with the planned intervention.

Once the access is deemed satisfactory, systemic anticoagulation therapy is initiated either with intravenous heparin bolus administration at 100 units per kg or, for those patients where heparin is contraindicated, bivalirudin (Angiomax) at 0.75 mg/kg intravenous bolus, followed by 1.75 mg/kg/hr intravenous infusion. During the procedure, activated clotting times are maintained between 250 and 300 seconds.

A starter J or straight tip wire is advanced just distal to the aortic arch under fluoroscopy. The micropuncture sheath is exchanged for a 90-cm 6Fr sheath, and its tip is advanced to the proximal thoracic aorta. Over the same wire, a 5 or 6Fr pigtail catheter is advanced retrograde through the arch into the proximal ascending aorta. The C-arm is positioned at 35 to 40 degrees in the left anterior oblique orientation and arch aortography is performed via the pigtail catheter using 15 to 20 mL of contrast by either power or hand injection. This imaging should provide sufficient anatomical detail for choosing an appropriate catheter to selectively cannulate the common carotid artery on the side of the pathology.

Typical aortic arch anatomy allows for use of a selective catheter with a simple curve (Berenstein, vertebral; Merit Medical, South Jordan, Utah), while increasingly complex and tortuous aortic arch anatomy requires the use of selective catheters that have either an intermediate curve (H1, Cook Medical; JR4, Cordis) or a complex curve (Simmons, Cook Medical; Vitek, Cook Medical). The pigtail catheter is then exchanged over a guidewire and the chosen catheter is advanced to the previously mapped area of interest. We use a floppy glide wire to select the common carotid with the aid of the catheter. The catheter is advanced to a reasonable purchase but kept proximal to the level of the carotid bulb. The guidewire is then exchanged for a stiffer wire and the 6Fr sheath is advanced either over the catheter or by exchanging the catheter for the sheath introducer to the distal common carotid artery.

If the purchase on the wire is not enough to advance the sheath, angiographic mapping and superselective cannulation of the external carotid artery often provides the required strength to advance the sheath into the common carotid (Fig. 1). Extreme care is given to avoid introduction of microthrombi and tiny air bubbles by frequent wiping of guidewires with Telfa nonadherent strips moistened with heparinized saline and by meticulous flushing of catheters and sheaths with heparinized saline solution.

After successful cannulation of the common carotid artery, a distal filter typically is used for embolic protection. The distal filter, attached to a 0.014-inch wire, is passed through the sheath, carefully maneuvered through the carotid stenosis under fluoroscopic control, and placed in the distal cervical ICA, where it is deployed with removal of its covering sheath. Very tight carotid stenosis that cannot be safely negotiated with the tip of the embolic protection device may require use of a low-profile microcatheter (Prowler; Johnson & Johnson) and steerable microwire (Transcend; Boston Scientific Corp,). Occasionally, predilation of a tight stenosis with a low-profile coronary angioplasty balloon may be necessary to allow subsequent crossing of the lesion with the distal filter. Also, problems imposed by vessel angulation and tortuosity can be resolved with use of a "buddy wire" to slightly straighten the anatomy and facilitate crossing of a lesion by the distal filter, angioplasty catheter, or stent. Furthermore, for situations in which passage of the distal filter is difficult, maneuvers such as having the patient take deep breaths, having the patient turn the head far to one side or the other, or careful manual pressure on the side of the patient's neck by an assistant can be helpful.

The stent is advanced over the wire to cover the carotid lesion. Because most lesions occur near the carotid bulb, tapered stents are better suited to accommodate any size mismatch of the common carotid and the internal carotid (Fig. 2). If a residual stenosis of more than 30% is present after stent placement alone, postdeployment balloon angioplasty is typically done with a balloon that is 5, 5.5, or 6 mm in diameter and 20 mm in length within the confines of

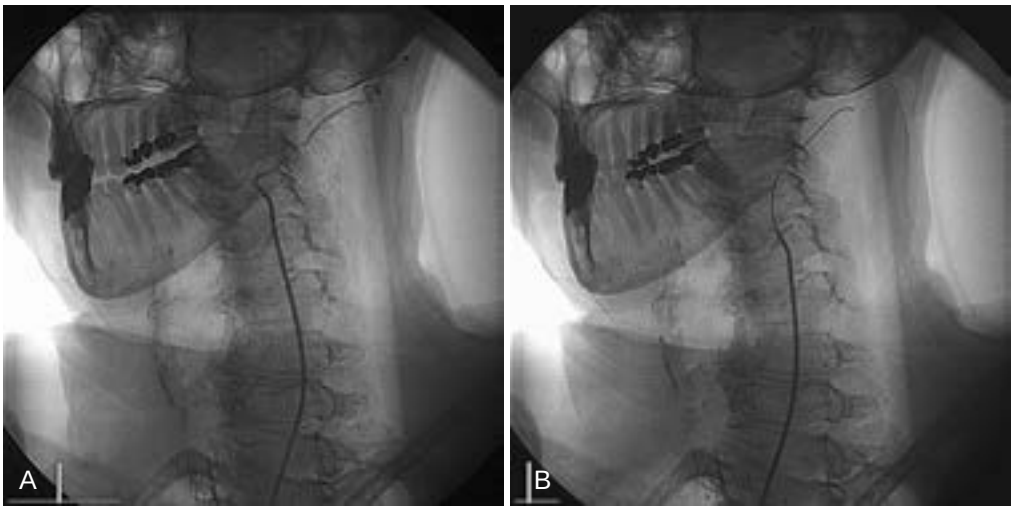

FIG. 1 **(A)** Selective injection to document catheter location in a posterior branch of the external carotid artery before placement of the exchange-length wire used for positioning of the long sheath into the distal common carotid artery. **(B)** Wire placement into the external carotid artery branch through the selective catheter. Inadvertent vessel perforation by the wire could be readily managed with manual compression against the posterior neck muscles.

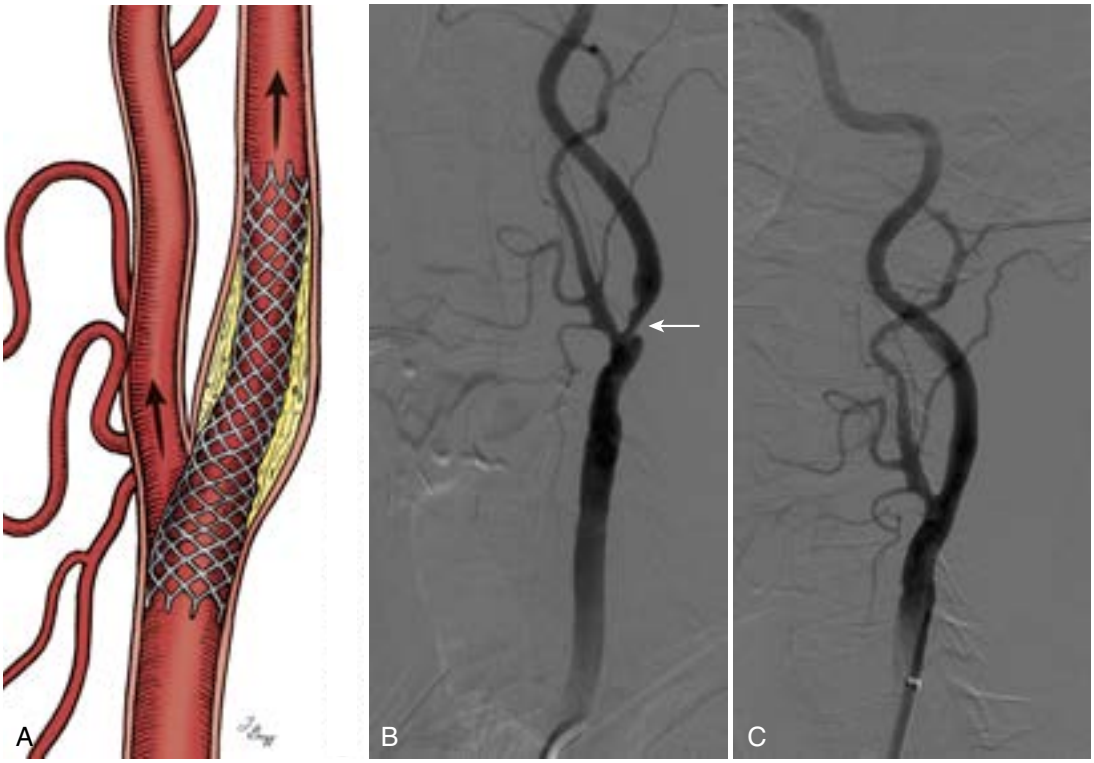

FIG. 2 **(A)** Schematic representation of a stent deployed across the carotid bifurcation to treat a proximal internal carotid artery lesion. the stent. Postdeployment balloon angioplasty is used to achieve an adequate angiographic result, not a perfect one (Fig. 3).

The balloon angioplasty catheters and the carotid stent are passed into position over the wire attached to the distal filter. The same wire is used for passage of a retrieval sheath that captures the filter along with any microemboli that have been trapped during the procedure. After retrieval and removal of the filter and its wire, completion arteriograms of the treated carotid artery and the cerebral territory that it supplies are obtained with injection of contrast through the long sheath. The long sheath is then removed over its dilator and a guidewire to avoid vessel trauma during exit. Systemic anticoagulation therapy is discontinued. After sheath removal, the femoral artery puncture site is sealed with either manual compression or use of a closure device.

TRANSCAROTID APPROACH FOR CAROTID ANGIOPLASTY

This intervention can be divided broadly into three steps: exposure and access of the CCA, the establishment of flow reversal and treatment of lesion, and cessation of flow reversal with closure. We usually employ general anesthesia when performing this approach. Alternatively, a regional block with a local anesthetic may be used.

A distance of 5 cm between the clavicle and the ipsilateral carotid bifurcation and a 6 mm CCA diameter are necessary to establish an ideal platform setup (Fig. 4). The depth of the CCA needs consideration. When a ratio of CCA depth to CCA distance from clavicle to bifurcation exceeds 1, then access with the sheath may prove challenging. If encountering issues with problematic access angles to the CCA, a tunneling technique facilitates a lower angle of access to the CCA. Intraoperatively, depth and length to bifurcation is confirmed with an on-table ultrasound. The vascular sheaths, carotid wires, and the flow reversal system described in this technique are provided by Silk Road Medical. Contralateral percutaneous femoral venous access is obtained, and the venous return sheath (VRS), 8Fr, is inserted and secured to the skin. A venogram is conducted to confirm proper venous placement. A transverse or longitudinal incision is made at the base of the neck, approximately one fingerbreadth above the clavicle, preferably in virgin territory. Dissection is carried through the subcutaneous tissue and platysma. A 3- to 4-cm segment of the CCA is exposed between the clavicular and sternal heads of the sternocleidomastoid muscle (Fig. 5). The patient is systemically heparinized to achieve an activated clotting time of 250 seconds or greater. Further intervention does not proceed until this number is established.

A preclosure stay U-stitch or figure-of-8 stitch with 5-0 Prolene (Ethicon US) is placed at the desired access location on the anterior surface of the CCA. During this process, manipulation of the internal carotid lesion should be avoided before establishing flow reversal. A provided 5F stiff micropuncture set is used, puncturing the artery through the previously placed stitch. The provided micropuncture wire used to access the common carotid artery is premarked to ensure that the lesion is not engaged before flow reversal. The micropuncture sheath is advanced into the common carotid artery at a length of 3 cm. An angiogram through the microsheath with an oblique view helps delineate the bifurcation and lesion location. The provided 0.035 J-wire should be inserted as close as possible to the bifurcation without engaging the lesion. This technique is referred to as the "stop short method." If selecting the ECA due to the need for additional wire purchase, then the provided 0.014

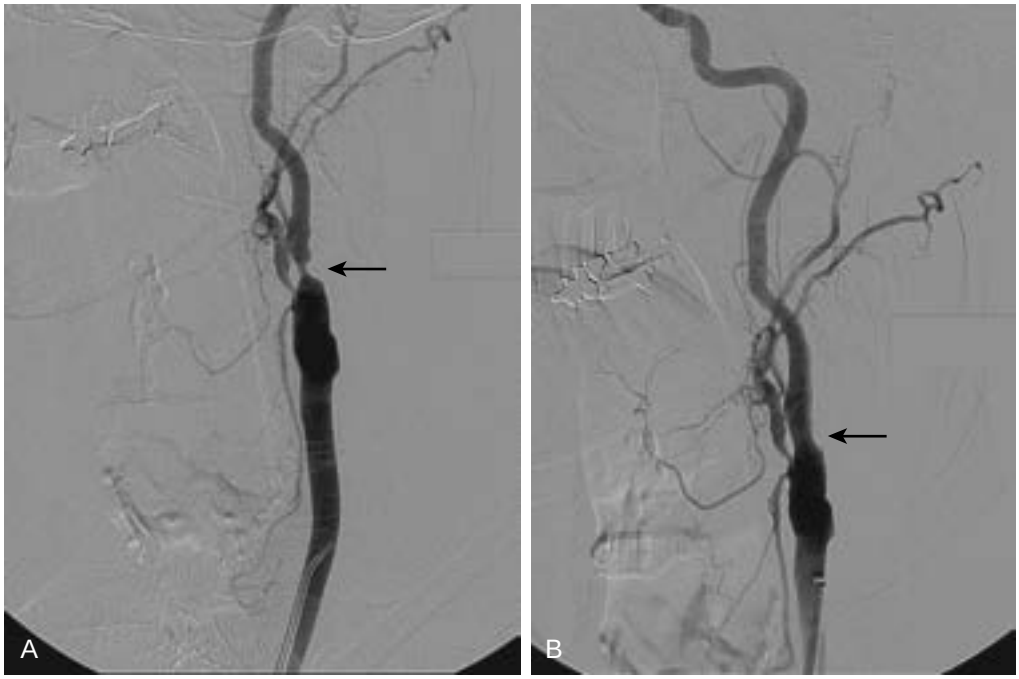

FIG. 3 **(A)** Digital subtraction arteriogram (DSA) of a left common carotid injection, lateral neck projection showing severe stenosis in proximal internal carotid artery *(arrow)*. **(B)** Completion DSA after carotid artery stenting. Notice the residual mild stenosis *(arrow)* at the site of the lesion, which was judged acceptable even though not angiographically perfect.

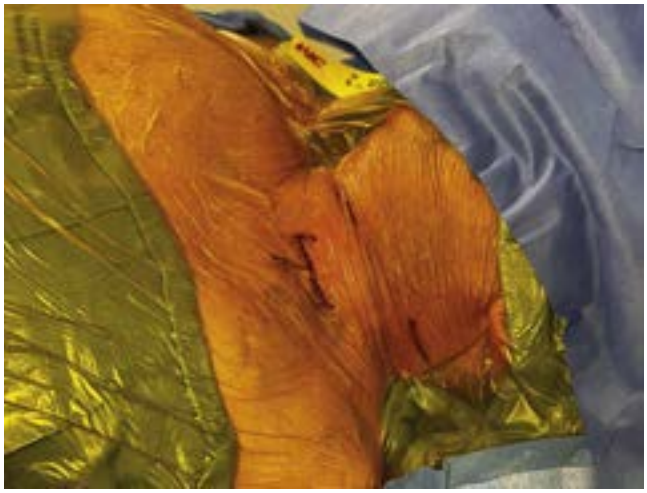

FIG. 4 A distance of 5 cm between the clavicle and the ipsilateral carotid bifurcation and a 6 mm CCA diameter are necessary to establish an ideal platform. These landmarks are identified intraoperatively with the use of ultrasound. *(Courtesy Dr. Rishi Roy, copyright 2021.)*

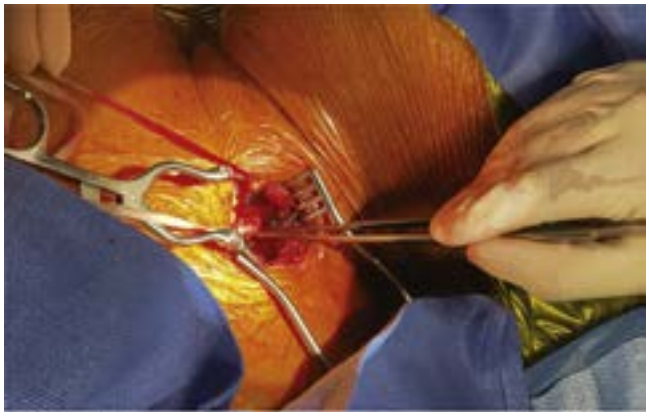

FIG. 5 Exposure of the common carotid at the base of the neck. Dissection is carried deep between the two heads of the sternocleidomastoid muscle to expose 3- to 4-cm segment of the carotid artery. *(Courtesy Dr. Rishi Roy, copyright 2021.)*

microstick wire followed by the sheath are used to select the ECA. Once ECA is selected, the microstick wire is removed and the J-wire is advanced into the ECA. This, again, ensures that the lesion is not engaged before flow reversal. After micropuncture sheath removal, the arterial access sheath (AAS) is advanced to the 2.5-cm marker, a length predetermined by the sheath stopper (Fig. 6). The sheath is sutured to the patient with gentle forward tension. Blood is aspirated, so flushing of heparinized saline through CCA sheath is generally avoided. Slow aspiration avoids ingress of air bubbles through the passive hemostatic valve. Of note, stopcocks are closed.

For the initiation of flow reversal, the flow controller is connected to the AAS. The circuit is prepared by passively allowing a column of blood to fill the line and filter device before connecting to the VRS. Once activated clotting time is confirmed, communication with the team about treatment steps and discussion concerning ideal blood pressure facilitates a smooth intervention. The CCA is occluded. A previously placed clamp, proximal to the arteriotomy, is used for occlusion. The flow controller has two flow settings and allows temporary cessation of flow via a flow stop button (FSB) for contrast injection. Flow reversal is confirmed by two means. The first one consists of stopping the flow to the VRS with the stopcock then clearing the line by injecting heparinized saline into the VRS line. When the stopcock is in the opened position, blood is seen returning in reverse from the flow controller to the VRS. The second way is by performing

FIG. 6 Once access in the common carotid artery is established, the working arterial access sheath is advanced to the 2.5-cm marker, a length predetermined by the sheath stopper. The sheath is sutured to the patient with gentle forward tension. *(Courtesy Dr. Rishi Roy, copyright 2021.)*

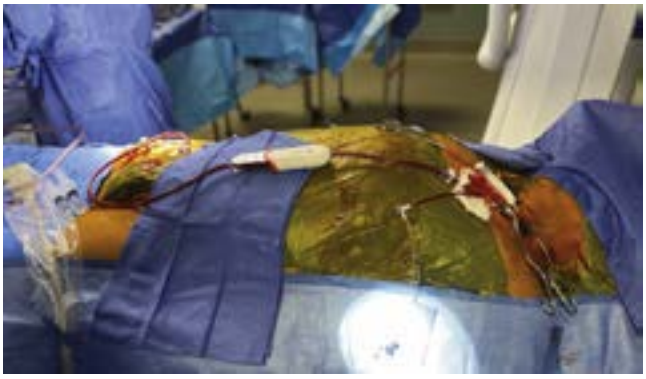

FIG. 7 Depiction of the flow reversal circuit after common carotid arterial access sheath and femoral venous access through the venous return sheath. *(Courtesy Dr. Rishi Roy, copyright 2021.)*

angiograms with a slow, gentle injection of a small volume of contrast to visualize just distal to the lesion while holding the FSB. Releasing the FSB confirms flow reversal within the carotid system (Fig. 7).

Before crossing the lesion, systolic blood pressure should be elevated to optimize flow reversal. Procedural steps are done through the AAS working channel. The ENROUTE transcarotid Neuroprotection System ([NPS] Silk Road Medical has an inner diameter of 8F and an outer diameter of 10F. It is compatible with all US Food and Drug Administration-approved carotid stents, including the ENROUTE transcarotid stent system. The close proximity to the lesion facilitates excellent crossing performance with 1:1 wire torque over a 0.014 wire. The treatment steps typically call for pre-stent ballooning of the stenosis to facilitate stent delivery and deployment at the site of the lesion. Upon completion, antegrade flow is restored by releasing the clamp and disconnecting the flow reversal system from the AAS and VRS. The CCA access sheath is removed, and the previously placed suture is tied for hemostasis. The venous sheath is removed, and hemostasis is achieved by manual compression.

PERIPROCEDURAL MANAGEMENT

Distal embolization is a principal concern with CAS, but the consequences of cerebral embolic events vary widely. Microemboli may produce radiographically apparent lesions on diffusion-weighted MRI scan without clinical evidence of neurologic sequelae. Emboli may also cause clinically significant neurologic deficit, the severity of which depends upon the location and extent of the cerebral tissue that has been rendered ischemic. Therefore, operators who perform CAS must be familiar with the anatomy of the brain and its vasculature so that intracranial cerebral branch vessel occlusion can be readily identified. It is equally important that operators be thoroughly familiar with normal neurologic function and the clinical manifestations of stroke. In addition, dedicated expert neurologic support is essential for a successful carotid stenting program.

Although uncommon, neurologic intolerance to flow reversal during TCAR may occur once the CCA is clamped and is usually manifested by confusion, agitation, or a slow decline in level of consciousness. Maintaining an elevated blood pressure, slowing down the flow reversal, stopping the flow reversal temporarily, converting to general anesthesia to decrease the metabolic demand of the brain and completing the procedure expeditiously are the maneuvers to consider to address this situation. If symptoms persist, aborting flow reversal and completing the procedure using a distal embolic protection is always an option.

Inflation of an angioplasty balloon in the proximal internal carotid artery sometimes provokes bradycardia and hypotension. This issue is addressed with intravenous atropine 0.4 mg either preemptively before balloon predilation or selectively when it occurs. Patients with severe aortic stenosis may be intolerant of even mild bradycardia and hypotension with balloon inflation, and consideration should be given in such patients to using monitored anesthesia and placing a temporary pacemaker before the procedure. Bradycardia and hypotension with carotid balloon angioplasty are rarely seen in patients who have previously undergone CEA, probably because of the denervating effect of surgical dissection near the carotid bulb.

Distal cervical ICA vasospasm is sometimes induced by catheter or wire manipulation or by distal filter or balloon placement. Avoidance of movement of the distal filter once deployed helps minimize vasospasm at the site. Resolution of the vasospasm often occurs spontaneously but can be hastened with transcatheter administration of nitroglycerin (200-μg bolus) into the involved artery.

As mentioned previously, antiplatelet therapy is essential for success of CAS. Dual antiplatelet therapy with clopidogrel (75 mg daily) and aspirin (81 or 325 mg daily) is the current standard. The considerable individual variation in the degree of platelet inhibition provided by antiplatelet therapy is now well known. Also, the impact of clopidogrel or aspirin resistance on long-term stent patency and restenosis rates is being increasingly recognized. Testing for such resistance is commercially available and should be considered preoperatively in all patients when timing allows.

If a patient has less than 20% inhibition on the platelet activity, a higher dosage of medication is warranted. This increase in the target level of inhibition does not translate into higher risk for bleeding. Ticlopidine (250 mg twice daily) can be used in patients who cannot tolerate clopidogrel. If a patient cannot take antiplatelet therapy, carotid stenting should be reconsidered, as the postprocedural stroke risk may then be unacceptably high.

Dual antiplatelet therapy should be continued for at least 3 months after the stent procedure, and daily aspirin should be continued indefinitely thereafter. Glycoprotein IIb-IIIa inhibitors are associated with increased risk of intracranial hemorrhage after carotid stenting, and their role should be confined to the treatment of acute thrombus formation during or immediately after the procedure.

For management of acute in-stent thrombosis, abciximab is administered by giving one-half of the 0.25 mg/kg bolus dose intraarterially near the clot and administering the second half of the bolus dose intravenously over 5 minutes, followed by an intravenous infusion of 10 mcg/min for 12 to 24 hours.

Postprocedural hypotension may accompany periprocedural bradycardia and is usually managed with volume expansion. Moderate bradycardia and mild hypotension, similar to that seen occasionally after CEA related to carotid baroreceptor stimulation, are best treated with fluid supplementation, close observation for any neurologic dysfunction, and occasional use of low-dose vasopressor support.

Control of postprocedural hypertension is important to minimize risk of cerebral hyperperfusion syndrome (CHS). Severe headache associated with hypertension after CAS should heighten suspicion of CHS, which can also present with seizures and focal neurologic deficits. Proper management of CHS entails early diagnosis, invasive monitoring, rapid control of hypertension, anticonvulsant therapy, osmotic diuresis, and neurologic consultation.

FOLLOW-UP

Patients are usually discharged from the hospital on the day after undergoing CAS. Follow-up office visit occurs 4 to 6 weeks after surgery, again 6 months later, and annually thereafter. Follow-up includes a complete neurologic assessment and carotid ultrasound scan examination. Each visit also includes a global cardiovascular evaluation with emphasis on possible coronary, renal, and peripheral arterial occlusive problems. Hypertension and hypercholesterolemia are managed aggressively. Because of the antiinflammatory and plaque stabilization effects, high intensity statin therapy is advised for almost all patients, even in the absence of laboratory evidence of cholesterol abnormalities. Healthy lifestyle habits are encouraged, with emphasis on regular aerobic exercise, dietary discretion, and complete abstinence from tobacco use.

Hemodynamically significant restenosis of carotid stents is not frequent and has been quoted as less than 5%. The application of carotid duplex velocity criteria of native vessels may overestimate the degree of stenosis in postoperative CAS surveillance. We follow the criteria of Stanziale and colleagues who use a peak systolic velocity of 350 cm/s or greater in the stent as a reliable indication of 70% or greater restenosis in a stented carotid artery.

SUMMARY AND PERSPECTIVE

Results of clinical trials have shown that both CAS and CEA are effective procedures for stroke prevention; each has an important place in carotid disease management. Currently, concerns about higher stroke risk with CAS, coupled with reimbursement restrictions and cost-effectiveness issues for asymptomatic CAS, make CEA the more commonly performed procedure. In the authors' practice, CAS is reserved for patients with recurrent stenosis after CEA, a history of neck irradiation or radical neck dissection, lesions located high in the neck (above the level of the C2 cervical vertebra), contralateral vocal cord paralysis, and traumatic dissections with neurologic symptoms in the absence of significant atherosclerotic disease.

Most patients undergoing CEA are at "high risk" based on traditional trial criteria, and only rarely are we compelled to use CAS because of extreme cardiopulmonary risk factors that make surgical treatment prohibitive. CEA should be used with reservation in situations where the risk of periprocedural stroke is higher than usual.

Specific clinical and anatomic factors preclude the use of transfemoral CAS in our practice. Clinical factors include age older than 80 years and recent (within 2 weeks) neurologic ischemic symptoms. Anatomic factors that may prevent CAS include vessel angulation greater than 60 degrees and a severely diseased aortic arch, especially when combined with branch vessel configuration that is hostile for sheath access. It has been proven that use of transcervical access lowers the stroke risk of CAS when compared with transfemoral approach. The 30-day stroke rate of only 1.4% for high-risk patients undergoing TCAR in the pivotal cohort mentioned earlier is worthy of consideration.

Finally, when deciding which procedure and what approach are most appropriate for each patient, skilled vascular surgeons, especially those trained and experienced in both CEA and CAS, bring a unique skill set, ability, and perspective to judging the multiple variables that must be considered carefully to achieve the best outcome for the patient.

Management of Aneurysms of the Extracranial Carotid and Vertebral Arteries

Virginia L. Wong, MD

Arterial aneurysms involving the extracranial carotid and vertebral arteries are rare, accounting for less than 1% of all peripheral arterial aneurysms. Of the many carotid interventions performed, only 0.1% to 2% are done for extracranial carotid artery aneurysms (ECAAs). Therefore, guidance for treatment of these lesions is based on single-center, retrospective series or literature reviews, rather than large multicenter, randomized trials. Extracranial vertebral artery aneurysm (EVAAs) are even less commonly encountered, and the available experience from case reports and small series provides only limited guidance for clinical management.

EXTRACRANIAL CAROTID ARTERY ANEURYSMS

Etiology

Historically, mycotic aneurysms were the most commonly encountered form of ECAA, associated with locally uncontrolled infection (e.g., peritonsillar abscess, mastoiditis). With increased access to antibiotic therapy, mycotic aneurysms are now unusual. A very low incidence (0.025%–0.85%) of carotid patch infection following carotid endarterectomy (CEA) has been reported. The most common causes of ECAA now are atherosclerotic degeneration and trauma. As with other degenerative peripheral artery aneurysms, weakening of the arterial wall layers is contributory, and most ECAAs of this type are located at the carotid bifurcation or involve the proximal internal carotid artery (ICA). Penetrating trauma, including iatrogenic injury from attempts at central line insertion, are a cause of arterial pseudoaneurysm, most commonly in zone I or II affecting the common carotid artery, though injury can occur at any place where an artery lies in the missile path. Blunt trauma associated with forceful cervical hyperextension or hyperflexion can cause vessel dissection, particularly in zone III near the skull base, with subsequent aneurysmal degeneration of the weakened arterial wall. Iatrogenic endovascular injury during percutaneous interventional procedures can lead to vessel perforation or degenerative aneurysm from intimal dissection anywhere along the traversed arterial distribution. Other etiologies of ECAA include fibromuscular dysplasia, collagen vascular and connective tissue disease, inflammatory disease (e.g., arteritis), radiation injury, cystic medial necrosis, and congenital defects.

Presentation and Diagnosis

Some patients with ECAA may be asymptomatic, their pathology having been identified on high-quality cross-sectional imaging for another indication. The most common presenting symptoms of ECAA are an acute neurologic event (i.e., stroke or transient ischemic attack) affecting nearly half of symptomatic patients. Patients also commonly present with a pulsatile neck mass. Compressive symptoms including vocal hoarseness, dysphagia, facial pain, or cranial nerve palsies may be present. Rupture and hemorrhage may be more common with infection or pseudoaneurysm. Other causes of neck mass include carotid or subclavian artery tortuosity and redundancy, carotid body tumor, cervical malignancy, lymphadenopathy, peritonsillar abscess, and branchial cleft cyst. Diagnostic studies including duplex ultrasound (DUS) and computed tomographic angiography (CTA) or magnetic resonance angiography (MRA) are the most helpful for evaluation as well as for diagnosing alternate pathology (Fig. 1). DUS may be limited in its ability to visualize very proximal or distal disease; however, it remains a good choice for initial evaluation given its cost-effectiveness and low procedural risk. High-quality tomographic studies are mandatory for planning intervention and generally provide all necessary information (Fig. 2).

Surgical repair of carotid artery aneurysms: a 10-year, single-center experience.* Ann Vasc Surg. *2010;24:100–105.)*

Therefore, traditional catheter angiography is less often required to assess anatomy preoperatively, but it may still be useful for balloon occlusion testing if this information would alter treatment options or the approach to therapy.

Indications for Treatment

The natural history of untreated, asymptomatic ECAAs is not well-known. Although some have reported successful medical management of select ECAAs using antiplatelet or anticoagulant therapy and surveillance imaging, the potentially high rate of embolic neurologic events associated with ECAAs is enough to consider a more aggressive approach in suitable patients with approachable anatomy. Further, there are no established criteria describing which type or size of ECAA would be suitable for noninterventional therapy. Symptomatic patients with neurologic events, compressive complaints, infection, or hemorrhage (rupture) require more urgent treatment.

Preoperative Considerations

Optimal treatment for ECAA will vary depending on the etiology, location, aneurysm morphology, medical suitability for surgery and anesthesia, and prior treatment for other conditions. A thorough history and physical examination will further define some of these characteristics. Consideration for open surgical repair includes cardiovascular and medical fitness, ability to extend and rotate the neck, and availability of suitable conduit or patch material for reconstruction. Access to a very distal ECAA may require unusual maneuvers for exposure or the assistance of a surgeon experienced in skull base procedures. An infectious etiology will require vascularized soft tissue coverage or reconstructive surgery. Consideration for endovascular repair includes availability of interventional expertise and equipment as well as suitable access vessels and anatomy. Endovascular repair may be most appropriate for sterile, nondegenerative ECAA with a low thrombus burden, such as those resulting from trauma or dissection and pseudoaneurysms. Medical unsuitability for surgery or a hostile neck would favor endovascular therapy, if possible. Traditionally, compressive symptoms were principally treated with open surgery; however, symptom relief after endovascular exclusion has been reported.

A morphologic classification of ECAA was proposed by Attigah et al. in a 2009 review of their experience with more than 60 open surgical reconstructions over 24 years, the majority of which were performed for atherosclerotic degeneration (Fig. 3). Although contemporary experience suggests that endovascular treatment may now be suitable or even preferable for some types of ECAA, it is clear that no single reconstruction or treatment is universally suitable for all aneurysm types. Nevertheless, standardizing the anatomic description of ECAA may enhance comparisons between open and endovascular repair for different aneurysm types and extent.

Open Surgical Repair

There are multiple techniques used for open surgical repair of ECAA, the most suitable of which will depend on the etiology, location, and extent of the aneurysm as well as some of the additional factors discussed earlier. Although standard CEA and more limited repair of the carotid arteries may be accomplished under local or regional anesthesia, general endotracheal anesthesia is recommended for the repair of most ECAAs because of the increased operative time required for extensive dissection and arterial reconstruction. Strong consideration should be given to using a shunt or some type of cerebral perfusion monitoring, given longer cross-clamp and hemispheric ischemia times than are typically encountered for standard CEA. Access to the extracranial carotid artery bifurcation is achieved via a longitudinal skin incision along the anterior border of the sternocleidomastoid muscle, a standard approach that is familiar to many surgeons. Proximal extension will be necessary for more proximal common carotid involvement and could require mini- or standard sternotomy if control is needed below the clavicle. The incision is extended cranially behind the ear for exposure of the distal extracranial ICA; division of the posterior belly of the digastric muscle and resection of the styloid process affords improved access to this area. If anticipated in advance, nasotracheal intubation and mandibular subluxation will facilitate distal carotid artery exposure. If the distal ICA is inaccessible for cross-clamping, control can also be obtained with an intraluminal balloon occlusion catheter or shunt. Exposure even more distally can be achieved by partial resection of the mastoid and petrous portion of the temporal bone, achieved with the assistance of an experienced skull base surgeon; however increased morbidity and risk of cranial nerve injury may be associated with these more extreme maneuvers.

Dissection around the aneurysm can be challenging because of the dense inflammatory reaction that often surrounds aneurysmal tissue. Several cranial nerves may be encountered in the field including the vagus and recurrent laryngeal nerve (X), hypoglossal (XII), glossopharyngeal (IX), spinal accessory (XI), and branches of the facial nerve (VII). Expansion of the aneurysm may distort usual anatomic relationships, and nerves may be densely adherent to the aneurysm surface or to surrounding structures. Meticulous dissection is required to identify all structures and protect them from injury. Care should also be taken to manipulate the aneurysm as little as possible during dissection, preventing dislodgement and distal embolism of aneurysm contents. Finally, once dissection and exposure are obtained, systemic heparin is administered to maintain anticoagulation while the carotid artery is cross-clamped and until arterial reconstruction is completed (Fig. 4A).

Primary suture repair is the most straightforward repair technique and may be suitable for focal or very limited pseudoaneurysms, such as those caused by trauma or iatrogenic injury. Interrupted sutures are placed in a transverse manner, as long as

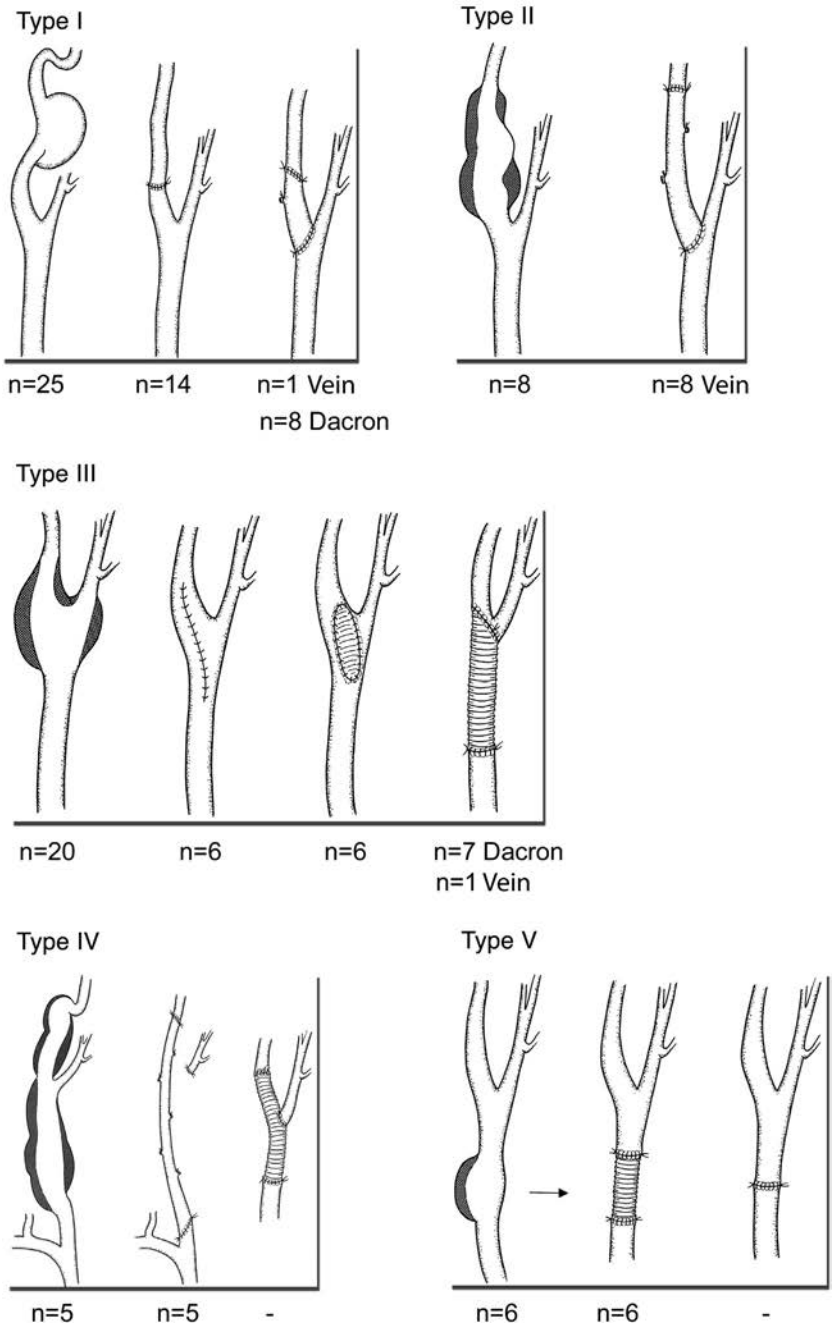

FIG. 3 Morphologic classification of the extracranial carotid aneurysms and possible vessel reconstruction alternatives. Type I: aneurysms of the internal carotid artery distal to the carotid bifurcation. Type II: aneurysm of the internal carotid artery. Type III: aneurysm of the carotid bifurcation. Type IV: aneurysm of the internal carotid artery and the common carotid artery. Type V: aneurysm of the common carotid artery. *(From Attigah N, Kulkens S, Zausig N, et al. Surgical therapy of extracranial carotid artery aneurysms: long-term results over a 24-year period.* Eur J Vasc Endovasc Surg. *2009;37:127–133.)*

this can be accomplished without narrowing the artery. Wider-based pseudoaneurysms or saccular aneurysms whose residual arterial defect account for <50% of the arterial circumference can be repaired with patch angioplasty. Acceptable patches can be constructed of autologous vein (e.g., saphenous), polyester or polytetrafluoroethylene (PTFE) prosthetic, or bovine pericardium (bioprosthetic) materials. If infection is a concern, only autologous material should be used. In cases in which sufficient mobilization of the carotid artery can be achieved, debridement of involved tissue and primary re-anastomosis may be possible (Fig. 4B).

More typically, and for situations in which a greater degree of the artery is involved, resection of the aneurysm and arterial reconstruction by interposition bypass grafting is necessary and would be considered the standard of open surgical repair for most ECAAs. Again, acceptable conduit depends on the circumstances but can include autologous vein or prosthetic materials. If autologous vein is not available, segmental harvest of the superficial femoral artery (SFA) for carotid reconstruction has been described; a chronically occluded SFA can be endarterectomized for use, while a healthy donor artery can be subsequently reconstructed with prosthetic material. The

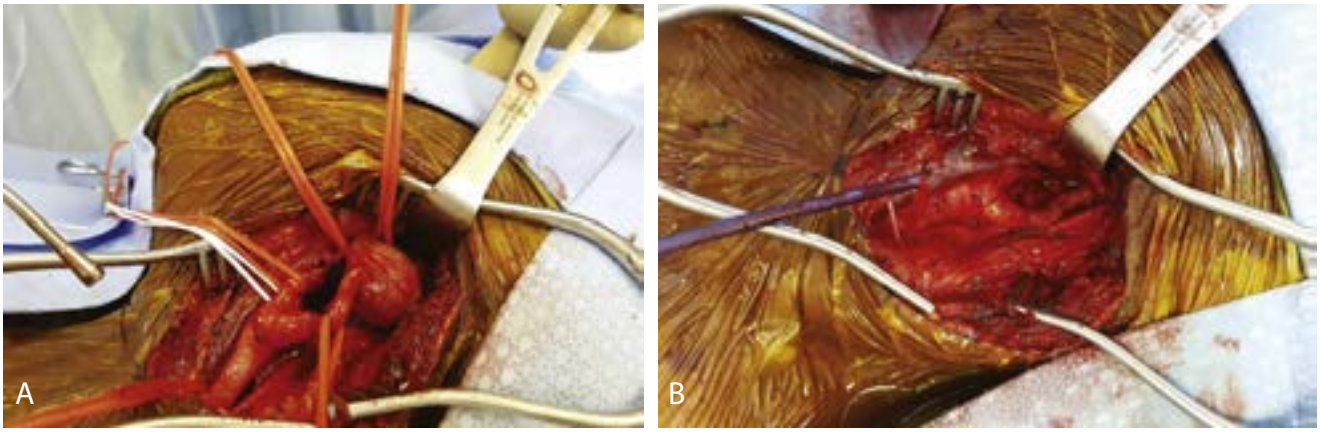

FIG. 4 **(A)** Left extracranial internal carotid artery (ICA) aneurysm; **(B)** Following aneurysm resection and primary ICA re-anastomosis. *(Photos courtesy Vikram Kashyap, MD.)*

external carotid artery (ECA) can typically be ligated without consequence, and division of this artery can provide improved mobility for reconstruction by primary carotid re-anastomosis. Alternatively, the ECA can be ligated distally and the proximal end transposed to the distal ICA (by end-to-end anastomosis) to serve as the "bypass" conduit.

Finally, ICA ligation may be considered, though it is often a choice of last resort given the historically high risk of stroke and mortality associated with this maneuver (in excess of 25%). Ligation may be the only available option in cases of exsanguinating hemorrhage from rupture or when access to the very distal ICA cannot be achieved sufficiently for arterial reconstruction. Patients who may tolerate ligation can be identified by performing a balloon occlusion test preoperatively (if the need for ligation is anticipated before surgery) or by measuring a carotid stump pressure intraoperatively. The balloon occlusion test is performed during preoperative catheter angiography after full heparinization. Balloon occlusion of the ICA distal to the anticipated aneurysm resection point is accomplished for 30 minutes, and the awake patient is monitored for neurologic symptoms. Intraoperatively, a carotid stump pressure is obtained in the heparinized patient by inserting a 20-gauge angiocatheter attached to pressure monitor tubing into the distal ICA and then occluding the common and external carotid artery inflow. A back-pressure measurement of >50 mm Hg suggests that cerebral collaterals are sufficient to allow for ligation of the ipsilateral ICA supply without neurologic sequelae. If either test suggests that a patient will not tolerate ICA ligation and arterial reconstruction is deemed impossible, then extracranial-to-intracranial (EC-IC) bypass should be considered. If ICA ligation is undertaken, therapeutic anticoagulation should be administered postoperatively and continued for at least 3 months to prevent distal embolization of thrombus that forms cranial to the point of ICA ligation (carotid stump syndrome).

Infected ECAAs require additional treatment to include broad-spectrum antibiotic therapy, subsequently tailored to intraoperative culture results; full debridement of all infected and devitalized tissue; and adequate coverage of vascular structures by well-vascularized, healthy tissue. The sternocleidomastoid muscle is readily available for use in most circumstances; however, previously irradiated or extensively operated fields may require myofascial or myocutaneous flaps for proper coverage.

Endovascular Repair

With increasing expertise and improved tools for endovascular therapy, modern series report a greater trend toward use of endovascular techniques for treatment of ECAAs. Many of the same advantages of using endovascular techniques instead of open surgery to treat other vascular conditions have also been reported for ECAA, the most significant benefit being a lower risk of cranial nerve injury. This is particularly the case with very high lesions near the skull base, but endovascular repair may be preferred for nondegenerative ECAAs and pseudoaneurysms. Endovascular treatment should be considered carefully for ECAAs of atherosclerotic etiology as the underlying disease process may result in further arterial degeneration, limiting the potential durability of endovascular treatment.

Endoluminal access to the carotid artery may be obtained from a standard transfemoral arterial approach if access vessel and aortic arch anatomy are suitable. Aortic arch angiography in a left anterior oblique projection is achieved using a multi-sidehole catheter and a power injector to identify the head vessel anatomy, followed by heparinization and advancement of a long arterial sheath into the common carotid artery. Selective carotid and cerebral angiography is then obtained, and a low-profile system is positioned across the carotid artery lesion for intervention. Alternatively, access to the proximal common carotid artery may be achieved by surgical cutdown. In either case, local anesthesia with sedation is usually sufficient unless general anesthesia is required due to hemodynamic instability or other considerations. Use of protection against distal cerebral embolization should be considered the standard of care as it is for stenting of non-aneurysmal carotid pathology. A distal embolic protection device (EPD) should be deployed as early in the procedure as possible. Alternatively, some authors are now reporting the use of transcarotid artery stenting (TCAR) and flow-reversal techniques to achieve embolic protection during endovascular treatment of ECAA.

Successful endovascular exclusion of the aneurysm while maintaining antegrade flow through the ICA can be achieved by placement of a bare metal stent or a covered stent graft across the aneurysm, landing each end of the stent into normal, healthy artery. Bare metal stents alone may be sufficient for exclusion of small aneurysms and more suitable for use in smaller arterial diameters or for treatment of concomitant arterial dissection (Fig. 5). Covered stents will provide more immediate aneurysm exclusion and may be better for traumatic ECAAs or those at imminent risk for rupture or hemorrhage. The external carotid artery will require embolization before coverage by a stent graft to prevent backbleeding into the aneurysm and a type II endoleak. Coil embolization of saccular aneurysms or larger pseudoaneurysms can be undertaken, followed by deployment of a stent to trap the material in place and preserve the antegrade flow lumen. Alternatively, if the aneurysm fails to thrombose after stenting, coil embolization can be performed through the interstices of a previously deployed closed-cell stent, either at the time of stenting or as a secondary procedure.

Post–stent-deployment balloon angioplasty must be undertaken with caution to avoid arterial dissection, and the possibility of

FIG. 5 Digital subtraction angiography of a left internal carotid aneurysm at the skull base with associated weblike stenosis. **(A)** Before treatment by bare metal stent placement. **(B)** After treatment. Note the absence of residual stenosis and presence of a small residual aneurysmal sac, which subsequently closed completely.

transient hypotension and bradycardia during balloon inflation near the carotid bifurcation should be anticipated. The patient's neurologic function is monitored throughout the procedure, and posttreatment completion angiography is obtained to assess for any technical complications. Vessel closure and management of procedural heparin anticoagulation is per routine. Posttreatment antiplatelet or anticoagulant therapy should be considered.

Results of Treatment

ECAA repair by either open or endovascular techniques appears to be effective and with similar early mortality and risk of cerebrovascular events. Although several reviews of the current experience are available, case numbers are too low for subgroup analysis or to describe outcomes of specific techniques (e.g., interposition arterial bypass vs. ECA transposition or bare metal stent-supported coil embolization vs. covered stent graft deployment). Further, these data are unable to establish which modality is more appropriate for a specific circumstance or aneurysm type. The repair technique selected may likely reflect ECAA etiology or anatomic location and extent; therefore, it may not be directly comparable from a retrospective standpoint. Data for late outcomes vary with length of follow-up and are more limited.

A 2015 review by Welleweerd et al. summarized published data for more than 900 patients undergoing open surgery for ECAA repair, finding a pooled 30-day mortality rate of 1.91% and a pooled 30-day stroke rate of 5.16%. A 2020 review of endovascular ECAA repair by Giannopoulos et al. examined more than 150 patients and reported low mortality and cerebrovascular event rates of 2.5% and 4.3%, respectively. A recent review by Galyfos et al. of comparative data from series reporting both open and endovascular ECAA repair found similar outcomes and no differences in this regard between treatment modalities. There do appear to be differences, however, in the risk of cranial nerve injury, as might be expected from our experience with CEA and carotid artery stenting for atherosclerotic disease. The risk of cranial nerve injury is much higher with open ECAA repair (ranging from 0 to 60%) and may be associated with the need for more extensive or distal dissection. Although some percentage of nerve deficits may be transient, it is striking that the rate of cranial nerve injuries in many series of endovascular repair is reported as 0% or very close to that. Few studies offer data on long-term outcomes, though the risk of late stroke also appears to be low after treatment, regardless of modality. Even without large, direct comparisons, outcomes using modern endovascular techniques appear to be acceptable for treatment of some ECAAs and offer many advantages over open surgery.

EXTRACRANIAL VERTEBRAL ARTERY ANEURYSMS

EVAAs are very rare, typically arising from aneurysmal degeneration of a prior intimal dissection or after traumatic injury (both blunt and penetrating). Connective tissue disorders that predispose to aneurysm formation in other arterial beds may be responsible for primary EVAAs. Most patients are asymptomatic, and the diagnosis is made by incidental finding during imaging for another indication. Those with symptoms may complain of persistent ipsilateral head or neck pain, particularly following trauma. EVAA can also result in vertebrobasilar insufficiency or a posterior cerebrovascular event (i.e., stroke or transient ischemic attack). DUS is less helpful for

evaluating EVAAs because it is unable to visualize the artery through its interosseus course (V2 segment) and then more distally through the V3 segment as it approaches the base of the skull. CTA and MRA provide sufficient imaging of EVAAs and their surrounding anatomy, which can be helpful for surveillance and procedural planning.

The natural history of EVAAs is not well described; therefore, the indications for intervention are not clear. Small, asymptomatic EVAAs can likely be safely observed with antiplatelet therapy; however, intervention should be considered for serial enlargement during follow-up or for those with significant thrombus burden that may be at higher risk for embolism. Intervention is recommended for all symptomatic EVAAs.

Open surgical exposure of the vertebral artery can be challenging, depending on the segment of the artery that is affected. The most proximal V1 segment may be approached through a transverse cervical incision, whereby ligation, resection with reconstruction, or transposition onto the carotid artery may be undertaken. Ligation should be well tolerated when the contralateral vertebral artery is normal, and preoperative evaluation of the opposite side by duplex, tomographic imaging, or catheter angiography (including a balloon occlusion test) can be helpful. Access to the V2 segment of the artery is complicated by the bony foramina through which it courses as well as by an associated venous plexus. Exposure of the V3 segment via a posterior approach can provide improved access to the artery near the base of the skull for a distal bypass anastomosis, but this exposure is less familiar to most surgeons and should probably be attempted only by those with considerable experience working in this area.

Given the challenges associated with surgical access to the extracranial vertebral artery, endovascular management of EVAAs is appealing. Endovascular coil embolization can be used as an alternative to open surgical ligation, particularly in cases of traumatic pseudoaneurysm or hemorrhage. Stenting of EVAAs is technically feasible, though tortuosity may preclude the ability to stent safely through some segments of the artery. Unfortunately, high rates of in-stent restenosis have been associated with stenting for vertebral artery occlusive disease; thus, the use of stents for aneurysmal disease should be considered with care, particularly if the contralateral vertebral artery or other posterior fossa collateral flow has been deemed inadequate.

Brachiocephalic Reconstruction

Gregory J. Pearl, MD, and Lauren Beliveau, MD

INTRODUCTION

The most common anatomic configuration of the brachiocephalic vessels off the transverse aortic arch is three separate and discrete branches from proximal to distal: the innominate artery, the left common carotid artery, and the left subclavian artery. The innominate artery gives rise to the right subclavian and right common carotid artery. The most common variant of arch anatomy is the bovine arch. In this variation, the left common carotid artery either shares a common origin with the innominate artery off the arch, or the left common carotid artery arises directly off the innominate artery. Interestingly, this is not the anatomic configuration of a cow's aortic arch, but rather resembles a cow with horns on illustration.

