The infantile umbilical hernia should be distinguished from more serious congenital anomalies, such as omphalocele and gastroschisis. Omphalocele (exomphalos) is the herniation through the umbilical ring into the base of the umbilical cord. There is no skin covering the hernia as in umbilical hernia, but the sac consists of peritoneum internally and amnion externally (Fig. 187.8). In gastroschisis, the defect (cleft) of the abdominal wall is lateral to the umbilicus, usually on the left. There is no sac, and the contents are usually intestines (Fig. 187.9).

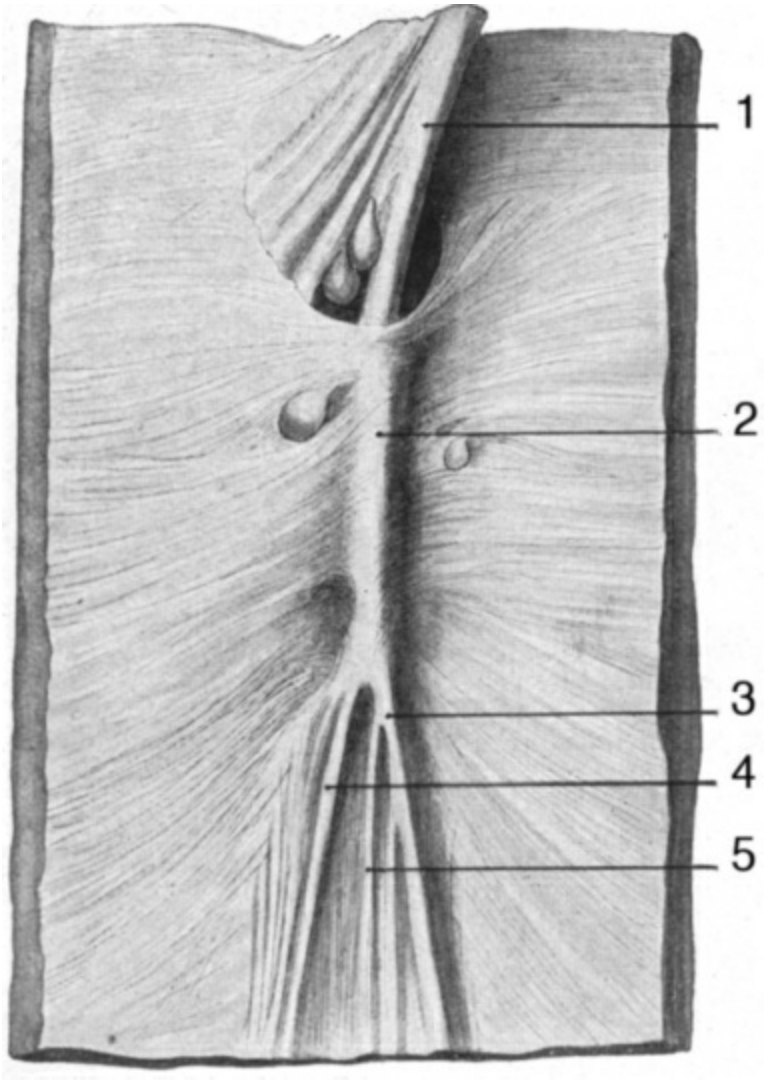

Figure 187.4. Umbilical region: umbilical fascia. 1, umbilical vein; 2, umbilical fascia; 3, right umbilical artery; 4, left umbilical vein; 5, urachus. (Modified from Rouviere H. *Anatomie Humaine. Descriptive et Topographique.* 5me edition. Tome I, Fasciule II. Paris: Masson et Cie; 1943.)

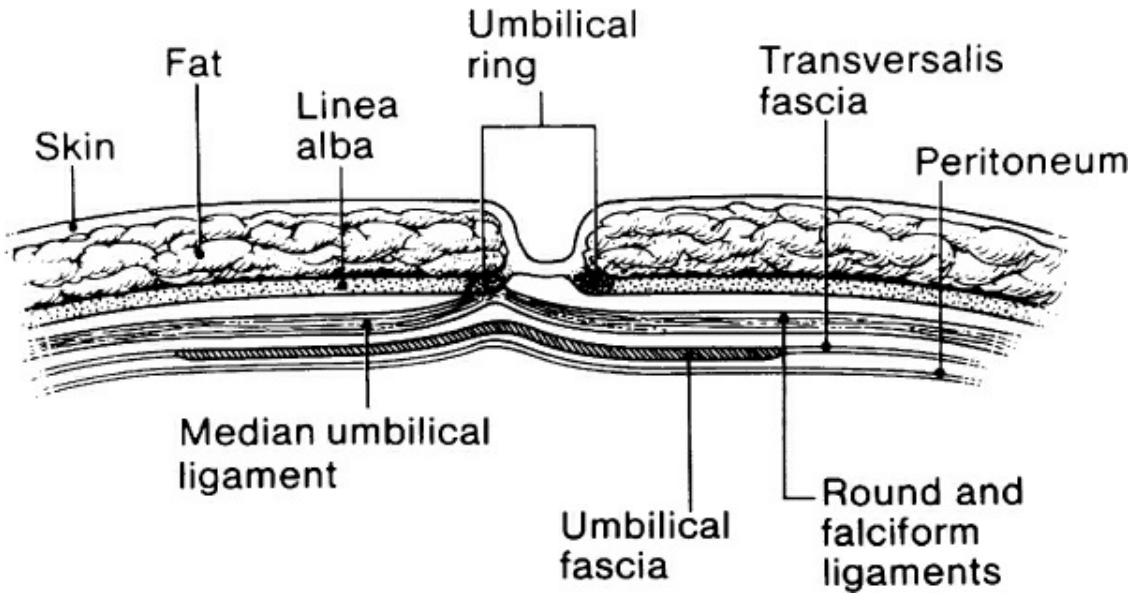

Figure 187.5. Diagrammatic sagittal section through a normal umbilicus showing the relation of the umbilical ring to the linea alba, the round ligament, the median umbilical ligament (urachus), and the umbilical fascia. The umbilical fascia is shown here as a thickening of the transversalis fascia; the latter is chapter revised and called membranous layer of the preperitoneal tissue. Observe the absence of subcutaneous fat over the umbilical ring. (From Skandalakis LJ, Gadacz TR, Mansberger AR Jr., et al. *Modern Hernia Repair.* Pearl River, NY: Parthenon; 1996, with permission.)

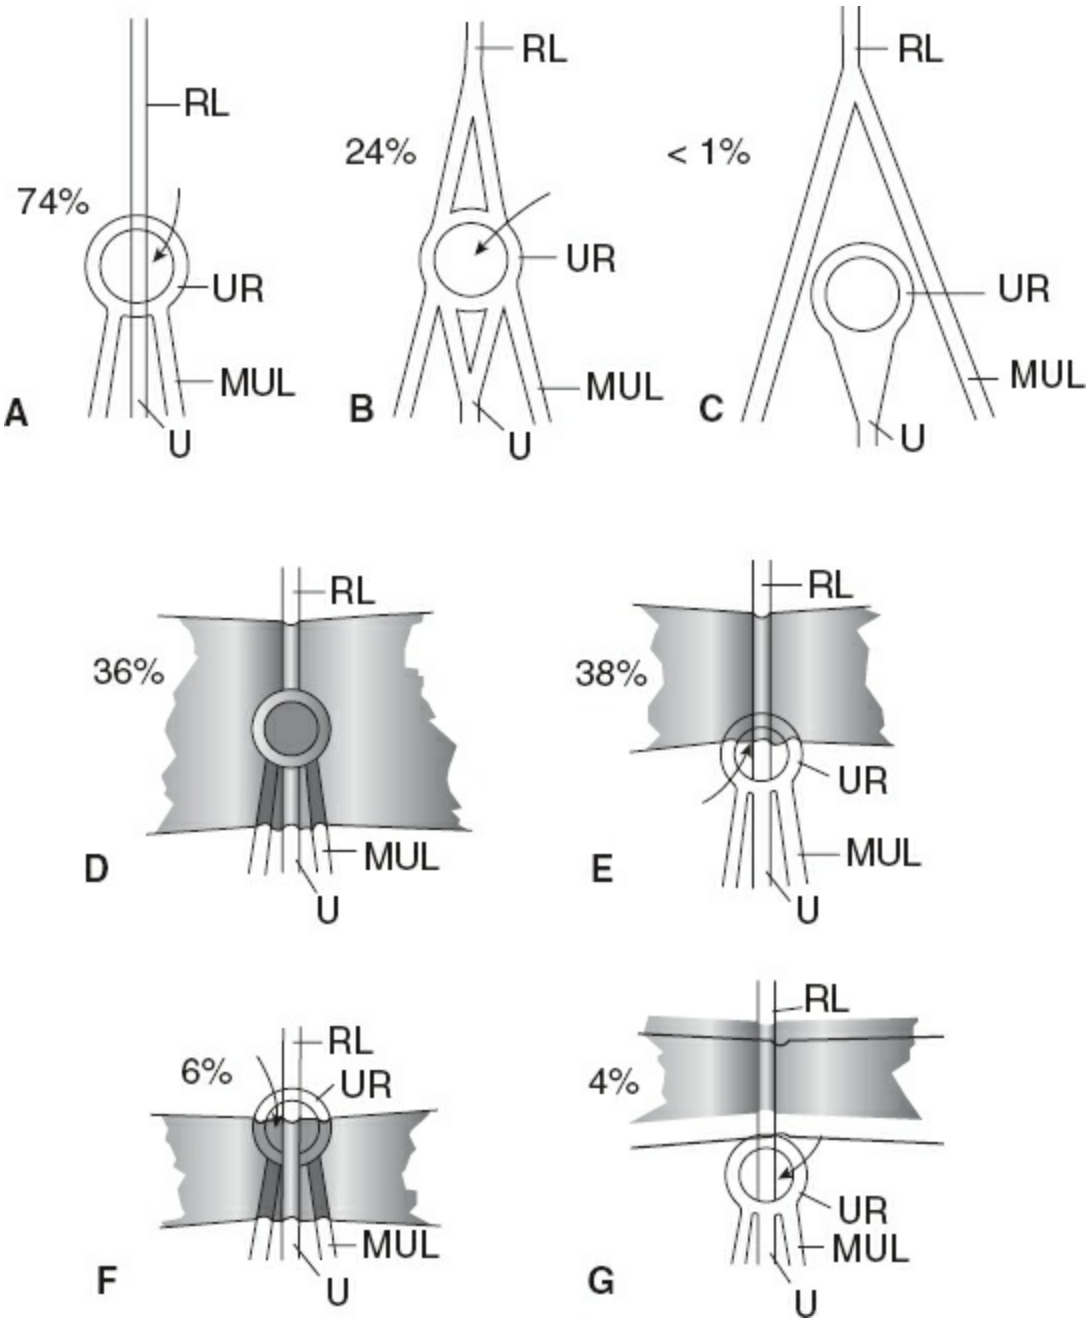

Figure 187.6. Variations in umbilical ring (UR) and umbilical fascia seen from posterior (peritoneal) surface of body wall. **A–C.** Variations in disposition of umbilical ligaments. *Arrows* indicate path of hernia. **A.** Usual relations (74%) of UR, round ligament (RL), urachus (U), and medial umbilical ligaments (MUL). RL crosses UR to insert on its inferior margin. **B.** Less common configuration (24%). RL splits and attaches to superior margin of UR. **C.** Rare configuration (>1%). RL branches before reaching UR. Each branch continues with the medial umbilical ligament without attaching to UR. **D–G.** Variations in presence and form of insertion of umbilical fascia. **D.** Thickened transversalis fascia forms umbilical fascia covering UR (36%). **E.** Umbilical fascia

covers only superior portion of UR (38%). **F.** Umbilical fascia covers only inferior portion of UR (6%). **G.** Although present, umbilical fascia does not underlie UR (4%). Fascia is entirely absent in 16% of cases (not shown). (From Orda R, Nathan H. Surgical anatomy of umbilical structures. *Int Surg* 1973;58:454, with permission.)

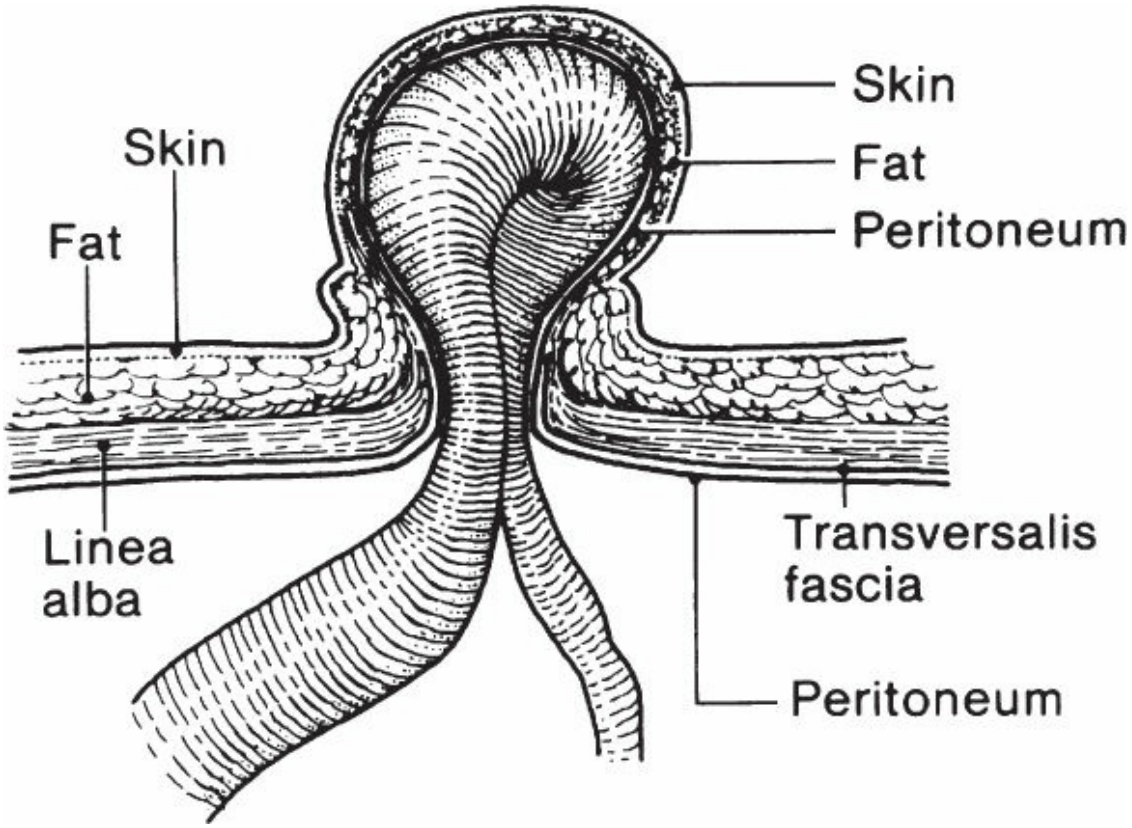

Figure 187.7. Diagrammatic sagittal section through a small umbilical hernia. The transversalis fascia shown here is in truth the membranous layer of preperitoneal tissue. (From Skandalakis LJ, Gadacz TR, Mansberger AR Jr., et al. *Modern Hernia Repair.* Pearl River, NY: Parthenon; 1996, with permission.)

SPIGELIAN HERNIA

Although named after Adriaan van der Spieghel, he only described the semilunar line (linea Spigeli) in 1645. Josef Klinkosch in 1764 first defined the spigelian hernia as a defect in the semilunar line. The latter is produced by and marks the site of transition from the aponeurotic part to the muscular part of the transverse abdominal muscle.

It is more exact to define the spigelian hernia in regard to the spigelian aponeurosis. Protrusion of a peritoneal sac, an organ, or preperitoneal fat through a congenital or acquired defect in the spigelian aponeurosis is

referred to as a spigelian hernia (hernia Spigeli). The spigelian aponeurosis is the aponeurosis of the transverse abdominal muscle limited by the linea semilunaris laterally and the lateral edge of the rectus muscle medially. Evidently, the spigelian aponeurosis is rather a zone than a line, as initially called.

The spigelian zone differs above and below the semicircular line (Fig. 187.10A). Above the semicircular line, the aponeurosis of the internal oblique splits and contributes to both anterior and posterior lamina. Below it, all aponeuroses pass in front (the external oblique has a somewhat more medial insertion toward the linea alba), and the posterior lamina of the rectus sheath consists only of the membranous fascia of the preperitoneal space (previously called transversalis fascia).

The majority (90%) of spigelian hernias lie in a 6-cm zone located above the interspinal plane (spigelian hernia belt). In this zone, the weakest point is at the intersection between the semilunar and semicircular line. The latter, known as arcuate line or line of Douglas, marks the caudal end of the posterior lamina of the aponeurotic rectus sheath and is found in the infraumbilical area. The deep inferior epigastric vessels enter the rectus sheath at or about this edge in the majority of cases (Fig. 187.10B).

A spigelian hernia must be conceived of first as a protrusion through an opening of the transversalis aponeurosis. The opening also includes the transversalis fascia, which is the inner investing fascia of the transverse muscle and aponeurosis. Then, the hernia protrudes toward the aponeurosis of the internal oblique. This aponeurosis may also rupture, but usually the aponeurosis of the external oblique is too strong to be penetrated by the hernia. This partial abdominal wall hernia presents anatomical challenges that cause difficulties in diagnosis. The space between the two oblique muscles is loose; thus, the sac usually expands in the space and adopts a T-shape or mushroom-like appearance. Possible locations of the sac are shown in Figure 187.10.

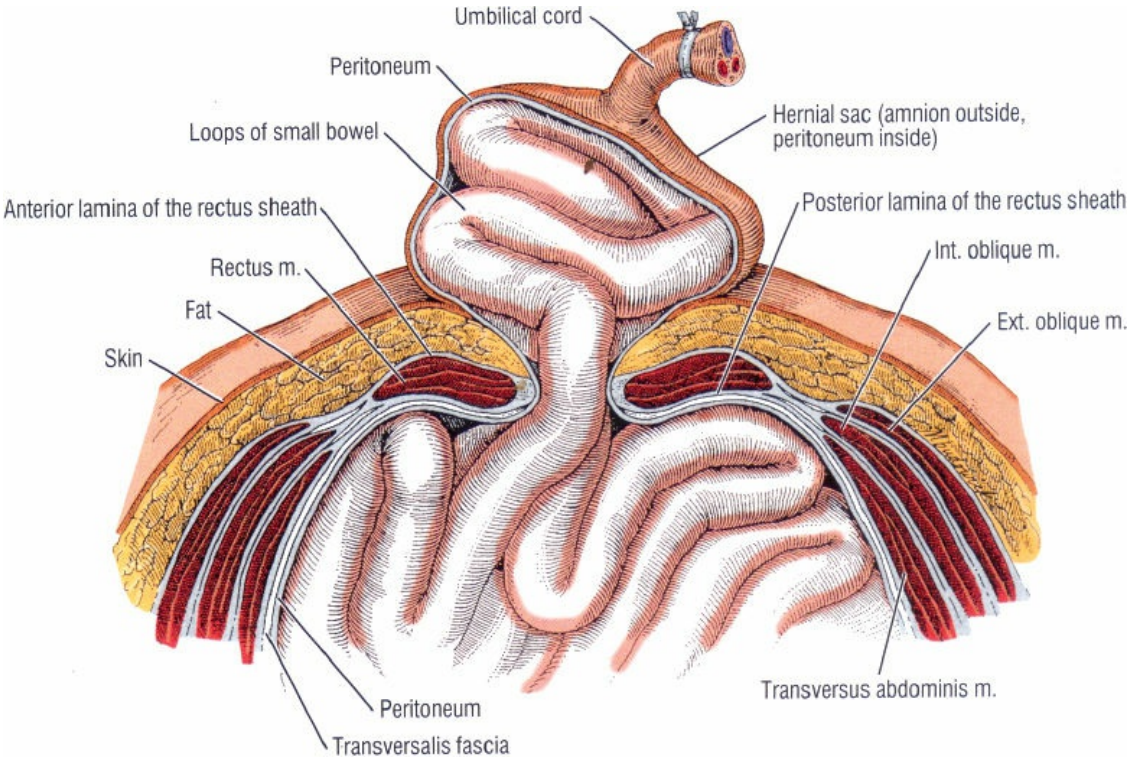

Figure 187.8. Sagittal section through a small omphalocele. (From Skandalakis LJ, Gadacz TR, Mansberger AR Jr., et al. *Modern Hernia Repair.* Pearl River, NY: Parthenon; 1996, with permission.)

GROIN HERNIA

The inguinal region (or groin) in man is the area behind and above the inguinal ligament. Because of the erect position of man, the groin is a weak area, prone to inguinal herniae, direct or indirect; to these are added the supravesical herniae. All of them originate from the fossae of the anterolateral abdominal wall. Adjacent, below the inguinal ligament, are encountered the femoral herniae (Fig. 187.11). To understand these herniae and the formation of the rings, knowledge of the anatomy of the groin and inguinal canal is essential.

The Inguinal Canal

The inguinal canal is an oblique passage through the abdominal wall that contains the spermatic cord or the round ligament of the uterus; embryologically, however, the canal develops before the descent of these entities. The inguinal canal has two openings, the deep and the superficial rings, an anterior and posterior wall, a roof and a floor. A progressing dissection of the inguinal canal, layer by layer, is offered in Figure 187.12.

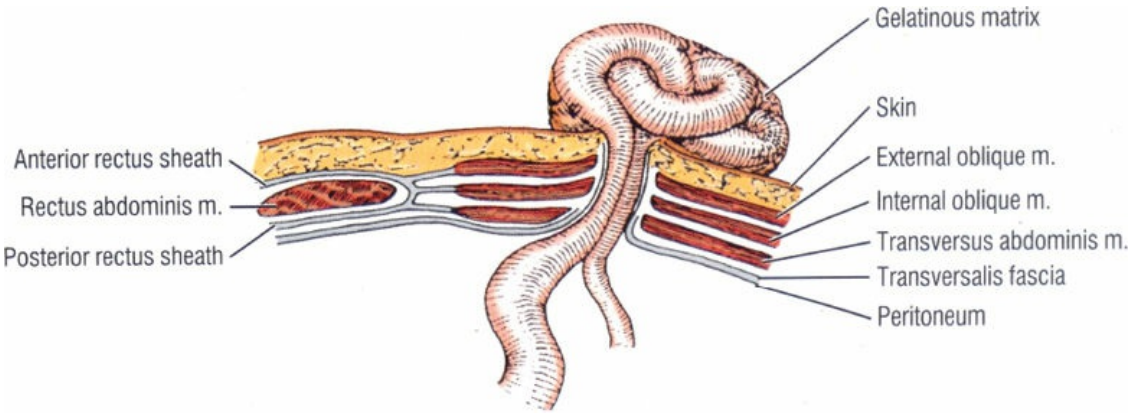

Figure 187.9. Gastroschisis. The herniation is lateral to the umbilicus, through a congenital muscular defect. A gelatinous matrix, but no sac, surrounds the herniated intestines. (Modified from Skandalakis JE, Gray SW, Akin JT Jr. The surgical anatomy of hernial rings. *Surg Clin North Am* 1974;54:1227, with permission.)

Boundaries of the Inguinal Canal

The anterior wall of the canal is formed by the aponeurosis of the external oblique. The external oblique muscle caudally ends in a thickening, the inguinal ligament (Poupart ligament), which extends from the anterior superior iliac spine laterally to the superior ramus of the pubis. This ligament is not cord-like, but the lower edge of the external oblique aponeurosis.

The posterior wall is given by the fascia transversalis and the transversus abdominis aponeurosis.

The roof of the canal is formed by the arched fibers of the lower edge of the internal oblique muscle and by the transversus abdominis muscle and aponeurosis. The internal oblique and the transversalis muscle attach to the lateral two thirds or one-half of the inguinal ligament and then arch over the spermatic cord to reach the pubic tubercle (and also the pectinate line). Close to the deep ring, the arch of the internal oblique muscle is more muscular, while that of the transversus more aponeurotic. Sometimes the lower fibers of these muscles fuse to be inserted together to the pubic tubercle, and thus form the so-called “conjointed tendon.” A true fusion is, however, rare (5%), and maybe the term “conjoined area” should be more exact to describe this mass of aponeuroses inserting together to the tubercle (Fig. 187.13). Many times the “conjoined tendon” has been confused with the falx inguinalis (ligament of Henle), which is the lateral, vertical expansion of the rectus sheath that inserts on the pectin of the

pubis (present in 30% to 50%) and fuses with the transversus abdominis aponeurosis.

The floor of the inguinal canal is formed by the shelving lower border of the inguinal ligament and the lacunar ligament (Gimbernat ligament). The lacunar ligament is in fact the extension of the inguinal ligament backward and laterally to attach to the pectineal line and form a triangular ligament with apex the pubic tubercle (Fig. 187.14). Occasionally, it forms the medial border of the femoral canal. A lateral periosteal extension of the lacunar ligament along the pectineal line forms the pectineal ligament (Cooper ligament). According to O'Rahilly, the pectineal ligament provides a firm anchor for the attachment of muscular, tendinous, and fascial layers of the groin, and thereof is used in the surgical repair of inguinal herniae.

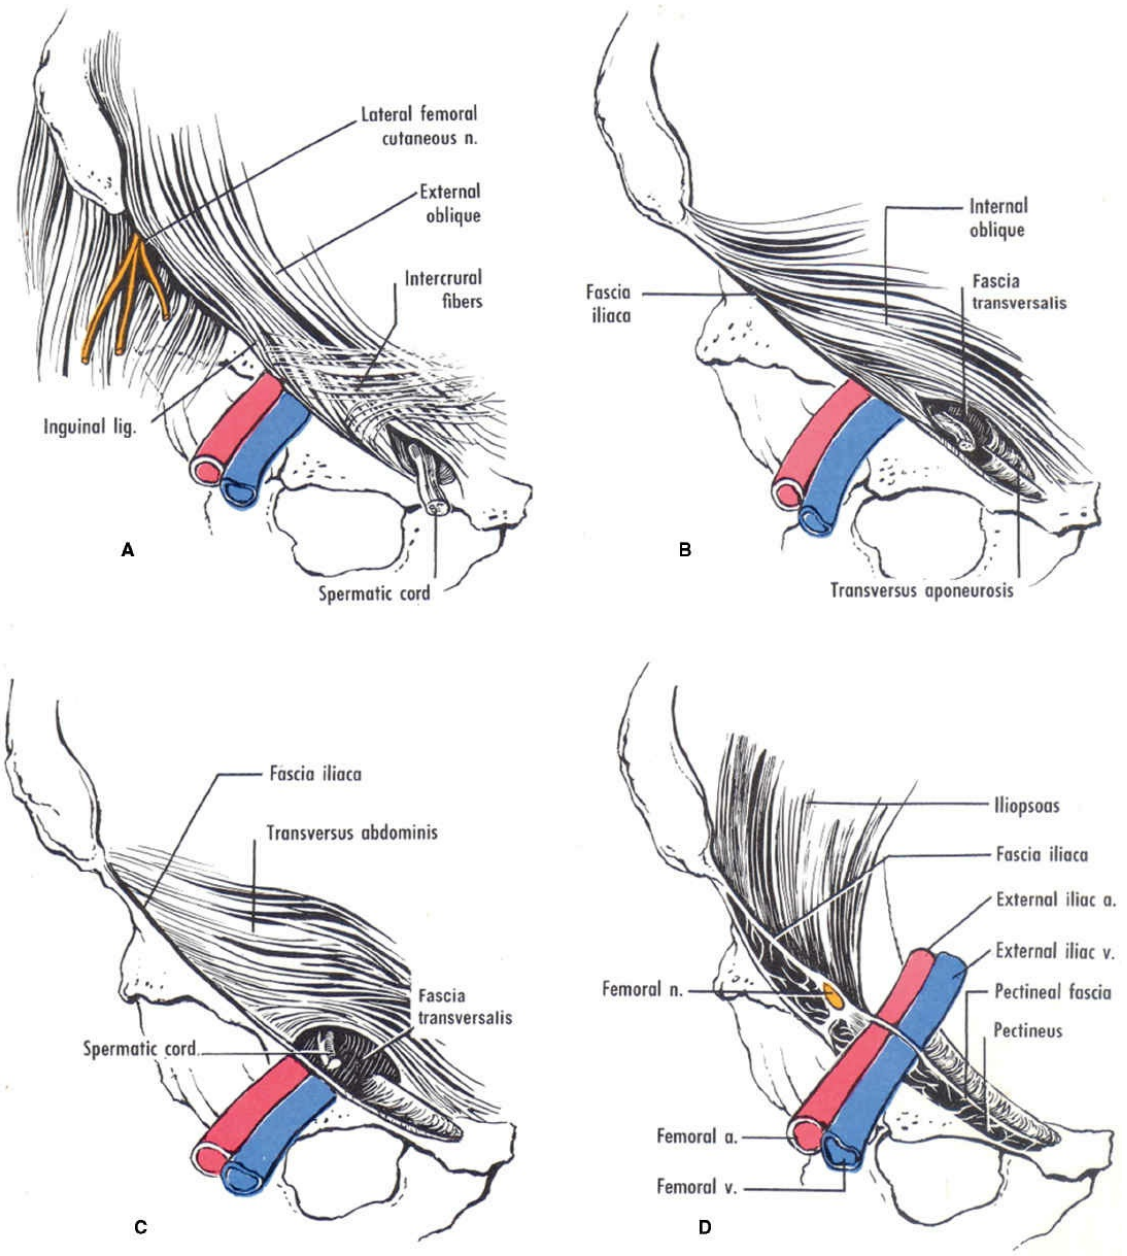

Figure 187.12. Anterior aspect of the inguinal region, progressing from the outside inward, layer by layer. **A.** External oblique muscle and superficial inguinal ring. **B.** Internal oblique muscle extending medially to reach pubis. **C.** Transverse abdominis and fascia transversalis. **D.** Iliopsoas and fascia iliaca, pectineus and pectineal facia. (From O'Rahilly R. *Gardner-Gray-O'Rahilly Anatomy: A Regional Study of the Human Structure.* 5th ed. Philadelphia, PA: WB Saunders Co; 1986, Fig. 33-8, p. 364.)

Beneath the inguinal ligament is found a collagenous band, the iliopubic tract, extending from close to anterior inferior iliac spine to the pubic tubercle (Figs. 187.14 and 187.15). It is said to be a thickening of the transversalis fascia below the inguinal ligament, or a band between the

transversalis fascia and the ligament, or even to disappear when the transversalis fascia is freed from the adjacent preperitoneal tissue (McVay and Anson). It arches over the femoral vessels and contributes to the medial margin of the femoral canal. In any case, the iliopubic tract is found in a deeper layer and should not be confused with the inguinal ligament.

The Deep (Internal) Inguinal Ring

The deep inguinal ring is an opening of the transversalis fascia. It resembles a funnel directed downward and medially. There is no opening of the transversalis aponeurosis for the passage of the spermatic cord—it courses under the arch of the transversus abdominis muscle (and aponeurosis). The iliopubic tract lies under the deep ring and is said to reinforce it (or contribute to it, according to others). These relations are evident when the peritoneum is removed and the deep ring is seen from within the abdomen: the deep ring is found laterally to the inferior epigastric vessels, delineated by the transverse abdominus arch supero-laterally and the iliopubic tract coursing inferolaterally. The vas deferens courses from the pelvis and is found medially; the gonadal vessels descend from the abdomen and are found laterally. Between the two descending resides the genital branch of the genitofemoral nerve (Fig. 187.15). After the internal ring, this nerve is not included in the part of the spermatic cord surrounded by the internal spermatic fascia (given from the internal oblique), but external to it, in companion with the cremasteric vessels.

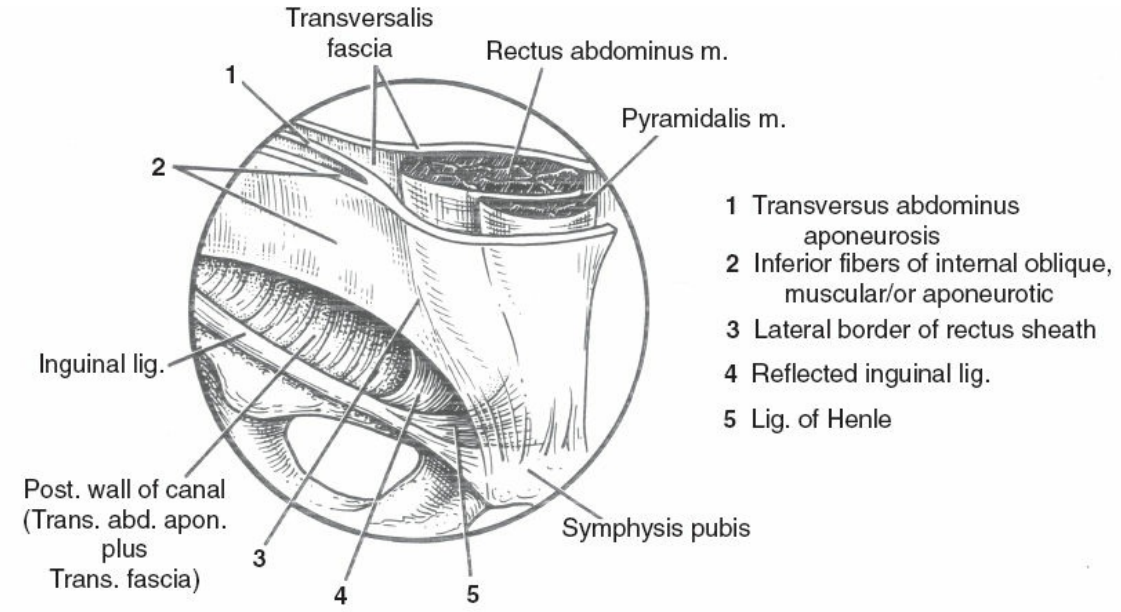

Figure 187.13. The “conjoined area.” (From Gray SW,

Skandalakis JE, McClusky DA. *Atlas of Surgical Anatomy for General Surgeons.* Baltimore, MD: Williams & Wilkins; 1985, with permission.)

The Secondary Internal Inguinal Ring

The secondary internal inguinal was first noted by Lytle in 1945, and later defined correctly in 1975 by Fowler. Our team has brought this ring back in focus (see Mirilas et al. *J Am Col Surg* 2008). The secondary internal inguinal ring arises from the membranous layer of the extraperitoneal fascia located immediately deep to the transversalis fascia. In males, the vas deferens hooks around the inferomedial lip of the secondary internal inguinal ring in order to enter the inguinal canal. The gonadal vessels, which lie lateral to the vas deferens in the extraperitoneal fat and deep to the membranous layer, also traverse the secondary internal inguinal ring in order to become incorporated in the cord. This is readily appreciated when viewing the deep ring from a preperitoneal exposure and is sometimes mistaken for the transversalis fascia during anterior exposure of the groin.

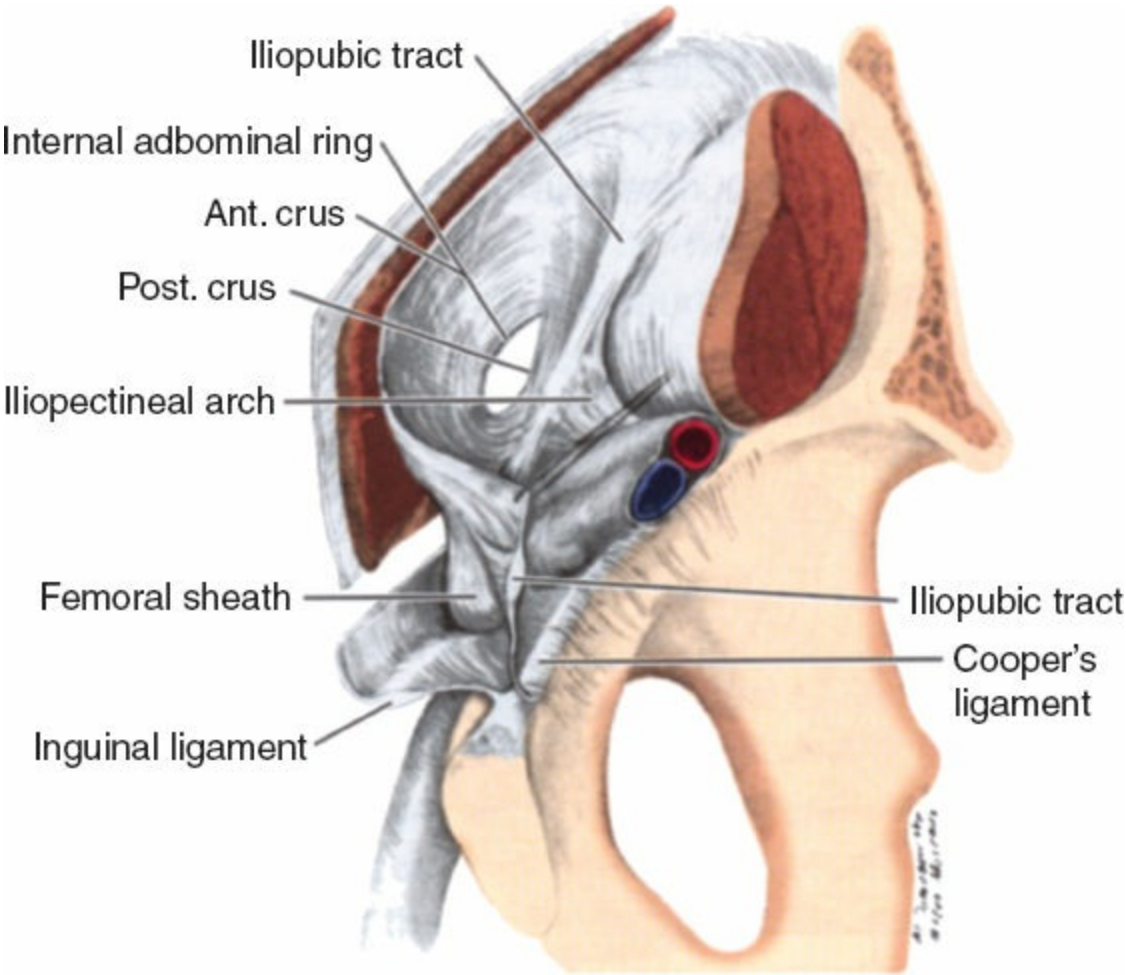

Figure 187.14. Ligamentous attachments of the deep inguinal region. (From Gray SW, Skandalakis JE, McClusky DA. *Atlas of Surgical Anatomy for General Surgeons.* Baltimore, MD: Williams & Wilkins; 1985, with permission.)

As said above, the membranous layer of the extraperitoneal fascia divides the extraperitoneal space into a parietal and a visceral plane. The parietal plane, between the transverasalis fascia and the membranous layer of the extraperitoneal fascia, contains the deep inferior epigastric vessels, the cremasteric vessels, and the genital branch of the genitofemoral nerve. The visceral plane, between the membranous layer of the extraperitoneal fascia and the peritoneum, contains the median and medial umbilical ligaments, the vas deferens/round ligament, the gonadal vessels, and the ureter (Fig. 187.16). This plane is equivalent to the space of Retzius, defined between the peritoneum and the "posterior lamina of the transversalis fascia," here redefined as membranous layer of the extraperitoneal tissue.

The secondary internal inguinal ring has important applications to surgery of the inguinal canal. During the repair of an indirect inguinal hernia, the correct site of sac ligation lies at the level of the secondary internal inguinal ring. Either using the inguinal or the preperitoneal open approach, the internal spermatic fascia should be incised to allow for exposure of the secondary internal ring. At this level, the membranous layer is incised in its thicker area, the peritoneum is detached from the cord structures, and a truly high ligation or inversion of the sac is performed.

The Superficial (External) Inguinal Ring

The superficial ring is an opening in the aponeurosis of the external oblique muscle found 2.5 cm above and laterally to the pubic tubercle in the adult. Although called "ring," it is somehow triangular, with a superolateral border (superior crus), an inferomedial border (inferior crus), and an open base related to the pubic crest. The superior crus is formed by the aponeurosis of the external oblique. The inferior crus is largely formed by the inguinal ligament, which also inserts in the pubic tubercle (Fig. 187.17). Usually, there are superficial transverse fibers superior at the beginning of the diversion of the crura. Superficially to these, there is a fascia that continues from the aponeurosis of the external oblique muscle on to the spermatic cord; this is the outer investing fascia of the muscle that gives the external spermatic fascia extending between the crura of the

ring (thereof also called “intercrural” fascia). After removal of the superficial fascia, the thin intercrural fascia is opened during surgical dissection, and the thick aponeurotic semicircle of the external ring is easily found.

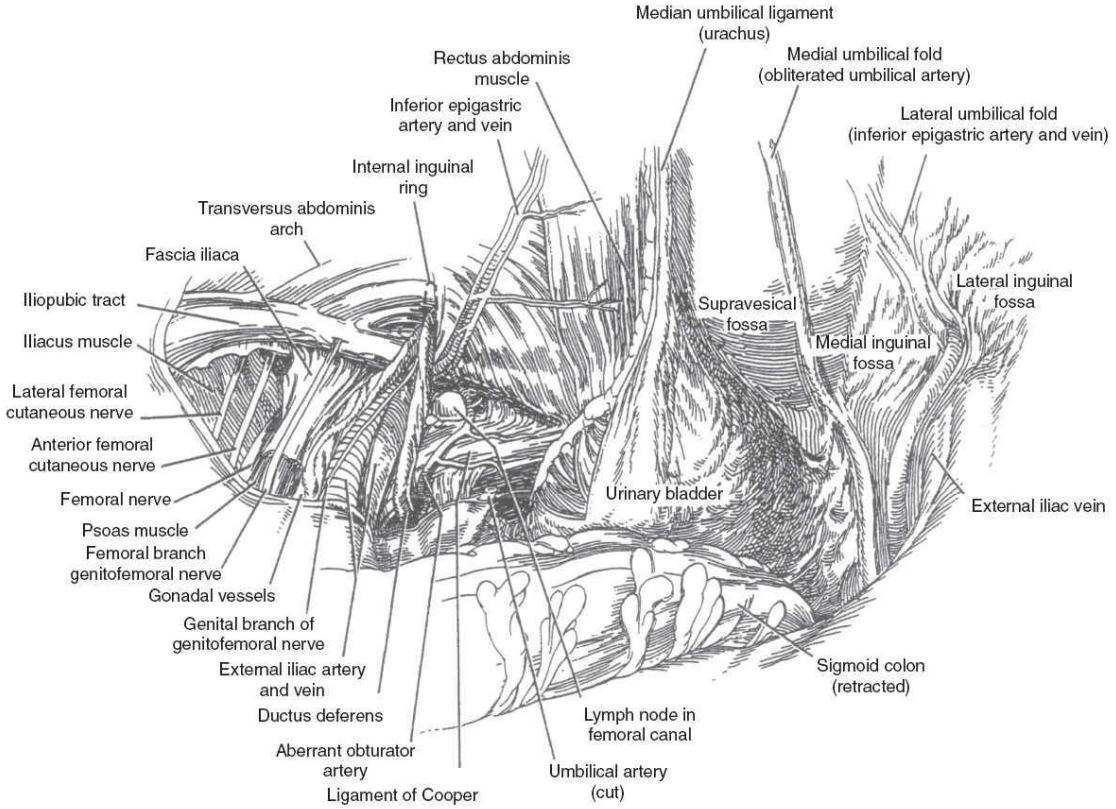

Figure 187.15. Panoramic extraperitoneal view of the anatomical entities of the inguinal area. (From Colborn GL, Skandalakis JE. Laparoscopic cadaveric anatomy of the inguinal area. *Prob Gen Surg* 1995;12:13, with permission.)

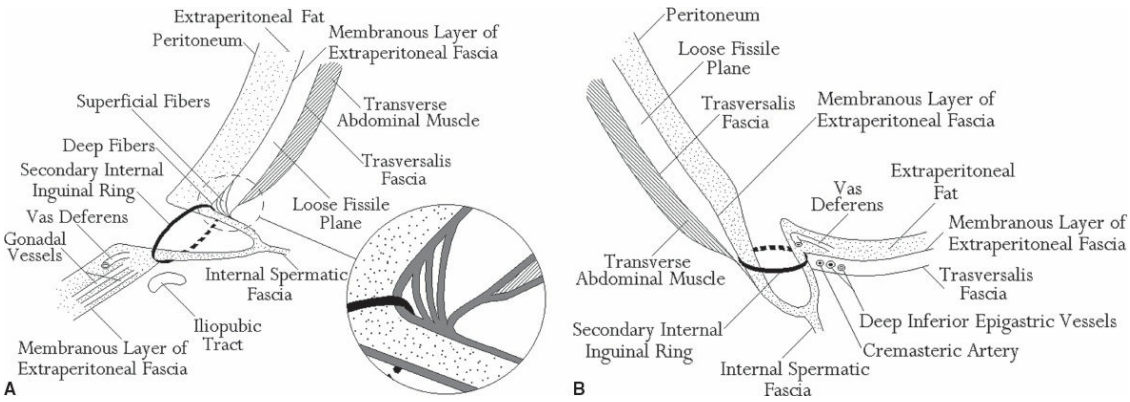

Figure 187.16. Diagrammatic representation of a parasagittal (**A**) and horizontal (**B**) section of the anterior abdominal wall through the area of the secondary internal inguinal ring. The term “loose fissile plane” stands for the areolar extraperitoneal tissue. (From

Mirilas P, Mentessidou A, Skandalakis JE. Secondary internal inguinal ring and associated surgical planes: surgical anatomy, embryology, applications. *J Am Coll Surg* 2008;206[3]:561–70. Copyright © 2008 American College of Surgeons, with permission.)

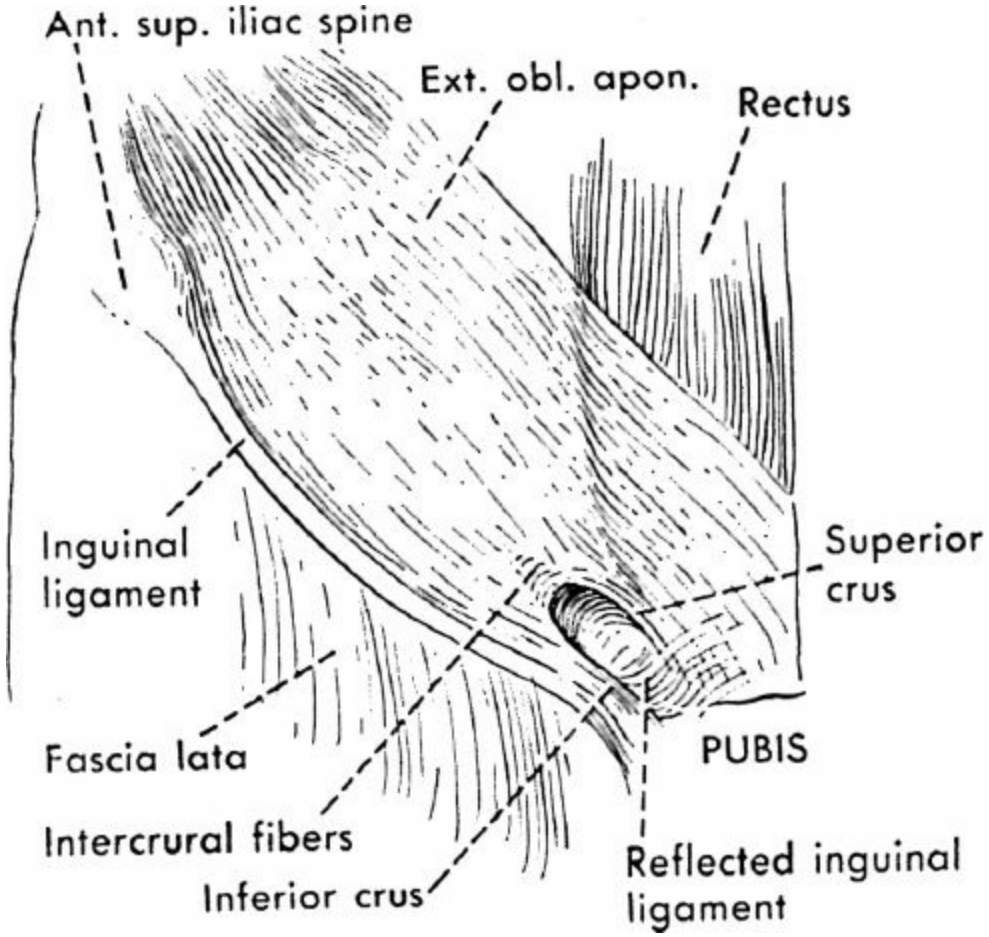

Figure 187.17. The external inguinal ring. (From Hollinshead WH. *Anatomy for Surgeons, vol. 2.* New York: Hoeber-Harper; 1956.)

The Secondary External Inguinal Ring

In our dissections we have rediscovered the secondary external inguinal ring, discovered by McGregor (1929) and described by Martin (1984)—forgotten thereafter (see Mirilas & Mentessidou, *Hernia* 2013). The secondary external inguinal ring arises from the membranous layer of the superficial fascia of the anterior abdominal wall below the classic superficial ring. It is tube-like arrangement of Scarpa fascia, which constitutes the entrance into the scrotum (Fig. 187.18). An examining finger can be easily inserted in the secondary external ring at the root of

the scrotum and follows the spermatic cord until the external inguinal ring. A similar ring-like arrangement of Scarpa fascia has been also noted around the round ligament in female cadavers.

The secondary external inguinal ring is implicated in several disorders of the inguinoscrotal area. Adhesive obstruction, underdevelopment, or congenital absence of the secondary external ring has been considered responsible for some cases of incomplete testicular descent or testicular ectopy. The secondary external ring usually constitutes an anatomical obstacle for hernia sacs to enter the scrotum. In the case that a hernia passes the secondary external ring, the hernia becomes scrotal.

Indirect Inguinal Hernia

An indirect hernia enters the inguinal canal and can be congenital or acquired. Characteristically the hernia starts laterally to the inferior epigastric vessels, in the lateral inguinal fossa (Figs. 187.10 and 187.19). Herniation may take place through all four inguinal rings, when the sac reaches the scrotum. The sac is a peritoneal projection made by the nonclosed (congenital hernia) or reopened processus vaginalis. The sac enters the secondary internal ring (membranous layer of the preperitoneal fascia) and the internal inguinal ring, and progresses in the inguinal canal, where it is covered by the covering layers of the endocanal spermatic cord (internal spermatic fascia, cremaster muscle and fascia—from internal oblique and transversus muscle). The sac exits the external ring and gains another covering from the investing fascia of the external oblique, the external spermatic fascia. When reaching the neck of the scrotum, it enters the secondary external inguinal ring (Scarpa fascia). The reader is invited to study the concept of the new secondary internal and external rings and their implication in indirect inguinal hernia in Figure 187.20.

The sac of the indirect inguinal hernia lies on the vessels and vas deferens, and encloses them like an Ω (omega). This can be designated as the visceral compartment of the spermatic cord. On an outer layer are the cremasteric muscle and vessels, accompanied by the (also parietal) genital branch of the genitofemoral nerve that supplies the scrotum. The ilioinguinal nerve also enters the inguinal canal, found on the cord, under the aponeurosis of the internal oblique muscle, to finally exit the external inguinal ring. Because of their importance, the nerves of the groin will be discussed further below.

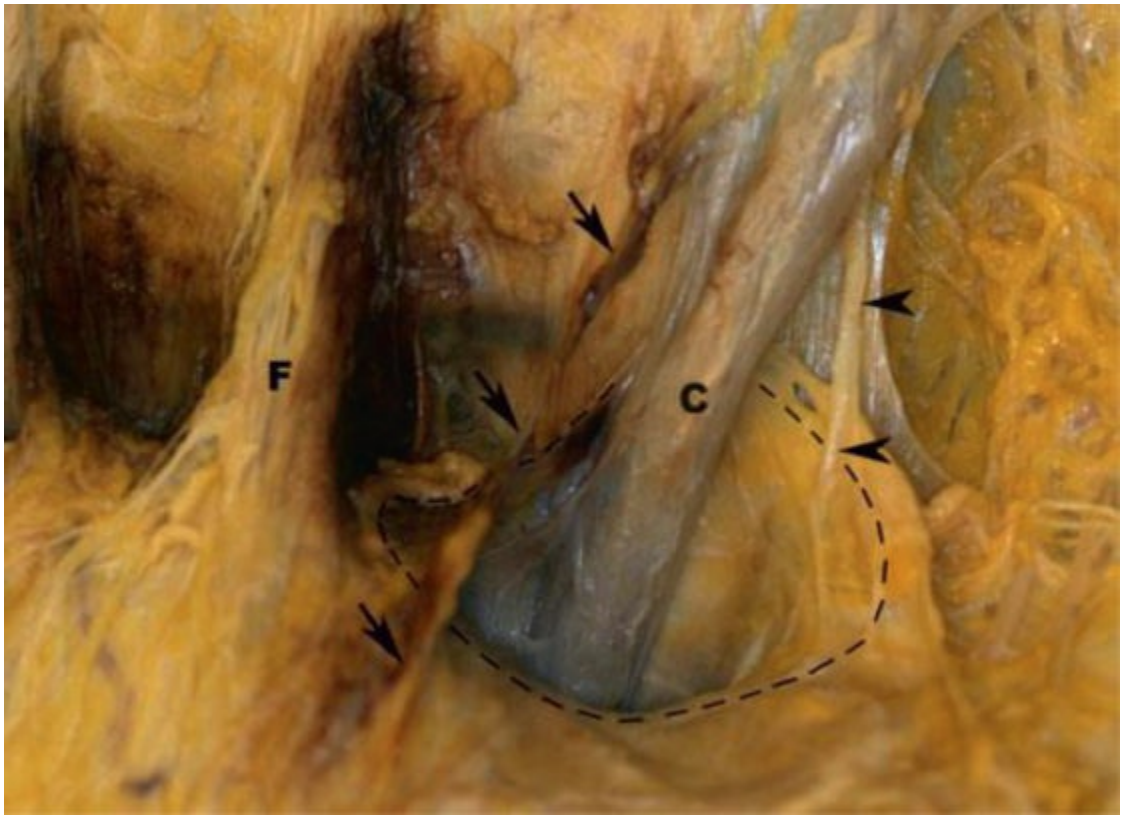

Figure 187.18. Photograph of the secondary external inguinal ring in an adult male cadaver, left side. After a wide transversal incision on the lowest anterior abdominal wall, the membranous layer of the superficial fascia was detached and reflected anteriorly, together with the superficial fat and skin. The ring can be immediately seen, without any further dissection (outlined by a *dashed line* here). Scarpa fascia forms the anterior border of the ring and gives off a lateral-posterior reflection and a medial-posterior reflection. The spermatic cord (C) and the ilioinguinal nerve (*arrowheads*) pass through the ring; here, the nerve can be seen distant from the cord, due to displacement resulting from opening and reflection of Scarpa fascia. The superficial inferior epigastric vessels (*arrows*) course outside the ring, aside to the fundiform ligament (F). (From Mirilas P, Mentessidou A. The secondary external inguinal ring and associated surgical planes: surgical anatomy, embryology, applications. *Hernia* 2013;17(3):379–89. Direct Inguinal Hernia

The ring of the direct hernia is located in the medial inguinal fossa within the “triangle of Hesselbach.” This triangle is topographically delineated by the deep inferior epigastric artery laterally, the lateral border of the rectus muscle medially, and the inguinal ligament as base; the base was originally defined to be the pubis and pectineal ligament, but this has been revised (Fig. 187.21). The base of the triangle is found immediately behind the external inguinal ring, from which according to Hollinshead (see references) is “separated by the transversalis fascia and fascio-aponeurotic derivatives of the transversus or internal oblique muscle.” Evidently, by “transversalis fascia” the membranous layer of the preperitoneal tissue is meant according to our view. The “conjoined tendon” or separately the apoeneuroses of the transversus and internal oblique muscles play a role in this area. This weak area is the site of direct inguinal hernias that may protrude through the external inguinal ring. The hernial ring is medial to the deep inferior epigastric vessels (lateral umbilical ligament) and lateral to the obliterated umbilical artery (medial umbilical ligament); the sac passes through the floor of the inguinal canal (Fig. 187.19).

External (Anterior) Supravesical Hernia

Supravesical hernias start in the supravesical fossa. The fossa is bounded between the median umbilical ligament (obliterated urachus), the medial umbilical ligament (obliterated umbilical artery), and the peritoneal reflection on the urinary bladder inferiorly (Fig. 187.15). The external hernias (as opposed to internal) extend directly through the anterior abdominal wall or through the inguinal, femoral, or obturator canals.

The external supravesical hernia can pass through the floor of the inguinal canal. It is our opinion that it is a form of direct hernia occupying the medial part of the Hesselbach triangle. The hernial ring may be small or large, partially or totally occupying the supravesical fossa. The defect may be small or it may involve into the triangle of Hesselbach extending to the median fold.

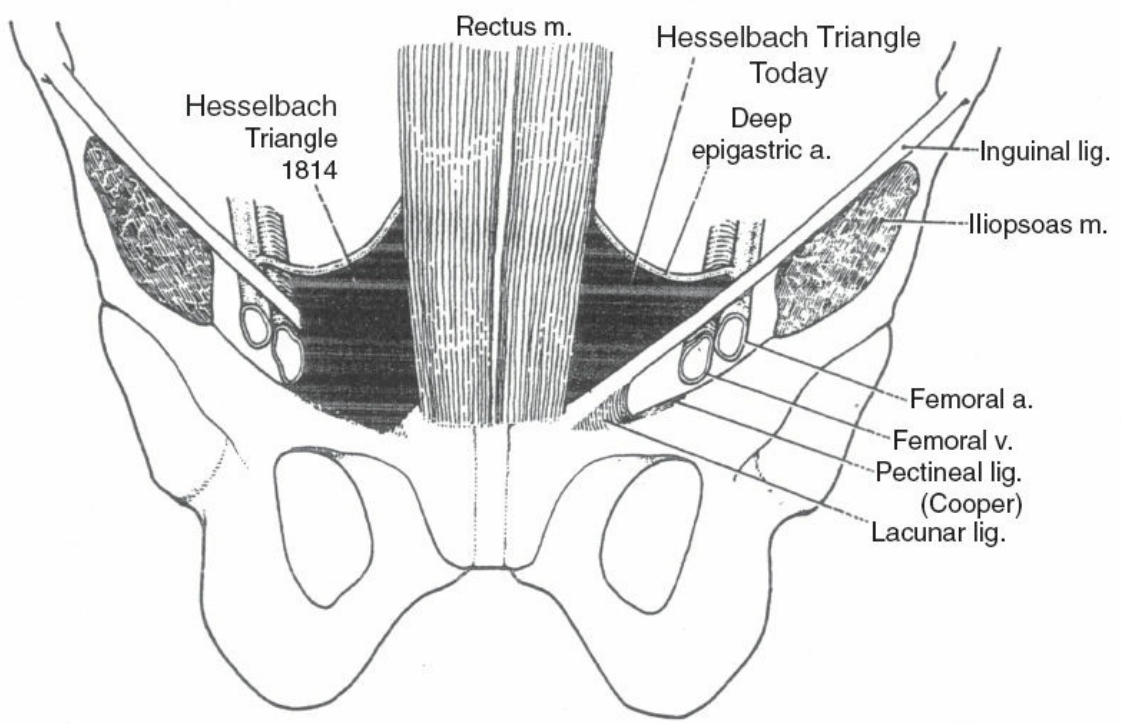

Figure 187.21. Hesselbach triangle. (From Skandalakis JE, Gray SW, Rowe JR. *Anatomical Complications in General Surgery.* New York: McGraw-Hill; 1983, with permission.)

The hernial sac of the external supravesical hernia or of the direct hernia rarely travels through the external ring. If such pathology is present and incarceration occurs, the subcutaneous hernial ring should be treated as in indirect hernia.

Femoral Hernia

A femoral hernia is a protrusion of preperitoneal fat or viscus through the femoral canal. The sac has to pass through the femoral ring that normally exists and a new opening (orifice) at the lower end of the femoral canal.

The femoral ring is bounded medially by the lacunar ligament (Fig. 187.22). Some authorities (McVay and Anson, Hollisnhead) suggest that it is really the transversus edge that forms the medial edge of the ring. Anteriorly the ring is bounded by the inguinal ligament and the iliopubic tract, posteriorly by the pectineal ligament (Cooper's) and laterally by connective tissue between it and the femoral (or iliac) vein. The femoral ring is prone to hernia because the "transversalis fascia" (in truth the membranous layer of the preperitoneal fascia) does not protect it, but passes downward to form the femoral sheath.

After entering the femoral ring, the hernial sac enters the femoral canal.

The boundaries of the femoral canal are the following:

Anterior: Iliopubic tract or the inguinal ligament (or both)
Posterior: Pectineal ligament (Cooper) and fascia iliaca
Lateral: A connective tissue septum and the femoral vein
Medial: The aponeurotic insertion of the transversus abdominis muscle and transversalis fascia or, rarely, the lacunar ligament

The femoral hernia sac passes behind or deep to the inguinal ligament. Thus, the exit orifice is found behind the fascia lata and in front of the fascia on the pectineus muscle. If the hernia is more pronounced, the sac will find an exit at a weak point of the fascia lata, which is the saphenous opening (fossa ovalis). The medial border of the hernia is the lacunar ligament. Laterally, it is the sheath of the femoral vessels. The orifice of a femoral hernia sac is found below the inguinal ligament, about 3 cm lateral to the pubic tubercle in the adult.

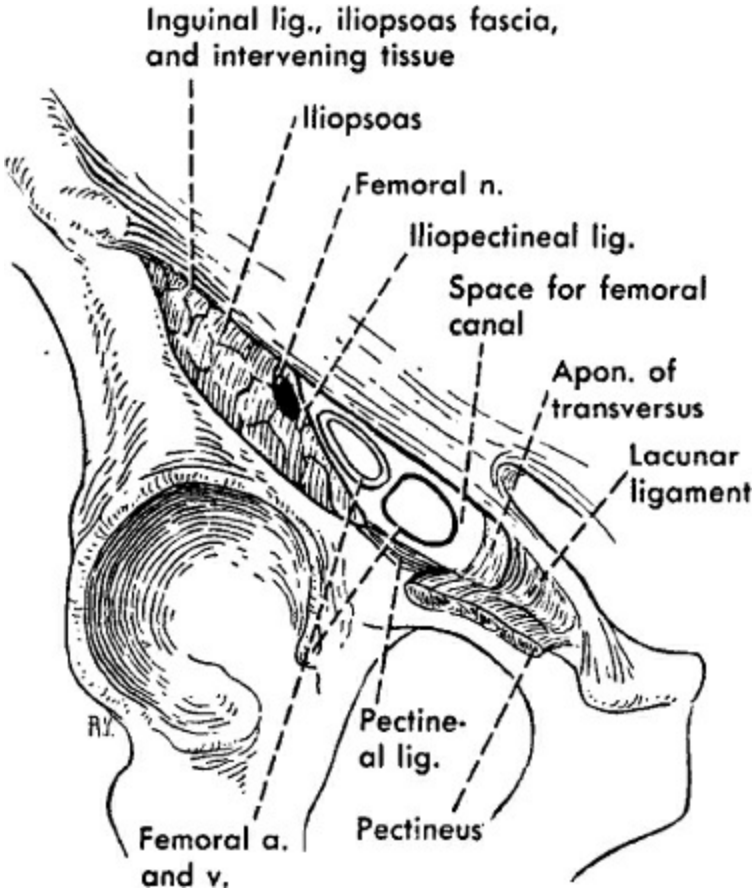

Figure 187.22. Schema of the region of the femoral canal, seen from below. The inguinal ligament is pulled upward so that the lacunar ligament can be seen. (From Hollinshead WH. *Anatomy for Surgeons, vol. 2.* New York: Hoeber-Harper; 1956.)

If there is incarceration, a small incision should be made to divide the inguinal ligament anteriorly or to divide the lacunar ligament medially. The incision of the inguinal ligament is preferred because the lacunar ligament is only 0.5 to 1.0 cm in length; division of the lacunar ligament may not enlarge the ring sufficiently.

We prefer the division of the inguinal ligament also because an aberrant obturator artery, found in >30% of cases and arising from the inferior epigastric artery, or, even more frequently, an aberrant vein, may pass across or medial to the femoral ring in the edge of the lacunar ligament rather than lateral to the ring. If the approach is made from above the inguinal ligament, and thus through the floor of the inguinal canal, the aberrant obturator can be seen clearly, and the lacunar ligament can be cut safely.

Nerves of the Inguinal Region

Anterior Exposure

Amid and colleagues stretched that the ilioinguinal, iliohypogastric, and the genital branch of the genitofemoral nerve must be identified during the anterior access for indirect inguinal hernia, in order to avoid postherniorrhaphy neuropathic pain. These nerves are responsible for the sensory innervation of the inguinal region.

Ilioinguinal nerve: Arises from the 12th thoracic and the first lumbar nerves. Lateral entry into the groin is via a path that courses through the transversus abdominis muscle medial to the anterior superior iliac spine. Normally, it follows the spermatic cord below the external oblique aponeurosis until it exits the deep ring. In 35% of cases, it can be found anterior to the spermatic cord within the cremasteric fibers. It can also be found to course through the external oblique aponeurosis anywhere between the deep and superficial rings.

Iliohypogastric: Arises from the 12th thoracic and first lumbar nerves. Its path courses through the transversus abdominis muscle superior to the ilioinguinal nerve to cross the groin in the plane between the external and internal oblique aponeuroses medial to the spermatic cord. It can be found during identification and dissection of the conjoined area. In some cases, the ilioinguinal and iliohypogastric nerves join prior to entry into the groin. Occasional absence of either the iliohypogastric or ilioinguinal nerves has also been reported.

Genital branch of the genitofemoral: Arises from the first and second

lumbar nerves. This follows the gonadal vessels as it enters the inguinal canal deep to the lateral crus of the deep ring. An aberrant ilioinguinal nerve may accompany the genital branch of the genitofemoral nerve in select cases.

Extraperitoneal Exposure

The iliohypogastric and ilioinguinal nerves, branches of the genitofemoral nerve, and the anterior and lateral femoral cutaneous nerves are found in the parietal compartment of the extraperitoneal (preperitoneal) space between the transversalis fascia and the membranous layer of the extraperitoneal fascia.

Ilioinguinal and Iliohypogastric: Both can be found along the upper lateral edge of the psoas entering the transversalis fascia above the iliac crest. These are rarely exposed during extraperitoneal exposure.

Branches of the genitofemoral: In contrast, the genital branch of the genitofemoral nerve is readily encountered as it travels with the gonadal vessels toward the deep inguinal ring. Inferolaterally, the femoral branch of the genitofemoral nerve can be found coursing over the fascia iliaca up toward the iliopubic tract.

Femoral cutaneous nerves: These nerves arise from the second and third lumbar nerves. Both the anterior and lateral femoral cutaneous nerves are located lateral to the fascia iliaca as they pass over the iliacus muscle and under the iliopubic tract. Because of the presence of these nerves lateral to the spermatic cord, the area beneath the ilopubic tract spanning from the gonadal vessels to the lateral pelvic wall toward the anterior superior iliac spine has been referred to as the “triangle of pain.” Nerve injury or entrapment here can cause neuralgia.

POSTEROLATERAL ABDOMINAL WALL (LUMBAR AREA)

Surgically, the lumbar area is defined as the area between the lower edge of the 12th rib superiorly, the iliac crest inferiorly, the erector spinae muscle medially, and the posterior border of the external oblique muscle laterally. Topographically, it is the area lateral to the midclavicular line and between the subcostal plane and transtubercular plane (which joins the tubercles of the iliac crests).

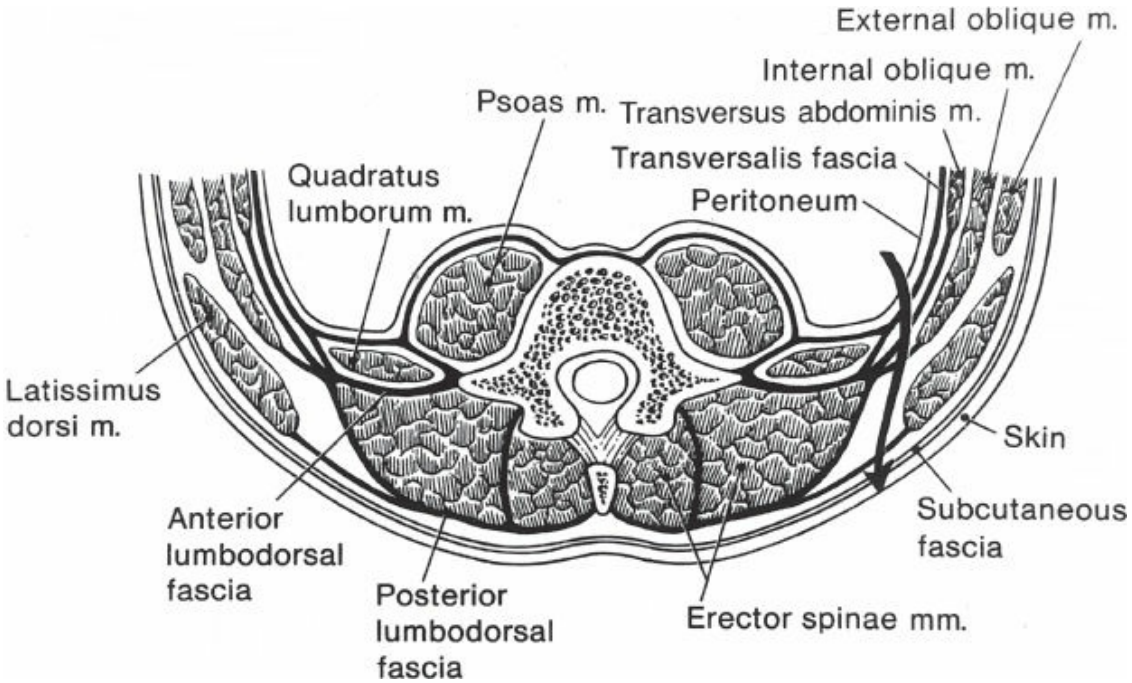

Figure 187.23. A diagrammatic cross-section through the posterior body wall in the lumbar region. *Arrow* indicates the pathway of a superior lumbar hernia. m, muscle. (Copyright (© 1996) From Skandalakis LJ, Gadacz TR, Mansberger AR Jr, et al. *Modern Hernia Repair: The embryological and anatomical basis of surgery.* Pearl River, NY: Parthenon; 1996. Reproduced by permission of Taylor and Francis Group, LLC, a division of Informa plc.)

The lumbar wall comprises the following anatomic entities: (1) extraperitoneal tissue with fatty and membranous layer; the membranous layer is continuous with the renal fascia; (2) transversalis fascia: this is the inner investing fascia of the transversous muscle; (3) deep muscular layer consisting of quadratus lumborum muscle and psoas muscle; (4) middle muscular layer consisting of sacrospinalis muscle, internal oblique muscle, and serratus posterior inferior muscle; (5) thoracolumbar (lumbodorsal) fascia, which is the union of aponeuroses and of all muscles; the innermost layer is continuous with the transversalis fascia; (6) superficial muscular layer consisting of latissimus dorsi muscle posterolaterally and external oblique muscle anterolaterally; (7) superficial fascia, formed by two layers: membranous and fatty; and (8) skin (Fig. 187.23).

Formation and Boundaries of the Lumbar Triangles

Hernial Ring of the Superior Triangle (of Grynfeltt) (Lesshaft Space)

The superior lumbar triangle is an inverted triangular space, with base the

12th rib and serratus posterior inferior muscle (Fig. 187.24, **right**). Anteriorly the triangle is bounded by the posterior border of the internal oblique muscle, and posteriorly by the anterior border of the sacrospinalis muscle. The roof is formed by the latissimus dorsi muscle. The floor is formed by the aponeurosis of the transversus abdominis muscle.

The superior lumbar triangle is related to the 12th thoracic and 1st lumbar nerves. The area of the fascial penetration of the 12th intercostal neurovascular pedicle is a very common site of herniation.

If incarceration occurs in a lumbar hernia, the ring of the superior triangle can be enlarged by medial or lateral incision midway between the 12th rib and the iliac crest.

Hernial Ring of the Inferior Triangle (of Petit)

The inferior lumbar triangle is an upright triangular space (Fig. 187.24, **left**). Its boundaries are the posterior border of the external oblique muscle anteriorly, the anterior border of the latissimus dorsi muscle posteriorly, and the iliac crest inferiorly, which forms the base of the triangle. Its roof is the superficial fascia. Its floor is the internal oblique muscle, with contributions from the transversus abdominis muscle and the posterior lamina of the lumbodorsal fascia.

If incarceration occurs, the ring of the inferior triangle can be enlarged by medial or lateral incision of the thoracolumbar fascia.

INCISIONAL HERNIA

It is not possible to provide a generalized description of the ring in an incisional hernia because each case is different. The ring may be small or large, the result of any incision of the anterolateral or posterolateral abdominal wall.

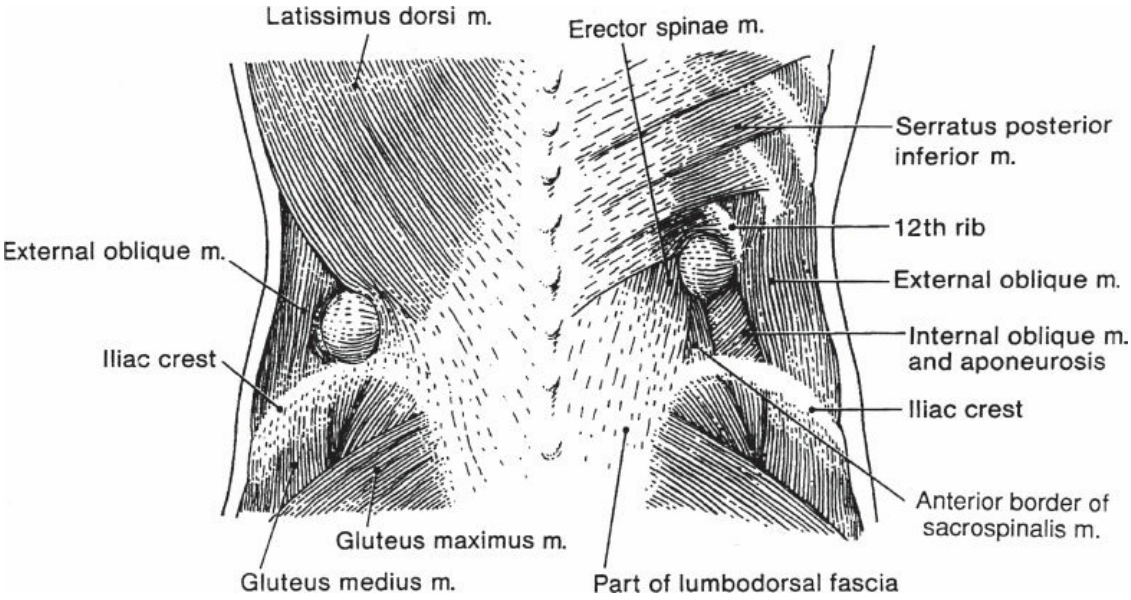

Figure 187.24. Left: An inferior hernia through Petit triangle. The base of the triangle is formed by the iliac crest. **Right:** A superior hernia through the Grynfeltt triangle. The base of the inverted triangle is formed by the 12th rib. m, muscle. PELVIC WALLS

The pelvic walls are formed by four walls—anterior, posterior, right lateral, left lateral—and by a floor.

Anterior Wall

The anterior wall is formed by the pubic bones and the pubic symphysis.

Posterior Wall

The posterior wall is formed by the sacrum and coccyx, sacroiliac joints, piriformis muscles, part of the pelvic diaphragm, and several ligaments.

Lateral Walls

The hip bones and the obturator foramen, with its membrane, form the lateral pelvic walls. The majority of the surface of the lateral pelvic walls is covered by the obturator internus muscles. The following anatomic entities are located medial to the obturator internus muscle: obturator nerve, obturator vessels, and branches of the internal iliac arteries and

veins.

The obturator internus extends posteriorly from the lesser pelvis, through the lesser sciatic foramen, and then laterally toward the greater trochanter of the femur.

Pelvic Floor

The pelvic floor is simply the pelvic diaphragm (Fig. 187.25), which is formed by the levator ani muscles, the coccygeus muscles, and the superior and inferior fascial layer that covers the muscles. The levator ani is formed by three muscles: pubococcygeus, puborectalis, and iliococcygeus.

SCIATIC HERNIA RINGS

There are three potential rings associated with the at-large sciatic hernia (Fig. 187.26). The suprapiriformic and infrapiriformic rings are associated with the greater sciatic foramen, above or below the piriformis muscle. The subspinous ring is associated with the lesser sciatic foramen.

Boundaries of the Sciatic Hernia Rings

Suprapiriformic Ring

Anterior: Sacroiliac ligament
Inferior: Upper border of piriformis muscle
Lateral: Ilium
Medial: Sacrotuberous ligament and upper part of sacrum

If incarceration occurs, the piriformis muscle should be transected by a posterior and inferior incision (downward and outward). Remember that the greater sciatic foramen is the “Monemvassia” (only gate) of the gluteal area. The surgeon must exercise care to avoid damaging any of the structures that lie in or pass through the foramen:

Piriformis muscle
Superior gluteal nerve and vessels
Inferior gluteal nerve and vessels
Pudendal nerve and internal pudendal vessels
Posterior femoral cutaneous nerve
Nerve to the internal obturator muscle
Nerve to the quadratus femoris muscle

Sciatic nerve

Infrapiriformic Ring

Above: Lower border of piriformis muscle
Below: Sacrospinous ligament
Posterior: Sacrotuberous ligament
Anterior: Ilium

With incarceration, the piriformis muscle should be transected by upward and inward incision. Keep in mind the proximity of the vessels and nerves passing through the greater sciatic foramen (see the previous section).

Subspinous Ring

Anterior: Ischial tuberosity
Superior: Sacrospinous ligament and ischial spine
Posterior: Sacrotuberous ligament

If incarceration occurs, incise the obturator internus and gemellus muscles, as necessary.

OBTURATOR HERNIA RING

An obturator hernia is the protrusion of either intraperitoneal or extraperitoneal organ or tissue through the obturator canal.

The obturator (or adductor) region lies in the medial portion of the upper thigh, between the flexor muscles of the thigh in front and the extensor muscles behind. It includes the origins of the adductor muscles from the circumference of the obturator foramen and the obturator membrane, and the obturator canal.

The obturator foramen is formed anteriorly and inferiorly by the rami of the ischium and pubis. It is closed by the obturator membrane, except for a small area, the obturator canal.

The obturator membrane is a continuation of the periosteum of the surrounding bones and of the internal and external obturator muscle tendons.

The obturator canal is a 2 to 3 cm long, 1 cm wide tunnel. It starts in the pelvis and follows an oblique downward course, exits the pelvis, and ends in the obturator region of the thigh. The obturator canal is bounded by the obturator groove of the pubic bone superolateraly, and by the free edge

of the obturator membrane and the internal and external obturator muscles inferiorly. The pelvic orifice of the obturator canal can be conceived as an opening of the obturator fascia, which is the continuation of the transversalis fascia, forming a general investing layer for the pelvic muscles. The external (superficial) opening of the obturator canal that also can be conceived of is found under the pectineus muscle, medially to the femoral vein.

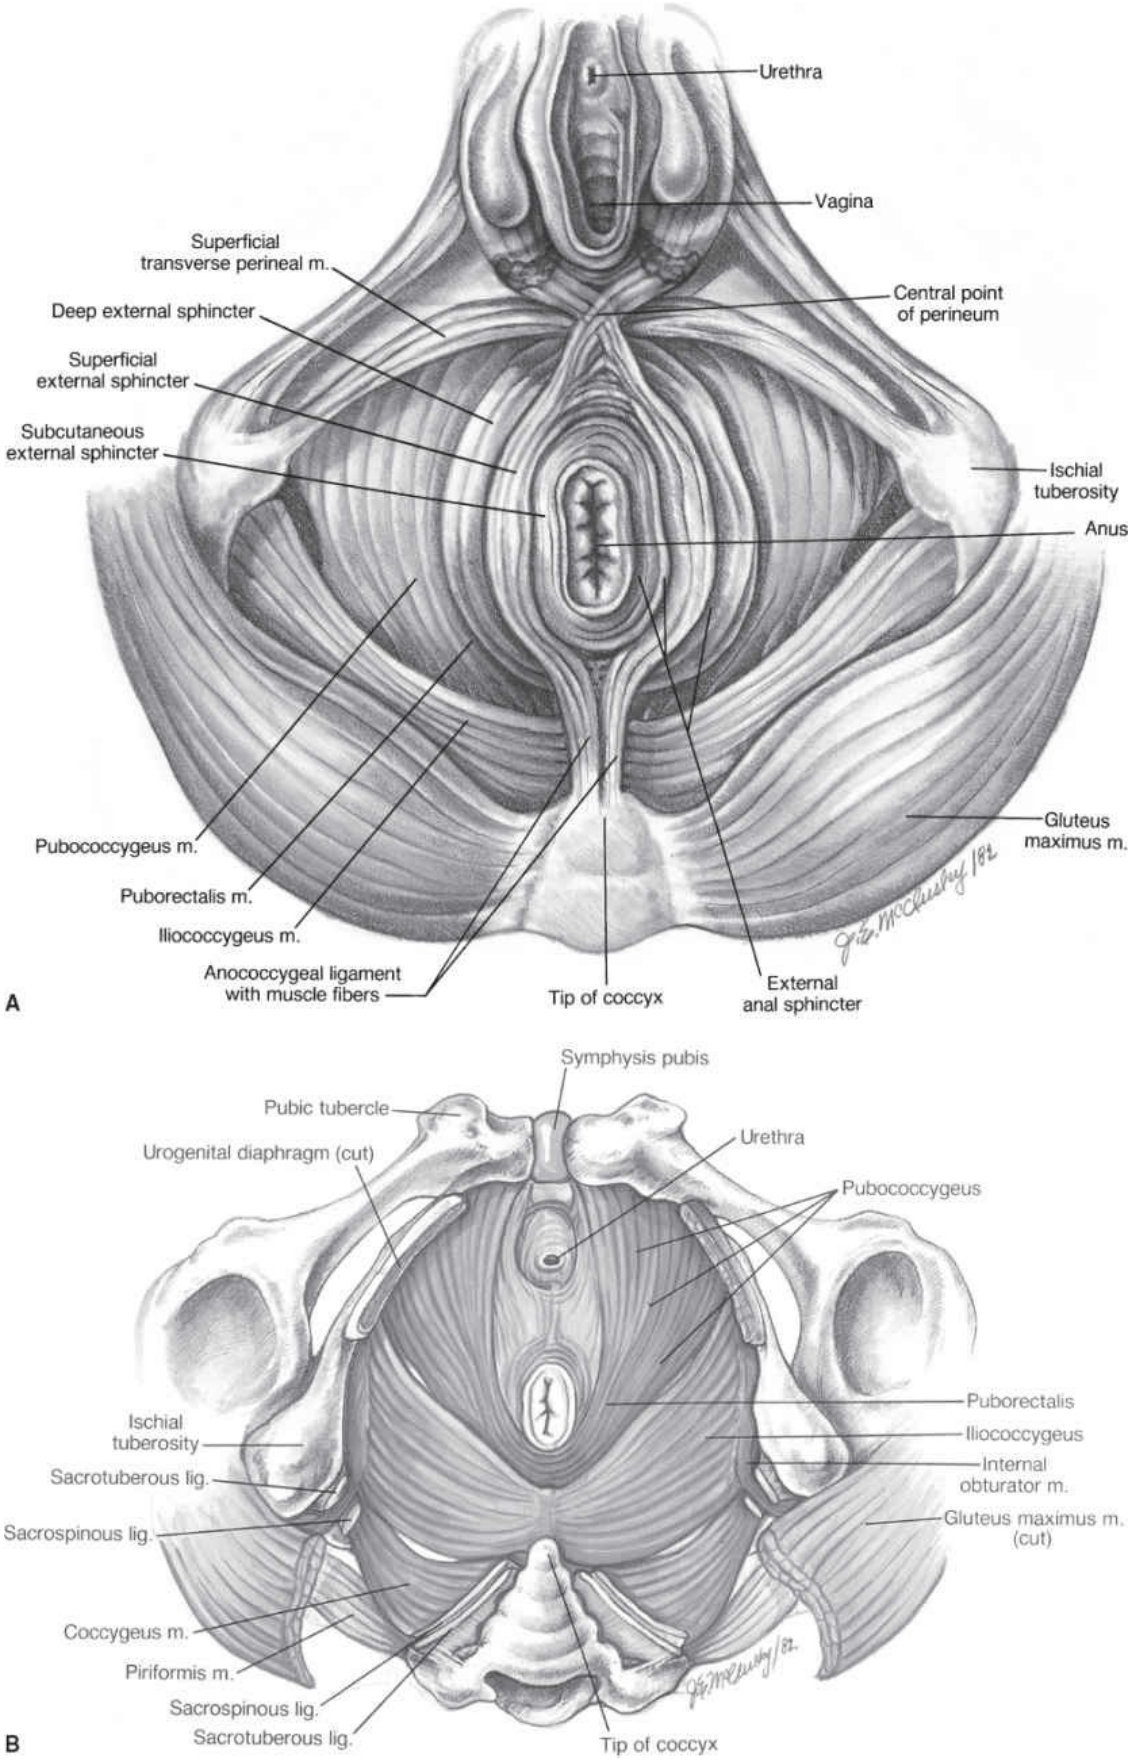

Figure 187.25. A. Female pelvic diaphragm, seen from below. m, muscle. **B.** Male pelvic diaphragm, seen from below. lig,

ligament; m, muscle. (From Gray SW, Skandalakis JE, McClusky DA. *Atlas of Surgical Anatomy for General Surgeons.* Baltimore, MD: Williams & Wilkins; 1985, with permission.)

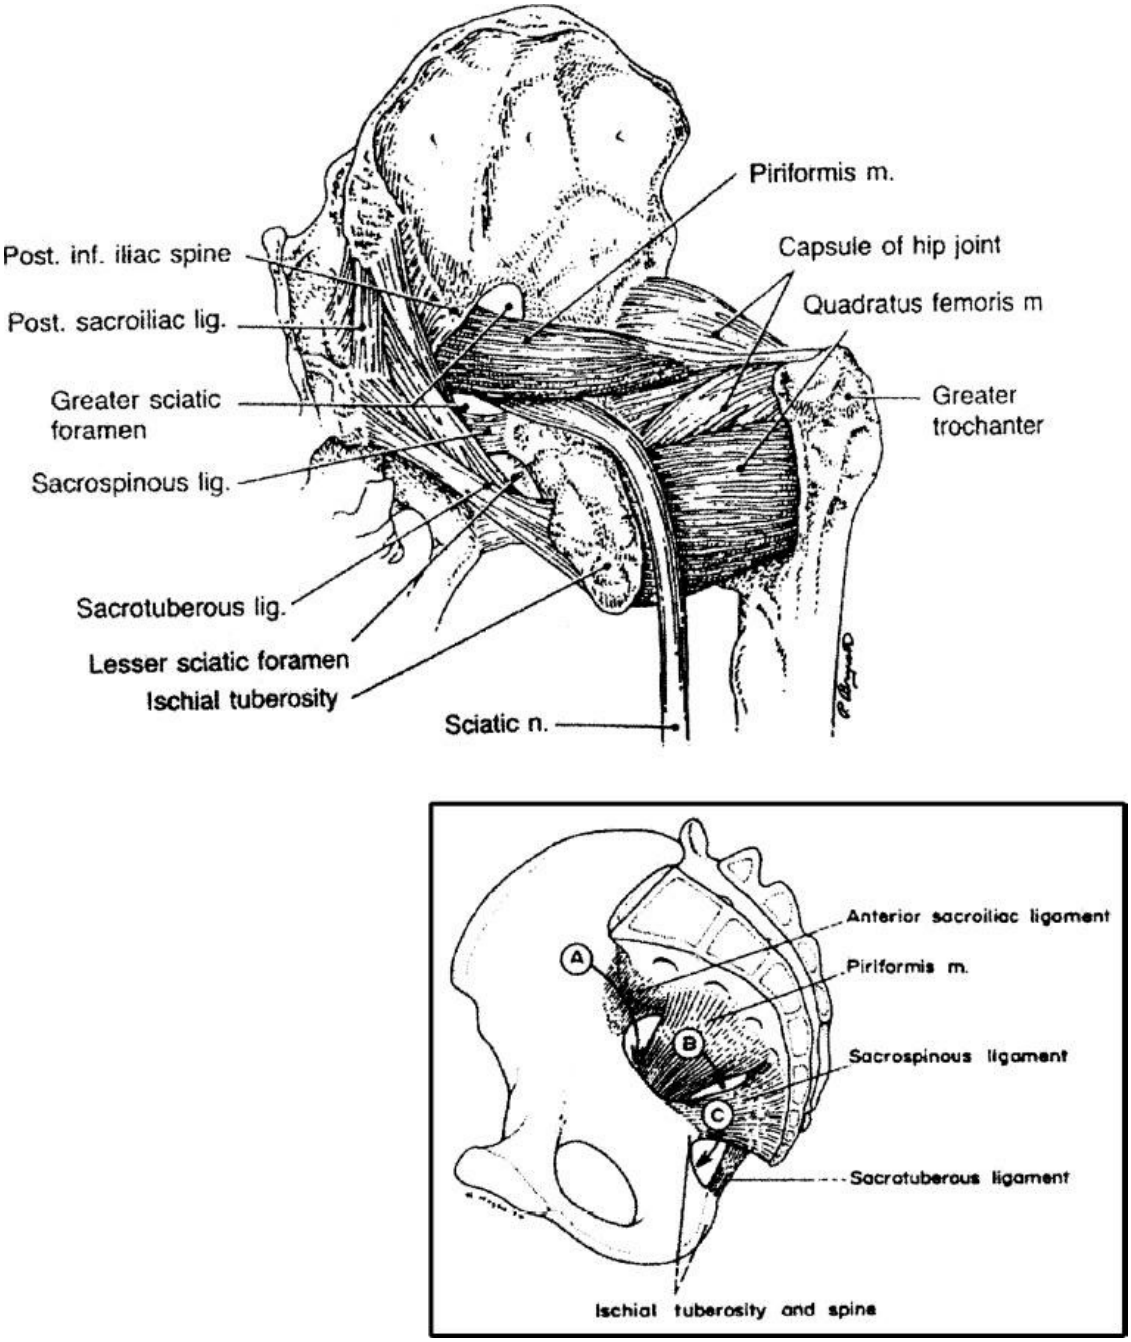

Figure 187.26. Right lateral external view of pelvis. The greater sciatic foramen transmits the piriformis muscle and sciatic nerve. **Inset:** Sites of potential herniae through the sciatic foramina. A, suprapiriformic sciatic hernia; B, infrapiriformic sciatic hernia; C, subspinous sciatic hernia through the lesser sciatic foramen. (Copyright (©1996) From Skandalakis LJ, Gadacz TR, Mansberger AR Jr, et al. *Modern Hernia Repair: The*

embryological and anatomical basis of surgery. Pearl River, NY: Parthenon; 1996. Reproduced by permission of Taylor and Francis Group, LLC, a division of Informa plc.)

Contents of obturator canal include the obturator nerve, artery, and vein (Fig. 187.27). They run in a bed of areolo-adipose tissue, which is the continuation of the extraperitoneal tissue of the pelvis toward the corresponding tissue of the thigh. This tissue is the "fat body" of the obturator canal.

PERINEUM

The perineum is defined as the region of the body lying below the pelvic diaphragm, between the inner aspects of the thighs and anterior to the sacrum and coccyx. The perineum is a diamond-shaped region. A transverse line between the right and left ischial tuberosities divides the diamond into an anterior urogenital triangle and a posterior anal triangle. More correctly the urogenital triangle is delineated posteriorly by the transverse perineal muscles.

The **urogenital triangle** comprises the following layers (superficial to deep): (1) skin; (2) adipose layer of superficial perineal fascia; (3) membranous layer of superficial perineal fascia; (4) deep perineal fascia, i.e., the investing fascia of the superficial muscles of the perineum; (5) the superficial muscles of the perineum (bulbocavernosus, ischiocavernosus, superficial transversus); (6) perineal membrane, consisting of strong fibrous tissue, which extends between the pubic arch and the ischiopubic rami; and (7) deep muscles of the perineum (deep transversus, sphincter urethrae) (Figs. 187.28 and 187.29). These are better understood when placed in spaces (compartments), as follows.

The *spaces of the urogenital triangle* as revised by our team (see Mirilas & Skandalakis, *J Am Col Surg* 2004) are: (1) subcutaneous perineal space, a potential space between the membranous layer of the superficial perineal fascia and the deep perineal fascia; (2) superficial perineal space (Fig. 187.29), between the deep perineal fascia and the perineal membrane, which contains the paired superficial transverse perineal muscles, the corpus spongiosum (male), the bulb of vestibule (female), the corpora cavernosa, the bulbospongiosus and ischiocavernosus muscles, and branches of the internal pudendal vessels and nerves; and (3) deep perineal space (Fig. 187.29), which extends from

the perineal membrane upward into the pelvic cavity. It contains the paired deep transverse perineal muscles, the sphincter urethralis (urethrovaginalis in the female), the bulbourethral (Cowper's) glands (in the male), and the internal pudendal artery and veins.

The **anal triangle** comprises the ischioanal fossae, one on either side, defined as the space between the skin below and the pelvic diaphragm above (Fig. 187.30). These fossae are filled with fat, but also in there pass the inferior rectal vessels and nerves.

PERINEAL HERNIA RING

A primary perineal hernia may occur anterior or posterior to the superficial transverse perineal muscle (Fig. 187.29).

Anterior Perineal Hernia Ring

An anterior perineal hernia passes through the pelvic diaphragm, lateral to the urinary bladder and vagina and anterior to the urethra, and enters the deep perineal space. It then penetrates the perineal membrane and is found in the superficial perineal space (Fig. 187.29).

The ring is located anterior to the superficial transverse perineal muscle through the urogenital diaphragm into a triangle formed by the bulbospongiosus muscle medially, the ischiocavernous muscle laterally, and the transverse perineal muscle posteriorly. The sac passes between the ischiopubic bone and the vagina, producing a swelling in the posterior half of the labium majus.

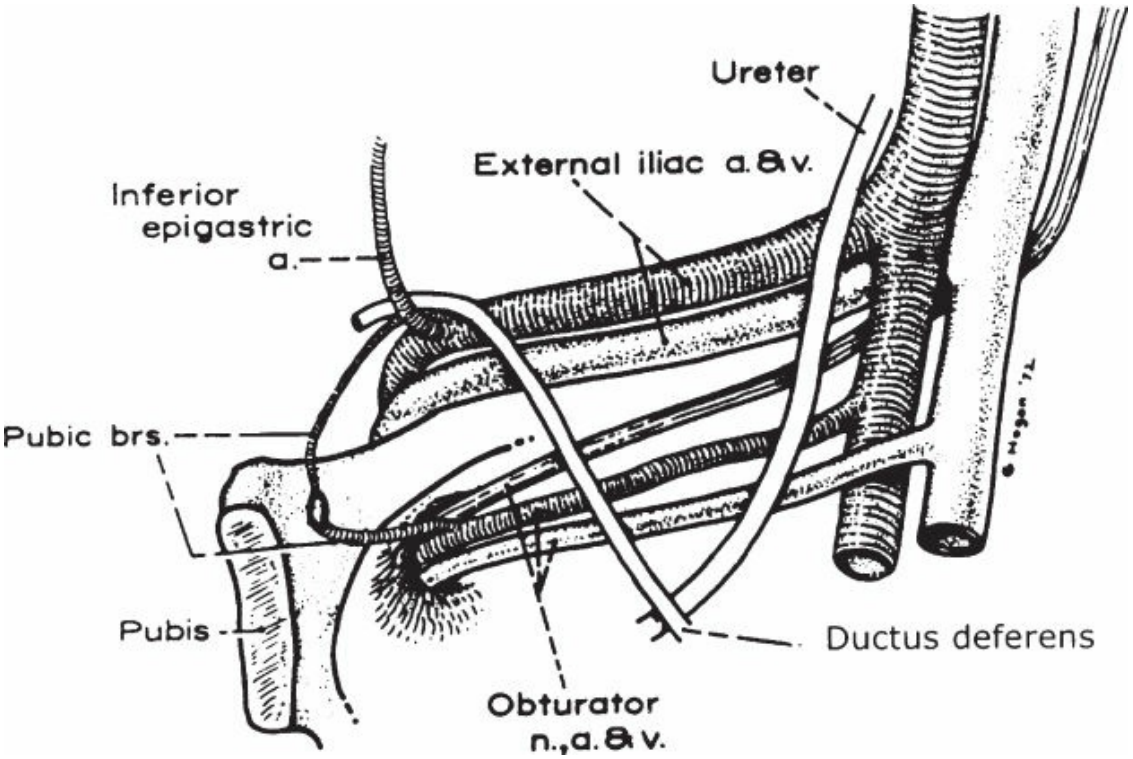

Figure 187.27. View of the medial wall of the male pelvis. The structures that pass through the obturator canal are shown. The obturator nerve lies superior to the obturator artery. The obturator artery lies superior to the obturator vein. An anastomosis between the obturator artery and the inferior epigastric artery is noted. (Reprinted from Gray SW, Skandalakis JE, Soria RE, et al. Strangulated obturator hernia. *Surgery* 1974;75:20–7. Copyright © 1974 Elsevier, with permission.)

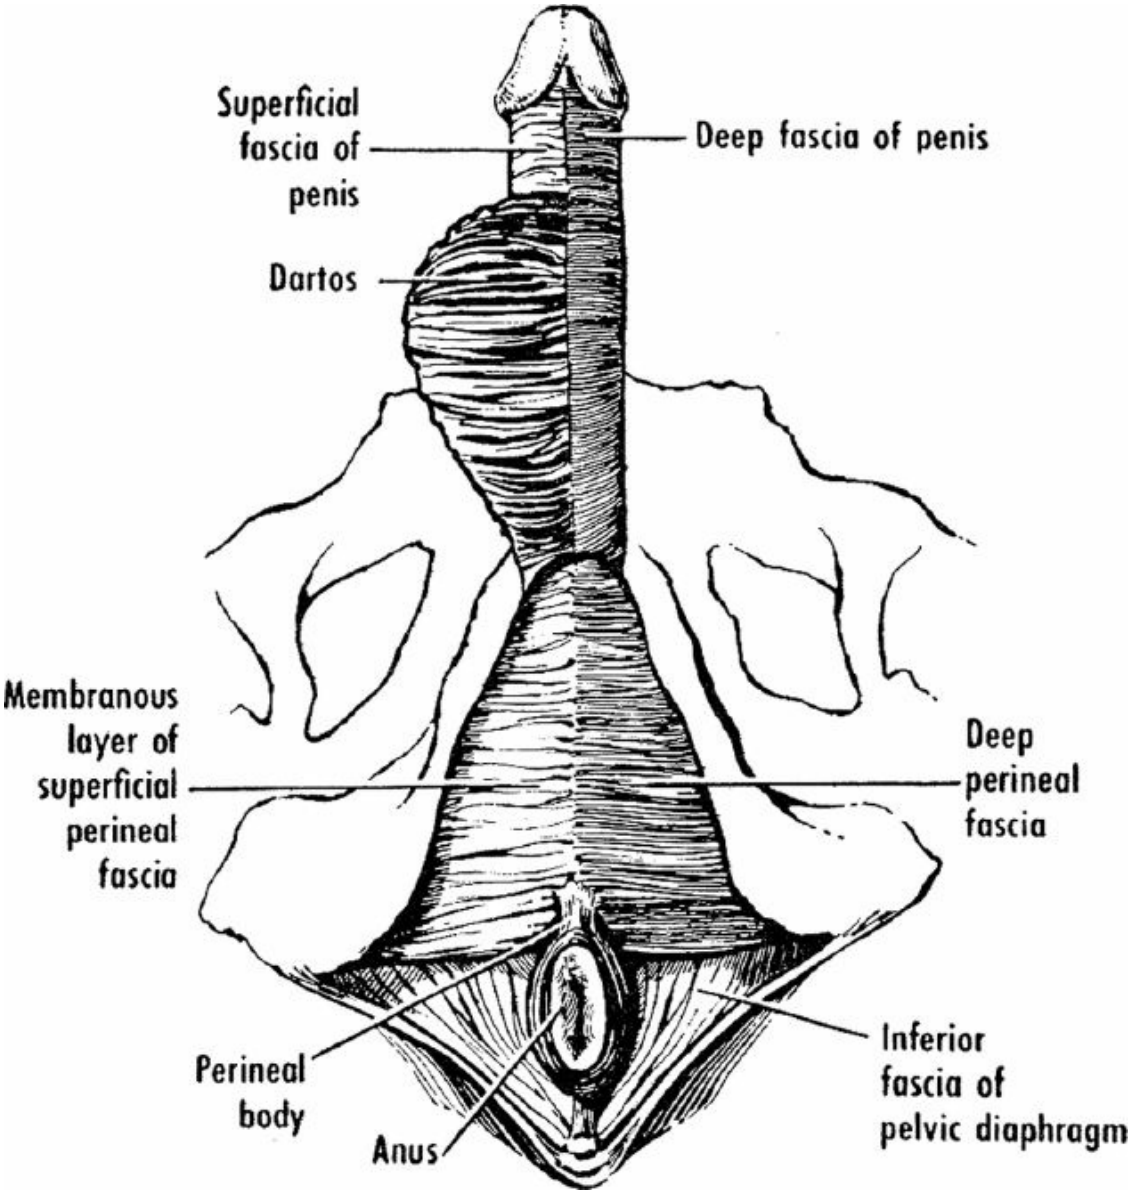

Figure 187.28. Schematic drawing of the male perineum, inferior view. The superficial fascia has been removed at the right. (From O'Rahilly R. *Gardner-Gray-O'Rahilly Anatomy: A Regional Study of Human Structure.* 5th ed. Philadelphia, PA: WB Saunders Co; 1986, with permission.)

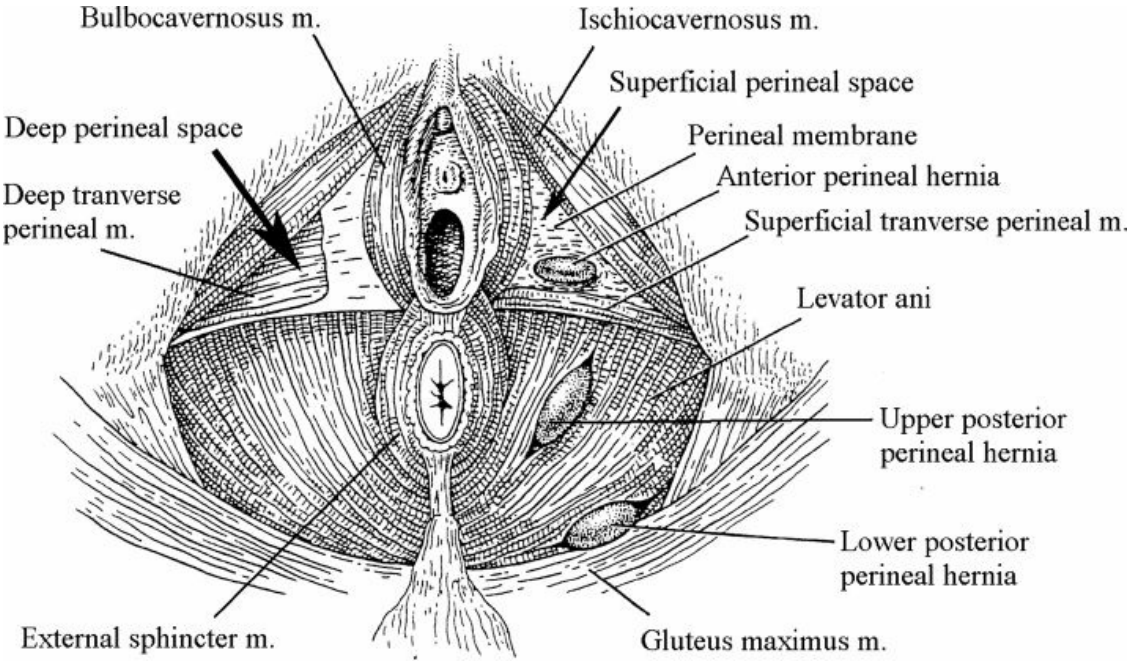

Figure 187.29. The perineum of the female, as seen from below. In this drawing, the investing fascia of muscles has been removed. The superficial perineal space can be seen exteriorly to the perineal membrane. The deep perineal space (containing the deep transverse perineal muscle) is seen interiorly to the perineal membrane. Sites of perineal herniation are shown. An anterior perineal hernia occurs anterior to the superficial transverse perineal muscles. It protrudes through the perineal membrane, into the superficial perineal space. A posterior perineal hernia occurs posterior to the superficial transverse perineal muscles. It protrudes through the pelvic floor. It may emerge either between components of the levator ani muscle or between the levator ani and coccygeus muscles. (Republished with permission of Taylor and Francis Group LLC Books, from Skandalakis LJ, Gadacz TR, Mansberger AR, et al., eds. *Modern Hernia Repair: The Embryological and Anatomical Basis of Surgery.* New York: Parthenon Publishing Group; 1996, permission conveyed through Copyright Clearance Center, Inc.)

If incarceration is present, the deep transverse perineal muscle, including the urogenital diaphragm, should be incised.

Posterior Perineal Hernia Ring

A posterior perineal hernia may pass either between muscles of the pelvic diaphragm (Fig. 187.29), or through a defect resulting from the nonunion of the obturator internus and the iliococcygeus muscles, known as the

hiatus of Schwalbe (Fig. 187.30, ***inset***). Posterior perineal hernias that pass between the pubococcygeus and iliococcygeus muscles are called upper posterior perineal hernias (Fig. 187.29). Those passing between the iliococcygeus and coccygeus muscles are named lower posterior perineal hernias (Fig. 187.30). After passing through the pelvic floor, a posterior perineal hernia enters the ischioanal fossa and presents as a lump below the lower margin of the gluteus maximus muscle or as a swelling between the anus and the ischial tuberosity.

Division of the levator ani muscle by a small incision is sufficient to release an incarcerated viscus. Care must be taken, however, to avoid the pudendal nerve, which lies in the perineum just deep to the levator ani.

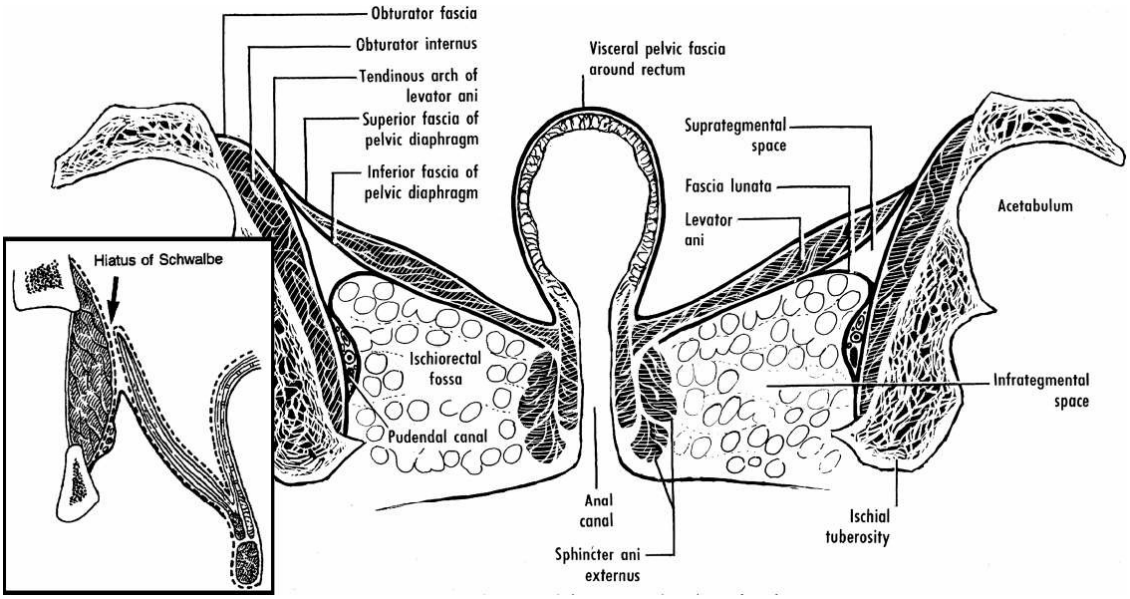

Figure 187.30. Ischioanal (ischiorectal) fossae. (From O'Rahilly R. *Gardner-Gray-O'Rahilly Anatomy. A Regional Study of Human Structure.* 5th ed. Philadelphia, PA: WB Saunders Co; 1986, with permission.) **Inset:** The hiatus of Schwalbe is produced by the nonunion of the investing fasciae (*dashed lines*) of the obturator internus and the iliococcygeus muscles. DIAPHRAGM

The following hernias are encountered:

Hiatal esophageal hernia (sliding hiatal and paraesophageal)
Congenital diaphragmatic rings

- Bochdalek (Posterolateral) ring
- Morgagni (Retrosternal) ring
- Pericardial ring

These hernias and the surgical anatomy of the respective rings are discussed in Chapter 63 “Surgical Anatomy of the Diaphragm.” They are briefly presented in Table 187.1.

PERITONEAL CAVITY

Hernias Through Mesenteries

Transomental Hernia

The transomental hernia passes through the greater omentum. The surgical anatomy of the ring appears in Figure 187.31. The ring is formed entirely by omentum. A vessel usually lies in one edge of the ring. Incise the omentum between clamps.

Transmesenteric Hernia

A transmesenteric hernia may pass through the mesentery of the small bowel, the transverse mesocolon, the pelvic (sigmoid) mesocolon, or the falciform ligament. The mesenteric ring may be located in the mesentery of the small intestine, the transverse mesocolon, or the sigmoid mesocolon (Fig. 187.32). At least one free edge of the ring is usually formed by a branch of the superior mesenteric or inferior mesenteric artery. Because there is no sac and the obstructed loop is invisible, decompress the dilated loop only and do not incise the neck. Vascular injury must be avoided.

Hernias Through Foramina and Fossae

Hernia Through the Epiploic Foramen of Winslow

The boundaries of the foramen of Winslow (Fig. 187.33) are:

Superior: Caudate process of liver and inferior layer of coronary ligament

Anterior: Hepatoduodenal ligament containing portal vein, hepatic artery, and common bile duct (cystic duct is also present in free edge of lesser omentum)

Posterior: Inferior vena cava

Inferior: First part of duodenum and transverse part of hepatic artery

For the incision, after clamping and decompressing the proximal intestinal loop, open the hepatogastric omentum. The hepatic artery should not be ligated. Remember that there is no excuse for dividing the neck of the sac. As J. E. Fischer commented in the edition (5th) of *Mastery of Surgery*: “It is difficult to conceive a situation in which one might divide the hepatic artery in order to decompress the bowel. Far better to clamp off the bowel, decompress it with a tube, and then extract the herniated bowel.”

Hernia Through the Paraduodenal Fossae (Paraduodenal Hernia Rings)

Right Paraduodenal Hernia

The hernial ring lies behind the superior mesenteric artery and vein or the ileocolic artery at the base of the mesentery of the small intestine (mesentericoparietal fossa of Waldeyer) (Fig. 187.34). The mouth of the sac opens to the left. The sac is directed to the right and usually lies in the retroperitoneal space behind the right mesocolon or transverse mesocolon. Typically the mouth of the sac lies behind the superior mesenteric artery or at its more posterior continuation, the ileocolic artery. The boundaries are:

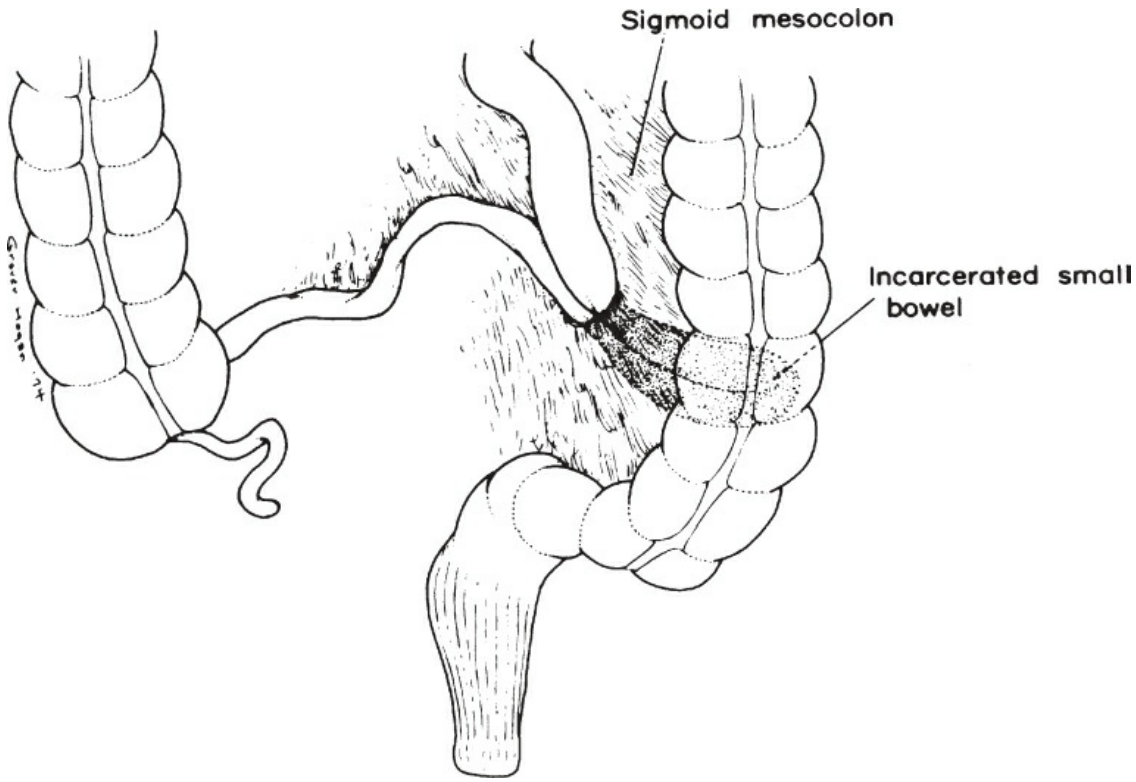

Figure 187.32. Transmesenteric hernia. (Reprinted from Skandalakis JE, Gray SW, Akin JT Jr. The surgical anatomy of hernial rings. *Surg Clin North Am* 1974;54(6):1227–46. Copyright © 1974 Elsevier, with permission.)

TABLE 187.1 Surgical Anatomy of Hernial Rings

Hernia	Definition	Boundaries	If Incarcerated
Anterolateral Abdominal Wall			
Epigastric (ventral)	Defect of linea alba anywhere from xiphoid to umbilicus	Medial edge of right or left rectus sheath (anterior and posterior laminae as well as lateral edge of muscle between) may form lateral border	Superior or inferior incision of linea alba; rarely lateral incision of anterior lamina of rectus sheath
Umbilical	Incomplete closure of early natural umbilical defect; absence of umbilical fascia	Superior and inferior—linea alba Lateral—rectus abdominis muscle	Isolate sac; ligate through superior or inferior incision of linea alba
Omphalocele	Herniation of intraperitoneal viscera into open umbilical ring	Umbilical cord; hernial sac covered by double layer of membranes (amniotic outside, peritoneum inside, Wharton jelly in between)	Right or left horizontal incision
Gastroschisis	Defect of anterior abdominal wall to right or left of the midline	Layers of the abdominal wall	May need to incise the lower edge of the ring
Spigelian	Herniation along the linea semilunaris of Spieghel (line of transition between the muscular fibers and the aponeurosis of the transversus abdominis muscle) anywhere above level of umbilicus lateral to the symphysis pubis	*If at intersection of linea semilunaris (Spieghel) and linea semicircularis (Douglas), or above the linea semicircularis but below and lateral to the umbilicus:* aponeurosis of internal oblique muscle and the aponeurosis of the transversus abdominis muscle *If above the level of the umbilicus:* ring is formed by tear in the transversus abdominus muscle and a defect of the aponeurosis of the internal oblique muscle	Transverse incision above swelling; oblique incision of aponeurosis of the external oblique muscle following the direction of the fibers
Groin—indirect	Herniation through the deep (internal) inguinal ring following the spermatic cord in male patients and the round ligament in female patients; may herniate through superficial (external) ring	*Boundaries of deep ring:* anterior and posterior—thickening of transversalis fascia "sling" inferior—iliopubic tract *Boundaries of superficial ring:* triangular opening of aponeurosis of external oblique composed of superior (medial) and inferior (lateral) crura; base of triangle is pubic crest	If at deep ring: internal oblique retracted medially by upward incision; open sac and release incarceration
Groin—direct	Herniation through floor of inguinal canal—covered by transversalis fascia and aponeurosis of the transversus abdominis muscle	Located at medial fossa	Rarely, through external ring; treat as indirect hernia incarceration
Groin—external supravesical	Herniation between midline and lateral umbilical ligament	Partially or totally occupying the supravesical fossa	Treat as indirect hernia incarceration
Femoral	Herniation through femoral canal (consisting of proximal ring and distal ring)	*Proximal ring:* anterior—iliopubic tract, inguinal ligament, or rarely, both Posterior—ligament of Cooper (pectineal ligament) Lateral—femoral vein Medial—insertion of iliopubic tract *Distal ring:* anterior—fascia lata Posterior—pectineal fascia Lateral—femoral sheath Medial—iliopubic tract or lacunar ligament	Small incision to divide inguinal ligament anteriorly; alternatively, divide the lacunar ligament medially; in the latter case, be aware of an aberrant obturator artery (30%) passing medial to the femoral ring in the edge of the lacunar ligament

Posterolateral Abdominal Wall (Lumbar)			
	Herniation through superior and inferior lumbar triangles	*Superior triangle:* base—12th rib and serratus posterior inferior muscle Anterior—posterior border of the internal oblique muscle Posterior—anterior border of sacrospinalis muscle Floor—aponeurosis of transversus abdominis muscle	Enlarge ring of the superior triangle by medial or lateral incision midway between the 12th rib and the iliac crest
		Roof—external oblique and latissimus dorsi muscle *Inferior triangle:* base—iliac crest Anterior—posterior border of external oblique muscle Posterior—anterior border of latissimus dorsi muscle Floor—internal oblique with transversus abdominis muscle and posterior lamina of thoracolumbar fascia of internal oblique	Enlarge ring of the inferior triangle by medial or lateral incision of the thoracolumbar fascia
Incisions	Varies according to the incision	Various	Incision of the ring is determined by topography
Pelvic Walls and Perineum			
Sciatic—suprapiriformic	Herniation through greater sciatic foramen above piriformis muscle	Anterior—sacroiliac ligament Inferior—upper border of piriformis muscle Lateral—ilium Medial—sacrotuberous ligament and upper part of sacrum	Posterior and inferior (downward and outward) incision of piriformis muscle; be aware of other structures in greater sciatic foramen
Sciatic—infrapiriformic	Herniation through greater sciatic foramen below piriformis muscle	Above—lower border of piriformis muscle Below—sacrospinous ligament Posterior—sacrotuberous ligament Anterior—ilium	Anterior and superior (upward and inward) incision of piriformis; be aware of other structures in greater sciatic foramen
Sciatic—subspinous	Herniation through lesser sciatic foramen	Anterior—ischial tuberosity Superior—sacrospinous ligament and ischial spine Posterior—sacrotuberous ligament	Incise obturator internus muscle
Obturator	Herniation through the obturator canal	Superior and lateral—obturator groove of the pubis Inferior—free edge of obturator membrane and the internal and external obturator muscles	Incision at lower margin of ring; be aware of obturator artery, vein, and nerve as they pass through the canal; inspect for aberrant obturator vessel(s)
Perineal—anterior	Herniation anterior to the superficial transverse perineal muscle	Medial—bulbospongiosus muscle Lateral—ischiocavernous muscle Posterior—transverse perineal muscle	Incise deep transverse perined muscle, including both layers of the urogenital diaphragm; sac passes between ischiopubic bone and the vagina; in male patients, very rare
Perineal—posterior	Herniation posterior to the superficial transverse perineal muscle	Ring formed through levator ani, or between the levator ani and coccygeus muscles	Small incision to divide the levator ani muscle
Diaphragm			
Hiatal esophageal (sliding or paraesophageal)	Herniation through diaphragmatic crura	In 50%, right and left limbs or the right crus; in remainder, both right and left crura are involved	Left lateral incision toward the central tendon (avoid injury to the phrenic nerve); hernial sac is always present

Diaphragmatic Rings			
Congenital—Bochdalek (posterolateral)	Herniation through the lumbocostal trigone (above and lateral to left lateral lumbocostal arch)	Located at the posterior portion of the diaphragm close to 10th and 11th ribs; if large, the central tendon is involved	Incise diaphragm laterally from margin of ring toward periphery (avoid branches of phrenic nerve)
Congenital—Morgagni (retrosternal)	Herniation through the sternocostal triangles (foramina of Morgagni)	Anterior—costal cartilage and xiphoid process Lateral and posterior—diaphragm Medial—diaphragm Ring located at fusion of central tendon and pericardium	Lateral incision to enlarge the ring (avoid phrenic nerve)
Pericardial ring	Herniation through the central tendon of the diaphragm and the pericardium	Various	Incision of the ring is determined by topography
Peritoneal Cavity and Anatomical Entities within			
Transomental	Herniation through greater omentum	Bordered entirely by omental tissues	Incise omentum between clamps since a vessel will usually lie in one edge of the ring
Transmesenteric	Herniation through mesentery of small bowel, transverse mesocolon, pelvic mesocolon, or the falciform ligament	Ring may be located in mesentery of small bowel, the transverse mesocolon, or the sigmoid mesocolon; at least one free edge of the ring is usually formed by a branch of the superior mesenteric or inferior mesenteric artery	Decompress dilated loop; do not incise the neck
Foramina or Fossae			
Epiploic foramen of Winslow	Herniation through the foramen	Superior—caudate process of liver and inferior layer of coronary ligament Anterior—hepatoduodenal ligament Posterior—inferior vena cava Inferior—first part of duodenum and transverse part of hepatic artery	After clamping and decompressing the proximal loop, open the hepatogastric omentum; do not incise the neck
Right paraduodenal	Herniation through right paraduodenal fossa	Superior—duodenum Anterior—superior mesenteric artery or ileocolic artery Posterior—lumbar vertebrae	Incise lower part of the mouth of the sac (sac lies behind the superior mesenteric artery or ileocolic artery at the base of the mesentery of the small intestine)
Left paraduodenal	Herniation through left paraduodenal fossa	Superior—duodenojejunal flexure or the beginning of the jejunum, pancreas, and renal vessels Anterior—inferior mesenteric vein and left colic artery Right—aorta Left—left kidney	Incise lower part of the mouth of the sac in downward fashion (sac lies behind the inferior mesenteric vein and the left colic artery to the left of the fourth part of the duodenum)
Superior ileocecal	Sac under right mesocolon or descending colon	Ileocolic (ileocecal) fold: formed by an anteriorly located semilunar elevation of the ileocolic mesentery by the anterior branch of the ileocecal artery	Avoid the right ileocolic and right colic arteries
Inferior ileocecal	Sac under cecum	Anterior ileoappendicular fold	Avoid the ileoappendicular artery present in the fold; avoid injury to ascending colon
Paracolic	Sac under proximal ascending colon	Paracolic fold located in the right gutter	

Internal Supravesical			
Anterior supravesical	Herniation of the supravesical fossa in front of the bladder	Superior—the upward continuation of the vesical fascia and its fusion with the transversalis fascia and the peritoneum Inferior—fold of vesical fascia and peritoneum Lateral—lateral umbilical ligament and peritoneum Medial—medial umbilical ligament and peritoneum	Incise the posterior margins upward
Retrovesical (posterior supravesical)	Herniation of the supravesical fossa behind the bladder	Superior and anterior—vesical fascia and peritoneum of posterior bladder wall Inferior and posterior—transverse vesical fold	Treat as anterior supravesical
Postsurgery			
After retrocolic gastrojejunostomy	Two potential spaces are created; upper: above the mesocolon; lower: posterior to the gastric remnant	Anterior—gastrojejunostomy and efferent or afferent jejunal loop Posterior—posterior parietal peritoneum Superior—transverse mesocolon and posterior wall of the gastric remnant Inferior—ligament of Treitz and duodenojejunal peritoneal fold	No incision should be made; perform an enterostomy to facilitate reduction and closure of the ring
Postsurgery			
After antecolic gastrojejunostomy (when afferent loop is attached to the lesser curvature of the stomach)	Rare, but more common than herniation of loop to greater curvature	Anterior—afferent jejunal loop with its mesentery Posterior—omentum, transverse colon, and mesoduodenojejunal peritoneal fold Inferior—jejunum with its mesentery	
After antecolic gastrojejunostomy (when afferent loop is attached to the greater curvature of the stomach)	Information is scant because the herniation is so rare	Anterior—gastrojejunostomy and afferent jejunal loop Posterior—omentum and mesocolon Superior—transverse colon and mesocolon Inferior—ligament of Treitz and duodenojejunal peritoneal fold	No incision should be made; perform an enterostomy to facilitate reduction

Superior: Duodenum
Anterior: Superior mesenteric vessels or ileocolic vessels
Posterior: Lumbar vertebrae

When incarceration occurs, the incision must be in the lower part of the mouth of the sac to avoid vascular injury. If vascular damage appears inevitable, the surgeon should open the mesentery and decompress the proximal intestinal loop before attempting reduction.

Left Paraduodenal Hernia

A left paraduodenal hernia is a hernia into the descending mesocolon. The mouth opens to the right. The mouth usually lies behind the inferior mesenteric vein and the left colic artery at the left of the fourth part of the duodenum at the duodenojejunal flexure, so that the first part of the duodenum enters the sac, which contains all the jejunum and ileum, except for the terminal ileum (Fig. 187.35). The sac is directed to the left and usually lies in the retroperitoneal space behind the left mesocolon. The

anterior lip of the sac contains the inferior mesenteric vein, and usually an accompanying branch of the left colic (inferior mesenteric) artery. The boundaries are:

Superior: Duodenojejunal flexure or the beginning of the jejunum, pancreas, and renal vessels
Anterior: Inferior mesenteric vein and left colic artery
Right: Aorta
Left: Left kidney

The inferior mesenteric vein is very likely to be at or very close to the mouth of the sac, mostly anteriorly. Anteriorly, the sac is also crossed by branches of the left colic artery. Thus, the incision should be made in the lower part of the mouth. McNair advised division of the inferior mesenteric vein. A downward incision of the mouth avoids this sacrifice.

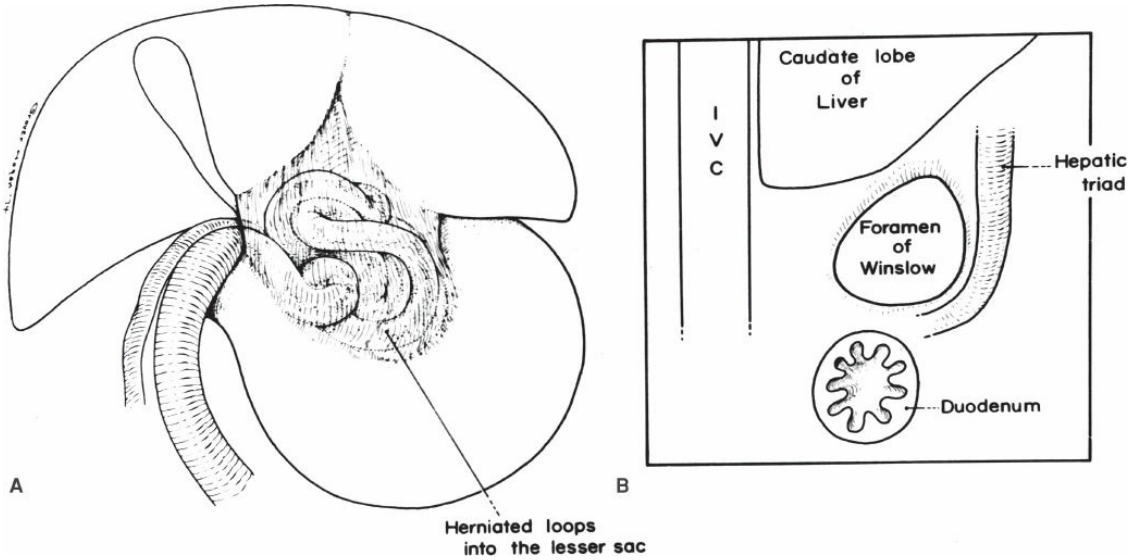

Figure 187.33. Hernia through the epiploic foramen of Winslow. **A.** The intestines have passed through the foramen into the lesser peritoneal sac (omental bursa). **B.** Diagram of the structures surrounding the foramen of Winslow. Hernia Through the Pericecal Fossae

The pericecal fossa is the most important boundary of the superior

ileocecal fossae in the presence of the ileocolic (ileocecal) fold. This fold is formed by an anteriorly located semilunar elevation of the ileocolic mesentery that contains the anterior branch of the ileocolic artery. The hernial sac travels under the right mesocolon or under the descending colon (Fig. 187.36). The surgeon must avoid the ileocolic and right colic arteries when incising the hernial ring. Aspiration of the proximal loop may be prudent.

The inferior ileocecal fossa has a prominent anterior ileoappendicular fold. This fold occasionally contains the ileoappendicular artery. The hernial sac is found under the cecum.

The paracolic fossa is located at the right gutter, resulting from nonfusion of the layers of the mesocolon of the lateral and posterior walls of the ascending colon. The hernial sac is formed by these mesentery layers, and the sac travels under the proximal ascending colon.

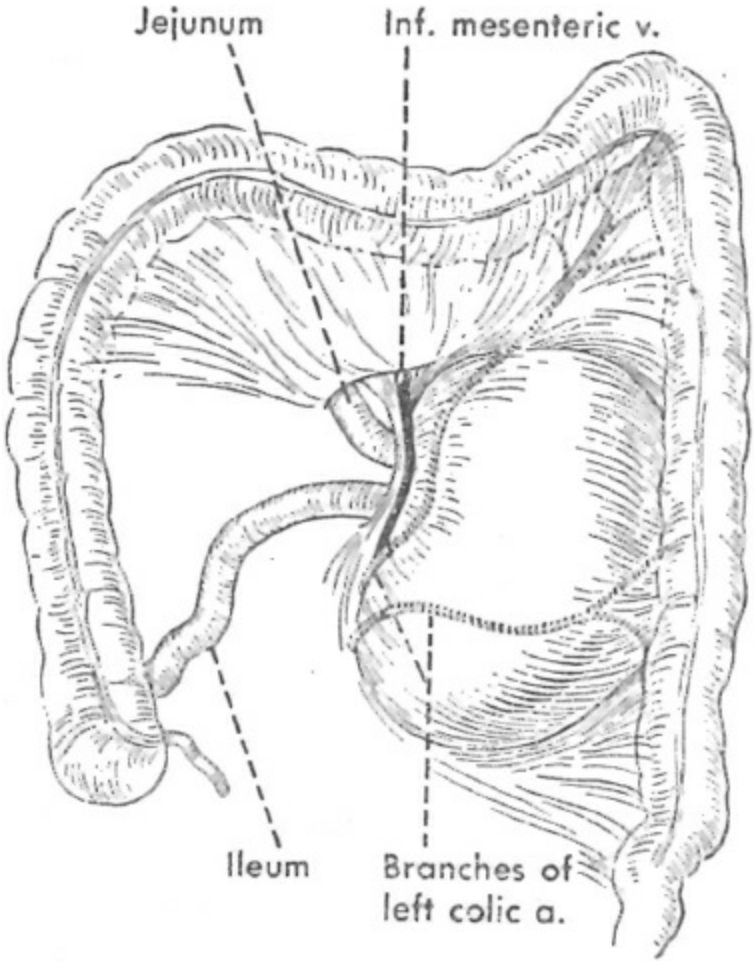

Figure 187.35. Drawing of a left paraduodenal hernia. Note the close relation of the inferior mesenteric vein, and, in this case, of and ascending branch of the left colic artery, to the mouth of the hernial sac. (From Hollinshead WH. *Anatomy for Surgeons, vol. 2.* New York: Hoeber-Harper; 1956.)

Internal Supravesical Hernia

Internal supravesical hernias are the hernias that do not exit through the abdominal wall, inguinal, femoral, obturator canal (these are called external, see specific section in groin hernia, above), but remain internal. There are several sites of internal herniation in the supravesical fossa. The hernia sac may pass in front of, beside, or behind the bladder, and accordingly the hernia is called prevesical, paravesical, or retrovesical (Fig. 187.37).

An anterior supravesical hernia may be retropubic or invaginating. The retropubic hernia is the herniation of the supravesical hernia in front of the bladder, into the space of Retzius (between the membranous layer of the preperitoneal fascia—the old posterior lamina of the transversalis fascia

and—and the peritoneum. Our opinion is that the sac passes through a defect of the umbilicovesical fascia (Fig. 187.38).

The boundaries of the ring of a retropubic hernia can be described as follows:

Superior: The upward continuation of the vesicoumbilical fascia and its fusion with the transversalis fascia and the peritoneum

Inferior: Fold of vesical fascia and peritoneum

Lateral: Lateral umbilical ligament and peritoneum

Medial: Medial umbilical ligament and peritoneum

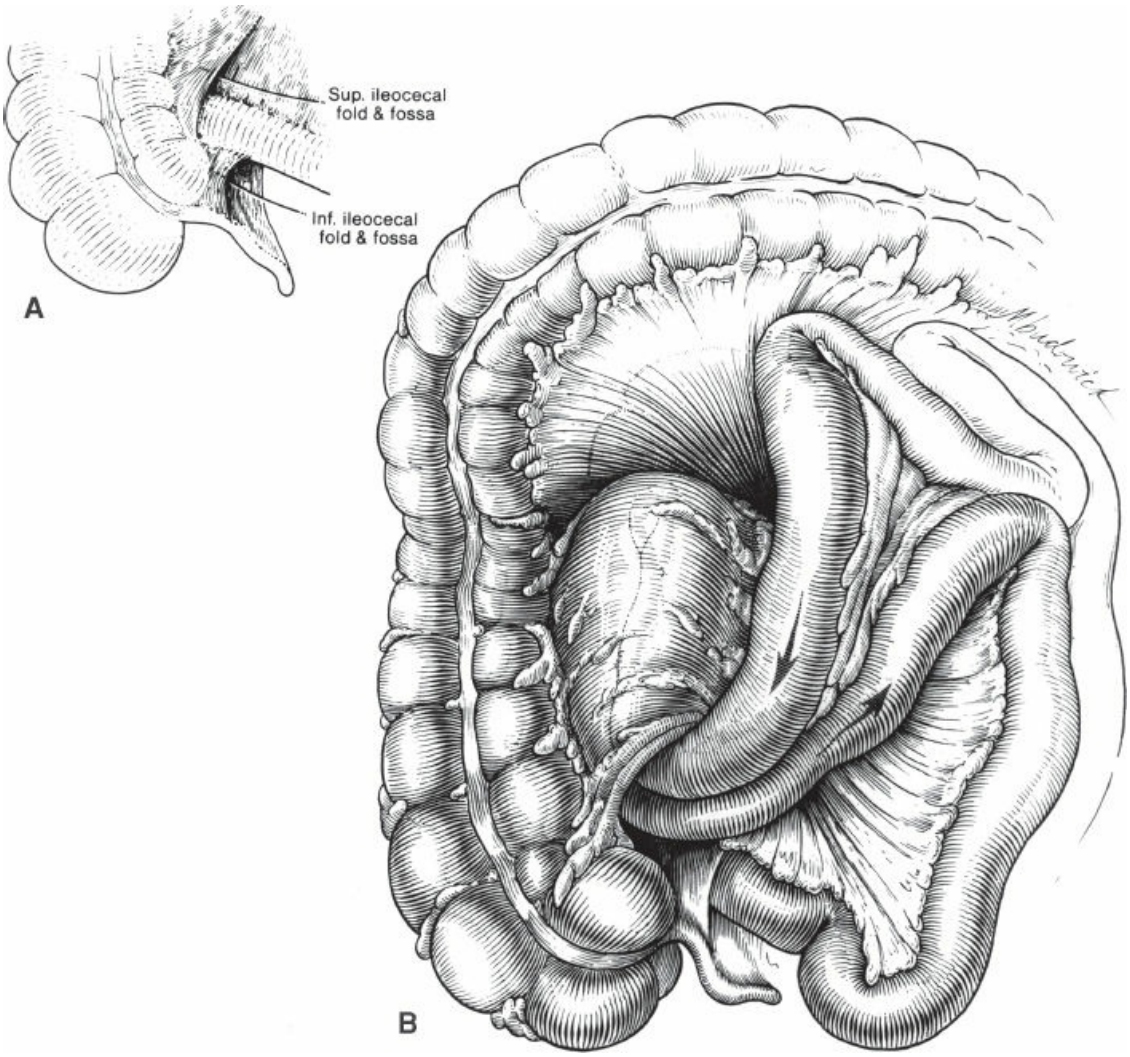

Figure 187.36. Hernia into the superior ileocecal fossa. **A.** Superior and inferior ileocecal folds forming fossae. Internal and external supravesical hernia. *Am Surg* 1976;42:142, permission conveyed through Copyright Clearance Center, Inc.)

The invaginating anterior supravesical (prevesical) hernia invaginates into the wall of the fundus of the bladder without protruding through the umbilicovesical fascia. This hernia does not enter the space of Retzius (Fig. 187.39).

The hernia may protrude laterally, into the paravesical space (right or left), and hence, by extension to a lateral pelvic position (see No. 2 in Fig. 187.40).

Last, the hernia may be retrovesical (see No. 3 in Fig. 187.40). The ring is at the transverse vesical fold of the bladder, between the latter and the vesical fascia and the peritoneum of the posterior wall of the bladder. The retrovesical hernia can also protrude in the rectovesical peritoneal pouch in men (Fig. 187.41) or in the vesicovaginal pouch in women (Fig. 187.42). A true retrovesical hernia is found in front of Denonvillier fascia (see No.1 in Fig. 187.41); in some occasions, however, the hernia may be found behind Denonvillier fascia, and the sac may be found protruding in the

mesorectum (see Nos. 2 and 3 in Fig. 187.41).

In all internal supravesical herniae, if enlargement of the ring is necessary, we recommend incising the posterior margins upward because of the anatomy of the area.

Postoperative Herniae

Retroanastomotic Herniae

Markowitz, an authority on iatrogenic retroanastomotic herniae, stated: "Construction of each gastrojejunostomy, either as a procedure by itself or as a step in the performance of a partial gastrectomy, results in the formation of an internal hernial ring which may be the cause of severe difficulties in the immediate or distant postoperative period."

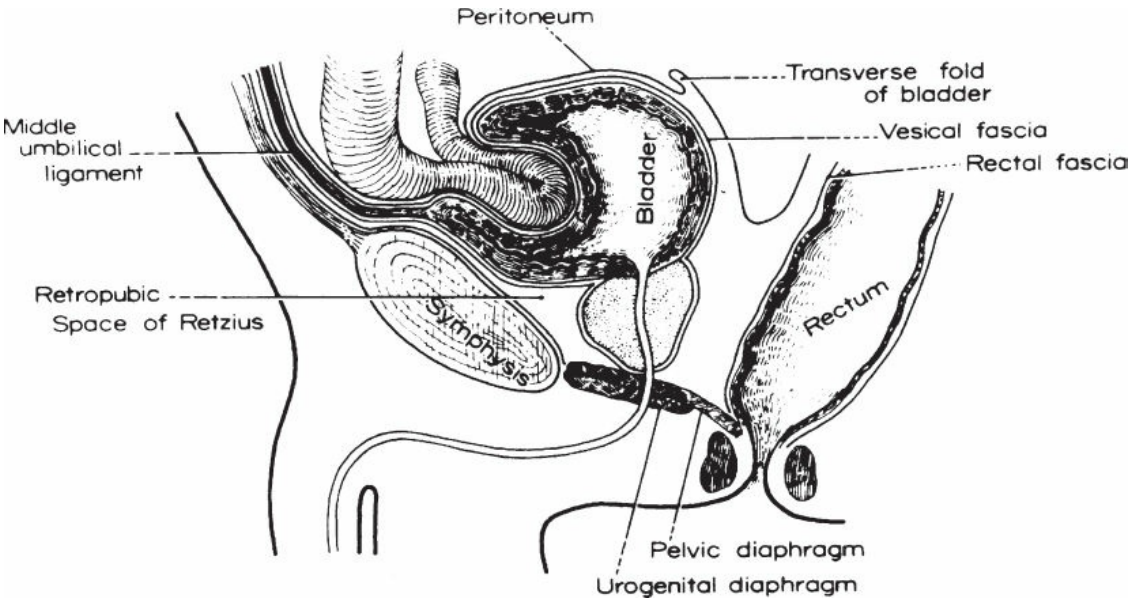

Figure 187.39. Invaginating type of anterior internal supravesical hernia. (From Skandalakis PN, Skandalakis LJ, Gray SW, et al. Supravesical hernia. In: Nyhus LM, Condon RE, eds. *Hernia.* 4th ed. Philadelphia, PA: JB Lippincott; 1995:400, with permission.)

Highly diagrammatic section of the body at the level of the acetabulum showing some of the landmarks of the spaces around the bladder. **Inset:** 1, location of sac in anterior internal (int.) supravesical hernia; 2, location of sac in lateral internal supravesical hernia; 3, location of sac in posterior internal supravesical hernia. (From Skandalakis PN, Skandalakis LJ, Gray SW, et al. Supravesical hernia. In: Nyhus LM, Condon RE, eds. *Hernia.* 4th ed. Philadelphia, PA: JB Lippincott; 1995:400, with permission.)

A. Hernia After Retrocolic Gastrojejunostomy

The surgical anatomy of the hernial ring after retrocolic gastrojejunostomy is seen in Figure 187.43. The boundaries of the ring are:

Anterior: Gastrojejunostomy and efferent or afferent jejunal loop (depending on whether the afferent loop is attached to the lesser or the greater curvature of the stomach)

Posterior: Posterior parietal peritoneum

Superior: Transverse mesocolon and posterior wall of the gastric remnant

Inferior: Ligament of Treitz and duodenojejunal peritoneal fold

In case of incarceration, no incision should be made. An enterostomy should be performed to facilitate reduction of the loop. Recurrence is prevented by closure of the ring.

B. Hernia After Antecolic Gastrojejunostomy

When the afferent loop is attached to the greater curvature of the stomach (Fig. 187.36B), the boundaries of the ring are:

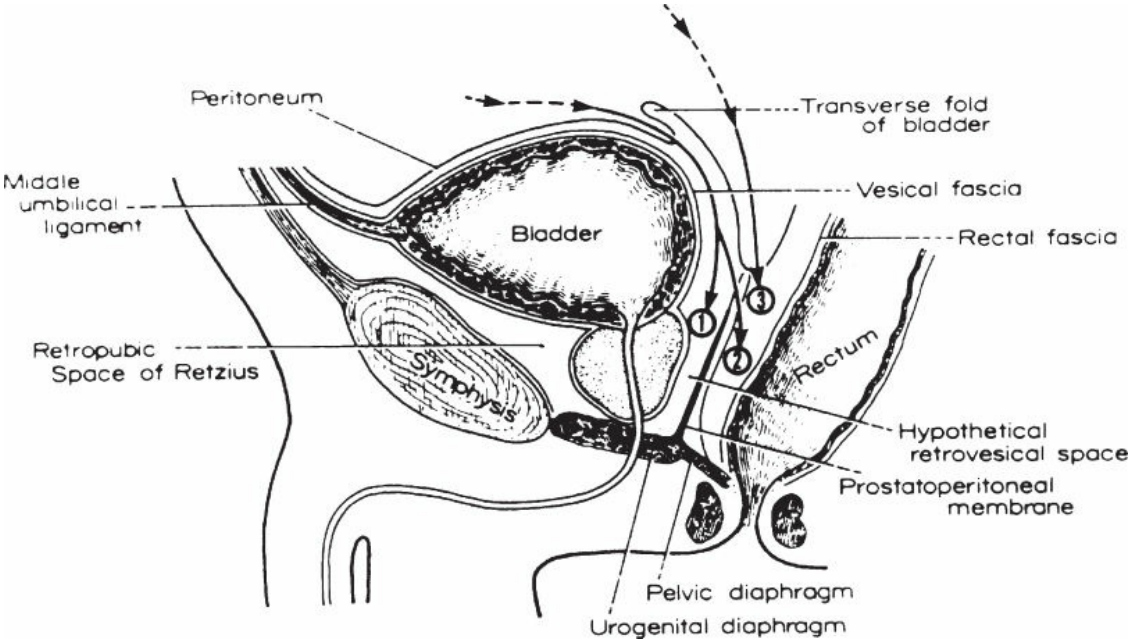

Figure 187.41. Three possible pathways of posterior internal supravesical herniae in men (*arrows*). **1**, path of true retrovesical hernia; **2**, path of retrovesical hernia; **3**, path of hernia through rectovesical pouch. (From Skandalakis PN, Skandalakis LJ, Gray SW, et al. Supravesical hernia. In: Nyhus LM, Condon RE, eds. *Hernia.* 4th ed. Philadelphia, PA: JB Lippincott; 1995:400, with permission.)

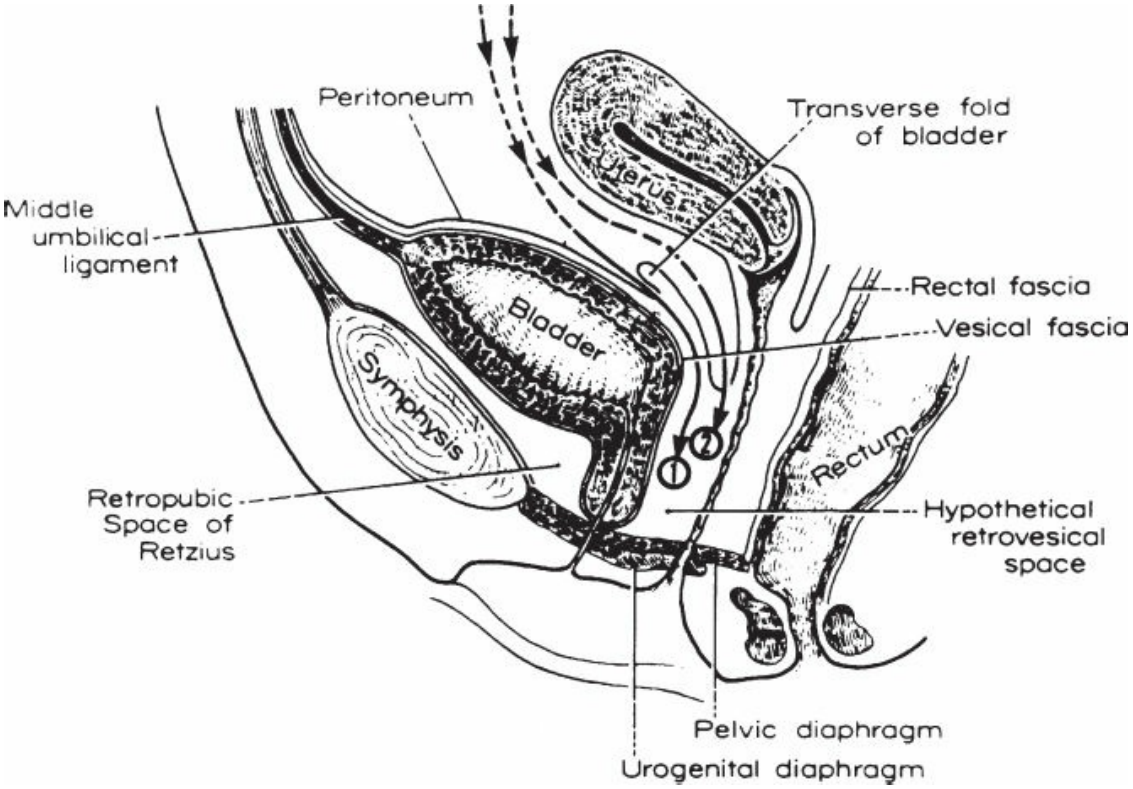

Figure 187.42. Two possible pathways of posterior internal supravesical herniae in women (*arrows*). **1**, path of true retrovesical hernia; **2**, path of hernia through vesicovaginal pouch. (From Skandalakis PN, Skandalakis LJ, Gray SW, et al. Supravesical hernia. In: Nyhus LM, Condon RE, eds. *Hernia.* 4th ed. Philadelphia, PA: JB Lippincott; 1995:400, with permission.)

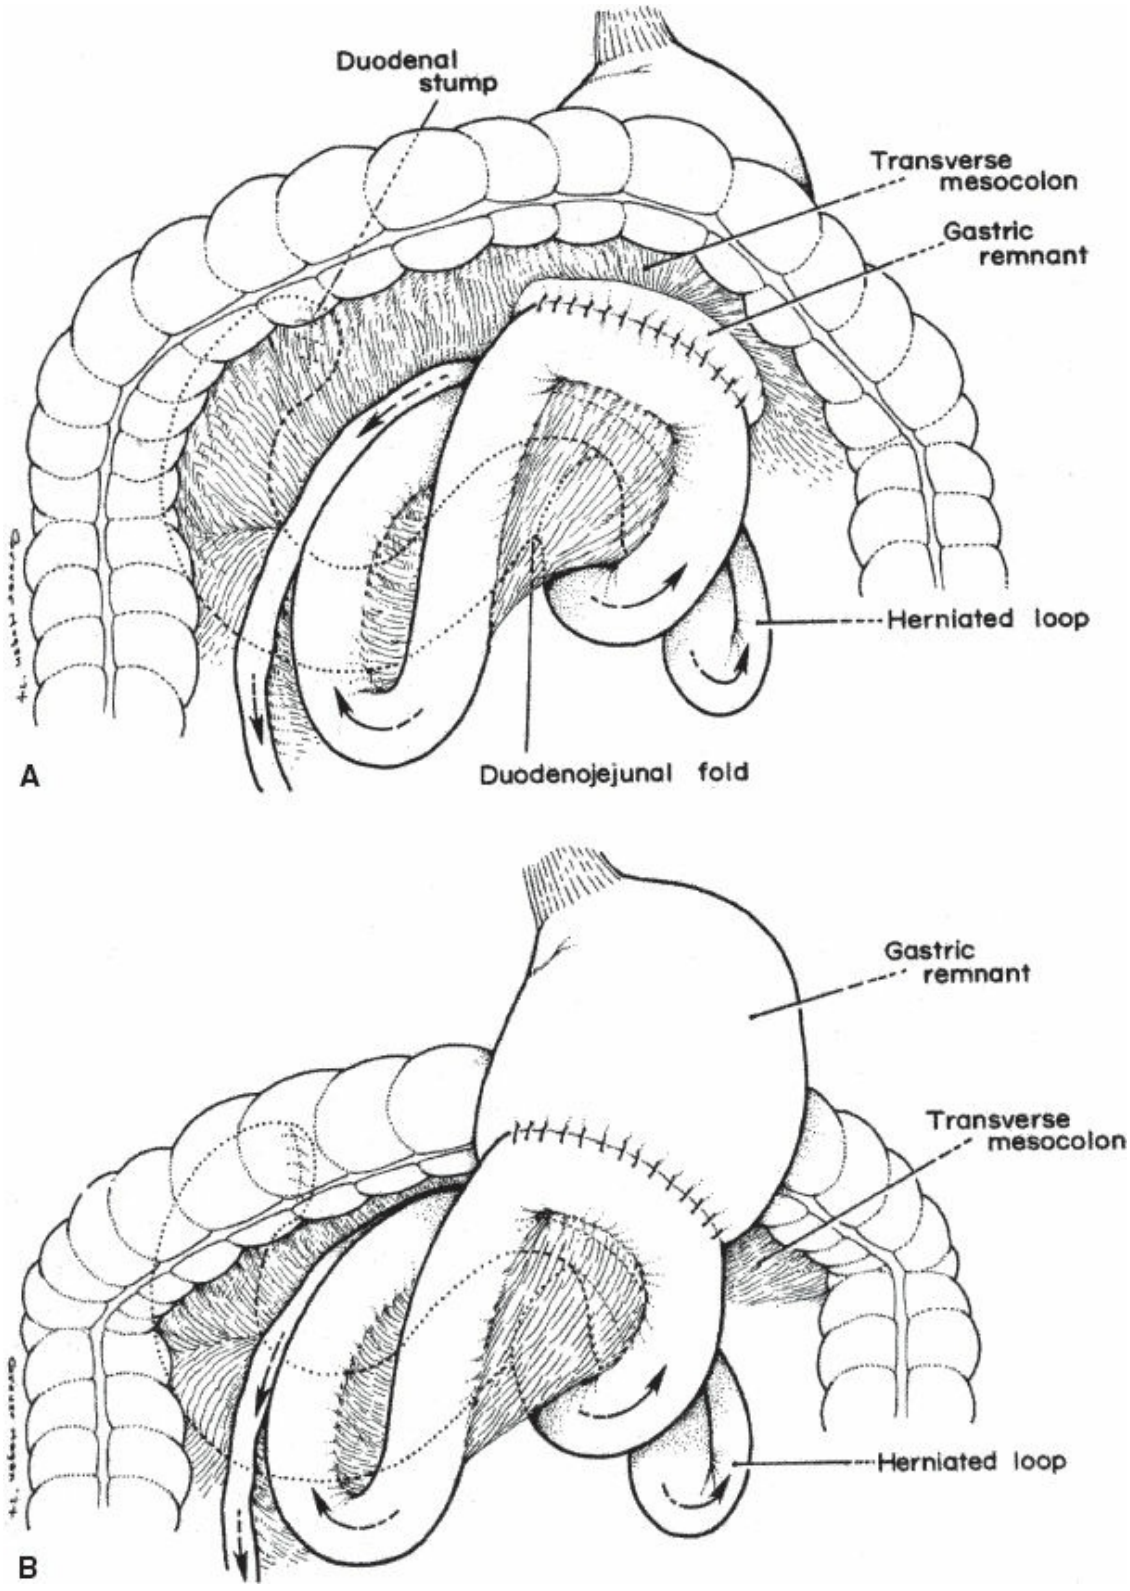

Figure 187.43. Retroanastomotic herniae. **A.** Hernia after retrocolic gastrojejunostomy. **B.** Hernia after antecolic gastrojejunostomy. (Reprinted from Skandalakis JE, Gray SW, Akin JT Jr. The surgical anatomy of hernial rings. *Surg Clin North Am* 1974;54(6):1227–46. Copyright © 1974 Elsevier, with permission.)

Anterior: Gastrojejunostomy and afferent jejunal loop
Posterior: Greater omentum and meso-colon
Superior: Transverse colon and meso-colon
Inferior: Ligament of Treitz and duodenojejunal peritoneal fold

When the afferent loop is attached to the lesser curvature of the stomach, the boundaries of the ring are:

Anterior: Afferent jejunal loop with its mesentery
Posterior: Omentum, transverse colon, and mesoduodenojejunal peritoneal fold
Inferior: Jejunum with its mesentery

With incarceration, no incision of the ring is required. Enterostomy facilitates reduction.

Table 187.1 gives a summary of the surgical anatomy of hernial rings as presented in this chapter.

EDITOR'S COMMENT

The authors of this masterful chapter, Lee J. Skandalakis and Petros Mirilas have with their usual meticulous attention to detail, given us a chapter concerning all of the hernia rings and every conceivable type of hernia which could occur. Lee Skadalakis learned his love of the topic from his father the late John E. Skandalakis. Dr. "Skan" as he was affectionately known in and out of medical circles was the late Chris Carlos Distinguished Professor and Director for the Centers for Surgical Anatomy and Technique at the Emory University School of Medicine. He has been immortalized for his contributions to the understanding of applied human anatomy.

The surgeon must know the precise surgical anatomy of the hernial rings to incise without any injury, and more care should be taken, when inserting a mesh in the abdomen, since the mesh becomes embroiled with some of the nerves that transit through these various spaces. Patients who undergo this surgery, I can tell you, caring for some of these patients, face many complications such as inability to walk, sit, go to work, and for certain types of mesh, although I have not been able to Figure out, they can barely sleep. Whether the surgeon employs

mesh or not it is essential to understand the anatomy of the abdominal well and the hernia rings.

History of Hernia Repair

Two excellent reviews of the history of various hernias have appeared recently. Awad and Fagan come down on the side of mesh (Awad SS, Fagan SP. Current approaches to inguinal hernia repair. *Am J Surg* 2004;188:9S–16S). The other by Banks and Cotlar come down on the side of classical repair, if only to remind us that many of us are in the business of training surgical residents. Given the fact that in most of the training programs, the tension-free repairs are the most taught, many residents and young surgeons will not even begin to think about doing a complicated repair such as a LaRoque Repair (Banks SB, Cotlar AM. Classic groin hernia repair…lest we forget. *Curr Surg* 2005;62:249–52).

There are approximately 800,000 cases per year of hernia repair done in the United States (Rutgow IM. Demographic and socioeconomic aspects of hernia repair in the United States in 2003. *Surg Clin North Am* 2003;83:1045–51). The male to female ratio was 12 to 1. The recurrence rate involving primary tissue repairs has varied from 1% to 15% and in some reviews, between 10% and 30% in primary repairs and greater than 35% in recurrent hernia repairs (Abrahamson. *Maingot's Abdominal Operations.* Vol 1. 9th ed. East Norwalk, CT: Appleton & Lang; 1990; Lichtenstein. *Hernia Repair Without Disability.* 2nd ed. St. Louis, MO: Ishiyaku Euroamerica, Inc.; 1986). However, as the authors state after realizing that this is an issue, the Shouldice repair is the only one in which a 2.2% recurrence rate has been published (Shouldice EB. The Shouldice repair for groin hernias. *Surg Clin North Am* 2003;83:1163–87). Whether this is because of the running, nonabsorbable suture or the emphasis on the transversalis fascia repair to reconstruct in an anatomically correct fashion the posterior wall of the inguinal canal and to reconstruct the internal ring is not clear. Mind you, what one is addressing is the overlay patch done openly.

While the Lichtenstein tension-free repair has been the standard for some years, other open mesh repairs, such as the Kugel technique, which utilizes a bilayer of polypropylene patch with a self-retaining outer memory recoil ring that is placed through a muscle-splitting incision. The mesh allegedly ends up in the same place as a properitoneal repair by the laparoscopic approach. Kugel reports 1468 repairs from 1994 to 2003 with a 0.4% recurrence rate (Kugel RD. The Kugel repair for groin hernias. *Surg Clin North Am* 2003;83:1119–39). However, as Awad and Fagan state, others have not been able to reproduce these results (Awad SS, Fagan SP. Current approaches to inguinal hernia repair. *Am J Surg* 2004;188:9S–16S). There is a steep learning curve, and the repair has been described as a touch-and-feel repair with up to 27.8% rate of recurrence in recurrent hernias (Schroeder DM, Lloyd LR, Boccaccio JE, et al. Inguinal hernia recurrence following preperitoneal Kugel patch repair. *Am Surg* 2004;70:132–6). My only comment regarding this is that while one should expect a lower recurrence, it is somewhat unfair to quote the recurrence rate for

recurrent hernias when comparing the data to first-time hernias.

Finally, Banks and Cotlar make the plea for teaching residents how to do classic groin hernia repairs (Banks SB, Cotlar AM. Classic groin hernia repair…lest we forget. *Curr Surg* 2005;62:249–52). They reproduce a number of the original drawings, which have been brought up to date and redone in contemporary techniques (Koontz AR. *Hernia.* New York: Appleton-Century-Crofts; 1963). They also make the point in Figures 187.3 and 187.4 that Halstead used a fourth layer of reinforcing fascia with the external oblique beneath the cord in his original article (Halstead WS. *Bull Johns Hopkins Hosp.* 1890;1:12–13). Later Halstead forswore the transplantation of the cord, since this is symptomatic in some patients, and buried it under the external oblique (Halstead WS. *Bull Johns Hopkins Hosp* 1903;14:208–14).

As for the Cooper ligament repair, I find the most difficult part of this repair (Anson/McVay) is the transition from Cooper ligament to Poupart ligament utilizing Thomson fascia over the femoral vein, a structure which in my experience, having grown up on the Anson/McVay repair, is frequently nonexistent. In addition, there remains a very substantial possibility of injuring the femoral vein in the McVay repair.

The Shouldice repair is well illustrated and is reproduced by Nyhus and Condon's book, *Hernia,* as is pictured by Bendavid and his rendering of the Shouldice repair (Nyhus LM, Condon RE. *Hernia.* 3rd ed. Philadelphia, PA: JB Lippincott; 1989).

Umbilicus and Umbilical Hernias

A number of pediatric surgeons are concerned about the cosmetic effects of an umbilical hernia repair. Kajikawa attempted what seems to be a fairly complicated umbilicoplasty in children in order to create a deep umbilical depression for the umbilicus (Kajikawa A, Ueda K, Suzuki Y, et al. A new umbilicoplasty for children: creating a longitudinal deep umbilical depression. *Br J Plast Surg* 2004;57:741–8). Personally, I had no idea that this was a cosmetic problem for children as my own technique for repairing an umbilical hernia in adults is simply to take one or two fine, nonabsorbable sutures in the overlay of the skin inferiorly and attach it to anterior fascia. After closing, I place a cottonoid dipped in mineral oil in the umbilicus and close the skin.

And it is only a matter of time that someone came up with a mesh plug repair for paraumbilical hernia. Sinha and Keith discuss such a mesh plug repair as an alternative to the Mayo technique as a standard method of repair of a paraumbilical hernia (Sinha SN, Keith T. *Surg J R Coll Surg Edinb Irel* 2004;2:99–102). The Mayo technique utilizes a double-breasted flap of rectus sheath. The authors have adopted the use of a mesh plug as consistent with the excellent repair techniques of femoral and inguinal hernia (more about this later). They undertook the review of hospital records and conducted telephone interviews of 34 patients who had paraumbilical hernias with mesh plug repairs over a period of 4 years. As is often the case, 76% of the patients were obese.

Out of the 32 patients, one had seroma postoperatively, and there was a single-wound infection with recurrence. Ninety-seven percent (32 out of 34) were satisfied with the procedure. A number of these patients, despite their obesity, were done under local anesthesia, thus this procedure could become the standard.

Spigelian Hernia

In my practice, spigelian hernia is a very rare occurrence and requires a great deal of diligence in order to make the diagnosis and repair it. Indeed, the anatomy chapter has cast a great light on what constitutes a spigelian hernia and the definitions of the various lines in the intersection of the linea semilunaris and linea semicircularis. In the *British Journal of Surgery,* Vos and Scheltinga concluded that a spigelian hernia is commonly encountered (Vos DI, Scheltinga MR. Incidence and outcome of surgical repair of spigelian hernia. *Br J Surg* 2004;91:640–4). As stated in his correspondence in response to the article, Mr. Ng surveyed 10 experienced clinicians in Hong Kong who had been in practice for over 25 years (Ng WT. *Br J Surg* 2004;91:1203). None had ever seen a spigelian hernia. The computerized database of the Hong Kong Hospital Authority with 40 hospitals serving a population of 6.8 million people revealed from 1998 to 2003, the incidence of spigelian hernia was 2, 2, 4, 3, 1, and 2 in each respective year. Mr. Ng also adds that there has only been a single case report from this part of the world in the English literature (Ng WT, et al. Facilitation of open Spigelian hernia repair by laparoscopic location of the hernial defect. *Surg Endosc* 2004;18:561–2). I would tend to agree with Mr. Ng that this is a rare occurrence.

My final advice for the surgeon is to know your anatomy!

J.E.F.

188 Overview of Inguinal and Femoral Hernia Repairs

Robert J. Fitzgibbons, Jr. and Michel Wagner

Groin hernia is one of the most common diseases known to mankind, and its repair has been referenced in medical writings as far back as 1500 BC in the Edwin Smith Surgical Papyrus. Nonoperative treatment in patients with minimal symptoms has been shown to be safe but is not curative. Surgery is the only definitive treatment for this condition, and hundreds of repairs have been described in the literature. Most are minor variants of three basic types of repairs: (1) tissue repair, (2) open prosthetic repair, and (3) laparoscopic prosthetic repair. In this chapter, after describing the pertinent anatomy, seven operations felt to be representative of the various types will be discussed in detail. These will include:

For the tissue repairs: Bassini, Cooper ligament, and Shouldice.

For the open prosthetic repairs: Lichtenstein tension-free herniorrhaphy (TFR) for the conventional anterior space and Stoppa's giant prosthetic reinforcement of the visceral sac for the preperitoneal space.

For the laparoscopic prosthetic repair: transabdominal preperitoneal (TAPP) and the totally extraperitoneal (TEP).

ETIOLOGY AND PATHOPHYSIOLOGY

The lifetime risk of developing a groin hernia is approximately 25% in males and 5% in females. Inguinal hernias are more common on the right than the left and are 10 times more likely in males than in females. In men, indirect inguinal hernias outnumber direct by about 2:1, with femoral hernias making up a much smaller proportion. For females, indirect inguinal hernias are most common and are 5 times more common than femoral hernias, with direct hernias occurring rarely. Overall, femoral hernias account for fewer than 10% of all groin hernias but are especially dangerous as 40% present as emergencies, with incarceration or strangulation and need emergency repair that is associated with higher morbidity. Femoral hernias are more common in older patients and in

those who have previously undergone inguinal hernia repair. Femoral recurrences are particularly common in women, in whom the diagnosis at the time of the primary repair was a direct inguinal hernia, strongly suggesting a missed femoral hernia at the original procedure since direct hernias are very rare in women.

The prevalence of inguinal hernia at any given age varies widely in the literature primarily due to a lack of a consistent reporting mechanism, for example, questioner versus actual physical examination. The most reliable data use hernia repair as a surrogate for the prevalence. After an initial surge to 1.4% in infancy, the percentage of persons in the population who are operated for a groin hernia decreases and then steadily increases through life to reach a peak percentage of 4.2% for males aged 75 to 80 years, falling off after that. The pattern is similar for females except that the peak percentage of woman aged 75 to 80 only reaches about 0.4%.

ANATOMY

The external abdominal oblique muscle takes its origin from the posterior aspects of the lower eight ribs and interdigitates with the serratus anterior and latissimus dorsi muscles. Its direction is nearly horizontal in its upper portion and oblique in its lower portion. The muscle fibers become tendons before inserting into the linea alba in the midline and inferiorly onto the anterior superior iliac spine, and the pubic tubercle results in important anatomical landmarks. The obliquely arranged anterior-inferior fibers of these insertions fold on themselves to form the inguinal ligament commonly called Poupart ligament (Fig. 188.1). The more medial fibers of the aponeurosis of the external oblique divide into a medial and lateral crus to form the external or superficial inguinal ring (Fig. 188.2). The spermatic cord (or round ligament) and branches of the ilioinguinal and genitofemoral nerves pass through this opening. The insertion on the pubic tubercle is fan-shaped spanning the space between the pubic tubercle and the pectineal line of the superior pubic ramus forming the lacunar ligament. It blends laterally with the pectineal (Cooper) ligament.

The internal abdominal oblique muscle fans out from the iliac crest obliquely upward toward its insertion on the lower ribs—upper and medially to its insertion on the linea alba and the pubis. It is mainly muscular in the groin region making up the cranial inferior border of the inguinal canal. The transversus abdominis muscle arises from the iliac crest and the lower six ribs and interdigitates with diaphragmatic fibers. Its

direction is mainly horizontal inserting on the linea alba. However, the lower fibers are arranged in a more inferior-medial course toward their site of insertion on the pubic tubercle and the pubic symphysis to form the falx inguinalis (Fig. 188.3). These fibers infrequently are joined by a portion of the internal oblique aponeurosis; only then is a true conjoined tendon formed. The fibers of the transversus abdominis terminate at a variable distance above the inguinal ligament, which results in the formation of the transversus aponeurotic arch. The space between this arch and the inguinal ligament lacks the protection provided by the muscle and, especially when high, may predispose to the development of a direct inguinal hernia. However, contraction of the transversus abdominis in response to increased pressure causes the arch to move down toward the inguinal ligament, which reinforces this weak area and prevents a hernia in most.

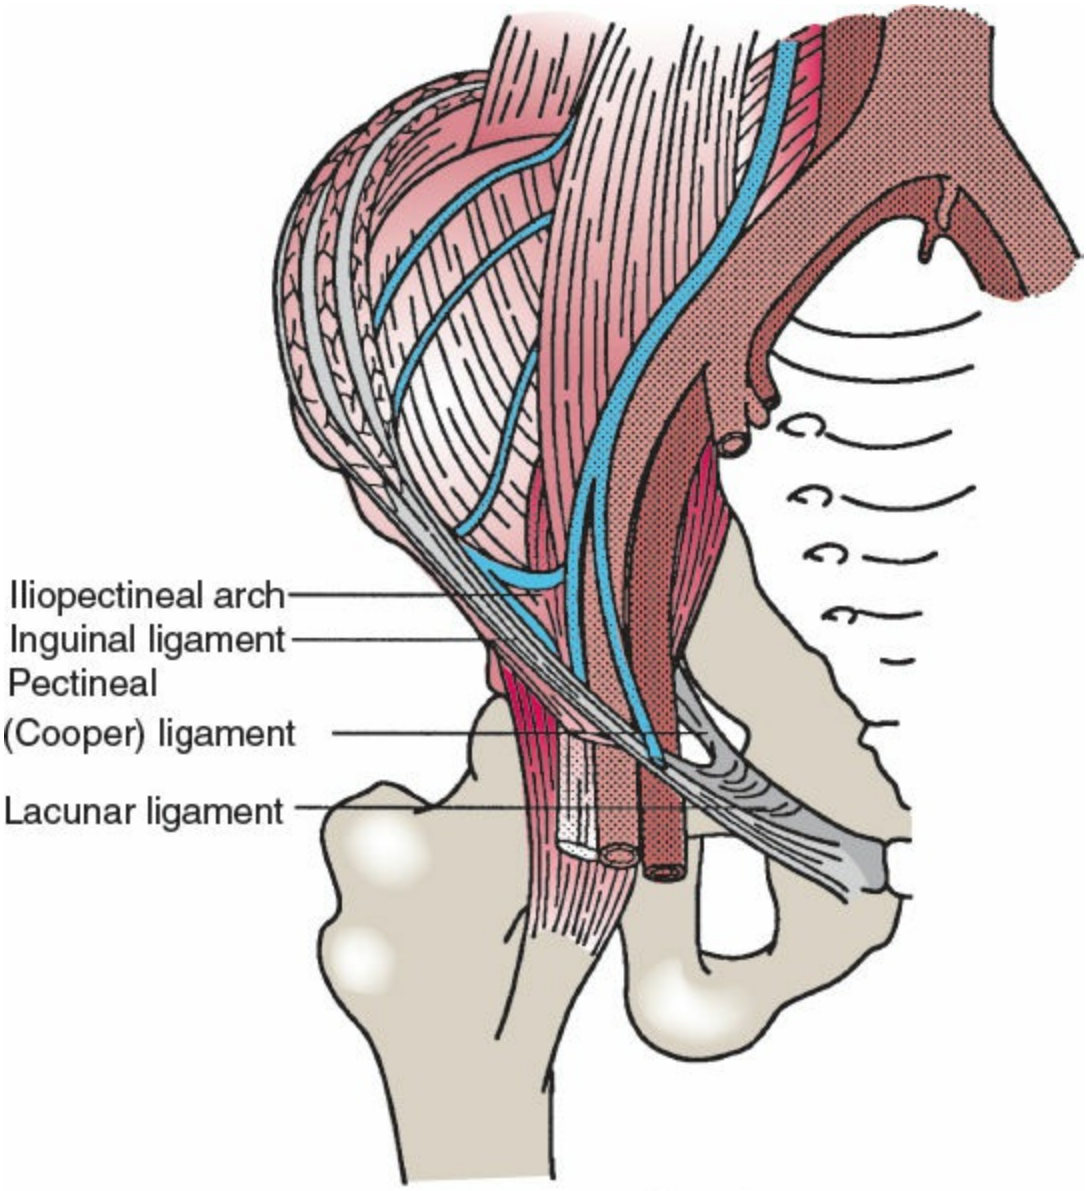

Figure 188.1. Ligaments formed by the lower insertion of the aponeurosis of the external oblique muscle.

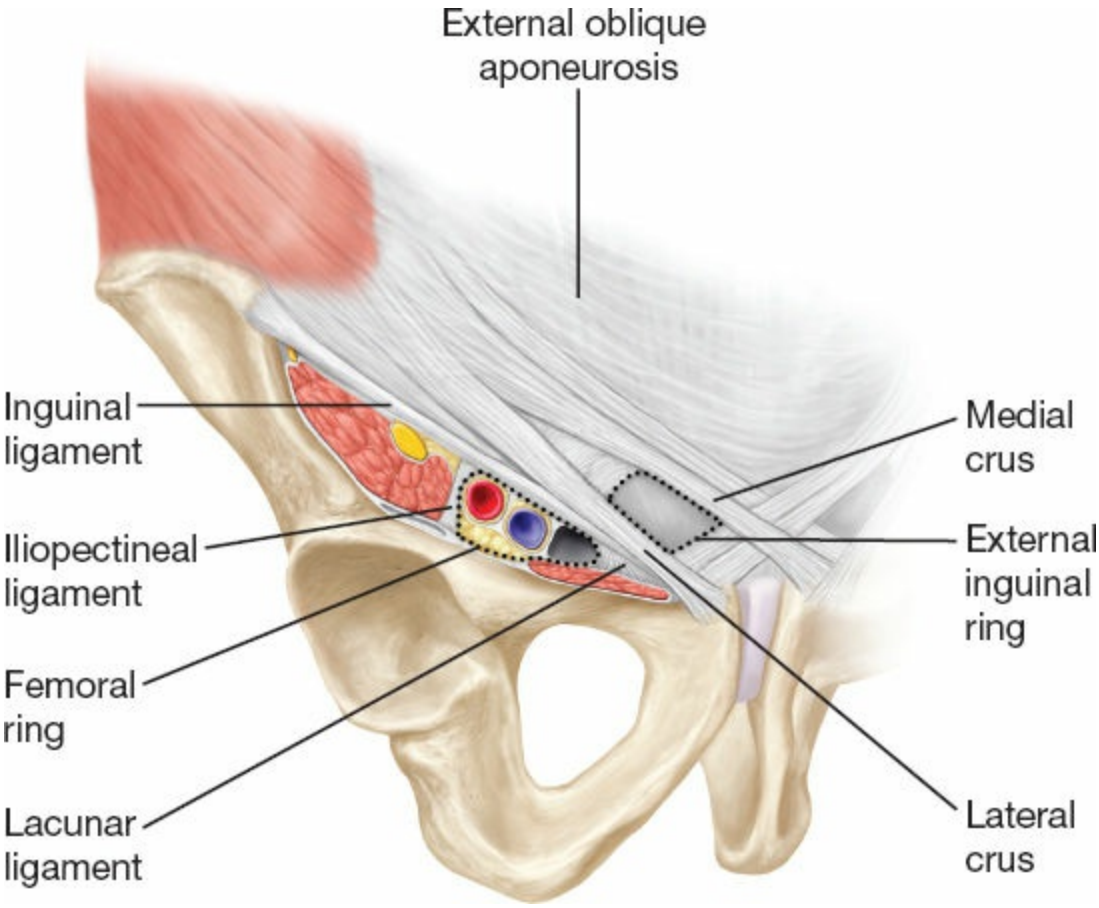

Figure 188.2. Fibers of the aponeurosis of the external oblique divide into a medial and lateral crus to form the external or superficial inguinal ring.

The inguinal canal is bounded by four walls and two rings on either end (internal and external rings). The definition of these four walls is highly variable in anatomical texts. For the purpose of this chapter, the definition in Table 188.1 will be used.

Hesselbach triangle is of historical interest in modern groin surgery classically depicting the site of direct inguinal hernias. Its boundaries are most commonly defined as the inguinal ligament for the base, the rectus abdominis on its medial side, and the inferior epigastric vessels superior-laterally (Fig. 188.4). When considering a preperitoneal perspective, Cooper ligament as originally described by Hesselbach is the base because the inguinal ligament cannot be seen from an abdominal vantage.

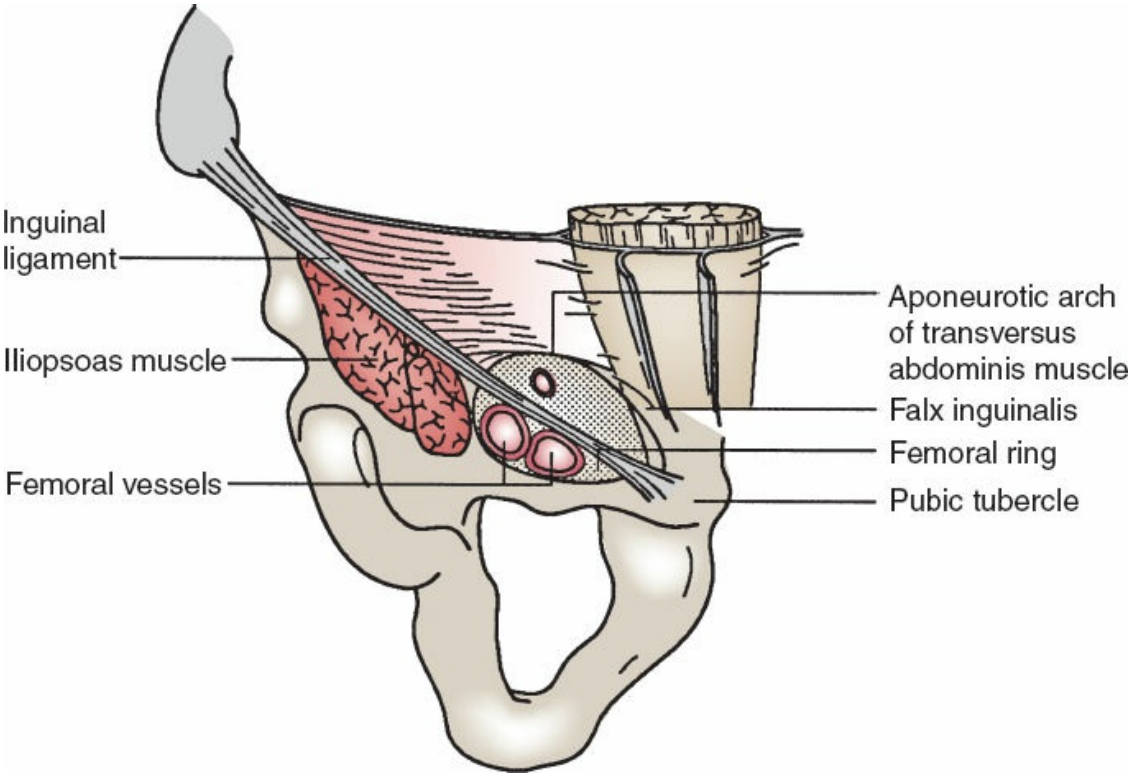

Figure 188.3. The aponeurotic arch and the myopectineal orifice.

TABLE 188.1 The Four Walls which Make Up the Boundaries of the Inguinal Canal

Superior (roof): Medial crus of the aponeurosis of the external oblique muscle, the musculoaponeurotic arches of internal oblique muscle, the transverse abdominal muscle
Anterior: Aponeurosis of external oblique reinforced by the fleshy part of internal oblique muscle laterally
Inferior (floor): Inguinal ligament, lacunar ligament and the iliopubic tract
Posterior: Transversalis fascia and the falx inguinalis

Many of the complications seen with the early laparoscopic repairs were directly related to a lack of appreciation of the anatomy of the

inguinal region from a preperitoneal perspective. In order to safely perform a preperitoneal herniorrhaphy, the anatomy must be learned in a reverse manner than is conventionally taught, that is, starting from the innermost layers. Initial inspection of the peritoneal surface of the inguinal region reveals several consistent landmarks (Fig. 188.5). The umbilical ligaments in most patients are quite prominent and easily identified. The unpaired median umbilical ligament covers the urachus, the fibrous remnant of the fetal allantois, and extends from the urinary bladder to the umbilicus. The urachus may be patent for a variable length along its course, usually close to the urinary bladder in adults and close to the umbilicus in children. The paired medial umbilical ligaments are created by the obliterated fetal umbilical arteries. The artery, like the urachus, may be patent in its proximal course and may contribute to the superior vesical artery. The paired lateral umbilical ligaments are created by the peritoneal coverings over the inferior epigastric vessels. The vas deferens and internal spermatic vessels can commonly be seen through the peritoneum especially in thin individuals.

Once the peritoneum and transversalis fascia are stripped away, important anatomical landmarks in the preperitoneal space can be further defined. These include the inferior epigastric vessels, Cooper's pectineal ligament, internal spermatic vessels, and vas deferens. The inferior epigastric vessels run superomedially along the medial margin of the internal ring toward the rectus sheath and give rise to two branches in the inguinal region: the external spermatic (cremasteric) vessels and the pubic branch that can arch over Cooper ligament and anastomose with the obturator circulation forming what is known as the "corona mortis." The presence of a corona mortis is highly variable and can be arterial or venous or both. It is important because of the significant bleeding that can occur if it is damaged when stapling or suturing around Cooper ligament or dissecting medially to reduce an incarcerated femoral hernia. Similarly, the iliopubic artery and vein track along the iliopubic tract toward the pubic symphysis and are susceptible to damage.

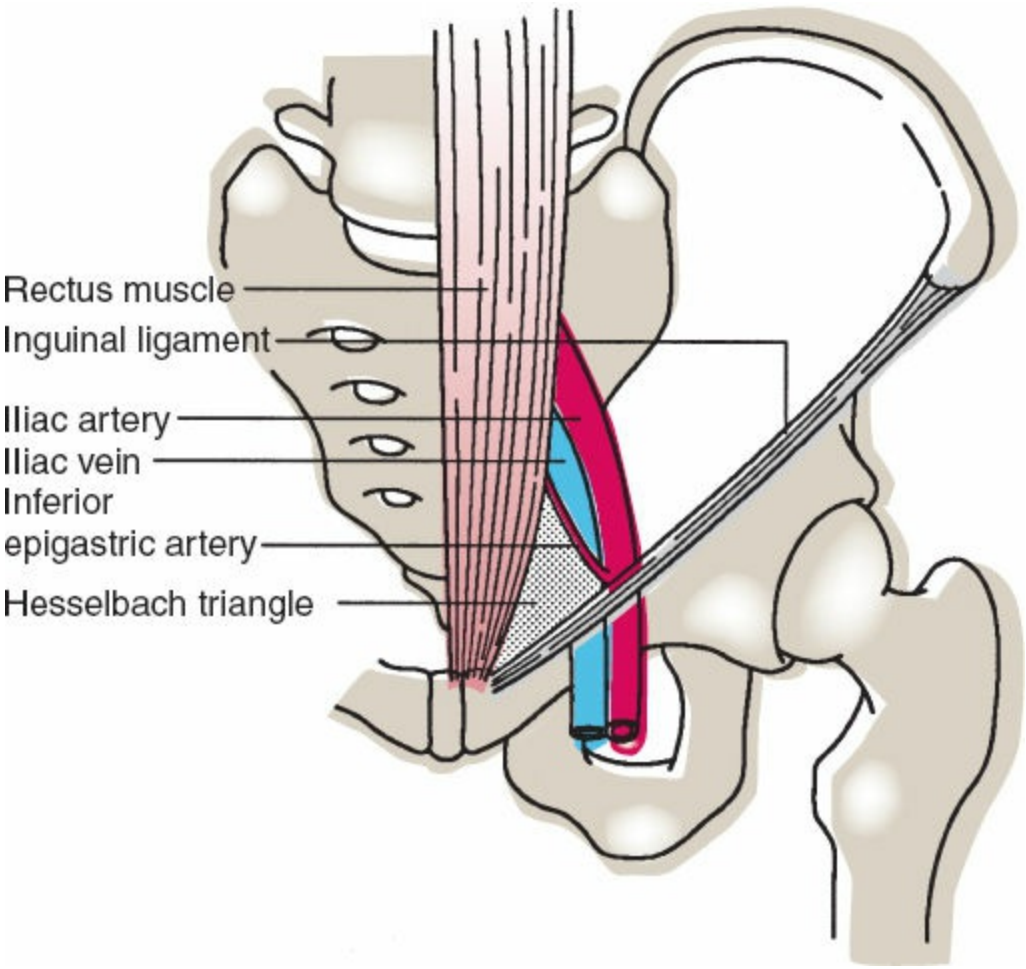

Figure 188.4. Hesselbach triangle as viewed from an anterior perspective.

The course of the nerves in this area needs to be appreciated by the surgeon working in the preperitoneal space so that damage to them can be avoided (Fig. 188.6). The genitofemoral and the lateral femoral cutaneous nerve are at greatest risk for injury. The ilioinguinal and iliohypogastric nerves exit the abdominal cavity above the iliac crest and are not within the normal field of dissection for a hernia repair in the preperitoneal space. However, it is possible to injure them if staples or tacks are placed deeply especially with a vigorous bimanual technique. Two triangular anatomical areas in this space have considerable importance when performing a preperitoneal groin hernia repair. The first is bounded by the spermatic vessels laterally, the vas deferens medially, and the inferior flap of the peritoneal dissection, inferiorly. This area has been referred to as the "triangle of doom" in that the external iliac vessels lie hidden beneath. It has been advised that stapling be done only medial to the vas deferens. The second triangle referred to as the "triangle of pain" is bounded by the

spermatic vessels medially, the iliopubic tract superiorly, and the lateral pelvic wall. In it lie the genital and femoral branches of the genitofemoral nerve, the femoral nerve, and the lateral femoral cutaneous nerve of the thigh. Sutures, staples, or tacks placed caudal to the iliopubic tract and lateral to the internal spermatic vessels can result in neuralgias.

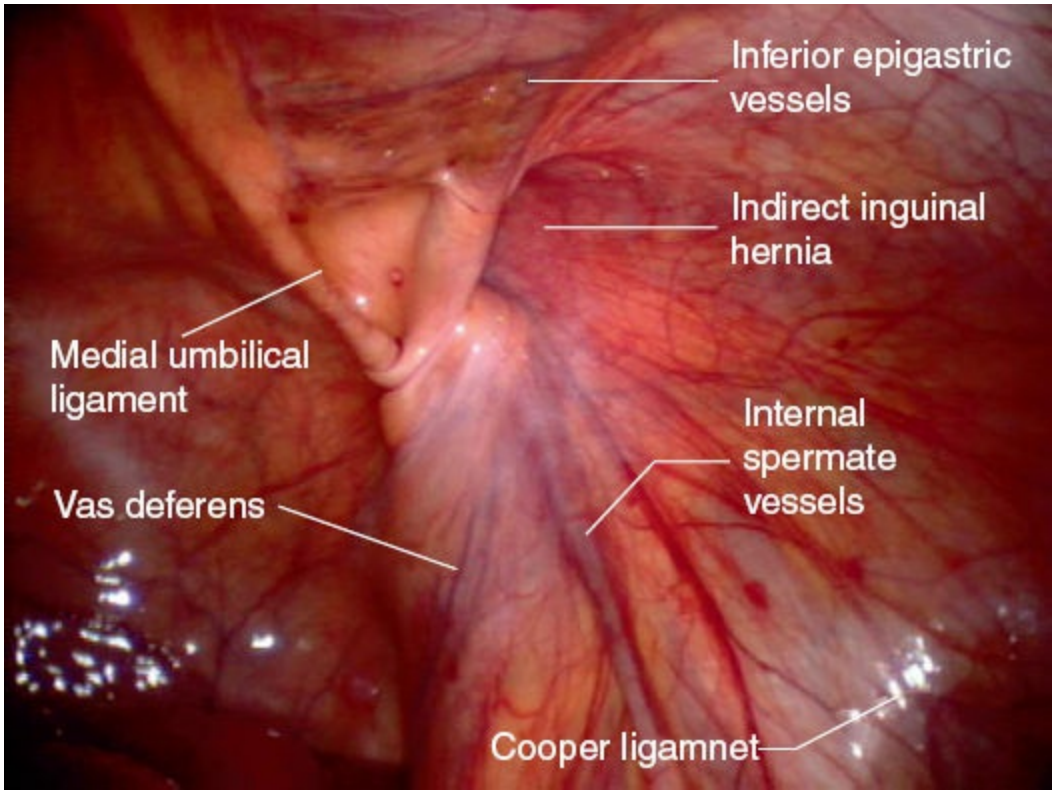

Figure 188.5. Important anatomical landmarks on initial inspection of the lower abdomen from a laparoscopic prospective.

Finally, the myopectineal orifice (sometimes called the musculopectineal orifice) of Fruchaud is important for surgeons performing conventional preperitoneal procedures. Although the exact definition varies as is so common in anatomical texts, for the purposes of this chapter, it is bounded medially by the lateral border of the rectus abdominus, laterally by the iliopsoas muscle, superiorly by the transversus abdominus and internal oblique muscles, and inferiorly by Cooper ligament and the pubis (Fig. 188.7).

CLINICAL PRESENTATION

The three classical groin hernias are direct (commonly referred to as “medial” outside of the United States) indirect (or “lateral”) and femoral.

The nomenclature can be confusing because some studies use the words inguinal and groin interchangeably. For the purposes of this review, direct and indirect hernias are considered inguinal and femoral stands alone.

INDICATIONS AND CONTRAINDICATIONS

In the past, it has been felt that all inguinal hernias should be repaired unless specific contraindications are present. This is because of a perception that there would be significant rates of complications of bowel obstruction and/or strangulation if left untreated. However, several recent randomized controlled trials have provided convincing evidence that watchful waiting is safe for the approximately one third of the total inguinal hernia population who have minimal or no symptoms. Coupled with the increasing awareness of the problem of debilitating postherniorrhaphy groin pain in a small but significant number of patients, watchful waiting has clearly become an acceptable treatment strategy. However, patients should be informed that although safe, long-term follow-up has shown that the vast majority of patients will eventually crossover to surgery because of increasing symptoms. Contraindications include intra-abdominal or groin infection and coagulopathy. Relative contraindications include severe underlying medical illness and ascites. For the laparoscopic procedures, all adult patients with inguinal hernias who are candidates for general anesthesia can be considered candidates for the repair. But relative contraindications also include significant intra-abdominal adhesions from previous surgery and previous “Space of Retzius” surgery because of the increased risk of bladder injury. Severe underlying medical illness is a more significant relative contraindication because of the added risk of a general anesthesia. These patients are better suited for a conventional operation under local anesthesia.

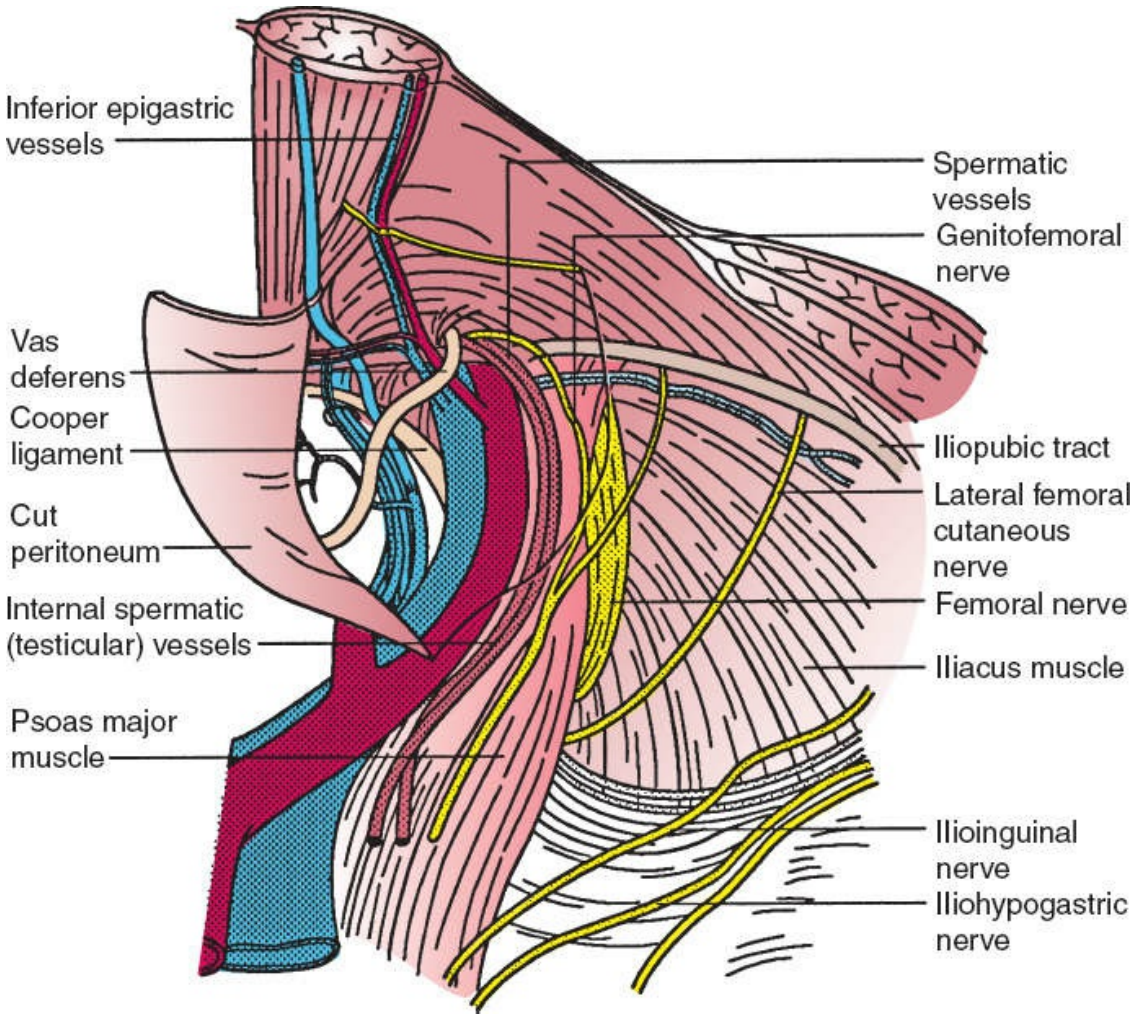

Figure 188.6. Key landmarks in the preperitoneal space as observed from a laparoscopic perspective after the peritoneum has been opened.

PREOPERATIVE PLANNING

Preoperative care should be guided by the patient's underlying physiologic status. The patient should have a detailed history and physical examination taken with concern toward the patient's anesthetic risks. This includes cardiac, pulmonary, and endocrine status. Concern about the ability of the patient to tolerate a general anesthesia mandates consultation with the anesthesia department. If the patient is not a candidate for a general anesthesia, local regional anesthesia should be considered and laparoscopy avoided. Optimization of the diabetic patient's blood sugar should be obtained resulting in an acceptable hemoglobin A_1C. Antiplatelet medication as well as anticoagulant medications should be stopped if possible. Preoperative acetaminophen and neuroleptic agents such as gabapentin can be considered to help with the postoperative pain

management.

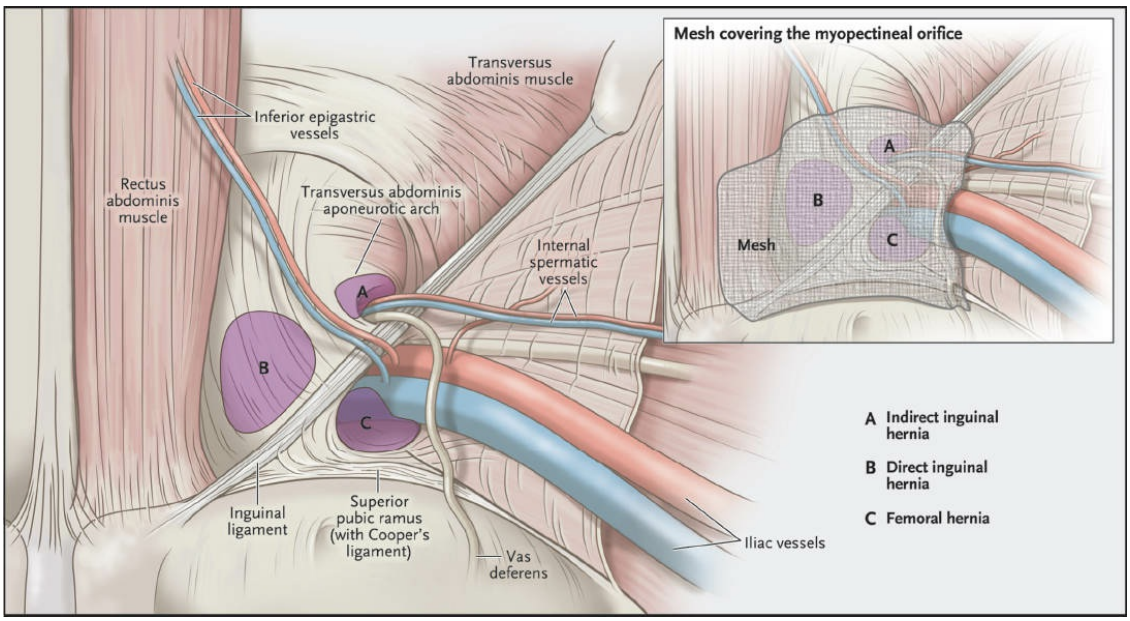

Figure 188.7. The myopectineal orifice of Fruchard is bordered by the arch formed by the termination of the aponeurotic fibers of the transversus abdominis muscle superiorly, the rectus abdominis muscle medially, the iliopsoas muscle laterally, and the superior pubic ramus with attached Cooper ligament inferiorly.

SURGICAL TECHNIQUE

The Tissue Repairs

Bassini

Edoardo Bassini (1844–1924) was born in Pavia, Italy, and received his doctorate in medicine from the University of Pavia at the age of 22. He joined the liberation forces of Garibaldi in the crusade for unification of Italy and in combat suffered a bayonet wound to the right lower quadrant of his abdomen, which was complicated by a fecal fistula. He was eventually transferred back to Pavia under the care of Professor Porta who supervised his recovery. During that time, he developed a close relationship with the Professor who convinced him that surgery was the best career path for him. He joined the staff at the University of Pavia where he commenced intense study of anatomy and surgical pathology of the groin. Bassini's radical cure of a groin hernia resulted from his studies as he was able to appreciate the importance of functional restoration of the inguinal canal to properly treat an inguinal hernia. The operation

revolutionized the field with a recurrence rate that was one fifth of what was accepted at the time and became the gold standard for inguinal hernia repair for most of the 20th century. The procedure was based on the development of several distinct steps that he felt were essential. These included:

1. Complete division of the external oblique aponeurosis and the transversalis fascia,
2. Differentiation between indirect and direct defects,
3. Isolation of the spermatic cord,
4. Ligation and removal of the sac at the deep inguinal ring flush with the peritoneum,
5. Oblique reconstruction of the inguinal canal with an anterior and posterior wall with an internal and external opening (ring).

Technique

Cutaneous Incision

The important landmarks to be identified prior to incising the skin are the anterior superior iliac spine, the symphysis pubis, and the pubic tubercle. In obese individuals, palpating through the base of the scrotum with a finger best identifies the latter two. A 6- to 7-cm skin incision is made 2 cm medial and parallel to a line between the pubic tubercle and the anterior superior iliac spine, which corresponds to the course of the inguinal ligament. Alternatively, in the interest of cosmesis, a more transverse incision can be used (Fig. 188.8).

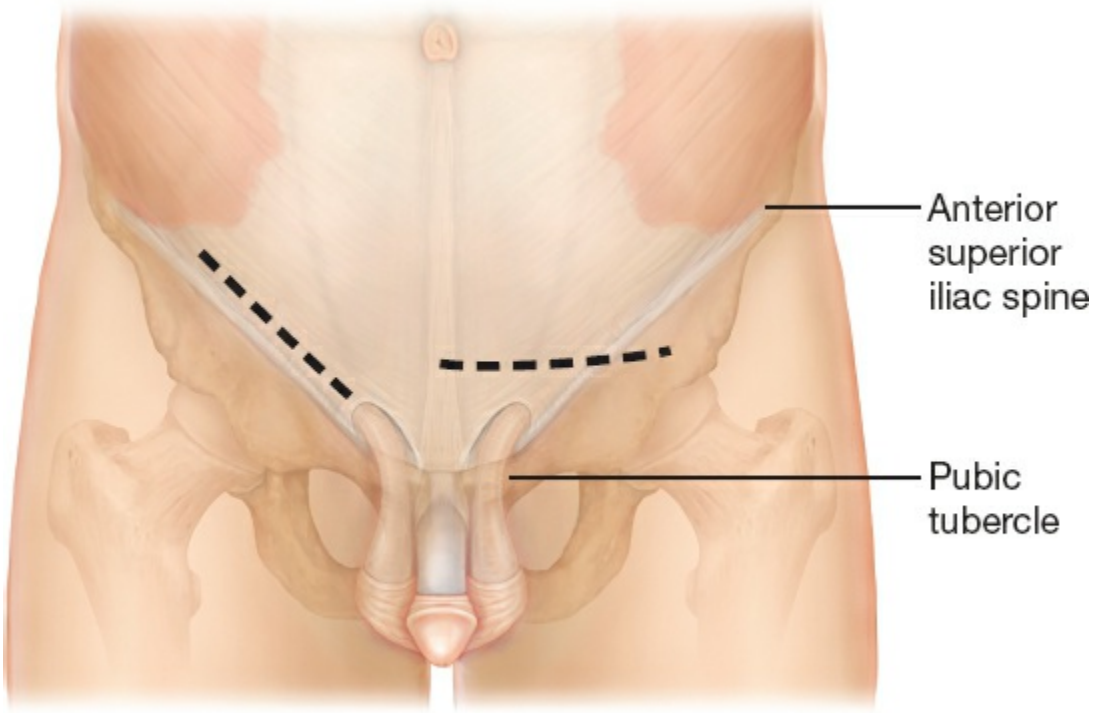

Figure 188.8. Possible skin incisions for the Bassini operation and other anterior inguinal herniorrhaphies.

Incision of External Oblique

The skin incision is extended through the Camper and Scarpa fascia, and the external oblique aponeurosis is identified. The superficial ring of the inguinal canal is located and the external oblique aponeurosis is incised at the upper margin of the superficial ring. When reapproximated, the suture line will not overlap the deep sutures (Fig. 188.9).

Isolating the Cord Structures

The upper flap of the external oblique aponeurosis is separated from the deeper internal oblique muscle and the lateral margin of the rectus muscle using blunt finger dissection or the handle of the scalpel. The ilioinguinal nerve is identified at this time and gently freed from the surrounding tissue. Care must be taken to avoid crushing the nerve with an instrument. A hemostat is used to keep it out of the field of surgery by passing the hemostat under the nerve and grasping the lower flap of the external oblique aponeurosis. This avoids injury to the nerve during surgery. The cord structures are then lifted en-masse with the fingers of one hand exactly at the pubic tubercle so that the index finger of the hand can be passed gently underneath to meet the fingers of the other hand. Once this is done, a finger is slid all the way to the deep inguinal ring completely

isolating the cord structures and a Penrose drain or rubber loop is used to hold them out of the way (Fig. 188.10).

Separation of the Cremaster Muscle and Other Coverings From the Sac

The cord structures are lifted with the help of the Penrose drain, and the cremaster muscle and spermatic cord with its vessels are gently separated. Extreme care must be taken to avoid injury to the vas deferens and the vessels. The cremaster muscle is incised longitudinally for the length of the cord structure in the inguinal canal beginning as close to the deep inguinal ring as possible. This in effect creates a lateral and medial flap. These flaps can be divided to provide more mobility of the cord. Traditionally the medial flap would be divided between hemostats and tied because of the likely presence of the cremasteric artery. Electrocautery is usually sufficient for the lateral flap. Bassini and Shouldice (as will be discussed later) considered division of the cremasteric muscle an essential step in their respective operations. However, today this is not universally agreed upon. Lipomas of the cord are removed at this stage (Fig. 188.11).

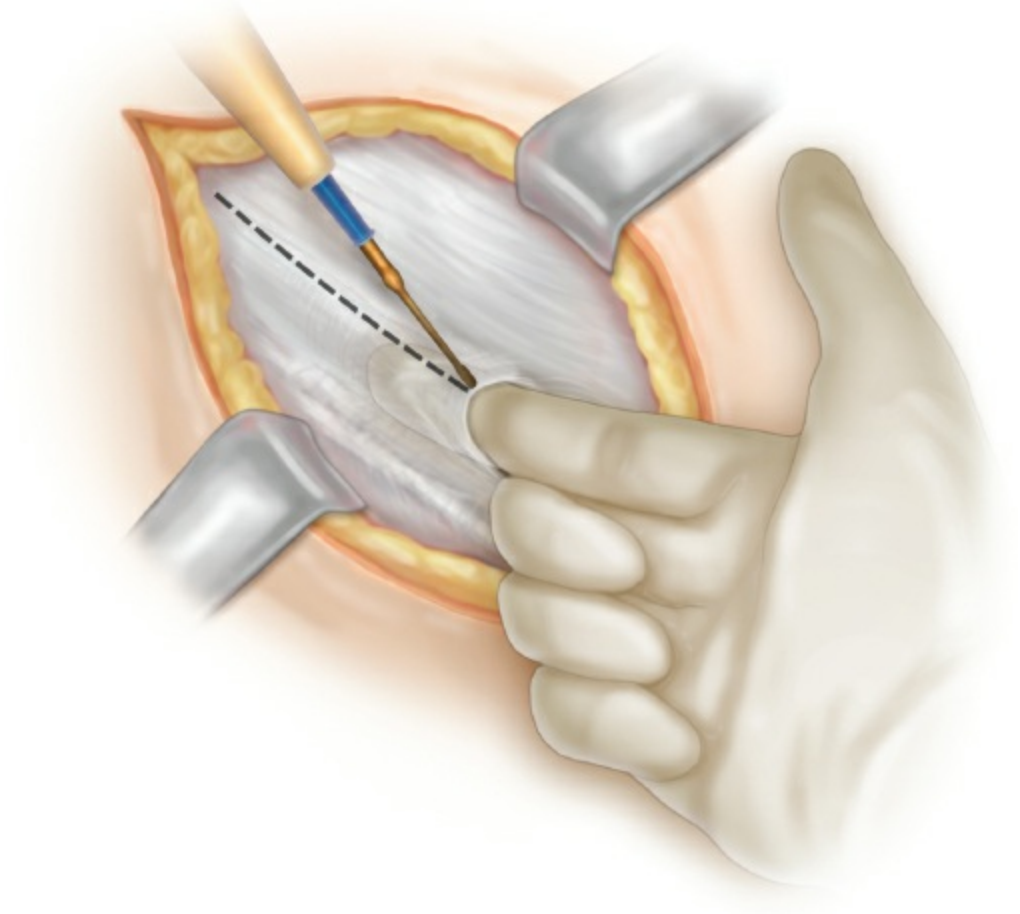

Figure 188.9. The extremal oblique aponeurosis is incised

through the external ring.

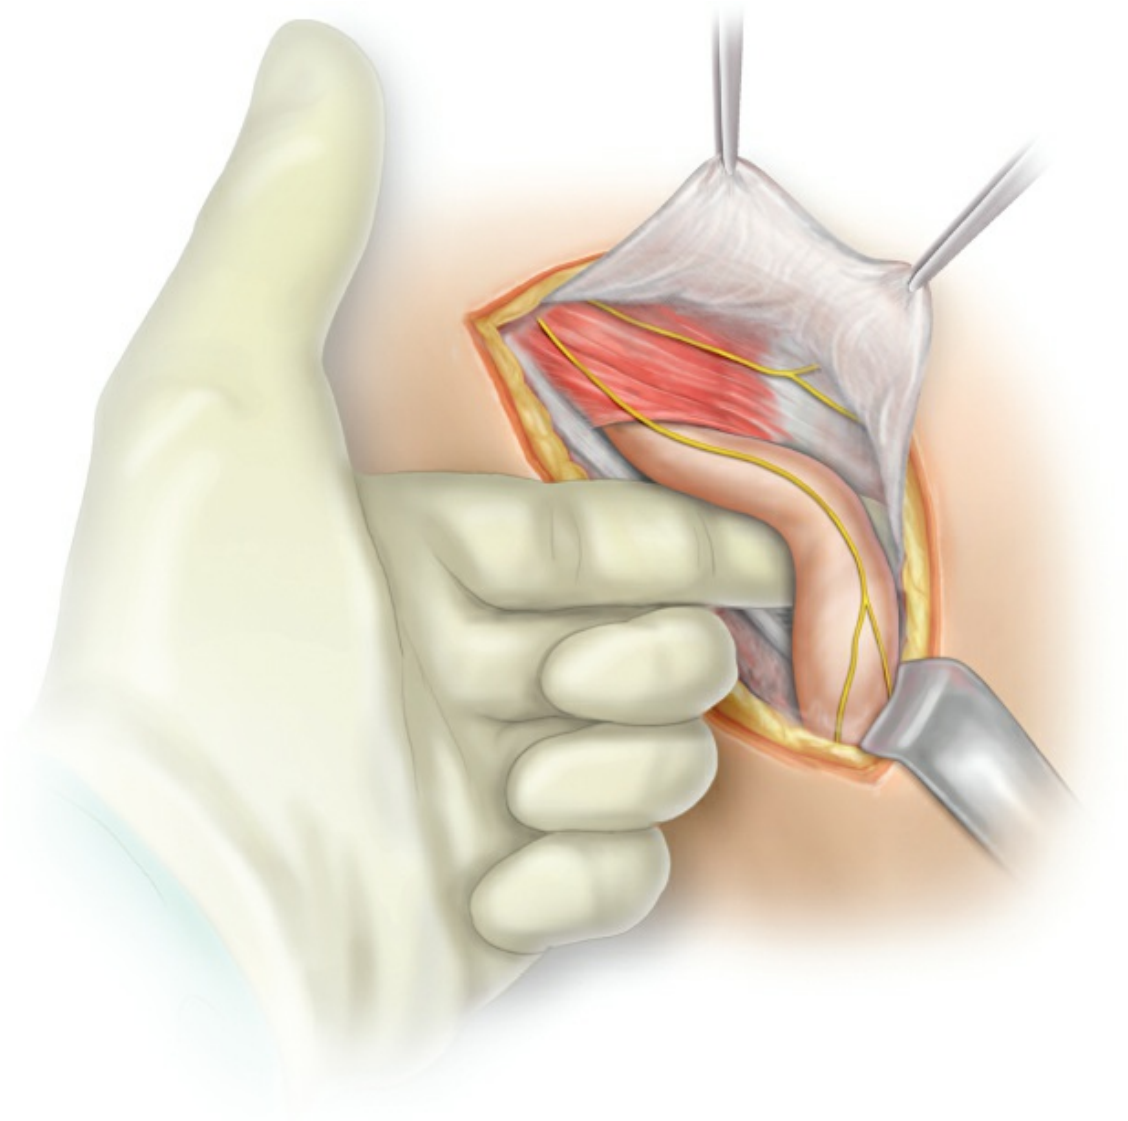

Figure 188.10. Cord structures are freed from the inguinal floor.

Isolation of the Spermatic Cord From the Sac

At this point, the cord should be dissected to determine if there is an indirect sac even if there is an obvious direct inguinal hernia. Even in the absence of an indirect hernia, there is always a tongue of peritoneum that protrudes at the anteromedial aspect of the cord and should be looked for to provide reassurance that an indirect hernia sac has not been missed. When a true indirect sac is found, the internal spermatic fascia is incised and the indirect sac is carefully separated from the spermatic cord dissecting as close to the sac as possible to avoid damaging the cord, especially its vascular elements. Once the sac is free from the cord structures and the vas deferens has been identified, the sac should be

divided and the proximal end ligated. It is imperative to make sure that there are no peritoneal contents in the sac. If necessary, the sac can be opened and the contents reduced back into the abdominal cavity before ligating it. For a large indirect inguinal scrotal hernia where complete removal of the sac might result in testicular complications due to vascular compromise because of the extensive dissection required to mobilize it, the sac is sometimes best transected at the midpoint of the cord structures leaving the distal sac in situ. The distal sac may be left alone or may be slit in its entirety, exposing the inner surface. Some surgeons will go so far as to invert the edges around the cord and suture behind it in an attempt to prevent a hydrocele when the distal sac is left in place. This is probably unnecessary as the experience with laparoscopic inguinal herniorrhaphy where the distal sac is not accessible has not revealed an excessive rate of hydrocele formation. For the usual indirect sac that is completely mobilized, many surgeons now prefer to simply reduce the sac back into the preperitoneal space feeling that either opening or excising the sac is unnecessary. Bassini probably would have considered this heresy, but experience has shown it to be as effective as excision. Proponents point out that simple reduction eliminates any possibility of damage to an incarcerated structure and there may be decreased pain because the richly innervated peritoneum is not incised.

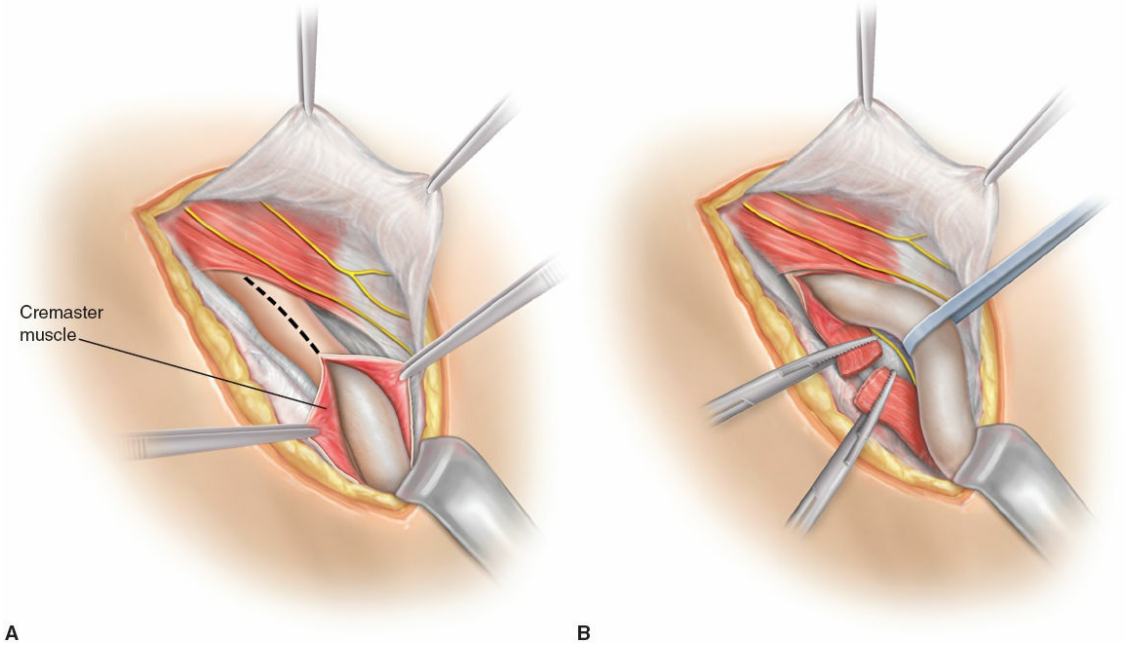

Figure 188.11. **A.** Cremasteric muscle is incised longitudinally. **B.** The caudal flap is divided between clamps.

Direct hernia sacs are almost never removed but instead are dissected from surrounding structures and reduced into the preperitoneal space. Dividing the transversalis fascia circumferentially at the neck (base) of the sac will aid in this reduction in some cases. The defect may be closed primarily at this point to maintain the reduction while a formal reconstruction is being performed. The latter is considered a matter of convenience and adds nothing to the strength of the final repair.

Division of the or Posterior Wall of the Inguinal Canal Over Its Full Length

The cord is retracted laterally and the transversalis fascia is divided from the internal ring to the symphysis pubis (Fig. 188.12A,B). This method of opening the inguinal floor by incising the transversalis fascia completes the creation of Bassini's famous "triple layer" that includes the edges of the transversalis fascia, transversus abdominis muscle, and the internal oblique muscle. Full mobilization is achieved by separating by blunt dissection the lateral margin of the rectus muscle and the triple layer from the aponeurosis of the external oblique above and from the preperitoneal fat below so that the triple layer can be approximated to the isolated posterior border of the inguinal ligament without tension on the suture line. The common modification of not opening the transversalis in favor of using "good stuff" grasped blindly with an Allis clamp underneath the internal oblique muscle is likely the reason for the poorer results when this operation was imported to North America. Once the transversalis fascia has been divided, the femoral ring is exposed from a preperitoneal perspective to make sure that a femoral hernia is not missed.

Suturing the Deep Layer and Closure the Incision

The first stitch includes the cut edge of the transversalis fascia, the transversus abdominis muscle, and internal oblique muscle with the medial side of the pubic tubercle and the rectus sheath. Most surgeons now try to avoid the periosteum of the pubic tubercle to decrease the incidence of osteitis pubis. The second stitch includes the rectus muscle that is approximated to both Cooper ligament and the inguinal ligament. The repair is then continued laterally using interrupted sutures securing the triple layer to the reflected inguinal ligament (Poupart ligament). These sutures are continued until the internal ring has been substantially narrowed on its medial side (Fig. 188.13). The cord is then repositioned resting on the newly reconstructed posterior wall, and the two flaps of the external oblique aponeurosis are sutured over the cord with a running

stitch, reconstructing the external ring. The subcutaneous tissue is closed, and the skin may be stapled or closed with a running subcuticular stitch.

Cooper Ligament Repair

These initial steps in the operation are identical to the Bassini. The key difference is that when the floor is reconstructed, Cooper ligament instead of the inguinal ligament is used for the medial portion of the repair (Fig. 188.14A–C). Classically it is the conjoined tendon that is actually sutured to Cooper ligament. However, as noted previously anatomists disagree about the exact definition of the conjoined making a precise description of this operation difficult. Some surgeons use the triple layer of Bassini, while others simply use the "good stuff" to Cooper ligament approach, perhaps accounting for the poorer results in some reported series with this method. Interrupted sutures beginning at the pubic tubercle and continuing laterally along Cooper ligament progressively narrow the femoral ring, and this constitutes its most common application, that is, treatment of a femoral hernia. The last stitch to Cooper ligament is known as a transition stitch and includes the inguinal ligament. The stitch has two purposes; the first is to complete the narrowing of the femoral ring by approximating the inguinal ligament to Cooper ligament as well as the medial tissue, and second it provides a smooth transition or step-up to the inguinal ligament over the femoral vessel so that the repair can be continued laterally identical to the Bassini. A relaxing incision should always be used given the considerable tension required to span such a large gap. This consists of incision in the lateral side of the rectus aponeurosis after the medial flap of the external oblique aponeurosis is reflected medially beginning just above the symphysis pubis and extending cranially for 5 to 10 cm (Fig. 188.15). Although this does serve to relieve some of the tension, it is still significant enough that it is felt by many to result in more pain than other herniorrhaphies and predisposes to recurrence. For this reason, the operation is rarely chosen with the notable exception of a femoral hernia in a patient with specific contraindications to mesh, for example, infection.

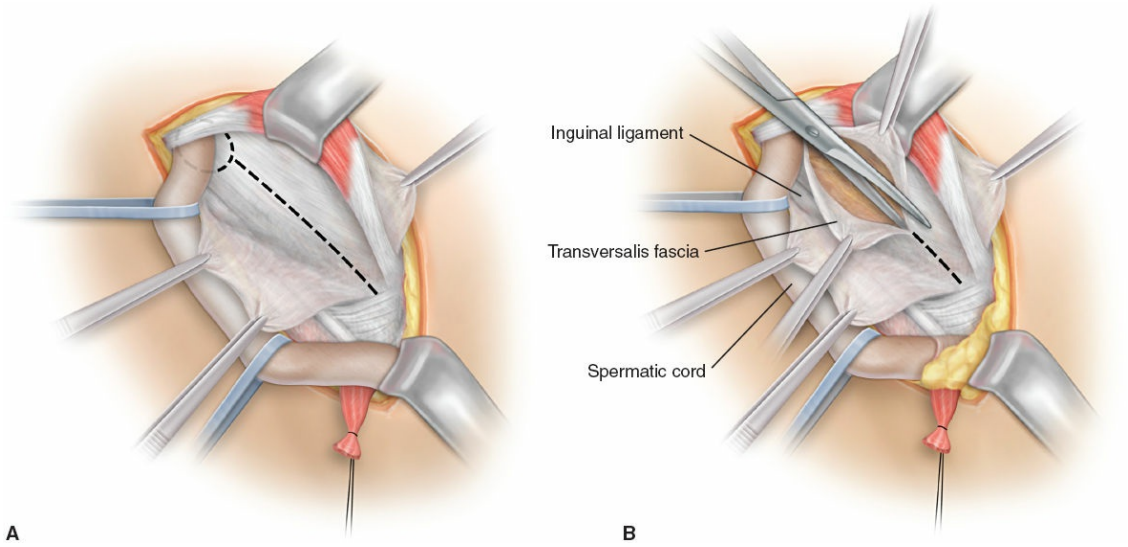

Figure 188.12. A,B. The transversalis fascia is opened from the internal ring to the symphysis pubis.

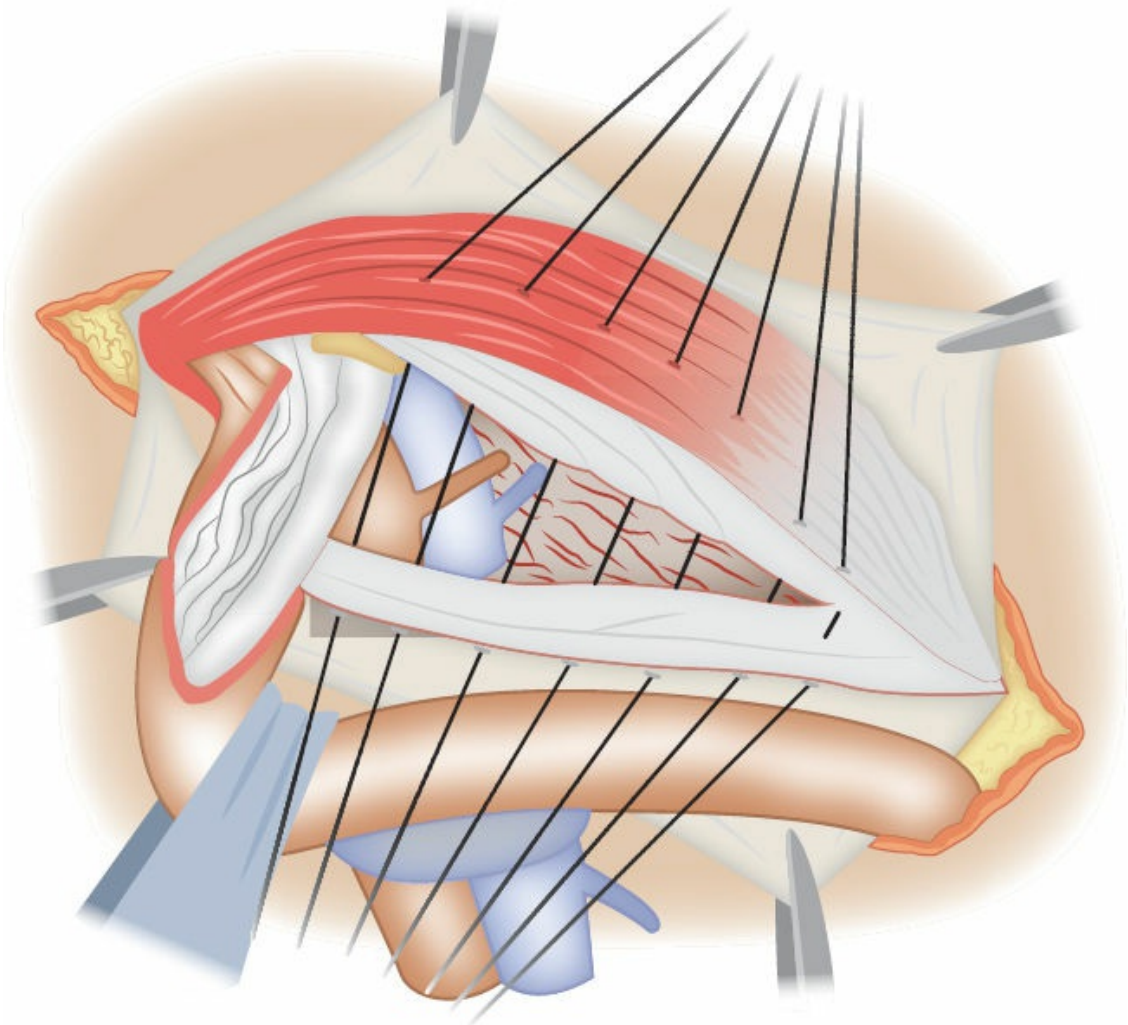

Figure 188.13. The triple layer is sutured to the shelving edge of the inguinal ligament beginning just medial to the pubic tubercle and continuing laterally until the internal ring is narrowed on its

medial side.

Shouldice

Perhaps the most important Bassini modification was popularized by the Canadian surgeon Earle Shouldice in 1945. His hospital stressed the importance of perioperative care of inguinal hernia patients including early mobilization, resuming normal activities as soon as possible, and short hospital stay at a time when such stays were 2 to 3 weeks. The recurrence rate decreased impressively to 1% in experienced hands and specialized clinics. In general practice, long-term results are less satisfying and show a recurrence rate of 1.7% to 15%. Nevertheless, the Shouldice technique is considered by most to be the best pure tissue repair for a primary inguinal hernia. Particular importance is placed on freeing the cord from its surrounding adhesions, resection of the cremaster muscle, high dissection of the hernia sac, and division of the transversalis fascia during the initial steps of the procedure similar to what has been described above with the Bassini operation. The major modification is the method of reconstruction of the posterior wall of the inguinal canal by a four-layer method instead of a single one. A continuous nonabsorbable suture (Shouldice preferred monofilament stainless steel wire) is used to repair the posterior wall. The Shouldice surgeons believe that a continuous suture distributes tension evenly and prevents potential defects between interrupted sutures that could lead to recurrence. Eventually, four continuous suture lines are developed between the iliopubic tract and external oblique aponeurosis laterally to the triple layer and internal oblique muscle medially.

The repair is started at the pubic tubercle by approximating the iliopubic tract laterally to the undersurface of the lateral edge of the rectus abdominis and the triple layer. The suture is continued laterally, approximating the iliopubic tract to the triple layer made up of the internal oblique muscle, the transversus abdominis muscle, and the transversalis fascia. The continuous suture is extended to the internal ring, where the lateral stump of the cremaster muscle is picked up to form a new internal ring (Fig. 188.16). Next, the direction of the suture is reversed back toward the pubic tubercle, approximating the medial edges of the internal oblique muscle and the transversus abdominis to Poupart ligament as far as the crest of the pubis where the wire is tied to itself as the first knot. Thus, two parallel lines are formed by the first suture.

A second suture is started near the internal ring, approximating the

internal oblique muscle and the transversus abdominis to a band of external oblique aponeurosis superficial and parallel to Poupart ligament—in effect, creating a second, artificial shelving edge of inguinal ligament. This third suture line continues to the pubic crest (Fig. 188.17). The suture is then reversed as a fourth suture line is constructed in a similar manner, superficial to the third line. At the Shouldice clinic, the cribriform fascia (the superficial fascia of the thigh that covers the saphenous opening) is always incised in the thigh, parallel to and just beneath the inguinal ligament, to make the inner side of the lower flap of the external oblique aponeurosis more mobile for these multiple layers and to check for a femoral hernia (Fig. 188.18). In general practice, however, this step is commonly omitted.

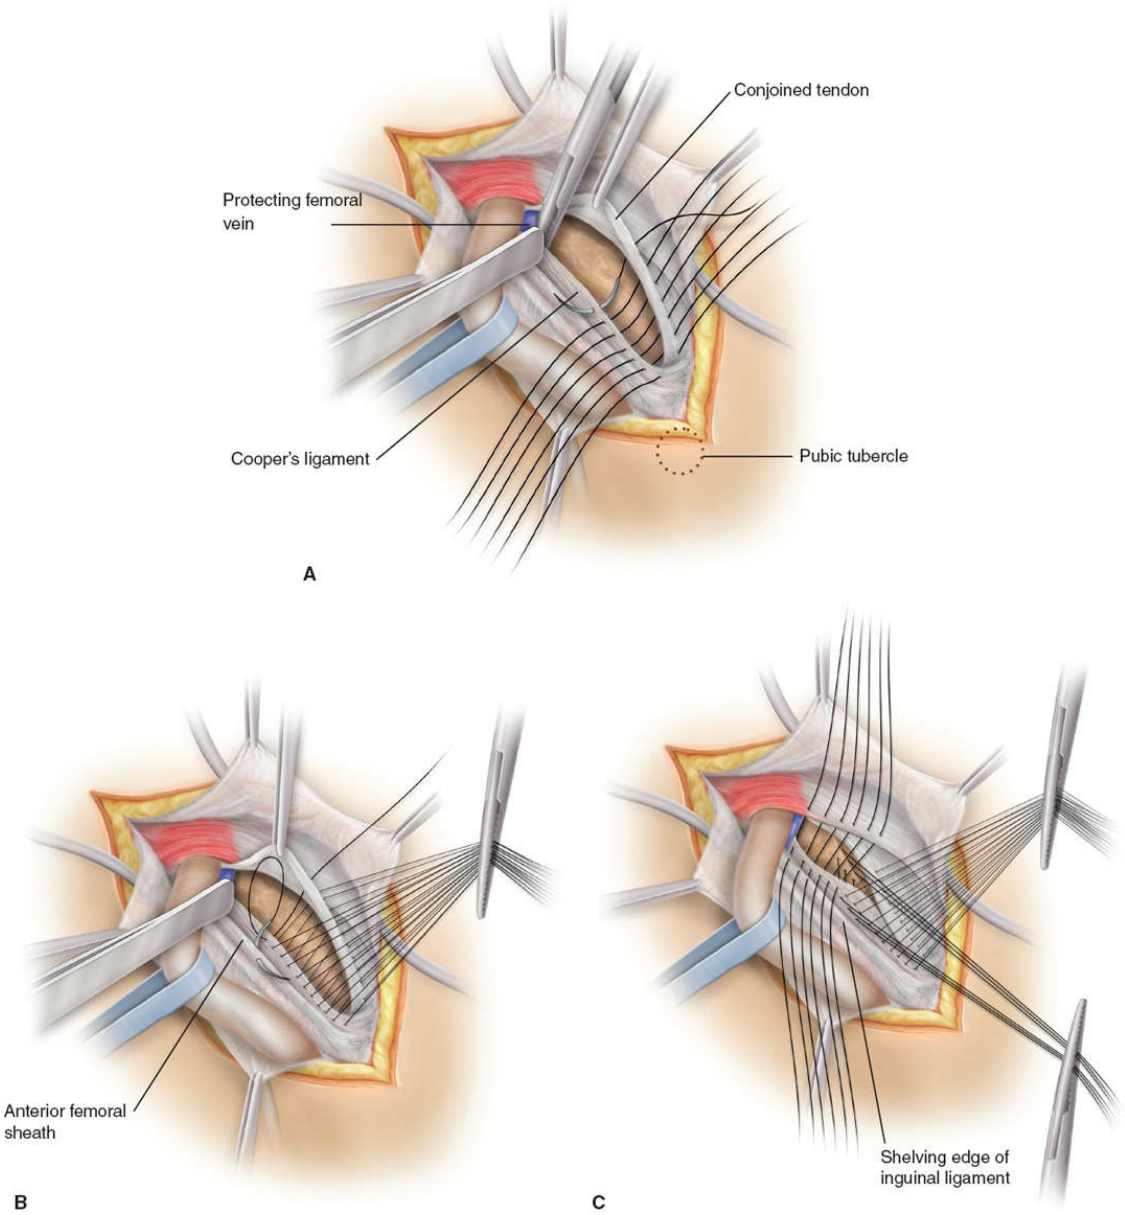

Figure 188.14. **A.** The medial elements of the inguinal canal are sutured to Cooper ligament beginning at the pubic tubercle. **B.** A transition stitch between the medial elements, Cooper ligament, and the shelving edge of the inguinal ligament. **C.** The repair is continued laterally to the inguinal ligament.

The results at the Shouldice clinic have been truly outstanding and continue to be so today. For a time, the Shouldice repair was the gold standard against which all newer procedures were compared. The major criticism of this operation is that it is difficult to teach because surgeons have problems understanding what is really being sewn to what. Unless one is specifically trained at the Shouldice clinic and has the opportunity to work with the surgeons there, one may find it hard to identify the various

layers in the medial flap reliably and reproducibly—a step that is crucial for developing the multiple suture lines. To compound the difficulty, modifications developed outside the Shouldice clinic have given rise to different versions of the procedure.

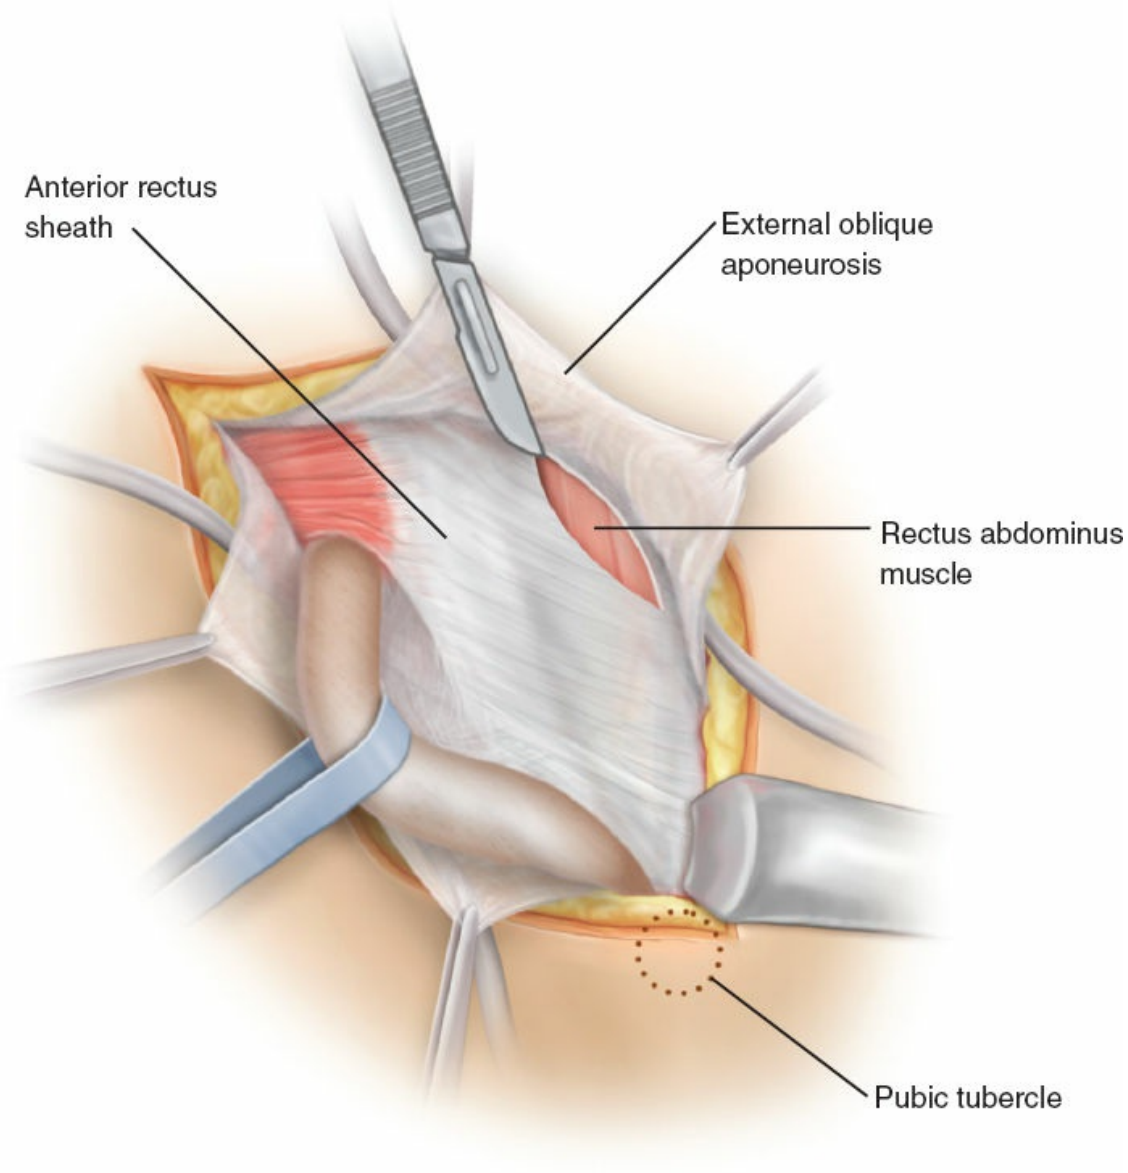

Figure 188.15. A relaxing incision is made in the anterior rectus sheath after the external oblique aponeurosis is reflected medially that begins just above the symphysis pubis and extends cranially for 5 to 10 cm.

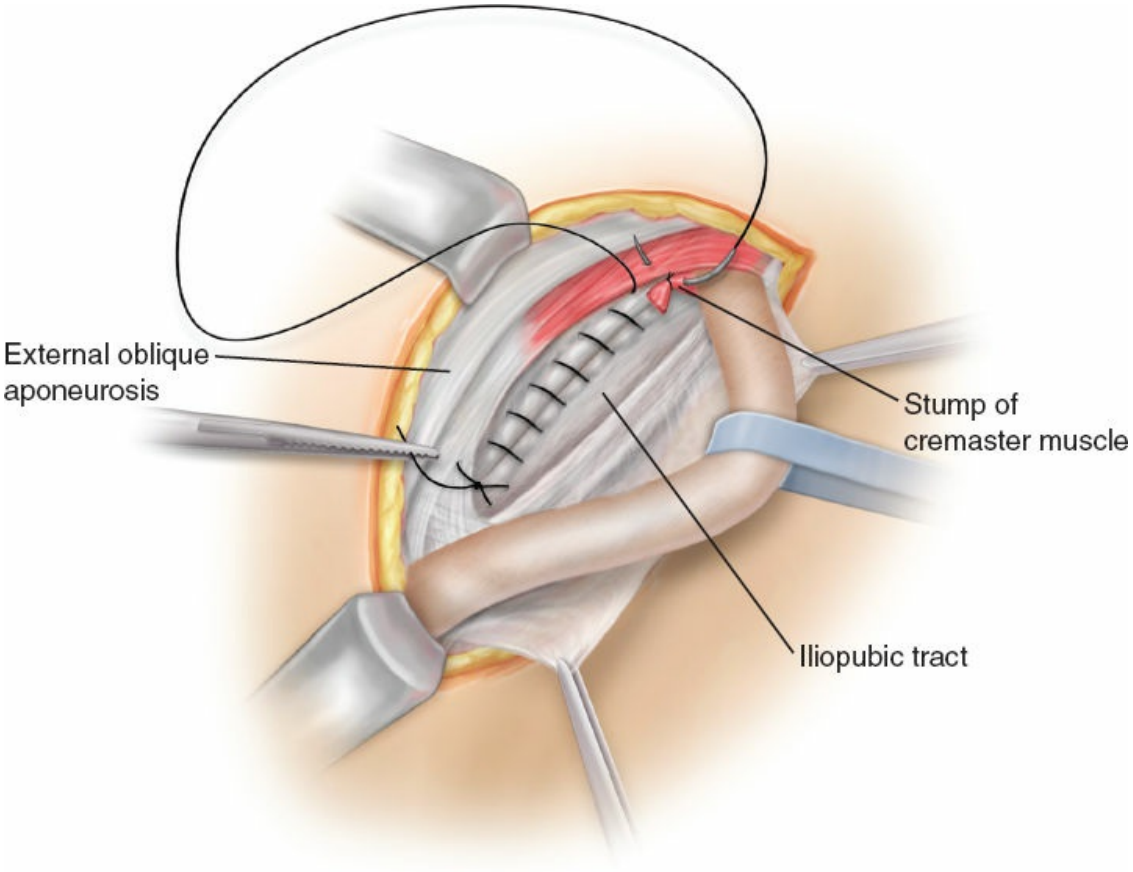

Figure 188.16. The repair begins near the pubic tubercle. The iliopubic tract is sutured to the posterior rectus sheath and then continued laterally to the triple layer until the stump of the divided crematerіc is incorporated.

OPEN PROSTHETIC REPAIR

Lichtenstein Tension-Free Herniorrhaphy (TFR)

Critics of the tissue repairs point out that by definition structures that are not normally in apposition are sutured together under some degree of tension. It is felt that this contributes to the long-term 10% to 15% recurrence rate reported in population-based studies, which is more reflective of general practice. By using a prosthesis to reconstruct the inguinal floor, this tension can be avoided. In 1958 Francis Usher introduced the first tension-free mesh inguinal hernia repair using polyethylene mesh. Anatomical reconstruction of the posterior wall was not performed in favor of reinforcing the inguinal floor with his mesh. In 1962 he introduced the polypropylene mesh that is still the mesh of choice today, especially in the United States.

The surgical technique proposed by Usher never became widely used

until Irving Lichtenstein in 1964 introduced the idea of performing the repair under local anesthesia and promoted its tension-free nature. Lichtenstein and colleges at the Lichtenstein clinic strongly promoted the approach so much so that the anterior tension-free mesh repair is now known as the “Lichtenstein tension-free repair” or TFR. By the 1990s, it had become the most common surgical repair for an inguinal hernia in the Unites States and many other parts of the world. The recurrence rate dropped significantly with this technique even in general practice, and it is still today considered the gold standard for an anterior inguinal hernia repair.

At the Lichtenstein clinic, the procedure is performed under local anesthesia with sedation using 50 cc or less of a 50:50 mixture of 1% lidocaine (Xylocaine) and 0.5% bupivacaine (Marcaine), with 1/200,000 epinephrine. General or regional anesthesia can also be used. The initial steps are similar to the Bassini operation.

Once the external oblique aponeurosis has been opened, the upper leaf is freed from the underlying internal oblique muscle and aponeurosis in an avascular plane beginning at least 2 cm medial to the pubic tubercle. This separation of the external oblique aponeurosis from the internal oblique muscle is continued laterally beneath the nonincised portion of the external oblique aponeurosis to the anterior superior iliac spine. Dissection is continued in this avascular plane from lateral to medial along the shelving edge of the inguinal ligament and iliopubic tract to the pubic tubercle. The purpose is to create a large space for the eventual placement of a prosthesis. The cord structures with their cremaster covering are swept off the pubic tubercle and separated from the inguinal canal. The ilioinguinal nerve, external spermatic vessels, and the genital branch of the genitofemoral nerve all remain with the cord structures.

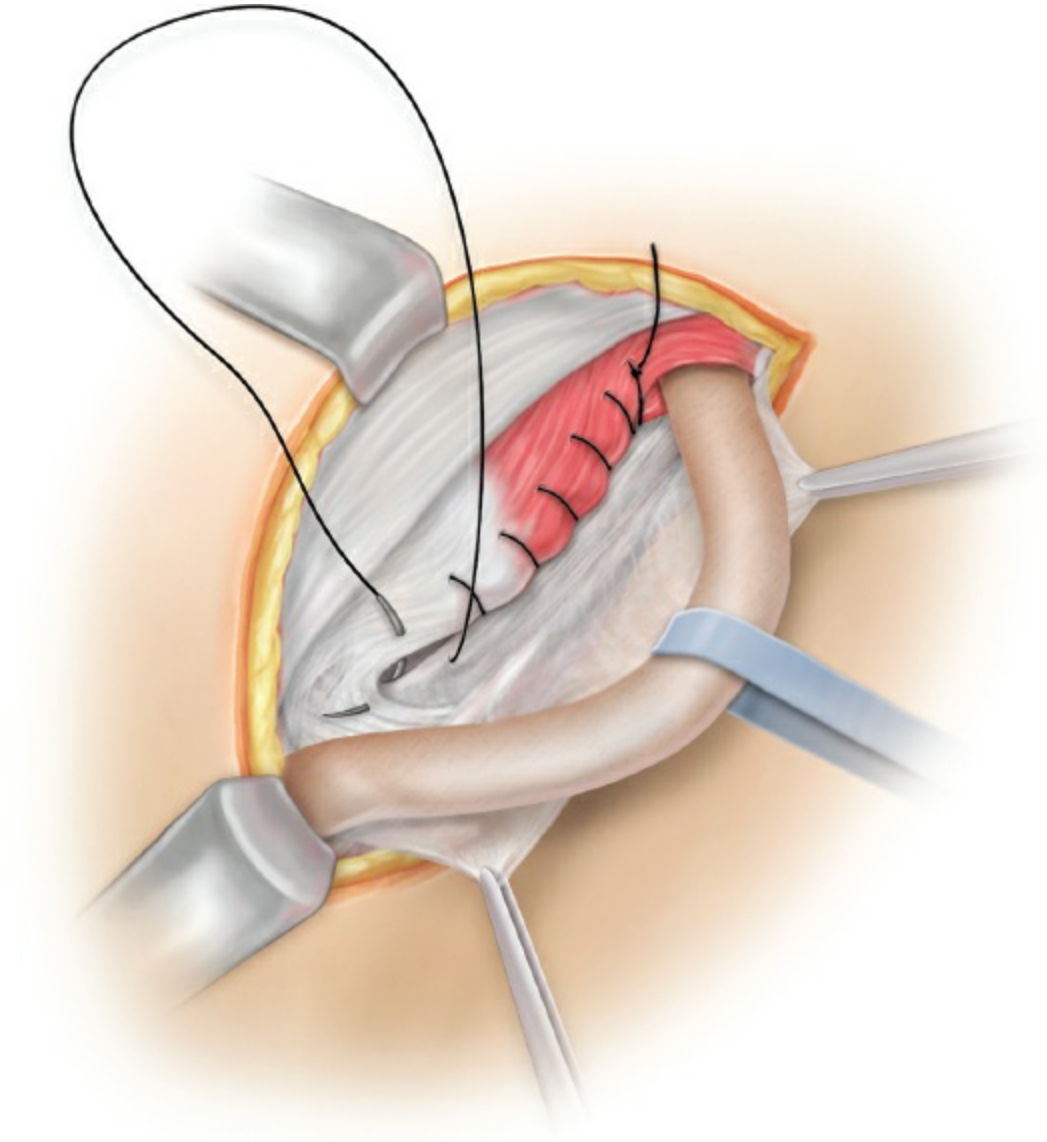

Figure 188.17. A second suture (third row in the repair) is begun at the internal ring approximating the internal oblique muscle to the external oblique aponeurosis along a line parallel and more superficial to the inguinal ligament, in effect creating a pseudo inguinal ligament. The suture is revesed at the pubic tubercle and another pseud inguinal ligament created.

For indirect hernias, the cremasteric muscle is incised longitudinally and the sac dissected free and reduced into the preperitoneal space. A theoretical criticism of this operation is that unless the inguinal floor is opened, an occult femoral hernia may be overlooked. However, an excessive incidence of missed femoral hernias has not been reported except in females with direct hernia. Direct hernias are separated from the cord and other surrounding structures and reduced back into the preperitoneal space. Dividing the superficial layers of the neck of the sac

circumferentially, which in effect opens the inguinal floor, usually facilitates reduction and aids in maintaining it while the prosthesis is being placed. This opening in the inguinal floor can also be used to palpate for a femoral hernia. Suture can be used to invert the sac but its purpose is simply to reduce it to allow the repair to proceed unencumbered by the sac continually extruding into the field especially when the patient strains

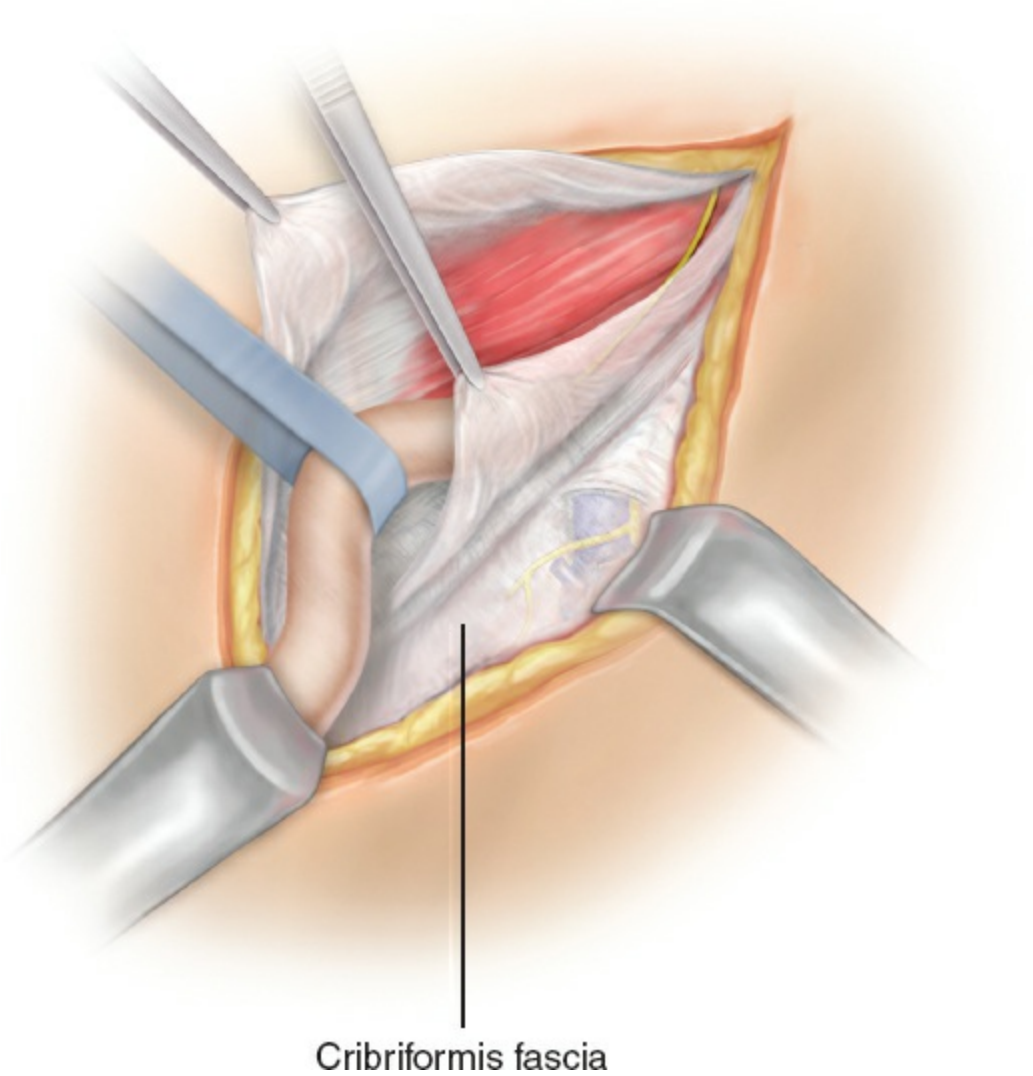

Figure 188.18. At the Shouldice clinic, the cribriform fascia is incised in the thigh, parallel to the inguinal ligament, to make the inner side of the lower flap of the external oblique aponeurosis more mobile for these multiple layers and to check for a femoral hernia.

A mesh prosthesis with a minimum size of 15 by 8 cm for an adult is positioned in the inguinal canal (Fig. 188.19A). The medial end is rounded to correspond to the patient's particular anatomy and secured to the

anterior rectus sheath a minimum of 2 cm medial to the pubic tubercle. Either nonabsorbable or long acting absorbable suture should be used. The wide overlap of the pubic tubercle is important to avoid the all too common pubic tubercle recurrences seen with other operations. The suture is continued in a running locking fashion laterally securing the prosthesis to either side of the pubic tubercle (not into it!) and then the shelving edge of the inguinal ligament. The suture is tied at the internal ring.

A slit is made at the lateral end of the mesh creating two tails—a wide one (two thirds) above and a narrower (one third) below. The tails are positioned around the cord structures and placed beneath the external oblique aponeurosis laterally to about the anterior superior iliac spine with the upper tail being placed on top of the lower. A single interrupted suture is used to secure the inferior surface of the superior tail to the inferior surface of the inferior tail and the shelving edge of the inguinal ligament in effect creating a shutter valve Fig. 188.19B. This later step is considered crucial for the prevention of the indirect recurrence that is occasionally seen when simple re-approximation of the tails is performed. It also serves to wrinkle the mesh somewhat medially, which may decrease any tendency for tension when the patient assumes an upright position. A few interrupted sutures are used to secure the superior and medial aspects of the prosthesis to the underlying internal oblique muscle and rectus fascia. If the iliohypogastric nerve crosses through the external oblique aponeurosis on the medial side, the prosthesis should be slit to accommodate it. The prosthesis can be trimmed in situ, but care should be taken to maintain sufficient laxity to account for a difference between the supine and upright positions as well as the fact that mesh shrinkage is probably a reality.

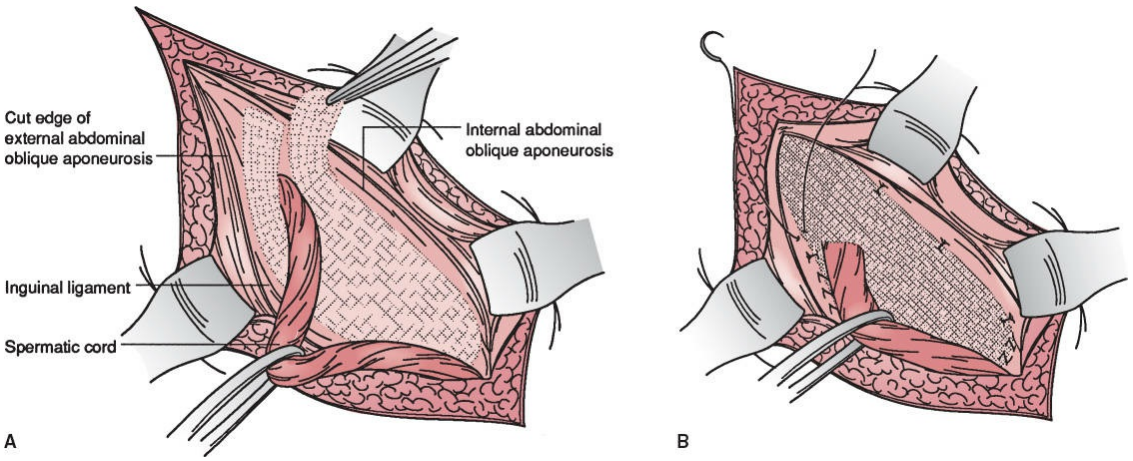

Figure 188.19. The Lichtenstein TFR. **A.** A prosthesis is placed

over the inguinal floor with a slit laterally to accommodate the cord structures. **B.** A continuous suture approximates the prosthesis to the inguinal ligament beginning 2 cm medial to the pubic tubercle. The slit is repaired around the cord laterally incorporating the inferior edge of the superior tail, the inferior edge of the inferior tail, and the inguinal ligament. The repair is completed with interrupted sutures medially and cranially.

If a femoral hernia is present, the posterior surface of the mesh is sutured to Cooper ligament after the inferior edge has been attached to the inguinal ligament. This closes the femoral canal. The wound is closed in layers.

Stoppa's Giant Prosthetic Reinforcement of the Visceral Sac for the Preperitoneal Space

In 1975 Dr. René Stoppa introduced a more invasive technique for repairing an inguinal hernia that was based on the placement of a nonabsorbable mesh in the plane in the preperitoneal space on the abdominal side of the defective myopectineal orifice. He developed the procedure, named the giant prosthetic reinforcement of the visceral sac or GPRVS, largely because of the influence of his teacher and mentor Henry Fruchaud who in 1956 described the myopectineal orifice (sometimes called the musculopectineal orifice) that bears his name. Fruchaud theorized that all groin hernias have a common etiology, which is failure of the transversals fascia to retain the peritoneum from penetrating his myopectineal orifice. Thus, subdividing hernias into direct, indirect, and femoral becomes less important. This concept led Stoppa to develop GPRVS, which reestablishes the containment of the peritoneal sac by inserting a large permanent prosthesis that entirely replaces the transversalis fascia over the myopectineal orifice, separating the internal "os" of a hernia from the peritoneum as opposed to the anterior approaches that address the problem at the external "os" (Fig. 188.7). Stoppa felt this approach would provide an unyielding tissue replacement that would use the intra-abdominal pressure to press a prosthesis against the orifices that he sought to protect from passage of the peritoneum and intra-abdominal contents.

Surgical Technique

GPRVS, also referred to colloquially as the Stoppa repair, is more involved than the anterior approaches previously described. A midline incision is classically made from the umbilicus to the pubis, although inguinal or Pfannenstiel incisions have also been described. The fascia overlying the space of Retzius is opened without entering the peritoneum. The hernia is reduced taking care that there are no structures that may remain at risk for strangulation in the reduced sac. Dissection is continued laterally posterior to the rectus abdominis and the inferior epigastric vessels to the iliopsoas muscle. The symphysis pubis, Cooper ligament, and the iliopubic tract are identified. Inferiorly, the peritoneum is generously dissected away from the spermatic cord structures and the iliac vessels with care to avoid injury to them. This dissection will create a large space that will eventually accommodate a prosthesis without the possibility of rollup. Stoppa emphasized the importance of completely mobilizing or "parietalizing" the spermatic cord to allow the vas deferens and internal spermatic vessels to be displaced laterally so that it will not necessary to split or keyhole the giant prosthesis that will eventually be placed.

Once the dissection is completed, a chevron-shaped mesh (Stoppa preferred Dacron) measuring on average 26 by 15 cm is placed in the preperitoneal space laterally to the borders of the psoas muscle using a sequential technique determined by eight strategically placed clamps (Fig. 188.20). The repair is completed by placing a single stitch at the apex of the mesh to the inferior aspect of the umbilicus. Once the peritoneum is released, the mesh will be held in place by the pressure of the peritoneal contents against the posterior aspect of the anterior abdominal wall. A unilateral variant of this procedure was popularized by Wantz.

LAPAROSCOPIC PROSTHETIC REPAIR

Laparoscopic inguinal hernia repair (LIHR) has several theoretical advantages consistent with its minimally invasive character, which include less postoperative discomfort/pain, reduced recovery time allowing earlier return to full activity, easier repair of a recurrent hernia that had been performed conventionally because the repair is performed in tissue that has not been previously dissected, less morbid treatment of bilateral hernias, the avoidance of a groin incision/ improved cosmesis, and the highest possible control of the hernia sac. These potential advantages of laparoscopic herniorrhaphy must be interpreted in the light of the

disadvantages of a laparoscopic approach. These include complications related to laparoscopy such as bowel perforation or major vascular injury, potential adhesive complications at sites where the peritoneum has been breached or prosthetic material has been placed, the need for a general anesthetic, increased cost because of the expensive equipment required and a steep learning curve. On the other hand, the conventional operation can be performed under local anesthesia on an outpatient basis with minimal risk of intra-abdominal injury, and the cost is less. The result is that widespread adoption in contrast to other minimally invasive operations has not been observed. The adoption rate varies dramatically from country to country. It is estimated that between 15% and 20% of inguinal hernias in the United States are repaired laparoscopically, but this number seems to be gradually increasing as newly trained surgeons enter the workforce.

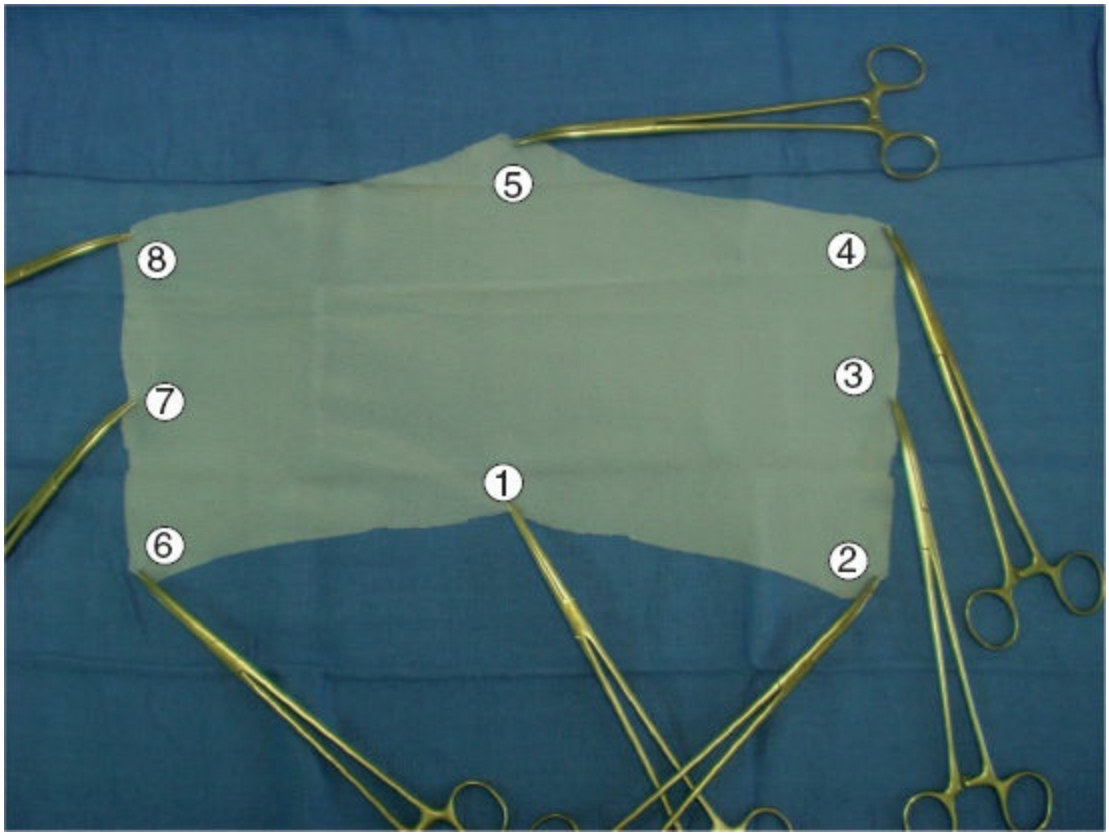

Figure 188.20. Photograph of the chevron-shaped prosthesis grasped by eight long Kelly forceps for their notouch handling and easy correct placement. The numbers 1 to 8 indicate the order of placement of the clamps, beginning on the right side of the patient.

The two most commonly performed laparoscopic herniorrhaphies are

the transabdominal preperitoneal (TAPP) and the totally extraperitoneal (TEP). The essential steps in the preperitoneal space are identical; only the access to the space as their names imply is different. An intraperitoneal onlay mesh (IPOM) procedure has also been described but has never gained popularity, which is somewhat surprising because of the frequent use of the procedure for ventral hernias. IPOM for inguinal hernias is considered by most to be a salvage procedure only. Variations in the two commonly performed laparoscopic repairs include the use of the robot and single port surgery, but these will not be discussed in detail.

TAPP

The TAPP procedure provides the best exposure to the preperitoneal space and is therefore easier to learn. The disadvantage is that the peritoneal cavity is entered, and therefore laparoscopic complications can occur such as visceral injury, adhesive complication, trocar site hernias, etc. In addition, the peritoneum has to be closed that adds time to the procedure.

Figure 188.21 depicts the operating room setup. The operation is performed under general anesthesia with the patient supine. Arms should be tucked at the side of the patient as outstretched arms may compromise the ability of the surgeon to obtain an optimum angle for fixing the prosthesis. A Foley catheter is placed to establish bladder decompression only if the patient does not void immediately prior to entering the operating room. A single video monitor is placed at the foot of the operating table. An angled laparoscope is essential to provide adequate visualization of the inguinal region because it is somewhat anterior. The surgeon stands on the opposite side of the table from the hernia. The first assistant stands opposite the surgeon. The first assistant usually acts as the camera operator as there is not enough room for a third person between the two primary surgeons and the head of the table. This assumes the primary surgeon will use a two-handed technique. Alternatively, some surgeons prefer to use a one-handed approach so that they can control the optics themselves since proper visualization is so critical to a successful laparoscopic herniorrhaphy. This is strictly a matter of personal preference.

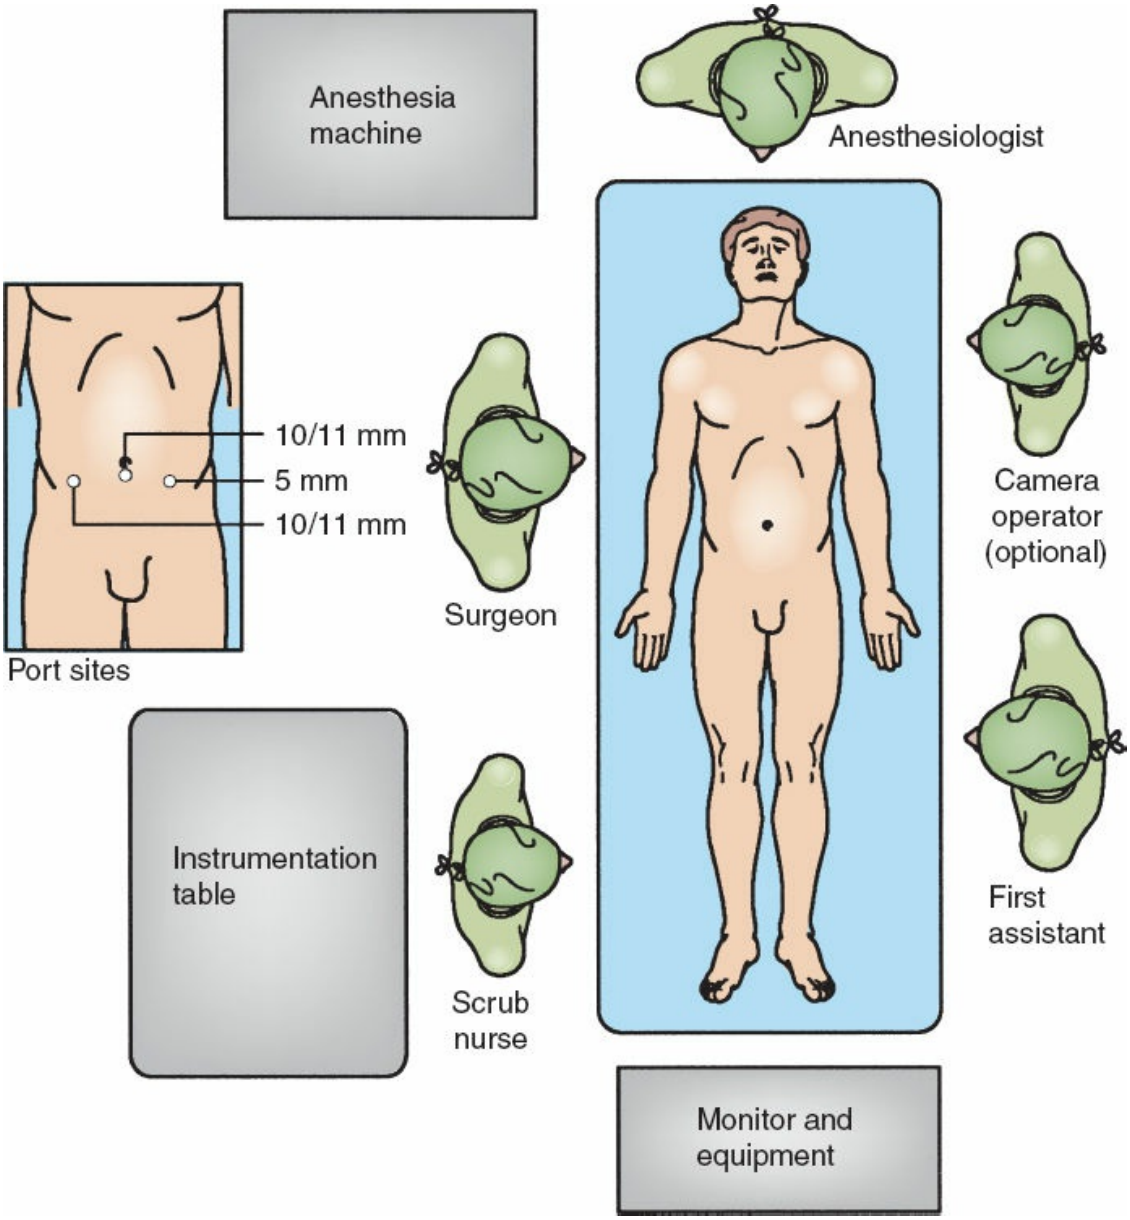

Figure 188.21. Typical operating room setup for laparoscopic inguinal herniorrhaphy.

The laparoscopy is begun by placing an 11-mm cannula at the umbilicus using an open Hasson technique. Alternatively, a Veress needle can be used. Two additional 5-mm cannulas are placed on either side of the midline at the level of the umbilicus, near the lateral edge of the rectus sheath. After a laparoscopic inspection of the entire abdominal cavity, the patient is placed in the Trendelenburg position that allows visualization of important anatomical landmarks through the peritoneum (Fig. 188.5). The peritoneum is incised using scissors approximately 2 cm above the superior edge of the hernia defect, and the space between the peritoneum and the transversalis fascia (spaces of Retzius and Bogros) is entered.

Occasionally the median umbilical ligament is divided if it appears to compromise exposure (Fig. 188.22). A radical dissection of the preperitoneal space is then performed. The key structures that must be identified are the ipsilateral and contralateral pubic tubercles, inferior epigastric vessels, Cooper ligament, and the iliopubic tract (Fig. 188.6). Dissection below the iliopubic tract must be careful to avoid the femoral branch of the genitofemoral and lateral femoral cutaneous nerves, which enter the lower extremity just below the Iliopubic tract. Skeletonizing the cord structures from the peritoneum completes the initial dissection. Direct hernias are much easier to deal with than indirect. The sac and preperitoneal fat are reduced from the hernia orifice by gentle traction separating the peritoneal sac from the thinned out transversalis fascia, which lines the abdominal wall portion of the hernia defect and is easily visualized as a white tongue of tissue that can be teased back into the defect in the abdominal wall. This characteristic layer is sometimes referred to as the “pseudosac.” For indirect hernias, there are two options. A small sac can be mobilized from the cord structures and reduced back into the peritoneal cavity. A large sac may be difficult to mobilize because of dense adhesions between the sac and the cord structures due to chronicity of the hernia. In this circumstance, it is prudent to divide the sac at a convenient point distal to the internal ring and only mobilize the proximal portion which is then closed with sutures of an endoloop. Once the hernia sac has been dealt with, the dissection is completed by mobilizing the inferior flap for a significant distance past the bifurcation of the vas deferens and the internal spermatic vessels. This step is considered essential to prevent rollup of the prosthesis that will be placed in the space leading to recurrence. By gently elevating the internal spermatic vessels, the peritoneum can be stripped off by counter traction. A similar maneuver can be accomplished with the vas deferens.

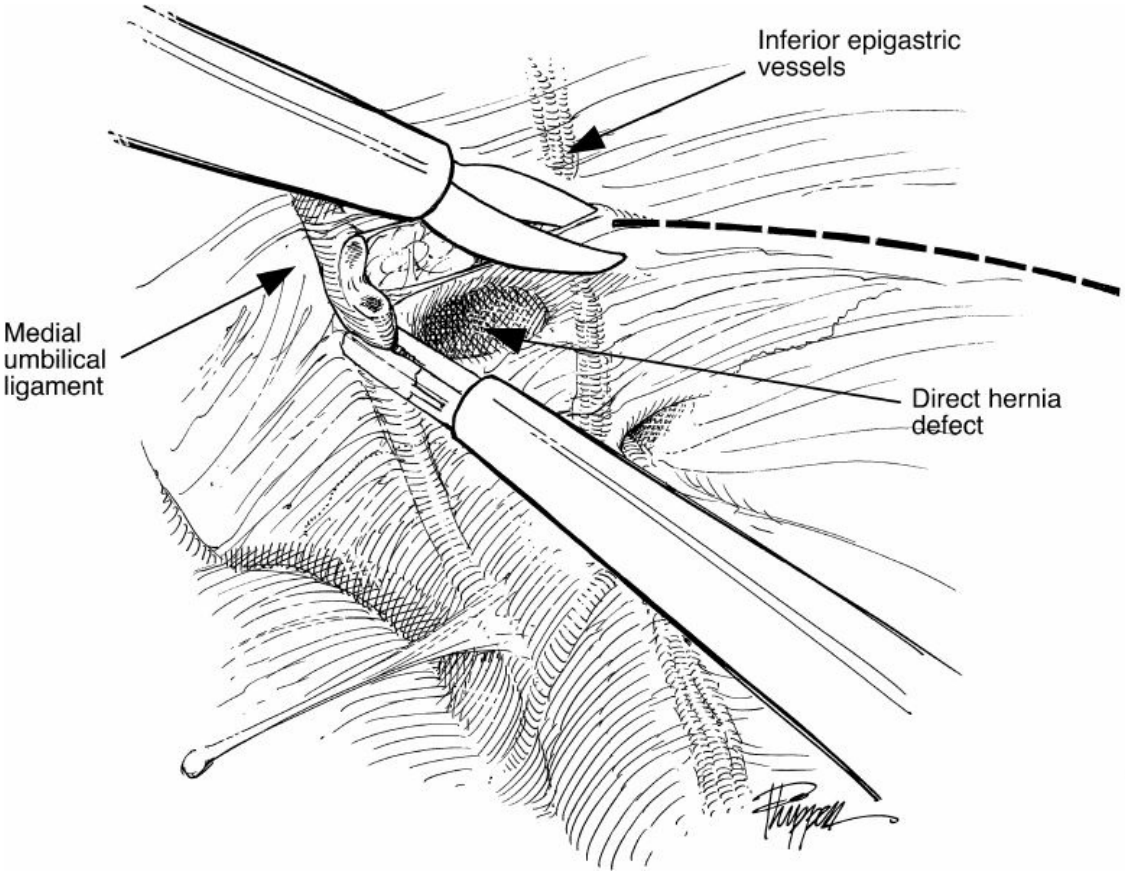

Figure 188.22. The peritoneum is incised beginning on the lateral side of the medial umbilical ligament, beginning about 2 cm above the hernia defect and extending toward the anterior superior iliac spine. Rarely is it necessary to actually divide the medial umbilical ligament.

Next a large prosthesis, at least 11 by 6 cm, is placed over the myopectineal orifice so that it completely covers the direct, indirect, and femoral spaces (Fig. 188.23). The prosthesis can either be simply laid over the cord structures or a slit can be made in the mesh to wrap around the cord structures (Fig. 188.24). Most surgeons now avoid the slit in the prosthesis because recurrences have been noted through these slits even when they have been repaired around the cord. The prosthesis can now be secured with staples, tacks, or glue. The medial edge is stapled or tacked to the soft tissue around the contralateral pubic tubercle and the symphysis pubis. The medial, inferior border is secured just above Cooper ligament. Next the prosthesis is secured along the superior border to the posterior rectus sheath and transversalis fascia, at least 2 cm above the hernia defect. If the prosthesis is large enough, no fixation is necessary. Staples or tacks are never placed below the iliopubic tract when lateral to the internal spermatic vessel because of the danger of damage to the important nerves

in this area. The last step is to cover the prosthesis by closing the peritoneum with sutures, tacks, staples, or glue. This step is aided by decreasing the pneumoperitoneum pressure.

For bilateral inguinal hernias, the same peritoneal incision and preperitoneal dissections are used. One can then either use individual prosthesis on either side or completely expose the symphysis pubis so that both preperitoneal dissections communicate with each other. This exposure allows the placement of one large prosthesis (at least 25 × 8 cm) that essentially covers the entire lower pelvis.

TEP

Because the peritoneal cavity is not intentionally entered, this technically is not a laparoscopic operation. However, since laparoscopic instrumentation is used, it is always grouped with the TAPP. The essential difference is that the preperitoneal space is entered by establishing a plane of dissection outside of the peritoneal cavity between the posterior surface of the rectus muscle and the posterior rectus sheath and peritoneum. An incision is made at the umbilicus as if one were planning to perform open laparoscopy. The rectus sheath is opened on one side and the rectus muscle is retracted laterally. The space is enlarged by placing a blunt instrument blindly or an operating laparoscope (a rigid laparoscope with a working channel). Once the surgeon is below the arcuate ligament, the preperitoneal space is entered and the dissection completed under direct vision. Two additional cannulas are placed in the midline, one approximately 5 cm above the symphysis pubis and the other midway between the umbilicus and the symphysis pubis. The operation then proceeds in an identical fashion to the TAPP procedure described above. A popular alternative is to use a water- or air-filled balloon dissector to perform the preperitoneal dissection (Fig. 188.25). Also the two accessory cannulas can be placed on either side of the umbilicus, similar to the TAPP procedure, instead of in the midline.

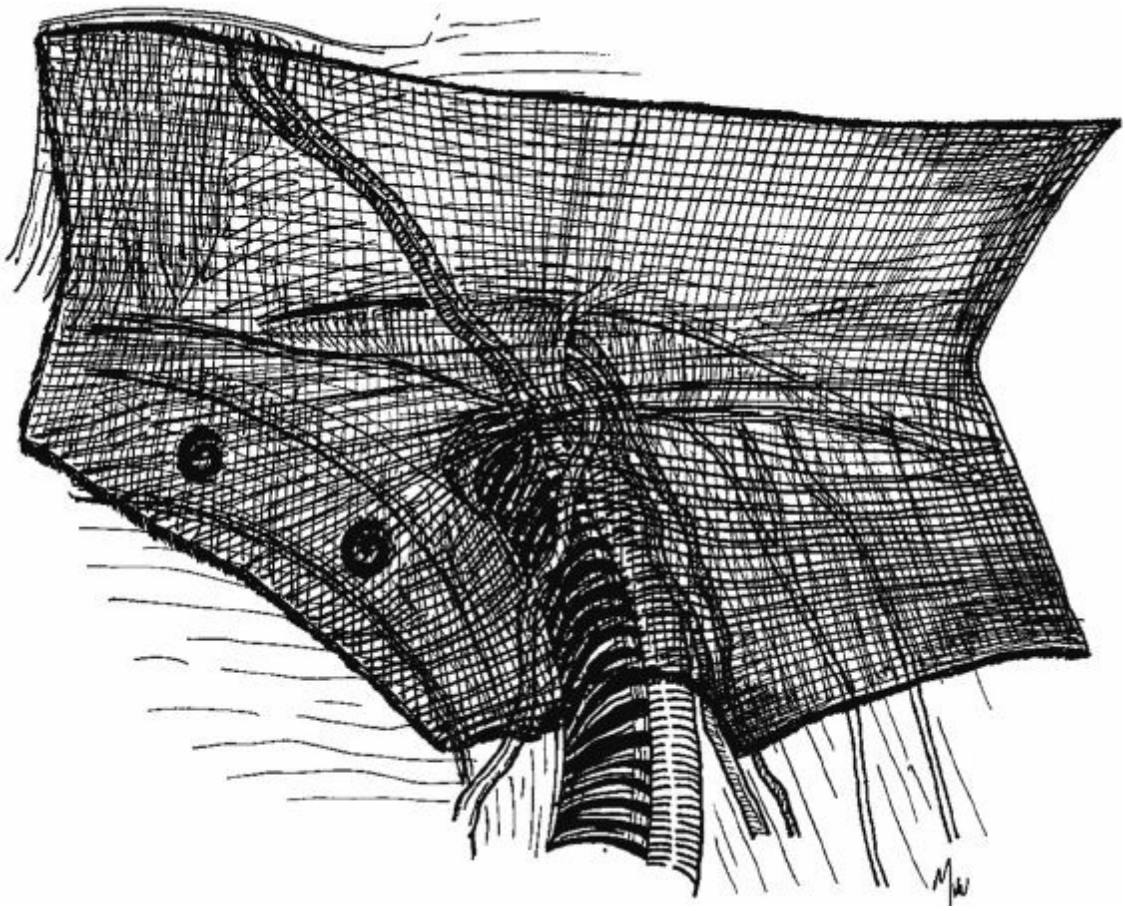

Figure 188.23. A large prosthesis is placed widely overlapping the entire myopectineal orifice. Many surgeons now prefer not to place tacks directly into Cooper ligament shown in illustration.

Postoperative Care

Most patients are discharged home the day of the operation. Those who have urinary retention or persistent nausea, vomiting, or pain that is not well controlled with oral medication are admitted for overnight observation. Empirically, a 15-lb weight restriction is suggested for 1 week. After this, patients are allowed to return to work and normal activity as dictated by pain tolerance. No specific restrictions are made after 2 weeks. Patients return for follow-up at 1 week, 6 weeks, and then as needed.

Complications

In the past, the recurrence rate has been the exclusive measure for determining the value of an individual hernia repair. However, two factors have surfaced that have served to decrease the importance of recurrence. The first is the incidence of postherniorrhaphy sequelae such as chronic

groin pain that occurs more frequently than had been appreciated in the past. Just how “successful” is a hernia repair that is not associated with a recurrence, yet the patient sustains a chronic postoperative syndrome that alters lifestyle? The second factor decreasing the importance of the recurrence rate is the development of the newer tension-free approaches that have brought the recurrence rate down to an essentially irreducible number (i.e., less than 1%) in experienced hands even outside of specialty clinic such as Shouldice.

Complications related to the cord and testicle include bleeding that produces a scrotal or groin hematoma that usually is managed by conservative treatment such as reassurance. Evacuation is rarely required. Ischemic orchitis is an inflammatory process of the testicle occurring within 1 to 5 days after surgery. It occurs in about 1% of primary hernioplasties, but is much more common with operations performed for recurrent hernias. The patient develops enlargement of the testicle that can be excruciatingly painful. A low-grade fever is common and examination discloses an enlarged, hard mass associated with the testicle. The etiology of this complication is not completely understood, but most authorities feel it is caused by thrombosis of the veins draining the testicle secondary to extensive dissection of the spermatic cord. Management consists of supportive care only, with scrotal support and anti-inflammatory agents, as the condition is usually self-limiting. Testicular atrophy can occur after an inguinal herniorrhaphy especially when the procedure is performed for a recurrent hernia. The development of this complication is unpredictable as most patients do not have a history of testicular problems associated with the index herniorrhaphy, for example, orchitis. Indeed, most patients who develop ischemic orchitis after a herniorrhaphy, or any other testicular complication for that matter, go on to recover without testicular atrophy.

Testicular descent can occur with division of the cremasteric muscle. In some patients, the testicle descends into the scrotum. Because of the elasticity of the scrotum, with time, gravity causes the scrotum to elongate. Patients complain their testicle “drops into the toilet.” It is felt that this can be prevented by suturing the distal stump of the divided cremasteric muscle to the tissue around the pubic tubercle. Complete division of the cremasteric muscle is not required with many of the newer procedures, so its incidence should decrease. The dysejaculation syndrome is characterized by searing, burning, painful sensations throughout the groin around the time of ejaculation. It is a rare complication (approximately

0.04%), which is fortunate because it is very hard to treat. It appears to be more common with mesh repairs than pure tissue.

Bladder injury can occur during a herniorrhaphy especially for preperitoneal repairs when there has been previous surgery in the space of Retzius. It is rare with hernia repairs in the anterior space. Bladder injuries are best treated by two-layer repair with absorbable suture, followed by extended indwelling Foley catheter drainage until a cystogram confirms bladder integrity (i.e., 10 to 14 days). Urinary retention can occur after an inguinal herniorrhaphy. It is felt to be related to the choice of anesthetic agent (highest with general and lowest with local), postoperative pain, use of opiates for analgesia, preexisting bladder outlet obstruction, and intraoperative overhydration leading to bladder distension. The treatment is indwelling Foley or repeated catheterizations with or without the use of oral alpha-blockers such as Tamsulosin or Alfuzosin. Voiding trials with ultrasound assessment of residual are begun in a few days usually as an outpatient.

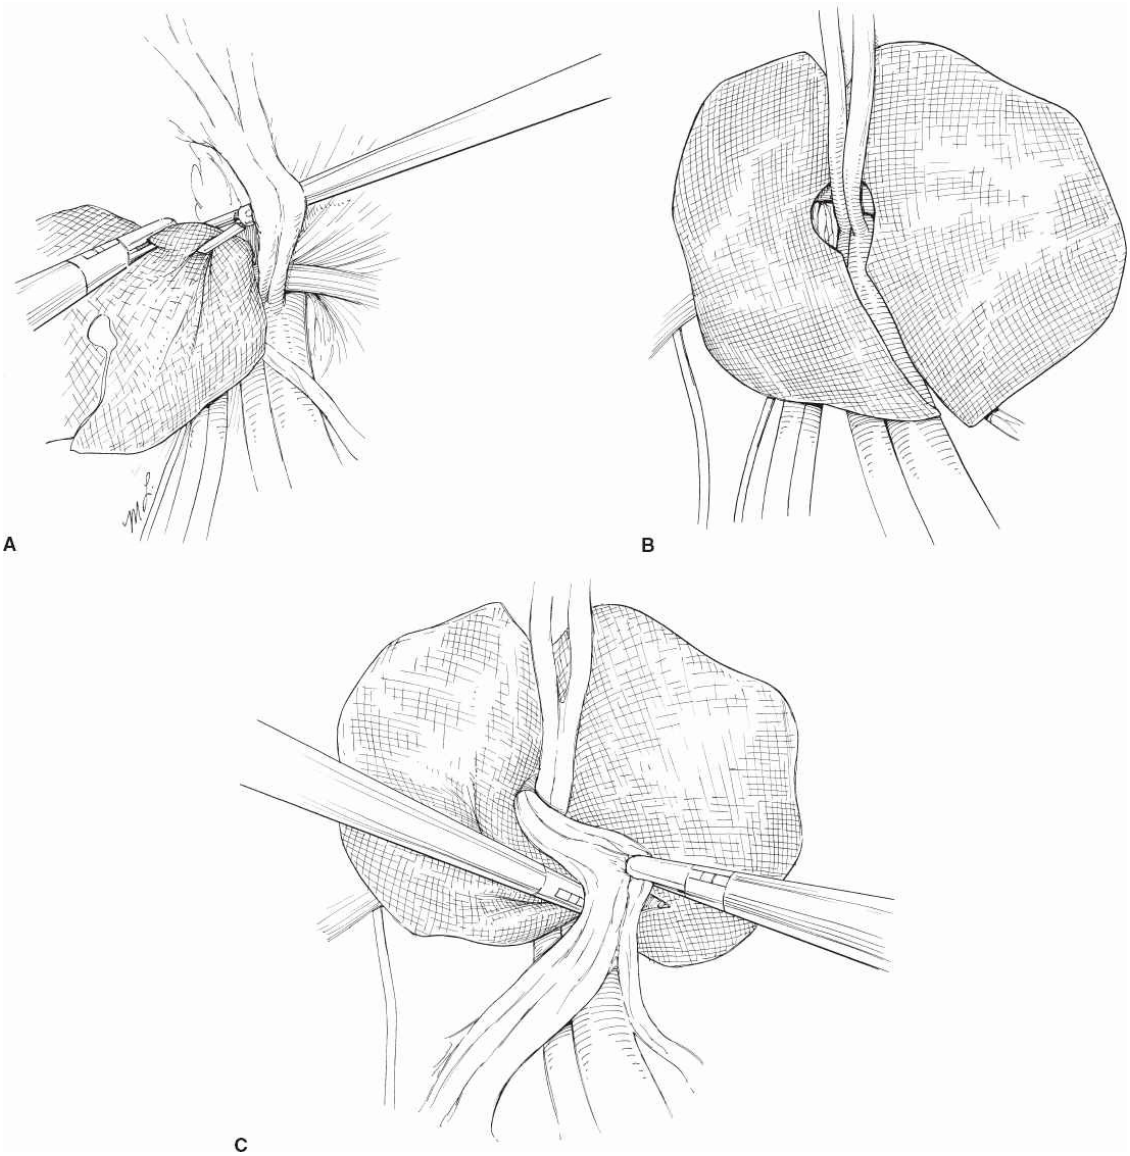

Figure 188.24. A mesh has been slit and a keyhole made and is being positioned beneath the inferior epigastric vessels. TAPP 4 B the mesh is deployed widely overlapping the entire myopectineal orifice TAAP 4C slit is then repaired beneath the cord structures.

Wound infection is surprisingly rare after groin hernia repair. The reason why the groin is apparently a protected area is unclear. When infections do occur in the groin, mesh prosthesis such as polypropylene can commonly be salvaged with drainage alone and this should be the initial treatment for all with removal being reserved for refractory cases. On the other hand, prosthesis made up of nonmesh material such as ePTFE can never be sterilized and virtually always has to be removed. Rejection of the prosthesis because of an allergic response is possible but extremely rare. What patients call rejection in their histories is usually the result of

infection. Seromas can occur especially with the use of synthetic mesh. The finding is most often seen with the laparoscopic hernia repairs. The problem is usual self-limiting as the fluid eventually resorbs spontaneously. Aspiration should be performed for symptomatic relief only as the procedure may result in secondary infection.

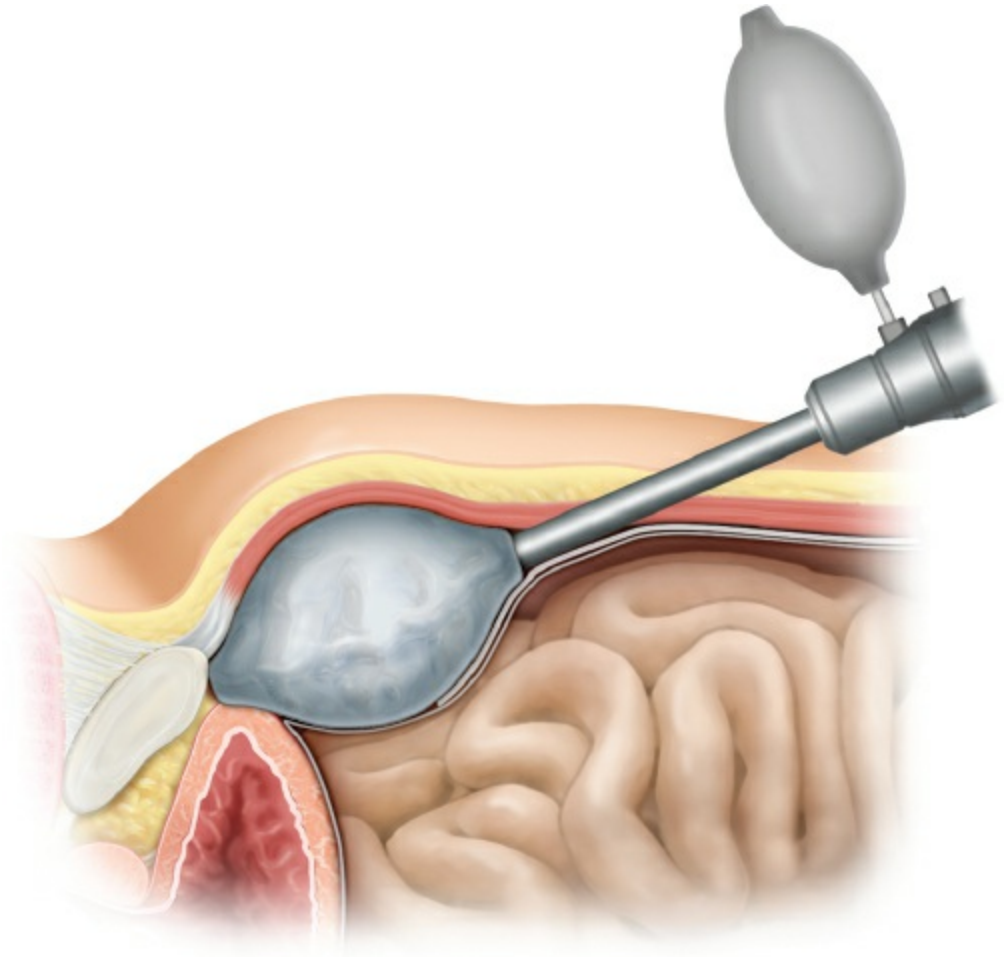

Figure 188.25. The extraperitoneal space is being developed with the aid of a dissecting balloon passed over the posterior rectus sheath into the preperitoneal space.

Osteitis pubis, a noninfectious inflammation of the pubis symphysis, is a known complication of opening the repairs. It is thought to be caused by sutures being placed in the periosteum. Thus, it can be prevented by not placing sutures in that structure. Treatment is largely supportive with heat or ice and anti-inflammatory medication. Rarely does the offending suture have to be removed.

Prosthetic complications include infection (covered above), shrinkage, and erosion into surrounding structures. An overlap in anticipation of an

average 20% contracture with polypropylene as well as other prosthetic materials should be planned. Erosion into the cord structures resulting in vasal obstruction and infertility has been described. Ironically, one of the major arguments for the routine use of mesh in inguinal hernia surgery is to preserve fertility. The theory is that by decreasing the generally accepted recurrence rate in the general population from 10% to 15% seen with Bassini and its variants to less than 5% with the mesh tension-free approach, reoperative surgery with its heavy toll of testicular loss is avoided.

Finally, a host of complications related not to the herniorrhaphy but to the laparoscopy have to be appreciated with the laparoscopic herniorrhaphies. These include laparoscopic accidents resulting in vascular or visceral injury that can be life-threatening, trocar site hernia, and adhesive complications.

EDITOR'S COMMENT

To me the most important aspect of doing a good herniorraphy is knowing the anatomy. Fitzgibbons and Wagner have provided figures with clear anatomical detail. For the novice recognizing landmarks intraoperatively can be difficult, but hernia repair has a steep learning curve. With laparoscopic anatomy, the surgeon must learn the anatomy in reverse and with confidence and a different set of landmarks to avoid injury to important structures.

The authors discuss little about preoperative work-up. As in preparation for any operation, a good history and physical is extremely important to the ultimate outcome. The surgeon needs to fix what he or she can fix prior to embarking on an operation. Any ailment of a patient that creates undue intra-abdominal pressure can be the cause of a failed hernia repair. In the male, a history of a poor urinary stream, urinary tract infection, or an enlarged prostate should be taken care of with a consult to the urology team, with medication and/or prostate surgery prior to hernia repair. Patients with chronic constipation or other bowel symptoms should have a colonoscopy. I would even go far as to say all patients, especially those over 50, should have a colonoscopy as studies have shown that nearly a quarter of these patients will have an abnormality that can be treated. On physical exam if the patient presents with a left indirect hernia even without symptoms of a right hernia, a thorough exam should be made for one on the opposite side, as the left testicle descends first. This is especially true in the pediatric population.

Patients who are smokers should undergo at least a trial of smoking cessation to decrease their risk of recurrence as well as postoperative morbidity. The risk of complications in a smoker is sevenfold that of a nonsmoker. Today, risk assessment and an estimate of the success of any elective operation should play a part in the decision as to whether a patient ultimately even gets an operation. If the patient is not willing to do their part to decrease their own risk of complications, is it incumbent on the surgeon to operate on them and incur the risk of a complication of which ultimately the hospital and surgeon will bear the cost? The American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP) database was used to evaluate the effect of tobacco use on outcomes of open versus laparoscopic inguinal hernia repairs. During the time period of the study, 90,162 patients underwent inguinal hernia repair (76% were open compared to 24% by laparoscopic repair). A third of patients were smokers. Failure to quit smoking prior to surgical repair was significantly associated with the complications of pneumonia and reoperation no matter what type of hernia repair was performed.

Most don't realize that the risk of complications of the morbidly obese is as much as that of the smoker. Attempts at weight reduction prior to any

nonemergent operation should be made. Today with the availability of permanent as well as temporary weight control measures such as gastric balloons and endoscopic gastroduodenal sleeves, real weight loss can be obtained prior to hernia surgery. Willoughby and colleagues queried the NSQIP database to examine 65,501 patients undergoing single-sided nonrecurrent hernias to determine if there was an ideal body weight at which the more expensive laparoscopic hernia repair would have less operating time, shorter hospital stay, and less complications than an open repair. There were 17,919 laparoscopic repairs and 46,582 open repairs. The overall morbidity was statistically greater in the open repair group when compared to the laparoscopic group ($p = 0.03$) for all complications across all BMIs. However, laparoscopic repair is significant and different complications not associated with open repair: bowel or major vascular perforation, adhesive complications and secondary hernias, as well as increased cost, need for general anesthesia, and increased length of operation.

Of course, with emergency hernia repairs none of the risk reduction measures can be implemented. However, the ACS-NSQIP database queried and found 4,298 cases of emergent anterior abdominal wall hernia surgery (within 2 days of hospitalization) of which 25.3% were inguinal hernias that were incarcerated, obstructed, strangulated, or gangrenous. The authors derived a risk model that had excellent discrimination for risk of death, which included in descending order of importance congestive heart failure (8.24-fold), age (5.52-fold), history of peripheral vascular disease (4.98-fold), presence of ascites (3.16-fold), preoperative BUN (1.35-fold), and WBC (1.22-fold).

Some of the morbidity of hernia repair can be avoided by the use of local anesthesia. A recent systematic review and meta-analysis by Prakash and colleagues studied a group of 1,379 patients from 10 randomized controlled trials and patients undergoing hernia repair who were anesthetized with local versus spinal anesthesia suffered significantly less pain, urinary retention, and anesthetic failure. In dealing with high-risk patients especially, one should consider utilizing local anesthesia.

One very important advantage of laparoscopic repair is in repair of bilateral hernias in the adult where a bilateral open repair may create too much tension. Along those same lines one may ask what is the long-term incidence and risk factors for contralateral hernia repair after a unilateral repair. Zheng R et al., using the New York Statewide Planning and Research Collaborative administrative data, examined the fate of 32,384 adults who had undergone initial inguinal hernia repair and who had 10-year follow-up. This group had a contralateral repair rate of 10.8%. Based on these data, one could pose an advantage in a bilateral laparoscopic primary hernia repair.

In regard to recurrent hernias, the European Hernia Society made specific recommendations for laparoscopic recurrent hernia repair following a previous open inguinal hernia repair. For recurrent hernias, after a failed laparoscopic repair an open repair is recommended. These recommendations were based on

six meta-analyses. In an attempt to determine compliance with these guidelines as well as a prospective comparison of outcomes, Kockerling and colleagues established the Herniamed Registry. A total of 4,812 men with unilateral recurrent inguinal hernia repair and 1-year follow-up were included in the study. Approximately half of the cohort had laparoscopic repair and the other half open repair of their primary hernia. Ninety percent of the recurrences after laparoscopic repair underwent secondary open repair, but only 38.5% of the recurrent open repairs underwent secondary laparoscopic repairs in accordance with the guidelines. This demonstrates a clear bias of those who do open repairs to keep doing open repairs. This despite the study showing a significantly higher incidence of perioperative complication and re-recurrence for repairs that did not follow the recommended guidelines.

189 The Shouldice Method of Inguinal Herniorrhaphy

Robert Bendavid

This Chapter can be accessed in the accompanying eBook edition (see inside front cover for access instructions).

In an Atlas of Hernia Surgery, all roads lead to Bassini.

—R. Bendavid (2005)

The treatment of inguinal hernias can truly be said to be following an orderly process of evolution. Much credit goes to the anatomists who described the important structures: Poupart, Hesselbach, Cooper, Thomson, Gimbernat, and Fruchaud, to name a few. The next step in this evolution was contributed by the surgeons: Bassini, Ruggi, Narath, Lotheissen, Halsted, and McVay, to name a few. From the late 1940s to the early 1950s, the introduction of synthetics provided the surgeon with a weapon that promised a certain cure and among the pioneers one must recall Acquaviva, Zagdoun and Sordinas, Newman, Lichtenstein, Rives, and Stoppa. From the early 1990s we have seen the introduction of laparoscopy and the emergence of a controversy that is far from settled in terms of safety, cost, learning curve, and complications. Experience reveals that, despite the advances made in the field of hernia surgery where prostheses and laparoscopy have made significant contributions, the need to know anatomy and to be able to perform a pure tissue repair has become indispensable and imperative. Recurrences are still common and often the result of inadequate dissection, failure to recognize a hernia, repair under tension, or an inappropriate use of a prosthesis, the latter being often, blindly, and erroneously considered a panacea for any and all hernias. Each of the above factors can be addressed effectively when one is familiar with anatomy. The anatomy of the groin is, by no means, the easiest to understand, incorporate, or retain!

As anatomy became clearer, early progress was achieved by the introduction of steps that would in some way improve pure tissue hernia

repair. Among these steps, the following stand out:

- Division of the posterior inguinal wall (Bassini, McVay, Fruchaud)
- Ligation of the hernia sac (Championniere, Marcy, Bassini, Fruchaud)
- Resection of the cremaster (Bassini)
- Use of the iliopectineal ligament (Narath, Lotheissen, McVay, Ruggi)
- Appreciation of the iliopubic tract or bandelette of Thomson (Fruchaud, Condon, Nyhus)
- Reconstruction of the posterior inguinal wall (Bassini, Halsted, McVay)

This process of evolution remains manifest as surgeons attempt and evaluate newer techniques. Among the controversial points, one is the value of resection of the hernial sac. Many surgeons believe that an adequate posterior inguinal wall reconstruction would be sufficient to contain the sac and, hence, a hernia. Others consider the resection of the cremaster unnecessary, particularly if a prosthetic repair is considered as an alternative for reconstruction of the posterior inguinal wall. Others still never split the posterior wall of the inguinal canal, under the pretext that this maneuver only promotes the formation of a recurrent hernia. An important aspect of this ongoing evolution in hernia surgery is the introduction of various mesh prostheses through open techniques or laparoscopy and their acceptance as part of the modern treatment of primary as well as the more difficult recurrent inguinal hernias.

The contribution of the Shouldice philosophy in this evolution is simply that it has chosen and implemented the specific steps that have been introduced over the past 120 years. More exactly, in the early 1950s, it was the well-informed staff surgeon Ernie Ryan, a recent addition to the Shouldice Hospital staff, who incorporated all the specific steps of the Bassini repair, which had been known since 1886. Bassini himself had brought together the pieces of this puzzle by acknowledging and implementing the observations of all the previously named surgeons. Bassini had, in a sense, gleaned the fertile fields of the past to produce an operation that was unique, original, and effective, and that would be emulated by at least a 100 techniques of pure tissue repairs to date. The Shouldice repair remains the most faithful reflection of the Bassini technique and therefore its success.

HISTORICAL BACKGROUND

E. E. Shouldice became interested in the treatment of inguinal hernias in

the 1930s. Operative results were then notoriously poor. In addition to attempts at perfecting his surgical technique, Shouldice looked on each patient as an individual who was to be cared for preoperatively as well as postoperatively.

Obesity, the bane of all surgery, was a factor that had to be brought under control before an operation. To that end, a clinic was set up where patients were to be evaluated while on a weight-reducing diet until their ideal weight was reached. Early ambulation was to be instituted postoperatively in a manner that was then considered heretical, namely, the patient walked away from the operating table, bed rest was minimal, and all activities were to be resumed as soon as possible without restriction. Only the patient's discomfort was a limiting factor. Such an approach had been emphasized by Leithauser in a voluminous publication, which he dedicated strictly to the subject of early ambulation. Shouldice, as evidenced by the correspondence he kept, was in contact with Leithauser and became an enthusiastic, adept, and firm believer in the postulates and advantages of early mobilization following all surgical operations.

Local anesthesia was of paramount importance and, to that end, procaine was retained. The basis for this choice of anesthesia was the actual safety of the technique as had been reported convincingly by Halsted, Bloodgood, and Cushing of Johns Hopkins who had published two series of inguinal hernia repairs carried out under local cocaine anesthesia. Cushing at that time provided the most accurate and unparalleled mapping of the innervation of the groin.

Perhaps the most critical contribution was to be the institution of a follow-up system. Unfortunately, the original follow-up and publication of a large series by Iles was flawed and statistics have followed in the same manner, where one is overwhelmed by staggering numbers, but without a closer scrutiny by a professional statistician. Two excellent studies from the Shouldice Hospital would subsequently confirm the serious flaw about the accuracy of their follow-up (Obney and Chan, Bendavid) and provide a more realistic assessment of their results.

The need for a center specializing in external hernias of the abdominal wall was fulfilled in 1945 when the Shouldice Hospital was established. With 10 full-time surgeons, about 7,500 operations are performed every year.

GENERAL PRINCIPLES

Anatomy

The inguinal region is arguably one of the most complex anatomic areas of the human body. One obvious obstacle is the nomenclature, a nomenclature that is academically correct and in place but whose irreverent usage has been corrupted and turned into a vocabulary reminiscent of a bad weed that has been difficult to eradicate. Cooper and Fruchaud are the two authors whose books have contributed most to the clarity and understanding of the groin. Unfortunately, those books have become extremely rare and, when found, unaffordable. For a necessary understanding of the groin, it is imperative that we clarify certain terms and that we adhere to them. It is crucial at all times to remember that anatomy is described with the subject in the standing position. The posterior inguinal wall must never be referred to as the “floor of the canal” as is done too frequently because of the supine position of a subject during surgery, when the posterior inguinal wall presents itself as the floor of the canal simply because it is parallel to the ground!

The transversalis fascia is part of the endoabdominal fascia and is the deepest part of the posterior inguinal wall. It is a thin layer that has no bearing on the genesis of a hernia though it may precede the peritoneum, and this is best seen with direct inguinal hernias. The true posterior inguinal wall is formed by the aponeurosis of the transversus abdominis. It is this layer, when it is weak and degenerated, that is seen to bulge and appear as a direct hernia, followed by the true transversalis fascia and peritoneum. What constitutes the true defect leading up to a direct inguinal hernia is a weakness of a layer of connective tissue situated between the transversus aponeurosis and the transversalis fascia and that Fruchaud has described as the vascular lamina. Posteriorly, in the retroinguinal space of Bogros this is referred to as the inferior epigastric lamina, which extends medial to but not lateral to the inferior epigastric vessels. It is a connective tissue layer that degenerates as a result of the metabolic defects that lead to hernias. These metabolic defects are beginning to be understood and account for the genesis of all hernias, regardless of their site.

Weight Control

Every effort is made to obtain the patient’s cooperation in shedding excess weight. This may require months, but the dividends are obvious and are reflected in an easier operation technically, in less tension during approximation of tissue layers, in early ambulation, and in a lesser

incidence of thrombophlebitis and pulmonary complications. Ironically, with inguinal hernias, there does not seem to be a convincing correlation between obesity and recurrences. The same cannot be said of incisional hernias. Still, the benefits of a lean patient are evident from both the patient's and surgeon's point of view.

Sedation

On the evening before the operation, all patients are given a sedative (diazepam, 5 to 10 mg) orally. On the day of operation, diazepam (10 to 25 mg) is given orally 90 minutes preoperatively, and meperidine (25 to 100 mg) is given intramuscularly 45 minutes preoperatively. These sedatives and analgesics can be varied and often are.

Anesthesia

Local anesthesia is used in 95% of operations. At the Shouldice Hospital, procaine hydrochloride has been used since 1945. It is an excellent drug; it takes effect within minutes, and this effect lasts as long as 2 hours. The effective concentration for the duration of the procedure is a 1% solution, with a maximum volume of 200 mL.

The desirability of local anesthesia may be appreciated when analyzing the patient population. A study at the Shouldice Hospital subsequently published revealed that 52.1% of all patients coming to surgery were older than 50 years (Table 189.1). Significant associated cardiac problems range from 15% to 50% (Table 189.2). The safety of local anesthesia increases the pool of patients who may undergo surgery. An added advantage is the lesser need for extensive consultations and investigations to assess the fitness of a patient to undergo surgery. This, in turn, drives down the cost of health care.

TABLE 189.1 Patient Population Older than Age 50[a]

Age Group (y)	Number of Patients	Number of Operations	Percent
50 to 59	1,116	1,369	19.1
60 to 69	1,330	1,533	21.4
70 to 79	603	689	9.6
80 to 91	124	144	2.0

[a]Data from 7,159 operations in 1990.

TABLE 189.2 Incidence of Associated Conditions in Patients Older than Age 50

Condition	Percent
Cardiac arrhythmias	50
Hypertension	20
Congestive heart failure therapy	17
History of myocardial infarction	15
History of angina	15
Anticoagulation (from warfarin, aspirin, sulfinpyrazone)	12

SURGICAL PRINCIPLES

The surgical aspect of the Shouldice Hospital repair can be broken down into two components: dissection and reconstruction. Before discussing each phase in detail, it would be of interest to emphasize some aspects of the procedure and to justify their importance. It must be stated that, at the Shouldice Hospital, though the technique is generally the same, all surgeons vary to a certain extent. These variations usually have to do with the degree of tension on sutures, the size of tissue bites incorporated, the extent of the dissection, full or partial division of the posterior wall of the canal, and time taken to perform a procedure.

Incision

The incision is lower than is described in most textbooks. It is made along a line joining the anterosuperior iliac spine and the pubic crest. This incision, once made, brings the inguinal area into full view without a strenuous retraction. The latter can be a source of discomfort under local anesthesia. The exposure, about the inguinal ligament, becomes ideal, and so does the pubic crest area.

External Oblique Muscle and Aponeurosis

The incision into the external oblique aponeurosis is extended from the

superficial inguinal ring to a point 2 to 4 cm lateral to the deep inguinal ring. This allows a thorough dissection of the deep ring and examination of the substance and quality of the fibers of the internal oblique and transversus abdominis muscles. Often, fatty infiltration of these muscles is seen near the deep ring, usually laterally and superolaterally, providing poor tissue for repair. One may also find preperitoneal fat protruding through this area, setting the stage for an interstitial hernia, a recurrent inguinal hernia, or an overlooked hernia. If need be, the deep ring is relocated by incising laterally the internal oblique and transversus abdominis fibers over a length of 1 to 3 cm.

Resection of the Cremaster

This important step seems to have been entirely forgotten. Few students have seen it performed, and fewer surgeons practice it. This step was clearly described and emphasized by Bassini, repeated by Catterina, and perpetuated by Shouldice. The resection of the cremaster and lateral retraction of the cord bring into view the posterior inguinal wall in a manner that can best be described as a "revelation." It becomes impossible, then, to overlook a direct or indirect inguinal hernia. The transversus abdominis aponeurosis (i.e., the posterior inguinal wall) is now in full view. Whenever possible, the cremasteric vessels should be doubly ligated separately from the cremasteric muscle.

Incision of the Posterior Wall of the Inguinal Canal

Division of the transversus abdominis aponeurosis and transversalis fascia (the true transversalis fascia, which is part of the endopelvic fascia and which lines the deep aspect of the groin) from the internal ring to the pubic crest is of paramount importance. It serves the purpose of identifying all hernial defects, however small. Redundant and weak transversus abdominis aponeurosis and transversalis fascias medial and lateral to the incision can be excised; this excision then defines the new edges, which will be sutured into the new posterior wall of the inguinal area.

In women, division of the posterior wall of the inguinal canal is not as crucial. Nevertheless, the lateral third of this wall must be incised to allow proper examination of the entire posterior wall and to verify the absence of a femoral hernia from the preperitoneal space, above the inguinal ligament. This attitude with regard to female patients was confirmed by a study carried out by Glassow. Between 1945 and 1959, 27,870 abdominal wall

herniorrhaphies were performed, 676 of them on women. Of these 676 inguinal hernias, 605 were indirect inguinal hernias (592 primary and 13 recurrences) and 71 were direct inguinal hernias (50 primary and 21 recurrences). Of the 50 primary direct inguinal hernias, 40 were accurately documented. The defect was located in the lateral half of the floor in 32 patients and in the medial half of the floor in eight patients. The solidity of the posterior inguinal floor in women is a fact easily observed in practice. The aforementioned figures place the incidence of a direct inguinal hernia in a woman at 0.2% of all abdominal wall hernias.

Search for a Peritoneal Protrusion

The search for a peritoneal protrusion must become a ritual. The experience of the Shouldice Hospital reveals that of all patients with recurrent inguinal hernias referred to that institution, 37% prove to have indirect inguinal hernias. It becomes imperative, then, during all inguinal herniorrhaphies to look for a peritoneal protrusion if an indirect sac is not identified. This protrusion is found on the medial aspect of the spermatic cord within the internal ring and deeper, closely adherent to the vas, from which it must be freed and allowed to retract back into the preperitoneal space. The presence of a peritoneal protrusion confirms the absence of an indirect inguinal hernia. Very rarely, two indirect sacs can be present.

Ligation of the Sac

The ligation and resection of a hernia sac can be likened to a symbolic gesture representing victory of surgery over disease. Most surgeons have resected this sac in the past, understandably so if it is elongated, tubular, or scarred or if strictures are present. Is “high” proximal or even simple resection necessary? Experience relating to sliding inguinal hernias reveals that once a sac and its contents are freed from the spermatic cord, the entire sac, regardless of its size, can simply and reliably be returned into the abdominal cavity. This fact emphasizes the importance and necessity of a good posterior inguinal wall and of its reconstruction as a barrier against recurrent herniation. It has been shown by Ryan and Welsh that the incidence of recurrence after repair of sliding indirect inguinal hernias is less than 1%. What is important, therefore, is that the dissection of an indirect sac be carried out as far as possible deep to the already enlarged internal ring. Once the sac is ligated (“high” or “low”) or even if it remains intact, it should easily be replaced and made to disappear in the

preperitoneal space.

Sliding Hernias

Sliding hernias need not present a problem. A surgeon about to enter practice generally anticipates with trepidation the first encounter with a "slider." So many procedures, often difficult to illustrate, abound in many texts and always prove to be confusing at best. In a report of 2,300 operations from the Shouldice Hospital analyzed by Welsh, only 11 recurrences were recorded. Of these 11, only one was a true recurrent sliding inguinal hernia; the other recurrences were five femoral hernias and five direct inguinal hernias. The standard Shouldice Hospital repair was used in each of the 2,300 operations. The emphasis here is on resection of the cremaster muscle; the proper dissection of the internal ring, which is already and usually enlarged, and resection of a peritoneal sac if such can be carried out safely. I generally prefer to leave the sac intact and simply reduce it. "High" ligation must never be the aim. If the least doubt emerges as to whether the sac can be safely incised, the sac must be left alone and returned to the preperitoneal space intact. This never presents a problem, because 90% of sliding hernias are easily reducible and do so spontaneously before surgical intervention.

Release of the Cribriform Fascia (Thigh Fascia)

After incision of the external oblique aponeurosis along the direction of its fibers, its lateral flap is held taut anteriorly and the fascia cribriforms, beneath the inguinal ligament, is incised from the level of the femoral vein to the medial aspect of the pectineus muscle. This maneuver frees the external oblique aponeurosis to an extent that makes it widely available for the inguinal repair. This step can be compared with the creation of a flap or a "plasty" or relaxing incision. This maneuver also allows examination of infrainguinal, femoral herniation.

Search for Multiple Hernias

Statistics show that a second, simultaneous, ipsilateral hernia was found, if adequately searched for, in 12.8% of the patients who underwent operation. This search in all instances must rule out an indirect hernia, a direct hernia, a femoral hernia, an interstitial hernia, a prevascular hernia, a Laugier hernia (through the lacunar ligament), a prevesicular hernia

(anterior to the bladder), and, lastly, lipomas, which on occasion perforate through the internal oblique and transversus muscles at the deep inguinal ring. The search must be established as a routine.

Relocation of the Superficial Ring

During reconstruction of the posterior inguinal wall, as we shall see, the fourth line of suture tacks down the medial 2 to 3 cm of the external oblique aponeurosis (the lateral flap) in such a manner as to cover the medial portion of the floor of the canal. This is the site of recurrence of most direct inguinal hernias (69.2% of recurrent direct inguinal hernias as reported by Obney and Chan). As a result, the superficial ring becomes relocated in a position slightly lateral from its original site.

Continuous, Nonabsorbable Suture

The continuous suture is considered to be significant, because it allows an even distribution of tension throughout the repair of the inguinal canal. Another important asset of the continuous suture is the elimination of any defect along the suture line, a defect that could otherwise enlarge with interrupted sutures and set the stage for a recurrence, perhaps.

Relaxing Incision

Relaxing incisions were introduced by Wölfler in 1892 and by Berger in 1902 and should be part of all inguinal herniorrhaphies in which tension is believed to be present along the suture line. The relaxing incision must be generous and extend from the level of the pubis to the level of the internal ring, on the anterior rectus sheath. To what extent tension is relieved has yet to be accurately measured. Yet, when the relaxing incision is made, whether a long single incision or several small (“pie-crusting”) incisions, an elliptical shape is immediately assumed. There is no need to cover the newly bare area caused by the relaxing incision since a new fascia develops to cover the denuded muscle, a fact recognized and reported by Koontz.

In a personal series of more than 15,000 operations, I have used a relaxing incision on more than 1,500 occasions without reservation or regret.

TECHNICAL ASPECTS OF THE SHOULDICE REPAIR

Local Anesthesia

The skin is infiltrated with 1% procaine hydrochloride from a level 2 to 3 cm away from the anterosuperior iliac spine, along a line directed toward the pubic spine. A wheal approximately 4 cm wide is raised. A volume of 60 to 90 mL of 1% procaine is required for this purpose (Fig. 189.1).

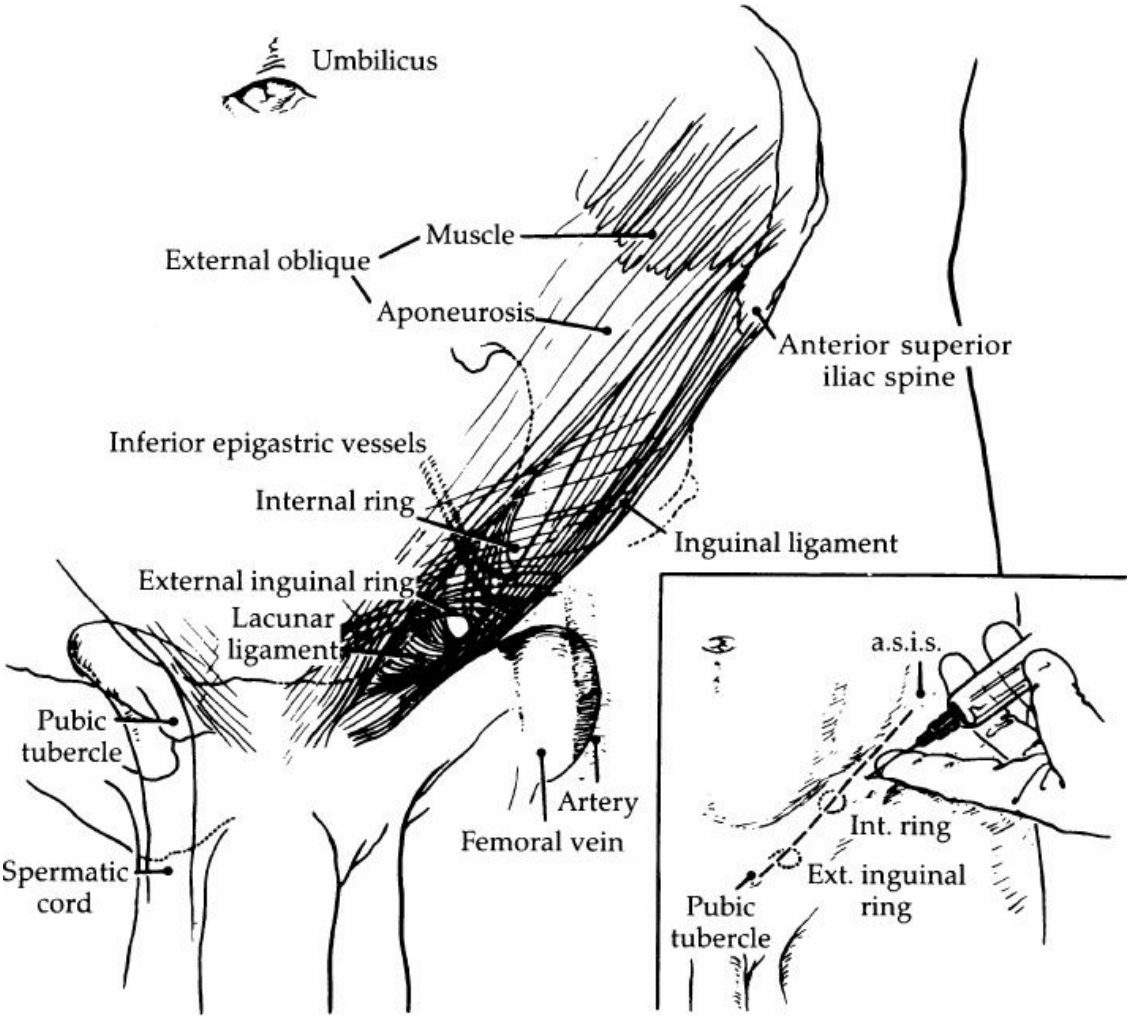

Figure 189.1. Local anesthesia along a line from the anterosuperior iliac spine to the pubic crest. Incision also follows that line; a.s.i.s., anterosuperior iliac spine.

Dissection

An incision is made over the medial two-thirds of a line joining the anterior superior iliac spine to the pubic spine. All subcutaneous bleeders are tied with polyglactin sutures. The external oblique aponeurosis now comes into view. Another 20 to 30 mL of procaine is injected deep to this aponeurosis (Fig. 189.2). Near the internal ring, the procaine is injected

deep enough to allow infiltration between the internal oblique and transversus muscles. This is the plane in which the ilioinguinal and iliohypogastric nerves emerge. More medially, these nerves are deep to the external oblique aponeurosis. The genital branch of the genitofemoral nerve, emerging at the internal ring, is more laterally placed, inferior and lateral to the spermatic cord, often within the substance of the cremaster.

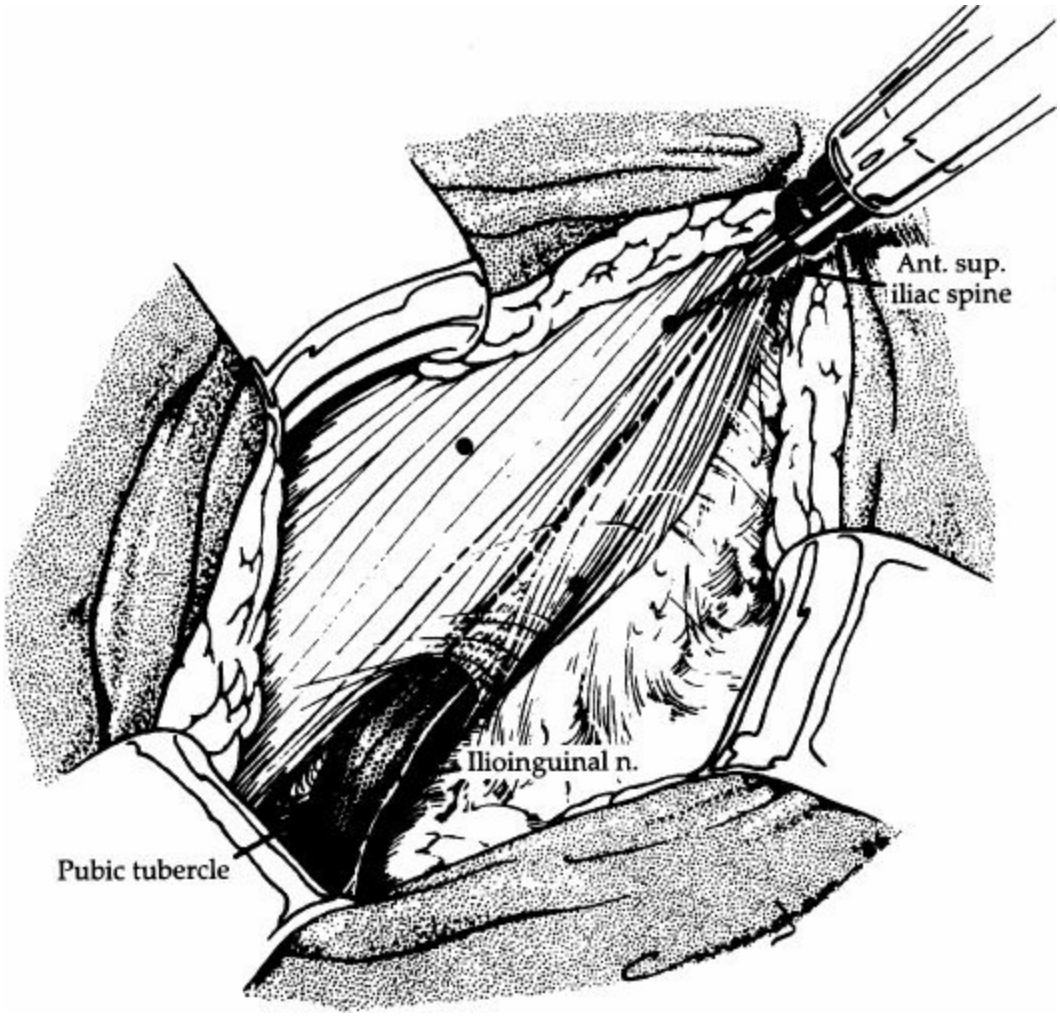

Figure 189.2. Local anesthetic should be generously injected deep to the external oblique aponeurosis.

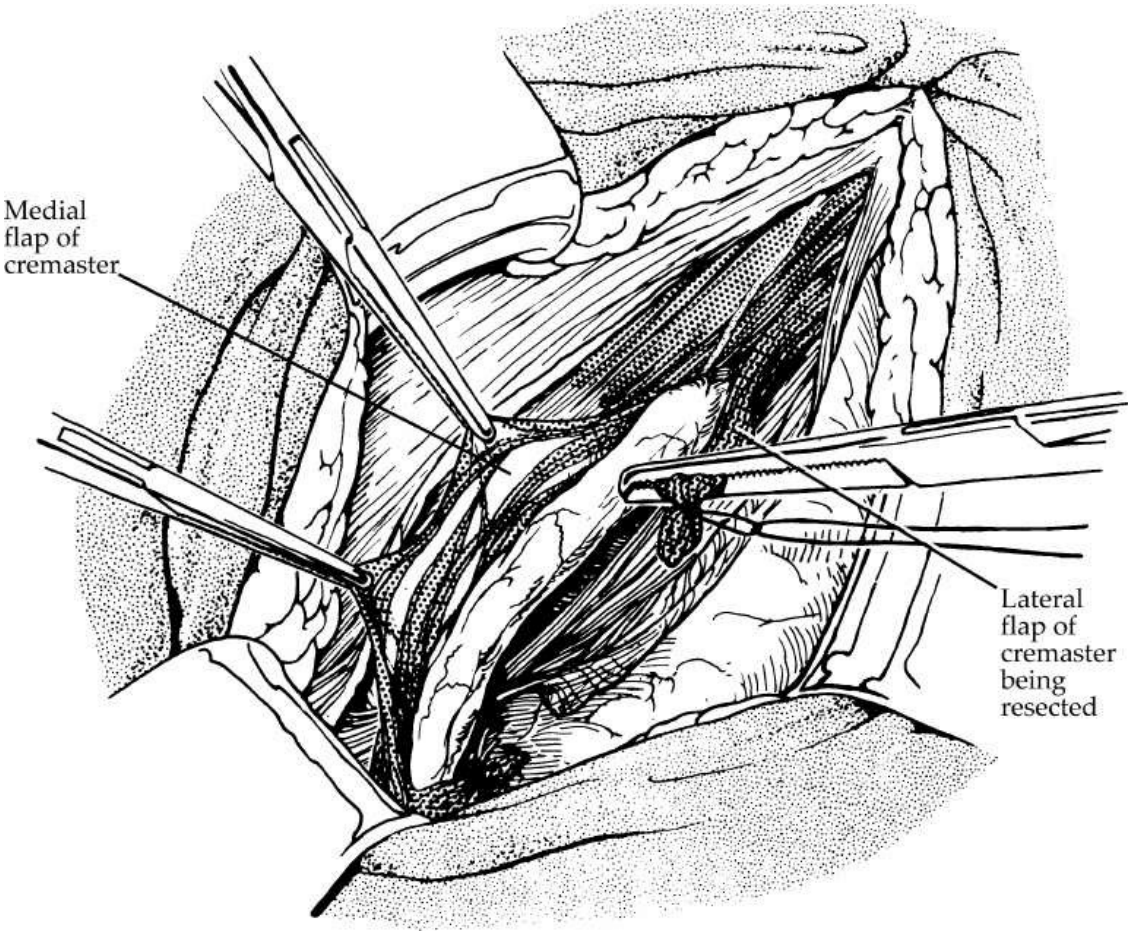

Figure 189.3. The cremaster muscle is divided longitudinally from pubic crest to internal ring.

The external oblique aponeurosis is now incised from the superficial ring to a point 2 to 3 cm lateral to the deep inguinal ring (Fig. 189.3). Each flap of the aponeurosis is widely undermined and freed. Each of the three nerves now becomes distinct and can again be infiltrated individually with 1 to 2 mL of procaine. Another 5 to 10 mL of procaine is injected within the loose areolar tissue around the spermatic cord at the deep inguinal ring and within the external spermatic fascia to block the conduction of the sympathetic pain fibers within this cord.

The cremaster muscle is now in full view and is incised on its anterior aspect, in the direction of its fibers. This incision is extended from the level of the pubic crest to the deep inguinal ring (Fig. 189.4). The vas deferens and accompanying vessels within and about the deep spermatic fascia are freed, leaving a thin flap of cremaster muscle medially and the other flap of cremaster with its cremasteric vessels and genital nerve laterally. This nerve is resected separately. The medial flap of the cremaster muscle is resected entirely. It often contains a small cremasteric

artery, which one must be careful to ligate. The lateral flap of the cremaster is doubly clamped and then divided, leaving two stumps, one medial and one lateral. Each stump is doubly ligated since it will contain cremasteric vessels that are substantial in size and could become a source of postoperative bleed. The double ligature of each stump will allow the insertion of a suture between the ligature, as we shall see later.

At this stage, another 10 to 15 mL of procaine is injected deep to the transversalis fascia. This anesthetizes smaller branches from the ilioinguinal and iliohypogastric nerves that perforate along the margin of the lateral edge of the rectus with the internal oblique–transversus muscle layer.

With the cremasteric muscle resected, it becomes impossible to miss an indirect sac. If no such sac is present, one must then dissect on the medial aspect of the cord along the vas deferens at the level of the internal ring to demonstrate a peritoneal protrusion. The protrusion is infiltrated with 2 to 3 mL of procaine, dissected free, and allowed to retract into the preperitoneal space.

If an indirect sac is found, the dissection is then carried out as deeply beneath the internal ring as feasible. The sac is resected, and the ligated stump of peritoneum retracts and disappears into the preperitoneal space. This ligation of the sac need not be as “high” as possible.

With the cremaster muscle out of the way and the spermatic cord retracted laterally, the posterior inguinal wall of the canal is in full view. The next step is an important one. It consists of dividing the posterior wall of the inguinal canal. This is performed by incising the transversus aponeurosis–transversalis fascia at the deep ring on its superomedial aspect to avoid injury to the inferior epigastric vessels (Fig. 189.5). This incision is extended to the pubic bone. Any direct inguinal herniation would be identified by separating the peritoneum from the transversus abdominis–transversalis fascia. A direct sac is rarely resected, unless a narrow or scarred neck is present. Once the transversus aponeurosis–transversalis fascia is divided, its two edges are trimmed. The lateral border is left 1 cm wide and is partly made up by the iliopubic tract (the bandelette of Thomson); the medial border is trimmed along the muscular edges of the internal oblique–transversus abdominis muscles.

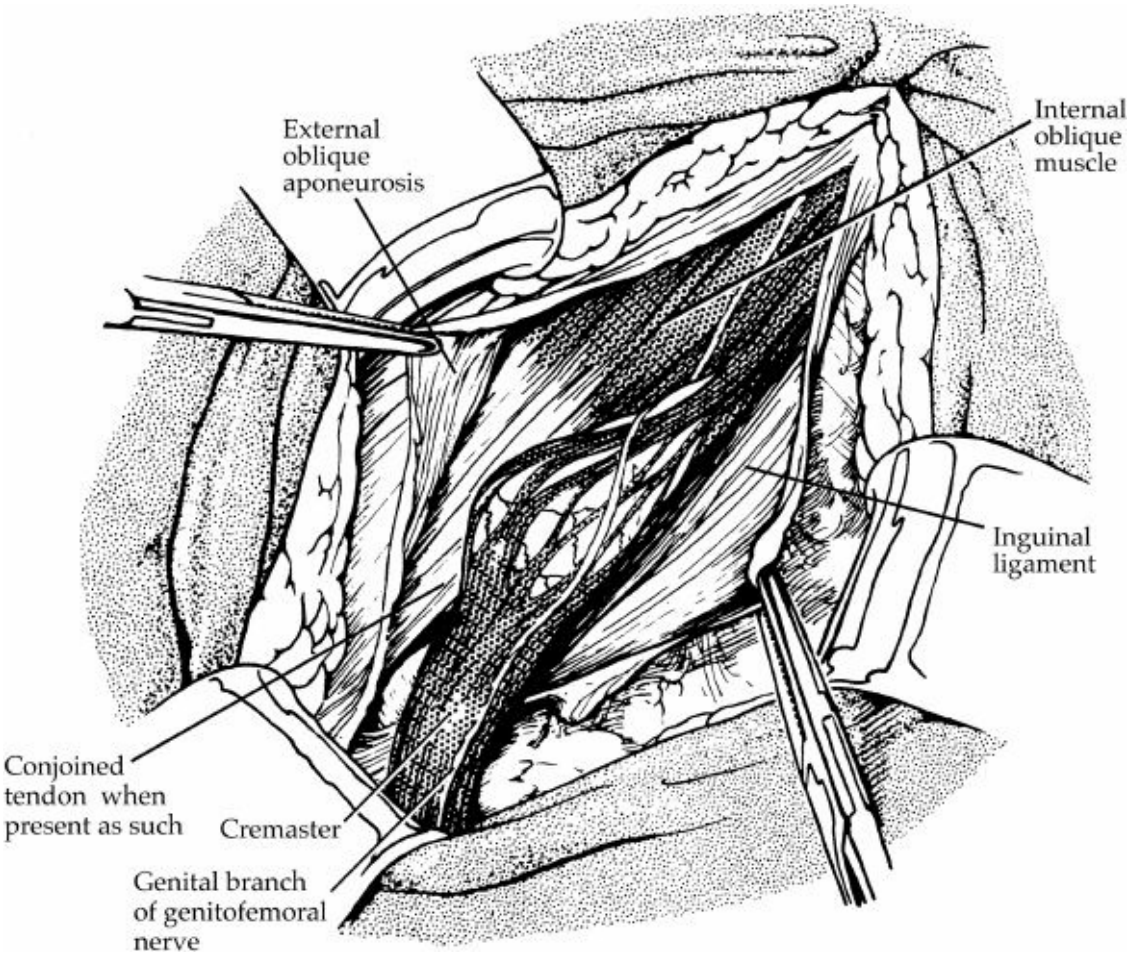

Figure 189.4. Exposure of the spermatic cord. An indirect inguinal hernia is identified.

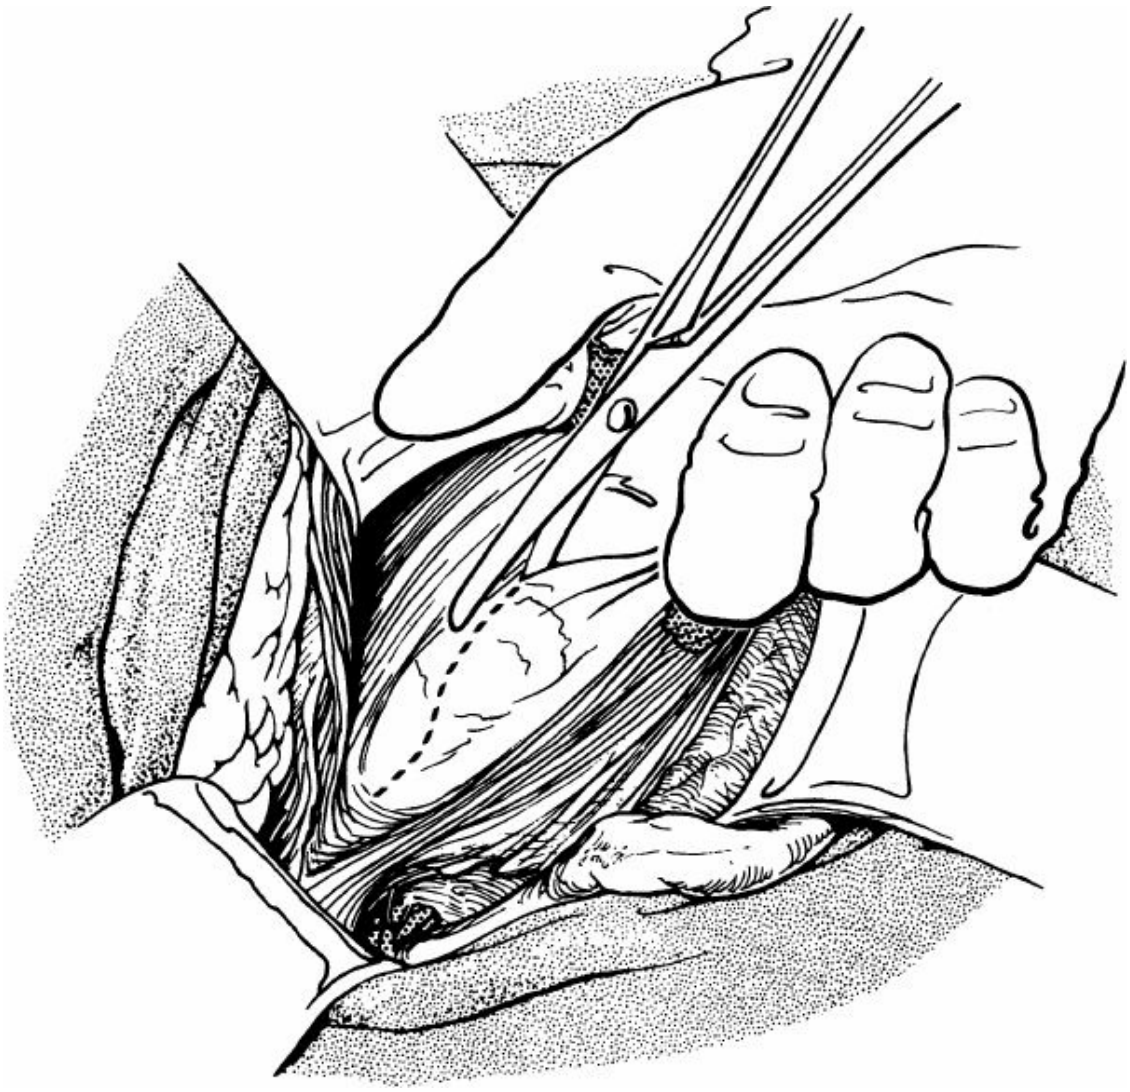

Figure 189.5. Splitting of transversalis fascia from the internal ring to the pubic crest (in all operations).

The dissection (Fig. 189.6) now reveals distinctly, on the medial side, from outside in, the edges of the internal oblique, transversus abdominis muscle to its aponeurosis, rectus abdominis, and, on occasion, the pyramidalis muscles, and deepest of all the true transversalis fascia, which is the inguinal portion of the endoabdominal fascia. Although the transversalis fascia is evident at this level, one can never rely on its solidity as a single layer. Laterally, however, the transversalis fascia thickens and becomes a part of the iliopubic tract. On the deep surface of this iliopubic tract, the superior pubic vein is identified, and care must be exercised to avoid injuring it. This vein can be the source of an important retropubic hematoma. The thigh fascia (cribriforms fascia) is now incised (Fig. 189.7) just beneath the inguinal ligament, from the level of the femoral vein to the pectineus and its overlying fascia. This maneuver frees the external aspect

of the lateral flap of the external oblique aponeurosis. It also allows examination of the inferior femoral opening. The superior femoral ring can be examined as well, because the division of the posterior inguinal allows access to the preperitoneal space of Bogros. The latter space is a lateral extension of the space of Retzius. The dissection is now complete.

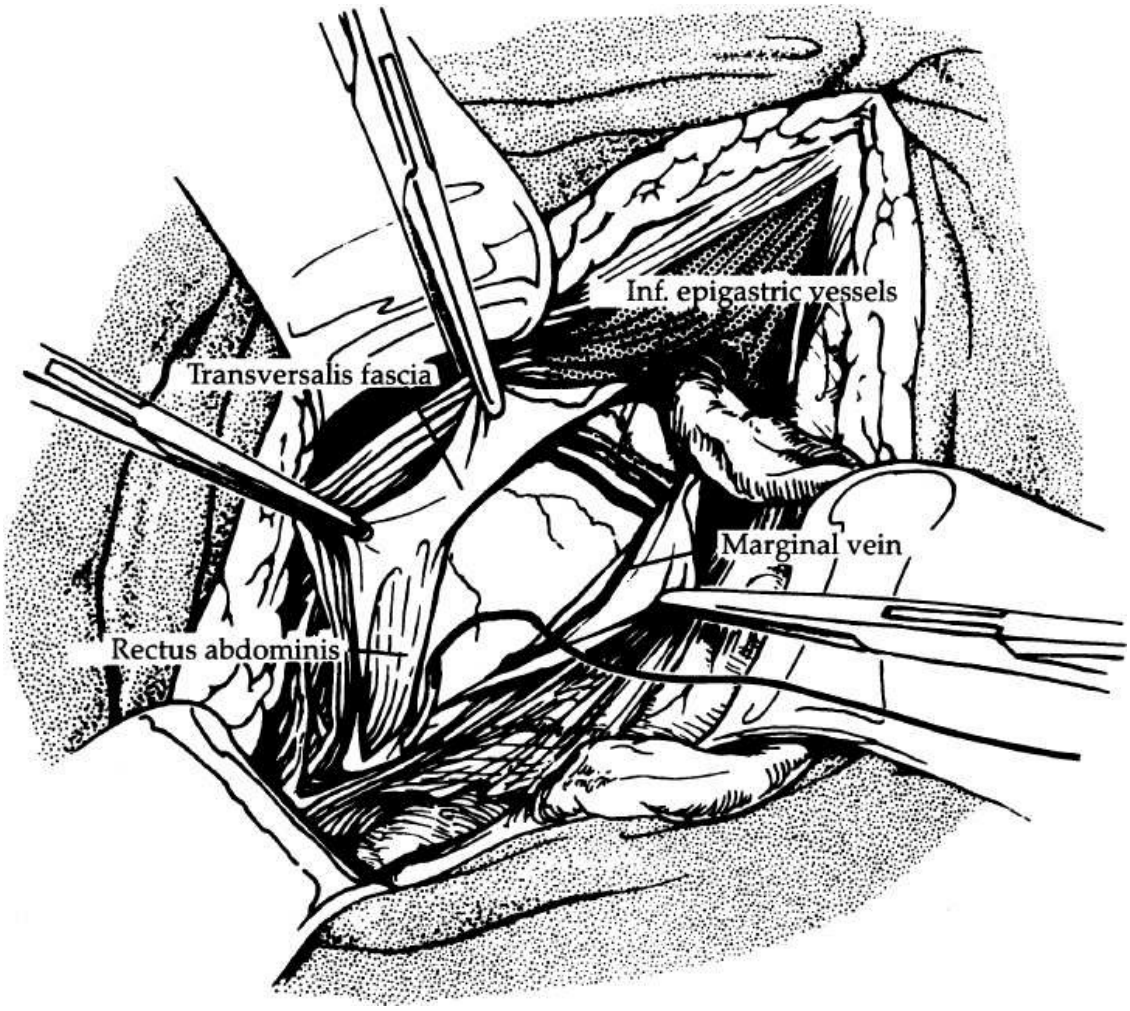

Figure 189.6. Appearance after completed dissection. Note the marginal iliopubic vein and the first line of suture.

Reconstruction

The repair can now begin, and the important objective becomes the construction of a solid posterior wall of the inguinal canal. Monofilament stainless-steel wire (32 or 34 gauge) has been used for many years, but this does not imply inadequacy of other suture materials, especially polypropylene.

The repair begins near the pubic spine (Figs. 189.6 and 189.8) by approximating the iliopubic tract laterally to the medial flap (which is

made up of the lateral edges of the rectus, the internal oblique and transversus abdominis muscles and/or aponeurosis, and the deepest layer, the transversalis fascia). The running suture is continued toward the internal ring. Halfway between the pubic spine and the internal ring, the lateral edge of the rectus abdominis becomes too distant and too medially placed and is no longer included in the running suture. Near the internal ring, the running suture picks up the lateral stump, between its two ligatures (Fig. 189.9), and then crosses over to the medial side to pierce through the transversalis fascia, transversus abdominis muscle, and internal oblique muscle, in that order, thus making the stump of the cremaster a deeper structure than the transversalis fascia. A new internal ring is thus recreated. The suture now reverses its course toward the pubic spine (Fig. 189.10). On its way, it approximates the medial edge (internal oblique and transversus muscles) to the shelving edge of the Poupart ligament. The two wire ends are knotted near the pubic spine. Two lines are thus made by the first wire.

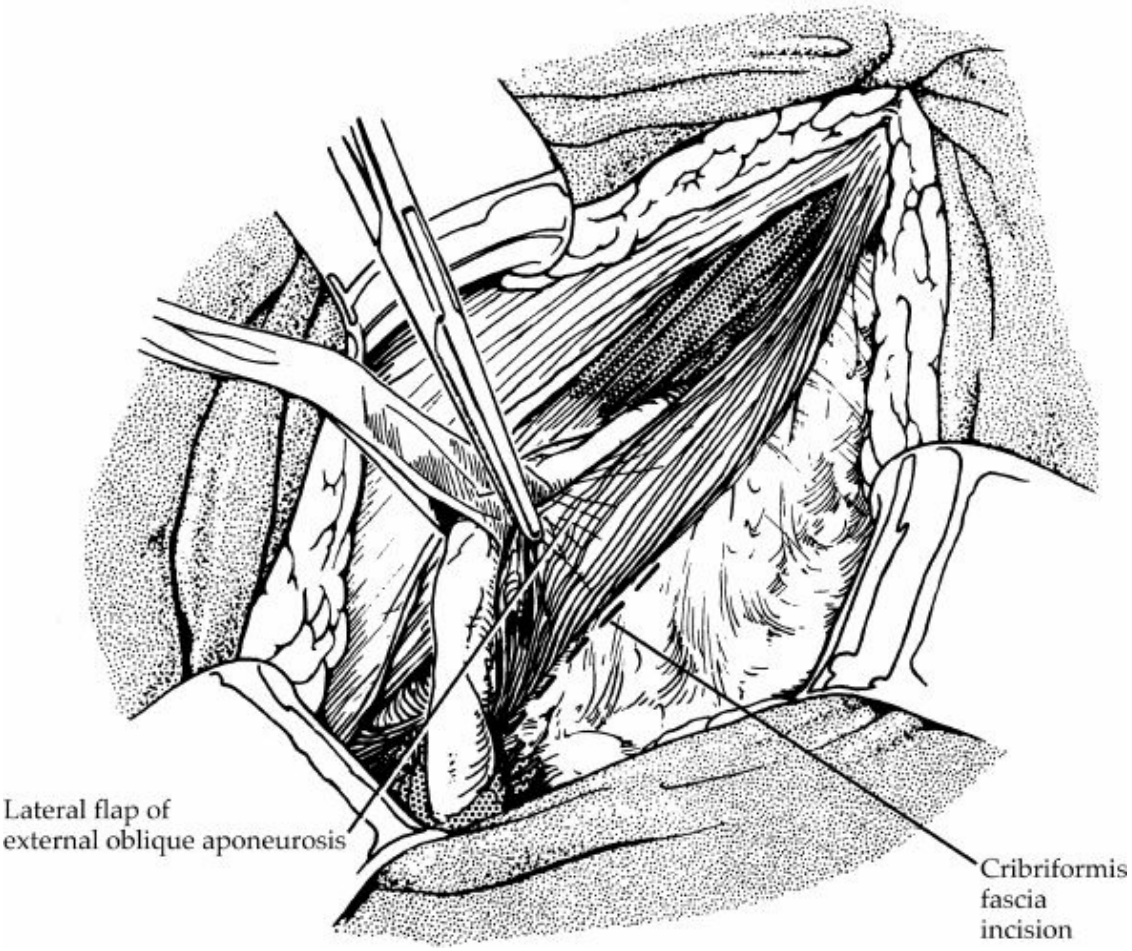

Figure 189.7. The undersurface of the inguinal ligament, medial to the femoral artery and vein, is freed from the thigh fascia to

rule out femoral hernias or femoral fat tabs.

Another two lines are now made by a second wire. The latter is started near the internal ring, picking up a full thickness of muscles medially (again, internal oblique and transversus) and approximating this layer to a band of external oblique aponeurosis (slightly superficial and parallel to the Poupart ligament) (Figs. 189.11 and 189.12). The third line is directed toward the pubic spine, where it then reverses its course back to the internal ring as a fourth line of wire suture. The fourth line again includes a full thickness medially (internal oblique and transversus muscles) to join the external oblique aponeurosis along a line yet more superficial and parallel to the inguinal ligament. The medial 2 to 3 cm of the external oblique aponeurosis, however, is made to lie completely flat on the medial aspect of the posterior wall of the inguinal canal (Fig. 189.13), reinforcing what is a common site for recurrences. This results in a lateral displacement (2 to 3 cm) of the superficial inguinal ring.

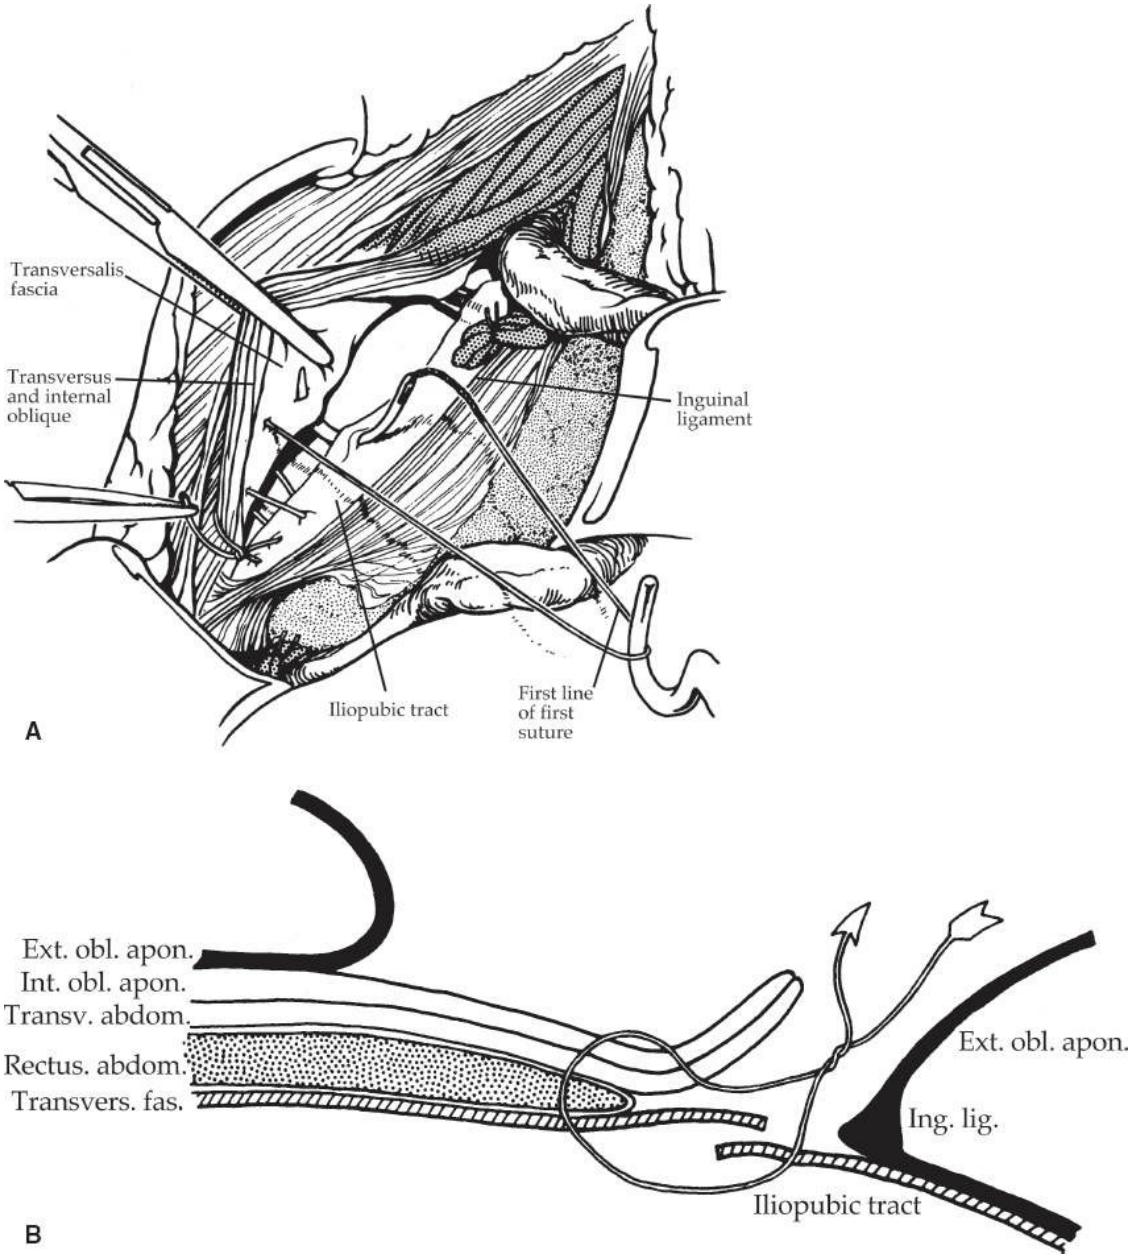

Figure 189.8. A: First line of suture continued. **B:** Cross section of (**A**).

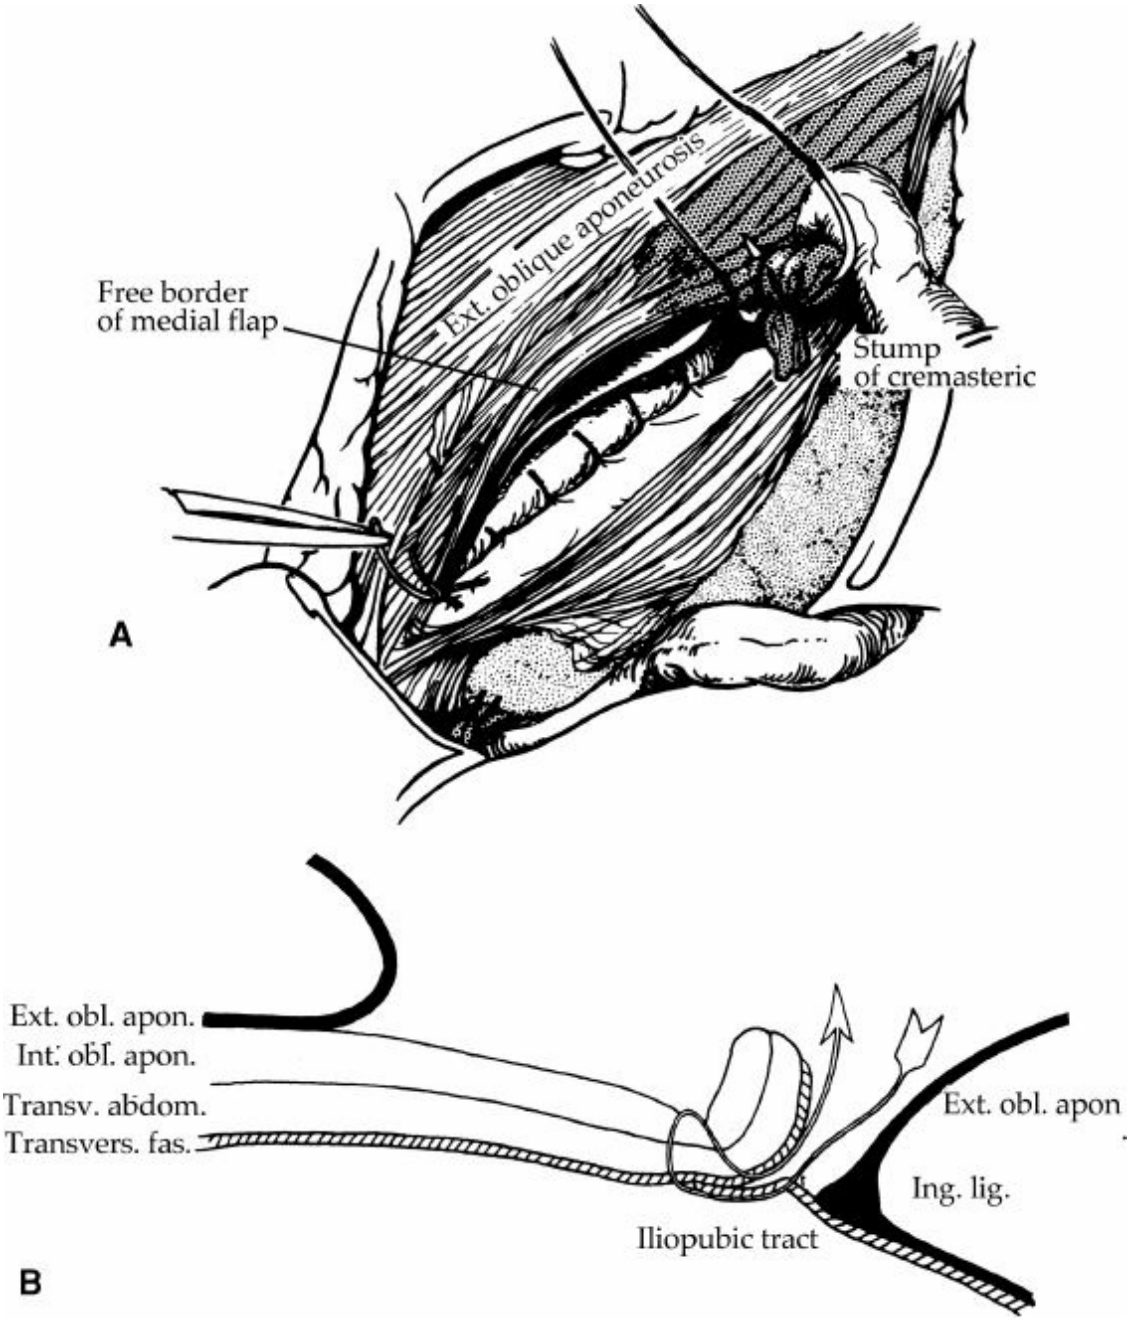

Figure 189.9. A: End of first line of suture and incorporation of the cremasteric stump. **B:** Cross section of (**A**).

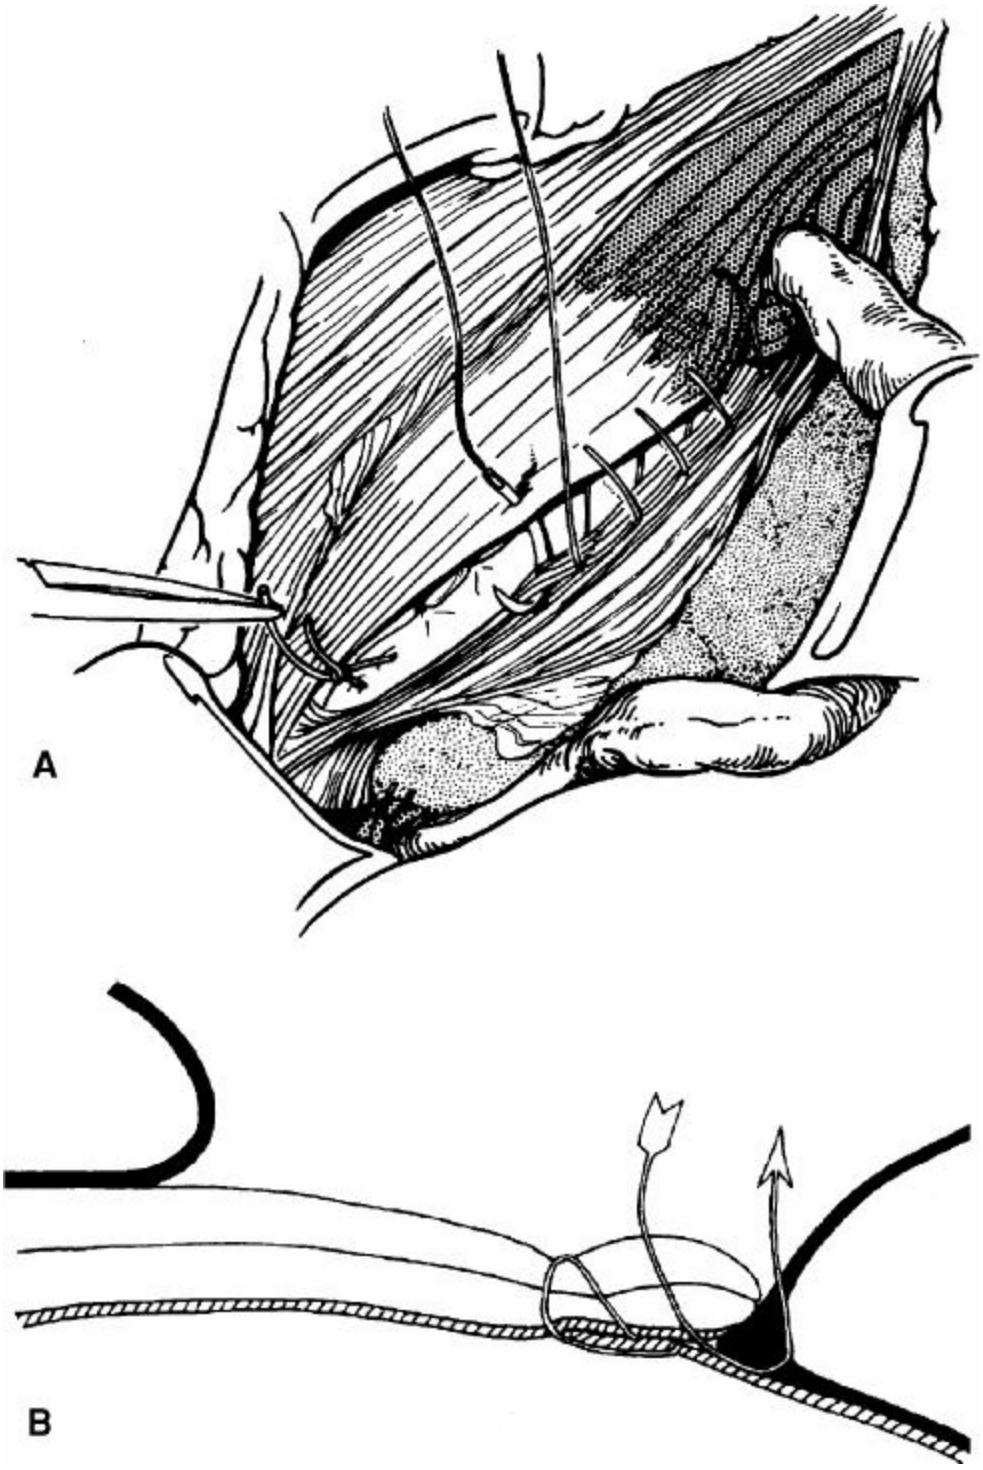

Figure 189.10. A: Second line of suture. This is really the first line of suture returning to the pubic crest to be tied. **B:** Cross section of (**A**).

Figure 189.11. **A:** Third line of suture. This is a different wire, which begins at the internal ring, goes toward the pubic crest, and returns as the fourth line to be tied at the internal ring. The running suture was left loose for the purpose of illustration. **B:** Cross section of (**A**).

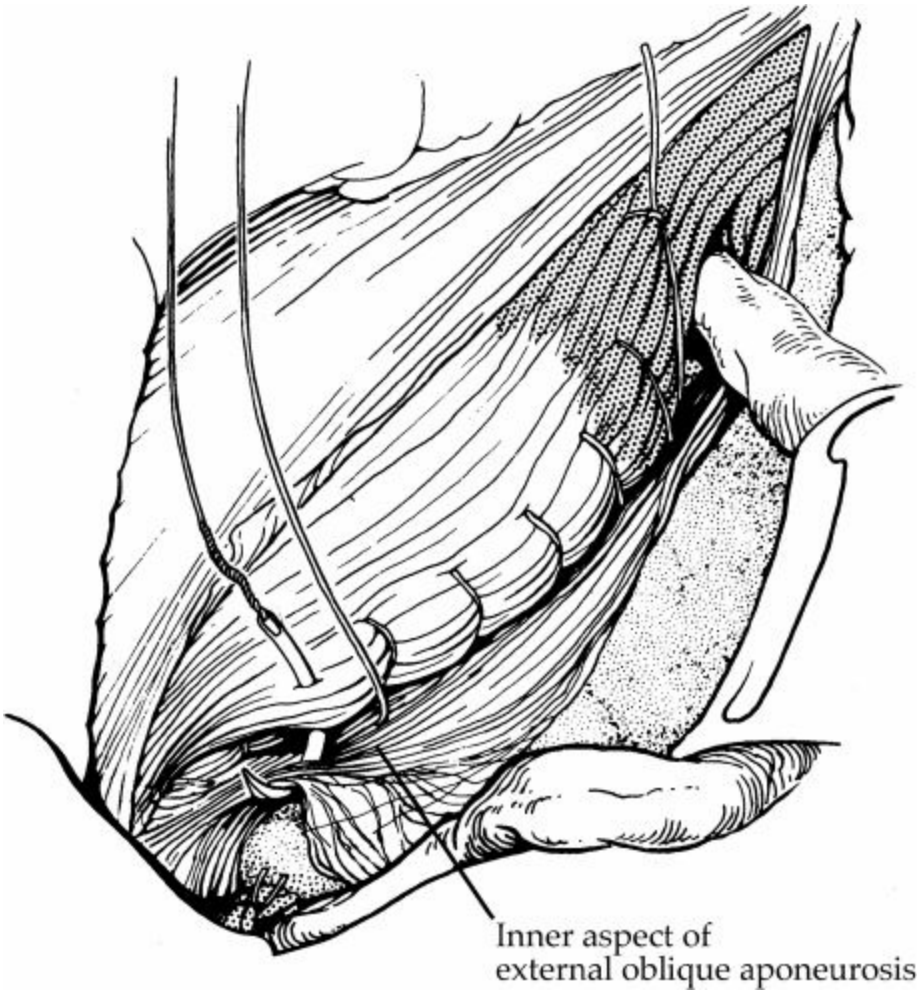

Figure 189.12. Continuation of third line.

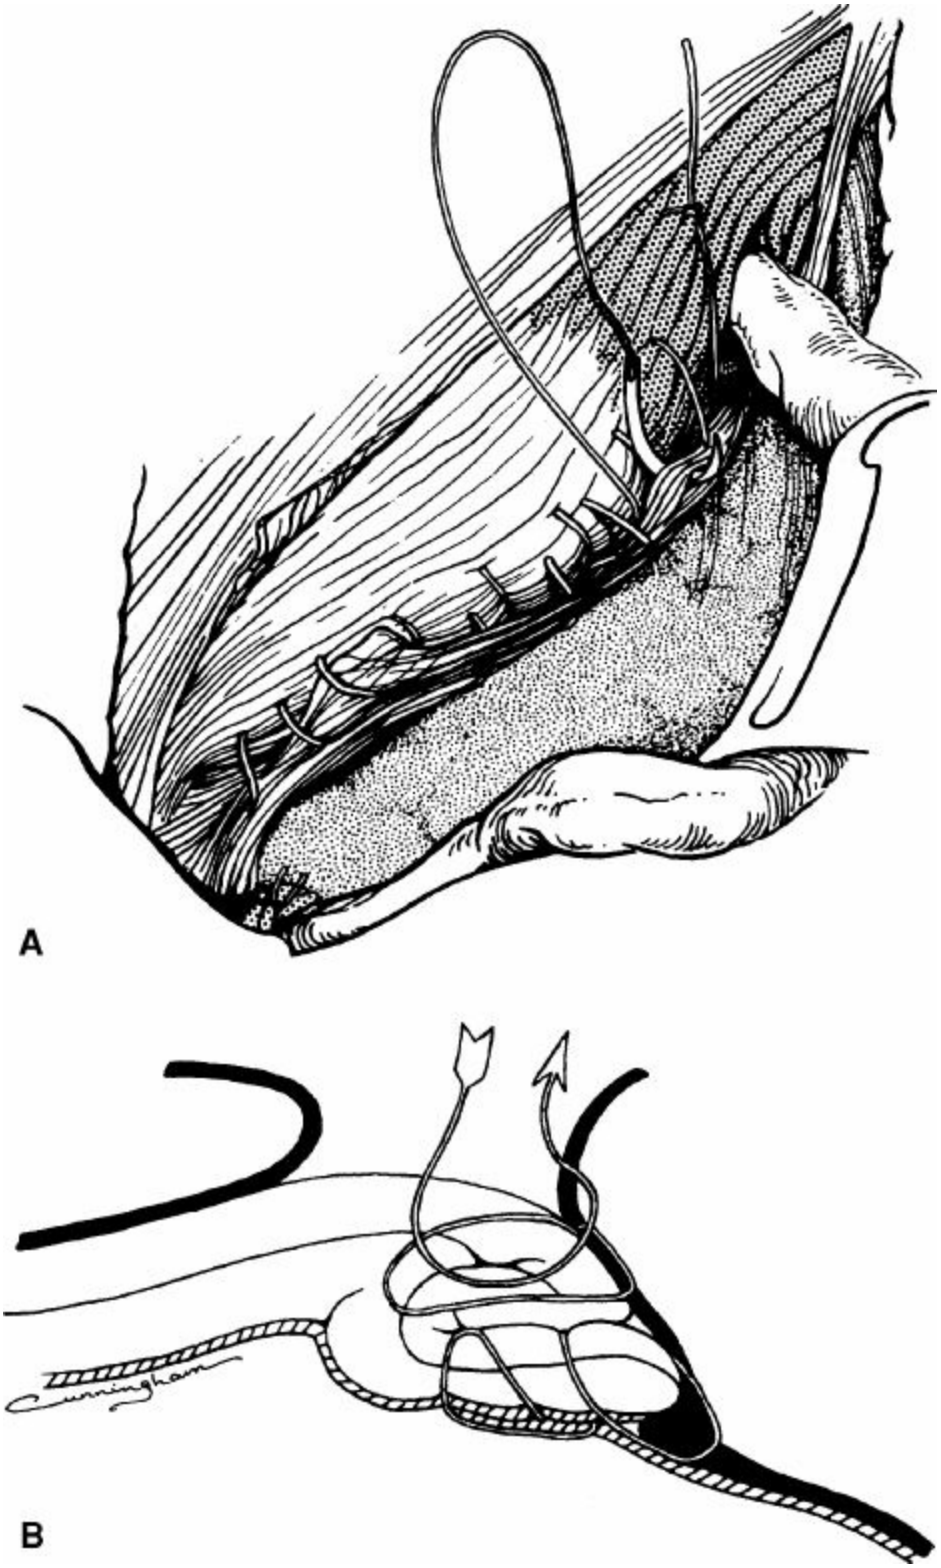

Figure 189.13. **A:** Fourth line of suture. **B:** Cross section of (**A**).

The medial stump of the cremaster muscle is now anchored to the most medial portion of the inguinal ligament or near the pubis–pubic ramus angle to prevent eventual drooping of the testicle. This drooping is a common complaint and is due to the resection of the cremaster and the

subsequent loss of its suspensory and retractile function. The spermatic cord is then replaced in its normal anatomic position, and the external oblique aponeurosis is approximated superficially to the cord (Fig. 189.14). The wound is closed with polyglactin sutures (subcutaneous tissues) and Michel clips (skin).

POSTOPERATIVE PERIOD

At the end of the operation, the patient stands and walks away from the operating table. Ambulation and activities are encouraged on the same day. Half of the Michel skin clips are removed 24 hours postoperatively, and the remaining clips are removed 48 hours postoperatively. I personally remove all clips the following day and apply Steri-Strips.

RESULTS AND FOLLOW-UP DATA

Since 1945, more than 300,000 herniorrhaphies have been performed. Although in 1945 the recurrence rate was 17.8%, the results have been improving: 3.2% in 1950, 1.4% in 1955, and 0.3% by 1980. The improvement was attributed to two factors: The implementation at the Shouldice Hospital (1952) by Ernest Ryan, to a large extent, of the revolutionary technical steps introduced by Bassini (1886) and, undoubtedly, the expertise of the surgeons who made hernia repairs their life's work, doing as many as 600 to a 1,000 cases a year! In an average year, approximately 7,500 operations are performed (Table 189.3).

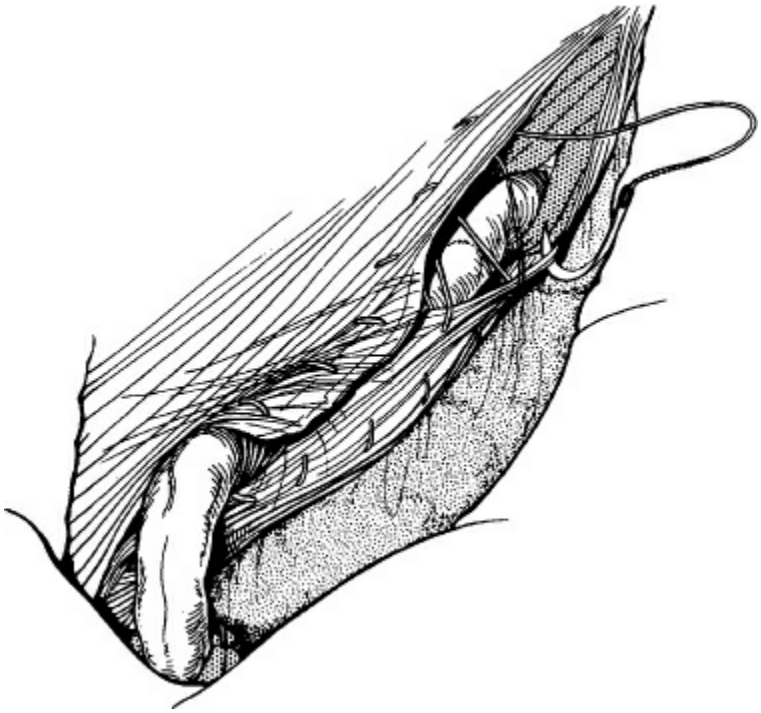

Figure 189.14. Fifth line of suture.

TABLE 189.3 Principal Hernias in 7,273 Operations in 1997

Hernia	Number of Hernias	Percent of Total
Indirect inguinal	4,057	55.8
Direct inguinal	2,460	33.8
Femoral	130	1.8
Umbilical	282	3.9
Epigastric	105	1.4
Incisional	131	1.8
Inguinofemoral	6	0.08
Others	102	1.4

Secondary hernias were seen in 12.8% of patients, a constant figure with little variation between 13% and 15%. A secondary hernia is defined as a second simultaneous hernia, lesser in size and importance, but, nevertheless, one that would have required surgical therapy. Such a hernia is usually discovered during an operation. The good results of the Shouldice repair have been reproduced in many centers, as shown in Table

189.4.

COMPLICATIONS

Complications of relative importance are recurrences, infections, hematomas, dysejaculation, hydroceles, and testicular atrophy.

Recurrences

The follow-up study is the most important critical index of the success of an operation. Follow-up findings were reviewed by Iles, and the same follow-up remains in use today. The data on 2,270 patients operated on in 1955 are presented in Table 189.5. Given the massive numbers, however, the follow-ups have not been statistically accurate and one can easily be overwhelmed and intimidated by those numbers. In a 10-year follow-up (in 1994) of 400 randomly selected patients who had their surgery in 1984, I was able to identify only 10% who had been followed up at least once or more times in that period, either by direct examination or by mail. A curve showing frequency of response reveals that patients are cooperative during the first year, less so after 2 years. The curve drops dramatically afterward. Though the follow-up may consist of 100,000 letters sent to patients, I was never too certain of the accuracy of a patient's own evaluation.

TABLE 189.4 Results of Shouldice Repairs at Other Centers

Author	Number of Cases	Follow-up (%)	Number of Years of Follow-up	Recurrence (%)
Shearburn	550	100	13	0.2
Volpe	415	50	3	0.2
Wantz (1)[a]	2,087		5	0.3
Bocchi	1,640	84	5	0.6
Myers	953	100	18	0.7
Devlin	350		6	0.8
Flament	134		6	0.9
Wantz (2)[a]	3,454		120	1.0
Moran	121		6	2.0
Berliner	591		25	2.7

[a]1 and 2 represent two different series published by G. Wantz.

Infections

More than 7,000 operations are performed yearly with an incidence of

infection of less than 1% and as low as 0.27%. All superficial abscesses were simply drained. I have never seen a deep abscess, that is, deep to the inguinal repair, within the preperitoneal space. If cellulitis was also evident, antibiotic coverage was added. In no instance was it necessary to take down the repair. The low incidence of infection reflects simply the fact that inguinal herniorrhaphies are "clean" operations performed in a "clean" environment. If a patient has any evidence, preoperatively, of any sepsis (e.g., in the genitourinary tract or lungs, or on the skin), the operation is deferred.

TABLE 189.5 Follow-up for 2,270 Patients (2,748 Repairs) Operated on at Shouldice Hospital, 1955

Year	Number of Recurrences
1955	3
1956	4
1957	1
1958	3
1959	3
1960	2
1961 to 1965	8
1966 to 1975	7
1976 to 1990	9
Cumulative total	40

Hematomas

A hematoma is a minor complication, but it may require taking the patient back to the operating room. In a personal series of 5,762 patients, there were 18 instances of hematoma formation (0.3%). All were subcutaneous, and all were recognized and treated within hours. Accurate knowledge of the circulation within the space of Bogros is essential as a preperitoneal bleed can be significant. I have been aware of three cases that have required blood transfusions at the Shouldice Hospital!

Hydroceles

Hydroceles after inguinal herniorrhaphies are a well-known complication.

Obney, from the Shouldice Hospital, reported an incidence of 0.7% after 14,442 inguinal repairs. He also pointed out that ligatures along the spermatic cord should be avoided, and that superficial and deep inguinal rings should be snug but not constrictive.

Testicular Atrophy

Testicular atrophy can be seen after the repair of recurrent inguinal hernias as well as primary hernias. Among 5,762 patients operated on from 1977 to 1984, there were five testicular atrophies after 4,782 repairs of primary inguinal hernias (0.1%) and nine testicular atrophies after 980 repairs of recurrent inguinal hernias (0.9%). The postoperative orchitis, which occurs more frequently, must not be mistaken for a threatening testicular atrophy, though it will mimic the clinical picture quite closely. The picture is one of pain, often excruciating, beginning anytime during the first 3 postoperative days, and swelling of the testicle with induration. This swelling may reach two to five times the size of a normal testis. The overlying skin is hot and stretched and shiny. A color Doppler examination will reveal the absence of circulation. Despite this clinical picture, a color Doppler will, in half the cases, reveal an intact circulation and those patients may be reassured that the testicle will survive the surgical trauma.

Dysejaculation

Dysejaculation is a clinical entity characterized by a burning and searing sensation just before, during, or after ejaculation. Although the condition was first reported at the Shouldice Hospital, there is no reason to believe that it is a complication of the Shouldice repair, but rather of all hernia repairs, with or without mesh. The mechanism is not clear and may be caused by strictures of the vas deferens with obstruction to the flow of ejaculate. Although the condition may at times be extremely painful, the prognosis is excellent. The patients identified numbered 26, with symptoms beginning 2 to 3 weeks after surgery and clearing in 1 to 5 years. By 1998, more than 200 cases had been identified.

TABLE 189.6 Postoperative Complications

Infection rate	0.3%
Recurrence rate	0.5% following primary repair 1.49% on 35-year follow-up
Testicular atrophy	0.1% after primary repair 1% after multiple repairs
Dysejaculation	0.25%
Pneumonia	Nearly nonexistent as a result of early ambulation
Phlebitis	
Atelectasis	
Pulmonary embolism	2
Renal failure	1
Stroke	7
Coronary thrombosis	20
Intestinal obstruction	4
Acute mesenteric thrombosis	1
Perforated duodenal ulcer	1
Spontaneous rupture of gallbladder	1
Necrotizing fasciitis	1
Mortality (of 229,000 operations, none direct result of surgery)	37 (0.0106%)

MAJOR COMPLICATIONS

Table 189.6 reports the list of major complications. There were 14 deaths in the hospital or within 30 days after the operation among 150,000 patients, a mortality of 1 in 10,000. In one case only was the mortality due to a femoral vein laceration and, therefore, was a direct result of the surgery.

EDITOR'S COMMENT

This is an excellent chapter on one of the classic methods of open hernia repair. Dr. Bendavid, a highly respected expert on hernia surgery, does an excellent job at the exposition of a repair, which has influenced hernia surgery around the world. After briefly reviewing the history of hernia surgery, starting with Bassini and his landmark contribution, which, as Dr. Bendavid says (and I agree), is basically the cornerstone on which all other hernia surgery is built; moving on to Fruchaud, with the myopectineal opening concept, which actually is the basis of many approaches, particularly the laparoscopic approaches and the extraperitoneal approaches; and then discussing work by Rives and Stoppa, who directly followed Fruchaud, this contribution is a landmark in its own right.

Dr. Bendavid emphasizes the dissection of the inguinal canal and its anatomy, which enables an excellent repair such as described. It is clear that this repair, which has influenced hernia surgery around the world, has become less common with the advent of the various meshes and not so much laparoscopic repair, which has not had a great deal of market penetration, at least in this country, and with the small incision patch or plus or what have you with artificial material. That is particularly unfortunate, since we are raising a generation of surgeons who have no understanding of the anatomy of the inguinal canal, which used to be a lot of fun in training residents. I personally do a modified Shouldice repair, or transversalis fascia repair, and I think in my

hands the recurrence rate is rather low and I donít have much in the way of inguinodynia to follow the repair. Just last week, a new chief resident asked if he could scrub in on one of the elective hernias that I was doing because he had never seen the anatomy of the inguinal canal after 7 years (two in research) in our program. He correctly stated that the reason he was scrubbing in was because there may be a time “when one needs to dissect out the inguinal canal.” Nonetheless, I think this is an enlightened attitude and one would rarely find it throughout most training programs in which the tension-free Lichtenstein repair or the Kugel plug or variations of the Gilbert plug and patch are utilized. I think this is most unfortunate because, at least in my practice, which generally consists of reoperative surgery, there is a need to know the inguinal canal, if only to correct the unfortunate situation of nerve entrapment by the mesh and inguinodynia, in which I have a thriving practice. It is probably fair to say that the knowledge of the inguinal canal by the average general surgeon who is confronted with a difficult situation will have to be referred to someone who for some reason has learned the anatomy of the inguinal canal, just like difficult right upper quadrants will have to be referred to a hepatobiliary or liver transplant surgeon because the average general surgeon will have so little exposure to the difficult right upper quadrant in which reoperation is required that it would be dangerous for that person to undertake it. I believe both of these situations are most unfortunate.

As I said in the introduction to this entire section, in the past 5 or 6 years, attention of the general surgical public has been turned from issues of recurrence to issues of postoperative pain or inguinodynia, and indeed this is largely the case. As I also have said previously, it is remarkable that the incidence of inguinodynia was substantial and yet no one seemed to recognize it. Nonetheless, recurrences and pain have been compared by three studies recently in which the Shouldice repair was compared with other approaches. Leibl et al. (*Br J Surg* 2000;87:780) started a randomized, prospective trial of transabdominal preperitoneal (TAPP) endoscopic technique versus the Shouldice repair. The end points were rates of recurrence, late complications, complaints, and patient satisfaction. This is a small study with only 48 patients in the TAPP group and 43 in the Shouldice group, and one wonders what the randomization was. There was one recurrence in the TAPP group and two recurrences in the Shouldice group. Five patients in the Shouldice group and three in the TAPP group reported slight discomfort in the inguinal region at the 6-year follow-up. The chronic pain syndrome was not observed. Of the 48 patients in the TAPP group, 96% (or 46), and of the Shouldice group, 81% (35 of 43) had complete satisfaction with the hernia report, the result not being statistically significant, but two patients in the laparoscopic group and eight in the Shouldice group were less than 100% satisfied, and this is statistically significant (P <0.05). In addition, the time to mobilization and the intake of postoperative analgesia was statistically significant between the two groups, favoring the laparoscopic group.

Fleming et al. (*Br J Surg* 2001;88:1183) in a somewhat larger study compared 117 total extraperitoneal endoscopic (TEP) and 115 Shouldice repairs. While the mean operating time was longer (70 vs. 56 min, $P = 0.0001$), patients were discharged earlier (68% vs. 48% within 1 d, $P = 0.00065$), returned to work quicker (14 vs. 30 d, $P = 0.01$), and had quicker lifestyle recovery (21 vs. 35 d, $P = 0.0001$). Open repair, however, was 40% cheaper. In an 86% follow-up after slightly over 1 year, the TEP repair had fewer complications (9% vs. 21%, $P = 0.05$) and had a better quality of life, work performance and satisfaction, physical symptoms, and well-being.

In a study that is probably more representative of the current surgery in the United States, Nordin et al. (*Br J Surg* 2002;89:45) compared a randomized clinical trial of the Shouldice procedure versus the Lichtenstein tension-free repair. Three hundred patients were randomized; however, in a novel addition five participating surgeons were taught to perform the two techniques in the standard fashion. The longest follow-up was 3 years, and it was done by a blinded assessor.

The Lichtenstein repair was considerably shorter. Seven recurrences were found in the Shouldice group and one in the mesh group, which was statistically significant, and chronic groin pain was reported at 4.2% in the Shouldice group and 5.6% in the Lichtenstein group. This was mild to moderate except in two patients who had the Shouldice operation. They concluded that the Lichtenstein repair was easier to learn, took less time, and resulted in fewer recurrences. Chronic pain syndrome was present in approximately 4% to 5% in both groups, with 2 patients out of the 300 having severe pain, both in the Shouldice groups.

Huang (*J Formosa Med Assoc* 1999;98[2]:122) reported on 212 patients with recurrent inguinal hernias who underwent surgical repair within a 10-year period. This is a complex paper that separates out unilateral first-time recurrent hernias, and they were treated by a modified Shouldice technique using the inguinal approach. Bilateral or multiple recurrent patients ($n = 125$) were treated with a Rives–Stoppa type of approach with a giant prosthesis reinforcement of the visceral sac, utilizing a midline preperitoneal approach. In the 87 patients who had the first-time recurrence there was testicular atrophy in three and femoral vein thrombosis in one. In the Stoppa-type repair in which the mesh was shortened by 2 cm from the classic description by Rives and Stoppa, scrotal fluid accumulation (nine patients), myocardial infarction (one patient) and failure of the peritoneum to grow over the mesh (one patient) were the principal complications. Interestingly, the average hospital stay was 3 days in the single recurrence and 6 days in the multiple recurrences, which probably reflects the social mores of Taiwan rather than medical necessity such as in the United States. Follow-up of up to 9 years revealed a 6% recurrence rate in the single recurrence group and a 2% recurrence rate in the Rives–Stoppa group, although in the summary of the article it is given as the UR group.

Thus, it appears as if the Shouldice repair can be performed in the hands of experts with quite a low recurrence rate, but perhaps is not as easily adaptable to

the general population. If one focuses on recurrence, it would appear that either a laparoscopic repair or a tension-free repair is most efficacious. Whatever the approach, it appears as if a 5% to 6% incidence of chronic pain of mild to moderate severity is a feature of inguinal hernia repair, although some contemporary series have reported up to 22%, which I find difficult to believe.

190 Iliopubic Tract Repair of Inguinal Hernia: The Anterior (Inguinal Canal) Approach

Robert E. Condon

*This Chapter can be accessed in the accompanying eBook edition (see inside front cover for access instructions).*

The fundamental defect in the structure of the anterior abdominal wall that allows the development of direct and indirect inguinal hernias lies in the deep—or transversus abdominis—musculoaponeurotic layer of the groin. Anatomic reconstruction of these hernias, therefore, involves closure of tissues within the transversus abdominis layer. Closure of the transversus abdominal layer is the only way of anatomically repairing the internal ring. The method of hernial repair described in this chapter—in which the hernia is repaired by the traditional anterior approach through the inguinal canal and the iliopubic tract is used as the anchor for the repair—evolved from an appreciation of groin anatomy gained by dissections in the anatomy laboratory, autopsy room, and operating room. In developing this method, I have emphasized the importance of reconstruction of relatively normal anatomy insofar as the individual situation allows. A thorough understanding of groin anatomy is absolutely essential to success in hernial repair.

The elements of successful construction of a sound primary repair of an inguinal hernia are as follows:

1. Know the anatomy, especially the structure of the transversus abdominis layer.
2. Remember that the anatomic relationships in the groin are relatively constant, although variation is the norm.
3. Identify the hernial defect intraoperatively by sharp dissection.
4. Excise the weak and redundant tissues overlying and surrounding the hernia.
5. Clear the borders of the hernial defect to strong tissue.

6. Test the tissue borders to ensure that they will retain sutures.
7. Close the defect by suture, avoiding tension by means of a relaxing incision when needed.
8. Insert a prosthesis whenever loss of tissue or the size of the hernia indicates that primary repair may not succeed.

In this chapter, techniques are described for the repair of typical indirect and direct inguinal hernias. Repair of a complete hernia—the variety of large indirect inguinal hernia that has destroyed the posterior wall of the inguinal canal—combines features of both indirect and direct repairs and is also discussed.

INDICATIONS

The anterior iliopubic tract repair is suitable for all varieties of indirect and direct inguinal hernias in adults. To avoid incision through the posterior inguinal wall, an area itself subject to herniation, femoral hernias should not be approached anteriorly; the posterior approach is preferred.

This method should not be used for repair of the small indirect inguinal hernia usually found in infants; such hernias do not greatly enlarge the deep inguinal ring and require only excision of the sac and, in some instances, one or two stitches to close the deep ring. Recurrence after previous repair of an indirect inguinal hernia typically occurs at the lateral aspect of the deep inguinal ring and can be repaired through an anterior approach; however, I prefer the posterior, or preperitoneal, approach through fresh tissue for repair of recurrent direct hernias under most circumstances. I also prefer a posterior approach for repair of suspected sliding hernias.

PREPARATION, INCISION, AND EXPOSURE OF THE HERNIA

Shave only the area around the proposed incision that will be covered by the dressing and adhesive tape postoperatively. It is not necessary to shave the entire perineum. Shaving should be done in the operating room immediately before skin preparation. Scrub the lower abdomen, perineum, scrotum, and upper thighs with an iodophor solution or chlorhexidine solution. Do not use alcohol-based solutions for skin preparation because they can cause painful scrotitis. In draping, place a sterile towel under the scrotum and a second one over it to permit aseptic access to the scrotum as

needed intraoperatively.

The deep inguinal ring, through which an indirect inguinal hernia obtrudes, is situated halfway between the pubic tubercle and the anterior superior iliac spine. The incision for repair of an indirect inguinal hernia is centered directly over the projected location of the deep inguinal ring and is made more or less transversely, following a natural skin crease or tension line (Fig. 190.1). In large or complete indirect inguinal hernias that involve the posterior wall of the inguinal canal, the incision is extended medially to provide additional access. In a direct inguinal hernia, the defect is situated between the deep inguinal ring and the pubic tubercle. The upper border of the hernial defect should be identified by palpation, and the incision should be placed just below the level of the superior margin of the direct inguinal hernial defect, centered on the hernial bulge, and made transversely, following a skin crease (Fig. 190.1). Incisions for repair of a direct hernia are located somewhat more medial and inferior to those used for repair of an indirect inguinal hernia.

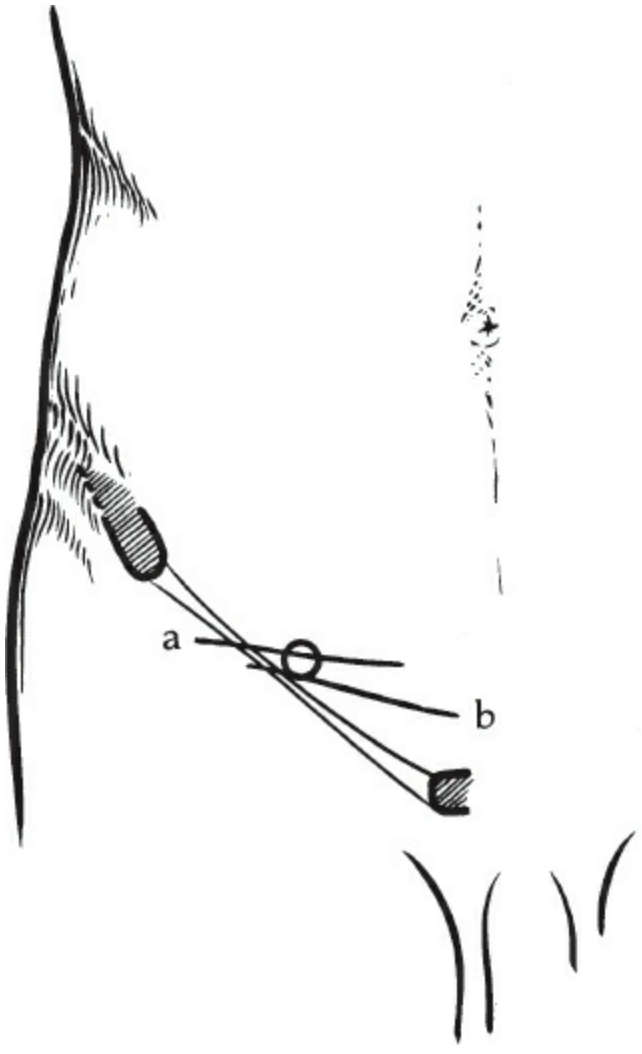

Figure 190.1. The incision for repair of an indirect hernia *(a)* is made transversely in a skin crease, centered on the projected location of the deep inguinal ring. The incision for repair of a direct inguinal hernia *(b)* is made transversely in a skin crease, centered on the hernial bulge and placed just below the palpable superior border of the hernial defect. (From Condon RE. Anterior iliopubic tract repair. In: Nyhus LM, Condon RE, eds. *Hernia.* 4th ed. Philadelphia, PA: Lippincott, 1995, with permission.)

The skin and most of the subcutaneous fat are incised in one sweep to expose the external oblique aponeurosis with its overlying investing (innominate) fascia. Branches of the superficial epigastric vessels are encountered in the medial half of the incision and of the superficial circumflex iliac vessels in the lateral half. The Scarpa fascia can sometimes be identified within the subcutaneous fat as an opaque layer; it does not need to be sutured during wound closure.

The skin and subcutaneous fat are retracted sufficiently to expose the upper portion of the superficial inguinal ring. It is not necessary to clean the external surface of the external oblique aponeurosis thoroughly. A small incision, approximately 1 cm long, is made with the knife between fibers of the external oblique aponeurosis in the middle portion of the main incision, placed so that, if extended, it carries into the apex of the superficial inguinal ring. The lower border of the external oblique incision is picked up with a Cushing forceps, and the closed points of a pair of Metzenbaum scissors are inserted and gently passed laterally on the deep aspect of the external oblique aponeurosis, separating the underlying internal oblique musculature and the iliohypogastric and ilioinguinal nerves from the external oblique aponeurosis.

One blade of the scissors is now inserted deep into the aponeurosis and the other blade is maintained superficial to it; the scissors, in a slightly open position, are pushed laterally between contiguous fibers of the external oblique aponeurosis to open the lateral aspect of this layer. Fine hemostats are applied to the edges of the incision in the external oblique aponeurosis to provide traction. The closed scissors tip is now directed medially beneath the external oblique aponeurosis, separating the underlying nerves and musculature, and the aponeurosis is split in a similar manner down to the superficial inguinal ring.

If dealing with an indirect inguinal hernia that has passed through the superficial ring into the scrotum, it may be necessary to open the

superficial ring; certainly, it is not necessary to do so on a routine basis. A self-retaining retractor is placed deep into the external oblique lamina at either end of the incision to maintain exposure of the deeper tissues. Care needs to be taken throughout this portion of the dissection to protect both the iliohypogastric and ilioinguinal nerves. Usually the ilioinguinal nerve has to be picked up gently and dissected free from the internal oblique muscle so that the nerve can be carried superiorly or inferiorly out of the surgical field and held behind a hemostat placed on the edge of the external oblique aponeurosis.

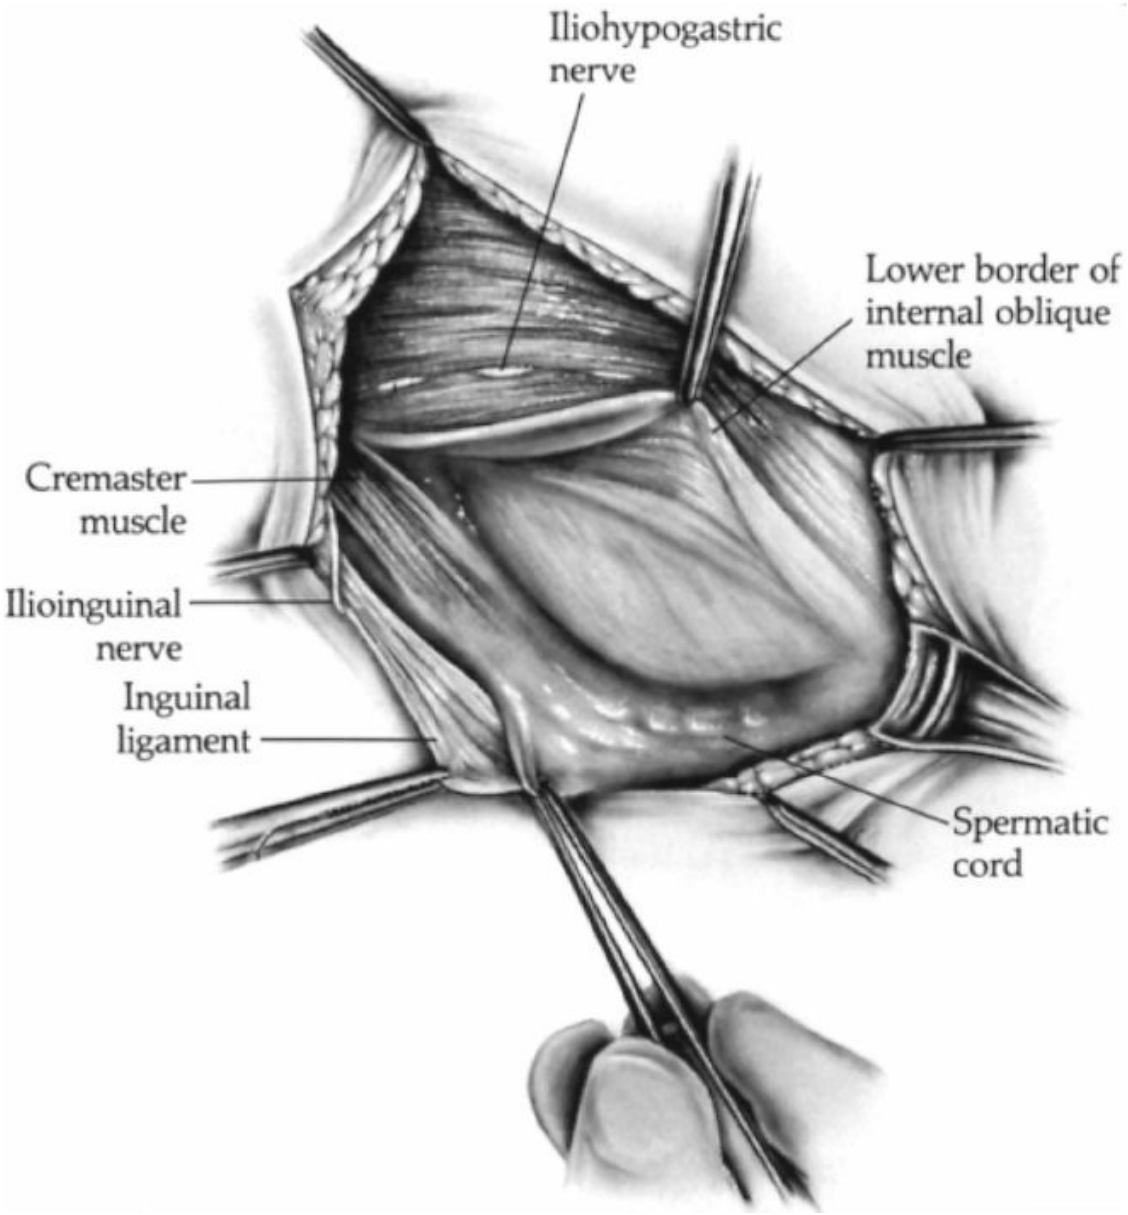

Figure 190.2. The plane between the internal oblique and cremaster muscles is completely opened between the pubic tubercle and the deep inguinal ring to begin mobilization of the

spermatic cord. (From Condon RE. Anterior iliopubic tract repair. In: Nyhus LM, Condon RE, eds. *Hernia*. 4th ed. Philadelphia, PA: Lippincott, 1995, with permission.)

The lower leaf of the external oblique aponeurosis is grasped in its middle portion and retracted inferiorly. The spermatic cord is grasped gently and retracted anteriorly and superiorly. The areolar attachments of the cremasteric fascia to the deep surface of the external oblique aponeurosis and the inguinal ligament are separated bluntly, the dissection continuing posteriorly until the deepest aspect (shelving border) of the inguinal ligament has been exposed from the pubic tubercle through the insertion of the cremaster muscle.

The spermatic cord is then gently retracted inferiorly. The lower border of the internal oblique muscle is found by identifying those muscle bundles that attach to the rectus sheath. The bundles of the cremaster muscle are identified by following them from their lateral attachment and noting that they continue with the spermatic cord. The lower border of the internal oblique muscle is retracted superiorly, the spermatic cord is retracted inferiorly, and the dissection is continued in the plane between the internal oblique and cremaster muscles on the superior and then the posterior aspect of the cord (Fig. 190.2), separating the cord from the posterior inguinal wall over the entire distance between the pubic tubercle and the medial border of the deep inguinal ring.

As mobilization of the spermatic cord proceeds, a small mesentery of cremasteric fascia on the deep aspect of the cord is developed. When the cord is sufficiently mobilized, the mesentery is transected or broken through bluntly, thrusting a finger from above to below and carefully avoiding the posterior wall of the inguinal canal. The cord is encircled with a small Penrose drain (Fig. 190.3A). The dissection is continued on the undersurface of the cord, progressing medially to the pubic tubercle and laterally beneath the deep inguinal ring to the origin of the cremaster muscle.

An indirect inguinal hernia can now be visualized as a bulging sac contained within the cremasteric fascia and the internal spermatic fascia and emerging through the deep inguinal ring on the superior aspect of the cord. A direct inguinal hernia presents as a diffuse bulge or redundancy of the posterior wall of the inguinal canal. A few fibers of transversus abdominis aponeurosis may be spread widely over the surface of a direct hernia, but for the most part, the hernial sac is composed of stretched

transversalis fascia and peritoneum.