Other common variants include the left vertebral artery arising directly off the arch between the left common carotid and the left subclavian arteries and the aberrant right subclavian artery that arises just distal and posterior to the left subclavian artery, coursing across the midline between the esophagus and anterior spinal ligament to the right upper extremity (Fig. 1). An aberrant right subclavian artery can be associated with dysphagia lusoria as a result of compression from the right subclavian artery on the esophagus.

The brachiocephalic vessels supply the upper extremities as well as the brain, so any disease entity that affects these vessels, either as a result of flow-limiting stenosis or as a source of embolization, may produce serious symptoms that are difficult to correct surgically (Fig. 2). The underlying lesions affecting the great vessels may be a result of and associated with disease arising in the aortic arch or may be secondary to lesions intrinsic to the brachiocephalic vessels themselves. The pathologic entities include atherosclerotic disease, inflammatory arteritides, blunt or penetrating trauma, or a pathologic process involving the ascending or transverse aortic arch such as aortic dissection or aneurysm. Additionally, occlusive or aneurysmal lesions of the subclavian arteries may be associated with arterial thoracic outlet syndrome. Debranching procedures of the brachiocephalic vessels have also become an important adjunct in the endovascular treatment of aortic dissections or aortic aneurysmal disease involving the transverse arch or proximal descending thoracic aorta.

CLINICAL PRESENTATION

The clinical manifestations of lesions involving the brachiocephalic arteries are in large part dependent on the underlying pathogenesis and extent of vessel involvement, such as single-vessel versus multivessel disease, as well as the anatomic location of the culprit lesions. In Berguer's report on brachiocephalic revascularization, he identified an approximately 40% incidence of multivessel involvement of the brachiocephalic arteries.

Atherosclerotic disease involving the arch vessels is not uncommon and in most instances is asymptomatic. At times, the only finding is an otherwise asymptomatic discrepancy in blood pressure in the upper extremities. Symptoms caused by occlusive lesions involving the brachiocephalic vessels may be those typical of carotid artery distribution transient ischemic attack (TIA) or stroke, vertebrobasilar events, or upper-extremity ischemia such as arm fatigue or digital ischemia. Lateralizing hemispheric neurologic events include amaurosis fugax, or transient monocular loss of vision, word-finding difficulty, and weakness or numbness involving one side of the body only.

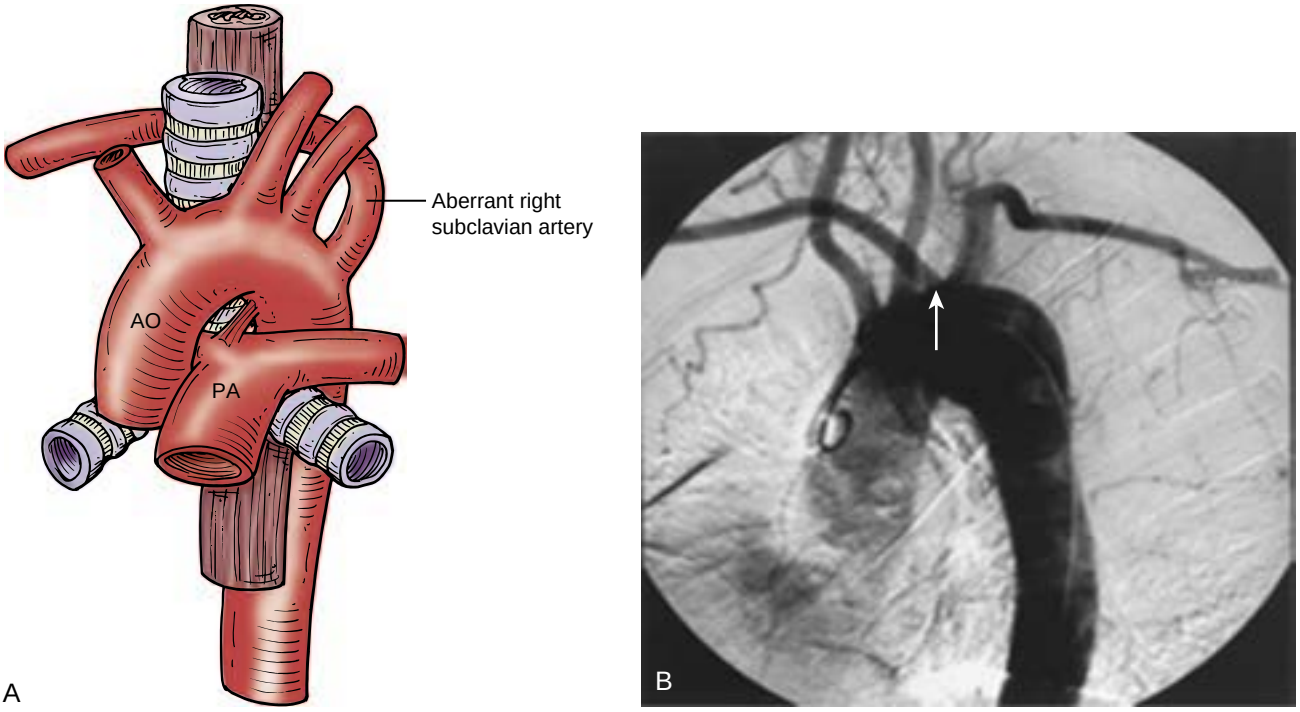

FIG. 1 Illustration **(A)** and digital subtraction arteriogram **(B)** demonstrating the anatomic configuration of an aberrant right subclavian artery *(arrow)*. *AO,* aorta*; PA*, pulmonary artery.

FIG. 2 Digital subtraction angiogram showing multivessel atherosclerosis involving brachiocephalic vessels.

Multivessel occlusive lesions, as seen in patients with advanced atherosclerotic disease or Takayasu arteritis, may produce nonlateralizing neurologic symptoms such as dizziness and visual disturbances secondary to cerebral hypoperfusion. Patients presenting with classic lateralizing hemispheric neurologic events that cannot be attributed to cervical or intracranial carotid disease should undergo aggressive interrogation of the brachiocephalic vessels as a potential source of these symptoms.

Severe occlusive disease in the proximal subclavian arteries may produce flow reversal in the ipsilateral vertebral artery, leading to a condition known as *subclavian steal syndrome*. Flow reversal in the vertebral artery noted on duplex ultrasound examination of the neck is not an uncommon finding and is frequently asymptomatic. However, in the classic clinical picture of subclavian steal, the patient will experience typical symptoms of vertebrobasilar insufficiency associated with arm exercise. These symptoms can include vertigo or "drop attacks" in which the patient suddenly falls to the ground without losing consciousness. Complaints of arm fatigue secondary to proximal subclavian atherosclerotic occlusive disease are uncommon because of the extensive capacity of collateral flow to the upper extremity combined with the decreased physical demands inherent in the atherosclerotic age group and therefore rarely require intervention. However, findings of unilateral digital ischemia as a result of microembolization should lead to a high index of suspicion for the culprit lesion to be located in the proximal subclavian or brachiocephalic vessels (Fig. 3). Interrogation for the source lesion in this setting should not be delayed and should be pursued aggressively because ongoing embolization could potentially lead to extensive distal tissue loss and consequent severe functional impairment.

DIAGNOSTIC EVALUATION

A thorough history and physical examination are paramount in the initial evaluation of these patients. Careful palpation of the carotid and upper-extremity pulses in conjunction with auscultation of the neck, including the parasternal and paraclavicular areas, for the presence of bruits is necessary. Bilateral upper-extremity blood pressure measurements may easily and quickly be performed and yield useful information if a significant discrepancy is discovered. Any significant alteration in the comparison of the quality of pulses, the presence or absence of bruits, or significant upper-extremity blood pressure

FIG. 3 Ulceration in patient with arterial thoracic outlet syndrome.

discrepancies of greater than 20 mm Hg is highly suggestive of hemodynamically significantly subclavian or brachiocephalic disease. Of note, a significant blood pressure discrepancy in the upper extremity in an asymptomatic elderly patient is not uncommon and does not necessarily warrant additional investigation in the absence of symptoms or worrisome physical findings of digital ischemia.

Duplex ultrasound is extremely useful and sensitive in the interrogation of the cervical portion of the carotid arteries. However, it is of more limited use in the assessment of the brachiocephalic vessels because of their intrathoracic location. A diminished carotid pulse noted on palpation in conjunction with altered low velocity and dampened waveforms in the carotid artery at the base of the neck may be indirectly indicative of a hemodynamically significant proximal occlusive lesion that may mandate further investigation depending on the clinical setting. As described earlier, duplex ultrasound can easily detect flow reversal in the cervical part of the vertebral artery, which is suggestive of proximal subclavian occlusive disease. Magnetic resonance angiography (MRA) and computed tomographic angiography (CTA) are additional noninvasive imaging modalities that are useful in the assessment of the aortic arch and brachiocephalic vessels. Both modalities require intravenous contrast administration for adequate imaging of these vascular structures. In our experience, MRA tends to be fraught with motion artifact related to the underlying cardiac cycle and respiratory variation, and it also tends to overestimate the degree of stenosis of the occlusive lesions. CTA seems to be better tolerated by patients because a much shorter time is required to complete the study, which obviates the problems associated with claustrophobia seen in many patients undergoing MRA. Multiplanar digital subtraction angiography remains the gold standard imaging modality, and despite its more invasive nature, it remains particularly appropriate in those patients for whom potential endovascular treatment of the brachiocephalic disease is being considered.

TREATMENT

Indication for Treatment

The most frequent indication for the treatment of brachiocephalic disease includes patients whose symptoms can be directly attributed the anatomic location of disease. The symptoms may include lateralizing neurologic hemispheric symptoms, vertebrobasilar insufficiency, or upper-extremity ischemic symptoms. One would expect to identify significant lesions in the common carotid, subclavian, or innominate artery compatible with the lateralizing neurologic clinical presentation of the patient. In patients with nonlateralizing symptoms related to global hypoperfusion, multivessel brachiocephalic involvement, bilateral carotid disease, or tandem lesions should be suspected and confirmed on thorough workup. Classic subclavian steal syndrome with onset of vertebrobasilar symptoms with arm exercise also indicates a need for treatment.

There is a paucity of natural history data to direct decision making in patients with asymptomatic brachiocephalic disease. The rich data from retrospective analyses and subsequent prospective analysis of the risks inherent in severe asymptomatic carotid bifurcation disease do not exist for asymptomatic brachiocephalic disease. General agreement exists that asymptomatic subclavian artery occlusive disease need not be treated other than in the occasional patient who requires normalization of subclavian artery flow to support the use of an internal mammary bypass graft for coronary artery revascularization or in the difficult hemodialysis patient who requires placement of dialysis access in the extremity supplied by the stenotic subclavian artery. In the patient with asymptomatic severe proximal common carotid artery occlusive disease, it seems intuitive that intervention should be considered for a preocclusive or critical stenosis at its origin to preserve patency of the common carotid artery and consequently reduce the long-term risk for stroke. Brachiocephalic reconstruction has also become increasingly used in conjunction with endovascular repair of thoracic aortic dissection or aneurysm.

Before the routine use of endovascular techniques in the cerebrovascular circulation, treatment of tandem carotid disease presented a quandary for the treating physician. In the symptomatic patient, it was often unclear whether the symptoms were related to a carotid bifurcation lesion or to a more proximally located common carotid or innominate lesion. Prioritization of which lesion to treat first could be quite problematic. The currently favored strategy involves a combined approach with open carotid endarterectomy and retrograde angioplasty and stenting of the proximal common carotid artery or innominate lesion. To be clear, the proximal disease only needs intervention for severe, flow-limiting stenosis. Mild or moderate proximal lesions do not need to be treated concomitant to carotid endarterectomy and should simply be observed prospectively. In patients with nonatherosclerotic conditions affecting the brachiocephalic vessels, the indications for treatment should be reserved for the symptomatic patient. In patients with inflammatory arteritis such as Takayasu arteritis, the acute inflammatory phase should be treated medically to quiescence, and intervention should be reserved for resultant fibrotic stenosis in the affected vessels based on symptoms and severity, as is done with atherosclerotic lesions (Fig. 4).

Treatment Options

A number of therapeutic modalities are currently available for the treatment of brachiocephalic disease. The treatment options are categorized into two groups: open surgical reconstruction or endovascular intervention. These two general approaches are not mutually exclusive, and as mentioned previously, certain clinical situations may require combined treatment with both modalities to best treat more complex disease. Open surgical approaches may be further categorized as direct (anatomic) reconstruction and indirect (extraanatomic) reconstruction. The direct approach requires a median sternotomy for treatment of innominate or left common carotid artery lesions or a left posterior lateral thoracotomy for treatment of proximal left subclavian disease. The anatomic reconstruction maintains antegrade laminar flow accomplished through a bypass arising from the ascending aorta to the innominate and/or left common carotid artery. In the setting of isolated focal lesions localized to the innominate artery alone, endarterectomy may provide a suitable treatment option. Open repair may be preferred in suitable

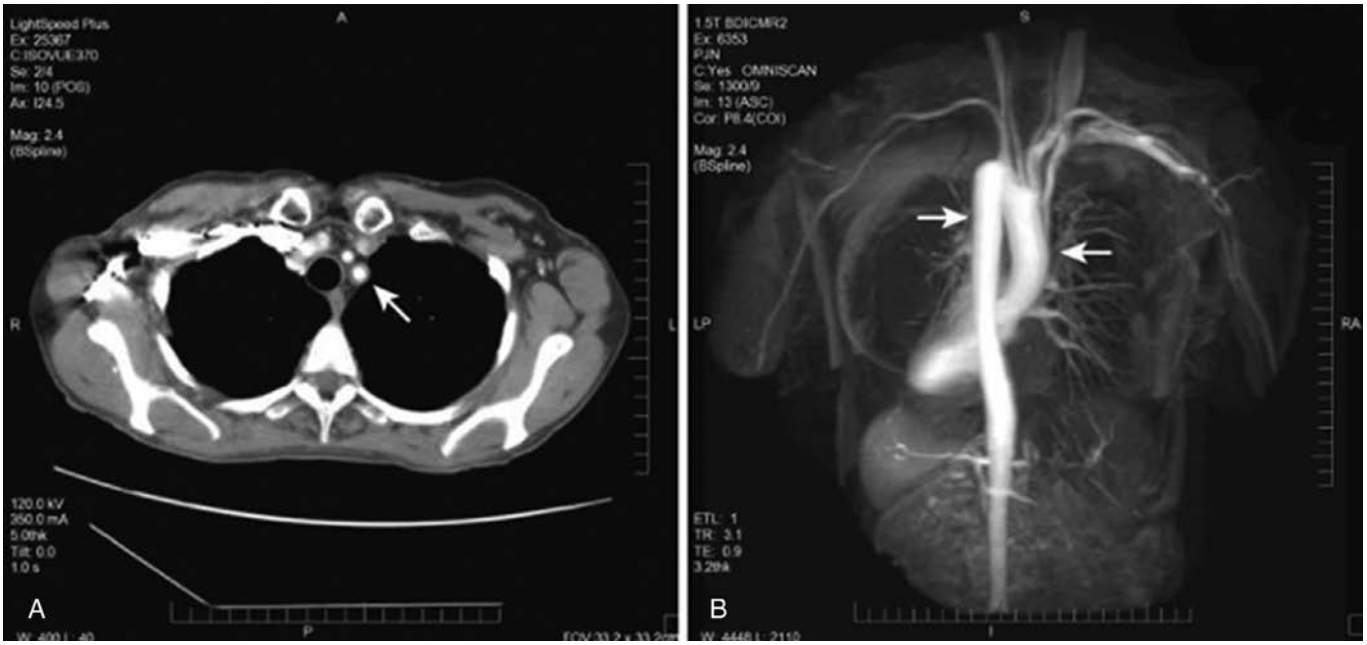

FIG. 4 Axial images from a CT angiogram **(A)** and three-dimensional reconstructed MRA **(B)** of a young woman with Takayasu's arteritis. Note the lucency surrounding the proximal brachiocephalic vessels on the CTA and the double contour of the ascending and descending thoracic aorta demonstrating wall thickening and inflammation.

risk patients with extensive severe calcific atherosclerotic disease at the origin of the vessel to be treated. If severe brachiocephalic disease is identified in a patient being considered for coronary artery bypass grafting, the coronary revascularization may be performed safely concomitant with the brachiocephalic revascularization.

In patients with severe calcific disease in the ascending aorta and aortic arch, in whom cross-clamping the aorta would be impossible or extremely hazardous and construction of a graft anastomosis would be difficult, or in patients deemed to be poor candidates for median sternotomy because of advanced age, prior sternotomy or mediastinal radiotherapy, or multiple comorbidities, the indirect approach is preferable. This procedure is performed through supraclavicular or cervical incisions and involves bypass grafting or arterial transposition. Extraanatomic procedures are very well tolerated, with inherently low morbidity and mortality rates, and excellent long-term patency rates have been reported. The choice between performing a direct or indirect vascular procedure for brachiocephalic disease is also dependent on a number of other anatomic/pathologic factors, including the number of vessels involved, the location and distribution of the occlusive lesions in the involved vessel, the underlying pathogenesis and nature of the symptoms (embolic vs. hypoperfusion), and the status of the other vessels supplying the brain not requiring or amendable to intervention, such as total internal carotid artery occlusion.

Advances in guidewire, angioplasty balloon, and stent design as well as the availability of covered stent grafts, have broadened the applicability of endovascular treatment of severe brachiocephalic disease. As the experience and skill of the interventionalist have grown with the technologic advances and improved device availability, endovascular treatment of fairly complex brachiocephalic disease has gained wider acceptance and use. With appropriate careful technique, excellent outcomes have been achieved with low associated morbidity. As is true for intervention in any vascular bed, close follow-up and regular surveillance is mandatory regardless of the type of intervention performed in the treatment of brachiocephalic disease.

ANATOMIC (DIRECT) REVASCULARIZATION

Endarterectomy

Endarterectomy may be considered for focal atherosclerotic lesions in the innominate artery. This would be performed via median sternotomy. It should not be attempted in patients in whom the lesion is located at the ostium of the vessel because these lesions are an extension of severe atherosclerotic disease in the aortic arch. The calcific atherosclerotic disease involving the aortic arch could make placing a side-biting clamp on the arch just proximal to the takeoff of the innominate artery quite hazardous, and achieving a satisfactory end point of the endarterectomy into the aortic arch would be difficult with the associated risks for embolization, residual flap formation, or dissection. Additionally, innominate artery endarterectomy should not be considered in patients possessing a bovine configuration because this would require temporary disruption of flow into the right and left carotid systems simultaneously. Accomplishing a satisfactory end point in the left common carotid artery may also prove difficult with this anatomy.

Proper endarterectomy for innominate arterial atherosclerotic lesions requires placement of a side-biting clamp across the aortic arch at the level of the takeoff of the innominate artery. This allows extension of the endarterectomy proximally onto the aortic arch itself to remove all of the plaque that arises from the aorta. The endarterectomy is performed through a longitudinal arteriotomy that typically does not require patch closure because of the large caliber of the vessel. Distribution of plaque into the right subclavian and right common carotid artery may require extension of the median sternotomy incision up into the right side of the neck along the anterior border of the sternocleidomastoid muscle. Again, achievement of satisfactory end points with this extent of disease may prove difficult, and bypass from the ascending aorta in these situations is probably more prudent.

Endarterectomy for isolated atherosclerotic lesions in the proximal left common carotid artery and left subclavian artery may be

performed; however, these procedures require a median sternotomy in the case of left common carotid lesions or a left thoracotomy in the setting of left subclavian origin disease, and they are more appropriately treated with extraanatomic approaches, which have proven to be better tolerated with excellent patency rates. An endovascular approach to these lesions (either through an antegrade transfemoral approach or, more commonly, a retrograde cervical approach for left common carotid artery lesions or a retrograde left brachial approach for left subclavian lesions) has been successfully performed with excellent technical success and patency rates. These techniques are discussed more fully later in this chapter.

Bypass Graft

Bypass grafts constructed in an antegrade configuration are performed through a median sternotomy incision, with the origin of the bypass graft arising from the anterolateral aspect of the ascending aorta. Careful palpation of the ascending aorta should be performed to avoid placement of the partially occluding side-biting clamp in an area of significant atherosclerotic disease. Intraoperative epiaortic ultrasound can be used as an adjunct to identify calcium in the ascending aorta. Careful sizing and positioning of the graft is mandatory to avoid kinking or graft compression in the retrosternal space when the sternum is closed. Additionally, the grafts are tunneled posterior to the innominate vein. A bulky graft may cause compression of the innominate vein, leading to left brachiocephalic vein occlusion and left arm swelling postprocedure. Therefore, in the clinical setting in which both the innominate artery and the left common carotid artery are to be bypassed, use of a bifurcated graft should be avoided because of the large volume and bulky nature of these grafts in this limited space.

Following systemic heparinization of 100 units/kg for a goal ACT >250, a partially occluding clamp is applied on the ascending aorta as previously described, and a 10- to 12-mm woven Dacron tube graft is anastomosed to the ascending aorta in an end-to-side fashion with 4-0 Prolene (Ethicon, Piscataway, NJ) suture. The graft is then clamped, tunneled, and distended with blood to assess hemostasis of the suture line and proper length of the graft before trimming. The distal anastomosis to the innominate artery is then performed either in an end-to-end or end-to-side fashion, depending on the clinical situation. When concomitant bypass to the left common carotid artery is required, an 8-mm knitted Dacron graft is taken off the innominate bypass graft in an end-to-side fashion above the thoracic inlet and left brachiocephalic vein to avoid graft kinking or compression. The distal anastomosis to the left common carotid artery may then be performed in an end-to-end or end-to-side configuration with 5-0 Prolene suture—again, depending on the clinical situation. Proximal occlusive lesions of the left subclavian artery are rarely symptomatic; therefore, a "triple bypass" of all three brachiocephalic vessels is rarely, if ever, indicated for occlusive disease. As noted previously, isolated left subclavian disease, when symptomatic, is best treated with endovascular treatment or extraanatomic bypass.

Brachiocephalic reconstruction may be performed safely with excellent outcomes. Multiple series have historically reported 30-day mortality rates of 4% to 7%, perioperative stroke rates ranging from 2% to 5%, and 5-year and 10-year patency rates exceeding 90%. As in the case of patients undergoing carotid endarterectomy, these patients must be followed closely with annual physical examinations and surveillance duplex ultrasound for assessment of graft patency.

EXTRAANATOMIC (INDIRECT) REVASCULARIZATION

Isolated unilateral proximal common carotid artery or proximal subclavian artery lesions are readily treatable with extraanatomic reconstructions. These indirect methods of revascularization are performed through supraclavicular and/or cervical incisions and are better tolerated, with less perioperative morbidity and mortality, and they achieve patency rates similar to those of direct reconstruction. The most common form of revascularization is for construction of a prosthetic bypass between the ipsilateral carotid and subclavian arteries. The prosthetic graft utilized is usually a 7-mm or 8-mm knitted Dacron or polytetrafluoroethylene (PTFE) conduit. For treatment of proximal lesions, the procedure is performed through a single transverse supraclavicular incision at the base of the neck. The clavicular head of the sternocleidomastoid muscle is divided, and the scalene fat pad is reflected cephalad, taking care to identify and protect the phrenic nerve coursing anterior to the anterior scalene muscle. Care should also be taken to preserve the lymphatics at this level. The anterior scalene muscle is then transected off its insertion to the first rib, exposing the underlying subclavian artery. The internal jugular vein is identified at the medial aspect of the supraclavicular incision and is mobilized laterally, exposing the underlying common carotid artery at the base of the neck. Care is taken to identify and protect the vagus nerve, which should be gently retracted laterally with the internal jugular vein. A short tunnel through the scalene fat pad is then made carefully behind the internal jugular vein and the vagus nerve. On the left side, great care should also be taken to avoid injury to the thoracic duct. In this exposure, a short bypass graft is constructed between the proximal common carotid artery and mid-subclavian artery in an end-to-side fashion with 5-0 or 6-0 Prolene sutures. It is not necessary to consider placement of a shunt during cross-clamping of the common carotid artery for performance of a carotid-to-subclavian bypass, and obviously a shunt is not necessary for a subclavian-to–common carotid artery revascularization.

In the performance of a subclavian-to-carotid bypass, it may at times be necessary to perform a concomitant carotid endarterectomy. In this setting, the procedure is performed through a supraclavicular incision at the base of the neck as well as an additional incision higher up the neck along the anterior border of the sternocleidomastoid muscle, as is typically performed in standard carotid exposure for endarterectomy. End-to-side anastomosis to the subclavian artery is constructed, and the bypass graft is then tunneled and brought up distally to the carotid bifurcation to the endarterectomy arteriotomy site with the distal subclavian-to-carotid anastomosis serving as a patch closure. This type of reconstruction is particularly required in situations in which the entire common carotid artery is occluded up to the level of the carotid bifurcation, and internal carotid artery patency has been preserved via retrograde filling through the external carotid artery and its branches. Our preference in the treatment of coexistent focal hemodynamically significant stenosis of the proximal carotid artery with severe carotid bifurcation disease remains performance of retrograde angioplasty and stenting of the proximal common carotid lesion with open carotid endarterectomy and patch angioplasty. The technique for retrograde angioplasty is discussed later in this chapter.

In settings in which the subclavian artery is not suitable for use as inflow for ipsilateral subclavian-to-carotid bypass, a carotid-to-carotid bypass may be considered. The contralateral carotid artery is used as the inflow vessel for revascularization. The common carotid arteries are exposed through bilateral longitudinal incisions at the base of the neck along the anterior border of the sternocleidomastoid muscle. The common carotid arteries are then dissected free and exposed in a standard fashion, and the pharynx is identified medially. A short retropharyngeal tunnel is then made between the pharynx and the anterior spinal ligament with a combination of sharp and blunt digital dissection. It is helpful to have a nasopharyngeal tube or an esophageal temperature probe in place to facilitate palpitation of the pharynx and ensure dissection in the proper plane. The retropharyngeal tunneling facilitates a shorter bypass graft and avoids the possibilities of skin erosion and the feeling of strangulation that sometimes occurs with subcutaneous tunneling of these grafts in the anterior neck. The grafts also pose a cosmetic issue in patients with a very slender neck when tunneled anteriorly. The prosthetic graft utilized is a 7- or 8-mm knitted Dacron or PTFE graft anastomosed in an end-to-side fashion at both common carotid arteries with 5-0 and 6-0 Prolene sutures. The common carotid arteries are not cross-clamped simultaneously; therefore, placement of a shunt is typically not required.

In rare instances, subclavian-subclavian or axillary-axillary bypasses have been utilized to restore pulsatile flow into the subclavian and vertebral arteries for symptomatic vertebral basilar disease, or in the presence of a total occlusion of the innominate artery, they may restore pulsatile flow to the right common carotid artery as well. The subclavian arteries are approached through supraclavicular incisions as described previously. The grafts are constructed in an end-to-side fashion and are tunneled across the suprasternal notch. The axillary-axillary bypass grafts are constructed through bilateral infraclavicular incisions. The pectoralis major muscle is split along the length of its fibers, and the clavipectoral fascia is incised. The axillary vein will be encountered initially during the dissection with the axillary artery located just posterior and slightly superior to the vein. The axillary vein is completely mobilized with ligation and division of multiple side branches to facilitate exposure to the axillary artery. The prosthetic graft is then anastomosed in an end-to-side fashion to the axillary artery and is tunneled subcutaneously across the front of the manubrium sterni. The subclavian-subclavian and axillary-axillary grafts are utilized in high-risk patients, usually those with hostile anatomy that would be encountered with the more standard direct or extraanatomic procedures.

ARTERIAL TRANSPOSITION

Subclavian-carotid or carotid-subclavian transposition has the advantage of avoiding prosthetic material and the small attendant risk of infection. The transposition procedure is more technically challenging than utilization of a bypass because of the requirement of a more extensive dissection and mobilization of the vessels. The dissection requires more retrosternal exposure of the proximal portion of the vessels, and particular attention must be paid to visualization and exposure of the internal mammary and vertebral arteries for transposition of the subclavian artery. The procedures are performed through a transverse supraclavicular incision. The dissection then proceeds along the anterior border or between the heads of the sternocleidomastoid muscle down to the internal jugular vein. The internal jugular vein and vagus nerve are then mobilized and gently retracted laterally, exposing the proximal common carotid artery. The subclavian artery is then exposed after identification and ligation/division of the vertebral vein. The subclavian artery is carefully dissected sharply, with dissection carried proximal to the takeoff of the internal mammary and vertebral arteries. In the subclavian-to-carotid transposition, the proximal subclavian artery is clamped with a Cooley-Darra clamp, transected, and carefully oversewn. Great care must be taken to avoid loss of control of this proximal stump because the stump is placed with tension to facilitate exposure in the upper mediastinum, and loss of this stump into the thoracic cavity before satisfactory suture ligation would be disastrous. The common carotid artery is then cross-clamped proximally and distally, and the subclavian artery is transposed and sewn in an end-to-side fashion with 5-0 or 6-0 Prolene suture. Care is taken to avoid kinking of the vertebral artery with the transposition. The indication and clinical situation requiring a carotid-to-subclavian transposition is much less common but is performed in a nearly identical fashion, with transection and suturing of the common carotid artery in the upper mediastinum and transposition of the common carotid artery to the subclavian artery just beyond the takeoff of the vertebral and internal mammary arteries. Subclavian-to-carotid transposition is our preferred technique in the event that debranching is required in the performance of thoracic aortic endograft treatment for aneurysm or dissection (Fig. 5). Newer techniques for management of the left subclavian artery during treatment of the thoracic aorta incorporate placement of a chimney stent graft in the proximal left subclavian artery or single-branch aortic grafts.

Outcomes for extraanatomic brachiocephalic reconstructions are excellent. Multiple series have shown low incidences of paraprocedural stroke, and 30-day mortality is less than 3%. The 5-year and 10-year patency rates exceed 90% in most series, and the patency rates of arterial transposition approach 100%.

FIG. 5 CTA of follow-up surveillance endovascular thoracic aneurysm repair in which debranching of the left subclavian artery with subclavian to left common carotid artery transposition *(arrow)* had been performed preoperatively.

ENDOVASCULAR TREATMENT

Numerous reports have demonstrated excellent results with open surgical revascularization in the setting of brachiocephalic disease with acceptably low 30-day mortality, stroke, and perioperative stroke as well as achievement of superb long-term patency of the reconstruction. However, as is true for all vascular beds, pursuit of minimally invasive procedures to treat brachiocephalic disease has been inevitable. Early reports of endovascular intervention in the arch vessels consisted mainly of lesions treated with angioplasty alone, and follow-up was limited. These studies revealed that endovascular intervention was feasible, and, as expected, utilization of endovascular techniques has increased with improvements in balloon and stent technology and maturation of technical skills in the treatment of cerebrovascular disease. In skilled hands, excellent outcomes with low morbidity and acceptable patency rates have been demonstrated.

Anatomic considerations are important in the planning of any treatment of brachiocephalic disease, but especially so if endovascular therapy is being considered. The anatomic characteristics of the lesions to be treated are key in the assessment for feasibility of treatment with catheter-based therapy. Endovascular intervention is preferable for stenosis rather than total occlusion and for nonostial, nonulcerative, and minimally calcified concentric lesions. Endovascular treatment is less favorable for severely eccentric lesions and lesions that extend contiguous to or into a major branch vessel, such as the vertebral artery arising off the subclavian artery, the left common carotid artery arising off the innominate artery in the bovine configuration, or minimal separation of the origins of the innominate and left common carotid artery off the arch. These configurations carry the added risk of the compromise of the origin of one vessel in

the treatment of another. Additionally, rotation of the vessel origin around the arch downward toward the ascending aorta for severe atherosclerotic disease affecting the aortic arch may make access and intervention of the brachiocephalic vessels much more challenging, and in these instances, open surgical treatment may be preferable.

INNOMINATE ARTERY INTERVENTIONS

Endovascular treatment of innominate lesions exposes the patient to potential embolization to both the right carotid and right vertebral artery distributions and therefore must be performed with great precision. Documentation of the position of the origins of the right common carotid and right subclavian artery branches in relation to the disease process is imperative. A kissing balloon technique is necessary to treat innominate lesions that extend directly proximate to or into the primary branches and to ensure proper distal stent placement. It is also important to ensure that the origin of the left common carotid artery is not compromised by angioplasty and stenting of a proximal calcific lesion in the innominate artery (Fig. 6).

The innominate artery has the most challenging angulation extending off the aortic arch for cannulation through an antegrade transfemoral approach. Prolonged attempts at cannulation should not be pursued from this approach because of the risk of trauma and consequent embolization from the associated atherosclerotic disease in the aorta. In this situation, a retrograde brachial access may be performed and safe traversal of the innominate lesion accomplished. The innominate lesion may then be treated over the wire placed from the retrograde brachial approach, or the retrograde brachial wire can be snared from below and brought down with a through-and-through technique for greater stability for passage of the sheath and angioplasty system.

For ostial lesions, 1 to 2 mm of the stent should protrude into the aortic lumen. If the angioplasty and stent are being performed through the retrograde right brachial approach, it may be difficult to inject adequate contrast to visualize the exact position of the innominate orifice relative to the aortic arch. It is helpful to have an angiographic pigtail catheter in place for arteriography and facilitation of better imaging. The transfemoral guidewire or angiographic catheter itself can act as a marker as it curves around the arch abutting the innominate orifice. With the brachial approach, the guidewire should be directed into the ascending aorta rather than making the sharp curve into the descending thoracic aorta because this facilitates in-line alignment for deployment of the stent.

The risk of embolization with primary angioplasty and stenting of innominate lesions appears to be low; therefore, the requirement for cerebral protection in these procedures remains unclear. In most instances, the simplest, most straightforward approach without protection is best unless a "high-risk" lesion with a worrisome potential for embolization is to be treated.

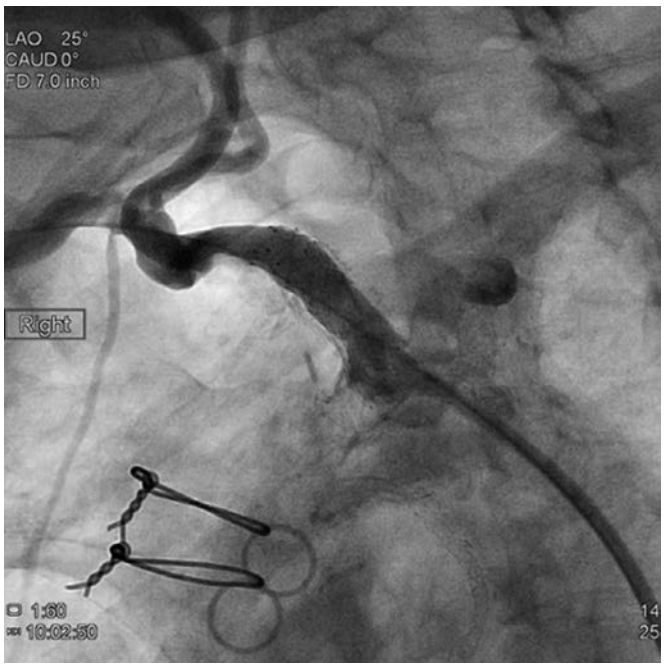

FIG. 6 Innominate artery following percutaneous transluminal angioplasty and stenting. Note the sternal wires from a previous coronary artery bypass, which would have made an open innominate artery revascularization technically challenging.

Left Common Carotid Artery

Endovascular treatment of left common carotid artery lesions at the level of the arch is feasible and safe and may be performed in an antegrade transfemoral approach similar to that described with the innominate artery intervention. In the situation of an angulated takeoff of the left common carotid artery from the arch and when better stability of the angioplasty system is required, a "buddy wire" may be positioned in the external carotid artery to facilitate maintenance of the guidewire and sheath position at the origin of the vessel, as is done in the treatment of more distal carotid disease. A protection device is frequently used with the antegrade transfemoral approach for endovascular interventions on "high-risk" lesions.

More commonly, proximal common carotid lesions are accessed in a retrograde fashion from the distal carotid artery via cervical incision. The carotid branches are thus readily controlled with application of a distal clamp, and cerebral protection is ensured.

Left Subclavian Artery

Antegrade transfemoral access to the left subclavian artery off the arch is the easiest of the three vessels to obtain. After accessing the origin of the vessel, a 0.035 guidewire is passed across the lesion into the distal subclavian artery. The guidewire may then be exchanged for a stiffer wire if deemed necessary. A long 6Fr or 7Fr sheath is then positioned just across the origin of the vessel at the level of disease. Predilation with a 4-mm angioplasty balloon may be necessary to facilitate passage of the stent. Correct sizing of the stent is essential to ensure that the area of disease is covered fully and that the vertebral artery origin is not "jailed." For ostial lesions, the stent should extend 1 to 2 mm into the aortic lumen (Fig. 7).

If the subclavian lesion approaches the origin of the vertebral artery, it may be important to protect the vertebral artery origin. This may be accomplished after placement of a larger sheath into the origin of the subclavian artery and exchange of the 0.035 wire for two separate 0.014 wires—one placed antegrade out into the axillary artery and the other placed antegrade in the vertebral artery. A balloon-expandable stent may be accurately placed over both 0.014 wires immediately at the takeoff of the vertebral artery. In another approach in which both antegrade transfemoral access and retrograde brachial access into the subclavian artery are obtained, the 0.014 wire is placed through the retrograde transbrachial sheath into the vertebral artery, and the angioplasty and stenting are performed across the 0.035 wire from the antegrade transfemoral approach. The retrograde transbrachial sheath also facilitates the imaging of the vertebral artery at the time of the intervention. Embolic protection of the vertebral artery has been described, but its routine use cannot be advocated because of the exceedingly low risk of emboli to the vertebral basilar system during subclavian artery intervention as well as the risk of dissection of the vertebral artery with instrumentation. Again, for emphasis, the simplest, most straightforward approach with the least guidewire and catheter manipulation is generally best.

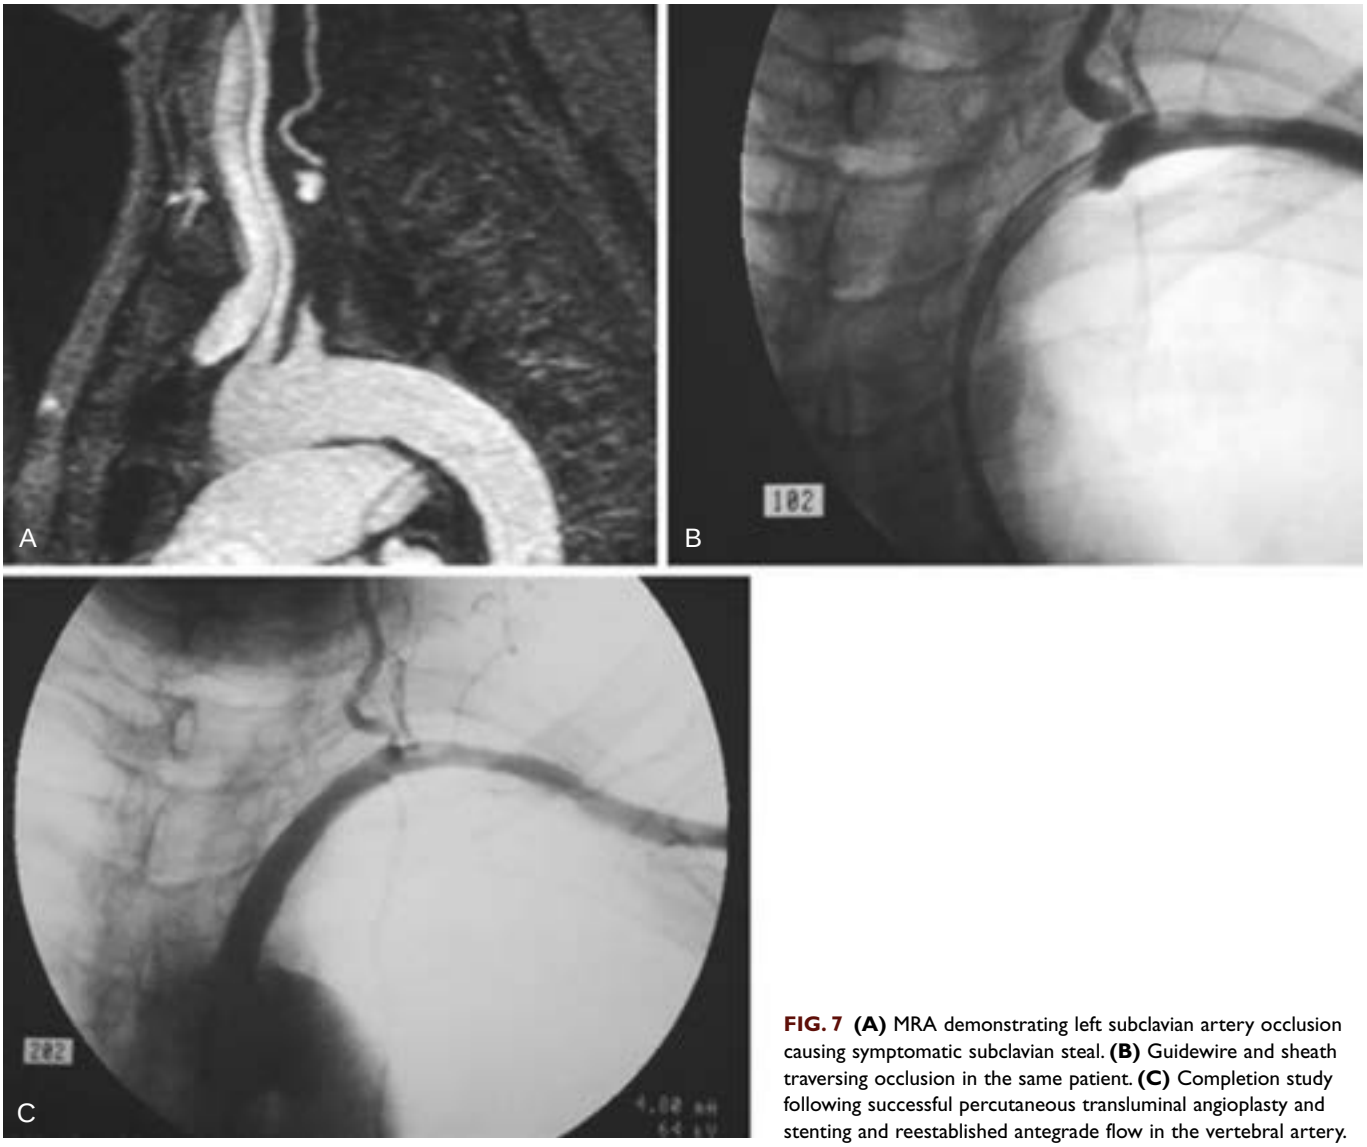

FIG. 7 **(A)** MRA demonstrating left subclavian artery occlusion causing symptomatic subclavian steal. **(B)** Guidewire and sheath traversing occlusion in the same patient. **(C)** Completion study following successful percutaneous transluminal angioplasty and stenting and reestablished antegrade flow in the vertebral artery.

MANAGEMENT OF THE LEFT SUBCLAVIAN ARTERY FOR THORACIC AORTIC ENDOVASCULAR REPAIR

For patients with a thoracic aortic aneurysm or dissection requiring endovascular repair, an adequate proximal seal length of 2 cm is recommended. Seal zone length is determined by preoperative three-dimensional reconstructed CTA. In up to 70% of patients presenting with dissection, the proximal extent of disease involves the left subclavian artery. This means coverage of the left subclavian artery is often required in treatment of these disease processes. In these cases, it is suggested that the left subclavian artery be revascularized before stent graft placement to maintain adequate spinal cord perfusion and prevent left upper extremity claudication or neurologic changes. This can be done via left carotid-to-subclavian bypass with endovascular plug of the left subclavian artery proximal to the vertebral artery or by subclavian-to-carotid transposition, as described earlier. Transposition is preferred if anatomy is favorable. We choose to perform this as a separate procedure if possible so the patient can be evaluated for complications from subclavian revascularization before thoracic aortic stent graft placement.

SUMMARY

The treatment of disease affecting the brachiocephalic vessels is safe, effective, and durable. Younger, low-risk patients are suitable candidates for direct anatomic reconstruction performed through a median sternotomy, particularly those patients with multivessel involvement. The direct anatomic reconstructions include a bypass arising from the ascending aorta or innominate arterial endarterectomy. Older adult patients with multiple comorbidities or patients with prior median sternotomies or a hostile mediastinum from other causes are better treated with an indirect extraanatomic approach or should be considered for endovascular intervention. Extraanatomic surgical reconstructions are performed with various types of prosthetic bypasses or arterial transposition. Endovascular therapy is performed via an antegrade transfemoral approach, a retrograde brachial approach, or, at times, a combination of both. Selection of the mode of treatment in each individual patient is based on various patient, anatomic, or pathologic factors in which one approach may be safer and more effective than another. The requirements for brachiocephalic reconstruction have increased with the ever-expanding treatment of aortic aneurysmal disease and aortic dissection for

the purposes of debranching and expansion of the applicability and appropriateness for endovascular treatment of aortic arch and descending thoracic aortic disease.

Upper Extremity Arterial Occlusive Disease

Aric Wogsland, MD, Virginia L. Wong, MD, and Vikram S. Kashyap, MD

Upper extremity (UE) arterial occlusive disease and ischemia is much less common than in the lower extremity (LE) and can be caused by a wide variety of etiologies. Due to extensive arterial collateralization around the shoulder and elbow, patients may remain asymptomatic despite significant chronic arterial obstruction. Although rare, ischemic symptoms of the hand and arm are poorly tolerated and can lead to significant loss of function and disability. Therefore, diagnosis and management of UE ischemia can be considerably more challenging than for LE disease.

ETIOLOGY

A wide variety of disease states may lead to UE ischemia (Box 1). Atherosclerosis and inflammatory arteritis tend to affect larger, more proximal vessels, including the innominate and axillosubclavian arteries. Digital and smaller forearm arterial disease is commonly seen in renal failure, diabetes, and with connective tissue disorders. Embolism and trauma commonly affect the brachial artery. Iatrogenic manipulation, such as for arterial catheterization or hemodialysis access procedures, may exacerbate the effects of underlying arterial disease and precipitate new ischemic symptoms.

Systemic Disease

In the United States, atherosclerosis is the most common cause of subclavian artery obstruction, affecting the left side more frequently than the right side. Patients usually have associated risk factors (e.g., hyperlipidemia, hypertension, smoking, diabetes) and/or manifestations of atherosclerotic disease in other arterial beds (e.g., peripheral artery disease, coronary artery disease). Takayasu's arteritis, a form of inflammatory arteritis, is typically described in younger women and frequently affects the supra-aortic trunk vessels. Temporal or giant cell arteritis (GCA), generally found in patients greater than 60 years of age, affects the axillary to brachial arteries, as well as the superficial temporal and ophthalmic arteries. Both diseases are associated with systemic inflammation, though many patients with GCA may manifest a much more indolent and less-well identified inflammatory phase than those with Takayasu's disease. The inflammatory phase can be characterized by fever, fatigue, generalized myalgia, and arthralgia, accompanied by elevated erythrocyte sedimentation rate (ESR). Both inflammatory diseases produce characteristic smooth, tapering arterial stenosis that differs in angiographic appearance from the irregular, heterogenous plaque typically seen with atherosclerotic disease (Fig. 1). Superficial temporal artery biopsy may provide definitive diagnosis in cases of GCA.

Occlusive disease of the more distal upper extremity arteries is associated with a number of autoimmune, inflammatory, and rheumatologic conditions. Scleroderma, CREST syndrome (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, telangiectasia), lupus, and rheumatoid arthritis are associated with small vessel disease, affecting palmar and digital arteries (Fig. 2). Thromboangiitis obliterans (Buerger's disease) affects small distal arteries and is strongly associated with ongoing tobacco use.

Embolism

Embolism is a frequent cause of acute upper extremity ischemia. Cardiac emboli secondary to arrhythmia is most common, with the majority of emboli lodging at the brachial artery terminus or more proximally at the origin of the deep brachial artery (Fig. 3). Other sources include proximal arterial aneurysm, ulcerated atherosclerotic plaque, and paradoxical embolus from deep venous thrombosis through a ventricular septal defect. Multiple emboli affecting smaller, more distal arteries should prompt evaluation for a proximal arterial source, especially in the absence of cardiac arrhythmia. Subclavian artery aneurysm or ulcerative lesion secondary to thoracic outlet obstruction can be a source of distal emboli (Fig. 4). Repetitive compression of the subclavian artery by myofascial and/or osseous structures at the thoracic outlet leads to poststenotic dilation and deposition of mural thrombus. Posttraumatic and infectious arterial aneurysms at any level can also result in embolization.

Trauma

Blunt and penetrating trauma involving the upper extremity can cause ischemia by multiple mechanisms, including arterial traction, intimal dissection, transection, and thrombosis. Iatrogenic pseudoaneurysm and thrombosis after brachial artery manipulation (e.g., arterial lines, interventional procedures) are complications that may not be recognized immediately due to the rich arterial collateral supply around the elbow. Effort-induced fatigue (i.e., arm "claudication") may develop later.

Repetitive trauma can also cause arterial injury. Hypothenar hammer syndrome, which affects the terminal portion of the ulnar

BOX 1 Causes of Upper Extremity Ischemia

Vasospasm
- Raynaud's disease
- Medication-induced vasopressors, β-blockers
- Ergot poisoning

Intrinsic Arterial Disease
- Atherosclerosis
- Radiation arteritis
- Azotemic arteriopathy
- Spontaneous dissection
- Fibromuscular dysplasia

Inflammatory Diseases
- Connective tissue disorders
- Buerger's disease
- Takayasu's arteritis
- Temporal (giant cell) arteritis
- Hypersensitivity angiitis

Noninflammatory Medical Disease
- Thrombophilic states
- Myeloproliferative disorders
- Cold injury
- Hepatitis-associated vasculitis
- Cryoglobulinemia
- Vinyl chloride exposure

Embolism
- Cardiac (most common)
- Proximal aneurysm
- Arterial thoracic outlet syndrome
- Atheroembolism
- Paradoxic embolus (with accompanying septal defect)

Trauma
- Iatrogenic
- Blunt arterial injury
- Penetrating arterial injury
- Hypothenar hammer syndrome
- Vibration

FIG. 1 Right upper extremity angiogram of a 57-year-old woman with temporal arteritis showing a classic, smooth, tapering stenosis in the proximal brachial artery. The patient's primary presenting complaint was forearm effort fatigue.

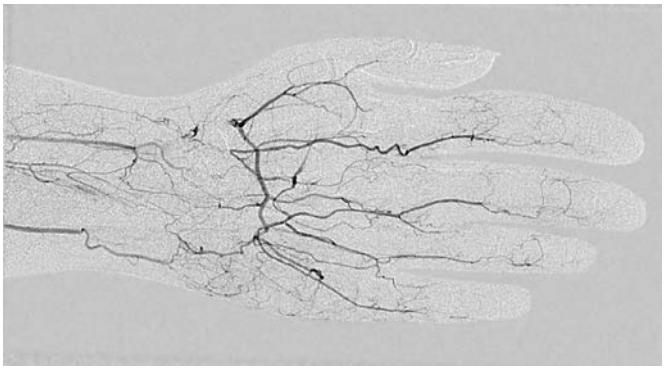

FIG. 2 Left-hand angiogram of a patient with scleroderma and small artery occlusive disease, producing multiple occlusions of the distal forearm, palmar, and digital arteries. The patient presented with severe Raynaud's syndrome and nonhealing fingertip ulcerations.