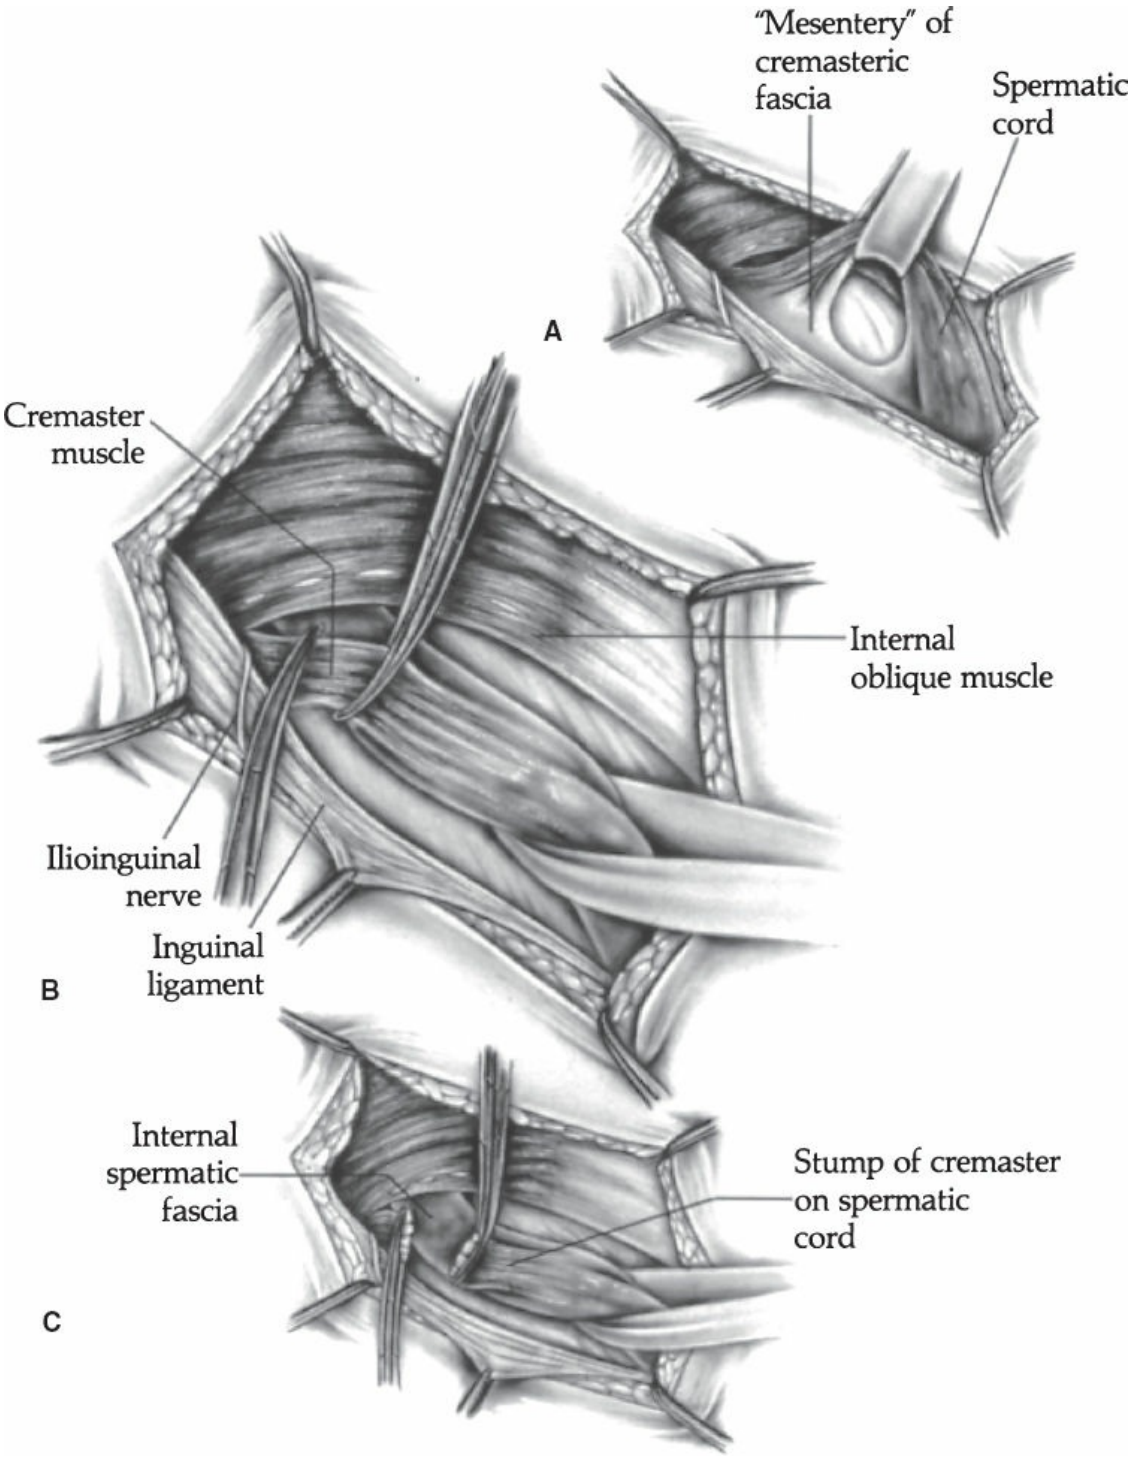

Figure 190.3. A: The mesentery of cremasteric fascia is opened bluntly and the cord retracted with a Penrose drain. **B:** The cremaster muscle is elevated near its origin and cross-clamped. **C:** The cremaster muscle is transected to expose the lateral side of the deep inguinal ring. (From Condon RE. Anterior iliopubic tract repair. In: Nyhus LM, Condon RE, eds. *Hernia.* 4th ed. Philadelphia, PA: Lippincott, 1995, with permission.)

The transversalis fascia is often opaque and may appear thick and

strong; the appearance, however, is illusory. Transversus aponeurosis, rather than transversalis fascia, must be identified and used for the repair. A complete inguinal hernia, the variety that begins as an indirect hernia but progressively enlarges medially to break down the posterior wall of the inguinal canal, has features of both indirect and direct hernias. At some point the displaced inferior epigastric vessels restrict the protrusion of peritoneum in a complete inguinal hernia, so that some "pantaloon effect" is usually present.

REPAIR OF AN INDIRECT INGUINAL HERNIA

In a typical indirect inguinal hernia, the sac is confined within the structures of the spermatic cord, and the posterior inguinal wall remains intact. It is essential that the entire circumference of the deep inguinal ring be exposed by dissection in the course of the hernial repair. This can be accomplished only by mobilization of the cremaster muscle to expose the lateral side of the deep inguinal ring, usually by transecting the cremaster muscle at its origin (Fig. 190.3B), although retracting the muscle is sufficient in some instances to provide the needed exposure.

At the lateral aspect of the deep inguinal ring, the tip of a hemostat is inserted bluntly from above downward, beneath the cremaster muscle but superficial to the iliopubic tract and the inguinal ligament. The ilioinguinal nerve is identified once again to be sure that it has been retracted and is protected. The cremaster muscle is mobilized and retracted to expose the lateral and inferior margins of the deep inguinal ring. Sometimes, to gain adequate exposure, it is necessary to transect the cremaster muscle. Paired hemostats are applied across the origin of the cremaster muscle, and the muscle is cut between the clamps (Fig. 190.3C). The proximal stump of cremaster muscle is suture-ligated to control the cremasteric artery; a simple ligature is sufficient to manage the distal stump.

Any remaining fascicular or areolar attachments of cremasteric fascia at the deep inguinal ring are transected about the entire circumference of the spermatic cord. Distal traction on the cord now makes the internal spermatic fascia (continuous with the transversalis fascia) stand out. The internal spermatic fascia is transected circumferentially around the hernial sac and cord approximately 1 cm distal to the deep inguinal ring. As this dissection proceeds at the inferior aspect of the deep inguinal ring, a small arterial branch, the external spermatic artery, may be noted perforating the transversalis fascia or the adjacent iliopubic tract to join the spermatic

cord; this vessel can be preserved or transected and ligated.

The peritoneal hernial sac, the margins of the deep inguinal ring, the iliopubic tract, and the transversus abdominis arch should now be identified. The iliopubic tract is present immediately adjacent to the inguinal ligament at the inferior aspect of the deep inguinal ring. The transversus abdominis arch can be palpated at the superior aspect of the deep inguinal ring after retracting the overlying lip of internal oblique muscle.

In most instances, the peritoneal sac protrudes through the superior aspect of the deep inguinal ring and is found along the anterior aspect of the cord. In unusual instances, the sac protrudes at the medial aspect of the deep ring between the spermatic cord and the inferior epigastric vessels. In recurrent hernias, the sac usually protrudes at the lateral aspect of the ring. Tendency to recurrence at the lateral aspect of the ring is dictated by the fact that this aspect of the ring usually has not been sutured by the surgeon performing the previous hernial repair.

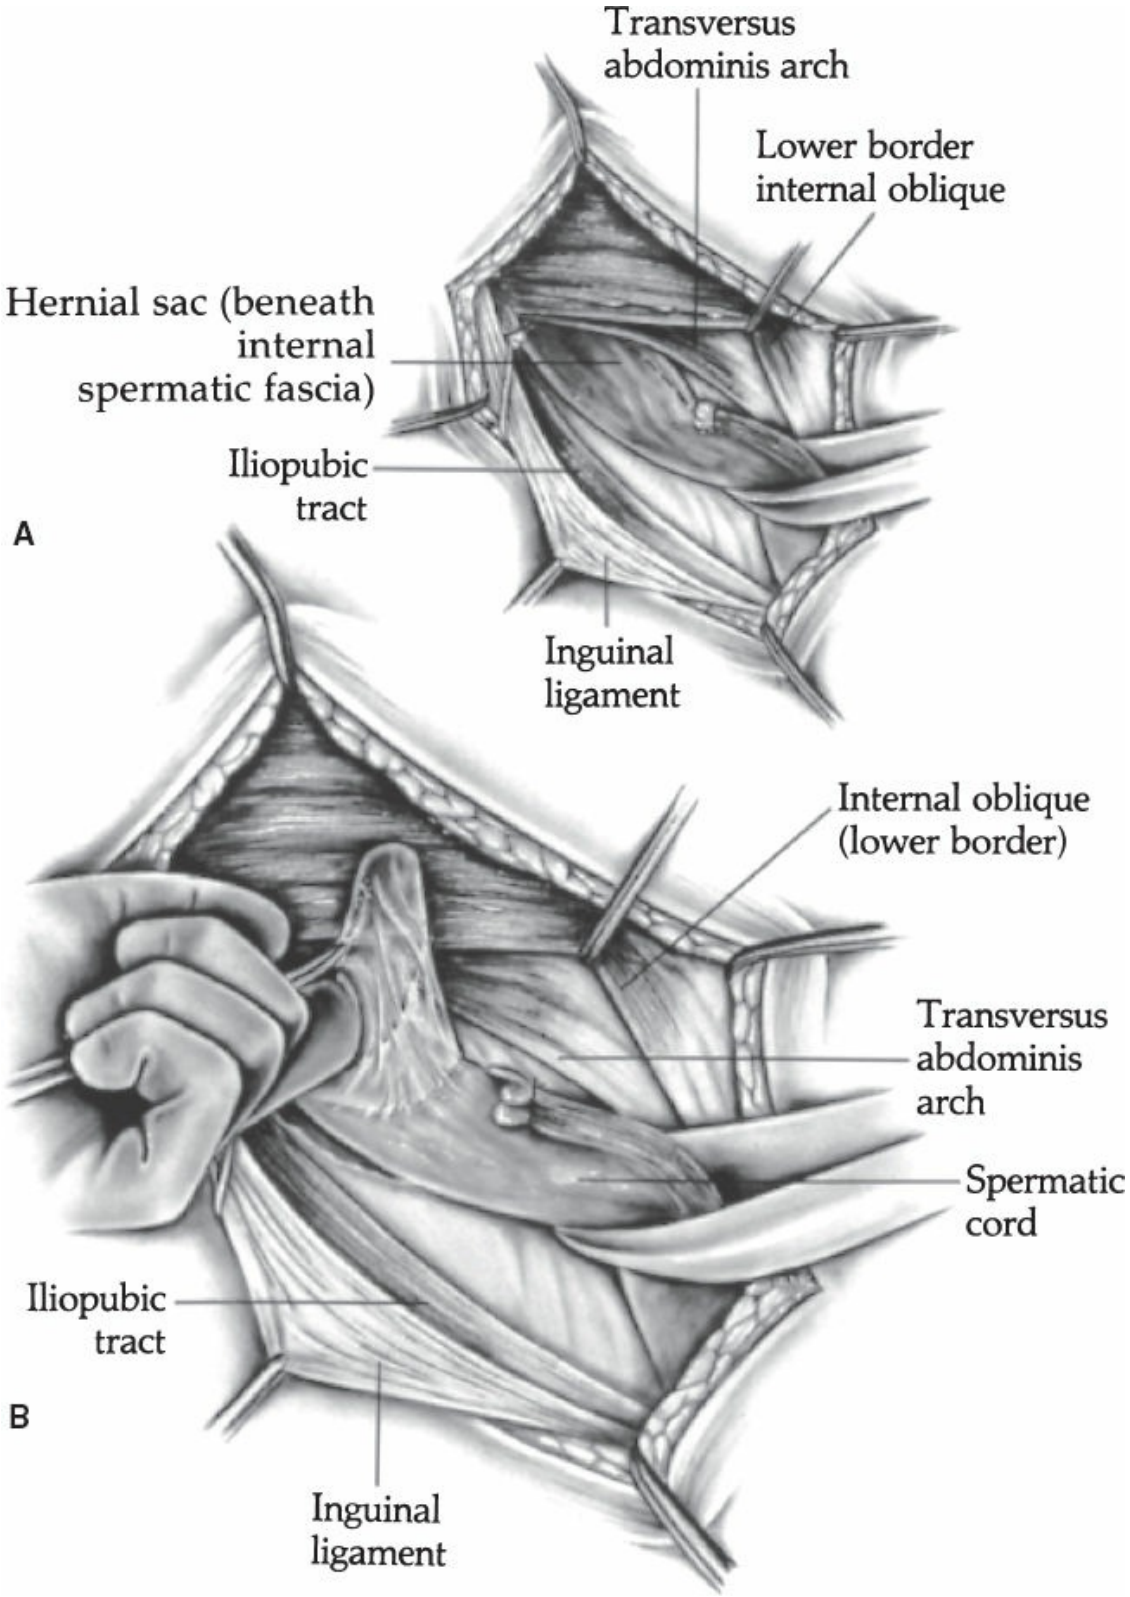

Figure 190.4. **A:** The peritoneal sac on the superoanterior aspect of the cord is incised just distal to the deep inguinal ring. **B:** The peritoneal sac is mobilized from the spermatic cord. (From Condon RE. Anterior iliopubic tract repair. In: Nyhus LM, Condon RE, eds. *Hernia*. 4th ed. Philadelphia, PA: Lippincott, 1995, with permission.)

The tissues covering the hernial sac within the cord—the cremasteric and internal spermatic fasciae—should be cleared from the sac by sharp dissection sufficiently to allow the surgeon to grasp the peritoneal sac directly. A small incision is made into the sac, 2 cm distal to the deep inguinal ring (Fig. 190.4A). The forefinger is inserted and directed distally through the incision. A fine hemostat is applied to the distal apex of the sac incision and held on traction in the palm of the operator's hand to facilitate subsequent dissection.

The sac is removed from the spermatic cord by upward and proximal traction maintained by flexing the forefinger within the sac while the cremasteric and internal spermatic fascia are cleared away, chiefly by sharp dissection (Fig. 190.4B). Sharp dissection is emphasized because blunt dissection increases the risk of injury to the blood vessels of the spermatic cord, which are spread out on the surface of the hernial sac. Clearing of the fascia from the hernial sac is facilitated by maintaining traction on the margins of the cremasteric and internal spermatic fasciae as the dissection proceeds. The dissection is made in the plane between the sac and fasciae, initially clearing the superior and anterior two-thirds of the circumference of the sac. As the initial segment is cleared, the incision in the sac is extended distally, the hemostat is replaced at the apex of the incision, the finger is thrust farther distally, and the dissection is continued until the apex of the sac is reached and mobilized. When the most distal end of the peritoneal sac is reached, the tip of the finger within the sac is flexed anteriorly, and dissection on the posterior aspect of the sac is continued back to the level of the deep inguinal ring.

Before excision and closure of the sac, a finger is inserted into the peritoneal cavity and the areas of femoral and direct inguinal herniation are palpated to ensure the absence of these hernias. In palpating the posterior wall of the inguinal canal from its internal aspect, sufficient pressure should be applied to the tissues to allow judgment as to whether the area is vulnerable to future direct herniation. If these tissues are relatively weak, the hernia should be managed as described later for a complete indirect inguinal hernia.

The finger is removed and the interior of the sac is inspected for the more or less continuous ring of peritoneal thickening and the scar that identifies the level of the deep inguinal ring. The sac can be either twisted and its apex transfixed with a suture ligature or closed with an external or internal purse-string suture placed at or above the level of the peritoneal

scar. The redundant peritoneal protrusion is then excised. Finally, the margins of the deep inguinal ring are cleared of any remaining bits of fatty or areolar tissue so that the entire circumference of the deep inguinal ring is clearly delineated.

The margin of the internal oblique muscle at the superior aspect of the deep inguinal ring is retracted superiorly. The underlying transversus abdominis arch is identified. The transversus abdominis arch is aponeurotic medially, becoming muscular laterally; aponeurotic fibers tend to run farther laterally on the deep aspect of this layer. It is important to be certain that the tissues of the transversus abdominis arch at the superior margin of the deep inguinal ring are sufficiently strong for sutures to be retained.

The iliopubic tract is visible along the inferior margin of the deep inguinal ring. Its full extent can be appreciated by grasping its upper margin with a forceps or hemostat and retracting superiorly while the inguinal ligament is retracted inferiorly. This maneuver also makes the line of demarcation between the iliopubic tract and the inguinal ligament quite clear.

A braided 00 nylon or polyester suture, swaged to a half-circle taper-point needle, is used for the repair. The spermatic cord is retracted to the lateral aspect of the deep ring. The first suture is placed through the transversus abdominis aponeurotic arch superior and medial to the deep inguinal ring, adjacent to the inferior epigastric vessels. The needle point is inserted from without to within the preperitoneal space and directed outward through the open deep inguinal ring.

After the needle is placed in the tissues, outward traction is applied to it to test the ability of the tissues grasped to hold the needle and, subsequently, the suture. As each bite of tissue is taken on each margin of the deep inguinal ring, the tissue is tested by tugging on the needle before its passage is completed to ensure that the tissues encompassed are sufficiently strong to retain the suture against moderate stress.

After the first suture is placed through the transversus abdominis arch, the needle is passed back through the deep ring into the preperitoneal space. It is directed just beneath the iliopubic tract and distally in a flat path anterior to the femoral vein for 1 cm or more before the point of the needle is rotated back through the iliopubic tract into the inguinal canal.

Occasionally, as the needle point turns back into the inguinal canal, it catches one or two fibers of the inguinal ligament. Although it is

unnecessary to include the inguinal ligament within the suture in most instances, I make no particular effort to replace the suture should a few fibers of the inguinal ligament happen to be caught within it. In those occasional instances in which the iliopubic tract is not sufficiently strong, it may be necessary to include a portion of the inguinal ligament deliberately to secure a sufficiently strong repair.

The ends of the initial suture are held and placed on moderate traction. A second suture is placed 5 to 7 mm lateral to the first, again encompassing a tested strong bite of transversus abdominis aponeurosis and muscle superiorly and iliopubic tract inferiorly. In passing the needle beneath the iliopubic tract, one must be aware that the deep circumflex iliac vessels are immediately subjacent; they are avoided by passing the needle tip flatly just beneath the iliopubic tract, encompassing a shallow amount of tissue in the anatomic anteroposterior plane but a substantial bite of tissue in the anatomic superoinferior plane.

Sufficient additional sutures are placed, spaced 5 to 7 mm apart, to accomplish closure of the medial portion of the deep inguinal ring. The objective is to place the exit of the spermatic cord through the reconstructed deep inguinal ring immediately superior and just lateral to the subjacent external iliac artery.

When all the medial sutures have been placed, the spermatic cord is retracted medially to expose the lateral aspect of the deep inguinal ring. Sutures are now inserted lateral to the spermatic cord, encompassing the transversus abdominis muscle above and the iliopubic tract and origin of the cremaster muscle below. In the lateral portion of the groin, the transversus abdominis arch may be almost entirely muscular; nonetheless, it must be tested by applying traction to ensure that the bite of tissue will hold the suture in place. Usually one to three sutures are used laterally to close the deep ring about the cord. The reconstructed deep ring should not be so tight as to cause undue swelling. In an occasional patient, the lateral margin of the deep ring is sufficiently strong and well defined so that suture closure is unnecessary; in such instances, the entire repair is conducted in the medial aspect of the ring. In the typical situation, however, both the medial and lateral aspects of the deep inguinal ring require reconstruction by suture if recurrence is to be prevented.

Sutures at the lateral aspect of the deep ring are tied after their placement. The cord is once again retracted laterally and the sutures in the medial portion of the repair are tied, beginning with the most medial suture

and progressing laterally. At the completion of reconstruction of the deep inguinal ring, it should be possible to pass the tip of a large, blunt hemostat alongside the cord.

REPAIR OF A DIRECT INGUINAL HERNIA

Although it is not necessary to excise the peritoneal sac of a typical direct inguinal hernia, it is necessary to incise the transversalis fascia and gain access to the preperitoneal space to facilitate identification and dissection of the fascial margins of the direct hernial defect. Redundant, stretched-out transversalis fascia is excised. In those rare instances in which there is also a great excess of peritoneum, the redundant peritoneum can be opened and the excess excised, followed by running closure with absorbable suture.

In the typical situation, a small incision is made through the transversalis fascia (posterior wall of the inguinal canal) approximately 1.0 to 1.5 cm above the superior ramus of the pubis. The lower margin of the transversalis fascia is grasped with a hemostat and retracted inferiorly. Blunt dissection with a “peanut” or smaller dissector is used to begin mobilization of the preperitoneal tissues from the overlying transversalis fascia. The underlying peritoneum and preperitoneal fat are pushed away from the internal aspect of the transversalis fascia all along the superior ramus of the pubis. This dissection should be carried out with care not to damage the arterial and venous blood vessels, or “corona mortis,” which are found lying on or near the Cooper ligament. The pubic tubercle, Cooper ligament, and adjacent portions of the iliopubic tract should be identified and cleared.

In dissecting along the medial aspect of a direct hernial defect, one must take care not to injure the urinary bladder, which may have become incorporated in a large direct inguinal hernia. Care also needs to be exercised to avoid entering the prevesical space or damaging the many blood vessels situated there.

The inferior epigastric vessels are identified along the lateral margin of the direct hernial defect and gently mobilized with the preperitoneal tissues and away from the overlying transversus abdominis aponeurosis and muscle. Finally, a finger is inserted into the developing preperitoneal dissection plane and is swept superiorly to identify the arch of the transversus abdominis aponeurosis along the superior margin of the direct hernial defect. Redundant and weakened transversalis fascia can now be excised to expose cleanly all the fascial margins about the direct hernia

defect.

If the patient is managed with a general anesthetic, the typical direct hernial defect can be closed primarily before a relaxing incision is made. A relaxing incision must be made, however, in all primary repairs of direct hernias. If the repair is conducted under a local anesthetic, a relaxing incision must be made before suture closure of the hernial defect is attempted. If there is any question about undue tension in the repair, a mesh prosthesis should be inserted.

Nonabsorbable 00 braided nylon or polyester sutures swaged to sturdy half-round taper-point needles are used for the repair. I prefer interrupted sutures, although running sutures are acceptable for repair of a direct hernia.

The initial suture is placed through the transversus abdominis aponeurosis immediately superior to the pubic tubercle, carried from without to within the preperitoneal space. Quite often this suture also grasps a portion of the rectus sheath, but the tendon of the rectus abdominis muscle must be avoided. As the needle is passed through the transversus abdominis aponeurosis, the strength of tissue encompassed is tested by placing the needle on traction.

The initial suture is extracted through the hernial defect, regrasped, passed back into the preperitoneal space, and carried through the periosteum and ligaments overlying the internal aspect of the pubic tubercle, testing for solid placement as described.

Sutures are placed successively (Fig. 190.5), approximately 7 to 8 mm apart, through the arch of the transversus abdominis aponeurosis, which forms the superior border of the direct hernial defect, and in turn through the Cooper ligament and the iliopubic tract along the inferior border of the direct hernial defect. In general, two or three sutures are placed through the Cooper ligament and the remainder through the iliopubic tract overlying the femoral canal. All the sutures are placed before being tied. The size of the femoral canal should be checked by palpation before the sutures are tied. If the canal seems particularly wide, an additional one or two sutures may be needed to close its medial aspect. The sutures are then tied, progressing from either medial to lateral or vice versa as convenient.

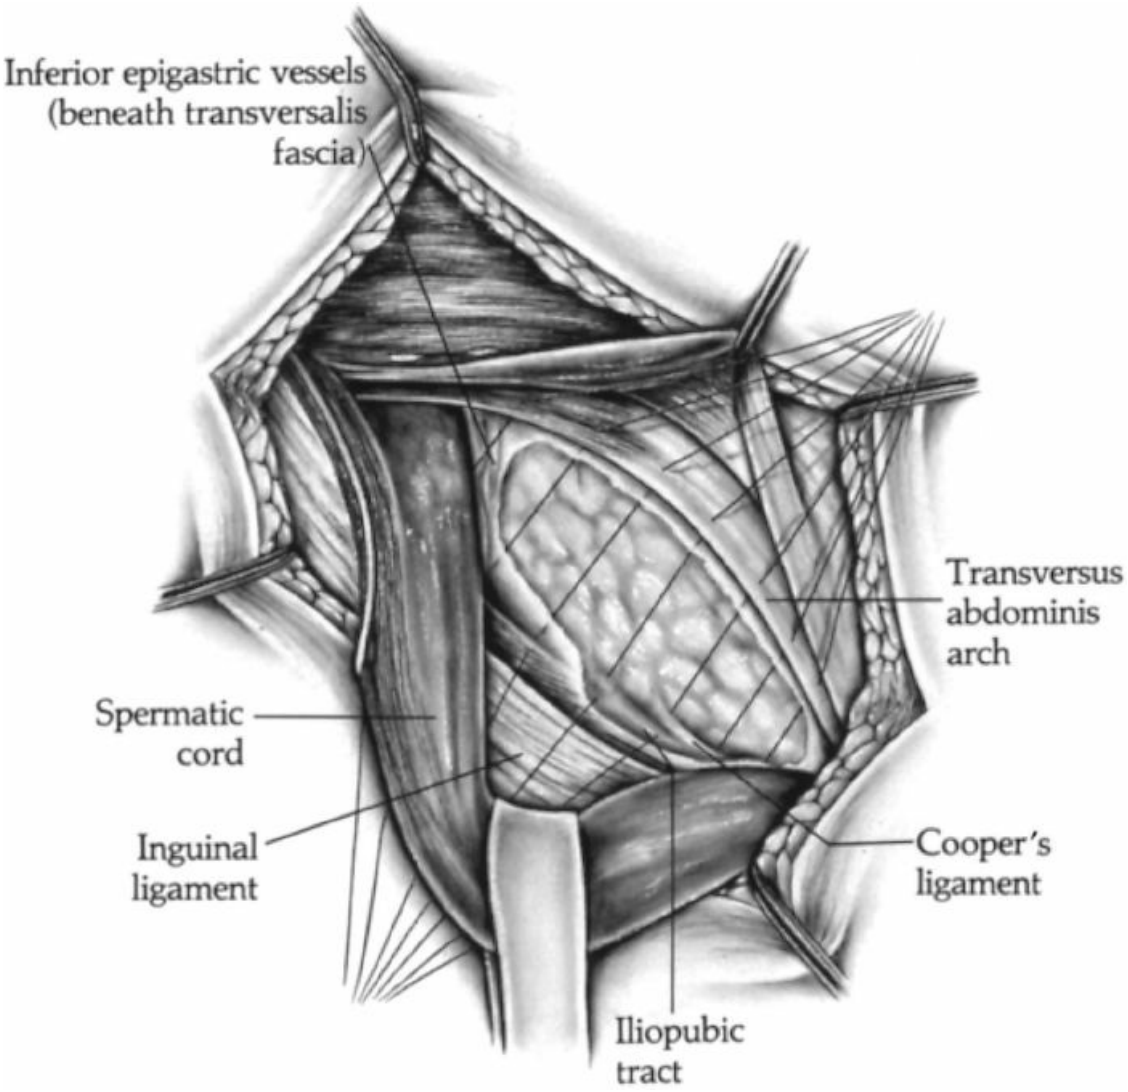

Figure 190.5. Redundant transversalis fascia has been excised and sutures have been placed in the transversus abdominis arch above and Cooper ligament and iliopubic tract below for repair of a direct inguinal hernia. (From Condon RE. Anterior iliopubic tract repair. In: Nyhus LM, Condon RE, eds. *Hernia*. 4th ed. Philadelphia, PA: Lippincott, 1995, with permission.)

RELAXING INCISION

A relaxing incision is used in every primary repair of a direct hernia, except for the smallest diverticular direct hernias, and in every repair of an indirect hernia that requires more than three or four stitches to complete reconstruction of the deep inguinal ring. A relaxing incision is essential in most hernial repairs if tension and consequent recurrence are to be avoided.

The superior flap of the external oblique aponeurosis is dissected bluntly back toward the linea alba in the area immediately above the pubic

symphysis. This plane of dissection is developed superiorly and laterally to a depth of approximately 10 cm. In effect, this dissection mobilizes the superficial lamina of the lower fourth of the rectus sheath.

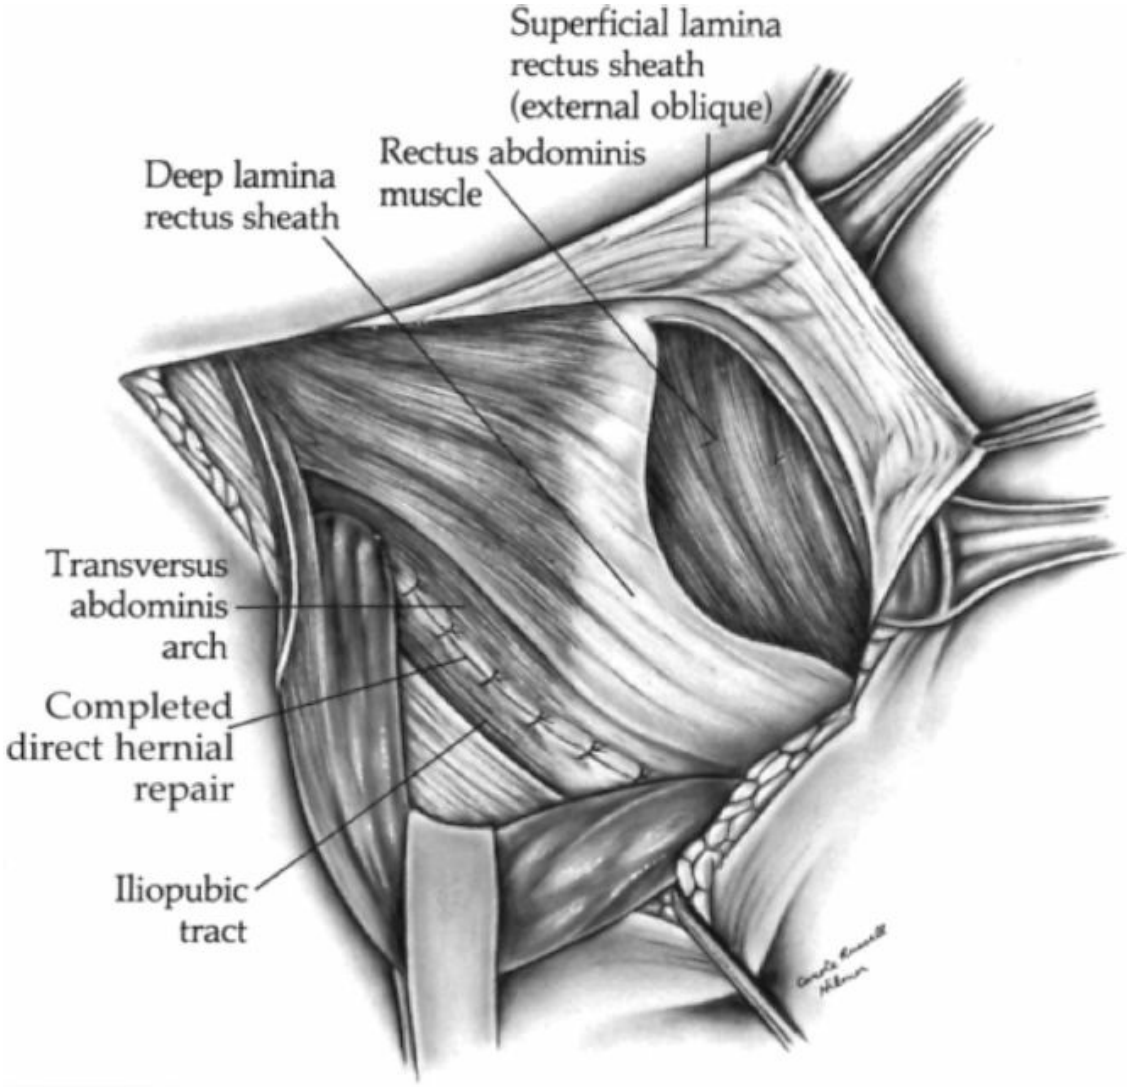

Figure 190.6. A relaxing incision allows the transversus abdominis aponeurosis to slide inferiorly as a bipedicle flap, reducing tension in the hernial repair. (From Condon RE. Anterior iliopubic tract repair. In: Nyhus LM, Condon RE, eds. *Hernia*. 4th ed. Philadelphia, PA: Lippincott, 1995, with permission.)

An incision is made through the deep lamina of the anterior rectus sheath to expose the underlying rectus abdominis muscle. The incision begins 2 to 3 cm above the symphysis pubis and immediately adjacent to the line of fusion of the superficial and deep laminae. It continues superiorly, following the line of laminar fusion, and then curves gently laterally toward the border of the rectus sheath. It is not necessary to

transect blood vessels and nerves that perforate the rectus sheath. The incision usually can be carried medial to (behind) the neurovascular bundles. Traction inferiorly on the transversus abdominis arch slides the resulting bipedicled musculoaponeurotic flap inferiorly and releases tension in the hernial repair (Fig. 190.6). If the deep lamina of the rectus sheath does not slide easily, its internal surface should be cleared by sharp dissection, again taking care not to injure branches of the inferior epigastric vessels.

COMPLETE INGUINAL HERNIA

In this variety of indirect inguinal hernia, the hernia has enlarged sufficiently medially to involve completely or nearly completely the posterior wall of the inguinal canal. Repair of this hernia combines features of the repair of an indirect hernia of more ordinary size with features of direct inguinal hernial repair, both described previously. Because the hernia is so large, the sac is often in the scrotum. The skin incision is made as for a typical indirect inguinal hernia but is carried farther medially. The inguinal canal is opened by splitting the external oblique aponeurosis. The cord is mobilized; the hernial sac and its contents often greatly enlarge the circumference of the cord. Nonetheless, the principles of mobilization are the same as for a more normal-sized spermatic cord.

After mobilization of the cord, the cremaster muscle may be transected at its origin as described for repair of a typical indirect inguinal hernia. Dissection of the peritoneal sac from the cord is occasionally a tedious process, but it follows the principles outlined for an indirect inguinal hernia. The initial incision in the sac is made approximately 2 cm distal to the deep inguinal ring. A finger is inserted distally, a hemostat is placed at the apex of the incision and used for traction, and the overlying cremasteric and internal spermatic fasciae are dissected away from the peritoneal sac by sharp dissection. The incision in the sac is extended distally as needed, and the dissection is continued successively until the tip of the sac is reached.

Sometimes, when mobilization of the hernial sac is completed, the scrotum is found to be inverted and the testicle is in the inguinal canal. In such instances, after excision of the peritoneal sac and its closure, the testicle should be replaced within the scrotum and normal relations of scrotum, testicle, and spermatic cord restored by gentle distal traction. It is

not necessary to anchor the testicle within the scrotum by suture unless the entire circumference of the testicle has been mobilized by sharp dissection. Ordinarily, this extent of mobilization is to be avoided. If the sac envelops the testicle as a hydrocele, that portion of the peritoneum adherent to the testicle should be left *in situ* and hemostasis along the cut margins achieved with a running locking stitch of absorbable suture material.

When the peritoneal sac has been mobilized from the cord, it is usually found to have a broad base. The redundant peritoneum in the area of the posterior wall of the inguinal canal should be reduced by traction on the peritoneal sac, after which the sac is closed, either by twisting and ligation or by a running suture, and the redundant peritoneal sac is excised.

Weakened and redundant transversalis fascia in the area of the hernia needs to be excised, leaving the transversus abdominis arch along the superior border of this large hernial defect cleanly dissected. Similarly, the lower border of the hernial defect must be cleared of areolar tissue and redundant transversalis fascia, beginning at the pubic tubercle and progressing along the Cooper ligament and the iliopubic tract to the lateral aspect of the deep inguinal ring. In this dissection, the external spermatic and cremasteric vessels may need to be ligated. Care is taken to avoid injury to the inferior epigastric vessels and their branches within the preperitoneal space.

Suture repair of this large defect is begun medially at the pubic tubercle. As in the closure of less extensive hernias, the strength of the tissue is tested by traction to ensure that the suture will hold as each needle is passed through the borders of the hernial defect. The initial suture is placed from the superficial to the deep aspect through the transversus abdominis arch just above the pubic tubercle; the needle is extracted through the hernial defect, regrasped, and passed from within to without through the periosteum of the pubis immediately internal and adjacent to the pubic tubercle. Sutures are placed every 5 to 7 mm along each border until the spermatic cord lies immediately superficial to the external iliac artery (Fig. 190.7A). The most medial sutures encompass the transversus abdominis arch above and the Cooper ligament below; usually, two or three such sutures are placed. The remaining sutures encompass the transversus abdominis arch above and the iliopubic tract below.

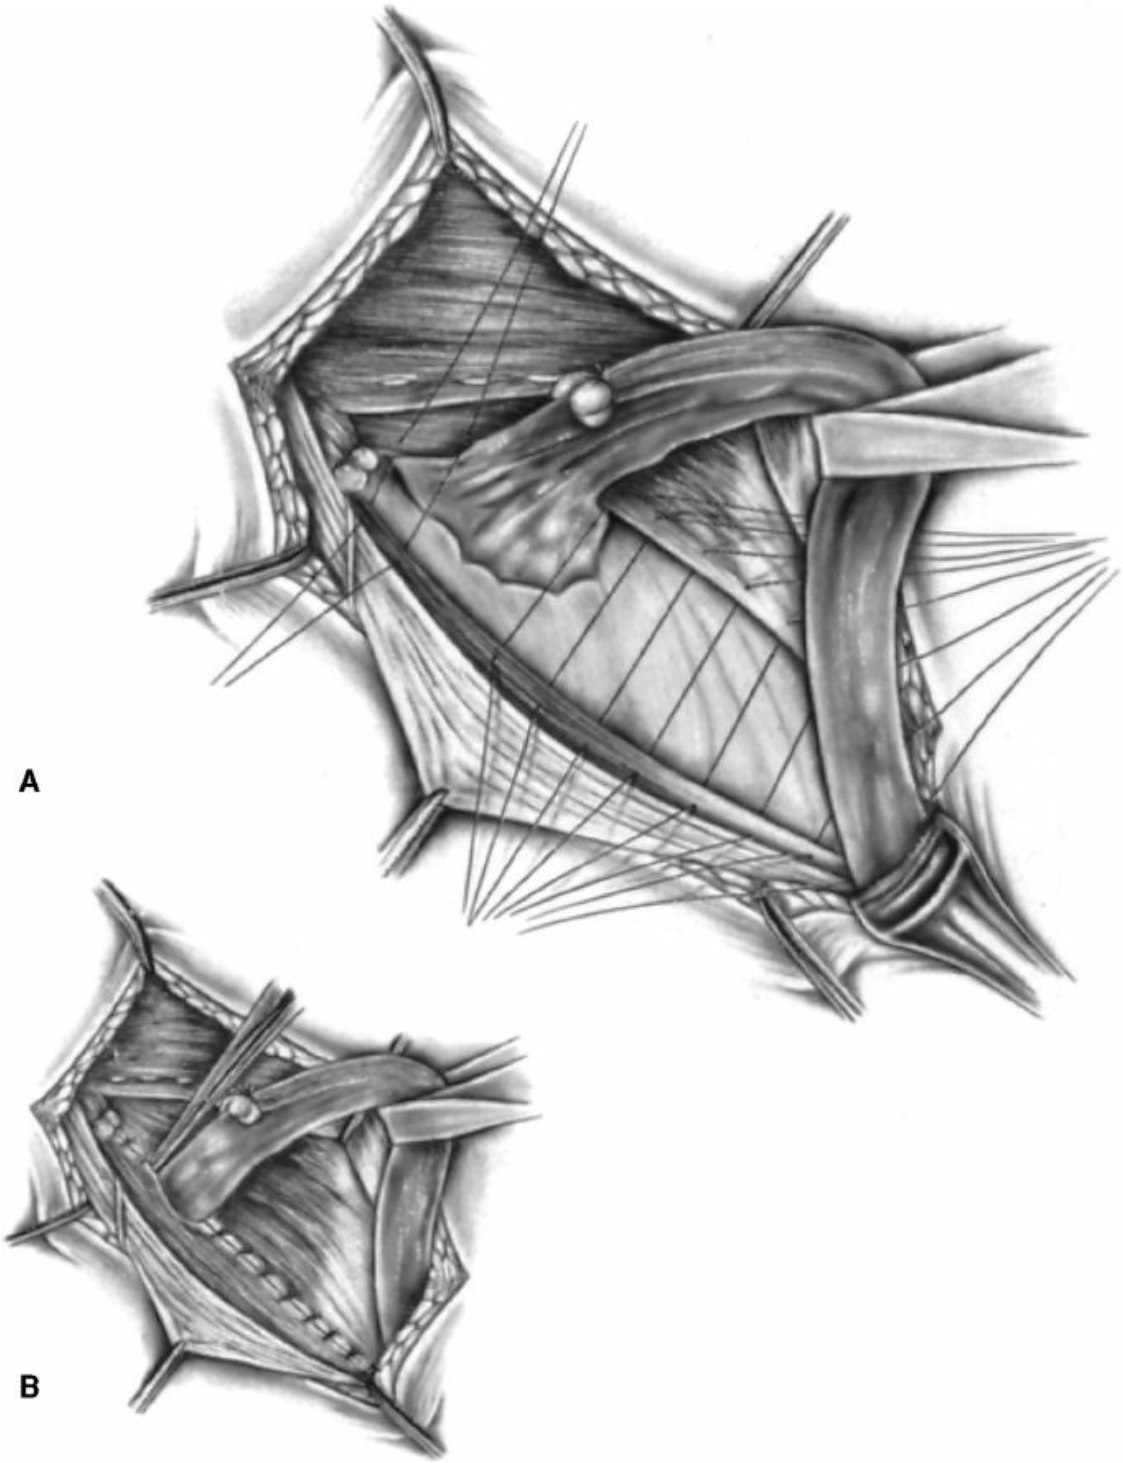

Figure 190.7. A: Sutures have been placed both medially and laterally for repair of a complete, combined indirect and direct hernia. **B:** The reconstructed deep ring should be snug but loose enough to admit the tip of a hemostat. (From Condon RE. Anterior iliopubic tract repair. In: Nyhus LM, Condon RE, eds. *Hernia* 4th ed. Philadelphia, PA: Lippincott, 1995, with permission.)

When sutures for the repair have been placed from the pubic tubercle to the medial aspect of the deep inguinal ring, the cord is retracted medially and the repair is completed on the lateral aspect of the deep inguinal ring with one to three additional sutures (Fig. 190.7B). A large relaxing incision is an essential feature of repair of an extensive hernia of this type. If there is any question of tension in the repair, then primary repair should not be done; a prosthesis should be placed.

WOUND CLOSURE

The wound is irrigated with saline or saline–antibiotic solution (kanamycin, 500 mg, and bacitracin, 50,000 units, in 500 mL normal saline solution). The retractors are removed, and hemostasis is ensured. The position of the testicle in the scrotum should be checked by having the assistant grasp it and exert gentle distal traction. This maneuver usually also accomplishes replacement of the spermatic cord neatly within the inguinal canal. No attempt is made to reattach the cremaster muscle to its origin. It becomes adherent to tissues within the inguinal canal and, surprisingly, appears to function reasonably well in a number of patients postoperatively.

The margins of the external oblique aponeurosis are reapproximated with interrupted or running sutures of 000 braided nylon. If the superficial inguinal ring has been widely dilated by passage of a scrotal hernia, it may be necessary to close the apical portion of the superficial ring by suture approximation of its crura. At completion of the closure of the external oblique lamina, it should be possible to insert the fingertip, but not more, into the superficial inguinal ring beside the spermatic cord.

Bupivacaine solution, 0.25%, is injected beneath the external oblique aponeurosis, into the areolar tissue laterally around the ilioinguinal nerve, and into the dermis of the skin incision.

The subcutaneous fat is not sutured. If the patient is excessively obese, dead space can be managed by placement of a few deep, locked mattress sutures or by use of a closed-suction catheter. The skin is closed with an interrupted or running fine monofilament nylon suture, and a dressing is applied.

CONVALESCENCE

Urinary retention may occur during the first postoperative evening. If the patient is unable to void 12 hours postoperatively, a Foley catheter should

be passed using an aseptic technique. If more than 300 mL of urine is contained in the bladder, the catheter should be connected to straight drainage overnight and removed the next morning.

Requirements for pain relief vary considerably after repair of a hernia. Patients who are very uncomfortable should receive adequate doses of anodynes, including morphine if necessary, in the early postoperative period. Some patients experience little discomfort and require practically no medication for pain relief. My impression has been that the extent of the hernia, the dissection of nerves, the use of a prosthesis, and the anesthetic technique bear only a tenuous relationship to the degree of pain experienced postoperatively.

Ambulation and resumption of normal activities of daily living should be encouraged immediately after recovery from the anesthetic. Of course, activity may be somewhat limited by discomfort in the area of the operation, but activity need not otherwise be restricted. A well-constructed hernial repair should be able to tolerate the usual daily activities of most patients, including going up and down the stairs and walking outdoors.

I have never been excited by the modern practice of early exposure of wounds. The dressing applied in the operating room is usually left in place until the sutures are removed on the fifth or sixth postoperative day. Of course, the dressing should be changed if it becomes stained with blood or serum, and it should be removed for inspection of the wound if there is any suspicion of a developing wound infection or other complication. Sutures are removed on the fifth or sixth postoperative day and replaced with sterile adhesive strips.

Male patients should avoid intercourse in the “missionary” position for a week postoperatively; the “woman-superior” position can be substituted during this period. Patients should also not engage in sudden maximal muscular effort—such as a “panic stop” while driving a car—or lift more than 25 lb during the initial 6 postoperative weeks. Most patients are rarely required to lift as much as 25 lb, even in the course of a job that entails manual labor.

Patients can return to work as soon as they feel ready. Many patients are back to work in less than 1 week postoperatively. Most patients should be back to work by the third or fourth postoperative week. Patients are seen in the office on the sixth postoperative day for suture removal and are monitored at biweekly intervals for a month. Follow-up thereafter at yearly intervals is primarily intended to detect recurrence; approximately half of

all recurrences occur within 3 years postoperatively.

EDITOR'S COMMENT

It has been 161 years since Alexander Thomson (*J Comm Ed Pract* 1836;4:137) described the iliopubic tract, a structure that has become such an integral part of hernial repair (*Surg Gynecol Obstet* 1965;121:601). It has been 37 years since Robert Condon, Henry Harkins, and I presented to the Pacific Coast Surgical Association a paper that emphasized, for the first time in the English-American anatomic–surgical literature, the value of the fascial structure (*Am J Surg* 1960;100:234). The observations on groin anatomy were based on fresh dissections in the autopsy laboratory by Dr. Condon (in Nyhus LM, Harkins HN, eds. *Hernia.* Philadelphia, PA: Lippincott, 1964:14).

There is still confusion regarding when to use the anterior or the posterior approach to the repair. Dr. Condon touches on this point, and I wish to reinforce his comments.

The anterior–inguinal canal–iliopubic tract approach serves best the repair of uncomplicated indirect (type II and type IIIB) and direct hernias (type IIIA) in adults. The posterior–preperitoneal–iliopubic tract approach is indicated for femoral hernias (type IIIC), large indirect hernias (e.g., sliding inguinal hernias), large direct hernias (when transversalis fascia in Hesselbach triangle is destroyed), and recurrent groin hernias of any type. A prosthetic mesh is placed as an inlay buttress after the defect has been sutured in all these complex hernial defects. The key to the repair of groin hernias is a thorough knowledge of the complex groin anatomy. The proper approach is only facilitative.

The iliopubic tract is key to both the anterior and the posterior approaches. The iliopubic tract repair as performed by the anterior approach is in certain respects similar to Cooper ligament repair. First, the medial stitches of an anterior iliopubic tract repair are placed into the Cooper ligament because the Cooper ligament and iliopubic tract insert together into the superior ramus of the pubis. Proceeding laterally, successive sutures are then placed from the transversus abdominis aponeurotic arch to the iliopubic tract below. As stressed by Condon, the anterior repair is not complete without a relaxing incision. Because of the routine use of the inlay prosthetic buttress, a relaxing incision

when operating from the posterior approach is not routinely recommended.

Although the iliopubic tract is not as readily apparent by the anterior approach because it is covered by the more superficial overlying edge of the inguinal ligament, I believe it has several advantages over Cooper ligament repair:

1. The distance that must be traversed in pulling down the "curtain" (shutter mechanism) of the transversus abdominis aponeurosis to the iliopubic tract is not as great as the distance in bringing down the aponeurosis to the Cooper ligament. Therefore, there is less tension on the suture line.
2. An integral part of the Cooper ligament repair, the transition suture into the anterior femoral sheath–iliopubic tract, is not necessary because all the sutures are placed into the length of the iliopubic tract from medial to lateral.
3. In small indirect hernias (types I and II), best treated by a plastic closure of the internal ring, incision of the intact posterior inguinal wall is not necessary. The crura of the transversalis fascia are seen directly and are easily sutured.
4. The iliopubic tract repair, both anterior and posterior approaches, restores the laminar structure and maintains synchronous movement at the deep ring to preserve the sphincter mechanism.

As a surgeon-anatomist, Dr. Condon must be credited with clarifying the fine anatomic nuances of hernial repair as performed by the anterior approach. Although the use of eponyms is discouraged, it seems correct to name the anterior approach and iliopubic tract repair that he described so well as the Condon operation.

EDITOR'S COMMENT

We have kept the comment of Dr. Nyhus from the third edition on this excellent chapter. There are a few other comments I believe need to be added.

In my opinion, it is not necessary to shave the patient. In a study carried out with Dr. J. Wesley Alexander (*Arch Surg* 1983;118:347), clipping has by far the lowest incidence of wound infection except for use of a depilatory, which is messy, difficult to control, and may result in skin reaction to it. Clipping should be carried out in the operating room immediately before surgery.

I was delighted to see the transverse skin incisions, which are much more comfortable for the patient, emphasized by Dr. Condon. A skin crease is an excellent place to carry out the skin incision. There are usually three vessels in a transverse, slightly curved skin incision. Two are medial and are branches of the superficial epigastric; the third is at the lateral edge of the wound and is a

branch of the superficial circumflex iliac vessel.

The comment of using a posterior approach to repair the femoral hernia is well taken. It makes little sense to destroy the transversalis fascia to reach the Cooper ligament, the use of which is necessary to properly repair a femoral hernia.

Dr. Condon's description of repair of an indirect inguinal hernia is classic. The meticulous identification of the anatomic structures is essential if one is to achieve a low recurrence rate.

I agree with almost all of the technical details, particularly the necessity for repairing the lateral aspect of the deep inguinal ring. One cannot emphasize too much that in placing these sutures, the ileoanal nerve must be retracted out of harm's way; otherwise, it is incorporated in these sutures.

I tend to close Scarpia's fascia. I also use a mixture of 1% Xylocaine and 0.5% bivucaine, as this gives adequate pain relief for 6 to 8 hours. Some patients do not require analgesics other than Tylenol or Bufferin.

The failure to void is a vexing problem, particularly in the ambulatory surgical setting. This complication can be almost completely avoided by the use of 10 mg of phenoxybenzamine orally immediately after the close of operation. It may need to be repeated once. Patients usually void after this and may be discharged home in the ambulatory setting, or in the case of the elderly, kept for a 23-hour admission.

J.E.F.

EDITOR'S COMMENT

In carrying out the reproduction of this excellent chapter by Dr. Condon, with minor edits, we have also kept the comments from Dr. Nyhus from the third edition. There are, however, a few comments that I think should be added.

Dr. Condon is responsible for the reidentification of the iliopubic tract 45 years ago, and 170 years since Alexander Thomson first identified the iliopubic tract. This repair is anatomically correct, that is, restoring the posterior wall of the inguinal canal, and as he has correctly emphasized, narrowing the deep internal ring, especially reinforcing the lateral border. I always put at least one suture in the lateral border of the internal ring, and Dr. Condon emphasizes that the area must be clearly exposed in order to obtain adequate visualization of the ring. The ilioinguinal nerve is very close to the deep internal ring and therefore must be protected or else it is either speared with the suture or incorporated. Both may result in postoperative pain.

Since this and many other "tension" repairs result in a 10% to 15% recurrence rate, the question that may be appropriately asked is, why is there a high recurrence rate despite the sound principles and the anatomic restoration of the structures that were originally intended to be together? Dr. Condon has

described many 2-0 nonabsorbable sutures placed at 5- to 7-mm intervals. Taking a cue from other studies on hernia repairs or abdominal wound repairs, especially those of Golligher, running monofilament sutures seem to be preferred (Golligher used stainless steel, which is not available in this country, in the supple manner of English wire). Perhaps this, as well as the use of several other layers, is the secret to the Shouldice repair, which is carried out with at least three and perhaps four layers, but using continual sutures, which then transmit the tension more evenly throughout the wound. The alleged recurrence rate of the Shouldice repair (very low, 0.3%) has been previously dealt with in several commentaries as well as Chapter 189 on Shouldice repair.

With respect to the repair of the femoral hernia, it makes little sense to me to destroy the transversalis fascia in order to carry out the Anson McVay repair, and I reserve this for femoral hernias. I do not like the posterior approach. To me, the weak point of the Anson McVay repair is the transitional suture above the femoral vein, supposedly incorporating Thomson's fascia, which, quite honestly, I have difficulty in identifying.

A few comments on technique. First, shaving. Although Dr. Condon does state that shaving should be limited to the area immediately around the incision and where one puts the dressing, J. Wesley Alexander and I (*Arch Surg* 1983;118:314) showed definitively in a randomized, prospective, four-arm trial that clipping in the operating room yielded by far the lowest incidence of infection. Anything that damages the skin, regardless of whether it is done in the operating room or not, seems to increase the incidence of infection. Depilatories probably have the lowest incidence of infection, but these are messy.

As for the incision, I'm delighted to see a transverse incision advocated because this is more comfortable for the patient, and certainly anatomically correct, and also has decreased pain. There are three vessels in the transverse, slightly curved incision; two are medial and are branches of the superficial epigastric and the third is the lateral edge of the wound, and is a branch of the superficial circumflex iliac vessel. A single swipe of the knife, which appeals to some of the various surgeons' swashbuckling tendencies, may be satisfying, but I believe that these three vessels should be clamped with hemostats and individually ligated with 4-0 absorbable ties. After opening the external oblique, in which care must be taken to identify the iliofemoral and hypogastric nerves, stay sutures should be placed in the edge of the external oblique aponeurosis and clipped to wound towels and drapes, thereby avoiding someone hauling on a retractor for the duration of the operation. I also use vessel loops around the nerves to get them out of harm's way.

In dealing with the cord, about midway through the posterior inguinal canal there is usually a vessel, the external spermatic artery, that may keep the testicle alive if for some reason there is a misadventure with the testicular artery and vein. It should be preserved if possible.

In dealing with the cord, I am surprised that Dr. Condon does not thin the

cord, as this allows one to narrow the deep inguinal ring alongside a hemostat with the thinnest possible cord. It is usually possible to salvage the vessels and the vas while taking off what is sometimes a very large cord lipoma. I do tend to reapproximate the cremaster around the cord with a 4-0 absorbable suture as it looks nicer and may keep the cord slightly buffered from various misadventures involving blows to the inguinal area.

With respect to the closure of the hernia sac, I usually carry this out with a purse-string suture started inside, and then drive this out laterally underneath the iliopubic tract in order to redirect the direction, as it were, of the peritoneal bulge in an indirect hernia. A free needle is used to get to the other end of the purse-string suture used. One must make certain to close the lateral edge of the iliopubic tract and the transversus abdominal arch after placing the suture.

The relaxing incision is described exactly as Dr. Halstead described it, and I agree with the practice of starting it 2 to 3 cm above the symphysis to avoid the rare complication of suprapubic hernia. I violently disagree with the practice of taking the first suture in the periosteum of the pubis, as all of us who have had ample opportunity to take these sutures out for patients who have “osteitis pubis.”

Skin closure continues with closing Scarpa’s fascia, adding more local anesthetic (most of the time, I do the hernias under field block) and large amounts of dilute Xylocaine and Marcaine, giving 5 to 8 hours of analgesia postoperatively. The analgesia is supplemented by injecting the edges of the wound in the subcutaneous tissue before closure. I use subcuticular absorbable sutures reinforced with Steri-Strips or Xeroform over the incision and a water-permeable dressing such as Tegaderm. That way, patients can shower when they go home, as almost all of these procedures, except in the elderly, are carried out on an outpatient basis. Each patient gets 10 mg of phenoxybenzamine or 1 mg of Hytrin so that the patient will void postoperatively (and not require an overnight stay).

I feel privileged to be able to comment on this classic of American surgical anatomic history, which is extraordinarily important.

J.E.F.

191 Iliopubic Tract Repair of Inguinal and Femoral Hernia: The Posterior (Preperitoneal) Approach

Lloyd M. Nyhus

This Chapter can be accessed in the accompanying eBook edition (see inside front cover for access instructions).

The posterior (preperitoneal, properitoneal, or extraperitoneal) approach to the repair of inguinal and femoral hernia had its origin with Annandale in 1876. Since then, interest in its use has waxed and waned, primarily because of a lack of understanding of the groin anatomy as seen posteriorly. The anatomic dissections of Condon first reported in 1960 presented with clarity the long-forgotten analogue of the transversalis fascia: the iliopubic tract. The intimate relation between the iliopubic tract and the abdominal wall defect was apparent, and the use of a strong band of fascia at the edge of each defect—the iliopubic tract—became the cornerstone of the repair. It soon became clear that the approach was mainly facilitative and that the iliopubic tract repair was the key to either an anterior or a posterior approach. In 1966, C. Thomas Bombeck and I presented both approaches and emphasized the iliopubic tract repair. The anterior approach and iliopubic tract repair are presented by Condon in Chapter 190.

SURGICAL ANATOMY

General and detailed concepts of groin anatomy are presented throughout this section. Although greater exposition would be redundant, a few anatomic considerations that relate to the iliopubic tract repair must be reiterated.

LAMINAR STRUCTURE OF THE INGUINAL REGION

The abdominal wall is composed of musculoaponeurotic layers protected externally by skin and subcutaneous fat and covered internally by preperitoneal fat and peritoneum. An anatomic hernial repair should restore the continuity and integrity of each disrupted musculoaponeurotic lamina. In uncomplicated groin hernias, only the transversalis fascia lamina is disrupted; other structures are merely displaced. In the repair of groin hernias, the essential task is the repair and restoration of the transversalis fascial layer.

The inguinal region is separated into two laminar structures. The spermatic cord is contained between these layers within a cleft or space: the inguinal canal. The group of structures that lies anterior to the spermatic cord constitutes the anterior inguinal wall, or the superficial musculoaponeurotic lamina, and is composed of the Scarpa fascia and the external oblique aponeurosis and its lowermost fibers, the inguinal (Poupart) ligament. The spermatic cord exits from the medial end of the inguinal canal by passing through the anterior wall at the external inguinal ring. The structures posterior to the spermatic cord constitute the posterior inguinal wall, or the deep musculoaponeurotic lamina, and are composed of transversalis fascia and the transversalis fascial analogues: the iliopubic tract, crura and sling of the internal abdominal ring, the transversus abdominis aponeurosis, the anterior femoral sheath, and the Cooper ligament. The spermatic cord enters the lateral end of the inguinal canal by passing through the posterior inguinal wall at the internal abdominal ring. The floor of the inguinal canal is formed primarily by the bony superior ramus of the pubis and its closely associated structures: the pectineus muscle, the pectineus fascia, and the more distal portion of the anterior femoral sheath.

TRANSVERSALIS FASCIA

A groin hernia results anatomically from a weakening and relaxation of the transversalis fascia. This concept is fundamental to understanding the anatomy of all repairs of groin hernias. If surgical cure of the hernia is expected, the anatomic integrity of the transversalis fascia must be restored, no matter what technique of repair is used. If the defect in the transversalis fascia is not repaired, a high rate of recurrence follows. In the usual anterior approach to hernial repair, the exposure of the transversalis fascia is less than ideal, which may account in part for continuing relatively high recurrence rates with the anterior approach.

Adherence to the principle of restoration of the anatomic integrity of the transversalis fascia in groin herniorrhaphy does not imply an unalterable commitment to use only transversalis fascia in the repair. It does imply, however, that all the structures used for repair must lie within the transversalis lamina of the inguinal region—in the posterior inguinal wall. This layer still forms the essential guide to repair because it defines the lamina within which repair should be carried out. This statement applies to femoral hernias as well as to direct and indirect hernias. Often used in the hernioplasty are a group of ligamentous and aponeurotic structures closely associated with the transversalis fascia. These are capable of retaining heavy sutures and provide the strength required for the reapproximation and restoration of continuity of the transversalis fascia.

ILIOPUBIC TRACT

The iliopubic tract (ligamentum iliopubicum thomsonii, *bandelette iliopubienne* of the French) is a strong fascial band that begins laterally along the crest of the ilium and at the anterosuperior iliac spine. In this area, it gives origin to the iliacus muscle and the lowermost fibers of the transversus abdominis muscle. The iliopubic tract arches over the psoas muscle and femoral vessels, where it forms an integral part of the anterior femoral sheath (Fig. 191.1). In its midportion, it lies immediately subjacent to the inguinal ligament. It is, however, completely separated from the inguinal ligament, and the relation is one of proximity only. Continuing medially, the iliopubic tract inserts fan-wise into the superior ramus of the pubis and into the Cooper ligament (Fig. 191.2). The most inferior fibers of the iliopubic tract—those that insert most laterally into the Cooper ligament—are sharply recurved in the normal groin. It is this recurved portion of the iliopubic tract that defines the medial border of the femoral canal, rather than the lacunar (Gimbernat) ligament of classic description.

The fundamental importance of the iliopubic tract in understanding the anatomy of groin hernias is that it forms one of the margins of the hernial defect in each of the common groin hernias. Direct and indirect inguinal hernial defects are limited on their posterior aspects by the fibers of the iliopubic tract; femoral hernial defects are similarly limited on their medial and anterior aspects in the transversalis lamina of the inguinal region.

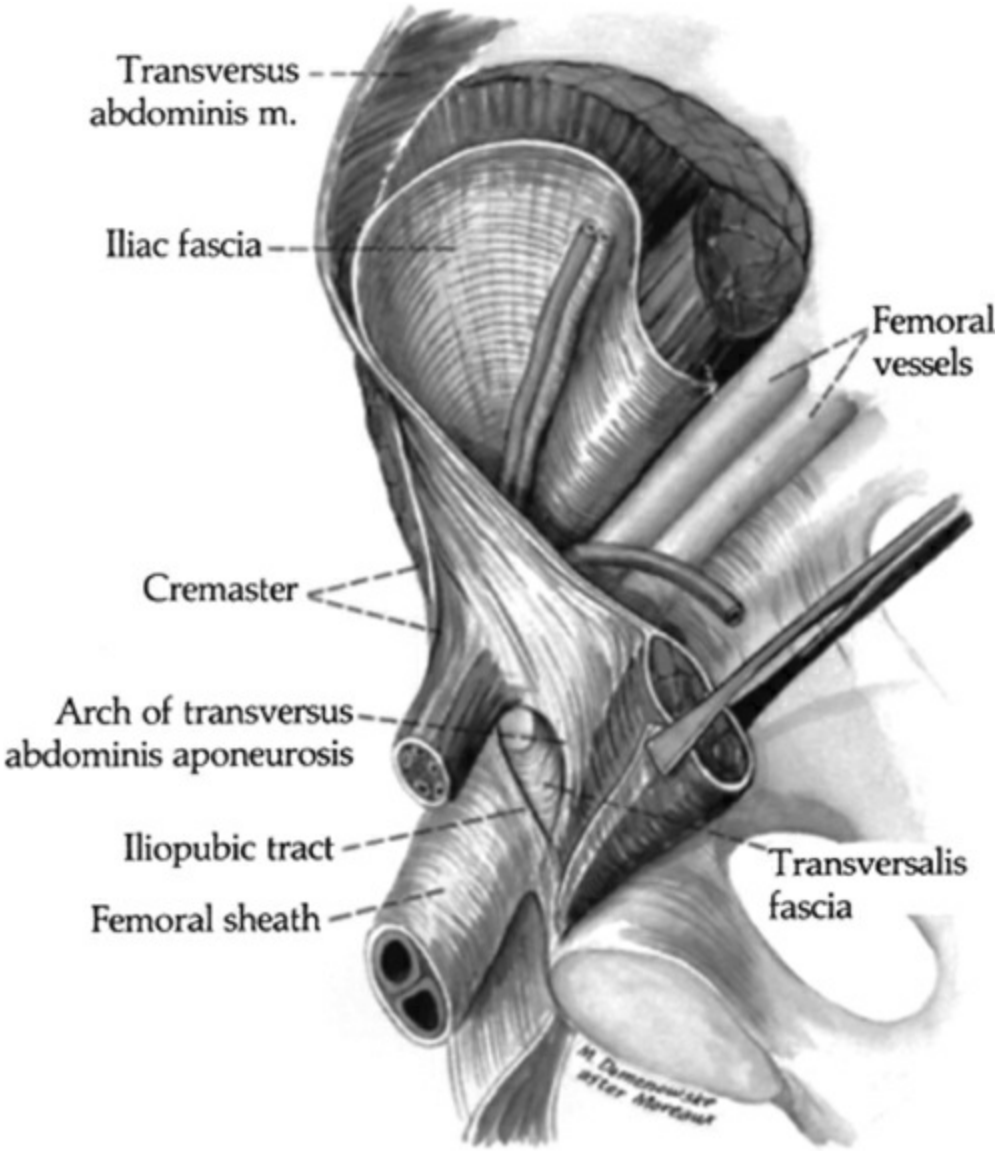

Figure 191.1. Continuity of transversalis fascia and transversus abdominis aponeurosis with iliac fascia, femoral sheath, and iliopubic tract. Inside–outside view of right posterior inguinal wall. The cremaster muscle and fascia originate from the internal oblique muscle and interparietal fasciae. (Reprinted from Nyhus LM. An anatomic reappraisal of the posterior inguinal wall. *Surg Clin North Am* 1964;44:1305. Copyright © 1964 Elsevier, with permission.)

TRANSVERSALIS CRURA AND SLING OF THE INTERNAL (ABDOMINAL) INGUINAL RING

The internal ring is given an elliptic shape by the presence on its anterior and posterior aspects of a double fold of transversalis fascia that cradles and supports the spermatic cord in this region. This sling, however,

appears to be open laterally. As is implied by the name *internal inguinal ring*, transversalis fascia can be delineated on all sides of the defect. The posterior crus, or arm, of this sling consists of fibers that parallel the iliopubic tract and finally fuse with it. The anterior crus is a more dense band that has an extensive origin in the transversalis fascia above the internal ring. The two crura are, of course, continuous with each other on the medial aspect of the internal ring and spermatic cord; because they are more prominent at this level, a sling effect is given, which gives rise to the term *transversalis fascial* sling of the internal inguinal ring. Lateral movement of this sling when straining closes the fascial ring around the spermatic cord. This natural protective mechanism (sphincter) should be enhanced during hernioplasty by placement of sutures only into the posterior lamina, avoiding cross-laminar sutures between the anterior crus and the inguinal ligament.

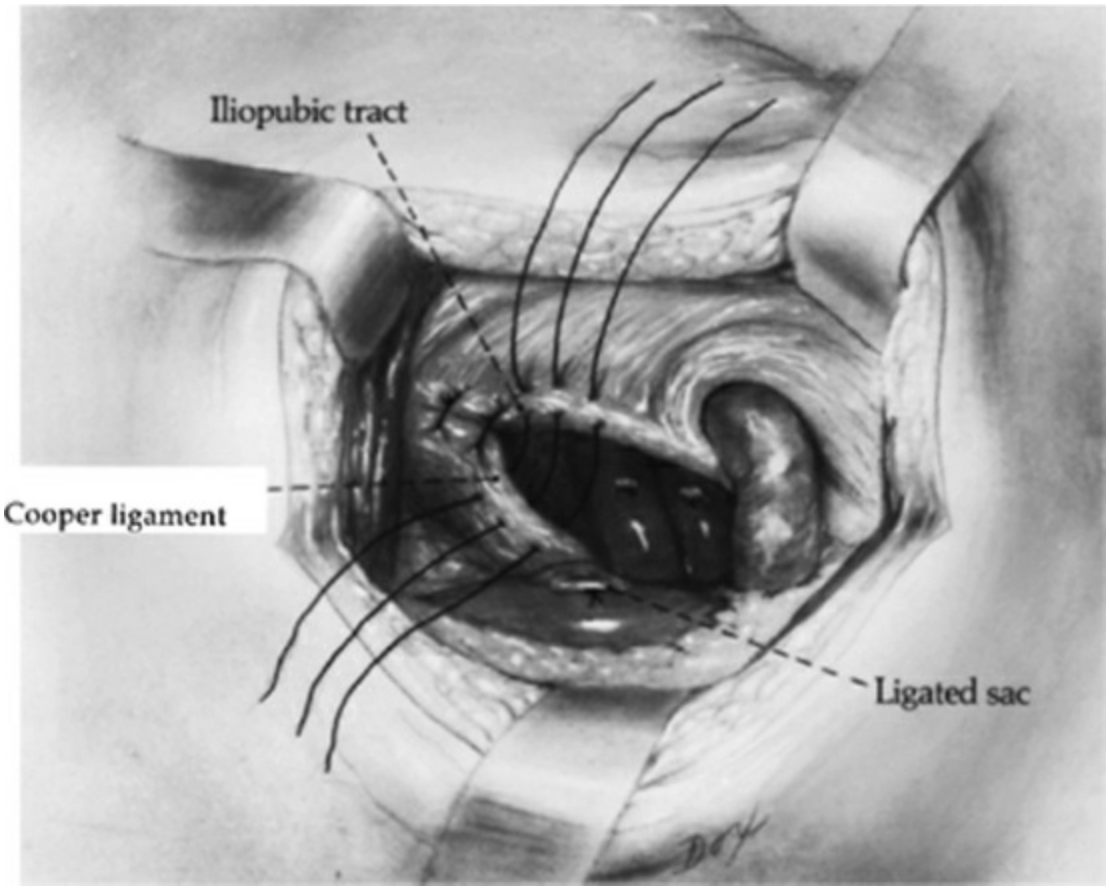

Figure 191.2. Relation of the iliopubic tract to the femoral vessels and to the ligament of Gimbernat. Medial cross section of right lower abdominal wall, viewed medially to laterally. (Reprinted from Nyhus LM. An anatomic reappraisal of the posterior inguinal wall. *Surg Clin North Am* 1964;44:1305. Copyright © 1964

Elsevier, with permission.)

LAYERS IN THE HESSELBACH TRIANGLE

Two layers of fascia cover the Hesselbach triangle: the transversalis fascia and fibers of the transversus abdominis aponeurosis. The adherence of these tissues to one another is also apparent at and above the heavy curved arch of the transversus abdominis aponeurosis. Thus, these structures are not isolated but are sutured as one layer in the repair.

The relevant structures contained within the posterior inguinal wall are illustrated in Figure 191.3.

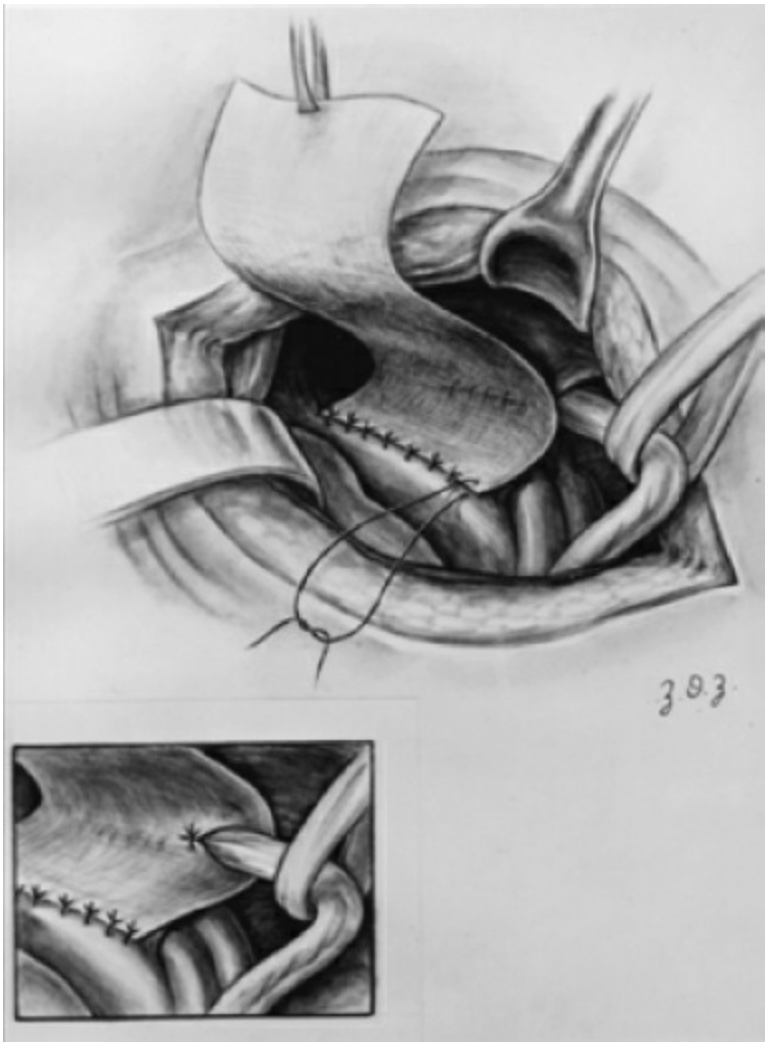

Figure 191.3. Fasciomusculoaponeurotic components of the lower abdominal wall. The spermatic cord has been removed and the iliopubic tract is reflected to demonstrate fascial continuity with the femoral sheath. The posterior inguinal wall (transversus abdominis—transversalis fascia lamina) is firmly “rooted” to the thigh at this point. The crura of the internal abdominal ring are

also shown clearly. (Reprinted from Nyhus LM. An anatomic reappraisal of the posterior inguinal wall. *Surg Clin North Am* 1964;44:1305. Copyright © 1964 Elsevier, with permission.)

TABLE 191.1 Classification of Groin Hernias

Type	Example
I: Indirect inguinal hernia	Internal inguinal ring normal (e.g., pediatric hernia)
II: Indirect inguinal hernia	Internal inguinal ring dilated but posterior inguinal wall intact
	Inferior deep epigastric vessels not displaced
III: Posterior wall defects	Direct inguinal hernia
	Indirect inguinal hernia (internal inguinal ring dilated, medially encroaching on and destroying effectiveness of transversalis fascia of Hesselbach triangle [e.g., massive scrotal, sliding, or pantaloon hernias])
	Femoral hernia
IV: Recurrent hernia	Direct
	Indirect
	Femoral
	Combination

A CLASSIFICATION OF GROIN HERNIA

The classification of groin hernia (Table 191.1) includes primary inguinal and femoral hernias (types I, II, and III) as well as recurrent groin hernias (type IV). Primary inguinal hernias are classified according to the severity of the damage to the underlying internal abdominal ring or the defect in the Hesselbach triangle. Small to massive (e.g., scrotal or sliding) indirect hernias can be viewed as a continuum of disease. Initially, they are confined to the internal abdominal ring (type I); then they enlarge medially (type II). In the final stages, they alter the posterior inguinal wall (type III). All direct hernias (small and large without involvement of the internal abdominal ring) are in the transversalis fascial layer and therefore are considered type III.

The classification of groin hernias is based on anatomic criteria. The challenge in devising a classification of this nature lies in formulating descriptions that are clear and specific. The recommended operative approaches to the various types of hernias are given in Table 191.2.

Type I

Type I hernias are indirect inguinal hernias (usually in infants, children, or

young adults) in which the internal abdominal ring is of normal size, configuration, and structure. The boundaries are well delineated and the Hesselbach triangle is normal. There is an indirect hernial sac, which extends variably from just distal to the internal abdominal ring to the midinguinal canal.

TABLE 191.2 Repair Individualized to Type of Hernia

Type of Hernia	Repair
I. Indirect with normal internal abdominal ring	High ligation of sac[a] No repair
II. Indirect with internal abdominal ring dilated, posterior abdominal wall intact	High ligation of sac Transversalis fascial repair of internal abdominal ring; no crura mesh
III. Posterior wall defects	
A. Direct	Anterior approach
B. Large indirect	IPTR without mesh (Condon) Shouldice repair Cooper's ligament repair Posterior approach IPTR with inlay buttress of prosthetic mesh Stoppa giant prosthetic reinforcement of the visceral sac with Mersilene
C. Femoral	Posterior approach IPTR without mesh
IV. Recurrent	Posterior approach IPTR with inlay buttress of prosthetic mesh

IPTR, iliopubic tract repair.
[a]Excision and ligation of hernial sac performed in all indirect and femoral hernias. A direct sac is usually not opened, excised, or ligated.

Type II

Type II hernias are indirect inguinal hernias in patients in whom the internal ring is enlarged medially and distorted without impinging on the floor of the inguinal canal. The Hesselbach triangle (floor of canal) is normal as palpated through the opened peritoneal sac. The hernial sac is not scrotal but may occupy the entire inguinal canal.

Type III

Type III classifies defects in the posterior inguinal wall (floor) into three subtypes: direct, indirect, and femoral. In direct inguinal hernias (type IIIA), the protrusion does not herniate through the internal abdominal

(inguinal) ring. The weakened transversalis fascia (posterior inguinal wall medial to the inferior epigastric vessels) bulges outward in front of the hernial mass. Again, all direct hernias, small or large, are type IIIA.

Type IIIB hernias are indirect inguinal hernias with a large, dilated ring that has expanded medially and encroaches on the posterior inguinal wall (floor) to a greater or lesser degree. Type IIIB hernias frequently have a scrotal position. Occasionally, the cecum on the right or the sigmoid colon on the left makes up a portion of the sac wall. These sliding hernias always destroy a portion of the inguinal floor (types IIIA and IIIB).

The internal abdominal ring may be dilated without displacement of the inferior epigastric vessels. Direct and indirect components of the hernial sac may straddle those vessels to form a pantaloon hernia (types IIIA and IIIB). Type IIIC are femoral hernias, a specialized form of posterior wall defect.

Type IV

Type IV hernias are recurrent hernias. They cause intricate management problems and carry a higher morbidity than other hernias.

POSTERIOR APPROACH AND ILIOPUBIC TRACT REPAIR INDICATIONS

The posterior approach is ideal for circumventing the scar tissue in operations for recurrent hernias. In addition, the posterior inguinal wall is usually not touched during previous operations, making iliopubic tract repair feasible in every instance. An inlay polypropylene mesh buttress over the posterior repair has become routine in this approach to all recurrent hernias.

Sliding hernias (type IIIB), so often the cause of consternation, are readily recognized and repaired. All incarcerated and strangulated hernias of the groin can be released with relative ease. The constricting ring can be cut with minimal danger to vital blood vessels and nerves.

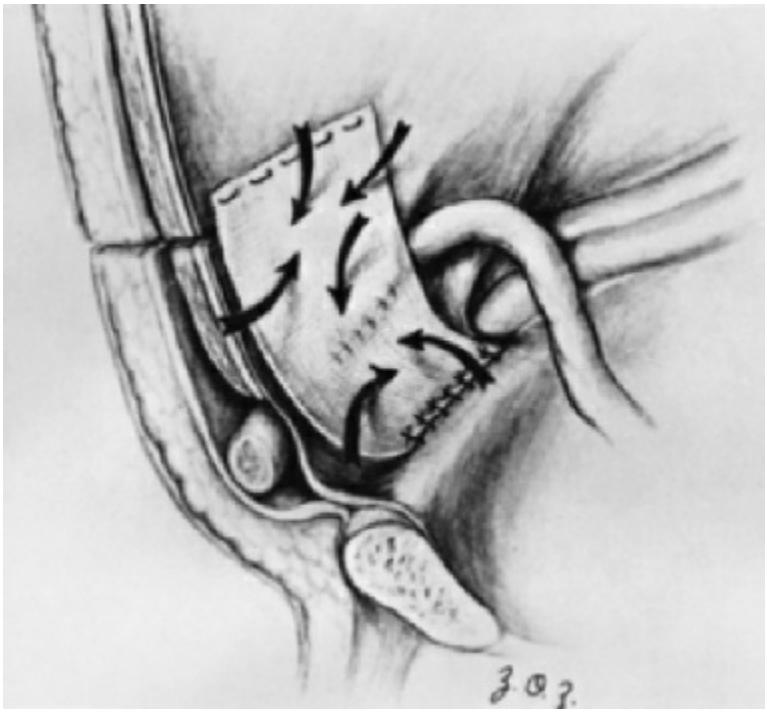

Figure 191.4. Use of the iliopubic tract in the repair of a direct or femoral hernia.

If it is necessary to resect necrotic intestine, the peritoneum can be opened and the appropriate resection and anastomosis undertaken. This approach is ideal for the correction of cryptorchidism.

Femoral hernias (type IIIC) are best approached posteriorly. In fact, as the technique evolved, my associates and I became convinced that it was good for all complicated groin hernias (Fig. 191.4).

CONTRAINDICATIONS

Poor Anesthesia

The lower abdominal wall must be relaxed to facilitate visualization of the posterior inguinal wall. The operation can be performed successfully with only one assistant, provided good abdominal wall relaxation is achieved by general or regional anesthesia (epidural).

Infants

There is general agreement that the technique of excision and high ligation of the hernial sac is sufficient for cure of the ordinary infant hernia (type I). Because repair of the posterior inguinal wall is unnecessary, and the hernial sac can be ligated readily by the anterior approach, the posterior

approach seems to be superfluous in infants. I do not use the posterior approach in children younger than 10 years.

Obesity

Extreme obesity complicates any hernial repair. Because of the necessity of dealing with an anterior abdominal wall flap during exposure of the posterior inguinal wall, the natural difficulties encountered in obesity are multiplied considerably by this approach. However, many of my colleagues do not agree that there is a disadvantage to the posterior approach in obese patients and persist in using it for all patients, lean or fat.

Direct Hernia (Type IIIA)

I do not consider a direct hernia a contraindication to the posterior approach. Recognition that the judicious use of an inlay polypropylene mesh to buttress the repair of large defects should regularly give good long-term results.

TECHNIQUE

Approach to the Preperitoneal Space

A preperitoneal space is entered through a transverse lower abdominal incision placed 3 cm above the inguinal ligament. The incision is approximately two fingerbreadths above the symphysis pubis and slightly above the inguinal incision usually used in conventional anterior hernial repair (Fig. 191.5).

The dissection is carried successively through the skin, subcutaneous tissue, and anterior rectus sheath. Before incision of the rectus sheath, exposure of the external inguinal ring may be helpful as a basic landmark for accurate estimation of the position of the internal abdominal ring. The incision through the anterior abdominal wall must be placed so that it is above (cephalad to) the internal abdominal ring. The initial incision is placed over the rectus muscle. The rectus muscle is retracted slightly toward the midline, and the transverse incision is extended laterally a few centimeters through the full thickness of the musculoaponeurotic layers formed by the external oblique aponeurosis and internal oblique and transversus abdominis muscles.

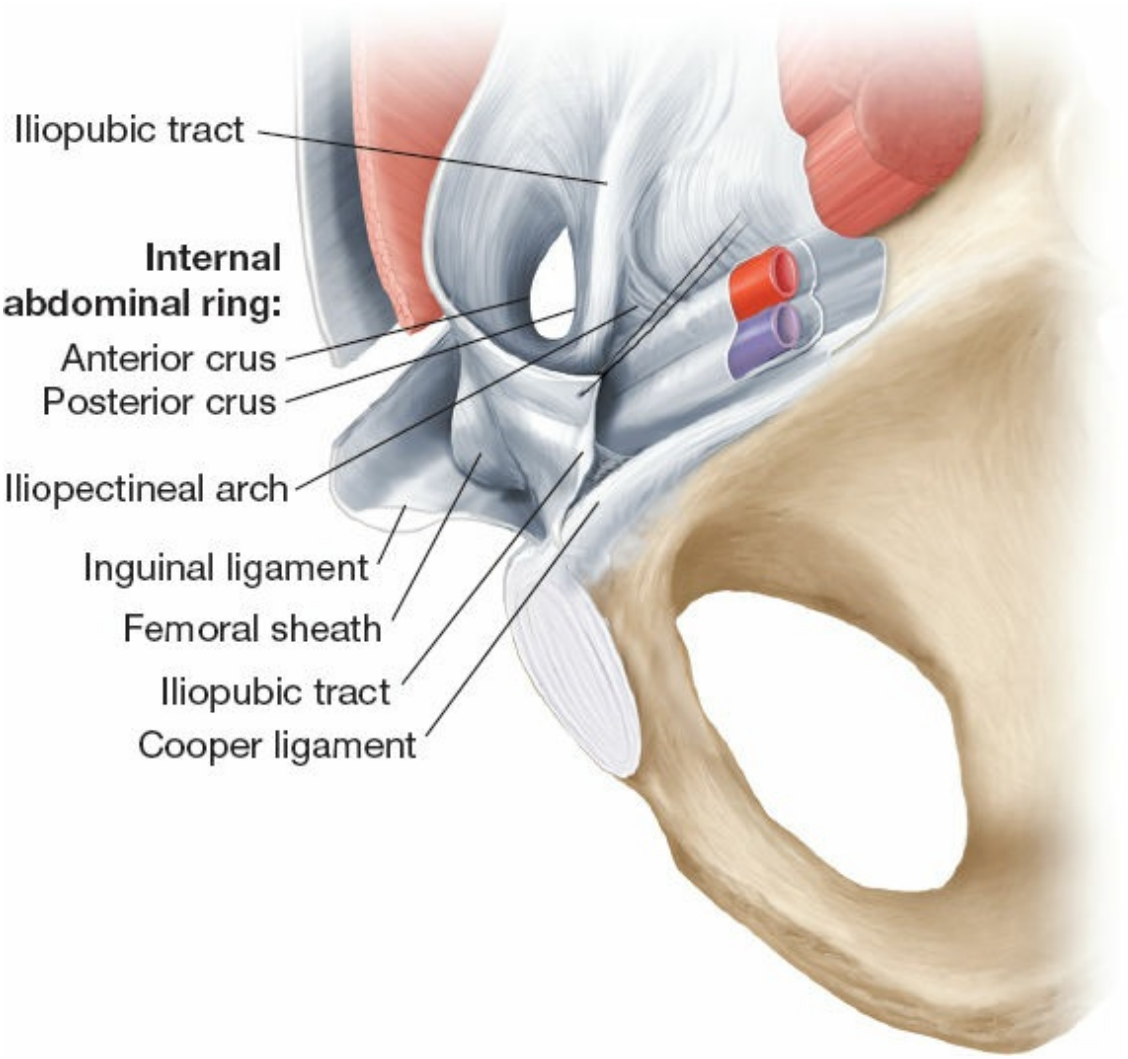

Figure 191.5. Incisions used in the anterior and posterior approaches. The preperitoneal space is approached through the transverse incision. The direct anterior approach is achieved through the longer incision in the lines of skin tension. (Redrawn after Nyhus LM, Bombeck CT. Anatomic and physiologic repair of groin hernia. *Am Fam Physician/GP* 1966;33:114.)

The transversalis fascia is now exposed. It is incised transversely, with special care taken not to enter the underlying peritoneum. The preperitoneal space has been entered. Slight retraction of the lower margin of the incision exposes the posterior inguinal wall and the area of herniation. The pelvic peritoneum and the preperitoneal fat are reflected by blunt dissection, and any peritoneal projections through the posterior inguinal wall are readily visualized.

Repair of a Direct Inguinal Hernia

A direct hernial sac is easily reduced by gentle traction and dissection. As the sac is reduced, the tissues should be carefully watched. The attenuated transversalis fascia at the apex of the sac everts along with the peritoneal sac and can be noted as a prominent fold or “white line.” This fascia can be grasped, and the margins of the hernial defect can be defined rapidly.

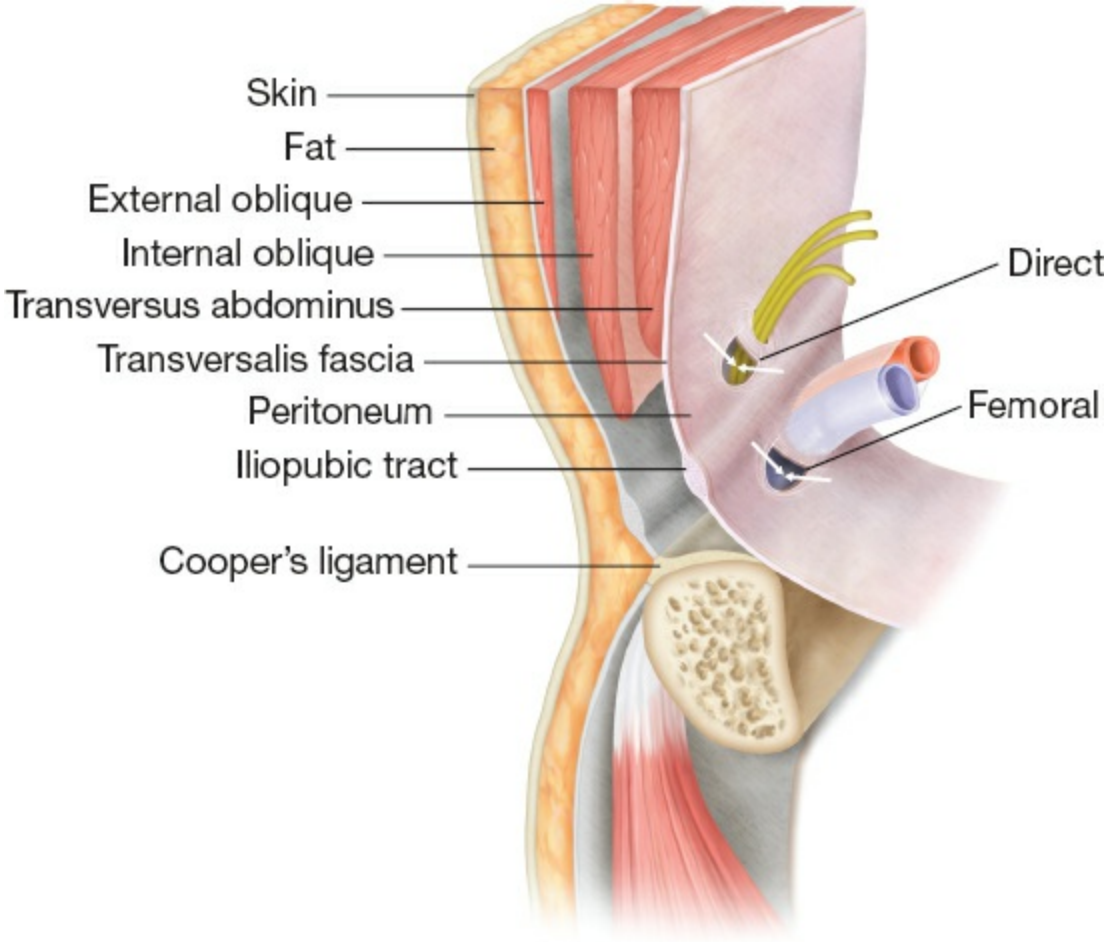

Figure 191.6. Direct hernial repair by the posterior approach. The direct sac has to be extracted and inverted, but not excised. The sutures are placed between the arch of the transversus abdominis aponeurosis above and iliopubic tract below. (Redrawn after Nyhus LM, Bombeck CT. Anatomic and physiologic repair of groin hernia. *Am Fam Physician/GP* 1966;33:114.)

The usual peritoneal sac associated with a direct hernia need not be removed; however, the sac can be invaginated into a purse-string suture. The proximity of the bladder in a direct hernia must be considered if a peritoneal sac is excised, and care must be taken to prevent damage to the bladder wall.

The direct hernial defect is repaired with interrupted sutures to approximate its upper and lower borders. The upper border of the defect is thickened transversalis fascia and arch of the transversus abdominis aponeurosis. The inferior margin of the direct defect is the iliopubic tract, which can be identified visually, by palpation, or by both methods. It is not unusual for the first and second medial sutures to be placed through both the iliopubic tract and the Cooper ligament. The more lateral sutures are placed into the iliopubic tract (Fig. 191.6). If the iliopubic tract has been attenuated by the pressure of a large direct hernia, all the lower sutures can be placed into the Cooper ligament.

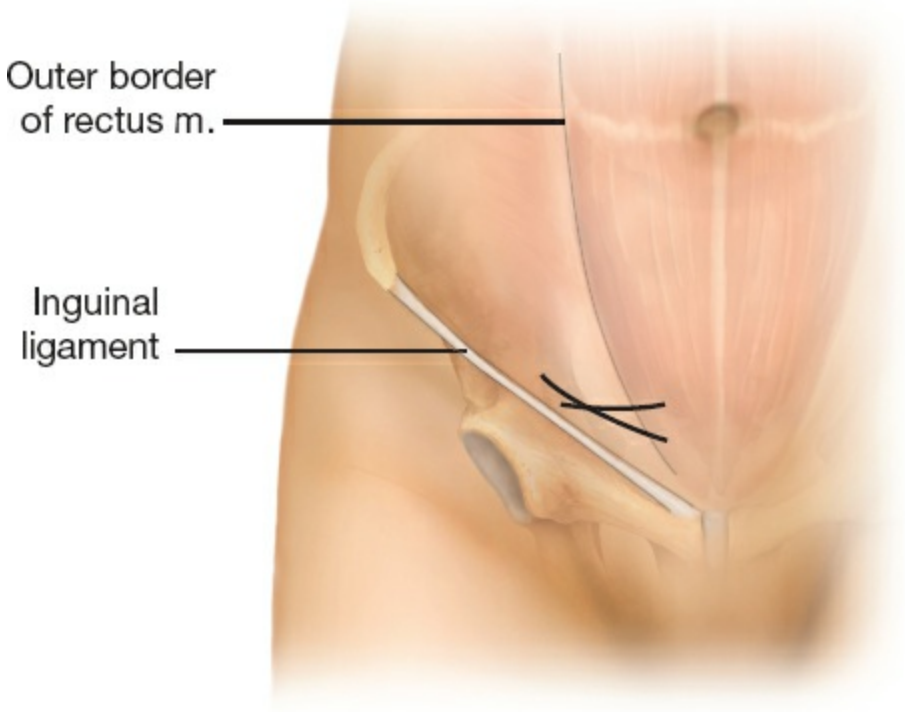

Figure 191.7. Indirect hernia, the posterior approach. The view is from above looking downward. All layers of the abdominal wall except the peritoneum and preperitoneal fat are elevated by the retractors, revealing the floor of the inguinal canal from above and within. Note the indirect sac protruding into the inguinal canal at the superolateral aspect of the internal ring. (Redrawn after Nyhus LM, Bombeck CT. Anatomic and physiologic repair of groin hernia. *Am Fam Physician/GP* 1966;33:114.)

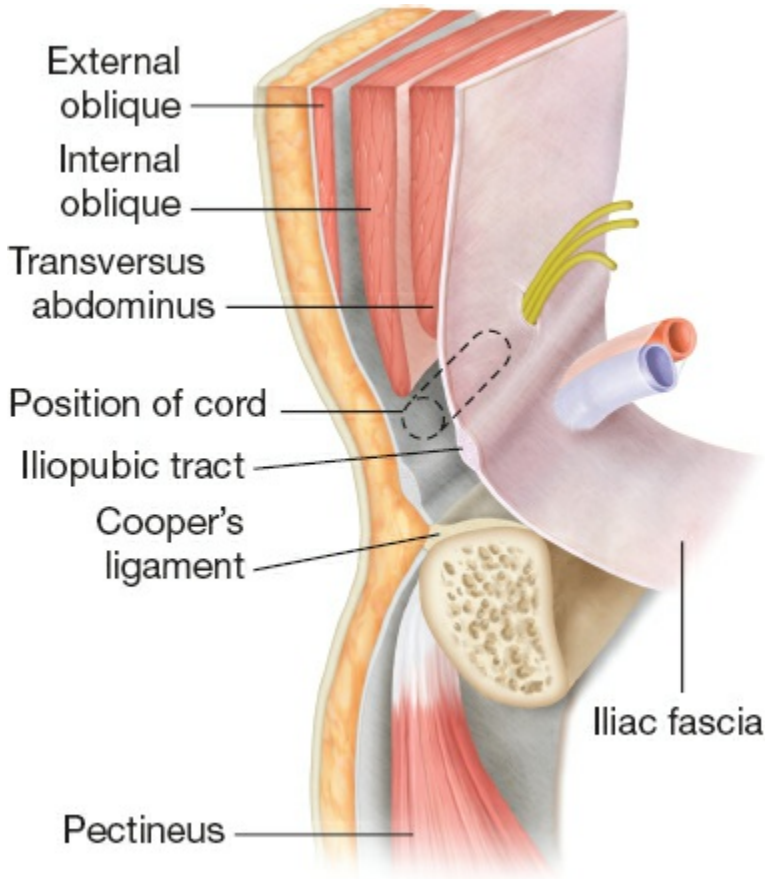

Figure 191.8. The indirect sac has been ligated and removed, and sutures are in place in the superior and inferior crura of the internal ring. The inferior crus blends into the iliopubic tract at varying distances from the medial margin of the internal ring. The sutures at this point are placed into the iliopubic tract. (Redrawn after Nyhus LM, Bombeck CT. Anatomic and physiologic repair of groin hernia. *Am Fam Physician/GP* 1966;33:114.)

Repair of an Indirect Inguinal Hernia

An indirect hernial sac is reduced by traction, a purse-string suture is placed about its neck, the excess sac is excised, and the purse-string suture is tied. An optimum high ligation is performed (Fig. 191.7). Alternatively, the sac can be left *in situ*, the contents reduced, the neck transected, and the peritoneum closed; the distal sac is left open. Although I usually reduce and excise indirect hernial sacs, it is preferable to leave them *in situ* if extensive dissection is needed for their mobilization. I have not encountered hydrocele formation when the distal sac is left *in situ*. Formation of an occasional hydrocele is preferable to the damage to the spermatic cord, vessels, and testicle that accompanies the difficult and extensive dissection needed to remove a scarred indirect sac. This

principle applies also to the conventional anterior approach to indirect inguinal hernias; it is not unique to the posterior approach.

After high ligation of the neck of the hernial sac, the hernial defect is repaired. For the smallest indirect hernias, a few sutures placed medial or lateral to the spermatic cord suffice, approximating fibers of the anterior crus of the internal ring to the posterior crus and iliopubic tract (Fig. 191.8). For larger indirect hernias, the cord is first gently retracted laterally, and sutures are placed between the anterior crus of the transversalis fascial sling and the iliopubic tract medial to the cord. Sufficient sutures—one or two in the usual hernia, more with extensive defects—are placed so that the internal ring and associated spermatic cord are restored to their normal anatomic position above and slightly lateral to the femoral artery. The cord is retracted medially, and the repair of the hernial defect is continued laterally. Two or three sutures usually suffice for the lateral closure. In massive indirect hernias with associated medial displacement of the inferior epigastric vessels and destruction of the posterior inguinal wall in the area of the Hesselbach triangle (types IIIA and IIIB), the principles of repair in both direct and indirect hernioplasty are used. The medial portion of the hernial defect is repaired as a direct hernia; the repair is continued laterally, and a new internal abdominal ring is made at the level of the femoral vessels. An inlay buttress of prosthetic mesh should always be used after repair of these large, complex defects.

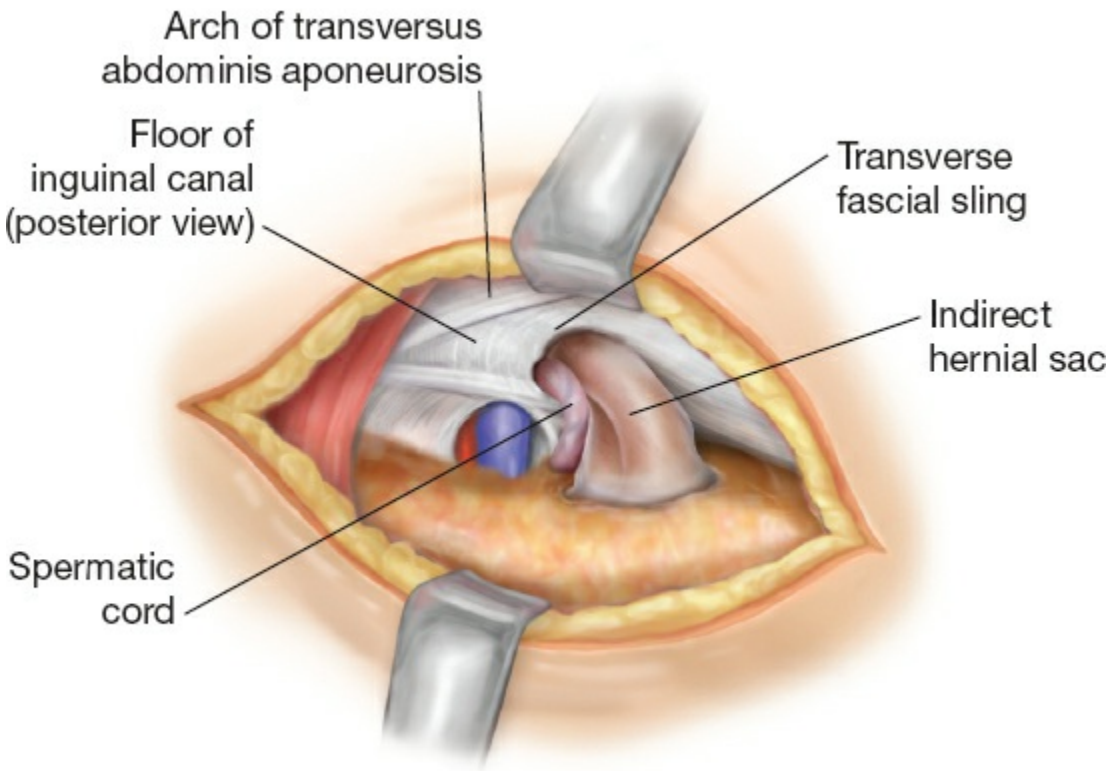

Figure 191.9. Femoral hernia, the posterior approach. The femoral sac protrudes into the femoral canal medial to the femoral vein, inferior to the iliopubic tract, above the Cooper ligament, and lateral to the reflected fibers of the iliopubic tract. The lacunar ligament is external to these structures and does not form one of the boundaries of the femoral defect in the posterior lamina of the transversalis fascia. (Redrawn after Nyhus LM, Bombeck CT. Anatomic and physiologic repair of groin hernia. *Am Fam Physician/GP* 1966;33:114.)

Repair of a Femoral Hernia

A femoral hernial sac is reduced by traction (Fig. 191.9). If the hernia is incarcerated, the sac is released by carefully incising the insertion of the iliopubic tract into the Cooper ligament at the medial margin of the femoral ring. The sac should be opened for inspection of its contents. Hernial repair is initiated with high ligation of the sac. The anterior margin of the hernial defect is formed by the iliopubic tract, and the posterior margin is formed by the Cooper ligament. The hernioplasty is completed by suturing these two structures together, thereby obliterating the femoral canal medial to the femoral vein (Fig. 191.10). In the posterior approach, there is no problem regarding visualization of the external iliac–femoral vein; it is easily seen and easily protected, and the correct degree of

closure of the canal medial to it without compressing it is more readily obtained. The aberrant obturator artery (corona mortis) crossing the Cooper ligament is seen and protected when present.

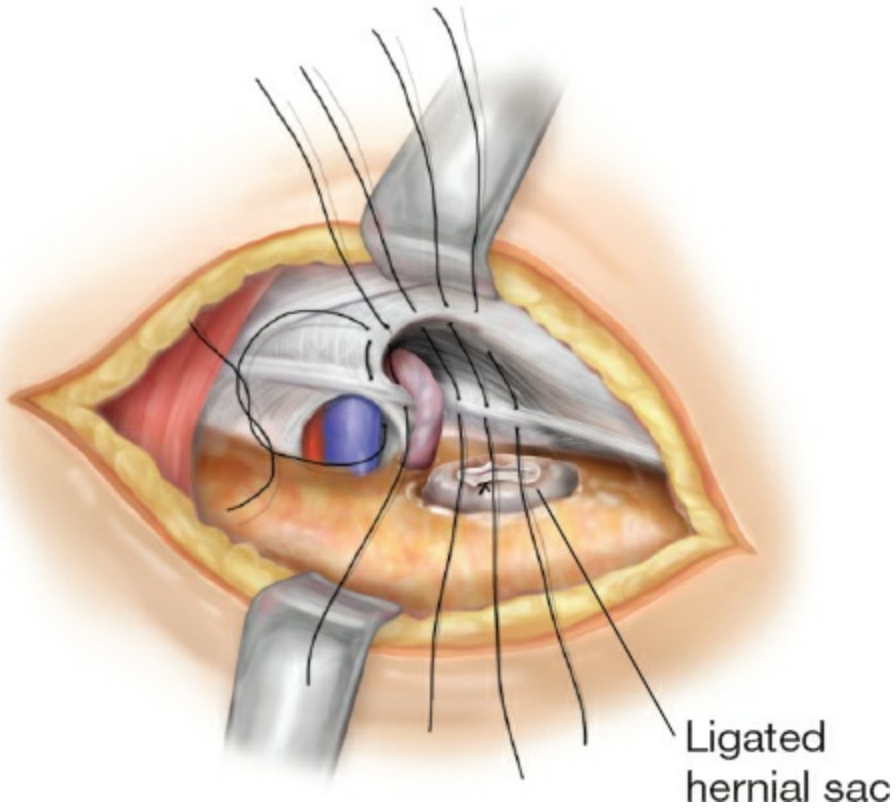

Figure 191.10. The femoral sac has been removed, and sutures are in place for the closure of the defect. The ease of exposure of the femoral defect makes this approach the procedure of choice for the repair of femoral hernias. (Redrawn after Nyhus LM, Bombeck CT. Anatomic and physiologic repair of groin hernia. *Am Fam Physician/GP* 1966;33:114.)

If the restraining fascia is distal in the femoral canal (Gimbernat ligament), release can be attained from above. There is, however, the rare possibility of performing a counterincision in the upper thigh over the femoral hernial mass for release of this restricting fascia. I have never found this necessary. Use of relaxing incisions or polypropylene mesh has not been necessary for the iliopubic tract repair of femoral hernias.

Closure of the Wound

After the hernial repair is completed, the remainder of the groin must be carefully searched for other hernias or areas of weakness. If such a

“missed” hernia is not discovered and repaired, it may appear postoperatively as a “recurrent” hernia.

Meticulous care must be taken to secure complete hemostasis before closure of the wound. The preperitoneal space is well irrigated with saline solution. The thin layer of transversalis fascia entered below the semicircular line of Douglas is usually not closed. The anterior rectus sheath and lateral muscle aponeuroses are sutured in layers with interrupted medium polypropylene followed by closure of the subcutaneous tissue and skin.

GENERAL REMARKS

In early experience, ligation of the inferior epigastric artery and vein was routine. As experience broadened, it was found that this maneuver was not necessary routinely for adequate exposure.

An Allis clamp is placed on the iliopubic tract at the level of the anterior femoral sheath and pulled laterally. This maneuver helps immeasurably to delineate the medial projection of the iliopubic tract. Similarly, lateral traction on an Allis clamp placed on the anterior sling of the internal inguinal ring—including transversalis fascia and transversus abdominis aponeurosis—helps to delineate the superior edge of direct hernial defects and the superior edge of large indirect hernial defects. The fascial bands and thickening may occasionally be easier to palpate than to visualize.

The iliopubic tract should be lifted in an anterior direction when placing sutures into it at the level of the femoral artery and vein. Unless this precaution is taken, the vessels may be traumatized.

I have vacillated in my choice of suture material. The standard suture material used in the fascial layer of the iliopubic tract repair is 0 polypropylene.

USE OF PROSTHETIC MATERIAL FOR RECURRENT HERNIA

The repair of recurrent hernias is technically intricate and is associated with a high incidence of secondary recurrence. I have adopted the preperitoneal approach to the inguinal region for all recurrent hernias repaired since 1978. Evidence that recurrences may result from a localized collagen metabolic defect has confirmed my belief that more than direct

reapproximation of the weakened posterior lamina is necessary if further recurrences are to be avoided. In this context, therefore, incorporation of the prosthetic mesh buttress to strengthen the repair is an important addition to the preperitoneal approach to the management of all recurrent groin hernias.

The posterior approach is expected to serve the following purposes:

1. Avoid dissection through nuisance scar tissue.
2. Allow thorough assessment of the hernial sac and hernial defects.
3. Allow confident exclusion of multiple hernial defects.
4. Facilitate the approach to repair by easy visualization of the Cooper ligament, iliopubic tract, and femoral sheath.
5. Apply the principle of intra-abdominal pressure to the inlay buttress (Pascal law), evenly fortifying its protection.

My 24-year experience suggests that this approach to the management of recurrent groin hernias is associated with minimal morbidity and few secondary recurrences.

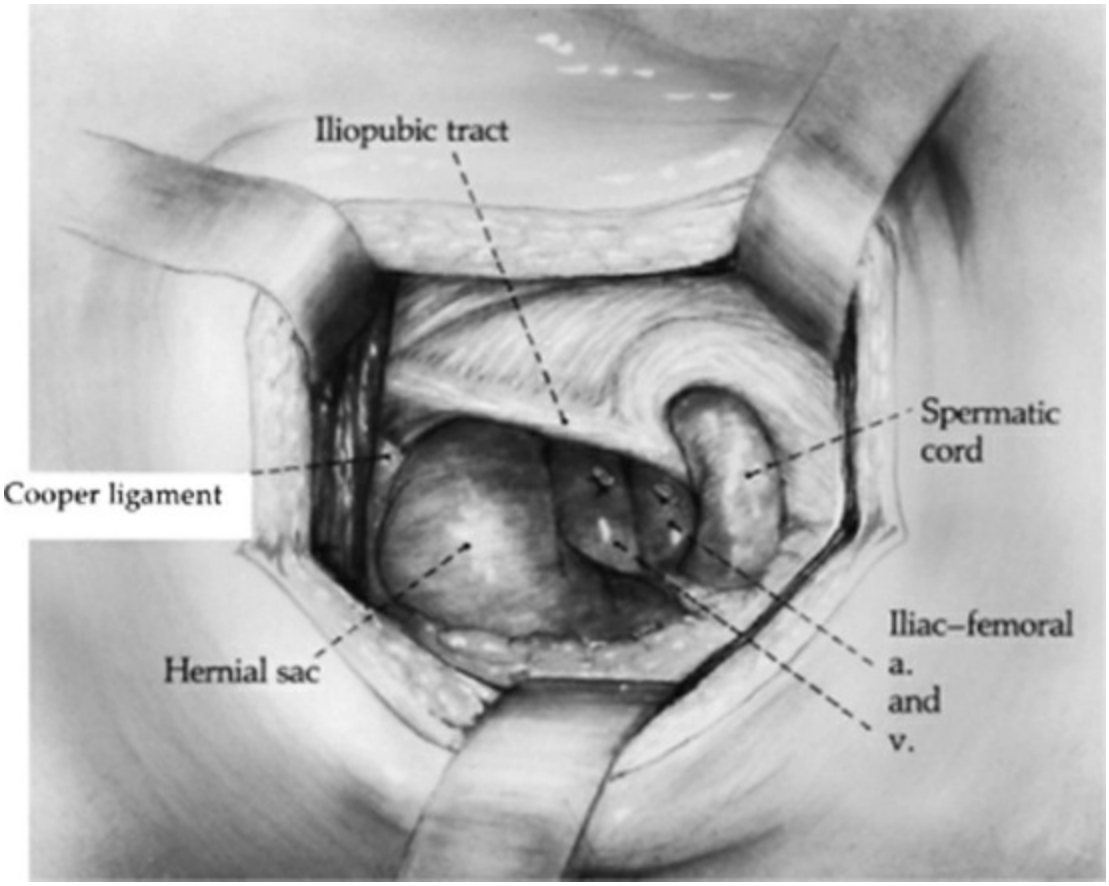

Figure 191.11. A polypropylene mesh buttress is attached posteriorly to the Cooper ligament (after repair of the recurrent defect in the wall) with 0 polypropylene suture material. If there is

concern about closure of the internal abdominal ring (indirect recurrence), the mesh can be folded around the spermatic cord (*inset*).

The steps to gaining access to the proper planes of dissection have been described. Fascial margins of the defects are approximated without excessive tension before the polypropylene mesh is applied to the posterior wall.

After the hernial defect is closed, a piece of polypropylene mesh, usually 10 × 5 cm, is cut. The Cooper ligament is visualized, and the mesh is sutured to it (Fig. 191.11). When a recurrent indirect hernia is being repaired, the spermatic cord should be incorporated into the mesh. The mesh is simply folded over the fascial repair and tacked to the posterior inguinal wall with 000 polypropylene. The polypropylene mesh can be tailored to fit the area that is to be covered. Finally, the mesh is sutured beneath the abdominal wound of entry to buttress the abdominal wall (Fig. 191.12).

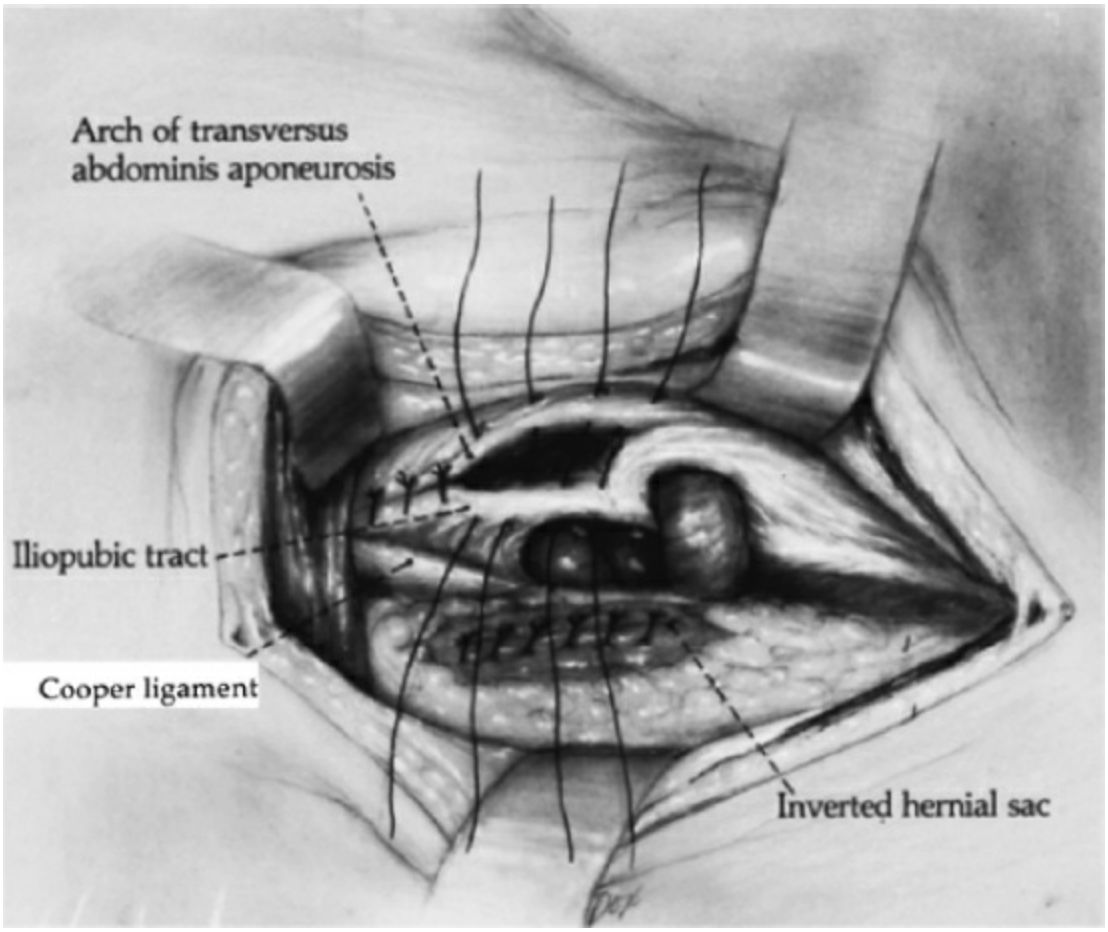

Figure 191.12. Inlay prosthetic mesh. *Arrows* show the Pascal

principle of even pressure applied to the prosthetic mesh. The suture line of the hernial defect remains intact and well protected. (From Nyhus LM. The recurrent groin hernia: therapeutic solutions. *World J Surg* 1989;13(5):541–4. Copyright © 1989 Société Internationale de Chirurgie, with permission from Springer.)

RESULTS OF TREATMENT

It has been shown that the posterior approach can give satisfactory results in the repair of all types of groin hernias. A specific method of repair, however, cannot be recommended unless surgeons understand the fine points of the method. For those who are insecure in the posterior technique, I advise an anterior approach and the repair described by Condon (Chapter 172).

INDIVIDUALIZING THE APPROACH

In 43 years of study of hernias, I have learned much about individualization of approach and repair (Table 191.2). The posterior approach and iliopubic tract repair is excellent for femoral hernias. Small indirect hernias (types I and II) are best treated from the anterior approach by high ligation of the sac alone or with plastic closure of the transversalis fascia at the internal ring. Large indirect hernias (e.g., sliding hernias), recurrent hernias, and incarcerated or strangulated hernias are ideally approached posteriorly. All direct hernias are best approached posteriorly. The larger complex hernial repairs should routinely be buttressed with an inlay of polypropylene mesh.

EDITOR'S COMMENT

This chapter by Dr. Nyhus is one of the classic articles in the hernia literature. It should be pointed out that not many surgeons use the preperitoneal approach in the sense of a suture repair. The approach theoretically is derived from Fruchaud's work, as mentioned in the introductory sections to these chapters, in which the myopectinate diaphragm is seen as the origin of all of the problems in the lower quadrants, with hernias presenting either through the internal or deep inguinal ring or through the femoral canal. As such, theoretically, one should interpose something between the myopectinate diaphragm and the site of increased intra-abdominal pressure, that is, the intraperitoneal organs and

contents. Indeed, as pictured elsewhere in this section, Stoppa and Rives used the concept of the myopectinate diaphragm to use a giant prosthesis, which theoretically would, if properly placed, prevent the emergence of hernias from posteriorly to anteriorly. Dr. Nyhus' chapter is somewhat different. In this chapter he is proposing suture repair, but using a buttressing synthetic material or mesh in an attempt to reinforce large or complex hernias and to prevent future herniation.

This repair is not often done. The concept, however, is ever-present whether one is talking about Stoppa's giant prosthetic patch or modifications such as the Kugel or the Gilbert repair, both presented in this section. The underlying hypothesis is that because increased intra-abdominal pressure results in hernias and recurrent hernias, the prosthesis belongs not anterior to the transversalis fascia but posterior to it. The problem that most people have is that it is an unfamiliar approach and they have difficulty in deciphering the anatomy.

I have found this approach useful at times when doing a sigmoid resection and there is a symptomatic hernia in the area; after changing gloves and gowns and instruments, I would then dissect off the peritoneum from the posterior structures and attempt to do a repair through the preperitoneal approach. Mind you, it is somewhat difficult to do and the anatomy is confusing to those of us who have not done this a great deal, but it is probably better than attempting a separate incision to repair a hernia.

This chapter was included because, in a sense, it is the forerunner of all of the preperitoneal repairs and is parallel to Fruchaud's concept of the myopectinate diaphragm, which increasingly is looked to as the anatomic basis for everything that happens in repairs.

J.E.F.

192 Kugel Technique of Groin Hernia Repair

Robert D. Kugel and John T. Moore

This Chapter can be accessed in the accompanying eBook edition (see inside front cover for access instructions).

INTRODUCTION

Hernia repair constitutes a major part of the typical general surgical practice. Expansive literature has been produced demonstrating benefits associated with a large number of repairs. Most of these repairs have focused on tension-free techniques. Tension-free repairs, when performed properly, reduce the risk of recurrence to low levels. These repairs also reduce postoperative pain and accelerate return to normal activity. Surgeons have been exposed to many mesh-designed tension-free repairs. In order to achieve the published results of these repairs, proper performance of the technique selected is the key element. These techniques require a thorough understanding of the procedures used as well as groin anatomy.

INDICATIONS

The Kugel technique for groin hernia repair is a tension-free, minimally invasive, yet open, preperitoneal or posterior abdominal wall groin hernia repair. It is applicable to the treatment of indirect and direct inguinal hernias as well as femoral hernias. It is particularly useful for the treatment of recurrent groin hernias after previously failed anterior repair. It can be used selectively in the patients having undergone prior radical prostatectomy or pelvic radiation, but should be avoided in the patients with recurrence after a failed laparoscopic groin hernia repair. This technique allows for rapid return to regular work and other activities without restriction. It further minimizes the risk of nerve injury and associated burdensome chronic pain syndromes because the inherent

nature of this repair is to avoid direct nerve injury and avoid exposure of the groin nerves to the mesh.

PATIENT'S SELECTION

The key elements in successful hernia surgery are proper patient selection and proper performance of the repair. However, not all patients with hernias need to be repaired. Elderly, debilitated, and inactive patients with asymptomatic hernias where the hernia is easily reduced may be best left alone with rare exceptions. Symptomatic patients should all be repaired promptly. Even here, postponement of the repair may be considered if the symptoms are minimal and the hernia is easily reduced. Factors to consider are cost (immediate and delayed), age, patient health, and type of work. There is no question delaying a repair may create a much more different repair later with more complications. Incarceration also is a rare threat.

Not every patient with groin pain needs surgery. The groin area is particularly susceptible to injury. Muscle and ligamentous tears and strains can cause groin pain and even result in chronic pain, which will not improve with the hernia operation. Very small and occult hernias exist and can be particularly difficult to diagnose, especially femoral hernias. These can cause pain in patients, but in the absence of clear physical findings for a hernia, observation seems to be the best initial course. Special caution in patients is also warranted with a very short history of symptoms or a very long history of symptoms, who do not demonstrate positive physical findings of a hernia. Ultrasound in these patients is sometimes helpful, but frequently overstates the presence of a hernia. The ultrasound also does not correlate well with the symptomatology. A wait-and-see approach is advised in these patients if the surgeon is to avoid the not uncommon patient complaint after surgery that "the pain is worse now than before the surgery" or even "the mesh must be causing the pain."

Though the bias of this presentation is that the Kugel technique is useful for the majority of groin hernias, there are incidences where it would be inappropriate (see indications) and even might not be the best technique. Although Kugel technique is great for bilateral hernias and for obese patients, it might be easier to treat the morbidly obese patient with a different technique.

THE MESH PATCH

The Bard Kugel patch (Davol, Cranston, Rhode Island) was developed to

facilitate performance of the Kugel hernia repair. Although it is started out as a simple single-layer mesh, it became progressively more intricate in order to make the performance of the procedure easier and the repair more secure.

The patch is composed of two overlapping layers of knitted monofilament polypropylene mesh material that are ultrasonically welded together (Fig. 192.1). A pocket of polypropylene is constructed on the outer edge of the patch which contains a single polyester fiber spring or stiffener that helps the patch unfold after placement and maintain its configuration. One centimeter of mesh material extends beyond the outermost welds into which have been cut multiple radial slits. This outer fringe allows the patch to conform and fill more perfectly in the preperitoneal space, particularly when the patch folds back over the iliac vessels. A transverse slit is made in the center anterior patch, which is utilized for insertion of a finger which helps in positioning the patch in the preperitoneal space. Just beyond the anterior slit and inside of the mesh ring are multiple 3 mm holes through both layers of the patch. These serve to allow tissue-to-tissue contact through the patch to prevent movement of the patch after placement. This movement prevention is further augmented by several small V-shaped cuts associated with all of these holes in the anterior layer only. These cuts create a triangle of mesh which tends to pop-up when the patch is placed, and these act as sutureless anchors for the patch.

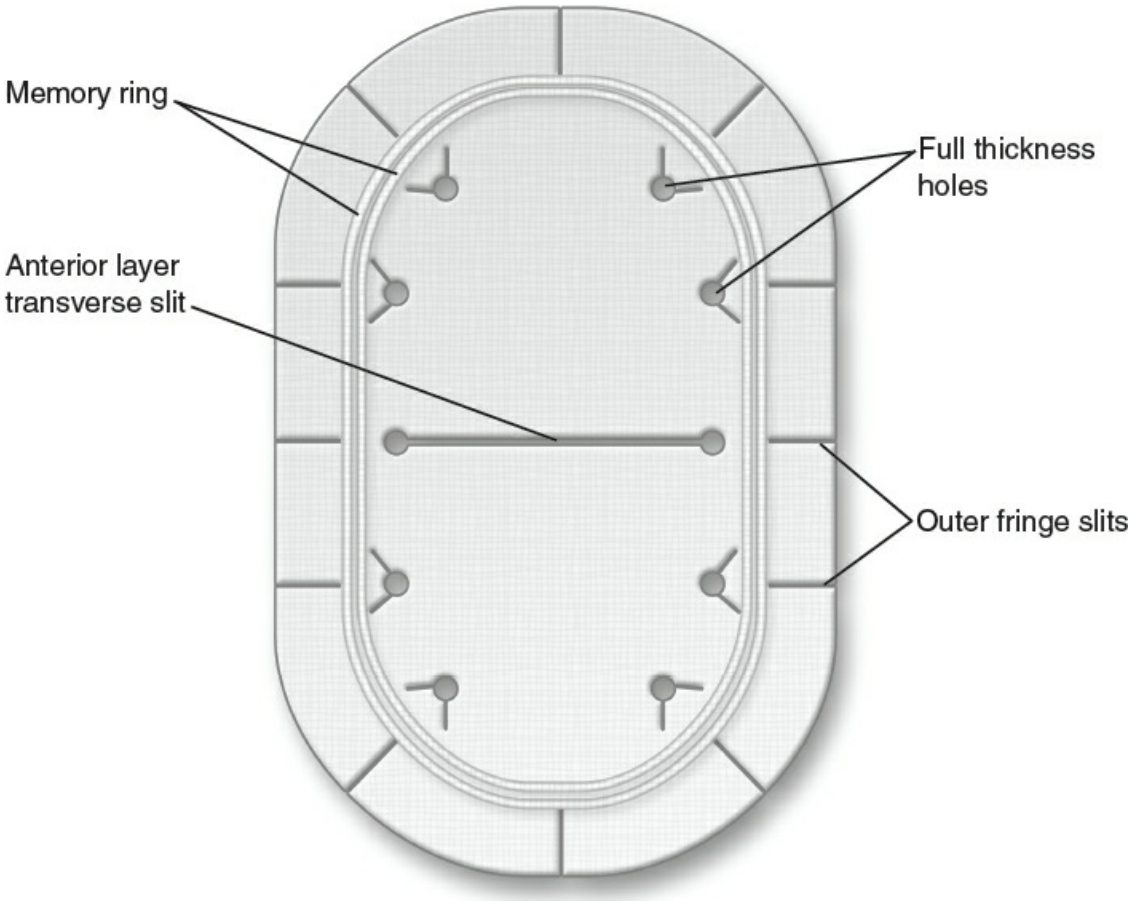

Figure 192.1. Memory ring, anterior layer transverse slit, outer fringe slits, and full thickness holes are illustrated.

There are two mesh sizes used for groin hernias. The small patch is 8 × 12 cm and the medium patch is 11 × 14 cm. The small patch is adequate in most patients; however, the medium patch does provide greater margin for error and is preferred in very large hernias. It is up to the surgeon to decide the appropriate size of the mesh patch to be used, recognizing that the greater amount of underlay will probably result in fewer recurrences.

OPERATIVE PROCEDURE

Anesthesia

1. **General Anesthesia:** This is the author's anesthetic of choice for this operation. The primary disadvantage of a general anesthesia is the limitation of the ability to test the repair at the completion of the operation.
2. **Regional Anesthesia:** This is the preferred choice for some patients with epidural anesthesia being preferred over spinal anesthesia. The epidural anesthetic has the advantage for re-dosing when the catheter is

left in place during the procedure. This not only allows for minimal initial dose, but also for the administration of additional doses as needed if the operation takes longer, which may happen with bilateral hernias. Furthermore, epidural anesthesia results in less muscle paralysis, enabling the patient to respond more forcefully when testing the repair following the operation.

3. **Local Anesthesia:** The author has preformed this procedure using local anesthesia and has monitored anesthesia care provided by an anesthesiologist, but maintenance of a relaxed patient is imperative to be able to enter and maintain appropriate visualization of the preperitoneal space through the incision. If the patient experiences pain and begins to bear down in response, it can make the procedure very difficult. Very obese patients with recurrent hernias or the patients who do not tolerate monitored anesthesia care should not be done under local anesthesia because of the loss of visualization associated with muscle contraction and discomfort.

PATIENT PREPARATION

Appropriate laboratory and radiographic evaluation of patients preoperatively depends on the surgeon and the policies and procedures of the facilities in which they practice. Because of the risk of bleeding into the preperitoneal space, it is recommended that Coumadin be stopped 3 to 5 days prior to the surgery. Use of prophylactic antibiotics is recommended due to the implantation of the foreign body into the wound. Although infection reduction is not clearly substantiated in controlled studies, antibiotics add little risk and may reduce graft infections.

Clipping of hair in the operative area is recommended over shaving at the time of the procedure, followed by an appropriate skin preparation.

The patient is positioned in a supine manner. During the operation, exposure is improved by placing the patient in a Trendelenburg position with slight rotation away from the site of the procedure.

SURGICAL TECHNIQUE

Regardless of the type of the hernia to be repaired, the mesh patch is placed in the same fashion into the preperitoneal space in every patient. The repair can be more difficult to achieve because of the lack of familiarity with the anatomy in the posterior space and the angle in which the repair is approached. Understanding the unique approach is the key to

the successful performance of this procedure. Ideal first patients are of average size or thin where the anatomy should be clearly visible. Avoid recurrent hernias or large scrotal hernias initially. One of the advantages of this repair is the ease with which it can be converted into an anterior repair. The surgeon needs to back out of the preperitoneal space, allow the internal oblique muscle to re-approximate, and extend the skin and external oblique incision through the external ring and perform an anterior repair.

INCISION

The author thinks it is critical to utilize a headlight during the performance of this operation. Because of the angle in which the repair is approached, the headlight helps illuminate extremely well the area of the preperitoneal space and allows for accurate placement and deployment of the mesh patch. In addition, use of a dedicated assistant is also extremely helpful. The operation can be performed with the surgical scrub functioning as the assistant. A dedicated assistant, particularly in larger patients, allows for continued visualization of the preperitoneal space through continuous retraction.

Incision placement is important and can have a bearing on how easy it is to perform the operation (Fig. 192.2). The most important thing is to avoid making the incision too low. The ideal is to pass directly through the skin, muscle, and fascia into the preperitoneal space. This approach is superior to the internal ring and lateral to the inferior epigastric vessels. It avoids the inguinal canal. Marking the anatomic landmarks on the surface of the patient will insure the correct placement of the incision. Identify the anterior superior iliac crest and the pubic tubercle. Measure the distance between these two points and mark the halfway point. This identifies the location of the internal ring. Measure directly superior to this point identified as the internal ring 2 cm and mark the site of the incision. This appropriately positions the incision in the high position to avoid entering into the inguinal canal. A 4-cm oblique incision is made with two-thirds of the incision being made medial to the point marked on the skin and one-third of the incision lateral. Four centimeters is an arbitrary measurement. In the initial performance of this operation, the surgeon may want to make a slightly larger incision as it does not affect the overall outcomes of this operation and may give better visualization.

The skin incisions can be made either transversely or obliquely, but

oblique incisions enable the surgeon to move into a more conventional anterior repair, if needed, with less difficulty. The author prefers to make an oblique incision. The incision is made straight down through the skin and subcutaneous tissue on to the external oblique fascia. The external oblique fascia is then opened a short distance in the direction of its fibers, but not through the external ring. This exposes the underlying internal oblique muscle. Frequently, the ilioinguinal and iliohypogastric nerves can be visualized on the surface of the internal oblique muscle when the external oblique fascia is split. Great care should be taken to avoid traumatizing a sensory nerve when splitting the internal oblique muscle, otherwise there is no need to directly visualize the ilioinguinal or the iliohypogastric nerves at this point. The internal oblique muscle is bluntly split in the direction of its fibers to expose the transversalis fascia. The muscle splitting of the internal oblique musculature when placed in the proper position frequently lies inferior to the iliohypogastric nerve and medial to the ilioinguinal nerve. Transversus abdominis muscles fibers that are occasionally encountered superficial to the transversalis fascia may need to be split as well. The transversalis fascia at this level is frequently a very thin and fragile structure. It can usually be penetrated by gentle blunt dissection. On occasion when it is more tenacious, a cutting of the fascia may be necessary. It is recommended that this is done in a vertical manner to avoid injury to the inferior epigastric vessels which lie in the medial aspect of the incision. Identification of the preperitoneal space is made by the characteristic appearance of the fat of the preperitoneal space and the identification of the inferior epigastric vessels in the medial aspect of the incision. A crucial aspect of the operation is to ensure that the surgeon dissects within the preperitoneal space. Identification of the inferior epigastric vessels, which lie in the medial portion of the incision within the preperitoneal fat keeping the dissection posterior to these vessels, will assure the surgeon will complete the operation in the correct compartment.

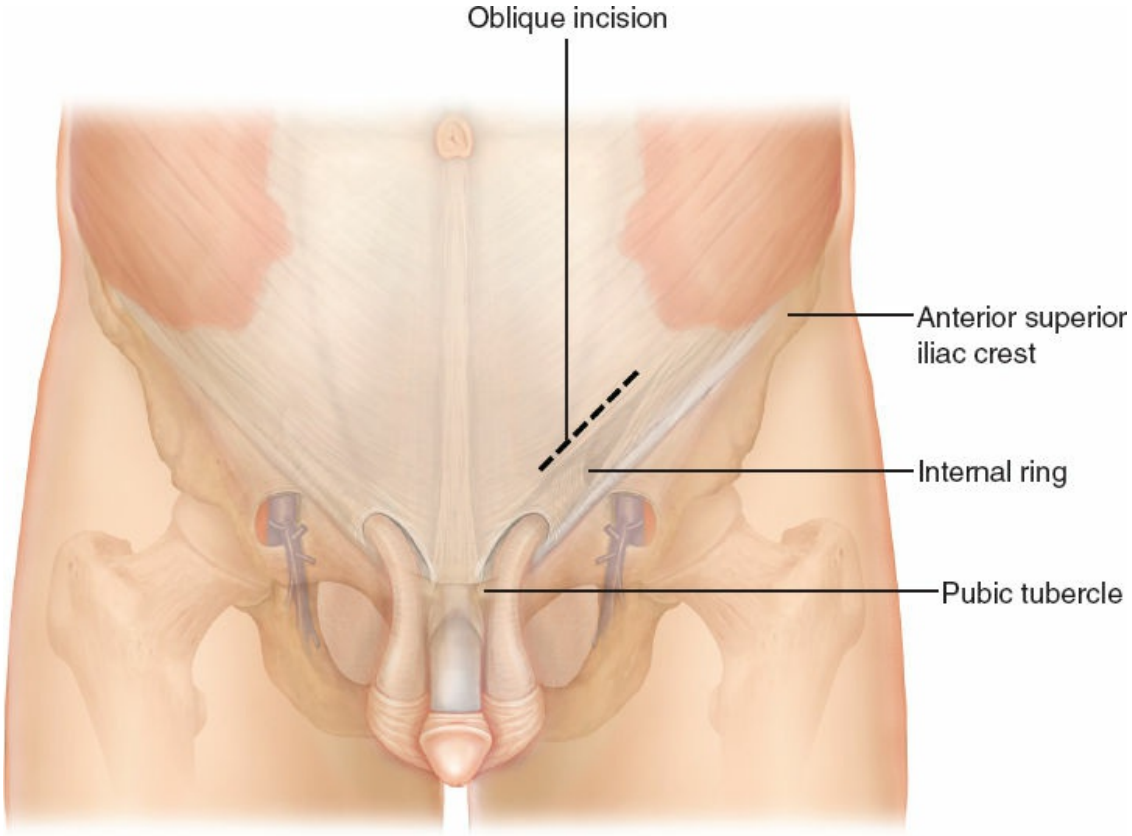

Figure 192.2. Incision.

PREPERITONEAL DISSECTION

Once the preperitoneal space is entered, it is important to become oriented to the anatomy. The internal ring will lie immediately inferior to your incision, with the cord structures lying anterior and lateral as they prepare to exit the preperitoneal space through the internal ring. Hesselbach's triangle will lie just inferior and medial to the inferior epigastric vessels. It is best to approach the dissection as consisting of two compartments: medial and lateral. In the medial compartment will be direct and femoral hernias. Indirect hernias will lie in the lateral compartment. The order of approaching the compartments depends on the surgeon's preference. My preference is to perform the medial dissection first unless there is such a large indirect hernia present that would prohibit entering into the medial compartment. This would require doing the lateral compartment dissection first. The principle in the medial compartment dissection that needs to be maintained is complete reduction of the preperitoneal contents from the attachments to the transversalis fascia. Clear visualization of cooper's ligament from the pubic tubercle to the external iliac vessel is essential. In so doing, the direct hernias will be reduced and femoral hernias, if present,

will be identified. This dissection is carried out using blunt dissection with the finger of the surgeon sweeping the preperitoneal contents posteriorly and superiorly. This medial compartment dissection should be carried out to a point just medial to the pubic tubercle and superior to the incision in the transversalis fascia, which will create the space for the mesh. The headlight and the retraction provided by the dedicated assistant greatly help the visualization.

Attention is then turned to the lateral compartment. The first step in the lateral compartment dissection is identification of the cord structures. The goal to be achieved is skeletonization of the cord, thereby identifying a potential indirect hernia. The peritoneal reflection should be reduced ~3 cm above the internal ring or to a point above the diversion of the vas deferens from the cord vessels. Once reduced, the indirect hernia sac can be left alone or ligated and amputated. Inspection should also be carried out to the area lateral and superior to the cord structures, creating space by freeing the preperitoneal contents, which will allow for free deployment of the mesh (Fig. 192.3). Again the headlight and the dedicated assistant greatly help the visualization.

The space is now ready for mesh insertion (Fig. 192.4). A useful technique is to use a narrow malleable retractor placed on the peritoneum, retracting it superiorly as the mesh is slid into position over the surface of the retractor. The Kugel inguinal mesh is specifically designed for this application. The transverse slit is designed into the mesh to allow for the surgeon to place the mesh over the index finger of the hand of the surgeon opposite to the patient's side upon which they are operating, that is, left-sided hernia right-handed insertion. The mesh is gently folded over the finger of the surgeon into their palm in the form of a taco to allow for this placement. The mesh is slid into the position with the extensor surface of the surgeon's hand sliding along the malleable retractor until the surgeon can easily palpate the pubic tubercle with the tip of the index finger that has been inserted into the mesh slit. The surgeon's hand is then withdrawn and replaced by the malleable retractor into the slit to stabilize and hold the mesh in position as the mesh is unfolded into its proper deployment. The mesh is then deployed back over onto the peritoneum in a curved but unbuckled profile covering all potential defects in the groin. The mesh chosen ought to be large enough to cover the opening in the transversalis fascia extending 2 to 3 cm above the opening that was made for the incision. Two sizes of mesh are available for insertion as previously

described. In our experience, ~75% of hernias have been repaired with the smaller patch. The mesh is secured to the transversalis fascia in the medial portion of the transversalis incision with one absorbable suture. The transversalis fascia is then closed over the surface of the mesh with a running suture. The internal oblique musculature is allowed to recompose itself without suture, thereby avoiding possible nerve entrapment. The external oblique and skin can be closed as per the surgeon's preference, again taking care not to entrap any underlying nerves.

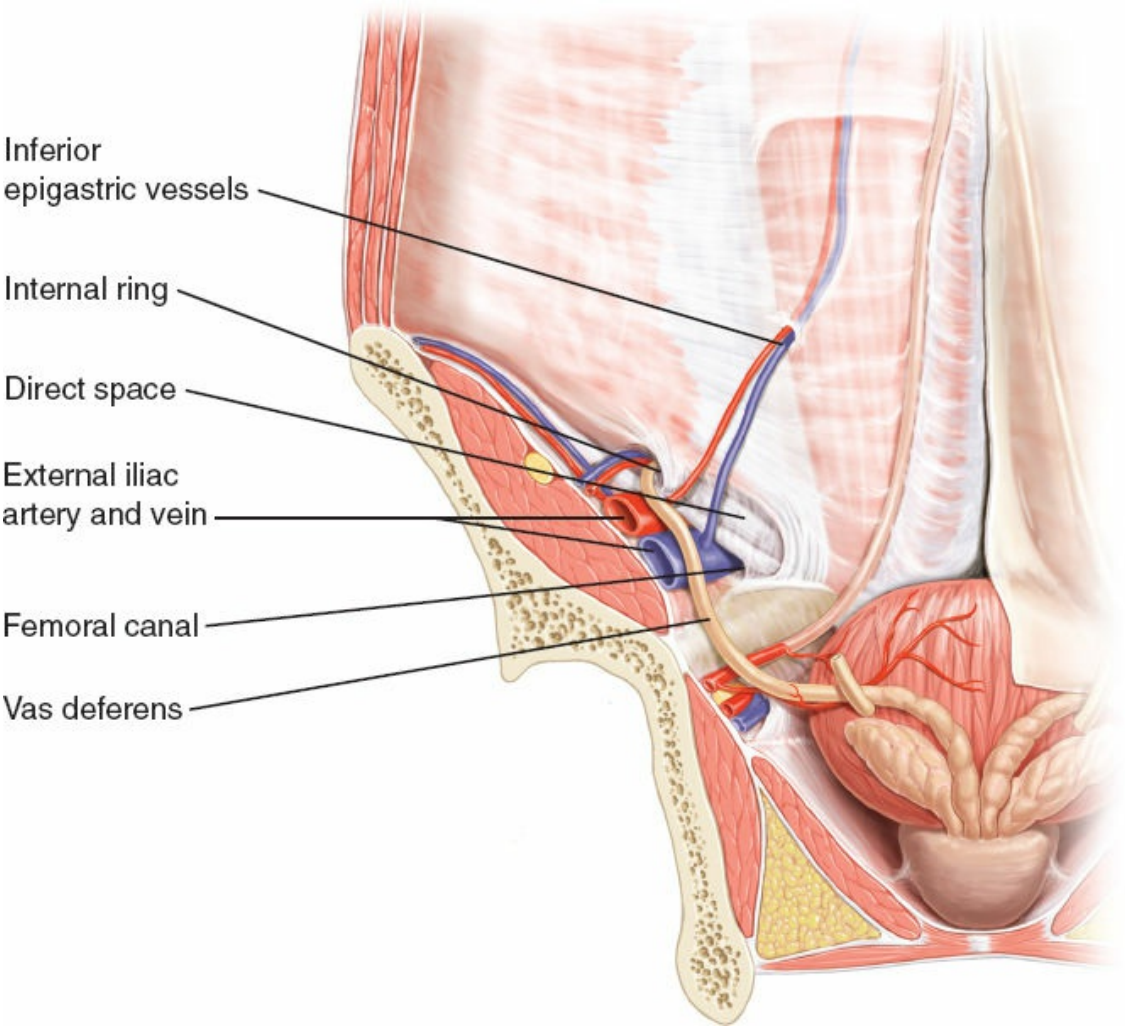

Figure 192.3. Inferior epigastric vessels, internal ring, direct space, pubic symphysis, femoral canal, external iliac artery, external iliac vein, and vas deferens are illustrated.

RECURRENT HERNIA

Repair of recurrent hernias following this repair or previous laparoscopic repair is best avoided using a Kugel approach. Recurrent hernias following prior anterior repair, however, are ideal candidates for this approach. The

majority of scar tissue from the original repair is avoided and the repair is generally not much more difficult than a primary repair. This approach allows for a more thorough evaluation of the posterior space and should reduce the risk of a missed second defect. The most common difficulty encountered with these repairs is scar tissue at the internal ring associated with a prior high ligation of the sac.

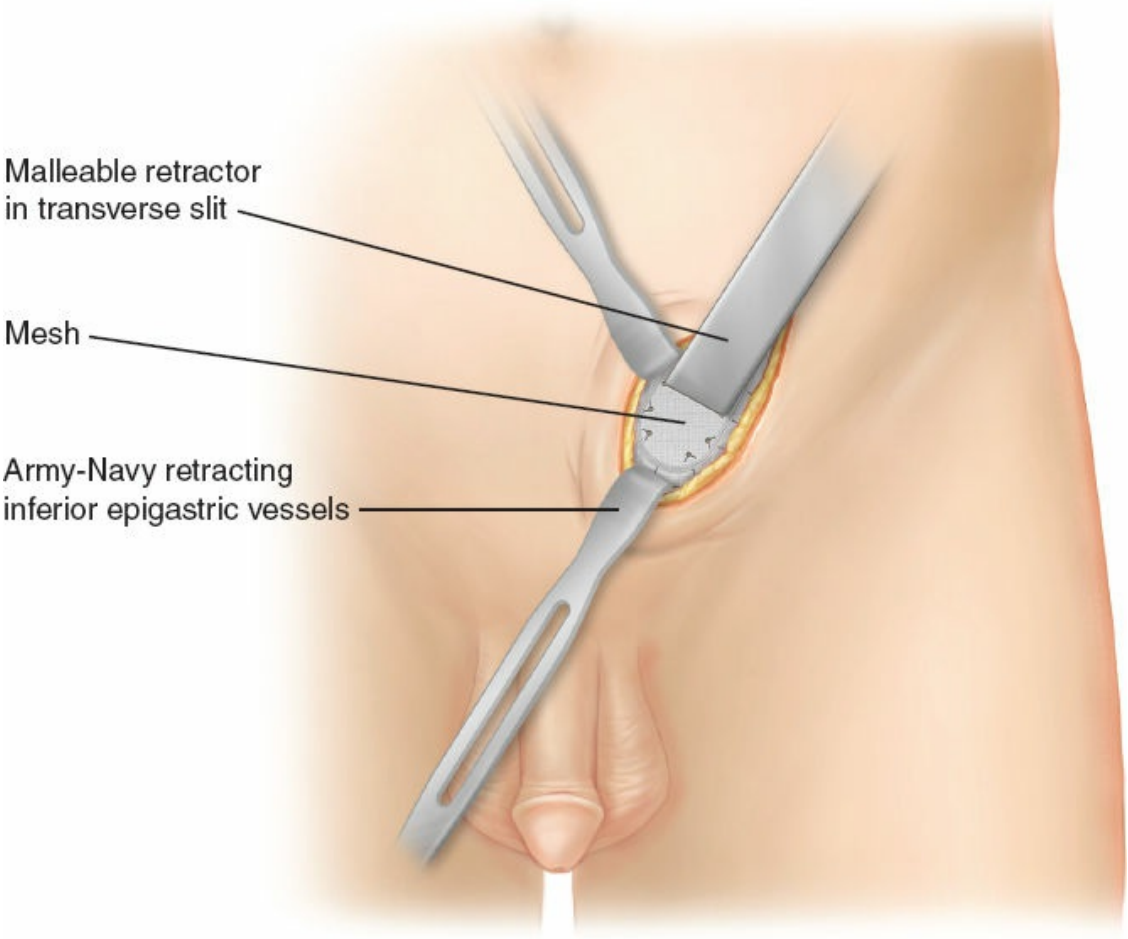

Figure 192.4. Mesh insertion.

FEMORAL HERNIAS

Experiences with this technique and with laparoscopic hernia repair suggest greater prevalence of femoral hernias than previously believed. These will sometimes be encountered unexpectedly during the surgery for an indirect or direct inguinal hernia. The hallmark of the femoral hernia from within the preperitoneal space is an obstructing mass just medial to the external iliac vein which extends into the femoral canal. This will prevent proper deployment of the preperitoneal pocket for the mesh patch until the mass is reduced.

POSTOPERATIVE MANAGEMENT

A majority of patients are discharged from the recovery area when appropriate. No specific restrictions are placed on them regarding all activity including lifting. The patient is cautioned that their greatest discomfort can be expected during the first 2 to 3 days and this should taper off rapidly thereafter. Patients are asked to increase their activities a little everyday until returning to normal. Most patients are usually able to resume most regular activities within a few days to a week. Most patients will require approximately three to ten mild narcotic pain relievers over the first few days following the operation, but generally these can be replaced with either nonsteroidal anti-inflammatory medications or other over-the-counter pain relievers. Most patients are seen in 1 to 2 weeks following surgery and then discharged.

RESULTS

In a previous edition of this text book, Dr. Robert Kugel reported 1662 groin hernia repairs. Of these, there were 803 primary right inguinal hernia repairs and 725 primary left inguinal repairs. There were 85 repairs performed for recurrent right inguinal hernias and 49 repairs performed for recurrent left inguinal hernias. In the 10 years following that initial report, there had been a total of seven recurrences. All of those recurrences were in the primary repairs with an overall recurrence rate of 0.42%.

My group reported the results in 2005. We did 1072 repairs with an overall recurrence rate of 0.47% with a mean followup of 23 months. We demonstrated rapid operating times, minimal postoperative pain, expeditious return to work, and no reports of chronic pain. Multiple other studies have been published since that time and with similar results.

COMPLICATIONS

Complications are infection, bleeding, recurrence, or chronic pain. These issues will be addressed individually.

1. **Infections:** Infections are early or late. Early infections occur within the first couple of weeks following the hernia procedure and should be treated as skin and subcutaneous infections. Aggressive local wound care and antibiotics are advised. I think the initial approach should be one with the idea of salvaging the mesh. CT scan imaging can be helpful to determine the depth of the infection. If the infection does not

penetrate into the preperitoneal space, the wound can be opened for good drainage. With antibiotics, salvaging the mesh is usually successful. If, however, there is clear evidence of infection extending into the preperitoneal space, I believe the most prudent course is to remove the mesh and handle the infection appropriately. It would be ill-advised to immediately place another synthetic mesh material into the wound. The use of biological meshes or tissue repair in this setting would be up to the discretion of the operating surgeon. Late infections usually occur well past the initial operation. It generally means a mesh infection is present. Prolonged antibiotics can be attempted, but they generally are not effective and in most cases the mesh will need to be removed. Early removal of the mesh results in a more rapid resolution of the problem rather than prolonging the problem with unsuccessful therapy.

2. **Recurrences:** There are few recurrences in the published reports. Causes and mechanisms of recurrences have not been clearly defined. One of the primary concerns involves the extent of mesh shrinkage secondary to the ongoing inflammatory reaction through the polypropylene in the mesh. This shrinkage has been estimated in multiple published reports to range between 5% and 30%. As long as an adequate-sized mesh is utilized and the mesh is deployed in the proper position, this should allow for the estimated shrinkage and prohibit recurrence from that point of view. In our experience of operating on our own recurrences as well as other recurrences, the most common cause was a missed indirect hernia. This probably resulted from the failure to completely skeletonize the cord structures at the time of the initial operation and recognize the presences of an indirect hernia. This resulted in a persistent indirect hernia rather than a recurrence.
3. **Bleeding:** Bleeding is not a common problem as the dissection is generally performed in a bloodless plane. A preperitoneal repair should be avoided or approached with caution in the patients who require aggressive preoperative anticoagulation secondary to other underlying hypercoagulable or thromboembolic conditions (i.e., mechanical cardiac valves). The preperitoneal space is very susceptible to ongoing hemorrhage secondary to the induced hypocoagulable situation. This ongoing hemorrhage can be extremely difficult to recognize in the preperitoneal space and significant hemorrhage can occur before it is picked up. It is therefore advisable that an anterior repair be carried out in these patients so that if bleeding does occur, it is obvious and can be

addressed immediately.

4. **Seromas:** Seromas commonly occur, particularly in direct hernia repairs. The patient will usually present at the initial postoperative visit complaining of persistence of the hernia. On exam, a smooth slightly tender mass, which is nonreducible and does not change with Valsalva, will be identified in the inguinal canal. If obtained, an ultrasound will demonstrate the presence of the seroma and we will reassure the surgeon as well as the patient. Unless there are clear signs of infection, no other intervention needs to be or should be taken in regards to the presence of the seroma. They will resolve spontaneously if left alone.
5. **Chronic groin pain:** Chronic groin pain or inguinodynia is defined as pain within the groin. General surgeons see this condition most often following inguinal hernia repair. The most common etiology for this chronic pain is suspected to be related to either direct injury or entrapment of one of the four nerves within the inguinal region. These nerves are the iliohypogastric, ilioinguinal, genitofemoral, and lateral femoral cutaneous nerves. Because of the performance of the Kugel hernia repair in regards to its muscle splitting technique and avoidance of sutures within the internal oblique, nerve injury and subsequent entrapment is rare. In addition, in the Kugel approach, there is no need for fixation within the preperitoneal space that could entrap the lateral femoral cutaneous nerve. The surgeon needs to be very aware of the anatomical course of these nerves and keep the dissection in the planes as described and avoid placement of sutures into the external oblique at the completion of the operation, which could entrap the ilioinguinal nerve.

MISCELLANEOUS COMPLICATIONS

There have been concerns about the direct exposure of the mesh to the iliac vessels. The mesh is specifically flanged on its peripheral 1 cm to prevent direct pressure onto the vessels as it is deployed over the surface of the peritoneum in the preperitoneal space. In addition, it is not necessary or recommended to skeletonize the external iliac vein, the most medial structure within the vascular bundle. Dissection only needs to be carried out at the level of the lacunar ligament to assure that no femoral hernia exists. Avoidance of this excessive dissection will protect the vessels from direct exposure with a surface layer of undisturbed tissue.

There have been intense medical and legal discussions in regards to fractured rings within the Kugel patches resulting in bowel injury. This

problem has only been reported in Extra Large Composix Kugel products utilized in ventral hernia repairs and never truly verified. No reports of such injuries have been reported in a Kugel inguinal repair with the Kugel hernia patch.

DISCUSSION

The preperitoneal mesh patch prosthesis utilizes those forces only available to a posterior repair. Intra-abdominal pressure works in securing the patch in position. A fully expended and appropriately sized patch, with its semi-rigid ring, is difficult to displace through any hernia defect encountered in the groin. Because the patch is placed without fixation sutures, hydrostatic tissue forces also come into play in securing the patch into position. The patch is allowed to more perfectly conform to the patient's unique anatomy, and the two wet surfaces on either side of the patch sandwich it in place and resist patch movement. This method of repair provides protection for the entire groin including the femoral canal and the surgical incision itself. It is an ideal approach following prior anterior hernia repair as it avoids most of the associated scar tissue from the prior repair.

The disadvantages of this repair are related to obtaining the appropriate visualization of the preperitoneal space, assurance of dissection within the correct preperitoneal space, and confidence on the part of the surgeon in regards to the proper deployment of the mesh into the appropriate space. Use of a headlight and a dedicated assistant reduces the disadvantages.

Working with an experienced surgeon on several cases before attempting the repair solo allows for the surgeon to gain the confidence in regards to being able to clearly identify the preperitoneal space and its anatomy as well as to recognize when proper deployment of the mesh is achieved.

SUMMARY

As incidence of recurrence, safety, ease of performance, and shortened disability periods are considered in selection of a hernia repair, the Kugel inguinal hernia repair demonstrates its attractive advantages. Accumulated experience has demonstrated it to be an effective repair.

EDITOR'S COMMENT

The Kugel hernia patch is supposed to do two things: the first is to prevent the emergence of a hernia through the internal inguinal canal and the second is to bring about a patch on the interior of the transversalis and to provide a remedy against any openings in the myopectineal shield. The Kugel repair has become a very popular procedure because there is not much in the way of dissection and there is a one suture fixation technique, which is to prevent the hernia from recurring. Make no mistake about it, the Kugel repair as well as many of the other contemporaneous repairs function to prevent recurrence. The individuals who have originated the Kugel repair did think about the risk of nerve injury and the chronic pain syndromes. They state that they avoid chronic pain syndromes by avoiding direct injury and/or exposures of the groin nerves to the mesh. They do not believe that this is useful for a younger pediatric population, but it may be used for older teenagers. They also add that the hernias, which appear in the younger population do not often need any change in the configuration of the various ligaments in the groin because although it is usually unnecessary, and all that is needed is a high ligation of the sac. I am not certain that this has been subjected to a true follow-up.

One of the refreshing things about this chapter is that somebody has finally

asked the question, “Do all patients with the hernia require surgery?” I think that is a very good question. It is a question that has become more eventful as we start to think about not recurrence, which is that various herniotomists think about whether or not people should have a mesh repair or not, but does the hernia need to run the chance of having a very painful result if mesh is placed? Indeed, there is a good discussion here about whether to do the repair or not. Very small and occult hernias, to quote the author, “do exist and can be particularly difficult to diagnose especially with femoral hernias.” A short history of symptoms is probably best observed because I think that patients may be better off not getting the hernia repair rather than getting inguinodynia. The mesh will cause pain on occasion as we will see in several of the papers, but hopefully it will be minimal. I do believe that patients who undergo mesh repairs do run a greater chance of having a chronic long-term pain of inguinodynia than the old-fashioned seeming type of repair, which in my hands the transversalis layer is added. This Kugel technique depends on “two concentric walls near the outer edge of the patch serve to contain a single polyester fiber spring or stiffener….” The 1 cm of mesh material extends beyond the outermost weld so that this has been cut into radial slits. I am not certain that this repair really deals with the entire myopectineal shield, but it at least tries. Dr. Moore does under “Incision” state that the incision should not be too low so that the mesh can pass comfortably through the skin, muscle, and fascia into the preperitoneal space superior to the internal ring and just lateral to the inferior epigastric vessel. Thus, it is out of the inguinal canal. In any event, as the author states, the best thing about a repair like this is hopefully not to entrap the nerves and yet prevent a recurrence. I am not certain that “the muscle splitting component when placed in the proper position frequently lies just inferior to the iliohypogastric nerve and just superior to the ilioinguinal nerve.” There are branches between the two nerves and if they are entrapped, my guess is they are as painful as if you trapped the main nerve. The author does say that the patch will end up “sandwiched between the peritoneum and its posterior aspect and tranversalis fascia on the other side.” The cord structures should be out of the way and Cooper’s ligament will be on the inferior aspect of the mesh. One hopes that with all of this description of the mesh and how we have avoided the inguinodynia or the entrapment of the nerves against the patch is minimal. I still get concerned about the focus being on recurrence and not on the groin pain. From the patients with groin pain that I see, I think that recurrence would be an easier thing to experience rather than what they currently have.

A number of people have been interested in some of the aspects of the Kugel repair, including the degree of inflammation. Bender et al. (*Surg Endosc* 2009;23:2657–61) have tried to see whether or not there is more inflammation after the Kugel repair as compared with the totally extraperitoneal (TEP) laparoscopic repair. They measured serum cortisol, high-sensitivity C-reactive protein, and interleukin concentrations before surgery and 1 and 24 hours after

surgery. They did not differ significantly between the two groups. They did say that the cost per patient was 546 dollars lower in the Kugel group, and therefore they do not think that this is a procedure, which is neither very expensive nor one that causes pain and inflammation. Of course pain is where it is at.

Another way of approaching this is by Fujii, T of the Graduate School of Medicine at Gunma University in Gunma, Japan (*Am Surgeon* 2011;77:243–4), in which he observed how the operation is actually done with a laparoscopic approach to see where the mesh actually ends up. This sounds like a reasonable idea and they point to the fact that they can get a Kugel repair or bilateral obturator hernia repair in only 43 minutes. They state that no symptoms have been observed with the diagnosis of the obturator hernia, and therefore this is a valid repair.

Having said all of this, a number of surgeons focus on the amount of pain the patients have with Kugel patches as opposed to other repairs. Van Nieuwenhove et al. (*Hernia* 2007;11:9–13) in a multicenter case series of 450 consecutive Kugel patch repairs reviewed at 1 year and short-term outcomes decided that eight recurrences were present after 18 months (1.9%) and that there was persistent inguinal pain in 15 patients (3.5%). Analgesics were used for 3 ± 2 days and paracetamol was the only painkiller that was used. Thirteen percent did not take any painkiller at all. Half of the patients returned to their daily activities after 9 days and half of the employed patients returned to work after 14 days. The authors concluded that this operation has a low recurrence rate and not too much in the way of pain.

Dasari et al. (*Ulster Med J* 2009;78:115–8) tried to compare the Lichtenstein tension-free repair to the Kugel tension-free repair of inguinal hernia. A total of 219 consecutive patients underwent inguinal hernia repair—92 using a standard Lichtenstein repair and 127 using a Kugel patch. It is likely that these patients were not randomly chosen. They actually summarized the usual characteristics —length of hospital stay, complication rates, and so on, and the endpoints were recurrence and chronic groin pain. There were 214 men and 5 women and they ranged in age from 18 to 87 years with a mean age of 54 years. Unfortunately, only 72% of postal questionnaires were returned. They actually tried to increase response rate by phone and finally got up to 80%. The bottom line is that immediate complications were similar in both groups and recurrence rate was 1.1% with the Lichtenstein repair and 6.3% for the Kugel patch. This difference was not statistically significant ($P = 0.09$). Severe chronic pain was not present in the Lichtenstein group but 1.6% of the patients in the Kugel patch group complained of severe chronic pain in the inguinal region. Thus, the recurrence rate and chronic pain were worse in the Kugel group but not significantly so.

Hompes et al. (*Hernia* 2008;12:127–32) investigated the area of chronic pain after a Kugel inguinal hernia repair. The endpoint in this study was chronic pain 1 year after the Kugel herniorrhaphy and to see whether they could identify the risk factors. All patients in this teaching hospital at the Catholic University in Leuven, Belgium underwent inguinal hernia repair between January 2002 and

June 2005. Analgesia consumption, postoperative function, and impairment and postoperative complications were recorded in all of these patients. One year after the repair, 57 of 377 patients (15.1%) complained of mild to moderate pain. The incidence of mild and moderate chronic pain was 14.3% and .8%, respectively and none of the patients had severe chronic pain. One patient reported numbness in the groin area. They did say that after, the difference was not significant; female patients seemed more prone to develop chronic pain. As their conclusion, they believe that the Kugel inguinal hernia repair is associated with a low rate of postoperative chronic pain. They think that the reason for this is that the minimally invasive preperitoneal approach to the Kugel technique probably causes less nerve damage and subsequently less neuropathic pain. I have no way of knowing one way or the other whether this is the case and it does seem that in the two studies that there were not a lot of patients who really had chronic pain. As I have said earlier in these commentaries, in this group of patients, I wonder whether or not one should take a recurrence rather than a nerve entrapment—a severely painful outcome. Time will tell I am afraid.

193 Generations of the Plug-and-Patch Repair: Its Development and Lessons From History

Jerrold Young and Arthur I. Gilbert

INTRODUCTION

The principle of hernia repair using an open approach for placing mesh in the properitoneal retromuscular space of Bogros is based on protecting the myopectineal orifice (MPO) from behind. This has been the theory behind the development of many techniques of hernia repair including those of Nyhus, Stoppa, Kugel, and more recently, laparoscopic techniques. Furthermore, the concept of protecting an opening from inside the defect has resulted in modification of the technique of repair of other hernias, including ventral, umbilical, and particularly, incisional hernias.

In 1985, Gilbert borrowed Lichtenstein's idea of creating a rolled plug and used it to repair indirect inguinal hernias. The intact indirect sac was dissected and invaginated. A hand-rolled mesh plug was placed into the internal ring and two permanent sutures were used to fix it to the crura of the ring (Fig. 193.1). To complement this, a flat mesh patch was used to reinforce the floor of the inguinal canal over Hesselbach's triangle. This worked well, but the plug was annoyingly palpable in some thin patients, a problem that was solved by altering the shape of the plug. Gilbert then changed to a hand-rolled plug which he placed through the internal ring into the properitoneal space, allowing it to unravel there—it became seated against the anterior abdominal wall. It literally blocked the peritoneal sac and its contents from protruding through the internal ring. Although no sutures were used, that technique proved satisfactory, providing a lasting repair for small- and medium-sized indirect hernias.

Gilbert soon recognized certain problems uniquely related to the rolled plug. These included its inability to consistently unravel enough to be anything but a wad of mesh, thus limiting its area of protection, and some patients still reported feeling it. Rarely, when a plug became infected, surgical drainage and antibiotics were insufficient to sterilize its multiple

layers, compelling its removal. To avoid these problems, and to protect a wider area, the mesh shape was changed from a rolled plug to an opened patch. The flat mesh was cut, folded to the shape of a closed umbrella, and passed through the internal ring into the properitoneal space. There it was allowed to open and regain its flat contour, avoiding a palpable plug, and providing wider protection (Fig. 193.2). Gilbert originated the procedure of using mesh within the internal ring to repair indirect inguinal hernias, and subsequently used the internal ring as the passageway to place mesh behind the anterior abdominal wall for the repair of all types of indirect hernias.

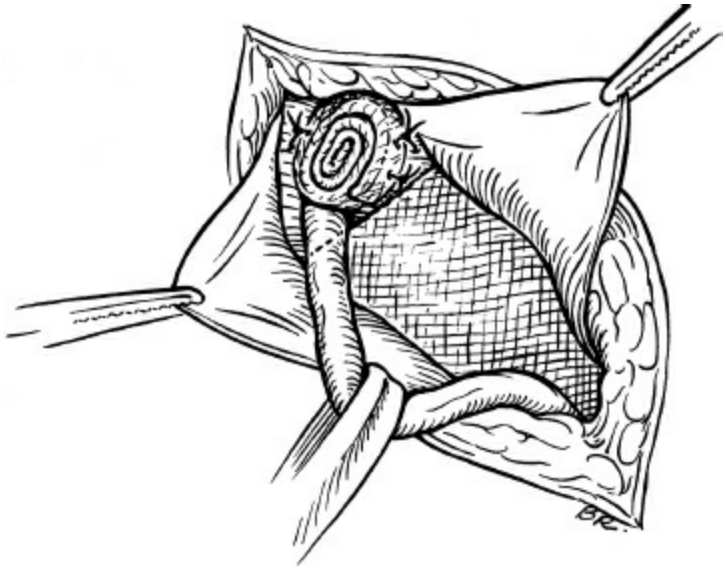

Figure 193.1. Original rolled plug sutured in internal ring and onlay patch.

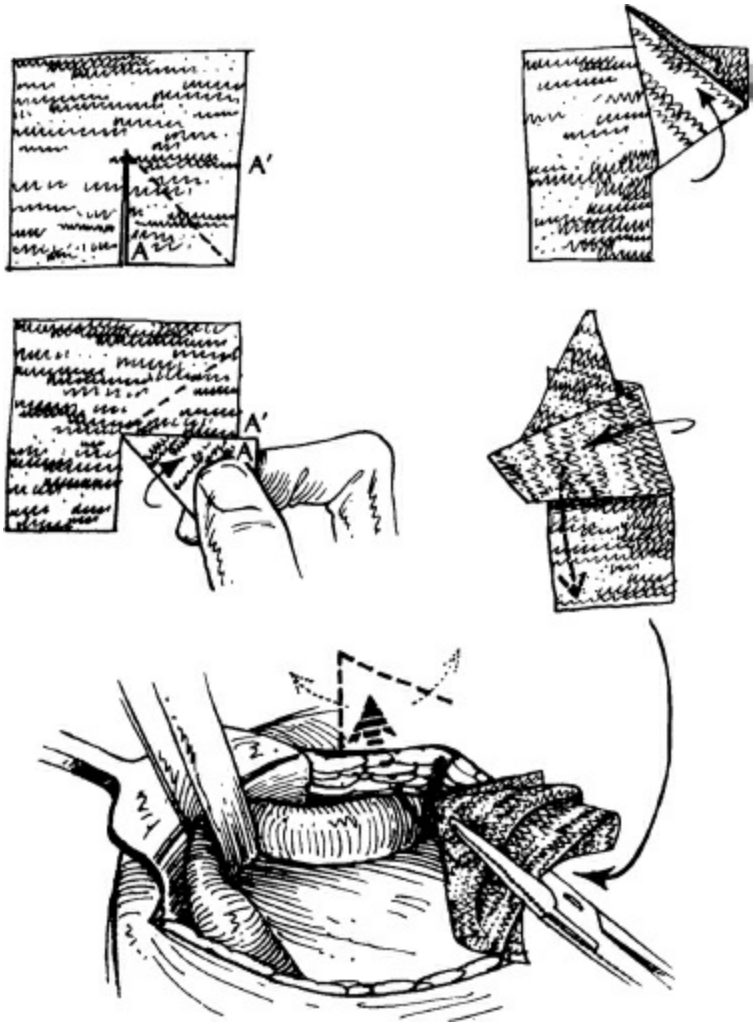

Figure 193.2. Creation and insertion of umbrella plug.

LESSONS FROM HISTORY—SUTURE REPAIRS

Gilbert's approach developed from the work of earlier surgeons interested in herniology. Bassini of Padua is credited with beginning the modern era of hernia surgery. Through an anterior open approach in the groin, he divided the posterior wall of the inguinal canal, ligated the peritoneal sac, and constructed a sutured, three-layered tissue repair in 262 patients, with a failure rate of <3%. A simplification of his technique avoided opening the posterior wall, but approximated the transversus arch, or so-called conjoined tendon, to the shelving edge of the inguinal ligament with interrupted sutures. This became known as the modified (North American) Bassini repair. Lotheissen of Austria and later Anson and McVay of South Dakota, popularized an anatomic repair that approximated the transversus arch to the pectineal ligament (Cooper's ligament), which also required opening the floor. The "McVay" repair became the preferred procedure for

treatment of femoral hernias and many direct inguinal hernias. In 1946, Shouldice of Toronto reincarnated Bassini's original operation, and equally important, popularized the use of local anesthesia. The technically difficult Shouldice operation requires a "thinning" of the cord by dividing the lesser cord, including the genital branch of the genitofemoral nerve, and a multilayered closure of the floor with stainless steel wire. However, suturing the transversus arch to the inguinal ligament creates tension at the suture line. This feature of the Bassini operation, and other sutured repairs, is most disadvantageous. Even with relaxing incisions to reduce suture line tension, patients still experienced a high level of postoperative pain, prolonged disability, and unacceptable failure rates because of the tension.

TENSION-FREE MESH REPAIRS

Usher of Texas, in 1960, reported suturing a polyethylene mesh inlay patch deep to the transversalis fascia to do a "tension-eliminating" inguinal hernia repair. Newman of New Jersey developed a tension-free technique for inguinal hernia using a polypropylene mesh onlay patch that he sutured over the floor. Lichtenstein and Amid popularized Newman's mesh technique, which has become a frequently used open, tension-free procedure for groin hernias worldwide. From 1958 to 1976, Gilbert used the modified Bassini technique with general or spinal anesthesia to repair all inguinal hernias, a technique that was estimated to have failed in 15% of primary hernias and 25% (or more) of recurrent hernias. After a visit to the Shouldice Hospital in Toronto in 1976, he began to perform the Shouldice repair under local anesthesia using 3-0 Prolene suture instead of wire. Failure rates of primary repairs dropped to <2% and of recurrent hernias to 8%. In 1984, to supplement the repair, Gilbert began placing a swatch of polypropylene mesh beneath the transversalis fascia, deep to the first suture line of the Shouldice operation. The failure rate was reduced to <0.5% for primary hernias and to 3% for recurrent hernias. Even before the open tension-free anterior repair of inguinal hernias became popular, open posterior repairs attracted surgeons' interest through the works of Nyhus of Chicago and Condon of Milwaukee. They described musculo-aponeurotic sutured repairs, sometimes adding mesh. Stoppa and Rives of France repaired bilateral groin hernias by widely wrapping the peritoneal base with large mesh netting (giant reinforcement of the visceral sac), thereby blocking the viscera from entering any defect through either MPO. After visiting and operating with Rene Stoppa in Amiens, Gilbert was

further convinced that the ideal place to position mesh is in the properitoneal space, between the force of the hernia and the defect in the abdominal wall.

ANATOMICAL AND FUNCTIONAL CONSIDERATIONS

All groin hernias protrude through the MPO, a window in the lower abdominal wall surrounded by musculo-aponeurotic structures described by Fruchaud in 1956 (Fig. 193.3). The MPO is bounded medially by the lateral edge of the rectus muscle and its fascia, superiorly by the transversus abdominis muscle, laterally by the iliopsoas muscle, and inferiorly by the pectineal (Cooper's) ligament. It is divided into smaller inguinal and femoral windows by the inguinal ligament anteriorly and the iliopubic tract posteriorly. The boundaries of the lateral triangle are the deep epigastric vessels, the middle third of the inguinal ligament, and a line from the junction of the upper and middle thirds of the inguinal ligament to where the deep epigastric vessels cross the lateral edge of the rectus muscle. Groin hernias occur because of poor collagen content in the MPO. The hernia that presents clinically is in that part of the MPO that initially gives way to intra-abdominal pressure. When performing any repair, one should consider the plasticity of the canal's posterior wall and the deformation effect on vulnerable tissues that surround that defect. Appreciation of these factors is important to the long-term success of any repair in which a prosthetic device is used.

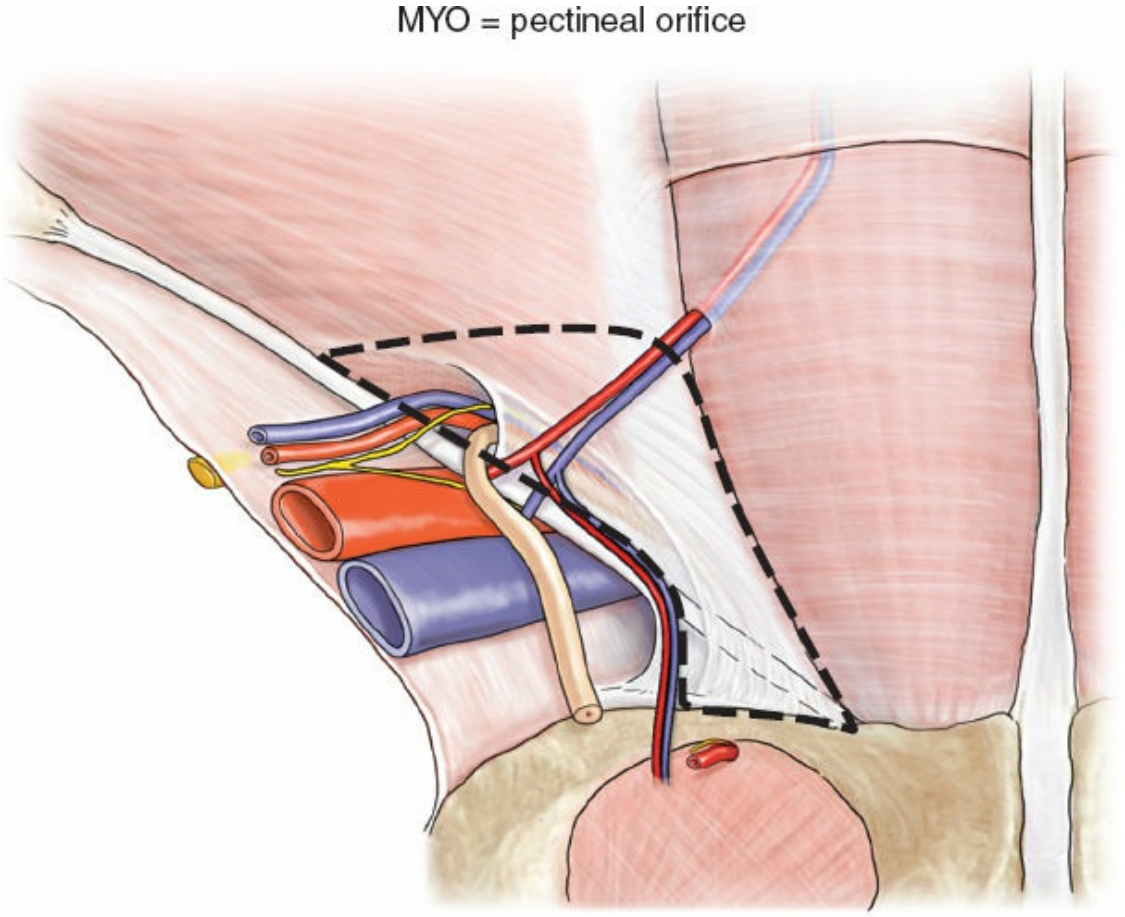

Figure 193.3. Myopectineal orifice.

Cadaver studies indicate that the mean MPO is 7.8 cm wide and 6.5 cm high. Coverage of the MPO can be accomplished from an open or laparoscopic posterior approach, an anterior patch, or a combination of anterior and posterior coverage. Preformed or handmade mesh plugs can be placed in the internal ring of indirect hernias or in the defect of direct hernias. The problem with using a plug without a patch in any primary hernia repair is that the remainder of the canal's unprotected posterior wall, medial and lateral to the plug, becomes subjected to an imbalance of plasticity. It is thereby rendered to have greater risk of herniation. It has been our observation that the majority of recurrences following pure tissue repairs presented in the medial triangle just above the pubic tubercle. Although half of tissue repairs that failed occurred within 5 years, other failures happened much later, some presenting decades after the original repair. On the other hand, failures following prior mesh repairs presented more commonly in the lateral triangle and became clinically evident within 2 years following the initial repair (Fig. 193.4). The reason for failure following mesh repair is that the mesh used initially did not cover the

entire MPO, leaving the unprotected area vulnerable. On occasion, a recurrent hernia may also penetrate the floor and remain under the mesh that was placed anteriorly. It is clear that an anterior patch acts as a lid, not as a stopper.

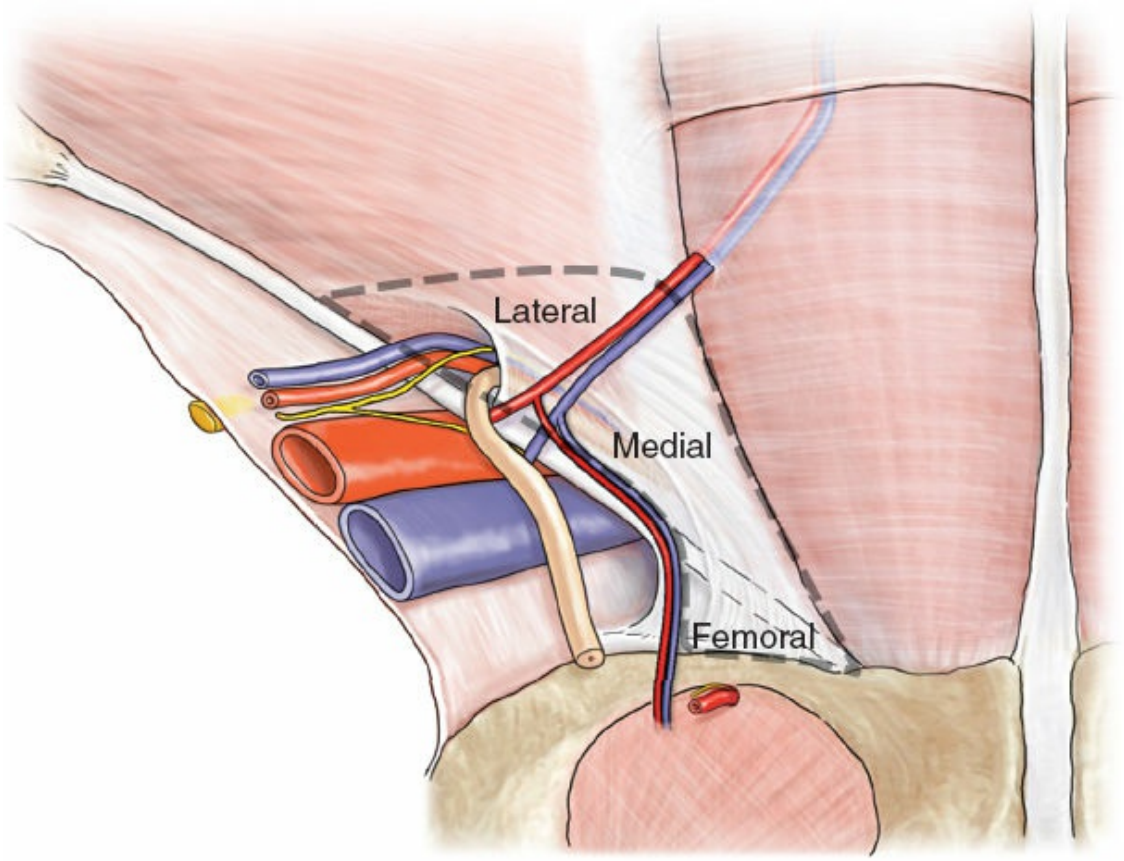

Figure 193.4. Triple triangles of the groin.

PRINCIPLES OF HERNIA REPAIR

The basic principle of every type of inguinal hernia repair is the reduction of the hernia contents and the prevention of passage of any intra-abdominal or properitoneal contents to outside the musculo-aponeurotic plane of the abdominal wall. Indirect inguinal hernia repair requires protection of the internal ring. Regardless of how the distal portion of the sac is treated, the peritoneal sac that resides within the deep inguinal ring of an indirect inguinal hernia must be carefully dissected from the cord and from the investing fibers of the transversalis fascia at the musculofascial threshold of the deep ring. A longer peritoneal sac or one densely adherent to the spermatic cord outside the internal ring should be divided, leaving its distal portion undisturbed, minimizing dissection near the spermatic cord. Further, the “shoulders” of the sac must be separated from the

transversalis fascia to actualize the potential space for the prosthesis (Fig. 193.5). For direct hernias, the floor must be opened to allow the mesh to be placed behind the transversalis fascia.

In Gilbert's original technique, and its two later generations, the mesh was interposed between the peritoneum and the transversalis fascia (the properitoneal space of Bogros) (Fig. 193.6). The principle of those repairs is that when the patient's intra-abdominal force is applied against the mesh, it will hold the patch in place to fortify the area covered. Each generation of technique incorporates the same three features: (a) the deep (internal) inguinal ring is an available and convenient passageway to be used to get to the properitoneal retromuscular space, (b) polypropylene mesh is an excellent permanent barrier to protect the deep inguinal ring, and (c) the body's intra-abdominal pressure is sufficient to permanently fix the mesh in its properitoneal position (Pascal's principle). Until April 1998, Gilbert used a tension-free polypropylene umbrella patch technique to repair all indirect inguinal hernias, and the Shouldice repair with a reinforcing underlay mesh patch (not tension-free) to repair all direct hernias. In doing so, the plug covered the primary defect from behind and the patch functions as an overlay on the full MPO.

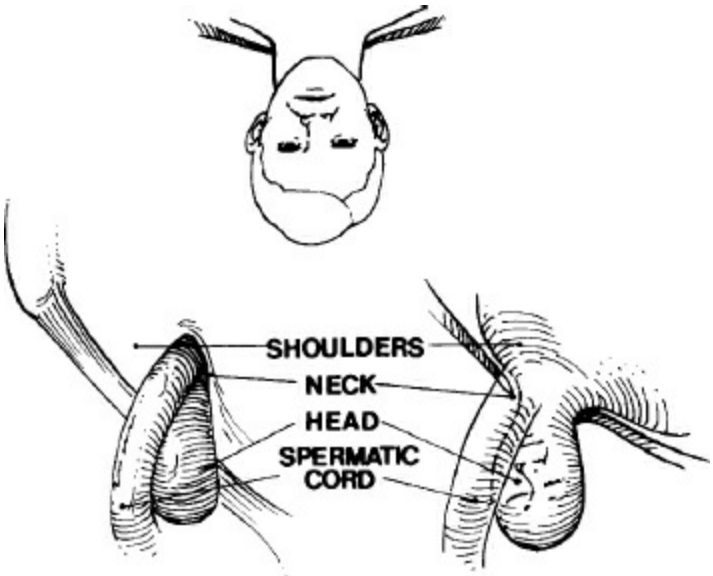

Figure 193.5. Head, neck, and shoulders of the peritoneal sac.

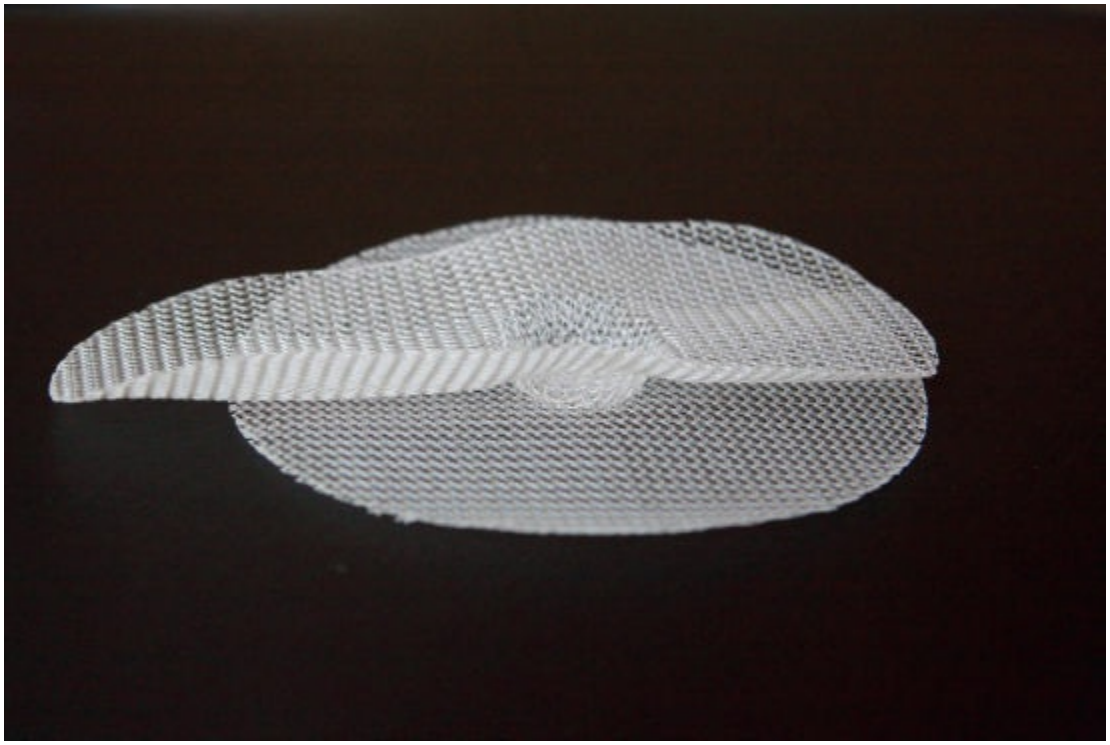

Figure 193.6. Prolene Hernia System device (polypropylene).

Primarily because of the complexity of the anatomy, over the years, there have been many different techniques described for inguinal hernia repair. The ideal hernia repair would be performed as an out-patient procedure under local anesthesia, with a short operative time, minimal post-op and long-term discomfort and disability, at low cost, with low risk for other side effects and complications, and have very few recurrences. The technique should have a short learning curve, with excellent reproducible results when performed by all general surgeons as well as experts. There is no single repair that has all of these desired outcomes—hence the continued investigation and analysis of new concepts and techniques. In 1997, Gilbert, with a personal experience of over 20,000 hernia repairs, designed the Prolene hernia system (PHS) (Fig. 193.7)—a polypropylene bilayer connected mesh device used to repair all types of direct and indirect inguinal hernias through an open anterior approach. The system has three components: a flat round underlay, an elongated overlay (oval shaped with flat edges), and a 1.5-cm round connector that joins these in the center. Three sizes—medium, large, and extra large—are available. The PHS is symmetrical in the longitudinal axis, and can be used on either the right or left side.

QUALITY-OF-LIFE ISSUES

As a result of the use of mesh and improved surgical technique, recurrence rates after hernia surgery have been reduced. Increased attention has been directed to quality-of-life issues, particularly the problem of chronic pain —a common consequence occurring in up to 10% of patients after hernia surgery. These symptoms of somatic, visceral, and neuropathic pain, as well as testicular pain, dysejaculation, and claims of sterility have been enough to warrant discussion at surgical meetings and in the literature. Post-op pain problems are in part related to the scarring, which occurs in both non-mesh and mesh repairs. The incidence of post-op chronic pain is greater in patients with suture repairs than in those with tension-free mesh repairs. Placement of mesh results in immediate strength of the repair. In addition, the mesh induces an inflammatory reaction and scarring, making the repair stronger as the scar creates a plate of tissue. This inflammatory reaction may affect structures, which are in direct apposition to the mesh, a situation that is present in all types of hernia repairs. Lateral to the internal ring, the mesh is placed on top of the internal oblique, and unavoidably comes into contact with the ilioinguinal and iliohypogastric nerves, which may result in inflammation and scarring involving these structures. In routine hernia repairs, nerves, muscle, the spermatic cord, and all structures in the inguinal canal may come in contact with the mesh. This is true in open anterior or properitoneal repairs, as well as in laparoscopic repairs.

Figure 193.7. Creating the anterior space between the internal and external oblique muscles.

There have been suggestions on how some of these post-op

consequences may be reduced by modifying the surgical technique. These include avoiding nerve trauma by blunt dissection, traction, and electrocautery; limiting dissection close to the spermatic cord to reduce scarring that may result in cord dysfunction, obstruction, and possible injury to the nerves and vessels that are present in the adventitia of the vas; avoiding placement of mesh in direct opposition to the vas when possible; using absorbable sutures with air knots and placing sutures in the internal oblique away from visible nerves; dividing a long indirect sac near the internal ring and avoid dissecting near the spermatic cord distally; and avoiding placement of sutures into the periosteum of the pubic tubercle. New products such as lightweight mesh, omega-3 fatty acid-coated mesh (C-Cur Lite®), and tissue glue instead of sutures are being investigated in an attempt to reduce inflammatory reaction and scarring, and possibly improve results. Further evidence-based studies are needed to document the efficacy of these concepts and products. However, preliminary reports indicate that many of these suggestions have sufficient basis to begin implementing them. As a result of this information, we have modified our surgical technique to attempt to limit dissection in the area of the nerves and the spermatic cord to attempt to reduce the incidence of these problems. In time, we will learn if some of the experimental data will hold up in the clinical setting. In addition, “watchful waiting”—conservative management of asymptomatic hernias—is an acceptable course of management in the appropriate patient (Table 193.1).

CURRENT TECHNIQUE

Preoperative Planning

When indicated, medical evaluation and clearance is requested. Groin and testicular ultrasound examination is often done in patients who have recurrent hernias or patients with testicular complaints, to document the location of the hernia, to check for multiple hernias, and to document testicular anatomy and blood flow. Appropriate informed consent is obtained—we have patients sign a “hernia-specific” informed consent, which is sent to the surgery center to become a part of the record. Although we have rarely seen bleeding problems related to Aspirin® and non-steroidal anti-inflammatory drugs, these drugs as well as Plavix® are stopped 7 to 10 days before surgery. If the patient takes Coumadin®, it is stopped 5 days before surgery. Depending on the indication for the anticoagulation, some patients require a short-acting subcutaneous

anticoagulant (Lovenox® or heparin) for the immediate pre-op and post-op period. Our current approach is to discuss this with the medical consultant familiar with the patient, who then will order these medicines. Clotting studies are done on the day of the operation. All other medications are continued up until midnight before surgery. The patient is advised to shower the morning of surgery using a parachlorometaxylenol-impregnated sponge to bathe the abdominal and groin areas, but not to shave the surgical site. In the pre-op suite, the patient is identified and the surgical site is confirmed and marked prior to administration of any sedative. Any hair at the operative site is clipped just prior to the surgery. A single dose of 1 g of cefazolin (or 600 mg of clindamycin for penicillin- or cephalosporin-allergic patients) is administered within 30 minutes of incision time (Table 193.2).

TABLE 193.1 Patient Demographics by Time Period

	Male	Female	Patients	Bilateral	Repairs	Recurrent	Inguinal	Femoral

Anesthesia and Preparation

Our preferred approach, used in almost all patients, is intravenous sedation and local anesthesia, in an ambulatory surgery setting. We prefer not to use epidural or spinal, or general anesthesia, in hopes of avoiding prolonged stay in the out-patient department, and an increased incidence of post-op urinary retention. Versed® and other anesthetic agents are administered by an anesthesiologist before patients are brought to the operating room. The local anesthetic mixture of 97 mL contains 60 mL of 0.25% Sensorcaine (Marcaine®), 30 mL of 3% chloroprocaine (Nescaine®), and 7 mL of 8.4% sodium bicarbonate. The bicarbonate neutralizes the acid pH of the local anesthetic and decreases the pain of injection. The skin of the lower abdomen is prepared with Betadine® solution. A “time-out” to identify the patient and the marked operative site is done with the attention of all personnel in the room prior to commencing (Table 193.3).

TABLE 193.2 Size of PHS Device Used

Preparation of the Anterior Space

There are four parts to a hernia repair with the PHS: preparation of the anterior space, dissection of the posterior space, deploying the underlay in the posterior space, and application of the overlay or patch.

The technique for preparation of the anterior space and application of the overlay patch is very similar to the technique that we use when we perform a Lichtenstein procedure. A 3- to 5-cm transverse incision extending laterally from the pubic tubercle is marked. Approximately 60 mL of the anesthetic solution is injected into the skin and subcutaneous layers. No attempt is made to block the nerves in the area by direct injection, which may cause nerve injury that can lead to neuropathy. The skin is incised and the subcutaneous layer is opened. The superficial epigastric vessels are retracted, or ligated and divided, and Scarpa's fascia opened. As soon as the external oblique aponeurosis (EOA) is exposed, 20 to 25 mL of anesthetic solution is infiltrated just beneath it—we use two or three puncture sites to flood the area, avoiding direct injection into the nerves. The subcutaneous tissues are cleared from the EOA, exposing the external ring. Care is taken not to stretch or otherwise damage the ilioinguinal nerve as it exits the external ring with the cord structures. At this time, examination is performed to rule out the presence of a femoral hernia by incising the cribriform fascia at the junction of the thigh. The EOA is opened in the direction of its fibers through the external ring. Its medial flap is elevated and separated from the internal oblique muscle and aponeurosis. The ilioinguinal and iliohypogastric nerves are identified and left undisturbed within the investing fascia on top of the muscle. The nerves are not dissected or retracted outside the EOA to "protect" them. We do not hesitate to sacrifice the nerve or a branch if its location interferes with the repair or if it will be under tension by the mesh. If a nerve is divided, it is ligated with Vicryl, and implanted into the muscle. The anterior space dissection is carried out laterally 3 to 5 cm beyond the internal ring (Fig. 193.8). The lateral flap of the external oblique is then elevated with careful dissection inferomedially toward Gimbernat's

ligament and the pubic tubercle. In patients with large hernias, reduction of the hernia contents at this juncture may facilitate this part of the procedure.

TABLE 193.3 Anesthesia Type by Time Period

	Number of patients

Elevation of the cord structures and creation of an arch for the mesh can be done in one of two ways. Our current preferred technique is to elevate the entire cord structures and cremasteric muscle from the floor of the inguinal canal near the pubic tubercle, and encircle them with a Penrose drain. Careful dissection is used to separate the cremasterics from the floor and the reflected edge of the inguinal ligament, limiting trauma to the genital branch of the genitofemoral nerve and the cremasteric vessels, which are left undisturbed as they lay within the lateral cremasterics. An arch is created to accommodate the overlay of the mesh. The cremasteric muscle is opened 2 cm from the internal ring for inspection for an indirect sac or lipoma. The cremasteric opening can be closed with a fine absorbable suture, avoiding the ilioinguinal nerve. This method of elevating the cord structures favors limiting dissection of the vas deferens within the internal spermatic fascia.

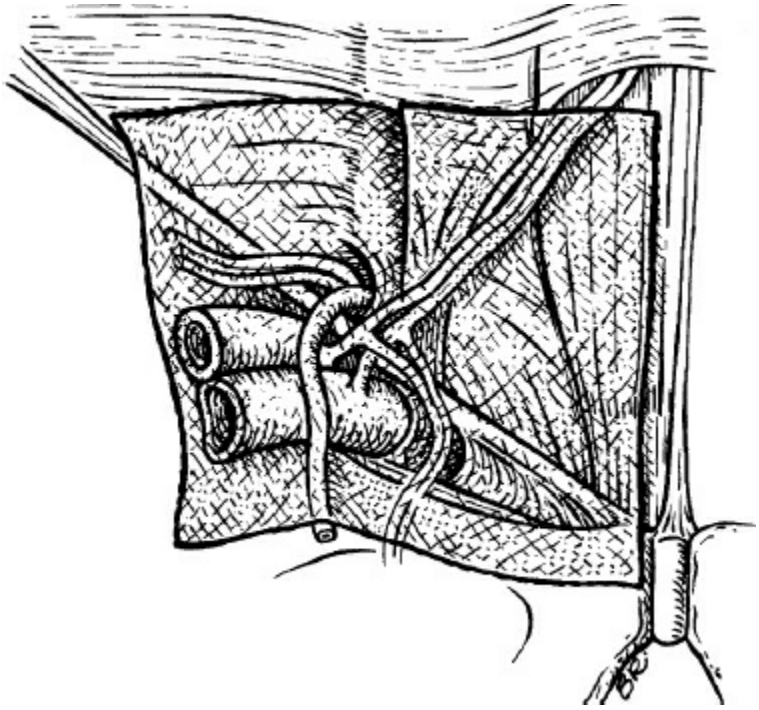

Figure 193.8. Posterior view of mesh covering entire myopectineal orifice.

An alternative approach is to open the entire cremasteric muscle, allowing direct visualization of the transparent, relatively avascular internal spermatic fascia that surrounds the spermatic cord. The spermatic cord and the testicular vessels are elevated with a Penrose and the arch is opened between these structures and the lesser cord, leaving the lateral cremasterics and the genital nerve branch and cremasteric and vessels attached to the floor, while the medial cremasterics are excised. This method allows easy access to the contents of the cord, including a true hernia sac and any lipomas, which may be found within the internal spermatic fascia, but requires more dissection near the vas deferens.

With either method, inspection for a patent processus vaginalis, or frank indirect hernia, is done up to the level of the true internal ring. If an indirect sac is identified and its distal part (head) is not firmly adherent to the cord, the sac is left intact and it is dissected up to its true neck. If the head of the sac is attached or scarred to or near the internal spermatic fascia vessels, its midportion is elevated and divided, leaving its distal portion in place, thereby limiting dissection close to the vas and vessels. Its proximal portion is dissected up to its true neck and ligated with 2-0 Vicryl ligature. The posterior wall, over the medial (Hesselbach) triangle, is inspected for any direct hernia or weakness.

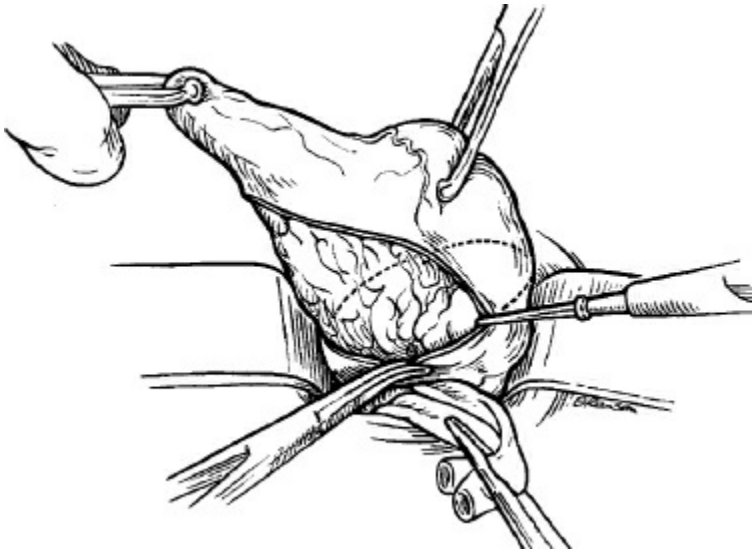

Figure 193.9. Opening a type 4 hernia into true yellow fat.

Posterior Space Dissection

The properitoneal space must be generously opened to allow the mesh to be fully deployed, no different than is properly done for other open mesh or laparoscopic mesh repairs. The space of Bogros behind the MPO is, in fact, more conical than flat in nature, so the underlay should not be expected to lie flat, but more like a cone. The space is relatively flat behind the transversalis fascia in the upper portion. However, inferiorly, below the inguinal ligament, it turns posterior to pass behind the iliopubic tract and Cooper's ligament medially, the femoral lymphatics, vein and artery in the center portion, and the spermatic cord and testicular vessels laterally. *For direct hernias,* the floor of the medial triangle is opened (Fig. 193.9), grasped with four hemostats, and its protruding contents are dissected from behind the transversalis fascia with a sponge to actualize the properitoneal space. The sponge's traction on the fat helps separate the properitoneal fat from the transversalis fascia superficial to it (Fig. 193.10). This dissection goes medially behind the pubic tubercle, inferiorly behind Cooper's ligament, superiorly behind the transversus abdominis muscle, and laterally behind the deep epigastric vessels. If the patient has no indirect defect, we limit this lateral dissection behind the epigastrics at this point, and use the overlay portion to protect the floor lateral to the internal ring. If a lipoma is present it is resected.

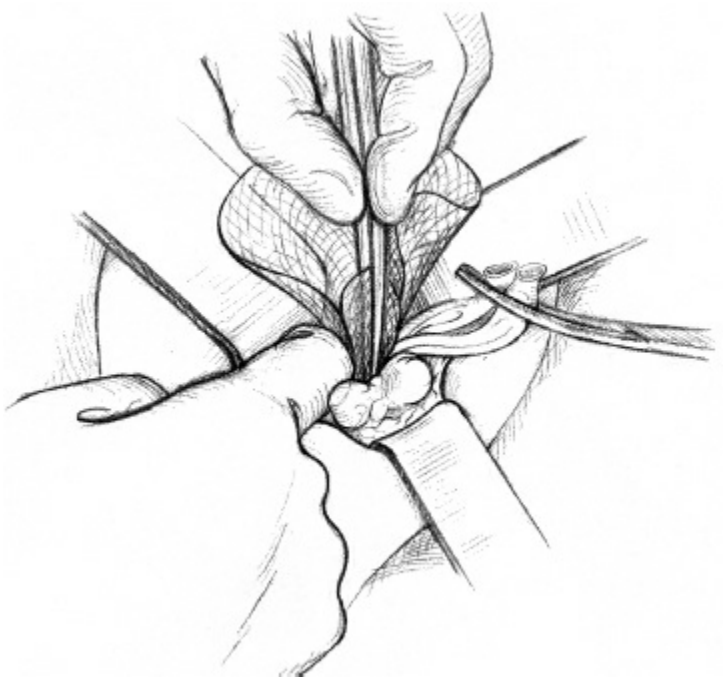

Figure 193.10. Sponge dissection of posterior space.