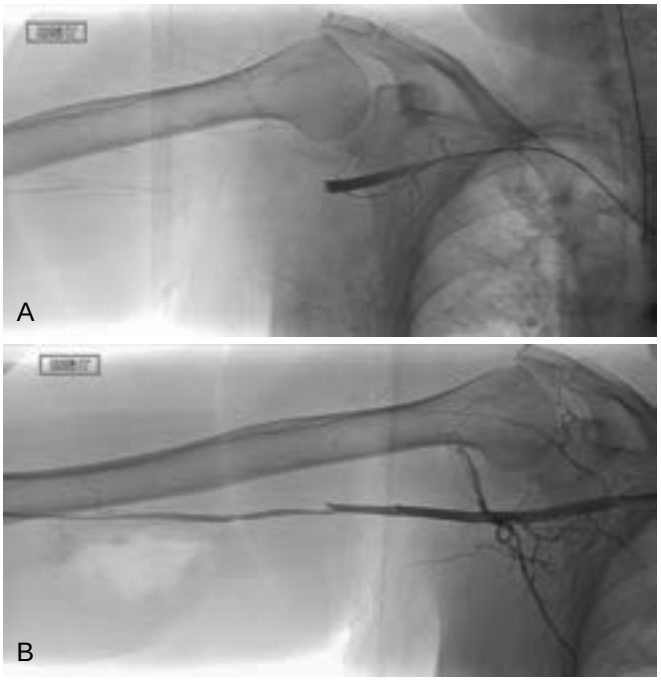

FIG. 3 **(A)** Embolic occlusion of the right axillobrachial artery secondary to atrial fibrillation. **(B)** Completion angiogram following surgical embolectomy.

artery in Guyon's tunnel (formed by the pisiform, the hook of hamate, and the transverse carpal ligament), results from repeatedly striking objects with the base of the palm. This can lead to segmental ulnar artery occlusion or aneurysm formation with subsequent digital artery embolism (Fig. 5). Vibration-induced digital artery injury has also been described from prolonged use of heavy tools such as jackhammers and chain saws.

EVALUATION

History and Physical Examination

A detailed history and physical examination are essential for diagnosing the correct etiology of upper extremity arterial disease. Symptoms may include digital color change, coolness, numbness, weakness, effort-induced fatigue (arm "claudication"), digital ischemic rest pain, and tissue loss (nonhealing digital ulcer or frank

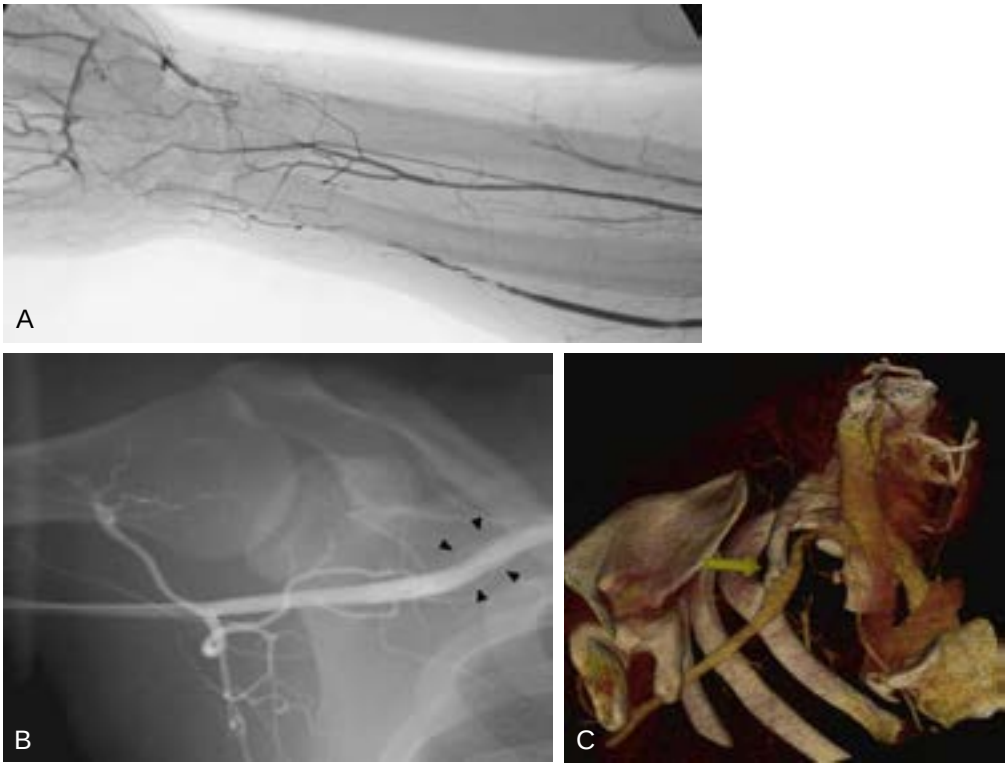

FIG. 4 **(A)** Right upper extremity angiogram in a 28-year-old, showing embolic shower to right forearm and hand arteries. **(B)** Right subclavian artery aneurysm with mural thrombus *(arrowheads)*. **(C)** Three-dimensional reconstruction of CT angiogram showing right subclavian artery pressed downward by overlying clavicle (removed from image for arterial visualization) onto bony exostosis between first and second ribs *(arrow)*.

gangrene). Raynaud's phenomenon may represent benign vasospasm, but it can also manifest secondary to fixed occlusive lesions, which must be ruled out. Involvement of the larger, more proximal arteries typically causes effort-induced fatigue. Digital tissue loss is nearly always associated with small vessel disease, with or without more proximal involvement. Patients who experience posterior circulation symptoms (e.g., dizziness, ataxia, diplopia) during prolonged use of the UE, may have subclavian steal syndrome. This is caused by siphoning of arterial flow away from the posterior cerebrum (via the vertebral artery) to provide antegrade flow to the ipsilateral UE in the face of an obstructing proximal subclavian artery (can also be innominate artery, if on the right side) lesion. Patients who have had coronary revascularization using the right or left internal mammary artery (i.e., RIMA or LIMA) may experience angina with use of the UE, as arterial flow is stolen away from the coronary bypass graft. Atherosclerotic risk factors, occupational activities, personal or family history of autoimmune or connective tissue disorders, and history of upper extremity arterial intervention or trauma should be investigated. Renal failure and vascular procedures for hemodialysis access should be noted.

A complete examination of the neck and upper extremities should be performed, documenting pulses at superficial temporal, common carotid, subclavian, axillary, brachial, radial, and ulnar locations on both sides. Diminished or absent pulses indicate significant stenosis or occlusion proximal to that location; symmetric disease may suggest a systemic condition. Auscultation over the proximal arteries for bruit and inspection of hands and digits for color, temperature, trophic changes, and tissue loss are important. Electrocardiogram and echocardiogram can diagnose arrhythmia and atrioventricular thrombus, which predispose to cardioembolism. Chest and cervical spine radiographs evaluate for cervical ribs or osseous anomalies causing arterial thoracic outlet obstruction. Computed tomography (CT) or magnetic resonance imaging (MRI) may be necessary to identify non-bony myofascial or ligamentous arterial entrapment. Serum studies for ESR, autoimmune markers (rheumatoid factor, antinuclear antibody, complement levels), hypercoagulable disorder (factor V Leiden, prothrombin gene mutation, antithrombin III, protein C and S deficiencies, antiphospholipid antibody, and hyperhomocysteinemia) may be helpful.

Noninvasive Vascular Evaluation

Evaluation in the noninvasive Vascular Laboratory should be undertaken in all patients with suspected UE arterial disease. Bilateral arm blood pressure measurement, segmental arterial limb pressures, wrist-brachial index (WBI), absolute digit pressures, digital plethysmography, and directed arterial duplex are useful for objective identification of upper extremity arterial disease and for quantifying the degree of ischemia. A blood pressure difference >20 mm Hg between right and left brachial arteries suggests unilateral axillosubclavian arterial disease. Diminishment of >15 mm Hg between ipsilateral arm segments suggests intervening hemodynamically significant arterial disease. Absolute resting digit pressure <50 mm Hg suggests significant ischemia. As with LE testing, arterial calcification due to diabetes or longstanding renal failure may result in falsely elevated pressures. Provocative positional testing can be helpful in diagnosing arterial thoracic outlet syndrome. Cold-induced digital waveform dampening in the face of normal WBI is helpful in diagnosing Raynaud's phenomenon and for ruling out more proximal fixed arterial lesions. Directed arterial duplex can provide detailed anatomic information for more peripheral lesions but is less useful for evaluation of intrathoracic lesions due to lack of sufficient visualization. Arterial duplex evaluation of the vertebral arteries can readily identify bidirectional or retrograde vertebral artery flow, which indicates stenosis or occlusion of the ipsilateral subclavian artery, proximal to the vertebral artery origin.

Advanced Imaging

Computed tomographic angiography (CTA) and magnetic resonance angiography (MRA) are important noninvasive modalities

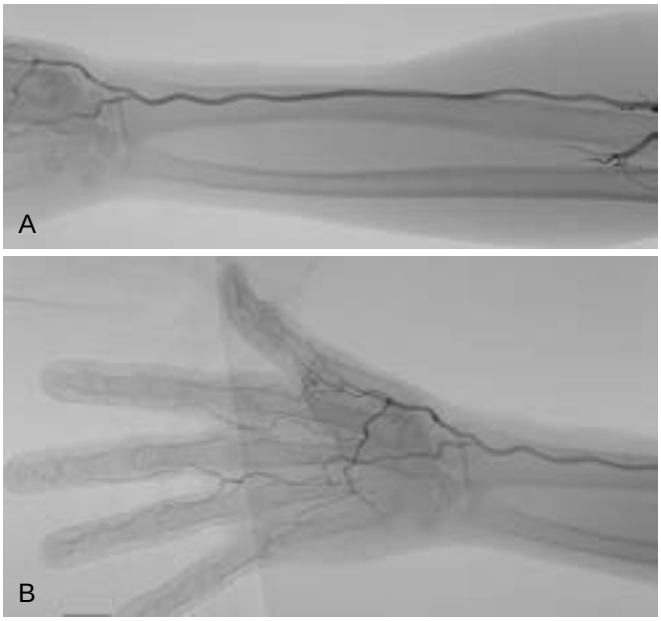

FIG. 5 Angiogram showing right ulnar artery occlusion in a 59-year-old retired millwright. Palmar and digital arterial supply is from the radial distribution. Hypothenar hammer syndrome is suspected.

for evaluating upper extremity arterial supply and the surrounding tissues. Aortic arch and large proximal artery visualization is excellent, while three-dimensional reconstruction and other postprocessing techniques are valuable for identification of thoracic outlet obstruction and planning surgical release or revascularization of these lesions (Fig. 6). Smaller forearm and hand arteries are less well visualized with tomographic imaging. Catheter angiography still provides the most detailed evaluation of the forearm, palmar, and digital arteries and may be necessary for preoperative planning. Heavily calcified arteries, metallic stents or operative clips, implanted vascular device leads or central venous catheters, and orthopedic hardware may produce significant artifact, obscuring diagnostic detail with any radiographic imaging modality. Risk of contrast-induced nephropathy must be considered when using CTA in patients with severe renal dysfunction. Risk of nephrogenic systemic fibrosis (NSF) may be a consideration with use of MRA in end-stage renal disease (ESRD) patients.

Catheter angiography remains a standard diagnostic imaging modality for UE arterial evaluation at any level and may also offer the opportunity for simultaneous endovascular treatment of selected lesions. Higher-quality images of smaller forearm and palmar arteries can be obtained with selective administration of contrast into the distal brachial artery. Provocative or diagnostic maneuvers such as catheter-directed vasodilator administration, pull-back intra-arterial pressure measurement, and angiogram with compression of flow through a patent ipsilateral arteriovenous access (evaluation for dialysis access-induced steal) can be performed during catheter angiography. Evaluation of the aorta and proximal upper extremity arteries requires aortic arch catheterization, usually from a transfemoral approach, while focal evaluation of distal brachial and forearm arteries can also be accomplished by antegrade or retrograde brachial arterial catheterization proximal to the level of suspected disease.

MANAGEMENT

Medical therapy represents the first line of treatment for many patients with UE arterial disease and is the preferred management during the acute phase of inflammatory arteritis. Surgery and intervention is generally recommended for patients with acute traumatic or embolic events, or for those with debilitating symptoms or significant ischemia. Endovascular techniques provide an opportunity for less-invasive treatment and have become the preferred option for focal proximal lesions that would otherwise require thoracotomy or sternotomy for direct access. Catheter-directed thrombolysis may be effective for acute small vessel thrombosis. However, the utility and durability of endovascular treatment is limited for more extensive and more distal arterial lesions, where surgical reconstruction is preferred.

Medical Therapy

For atherosclerosis, risk factor modification is indicated for all patients, including abstinence from tobacco and the use of lipid-lowering and antiplatelet therapy. Complete tobacco cessation is mandatory for a diagnosis of thromboangiitis obliterans (Buerger's disease), the symptoms of which may be improved simply by abstinence; however, the disease cannot be controlled in the face of continued tobacco exposure. Cold avoidance and calcium channel blockade with nifedipine may be useful for treatment of Raynaud's symptoms. The acute inflammatory stage of Takayasu's disease and GCA is treated with corticosteroids or other antiinflammatory agents such as cyclophosphamide, methotrexate, azathioprine, infliximab, or mycophenolate mofetil. Interdisciplinary management with rheumatology and other medical specialties is helpful. If possible, interventional treatment with endovascular or surgical techniques should be avoided during the acute inflammatory stage, due to poor results and high restenosis rates.

Endovascular Therapy

Endovascular therapy is particularly suited for short, focal obstructive lesions in the innominate, subclavian, and axillobrachial arteries. A transfemoral approach allows for antegrade aortography and selective UE angiography through a long, supportive sheath. Retrograde access from the ipsilateral brachial artery is another common approach and affords the most direct access to orificial supraaortic trunk lesions. However, retrograde passage of large sheaths for the delivery of interventional devices may be limited by brachial artery diameter and may require preemptive surgical exposure (i.e., cutdown) to repair the access site following sheath decannulation and avoid access site complications. Intraprocedural and postoperative anticoagulation management and monitoring for hand ischemia and median nerve compression symptoms caused by brachial sheath hematoma are routine. In 2019, Madden and colleagues evaluated brachial artery complications associated with percutaneous access for endovascular interventions. They reported a 10% complication rate, including the need for surgical exploration for bleeding and thrombosis. The incidence of complications increased with larger sheath diameters: 5.4% for 5Fr, 12.4% for 6Fr, and 12.5% for 7Fr. The liberal use of open surgical exposure and primary arterial repair is recommended when using the brachial artery for access, especially when larger sheath access is anticipated.

Once wire access across the lesion has been achieved, balloon angioplasty alone may provide sufficient treatment. Self-expanding bare metal stents are used for significant residual stenosis (>20% luminal diameter stenosis or persistent pressure gradient >20 mm Hg), immediate elastic recoil, or dissection following angioplasty. Balloon-expandable stents are useful for treatment of focal calcific lesions at the innominate, carotid, or left subclavian artery orifice, where obstruction is due to spillover aortic plaque; these lesions typically require higher radial force and precise stent deployment for treatment (Fig. 7). Covered stents can be used to treat traumatic arterial pseudoaneurysm or for rupture following balloon angioplasty. Care should be taken to avoid using balloon-expandable stents in areas where they may become easily deformed by UE movement, such as through the midsubclavian artery at the thoracic outlet or in the axillary artery. Even repeated compression of self-expanding stents in these locations can result in stent fracture. However, stenting

FIG. 6 **(A)** MRA of the aortic arch and supra-aortic vessels. **(B)** Coronal reconstruction CT angiogram demonstrating aberrant right subclavian artery origin from distal posterior aortic arch, beyond innominate and left common carotid artery origins.

lesions in this area may be considered once surgical decompression of the thoracic outlet has been achieved and is a common adjunctive procedure for treatment of thoracic outlet syndrome. Following stent therapy, antiplatelet agents are routinely administered.

While open surgical balloon catheter thromboembolectomy provides the most rapid restoration of arterial flow in patients with severe, acute ischemia due to thrombosis or embolism, access to smaller arteries of the hand and digits is not possible in this manner. Catheter-directed thrombolysis can be very useful for thrombosis of distal forearm, palmar, and digital arteries. The transfemoral approach is preferred, using a long, supportive sheath for delivery of the thrombolytic agent via an infusion wire or catheter advanced into the thrombus, or positioned to allow the agent access to affected vessels. Continuous thrombolytic infusion is continued, monitoring for signs of hemorrhage and for a decrease in serum fibrinogen level. Angiography through the existing catheter takes place at intervals to assess thrombolytic progress or adjust catheter position for maximum gain. Therapy is complete when an acceptable clinical or angiographic result is obtained or is terminated when no further progress is made or if bleeding or a critical drop in serum fibrinogen occurs. Risk of bleeding complications increases with duration of therapy and total amount of lytic agent delivered. Forearm or hand fasciotomy may be required for release of compartment syndrome following revascularization in patients with severe ischemia lasting more than 6 hours or in those who exhibit compromised neuromotor function.

Surgical Therapy

Exposure techniques, revascularization options, and procedural success vary depending on the etiology and extent of arterial disease, as well as the anatomic location of the lesion.

Operative Exposure of the Subclavian Artery

Due to the oblique and posterior course of the aortic arch, different approaches are needed to access the proximal right or left subclavian artery. The origin of the right subclavian artery is best exposed

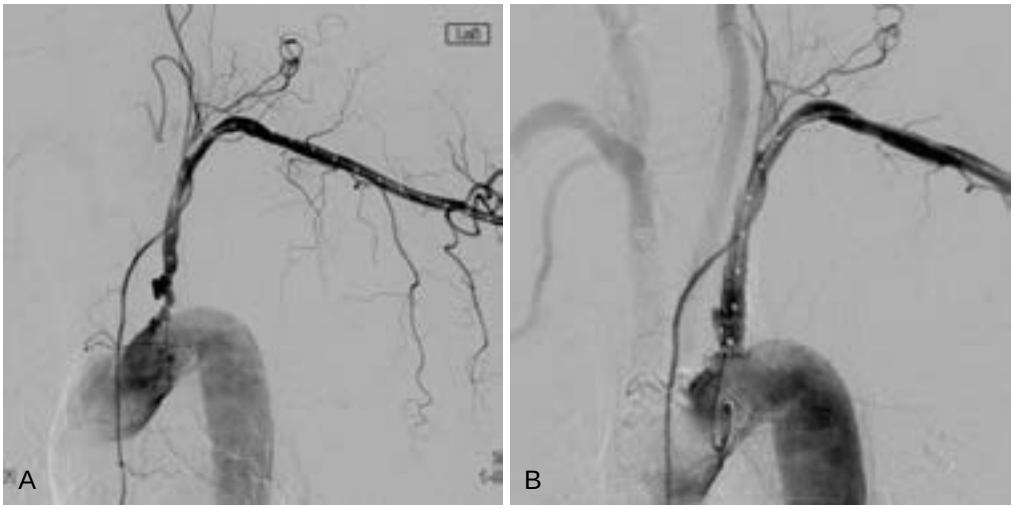

FIG. 7 **(A)** Aortogram from retrograde left brachial artery approach showing orifical subclavian artery stenosis. **(B)** Aortogram following deployment of a balloon-expandable bare metal stent across the lesion.

through a median sternotomy. Mobilization of the overlying left brachiocephalic vein allows complete visualization of the innominate artery and its bifurcation into the right subclavian and common carotid arteries. Cervical extension of the incision allows access to the right carotid sheath. Care must be taken to avoid injury to the right recurrent laryngeal nerve, which courses inferiorly around the proximal right subclavian artery and ascends medially between the esophagus and trachea. The preferred approach to the more posteriorly positioned left subclavian artery origin is through a left lateral thoracotomy, sited between the 4th and 5th ribs. Following entry into the pleural cavity, inferior retraction of the left upper lobe will reveal the aortic arch, visible through the mediastinal pleura. The vagus nerve passes anterolateral to the left subclavian artery, and the thoracic duct lies posteromedial to the artery. Care must be taken to avoid injury to either of these important structures. Given the development of endovascular techniques that provide good treatment results for orifical subclavian artery lesions, the morbidity associated with direct open surgical approach can often be avoided. Limited exposure of either the right or left proximal subclavian artery can be achieved via a supraclavicular cervical incision and is useful for the revascularization procedures described later.

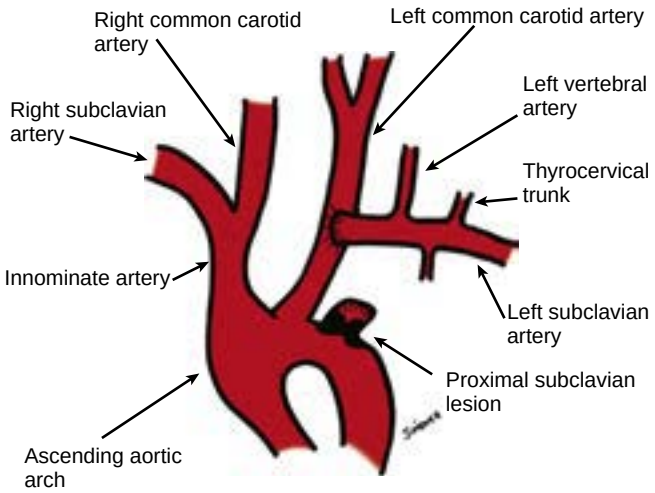

FIG. 8 Left subclavian artery transition.

Surgical Reconstruction for Proximal Subclavian Artery Lesions

Carotid-subclavian artery bypass and subclavian artery transposition have both been described extensively for operative treatment of proximal subclavian artery obstruction, with 75% to 90% patency at 5 years and acceptable morbidity. Preoperative evaluation should include carotid duplex to determine whether common carotid and/or bifurcation disease also requires treatment and to evaluate the vertebral arteries. Advantages of transposition include completely autogenous reconstruction and the need to perform only one anastomosis. Bypass avoids the need to obtain very proximal subclavian artery control deep in the incision and is better suited for extensive lesions beyond the orifice. Bypass is also preferred for preservation of a patent internal mammary artery to coronary artery bypass graft.

Subclavian Artery Transposition

The patient is placed in a supine position, with the head turned away from the operative side. A small roll placed under the shoulders helps provide better neck extension. A short, transverse cervical incision is made 2 cm above the clavicle and parallel to it, from the sternoclavicular joint toward the midclavicle. The platysma is divided, and then the clavicular head of the sternocleidomastoid muscle is divided for better visualization. The scalene fat pad is mobilized superiorly, exposing the anterior scalene. The phrenic nerve, which runs from lateral to medial across the anterior scalene on its way into the chest, must be identified and preserved. The anterior scalene is divided from its attachment to the first rib. The internal jugular vein is mobilized and retracted laterally to allow access to the common carotid artery. The vagus nerve should be identified and preserved. On the left, the thoracic duct may require ligation; injury will cause serious lymphatic leak. The subclavian artery is skeletonized, obtaining control of the thyrocervical trunk, vertebral, and internal mammary arteries. Following heparinization, branch vessels are occluded first to prevent embolism. The subclavian artery is clamped and divided as far proximal as possible. The proximal arterial stump is then secured with stay sutures and immediately oversewn to avoid retraction of the artery back into the chest before secure closure can be achieved. The common carotid artery is clamped. Shunting is usually not required so long as the carotid artery bifurcation remains open. The common carotid artery is opened longitudinally on its posterolateral surface, and end-to-side anastomosis is performed between the transected subclavian artery and the common carotid artery (Fig. 8). If the subclavian artery is too short to reach, mobilization of the common carotid artery may

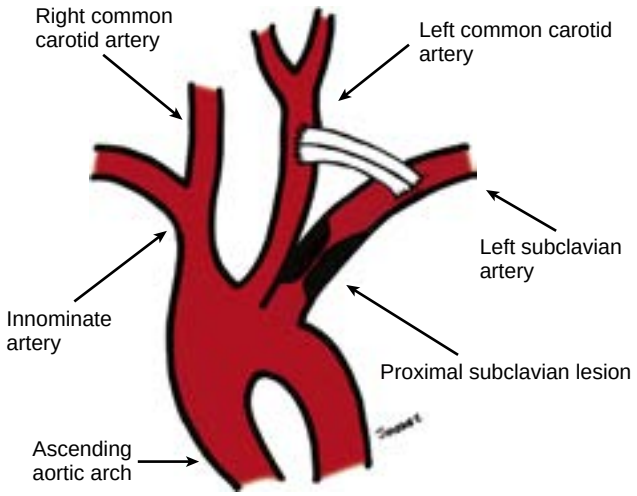

FIG. 9 Carotid-subclavian bypass.

bring it farther laterally. Division of the internal mammary artery may provide more length as well. The incision is closed over a closed suction drain, left in place for 24 hours. The drain is removed when sanguineous and/or lymphatic drainage has diminished.

Carotid-Subclavian Bypass

Patient positioning and exposure is as discussed earlier for subclavian artery transposition. For bypass, only a short segment of the subclavian artery needs to be exposed. The usual site is just distal to the thyrocervical trunk. As such, most of the dissection takes place lateral to the clavicular head of the sternocleidomastoid muscle. Phrenic nerve injury is more common with this more lateral approach, and a concerted effort to identify this structure early in the dissection is required. A short polytetrafluoroethylene (PTFE) graft is tunneled beneath the internal jugular vein, and end-to-side anastomosis is performed to the common carotid and subclavian arteries (Fig. 9). Beveling the carotid end of the graft 20 to 30 degrees is necessary to direct the bypass graft downward toward the subclavian artery.

Axillary Artery

Occlusive lesions of the axillary artery are rare. Exposure may be required for trauma or for proximal anastomosis of an axillofemoral bypass. The ipsilateral arm is abducted onto an arm board. An infraclavicular incision is made two fingerbreadths below the midclavicle and extended to the deltopectoral groove. Fibers of the pectoralis major muscle are split, and the underlying clavipectoral fascia is opened. The pectoralis minor muscle is divided at its tendinous insertion onto the acromion for better visualization. The axillary vein lies slightly anterior and inferior to the artery; overlying venous branches may require division for full exposure of the artery. Care must be taken to avoid transection of the lateral pectoral nerves, which may lead to postoperative pectoralis muscle atrophy.

Surgical revascularization of the axillary artery for occlusive disease is required infrequently. Carotid-axillary, carotid-brachial, subclavian-brachial, and axillobrachial bypasses have been described and may be required for extensive subclavian artery lesions, trauma, or revascularization of failed, less-extensive bypasses. Autogenous vein appears to be the preferred conduit in this location, likely due to the length of graft required for revascularization.

Brachial Artery

For access to the brachial artery, the ipsilateral arm is abducted onto an arm board or table. Exposure can be achieved through a longitudinal incision made anywhere along the bicipital groove on the medial limb, between the biceps and triceps muscles. The basilic vein will be medial and superficial to the brachial sheath. The median nerve lies immediately adjacent to the brachial artery and is usually encountered first upon opening the brachial sheath. Care must be taken with the use of traction and cautery to avoid injury to this large sensorimotor nerve. Mobilization over several centimeters will allow enough slack for gentle vessel loop retraction of the nerve away from the underlying brachial artery. Crossing branches from paired brachial veins may require division for full exposure of the artery. Exposure of the terminal branchial artery and its bifurcation into radial and common ulnar interosseous arteries can be achieved by extension of the arm incision onto the anterior forearm in "lazy S" fashion so as to avoid longitudinal scar contracture across the antecubital crease. Division of the bicipital aponeurosis is necessary to achieve contiguous exposure of the artery across the antecubital space. A number of patients (estimated at 10%–25%) have a radial artery origin much more proximally in the limb (so-called brachioradial artery variant), which may be located anywhere between the axillary artery and the brachial artery terminus. This artery is usually encountered as a smaller caliber, more superficial vessel, which is not in immediate proximity to the median nerve. The identification of two arterial structures at the antecubital crease or in the distal arm on preoperative or intraoperative duplex raises the suspicion for this variant. It is the most commonly identified upper extremity arterial variation, distinct from the rare superficial brachial artery or truly duplicated brachial artery variations. Definitive identification of variant radial artery anatomy requires complete duplex ultrasound visualization (from origin to wrist), extensive proximal exposure for direct visualization, or angiography; however, persistence of a radial pulse at the wrist following brachial artery cross-clamping should help confirm anatomy.

For localized brachial artery trauma or for catheter retrieval of thromboembolic material, exposure and mobilization of a relatively short distance of the brachial artery will suffice. Control of the uninvolved proximal and distal artery should be obtained. Primary suture repair or reanastomosis can be considered if adequate length and sufficient vessel circumference remain following debridement of devitalized tissue. Patch angioplasty or interposition graft may be required for repair or bypass of more extensive lesions. Saphenous vein is the preferred conduit for brachial artery bypass, due to size match and improved patency over prosthetic material. Only autologous material should be used in infected or contaminated fields. Penetrating or extensive blunt trauma may also be associated with nerve injury; detailed sensory and motor examinations should be performed before and after revascularization.

Radial and Ulnar Arteries

Exposure of the radial artery in the forearm is achieved via a longitudinal incision oriented along a line extending from the antecubital crease to the styloid process of the radius. The fascia is opened along the medial border of the brachioradialis muscle. Proximally, the artery lies beneath the muscle. More distally, the artery lies deep to the antebrachial fascia, between the brachioradialis and flexor carpi radialis tendons. At the wrist, the radial artery is quite superficial, lying just beneath the antebrachial fascia and medial to the radius. Exposure of the ulnar artery in the forearm is achieved by following a plane between the flexor carpi ulnaris and flexor digitorum superficialis muscles. In the midforearm, the artery lies beneath the flexor carpi ulnaris muscle and adjacent to the ulnar nerve. Distally, the artery lies just beneath the antebrachial fascia. Bypass to the forearm arteries is rarely used and is most often required for trauma or neglected embolic occlusion.

RESULTS OF TREATMENT

Open surgical bypass has long been the preferred option for extensive or more distal arterial disease. In 1993, Mesh et al. performed 95 upper extremity arterial bypass procedures over a 15-year period with an overall 5-year patency of 63%. Autogenous conduit

demonstrated superior patency at all anatomic sites compared with prosthetic material (71% vs. 38%). All far distal forearm prosthetic grafts failed within 1 year. A series by Spinelli and colleagues from 2009 reported on 23 upper extremity bypasses performed over a 10-year period, primarily in patients with critical limb ischemia. They achieved 83% primary 3-year patency, using autogenous conduit in more than 80% of cases. Thus, the surgical literature supports using arterial bypass with autogenous conduit.

With regard to less extensive and more proximal lesions, Ziomek and colleagues reported that prosthetic graft is the conduit of choice for short-length carotid-subclavian bypasses, with superior long-term patency than for autogenous vein bypass (94% vs. 58% at 5 years). However, they and others conclude that subclavian transposition may yield slightly better results then bypass. Systematic review in 2002 by Cina et al. found higher mean 1-year patency and symptomatic freedom rates associated with transposition (98% and 99%) compared with bypass (84% and 88%).

In 2007, AbuRahma et al. compared results of endovascular therapy using subclavian artery balloon angioplasty/stenting with those from carotid-subclavian bypass for symptomatic lesions. Over a 10-year period, 121 patients were treated with balloon angioplasty/stenting, while 51 patients were treated with surgical bypass. There was no difference in survival between the two groups. Primary patency at 1 year was 93% for angioplasty/stenting and 100% for bypass. Superior primary patency was noted at 5 years in the surgery group (96%), compared with the endovascular group (70%), though in higher risk or older patients, endovascular therapy may be quite acceptable.

SUMMARY

Upper extremity arterial occlusive disease and ischemia are less common than in the lower extremity, but when symptomatic, it can cause significant disability. The etiology is diverse and may include systemic conditions, necessitating a thorough clinical evaluation before deciding upon a treatment strategy. Medical management is useful for optimizing and controlling systemic disease. Endovascular therapy is acceptable as an effective, less-invasive treatment option, particularly for less extensive or intrathoracic lesions. Surgical revascularization remains the standard therapy for more extensive lesions and for more distal disease, with acceptable results for most upper extremity bypass procedures.

Aortoiliac Occlusive Disease

Maryam Ali Khan, MD, Claire Janssen, MD, and Mahmoud B. Malas, MD, MHS

INTRODUCTION

Peripheral arterial occlusive disease (PAOD) affects an estimated 4.3% of the population in the United States and is anticipated to increase in prevalence with a growing aging population. Atherosclerosis is the most frequent cause of aortoiliac occlusive disease. Risk factors include age, smoking, gender, race, ethnicity, diabetes, hypertension, dyslipidemia, a family history of PAOD, chronic kidney disease, and hyperhomocysteinemia. Cigarette smoking, the strongest risk factor, has been found to have a dose-related relationship with the development and severity of PAOD. The prevalence of PAOD increases with age older than 40 years, with prevalence increasing to 15% in those older than 70 years and almost 25% in patients older than 80 years. PAOD generally affects men more than women, although some studies have shown higher disease prevalence in women. Notably, at any given age, the rate of PAOD among African Americans is almost double that of non-Hispanic whites. Although nonatherosclerotic causes of aortoiliac occlusive disease including trauma, radiation-induced aortoiliac occlusive disease, cystic adventitial disease, iliac endofibrosis, and a congenital persistent sciatic artery can present similarly, they will not be discussed herein.

The presenting symptoms of PAOD depend on the location(s) and severity of the distribution. Commonly asymptomatic, it is discovered incidentally in most cases. However, symptoms may range from claudication (i.e., activity-induced pain) to critical limb-threatening ischemia (CLTI) characterized by the presence of PAOD in conjunction with rest pain, or tissue loss (gangrene, or lower limb ulceration). Ankle-brachial indices are a reliable physiologic screening modality and correlate with disease progression (normal ≥0.9). Patients with CLTI are at high risk for limb amputation at an estimated rate of 10% to 20% within 1 year of diagnosis. But only an estimated 10% of the asymptomatic patients are expected to progress to CLTI. On the contrary, cardiovascular morbidity (e.g., stroke and myocardial infarction) and mortality risks remain high. All-cause mortality and cardiovascular mortality in patients with PAOD are slightly higher in symptomatic patients (5-year risk of 24% and 7.7%, respectively) than asymptomatic patients (5-year risk of 19% and 7.3%, respectively). However, patients presenting with gangrene have a 5-year risk of all-cause mortality over 50%.

Three major patterns of arterial disease have been described. *Inflow disease* refers to lesions that limit blood flow to the common femoral artery. *Outflow disease* consists of occlusive lesions in the lower extremity arterial tree below the inguinal ligament. Last is a combination of inflow and outflow disease. Aortoiliac occlusive disease (AIOD) is primarily an inflow disorder; however, it can be associated with a more progressive disease pattern. In this chapter, we will focus attention on PAOD affecting the aortoiliac distribution.

DIAGNOSTIC EVALUATION

History and Physical Examination

A thorough history with identification of atherosclerosis risk factors is paramount as the risk-factor modification is a cornerstone of treatment for PAOD. Symptoms of aortoiliac disease are typified by hip, buttock, thigh, and or leg claudication, leg muscle atrophy, male impotence or erectile dysfunction, and absent or diminished femoral pulses. When the constellation of proximal claudication, leg muscle atrophy, erectile dysfunction, and absent femoral pulses is present, it is described as Leriche syndrome, defined by René Leriche in 1948. *Pseudoclaudication* is pain that is position-dependent, not

stereotypically associated with activity, and can occur in the absence of activity. It is imperative to differentiate pseudoclaudication from true PAOD symptoms. Causes of pseudoclaudication include musculoskeletal issues (e.g., spinal stenosis, radiculopathy) or neurogenic issues (e.g., sciatic nerve impingement or diabetic neuropathy). Vascular claudication is characterized by intermittent pain that is exacerbated by walking, is relieved by rest, and is reproducible at a similar distance or effort for each patient. The severity of claudication is inversely related to the distance traveled, and the involvement of certain muscle groups can help with disease localization. Aortoiliac illness often presents as proximal claudication in the hip, buttock, and thigh; however, individuals with multisegmental disease may also present with distal calf or rest discomfort. Meanwhile, neurogenic claudication is characterized as deep aching or burning postural pain that originates in the back or buttocks and is exacerbated by walking or prolonged standing and alleviated by stooping, sitting, or leaning forward. One way to differentiate neurogenic from vascular claudication is the fact that neurogenic claudication often requires sitting to relieve the pain, while vascular claudication usually only requires stopping. Once confirmed that the patient's symptoms are caused by vascular insufficiency, it is important to quantify the severity of claudication and whether it is lifestyle limiting to potentially drive an appropriate intervention. In many cases, clinical history and thorough physical examination are sufficient for the diagnosis of aortoiliac occlusive disease. Absent palpable pulses in the entire limb or both limbs from the level of the common femoral artery down to the foot help confirm the unilateral or bilateral inflow level of PAOD, respectively. Except in the event of acute or subacute ischemia such as embolization, chronic aortoiliac illness alone is rarely responsible for ischemic rest pain or tissue loss. This is caused by a rich collateral network robust enough to supply the lower extremities with sufficient resting tissue perfusion. When rest pain or tissue loss is present, the disease is usually diffuse at multilevels and includes both inflow and outflow vessels.

Physiologic Testing

The ankle-brachial index (ABI) and Doppler studies serve as the best initial physiologic test for the evaluation of PAOD. With a compatible history, ABIs less than 0.9 are diagnostic of PAOD and can correlate with the severity of the disease. In general, with progressively more levels of occlusive disease (e.g., aortoiliac plus femoropopliteal plus tibial occlusive disease), the severity is increased and, consequently, the ABI will be lower. ABIs 0.7 to 0.9 indicate mild arterial disease, and patients are usually asymptomatic. ABIs 0.4 to 0.6 indicate moderate disease, and patients usually experience claudication. ABIs less than 0.4 indicate severe disease, and patients can present with rest pain or tissue loss. In cases with clear symptoms of arterial claudication but with palpable pulses on physical examination and normal ABI at rest, an exercise ABI could confirm the diagnosis of PAOD. A significant decrease in ABI with exercise by walking on the treadmill with 12.5% grade at 2 miles per hour for 5 minutes or until symptoms occur is diagnostic. In cases of severe calcification, ABI can be falsely elevated, and toe pressure will be a more accurate test. This is seen in diabetic and/or hemodialysis patients in whom calcification spares the digital arteries. Duplex ultrasonography (DUS) or segmental limb pressures combined with ABIs give a more complete picture of the level and extent of disease. DUS shows a significant increase in velocity in blood flow in the area of focal stenosis in the vessels. It can also confirm complete occlusion. DUS is limited by echo-shadowing from severe calcification in the vessels and obese patients.

Imaging

Computed tomography angiography (CTA), magnetic resonance angiography (MRA), and/or conventional arteriography can be used to delineate the extent and severity of the aortoiliac segment disease. Although conventional contrast angiography is considered the gold standard for PAOD, CTA has largely supplanted it as the diagnostic modality of choice. Compared with conventional angiography, CTA gives better contrast resolution and provides three-dimensional views of the aortoiliac segment, but it does not allow assessment of live flow through the segment. An arterial duplex/ABI and cross-sectional imaging with CTA is sufficient for initial evaluation. Additional information obtained regarding anatomic classification of the lesion and calcification can further aid in the selection of a treatment strategy.

MEDICAL TREATMENT

Medical management is the cornerstone of the treatment of PAOD, to reduce cardiovascular morbidity and mortality. Stepwise management beginning with risk-factor modification includes cessation of tobacco use, initiation of antiplatelet therapy (e.g., aspirin and/or clopidogrel), initiation of HMG-CoA reductase inhibitors (i.e., statins), and management of other cardiovascular and PAOD risk factors (diabetes and hypertension). Further medical therapy can include cilostazol, a phosphodiesterase inhibitor, to provide symptomatic improvement in exercise tolerance and walking distance in patients with claudication.

The CLEVER (Claudication: Exercise Versus Endoluminal Revascularization) trial, a randomized controlled trial comparing supervised exercise therapy with endovascular treatment of aortoiliac disease, showed that the supervised exercise therapy group had more improvement in short-term walking performance than the group undergoing endovascular intervention. In general, walking exercise is recommended three to four times a week for a duration of 30 to 45 minutes for at least 12 weeks and can lead to an improvement in walking distance by approximately 180 meters. The Centers for Medicare and Medicaid Services (CMS) recently approved coverage for a supervised exercise program as a risk factor modification for patients with well-documented PAOD. Medical management is imperative for all patients with PAOD, if for no other reason than to improve overall cardiovascular health.

Decision Making for Intervention

The need for intervention is best assessed on a case-by-case basis, taking into account the severity of occlusive disease, the severity of symptoms, and the overall condition of the patient. In many cases, the risk-to-benefit ratio favors endovascular therapy, particularly in the treatment of aortic occlusive disease.

The optimal technique of revascularization for a patient with claudication is determined by balancing the risks of the specific intervention with the degree and duration of improvement that may be predicted from the intervention. Percutaneous intervention has been found to be safe and effective in patients with claudication and proximal lesions who failed medical management and an exercise program. Patients with multisegmental disease usually present with critical limb-threatening ischemia and should undergo open or endovascular revascularization to fix the inflow in addition to outflow disease to prevent limb loss. Interventions include an endovascular approach, an open surgical strategy, or a combined endovascular and open (hybrid approach). Considerations for intervention selection will be described later in this chapter.

ENDOVASCULAR TREATMENT

The 2007 Inter-Society Consensus for the Management of Peripheral Artery Disease guideline (TASC II) provided a framework to aid in choosing an endovascular or open surgical approach for specific anatomic aortoiliac occlusive lesions (Fig. 1). The guidelines recommend endovascular therapy for short, simple type A and type B lesions. Insufficient evidence concerning TASC C lesions precludes the definitive recommendation of one modality over the other, but surgery is preferred for more extensive and complex type C

Type A lesions

- Unilateral or bilateral stenoses of CIA
- Unilateral or bilateral single short (≤3 cm) stenosis of EIA

Type B lesions

- Short (≤3 cm) stenosis of infrarenal aorta
- Unilateral CIA occlusion
- Single or multiple stenosis totaling 3-10 cm involving the EIA not extending into the CFA
- Unilateral EIA occlusion not involving the origins of internal iliac of CFA

Type C lesions

- Bilateral CIA occlusions
- Bilateral EIA stenoses 3-10 cm long not extending into the CFA
- Unilateral EIA stenosis extending into the CFA
- Unilateral EIA occlusion that involves the origins of internal iliac and/or CFA
- Heavily calcified unilateral EIA occlusion with or without involvement of origins of internal iliac and/or CFA

Type D lesions

- Infrarenal aortoiliac occlusion
- Diffuse disease involving the aorta and both iliac arteries requiring treatment
- Diffuse multiple stenoses involving the unilateral CIA, EIA, and CFA
- Unilateral occlusions of both CIA and EIA
- Bilateral occlusion of EIA
- Iliac stenoses in patients with AAA requiring treatment and not amenable to endograft placement or other lesions requiring open aortic or iliac surgery

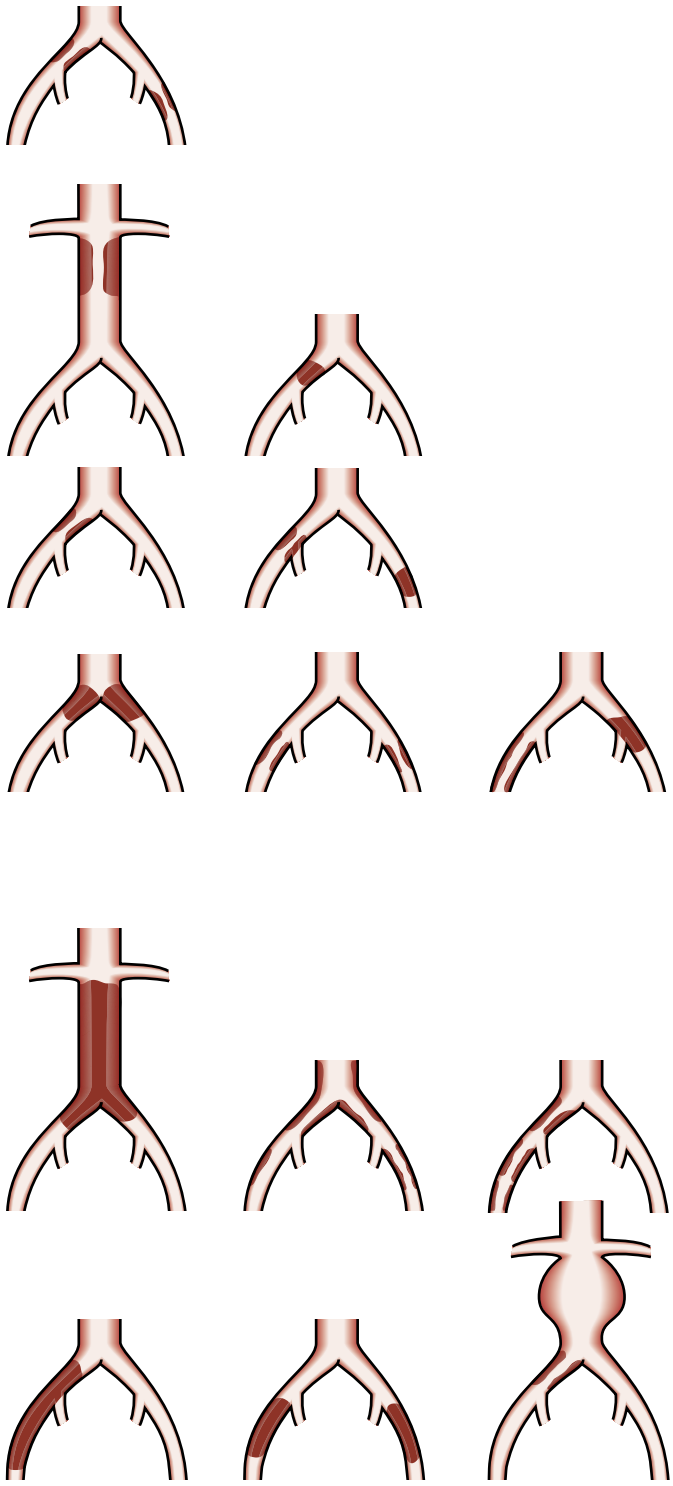

FIG. 1 Inter-Society Consensus for the Management of Peripheral Arterial Disease (TASC II). *AAA,* Abdominal aortic aneurysm; *CFA,* common femoral artery; *CIA,* common iliac artery; *EIA,* external iliac artery.

and D lesions. Recently, however, an endovascular-first strategy is being increasingly employed with success because of the advent of improved imaging, techniques, and endovascular devices. Relative contraindications for aortoiliac angioplasty and stenting include circumferential calcification of more than 1-mm thickness because of the risk of rupture. Stent choice is influenced by the physician's expertise, vessel tortuosity, and other lesion characteristics.

Endovascular intervention involves the following steps:

1. Establishing arterial access
2. Diagnostic arteriogram and identification of the culprit lesion(s)
3. Crossing the lesion(s)
4. Balloon angioplasty (PTA) with stenting
5. Completion arteriogram to assess the result
6. Successful closure of the arterial access site

Establishing Arterial Access

The anatomic site for access is dictated by the anticipated site(s) of intervention and can be assessed with noninvasive imaging DUS and CTA for the most favorable access site(s). Aortoiliac lesions can be approached via a percutaneous or open exposure of the ipsilateral and/or contralateral common femoral artery (e.g., unilateral or bilateral access) or the brachial artery. The distribution and extent of disease will dictate the access site(s). Using DUS to guide the access is the standard of care today because several studies have shown improved safety by reducing the risk of access site hematoma and pseudoaneurysms. After access with a "micropuncture" small-caliber access needle and 0.018 wire and microsheath, arterial access is secured by switching to 5Fr sheath over an 0.035-inch guidewire. An Omniflush catheter is used for diagnostic arteriography (Fig. 2).

Diagnostic Arteriogram and Identification of the Culprit Lesion(s)

Anteroposterior and oblique images are obtained of the aortoiliac and common femoral bifurcations. Arteriography of the lower extremities is obtained. In cases of frank occlusions, the flush catheter should be positioned to fill the collateral network to opacify the distal extent of occlusion and reconstituted vessels. Careful review of the diagnostic arteriogram identifies the culprit lesion(s). A 50% or more diameter reduction or a pressure drop of 15 to 20 mm Hg across the stenosis defies a hemodynamically significant lesion. It is critical to measure pull-back pressure with a single-hole catheter across mild or moderate angiographic lesions because the degree of stenosis can be underestimated on iliac angiography because of the tortuosity of the vessels and eccentricity of the disease within the lumen. The patient should then receive a bolus of 80 to 100 units/kg of systemic heparin. In the case of CIA occlusion, contralateral flush catheter placement can allow access to protect the contralateral CIA from damage during an ipsilateral intervention. Meanwhile, a contralateral approach for the external iliac artery is recommended.

FIG. 2 Diagnostic angiogram showing complete occlusion of the left common iliac artery and bilateral external iliac arteries.

Crossing the Lesion(s)

Stenoses and occlusions are approached differently. In cases of stenoses, a steerable tip, angled, hydrophilic guidewire is chosen. The wire is steered through the stenosis. After traversal, an exchange or support catheter is advanced over the wire through the stenosis. The wire is then removed, and a small contrast injection is done to confirm a successful true lumen location. A transbrachial approach reduces the risk of aortic dissection when the femoral approach is unsuccessful.

Crossing an occlusion can be accomplished with several techniques. An angled support catheter in combination with a straight, stiff hydrophilic wire can be used to attempt luminal traversal. If the occlusion is successfully crossed, the position is confirmed with a small contrast injection. The wire is then exchanged for a non-hydrophilic, stiff support wire. If unsuccessful with this approach, a subintimal traversal is attempted. This involves passing a hydrophilic angled guidewire into the subintimal plane with reentry at the distal end of the occlusion back into the luminal space. Inability to reenter luminally can be facilitated by the use of a reentry catheter (e.g., Outback [Cordis] or Pioneer [Philips Volcano]). This approach can be done as antegrade interventions (e.g., unilateral iliac disease approached via the contralateral groin or brachial approach) of the iliac system or as retrograde from the ipsilateral common femoral artery. The outback catheter requires critical orientation to direct a reentry needle into the true lumen of the vessel past the occlusion. This is accomplished with two angiographic views at 90-degree angulations. The Pioneer catheter has an adjunct of intravascular ultrasonography (IVUS) to help guide the reentry needle into the true lumen. These techniques are more complex and require advanced endovascular skills.

Balloon Angioplasty with Stenting

Balloon angioplasty is performed with a balloon diameter that approximates the normal diameter of the reference vessel. The length of the balloon should approximate the length of the diseased segment with care to avoid angioplasty in the normal adjacent artery. In general, balloon angioplasty is performed slowly and deliberately. This affords the best angiographic result and minimizes the potential risk for dissection, perforation, or embolism. Overall, angioplasty is most successful for short, eccentric, calcified focal lesions. After angioplasty, contrast injection is performed to assess the result. Suboptimal angioplasty results (e.g., elastic recoil, dissection, or residual stenosis) should prompt stent placement. In general, PTA alone is rarely used today in the aortoiliac vessels because data on increased durability with additional stenting are very convincing. PTA is usually performed to prepare the vessels for stenting in cases with severe lesions. PTA is also performed after placement of a self-expanding stent (SES) for modeling the stent to the vessel wall. Balloon expandable stents (BES) are preferred for the common iliac arteries because they have more radial force that can help expand high-resistant orifical lesions. They also have the advantage of more accurate placement. They should be sized to fit the nominal diameter of the reference vessel. Aggressive oversizing is avoided with BESs. SESs are usually made from nitinol, making them more flexible than BESs. Thus they are preferred for the external iliac arteries because of vessel mobility and significant tortuosity. They are also more deliverable from the contralateral side above the aortic bifurcation. These stents should not be oversized by more than 10% to the reference vessel diameter to avoid harming the normal artery. SESs deploy less accurately than BESs and tend to migrate distally during deployment. Thus deployment should be done carefully under fluoroscopic guidance with magnification views to allow for micro-adjustment. If ostial common iliac disease and/or distal aortic disease with the common iliac disease are identified, a "kissing" stent technique is used (Fig. 3). Even in the case of a unilateral lesion, simultaneous balloon dilation at the source of each CIA is recommended to protect the contralateral CIA from dissection, plaque dislodgement, or

FIG. 3 "Kissing" stent technique.

embolization. Both balloon-expandable and self-expanding stents have been used for kissing stents. In the common iliac arteries, covered BESs are preferred over bare metal BESs, specifically for TASC C or TASC D lesions to minimize the risk of iatrogenic perforation and arteriovenous fistulas. Otherwise, bare-metal stents and covered stents have equivalent results in the common iliac arteries. In principle, covered stents should minimize in-stent restenosis by keeping the diseased segment out of circulation; nevertheless, experimental results show that they may cause greater neointimal outgrowth at the end of the stent-graft compared with bare stents. Calcium burden in the aortoiliac system can be challenging. Aggressive balloon angioplasty in calcified vessels risks vessel perforation. Therefore, in highly calcified lesions worrisome for the risk of perforation, either balloon-expandable covered stents (e.g., Gore VBX stent) or self-expanding covered stents (e.g., Gore Viabahn stent) are used. The majority of arterial ruptures occur during angioplasty or stenting of small, highly calcified external iliac arteries. Patients generally experience considerable flank or back pain when the artery ruptures because most of these cases are conducted under local anesthesia. Another complication of intervention is iliac dissection, which can continue proximally or distally. Overdilation of a small, calcified artery is the most common cause of dissection in these interventions. Intraoperative identification of dissection is imperative, and treatment of flow-limiting blockage consists of stent extension.