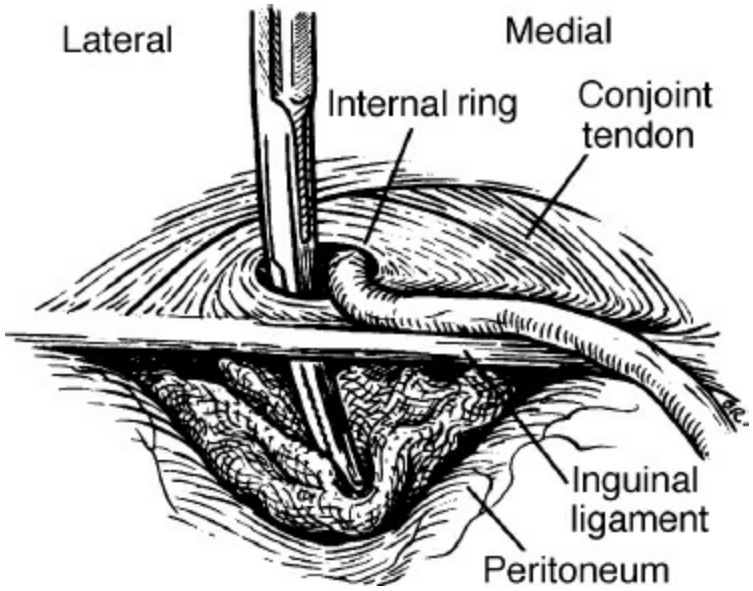

Figure 193.11. Dissecting properitoneal space with sponge.

For indirect hernias, after the head and neck of the entire sac (or ligated sac) have been fully dissected, the sac is grasped with a forceps and invaginated through the internal ring. The surgeon's forefinger is inserted through the internal ring adjacent to the forceps. The forceps are extracted, leaving the forefinger in place. The forefinger palpates the iliac artery, pulsating lateral to it. An opened dry 4 × 4 sponge is passed on the medial side of the forefinger to develop the properitoneal space (Fig. 193.11) and helps separate the hernia contents from the elements of the cord. The

dissection through the internal ring is done superiorly and laterally behind the transversus abdominis muscle. Medially, we go behind the deep epigastric vessels and dissect under the floor of Hesselbach's triangle to behind pubic tubercle and inferiorly behind Cooper's ligament. An army-navy retractor placed behind the epigastric vessels facilitates this dissection. We prefer creating this space with the opened 4 × 4 sponge, but it is also possible to do it with the index finger alone, or forceps and cautery. The sponge is temporarily left in place to maintain the passageway and facilitate continuing the insertion maneuver. *For small indirect hernias*, the mesh can be inserted through an opening in the floor just medial to the epigastric vessels, and the indirect space can be covered by the overlay.

In some cases of *pantaloon hernias*, the transversalis fascia is opened both medial and lateral to the epigastrics, a Penrose drain is placed around the epigastric vessels (or the vessels can be divided), and the two spaces are joined. In no case is it possible to successfully create the space using the device as a ramrod without a careful dissection. Such attempts leave the mesh as a wad rather than a fully expanded patch as it is intended to be.

Insertion and Deployment of the PHS Underlay

The PHS overlay is triple folded on itself longitudinally, and the tails are pulled up and grasped with a sponge stick near the connector, creating an appearance of a "taco" in the underlay. The sponge stick is rotated before insertion so that the lateral flap will align with the inguinal ligament. The device is inserted until the perimeter of the underlay is under the floor. The technical goal of deployment is to spread the edge of the underlay patch circumferentially to be seated at maximum distraction from its connector. By doing so, the underlay patch covers the majority of the MPO—the overlay will complete the coverage. For inguinal hernias, sutures are not necessary in the underlay—the intra-abdominal pressure pushes the mesh against the floor and holds it in place.

For a direct hernia, the device is inserted straight down (posteriorly), at a right angle to the opening. Using a long forceps or the forefinger, the edge of the circular underlay patch is deployed by separating the perimeter of the mesh from its connector (Fig. 193.12) as the onlay component is gently extracted. The perimeter of the underlay is placed behind the previously dissected structures—medially behind the pubic tubercle,

inferiorly behind Cooper's ligament, superiorly behind the transversus abdominis muscle, and laterally behind the deep epigastric vessels. The underlay will have some radial folds to accommodate the conical shape of the space—it will not be flat. The underlay can be trimmed laterally where it will be placed behind the epigastric vessels. The opening in the floor of the medial triangle is closed snugly around the connector with one or two figure-of-eight absorbable sutures, leaving it comfortably seated. If there is a femoral hernia, prior to inserting the device, a single 2-0 Prolene suture can be placed to secure the underlay to Cooper's ligament.

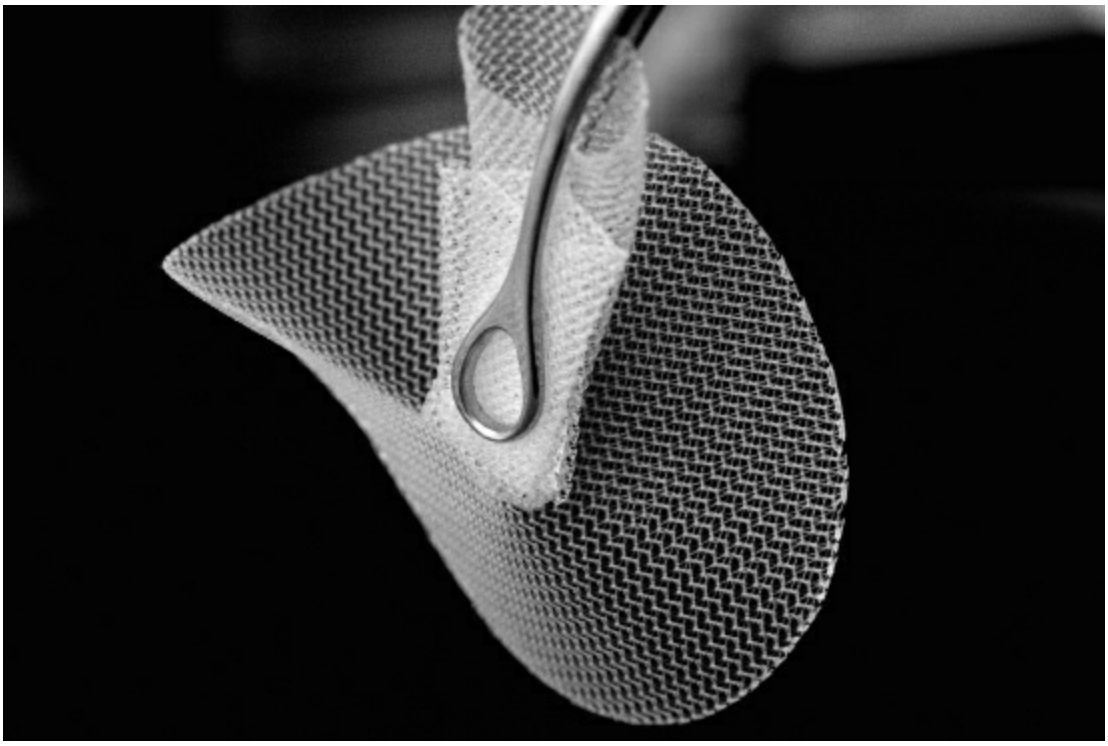

Figure 193.12. Triple fold of overlay.

For indirect hernias, the surgeon's forefinger is placed in the lateral aspect of the dissected internal ring, and the device is slid down the medial side of the finger into the properitoneal space—the direction of insertion is medial and superior, aiming just beneath the umbilicus. The underlay perimeter is placed behind the transversus abdominis muscle superiorly and laterally, where it lies in the horizontal plane, while medially it is deployed behind the epigastric vessels and the pubic tubercle. Inferiorly, the perimeter is directed more posterior, covering the femoral canal and the tissues behind Cooper's ligament, and it separates the hernia contents from the cord contents. Typically, when repairing an indirect hernia, unless it is a large type III defect, the internal ring is not tightened around

the connector—the obliqueness of the internal ring offers additional protection to the underlay patch. Effectiveness of the underlay patch alone can be evaluated by having the patient cough and perform the Valsalva maneuver before any sutures are placed in the onlay patch. After the operation, when the patient stands, intra-abdominal pressure flattens the underlay is against the abdominal wall between the peritoneum and the transversalis fascia.

Application of the PHS Overlay

The sponge stick is used to extract the onlay component to the level of the internal oblique, released, and the tips of the overlay are simultaneously pulled apart to a flat shape (Fig. 193.13). Once extracted, the surgeon inserts the lateral flap beneath the external oblique into the anterior space. The medial part of the onlay patch is then flattened against the transversus arch with the medial end positioned 2 cm over the pubic tubercle. Very early in our series, a suture-less technique was attempted. Two patients with large type III hernias developed almost immediate recurrences by "popping" out the mesh, prompting us to use at least one suture medially. We suggest that the onlay patch be sutured with absorbable sutures (2-0 Vicryl) in three places: one to the soft tissues (not into the periosteum) supero-medial to the pubic tubercle, one at the middle of the transversus arch (using an air knot and avoiding the iliohypogastric nerve), and one at the middle of the inguinal ligament (Fig. 193.14). To accommodate the spermatic cord through the onlay patch, either a central or lateral slit is made (Fig. 193.15). In most indirect hernias, a slit with a "T" is made in the inferior edge of the overlay, close to the connector, adjacent to the midportion of the internal ring. The cord structures are passed through the slit, and the edges of the slit are then sutured to the reflected edge of the inguinal ligament (Fig. 193.16). This opening should be large enough to comfortably accommodate the spermatic cord and its contents without compression. The underlay component is there to prevent herniation in this area. For most direct hernias, a slit in the lateral flap of the onlay patch (Fig. 193.17) serves well. The tails of the lateral flap are crossed and fixed with a single suture to prevent herniation through the slit, similar to a Lichtenstein repair. It is not necessary to suture the lateral flap that lies flat in the anterior space and is well covered by the EOA. The overlay should be trimmed if any excess is noted where the mesh folds on itself, usually on the inferior edge of the lateral and medial flaps. The spermatic cord and

ilioinguinal nerve are replaced over the onlay patch. All layers are irrigated with Bacitracin®—Polymyxin® solution. The external oblique is closed with 3-0 continuous Vicryl® suture, re-creating the external ring, being careful not to make it too tight, anticipating that some swelling of the cord structures will occur. The subcutaneous layer is closed with 3-0 Vicryl® sutures, and the skin with a sub-cuticular 3-0 Vicryl Rapide® suture. The skin is covered with Dermabond® or Steri-strips®.

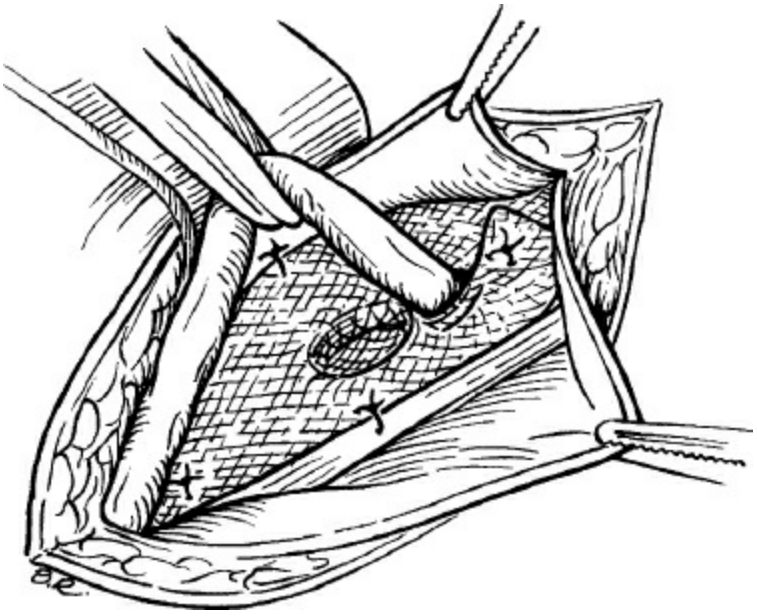

Figure 193.15. Slit in lateral flap of onlay patch for direct hernia.

Most patients go directly to the outpatient discharge area, or to the recovery room if they are too sleepy or need monitoring. An ice bag is applied immediately, and is used for 2 days. After a light meal and being able to urinate, the patient leaves the ambulatory center, 45 minutes to 1 hour after the operation. The patient is encouraged to ambulate often (if not light-headed) and to resume all activities that are not uncomfortable. Milk of magnesia is recommended if the patient has not had a bowel movement by the next day. Patients are told that they will have some ecchymosis around the incision and into the scrotum, and often some

testicular swelling that will last for several days. Swelling in the wound forms a firm wound healing ridge that lasts 6 to 8 weeks. As the healing ridge becomes more prominent, it narrows and rises before it flattens. Patients are told to expect mild to moderate pain, sometimes going down to the testicle, for 1 to 2 days, after which the pain diminishes significantly. All patients are given a prescription for a narcotic analgesic such as oxycodone and acetaminophen. Patients who live geographically close to the surgery center are encouraged to return in 7 to 14 days for a wound check. For those who live farther away, we have a toll-free telephone number and encourage patients to stay in contact regarding their progress.

RESULTS

From April 1998 to December 2008, four surgeons used the PHS to repair 8,791 groin hernias in 7,737 patients at the Hernia Institute of Florida. Male patients outnumbered female patients 7,248 to 489. Simultaneous bilateral repairs were done in 1,054 patients; 986 repairs were for recurrences of one to six times. Inguinal hernias outnumbered femoral hernias 8,643 to 148. All sizes of PHS were used, although our preference in 90% of adult male patients was the EPHS (extended size). All patients not covered by workers' compensation were recalled annually by postcard for cost-free follow-up examination. Twenty percent of the patients complied; many others called and related that their hernia repairs were fine but they did not want to take time to come for a checkup. All patients, including those covered under workers' compensation, were emphatically instructed to return if they suspected a recurrence or were bothered by unrelenting discomfort.

To the best of our knowledge, the total number of recurrences in our series since April 1998 is 12. Even if we assume that there are two or three times as many recurrences that we are not aware of, our percentage is well below one-half percent. Early in the series, two patients with large type III hernias, in whom the mesh overlay was not secured, developed immediate recurrences. Two recurrences were in the medial triangle. There were three

femoral recurrences, one that was missed and two that developed following repair of type II indirect hernias. Four recurrences were at the internal ring—all after indirect hernia repairs. Two were in patients who did heavy labor and one in a weight-lifter. One patient who had a repair of a large type III recurrent hernia developed severe bronchitis that lasted for 6 weeks 4 months after surgery and re-recurred. He was referred for a laparoscopic repair of the recurrence. Infection or drainage, that required opening the wound, occurred in 41 patients between 1998 and 2005 and in four patients from 2006 to 2009. In one case, suspicious of containing a gas-forming organism, the mesh was removed. In another, infection presented 3 weeks after surgery in a patient who had a history of lymphoma treated with chemotherapy. Cultures grew out a rare *Mycobacterium fortuitum* organism. The prosthesis was removed and a suture repair was done with a monofilament absorbable suture. After 2 years of follow-up there has been no recurrence of the hernia or the infection. In all the other cases, the mesh did not have to be removed to get complete wound healing. None of the repairs that involved infection failed. There were 35 hematomas that required drainage, 90 seromas, of which 15 required aspiration, and one patient who developed an atrophic testicle following repair for a second-time recurrent hernia.

Thirty percent of patients used only acetaminophen for pain. The remainder used the prescribed narcotic, on the average taking four tablets over 2 days. Ninety-five percent used no analgesics after the first 2 days. Most patients with ongoing discomfort were given naproxen. Ten percent of workers had ongoing pain that lasted between 3 and 6 months. Four patients, including two workers, who had significant chronic postoperative pain lasting longer than 6 months were referred for pain management. One patient had his mesh removed for pain by a surgeon elsewhere. Patients who experienced some degree of testicular pain from epididymitis were treated with sitz baths, naproxen, and Cipro®—all reported that the pain subsided in 3 to 8 weeks.

General surgeons trained in the PHS technique by instructors have been able to reproduce our own results. In 2005, in a report of 21,791 PHS repairs by 42 trained general surgeons, there were only 28 recurrences, for a failure rate of 0.0013.

The PHS has been used successfully by surgeons to do various other hernia repairs. We have used PHS to repair umbilical hernias in 75 obese patients with a mean BMI of 33 without a recurrence. In these patients,

with a high risk for recurrence, we use a sandwich technique with "bilayer" sutures passed through both the mesh layers and the fascia in between. Polat reported benefit using PHS for umbilical hernia repairs. Del Pozo used the PHS for ambulatory surgery in 32 patients to repair trocar site hernias, umbilical hernias, spigelian hernias, epigastric hernias, and small incisional hernias. Mayagoita compared the PHS repair with the Lichtenstein technique in 250 patients with inguinal hernias and found the results comparable; however, the patients who received the Lichtenstein repair had more complications. Huang compared the PHS repair with the mesh-plug repair and found that the mesh-plug repair took less time than the PHS repair, but the mesh-plug repair was associated with three times the number of patients with groin pain. Kingsnorth compared the PHS repair with the Lichtenstein technique and noted that patients with PHS repair returned to work sooner, and that it took slightly less operating time to do the PHS repair.

To perform lasting groin hernia repairs, surgeons must have a stronger appreciation for the need to protect the entire vulnerable area. Only by complete protection of the entire MPO can disparity of resistance and deformation of the remainder of the posterior wall be avoided. This can be accomplished from inside, or from outside, or by a combination of both. Patients have different anatomy, and their hernia problems differ by size and location. Some patients may be more susceptible to recurrence because of age, occupation, activities, body habitus, collagen disorders, and smoking. Although a single technique can be used to repair all different types and sizes of inguinal hernias, the choice of procedure for an individual patient should be based on the anatomical findings and the type of defect, and the expertise of the surgeon with the technique being used. Some techniques are easier to perform, but may not offer good results. The success of the procedure will ultimately depend on the skill of the surgeon —both in choosing the correct procedure and in performing it (Table 193.4).

TABLE 193.4 Complications in 7737 Patients

Complication	Number of patients	Percent
Infection	45	0.58
Infected mesh removal	4	0.05
Hematoma	42	0.54
Seroma	100	1.29
Testicular atrophy	1	0.01
Chronic pain	90	1.16
Pain management referral	10	0.13
Mesh removal for pain	3	0.04
Recurrence	12	0.16

Recently, new products with the underlying concept of the plug and patch have been introduced. The ProLoop® mesh plug is a lightweight, preformed, three-dimensional plug constructed of knitted rows of monofilament polypropylene with multiple protruding monofilament loops (Fig. 193.18). This design offers the benefit of flexibility and pliability—it has a self-forming characteristic that accommodates to the size and shape of the insertion site, and resists "mesh hardening" compared to a solid plug (Fig. 193.19). In a blinded randomized study, Sanders compared the ProLoop® to the Lichtenstein and PerFix® plug repairs. They found it to be a safe, effective, alternative technique compared to the other repairs. It is easy to use, and can be combined with a lightweight patch of ProLite® or omega-3 fatty acid coated C-Cur Lite®. The principle of the omega-3 fatty acid coating is to reduce inflammation in the anterior space, and perhaps reduce pain. The offshoot of the PHS is the bilayer Ultrapro® hernia system (UHS). This has an overlay of a soft lightweight product with a component that is absorbed. The underlay is "stiffened" by an absorbable element that dissolves over several days, but we found the stiff underlay difficult to deploy in comparison to the PHS. In addition, several manufacturers have developed partially or completely absorbable plugs to try to reduce the bulk of the permanent component, to reduce scarring and hopefully, the amount of postoperative pain. The underlying principles of these devices seem clear, but more studies with evidence-based data are needed before a final determination can be made as to the efficacy of these products.

The low failure rate of the plug-and-patch devices is due to complete coverage of the MPO. The plug or underlay component covers the existing defect and a portion of the MPO from behind, while the overlay adds the protection of the remainder of the area to prevent other hernias from

forming. In the case of the PHS, the connector stabilizes the other two components and adds to its strength. With its high success rate and ease of use for all surgeons, the plug-and-patch method using the PHS and some of the newer lightweight materials such as the ProLoop® plug, and partially absorbable plugs, will remain a prime hernia repair technique in the armamentarium of future generations of surgeons.

EDITOR'S COMMENT

This section provides a good review of the plug and patch technique, one of the principal techniques now carried out in the United States and throughout the world, which has evolved from the original idea of Arthur Gilbert who is the head of the Hernia Institute of Florida, and Jerrold Young, his successor. At one time, and perhaps still now, Delta Airlines would fly all its employees with hernia to the Hernia Institute in Miami for repair. As Dr. Young recalls the evolution of the technique, Dr. Gilbert, who I know well, evolved the technique from the Lichtenstein repair. He had in mind to prevent the hernia sac from reoccurring through the internal inguinal canal, as well as protecting the myopectineal orifice. The evolution of inguinal hernia repair over the past two decades has been from the open repair, which while it did not result in long-term inguinodynia, or if it did, certainly not in the 10% range, which now is what is commonly accepted for mesh repairs has a very low incidence of

recurrence. The hernia repair world has moved in the direction of mesh almost 100%, certainly over 90%, as recurrence seemed to be the principal focus. I do wonder about this, because the incidence of inguinodynia is significant, whatever it is, whether it is 3%, 5%, or 10%, the figure of 10% is generally accepted. As I see a lot of these patients with inguinodynia, I can tell you that their lives may be ruined and the pain may be excruciating, and although one can cut all three nerves, resect, and bury them and also deal with the crural nerve or the genital branch of the genitofemoral nerve, laparoscopically in the retroperitoneum, the repair is only successful in about 80% and in the remaining it is a life of suffering indeed. I do wonder why the focus is on recurrence, when avoidance of pain is such a huge problem.

In discussions with Dr. Young as he was writing the chapter, two things emerged. First, the incidence of pain and the suffering that Dr. Young has seen has changed his approach to patients with relatively small hernias. He said that in the past when he first started doing the plug and patch repair, he would fix anyone who would appear on his doorstep with a small hernia. However, as he became aware of the not insignificant incidence, whatever it was, of mesh entrapment of nerves, he did leave the fascia over the nerve intact as Professor Amid advocated, but more important, he was more selective in the patients that he chose to repair, and that is, if patients who did not have very many symptoms but had a hernia that appeared and really did not bother them, then he did not repair them immediately. He told me that he estimated that of the patients he saw, he operated on 20% and observed 80%, which was a real difference from the original numbers. In keeping with this, there is an entire study as I will detail in the chapters that I have had the opportunity to review as to the incidence of recurrence, which now does not seem to be as great a problem in what exactly happens to these patients postoperatively, and what is the incidence of pain?

There are a number of randomized prospective trials that have taken place in many countries, which give us some idea of what the incidence of recurrence is and what the incidence of discomfort or pain is. The first study is from the Beijing Shijitan Hospital (Gong K, et al., *Surg Endosc* 2011;25:234–9), which compared an open tension-free mesh-plug, a transabdominal preperitoneal (TAPP), and a totally extraperitoneal (TEP) laparoscopic technique for unilateral inguinal hernia repair. This is a randomized prospective trial, which was meant to compare the open Lichtenstein type of technique with two laparoscopic techniques that are commonly used in China. The authors state that the choice of the proper technique is still controversial in China and therefore this study was undertaken. There were 164 male patients with a primary unilateral inguinal hernia who were randomized, apparently correctly, to undergo an open operation with a mesh-plug and patch, very similar to the technique described by Dr. Young and Dr. Gilbert, or the laparoscopic technique (TAPP) with 50 and 52 had TEP. The follow-up was for 16 months. The usual parameters for operating time were analyzed, and the open repair was

shorter in duration, significantly so that given the relatively short operating times, that does not seem to be of tremendous significance. I take the authors at their word that the randomization is correct, although seeing these slight differences for the open technique. The open tension-free mesh-plug repair took 66 minutes, the TAPP group took 76 minutes, and the TEP group took 79 minutes; both of the laparoscopic groups took significantly longer than the open group. Pain scores, however, in the open-mesh group, which is what they were interested in, were significantly higher than in the other two groups ($P < 0.01$). Recovery time was significantly longer in the open repair group than in the other two groups. None of the groups demonstrated any recurrence. Reviewing the data in Table 193.3, it does appear as if wound healing problems were 3 of 62 or 4.8% in the open mesh-plug group, infection was 3.2% or 2, whereas there was no infection in the other group. I am not sure what to make of the pain scores. The pain was measured at 24 hours and 1 week, and there was no significant difference between the TAPP and the TEP. At 1 week, the score was 1.5 ± 0.9 versus 0.3 ± 0.5 in the TAPP and the TEP. They state that the result is statistically significant, but it must be a slightly different series of statistics than I am accustomed to. They are entitled to use whatever repair they want, but I do not see the data here, which indicates that postoperative pain of a longer duration is present. They do say in their last paragraph of the discussion that although open mesh-plug hernia repair resulted in significantly more postoperative pain than the two laparoscopic techniques, it had less postoperative pain than traditional surgical procedures and others have used a new type of patch and plug system.

I am left somewhat confused about the data as to randomization and to why they make the statement of postoperative pain unless they are talking about 1 week postoperatively because I see no sign of long-term follow-up.

A longer follow-up on patients with a modified plug and patch inguinal herniorrhaphy was reported from the Royal Gwent Hospital in Newport, South Wales. Bhattarcharjee et al. (*Hernia*, 2010;14:171–4) operated on 200 consecutive unselected men who underwent a hernia repair in 2002 ($n = 89$) and 2004 ($n = 111$). They were followed up by a questionnaire of which 57% and 78%, respectively, replied. They were neither called back nor examined in this study. The questionnaire was allegedly “patient friendly,” which evaluated the frequency and severity of groin “discomfort” and “pain.” Significant groin discomfort, which was not evaluated for frequency, was described by three (6%) and four (5%), respectively, in 2002 and 2004. Overall, only four patients (3%) said that their symptoms restricted their daily activities. Thirteen patients had inguinal surgery on the other side, and 99% (105 out 106) of respondents would undergo a similar future procedure on the opposite side. Interestingly enough, this included all but one of the patients who had pain after their hernioplasty. The authors conclude that a “modified” plug and patch with a well-dissected procedure is associated with minimal chronic groin symptoms 5 to 7 years later in patients willing to undergo a procedure on the opposite side,

indicating satisfaction.

Yet another prospective randomized control trial compared a Prolene Hernia System (PHS), Lichtenstein mesh, and a plug and patch for primary inguinal hernia repair from Gothenberg (Dalenbäck J, et al., *Hernia* 2009;13:121–9). This was a randomized control trial of a total of 472 male patients between 30 and 75 years of age, with primary inguinal hernia. They were randomized to Lichtenstein mesh, PerFix Plug, or to the PHS procedure. All patients were seen and followed up on; data was collected after 2 weeks, 3 months, 1 year, and 3 years. The follow-up rates were between 95% and 100%, the 95% being in the PHS procedure. The usual statistics as far as operative time is normally meaningless, but it was 40.4 minutes for the Lichtenstein repair, 35.5 for the PerFix Plug, and 37.4 for the PHS. More than 85% of the procedures were performed under local anesthesia, and there were no statistically significant differences between the groups concerning early or late complications, return to full function, early pain response, analgesic consumption, and the late-outcome parameters after 3 years of observation. Seven patients (1.5%) with recurrences were varied between the groups and did not accumulate in any single group. The authors conclude that the operating times were significant, but to me they are meaningless. Early and late outcomes are comparable and so there is nothing to choose between these three mesh types of procedures.

In another procedure in another study, this time from two hospital centers, in which there was at least a blinded randomized control study comparing the Lichtenstein patch to the PerFix plug and the ProLoop plug in a new type of procedure for a new type of prosthesis in the repair of primary inguinal hernia. It was reported by Sanders et al., from the Department of Surgery at Derriford Hospital, Plymouth as well as the Department of Surgery at Lake Forest Hospital, Illinois (*Hernia* 2009;13:499–503). The patients who were randomized were over the age of 18, with a single, primary unilateral hernia; they were randomized between the three groups: Lichtenstein tension-free mesh repair, PerFix plug, and the ProLoop plug. Follow-up was at 2 weeks, 6 months, and 12 months, which is short. The endpoints were operative time, pain scores, return to daily activity, complications, and length of hospital stay. There were 295 consecutive patients randomized to the study—93 to the ProLoop plug, 101 to the PerFix plug, and 101 to the Lichtenstein tension-free mesh repair. There was no significant difference among the three groups in terms of age, sex, or importantly, BMI. Operative time was essentially the same, bodily pain scores were no different, and there were no statistical differences in complication rates or in returns to daily activity. The purpose of this study was apparently to show that the ProLoop plug made by Atrium is a safe and effective method in repairing primary inguinal hernias. It is apparently lighter than the thicker mesh plugs, and “it may offer benefit in terms of long-term patient comfort.” And now a word from our sponsor, “the ProLoop plug (Atrium) represents a new effective alternative to the established mesh repairs.” It is of interest that the authors did not report any conflicts of interest.

J.E.F.

194 Postherniorrhaphy Inguinodynia: Causes, Prevention, and Surgical Treatment: Triple Neurectomy

Parviz K. Amid and David C. Chen

BACKGROUND

While the recurrence rate of inguinal hernia repairs maybe significantly reduced in some hands by use of mesh and perhaps other tension-free techniques, postherniorrhaphy chronic pain remains the concern of hernia surgeons around the globe with an incidence ranging from 4% to 20%. Based on the classification of pain by the International Association for the Study of Pain (IASP), postherniorrhaphy inguinodynia can be broadly divided into nociceptive and neuropathic pain. There is no sharp line between the nociceptive and neuropathic pain, and the gray zone is further complicated by social, genetic, patient, and psychological factors.

Nociceptive pain is caused by activation of nociceptors by nociceptive molecules due to tissue injury or inflammatory reaction, and transmitted to the brain via A-delta and C-fibers. Nociceptive pain can be reduced by gentle tissue handling, using local anesthesia to reduce production of nociceptive molecules, and avoiding forceful tissue retraction.

Neuropathic pain is caused by direct nerve injury and characterized by inguinodynia with radiation to the scrotum/femoral triangle, paresthesia, allodynia, hyperpathia, hyperalgesia, hyperesthesia, hypoesthesia, and positive Tinel sign. Neuropathic pain can be reduced from the universally reported rate of 5% to 8% to a fraction of 1% by identification of nerves and their protection from direct contact with mesh that can lead to structural changes of nerve fibers. In-depth groin neuroanatomy knowledge is of paramount importance if postherniorrhaphy chronic pain is to be avoided.

GROIN NEUROANATOMY WITHIN THE INGUINAL CANAL

The ilioinguinal nerve is located over the spermatic cord, covered and protected from the mesh by the investing fascia of the internal oblique muscle (Fig. 194.1). This protective fascia should not be damaged by removing the nerve from its natural bed. Dissecting the ilioinguinal nerve from the cord and placing it below the inguinal ligament, which was the teaching of a prior era, destroys the protecting fascia of the nerve and risks perineural scaring and direct contact of the nerve with mesh.

The genital branch of the genitofemoral nerve is located under the cord, covered and protected from direct contact with mesh by the deep cremasteric fascia. Although small and difficult to see, its location can be determined by the easily visible “blue line” of the external spermatic vein that is always adjacent to the nerve (Fig. 194.2). To ensure safety of the nerve it must be kept with the cord while the cord is separated from the inguinal floor under direct vision. Grasping the cord with the thumb and index fingers and pulling it off the floor also should be avoided as this technique damages the deep cremasteric fascia, which can also lead to perineural scaring and direct contact of the genital nerve with the implanted mesh.

The iliohypogastric nerve is located between the external and internal oblique layers covered and protected from mesh, if one must use it, by the investing fascia of the internal oblique muscle (Fig. 194.3). The key step to expose the iliohypogastric nerve is opening the anatomic cleavage between the internal and external oblique layers high enough to expose the internal oblique aponeurosis. This step, that takes only a few seconds, easily and automatically exposes the iliohypogastric nerve. The iliohypogastric nerve has an easily visible part over the internal oblique aponeurosis; however, below the point marked by the arrow in Figure 194.4, the nerve has a hidden segment that runs inferiorly and laterally within the internal oblique muscle (Figs. 194.4 and 194.5). This segment of the iliohypogastric nerve is the most vulnerable neural structure of the inguinal area because it is not visible within the operative field. Passing suture through the internal oblique muscle, or the so-called conjoined tendon, for its fixation to the inguinal ligament, flat mesh, or plug has the potential risk of injuring the intramuscular segment of the nerve with the needle, or entrapping it by the suture. In less than 5% of patients, the iliohypogastric nerve runs under the internal oblique aponeurosis in a subaponeurotic location. In these cases the location of the nerve must be determined by noting the point of its simultaneous exit from the external and internal oblique layers (Fig.

194.6). Furthermore, in these instances, no suture or fixating device should be inserted into the internal oblique aponeurosis below the area marked by the “xs” in Figure 194.6 to avoid injuring the nerve that runs inferiorly and laterally underneath the internal oblique aponeurosis (Fig. 194.5).

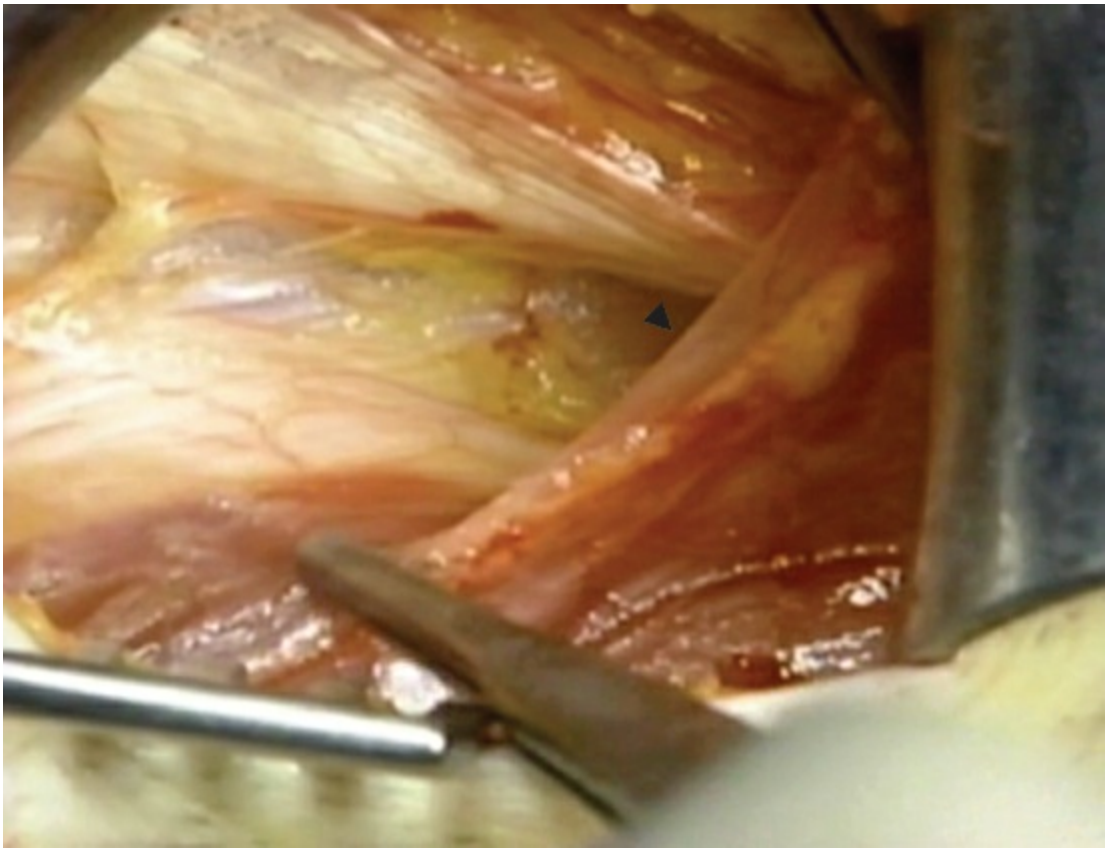

Figure 194.1. Ilioinguinal nerve is located over the cord, covered and protected by the investing fascia of the internal oblique fascia (pointed to by the *arrow*).

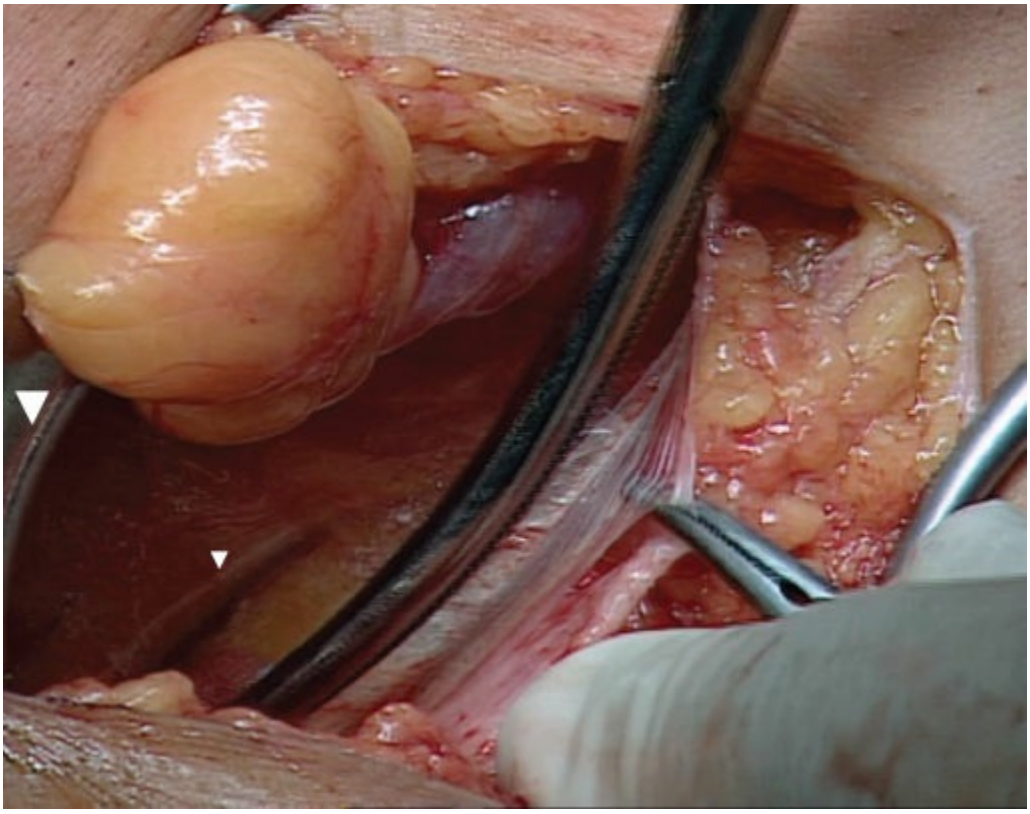

Figure 194.2. Inguinal segment of the genital branch of the genitofemoral nerve is located under the cord (pointed to by the *arrow*), covered and protected by the deep cremasteric fascia.

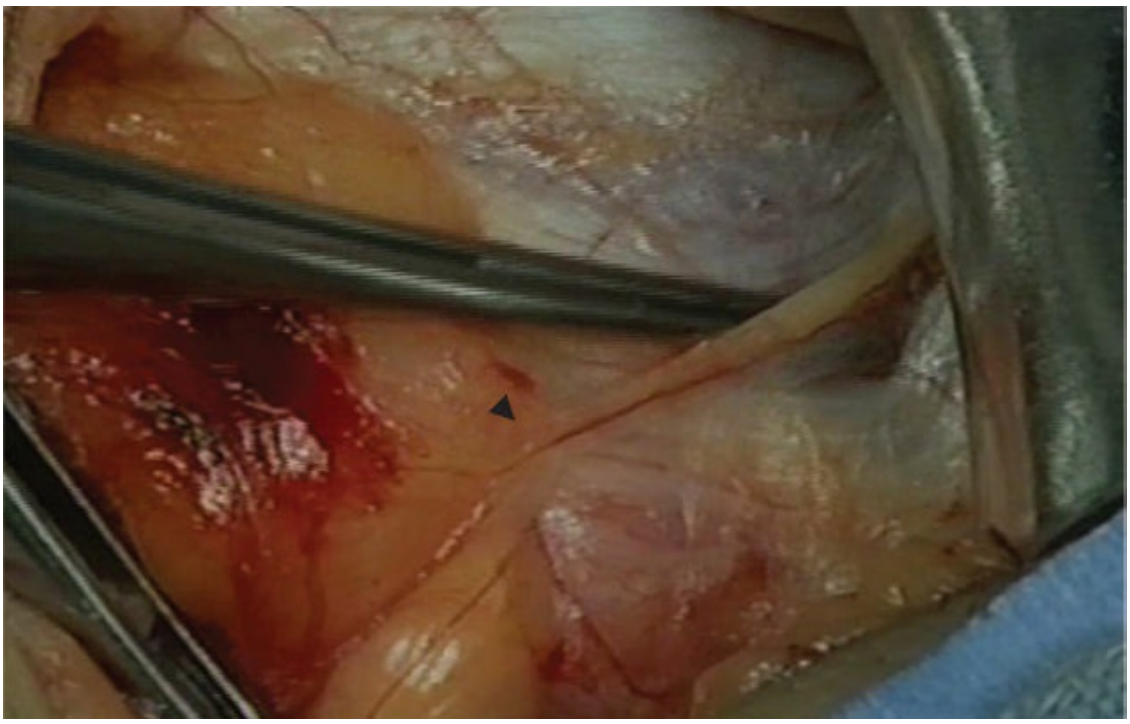

Figure 194.3. Iliohypogastric nerve is located between the external and internal oblique layers, covered and protected by the investing fascia of the internal oblique muscle. The *arrow* shows

the junction of the visible and hidden (intramuscular) segment of the nerve.

CAUSES OF NEUROPATHIC PAIN

Neuropathic pain can be caused by (a) structural injuries such as axonotmesis (disruption of axon and myelin sheath with preservation of the connective tissue covering of the nerve), neurotmesis (partial or complete severance of a nerve, with disruption of the axon and its myelin sheath and the connective tissue elements) due to cutting, thermal, or traction injuries leading to traumatic neuroma formation, and myelin degeneration and separation, axon crystallization due to direct contact of nerves with mesh; (b) entrapment injuries by suture, fixating devices, or wrinkled mesh or meshoma.

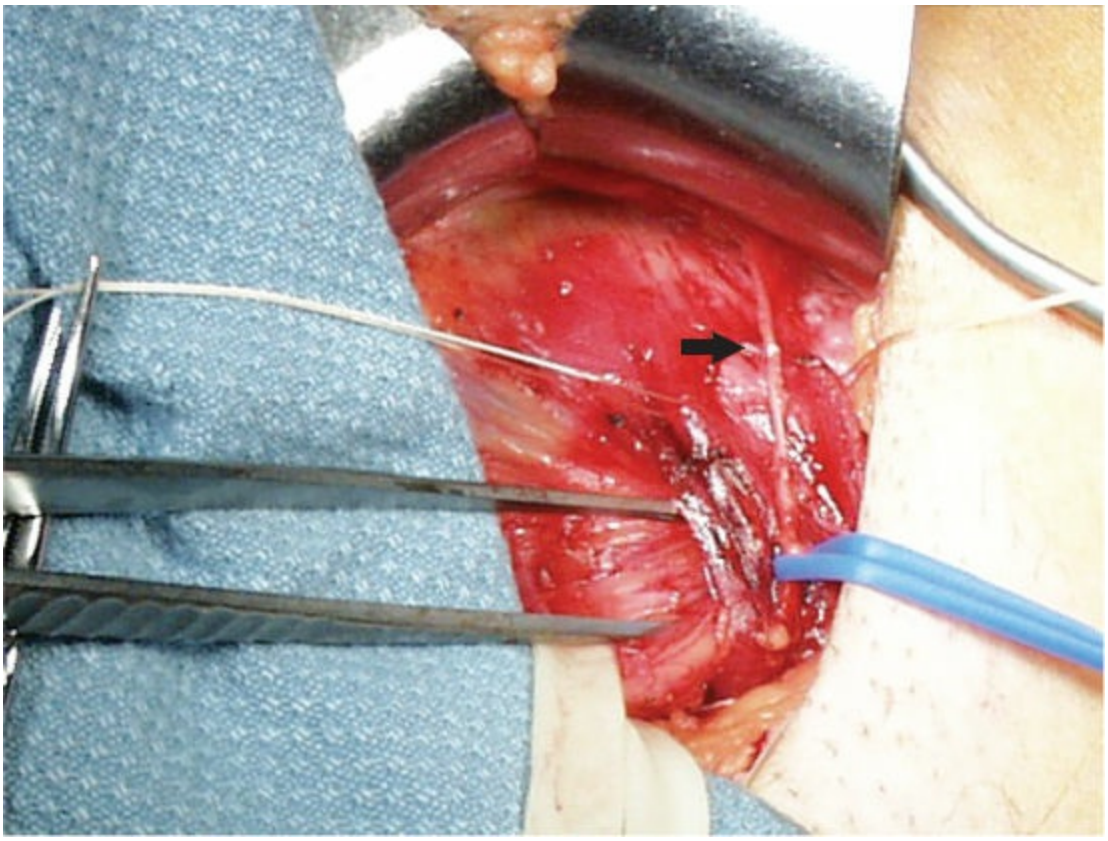

Figure 194.4. Intramuscular segment of the iliohypogastric nerve (below the *arrow*) exposed by the white sutures retracting the edges of a slit made in the internal oblique muscle to visualize the intramuscular segment of the nerve. Tip of the forceps is inside the internal ring.

SURGICAL TREATMENT OF NEUROPATHIC PAIN

Triple neurectomy, advocated by us in 1995, is currently a universally accepted surgical treatment for neuropathic pain refractory to nonsurgical modalities. Neurolysis, which does not address ultrastructural changes of nerve fibers, is no longer recommended. Also, removal of entrapping sutures or fixating devices that leave the injured crushed nerves behind is not recommended. Moreover, we do not recommend single or double neurectomy, as it does not address structural changes of the nerves that are not visible by naked eyes. The nerves should be resected proximal to the field of original hernia repair and as distally as possible. Although there are no data available, we recommend *ligation of the cut ends of the nerves to avoid neuroma* formation, and inserting the proximal cut end into the muscle to keep the nerve stump away from the future scarring of the operative field. The ilioinguinal nerve can be identified lateral to the internal ring, between the ring and the anterior superior iliac spine. If the nerve cannot be easily seen, it could be found underneath the fat-covered grooves in the internal oblique muscle fibers. The iliohypogastric nerve can be easily found within the anatomic cleavage between the external and internal oblique aponeurosis. After visualization, the nerve should be traced proximally within the fibers of the internal oblique muscle to a point lateral to the field of the original hernia repair. Failure to do so may leave the injured intramuscular segment of the nerve behind. It is important to know that in those instances where the iliohypogastric nerve has a subaponeurotic course, the internal oblique aponeurosis is split below the point of its simultaneous exit from the internal and external oblique aponeurosis to visualize the hidden nerve (Fig. 194.5). The inguinal segment of the genital branch of the genitofemoral nerve can be identified between the cord and the inguinal ligament and traced laterally to the internal ring where it is severed. An easier alternative is to visualize the nerve within the internal ring through the lateral cruse of the ring.

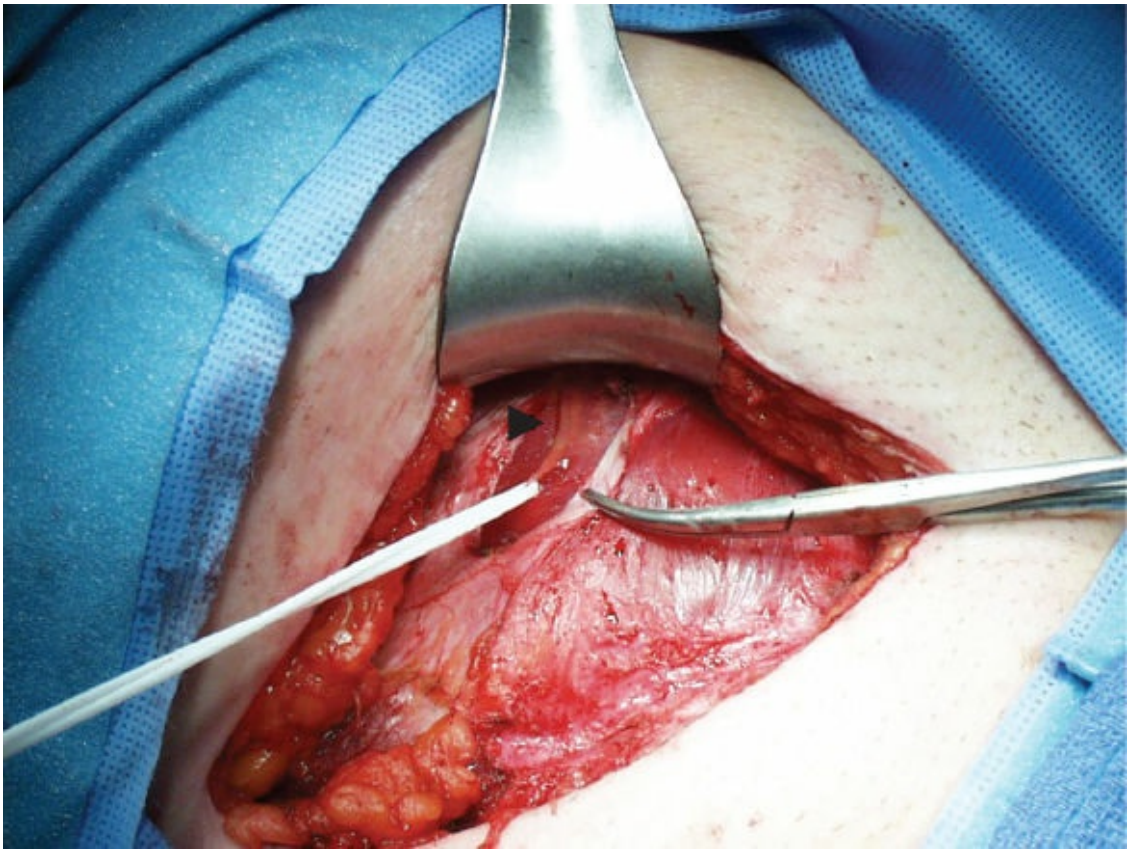

Figure 194.5. Internal oblique aponeurosis below the point of its exit is slit to visualize the inferior and lateral course of the iliohypogastric nerve (pointed to by the *arrow*) underneath the internal oblique aponeurosis.

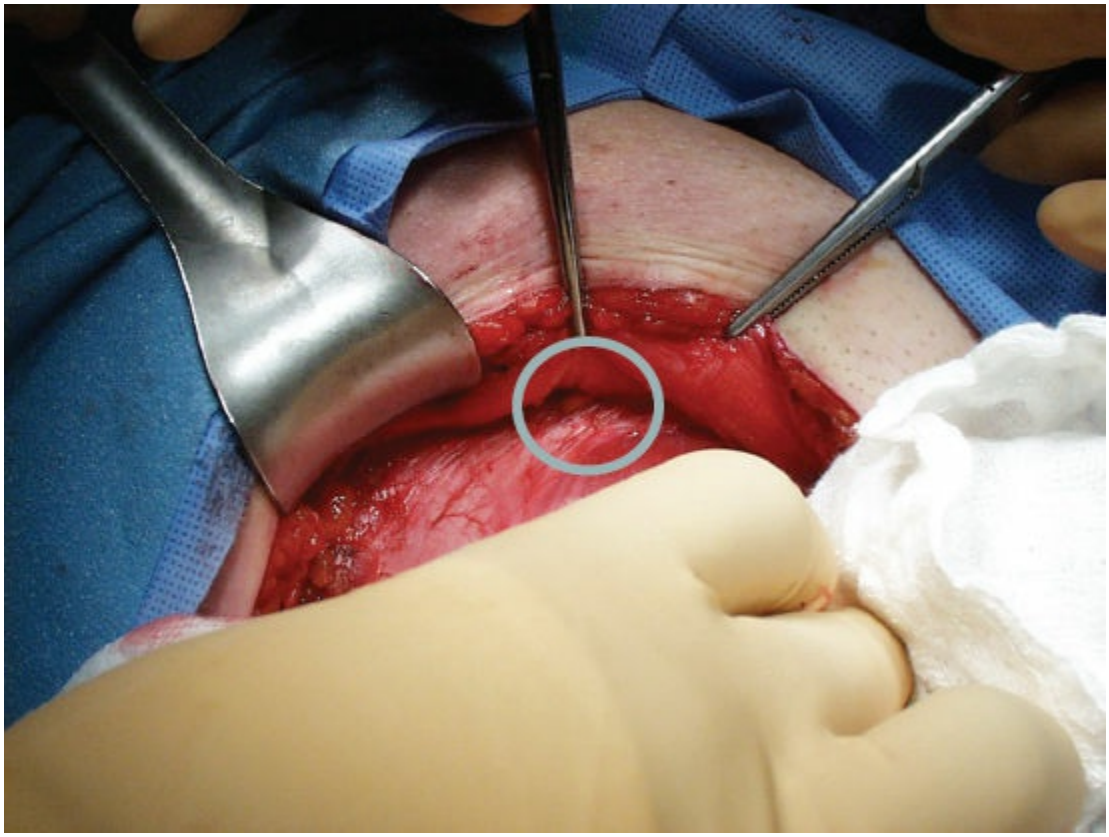

Figure 194.6. Point of simultaneous exit of a subaponeurotically located iliohypogastric nerve (inside the *circle*) from the internal and external oblique aponeurosis.

INDICATION FOR TRIPLE NEURECTOMY AND RESULTS

Recommended timing for surgical treatment of chronic postherniorrhaphy pain, not responding to nonsurgical treatment, is 6 months to 1 year after the original hernia repair. It is important to ask, and document, if the patient had groin pain prior to the original hernia repair and whether the postoperative pain is different from the preoperative pain. Best candidates for the operation are those patients who have no mesh material in their preperitoneal space. This is because “triple neurectomy” does not address neuropathic pain caused by neuropathy of the preperitoneal nerves, unless the operation is extended to include segmental resection of the main trunk of the genitofemoral nerve over the psoas muscle through the same split made in the internal oblique muscle for resection of the intramuscular segment of the iliohypogastric nerve (also see “Chronic Pain After Open and Laparoscopic Preperitoneal Hernia Repairs”). Our series now stand at 500 patients. Prior to including the intramuscular segment of the

iliohypogastric nerve, 85% of our patients in whom the original hernia operation was limited to the front of transversalis fascia had satisfactory results. After extending the procedure to include the intramuscular segment of the iliohypogastric nerve, 95% of our patients had satisfactory results. Triple neurectomy in women leads to numbness on the corresponding labia and sexual dysfunction. This issue requires serious consideration and should be discussed with the patient and adequately recorded.

POSTHERNIORRHAPHY ORCHIALGIA

Based on our limited observation of 17 patients, neuropathy of the nerve fibers within the lamina propria of the vas deferens, referred to as “paravasal nerves” and originating from the deep pelvic plexus, may be responsible for postherniorrhaphy orchialgia. In 17 patients with groin pain associated with orchialgia, segmental resection of the lamina propria of the vas together with triple neurectomy eliminated the testicular pain. Although our experience with paravasal neurectomy for postherniorrhaphy orchialgia is limited, it seems promising and deserving of additional study.

CHRONIC PAIN AFTER OPEN AND LAPAROSCOPIC PREPERITONEAL HERNIA REPAIRS

Pain after preperitoneal herniorrhaphy (both open and laparoscopic) presents special problems. The preperitoneal nerves, including the main trunk of the genitofemoral, its femoral branch, and the preperitoneal segment of its genital branch, are particularly vulnerable to neuropathy from direct contact with mesh. Because contrary to the nerve within the inguinal canal that are covered and protected by a layer of fascia, nerves in the preperitoneal space have no protecting fascia against the mesh. An additional problem related to laparoscopic preperitoneal hernia repair using fixating devices is penetration of fixating devices through the transversalis fascia and abdominal muscles and entrapment of the nerves within the inguinal canal (Fig. 194.7).

CONCLUSION

According to the Swedish Hernia Registry, at this point in time the incidence of postherniorrhaphy chronic pain is greater than that of its recurrence, and ranges between 6% and 8%.

Based on level A evidence from the Netherlands, Denmark, and Italy, nerve identification and protection during inguinal hernia repair reduces the rate of chronic pain to a fraction of 1%.

There is no sharp demarcation between nociceptive and neuropathic pain, and the gray zone is further complicated by genetic, social, psychological, and patient factors. Furthermore, our collaborative study with a group of investigators from Germany suggests that there may also be some biochemical factors at work. These factors include higher-level collagen-3 in the harvested nerves from the patients with neuropathic pain. In addition, chronic inguinodynia is a problem for which there is no universally accepted definition, etiology, classification, and surgical treatment except for triple neurectomy where there is no mesh material in the preperitoneal space. Therefore, at this point in time, the best we can do for our patients is preventing this debilitating complication of hernia surgery. The latter requires in-depth knowledge of pathophysiology of pain and groin neuroanatomy. A number of investigators have shown that failure to identify the nerves is a risk factor for development of chronic pain: some have gone so far to advocate prophylactic neurectomy to avoid chronic pain, a maneuver that we and others believe is an inferior alternative to careful nerve handling. At any time if a nerve is in the way of the repair or suspected of being injured, its resection is universally recommended. In summary, chronic pain can be significantly reduced by not damaging the protective fascia of the ilioinguinal nerve by removing the nerve from its natural bed, by not passing suture through the internal oblique muscle to avoid injuring its intramuscular segment, and by not damaging the deep cremasteric fascia, the protective fascia of the genital nerve, by careful dissection of the cord from the inguinal floor.

EDITOR'S COMMENT

This is an important chapter in this book. It is interesting to note that there seems to be a great deal of denial, inconsistent follow-up, or else the results in various series are so different that there are a large group or series in which there is no postherniorrhaphy incisional pain. However, it does seem to me that there are an awful lot of papers that deal with either prophylactic neurectomy or neurectomy following inguinal herniorrhaphy. By employing mesh have we have traded off the absence of recurrence or minimal recurrence for a fairly large group of patients who had posthernia pain, some of which may be severe? Despite technologic advances with light with polypropylene, postherniorrhaphy continues to be a problem many patients. A recent series reported pain at 1 year in 13% and 25% at 2 years. Is polypropylene as inert as we all think? Nerves become adherent to it. In addition a recent study documented oxidative stress related to polypropylene mesh that was proportionate to the amount of material used (Donati M, Brancato G, Grosso G, et al. Immunological reaction and oxidative stress after light or heavy polypropylene mesh implantation in inguinal hernioplasty: A CONSORT-prospective, randomized, clinical trial. *Medicine* 2016;95(24):e3791). Today patients are now asking for mesh-free hernia repairs. In the paragraphs below we review methods of reducing pain by nerve excision but perhaps we should do more repairs without mesh.

All of this is concerning. There seems to be a trend as some in the surgical community would rather remove nerve tissue at the time of hernia repair rather than doing a mesh-free repair. Johner et al. report in a systemic literature search (Johner A, Faulds J, Wiseman SM. Planned ilioinguinal nerve excision for prevention of chronic pain after inguinal hernia repair: a meta analysis. *Surgery* 2011;150(3):534–41) that during an operation for hernia that has no postoperative pain, it does seem that there is increasing literature activity concerning excision of ilioinguinal or iliohypogastric and genitofemoral nerves for an operation, which has been reported as having no postoperative pain. Chronic postherniorrhaphy pain has reached the point that is truly a public health problem. At least 5% of the population (mostly males) will develop a groin hernia in their lifetime, making groin hernia repair one of the most common operations performed by general surgeons. With more recent attention paid to patient outcomes, apparently "chronic postoperative pain is now considered the most frequent and disabling complication of hernia repair" (Nienhuijs S, Staal E, Strobbe L, et al. Chronic pain after mesh repair of inguinal hernia: a systematic review. *Am J Surg* 2007;194(3):394–400). There seem to be an awful lot of prophylactic studies on excising various nerves, including ilioinguinal, iliohypogastric, and genitofemoral for a problem that does not exist. To do their review, Johner et al. underwent a systematic literature review to identify studies investigating the influence of ilioinguinal nerve excision on the development of chronic pain after inguinal hernia repair.

Once the studies were identified, an analysis of the pool of data was carried out. A total of 6,023 abstracts were reviewed of this supposedly nonexistent problem. Four high-quality randomized controlled trials were identified, and the endpoint is the pooled mean difference in degree of pain at 6 months postoperatively on a 10-point scale. The evidence favored neurectomy to decrease the chance of developing chronic pain. As the authors state in their abstract, "not surprisingly, those individuals undergoing neurectomy were also more likely to develop altered sensation at the same time point." This was statistically significant. The authors concluded that the planned neurectomy seemed to decrease the incidence of chronic postoperative pain.

This controversy is not new. In the past, Lichtenstein and his successor Amid, who is the author of this chapter, recommended preservation of the ilioinguinal, iliohypogastric, and genitofemoral nerves (Lichtenstein IL, Shulman AG, Amid PK, et al. Cause and prevention of postherniorrhaphy neuralgia: a proposed protocol for treatment. *Am J Surg* 1988;155(6):786–90 and Amid PK. Lichtenstein tension-free hernioplasty: its inception, evolution, and principles. *Hernia* 2004;8(1):1–7), whereas Wantz of Cornell (Wantz GE. Complications of inguinal hernia repair. *Surg Clin North Am* 1984;64(2):287–98) recommended intentional nerve division. It is of interest that George Wantz, a very well-known herniorrhaphy specialist recommended inguinal nerve division, whereas in my experience, simple inguinal nerve division is not satisfactory and one must do a resection of all the three nerves since they communicate. It does appear that if in this study as if the ilioinguinal neurectomy there was a significant amount of altered sensation at 6 months after surgery, with decreased touch sensation at 6 months following herniorrhaphy. The authors do conclude on the basis of this data that inguinal neurectomy does prevent chronic pain, which may very well be troublesome—a conclusion also supported by Wijsmuller AR et al., from Holland (Wijsmuller AR, van Veen RN, Bosch JL, et al. Nerve management during open hernia repair. *Br J Surg* 2007;94(1):17–22).

Another paper, "Ilioinguinal nerve excision in open mesh repair of inguinal hernia—results of a randomized clinical trial: simple solution or a difficult problem?," which proposes a solution to this nonexistent problem comes from the Department of Community Medicine in Tehran by Malekpour F, et al. (Ilioinguinal nerve excision in open mesh repair of inguinal hernia—results of a randomized clinical trial: simple solution for a difficult problem? *Am J Surg* 2008;195:735–40). In this study, the authors carried out a double-blind randomized clinical trial performed on 121 patients undergoing open anterior mesh repair of inguinal hernia in one center from April 2005 to June 2006. In half of the patients, the ilioinguinal nerve was excised (but not buried) and in the other half, it was preserved. Pain and hypesthesia on postoperative day 1, and 1 and 6 months after surgery, and 1 year after surgery were evaluated in both groups using a visual analog scale. Of the 121 patients, who were aged between 18 and 86 years, 115 (95%) were male. There were 61 in the nerve-

excision group and 60 in the nerve-preservation group. Follow-up was performed on 100 patients at the end of the first year. The mean scores of the nerve-excision group were 2.2 ± 0.8 versus 2.8 ± 0.7 in the nerve-preservation group ($P < 0.01$). Between 6 months and a year after surgery, median scores of zero were detected in both groups. After postsurgical day 1, the median score of hypesthesia was near zero in both groups, and 13 patients, interestingly enough, developed chronic inguinodynia—10 of whom were in the nerve-preservation group, and presumably three were in the nerve-excision group. Chronic postsurgical inguinodynia was seen in 6% of patients in the ilioinguinal nerve-excision group and in 21% of the patients in which the ilioinguinal nerve-preservation group was preserved. To me this is not surprising. Inguinodynia is a curious phenomenon, but it cannot be completely obviated by excision of the nerve unless I believe one takes the nerve all the way back to its most lateral extent, splits the muscle, ties off the nerve with 6-0 Prolene, touches the nerve with phenol and alcohol, and then buries the nerve in the muscle. It does not appear as if this was done. In addition, if one just takes one of the nerves, in this case the ilioinguinal nerve but not the iliohypogastric and the genitofemoral, then I believe that the incidence of inguinodynia is increased and that is the reason why inguinodynia is 21%.

In another two papers, this time from Veldhoven, the Netherlands, a randomized control trial of injection therapy versus neurectomy for postherniorrhaphy neuralgia was first described as to its design (Loos MJ, Verhagen T, Scheltinga MR, et al. A randomized controlled trial of injection therapy versus neurectomy for post-herniorrhaphy inguinal neuralgia: rationale and study design. *Hernia* 2010;14(6):593–7) and then in follow-up by Loos and his colleagues (Tailored neurectomy for treatment of postherniorrhaphy inguinal neuralgia. *Surgery*, 2010;147(2):275–81). In this study, the registry of patients for postherniorrhaphy groin pain treated by a neurectomy, a study that was designed in the previously mentioned paper, is analyzed. They received a questionnaire evaluating the current pain intensity, overall treatment results, and specifically the effect of sexual intercourse–related pain. The risk factors for failure, and not surprisingly, I think a very good one, the presence of a learning curve is identified. There were 54 patients who underwent a neurectomy over a 5-year period. Of the 54, 49 (91%) responded, 52% claimed to be almost free of pain (good to excellent), 24% reported some relief (they still felt pain on a regular interval), and 24% did not benefit. Sexual intercourse–related pain apparently responded favorably to neurectomy in two thirds of patients. There seemed to be a steep learning curve in performing the procedure and poor treatment results also depended on previously received pain regimens ($P = 0.021$). The authors concluded, and I do not agree, that a selective operative neurectomy for postherniorrhaphy groin neuralgia provides good long-term pain relief in most patients, which I do not believe is true. They and the abstract state as follows: hernia surgeons who are responsible for this iatrogenic complication should consider incorporating selective neurectomy in their surgical

armamentarium. I am not sure that I agree with this conclusion. As I take on a number of these patients, and there are many surgeons who are not particularly interested in dealing with their patients—whether they are their own patients who develop postoperative neural pain or whether they are someone else's, there is a steep learning curve in learning how to deal with these patients. One must resect all three nerves and enter into the internal inguinal canal to resect the crural nerve. If the resection of the genitofemoral nerve either fails or it cannot be found, it is necessary to do a follow-up of a laparoscopy entrance into the retroperitoneum and separate the genitofemoral nerve's origin from that of the lateral femoral cutaneous nerve. The ilioinguinal and iliohypogastric nerves need to be dissected completely, taken back as far laterally, tied off, touched with phenol alcohol, in my humble opinion to prevent the nerve from being alive even as one cohort is buried. Even so, this is not a procedure which works 100% of the time; it is successful closer to 80% of the time. The cavalier way in which some of the authors refer to this procedure is out of place. Many of these patients' lives are ruined.

Finally, the inguinal incision and nerve excision is not only for inguinodynia. This pain also occurs following a Pfannstiel incision, which I like to use for certain operations, and if one wanders off how one does during a Pfannstiel incision, it is entirely possible to entrap the ilioinguinal lump and iliohypogastric nerve. Loos et al., the same group from the Netherlands, have identified 27 women with Pfannstiel-related neuralgia between 2000 and 2007. They say that a single diagnostic nerve block provided long-term pain relief in five patients, which occasionally is true, especially if triamcinolone is included. The remaining 22 underwent neurectomy of which 22 had good to excellent results in 73%, moderate in 14%, and poor in 13% after a median follow-up of 2 years. In particular, successful treatment improved intercourse-related pain in most patients. Lumbosacral radicular syndrome was apparently eliminated as best that the authors could in an effort to identify those patients who had significant pain. That was likely to be from the lumbosacral joint.

This is an important chapter. Given the number of hernias that are done, the fact that mesh is utilized in almost all and the fact that the preventive methods, which have been identified in this chapter by Dr. Amid, which is leaving the nerves within their fascial envelope, is not universally carried out; there are a large number of people who have inguinodynia. Since I have treated them, several have had their lives ruined and one particular patient committed suicide not so much because of his inguinodynia, which was well treated, but because of congestive heart failure. He had had enough. Dr. Amid has experienced more than 500 patients with inguinodynia; he hopes that surgeons will pay attention to the nerves and leave them within their fascial envelope, which I suspect they do not. Once the syndrome is identified, it behooves one to try injections for the trigger point using xylocaine, marcaine, and triamcinolone and if there is no relief, then the patients ought to undergo triple neurectomy as is proposed in this group and in this chapter. The admonition that triple neurectomy does not

address neuropathic pain “caused by neuropathy of the preperitoneal nerves, unless the operation is extended to include segmental resection of main trunk of the genitofemoral nerve over the psoas muscle” prior to the split; this can only be entered retroperitoneally, though more easily laparoscopically, is a statement that I agree with entirely. To get the trunk of the genitofemoral nerve it will also be necessary to render the area of the lateral femoral anterior cutaneous nerve anesthetic, which may be a sensation the patients do not like. Dr. Amid is an expert in this area, and there will be more and more people who will be carrying out triple neurectomies and nerve dissections in order to rid patients of this complication. Since 5% of patients have inguinal hernias and with mesh repairs, probably about 10% will have some sort of neuropathic pain postoperatively, there is enough work to go around. Perhaps we have come full circle and mesh-free hernia repair will see a recrudescence. We predict consumerism will drive mesh-free hernia repair.

SECTION IX

VASCULAR SURGERY

A CEREBROVASCULAR DISEASE

195 Carotid Bifurcation Disease: Carotid Endarterectomy and Stenting

Sapan S. Desai

ETIOLOGY AND PATHOPHYSIOLOGY

Epidemiology

Stroke is the result of a focal disruption of the intracranial blood supply leading to a discrete neurologic deficit that lasts for over 24 hours. There are two types of stroke: ischemic stroke is the result of arterial occlusion, while hemorrhagic stroke occurs due to vessel rupture. Approximately 87% of the more than 600,000 new strokes annually within the United States are ischemic. Ischemic stroke can be due to cerebrovascular disease (17%), cardioembolism (30%), lacunar infarcts (16%), and unknown etiology (37%).

While the overall rate of stroke has decreased over the past 20 years, potentially due to the use of statins, antihypertensives, and better control of risk factors, such as smoking and diabetes, stroke still remains the fourth leading cause of death within the United States and leads to almost $80 billion in direct costs. Only about 10% of patients with stroke return to their baseline function, and this lost productivity leads to an additional $35 billion in indirect costs.

Etiology

Stroke due to cerebrovascular disease is primarily from stenosis of the internal carotid artery (ICA), and most commonly presents as thromboembolism within the distribution of the anterior cerebral arteries

(ACAs) or middle cerebral arteries (MCAs). The risk of stroke increases according to the severity of the atherosclerotic stenosis. In asymptomatic patients with less than 50% ICA stenosis, the annual risk of stroke is <1%; between 50% and 80%, the annual risk of stroke is 0.8% to 2.4%; and over 80% is associated with a 1% to 5% annual risk of stroke. Carotid artery thrombosis and low-flow states are rare causes of cerebral ischemia.

Pathophysiology

Atherosclerotic carotid artery disease leads to plaque formation at areas of low shear stress and flow stagnation, which primarily occurs at the posterolateral portion of the carotid bifurcation. Most plaques are characterized by a fibrous cap, areas of focal calcification, lipid accumulation, and neovascularization. Unstable plaques may become ulcerated, are more prone to atheroembolization, and are characterized by rupture, large lipid cores, hemorrhage within the plaque, and inflammation. Plaques that lead to progressive stenosis over time are also associated with an increased stroke risk; however, they are much more significant indicator of overall cardiovascular disease burden and subsequent risk of myocardial infarction (MI).

Risk Factors

Risk factors for cerebrovascular disease include advanced age, male gender, African American race, hypertension, smoking, hyperlipidemia, diabetes, and renal failure. Atherosclerotic carotid artery disease is present in about 2.5% of all patients, and increases to 5.5% of women and 10.5% of men over the age of 60. Transient ischemic attacks (TIAs) are focal neurologic deficits that resolve within 24 hours, and are a strong risk factor for future stroke.

Anatomy

Aortic Arch

Mastery of the cerebrovascular anatomy is essential to surgical success. The blood supply to the brain originates from branches of the aortic arch. In the normal configuration (found 75% of the time), the three great vessels from the arch include the brachiocephalic artery, left common carotid artery (CCA), and the left subclavian artery. The brachiocephalic artery, sometimes referred to as the innominate artery, divides into the

right subclavian and right CCAs. Each CCA travels within a carotid sheath, along with the internal jugular vein and vagus nerve. The CCA bifurcates into the external carotid arteries (ECAs) and ICAs at the level of the fourth cervical vertebra. The ICA then travels directly into the skull through the carotid canal.

External Carotid Artery

The ECA is differentiated from the ICA near the bifurcation by having a branch that comes off within the first centimeter of the vessel's origination. The superior thyroid artery is the first branch of this vessel before the ECA travels toward the face. The remaining branches of the ECA include the ascending pharyngeal artery, lingual artery, facial artery, occipital artery, and posterior auricular artery. The two terminal branches of the ECA are the maxillary artery and superficial temporal artery.

There are over a dozen connections between the extracranial and intracranial (EC and IC) circulation. While not large enough to prevent major stroke if there is sudden occlusion of the ICA, these anastomoses can be the source of collateral blood flow, but also potentially are associated with thromboembolism to the brain. The most important of these collateral pathways include branches of the internal maxillary artery and superficial temporal artery (ECA branch) to the ophthalmic artery (ICA branch). Branches of the ascending pharyngeal artery (ECA branch) can connect to the caroticotympanic artery (ICA branch). Due to their proximity, a surgical bypass between the superficial temporal artery (ECA branch) and MCA, known as an EC–IC bypass, can be performed in some situations.

TABLE 195.1 Major Segments of the Internal Carotid Artery

Segment	Name	Description
C1	Cervical segment	Extends from carotid bifurcation to carotid canal No branches for extracranial ICA
C2	Petrous segment	Extends from temporal bone to foramen lacerum First branch is caroticotympanic artery
C3	Lacerum segment	Extends from foramen lacerum to periosteal portion of the sphenoid bone
C4	Cavernous segment	Surrounded by cavernous sinus Risk of carotid artery to cavernous sinus fistula
C5	Clinoid segment	Extends from cavernous sinus to subarachnoid space
C6	Ophthalmic segment	Major branch is ophthalmic artery
C7	Communicating segment	Terminal branches of the ICA (ACA and MCA)

Internal Carotid Artery

The ICA is divided into seven distinct segments, which are described in Table 195.1.

Vertebral Artery

The vertebral artery is the first branch off the first part of the subclavian artery on each side. The vertebral artery is divided into four parts. The first part emanates from the subclavian artery, travels to the transverse process of the C6 vertebra, and is accessible for surgical bypass or transposition. The second part travels within the foramina of the transverse processes between C2 and C6 and is generally inaccessible. The third part travels from the C2 transverse process foramen to the vertebral canal, and is accessible for surgical bypass. The fourth part is primarily intracranial and joins together with the contralateral vertebral artery to form the basilar artery. The basilar artery is the chief blood supplier to the posterior portion of the circle of Willis.

Circle of Willis

The circle of Willis is a major cerebral circulatory anastomosis that provides redundant blood supply between the right and left brain, and anterior and posterior brain. The right and left ACAs have a small communicating branch known as the anterior communicating artery. Emanating from the MCA, the posterior communicating arteries connect to the basilar artery.

The five segments of the ACA supply the anterior midline of the brain, including the frontal and superomedial parietal lobes, the caudate nucleus, and the anterior limb of the internal capsule. The four segments of the MCA supply the lateral cerebral cortex, including the frontal, parietal, and temporal lobes, the basal ganglia, and the insula.

The posterior communicating artery connects the circle of Willis to the posterior circulation, including the posterior cerebral artery (PCA) and branches of the basilar artery. This communicating artery is usually small; thus, occipital lobe and cerebellar strokes are a rare manifestation of carotid artery disease.

Management

Treatments of clinically significant atherosclerotic carotid artery disease include medical management, carotid endarterectomy (CEA), carotid artery stenting (CAS), and carotid artery bypass. Carotid artery bypass options include EC-IC bypass, and a CCA to ICA bypass. EC-IC bypass for carotid artery stenosis is associated with poor outcomes and is typically reserved for obliterative diseases, such as Moyamoya disease. CCA to ICA bypass is an uncommon procedure reserved for cases where endarterectomy or stenting cannot be completed. CEA and CAS are discussed below.

Best medical therapy includes amelioration of key risk factors and stabilization of the plaque. The blood pressure should be normalized as close to 120/80 mm Hg as possible for hypertensive patients. The goal HgbA1c should be less than seven for diabetics. Absolute smoking cessation and alcohol consumption reduced to less than two drinks per day are urged. Hyperlipidemia should be corrected to obtain low-density lipoprotein (LDL) levels below 70 mg/dL and high-density lipoprotein (HDL) levels above 40 mg/dL. While statins are typically the first-line therapy for the treatment of hyperlipidemia, they should be initiated in all patients with vascular disease due to their plaque-stabilization, antithrombotic, and anti-inflammatory properties. Finally, patients should also be on one or more antiplatelet agents, such as 81 mg of aspirin daily and/or 75 mg of clopidogrel daily. Dual antiplatelet therapy is most commonly indicated for patients undergoing CAS.

CLINICAL PRESENTATION

TIA/Stroke

TIAs are the result of ischemia to a specific portion of the brain due to hypoperfusion secondary to stenosis or thromboembolism. TIAs have no sequelae beyond 24 hours and the patient returns to their baseline status by this time. Any defect beyond 24 hours is a stroke. Almost 30% of patients who develop a TIA will have a stroke within 5 years.

Stroke is a neurologic deficit lasting more than 24 hours. While acute symptoms can be devastating, the permanent deficit tends to be less as the ischemic portion of the brain improves. Loss of cerebral matter leads to permanent deficits, but loss of function can sometimes be improved with rehabilitation and surgery.

The neurologic deficit following TIA or stroke depends upon the vessel affected. Disruption of the ACA leads to motor and sensory loss of the contralateral lower extremities and changes to the personality. In the acute phase, urinary incontinence can be present, particularly with large strokes that cause bilateral ischemia. Disruption of the MCA can present as motor and sensory loss of the contralateral upper extremities and the face. A left hemispheric stroke can lead to Broca or Wernicke aphasia in left hemisphere dominant (i.e., right-handed) people and neglect of the contralateral side. Motor deficits can range from minor loss of motion to total hemiparalysis. Sensory deficits have a similar gamut ranging from mild numbness to total paresthesia.

Thromboembolism to the ophthalmic branch of the ICA can affect the retinal artery and lead to temporary blindness, known as *amaurosis fugax*. Stereotypical deficits from multiple TIAs or stroke indicate a high likelihood of carotid artery disease, whereas a mixed picture of right and left-sided deficits over time is more typical of cardiac emboli.

PCA-distribution deficits are rare with carotid artery disease and should prompt an exploration of vertebral artery disease. Patients who present with vestibular deficits such as dizziness, vertigo, or abnormalities of gaze, tonic/clonic deficits, loss of consciousness, new onset migraine headaches, amnesia, and confusion are more likely to have disease affecting their vertebrobasilar vascular system. Stroke leading to loss of pain and temperature, visual field defects, Horner syndrome, and facial nerve palsies of the lower face are also uncommonly related to carotid artery disease.

Hypoperfusion Syndrome

Hypoperfusion syndromes leading to global ischemia are rare. These

patients present with syncope or unconsciousness and most cases are due to severe cardiovascular compromise. Severe flow-limiting lesions affecting the carotid arteries do occur occasionally and necessitate treatment of the cerebrovascular blood supply. In rare circumstances, patients with severe disease of the vertebrobasilar system who rely upon the collateral anterior circulation system may develop progressive posterior circulation symptoms due to worsening ICA disease. These patients have a flow-limiting syndrome that may improve with the treatment of the carotid artery disease.

Lacunar Infarct

Lacunar infarcts occur with thrombosis of small vessels within the brain and not usually related to carotid artery disease, due to the larger deficits that tend to occur from atheroembolic sources.

INDICATIONS AND CONTRAINDICATIONS

All patients with cerebrovascular disease should have risk factor modification. Antiplatelet agents and statins are indicated in virtually all patients with an atherosclerotic disease burden. A subset of patients with more clinically significant disease may be candidates for carotid revascularization, such as CEA or CAS. The American Heart Association (AHA), European Society of Cardiology (ESC), and Society for Vascular Surgery (SVS) have published guidelines describing the indications and contraindications to surgery for these patients.

Asymptomatic Carotid Artery Disease

Asymptomatic patients with at least 60% ICA stenosis who are expected to have a 3- to 5-year survival and are likely to survive an intervention and therefore are candidates for surgery. Due to the higher stroke rate associated with CAS, most of these patients should undergo CEA. CAS can be considered in these patients if the interventionalist has a <3% risk of complications or it is being done as part of a clinical trial. High-risk patients or those with poor likelihood of long-term survival should undergo best medial therapy. Due to the improvement in medical management of risk factors and increased use of statins, most clinicians will wait until at least 70% ICA stenosis before proceeding with CEA in asymptomatic patients (Table 195.2).

TABLE 195.2 Indications for Carotid Revascularization

Asymptomatic Disease	Symptomatic Disease
>70% carotid artery stenosis	>50% carotid artery stenosis
>50% carotid artery stenosis and ulcerated plaque	Symptoms within 3 months
<3% risk of complications by surgeon	<6% risk of complications by surgeon
Life span at least 3–5 years	Able to survive intervention

Symptomatic Carotid Artery Disease

Symptomatic patients with at least 50% carotid artery stenosis are candidates for an intervention, according to the AHA and SVS guidelines. The ESC guidelines indicate intervention for patients with at least 70% stenosis. For most clinicians within the United States, low-risk symptomatic patients with at least 50% carotid artery stenosis will undergo CEA. Patients with major cardiac risk factors, hostile necks, or other high-risk situations may undergo CAS. Symptomatic patients should undergo surgery within 2 weeks whenever possible, as most of the risk of recurrent stroke occurs within that 2-week period. Presently, CAS is generally indicated only in symptomatic patients and only when the risk associated with CEA is too high (Table 195.3).

Timing of Surgery

A subgroup analysis of the North American Symptomatic Carotid Endarterectomy Trial (NASCET) found that symptomatic patients with carotid artery disease have a high likelihood of having a recurrent TIA or stroke. The risk is highest within the first 2 weeks of the initial episode; therefore, early operation in appropriate patients is likely to confer the greatest long-term benefit of CEA for these patients. For example, the absolute risk reduction is as high as 30.2% in patients with over 70%

carotid artery stenosis if they are operated on within 2 weeks. This drops to 8.9% if there is a more than 3-month delay, and there is no benefit to surgery in patients with 50% to 69% stenosis.

TABLE 195.3 Indications for CAS and CEA

Indications for CEA	Indications for CAS
Meets criteria for asymptomatic or symptomatic disease	Meets criteria for symptomatic disease and not a candidate for CEA
Severe or unstable plaque (relative indication)	Consider CAS if prohibitive cardiac risk factors (relative indication)
Renal disease (relative indication)	
Age >80 (relative indication)	

Crescendo TIA and Stroke in Evolution

Indications for urgent surgery include crescendo TIA and stroke in evolution. Crescendo TIA occurs when there are multiple TIAs within a few days or weeks and is associated with a high-risk plaque. Stroke in evolution leads to worsening neurologic deficits after the initial event, indicating promulgation of the initial injury and clinically significant ischemia along the penumbra. Both of these classes of patients benefit from early surgery to help limit the area of ischemia and forestall additional injury.

Internal Carotid Artery Occlusion

A small subset of patients may be found to have occlusion of the ICA. While acute occlusion of the ICA is associated with up to a 40% rate of major stroke, chronic occlusion only rarely leads to stroke in a condition, known as *ICA stump syndrome*. Endarterectomy or thrombectomy is not

indicated for occlusion due to the high risk of thromboembolism and the complications associated with retrieving major clot within the intracranial circulation. Stump syndrome occurs when ipsilateral hemispheric defects occur despite thrombosis of the ICA, and is thought to be due to microemboli from within the stump of the occluded ICA passing into the ECA distribution and subsequently into the EC–IC collateral pathways. Patients with stump syndrome are treated with endarterectomy of the ECA and ligation of the ICA stump.

CEA Versus CAS

CEA is generally preferred to CAS in most patients with clinically significant carotid artery disease. However, there are situations where CAS may be utilized due to a higher than normal risk of harm to the patient from CEA. Patients with prior major neck surgery such as a modified radical neck dissection have obliteration of the normal planes of dissection. Identifying cranial nerves (CNs), particularly the hypoglossal (CN XII), vagus (CN X), glossopharyngeal (CN IX), spinal accessory (CN XI), recurrent laryngeal nerve, and superior laryngeal nerve become significantly more complex in repeat neck operations. In a study completed by the Vascular Study Group of New England using a quality improvement registry, the risk of CN injury in redo CEA is not significantly greater (OR 1.0, $p = 0.90$). However, results from the European Carotid Surgery Trial (ECST), redo neck operations are associated with longer operating time, and operation over 2 hours is associated with an increase in risk of CN injury (OR 1.6, $p < 0.05$). A similar obliteration of normal planes occurs with neck radiation. As a result of this potential increase in risk, prior neck surgery (including prior CEA) and radiation exposure are relative indications for CAS in patients with symptomatic carotid artery disease.

CEA is also associated with a higher risk of cardiac complications compared to CAS. The Carotid Revascularization Endarterectomy vs. Stenting Trial (CREST) compared CEA to CAS and was published in 2010. While there was no difference between these two groups when using a composite end point of MI, stroke, and death, patients who underwent CEA were more likely to develop an MI (2.3% vs. 1.1%, $p = 0.03$) but less likely to develop a stroke (2.3% vs. 4.1%, $p = 0.01$ for minor stroke; equivalent rates for major stroke). MI in the CREST study was defined using biochemical markers and a subsequent quality of life survey revealed

no significant differences between CEA and CAS for MI. Despite these findings, many practitioners will favor CAS over CEA in a patient with major cardiac risk factors. As a result, major cardiac risk factors are a relative indication for CAS in patients with symptomatic carotid artery disease.

While there are some relative indications for CAS, there are also strong indications for CEA over CAS. As discussed earlier, asymptomatic patients with clinically significant stenosis should undergo CEA. Based off a post hoc analysis of the Stent-Protected Angioplasty vs. Carotid Endarterectomy (SPACE) trial, patients over the age of 80 have been found to have a higher risk of stroke following CAS. This is likely due to the increase in atherosclerotic disease burden within the aortic arch, leading to an increase in atheroembolic complications secondary to wire and catheter manipulation. Patients with severe or unstable plaques are also poor candidates for CAS due to the risk of causing embolism. Finally, patients with severe renal disease are not candidates for CAS as the IV contrast dye may precipitate renal failure. Some of the indications and contraindications discussed in this section continue to evolve in response to advances in best medical therapy and findings from ongoing clinical trials.

PREOPERATIVE PLANNING

History and Physical Examination

The management of patients with carotid artery disease begins with the completion of a relevant history and physical examination. Any symptoms should be documented with an emphasis on their onset, specific deficit(s), associated symptoms, duration, and probable causes. A distinction between right and left hemisphere symptoms should be made. Specific motor, sensory, speech, visual, and behavioral changes should be noted. Posterior circulation symptoms should also be noted. Recent symptoms should be noted, particularly the most recent time they occurred. Symptomatic patients benefit the most from surgery completed within 2 weeks.

Past medical history should be evaluated for all pertinent risk factors, including hypertension, diabetes, hyperlipidemia, smoking, and alcohol use. The cardiac history should be documented, including the presence of atrial fibrillation, other arrhythmias, prior MI, and congestive heart failure. The renal status should be evaluated with a particular note made for severe

renal disease. Past surgical history is relevant especially for any prior neck surgeries and radiation exposure to the neck. If CAS is being considered, any groin procedures should also be noted. Risk factor management is indicated in all patients and can help reduce the risk of recurrent disease or forestall contralateral disease.

Medication history is especially relevant for anticoagulants, antiplatelet agents, and antiarrhythmics. All current medications and allergies should be documented. Anticoagulation should be held prior to surgery, but most vascular surgeons will proceed with antiplatelet drugs. In fact, aspirin and clopidogrel are indicated for patients who require CAS.

Physical examination should include an examination of all key systems, a complete neurologic assessment, head and neck evaluation, and cardiovascular evaluation. Vital signs should be assessed with blood pressures taken in both arms. If CAS is being considered, a thorough pulse examination should be documented.

Basic laboratory studies should be completed in patients undergoing carotid surgery. Studies include a complete blood count, basic metabolic profile, lipid profile, HgbA1c for diabetics, and a type and screen.

Imaging

Duplex Ultrasound

The severity of carotid artery stenosis is determined by imaging studies. Options include duplex ultrasound (US, Fig. 195.1), computed tomographic angiogram (CTA), magnetic resonance angiography (MRA), and digital subtraction angiography (DSA). While DSA has the highest sensitivity and specificity of all of these tests, it is an invasive test that is associated with a 0.6% periprocedural stroke rate. As a result, its use as a diagnostic test has been supplanted by the other noninvasive tests. Of the three remaining tests, CTA and MRA have the highest overall sensitivity and specificity for carotid artery disease. However, these tests are expensive, time-intensive, and require the use of intravenous (IV) contrast dye (for CTA and gadolinium-enhanced MRA). US rivals CTA and MRA in sensitivity and specificity, especially for patients with ≥70% stenosis (Fig. 195.1D), <50% stenosis, or ICA occlusion. US also provides valuable information about flow dynamics and can help to identify subclavian and innominate artery disease. Due to its low expense and high availability, US is also an ideal screening test, especially in patients with carotid bruit, major cardiac disease, and prior TIA/stroke. Unlike CTA and

MRA, US results may vary by sonographer. Vascular labs with low intersonographer variability and high accuracy (such as those certified by the Intersocietal Accreditation Commission) can generate results that are sufficient for surgical planning.

CTA and MRA

Diagnostic imaging with CTA or MRA provides more robust information about the vascular anatomy. Variations in the aortic arch, calcification of the great vessels, unstable plaques, coils and kinks of the ICA, intracranial disease, circle of Willis variations, and anatomic malformations are more readily identified on CTA and MRA. Unclear or suspicious findings on US should prompt additional imaging. Patients with atypical symptoms, posterior circulation deficits, or other clinical suspicion for issues such as proximal lesions of the innominate or subclavian steal syndrome may also benefit from CTA/MRA. CTA/MRA may also be helpful for symptomatic patients with 50% to 69% stenosis on US due to the low sensitivity of US for these lesions. Complex patients with prior neck surgery may also benefit from CTA/MRA to assist with surgical planning through the creation of detailed 3D reconstructions and multiplanar views (Fig. 195.2). The major limitation associated with MRA is that this study overestimates the extent of stenosis and is susceptible to motion artifacts; both of these issues can be corrected with the use of contrast-enhanced MRA with gadolinium or by completing a CTA. Gadolinium contrast is contraindicated in patients with severe renal disease due to the risk of nephrogenic systemic fibrosis. IV contrast dye used with CTA is also contraindicated in these patients due to the risk of precipitating renal failure. There is no information on flow dynamics with CTA or MRA.

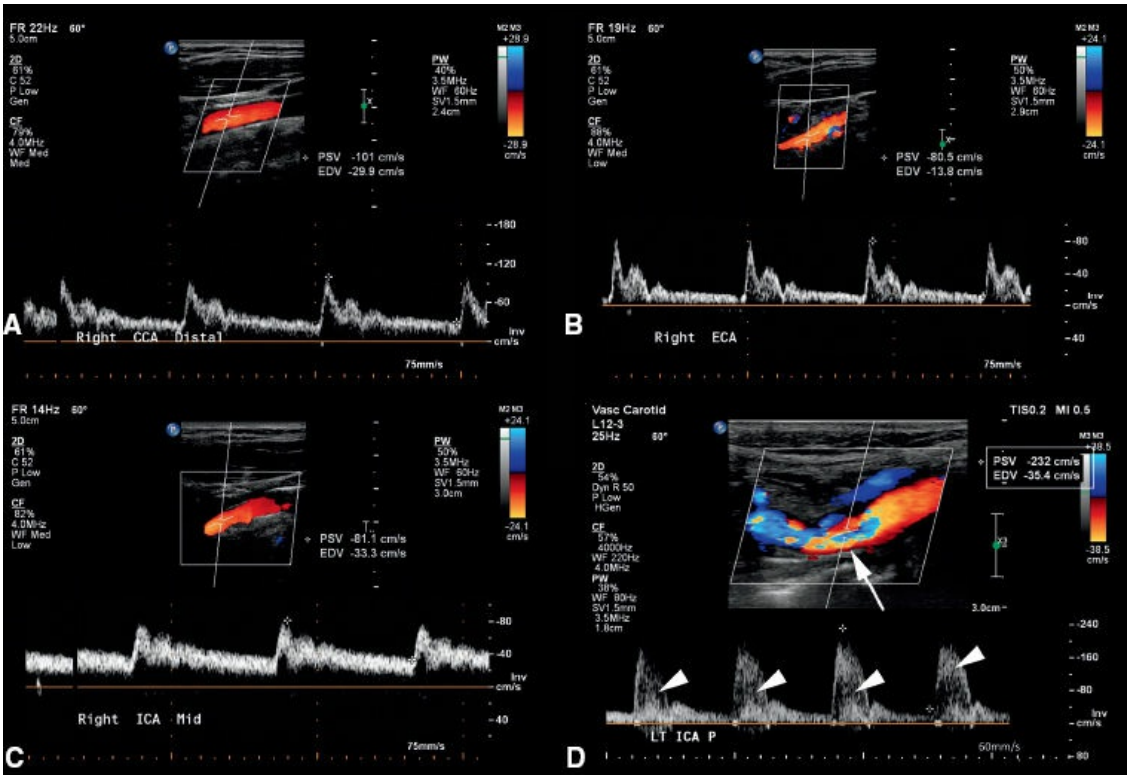

Figure 195.1. Carotid duplex ultrasound. **A.** Color flow and duplex imaging of the right common carotid artery in a healthy patient with no evidence of carotid artery stenosis. **B.** Color flow and duplex imaging of the right external carotid artery in the same patient showing no evidence of stenosis. The waveform here indicates high resistance flow, as noted by the sharp peaks. **C.** Ultrasound of the right internal carotid artery in the same patient showing no evidence of stenosis. There is more spectral broadening and a duller peak noted, which indicates low resistance flow to the brain. Despite this increase in "noise," the color flow remains orange-red and there remains a window underneath the waveform. **D.** A patient with 50% to 79% left internal carotid artery stenosis showing spectral broadening and low of the window (*arrowheads*). Note the mixed color flow (*arrow*), showing turbulent flow within this vessel.

PET scans have a limited diagnostic role for patients with carotid artery disease due to their expense and inaccessibility. The use of specific biomarkers attached to PET-sensitive tracers may help to identify unstable plaques in the future, but this remains investigational for now.

Medical Management

Appropriate preoperative medical management reduces the risk of postoperative complications following this intermediate risk operation.

Cardiac evaluation involves in competing a 12-lead ECG with stress testing indicated only for significant ECG abnormalities or major cardiac risk factors such as recent MI, CHF, or angina. Interventional cardiac procedures may be indicated prior to carotid surgery for patients with three vessel disease, severe left anterior descending (LAD) artery disease, and unstable angina. Clinically significant CAD severe enough to warrant treatment is found in up to 20% of patients who are candidates for CEA.

Patients who are acceptable risk following cardiac evaluation should be on an antiplatelet agent (such as aspirin or clopidogrel) and statin. Aspirin has been associated with a 25% decrease in stroke risk, while statins are associated with a significantly lower 30-day risk of stroke after CEA. Beta blockers should be continued if the patient is already on them, but initiating perioperative beta blockade in the absence of specific indications is associated with a higher risk of cardiac complications.

Laryngoscopy

Patients who have previously had CEA on the contralateral side should be evaluated by an otolaryngologist to ensure that there is no vocal cord paralysis from disruption of the recurrent laryngeal nerve. Cord medialization may be necessary prior to operating on the ipsilateral side to prevent an inability to protect the airway if there is inadvertent injury to the ipsilateral recurrent laryngeal nerve.

Special Considerations for CAS

Patients undergoing CAS should receive a 325 mg aspirin and a loading dose of 300 mg of clopidogrel at least 6 hours prior to the procedure. An alternative regimen is 325 mg of aspirin and 75 mg of clopidogrel daily for at least 4 days prior to CAS. Dual antiplatelet therapy minimizes the risk of intrastent thrombosis. Both the Management of Athero Thrombosis with Clopidogrel in High-risk patients with recent TIA or ischemic stroke (MATCH) trial and Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management and Avoidance (CHARISMA) trial found a reduction in stroke, MI, and mortality risk in high-risk patients, but with a concomitant rise in bleeding complications. Dual antiplatelet therapy should continue for at least 30 days after CAS.

SURGICAL TECHNIQUE

Carotid Endarterectomy

Informed Consent

The informed consent for patients undergoing CEA should include a discussion of all of the risks, benefits, and alternatives to surgery. A discussion of the surgery, length of hospitalization, time for recovery, and potential complications should also be done with the patient and family. CEA does not "cure" stroke, nor does it prevent cardiac emboli or contralateral atheroemboli. Setting proper expectations with patients will help with management should there be unexpected events postoperatively.

The specific risks of CEA include a risk of perioperative stroke or death (<3% if asymptomatic, based on ACAS; <6% if symptomatic, based on NASCET), CN injury (~1% permanent, 5% to 20% temporary, most commonly the hypoglossal), cardiac complications (1%), infection (<1%), and bleeding requiring reoperation (~1%). Improvement in cognitive deficits and reversal of deficits from stroke are possible but the extent to which CEA leads to these improvements is controversial.

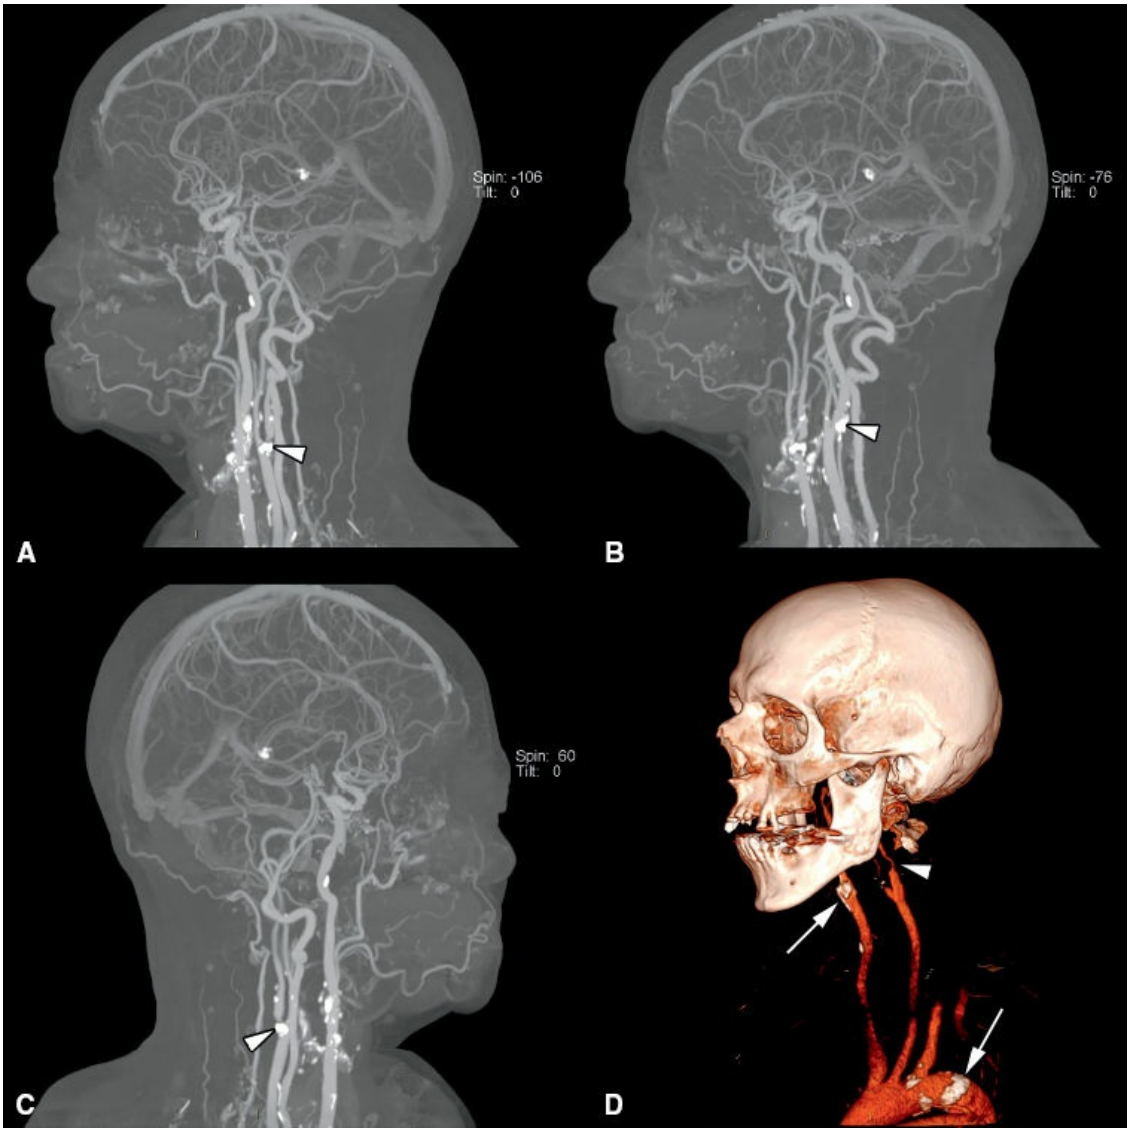

Figure 195.2. CT angiogram with reconstruction. **A**–**C.** CT of the head and neck with IV contrast showing the relationship of the carotid arteries. Calcium is prominently shown near the bifurcation of the carotid artery (*arrowheads*). **D.** 3D vessel reconstruction with subtraction of the bones showing an area of approximately 90% stenosis of the left internal carotid artery (*arrowhead*). Calcium is also noted throughout the aortic arch and the right common carotid artery (*arrows*).

Anesthesia

A variety of choices are available for anesthesia when completing a CEA, including local anesthesia, monitored anesthesia care with a regional block, and general anesthesia. There is no advantage of one approach over another with regard to stroke, death, MI, and length of stay. The primary benefit of using local anesthesia for completing a CEA is to serve as an

indication to shunt. Neurologic monitoring while completing an awake CEA is the gold standard indicator of cerebral ischemia and can prompt shunting with a higher degree of sensitivity and specificity than other modalities that are used during general anesthesia. This theoretical advantage has not been borne out by clinical studies. Nasotracheal intubation should be completed if subluxation of the mandible will be necessary for more cephalic exposure of the ICA.

Routine invasive blood pressure monitoring for CEA is helpful due to the blood pressure changes that can occur during surgery. Working around the carotid bifurcation can stimulate the carotid body and decrease the heart rate abruptly. There is a risk of cerebral hyperperfusion syndrome following revascularization and maintaining the blood pressure near normal after surgery is essential to preventing complications. Artificially raising the blood pressure when clamped may also help minimize cerebral ischemia.

Suitable antecubital IV access can usually be obtained. Central venous access is not necessary in most cases. Urinary catheterization is also not necessary in most cases unless the operation is expected to be more involved, such as in patients with prior neck surgery.

Patient Positioning

The patient should be positioned supine with a shoulder roll to hyperextend the neck. A ring pillow is placed for support of the head. The head should be turned away from the side of the operation and if general anesthesia is being used, the endotracheal tube should be positioned away from the side of the incision. The patient should be placed as close to the lateral and top edge of the operating table as safely possible to permit easy access by the surgeon. Safety straps should be used to secure the patient. The ipsilateral arm is secured next to the patient, while the contralateral arm can be left out to permit access by anesthesia. Drapes at the head of the bed should be left down on the surgical side to permit access by the surgeon. If the patient is awake, raising the contralateral drape can help prevent claustrophobia and allow some air movement for patient comfort.

Time Out

A comprehensive time out should be completed and identify the patient, operation, side of surgery, plan, and any safety concerns. Shunts, patches, sutures, and neurologic monitoring should all be confirmed and available at this time.

Incision and Exposure

The standard CEA incision is made on the anterior border of the sternocleidomastoid and turned posterior to the auricle (Fig. 195.3). An alternate incision can be made in the skin crease of the neck located 2 cm inferior to the angle of the jaw, and the resulting scar can be nearly invisible if closed with meticulous technique. The incision can be perfectly centered over the bifurcation and its size minimized through the use of preoperative imaging.

Following incision, the platysma muscle is divided and hemostasis of numerous skin edge bleeders secured. The external jugular vein should be identified and protected. Injury to the greater auricular nerve in the superior portion of the incision should be avoided to prevent numbness to the earlobe. The dissection continues until the medial border of the sternocleidomastoid muscle is identified.

The medial border of the sternocleidomastoid muscle is mobilized and the carotid sheath entered. Early identification of the internal jugular vein and CCA helps to identify the proper surgical plane. The CCA should be dissected free of surrounding tissue and a proximal clamp site identified. Care should be taken to avoid damage to the vagus nerve, which usually runs immediately posteriorly between the internal jugular vein and CCA. Rarely, the vagus nerve can run more superficially and may be susceptible to injury. The *ansa hypoglossi* is a fine branch of the hypoglossal nerve and usually runs on the anterior surface of the CCA. Mobilization of this plexus can usually be achieved but transection may be necessary of this mostly sensory nerve in order to obtain adequate access to the bifurcation. A vessel loop should be looped twice around the CCA (Pott’s tie).

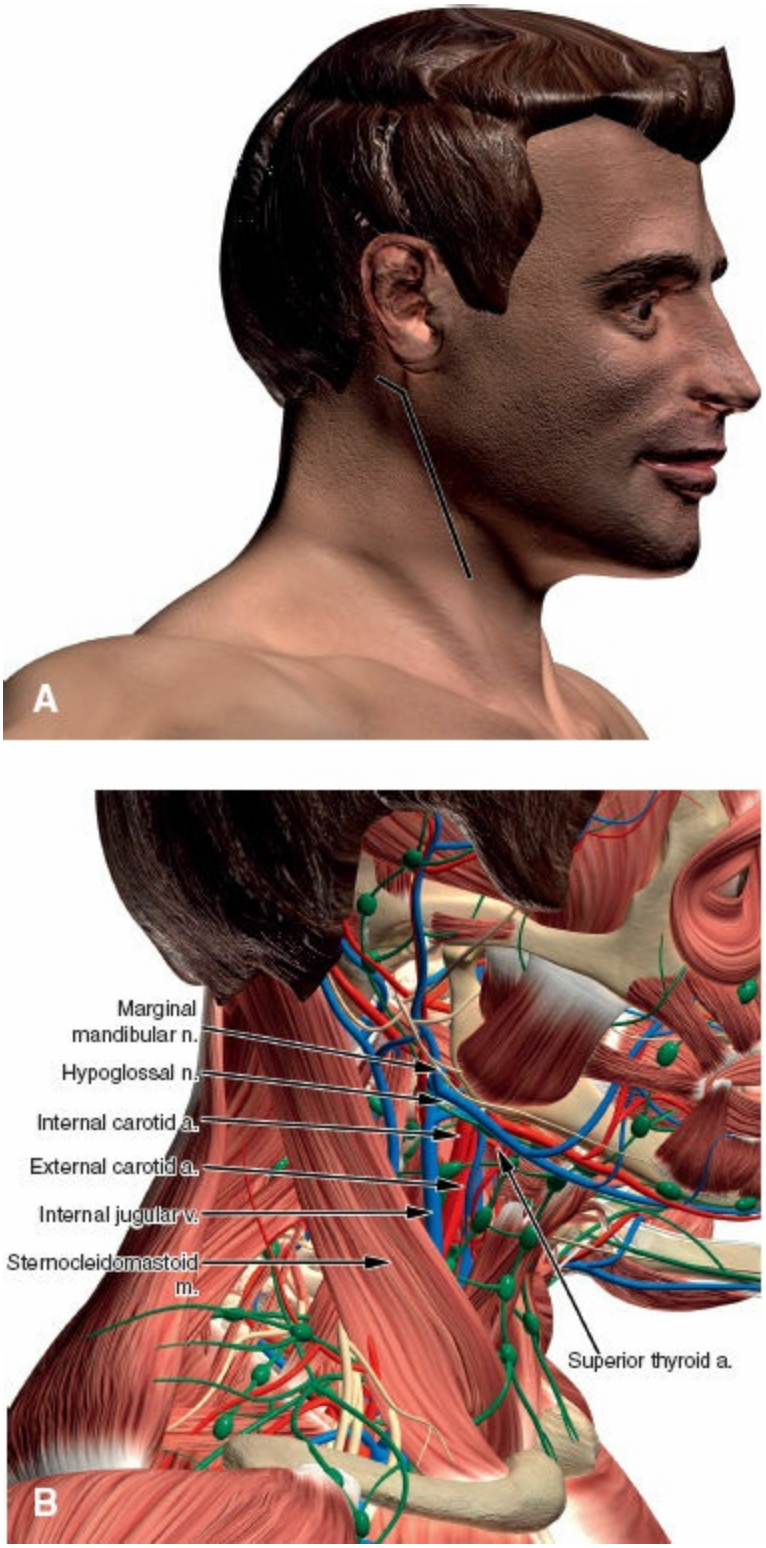

Figure 195.3. Carotid endarterectomy. **A.** Incision for carotid endarterectomy. **B.** Exposure of the carotid arteries.

The dissection proceeds from inferior to superior. The facial vein branch of the internal jugular vein will be encountered and may be safely ligated. At this point, the jugular vein and sternocleidomastoid can be

safely retracted posteriorly to bring the carotid bifurcation into view. Dissection beyond the bifurcation should be done only under direct visualization and by staying as close to the ICA as possible. From inferior to superior, the first major CN that will be encountered is the hypoglossal nerve. This nerve is usually anchored by a small sling and travels with a small arterial branch. Mobilization of the hypoglossal nerve should be done without directly touching any portion of it and by avoiding any tension. Dissecting along the posterior border minimizes the risk of injury to this nerve. Mobilization is not always required and should be done only if access to a more cephalad portion of the ICA is necessary (Fig. 195.3).

In rare circumstances, further cephalad exposure is necessary. The next CN to be encountered is the glossopharyngeal nerve and travels directly inferior to the styloglossus muscle and parallel to the vagus nerve for the first 2 to 3 cm. More posterior exposures may expose the spinal accessory nerve but this is more commonly done for ECA to vertebral artery bypasses. Medially, dissection around the ECA should be done with care to avoid trauma to branches of the superior laryngeal nerve, particularly as they pass perpendicular to the ECA. The recurrent laryngeal nerve passes medial to the CCA and injury to this nerve is uncommon when the dissection is done directly on top of the artery.

Dissection around the carotid body can stimulate the baroreceptors in this area and lead to profound bradycardia. Injection of 1% lidocaine can help minimize this effect. IV atropine may be necessary if there is hemodynamic instability.

The ECA should be isolated next. This is commonly done just distal to the first branch, the superior thyroid artery. A small temporary clip or 4-0 silk tie twice looped around the superior thyroid artery is sufficient for vascular control. A vessel loop is twice looped around the ECA. Dissection of this artery should be done as close to the vessel as possible, especially on the posterior portion, to avoid injury to the superior laryngeal nerve branches.

Attention is then diverted to the ICA. This vessel is dissected free at least 1 to 2 cm distal to the plaque to a region that is soft and amenable to clamping. Sometimes, more extensive cephalad exposure is necessary to reach a safe region. To facilitate exposure, the neck incision can be extended posteriorly below the auricle. Care should be taken not to enter the parotid gland due to the risk of fistula formation and inadvertent injury to the facial nerve. Further cephalad exposure can be obtained through

division of the posterior belly of the digastric muscle. Great care should be taken in dividing this muscle as it is immediately deep to the hypoglossal nerve, and the glossopharyngeal nerve is immediately deep to the muscle. The spinal accessory nerve is just posterior to this muscle near the upper portion of it. Division of this muscle can usually help the surgeon obtain another centimeter of exposure of the ICA.

Further exposure can be obtained through resection of the styloid process along with the styloglossus, stylohyoid, and stylopharyngeus muscles. The occipital artery is usually sacrificed due to its proximity to the muscles and styloid process. Note that the styloid process is a landmark used to identify the facial nerve, and great care must be exercised to avoid trauma to this CN. An additional centimeter of exposure can be obtained through this maneuver.

If knowledge of a high bifurcation is available prior to surgery, nasotracheal intubation can be completed to facilitate anterior subluxation of the mandible. This procedure can be done when there is ICA disease within 2 cm of the skull base. Subluxation, also known as a partial, self-reducing dislocation, is done by placing a wire from the ipsilateral mandibular bicuspid to the contralateral maxillary bicuspid. An alternative technique is to place a wire around the ipsilateral mandible through the anterior nasal spine. Subluxation can provide an additional 1 to 2 cm of exposure and may be critical to exposing the ICA near the skull base. If further exposure is necessary, a small portion of the mandibular ramus may be resected. Reconstruction with a small plate can be completed prior to closure.

Once adequate ICA exposure is obtained, a small vessel loop is twice looped around the artery at least 1 to 2 cm distal to the plaque. During dissection of the carotid arteries, a no-touch technique should be utilized and movement of the vessels should be kept to a minimum to avoid disrupting the plaque. Careful dissection, minimal vessel trauma, and adherence to safe operating principles will help prevent neurovascular injury and iatrogenic stroke.

Shunting

The question of shunting should be answered before proceeding to endarterectomy. There are three strategies for shunting: always placing a shunt, selectively placing a shunt, and never using a shunt. Proponents for always shunting highlight that shunting is relatively safe, provides continuous flow to the brain, and minimizes the risk of propagating

ischemic damage, particularly in symptomatic patients with recent stroke. Routine shunting in all patients is associated with a nonzero rate of iatrogenic thromboembolism and vessel damage, but many cases may be due to poor technique. Proponents for never shunting commonly do eversion endarterectomy, where shunting is more difficult and may disrupt the end point of the endarterectomy. This is associated with a nonzero risk of ischemic stroke and propagation of injury to the penumbra in symptomatic patients.

Selective shunting requires decision making based off intraoperative cerebral monitoring. Using this strategy, shunting is indicated whenever there is significant risk of cerebral ischemia. For the awake patient, this is simply a change in the neurologic status. For patients under general anesthesia, the gold standard is electroencephalographic (EEG) and somatosensory evoked potential (SSEP) monitoring. Although associated with numerous false positives, EEG and SSEPs are the most sensitive marker for cerebral ischemia.

Transcranial Doppler ultrasonography is another mechanism to detect cerebral ischemia and has the added benefit of identifying microemboli during surgery. Its true sensitivity and specificity are controversial and there may be numerous false negatives with this method.

Stump pressures are a relatively crude method to gauge cerebral pressures. A stump pressure of less than 40 mm Hg is thought to be associated with poor collateral cerebral circulation and an indication to shunt. However, pressures greater than 50 mm Hg are not associated with satisfactory perfusion throughout all portions of the brain when compared with EEG findings. These false negatives may lead to propagation of injury or iatrogenic stroke due to cerebral ischemia. An alternative is to monitor cerebral oximetry levels, but results appear to be similar to monitoring stump pressures.

In response to some of these limitations, proponents of selective shunting may opt to shunt patients with prior stroke and contralateral carotid occlusion in addition to anyone who meets criteria based off the aforementioned cerebral monitoring tools. Many surgeons may also artificially increase the blood pressure above 120/80 mm Hg during clamping to ensure sufficient collateral circulation. The best overall shunt strategy remains controversial.

Prior to clamping, 100 U/kg of IV heparin should be given as a bolus and allowed to circulate for 3 minutes. A satisfactory level of

anticoagulation may be confirmed using activated clotting times (ACT) over 250 seconds. Using ACT to monitor the level of anticoagulation can also help estimate the dose of protamine to reverse the anticoagulation at the end of the case, if this strategy is used. The vessel loops themselves can be used to clamp, two angled Debakey (CCA and ECA) and one profunda clamp (ICA) can be placed, or a combination of the two approaches used. Repeated clamping and unclamping should be avoided. Clamping should be done under direct visualization to avoid trauma to CNs, especially to the vagus nerve under the CCA, the superior laryngeal nerve under the ECA, and the hypoglossal and glossopharyngeal nerves near the ICA. Clamps are placed in sequence starting with the ICA, CCA, and ECA. This particular sequence prevents debris from washing into the intracranial circulation.

Standard Endarterectomy

The endarterectomy can be done in one of two ways. Standard endarterectomy involves making a longitudinal incision starting on the CCA and extending onto the ICA. The incision is made on the anterior surface but lateral to the flow divider at the bifurcation. If shunting, the ICA end is placed first, allowed to backbleed, then inserted into the CCA. The incision should extend beyond the endarterectomy site on the ICA in order to allow clear visualization of end points and permit tacking of any loose intima/media.

The endarterectomy is started at the CCA where a Freer elevator and fine mosquito clamp is used to create as thin an endarterectomy plan as safely possible. The plaque is neatly trimmed at the CCA to permit a clean plane free of debris. The plaque is then circumferentially dissected along the CCA and into the ECA. A complete endarterectomy of the ECA is completed to prevent any backwash of debris into the ICA. Back bleeding of the ECA is done after the endarterectomy to ensure that any loose debris is washed out. Attention is then turned to the endarterectomy of the ICA. Care is taken to create a smooth, tapered plane into the ICA to prevent a dissection flap and subsequent thrombosis of the artery. If a perfect endpoint cannot be created, sharply dissecting the plaque and placing 7-0 Prolene sutures to tack the intima/media to the artery should be placed. Tacking sutures should be used sparingly due to their association with perioperative stroke.

Completing a standard endarterectomy with primary closure is associated with a higher rate of perioperative stroke compared to

endarterectomy with patch angioplasty (4% vs. 0%) due to vessel thrombosis, and an increase in recurrent stenosis at 5 years (14% vs. 1%). Options for patching include autologous vein derived from the external jugular or great saphenous vein, bovine pericardium, Dacron, and polytetrafluoroethylene (PTFE). Of these choices, only autologous vein patches are resistant to infection. Patch rupture can occur with autologous vein. To prevent this complication, great saphenous vein with a diameter larger than 3.5 mm should be used, which is more likely to be found in the thigh instead of the ankle. The patch is sewn using 6-0 Prolene suture with care taken to tack down the end points under direct visualization to prevent artificial narrowing and dissection flaps.

If a shunt was used, it is removed once the patch is mostly sewn in. The clamps are released in the reverse order in which they were placed. The ECA clamp is removed first and the endarterectomy site flushed to ensure that any remaining debris is removed. This process is repeated for the CCA and ICA. The remaining patch is sewn in and the ECA clamp released. Hemostasis is confirmed, and the CCA, then ICA clamps released.

Eversion Endarterectomy

Eversion endarterectomy is an alternative to standard endarterectomy. This approach involves sharply transecting the ICA from the bifurcation, carefully everting the artery around the plaque, and gently pulling the plaque out. Any remaining plaque within the ECA and CCA is removed using the Freer elevator. The ICA is then sewn back onto the bifurcation using 6-0 Prolene suture. No patch is necessary. Shunting is possible with this technique, but can be difficult to do, and some proponents of eversion endarterectomy advocate no shunting due to the rapidity in which this procedure can be performed. This technique is particularly well suited for ICA coils and kinks. The vessel can be truncated to reduce redundancy and sewn back to the bifurcation.

Eversion endarterectomy was compared with the standard technique as part of the EVEREST study. No significant differences in outcomes were found between the two approaches with regard to restenosis, stroke, or death. However, eversion endarterectomy was associated with a lower long-term rate of restenosis.

Completion Imaging

Completion imaging remains controversial, with some centers advocating

mandatory completion imaging and others recommending a simple neurologic assessment at the end of the case. Options include continuous wave Doppler, duplex US, and intraoperative angiography. Continuous wave Doppler has the advantage of being simple to use, but does not allow visualization of the lumen. As such, it cannot identify dissection flaps, areas of stenosis, or other technical errors. Duplex US allows B-mode imaging of the lumen and color flow evaluation. The latter permits measurement of velocities and gives immediate anatomic and physiologic data regarding the patch angioplasty. Dissection flaps, areas of stenosis, and other technical defects can be identified. Finally, completion angiography with a needle in the CCA provides excellent information on the quality of the closure. Completion imaging is associated with a lower long-term rate of restenosis, but has no discernable impact on 30-day stroke or death rates. As a result, completion imaging is most strongly indicated when there is doubt about the end point.

Closure

The anticoagulation can be reversed at this point using protamine. Protamine reversal is associated with a small rate of stroke, but failure to reverse is associated with a risk of postoperative hemorrhage. Protamine itself should be given slowly as a bolus dose is associated with profound systemic hypotension.

In order to maximize closure of dead space, we advocate reapproximating the sternocleidomastoid muscle to the soft tissue. This also provides some muscle coverage over the patch. A drain can be left over this layer if there is concern for postoperative hemorrhage. The purpose of this drain is to serve as an early warning indicator for bleeding and allow some drainage of blood while the patient is being taken back to the operating room for a washout and repeat closure. This approach may help to minimize airway compromise from hematoma, but there are no definitive studies that have evaluated this.

The platysma is reapproximated using 3-0 Vicryl suture, followed by deep dermal sutures using 3-0 Vicryl suture. The skin is closed using 4-0 Monocryl suture. Dermabond is placed over the incision. The surgeon stays with the patient during extubation, if general anesthesia was used during the case. Light pressure over the surgery site can be held to minimize pressures at the patch site if the patient coughs. Deep extubation is advocated if experienced anesthesia staff are available to minimize coughing. A full neurologic assessment is done.

Carotid Artery Stenting

Informed Consent

Similar to CEA, patients undergoing CAS should have a discussion of all of the risks, benefits, and alternatives to the procedure. Expectations for management and a discussion of common complications should be had with the patient and family. The specific risk of CAS varies by clinician and there is some evidence that clinicians who do not do CAS very often may have a higher rate of stroke compared to those who work at high-volume centers. The risk of stroke, death, or MI is approximately 5% at 30-day based off the results of the CREST study. The risk of CN injury is minimal, and the risk of groin hematoma is 1% to 3%.

Anesthesia

Local anesthesia using 1% lidocaine is sufficient for the puncture site. Mild conscious sedation is recommended for patient comfort and can be achieved with 25 to 50 μg IV fentanyl and 1 to 2 mg of midazolam. The patient should be awake enough to respond to commands and demonstrate intact motor function (such as squeezing a rubber ducky). Invasive arterial monitoring is recommended and dedicated personnel should be available to care for the patient while the procedure is ongoing.

Patient Positioning

The patient is positioned in a supine manner and a small pillow used for comfort. The arms are strapped to the sides and the patient secured in position. Both groins should be prepped for access, if proceeding with the femoral approach. Some patients with a diseased aortic arch who are not candidates for CEA may require a cervical approach. Occasionally a brachial approach may be used in selected patients.

Time Out

The time out process should confirm that all wires, catheters, sheaths, stents, balloons, embolic protection devices, and other essential equipment are ready and available.

Access

CAS involves precise placement of a stent across a stenotic lesion in an artery that goes directly to the brain, and success is contingent upon having fine control over all aspects of this technique. Access via the femoral or brachial sites requires that the wires, catheters, and stent travel some

distance in order to reach the ICA. Two methods help ensure stability and control during this process. One is to use a long 90-cm sheath placed directly into the distal CCA 3 cm below the bifurcation. A 6F sheath is necessary to permit the use of 5F catheters. An alternative method is to place a short sheath for percutaneous access, but to then do all exchanges and the stent placement using a long 6F guiding catheter. Orienting the sheath or catheter properly within the CCA requires navigating the aortic arch, making one or more turns, and reaching the vessel without causing any embolization. This process can be aided through the use of special, precurved catheters such as a Simmons 1, Headhunter, or Vitek catheter. More complex anatomy such as a type II or III arch in which the innominate and/or left CCA come off the aorta below the apex typically requires a sharper curvature to the catheter. The patient should be heparinized to an ACT of at least 250 seconds.

DSA with multiple views of the carotid and intracranial circulation should be completed to confirm the lesion and ensure that safe access is possible. Confirmation of the ICA should be made at this point and splaying open the bifurcation through left or right anterior oblique imaging is helpful. 3D imaging using rotational angiography can also be useful in complex patients (Fig. 195.4A).

Embolic Protection

Once the patient is confirmed to be a suitable candidate for CAS, an embolic protection device is deployed. Embolic protection devices were found to significantly decrease the risk of iatrogenic stroke due to embolism that can occur during wire manipulation and stent deployment during the EVA-3S trial (7.9% vs. 25% at 30 days). There are several options available, including flow reversal devices, distal occlusion balloons, and distal filters. Flow reversal devices use an occlusion balloon within the CCA and another within the ECA with aspiration of the CCA/ICA done on a regular basis to capture any back-flowing debris. A variation in this device uses a temporary arteriovenous fistula to ensure continuous backward flow. Flow reversal devices have the advantage of not having to cross the lesion, but may not be tolerated by patients who depend on forward flow of their ICA. Distal occlusion balloons function by occluding the distal ICA and require aspiration prior to removal. They are not well-tolerated by patients and the balloon can cause a secondary spasm of the distal ICA. This embolic protection device is thus rarely used today. The most commonly used device is the distal filter. This device is a

small wire basket that crosses the lesion using a 0.014-inch guide wire and opens to capture any particles larger than 100 μm. Its major disadvantage is having to cross the lesion, which increases the risk of embolism.

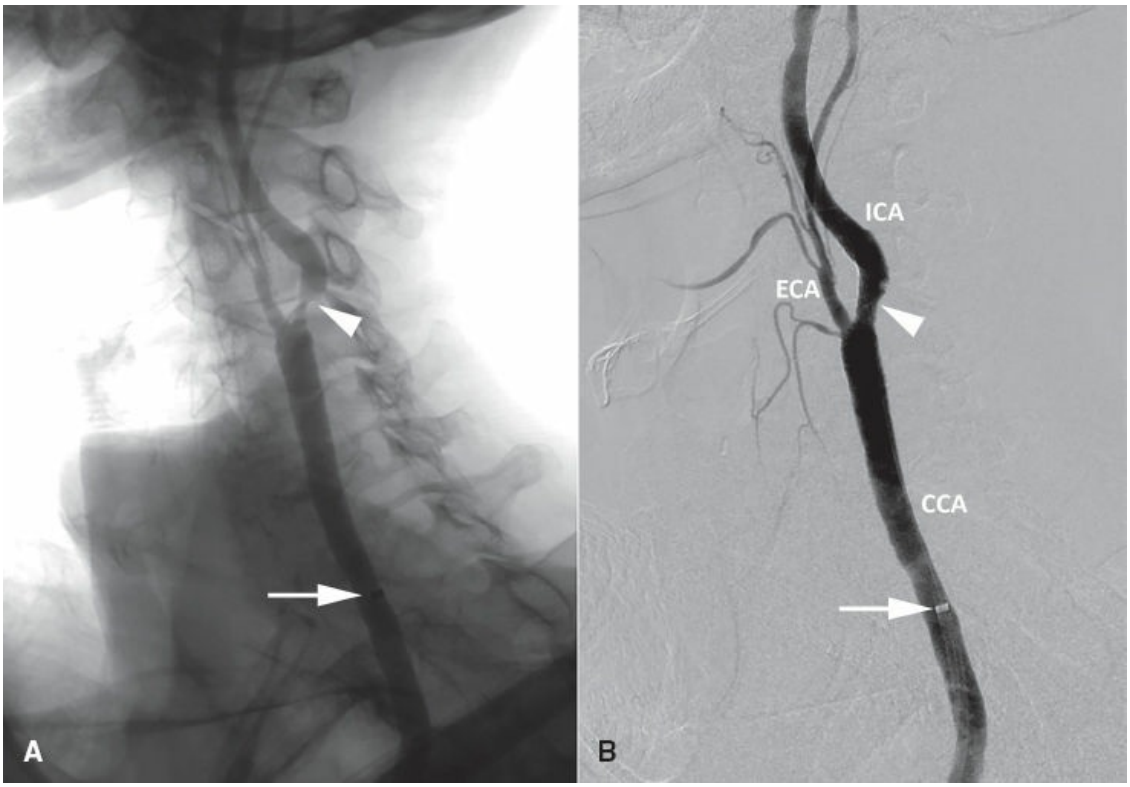

Figure 195.4. Carotid angiogram with stent. **A.** A carotid angiogram of the left common carotid artery is shown. The catheter (*arrow*) is shown within the common carotid artery, and the area of stenosis is indicated (*arrowhead*). **B.** Deployment of a stent across the internal carotid artery and into the common carotid artery resolved the stenosis.

Angioplasty and Stent

Once successful placement of the embolic protection device has been achieved, attention is turned to successfully crossing the lesion with a stent and deploying it. Some severe lesions will not tolerate crossing by the stent and require predilation with a 4.0 mm balloon at low pressure. A self-expanding stent sized to the distal CCA (usually 7 to 10 mm) is then placed across the bifurcation. Most lesions can successfully be treated with a 3 to 4 cm long stent. Balloon angioplasty of the stent is sometimes completed to ensure satisfactory apposition. The balloon is sized to the diameter of the ICA. Following successful stent placement, a completion angiogram is performed and the embolic protection device removed (Fig.

195.4B).

POSTOPERATIVE CARE

Patients without any intraoperative issues following CEA or CAS should be recovered in a postanesthesia care unit. Absent any hemodynamic instability or severe hypertension, invasive arterial monitoring can be removed. Patients should be admitted overnight to an intermediate care unit with telemetry. A routine postoperative check should ensure that the incision site is clean, dry, and intact, that there is no evidence of a hematoma or tracheal deviation, and that the postoperative neurologic assessment continues to be normal or at baseline. The blood pressure and heart rate should be normal. If a drain is present, it should be evaluated to ensure no active collection of bright red blood is present. The patient should be comfortable, relatively pain free, mentating normally, and without any complaints of significant headache, the latter of which could be a precursor to cerebral hyperperfusion syndrome.

The patient may be discharged the following day if there were no significant events overnight. The drain is typically removed the morning of discharge if there is minimal collection. The patient should follow up in clinic and have a duplex US of the carotid done at that visit. The standard of care is to presently obtain a follow-up US at 6 months, then annually thereafter.

If elevated velocities were initially detected on the contralateral side, a repeat duplex becomes critical for proper decision making. Following carotid revascularization, the contralateral velocities often decrease and may place the patient at a degree of stenosis that no longer requires intervention. If a contralateral intervention is indicated, laryngoscopy should be done prior to surgery to ensure normal functioning of the vocal cords and confirm no trauma to the recurrent laryngeal nerves.

COMPLICATIONS

Perioperative Stroke

Perioperative stroke may be due to arterial thrombosis, thromboembolism, ischemia during clamping, dissection due to vessel trauma or an intimal flap, and embolism of debris due to clamp injury. A patient who wakes up with a deficit, or develops one in the recovery room, should be immediately evaluated. Duplex ultrasonography should be used to image

the artery. If no flow is detected, or there is a technical defect such as an intimal flap or stenosis, immediate re-exploration is necessary. Correction of the technical defect is mandatory to prevent recurrence of the problem. If there is thrombosis of the ICA, a distal clamp is not placed. Instead, a Fogarty balloon can be gently inserted and used to complete a mechanical thrombectomy. Care must be taken not to blow the balloon up too large or insert it too far into the ICA, as this can lead to a carotid-cavernous fistula. In rare circumstances, bypass of the ICA to a healthier portion of the vessel may be necessary if the technical defect cannot be easily corrected.

If flow is detected on US, the next step is to complete an arteriogram to evaluate the intracranial circulation. If a thromboembolism is identified, mechanical thrombectomy or catheter-directed thrombolysis can be attempted with angiographic guidance. Complex intracranial maneuvers may require the assistance of a neurointerventional radiologist.

If no technical defects are identified, and angiography demonstrates no evidence of an intracranial pathology, the patient may be awakened from anesthesia and allowed to recover. If signs of stroke continue when the patient is fully awake, a CTA should be completed.

Cranial Nerve Injury

The rate of CN injury varies between 5% and 20%, depending on how the evaluation is completed. The risk of permanent nerve injury is about 1%. The most commonly injured nerve is the hypoglossal, which presents as deviation of the tongue ipsilateral to the side of injury. Injury to the recurrent laryngeal nerve is next, and can lead to ipsilateral vocal cord paralysis. Unilateral injury is often asymptomatic, but bilateral injury can lead to inability to protect the airway. Injury to the superior laryngeal nerve leads to inability to produce high-pitched sounds and can also lead to weakness of the voice. The marginal mandibular nerve, a branch of the facial nerve, can be injured from exuberant retraction during surgery and leads to a drooping lip and paresthesia over the side of the mouth. Injury to the glossopharyngeal nerve is uncommon and presents with dysphasia and aspiration. Injury to the spinal accessory nerve is rare and presents with a drooping shoulder (Table 195.4). Injury to cutaneous nerves can lead to paresthesia along the ear and side of the neck. Most temporary nerve injuries typically resolve within 6 to 12 months.

TABLE 195.4 Cranial Nerve Injuries (Listed From Highest to Lowest

Risk) and Symptoms

Nerve	Symptoms of Injury
Hypoglossal nerve (CN XII)	Ipsilateral tongue deviation
Vagus nerve (CN X)	Variable
Superior laryngeal nerve	Lack of high-pitched sounds, weak voice
Recurrent laryngeal nerve	Asymptomatic if unilateral; inability to protect airway if bilateral
Marginal mandibular nerve	Drooping of the ipsilateral lower lip
Glosospharyngeal nerve (CN IX)	Dysphasia, aspiration
Spinal accessory nerve (CN XI)	Drooping shoulder

Cerebral Hyperperfusion Syndrome

The brain has the capacity to autoregulate intracerebral flow across a wide range of blood pressures. Patients who have severe bilateral carotid artery stenosis have significant vasodilation to decrease the poststenosis resistance and try to improve the blood flow to the brain. Following endarterectomy, there is a sudden increase in the flow volume to the brain, and some patients may not be able to compensate for this increase in flow due to a diminished autoregulatory response. Combined with hypertension, this increased flow rate and pressure can lead to a severe headache. Left uncorrected, seizures, and a severe hemorrhagic stroke can occur and lead to death.

Patients who complain of a headache after carotid revascularization should be treated with strict blood pressure control with a goal of less than 140/80 mm Hg. If symptoms continue, a CTA of the head is urgently indicated to ensure that there is no hemorrhagic stroke. Aggressive blood pressure control to even lower levels may be necessary until the autoregulatory response returns to normal.

Cardiac Complications

The most common cause of death after carotid revascularization is MI. However, the overall 30-day rate of MI after CEA is about 1%. Postoperative cardiac complications can be reduced through aggressive preoperative risk factor control. Cardiac revascularization may be necessary in patients with ST elevation MI or significant cardiogenic shock.

Patients with major cardiac risk factors who also require carotid revascularization should ideally undergo staged intervention due to the

higher risk of stroke in the simultaneous procedure. Ideally, the symptomatic lesion should be treated first whenever possible. If simultaneous surgery is necessary in patients with high-grade, symptomatic carotid and coronary lesions, CAS may have an advantage if there is favorable anatomy. If CAS is not an option, CEA should be done first before the CABG. CABG followed by CEA is associated with a significantly higher stroke rate compared to either simultaneous surgery or CEA followed by CABG.

Hemodynamic Instability

Hypotension after CEA or CAS can occur due to disruption of the baroreceptor reflex and subsequent bradycardia. Severe bradycardia is best treated with atropine, but pressor support may be necessary to maintain an adequate cerebral perfusion pressure. Common causes of hypotension should be sought and conditions such as hypovolemia and cardiogenic failure should be immediately corrected. Most patients have correction of their hypotension within 24 hours. Patients with perioperative or immediate postoperative hemodynamic instability should be kept in an intensive care unit with invasive monitoring.

Recurrent Stenosis

The etiology of recurrent stenosis is dependent upon the time course in which it happens. “Recurrent” stenosis identified within 30 days can be due to technical error or a missed lesion, and is most commonly detected on routine postoperative duplex imaging. Stenosis that occurs within 2 years is commonly secondary to intimal hyperplasia. Many of these cases may regress with time. Repeat endarterectomy is challenging in these cases due to the nature of the intimal hyperplasia, and cases where intervention is indicated may best be served with CAS.

Stenosis that occurs after this time period, usually at 3 years and beyond, is often due to recurrent atherosclerotic disease. This occurs in about 4% of patients and risk factors include female gender, diabetes, hyperlipidemia, hypertension, and smokers. Clamp injury and tacking sutures also contribute to an increased risk of recurrent stenosis. Restenosis due to progression of atherosclerotic disease should be managed by either CEA or CAS, depending on the patient’s risk factors and symptoms. The use of antiplatelet agents, statins, and aggressive risk factor control may decrease the incidence of recurrent atherosclerosis-

mediated stenosis.

Repeat CEA is a safe but challenging procedure in many patients. While there is a theoretical increased risk of CN damage and other complications, studies using the vascular quality initiative database have found only a slight increase in hematoma and no increase in the risk of CN injury, stroke, MI, or death.

Infection

Infection after CEA is uncommon and occurs in fewer than 1 in 1,000 cases, even with the use of a synthetic patch. The risk of infection increases in patients who require re-exploration or develop a neck hematoma. Some difficulty with healing is also seen in patients with prior neck radiation. Patch infections can lead to pseudoaneurysm formation with a high risk of mortality in the event of a blow out. Urgent exploration and replacement with autologous vein patch are indicated in this situation.

Bleeding

Postoperative hemorrhage necessitating a return to the operating room occurs in about 1% of cases. Risk factors include dual antiplatelet therapy and heparinization without reversal with protamine. The accumulation of bright red blood in a drain is an indication for immediate re-exploration due to potential disruption of the patch. Any hematoma that causes compression upon the airway also requires urgent re-exploration and drainage to prevent loss of the airway.

OUTCOMES

ACAS, ACST, and the REACH Registry

The Asymptomatic Carotid Atherosclerosis Study (ACAS) tracked 1,662 patients with asymptomatic ≥60% ICA stenosis over a 5-year period. It found an 11% 5-year risk of stroke with best medical therapy, which was reduced to 5.1% over a 5-year period with best medical therapy and CEA (p = 0.004). The conclusion of this study was that CEA is indicated for asymptomatic patients with ≥60% stenosis. The findings of this trial were confirmed by the Asymptomatic Carotid Surgery Trial (ACST), which similarly found a reduction from 11.8% to 6.4% for ≥60% stenosis treated with best medical therapy and CEA. Both the ACAS and ACST studies found that the risk reduction was disproportionately greater for men than

women, and that the perioperative stroke risk was larger for women. Overall, CEA was associated with a perioperative stroke risk of about 2.3% to 2.8% (Table 195.5).

TABLE 195.5 Landmark Studies for Carotid Artery Disease

ACAS	CEA and best medical management is associated with fewer strokes compared to just best medical management for asymptomatic carotid artery stenosis ≥60%
ACST	CEA and best medical management is associated with fewer strokes compared to just best medical management for asymptomatic carotid artery stenosis ≥60%
REACH	CEA and best medical management (including statins) is most effective for asymptomatic carotid artery stenosis ≥70%
NASCET	Symptomatic patients ≥50% carotid artery stenosis benefit from CEA
ECST	Symptomatic patients ≥50% carotid artery stenosis benefit from CEA (when measured using the NASCET method)
SAPPHIRE	No significant difference in death, stroke, or MI between CAS with distal embolic protection and CEA for patients at high surgical risk
EVA-3S	CAS is inferior to CEA with regard to stroke or death at 4 years
EVEREST	Eversion and standard endarterectomy are similar with regard to patency
CREST	CAS is associated with more strokes than CEA, and CEA is associated with more MIs than CAS

While the ACAS and ACST studies demonstrated a significant decrease in stroke with CEA and best medical therapy, neither study included statins as part of their medical management. Statins have significantly reduced the risk and extent of stroke, thereby reducing the effectiveness of surgery for asymptomatic patients. Effective risk factor management may further increase the number needed to treat, potentially reaching a point where the risk of stroke from surgery outweighs the 5-year risk of stroke from best medical management. Despite advances in medical management, the risk of stroke with current best medical management remains at least twofold higher than best medical therapy and CEA for patients with ≥70% asymptomatic carotid artery stenosis. This was the conclusion of the Reduction of Atherothrombosis for Continued Health (REACH) Registry. In response to evolving medical management and these recent studies, most practitioners continue to recommend CEA for patients with ≥70% asymptomatic carotid artery stenosis. High-risk plaque characteristics may prompt some clinicians to operate sooner, but even in these situations most surgeons will still look for >50% stenosis.

NASCET and ECST

The NASCET was published in 1991 and demonstrated the beneficial effect of CEA in patients with symptomatic carotid artery disease. The intent of the study was to compare outcomes in patients with best medical therapy to those who underwent best medical therapy and CEA over a 5-year period. Patients with over 70% stenosis were found to have a disproportionate benefit for surgery over just a 2-year period (26% rate of events in the medical group vs. 9% in the surgery group). Patients with 50% to 69% stenosis were found to have a reduction in events from 22.2% to 15.7% with surgery over a 5-year period. NASCET also identified fewer recurrent strokes if surgery was completed within 2 weeks of the initial event. NASCET measured ICA stenosis as the ratio between the point of maximal stenosis and a normal ICA diameter distally. ECST had conclusions similar to NASCET but measured stenosis differently. ECST measured ICA stenosis as the ratio between the diameter at maximal stenosis and the carotid bulb.

CREST

The CREST compared these two procedures with regard to stroke, MI, and mortality. When using this composite end point, no differences between either technique were found. A subgroup analysis evaluating individual end points found that MI, as diagnosed by an elevation in cardiac enzymes plus chest pain or ECG changes consistent with ischemia, was more common following CEA; stroke was more common after CAS. Unlike many of the preceding trials, CREST required investigators to use a distal embolic protection device when doing CAS, and preferentially selected high-volume CAS centers. CREST confirmed results from other studies that CAS in older patients is associated with an increased risk of thromboembolism, likely related to the increased atherosclerotic disease burden in these patients.

Despite these positive results, CREST has several limitations and some criticisms. Quality of life surveys for patients revealed that those who suffered from stroke had an inferior quality of life compared to those who had an MI. Use of a composite end point masks the differences in patient impact and makes CAS appear safer than it truly may be. Further, the high volume of CAS by individual practitioners minimizes the risk associated with doing few of these procedures, and may make some of the findings difficult to interpret.

CONCLUSION

Carotid revascularization is indicated for symptomatic patients with over 50% ICA stenosis, and asymptomatic patients with over 70% ICA stenosis. CEA remains the preferred modality for treatment, unless the patient has prohibitive risk factors for surgery. CEA for asymptomatic disease is a prophylactic operation with a relatively safe risk profile, but there remains no substitute for sound clinical judgment and excellent technical skill in the conduct of these procedures.

EDITOR'S COMMENT

Carotid endarterectomy (CEA) remains under siege. Developed as a surgical treatment to prevent stroke from internal carotid artery (ICA) stenosis, and holding up in randomized trial after randomized trial (Endarterectomy for asymptomatic carotid artery stenosis. Executive Committee for the

Asymptomatic Carotid Atherosclerosis Study. *JAMA* 1995;273(18):1421–8; North American Symptomatic Carotid Endarterectomy Trial Collaborators. Beneficial effect of carotid endarterectomy in symptomatic patients with high-grade carotid stenosis. *N Engl J Med* 1991;325(7):445–53), it is now believed that we are performing too many asymptomatic CEAs. Add to this the overwhelming push by industry and carotid artery stenting enthusiasts to force the government to pay for stenting of asymptomatic high-grade internal carotid stenosis, it is little surprise that both caregivers and patients are confused about how to manage carotid artery stenosis.

The rationale for treating carotid stenosis is to remove the inciting plaque at the carotid bifurcation, thereby reducing the risk of plaque embolization to the brain and subsequent stroke. While I am not sure if this is still true given our burgeoning practice in dialysis access from our ever increasing obese and renal failure population, at one point, CEA was the most common vascular procedure performed in the United States. Management of carotid artery stenosis is something all surgeons should have contemporary knowledge about.

In this outstanding chapter by Desai, he very nicely describes both the pros and cons of CEA and CAS. While the chapter leans a little in favor of CEA, I think it realistically provides a nice balance of the two approaches in managing significant ICA stenosis. The chapter concludes with a review of many of the randomized clinical trials comparing CEA and CAS (CREST Investigators. The carotid revascularization endarterectomy versus stenting trial (CREST): stenting versus carotid endarterectomy for carotid disease. *Stroke* 2010;41(10 Suppl):S31–4). The data in my own mind is pretty clear and is based on many of the cited trials. CEA is associated with fewer strokes, while CAS is associated with few myocardial infarctions (MIs). This is especially true in elderly patients who appear not to tolerate CAS very well. I would also note that this chapter also documents that patient satisfaction data strongly suggests that patients would rather have an MI than a stroke.

I do not want to seem like a zealot favoring CEA over CAS, as I think there is a role for CAS for sure. Patients with radiated necks and recurrent or difficult to access distal ICA lesions should likely undergo CAS. There have been amazing advances in the technology leading to improved outcomes with CAS. I remember as a trainee reading about a trial in Europe that had to be stopped because of the high stroke rate in the CAS group. I am also pretty sure that embolic protection devices could be improved upon and am not completely convinced they prevent stroke (even though no one will perform a CAS without an embolic protection device!). I am a big fan of flow reversal systems which remove the aortic arch from play and can be performed in a very short period under local anesthesia (Kwolek CJ, Jaff MR, Leal JI, et al. Results of the ROADSTER multicenter trial of transcarotid stenting with dynamic flow reversal. *J Vasc Surg* 2015;62(5):1227–34). I hope this technology is advanced and believe that we may likely end up with some sort of hybrid technology to treat both asymptomatic and symptomatic ICA stenosis.

Finally, I would be remiss if I did not mention the ongoing CREST II trial (Lal BK, Meschia JF, Brott TG. CREST-2: Guiding treatments for asymptomatic carotid disease. *Endovascular Today* 2013:73–6). This randomized, controlled trial compares CEA versus best medical therapy, as well as CAS versus best medical therapy. There is little doubt that medical therapy with statins is better than it was when ACAS1 and NASCET2 were performed. However, as my friend and carotid expert Dr. Bruce Perler is quick to point out, we are doing better with our results following CEA as well. Let us not throw out the baby with the bath water, but continue to assess the pros and cons of CEA and CAS as complementary rather than competitive. Let us do what is best for the patient and clearly having more options/tools in our tool bag is likely a good thing for the patient.

196 Brachiocephalic Reconstruction: Open and Endovascular

Joseph-Vincent V. Blas and John F. Eidt

ETIOLOGY AND PATHOPHYSIOLOGY

The supra-aortic trunks (SAT) are defined as the vessels arising from the aortic arch and terminating at the carotid bifurcation or the vertebral artery origin. Common anatomic variants include the so-called “bovine arch” (left common carotid originating from the innominate artery) (15% to 25%), a left vertebral artery originating from the aortic arch (2% to 6%), or an aberrant right subclavian artery originating distal to the left subclavian artery (～1%) that passes posterior to the esophagus.

Atherosclerosis is, by far, the most common cause of occlusive disease affecting the aortic arch branches. Distribution of atherosclerosis-related occlusive disease is determined by local hemodynamics, including shear stress, turbulent blood flow, and flow separation dynamics. Other, less common causes of arch vessel occlusive disease include Takayasu’s arteritis and radiation injury. Atherosclerotic occlusive disease in the SAT can produce symptoms due to thromboembolism or low-flow states, either alone or in combination. In comparison to occlusive disease, aneurysmal disease is much less frequent.

The number of open surgical procedures for SAT pathology has declined dramatically in the past 15 years due to the rarity of the underlying pathology and the appeal of endovascular alternatives. This trend has resulted in reduced operative experience for surgical trainees. Nevertheless, open surgical reconstruction remains an effective and durable option for selected patients. This chapter will review both endovascular and open reconstructive options for vascular conditions affecting the SAT.

CLINICAL PRESENTATION

Occlusive lesions in the SAT are often asymptomatic, found incidentally on imaging or identified by asymmetrical arm blood pressures. When

symptomatic, these lesions produce either thromboembolic symptoms or symptoms from low-flow states. In general, thromboembolic symptoms are more common.

The subclavian artery is the most commonly affected of the supra-aortic vessels. Atherosclerotic obstruction is typically localized to the first few centimeters of the subclavian artery. It should be suspected in a patient with asymmetric upper extremity pulses or a difference between brachial artery systolic blood pressures (typically a difference of 15 to 20 mm Hg is clinically relevant). One of three clinical presentations usually predominates: upper extremity exercise-induced pain (incorrectly referred to as “claudication,” which is derived from the root “to limp”), atheroembolic disease to the hands and fingers, or least commonly, vertebrobasilar symptoms. Patients with extremity symptoms may have easy fatigueability or a sensation of heaviness. Less frequently, patients present with evidence of microembolism to the hand or fingers. Neurologic symptoms are characteristically vague, and include dizziness, vertigo, unsteadiness, drop attacks, visual disturbances, or hemisensory abnormalities. The “textbook” presentation of the onset of vertebrobasilar symptoms with arm exercise is exceedingly uncommon. Asymptomatic subclavian steal, or the isolated finding of reversed flow in the vertebral artery ipsilateral to a proximal subclavian stenosis or occlusion, is usually not clinically relevant. It represents a stable and physiologically appropriate collateral pattern of blood flow, and does not usually warrant treatment.

Coronary subclavian steal may result in angina due to subclavian stenosis or occlusion proximal to the origin of an internal mammary coronary artery bypass graft and is now one of the most frequent indications for intervention.

Innominate artery occlusive disease may affect the two vascular territories that it supplies: the right arm and the right brain. Cerebral symptoms may be focal and reproducible due to atheroembolic events, or may be vague and nonspecific due to global hypoperfusion. Furthermore, tandem disease in the right carotid or vertebral arteries may make it difficult to identify the culprit lesion with certainty. Right upper extremity symptoms may include arm fatigue, pain with exertion, paresthesia, or sensation of a cool extremity. Atheroembolic disease to the right upper extremity may manifest as subungal splinter hemorrhages, discolored fingertips, or finger ulceration.

Aneurysmal disease of the SAT is uncommon. The subclavian artery is the most common artery affected. As with aneurysms elsewhere, aneurysms of the SAT may cause thromboembolic symptoms, compressive symptoms, or rupture. The aberrant right subclavian artery presents a unique challenge for vascular specialists. The aberrant right subclavian artery originates distal to the left subclavian origin off the aorta, and most frequently passes posterior to the esophagus. A Kommerell diverticulum is an aneurysmal origin that may occur in up to 60% of aberrant right subclavian arteries. Most patients with nonaneurysmal aberrant right subclavian artery aneurysms are asymptomatic. When present, symptoms include dysphagia (due to the compression of the esophagus with pulsations), odynophagia, or hoarseness.

DIAGNOSIS

Asymmetrical arm pressures at rest indicate a hemodynamically significant stenosis (e.g., >50% luminal diameter stenosis). Less severe stenoses may be detected by increasing flow across a site of stenosis (e.g., arm exercise or suprasystolic cuff inflation). Microembolism may be detected by reduced amplitude of finger plethysmographic waveforms or blood pressures. Finally, subclavian steal can be demonstrated on arterial duplex with evidence of reversal of flow through the ipsilateral vertebral artery.

Computed tomography angiography (CTA) has replaced catheter-based angiography in many institutions as the primary diagnostic test of choice. It avoids the small, but measurable, risk of embolism associated with catheter-based angiography (～1% risk of embolism). Despite reported accuracy equivalent to CTA, magnetic resonance angiography (MRA) has, for a variety of reasons related predominately to availability, not gained widespread adoption as the primary imaging modality.

PATIENT SELECTION FOR INTERVENTION

In general, treatment of aortic arch branch vessels should be considered for: (1) all arterial lesions that are the source of atheroembolism to the arm or cerebral circulation, (2) lesions that are symptomatic by virtue of global reduction in cerebral or extremity blood flow, or (3) selected asymptomatic patients who are believed to be at elevated risk of future adverse events. Although generally unnecessary, intervention for asymptomatic disease may be appropriate prior to, or in conjunction with, internal mammary coronary artery bypass, or aortic arch branch

reconstruction prior to extra-anatomic bypass. Of special note, coexistent coronary artery disease, which has been reported in 25% of patients with significant SAT disease, should be identified prior to planned open surgical procedures to avoid the need for re-operative sternotomy.

OPEN SURGICAL RECONSTRUCTION

Open brachiocephalic reconstruction may be accomplished by a direct (i.e., trans-sternal) or an extra-anatomic approach. The choice of operation is based on several important factors, including patient frailty, number of arteries requiring intervention, and a history of previous procedures. In general, direct reconstruction of the aortic arch branches should be considered in younger patients with good cardiopulmonary function who have not had a previous sternotomy.

Approaches to the Aortic Arch

The median sternotomy is the most common approach to the aortic arch. Some prefer to use a so-called mini-sternotomy that provides limited exposure to the upper mediastinum. Finally, the ascending aorta can be accessed through a limited right thoracotomy through the third intercostal space.

Median Sternotomy

The patient is supine with arms tucked. Techniques to prevent hypothermia (warming blankets, blood warmers, increased room temperature) should be employed. Intravenous prophylactic antibiotics are administered. A radial arterial line and adequate large-bore peripheral intravenous catheters are placed. Iodine-impregnated adhesive plastic skin drapes are used to reduce the risk of skin contaminants. The incision extends from the sternal notch to the xiphoid (Fig. 196.1). The incision may be extended to the base of the right neck to facilitate exposure of the innominate artery bifurcation (Fig. 196.2). Electrocautery is used to expose the sternum and can be used to mark a target line for the sternal saw in the middle of the sternum. Blunt finger dissection beneath the sternum at the cranial and caudal ends helps to protect any large veins from injury with the sternal saw. Ventilation should be suspended during the sternotomy. After dividing the sternum, a lap pad is placed in the wound and the cut edges of the periosteum are cauterized, and bone wax or other hemostatic agents may be applied to the bone marrow. A self-retaining retractor (e.g.,

Finochietto retractor/rib spreader) is placed. The thymus and upper mediastinal fat pads are mobilized. The innominate vein is completely mobilized. Routine division of the left innominate vein is not necessary, but this can be done to improve exposure as necessary. The innominate artery is easily exposed through a complete median sternotomy, although some experienced surgeons may prefer a partial or mini-sternotomy. The origins of the innominate artery and left common carotid artery are exposed, and the pericardium is opened to expose the proximal aortic arch.

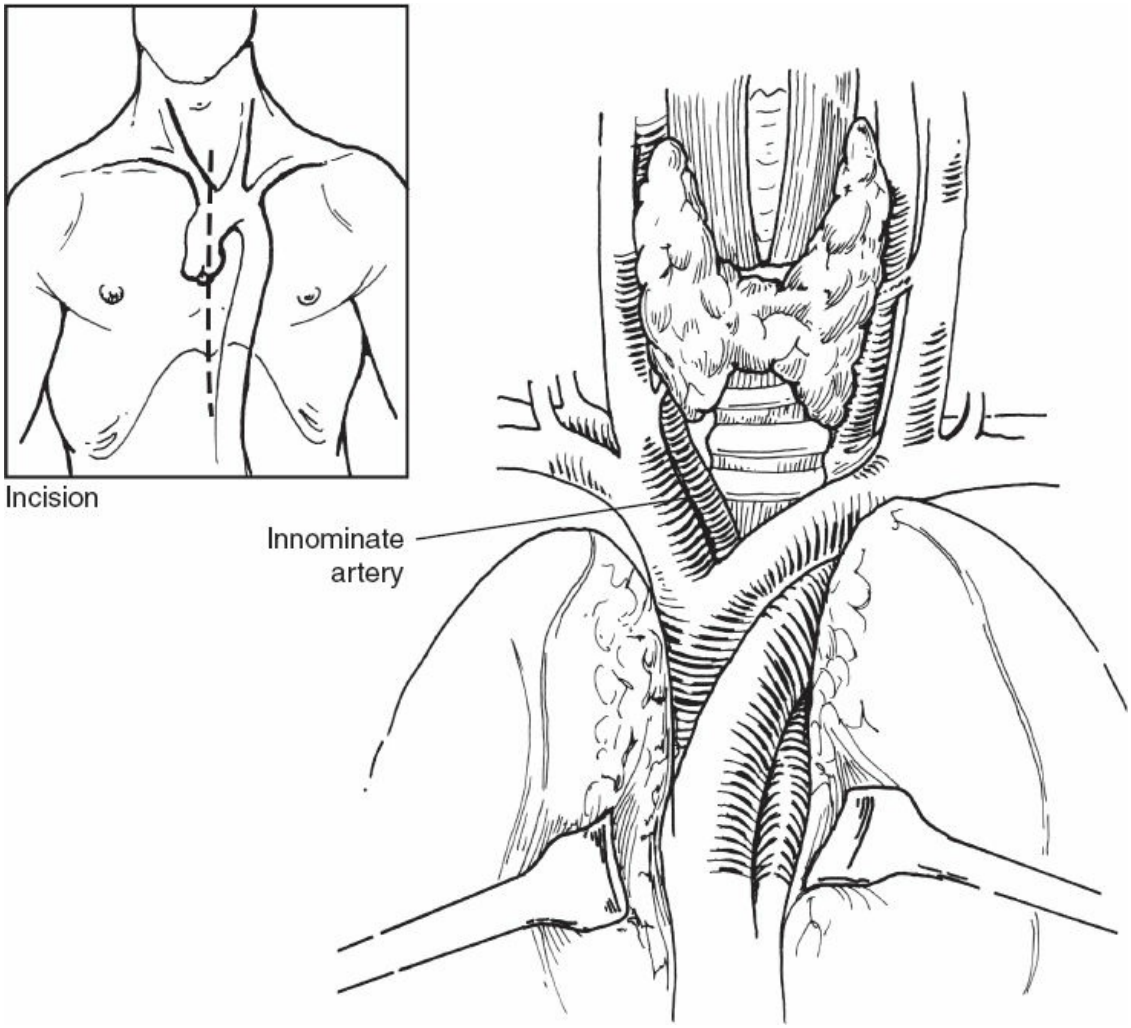

Figure 196.1. Median sternotomy.

Mini-Sternotomy

Preparation for the mini-sternotomy is identical to that for complete sternotomy. The sternum is partially divided longitudinally, with a reciprocating saw, to the inferior border of the third rib. The sternum is divided transversely at this level taking care to avoid injury to the internal mammary arteries, which lie just beyond the lateral borders of the sternum.

Again, a self-retaining retractor is used to separate the sternum sufficiently to provide access to the ascending aorta.

Right Thoracotomy

The ascending aorta and the aortic root may also be approached via a right anterior thoracotomy and segmental resection of the third rib (Fig. 196.3). Use of a wound spreader and avoidance of rib fractures reduces postoperative pain.

INNOMINATE ARTERY RECONSTRUCTION

The origins of the right subclavian and right common carotid arteries are controlled. Care is taken to identify the right vagus nerve and recurrent laryngeal nerve, which wraps around the right subclavian artery just beyond its origin. The phrenic nerve takes a slightly more lateral course between the subclavian artery and vein and is usually not in jeopardy. While the pleura can usually be bluntly dissected without perforation, a pneumothorax should be suspected if inspiratory pressures suddenly rise.

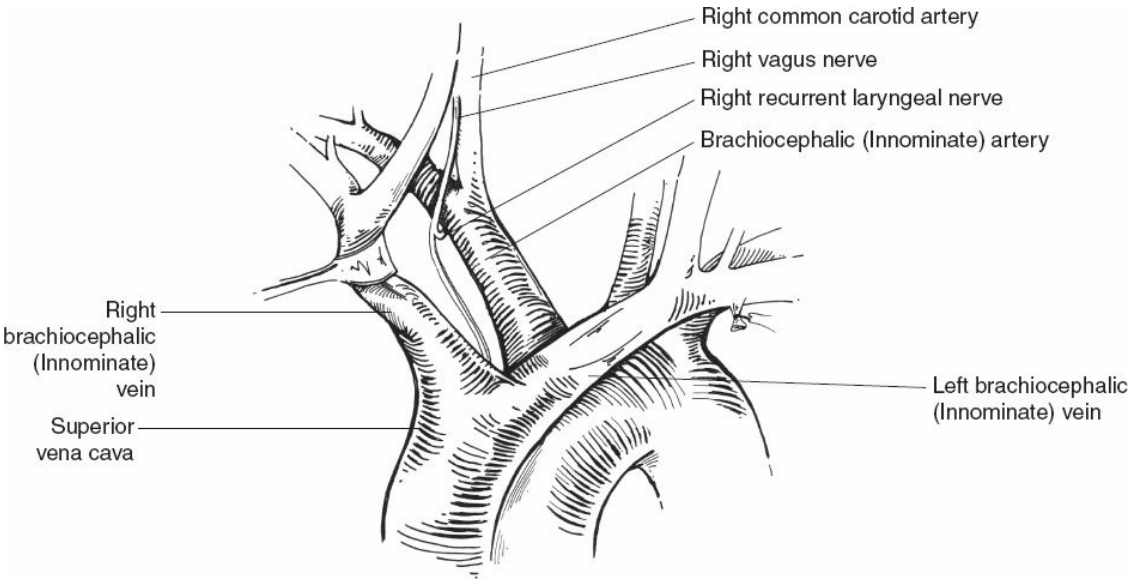

Figure 196.2. Approach to the innominate artery.

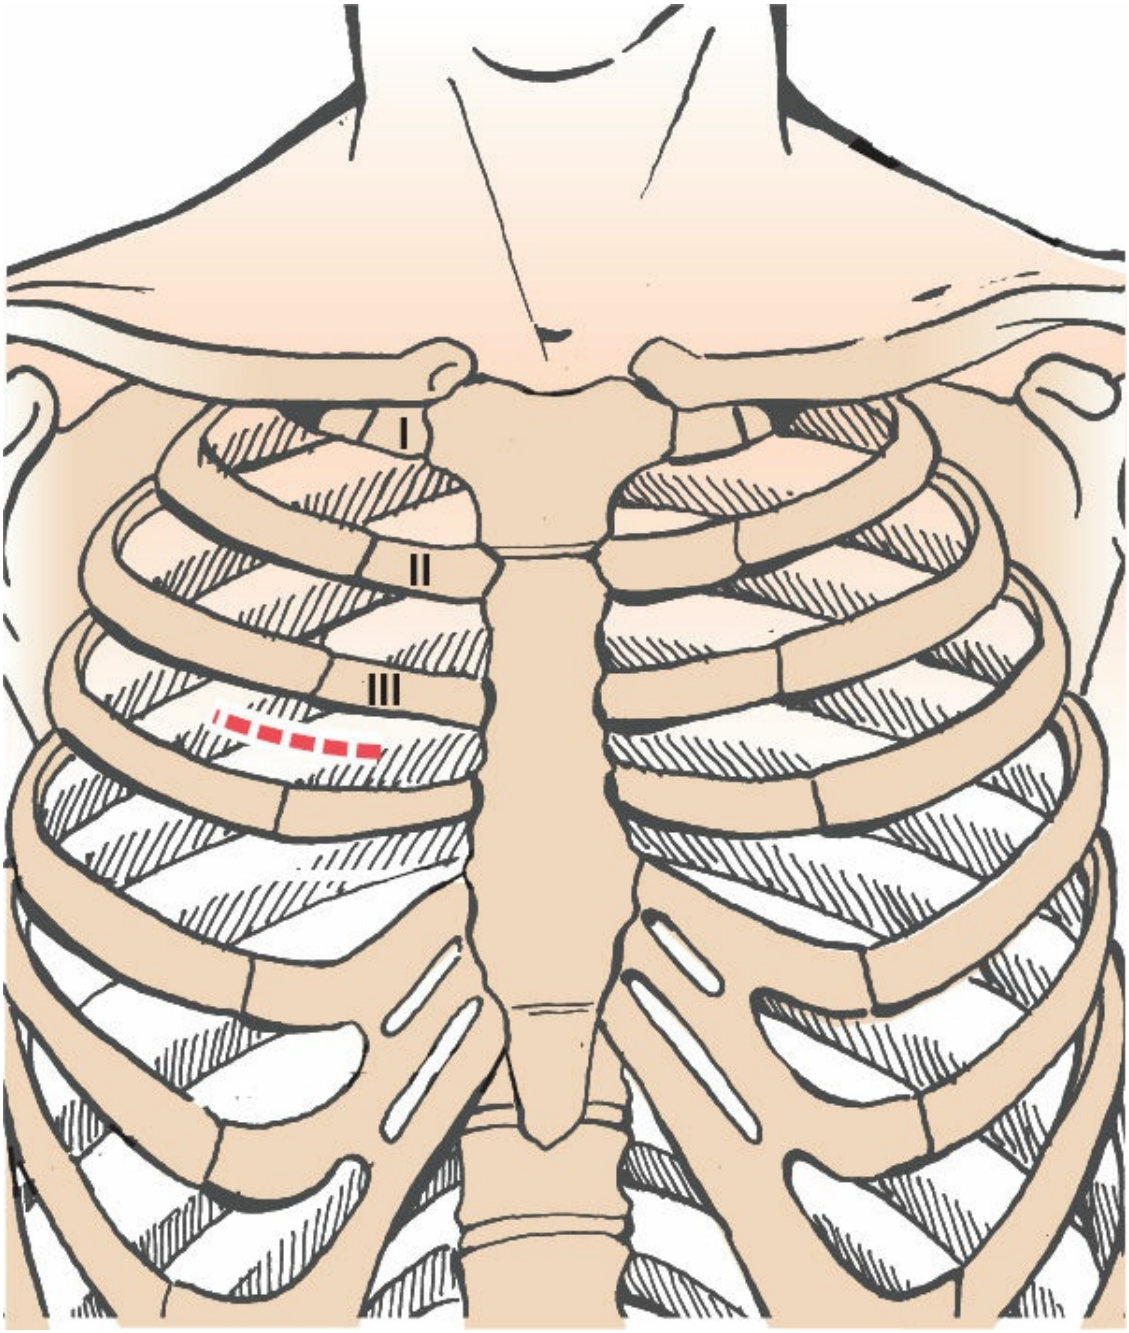

Figure 196.3. Right anterior third space thoracotomy.

At this point, the extent of the arterial lesions must be determined. The aortic arch should be gently palpated to determine suitability for clamping. Areas of heavy calcification should be avoided. Intraoperative ultrasound can be helpful to visualize potential embolic sources in the aortic arch. Endarterectomy or bypass is reasonable for occlusive lesions of the innominate artery. In general, bypass is preferred if the lesion extends to, or beyond, the innominate bifurcation, if the lesion arises from a large aortic plaque that extends into the innominate artery, if there is insufficient

distance between the innominate artery and the left common carotid artery to allow for clamping, if there is significant inflammation or adhesions due to radiation or arteritis, or if there is recurrence after prior endarterectomy.

INNOMINATE ENDARTERECTOMY

Intravenous heparin is administered (100 U/kg). The right common carotid artery is controlled before clamping the aorta to reduce the risk of cerebral embolism during manipulation of the arch (Fig. 196.4). The systemic pressure is maintained at or below a mean pressure (MAP) of 65 to 70 mm Hg. An appropriate-shaped C-clamp, such as the Lambert–Kay or Lemole–Strong clamp, is placed on the aorta at the base of the innominate artery. Aortic pulsations may cause the C-clamp to migrate during the procedure leading to sudden, unexpected hemorrhage. The distal innominate artery or right subclavian and common carotid arteries are controlled. Shunting is not usually required during reconstruction of the innominate artery.

A longitudinal arteriotomy is made in the innominate artery to accommodate the endarterectomy. Traction sutures may be used to evert the arterial edges. The endarterectomy is carried out in the standard fashion. Tacking sutures should be avoided unless absolutely necessary to avoid a distal intimal flap. The arteriotomy is closed with a running 4-0 or 5-0 polypropylene suture. Patch angioplasty is not usually necessary. Prior to closure of the arteriotomy, the common carotid and subclavian arteries are back-bled and the innominate artery is forward flushed to expel any debris or air. Trendelenburg position facilitates the elimination of arterial air. Flow should be restored to the subclavian artery prior to restoring flow to the carotid to reduce the risk of cerebral embolism. When removing the C-clamp, it is necessary to maintain slight downward pressure toward the aorta to prevent the clamp from inadvertently disrupting the suture line. A closed suction drain is placed in the mediastinum for 24 hours. The sternotomy is closed in the usual manner. A postoperative chest x-ray should be obtained to detect occult pneumothorax.

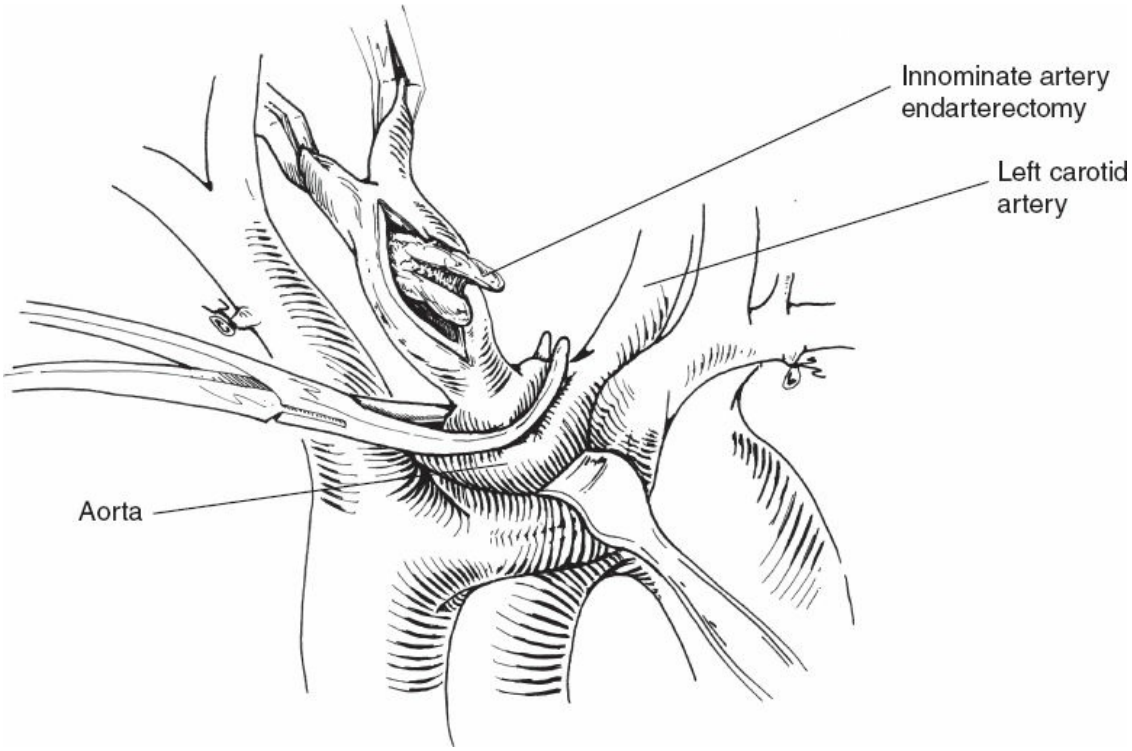

Figure 196.4. Innominate artery endarterectomy.

INNOMINATE ARTERY BYPASS

The innominate artery is exposed for bypass in the same manner as for endarterectomy (Fig. 196.5). The aorta is usually selected for inflow unless the proximal innominate artery is completely free from disease. A soft location on the intrapericardial ascending aorta that is free of disease is selected for the proximal anastomosis. A side-biting C-clamp is applied to the ascending aorta. A sufficient bite of aorta should be taken to accommodate separating the edges of the arteriotomy during suturing. An aortotomy is made along the right anterolateral side of the aorta and extended with a cardiac punch. An 8- or 10-mm low-porosity knitted polyester graft is usually selected for innominate reconstruction. Polytetrafluoroethylene (PTFE) grafts are not typically used in this location due to needle hole bleeding that can be troublesome. The graft is beveled appropriately to avoid a right angle at the origin and sutured in place with a running 4-0 polypropylene suture. The graft is flushed by briefly releasing the aortic clamp to remove any air or debris from the aorta. The clamp is then applied to the graft, and the aortic clamp removed.

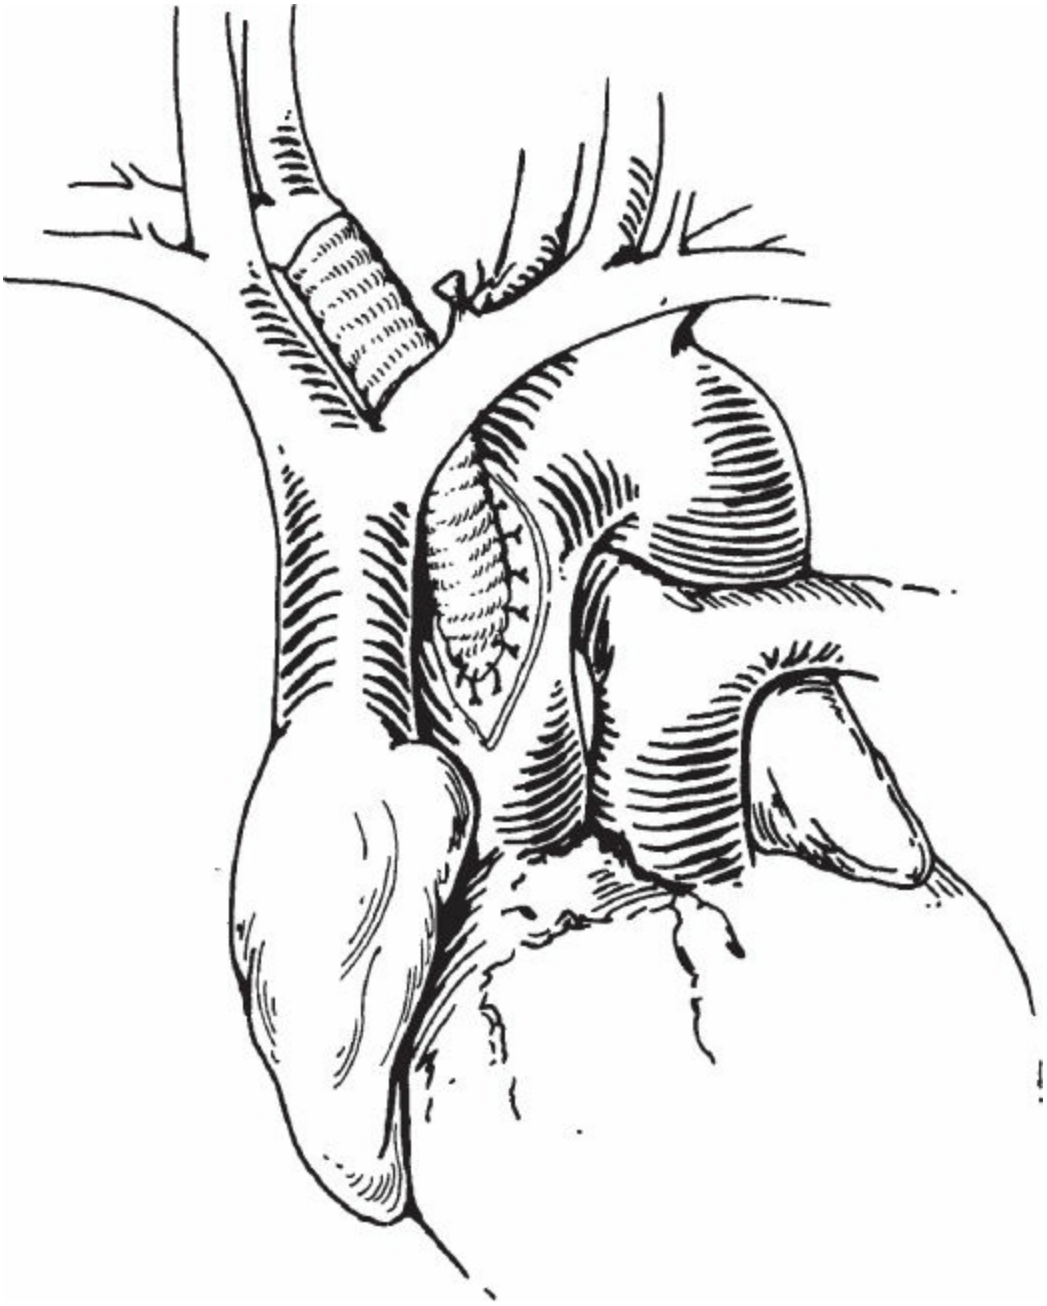

Figure 196.5. Innominate artery bypass.

After obtaining distal control, the innominate artery is transected beyond the lesion. The origins of the subclavian and common carotid arteries are inspected for extension of plaque into their orifices. An end-to-end anastomosis is constructed with a 4-0 or 5-0 polypropylene suture. The graft is irrigated with heparinized saline to remove any particulate debris. Again, the distal vessels are back-bled and the graft forward flushed before restoring flow first to the subclavian artery and then to the carotid.

RIGHT SUBCLAVIAN BYPASS

If the occlusive lesion extends into the proximal subclavian or common carotid arteries, the graft must be extended beyond the bifurcation of the innominate artery. If both the right subclavian and right common carotid artery must be revascularized separately, a bifurcated polyester graft is selected based on the diameter of the outflow vessels, typically 14 mm × 7 mm or 16 mm × 8 mm graft. Larger-diameter grafts are usually avoided due to the excessive arteriotomy that must be made in the aorta. The body of the bifurcated graft should arise the right lateral side of the proximal ascending aorta to avoid kinking, particularly during closure of the sternotomy. Reul et al. have emphasized the importance of leaving a long body on bifurcated grafts and creating an oblique aortic anastomosis to reduce the risk of kinking. Some prefer to use branched custom-made grafts with diameters ranging from 7 to 10 mm in diameter.

DIRECT RECONSTRUCTION OF INNOMINATE OR SUBCLAVIAN ANEURYSM

Exposure for reconstruction of innominate or subclavian aneurysms is the same as for occlusive disease; however, additional distal exposure may be necessary (Fig. 196.6). The position and location of the vagus and recurrent laryngeal nerves may be obscured by the aneurysm. Circumferential dissection of the aneurysm is not recommended, but this may leave intact branch vessels (e.g., internal mammary artery) that must be ligated once the aneurysm is opened. Aneurysm of the proximal subclavian artery often involves the origins of the internal mammary artery and the vertebral artery. If the contralateral vertebral artery is patent, ipsilateral vertebral artery ligation is well tolerated. Reimplantation may be considered otherwise. It is uncommon to reimplant the mammary artery unless coronary bypass is anticipated.

DIRECT RECONSTRUCTION OF MULTIPLE AORTIC ARCH VESSELS

Direct reconstruction of multiple arch vessels is limited only by the surgeon’s imagination and creativity. In the setting of bilateral common carotid artery occlusion, a bifurcated graft arising from the proximal aortic arch can be used to supply both carotid arteries. Side branches to one or both subclavian arteries can be added as needed. Exposure and visualization of the left subclavian are severely limited through a median

sternotomy. Consequently, direct reconstruction of the origin of the left subclavian artery is best approached through a formal left thoracotomy.

CAROTID SUBCLAVIAN BYPASS

A transverse incision is made 1 to 2 cm above the medial third of the clavicle (Fig. 196.7). The platysma and clavicular head of the sternocleidomastoid are divided. The prescalene fat pad is retracted laterally. The phrenic nerve is identified on the surface of the anterior scalene muscle coursing diagonally from lateral (cephalad) to medial (caudad). The anterior scalene muscle is divided, with care to avoid injury to the nerve. On the left side, the thoracic duct should be identified as it enters the junction of the internal jugular and subclavian veins, and protected or ligated. The subclavian artery lies just deep to the anterior scalene muscle. The thyrocervical trunk, internal mammary artery, and vertebral artery are encircled with vessel loops. The vertebral vein may be divided if needed. The lower cords of the brachial plexus are located posterolateral at this level. The jugular vein is retracted medially, and the common carotid artery is controlled, with care to avoid injury to the vagus nerve.

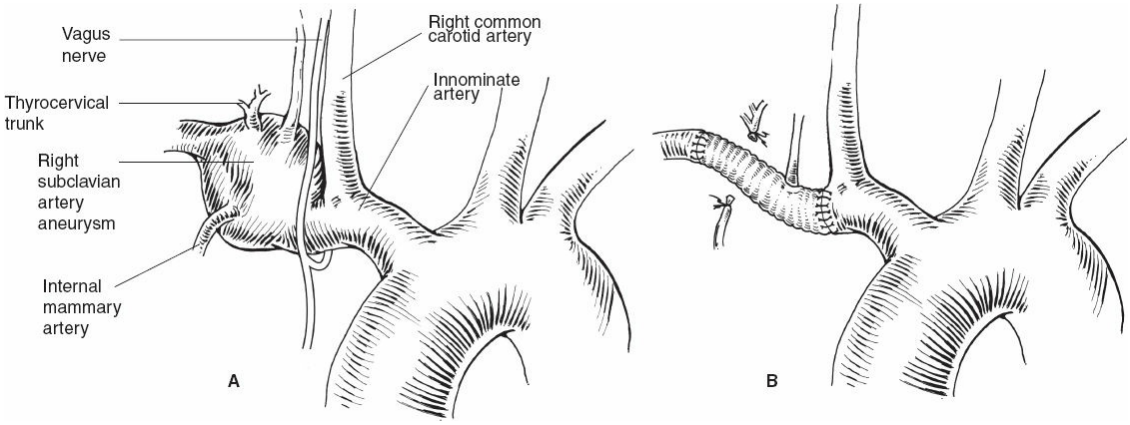

Figure 196.6. Right subclavian aneurysm. **A.** Preoperative view. **B.** Postoperative view.

A site on the lateral wall of the common carotid artery should be marked with ink prior to clamping. It is important to avoid an anastomosis on the anterior surface of the common carotid artery because this may kink the graft. The clamps can be used to rotate the artery to facilitate the anastomosis. Following heparinization, a small arteriotomy is made in the lateral wall of the common carotid and enlarged with a coronary punch.

The arteriotomy is made low in the neck so that the graft lies almost parallel to the apex of the subclavian artery and is as short as possible (2 to 4 cm). An 8-mm polyester graft is typically used, but the size should be chosen to match the subclavian outflow. An end-to-side anastomosis is made between the end of the graft and the side of the carotid artery with a 5-0 polypropylene monofilament suture. The graft is routed posterior to the internal jugular vein. The anastomosis to the subclavian artery is usually placed distal to the origin of the vertebral artery. The thyrocervical trunk may be ligated to facilitate placement of the anastomosis. The relationship of the phrenic nerve to the graft should be recorded in the operative note in the event of reoperation. There is no evidence that carotid subclavian bypass steals blood from the internal carotid artery in the absence of occlusive disease in the common carotid artery proximal to the origin of the bypass.

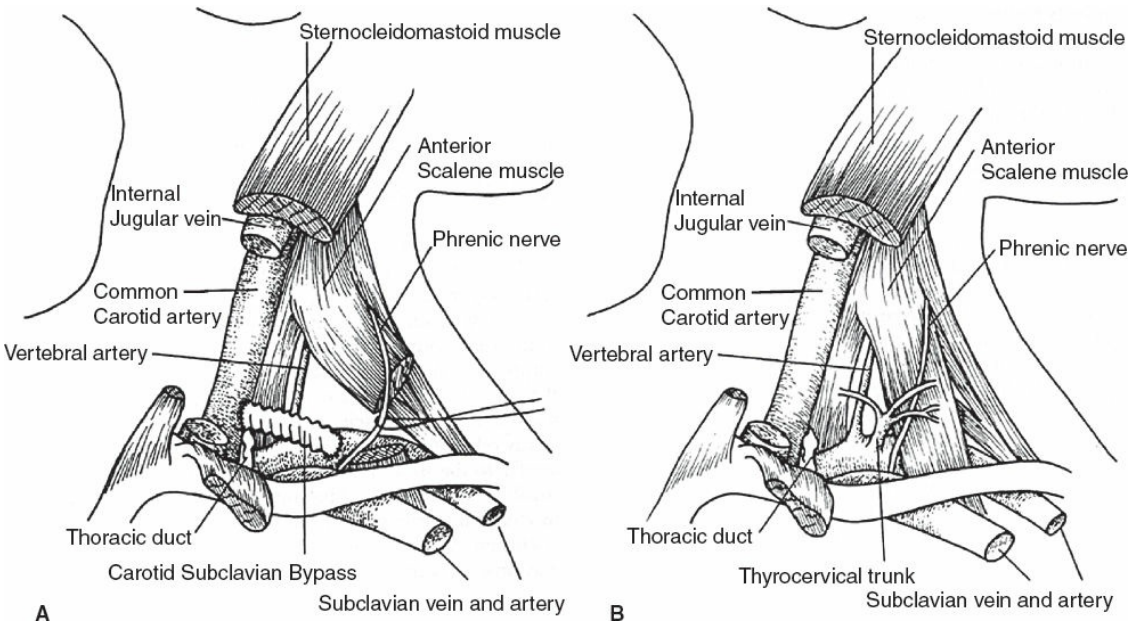

Figure 196.7. A. Synthetic carotid–subclavian bypass graft. **B.** Surgical exposure of the left subclavian artery and common carotid artery through a supraclavicular incision.

SUBCLAVIAN ARTERY TRANSPOSITION

As an alternative to bypass, the subclavian artery can be directly anastomosed to the ipsilateral common carotid. The common carotid artery is approached in the same manner as described for bypass. Again, care is taken to avoid injury to the thoracic duct and phrenic nerves. The subclavian artery must be transected close to the origin to have sufficient

length to reach the common carotid artery. Care must be taken to avoid loss of control of the proximal subclavian stump as it will retract into the thorax and will be challenging to control. If the distance is too great, a short synthetic interposition graft may be interposed between the common carotid artery and the subclavian artery. The anastomosis with the carotid artery is constructed as low in the neck as possible to create an oblique anastomosis rather than a right angle. A low anastomosis between the subclavian artery and the carotid artery also reduces the risk of kinking the origin of the vertebral artery.

ENDOVASCULAR RECONSTRUCTION

Patients are generally pretreated with aspirin (325 mg) and clopidogrel (75 mg) prior to intervention. Both groins are prepared in a sterile fashion; the left and the right antecubital fossae may also be prepped if anticipation of a retrograde brachial approach is anticipated. Retrograde access to proximal arch-branch disease through direct surgical exposure of the carotid arteries is particularly appealing for complex, high-grade lesions in types II and III arches. Use of a long sheath fastened to the drapes (e.g., 8-F 25 cm) greatly simplifies the retrograde carotid approach and reduces radiation to the operators' hands. An arch aortogram is performed prior to intervention in a left anterior oblique (LAO) projection to define the origins of the SAT and to identify any anomalies. Prior to any further intervention, heparin is administered to achieve an activated clotting time (ACT) between 250 and 300 seconds. Distal protection is not usually employed because the filter may be dislodged during the introduction of relatively stiff, large diameter devices. If distal protection is desired, use of an .014 in buddy wire may be useful to provide sufficient support for the devices. The devices can be delivered over both the filter wire and the buddy wire simultaneously.

LEFT SUBCLAVIAN INTERVENTION

Following arch aortogram, a selective view of the left subclavian artery is performed with a simple angled 5-F selective catheter. Lesion length, character, and location of the vertebral and internal mammary arteries are carefully determined. With high-grade stenoses or occlusions, retrograde flow in these branch vessels may preclude adequate visualization until the lesion is crossed. A soft-tipped 0.035-in guidewire (e.g., Glidewire, Glidewire Advantage, or Wooley) is used to cross the lesion, and is

advanced into the axillary artery. For chronic occlusions, a hydrophilic glidewire may be necessary to cross the lesion. In some instances, the lesion cannot be traversed in an antegrade fashion, and access from the brachial artery will be necessary to complete the procedure (Fig. 196.8). Once the lesion is traversed, a 7-French sheath (with dilator) is advanced across the lesion. A balloon-expandable stent (typically 6 to 8 mm diameter) is then advanced into the sheath. As the sheath is withdrawn into the aortic arch and the stent exposed, contrast is injected through the sheath sidearm to visualize the origins of the vertebral and internal mammary arteries and the subclavian–arch junction. The stent can be carefully repositioned as necessary to ensure that it does not cover the origins of these important branch vessels distally and that its proximal portion is 1 to 2 mm into the arch (for ostial lesions). Vertebral protection is not typically employed.

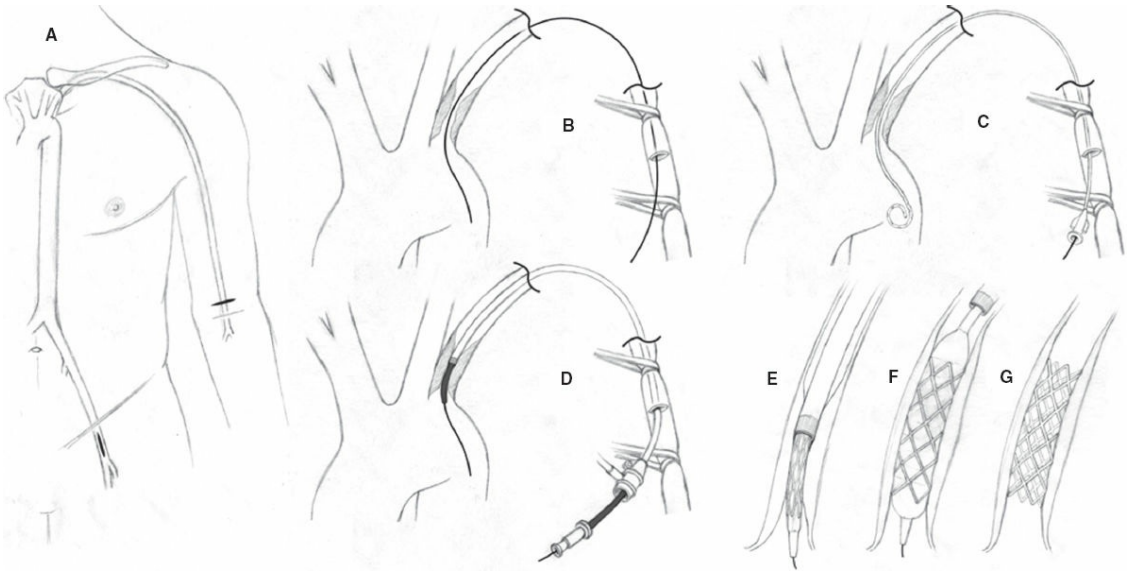

Figure 196.8. Angioplasty and primary stenting of the left subclavian artery via left brachial approach.

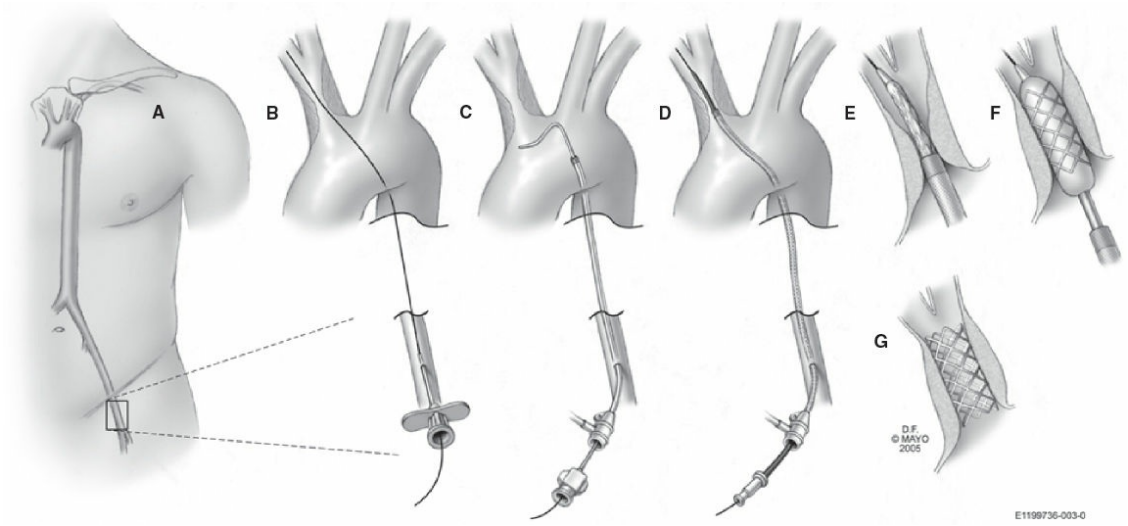

Figure 196.9. Angioplasty of the innominate artery via femoral approach. (D.F. © Mayo 2005.)

INNOMINATE ARTERY INTERVENTION

The innominate artery can be approached from either the right brachial or femoral access (Fig. 196.9). For difficult aortic arch anatomy (type II or III aortic arches), innominate artery lesions may be more easily traversed via a right brachial approach. The same basic techniques of angioplasty and stenting apply as for subclavian artery intervention, including advancing the sheath with dilator, delivery of a balloon-expandable stent to the lesion under protection of the sheath, and deployment after careful adjustment of stent position. For high-grade stenosis in a large diameter innominate artery (e.g., >12 mm), it may be appropriate to use as smaller diameter stent (e.g., 6 to 8 mm) initially and post-dilate to an optimal diameter. This technique avoids extending the shoulder of a large diameter balloon into the origin of the common carotid or subclavian arteries.

POSTOPERATIVE CARE AFTER ENDOVASCULAR INTERVENTION

Patients are maintained on clopidogrel (75 mg/day) for 30 days following intervention, and on aspirin for life. Follow-up studies include an annual physical examination (with evaluation of upper extremity pulses and blood pressure) and a duplex ultrasound. There is a 15% to 25% risk for recurrent stenosis within 3 to 5 years, with half of them being symptomatic. There are no standardized velocity criteria for recurrent stenoses of these lesions. For patients with symptomatic recurrence or

severely elevated velocities by duplex, reintervention or surgical reconstruction can be considered.

OUTCOMES

Open surgical revascularization has shown durable results in large studies. Patency rates for direct innominate artery reconstruction at 5 and 10 years of 80% to 98.4% and 88% to 96%, respectively, have been reported in large studies. They are associated with a 2.9% to 8% risk of stroke, 1.5 to 3% risk of myocardial infarction, and a 3% to 8% mortality rate. Carotid-subclavian bypass is associated with a mortality rate of 1%, stroke risk of 2.1%, and risk of myocardial infarction of approximately 2%. Patency rates at 5 and 10 years are 94 and 89%, respectively. Similarly, subclavian transposition is associated a 1% mortality rate, and a 99% patency rate.

Endovascular reconstruction appears to be associated with decreased patency compared to open reconstruction. One-year primary patency rates vary from 88.5% to 97%, and 5-year primary patency rates vary from 77% to 89%. Secondary patency rates, however, appear comparable to open surgical results (90% patency at 36 months).

EDITOR'S COMMENT

If one ever pines for the "good old days" in terms of open surgical operations, then reconstruction of the brachiocephalic trunks is one of those operations that older surgeons remember fondly while many surgeons finishing today may never actually perform, at least for primary occlusive disease. I used to perform about two to four of these a year, whereas now I will go entire years without performing one. Well described in this chapter by Eidt and his coauthor, open brachiocephalic operations are one of the most elegant and durable operations performed by cardiovascular surgeons. Primarily using the ascending aorta as an inflow source, these operations typically use large diameter bypass grafts and are sewn end to end to the innominate, carotid, or subclavian artery. The patency rates of these bypasses, as described at the end of this chapter, are superb. However, much like most of vascular surgery, the endovascular revolution has made the stenting of most brachiocephalic lesions relatively simple without a stenotomy and obviating the need to clamp the ascending aorta.

One of the issues that I always struggled with when deciding to perform open brachiocephalic reconstruction is what to do to determine the presence of coronary disease. With open aortic aneurysm repair, we are happy to perform noninvasive cardiac imaging to determine a patient's cardiac risk as low,

moderate, or high. However, open brachiocephalic reconstruction required a median sternotomy, and therefore I always felt like it was in the patient's best interest to get a cardiac catherization prior to the operation. Granted one might find an asymptomatic occluded right coronary artery, but I always thought that it was important to know and consult with a cardiologists or cardiac surgeon prior to proceeding. There are really no data on what the right answer is to this, and I am sure that it partially depends on the age and other risk factors for coronary artery disease the patients have.

It seems like stenting of brachiocephalic lesions has rapidly taken over as the primary mode by which to treat these occlusive lesions. The technical success rate of these brachiocephalic stents is high with fewer posteroperative strokes or death (Ben Ahmed S, Benezit M, Hazart J, et al. Outcomes of the endovascular treatment for the supra-aortic trunks occlusive disease: a 14-year monocentric experience. *Ann Vasc Surg* 2016;33:55–66). However, the long-term patency of this approach is somewhat lacking, and there appears to be a relatively high (16.4%) incidence of restenosis. It is unclear to me whether a covered or uncovered stent is better, but I prefer covered, balloon expandable stents.

Often one is called upon to perform a carotid endartectomy (CEA) and a retrograde stent of the innominate or left common artery. Some have even suggested that this can be done under regional block, even though I much prefer doing these combined cases under general anesthesia (Heyn J, Rosch F, Treitl M, et al. Carotid endarterectomy and retrograde stenting of the supra-aortic trunk: does cervical block offer advantages? *Ann Vasc Surg* 2016;34:193–9). Others have suggested that combined CEA and brachiocephalic stenting increases the risk of stroke, and therefore caution was urged when performing this combination operation, especially in asymptomatic patients (Clouse WD, Ergul EA, Cambria RP, et al. Retrograde stenting of proximal lesions with carotid endarterectomy increases risk. *J Vasc Surg* 2016;63[6]:1517–23).

Honestly, I much prefer to perform all brachiocephalic stents under general anesthesia and through a small cervical incision to expose the proximal common carotid artery. The cerebral vessel is only clamped for a very short time, and almost all patients can tolerate it. It also affords one the ability to flush all the debris out the common carotid artery with a clamp distal to the arteriotomy. I typically also, when stenting the innominate artery, use a small sheath in the brachial artery to place a balloon in the proximal subclavian artery to protect the vertebral arteries as the stent is being deployed. I know others who put filter wires up the carotid and vertebral arteries from below, and this is likely done more commonly than what I do. However, the vertebral artery loves to dissect, and I have seen that as well when someone placed a filter wire in it.

Finally, we are about to experience an explosion in the use of extra-anatomic bypasses of the brachiocephalic arteries, as well as stenting of brachiocephalic arteries, as all aortic arch pathology will soon be managed in the United States (and is already managed in many areas of the world) primarily by endovascular stent grafts. This will likely be true for both the treatment of occlusive and

aneurysm disease, as well as with aortic dissections (Alberta HB, Takayama T, Smits TC, et al. Aortic arch morphology and aortic length in patients with dissection, traumatic, and aneurysmal disease. *Eur J Vasc Endovasc Surg* 2015;50[6]:754–60). Presently, we are resigned to chimney's and homemade fenestrations of these complex aortic arch lesions (Liu H, Shu C, Li X, et al. Endovascular aortic repair combined with chimney technique in the treatment of stanford type B aortic dissection involving aortic arch. *Ann Vasc Surg* 2015;29[4]:758–63; Redlinger RE Jr, Ahanchi SS, Panneton JM. In situ laser fenestration during emergent thoracic endovascular aortic repair is an effective method for left subclavian artery revascularization. J Vasc Surg 2013;58[5]:1171–7), but the trials are beginning to be performed, and by the next edition of *Mastery of Surgery*, we will likely have a new chapter entitled "Aortic Arch Stent Grafting!"

Gilbert R. Upchurch

197 Carotid Body Tumors

Wesley S. Moore

The only known pathologic condition associated with the carotid body is a carotid body tumor. The carotid body was first described by Von Haller in 1743, and Heller coined the term *glomus tumor* in 1762. In spite of the long history, these lesions, even today, remain a topic surrounded by considerable misunderstanding and confusion. Much of this misconception can undoubtedly be traced to the lack of established data related to the histologic origin, biologic behavior, and incidence of malignancy associated with carotid body tumors. As one might predict, this situation has generated considerable controversy regarding the appropriate management of these lesions.

Carotid body tumors are uncommon neoplasms. Their exact incidence remains unknown. In 1971, approximately 500 cases had been recorded in the world literature, and by the early 1980s this figure had doubled to just more than 1,000. Like most other types of benign and malignant neoplasms, the precise cause of carotid body tumors is not known. Also, as is frequently the case with other tumors that have the potential for endocrine activity, these lesions are recognized to occur in three distinct forms: sporadic, familial, and hyperplastic. The sporadic form is more common, although the familial pattern has been recognized in as many as 10% of cases by some authors. A review of familial cases of cervical paragangliomas suggests an autosomal dominant inheritance pattern. Hyperplastic lesions are associated with hypoxia and include patients with chronic obstructive pulmonary disease (COPD), congenital heart disease, and those living at high altitude. It has long been appreciated that chronic hypoxia is associated with enlargement of the carotid body in some patients. Although these changes are usually not classified as tumors, histologic examination of carotid body tissue from these patients frequently reveals marked cellular hyperplasia. This observation, combined with epidemiologic data that suggest an increased incidence of carotid body neoplasms occurring in individuals who live at high elevations, has led some investigators to implicate prolonged hypoxemia

as a possible causal factor related to the development of these uncommon tumors.

This chapter reviews my current practice for the treatment of patients who have carotid body tumors. Because many of these management principles are based on an understanding of the pathology and biologic behavior of these lesions, I have included a summary of the current understanding of these important topics. With an appreciation of these principles and the use of operative techniques developed from them, one should be able to safely manage even the most challenging carotid body lesions. Alternatively, inadequately planned neck explorations in improperly prepared patients or biopsies of seemingly unimpressive neck masses often result in disastrous consequences. Even when the presence of a carotid bifurcation paraganglioma is correctly diagnosed preoperatively, resection of this lesion can be a humbling experience even for the most experienced surgeons.

PATHOLOGY

The normal carotid body is an ovoid nodule, measuring approximately 0.5 cm × 0.5 cm, located along the posterior surface of the carotid bifurcation. This structure represents the largest mass of chemoreceptive tissue found anywhere in the body. The blood supply to the carotid body is usually derived from branches of the external carotid artery, and the venous return occurs through tributaries of the lingual and laryngopharyngeal veins. The innervation is exclusively sensory. Small nerve fibers arising from the carotid body join the larger glossopharyngeal nerve before entering the cranium through the jugular foramen. Stimuli that evoke a response by the chemoreceptor cells include increases in the plasma carbon dioxide tension or blood temperature, or a decrease in the plasma pH or arterial oxygen tension. Once activated, the stimulation of carotid body chemoreceptors causes several physiologic responses, including increased minute volume ventilation, increased pulse rate, and an elevation of the mean systemic blood pressure. Embryologically, the carotid body derives elements from both neural crest ectoderm and mesodermal tissue originating from the third branchial arch. The neural crest ectoderm differentiates into chemoreceptor cells that migrate in close association with the autonomic ganglion cells, and are therefore frequently referred to as *paraganglioma cells.* The mesodermal tissue develops into a highly vascular fibrous stroma that supports and nurtures these clusters of chemoreceptor cells.

Carotid body tumors are neoplastic growths that arise from these chemoreceptive structures. The morphologic appearance of carotid body tumors closely resembles that of normal carotid body tissue. Grossly, the tumor is reddish brown and highly vascular. Microscopically, one sees chemoreceptor cells embedded in a fibrous stroma situated adjacent to abundant capillaries. Overall, the lesions have a very well-differentiated benign appearance. Degenerative malignant characteristics, such as unusual nuclear forms, increased mitotic activity, and vascular invasion, are only very rarely seen. Historically, there has been considerable confusion regarding the terminology and classification of these tumors. The term *glomus tumor* is a misnomer and was introduced based on the mistaken impression that these highly vascular tumors were in fact a form of neurovascular arteriovenous malformation. Mulligan introduced the term *chemodectoma* to describe these lesions in 1950 because these tumors are composed of cells with both chemoreceptor and secretory function. Advanced immunohistochemical studies have subsequently suggested that carotid body tumors are capable of synthesizing numerous different neuroendocrine substances. Secretory granules containing a wide variety of neuropeptides and several enzymes involved in the cytoplasmic synthesis of catecholamines have all been demonstrated. For unclear reasons, however, patients who have carotid body tumors almost never manifest any clinical evidence of excessive endocrine hormone secretion. Sporadic case reports have noted secretory activity of norepinephrine and dopamine, but these are the exceptions. Because it is believed that these tumors arise embryologically from epithelioid cells of the neural crest that have migrated with neural tissue adjacent to the autonomic ganglion, they have also been referred to as *paragangliomas.* Paragangliomas actually comprise a family of neoplastic tumors that can occur anywhere along the autonomic ganglion chain, from the organ of Zuckerkandl to the glomus intravagale. Classically, paragangliomas arising in the adrenal medulla secrete high levels of catecholamines and usually stain positive for chromaffin. Despite having been found to contain granules rich in catecholamines within their cytoplasm, carotid body tumors are most commonly nonfunctional and classically stain negative for chromaffin.

Grossly, these tumors are highly vascular and often invade the adventitia of the adjacent carotid vessels. The tumors grow slowly, beginning along the posterior aspect of the carotid bifurcation. As they enlarge, they typically gradually widen the angle between the internal and

external carotid arteries. Frequently, when carotid body tumors grow very large, they encase the main trunk and proximal tributaries of the external carotid artery. Without explanation, however, they only rarely do the same to the internal carotid vessel. This phenomenon may be related to the origin of the blood supply to the tumor from branches of the external carotid artery. Nonetheless, it is a consistent feature found in large carotid body tumors and has important ramifications related to the strategy for resection, which is discussed in more detail later in Resection of the Tumor.

Although most carotid body tumors are considered benign lesions, malignancy does occur. It is generally accepted that the biologic behavior of a given carotid body tumor cannot be predicted based solely on the histologic appearance of the resected specimen. Benign-appearing tumors are capable of both locally aggressive growth and nodal and distant metastatic spread. Adherence to vascular and neurologic structures is well known, and even extension through the base of the skull into the cranium has been described. Therefore, as is the case with many other neuroendocrine tumors, malignancy is determined by how the lesion behaves clinically. This is quite different from most other types of cancers, in which histologic appearance remains the primary criterion for identification of malignancy. If enlarged lymph nodes are encountered during dissection, they should be removed for biopsy. The presence of carotid body cells within an adjacent lymph node is diagnostic of malignancy.

CLINICAL PRESENTATION

By far, the most common presentation of a carotid body tumor is that of an incidentally noted asymptomatic neck mass. The lesion typically causes no pain and is located just below the angle of the mandible. Usually the tumors grow slowly over several years; however, more rapidly growing lesions are occasionally encountered. In a review by Patetsios et al. from Baylor University in Dallas, they found that 62% of their cases presented with a painless neck mass; 10% with a painful mass, and a few with cranial nerve deficits. Most carotid body tumors are diagnosed in the third or fourth decade of life, but they have been reported in younger and older patients. No gender predominance has yet been established. When the tumor occurs in a familial pattern of inheritance, there is up to a 30% incidence of bilateral tumors, as opposed to 2% to 20% in nonfamilial

cases.

Occasionally when a carotid body tumor becomes very large, compression or local invasion of adjacent structures can lead to a variety of different symptoms. Local discomfort such as pain, fullness, and numbness is not uncommon. In this situation, some patients may complain of difficulty in swallowing, hoarseness, and chronic cough due to compression of the airway or involvement of adjacent cranial nerves.

Despite the fact that carotid body tumors are frequently classified as neuroendocrine neoplasms, clinical evidence of any endocrine imbalance resulting from secretory function of these lesions is almost never encountered. Interestingly, however, the histologic machinery to do so is apparently present. As was mentioned previously in the Pathology section, careful ultrastructural and immunohistochemical examination of these tumors has revealed that carotid body tumors are capable of producing secretory granules containing a large variety of catecholamines. Nevertheless, “functional” cervical paragangliomas are exceedingly rare. Only very rarely is a case reported describing a patient who has both hypertension and a concomitant neck mass and in whom the hypertension resolves after resection of the associated carotid body tumor. The assumption, although not proven, is that the hypertension in these cases occurs on the basis of excessive “tumor related” catecholamine secretion.

On examination, these lesions are often described as painless fixed masses located at the angle of the jaw. In fact, more careful examination usually demonstrates that, although movement is limited longitudinally, the tumor can readily be moved in a lateral direction. This is an important feature of the physical examination and helps to establish an association of the mass with the longitudinally running neurovascular structures. Typically, the mass is firm, smooth, and lobulated. Frequently, transmission of the carotid pulsation is appreciated during palpation. Furthermore, in approximately 30% to 40% of patients, an audible bruit is present over the tumor, giving testimony to the highly vascular nature of the tumor. Locally aggressive tumors may invade or compress adjacent cranial nerves. In fact, careful examination yields clinical evidence of nerve dysfunction in approximately 10% of patients who present with carotid body tumors. Most commonly the hypoglossal or vagal nerves are affected, but laryngeal nerve involvement and Horner syndrome have also occasionally been reported. Large tumors can extend into the base of the skull or present as a bulge in the lateral wall of the oropharynx with

deviation of the soft palate. Ischemic cerebrovascular symptoms rarely, if ever, occur. Patients who have carotid body tumors who also present with transient or permanent ischemic events are usually found to have concomitant carotid bifurcation atheroma or another unrelated cause to account for the cerebrovascular systems.

The differential diagnosis of a patient who presents with an enlarging neck mass is extensive. Congenital lesions, such as branchial cleft abnormalities, hygromas, and vascular malformations, should all be considered. Chronic lymphadenitis, reactive lymphadenopathy, and other inflammatory reactions must also be excluded. Many other benign and malignant neoplastic processes, such as lipomas, neurofibromas, salivary gland and parotid tumors, metastatic head and neck cancers, leukemias, and lymphomas, can also present in this way. It should also be remembered that other cervical paragangliomas exist. These include the glomus vagale, and the glomus jugulare. It is beyond the scope of this chapter to describe their management other than to mention that it may be quite different from the management of carotid body tumors. Vascular abnormalities, such as carotid aneurysms, coils, and kinks, should also not be overlooked. A thorough history and physical examination combined with carefully selected diagnostic studies can usually distinguish these other pathologies and successfully identify most cervical paragangliomas. Clearly, however, this orderly workup is critical, as the appropriate treatment for many of these lesions varies greatly.

NATURAL HISTORY AND INDICATIONS FOR SURGERY

Once identified, all carotid body tumors should be removed. Although these lesions are slow-growing neoplasms with a relatively low risk of malignancy, small tumors are easier to excise, and eventually most, if not all, will progress and become locally invasive. These tumors continue to grow and, in time, extension to the base of the skull or involvement of cranial nerves may complicate their management. In addition, the threat of distant metastases, although low, is real. Despite being categorized as generally benign, malignant transformation of carotid body tumors has been reported. The exact incidence of malignancy is difficult to quantitate and depends on the definition of the term used. The biologic behavior and malignant potential of a given carotid body tumor cannot be predicted by histologic examination. Rather, malignant potential is identified by clinical behavior. If strict criteria of regional lymph node or distant metastatic

spread were used, the incidence of metastatic spread from carotid body tumors would be quite low, although it is definitely not zero. Some reports have suggested that the true incidence of distant metastases in untreated lesions approaches 10%. However, locally aggressive growth patterns of carotid body tumors are not at all uncommon, and certainly lesions that invade adjacent structures can be considered at least potentially malignant. Consequently, most authorities consider all cervical paragangliomas capable of malignant behavior. Death from carotid body tumors does occur, and not always from metastatic disease. Relentless local growth of these lesions can cause death by airway compression, cranial neuropathies, or intracranial extension. Also, regional lymph node and distant metastases, which are exceedingly rare at presentation, can occur years after the primary tumor has been resected. It should also be mentioned that, because of this low risk of malignancy, a case could be made against operative treatment in the high-risk or elderly surgical patient who presents with a small, asymptomatic carotid body tumor. In most cases, however, in view of the natural history of progressive enlargement, frequent local invasion, and small but unpredictable risk of distant metastases, most surgeons recommend surgical resection once the diagnosis of a carotid body tumor has been established.

PREOPERATIVE PLANNING

The preoperative evaluation of patients being considered for resection of a carotid body tumor is important and should be directed to address several questions:

- What is the overall general medical condition of the patient?
- Are other cervical paragangliomas present?
- What is the anatomic extent of the lesion under investigation?
- Is there any cranial nerve involvement detectable preoperatively?
- Is there any evidence of endocrine dysfunction or hormonal imbalance?

Each patient should undergo a thorough history, and important risk factors should be identified. Likewise, the physical examination should be complete, with particular emphasis on the neurologic and cerebrovascular systems. Clearly, an asymptomatic elderly patient who is considered to be a poor operative risk may not be well served by a potentially hazardous resection of what is most commonly a benign neoplasm. Likewise, the presence of multiple lesions or extension of a tumor into the base of the

skull would obviously influence the operative approach. Involvement of cranial nerves suggests at least a locally aggressive tumor, and documentation of these deficits preoperatively is obviously very important. Several imaging techniques are now available to diagnose and characterize carotid body tumors. As is frequently the case, each of these modalities has specific strengths and weaknesses that should be carefully considered.

The preoperative evaluation of patients who have carotid body tumors has traditionally relied on the results of selective carotid angiography. This is largely due to the unmatched demonstration of anatomic detail in a familiar format that is easily interpreted by most clinicians. The carotid bifurcation is particularly easy to demonstrate with this examination. Information regarding the overall size, proximal and distal extent, and degree of vascularity of the lesion can usually be easily assessed (Fig. 197.1).

Information regarding the major arterial blood supply to the tumor is also obtained. Infrequently, an unusual tumor blood supply from an aberrant ascending cervical or vertebral artery branch is identified, which can be very important preoperatively. Another advantage of angiography is its ability to evaluate the entire distribution of the brachiocephalic and cerebrovascular tree, including the origin of the vessels as they arise from the aortic arch and the intracranial portion of the branch vessels. This is important because angiography is an extremely sensitive method of identifying cervical paragangliomas and allows the surgeon to easily detect occult nonpalpable synchronous or contra lateral tumors. Also, angiography can occasionally suggest malignancy by demonstrating encasement of the carotid vessels. Rarely, this may alert the surgeon to the presence of extensive internal carotid involvement and allow preoperative planning for the possible need for a vascular reconstruction. Last, by imaging the lumen of the carotid vessels, any atheromatous plaques or significant ulcerations can be documented. Kinks, coils, aneurysms, and any other unsuspected anatomic variations are also all easily identified with this technique. Intracranial pathology that may influence management decisions includes arteriovenous malformations, cerebral aneurysms, and significant siphon stenoses. Finally, some authors have reported the use of preoperative embolization as an adjunct before the resection of particularly large or highly vascular carotid body tumors. As such, although I have not found this necessary (and consider it potentially hazardous), one might qualify the ability to consider this treatment option as another potential

advantage to support the use of angiography during the preoperative evaluation of these patients.

The risks associated with cerebral angiography are numerous. First, this technique is an invasive procedure that requires arterial access, and wound complications are therefore not infrequent. Hematoma formation, acute arterial dissection, false aneurysms, and distal embolization have all been reported. The incidence of these complications has not been documented consistently; however, they probably occur in between 1% and 2% of cases. Second, catheter manipulation within the carotid artery can lead to serious complications as a result of dissection or embolization. In one review of over 5,000 cerebral angiographic procedures, the overall risk of neurologic sequelae was 0.9%, with 0.06% of patients experiencing a permanent stroke. Others have placed the risk of neurologic events and stroke at 2.6% and 0.6%, respectively. Although most of these reviews include patients being evaluated for atherosclerotic vascular disease and not carotid body tumors, it is probably accurate to estimate that, during cerebral angiography, the risk of a neurologic event is approximately 1%. Finally, the contrast injected during angiography can induce allergic reactions, renal failure, and alterations in the coagulation system. Allergic reactions range from mild rashes and gastrointestinal upset to life-threatening hypotension, bronchospasm, pulmonary edema, and cardiac arrhythmias. The risk of contrast reactions in all types of angiographic studies varies between 2% and 8%. For cerebral examinations, risk is in the lower range, with a rate of approximately 2%. In high-risk patients who have antecedent renal disease, the risk of acute renal failure after the administration of contrast can be as high as 40%, with more than 8% of patients requiring permanent dialysis. Finally, depending on the institution, the cost of angiography is as high as $5,000 per procedure.

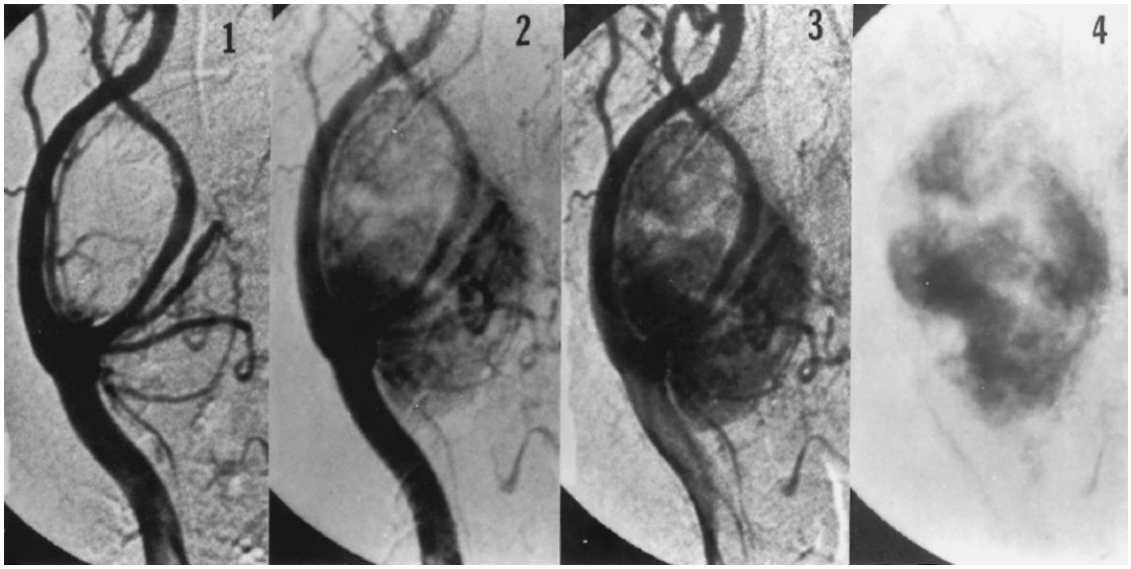

Figure 197.1. Typical angiographic appearance of a carotid body tumor. Initial injection view (1) demonstrates the characteristic "splaying" of the carotid bifurcation. Subsequent delayed views (2–4) show the anatomic extent of lesion and the degree of vascularity.

In summary, angiography has long been considered the "gold standard" for the evaluation of patients who have carotid body tumors. Indeed, some surgeons consider this examination mandatory before performing a resection of this neoplasm. However, as described, this imaging technique is not without risk, and with the emergence of newer, noninvasive imaging modalities, others have questioned whether this study is really necessary in all cases. Also, because the morbidity of any preoperative examination must be added to the overall risk associated with the surgical intervention, methods of safely treating these generally benign tumors without routine angiography are even more desirable. These forces have led several investigators to attempt to gain experience managing these lesions without the benefit of angiographic data.

Duplex scanning has emerged as an accurate noninvasive method of evaluating patients who have carotid body tumors. In terms of technical performance, it clearly has several advantages over angiography. The examination is noninvasive and involves little or no patient discomfort. In contrast to the multiple wound and contrast-related problems associated with angiography, duplex scanning is essentially without risk. The anatomic detail, although not as good as with angiography, is quite satisfactory. The tumor can be localized to the carotid bifurcation and, with the addition of color-flow technology, an estimate of the vascularity

of the lesion can be obtained. Also, as with angiography, tumor size can be estimated and the bifurcation screened for evidence of tumor encasement or concomitant atherosclerotic disease. Finally, most hospitals charge approximately $300 to $400 for a duplex scan, or roughly one-tenth the cost of a cerebral angiogram.

The major limitation of duplex scanning is its inability to clearly image either the proximal or very distal areas within the neck. Proximal and distal extensions of very large lesions are poorly visualized. Also, any significant intracranial component to a tumor invariably goes unrecognized. In addition, this study is not as sensitive for very small lesions, and, when compared to angiography, small occult tumors may not be readily identified. Likewise, potentially helpful detail, such as the presence of an important aberrant blood vessel, is unlikely to be obtained during duplex scanning. Last, and perhaps most important, the reliability of any duplex study depends on the individual performing the examination, and results obtained by different operators vary greatly.

When more information is required, computed tomography (CT) and magnetic resonance (MR) scanning are useful techniques. Both tests can be extremely helpful, particularly in large tumors or when multiple lesions are suspected (Figs. 197.2 and 197.3).

Unlike with duplex scanning, large lesions can be defined even in the proximal or distal portions of the neck. Also, both studies can reveal tumor encasement of the vascular structures or invasion of an aggressive lesion into the base of the skull. MR images have the additional advantage of being able to be analyzed by software that reconstructs angiographic detail. These MR angiograms have gained popularity by virtue of their ability to noninvasively depict the cerebral vessels in a format similar to that of conventional arteriography. Whether these images possess enough accuracy to safely plan carotid body resections and replace conventional angiography remains unproved.

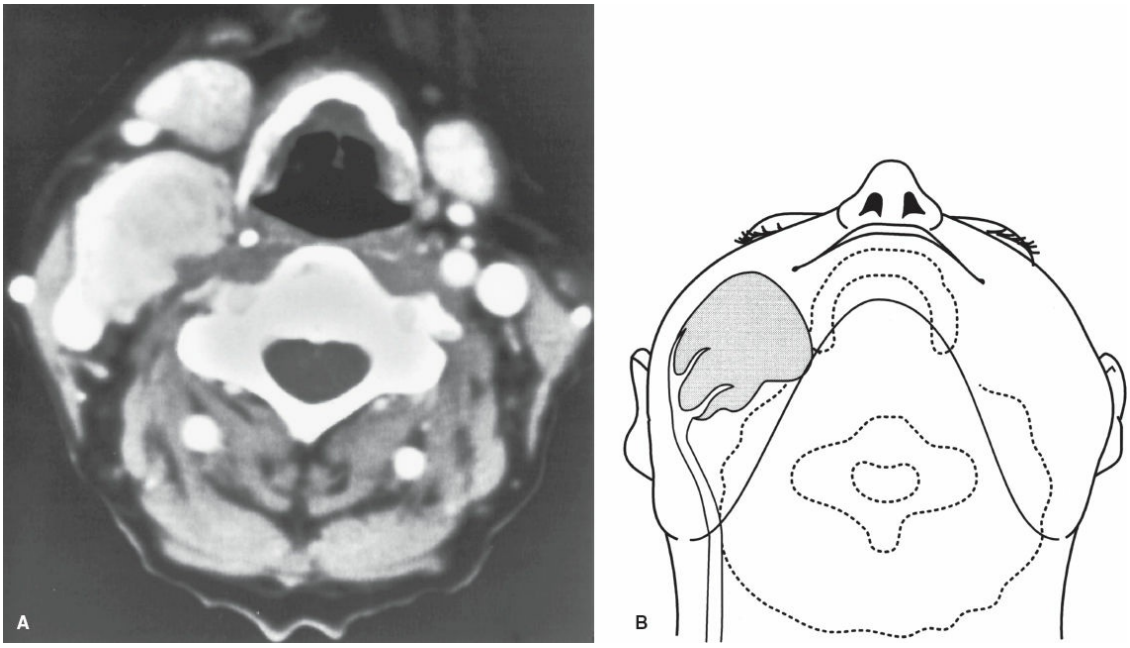

Figure 197.2. **A.** Computed tomographic scan demonstrating large carotid body tumor with probable encasement of the external carotid artery. **B.** This is the artist's concept of the relationship of the carotid body tumor to the carotid artery, as seen in (**A**).

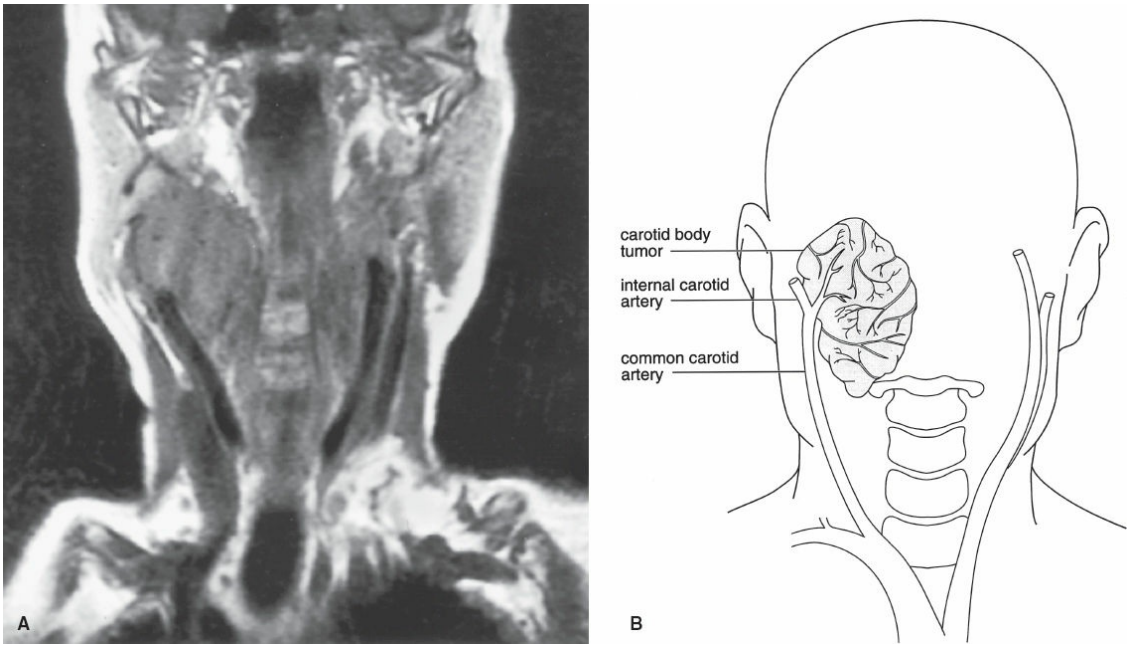

Figure 197.3. **A.** Magnetic resonance image showing large right-sided carotid body tumor. **B.** This artist's concept clarifies the magnetic resonance image, showing the relationship of the carotid body tumor to the common carotid artery and carotid bifurcation.

In 1971, Shamblin and colleagues, from the Mayo Clinic, described their overall experience with 101 patients who were treated at the Mayo Clinic from 1931 through 1967. In reviewing the operative reports, they developed a classification based upon tumor extent and neurovascular involvement. Group I tumors could be freely dissected away from the wall of the carotid artery. Group II tumors partially surrounded the circumference of the carotid artery. Group III tumors had intimate adherence to the entire circumference of the carotid bifurcation. With today's modern imaging, it is now possible to use the Shamblin classification, preoperatively in order to anticipate the degree of difficulty with planned surgical resection. Some surgeons routinely carry out preoperative tumor embolization in patients with Shamblin II and III lesions in hopes of facilitating operation and reducing blood loss. In a 2012 publication, Power and colleagues reported on 144 carotid body tumors treated at the Mayo Clinic between January 1985 and December 2010. They carried out a retrospective comparison of patients with Shamblin II and III lesions who underwent preoperative embolization with those patients who had surgery without preoperative embolization. They found that those patients who underwent preoperative embolization required less extensive procedures. However, there was no difference in operative time, cranial nerve palsy, or postoperative length of stay. They did find that preoperative embolization added significantly to the overall cost of patient care. In my own experience, I have never used preoperative embolization and therefore have no basis for comparison.

To summarize, the duplex scan is an accurate, noninvasive imaging technique that is useful for screening patients who have neck masses. It can most often establish an association between the mass and the carotid bifurcation, but it frequently cannot provide enough anatomic detail to establish the diagnosis of a carotid body tumor or safely plan for its resection. Traditionally, most surgeons have used cerebral angiography to accomplish these goals; however, there is no question that arteriography exposes patients to an increased risk that must be added to the operative morbidity when calculating the overall risk of surgical therapy. Experience with CT and MR scanning has grown and has largely replaced the need for catheter-based angiography when information from carotid duplex scanning, alone, is not sufficient for diagnosis or preoperative planning.

SURGICAL TECHNIQUE

In experienced hands, the removal of a carotid body tumor can be accomplished with very low morbidity and mortality. However, several important operative principles must be appreciated to consistently achieve these results. It cannot be overemphasized that carotid body tumors are, as a rule, extremely vascular lesions. In fact, one can safely say that an inexperienced surgeon who does not appreciate this characteristic and fails to plan his or her operative approach accordingly will not soon forget the operative experience.

My technique for safe resection of even very large carotid body tumors is based on several observations. First, the majority of the blood supply to carotid body tumors arises from a rich matrix of small vessels that surround the bifurcation in a periadventitial plane and originate mostly from small branches of the external carotid artery. Second, perhaps because of this blood supply pattern, very large carotid body tumors frequently completely encase the external carotid artery but only rarely do the same to the internal. Third, all but the very smallest tumors frequently distort the normal anatomy, and often displace important cranial nerves from their usual location. Last, it is critical to bear in mind the relative importance of the internal carotid circulation compared to the external and its branches.

Together, these observations have influenced an operative approach that combines isolation and protection of the internal carotid system with the safe and bloodless resection of these highly vascular lesions. To avoid several unnecessary complications during the resection, it is extremely important to minimize bleeding during the dissection. Excessive hemorrhage may persuade a less experienced surgeon to attempt ill-advised maneuvers to control the bleeding. These maneuvers are commonly the cause of postoperative cranial nerve injuries and strokes. Also, excessive bleeding can occasionally lead to unnecessary transfusions along with their well-known associated complications. Using the operative approach described later, I have not had to administer blood products to a patient undergoing resection of even the largest of carotid body tumors.

Preoperative Embolization

One technique that can aid in the management of very large and hypervascular carotid body tumors is preoperative selective arterial embolization. Using a percutaneous catheter technique, the external carotid artery is selectively catheterized. Thrombogenic particles, such as Gelfoam

(Pharmacia & Upjohn, Kalamazoo, MI) or coils, are introduced into the large nutrient vessels that feed the tumor. This technique has been shown to be effective and can greatly facilitate the resection of very vascular tumors that would otherwise have been difficult to approach safely. However, embolization only reduces tumor vascularity to a small extent—use of preoperative embolization may lead to a false sense of security for the less experienced surgeon. Reported series that include cases with and without embolization have failed to demonstrate any difference in operative blood loss. As mentioned previously, I have not found this technique to be necessary in the majority of patients and have serious concerns about its safety. There are case reports of stroke related to inadvertent embolization of the internal carotid artery. However, it is an available treatment adjunct and can be performed with relatively low morbidity by a sufficiently experienced individual.

Anesthesia

Local or general anesthesia can be used for this type of surgery. Local techniques usually include a regional cervical block in combination with direct skin infiltration of anesthetic agents. Regional cervical block is easily accomplished by infiltrating the cervical plexus with a mixture of 1% lidocaine (Xylocaine) and 0.5% bupivacaine hydrochloride (Marcaine). Rapid skin anesthesia with a prolonged duration can also be obtained by this combination. Subcutaneous injections, as well as deep injections along the posterior border of the sternocleidomastoid muscle to anesthetize the superficial nerves of the cervical plexus, complete the local block. Occasionally, additional injections within the carotid sheath may be required.

The advantages of local anesthesia are related to the avoidance of the cerebral and myocardial depressant effects of general anesthesia. The improved tolerance of the elderly or cardiac-impaired patient to local anesthesia allows for a safer operation in these high-risk individuals. Most surgeons, however, prefer general anesthesia for patients undergoing resection of carotid body tumors. It provides a more controlled operative setting, including excellent airway control and less movement in the operative field.

Cerebral Monitoring and Protection

Because reconstruction, or at least temporary occlusion, of the internal

carotid artery is occasionally necessary during resection of a carotid body tumor, I believe that some method of cerebral monitoring and protection should always be used during resection of these lesions. Several techniques are available to monitor cerebral perfusion during carotid surgery. These include measurement of distal internal carotid artery back pressure, continuous scalp-recorded electroencephalographic (EEG) monitoring, and direct observation and continuous assessment of the awake patient. In general, although a conscious patient is a sensitive intraoperative indicator of adequate cerebral blood flow, as was already mentioned, I prefer general anesthesia for operations on the carotid artery. At the University of California at Los Angeles, my practice has been to use brain-mapping technology in conjunction with continuous scalp-recorded EEG in all patients undergoing carotid surgery. This technique uses several scalp electrodes, normally placed over the distribution of the middle cerebral artery. The EEG is recorded continuously throughout the operation and represents the summation of cortical neuron postsynaptic potentials located beneath each electrode. The newer-generation machines equipped with brain-mapping capabilities use multiple electrodes and color output displays to divide each hemisphere into smaller monitoring parcels and therefore detect more focal abnormalities. Changes in the recorded EEG strongly correlate with alterations in cerebral blood flow. Cortical ischemia is detected by a reduction in the recorded wave amplitude or frequency. In those instances when carotid clamping produces measured cerebral ischemic changes, cerebral protection (using an internal carotid artery shunt) can then be used.

As was mentioned previously, an alternative method of determining when cerebral protection is necessary is the internal carotid artery back pressure measurement. Using this technique, the adequacy of collateral blood flow to the ipsilateral hemisphere during proximal artery occlusion is determined by measurement of the back pressure. A 22-gauge needle is bent 2 cm from the tip, to an angle of 45 degrees, and connected to an arterial pressure transducer. The needle is inserted into the common carotid artery, with the angulated tip lying longitudinally in the lumen and directed toward the bifurcation. First, an open carotid artery pressure is measured, and it should be compared to the peripheral radial artery catheter or cuff pressure to ensure that the carotid pressure transducer is functioning correctly. Then, with the external and proximal common carotid arteries temporarily occluded, the internal carotid artery back

pressure is recorded. Although no precise consensus has been reached, most authorities define the range of 30 to 50 mm Hg as the pressure below which cerebral protection is mandatory. If this is the case, the clamps on the external and proximal common carotid arteries are removed and preparations are made for use of an internal bypass shunt.

Whichever method of cerebral monitoring is used, once it is determined that cerebral perfusion is inadequate during carotid cross-clamping, the ipsilateral cerebral cortex must be protected by insertion of a temporary internal bypass shunt. Safe placement of a carotid artery shunt requires an appreciation of several principles. Most important, full exposure of all three major carotid vessels is mandatory. This allows complete proximal common carotid control and full appreciation of the distal extent of any concomitant atherosclerotic disease in the internal and external carotid arteries. With the internal and external carotid arteries controlled, the common carotid is occluded proximally with a soft clamp. The arteriotomy in the common carotid vessel should be placed comfortably away from the proximal extent of the tumor. The distal internal carotid is allowed to back bleed, and an internal shunt with an appropriate diameter is gently inserted. I prefer to use the Javid shunt; however, other types are available. The shunt is flushed, clamped, and subsequently inserted into the common carotid artery proximally. Snares (Rumel tourniquets) are used to secure the shunt, and the occluding clamp on the common carotid is removed. Thus, in the final configuration, the shunt is in place with only a single occluding clamp in its midportion. One should remove this clamp slowly, watching carefully for air or debris that may be visible through the proximal portion of the shunt. Once the shunt is in place and cerebral protection accomplished, attention can be directed toward resection of the tumor. If reconstruction of the internal carotid becomes necessary, it is possible to maintain cerebral perfusion at all times by interposing a graft over the shunt while it remains in situ. After completion of the procedure, the shunt is always clamped and removed, and the carotid vessels are flushed, beginning distally. The arteriotomy closure is then completed, with the vessels temporarily occluded. This technique is used for vascular operations on the carotid artery, but has limited application to patients with carotid body tumors since early control of the external carotid artery is not possible since the external carotid artery is usually surrounded by the tumor mass. An alternative technique involves the use of an internal shunt that uses inflatable balloons, proximally and distally, as an alternative to

external control with Rumel tourniquets. The shunt is first inserted into the common carotid artery that has been controlled proximal to the carotid bifurcation and the tumor mass. Using digital control of the distal common carotid artery, the shunt is first advanced into the internal carotid artery. The distal balloon is then inflated and the shunt is back-bled and clamped. The proximal shunt is then passed retrograde into the common carotid artery, the proximal balloon is inflated, and the clamp on the shunt is removed. This technique not only restores flow to the internal carotid artery, but effectively obstructs inflow to the external carotid artery. This technique can also be used to reduce the blood supply to the tumor since it effectively occludes the proximal external carotid artery.

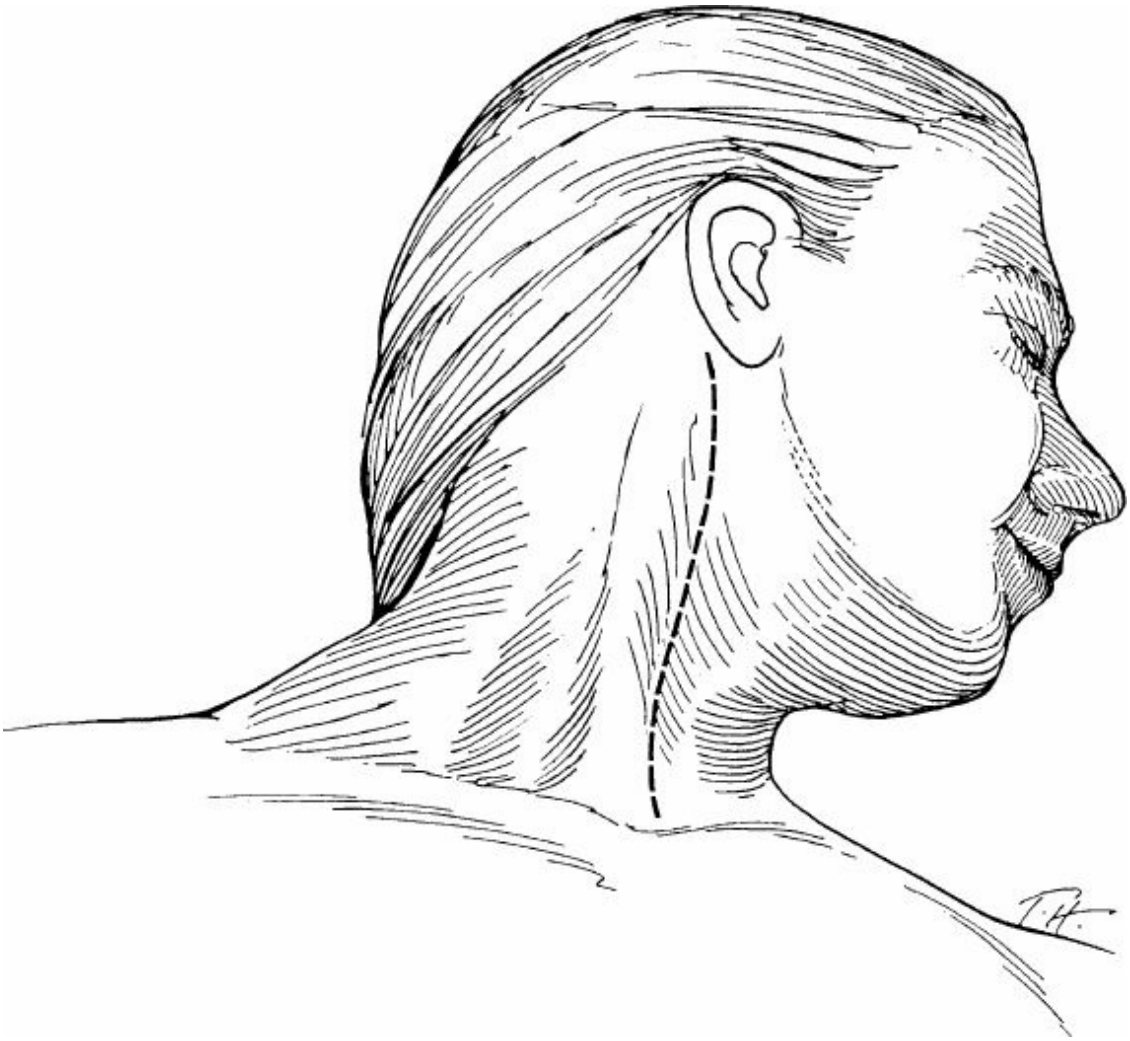

Figure 197.4. Location of the incision along the anterior border of the sternocleidomastoid muscle with the head rotated away from the operative side. For additional cephalad exposure, the incision can be curved posteriorly and extended across the mastoid process behind the ear.

Exposure

The patient should be positioned supine on the operating table and the head rotated away from the operative side. The head of the table is raised 10 to 15 degrees, which reduces venous pressure and minimizes incisional blood loss. Depending on individual differences in body habitus, the neck can be extended by the placement of a small towel roll beneath the shoulders.

A longitudinal incision is made that follows the anterior border of the sternocleidomastoid muscle (Fig. 197.4).

The approximate position of the carotid bifurcation can often be determined by palpation of the lesion or from preoperative diagnostic studies. Ideally, the incision should be centered longitudinally so that the bifurcation is below the midpoint. When necessary for additional exposure, this incision can be continued down to the sternal notch and cephalad to the mastoid process. The plane of dissection remains along the anterior border of the sternocleidomastoid until the belly of this muscle can be reflected off the carotid sheath. Often, the posterior tail of the parotid gland is encountered at this level, and further dissection is required. The gland should be mobilized and reflected anteriorly, rather than divided. Transecting the gland can cause excessive bleeding and occasionally lead to a salivary fistula. Once the carotid sheath is visualized, it should be opened along the anterior border of the jugular vein, which can usually be easily identified through the sheath. The jugular vein is mobilized completely and any large branches identified. The common facial vein is a broad-based tributary that commonly joins the jugular vein just above the carotid bifurcation. This vein provides a useful marker for the location of the carotid bifurcation and, once identified, should be divided between ligatures. Particularly in high bifurcations, the hypoglossal nerve can also be located deep to the facial vein, and care must be taken to avoid inadvertent injury to this structure.

After the facial vein is divided, the jugular vein can be reflected laterally, providing exposure of the carotid vessels (Fig. 197.5).

The vagus nerve, which is ordinarily posterior, can be located anywhere within the carotid sheath. Therefore, in each case, its course must be identified and protected to avoid injury. The laryngeal nerves, which are usually recurrent and therefore in the tracheoesophageal groove, may come off the vagus directly and cross anterior to the carotid artery near the bifurcation, where it enters the vocal musculature. When not recognized,

division of this nerve will lead to vocal cord paralysis. It should also be mentioned that, although this anomaly is more common on the left side, its presence has also been described on the right.

Once the sheath has been entered and all pertinent structures identified and protected, the common carotid artery is sufficiently mobilized proximally to allow complete delineation of the extent of disease and to provide sufficient length in case a bypass shunt is required. Once the common carotid artery is circumferentially mobilized in the perivascular plane of Leriche, dissection is continued on the lateral aspect of the internal carotid artery within that plane until the top of the tumor mass is reached at which point the distal internal carotid artery can be circumferentially mobilized. Dissection can then be continued on the medial aspect of the internal carotid artery in the same perivascular plane. This plane is often erroneously referred to as a subabvential plane in the literature. This incorrect reference has often led to inexperienced surgeons attempting to enter the plane between the adventitia and the media with disastrous arterial injury. Dissection continues down toward the bifurcation at which point the external carotid artery can be identified. In the case of small tumors, the external carotid artery can often be salvaged. In the case of large tumors, the external carotid artery should be divided and the proximal stump over sewn. By leaving a clamp on the tumor side of the external carotid artery, this will provide an excellent handle to begin to lift and dissect the tumor circumferentially from the surrounding tissues. The dissection should stay on the capsule of the tumor, and branches of the external carotid artery should be divided and ligated as the surgeon progresses distally. The 12th cranial nerve should be carefully identified and separated from the anterior surface of the tumor mass as it courses superficial to and oblique to the internal carotid artery. Once the posterior, lateral, and medial aspects of the tumor are freed from surrounding tissues, the superior extent is divided between ligature and the mass removed. Reflex bradycardia can occur during manipulation of the carotid bulb as a result of stimulation of the carotid body. This can be prevented, or reversed when necessary, by a local injection of an anesthetic agent to block the nerves that arise from the carotid body.

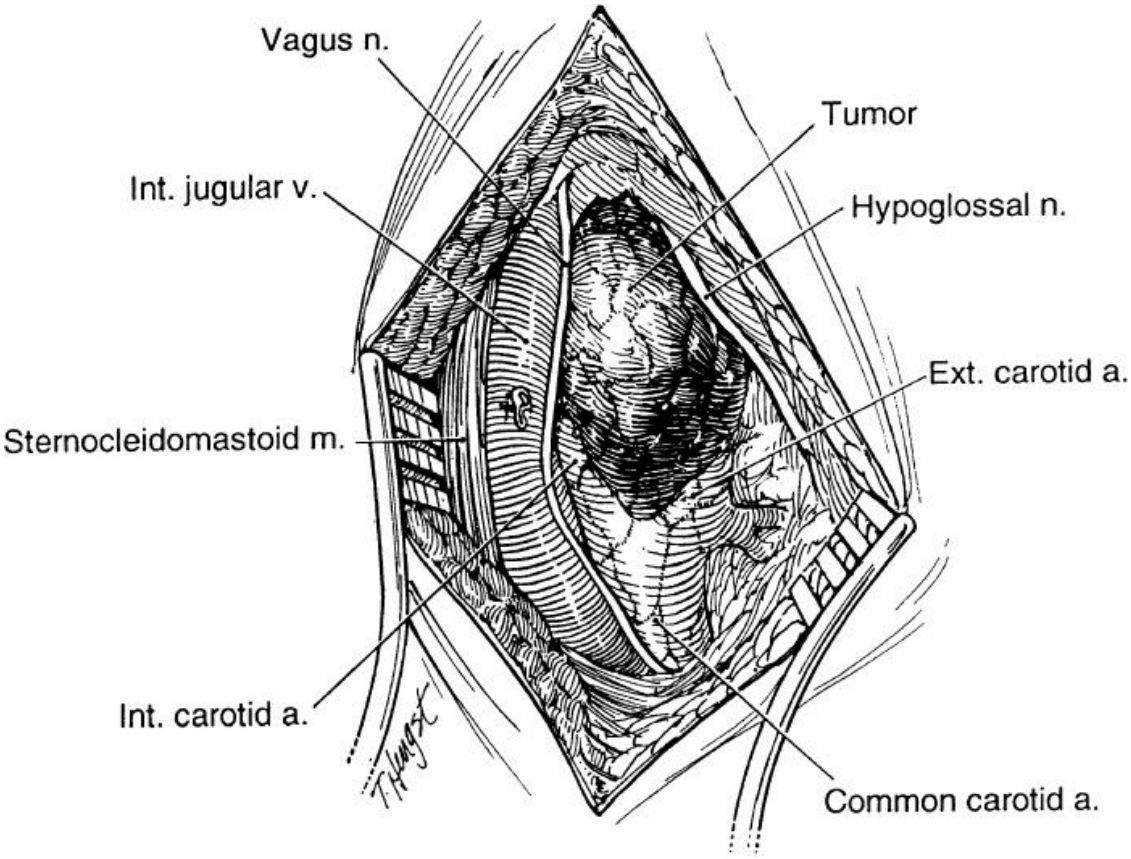

Figure 197.5. Diagram showing typical exposure after ligation and division of the common facial vein and lateral retraction of the sternocleidomastoid muscle and jugular vein.

Extended Exposure Techniques

When one encounters a very large tumor that extends up toward the base of the skull, or when a particular patient's carotid artery bifurcates high in the neck, it may be necessary to obtain additional exposure in the superior aspect of the incision. Several techniques have been described to increase exposure in this area, and surgeons performing carotid surgery should be familiar with these maneuvers. The simplest and most important technique is to extend the skin incision completely across the mastoid process behind the ear. This allows additional mobilization of the sternocleidomastoid muscle up to its tendinous insertion. The spinal accessory nerve enters the muscle at this level and must be preserved. When additional exposure is necessary, the posterior belly of the digastric muscle can be detached from its origin or divided. The digastric muscle consists of two muscle bellies united by a rounded tendon. The posterior belly arises from the mastoid process, and the anterior portion inserts on the mandibular symphysis. It is helpful to appreciate the superficial anatomic position of the posterior

digastric muscle when dissecting in this area. All important neurovascular structures lie deep to the digastric at this level. Only the external jugular vein and branches of the facial and great auricular nerves pass superficial to the posterior belly of the digastric. Below the muscle, particular care must be taken to avoid injury to the hypoglossal and spinal accessory nerves, as well as the facial branch of the external carotid artery. In addition, it should be mentioned that the stylohyoid muscle can also be divided. This muscle stretches between the styloid process and the hyoid bone, and its removal, along with that of the styloid process, can provide additional exposure of the distal internal carotid artery at the base of the skull. When the tumor extends very high, it is possible to gain additional exposure by anteriorly subluxating the condylar process of the mandible. The displaced mandible can be secured in place with inter-dental wires. This maneuver alters the geometry at the base of the skull by turning a triangular space into a rectangle, thereby enlarging the operative field. Lastly, techniques by which the ramus of the mandible is divided have also been described. This is an involved procedure that greatly complicates the postoperative course of these patients. In my experience, I have never found this maneuver necessary.

Resection of the Tumor

After completion of the exposure, the initial dissection is directed toward the proximal common and distal carotid branches, staying away initially from the area of the carotid bifurcation (Fig. 197.6). Control of the common and internal carotid arteries should be obtained before dissection of the tumor. Small tumors can be approached directly, and a periadventitial dissection plane can usually be developed. However, as was mentioned earlier, these lesions are typically extremely vascular and, especially in large adherent tumors, the correct plane for safe dissection is often difficult to locate adjacent to the bifurcation. Therefore, I suggest placing a vessel loop on the proximal common carotid artery, as well as on both the internal and external carotid vessels distal to the tumor, before beginning the resection. My first concern during the dissection is to resect the tumor away from the internal branch of the carotid artery and preserve normal intracranial perfusion. Thus, after control has been achieved with vessel loops, the extensive periadventitial matrix of small vessels is ligated with fine suture, beginning at a convenient spot along the common carotid proximal to the lesion.

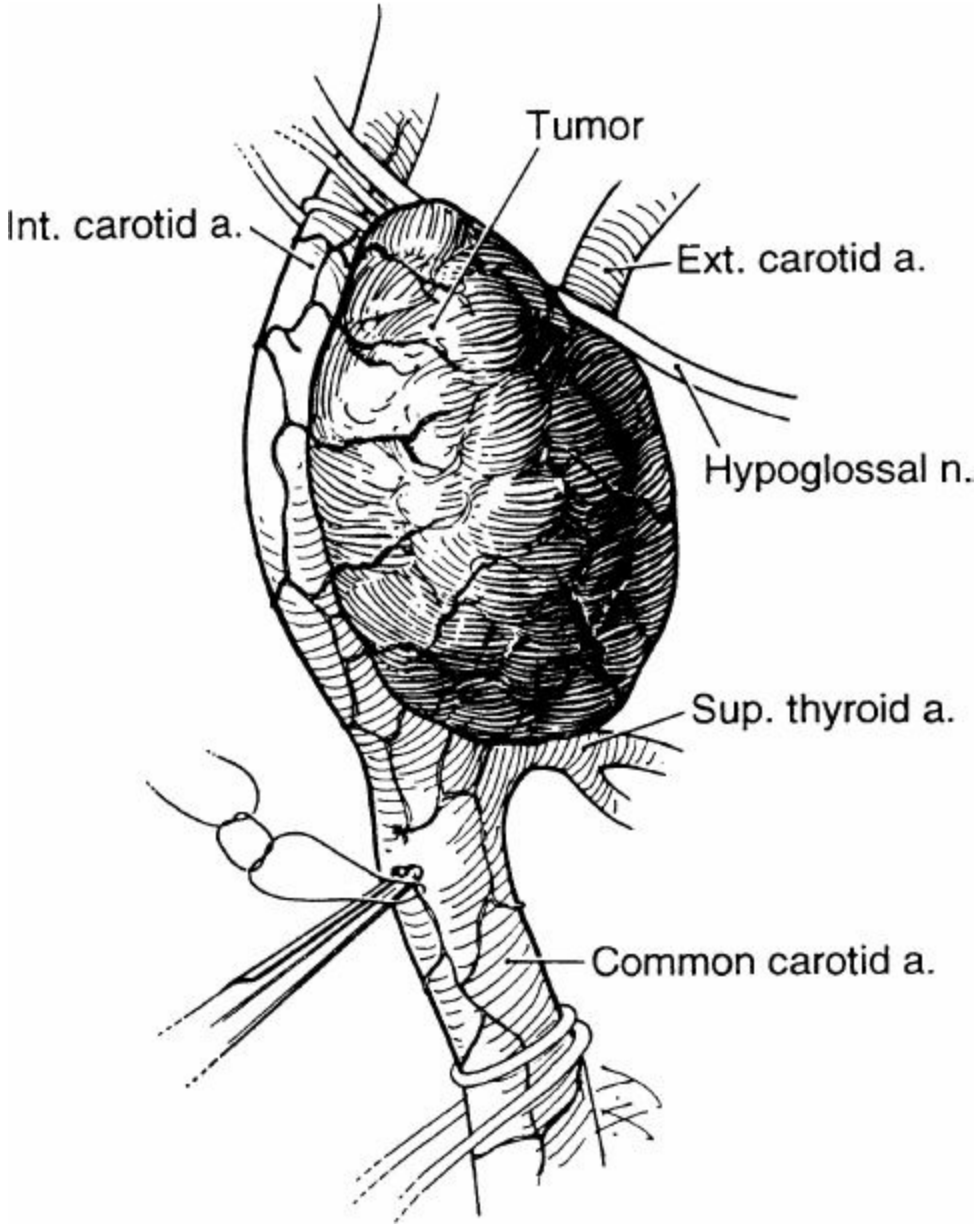

Figure 197.6. After obtaining proximal and distal control with vessel loops, the extensive periadventitial matrix of small tumor feeding vessels is ligated with fine suture, beginning along the proximal common carotid artery in an area located 180 degrees opposite the takeoff of the external carotid.

This dissection is continued distally, following the course of the internal carotid artery along a longitudinal plane located 180 degrees opposite the takeoff of the external carotid branch (Fig. 197.7).

Because carotid body tumors frequently grow around the external carotid while pushing away the internal, beginning the dissection in a plane opposite the origin of the external is the safest technique for isolating and separating the tumor from the cerebral circulation. Once the

periadventitial vessels have all been divided to a point beyond the distal extent of the tumor, the dissection is directed proximally toward the bifurcation along the inner surface of the internal carotid (Fig. 197.8). At this point, the tumor is carefully separated from the bifurcation. Nutrient vessels supplying the tumor are often encountered in this location and should be ligated. When the tumor is large or particularly adherent, division of the origin of the external carotid artery can be a useful maneuver. This allows rotational mobilization of the lesion and, because feeding vessels often arise from branches of the external carotid, can reduce blood loss (Fig. 197.9). Otherwise, it is usually possible to meticulously dissect the carotid body tumor away from the external carotid and its branches, ligating each nutrient tumor vessel as it is encountered (Fig. 197.10). Rarely, resection of the tumor cannot be accomplished without complete removal of the carotid bifurcation. This situation is almost always indicative of malignancy. When necessary, vascular reconstruction can be accomplished by the placement of an interposition graft. I prefer to repair the carotid using a prosthetic PTFE interposition graft. Others have advocated the use of autologous vein for the repair.

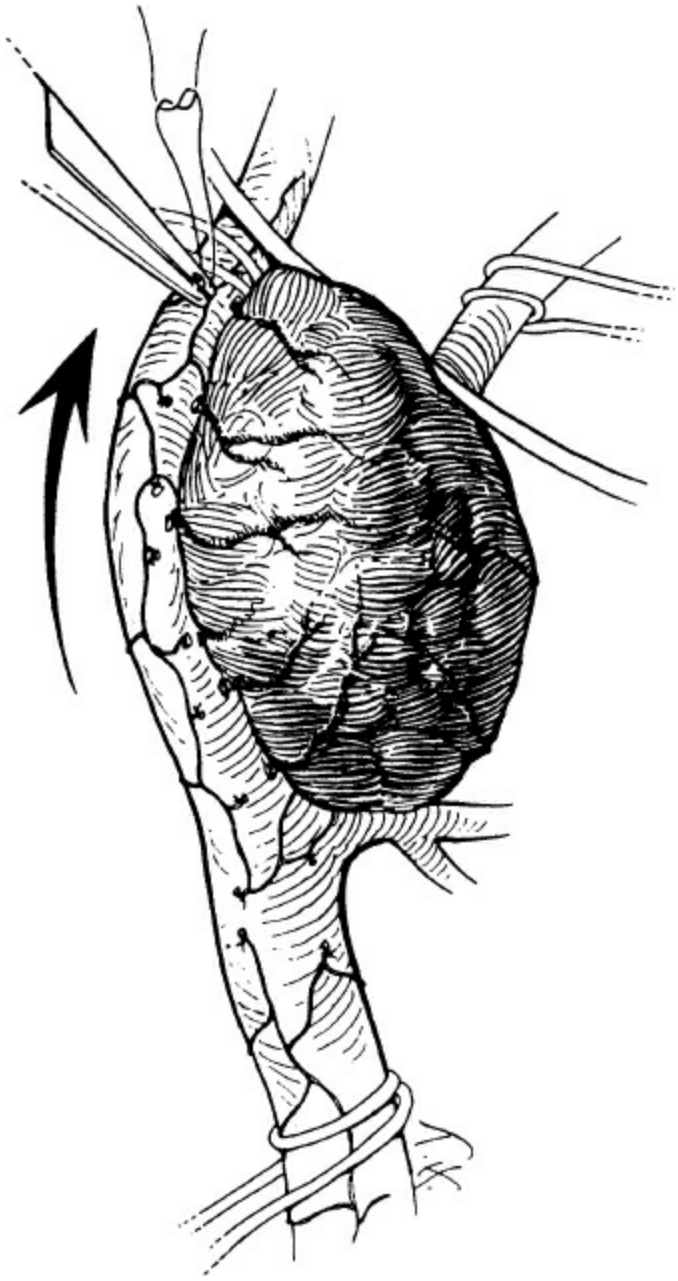

Figure 197.7. The dissection is continued cephalad, following the course of the internal carotid artery (*arrow*), again staying in a periadventitial longitudinal plane located 180 degrees opposite the origin of the external carotid artery.

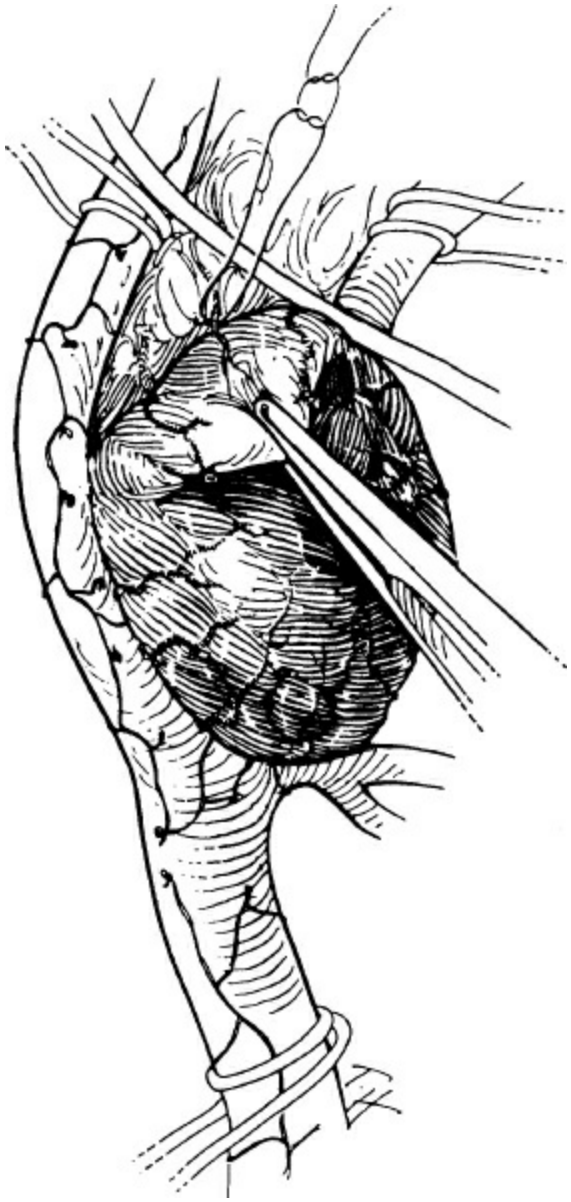

Figure 197.8. Once the tumor feeding vessels located along the internal carotid have been divided to a point beyond the distal extent of the tumor, the dissection is continued proximally toward the bifurcation along the inner surface of the internal carotid.

On occasion, the vagus nerve can be surrounded by or pass through the tumor mass. In the past, I felt obliged to divide the nerve in order maintain the integrity of the tumor mass. This will lead to vocal cord palsy usually requiring collagen injection of the cord to improve phonation. More recently, and in recognition of the benign nature of the tumor, I have been able to split the tumor to allow freeing and preservation of vagus nerve integrity. It is best to delay this maneuver until the tumor mass is fully mobilized and all branches of the external carotid artery are divided in order to minimize bleeding. Sometimes it is necessary to carry out this

maneuver in order to proceed with tumor mobilization. In this instance, the use of bipolar forceps to incise the tumor is helpful in reducing blood loss.

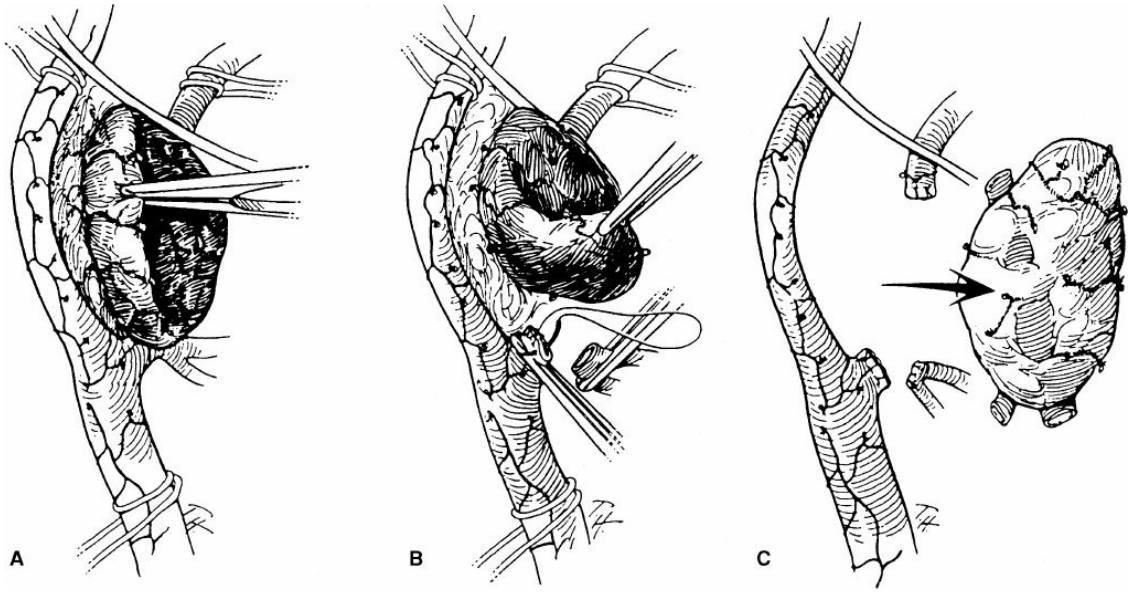

Figure 197.9. When the tumor is very large or particularly adherent, division of the origin of the external carotid artery can be a useful maneuver. After detachment of the tumor from the internal carotid artery, the tumor is carefully separated from the bifurcation (**A**). Next, the origin of the external carotid is clamped and divided (**B**). This allows rotational mobilization of the lesion and ligation of nutrient tumor vessels, which are often encountered posteriorly in this location. Finally, division of the superior thyroid and distal external carotid artery (or its branches) allows for the safe removal of the carotid body lesion (**C**). *Arrow* indicates tumor.

Wound Closure

Closure of the incision after a carotid body tumor resection should be meticulous and should adhere to all of the basic principles of surgery. The wound should be irrigated generously with warm saline solution and perfect hemostasis ensured. The platysma is reapproximated with a running suture, and the skin is closed with either subcuticular sutures or stainless steel staples. I only rarely place a drain, but, should this option be selected, it should be a closed suction drain system that is placed beneath the platysmal layer and brought out through a separate stab wound. Last, a sterile dressing is applied and the patient observed carefully while awakening from anesthesia.

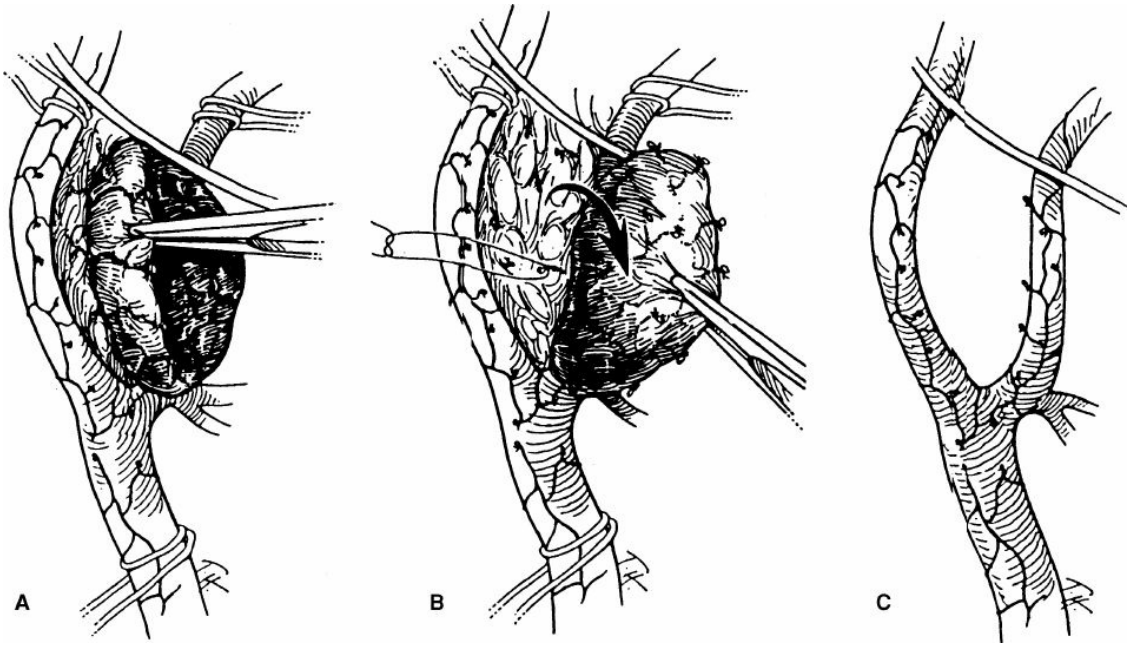

Figure 197.10. Alternatively, with careful dissection, it is frequently possible to remove the carotid body tumor without sacrificing the external carotid artery or any of its main branches. Once again, the tumor is carefully separated from the bifurcation (**A**). Again, by rotating the lesion along the axis of the external carotid, nutrient vessels supplying the tumor posteriorly can usually be ligated easily (**B**). Finally, the carotid body tumor is meticulously dissected free, leaving the carotid bifurcation intact (**C**).

POSTOPERATIVE MANAGEMENT

Immediately after the patient awakens from anesthesia, a preliminary neurologic assessment should be made. Subsequently, the patient is transferred to the recovery room. Particular attention should be made to frequently assess the systemic blood pressure and neurologic function during this period. In addition, careful wound observation is essential to detect the formation of a hematoma, which can threaten the patient's airway. I seldom find it necessary to use an intensive care unit for these patients. After 24 hours, the closed suction drain, if placed, can be removed and the patient considered for hospital discharge. Most patients undergoing carotid surgery are admitted to the hospital the morning of operation and are discharged home on the first or second postoperative day.

RADIATION THERAPY

For completeness, a comment regarding the use of radiation therapy, either as an adjunct or as a primary therapeutic option in the treatment of carotid body tumors, is appropriate. Traditionally, the statement has been made that cervical paragangliomas are not radiosensitive lesions. Very few clinicians have acquired sufficient experience to make sound conclusions regarding the efficacy of this treatment modality in this setting. Most often, radiation is reserved for bulky, inoperable, or recurrent tumors, which may account for the disappointing reported results. There are, in fact, a number of sporadic reports indicating successful control of carotid body tumors by radiotherapy. Long-term follow-up for most of these anecdotal cases is currently not available. I admit little experience with this method of treating these tumors and prefer surgical excision due to its safety and excellent documented long-term success. I acknowledge, however, that in poor surgical candidates with aggressive symptomatic lesions, radiotherapy may have a role in the management of carotid body tumors. This form of treatment requires further investigation.

COMPLICATIONS

An uncomplicated resection of a carotid body tumor is an extremely well-tolerated operation. The tissue trauma and operative blood loss are normally minimal, and patients are routinely discharged from the hospital on the second or third postoperative day. For this reason, perioperative complications are particularly discouraging and must be avoided at all costs. Operative intervention, particularly in the setting of a histologically benign neoplasm, continues to be justified only by keeping the operative morbidity and mortality of the procedure to a minimum.

Technical errors that occur during any operative procedure are preventable. As mentioned earlier, one major cause of technical complications occurring during the resection of carotid body tumors is inadequate hemostasis. Clamping of incompletely identified structures or the temporary occlusion of major cerebrovascular vessels can lead to cranial nerve or neurologic injuries.

As described previously in the Exposure and Extended Exposure Techniques sections, several peripheral nerves must be identified and protected during exposure of the carotid bifurcation. The frequency of injury to these structures is difficult to quantitate, but it is probably in the range of 1% to 15%. This difference is due at least in part to the variable expertise of the individual making the assessment. It must also be

remembered that many cranial nerve deficits are related to tumor involvement and not caused intraoperatively. Once again, the importance of carefully examining the function of these structures preoperatively cannot be overemphasized. Nonetheless, at least half of all postoperative cranial nerve injuries go unnoticed by the surgeon and the patient. The remainder of injuries is usually either very obvious or otherwise identified only after a detailed examination. Most of these injuries are not permanent. It should be acknowledged, however, that all cranial nerve injuries that occur during carotid surgery could be prevented if surgeons became familiar with the normal and possible abnormal anatomic neurovascular relationships and carefully protected these structures during the procedure.

RESULTS

Results after resections for carotid body tumors are excellent. However, this has not always been the case. Early series from the 1950s consistently reported a mortality of 5% to 15% of patients, cranial nerve injuries in 30% to 40% of patients, and significant cerebrovascular complications in as many as 10% to 20% of patients. Advances in preoperative diagnosis and localization, intraoperative anesthetic and surgical management, and postoperative care have all contributed to a significant decrease in these complication rates. Today, in experienced hands, a perioperative mortality of less than 0.5%, essentially no significant cerebrovascular sequelae, and a cranial nerve injury or other minor complication rate of no higher than 5% can be expected.

EDITOR'S COMMENT

This chapter on carotid body tumor (CBT) resection by Dr. Moore remains rather timeless as we have not yet found a way to manage this disease process less invasively. While in general we have moved away from large incisions to smaller incisions, one of the remaining principles in dealing with CBTs is wide exposure. Most vascular surgeons will see one or two CBTs a year and treating them can be very satisfying when the resection goes well.

There are a couple of points to make specifically about technically managing CBTs. First, I learned the utility and necessity of a bipolar cautery from Drs. Jim Stanley and Ramon Berguer. This instrument alone as far as I can tell has helped to revolutionize the resection of these tumors and has really sped up resection times. Using the bipolar cautery also likely has helped to decrease the

blood loss during resection. While I have had to divide the external carotid artery before to get one of these out, I have never had to resect the internal carotid artery. Yet, I still as Dr. Moore suggests always use some sort of cerebral monitoring on these cases. Finally, just specifically in terms of anesthetic techniques, I would personally never do one of these under regional anesthesia unless the patient was a pulmonary or cardiac cripple (and then I would consider radiation). Given the complexity of the surgery, I prefer to put the patients to sleep and nasotracheally intubate them.

There is literature out there on whether these tumors should be embolized preoperatively or not. A recent meta-analysis using the Medline database from 1967 to 2013 used 60 studies to attempt to answer the question of whether embolizing these tumors preoperatively was necessary or better (Economopoulous KP, Tzani A, Reifsnyder T. Adjunct endovascular interventions in carotid body tumors. *J Vasc Surg* 2015;61:1081–91). The authors found no randomized, controlled trials examining the subject, but reported on 465 patients with a mean age of 39.8 years. Their review concluded that preoperative selective endovascular embolization in Shamblin II and III tumors "may be beneficial." For the most part, I agree with Dr. Moore that large tumors get embolized, while small ones do not. Dr. Moore suggests the use of Gel foam slurries or coils when these tumors are embolized preoperatively and that has been our practice. Some have performed embolization of these tumors with Onyx (ethylene vinyl alcohol), a material often used to treat endoleaks in patients with endovascular aortic aneurysm repairs, either preoperative or palliatively. This would seem to be attractive as Onyx seeks blood before hardening and might provide a more radical embolization of these tumors. However, in one case series this resulted in a more difficult surgical resection in 50% of cases and the authors concluded that "preoperative Onyx embolization of CBPs is not recommended" (Michelozzi C, Januel AC, Cuvinciuc V, et al. Arterial embolization with Onyx of head and neck paragangliomas. *J Neurointervent Surg* 2015; May 2 [Epub ahead of print]).

The link between the role of the carotid body and its function in elevating blood pressure, especially in patients with essential hypertension, has been examined and is intriguing. Fudim and coauthors performed a retrospective analysis of 20 hypertensive patients who had undergone CBT resection. Their results documented that both short- and long-term blood pressure was significantly lower following CBT resection (Fudim M, Groom KL, Laffer CL, et al. Effects of carotid body tumor resection on the blood pressure of essential hypertensive patients. *J Am Soc Hypertens* 2015;9(6):435–42). This observation lends some credence to the idea of using carotid body stimulators (and obliteration!) to control blood pressure in patients with essential hypertension, even though this is by no means direct evidence or an endorsement for carotid body stimulation techniques.

Finally, many of these tumors are found in families and are clearly associated with genetic mutations. Some may even be secretory. A recent review of the

literature suggests that approximately 30% of all CBTs are associated with various tumor syndromes. Three syndromes have been described as PGL1, 3, and 4. They are all related to mutations in the succinate dehydrogenase (SDH) gene. Importantly, based on the data on these rare genetic cohorts, SDHD and SDHB account for over 70% of head and neck paragangliomas with a positive family history, but also less than 8% without a positive family history. A certain percentage of these tumors can also secrete catecholamines. This suggests that there is a role, yet undefined, for having these patients seen by an endocrinologist when hypertensive or by a genetics counselor when familial.

B ANEURYSMAL DISEASE

198 Open Thoracoabdominal Aortic Aneurysm Repair

Mark F. Conrad and Richard P. Cambria

INTRODUCTION

Aneurysms that simultaneously involve the thoracic and abdominal aorta, and/or those aneurysms including the visceral aortic segment are referred to as thoracoabdominal aortic aneurysms (TAA). Such aneurysms are uncommon when compared to isolated infrarenal aneurysms and comprise no more than 2% to 5% of the total spectrum of degenerative aortic aneurysms. The most recent natural history studies looking at patients with TAA show that up to 30% of said patients will also have an abdominal aortic aneurysm (AAA) in their lifetime. The modern era in the surgical management of TAA began with the pioneering work of E. Stanley Crawford who described a simplified operative approach to these lesions that involved the reconstruction of the aneurysmal aorta with direct anastomoses of the aortic origin of visceral and intercostal vessels to the main Dacron graft. This approach inherently leads to some degree of ischemia to the spinal cord, visceral vessels, and lower extremities with the potential for significant morbidity from end organ damage. Indeed, a number of surgical and nonsurgical adjuncts (many discussed herein) intended to minimize distal ischemia and improve outcomes have been investigated, and our approach to these complex aneurysms has evolved over time. Despite improvements in operative strategies, open repair of TAA still carries a 5% to 10% risk of perioperative morbidity and mortality in the form of renal, respiratory, and spinal cord ischemic complications. Endovascular repair of TAA using modular grafts with branched and fenestrated technologies is continuing to gain favor especially in patients who are high risk for open repair but issues of long-term durability and a high rate of spinal cord ischemia need to be

addressed before it will supplant open repair as the standard of care.

ETIOLOGY

Aneurysms of the descending thoracic aorta develop through a complex process involving a combination of genetic and environmental factors. The majority of thoracic aortic aneurysms are degenerative in nature, and indistinguishable on either gross or microscopic pathology from the more typically encountered AAA. However, genetic predisposition remains an important etiologic factor as 20% to 30% of aortic aneurysm patients have a first-order relative with the disease. While there continues to be debate over whether aneurysmal degeneration is a sequela of atherosclerosis or a primary connective tissue weakness, recent studies have shown that although there is significant overlap between the two populations, the propensity to develop weakening of the adventitia and media seen with aneurysmal disease is certainly different from the intimal proliferative process associated with atherosclerosis. Indeed, both processes can diminish aortic compliance and wall tensile strength resulting in aneurysm formation such that the terms “atherosclerotic” and “degenerative” are used interchangeably when applied to aortic aneurysms.

The second most common etiology of TAA (around 20% in most series) is as a late complication of chronic aortic dissection. Of patients experiencing acute aortic dissection, 25% to 40% will develop chronic aneurysmal dilatation of the outer wall of the false lumen that renders them susceptible to late aneurysm rupture and death. Other causes of TAA are less common. Aneurysms secondary to the sequelae of giant cell arteritis are typically seen in women and can result from either Takayasu disease, the nonspecific variety of giant cell aortitis, or there may be no known prior diagnosis of collagen vascular disease. A TAA secondary to an infectious process presents challenging management issues because the dual goals of eradication of sepsis and arterial reconstruction typically demand an in situ type of reconstruction, i.e., placement of a prosthetic graft in a contaminated field. In contemporary practice, the pathogenesis of these lesions is usually hematogenous seeding of atherosclerotic plaque that leads to the development of focal aortitis and dissolution of the aortic wall resulting in the formation of a false aneurysm. Such aneurysms are, in fact, contained aortic ruptures.

Patients with Marfan syndrome may have true cystic medial necrosis, a rare pathology that predisposes the thoracic aorta to aneurysmal

degeneration and dissection. Marfan syndrome is an autosomal dominant, inherited mutation of the fibrillin-1 gene, a structural protein that is the major component of the microfibrils that form elastin. Such mutations lead to a decrease in the amount of elastin in the aortic wall and the deposition of disarrayed microfibrillar connective tissue precipitating subsequent aortic degeneration. The frequency of the various etiologies of TAA is as follows: 80% are degenerative, 15% to 20% the sequelae of chronic dissection (including 5% of patients with Marfan syndrome), 2% related to infection, and 1% to 2% are the sequelae of previous aortitis.

CLASSIFICATION AND NATURAL HISTORY

Anatomy

TAA are classified according to the scheme originally devised by Crawford, which in the most basic terms considers whether the lesion is primarily a caudal extension of a descending thoracic aneurysm or a cephalad extension of a total AAA (Fig. 198.1). This classification is especially useful in patients requiring operative repair since it has direct implications for both the technical conduct of operation and the incidence of operative complications; in particular, ischemic spinal cord injury (SCI). There is considerable variation in the operative approach required to manage different TAA lesions. For example, a type IV TAA can be repaired with the clamp-and-sew approach and should be accomplished with an expected morbidity and mortality that is similar to that of an open AAA repair. But, the same cannot be said for the more extensive type II TAA lesions where the entire descending thoracic aorta is involved and repair is accomplished using distal aortic perfusion with atrial femoral bypass.

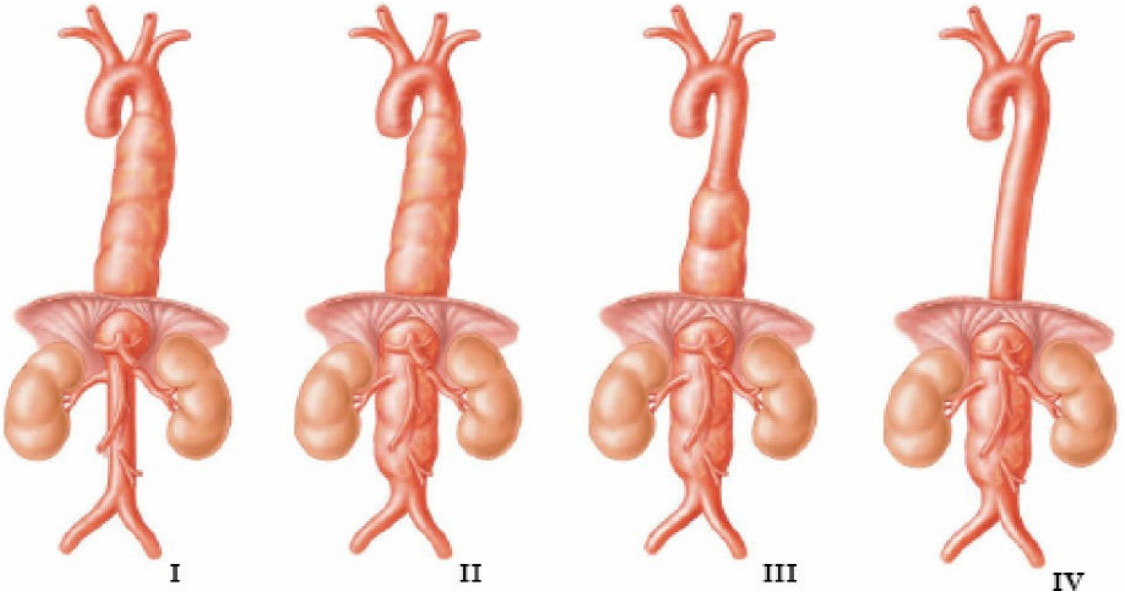

Figure 198.1. Crawford classification of the extent of thoracoabdominal aortic aneurysms.

Natural History

The expected natural history of TAA is progressive enlargement and eventual rupture regardless of etiology or location. Since thoracic aneurysms are uncommon when compared to AAA, fewer natural history studies are available. A recent longitudinal study found that the mean rate of growth for TAA is 0.2 cm per year. This is accelerated in patients with dissections and connective tissue disorders such as Marfan syndrome. The size of the aorta at initial diagnosis has been shown to be an important predictor of future dilation, but there still remains substantial variation in individual aneurysm growth rates making prediction of future aortic size difficult. Population-based studies place the incidence of TAA at 5 to 6 per 100,000 people with a 5-year actuarial survival of 13% if left untreated and aneurysm rupture identified as the cause of death in nearly 75% of untreated patients. Factors associated with increased risk of rupture include increasing aneurysm diameter, an increased rate of expansion, the presence of chronic obstructive pulmonary disease (COPD), steroid use, female gender, advanced age, and the presence of renal insufficiency. Contemporary series indicate that the rupture risk is negligible in TAA <5 cm, equivalent to the risk of surgical morbidity in the 5- to 6-cm range, and increases substantially at aneurysm diameters larger than 6 cm and/or growth rates of ≥10 mm per year. To wit, 6 cm is the surgical threshold for consideration of intervention in patients with degenerative TAA. For patients with TAA secondary to chronic dissection and/or those with

Marfan syndrome, a 5-cm threshold is often used.

CLINICAL PRESENTATION AND PREOPERATIVE EVALUATION

Clinical Presentation

Although patients commonly present in an asymptomatic fashion with incidental detection during radiologic surveillance for other causes, symptoms referable to TAA do occur and should be evaluated in a timely manner. In addition to the acute onset of severe pain, which may be associated with aneurysm expansion, rupture, and/or acute dissection, large thoracic aneurysms may produce symptoms of back, epigastric, or flank pain related either to compression of local structures or chronic inflammatory changes of the mediastinal pleura. Unlike AAA where back pain usually indicates an acute event, the pain associated with thoracic aneurysms may be atypical or chronic in nature and the presence of even uncharacteristic pain is an independent risk factor of rupture and should be taken seriously. When the aneurysm erodes into the thoracolumbar spine or chest wall, complaints of chest and back pain can be prominent and again may be present for weeks or even months. In severe cases, such complaints are often related to a chronic state of contained aneurysm rupture. The new onset of hoarseness can be related to a left recurrent laryngeal nerve palsy, while compression or erosion of the tracheobronchial tree or pulmonary parenchyma will produce a chronic cough, hemoptysis, dyspnea, or dysphasia lusoria. Perhaps related to reluctance to recommend operation because of the threat of surgical morbidity, up to 40% of thoracic aortic aneurysm patients will present with symptoms. This explains the higher incidence of patients treated for rupture when compared to AAA series. Our results are consistent with those available from a review of the literature indicating that some 25% of patients will be treated under urgent or emergent circumstances with approximately half of these presenting with a frank rupture. Unfortunately, we and others have demonstrated that such nonelective operations are associated with a significant increase in morbidity.

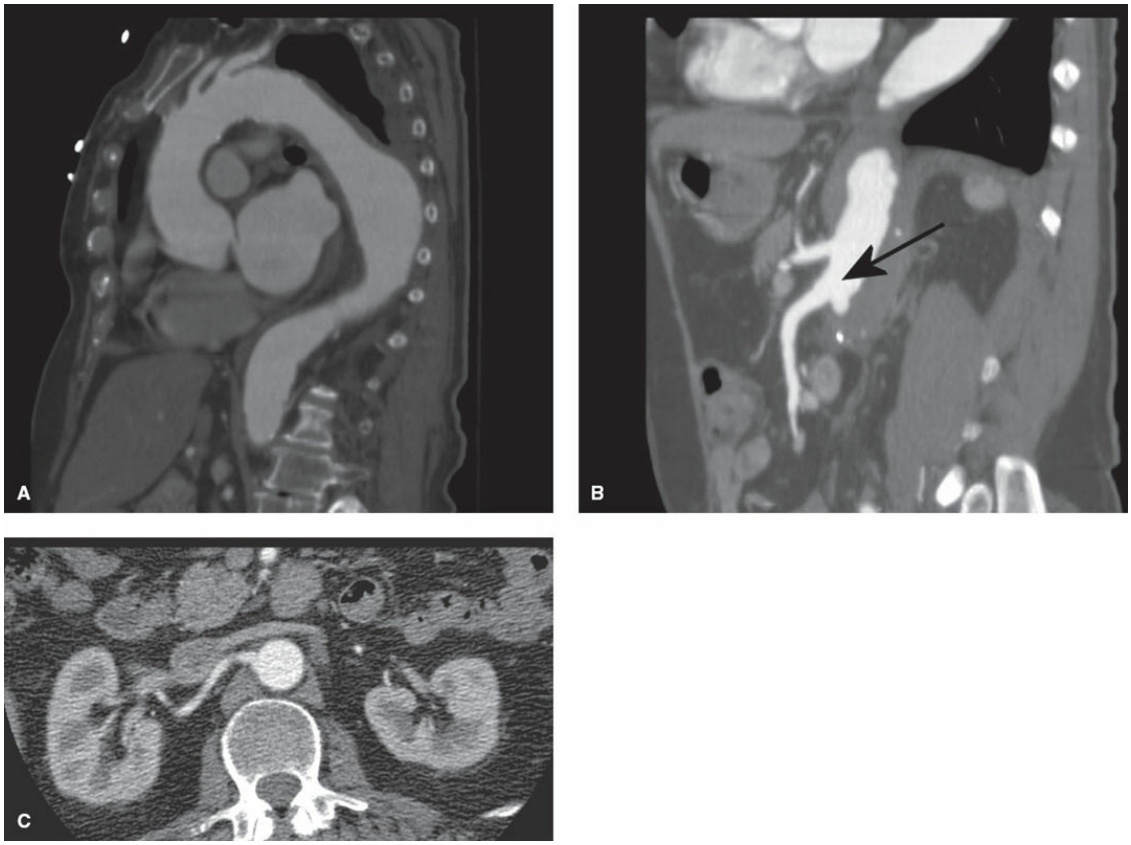

Figure 198.2. Helical CT with reconstruction is the only imaging study required in the majority of cases. It provides evaluation of aortic quality, luminal thrombus (**A**), aortic and branch topography (**B**, *arrow* pointing to patent SMA), renovisceral patency (**C**), and aortic cross-clamp site or proximal and distal seal zones depending on the planned method of repair.

Diagnostic Imaging

Several characteristic findings of thoracic aneurysmal disease seen on a plain chest x-ray include widening of the mediastinal silhouette, enlargement of the aortic knob, and tracheal deviation. Although thoracic aortic aneurysms are often evident on chest x-ray, it is difficult to differentiate between normal thoracic aortic tortuosity associated with advancing age (usually identified as an “ectatic aorta” by radiologists) and actual aneurysmal dilatation. Consequently, it is important to have a low threshold for obtaining more detailed imaging when findings associated with aortic pathology are encountered on plain film.

Accurate and complete radiographic evaluation is essential for precise operative planning with no equivocation in the surgeon’s mind as to the proximal and distal extent of aortic resection. In contemporary practice, a dynamic, fine-cut, contrast-enhanced computed tomography (CT)

angiogram with or without helical reconstruction (Fig. 198.2) provides the physician with the following information:

1. The proposed location of and a qualitative assessment of the aorta in the region of the proximal cross-clamp.
2. The assessment of patency of the visceral vessels.
3. The topography and location of the renal artery origins as well as kidney size and adequacy of perfusion.
4. The distal extent of the resection.
5. Aneurysmal status of the iliac vessels and possible occlusive disease in the pelvis (important if retrograde transfemoral aortic perfusion is to be used).

Accurate assessment of the size of thoracic aortic aneurysms is contingent upon measurement in the appropriate perpendicular plane. When imaging a tortuous aorta or evaluating sections through the aortic arch or lower descending aorta, it is important to understand that individual axial images may section the aorta in a plane that is off axis (Fig. 198.3). Such measurements result in an erroneous overestimation of aortic diameter, and underscore the importance of personally viewing CT scans prior to initiation of therapy. One way to avoid this error is through three-dimensional reconstruction of the thoracic aorta with determination of the centerline of axis that ensures that any cross-sectional measurement will be perpendicular to the aortic axis. The quality of current CT scanners with three-dimensional reconstruction is exceptional, and in our practice, this has become the image modality of choice for the evaluation and treatment of thoracic aortic aneurysms.

PATIENT SELECTION AND PREOPERATIVE EVALUATION

Since the majority of patients seen in consideration for TAA resection are those with degenerative aneurysms, demographic and clinical features typical of a patient population with diffuse atherosclerosis are the rule. Patients treated for degenerative aneurysms average 70 years in age, and a history of hypertension is nearly universal. Cigarette smoking and/or significant COPD are frequently encountered with 25% of patients having significant COPD with an FEV_1 of <50% predicted. Cerebrovascular disease, prior stroke, and symptomatic manifestations of lower extremity arterial occlusive disease occur in 15% of patients. Associated visceral

and/or renovascular occlusive disease occur to some degree in 30% of patients. Such lesions have direct implications for the technical conduct of the operation and the risk of postoperative renal insufficiency. The coexistence of renovascular disease and some degree of renal insufficiency is commonplace in TAA patients and has important implications for accurate assessment of perioperative risk and long-term preservation of renal function. Because the majority of TAA present with involvement of the entire visceral aortic segment, occlusive lesions of the mesenteric and renal arteries or total ostial occlusion of one or more of these vessels frequently accompanies aneurysmal dilation of this region of the aorta. Accordingly, we believe extreme levels of preoperative azotemia (serum creatinine >2.5 cm/dL) constitute a relative contraindication to elective operation unless preoperative studies indicate some potential for salvage or retrieval of renal function with renal artery reconstruction. In many series, the presence of an abnormal preoperative serum creatinine is at least a univariate correlate of perioperative mortality. Indeed, assessment of renal function and associated renovascular disease is an important component of patient evaluation and choice of therapy.

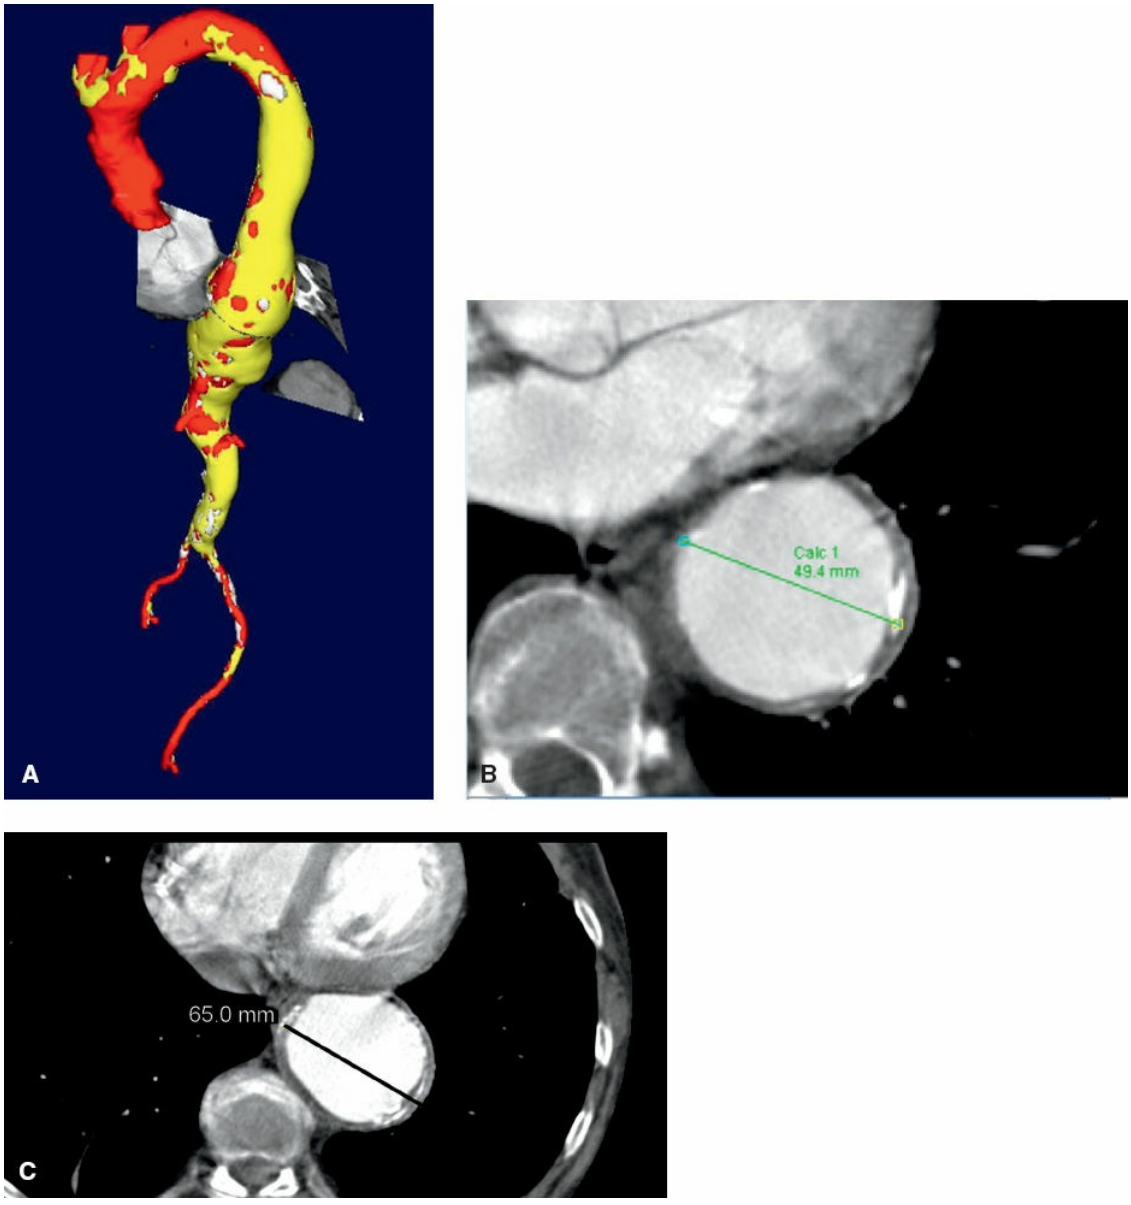

Figure 198.3. Helical CT with reconstruction showing the variation of aortic measurement with changes in axial plane. **A.** 3D reconstruction showing adjusted axial plane to ensure diameter measurement along the centerline axis. **B.** Axial image along plane in 5A yields diameter of 4.9 cm. **C.** Axial image at same level with traditional CT plane overestimates aortic diameter by 1.6 cm.

CARDIAC AND PULMONARY RISK STRATIFICATION

Despite the firm literature base against routine preoperative cardiac testing, all patients should be evaluated with physiologic testing to assess perioperative myocardial ischemic potential. In addition, patients with a history or symptoms suggestive of heart failure should have an assessment of left ventricular function. While patients with significant impairments of

pulmonary reserve can usually be detected on a historical basis alone, we routinely obtain preoperative pulmonary function studies. Preoperative consultation with a pulmonologist for optimization of bronchodilator therapy and pulmonary toilet is an important component in the management of patients with significant COPD. However, institution of preoperative steroid therapy with the intent of improving respiratory function is contraindicated since we have observed this maneuver to precipitate aneurysm rupture. Advanced age is an important component only in as much as it is accompanied by overall fragility and impaired functional status.

SURGICAL TREATMENT

Treatment Options

Graft replacement by direct surgical approach is the current standard of care for TAA. Total endovascular repair continues to evolve but remains limited by a lack of commercial availability of branched/fenestrated grafts and unacceptable early morbidity with several centers reporting SCI rates of >30%. The hybrid approach that combines visceral artery debranching with endovascular exclusion of the TAA has allowed surgeons who lack the resources to perform distal perfusion to offer TAA repair to their complex patients but the reported results compare poorly with open repair at high-volume centers. Medical therapy is appropriate in patients who are frail, have prohibitive associated comorbid conditions or small aneurysms. This consists of aggressive blood pressure control with beta-blockade, which has been shown to decrease the rate of aortic dilation. The goal of anti-hypertensive therapy is to keep the systolic pressure at a low-normal range of 105 to 120 mm Hg, and this often requires additional medications to maintain. Risk factor modification is another important aspect of patient education regarding TAA. Patients should be counseled regarding smoking cessation and given appropriate support to achieve this goal.

Renal and Spinal Cord Protection

Outcomes of TAA repair are closely correlated with renal and spinal cord complications; accordingly, operative adjuncts to minimize these complications have been principal drivers of the technical conduct of the operation. Consistent with a firm literature base supporting regional hypothermic protection of the kidneys, our approach involves direct

installation of renal preservation fluid (lactated Ringers with 25 g of mannitol/L and 1 g/L methyl prednisolone at 4°C) into the renal ostium during ischemia. In type IV TAA, the left renal artery is transected prior to placing the proximal aortic clamp and 250 mL of the renal cold solution is instilled into the artery followed by a continuous drip through a 6-Fr perfusion balloon-tipped catheter. Once the aorta is opened, renal cold is infused in the right renal artery through the ostium, which should be coursing down and away from the surgeon. In more complex TAA (types I to III), where distal perfusion is used, renal cold is given prior to the start of the visceral reconstruction. Experience has shown that such an infusion will result in a rapid decline of renal parenchymal temperature to 15°C after the bolus infusion. During the continuous infusion, renal core temperatures remain in the 25°C range as monitored by direct temperature probes in the renal cortex.

It is evident that most of the nuances that drive the technical conduct of TAA repair are directed toward the prevention of SCI; to wit, is the abundance of adjuncts that have been championed to minimize this dreaded complication. To date, only cerebrospinal fluid drainage is appropriately evidence-based and used by most surgeons. Other adjuncts aimed at preserving spinal cord blood flow such as intercostal vessel reconstruction (IC) have been championed and/or routinely practiced despite its empiric nature and evidence base limited to retrospective studies including our own. The alternative position with specific respect to IC vessel reconstruction is that it is unnecessary (related to the collateral network), and expends cross-clamp time and blood turnover. Distal aortic perfusion via left atrial femoral bypass used in conjunction with intraoperative motor evoked potential (MEP) monitoring to dynamically assess spinal cord ischemia during the operation has replaced epidural cooling as our principal cord protective strategy in patients with more extensive TAA (types I to III). This is based upon a series of studies that used magnetic resonance imaging combined with intraoperative MEP to show that individual intercostal vessels were typically not critical for cord preservation and most collaterals that support the cord originated from the pelvis (i.e., hypogastric arteries); thus, preservation of continuous perfusion of the pelvis is logical and prudent. The addition of MEP monitoring affords the surgeon objective criteria to direct selective IC reconstruction and thus replaces the subjective application of or routine posture toward intercostal vessel reimplantation. The use of MEP

monitoring does mandate a departure from anesthetic techniques typically used in North America, and the technical requirements of such monitoring can only be satisfied by a dedicated team specialized in neurophysiology.

TECHNICAL COMPONENTS

Operative Exposure

Irrespective of individual preferences concerning the technical components of the operation, the key to operative success remains the provision of broad, continuous exposure of the entire left posterolateral aspect of the thoracoabdominal aorta (Fig. 198.4). The patient is positioned on the table in the right lateral decubitus position. The location and extent of the thoracic portion of the incision are determined by the proximal extent of the aneurysm as the posterior portion of a standard posterolateral thoracotomy incision is only necessary for type I and type II aneurysms. We keep the thoracic portion of the incision low and have found that the fifth or sixth interspace with posterior division of the sixth or seventh rib provides adequate exposure for even the more proximal aneurysms. The costal margin is divided at the level of the sixth interspace, and a self-retaining retractor system is placed in order to ensure continuous exposure of the entire operative field. A thoracoabdominal incision at the eighth interspace will usually provide adequate exposure for a type IV TAA, and a double lumen tube for deflation of the left lung is generally not necessary in these cases. The abdominal portion of the incision is not extended to the midline; rather, it is kept well lateral on the abdominal wall along the edge of the rectus. The advantage of this approach is that it allows the visceral contents to lie within the abdominal cavity, thus decreasing evaporative fluid and heat losses. The abdominal portion of the incision is transperitoneal, allowing direct inspection and assessment of the visceral circulation when the case is completed.

Exposure of the left posterolateral aspect of the abdominal aorta is obtained by entering the plane posterior to the spleen, left kidney, and left colon. The abdominal contents are then reflected to the patient's right and the left ureter is identified and preserved under laparotomy pads (Fig. 198.4). The retroperitoneal fatty and lymphatic tissues overlying the aorta are transected with electrocautery, and the renal-lumbar vein that courses across the aorta is identified and divided. Located topographically close to this vein is the left renal artery. Once identified, the left renal artery is dissected toward its origin on the aorta. This serves as a suitable point to

initiate the cephalad and caudal division of the retroperitoneal tissues over the aorta inferiorly and division of the median arcuate ligament and diaphragmatic crura superiorly.

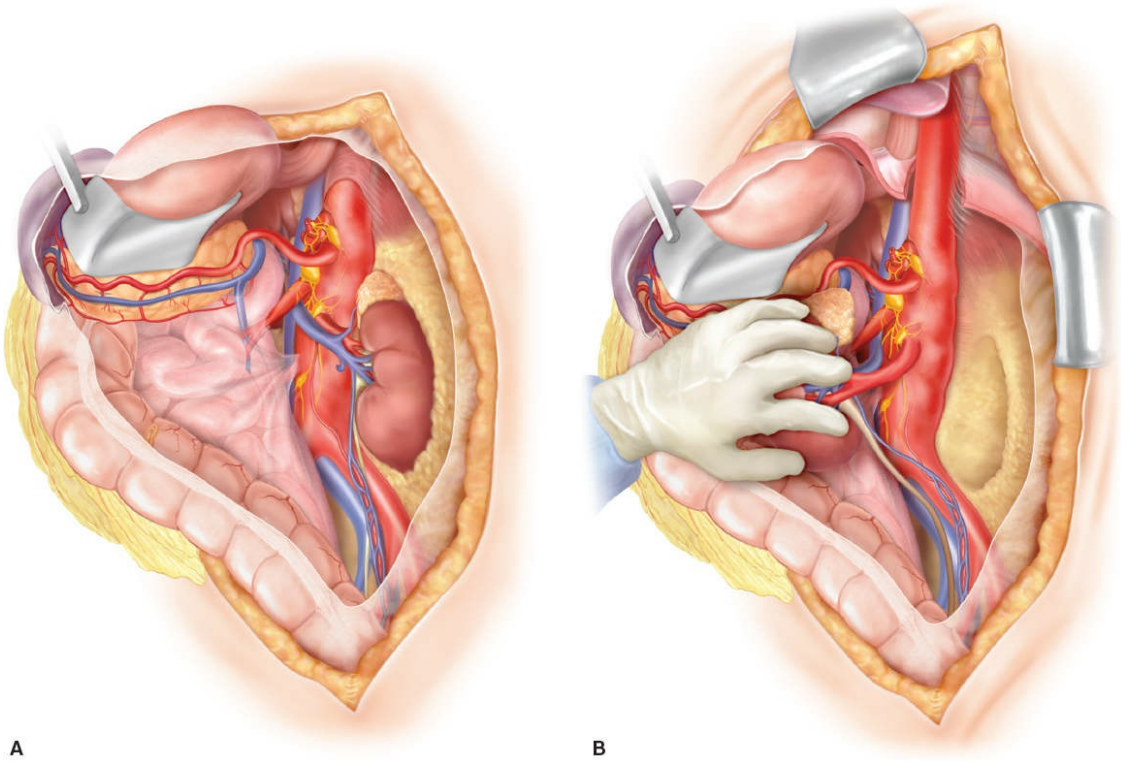

Figure 198.4. Schematic of exposure for TAA repair. **A.** Exposure of the left chest and abdomen through a thoracoabdominal incision with the spleen, pancreas, and left colon reflected up. Note, the left kidney lies in situ and certain situations (such as single functioning left kidney) are best approached in this manner. **B.** Thoracoabdominal exposure of the aorta with the kidney up. This exposes the entire left posterolateral aspect of the TAA.

There are several methods by which the incision in the diaphragm may be managed. The quickest and simplest method that affords excellent exposure is direct radial division of the diaphragm from underneath the costal margin to the aortic hiatus. This approach, however, will irrevocably paralyze the left hemidiaphragm and ultimately contribute to postoperative respiratory embarrassment. A second approach involves the circumferential division of the diaphragm through its muscular portion leaving a few centimeters attached laterally to the chest wall. There is benefit to preserving the phrenic innervation to the left hemidiaphragm by dividing only a portion lateral to the phrenic nerve insertion and then

taking down the muscular fibers of the aortic hiatus. A large Penrose drain can be passed around the diaphragm pedicle and used to retract superiorly and inferiorly as needed during the reconstruction. We have applied this method liberally, particularly in patients with evidence of preoperative pulmonary compromise.

Dissection of Left Pleural Space

After deflation of the left lung, the thoracic component of the dissection is typically straightforward. Electrocautery is used to divide the mediastinal pleura over the aneurysm and proximal aorta. For type I and II aneurysms, proximal control of the aorta in the region of the left subclavian artery origin is necessary. Further mobility of the vagus nerve is gained by dividing it distal to the origin of the left recurrent nerve, which should be identified and preserved. Should more proximal control be necessary, the ligamentum arteriosum is divided on the underside of the aortic arch. Care must be taken to keep the dissection directly on the aortic arch in order to avoid injuring the left main pulmonary artery. When degenerative aneurysm is the underlying pathology, dissection in this area is usually straightforward. However, in patients with chronic dissection, the prior inflammation from the dissecting process makes exposure more difficult. The aorta is surrounded with a vessel tape on either side of the left subclavian artery depending on the proximal extent of the aneurysm. Blunt dissection on the posterior aspect of the aorta is used to clear sufficient normal aorta to allow placement of the cross-clamp while maintaining adequate length of aorta for an accurate proximal aortic anastomosis. External control of the left subclavian artery is desirable but not mandatory as intraluminal balloon control can be obtained if the aortic clamp is placed proximal to the left subclavian artery. During the thoracic portion of the dissection, the left inferior pulmonary vein is isolated in cases where atrial femoral bypass is used; a 4-0 prolene purse-string suture is used to introduce the venous cannula, which in our experience need not be larger than 19 Fr.

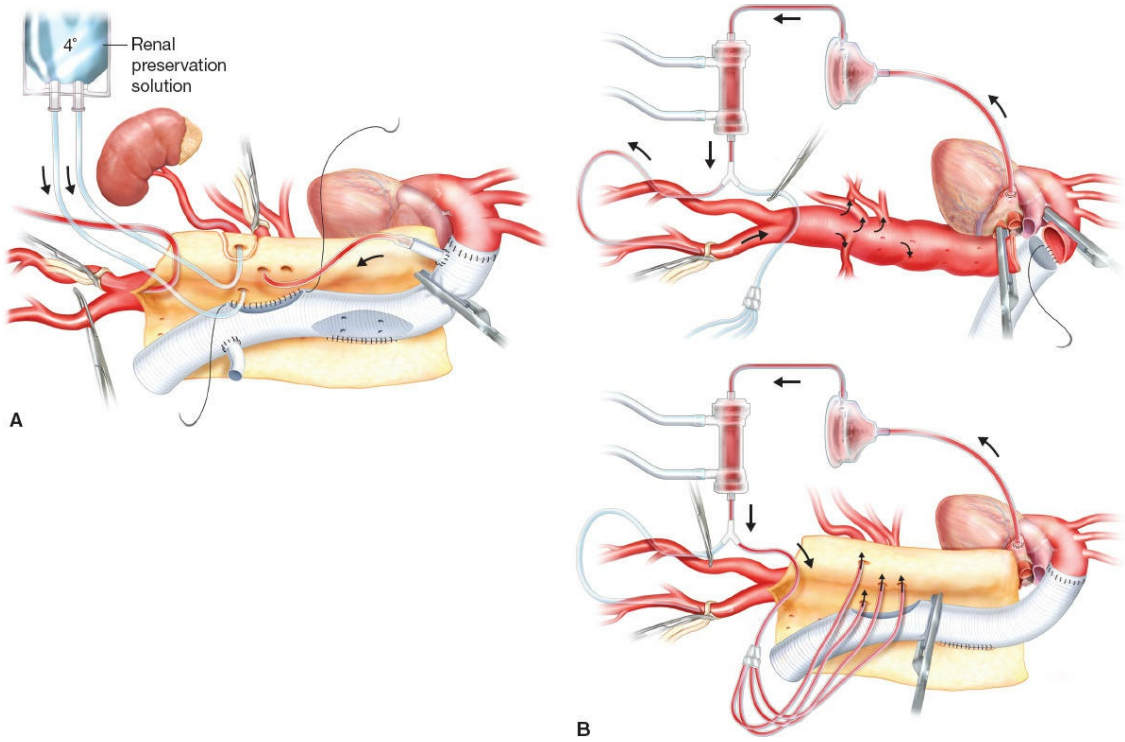

Figure 198.5. Approaches to operative conduct of thoracoabdominal aneurysm repair. **A.** Clamp-and-sew technique with associated adjuncts of mesenteric shunting, renal cold perfusion, and epidural cooling (not shown). **B.** Distal perfusion (left heart bypass) using the heparin-impregnated Bio-Medicus pump where perfusion distal to the proximal cross-clamp is initially maintained via the femoral artery and then by multiple perfusion catheters once reconstruction proceeds distally.

Clamp-and-Sew Versus Atrial-Femoral Bypass

In contemporary practice, the clamp-and-sew technique with adjuncts to minimize warm ischemic time is the best way to approach type IV TAA. The technique of distal perfusion through atrial femoral bypass via a centripetal, motorized pump is the simplest form of distal perfusion and requires no or low doses of systemic heparin to function. Conversely, cardiopulmonary bypass using a femoral vein to femoral artery technique requires an in-line oxygenator and full pump doses of heparin, making it less desirable given the extensive dissection required to complete TAA repair. Most surgeons have adopted the liberal use of atrial femoral bypass for extent I to III TAA. This is again based largely on the concept of the spinal cord collateral network, which has emphasized the importance of the pelvic/hypogastric vessels and the ability to apply a selective rather than routine approach toward intercostal vessel reconstruction based upon

intraoperative MEP monitoring. We prefer to continuously perfuse the mesenteric circulation during reconstruction of the visceral aortic segment. This can be accomplished with either a Y-connection from the atrial-femoral bypass circuit or with in-line mesenteric shunting from the proximal graft after completion of the proximal anastomosis (Fig. 198.5).

Clamping Sequence and Proximal Anastomosis

Next, the aortic prosthesis is prepared by attaching a 6-mm polytetrafluoroethylene (PTFE) side-arm graft that will serve as the conduit for left renal artery reconstruction. An additional side-arm graft of 10-mm PTFE may be placed proximally to provide inflow for the in-line mesenteric shunt. For most aneurysms, a Dacron prosthesis is the preferred conduit. However, a PTFE conduit is used to repair mycotic aneurysms because of its decreased susceptibility to infection.

Atrial femoral bypass is initiated by cannulation of the left atrium through the left inferior pulmonary vein and the arterial return is via the left common femoral artery. Flows are initially adjusted to maintain distal mean perfusion pressures of at least 60 to 70 mm Hg; any deterioration in MEP should prompt either an increase in the stimulus intensity or an increase in distal perfusion pressures. A sudden drop in MEP amplitude (occurring within 2 to 10 minutes) or a sustained progressive drop (within 10 to 40 minutes) of >75% from baseline is considered significant and should be addressed. The clamping sequence is begun in close cooperation with the anesthesia team. Efforts are made to place the first sequential clamp so as to allow lower intercostal and visceral retrograde perfusion.

In cases where the entire descending thoracic aorta is resected, proximal intercostal vessel orifices between T_4 and T_8 typically vigorously back-bleed and those are rapidly oversewn. Intercostal vessels in the critical T_9 to L_1 aortic segment are evaluated for potential reimplantation, usually guided by changes in MEP signals. These vessels are controlled with balloon occlusion catheters to prevent ongoing back-bleeding and also to prevent the negative “sump” effect on net spinal cord perfusion that can result from these vessel orifices when exposed only to atmospheric pressure. Unless there are prompt, significant changes in MEP, we defer any intercostal reconstruction to later stages of the operation. Next, the proximal aortic neck is prepared for reconstruction. Circumferential division of the aorta avoids the late complication of suture line esophageal erosion, and permits the use of circumferential Teflon felt wrap if the aorta

is particularly fragile and/or dissected. After completion of the proximal anastomosis, a clamp is placed on the main aortic graft distal to the mesenteric shunt sidearm (if present). The clamp is moved to the distal sequential clamp position and the visceral aortic segment is opened.

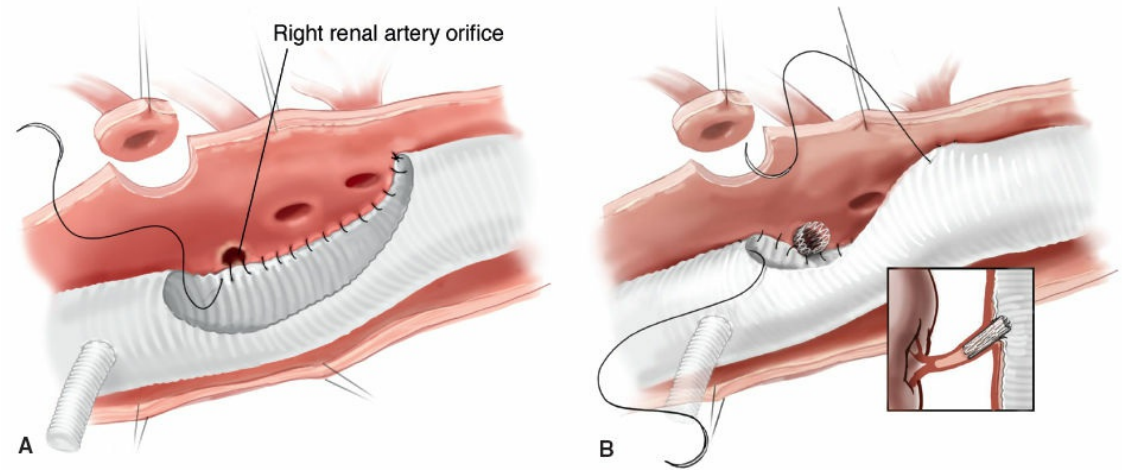

Figure 198.6. **A.** Creation of visceral button inclusion anastomosis of the celiac axis, SMA, and right renal artery and 6-mm PTFE sidearm bypass for left renal artery reconstruction. When performing this, we use a 12-Fr perfusion catheter as a stent of sorts in the right renal artery to prevent compromise of its orifice as the anastomosis is carried around these arterial origins. **B.** Deployment of balloon-expandable stent into the right renal orifice to either treat occlusive lesions or prevent encroachment by the suture line, which should be placed immediately at or into the vessel ostia.

Renal/Visceral Artery Reconstruction

Visceral and renal artery reconstruction is carried out next. Orificial endarterectomy should be performed when significant occlusive lesions of the right renal and superior mesenteric arteries exist. This involves incising the diseased intima and media and developing a proper endarterectomy plane that can be verified by noting the pinkish color of the inner adventitia. In cases where aortic endarterectomy is required, the superior mesenteric and celiac arteries should be dissected sufficiently to facilitate countertraction from the external side of the vessel if necessary. This, however, is not possible with the right renal artery. In the event that the calcified end of the obstructing plaque doses not feather nicely, sharp excision under direct vision is the best way to end the endarterectomy plane.

The most common method of visceral and renal artery reconstruction that has been employed in the majority of our cases is a single inclusion button that encompasses the origins of the celiac, superior mesenteric, and right renal arteries (Fig. 198.6). If the aneurysm is excessively large in the visceral aortic segment, the wide separation of the visceral/renal ostia may necessitate individual inclusion button anastomoses for each vessel. Alternatively, the superior mesenteric artery and right renal artery can be reimplanted as a single inclusion while reconstruction of the celiac trunk is deferred until later. The aortic graft is placed under tension and an elliptical side island is excised from the main aortic graft. This ellipse usually begins on the lateral aspect of the graft and spirals posteriorly in the region of the right renal artery reconstruction. With the graft under tension, it is possible to complete the posterior portion of the anastomosis using single bites of the suture passing through both the aorta and the Dacron graft. Suture bites are taken close to the origin of the visceral vessels in order to avoid leaving excess aneurysmal aortic wall. As the posterior aspect of this suture line continues around the inferior border of the right renal artery, we exchange the 6-Fr perfusion catheter for a 12-Fr perfusion catheter to temporarily stent the origin of the right renal artery. The catheter is gently agitated up and down as the suture line moves around the renal artery orifice to ensure that it is not compromised by generous suture bites as they pass outside of the aorta. It is important to identify the course of the right renal artery with this indwelling catheter in order to avoid renal artery occlusion in circumstances where the right renal artery drapes over a large infrarenal component of the aneurysm. Recently, we have used a 6 × 15 or 6 × 18 balloon expandable stent to ensure that the suture line does not compromise right renal artery flow. The stent is placed under direct vision after the proximal suture line is beyond the orifice of the artery (Fig. 198.6). Just prior to completion of this suture line, backbleeding and patency of the celiac, superior mesenteric and right renal arteries are verified and the in-line mesenteric shunt is clamped and removed. A single flush of the proximal aortic cross-clamp is performed in order to ensure that no clot or debris has built up in the graft.

In extent IV TAA, 90% of the proximal reconstructions are carried out with a single beveled anastomosis incorporating the right renal, superior mesenteric and celiac arteries in the proximal descending aorta. A similar reconstruction often suffices for the distal anastomosis in type I TAA (Fig. 198.7).

Reconstruction of the left renal artery is now accomplished with a separate side-arm graft of 6-mm PTFE. This provides a direct deliberate anastomosis in end-to-end fashion while allowing flexibility to deal with the spectrum of occlusive lesions, multiple renal arteries, and other wrinkles that may be encountered. It is important to orient this side-arm graft so that it will not kink when the left renal artery is returned to its anatomic position (Fig. 198.6). Some surgeons advocate the use of a single inclusion button that contains the renal arteries and the visceral vessels. This often requires the inclusion of too great an area of the native, aneurysmal aorta unless the aneurysm is small in the visceral artery segment. A single, pristine left renal artery and orifice may be directly reimplanted and the clamp is then advanced to a position inferior to the origin of the left renal artery graft prior to completing the distal aortic anastomosis.

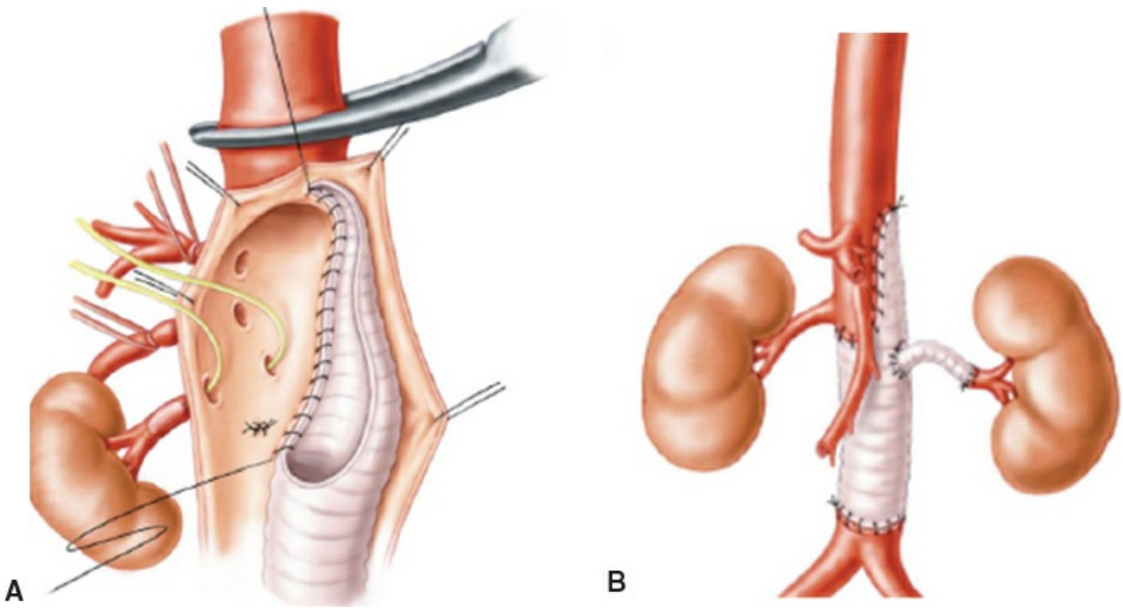

Figure 198.7. Visceral branch management in (**A**) type IV and (**B**) type I TAA. Beveled anastomosis is used for both repairs. Also shown is the reconstructed left renal artery bypass used routinely in type II to IV repairs.

Reconstruction of Intercostal Vessels

The next step in the operation involves reconstruction or oversewing of the intercostal vessels in the T_9 to L_1 segment. If there have been no changes in the MEP during the operation, the occlusion balloons are removed and the remaining intercostals are oversewn with silk sutures. If, however,

reconstruction is desired, it can usually be accomplished through an inclusion button anastomosis. Intercostal arteries in the region of a proximal or distal aortic anastomosis can be reconstructed using a long beveled suture line. Other methods of intercostal vessel revascularization include the attachment of additional short side-arm grafts to the main aortic graft or, in cases where the vessel origin is rotated superiorly and to the patient's left side, implantation to the main aortic graft using Carrel patches of aorta that contain the intercostal vessels may be feasible (Fig. 198.8). Depending on the topography of the origins of the intercostal vessels and/or data from MEP monitoring, it is usually possible to defer reconstruction until after completion of the visceral vessel anastomosis by utilizing partial occluding clamps on the main aortic graft. The intercostal vessels in the T_9 to L_1 segment are crucial to spinal cord perfusion and reconstruction with the inclusion button often overlaps (on the opposite side of the aorta) the inclusion button for reconstruction of the visceral vessels. Accordingly, attempts to clamp the aortic graft distal to the intercostal inclusion button can interfere with reconstruction of the visceral vessels.

Distal Anastomosis

We make every effort to perform tube type of reconstructions to the aortic bifurcation unless there is gross aneurysmal disease of the proximal common iliac arteries. Extending the reconstruction to separate iliac artery reconstructions or, indeed, tunneling to an aortofemoral graft configuration is only performed when no other technical alternative exists. After reestablishment of flow to the lower extremities and verification of adequate lower extremity perfusion by intraoperative pulse volume recordings, Doppler signals in the left renal, celiac, and superior mesenteric vessels are checked in addition to palpation of the superior mesenteric artery pulse in the root of the mesentery.

Hemostasis will usually be adequate upon completion of the distal anastomosis, but infusions of platelets and fresh frozen plasma are typically increased at this point in the operation when a final check for surgical hemorrhage is made. Indeed, careful attention to hemostasis from the beginning of the operation combined with minimal heparin use is an important component of care; we previously identified total blood turnover as an independent correlate of operative mortality. Careful inspection of the inferior aspect of the aneurysm sac in both the chest and abdomen is

necessary to detect back-bleeding lumbar and/or intercostal vessels, which can be a source of significant postoperative hemorrhage. The redundant aneurysm sac is then sutured securely over the aortic prosthesis in the abdomen and the chest. Prior to closure, renal artery reconstructions are interrogated one final time. Occasionally, in patients with modest-size aneurysms, chronic dissections, or prior proximal aortic grafts, there is insufficient aneurysm wall to totally cover the proximal suture line and aortic graft. In select cases, we have used a PTFE or bovine pericardial patch to exclude the aortic prosthesis from the left lung. As the left kidney is returned to its anatomic position, the perinephric fat usually suffices to provide adequate coverage of the aortic graft in the region of the visceral aortic segment. A single pleural tube is placed, and a closed suction drain may be left in the retroperitoneum if hemostasis is in question. Closure of extensive incisions typically takes close to an hour, and two teams are often utilized. Clamp times, blood turnover, and blood component replacement will vary as a function of aneurysm extent, but overall operative time can be kept in the 5 to 6 hours range for most patients.

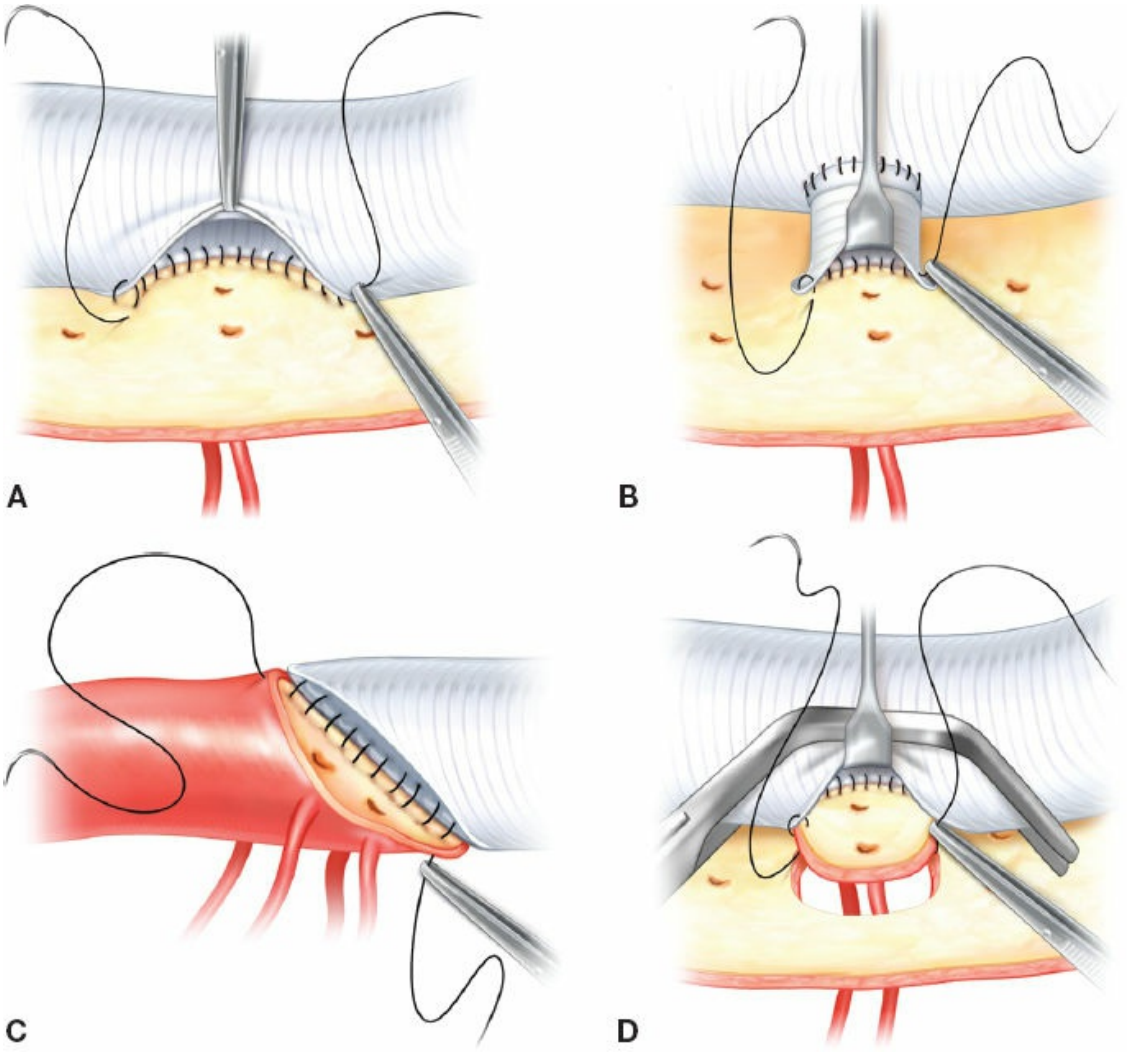

Figure 198.8. Methods of management of critical intercostal arteries. **A.** Inclusion button anastomosis. **B.** Separate sidearm graft. **C.** Beveled anastomosis preservation when possible. **D.** Carrell patch mobilization and direct reimplantation into the graft.

Postoperative Care

Postoperatively, patients should be monitored in an intensive care unit (ICU) setting. It is important to limit hemodynamic shifts as these can contribute to complications such as renal failure and spinal cord ischemia. Blood pressure parameters should be tailored to the patient with the goal of maintaining adequate perfusion to preserve urine output, cardiac function, and spinal cord perfusion. Oxygen delivery is important in the early phase of recovery, and we rarely extubate patients in the early postoperative period. If they have stabilized overnight, we will pull the tube in the morning. It is important to monitor the hematocrit for signs of ongoing bleeding, and all coagulation disorders should be aggressively corrected

with the appropriate products. We typically support intravascular volume with fresh frozen plasma infusions for the initial 12 hours after the operation. Cerebrospinal fluid drainage is arbitrarily continued for 48 hours postoperatively, and the drain is then capped for 24 hours of observation prior to removal. Discontinuation of some preoperative antihypertensive medications may be necessary to maintain the relative hypertension necessary to avoid delayed SCI.

RESULTS OF TREATMENT AND COMPLICATIONS

Operative Mortality

The operative mortality after TAA ranges from 8% to 16% in large clinical series. Preoperative patient characteristics influence the patient's outcome regardless of the conduct of the operation. In a recent update of our experience with type I to III TAA, 30-day mortality was 4.4% for elective TAA repaired with atrial femoral bypass and MEP monitoring. As the number of comorbid conditions increases so does the overall operative risk, and individual series have reported that preoperative coronary artery disease, COPD, and renal insufficiency contribute to postoperative organ-specific complications and increased mortality. The influence of TAA extent is often (and appropriately) emphasized as having a dominant effect on, in particular, spinal cord ischemia. In particular, perioperative death after type IV TAA repair should mirror that of infra-renal repair. To wit, in our recent published experience, the 30-day mortality for type IV TAA repaired with the clamp-and-sew method was 2.8%.

Renal Failure

We have traditionally defined postoperative renal failure as a doubling of the baseline serum creatinine level or an absolute postoperative creatinine level of >3.0 mg/dL. Minimizing renal ischemic times, the use of cold perfusate, avoidance of intraoperative hypotension, and a posture of aggressive treatment of stenotic lesions with either bypass or open stent placement are all strategies used to avoid postoperative renal insufficiency. Most cases are self-limited. We reserve dialysis for patients who need it for specific clinic indications, such as volume overload, hyperkalemia, or acidosis. When needed, continuous venovenous hemodialysis is our preferred method as it provides for a smoother hemodynamic course than conventional hemodialysis. For those patients who continue to require

dialysis, conventional hemodialysis is instituted once the patient is out of the intensive care unit, and out of the window of risk for spinal cord ischemia. In our experience, and that of others, preoperative renal insufficiency is the most powerful predictor for the development of postoperative renal failure, and postoperative renal dysfunction remains independently associated with short- and long-term survival.

Respiratory Complications

Although most clinical series emphasize spinal cord and renal complications, respiratory failure is the single most common complication after TAA repair. Indeed, if strict criteria are used, up to 40% of patients suffer some type of respiratory complication. Contributing factors include paralysis of the left hemi-diaphragm and the pain associated with an extensive chest wall incision that impedes pulmonary toilet. Accordingly, a diaphragm sparing technique is applied when possible in contemporary practice. For patients who fail extubation, we favor early placement of a tracheostomy, although this procedure has been needed in <10% of patients. A slow wean from ventilatory support, often planned to proceed over several days, is appropriate management in patients with extensive TAA resection, particularly those with baseline pulmonary insufficiency. The variables that have been shown to be predictive of postoperative respiratory failure include: active cigarette smoking, baseline COPD (especially those with significant reductions in FEV_1) and cardiac, renal, or bleeding complications.

Spinal Cord Ischemia

Since the first descriptions of TAA repair, SCI has been the most feared and devastating nonfatal complication associated with TAA reconstruction. Although, advances such as epidural cooling, distal perfusion, and the intraoperative monitoring of MEP have improved outcomes, this remains an unsolved problem. The pathogenesis of SCI after aortic replacement is likely multifactorial, but ultimately results from an ischemic insult caused by temporary or permanent interruption of the spinal cord blood supply. SCI manifests along a clinical spectrum from complete flaccid paraplegia to varying degrees of temporary or permanent paraparesis and the degree of SCI directly predicts long-term survival after TAA repair (Table 198.1). Patients with incomplete deficits typically made a reasonable or complete functional outcome and have a long-term

survival that is similar to those without SCI. However, patients with an SCID I score (flaccid paralysis) rarely live beyond the first year. The most common predictors of SCI after TAA repair include extent I and II aneurysms and urgency of operation. While the majority of cases of SCI are detected in the immediate postoperative period, there is a trend toward an increase in delayed paralysis in recent series.

TABLE 198.1 Short- and Long-Term Survival of 576 Patients Undergoing Open TAA Repair at the Massachusetts General Hospital Stratified by Spinal Cord Ischemic Deficit (SCID)

SCID Category	30-Day Survival (%)	1-yr Survival (%)	5-yr Survival (%)
SCID 0: No SCI	92	73	51
SCID I: Flaccid paralysis	54	21	0
SCID II: Average neurologic muscle Grade <50% function	87	70	41
SCID III: Average neurologic muscle Grade >50% function	100	73	45

Late Outcomes

While some studies report significant continued mortality throughout the first year after operation (up to 30%), these reports include centers where the perioperative mortality approached 19%. It is therefore difficult to put these data into context with data from centers where the perioperative mortality is 5% to 8%. We found late survival in our patients was identical to that from a population-based study of patients who underwent elective AAA. In addition, late aortic events occur in about 10% of patients but few of these are graft related. Graft-related complications include occlusion of visceral vessel reconstructions, graft infections (including aortoesophageal fistulas), and the appearance of inclusion patch aneurysms and are rare in our experience. Most late aortic events are the result of native aneurysmal disease in remote (or noncontiguous) aortic segments. These data indicate that the substantial resource investment required to bring these patients through successful operation and recovery is an appropriate expenditure of such resources. With improvement of perioperative outcomes, the focus of long-term follow-up has shifted to examination of the impact of TAA repair on functional outcome. Several reports have emerged validating that

the majority of operative survivors return to their preoperative independent living status.

EDITOR'S COMMENT

There are fewer operations performed compared with thoracoabdominal aortic aneurysm (TAAA) repair where the patient is placed at a high risk for not only mortality, but also the devastating complications of renal failure requiring dialysis and paraplegia (Cowan JA Jr, Dimick JB, Henke PK, et al. Surgical treatment of intact thoracoabdominal aortic aneurysms in the United States: hospital and surgeon volume-related outcomes. *J Vasc Surg* 2003;37(6):1169–74). Clearly, there have been tremendous strides made in the operative and critical care of these patients. In this chapter by Conrad and colleagues, the

state-of-the-art care of these patients is well-described.

The evolution of the treatment of repair of TAAAs is well-documented and likely one of the real success stories in surgery. There are multiple examples of significant strides made in the care of these patients. For the most part, the old "clamp and sew" technique has been largely abandoned in favor of more sophisticated techniques aimed at avoiding the significant ischemia reperfusion that occurs to the spinal cord, intestines, kidneys, and lower extremities following TAAA repair. The use of spinal drains has been studied extensively in open TAAA repair and been shown to significantly decrease the risk of paraplegia (Khan NR, Smalley Z, Nesvick CL, et al. The use of lumbar drains in preventing spinal cord injury following thoracoabdominal aortic aneurysm repair: an updated systematic review and meta-analysis. *J Neurosurg Spine* 2016;8:1–11). The use of spinal drains has also been implemented in patients undergoing thoracic endovascular aneurysm repair (TEVAR) and also decreases the incidence of paraplegia in this operation as well (Arnaoutakis DJ, Arnaoutakis GJ, Beaulieu RJ, et al. Results of adjunctive spinal drainage and/or left subclavian artery bypass in thoracic endovascular aortic repair. *Ann Vasc Surg* 2014;28(1):65–73).

One wonders whether a "zero paraplegia risk" will ever be attained, regardless of whether an open or endovascular approach is used. For open TAAA repair, the use of motor and sensory evoked potentials has been studied in detail (Keyhani K, Miller CC 3rd, Estrera AL, et al. Analysis of motor and somatosensory evoked potentials during thoracic and thoracoabdominal aortic aneurysm repair. *J Vasc Surg* 2009;49(1):36–41). Others have used various pharmacologic therapies to decrease the risks of spinal cord injury (Acher CW, Wynn MM, Hoch JR, et al. Combined use of cerebral spinal fluid drainage and naloxone reduces the risk of paraplegia in thoracoabdominal aneurysm repair. *J Vasc Surg* 1994;19(2):236–46; discussion 247–8). With a purely endovascular approach, people have moved to fixing the thoracic portion first, followed by some interval time before taking on the complex abdominal portion of the TAAA (O'Callaghan A, Mastracci TM, Eagleton MJ. Staged endovascular repair of thoracoabdominal aortic aneurysms limits incidence and severity of spinal cord ischemia. *J Vasc Surg* 2015;61(2):347–54). This is not really practical with open TAAA repair, but using a staged hybrid approach (see below) seems like a nice merger of open and endovascular approach (Jain A, Flohr TF, Johnston WF, et al. Staged hybrid repair of extensive thoracoabdominal aortic aneurysms secondary to chronic aortic dissection. *J Vasc Surg* 2016;63(1):62–9).

The continued evolution in the treatment of patients with TAAAs will likely come from the extension of endovascular techniques into the thoracoabdominal aorta, bridging the aorta between the isolated thoracic and isolated abdominal aorta. At present, complicated fenestrated and branched endografts are widely available in Australia and Europe, as well as in clinical trial in the United States. I suspect there will likely never be an endovascular solution for all TAAAs,

especially those associated with dissections. We have moved to repairing these patients with a combined TEVAR and subsequent open distal TAAA repair, the so-called hybrid TAAA repair. The results from this combined approach have been encouraging so far (Jain A, Flohr TF, Johnston WF, et al. Staged hybrid repair of extensive thoracoabdominal aortic aneurysms secondary to chronic aortic dissection. *J Vasc Surg* 2016;63(1):62–9).

Finally, our understanding of the genetics of aneurysms of the thoracic and thoracoabdominal aorta is growing exponentially (Milewicz D, Hostetler E, Wallace S, et al. Precision medical and surgical management for thoracic aortic aneurysms and acute aortic dissections based on the causative mutant gene. *J Cardiovasc Surg (Torino)* 2016;57(2):172–7). From syndromes to single gene mutations, we are now using our knowledge about the genetics of the aorta to help guide us making clinical decisions. There are still a number of questions to be answered especially in patients with connective tissue disorders, including whether TEVAR should ever be used in these patients and how one technically performs surgery in these patients. We have moved to routinely doing end-to-end anastamoses for all bypasses. Others prefer to only do end-to-end anastamoses in patients with connective tissue disorders or in TAAAs secondary to dissections. Likely before the next edition of *Mastery of Surgery*, these questions will be answered.

199 Open Infrarenal and Pararenal Aortic Aneurysm Repair

Gregorio A. Sicard and Jeffrey Jim

INFRARENAL AND PARARENAL AORTIC ANEURYSMS: OPEN

INTRODUCTION

The surgical treatment of abdominal aortic aneurysms (AAAs) was initially described in 1952 when Dr. Charles Dubost reported resection of an aneurysm and replacement with a preserved human arterial graft. In 1967, the development of a synthetic graft by DeBakey led to improved patient outcomes and since then, the techniques of open surgical repair of AAAs remain largely unchanged. In 1991, Parodi described the first endovascular aortic aneurysm repair (EVAR) with endovascular stent grafts. Even though EVAR is now the preferred treatment modality, there remains a subset of patients that require open repair.

ETIOLOGY AND PATHOPHYSIOLOGY

An aneurysm is defined as segmental, full-thickness dilation of a blood vessel to 50% greater than its normal diameter. As the normal adult human aorta is estimated to be 2 cm in diameter, an aorta that measures greater than 3 cm is considered to be aneurysmal. AAAs are classified based on their extent relative to the involvement of the renal and visceral arteries. The major classification as recommended by the Society for Vascular Surgery include:

1. *"Infrarenal":* The proximal extent of the aneurysm is below the renal arteries; that is, with an adequate aortic neck for placement of a clamp below the renal arteries during surgical repair.
2. *"Juxtarenal"* or *"pararenal":* The proximal extent is at the level of the renal arteries with no normal aorta between upper extent of aneurysm and renal arteries; that is, surgical repair will require

placement of the clamp above one or both renal arteries.

3. *"Suprarenal":* The aneurysm originates above the level of the renal arteries and may have splanchnic and renal arterial involvement; that is, requires splanchnic or renal revascularization (bypass or implantation).

The incidence of juxtarenal/pararenal aneurysms have been estimated to be between 8% and 15% in large intra-abdominal aneurysm series. With the introduction of EVAR, there has been a need to clarify the definition of juxtarenal aneurysms. Many practitioners mistakenly consider patients that cannot be treated with standard EVAR as having a juxtarenal aneurysm. In patients with infrarenal aneurysms, where the distance between the renal arteries and the beginning of the aneurysms is less than 15 cm, the anatomy falls outside of the instructions for use of standard EVAR devices but these are still infrarenal aneurysms where an open repair can be performed with placement of the clamp in the infrarenal location. The development of fenestrated endovascular aneurysm repair (FEVAR) has placed true juxtarenal aneurysms into the realm of potential endovascular repair depending on the characteristics of the juxtarenal area anatomy. Based on the current nomenclature, a juxtarenal aneurysm means that there is *no* measurable neck below the lowest level of the renal artery and the beginning of the aneurysm. By definition, aortic cross-clamping will occur, either above the renal arteries or in the supramesenteric or supraceliac portion of the infradiaphragmatic aorta for control and repair. The aortic clamp location is a crucial and critical aspect, not only due to the technical aspects of the surgical repair but also it is a strong predictor of mortality and morbidity. Aortic cross-clamping for suprarenal or supraceliac control significantly increases the risk of splanchnic and renal ischemia. A direct correlation between duration and location of cross-clamping has been demonstrated to affect postoperative renal dysfunction and coagulopathic complications.

The exact pathophysiology of aneurysmal degeneration remains unclear. It is felt that this is a degenerative disease process and standard atherosclerotic risk factors (such as hypertension, tobacco use, and hypercholesterolemia) are associated with aneurysm development, expansion, and rupture. Molecular studies have demonstrated the role of degradation of structural proteins and smooth muscle cells in aneurysm formation. The role of matrix metalloproteinases (MMPs) have been implicated as part of the pathophysiologic process.

CLINICAL PRESENTATION

Most aneurysms are asymptomatic and most often diagnosed incidentally during a physical examination or with abdominal imaging (e.g., computed tomography [CT] scan or magnetic resonance [MR] imaging). Detection of an AAA by abdominal palpation is most likely when an aneurysm is large or in patients with a thin body habitus. The sensitivity of abdominal palpation in large studies was 29% for AAA 3.0 to 3.9 cm in diameter, 50% for AAA 4.0 to 4.9 cm, and 76% for AAA 5.0 cm or greater. The abdominal circumference also affects the sensitivity of detection. There is an overall sensitivity of 91% for patients with waistline <40 in (100 cm) versus 53% for >40 in (100 cm). For a waistline of <40 in, abdominal palpation had a 100% sensitivity for detecting an aneurysm >5.0 cm. When the presence of an aneurysm is suspected during physical examination, the diagnosis should be confirmed with additional imaging. In instances where patients present with symptoms, this is related to aneurysm expansion or compression of adjacent structures.

A ruptured aneurysm can present with pain (abdominal, flank, or back), abdominal distention, and hypotension. A patient that presents with abdominal pain in the setting of a known aneurysm must undergo emergent additional testing to rule out a rupture.

INDICATIONS AND CONTRAINDICATIONS

As most aneurysms are asymptomatic, treatment is considered to prevent future rupture. As the mortality of ruptured aneurysms approach 90%, surgical intervention is considered in those that are fit for surgery. A careful consideration of the patient's aneurysm rupture risk, operative risk, and life expectancy is necessary. The best predictor for aneurysm rupture is maximal transverse diameter. The annual rupture risk for aneurysms can be seen in Table 199.1. At the current time, the size threshold of elective repair is 5.5 cm for asymptomatic infrarenal AAAs. Two large randomized clinical trials (United Kingdom Small Aneurysm Trial and Aneurysm Detection and Management Trial) demonstrated the safety of surveillance for patients with small aneurysms and no benefit for early surgery for patients with 4.0 to 5.4 cm aneurysms. However, more recent data suggest that a lower size threshold for women (5.0 cm) may be appropriate.

TABLE 199.1 Estimated Annual Aneurysm Rupture Risk

AAA Diameter (cm)	Rupture Risk (%/yr)
<4	0
4–5	0.5–5
5–6	3–15
6–7	10–20
7–8	20–40
>8	30–50

Report of a subcommittee of the Joint Council of the American Association for Vascular Surgery and Society of Vascular Surgery. *J Vasc Surg* 2003;37(5):1106–17; with permission from Elsevier.

PREOPERATIVE PLANNING

Prior to proceeding with operative intervention, all patients should undergo a thorough preoperative evaluation. This should include a thorough history including particular attention to cardiovascular risk factors as cardiac complication remains the most significant comorbidity related to open aneurysm repair. The availability of multislice thin cut computed tomography angiography (CTA) and three-dimensional (3D) reconstruction has allowed for very precise preoperative planning in terms of the aortic clamp location for open repair of juxta and pararenal aneurysms (Fig. 199.1A,B). The predicted location of the aortic cross-clamp site helps the surgeon predict the risk factors that would impact the intraoperative and postoperative outcomes. Any cross-clamp above the renal arteries for ≥30 minutes significantly increases the risk of renal ischemia and postoperative renal dysfunction. This has been clearly demonstrated in the multiple recently reported series (Table 199.2). Occasionally, the space between the superior mesenteric artery and the renal arteries permits for aortic cross-clamping for repair of a true juxtarenal aneurysm, and if the warm ischemia is maintained below 30 to 45 minutes, usually renal insufficiency will be temporary and the risk of hemodialysis, either temporary or permanent, decreases significantly. On

the other hand, the need for aortic cross-clamping at the supraceliac artery with reconstruction of the celiac, superior mesenteric artery, and renal arteries portends a longer cross-clamp and revascularization time and an increase in the incidence of postoperative renal dysfunction as well as hemorrhagic complications. The current imaging modalities with thin cut CTA and 3D reconstruction does permit preoperative assessment to indicate the exact location where the aortic cross-clamp will take place and to plan the reconstruction of the visceral and renal vessels in an expeditious manner to minimize liver, bowel, and renal ischemia. Techniques to decrease the effect of renal ischemia by surface or intra-arterial cold perfusion will be addressed in the technical consideration section. In addition to aortic neck evaluation, the presence of other intra-abdominal pathology (e.g., malignancy) or anatomic variants (such as retroaortic renal vein, pelvis kidney) should be clearly delineated prior to surgery repair.

SURGICAL TECHNIQUE (INCLUDING DIAGRAMS)

The patient's body habitus, preoperative CTA assessment of cross-clamp location, presence of previous procedures, and surgeon's experience usually dictate the best technical aortic exposure indicated for a specific patient. There are two preferred approaches to repair of AAAs: transperitoneal and retroperitoneal (Fig. 199.2). Other techniques (laparoscopic or minilaparotomy) have been described but have not been widely adopted. Most practitioners are more familiar with the transperitoneal approach but this requires an experienced surgeon to be able to obtain enough length of normal aorta to cross-clamp for repair in a juxtarenal aneurysm. Transabdominal techniques including enhancement of the proximal neck by left renal vein mobilization or division have been well described, with minimal renal impairment. It does create some difficulties should intraoperative mishaps require higher cross-clamping. The use of the left medial visceral rotation (Fig. 199.3) is a transabdominal technique that allows for full visualization and repair of the infradiaphragmatic aorta. This does require extensive medial visceral mobilization of the left colon, as well as the spleen and pancreas, and the division of the left crux of the diaphragm to allow for cross-clamping up to just below the diaphragm and above the celiac axis. This technique is mostly indicated for surgeons that do not have experience with the retroperitoneal approach and/or primarily in cases with emergency (trauma) situations in which quick and immediate access to the supraceliac aorta is necessary. The retroperitoneal approach is ideal for pararenal and suprarenal aneurysms. The retroperitoneal (and thoraco-retroperitoneal) approach allows clear exposure of the more proximal aorta necessary for these repairs and is also utilized in order to avoid a hostile abdomen (prior operations, presence of ostomies); in treatment of inflammatory aneurysm, or in patients with a pelvic kidney.

Transabdominal Approach

The patient is commonly placed in the supine position and the abdomen is entered through a generous midline or transverse laparotomy incision (Fig. 199.2). There should be a careful inspection of the abdominal cavity and the viscera to evaluate for the presence of any other pathologic processes. The transverse colon and omentum is then elevated and retracted superiorly and the small bowel is eviscerated and packed to the left of the patient. A self-retaining retractor is then placed with care. A longitudinal incision is then made in the posterior peritoneum overlying the aneurysm which can usually be easily palpated. The incision is extended caudally to the entire extent of the aneurysm. Exposure of the bilateral common or external iliac arteries may be necessary if there are concomitant iliac aneurysms. The ureters should be identified and carefully preserved during the entire procedure. In cases of anticipated difficult exposure (e.g., reoperative intervention or significant inflammation), placement of ureteral stents preoperatively may assist in identification of the ureters. Care should be taken to minimize dissection around the left common iliac artery as the autonomic plexus courses in this location and extensive dissection can lead to postoperative complications of sexual dysfunction (retrograde ejaculation) in men. The inferior mesenteric artery (IMA) should be clearly identified during the dissection (Fig. 199.4). The proximal extent of the aortic exposure is dictated by the extent of the aneurysm. For an infrarenal aneurysm, the left renal vein should be identified and dissected from the surrounding tissues to allow cephalad retraction during clamp placement. The presence of a retroaortic left renal vein needs to be identified in the preoperative imaging studies. It is important to identify any significant tributaries to the renal vein (e.g., descending lumbar vein) and these may have to be ligated to allow full mobilization. The left adrenal and gonadal veins may be divided in order to obtain adequate mobilization of the renal vein if necessary for juxtarenal aortic cross-clamping. These branches should be preserved in cases where division of the main left renal vein is anticipated. In cases where the renal vein is dilated, reanastomosis is often not necessary unless there is renal vein engorgement suggestive of inadequate collateral drainage. The extent of the dissection requires exposure of healthy (i.e., nonaneurysmal segments free of significant calcification and thrombus) aorta and iliac arteries for placement of the proximal and distal clamps.

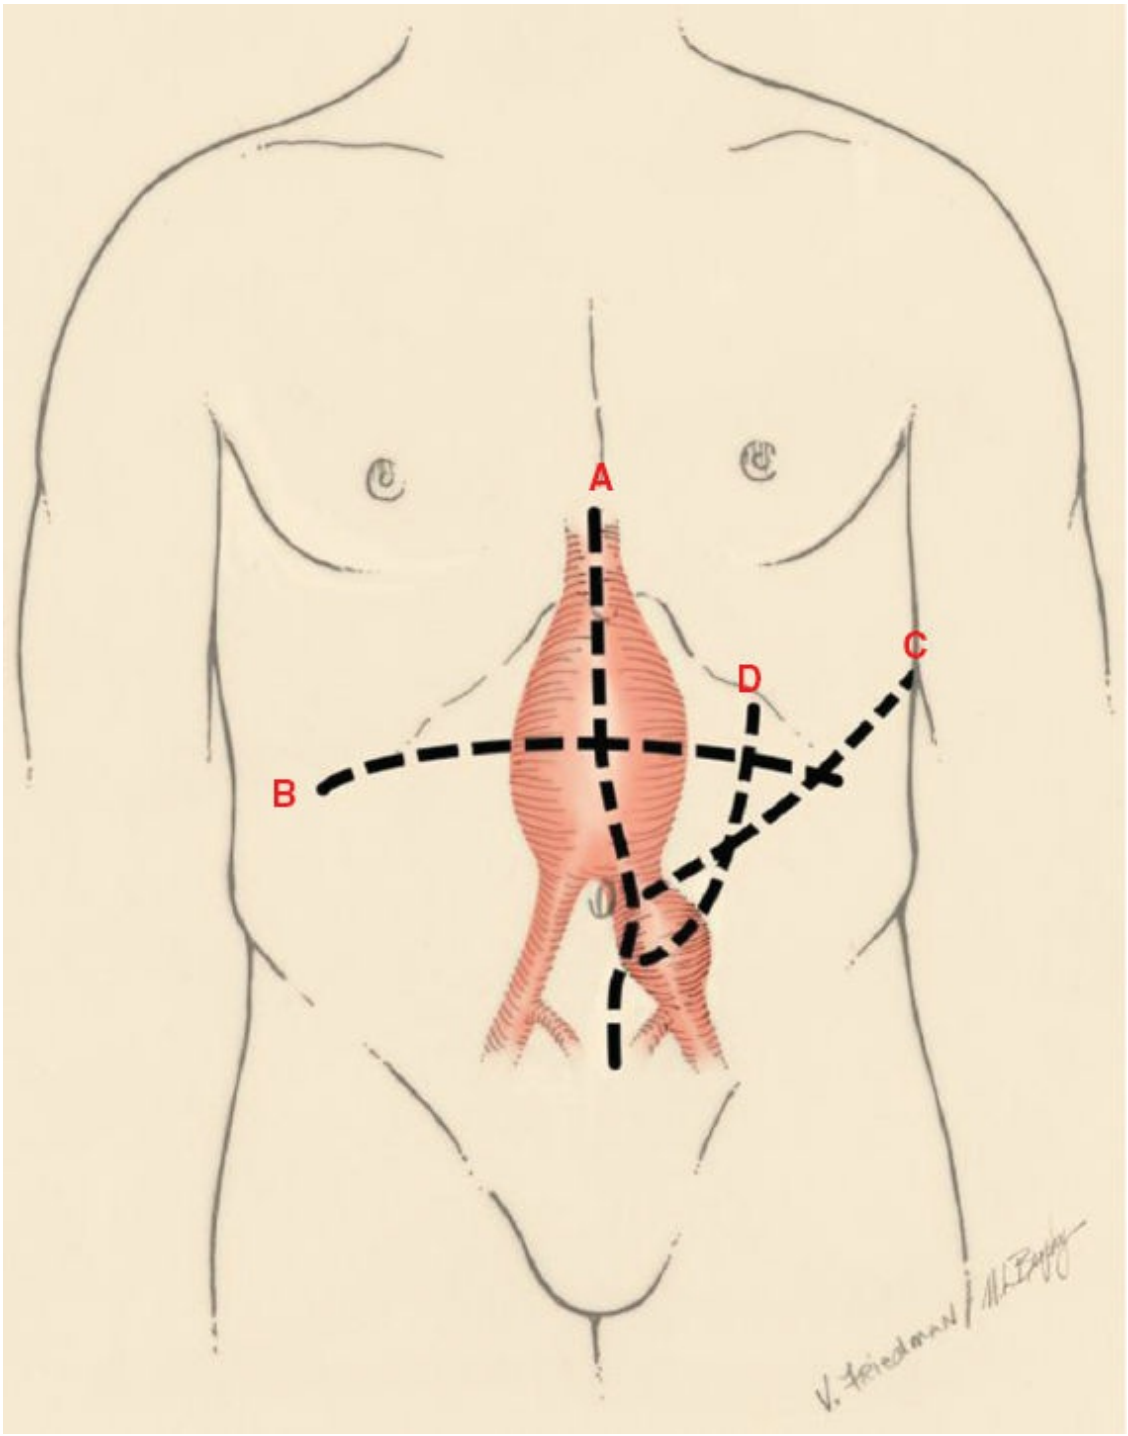

Figure 199.2. Most frequent surgical approaches for infrarenal aneurysm repair. *A,* midline; *B,* transverse; *C* and *D,* retroperitoneal approach depending on body habitus and extent of aneurysm.

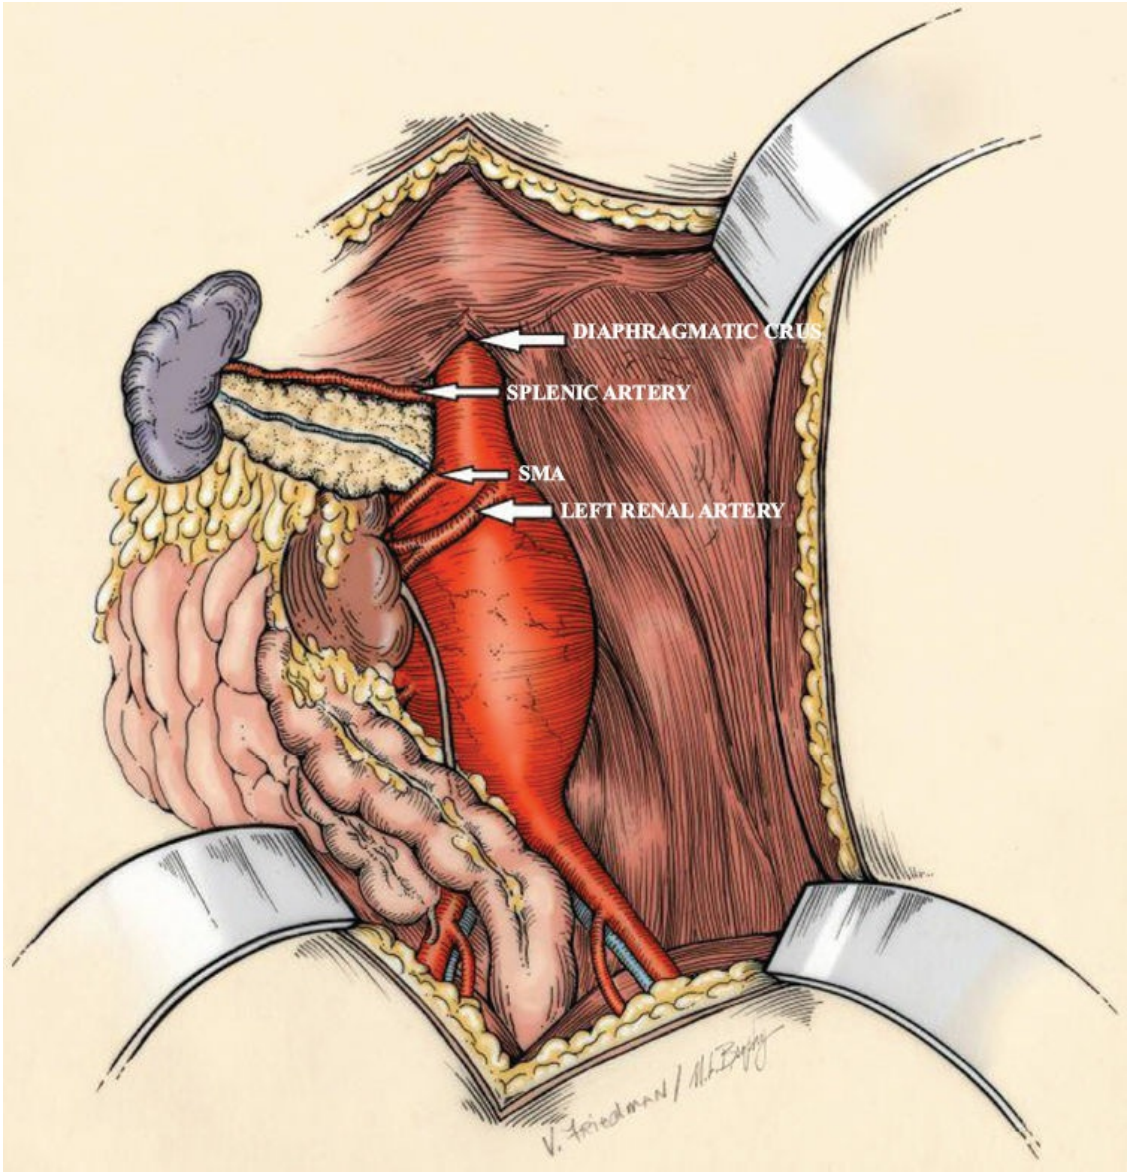

Figure 199.3. Left medial visceral rotation for exposure of entire infradiaphragmatic aorta and iliac vessels.

In cases of pararenal aortic aneurysms, more extensive proximal dissection may be necessary in order to expose an adequate site for proximal clamp placement. The clamp can be placed above one or both renal arteries. For more proximal exposure, a retroperitoneal exposure is ideal for this situation. However, a medial visceral rotation also allows adequate exposure of the proximal aorta with a transabdominal approach. Alternatively, exposure of the supraceliac aorta can be obtained by first mobilizing the left lobe of the liver and dividing the triangular ligament. With the liver gently retracted laterally, the gastrohepatic ligament can be divided along with the left diaphragmatic crural fibers to expose the aorta at this location for clamp placement.

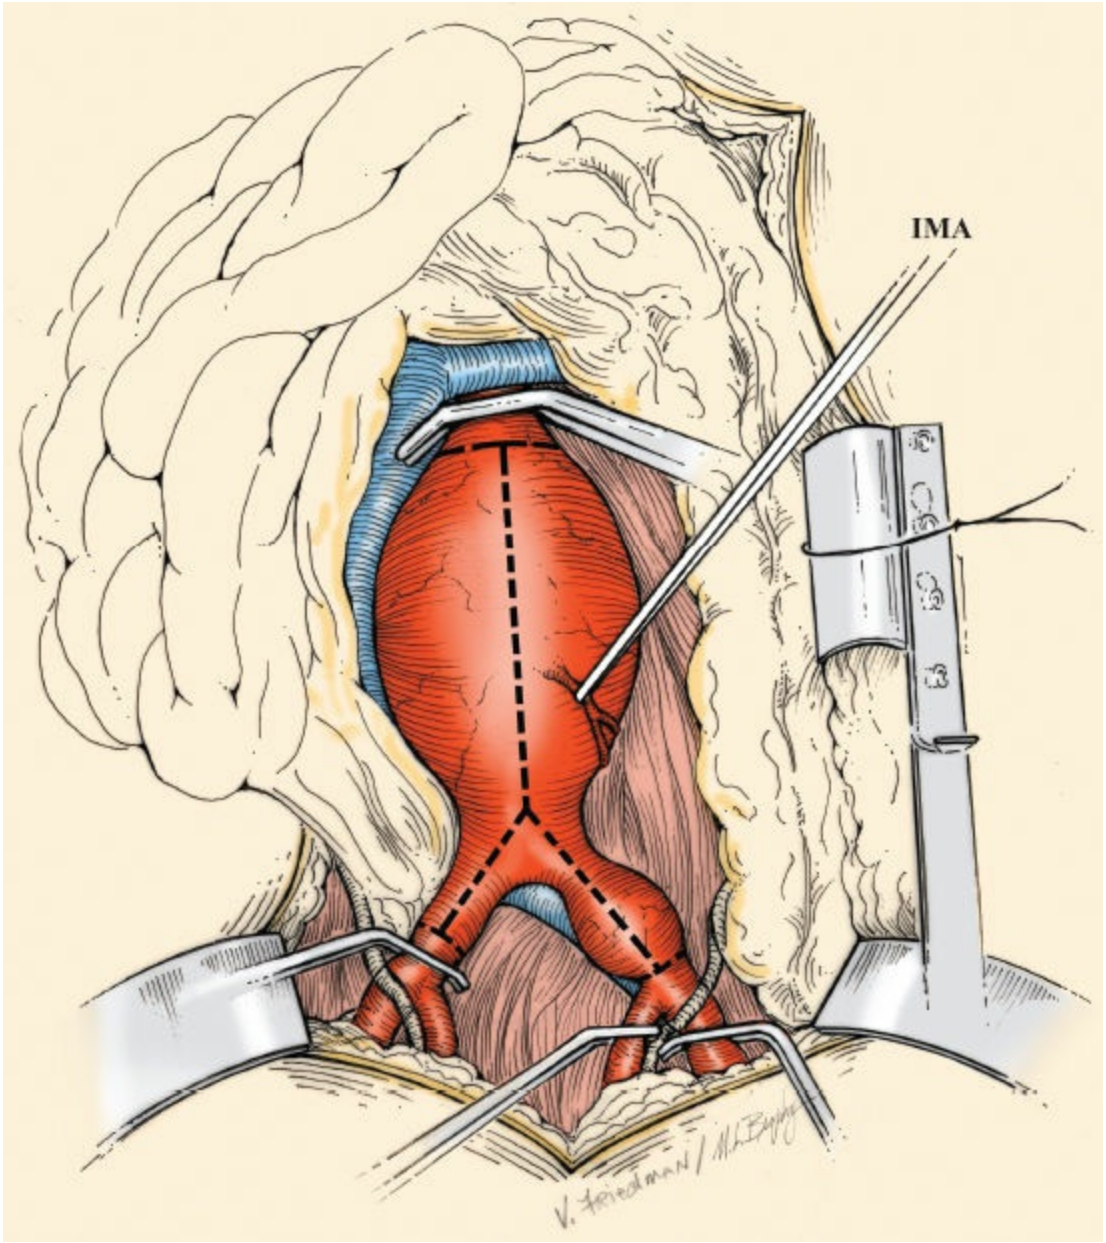

Figure 199.4. Infrarenal aortic and iliac arteries cross-clamped. Notice aneurysm and incision to the right of the inferior mesenteric artery (IMA).

Once adequate exposure is obtained, the proximal and distal clamp positions are identified. As noted above, careful assessment of available preoperative imaging helps guide identification of the location within the arterial vasculature for clamp placement. A disease-free area should be identified to minimize the potential for clamp injury as well as potential embolization of arterial debris. There are instances when the iliac arteries are so severely calcified that safe clamp placement is deemed as not feasible. In these instances, temporary balloon occlusion should be

planned.

The extent of the arterial replacement and graft configuration is balanced between removing all aneurysm tissue and performing an expeditious repair. The proximal extent of aortic replacement should include all aneurysm tissue. In cases of infrarenal aneurysm, the proximal extent of the repair should be just at the level of the renal arteries in order to avoid the future sequelae of continued aneurysm degeneration in the remaining native infrarenal aorta. A straight “tube” graft configuration can be utilized in just under half of infrarenal repairs when there is no aneurysmal degeneration of the iliac arteries. This configuration is the most expeditious repair as there is only one distal anastomosis required. In the remaining cases, a “bifurcated” graft is required with separate distal anastomoses done on the right and left side. This is required if there is aneurysm degeneration of one or both iliac arteries or if the distal aorta is so severely calcified that an anastomosis cannot be performed safely. Different conduits (such as polyester/Dacron or polytetrafluoroethylene) have all been utilized with no clear evidence to support the superiority of one type over another.

Prior to placement of the vascular clamps, the patient should be systemically anticoagulated with intravenous heparin (80 units/kg). Activated clotting times (ACT) can be measured to determine if additional boluses are necessary. We prefer to keep ACT greater than 250 during aortic cross-clamping. The sequence of clamp placement is determined by first placing clamps at locations with the least atherosclerotic burden (typically the distal clamps at the iliac arteries) to prevent embolization. After all proximal and distal clamps have been placed, the aneurysm sac is palpated to ensure the loss of pulsatility. The anterior wall of the aneurysm sac is then opened longitudinally away from the orifice of the IMA. The thrombus within the aneurysm sac is then manually removed and back-bleeding from lumbar arteries can be controlled with suture ligation. If the IMA is patent, then it should be controlled (in most cases) by suture ligation from within the aneurysmal sac (Fig. 199.5).

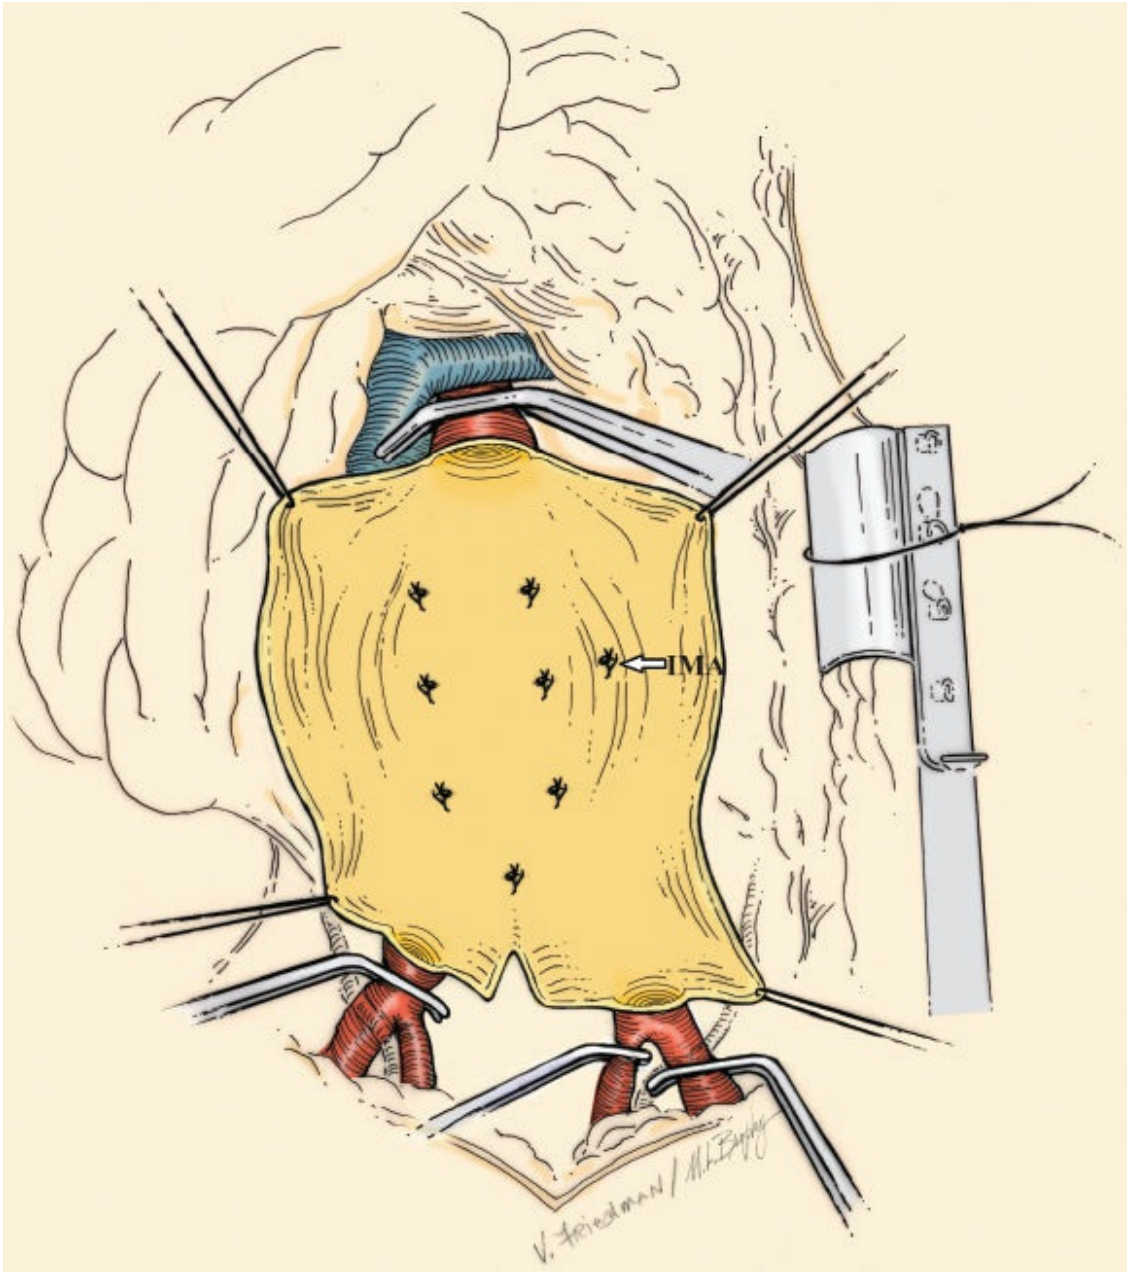

Figure 199.5. Opening of aneurysm sac and suture ligation of lumbar arteries and IMA.

Once hemostasis is achieved, the remainder of the aortic thrombus is removed. The aortotomy is then extended in a cephalad fashion and the aorta is then transverse divided at the level of the proximal neck. While circumferential division may facilitate visualization, this is not necessary and often the posterior aspect of the aorta is left intact. A graft with the appropriate proximal diameter is chosen and an end-to-end anastomosis is created with polypropylene sutures. Care should be taken to ensure that adequate “bites” of native aortic wall is taken to ensure stability of the anastomosis. In cases of friable aortic tissue, a strip of pledget can be

utilized to reinforce the anastomosis. After completion of the anastomosis, heparinized saline can be forcibly infused with a bulb syringe into the distal aspect of graft to test the proximal anastomosis. If this appears to be hemostatic, a separate clamp is placed on the proximal aspect of the graft and the proximal aortic clamp is released. For “tube” graft configurations, the distal anastomosis is created in a similar fashion and encompasses both orifices of the common iliac arteries. If the distal anastomoses are created to the iliac arteries (“bifurcated” configuration), then the anterior wall of the iliac arteries are longitudinally divided to allow visualization and end-to-end anastomoses are created to healthy iliac arteries. In cases where there is aneurysmal dilatation of the distal common iliac artery, the distal anastomosis will be created to the bifurcation of the internal and external iliac artery. The proximal tube component of a bifurcated graft should be kept short and the limbs stretched to avoid redundancy that may lead to future kinking once flow is re-established. The fate of the internal iliac artery is determined by the status of pelvic circulation. If the contralateral internal iliac artery is patent, then the ipsilateral internal iliac artery can simply be ligated and oversewn. If the contralateral internal iliac is either occluded or has a severe stenosis, then considerations should be made to either reimplant the internal iliac or perform a separate bypass graft to it to maintain adequate antegrade perfusion of the pelvic organs. In a bifurcated repair, distal flow should be restored when one anastomosis is completed prior to working on the contralateral anastomosis. There should be aggressive flushing maneuvers to ensure that any debris or thrombus is not allowed to embolize distally. Once the extremity and pelvic circulation is restored, the bowel is carefully assessed to determine if a patent IMA should be reimplanted. The IMA can be ligated if was identified to be occluded preoperative (on imaging) or have strong pulsatile back-bleeding (suggestive of adequate collateral flow from the superior mesenteric artery branches). If there is poor back-bleeding from a patent IMA, presence of SMA stenosis, or if the sigmoid or pelvis perfusion appears to be inadequate, a circular patch of aortic wall encompassing the IMA orifice is then re-implanted onto the prosthetic graft as a Carrel patch. Once adequate perfusion is ensured, the patient may receive protamine sulfate (and additional blood products as necessary) to aggressively reverse the anticoagulation. The native aortic wall is then reapproximated over the prosthetic graft and the retroperitoneum is closed to separate the graft from the adjacent small bowel to prevent future development of an aortoenteric

erosion or fistula. A piece of omentum can also be utilized to create a barrier anterior to the prosthetic graft. A careful inspection of the abdominal contents is then performed again and returned to the normal anatomic location prior to abdominal wall closure.

Retroperitoneal Approach to Juxtarenal Aneurysms

The patient is placed in the right lateral decubitus position with the use of a bean bag to maintain the position of the patient throughout the operation. For most supraceliac exposure using a retroperitoneal approach, the patient is usually placed in a 45-degree angle with appropriate cushioning of pressure points (Fig. 199.6A,B) to avoid iatrogenic pressure injuries. Depending on the proximal extent of the aneurysm and the previously planned aortic cross-clamping site, the incision is then selected. For the retroperitoneal exposure of juxtarenal aneurysm, a curvilinear incision from the lateral border of the left anterior rectus muscle to the tip of the 12th rib or the space between the 11th and 12th ribs is preferred. In very thin patients, just going to the tip of the 12th rib provides enough exposure for juxtarenal cross-clamping.

After the incision is made, the subcutaneous tissue is divided with electrocautery. The left lateral border of the anterior rectus sheath is then incised and the external oblique muscle is divided. It is at this junction between the lateral border of the anterior rectus sheath and the lateral abdominal wall muscles that the dissection is carried out to enter the retroperitoneal space. Once the posterior transverse fascia is incised, the peritoneum is swept medially and superiorly, allowing for the division of the lateral abdominal wall muscle. The division of intercostal muscles should be avoided if at all possible. Once the retroperitoneum is entered, identification of the left ureter is made and a vessel loop is placed around it, with enough tissue surrounding it to avoid ureteral devascularization. The ureter is then mobilized down to the iliac vessels inferiorly and superiorly to the renal pelvis. The space between Gerota fascia and the peritoneum is then bluntly entered and the kidney is allowed to fall backward in its fossa as the peritoneum is swept medially and the left renal vein is easily identified (Fig. 199.7). It is of note that for juxtarenal aortic cross-clamping, the kidney can be safely maintained in its renal fossa, although in obese patients with a very short neck, between the superior mesenteric artery and the renal arteries; then, the mobilization of Gerota fascia to allow the kidney to be elevated and fully mobilized provides a

retrorenal exposure to the juxtarenal aorta when indicated.

The gonadal vein is then identified and ligated right at the junction with the left renal vein. Medial mobilization of the peritoneum and the perirenal vein tissue will then expose the juxtarenal neck of the aorta. After placing the appropriate retractors, the neck of the juxtarenal aorta is mobilized. Because of poor visualization of the right renal artery, careful mobilization of the left renal vein should be made as far to the right as safely possible. If a suprarenal but inframesenteric cross-clamp is needed, then the lower aspect of the left crux of the diaphragm would have to be mobilized to allow the space between the superior mesenteric artery and the left renal artery to be exposed. If cross-clamping is going to be performed just above the renal arteries, every attempt should be made to at least digitally palpate the right renal artery to avoid, if possible, any injuries during aortic cross-clamping. Once the neck has been appropriately dissected, the mobilization of the peritoneum distally to, if possible, expose the right common iliac artery should be attempted. In thin patients this is easily performed, but in obese patients the best option is to cross-clamp the left common iliac artery and the right will be controlled by an intraluminal occlusion balloon after proximal aortic clamping and opening the aneurysmal sac.

After adequate exposure of the proximal and distal clamping sites, the patient is systemically anticoagulated as described above. The iliac arteries are initially clamped and then the aortic cross-clamp is applied, either just below the renal arteries or immediately above the renal arteries with an aortic cross-clamp. If intraluminal control of the right common iliac artery is necessary, this is done after the aneurysm sac is opened and the clot removed. There should be a careful attempt to avoid sweeping the clot down toward the aortic bifurcation. The clot should be removed superiorly to avoid impaction of thrombus in the proximal right common iliac artery. As soon as clear visualization of the ostium of the right common iliac artery is made, an intraluminal occlusion balloon is inserted to control back-bleeding. Once this is performed, the appropriate retractors are placed in the aortic sac to allow for full exposure of the proximal and distal anastomotic sites. If the IMA has retrograde bleeding, this can be easily controlled with suture ligatures from within the aneurysm sac. Any retrograde bleeding lumbar arteries are similarly controlled with suture ligatures. At this point, an end-to-end anastomosis is performed to the proximal aortic neck as well as end-to-end anastomosis (-es) either to the

distal aorta or to the common iliac arteries as needed.

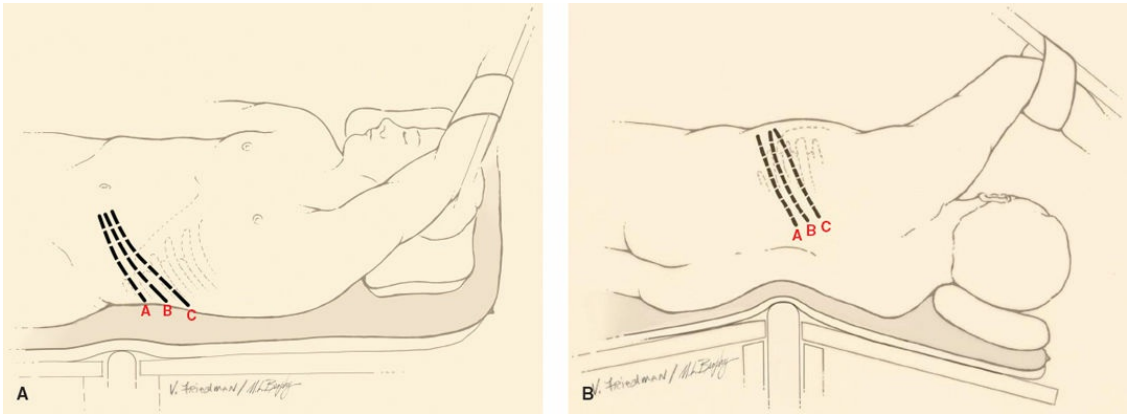

Figure 199.6. Anterior (**A**) and posterior (**B**) views of patient position for retroperitoneal approach to the aorta. Incisions *A* and *B* for infrarenal and juxtarenal, and *C* for suprarenal exposure.

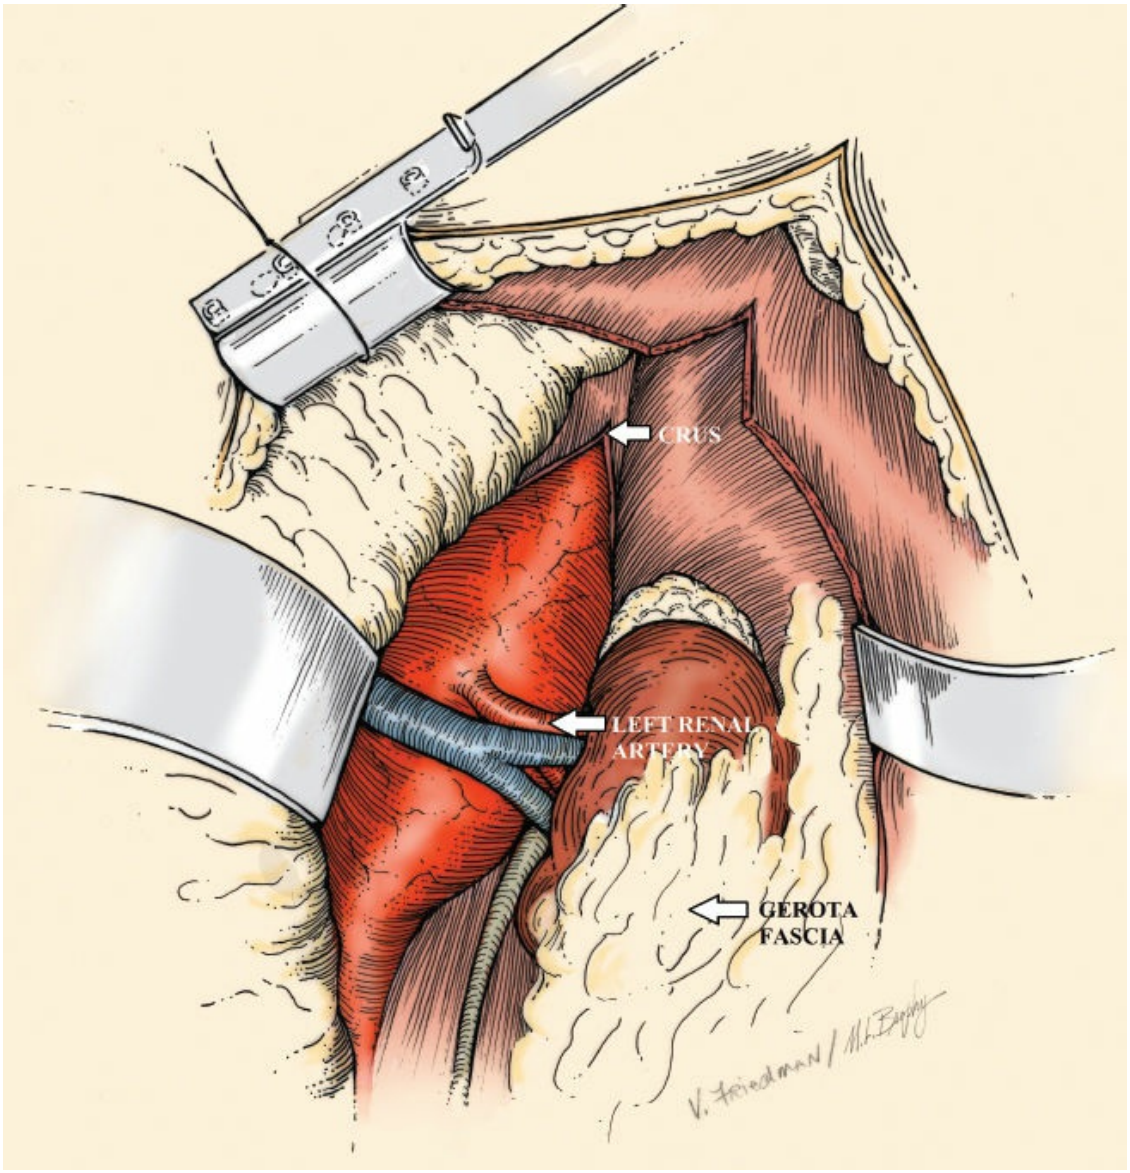

Figure 199.7. Retroperitoneal exposure of suprarenal aorta after mobilization of Gerota fascia. Note crus of diaphragm.

Retroperitoneal Approach to Suprarenal Aneurysms

If the aneurysm extends above the renal arteries but below the celiac axis, then exposure of the suprarenal aorta up to the celiac axis and above may be indicated. The incisions in terms of where they would be carried out on the chest wall are delineated. In these cases, the space in between the ribs will go from the tenth to the eighth space depending on the body habitus of the patient and how high up the aortic cross-clamp will be applied. Following the same maneuvers that were described for the juxtarenal aorta, Gerota fascia should be fully mobilized as to allow exposure to the aorta from a retrorenal approach rather than from the anterior aspect of the renal vessels. Once the left kidney is completely mobilized from Gerota

fascia, the kidney with its vessels are then mobilized to the right and superiorly, allowing for exposure of the left crux of the diaphragm. This is divided up to the diaphragmatic hiatus, allowing for exposure of the entire infradiaphragmatic aorta (Fig. 199.8). It must be remembered that when the left kidney is superomedially mobilized, a large lumbar vein is frequently encountered that drains into the posterior wall of the left renal vein and this must be ligated to avoid any venous injury. After the crux of the diaphragm is divided, the infrarenal exposure is performed in a similar manner as the description for juxtarenal aneurysm repair.

When the proximal aortic cross-clamp site will be at the supramesenteric or supraceliac level, exposure of this space requires the anterior division of the diaphragm in a radial fashion for 3 to 5 cm, so that when the retractors are placed, neither the ribs fracture nor the diaphragm tears. This diaphragmatic division will be appropriately repaired during the closure. Once the appropriate retractors are placed, if the supraceliac aorta is clamped, it is best that the revascularization of the mesenteric and renal vessels are accomplished by either an end-to-end anastomosis of the supraceliac aorta as a Carrel patch to incorporate the right renal artery, superior mesenteric artery, and celiac axis and allowing blood flow to these vessels initially as a side branch that has been previously sutured to the graft is used to revascularize in an end-to-end fashion the left renal artery (Fig. 199.9). In our experience, because the warm ischemia time of the left kidney in this type of reconstruction usually approaches or exceeds 30 minutes, we prefer to maintain the left kidney covered by a laparotomy sponge with ice slush. If more complex reconstruction is required (duration more than 40 minutes), then cold renal perfusion with lactated Ringer’s is performed to the left renal artery to protect it while performing the reconstruction.

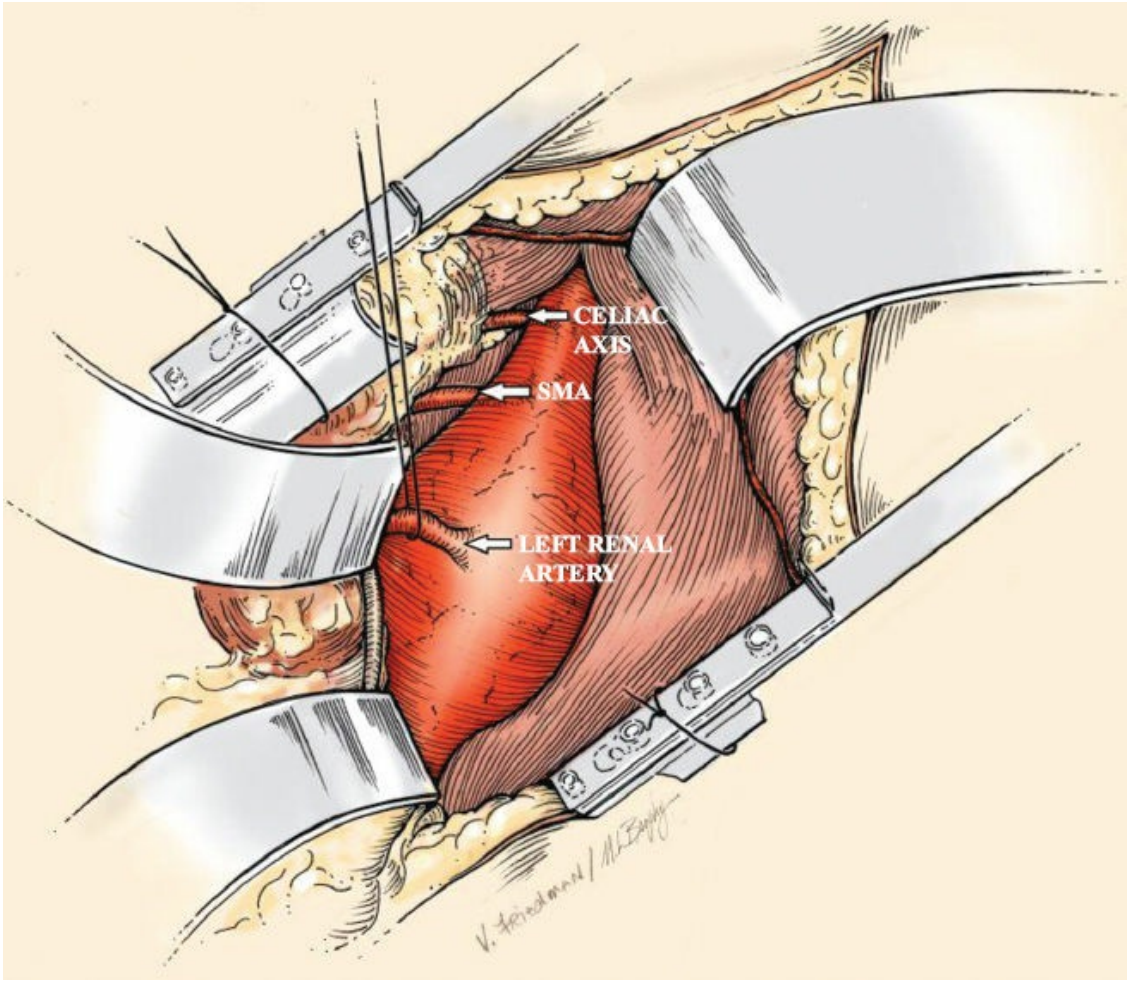

Figure 199.8. Exposure of infradiaphragmatic aorta after dissection of left diaphragmatic crus. Notice exposure with kidney mobilized anteriorly.

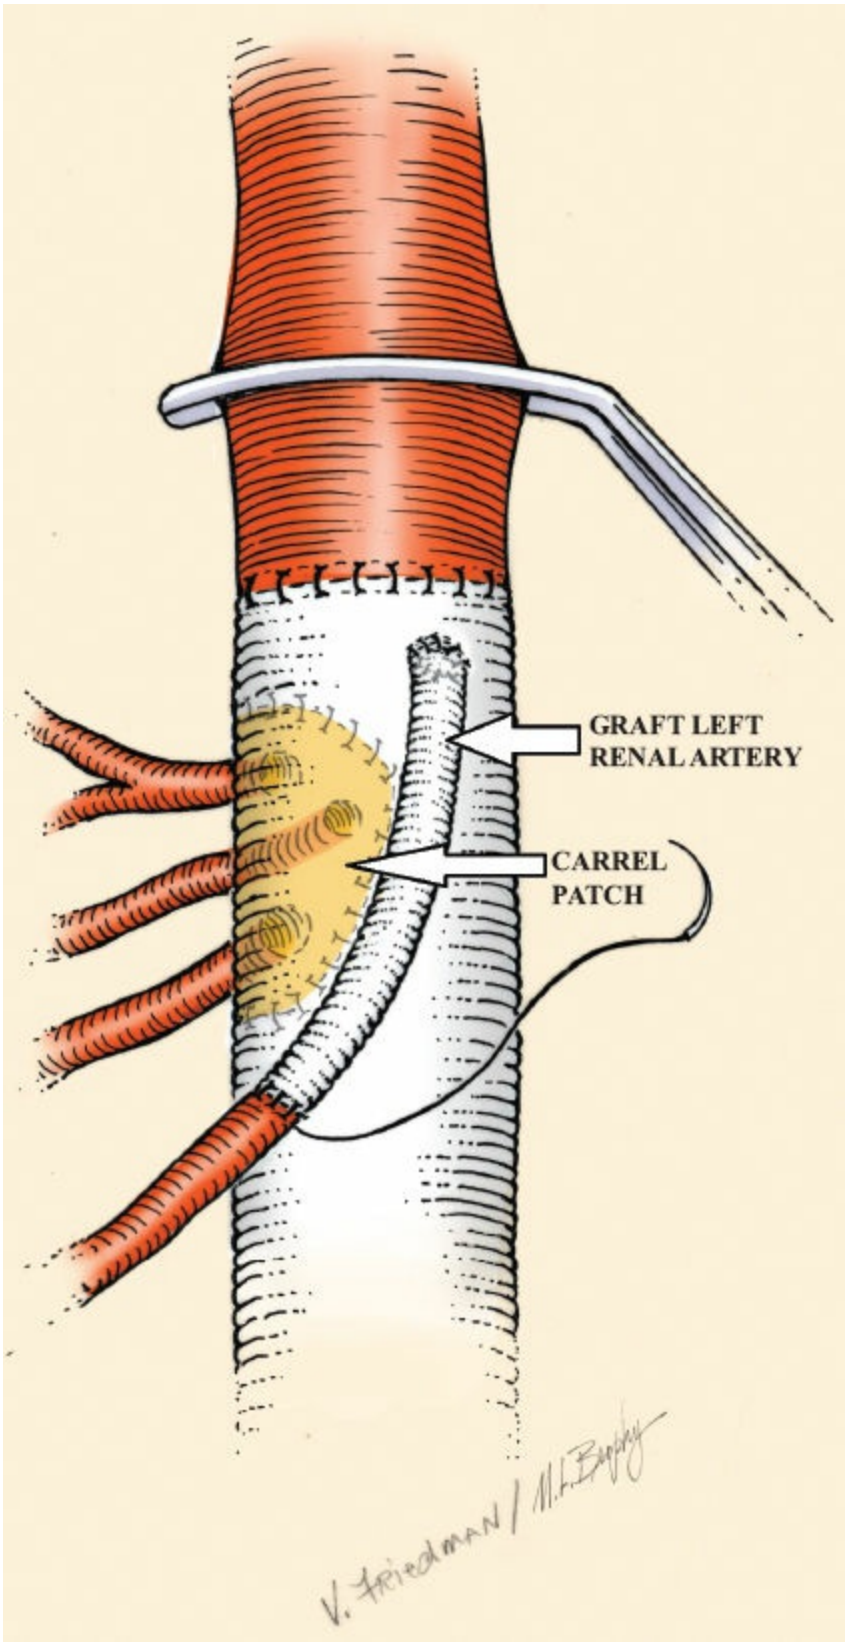

Figure 199.9. Reconstruction of suprarenal aneurysm with Carrel patch to include celiac axis, superior mesenteric artery, and right renal artery. Separate graft for left renal artery.

POSTOPERATIVE CARE AND COMPLICATIONS

Perioperative complications are not uncommon after open aortic aneurysm repair. After completion of the surgical repair, the patient is admitted to the intensive care unit and should be aggressively rewarmed and any postoperative coagulopathy reversed. Despite the increasing case complexity for open aneurysm repair in the endovascular era, the mortality rates have in fact remained the same or decreased with advances in critical care medicine, between 3% and 5% in large reported series. Myocardial infarction remains the leading cause of death. However, postoperative complications include pulmonary dysfunction, myocardial infarction, renal failure, need for dialysis, bleeding complications, colonic ischemia, limb ischemia, and venous thrombosis. Colonic ischemia should be suspected in a patient with acidosis, abdominal distention, or guaiac positive stools. There should be high index of clinical suspicion and bedside flexible sigmoidoscopy is performed to document the extent of ischemia. Aggressive resuscitation with intravenous hydration and broad spectrum antibiotics may suffice to treat limited cases, but colectomy and creation of an end colostomy is needed in case of transmural necrosis. Late complications of open aneurysm repair include anastomotic pseudoaneurysm, incisional hernia and bulges, bowel obstruction, graft infection, and aortoenteric fistula. For long-term follow-up, a CTA of the chest, abdomen, and pelvis is obtained every 5 years to evaluate aneurysm degeneration of the remaining native arterial vasculature.

OUTCOMES OF JUXTA AND PARARENAL OPEN ANEURYSM REPAIR

Recent series have reported acceptable 30 day postoperative mortality with juxtarenal and pararenal aneurysm repair (Table 199.2). Postoperative renal dysfunction and need for dialysis remains a common postoperative morbidity that affects short- and long-term survival. Similar observations have been reported for fenestrated juxtarenal and pararenal aneurysm repair. Perioperative and intraoperative maneuvers to diminish this significant complication rate remains an important area of clinical research.

ACKNOWLEDGMENT

We would like to express our gratitude to nurse practitioner, Dawn Sander,

for her assistance with the editorial completion of this chapter.

EDITOR'S COMMENT

Open aortic aneurysm repair is quite honestly the reason I became a vascular surgeon. When I trained open AAA repair was really the only method for repair and it was a massive, but beautiful, insult which parallel the ischemia reperfusion injury we often created in the laboratory. Where I trained, we would admit these patients to the intensive care unit, place a PA catheter, and then do a fluid challenge to determine that their heart could handle the fluid challenge. We would then go to the operating room the next day with the patient already fluid overloaded, perform open aneurysm repair, and then continue to flood the patient with crystalloid for another 48 hours. This is in contrast to what is performed today in which patients are almost never admitted the night before, undergo operations often without a blood transfusion, are extubated on the operating room table, then go to intermediate care floors that are not intensive care units (Vandy FC, Campbell D, Eliassen A, et al. Specialized vascular floors

after open aortic surgery: cost containment while preserving quality outcomes. *Ann Vasc Surg* 2013;27(1):45–52). Wow have we come a long way!!!

In this chapter by Dr.'s Sicard and Jim, they have done an excellent job of describing the technical details of open AAA repair. Dr Sicard in particular has a long-standing history of an academic interest in this subject. In particular, he performed one of the only randomized trials to examine the transabdominal (TAI) versus retroperitoneal (RPI) open aortic repair. In this landmark study in which 145 patients with both aortic aneurysm and occlusive disease were randomized and there were no differences in mortality between the two groups (overall postoperative mortality rate [two deaths] was 1.4%, with both occurring in the TAI group, $p = 0.507$). However, after surgery, the incidence of prolonged ileus ($p = 0.013$) and small bowel obstruction ($p = 0.05$) was higher in the TAI group. Overall, the RPI group had significantly fewer complications ($p < 0.0001$). The RPI group also had significantly shorter stays in the intensive care unit ($p = 0.006$), a trend toward shorter hospitalization ($p = 0.10$), lower total hospital charges ($p = 0.019$), and lower total hospital costs ($p = 0.017$). The authors concluded that the RPI approach for abdominal aortic surgery was associated with fewer postoperative complications, shorter hospital and intensive care unit stay, and lower cost. I believe this is still the best study examining these two operative approaches, even though I view these approaches as complementary and usually tailor my approach to repair based on patient (obesity, redo nature, etc.) and aortic characteristics.

There is no doubt this is a beautiful and elegant operation that we have made significant improvements on. In a recent snapshot of open versus endovascular repairs across the United States, while the number of open AAA repairs has decreased over the last decade, the mortality of open AAA repair has also decreased and is now only 4% (Dua A, Kuy S, Lee CJ, et al. Epidemiology of aortic aneurysm repair in the United States from 2000 to 2010. *J Vasc Surg* 2014;59(6):1512–7). This is remarkable given the observation that most of the patients are not endograft candidates which suggests that their aortic anatomy is even more complex.

While some have suggested that regionalization of endovascular care be performed, there is also a notion that perhaps open aneurysm repair might be even better for regionalization. This has occurred as vascular surgery training programs have performed a higher and higher percentage of their aortic cases endovascularly. It is highly likely that the finishing vascular surgery fellows may have performed less than 10 open AAA repairs in their entire fellowship (Dua A, Upchurch GR Jr, Lee JT, et al. Predicted shortfall in open aneurysm experience for vascular surgery trainees. *J Vasc Surg* 2014;60(4):945–9; Dua A, Koprowski S, Upchurch G, et al. Progressive shortfall in open aneurysm experience for vascular surgery trainees with the impact of fenestrated and branched endovascular technology. *J Vasc Surg* 2017;65(1):257–61). It is almost predictable with so few open AAA repairs, perhaps some form of regionalization is already occurring. I personally noticed a shift in my own

practice as I was an early adopter of endovascular AAA repair (EVAR). However, over time as EVAR became the new standard and matriculated into community hospitals, now patients with poor anatomy are often referred to tertiary referral centers. Thank goodness for this pattern as I love open aortic surgery!!!

200 Endovascular Repair of Abdominal Aortic Aneurysms

Gregorio A. Sicard and Dawn Sander

Endovascular aneurysm repair (EVAR) has become a consequential less invasive alternative to the treatment of infrarenal abdominal aortic aneurysms (AAAs). Initially reported by Dr. Juan Parodi and collaborators in Buenos Aires in 1991 as an attractive alternative for patients with AAA deemed unfit for open aneurysm repair due to significant comorbidities. Although the initial experience in the 1990s and early 2000s were limited to high-risk patients, the initial good results from randomized clinical trials (RCTs) along with patient preferences for a less invasive approach significantly expanded its use to most elect AAA repair. Industry along with clinical investigators have played a critical role in introducing various devices that have been carefully scrutinized by FDA-approved clinical trials. This relationship between industry, FDA, and surgical investigators has led to various generations and impactful modifications of endografts. Currently there are six FDA-approved and commercially available devices (Table 200.1) each with its structural characteristics and specific Instructions for Use (IFUs).

In the United States, approximately 45,000 patients undergo AAA repair annually. Based on 2010 Medicare data, EVAR was the method used in 74% of beneficiaries. This number is actually higher (>80%) for large centers with significant experience where endovascular alternatives are being utilized even for complex infrarenal and juxtarenal AAA repair. This dramatic increase in the use of EVAR over the last 20 years has created challenges for vascular training programs to provide sufficient, meaningful experience in open AAA repair for trainees. This challenge has further increased with the more frequent use of fenestrated/branch devices for juxta-, suprarenal, and even thoracoabdominal AAA repair. Similar challenges have occurred in laparoscopic versus open intra-abdominal surgery (i.e., cholecystectomy, colon resection, hernia repair etc.).