Technical success is defined as less than 20% residual stenosis and a systolic pressure gradient of less than 10 mm Hg. The translesional pressure gradient measurement should be used to determine the success of the angioplasty/stenting.

Closure of the Arterial Access Site(s)

The most common complications associated with endovascular interventions involve the arterial access site. Appropriate patient selection for percutaneous versus open surgical access is paramount for a successful intervention. Percutaneous closure devices are available to the interventionalist to assist with closure. The optimal choice of the closure device is dependent on operator familiarity, the size of the access sheath, and the state of the access vessel. Instructions for use, indications, and contraindications must be followed for each device. In patients who are not candidates for the use of percutaneous closure devices, manual pressure may be used for access site management and may be appropriate in certain situations (e.g., brachial artery access, highly scarred groin, densely calcific access artery). However, recent studies have shown that vascular closure devices are associated with fewer complications including hematomas and pseudoaneurysms. Additional benefits may include earlier ambulation after a procedure, reducing the length of stay in the hospital or outpatient interventional suite.

Results

Balloon angioplasty remains an option for isolated, short-segment iliac disease up to 7 to 10 mm. Primary stenting, however, has become the most common approach for the majority of lesions because of its improved long-term primary patency. Primary patency varies based on the TASC classification, with the worst primary patency observed with TASC C lesions at 65%. Stenting of TASC types A and B common iliac lesions achieve patency similar to that of open surgical reconstruction. The prospective, randomized Covered versus Balloon Expandable Stent Trial (COBEST) concluded that covered BESs have less incidence of restenosis, less incidence of stent occlusion, and therefore better long-term patency rates than bare metal BESs in aortoiliac occlusive disease, particularly in TASC C and TASC D lesions at 5-year posthoc analysis (Fig. 4). However, the number of patients at risk in this trial was very small. Recent meta-analysis, however, has corroborated this finding with a significantly higher primary patency of 92% with the covered stent compared with 75% in noncovered stents. Perioperative mortality is less than 1%, and morbidity ranges from 5% to 20%. External iliac disease is a strong predictor of reduced primary and primary assisted patency rates. Additionally, female gender, renal insufficiency, and CLI have been associated with worse outcomes.

Covered Endovascular Reconstruction of the Aortic Bifurcation

Covered endovascular reconstruction of the aortic bifurcation (CERAB) is an evolving technique proposed to treat extensive disease involving aortic bifurcation through reconstruction using three covered BESs. Typically, a kissing stent technique has been employed; however, recent studies have shown that this configuration has the potential to cause flow disturbances leading to neointimal hyperplasia, thrombosis, and restenosis.

Technique

To begin, two introducer sheaths are inserted into the common femoral arteries. Depending on the features of the lesion, the lesion

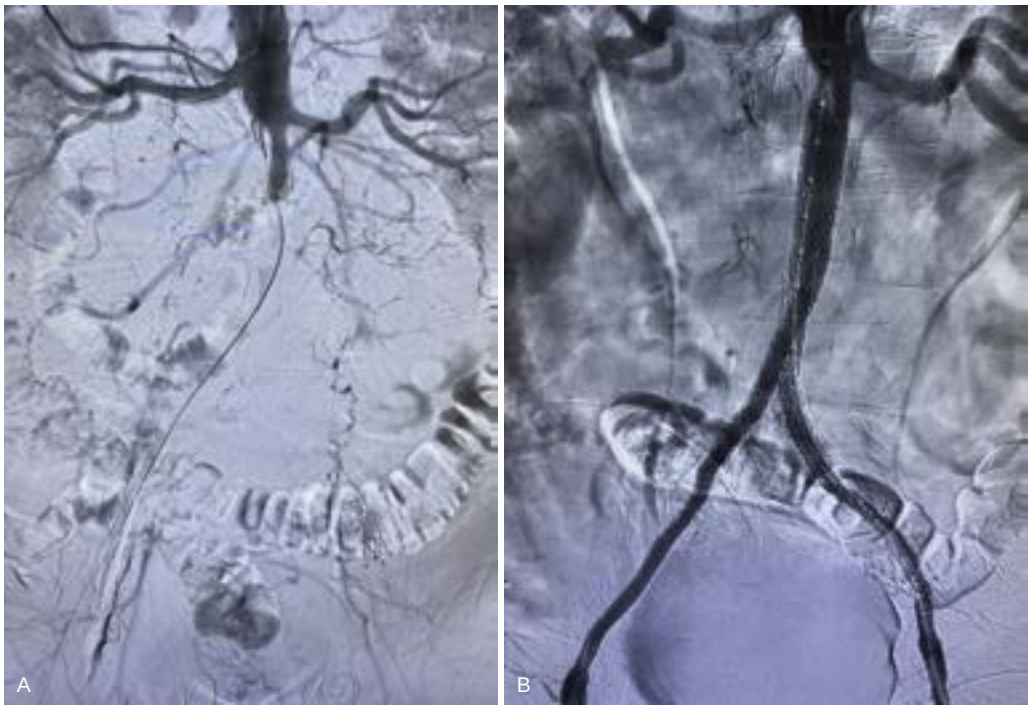

FIG. 5 Covered endovascular reconstruction of aortic bifurcation (CERAB) before device deployment. **(A)** Aortic angiography showing complete occlusion of the aorta and bilateral common, external, and internal iliac arteries. A prior failed stent is seen in the left external iliac artery. Large lumbar arteries collateralize the flow back to the left internal iliac artery and later to the deep femoral artery to reconstitute the common and superficial femoral. **(B)** Complex techniques involved a reentry device to enter the aorta just below the renal glands with access from left the common femoral artery after crossing the occlusion in a subintimal fashion. It was not possible to cross/reenter from the right side, so transbrachial access was performed to cross the right common iliac artery in an antegrade fashion, and the wire was then snared in the right external iliac artery retrograde from the right femoral artery. Once we had bilateral wire access into the true aortic lumen, a 16-mm cover stent was placed in the aorta, and two 8-mm cover balloon expandable stents were placed in the common iliac arteries extending 2 cm into the aortic stent. Additional self-expanding stents were placed in the bilateral external iliac arteries. This is a final completion angiography showing wide-open vessels. *(Courtesy Dr. Mahmoud Malas)*

is traversed endoluminally or subintimally. A 9Fr introducer sheath is placed above the proximal border of the aortic lesion after predilation. Then, in the distal aorta, a 12-mm balloon-expandable polytetrafluoroethylene-coated stent is placed. To promote canalization, the distal end of the stent is positioned roughly 15 to 20 mm above the bifurcation. To achieve complete apposition to the aortic wall, this stent is flared proximally with a balloon suited to the natural diameter of the distal aorta, generally 16 mm. This results in a funnel-shaped stent with a distal section 12 mm in diameter. Following that, two iliac covered stents, generally 8 mm in diameter, are placed in the conic segment of the aortic stent and concurrently inflated. When distal extension may be necessary, internal iliac artery preservation using a bare-metal stent is attempted to prevent buttock claudication and erectile dysfunction. As with standard endovascular procedures, statin treatment and dual antiplatelet therapy for at least 6 months are recommended (Fig. 5).

Results

Early results of this technique have been promising, with primary patency at 1 year and 3 years of 86% and 82%, respectively. Primary assisted patency is 91% and 89% at 1 year and 3 years, while secondary patency is 97% at both 1 year and 3 years. Additionally, limb salvage rate is 98% and 97% at 1 year and 3 years of follow-up.

SURGICAL TREATMENT

Open surgical revascularization is broadly categorized into *anatomic* versus *extraanatomic* revascularization procedures. For the aortoiliac segment, anatomic revascularization refers to aortofemoral, inline iliofemoral bypass, or aortoiliac endarterectomy.

Extraanatomic bypass refers to any bypass graft, autologous or not, that is implanted in a location other than the native artery segment being bypassed. These procedures include femorofemoral bypass, cross ilioiliac or iliofemoral bypass, axillofemoral bypass, or thoracofemoral bypass. Extraanatomic bypasses are generally reserved for patients considered high risk for a major open abdominal surgery because of underlying comorbidities or hostile abdominal features such as active infection, adhesions, stomas, or fistulae. The most common procedures will be discussed.

Potential complications seen in both procedures are common to any aortic procedures including intestinal ischemia, graft infection, and graft thrombosis. A review of 5-year outcomes for the different procedures is provided in Table 1.

Aortofemoral Bypass

Aortofemoral (or aortobifemoral) bypass is still considered the gold standard for aortoiliac revascularization. Several important anatomic factors dictate the operative approach and procedure. These factors should be extensively assessed with high-quality cross-sectional imaging (e.g., CTA). Assessment of concomitant renal or visceral artery disease is critically important. The proposed proximal aortic clamp site should be free from large atherosclerotic burden or calcium. The left renal vein typically will serve as the anatomic landmark for the renal arteries and the proximal aortic clamp site. A retro-aortic left renal vein is present in approximately 2% of patients,

TABLE 1 Outcomes of Surgical Revascularization

Procedure	5-Year Patency (%)	Perioperative Morbidity (%)
Aortofemoral bypass	80–90	<5
Aortoiliac endarterectomy	90–92	~2.7
Iliofemoral bypass	72–85	~2.7
Axillofemoral bypass	80–84	<5
Femorofemoral bypass	65–70	<5
Thoracofemoral bypass	60–79	5–6

and a circumaortic left renal vein is present in approximately 8% of patients. These left renal vein variants are very vulnerable to injury, with a rate of 40% of cases. Needless to say, careful assessment of the preoperative CT scan imaging and evaluation of these anatomic variations is crucial in reducing injury during dissection and proximal clamping.

The status of a patient's pelvic circulation may influence the proximal anastomotic configuration (end-to-end vs. end-to-side). Most favor an end-to-end configuration, which allows for direct aortic thromboendarterectomy, more favorable blood flow dynamics, and theoretically less risk of development of an aortoduodenal fistula.

However, the end-to-side configuration should be strongly considered in patients whose pelvic perfusion or inferior mesenteric artery perfusion would be entirely sacrificed with an end-to-end configuration. For example, in patients with severe external iliac artery disease or bilateral external iliac occlusions, an end-to-side proximal anastomosis would confer continued antegrade pelvic flow through the existing patent common iliac and hypogastric arteries (Fig. 6).

Another example is a patient with a large, patent inferior mesenteric artery with concomitant proximal visceral disease (e.g., celiac or superior mesenteric artery stenosis). Bowel perfusion would be maintained with an end-to-side proximal anastomotic configuration in this scenario (Fig. 7). Finally, a patient with a sizeable accessory renal artery arising from the infrarenal aorta that would lose substantial kidney function with a sacrifice of antegrade renal artery flow in an end-to-end configuration would also be best served with an end-to-side anastomosis.

Technique

1. Bilateral femoral artery exposure and control
2. Aortic exposure via abdominal or retroperitoneal approach
3. Creation of a tunnel
4. Heparinization
5. Aortic clamping
6. Anastomoses (proximal then distal)
7. Assessment of patency/perfusion
8. Coverage and closure

The patient is widely prepped and draped from the level of the nipples to the feet bilaterally. The procedure begins with bilateral groin incisions to expose the common femoral, profunda femoral, and superficial femoral vessels. Performing groin incisions before the abdominal incision limits insensible fluid loss. In unique situations in which the external iliac arteries and femoral arteries are spared of disease, an aortoiliac bypass may be performed to the distal external iliac arteries via a transabdominal approach. This technique reduces the risk of infection by avoidance of groin incisions. Assessment of the femoral vessels is important to determine the need for a common femoral or profunda femoris endarterectomy and/or angioplasty. In general, a distal anastomosis incorporating the origin of the profunda femoris artery is critical for achieving durable long-term patency of the graft. With chronic occlusive disease, the inferior epigastric and circumflex iliac arteries can develop into large collateral vessels and should be meticulously protected and maintained. The aorta is exposed through either a midline laparotomy incision or retroperitoneal incision. The retroperitoneal approach may be attractive in patients with previous abdominal operations or a hostile abdomen (the retroperitoneal approach is described in detail in the Unilateral Iliofemoral Bypass section). After entering the peritoneum through a midline laparotomy, the abdominal cavity is inspected for unanticipated concomitant pathology (e.g., malignancy). A nasogastric tube is placed to decompress the stomach and to aid in identifying the esophagus in cases in which supraceliac aortic control is anticipated. The transverse colon is retracted cephalad, and the small bowel is

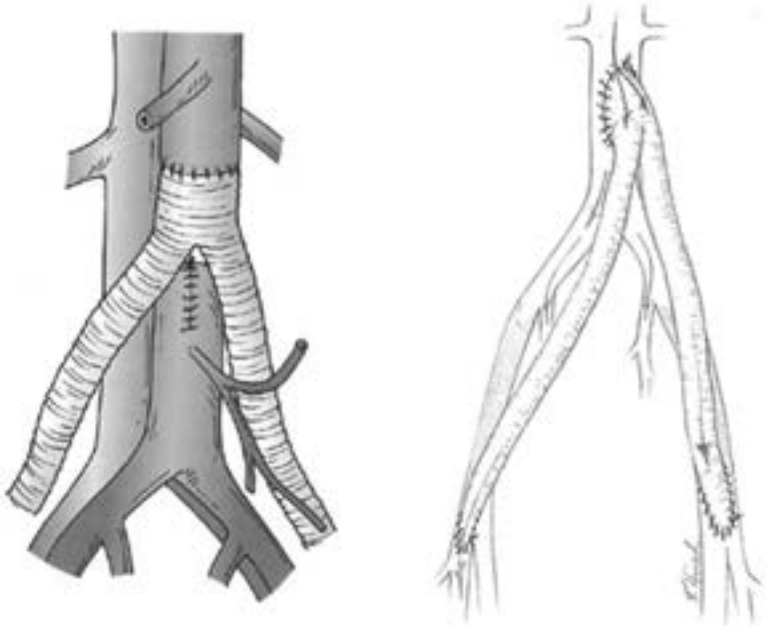

FIG. 6 Proximal anastomosis. End-to-end configuration versus end-to-side configuration. *(Modified from Cronenwett JL, Johnston, KW,* Rutherford's Vascular Surgery. *7th ed. Philadephia: Elsevier; 2010; and Zarins CK, Gewertz BL.* Atlas of Vascular Surgery, *St. Louis: Elsevier; 2005.)*

FIG. 7 Aortoiliac occlusive disease with a large patent inferior mesenteric artery.

retracted to the right upper quadrant. A fixed retractor system (i.e., Omni-Tract) is placed. The retroperitoneal tissue overlying the aorta and the ligament of Treitz is incised to expose the underlying aorta from the renal arteries to the aortic bifurcation. If necessary, the inferior mesenteric vein is ligated to provide better exposure. Care is taken to protect the left renal vein, the inferior mesenteric artery, and the autonomic nerve plexus located near the bifurcation and left common iliac origin. Construction of the tunnels for the bypass graft limbs is done by gentle, blunt dissection simultaneously from the groin posterior to the inguinal ligament and the abdomen over the occluded native iliac arteries. The tunnel must be constructed to run posterior to the ureters to prevent the development of hydronephrosis. Umbilical tape or red rubber catheters are inserted through the tunnel to facilitate passage of the graft limbs.

The patient is systemically anticoagulated with 80 to 100 U/kg of intravenous heparin to achieve an activated clotting time greater than 250 seconds. The aorta is clamped distally and then proximally just inferior to the renal arteries to minimize the chance for embolization. In cases with posterior calcific plaque, clamping the aorta in an anterior-to-posterior fashion may limit the potential for aortic clamp injury and embolization. Other proximal aortic clamp sites include the suprarenal or supraceliac aorta. Percutaneous insertion of an occlusion balloon is another option for proximal control. If suprarenal or supraceliac control is performed, the clamp should be moved caudally to the renal arteries as soon as the proximal anastomosis is performed successfully to limit visceral and renal ischemia time. In cases with severe disease extending to the renal arteries, suprarenal clamping with control of bilateral renal arteries with vessel loops to prevent embolization is mandatory. Quick endarterectomy of the infrarenal aortic neck is performed including the orifice of the renal arteries. A quick bloodletting of the proximal clamp allows release of any residual atheroma followed by aggressive flushing of heparinized saline. The infrarenal clamp is placed followed by the release of the suprarenal clamp and loops on the renal arteries. If an end-to-end configuration is chosen, the aorta at the proximal anastomotic site is transected. The distal stump is oversewn with a permanent monofilament suture (e.g., polypropylene). Pledgeted sutures may be needed for a highly diseased distal aortic stump. An appropriately sized knitted polyester (Dacron) graft is chosen to match the femoral artery diameter. Typically used bifurcated grafts include 18 mm × 9 mm grafts or 16 mm × 8 mm grafts for men and 14 mm × 7 mm grafts or 12 mm × 6 mm grafts for women. The main body of the graft is trimmed 3 to 4 cm from the bifurcation. The proximal anastomosis is performed using a running 3-0 polypropylene suture. If the aortic cuff is thin or fragile, a 3-0 polypropylene interrupted mattress, pledgeted suture technique is advisable. In the end-to-side proximal anastomotic configuration, the aorta is clamped as described earlier. If significant back bleeding is encountered from the collateral lumbar vessels, two overlying side clamps or a large Satinsky clamp can control the bleeding. A longitudinal aortotomy is made, and the edges of the aorta are trimmed to form an ellipse for the anastomosis. The graft is trimmed and beveled to achieve as low a profile as possible. This limits the risk of kinking and limits the amount the graft contacts the duodenum to theoretically limit the risk of aortoduodenal fistula formation. The anastomosis should start near the renal arteries and extend distally to facilitate a low-profile anastomosis. In either proximal anastomotic configuration, after completion of the anastomosis, the proximal clamp is released after clamping the main body of the graft or both iliac limbs to examine the proximal anastomotic integrity and hemostasis. Pledgeted sutures may be used to reinforce the anastomosis. The graft limbs are passed through the preformed tunnels with care to avoid twisting. The limbs should be flushed out after tunneling to confirm great inflow and release any residual debris. The femoral anastomosis is performed in an end-to-side configuration using running 5-0 polypropylene. As stated previously, outflow through the profunda femoris is crucial for long-term graft patency. In cases requiring a profunda femoris artery endarterectomy or profundaplasty, the distal end of the aortofemoral graft can be used as a profunda femoris artery patch angioplasty. Alternatively, an autogenous vein patch or prosthetic patch can be used for the patch angioplasty with the anastomosis subsequently performed to the patch. In cases of chronic superficial femoral artery occlusion, the primary outflow vessel is the profunda femoris artery.

Adequate outflow through the profunda femoris is assessed on the preoperative cross-sectional imaging and/or angiography. In addition, at the time of operation, the profunda femoris can be assessed with a deflated embolectomy balloon catheter to interrogate the length of the profunda femoris artery. A profunda femoris origin that accepts a 4-mm-diameter probe and measures 20 to 25 cm in length is adequate to sustain an aortofemoral graft. Concomitant distal revascularization (e.g., femoropopliteal or femorotibial bypass) is necessary in about 15% to 25% of patients and is indicated in cases of compromised outflow. Before completion of the anastomosis, the distal vessels are allowed to back-bleed, and the graft is flushed of debris. In general, with the chronic occlusive nature of the disease, reestablishment of leg perfusion results in only small hemodynamic changes. Communication with the anesthesia team is paramount, however, before reestablishment of distal perfusion to limit the potential for hemodynamic lability. The distal leg is assessed for perfusion with palpable pedal pulses or audible multiphasic signals. Lack of distal perfusion with adequate inflow (i.e., vigorous flow through the graft) should prompt evaluation of the distal anastomosis for a technical error or raise concern for a distal embolism. Angiography can help delineate the underlying problem. Redo anastomosis is indicated for an anastomotic technical error. Distal embolization is treated with balloon catheter embolectomy. After satisfactory perfusion is assessed through target artery Doppler signals, we reverse the effects of heparin with protamine and ensure adequate hemostasis. Abdominal closure begins with reapproximation of the retroperitoneal tissue to cover the graft, if possible. An alternative coverage option is to mobilize an omental pedicle placed via a transverse colon mesenteric window. The abdomen is closed in the standard fashion. Meticulous groin incision closure in multiple layers is important to limit the risk of infection and wound complications. Wound vacuum dressing has been shown to reduce the risk of groin incision infection in vascular patients who are at high risk because of associated comorbidities such as redo surgery, obesity, and diabetes.

Results

Perioperative mortality is less than 5%. Primary graft patency approximates 100% initially, with 5-year and 10-year primary patency ranging from 80% to 90% and 75% to 85%, respectively. Cumulative secondary graft patency for 2, 5, and 10 years was 97.7%, 95.9%, and 94.4%, respectively. Inferior patency results are documented for patients with ulceration or tissue loss compared with patients with claudication or ischemic rest pain. In addition, age and native aortic diameter have been shown to influence patency after aortofemoral bypass. Patients younger than 50 years of age and those with aortic diameters 18 mm or less have much lower primary patency rates after aortofemoral bypass (50%–65% 5-year primary patency). Infection occurs in 0.3% to 0.7% of cases, and anastomotic pseudoaneurysm formation occurs in 1.4% of cases.

Aortoiliac Endarterectomy

Aortoiliac endarterectomy is an option for patients with localized aortoiliac disease limited to the distal aorta and proximal common iliac arteries who are at high risk of embolization or those with small-caliber vessels, commonly found in young or middle-age women with a history of tobacco use. With the increased use of endovascular interventions and the long-term durability and success of aortofemoral bypass, aortoiliac endarterectomy is uncommonly chosen as a primary procedure. However, it remains a viable option as a secondary procedure in the setting of the infected bypass graft.

Technique

1. Aorto-iliac exposure
2. Systemic heparinization
3. Aortic and iliac clamping
4. Arteriotomy
5. Enterectomy in subintimal plane
6. Patch angioplasty or primary closure
7. Wound closure

Operative exposure is done through a standard midline laparotomy, similar to the abdominal portion of an aortofemoral bypass procedure. Complete mobilization of the distal aorta, inferior mesenteric artery, aortic bifurcation, and proximal bilateral common iliac arteries is achieved with care to protect the autonomic nerve plexus (nervi erigentes) and to avoid injuries to the iliac veins located behind the arteries. A longitudinal aortic incision is made and may be carried onto one of the common iliac arteries. A counter-incision in the contralateral common iliac artery can be made in the case of bilateral common iliac disease. Endarterectomy is performed in the subintimal plane with care to taper or feather the distal end of the endarterectomy. Tacking mattress sutures at the distal edge of the endarterectomy can be used to prevent dissection. The proximal plaque is transected to a smooth edge. The aorta and iliac arteries are flushed of debris, and assessment of the proximal and distal ends of the endarterectomy are performed before closure. The arteriotomies are closed either primarily with 4-0 or 5-0 polypropylene sutures or with a patch (Fig. 8).

Results

Perioperative mortality rates are similar to aortofemoral bypass grafting (2.7% perioperative mortality). Patency rates appear similar to aortofemoral bypass and are 90% to 92% for 5-year patency and 89% for 10-year patency. Complications include limb ischemia secondary to embolization or dissection and aneurysmal dilation in the long term.

Unilateral Iliofemoral Bypass

Unilateral iliofemoral bypass is indicated in cases with limited distal aortic disease and limited ipsilateral proximal common iliac disease. Otherwise, aortofemoral bypass is preferred. High-risk patients for open abdominal surgery (e.g., severe cardiopulmonary dysfunction) may also be candidates for this procedure as this is typically performed through limited retroperitoneal exposure.

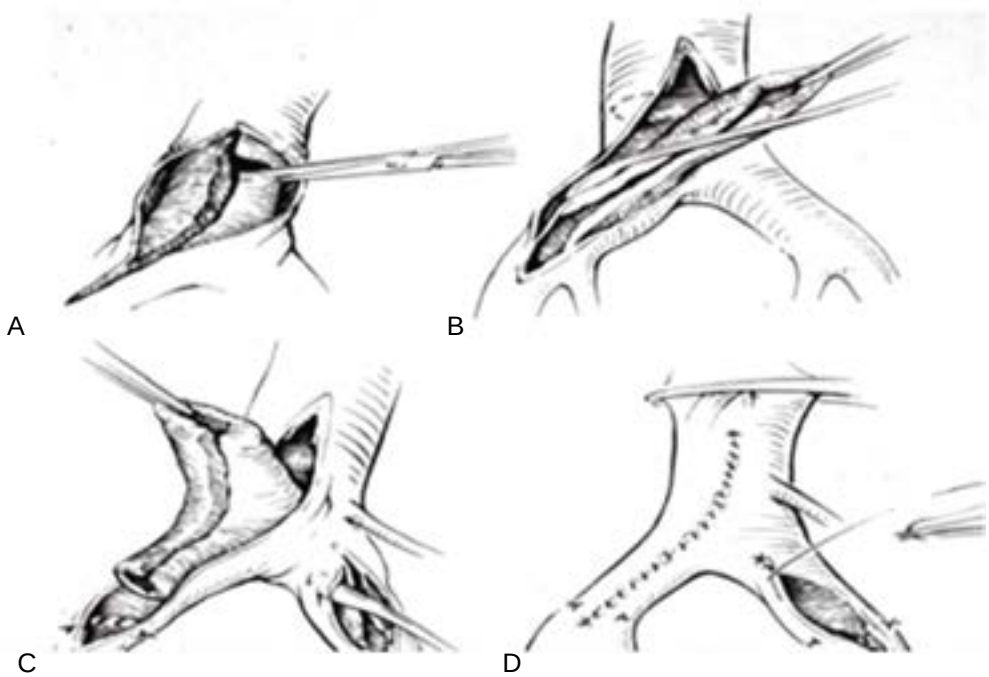

FIG. 8 Aortoiliac endarterectomy. **(A)** The initial incision starts above the occlusive disease and extends to the bifurcation of the right iliacs. **(B)** Endarterectomy begins with a dissecting spatula. **(C)** A counter-incision in the left common iliac permits bifurcation disease to be removed beneath the artery bridge. Endarterctomy is taken into the internal iliac orifice. **(D)** The incision is closed with running suture. *(From Connolly JE, Price T. Aortoiliac endarterectomy: A lost art?* Ann Vasc Surg. *2006;20[1]:56–62.)*

Technique

The patient is positioned supine. Retroperitoneal exposure is facilitated by a "bump" placed under the ipsilateral flank and/or flexing the table to expand the space between the ribs and the anterior-superior iliac spine. A retroperitoneal curvilinear incision is extended from the anterior axillary line to the midline inferior to the umbilicus along the line of the 10th rib. The anterior rectus sheath is incised, and the rectus abdominis muscle is spared and retracted medially. The posterior rectus sheath is incised. The internal and external oblique muscles are incised with electrocautery to expose the transversus abdominis muscle. Beginning laterally, the transversus abdominis muscle and the underlying transversalis fascia are opened to enter the retroperitoneal space. The peritoneum is stripped from the lateral pelvic wall and retracted medially with the intraabdominal contents to expose the underlying psoas muscle. The ureter is identified, protected, and retracted medially. The external iliac artery is readily identified in the distal aspect of the wound and can be followed proximally to the common iliac artery and aortic bifurcation. The proximal clamping site may be found at the proximal ipsilateral common iliac artery or the distal aorta and contralateral proximal common iliac artery. Standard exposure of the common femoral artery, similar to that described earlier for an aortofemoral bypass, is performed. A tunnel is created anterior to the external iliac artery and posterior to the inguinal ligament.

The patient is systemically heparinized. An 8-mm polyester graft is the typical conduit of choice. Proximal anastomosis is performed to the ipsilateral common iliac artery using 4-0 or 5-0 polypropylene sutures. The graft is tunneled distally under the inguinal ligament or in some cases through the obturator foramen, and a distal anastomosis is fashioned similar to an aortofemoral bypass described earlier. The graft is placed deep within the pelvis, where it is less vulnerable to external compression or kinking. After satisfactory reperfusion and hemostasis, the retroperitoneal incision and groin incision are closed in the standard fashion.

Results

Perioperative mortality mirrors aortoiliac endarterectomy at 2.7%. Review of literature shows primary patency rates of 92% at 1 year and 72% to 85% at 5 years. Primary assisted patency at 1 year and 5 years is 91% and 81%, respectively. Secondary patency is 97.5% at 1 year and 93.3% at 5 years. Limb salvage at 5 years is 94%.

Axillofemoral Bypass

In severely high-risk or elderly patients with critical limb ischemia, an axillofemoral (or axillobifemoral) bypass is an alternative to direct aortoiliac revascularization. In addition, it is a reasonable alternative for patients with a "hostile" abdomen, previous radiation therapy, intestinal stomas, infected prosthetic arterial grafts, or aortoenteric fistulae. The axillary artery serves as the inflow for both lower extremities. The axillary artery with higher systolic blood pressure is chosen; however, if both sides are hemodynamically competent, the side ipsilateral to the ischemic leg is given preference.

Technique

1. Determine the best axillary artery for inflow
2. Infraclavicular exposure and control of the axillary artery
3. Bilateral femoral artery exposure and control
4. Tunnel creation
5. Heparinization
6. Axillary then femoral then fem-fem anastomoses created
7. Coverage and closure

Blood pressures are obtained in both arms to determine the optimal side for inflow. Although previous studies have shown improved patency of axillobifemoral bypasses over axillounifemoral bypasses, more recent studies show no significant difference. The patient is positioned supine with the donor arm abducted to 90 degrees. A rolled towel may be used to lift the torso on the donor side to improve axillary artery exposure. The patient is prepped from the neck and chest down to the knees or bilateral feet. A transverse infraclavicular incision is made along the midportion of the clavicle. The underlying pectoralis major is split along its fibers to expose to underlying clavipectoral fascia. The clavipectoral fascia is incised to expose the underlying neurovascular bundle and axillary sheath with its contents. The axillary anastomosis is generally performed in the first part of the axillary artery because of its relationship with the brachial plexus. At this site, the brachial plexus runs posterior to the axillary artery conferring less risk for injury. In the lateral wound, the pectoralis minor is identified and retracted laterally or transected. The lateral pectoral nerve runs just posterior to the medial border of the pectoralis minor and should be protected. The axillary sheath is incised. The axillary vein is anterior in the sheath and is encircled and retracted inferiorly to expose the axillary artery. Proximal and distal control and control of branches are obtained with silastic vessel loops. The bilateral femoral arteries are exposed, as previously described. An externally supported 8-mm-diameter prosthetic graft is chosen. Tunneling is performed with a blunt tunneler routed parallel and anterior to the axillary artery, posterior (under) the pectoralis minor muscle, and down the anterior axillary line in the subcutaneous space anterior to the iliac crest down to the ipsilateral groin. A subcutaneous tunnel is created between each groin in an inverted-*U* configuration. The graft(s) are passed through the tunnels. The patient is systemically heparinized. The proximal anastomosis is created by running a 5-0 or 6-0 polypropylene suture and is oriented parallel to the axillary artery. Placement of the axillary anastomosis in the first portion of the axillary artery and tunneling parallel to the artery in the midaxillary line and posterior to the pectoralis minor allows some redundancy in the graft to prevent anastomotic disruption with arm abduction. The ipsilateral end-to-side femoral anastomosis is created with 5-0 polypropylene sutures. The femorofemoral component is created onto the hood of the axillofemoral bypass graft using 5-0 polypropylene suture. The contralateral femoral anastomosis is created in a standard fashion, as described earlier. Prefabricated externally supported expanded polytetrafluoroethylene (ePTFE) axillobifemoral grafts are also available. This prefabricated graft saves one anastomosis but requires a specific tunneling sequence by pulling the long limb from the ipsilateral groin back to the axilla first and then the short limb from the ipsilateral to contralateral groin incisions. Skip incision might be needed for a tall patient, which makes the tunneling more challenging. It is critical to demonstrate sufficient blood flow in the donor arm beyond the axillary anastomosis by verifying a good radial pulse or appropriate oxygen saturation (as measured by pulse oximetry).

Results

Historically, the patency rates for axillofemoral bypasses varied widely (30%–85%). Perioperative mortality remains less than 5%; however, published long-term survival rates are reported to be approximately 50%, confirming the high-risk status of these patients. More contemporary studies have shown improved primary 1-year and 5-year patency rates of 75% to 96% and 80% to 84%, respectively, which are comparable to aortofemoral bypass. No significant difference in patency is evident between unifemoral or bifemoral distal configurations.

Femorofemoral Bypass

Femorofemoral bypass is used as an alternative revascularization strategy to aortofemoral or iliofemoral bypass in high-risk patients with unilateral common or external iliac artery occlusive disease or in patients with a hostile abdomen. It is dependent on the capacity of one iliac arterial system to deliver enough blood flow to sustain both legs. Thus the status of the donor artery must be assessed. The presence of a pressure gradient greater than 5 to 10 mm Hg down the proposed donor iliac artery necessitates intervention to prevent the arterial steal phenomenon.

Technique

The patient is positioned supine. This procedure can be done with locoregional or spinal anesthesia in patients who are at high risk for general anesthesia. The bilateral femoral arteries are exposed, as previously described. A subcutaneous tunnel between incisions is made to achieve an inverted-*U* configuration. This configuration reduces the acute angle of the anastomosis and reduces the risk of kinking. Tunneling is done in the subcutaneous space. The subcutaneous tunnel prevents bladder or bowel injury and may be necessary for patients with hostile abdominal conditions. Typically, prosthetic grafts are used as a primary conduit (8 mm externally supported ePTFE) as there is no current evidence to suggest superiority of one prosthetic conduit choice over another. Standard end-to-side anastomoses to the femoral arteries and layered groin closure complete the operation. After the anastomoses are completed and all clamps are released, it is critical to demonstrate augmentation of flow in the recipient vasculature and sustained flow in the outflow vessels beyond the donor-side anastomosis, typically using continuous-wave Doppler.

Results

Perioperative mortality is less than 5%. The primary patency rates at 5 years and 10 years are 71.8% and 55.6%, respectively, in a contemporary study. Primary assisted patency rates at 5 years and 10 years are 84.3% and 74.8%, respectively. Secondary patency rates at 5 years and 10 years are 89.8% and 82.9%, respectively.

Thoracofemoral Bypass

This technique utilizes descending thoracic aorta as an inflow source for revascularization in patients with a hostile abdomen, multiple failed anatomic abdominal aortic operations (e.g., failed aortofemoral bypasses), multiple failed extraanatomic revascularization attempts because of compromised inflow, or aortic graft infection.

Technique

The patient is positioned in a modified right lateral decubitus position with a double-lumen endotracheal tube to allow deflation of the left lung; however, some find single-lung ventilation unnecessary. The thorax is elevated 30 to 45 degrees, and the pelvis is maintained as flat as possible to allow access to the right groin. A left thoracotomy incision is made, typically as high as the sixth intercostal space or as low as the ninth intercostal space. The exact location of the thoracotomy is dictated by the proposed site for proximal anastomosis that is free from disease. Bilateral groin incisions are made, as previously described. A 10-mm externally supported prosthetic graft is the usual conduit. A retroperitoneal counter-incision is made in the left flank to facilitate tunneling from the posterior diaphragmatic recess to the left groin. A standard femorofemoral tunnel is created. After systemic anticoagulation, an end-to-side proximal anastomosis is created using 3-0 polypropylene sutures. Proximal control for the anastomosis is obtained using partial occlusion Satinsky clamps or standard proximal and distal clamps. Distal anastomoses are fashioned to preexisting grafts or the femoral arteries, as previously outlined. Chest tube drainage and closure of the incisions complete the procedure.

Results

Perioperative mortality remains around 5% to 6%. The primary patency rate at 1 year is 89%, and at 3 years 80% in different reports, with secondary patency rates of about 83%% at 5 years of follow-up.

Hybrid Revascularization Procedures

In unilateral or bilateral aortoiliac disease extending into the common femoral arteries, a hybrid open surgical technique is an alternative to aortofemoral or iliofemoral bypass grafting. This approach treats the common femoral arteries with endarterectomy and vein patch angioplasty combined with a retrograde approach through the new patch for endovascular angioplasty and stenting to treat the iliac or inflow vessels. Treating one iliac artery with angioplasty and stenting to ensure adequate inflow for femorofemoral bypass has been well described and shown acceptable mid- and long-term durability. Perioperative mortality is around 2% to 15%, reflecting the overall patient health undergoing these procedures. Initial technical success with this approach is reported to be 99% to 100%, with 2-year primary patency rates of 80% to 100% and secondary patency rates of 90% to 100%.

Follow-up

It is important to follow all patients with PAOD who received open or endovascular intervention. It is our practice to see our patients at 1, 6, 12, 18, and 24 months and yearly to ensure patency and maximize medical management. In addition to the physical examination, DUS and ABI are obtained at each visit. If severe stenosis is identified, we intervene proactively with minimally invasive angioplasty to prevent complete occlusion. This dramatically improves the patency of these grafts. Aggressive management of medical comorbidities with smoking cessation, statin therapy, and antiplatelet therapy is crucial in improving long-term survival in PAOD patients.

SUMMARY

Aortoiliac occlusive disease can be a debilitating disease. A structured approach to diagnosis and treatment is crucial for successful results. Management is dictated by the severity of the disease and the health of the patient. With continued advancement in revascularization options, the surgeon should tailor the approach on a case-by-case basis.

Femoropopliteal Occlusive Disease

Zachary T. AbuRahma, DO, and Ali F. AbuRahma, MD

INTRODUCTION

Peripheral artery disease (PAD) is a global epidemic that affected more than 200 million patients worldwide in 2010. Most of these patients are asymptomatic; however, patients with intermittent claudication usually experience a limb loss rate of <5% over 5 years, while patients with critical limb ischemia (CLI) have a 1-year major amputation rate of 25% and death rates of 25%.

Femoropopliteal disease has been treated traditionally with open surgery (femoropopliteal bypass; FPBP) with a favorable 5-year patency rate when saphenous vein (ASV) grafts are used. Several meta-analyses have shown that CLI did not occur for up to 5 years in 50% to 70% of patients who underwent ASV grafting to tibial or pedal targets, with perioperative mortality and limb salvage rates of 3% and 80%, respectively.

A recent study of 467 bypass grafts compared outcomes for ASV and polytetrafluoroethylene (PTFE) grafts and showed the patency rate with ASV was better than PTFE grafts at 5 years (82% vs. 26%, $P < .05$); however, good quality vein may not be available (20%–30%). Bypass with PTFE should therefore be limited to select patients.

Open surgical bypass has certain limitations, for example, postoperative morbidity/wound complication rate of 10% to 20%, prolonged hospital stay/outpatient care, and patient discomfort. De novo stenosis in vein grafts may also occur in 30% to 40% of patients in the first 2 years, which may necessitate graft surveillance or reintervention. Other systemic complications may occur (e.g., cardiac, pulmonary, and renal).

Recently, endovascular therapy has been advocated as an alternative to open bypass. Several studies analyzing outcomes of patients with CLI treated with endovascular therapy have largely been retrospective single-center with significant heterogeneity. The OLIVE registry, a multicenter prospective study, analyzed the outcomes of endovascular therapy for infrainguinal disease in 314 patients with CLI, which showed a 12-month amputation-free survival of 74%, whereas 34% of patients required reinterventions (endovascular, 31.7%, and bypass surgery, 2.6%). These results were satisfactory in these high-risk patients (71% diabetics and 52% on hemodialysis)

and with severe anatomic disease (42% below the knee lesions and >50% TASC types C and D).

OUR CLINICAL EVALUATION/IMAGING

A thorough history and physical examination is important. Cardiovascular risk factor identification is critical, which includes cigarette smoking, hypertension, diabetes, dyslipidemia, etc. In general, the patient's clinical symptoms and a thorough pulse examination should facilitate in diagnosing PAD. Femoropopliteal occlusive disease can be asymptomatic or present with intermittent claudication or limb-threatening ischemia (rest pain and/or trophic changes, e.g., ulceration or gangrene). Claudication (from the Latin word *claudicare*, which means "limping") generally manifests as crampy achy pain in the calf precipitated by walking that occurs at a reproducible distance, relieved with rest, and the location of pain is almost one joint distal to the occlusion. Once the clinical diagnosis is made, noninvasive vascular laboratory can be helpful in confirming the diagnosis and localizing the disease. The most common testing is obtaining the ankle-brachial index (ABI), which can be combined with color duplex scanning of the lower extremity. The ABI is generally calculated as the ratio of the higher systolic pressure in the arm divided by the highest systolic pressure at the ankle, whether the dorsalis pedis or the posterior tibial artery. A normal ABI is generally around 1 ± 10%; an ABI of <0.9 is diagnostic of PAD. It is generally believed that ABI between 0.4 and 0.9 is present in patients with claudications, while an ABI below 0.4 is compatible with rest pain or tissue loss. An ABI >1.2 may be indicative of arterial calcification, which is seen in diabetics and end stage kidney disease (CKD). Some believe that, in these patients, an ABI can be >1.3 to 1.4. Patients with vasculogenic claudication will also show an ABI drop when the patients walk to the point of calf claudications using treadmill testing. If ABI is >1.2 to 1.3, particularly in diabetics or in patients with CKD, obtaining Doppler toe pressures and/or pulse volume recordings might be helpful. A toe-brachial index (TBI) of <0.7 is indicative of significant disease. Color duplex ultrasound is also available in many of the vascular laboratories, where B-Mode imaging and color flow Doppler sampling will determine the location and severity of the disease, including occlusion, which will facilitate proper treatment (i.e., open or endovascular therapy). For patients who need invasive therapy, further imaging is obtained to show both inflow and outflow arteries (e.g., contrast CTA or MRA if CTA is contraindicated). However, if endovascular therapy is anticipated, contrast arteriography might be all that is needed to minimize cost.

TREATMENT

Conservative/Medical Therapy

It is offered to patients with nondisabling claudications or even as an initial step for patients with disabling symptoms. It includes risk factor modifications (e.g., smoking cessation, dietary and pharmacologic therapy) to include statin to lower density lipoprotein cholesterol and triglyceride for treatment of hypertension and diabetes. They should also be given aspirin to reduce the risk of cardiovascular morbidity and mortality. Cilostazol (a phosphodiesterase inhibitor) may provide symptomatic improvement in certain patients with claudication. Exercise programs have been advised to improve walking distance. Supervised exercise programs are more effective than unsupervised. However, if an unsupervised program is initiated, it should be performed at least three times a week for a duration of 30 to 45 minutes, and patients should be encouraged to do it to a point where the claudication symptoms appear. Medical treatment is not the first line of therapy for patients with CLI.

Open Surgical versus Endovascular Therapy

The decision to perform open surgical therapy versus endovascular therapy should be based on several factors including patient's age, severity of ischemia, long-term prognosis, and anatomic complexity. To many, open surgical therapy is still considered the gold standard for patients with ischemic rest pain or tissue loss. However, for many others, endovascular therapy has been advocated as initial therapy. The classification of arterial lesions established by the Trans-Atlantic Inter-Society Consensus for the Management of PAD (TASC II) may be helpful in choosing the appropriate therapy (Fig. 1). It is agreed upon that endovascular therapy is preferable for Type A, B, and C lesions; however, Type D lesions are treated mostly by an open

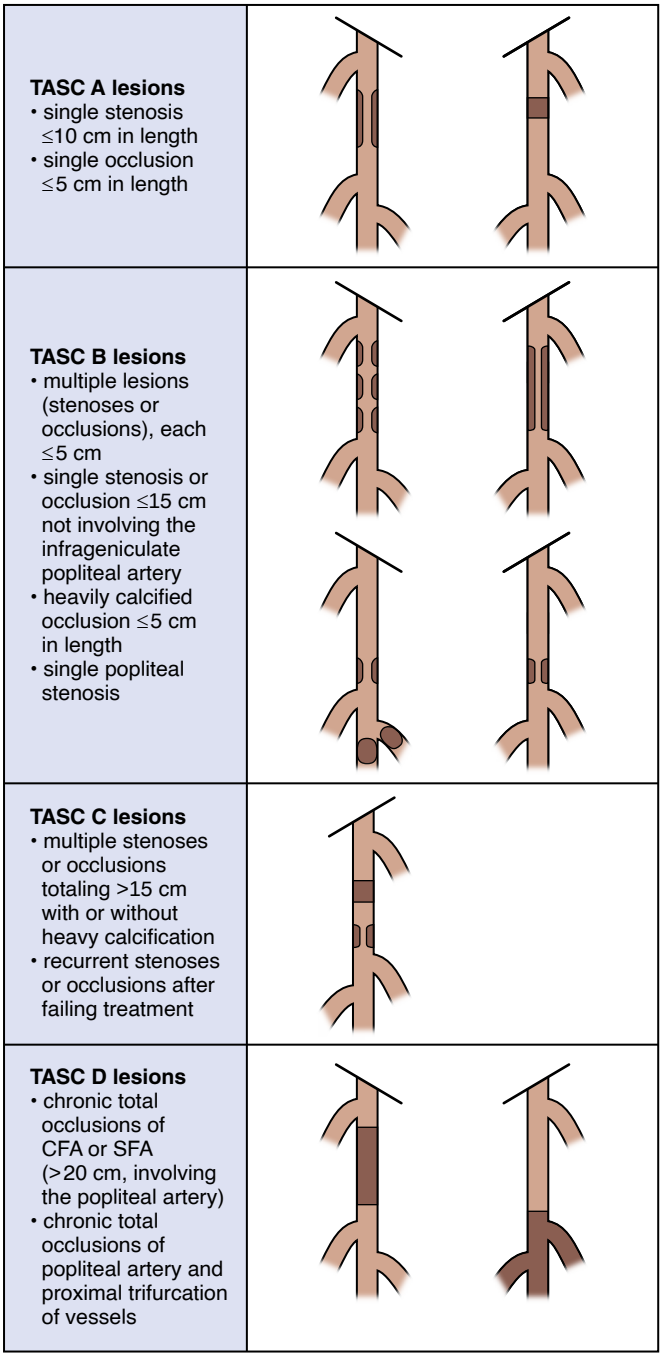

FIG. 1 Treatment of choice for femoropopliteal disease: endovascular vs. open (according to TASC classification). *(From Norgren L, Hiatt WR, Nehler MR, et al., on behalf of the TASC II Working Group. Inter-Society Consensus for the Management of Peripheral Arterial Disease [TASC II].* Eur J Vasc Endovasc Surg. *2007;33:S1–S75.)*

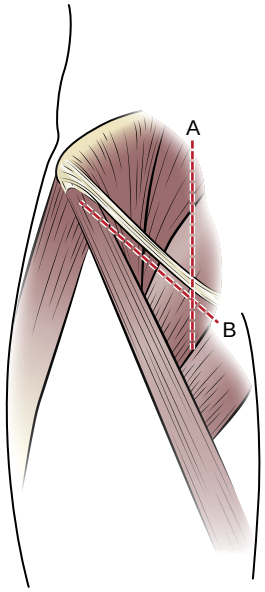

FIG. 2 Groin incision can be done either as vertical *(A)* or oblique *(B)* just above the crease.

surgical bypass. However, some authorities recommend endovascular therapy even for Type D lesions as initial therapy with open bypass if it fails.

Open Surgical Therapy

FPBP is the procedure of choice, which involves a bypass of the occlusive disease with or without endarterectomy of the common femoral artery (CFA), if needed. For successful bypass, adequate inflow site (aortoiliac), outflow vessels, and conduit are needed. The proximal target should be the CFA; however, the superficial femoral artery (SFA) or the proximal profunda can be used with caution. The distal target site can be an above- or below-knee popliteal segment or the tibial vessels. The groin incision can be done either as vertical or oblique just above the crease (Fig. 2). Vertical incision is preferable if common femoral endarterectomy or profundoplasty is needed. A good outflow vessel should be the least diseased with continuous flow to the foot. Every effort should be made to revascularize the target artery that supplies the area if ulceration is present (Fig. 3) based on the angiosome concept.

Exposure of Above- and Below-Knee Popliteal Artery

The above-knee popliteal artery is exposed with a longitudinal incision placed along the anterior border of the sartorius muscle in the distal thigh (Fig. 4). Incision is deepened through subcutaneous tissue in the muscular fascia between the vastus medialis anteriorly and sartorius posteriorly. The adductor hiatus is identified to expose the popliteal artery emerging from the distal SFA. The artery lies medial to its accompanying vein upon entering the vascular sheath. Small branches of the popliteal artery should be handled carefully and not divided to minimize compromising leg circulation if the graft fails. To expose below-knee popliteal artery, the incision is positioned below the knee along the medial aspect (Fig. 4). If this was anticipated before vein harvest, the same below-knee incision for vein harvest can be used. This incision is generally placed one fingerbreadth posterior to the tibia and carried through the fascia. The gastrocnemius muscle is identified and retracted posteriorly to expose the popliteal space. Further, proximal exposure of the popliteal artery/space may be obtained by dividing the tendinous attachment of the sartorius, gracilis, and semitendinosus muscles. For distal grafting to individual tibial vessels, the dissection should continue by detaching some of the soleus muscle fibers, which will expose the tibioperoneal trunk, posterior tibial, and peroneal artery. The anterior tibial artery is generally identified once this process is done.

The Conduit of Choice

Autogenous vein has been the first choice for all infrainguinal bypasses. The great saphenous vein is the preferred choice and should be evaluated with preoperative duplex vein mapping. If this vein is inadequate, a mapping of alternative veins including a lesser saphenous, contralateral greater saphenous vein, and upper arm veins (basilic and cephalic arm) is done. The vein should be nondiseased and at least 3 mm in diameter. Vein bypasses can be placed in a reversed, nonreversed, or in situ configuration. Both reversed and nonreversed vein bypasses have similar patency, particularly for above-knee positions. The in situ is reserved for the distal popliteal artery or tibial vessels because of better matching between the arteries and the vein. Other conduits have been used (e.g., PTFE or Dacron), with or without heparin bonding, with no clear superiority of one over the other. Cryopreserved and human umbilical veins might be used with a similar patency as a prosthetic graft; however, they are expensive and used only in exceptional cases.

Vein Harvest/Bypass Technique

Vein harvest is generally done with several long anterior incisions with skip incisions, which we prefer, versus a continuous long incision. Endoscopic vein harvest can also be done; however, comparative result with open vein harvest has been unsatisfactory. The incision is extended distally along the path, which is marked at the time of preoperative vein mapping or using a bedside ultrasound machine. Vein harvest must be meticulous to minimize damage to the vein. A vessel loop can be used to retract the vein from side to side and help identify all side branches, which should be tied 1 to 2 mm away from the vein to minimize kinking or narrowing of the vein. Once the vein is removed, gentle dilatation with heparinized saline solution is done. Every effort should be made to minimize the time of the harvested vein from not being perfused with the patient's blood. We generally prepare the vein just after exposing both proximal and distal inflow and outflow arteries, so once the vein is harvested, it is ready to be used. For in situ use, the vein is spatulated, and if nonreverse or in situ, the most proximal valve is excised with direct vision. The end-to-side anastomosis is created with 5-0 or 6-0 polypropylene suture. Flow is then restored into the bypass. Valvulotome (LeMaitre) is then used and inserted from the distal end where the remaining valves are gently cut. If the bypass is done in reverse fashion, a tunneler is used, which is inserted just deep to the sartorius muscle and superficial to the SFA; for below-knee popliteal artery bypass, the graft is inserted from above- to below-knee with the index finger creating a tunnel between the heads of the gastrocnemius muscle to prevent compression.

Once the tunnels and conduit are prepared, the patient should be heparinized with 80 to 100 U/kg intravenously. A few minutes later, the procedure starts by occluding the CFA, profunda femoral and SFA, and any other branches. A longitudinal incision is made in the CFA with a #11 blade and extended using angled Potts scissors. Using double-armed 5-0 or 6-0 polypropylene sutures, the proximal anastomosis is done bidirectionally. The vein is allowed to distend with blood after loosening the vascular loops. It is then marked along one side to maintain orientation and prevent vein twisting. Once the vein is tunneled distally, the distal anastomosis is performed in a similar fashion using 6-0 polypropylene sutures (Fig. 5).

It is generally recommended to have completion duplex imaging to assess both proximal and distal suture line, including the conduit. However, completion contrast angiography can be used if there is any

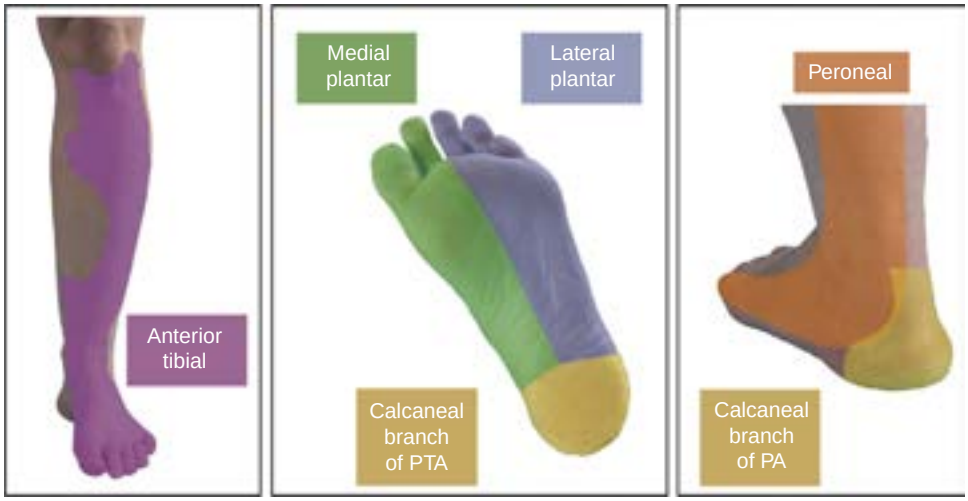

FIG. 3 Angiosome concept. Six angiosomes of the foot and ankle are supplied by three main arteries. *Left,* The anterior tibial artery (ATA) becomes the dorsalis pedis artery that supplies the dorsum of the foot and dorsum side of the toes. *Middle,* Three main branches of the posterior tibial artery (PTA) supply distinct portions of the sole: the calcaneal branch to the heel, the medial plantar artery to the medial foot, and the lateral plantar artery to the lateral midfoot and the forefoot. The PTA supplies the plantar side of the toes, the web spaces between the toes, the sole of the foot, and the inside of the heel. *Right,* The peroneal artery (PA) supplies the lateral border of the ankle and the outside of the heel. *(Iida O, Soga Y, Hirano K, Kawasaki D, Suzuki K, Miyashita Y, Terashi H, Uematsu M. Long-term results of direct and indirect endovascular revascularization based on the angiosome concept in patients with critical limb ischemia presenting with isolated below-the-knee lesions.* J Vasc Surg. *2012;55:363–370.e5.)*

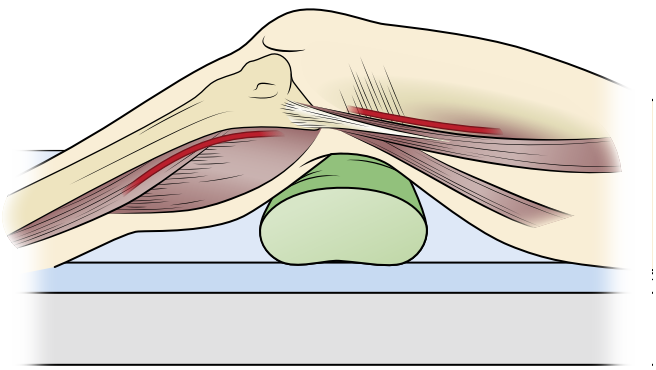

FIG. 4 Exposure of above- and below-knee popliteal artery.

question concerning the technical results. It is critical to evaluate the distal pulses by palpation and the use of continuous wave Doppler. The groin is then closed with multiple layers of absorbable sutures. The skin is closed as usual.

Perioperative Management

Medications are started, including statin and β-blockers. All patients are given one aspirin daily, which continues indefinitely. A soft cast or compression garment is applied on postoperative day 1 and is applied from the knee down. Physical therapy is generally started to help patient's ambulation, and discharge is usually done within a few days postoperatively.

Postoperative Graft Surveillance

There is strong evidence that vein graft surveillance is effective in maintaining graft patency. We generally obtain a first follow-up duplex scan before discharge or, if not feasible, on the first visit to the vascular clinic. If a bypass is normal, then the patient is checked every 4 to 6 months for 24 months and then yearly thereafter. It is believed that nearly one-third of vein grafts will develop lesions, which may threaten patency. Loss of graft patency within the first 30 days implies to a technical factor. Graft failure or impending failure within the first 2 years is secondary to myointimal hyperplasia and after 2 years is due to progressive atherosclerosis. The following noninvasive findings may indicate impending or failing graft: (1) a focal elevated peak systolic velocity >300 cm/s; (2) a peak systolic velocity ratio of ≥3 to 4 in comparison to an adjacent normal segment; (3) a low-flow velocity of <40 cm/s; and (4) a drop of ABI of ≥0.15 from the previous one. Intervention on these failing grafts can be done by open revision or endovascular means.

Femoropopliteal Bypass Using Prosthetic Conduit

Both PTFE or Dacron with heparin bonding has been utilized in this location, particularly when above-knee. The technical aspect is similar to what was described earlier without the need for vein harvesting. Conduit diameter used is generally between 6 to 8 mm; however, we prefer 8 mm conduit for an above-knee location. FPBP below-knee using prosthetic grafts is generally not recommended because of poor patency and is only utilized as a last option.

We previously conducted a prospective controlled study of PTFE grafts versus saphenous veins in disabling claudicant patients with bilateral AK-FPBP in 43 patients (86 limbs) who had SFA occlusion and above-knee reconstitution with 2 to 3 vessel runoffs. Patients were treated on one side with PTFE and on the other side with SVG. They were sequentially assigned to PTFE-SVG alternating with SVG-PTFE. All patients were followed using duplex ultrasound and ankle/brachial indexes at 1 month and every 6 months thereafter. The perioperative complication rates were 5% for PTFE and 12% for SVG. There was no operative death or perioperative amputation for either procedure. The Kaplan-Meier estimate of primary, assisted primary, and secondary patency rates at 72 months were 68%, 68%, and 77% for PTFE and 76%, 83%, and 85% for SVG, respectively.

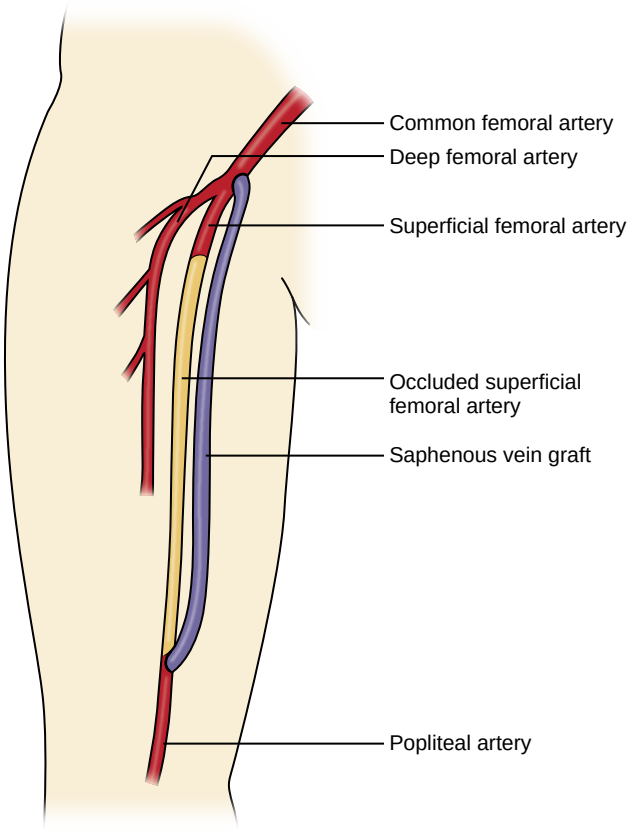

FIG. 5 Bypass done in reverse fashion.

There were no statistically significant differences between primary and secondary patency rates for both grafts; however, the assisted primary patency rates were higher for SVG (P <.05). The crude limb salvage rate at 72 months was 98% for PTFE and 98% for SVG. We concluded that PTFE and SVG for above-knee bypasses have comparable patency and limb salvage rates in claudicant patients with bilateral SFA occlusion and 2 to 3 vessel runoffs. This may justify the use of PTFE for above-knee locations in these selected patients.

Result of Open Surgical Bypass

Several studies compared the result of autogenous vein versus prosthetic FPBP in both above- and below-knee locations. A recent meta-analysis showed that SVG were superior to prosthetic bypasses in both above- and below-knee locations. However, as indicated earlier by our experience, some authorities believe patients who are claudicant and needed only above-knee FPBP who had good runoff (2–3 vessels) might be better off served by the use of PTFE or a prosthesis with the understanding the vein can be saved for future use for below-knee or distal vessels. If autogenous veins were not available for below-knee locations, a PTFE graft with distal anastomotic vein cuff has been suggested to be superior to prosthetic distal anastomosis alone (Table 1).

ENDOVASCULAR THERAPY FOR FEMOROPOPLITEAL DISEASE

Current endovascular therapy includes percutaneous transluminal angioplasty (PTA) stenting, cutting PTA, atherectomy, covered stents, drug-coated balloons/stents, and cryoplasty. The following is a review of the commonly used modalities.

TABLE 1 Graft Patency, Aggregate of Multiple Studies

	Supragenicular Femoropopliteal Bypass			Infragenicular Femoropopliteal Bypass			Femorotibial Bypass		
Type of bypass	**1 y**	**3 y**	**5 y**	**1 y**	**3 y**	**5 y**	**1 y**	**3 y**	**5 y**
SAPHENOUS VEIN									
Primary patency	86%	79%	75%	86%	83%	71%	82%	72%	69%
Secondary patency	89%	83%	80%	82%	87%	83%	88%	79%	79%
Limb salvage	82%	80%	81%				94%	87%	89%
Survival	86%	81%	70%		68%	74%	85%	69%	60%
PTFE									
Primary patency	80%	58%	53%	74%	53%	44%	60%	40%	24%
Secondary patency	87%	65%	70%	69%	48%	46%	65%	47%	28%
Limb salvage	86%	79%	72%	74%	71%	63%	75%	69%	57%
Survival	86%	81%	70%			42%	74%	55%	40%
DACRON									
Primary patency	79%	67%	62%	74%	46%	51%			
Secondary patency	88%	75%	75%						
Limb salvage		94%							
Survival	87%	77%	77%	86%		60%

Angioplasty/Stenting

The principle of angioplasty is balloon dilation of the reference lesion by inflating the balloon (to several atmospheric pressures) and cracking the plaque. PTA is considered by many to be a controlled dissection. PTA has a favorable outcome in larger caliber arteries, stenosis rather than occlusion, short, and focal rather than multiple with good runoff. PTA has a better result when the indication is claudication rather than CLI.

Technical Consideration

It starts by obtaining arterial access, then identifying the lesion with diagnostic arteriography, followed by crossing the lesion with a guidewire, balloon angioplasty, with or without stenting, and completion angiography to evaluate the result. The contralateral CFA is preferable arterial access; however, in certain thin patients, the ipsilateral CFA may be used for antegrade access. The brachial artery may be used occasionally, particularly in patients with previous aortobifemoral artery bypass graft. The access is either obtained by conventional standard 18-gauge puncture needle or a micropuncture small catheter access needle. Once an access is obtained, a 0.035-inch guidewire can be advanced into the iliac system and then the aorta using a contralateral catheter, and access is obtained to the ipsilateral iliac, CFA, then the SFA/popliteal artery through the lesion. To facilitate the intervention exchanging the access (5Fr 10-cm sheath) for a longer 45 to 55 cm (5Fr or 6Fr sheath), which is positioned at the level of the external iliac or CFA on the side of the intervention, which facilitates wire and catheter support. Spot angiography is used to delineate the lesion. The size and length of the balloon is tailored to the size and length of the artery. Every effort should be made to avoid ballooning a healthy native artery. After completion of angiography, if more than 30% residual stenosis exists or if angioplasty has created a dissection (with significant impairment of the flow), then a self-expanded stent should be placed across the lesion. We prefer giving 3000 to 5000 units of Heparin, which is administered intravenously at the start of the procedure once access is achieved. All patients should already be on aspirin regimen for intervention, which is continued afterward, in addition to clopidogrel (Plavix), which is prescribed for 6 weeks after PTA. PTA after stent placement is usually necessary for complete expansion of the stent.

Crossing an occlusion can be accomplished with several techniques. An angle support catheter in combination with a straight, stiff hydrophilic wire is generally used initially to traverse total occlusion. A combination of the support catheter and hydrophilic guidewire allows crossing many of these total occlusions. However, if that is not successful, other maneuvers might be utilized including subintimal traversal if necessary. This can be achieved by passing a hydrophilic angle guidewire into the subintimal plane with a loop orientation. Using catheter support, the loop is shortened to provide a smaller profile to reenter the luminal space. If that is not successful, reentry into the lumen may be done using a reentry catheter (e.g., the Pioneer or the Outback).

It is generally not recommended to stent the popliteal artery since it is highly mobile and because of its location across the joint, which may lead to stent fracture and higher restenosis rate. Therefore, stenting in this location should be done in select patients. Use of Supera stent by Abbott has been associated with favorable results in this location.

Once the procedure is done, the arterial access site can be closed using a variety of closure devices based on the size of the access sheath and the state of the access vessel (particularly calcification). Manual pressure may be appropriate for smaller access sheath and certain calcific lesions.

PTA for CLI can achieve a 5-year limb salvage rate of 89%, similar to earlier reported values with surgical revascularization, which ranged from 70% to 80%. Although the primary patency after PTA for CLI may be low, the limb salvage rate is quite high. SCVIR Transluminal Angioplasty and Revascularization (STAR) registry analyzed 205 patients (79% with stenosis and 11% with occlusions were treated) with mean lesion length of 3.8 cm for stenotic lesions and 4.7 cm for occlusions. The technical success rate was 95%. The primary patency rates were 87%, 80%, and 69% at 1, 2, and 3 years, respectively. Diabetes and poor runoff scores were associated with decreased patency rates.

The use of stents was initially advanced to improve long-term patency rates from PTA, especially in longer-segment disease. Stenting may reduce elastic recoil and provide a scaffold in the setting of dissection. Initial study results were disappointing, with several randomized trials failing to show any benefit of stent placement over PTA alone. These findings led to the recommendation for stenting only in the setting of a suboptimal technical result following PTA. However, these studies were done using balloon-expandable stainless steel stents, and more recent studies using self-expanding nitinol stents have shown significantly better results. Three major randomized trials comparing primary nitinol stent placement with stent-assisted angioplasty have been reported and show differing results.

The Femoral Artery Stenting Trial (FAST) analyzed outcomes with stand-alone PTA versus primary stenting with a single self-expanding nitinol stent. Only single short-segment lesions of <10 cm were included, with a mean lesion of 45 mm for both groups; 123 patients were assigned to primary stenting and 121 were randomized to PTA alone. Technical success was achieved in 79% of the PTA group versus 95% of the stenting group. Restenosis rates at 1 year, as determined by ultrasound, were not significant (39% in PTA, 32% in stent). Maximal walking distance was slightly improved in the stenting group, but there was no difference in resting ABI or change in Rutherford class. Stent fractures were found in 12% of patients, with no significant increase in restenosis with the presence of fractures.

The RESILIENT Trial is a prospective multicenter trial of 234 patients that compared bare nitinol stents (LifeStent, C. R. Bard) in patients with a mean lesion length of 7.1 cm to PTA patients with a mean lesion length of 6.4 cm. Forty percent of patients with PTA had bailout stent for >30% residual stenosis or dissection. This study suggested a statistical advantage of improved patency with stent over PTA alone. The technical success rate was better with stenting (96% vs. 84%). Freedom from target lesion revascularization was better in the stent group than the PTA group at 6 and 12 months: 94% and 81% versus 47% and 37%, respectively. The stent fracture rate was 3% at 12 months and was not associated with any adverse clinical sequelae. The study showed continued advantages of bare metal stents versus PTA at 3-year follow-up. The authors concluded that, for moderate length lesions, primary stent placement is superior to PTA alone.

The ABSOLUTE Trial (Balloon Angioplasty versus Stenting with Nitinol Stents in the SFA) included 104 patients with severe intermittent claudication and/or tissue loss (Rutherford classes 3–5) with lesions longer than 30 mm. Patients were randomized to PTA plus optional stenting or primary stenting. Mean target lesion length was 112 mm for the stent group and 93 mm for the PTA group. Restenosis rates were significantly lower in the primary stenting group at 2 years (46% vs. 69%). There was no difference between the two groups with respect to Rutherford class upon follow-up, but there was a trend toward improved walking capacity and resting ABI in the stent group. Overall, reintervention rates were lower in the primary stent group.

Challenges in Stenting SFA/Popliteal Lesions

The SFA and popliteal arteries, unlike other arteries, are subject to triplanar intermittent mechanical stresses, including contraction, extension, torsion, flexion, and compression. The efficacy of stents in this location is limited by the fact that they can only deform to a limited extent to stresses exerted on the artery. This lack of flexibility and resistance to stress may induce stent fractures and promote poorer patency.

Cutting Balloon Angioplasty

Cutting ballon angioplasty uses low-pressure balloon catheters mounted with microsurgical blades or microtomes that cut into luminal vessel during inflation. The mechanism of action is controlled disruption of the vessel wall, resulting in more controlled dilatation at lower balloon inflation pressures.

A prospective randomized controlled trial of *de novo* SFA lesions of 43 patients (19% had CLI) compared cutting balloon PTA versus conventional PTA and showed a restenosis rate of 32% in PTA and 62% in the cutting balloon PTA group at 6 months ($P = .048$). Therefore, cutting balloon PTA is not routinely used due to higher costs and inferior results but can be used for in-stent restenosis and diseased arteries in flexion points (CFA or popliteal artery–stent fracture risk).

Atherectomy

Atherectomy involves debulking or atherosclerotic plaque removal. Current devices for this modality include rotational, directional, orbital, and laser atherectomy. Atherectomy for PAD patients is currently used as adjunctive/alternative therapy to traditional PTA or stenting. Plaque debulking leads to an immediate increase in lumen size, which should result in reduced stretch injury of the arterial walls. One potential complication is embolization, although the TALON registry reports a very low embolization rate (0.1%).

The DEFINITIVE Ca++ study included 133 patients with calcified femoropopliteal lesions treated with the Silverhawk or Turbohawk (Covidien) and distal embolic protection. They reported a 93% freedom from major adverse events, which included clinically significant embolization. However, the definitive clinical benefit of atherectomy over PTA was not clear. Larger prospective multicenter trials are needed to highlight the role of atherectomy in femoral popliteal arterial disease.

Covered Stents

Stent-grafts using endovascular techniques attempt to duplicate open prosthetic FPBP. The Viabahn stent-graft (W.L. Gore & Associates, Inc.) consists of a self-expanding nitinol stent bonded to a graft made of expanded PTFE. They perform well in long segment occlusions and SFA restenosis; however, appropriate sizing and adequate runoff are required for optimal outcome and also dual antiplatelet therapy for at least 6 months.

The VIASTAR Trial (Viabahn Endoprosthesis) with Propaten Bioactive Surface versus Bare Nitinol Stent in the Treatment of Long Lesions in SFA Occlusion studied 141 patients randomized to Viabahn or bare metal stents. The 1-year patency rate was higher with long lesions (>20 cm) with covered stents versus bare metal stents (71% vs. 37%, $P = .01$). The Viabahn stent was then modified, and heparin was bonded to the stent. This was examined in the VIPER trial for the treatment of SFA occlusion where the primary and secondary patency rates were improved to 73% and 92%. Lammer et al. reported that PAD patients with long femoral popliteal lesions had significantly improved primary patency rates with covered versus bare metal stents at 24 months; however, there was no significant impact on clinical outcomes and target lesion revascularizations.

Drug Eluting Balloons and Stents

Drug-coated angioplasty balloons (DCB) and drug-eluting stents (DES) are designed to limit the proliferative, reactionary process of neointimal hyperplasia. DCBs were developed to improve the durability of PTA, without the potential drawbacks of stents. It has been hypothesized that stents may actually increase neointimal hyperplasia by causing repetitive trauma and an increased inflammatory reaction. DCBs are designed to curb neointimal hyperplasia by delivering large doses of anticell proliferation agents directly to the site of vessel injury.

Paclitaxel is a proven antiproliferative drug that stops cell division and induces apoptosis. The IN.PACT Admiral DCB coating consists of paclitaxel and urea, a carrier molecule. When exposed to blood during inflation, the urea hydrates and releases paclitaxel. Subsequently, the drug transfers into the wall of the artery and migrates through the vessel wall into the media. The IN.PACT Admiral DCB delivers paclitaxel in solid-phase, thus establishing reservoirs of drug within the vessel wall. These reservoirs permit sustained drug availability (up to 6 months) and release with subsequent long-term antiproliferative effect.

There are several ongoing studies of paclitaxel DCBs in *de novo* and restenotic femoral popliteal lesions. Using DCBs to treat in-stent restenosis is preferred over placing additional stents because additional overlapping stents are associated with a higher rate of stent fracture and restenosis. Currently, there are two DCBs approved for use in the United States, Lutonix 035 (Bard) and IN.PACT Admiral (Medtronic). The majority of clinical trial data on DCBs has predominantly included patients with claudication and lower Rutherford classifications, as opposed to CLI patients. Late lumen loss, target lesion revascularization, and angiographic restenosis significantly favored DCBs in these trials.

FDA approval of the Ranger balloon was based on a Ranger SFA trial that was a randomized controlled trial of 105 patients with 3:1 ratio of DCB vs. plain balloon angioplasty over a 12-month period for patients with Rutherford class 2–4. Mean lesion length was 82.5 mm for the Ranger DCB group and 79.9 mm for the control group. DCB group had a patency rate of 86.4% versus 56.5%, and the estimated freedom from target lesion revascularization was 91% in the DCB group versus 69.9% in the control group with a significantly longer time to reintervention.

In our group, we analyzed 228 patients with femoral and popliteal disease treated with DCB angioplasty. Forty percent of patients had claudication (Rutherford Stage 2–3) and 60% were classified as CLI (Rutherford Stage 4–5). Mean follow-up was 12 months. Primary patency rates were 82% and 71% for 1 and 2 years in patients with TASC A-C lesions vs. 29% and 14% for TASC D lesions. Symptom improvement was 76% for claudication vs. 49% for CLI. Limb salvage rates at 1 and 2 years were 100% for claudicants vs. 85% and 74% for CLI.

The LEVANT Trial (Lutonix Paclitaxel CB [Bard] for Prevention of Femoral Popliteal Restenosis) randomized 101 patients to Lutonix DCBs or uncoated balloons. There was a significant increase in primary patency at 12 months with the Lutonix 035 DCB versus plain balloon angioplasty (74% vs. 57%, $P < .001$). At 24 months, the major adverse events (death, amputation, target lesion thrombosis/reintervention) were 39% for DCB and 46% for uncoated balloon patients ($P = .45$). It should be noted that the results of DCBs have not been encouraging for below-knee vessels. The IN.PACT DEEP study identified a potential safety signal with a trend toward an increased rate of major amputations in the DCB study arm.

Medtronic's IN.PACT SFA trial is a prospective, multicenter, randomized trial in which 331 patients with intermittent claudication and CLI, secondary to femoral popliteal PAD, were randomly assigned in a 2:1 ratio to treat with DCB (Paclitaxel) or PTA. Over 90% of lesions were *de novo*, with a mean lesion length of ≥8 cm in both groups. A higher primary patency at 12 months in the IN.PACT Admiral DCB group was noted, compared with the PTA group (82% vs. 52%, $P < .001$). The rate of clinically driven target lesion revascularization was 2.4% in the DCB group versus 20.6% in the PTA group ($P < .001$). There was no device/procedure related death or major amputation.

The THUNDER trial followed 154 patients who were treated with DCBs, angioplasty with paclitaxel in contrast medium, or no paclitaxel (control group) for 5 years. The target lesion revascularization was significantly lower in the DCB versus the control group (21% vs. 56%, $P = .0005$). DCBs also had lower binary restenosis (17% vs. 54%, $P = .04$). DCBs had reduced target lesion revascularization over 5 years.

Limitations of DCB

The use of cytotoxic agents, such as paclitaxel, may have an adverse impact on wound healing. Furthermore, patients with PAD,

especially those with CLI, often present with calcified plaque, which is difficult to treat and is often associated with poor procedural and long-term success. Preparing the vessel with atherectomy before using DCBs is a strategy that may hold some promise in improving the therapeutic effect of DCBs in calcified lesions.

Concern for increased risk of cardiac death from paclitaxel led to a multicenter, randomized, open registry-based clinical trial of 2289 patients published in the *New England Journal of Medicine* that randomly assigned patients to drug-coated device vs. an uncoated device. Patients had peripheral vascular disease ranging from claudication to chronic limb ischemia. Endpoint was all-cause mortality.

Patients with chronic limb ischemia during the entire follow-up showed incidence of death of 33% in the drug-coated group versus 33% in the uncoated drug group. Among claudicants, rates were 10% versus 9% subsequently.

During follow-up of 1 to 4 years, there was no difference in all-cause mortality of drug-coated versus uncoated device.

Drug-Coated Stents (DCS)

SIROCCO I and II Trials: Sirolimus-eluting stents (Cordis Smart nitinol self-expanding stent) were compared with bare metal stents. There was no difference of in-stent restenosis at 6 months and 2 years. However, the Zilver PTX (paclitaxel) stents (Cook Medical) proved to be safe, efficient, and superior to PTA with provisional stent placement. In a study by Dake et al. with the Zilver PTX stent, 474 patients were randomized to primary DES or PTA with provisional stents with subsequent secondary randomization to bare metal stents or DES for patients requiring provisional stents. The event-free survival at 1 year was 90% for primary DES versus 83% for the control arm ($P = .004$). The primary patency rate at 1 year was 83% for DES versus 33% for PTA alone.

Later studies with Zilver PTX stents reported a primary patency rate of 83% for DES and 65% for PTA, excluding acute PTA failure ($P < .001$). The data still supported safety and efficacy of DCS at 5 years. In a larger prospective registry of 787 patients, the 2-year freedom from target lesion revascularization with primary DES placement was 80.5% in the single-arm study. The Zilver PTX stent was also examined for the treatment of in-stent restenosis. In patients with a mean lesion length of 13 cm (31% total occlusions), procedural success was 98%, primary patency rate at 1 year was 79%, and freedom from target lesion revascularization at 2 years was 61%. Dual antiplatelet therapy is recommended for 6 months with the use of the Zilver PTX. Later 5-year data showed that DCS (paclitaxel) had better patency rates than standard PTA (66.4% for lesions 65 ± 40 mm in length) and better freedom from target lesion revascularization (85%).

More recently, the results of the Imperial Study, which was a randomized trial of comparison in patients with femoral popliteal disease comparing Eluvia paclitaxel stent (Boston Scientific) and the Zilver PTX paclitaxel stent (Crook), were reported. The trial was conducted at 65 centers randomizing 465 patients with femoral and popliteal disease in a 2:1 ratio of Eluvia versus Zilver PTX in Rutherford class 2–4. Mean lesion length was 83 cm. One-year primary patency rate was superior with Eluvia at 86.8% vs. 81.5% with Zilver PTX, a difference for noninferiority (primary endpoint) and superiority. Primary safety endpoint of major adverse events (including MALE and MACE) Eluvia was shown to be noninferior to Zilver PTX (4.9% vs. 9%).

At 24 months, target lesion revascularization was less for patients with Eluvia vs. Zilver PTX (12.7% vs. 20.1%). Primary patency rate at 24 months was 83% for Eluvia and 77% for Zilver PTX.

DCB versus DES for SFA Interventions

Lesion length, type of recanalization (subintimal vs. intraluminal), degree of calcification, and lesion site (ostial, popliteal) should all be considered when choosing a primary strategy. As a general rule, one must avoid stenting when unnecessary due to the possibility of a worse behavior of stent restenosis. It is generally recommended to use a DCB for a TASC B, C, or D lesion upon first presentation and also for restenotic lesions, as well as for in-stent restenosis in the femoropopliteal area. If significant flow-limiting dissection remains, use of a DES as a kind of bailout stent is appropriate.

Primary Amputation

Some authorities feel primary amputation may be appropriate in select patients (e.g., those with significant tissue loss who are not likely to return to ambulation and with long-standing functional impairment). Patients who are also paralyzed with contractures or have short life expectancy, severe sepsis, end-stage renal disease, or other systemic disease would be better served with primary amputation.

CONCLUSION

Based on a nearly universal procedure success rate, low morbidity and mortality, and improving patency rates with new devices, endovascular therapy is the recommended treatment of choice for TASC A–C lesions, although open surgical bypass with ASV grafts is a durable choice in low-risk patients. Two new studies, BASIL-2 and -3 and BEST-CLI, are enrolling patients to further compare open versus endovascular therapy for selected patients with CLI. Until more well-designed randomized trials are completed, physicians should rely on their best clinical judgment.

Tibioperoneal Arterial Occlusive Disease

Natalia O. Glebova, MD, PhD

Approximately 8 to 12 million people suffer from peripheral arterial disease (PAD) in the United States, which rivals the prevalence of coronary artery disease. In 2001, US Medicare spent more than $4.3 billion on PAD treatment, and an estimated $21 billion was spent in the United States on vascular-related treatment, with the majority being treatment for PAD. PAD is a systemic inflammatory process that affects the entire arterial tree; however, the anatomic patterns of distribution are associated with specific patient demographics, medical risk factors, and symptoms. The symptoms of PAD are caused by inadequate blood flow to a skeletal muscle bed due to a more proximal flow-limiting arterial stenosis or occlusion. Claudication (from the Latin *claudico*, meaning "to limp") is defined as pain in the thigh or calf muscles with exercise that is relieved at rest. Typically, patients with claudication symptoms alone are not at a greatly increased risk of limb loss. Critical limb ischemia (CLI) occurs when there is such limited blood flow to the leg that, even at rest, the metabolic demands of the tissue are not met. CLI is characterized by pain at rest and/or tissue loss (ulceration or gangrene). Patients with CLI are at risk for limb loss if expeditious intervention to restore arterial perfusion is not performed. Patients with a predominant distribution of atheroocclusive disease in the tibial and peroneal arteries are more likely to initially present with signs and symptoms of CLI than patients with proximal femoropopliteal disease secondary to the absence of collateral vessel flow to the foot. Revascularization in these patients is often challenging due to anatomic factors, disease severity, and patient comorbidities. Patients with tibioperoneal occlusive disease (TPOD) are typically diabetic with a high prevalence of renal insufficiency compared with patients with PAD in more proximal arterial distribution. These patients are also at significant risk for vascular disease of the coronary, cerebral, and renal arteries; thus, when an intervention is planned, the surgeon must consider the patient's comorbidities to weigh the risks and benefits of the planned intervention.

PATIENT ASSESSMENT

In the assessment of a patient with TPOD, a complete history and physical examination are critical for planning treatment. This evaluation should include an assessment of the patient's functional status with regard to current ability to ambulate, the patient's expectations of therapy, risk stratification for major adverse cardiac events (MACE), as well as the patient's social and home support. The 2014 American College of Cardiology/American Heart Association (ACC/AHA) guidelines outline the recommended perioperative cardiovascular evaluation. For patients who have less than a 1% chance of MACE based on combined surgical and patient characteristics, no further cardiac workup is required. Several risk calculators are available online for convenient determination of a patient's cardiac risk, including one developed by the American College of Surgeons. Unfortunately, the majority of vascular patients and vascular procedures fall under the "elevated risk" category where there is a 1% or greater risk of MACE. If a patient has moderate or greater functional capacity defined as four or more metabolic equivalents (classically described as being able to "walk up a flight of stairs"), then no further workup is typically required. In patients with CLI, such symptomatic evaluation is often limited as patients are often unable to walk for any significant distance secondary to leg pain from critically low blood flow, and this may preclude the identification of significant cardiac disease that would become symptomatically apparent if the patient was able to walk. If a patient has poor or unknown functional capacity and the results of further testing would influence decision making or perioperative care, then pharmacologic stress testing is warranted with subsequent coronary revascularization if an abnormality is found.

A thorough examination of the leg and foot helps determine the likelihood of functional salvage. The examiner should note the patient's ability to walk, evidence of flexion contractures, or other neuromuscular disabilities that may affect ambulation. The presence of local infection, soft tissue edema, venous disease, and prior surgical incisions may influence the choice of intervention. Physical examination should also focus on the arterial perfusion of the symptomatic limb. The ankle-brachial index (ABI) is one noninvasive test used to diagnose PAD. An ABI of 0.9 or less signifies a hemodynamically significant stenosis. The ABI can be falsely elevated with calcified vessels, and if the ABI is found to be 1.4 or greater, it is likely unreliable. In this case, the toe-brachial index (TBI) may be a more accurate tool to determine the presence of PAD (a TBI of 0.7 or less is indicative of a significant arterial stenosis). CLI in general occurs at ABI <0.4 or TBI <0.5, but this is patient-dependent. The examiner should note the presence and quality of the femoral, popliteal, posterior tibial, and dorsalis pedis pulses. The quality of femoral pulses is a crucial aspect of the examination because diminished femoral pulses reveal concomitant suprainguinal occlusive arterial disease, for which an inflow revascularization procedure would be indicated. Inflow disease involving the common and external iliac arteries should be addressed before or during distal revascularization. Likewise, an atherosclerotic common femoral artery can be reconstructed with endarterectomy at the time of bypass. A palpable pulse in the popliteal artery usually indicates absence of flow-limiting proximal stenosis or occlusion in the femoral artery. This is a common finding in young diabetic patients who have disease predominantly in

the tibial and peroneal arteries. Dorsalis pedis and posterior tibial pulses are often not palpable in patients with TPOD, and Doppler assessment with a handheld probe is most helpful. Triphasic signals indicate normal arterial wall transduction of systolic and diastolic pressures; transduction signals become attenuated to a biphasic pattern with mild to moderate disease and become monophasic with severe disease. Absence of hair and presence of a shiny tone of the skin on the lower leg reflect chronic arterial insufficiency, and evidence of ulceration is a sign of severe ischemia and high risk for limb loss. Along with a thorough physical examination, preoperative laboratory tests are conducted, with particular attention to renal function, in anticipation of imaging studies with contrast materials that may be nephrotoxic.

The vascular laboratory is a crucial adjunct to the preoperative evaluation. Not only can the vascular laboratory provide ABIs and TBIs, but arterial perfusion can also be estimated from segmental blood pressures measured at the upper thigh, mid-thigh, calf, and ankle. A pressure change greater than 20 mm Hg between each segment indicates an intervening flow-limiting stenosis and is helpful to determine the level of disease. If a venous conduit is to be considered for surgical bypass, a duplex ultrasound of bilateral lower extremities should be performed to ensure that the proposed vein is adequate, with a diameter of at least 3 mm throughout its length.

Once a patient is determined to have CLI, it is imperative to plan an expeditious revascularization procedure with endovascular techniques or surgical bypass because the risk of limb loss within 1 year of diagnosis is 40%. One may assume that primary amputation is a less morbid procedure in the patient with CLI who is at high operative risk; current data reveal that the 30-day mortality rates for endovascular intervention (2%–8%) and surgical bypass (2%–6%) in CLI are similar, whereas the rate is generally higher for primary amputation (6%–12%). High-resolution imaging is essential for planning revascularization, regardless of whether a surgical or endovascular approach is being considered. While computed tomographic angiography (CTA) is excellent in evaluation for proximal arterial disease of the aorta, iliacs, and femoral arteries, it is limited in assessment of tibial disease due to the small caliber of vessels and frequent presence of arterial calcifications interfering with one's ability to distinguish between contrast and calcification. Digital subtraction angiography (DSA) with iodinated contrast material delivered via an intraarterial catheter is considered the gold standard for evaluation of TPOD. DSA image quality is not compromised by calcification of the arterial wall, and selective catheter placement in the femoral artery or distally can provide high-quality images of the tibial vessels, which can be difficult to evaluate with other modes of imaging. If a tibial bypass is planned, we recommend a diagnostic angiogram, which can be done either before the day of surgery or concomitantly with the planned bypass to verify the suitability of the bypass target. In diabetic patients and patients with renal insufficiency, nephrotoxicity of iodinated contrast material can be minimized with preprocedure and postprocedure hydration with normal saline, administration of acetylcysteine, and selection of a nonionic contrast agent. Carbon dioxide (CO_2) gas can be used as a contrast agent during angiography; imaging with CO_2 is often quite good for endovascular intervention or visualization of a potential bypass target. CO_2 can also be used as an adjunct to allow selection of the most distal artery in the treatment leg, which allows minimization of contrast injection if contrast is indeed required for adequate visualization of a tibial bypass target. Multiple-slice spiral CTA is a noninvasive technique for imaging the entire arterial tree from the abdominal aorta to the level of the foot; it provides superb spatial and temporal resolution with a single-bolus infusion of contrast agent. The accuracy of CTA in visualizing lumen patency is restricted by calcification in the vessel wall, a frequent occurrence in the tibial arteries of diabetic patients. Magnetic resonance angiography (MRA) has poorer resolution compared with CTA but is not affected by calcification. Use of gadolinium-based contrast helps increase image quality but is limited in patients with renal failure (glomerular filtration rate of 60 mL/min/1.73 m^2 or less) because of the risk of nephrogenic systemic fibrosis. Time-of-flight MR imaging can be used without contrast and can yield high quality imaging.

In the initial planning for intervention for the patient with TPOD, noninvasive testing should be performed first, which includes ABIs, segmental pressures with toe pressures, and, if abnormal, followed with arterial duplex ultrasound of the symptomatic extremity. If on physical exam the patient has symmetric femoral pulses and there is no evidence of inflow disease on noninvasive vascular studies, the next step in imaging should be diagnostic angiography for possible endovascular intervention or to obtain high-resolution images of a potential bypass target. If there is evidence of inflow disease, then a CTA or MRA of the abdomen/pelvis with lower extremity runoff should be performed. In the planning of a surgical bypass, the target artery chosen for the distal anastomosis should have continuous unimpeded flow to the plantar arches of the foot, especially in patients with tissue loss. In many diabetic patients, the peroneal artery is the only remaining patent artery below the knee; however, either the anterior branch to the dorsalis pedal artery or the posterior branch to the posterior tibial artery (ideally both) must be intact to provide perfusion to the foot as the peroneal artery terminates above the ankle. In patients with occlusion of the tibial and peroneal arteries throughout the lower leg, the plantar and tarsal arteries should be examined as possible sites for a distal anastomosis for limb salvage. In the angiosome model of revascularization, if multiple tibial vessels are available for bypass, then the artery providing the majority of flow to the wound should be revascularized. Typically, the anterior tibial artery supplies the anterior ankle and dorsum of the foot, the posterior tibial artery supplies the plantar aspect of the foot, and the peroneal artery supplies the anterolateral ankle.

SELECTION OF INTERVENTION

Patients who present only with claudication should initially be managed nonoperatively, as fewer than 5% of such patients progress to CLI and limb loss. Furthermore, arterial interventions in claudicants are associated with a three- to fourfold increased risk of limb loss as compared with medical management in a 2021 Veterans Health Administration study and should be avoided with preference given to medical treatment of claudication. Treatment should focus on cardiac risk factor modification. Patients should stop using all tobacco products, be placed on aspirin and statin if not contraindicated, and have medication adjustments for optimal blood pressure and glycemic control. A supervised exercise program of 30 to 60 minutes of exercise, such as walking three times a week, should be instituted; treatment with Cilostazol may be considered to improve exercise tolerance in claudicants.

Patients with rest pain or tissue loss should be offered prompt intervention to prevent limb loss. The primary objectives in treating patients with TPOD are to relieve pain, promote healing of ulcers, preserve a functional limb, and restore or maintain the ability to ambulate. These objectives must be tempered by the patient's general medical condition, current ambulatory status, and previous operations. In general, the success of surgical bypass depends on the availability of a single segment of autogenous vein of suitable diameter, whereas success of endovascular treatment is determined by extent of atherosclerotic disease, as quantified by the Trans-Atlantic Inter-Society Consensus (TASC) II Working Group. Infrapopliteal lesions are categorized in severity from classes A to D (Fig. 1). The Bypass versus Angioplasty in Severe Ischaemia of the Leg (BASIL) trial is the only randomized trial (452 patients) in which outcomes of surgical bypass and percutaneous transluminal angioplasty (PTA) were compared for treatment of severe infrainguinal PAD and provides level 1 evidence in the field. At 1 year, the amputation-free survival (AFS) rates were equivalent; however, at 2 years, AFS rates were better among the patients undergoing bypass. The BASIL authors concluded that bypass with autogenous vein is the best treatment for patients with severe limb ischemia expected

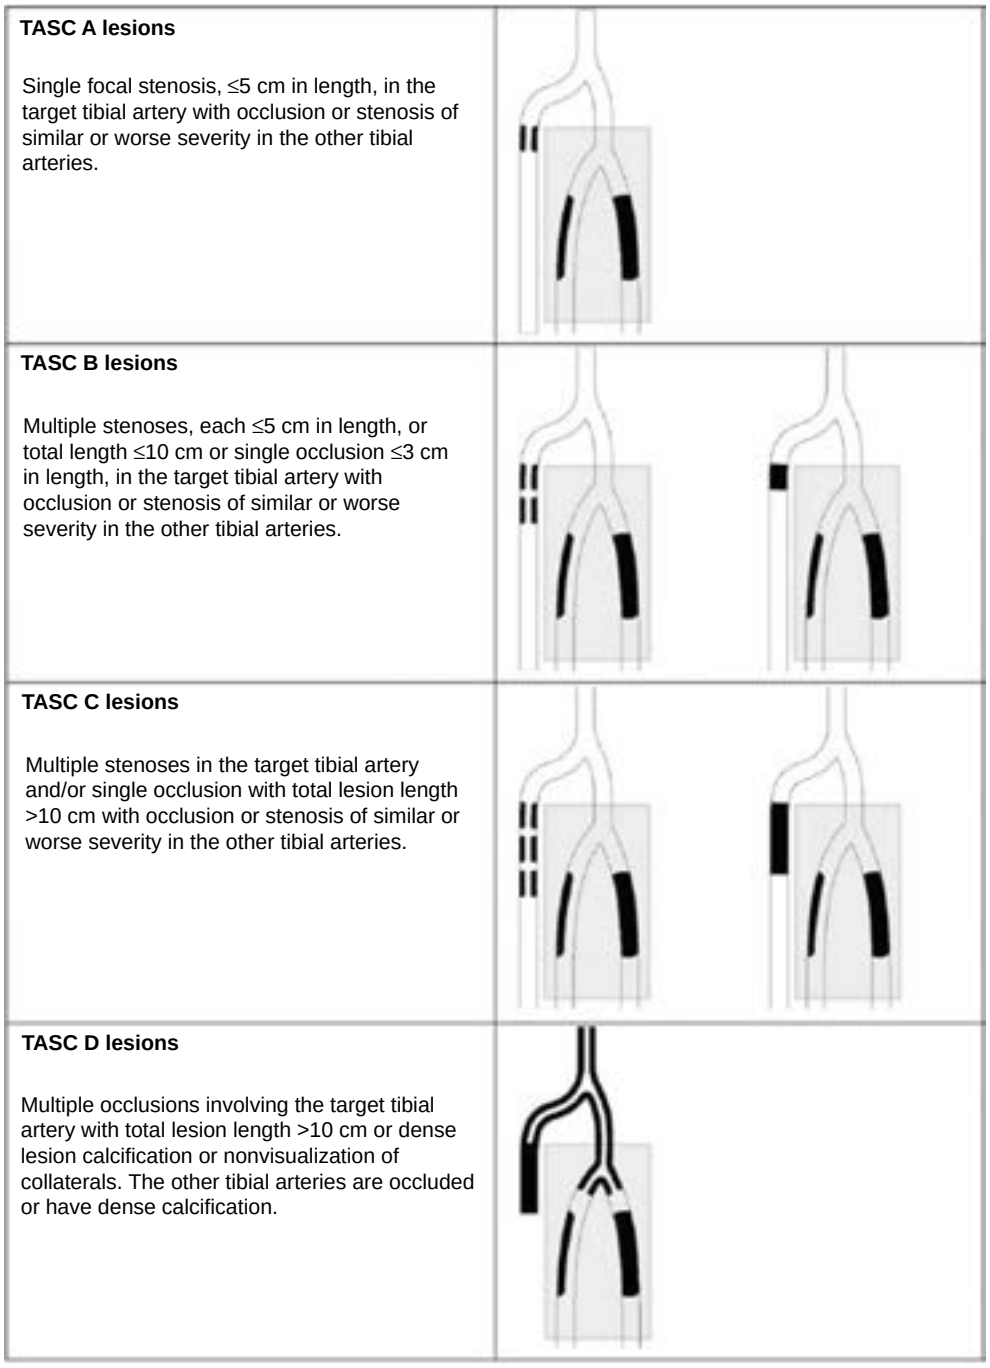

FIG. 1 Inter-Society Consensus for the Management of Peripheral Arterial Disease (TASC) classification of infrapopliteal lesions. The unshaded area represents the target lesion; area inside the shaded rectangle represents typical background disease. *(Reprinted from Jaff MR, White CJ, Hiatt WR, et al. An update on methods for revascularization and expansion of the TASC lesion classification to include below-the-knee arteries: a supplement to the Inter-Society Consensus for the Management of Peripheral Arterial Disease (TASC II).* Vasc Med. *2015;20[5]:465–478.)*

to survive more than 2 years, and bypasses with prosthetic grafts in patients without sufficient autogenous vein are associated with poor results. Endovascular interventions are the preferred option for TASC classes A, B, and single-level C lesions, whereas surgical bypass has been recommended for multilevel TASC classes C and D lesions in a patient with average surgical risk. Bypass historically has been the first choice with significant tissue loss (ulcer larger than 1 cm or gangrene involving the foot; Fig. 2). However, some patients with TASC D lesions with severe comorbidities precluding significant anesthetic administration or renal insufficiency may be better served with endovascular intervention which may have limited long-term patency but may be adequate to heal current tissue loss while minimizing short term perioperative morbidity and mortality. In fact, some studies show that endovascular-first approach is associated with improved AFS in patients with CLI, especially those with dialysis dependence, as compared with surgical bypass treatment. Much-anticipated results of the BASIL-2 and the Best Endovascular versus best Surgical Therapy in patients with Critical Limb Ischemia (BEST-CLI) may change the currently accepted choice of initial intervention in patients with CLI.

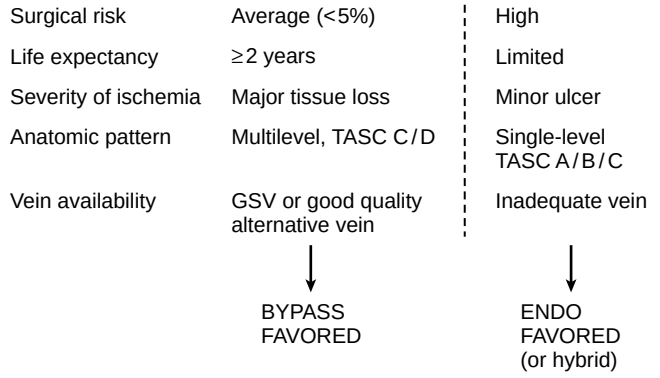

FIG. 2 Schema for bypass or endovascular treatment (ENDO). *GSV,* Greater saphenous vein; *TASC,* Trans-Atlantic Inter-Society Consensus (class). *(From Conte MS. Critical appraisal of surgical revascularization for critical limb ischemia.* J Vasc Surg. *2013;57:2.)*

SURGICAL BYPASS

All patients are maintained on aspirin before the surgical procedure. Clopidogrel therapy can be continued as well if the patient is on this medication preoperatively. Unless it is contraindicated, warfarin (Coumadin) as well as the direct oral anticoagulants (DOACs), need to be stopped several days before elective open operations. If limb ischemia is acute, however, patients are admitted and undergo systemic anticoagulation with intravenous heparin, which can be stopped en route to the operating room.

Anesthesia and Positioning

Options for anesthesia include local, epidural, regional block, and general anesthesia. We prefer general anesthesia for patient comfort, as most surgical bypasses to the tibial arteries require 4 to 6 hours, but the choice of anesthesia should be tailored to the patient and their associated risks. Regional anesthesia with epidural is another excellent choice for a higher perioperative risk patient. The patient is placed supine on the operating fluoroscopy table, and any open wounds are covered with an Ioban drape. Hair is clipped over the anticipated incision sites. We mark the course of the greater saphenous vein (GSV) on the skin using duplex ultrasonography guidance before the start of the operation to help prevent the creation of skin flaps. The skin of the lower abdomen, both groins, the operative leg(s), and feet are painted with ChloraPrep. Two Bovie electrocautery devices are used to enable simultaneous arterial exposure and vein harvest.

Operative Exposures

Inflow Vessels

The CFA is the artery most commonly used for the proximal anastomosis and is easily exposed with either a transverse incision in the groin crease or a longitudinal incision centered over the femoral pulse. We prefer to use the transverse incision as it heals better in our experience. Even when an endarterectomy of the inflow artery is necessary, we find that with appropriate retraction, exposure may be attained via a transverse groin incision such that endarterectomy from the external iliac to the common femoral artery bifurcation and even the profunda femoris (PFA) is possible. Subcutaneous dissection is performed with the help of Bovie electrocautery, and obvious lymph nodes and lymphatics are controlled with ties. The proximal CFA, PFA, and superficial femoral arteries (SFA) are circumferentially controlled with vessel loops. If conduit length is limited and there are no flow-limiting lesions in the CFA or SFA, alternative inflow sites for the proximal anastomosis include the PFA, middle and distal SFA, and the popliteal artery above and below the knee. A lateral approach to the profunda is a useful approach for inflow when the patient has a normal CFA to avoid a redo groin operation or to stay away from an infected field. Diabetic patients frequently have no significant arterial occlusive disease above the knee, and a popliteal-tibial bypass is a reasonable choice in such situations when available conduit length is limited.

Outflow Vessels

When a tibial bypass is necessary, the anterior or posterior tibial arteries are the first choice for the distal outflow anastomosis because they are more accessible and in direct continuity with the arterial arches of the foot. The peroneal artery is selected if the anterior tibial and posterior tibial arteries are diffusely diseased. The target for the distal anastomosis must be free of calcified plaque as this may lead to dissection of the intima and compromise graft patency. Preoperative imaging with DSA is utilized to help determine the most suitable distal target.

Proximal Posterior Tibial and Peroneal Arteries

To expose the tibioperoneal trunk and the proximal segments of the posterior tibial and peroneal arteries, an incision is made approximately 2 cm posterior to the medial edge of the tibia, starting just below the knee joint and extending distally for 10 to 15 cm. If the ipsilateral GSV is being used as a conduit, one can make the incision directly over the course of the vein, which is marked on the skin preoperatively. The fascia of the gastrocnemius muscle is incised, and the medial head is retracted posteriorly with a Weitlaner retractor with dull prongs. The popliteal fossa is entered, and the popliteal vein is encountered medial and anterior to the artery and usually has several large tributary branches at the level of the tibioperoneal trunk that should be ligated and divided. The popliteal vein is then mobilized with sharp dissection and retracted posteriorly with a vessel loop, which exposes the distal popliteal artery. The soleus muscle is detached as close as possible to the tibia, and a second Weitlaner retractor is placed. Meticulous dissection with Metzenbaum scissors exposes the distal popliteal artery and is continued distally to expose the tibioperoneal trunk, which then bifurcates to the posterior tibial and peroneal arteries usually approximately 2.5 cm from the origin of the anterior artery. Care must be taken because there are multiple vein branches that tear easily; thus these should be ligated and divided when encountered to avoid bleeding, as the transected vein will retract into the muscle if inadvertently torn. The two concomitant veins that usually run parallel to each artery are equally friable and send branches that cross the arteries at frequent points; these branches should be ligated.

The middle segment of the posterior tibial artery is exposed with a longitudinal incision approximately 2 cm posterior to the medial edge of the tibia (Fig. 3A) and extended for 10 cm. The fascia is incised longitudinally, and soleus is divided off the tibia. Once the soleus is retraced posteriorly, the posterior tibial artery can be found in the plane between the flexor digitorum longus and soleus muscles. The artery is dissected sharply on the anterior surface with Metzenbaum scissors, again with care to ligate and divide venous branches that cross the artery anteriorly (Fig. 3B). When isolating tibial arteries, we avoid circumferential dissection and only clear the artery on the most anterior surface facing the surgeon. This avoids inadvertent damage to the artery from sharp dissection. Circumferential dissection of tibial arteries is unnecessary as we use tourniquet control for the distal anastomosis (described later) and never clamp the tibial arteries to avoid damaging these fragile vessels.