TABLE 200.1 Commercially FDA Approved Infrarenal Endograft Devices

Company	Commercial Device Name	Endoprothesis Diameter (mm)	Attachment and Sealing
W. L. Gore	Excluder	23–35	Barbs
Medtronic	Endurant	23–36	Suprarenal bare stent with hooks
	Talent	22–36	Bare stent—suprarenal
Cook	Zenith-Flex	22–36	Suprarenal stent with hooks
Endologix	AFXs	25–34	Suprarenal stent with hooks
	Ovation	16–30	Suprarenal stent and neck rings for polymer injection

TECHNICAL CONSIDERATIONS

Different from open aneurysm repair, strict anatomical requirements must be met prior to considering a patient to be a suitable candidate for EVAR. A number of requirements for each device have been established and recommended by the FDA and industrial partner and termed IFUs. Amongst these requirements are included: a proximal aortic neck diameter below the lowest renal artery of equal to or less than 32 mm and equal to or greater than 15-mm aortic neck length. Suitable iliac artery diameters to allow insertion of the device is also important. The neck dimensions and characteristic of the aortic neck remain the primary restrictions for the use of EVAR. Despite these limitations, 80% of patients are candidates for EVAR with current devices. Lower profile devices, as well as techniques to create iliac conduits, have been described to resolve anatomical restrictions of the iliac arteries which are frequently encountered in women. In order to follow the “strict” anatomical requirements, accurate preoperative imaging with CT scan with IV contrast (CTA) and 3D reconstruction are required. The 3D reconstruction and centerline measurements allow for accurate measurements of the diameter and length of the aortic neck from the level of the lowest renal arteries to the common femoral arteries. Due to the frequently seen tortuosity of the infrarenal aortic neck and iliac arteries, precise diameter measurements is best accomplished with 3D reconstruction of thin sliced CT images (1 to 3 mm) and centerline measurement at the appropriate anatomical sites. Contrast CT scan can also identify the presence or absence of thrombus, calcium, or significant atheromatous disease in the aortic neck or in the iliac arteries that may interfere with the delivery of the endograft and the seal at attachment sites. Enhanced images with CTA can also identify polar artery (ies) that affects the true aortic neck (≥15 mm). The use of preoperative thin sliced contrast CT scan and 3D reconstruction with centerline measurement has become the norm for preoperative EVAR evaluation and has practically eliminated the need for preoperative arteriography except

for rare selected cases. In patients with abnormal renal function (serum creatinine equal to or greater than 1.6 mg/dL), magnetic resonance arteriography (MRA) with gadolinium can be useful in providing all the anatomical information required. The use of gadolinium is restricted for patients that have markedly abnormal renal function but the technique of time-of-flight MRA can be useful and avoid the use of gadolinium.

Endograft selection is based on the anatomical characteristics of the specific patient's anatomy, specifically as it related to aortic neck size, aortic neck type (straight vs. tapered), supra- and infrarenal aortic neck angulation, absence/presence of iliac artery aneurysms, and size of the external iliac arteries. Many new devices have been introduced to expand the patient population that can be offered EVAR. Neck angulations of equal to or more than 60 degrees has clinically been associated with graft migration and Type I endoleaks in association with an increased incidence of aneurysm rupture. Because of this, patients that have significant angulation (equal or more than 60 degrees) require devices that are flexible in the proximal portion and have been specifically designed for that type of anatomical variant. Recently, an endostaple has been introduced (Aptus Endosystem) which in reverse tapered aortic necks or in patients with persistent Type I endoleaks can be used to secure the endograft to the aortic wall providing a fixation and seal in this portion of the repair.

OPERATIVE TECHNIQUE

The most common approach for the insertion of the device is through open groin incisions and insertion of the main body and either percutaneous or open insertion of the contralateral limb (Fig. 200.1A,B).

Another important clinical advancement has been the development of arterial closure devices, which permits the use of percutaneous endoluminal repair of aneurysms using devices such as a Perclose or Prostar. The percutaneous approach to EVAR has decreased operative time and groin wound complications, as well as decreased hospital length of stay. Using this approach (percutaneous EVAR), many vascular groups have performed, in selected patients, this procedure as outpatient or as a short stay.

Each endograft has a different construction in terms of the type of stent (nickel titanium alloy, cobalt chromium alloy, or stainless steel), the type and thickness of the graft material used (Dacron, ePTFE), as well as different attachment mechanisms at the proximal and/or distal landing

zones. Even though all the devices rely on the radial force of the stent for attachment (Powerlink), some devices have added hooks (Excluder) or a suprarenal bare stent extension with or without hooks for proximal fixation (Zenith, Endurant, Talent, Ovation) and/or proximal sealing rings filled with a polymer (Ovation). In order to accomplish maximal expansion and appropriate sealing at the landing zones, the diameter of the endograft selected must be 10% to 20% larger at full expansion than the diameter of the proximal (infrarenal aortic) neck and distal iliac arteries. The surgeon must become familiar with the construction of the device, sheath size (profile), delivery system characteristics, configuration and the various diameters, as well as the limbs and extension diameters and lengths. In addition, the surgeon must follow the recommendations by the manufacturer in the IFUs regarding maximal aortic neck diameter and length, as well as neck angulation. Deviation from the IFU has been clearly demonstrated to be associated with higher peri- and postoperative complications (migration, Type I endoleak etc.). Most commercially available devices used (i.e., Zenith, Excluder, etc.) have a modular design, with the main body and ipsilateral limb as one component and the contralateral limb inserted from the contralateral femoral artery which connects to the “cage” of the main body component, thus creating a bifurcated aortoiliac bypass (see Technique for Endograft Insertion below). The only single body device commercially available is the AFX from Endologix. In this device a proximal extension is frequently necessary in the region of the aortic neck. Aortouniiliac configuration devices are currently available from various manufacturers and used for specific anatomic situations. When an aortouniiliac device is used, a contralateral common iliac occluder must be inserted and a femorofemoral bypass constructed (Fig. 200.2).

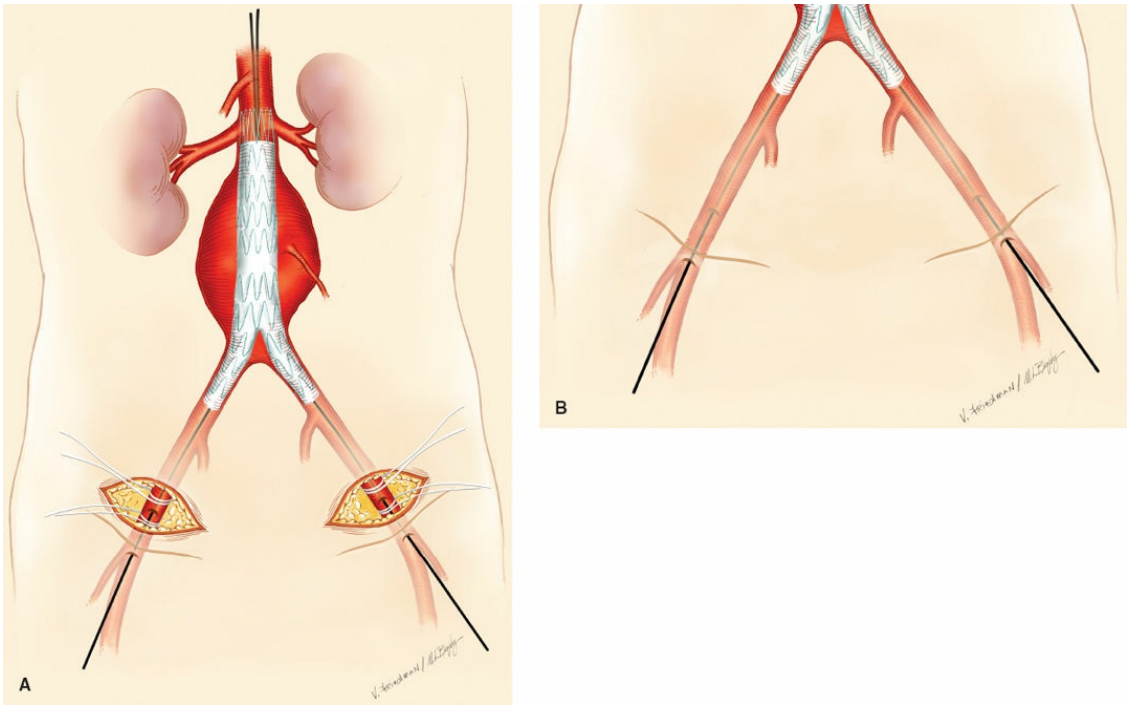

Figure 200.1. A. Endoluminal aneurysm repair by open femoral access. Device depicted has suprarenal stents with hooks for anchors. **B.** Drawing showing percutaneous femoral access for EVAR.

When IFUs are followed, all commercially available devices have demonstrated significantly reduced perioperative mortality, hospital length of stay, and the need for postoperative rehabilitation when compared to open AAA repair. In terms of total hospital costs different studies have demonstrated slightly increased costs with the endovascular repair technique and with the need for further interventions (either endovascular or open) the total long-term cost is significantly higher for endovascular techniques. Long-term results of all of these devices are similar in terms of long-term patient survival.

POSTOPERATIVE SURVEILLANCE

Postoperative imaging at 1, 6, 12 months, and yearly thereafter is of importance to provide early detection of complications associated with the endovascular technique (Type I or III endoleaks, migration and fabric and/or stent integrity). Although most investigators use CTA for follow up, in stable patients, over time, the follow-up can be limited to every 6 to 12 months abdominal aortic ultrasound which will detect expansion of the old aneurysm sac and or any new flow within the aneurysm sac (endoleak). If

any interval abnormality is detected then obviously a confirmatory contrast CT scan is necessary to better define the abnormality.

Clinical Outcomes

RCTs performed in Europe, the United Kingdom, and the United States (Dutch EVAR trial, EVAR 1, EVAR 2, and OVER Trial) have all demonstrated similar significant advantages of EVAR when compared to open aneurysm repair in terms of perioperative mortality, hospital length of stay, and need for rehabilitation.

The most contemporary RCT comparing EVAR to open AAA repair was the OVER Trial. This multicenter aneurysm Veterans Administration trial randomized 881 open versus EVAR using second generation endografts. The 30-day mortality was significantly lower for EVAR when compared to open repair (0.5% vs. 3.0%, $p < 0.004$). Similarly, EVAR had a statistically shorter length of stay compared to open repair (3 vs. 7 days).

All RCTs and nonrandomized trials have demonstrated a higher number of long-term complications after EVAR when compared to open AAA repair. Most of these complications (migration, Type I, II, and III endoleaks) can be resolved by endovascular means. With the continued increase and success of EVAR further expansion of the technology to include juxta- and supra-renal endoluminal repair was to be expected.

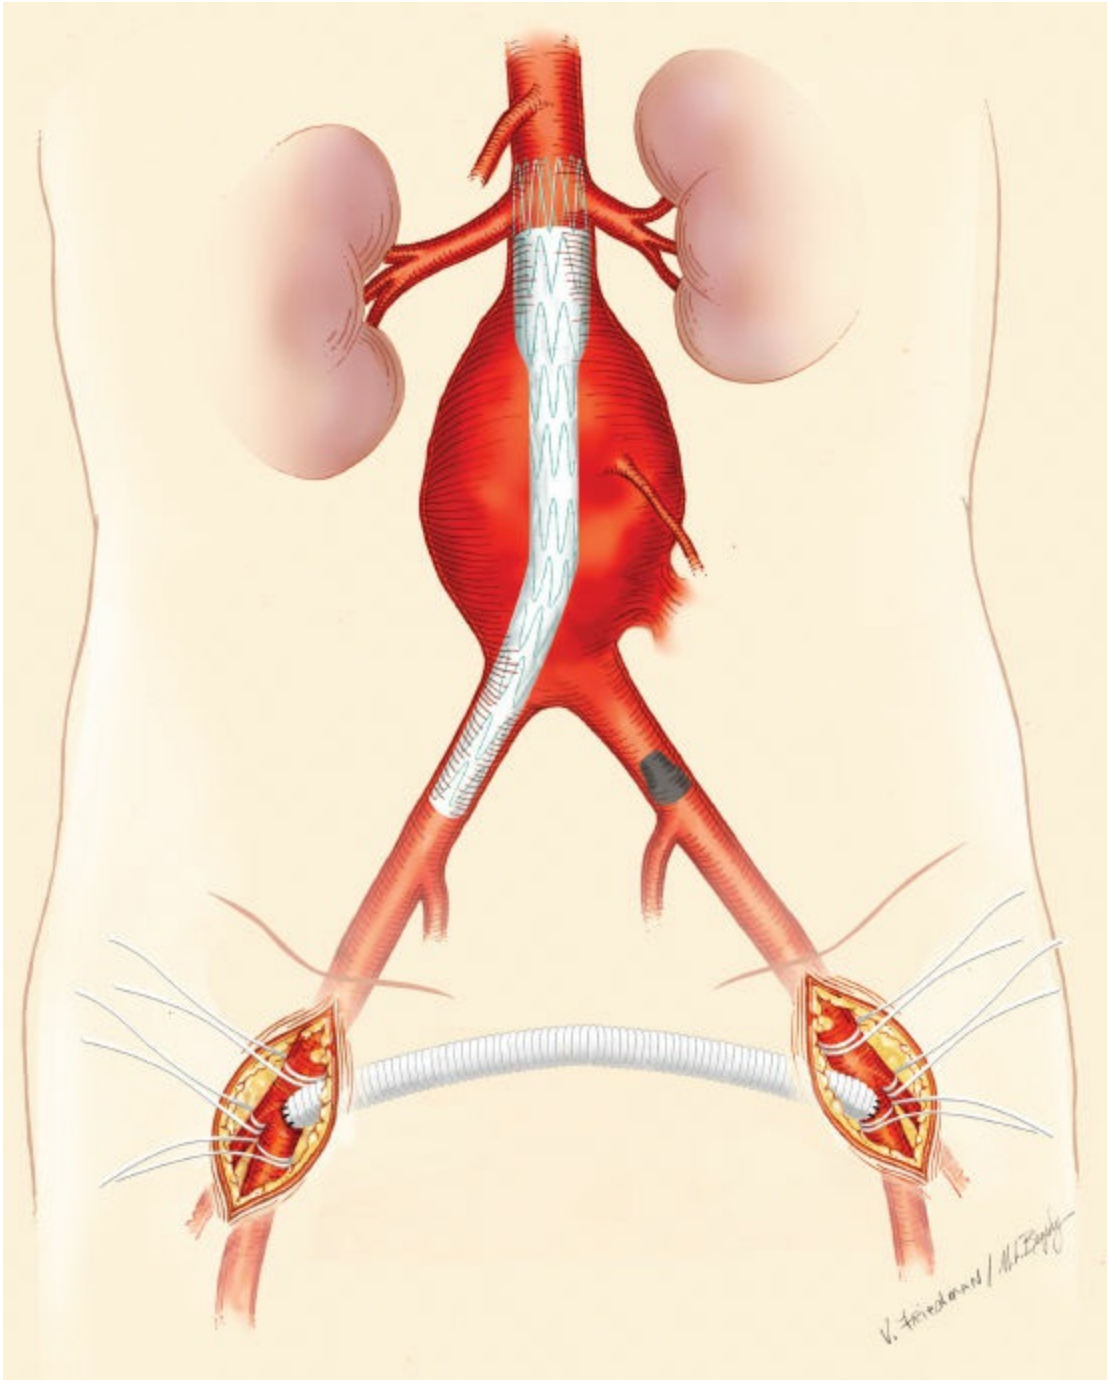

Figure 200.2. Aortouniiliac endograft with left common iliac occlude; notice right to left femoral to femoral prosthetic bypass graft.

New Devices

Currently a Phase II trial in the United States is being conducted for a new concept of EVAR. The Nellix Device by Endologix is two stents which are surrounded by a sealing bag that is inflated with polymer after the two stents are positioned in the juxtarenal aorta. The filling of the bags with

polymer seals the neck and fills the aneurysm sac with a polymer filled bag whose intent is not only to stabilize the two stents, but also eliminate or diminish Type II endoleaks. Early results from Europe are encouraging and a Phase II trial is currently being performed in this country.

ENDOLUMINAL REPAIR OF JUXTA- AND SUPRARENAL AORTIC ANEURYSM

Throughout the mid 1990s and early 2000s various centers nationally and internationally expanded the use of endoluminal aneurysm repair to endoluminal repair of juxtarenal and suprarenal aortic aneurysms. Over the last decade, the use of fenestrated devices (FEVAR) has increased throughout the world. The device with the largest clinical experience has been the Zenith Fenestrated device (Z Fen). This device has demonstrated outstanding results in terms of decreasing perioperative mortality and morbidity, as well as hospital length of stay and patency of target vessels (renals, SMA, etc.) when compared to open repair.

Technical Considerations

The technical aspects of FEVAR is similar in terms of the preoperative preparation and intraoperative technical aspects. Currently, fenestrated devices are custom made based on the specific location of the renal arteries and SMA determined by thin slice CTA with centerline reconstruction. The current delay in construction of the fenestrated device is 3 to 6 weeks. A clinical trial is underway for an off–the-shelf device (P-Branch) for selected patients with anatomy of the location of the renal arteries and SMA that can be used in approximately 70% of patients. Commercial availability of “off-the-shelf” device awaits completion of the trial, although it has obtained CE approval and the results in Europe have been encouraging.

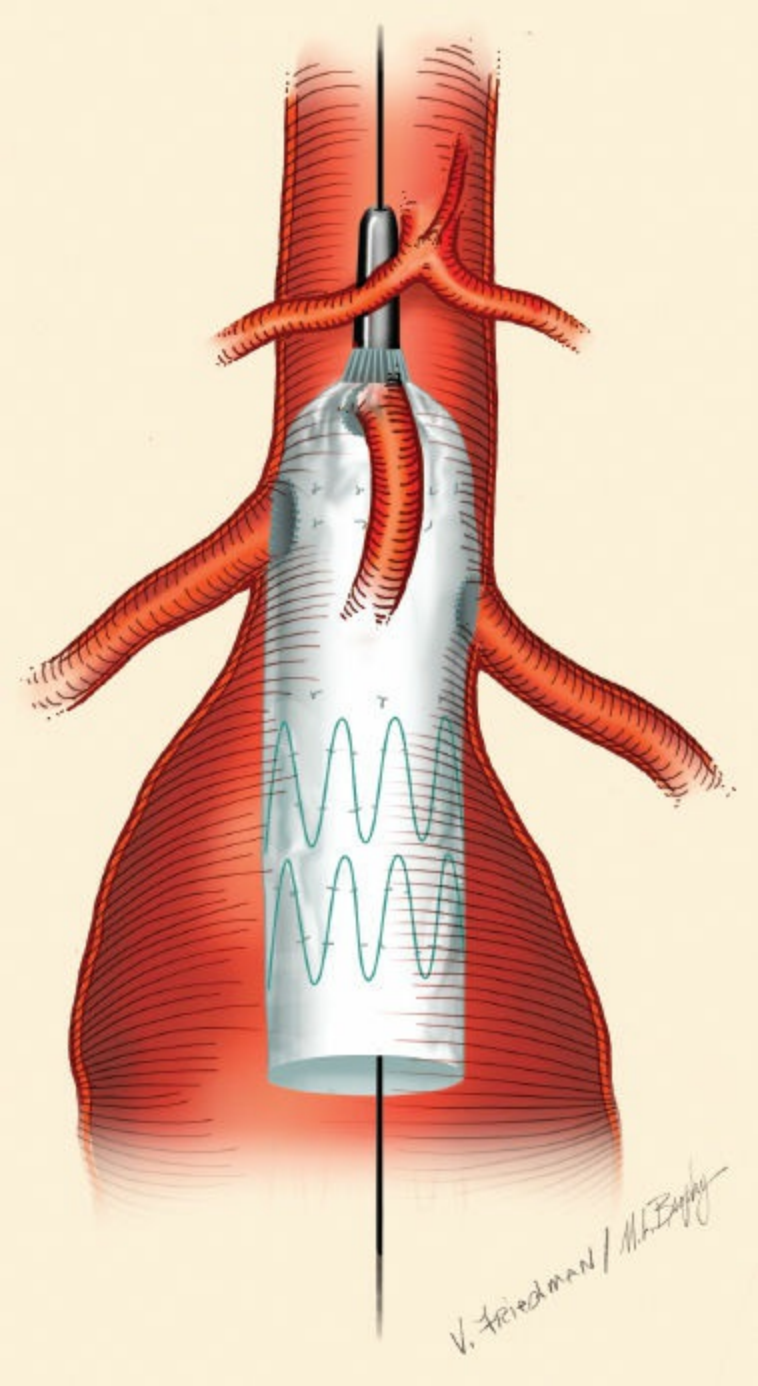

Figure 200.3. Open fenestrated endograft with alignment of fenestrations to renal ostia and scallop to SMA artery. Notice restrained suprarenal attachment which allows rotation of device for proper renal and SMA alignment of fenestration/scallop.

The devices are usually performed either open or percutaneously through the femoral arteries and the fenestrated main body is delivered to the juxtarenal aorta.

The preoperative precise identification of the location of the renal

arteries becomes an important component of the actual construction of the device to ascertain appropriate alignment for the specific patient. Intraoperative after deploying the device with the proximal portion still constrained allows for movement of the main body to make certain the fenestrations align properly with the ostium of the renal arteries (Figs. 200.3 and 200.4).

Once the deployment and ballooning of the renal stents is completed proximal attachment hooks are deployed which will open the scallop that accommodates the superior mesenteric artery (Fig. 200.5). After this portion is completed, a bifurcated Zenith device is placed inside of the tubular fenestrated main body with iliac limbs to ascertain a complete endovascular repair of the entire juxta- and infrarenal aorta.

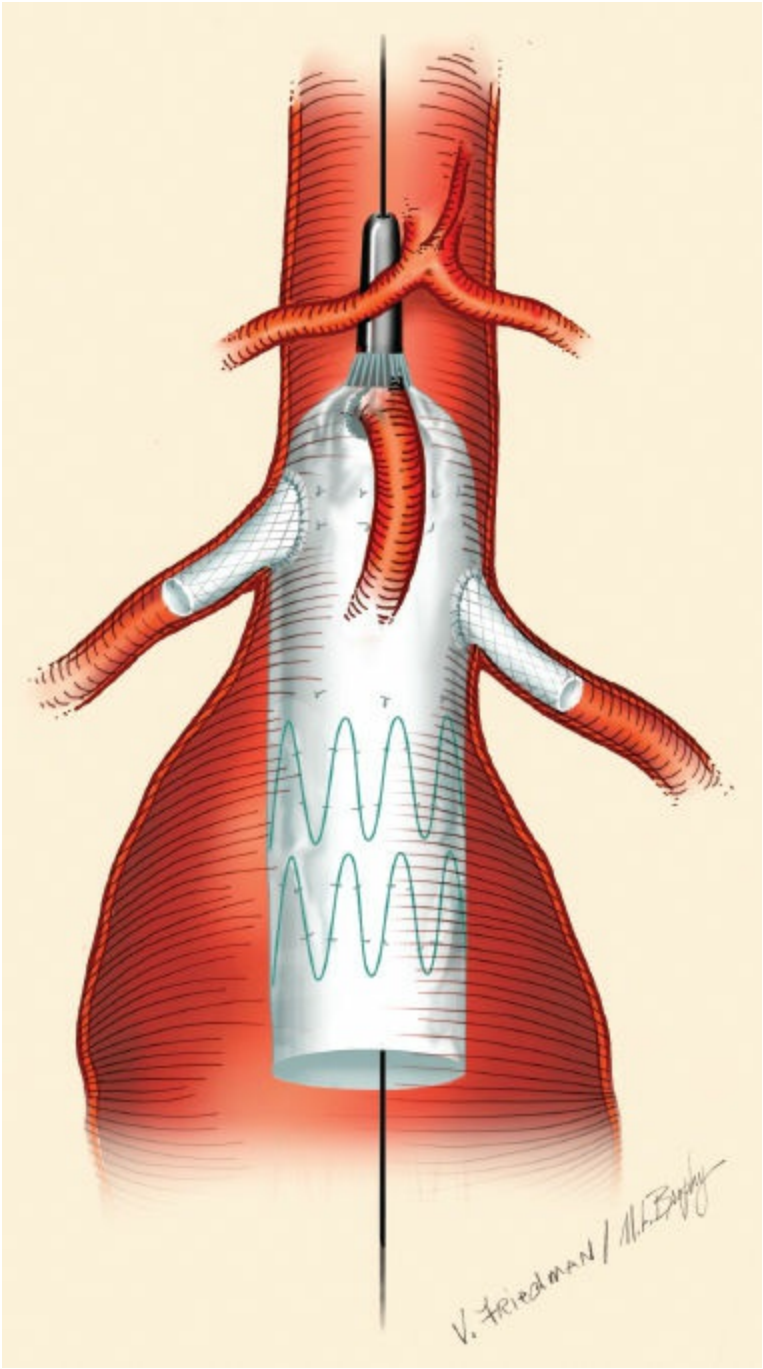

Figure 200.4. Depicts bilateral renal covered stents deployed prior to release of proximal bare stent/hook deployment.

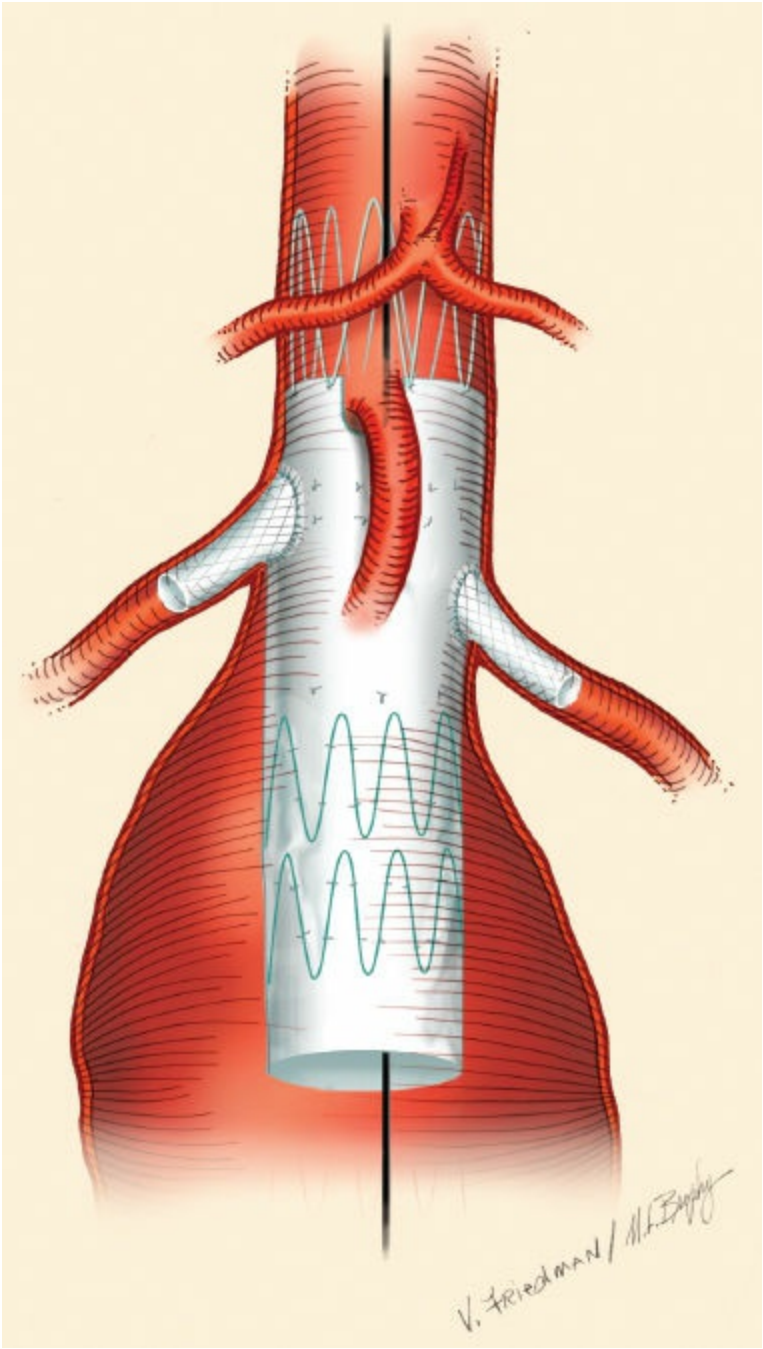

Figure 200.5. Complete deployment of proximal device with bilateral renal stents, scallop SMA, and supra SMA attachment. Bifurcated endograft device will be overlapped to this fenestrated device.

In aneurysms that reach the SMA, a third fenestration for the SMA is incorporated in the main body device and two covered stents are deployed in the renal arteries. In this particular situation, below the celiac artery is as proximal as the aortic endograft can go. Aneurysms that include the celiac artery (Type IV TAA) are being repaired using fenestrated/branch

investigational devices more frequently.

In summary, the introduction of endovascular aortic aneurysm repair in the last 25 years has revolutionized the treatment of this condition. The manufacturing and success of multiple devices that fit different anatomic characteristics in patients with infrarenal AAAs has allowed for the continued expansion of this technology for elective and ruptured aneurysm repair. Further advancements in technology has allowed for expansion of endografts to treat patients with juxta- and suprarenal and aortic aneurysms. Continued technologic advances, introduction of new devices, and carefully designed studies allow for further refinements of these techniques, thus helping most patients to avoid major open surgical repair.

ACKNOWLEDGMENT

We would like to express our gratitude to nurse practitioner, Dawn Sander, for her assistance with the editorial completion of this chapter.

EDITOR'S COMMENT

As an aspiring general surgery resident, I was attracted to vascular surgery in particular by the complex and technically challenging operations performed to repair aortic aneurysms. I remember one distinct day as a resident that we performed three open abdominal aortic aneurysm (AAA) repairs and feeling like I wanted to spend the rest of my life dedicated to performing that operation. While where I trained was not an early adapter of EVAR, it was clear when I was a fellow that EVAR was here to stay and that even early with first-generation devices patients really benefited from EVAR in terms of decreased mortality, decreased hospital and intensive care unit (ICU) length, fewer transfusions, and earlier return to functions associated with daily living.

It has been almost 20 years since the first EVAR in humans and now what was once a cottage industry has turned into a burgeoning multimillion dollar business with endovascular approaches soon to be available to treat the entirety of the aorta and all of its branches (Parodi JC, Palmaz JC, Barone HD.

Transfemoral intraluminal graft implantation for AAAs. *Ann Vasc Surg* 1991;5(6):491–9). In this chapter by Sicard and Jim, the basics of how to perform an EVAR are well-described and illustrated. Functionally, using almost a purely percutaneous approach the concept is really simple: a reinforced stent graft is placed inside the aneurysm to, in the best scenario, exclude the aneurysm and decrease/eliminate the pressure on the aortic wall thus eliminating aortic rupture. While the aneurysm is not removed or eliminated, the concept is that we functionally convert the aneurysm to a chronic problem that allows the patients, who are typically older with multiple comorbidities, to die from some disease.

Unfortunately, as with almost all surgical therapies that we provide patients, there are a few "Achilles heels" associated with this technology. First, somewhere close to 30% of patients will end up with an endoleak, which represent continued blood flow into the aneurysm sac and can result in increased risk of aortic rupture (Schanzer A, Greenberg RK, Hevelone N, et al. Predictors of AAA sac enlargement after endovascular repair. *Circulation* 2011;123(24):2848–55; Lal BK, Zhou W, Li Z, et al.; OVER Veterans Affairs Cooperative Study Group. Predictors and outcomes of endoleaks in the Veterans Affairs Open Versus Endovascular Repair (OVER) Trial of Abdominal Aortic Aneurysms. *J Vasc Surg* 2015;62(6):1394–404). Some of these endoleaks are considered benign, especially in the setting of decreased aneurysm size over time, while others are not (endoleaks caused by failure of attachments or disconnects of the modular components of an endograft). These latter types of endoleaks are associated with increased rupture risk and the patients unfortunately are unknowing that there is a problem associated with their endograft.

Second, unlike what typically happened when we performed open AAA repair, patients who have endografts inserted are subjected to long-term radiographic surveillance. The good news about this is that we have realized that the natural history of patients who have AAAs who undergo repair have a fairly high incidence of a metachronous aneurysm over time, likely somewhere close to 5%. That is approximately 5% of patients will develop an aneurysm remote from their original EVAR repair site. I suspect this has served to further emphasize to those of us that study the pathogenesis of aortic aneurysm that it is a systemic disease! Unfortunately, this has translated into lifelong imaging that originally was primarily CT angiography based. Patients were getting as many as four CT scans per year with all of the associated radiation and iodinated contrast. I think most of us have moved to, especially for EVAR, trying to use ultrasound as much as possible for follow-up imaging (David E, Cantisani V, Grazhdani H, et al. What is the role of contrast-enhanced ultrasound in the evaluation of the endoleak of aortic endoprostheses? A comparison between CEUS and CT on a widespread scale. *J Ultrasound* 2016 23;19(4):281–87). I would say we are also really heightened to the amount of radiation vascular surgeons who insert endografts are exposed to (Ruz R, Lee K, Power AH, et al.

Anatomic and procedural determinants of fluoroscopy time during elective endovascular aortic aneurysm repair. *Vascular*. 2016;24(1):19–24). Now that this has been brought to light, new imaging systems with programs aimed at reducing radiation exposure are being employed.

Finally, the cost of the actual endograft remains a problem in that in typically is approximately two thirds of the total hospitalization cost when patients undergo EVAR. We performed an interesting study a few years ago which showed that while the contribution margin of EVAR on a per cases basis was surely less than open AAA, the deceased contribution margin was offset by a decreased hospital and ICU length of stay making EVAR overall a margin positive operation (Rosenberg BL, Comstock MC, Butz DA, et al. Endovascular abdominal aortic aneurysm repair is more profitable than open repair based on contribution margin per day. *Surgery* 2005;137(3):285–92). I suspect this ultimately depends on local contracts for endograft prices and whether patients have complications or not, which clearly drives up the cost of both open and endovascular AAA repair. I still cannot figure out with as many as six different endografts available, why the price of endografts has not come down. Endograft pricing has really not followed the law of supply and demand. It will be interesting to see if the same thing happens in TAVR pricing as well.

201 Ruptured Abdominal Aortic Aneurysms

Manish Mehta, Philip S. K. Paty, and Mehdi J. Teymouri

Ruptured abdominal aortic aneurysm (AAA) treatment strategies have witnessed a paradigm shift over the past decade. From 1950s to 1990s, there were marginal improvements in ruptured AAA patient survival, and mortality remained around 50%. In the 1990s, endovascular technology entered the vascular domain and revolutionized ruptured AAA treatment strategies that became more catheter directed, and for the first time had a significant reduction in ruptured AAA mortality to approximately 20%. This chapter will focus attention to historical perspectives, epidemiology, clinical presentation, initial management and triage, operative strategies for endovascular and open surgical repair, associated complications, and outcomes.

HISTORICAL PERSPECTIVES

The first reported operation for ruptured aorto-iliac aneurysm was by Astley Cooper in 1817 when he ligated the aorta for hemorrhage control. The patient survived the operation, and died on the second postoperative day. It was not until 1923 when Rudolph Matas successfully ligated the aorta of a 28 year old with a ruptured syphilitic aortic aneurysm who survived for 28 months; finally succumbing to tuberculosis. Not much changed in the management of ruptured AAA until 1954, when Cooley and DeBakey had treated six patients with surgical reconstruction beyond just aortic ligation and reported a 50% survival rate. Over the next 40 years, centers across the United States and globe adopted open surgical repair and reconstruction as the primary treatment for ruptured AAA with an acceptable mortality of 50%. In the 1990s endovascular technology was evolving and entering the vascular world and shortly after the first reported elective endovascular AAA repair by Juan Parodi in 1991, Yusuf et al. first reported endovascular repair of a ruptured AAA. Over the past two decades we have seen unprecedented acceptance of endovascular

technology for managing elective and reputed aortic aneurysms with significant reductions in patient mortality.

PATHOPHYSIOLOGY

Several risk factors portend rupture. The first is aortic diameter. In the only population-based US study, Nevitt reviewed the outcomes for 370 residents of Rochester, Minnesota followed from 1951 to 1984 and reported no rupture during 5-year follow-up for AAAs <5 cm, but a 5% annual rupture risk for AAA >5 cm at initial presentation. In the most recent analysis of these data, Reed estimated annual rupture risk (with 95% confidence intervals) to be 0% (0% to 5%) for AAA <4 cm, 1% (0% to 5%) per year for 4.0 to 4.9 cm AAAs, 11% (1% to 21%) per year for 5.0 to 5.9 cm AAAs and 26% (7% to 46%) per year for 6.0 to 6.9 cm AAAs. These estimates mirror the findings of the UK Small Aneurysm Trial, which randomized 1,090 patients to surgery or follow-up. The annual rupture rate was calculated as 0.3% for AAAs <4 cm diameter, 1.5% for 4.0 to 4.9 cm AAAs, and 6.5% for 5.0 to 5.9 cm AAAs. It is possible that both these studies underestimated rupture risk since some AAAs underwent elective repair for rapid expansion or symptoms.

Aneurysm rupture represents failure of the aortic wall to bear the load or tension to which it is exposed. When the force of the blood pressure exceeds the ability of the aortic wall to bear that load, the aneurysm wall ruptures and blood extravagates. In vitro testing has demonstrated that the failure strength of human aneurysmal aortic wall is 65 N/cm^2 versus 121 N/cm^2 for nonaneurysmal human aortic wall. This indicates that the aneurysmal aortic wall is weaker. Laplace law (tension is proportional to radius times pressure) relates wall tension to pressure, thus emphasizing the importance of size. Although this method may be satisfactory for symmetric structures, it does not take into account the complex geometry of individual AAAs.

The engineering technique of finite element analysis has been applied to AAAs to estimate regional variations in peak wall stress throughout the entire aneurysm wall. Initial studies assumed that AAAs had uniform wall thickness and material isotropy (uniform strength in all orientations), but several studies show this is not the case and that there are localized “hot spots” of matrix metalloproteinases activity that are variable and depending on wall thickness, stiffness, and regional heterogeneity could cause focal weakening of the aneurysm and rupture at relatively low levels

of intraluminal pressure. Matrix metalloproteinases (MMPs) are a family of 28 endopeptidases that comprise collagenases, gelatinases and stromelysins. They degrade extracellular tissues, cleave cell surface receptors and are involved in tissue remodeling. They are inhibited by four endogenous tissue proteins called Tissue Inhibitors of Metalloproteinases (TIMPs). ILT contains high levels of matrix metalloproteinase 2 and 9 and trapped neutrophils rich in matrix metalloproteinase-9 and Neutrophils Gelatinase Associated Lipocalin, which neutralizes the defensive actions of tissue inhibitor metalloproteinases. An autopsy study of 78 patients who died from ruptured infrarenal AAAs showed 80% of ruptures occurred at the site of mural thrombus.

CLINICAL PRESENTATION

The “classic” presentation for a patient with a ruptured AAA is a male patient over the age of 60 years complaining of acute onset abdominal and back pain. Back pain is severe and unremitting and caused by rupture of the aneurysm into the retroperitoneal space. Patients may describe pain to be nonspecific and present anywhere in the torso with our without radiation to the flank or testes. On examination, the patient is usually pale, diaphoretic and hypotensive with a tender, pulsatile abdominal mass. A patient with a known history of AAA that presents with hypotension and abdominal and/or back pain should be considered to have a ruptured AAA until proven otherwise. A rapid, accurate history and examination are critical. The differential diagnosis may include renal colic, diverticulitis, pancreatitis, gastrointestinal hemorrhage, inferior myocardial infarction, and perforated ulcer. Although the signs and symptoms of ruptured AAA can be clear-cut, in the early stages it may be difficult to recognize. Many patients will initially have relatively normal blood pressure on arrival into the Emergency Room, following fluid resuscitation en route. Some may give a history of pain extending over the course of 3 to 4 days, as the ruptured AAA has bled, sealed, and then bled again. In the affected age group, chronic back problems are common, so the physician may be tempted to ascribe symptoms to an exacerbation of a long-standing problem. The other misdiagnosis is to confuse the presentation with ureteral colic. Symptoms may be incorrectly attributed to acute diverticulitis or a perforated duodenal ulcer, particularly in presence of leukocytosis.

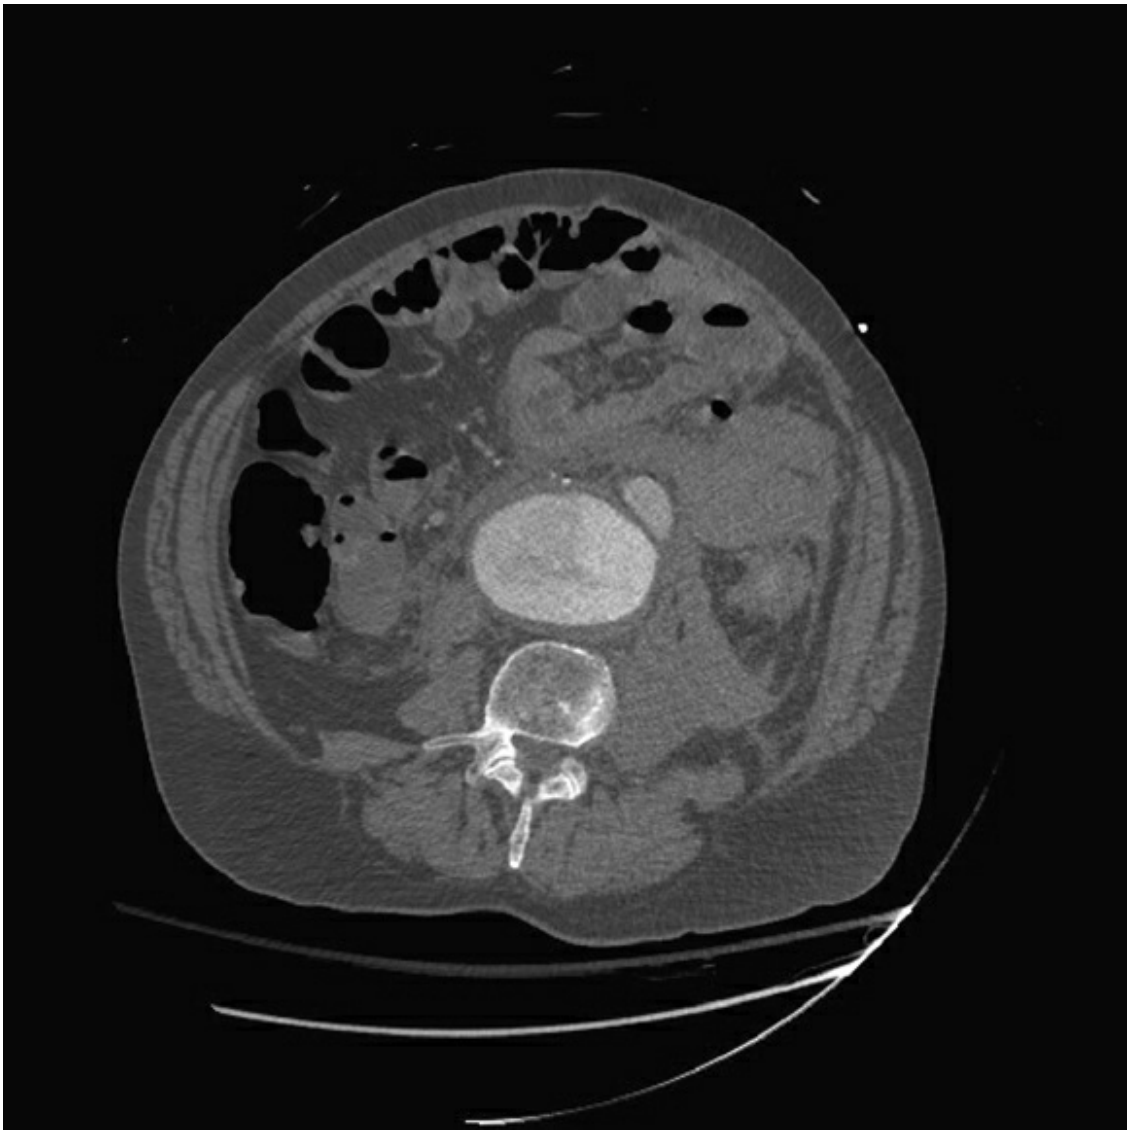

Figure 201.1. Ruptured AAA with extravasation outside aneurysm sac.

Plain radiography is now less frequently performed than ultrasound or CT in patients with abdominal pain. However, if the aortic wall is sufficiently calcified, an aneurysm not otherwise suspected can be identified on radiographs. The introduction of bedside ultrasound in the emergency department and training of emergency physicians in its application for trauma have led to its use for imaging of the abdominal aorta in cases of suspected rupture. Focused assessment with sonography in trauma (FAST) ultrasound protocols can rapidly identify fluid collections, evaluate aortic diameter, and diagnose ruptured AAA, FAST, however, has a limitation in that it cannot be used to exclude ruptured AAA, and further computed tomography imaging is often necessary.

The most accurate method of diagnosing ruptured AAA is CT, which

also provides important information about associated abnormalities and conditions. A non–contrast-enhanced CT scan can identify retroperitoneal hemorrhage associated with a ruptured AAA and can also provide important anatomic information (Fig. 201.1). CT scanning with contrast enhancement is required for ideal planning of ruptured AAA repair with commercially available stent-graft devices for the same reasons that it is required for elective repair. Pre-existing renal insufficiency or contrast allergy might pose limitations in obtaining an appropriate CT and these factors need to be considered on an individual basis for optimum patient care.

INITIAL MANAGEMENT AND TRIAGE

Patients with ruptured AAA are at imminent for death and require immediate vascular surgery evaluation. Hospitals that lack vascular surgery expertise and cannot offer definitive treatments should consider establishing networks with larger institutions that have vascular surgery services and can offer repair by endovascular or open surgical means, as needed. The impact of transferring ruptured AAA patients to regional centers where repair can be carried out by experienced vascular teams has been studied. Rural hospitals without vascular surgery expertise tend to face a higher burden of ruptured AAA patients and national trends suggest they are more likely to transfer patient to regional centers. Although patient transfer might increase the time of arrival from the initial hospital to the operating room, the vast majority of studies suggest that high volume regional centers significantly lower the mortality for ruptured AAA patients. Furthermore, as US nationwide trends suggest increased utilization of EVAR for ruptured AAA, it is likely that regionalization of patient care will significantly impact management of ruptured AAA patients.

Preoperative resuscitation of ruptured AAA patients with hypotension must be judicious. Aggressive resuscitation with large volumes of intravenous fluids, and the resultant elevation in blood pressure can lead to further hemorrhage by overcoming the tamponade that stabilized the initial rupture. It further results in hemodilution, coagulopathy, hypothermia, and acidosis; all factors having a further deleterious cascade. Similar to transfusion protocols that restrict aggressive fluid resuscitation in hypotensive trauma patients with hemorrhagic shock, permissive hypotension for ruptured AAA patients in which resuscitation is

minimized to maintain consciousness, prevent ST depression, and usually keep the systolic pressures of 70 to 80 mm Hg are recommended. A balance should be achieved between organ ischemia from inadequate resuscitation versus the risk of rebleeding from overaggressive resuscitation. Currently, evidence regarding resuscitation with blood versus crystalloids is limited, and if blood is available, without delays in patient transfer, it should accompany the patient and can be given instead of crystalloids solutions to maintain consciousness.

ENDOVASCULAR REPAIR OF RUPTURED AAA

The evolution of endovascular aneurysm repair (EVAR) has led to improvements in our ability to treat AAAs in elective as well as in emergent circumstances when patients present with rupture. The implications of improvements in our technical ability to offer EVAR to patients presenting emergently with ruptured AAA are significant: to date, no other therapy has offered such a survival advantage to these high-risk patients presenting with ruptured AAA. When considering these endovascular techniques for treating ruptured AAA, one has to prepare for the challenges of streamlining patient care from the emergency room to the operating room and the subsequent endovascular procedure that often requires a multidisciplinary approach and a change in paradigm and local cultures. This article will focus on a comprehensive and standardized technical approach for treating ruptured AAA by endovascular means that can maximize our ability to offer this treatment of ruptured AAA to most patients.

The metamorphosis of ruptured AAA treatment from open surgical repair to EVAR has evolved significantly over the past two decades. Since its first report by Yusuf in 1994, ruptured EVAR has evolved from being performed selectively by a few centers in hemodynamically stable patients only to being performed by most endovascular specialists in many centers in patients with varying degrees of hemodynamic instability. Collectively, worldwide experience demonstrates that an increasing number of ruptured AAA are being treated by EVAR. The endovascular approach is less invasive, eliminates laparotomy, eliminates aortic cross clamping, decreases surgical bleeding, and possibly general anesthesia, and has been shown to decrease the mortality of ruptured AAA repair with fewer complications, shorter hospital length of stay, and more patients being able to return home rather than going to institutional care after these emergent

procedures. It is of critical importance when evaluating the evidence in favor of or against of ruptured EVAR is an understanding of the context in which the ruptured AAA patients were treated; the underlying patient selection, and the local, regional, and national influences in offering endovascular treatments to ruptured AAA patients.

Data on 4,972 patients with ruptured aneurysms from 1994 to 2010 were reviewed and showed a decline in mortality from 38% to 28%, which was credited to the introduction of EVAR. The most ambitious review of population data was by Mani et al. using the Vascunet database. In 2011, they collated outcomes for ruptured AAA repair in 7,040 patients from national and regional registries in nine countries (Australia, Denmark, Finland, Hungary, Italy, Norway, Sweden, Switzerland, and the United Kingdom). The overall mortality rate was 31.6%, but it declined by 4.2% between 2005 and 2009. This was again attributed to more liberal use of EVAR. The high postoperative mortality rates after aortic rupture are secondary to a high incidence of myocardial infarction, renal failure, and multiple organ failure. Aortic rupture and open surgical repair result in a combination of ischemia–reperfusion injuries, hemorrhagic shock, and lower torso ischemia. The synergistic effect of the total-body ischemia caused by hemorrhagic shock and the lower torso ischemia that occurs during repair, followed by reperfusion secondary to resuscitation and aortic unclamping, has been proposed to explain the high incidence of multiple organ failure and mortality after repair. This hypothesis is supported by data from both animal experimentation and human clinical studies. The application of ruptured EVAR reduces the operative and ischemic insult in two ways. First, it avoids a laparotomy, thus reducing the potential for iatrogenic arterial and venous operative injuries and their associated blood loss. Second, it minimizes the duration and severity of the lower torso ischemic insult. Recent data from large administrative databases in the United States have demonstrated increased application of EVAR to ruptured AAA.

THE FUNDAMENTALS OF RUPTURE EVAR

Introduction of EVAR for ruptured AAA has forced us to reevaluate protocols that facilitate expeditious patient transfer to the operating rooms for EVAR or open surgical repair. Today, the question is not whether patients with ruptured AAA should undergo EVAR, rather how to develop systems that allow for broader utilization of these complex procedures that

have shown great benefit in high risk patients with aneurysm rupture. There remain several fundamental concerns regarding EVAR for ruptured AAA that include anatomical suitability for EVAR, the availability of dedicated staff and equipment to perform emergent EVAR at all hours, feasibility of treating hemodynamically stable and unstable patients by EVAR, and the surgeon/interventionists ability to manage unexpected scenarios under emergent circumstances. Many of the high-volume institutions have adopted a standardized protocol-based approach that includes a heightened awareness among the ER staff to suspect the diagnosis of ruptured AAA and notify the on-call vascular surgeon and the operating room staff. In the emergency room, hemodynamically stable patients undergo expeditious CT scan and are subsequently transferred to the operating room, and hemodynamically unstable patients are directly transferred to the operating room without a preoperative CT scan for endovascular-first approach and conversion to open surgical repair as needed. Thin-slice CT with contrast enhancement can be accomplished with lower volumes of contrast agent to assess neck diameter, angulation, and iliac size.

Operating Room Setup: Since not all patients with ruptured AAA can undergo ruptured EVAR, all operating room/hybrid endovascular-operating room suits should be setup to facilitate ruptured EVAR as well as open surgical repair. Depending on the size of the room and the fluoroscopic equipment which can be fixed or portable with viewing screens and power injectors, one has to customize the layout of the operating room suite that is conducive for ruptured EVAR and ruptured open surgical repair; it is best to setup the room for endovascular repair with standard needles, wires, catheters, and sheaths open on a sterile table, have the surgical instruments in the room if needed, situate the patient on the operating room table, and as the anesthesiology team prepares the patient setup the fluoroscopic equipment and supplies.

ENDOVASCULAR SETUP AND TECHNIQUES

Adequate resuscitation of patients with ruptured AAA is vital to a successful outcome. As long as the patients maintain a measurable blood pressure, the techniques of “permissive hypotension” by limiting the resuscitation to maintain a detectable blood pressure can help minimize ongoing hemorrhage. The patient is prepped and draped in supine position and via a percutaneous (preferable) or femoral artery cut-down ipsilateral

access is obtained using a needle, floppy guidewire, and a guiding catheter. The floppy guidewire is exchanged for a super-stiff wire that can be used to place a large sheath (12 to 14 Fr × 45 cm length) in the ipsilateral femoral artery and the sheath advanced up to the juxtarenal abdominal aorta so it is ready to be used to deliver and support the aortic occlusion balloon if needed. A compliant occlusion balloon should always be available in these procedures, and in hemodynamically unstable patients, the occlusion balloon is advanced through the ipsilateral sheath over the super-stiff wire into the supraceliac abdominal aorta under fluoroscopic guidance, and the balloon is inflated as needed. Contralateral femoral access is subsequently obtained via percutaneous (preferable) or cut-down approach in a similar fashion, and a “marker flush-catheter” advanced to the juxtarenal aorta for an arteriogram.

The placement of the stent graft main body is planned based on the aortoiliac morphology that is best suited for EVAR. Unless prohibitive, in hemodynamically stable patients, following the initial arteriogram, the aortic occlusion balloon is removed from the initial ipsilateral side and the stent graft main body advanced under fluoroscopic guidance; this limits the number of catheter exchanges. In hemodynamically unstable patients that require inflation of the aortic occlusion balloon, the “marker flush-catheter” is exchanged for the stent graft main body, which is delivered up to the aortic neck. An arteriogram is done via the sheath that is used to support the aortic occlusion balloon, the tip of the stent graft main body is aligned with the lowermost renal artery, the occlusion balloon is subsequently deflated and withdrawn back with the delivery sheath into the ruptured AAA, and the stent graft main body deployed. The remainder of the ruptured EVAR procedure is performed similar to as in elective circumstances: (1) the tip of the stent graft main body aligned with the lowermost renal artery; (2) the contralateral gate aligned to facilitate expeditious “gate-cannulation”; (3) and the ipsilateral and contralateral iliac extensions planned and deployed as needed.

There are several important technical aspects that merit discussion, including: (1) availability of preoperative CT, (2) anatomic suitability for EVAR, (3) choice of anesthesia and percutaneous versus femoral cut-down approach, (4) aortic occlusion balloons, (5) bifurcated versus aorto-uni-iliac stentgrafts, (6) abdominal compartment syndrome, (7) and conversion to open surgical repair.

Availability of Preoperative CT Scan

The hemodynamic status of the ruptured AAA patient generally dictates the need for a preoperative CT scan, and although while planning for this emergent open surgical repair a preoperative CT is not considered a necessity, while planning an emergent ruptured EVAR, most would agree that we would like to have a CT scan for evaluating the feasibility of ruptured EVAR as well as for stent graft sizing. Therefore, the question is whether one has the time to get an emergent CT scan prior to ruptured EVAR, and if not are there other tools available that might help us manage these hemodynamically unstable patients by endovascular means? Published data on the feasibility of preoperative CT in patient with ruptured AAA would indicated that 88% (49 of 56) patients died >2 hours after admission with the diagnosis of ruptured AAA, the median time interval from the onset of symptoms to admission to the hospital was 2.5 hours, and the interval between hospital admission with the diagnosis of ruptured AAA and death was 10.5 hours. This data would clearly suggest that majority of patients with ruptured AAA have the time to undergo an emergent CT scan, particularly if there is an established protocol that facilitates early diagnosis and transfer of patient from the emergency room to the operating room.

Anatomic Suitability for EVAR

The proportion of ruptured AAA patients that are suitable for ruptured EVAR is variable and on the basis of two meta-analysis ranges from 47% to 67%. It has also been reported is that when compared to elective AAA, ruptured AAA patients have larger infrarenal aortic diameters and shorter aortic neck lengths. These differences in AAA morphology likely have an affect the ability to perform EVAR, and it is likely that institutions that treat a higher proportion of ruptured AAA by EVAR expand on the stent grafts indications for use of these high-risk patients. Several institutions including ours have tried to identify the impact of ruptured EVAR in patients with favorable versus unfavorable aortic neck morphology. Mehta and colleagues analyzed aortic neck morphology via CT scans in 180 consecutive patients with ruptured AAA that underwent ruptured EVAR (74, 41%) or ruptured open surgical repair (106, 59%). Based on EVAR device specific favorable versus hostile aortic neck morphology, we identified that only 34% of patients with ruptured AAA had neck morphology that would meet the “indication for use” for available stent

grafts. The ruptured EVAR patients with hostile aortic necks had a significantly higher incidence of female gender (32% vs. 19%, $p < 0.01$), mean maximum AAA diameter (7.4 cm vs. 5.5 cm, $p < 0.01$), abdominal compartment syndrome (20% vs. 4%, $p < 0.01$), Type I endoleaks (16% vs. 4%), and the need for all secondary interventions (77% vs. 40%, $p < 0.01$) during long term follow-up. The 30-day mortality was the lowest in ruptured EVAR patients with favorable aortic necks and the highest in the open surgical repair patients (favorable 8%; hostile 23%; ruptured open surgical repair 43.4%; $p < 0.01$), and both favorable and hostile ruptured EVAR patients had a better cumulative 3-year survival than ruptured open surgical repair (favorable 64%, hostile 67%, ruptured surgical repair 44%, $p < 0.01$).

Choice of Anesthesia and Approach

Depending on one's comfort level and the logistics, ruptured EVAR can be performed under local anesthesia via percutaneous approach to general anesthesia and femoral artery cut-down. The potential benefits of local anesthesia/conscious sedation and percutaneous approach is that it might avoid the loss of "sympathetic-tone" in the compromised ruptured AAA patients. One has to be comfortable with obtaining percutaneous access and using closure devices in patients that might be hemodynamic unstable with difficult to palpate femoral pulses. Although the advantage may be significant, it must be balanced by the potential difficulties encountered during these emergent procedures, as the patient might not be coherent and co-operative enough to lie still. Furthermore, to optimize time management, particularly in hemodynamically unstable patients, some have suggested to start the procedure under local anesthesia, obtain percutaneous access, position the aortic occlusion balloon as needed, perform ruptured EVAR, and following ruptured AAA exclusion induce general anesthesia and remove femoral sheaths via femoral cut-down. Others have recommended total percutaneous approach with local anesthesia and conscious sedation.

Aortic Occlusion Balloon

The appropriate use of aortic occlusion balloons is hemodynamically unstable patients is vital to the success of ruptured EVAR. Access for aortic occlusion balloons can be obtained via the brachial or the femoral artery. There are several advantages of the femoral approach: (1) it allows

the anesthesia team to have access to both upper extremities for arterial and venous access, (2) the patients who require the aortic occlusion balloon are often hypotensive and, in these patients, percutaneous brachial access can be more cumbersome and time consuming than femoral cut-down, and (3) the currently available aortic occlusion balloons require at least a 12- to 14-Fr sheath, which requires a brachial artery cut-down and repair, and stiff wires and catheters across the aortic arch without prior imaging under emergent circumstances might lead to other arterial injuries and/or embolization causing stroke. Occlusion balloons are composed of compliant materials such as polyurethane latex, or silicone, and have low burst pressures of <5 atm. Their primary function if not angioplasty, but molding to the surrounding with gentle inflation and function in capacity of obtaining proximal aortic occlusion during ruptured EVAR.

Several important points should be considered during placement of the aortic occlusion balloon. The sheath supporting the balloon should be advanced and supported fully into the aortic neck prior to inflation of the occlusion balloon, as this will prevent downward displacement and prolapse of the occlusion balloon into the AAA (Fig. 201.2). Inability to fully engage the sheath into the aortic neck due to the presence of significant aortoiliac stenosis, calcifications, or tortuosity might result in downward displacement of the inflated occlusion balloon; this often required forward traction on the inflated balloon catheter to maintain adequate position at the suprarenal/supraceliac aorta. If inflation of the aortic balloon is required to maintain a viable blood pressure, just prior to deployment of the stent graft main body, the aortic occlusion balloon should be deflated from the suprarenal level and withdrawn. The stent graft main body is subsequently deployed; this will avoid trapping the compliant aortic occlusion balloon between the aortic neck and the stent graft. This temporary deflation of the aortic occlusion balloon rarely results in hemodynamic collapse and usually is of little consequence. In hemodynamically unstable patients, the occlusion balloon can be redirected into the aortic neck from the side ipsilateral to the stent graft main body and reinflated at the infrarenal aortic neck within the stent graft main body; this allows for aortic occlusion and does not interfere with the remainder of the endovascular procedure (Fig. 201.3A–E).

Bifurcated versus Aorto-Uni-Iliac Stent Grafts for Ruptured AAA

The decision to use a particular stent graft type is determined by the

patient’s aorto-iliac morphology, and there are several factors to consider regarding the use bifurcated versus aorto-uni-iliac stent grafts for ruptured AAA: (1) inability to access the contralateral gate expeditiously, and (2) inability to access the contralateral iliac artery due to significant occlusive disease and/or tortuosity. The use of aorto-uni-iliac devices during elective or emergent EVAR does require interruption of flow from the contralateral common iliac artery into the AAA via a placement of an occluder device, and a femoral–femoral bypass. Several studies have documented the use of aorto-uni-iliac devices for ruptured EVAR with outcomes similar to the use of bifurcated stent grafts. It is likely that use of aorto-uni-iliac devices might expand on the applicability for ruptured EVAR.

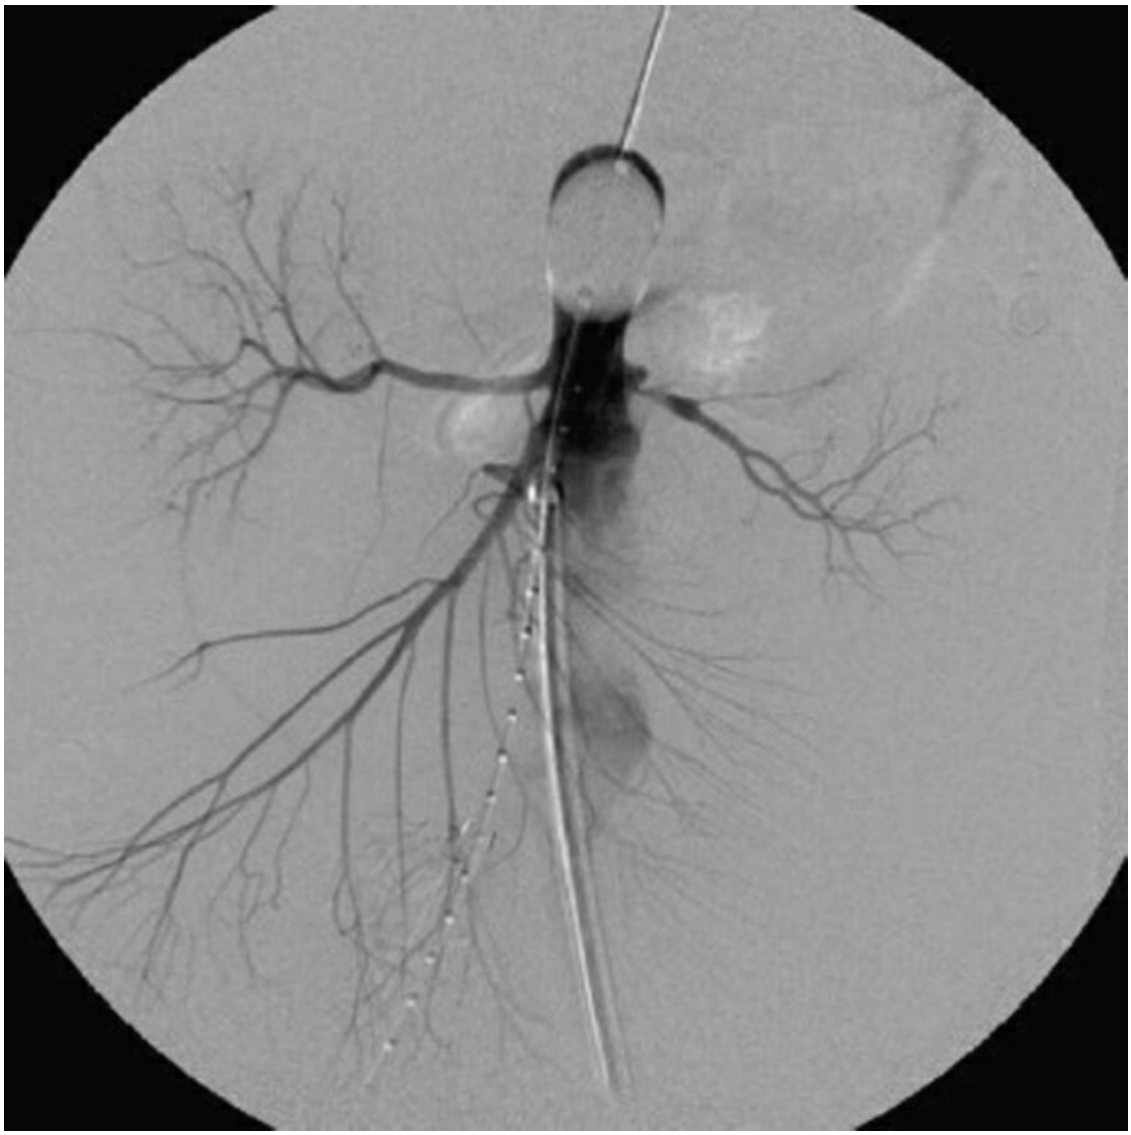

Figure 201.2. The sheath supporting the aortic occlusion balloon should be advanced and supported fully into the aortic neck to prevent downward displacement and prolapse of the occlusion

balloon into the abdominal aortic aneurysm. (From Mehta M. Endovascular aneurysm repair for ruptured abdominal aortic aneurysm: the Albany Vascular Group approach. *J Vasc Surg* 2010;52(6):1706–12; with permission from Elsevier.)

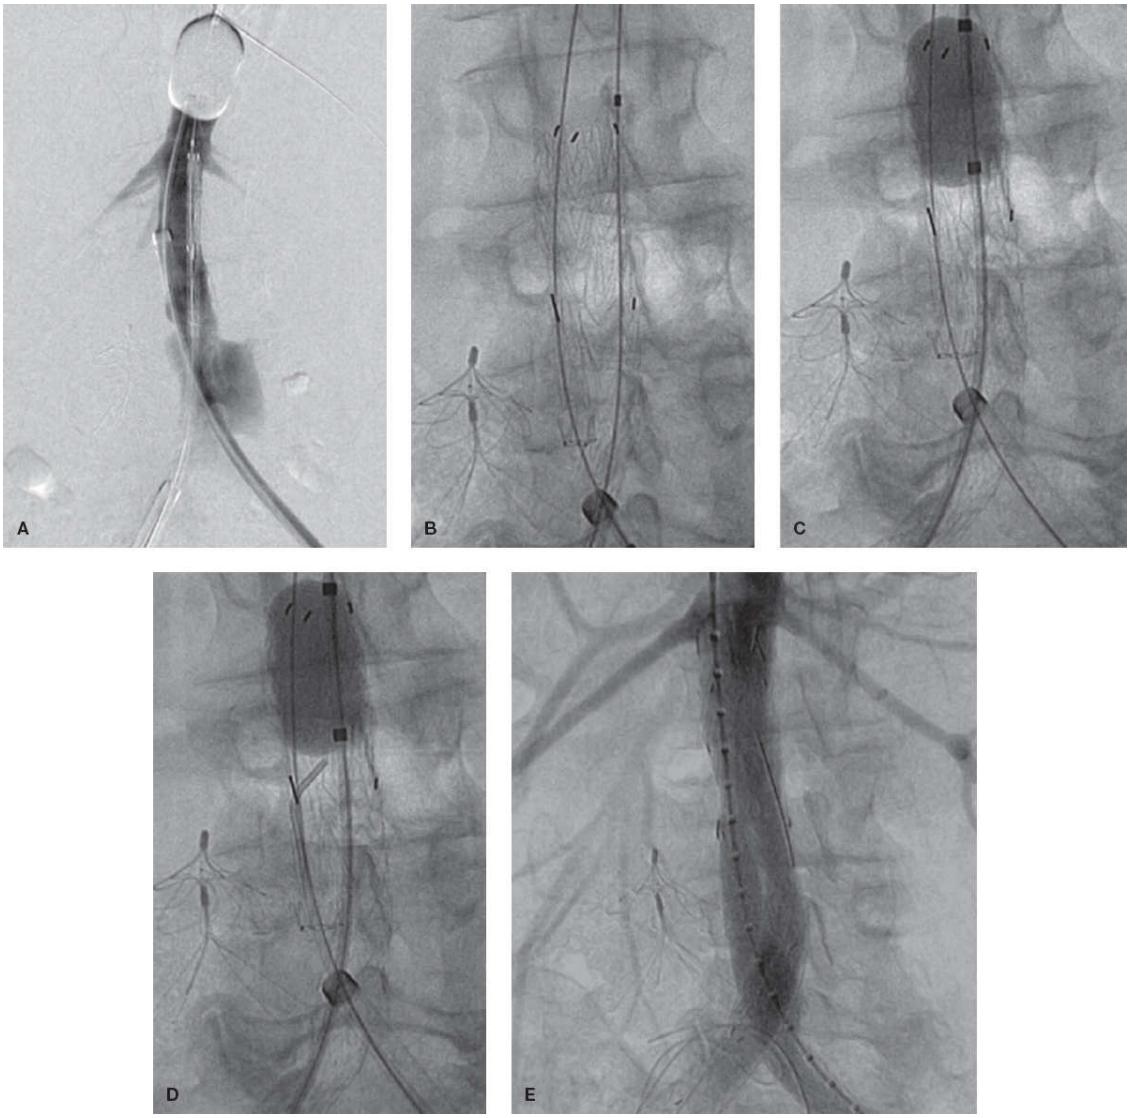

Figure 201.3. A–E. Managing the aortic occlusion balloon during stent graft deployment. **A.** The inflated suprarenal aortic occlusion balloon is advanced through the left femoral approach, the stent graft main body is advanced through the right femoral approach, and the arteriogram is done through the left femoral sheath supporting the occlusion balloon. **B.** The aortic occlusion balloon is deflated and retracted back from the aortic neck, and the stent graft main body is subsequently deployed. This avoids trapping of the compliant aortic occlusion balloon between the aortic neck and the stent graft. **C.** In hemodynamically unstable patients, the occlusion balloon can be redirected into the aortic neck from the side ipsilateral to the stent graft main body and reinflated at the infrarenal aortic neck within the stent graft main body before contralateral gate cannulation. **D.** After the occlusion balloon is reinflated in the stent graft main body in hemodynamically unstable patients, the contralateral stent graft gate can be cannulated and contralateral stent graft extensions

are placed as needed. **E.** After contralateral iliac extension and ruptured abdominal aortic aneurysm exclusion, the occlusion balloon can be removed, as shown in the completion arteriogram. (From Mehta M. Endovascular aneurysm repair for ruptured abdominal aortic aneurysm: the Albany Vascular Group approach. *J Vasc Surg* 2010;52(6):1706–12; with permission from Elsevier.)

Assessing for Abdominal Compartment Syndrome

With increasing use of endovascular techniques for treating ruptured AAA, there is an increased recognition of new complications, such as intra-abdominal hypertension and abdominal compartment syndrome. Intra-abdominal hypertension is graded on the basis of bladder pressures; Grade I (10 to 15 mm Hg), Grade II (16 to 25 mm Hg), Grade III (26 to 35 mm Hg), and Grade IV (>35 mm Hg). Abdominal compartment syndrome is defined as an acute and rapid elevation in intra-abdominal pressure of greater than 20 mm Hg that is associated with cardiovascular, pulmonary, renal, and splanchnic organ dysfunction. Decompression laparotomy and resuscitation is recommended for Grade III and IV intra-abdominal hypertension. Bladder pressure is reflective of intra-abdominal pressure when the bladder volume is between 50 and 100 mL. To measure this pressure, the bladder is drained and then filled with 50 to 100 mL of sterile saline. The drainage tubing is clamped beyond the aspiration port, and a needle is inserted to the aspiration port and connected to the pressure transducer. The transducer is zeroed at the pubic symphysis.

The presenting signs and symptoms include tense distended abdomen, respiratory failure (elevated peek inspiratory pressures, decreased tidal volume, and elevated Pco_2), diminished cardiac output, and oliguria. The pathophysiology of abdominal compartment syndrome after ruptured EVAR is multifactorial: (1) the retroperitoneal hematoma is a space-occupying lesion and a significant factor contributing to intra-abdominal hypertension, (2) ongoing bleeding from lumbar and inferior mesenteric arteries into the disrupted aneurysm sac in the setting of severe coagulopathy might be a contributing factor, and (3) the shock state associated with ruptured AAA is associated with alterations in microvascular permeability that can lead to visceral and soft tissue edema. Patients with abdominal compartment syndrome following ruptured EVAR have increased mortality of >50%, and factors such as the need for aortic occlusion balloon, need for massive blood transfusions,

coagulopathy, and hemodynamic instability have been implicated with increased risk for abdominal compartment syndrome following ruptured EVAR. Abdominal compartment syndrome requires prompt recognition and treatment, which includes decompression laparotomy.

Conversion to Open Surgical Repair

Regardless of all the improvements in endovascular techniques there are times when on-table conversion to open surgical repair is needed and this approach should be in the armamentarium of all surgeons involved in treating ruptured AAA patients. When on-table surgical conversion is needed, the use of aortic occlusion balloon can be extremely valuable in maintaining hemodynamic stability; the techniques of aortic occlusion balloon have been discussed above. In addition, during the time of laparotomy and open surgical conversion it is crucial to maintain the position of the aortic occlusion balloon and its delivery sheath; failure to do so might result in aortic occlusion balloon prolapse into the ruptured AAA and loss of aortic occlusion. If open surgical conversion is needed subsequent to stent graft deployment, the exact approach should be tailored to the type of stentgraft, the type of proximal and distal fixation including suprarenal versus infrarenal stents and barbs.

EVIDENCE FOR RUPTURED EVAR

Worldwide, more ruptured AAA are now treated by ruptured EVAR. The endovascular approach is less invasive and, in some reports, decreases mortality. The following studies summarize the results of ruptured EVAR compared with ruptured open surgical repair in the management of ruptured AAA.

Mehta et al. have documented the largest single-center experience in comparing ruptured EVAR with ruptured open surgical repair for ruptured AAA. In this prospectively collected data set on an intention-to-treat basis, 283 patients with ruptured AAA underwent EVAR (120, 42%) or open surgical repair (163, 58%); outcomes were evaluated by a logistic regression multivariable model and Kaplan-Meier analysis. The ruptured EVAR patients had a significantly lower 30-day mortality than that of the ruptured open surgical repair patients (24% vs. 44%; $P < 0.005$) and better cumulative 5-year survival (37% vs. 26%; $P < 0.005$). Men benefited more from ruptured EVAR (mortality: 21% for EVAR vs. 44% for open surgical repair; $P < 0.001$) than did women (mortality: 32% vs. 44%; $P = 0.39$). Age

older than 80 years was a significant predictor of death for ruptured EVAR (odds ratio [OR], 1.07; $P = 0.003$) but not for ruptured open surgical repair (OR, 1.04; $P = 0.056$). The odds for 30-day mortality in the ruptured open surgical repair patients were 2.48 times the odds in the ruptured EVAR group (95% CI, 1.48–4.18; $P = 0.001$). A multivariate logistic regression analysis indicated that ruptured open surgical repair; age, aneurysm size, and hypertension significantly increased the 30-day mortality. During long-term follow-up, we found that 23% of ruptured EVAR patients required further intervention; 57% of secondary procedures were performed for type II endoleaks, and 3.3% were emergent conversion to ruptured open surgical repair. Last, Kaplan–Meier life-table analysis of survival showed that the overall cumulative survival curves were significantly better in the ruptured EVAR group at 5 years.

Many centers have developed a standardized protocol for ruptured AAA patients, which emphasize use of ruptured EVAR. This has been demonstrated to improve outcomes compared with open surgical repair. Today, many centers have developed protocols for rapid transfer of a ruptured AAA patient from the emergency department to the operating room for ruptured EVAR. Although procedures vary from one institution to another, the fundamentals are simple: early diagnosis of ruptured AAA, an expeditious CT scan to evaluate the aortoiliac morphology, and rapid transfer to an operating room that is equipped to perform ruptured EVAR as well as ruptured open surgical repair. This allows patients who are hemodynamically unstable to be offered ruptured EVAR. The patient's hemodynamic status has been shown to affect the outcomes of ruptured EVAR and ruptured open surgical repair of ruptured AAA. A study from Mehta et al. comparing hemodynamically stable versus unstable ruptured EVAR patients reported notable differences between the groups; hemodynamically unstable patients needed an aortic occlusion balloon more often (41% vs. 5%), lost more blood (744 mL vs. 363 mL), developed compartment syndrome more frequently (29% vs. 4%), and had higher mortality (33% vs. 18%).

An Italian study reported similar findings in comparing hemodynamically stable versus unstable patients with ruptured AAA; the 30-day mortality for hemodynamically stable patients was significantly lower for ruptured EVAR than for ruptured open surgical repair (EVAR, 11% vs. 53%; open surgical repair, 21% vs. 61%). A meta-analysis of observational studies also indicated that the use of standardized algorithms

for managing ruptured EVAR patients was a surrogate marker for improved outcomes; mortality was significantly lower in studies reporting a standardized algorithm compared with those without (18% vs. 32%).

In a multicenter study, authors from the University Hospital of Zurich and Örebro reported their combined 14-year experience of ruptured EVAR and ruptured open surgical repair to address the impact of complete replacement of ruptured open surgical repair for ruptured AAA by ruptured EVAR. Mayer et al. retrospectively evaluated their data during two time periods: during the initial period (1998 to 2009), all ruptured AAA patients were offered ruptured EVAR and ruptured open surgical repair; during the later period (2009 to 2011), all patients were offered ruptured EVAR only. Their overall results indicated a significantly lower 30-day mortality for ruptured EVAR compared with ruptured open surgical repair (17.9% vs. 37.4%; OR, 3.3; 95% CI, 1.4–7.5; $P = 0.004$). Similar 30-day mortality was observed during the period when ruptured EVAR and ruptured open surgical repair were offered (25.5%) and in the later period when only ruptured EVAR was offered (24.3%). However, with the transition to the ruptured EVAR-only period, the overall 30-day mortality of ruptured EVAR increased at both institutions from 10.8% to 24.3% as during this time there was increased use of ruptured EVAR for challenging cases, increased use of adjunctive procedures, and decreased turndown rate from 10% to 4%. The study limitations were that the authors did not analyze outcomes in the 24.3% of ruptured EVAR patients who required secondary procedures, which might have resulted in a higher mortality. Therefore, the ruptured EVAR-only approach for all ruptured AAA will require more secondary procedures and increase the ruptured EVAR mortality, and surgeons need to offer both ruptured EVAR and ruptured open surgical repair to optimize patient outcomes.

Large administrative databases such as the U.S. Nationwide Inpatient Sample and the U.S. Centers for Medicare and Medicaid have the advantage of examining large patient populations over time. Data from the Nationwide Inpatient Sample show EVAR use has significantly increased over time (5.9% in 2001 to 18.9% in 2006). Independent predictors for the use of ruptured EVAR in managing ruptured AAA patients include high institution elective ruptured EVAR volume, treatment at a teaching institution, and advanced age of the patient. More recent data published on U.S. Medicare beneficiaries in 2014 indicated that by 2008, the proportion of ruptured AAA treated by ruptured EVAR had increased to 31%.

A report on the U.S. National Surgical Quality Improvement Program database that collectively evaluated 427 ruptured AAA patients from 2005 to 2007 who underwent either ruptured EVAR (23%) or ruptured open surgical repair (77%) indicated that ruptured open surgical repair was associated with a significantly higher 30-day mortality (OR, 1.9; P = 0.006) compared with ruptured EVAR. Furthermore, in a recent population outcome analysis in England, ruptured EVAR was performed in 7.6% of 4,414 ruptured AAA repairs; a propensity scored analysis indicated that ruptured EVAR was associated with a significant reduction in mortality and offered a survival advantage compared with ruptured open surgical repair (OR, 0.527; $P < 0.001$).

Several meta-analyses and a Cochrane review have been published on ruptured EVAR to determine whether this therapy reduces mortality of ruptured AAA. A meta-analysis of 23 published studies on ruptured EVAR versus ruptured open surgical repair analyzed outcomes in 7,040 patients who underwent ruptured EVAR (N = 730, 10%) or ruptured open surgical repair (N = 6,310, 90%). The findings indicated that ruptured EVAR was associated with a significant reduction in 30-day mortality and operative duration; mean intensive care unit length of stay was lowered by 4 days and mean hospital length of stay by 9 days.

Several randomized trials have evaluated the efficacy of ruptured EVAR have been completed to date. The Dutch multicenter randomized trial, which evaluated death and severe complications as its primary endpoints. The Dutch trial findings indicate that death and severe complications occur in 42% of patients after ruptured EVAR and in 47% after ruptured open surgical repair, which was not significantly different. The Dutch trial was conceived in 2003 and randomized 116 patients during a nearly 8-year period. In this period, 520 patients were enrolled in the trial. Of the 520 patients, 395 (76%) were evaluated by CT scan, of which 240 (61%) were found to have unfavorable anatomy for ruptured EVAR and were excluded. Another 39 (10%) patients were excluded for a variety of reasons. The remaining 116 (22%) patients were randomized to ruptured EVAR or open surgical repair. For a prospective randomized multicenter trial, this trial had a significant patient selection bias, rendering its outcomes questionable in the real-world scenario. The Dutch trial also reported ruptured EVAR mortality of 21% versus ruptured open surgical repair mortality of only 25%. Although this ruptured EVAR mortality was comparable to what is reported in the literature, the ruptured open surgical

repair mortality was remarkably lower than what has historically been reported.

The latest randomized trials, IMPROVE (Immediate Management of the Patient with Rupture: Open Versus Endovascular Repair), compares ruptured EVAR versus ruptured open surgical repair in a heterogeneous group of patients with a primary focus on comparing endovascular-first to open surgical–first strategies; the investigators randomized 613 ruptured AAA patients to ruptured EVAR (n = 316) and ruptured open surgical repair (n = 297) over a 4-year period. The study indicated that overall ruptured EVAR mortality was 35%, and ruptured open surgical repair mortality was 37%, and hence ruptured EVAR first strategy is comparable to ruptured open surgical repair first strategy. This was further interpreted as if the 2 therapies were comparable in managing ruptured AAA patients. The problem with IMPROVE's trial design was that it did not answer the fundamental question of how ruptured EVAR compare to ruptured open surgical repair in patients with ruptured AAA when ruptured EVAR is possible? A detailed data analysis indicated that of the 316 ruptured AAA patients that were randomized for ruptured EVAR, only 59% received ruptured EVAR and 41% were crossed-over and received ruptured open surgical repair; regardless of the treatment received, the overall mortality of 35% was assigned to ruptured EVAR cohort. Similarly of the 297 ruptured AAA patients that were randomized for ruptured open surgical repair, 84% had ruptured open surgical repair and 16% were crossed-over and received ruptured EVAR; regardless of the treatment received, the overall mortality of 37% was assigned to ruptured open surgical repair cohort and hence no difference was noted in the two groups. If the data were evaluated on the basis of the treatment received, and not which arm the patients initially randomized to, the ruptured EVAR mortality would be significantly lower at 26%, when compared to the ruptured open surgical repair mortality of 43%. The IMPROVE trial confirmed that ruptured EVAR offers survival advantage to ruptured AAA patients that are considered suitable for endovascular therapy.

SECONDARY INTERVENTIONS

Late reinterventions occur after both ruptured EVAR and ruptured open surgical repair. In recent series reporting concurrent ruptured open surgical repair and ruptured EVAR, rates of surgical reintervention ranged from 10% to 28% for ruptured open surgical repair cases versus 19% to 23% for

ruptured EVAR cases. After ruptured EVAR, reinterventions were required for endoleaks, stent-graft migration, limb thrombosis, infection, and rupture; those following ruptured open surgical repair included exploration for bleeding, bowel obstruction, ischemia, and hernia repair. To date, the only report on long-term follow-up after ruptured EVAR in 120 patients indicates that among 91 survivors, late interventions for graft-related complications were performed in 21 patients (23%). Of all secondary interventions collectively, the etiology included type I endoleaks (14.3%), type II endoleaks (57.1%), proximal stent-graft extensions for migration (9.5%), femoral–femoral bypass for limb thrombosis (9.5%), and stent-graft explant for infection (9.5%) during a mean follow-up of 34 months.

RUPTURE AFTER EVAR

The goal of ruptured AAA repair is to reduce the risks for aneurysm rupture and death. However, none of the currently available stent-grafts is completely effective in preventing aneurysm rupture after ruptured EVAR, and lifelong surveillance is needed. We evaluated our experience of delayed AAA rupture after EVAR and found that the most common risk factors contributing to rupture included type I endoleaks with stent-graft migration (63%), type I endoleaks without stent-graft migration (11%), type II endoleaks (19%), and undetermined etiology (7%). In this series, 41% of patients with ruptured AAA after EVAR underwent another secondary EVAR procedure with an operative mortality of 9%, whereas 55% required conversion to open surgical repair with an operative mortality of 20%. Data from 1,442 EVAR 1 and 2 trial patients indicate that after EVAR, complications of type I endoleaks, type II endoleaks with aneurysm sac expansion, type II endoleaks, and stent-graft migration significantly increase the risks for aneurysm rupture (adjusted hazard ratio, 8.8 [95% CI, 3.76–20.76]; $P < 0.0001$). Interestingly, several studies have suggested that an existing stent-graft might provide hemodynamic stability when aneurysms rupture after an elective EVAR due to endoleaks, which might be responsible for reduced mortality in patients with ruptured aneurysm with prior EVAR.

Open Surgical Repair of Ruptured AAA

The first priority in the management of ruptured AAA regardless of approach is proximal aortic control. The two choices for open surgical

exposure are retroperitoneal and transperitoneal. The authors' preference for open repair of ruptured abdominal aneurysm is the extended left retroperitoneal approach. The rationale is as follows. First, the aorta is a retroperitoneal structure. There is therefore no need to directly manipulate or avoid bowel or other intraperitoneal structures in order to expose the aorta. Second, exposure of the entire abdominal aorta from the level of the diaphragm to the iliac bifurcation is easily obtained. The surgeon has facile exposure of the paravisceral aortic segment for supra celiac aortic control, clamp placement and visceral branch reconstruction if necessary. It is also the author's opinion that the physiologic insult to the patient with this exposure is less and the ability to treat patients with prior endovascular aortic replacement who present with secondary rupture is improved. We do recognize that some surgeons may be more comfortable with a transperitoneal and have therefore described both techniques.

Extended Left Retroperitoneal Approach

A suction bean bag (Olympic Vac-Pac) is placed on the operating table before the patient is brought into the operating suite. The patient is initially placed supine on the bean bag to facilitate central venous and arterial line placement if the patient is hemodynamically stable. After the induction of general anesthesia, the patient is rotated into a modified right lateral decubitus position (left flank up). The patient is positioned with the table break approximately 10 cm cephalad to the left iliac crest with the torso shifted toward the right and rotated until the left shoulder is elevated 45 to 60 degrees from the horizontal position while the pelvis is rotated 15 to 30 degrees to the right to allow access to both groins (Fig. 201.4). The left upper extremity is brought across the chest and supported by blankets or a stand. The left thigh is elevated above the horizontal plane to relax the iliopsoas muscle. This maneuver improves access to the distal aorta and left iliac arteries. To open the space between the iliac crest and the costal margin the table is flexed at the table break. At this point, the operating table should be tilted in a slight reverse Trendelenburg position so that the plane of the planned retroperitoneal incision is level with the horizontal plane.

The patient is prepped and draped from the mid chest to the mid thighs bilaterally. Ideally, a self-retaining abdominal wall retractor like the Buchwalter is anchored to the left rail of the operating table. The incision is made sharply from the lateral edge of the left rectus muscle between the umbilicus and pubic symphysis in an oblique fashion directed posteriorly

and superiorly through the 10th interspace to the posterior axillary line. The use of this higher incision allows exposure of the paravisceral and supra celiac portions of the aorta.

The muscle layers of the lateral abdominal wall are divided in line with the skin incision. The deepest layer, the transversus abdominis, is divided from a lateral to medial direction to aid the separation of the anterior abdominal wall from the peritoneum, which is usually thicker and more defined laterally. The intercostal muscles are divided on the superior margin of the underlying 10th rib. Any entrance into the pleural cavity is repaired at the end of the procedure.

In the setting of rupture, the hematoma may have already created the retroperitoneal dissection plane, but in general initial exposure is performed laterally and posterior superior to the left kidney so as to avoid disturbing the hematoma that may have tamponaded the bleeding resulting in hemodynamic collapse. The surgeon should place his left palm on the surface of the left psoas muscle and direct it cephalad to the posteromedial diaphragm and crus in order to elevate the peritoneum gently off the posterior dome of the diaphragm. The surgeon should be careful to not go deep to the fascia overlying or into the crevice lateral to the psoas major muscle to minimize dissection related bleeding and genitofemoral nerve injury. The blunt medial cephalad dissection is complete when the supra celiac aorta is palpable beneath the diaphragmatic crus directly on the distal thoracic vertebral column.

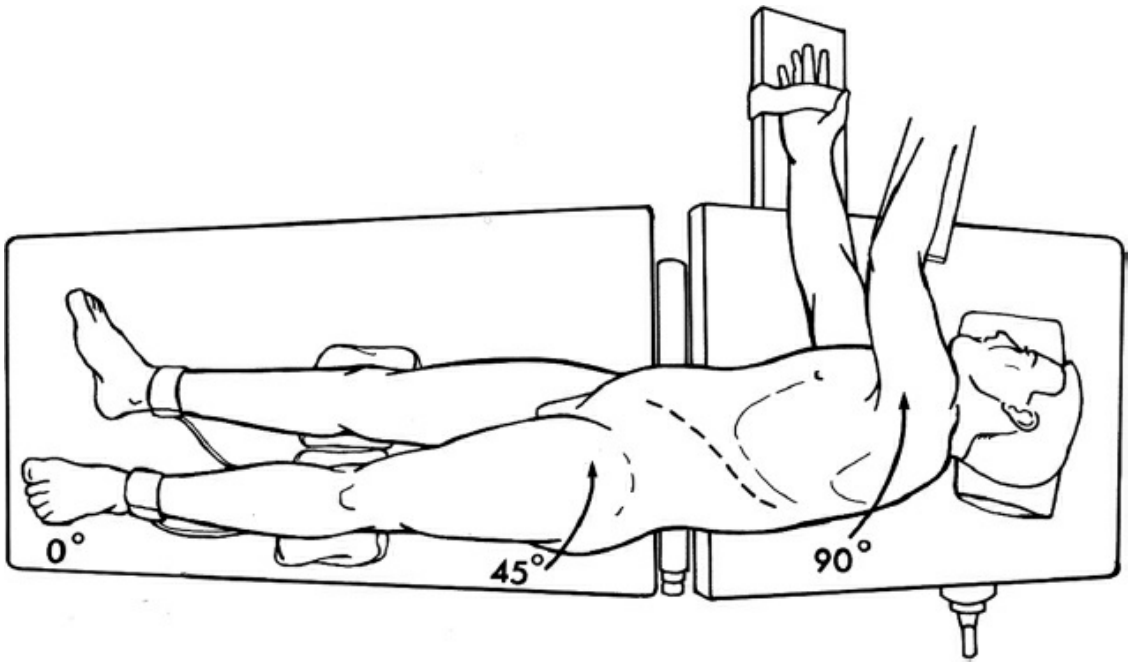

Figure 201.4. Positioning for left retroperitoneal approach.

At this point, the prime consideration is placement of the proximal supra celiac aortic clamp. An assistant should be positioned on the right side of the table and using a large deep handheld Dever retractor medially retract the peritoneum and its contents to allow the surgeon to visualize the crus overlying the supraceliac aorta Vigorous retraction of the anterior and cephalad margin of the incision should be avoided as this may result in splenic or renal injury

Initially, the supra celiac aorta is compressed posteriorly with the tips of the fingers of the left hand against the anterior portion of the thoracic vertebrae. The crural fibers are then snipped transversely with a scissors to expose and directly visualize the supraceliac aorta for clamp placement. The authors' preference is to use a padded type clamp such as a long Fogarty Clamp as we believe it is less traumatic. Our preference is not to systemically heparinize the patient.

The retroperitoneum is widely exposed at this point, and the left kidney is retracted medially and cephalad. This is the key aspect of the extended left retroperitoneal approach that allows the surgeon to exposure the entire abdominal aorta. The blades of the self-retaining retractor are padded to minimize the risk of traction injuries to underlying organs. In addition, dissection is maintained posteriorly to identify and avoid any injury to the left ureter.

As most AAAs rupture infrarenally, the next step is to define the immediate infrarenal aorta. The landmarks for this portion of the aorta are the origin of the left crus of the diaphragm, the lumbar branch of the left renal vein, and the left renal artery. Once the lumbar branch of the left renal vein (which crosses the aorta in a posterior and perpendicular fashion and caudad to the left renal artery) is securely ligated and the lympho-areolar tissue is dissected, the infrarenal aorta is dissected free on its lateral anterior and posterior surfaces. The clamp is then released sequentially and moved down from the supraceliac to the infrarenal location. This will allow any stasis clot proximal to the supraceliac clamp to flush distally and not into the renal and visceral arteries. If there is no infrarenal aortic neck, the authors' preference is to leave the supra celiac clamp in place and control the celiac, superior mesenteric and renal arteries separately.

The next priority is distal arterial control. The distal aorta, proximal right common iliac artery and entire left iliac system can be exposed and clamped through the left extended retroperitoneal exposure. If there is

significant distal involvement of the distal right common or external iliac arteries then a small suprainguinal counter incision can be made in the right lower quadrant by a second surgeon to obtain extra peritoneal exposure of the external iliac artery. Alternatively, right common iliac artery control can also be obtained with a balloon occlusion catheter through the left flank incision at the time the aneurysm is opened. If there is extensive pelvic aneurysmal or occlusive disease, vertical groin incisions are made to expose the femoral arteries for distal arterial control and anastomosis. As the patient is not systemically heparinized, flushing the outflow arteries with local heparin prior to clamp placement may prevent distal arterial thrombosis due to stasis. The sac is then opened with electro cautery; lumbar arteries and the inferior mesenteric artery can be suture ligated within or clipped from outside the opened AAA sac with clips. The aneurysm neck may be transected completely or partially with the posterior medial wall remaining intact. The authors' preference is to completely transect the aorta to allow precise suture placement through the full aortic wall thickness, thus minimizing later development of pseudoaneurysm.

The proximal graft anastomosis is performed using a parachuted anastomotic technique with a continuous 3-0 polypropylene suture. The anastomosis starts medially at the 9 o'clock position and is parachuted anteriorly to the 12 o'clock position. At this point the graft is loosely retracted up anteriorly to allow visualization of the medial and posterior aspect of the aorta to which the graft is sewn next to the 6 o'clock position. The anastomosis is the tightened and the remainder of the anastomosis is completed. Once the suture line is tested, the graft is bled to rid the aorta of any stasis clot and the clamp is replace on the proximal graft, which is then flushed with heparinized saline.

In the setting of a ruptured pararenal aneurysm, an infrarenal anastomosis may not be possible. In this setting, the left extended left retroperitoneal approach allows other variations such as a beveled proximal anastomosis with branch grafts to the involved renal vessels similar to a Type IV thoracoabdominal aortic aneurysm repair. Though this approach, the entire left renal artery may be visualized. With further division of the left crus, the lateral pararenal/visceral aorta is well visualized. The right renal artery is best exposed once the aorta has been divided. The right renal artery can be exposed up to its transverse portion beneath the inferior vena.

Next the distal aortic, iliac, or femoral anastomoses are completed. The distal graft limbs of the graft are tunneled anatomically along the axis of the iliac vessels. On occasion, it may not be possible for limbs to be tunneled anatomically due to inflammation or prior surgery. In this situation, the right limb graft limb can be tunneled through the space of Retzius. Prior to performing distal anastomoses, embolectomy catheters should be passed distally to retrieve any stasis thrombus, 4 Fr for iliac and 3 Fr for femoral arteries. Distal anastomoses are performed end to end to common iliac and end to side to external iliac and femoral arteries with 5-0 or 6-0 Prolene continuous sutures. Hand held Doppler is used to assess distal flow after release of clamps.

If there is any concern regarding intestinal viability or traction injury to the spleen, the peritoneum can be purposefully incised to allow for direct inspection of the intra-abdominal contents. At this point, any defects in the peritoneum are repaired. If entrance into the pleural cavity does occur, it is fixed directly upon incision closure by sewing the cut diaphragmatic edge to the next highest rib while catheter suction is maintained in the pleural cavity. Alternatively, tube thoracostomy can be placed. The abdominal wall musculature is closed in layers followed by closure of the subcutaneous tissue and skin. Closure of the wound is made easier by taking the flex out of the table, which allows a tension free repair.

Transperitoneal Approach

The patient is brought to the procedure table and placed in a supine position. As general anesthesia is induced, the patient is prepped from the nipples to the mid-thigh area. If the patient is in extremis, percutaneous femoral artery access may be obtained and a 7-Fr sheath placed for placement of an intra-aortic balloon occlusion catheter. Alternatively control can be gained by clamp placement after a midline laparotomy incision is made or through a small left thoracotomy incision to clamp the distal thoracic aorta as is done during a trauma arrest situation.

A midline incision is made from the xiphoid process to the pubic symphysis. A self-retaining abdominal wall retractor such as a Buchwalter retractor is very helpful to aid exposure and reliable retraction. Depending on the patient’s hemodynamic status and the location hematoma and extent of hemorrhage, placement of a supraceliac aortic clamp may be necessary. The most expeditious way to accomplish this is through the lesser omental sac. The triangular ligament of the left lobe of the liver is divided and retracted to the patient’s right as necessary and the esophagus with a

nasogastric tube in place is retracted to the patient's left to expose the diaphragmatic crural fibers overlying the supraceliac aorta. Blunt dissection with the surgeon's fingers or sharp scissor dissection is used to divide the crus and expose the aorta, which is then clamped. If the hematoma is mainly distal and the patient stable, the aorta can be approached initially infrarenally for clamp placement.

Alternatively, the entire abdominal aorta can be exposed by incising the left posterior peritoneal attachments lateral to the left colon and solid abdominal visceral and reflecting them medially. This medial visceral rotation (Maddox Maneuver) allows exposure of the entire abdominal aorta from the supraceliac level to the aortic bifurcation. This is similar to the extent and breadth of exposure possible with the extended left retroperitoneal approach.

At this point, the transverse colon is retracted cephalad and the small intestines either retracted and packed into the right lower quadrant or eviscerated and placed into bowel bag or warm saline soaked gauze. The ligament of Treitz is incised allowing retraction of the duodenum and exposure of the retroperitoneal tissue overlying the aorta. If possible, the surgeon should avoid entering the hematoma until the aorta is clamped or the infra renal neck of the aorta is exposed. In general, dissection is limited to the anterior and lateral aortic walls. Exposure and aortic clamp placement is facilitated by exposure and cephalad retraction of the left renal vein which is usually anterior to the aorta. Limiting circumferential aortic dissection also avoids potential venous injuries especially in the setting of a retro-aortic left renal vein. If necessary, the left renal vein can be divided, but this should be done as close to the inferior vena cava as possible to preserve collateral venous drainage from the adrenal and lumbar branches. If there is a segment of nonaneurysmal aorta infrarenally, the aorta should be clamped in this location and supraceliac clamp placement released. At this point communication with the anesthesia team is required to anticipate declamping hypotension from liver and intestinal reperfusion. If the anatomy is obscured or distorted by the hematoma, it may be necessary after supraceliac clamping to enter the aortic sac, define the aortic neck and then place the proximal clamp as distally as possible in order to perfuse the renal and visceral outflow.

After placement of the proximal aortic clamp, a dose of heparin can be given intravenously. It is the authors' preference is not to give systemic Heparin and thereby minimize the exacerbation of coagulopathy. At this

point, the iliac or femoral arteries should be controlled. Ideally, the iliac arteries should be clamped but if the anatomy is difficult to define, the aortic sac can be opened and 14-Fr Foley or large caliber Fogarty catheters placed into the iliac arteries with balloon inflation for control. These catheters can then be irrigated distally with heparinized saline. Within the aortic sac, the lumbar and inferior mesenteric arteries are controlled with 3-0 Prolene suture ligatures.

Whenever possible, aortic reconstruction should be performed with a tube graft prosthesis to expedite getting the patient off the operating table. If there is extensive aneurysmal or occlusive disease then a bifurcated prosthesis should be placed. The proximal anastomosis should be started on the posterior aortic wall. The author's preference is with a continuous monofilament suture such as 3-0 Prolene. As this part of the aorta has not been circumferentially dissected, the surgeon should use a "Creech" type endoaneurysmorraphy. In order to assure incorporating the adventitial layer, the surgeon should aim the needle directly posteriorly and may include the anterior longitudinal spinal ligament in the posterior anastomotic suture line. The anastomosis should be accomplished using a parachuted technique in order to assure appropriate spacing of the needle bites. Once the posterior suture line is completed, the suture line is tightened, the graft brought down and the remaining lateral and anterior aspects are completed. A clamp is the placed on the proximal graft and the suture line is tested. Any significant bleeding is controlled with pledgeted sutures, as the aortic wall may be friable.

If a tube graft is placed, the distal aortic anastomosis is performed similarly. In this situation, flow is restored to the iliac arteries sequentially to limit significant declamping hypotension. This should be coordinated with the anesthesia staff to allow appropriate predeclamping intravenous fluid resuscitation. With bifurcated distal reconstruction, anastomosis is generally performed end to end to the common iliac arteries and end to side to the external iliac and femoral arteries.

The graft is separated from interaction with bowel by approximating the retroperitoneal layer and decompressed aortic sac over the graft prosthesis with a suture closure. Closure of the fascial incision is performed with a continuous or interrupted monofilament suture. In cases of shock with massive fluid resuscitation, it may not be possible to close the incision; and in this situation, the abdomen can be packed with saline soaked laparotomy pads, the patient kept under deep anesthesia with planned

return to the operating suite in 48 to 72 hours for reassessment and closure.

Treatment of AAA Sac Rupture After EVAR

Treatment of AAA sac rupture after prior EVAR can be a technically challenging endeavor. Ideally, this is treated with a secondary endovascular repair. When this is not possible open repair may be required. Although either transperitoneal or retroperitoneal approach can be used, the authors' preference is the extended left retroperitoneal approach as described above for endograft explant and reconstruction. A surgeon's familiarity with the retroperitoneal exposure in elective situations involving infrarenal, juxtarenal and pararenal AAAs lends itself to the use of this approach to more complex clinical scenarios. The same attributes of the left retroperitoneal exposure that facilitate repair in ruptured aneurysm, such as the ability to control the entire abdominal aorta from the distal thoracic segment to the iliac bifurcation, apply to open repair in patients with rupture after failed endovascular repair. The positioning, incision and exposure are identical to the technique for repair of ruptured AAA previously described.

The paramount concern for any type of open repair for AAA rupture is proximal control and stable dissection. Depending on the type of endograft deployed, there is often a varying degree of inflammation present in the retroperitoneum due to several factors including infra versus suprarenal fixation, endostapling and/or translumbar coiling of prior endoleak. The ability to minimize dissection related injury to adjacent structures such as the duodenum and renal veins is easier with a retroperitoneal exposure. Maneuvers such as maintaining the dissection as posterior as possible within the retroperitoneum and identifying the ureter early with or without the use of preoperatively placed stents confer safety. The supraceliac aortic dissection is usually free of inflammation as compared to the infra and juxtarenal portions which are often significantly inflamed and the dissection hazardous. The safest method to avoid mishap is to approach the lateral and posterior aspect of the infrarenal aortic segment after initial clamp placement. One alternative measure mentioned previously is to obtain control with an intra-aortic balloon directed from one of the femoral arteries and inflated at the supra celiac aortic level.

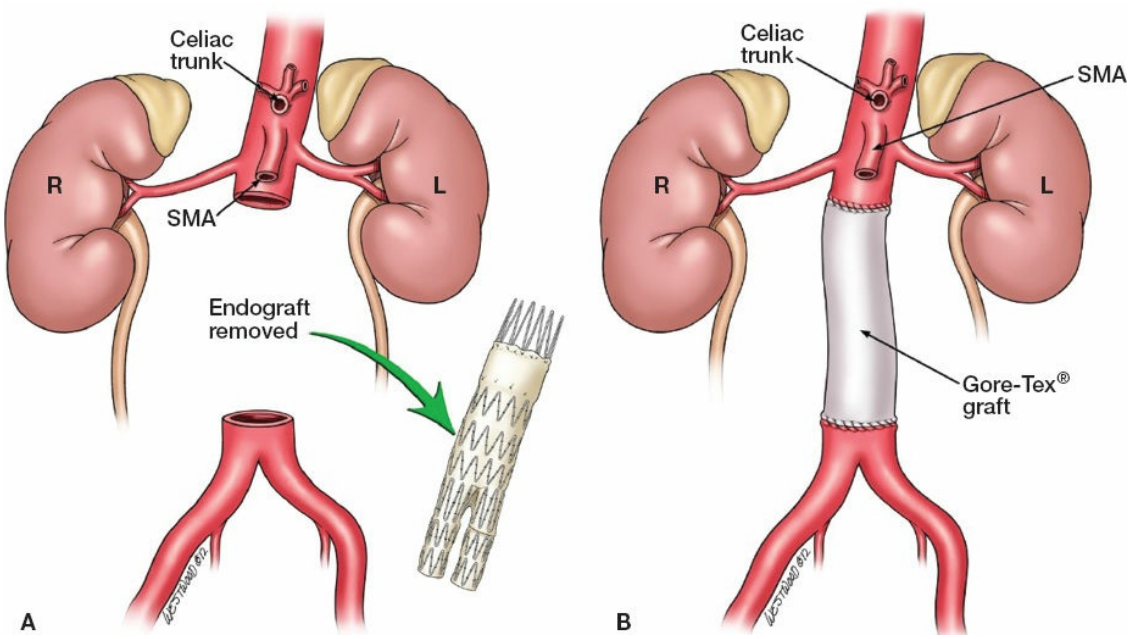

Figure 201.5. A. Complete explant of aortic endograft. **B.** Tube graft aortic replacement after complete explant.

If further dissection of the infra or juxtarenal aortic neck cannot be safely performed, the supraceliac aortic clamp is left in place, renal/visceral arteries are controlled, distal clamp(s) are placed and the aneurysm sac is opened. If information is available regarding the previously deployed endograft in terms of suprarenal versus infra renal fixation, this may help plan subsequent control and clamping of the distal aorta. In patients with a known suprarenal fixation, it is often preferable to leave the aortic cross clamp in place but unclamped on the supraceliac aorta. With a known infrarenal device, assuming the aorta can be accurately dissected, is minimally diseased and has no significant aneurysmal component, the cross clamp can be moved to the infra renal aorta.

The surgeon needs to remember that the goal is to control bleeding and reconstruct in line flow as expeditiously as possible. Ideally, one should try to completely explant the endograft but not at the expense of compromising an expeditious procedure. The single most important factor in deciding between partial or complete stent graft explant is whether the endograft can be completely removed without destroying the aortic wall. Other considerations include the type of stent graft fixation (suprarenal versus infra renal, and active with hooks/barbs versus passive with self-expanding stent only), as this may influence the site of aortic clamping and the possible adjunctive need for visceral endarterectomy and/or

revascularization with complete stent graft explant. Infra renal aortic clamping with partial stent graft explant might be a significantly less morbid procedure when compared with supra celiac aortic clamp and complete stent graft explant, with possible visceral reconstructions, particularly in the patient with aneurysm rupture. In cases of rupture secondary to a Type IA endoleak, the proximal endograft may slide out easily. Lastly, some endografts with suprarenal fixation can be "recaptured" with a cut syringe, thereby facilitating explant.

In AAA rupture patients with infra renal stent grafts, the proximal aortic clamp is placed at the supra-renal level, the aneurysm sac opened, the entire infra renal stent graft is explanted including the iliac limbs, and aorto iliac reconstruction performed as needed (Fig. 201.5A,B). In AAA rupture patients with suprarenal self-expanding stents for fixation, aortic control is obtained by placing a supra celiac aortic clamp. In these cases, if the graft cannot be recaptured as mentioned previously, partial stent graft explant with transaction of the stent graft within the proximal aortic neck is performed. A bone cutter may be necessary to cut the wire scaffold of the prior endograft. In AAA rupture patients with stent grafts that have placement of proximal Palmaz stents, aortic control is obtained via a supra celiac aortic clamp, or an aortic occlusion balloon, with partial or complete stent graft explant. When the proximal aortic stent graft is partially explanted, the proximal graft is sewn to the composite endograft/proximal aorta with or without pledgets depending on the friability of the aortic wall (Fig. 201.6). Renal arterial reconstruction may be necessary as previously detailed depending upon the wall integrity and extent of the proximal aortic aneurysm (Fig. 201.7A,B).

If the entire distal portion of the endograft can be removed, the aortic graft is sewn to the distal aorta, iliac or femoral arteries depending on the extent of aneurysmal and occlusive disease. In instances when the iliac limbs cannot be explanted due to scarring, either the distal anastomosis is constructed beyond the iliac stent grafts and the aortic bifurcation is then over sewn (Fig. 201.8), or the limbs are transected at the aortic bifurcation and aortic tube grafts is sutured directly to the distal aortic bifurcation, and the stent graft limbs are incorporated within the anastomosis. Alternatively, the limbs of a bifurcated graft can be sewn individually to the remaining endograft limbs or the distal body of the endograft (Fig. 201.9). Interrupted 5-0 polypropylene sutures are then used to secure the native distal iliac arteries to the distal portion of the remaining EVAR

limbs.

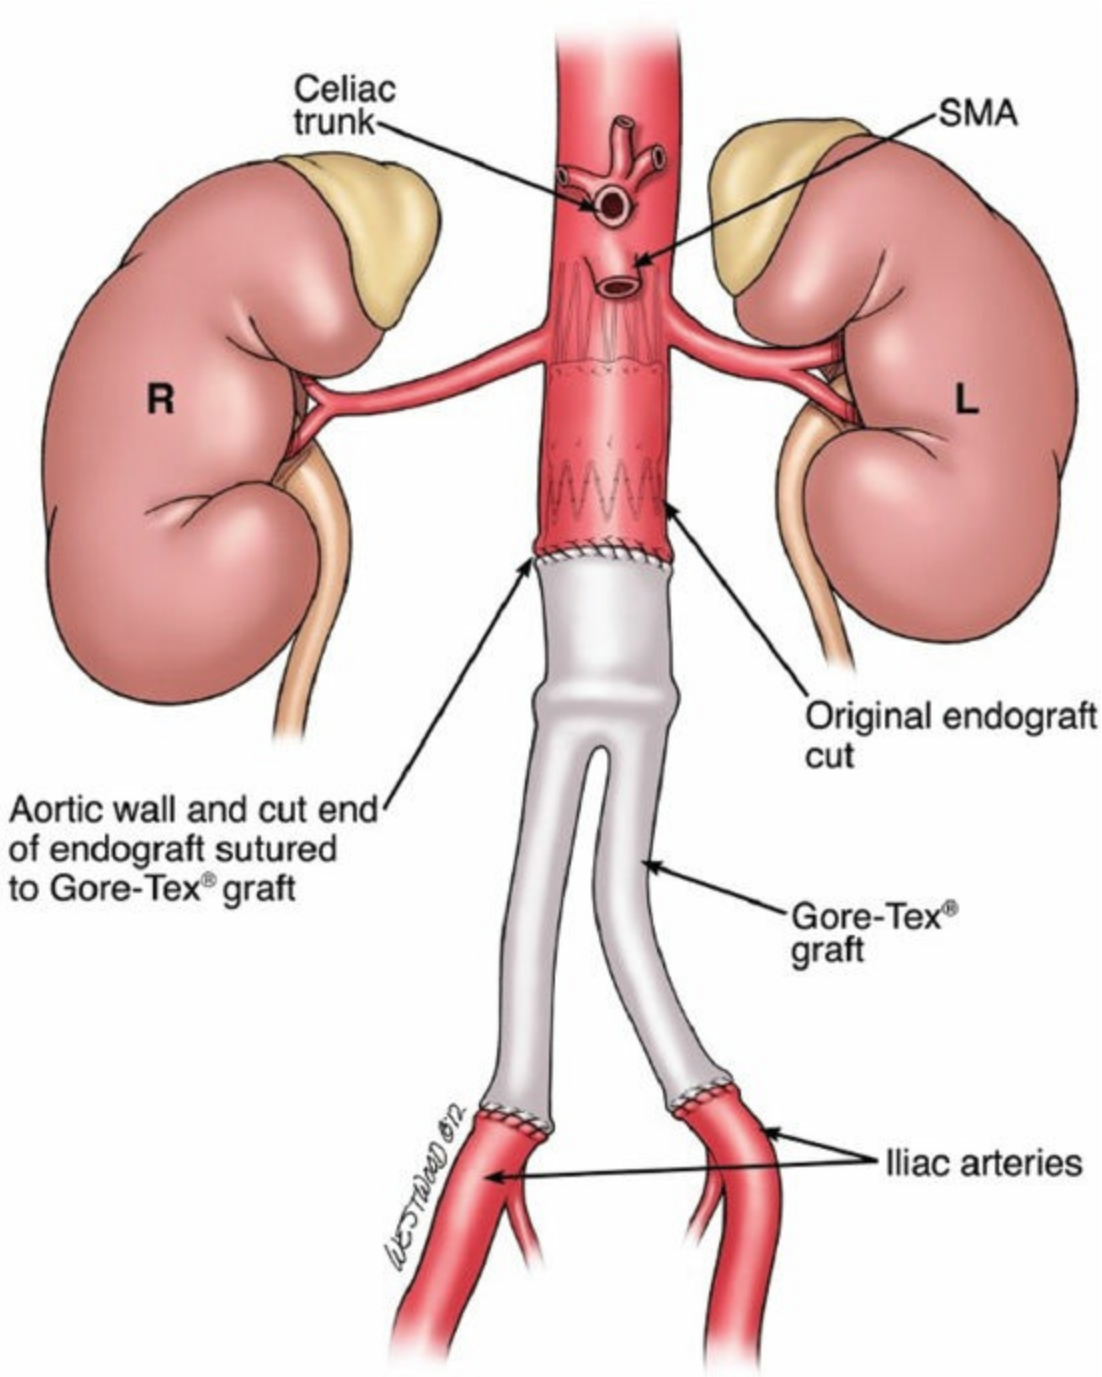

Figure 201.6. Partial proximal and complete distal endograft explant with bifurcated graft reconstruction.

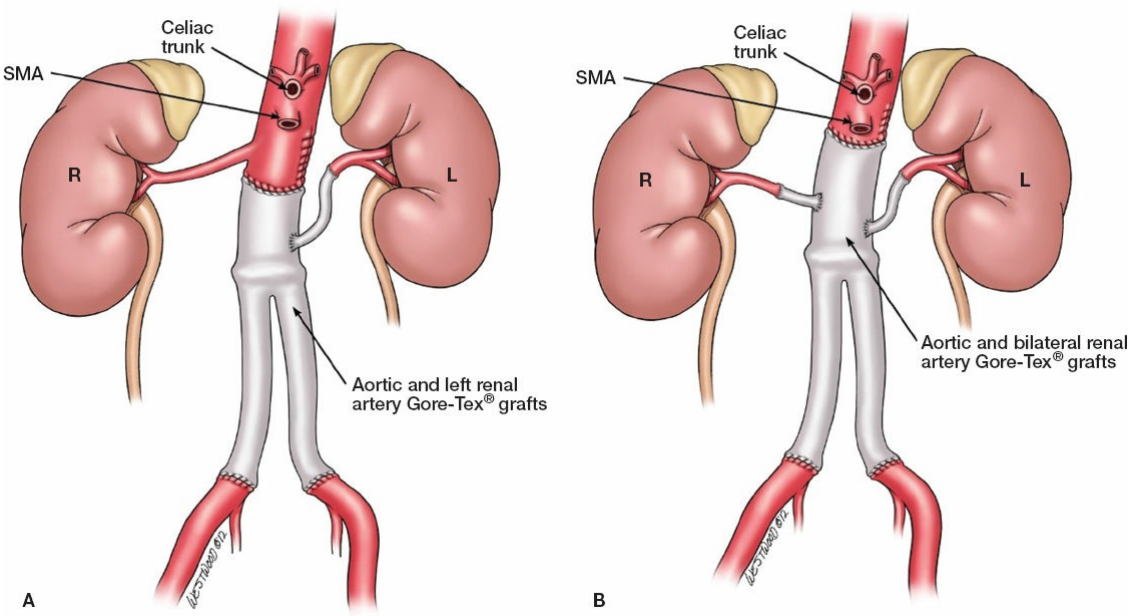

Figure 201.7. **A.** Complete explant of endograft with suprarenal fixation and subsequent aortic reconstruction with left renal bypass. **B.** Complete explant of endograft with suprarenal fixation and subsequent aortic reconstruction with bilateral renal artery bypass.

COMPLICATIONS OF RUPTURED ABDOMINAL AORTIC ANEURYSM REPAIR

Local Complications

Following open surgical repair, postoperative bleeding can occur in as many as 12% to 14% of patients. The incidence is related to the presence of coagulopathy in patients with shock and hypothermia. Limb ischemia can be related to in-situ graft limb thrombosis or distal thromboembolism. With ruptured EVAR, most local complications are access related and dependent on percutaneous approach versus femoral artery cut-down. Local complication of bleeding and clotting are generally in the range of 7% to 10% following ruptured EVAR.

Colonic Ischemia

Colonic ischemia is a lethal consequence of any AAA repair, particularly when it occurs following ruptured AAA repair. The most recent prospective data using sigmoidoscopy noted an ischemic colitis incidence of 38% with open ruptured AAA repair, and 23% following ruptured EVAR. In a prospective analysis of ruptured AAA, patients who survived 24 hours postoperatively, a 26% incidence of grades I & II ischemia was

detected with colonoscopy, with 10% having grade III changes. Of those with grade I, or II changes, 11% progressed to grade III within 48 hours. Those with grade III changes were found at surgery to have extensive sigmoid and frequently rectal necrosis and even with surgical management had a mortality rate of 55%. At the conclusion of open surgical repair, careful examination of the bowels and Doppler evaluation of the mesentery should be routinely performed. When in doubt, reimplantation of the inferior mesenteric artery should be considered.

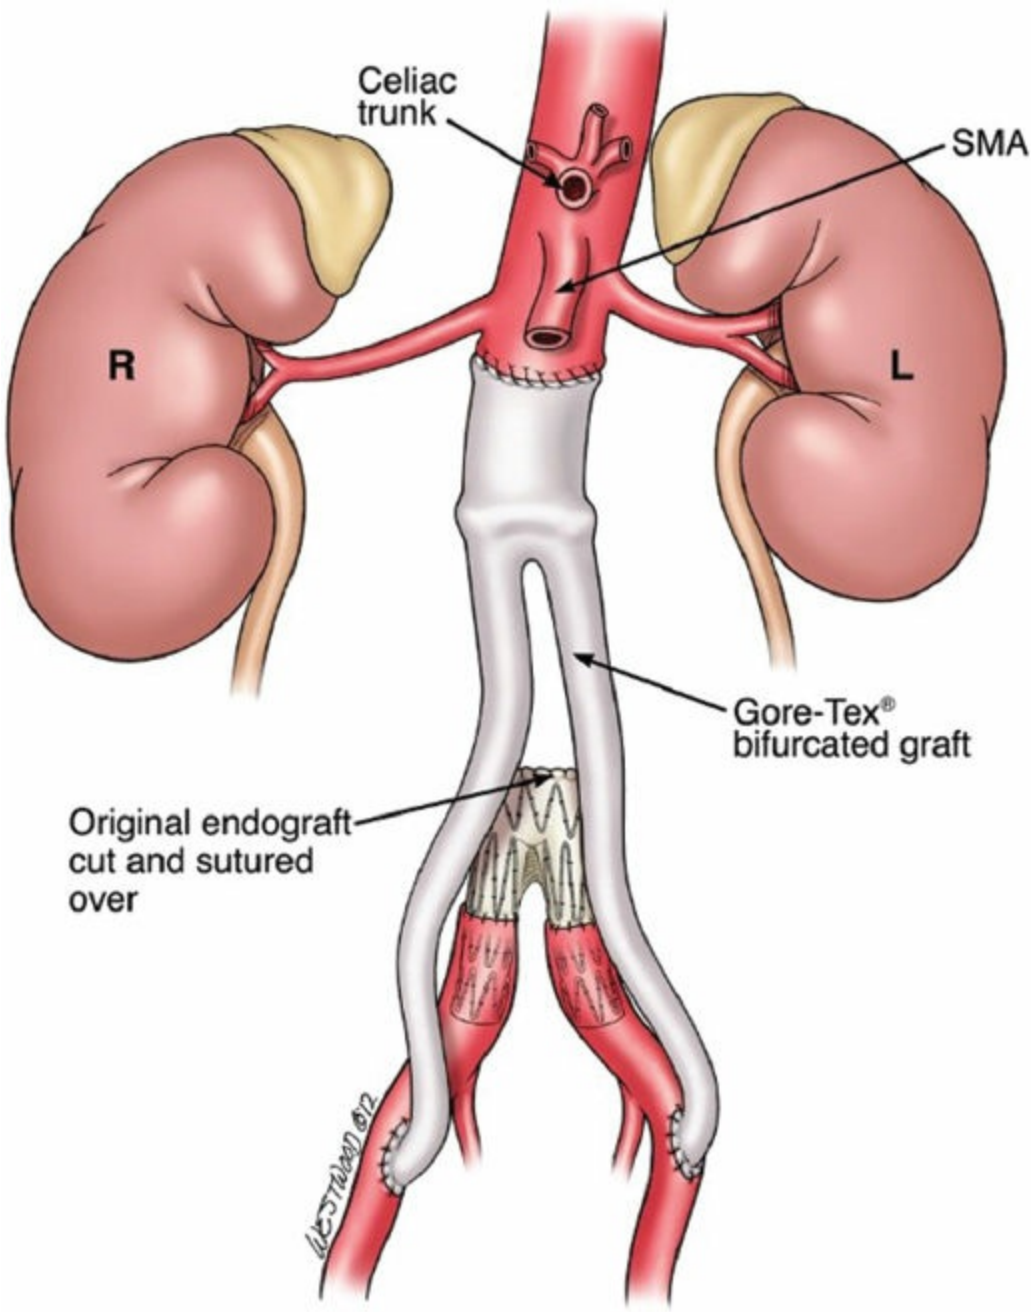

Figure 201.8. Complete proximal and partial distal endograft explant with bifurcated aortic reconstruction to native distal iliac

arteries.

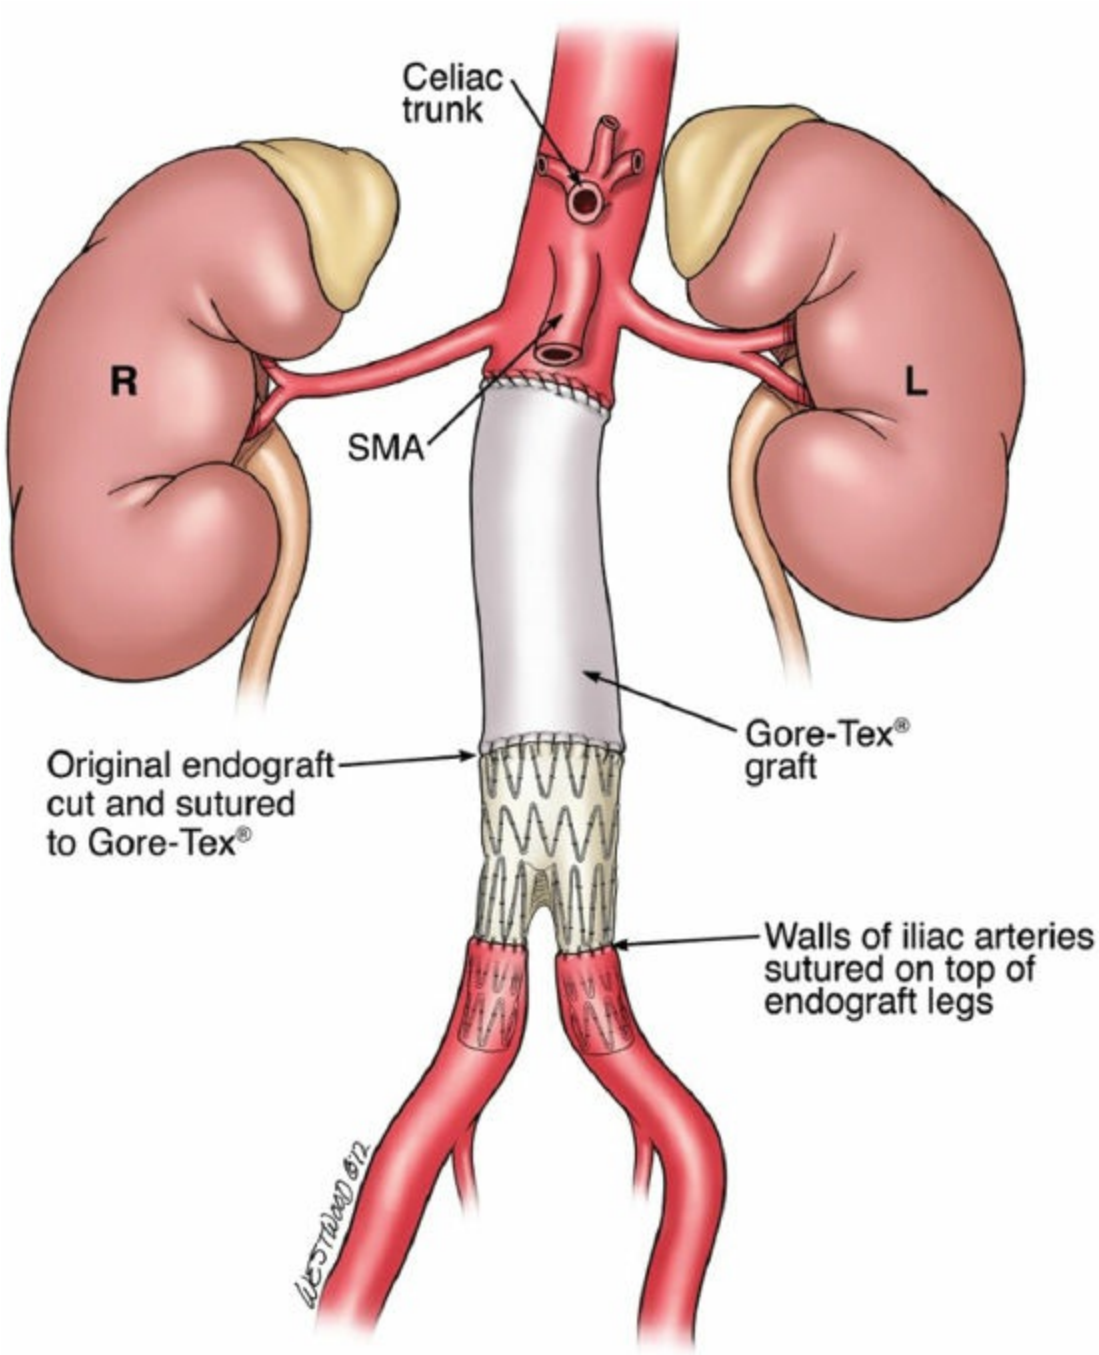

Figure 201.9. Complete proximal and partial distal endograft explant with tube graft reconstruction to remaining endograft body. Remaining endograft iliac limbs are secured to native iliac arteries with interrupted 5-0 Prolene sutures.

Cardiac Complications

Pre-existing coronary artery disease has been shown to increase the risk for myocardial infarction and death after open surgical and endovascular

ruptured AAA repair. Myocardial infarction develops secondary to the increased demand placed on the heart to compensate for the blood loss, resuscitation, aortic clamping and declamping, particularly in the setting of pre-existing coronary artery disease. Myocardial infarction after ruptured EVAR is occurs in 5% to 10% of patients and is associated with a far lower mortality than after open surgical repair. After open surgical repair of ruptured AAA, myocardial infarction develops in 10% to 25% of patients and is associated with a mortality rate of 17% to 66%, while arrhythmias and congestive heart failure develops in nearly 20% of patients and are associated with a mortality of nearly 40%.

Respiratory Failure

Respiratory failure develops in 26% to 47% of patients after open ruptured AAA repair and is dependent on pre-existing chronic obstructive pulmonary disease, and is associated with a mortality of 34% to 68%. It is characterized by high oxygen requirements, increased lung permeability, and a decrease in lung compliance. Administration of large volumes of fluid and blood products, as well as preexisting pulmonary dysfunction and long cross-clamp times, predisposes to the development of respiratory failure. Respiratory complications following ruptured EVAR are as expected noted less frequently and occur in approximately 20% of patients.

Renal Dysfunction

Renal dysfunction in ruptured AAA patients has long been recognized to have a significant deleterious impact on mortality and can range from 26% to 42%. Furthermore, in patients that require dialysis (11% to 40%) the mortality rate is between 76% and 89%. Renal dysfunction has been found to be increased in those with suprarenal cross clamping, longer duration of cross clamping, pre-existing renal insufficiency, shock, and increased age. The incidence of renal dysfunction is significantly reduced after ruptured EVAR (14.8%) when compared to open surgical repair (24.8%).

Multisystem Organ Failure

Multisystem organ failure following ruptured AAA repair tends to occur more frequently after ruptured open surgical repair than ruptured EVAR, and is associated with elevated mortality rates. The incidence of death in patients with postoperative multisystem organ failure has been reported to range from 64% to 93%. The risk factors for the development of

multisystem organ failure center on the magnitude, number, and timing of the inducing inflammatory insults. Evidence from clinical ruptured AAA data suggests that suprarenal location as well as duration of clamping, and development of abdominal compartment syndrome is associated with higher rates of postoperative complications and death. The incidence of multisystem organ failure was noted to be 3.8% after elective AAA repair, 38% after urgent AAA repair, and 64% after ruptured AAA open surgical repair. In this series, the mortality rate of ruptured AAA patients with multisystem organ failure was 69% versus 0% in those who did not have multisystem organ failure.

It is likely that the "Two-Hit" hypothesis of multisystem organ failure accounts for the extensive complications and the persistent high and unchanging mortality in the patients undergoing ruptured AAA repair; the first hit is the hemorrhagic shock that results in total body ischemic event primes the inflammatory response and the aortic cross-clamping leads to ischemia and is the second hit. Reperfusion occurs as a result of resuscitation and the removal of aortic clamp or the aortic occlusion balloon. When the events were combined, a synergistic effect resulted in the rapid onset of systemic organ injury that resembled the clinical situation. Animal studies of hemorrhagic shock have demonstrated that cardiac contractile dysfunction develops after resuscitation and may further reduce tissue perfusion, thereby contributing to a higher incidence of cardiac events after ruptured AAA.

EDITOR'S COMMENT

In this outstanding chapter by Mehta and coauthors describing both endovascular and open RAAA repair, I am at first reminded of the futility we felt for the longest period of time regarding the management of ruptured AAAs. Despite improvements in blood banking and critical care, including the realization that keeping the patients warm is important, mortality following RAAA only decreased approximately 3% per decade. As described in this

chapter, the onset of elective endovascular aneurysm repair (EVAR) in the early 1990s with improved short-term mortality relatively quickly led to the adoption of EVAR for RAAA (Wainess RM, Dimick JB, Cowan JA Jr, et al. Epidemiology of surgically treated abdominal aortic aneurysms in the United States, 1988 to 2000. *Vascular* 2004;12(4):218–24; Dua A, Kuy S, Lee CJ, et al. Epidemiology of aortic aneurysm repair in the United States from 2000 to 2010. *J Vasc Surg* 2014;59(6):1512–7). As more and more endografts became FDA approved, the ability to treat a wider range of aortic anatomies was realized. While likely we will never be able to treat all RAAAs with EVAR, today as many as 70% to 80% of RAAAs are treated with EVAR (McPhee J, Eslami MH, Arous EJ, et al. Endovascular treatment of ruptured abdominal aortic aneurysms in the United States (2001–2006): a significant survival benefit over open repair is independently associated with increased institutional volume. *J Vasc Surg* 2009;49(4):817–26). There are certain aortic characteristics, including a large diameter aorta and a short aortic neck at the level of the renal arteries, which both portend poor outcomes following EVAR for RAAA. People have used “snorkel” or paragraft techniques are well described to extend the seal zone proximally. Others have intentionally covered or sacrificed renal arteries or the superior mesenteric by covering them with stent graft (Weinberger JB, Long GW, Bove PG, et al. Intentional coverage of a main renal artery during endovascular juxtarenal aortic aneurysm repair in symptomatic high-risk patients. *J Endovasc Ther* 2006;13(5):681–6). There are most certainly surgeons in practice who will not offer patients open AAA repair. It is really hard to know whether this really represents progress as it probably does not, as I have operated on many a patient with a RAAA and open repair who have survived and done well.

One of my favorite sayings I use with patients is to say, the best way to fix a ruptured AAA is to fix it before it ruptures (i.e., tell the patient they need an elective repair). Imaging with thin slice CT angiography, which is used with computer programs that allow for creation of three-dimensional images that are then used for accurate and timely anatomic measurements, removed much of the guess work out of sizing the endografts even in the RAAA setting. The authors describe the unsettling situation of what to do with the RAAA, who when you are finished still may have an endoleak. Clearly, this is a very controversial area and I am not sure people have really written much about this. My practice is always to get a CTA on patients in the near perioperative period. I think if there are type 1 or 3 endoleaks seen, they should be treated before the patient is discharged from the hospital. The data is pretty convincing that patients who are treated with EVAR for RAAA are more prone to rerupture. Therefore, my bias is to make these endografts as good as they can be, especially in the setting of a rupture.

While it was touched upon in this chapter, I think it really needs to be highlighted that there are real differences in the presentation and outcomes for males and females when it comes to RAAAs (Katz DJ, Stanley JC, Zelenock

GB. Gender differences in abdominal aortic aneurysm prevalence, treatment, and outcome. *J Vasc Surg* 1997;25(3):561–8). Female patients present more often with RAAA than males. It is really hard to Figure out what part of this is social (i.e., physicians do not think about AAAs in females as it is primarily a disease of males and screening is not widely recommended) and which part is biologic (i.e., females have more inflammation in the aortic wall) (Rasmussen TE, Hallett JW Jr, Tazelaar HD, et al. Human leukocyte antigen class II immune response genes, female gender, and cigarette smoking as risk and modulating factors in abdominal aortic aneurysms. *J Vasc Surg* 2002;35(5):988–93). This observation suggests that we should be electively repairing AAAs in females when their aortas are between 4.5 and 5 cm, instead of waiting until their aortas are 5.5 cm. In addition, females are less likely to anatomically be candidates for EVAR for RAAA. As endografts continue to become low profile, hopefully this bias will go away.

Finally, I think there is ample data to suggest that most patients with RAAA can safely undergo transfer to a center of excellence for repair of their aorta (Warner CJ, Roddy SP, Chang BB, et al. Regionalization of emergent vascular surgery for patients with ruptured AAA improves outcomes. *Ann Surg* 2016;264(3):538–43). The group from Albany as well as Dr. Mehta has really been a thought/action leader in this area and his data is convincing. My bias of course is that RAAA repair is similar to most operations, that is, the more we perform, the better we are at them. The group from Pittsburgh has written extensively on this and suggests that both elective EVAR and open AAA repair volumes impact outcomes for EVAR for RAAA (Zettervall SL, Schermerhorn ML, Soden PA, et al. The effect of surgeon and hospital volume on mortality after open and endovascular repair of abdominal aortic aneurysms. *J Vasc Surg* 2017;65(3):626–34). I for one do not believe we need a randomized, clinical trial to prove the obvious; namely, that if the anatomy is suitable, EVAR saves lives in the setting of RAAA!

Gilbert R. Upchurch Jr.

202 Femoral and Popliteal Artery Aneurysms

Mohammad H. Eslami

Peripheral artery aneurysms involve aneurysmal dilatation of the arteries in the upper and lower extremities. Traumatic injury to these vessels (e.g., femoral artery injuries after peripheral interventions), infection, or true aneurysmal degeneration may lead to aneurysm formation. Unlike abdominal or thoracic aorta aneurysms, peripheral artery aneurysms can often be detected by physical examination. The focus of this chapter is on the most common type of peripheral artery aneurysms: femoral and popliteal artery aneurysms (PAAs). It is important to distinguish true degenerative aneurysms, where all three layers of artery are involved, from false aneurysms (pseudoaneurysms), where weakness of the arterial layer leads to out-pouching of the vessel. This distinction has significant therapeutic implications.

FEMORAL ARTERY ANEURYSMS

The prevalence of femoral artery aneurysms is on the rise owing to a significant increase in the number of peripheral interventions via the femoral vessels for both peripheral and coronary interventions. Although true femoral artery aneurysms are rare (5 patients per 100,000), the combination of pseudoaneurysms and true aneurysms makes this the most commonly operated peripheral artery aneurysm. The clinical significance of femoral artery aneurysms is that they can thrombose and lead to limb loss. In addition, femoral artery pseudoaneurysms can rupture. True aneurysms are most commonly secondary to atherosclerotic degeneration of the femoral artery, whereas pseudoaneurysms can result from infection (mycotic aneurysms), trauma (e.g., peripheral intervention), or anastomotic degeneration.

Normal Femoral Artery Anatomy and Size

The femoral artery is the artery that begins distal to the inguinal ligament

and is continuation of the external iliac artery. The artery passes over the superior ramus of the pubis and the anterior superior iliac spine. It then passes distally along the medial aspect of the thigh. The proximal portion of the artery is called the common femoral artery, and it is usually 2 to 5 cm in length. This artery then divides into two arteries—the superficial and deep (profunda) femoral arteries. The common femoral artery is a subcutaneous structure and is easily palpated. Because of the ease of palpation and the artery's size, the femoral artery is the most common artery used for cardiac or peripheral interventions. It is important to have an appreciation of the normal size of the femoral artery. Femoral artery diameter measures about 0.78 to 0.85 cm in women and 0.78 to 1.12 cm in men. Aneurysm formation is defined when the artery diameter is increased by >50% compared to the expected normal diameter.

Degenerative (Atherosclerotic Femoral Artery Aneurysm)

Incidence and Risk Factors

Isolated degenerative femoral artery aneurysm is rare occurring in 5 patients per 100,000 hospitalized patients. The incidence is significantly higher among patients already diagnosed with aneurysm disease. For example, these aneurysms are reported in about 6.8% of patients with abdominal aortic aneurysms (AAA). Conversely, the presence of femoral artery aneurysm is a significant predictor of the presence of AAA as 85% of patients with femoral artery aneurysm have AAA.

The majority (72%) of patients with a diagnosis of a true degenerative femoral artery aneurysm have bilateral femoral aneurysmal disease, and 44% of these patients also have PAAs. Patients diagnosed with common femoral artery aneurysm, therefore, must undergo surveillance for the presence of other aneurysms.

These aneurysms are commonly seen among elderly patients (>70 years old) with a male to female ratio of 16:1. In addition to male gender, history of smoking and hypertension are the most significant risk factors among these patients. The most common etiology of common femoral artery aneurysm is degenerative and is caused by atherosclerosis, but other pathology, such as Behçet syndrome, acromegaly, and arteriomegaly, may also cause femoral artery aneurysms.

Anatomy and Natural History

Aneurysm degeneration of femoral artery can involve the common,

profunda, or superficial femoral arteries. The most common type of isolated femoral artery aneurysm involves only the common femoral artery. These occurred in more than 80% of cases in a recent series of isolated femoral artery aneurysms. Isolated aneurysms of superficial femoral artery (14.4%) and profunda (4.6%) are less common. Among patients with common femoral artery aneurysms, if the aneurysm only involves the proximal common femoral artery, this is classified as *type I*. If the aneurysm extends to the orifice of profunda femoral artery, this is classified as *type II*. This classification, introduced by Cutler and Darling, is important, as the reconstruction of type II aneurysm is more complex than type I.

The exact natural history of true degenerative femoral artery aneurysm is unknown due to rarity of these aneurysms, and it is perhaps less benign that was initially reported. Femoral artery aneurysms are commonly asymptomatic in more contemporary series. It is possible that these aneurysms are currently being diagnosed earlier due to the use of more diagnostic studies for other clinical concerns.

Untreated, common femoral artery aneurysms may thrombose or cause distal embolization. These aneurysms rarely rupture. The nature of any symptoms is related to the specific location of these aneurysms. Thrombosis of these aneurysms can lead to limb loss and has been reported in up to 15% of older studies. However in a more recent case series, thrombosis rate was noted to be present in only 1% of patients. Femoral aneurysms at other locations can present with thrombosis or rupture. About 50% of aneurysms in the profunda femoral artery and one third of superficial femoral artery aneurysms rupture. The higher propensity of rupture is perhaps related to deeper location of these aneurysms that may delay diagnosis until these deeper aneurysms are larger and therefore perhaps more prone to rupture.

Clinical Manifestations

The clinical manifestations of femoral artery aneurysms have changed over the past few decades. In the most contemporary series, about 60% of the aneurysms repaired on asymptomatic patients were detected by physical examination or by unrelated diagnostic studies. This is in contradistinction to older studies, some of which found only 40% of the cases were performed on asymptomatic patients with 42% of cases operated on patients with severe ischemic consequences of femoral artery aneurysms. In contemporary series, the most common symptom was the

presence of a palpable mass. Local pain due to the enlarging aneurysm was seen in 10% of patients. In large contemporary series, ischemic symptoms ranged from mild (e.g., claudication, 22%) to severe (e.g., rest pain, 1%). In older series, 42% of femoral artery aneurysm repair was performed for severe ischemic complications of these aneurysms. Embolization (10%) is reported among patients with femoral artery aneurysms and should be in the differential diagnosis among patients with spotty discoloration of their toes in the presence of palpable distal pulses. The rate of thrombosis and rupture for isolated common femoral artery aneurysm is 1% to 6% in multiple series. Leg edema secondary to venous obstruction due to the aneurysm dilation of the adjacent artery is a very rare clinical manifestation of these aneurysms.

Diagnosis

The physical examination finding of a pulsatile mass in the groin may increase the suspicion of femoral artery aneurysm. Physical examination can be misleading if a patient is morbidly obese, the examiner is unfamiliar with the vascular exam, the aneurysm is small or thrombosed or in presence of groin lymphadenopathy.

Radiographic studies such as duplex ultrasound, computed tomography angiography (CTA), or magnetic resonance angiography (MRA) can reliably confirm the diagnosis and the diameter of the aneurysm when there is clinical suspicion. In contemporary series, patients were often diagnosed with femoral artery aneurysm while they are undergoing diagnostic tests for unrelated pathology. Conventional angiography is not very precise in detecting aneurysms or for size measurements and provides only limited size information due to the presence of lumen in the dilated artery. Conventional angiography and CTA are helpful in the operative plan by defining the vascular anatomy particularly if complex reconstruction is required.

Indication for Treatment

Symptomatic femoral artery aneurysms are treated operatively regardless of the size of the aneurysm. In symptomatic cases, repair is indicated to alleviate the antecedent limb-threatening ischemia, local pain, or to remove the source of distal embolization. The current recommendation for treatment of asymptomatic femoral artery aneurysm is repair of the aneurysm when it reaches a diameter of 2.5 cm in patients of acceptable risk. Aneurysms <2.5 cm can be observed by routine ultrasound performed

at regular intervals. The size was chosen because the rate of complications of aneurysms <2.5 cm is reported to be only 1% to 2% annually. Special consideration is also given to smaller aneurysms if they are filled by thrombus.

Most practitioners perform a careful examination for occult symptoms (e.g., embolization) and obtain a Duplex every 6 months to follow patients with these smaller aneurysms (<2.5 cm). The development of symptoms, change in the distal pulse examination, or aneurysmal enlargement is also an indication for operative treatment. Recent studies challenge these size recommendations among asymptomatic patients. In a recent large case-series study, aneurysms >4 cm were associated with increased risks of developing symptoms. This study may, therefore, challenge the current size indication for repair, but further studies are warranted and at the current time, asymptomatic common femoral artery aneurysm >2.5 cm should be electively repaired.

Surgical Therapy and Preoperative Planning

The basic principal behind surgical therapy is resection of the aneurysm and re-establishment of the flow to the lower extremity. In the setting of patients with multiple aneurysms, repair should be staged. Aneurysm surgery for aorta and popliteal artery takes precedent over femoral artery aneurysm in cases of patients with multiple aneurysms unless the femoral artery repair is planned as part of the aorta or PAA repair.

In the patients undergoing endovascular abdominal aorta repair (EVAR), formal exposure of the aneurysmal femoral artery for the introduction of aortic stent and interposition of the aneurysmal femoral artery is indicated at the conclusion of successful EVAR. If open aortic surgery is contemplated and aortofemoral bypass is required, the femoral anastomosis must be performed to an interposition graft after the replacement of the aneurysmal femoral artery. A similar principal applies if the aneurysmal femoral artery is the inflow vessel for a femoropoliteal or femorotibial bypass graft performed for ischemia. No anastomosis should be performed to an aneurysmal femoral artery, as this anastomosis will degenerate. As part of the surgical planning, the arterial anatomy of patient’s circulation must be delineated prior to surgical intervention. This often requires a lower extremity angiogram or CT angiogram.

Surgical Technique

As noted above, the principal basis is resection of aneurysm and

establishment of blood flow to the lower extremity. The surgical techniques and options, therefore, depend on the location of the femoral artery aneurysm. The femoral artery exposure is performed by making a vertical groin incision. If the proximal extent of the aneurysm involves the very proximal common femoral artery, retroperitoneal exposure of the external iliac artery may be required for proximal arterial control. Endovascular control of the distal external iliac artery is possible using percutaneous placement of a balloon through a contralateral femoral artery approach.

For isolated type I common femoral artery aneurysms, distal control may involve controlling the distal common femoral artery or the proximal superficial femoral and profunda femoris arteries. After systemic heparinization and proximal and distal arterial control, the aneurysm is entered. After removing the thrombus, end-to-end reconstruction of the artery is performed using Dacron or expanded polytetrafluroethylene (ePTFE). This graft is sewn to the proximal normal common femoral artery and distally to normal distal common femoral artery or the femoral bifurcation. Smaller aneurysms may be resected, whereas large aneurysms resection may be difficult and they are often left in place. They can be wrapped around the graft to avoid serous fluid collection.

For type II common femoral artery aneurysms, the repair depends on the extent to which the aneurysm involves profunda or superficial femoral arteries. If the profunda and common femoral arteries are involved, an interposition graft between the normal common femoral and profunda is created and the superficial femoral artery is implanted on the side of this graft. Similarly, if the superficial femoral artery is aneurysmal, the interposition graft between normal common and superficial femoral artery is created and the profunda femoris is implanted on the side of this graft.

In patients with lower extremity symptoms or thrombosis of the common and superficial artery, bypass operations and thrombectomy may also be required. In selected symptomatic cases, infusion of catheter-directed thrombolytic agents or endovascular mechanical thrombectomy may be tried prior to open operative technique. Given the ease of femoral artery exposure, this is rarely needed.

Endovascular repair of the common femoral artery has been reported. Endovascular repair may include coil embolization of the artery or use of covered stent grafts. Endovascular intervention should be performed very cautiously and only in selected cases. This is due to the location of the

common femoral artery aneurysm and its proximity to the inguinal ligament, hip flexor, and profunda femoral artery. Stent graft coverage of common femoral artery aneurysm may lead to blockage of the profunda and stent fracture. Profunda femoral artery aneurysm can be treated by coil embolization of feeding arteries and occlusion of the aneurysm provided there is adequate collateral circulation. Covered stents can also be used in the proximal superficial femoral artery or the profunda femoral artery, but as this will lead to a change in the collateral flow, it should be performed cautiously and only in selected cases, such as in patients with many comorbidities who may not be able to tolerate open surgical intervention.

Results

Long-term results are dependent on the quality of distal circulation. In asymptomatic femoral artery aneurysms, 85% 5-year patency results are reported. In symptomatic patients with lower extremity ischemia, the 5-year patency is lower with about 70% of cases achieving good long-term results. The overall postoperative mortality rate for open common femoral artery aneurysm is low (2% to 5%).

Femoral Artery Pseudoaneurysms

In contradistinction to true aneurysms, false aneurysms or pseudoaneurysms are caused by an arterial defect. Blood exits the artery through this defect and swirls in a space composed of surrounding soft tissue and thrombus instead of the three layers that compose the arterial wall and are present in any true aneurysm. Arterial defects can be caused due to injury (e.g., iatrogenic such as postinstrumentation) (Fig. 202.1), infection (mycotic femoral aneurysm), or anastomotic disruption (Fig. 202.2).

Post-Instrumentation Femoral Artery Pseudoaneurysms

Incidence and Risk Factors

The incidence of iatrogenic pseudoaneurysm of femoral artery has risen significantly due to the increased number of peripheral vascular interventions. The common femoral artery is the most common artery used for peripheral interventions, and pseduoaneurysm occurs in 0.6% to 6% of femoral interventions. The incidence increases with the use of postprocedure antiplatelet or anticoagulation medications. Other risk factors are female gender, use of larger sheaths for peripheral interventions

(>7 French), combined artery and vein access, obesity, faulty puncture technique (“high stick”), poor manual compression or failure of the arterial closure device, presence of calcified vessels, hypertension, and patients with chronic renal failure who are on hemodialysis. Use of vascular ultrasound during arterial access has significantly decreased the rate of femoral artery pseudoaneurysm formation. Percutaneous closure devices have also been shown to decrease the rate of arterial injuries by a factor of 10 during interventional procedure where larger sheaths are used.

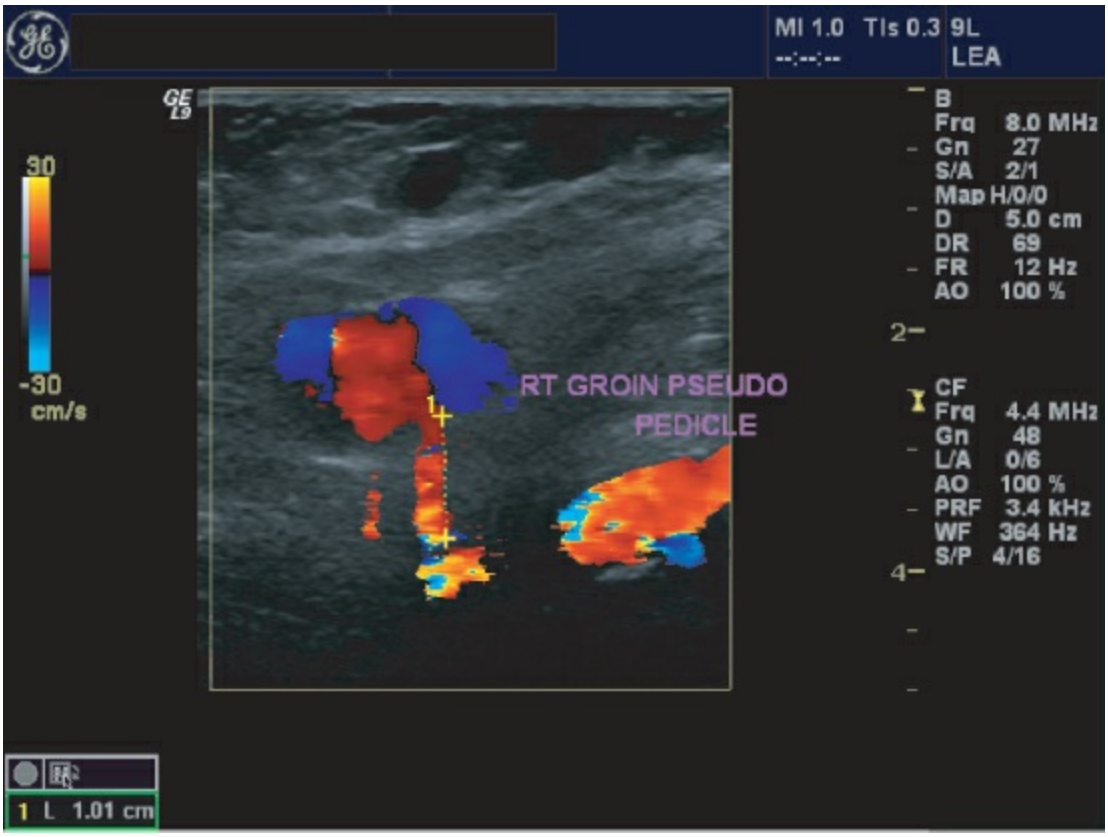

Figure 202.1. Duplex of femoral pseudoaneurysm after arterial catheterization.

Natural History

Many femoral pseduoaneurysms resolve spontaneously, and this is directly related to the size of the false aneurysms and patient’s anticoagulation status. In one series, 90% of aneurysms <3 cm were thrombosed by 23 days, but this rate decreased to 56% in another series in the presence of anticoagulation. Current guidelines suggest that pseudoaneurysms <2 cm can be safely observed with routine ultrasound examination to evaluate for thrombosis. The aneurysms that do not thrombose may enlarge, which may lead to rupture and distal embolization, as well as necrosis of the skin

overlying larger aneurysms. Aneurysm >2 cm or those that do not thrombose require repair.

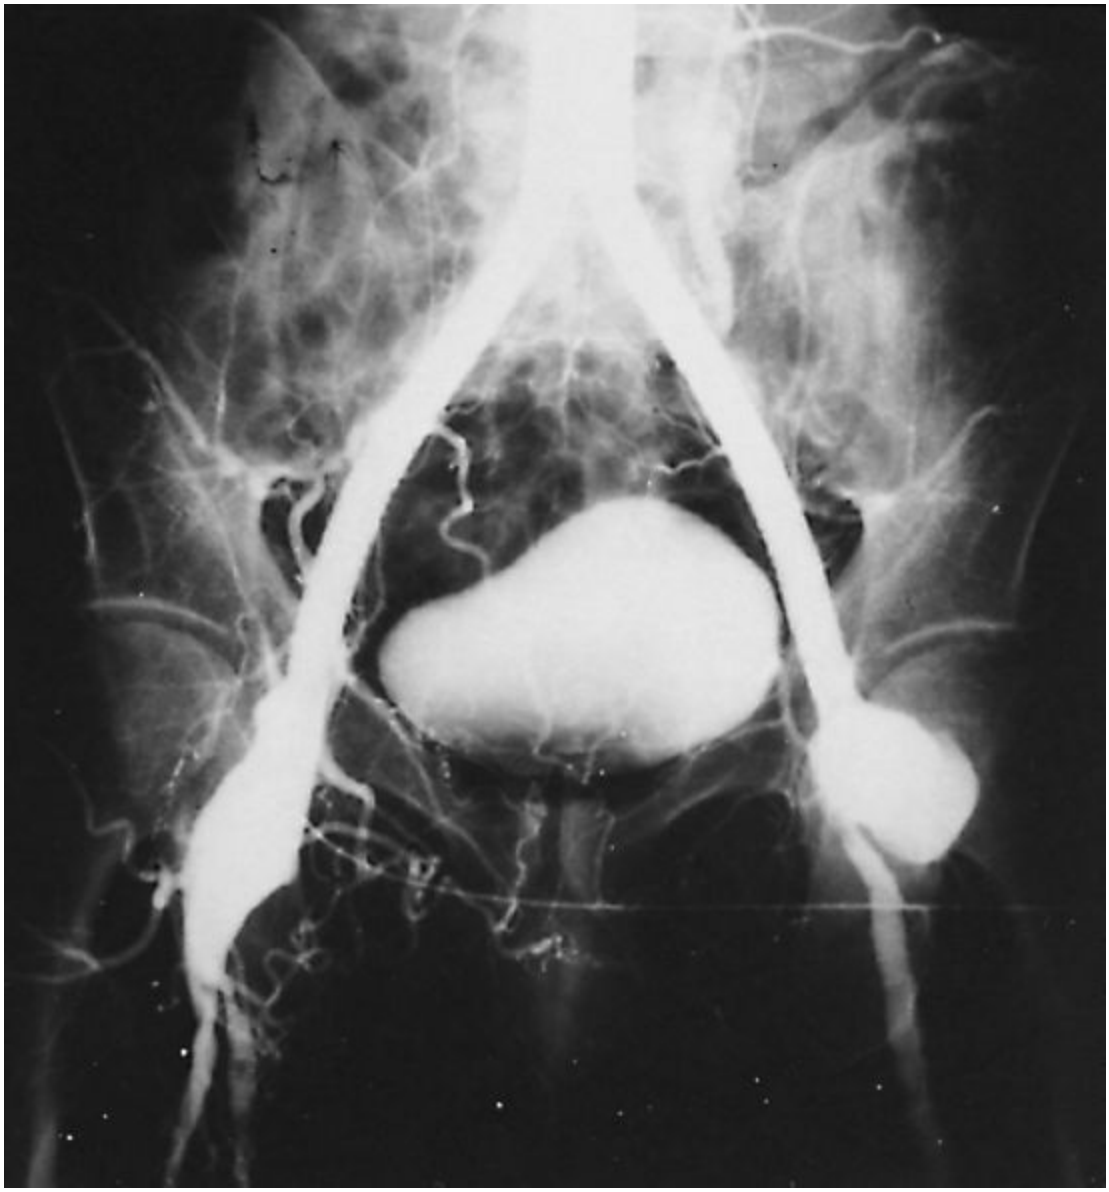

Figure 202.2. Angiogram demonstrating anastomotic femoral pseudoaneurysms after aortobifemoral bypass.

Clinical Manifestations

Patients may present with a pulsatile mass, pain over the femoral access, femoral thrill or bruit, neuralgia from nerve compression, or edema from common femoral vein compression. If the psedoaneurysm is large, patients may also present with skin ischemia and necrosis. Large psedoaneurysms may also present with arterial thrombosis or distal embolization resulting in lower extremity ischemia.

Diagnosis

In addition to physical examination, duplex ultrasound is the most common radiographic study used to confirm the diagnosis of femoral artery pseuduoaneurysm. This study has 94% sensitivity and 97% specificity (Fig. 202.3). In addition, duplex provides information about the size, location, and degree of thrombosis of pseduoaneurysm. Duplex also provides information about the presence of arteriovenous fistula and the size of pseduoaneurysm's neck (diameter and length; Fig. 202.3) CT scan with contrast can also be used for diagnosis, but this is more costly and incurs radiation exposure.

Treatment

The three modalities used to treat femoral artery pseduoaneurysm are ultrasound-guided compression, ultrasound-guided thrombin injection, and surgery. Endovascular interventions have been attempted, and these include direct coil embolization or fibrin glue injection and placement of covered stents across the injured femoral artery. Pseuduoaneurysms that are <2 cm may be observed with repeat ultrasound; and if they become larger, they may need treatment.

Ultrasound-Guided Compression

Ultrasound-guided compression can be used to treat femoral artery pseuduoaneurysms. This technique was introduced in 1991 and is effective for smaller aneurysms (<3 cm) that have a neck visible by ultrasound. The neck is identified by ultrasound and pressure is applied directly to the neck of the psedoaneurysm by the ultrasound probe to cause cessation of flow into the pseduoaneurysm sac on Doppler imaging. Pressure is held in cycles of 10 to 20 minutes. The sac is evaluated for thrombosis; and if no thrombosis is noted, then another cycle is repeated. After the second cycle, if the sac is still patent, patients should receive another treatment. If sac has thrombosed, the patient is placed on bed rest and duplex is repeated in 24 to 48 hours to ensure continued pseduoanaeurysm thrombosis.

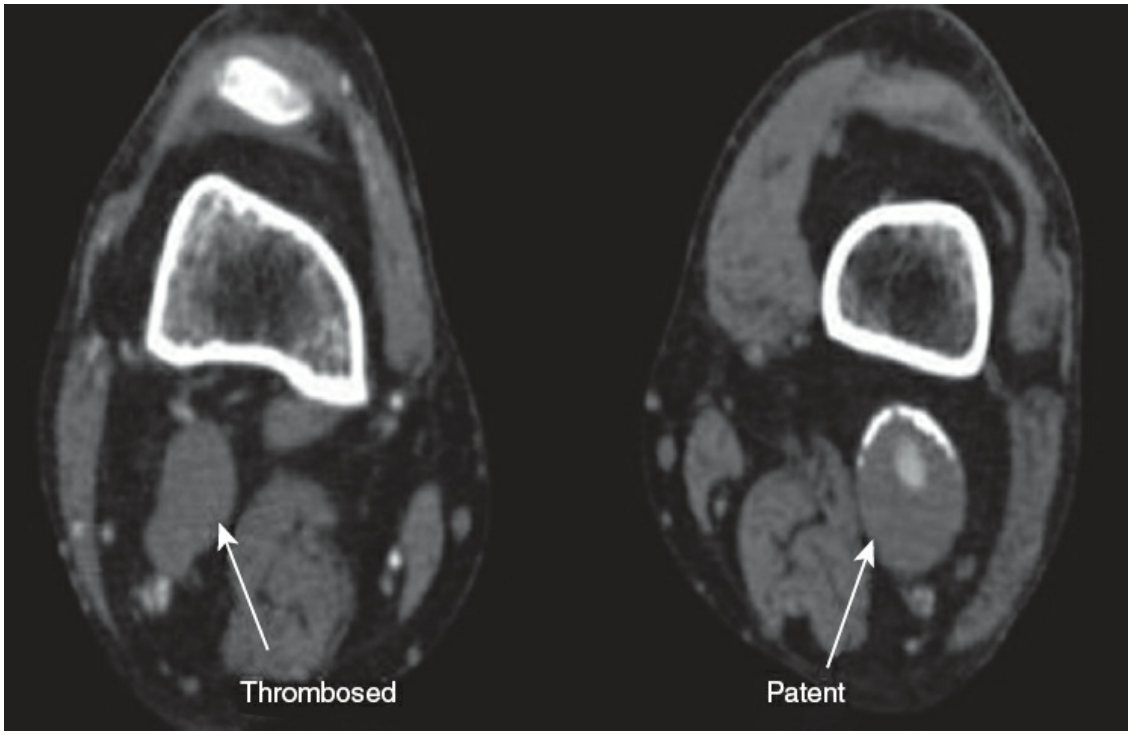

Figure 202.3. A patient with bilateral PAA presented with ischemic symptoms related to thrombosed right PAA and asymptomatic left PAA.

Success rates using this technique are reported to be 66% to 86% with 30 to 44 minutes of compression, but this decreases to 44% when the patient is on anticoagulation. This technique is not well tolerated by most patients secondary to the application of pressure in a traumatized and sensitive area, which often requires sedation and pain control. Another drawback is that there is a 4% risk of recurrence in addition to complications related to the procedure, such as sac rupture, femoral artery occlusion and lower extremity ischemia, and hypotension (vasovagal during compression or due to sedation). Factors that lead to failure, in addition to anticoagulation, include large body habitus and the larger-sized pseudoaneurysms. Given these drawbacks, this technique has been largely replaced by ultrasound-guided thrombin injection as the nonoperative procedure of choice in most instances.

Ultrasound-Guided Thrombin Injection

This technique is a more reliable and better-tolerated nonoperative choice of treatment for most femoral artery pseudoaneurysms. Since thrombin directly converts fibrinogen to fibrin and is not affected by heparin or warfarin, patient's anticoagulation status does not affect the success of this

intervention. In this technique, the pseduoaneurysm is identified by duplex (Fig. 202.3) and is directly punctured under ultrasound guidance by a needle directed away from the pseduoaneurysmal neck after the application of local anesthesia. Then 0.1 to 0.2 mL of 1,000 units/mL of thrombin is slowly injected over 10 to 15 seconds. If thrombosis does not occur, a second injection may be needed. As soon as thrombosis is noted, the injection is stopped to avoid propagation of thrombosis into the femoral artery. After thrombosis, patient is placed on bed rest and the pesduoaneurysm is evaluated by Duplex to assure persistent thrombosis. Additional injections may be required. In cases in which the neck is large, and patient is a poor surgical candidate, an angioplasty balloon may be placed at the neck of the pseduoaneurysm and dilated while thrombin injection is applied. This helps to avoid thrombin propagation in the femoral artery or distal embolization.

The success rates of ultrasound-guided thrombin injection are reported to be 90% to 100% with a recurrence rate of 3%. Complication rates of 0% to 4% are reported and include distal embolization, groin abscess, femoral artery thrombosis, and anaphylaxis in patients previously treated with thrombin injection. Distal embolization should be treated initially by institution of intravenous heparin. If symptoms do not resolve quickly, catheter-directed thrombolysis is added. Pseduoaneurysms with short (<2 mm) or wide (>5 mm) necks should not be treated by this technique, and these patients should be treated with open surgical repair. Other contraindications to ultrasound-guided thrombin injection are skin necrosis or patients with infection, allergy to bovine thrombin or history of thrombin injection, presence of arteriovenous fistula, lower extremity ischemia, and pregnancy.

Surgical Management

The indications for open surgical repair of femoral pseduoaneurysms are large pseduoaneurysms, those with large and short neck, presence of skin necrosis and infection, pseudoaneurysm rupture and expansion, lower extremity ischemia, and when nonoperative therapies fail. Surgical technique involves proximal and distal control of the pseudoaneurysm, which is achieved by a vertical groin incision positioned over femoral artery. Proximal control may require open retroperitoneal exposure of the external iliac artery or balloon control via a contralateral femoral access. Distal control may require individual control of the superficial and profunda femoral arteries. In a stable patient, the sac should not be entered

without proximal and distal control as this may cause significant bleeding in patients who often have other comorbidities. In the presence of rupture, the sac may be entered and manual compression is applied while arterial control is achieved. Once proximal and distal control is achieved, the patient is heparinized, vessels are controlled, and the sac is entered. After evacuation of sac contents, the femoral artery should be repaired. This often may require simple suture closure with one or two stitches using 5-0 or 6-0 prolene sutures. If the femoral artery defect is larger, the wall may be repaired using a vein patch or prosthetic patches, such as bovine pericardium. In rare cases, an interposition graft may be required if artery is badly damaged. Every effort should be made to use autogenous vein when patch angioplasty or interposition graft is required.

Anastomotic Pseudoaneurysms of Femoral Artery (APFA)

Incidence and Risk Factors

Disruption of the arterial anastomosis may cause separation of the graft from the host artery and leads to pseduoaneurysm formation. Since the femoral artery is the most common inflow or outflow vessel, this is the most common site of anastomotic pseduoaneurysm accounting for 80% of these pseduoaneurysms. This is often a late complication of vascular bypass and is seen on average 6 years after bypass procedure. Femoral artery pseduoaneurysm affects 3% of all femoral anastomoses and 6% of the aortobifemoral procedures. Among patients with infrainguinal bypass procedures, the highest incidence is seen among patients with prosthetic conduits. This is observed in 6% of the cases with PTFE conduits and 0.9% of cases with Dacron conduits. In addition to the conduit choice, other risk factors for creation of anastomotic pseudoaneurysm are patients with chronic obstructive pulmonary disease, patients who are current smokers, and those with a postoperative groin infection.

Natural History

These aneurysms should be repaired once they are diagnosed as they enlarge and may lead to rupture and loss of graft and possible significant lower extremity ischemia.

Clinical Manifestations and Diagnosis

The majority of these aneurysms are painless, and patients may notice them during examination as a painless pulsatile mass in the groin incision. Any evidence of infection must be investigated by ruling out any overt

sign and symptoms of infection. Symptoms suggestive of infection include fever, chills, night sweats, and pain. Signs of infection include erythema, sinus tract formation, drainage and tenderness of the pulsatile mass, elevated white blood cell count, and positive blood cultures.

To further rule out infection, CTA is performed of the entire graft to rule out any evidence of air or fluid surrounding the graft. Other tests to rule out infection, such as white blood cell scan, can be used if CTA is not diagnostic, but many false positives make this test difficult to interpret. Angiographic studies may be helpful in operative planning and can show anastomatic pseudoaneurysms (Fig. 202.4).

Treatment

Treatment depends on the presence or absence of infection. If no infection is documented, simple resection of the pseduoaneurysm with reconstruction of the anastomosis is warranted. This may be performed safely with prosthetic material. If the pseudoaneurysm is infected, the repair is more complicated. The principal is resection of the infected material, and revascularization must be performed using autologous vein or prosthetic material through noninfected tissue planes. Treatment of the infected anastomotic pseudoaneurysm depends on the extent of infection. For example, if infection is localized to the distal segment of a limb of aortobifemoral bypass graft, the pseudoaneurysm is resected. If the proximal portion of the limb is well incorporated, this can be chosen for inflow and distally the graft is tunneled through the obturator foramen to a distal location. If the proximal portion of aortobifemoral bypass graft is also infected, resection of the entire graft is necessary. Options to perform in-line revascularization or extranatomic revascularization are often performed in two stages. Overt femoral artery infection may necessitate bilateral axillo-profunda or axillo-popliteal bypass grafts prior to aortic graft removal. After closure of the wounds, the infected aortobifemoral bypass graft is removed and the aortic stump is oversewn. Often this is performed in two stages 24 to 48 hours apart. In-line flow can also be achieved performing neo-aortoiliac system (NAIS) using superficial and deep femoral veins bilaterally. This operation, which is championed by Clagett and his colleagues at UT Southwestern, requires the exposure of bilateral superficial and deep femoral veins, which are then resected and sewn together to create an NAIS. Other authors have used cadaveric artery homografts or rifampin-soaked bifurcated Dacron grafts for in-line revascularization after resection of the infected graft. In both cases,

patients need to be on long-term antibiotics and closely observed for aneurysm degeneration and reinfection of the graft.

Figure 202.4. A patient with “blue toe” syndrome from PAA.

In the case of infected femoral-distal bypass grafts, graft resection and repair of femoral artery is the most common mode of initial therapy. If revascularization is indicated, use of vein bypass graft should be the primary choice with the extra-anatomic bypass revascularization with alternative conduit when no autologous vein is available. When there is no sign of infection during preoperative evaluation, the treatment is resection

of the pseudoaneurysm after proximal and distal control and reconstruction of the femoral artery anastomosis, which may require interposition graft repair of damaged common femoral artery.

Even with no signs of infection, the graft may appear to be unincorporated upon exploration indicating graft infection; the most common causative organism is *Staphylococcus epidermidis.* This is a nonvirulent, slime-producing organism. The graft infection can often be managed with resection of the graft to well-incorporated material, debridement of infected arterial wall and soft tissue, and interposition grafting with ePTFE that is generally thought to be more resistant to infection than Dacron. Authors have recommended using a sartorius flap to wrap the graft. This sartorial rotation flap is created by mobilizing the sartorius and dividing it from its attachment on the iliac spine, and then rotating it over the femoral graft and tacking it in place with absorbable sutures.

If frank pus is found on exploration, or if the infection is secondary to a Gram- negative organism, such as *Pseudomonas*, then complete resection of infected material and revascularization through noninfected field is required. In this situation, a sartorial flap is still used to help protect the oversewn femoral vessels from blowout.

Mycotic Femoral Aneurysms

The term “mycotic aneurysm” is currently used to refer to any infected aneurysm. Mycotic aneurysms today are often a complication of parental drug abuse, but can follow arterial trauma of any form, including invasive diagnostic and therapeutic procedures. In the past, septic emboli from bacterial endocarditis were the major cause of mycotic aneurysm degeneration, but this is less common today. With the advent of antibiotics, aneurysms secondary to syphilis or tuberculosis are rare. With this shift in etiology, the location of mycotic aneurysms has shifted from central to peripheral arteries with the femoral artery being the most common site. The importance of mycotic aneurysms is based on their propensity to rupture.

Pathogenesis

The pathogenesis of mycotic aneurysms can be divided into four major categories, although other less common causes also exist. First, septic emboli from bacterial endocarditis may lodge in normal arteries, causing infection that weakens the arterial wall, resulting in aneurysm formation.

These lesions are often multiple. Second, during an episode of bacteremia, microorganisms may lodge in a preexisting atherosclerotic plaque or aneurysm and begin to multiply with the same result. Third, mycotic aneurysms are caused by contiguous spread of bacteria from a local abscess. The inflammatory process destroys the arterial wall, causing pseudoaneurysm formation. Finally, trauma to the artery with concomitant contamination may result in formation of an infected pseudoaneurysm. Mycotic aneurysms are currently being seen more frequently, coincident with the increased use of catheter-based procedures. Bacteria may be introduced concomitantly with needle puncture or by migration during prolonged arterial catheterization, for example, in patients who may require indwelling catheters for thrombolysis. Mycotic aneurysms accompanying drug abuse may be secondary to direct contamination of the arterial wall, or they may result from destruction of the vessel wall by a local abscess.

The bacteriology of arterial infections depends upon the cause of the lesion. Aneurysms secondary to bacterial endocarditis grew *Pneumococcus*, *Streptococcus*, and *Enterococcus* species most frequently in the past, but recently, organisms such as *Staphylococci*, *Salmonella*, *Escherichia coli*, and *Proteus* have also been cultured. *Staphylococcus aureus* is the most common pathogen in mycotic femoral artery aneurysm secondary to trauma and drug abuse, occurring in >65% of cases. In this population, at least 50% of the *S. aureus* organisms are resistant to methicillin.

Clinical Manifestations

The typical patient with a mycotic femoral aneurysm presents with a history of chills and fever, and a tender, enlarging, pulsatile groin mass. The patient may have a history of intravenous drug use, recent arterial catheterization, penetrating trauma, or bacterial endocarditis. Local signs of infection, including tenderness, erythema, and warmth are noted on physical examination. Lower extremity edema may occur secondary to venous or lymphatic obstruction. Petechial skin lesions, splinter hemorrhages, cutaneous abscesses, and septic arthritis may occur as a result of emboli originating from a mycotic aneurysm. A “sentinel bleed” may occur and indicates risk of impending rupture and life-threatening hemorrhage. Emergency surgery is indicated.

Diagnosis

The diagnosis of a mycotic aneurysm is usually straightforward, but distinguishing an abscess adjacent to the femoral artery from a femoral mycotic aneurysm may be difficult. In the patient with a pulsatile groin mass, laboratory findings including leukocytosis, elevated erythrocyte sedimentation rate, while positive blood cultures are suggestive, but not specific, for a mycotic aneurysm. Multiple blood cultures or downstream arterial blood cultures may be necessary to yield positive results. Ultrasonography and CT angiography are helpful in establishing the diagnosis of an aneurysm, but lack precision in distinguishing infected from bland aneurysms. The diagnosis of a mycotic aneurysm is confirmed at operation by the demonstration of organisms on Gram stain or by positive cultures of the aneurysm wall.

Treatment

Mycotic aneurysms represent a serious life- and limb-threatening disease because their natural history is one of expansion and rupture. Therefore, mycottic aneurysms must be addressed surgically. First, the goal of treatment is eradication of the infection by excision of the aneurysm and debridement of adjacent infected tissue as well as by long-term antibiotic therapy. Second, adequate distal circulation must be restored. Before operative intervention is performed, the patient is started on antibiotics that are modified based on sensitivity testing of intraoperative cultures. Stent grafts have been used in selected cases of mycotic aneurysms when other approaches were not feasible; however, concern about latent infection of the stent graft often renders this as a bridging technique rather than a long-term solution.

The complexity of the operative procedure varies with the location and extent of the mycotic aneurysm. Although a direct approach to the femoral artery may be taken, retroperitoneal exposure of the distal external iliac artery for proximal control is sometimes preferred for large or proximal femoral lesions to avoid excessive hemorrhage. As noted above, with large pseudoaneurysms of the femoral artery, proximal control can be achieved using an angioplasty balloon. When an infected femoral artery aneurysm is confined to only one arterial segment (common, superficial, or deep femoral artery), the aneurysm is excised and the proximal and distal arteries are ligated in emergent situations. In those cases in which an isolated arterial segment is ligated, severe ischemia resulting in amputation is unusual. In >50% of cases, however, the mycotic aneurysm involves the femoral artery bifurcation, and treatment requires resection of the femoral

bifurcation and debridement to healthy arterial wall. The distal external iliac or proximal common femoral artery, as well as the superficial and deep femoral arteries, is oversewn with nonabsorbable monofilament suture. This results in significant ischemia in most patients, but with the patient heparinized, symptoms gradually improve as collateral circulation increases. The majority of patients will not need revascularization for limb salvage, but up to one third of patients may have limb-threatening ischemia. In patients in whom sepsis can be adequately controlled at the initial procedure, aggressive debridement may be followed by immediate revascularization using autogenous saphenous vein graft as the conduit and covering the graft with a sartorius muscle flap. Another option is to observe patients for 24 hours after arterial ligation and selectively revascularize only those patients in whom limb-threatening ischemia persists. Use of prosthetic material is avoided because of the high incidence of early and late septic complications, although they can occasionally be necessary through uninfected tissue planes, such as the obturator or lateral femoral route. Antibiotics are begun preoperatively and are continued for at least 6 weeks postoperatively. Endovascular interventions have no role in the treatment of mycotic aneurysms, except for possibly obtaining proximal control when the aneurysm is too large.

Popliteal Artery Aneurysm

PAAs are the most common peripheral artery aneurysms accounting for 85% of all peripheral artery aneurysms. Although the initial reports of the treatment for PAAs were for syphilitic PAAs, contemporary PAAs are true degenerative aneurysms.

Normal Anatomy and Size

The distal extension of the superficial femoral artery is called the popliteal artery as the artery exits the opening in the adductor magnus distally and enters the popliteal fossa. The artery courses lateral to the intercondylar fossa of femur, and then distally travels behind the knee and between the two heads of gastrocnemius and popliteus muscle. It is a relatively short artery, and most of the branches are in the supra-geniculate portion of the artery. The artery can be approached both medially and laterally. At the lower border of the popliteus muscle, it divides into the tibial arteries.

The popliteal artery is slightly smaller than the femoral artery and is considered aneurysmal when it is 2 cm or 1.5 times the normal caliber.

Incidence and Risk Factors

PAA is the most common peripheral artery aneurysm and is reported in 1% of men aged 65 to 80 years and is often associated with other aneurysms. In >50% of cases, these aneurysms are bilateral and are associated with AAA (40% to 50% of cases) or femoral artery aneurysms (40% of cases). Conversely, PAA is observed in 6% to 14% of patients who present with abdominal aorta aneurysm.

The most common cause of PAA is atherosclerotic degeneration, but other causes including Marfan syndrome, Behçet disease, and mycotic degeneration may also lead to aneurysm changes of popliteal artery. The typical patient with a popliteal aneurysm is a male in his 60s or 70s with the usual risk factors for atherosclerosis. Of patients with popliteal aneurysms, 50% to 75% are smokers, 40% to 60% have hypertension, and about 15% have diabetes mellitus. Other manifestations of cardiovascular disease are also common, with 10% of patients having manifestations of cerebrovascular disease and >40% having evidence of significant cardiac disease.

Natural History

The natural history of popliteal aneurysms is not well delineated. These aneurysms show a differential annual rate of enlargement that depends on the diameter of the PAA at the time of diagnosis. Although many of these aneurysms do not enlarge, those <2 cm enlarge at a rate of 0.7 to 1.5 mm/yr whereas those >2 cm enlarge at higher rate (1.5 to 3.7 mm/yr). In asymptomatic patients with PAA >2 cm, about 25% develop complications related to embolic or thrombotic events within the 1st year of diagnosis. Left untreated at 5 years, about 70% of these patients develop ischemic symptoms ranging from embolic episodes to thrombotic limb-threatening events. Given these observations, current treatment recommendation is for aneurysms >2.0 cm. This may be challenged given that a large population-based study shows the median diameter of PAA when symptoms developed was when these aneurysms were 3 cm (range of 1.4 to 4.6 cm). In addition to popliteal artery aneurysm size, since the presence of thrombus within popliteal aneurysm is a significant risk factor for developing ischemic symptoms, has led some authors to suggest repairing smaller aneurysms if there is significant thrombus burden in the PAA (Fig. 202.5) particularly when the arterial outflow is poor.

Clinical Manifestation

The clinical manifestations of PAAs range from an asymptomatic pulsatile mass to severe lower-extremity ischemia. The majority of patients are symptomatic with patients presenting with symptoms of limb ischemia, usually claudication, but the ischemia may be more advanced and manifest as rest pain or gangrene. Local symptoms, including sensation of a posterior knee mass, local pain, and leg swelling or phlebitis secondary to compression of the adjacent vein, account for the remainder of symptoms. A PAA may be complicated by thrombosis, embolization, or rarely rupture. Thrombosis is reported in 40% of patients, and embolization occurs in about 25% of cases. Some patients present with classic "blue toe syndrome (Fig. 202.4)," but more commonly, repeated episodes of embolization occlude the outflow vessels and result in thrombosis of the aneurysm. Rupture occurs in <5% of popliteal aneurysms, and in these cases the hemorrhage is usually confined to the popliteal space, thus permitting surgical intervention and arterial reconstruction in a timely fashion. Rupture or thrombosis of PAA, however, is a limb-threatening event with amputation rates of 50% to 70% in some series. The asymptomatic cases are often diagnosed during screening of patients for other aneurysm disease.

Diagnosis

The diagnosis of PAA is usually first suspected on physical examination. Palpation of the popliteal space with the knee flexed reveals a pulsatile mass in approximately two thirds of patients. Small aneurysms may not be palpable on physical examination, and if thrombosis has occurred the mass may not be palpable. Radiographs of the knee demonstrating a calcified arterial wall occasionally suggest the diagnosis of a PAA, but duplex ultrasonography, CT, or magnetic resonance imaging (MRI) must confirm it. These diagnostic modalities can establish the diagnosis of PAAs and exclude other entities that could be responsible for a nonpulsatile popliteal fossa mass (tumor or Baker cyst). Ultrasonography, CT, or MRI is also useful in the detection of associated aneurysms, particularly abdominal aortic and femoral artery aneurysms. Angiography can be misleading in the diagnosis of aneurysms because intraluminal thrombus may obscure the true size of the vessel; however, it is essential for visualization of the inflow and outflow vessels necessary for revascularization, and it is a reasonable option if thrombolytic options are contemplated for a thrombosed PAA. CT angiography can be a noninvasive way to provide this information (Fig. 202.5).

Figure 202.5. CT angiography of popliteal artery aneurysm in right lower extremity.

Treatment

The choice of treatment depends on the size and presence of symptoms. Asymptomatic PAA <2.0 cm are managed conservatively with duplex every 6 months until these become >2.0 cm or develop symptoms. For those asymptomatic aneurysms >2.0 cm, the aneurysm can be repaired by open surgical repair (Fig. 202.6) or endovascularly using covered stents (Fig. 202.7).

Most PAAs are easily approached through standard medial thigh and calf incisions for exposure of the distal superficial femoral artery and the distal popliteal artery, respectively (Fig. 202.6A). The proximal

anastomosis will need to originate from normal proximal popliteal artery or distal superficial femoral artery. The distal anastomosis is to the normal distal popliteal artery. The artery intervening is ligated. The choice of conduit is greater saphenous vein, in reversed configuration, which is tunneled anatomically. The disadvantage of this approach is that the feeding branches may not be ligated and the aneurysm continues to receive collateral flow and enlarge. For this reason, authors have suggested a prone or posterior approach to these aneurysms (Fig. 202.6B) that allows direct oversewing of the feeding branches after the aneurysm sac is entered. In this approach, the patient is placed in prone position and an S-shaped incision is used behind the knee with the superior longitudinal portion on the posteromedial aspect of the lower thigh, horizontal portion across the flexion crease and the inferior portion laterally. The deep fascia is then divided vertically and anteromedially, and the popliteal vein is identified with popliteal artery as its immediate lateral structure. The artery is controlled and the aneurysm sac is entered, and all the feeding vessels are oversewn. Because of the size mismatch between the popliteal artery and the greater saphenous vein, an interposition graft with ePTFE or Dacron is often used. Overall open surgical repair results are excellent with 5-year graft patency rates in excess of 85%.

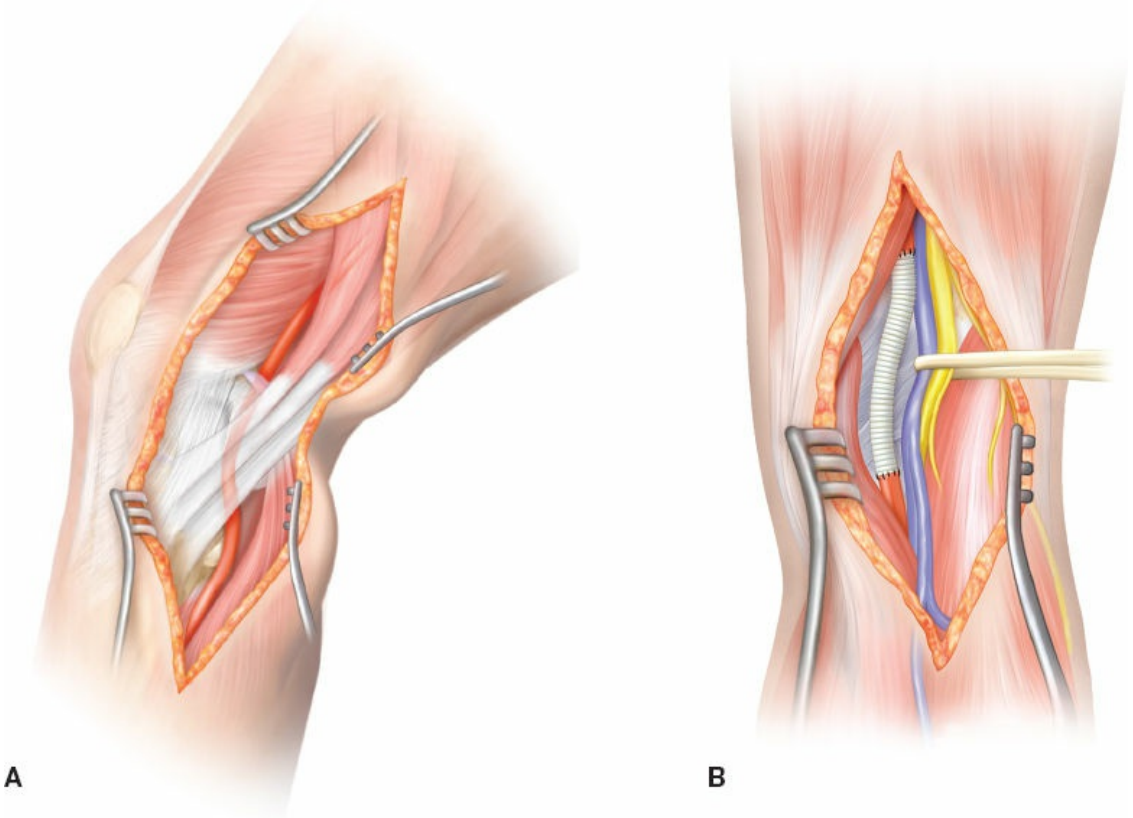

Figure 202.6. Open popliteal artery aneurysm repair. **A.** Supine approach to PAA repair. **B.** Prone approach to PAA repair.

An alternative to open surgical repair is the use of a covered stent graft and exclusion of the aneurysm endovascularly (Fig. 202.7). This is a less invasive procedure and can be performed in antegrade or retrograde fashion with local anesthesia. The artery is crossed and covered stent(s) proximally from normal artery to distal artery excludes the aneurysm sac. Similarly excellent results are reported in both single center analyses and metanalyses with complications being stent fracture, thrombosis, and endoleak. A prospective randomized trial is ongoing to address if one modality is better than the other. In a retrospective analysis of the largest series of asymptomatic PAAs, however, we should note that open repair outcomes were better than endovascular options. Ultimately the role of endovascular repair will be better defined in the future.

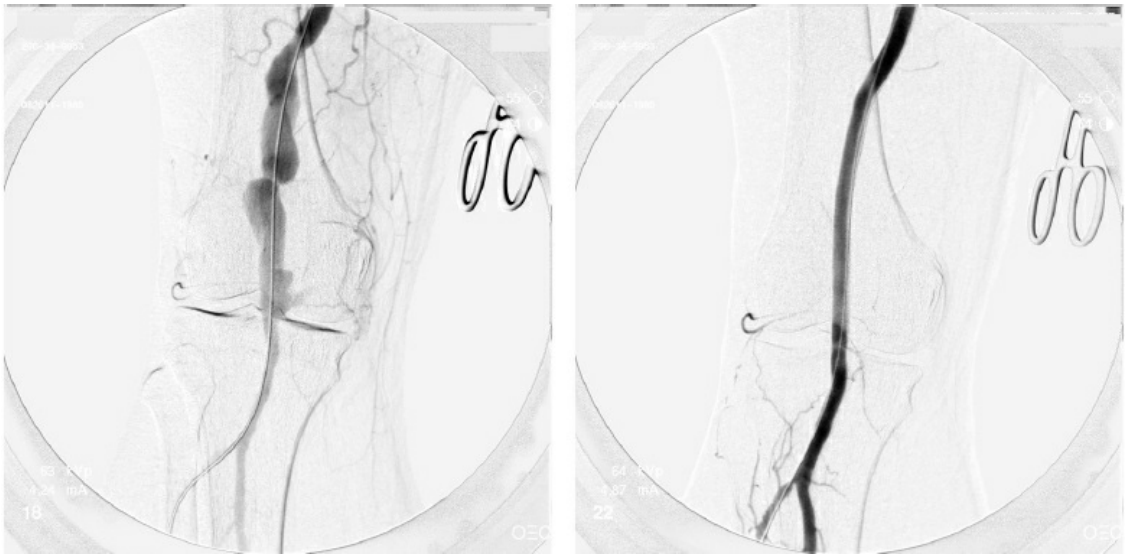

Figure 202.7. Endovascular repair of a large asymptomatic PAA. (Courtesy of Dr. Andres Fajardo from Indiana University.)

For thrombosed PAA, the initial therapy consists of infusion of catheter-directed thrombolysis or open surgical embolectomy and surgical revascularization. Successful catheter-directed thrombolysis is then followed with urgent operative repair. The success of surgical repair and limb salvage depends on the degree of ischemia and the status of the outflow vessels. For patients with Rutherford class I or IIa, excellent graft patency rates of 68% to 100% and limb salvage rates of 73% to 100% are reported. In patients who present with more severe ischemic symptoms,

the amputation rate is significantly higher.

EDITOR'S COMMENT

The management of popliteal artery aneurysms has evolved much like the management of all vascular disease, especially the treatment of aneurysm pathology. Unlike aortic aneurysms that are more prone to rupture, I always tell patients popliteal artery aneurysms won't kill you. Instead they will leave you with an above knee amputation when the popliteal artery aneurysm clots off, after chronically embolizing to your outflow tibial vessels insidiously over time. Unlike aortic aneurysms that tend to rupture as they get larger, popliteal artery aneurysm can embolize and thrombose even when they are small (Mousa AY, Beauford RB, Henderson P, et al. Update on the diagnosis and management of poplitealaneurysm and literature review. *Vascular* 2006;14[2]:103–8). They almost always occur in men with hypertension, and are common in patients with abdominal aortic aneurysms (AAA). Ultrasound of the femorals and popliteal arteries likely should be part of the standard preoperative workup of any male patient with an AAA, as the incidence of femoral and popliteal artery aneurysms is 14% in patients with AAA (Diwan A, Sarkar R, Stanley JC, et al. Incidence of femoral and popliteal artery aneurysms in patients with abdominal aortic aneurysms. *J Vasc Surg* 2000;31[5]:863–9). It should be noted that a popliteal artery aneurysm on one side is also predictive of one in the other leg and aortoiliac artery aneurysms (Whitehouse WM Jr, Wakefield TW, Graham LM, et al. Limb-threatening potential of arteriosclerotic popliteal artery aneurysms. *Surgery* 1983;93[5]:694–9). This is the fodder by which many in service and board questions are made.

I have classically approached popliteal artery aneurysms from a medial approach. The medial approach makes the harvest of the greater saphenous vein easier, and usually these patients can have a short above knee to below knee popliteal artery bypass. Patency rates for these bypasses approach 90% at 5 years, assuming that the conduit and outflow are good and you can sew to the below knee popliteal artery (Upchurch GR Jr, Gerhard-Herman MD, Sebastian MW, et al. Improved graft patency and altered remodeling in infrainguinal vein graft reconstruction for aneurysmal versus occlusive disease. *J Vasc Surg* 1999;29[6]:1022–30). We examined a large series of these bypasses a number of years ago, and there is clearly something different about the veins in these patients (Upchurch GR Jr, Gerhard-Herman MD, Sebastian MW, et al. Improved graft patency and altered remodeling in infrainguinal vein graft reconstruction for aneurysmal versus occlusive disease. *J Vasc Surg* 1999;29[6]:1022–30). Much like the dilated arteries, the veins tend to be large when harvested and continue to dilate over time, leading to a patency advantage over time compared with bypasses done for peripheral arterial disease.

There are reports of using a medial approach to the popliteal artery for bypass with proximal and distal ligation, where the aneurysm continues to enlarge and can cause compressive symptoms on the nerve or the vein (Ebaugh

JL, Morasch MD, Matsumura JS, et al. Fate of excluded popliteal artery aneurysms. *J Vasc Surg* 2003;37[5]:954–9). I have had to go in posteriorly and open an excluded popliteal artery aneurysm and oversew geniculate arteries from inside the aneurysm sac. This actually does not happen that often and it is sort of fun to do, so I would not even hardly consider this a disadvantage in using the medial approach.

Others swear by repairing popliteal artery aneurysms from a posterior approach. The operation is eloquent for sure, but harvesting the saphenous vein from a medial approach and then flipping the patient prone and doing a posterior approach to the popliteal artery are honestly sort of painful. I also rarely find patients with such a small segment of popliteal artery that is aneurysmal where this is effective. The one place where I do like this approach is when the patient has poor or no autogenous venous conduit. A posterior approach with an in-line replacement is a good operation. I have not had patients complain of increased pain with this approach, even though historically people have said this was a more painful approach.

Finally, the issue about whether an endovascular approach is as good as an open approach was the attempted subject of a randomized trial by Dr Eslami (Eslami MH, Rybin D, Doros G, et al. Open repair of asymptomatic popliteal artery aneurysm is associated with better outcomes than endovascular repair. *J Vasc Surg* 2015;61[3]:663–9; Eslami MH, Doros G, Goodney PP, et al. Using vascular quality initiative as a platform for organizing multicenter, prospective, randomized clinical trials: OVERPAR trial. *Ann Vasc Surg* 2015;29[2]:278–85). I have placed plenty of stent grafts behind the knee for popliteal artery aneurysms, and I am sure that the long-term patency is not as good as a vein graft. However, they are likely to be useful in a subset of patients who are elderly and have good outflow. The use of Plavix postintervention seems to be associated with better patency (Tielliu IF, Verhoeven EL, Zeebregts CJ, et al. Endovascular treatment of popliteal artery aneurysms: results of a prospective cohort study. *J Vasc Surg* 2005;41[4]:561–7).

Gilbert R Upchurch Jr.

203 Treatment of Splenic Artery Aneurysms: Open and Endovascular

Dawn M. Coleman and Gilbert R. Upchurch, Jr.

ETIOLOGY AND PATHOPHYSIOLOGY

While rare, splenic artery aneurysms (SAAs) are the most common of splanchnic artery aneurysms, accounting for approximately 60% of such, and the third most common intra-abdominal arterial aneurysm (Fig. 203.1). The prevalence of these aneurysms among the general population is estimated as 0.16% to 0.8%. Women are affected two to four times more often than men with multiparity being a well-recognized risk factor.

Hormonal and local hemodynamic events likely contribute to the evolution of SAAs, as illustrated by the etiologic classification system proposed by Stanley et al. that implicates arterial dysplasia, portal hypertension, local inflammation, and hormonal and hemodynamic events in their pathogenesis.

More than half of patients with SAAs are also afflicted with hypertension. Approximately 20% will demonstrate concurrent aneurysms affecting alternate arterial beds. Additional risk factors for true aneurysms include septic emboli, polyarteritis nodosa, systemic lupus erythematosus, and connective tissue disorders; splenic pseudoaneurysms are typically attributed to chronic pancreatitis, pseudocyst, and trauma.

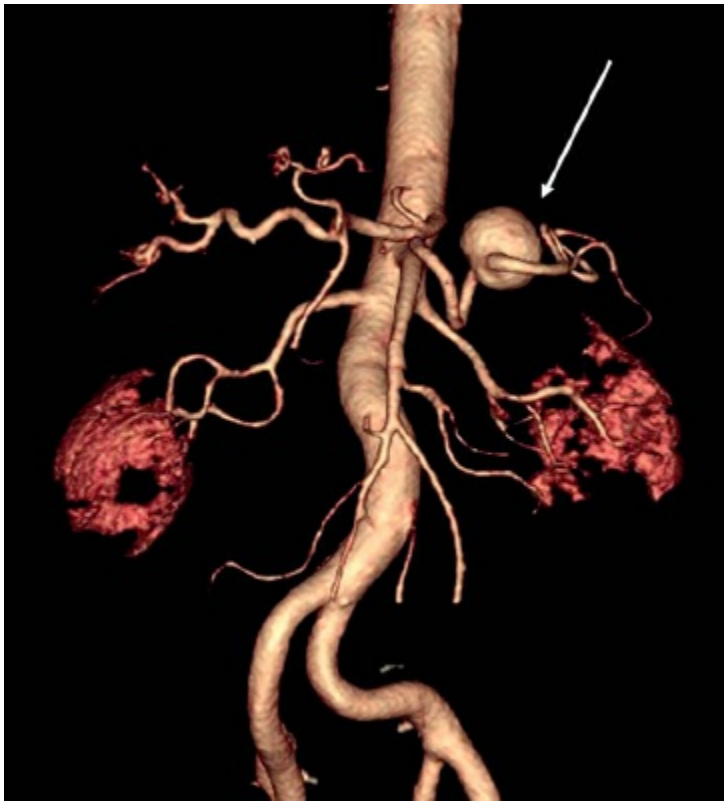

Figure 203.1. CT-angiogram with three-dimemsional reconstruction demonstrating a >3-cm aneurysm affecting the mid-splenic artery.

The majority (80%) of splenic aneurysms are solitary and saccular. Aneurysm location is typically at a distal branch point of the main splenic artery, tortuosity of which is common. These aneurysms are often calcified and may contain mural thrombus; the calcification is felt to reflect a secondary event.

CLINICAL PRESENTATION AND NATURAL HISTORY

Like most splanchnic aneurysms, SAAs rarely produce symptoms. These aneurysms are most often detected as an incidental finding by cross-sectional imaging for unrelated disease. In addition, a curvilinear, signet ring-like calcification in the left upper quadrant by roentgenography may prompt the diagnosis. When symptoms are described, vague epigastric or left upper quadrant discomfort is most commonly described.

Rupture complicates approximately 2% to 5% of SAAs, and the risk of such appears unrelated to age, blood pressure, and aneurysm calcification. Splenic aneurysms typically rupture into the lesser sac with limited self-containment and tamponade; later hemorrhage into the peritoneal cavity

through the foramen of Winslow results in cardiovascular collapse (i.e., “double rupture” presentation). Contemporary aneurysm growth rates are estimated 0.2 mm/year and while increased levels of aneurysmal peripheral calcification are associated with smaller aneurysm size at the time of diagnosis, like rupture risk calcification appears to have no impact on aneurysm growth. Historic rupture-associated mortality rates approached 25% to 70%; more contemporary series suggest mortality rates <25%, likely reflecting improvements in peri-operative care and the increasing utility of endovascular techniques. In comparison, rupture-associated mortality dramatically increases (up to 75%) in the peri-partum with fetal mortality rates that approach 100%. Gestational rupture occurs mainly during the third trimester. While historically a strong association between pregnancy and splenic aneurysm rupture has been reported, a contemporary series reporting on >67,000 consecutive live births over 5 years identified no cases of SAA rupture. Rupture risk is also increased twofold by liver transplantation, the mortality following which is 50%.

INDICATIONS FOR INTERVENTION

Indications for treatment include rupture, symptoms, size >2.0 to 2.5 cm, and any size asymptomatic aneurysm at the time of liver transplantation or in women of childbearing age. Endovascular therapy has become the standard of care for the elective management of SAAs and for cases offering decreased early morbidity, mortality, and hospital length of stay. Open surgical techniques are reserved primarily for pregnant patients (to avoid irradiation) and those who have failed efforts at percutaneous endovascular embolization.

PREOPERATIVE PLANNING

Cross-sectional imaging, mainly in the form of computed tomography angiography (CTA), is invaluable for procedural planning (Fig. 203.2). Axial imaging will identify the angle of the celiac artery origin, tortuosity of the splenic artery, and aneurysm number and location. These factors may influence the complexity of the procedure, the vascular access site (i.e., femoral vs. brachial artery), and available equipment for percutaneous embolization. Those patients with an iodinated contrast allergy require appropriate pretreatment, typically with anti-histamine and steroid therapy; alternative contrast agents may be considered (i.e., carbon dioxide).

Figure 203.2. Reformatted CT-angiogram of a single splenic artery aneurysm.

In cases of elective and planned splenectomy, vaccinations against the encapsulated bacteria *Streptococcus pneumonia*, *Haemophilus influenza*, and *Neisseria meningitides* (i.e., *Meningococcus*) should be administered preoperatively. Patients should be counseled accordingly on the <0.5% per year risk of overwhelming postsplenectomy infection (OPSI) (lifetime risk of 5%) and its associated 50% mortality rate.

OPEN SURGICAL TECHNIQUE

Aneurysm location should dictate surgical approach (Fig. 203.3). While a vertical midline laparotomy incision will yield exposure for most aneurysms, an extended right subcostal incision facilitates exposure of the proximal splenic artery and a left subcostal incision facilitates exposure of the distal splenic artery and hilum for the intent of splenic mobilization and splenectomy. Arterial ligation and aneurysm excision are preferable when technically feasible as this facilitates splenic preservation and host immunity. Arterial reconstruction is not required because splenic viability is maintained through short gastric arterial collaterals. Proximal SAAs are best exposed through the lesser sac following mobilization of the left lateral hepatic lobe and division of the gastroheptic ligament along the

lesser curve of the stomach. Arterial in-flow and out-flow branches are ligated, and the aneurysm should be excised if not embedded within pancreatic tissue. For aneurysms of the mid-splenic artery that are embedded within pancreatic tissue, the aneurysm should at a minimum be opened to ensure that all branches are ligated; alternatively the mid-splenic artery may be exposed from a retroperitoneal approach that includes pancreatic mobilization and anteromedial elevation. Distal SAAs and those affecting the splenic hilum are best visualized with splenic mobilization. While simple suture obliteration of small distal and hilar SAAs when technically feasible facilitates splenic preservation at the cost of downstream segmental splenic infarction, those patients with multiple and peri-hilar aneurysms may in fact require splenectomy.