The distal posterior tibial artery can be exposed at the medial ankle with an incision 1 cm posterior to the distal tibia; this may be extended posterior to the medial malleolus. The flexor retinaculum is divided, and the artery is found between the tendons of the flexor

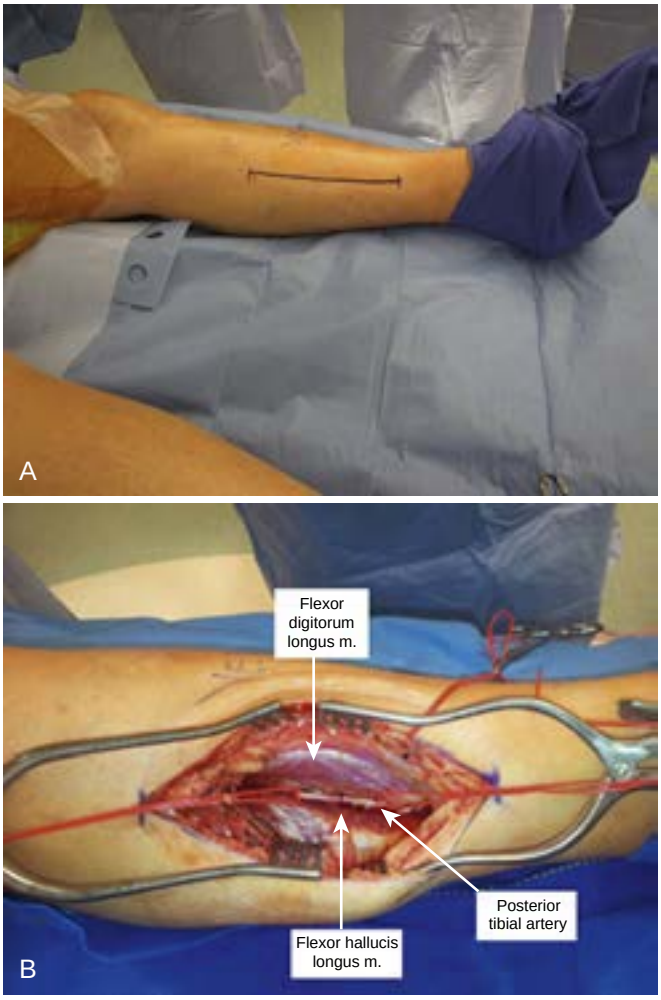

FIG. 3 Exposure of the posterior tibial artery. **(A)** An incision is made on the middle third of the medial portion of the leg. **(B)** The posterior tibial artery lies between the flexor digitorum longus and flexor hallucis longus muscles, which are separated with sharp and blunt dissection.

digitorum longus and flexor hallucis longus muscles. The bifurcation of the posterior tibial artery into the medial and lateral plantar branches can be found by creating a curvilinear incision from behind the medial malleolus to the instep of the foot for 5 cm. Division of the abductor hallucis muscle is usually necessary to facilitate exposure. The lateral plantar artery takes a slightly more inferior course to the medial plantar artery and is often larger. Usually a segment suitable for bypass can be exposed before it courses laterally across the sole of the foot.

The middle segment of the peroneal artery can be exposed through the same incision used to expose the posterior tibial artery (2 cm posterior to the tibia). Once the fascia is incised, the soleus is divided off the tibia and retracted posteriorly, taking the posterior tibial neurovascular bundle with it. The fascia over the flexor digitorum longus muscle is divided, and the plane of dissection is carried deeper, where the peroneal artery can be found. The distal peroneal artery can be exposed via a lateral incision and partial fibulectomy. The skin incision is placed laterally over the fibula, and the bone is cleared of all muscular and tendinous attachments (Fig. 4A and B). The bone is then gently resected for a distance of at least 8 cm, and the peroneal artery is found medially on the flexor hallucis longus muscle (Fig. 4C and D).

Anterior Tibial Artery and Dorsalis Pedis Artery

The anterior tibial artery is exposed through a longitudinal incision placed between the tibia and fibula (Fig. 5A). The fascia overlying the tibialis anterior and the extensor digitorum longus muscles is opened, and the groove between these two muscles is separated (Fig. 5B), which exposes the anterior tibial artery, its concomitant veins, and the deep peroneal nerve (Fig. 5C). The dorsalis pedal artery is the continuation of the anterior tibial artery onto the dorsum of the foot and is exposed by an incision made between the first and second metatarsal bones. The incision is made off to the side of the artery, not directly over it; this allows for the creation of a skin flap to provide tissue coverage for the bypass graft. After the deep fascia is incised, one separates the extensor hallucis longus and brevis muscles to expose the artery.

Conduit

For patients with TPOD, bypass grafting with single-segment GSV remains the best conduit option for long-term patency; 1-year and 5-year limb salvage rates exceed 90% and 80%, respectively. If the ipsilateral portion of the GSV is inadequate or was previously used for bypass, then the GSV from the contralateral leg should be used. If no GSV is available and endovascular attempts for revascularization are unsuccessful, then the lesser saphenous vein or the basilic and cephalic veins from the arms are other options, if they are of adequate diameter. The basilic and cephalic veins, if not damaged by repeated venipuncture, can be harvested as a single continuous graft of significant length. Splicing of multiple vein segments is sometimes required to obtain the required conduit length. We splice vein segments over a pediatric feeding tube to facilitate the creation of the conduit with two 7-0 polypropylene sutures to prevent purse stringing of the venovenous anastomosis that can occur with a single running stich. A distal origin bypass from the profunda or distal SFA/popliteal artery can be considered if no proximal stenosis is identified to minimize the conduit length needed. Bypass to the tibial vessels should be with autogenous conduit. If no leg or arm vein is available, then bypasses with heparin-bonded expanded polytetrafluoroethylene (ePTFE) with a distal vein patch, or cryopreserved vein may be considered, although the use of prosthetic conduits or cryopreserved vein in infrapopliteal revascularization is suboptimal as 2-year patency with such conduits is as low as 20%, with even lower limb salvage rates when compared with native vein conduits.

The GSV can be procured with either open or endoscopic techniques (Fig. 6). For open vein harvests, a long continuous incision can be used or multiple skip incisions of 10 cm in length separated by a 3- to 5-cm skin bridge may be made. It is crucial that the GSV be exposed and extracted with meticulous technique because injury and repair may compromise patency. The vein side branches should be ligated approximately 1 to 2 mm distal to their origin from the GSV to prevent crimping and luminal narrowing of the GSV. The final harvesting of the conduit should be done after exposure of the proximal and distal arterial targets, which allow estimation of the length of conduit necessary and helps minimize ischemia of the vein. The GSV can be used in a reversed, nonreversed, or in situ manner. For bypass to the tibial arteries, the best lumen size match is typically found with a nonreversed GSV, which requires valvulotomy. To help facilitate valvulotomy, we recommend completing the proximal anastomosis, which will allow distension of the vein with blood and using a Mills valvulotome to lyse the valves that can be visualized through the dilated vein. If size mismatch is not significant, the GSV may be used in a reversed fashion. In situ GSV bypasses are limited by proximity of the GSV to the inflow and outflow vessels and are used typically for femoral to proximal tibial bypasses in patients who are at low risk for wound infection that could expose the nontunneled GSV (and thus usually not used in diabetics and smokers, who are at high risk for wound infection in general).

Inflow Anastomosis

The distal external iliac artery, CFA, PFA, and SFA are exposed as previously described. Tunnels for the bypass graft are created

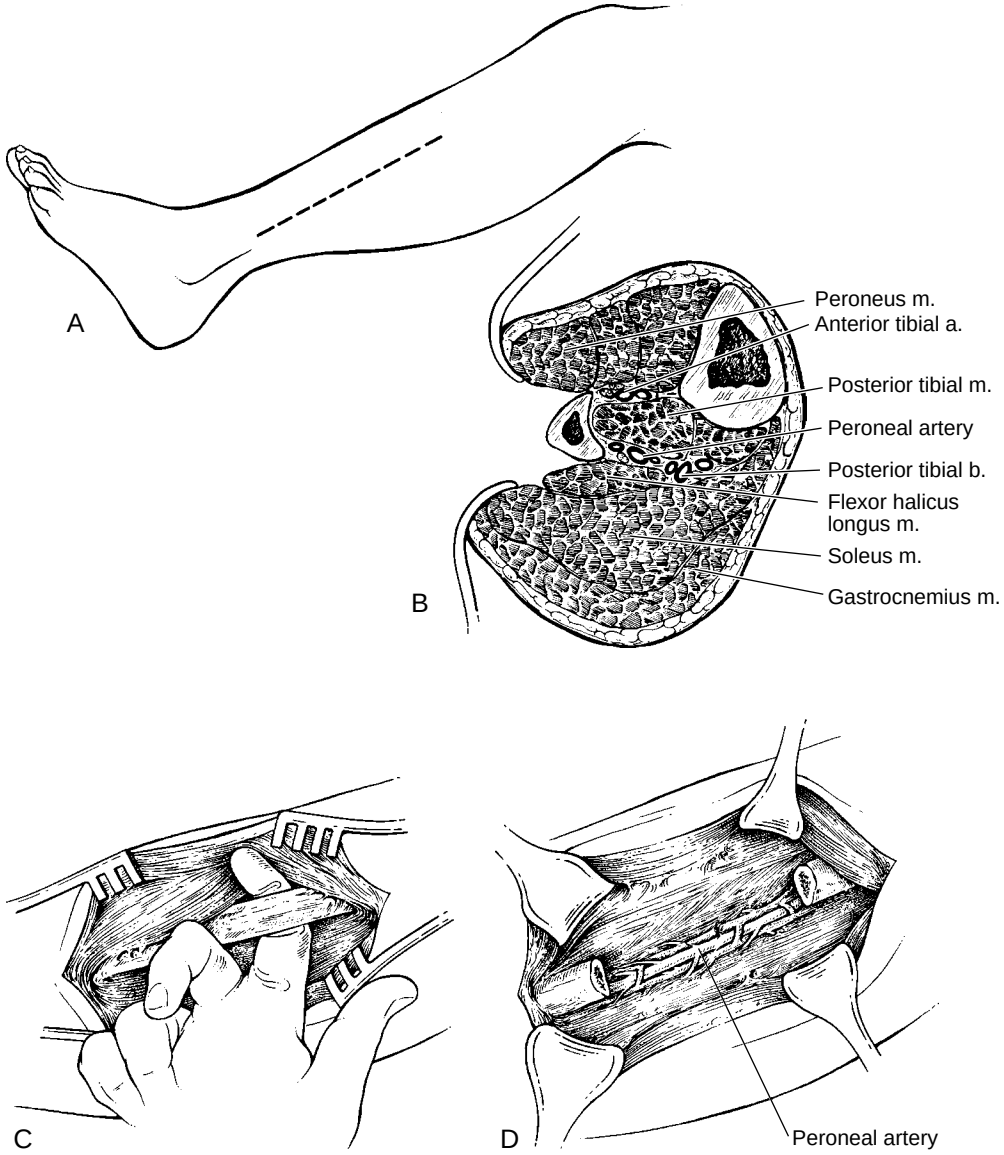

FIG. 4 Lateral exposure of the peroneal artery. **(A)** The incision is made longitudinally over the fibula. **(B)** Cross-section view of the lower leg, illustrating the lateral approach with fibula resection. **(C)** The muscle and fascia are stripped from the fibula, and an 8-cm section is removed. **(D)** The peroneal artery is exposed and seen to lie on the surface of the hallucis longus muscle. *(Copyright Herbert Dardik, 2001).*

(described later), and the patient undergoes systemic anticoagulation with heparin at an initial dose of 100 units/kg, followed by periodic boluses to maintain an activated clotting time of greater than 250. The CFA is palpated to determine the site that is most free of atherosclerosis. Atraumatic clamps are placed on the SFA, PFA, and proximal portion of the CFA, and an arteriotomy is created with a No. 11 scalpel blade. The arteriotomy is extended with Potts scissors to 25 to 35 mm, depending on the diameter of the GSV. The proximal portion of the GSV is beveled to accommodate the arteriotomy and the anastomosis is created with 5-0 or 6-0 polypropylene suture in a continuous manner. In patients without proximal flow-limiting lesions, more distal sites can be used for the proximal anastomosis including the profunda and popliteal arteries.

Tunnels for Bypass Grafts

Before the patient receives heparin for the proximal anastomosis, a tunnel for the bypass graft is created by advancing a tunneling device or a large aortic clamp in either an anatomic or subcutaneous fashion. We prefer an anatomic tunnel because it requires less conduit length, the vein graft has less of an acute angle as it turns to the distal anastomosis, and it is protected by the soft tissues of the leg and distanced from the skin and wounds in patients with TPOD who are usually poor healers due to diabetes and tobacco abuse. To reach the proximal third of the posterior tibial and peroneal arteries, the graft is tunneled from the adductor hiatus thorough the popliteal fossa to maintain a straight path. One must ensure that the vein passes between the heads of the gastrocnemius muscle at the popliteal fossa to avoid compression of the vein. The main advantage of the subcutaneous tunnel is that the graft is close enough to the skin to allow for percutaneous access for future endovascular procedures if needed, as well as easier access to the graft for open revisions. If the ipsilateral vein is harvested, subcutaneous tunneling is still possible, but one must stay away from the harvest site to avoid possible exposure of the bypass graft to a wound infection involving the vein harvest site. Once the proximal anastomosis is completed, the vein graft is clamped distally and inflated with blood. The vein is marked

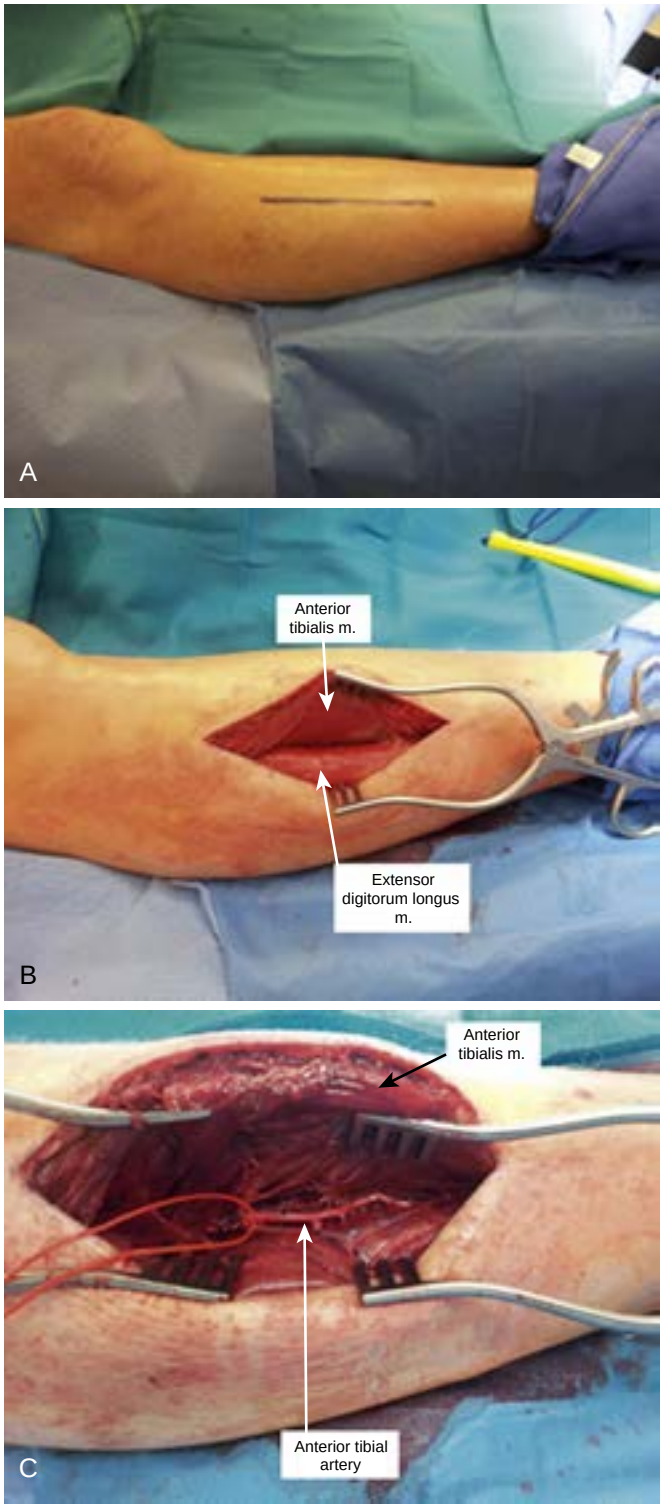

FIG. 5 Exposure of the anterior tibial artery. **(A)** A longitudinal incision is placed lateral to the anterior border of the tibia. **(B)** The groove between the tibialis anterior and the extensor digitorum longus muscles is separated. **(C)** The anterior tibial artery is exposed.

longitudinally on its anterior surface to prevent twisting and passed through the tunnel. Vein flow is then checked; any twisting in the tunnel will result in a reduced blood flow after tunneling as compared with the strength of the blood flow before tunneling of the vein. We prefer to use the Oregon tunneler as it allows the creation of the tunnel from either the distal or the proximal aspect of the wound.

FIG. 6 The greater saphenous vein is exposed with a series of incisions along its course on the medial aspect of the leg. Skin bridges are left in place to minimize tension on the incision closure and prevent wound dehiscence. Alternatively, a continuous incision may be made along the entire length of the greater saphenous vein.

Outflow Anastomosis

Creation of the outflow anastomosis requires adherence to meticulous technique and gentle manipulation of arteries, many of which are calcified. Loupe magnification is essential. We do not control tibial vessels with vessel loops or clamps, and we do not dissect tibial vessels circumferentially. Instead, we use a pneumatic tourniquet placed on the thigh and inflated after the leg is exsanguinated with an Esmark. An arteriotomy is initiated with a Beaver blade, with care not to lacerate the posterior wall of the artery. In general, the arteriotomy should be approximately 1.5 times the diameter of the vein graft because longer anastomoses tend to flatten the hood of the vein and create a sharp angle at the heel, which lead to flow turbulence and consequently a nidus for intimal hyperplasia. A 7-0 polypropylene suture is used to create the distal anastomosis. The tibial artery is handled minimally; it is touched with fine pickups only when necessary and very gently.

ENDOVASCULAR REVASCULARIZATION

Indications for Intervention

With lower rates of perioperative morbidity and mortality, high rates of technical success, and equivalent rates of limb salvage, PTA of the tibial and peroneal arteries is a critical skill of the vascular surgeon. Evidence of long-term efficacy was provided by the Beth Israel Deaconess Medical Center, which demonstrates that PTA of the tibial and peroneal arteries results in 1- and 5-year primary patency rates of 57% and 38% and limb salvage rates of 84% and 81%, respectively. According to the TASC II classification for infrapopliteal lesions, PTA is recommended for TASC classes A, B, and single-level C lesions in the tibial or peroneal arteries. In general, lesions that are more amenable to successful endovascular interventions are stenoses shorter than 4 cm or segments of occlusion shorter than 2 cm. Extensive disease that involves the trifurcation, numerous stenoses, a diffusely diseased tibioperoneal artery, or long occlusions are best treated with surgical bypass. In these situations, endovascular therapies may be employed as an adjunct to open surgical bypass to improve inflow or outflow during bypass procedures or for patients

who are poor candidates for open surgical bypass because of either a lack of conduit or significant medical comorbid conditions.

Vascular Access and Imaging

Preprocedure imaging with CTA is most helpful in planning the point of arterial access and locations of critical stenoses and occlusions. For tibioperoneal interventions, the contralateral CFA is the preferred access site. If this is not a suitable option, either because of extensive atherosclerosis or because of the presence of an aorto-bifemoral graft, then the left brachial artery or ipsilateral CFA can be accessed with an antegrade approach. The contralateral CFA is accessed with a 21-gauge needle with ultrasound guidance and a microwire is advanced under fluoroscopic guidance. A 5Fr transitional dilator is then placed. Over a stiff wire, a 5F or 6F sheath is placed in the artery. A diagnostic catheter is advanced into the abdominal aorta and exchanged for a catheter designed to go over the bifurcation. As with open surgical bypass, inflow and outflow must be considered in maintaining perfusion throughout the infrapopliteal system. The advantage of contralateral retrograde access is that it allows for access to the aortoiliac and femoropopliteal regions; stenoses in these areas can be addressed at the same time as the infrapopliteal intervention in many cases. Once the aortic bifurcation is crossed, the short sheath is then exchanged for a longer and stiffer sheath that is placed in the ipsilateral femoral or distal external iliac artery for diagnostic imaging. The sheath can then be advanced into the SFA for stable access to support the various devices and catheters used in infrapopliteal interventions. A crossing catheter is used to provide adequate support to cross-tibial arterial occlusions. We tend to use 0.014- or 0.018-inch wires with added weight at the tip, which provide pushability to cross the infrapopliteal lesions. If this route is unsuccessful, pedal arteries can be cannulated under ultrasound guidance, and a wire can be advanced in a retrograde direction. A snare device can then be employed to grasp the proximal wire and navigate it through the tibial arteries (Fig. 7A–D). Careful consideration must be had if one decides on retrograde tibial access as one does not want to damage the distal outflow and eliminate a possible bypass target.

Precise mapping of infrapopliteal anatomy is crucial for proper intervention. Imaging of the trifurcation is usually performed with a zero-degree anterior-posterior view. A 30-degree ipsilateral oblique or 90-degree true lateral view may be needed to properly detail the anterior and posterior tibial arteries. While tibial vessels are imaged, the catheter should ideally be positioned in the distal popliteal artery.

Balloon Angioplasty and Stent Placement

The mainstay of endovascular treatment of the tibioperoneal vessels has been PTA. Balloons suitable for these interventions range from 1.5 to 4 mm in diameter and are up to 22 cm in length. Currently available tibial arterial balloons are delivered in shaft lengths of up to 170 cm. It is better to use a balloon length that will cross the entire lesion in a single pass. These balloons are noncompliant and low profile, and a long inflation time of 1 to 3 minutes reduces the risk of dissection of the artery. If disease is still present, then the balloon can be inflated for 3 to 4 minutes.

The use of stents has previously been a bailout technique after PTA if there was greater than 30% stenosis or flow limiting dissection after balloon inflation. The stents used in these situations were classically bare metal, and the restenosis rate was approximately 50% at 6 months. There had been a growing trend toward placement of drug eluding stents (DES) in hopes of improving patency rates similar to those observed with the use of DES in coronary revascularization. Because of the comparable caliber of coronary and tibioperoneal arteries, researchers in several studies have employed coronary DES in the infrapopliteal arteries. There are now four randomized trials with four meta-analyses to show that DES have better patency, reduced reinterventions, reduced amputation rates, and improved event-free survival over PTA alone or with bare metal stent placement. Drug eluting balloons (DEB) have also been used in infrapopliteal lesions but are currently somewhat controversial due to unresolved issues involving possible increase in mortality and questionable long-term benefits. Once the decision has been made to perform an intervention, the patient should be systemically heparinized with an initial dose of 100 units/kg followed by periotic boluses to maintain an activated clotting time above 250 seconds. All lesions should be treated if possible, and completion angiography should be performed to evaluate distal runoff. At the end of the procedure, several arterial closure devices are available. Protamine can be administered at the physician's discretion to reverse the anticoagulation. Closure devices have a similar complication rate as compared with manual pressure but decrease the time needed to hold pressure and shorten the time to patient ambulation.

OTHER TECHNOLOGIES

Mechanical atherectomy devices, both rotational and directional, can be used to remove a portion of the atheromatous plaque from the luminal surface. The advantage of this method is a decrease in the plaque burden in comparison with PTA and stent placement; however, there is concern for distal embolization of plaque when using these devices, and the use of a distal embolic protection device is encouraged. Furthermore, high quality data are currently lacking to show efficacy or advantage of using atherectomy in addition to PTA or stenting for infrapopliteal lesions. For occluded lesions, several crossing devices are available, if a wire and support sheath are not adequate to cross a lesion.

POSTINTERVENTION MANAGEMENT AND SURVEILLANCE

After intervention, patients are placed in a monitored setting in which pulses are routinely checked every 1 to 2 hours. Patients who received an endovascular intervention with percutaneous access to the groin are kept on strict bedrest with the hip in a neutral position for 6 hours if manual pressure was held for hemostasis and no closure device was used. After a period of observation of 6 hours and if no hematoma is present at the access site, discharge may be considered for patients who underwent percutaneous endovascular intervention. Those who undergo an open surgical bypass are kept in a monitored setting overnight or longer to assess for hemodynamic stability and fluid shifts. After this period of time, the focus can then shift to physical therapy and mobility. The leg after a bypass typically becomes swollen; this may increase patient discomfort, as well as result in problems with wound healing. We routinely use a multilayer compressive dressing of cast padding and Coban self-adherent wrap (3M) (unless contraindicated by subcutaneous bypass tunnel). Limitation of intravenous fluids as well as diuresis once hemodynamically stable are also important for postoperative care. All patients should be maintained on aspirin after intervention. Dual antiplatelet therapy of aspirin and clopidogrel is prescribed to endovascular therapy recipients. Statin therapy has been shown to improve the patency rate in bypass recipients, and this is routinely started or continued.

Patients who have undergone bypass grafting should have stringent outpatient follow up. Particular attention should be paid to symptoms (return of claudication, development of new wounds, or reopening of prior wounds) and physical exam. Bypass surveillance should be performed. Noninvasive vascular imaging is performed with measurement of the ABI and arterial bypass duplex ultrasound before discharge after the operation and then again at 1 month, 3 months, and then every 6 months for up to 2 years followed by yearly evaluation in the clinic. Increasing focal velocities within the bypass or at the anastomoses or a decrease in the ABI of more than 0.15 should prompt further investigation with angiography and angioplasty of any hemodynamically significant stenoses to prevent

Akingba, MD, PhD).*

graft failure. Patients with endovascular interventions are monitored at similar intervals.

COMPLICATIONS

Immediate complications include hemorrhage or graft thrombosis and necessitate reoperation. Hemorrhage manifests as an expanding hematoma in the groin or leg and possibly hemodynamic instability. Affected patients should be taken back to the operating room for exploration and evacuation of the hematoma to prevent shock, infection, or formation of a pseudoaneurysm. Early graft thrombosis is usually the result of a technical error, but can arise from compression of the graft, twisting of the graft, undiagnosed inflow disease, or an unknown hypercoagulable state. Affected patients should undergo thrombectomy and arteriography to evaluate for technical problems related to anastomoses, twisting of the graft, an intimal flap, or inadequate outflow. Late complications include infection, pseudoaneurysm formation, and graft thrombosis. Graft thromboses up to 24 months after the initial operation probably result from neointimal hyperplasia at the distal anastomosis, whereas those that occur after this period are typically caused by recurrent atherosclerotic disease. For endovascular treatment, the most common complication is access related complicating up to 4% of all catheter-based treatment. A high puncture is associated with a retroperitoneal hematoma that

may require arterial repair in the operating room, and low punctures are associated with arteriovenous fistula development or thigh hematoma and pseudoaneurysm formation.

FUTURE TREATMENT: CELL-BASED THERAPIES

Although revascularization with either surgical bypass or endovascular techniques can result in exceptional improvements in patients to TPOD with acceptably low rates of morbidity and mortality, approximately 20% to 40% of patients with CLI are not candidates for these interventions because of lack of conduits or because of extensive disease within the outflow tibial vessels. For these patients with unreconstructable small vessel arterial disease, medical management with cardiovascular risk factor optimization and use of pentoxifylline and ArtAssist intermittent compression treatment device may help in avoiding amputation. In addition, stem cell therapies are emerging as a potential option, with some prospective study data showing improvement in wound healing and freedom from amputation in patients with severe limb threatening PAD without revascularization options injected with bone marrow mononuclear cells harvested from the iliac crest. Upcoming prospective randomized clinical trials such as the NOMA (No More Amputations) trial will further evaluate the potential for cell-based therapies for CLI.

Popliteal and Femoral Artery Aneurysm

Rae S. Rokosh, MD, Daniel J. Wong, MD, MHS, and Elliot L. Chaikof, MD, PhD

FEMORAL ANEURYSM

True aneurysms and pseudoaneurysms of the femoral artery are the most common type of peripheral aneurysms encountered. Femoral artery aneurysms can be further classified into degenerative true aneurysms; pseudoaneurysms, including iatrogenic, traumatic, or para-anastomotic; and infected or mycotic aneurysms. Treatment options vary significantly depending on the etiology, presence of infection, and location of the aneurysm, and thus the diagnosis, management, and procedural concerns for each subtype will be discussed separately.

Degenerative Femoral Artery Aneurysm

True degenerative aneurysms of the femoral artery are rare. The common femoral artery (CFA) is the most likely location, while isolated aneurysms in the distal superficial femoral artery (SFA) or profunda femoris artery (PFA) are less frequent. Population-based studies in the 1990s estimated a prevalence of femoral aneurysm of 5 per 100,000 in the United States with a heavy male predominance. An important consideration in the patient with a femoral aneurysm is the synchronous presence of a contralateral femoral aneurysm (26%–50%), abdominal aortic aneurysm (AAA; 48%–90%), or popliteal aneurysm (27%–48%). An aortic aneurysm that meets the threshold for repair should be addressed before, or in conjunction with, an asymptomatic peripheral aneurysm. Approximately half of patients are asymptomatic at the time of peripheral aneurysm diagnosis, with symptomatic patients presenting with a pulsatile mass, pain, or distal ischemia. Ultrasound and cross-sectional imaging such as CT or MRI can be used to characterize the size of the aneurysm and simultaneously screen for the presence of other aneurysms.

Indication for Repair

Patients presenting with symptoms from local compression or distal ischemia should undergo repair. In the presence of an asymptomatic aneurysm, the goal is to prevent distal ischemia due to thrombosis, embolization, or, rarely, rupture. Historical series suggested that a femoral aneurysm >2.5 cm should be repaired, but more contemporary literature suggests that a femoral aneurysm <3.5 cm with absent or chronic intraluminal thrombus is unlikely to present with rupture or embolism. While perioperative mortality for open femoral aneurysm repair is ≤1%, morbidity may be observed in 10% to 20% of patients.

Approach

Surgical repair, rather than an endovascular-first approach, is the treatment of choice for CFA aneurysms. The routine use of stent grafts to exclude degenerative femoral aneurysms is not the preferred approach due to the risk of stent fracture in the setting of dynamic hip flexion and the preference to avoid PFA orifice occlusion. In the setting of distal embolization, thromboembolectomy or pharmacomechanical thrombolysis may be used initially to restore distal perfusion.

Open surgical repair of a femoral artery aneurysm requires reconstruction with an interposition vascular graft (Fig. 1). A longitudinal incision is made over the femoral artery with dissection to the nonaneurysmal proximal common femoral or distal external iliac artery. Exposure of the distal external iliac artery will require division of the inguinal ligament or a retroperitoneal approach via an oblique incision two to three fingerbreadths above the inguinal ligament. Exposure of the SFAs and PFAs should also be obtained. If dissection of the PFA proves difficult due to the size or location of the aneurysm, control of the profunda femoris can be obtained by balloon occlusion using a 3Fr Fogarty catheter positioned 1 cm distal to the orifice after the aneurysm is opened (Fig. 2).

Once proximal and distal control has been obtained, the patient is heparinized, vessels are occluded, the sac is opened, and the thrombus is removed. If the aneurysm is confined to the CFA without

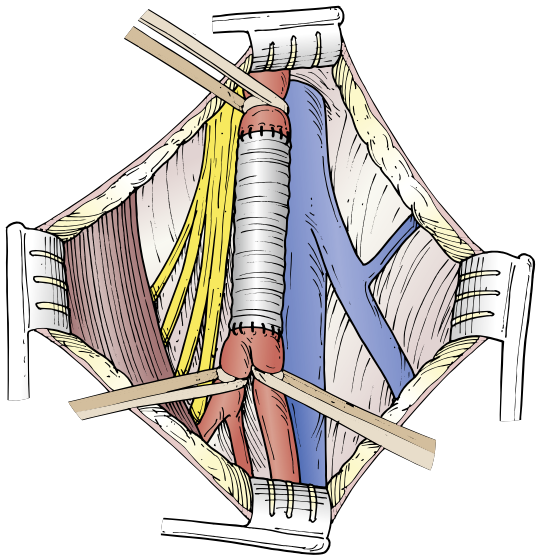

FIG. 1 Interposition graft repair of a femoral artery anastomotic pseudoaneurysm. *(From Cronenwett JL, Johnston KW. Rutherford's Vascular Surgery. Philadelphia: Elsevier; 2014.)*

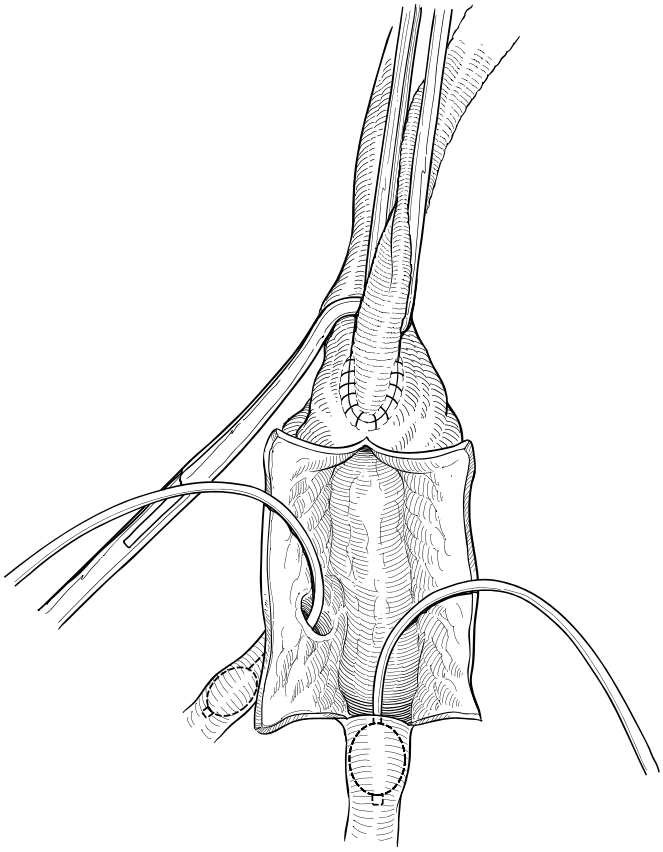

FIG. 2 Distal control of the profunda and superficial femoral arteries can be achieved from within the aneurysm using occlusive balloon catheters after the aneurysm is opened. *(From Chaikof EL, Cambria R. Atlas of Vascular Surgery and Endovascular Therapy: Anatomy and Technique. Philadelphia: Elsevier; 2014.)*

involvement of the SFA or PFA, the vessel can be reconstructed using an 8- or 10-mm interposition polytetrafluoroethylene (PTFE) or Dacron graft. If the aneurysm is more extensive and involves the SFA or PFA, interposition grafting should be performed with either reimplantation or use of a jump graft to the PFA. If the PFA cannot be revascularized, distal perfusion should be ensured. In the setting of concomitant occlusive disease, femoral-popliteal or femoral-tibial bypass may be required.

Iatrogenic Femoral Artery Pseudoaneurysm

The incidence of femoral artery pseudoaneurysm following diagnostic or therapeutic catheterization varies from 0.05% to 4%. Risk factors include large sheath size, anticoagulation, obesity, and a high arterial puncture site. Prevention of a pseudoaneurysm is best achieved by routine use of ultrasound-guided vascular access. A femoral pseudoaneurysm may present as a pulsatile mass, although physical exam can be limited by body habitus or hematoma. Duplex ultrasound is the primary means of diagnosis, which allows evaluation of pseudoaneurysm size, neck dimension, and evaluation for the presence of a concomitant arteriovenous fistula.

Indication for Intervention

In the absence of compressive symptoms, including pain, skin blisters, or symptoms of femoral nerve entrapment, small pseudoaneurysms (<1 cm) will often thrombose spontaneously or with ultrasound-guided compression if the patient is not systemically anticoagulated. Follow-up ultrasound should be conducted within 2 weeks to confirm thrombosis. A pseudoaneurysm that is >2 cm, symptomatic, or persistent should be treated.

Approach

For iatrogenic asymptomatic pseudoaneurysms >2 cm, ultrasound-guided thrombin injection into the pseudoaneurysm sac has become the preferred method of treatment, provided there is a narrow, long neck between the pseudoaneurysm and the femoral artery to minimize the risk of thrombin injection reflux into the artery. Ultrasound-guided compression alone, in the absence of thrombin injection, remains an option but is often less well tolerated due to the pain of sustained compression, typically three successive 20-minute compressions, and has a lower success rate for pseudoaneurysms >1 or 2 cm. For thrombin injections, a two-syringe method can be used with one syringe containing 3 mL of saline and the other containing a thrombin solution connected using a three-way stopcock (Fig. 3). Originally thrombin concentrations as high as 1000 IU/mL were used, but with increased experience, concentrations as low as 20 to 100 IU/mL have been reported in the literature to be effective. Visualization of the tip of the 22- to 25-gauge needle can be assisted using an echogenic needle. The pseudoaneurysm is punctured and a test injection with saline is visualized on ultrasound. This serves a dual purpose to both confirm needle placement within the pseudoaneurysm, as well as to minimize the risk of accidental injection of thrombin into the native artery, which can result in thrombosis or distal emboli. Small amounts of thrombin (0.1–0.2 mL) are then injected until cessation of flow within the sac is confirmed. For multilobulated pseudoaneurysms, the lobe most proximal to the native vessel is targeted to promote subsequent thrombosis of the more distal lobes. Preserved flow in the femoral artery and vein is confirmed via ultrasound at the end of the procedure. If there is a wide neck and the patient is a prohibitive risk for open repair, an intraarterial balloon may be inserted from the contralateral femoral artery and inflated to exclude the pseudoaneurysm during thrombin injection. A follow-up ultrasound is performed 24 hours after injection to confirm thrombosis.

Open surgical repair is indicated for an iatrogenic pseudoaneurysm that is expanding, fails nonoperative treatment, displays unsuitable anatomy for thrombin injection, or is associated with a painful hematoma, skin breakdown, or symptoms suggestive of femoral nerve entrapment. A longitudinal groin incision over the aneurysm

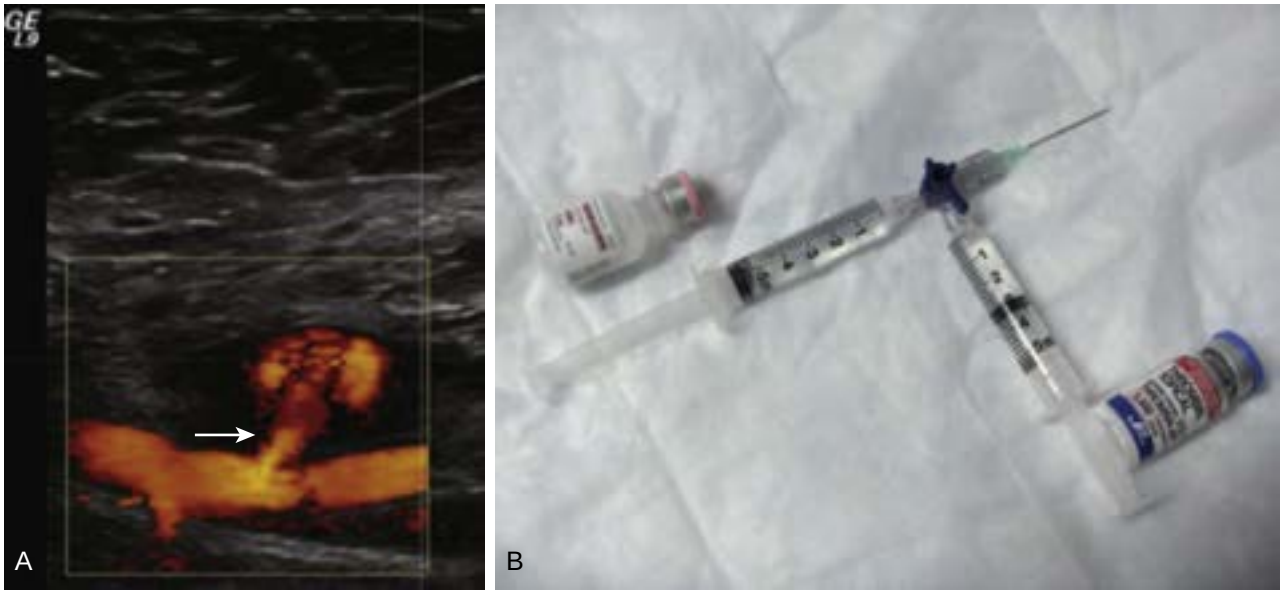

FIG. 3 **(A)** Duplex ultrasound demonstrating femoral pseudoaneurysm with neck (*arrow*). **(B)** Two syringes with saline and thrombin connected with 3-way stopcock used for injection of pseudoaneurysm. (***A*** *from From Cronenwett JL, Johnston KW.* Rutherford's Vascular Surgery. *Philadelphia: Elsevier; 2014;* ***B*** *from Webber GW, Jang J, Gustavson S, Olin JW. Contemporary management of postcatheterization pseudoaneurysms.* Circulation. *2007;115:2666–2674.)*

is performed and proximal and distal control achieved. If the sac is inadvertently entered, bleeding is controlled by digital pressure until proximal control is gained and the puncture site primarily repaired with a 5-0 Prolene suture. The hematoma is evacuated and a 7-mm Jackson-Pratt drain placed in the wound.

Paraanastomotic Femoral Artery Aneurysm

The femoral artery is the most common location of an anastomotic aneurysm associated with an aortofemoral bypass graft, commonly presenting years after the initial operation as a pulsatile groin mass. An anastomotic pseudoaneurysm may occur due to suture line disruption, infection, or arterial wall degeneration.

Indication for Repair

Operative repair of an anastomotic femoral pseudoaneurysm is recommended if greater than 2.0 cm in diameter or if infection is suspected by the presence of a draining sinus, erythema, or perigraft fluid. CT imaging can assess for the presence of synchronous anastomotic pseudoaneurysms at the aortic anastomosis or in the contralateral groin.

Approach

Noninfected Anastomotic Pseudoaneurysm

In the absence of infection, exposure of the graft limb, common femoral, superficial femoral, and profunda femoris arteries should be performed. As needed, proximal control of the graft limb can be achieved by dividing the inguinal ligament or retroperitoneally via an oblique suprainguinal incision. In a heavily scarred operative field, control of the SFAs and PFAs can be achieved using Fogarty balloon catheters from within the aneurysm (see Fig. 2). Following heparinization, the aneurysm sac is opened, thrombus removed, distal graft resected, and reconstruction performed using a 6- to 8-mm interposition PTFE graft or patch angioplasty, with revascularization of the SFAs and PFAs as indicated.

Infected Femoral Anastomotic Pseudoaneurysm

If infection is suspected, blood cultures should be sent and empiric antibiotics initiated. Graft infection should be suspected if exploration reveals a poorly incorporated graft or perigraft fluid. This scenario requires removal of the infected graft with restoration of distal perfusion via extraanatomic reconstruction or the use of an autologous vein or a cryopreserved allograft. CT imaging can help to determine whether infection is limited to the groin or involves the proximal graft or contralateral limb. If infection is confined to the distal limb, the clean portion of the procedure is conducted initially. Proximal control of the uninfected portion of the limb is achieved through a retroperitoneal approach via an oblique incision, extending lateral to the rectus, 3 cm above the inguinal ligament, to a point halfway between the costal margin and iliac crest in the midaxillary line. The proximal uninfected graft limb is exposed, avoiding injury to the ureter, and divided with a small margin sent for culture. The distal end of the graft is oversewn, mobilized from surrounding tissues, and displaced distally. Extraanatomic options for revascularization include an obturator bypass, an axillofemoral bypass to the SFA, or an axillopopliteal bypass. An obturator bypass requires creating a tunnel through the medial aspect of the obturator foramen avoiding injury to the obturator artery and nerve, to the SFA in the midthigh. An end-to-end anastomosis is created using an externally supported PTFE interposition graft between the end of the uninfected graft limb and an end-to-side anastomosis to the SFA. Incisions are closed, an occlusive dressing placed, and the contaminated portion of the procedure performed. A groin incision is made, vascular control obtained, the infected graft removed, and intraoperative cultures sent. Infected tissues should be debrided, robustly irrigated, and the femoral artery defect closed with a vein patch to preserve flow to the PFA. A sartorius muscle flap should be mobilized to cover the femoral vessel. In patients with prohibitive surgical risks and limited lifespan, or for those presenting with rupture, several case series report the feasibility of endovascular stenting as a temporizing measure followed by either lifelong antibiotic therapy and secondary surgical debridement or definitive management.

Primary Infected Femoral Artery Aneurysm

A primary infection of the femoral artery most often occurs due to a contaminated percutaneous closure system or intravenous drug use. Patients may present with an enlarging pulsatile mass, sepsis, distal emboli or hemorrhage. Blood cultures are obtained and

empiric antibiotics initiated. Goals of the operation include removal of infected tissue, repair of the femoral artery, and restoration of distal perfusion. Options for repair depend upon the extent of local arterial destruction. If limited damage, a vein patch angioplasty may be feasible, but more extensive arterial destruction may require reconstruction with autologous femoral vein, cryopreserved vein, or an extra-anatomic bypass. An obturator bypass may be preferable when the aneurysm is secondary to intravenous drug injection to minimize the likelihood of future needle sticks. Cultures should be obtained and antibiotics continued at least 6 weeks postoperatively. A sartorius muscle flap should be used to provide direct coverage of the arterial repair.

POPLITEAL ANEURYSM

The popliteal artery is generally considered aneurysmal when >1.5 cm in diameter. Risk factors for popliteal artery aneurysm (PAA) growth include initial aneurysm size at presentation and presence of intramural thrombus. As the incidence of PAA is relatively rare, less than 3% in the general population, there have been few modern natural history studies of PAAs. Approximately 50% patients have contralateral popliteal aneurysms and 30% to 40% have synchronous AAA, which occur in a higher proportion of patients if bilateral popliteal aneurysms are present. The majority of PAAs are true degenerative aneurysms. Rupture is rare, whereas distal ischemia from thromboembolization is the most common cause of morbidity. Duplex ultrasound, CT, and MRI are effective methods for diagnosis and establishing size. In contrast to a femoral aneurysm, endovascular treatment of a popliteal aneurysm with a self-expanding covered stent graft may be feasible in many patients. Important considerations to determine whether an endovascular or surgical approach is most appropriate include the patient's operative risk, size of the aneurysm, presence of intraluminal thrombus, compressive symptoms, adequate landing zones, number of patent runoff vessels, and presence of distal ischemia.

Indication for Repair

Asymptomatic aneurysms that are ≥2 cm in size should be repaired in the healthy adult. For high-risk asymptomatic patients, the most recent guidelines suggest repair can be deferred until the PAA is ≥3 cm, particularly in the absence of intraluminal thrombus. All symptomatic PAAs should be repaired.

Open Surgical or Endovascular Repair

Historically, surgical bypass has been the gold standard for PAA repair, with excellent long-term patency and limb salvage rates. However, as endovascular techniques and endoprostheses have improved, endovascular repair of PAA has become increasingly more common. To date, there are no trials directly comparing the two repair modalities, but there is growing evidence to support the use of endovascular repair in the appropriate clinical context. For those asymptomatic patients with ≥5 year life expectancy, current guidelines recommend open surgical repair over an endovascular approach. Open repair consists of revascularization from the distal superficial femoral or proximal above knee popliteal artery to the below knee popliteal or tibioperoneal trunk using a saphenous vein or synthetic bypass graft via a medial or posterior approach. An autologous vein graft is preferred in the presence of an adequate great saphenous vein >3 mm in diameter. For those patients with more proximal popliteal or distal SFA aneurysms that do not cross the knee, or those of advanced age with significant medical comorbidities who are anatomically suitable, endovascular repair is a viable alternative. Anatomic criteria to achieve good outcomes with endovascular repair include proximal and distal landing zones of at least 15 mm in length within normal healthy vessel to achieve an adequate seal for the stent graft, minimal aneurysmal kinking or tortuosity, and good tibiopedal runoff (≥2 vessels). Recent evidence has demonstrated that endovascular repair in the appropriate clinical context is associated with decreased length of stay and reduced wound complications, as well as similar reintervention rates and primary patency at 1 and 3 years when compared with open surgical repair.

Approach: Repair in the Absence of Acute Thrombosis

Preoperative vein mapping, baseline ankle-brachial index (ABI), and a lower extremity CTA, MRA, or conventional arteriogram are conducted in preparation for repair to evaluate aneurysmal morphology as well as the identification of either appropriate inflow and outflow targets for surgical bypass or adequate landing zones and endoprosthesis sizing for endovascular repair.

Two anatomic approaches are commonly used for surgical repair, a medial or posterior approach. The medial approach is preferred for those aneurysms extending beyond the popliteal fossa. The knee is bent and the leg externally rotated. The saphenous vein is harvested, and proximal and distal control obtained. A tunnel is created from the above to below knee popliteal fossa. After heparinization, the aneurysm is opened, any arterial backbleeding branches ligated from within the aneurysm sac, and a standard bypass performed with either saphenous vein or a prosthetic graft. If patent at the time of repair, the PAA must also be ligated both proximally and distally as close as possible to the sac itself. Care should be taken to avoid division of the medial musculotendinous attachments of the knee if possible, as this maneuver is associated with marked pain postoperatively.

The posterior approach is advantageous for a large aneurysm confined to the popliteal space or to decompress an enlarging aneurysmal sac after previous bypass and ligation. The patient is positioned prone, and a "lazy S" incision is performed with the lateral portion across the posterior flexion crease (Fig. 4) to minimize risk of wound contracture or dehiscence. Access to the artery is direct and the popliteal vein can be retracted laterally. Proximal and distal control is established with care to preserve the tibial and peroneal nerves, which usually course lateral to the aneurysm and can be retracted laterally with the popliteal vein for appropriate arterial exposure. Following heparinization the sac is opened, thrombus removed, collateral vessels suture ligated, and an interposition graft performed. In the event that there is a large size mismatch between conduit and popliteal artery, a bypass can be performed as well via this posterior approach.

Endovascular repair of a popliteal aneurysm is performed with a flexible nitinol self-expanding covered stent, such as the Viabahn endoprosthesis (W.L. Gore & Associates, Inc., Flagstaff, AZ). Characteristically, ipsilateral antegrade femoral artery access is obtained. Angiographic views with the knee in a flexed position are helpful to confirm appropriate stent sizing and to avoid stent termination or overlapping stents in the region of maximum flexure. Stent grafts should be oversized by 10% to 15% and, if multiple stents are required, 2 cm of overlap is recommended (Fig. 5). Appropriate stent apposition between healthy vessel and any additional regions of stent overlap can be achieved with noncompliant balloon conformation. Angiography with and without knee flexion at case completion should be performed to confirm baseline distal runoff as well as assess for any stent occlusion, kinking, or migration with dynamic knee mobility.

Irrespective the route of repair, routine postoperative surveillance includes clinical evaluation, ABI, as well as duplex ultrasound at 3, 6, and 12 months during the first year and, if stable, annual duplex imaging thereafter. There is a paucity of high-level data regarding the best antithrombotic approach after lower extremity revascularization, and the vast majority of available evidence is derived from peripheral occlusive arterial disease rather than PAAs. Therefore, postoperatively patients should be maintained on a minimum of

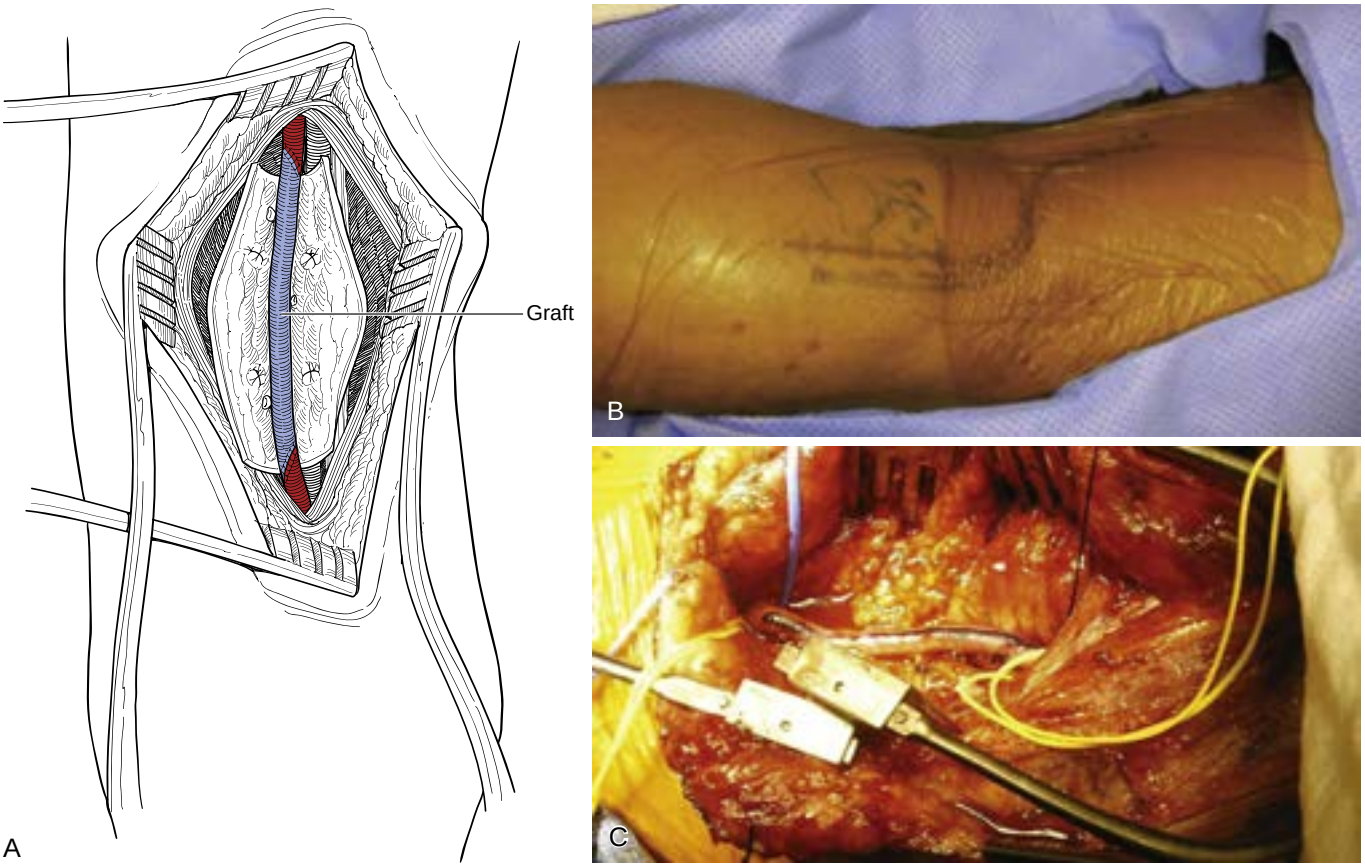

FIG. 4 Posterior approach to popliteal aneurysm repair. **(A)** Illustration of saphenous vein interposition graft. **(B)** Lazy S incision is used with superior portion beginning medially and extending laterally over flexion crease. **(C)** Completed saphenous bypass interposition graft. *(From Chaikof EL, Cambria R.* Atlas of Vascular Surgery and Endovascular Therapy: Anatomy and Technique. *Philadelphia: Elsevier; 2014.)*

aspirin 81 mg indefinitely. The decision to use dual-antiplatelet or anticoagulation therapy should be individualized with careful evaluation of the risk-benefit profile.

Approach: Repair in the Presence of Acute Thrombosis

Patients presenting with a popliteal aneurysm and acute limb ischemia, as evident by diminished or absent pedal signals accompanied by pain, motor, or sensory findings, have a significantly increased risk for major amputation. Anticoagulation is initiated and a CTA or conventional angiography performed to determine if the aneurysm is occluded, evaluate the presence and extent of distal embolization, and assess the patency of the tibiopedal runoff arteries. If motor and sensory function is intact or symptoms are mild, catheter-directed thrombolysis can be performed to reestablish patent runoff followed by definitive endovascular or surgical repair. Should there be evidence of profound limb threatening ischemia, the patient should proceed directly to an operating room with imaging capability. Thromboembolectomy of the popliteal artery and distal tibial vessels can be conducted with the aid of adjuncts such as pharmacomechanical thrombolysis; the aneurysm excluded; and a bypass performed. Concern for or evidence of compartment syndrome necessitates a four-compartment fasciotomy. Limbs that are not candidates for salvage at presentation should undergo primary amputation rather than risk the complications associated with the revascularization of a nonviable limb.

Treatment of Claudication

Qingwen Kawaji, MD, and Margaret W. Arnold, MD

It is estimated that peripheral arterial disease (PAD) affects 8 to 12 million Americans and over 200 million citizens globally. The prevalence of PAD is on the rise, both domestically and internationally. Recent analysis showed a relative increase of 23.5% during the first decade of the new millennium; this trend was present in low-income, middle-income, and high-income countries. Women of low-income and middle-income countries were diagnosed with PAD more often than men even at a younger age. Although only 1% to 3% of patients diagnosed with PAD will develop critical limb ischemia, PAD is associated with coronary heart disease and cerebrovascular disease. The 1-year incidence of myocardial infarction and stroke was higher in patients diagnosed with PAD than coronary arterial disease. Not only is PAD associated with higher morbidity and mortality, but it is also costly. In the United States, the Reduction of Atherothrombosis for Continued Health (REACH) registry estimated that $21 billion was spent in 2004 for vascular-related hospitalizations, and the US Medicare program estimated that more than $4.3 billion was spent on PAD–related treatments in 2001. The cost of PAD is unlikely to decrease given the increasing prevalence as well as use of invasive treatments in the United States.

Globally, the strongest risk factors for PAD include age, diabetes, and smoking. Other risk factors for PAD are similar to those of other atherosclerotic vascular diseases, such as elevated C-reactive protein, hyperhomocysteinemia, hyperlipidemia, hypertension, and chronic kidney disease. Men and postmenopausal women have a similar prevalence of PAD. However, women are most likely to be misdiagnosed as a result of atypical symptoms. African Americans have a lower ankle-brachial index (ABI) than Caucasians after risk factor adjustments; this may not be clinically relevant as it is present among healthy patients. The treatment of PAD and appropriateness of such treatments have been debated rigorously in the past few years. Race, socioeconomic status, and rurality have been reported to influence treatments of PAD.

ASSESSMENT

Screening

Despite PAD's association with other comorbid diseases, the US Preventive Services Task Force does not recommend routine screening of PAD with ABI because of insufficient evidence. A systematic review published in 2015 by Alahdab et al. and commissioned by the Society of Vascular Surgery examined data on benefits, harms, and cost-effectiveness of 43 studies and found that current quality of evidence supporting routine screening was low. It is important to note that patients with PAD have increased risk factors for atherosclerosis in other arterial beds such as coronary, carotid, and renal arteries. Furthermore, PAD is also a recognized risk factor for abdominal aortic aneurysm (AAA). Currently there are no data on AAA screening in patients with asymptomatic PAD; the American Heart Association and American College of Cardiology (AHA/ACC) recommend a screening duplex ultrasound examination for AAA in patients with symptomatic PAD. There is no sufficient evidence to support routine screening in all patients with PAD for asymptomatic atherosclerosis in other arterial beds.

Clinical Presentation and Evaluation

Claudication, defined as fatigue, discomfort, pain, and cramping caused by imbalance of blood perfusion and muscle metabolic demand, is the most common symptom of lower extremity PAD. Typical claudication symptoms are induced by exercise and relieved with resting. They can affect the buttock, hip, or leg and may

cause muscular weakness and instability. However, it is important to remember that only 10% of individuals with PAD have classic symptoms of intermittent claudication (IC); the majority of others experience other symptoms or are completely asymptomatic. Therefore, a detailed history and physical examination is the cornerstone of diagnosis.

When taking a history, it is important to spend time on the details of the symptoms patients are experiencing, such as distance walked before onset of symptoms, time elapsed before resolution of symptoms, specific movements/exercises/positions that worsen/alleviate discomfort, functional status, and any other associated symptoms. Other differential diagnoses may present similarly as claudication, and it is important to differentiate them from one another (Table 1). Furthermore, risk factors associated with PAD should also be documented: age, diabetes (how well it is controlled), kidney disease, smoking status, hyperlipidemia, hypertension, other inflammatory disease, other known atherosclerotic disease (coronary, carotid, subclavian, renal, mesenteric artery, AAA), and family history of PAD. Physical examination should include a full vascular assessment of cardiac, coronary, abdominal, and peripheral systems. Pulse palpation

TABLE 1 Differential Diagnosis of Intermittent Claudication

Condition	Location	Characteristic	Effect of Exercise	Effect of Rest	Effect of Position	Other Characteristics
Calf IC	Calf muscles	Cramping, aching discomfort	Reproducible onset	Quickly relieved	None	May have atypical limb symptoms on exercise
Thigh and buttock IC	Buttocks, hip, thigh	Cramping, aching discomfort		Quickly relieved	None	Impotence; may have normal pedal pulses with isolated iliac artery disease
Foot IC	Foot arch	Severe pain on exercise	Reproducible onset	Quickly relieved	None	Also may present as numbness
Chronic compartment syndrome	Calf muscles	Tight, bursting pain	After much exercise	Subsides slowly	Relief with elevation	Typically heavy muscled athletes
Venous claudication	Entire leg, worse in calf	Tight, bursting pain	After walking	Subsides slowly	Relief speeded by elevation	History of iliofemoral deep vein thrombosis, signs of venous congestion, edema
Nerve root compression	Radiates down leg	Sharp lancinating pain	Induced by sitting, standing, or walking	Often present at rest	Improvement by change in position	History of back problems, worse with sitting, relief when supine or sitting
Symptomatic Baker's cyst	Behind knee, down calf	Swelling, tenderness	With exercise	Present at rest	None	Not intermittent
Hip arthritis	Lateral hip, thigh	Aching discomfort	After variable degree of exercise	Not quickly relieved	Improvement when not weight bearing	History of degenerative arthritis
Spinal stenosis	Often bilateral buttocks, posterior legs	Pain and weakness	May mimic IC	Variable relief, but can take a long time to recover	Relief by lumbar spine flexion	Worse with standing and extending spine
Foot/ankle arthritis	Ankle, foot, arch	Aching pain	After variable degree of exercise	Not quickly relieved	Possible relief by not bearing weight	Variable, may relate to activity level and present at rest

IC, Intermittent claudication.
Modified from Inter-Society Consensus for the Management of Peripheral Arterial Disease (TASC II).

and auscultation for bruits should be performed for carotid, abdominal, and femoral systems. The lower extremity should be carefully examined for signs of PAD and chronic limb-threatening ischemia (CLTI): dry skin/skin breakdown, wounds, infection, muscle atrophy, discoloration, absent distal hair growth, and weakened/absent distal pulses. Clinical history and examination are used to stage PAD, either with Fontaine's or Rutherford's classification systems (Table 2).

As a component of physical examination, measurement of the ABI is the primary method for establishing a diagnosis of PAD (Figure 1). ABI is performed by measuring the systolic blood pressure from the bilateral brachial arteries, dorsalis pedis, and posterior tibial arteries while the patient is supine. The ratio is calculated by taking the higher pressure of two arteries on each leg divided by the higher of the two brachial pressures. An index of less than 0.9 is diagnostic for PAD. ABI could be falsely elevated due to noncompressibility of the arteries from calcification; when ABI is ≥1.4, a toe-brachial index (TBI) is useful as digital arteries are less calcified. A TBI ≤0.7 is significant for hemodynamic arterial insufficiency. In patients who present with classic symptoms of PAD/claudication and a normal/borderline ABI at rest, an exercise ABI can be helpful in making the diagnosis. Using exercise ABI in diagnosing PAD can be challenging because of the variety of protocols for this test. Overall, the ABI is obtained immediately after completing the exercise. A decrease in ABI to a value ≤0.9 is indicative of hemodynamically significant arterial stenosis. Additional studies such as duplex ultrasound, computed tomography angiography (CTA), magnetic resonance angiography (MRA), and invasive angiography are reserved generally for highly symptomatic patients who may benefit from revascularization. It is recommended that all patients with IC follow up annually for assessment of lifestyle modifications, medical therapy optimization, and disease progression monitoring with ABIs.

TREATMENT

Management of patients with PAD includes treatment of comorbid disease, functional status improvement, and limb preservation. This can be achieved through lifestyle modification, optimization of treatment of comorbid diseases, and revascularization. IC severely affects quality of life and is associated with reduced survival. Upon initial diagnosis of PAD, patients must be educated on the progression of PAD and the importance of treatment compliance and follow-up regardless of symptoms. Patients with diabetes may develop CLTI without developing claudication first.

Medical Management

Smoking Cessation

The association between smoking and PAD is well recognized and studied. The severity of PAD symptoms correlates to the extent of smoking history. Smoking cessation reduces mortality risk,

TABLE 2 Fontaine's Classification of Peripheral Arterial Disease and Rutherford's Classification of Chronic Limb Ischemia

Fontaine		Rutherford			
Stage	**Clinical Findings**	**Grade**	**Category**	**Clinical Findings**	**Objective Criteria**
I	Asymptomatic	0	0	Asymptomatic	Normal treadmill or reactive hyperemia test
IIa	Claudication symptoms at distances >200 m	I	1	Mild claudication	Completes treadmill exercise; ankle pressure after exercise >50 mm Hg, but at least 20 mm Hg lower than resting value
IIb	Claudication symptoms at distances <200 m		2	Moderate claudication	Between categories 1 and 3
			3	Severe claudication	Cannot complete standard treadmill exercise; ankle pressure after excise <50 mm Hg
III	Ischemic rest pain, mostly in feet	II	4	Ischemic rest pain	Resting ankle pressure <40 mm Hg; ankle or metatarsal pulse volume recording flat or barely pulsatile; toe pressure <30 mm Hg
IV	Necrosis and/or gangrene of the limb	III	5	Minor tissue loss: nonhealing ulcer, focal gangrene with diffuse pedal ischemia	Resting ankle pressure <60 mm Hg; ankle or metatarsal pulse volume recording flat or barely pulsatile; toe pressure <40 mm Hg
			6	Major tissue loss: extending above transmetatarsal level, functional foot no longer salvageable	Same as category 5

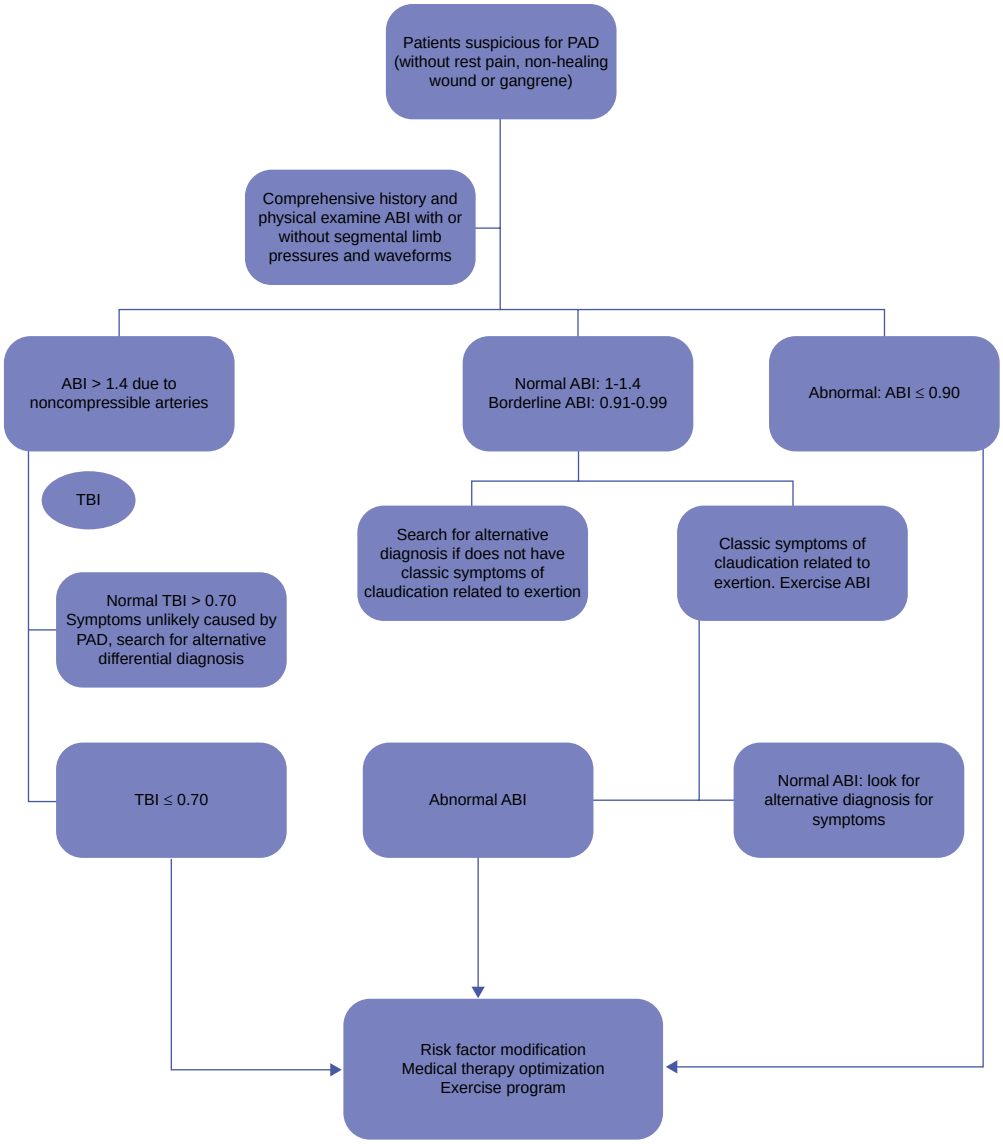

FIG. 1 Algorithm for peripheral arterial disease diagnosis in symptomatic individuals without signs of chronic limb-threatening ischemia.

progression of PAD to CLTI, amputation, heart attack, stroke, and bypass graft failure. Patients should be referred for counseling. The use of bupropion and varenicline have shown improved rates of abstinence.

Diabetes Mellitus

About one-third of patients with diabetes mellitus also have PAD. They are also more likely to develop wounds and progress to CLTI without having claudication symptoms. These patients are 5 to 10 times more likely to undergo amputation than nondiabetic PAD patients. The Society for Vascular Surgery practice guidelines recommend optimizing diabetes control with a hemoglobin A1c goal of <7.0%.

Hypertension

Hypertension is risk factor for cardiovascular disease as well as PAD. Recommendations for hypertension management have been published extensively. Previous concerns regarding worsening claudication as a side effect of beta blockers were proven invalid in a randomized controlled trial published in 1991 by Radack et al. Angiotensin-converting enzyme inhibitors (ACEIs) are shown to reduce mortality and cardiac events in patients with left ventricular dysfunction; use of ramipril showed a 25% cardiac event reduction in patients with PAD.

Hyperlipidemia

Evaluation of statin therapy initiation in patients without an atherosclerotic cardiovascular disease (ASCVD) diagnosis is based on the estimation of 10-year cardiovascular risk rather than specific lipid levels according to the 2018 AHA/ACC guidelines on management of blood cholesterol. Although the risk calculator does not include PAD specifically, it includes major risk factors for PAD such as age, gender, race, blood pressure, diabetes, and smoking status. Patients with clinical ASCVD such as acute coronary syndrome, history of myocardial infarction, stable or unstable angina, arterial revascularization, stroke, transient ischemic attack, aortic aneurysm, or PAD are recommended to begin high-intensity statin therapy with an aim of achieving a 50% or greater reduction in low-density lipoprotein

cholesterol (LDL-C) levels. Aside from cardiovascular risk reduction, statin therapy has also been shown to increase walking distance in two studies published in 2003 by Mohler et al. and Mondillo et al.

Antiplatelet and Antithrombotic Therapy

Antiplatelet therapy with aspirin in doses of 75 to 325 mg/day has shown to decrease cardiovascular events and vascular-related deaths in patients with symptomatic PAD. Clopidogrel has shown to be just as effective if not more in risk reduction; it is a comparable alternative for patients who have aspirin intolerance. Currently, there is no evidence to suggest that dual antiplatelet therapy is more effective than a single agent, especially with the elevated bleeding risk. There is a lack of evidence to suggest benefits of warfarin in the PAD population.

Homocysteine-Lowering Therapy

Homocysteine is a known risk factor for PAD. The association of homocysteine with atherosclerosis was initially documented in 1969 by McCully et al. when studying the vascular pathology of children with inherited disorders of homocysteine metabolism. Approximately 1 in 3 patients diagnosed with PAD also have an elevated homocysteine serum level, whereas the prevalence of elevated homocysteine in the general population is 1%. Although clinical trials have shown that folic acid and cobalamin (vitamin B_{12}) can lower homocysteine levels, there is no strong evidence currently to suggest that lowering homocysteine levels correlates with reduction of cardiovascular adverse events in patients with PAD.

Cilostazol and Pentoxifylline

In the United States, cilostazol and pentoxifylline are the only two medications currently approved by the US Food and Drug Administration (FDA) for IC symptom relief. Pentoxifylline was approved in 1984; it works by reducing blood viscosity and platelet aggregation to enhance blood flow. Its effects are modest, but it is generally a well-tolerated and safe drug. Dosing of pentoxifylline starts at 400 mg three times a day, with a maximum dosage of 1800 mg per day. Side effects of pentoxifylline include nausea, headache, drowsiness, anorexia, and exacerbation of hypertension. Cilostazol, a phosphodiesterase III inhibitor, was approved by the FDA for IC in 1999. Cilostazol works by direct vasodilation and platelet aggregation suppression; it can increase maximal walking distance in as short as 4 weeks. Cilostazol is contraindicated in patients with any level of heart failure and can cause headache and diarrhea. Effectiveness of cilostazol and pentoxifylline were studied in a randomized controlled trial by Dawson et al. In this study, cilostazol had a 54% maximal walking distance improvement, while pentoxifylline had a 30% improvement. The Society for Vascular Surgery guideline currently recommends a 3-month trial of cilostazol (100 mg twice a day) in patients without congestive heart failure and pentoxifylline (400 mg three times a day) for patients with contraindications to cilostazol.

Exercise Therapy

The effectiveness of exercise therapy in the management of claudication has been well studied and is the foundation of claudication therapy (Box 1). Benefits of an exercise program include collateral blood vessel enlargement, angiogenesis, nitric oxide–induced vasodilation, enhancement of bioenergetics of skeletal muscle, and hemorheology. Before initiating any exercise program, it is important to address medical therapy for optimization of comorbid disease as well as atherosclerotic risk reduction. Patients should be screened to ensure that their participation in an exercise program is safe. These programs come in a variety of forms: they can be self-directed, supervised, institution based, or home based and of varying intensity and duration. Studies have found that walking is superior to other forms of lower extremity exercise and that the greatest effects were achieved with walking programs that had at least three sessions per week with a duration of more than 30 minutes per session and the usage of near-maximal claudication pain as an endpoint.

BOX 1 Sample Walking Program Handout for Patient Use

Benefits of a Walking Program

Using a walking program to treat claudication has many benefits. It not only enables you to walk farther and faster, but it also helps with weight reduction and improves your outlook on life (as any exercise program will). Walking is the appropriate exercise for people with claudication (pain in calves or thighs with walking) because walking is the activity that is limiting you.

Rules of a Walking Program

1. Walk 6 days a week. Take the same day off each week. For example, if you take Sunday off the first week, it is the day you will take off each week.
2. Walk at about the same time each day. This enables your walking program to become part of your daily routine. After 1 or 2 weeks, your spouse, family, and friends will know that you will not be available at that time of day unless they want to walk with you.
3. Start by walking a 30 minutes a day. The time you take to rest (to let the pain subside) counts as part of your 30 minutes of exercise. Eventually you will be walking nonstop for the entire 30 minutes. After 2 months, increase your time to 45 minutes, and only increase it further if desired.
4. A slow, steady walk is best if you want to walk a maximum distance. Shorter, faster walks with more frequent rests will increase your endurance quicker; our recommendation is to start out with slow, steady walks for the first 1 or 2 months. After that, try faster, shorter walks several times each week with slower walks on the other days.
5. Remember that the pain that you feel in your legs is not an indication of any damage. It may be annoying and make you stop, but you are not damaging your muscles. If you can walk with the pain for a while, it will help increase your endurance.

Good luck! You will enjoy your walks. Caution: smoking is not permitted while walking.

Published in 2012, the CLEVER trial randomized 111 patients with IC caused by aortoiliac occlusive disease to optimal medical care, medical care with supervised exercise therapy, or medical care with stent revascularization. The study found that at 6 months, exercise therapy with optimal medical care provided the greatest improvement in peak walking time, and the stent revascularization group had the greatest improvement in quality-of-life parameters. There was no statistically significant difference found in peak walking time between the supervised exercise group and stent revascularization group. Currently, there is no strong evidence to prefer endovascular interventions over exercise therapy for the treatment of claudication when the patient is eligible for both. However, it is important to note that exercise therapy is not only a primary treatment for claudication, but it can also be an adjunct treatment to patients who underwent surgical intervention for claudication.

Current recommendations state that a supervised exercise program consisting of walking at least three times a week for a duration of 30 to 60 minutes for at least 12 weeks is the first-line therapy. When supervised programs are unavailable, home-based exercises with a minimum of 30 minutes of walking three to five times a week are desirable. Patients who have undergone revascularization for IC should participate in either a supervised or home-based exercise program.

Revascularization

When treated with optimized medical therapy, less than 5% of patients with claudication will progress to CLTI such as rest pain and

tissue loss or require amputation. Although IC is relatively benign, its effect on loss of ambulatory function, activities of daily living, occupation, and quality of life should not be minimized. Between 20% and 30% of patients with IC will eventually require intervention as a result of worsened disability despite lifestyle modifications and optimized medical therapy. Prophylactic intervention in patients with IC that is well tolerated is not indicated. ABIs or anatomic findings do not dictate the need for intervention in IC either. The decision to perform revascularization for IC is highly individualized; it should be based on the patient's functional impairment, quality-of-life changes, evidence of significant disease, and assessment of benefit versus risk.

It is important to remember that claudication may not be the only source of decreased functional status. Other factors such as arthritis, spinal stenosis, or myositis should be investigated and considered when discussing treatment options and potential outcomes after intervention. Patients with significant cardiovascular disease, chronic obstructive pulmonary disease, morbid obesity, or stroke may not benefit from intervention for IC as their comorbid diseases have a greater impact on their functional status and quality of life. Some studies have shown that although surgical and endovascular therapy are superior to medical therapy alone for improvement in walking performance, they are not superior to supervised exercise programs. Therefore, patients with IC should be managed with a 6-month trial of smoking cessation, medical therapy, and an exercise program with or without cilostazol before surgical or endovascular intervention.

Numerous studies have been published regarding the appropriateness and outcome of peripheral vascular intervention (PVI) for claudication. Using Medicare data between 2015 to 2017, Hicks et al. found that 3.2% of patients underwent PVI within 6 months of initial claudication diagnosis, and 320 physicians had an early PVI rate of ≥14%. Another study published in 2020 by Bath et al. discovered that of the 16,152 patients who underwent intervention for IC, only 32% were free from IC occurrence according to life table analysis, which did not meet the Society for Vascular Surgery guidelines for long-term freedom from recurrent symptoms of >50% at 2 years. This study also found that before undergoing intervention, medical management for many patients was not optimized. The personalized nature of PVI for IC and variety of methods/devices available for revascularization prompt future studies to further investigate the optimal intervention of choice and standardization of treatment.

Pseudoaneurysms and Arteriovenous Fistulas

Amani D. Politano, MD, MS

A pseudoaneurysm (PSA), or false aneurysm, is a focal outpouching of an artery that does not include all layers of the arterial wall. This outpouching may be contained by the adventitia or may consist only of a rim of fibrous tissue containing thrombus and arterial flow in continuity with a defect in an artery. In other words, it is a contained bleed from a focal site of the arterial wall. PSAs most commonly result from iatrogenic injury to the arterial wall but can be attributed to other etiologies as well (Box 1). Injury to the arterial wall results in pulsatile flow into the perivascular space, dissection into surrounding tissues, and hematoma formation. A persistent passage from the injury site results in a flow channel, or *neck,* leading into a false lumen, or *sac,* with to-and-fro arterial flow between the artery and the sac (Fig. 1). PSAs, unlike true aneurysms, lack all three normal elements of the arterial wall and are therefore at increased risk of rupture with potentially catastrophic bleeding. Postcatheterization femoral artery PSAs are the focus of this chapter.

RISK FACTORS

PSAs are most frequently seen as a complication related to percutaneous arterial access. The common femoral artery (CFA) is the most common access site for catheter-based interventions for cardiologists, interventional radiologists, and vascular surgeons alike. Techniques for accessing the CFA vary and include direct palpation of the pulse, fluoroscopic guidance, and ultrasound-guided access. The latter has become more prevalent because it results in fewer access-related complications and is considered the standard of care. Nonetheless, the incidence of femoral artery PSAs is increased when the puncture site is not in the CFA, but rather in the external iliac artery, superficial femoral artery (SFA), or profunda femoral arteries (PFA).

Risk factors for the development of iatrogenic PSAs associated with arterial access procedures are listed in Box 2. These can be divided into procedure-related and patient-related factors. Increased complexity of intraarterial interventions has been shown to increase the risk of vascular complications. Therapeutic interventions such as arterial angioplasty and stenting, atherectomy, and thrombolytic therapy have a higher rate of PSA formation (2%–8%) than diagnostic procedures (0.05%–2%). Related to both the therapeutic nature and complexity of interventions, larger diameter catheter or sheath use is also correlated with higher rates of PSA formation. Other procedural-related risk factors include simultaneous arterial and venous puncture, urgent versus elective procedures, the use of arterial closure devices, and insufficient duration of puncture site compression after the sheath is removed. PSA formation is less common when ultrasound guidance or fluoroscopic localization of the middle one-third of the femoral head is used for common femoral artery puncture. Patient-related risk factors contributing to PSA formation include advanced age, female gender, obesity, preprocedural thrombocytopenia, and postprocedural antiplatelet or anticoagulation use.

Diagnosis

PSAs may be asymptomatic or may present with mild tenderness to palpation or swelling in the groin after catheterization. Although

BOX 1 Etiologies of Pseudoaneurysm Formation

FIG. 2 Mass effect of a pseudoaneurysm causing pressure necrosis of the overlying skin.

this is the most common presentation of a PSA, more severe symptoms can be seen related to the mass effect of a PSA and associated hematoma. Large PSAs with associated hematoma may result in skin necrosis (Fig. 2) and/or compression of nerves and vessels in the groin. Lower extremity swelling, deep venous thrombosis, and/or ischemia secondary to vessel compression are rare but serious findings. Ruptured PSAs may present with hemodynamic collapse and significant groin or thigh swelling.

Any patient who experiences pain disproportionate to that expected after a percutaneous procedure should undergo evaluation to exclude PSA. Examination should include a thorough peripheral pulse examination, documentation of the ankle-brachial index, and limited ultrasonography of the vasculature in the affected groin. Laboratory assessments such as decreased platelet count (<200,000/L) or elevated D-dimer values have been shown to correlate with diagnosis of a PSA on duplex.

The diagnostic examination of choice is duplex ultrasound (DUS, 5- to 7-MHz linear transducer). Because B-mode imaging alone is unable to differentiate a PSA from a hematoma, color Doppler should be used to enhance the diagnostic accuracy of ultrasound (sensitivity, 94%; specificity, 97%) as it allows for identification of pulsatile flow within the sac. The typical appearance of a PSA on DUS is demonstrated in Figures 3 and 4. Active flow within the PSA sac is often referred to as *to-and-fro flow* or a *yin-yang pattern*. The PSA sac size (maximal diameter) and the length and width of the

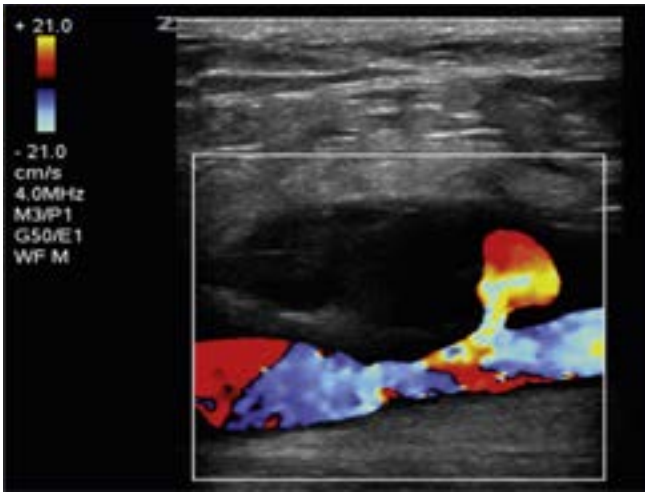

FIG. 3 Duplex ultrasound findings of a pseudoaneurysm include a fluid collection adjacent to the femoral artery, a high-velocity jet through the arterial wall, and a neck or communication with the artery.

neck should be measured with DUS because they are important for guiding treatment options. If an arterial duplex examination cannot be performed or if the results are equivocal, computed tomography imaging (with intravenous contrast) can be used to make the diagnosis of PSA (Fig. 5) or to obtain more detailed anatomic information to plan a surgical repair. In addition to assessing the PSA, DUS or computed tomography angiography should assess for secondary injuries, including posterior intimal arterial injury and presence of an arteriovenous fistula (AVF).

Treatment

Several treatment options for iatrogenic femoral PSAs exist. The therapeutic choice depends on the PSA size, neck characteristics, and the patient's symptoms. Treatment options include observation, ultrasound-guided compression (USGC), percutaneous ultrasound-guided thrombin injection (UGTI), and open surgical repair. More recently, creative therapeutic approaches have been described, including more advanced endovascular occlusion of the PSA neck, saline or glue injection, or hybrid endovascular/open and endovascular/injection techniques.

Observation

Studies have shown that most small PSAs (<2–3 cm) thrombose spontaneously within 4 weeks for patients not on anticoagulants. Conservative management, or a watch-and-wait policy, has been advocated for small and asymptomatic PSAs. Spontaneous resolution can be unpredictable; therefore, patients with small PSAs require periodic surveillance with DUS. The disadvantage of this watch-and-wait policy is that patients undergoing surveillance may have activity restrictions, discomfort with serial DUS, and prolonged hospital stays. PSAs that do not thrombose risk enlargement and additional complications; thus, adhering to a scheduled follow-up is critical. Patients considered at risk for being lost to follow-up should undergo definitive treatment initially.

USGC

USGC therapy has been shown to be a safe and noninvasive method for treatment of PSAs with success rates ranging between 73% and

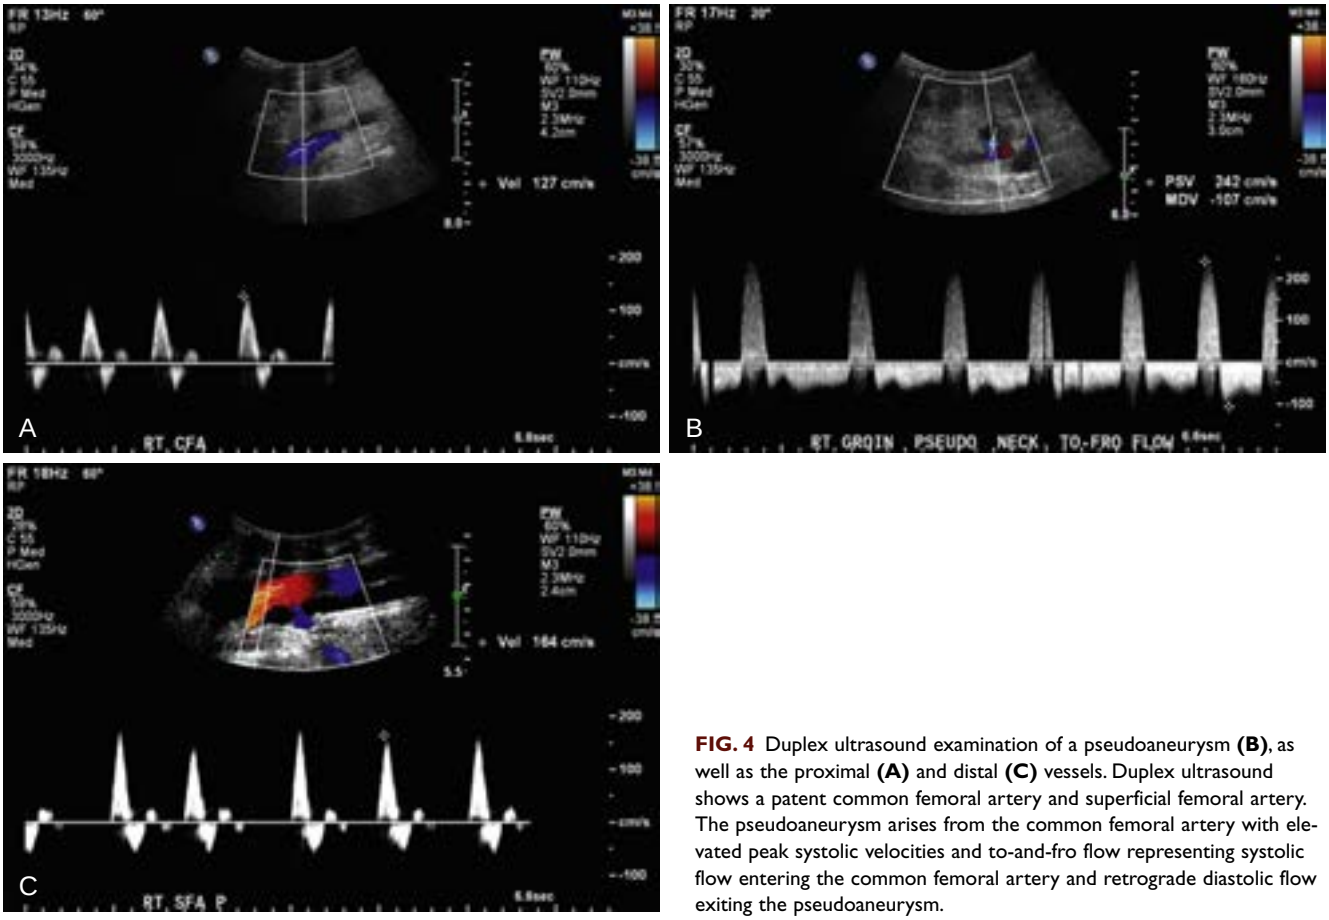

FIG. 4 Duplex ultrasound examination of a pseudoaneurysm **(B)**, as well as the proximal **(A)** and distal **(C)** vessels. Duplex ultrasound shows a patent common femoral artery and superficial femoral artery. The pseudoaneurysm arises from the common femoral artery with elevated peak systolic velocities and to-and-fro flow representing systolic flow entering the common femoral artery and retrograde diastolic flow exiting the pseudoaneurysm.

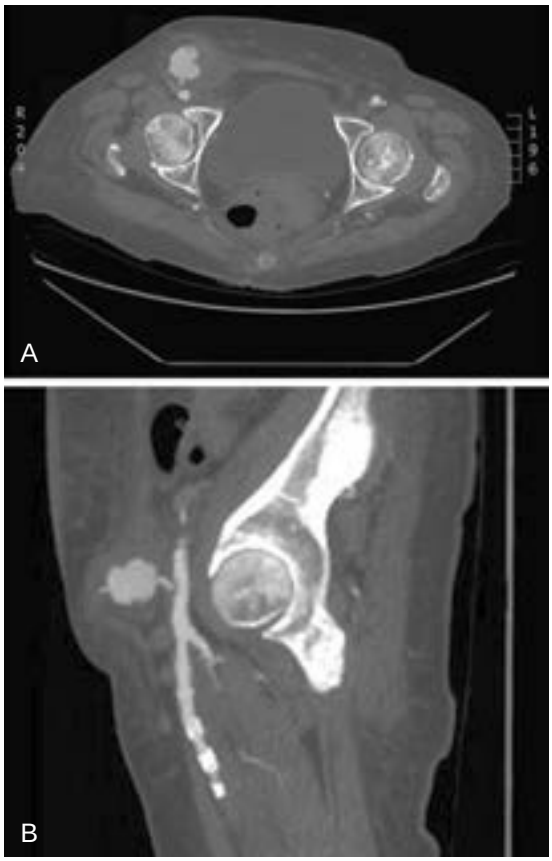

FIG. 5 Axial **(A)** and sagittal **(B)** CT angiographic images of a right femoral pseudoaneurysm and neck.

93%. Ultrasound is used to identify the PSA sac and neck. The ultrasound transducer is positioned over the PSA neck, and pressure is applied until there is obstruction of flow within the neck and sac. During compression of the PSA, cessation of flow within the PSA is verified with continual duplex imaging, whereas flow in the native artery is preserved. Blind manual compression has also been described but lacks continual monitoring to ensure complete occlusion of flow into the PSA and therefore risks inadequate treatment, especially when even small position changes by the patient can require the operator to make similar adjustments to maintain complete occlusion. Compression is usually held for increments of 10 to 15 minutes. This is repeated until successful PSA sac thrombosis is achieved, or until a discretionary failure time is met. Compression times average 33 minutes for acute PSAs and 51 minutes for more chronic PSAs (>14 days).

Limitations of USGC include both patient-specific and operator-dependent factors. Patient-specific concerns include the location of the PSA, body habitus, and ability to be compliant with or tolerate compression. Suprainguinal PSA compression is generally not recommended because it may result in PSA rupture and inability to quickly control bleeding. Brachial artery PSAs usually require operative decompression because of symptomatic nerve compression. It is more technically challenging to both achieve and maintain compression in an obese patient without operator fatigue. Compression is also time consuming and may not be well tolerated by patients. Conscious sedation can be administered with improved tolerance but requires increased resources (such as advanced nursing care and appropriate bed/unit placement during the procedure and recovery) and may increase overall risk to the patient. Operator-dependent factors include variable or inadequate compression, fatigue, and the time-dependent nature of the task.

Predictors of poor outcome with USGC include concomitant anticoagulation, large PSA size (>4 cm), and patient obesity. Patients with these negative predictors generally have lower technical success rates (25%–35%), higher recurrence rates (20%), and greater complication rates (3.6%) than patients without these factors. Complications and contraindications to USGC are listed in Box 3.

UGTI

UGTI has become the treatment of choice for medium-sized postcatheterization PSAs (2–5 cm). Thrombin is injected into the PSA sac for immediate thrombosis of the PSA (Fig. 6 and Box 4). This is an off-label use of thrombin; it is US Food and Drug Administration–approved for topical use only. UGTI is contraindicated in the setting of lower extremity ischemia, infection, AVF, and pregnancy.

UGTI has several advantages compared with USGC for the treatment of PSAs. The procedural time is shorter, the procedure is better tolerated by patients, and the technical success rate is greater (>96%). In addition, UGTI can be used effectively in the setting of concomitant anticoagulation or for suprainguinal PSAs. The ability to perform this procedure in the outpatient setting or at the bedside also reduces the relative cost. Complications of UGTI include arterial thrombosis (<2%), PSA rupture, treatment failure, or allergic response to bovine thrombin. Arterial thrombosis has been associated with the treatment of small PSAs (<2.5 cm). Complications related to neck length are more variably reported; arterial thrombosis has been shown not to be related to short neck length (<5 mm) although necks shorter than 2 mm have demonstrated increased risks of embolic complications. Exposure to bovine factor V may cause some patients to form antibodies that cross-react with human factor V and induce coagulopathy. Patients who undergo UGTI should have a follow-up duplex in 24 to 48 hours to ensure continued thrombosis of the PSA.

Endovascular Repair

Covered stents have been widely used in the treatment of aneurysms, but their use in femoral PSAs is limited. Current barriers include high cost, lower patency rates, the need for larger delivery systems, and the lack of long-term data. Endovascular repair is not recommended if treatment of the PSA requires placing a stent across the groin crease or across the origin of the PFA. Covered stent use can be considered for treatment of suprainguinal PSAs where the distal endpoint of the stent does not cross beneath the inguinal ligament. Complications unique to covered stents include infection, migration, and thrombosis. Long-term duplex surveillance is required postprocedure to monitor for in-stent restenosis and stent patency.

The use of covered stents for treatment of infected PSAs is not recommended. In the setting of advanced cancer, definitive treatment

PSA, Pseudoaneurysm.

FIG. 6 Ultrasound-guided thrombin injection. A 1-mL syringe containing bovine thrombin (1000 units/mL) and a 5-mL syringe with sterile normal saline flush are connected to a three-way stopcock fitted with a 22-gauge needle (40 mm or 70 mm). If the pseudoaneurysm (PSA) is deeper than 3.75 cm, then a 21-gauge × 9 cm Echotip needle (Cook Medical) can be used. The PSA sac is visualized in transverse and longitudinal views on duplex ultrasound. The thrombin port is placed in the "off" position and the saline port is placed in the "on" position. The needle and transducer are kept parallel as the needle is advanced under ultrasound guidance. Puncture into the sac is kept superficial and far from the PSA tract. Proper needle placement is confirmed by aspiration of blood, and a small injection of saline will produce a flash of color on duplex ultrasound. The thrombin port is placed in the "on" position and the saline port is placed in the "off" position. Thrombin is then injected into the PSA sac in 0.2-mL aliquots until there is cessation of blood flow in the PSA sac and tract. This can usually be achieved in seconds. The tract should never be directly injected because of the risk of thrombosis of the native artery. An average of 300 units (0.3 mL) of thrombin (range, 50–1000 units) is required to thrombose the PSA sac. An arterial duplex is repeated 24 hours postprocedure to check for recurrence (0%–9%) and to rule out postprocedure complications.

of a PSA via covered stent placement with or without coiling and covering of the PFA may have a role. Covered stent use has also been described in intravenous drug abusers who present with ruptured PSAs or acute sepsis associated with an infected PSA. In these settings, the stent provides a bridge to arterial reconstruction by obtaining hemostasis or allowing for surgical debridement of the infected tissue before reconstruction. When definitive arterial reconstruction is anticipated, preservation of the profunda is recommended.

Some authors have described using endovascular balloon occlusion of the origin of the PSA at the time of thrombin injection to reduce the risk of intraarterial thrombosis, especially if there are concerns for a wide or short neck. This risks access site complications at the contralateral femoral access site but has been performed successfully. Case reports have also described the use of various arterial closure devices (e.g., Angio-Seal and Star-Close, Perclose ProGlide, Amplatzer plug) to treat iatrogenic PSAs.

Open Surgical Repair

Noninfected Pseudoaneurysms

Patients with contraindications to compression therapy or thrombin injection should be considered for open surgical repair. These include peripheral or cutaneous ischemia, infection, presence of a surgical graft, large suprainguinal PSAs, or those who present with complicated PSAs (i.e., rapid enlargement, distal embolization, rupture) (Fig. 7). Repair of suprainguinal PSAs requires retroperitoneal access to achieve proximal control of the iliac vessels. Hybrid open and endovascular techniques, in which endovascular balloon occlusion is used to provide proximal and/or distal control through either the PSA itself or via contralateral femoral access, have been described.

Once proximal and distal control are obtained, the PSA can be opened and the defect repaired. Often, the actual arterial injury is small and can be repaired with a simple, interrupted polypropylene suture. The back wall of the artery should be inspected to ensure no posterior arterial injury. Patch angioplasty may be required if the arterial wall is significantly damaged or if there is luminal narrowing of the artery with primary repair. Any hematoma should be evacuated, and in the setting of a large tissue defect or hematoma, drain placement may be necessary. Complications associated with open surgical repair include wound infection, bleeding, lymphocele, radiculopathy, perioperative myocardial infarction, and death.

BOX 4 Three-Way Stopcock Technique of Ultrasound-Guided Thrombin Injection

- The patient's groin is prepped and draped in the usual sterile fashion.
- The distances from the skin to the most superficial portion of the PSA sac and the distance to the PSA tract are measured.
- The skin and subcutaneous tissue are infiltrated with 1%–2% lidocaine.
- A three-way stopcock is prepared as described in Figure 6.
- The needle is advanced under DUS guidance to the depth measured in step 2 and the PSA sac is entered superficially. Entry into the PSA sac is confirmed by aspiration of blood and proper placement of the needle tip is confirmed by saline injection on DUS. The needle must be in the PSA sac and *not* in the tract, artery, or vein.
- The thrombin port is turned on and the saline port is turned off. Thrombin is injected gently in 0.2-mL aliquots until the PSA sac and tract are thrombosed or until 1.0 mL (1000 units) of thrombin is used.
- If there are ≥2 PSA sacs, then the most superficial sac is injected first.
- If the tract persists, do *not* inject directly into the tract. Follow the patient as the tract normally thromboses within 24 hours.
- A DUS is repeated 24 hours postprocedure to check for recurrence (0%–9%) and rule out postprocedure complications such as arterial or venous thrombosis.
- This procedure may be performed on an outpatient basis with the patient discharged immediately after injection.
- A PSA that recanalizes after thrombin injection may be reinjected on follow-up visit.

DUS, Duplex ultrasound; *PSA*, pseudoaneurysm.

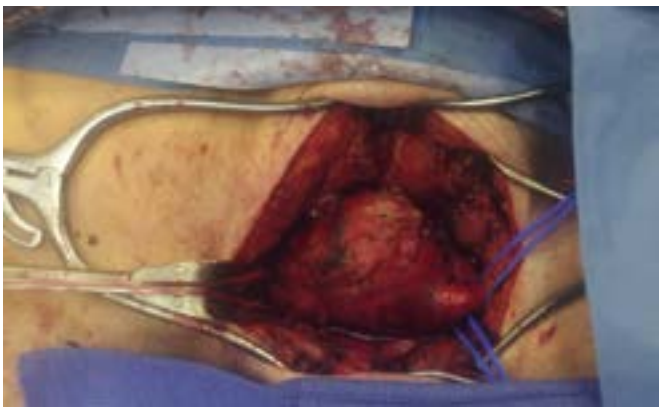

FIG. 7 Noninfected femoral pseudoaneurysm requiring open surgical repair because of its large size and overlying skin necrosis.

Infected Pseudoaneurysms

Compression or injection of infected PSAs is contraindicated, and they must be treated promptly and operatively. Management includes appropriate antibiotic coverage, debridement of infected tissue, and arterial repair or replacement with autogenous vein graft. Arterial ligation without revascularization is reserved for aggressive bacterial infection and may be associated with intermittent claudication or limb loss. Muscle flap coverage of the tissue defect may be required to further protect the repair. Except for rare circumstances, such as providing immediate hemostasis of an acute rupture with planned definitive management including stent removal once the patient is stabilized, endovascular occlusion with covered stents should be avoided.

Alternate Percutaneous Methods

Paraaneurysmal saline injection has been described as an alternate method to either USGC or UGTI for PSAs. This technique uses ultrasound guidance to position a needle outside of the artery along the PSA neck, and injects normal saline (30–80 mL) into the extravascular tissue to cause external compression of the PSA neck and obliteration of flow within the PSA. A second injection on the opposite side of the PSA neck is sometimes required, and the injection is followed with five minutes of manual compression.

Cyanoacrylate glue has also been used for percutaneous treatment of PSAs. Various reports describe intrasac injection, much like thrombin, or injection into the collapsed PSA walls. This second method uses USGC of the PSA before injection, with subsequent injection of small aliquots of the glue directly into the apposed walls of the PSA. Compression is continued for 5 minutes, and injection and compression are repeated if signs of reperfusion are seen with gradual release of compression. Administration of cyanoacrylate glue has also been described using contralateral arterial access to provide balloon occlusion across the PSA neck during injection.

Although studies have demonstrated initial success with each of these techniques, further investigation is warranted.

Anastomotic Pseudoaneurysms

Anastomotic PSAs are an infrequent but important late complication of prosthetic arterial reconstruction (Fig. 8). The femoral arterial anastomosis is the most common site for an anastomotic PSA (13.6%). The presence of an anastomotic PSA should raise suspicion of a graft infection, and treatment should be planned with this in mind. An anastomotic PSA is typically composed of a fibrous pseudocapsule surrounding an occult graft infection or arterial degeneration in a previously endarterectomized artery. Because anastomotic PSAs are unpredictable and are associated with a high incidence of rupture, they should be treated early and aggressively.