Laparoscopic and robotic techniques at ligation, aneurysm resection, and splenectomy have become commonplace alternatives to open surgery offering negligible risk of open conversion, need for reoperation, and mortality.

ENDOVASCULAR SURGICAL TECHNIQUE

After percutaneous femoral access is obtained, the celiac artery can often be cannulated without formal aortography. In cases of a severe celiac angulation or extensive femoral artery disease burden, brachial artery access may be considered. Celiac arteriogram will identify the splenic artery with any associated tortuosity or coils along with aneurysm location; these factors will govern the mode of aneurysm exclusion (Fig. 203.4). Embolization with coils, gelfoam, glue, thrombin, and vascular plugs has been advocated for saccular aneurysms with narrow necks, while larger vessels with complex wide-neck aneurysms may be better approached with covered stents or stent-assisted coil embolization.

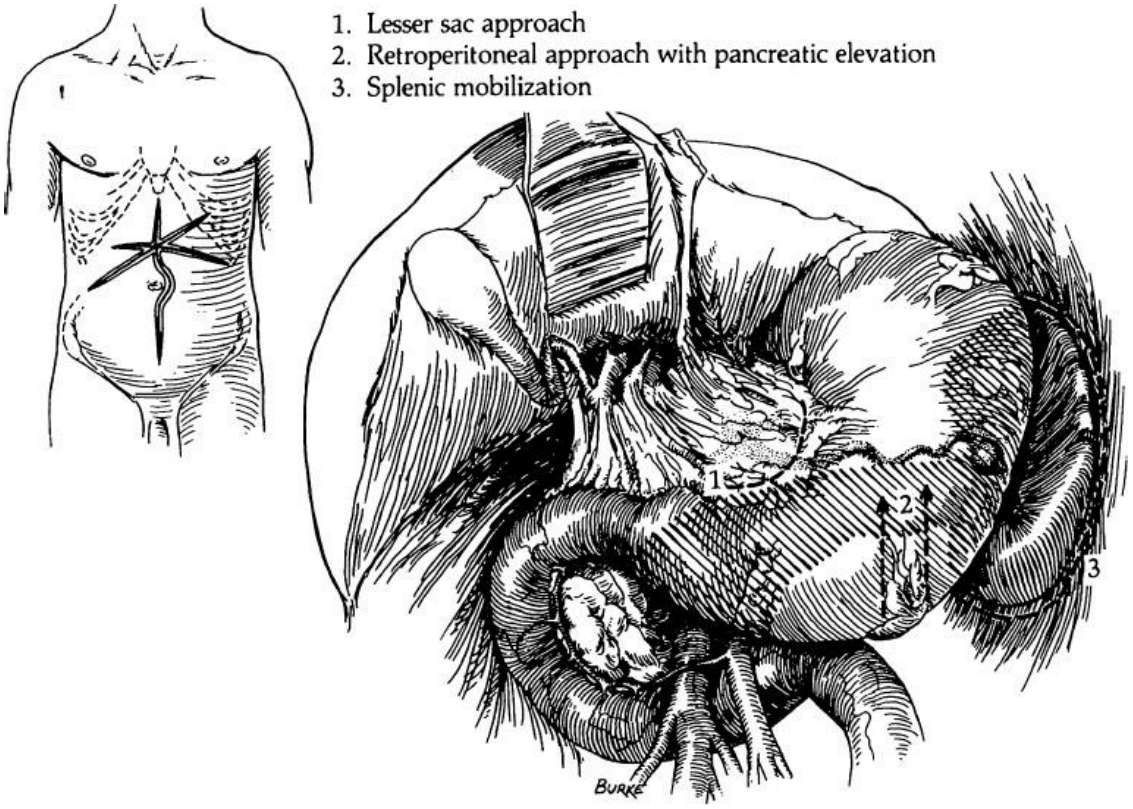

Figure 203.3. Surgical approaches in patients with splenic artery aneurysms include extended right subcostal, left subcostal or transverse epigastric, and vertical midline incisions. Specific intra-abdominal exposure depends on the location of the splenic artery aneurysm.

Figure 203.4. Splenic arteriogram demonstrating a mid-splenic artery aneurysm with mild vascular tortuosity.

For those proximal aneurysms without associated excessive splenic

artery tortuosity, the artery distal to the aneurysm is selected; to secure this platform, a long sheath is typically positioned into the celiac artery or proximal splenic artery when possible. Vascular plugs or a covered stent may be deployed for aneurysm exclusion. Given the size and stiffness of these current devices, their use is limited in those patients with splenic arterial tortuosity and distal or hilar aneurysms. It is far more common to build a more advanced platform for highly tortuous splenic arteries and for those aneurysms affecting the distal splenic artery. With a sheath positioned in the celiac axis and a catheter positioned within the proximal splenic artery (Fig. 203.5), a microcatheter is used to select the outflow branches of such aneurysms (Fig. 203.6). These outflow branches are embolized sequentially (Fig. 203.7); thereafter, the aneurysm sac is commonly packed with coils followed by the main splenic arterial inflow (Fig. 203.8). Care should be taken when employing glue (i.e., n-butyl-cyanoacrylate) for embolization to prevent reflux into the celiac axis. Technical success for endovascular treatment is 93% to 98%, limited primarily by vessel tortuosity that may be overcome with newer, steerable catheters and sheaths. Conversion to open surgery is rarely necessary to accomplish successful aneurysm exclusion.

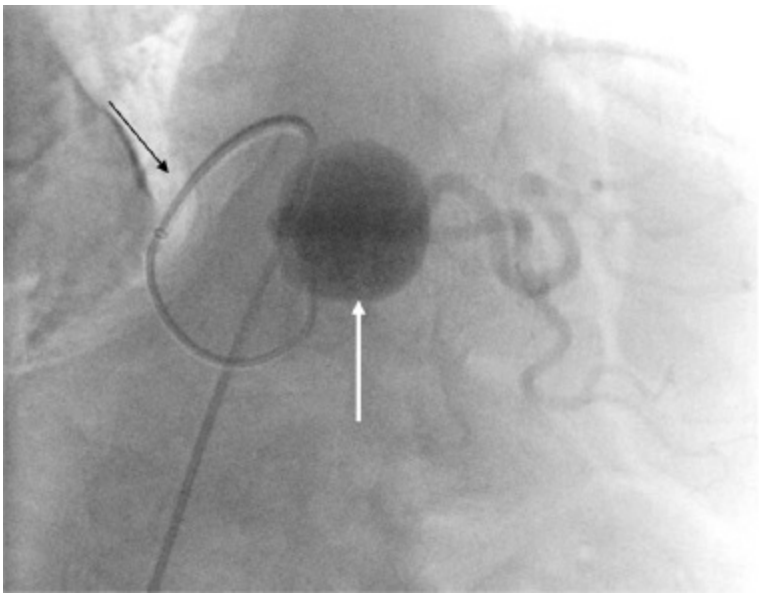

Figure 203.5. Selective catheterization of the splenic artery through sheath positioned in the celiac artery (*black arrow*); splenic arteriogram reveals a mid-splenic artery aneurysm (*white arrow*).

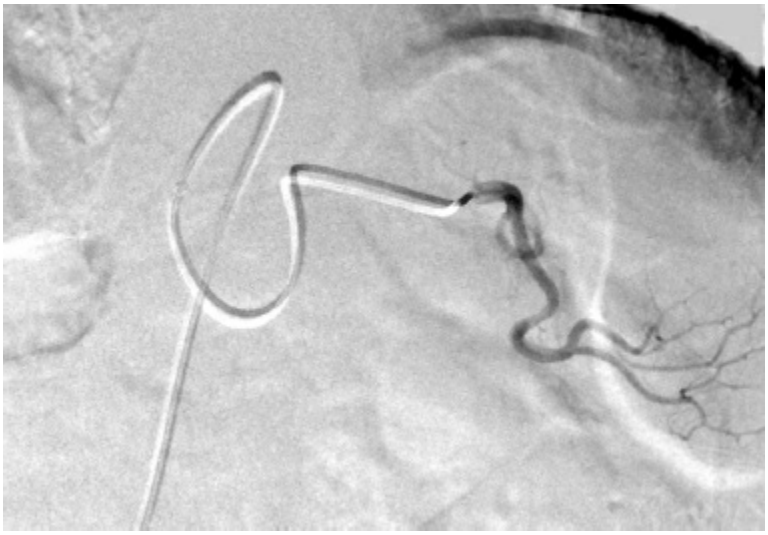

Figure 203.6. Outflow branch selection distal to a mid-splenic artery aneurysm.

COMPLICATIONS AND THEIR MANAGEMENT

Postembolization syndrome (PES) complicates up to 30% of cases and may result in left upper quadrant pain, fever, ileus, platelet dysfunction, leukocytosis, and pancreatitis. Imaging may or may not reveal radiographic evidence of splenic infarction. Up to 20% of patients will demonstrate major splenic infarct and may even require reintervention for splenic abscess by way of percutaneous drainage or splenectomy. This risk is increased in cases of portal hypertension.

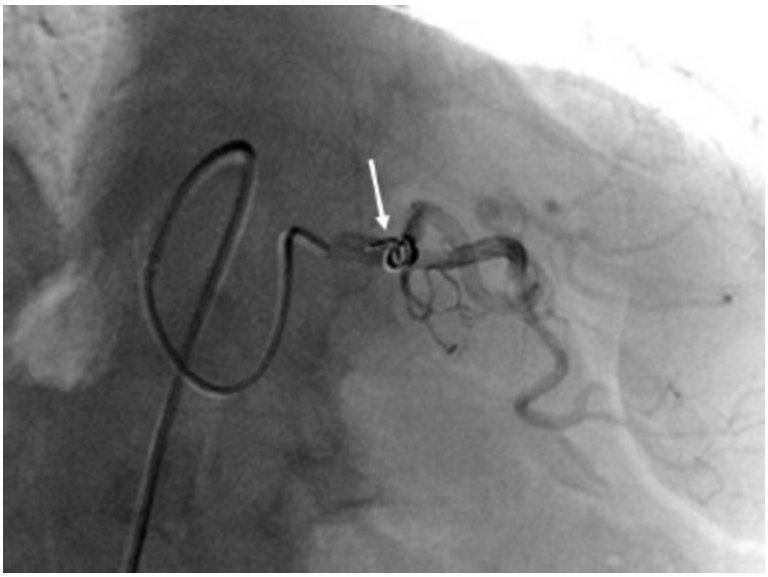

Figure 203.7. Coil embolization (*arrow*) of the main splenic artery outflow tract distal to the aneurysm.

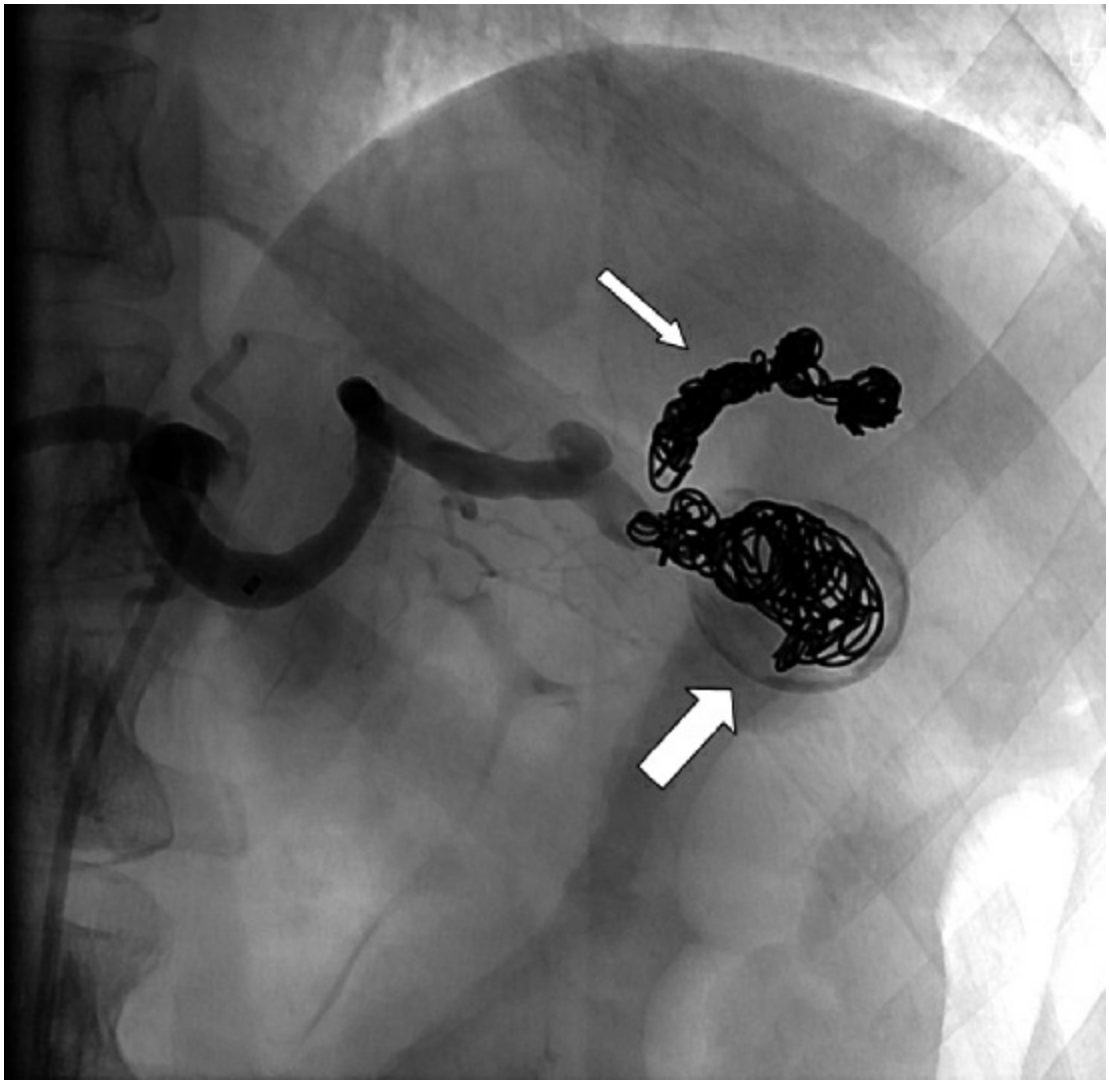

Figure 203.8. Calcified splenic artery aneurysm embolized by packing coils in the aneurysm and inflow tract (*large arrow*); coils in the outflow tract (*small arrow*).

OUTCOMES

Patients with splenic aneurysms have long-term survival rates that approach 90% at 10 years following aneurysm-directed treatments, and the ultimate cause of death is typically unrelated to the aneurysm. This point emphasizes the importance of durability in aneurysm treatment. Perioperative morbidity and mortality following open surgery are estimated as 9% to 25% and 1% to 5% respectively across series. Notably, a recent meta-analysis of splenic aneurysm treatments identified significantly greater technical success and greater 30-day mortality following open repair in comparison to endovascular aneurysm exclusion, which offered higher rates of acute minor complications, late

complications, and need for reinterventions. Long-term postembolization imaging is warranted to assess for aneurysm recanalization with cross-sectional imaging, although follow-up imaging is complicated by artifact produced by radiopaque embolization material (Fig. 203.9). Following successful embolization, an average aneurysm size regression rate of 1.5 mm/year has been demonstrated. The incidence of late complication following embolization is <4%, but this is associated with a 3% rate of reintervention per year.

Figure 203.9. Follow-up CT scan of a splenic artery aneurysm after coil embolization. Note the streaking artifact that complicates vascular interpretation.

EDITOR'S COMMENT

Splenic artery aneurysms (SAAs) remain the most common true visceral artery aneurysm. The standard teaching regarding the treatment of these aneurysms has been that they should be treated regardless of size in females of childbearing age. I think that is likely true as the downside to treatment in the elective setting is really negligible compared with the disastrous outcomes of pregnant women presenting with SAA rupture. In contrast, the much more common clinical scenario is to see a patient in the clinical setting with an SAA 1.8 cm in diameter with vague abdominal pain. While I recognize that there is a relatively low risk of aneurysm exclusion, I still believe that we treat too many SAAs because the majority of them are now treated endovascularly. I would suggest that we have likely lowered our threshold for therapy, given the lower short-term mortality and morbidity associated with coiling of SAA.

Part of my bias about how we manage SAAs is that the vascular low frequency disease consortium (VLFDC) has begun to study a number of these so-called rare vascular diseases, which we often use large, single center series with fewer ruptures to dictate global therapy. For example, recently the VLFDC has recently examined both renal artery aneurysms and femoral artery aneurysms, and the conclusion from both of these studies is that we are too aggressive based on a more extensive, multi-institutional natural history in that few of these rupture below 3 cm (Klausner JQ, Lawrence PF, Harlander-Locke MP, et al.; Vascular Low-Frequency Disease Consortium. The contemporary management of renal artery aneurysms. *J Vasc Surg* 2015;61(4):978–84; Klausner JQ, Harlander-Locke MP, Plotnik AN, et al. Current treatment of renal artery aneurysms may be too aggressive. *J Vasc Surg* 2014;59(5):1356–61; Lawrence PF, Harlander-Locke MP, Oderich GS, et al.; Vascular Low-Frequency Disease Consortium. The current management of isolated degenerative femoral artery aneurysms is too aggressive for their natural history. *J Vasc Surg* 2014;59(2):343–9).

It is difficult to find head-to-head comparisons of open versus endovascular therapy. Some series have compared open and endovascular therapy with conservative management of SAAs (Hogendoorn W, Lavida A, Hunink MG, et al. Open repair, endovascular repair, and conservative management of true splenic artery aneurysms. *J Vasc Surg* 2014;60(6):1667–76). As one might expect, more patients who present with rupture undergo open aneurysm repair/ligation and thus there is higher mortality associated with open repair. These series are often filled with institutional biases that often change temporally (i.e., open surgery in days past and endovascular therapy in present).

While not addressed in detail in this chapter, a recent report has heralded the laparoscopic approach as a potential new and preferred method to treat SAAs. In this study of 11 patients, laparoscopic aneurysmectomy of SAAs was described as a safe treatment method with good short- and long-term results (Małczak P, Wysocki M, Major P, et al. Laparoscopic approach to splenic aneurysms. *Vascular* 2016 Jan 1. doi: 10.1177/1708538116682164. [Epub ahead of print]). The authors also importantly highlight the observation that laparoscopy in most settings allows for permanent treatment of SAA, while maintaining splenic function. However, to the authors's credit they suggest that a complete evaluation of lapaoscopic SAA repair/treatment requires further research on a larger study group.

Finally, when I perform a search based on the terms follow-up and splenic artery and embolization, I note there are functionally no papers. Part of the issue is that there is no "gold standard" for coil materials used for these aneurysms as discussed in this chapter by Coleman. In addition, especially in the setting of postcoiling or embolization, it is really difficult to get good cross-sectional or ultrasound imaging of splenic artery aneurysms in terms of determining aneurysm diameter. I also believe that patients honestly think their aneurysm is "fixed" even when merely embolized. We know from the way we manage

cerebral artery aneurysms and how they are saccular and are primarily treated via embolization (just like SAAs) that a certain number of these aneurysms are incompletely coiled and can functionally reperfuse. The risk of course is that patients who believe they have had an SAA “treated” will present catastrophically with rupture (Kingma KD, van der Linden AN, Roumen RM. Rebleeding of a splenic artery aneurysm after coil embolisation. *Case Rep Surg* 2016;2016:1858461. Oct 31, 2016 [Epub ahead of print]).

Gilbert R. Upchurch, Jr.

C CHRONIC LOWER EXTREMITY OCCLUSIVE DISEASE

204 Aortofemoral Bypass

David C. Brewster

INTRODUCTION

The infrarenal abdominal aorta and iliac arteries are among the most common sites of occlusive atherosclerotic disease responsible for symptomatic arterial insufficiency of the lower extremities. Because atherosclerosis is a systemic process, patients with aortoiliac disease frequently have coexistent disease below the inguinal ligament. Nonetheless, the disease is usually segmental in distribution and therefore amenable to effective surgical treatment. Even in patients with significant concomitant infrainguinal disease, successful revascularization of the aortoiliac segment frequently leads to adequate improvement of ischemic symptoms.

Since the introduction of the initial methods of aortoiliac reconstruction more than 50 years ago, improvements in surgical techniques, graft materials, and perioperative care have all contributed to significant reduction of perioperative morbidity/mortality and excellent long-term results in terms of both graft patency and symptom relief.

INDICATIONS

The most common indications for aortoiliac revascularization are severe intermittent claudication and limb-threatening ischemia secondary to atherosclerotic occlusive disease involving the infrarenal aorta and both iliac systems. Almost all patients with severe ischemia manifested by rest pain or tissue loss are found to have multilevel disease involving the aortoiliac and infrainguinal arterial segments. In such patients, initial correction of inflow disease by aortoiliac revascularization is appropriate.

Establishing adequate flow to the profunda femoris affords satisfactory clinical relief of the ischemic symptoms in 75% to 80% of patients despite the uncorrected infrainguinal disease.

A less frequent but well-recognized indication is peripheral atheromatous embolization (blue toe syndrome) from proximal ulcerated atherosclerotic plaques in the aortoiliac system. If a likely source of such events can be identified by arteriographic evaluation, aortobifemoral bypass with exclusion of the native aortoiliac segment is often advisable, even if the lesions are not hemodynamically significant.

PREOPERATIVE ASSESSMENT

There are numerous options for revascularization in patients with aortoiliac disease. Selection of the most appropriate method depends largely on two factors: (a) the patient's surgical risk and (b) the extent and distribution of occlusive disease. Aortobifemoral bypass provides superior long-term results in terms of durability and sustained symptom relief. However, it is a major operative procedure that may not be well suited for patients with serious comorbid medical conditions. Thus, careful preoperative evaluation is important. For patients with relatively limited areas of disease, particularly for unilateral iliac disease, alternative "lesser" procedures such as percutaneous transluminal angioplasty (PTA) with or without intraluminal stents, femorofemoral bypass, or unilateral iliofemoral grafting may be more appropriate. For high-risk patients with bilateral iliac disease or patients with relative contraindications to direct aortic reconstruction such as heavy retroperitoneal scarring or contamination, the extra-anatomic axillobifemoral bypass may be a better alternative. However, the long-term patency rates of these grafts are inferior. Although all of these options may be appropriate in selected circumstances, aortobifemoral grafting provides clearly superior long-term results in terms of durability and sustained symptom relief.

Careful preoperative evaluation is important to identify and potentially correct any comorbid conditions that might increase the risk of revascularization. Preoperative evaluation of coronary artery disease is important for patients with evidence of ischemic heart disease by either history, symptoms, or electrocardiography. If the noninvasive screening studies such as exercise stress testing, adenosine thallium, dobutamine stress echocardiography, or similar studies suggest significant myocardial ischemia, preoperative coronary arteriography may be advisable.

Similarly, significant abnormalities of pulmonary, renal, or coagulation function should be routinely evaluated and optimized.

High-quality preoperative arteriography remains of paramount importance before aortoiliac revascularization. In addition to standard anteroposterior views, lateral and oblique images of the visceral, iliac, and profunda femoral vessels should be obtained. Complete, bilateral infrainguinal arteriograms are also generally advisable, both for operative planning and minimizing the chances of technical misadventure. In recent years, alternative imaging techniques such as contrast-enhanced computed tomographic angiography (CTA) and magnetic resonance angiography (MRA) with gadolinium administration have been increasingly employed for preoperative imaging evaluation. In addition, duplex ultrasound scanning may be employed to identify patients with likely aortoiliac occlusive disease. Most often these alternative imaging modalities are used for screening, and cannot match the visual clarity, detail, spacial resolution, and overall accuracy of standard catheter-based contrast arteriography.

Noninvasive vascular studies are generally performed in all patients. Segmental lower extremity pressure measurements and pulse volume recordings (plethysmography) confirm the diagnosis, quantify its severity, and establish a baseline for assessing the results of revascularization. Furthermore, exercise stress testing can serve to quantify the walking distances among claudicants.

SURGICAL TECHNIQUE

Aortobifemoral Bypass

Two to four units of packed red blood cells are typed and cross-matched. Preoperative donation of 2 units of autologous blood is encouraged and is generally possible in elective circumstances. Adequate preoperative hydration is ensured, including administration of intravenous fluids if clinically necessary. A broad-spectrum prophylactic antibiotic such as cefazolin (1 g) is given intravenously 1 to 2 hours before surgery and continued for 1 or 2 days postoperatively. In patients with infected lower extremity ischemic lesions or any other possible source of bacteremia, culture-specific oral antibiotics are often started several days before operation.

The patient is placed supine on the operating table with both arms extended at right angles on armboards to permit appropriate monitoring

during anesthesia and to establish vascular access. A radial artery cannula is inserted for continuous blood pressure monitoring and arterial blood gas determinations. A Swan-Ganz catheter is inserted in selected patients based on the preoperative assessment of cardiac and renal function. Most patients undergoing aortic surgery in contemporary practice are anesthetized with a combination of epidural analgesia and inhalation agents (combined general and epidural technique). Continuation of the epidural analgesia in the early postoperative period for pain control has had a significant impact on limiting systemic narcotic use, facilitating early extubation and reducing respiratory complications after aortic surgery. Warmed intravenous fluids and any one of the commercially available external wrapping devices (such as the Bair Hugger) can be very useful in maintaining body temperature and avoiding the potentially deleterious effects of hypothermia secondary to heat loss.

Incisions and Dissection

The infrarenal abdominal aorta may be exposed for the aortofemoral reconstruction using a variety of incisions. A long vertical midline incision is used most often (Fig. 204.1) and is generally preferred because it is fast, is easy to close, and affords maximal exposure and thereby technical flexibility in most patients. Alternatively, a retroperitoneal approach may be employed and may be advantageous in obese patients as well as those with hostile abdomens or previous aortic surgery. I generally prefer to first expose the femoral vessels before making the abdominal incision in order to minimize the length of time that the abdomen is open and thereby limit evaporative fluid and heat losses. As shown in Figure 204.1, the groin incisions are oriented slightly obliquely and placed so that the cephalad one third of the incision lies above the inguinal ligament. Retraction by an assistant during construction of the femoral anastomosis is generally unnecessary when the incisions are placed in this manner.

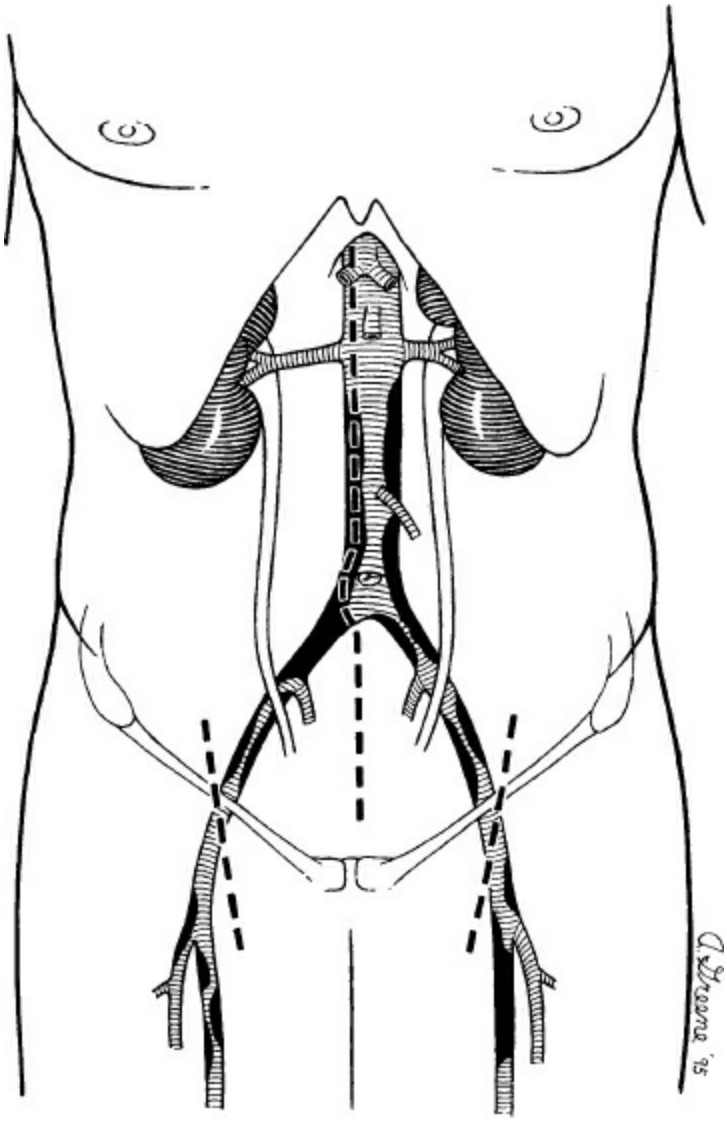

Figure 204.1. Standard incisions for aortobifemoral bypass.

Dissection is carried directly onto the anterior surface of the common femoral artery and then cephalad to the inguinal ligament. The lymph nodes and/or lymphatic tissue are best divided between clamps and then suture-ligated to minimize the possibility of a postoperative lymphatic leak with its associated risk of wound or graft infection. The caudal border of the inguinal ligament is partially divided directly over the femoral artery to ensure ample space for tunneling of the graft limb without compression. Dissection is then carried caudally to expose the common femoral artery bifurcation, and the proximal aspect of both the superficial and the profunda femoral arteries is encircled with vessel loops (Fig. 204.2). Similarly, any sizable side branches of the femoral arteries are preserved and controlled with such loops. If significant occlusive disease is found in the proximal profunda femoris artery on the preoperative arteriogram or by

intraoperative palpation, the vessel is exposed further caudally beyond the significant disease to allow concomitant profundaplasty at the time of distal anastomosis. This usually requires exposing an additional 2 to 3 cm of the vessel and often necessitates division of one or more branches of the profunda femoral vein that typically cross the anterior surface of the proximal deep femoral artery.

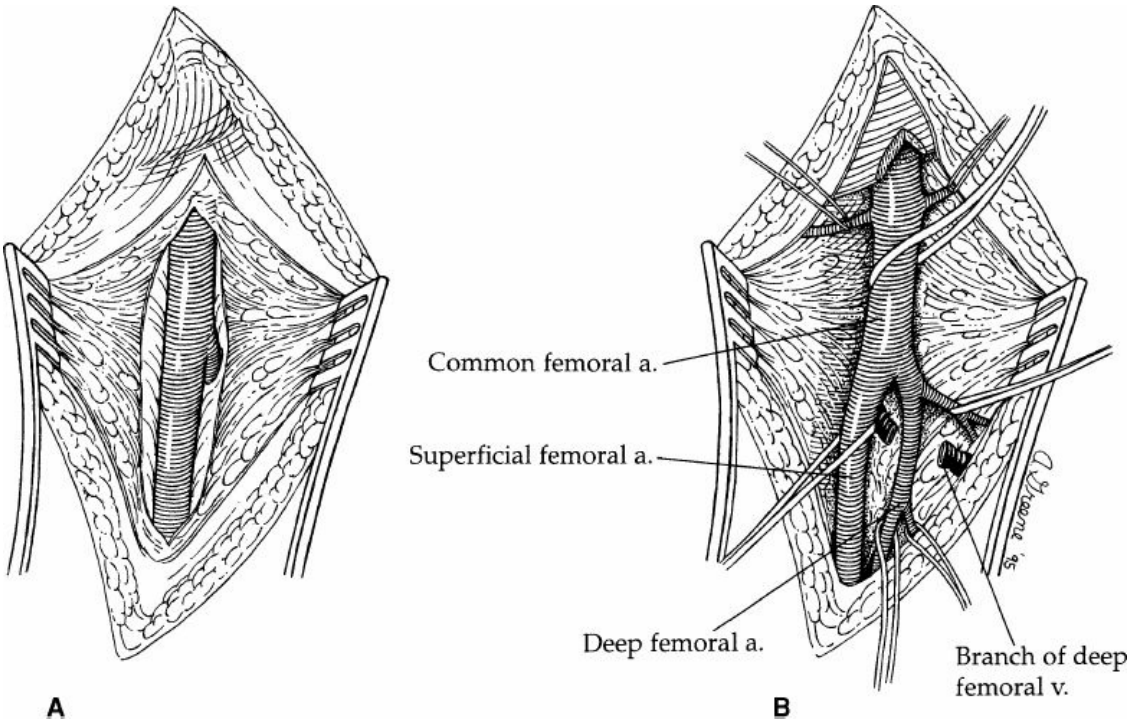

Figure 204.2. A. The common femoral artery is exposed from the inguinal ligament to the proximal portions of its superficial and profunda branches. **B.** More distal exposure of the profunda femoris usually requires division of one or more branches of the deep femoral vein that cross the artery anteriorly. The inguinal ligament has been partially divided to provide ample space for tunneling of the graft.

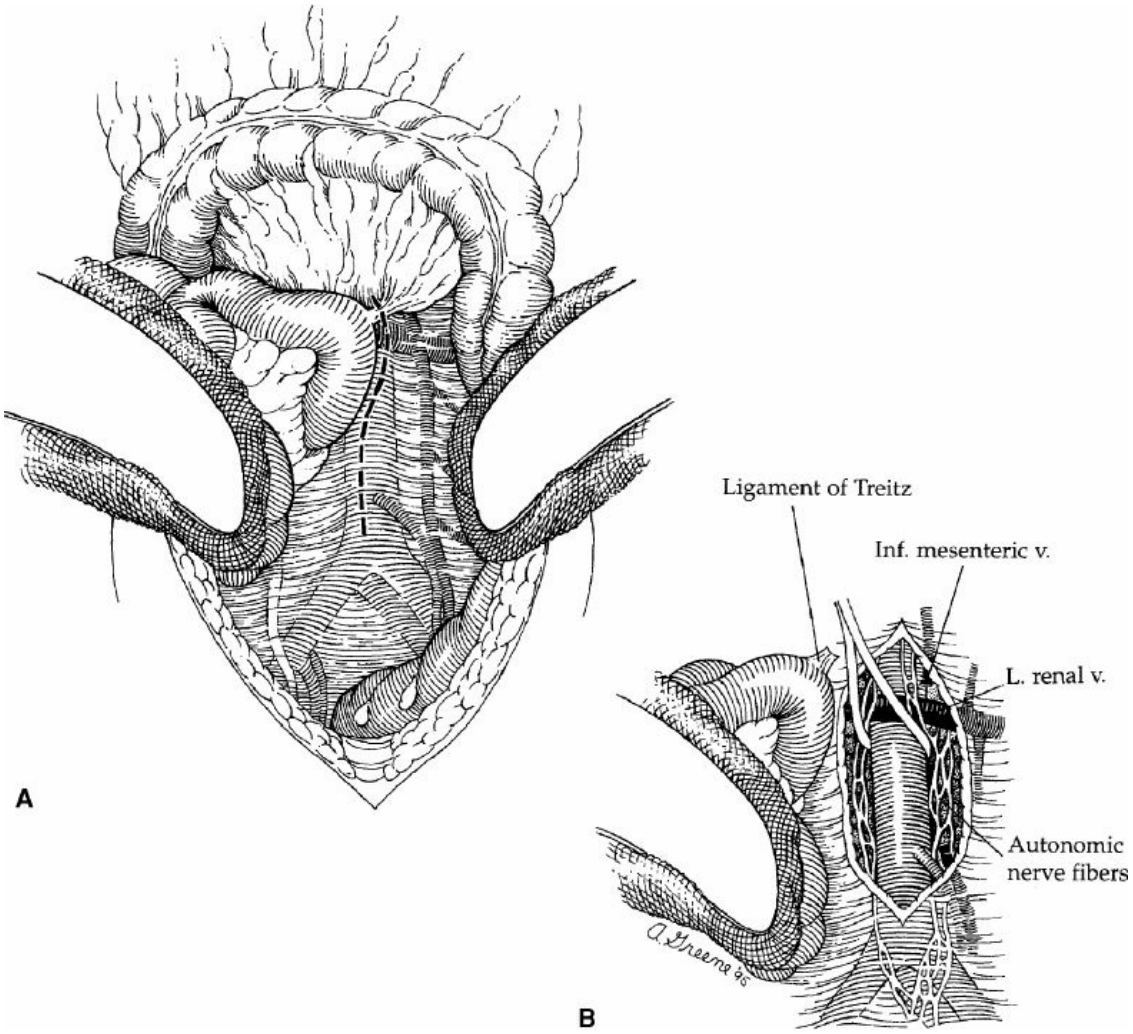

Figure 204.3. A. Following evisceration of large and small bowel, the retroperitoneum overlying the aorta is opened from the aortic bifurcation to above the crossing left renal vein, and the ligament of Treitz is divided to allow mobilization of the duodenum off the aorta. **B.** The inferior mesenteric vein will often require division. Automatic nerve plexuses are preserved as best as possible, and dissection in the region of the aortic bifurcation is avoided.

A midline abdominal incision is then created extending from the xiphoid to the pubis. After careful exploration of the intraabdominal organs, the transverse colon and greater omentum are elevated and retracted cephalad, and the entire small bowel eviscerated and displaced to the right (Fig. 204.3). The descending and sigmoid portions of the colon are retracted laterally and caudally. After these maneuvers, the posterior parietal peritoneum overlying the infrarenal aorta is visualized, and this is incised along the longitudinal axis of the aorta starting between the duodenum on the patient's right and the inferior mesenteric vein to the left.

Care is taken to avoid the plexuses of autonomic nerve fibers (Fig. 204.3B) that course primarily along the left anterolateral aspect of the infrarenal aorta and the proximal left common iliac artery. Careful dissection helps preserve these autonomic nerves and helps reduce the incidence of postoperative sexual dysfunction in male patients.

The retroperitoneal incision is extended cephalad and the ligament of Treitz is divided. This allows mobilization of the fourth portion of the duodenum off the aorta and facilitates visualization of the left renal vein as it crosses anterior to the aorta just below the renal artery origins. The left renal vein is an important landmark because the proximal graft anastomosis should be placed as close to it (and the renal arteries) as possible. This serves to minimize the potential for recurrent occlusive disease in the infrarenal aorta above the proximal anastomosis that could potentially compromise the late patency of the graft. The aortic dissection is extended distally just beyond the origin of the inferior mesenteric artery. This extent of aortic exposure is sufficient to allow construction of a proper proximal graft anastomosis and tunneling of each graft limb to the groin. Furthermore, it minimizes the dissection in the region of the aortic bifurcation itself, thereby reducing the possibility of autonomic nerve injury.

After completion of the aortic and femoral dissections, retroperitoneal tunnels are next made for the passage of each graft limb from the aorta to the groins. Such tunnels are best made by gentle blunt dissection using both index fingers in a simultaneous fashion with one extending from the groin cephalad and the other from the aortic bifurcation caudal (Fig. 204.4A). Dissection should be kept on a plane directly anterior to the common and external iliac vessels to guarantee that the graft is subsequently placed posterior to the ureter. This is important because passage of the graft anterior to the ureter may lead to compression and obstruction of the ureter with hydronephrosis. When starting the tunnel in the groin, care must be taken not to tear the circumflex iliac venous branches that cross the distal external iliac artery just above the inguinal ligament. After appropriate tunnels have been created to both groins, a long blunt-tipped clamp is placed through the tunnel and a Penrose drain drawn through the tunnel (Fig. 204.4B). Elevation of both ends of the drain facilitates later passage of the graft limbs.

Proximal Aortic Anastomosis

A variety of prosthetic grafts are available for aortobifemoral bypass, including conventional Dacron (knitted and woven), coated Dacron (collagen, albumin, or gelatin), and polytetrafluoroethylene (PTFE). Available data do not suggest that any graft material or fabrication has superior patency, and selection is based mostly on the surgeon's personal preference.

Use of a properly sized graft is important to minimize the possibility of sluggish flow and deposition of excessive laminar thrombus that is likely to occur in an oversized graft. For aortoiliac occlusive disease, a 16 × 8 mm bifurcated graft (body diameter, 16 mm; limb diameter, 8 mm) is used most commonly, but a 14 × 7 mm prosthesis may be more suitable for patients with a relatively small-caliber aortoiliac segment (predominantly women). For most patients, an end-to-end aortic anastomosis (Fig. 204.5) is preferred for several reasons. First, because all blood flows through the graft, there is less chance of "competitive" flow through the native aortoiliac vessels that may potentially increase the incidence of graft limb thrombosis. Second, an end-to-end anastomosis is theoretically a hemodynamically superior configuration. It is associated with less perianastomotic turbulence and therefore a smaller likelihood of developing recurrent atheroma or an anastomotic aneurysm. In addition, the end-to-end anastomosis is less likely to cause distal atheromatous embolization and is easier to cover with retroperitoneal tissue after implantation than the end-to-side anastomosis, which tends to protrude anteriorly off the aorta. This consideration may reduce the potential for late graft-enteric fistula formation. However, end-to-side anastomosis may be advantageous in certain anatomic patterns of disease to be described subsequently.

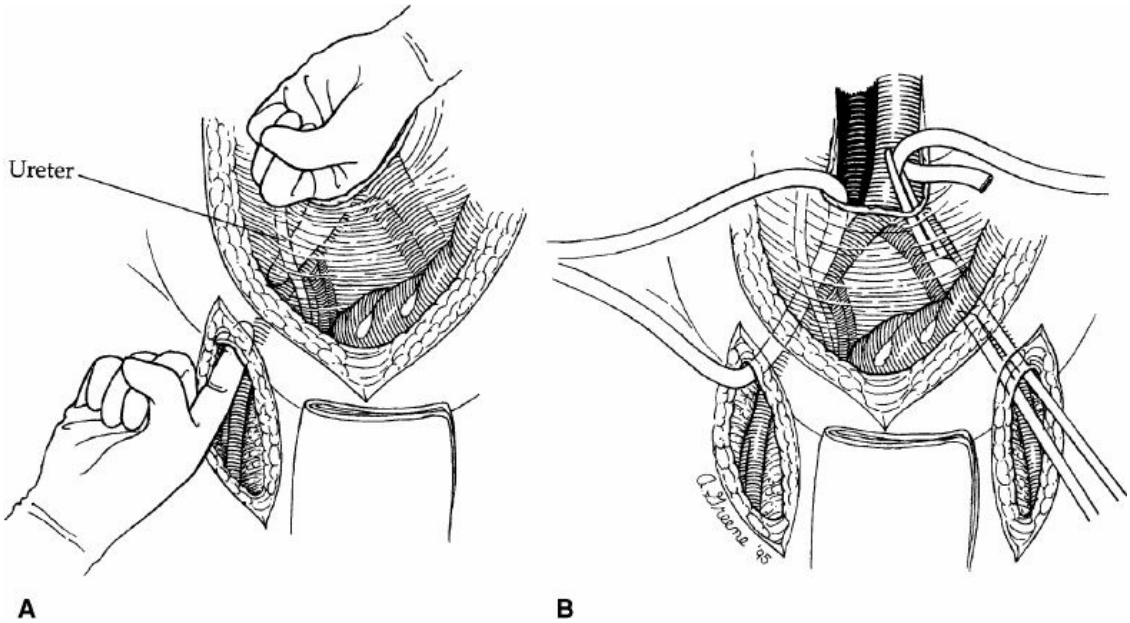

Figure 204.4. **A.** Retroperitoneal tunnels are constructed between the area of aortic exposure and femoral artery dissection in each groin. Tunneling is best performed by simultaneous blunt finger dissection from above and below, immediately on the anterior surface of the iliac arteries. This ensures passages of the graft limb posterior to the ureter that usually crosses the iliac vessels at their bifurcation. **B.** After tunneling is completed, a long clamp is passed through each tunnel and a rubber Penrose drain is pulled through the tract. Anterior traction on the drain facilitates proper passage of the graft through the tunnel at a later stage of the procedure.

After intravenous administration of 5,000 to 7,500 units of heparin, appropriate vascular clamps are applied to the aorta just caudal to the left renal vein and immediately caudal or cephalad to the inferior mesenteric artery (Fig. 204.5A). The aorta is then transected, and a 3- to 4-cm long segment between the clamps is resected. Any patent lumbar artery branches arising from this segment are clamped and ligated. Care should be taken to maintain a resection plane immediately on the posterior wall of the aorta to prevent injury and troublesome bleeding from the adjacent lumbar veins.

The transected distal aortic end is next oversewn in two layers with a 3-0 vascular suture (Fig. 204.5B). If this segment is heavily calcified or diseased, a limited endarterectomy of the calcific plaque and use of Teflon-pledgeted sutures may be necessary to achieve a secure and hemostatic closure. The body of the bifurcated prosthetic graft is shortened, leaving approximately 3 to 4 cm of the graft trunk to the graft

bifurcation. This allows the short graft body to be situated in the bed of the resected aortic segment, which facilitates closure of the retroperitoneum over the graft and separation of the anastomosis from the duodenum and other viscera. The short graft body also serves to advance the level of the graft bifurcation more cephalad and diminishes the takeoff angle of the graft limbs, thereby reducing the chance of kinking the graft at the origin of the limbs.

The divided proximal end of the aorta is inspected and thrombus or loose atheromatous debris removed. Standard graft anastomosis using a running 3-0 monofilament vascular suture is then performed (Fig. 204.5D). I usually start the anastomosis in the midline posteriorly using a double-armed suture. The anastomosis is performed in a running fashion extending both clockwise and counterclockwise approximately half the circumference of the aorta. A similar suture is then started on the midanterior aspect of the anastomosis and is similarly run in opposite directions. The anterior and posterior sutures are then tied to each other on the lateral aspects of the aorta to complete the anastomosis.

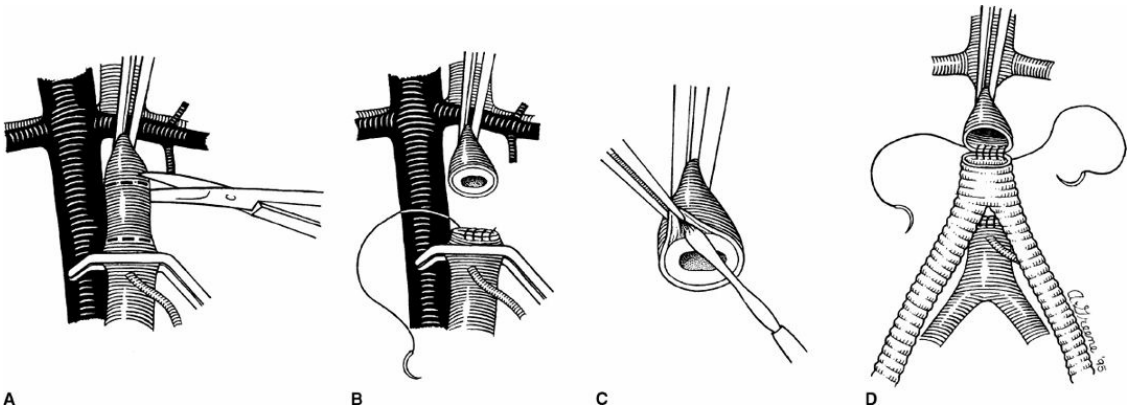

Figure 204.5. A. Following administration of systemic heparin, the aorta is clamped proximally and distally, and a segment of aorta ~3 to 4 cm long is resected. **B.** The distal aorta is oversewn with an over-and-over running suture. **C.** Thromboendarterectomy of the proximal aortic cuff below the cephalad clamp may be necessary if a thickened or calcified intima and media compromise its lumen. **D.** Proximal anastomosis is begun posteriorly with monofilament running vascular suture. The body or stem of the bifurcated graft is cut short, leaving a body that is only 3 to 4 cm in length so that it will occupy the area of the previously resected segment of native aorta.

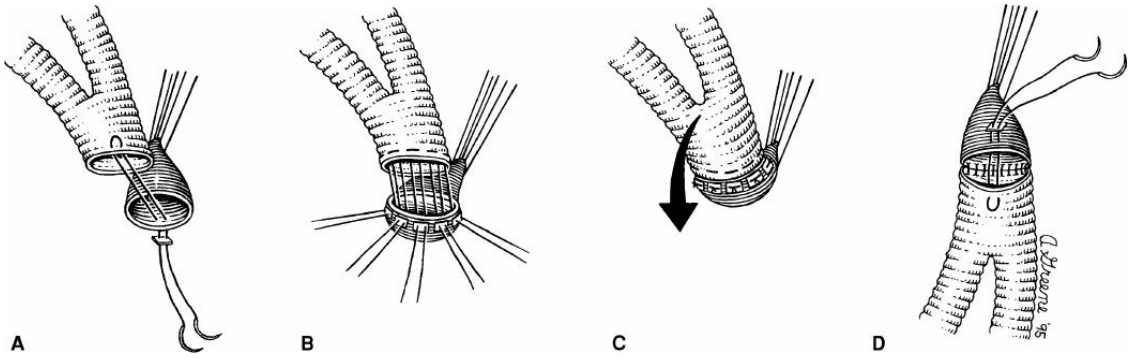

Figure 204.6. Technique of interrupted mattress suture anastomosis, often useful for a fragile diseased aorta or following cuff endarterectomy, is illustrated. **A.** The graft is oriented with its limbs directed superiorly and the anastomosis begun by a double-armed mattress suture in the midline, each needle passed from the outside of the posterior graft wall, then from the inside of the posterior wall of the aorta, and finally through a pledget of Teflon felt. **B.** Placement of five such mattress sutures around the posterior one-half circumference of the graft and aorta, tied down over the felt pledgets, completes the back wall of the anastomosis. Care is taken to place each mattress suture immediately adjacent to its neighbor, with proper spacing achieved by altering the width of travel between the two limbs of each individual mattress suture. **C.** After the back wall is completed, the graft is flipped down into a proper anatomic position, and (**D**) the anastomosis is completed by insertion of a similar anterior row of mattress sutures.

If the proximal transected infrarenal aorta is significantly diseased and its lumen compromised, I often perform a thromboendarterectomy of the aortic stump up to the level of the proximal clamp (Fig. 204.5C). The remaining adventitial layer is often quite thin, but usually holds sutures well and allows a technically perfect anastomosis. In this circumstance, I always prefer to use an interrupted mattress suture technique with each suture bolstered by a Teflon felt pledget (Fig. 204.6).

After the completion of the aortic anastomosis, the graft is clamped with an atraumatic vascular clamp (Fogarty soft-jawed clamp) and the proximal anastomosis tested by a slow release of the proximal aortic clamp. If inspection reveals any leaks or defects, they are repaired with interrupted mattress sutures with pledgets. After a hemostatic and secure anastomosis has been verified, the proximal aortic clamp is reapplied and the graft thoroughly suctioned to remove any clot or debris.

Attention is then directed to the femoral region. The Penrose drains,

previously placed in the graft tunnels, are elevated, and a long, blunt-tipped, slightly curved clamp such as a large DeBakey aortic clamp is passed from each groin incision to the region of the aortic dissection. The distal end of each femoral graft limb is then grasped with the clamp under direct vision, and each graft limb is pulled down through the tunnel (Fig. 204.7A). Care must be exercised to avoid twisting of the graft limbs. Fortunately, most of the currently utilized vascular grafts have stripes or marks that help maintain the correct orientation. Again, it is important to ensure the passage of each graft limb posterior to the ureter. This is usually best accomplished by properly constructing the initial graft tunnel immediately anterior to the iliac vessels and then elevating the Penrose drain “sling” that encompasses the ureter within the overlying retroperitoneal tissues during the actual pulling down of the graft limb. The ureter may be palpated at times as well. Gentle tension is applied to both graft limbs to eliminate any kinking or redundancy, but excessive tension must be avoided because this may contribute to late anastomotic aneurysm formation.

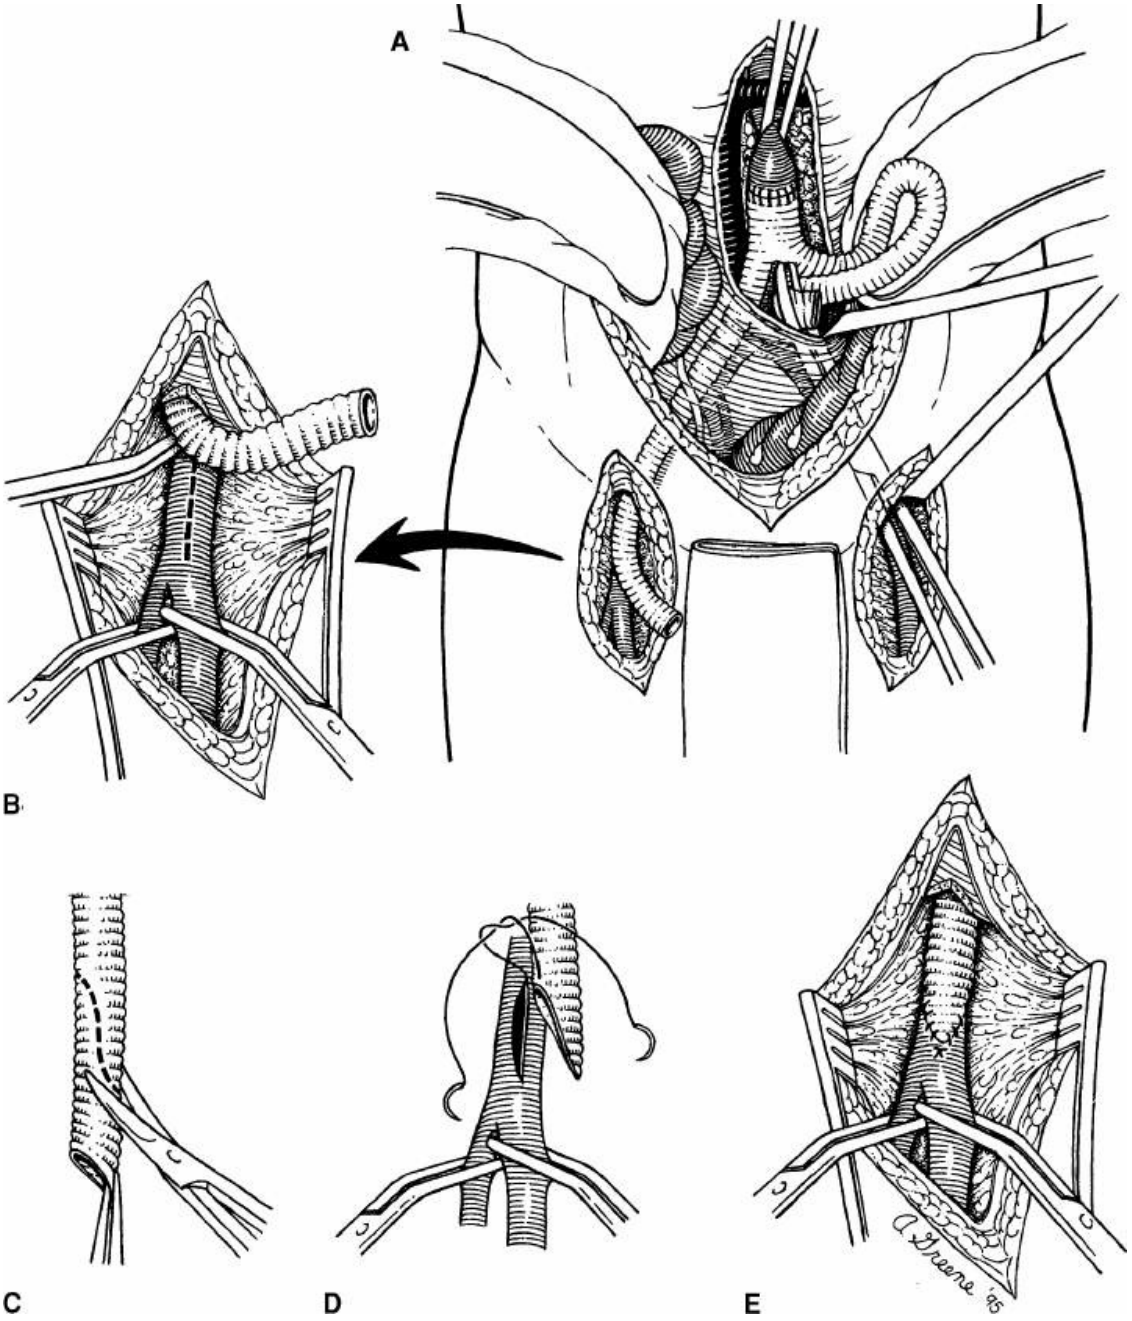

Figure 204.7. **A.** Passage of graft limbs through the retroperitoneal tunnels. Elevation of the Penrose drain sling facilitates graft tunneling and ensures positioning behind the ureter. **B.** Location of common femoral arteriotomy in the absence of any significant profunda origin disease. **C–E.** Cutting graft to appropriate length and construction of femoral anastomosis.

Femoral Anastomoses

Performance of a technically flawless femoral anastomosis is probably the most important technical aspect of the aortobifemoral bypass and the most

significant determinant of late graft patency. It is particularly critical to ensure unimpeded flow to the profunda femoris artery on each side. As previously emphasized, the majority of patients undergoing aortobifemoral bypass have diseased or occluded superficial femoral arteries at the time of surgery. In other patients, progressive distal occlusive disease may result in later development of superficial femoral artery obstruction. Prolonged graft limb patency is therefore heavily dependent on profunda outflow. Hence, it is imperative to detect and correct any disease at the origin of the profunda at the time of the femoral anastomosis.

The femoral anastomosis is begun by occluding the proximal common femoral artery at the level of the inguinal ligament and the proximal superficial femoral and profunda branches using appropriate atraumatic vascular clamps. The anterior surface of the mid common femoral artery is incised with a No. 11 scalpel blade and the femoral arteriotomy extended both proximally and distally with Potts scissors (Fig. 204.7B). The graft limb is gently stretched out with a slight tension and cut with a slightly curved bevel to a length appropriate to match the size of the arteriotomy. A standard vascular anastomosis is then performed with 5-0 monofilament vascular suture. I prefer to begin with a mattress suture placed at the “heel” of the graft. I usually tie this suture down and then continue the anastomosis in a running fashion down each side to its midpoint, but a “parachute technique” may be used if preferred. The direction of suture placement is always from outside to inside on the graft and inside to outside on the artery to minimize the chance that plaque or diseased layers of the vessel wall will be lifted or displaced and thus act as a potential obstructive flap. This is more apt to occur if the suture is passed from outside to inside on the vessel wall. At the midpoint of each side of the anastomosis, the running sutures are tagged with a rubber-shod hemostat to maintain some tension on the suture line, and a new suture is begun at the “toe” of the graft and distal apex of the arteriotomy. This is tied down and run on both sides to meet the previously tagged sutures at the midpoint (Fig. 204.7D).

If the superficial femoral artery is occluded or any significant occlusive disease is detected at the orifice of the profunda femoris, a simple anastomosis to the common femoral artery alone is not recommended. In this situation, the femoral arteriotomy is best carried into the proximal profunda femoris beyond its orificial stenosis (Fig. 204.8A) to construct a reliable outflow tract for the graft limb. In most circumstances, a “patch”

profundaplasty can be adequately performed using the long beveled toe of the graft (Fig. 204.8C). When the toe of the graft anastomosis is placed on the profunda, I recommend that three to five interrupted mattress sutures be used at the apex (Fig. 204.8D). These should be placed under direct vision and left untied until the final one is placed to optimize their accurate positioning and minimize any potential for narrowing this critical outflow vessel.

It is important to both flush the graft limbs and sequentially restore blood flow to the lower extremities to minimize the potential for distal thromboemboli and the so-called declamping hypotension, respectively. The surgeon should alert the anesthesiologist that blood flow will soon be reestablished in the lower extremities 5 to 10 minutes before the anticipated completion of the first femoral anastomosis. This enables the anesthesiologist sufficient time to optimize blood volume status and briefly administer vasoconstrictor medications if necessary to overcome the vasodilatory effects of the epidural anesthesia. Just before the completion of the femoral anastomosis, I place atraumatic vascular clamps (Fogarty soft-jawed clamp) on both proximal graft limbs and remove the aortic clamp to again ensure that the aortic anastomosis is hemostatic. The appropriate graft limb is then vigorously flushed through the nearly completed femoral anastomosis by briefly releasing the clamp on the graft limb (Fig. 204.9A). The clamp is reapplied, and the femoral artery clamps are released to back-bleed the native arterial system. The anastomosis is then rapidly completed and the graft limb slowly opened. The superficial femoral and profunda vessels are gently occluded so that all flow is initially retrograde up into the pelvic circulation, thereby further minimizing the chances of any distal embolization of clot or debris (Fig. 204.9B). Flow into the profunda and finally the superficial femoral artery is then reestablished by removing the distal arterial clamps (Fig. 204.9C). If any significant hypotension is observed, the graft limb is manually occluded and further fluid volume, sodium bicarbonate, and vasoconstrictors are administered as necessary. The limb is then slowly reopened as tolerated. Afterwards, the contralateral femoral anastomosis is completed in a similar fashion using the same sequence of flushing/declamping to complete graft implantation.

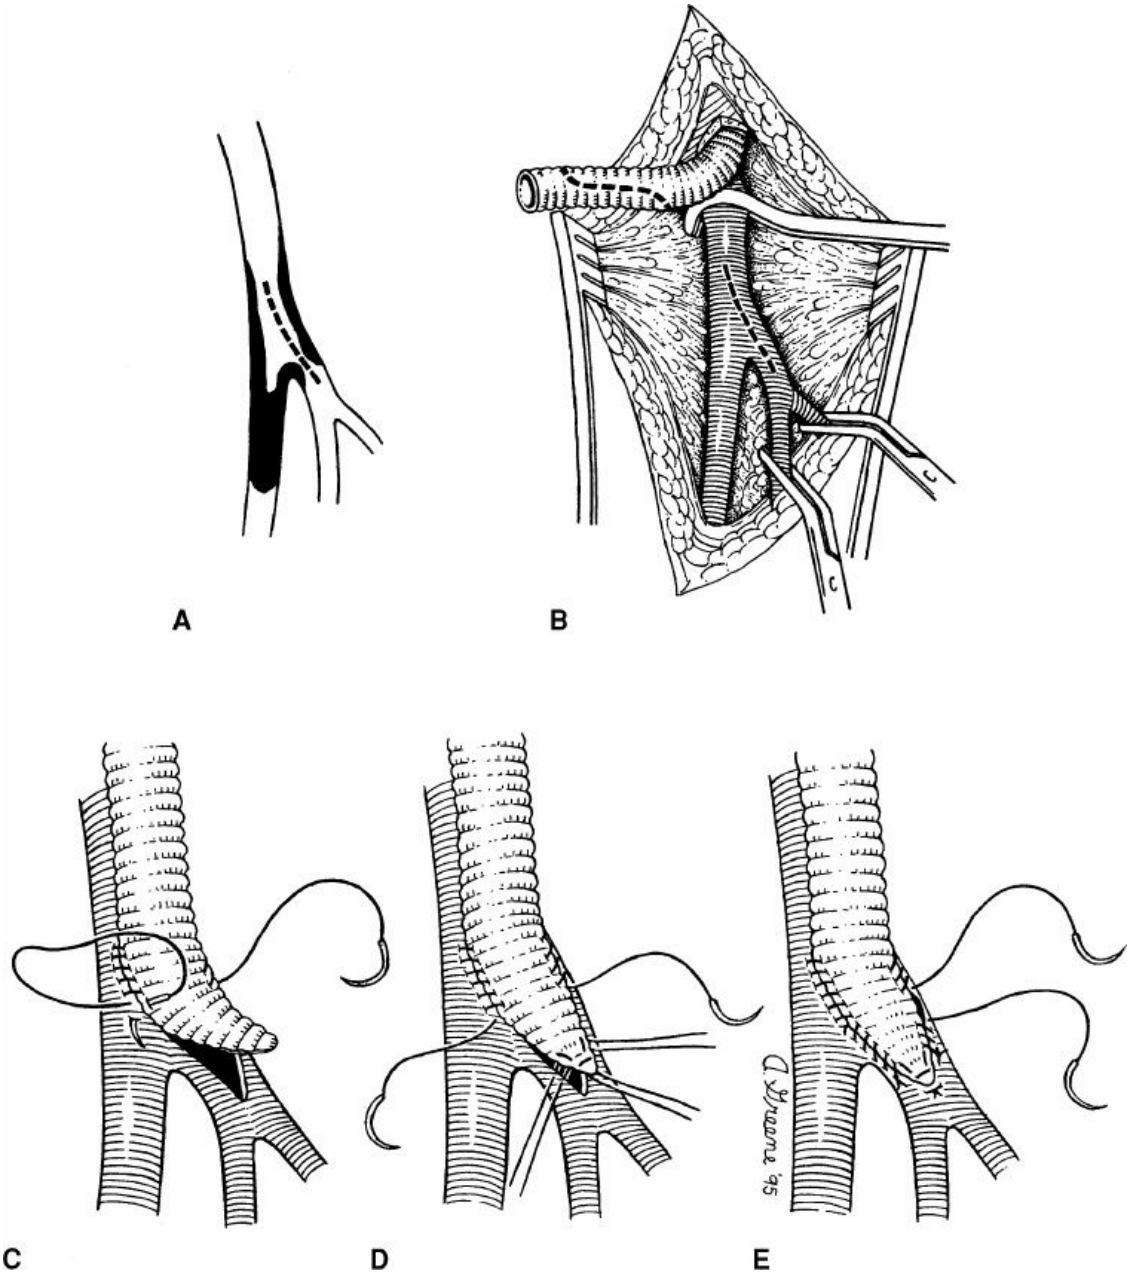

Figure 204.8. A. If significant profunda disease exists, especially with superficial femoral artery occlusion, the femoral arteriotomy is carried into the profunda beyond the orificial disease. **B.** The graft limb is cut to form a long beveled “hood” of approximate length. **C–E.** Construction of anastomosis. Interrupted mattress sutures are placed at the tip of the graft to ensure optimal visualization and suture placement and, thus, minimize the chance of constricting this critical aspect of the graft outflow tract.

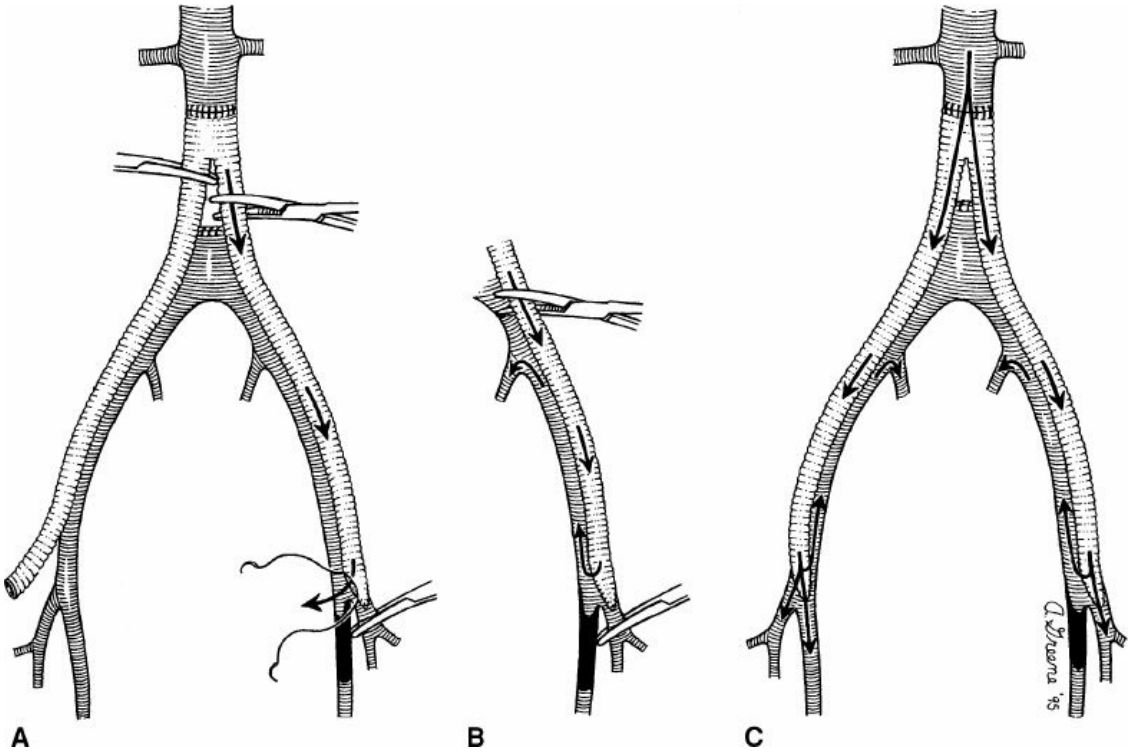

Figure 204.9. A–C. Sequence of graft limb flushing and restoration of blood flow to the extremity (see text).

End-to-Side Aortic Anastomosis

Although I prefer an end-to-end graft-to-aorta anastomosis in the great majority of patients, certain anatomic patterns of disease may make an end-to-side configuration potentially advantageous. As shown in Figure 204.10A, these anatomic patterns include patients with either a sizable accessory renal artery arising from the infrarenal aorta or a large, patent inferior mesenteric artery. Although these branch vessels may be preserved by reimplanting them into the body of an end-to-end graft, it is clearly easier to achieve this objective with the end-to-side aortic anastomosis that maintains the native antegrade aortic blood flow. More commonly, an end-to-side or “onlay” graft is used in patients in whom most of their occlusive disease is located in the external iliac arteries. In many of these patients, the aorta, common iliac, and internal iliac (hypogastric) arteries are relatively well preserved, with the latter providing the majority of collateral blood flow for the lower extremities. With such a pattern of disease, the retrograde blood flow in the external iliac arteries from the femoral artery anastomosis may not be sufficient to maintain pelvic perfusion if an end-to-end aortic anastomosis is constructed. The potential hemodynamic consequences include impotence in male patients, a higher

risk of postoperative colonic ischemia, and even rare instances of lower extremity neurologic dysfunction due to lumbosacral or cauda equina ischemia. An end-to-side graft configuration that maintains antegrade pelvic circulation via the hypogastric systems is clearly desirable in these circumstances (Fig. 204.10C).

The infrarenal aorta is exposed in an identical manner to that previously described. Although a partially occluding "side-biting clamp" may be used, I generally find it better to totally occlude the aortic segment with a standard horizontal aortic clamp and distal vertical clamp angled acutely posterior to the aorta to occlude the posterior lumbar arteries branches (Fig. 204.10B). The anastomosis is placed as cephalad as possible on the infrarenal aorta. I generally excise a bit of the aortic wall along the edges of a longitudinal arteriotomy in the excluded aortic segment to produce a slightly elliptical opening for the anastomosis. After the aorta is opened, any loose atheroma or thrombus is removed by a limited local endarterectomy. The body of the aortic graft is then tailored to the appropriate length for the arteriotomy with a bevel of ~60 degrees that extends close to the graft bifurcation. The anastomosis is constructed with two double-armed 3-0 monofilament vascular sutures with a suture starting at both the heel and the toe of the graft. These are extended in both directions (clockwise and counterclockwise), and the strands are tied to each other at the midpoint of the lateral aspect of the anastomosis. It is important to back-bleed the distal native aorta as much as possible before the completion of the anastomosis to evacuate any atheromatous debris that may have been dislodged by application of the distal clamp, since this debris may embolize when the flow is restored through the native aortoiliac vessels. Graft tunneling and femoral anastomoses are then completed as previously described.

Juxtarenal Aortic Occlusion

Juxtarenal aortic occlusion denotes a complete thrombosis of the aorta up to the level of the renal artery origins. In almost all circumstances, the causative obliterative atherosclerotic lesion itself is located more distally. Progression of disease leads to thrombosis of the aorta and retrograde propagation of clot to the level of the renal arteries unless the aortic outflow can be maintained by a patent inferior mesenteric artery or dominant lumbar arteries. Although the principles of aortobifemoral bypass are similar, several important modifications of the technique are

necessary. Specifically, the infrarenal aorta should not be clamped near the renal arteries until the occluding thrombotic material is removed for fear that the debris will be dislodged and "milked" superiorly by the clamp. This has the potential to occlude the renal arteries or cause distal embolization that may significantly compromise renal function. Although some surgeons advocate transecting the aorta several centimeters below the renal origins without applying an aortic clamp and extruding the thrombotic material using just arterial pressure, I have not found that this is satisfactory in terms of a thorough and complete evacuation of the clot. I prefer to briefly occlude the aorta above the renal arteries either at the supraceliac level via an approach through the lesser omentum or between the superior mesenteric and renal arteries as shown in Figure 204.11A. It is generally recommended that the renal arteries themselves also be temporarily occluded with Silastic vessel loops or gentle bulldog clamps to prevent embolization. After complete transection of the proximal infrarenal aorta, the thrombotic plug is teased out with an endarterectomy spatula (Fig. 204.11B). A deep endarterectomy plane is avoided to prevent creating flaps that might extend into the renal arteries and obstruct blood flow to the kidneys. After the thrombotic plug is removed, the lumen of the infrarenal aortic cuff is débrided with a gauze "peanut," the aorta is vigorously flushed, and the renal arteries are back-bleed. The aortic clamp is then reapplied at the standard infrarenal location, and flow is restored to the renal arteries. The graft is subsequently implanted using the standard technique described (Fig. 204.11C). Using this approach, the duration of renal ischemia is limited to ~15 minutes and the chances of inadequate clot removal and/or inadvertent renal embolization are minimized.

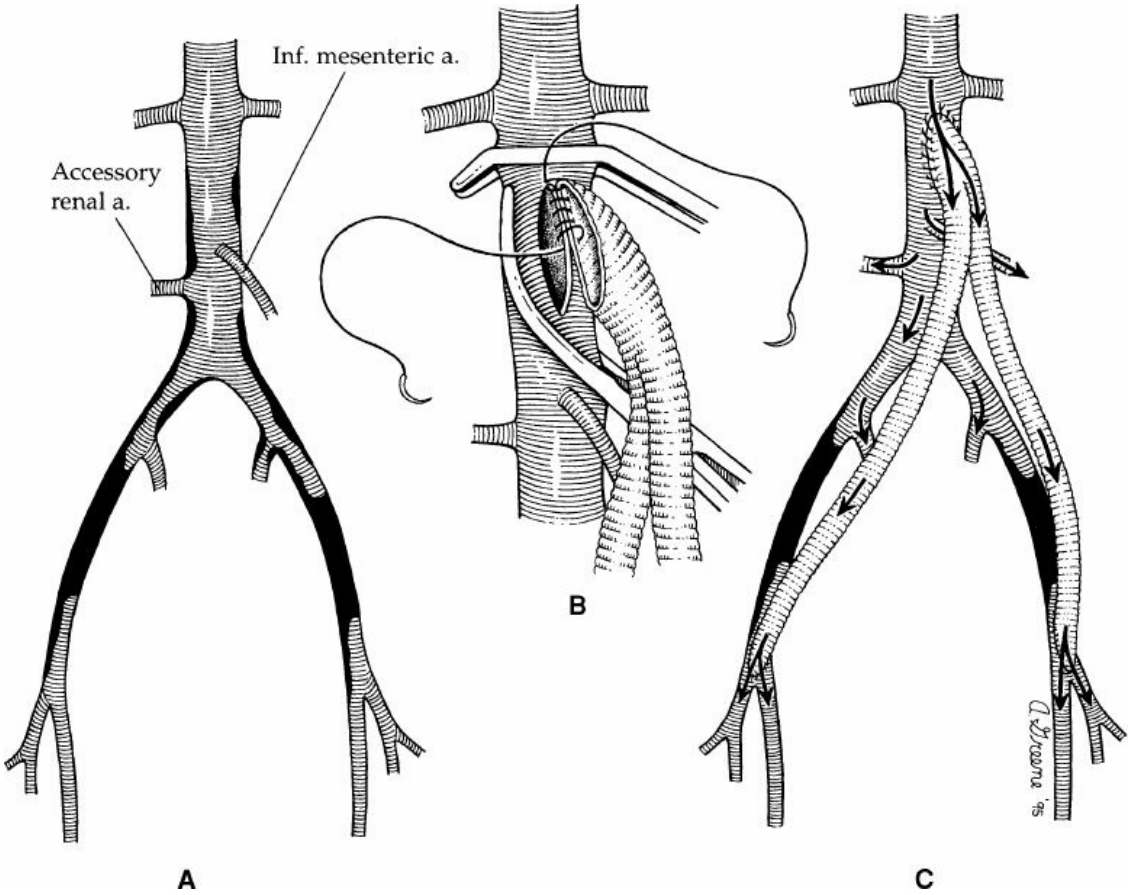

Figure 204.10. A. Pattern of aortoiliac occlusive disease favoring end-to-side proximal graft anastomosis. **B.** A longitudinal aortotomy is made in a segment of the proximal infrarenal aorta between two occlusive clamps, and a running suture is used for anastomosis of the beveled body of the bifurcation graft. **C.** Completed end-to-side bypass, with flow preserved into the pelvis via the native aortoiliac system, a patent inferior mesenteric artery, and an accessory renal artery branch arising from the aorta.

Aortoiliac Endarterectomy

Aortoiliac endarterectomy may be appropriate in 5% to 10% of patients with truly localized aortoiliac occlusive disease (type 1). Endarterectomy offers several theoretic advantages, including the fact that no prosthetic material is inserted, the infection rate is practically nonexistent, and the resulting inflow to the hypogastric arteries is likely better than after bypass procedures, thereby potentially improving erectile function in the male patient. Finally, because the procedure is totally autogenous, it may be utilized in unusual circumstances in which reoperation in a contaminated or infected field requires innovative reconstructive methods.

Despite its theoretic appeal, endarterectomy is definitely contraindicated in patients with aneurysmal disease, juxtarenal aortic occlusions, and extensive aortoiliac occlusive disease (types II and III). It is contraindicated in patients with aneurysmal disease because of the potential for continued aneurysmal degeneration in the endarterectomized segment. In patients with juxtarenal aortic occlusions, simple transection of the aorta below the renal arteries with thrombectomy of the aortic cuff followed by graft insertion as outlined above is technically easier and far more expeditious. Lastly, the success rate after extensive aortobifemoral endarterectomy is inferior to that after aortofemoral bypass and is associated with a higher incidence of early thrombosis and late failure due to recurrent stenosis. These difficulties are likely related to the fact that the external iliac artery is smaller in diameter, longer in length, more difficult to expose, and more difficult to endarterectomize than the common iliac arteries due to the adherent layers of the vessel wall. Indeed, extended aortoiliac endarterectomy has been essentially abandoned and replaced by aortofemoral bypass grafting.

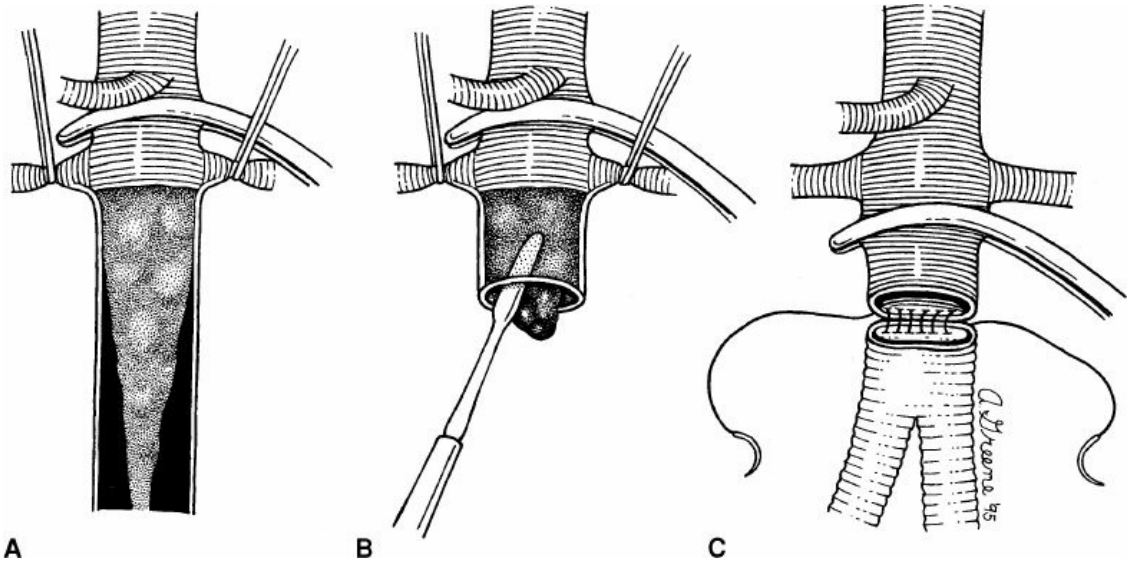

Figure 204.11. **A.** Total juxtarenal aortic occlusion is best managed by brief suprarenal clamping and protection of the kidneys by brief renal artery occlusion during removal of thrombus. **B.** With inflow occlusion, the aorta is divided several centimeters below the renal artery origin and the obstructing thrombus freed up with an endarterectomy spatula, but true endarterectomy is avoided (see text). **C.** Following removal of the juxtarenal thrombus, the aorta is clamped infrarenally, renal blood flow is restored, and standard aorta-graft anastomosis is performed.

Aortoiliac endarterectomy may be considered in carefully selected circumstances. The atherosclerotic disease process should terminate at the bifurcation of the common iliac arteries, thereby allowing the surgeon to achieve a satisfactory endpoint for the endarterectomy without extending >1 to 2 cm into the external iliac segment. Longitudinal arteriotomies are generally used with one extending caudal from the infrarenal aorta to the common iliac artery and the other confined to the contralateral common iliac artery (Fig. 204.12A). It is important to establish the endarterectomy plane at the level of the external elastic lamina and to secure a proper distal end point (Fig. 204.12B,C). The latter objective may require the use of interrupted tacking sutures. Primary closure of the arteriotomies is generally feasible (Fig. 204.12D), although a patch closure with either prosthetic materials or vein may occasionally be required. Aortoiliac endarterectomy can provide excellent and durable results when properly performed in the appropriate subset of patients. However, it must be acknowledged that patients with the localized aortoiliac occlusive disease amenable to endarterectomy are usually managed by means of angioplasty and/or stenting in current practice.

Iliofemoral Bypass

Patients with iliac occlusive disease may occasionally present with unilateral symptoms and a normal contralateral femoral pulse. Management of unilateral iliac occlusive disease remains controversial. The potential options include standard aortobifemoral bypass, unilateral aortofemoral bypass, iliofemoral bypass, extra-anatomic femoral-femoral bypass, and a variety of catheter-based or endovascular therapies. Admittedly, each option has vocal proponents and is associated with some real and/or theoretic benefits.

If unilateral disease is largely confined to the distal common and external iliac arteries, iliofemoral bypass offers a useful alternative. As shown in Figure 204.13, the common iliac artery is exposed using a retroperitoneal approach through a lower quadrant oblique abdominal incision while the femoral vessels are exposed using a separate standard vertical groin incision. An 8-mm prosthetic graft is generally used with both the proximal and distal anastomoses constructed in an end-to-side fashion. It is usually possible to obtain vascular control of the common iliac artery using a pair of straight vascular clamps placed on the proximal and distal aspects of the vessel. Patients with occlusive disease involving

the entire common iliac artery are likely better candidates for an aortounifemoral or aortobifemoral bypass procedure. The arteriotomy in the common iliac artery is extended along the longitudinal axis of the vessel between the occluding clamps, and the anastomosis is usually performed with a 4-0 monofilament vascular suture. The bypass graft is tunneled deep to the inguinal ligament along the anatomic course of the external iliac vessel. The graft is passed posterior to the ureter, but this is not usually a concern because the visceral structures and the ureter are usually reflected medially as part of the initial retroperitoneal dissection. The femoral artery anastomosis is performed as outlined above under the aortobifemoral bypass graft. Notably, the long-term patency rates for iliofemoral bypass grafts are quite good and the procedure can be performed with minimal morbidity.

Figure 204.12. A. The infrarenal aorta and iliac vessels are exposed and controlled. The surgeon should ensure that occlusive disease stops at, or just beyond, the iliac bifurcation by the preoperative arteriogram or by intraoperative palpation. An arteriotomy is begun in one common iliac artery and extended into the abdominal aorta. On the contralateral side, the arteriotomy is confined to the mid- and distal common iliac artery. **B,C.** A proper endarterectomy plane is established deep to the diseased media, and plaque mobilized with an endarterectomy spatula. It is essential to achieve a secure end point distally in both iliac arteries. If disease does not “feather out” distally, the arteriotomies may be extended 1 to 2 cm into each external iliac and the intimal flap in the external iliac may be tacked down with several 5-0 and 6-0 sutures. **D.** Closure of the arteriotomies can usually be performed primarily, but a patch closure may be necessary for smaller vessels. (From Brewster DC. Direct open revascularization for aortoiliac occlusive disease. In: Zelenock GB, Huber TS, Messina LM, et al., eds. *Mastery of Vascular and Endovascular Surgery.* Philadelphia, PA: Lippincott Williams & Wilkins, 2005.)

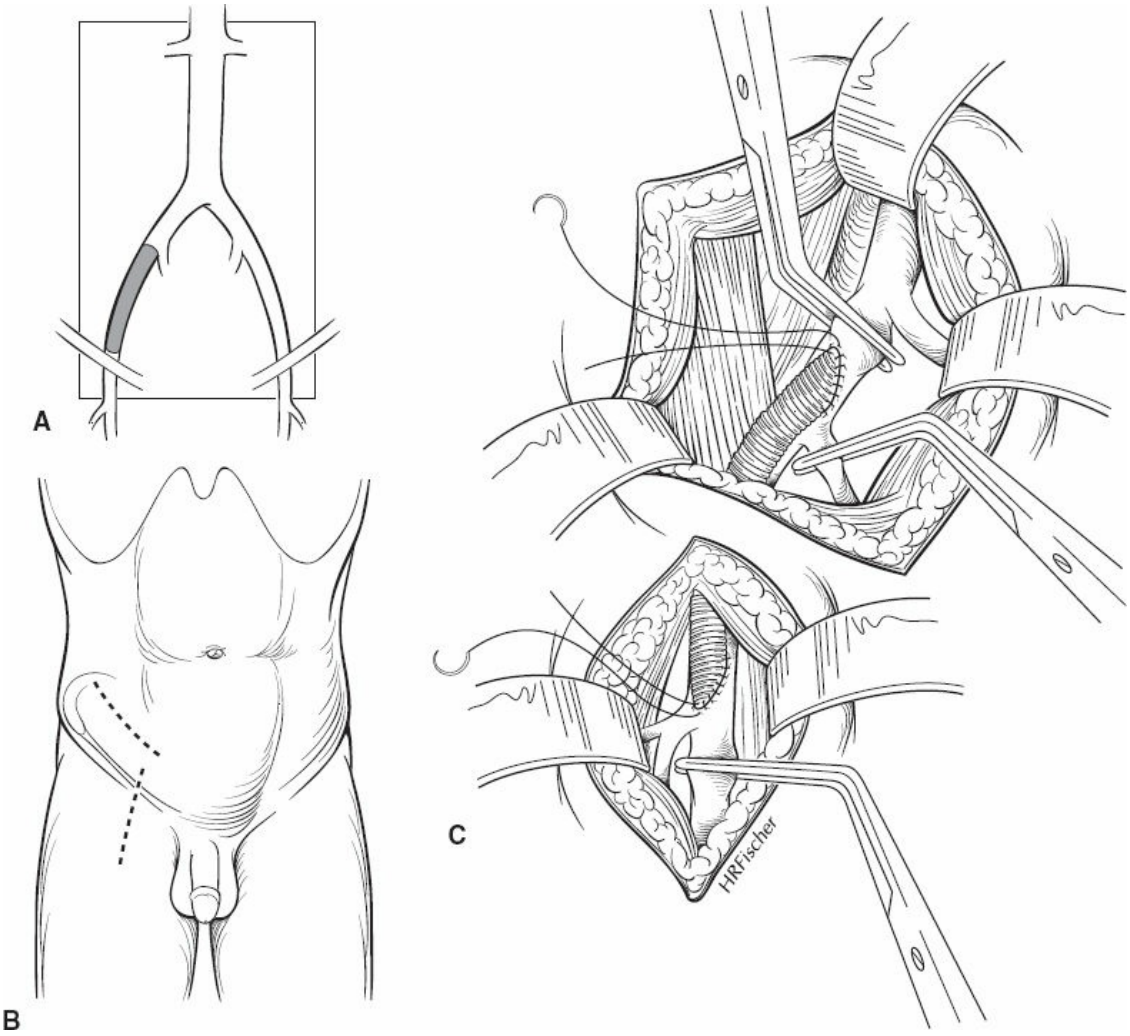

Figure 204.13. A. Disease must be limited to the distal common iliac and/or external iliac artery, thereby allowing a proximal anastomosis to a relatively disease-free segment of proximal common iliac artery. **B.** Separate lower quadrant abdominal wall and vertical groin incisions are preferred. **C.** The in-line graft is placed retroperitoneally and tunneled posterior to the ureter for an end-to-side anastomosis to the femoral artery using the standard technique. (From Brewster DC. Direct open revascularization for aortoiliac occlusive disease. In: Zelenock GB, Huber TS, Messina LM, et al., eds. *Mastery of Vascular and Endovascular Surgery.* Philadelphia, PA: Lippincott Williams & Wilkins, 2005.)

COMPLICATIONS

Aortobifemoral bypass and other direct revascularization procedures for aortoiliac occlusive disease are major operative procedures and are associated with multiple potential complications. Fortunately, the overall perioperative mortality rate is <5% and usually in the 1% to 2% range for

most large institutional series. The majority of the perioperative deaths are related to cardiac causes as would be predicted considering the patient population and the systemic nature of atherosclerosis. This observation underscores the importance of identifying and optimizing all significant coronary artery diseases during the preoperative assessment. The overall major complication rate should be <10% and includes the complications related to all major intraabdominal vascular procedures as well as those related more specifically to aortoiliac bypass. The former “generic” group of complications includes postoperative organ system failure (cardiac, pulmonary, renal, and pancreas), inadvertent intraoperative injury to the visceral structures (bowel, ureters, major veins, and spleen), abdominal wound breakdown, and intraabdominal bleed. Although these “generic” complications cannot become completely eliminated, they can be reduced by the guiding surgical principles of proper patient selection, thorough preoperative preparation, attention to detail intraoperatively, and a commitment to a technically perfect operation. The specific complications related to the aortoiliac bypass include colon/pelvic ischemia, atheroembolization, lower extremity ischemia, male sexual dysfunction, and groin wound complications.

Pelvic ischemia after aortoiliac bypass is fortunately very rare, although it can be both devastating and irreversible. It can manifest as colonic ischemia, infarction of the buttock musculature/surrounding skin, or cauda equina/lumbar plexopathy with neurologic deficit. The responsible mechanism is interruption of the pelvic blood flow. This has led to the generally accepted principle of maintaining flow in at least one internal iliac artery. The status of the pelvic circulation should be assessed during the operative planning as mentioned above, and consideration should be given to performing an end-to-side aortic anastomosis when indicated by the distribution of occlusive disease. Alternatively, one (or both) of the internal iliac arteries may be revascularized directly by using a limb of the bifurcated graft, then jumping off that limb down to the femoral artery in the groin with a second prosthetic graft.

Atheromatous debris may embolize at any time during the operative procedure, although the most vulnerable times occur when the vessels are manipulated such as during dissection or clamp application. The sequelae are dependent upon the size of the debris and the distribution of the involved vessels. Macroscopic particles may occlude the major, named vessels with the debris frequently lodging at the various arterial

bifurcations. Fortunately, the majority of these are amenable to removal with a thromboembolectomy catheter. In contrast, the microscopic particles lodge in the corresponding sized vessels and are not usually amenable to removal or treatment. They can result in a wide spectrum of injury ranging from the classic “blue toe” to extensive tissue loss of the buttock and lower extremity. The potential for embolization may be minimized using the strategies outlined above in the technique section, including rigorous flushing of the vessels before reperfusion with selective flushing into the pelvic and profunda femoris circulation before reestablishing flow to the superficial femoral artery.

Patients may develop ischemia of their lower extremities that may present either intraoperatively after the completion of the bypass or during the early postoperative period. The specific concerns vary slightly with the temporal presentation but include atheroemboli, in situ thrombosis, and technical problems. The remedial treatment is contingent upon the precipitating cause, although it is imperative that all potential technical defects such as a twist/kink in the graft limb or a narrowed anastomosis be excluded. The femoral anastomosis is usually interrogated first and thromboembolectomy catheters are passed both proximally (graft limb/aorta) and distally (superficial/profunda femoral). A thromboembolectomy of the popliteal and tibial vessels through a below-knee popliteal artery exploration may be necessary if the femoral thromboembolectomy is unsuccessful and no obvious causes for the problem identified. Infrainguinal revascularization is occasionally necessary in patients with persistent lower extremity ischemia, although the morbidity/mortality rates of combined inflow/outflow procedures are significant.

Male sexual dysfunction can occur after aortoiliac revascularization due to either inadequate pelvic perfusion or interruption of the autonomic nerves that course over the distal aorta and common iliac arteries. The reported incidence ranges from 5% to 15%. Notably, the injury to the autonomic nerve results in the disruption of the internal sphincter mechanism and retrograde ejaculation. The status of the pelvic circulation should be factored into the operative plan, and care should be exercised during the procedure to avoid injury to the responsible nerves. Furthermore, it is imperative that the potential for sexual dysfunction be discussed with patients preoperatively.

POSTOPERATIVE MANAGEMENT

The immediate postoperative care after aortofemoral bypass is comparable to that after other major intraabdominal vascular procedures. Patients are usually monitored in the intensive care unit on the night of their procedure, and then transferred to the general care floor. They are seen by the physical therapists when they reach the general care floor and are encouraged to start ambulating early. Their nasogastric tube is usually removed on the 2nd or 3rd postoperative day or when bowel function returns. Patients are usually discharged on their 6th or 7th postoperative day, but have to be sufficiently independent to care for themselves, eating adequately, and having normal bowel function. Patients are seen in the outpatient clinic biweekly until their wounds are healed and then at 6-month intervals indefinitely. Ankle brachial indices are obtained in the early postoperative period and at each 6-month follow-up visit.

The long-term outcome after direct aortoiliac revascularization is excellent. The reported patency rates after aortobifemoral bypass range from 80% to 90% at 5 years. The corresponding patency rates for aortoiliac endarterectomy are comparable, while those for unilateral iliofemoral bypass are nearly as good. Unfortunately, the long-term patient survival after aortoiliac bypass is only 75% and less than the corresponding age-matched controls. Majority of the late deaths are secondary to cardiovascular causes and further emphasize the importance of aggressive medical management of coronary artery disease and the associated risk factors for atherosclerosis. Approximately 5% of the patients may develop late anastomotic pseudoaneurysms, although the incidence is dependent upon the duration of follow-up and may exceed this value. These occur most commonly at the femoral anastomoses and can be related to technical errors, suture breakage, graft infection, and degeneration of the native artery, among other causes. The incidence of prosthetic graft infections after aortoiliac bypass is ~1% to 2%.

EDITOR'S COMMENT

The chapter by Dr. Brewster is written by a master surgeon who has a long published clinical experience with the aortofemoral bypass (AFB) technique for aortoiliac occlusive disease (AIOD). This is a procedure that is decreasing in number, but provides durable and safe revascularization (Bredahl K, Jensen LP, Schroeder TV, et al. Mortality and complications after aortic bifurcated bypass procedures for chronic aortoiliac occlusive disease. *J Vasc Surg* 2015;62:75–82). Certain factors may portend worse outcomes; namely, younger aged patients with small aortas and these factors should be kept in mind when choosing who to intervene on (Reed AB, Conte MS, Donaldson MC, et al. The impact of patient age and aortic size on the results of aortobifemoral bypass grafting. *J Vasc Surg* 2003;37:1219–25). I also am hesitant to perform these procedures on active smokers. There are numerous good technical points and pearls of wisdom throughout this chapter. There are several things that I do differently and will comment on.

First, I don't agree arteriography is required for most preoperative assessment of aortoiliac disease. Indeed, the high-quality thin-cut CT scans

denote accurately the anatomy from the aortic segment all the way to the superficial femoral arteries. Certainly, below the knee arteries are less well imaged, but saving a patient an invasive diagnostic procedure seems worthwhile for AIOD treatment planning.

Second, with regard to preoperative preparation, Swan-Gantz catheterization is rarely used or needed for these patients. If one is going to be clamping below the renals, a central line may occasionally be needed if the patient has poor intravenous (IV) access, but we try to get away from deep lines due to infection risk. Indeed, two large bore peripheral IVs should suffice. Furthermore, intraoperative transesophageal echocardiography is currently used by our anesthesiologists to guide intraoperative resuscitation on a real time basis.

In compliance with nationwide quality measures, prophylactic IV cefazolin is usually only continued for 24 hours rather than longer, as suggested in the chapter. If the patient is MRSA positive, we use vancomycin in addition to cefazolin (Alexander JW, Solomkin JS, Edwards MJ. Updated recommendations for control of surgical site infections. *Ann Surg* 2011;253:1082–93).

In terms of tunneling, this is critical technical aspect of the AFB as it is a blind procedure. Going fingertip to fingertip for safety as described makes a lot of sense. Rather than putting a tape or a Penrose drain, I use a curved sponge stick that then just sits in place while we are doing the proximal anastomosis. Perforating the colon with poor tunneling technique is a disaster, but it does occur.

Typically, if we do an end-to-end aortic bypass, we will use a continuous felt buttressing if the wall is particularly thin. This has saved a lot of issues with regard to problematic anastomotic bleeding. Whether the proximal anastomosis is done end to end or end to side, personally I don’t think it matters. I have found no data to support one over the other. Rather, it is whichever the surgeon is most comfortable with as well as what the anatomic issues are on the preoperative CT scan.

I do fully agree with Dr. Brewster that patients with a totally occluded aorta will ensure renal artery control and blowing out the thrombotic debris prior to any type of clamping. We may even occasionally place a suprarenal and then an infrarenal clamp, flush the material, and then clamp infrarenally as described in the chapter. Patients who have atherosclerotic debris embolization to the kidneys often go into complete renal failure. Even worse, if this material embolizes into the superior mesenteric artery, the patient often develops a diffuse gut ischemia and death.

In terms of other technical aspects, dividing the circumflex iliac vein electively rather than thinking you will be able to tunnel over these and not tear them always makes sense. It only takes one time where you have torn one of these veins high under the inguinal ligament (and after a liter of blood loss finally get control) to emphasize the benefit of this prophylactic measure.

I would note the postoperative management is most often complicated by

groin complications these days (Burke CR, Henke PK, Hernandez R, et al. A contemporary comparison of aortofemoral bypass and aortoiliac stenting in the treatment of aortoiliac occlusive disease. *Ann Vasc Surg* 2010;24:4–13). I speculate that multiple prior catheterizations and other endoluminal injury the lymphatic system for leaks in the groin. We not frequently see up to 10% to 15% of lymphatic leaks after groin incisions for aortofemoral or other femoral open access procedures: both our own patients and transfers from other institutions. Certainly closing the groin in multiple layers, absorbable skin sutures, and skin glue seems to cut down on this. Whether an external vacuum dressing type device will help decrease this even further is suggested by one study (Matatov T, Reddy KN, Doucet LD, et al. Experience with a new negative pressure incision management system in prevention of groin wound infection in vascular surgery patients. *J Vasc Surg* 2013;57:791–5) and bears more prospective evaluation.

Peter Henke

205 Aortoiliac Occlusive Disease: Extraanatomic Bypass

Enjae Jung, Gregory J. Landry, and Gregory L. Moneta

INTRODUCTION

Extraanatomic bypass typically refers to femorofemoral, axillofemoral, and axillobifemoral bypasses. The technique was developed in the 1950s and 1960s. Freeman and Leeds performed the first femorofemoral bypass in 1952 using an endarterectomized superficial femoral artery tunneled subcutaneously to the contralateral femoral artery, and both Blaisdell and Louw reported the first axillofemoral bypasses independently in 1963. Since then, the treatment of aortoiliac occlusive disease has dramatically evolved as endovascular techniques continue to improve and indications for their use continue to expand. Although extraanatomic bypass is largely regarded as a second-choice alternative to standard aortoiliac and aortofemoral reconstruction, it can be a life- and limb-saving procedure for a patient requiring aortofemoral reconstruction who is not a candidate for an open abdominal aortoiliac or aortofemoral grafting or a percutaneous revascularization. Extraanatomic bypass, however, remains a reliable and durable option for lower extremity revascularization that should be a part of the armamentarium of vascular surgeons.

INDICATIONS AND CONTRAINDICATIONS

Extraanatomic bypass has traditionally been reserved for the treatment of symptomatic aortoiliac occlusive disease in patients at high risk for direct aortoiliac replacement either from severe systemic illness increasing operative risk or in patients with local factors increasing the risk or difficulty of standard aortofemoral reconstruction. These factors include prior aortoiliac procedures, prior radiation, extensive intra-abdominal adhesions, severe aortic calcification, abdominal malignancy, intra-abdominal infection, aortic or aortic graft infection, colostomy or ileostomy, and enterocutaneous fistula. While infrequently used, endovascular repair of abdominal aortic aneurysms with an aortouniiliac

device has also resulted in an additional indication for femorofemoral bypasses. Femorofemoral or unilateral axillofemoral bypass is indicated for unilateral aortoiliac occlusive disease, with axillobifemoral bypass indicated for bilateral disease.

Extraanatomic bypass, similar to any surgical procedure, is contraindicated in patients with extreme risk for surgery or with a very short life expectancy. However, since femorofemoral bypasses can be performed with spinal or epidural anesthesia, and monitored local anesthesia can be used for both femorofemoral and axillofemoral bypasses, there are relatively fewer patients who are truly medically contraindicated for these procedures.

PREOPERATIVE PLANNING

Patients with aortoiliac occlusive disease of sufficient severity to warrant extraanatomic bypass grafting typically have absent or weak femoral pulses. Noninvasive vascular examination of the lower extremities is helpful in documenting the severity of ischemia and level of distal disease. Computed tomography angiography (CTA), magnetic resonance angiography (MRA), or digital subtraction angiography (DSA) is routinely performed for elective cases, but often is not essential in urgent or emergent cases. Unilateral iliac artery angioplasty and stenting can occasionally be performed to facilitate femorofemoral bypass.

The adequacy of axillary inflow can be determined noninvasively in most cases. Blood pressure in each arm is measured to select the optimal site for the proximal anastomosis. If pressures are equivalent, the right axillary artery is preferred for the proximal anastomosis, since the left subclavian artery has a higher reported incidence of developing atherosclerotic occlusive disease. A pressure difference >15 mm Hg between arms indicates significant occlusive disease and necessitates further workup, typically with upper extremity arteriography or CT angiography. Subclavian artery angioplasty with or without stenting can be performed when indicated to improve axillary artery inflow.

Prophylactic intravenous antibiotics, usually a first-generation cephalosporin, are administered within an hour prior to incision. Aspirin therapy (81 mg/day) is started preoperatively and continued indefinitely postoperatively. Ideally patients are also treated with a statin medication. Patients with an identified hypercoagulable state or a history of multiple graft failures should also be considered for long-term anticoagulation.

SURGICAL TECHNIQUE

Anesthesia

General anesthesia with endotracheal intubation is preferred. Femorofemoral bypasses can be performed with spinal or epidural anesthesia in higher risk cases. Monitored anesthetic care with local anesthesia can be used for axillofemoral and femorofemoral bypasses. Tunneling of the grafts will require supplemental sedation.

Patient Positioning and Draping

Patients are supine. For axillofemoral bypasses, some surgeons perform the operation with the donor side arm at the patient's side, but we prefer the arm abducted to 90 degrees. This position maximizes the distance between the axillary and femoral arteries, thereby minimizing tension on the axillary anastomosis postoperatively. It also allows visualization of the flank and lateral chest wall while passing the graft tunneling device to ensure that it passes over and not under the costal margin. Femoral regions are widely prepped and draped for femorofemoral bypasses, and the supra- and infraclavicular regions, axilla, chest, abdomen, and femoral regions for axillofemoral bypasses. Ideally, the lower extremities are prepped and draped into the operative field in case unanticipated adverse circumstances require additional infrainguinal revascularization. The operative sites are then covered with an iodine-impregnated incision drape. To minimize operative time, a multiple team approach is preferred if possible, with separate surgical teams operating simultaneously at each of the operative sites.

Femoral Artery Dissection

The femoral arteries are exposed through bilateral vertical groin incisions. Transverse or oblique groin incisions can be used, and should be considered in obese patients, but are less versatile if exposure must be extended distally. The choice of site for the distal anastomosis is based on patient circumstances and vessel patency, which is determined by preoperative imaging. Accordingly, the distal graft anastomoses may be to the common, profunda, or superficial femoral arteries. In most cases, the common femoral artery just proximal to the common femoral bifurcation is the preferred site for the distal anastomosis. Occasionally, endarterectomy of the outflow vessels is required. In special circumstances, distal anastomoses may be to more distal portions of the

profunda or superficial femoral arteries, and lateral approaches to these vessels may be used, especially in the presence of infection of previously placed femoral grafts or extensive scarring from multiple previous operations in the groin. In obese patients, more distal anastomotic sites are preferred to minimize perianastomotic graft kinking when the patient is in a sitting position.

Axillary Artery Dissection

We use the first part of the axillary artery for the proximal anastomosis. It only has a single collateral branch and is relatively fixed in position, so placing the axillary anastomosis as medially as possible avoids tension on the axillary anastomosis when the arm is abducted. In addition, the brachial plexus nerves interdigitate with the axillary artery and its branches. The first part of the artery lies anterior to the brachial plexus. The divisions and cords of the brachial plexus lie anterior to the third part of the artery. The second part of the axillary artery is enveloped by the brachial plexus cords passing from posterior to anterior. These anatomic relationships point out the advantages of using the first part of the axillary artery for the proximal anastomosis.

An infraclavicular incision is made approximately two fingerbreadths below the middle third of the clavicle, not directly parallel to the clavicle but along the anticipated course of the axillary artery. The fibers of the pectoralis major muscle are bluntly separated, revealing the clavipectoral fascia, which is incised. The pectoralis minor muscle is mobilized but not divided and serves as the lateral border of the dissection. If necessary, the pectoralis minor muscle may be divided to improve operative exposure but the graft should always be placed on the axillary artery medial to the pectoralis minor muscle. The axillary vein is mobilized and retracted caudally to reveal the axillary artery, a step that requires ligation and division of the cephalic vein and other small venous branches along the cephalad portion of the vein. The axillosubclavian arteries are considerably more fragile than the femoral arteries, and care must be taken not to injure them or the adjacent nerves and veins during dissection or during placement of retractors or vascular clamps. The thoracoacromial artery is left intact and used as the marker for the lateral corner of the anastomosis. Sufficient length of artery is dissected and mobilized medial to the thoracoacromial artery for the proximal anastomosis.

Femorofemoral Tunnel

A subcutaneous, suprapubic, inverted U tunnel is created bluntly between the two femoral incisions with fingers, curved aortic clamp, or tubular tunneler. The tunnel lies directly anterior to the external oblique and anterior rectus fascia. By placing the tunnel directly on top of the fascia and avoiding placement of the tunnel in the suprapubic fat, motion of the graft with positional changes and kinking in the groin area is minimized, which is particularly important in obese patients with a large suprapubic pannus. Dacron or polytetrafluoroethylene (PTFE) grafts have been used with equally good results. Cryopreserved femoral vein also is a suitable conduit and may have advantages when there is active infection in the groin. We prefer, however, in most cases, an externally supported PTFE graft (8 mm × 40 cm) for the cross-pubic graft.

Axillofemoral Tunnel

A subcutaneous tunnel is begun at the ipsilateral femoral incision. The standard tunnel passes medial to the anterior superior iliac spine and then along the lateral aspect of the abdomen in the midaxillary line. Grafts tunneled too anterior to the midaxillary line are prone to kinking due to the costal margin being more prominent anteriorly than in the midaxillary line. The tunnel continues posterior to the pectoralis major and minor muscle into the axilla (Fig. 205.1). The use of a long graft tunneling device allows the tunnel to be made without the need for counter incisions in all but taller patients. An externally supported PTFE graft (8 mm × 70 to 90 cm) is passed through the subcutaneous tunnel.

Graft Anastomoses

Femorofemoral Bypass

After completion of the tunnels, intravenous heparin is administered at a dose of 100 units/kg. The arteries are controlled proximally and distally with atraumatic vascular clamps or Silastic vessel loops. Bilateral end-to-side anastomoses are created to femoral arteriotomies with CV-6 PTFE sutures. The arteriotomies are typically 2.5 times the diameter of the graft in length. The anastomosis to the outflow artery depends on the patency of the outflow vessels. If the superficial and profunda femoral arteries are patent, the anastomosis can be placed on the common femoral artery. If the superficial femoral artery is occluded, as is often the case in patients with advanced atherosclerosis, the distal anastomosis can still be placed on the common femoral artery if the origin of the profunda femoral artery is

widely patent. The anastomosis can be extended across the profunda femoris origin or placed on the profunda itself if there is occlusive disease involving the origin of the profunda femoris artery.

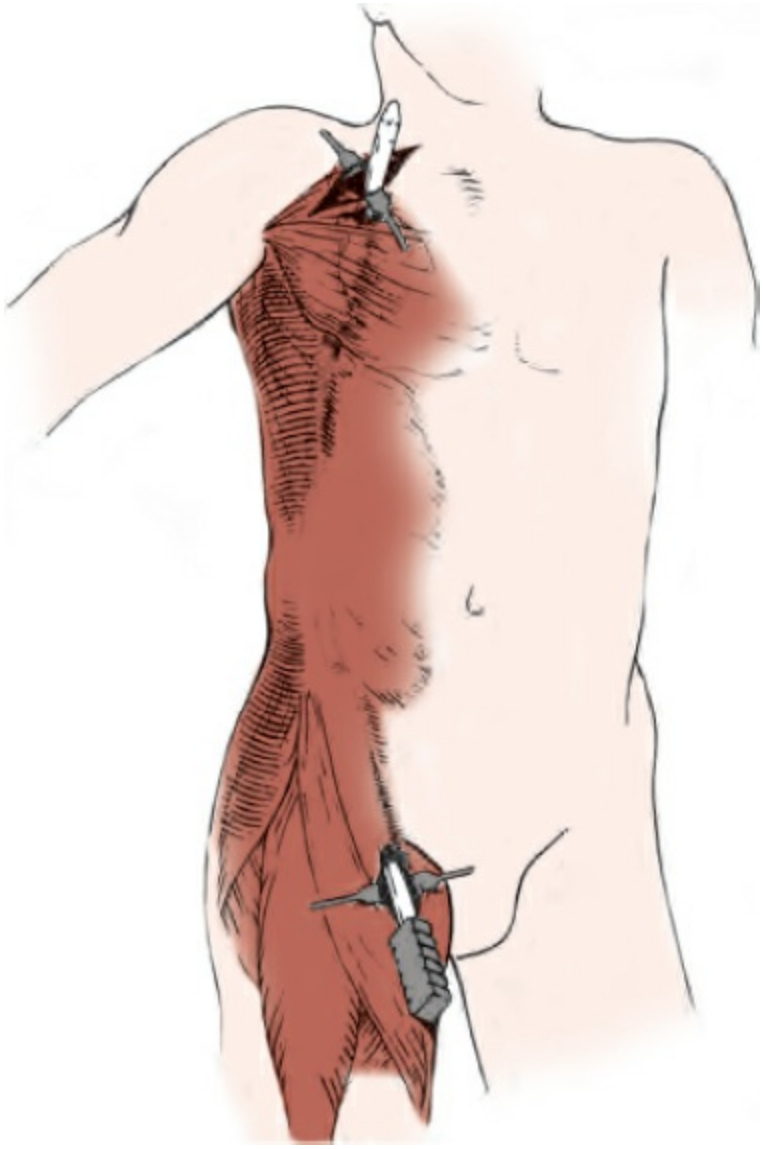

Figure 205.1. Route of subcutaneous axillofemoral tunnel made with a graft tunneler. The tunnel runs medial to the anterior superior iliac spine, along the midaxillary line, and posterior to the pectoralis minor muscle.

The anastomosis is at risk for kinking in both the coronal and sagittal planes, and careful attention is required during placement of the anastomosis to avoid this. Using a slight excess of graft material and making the tunnel as a continuous curve between the femoral incisions help reduce the tendency of the graft to kink at the heel of the anastomoses in the coronal plane. Kinking in the sagittal plane can be more pronounced

in an obese patient or patient with a more protuberant abdomen. Performing the anastomosis to a more distal part of the femoral arterial system or making a shorter arteriotomy and anastomosis can mitigate this. Extending the anastomosis at least partially onto the profunda may also be very helpful in reducing the tendency of the graft to kink in both the sagittal and coronal planes.

The graft is spatulated to create a “cobra-head” anastomosis. Sutures are placed in the heel and toe of the anastomosis and are run continuously out of each corner. Alternatively, a single suture can be placed in the heel and sewn circumferentially. The graft and vessel edges are everted, with suture bites approximately 1 mm in depth and travel between bites. The arteries are flushed and backbled prior to completion of the anastomosis.

Axillofemoral Bypass

The axillary anastomosis is also performed in an end-to-side fashion using a CV-5 PTFE suture. A longitudinal arteriotomy on the anterior-inferior surface of the first part of the axillary artery, medial to both the pectoralis minor muscle and the thoracoacromial artery, is made. The graft is routed parallel and adjacent to the axillary artery posterior to the pectoralis minor muscle for approximately 8 to 10 cm before beginning a gentle curve at the beginning of its inferior course (Fig. 205.2). This redundancy allows for arm extension, distributing any potential tension across the curve of the graft rather than at the proximal anastomosis. This is intended to prevent proximal anastomotic disruption. A finger is placed along the graft in the axilla to maintain the graft redundancy at this location, and the graft is then pulled tautly from the inguinal incision to remove any redundancy from the longitudinal portion of the tunnel. The graft is thereby mobile in its area of axillary redundancy but otherwise relatively immobile.

The distal end of the axillofemoral graft is then anastomosed in an end-to-side fashion to the cobra-head of the ipsilateral side of the femorofemoral graft (Fig. 205.3). This configuration maximizes the flow through the entire length of the axillofemoral graft. The final graft configuration is shown in Figure 205.4. When a femorofemoral graft is not simultaneously performed, the distal anastomosis is placed on the common, superficial, or profunda femoral artery depending on the quality of the arteries and their outflow. Hemostasis of needle-hole bleeding is obtained using topical spray thrombin and Gelfoam or other commercially available topical sealants. Heparin is reversed with protamine sulfate at a dose of 1 mg/100 units heparin given.

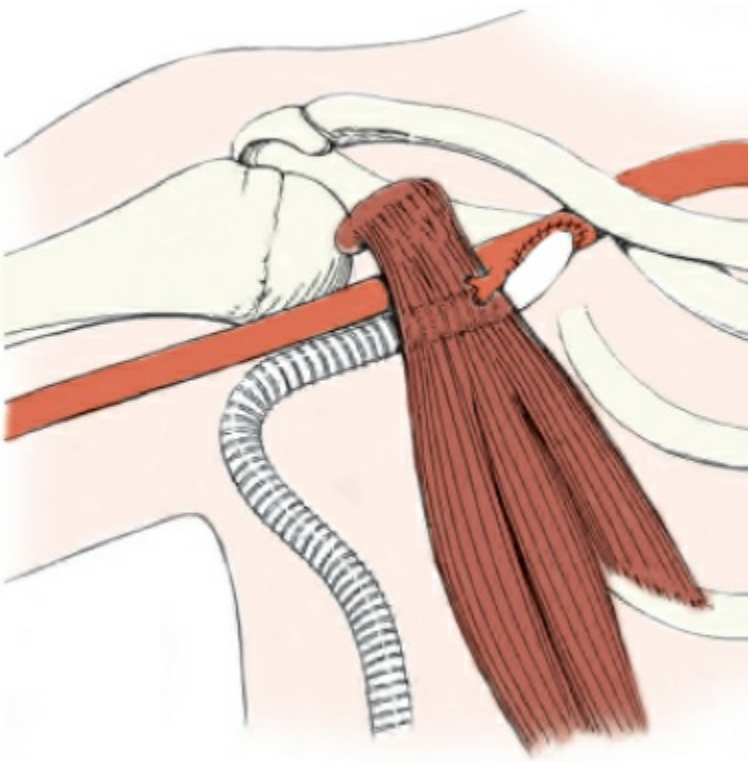

Figure 205.2. Axillary anastomosis showing end-to-side graft anastomosis. The anastomosis is to the first part of the axillary artery. The graft is routed parallel and adjacent to the axillary artery posterior to the pectoralis minor muscle for 8 to 10 cm before forming a gentle curve to its inferior course.

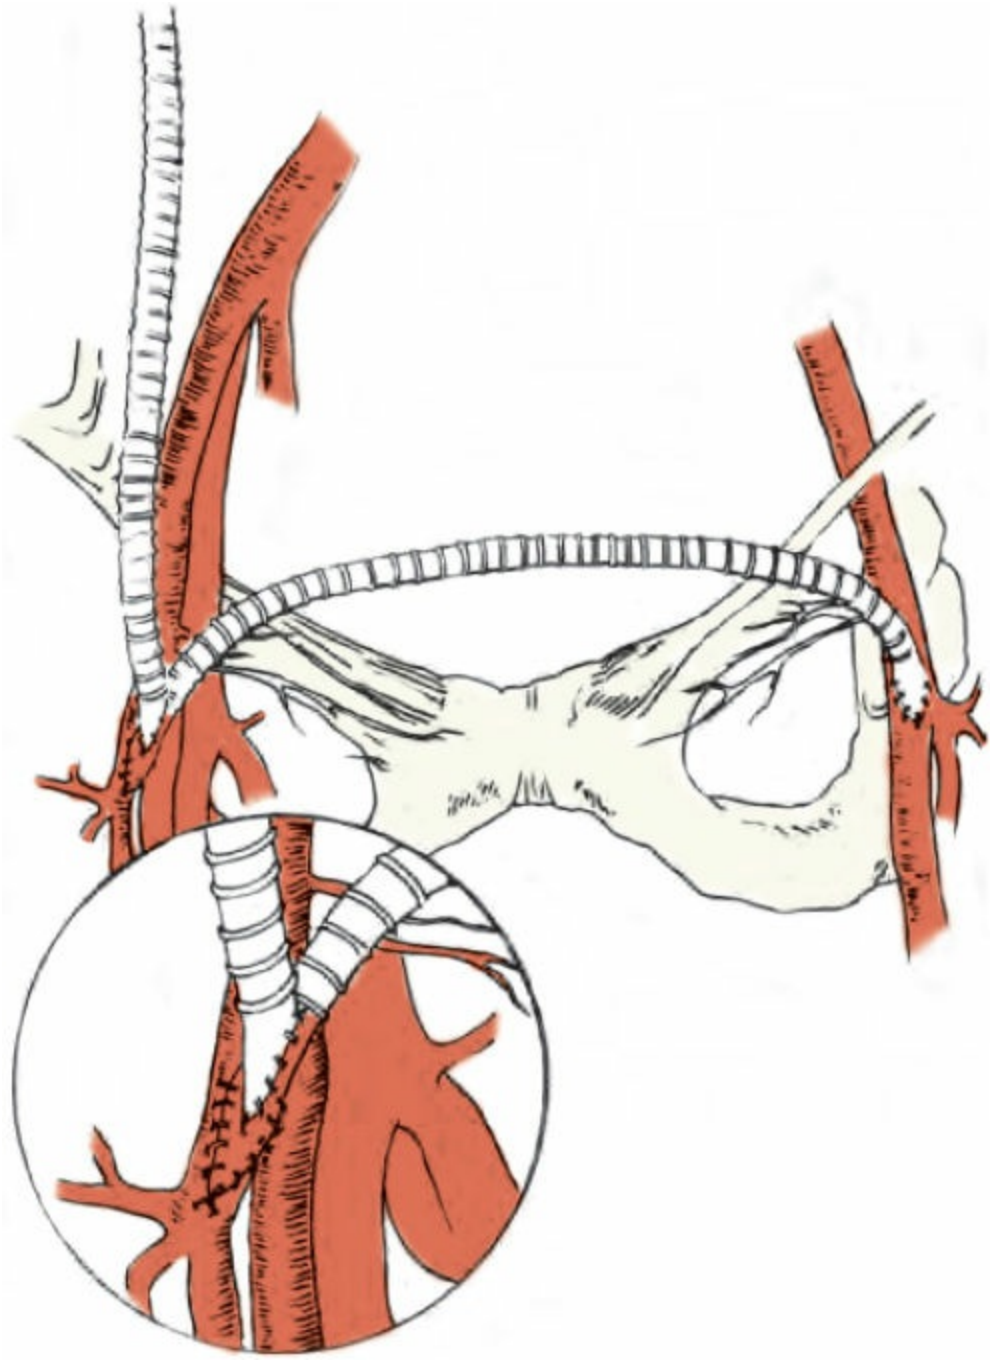

Figure 205.3. Distal axillofemoral anastomoses. The femoral–femoral graft is anastomosed in an end-to-side fashion to the femoral arteriotomies. The distal end of the axillofemoral graft is anastomosed in an end-to-side fashion to the femoral–femoral graft (*inset*).

Wound Closure

Following wound irrigation, all incisions are closed in three layers. In the femoral incision, running absorbable sutures are used to cover the grafts and the subcutaneous tissue. In very thin patients or where risk of wound

breakdown is increased, a rotational sartorius muscle flap can be placed over the graft in the groin. Running absorbable sutures are also used in the axillary incision to close the pectoral fascia and subcutaneous tissue. The skin is closed with a running absorbable subcuticular suture.

Special Situations

Aortobifemoral Graft Infection

Aortic graft infection can be treated with axillobifemoral grafting followed by complete excision of the infected graft. This sequence allows the performance of the sterile procedures prior to exposure of the infected field. In addition, it eliminates a prolonged period of leg ischemia prior to revascularization. The successful performance of axillofemoral grafting prior to excision of infected grafts requires special attention to the technique of patient preparation and draping, as well as modified graft tunneling and arterial exposure.

Most aortobifemoral graft infections are caused by Staphylococcal species, although other bacterial species can also be involved. Patients should be placed on the appropriate antibiotic coverage as soon as graft infection is noted, and this should be continued throughout the perioperative period. Prior to entering the operating room, any open wounds or sinus tracts are packed with iodine-soaked gauze and covered with an iodine-impregnated incision drape. The entire operative field is then sterilely prepared and covered with a complete layer of sterile occlusive plastic.

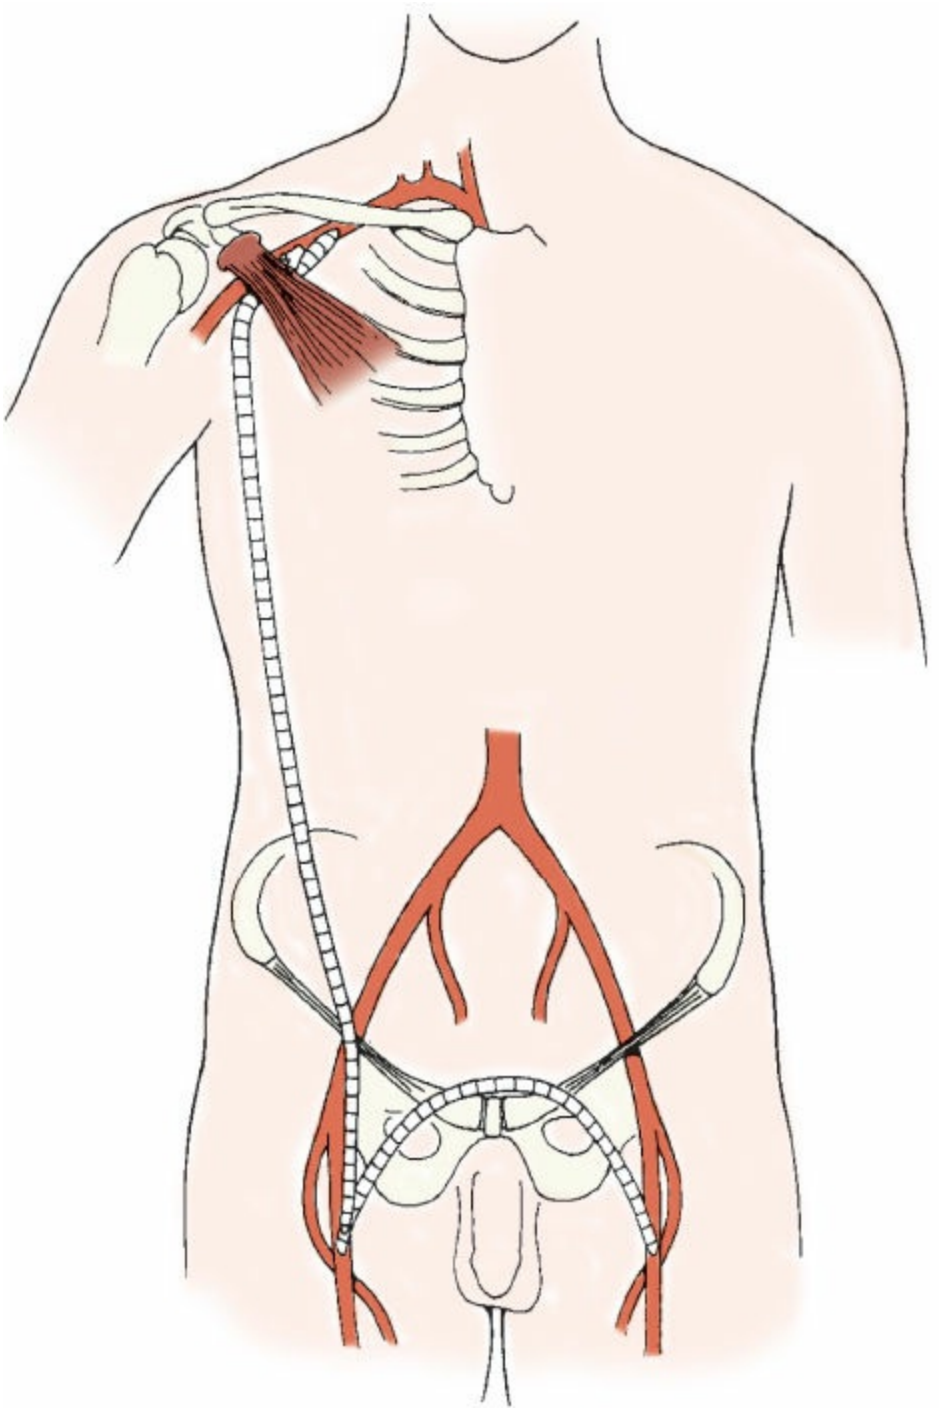

Figure 205.4. Final graft configuration of axillobifemoral bypass.

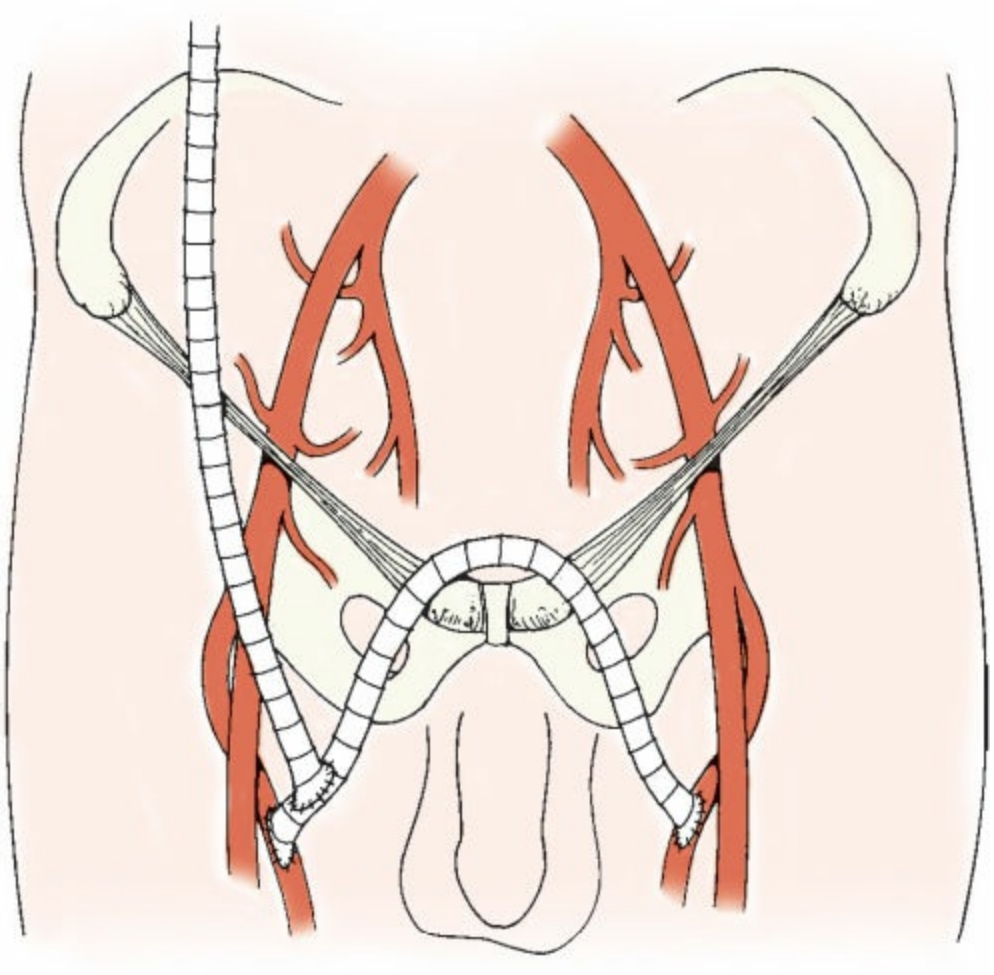

Figure 205.5. Axillofemoral graft configuration in the presence of groin infections. The axillofemoral graft is routed lateral to the anterior superior iliac spine. Femoral anastomoses are made to midsuperficial femoral arteries. The femoral–femoral graft is routed low over the midline to avoid infected fields.

Fresh incisions that are distal to and separate from the previous groin incisions are made to expose the midsuperficial femoral arteries, or if the superficial femoral arteries are occluded, the distal portion of the deep femoral arteries. A lateral approach to these vessels is frequently useful. Tunneling of the femorofemoral bypass is then performed subcutaneously under the medial thigh skin, very low over the midline, below the level of the pubic symphysis, just above the base of the penis or clitoris, in an effort to avoid the previous groin incisions. The axillofemoral graft is tunneled lateral and posterior to the anterior superior iliac spine, with the graft passing under the sartorius muscle arriving at its connection with the femorofemoral graft from the lateral side (Fig. 205.5). In a few cases, the authors have performed an axillary-to-contralateral femoral artery bypass

to avoid infected incisions in the ipsilateral groin or flank. The grafts were routed beneath the pectoralis major muscle and then subcutaneously across the chest and abdomen to the contralateral groin (Fig. 205.6). No adverse effects on patency have been noted with this graft configuration. In addition, when the extent of sepsis in the femoral areas precludes a femorofemoral synthetic graft, bilateral axillofemoral grafts may be placed or the cross-femoral component of the bypass constructed from femoral vein, or cryopreserved cadaveric femoral vein. A single femoral vein harvested from just above the knee to just below the profunda femoris vein usually provides adequate length for a femorofemoral bypass when anastomoses are to the common femoral arteries bilaterally.

Following completion of the axillobifemoral graft, the incisions are closed and covered with another layer of occlusive plastic drapes. Since the clean portion of the operation is now complete, it is not necessary to reprepare and drape the patient. Appropriate incisions are now made into the infected areas to allow graft removal. Obviously, use of multiple operating teams for such extensive procedures required for treatment of graft infections significantly shortens what is already a prolonged operation.

POSTOPERATIVE CARE

Patients with extensive comorbidities or infected aortic graft removal and reconstruction are transferred initially to a surgical intensive care unit. It is frequently difficult to evaluate the newly placed PTFE graft with ultrasound due to the presence of air within the graft interstices. Frequent physical examination and continuous wave Doppler examination of the dorsalis pedis and posterior tibial arteries assist in determining graft patency. Aspirin therapy is continued. Routine anticoagulation with heparin and warfarin is not advocated unless a known hypercoagulable state has been identified. Early ambulation is encouraged. Patients are cautioned to avoid placing the donor arm over the head for the first 6 weeks following surgery to avoid excess graft tension and potential axillary anastomotic disruption.

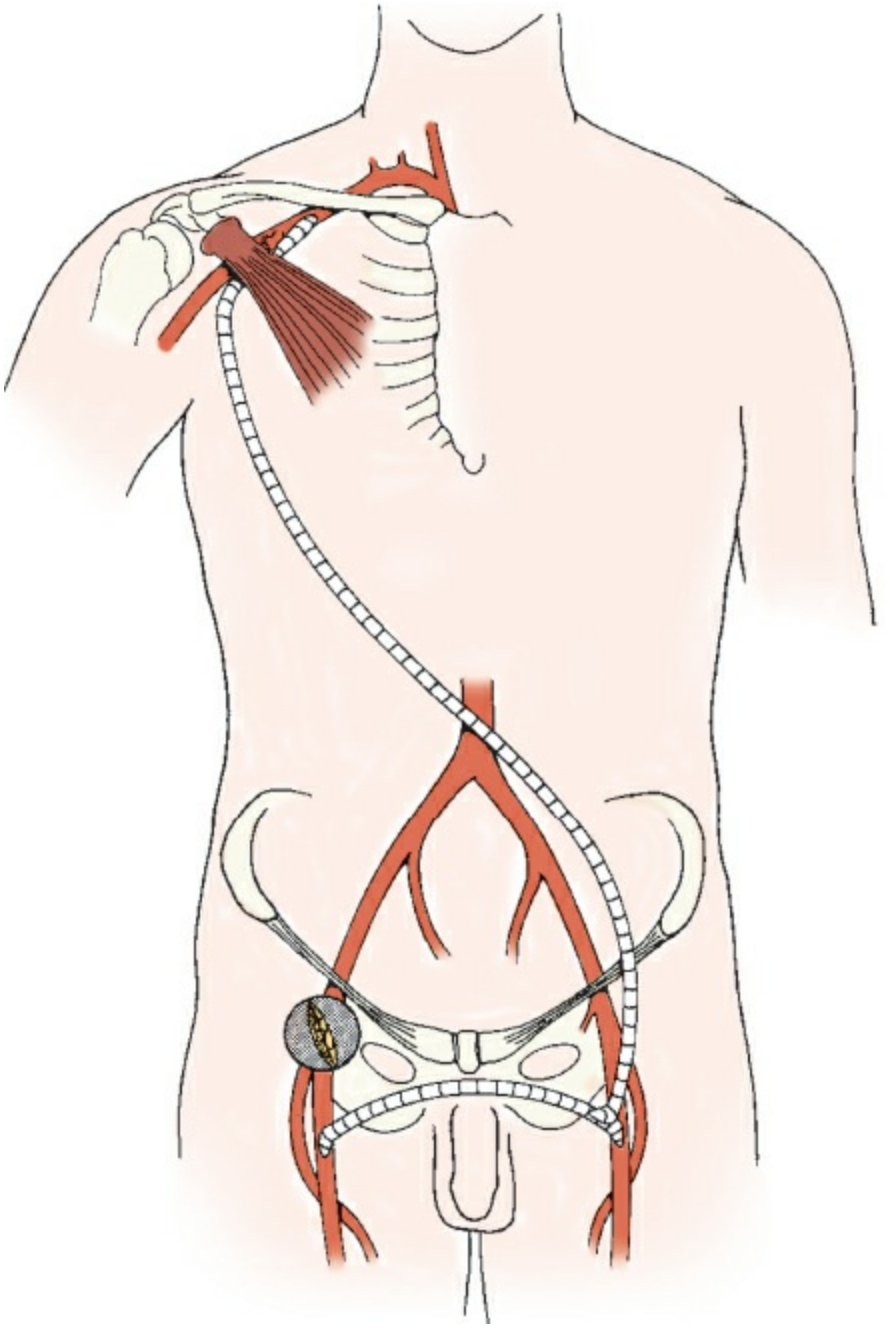

Figure 205.6. Axillary-to-contralateral femoral artery bypass used to avoid infected incision in ipsilateral groin (*shaded areas*).

Postoperative graft surveillance is performed by vascular laboratory duplex every 3 months for the first postoperative year, and then every 6 months. Flow velocities vary widely within axillofemoral grafts. In our experience, patency is associated with a midgraft peak systolic velocities >150 cm/s. A midgraft peak systolic velocity <80 cm/s is a risk factor for occlusion. Arteriography is performed when vascular laboratory testing suggests graft stenosis.

COMPLICATIONS

Graft Occlusion

Patency rates for axillofemoral and femorofemoral bypass are highly variable and are influenced by the operative indications, the graft configuration, and the status of the runoff vessels. Early studies reported disappointing 3-year primary patency rates <50%, but over the years, patency rates have improved considerably. With proper technique, 5-year primary patency of axillofemoral grafts approaches that of aortobifemoral reconstruction, ranging from 69% to 75%. Five-year patency of femorofemoral grafts ranges from 50% to 90%.

Proximal Graft Disruption

Disruption of the proximal anastomosis of the axillobifemoral grafts occurred in approximately 5% of patients in our early experience. They frequently occurred in early postoperative period (range 1 to 46 days; mean 21 days). Perioperative graft disruption was most often associated with forceful arm abduction or shoulder elevation, but also occurred in the absence of reported activity. The most frequent presenting symptoms were infraclavicular pain and swelling. Upper extremity ischemic symptoms were rare. Anastomotic disruption has been treated by emergent surgery, with the subclavian artery generally controlled through a supraclavicular incision prior to opening the infraclavicular incision. Operative findings have included sutures pulling through the graft or the vessel at the anastomosis, or graft disruption adjacent to but separate from the anastomosis (Fig. 205.7). In most cases, the grafts were trimmed back to undisrupted material and lengthened with an interposed segment of the same graft material with reanastomosis to the same site on the axillary artery.

Graft disruption is clearly related to excessive tension on the anastomosis from the marked changes in distance between axillary and femoral arteries with changing arm position. This tension can be minimized by incorporating considerable redundancy into the grafts as well as by positioning the anastomosis on the most proximal portion of the axillary artery. Since adopting the axillary anastomotic configuration described in this chapter, no additional anastomotic disruptions have occurred in our experience.

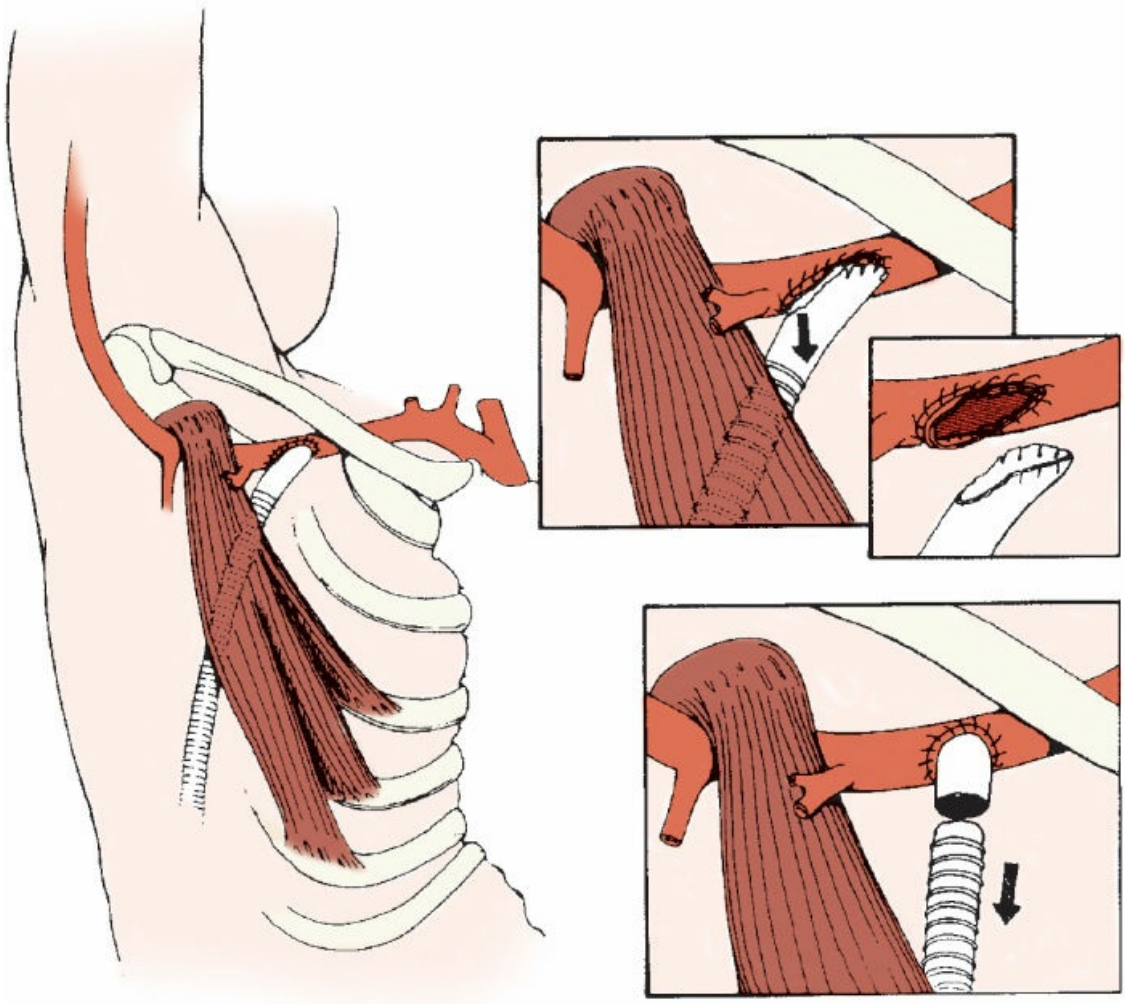

Figure 205.7. Proximal graft disruption. Causative factors include forceful arm abduction and lack of redundancy in the proximal portion of the graft. Operative findings include sutures pulling through the heel of the graft (*upper inset*) or graft disruption adjacent to but separate from the anastomosis (*lower inset*).

Thromboembolism

Thromboembolism to the donor upper extremity is relatively rare and does not occur in patients with a patent graft. In most cases of axillofemoral bypass graft occlusion, immediate graft revision has been performed following occlusion to restore lower extremity circulation. In rare cases, donor arm thromboembolism occurred simultaneously with graft occlusion, and in these cases, graft and arm embolectomy were performed. In a few cases, flow was not reestablished through occluded axillofemoral grafts, with lower extremity circulation provided by other means. Of these patients, up to 80% developed delayed thromboembolism to the upper extremity months to years (range 26 days to 7 years) following graft

occlusion. Upper extremity arteriograms in these patients revealed a blind stump in the occluded axillofemoral graft, which presumably serve as an embolic source. These patients were treated with graft disconnection, distal embolectomy, and patch repair of the axillary artery. Given the high risk of axillary graft stump syndrome, consideration should be given to disconnecting the graft from the axillary artery in appropriate risk patients with occluded bypass graft not requiring revascularization.

Infection

Extraanatomic graft infection occurs most frequently in the groins. CT is necessary to determine the extent of graft infection, since the entire graft is at risk for infection. The principles of graft replacement are the same as those described above for aortic graft infection. If the entire graft is involved, a new extraanatomic bypass is placed in noninfected tissue followed by removal of the involved graft. In cases of partial graft infection, it is usually sufficient to remove only the involved portion. Again, a new graft is placed in noninfected tissue prior to removing the infected graft segment.

Perigraft Seroma

Perigraft seroma is a rare complication following axillobifemoral bypass grafting. It consists of a sterile perigraft fluid collection surrounded by a fibrous pseudocapsule. The fluid appears to be a serum ultrafiltrate. The cause is unknown, although it has been suggested to be the result of a fibroblast growth inhibitor preventing graft incorporation by the surrounding tissues. Most cases will resolve with conservative therapy, although the length of time to resolution is variable. Aspiration is typically followed by fluid reaccumulaton. Repeat aspirations have not been shown to be more effective than conservative therapy and have been associated with a higher incidence of infection. Sclerotherpy is discouraged due to high incidences of infection and graft thrombosis. In symptomatic patients or for persistent seromas, the preferred treatment is complete graft and cyst excision with placement of a new graft in a different tissue plane. Using a graft of a different material has been shown to reduce the likelihood of perigraft seroma formation in the new graft.

OUTCOMES

Using the above technique, we have achieved 5-year life-table primary

patency, limb salvage, and survival rates of 71%, 92%, and 52%, respectively. The main cause of mortality is related to cardiac comorbidities, reflecting the overall poor health frequently noted in patients undergoing this procedure. Others have reported similar favorable results.

Patency rates for extraanatomic bypass are strongly influenced by the operative indications, the graft configuration, and the status of the runoff vessels. Axillobifemoral bypass performed for graft infection following aortic aneurysm repair with patent superficial femoral artery runoff has much higher reported 5-year patency rates than axillounifemoral bypass performed for atherosclerotic disease with an occluded superficial femoral artery. Similarly, patency rates for femorofemoral grafts placed during aortouniiliac endovascular abdominal aortic aneurysm repair exceed 90% at 4 years, greatly surpassing the patency rates noted in patients with occlusive disease.

Secondary patency rate is higher than primary patency rate, and effort should be made to restore the flow and revise the grafts when necessary. For graft failure due to thrombosis, graft replacement and/or anastomotic revision has superior patency rates to thrombectomy alone. In our series, patency rates of occluded grafts that were replaced or revised were 54% at 18 months versus 11% in those undergoing only thrombectomy.

CONCLUSION

Axillobifemoral bypass is an effective method for lower extremity revascularization for aortoilic occlusive disease or for patients with aortic sepsis. Historically, inferior patency rates compared with aortobifemoral bypass have resulted in the perception that it is a second-choice procedure. However, modern series report patency rates rivaling aortobifemoral bypass, suggesting that it may be appropriate to broaden the surgical indications in patients with aortoiliac occlusive disease not amenable to percutaneous endovascular therapy.

EDITOR'S COMMENT

The nicely written and detailed chapter by Dr. Jung et al. describes common extraanatomical bypass constructions for aortoiliac occlusive disease, namely the axillofemoral and cross-femoral artery bypasses. These techniques should be in every vascular surgeon's armamentarium as there are many times when the access to the abdominal or thoracic aorta is not able to be done safely. Similar indications include patients who are too ill to undergo abdominal surgery with an aortic cross-clamping. Often times, patients who undergo an axillofemoral graft are sicker than those undergoing aortofemoral bypass (AFB) (Passman MA, Taylor LM, Moneta GL, et al. Comparison of axillofemoral and aortofemoral bypass for aortoiliac occlusive disease. *J Vasc Surg* 1996;23:263–9; discussion 269–71). The preformed 8-mm axillofemoral grafts are convenient, and allow one less anastomosis to be created.

I agree with the authors that the current patency rate of axillobifemoral bypasses is likely better than historical series, but it certainly is dependent on the degree of the patient's outflow artery disease, particularly the deep femoral anatomy. For example, recent series suggest a good secondary patency of 70% to 86% (Passman MA, Taylor LM, Moneta GL, et al. Comparison of axillofemoral and aortofemoral bypass for aortoiliac occlusive disease. *J Vasc Surg* 1996;23:263–9; discussion 269–71; Liedenbaum MH, Verdam FJ, Spelt D, et al. The outcome of the axillofemoral bypass: a retrospective analysis of 45 patients. *World J Surg* 2009;33:2490–6). However, decreased patency is found in patients with aggressive early atherosclerosis and continued smoking. They often suffer repeated occlusive events, and have poor long-term success. Patients who require thrombectomy or thrombolysis of their extraanatomic bypass usually require warfarin and antiplatelet therapy, but there is no strong evidence for this; only clinical experience. Using anticoagulation for all axillobifemoral grafts is not supported by any evidence, and likely increases the risk of bleeding without benefit.

I would also state the cautious view that while the extraanatomic bypass techniques are useful, I think using these reconstructions when either endoluminal or aortofemoral bypass is possible is not wise. For example, endoluminal approaches are generally safe, technically successful, and are now most common for aortoiliac occlusive disease (Hong MS, Beck AW, Nelson PR. Emerging national trends in the management and outcomes of lower extremity peripheral arterial disease. *Ann Vasc Surg* 2011;25:44–54). Second, in-line blood flow with an AFB has the best durability. We often see patients referred after multiple extraanatomical bypass failures, when in-line flow is safe and possible. Thus, the extraanatomic bypass should be generally the third choice for aortoiliac reconstruction.

As most abdominal aortic aneurysms are treated with endovascular techniques, the use of the femoral to femoral bypass for aortounifemoral endovascular aneurysm repair with contralateral iliac occlusion is now much more common. This represents a different indication than occlusive disease, and often these patients do quite well, with excellent patency rates. One series reported an 11% rate of groin complications and 5-year patency of 83% (Hinchliffe RJ, Alric P, Wenham PW, et al. Durability of femorofemoral bypass grafting after aortouniiliac endovascular aneurysm repair. *J Vasc Surg* 2003;38:498–503). Monitoring with postoperative CT imaging that is done for endovascular aneurysm surveillance maybe of use in detecting inflow stenosis, which can cause bilateral lower limb ischemia. Similarly, duplex ultrasonography can detect stenosis directly if the waveform becomes monophasic. Nonetheless, due to the groin incision location, infection risks still remains, and more long term clinical series data is required.

One of the biggest issues that the authors very nicely detail is how to avoid axillo-graft disruption. As a surgeon who has had this happen, I entirely agree with the techniques they describe to diminish this risk. First, creating some

redundancy in the graft or having it go parallel to the artery for a distance makes sense and allows some flexibility. Second, keeping the arm abducted during the procedure to put maximum stretch on the axillary artery is also wise. Third, the patient should restrain from active and vigorous arm exercise for at least 6 weeks after the procedure. Fourth, unlike the authors, we usually divide the pectoralis minor, which also decreases the risk of disruption, as it can act as a fulcrum for graft stress.

In terms of emergency bail-outs for an acute axillo-graft disruption, a covered stent graft can be placed percutaneously via retrograde brachial approach to seal the axillary arteriotomy and this maybe lifesaving, if the bleeding is excessive. If able to potentially salvage the graft, then a temporary percutaneous balloon occlusion via the same route is reasonable to control of bleeding, and re-anastomosis of the graft. These hybrid techniques also allow vascular control without damaging the nerves and subclavian-axillary vein in the area. If a covered stent graft is used, this means a new graft will likely need to be constructed from the contralateral axillary artery. In terms of the distal graft arterial anastomosis, the bifurcation of the common femoral artery is, I believe, the best choice with the profunda patch angioplasty if the superficial femoral artery is occluded. This is a similar principle to AFB constructions.

It is not uncommon to develop a postoperative hematoma along the track of the graft, but usually this resolves without any sequelae. This is particularly common if the patient requires heparin anticoagulation postoperatively. If the graft is placed to treat a femoral graft groin graft infection, such as with an aortofemoral graft, the use of femoral vein can be used as a crossover graft as described by the authors, or using the basilic vein, which is often 3.5 to 6 mm in diameter and quite durable in this location.

Peter Henke

206 Endovascular Procedures for Aortoiliac Occlusive Disease

Vikram S. Kashyap and Karem C. Harth

ETIOLOGY AND PATHOPHYSIOLOGY

Aortoiliac occlusive disease (AIOD) is associated with a multitude of risk factors. Most commonly, patients with AIOD have a long-standing history of smoking, diabetes, hypertension, and hypercholesterolemia. Treatment of patients with peripheral arterial disease (PAD) requires attention to the ravages of atherosclerosis on a systemic level, as well as to the burden of disease in their limbs. Risk factor modification can diminish the long-term effects of atherosclerosis on the cardiovascular system in these patients and ameliorate systemic comorbidities at the time of operative or endovascular treatment. Controlling blood sugar, serum cholesterol, blood pressure, and importantly smoking can lead to substantial short- and long-term benefits. In consultation with the patient's medical physician, antihyperglycemic treatment, smoking cessation, lipid lowering therapy, and antihypertensive therapy are instituted for the appropriate risk factors. Antiplatelet therapy is generally in the form of low-dose aspirin. Less common therapies such as homocysteine-lowering therapy and antithrombotic therapy are considered. Patients with nondisabling claudication can be considered for supervised exercise programs, as well as cilostazol (Pletal, 100 mg BID) pharmacotherapy for at least 3 months. The importance of smoking cessation programs cannot be overemphasized. However, despite pharmacologic and counseling interventions, recidivism remains disappointingly high.

CLINICAL PRESENTATION

Extensive AIOD often results in debilitating symptoms. The majority of patients will present with claudication, while those with multilevel disease will have rest pain or tissue loss. Careful physical examination will be consistent with absent or faint femoral pulses. Calcification in the femoral region can also be appreciated in thin patients and in those with associated

femoral disease. Pedal pulses are usually absent, and ulceration or gangrene may result from concomitant infrainguinal occlusions.

INDICATIONS AND CONTRAINDICATIONS

Clinically, patients with AIOD considered for therapy will present with claudication or limb-threatening symptoms such as rest pain and ischemic ulceration. In the latter situation, improving inflow would aim to place the patient out of a limb-threatening state with the plan to reevaluate symptom improvement prior to any planned intervention on the distal disease.

Severe AIOD has been classically treated via open vascular reconstruction using aortobifemoral bypass (ABF). An endovascular-first approach has become a more increasingly favorable approach in the last two decades. The Trans-Atlantic Inter-Society Consensus (TASC) statement on treatment of PAD initially created in 2000 and updated in 2007 aimed to organize and review the available literature on patients with PAD. The framework allowed stratification of atherosclerotic lesions by length and morphology. According to the TASC definitions for iliac occlusive disease, short focal iliac *stenoses are* classified as TASC-A. *Iliac occlusions* can be stratified as B, C, and D lesions. TASC-B lesions include unilateral common iliac occlusions only. TASC-C iliac lesions include unilateral external iliac occlusions not extending into the common femoral artery, or bilateral common iliac occlusions. TASC-D lesions are bilateral external iliac occlusions or ipsilateral common and external iliac occlusions or diffuse disease of the aorta and both iliac arteries. Endovascular procedures are thought to be the treatment of choice for type A lesions (stenoses <3 cm only), and open surgical therapy is the procedure of choice for type D lesions. According to the TASC statement, more evidence is needed for type B and C lesions with a preference for endovascular methods for the former and surgical methods for the latter. This consensus statement reinforced the concept of treating short, focal stenoses via endovascular means and using surgical revascularization for long-segment occlusions based on the available data at that time. Treatment of aortoiliac *occlusions* remains a more challenging endovascular treatment modality than the treatment of iliac stenoses. As endovascular therapies have evolved, this has been mirrored by a decreasing number of patients undergoing ABF.

We believe that endovascular therapies can be used as first-line therapy for AIOD, irrespective of TASC classification. This is based on improved

catheter-directed techniques allowing recanalization and new angioplasty and stent designs. In addition, there is an increasing capability of vascular specialists in treating more complex disease with catheter-based methods. Lastly, we preferentially use endovascular procedures because operative options are not lost, even if the endovascular therapy is unsuccessful. In our elderly patients with severe comorbidities, in patients with life expectancy or a hostile abdomen, a minimally invasive option for revascularization leads to decreased morbidity and length of recovery.

There are situations where endovascular therapy may be precluded or should be carefully approached. These include the presence of abdominal aortic aneurysmal disease, occluded abdominal aorta, circumferential calcification making plaque fracture by angioplasty difficult without arterial rupture, or atrophic chronically occluded iliac vessels. If circumferential iliac calcification raises concern for iliac rupture, then the need for covered stent grafts should be anticipated if an endovascular approach is to be chosen. Disease extending into the aortic bifurcation may require contralateral iliac balloon angioplasty at the time of intervention to prevent plaque shift and subsequent contralateral iliac injury. Simultaneous femoral disease may not allow for a purely percutaneous approach, and a hybrid intervention would be more successful. In addition, acute iliac occlusive disease has the risk of embolizing thrombus, and these scenarios should be preceded by either thrombolytic therapy or open thrombectomy to protect outflow vessels.

PREOPERATIVE PLANNING

Paramount to the preoperative evaluation of patients with AIOD is careful evaluation of their cardiac and pulmonary status. A significant portion of patients with AIOD will have undiagnosed coronary disease. In the setting of no limb-threatening aortoiliac disease, symptomatic coronary disease will take precedence. Those with asymptomatic disease may still be considered for endovascular intervention. A case-by-case evaluation is needed as this particular group of patients may be asymptomatic secondary to a sedentary lifestyle and inability to ambulate. In these settings, preoperative cardiac stress testing should be considered.

Various imaging modalities will confirm a clinical diagnosis of AIOD but will also facilitate surgical management. Noninvasive vascular laboratory imaging with either segmental pressures/pulse volume recordings (PVRs) (Fig. 206.1) or duplex examination is helpful in

determining the level and degree of disease present. In the setting of AIOD, high-thigh segmental pressures and waveforms will be diminished. In unilateral disease, a horizontal gradient will be present. The presence of diabetes, renal disease, or a long history of smoking may lead to significant calcification in the iliac and femoral vessels causing noncompressibility and false elevation of the pressures. In these cases, PVR assessment and toe-brachial indices are more sensitive.

We choose additional imaging with workup with computed tomographic angiography (CTA). This allows cross-sectional imaging, as well as three-dimensional reconstruction to assist in the planning of treatment in patients with extensive AIOD (Fig. 206.2). CTA is very helpful in determining the extent of AIOD, the degree of calcification, presence of aortic occlusion, or the rare presence of an abdominal aortic aneurysm. Diagnostic angiography becomes less critical with good-quality CTA evaluation.

SURGICAL TECHNIQUE

Using endovascular techniques to treat chronic occlusive disease in the aortoiliac segment requires a creative approach tailored to the lesion anatomy in an individual patient. The specific steps are access, recanalization, angioplasty, and then usually stenting. In addition, one should fully evaluate the entire aortoiliac system, using oblique views and also evaluate the distal femoral-popliteal runoffs in a nonselective manner, as this will affect long-term outcomes. Each step requires specific skills and instrumentation. Experience with multiple means of access (i.e., femoral, brachial), a wide variety of guidewires and catheters, and an operative environment that allows surgical exposure of arteries are critical. We believe an endovascular suite (hybrid operating room) allows the high-fidelity fluoroscopic imaging combined with operating room facilities to allow the safe and efficient performance of these procedures. This allows for combined (hybrid) open and endovascular surgery in some challenging scenarios where arterial pathology prohibits a purely endovascular approach. Attention must be paid to operative sterility and radiation exposure. One critical clinical decision in planning for endovascular therapy for AIOD is whether a purely percutaneous procedure can be performed. If so, conscious sedation, rather than anesthesia, can be organized simplifying the logistics of the procedure. If femoral reconstruction is planned, regional or general anesthesia may be required.

In patients with occlusive disease of the aortoiliac segments that does not extend into the common femoral arteries, a purely percutaneous procedure can be planned. Conscious sedation using short-acting opiates and anxiolytics is given. Access is usually performed with ultrasound guidance since the femoral pulses are either barely or not palpable. This is done with an anterior wall puncture only. Retrograde access to the iliac artery with less atherosclerotic burden allows catheter placement (Fig. 206.3A) and aortography with special pelvic oblique views to assess hypogastric patency if present. Subsequent imaging of the contralateral limb can be done via nonselective aortography (Fig. 206.3B) or selective catheterization using an "up and over technique." Alternatively, brachial artery access can be the initial source of entry in cases with complete aortic occlusion, previous aortobifemoral graft, or heavily diseased femoral arteries. One must keep in mind that left brachial access does require a longer overall system, including long sheaths and catheters sometimes >100 cm. Additionally, if a brachial approach is planned and there is an absent or weak left radial pulse, evaluation for subclavian occlusion or stenosis should be considered as this would dictate feasibility.

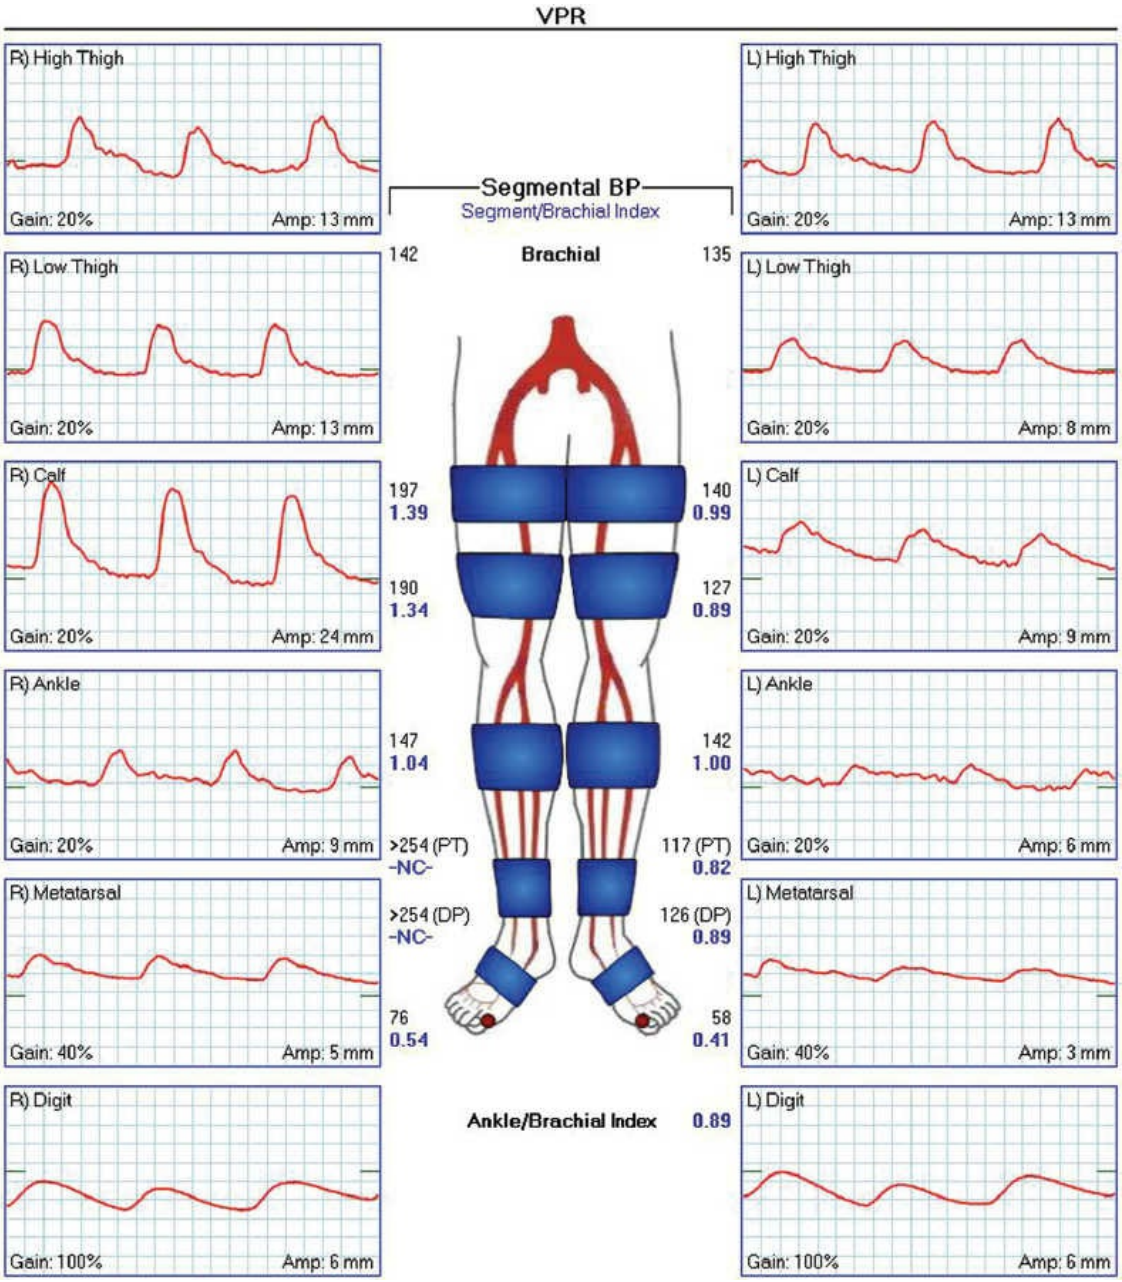

Figure 206.1. Segmental pressures and pulse volume recordings in a patient with left-sided inflow disease. Note the horizontal gradient at the high thigh level and the diminished waveforms secondary to left iliac occlusive disease.

For diagnostic angiography, percutaneous access, the placement of a 5-French (Fr) sheath, and eventual manual compression for hemostasis are common. However, if endovascular intervention is to be performed, larger sheaths (6 to 8 Fr) are often needed to accommodate delivery of the endoluminal devices and we often use a closure device at the completion of the procedure.

During diagnostic angiography, if a lesion is of questionable clinical

significance, one can measure intra-arterial pressures via different approaches and include provocative testing with papaverine (30 to 60 mg) or nitroglycerine (100 to 200 ug/mL) in order to unmask their hemodynamic impact. If the iliac artery ipsilateral to a femoral sheath is being evaluated, the sheath side arm can be connected to an arterial pressure monitor and compared to an arterial line in the upper extremity. Alternatively, an end hole catheter can be used to measure pressures proximal and distal to the lesion. Generally a gradient >10 mm Hg is considered significant. After diagnostic aortography and confirmation of preoperative AIOD burden, the contralateral femoral artery is accessed. A short, curved catheter (i.e., Kumpe, angled Glide) is brought to the level of the occlusion or high-grade stenosis for a retrograde angiogram (Fig. 206.3C). Following this, recanalization of an occluded segment is usually done using a standard Glide wire (Terumo, Inc.). This allows passage from the true lumen below to the aortic true lumen above.

Aortoiliac occlusions are more complex and challenging to treat via endovascular means than stenoses with chronic iliac occlusions representing 13% or more of the lesions in AIOD. Recanalization can be the most challenging portion of this endovascular procedure. The most common technique for recanalization of an occlusion is either intraplaque or subintimal passage of a hydrophilic wire and catheter via either antegrade or retrograde approaches. Reentry devices are not routinely used but are available. A slightly curved catheter with a hydrophilic coating helps direct a hydrophilic 0.035-in wire. In recanalization procedures, we have found that significant force has to be applied to the guidewire/catheter combination to cross a heavily calcified and diseased artery. This is best done via a femoral retrograde approach because of the “pushability” of the catheter system. Even with a retrograde approach, a subintimal passage may occur without successful reentry into true lumen. This then necessitates an antegrade approach using brachial access and placement of a long sheath in the aorta. The “pushability” from a left brachial artery approach is not as effective, as much of the force is dissipated via the multiple turns that the catheter has to traverse including the aortic arch. Thus, despite a long sheath, pushing on wire from the left brachial often does not translate to the effect desired in comparison to a straight retrograde trajectory.

Once a wire has successfully traversed the iliac occlusion, a snare capture device can be used to secure the brachial wire, withdraw it through

the femoral sheath, exchange catheters, and place a stiff wire from the femoral location. At this point, confirmation of true lumen location should be done by antegrade angiography. Larger sheaths can then be placed from the groin rather than the arm, where the brachial artery is subject to injury. After the target lesion is crossed, floppy hydrophilic wires are exchanged for stiffer braided wires to provide a stable system on which devices and balloons can be used.

Figure 206.2. Computed tomographic angiography scan of a patient with severe aortoiliac occlusive disease. Note the bilateral severe iliac occlusive disease and extensive calcification. This patient is traditionally treated with open reconstruction with aortobifemoral bypass. We performed a hybrid procedure with bilateral femoral endarterectomies, recanalization of the iliac arteries, and angioplasty with stenting (R/PTAS).

Following recanalization, angioplasty using a high-pressure balloon

allows a lumen to be created through the diseased section. A small 3- to 4-mm balloon is sufficient to achieving enough lumen through which to advance delivery devices or larger sheaths. This will also prevent aggressive angioplasty leading to iliac rupture. We have adopted a liberal posture to stenting these diseased vessels. Some may argue that percutaneous balloon angioplasty (PTA) may suffice, but in our experience significant recoil occurs in diseased, calcified iliac arteries. Either an uncovered balloon-expandable stent or nitinol, self-expanding stent is usually deployed. Balloon expandable stents, when being placed in high-grade stenoses or in the setting of recanalization, require delivery via long sheaths that go beyond the lesion in order to prevent stent dislodgement. Once the stent is in place, the sheath can be pulled back to expose the balloon mounted stent. Recently, covered stenting has been used for calcific hard plaque where recoil and rupture is a concern (Fig. 206.3D). Stent sizing can be judged by adjacent normal segments while road mapping or smart mask can guide accurate stent deployment. Aortic bifurcation disease may require implementation of “kissing stents” up front or additional intervention with either angioplasty +/− stenting on the contralateral iliac artery after completion angiography shows a concerning plaque shift. Remnant disease elsewhere should similary be evaluated and treated accordingly. Occasionally, intravascular ultrasound (IVUS) is utilized to ensure stent apposition.

In cases where the AIOD continues to the femoral region, femoral endarterectomy in combination with endovascular therapy is required. This is necessary in approximately one-quarter of our patients with AIOD. Thus, these patients need either general or regional anesthesia to adequately allow femoral dissection, endarterectomy, and patch closure. The steps in this procedure are as follows:

1. Femoral exposure
2. Sheath placement via the diseased femoral artery
3. Recanalization
4. Endarterectomy and patch closure (90%)
5. PTA/S via a large sheath through the incomplete suture line of the patch
6. Completion of the patch

Some technical issues are worthy of discussion. Recanalization of heavily calcified vessels can be challenging. Ensuring catheter delivery to the true lumen, both above and below the recanalized segment via targeted

angiography, is critical to successful therapy. In past years, thrombolysis was used in selected patients to decrease the chronic thrombus burden in the aortoiliac segments prior to recanalization, angioplasty, and stenting. This has largely been abandoned and reserved only for patients with acute limb ischemia and evidence of acute thrombosis. Systemic heparinization during the procedure is routine. External iliac disease is generally better approached via an antegrade brachial approach or from a contralateral femoral access point. Treatment of this lesion location may require angioplasty and stenting up to the inguinal ligament, which is not feasible from an ipsilateral access point. There are some specifics to keep in mind when choosing a stent. Self-expanding stents are mounted on a constraining sheath, thus being protected as they are introduced across a lesion. They generally require some (2 to 5 mm) oversizing to maintain radial force, come available in nitinol, are flexible and good for significant tortuosity, and come in smaller diameters. Balloon expandable stents come premounted on a balloon, do not come in a constraining sheath, can be expanded above their intended diameter with further balloon angioplasty, and are more rigid. Finally, covered stents are generally composed of polytetrafluoroethylene (PTFE) mounted on a stent and are theoretically intended to decrease tissue ingrowth and subsequent neointimal hyperplasia. Certainly, their role in a high rupture risk iliac lesion is important.

POSTOPERATIVE CARE

Antiplatelet therapy with Clopidogrel (Plavix) is usually instituted after endovascular therapy to prevent stent thrombosis at the loading dose of 300 mg once, followed by 75 mg/day for at least 3 months. Postoperative clinical and vascular laboratory evaluation for symptom improvement and physiologic response to treatment follows a standard paradigm for peripheral interventions. Noninvasive vascular studies can be performed at initial outpatient follow-up and then every 6 months for the first 2 years and then annually. In order to optimize primary patency rates, diagnostic angiography should be planned when arterial duplex velocities are >300 cm/s or patient symptoms recur. CTA may be useful in the postoperative period to confirm high velocities on duplex in the asymptomatic patient and avoid an invasive study.

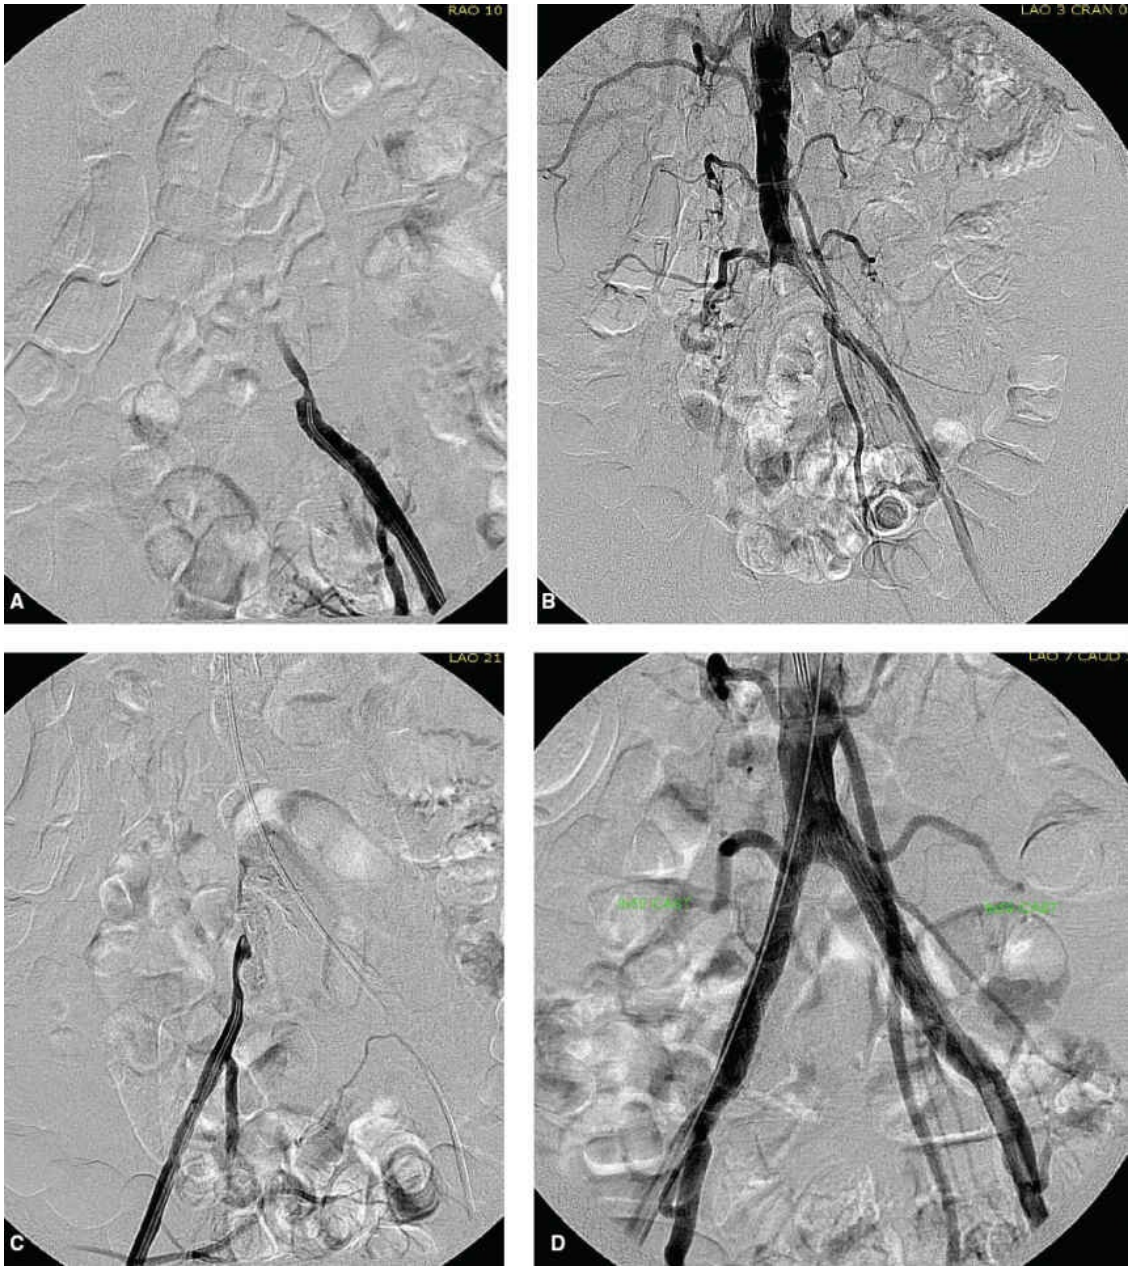

Figure 206.3. A. A young male with debilitating claudication and inability to work presents with extensive aortoiliac occlusive disease. After evaluation and risk factor optimization, endovascular therapy is performed. Femoral puncture is performed with ultrasound guidance, and retrograde access to the iliac artery with the less atherosclerotic burden allows catheter placement. **B.** Aortography allows imaging of the aorta and both ipsilateral and contralateral limbs. **C.** The contralateral femoral artery is accessed using ultrasound and a short, curved catheter is brought to the level of the occlusion for a retrograde angiography. **D.** Completion imaging after covered stenting (iCAST, Atrium Medical, Inc.) for calcific, hard plaque in the proximal common iliac arteries. Note the inferior mesenteric artery is preserved with prograde blood flow, as well as the

lumbar arteries and the hypogastric arteries (not shown on this image), lessening the chance of bowel or spinal cord ischemia.

COMPLICATIONS AND THEIR MANAGEMENT

The various specific steps in the endovascular treatment of AIOD should be carefully approached in order to prevent known potential complications. Percutaneous access and closure are associated with complications, including bleeding, infection, thrombosis or creation of a pseudoaneurysm, or arteriovenous fistula. The complication rate of major bleeding at the femoral artery is ~2%. The risk of access complication is slightly higher in the brachial location, especially in the setting of multiple catheter exchanges, larger sheaths, or in patients with small vessels, including many women. Open brachial exposure is an option here to minimize complications.

Iliac recanalization has been associated with distal embolization in the past, but we have not found embolization to be a significant concern as long as one does not angioplasty arteries with acute thrombosis. These patients with fresh thrombus need thrombolysis prior to intervention, or if embolization has occurred, require percutaneous/open thrombectomy for revascularization. Another risk in patients with severe, calcific disease relates to the ability to stretch the artery via angioplasty and stenting with the potential for rupture. CTA helps identify patients with “coral reef” atherosclerosis or circumferential calcification where controlled fracture of the plaque with angioplasty may lead to rupture of the artery (Fig. 206.4A–D).

Appropriate sizing of the balloon for PTA is critical, especially at the iliac bifurcation where the size of the native common iliac diminishes drastically to the smaller external iliac artery. This can be discerned via a combination of preoperative imaging, angiography, and adjunct use of IVUS. In the awake patient, excessive pain in conjunction with hemodynamic instability may be a sign of rupture. If this occurs, gentle balloon angioplasty in the area of rupture can be used to control the bleed while alternative access and/or a covered stent is prepared for deployment. Arterial dissection can occur anywhere along the working arterial path and should be carefully evaluated at various points when angiography is performed and certainly on completion angiography as it may require additional endovascular therapy. Untreated dissection either from PTA or wire/catheter trauma can result in early postoperative thrombosis.

Certainly, contrast-induced nephropathy can be a problem postoperatively. Periprocedural hydration, sodium bicarbonate protocols, using CO_2 angiography, and diluted contrast are some strategies to minimize this risk. Long-term, de novo stenosis or in stent stenosis can develop in up to 25% of patients at 2 years. Surveillance protocols and early intervention should be instituted.

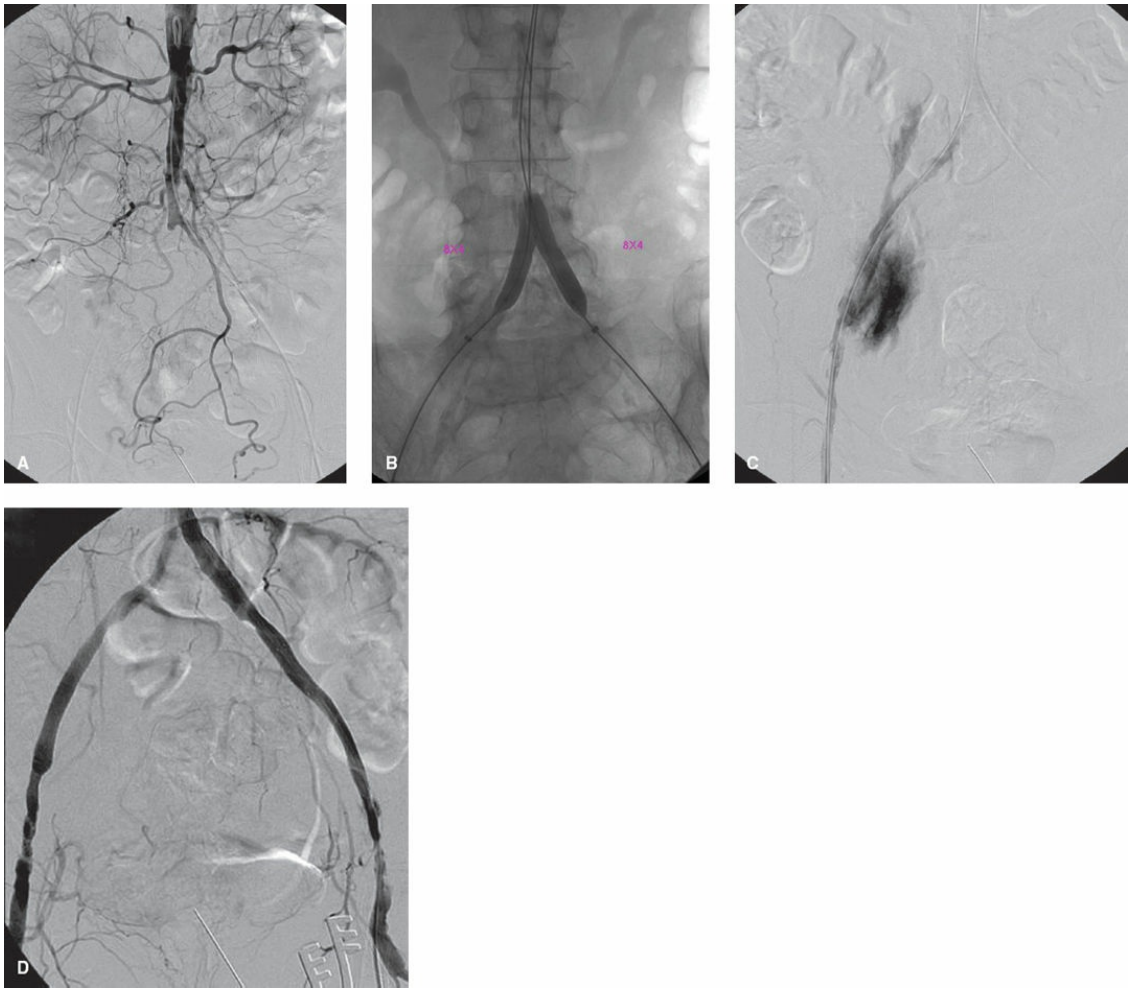

Figure 206.4. A. An elderly female with rest pain is identified as having extensive aortoiliac occlusive disease with femoral occlusive disease. Combined femoral endarterectomy and endovascular therapy is performed. After bilateral femoral exposure, femoral artery puncture and recanalization allow aortography, which reveals extensive bilateral iliac occlusive disease. **B.** After bilateral recanalization, percutaneous balloon angioplasty (PTA) is performed over stiff guidewires in a "kissing technique." PTA is continued through the iliac segments. **C.** The patient experienced sudden hypotension. Retrograde arteriography from the right-sided sheath documents free extravasation of blood from the proximal external iliac artery into the retroperitoneum. Rapid inflation of an angioplasty balloon across the iliac bifurcation halts the hemorrhage. **D.** Completion imaging after covered stenting (Viabahn, Gore, Inc.) allows sealing of the ruptured iliac artery and salvage of the situation. The patient did well, rest pain resolved, but she required a 5-day hospitalization to recover from an ileus.

OUTCOMES

In our experience, we have preferentially used primary stenting after recanalization of occluded iliac segments. A meta-analysis of trials after 1990 comparing PTA to PTA/S in iliac atherosclerotic disease has been performed. The majority of patients had iliac stenoses. However, for both stenoses and occlusions, stenting consistently gave better 4-year patency rates than PTA alone. The risk of long-term failure was reduced by 39% after stenting as opposed to PTA alone. The Dutch iliac stent trial compared a strategy of primary stenting to a strategy of PTA with provisional stenting for hemodynamic PTA failures. In this study of 279 claudicants, primary stenting did not result in improved initial success or 2-year clinical results. However, in the small group of iliac occlusions, 10 of 12 initially treated with PTA alone required eventual stent placement. The use of a stent increases the cost at the initial procedure, but may provide improved durability and thus reduce repeat interventions.

Since 1995, a review of the published data regarding endovascular treatment of complex aortoiliac occlusions reveals the primary patency ranges from 69% to 76% at 2 years with secondary patency rates of 85% to 95% at 2 years. Furthermore, overall complication rates were low in recent series (1.4% to 4.8%), likely due to improvements in technique and device technology.

Our current results in patients with severe AOID (TASC-B or higher) demonstrate an increasing ability by a multi-physician vascular surgery group to treat extensive iliac disease by endovascular means. Between 1998 and 2004, 86 patients (161 limbs) underwent open reconstruction, mostly with ABF. During the same interval, 83 patients (127 limbs) underwent endovascular therapy (recanalization and PTA/S). During this time interval, ~800 procedures for aortoiliac stenosis (TASC-A or B) were performed. All patients had severe symptomatic AIOD with claudication (53%), rest pain (28%), tissue loss (12%), or in rare cases, acute limb ischemia (7%). Patients undergoing ABF were younger (60 years) than patients undergoing endovascular therapy (65 years), and had higher rates of hyperlipidemia and smoking. All other clinical variables including cardiac status, diabetes, symptoms at presentation, TASC stratification, and presence of poor outflow were similar between the two groups. Patients underwent ABF with general anesthesia, often with concomitant treatment of femoral or infrainguinal disease with the majority undergoing common femoral endarterectomy and/or

profundaplasty. Patients underwent endovascular therapy with local anesthesia/sedation in 78% cases. Technical success was universal in both groups with marked improvement in ankle-brachial indices (0.48 to 0.84). Twenty-one percent of patients undergoing endovascular therapy underwent femoral endarterectomy/profundaplasty for concomitant infrainguinal disease. Postoperative complications occurred in both groups with slightly higher rates of respiratory failure and wound infection in the ABF group and slightly higher rates of limb ischemia/thrombosis and renal dysfunction in the endovascular group. None of these complications were statistically different.

Limb-based primary patency at 3 years was significantly higher for ABF than for the endovascular group (93% vs. 74%, $P = 0.002$). Most of the endovascular failures simply underwent repeat intervention with balloon angioplasty or additional stenting. For primary patency, univariate analyses indicated the presence of diabetes, and distal occlusive disease requiring a bypass significantly decreased primary patency of all patients treated for severe AIOD.

Secondary patency rates (97% vs. 95%), limb salvage (98% vs. 98%), and long-term survival (80% vs. 80%) were similar between the two groups. For overall survival, multivariable analyses indicated that worsening renal function adversely affected survival (HR 12). In addition, poor outflow as defined by superficial femoral artery occlusion was associated with diminished survival (HR 2).

In our experience, TASC classifications were the same in both open and endovascular groups indicating that the burden of occlusive disease was similar in both groups, and those easier, less extensive cases were not reserved for endovascular treatment.

In summary, the treatment of extensive aortoiliac artery occlusive disease can be accomplished via endovascular means with little morbidity and acceptable patency and limb salvage rates. The TASC stratification is an important tool in allowing us to assess the extent of lesion morphology, but extensive lesions do not preclude successful endovascular treatment. The fate of the limb is dictated by the infrainguinal disease that is often present in patients with complex iliac occlusions. Repair of the concomitant femoral occlusive disease is often needed regardless of open or endovascular treatment. Infrainguinal disease negatively impacts both durability of the procedure and survival of the patient. We believe that endovascular attempts should be exhausted prior to attempt at open

surgical repair of iliac occlusions since the perioperative morbidity and midterm durability rivals open reconstruction.

Treatment of AIOD remains gratifying for the patient and surgeon. Often, operative or endovascular treatment results in rapid symptom abatement, clearly discernible hemodynamic changes, and durable prevention of recurrent symptoms. We anticipate that with advances in our endovascular armamentarium, our ability to treat more complex and extensive AIOD will similarly improve.

EDITOR'S COMMENT

The chapter by Kashyap and Harth details common endovascular approaches for the treatment of aortoiliac occlusive disease (AIOD), a very common revascularization method for peripheral arterial disease (Hong MS, Beck AW, Nelson PR. Emerging national trends in the management and outcomes of lower

extremity peripheral arterial disease. *Ann Vasc Surg* 2011;25:44–54). Indeed, first-line therapy for almost for all AIOD now is endoluminal, which if unsuccessful or fails long-term, can often be salvaged with an open aortofemoral bypass. Of course, experience and judgment are essential in choosing the best approach for these patients.

Several important points bear discussion from this chapter. First, I always tell the residents and students the most important pulse to check in vascular surgical patients is the femoral pulse exam. This defines inflow (e.g., AIOD) and outflow disease, and of course the inflow needs to be addressed first. Treating the AIOD usually suffices to relieve the patient's vascular symptoms, regardless of outflow status if a patent profunda artery is present. Interestingly, when the Transatlantic Inter-Society Consensus group devised its anatomical staging system for AIOD, it was felt that short and medium length arterial blockages were best treated endoluminally, and for long segment blockages that open surgery was recommended (Norgren L, Hiatt WR, Dormandy JA, et al. Inter-society consensus for the management of peripheral arterial disease (tasc ii). *J Vasc Surg* 2007;45(Suppl S):S5–67). As the authors' note, with new techniques of arterial recanalization, reentry devices, better imaging, and covered stents, most AIOD lesions now can be treated regardless of lesion characteristics.

Hybrid operative procedures are now much more commonly performed, as recently detailed (Chang RW, Goodney PP, Baek JH, et al. Long-term results of combined common femoral endarterectomy and iliac stenting/stent grafting for occlusive disease. *J Vasc Surg* 2008;48:362–7), with open surgical treatment of common femoral occlusive disease and retrograde iliac revascularization. Hybrid procedures take advantage of being able to clear the bulky obstructive lesions at the common femoral and profunda artery junction that is not possible with purely percutaneous techniques. A prosthetic or bovine pericardial patch for the angioplasty is often used, and through which the wire and sheath are placed. Whether you do the endoluminal procedure and then the endarterectomy, or the endarterectomy and then the endoluminal procedures depends on the degree of disease in the femoral vessel. I have found placing a wire through the common femoral artery into the iliac artery prior to the endarterectomy avoids the subintimal dissection with retrograde access after the endarterectomy that can be troublesome. I usually do the endoluminal procedures second, and get a final confirmatory angiogram particularly to assess end of external iliac plaque at endarterectomy site.

There are numerous techniques for recanalization, but usually a hydrophilic glide wire with a cobra catheter or glide catheter is most successful for reestablishing continuity to the aorta. Use of snare approach via access from the arm or the contralateral side is also useful in these sometimes challenging cases, the so called "body floss" technique. Patience and persistence are essential.

A definite consideration is whether open aortofemoral bypass is better for long segment AIOD versus endoluminal revascularization. This also certainly seems to be institution dependent, with more aggressive endoluminal centers

doing most everything endovascular, versus a more conservative approach using open surgery for extensive, diffuse AIOD or aortic occlusions. No randomized controlled trials are available comparing these modalities. Recent systemic review suggests safety and good durability with endovascular therapy for AIOD, with secondary patencies at 5 years of 80% (Jongkind V, Akkersdijk GJ, Yeung KK, et al. A systematic review of endovascular treatment of extensive aortoiliac occlusive disease. *J Vasc Surg* 2010;52:1376–83). We reviewed our own series of open surgery versus endoluminal therapy for AIOD and found very similar outcomes, with somewhat less durability of endoluminal procedures but greater morbidity form surgery (Burke CR, Henke PK, Hernandez R, et al. A contemporary comparison of aortofemoral bypass and aortoiliac stenting in the treatment of aortoiliac occlusive disease. *Ann Vasc Surg* 2010;24:4–13). Certainly, having both endovascular options and open surgical options is best to allow tapering of therapy to the individual patients.

Peter Henke

207 Reversed Vein Bypass Grafts to Popliteal, Tibial, and Peroneal Arteries

Joseph L. Mills and Layla C. Lucas

The use of venous autografts dates back to the beginning of the 20th century with Alexis Carrel and Charles Guthrie's description of the technique of vascular anastomosis in a canine model. In 1906, they published their experience of early bypass grafting using venous transplantation, work for which Carrel was subsequently awarded the Nobel Prize (Physiology and Medicine) in 1912. In 1948, Jean Kunlin's successful femoral-popliteal bypass using reversed saphenous vein graft in a 54-year-old man with tissue loss, who was a patient of Rene Leriche, generated enthusiasm for the arterial bypass era of vascular surgery, an era that lasted nearly half a century. The basic vein bypass techniques described by Kunlin remain in widespread use today.

Although endovascular interventions are increasingly utilized to treat peripheral artery disease (PAD), a significant number of patients continue to require open bypass either due to disease extent or after failure of endovascular therapy.

CLINICAL PRESENTATION

Patients with PAD may be asymptomatic. Those who are symptomatic generally present either with intermittent claudication (IC) or limb-threatening ischemia manifested by rest pain, ulceration, or gangrene. The diagnosis of PAD can usually be made based on a thorough history and physical examination. Claudicants most often complain of cramping or burning muscular calf, thigh or buttock pain that occurs with walking, resolves with rest, and is reproduced by the same walking distance and exertion level. Ischemic rest pain is an early manifestation of limb-threatening ischemia and typically occurs in the forefoot, with onset when the leg is flat or elevated and resolution when the limb is placed in a dependent position. The pain classically occurs when a patient goes to bed

at night and is relieved by sleeping upright or hanging the affected limb over the edge of the bed. Patients with limb threat may also develop non-healing ulcers that either arise spontaneously or in response to minor trauma. Gangrene is a late sign of severe limb ischemia. Nearly universal physical findings in such patients include absent pedal pulses, trophic changes, and dependent rubor with pallor on elevation. Gangrene and non-healing ulcers typically appear on the toes and forefoot or over bony prominences, especially in those with diabetes. Patients with diabetes less commonly complain of rest pain; neuropathy is a major contributory factor for most diabetic foot ulcers (DFU) that develop over bony prominences due to loss of protective sensation, deformity, and repetitive trauma. PAD is common in patients with DFU and may contribute to non-healing or delayed healing in as many as 50% of those so affected. The Society for Vascular Surgery WIfI classification for threatened limbs is useful to stage patients with non-healing, lower extremity ulcers to identify those most likely to require and benefit from revascularization.

DIAGNOSIS

Noninvasive vascular laboratory tests are generally indicated in symptomatic PAD patients, especially when intervention is planned, to confirm the diagnosis, document the degree of limb ischemia, determine the anatomic site(s) of involvement, and differentiate stenotic from totally occlusive lesions. The simplest baseline measurements are physiologic or hemodynamic tests. An ankle-brachial index (ABI) less than 0.9 is diagnostic for hemodynamically significant occlusive disease and has been found to be 95% sensitive in identifying angiographically confirmed PAD. Claudicants with single-level stenoses may only show a reduced ABI after exercise. A 20% or greater reduction in the ABI postexercise is abnormal. Arterial waveform patterns, toe waveforms and Doppler-derived pressures, and transcutaneous oxygen saturations are useful when the ABI cannot be measured due to medial calcinosis. Medial calcinosis is present when the ABI is >1.3 and is common in individuals with diabetes.

If intervention is planned, we generally next perform arterial duplex imaging. It is relatively inexpensive, does not require contrast or radiation exposure, is easily performed in the outpatient, office setting and readily identifies culprit lesions (sites of arterial occlusion or stenosis) which are characterized by color flow changes and elevated peak systolic velocities and velocity ratios. Duplex is extremely useful in predicting which patients

are good candidates for endovascular therapy and aids in planning the best approach. We reserve computed tomography (CT) or magnetic resonance (MR) angiographic imaging for those patients who have markedly diminished or bilaterally absent femoral pulses. These imaging techniques define the length and extent of aorto-iliac disease and the common femoral artery (CFA) disease burden, factors critical in selecting whether endovascular therapy or major open surgery such as aorto-bifemoral bypass is the better option. We perform percutaneous angiography for those patients in whom endovascular therapy is planned, usually at the same setting, or for patients with long-segment femoro-popliteal and/or tibial disease in whom bypass is planned in order to identify optimal inflow and outflow sites.

PREOPERATIVE ASSESSMENT

PAD is a systemic disease and a coronary artery disease (CAD) "equivalent." PAD is more of a marker for cardiovascular mortality, heart attack and stroke than it is a harbinger of limb loss. Mortality in patients with PAD averages 2% per year, and the incidence of nonfatal myocardial infarction, stroke, and vascular death is estimated at 5% to 7% per year for PAD patients. Therefore, medical therapy and risk factor modification are mandatory in all PAD patients, regardless of whether intervention is planned. Treating lesions by endovascular therapy or open bypass surgery without maximizing these noninvasive aspects of care is inadequate therapy.

The Society for Vascular Surgery (SVS) and American Heart Association (AHA) guidelines offer evidence-based recommendations for the medical management of important PAD risk factors. The major modifiable risk factors are smoking, hyperlipidemia, hypertension, and diabetes. Antiplatelet therapy should be routinely administered.

Smoking is an independent risk factor for PAD, increasing its prevalence and severity. Smokers are three to five times more likely to require amputation than nonsmokers. Physician advice, group counseling, nicotine replacement, and antidepressant drug therapy increase the success of tobacco abstinence.

Hyperlipidemia is an independent risk factor for PAD best controlled by statin administration and dietary modification. Target levels are a low-density lipoprotein (LDL) <70 mg/dL in patients with coronary disease/PAD and <100 mg/dL in those without. Statin administration has

pleiotropic effects, however, and seems to improve outcomes in patients with PAD regardless of LDL levels. Fibrates and/or niacin are useful in lowering triglycerides and in raising HDL, although raising HDL has yet to show clinical benefit.

Hypertension is another major PAD risk factor. Blood pressure control can reduce PAD-related complications by 22% to 26% and also significantly reduces both cardiovascular and cerebrovascular events. Current recommendations are a target blood pressure <140/90 mm Hg (<130/80 mm Hg in those with diabetes or renal insufficiency) in PAD patients. Comprehensive diabetes management is also an important component of PAD care. Large-scale studies have shown that diabetes management with a target hemoglobin A1c is <7.0% reduces diabetes-related myocardial infarcts and other diabetes-related endpoints.

Antiplatelet therapy is an essential tool to reduce subsequent cardiovascular and cerebrovascular events. Daily aspirin therapy confers a 25% reduction in cardiovascular events. Low-dose aspirin is as effective as full-dose aspirin with fewer adverse reactions. Other antiplatelet drugs are effective but may carry a higher risk of bleeding.

INDICATIONS FOR INFRAINGUINAL BYPASS

The presence of either limb-threatening ischemia or lifestyle-limiting IC is an indication for intervention. Once the diagnosis is established and the extent of disease determined, an assessment of the patient's ability to tolerate revascularization is necessary. A chest radiograph and electrocardiogram will give rough estimates of cardiopulmonary status. Further cardiac evaluation and/or optimization are recommended if the patient has unstable angina, significant arrhythmias, or symptoms of congestive heart failure.

Preoperative Planning

Selection of Inflow Artery

The inflow target for femoral-popliteal bypass is based on physical examination and noninvasive studies and confirmed by preoperative or immediate pre-bypass angiography. Hemodynamically significant aorto-iliac inflow lesions should be addressed before or in conjunction with the infrainguinal bypass procedure. Although the CFA frequently serves as the graft origin, distal origin sites, when appropriately selected, are equally effective, especially in redo operations and when vein conduit is limited. If

the CFA is significantly diseased, it is prudent to consider CFA endarterectomy to include the profunda femoris artery (PFA) origin if also involved. CFA exposure may be prohibitive in reoperative procedures or morbidly obese patients. The PFA or superficial femoral artery (SFA) can often serve as alternate inflow sources. Regardless of site of origin, adequate inflow is crucial to bypass success.

Selection of Outflow (Target) Artery

The distal target artery is ideally normal in caliber, free of stenosis and in general, should be in continuity with at least one of the arteries supplying the foot. The above-knee popliteal artery (AKP) has a higher incidence of atherosclerotic disease extending from the SFA. Therefore, the below-knee popliteal (BKP) artery is more commonly used for femoral-popliteal bypass. If the popliteal artery (PA) is highly diseased or occluded, the tibial artery with the best runoff to the foot should be selected as the target. With the increased prevalence of diabetes, it is increasingly important to consider the location of the foot ulcer. The angiosome model may be important to consider in patients with extensive pedal and arch occlusive disease in whom hindfoot and forefoot flow may be compartmentalized. A common example of this issue includes deep heel ulcers in patients with renal failure. Improper selection of the outflow target artery may precipitate graft failure and potentially jeopardize limb viability. Both preoperative duplex imaging and detailed angiography, including lateral magnified views of the foot, are essential to select the most appropriate target. Evidence to date suggests that when possible, angiosome-directed revascularization shortens wound-healing times.

Preoperative Assessment of Vein Quality

A complete history and physical examination will often reveal whether the great saphenous vein (GSV) has been previously used for coronary bypass, lower extremity revascularization, or stripped for varicosities. Preoperative venous duplex mapping should be routine because conduit quality is the key to both short- and long-term bypass patency. Vein mapping should evaluate the diameter, compressibility, wall thickness, and flow through the prospective conduit. The cephalic, basilic, and small saphenous veins should be evaluated if the GSV is absent or inadequate. Vein conduit diameter should be at least 3 mm to optimize patency. The location of the vein should be marked on the skin with an indelible marker to facilitate harvest and minimize creation of skin flaps during harvest.