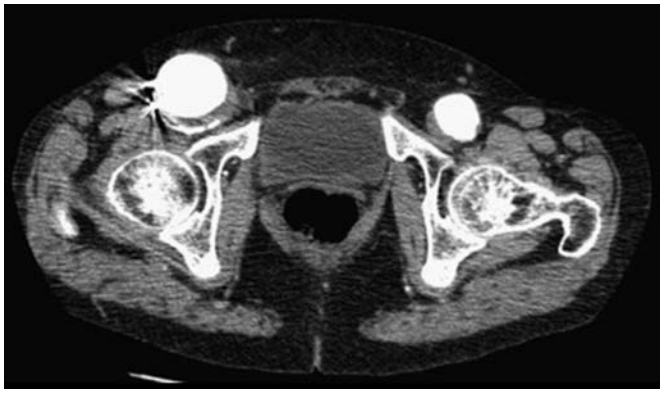

FIG. 8 Bilateral femoral anastomotic pseudoaneurysms. This patient underwent bilateral common femoral endarterectomies and an aortobifemoral bypass for aortoiliac occlusive disease 15 years before presentation. There are no fluid collections or edematous streaks within the tissue surrounding the pseudoaneurysms, which suggests no evidence of infection. On physical examination and laboratory testing, no clinical evidence of infection was found.

Observation can only be recommended for patients with very small PSAs, prohibitive operative risk, or short life expectancy. Operative repair is generally recommended for all groin anastomotic PSAs greater than 3 to 4 cm in diameter. If there is no evidence of infection and a well-incorporated graft, interposition graft replacement of the degenerative aneurysmal portion of the existing graft can be performed safely. If the graft is infected, removal and replacement of all infected graft and tissue is necessary. Revascularization may require extraanatomic bypass grafting through a noninfected field or replacement of the infected conduit with autogenous femoral vein. Grossly infected arterial beds may require coverage with sartorius or rectus femoris muscle flaps. Endovascular repair of femoral artery anastomotic PSAs has been reported; however, it is generally not recommended in the setting of infection or when stenting would result in occlusion of the PFA origin.

ARTERIOVENOUS FISTULA

An AVF is an abnormal communication between an artery and vein. Although AFVs can be congenital, they are more frequently iatrogenic or traumatic. Femoral AVFs almost always develop secondary to penetrating injuries or percutaneous vascular interventions. The incidence of postcatheterization femoral AVF is 0.2% to 2%. Patient-related risk factors include female gender, hypertension, and ongoing anticoagulation. Age and morbid obesity have not been identified as risk factors. Procedural-related risk factors include left-sided groin punctures and high levels of anticoagulation (>12,500 units of periprocedural heparin). Postcatheterization femoral AVFs will be the focus of this section.

Diagnosis

The diagnosis of an AVF in the extremities can be made with history and physical examination. Physical examination may reveal a loud bruit on auscultation and a thrill on palpation. A to-and-fro holosystolic/diastolic bruit at the puncture site is pathognomonic for an AVF, and the intensity of the sound on auscultation typically correlates with the size of the fistula. Large AVFs may also present with unilateral limb swelling, mild to severe limb ischemia (claudication or tissue loss), or heart failure. If physical examination findings are not diagnostic but an AVF is suspected, DUS can be a useful diagnostic tool. AVFs are characterized by high arterial peak systolic velocities proximal to the fistula resulting from low resistance at the fistula site. Reduced arterial flow distal to the fistula is secondary to shunting, and bidirectional or turbulent flow is seen at the fistula site. The venous side of the AVF demonstrates pulsatile flow with elevated peak systolic velocities that result from mixing of arterial and venous flows.

Treatment

Iatrogenic AVFs, unlike traumatic AVFs, may close spontaneously. Studies have shown that 38% to 56% of iatrogenic postcatheterization femoral AVFs resolve spontaneously. Iatrogenic AVFs are more likely to persist in patients with chronic renal insufficiency or concomitant steroid use. Patients with small or low-flow AVFs may never develop symptoms and can be safely managed conservatively. Repair is indicated for all symptomatic patients.

Open Surgical Repair

Surgical repair is the traditional method for treating femoral AVFs and is associated with morbidity and mortality rates of 25% and 8%, respectively. The principle of surgical repair is obliteration of the connection between the artery and vein with restoration of vessel

patency. Proximal and distal control of both the artery and vein is required. Because AVFs can result in significant enlargement of venous structures, operative repair can be associated with significant blood loss. Preoperative placement of arterial or venous balloons for intraoperative occlusion may help decrease blood loss during the repair, and cell-saver and rapid-infusion devices can be used when large volumes of blood loss are anticipated. Repair can be achieved with primary closure of the fistula tract, vein patch angioplasty, or interposition bypass graft.

Endovascular Repair

Endovascular treatment of iatrogenic or traumatic femoral AVFs is becoming more commonplace. Catheter-based interventions are indicated for high-risk surgical patients, or those who present with "hostile" anatomy such as morbid obesity, previous femoral interventions, or prior groin surgery, and those with obvious massive enlargement of venous collaterals. The most common endovascular method of treating AVFs is placement of a covered stent in the arterial system to occlude the connection between artery and vein. Contraindications to endovascular repair include patients in whom endovascular stenting will obliterate the PFA or cross the groin crease. The placement of CFA stents also precludes use of that site for future endovascular access. Venous stents are usually reserved for iliac vein or inferior vena cava AVF occlusion after unsuccessful intraarterial stent placement. SFA stent grafts for iatrogenic femoral AVFs have a reported 1- and 4-year primary patency of 76% and 55%, respectively, and a 4-year secondary patency rate of 80%.

Alternative endovascular methods for treatment of AVFs include embolization with coils, cyanoacrylate glue, collagen or gelatin, and others. During embolization, percutaneous venous access with balloon inflation may be required to occlude the venous outflow if there is a short tract connecting the artery and vein. Using detachable coils and packing smaller coils after larger coils can reduce inaccurate placement. Amplatzer plug occlusion of a femoral PSA with concomitant AVF has also been described.

Management of Peripheral Arterial Thromboembolism

Alik Farber, MD, and Elizabeth Gherardi King, MD

BACKGROUND/OVERVIEW

Embolus, derived from the Greek word *embolus* or *plug,* refers to intravascular material that originates in one location and travels to a remote site. When an embolus lodges in a distal artery or arteriole, it causes interruption of blood flow to downstream tissue. In the case of the peripheral arteries, this often leads to acute limb ischemia (ALI). A vascular emergency occurring in approximately 1.5 in 10,000 patients per year, ALI can result in severe morbidity and mortality if not diagnosed and managed expeditiously. Acute limb ischemia presents a challenge for the surgeon because of the consequences of potential tissue injury and the associated medical comorbidities inherent to this patient population. Diagnosis of ALI secondary to embolism can often be made by a comprehensive history and physical examination along with selective use of diagnostic imaging studies. The goals of management of peripheral arterial embolism include immediate anticoagulation and expeditious restoration of arterial circulation using open or endovascular techniques as well as identification and appropriate treatment of the embolic source.

CLASSIFICATION, SITE, AND SOURCE OF EMBOLISM

Peripheral arterial embolism can be classified according to the size of the embolus (macro or micro), the site of embolism (extremity, visceral, or cerebral), and the source of embolism (cardiac and noncardiac) (Table 1).

Macroemboli are usually composed of organized thrombus, with the heart being the most common source. Anatomically, arterial emboli to the extremities typically lodge at bifurcations, obstructing flow and resulting in distal ischemia with the lower extremities more often affected than the upper extremities. In the lower extremity, the most common site is the bifurcation of the common femoral artery (CFA), followed by the aortoiliac arterial segment and the popliteal artery. In the upper extremity, the most common location is the brachial artery at the bifurcation of the radial and ulnar arteries, followed by the axillary artery at the origin of the deep brachial artery. Embolism is the most common cause of upper extremity ALI. In the lower extremity, because of the high prevalence of arterial occlusive disease, ALI is most commonly a result of in-situ thrombosis.

Cardiac causes of peripheral embolism account for approximately 80% of all cases. This includes emboli originating in the left atrium of patients with atrial arrhythmias, left ventricular thrombus in the setting of a recent myocardial infarction (MI), prosthetic heart valves, valvular heart disease caused by rheumatic fever or endocarditis, and atrial myxomas. Approximately 0.5% of patients with atrial fibrillation (AF) will experience clinically significant non-cerebrovascular systemic embolic events translating into an incidence of 0.24 per 100 patient-years. Two-thirds of these events affect the extremities, and one-third affect the visceral-mesenteric circulation. Patients with permanent rather than paroxysmal AF and those with AF of longer duration (>2 years) are at highest risk. The use of anticoagulation in this patient population has been associated with a lower incidence of systemic embolic events, with direct oral anticoagulants (DOACs) shown to be at least as effective as vitamin K antagonists. The 30-day mortality after experiencing a systemic embolic event in this patient population is 15% to 25% and has remained relatively unchanged over the past three decades. Additionally, 18% of these patients experience major adverse cardiac events within 1 year of a

lower extremity thromboembolic event. The thromboembolic risk for prosthetic heart valves ranges from 0.6% to 2.3% per patient year, with similar rates among patients with mechanical valves on therapeutic anticoagulation and patients with bioprosthetic valves. Mitral prosthetic valves have a two to three times greater risk compared with prosthetic aortic valves because of differences in flow hemodynamics.

Noncardiac etiologies of peripheral arterial emboli account for 15% to 20% of peripheral arterial emboli. Sources of emboli include arterial aneurysms, most commonly involving the aorta or popliteal artery, atherosclerotic plaques, trauma, thrombosed native arteries or bypass grafts, and paradoxical emboli from a deep venous thrombosis that embolizes into the arterial circulation through an intracardiac septal defect.

In contrast with macroemboli, microemboli are typically composed of platelet aggregates or cholesterol crystals originating from atherosclerotic plaque. They can occur spontaneously as a result of plaque rupture or secondary to plaque disruption caused by arterial instrumentation during a percutaneous endovascular procedure. Embolization of this debris into small arterioles induces an inflammatory response leading to luminal occlusion and focal ischemia without major tissue loss. However, the degree of injury correlates with the aggregate volume of embolus and can be extensive in some cases.

CLINICAL PRESENTATION

Acute ischemia is often characterized by the "six *P*s": pain, pulselessness, poikilothermia, paresthesia, pallor, and paralysis. The clinical presentation may vary depending on location of embolus, duration of occlusion, extent of collateral circulation caused by existing arterial occlusive disease, and underlying etiology.

History and physical examination help differentiate an acute embolic event from a thrombotic occlusion or chronic peripheral arterial disease (PAD). Pertinent history includes prior embolic episodes, recent MI, arrhythmias, valvular heart disease, aneurysmal disease, dissection, prior vascular interventions, and hypercoagulable states. Overall cardiovascular risk factors including hypertension, hyperlipidemia, diabetes, and smoking should be assessed. A critical detail to note is the duration of symptoms, as irreversible muscle and nerve injury starts after 6 to 8 hours of severe acute ischemia.

Acute onset of ischemic pain in a patient without preexisting symptoms of PAD and a normal vascular examination of the nonischemic limb suggests an embolic event. Such patients are often able to pinpoint the exact onset of symptoms, and the degree of limb ischemia is usually severe. A history of AF, prior MI, or valvular disease may be present. In contrast, older patients with a history of claudication, rest pain, or nonhealing ulcers are likely to have preexisting PAD, and symptoms usually reflect in-situ thrombosis of a diseased vessel. In patients with an acute-on-chronic process, the established collateral circulation may limit the magnitude of ischemia. However, it can be difficult to reliably distinguish between embolic and thrombotic causes, especially in older adult patients with risk factors for PAD. Differential diagnosis of ALI also includes acute aortic dissection, aneurysmal disease, iatrogenic trauma, or a hypercoagulable state.

Physical examination is used to determine the severity of acute limb ischemia and level of occlusion, and it aids in determining the most appropriate management. Acute limb ischemia is graded using Rutherford's classification based on the neurologic and vascular examination of the affected limb (Table 2). The affected extremity is visually evaluated for color, livedo reticularis, and cyanotic mottling and felt for changes in temperature while comparing such findings to the contralateral limb. Motor and sensory examination aims to localize areas of decreased or abnormal sensation and muscle weakness or paralysis. In the lower extremity, the deep peroneal nerve in the anterior compartment is most susceptible to ischemia and can manifest with diminished sensation at the first web space and weakness of dorsiflexion. This is often an early sign of severe ischemia. Asymmetric loss of palpable distal pulses and Doppler signals with an accompanying "water-hammer" pulse proximal to level of occlusion, as well as delayed or absent capillary refill may be noted.

Peripheral microembolism typically presents with localized toe or finger pain and is more commonly observed in the lower extremities. Patients with lower extremity microembolization or "blue toe syndrome" develop painful and discolored toes. Depending on the degree of embolization, patients may have palpable pedal pulses. Involvement of the toes on both feet suggest that the culprit lesion is proximal to the aortic bifurcation. Other potential skin manifestations include petechiae, purpura, and splinter hemorrhages. Palpation of the abdomen, popliteal fossa, and groin is important as it may reveal culprit aortic, popliteal, or femoral aneurysms.

DIAGNOSTIC EXAMINATION

Imaging can help elucidate the etiology to identify the responsible ulcerative plaque; exclude dissection, a thrombosed aneurysm, or acute thrombosis of an atherosclerotic vessel; and aid in operative planning. However, imaging should not delay the need for emergent

TABLE 2 Clinical Categories of Acute Limb Ischemia

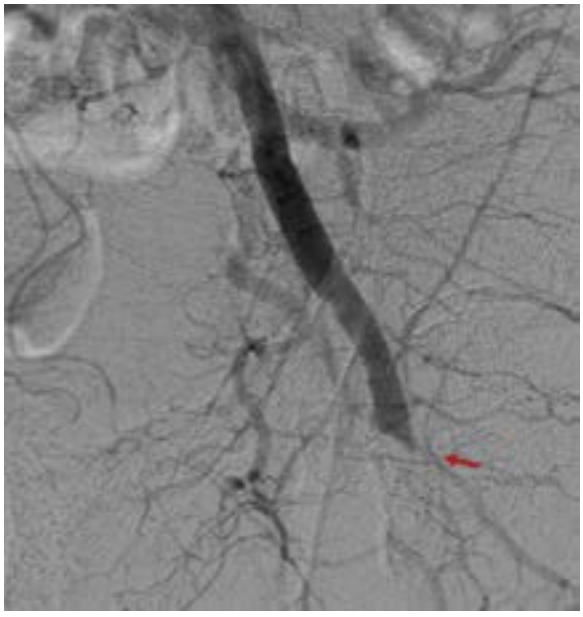

FIG. 1 Angiogram showing an abrupt cutoff of the left common femoral artery consistent with the appearance of an embolus *(arrow)*.

revascularization in patients with profound ischemia given the risk of irreversible muscle and peripheral nerve damage.

Current imaging modalities include duplex ultrasonography (DUS), magnetic resonance angiography (MRA), computed tomographic angiography (CTA), and digital subtraction angiography (DSA). CTA of the chest, abdomen, and pelvis with lower extremity runoffs is preferred as it can be performed expeditiously at most centers. CTA requires a large volume of iodinated contrast, which should be considered in patients presenting with renal insufficiency. In such cases, direct intraoperative assessment with DSA using a limited volume of contrast dye or carbon dioxide may be preferred. The typical angiographic appearance of an acute embolus is that of an abrupt vessel occlusion with a "meniscus" sign and minimal contrast filling distal to the occlusion (Fig. 1).

MANAGEMENT

Initial Medical Management

When peripheral artery embolism is suspected, initial management includes intravenous fluid resuscitation and anticoagulation. Fluids should be isotonic and avoid added potassium until baseline renal function is assessed. In the absence of contraindications to therapeutic anticoagulation, a loading bolus of 80 to 100 U/kg of intravenous heparin should be administered to prevent propagation of the thrombus and maintain patency of collateral vessels. This is followed by a 15–18 U/kg per hour infusion to achieve an activated partial thromboplastin time (aPTT) goal of 60 to 100 seconds. Direct thrombin inhibitors, lepirudin (cleared renally) or argatroban (metabolized by the liver) may be used in patients with intolerance to heparin with a similar aPTT goal. A 12-lead ECG should be obtained to evaluate for arrythmia. Laboratory studies, including a complete blood count, basic metabolic panel, coagulation studies, creatinine phosphokinase (CPK), lactate, and blood bank sample for type and screen should be ordered.

Selection of Approach

The two primary approaches for treatment of ALI caused by peripheral artery thromboembolism are open surgical thromboembolectomy and percutaneous endovascular therapy consisting of catheter-directed thrombolysis (CDT), pharmacomechanical thrombectomy (PMT), or aspiration mechanical thrombectomy (AMT).

A Cochrane meta-analysis of five prospective randomized controlled trials compared catheter-directed thrombolysis using recombinant tissue plasminogen activator (rtPA) or urokinase with surgical embolectomy in patients with ALI. The 1-year death and amputation rates were similar; however, significantly higher rates of stroke (1.3% vs. 0%), major bleeding (8.8% vs. 3.3%), and distal embolization (12.3% vs. 0%) were observed in patients who underwent thrombolysis. Unfortunately, these trials did not include more contemporary methods of PMT. A more recent meta-analysis including 25 studies examining endovascular and surgical revascularization techniques in ALI also concluded that catheter-driven thrombolysis techniques had comparable limb salvage rates to open surgery albeit with a higher risk of hemorrhagic complications. However, conclusions regarding the use of a hybrid approach or comparisons between various endovascular techniques could not be made.

Several factors including severity of ischemia, time to reperfusion, chance of recovery, etiology, location of embolus, procedural risks, comorbid conditions, and cost should be considered when selecting the approach to revascularization in any given patient.

An endovascular approach should be contemplated in patients with a marginally threatened limb (Rutherford I and IIa), those at medically high-risk for open surgery, and in the setting of a thrombotic occlusion. Patients with distal emboli, as observed in patients with a normal femoral pulse but absent distal pulses, may benefit from an initial angiogram and CDT/mechanical thrombectomy. This strategy may be more effective in establishing reperfusion of

smaller distal vessels as well as elucidating concomitant atherosclerotic lesions that may be treated endovascularly. In the case of thromboembolism associated with a popliteal artery aneurysm, establishment of distal peripheral circulation using thrombolysis is the recommended strategy in the absence of immediate limb threat. The disadvantage of CDT is the relatively longer period required to achieve tissue reperfusion and the risk of potential bleeding complications. Percutaneous mechanical thrombectomy techniques were introduced to address these shortcomings, decreasing the need for prolonged infusion times and reducing the need for multiple procedures required for successful thrombolysis. Absolute contraindications to pharmacologic thrombolysis include active bleeding, stroke or neurosurgical procedure within 3 months, malignant intracranial neoplasm, history of hemorrhagic stroke, or recent gastrointestinal bleed. Relative contraindications include severe hypertension, central nervous system tumors or known intracranial pathology, trauma, and major surgery within 3 weeks.

Open embolectomy is preferred in patients with an immediately threatened limb (Rutherford IIb) because of the ease and speed of establishing reperfusion and in patients with a contraindication to fibrinolytic therapy. Ideally these cases are performed in a hybrid operating room that allows for use of adjunctive endovascular techniques and completion angiography. An open femoral embolectomy is indicated in patients with an absent or water hammer ipsilateral femoral pulse and normal contralateral femoral pulse, while the absence of both femoral pulses suggests an aortic thrombus requiring bilateral femoral embolectomies. Upper extremity emboli are most often managed with an open approach because of small vessel size, ease and speed to reperfusion, and few complications.

In patients with irreversible ischemia (Rutherford III) with complete loss of motor and sensory function, inaudible arterial and venous Doppler signals, and the presence of livedo reticularis, revascularization may cause life-threatening physiologic changes with little chance of functional limb salvage. A primary amputation in this setting is preferable to avoid multiple organ failure and death.

Open Surgical Technique

The balloon embolectomy catheter, introduced by Thomas J. Fogarty and colleagues in 1963, remains the primary open surgical technique in the treatment of acute peripheral arterial embolism. The Fogarty embolectomy catheter allows for thromboembolic material to be extracted distal and proximal to the arteriotomy site.

The choice of arteriotomy depends on several factors, including anticipated location of emboli, convenience of vascular exposure, and the ease of arteriotomy closure. For iliac, femoral, and popliteal emboli, the CFA is the access of choice because of ease of exposure and relatively large diameter. Bilateral CFA access is required for embolectomy of an embolus at the aortic bifurcation. A popliteal or tibial thrombus can be approached using the below-knee popliteal artery. The distal brachial artery, at its bifurcation, is usually accessed during upper extremity embolectomy. Smaller arteries, at the ankle or wrist, can also be accessed in selected cases.

Open surgical exposure is performed with proximal and distal control obtained using vessel loops. Systemic heparin is administered. An arteriotomy is created at the arterial bifurcation to allow intraluminal access to branch vessels. The decision to perform a transverse or longitudinal arteriotomy depends on the quality of the artery, extent of arterial occlusive disease, and possible need to use the arteriotomy for inflow of a distal bypass graft. A transverse arteriotomy is used when the artery is relatively normal, whereas a longitudinal arteriotomy is preferred if the artery is diseased and further access to the artery is needed for endarterectomy or bypass.

The balloon-tipped catheter is introduced through the arteriotomy and advanced beyond the embolus. Inflation of the balloon is performed during slow withdrawal of the catheter and leads to concomitant clearance of the occlusive material (Fig. 2). Care must be taken with this technique as there is potential for inducing further arterial trauma. Although saline is used to fill the balloon by some, we believe that use of air allows for better sense of the appropriate amount of tension between the inflated balloon and the intimal surface of the artery. Inflation of the balloon should only occur as the catheter is moved to gain a sense of when enough air fills the balloon to result in some resistance between the balloon and the arterial wall. The presence of atherosclerotic disease may result in increased resistance to withdrawal, in which case the balloon should be partially deflated to prevent injury to the diseased vessel. Overdistention of the balloon or passage into a branch vessel may result in arterial dissection or rupture. The embolectomy catheter is used to clear the vessel proximal and distal to the arteriotomy until at least two passes result in no further withdrawal of embolic material. Adequate proximal inflow and distal back bleeding suggest a successful result but do not confirm complete thrombus retrieval. Pathologic analysis of the embolus should be considered in cases of unclear etiology to evaluate for tumor thrombus, myxoma, or an infectious source.

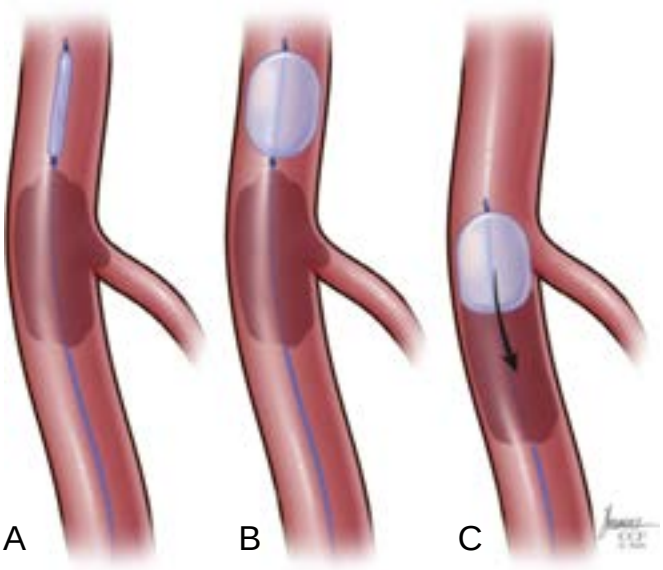

FIG. 2 Balloon thromboembolectomy technique. **(A)** The balloon-tipped catheter is introduced via arteriotomy and passed through the embolus beyond the occlusion. **(B)** The balloon is inflated while slowly withdrawing the catheter to prevent damage to the arterial wall. **(C)** The inflated balloon catheter is withdrawn to clear the thromboembolic material.
(From Seegmiller CJ, Cogbill TH. Management of peripheral arterial thromboembolism. In Cameron JL, Cameron AM, eds. Current Surgical Therapy. *13th ed. Philadelphia: Elsevier: 2020:1016.)*

The arteriotomy is closed and the affected limb examined for evidence of restored perfusion. A transverse arteriotomy is closed primarily, while a longitudinal arteriotomy usually requires closure using a patch to avoid creation of a stenosis. Intraoperative angiography should be performed if the limb remains inadequately perfused and there is need to delineate arterial anatomy to locate residual thrombus or identify a potential bypass target. Residual thrombus may be treated with 2 to 4 mg of recombinant rtPA flushed into the distal arterial bed. In the event of vasospasm of the distal arteries, intra-arterial vasodilators such as papaverine or nitroglycerin can be administered. If revascularization is inadequate and a suitable distal target vessel is present, open surgical bypass may be indicated. In the absence of a distal bypass target, anticoagulation should be continued and the extremity observed to determine the level of amputation required.

Arterial thromboembolectomy is associated with high morbidity and has an operative mortality approaching 30%. This underscores the critically ill nature of patients with acute limb ischemia and the

importance of an experienced anesthesia provider. Consideration should be given to performing brachial and femoral embolectomies under local anesthesia; however, more difficult technical approaches and those requiring correction of underlying atherosclerotic disease will likely require general anesthesia.

Aortic and Lower Extremity Embolectomy

An embolus at the aortic bifurcation should be approached with bilateral femoral artery exposures. The common, superficial, and deep femoral arteries should be identified and controlled. After systemic heparinization, arteriotomies are created in the distal CFA and a 5Fr or 6Fr embolectomy catheter is passed cranially, approximately 25 cm into the infrarenal aorta. The contralateral femoral artery should be occluded during each passage of the embolectomy catheter to minimize inadvertent embolization from the aorta down the opposite limb. After inflow is established, distal embolectomy of the superficial femoral and popliteal arteries is performed with a 3Fr or 4Fr catheter, and embolectomy of the deep femoral artery (DFA) is performed with a 3Fr catheter. Care must be taken not to advance the embolectomy catheter farther than 20 mm into the DFA to prevent injury to its smaller branches. An embolus to the CFA is approached in a similar fashion.

Emboli to the tibial vessels can be challenging to treat**.** When the embolectomy catheter is inserted through the superficial femoral artery, it usually takes a straight path into the peroneal artery. Insertion of the catheter into other tibial vessels can be facilitated by bending the catheter tip. If blind insertion is unsuccessful, over-the-wire Fogarty catheters are a modification to the original device and allow selective passage into target vessels under fluoroscopic guidance. If unsuccessful reestablishing distal flow, an open exposure of the below-knee popliteal artery is performed through a medial lower-leg incision. Control of the popliteal artery proximally and the anterior tibial, posterior tibial, and peroneal arteries distally is obtained. Because of the smaller vessel size, a longitudinal arteriotomy is created over the origin of the anterior tibial artery with plan for patch closure. A 2Fr embolectomy catheter is then advanced distally. Retrograde embolectomy via cutdown on the dorsalis pedis or posterior tibial arteries at the ankle is performed when other maneuvers do not allow adequate thrombectomy of the distal tibial arteries.

Brachial Embolectomy

The distal brachial artery is exposed through a longitudinal incision proximal to the elbow and may be extended across the antecubital fossa in an S-shaped incision to expose the proximal radial and ulnar arteries. After proximal and distal control is obtained, a transverse arteriotomy is created over the brachial bifurcation and a 3Fr or 4Fr embolectomy catheter is passed proximally into the subclavian artery. Inadvertent embolization to the cerebral circulation may occur if the catheter is passed into the aortic arch. Measuring the catheter externally against the patient's chest and arm can help estimate distance and prevent passage proximal to the subclavian artery origin. Distally, a 2Fr embolectomy catheter is passed into radial and ulnar arteries. Forearm artery exposure at the wrist may be required.

Percutaneous Endovascular Techniques

Catheter Directed Thrombolysis

Ultrasound guidance to the contralateral femoral artery is obtained, and a diagnostic angiogram is performed to guide further therapy. In addition to providing a more complete evaluation of the arterial inflow, obtaining access remote from the embolus decreases the risk of bleeding complications because of the proximity of the puncture site to the delivery of the thrombolytic agent. After the occlusion is identified on arteriography, a sheath of appropriate length is inserted and a hydrophilic coated angled guidewire is passed through the occlusion. If the guidewire is unable to cross the thromboembolus, this may represent acute thrombosis of a preexisting atherosclerotic plaque. Once the occlusion is crossed, a multi sidehole catheter is advanced over the wire and positioned across the clot. A bolus of thrombolytic, most commonly 10 mg of rtPA is delivered, followed by initiation of a continuous infusion through the catheter at 0.5–1 mg/hour. The sheath is secured in place, and a continuous heparin infusion at a constant rate of 500 U/hour is administered through the side port to prevent catheter-associated thrombosis. The patient is admitted to the intensive care unit for close neurovascular monitoring as well as monitoring of the access site. Laboratory tests, including aPTT and fibrinogen, should be checked every 4 to 8 hours to monitor for systemic thrombolysis. The tPA infusion is held if the fibrinogen level drops below 100 mg/dL or more than 50% from baseline. Reimaging is performed in 12 to 24 hours after initiation of lysis to assess for resolution.

Pharmacomechanical Thrombectomy

Under ideal circumstances, percutaneous mechanical thrombectomy expeditiously reduces overall clot burden and increases the surface area of exposed clot to enable more effective pharmacologic lysis. Various devices have been designed to use suction, rotational infusion, ultrasound, or a high-velocity rheolytic jet to achieve mechanical thrombectomy. Pharmacomechanical thrombolysis uses the percutaneous device to first lace the thrombus with a bolus of thrombolytic, typically 10 mg of rtPA. After a dwell time of 20 minutes, mechanical thrombectomy is performed. The AngioJet Thrombectomy System (Boston Scientific, Marlborough, MA) is a rheolytic device that works on the premise of Bernoulli's principle. Circumferentially oriented pressurized saline jets fragment the thrombus with creation of a low-pressure zone, which facilitates the removal of the resultant thrombotic debris through catheter side holes. In a large multicenter registry, successful outcome, defined as completion of the procedure without need for revascularization, bypass, or amputation and absence of substantial or complete occlusion in any vessel, was achieved in 83% of patients. More than one-half of the patients (52%) did not require adjunctive catheter-directed thrombolysis.

Aspiration Mechanical Thrombectomy

Another option for removal of fresh thromboembolic material without the need for use of fibrinolytics is the Indigo continuous AMT system (Penumbra Inc, Alameda, CA). This technology, available in the United States since 2008 for cerebral revascularization in acute ischemic stroke, utilizes a catheter delivered over a wire to the site of occlusion, through which continuous vacuum suction is applied to extract the thrombus.

Compartment Syndrome

Despite successful revascularization, limb loss may occur from development of acute compartment syndrome as previously ischemic tissue swells within the confined fascial space of the calf or forearm (Fig. 3). The more severe the ischemia, the more likely a reperfusion compartment syndrome is to develop. In patients with a history of prolonged ischemia (>6 hours) and those with limb edema observed after reperfusion, prophylactic fasciotomies are recommended. Four compartment fasciotomies of the lower leg are performed through medial and lateral incisions (Fig. 4). Upper extremity ischemia is often less severe because of collateral circulation; however, fasciotomies to release the volar and dorsal forearm compartments may be required (Fig. 5). If tissue swelling extends to the hand, consultation with a hand surgeon is recommended for additional carpal tunnel release and hand fasciotomies. Fasciotomy wounds are left open, and a vacuum-assisted closure device is applied in the postoperative period to decrease muscle edema. Incomplete skin release and attempts at early closure must be avoided as they may lead to muscle necrosis.

Patients who have not undergone fasciotomy are followed closely with serial examinations, and compartment syndrome is suspected in those who develop a tense swollen extremity with pain on passive

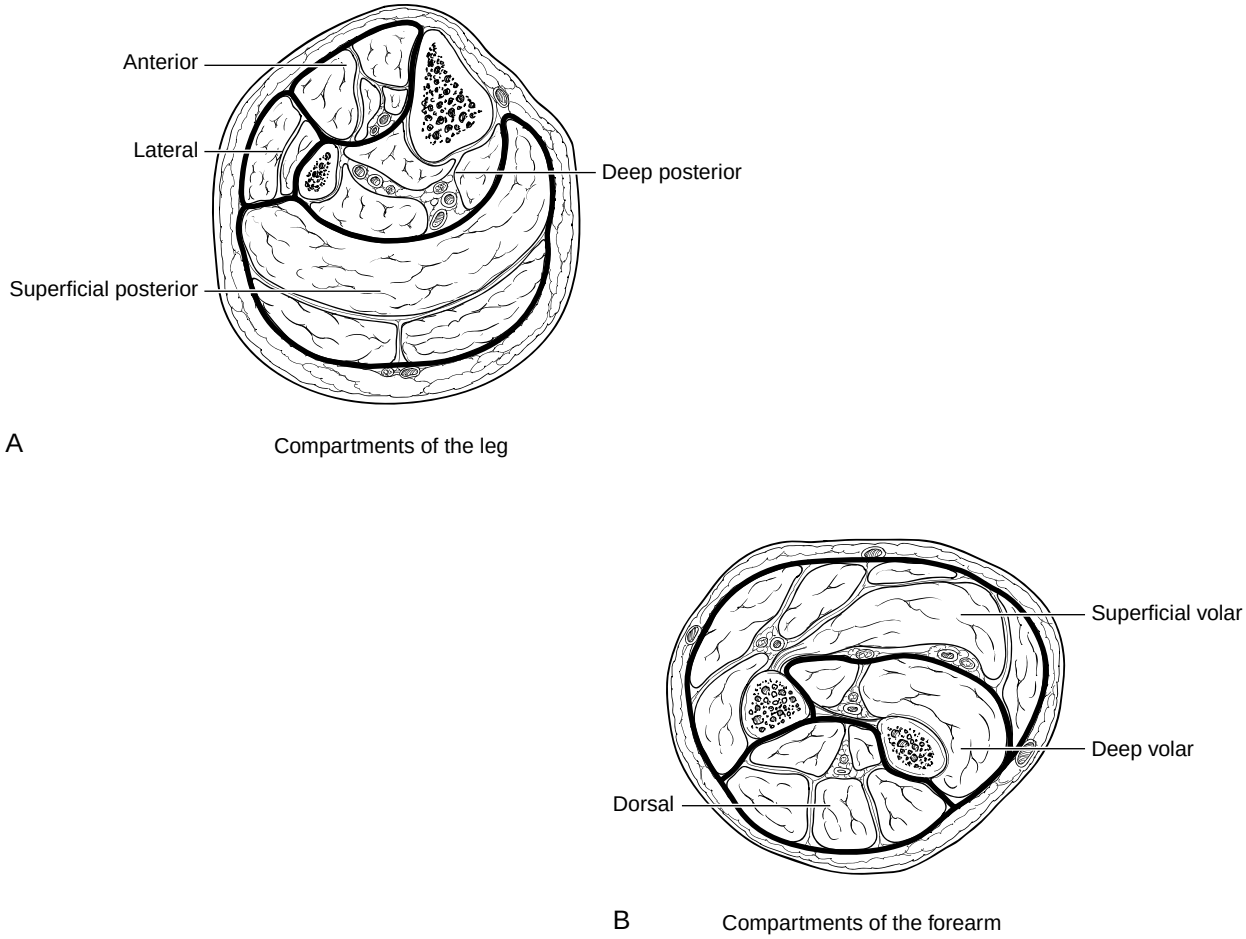

FIG. 3 Compartments of the calf **(A)** and forearm **(B)**. *(From Rasmussen TE, White JM. Upper and lower extremity fasciotomy. In: Chaikof EL, Cambria RP.* Atlas of Vascular Surgery and Endovascular Therapy. *Philadelphia: Elsevier: 2014:619–623.)*

motion; weakness; or decreased sensation. In sedated, neurologically impaired or uncooperative patients who cannot be followed with serial examinations, direct compartment pressures can be measured. Fasciotomy should be performed if compartment pressures are elevated (>30 mm Hg), the difference between the diastolic pressure and compartment pressure is <10 mm Hg, or if there is high clinical suspicion despite normal compartment pressures. Delay in diagnosis and management of compartment syndrome has devastating consequences and can lead to both limb loss and mortality. Elevated CPK levels and myoglobinuria are late markers of tissue destruction and should not be used to establish the diagnosis of compartment syndrome.

Postoperative Management

Hemodynamic monitoring, routine laboratory analysis with correction of acidosis and electrolyte imbalance resulting from intracellular potassium leak and hydrogen ion release, and serial neurovascular examinations are necessary. Urine output should be trended as a systemic effect of muscle ischemia is rhabdomyolysis, which may cause acute tubular necrosis and renal failure. Aggressive resuscitation with intravenous fluids is the main treatment modality, titrating to urine output >100 cc/hour until the CPK is <5000 U/L. Urine alkalinization with bicarbonate may also be required in patients with significant tissue damage and increasing CPK.

After successful thromboembolectomy, patients should be anticoagulated with heparin and converted to Coumadin or a DOAC as the risk of recurrent peripheral arterial embolism approaches 30%. Patients are maintained on lifelong anticoagulation in the setting of cardiogenic embolism and if the source of embolism is not surgically correctable or cannot be identified.

Patients with microembolism caused by atherosclerotic plaque rupture benefit from antiplatelet agents and statin therapy, which are purported to "stabilize" ulcerative plaque**.** Additionally, there is evidence that nonsteroidal antiinflammatory drugs reduce the local inflammation associated with microemboli.

Once the acute ischemic episode and its sequelae have been managed, the underlying embolic etiology should be investigated. Electrocardiography is performed to identify cardiac dysrhythmias, ischemia, or prior MI. Echocardiography is used to evaluate the heart when a cardiogenic embolism is suspected. Transthoracic echocardiography (TTE) is noninvasive and is performed first. An enlarged atrium, wall motion abnormality, intracardiac thrombus, vegetation, or tumors may be identified. Transesophageal echocardiography (TEE) is more sensitive and should be ordered if the TTE is negative yet suspicion for a cardiac source is high. A TEE with bubble study can identify a patent foramen ovale and lead to the diagnosis of paradoxical embolism. CTA including the chest, abdomen, and pelvis is performed to evaluate for aortic atheroma or aneurysm. Lower extremity runoff is included if the source is thought to arise from a more distal vessel. Bilateral lower extremity DUS for deep vein thrombosis should be performed if a paradoxical embolus is suspected. A hypercoagulable workup may be indicated in patients suspected of having a hypercoagulable state.

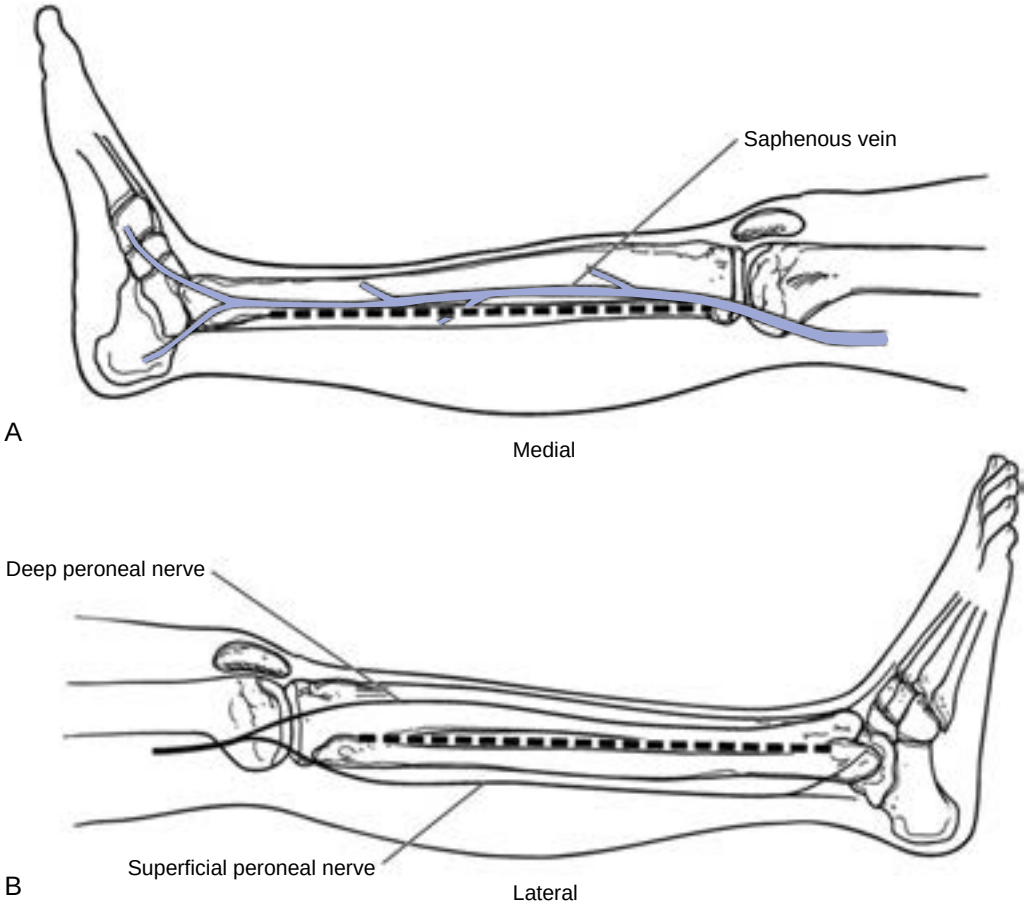

FIG. 4 Lower extremity fasciotomy. **(A)** Both posterior compartments are released through a medial incision 2 to 3 cm posterior to the medial border of the tibia. The fascia of the superficial posterior compartment is incised, and the soleus muscle attachments to the tibia and interosseous membrane are divided to release the deep posterior compartment. **(B)** The anterior and lateral compartments are exposed through a longitudinal skin positioned between the anterior crest of the tibia and the fibula. Parallel incisions are used to release the fascia of the anterior and lateral compartments, which are separated by the intermuscular septum. Care is taken to avoid injury to the superficial peroneal nerve. *(Modified from Rasmussen TE, White JM. Upper and lower extremity fasciotomy. In Chaikof EL, Cambria RP.* Atlas of Vascular Surgery and Endovascular Therapy. *Philadelphia: Elsevier: 2014:619–623.)*

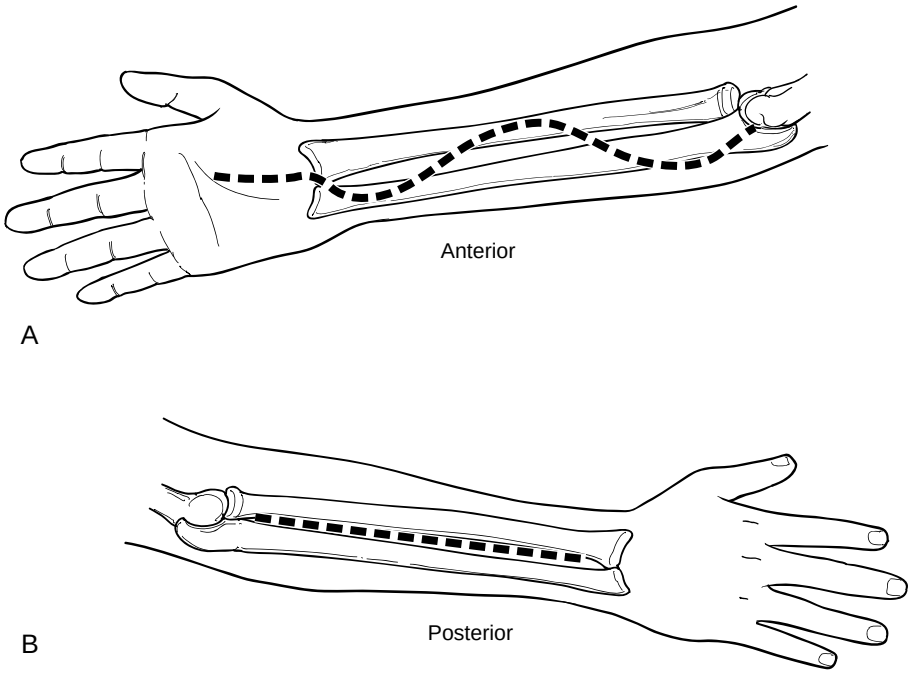

FIG. 5 Forearm fasciotomy. **(A)** Fasciotomy of the upper extremity begins medially in the arm and becomes sinusoidal from medial to lateral at the antecubital fossa, incorporating the bicipital aponeurosis. The incision must extend sufficiently lateral to open the fascia over the mobile wad. The fascia of the deep compartment is incised between the flexor carpi ulnaris and flexor digitorum superficialis, retracting the ulnar nerve and artery laterally. **(B)** The extensor compartment is released through a longitudinal incision from the lateral epicondyle extending to the distal one-third of the posterior forearm. *(Modified from Rasmussen TE, White JM. Upper and lower extremity fasciotomy. In Chaikof EL, Cambria RP.* Atlas of Vascular Surgery and Endovascular Therapy. *Philadelphia: Elsevier: 2014:619–623.)*

If a discrete noncardiogenic source is identified, it is treated if the risk of the procedure is acceptable. Stent-grafts can be used in the thoracic and abdominal aorta to address both aneurysms and ulcerative plaque responsible for embolization. Aortobifemoral bypass and infra-inguinal bypass can also be utilized. Atherosclerotic lesions in the aortic arch are difficult to treat and therefore tend to be managed conservatively.

CONCLUSION

Patients with acute peripheral arterial thromboembolism are usually elderly with multiple associated medical comorbidities. Expeditious diagnosis and treatment are of utmost importance in reducing severe morbidity and mortality. Management of these patients is challenging, and operative mortality with open embolectomy is reported to be between 20% and 30%. Limb salvage for survivors, however, is excellent, with rates approaching 80%. In patients with in-situ thrombosis, limb salvage rates tend to be significantly lower. Depending on the source, recurrent emboli can occur in up to 20% to 30% of patients despite appropriate anticoagulation.

Acute Peripheral Arterial and Bypass Graft Occlusion: Thrombolysis and Thrombectomy

Gray R. Lyons, MD, and Robert P. Liddell, MD

BACKGROUND

Acute limb ischemia (ALI) is a vascular emergency caused by sudden occlusion of native arteries or bypass grafts. Timely management of ALI requires expedited clinical evaluation, diagnostic workup, and initiation of appropriate treatment. In addition to open surgical options, endovascular therapies include catheter-directed thrombolysis (CDT) and mechanical thrombectomy. Patients with severe ALI require immediate revascularization, whether by surgical or endovascular thrombectomy. Patients with less severe disease and no contraindication to thrombolytic infusion may be candidates for CDT. The relative risks and merits of each approach should be considered in the clinical context based on patient presentation and available resources. This chapter describes how to select the appropriate therapy for ALI, with an emphasis on the role of endovascular techniques.

INDICATIONS

Clinical Assessment

The clinical assessment of a patient with ALI should begin with a thorough history, focusing on the patient's presenting symptoms and current overall health. A history of rest pain, claudication, myocardial infarction, stroke, hypertension, diabetes mellitus, atrial fibrillation, aneurysmal disease, smoking, high cholesterol, vasculitis, and prior vascular or endovascular surgery is important to obtain. The initial physical examination should assess for the dominant clinical signs and symptoms of ALI, which traditionally include the "six "*Ps*": pain, pulselessness, poikilothermia, paresthesia, pallor, and paralysis. The presence of one or more of these findings and the abruptness of their onset may also aid in determining the underlying etiology. New or asymmetric neurologic deficits suggest an advanced state of ischemia, with sensory deficits preceding motor deficits. Fixed mottling of the skin with muscle necrosis and induration implies irreversible limb ischemia.

A formal stratification system, developed by Rutherford, helps guide the evaluation and management of ALI while defining prognosis (Table 1). Acutely ischemic limbs are described as *viable, threatened,* or *irreversibly ischemic*. Viable limbs are not immediately threatened and do not exhibit loss of sensory or motor function. Threatened limbs demonstrate mild to moderate sensory deficits, sometimes with associated motor deficits, and are salvageable with appropriate, timely intervention. Irreversibly ischemic limbs with profound neuromuscular deficits cannot be salvaged with revascularization and ultimately require amputation. Therefore, the minimum necessary components of the physical examination include assessment of limb sensory and motor function to triage the patient to the appropriate treatment category.

The presentation of ischemia is determined by a number of factors, including the etiology of the obstruction, level of obstruction, adequacy of collateral circulation, extent of thrombus propagation, underlying peripheral vascular disease, and cardiac output. Although variable based on the network of existing collaterals, a period of 6 hours is generally accepted as the window in which revascularization is absolutely necessary for ALI. However in practice, the degree of ischemia is more important than the absolute duration of ischemia; therefore patients must be assessed on an individual basis and in a timely fashion.

IMAGING ASSESSMENT

Imaging is done to evaluate the extent of blood flow compromise, localize culprit flow-limiting lesions, and identify other sequelae of peripheral vascular disease (dissection, aneurysmal disease, thrombus, vasculitis). An acutely ischemic limb may be imaged with Doppler ultrasound (DUS), computed tomography angiography (CTA), magnetic resonance angiography (MRA), or digital subtraction angiography (DSA) before treatment. When choosing an imaging modality for native vessel disease, clinicians should take into account whether the patient has underlying renal insufficiency, diabetes, or implanted metal devices. For patients who have normal renal function and are not diabetic, initial evaluation with either CTA or MRA is reasonable based on their similar excellent diagnostic capabilities. DUS imaging is more operator dependent than cross-sectional imaging but has the advantages of a noncontrast technique, dynamic

TABLE 1 Clinical Categories of Acute Limb Ischemia

		Findings		Doppler Signals	
Category	**Description/Prognosis**	**Sensory Loss**	**Muscle Weakness**	**Arterial**	**Venous**
I. Viable	Not immediately threatened	None	None	Audible	Audible
II. Threatened					
a. Marginally	Salvageable if promptly treated	Minimal (toes) or none	None	Inaudible	Audible
b. Immediately	Salvageable with immediate revascularization	More than toes, associated with rest pain	Mild, moderate	Inaudible	Audible
III. Irreversible	Major tissue loss or permanent neurologic damage	Profound, anesthetic	Profound, paralysis (rigor)	Inaudible	Inaudible

Modified from Rutherford RB, Baker JD, Ernst C, et al. Recommended standards for reports dealing with lower extremity ischemia: revised version. *J Vasc Surg.* 1997;2:517–538.

assessment, and radiation-free imaging. DUS can be augmented with concurrent noninvasive physiologic testing, including segmental blood pressure and pulse volume recordings.

DSA provides the most anatomically detailed imaging of the vascular system. The chief benefit of DSA is that endovascular therapies may be initiated in the same setting as diagnostic angiography, as arterial access is already achieved. Although DSA is a more invasive technique when compared with MRA and CTA, the risks associated with arterial access are minimal.

SELECTION OF THERAPY

Once the diagnosis of ALI is made, treatment should be initiated as soon as possible with the goal of reperfusion of the ischemic limb. Regardless of the etiology, all patients without contraindications receive IV fluids, supplemental oxygen, an 81-mg dose of aspirin, and a 100 U/kg bolus of IV heparin followed by a continuous infusion titrated to a partial thromboplastin time of 2.0 to 2.5 times control. Patients with viable, nonthreatened limbs (Rutherford class I) are treated with heparin and observation, followed by more definite therapy once comorbidities, functional status, and activity level are determined. Patients with threatened limbs can benefit from revascularization, and the immediacy of treatment is dictated by the degree of threat: marginal (class IIa) or immediate (class IIb). The selection of therapy type is based on provider experience and resources as well as patient clinical and anatomic factors. Limbs that are revascularized late in the progression of disease may require fasciotomy of affected compartments to prevent further tissue loss, and these patients risk hyperkalemia, myoglobinemia, acute kidney injury, and sepsis. Revascularization should not be attempted in patients with cadaveric limbs (class III) because of the futility of the treatment and the potential for life-threatening complications.

Recommended Interventions for Disease in Native Arteries

Catheter-directed thrombolysis was first described by Charles Dotter in 1974. When compared with high-dose systemic intravenous thrombolysis, CDT resulted in significantly more favorable outcomes with fewer adverse bleeding events. A number of randomized multicenter trials have been conducted to compare CDT with surgery for ALI. The Surgery versus Thrombolysis for Ischemia of the Lower Extremity (STILE) trial showed that CDT produces outcomes similar to surgery when used to treat thrombosed native arteries presenting within 2 weeks of the onset of symptoms. In patients presenting greater than 2 weeks from the onset of symptoms, surgery showed more favorable outcomes. The Thrombolysis or Peripheral Arterial Surgery (TOPAS) trial showed that CDT may be attempted and then abandoned when unsuccessful in favor of more localized surgery, without increasing mortality or amputation rate. A number of retrospective studies have also demonstrated that performing CDT and angioplasty before attempting surgery can reduce the number of patients who will ultimately require surgical bypass or amputation. Although these studies do not provide definitive answers to a preferred treatment in all cases, they do suggest that CDT may improve outcomes without compromising the efficacy of subsequent surgery. Therefore, if readily available, CDT should be the first-line therapy for acute native artery occlusion, with endovascular or surgical intervention to treat underlying disease once unmasked.