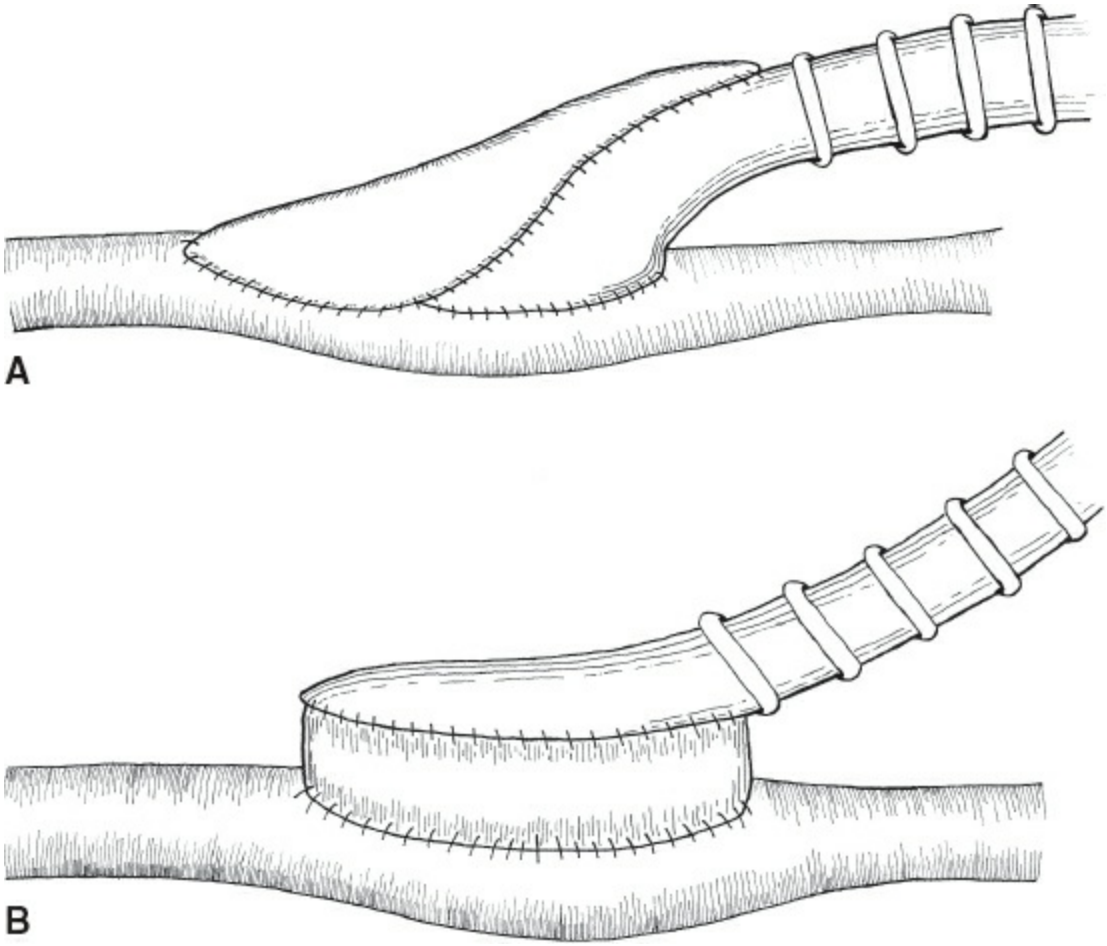

Figure 207.1. The Taylor patch (**A**) and Miller cuff (**B**) are useful adjuncts to aid in the anastomosis of PTFE grafts to smaller caliber tibial arteries and may improve short-term and intermediate graft patencies. (Reprinted from Rutherford RB. *Vascular Surgery*. 6th ed. Philadelphia, PA: Saunders; 2005. Copyright © 2005 Elsevier, with permission.)

Conduit Selection

Autogenous vein grafts provide the best patency rates in arterial bypass for all infrainguinal reconstructions, regardless of distal target level. The conduit of choice for a femoral-popliteal bypass is therefore ipsilateral GSV. Reversed and in situ configurations are equally effective, but reversed vein is applicable to more patients and generally simpler to employ. Although our own group and others prefer reversed vein, equivalent success has been reported with in situ vein conduits. If ipsilateral GSV is inadequate or unavailable, contralateral GSV is the next best option. Splicing the short saphenous veins (SSVs), and/or the cephalic and basilic veins from the arms often provides enough length for bypass in the absence of suitable leg vein.

Nonautogenous options exist for the uncommon patient who truly lacks suitable vein conduit. The most commonly used prosthetic conduit for femoral-popliteal bypass is PTFE (polytetrafluoroethylene). Recent clinical studies suggest that heparin-bonded PTFE may confer improved patency rates for femoropopliteal bypass comparing to ePTFE without heparin. In the case of femoral above-knee popliteal bypass, PTFE grafts have patency rates similar to RSVG for the first 2 years, but vein is superior thereafter and is thus preferable. Prosthetic bypasses to the BKP and tibial arteries have uniformly poor patency that can be modestly improved by the use of an adjunctive vein cuff (Miller or St. Mary's) or Taylor patch (Fig. 207.1). Cryopreserved vein grafts are expensive, have exceedingly poor patency rates and should be reserved as conduits of last resort for limb salvage indications; they may also have a niche in the management of patients with infected prosthetic grafts who require revascularization.

In Situ or RSVG

Nearly all randomized trials have shown equivalent patency and limb salvage rates for in situ and reversed vein. Small caliber veins perform poorly in either configuration. Reversed vein conduits are more user friendly and readily adaptable to a variety of clinical scenarios. Expected graft patency rates are shown in Table 207.1.

ANATOMY

Surgical Anatomy of the Femoral, Popliteal, and Tibial Arteries

The femoral triangle is an important anatomic space bordered by the inguinal ligament superiorly, the sartorius muscle laterally, and the adductor longus muscle medially. The floor of the femoral triangle consists of the iliacus, psoas major, pectineus, and adductor longus muscles. The vascular structures in the femoral triangle are contained within a fascial covering, the femoral sheath. The CFA is the continuation of the external iliac artery as it exits beneath the inguinal ligament. In the femoral triangle, it divides into two major branches (Fig. 207.2). The PFA is most commonly a posterolateral branch and not only provides blood to the thigh, but also serves as an important collateral in patients with SFA occlusive disease. The SFA is the continuation of the CFA and supplies blood to the lower leg. Exiting the femoral triangle, the SFA proceeds distally on its course into the adductor canal. The common femoral vein

(CFV) is located just medial to the CFA in the triangle and the GSV enters the CFV at the fossa ovalis. Other important structures in the femoral triangle include the femoral nerve, lying lateral to the artery and providing motor and sensory function to the lower extremity. The lymphatics are medial to the CFV.

TABLE 207.1 Expected Primary Patency Rates (%) of Infrainguinal Bypass Grafts

	1 Year	3 Year	5 Year
Above-Knee Popliteal			
Reversed vein	84	73	70–76
Arm vein	82	60	
PTFE	79	66	37–52
Below-Knee Popliteal			
Reversed vein	84	78	
In situ vein	80	73	
PTFE	65	29–44	
Infrapopliteal[a]			
Reversed vein	77	66	
In situ vein	82	74	
PTFE	46	<25	

[a]Limb salvage rates are 75–83% at 4 years (vein) and 48% (PTFE).

The popliteal fossa is another important anatomic location in lower extremity revascularization. It is a diamond-shaped space defined anteriorly by the femur, upper tibia, and popliteus muscle; posteriorly by the skin, subcutaneous tissue and fascia; laterally by biceps femoris and gastrocnemius muscles; and medially by semitendinosus and semimembranosus muscles. The SFA exits the adductor canal at the apex of the popliteal fossa where it becomes the PA. Paired popliteal veins are closely adjacent.

The below-knee PA in the distal popliteal fossa is variable in length before dividing into the anterior tibial (AT) artery and the tibioperoneal (TP) trunk. Most commonly, the AT is the first to originate and travels laterally to enter the anterior compartment of the lower leg and continues to the foot where it becomes the dorsalis pedis artery. The TP trunk subsequently branches into the posterior tibial (PT) artery and the peroneal artery, which enter the deep posterior compartment of the lower leg. They are exposed in their proximal and mid portions through medial calf

incisions, usually through the same incision used to harvest the GSV. After dividing the fascia to enter the superficial posterior compartment, the medial head of the gastrocnemius muscle is retracted posteriorly. The soleus is taken down off the tibia to gain entry into the deep posterior compartment, within which the posterior tibial artery is more superficially located while the peroneal artery is deeper, adjacent to the fibula.

The AT artery is exposed through a vertical incision in the anterior compartment 1 to 2 fingerbreadths lateral to the tibia. The proper plane is between the AT muscle and the extensor digitorum longus. The distal one third of the peroneal artery can be most expeditiously approached through a lateral leg incision directly over the fibula. Careful removal of a short segment of fibula uncovers this segment of the artery. Posterior approaches to the peroneal tibial arteries have also been described and are useful for performing popliteal-distal bypasses with SSV in patients lacking GSV (Fig. 207.3).

SURGICAL TECHNIQUE

Operative Technique for GSV, SSV, and Arm Vein Harvest

The GSV can be found in the femoral triangle through the same incision used to expose the CFA. Preoperative skin marking with duplex vein mapping is helpful, especially in obese patients. Skin incisions should be made directly over the vein to avoid undermined, subcutaneous flaps that are prone to necrose. The GSV should be clearly identified in the fossa ovalis as it enters the CFV and differentiated from its anterior branch. Gentle retraction provides exposure as the periadventitial tissue is sharply dissected from the vein. Small tributaries are ligated with silk suture. When tying close to the vein one should leave a short stump of the divided branch to avoid narrowing the conduit. Dissection is continued distally to obtain an adequate length of GSV. We prefer skip incisions, allowing bridges of skin to remain intact (Fig. 207.4). A small clamp is then placed flush with the CFV to maximize length of the conduit. The GSV is divided and the short proximal stump oversewn with running monofilament suture. The GSV should be treated gently to minimize trauma during the harvest.

The GSV is then prepared for use as a conduit by first placing it in a bath of heparinized saline and papaverine. The proximal end of the vein is clamped with a small bulldog clamp. Heparinized saline is flushed from the distal end. Small tears or missed branches are meticulously repaired with simple 7-0 polypropylene suture to avoid stenosis. The vein should be

blue in color, not thickened, soft and distend fully with gentle irrigation. Overdistension of the vein should be avoided. Irrigant should readily flow through the prepared conduit when the clamp is released. Focal areas of sclerosis may require resection. After preparation, the vein is stored on a back table in chilled, autologous heparinized blood until needed. Endoscopic GSV harvesting is an alternative less invasive method to obtaining the conduit. In our view, this technique has a steep learning curve, has minimal advantages in most circumstances, and may compromise conduit performance.

The SSV is most easily harvested with the patient prone. A longitudinal incision is created on the posterior aspect of the calf lateral to the tendo-Achilles. The subcutaneous tissue is carefully divided with scissors until the vein is identified. Small branches are carefully tied a short distance away from the vein. The sural nerve runs along the course of the SSV and should be protected during harvest.

If leg veins are unavailable, arm veins, as identified by preoperative duplex, should be used. Both the cephalic and basilic veins are useful conduits when of good caliber and unscarred or fibrotic from previous venipunctures. The cephalic and basilic veins originate at the wrist and extend to the shoulder. They may be joined at the elbow by the median antecubital vein. Multiple configurations of the arm and forearm components of both veins can be used to create a conduit for leg bypass. If two segments are connected by the median antecubital vein, the nonreversed segment will need valvulotomy. Segments of arm vein that are not in direct continuity will require splicing. When arm veins are needed, the use of two surgical teams expedites the procedure. While one team exposes the inflow and outflow arteries, the other may harvest and prepare the arm vein conduit.

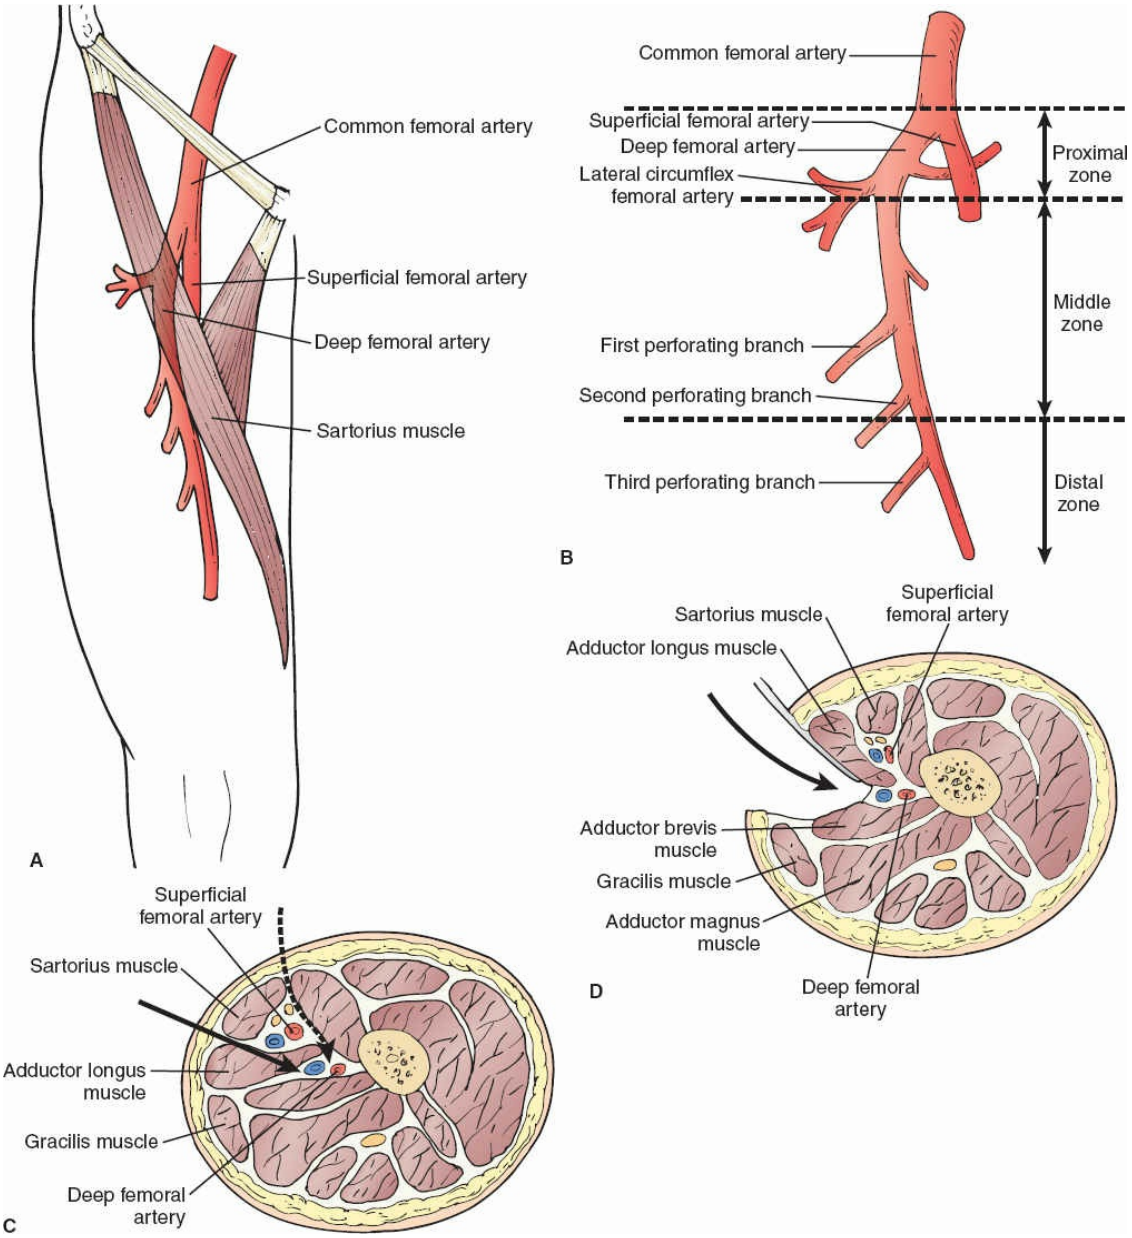

Figure 207.2. Alternate approaches to the distal deep femoral artery (DFA) are useful for reoperative femoral-distal bypass cases and when it is desirable to shorten the bypass due to limited length of vein conduit. **A.** Anatomy of the DFA showing surface landmarks used to identify the course of the DFA. **B.** The DFA can be divided into three zones. **C.** Transverse section of the thigh (viewed from above) shows the plane of dissection when the anterior-medial approach (*solid arrow*) is used. Alternatively, the DFA can be approached through an even more anterior route (*dashed arrow*) by an incision along the lateral border of the sartorius and by retracting this muscle and the superficial femoral neurovascular bundle medially to reach the distal DFA. **D.** Posterior approach to the distal DFA. Note the fascial plane and structures separating DFA from superficial

femoral vascular structures and isolating it from the subsartorial canal. (Reprinted from Rutherford RB. *Vascular Surgery*. 7th ed. Philadelphia, PA: Saunders; 2010. Copyright © 2010 Elsevier, with permission.)

Construction of a Spliced Vein Bypass

The surgeon may connect vein segments by performing a veno-venostomy to create a conduit of sufficient length for the intended bypass. Spliced vein conduits are particularly useful when using arm vein. The ends of each vein are spatulated to accommodate size mismatch and to create a wide oval anastomosis. Interrupted fine polypropylene sutures are recommended to avoid purse stringing and stenosis. Arm veins frequently harbor sclerotic segments or valve defects and should be assessed by careful inspection and either completion duplex imaging or angioscopy (if available).

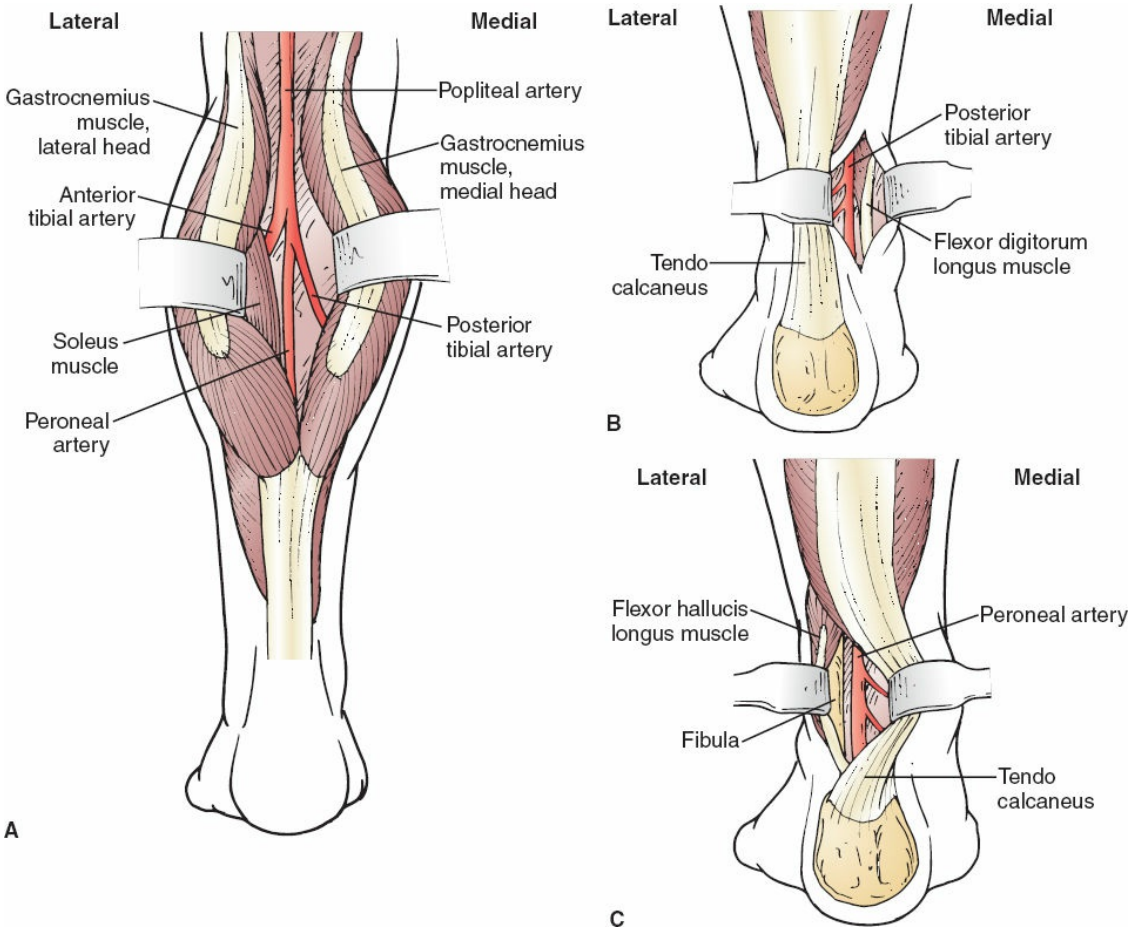

Figure 207.3. Posterior exposures of the infrageniculate arteries (**A, B, C**). **A.** Exposure of popliteal and proximal crural arteries via a posterior approach. Two heads of gastrocnemius muscle

are separated and soleus muscle is lysed from its tibial origin. **B.** Exposure of PT artery through posterior approach. Tendo calcaneus is retracted laterally. Flexor digitorum longus muscle is reflected medially in the lower portion of calf because artery lies posterior to lateral border of this muscle near level of malleoli. **C.** Exposure of peroneal artery through posterior approach. Tendo calcaneus is retracted medially and flexor hallucis longus muscle is reflected laterally to expose artery in groove next to fibula. (Reprinted from Rutherford RB. *Vascular Surgery*. 7th ed. Philadelphia, PA: Saunders; 2010. Copyright © 2010 Elsevier, with permission.)

Figure 207.4. A. Skip incisions for vein harvesting are used when possible. **B.** This technique avoids long incisions and extensive flaps that may necrose or compromise healing (incision well healed at 7 weeks).

Operative Technique for Femoral to Above-Knee Popliteal Bypass

The CFA is the inflow source used most frequently for AKP bypass. The

CFA pulse can be palpated midway between the pubic tubercle and anterior superior iliac spine below the inguinal ligament. A vertical incision is made directly over this pulsation. The soft tissue is dissected with electrocautery down to the femoral sheath. Self-retaining retractors provide adequate exposure. The CFA is sharply dissected and exposed proximally to the inguinal ligament. Distally, the dissection is carried out onto the proximal SFA. The PFA is identified and exposed. A blunt right-angle is employed to place medium silastic vessel loops around each vessel, facilitating subsequent clamp placement or providing vessel control if the artery is soft and nondiseased.

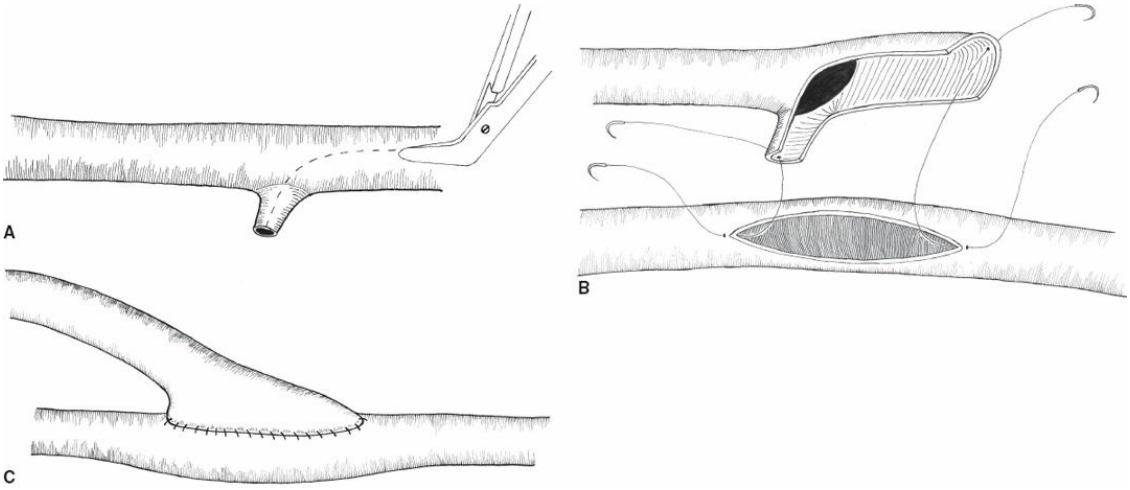

Figure 207.5. The venotomy through the reversed vein is extended out through a suitable side branch (**A**) and anastomosed to the inflow artery (**B** and **C**) to avoid anastomotic stenosis at the graft heel. This technique may be used both at the proximal anastomosis or the distal anastomosis and is useful when vein caliber is small or the arterial wall is thickened. (Reprinted from Rutherford RB. *Vascular Surgery*. 6th ed. Philadelphia, PA: Saunders; 2005. Copyright © 2005 Elsevier, with permission.)

The AKP is exposed from the medial thigh. A longitudinal incision is carried out anterior to the sartorius muscle above the knee. The soft tissue is divided with electrocautery and the sartorius muscle is retracted posterolaterally. The deep fascia overlying the adductor canal is then visualized and divided sharply to expose the popliteal fossa. The artery is dissected and mobilized to ensure adequate length for control and creation of an anastomosis. Palpation is used to identify a healthy segment of artery for the distal anastomosis. Proximal and distal vessel loops are placed.

Once proximal and distal arterial targets have been properly prepared, the conduit can be tunneled. A long hollow-bore, curved tunneling device with a removable blunt tip is passed from the groin incision to the popliteal fossa in the anatomic plane (or the subsartorial plane in reoperative cases). The prepared vein conduit is again checked for leaks. It is gently distended with heparinized blood and marked along its length in order to avoid twisting and to validate its correct orientation after tunneling. The proximal end of the vein conduit is attached to the obturator of the tunneler and pulled into position. The tunneler is then removed and proper orientation of the vein is reconfirmed. Systemic heparin is administered and allowed to circulate for 5 minutes prior to clamp placement.

The proximal anastomosis is performed first. If the distal vein was divided at a branch point, an incision is made through both branches to spatulate the end (Fig. 207.5). Otherwise, a longitudinal incision is made in the vein at least 1.5 times its diameter and tailored. The inflow vessels are clamped. An arteriotomy is created with an #11 blade scalpel on the anterior wall of the CFA and extended proximally and distally with Potts scissors to an appropriate length. Typically, running 5-0 or 6-0 polypropylene suture is used to create the anastomosis. The heel of the graft is secured first and the graft is sutured continuously to a point halfway toward the toe. A second suture is started at the toe and continued toward the heel suture. As the anastomosis progresses, attention is paid toward everting the suture line. After flushing, the clamps are then released and a surgical hemostatic agent applied. Single-repair sutures of 6-0 polypropylene are used if bleeding between running sutures is encountered. A soft bulldog clamp is placed on the proximal vein graft until the distal anastomosis is completed.

The distal anastomosis is performed in similar fashion. The AKP is most often controlled with vessel loops or clamps. A long arteriotomy is again performed 1.5 times the diameter of the graft. Fogarty catheters can be used for control in the presence of excessive calcification. Vein graft orientation is rechecked; release of the bulldog clamp should result in highly pulsatile flow. The vein is tailored appropriately. The heel is secured with a running 6-0 polypropylene suture and continued toward the toe. A second suture starting from the toe is sewn until it meets the first suture. Once the clamps or vessel loops are released, measures to ensure hemostasis are employed.

Operative Technique for Femoral to Below-Knee Popliteal Bypass

The BKP is exposed through a longitudinal incision 1 to 2 cm posterior to the medial edge of the tibia. The subcutaneous tissue is divided with electrocautery. The pes anserinus tendon is divided. The posterior fascia is identified and divided longitudinally as well. The medial head of the gastrocnemius muscle is bluntly mobilized and retracted posteriorly to expose the popliteal fossa. Gentle blunt dissection is performed until the neurovascular contents of the fossa are identified. Self-retaining retractors are placed. The fascial sheath around the vessels is entered with Metzenbaum or tenotomy scissors. The adherent popliteal vein(s) are carefully dissected from the artery and small venae comitantes are divided and ligated with 4-0 silk. Proximal and distal control is obtained with large vessel loops. The tunneler is advanced from the popliteal fossa between the heads of the gastrocnemius muscle to the groin incision. The gently distended conduit is passed through the tunneler, ensuring proper orientation. Anastomoses are created in the same fashion as for AKP bypass.

Operative Technique for Tibial Bypass

Inflow and outflow sites are exposed as described above. After a suitable conduit has been prepared, the reversed graft is tunneled in an anatomic plane using a large hollow bore tunneler. In reoperative settings or when arm or spliced vein from sites other than the ipsilateral extremity are used, we prefer to tunnel the graft in a deep subcutaneous plane. This technique is especially applicable when performing a redo bypass and in patients with threatened limbs and diabetes, in whom we often perform BKP to tibial or pedal bypass. In the latter case, thigh vein is harvested through skip incisions. Short incisions are used to expose the BKP and the tibial target artery. The graft is then reversed and tunneled in a deep subcutaneous plane beneath intact skin. This technique avoids wound complications and potential graft exposure associated with calf vein harvest (Fig. 207.4).

An additional concern is vessel wall calcification. The tibial arteries, particularly in patients with diabetes, are often heavily calcified. In such cases, the vessels should not be clamped and usually cannot be controlled with vessel loops alone. A tourniquet can be used for control. Alternatively, intraluminal control after arteriotomy can be obtained with

small 2 or 3 mm Fogarty catheters or intraluminal devices of an appropriate diameter such as a Flo-Rester (Synovis Surgical Innovations; St. Paul, Minnesota). The anastomoses should be created to the least calcified region possible. If calcification is excessive, a CC (calcified coronary) needle is extremely useful. Formal endarterectomy should be avoided; loose-calcified fragments that develop during anastomosis creation should simply be removed or flushed out. Running 6-0 or 7-0 Prolene suture is usually employed.

Intraoperative Bypass Graft Assessment

Intraoperative assessment should confirm graft patency, establish the integrity of the conduit, confirm adequacy of the outflow, and identify potential conduit, anastomotic, and technical defects that may predispose to thrombosis. A sterile Doppler probe is the easiest way to assess graft flow and flow in the foot. Intraoperative duplex imaging can also be used to detect technical or intrinsic conduit defects. Because of ease of use and the widespread availability of quality intraoperative imaging, we routinely perform completion arteriography by inserting a 21-gauge butterfly needle connected to a 3-way stopcock and extension tubing into the hood of the proximal anastomosis. DSA is performed to visualize from the proximal graft to the foot. The anastomoses, conduit and outflow should all be imaged and any major defects corrected.

Wound Closure

After confirming patency and achieving hemostasis, the wounds are closed in layers. The fascia and deep subcutaneous tissue are reapproximated with absorbable suture. In elective procedures, the skin can be closed in a subcuticular fashion. In patients with significant edema, the skin (particularly below the knee) should be closed with skin edge eversion using interrupted 3-0 or 4-0 nylon mattress sutures. A closed suction drain is occasionally placed in the groin if there is a concern for lymphatic leak, especially in reoperative procedures. Sterile dry gauze or skin glue is then used to cover the incisions.

Alternative Inflow Sources

The length of available vein may be insufficient to allow bypass origination from the CFA. In other instances, CFA exposure may be

prohibitive due to excessive scarring from previous revascularizations. The PFA may serve as a useful alternative inflow source (Fig. 207.2). The mid or distal PFA is exposed by a longitudinal incision on the upper thigh lateral to the sartorius muscle. The soft tissue is dissected until the sartorius can be retracted medially. The SFA is visualized and retracted medially as well. Dissection is carried out between the adductor longus and vastus medialis to expose the PFA. Ligation and division of crossing veins are often necessary to provide adequate exposure. Small PFA branches are controlled with silastic loops.

The SFA may also be used selectively as an alternate inflow source. If a vertical incision has been made in the groin, it can be extended distally. The sartorious is retracted laterally to further expose the SFA. The mid and distal SFA may be approached via a vertical medial thigh incision near the posterior border of the sartorious. The fascia is divided and the sartorious retracted anteriorly to expose the SFA in Hunter's canal.

Shortening the bypass is a useful technique to allow use of a single segment of optimal conduit. Adequate inflow and outflow should be assured by preoperative vascular lab studies and imaging and confirmed by intraoperative pulse palpation and completion angiography. If the proposed bypass cannot be shortened due to disease extent, additional good quality vein should be harvested and spliced to create a conduit of sufficient length.

Intraoperative Troubleshooting and Pitfalls

Distal bypass is one of the most taxing operations that vascular surgeons perform. Achieving optimal results requires proper planning, meticulous technique, and prudent judgment. A number of issues may arise during or early after leg bypass that must be carefully addressed to avoid graft failure and potential limb loss.

Inadequate Vein Conduit

The majority of vein conduit problems can be anticipated preoperatively if high-quality duplex vein mapping is performed. When vein problems are unexpectedly encountered, several options are available. If the vein abnormality is focal (sclerosis), the segment may be resected and a veno-venostomy performed. The ends should be spatulated to create a wide anastomosis. In the event that long segments of the vein are unusable, additional vein should be harvested from an alternate site—contralateral

GSV, SSV, or arm veins. Creating the proximal anastomosis to the PFA or SFA can allow utilization of shorter segments of vein.

Small-Caliber Vein

At times, there is a size mismatch between the small-caliber reversed vein and a larger, thick-walled artery at the proximal anastomosis. If possible, a large branch at the distal end of the GSV should be preserved during harvest. The venotomy can incorporate this branch to create a heel that sits up away from the artery (Fig. 207.5), avoiding suture line stenosis.

Unexpected Inflow Disease

Optimal diagnostic angiography (including oblique views of the iliac arteries with pull back pressures if uncertainty exists) will typically detect the presence of inflow disease. Atherosclerotic disease of the CFA and PFA can be addressed with an endarterectomy. This may entail partial division of the inguinal ligament to allow clamp placement on nondiseased external iliac artery. A long venotomy can be used for the anastomosis if the conduit is of adequate caliber. Otherwise, the arteriotomy may require a vein or Linton patch (Fig. 207.6) with subsequent anastomosis of the bypass conduit to the patch. Alternatively, a segment of occluded SFA can be endarterectomized and used to patch the arteriotomy.

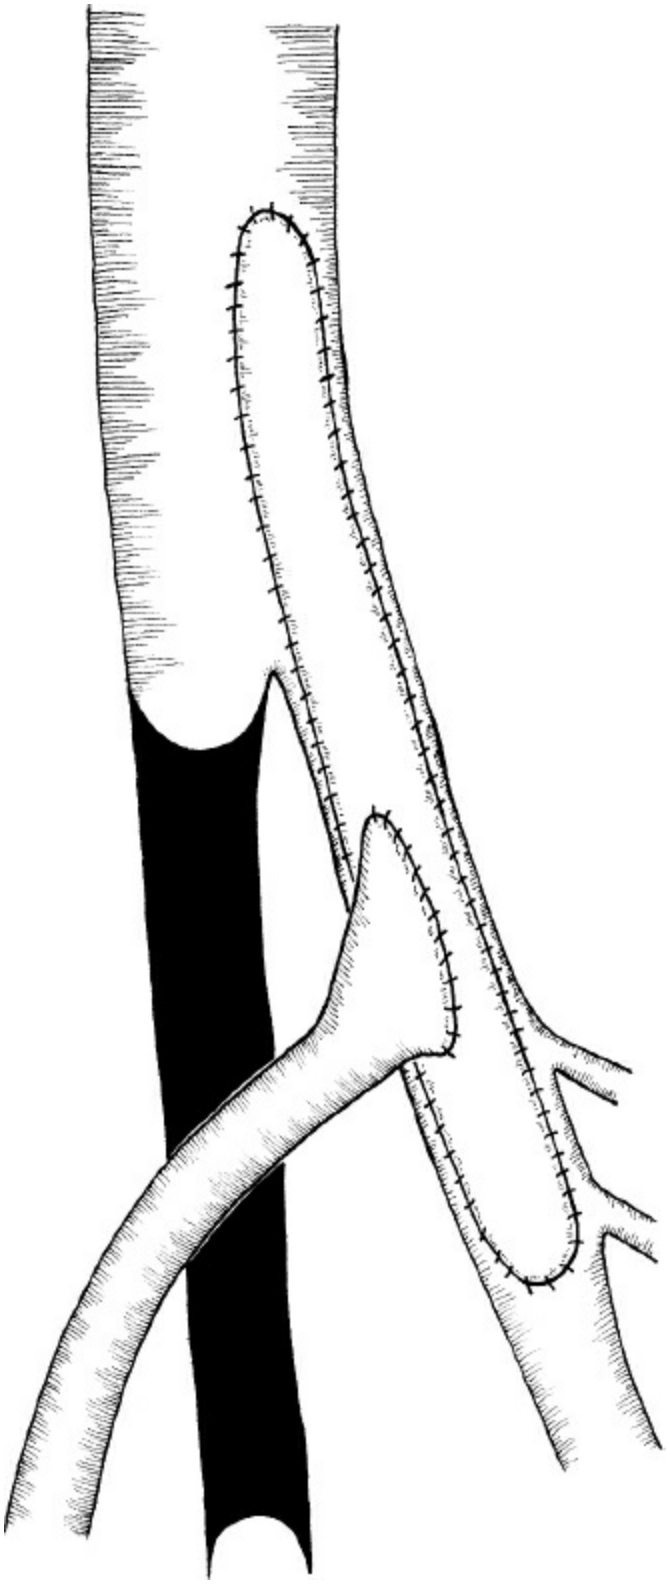

Figure 207.6. Use of Linton vein patch technique following endarterectomy of the distal common and proximal DFAs with anastomosis of the reversed vein graft to the patch. (Reprinted from Rutherford RB. *Vascular Surgery*. 6th ed. Philadelphia, PA: Saunders; 2005. Copyright © 2005 Elsevier, with permission.)

Unexpected Outflow Disease

The distal target for a femoral-popliteal bypass graft is generally an area free of disease with at least one continuous runoff artery to the foot. Unexpected, significant popliteal disease may require bypass extension to more distal tibial or pedal targets. Intraoperative angiography is employed to locate the most proximal segment of tibial or peroneal artery that is continuous with the foot. The bypass is performed to this site.

Sequential bypass is useful for situations in which an isolated patent popliteal segment exists between severely diseased SFA and distal popliteal-tibial arteries. A bypass graft from the thigh is connected to the proximal portion of the popliteal island. A separate bypass graft uses the distal popliteal segment as inflow and connects to a tibial or pedal vessel that is in continuity with the foot. The advantage of this technique is that it permits use of shorter vein segments and avoids the need to splice veins.

Tunneling Problems

An experienced member of the operative team should tunnel the conduit. Passing the conduit through a large bore tunneler protects it from tearing or shearing as it is pulled into place. The vein conduit should always be distended as it is passed in order to avoid twists or kinks. After tunneling, irrigation through the proximal end of the graft should produce vigorous flow. After completing the proximal anastomosis, the graft flow should be highly pulsatile. If these are not observed, the graft should be re-tunneled.

Anastomotic Stenosis

Prevention is the key to avoid anastomotic stenosis. Diligence in tailoring the graft during the anastomosis usually prevents this problem. When a size mismatch exists between the vein conduit and the artery, a suitable branch of the vein graft should be incorporated into the venotomy or a modified Linton patch utilized as already described. Completion angiography, intraoperative Doppler or duplex ultrasound will identify anastomotic stenoses that occur despite careful operative technique. If a stenosis occurs, the anastomosis is examined and any trapped adventitia is freed. If the narrowing persists, the anastomosis should either be redone or patched with vein.

Reoperative Bypass

Reoperative bypass can be difficult, even for the most experienced surgeon. Preoperative vein mapping and careful planning are critical.

Autogenous conduit should be used if at all possible. It is prudent to simplify dissection by avoiding previously operated fields through the use of alternative inflow and outflow sites; these approaches may require exposure of the distal PFA, SFA, and alternate tibial artery exposures.

COMPLICATIONS

Graft Thrombosis

Early vein graft thrombosis most often results from technical error, poor conduit, or poor outflow. In order to preserve the graft and distal perfusion, the patient requires timely return to the operating room. The presence of valves presents a challenge for graft thromboembolectomy. The incision for the popliteal exposure is reopened and the distal anastomosis is controlled. A dose of intravenous heparin is given. A longitudinal venotomy is made over the hood of the graft. Visible clot in the graft is teased out. An embolectomy catheter is then passed distally to treat the runoff vessels. An attempt is made to pass the embolectomy catheter proximally. If valves prevent catheter passage, the proximal anastomosis is re-exposed. After proximal control, an incision is made in the hood of the graft. The embolectomy catheter is passed proximally to distally and out the distal graftotomy. A separate embolectomy catheter is tied to the distal aspect of the first catheter, which is then retracted proximally. The tie is cut and the balloon on the catheter passed from below inflated and this catheter withdrawn in the direction of the valves and the thrombus retrieved through the distal graftotomy. The graft is then vigorously flushed with heparinized saline. Any evident anastomotic defect or intimal flap is corrected and patched if needed. Completion angiography is performed to assess the adequacy of thromboembolectomy and to ensure there are no residual conduit defects, tunneling problems or outflow issues. If there is concern for reperfusion syndrome, four-compartment fasciotomy should be considered.

Specific patient subgroups may be more prone to early graft thrombosis. A report based on the National Surgical Quality Improvement Program (NSQIP) evaluated 14,788 patients undergoing infrainguinal bypass. Patient factors associated with early graft thrombosis were age <60 years, African-American race, nondiabetics, and bypass to tibial vessels.

Late graft thrombosis occurs after 30 days and is usually not technical in nature. Vein grafts develop intimal hyperplasia, a process that is usually self-limited; 20% to 30% of vein bypass patients develop a graft-

threatening stenosis, usually solitary and focal, and most often within 2 years of graft implantation. Routine duplex surveillance identifies and monitors such lesions for progression, allowing timely intervention by percutaneous or open intervention to maintain graft patency and limb salvage.

Bleeding

Bleeding complications can be reduced by meticulous technique. When harvesting vein grafts, all small side-branches must be ligated. Larger branches, especially on delicate arm veins are suture ligated with fine Prolene. Hemostatic clips on the vein graft itself may become dislodged during tunneling and should be avoided. Careful inspection of the vein on the back table is time well spent. Bleeding of the vein graft in the tunnel can be repaired by direct cut down onto the area of concern. Focal bleeding from the anastomosis usually requires placing single-repair sutures. Severe bleeding from the anastomosis may be the result of improper technique, failure to include all layers of the arterial wall when suturing, poor vessel wall integrity, or excessive tension. The anastomosis may need to be redone if this occurs. Early postoperative bleeding is usually technical in nature or due to anticoagulation and antiplatelet therapy. Prompt return to the operating room with repair minimizes further complications.

Infection and Lymphatic Leak

Infection is a troublesome complication of leg bypass. In patients with pre-existing foot infection, appropriate systemic antibiotics should be administered and adequate drainage to control infection performed prior to bypass. In the absence of preoperative infection, a single perioperative dose of antibiotics to cover skin flora should be adequate. Surgical site infections are most often superficial and can be treated with drainage, simple dressing changes, and antibiotics. Deep wound infections may lead to graft exposure and even rupture. They require aggressive, early debridement, and muscle flap closure.

Lymphatic complications such as lymphocele or lymphatic leak may cause significant morbidity and increase late graft infection risk. These complications result from the disruption of the lymph channels, most commonly in the groin. Careful longitudinal dissection directly over the femoral artery with ligation of lymphatics during the initial operation helps

reduce lymphatic leaks. Reoperative procedures in the groin, however, are prone to the formation of lymphoceles and lymph leaks. Closed suction drains may be useful in selected redo operations. The wound should be re-explored and the offending lymphatics ligated for significant or persistent lymph leaks. Wound VAC (vacuum-assisted closure) therapy has been described both for prophylaxis and treatment of lymphatic leaks.

One of the best estimates of the real-world operative morbidity related to vein bypass operations comes from the PREVENT III trial, which enrolled over 1,400 patients from 83 different centers with limb-threatening ischemia. Thirty-day perioperative mortality was 2.7%. Early graft occlusion occurred in 5.2% of patients, while major wound complications (4.8%) and rates of hemorrhage (0.4%) were quite low.

POSTOPERATIVE MANAGEMENT

Postoperative leg bypass patients should be admitted to an appropriate surgical unit for cardiac monitoring and frequent neurovascular assessments. Any change in neurovascular status should provoke a complete evaluation for graft patency. In the event of early graft thrombosis, prompt return to the operating room is usually indicated. Although very uncommon in patients operated on for chronic limb ischemia, a developing compartment syndrome should not be overlooked.

Fluid and electrolytes should be monitored closely in the early postoperative period. PAD patients often suffer from concomitant cardiac disease. Antiplatelet therapy should be continued, as should antihypertensive medications and β-blockers. Any cardiac-related symptoms should be taken seriously and appropriately investigated. Unless the patient suffers from postoperative nausea and vomiting (we prefer regional techniques for most leg bypasses), diet can usually be resumed in the early postoperative period. Adequate pain control is important to allow early mobilization and to prevent complications related to immobility, such as deep venous thrombosis or generalized deconditioning. Physical therapy should be initiated early.

CONCLUSIONS

Resource utilization associated with leg bypass surgery is directly related to graft patency and the stage of limb-threatening ischemia (SVS WIfI) at presentation. Despite a widespread paradigm shift toward an endovascular first strategy, a balanced view would suggest that many patients with

severe PAD are best served with a bypass if their life expectancy is reasonable, operative risk is low or moderate, and good quality autologous vein is available. A comprehensive, longitudinal care approach includes performing every infrainguinal bypass with meticulous technique, using autogenous vein whenever possible, and following the patient closely with a serial, duplex surveillance program to optimize long-term graft patency. Long-term, ongoing medical treatment of PAD risk factors is also essential to prevent secondary cardiac and cerebrovascular events.

EDITOR'S COMMENT

Peripheral arterial disease (PAD) is the primary disease for which arterial revascularization is often performed. It is a marker of systemic atherosclerosis, as highlighted by the authors of this well-written chapter on reversed vein arterial bypass technique. However, the medical management is as important and relevant for all patients with PAD. This section is well detailed by the authors and I won't reiterate the details—suffice it to say, identification of vascular claudication is the first step, and then evidence-based therapies such as antiplatelet therapy, statins, and blood pressure control are paramount. I would add that all patients with PAD have their blood pressure goal be 120/80, as highlighted by the large SPRINT trial (Cushman WC, Whelton PK, Fine LJ, et al.; Group SSR. SPRINT Trial results: latest news in hypertension management. *Hypertension* 2016;67:263–5) and that Plavix did show a benefit in those patients with PAD, as compared with those that did not (CAPRIE Steering Committee. A randomised, blinded, trial of clopidogrel versus aspirin in patients at risk of ischaemic events (CAPRIE). CAPRIE Steering Committee. *Lancet* 1996;348:1329–39).

Mills and Lucas clearly describe the basics and the important caveats to make the reversed vein bypass successful—clearly from long experience. The details herein of performing the reversed vein technique will prevent common problems that may occur, and the technical points they make are almost exactly how I do my bypasses. I agree with the authors that the reversed technique is similar to the in situ technique with regard to patency and long-term success. Single-center series may suggest benefit of one technique over the other, but no large well-powered randomized controlled trials exist. Further, I believe that the surgeon should be comfortable with both techniques and use whichever one is most applicable to the clinical situation. For example, I mainly use the reversed vein technique, except for more distal bypasses such as posterior tibial and

peroneal. I like the reversed for above-the-knee and below-the-knee bypass targets, or when bypassing to the anterior tibial artery via a lateral pathway. The reversed technique tends to be a bit easier and has the advantage of anatomical tunneling, beneficial in patients with thin skin or at-risk patients for skin flap infection or breakdown that could lead to graft exposure with the in situ technique.

Recent data suggest that the conduit quality, greater than 3 mm and undamaged, is probably the most important factor influencing graft patency (Nguyen LL, Conte MS, Menard MT, et al. Infrainguinal vein bypass graft revision: factors affecting long-term outcome. *J Vasc Surg* 2004;40:916–23). I believe this plays a role in propensity to graft stenosis. The authors appropriately note that approximately 20% to 30% of patients with a reversed vein graft will develop significant neointimal hyperplasia with resultant stenosis —and can lead to graft thrombosis. One lesson learned by our group over the years is when you diagnose by duplex ultrasound surveillance a critical graft stenosis in clinic, don't let them leave. We admit these patients for heparinization and then next day endovascular cutting balloon angioplasty. This prevents the patient from returning with a thrombosed graft, even if only a few days. This also underlies the importance of post bypass duplex surveillance for any vein graft (Tinder CN, Bandyk DF. Detection of imminent vein graft occlusion: what is the optimal surveillance program? *Semin Vasc Surg* 2009;22:252–60).

Another aspect to highlight is in what circumstances to use anticoagulation after vein grafting. A cogent review (Hess CN, Norgren L, Ansel GM, et al. A Structured review of antithrombotic therapy in peripheral artery disease with a focus on revascularization: a TASC (InterSociety consensus for the management of peripheral artery disease) initiative. *Circulation* 2017;135:2534–55) suggests in high-risk grafts, such as a redo procedure or poor arterial outflow—that anticoagulation may be beneficial. We tend to follow this strategy, with low-dose heparin for the first 48 hours, then full IV heparin to bridge to Warfarin. It is not known whether the direct oral anticoagulants confer the same benefit, but is likely, and clinical experience will accrue.

Another technical aspect highlighted is careful and gentle dissection of the vein. I don't skeletonize the vein, but rather leave a good amount of periadventitial tissue as I think this leads to less local vein ischemia. There is no direct evidence for this, but I see no disadvantage. In addition to the heparinized blood for distending and testing the vein graft for leaks, we add papaverine to the blood solution to help break the vasospasm. Overdistension of the vein likely damages the endothelium, and may lead to neointimal hyperplasia.

Finally, for any type of revascularization in a patient with PAD, adhering to the proper indications cannot be overstated. Simply stated, severe claudication, rest pain, and tissue loss are the main ones. I recommend all surgeons who do vascular surgery to review the new consensus guidelines for treatment of PAD,

as the document is very clear and supported by multiple societies (Gerhard-Herman MD, Gornik HL, Barrett C, et al. 2016 AHA/ACC guideline on the management of patients with lower extremity peripheral artery disease: a report of the American college of cardiology/American heart association task force on clinical practice guidelines. *Circulation* 2017;135:e726–79). Even with an expertly performed reversed vein bypass, of which the durability can be greater than 10 to 15 years, some do fail and the patient may be worse (although less so than when a prosthetic bypass fails). Each later procedure or redo bypass has a greater chance of failure, and greater chance of leading to limb loss.

Peter Henke

208 Peripheral Arterial Disease: Prosthetic Bypass

Ahmed Kayssi, Ken Lee, and Richard F. Neville

INTRODUCTION

In the modern era of treating vascular disease, there has been a dramatic increase in the number of endovascular interventions and a corresponding reduction in the number of surgical bypasses performed for lower extremity peripheral arterial disease. The advent of endovascular therapy, however, has also resulted in an increase in the complexity of patients requiring bypasses for symptom relief, healing, and limb preservation, especially after failed endovascular intervention. For the foreseeable future, surgical bypass will continue to play an important role in the revascularization of patients with limb ischemia. A survey of vascular surgeons identified the following scenarios in which bypass continues to play a primary role in lower extremity revascularization: common femoral artery pathology, extensive tissue loss as an indication for revascularization, patients with a good life expectancy in whom durability is paramount, and long segment, infrageniculate occlusive disease especially in the setting of single tibial artery runoff.

Although surgical bypass with autogenous vein has an established clinical record, with excellent long-term patency rates, a certain proportion of patients needing bypass surgery lack suitable autogenous conduit. Reasons for the lack of vein include previous harvesting for lower extremity bypass, coronary bypass, small caliber or poor quality of the vein, varicose veins, or superficial thrombophlebitis. Several past series studying bypass with prosthetic conduit did not reflect a durable revascularization. In fact, primary amputation was considered as opposed to bypass with prosthetic conduit, especially if a tibial revascularization was required. But, more recent advances in technique and graft technology have led to improved results such that prosthetic conduit can now be considered a reasonable option for lower extremity bypass.

PREOPERATIVE PLANNING

Three factors must be considered when planning for a vascular bypass: the site from which the bypass will originate (the inflow), the site at which the bypass will restore flow (the outflow), and the choice of conduit for creating the bypass. Appropriate inflow and outflow sites are determined by the patient's clinical exam and preoperative imaging. The most commonly used inflow artery for a prosthetic infrainguinal bypass is the common femoral artery. However, the superficial femoral and popliteal arteries may be used in the absence of proximal occlusive disease as shorter bypasses have demonstrated excellent patency. However, one of the advantages of prosthetic conduit is length not functional as a factor to remain proximal to lesions affecting inflow. The most commonly performed lower extremity bypass with prosthetic conduit is the femoral-popliteal bypass. However, tibial bypass with prosthetic conduit has also been performed in numerous recent clinical series with encouraging results. Another consideration in the choice of target artery is the angiosome in which a non-healing wound or gangrene is located. Revascularization of the artery feeding the appropriate angiosome may lead to enhanced healing and limb preservation. Although this is merely one factor in the decision-making process, the use of prosthetic conduit, without length being a consideration, may allow revascularization of the appropriate angiosome and enhance tissue healing. Obviously, in planning a lower extremity bypass and prior to the use of a prosthetic conduit, careful examination should be made of all extremities for the presence of vein as an autogenous conduit supplemented with imaging in the noninvasive vascular lab.

GRAFT MATERIALS AND PROPERTIES

The ideal prosthetic graft would take advantage of many factors: impermeable to surrounding cells and fluids, resistant to thrombosis and infection, optimal compliance, biocompatibility, durability, availability in varying sizes, and cost-effectiveness. Electronegativity on the graft surface has been thought to be an advantage regarding inhibition of platelet aggregation with theoretic enhancement of this property by carbon coating of the luminal graft surface, although this has been difficult to prove in clinical application. Graft porosity has not been shown to significantly affect graft function, but may be implicated in tissue ingrowth. Several grafts have been developed with these properties in mind, but the most

commonly used prosthetic materials are Dacron and expanded polytetrafluoroethylene (ePTFE).

Dacron

The polyester fabric Dacron was developed by British chemists Whinfield and Dickinson in 1941, and is one of the oldest continuously used fabrics on the market. Dacron grafts can be knitted or woven. Knitted grafts have the advantage of better compliance, but have larger pores that tend to leak and require preclotting. As such, current versions of the knitted Dacron grafts are often coated with albumin to prevent leakage from those pores. Dacron is a resilient fabric estimated to last well over 30 years, but these grafts are at a higher risk of dilation compared with other graft materials. Dacron is currently used primarily as a large-diameter graft in the aortic position, but does maintain a role in lower extremity bypass surgery.

Expanded Polytetrafluoroethylene (ePTFE)

ePTFE is configured on a mandrel process with a nodal-fibril porous configuration with carefully constructed internodal distances to optimize function and healing properties. ePTFE grafts are available in several configurations: thin walled, ringed, and precuffed. The precuffed configuration was an attempt to optimize graft hemodynamics, but this has been difficult to confirm and may in fact be disadvantageous for optimal flow patterns. ePTFE grafts are produced by extruding a low porosity conduit in the form of a tube that is compliant, easy to suture, and should not be preclotted or soaked prior to implantation.

Several studies have been carried out to compare Dacron and ePTFE grafts for lower extremity bypasses. Rychlik and colleagues published a meta-analysis in 2014 that reviewed 91 publications and assessed 1,192 patients who underwent above-knee femoropopliteal bypass using Dacron versus ePTFE. The authors reported similar primary patency between the grafts up to 10 years, and no difference in the incidence of amputation, morbidity, or mortality between the patient populations. A Cochrane Review published in 2010 similarly reported that vein grafts were superior to prosthetic grafts, but that long-term outcomes when using Dacron and ePTFE for prosthetic bypass in the lower extremities were similar.

Polypropylene

Early experience with the use of this hydrocarbon material in the early 1990s was promising. A study of 4-mm lower extremity polypropylene grafts implanted in dogs by Greisler and colleagues from Illinois reported a 16-month patency of 81% compared with 69% and 20% for Dacron and ePTFE, respectively. Because of its susceptibility to oxidation, however, it is currently available only as part of multicomponent grafts that render the material inert.

Polyurethanes

Polyurethane grafts are produced by the reaction of isocyanates with an alcohol group. The advantage of this material is its high elasticity, but its poor biostability and loss of compliance after implantation have limited its widespread clinical application. This concern has been addressed by manufacturing a carbonate-reinforced polyurethane that is less susceptible to premature degradation.

Composite Grafts and Allografts

The successful implementation of prosthetic grafts has triggered the development of more novel materials such as composite grafts, which are biologic graft materials using human umbilical vein or ovine collagen. One such novel material is the Cytograft Tissue Engineering graft (Novato, California), which involves bilayer of living fibroblasts derived from cells extracted from patients rolled and matured over a steel mandrel. While this type of material has yet to be used in lower extremity bypasses, it has been used as a conduit in a hemodialysis access graft, which may hold an exciting future in the realm of prosthetic grafts.

Cryopreserved vein and human umbilical vein are alternative conduits that are biologic in their properties and therefore have an intrinsic appeal for distal reconstruction. First utilized in the 1960s, cryopreserved grafts are expensive when compared with other conduits, and have a greater incidence of aneurysmal degeneration and thrombosis from late rejection. The current data from multiple centers reported a 30% to 58% patency rate at 1 year using cryopreserved veins for infrapopliteal bypass, which are inferior to autologous conduits and inferior to heparin bonded ePTFE grafts. Some centers, however, have shown reasonable limb salvage rates, and therefore this material may have some value in bypasses that must traverse infected fields in the absence of any autogenous conduit options. The initial use of human umbilical vein grafts was also impeded by

aneurysmal degeneration of the graft material. This complication was addressed with modifications of the graft design; however, these grafts met with limited success when used for tibial bypass. In a large National Surgical Quality Improvement Program (NSQIP) database, human umbilical vein composite grafts had a significantly higher 30-day failure rate at 15.4% compared to 10.5% in PTFE grafts and 7.5% in great saphenous vein (GSV) conduits.

STRATEGIES FOR IMPROVING PROSTHETIC GRAFT FUNCTION

As previously mentioned, clinical outcomes with early prosthetic grafts were suboptimal especially for tibial artery bypass, with 1-year patency rates of 20% to 50% and 3-year patency rates of 12% to 40%. A comparison of venous and prosthetic conduits for infrapopliteal bypasses reinforced these findings, with 38% 2-year patency for ePTFE bypasses to tibial arteries. Beyond technical errors in the perioperative period, prosthetic graft failure occurs due to the development of myointimal hyperplasia (commonly between 6 and 24 months), or acceleration of atherosclerosis in the proximal or distal arterial bed (beyond 2 years). Efforts to improve outcomes for prosthetic grafts have focused on a reduction in graft thrombogenicity and myointimal hyperplasia formation. These efforts involve venous adjuncts at the distal anastomosis, heparin bonding to the graft surface, and addition of a distal arteriovenous fistula.

Vein Patches and Cuffs

Attempts to improve the performance of prosthetic grafts by altering the effect of anastomotic hyperplasia and graft thrombogenicity while improving hemodynamics and ease of suturing involved interposition of venous adjuncts at the distal anastomosis. The Miller cuff interposed autogenous vein at the distal anastomosis in a cuffed configuration (Fig. 208.1). Miller reported on 114 infrainguinal procedures using a vein cuff technique with a patency rate of 72% noted at 18 months. However, several disadvantages were recognized with this configuration, including significant turbulence at the anastomotic reservoir and difficulty in achieving an adequate angle between the graft and recipient artery. These factors may explain the immediate and early graft failures reported in Miller's initial series.

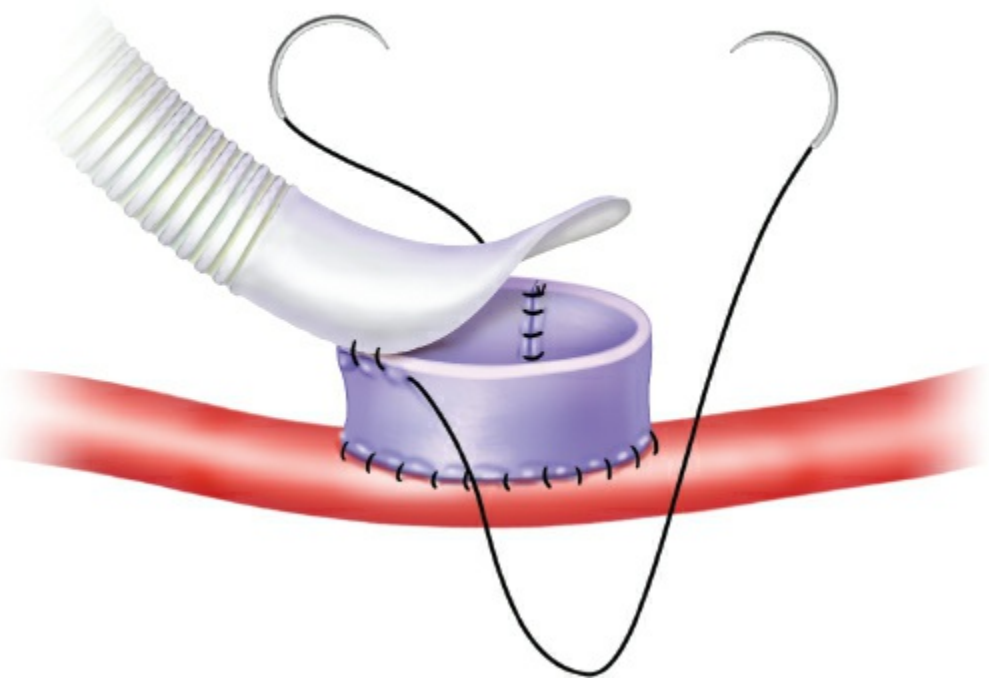

Figure 208.1. The Miller cuff technique. A venous cuff is interposed between a prosthetic graft and the target artery.

Taylor described a technique to address several of these concerns reporting on 256 grafts with 83 tibial bypasses, with 1-, 3-, and 5-year patency rates of 74%, 58%, and 54%, respectively (Fig. 208.2). However, there are also disadvantages to the Taylor patch technique. The tibial artery is directly exposed to PTFE graft material for the proximal portion of the anastomosis, thereby losing the advantage of venous endothelium for half the anastomosis. There can also be a point of anastomotic constriction where the three suture lines converge between the artery, ePTFE, and vein patch. Finally, a significant length of vein must be available to accomplish the anastomosis using the Taylor technique.

Several authors have reported their results with these techniques. Pappas obtained improved patency for prosthetic bypasses with the Miller cuff when as compared to historical controls with straight ePTFE. A prospective, randomized trial utilizing ePTFE grafts with and without a Miller vein cuff was reported by Stonebridge. This series did not demonstrate a statistically significant benefit for the vein cuff technique in tibial bypasses, although there was a trend toward improved patency at 24 months. Kreienberg compared grafts using ePTFE with a vein cuff versus composite saphenous vein grafts. Primary patency was similar at 2 years: 49% cuff versus 44% composite vein with secondary patency rates somewhat better for the composite vein group. The Albany group

compared all bypasses with spliced vein segments to ePTFE and a Miller vein cuff. The patency was better with the vein bypasses, although 25% of the spliced vein procedures required revision to obtain these results. In addition, spliced vein procedures involved increased operative time, hospital stay, intraoperative blood loss, and perioperative morbidity. Therefore, composite grafts of poor quality vein do not function any better than ePTFE with a vein cuff or patch and generate a higher rate of morbidity and use of hospital resources.

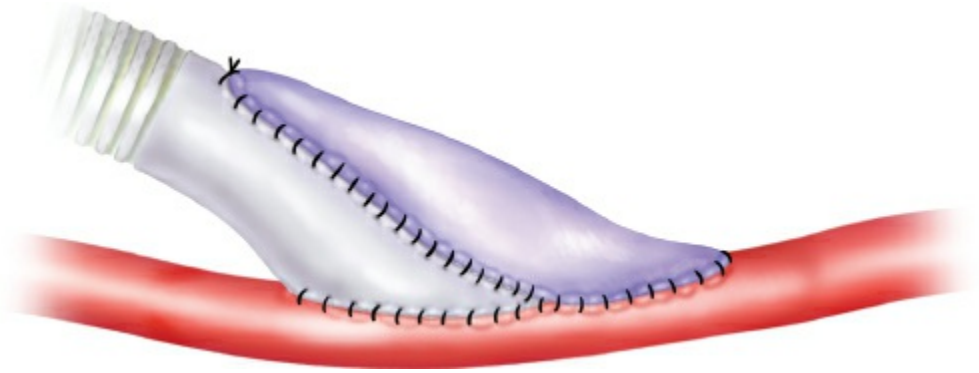

Figure 208.2. The Taylor patch technique. The graft is partially sutured onto the target artery, and a vein patch is used to suture the rest of the graft onto the artery and increase the anastomotic surface area.

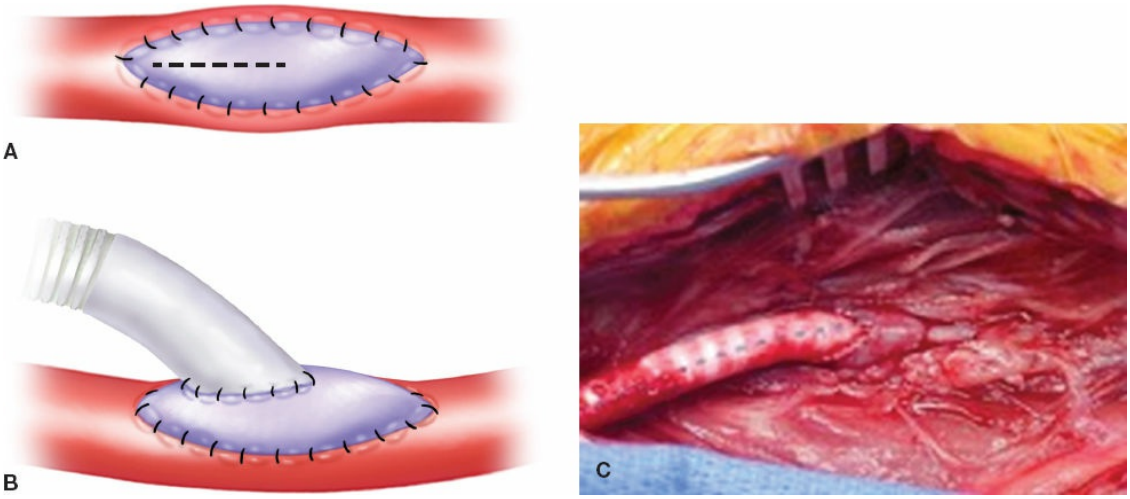

Figure 208.3. A. The Neville distal vein patch technique. A vein patch is created onto the target artery (**A**), and (**B, C**). A prosthetic graft is then sutured directly onto the vein patch.

The distal vein patch (DVP) technique was developed due to ease of technique and maintenance of the proposed advantages leading to improved outcomes for prosthetic grafts (Fig. 208.3A,B). The initial series

of tibial artery bypasses describing the DVP technique for patients with limb-threatening ischemia was reported in 1997. A subsequent initial clinical series using the DVP technique resulted in improved 4-year patency (62%) and limb salvage (79%) in a group of patients without adequate saphenous vein conduit options (Fig. 208.4). Since those initial reports, an expanded series with more robust follow-up has resulted in 51% patency at 4 years in a 290 patient cohort using the DVP technique for tibial bypass. This result is an improvement over reports of tibial bypass with straight prosthetic conduit and may be a better reflection of real-world clinical outcomes as compared to the initial publications.

Heparin-Bonded Grafts

The bonding of heparin to the inner surface of a prosthetic graft has been hypothesized to reduce graft thrombosis and hyperplasia. The ideal method of bonding uses end-point covalent bonding of heparin to the luminal surface of the graft to maintain the bioactivity of the heparin molecule. This process reduces platelet adherence, acute thrombus formation, and anastomotic myointimal hyperplasia in canine and primate models. The initial clinical experience with the heparin-bonded ePTFE graft was encouraging as Walluschek obtained 80% 1-year patency for below-knee bypasses. Peeters reported primary and secondary 1-year patency rates of 82% and 97%, respectively, with little difference between popliteal and tibial bypasses. Many other series followed with similar success. Devine reported a multicenter, randomized trial of heparin-bonded Dacron versus ePTFE for femoropopliteal bypass and reported significantly greater patency rates with the heparin-bonded grafts at 3 years, but the difference was no longer statistically significant at 5 years. This, however, was a small study of primarily above-knee bypasses, which limits its generalizability to the smaller vascular beds. Daenens and colleagues reported that bypasses with heparin-bonded grafts were statistically equivalent to saphenous vein for popliteal and tibial bypass. In order to confirm these findings, a comparison of tibial bypasses using heparin bonded ePTFE versus those with saphenous vein grafts was performed. This analysis showed that quality, single segment saphenous vein remained a superior conduit to heparin-bonded ePTFE. However, the use of a heparin-bonded conduit in combination with a venous adjunct at the distal anastomosis led to 1-year primary patency without a statistically significant difference when compared to the patency obtained with venous

conduit for tibial artery bypass (Fig. 208.5). Several additional series have been reported comparing standard PTFE to heparin-bonded ePTFE with apparent benefit in the femoral-femoral and femoral-popliteal configuration.

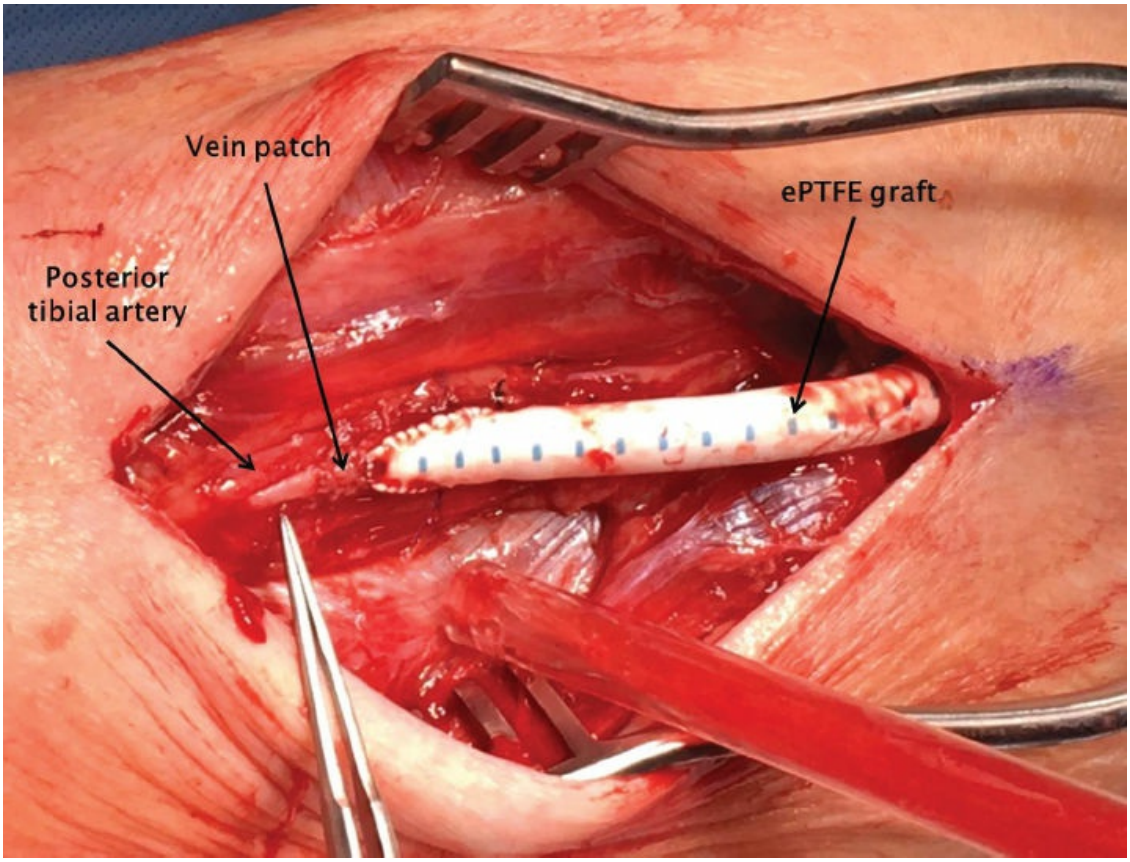

Figure 208.4. The Neville distal vein patch technique for creation of 6-mm ePTFE graft anastomosis onto the posterior tibial artery.

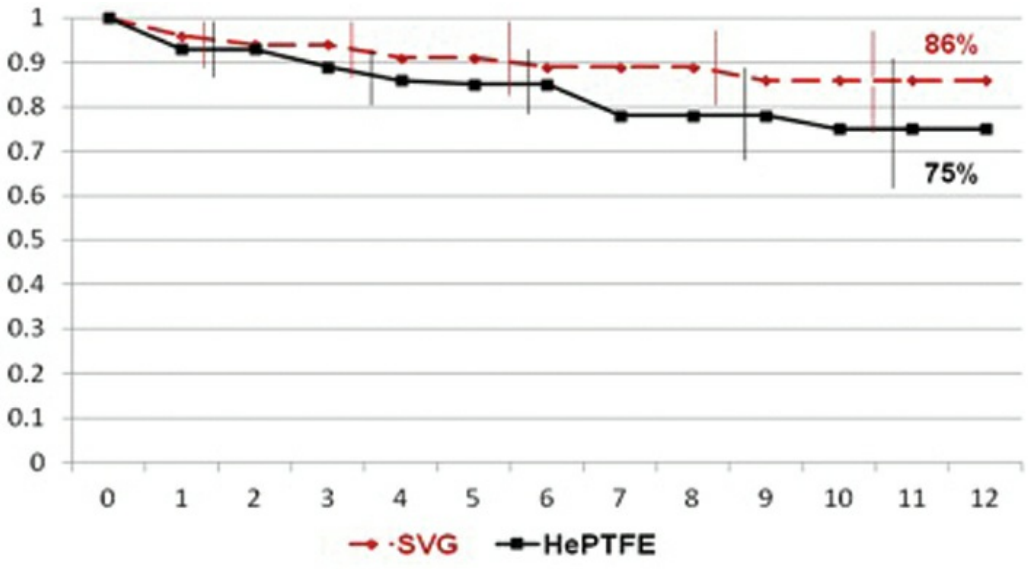

HePTFE	62	57	57	52	51	47	47
Vein	50	48	48	43	43	43	43

Figure 208.5. Kaplan–Meier survival curves with log-rank analysis show primary patency over 12 months by graft type. The error bars show the 95% confidence interval. Survival functions for patency between graft types did not differ significantly. SVG, saphenous vein graft; HePTFE, heparin-bonded ePTFE graft. (From Neville RF, Capone A, Amdur R, et al. A comparison of tibial artery bypass performed with heparin-bonded expanded polytetrafluoroethylene and great saphenous vein to treat critical limb ischemia. *J Vasc Surg* 2012;56(4):1008–14; with permission from Elsevier.)

A potential side effect of implanting heparin-bonded grafts is heparin-induced thrombocytopenia (HIT). This complication has been described in case reports of patients undergoing lower extremity bypass grafts for elective and urgent indications, necessitating graft explantation and replacement. However, it has been noted that patients' platelet counts were improving prior to graft explantation in cases where covalently bonded grafts were used, as compared with older grafts that used ionic interaction with the graft surface, leading subsequent release of the heparin into the bloodstream. Furthermore, a study of covalently bonded grafts found no increase in the systemic markers of hemostasis in vivo, and no antibodies against heparin were detected up to 6 weeks after implantation.

Distal Arteriovenous Fistula

When the target artery of a distal bypass is concomitant with arterial

outflow that is disadvantaged, the addition of an arteriovenous fistula at the distal anastomosis has been used to increase the chances of bypass success especially in regards to prosthetic conduit. A distal arteriovenous fistula has been used when the target artery for bypass is small, diseased, or discontinuous, leading to a runoff bed of presumed high resistance. In theory, the addition of the fistulous connection serves to decrease outflow resistance and maintain flow in the prosthetic conduit above the graft's critical thrombotic threshold for thrombosis. Intrinsic to the fistulous connection, some graft flow will be into the venous system and some mild edema is expected with a successful result. But, the fistula can help maintain graft patency in the face of disadvantaged arterial outflow. Dardik described a common ostium arteriovenous fistula in an attempt to decrease graft thrombosis by reduction of outflow resistance. Ascer described a technique involving construction of an arteriovenous fistula between the target tibial artery and corresponding tibial vein with a ePTFE bypass to the involved vein. Reported patency rates with this technique were 62% at 36 months, despite a fistula thrombosis rate of 37%. A prospective, randomized trial that compared distal bypasses using ePTFE with a Miller vein cuff with and without an arteriovenous fistula did not demonstrate a benefit to such an anastomotic fistula, but the authors did not stratify patients based on arterial runoff.

The incorporation of a common ostium arteriovenous fistula in combination with a DVP at the anastomosis of a prosthetic bypass has also been described (Fig. 208.6A,B). This modification has been performed only in those challenging patients with limb-threatening ischemia and no vein available for the bypass conduit and severely disadvantaged arterial runoff. The target tibial artery is opened longitudinally with a longitudinal venotomy in the corresponding tibial vein. A vein patch is then sutured to the common ostium created by this fistulous connection in a similar manner to the DVP technique. An anastomosis is then constructed between the ePTFE conduit and the vein patch as described in the DVP bypass configuration. Theoretically, the arteriovenous fistula decreases outflow resistance, reduces overload on a fixed arterial circuit, and increases flow velocity in the graft above the critical thrombotic threshold to improve graft outcomes. This technique has led to 62% primary patency and 57% limb salvage at 24 months in a patient group who would otherwise have been offered primary amputation.

Adjunct Medical Therapies

The role of adjunct medical therapy in improving prosthetic graft patency has been debated, and there are no guidelines in regards to ideal medical therapy to improve the patency and function of prosthetic grafts. Common practice often involves antiplatelet therapy after bypass with consideration of anticoagulation in association with prosthetic grafts. However, a Dutch multicenter randomized trial comparing more than 2,000 patients who had undergone infrainguinal bypass using vein or prosthetic grafts and were randomly assigned to aspirin or warfarin postoperatively revealed no statistically significant advantage of one therapy over another. But when separated into prosthetic conduit and vein grafts, the prosthetic group had better results with aspirin, whereas the vein group had better results with warfarin. The Boston Veterans Affairs (VA) Hospital Prospective Study compared warfarin and aspirin dual therapy versus aspirin alone, and showed no difference in overall patency between the two groups. However, dual therapy showed moderate benefit for smaller diameter (6 mm) ePTFE grafts with a noted increase in hemorrhagic complications and overall mortality. A randomized study from the United Kingdom (CASPAR trial) examined the efficacy of dual antiplatelet therapy (clopidogrel and aspirin) versus aspirin alone in femoral-distal bypasses. Dual therapy did not reduce the occlusion rates in venous bypasses; however, in a subgroup of patients with prosthetic grafts, dual platelet therapy reduced graft occlusion with a 35% relative risk reduction and no side effects or hemorrhagic events. Bedenis and colleagues published a Cochrane Review on the role of antiplatelet medications in preventing postoperative thrombosis after lower extremity bypass, and similarly reported an improved graft patency with aspirin up to 12 months after

surgery in patients with prosthetic grafts. The role of direct thrombin inhibitors and Factor Xa inhibitors in association with peripheral bypass grafts has not been adequately explored. Some attempts have also been made to develop novel agents to prevent intimal hyperplasia to improve graft patency; however, no new agents have successfully achieved this goal. The DVP bypass experienced a higher failure rate in those patients who did not or could not take warfarin in combination with aspirin. Seemingly, aspirin should be included for the postoperative medical management of bypass patients with warfarin anticoagulation reserved for those patients with prosthetic tibial grafts or a history of hypercoagulable graft failure.

GRAFT COMPLICATIONS

Complications after placement of a prosthetic graft can include bleeding, infection, graft thrombosis, seroma formation, pseudoaneurysm, and steal phenomenon secondary to inadequate proximal blood flow. The two most problematic complications associated with prosthetic conduit will be discussed.

Graft Thrombosis

Prosthetic graft thrombosis occurs in the perioperative period due to technical issues, hypercoagulable conditions, and poor runoff as described above. Technical problems involve more than just technique and include judgment in planning the bypass such as choice of the proper target artery and avoidance of postoperative hematomas and incisional complications. Hypercoagulability should especially be considered in younger patients and prior failed bypasses. Beyond the perioperative period (predominantly 6 to 24 months), myointimal hyperplasia can lead to anastomotic stenosis and reduction in flow leading to eventual graft thrombosis. When myointimal hyperplasia results in the development of a hemodynamically significant stenosis prior to actual graft thrombosis, the bypass is referred to as a “failing graft” with diminished function. Flow in a “failing graft” is hemodynamically compromised, but may not result in clinical signs or symptoms of diminished flow. Therefore, many advocate a regular system of graft surveillance to detect the “failing graft” prior to occlusion. When graft failure does occur, the result is often a return of the patient’s original symptoms or a significant increase in symptom severity with possible limb-threatening ischemia. Revision of a failing graft is less demanding

and more often successful than attempted restoration of flow in an occluded graft or new bypass after graft occlusion.

Prosthetic grafts, as stated above, have a higher occlusion rate and lower patency compared with autogenous conduits, and graft occlusion can lead to significant morbidity if the recipient artery is involved in the thrombotic process. Thrombosis of bypasses performed for intermittent claudication can lead to limb-threatening ischemia and possible limb loss. The treatment of lower extremity prosthetic bypass graft occlusion is tailored to the patient and guided by the clinical presentation and patient's anatomy. A patient with an occluded graft but no concurrent signs of acute, critical limb ischemia may benefit from a trial of thrombolysis to both restore flow within the graft and unmask any underlying stenotic lesions that would be amenable to endovascular or open surgical treatment. Conversely, a patient with acute, critical ischemia or a chronically occluded graft may be better served by open thrombectomy or creation of a new bypass. Grafts performed with the DVP technique can undergo graft thrombectomy through a minimal incision over the distal anastomosis. The DVP configuration offsets the hyperplastic process from the target artery interface to the graft-vein patch interface leaving the target artery patent. The hood of the distal anastomosis can be incised, hyperplastic tissue excised, and a new patch placed across the stenotic lesion. This is done in conjunction with graft thrombectomy per the incision in the hood of the graft to reestablish graft inflow. The entire thrombectomy and revision can often be performed using local anesthesia with sedation.

Since its introduction in the 1970s as a technique to restore occluded arteries, thrombolysis is now also used for treating occluded prosthetic grafts. Thrombolysis can be administered systemically or as part of a catheter-directed or mechanical approach using specialized catheters. However, there are contraindications to this treatment approach, including recent surgery, hemorrhagic strokes, bleeding disorders, and a nonviable limb. Several retrospective studies have described a range of early technical success from 48% to 90% and a limb-salvage rate of 56% to 82% after thrombolysis. The STILE trial (Surgery or Thrombolysis for the Ischemic Lower-Extremity) and the TOPAS trial (Thrombolysis or Peripheral Arterial Surgery) assessed thrombolysis versus thrombectomy for limb ischemia, and reported that thrombolysis was superior to surgical thrombectomy in patients with less than 2 weeks of symptom duration, whereas surgical thrombectomy was superior to thrombolysis when

symptoms lasted for 2 weeks or longer. The treatment paradigm outlined by Greenberg and Ouriel for the management of bypass graft occlusion remains useful. Patients with more than 2 weeks of symptom duration should be treated with operative intervention and placement of a new bypass graft. Conversely, patients with acute (less than 2 weeks' duration) prosthetic graft occlusions and no evidence of critical limb ischemia should undergo a trial of thrombolysis, but consideration should be given to creating a new bypass graft if there is a suitable outflow target vessel and an adequate length of autogenous conduit is available. However, if the patient manifests sensory-motor dysfunction and impending tissue loss, surgical revision may be considered to establish perfusion in a more rapid manner.

Graft Infection

Prosthetic graft infection occurs in 1% to 6% of patients undergoing lower extremity prosthetic bypass. Graft infection is associated with considerable morbidity, including subsequent amputation and mortality rates as high as 20%. The most common causative organisms are *Staphylococcus* species: *Staphylococcus aureus* and *Staphylococcus epidermidis.* Graft infection can arise if microorganisms are seeded at the time of operation or post-operatively through wound complications, adjacent infections, or a bloodstream infection from a distant source. Predictors of prosthetic graft infection include repeat bypass, female gender, diabetes, and active infection at the time of bypass. There is no evidence that graft material, such as Dacron or ePTFE, is more predisposed to infections compared with other inert materials.

The diagnosis and management of graft infections are guided by the patient's clinical status and the type and extent of the infection. Patients typically present with fever and malaise, with or without an obvious wound infection and purulent discharge. Elderly, malnourished, and frail patients may not mount an adequate inflammatory response to indicate an active infection. Patients with suspected graft infections should have blood cultures and, if applicable, deep tissue cultures should be sent. Patients should then be started on broad-spectrum antibiotics that are reviewed and revised when culture results and antibiotic sensitivities become available. Imaging should be obtained early in the workup of patients with a suspected graft infection. Cross-sectional imaging such as computed tomography (CT) angiography and magnetic resonance imaging (MRI) has

the advantage of identifying any fluid collections in proximity to the graft or in the surrounding soft tissue. Other suggestive findings include perigraft air, fluid or soft-tissue attenuation, and pseudoaneurysm formation. Gallium scans and labeled white blood cell scans are used selectively.

There are several treatment strategies for prosthetic graft infections, depending on the patient's status and the type of infective organism. Graft preservation is sometimes possible in patients with limited infections and no signs of sepsis or extensive graft involvement. Grafts that are infected with *Pseudomonas* and methicillin-resistant *Staphylococcus aureus* (MRSA) are particularly virulent organisms, however, and require removal of the infected graft. In patients with graft thrombosis and clinical evidence of adequate collateralization, graft excision alone might be sufficient. In patients who require revascularization of the excised graft segment, an in situ graft might be considered or an extra-anatomic bypass might be created. Conduit options include autogenous and Rifampin-soaked prosthetic grafts. The graft excision and replacement may be done concurrently or in a staged manner, depending on the patient's clinical status.

If patients are known to be MRSA-positive, then a decolonization strategy in conjunction with an infectious diseases specialist should be pursued prior to the surgery whenever possible. Moreover, given the devastating complications associated with prosthetic graft infections, some have advocated for regular preoperative screening and, when detected, decolonization of MRSA. Lee and colleagues from Pennsylvania, for example, analyzed the economic impact of screening all vascular surgery patients prior to any vascular surgical procedure, and demonstrated that testing and decolonizing patients for MRSA may be cost-effective.

GRAFT SURVEILLANCE

As mentioned above, a graft surveillance program is very important especially for prosthetic grafts. Despite technological advances leading to improved performance of prosthetic conduits, graft failure continues to occur perioperatively and during follow-up. As such, it is important to detect the failing graft prior to thrombosis because the management and treatment of such grafts are often more complex than procedures required prior to graft occlusion. Early identification of these patients allows for a more tailored medical therapy that may improve outcome in the future, and

warfarin can be added in the medical management of patients with low-velocity grafts. Close surveillance also allows for early endovascular intervention, which may assist in maintaining patency. A failing graft can often be managed with endovascular techniques or more simplified surgical procedures such as local revision with patch angioplasty, resulting in enhanced secondary patency and enhanced limb preservation. Therefore, graft surveillance programs have been incorporated in most vascular surgical practices to detect the failing graft and intervene early enough to improve graft function and secondary patency of the vascular reconstruction.

Graft surveillance involves clinical evaluation for recurrent or new symptoms of limb ischemia, as well as an examination of pulses and an ankle brachial index. However, clinical assessment alone does not always identify significant stenoses that threaten graft function, especially in patients initially treated for critical limb ischemia. Therefore, vascular laboratory imaging has been added to surveillance protocols as a noninvasive assessment of graft function. While the overall benefit of graft surveillance has not been well-documented for prosthetic grafts, regular interval duplex ultrasound studies obtained at 3, 6, and 12 months postoperatively and then annually have been employed in many practices to identify threatened bypasses before they occlude.

Numerous authors have attempted to define the Doppler ultrasound criteria that should prompt further workup and potential repair of a stenotic graft. Bandyck and colleague have suggested that a peak systolic velocity exceeding 300 cm/s on Doppler ultrasound and a peak systolic velocity ratio across the stenosis exceeding 3.5 correlate with more than 70% stenosis in a graft. Another study led by Brumberg demonstrated that mid-graft peak velocity of 45 cm/s or less was predictive of graft failure. Sanchez and colleagues reported a series looking at surveillance to detect failing ePTFE grafts. These authors reported on a 12-year experience with over 90 ePTFE grafts and surmised that ultrasound surveillance was useful despite the observation that the progression of proximal and distal arterial disease was the primary cause of ePTFE graft failure in the series. These authors concluded that frequent graft surveillance may allow for the detection of hemodynamically threatening lesions prior to graft thrombosis and enhance long-term graft patency and function as the 5-year patency and limb preservation rate for treating “failing” ePTFE grafts was substantially improved over that for ePTFE grafts that have gone on to

occlude. A smaller study from Sweden randomized 156 patients between clinical surveillance and surveillance that included Duplex ultrasound evaluation. Although only 40 of the grafts in the trial were ePTFE grafts, the authors noted improved assisted primary and secondary patency in the group with regular Duplex ultrasound surveillance. More recently, a combined experience from Boston and the Netherlands found ultrasound surveillance to be effective in leading to a reduction in amputation and cost.

CONCLUSION

Surgical bypass continues to play a therapeutic role for those patients in need of lower extremity bypass. This patient cohort includes those with a good life expectancy, extensive long and long segment arterial occlusive disease, significant tissue loss requiring robust perfusion, and those with failed endovascular therapeutic attempts. Although saphenous vein remains the ideal conduit for lower extremity bypass, in today's practice, many patients needing surgical revascularization may not possess a quality venous conduit. Advances in technique and technology as described in this chapter have led to improved results with current prosthetic grafts. It is hoped that the reader will investigate more deeply the data summarized here. These results should stimulate consideration of prosthetic grafts with anastomotic configurations in place of poor quality vein, alternative venous conduits, or amputation due to the lack of a venous conduit.

EDITOR'S COMMENT

Although autologous vein, which is primarily greater saphenous vein, is best for

peripheral arterial bypass, many times the patient doesn't have adequate vein. Neville and colleagues describe prosthetic bypass techniques for patients who have one of the primary indications for vascular in peripheral artery disease, namely, severe life-limiting claudication, rest pain, or tissue loss. Critical limb ischemia patients are not controversial as often bypass procedures are indicated for limb salvage. However, most patients who have lifestyle-limiting claudication need to have exercise therapy and medical management prior to any invasive therapy (Gerhard-Herman MD, Gornik HL, Barrett C, et al. 2016 AHA/ACC Guideline on the Management of Patients With Lower Extremity Peripheral Artery Disease: Executive Summary: A Report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *J Am Coll Cardiol* 2017;69(11):1465–508.).

As compared to the above-the-knee arterial target, below-the-knee prosthetic bypasses are prone to high failure rates. A stipulation for the below-the-knee prosthetic bypass is if the patient has marginal vein or would need a composite of arm and leg vein that may also be inadequate. The venous conduit quality is critical for outcomes of the bypass (Schanzer A, Hevelone N, Owens CD, et al. Technical factors affecting autogenous vein graft failure: observations from a large multicenter trial. *J Vasc Surg* 2007;46:1180–90). As clearly described in this chapter, backed by the authors' publications, is the use of PTFE graft with a distal vein patch angioplasty in those without adequate autologous conduit for infrapopliteal bypasses. Personally, I have found this procedure to be a reasonably good option for patients who don't have adequate vein as conduit. Indeed, in my practice, I perform a prosthetic bypass with a distal vein patch angioplasty prior to using a marginal arm vein or composite vein. The more complex distal artery adjuncts don't have clear superiority in my opinion. The reported average patency rates are at least 60% at 5 years, similar to my anecdotal experience, and confirmed with the data presented in the chapter. Anticoagulation postprocedure I believe is the key, and is typically Warfarin, with an INR targeted to 2.5 to 3. Whether the direct oral anticoagulants are effective here is not yet known.

I have never personally used cryo-vein or umbilical vein due to the fact I think they have no real advantage over prosthetic bypasses with a distal adjunct, in terms of greater patency. However, they have all the disadvantages of prosthetic and pseudo-aneurysm formation. Of note, the use of dual antiplatelet therapy for above-the-knee popliteal prosthetic bypasses is well supported now (Belch JJ, Dormandy J, Biasi BM, et al. Results of the randomized, placebo-controlled clopidogrel and acetylsalicylic acid in bypass surgery for peripheral arterial disease [CASPAR] trial. *J Vasc Surg* 52:825–33, 833 e1–2), and the use of anticoagulation such as warfarin plus aspirin for below-the-knee popliteal bypasses seems to be the best strategy. This has been confirmed by several series, referenced in the chapter.

While patency is the major outcome consideration related to prosthetic bypasses, prosthetic graft infection is another major one. While the overall rates

as listed in the chapter are 6% or less from the literature, I would bet this is much higher due to under reporting and the fact that often the graft infection is treated at an institution that is different than the primary institution where the bypass was placed. These occurrences are disasters for patients, often leading to limb loss. Standard perioperative factors to reduce graft infection include appropriate preoperative antibiotics, redosing of antibiotics, use of chlorhexidine skin preparation, and limiting blood transfusions (Davis FM, Sutzko DC, Grey SF, et al. Predictors of surgical site infection after open lower extremity revascularization. *J Vasc Surg* 2017;65(6):1769–78 e3). A careful but speedy operation helps too.

Graft surveillance is generally performed for autologous vein grafts with good efficacy, allowing detection of neointimal hyperplasia within the graft. This is also a performance measure from a large multispecialty consensus document (American College of Cardiology F, American Heart Association Task Force on Performance M, American College of R, Society for Cardiac A, Interventions, Society for Interventional R, Society for Vascular M, Society for Vascular N, Society for Vascular S, Olin JW, Allie DE, Belkin M, et al. ACCF/AHA/ACR/SCAI/SIR/SVM/SVN/SVS 2010 performance measures for adults with peripheral artery disease. A report of the American College of Cardiology Foundation/American Heart Association Task Force on Performance Measures, the American College of Radiology, the Society for Cardiac Angiography and Interventions, the Society for Interventional Radiology, the Society for Vascular Medicine, the Society for Vascular Nursing, and the Society for Vascular Surgery (Writing Committee to Develop Clinical Performance Measures for Peripheral Artery Disease). Developed in collaboration with the American Association of Cardiovascular and Pulmonary Rehabilitation; the American Diabetes Association; the Society for Atherosclerosis Imaging and Prevention; the Society for Cardiovascular Magnetic Resonance; the Society of Cardiovascular Computed Tomography; and the PAD Coalition. Endorsed by the American Academy of Podiatric Practice Management. *J Vasc Surg* 2010;52:1616–52). I find surveillance useful for detecting low velocities in prosthetic grafts, mandating placement of these patients on full anticoagulation to protect against thrombosis (Brumberg RS, Back MR, Armstrong PA, et al. The relative importance of graft surveillance and warfarin therapy in infrainguinal prosthetic bypass failure. *J Vasc Surg* 2007;46:1160–6). However, I have not found it is useful for detecting proximal or distal anastomotic stenosis that needs to be treated. This may be a sampling error on my part, but is reflective of my partners' practice as well.

Peter Henke

I agree entirely with Dr. Henke in that the rate of the prosthetic graft infection is likely much higher than the listed 6% or less. When graft infection occurs, the patient is usually transferred to another institution rather than the primary institutions for various reasons. For one, infection is a disaster, for another

limb loss is a common outcome; for a third institution with experience one may get a better outcome.

209 Dorsalis Pedis, Tarsal, and Plantar Artery Bypass

Bernadette Aulivola and Frank B. Pomposelli

INTRODUCTION

Arterial reconstruction to the arteries of the distal ankle and foot has become commonplace in those patients with occlusive disease of the infrapopliteal vessels, precluding bypass to a more proximal target vessel. This is especially the case in patients with diabetes mellitus presenting with ischemic foot lesions due to a characteristic pattern of occlusive disease, where the tibial and peroneal arteries are occluded but the foot vessels, especially the dorsalis pedis artery, remain patent (Fig. 209.1). Extending vein bypass grafts to the dorsalis pedis artery (DP bypass) when a more proximal suitable bypass target is not available has expanded our ability to salvage limbs in patients who would otherwise have required amputation. Our initial results with these patients were impressive enough that we standardized our technique and began performing DP bypass in preference to other more proximal target arteries. We also found that pedal bypass could be performed safely in patients presenting with foot infection and ischemia and worked well for healing heel ulcers. Others have documented better rates of wound healing and limb salvage in patients with critical limb ischemia with infrapopliteal occlusive disease after angiosome-targeted revascularization. In the era preceding the widespread application of endovascular therapy for limb ischemia, pedal bypass comprised 30% of all limb salvage bypasses done in our practice, which was composed of a large proportion of diabetic patients. Over a 13-year period prior to the routine use of endovascular intervention for tibial occlusive disease, 2.6% of over 4,700 lower extremity arterial bypass procedures performed by our group involved outflow to the tarsal and plantar arteries.

As is the case in other vascular domains, endovascular options for the treatment of tibial artery occlusive disease have been increasingly utilized over the past several years. Our own experience with infrapopliteal

angioplasty and selective stenting in 176 limbs over a 3-year period revealed that this treatment is a technically feasible and a reasonable option for revascularization of the ischemic foot in many patients. However, the technical success of endovascular intervention on tibial arteries decreases with progressive TransAtlantic Inter-Society Consensus (TASC) classification severity (Table 209.1). Technical success was 93% overall, but decreased from 100% in TASC A, B, and C lesions to 75% in TASC D lesions. Infrapopliteal angioplasty primary patency rates at 1 and 2 years were 53% and 51%, inferior to that noted in those undergoing surgical bypass, and presumably would decline further with a longer duration of follow-up. Our current practice is to consider endovascular intervention first for tibial artery occlusive disease that is limited to lower TASC classes or in patients without any suitable native conduit in the upper or lower extremities. Multiple comparisons of infrapopliteal angioplasty to surgical revascularization for limb salvage have been made in the literature. These studies may have limited applicability given that endovascular intervention is typically used as first-line therapy for patients with disease limited to stenoses or short occlusions, whereas surgical revascularization is more often used as first-line therapy for more extensive occlusive disease. In evaluating outcomes of surgical revascularization versus angioplasty for the treatment of critical limb ischemia in the presence of infrapopliteal disease, some data utilizing propensity score analysis to adjust for differences have documented better rates of wound healing and limb salvage with surgical revascularization over angioplasty. However, pedal bypass following failed endovascular intervention of the infrapopliteal arteries has been demonstrated to yield acceptable patency and limb salvage results with no change in outcomes in patients first undergoing endovascular intervention. Given that extensive tibial artery occlusive disease is the most common pattern of disease encountered in the diabetic population, the continued importance of extreme distal bypass to the foot arteries in limb salvage efforts for foot ischemia in these patients cannot be overemphasized. This chapter will outline our evaluation and approach to foot-level arterial bypass for limb salvage.

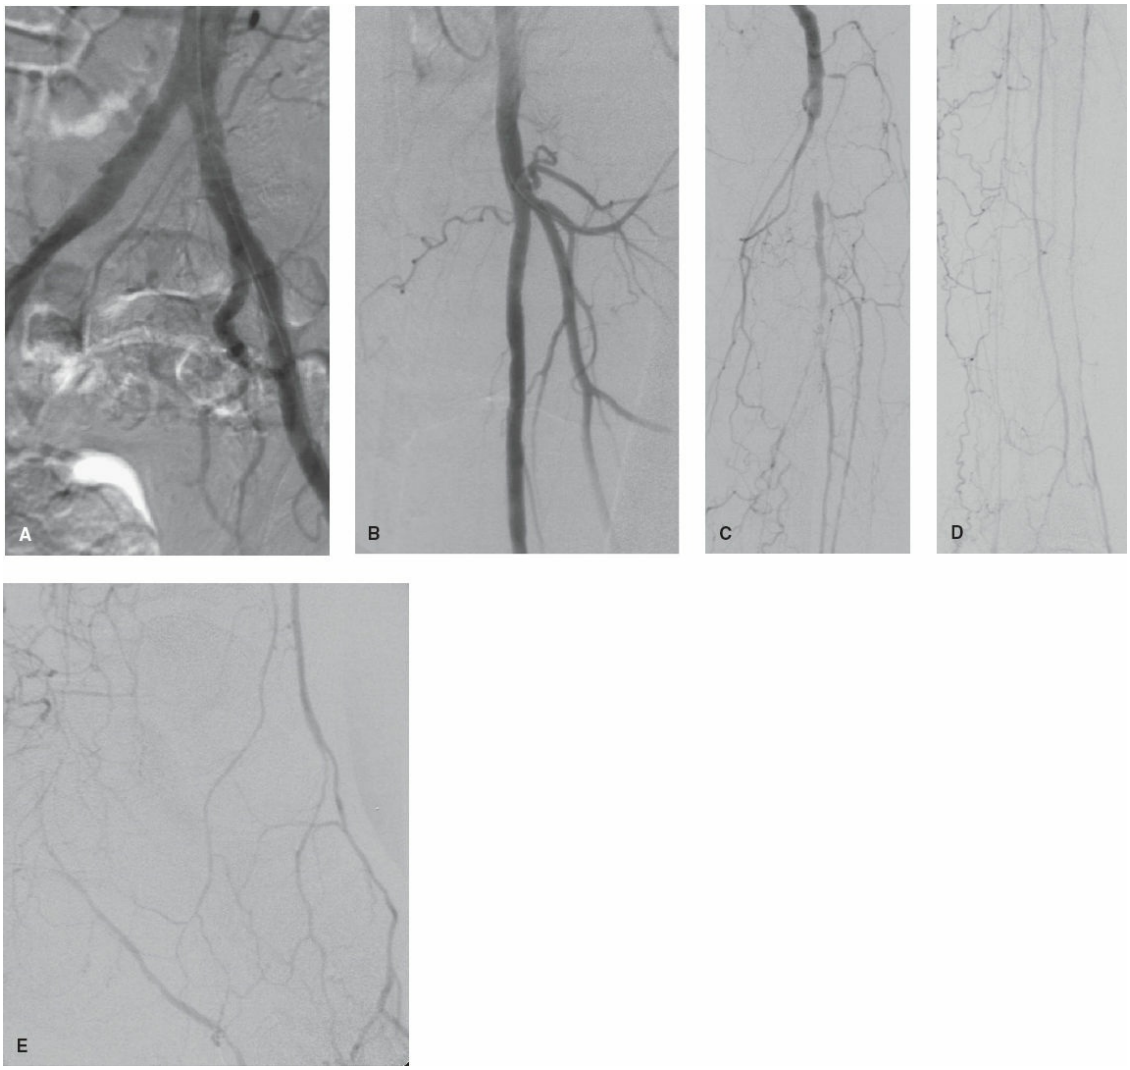

Figure 209.1. Intra-arterial digital subtraction arteriogram demonstrating the characteristic pattern of occlusive disease in diabetes. The aorta, iliac arteries (**A**), superficial femoral and profunda femoris arteries, (**B**) and popliteal arteries (**C**) are uninvolved. The tibial/peroneal arteries (**C, D**) are diffusely diseased and the dorsalis pedis artery (**E**) is patent. TABLE 209.1 TransAtlantic Inter-Society Consensus (TASC) Classification of Occlusive Disease in the Infrapopliteal Arteries

TASC A: Single stenosis <1 cm long
TASC B: Multiple focal stenoses <1 cm long or 1 or 2 stenoses <1 cm involving the trifurcation
TASC C: Stenoses 1–4 cm long, occlusion 1–2 cm long, or extensive stenosis involving the trifurcation
TASC D: Occlusion >2 cm long or diffusely diseased

Compiled from Management of peripheral arterial disease (PAD). TransAtlantic Inter-Society Consensus (TASC). *Eur J Vasc Surg* 2000 Jun 19.

CLINICAL PRESENTATION

Arterial insufficiency can present with a spectrum of clinical signs and symptoms. In some patients, arterial insufficiency may be completely asymptomatic, diagnosed on the basis of nonpalpable foot pulses or decreased ankle-brachial indices alone. As chronic arterial insufficiency progressively worsens, patients may present with symptoms of intermittent claudication, which manifests typically as cramping or tiredness in the calves with walking that is relieved by rest. More severe symptoms of arterial insufficiency are categorized as critical limb ischemia, which can present with ischemic rest pain or tissue loss. Tissue loss represents the most severe manifestation of critical limb ischemia and may present as non-healing ulceration or gangrene. This chapter focuses on surgical revascularization in patients presenting with critical limb ischemia. Often, in the diabetic population, critical limb ischemia is noted in patients with no discernable history of prior claudication symptoms. This illustrates that the development of severe critical limb ischemia does not always follow an orderly progression through each stage of ischemia severity.

INDICATIONS AND CONTRAINDICATIONS

Foot-level arterial bypass is reserved for patients with limb-threatening ischemic symptoms, including rest pain, non-healing ulcers, gangrene, or poor healing of toe amputations or other foot surgical sites. These surgical revascularization procedures are not appropriate for the treatment of intermittent claudication symptoms. In fact, claudication is rarely improved by pedal level bypass, since the arteries of the calf are occluded and rarely adequately perfused retrograde through the pedal circulation.

Good outcomes in efforts toward limb salvage often involve a multidisciplinary approach. Patients with extensive tissue loss in whom lower extremity revascularization is considered should be evaluated by a podiatrist preoperatively to confirm options for foot salvageability. If the

degree of ulceration or gangrene precludes salvage of the foot, revascularization may not be indicated, as the patient may be best served with primary major amputation. It is important to keep in mind that foot salvageability is dependent not only on adequate arterial perfusion, but also on adequate nutritional support and treatment of concomitant foot infection with antibiotics and possible incision and drainage. Foot salvage also, at times, requires toe, ray, or other minor foot amputations to achieve infection control and healing. The confirmation of an arterial bypass target vessel is a prerequisite to planning an inframalleolar bypass. This is generally achieved by performance of preoperative duplex and digital subtraction angiography (DSA) studies of the lower extremity arterial system. In very rare cases, when no suitable bypass target artery is identified, the patient may not be a suitable candidate for revascularization.

PREOPERATIVE PLANNING

Comprehensive, high-quality intra-arterial DSA is a key component in the planning process for DP or other inframalleolar artery bypass (Fig. 209.1). Appropriate evaluation of the lower extremity circulation includes imaging of the entire arterial tree from the renal arteries to the toes in all patients with critical limb ischemia. Proper imaging of the foot vessels requires magnified anteroposterior and lateral views in order to fully appreciate the quality of the DP, tarsal, and plantar arteries to assess their potential use as outflow target vessels. Magnetic resonance angiography (MRA) is used infrequently in our practice, and is generally reserved for those patients who are unable to undergo DSA, some due to severe contrast allergies. Some data suggest that occult foot vessels on DSA may be unmasked with MRA, resulting in successful bypass to these vessels. “Blind” operative exploration may also be performed in the case of nonvisible foot arteries on DSA in cases where patency is suspected on the basis of an audible Doppler signal, although this is rarely required due to the precise imaging capabilities of modern DSA. The less invasive nature of MRA makes it a more attractive imaging option in certain patients. In the past, MRA was considered a safer option than DSA for arterial imaging in the patient with chronic renal insufficiency given the risk of iodinated contrast-induced nephropathy with DSA. However, more recent data suggest that gadolinium-induced nephrogenic systemic fibrosis and acute renal insufficiency are more common than previously noted. Nearly all patients in our practice undergo intra-arterial DSA imaging prior to lower

extremity bypass surgery. Carbon dioxide (CO_2) gas DSA imaging can also significantly reduce the contrast load required to image the lower extremity arteries.

Given that many patients with tibial artery occlusive disease have diabetes and chronic renal insufficiency, care must be taken to perform arterial imaging in the safest way possible. This often entails taking precautionary measures prior to DSA imaging if using iodinated contrast agents. In patients with a creatinine level of ≥1.5 mg/dL or an estimated glomerular filtration rate (GFR) of <30 mL/min/1.73 m^2, corresponding to Stage 4 or 5 chronic kidney disease, use of sodium bicarbonate infusion has been demonstrated to have a more significant protective effect against contrast-induced nephropathy than sodium chloride infusion. The protocol for sodium bicarbonate infusion utilizes a 150 mEq/L sodium bicarbonate in D5W solution administered as a bolus of 3 mL/kg/h for 1 hour prior to the procedure and 1 mL/kg/h for 6 hours after the procedure.

The decision to perform inframalleolar bypass is made on the basis of several important anatomic and clinical factors. The goal of restoring a palpable foot pulse when possible in patients with diabetes and tissue loss is based upon our observation that this end point most reliably leads to healing and foot salvage in the setting of the compromised biology of the ischemic diabetic foot. If a more proximal outflow target artery cannot achieve that goal, preferential bypass to the DP artery should be considered. In situations of ischemic rest pain without tissue loss, the DP artery should be chosen as the outflow target vessel when it is the best-quality vessel for bypass or the only available outflow vessel as determined on DSA evaluation. In circumstances where a more proximal outflow vessel would restore a palpable foot pulse and tissue loss is the indication, DP bypass is not necessarily the procedure of choice. In cases of tissue loss or gangrene, however, DP bypass is often chosen in preference to a patent peroneal artery, given the technical ease of this bypass configuration. However, when the peroneal artery is evaluated to be a superior target vessel to the DP artery on DSA, or when the length of available autogenous vein conduit is inadequate for bypass to the DP artery, peroneal bypass may be considered. In cases of severe dorsal foot infection, or when the indication for arterial reconstruction is claudication alone, DP bypass is not preferentially performed. Bypass to the tarsal or plantar arteries is indicated less frequently and is generally preserved for cases in which the DP artery is not a viable option for bypass outflow.

Many limbs requiring DP, tarsal, or plantar artery bypass have undergone previous ipsilateral limb revascularization. In our own published collection of 98 tarsal or plantar bypasses over a 13-year period, ~18% had undergone previous bypass procedures and 5% had undergone previous DP bypass on the ipsilateral extremity. The most frequent indication for bypass in these patients was tissue loss present in 95%, with ischemic rest pain in an additional 3%, and failing bypass graft in 2%. All cases of tarsal or plantar artery bypass had no other reasonable bypass outflow target, including the DP artery.

In addition to DSA imaging of the affected extremity, preoperative planning includes routine duplex venous mapping for assessment of the most appropriate vein conduit for bypass graft use. In some cases, the availability of autogenous vein conduit may alter anatomic planning for inframalleolar-level bypasses. In our experience, patients presenting for inframalleolar arterial reconstruction have undergone ipsilateral lower extremity revascularization in ~18% of cases and coronary artery bypass grafting in just over 20% of cases. Given their prior history of other revascularization procedures, ipsilateral great saphenous vein, the conduit of choice, is not always available for use. Our preoperative venous mapping protocol includes evaluation of bilateral great and small saphenous veins and, when indicated, evaluation of bilateral upper extremity basilic and cephalic veins. When ipsilateral great saphenous vein is not available for use, contralateral great saphenous or arm vein may be used as bypass conduit. Venous mapping provides crucial information regarding possible vein conduit, including vein diameter and the presence of vein thrombosis or sclerosis. Vein diameter of >2 mm is desirable for adequate conduit. Especially in the upper extremity veins, which have typically undergone multiple punctures for blood draws or intravenous lines, preoperative venous mapping provides critical information regarding the condition of the vein. In patients with end-stage renal disease on hemodialysis, we do not generally consider arm vein as a conduit option. Venous mapping can also be used to plan composite vein conduit construction to yield adequate total length to bridge between the inflow and outflow target vessels.

SURGICAL TECHNIQUE

Dorsalis Pedis Artery Bypass

The overall strategy of DP bypass is designed to simplify the procedure

and minimize the use of prosthetic graft material. The key principles include the use of distal inflow artery sites and short, translocated, great saphenous vein grafts whenever possible. Short vein grafts with distal inflow have been demonstrated to result in acceptable limb salvage even in the face of poor arterial runoff and high outflow resistance. In rare cases of questionable adequacy or patency of an inframalleolar artery for bypass outflow, exploration of the target artery may be performed first such that extensive dissection is not carried out only to realize that the outflow vessel is inadequate.

Bypass procedures originating from the femoral level with an intact great saphenous vein are well suited for use of the in situ technique with angioscopy for valve lysis under direct visualization. Vein tributaries are ligated with silk suture. The length of saphenous vein needed is confirmed. The saphenofemoral junction is divided, and the stump on the femoral vein is oversewn with a silk suture ligature. The saphenous vein is divided distally at the appropriate location. The use of an angioscope with a pump irrigation system facilitates valve lysis and allows for thorough evaluation of the vein conduit for webs or stenoses. A 2-mm disposable angioscope is inserted into the proximal end of the vein graft, and a long flexible valvulotome is inserted from the distal end for valve lysis prior to performing the anastomoses (Fig. 209.2). Use of the pump irrigation system has been shown to decrease the amount of crystalloid infused while aiding in the clarity of the angioscopic examination. When transposed vein conduit is used, the vein may be harvested and angioscopy with valve lysis may be performed on a side table prior to performing the anastomoses. Composite grafts composed of multiple vein segments may also be used, but are only required on occasion. The use of angioscopy is especially important in evaluating the quality of arm and composite vein conduits. Vein conduit may be utilized in a reversed, nonreversed, or in situ fashion, although preference to in situ conduit exists for bypasses with inflow at the femoral level. For translocated vein conduit, the reversed vein technique is used if the distal vein is of greater caliber; otherwise, the vein is positioned in the nonreversed orientation after valve lysis. Evidence in the literature suggests that primary patency in ankle and foot level bypasses is superior with the use of nonreversed rather than reversed or composite vein conduit.

The importance of using the most distal appropriate inflow vessel is especially salient in cases of limited vein conduit. In these cases, every

effort should be made to originate the bypass at a distal inflow site. If the superficial femoral artery (SFA) has mild disease that is not felt to be hemodynamically significant, <50%, then the bypass may be originated from the popliteal artery. SFA stenoses of >50% diameter reduction are considered to be hemodynamically significant and should be treated. If adequate vein conduit allows, the inflow bypass anastomosis may be originated proximal to the stenosis. When significant yet focal SFA disease is present, an endovascular approach to treating areas of stenosis may be used in conjunction with a more distal inflow site. Angioplasty with or without stenting for treatment of areas of stenosis in the iliofemoral vessels may be performed either during the preoperative DSA or in the same setting as the bypass procedure. When performing SFA angioplasty in the same setting as a popliteal to DP bypass, the popliteal artery may be accessed during the surgical dissection, passing a sheath in the retrograde direction for SFA intervention prior to performing the proximal bypass anastomosis. Alternatively, when vein conduit is limited and more extensive SFA disease is present, then performing a simultaneous femoral to proximal popliteal bypass with a prosthetic graft and distal popliteal to DP bypass with vein may be considered, if anatomically feasible.

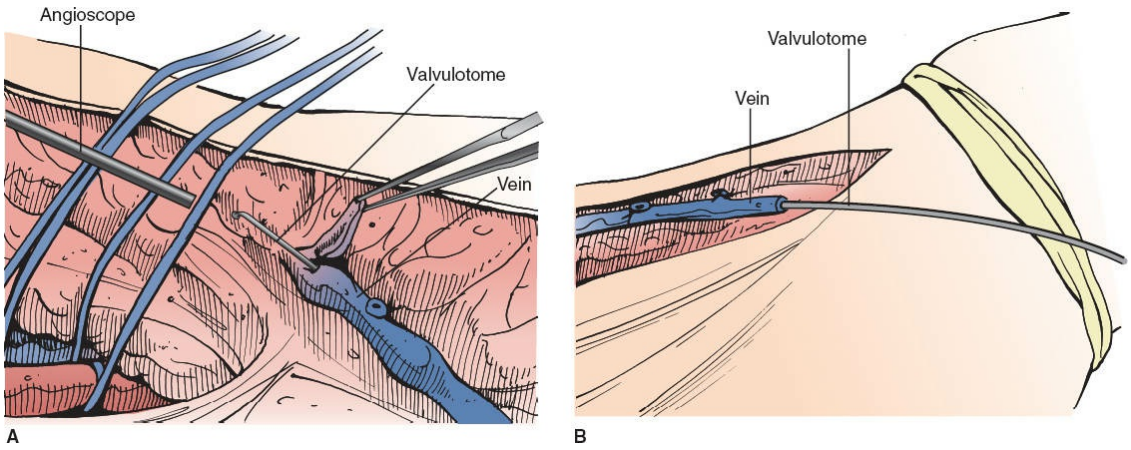

Figure 209.2. Insertion of the angioscope into the proximal great saphenous vein (**A**) and insertion of the valvulotome into the distal vein (**B**) for valve lysis under direct visualization.

The DP artery at a level just distal to the ends of the malleoli is usually located ~1 cm lateral to the extensor hallucis longus tendon (Fig. 209.3). Exposure of this artery is accomplished with a longitudinal incision directly over the Doppler signal of the artery on the dorsal foot. Occasionally, the artery may be located more laterally, underscoring the

importance of careful examination of the preoperative DSA and use of Doppler intraoperatively to precisely locate the artery prior to making the incision. The dissection is carried through the extensor retinaculum, under which the DP artery lies. The DP artery gives rise to the medial and lateral tarsal arteries proximally and bifurcates more distally, at the level of the proximal first metatarsal. At this level, the DP artery branches into the deep plantar artery and the first dorsal metatarsal artery. In most cases, the DP artery is amenable to bypass grafting between these two branch points. An internal luminal diameter of >1 mm is optimal. The heavily calcified dorsalis pedis artery may be controlled with an intraluminal coronary occluder rather than vascular clamps or vessel loops or by the use of a sterile tourniquet placed at the distal thigh. The use of tightened vessel loops or vascular clamps for control of the calcified foot vessel may cause crush injury, which may be detrimental to outflow from the bypass graft. The distal anastomosis is typically completed with a 6-0 or 7-0 monofilament polypropylene running suture. If the artery is calcified, a cardiovascular cutting needle may be used. Management of extensive circumferential calcification has been described with a fracture technique, but we find that this is generally not necessary with the use of small cutting needles, which pierce through the calcified vessel wall. Care should be taken to support the outer wall of the artery with forceps when the cutting needle is passed through the calcified wall to avoid tearing the artery.

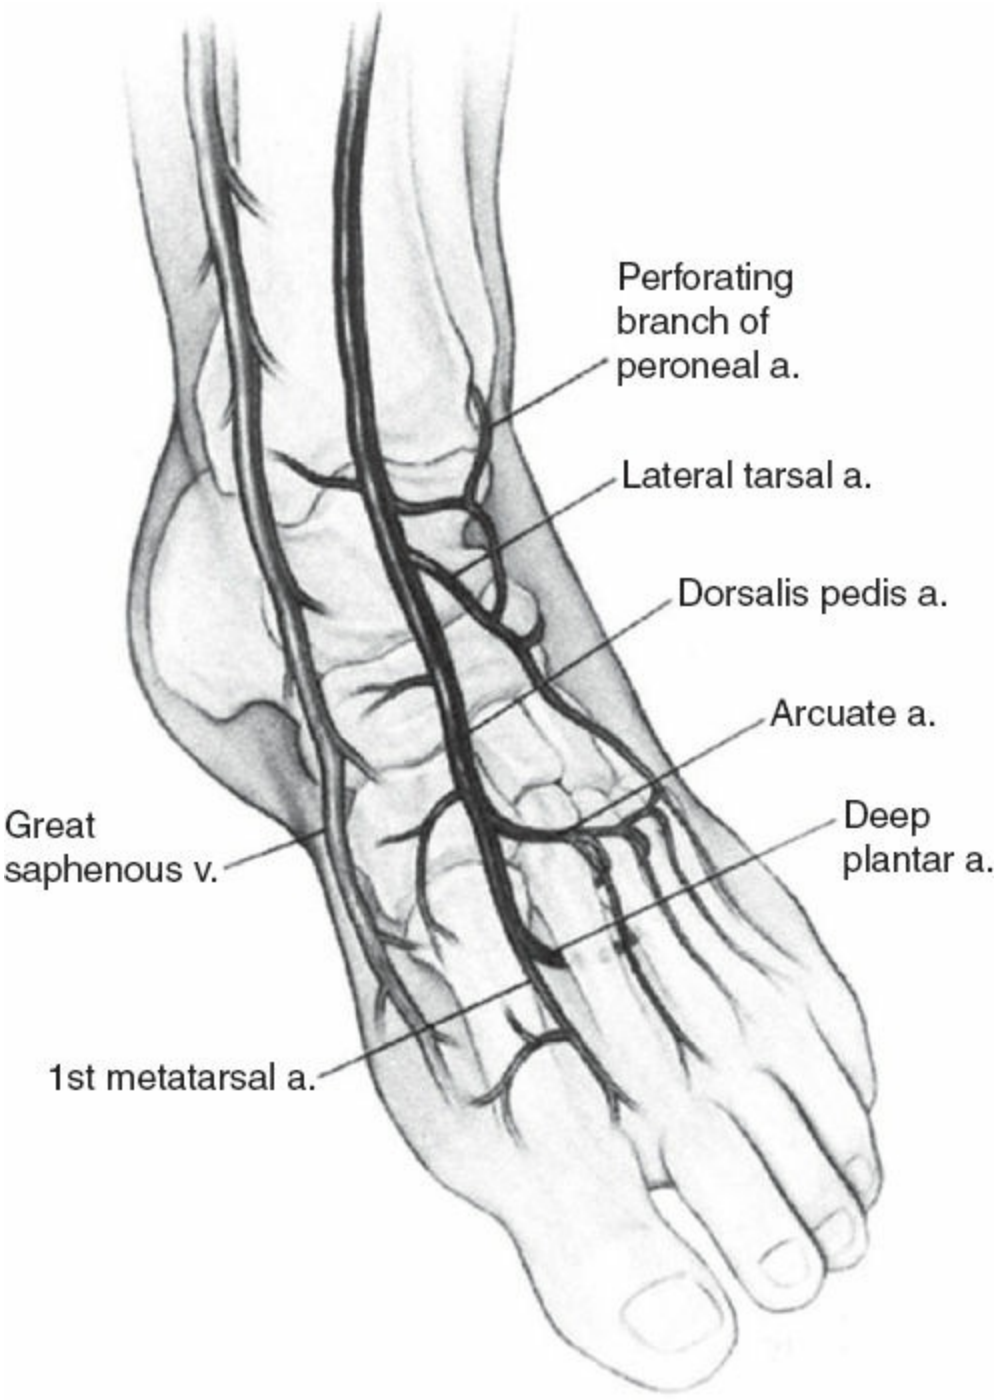

Figure 209.3. Anatomy of the dorsalis pedis artery and its branches. (Reprinted with permission from Pomposelli FB Jr, Jepsen SJ, Gibbons GW, et al. Efficacy of the dorsal pedal bypass for limb salvage in diabetic patients: short-term observations. *J Vasc Surg* 1990;11(6):745–752; with permission from Elsevier.)

When an in situ vein graft is used, it is tunneled at a gentle angle between the saphenous vein harvest incision and the parallel, more

laterally located, dorsal foot incision used to expose the DP artery, never directly under the resulting skin bridge (Fig. 209.4). Tunneling directly under the skin bridge may predispose this area to skin necrosis and subsequent wound complications over the distal anastomosis of the bypass graft. Foot wounds are usually closed primarily without the use of advancement or rotational flaps, but must be meticulous, avoiding undue tension. Closure of these incisions is best completed using a single layer of a 4-0 absorbable subcuticular or simple interrupted nylon suture. If the foot vessel exposure is performed early in the procedure, this wound may be difficult to close at the end of the case if foot edema develops during the interim. For this reason, foot artery exposure should be either performed last, or the incision may be temporarily held closed after arterial exposure with a single skin staple, such that the skin edges do not retract from each other, which may make closure without tension a challenge. Continuous wave Doppler interrogation of the bypass graft and outflow vessel is useful in evaluating the flow through the graft at the end of the case. Evidence has previously shown that most technical failures are associated with choice of poor conduit, which we believe is best avoided with the use of angioscopy in preparation of the vein. Completion arteriography is rarely necessary and should be reserved for cases where a particular concern exists regarding the bypass or Doppler signals at the end of the case.

Tarsal Artery Bypass

The medial and lateral tarsal branches of the DP artery usually originate at the level of the navicular bone. The lateral tarsal artery runs alongside the lateral branch of the deep peroneal nerve, underneath the extensor digitorum brevis muscle toward the fifth metatarsal bone. Exposure of the lateral tarsal branch is facilitated by Doppler localization and dissection of the DP artery first, as described above. The DP artery is followed distally to expose the lateral tarsal branch. The extensor hallucis brevis muscle may be partially transected to aid in exposure. The extensor digitorum longus tendon may either be retracted laterally or, if necessary, be transected to aid in exposure. The distal bypass anastomoses technique is the same as with DP bypass.

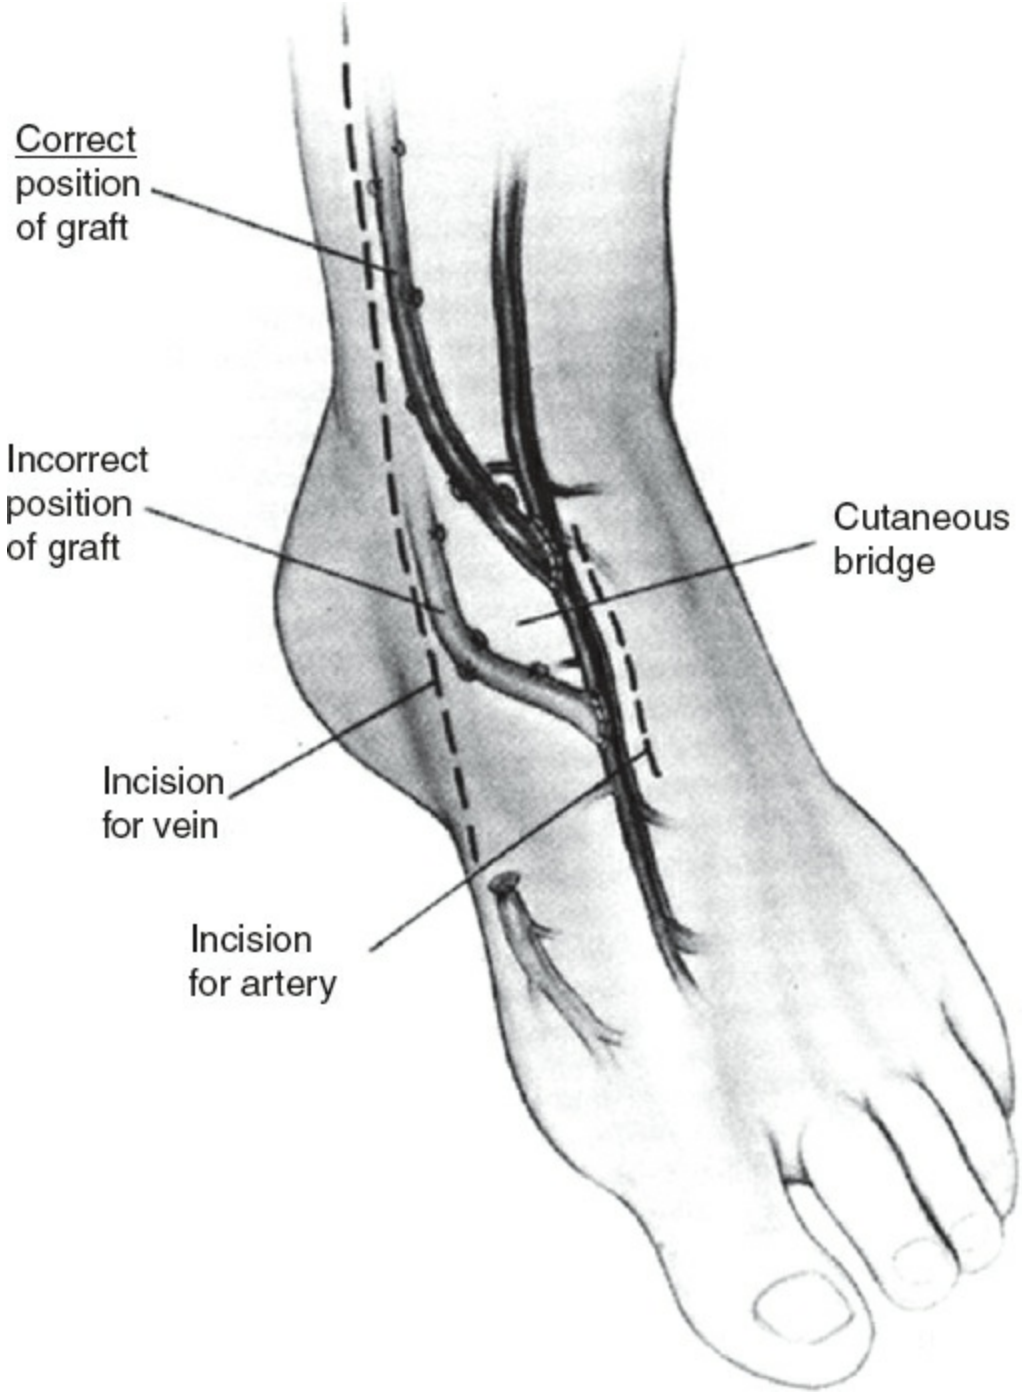

Figure 209.4. Correct and incorrect pathways for tunneling the saphenous vein for an in situ dorsalis pedis bypass. (Reprinted with permission from Pomposelli FB Jr, Jepsen SJ, Gibbons GW, et al. Efficacy of the dorsal pedal bypass for limb salvage in diabetic patients: short-term observations. *J Vasc Surg* 1990;11(6):745–752; with permission from Elsevier.)

Plantar Artery Bypass

Bypass to the plantar artery often poses the same technical challenge as DP

bypass, with small arterial lumen and significant wall calcification. The technical concerns associated with plantar bypass are quite similar to those important in bypass to the major infrapopliteal vessels and have been previously described. The plantar arteries arise from the posterior tibial artery, with the lateral plantar artery continuing on, alongside the lateral plantar nerve, to form the main plantar arch. The lateral plantar branch usually measures larger in diameter than the medial branch; therefore, this is often the best target of the plantar branches. In cases of lateral plantar branch occlusion, however, the medial branch may enlarge, offering an option for bypass outflow as well. Optimal operative positioning includes external rotation of the knee with the foot pronated and a rolled towel placed under the lateral malleolus. The operative approach includes an incision just posterior to the medial malleolus, first exposing the distal posterior tibial artery. This artery is followed distally, and the incision is extended onto the sole of the foot. The initial exposure of the retromalleolar posterior tibial artery facilitates localization of its distal branches, which tend to be small and located deep within the sole of the foot, making primary dissection of these branches more technically challenging. Once the dissection encompasses the bifurcation of the posterior tibial artery, the lateral and medial plantar branches can be distinguished from each other by their relative location, as the lateral branch is located inferiorly when the foot is in an externally rotated position on the operating table. Bypass anastomosis may be performed using whichever plantar artery provides the best outflow to the distal foot based upon preoperative DSA imaging. The distal bypass anastomosis may be located on the lateral or medial plantar artery entirely, or at the bifurcation of the plantar vessels, if this region is not significantly diseased.

POSTOPERATIVE CARE

The main components of the postoperative management of DP, tarsal, and plantar artery bypass are surgical wound care, physical rehabilitation, and bypass graft surveillance. In addition, any foot ulcerations or minor amputation sites must be cared for appropriately. Surgical wounds are kept clean and dry. Care is taken to protect the distal bypass surgical site from contamination with drainage from other foot wounds, especially if infection is present. An adherent occlusive dressing may be applied to the surgical site and left in place for several days if clean and dry. The

extremity is kept in a compression wrap from the foot proximally to at least the level of the proximal anastomotic site to prevent edema. Elevation of the foot on a pillow may also aid in edema prevention in the first few days after revascularization. Staples and sutures are removed after at least 2 weeks of healing, sometimes longer if indicated, especially when edema is present. Physical therapy is instituted within 2 to 4 days of revascularization, with care taken to avoid prolonged periods of the limb being in the dependent position to minimize edema.

Given the superficial location of the distal anastomosis in DP bypass, graft pulsations are quite easy to detect. Prior to discharge from the hospital, patients are instructed on monitoring the graft pulse by palpation over the dorsum of the foot. Graft surveillance duplex is performed at routine intervals, typically at 1, 3, 6, 12, 18, and 24 months, and annually thereafter. If on follow-up duplex, significant (>50% diameter) graft stenosis is suspected, more detailed imaging such as DSA should be performed. In the interest of prolonging the patency of the graft, confirmed stenosis should be intervened upon by balloon angioplasty or surgical revision promptly.

COMPLICATIONS AND THEIR MANAGEMENT

Many wound complications originate as a result of the significant leg edema that nearly always occurs postoperatively after bypass to inframalleolar vessels. A crucial component of the initial management of the limb is aimed at reduction of postoperative edema with the goal of avoiding wound complications. Patients should be restricted from weight bearing on the foot for 2 to 4 days or more, depending on the progress of surgical wound healing and location of other ulcers on the foot. Ambulation is resumed gradually and may require the use of partial weight bearing on crutches or a walker and the use of open-toe postoperative sandals until the foot is well healed. The leg should be elevated frequently and wrapped in an elastic bandage over the first few weeks to reduce edema. Despite taking these measures, some foot and leg wounds may have difficulties with healing. Minor skin dehiscence remote from the graft is common and usually responds well to conservative measures, such as local dressing care, debridement, elastic compression, and weight-bearing restriction. More serious wound issues including infection with graft exposure occasionally occur and may require more complex treatment, such as myocutaneous free tissue transfer, bypass graft revision with

rerouting, or skin grafting. Wound dehiscence, particularly when it occurs over the distal anastomotic site, can lead to anastomotic disruption and hemorrhage. Aggressive efforts should be made to address such wound issues before this happens. Graft thrombosis, bleeding, and infection are rare, but well-described complications of inframalleolar bypass and early recognition of such events are crucial to their treatment.

OUTCOMES

Dorsalis Pedis Artery Bypass

Our series of 1,032 DP bypasses comprises the largest collection of such patients reported to date. Perioperative mortality associated with DP bypass was 0.9%. Graft failure within 30 days was 4.2%. Clinically apparent cardiac morbidity occurred in only 3%. Limb-threatening postoperative wound infections occurred in 2% of extremities. Early reoperation for graft thrombosis, postoperative bleeding, or infection was required in 6.6%. Primary and secondary patency rates were 56.8% and 62.7% at 5 years and 37.7% and 41.7% at 10 years, respectively. Limb salvage was 78.2% at 5 years and 57.7% at 10 years (Figs. 209.5 and 209.6). Patient survival was 48.6% and 23.8% at 5 and 10 years, respectively, and did not differ significantly between male and female patients. Primary patency was 46.4% for female patients versus 61.6% for male patients at 5 years ($P < 0.009$). Other published reports have demonstrated similar findings of lower patency rates in females. Diabetic patients demonstrated superior secondary patency rates at 5 years. Saphenous vein grafts performed better than all other conduits, with a secondary patency rate of 67.6% versus 46.3% at 5 years ($P < 0.0001$) (Fig. 209.7).

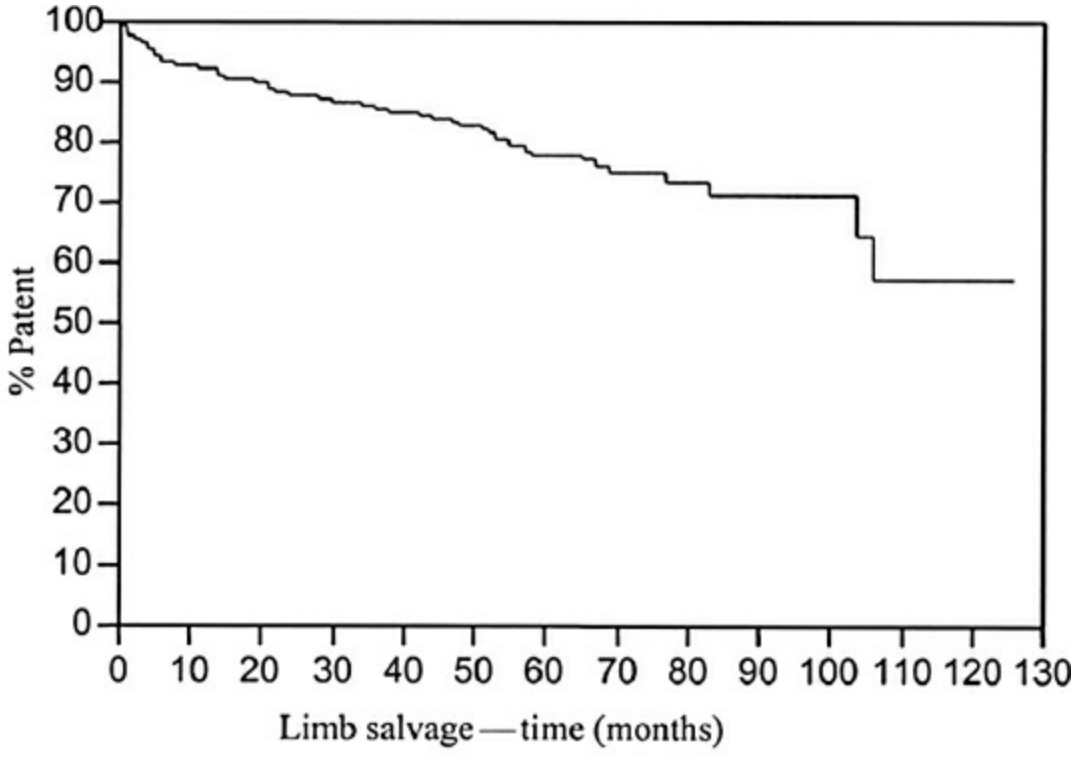

Figure 209.6. Limb salvage rates of dorsalis pedis bypass. (Reprinted with permission from Pomposelli FB, Kansal N, Hamdan AD, et al. A decade of experience with dorsalis pedis artery bypass: analysis of outcome in more than 1,000 cases. *J Vasc Surg* 2003;37(2):307–315; with permission from Elsevier.)

Smaller series have reported variable rates of graft patency for pedal bypass, with one early series of 73 cases documenting a primary patency of 59.2% at 2 years. Another series of 41 limbs in patients with end-stage renal disease undergoing DP bypass documented a primary assisted patency rate of 62% at both 1 and 2 years. This series reported a dismal limb salvage rate of 56% and 50% at 1 and 2 years, respectively, and pointed out that 44% of amputated limbs had functioning bypass grafts at the time of amputation. Notably, heel gangrene was a predictor of negative

outcome, including limb loss, a finding refuted by our series documenting the aid in healing of heel ulcers after DP bypass. Improved results have been noted in more recent series, such as one involving 49 DP bypasses with reported primary patency and limb salvage rates of 89% and 87% at 2 years, respectively. In a large series of patients in whom either peroneal or DP bypass options existed, outcomes for graft patency, limb salvage, and wound complications were similar. This series demonstrated a secondary patency of 67% for DP and 78% for peroneal bypasses at 5 years. Limb salvage was 86% for DP and 93% for peroneal bypass, failing to demonstrate statistical significance. In patients where a choice exists between these vessels, selection may depend on the length of available conduit or presence of adjacent soft tissue infection.

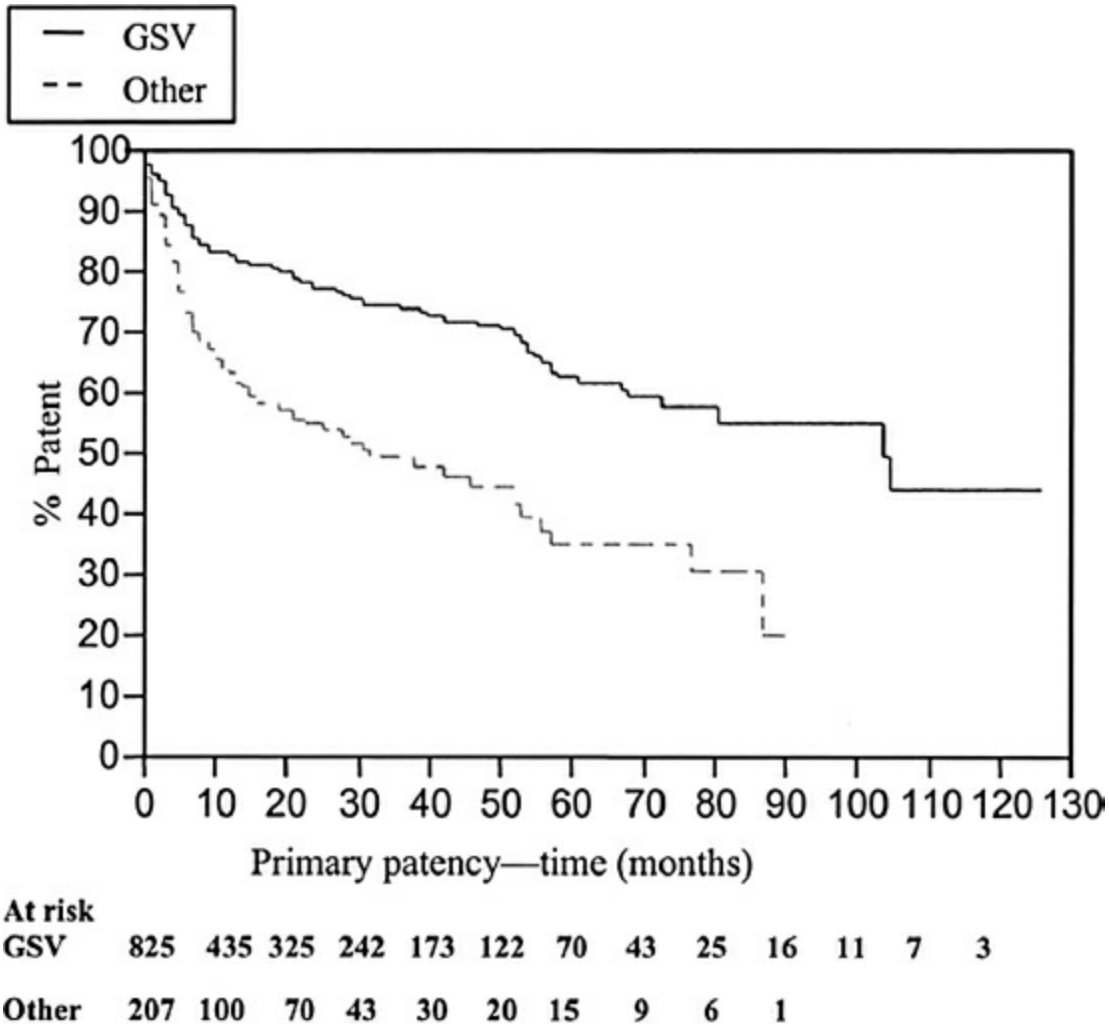

Figure 209.7. Primary patency rates for great saphenous vein versus all other conduit for dorsalis pedis bypass. (Reprinted with permission from Pomposelli FB, Kansal N, Hamdan AD, et al. A decade of experience with dorsalis pedis artery bypass: analysis

of outcome in more than 1,000 cases. *J Vasc Surg* 2003;37(2):307–315; with permission from Elsevier.)

Tarsal and Plantar Artery Bypass

In cases requiring bypass to the tarsal or plantar arteries due to unavailability of a DP or more proximal outflow target, patency rates comparable to those seen in DP bypass have been noted. Most reports document <5% of all infrainguinal arterial reconstructions involving outflow to the inframalleolar vessels. Our own published experience with 98 plantar and tarsal bypass procedures performed over a 13-year period revealed a perioperative mortality rate of 1%. Primary and secondary patency rates were 67% and 70% at 1 year and 41% and 50% at 5 years, respectively. Graft failure within 30 days postoperatively was 11%, as compared to only 4.2% in our DP bypass population. Limb salvage after bypass to the tarsal or plantar arteries approximated 75% at 1 year and 69% at 5 years. As has been demonstrated in our large series of DP bypass cases, the use of saphenous vein conduit was associated with a significantly higher 1-year patency rate of 83% versus 47% for all other conduit.

One series documented a primary patency rate of 72% at 2 years for 22 pedal branch bypasses in patients without a suitable DP bypass target. A similar report of 24 cases compared outcomes for pedal branch bypass to that for perimalleolar bypass within the same institution and found no significant difference in graft patency or limb salvage. In addition, above-knee versus below-knee inflow had no impact on outcome. One of the largest series of bypasses to the lateral plantar artery consists of 20 such bypass grafts. Follow-up yielded a primary patency rate of 73% at 2 years. The incidence of diabetes and the presence of gangrenous lesions with sepsis in this series were noted to be double that in the overall infrainguinal bypass population.

CONCLUSION

Bypass to the foot vessels for critical limb ischemia is a safe, effective, and durable procedure. In many patients, bypass to the DP, tarsal, or plantar arteries offers a reasonable alternative to major limb amputation. Graft patency and limb salvage rates are similar to those seen with more proximal infrainguinal arterial reconstructions. Optimal results are obtained with the use of autogenous saphenous vein, with excellent

durability and patency documented for >10 years in some patients. The typical distribution of atherosclerosis observed in the diabetic patient population mainly affects the tibial and peroneal arteries, often sparing the inframalleolar arteries. Therefore, bypass to the foot vessels is well suited to the treatment of foot ischemia in this patient population. For many patients, the DP artery may be the only outflow target artery available for bypass, and should always be included in the preoperative arteriogram. Tarsal and plantar artery bypass should be considered when the DP artery is occluded. While results are inferior to DP bypass, they are certainly reasonable and often preferable to performing a primary major amputation without an attempt at a limb-salvaging revascularization procedure.

In our practice, embracing the use of DP, tarsal, and plantar artery bypass appears to have had a significant impact on the decrease in the number of both major and minor amputations performed for treatment of ischemia over a 10-year follow-up period. The advantage of inframalleolar bypass seems intuitive in that restoration of arterial perfusion to the ischemic diabetic foot is direct, in close proximity to the ischemic lesion, and not dependent on terminal branches or collaterals. More importantly, when given equal consideration to popliteal or crural outflow targets, inframalleolar bypass adds another potential revascularization option, resulting in the ability to perform a limb-sparing arterial reconstruction in a group of patients previously offered primary amputation. Angioplasty of the more proximal arteries in conjunction with a shorter bypass may offer an alternative to primary amputation in patients with limited vein conduit. Inframalleolar bypass will continue to be a mainstay in our treatment of ischemic foot salvage in patients with diabetes mellitus. Bypass to the DP, tarsal, and plantar arteries should be in the armamentarium of all vascular surgeons caring for patients with diabetes mellitus and advanced limb ischemia.

EDITOR'S COMMENT

In their chapter on distal arterial infrapatellar bypass, Aulivola and Pomposelli detail almost a lost art, which is the peripheral arterial bypass with autologous vein. The number of open bypass procedures has declined over time by 42% as endoluminal procedures and technology have exploded (Goodney PP, Beck AW, Nagle J, et al. National trends in lower extremity bypass surgery, endovascular interventions, and major amputations. *J Vasc Surg* 2009;50:54–60). Moreover, the educational trainee exposure to lower extremity bypass has decreased by 66% between 1999 to 2012 (21 to 7 index procedures) (Krafcik

BM, Sachs TE, Farber A, et al. Assessment of open operative vascular surgical experience among general surgery residents. *J Vasc Surg* 2016;63:1110–15). These trends suggest that our vascular residents and fellows may not get enough experience with these often technically demanding procedures. Ultimately, peripheral bypass may be relegated to vascular surgeons who really specialize in this procedure.

It is still an open question of whether peripheral bypass first or endoluminal first for severe peripheral arterial disease is best. However, I argue that a bypass is more durable than a long segment recanalization of popliteal and tibial arteries, as compared to the more proximal artery (e.g., iliac and superficial femoral) endoluminal success. The best endovascular versus best surgical therapy in patients with critical limb ischemia (BEST-CLI) trial is currently ongoing to answer this question as it was fairly equivocal in the Bypass versus angioplasty in severe ischaemia of the leg (BASIL) trial, which was done more than 15 years ago (Adam DJ, Beard JD, Cleveland T, et al. BASIL: multicentre, randomised controlled trial. *Lancet* 2005;366:1925–34).

The ability to be creative when determining the best inflow and outflow targets as well as dealing with often very diseased vessels requires a lot of operative experience. Many important technical pearls are described within this chapter. This is an experienced group that has many thousands of bypasses under its belt, and it bears paying attention to many of the tips and techniques herein.

Additional technical issues that I think are important to highlight include the use of duplex ultrasonography to define the dorsalis pedis or posterior tibial arteries, the target size, and flow rates. Duplex often helps if the arteriogram does not delineate these targets sufficiently.

The most common indication for those requiring a pedal bypass is critical limb ischemia, encompassing rest pain and tissue loss, and often times, renal insufficiency is present. To avoid contrast-induced nephropathy, carbon dioxide arteriography is useful, and with proper technique of leg elevation and long duration filming allows visualization of smaller vessels not possible with contrast arteriography.

Choosing who to perform a peripheral bypass on is sometimes a challenge. The new WiFi Score (Mills JL Sr, Conte MS, Armstrong DG, et al.; Society for Vascular Surgery Lower Extremity Guidelines C. The society for vascular surgery lower extremity threatened limb classification system: risk stratification based on wound, ischemia, and foot infection (wifi). *J Vasc Surg* 2014;59:220–34 e221–2), promoted by the Society for Vascular Surgery, helps to stratify patients who are best served by improving their arterial flow as compared to those who may be best served with an amputation or other measures. In other words, it provides a multidimensional view of tissue loss rather than just the broad category of tissue loss that ranges from a small toe ulcer to extensive foot tissue involvement.

While having a vein bypass directly to the foot does provide palpable,

pulsatile blood flow, a series about a decade and a half ago showed that anastomosing to the peroneal artery as compared with the post tibial or dorsalis pedis was equivalent for limb salvage (Bergamini TM, George SM Jr, Massey HT, et al. Pedal or peroneal bypass: which is better when both are patent? *J Vasc Surg* 1994;20:347–55; discussion 355–6). This highlights the fact that the venous conduit quality is a very important determinant of bypass success and ultimately patency (Robinson WP 3rd, Owens CD, Nguyen LL, et al. Inferior outcomes of autogenous infrainguinal bypass in hispanics: an analysis of ethnicity, graft function, and limb salvage. *J Vasc Surg* 2009;49:1416–25). A vein graft of over 2.5 mm and preferably 3 mm yields much better results in those that are more marginal. Most bypass series show secondary patency of >70%.

Whereas I agree that a shorter bypass is generally better, such as a bypass from the above the knee popliteal to tibial artery, progression of superficial femoral artery disease does have to be monitored and occasionally treated. It is not an uncommon scenario that the bypass flow rates by duplex ultrasonography may diminish overtime, suggesting proximal disease. Then, either angioplasty and stenting or doing a sequential bypass from the femoral artery to the graft itself (hopefully with vein), can be done to salvage the graft. Long-term surveillance is the key.

Lastly, it is very important to maintain these patients in clinical follow-up. One of the joys of vascular surgery is seeing your patient back year after year with a patent graft and functional limb. It is always disheartening to get the call from the emergency room or have your patient come to clinic with an occluded bypass, and then unlikely able to be salvaged. Equally, should graft stenosis arise, prompt treatment almost always allows graft salvage.

210 Peripheral Vascular Occlusive Disease: Endovascular

Richard Powell, Ryan Svoboda, and Jessica Wallert

PATIENT SELECTION

Patients with lifestyle-limiting claudication or critical limb ischemia in the form of rest pain or ischemic tissue loss are candidates for lower extremity angiogram and possible endovascular intervention. Patients with claudication can be given a trial of medical therapy with aspirin, statin, and cilostazol 100 mg bid, prior to considering intervention in those patients in whom the claudication is lifestyle limiting. Patients with present femoral pulses but absent popliteal pulses are likely to have hemodynamically significant lesions in the femoropopliteal segment, while those with present popliteal pulses and absent pedal pulses likely have tibial disease. In addition, tibial disease tends to occur more commonly in diabetic patients. Patients with ischemic rest pain or tissue loss typically have multilevel vascular disease.

PREOPERATIVE IMAGING

Preoperative imaging and noninvasive vascular laboratory studies are essential for procedure planning. All patients being considered for endovascular intervention should undergo noninvasive vascular laboratory studies, which should include, at a minimum, ankle-brachial index (ABI) measurement and segmental pressures. Diabetic patients should undergo toe pressure measurement, due to the possibility of falsely elevated ABIs secondary to tibial calcinosis. Patients with unilateral symptoms, fewer risk factors for atherosclerotic disease, and strong contralateral pedal pulses should undergo bilateral popliteal artery Duplex to rule out popliteal artery aneurysm. In patients with a decreased or absent femoral pulse and normal renal function, computerized tomography arteriography (CTA) or magnetic resonance arteriography (MRA) can be performed to rule out concurrent aortoiliac disease. In addition, CTA and MRA can be valuable to assess the degree of common femoral, superficial femoral artery (SFA),

and popliteal disease. We have not found these studies adequate to assess the severity of tibial disease.

Preoperative studies and intraprocedural angiogram are used to assess the location and length of stenosis or occlusion, as well as the degree of calcification. Lesions are categorized according to the Trans-Atlantic Inter-Society Consensus (TASC) II guidelines (Table 210.1). TASC A and B lesions are typically treated with endovascular therapy. TASC C and D lesions can be treated with endovascular therapy if the patient is not a suitable candidate for bypass or does not have a good conduit option.

PROCEDURAL DETAILS

Endovascular treatment of infrainguinal peripheral artery occlusive disease involves a customized approach for each individual that is determined by anatomic and lesion-specific characteristics of the disease being treated. However, the following basic algorithm applies in most circumstances.

Arterial Access and Diagnostic Imaging

The patient is consciously sedated using short-acting opiate and benzodiazepine medications. The site of arterial access is determined by preoperative imaging and pulse assessment. Typically, for more proximal lesions, contralateral femoral access is obtained overlying the femoral head. For more distal popliteal and tibial lesions, ipsilateral antegrade femoral access may be beneficial. After infiltration of local anesthetic, a 21-gauge 4-Fr micropuncture set is used under fluoroscopic and ultrasound guidance to gain access. After initial access is gained, the micropuncture catheter is exchanged for a 10-cm 5-Fr sheath over a 0.035-in J-wire. In patients for whom retrograde contralateral access has been obtained, an abdominal aortogram is performed through a flush catheter seated in the pararenal position (L1 to 2 disc space) in order to rule out disease in the infrarenal aorta and iliac vessels. The catheter is then lowered to just above the aortic bifurcation, and oblique pelvic arteriography is performed to assess the common and external iliac arteries (30 degrees contralateral). Our practice is to use a contrast medium that is cut by one half or one third. For aortic arteriography, we use a flow rate of 15 mL/s for a total volume of 30 mL. For a pelvic arteriogram, a flow rate of 10 mL/s and volume of 20 mL are used. Next, we typically use a curved catheter such as an Omni Flush in combination with a soft wire such as a 0.035-in J-wire or an angled gluide wire in order to cross “up and over” the aortic

bifurcation to the side of the affected extremity. The wire is advanced, the catheter is placed in the common femoral artery, and the entire extremity is imaged in a "bolus-chase" fashion using a flow rate of 5 mL/s for a total volume of 20 to 25 mL/s. Additional oblique views (30 degrees ipsilateral) can be useful for examining the common femoral artery bifurcation. If the patient has suboptimal renal function, selective single-station angiograms can be performed in lieu of a bolus-chase image, or CO_2 can be used instead of intravenous contrast. When imaging the tibial vessels, if significant vasospasm is suspected, a mixture of 500 mcg of verapamil, 50 mcg of nitroglycerin, and 500 units of heparin is administered through the sheath and the images repeated.

TABLE 210.1 Lesion Characteristics Used to Define the Trans-Atlantic Inter-Society Consensus (TASC) II Guidelines for Characterizing Infrainguinal Peripheral Vascular Disease

TASC Classification	Lesion Characteristics
Type A	Single stenosis ≤10 cm OR Single occlusion ≤5 cm
Type B	Multiple stenoses or occlusions, each ≤5 cm OR Single stenosis 10–15 cm or occlusion 5–15 cm (of the SFA or suprageniculate popliteal artery) OR Heavily calcified occlusion ≤5 cm OR Single infrageniculate stenosis or occlusion
Type C	Multiple stenosis or occlusions, >15 cm total OR Recurrent stenosis or occlusions that have undergone ≥2 prior endovascular interventions
Type D	Chronic total occlusion of the superficial femoral artery ≥20 cm, with extension into the popliteal artery OR Chronic total occlusion of the popliteal artery and proximal tibial vessels

Source: Norgren L, Hiatt WR, Dormandy JA, et al. Inter-Society Consensus for the Management of Peripheral Arterial Disease (TASC II). *J Vasc Surg* 2007;45(1):S5–67.

Crossing the Lesion

Following angiogram, the location and characteristics of the lesions are

considered and will dictate the approach to recanalization and treatment. If the lesions appear appropriate for endovascular treatment, a sheath is placed over the aortic bifurcation. If the planned treatment includes disease in the proximal SFA, the 10-cm 5-Fr sheath is exchanged for a 45-cm peripheral guiding sheath (Destination, Terumo) over a stiff 0.035-in wire (Stiff glide wire, Teruma or Amplatz Super Stiff, Boston Scientific) and the patient is heparinized (100 units/kg). If the lesion to be treated is in the distal SFA or popliteal region, a 65-cm peripheral guiding sheath is placed. Lastly, if only tibial disease is being treated, a 90-cm sheath (Flexor Shuttle Guiding Sheath, Cook Medical) is placed. The sheath diameter is largely dictated by the planned intervention. Many atherectomy devices require a 7-Fr sheath. Most Stents will go through a 6-Fr sheath. The treatment of tibial disease can frequently be performed with a 5-Fr sheath to accommodate 0.018- and 0.014-in balloons and coronary stents.

Superficial Femoral Artery Lesions

If the patient has an SFA lesion, it is recanalized and treated first. Attempts to cross an SFA stenosis are performed using any combination of 0.035-, 0.018-, or 0.014-in wires with a straight-tipped or angled-tipped catheter. See Table 210.2 for preferred wire and catheter selections. Total occlusions are treated with initial attempts at intraluminal recanalization. Weighted-tip wires (Victory, Boston Scientific) or devices such as the TruePath (Boston Scientific), a motorized diamond–coated tipped catheter on a 0.018-in platform, can assist in achieving intraluminal recanalization and are most helpful for entering a heavily calcified occlusion. If intraluminal recanalization is unsuccessful, subintimal recanalization can be performed and is often required for longer lesions. To attempt subintimal recanalization, a hydrophilic stiff wire is passed and forms a loop as it enters the subintimal plane. This requires the support of a catheter (Fig. 210.1). The wire will often reenter the lumen once the lesion is passed; however, if this does not occur, advancement of an angled catheter over the wire and guidewire manipulation usually results in successful reentry into the lumen. If attempts at reentry are unsuccessful, a reentry device (OffRoad, Boston Scientific; Outback LTD, Cordis; Pioneer, Volcano Corporation) can be used. Once recanalization has been achieved, a single-station angiogram performed through the catheter is vital to confirm of intraluminal position prior to additional intervention.

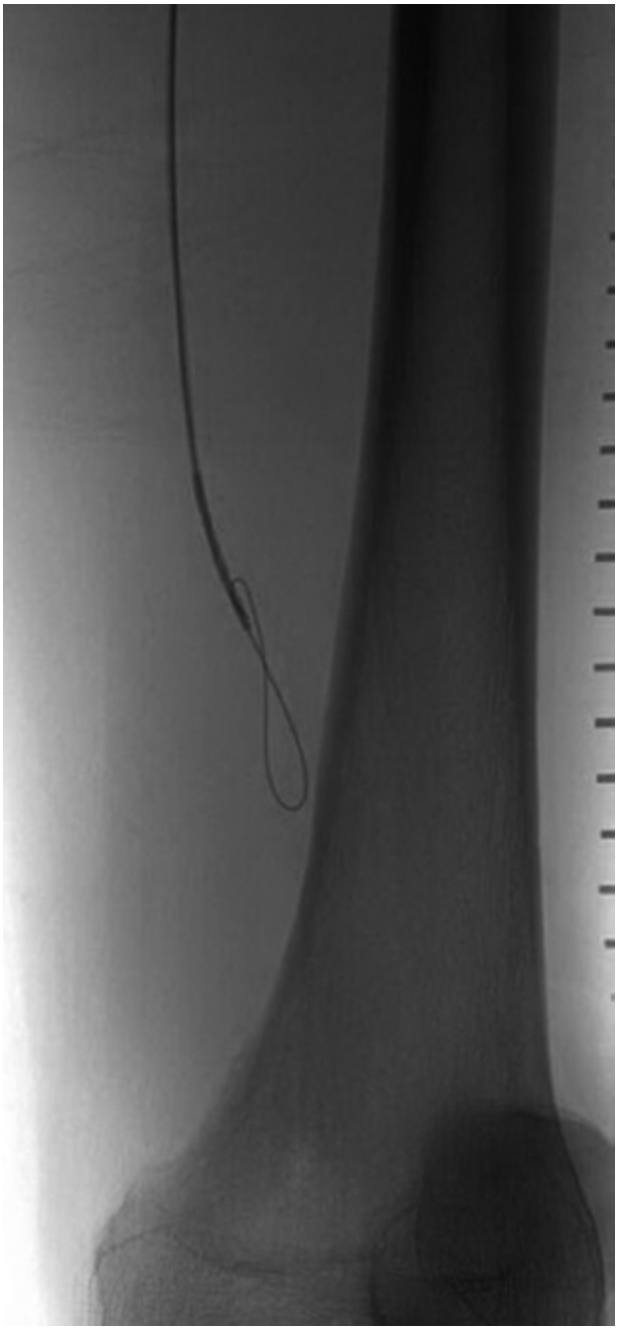

Figure 210.1. A hydrophilic stiff wire is passed and forms a loop as it enters the subintimal plane.

For patients with SFA lesions that cannot be crossed via an antegrade approach, direct popliteal artery access can be obtained. The patient is placed in a prone position on the angiography table, and ultrasound guidance is used to access the popliteal artery directly with a 4-Fr micropuncture kit. The lesion is then crossed in a retrograde fashion, the wire is snared from the groin, and the lesion can then be treated antegrade.

Popliteal Artery Lesions

Popliteal artery lesions are crossed in a manner similar to that described for the SFA. It is important to note that chronic total occlusions of the below-knee popliteal artery with extension into all three proximal tibial vessels pose a significant challenge to safe reentry into the intraluminal space. In our practice, if a patient with such a lesion is a good surgical candidate and has adequate conduit for bypass, we will often opt for this method of treatment over endovascular attempts. If bypass is unfavorable or precluded due to patient-related factors, distal access of a patent pedal vessel and attempt at retrograde recanalization of the lesion may be performed.

Tibial Artery Lesions

Following treatment of any proximal lesions, attention is turned to recanalization of the tibial arteries. A 0.014- or 0.018-in wire is used in combination with a catheter to select the tibial artery of interest. For the anterior tibial artery, we prefer an angled catheter, whereas for the peroneal and posterior tibial arteries, a straight crossing catheter can usually be used (Table 210.2). After the target artery is selected, the lesion is crossed using the 0.014-in wire and crossing catheter in combination. If two of the tibial arteries have proximal lesions requiring endovascular treatment, a second “buddy wire” is used to select the second artery and recanalization is performed in a similar fashion.

Occasionally, if antegrade recanalization is unsuccessful, the occlusion can be crossed in a retrograde fashion via pedal access. This approach is typically reserved for patients with critical limb ischemia (Rutherford class IV–VI) who are not candidates for tibial bypass. In these cases, retrograde access of the dorsalis pedis or posterior tibial artery is performed under ultrasound guidance. A 22-gauge needle and a 0.014- or 0.018-in wire are placed. The inner cannula of a 4-Fr micropuncture sheath serves as the “sheath” (Fig. 210.2). If a crossing catheter is needed, a straight or curved crossing catheter (Table 210.2) is placed bareback through the skin and is used to cross the lesion. Although a 2- to 3.5-mm angioplasty balloon can be used to treat the lesion from a retrograde fashion, we prefer to recanalize the lesion from a retrograde fashion and use a snare to capture the retrograde wire and bring it through an antegrade catheter introduced through the common femoral artery, so that any treatment can then be performed through a stable platform.

Intervention

Once an arterial lesion is successfully crossed and angiography confirms intra-luminal access proximal and distal to the point of interest, attention is turned to intervention. Three general treatment strategies are employed:

Angioplasty

Angioplasty can be performed with one of three types of balloons: plain, cutting, or drug-coated. Plain old balloon angioplasty (POBA) has been shown to have inferior results to other forms of SFA treatment in all but short (TASC A) lesions not in the region of the adductor canal. We rarely use cutting balloons in everyday practice for treating infrainguinal disease. These are often reserved for treatment of anastomotic bypass lesions where neointimal hyperplasia has occurred. Drug-coated balloons have been shown to reduce rates of restenosis compared to POBA and in two early randomized placebo-controlled trials and approached patency rates similar to SFA stent placement at 1 year. There are currently two such devices approved by the FDA for use in the femoropopliteal system in the United States: Lutonix (Bard) and In.Pact Admiral (Medtronic) are both paclitaxel-coated balloons, which are available in a variety of treatment diameters and utilize a 0.035-in treatment platform. It is too early to recommend the utilization of drug-coated balloon angioplasty (DCB) as an adjunct to other treatments, such as atherectomy but early results are promising. For all angioplasty, a balloon diameter that is 5% to 10% larger than the target vessel is chosen (typically 5 to 7 mm for SFA lesions, 4 to 6 mm for popliteal, and 2 to 3 mm for tibial arteries). Balloon length is chosen to be slightly longer than the lesion length. All lesions are dilated under fluoroscopic guidance (Fig. 210.3).

Stenting

Stenting of the SFA or popliteal artery is recommended for most TASC A and B lesions, for vessel recoil, or for flow-limiting dissection that occurs following angioplasty or atherectomy. We consider three primary types of stents: balloon-expandable (bare or covered), self-expanding (bare or covered), and drug-eluting. Advantages to balloon-expandable include high radial force, minimal migration with placement, and the ability to overexpand the stent. These are all qualities that are more important when treating disease outside of the infrainguinal region. For this reason, we preferentially use self-expanding stents for treating femoropopliteal disease, which offer the advantages of increased flexibility and resistance to deformity. Specifically, for SFA lesions, self-expanding nitinol stents

can be deployed over a variety of wires. These cannot be overexpanded, thus upsizing 5% to 10% of the intended vessel diameter to ensure that apposition of the stent is recommended (Fig. 210.4). For long chronic total occlusions, a self-expanding covered stent, such as a Viabahn (Gore), due to its inherent flexibility can be used and may have improved patency compared to bare metal stents. We also often utilize drug-eluting stents (Zilver PTX, Cook Medical) for treating SFA disease. One additional advantage to the Zilver PTX is its low profile and ability for many sizes to be delivered through a 5-Fr platform. Following stent placement, angioplasty using a balloon of size equal to the stent or 1 to 2 mm smaller is performed.

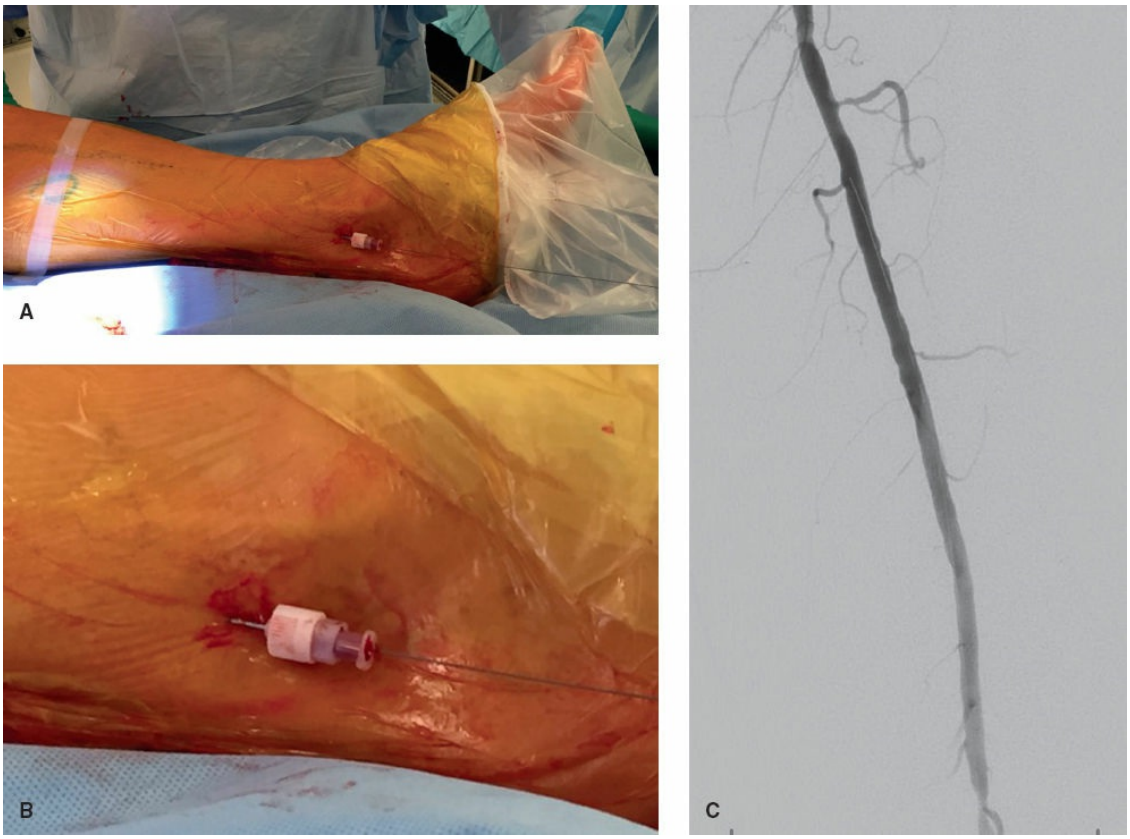

Figure 210.2. In some circumstances, when an occlusion is not successfully crossed in an antegrade fashion, retrograde pedal access is obtained, either via a percutaneous or direct cutdown approach (**A**). The lesion is then crossed retrograde (**B**), the wire snared from above, and the lesion can then be treated in an antegrade fashion (**C**).

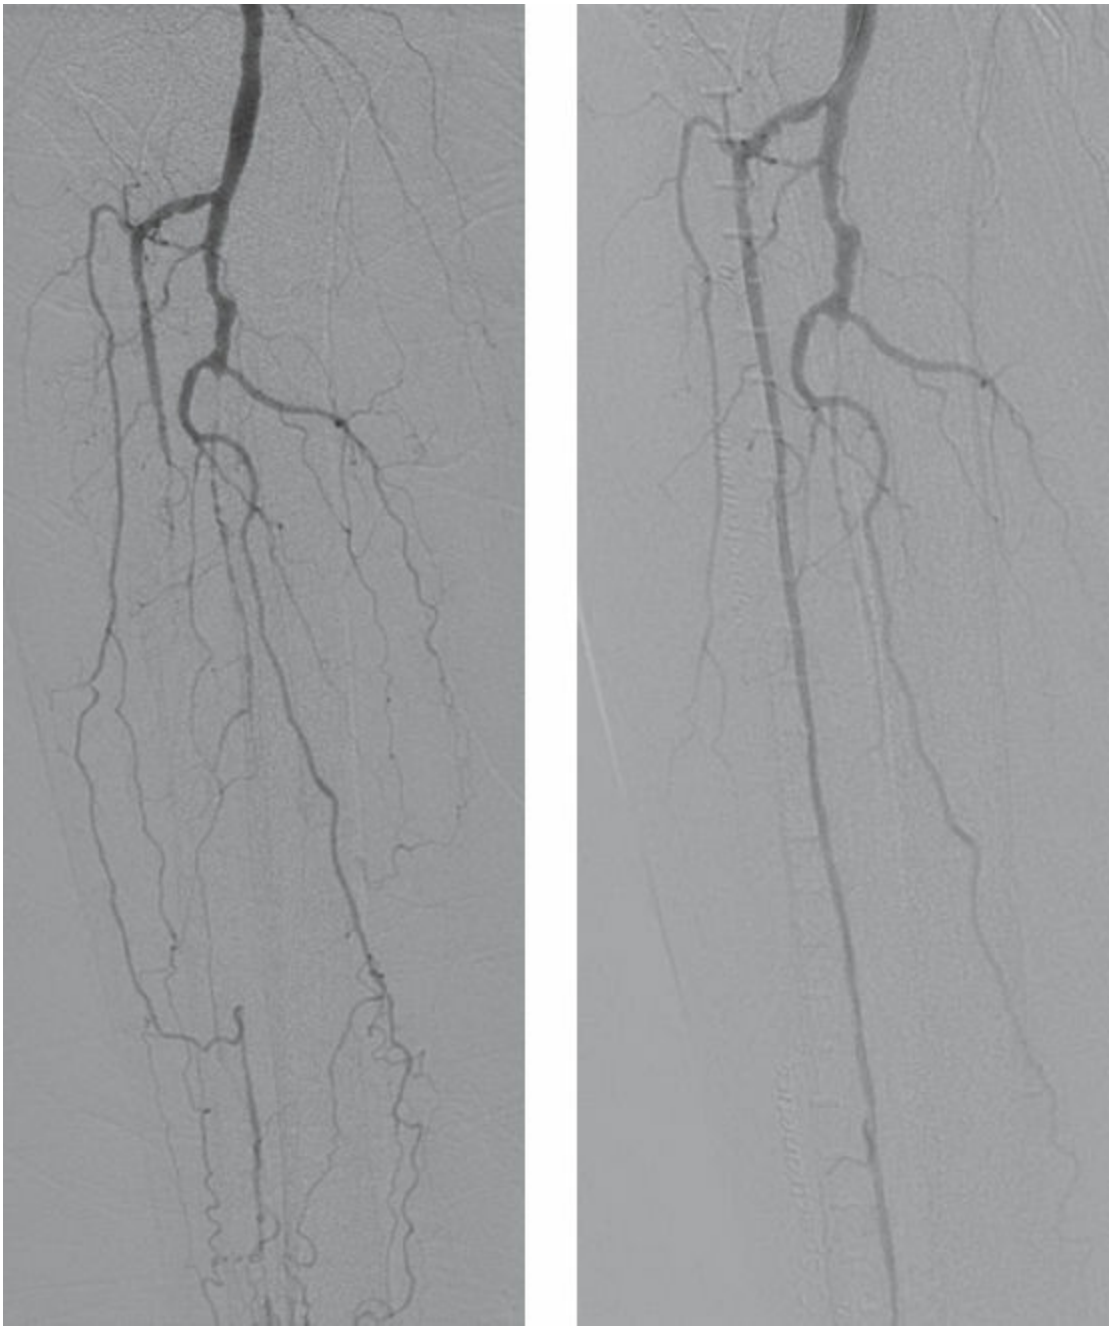

Figure 210.3. Example of a recannalized anterior tibial artery occlusion following treatment with balloon angioplasty.

Popliteal lesions distal to the femoral epicondyles are preferentially managed with balloon angioplasty alone if possible, as this is traditionally considered to be a “no-stent” zone due to the proximity to the knee joint and increased propensity for stent fracture. Atherectomy or drug-coated balloons, either alone or in combination, may obviate the need for a stent in this area.

Regarding tibial artery lesions, there is no high-level evidence showing superiority of primary stenting versus angioplasty alone. A recent meta-

analysis by Wu et al. (2014) showed that primary stenting was associated with a trend toward a higher primary patency rate and a lower secondary patency rate, but neither finding reached statistical significance. Thus, the authors concluded that there is insufficient evidence to judge superiority of one method versus the other. In our practice, we routinely treat tibial lesions with balloon angioplasty, reserving stenting for patients who experience restenosis following angioplasty.

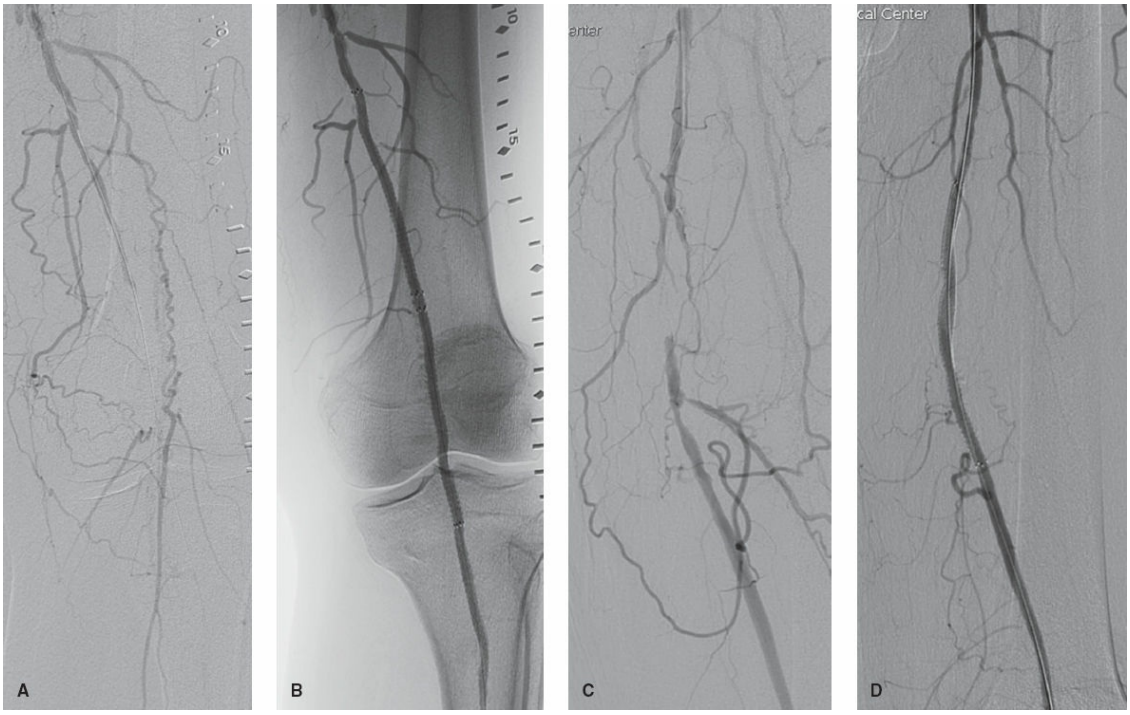

Figure 210.4. Example of a superficial femoral artery (**A, B**) and popliteal artery (**C, D**) occlusions successfully treated with bare metal stenting.

Atherectomy

Atherectomy devices can be classified in one of three ways (directional, rotational, laser) and are used to eliminate plaque. Directional devices (SilverHawk, Covidien) are best used to treat focal, calcified lesions. Rotational devices (JetStream, Boston Scientific; Diamondback 360, Cardiovascular Systems, Inc) use a high-speed burr mechanism to eliminate plaque. Laser recanalization (Turbo-Elite, Spectranetics) uses a specific wavelength of light to ablate plaque in both de novo and in-stent lesions. Our preferred practice is to use the Jetstream for de novo stenosis or occlusions. This is an over-the-wire, front-cutting rotational device with aspiration. It is approved for use in each the SFA, popliteal, and tibial vessels with a variety of catheter sizes available, and can treat multiple

morphologies from heavily calcified plaques to fresh thrombus (Fig. 210.5). It is unclear if the combination of atherectomy plus drug-eluting balloon will be superior to stent placement for calcified SFA lesions (Fig. 210.6). For in-stent restenosis, laser atherectomy can be used, and is also available in a wide range of sizes to treat both femoropopliteal and tibial vessels.

Posttreatment Assessment and Case Completion

Following treatment with any of the above listed interventions, completion arteriogram is mandatory to confirm proper treatment and absence of unintended consequences. Typically, this is performed via single-station angiography. If the result is suboptimal, adjunctive procedures can be considered. Once the operating surgeon is satisfied with the treatment result, the sheath is removed over a wire and the arteriotomy is closed with a closure device (Mynx, Cardinal Health; Perclose Proglide, Abbott) or manual compression. Protamine is administered if the bleeding risk is deemed to outweigh the risk of thrombosis of the endovascular repair.

OUTCOMES

Femoropopliteal Disease Outcomes

Outcomes following femoropopliteal interventions vary by type of intervention. In 2007, Rocha-Singh et al. published a report demonstrating an overall primary patency rate of 33% at 12 months following plain balloon angioplasty among patients with debilitating claudication. This effect varied by lesion length, with poorest results among those with long lesions (16% primary patency at 12 months for those with lesions 11.1 to 15 cm). Multiple trials show improved primary patency following stenting (Fig. 210.6). As with angioplasty, patency varied by lesion length, as well as by stent design; however, overall primary patency ranged from 70.8% to 86.3% at 12 months. Results from drug-eluting stents are proving even more favorable. A randomized trial comparing primary angioplasty to a paclitaxel-coated drug-eluting stent, Zilver PTX (Cook Medical) demonstrated superior rates of primary patency at 12 months for the drug-eluting stent (83% vs. 33%). This same trial noted increased primary patency for the drug-eluting stent over bare-metal stents for those patients who failed primary angioplasty alone and underwent provisional revascularization (90% vs. 73%). Data pertaining to drub-coated balloons

are limited. One trial, the LEVANT I, compared the Lutonix (Bard) paclitaxel-coated balloon to plain balloon angioplasty, and demonstrated improved rates of late lumen loss at 6 months following intervention (0.46 vs. 1.09). Similarly, data pertaining to atherectomy devices are also sparse, which is why our practice is typically to use these methods primarily as adjuncts to stenting in the femoropopliteal region.

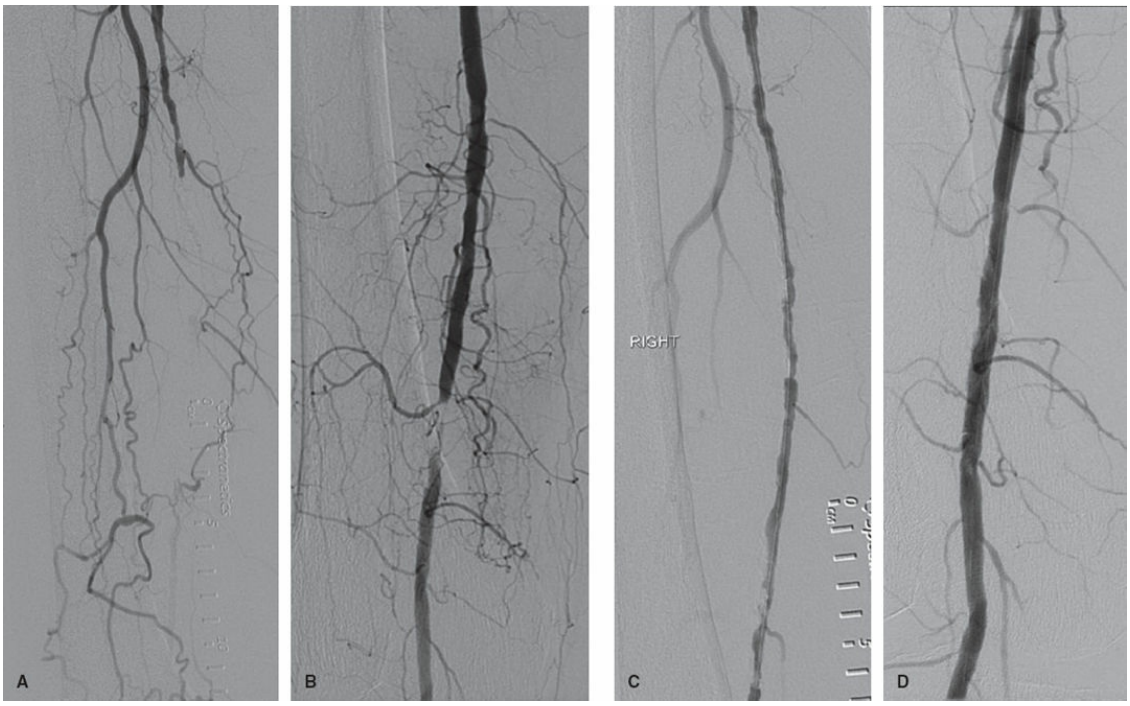

Figure 210.5. Examples of superficial femoral artery occlusions (**A** and **B**) that have been successfully crossed and treated with Jetstream Atherectomy System (Boston Scientific) (**C** and **D**).

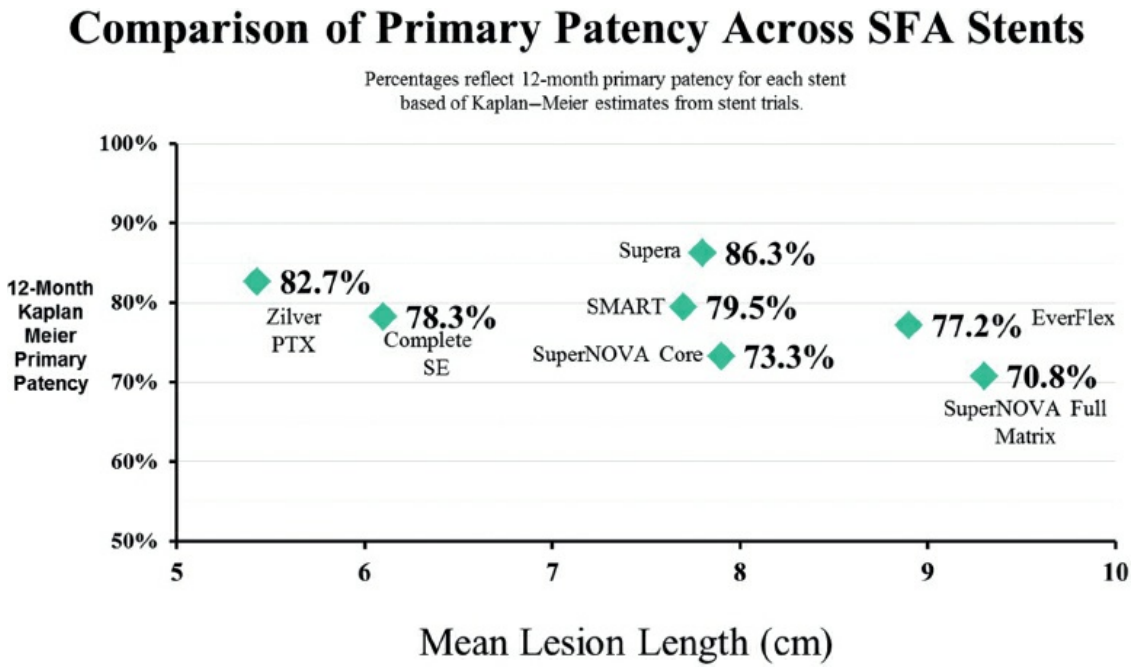

Figure 210.6. Comparison of primary patency across superficial femoral artery (SFA) stents.

Tibial Disease Outcomes

Outcomes following tibial angioplasty are generally poor, with technical success ranging from 89% to 95%, but 1-year primary in the realm on 53% to 68%. Despite this, reported limb salvage rates are higher, typically ranging from 84% to 86% at 1 year. Retrospective studies have shown similar results for bare metal stents placed in the tibial arteries. Limited data suggest that drug-eluting stents placed in the tibial system display superior patency rates—up to 81%—when compared to bare metal stents.

COMPLICATIONS

Complications following infrainguinal endovascular repair typically fall into one of four categories based on complication site: puncture site, treatment site, distal vessel, and systemic. Puncture site complications occur in approximately 4% of patients, with simple hematoma being the most common. Pseudoaneurysm, arteriovenous fistula, and retroperitoneal hematoma are less common complications of arterial puncture. In order to decrease the likelihood of these complications, accurate sheath placement in the common femoral artery is essential. In our practice, we routinely order a Duplex ultrasound to rule out pseudoaneurysm for patients with enlarging groin hematomas following endovascular procedures. If a pseudoaneurysm is present, we begin treatment with 30 minutes of

ultrasound-guided compression. If this fails, we typically treat large pseudoaneurysms with thrombin injection if the neck is long and narrow, or open surgical repair if the neck is short and wide. Retroperitoneal hematoma can be a lethal complication and should be suspected in any patient with back pain and hypotension following infrainguinal endovascular intervention.

Treatment site complications occur approximately 3.5% of the time and include dissection with or without acute thrombosis, and rupture. Completion angiography is essential to rule out a local complication. If dissection is noted following angioplasty, a stent is placed over the dissected area to “tack down” the dissection plane.

Complications in distal vessels occur approximately 2.7% of the time and include embolization and extension of arterial dissection. Use of distal embolic protection devices reduces risk of embolization and may be indicated when treating high-risk lesions or utilizing certain treatment modalities such as orbital atherectomy.

Finally, systemic complications are rare and most commonly occur in the form of contrast-induced nephropathy. In our practice, we routinely treat patients with chronic kidney disease and a baseline estimated GFR of less than 60 with a sodium bicarbonate infusion starting at 3 mg/kg/h for 1 hour prior to the procedure and continuing through the procedure followed by 4 hours after the procedure at 1 mg/kg/h. We no longer routinely treat with N-acetyl-cysteine due to the lack of evidence supporting this practice.

SUMMARY

Patients with lifestyle-limiting claudication or critical limb ischemia are candidates for lower extremity angiogram and intervention. Endovascular approaches to treating infrainguinal disease are variable and must be carefully individualized for each patient. However, in general, endovascular interventions can be divided into two primary aims: crossing a lesion and treating a lesion. Once a lesion is crossed, techniques for treatment vary and can include the use of atherectomy devices to debulk a lesion, plain balloon or drug-eluting balloon angioplasty, bare-metal stenting, drug-eluting stenting, and, in some circumstances, stentgrafting.

EDITOR’S COMMENT

This clearly written and comprehensive chapter by Powell highlights the now

standard, often initial revascularization procedure for claudication and critical limb ischemia; namely, endovascular revascularization. Over the last 15 years, with the advent of new techniques, devices, and technologies, the endovascular first approach is often the way it's done for everything from a short segment femoral artery stenosis to long segment femoral, popliteal, or tibial occlusions. The rapidly increasing use of endovascular techniques and decrease in open revascularization surgeries is significant. For example, endoluminal procedures have increased threefold and surgeries have decreased 42% (Goodney PP, Beck AW, Nagle J, et al. National trends in lower extremity bypass surgery, endovascular interventions, and major amputations. *J Vasc Surg* 2009;50:54–60). Indeed, the low-profile sheaths and closure devices allow almost any artery to be opened up with a good safety profile. However, several issues are relevant with these techniques.

One primary issue with endovascular revascularization is appropriateness, due to wide ranging specialists who perform catheter-based interventions, and a relatively limited evidence basis for procedural indications. Appropriateness issues are being raised in many areas of medicine, as evidenced by the "choose wisely" campaign (Rao VM, Levin DC. The overuse of diagnostic imaging and the Choosing Wisely initiative. *Ann Intern Med* 2012;157:574–6). There is a large grey zone of claudication severity, most of which is not truly lifestyle limiting, yet may be treated too aggressively with an endoluminal procedure. Unfortunately, failure of endovascular procedures may accelerate or worsen the natural history in a claudicant, rendering their limb at risk. Thus, I recommend the same conservative criteria for revascularization using an endolumenal approach as for an open procedure. Conversely, little concern or controversy exists regarding aggressive treatment for patients who have critical limb ischemia manifesting as rest pain or tissue loss.

The use of the Trans-Atlantic Inter-Society Consensus Document on Management of Peripheral Arterial Disease–II (TASC II) classification (Norgren L, Hiatt WR, Dormandy JA, et al. Inter-Society Consensus for the Management of Peripheral Arterial Disease (TASC II). *J Vasc Surg* 2007;45 Suppl S:S5–S67), while still commonly used, may be somewhat outdated and revisions are pending. However, it still provides a common language as an anatomic categorization system for most vascular interventialists. There is no discrete evidence for or against treating TASC A and B by endoluminal means, as compared with TASC C and D with a surgical bypass. Technically, TASC A or B lesions are generally easier to treat. The Bypass versus Angioplasty in Severe Ischemia of the Leg trial (Adam DJ, Beard JD, Cleveland T, et al. Bypass versus angioplasty in severe ischaemia of the leg (BASIL): multicentre, randomised controlled trial. *Lancet* 2005;366:1925–34) suggested equivalent early outcomes between endovascular and surgical revascularization, but surgical bypass may be better for those with a greater than 2-year life expectancy. A larger multicenter United States trial is undergoing recruitment, and will provide more definitive answers.

Advanced fixed imaging hybrid rooms are now standard at most major vascular practices, including inpatient and outpatient venues. Indeed, these new generation imaging machines enhance visualization as well decrease radiation exposure. Of note, the use of CO_2 angiography, as mentioned by authors, requires some technical changes for imaging acquisition, but is very useful in patients with renal insufficiency. It is possible to use only 10 to 15 cc of iodinated contrast, with much of the anatomical imaging obtainable using only CO_2 contrast. Details of CO_2 angiographic techniques are published (Caridi JM, Kyung J, Cho M, et al. Carbon dioxide digital subtraction angiography (CO_2 DSA): a comprehensive user guide for all operators. *Vasc Dis Manag* 2014;11:E221–56).

In terms of crossing femoral artery stenosis or occlusions, patience is critical as this often is quite a tedious process around a calcified, bulky lesion at the adductor canal. Performing retrograde arterial puncture, snaring the wire in proximal femoral artery may get around this problem. Indeed, this technique with the distal access and snaring, so the called “subintimal arterial flossing with antegrade–retrograde intervention” techniques, is commonly utilized now with good anecdotal success (Spinosa DJ, Harthun NL, Bissonette EA, et al. Subintimal arterial flossing with antegrade-retrograde intervention (SAFARI) for subintimal recanalization to treat chronic critical limb ischemia. *J Vasc Interv Radiol* 2005;16:37–44). One important technical aspect for success is a good inflow artery pressure and at least one good outflow artery, usually a tibial artery.

The use of drug-eluting balloons and drug-eluting stents has skyrocketed in treating peripheral artery disease. This is based in part on a modest number of patients in the trial of Paclitaxel-coated stents, as compared with angioplasty or bare metal stents, showing that drug-eluting stents have superior patency (Dake MD, Ansel GM, Jaff MR, et al. Sustained safety and effectiveness of paclitaxel-eluting stents for femoropopliteal lesions: 2-year follow-up from the Zilver PTX randomized and single-arm clinical studies. *J Am Coll Cardiol* 2013;61:2417–27). Despite reasonable efficacy with non–drug-eluting self-expanding nitinol stents, in our own practice most femoral artery stenting is performed with the drug-eluting type stents. Whether this is cost-effective is unclear. Certainly, if reduced need for vascular re-intervention is factored in to costs, then these stents may be cost-effective. However, this still needs to be proven with apples to an apples comparison in randomized controlled trials.

Another important issue, and a difficult one to answer, is whether the endovascular revascularization first approach “burns bridges” for later open surgical bypass options when the stents occlude. In other words, do the endoluminal technique and subsequent failure cause loss of outflow arteries that could accept a surgical bypass? At least one retrospective study suggests lower graft patency after failed endoluminal therapy (Gifford S, Stauffer K, De Martino R, et al. Impact of femoropopliteal endovascular interventions on subsequent open bypass. *J Vasc Surg* 2016 Sep;64(3):623–8). In my practice, I

have seen multiple patients who received a fully stented femoral artery, and an open above knee popliteal artery that upon return with stent occlusion, now presents with severe leg ischemia symptoms, and more limited outflow targets. This has a very negative impact on patients, as longer length and/or tibial bypasses have lower patency and conduit for these bypasses may be limited. Again, the critical issue is the initial revascularization appropriateness, and risk-benefit analysis for informed patient decision making.

Peter Henke

211 Minor Amputations

Peter Henke

INTRODUCTION

In the United States, hospital admissions for foot ulceration are very common. One of the most important and overlooked aspects of successful limb salvage in these patients is a properly timed and executed minor amputation, with preoperative assessments of blood flow and good postprocedure orthotics. Minor amputations are performed twice as frequently as major amputations. Avoidance of major amputation is critical for a myriad of reasons. Transtibial and transfemoral amputations result in inefficient ambulation. The increase in metabolic cost after these procedures is proportional to the number of functional joints that are lost.

DIABETES MELLITUS AND FOOT ULCERATION

Currently, there are over 25 million diabetics in the United States and the prevalence continues to rise. The CDC report shows that the percentage of US citizens with diabetes has increased from 4.9% in 1990 to 9.3% in 2014. Diabetes mellitus is the leading cause of lower-extremity amputation worldwide. Approximately 80% of all lower-extremity amputations are precipitated by foot ulceration. The overall prevalence of foot ulcers in diabetics in the United States is 12% with a 20-year cumulative incidence approaching 10% and a lifetime incidence up to 25%, most of whom will require hospitalization for this condition. Indeed, foot ulcerations are the most frequent cause of diabetes-related hospital admission. The length of stay is significantly longer than that of other diabetes-associated complications with a yearly cost in the tens of billions of dollars. After amputation, diabetics heal at a rate similar to that of nondiabetics, but their overall survival is significantly worse.

The continued development of our understanding of the pathophysiology of foot ulceration in diabetics has led to numerous advances in limb salvage. In the past, microvascular arterial obliteration or “small vessel disease” was thought to result in poor skin perfusion and

necrosis. We now understand ulceration to be a result of a complex interplay between various sequelae of diabetes mellitus, often with large artery atherosclerosis.

Nerve damage in diabetics can result in a sensory dysfunction. The loss of protective sensation in the foot leads to injury from abnormal repetitive stress, poorly applied footwear, and even undetected hazards such as a foreign object in a shoe. Diabetics with reduced sensation are more likely to injure their feet and are less likely to notice injuries, resulting in delayed treatment. Peripheral neuropathy can also lead to changes in foot structure. Denervation of the intrinsic arch muscles can cause the toes to be pulled back by the now-unopposed long tendons, leading to hammertoe formation. Plantar and intrinsic muscle atrophies result in prominent metatarsal heads and less foot surface area overall to bear weight, a common source of pressure ulceration. Repetitive injury to a malformed insensitive foot leads to ligament laxity and further abnormal pressure points such as those seen in Charcot deformity. Autonomic neuropathy produces dry skin and decreased sweating. Callus formation is thus initiated, triggering abnormal pressure points and ulcer formation. All these factors increase the chance for ulceration and infection.

Clinical Presentation and Diagnosis

If the patient is a known diabetic, glycosylated hemoglobin should be sent. If the patient states they are not diabetic, our preference is to perform a screening fasting glucose level according to the American Diabetes Association guidelines (Table 211.1). In our experience, nearly half of the patients who present with a foot ulcer and are not a known diabetic will test positive for occult diabetes or prediabetes. The patient must be asked whether they suffer from complications of diabetes including neuropathy, retinopathy, and nephropathy. The existence of end-stage renal disease (ESRD) will negatively affect the patient's ability to heal as well as dramatically reduce his or her overall life expectancy.

TABLE 211.1 The American Diabetes Association Guidelines for Fasting Blood Glucose Screening

Fasting Plasma Glucose (mg/dL)	Result
<100	Normal fasting glucose
100–125	Prediabetes
>126 on two measurements	Diabetes mellitus
≥200	Diabetes mellitus

The majority of patients who require lower-extremity amputation will present initially with a foot ulcer. A thorough history and physical examination is the cornerstone for developing an effective treatment plan and limiting the extent of amputation required. Pertinent questions include a history of previous ulceration and length of healing involved. For example, how long has the current ulcer been present? Does it appear to be healing with healthy granulation tissue? Signs of systemic infection including fever, chills, and difficulty with glucose control should be solicited. If the patient has been recently hospitalized or immobilized, a pressure etiology must be suspected, especially for ulcers in the posterior heel location. The patient's functional status and capacity for independence will also help determine the ideal amputation level.

Physical examination of the involved extremity is essential. Pulses should be palpated manually, and with handheld Doppler as necessary, in the femoral, popliteal, posterior tibial, and dorsalis pedis artery locations. In the foot itself, look for any structural deformity, which is simply defined as a contracture that cannot be manually reduced. Investigation of the circulatory status of the patient begins with the history and physical examination and proceeds to the noninvasive laboratory. Ankle brachial indices are obtained first, with normal findings usually defined as >0.95. Unfortunately, the calcified arterial media in many diabetics lead to falsely elevated readings; therefore, we augment our investigation with pulse volume recordings and toe pressures when possible. Transcutaneous oximetry ($TcPO_2$) has been advocated by many practitioners as both a screening test for peripheral vascular disease as well as a marker for determining healing potential. It is important to note that oximetry measures oxygen partial pressure in the adjacent skin and not in the wound itself. Also, after revascularization the maximum measured increase in

$TcPO_2$ may be delayed by as much as 72 hours.

Limited joint mobility is a marker for diabetes and a risk factor for ulcer formation. Fissures and calluses may mask underlying wounds. All toenails should be inspected for both fungal infection and as a possible source of pressure ulceration. The performance of a 10 g Semmes-Weinstein monofilament test on three ipsilateral foot sites (heel, first and fifth metatarsal areas) by an experienced physician is a well-validated and sensitive test for peripheral neuropathy.

The location and characteristics of a wound ulcer must be carefully examined and recorded. Constant low pressure such as that caused by ill-fitting footwear usually leads to medial ulceration. Plantar ulcers suggest repetitive stress to abnormal pressure points such as the metatarsal heads or the midfoot in the case of Charcot deformity. Circumferential involvement of the distal toes is suggestive of ischemic gangrene rather than trophic ulceration. Wound depth and size should be vigilantly measured, the latter preferably using wound tracing or digital planimetric assessment since manual measurements are notoriously inconsistent. Signs of infection such as drainage and erythema should be sought. Osteomyelitis can be assumed if bone is contacted during exploration of the ulcer with a sterile probe. The use of a documented ulcer classification system has many benefits including standardized communication among involved physicians, monitoring of wound healing, and as a tool to validate investigational treatment methods. Though the most popular system is the Wagner Ulcer Classification System (Table 211.2), the author prefers the newly validated Society for Vascular Surgery Wound, Ischemia and Foot Infection (WIfI) system (Table 211.3). The WIfI score is also very useful for limb salvage prognosis.

TABLE 211.2 The Wagner Ulcer Classification System

Grade	Ulcer

Though a simple probe examination will uncover many cases of osteomyelitis, in nearly one third of patients it will be nondiagnostic. Therefore, if bone is not readily encountered during the sterile probe examination, the next step is to obtain plain x-ray imaging of the foot. Classic findings of osteomyelitis on plain film are demineralization, periosteal reaction, and bony destruction, whereas lesser signs include effacement of fat planes and soft tissue edema. It is important to note that these findings may be delayed or absent in early cases. In addition, osteomyelitis is rare without a point of entry; if bone degradation is present with intact skin, osteoarthropathy should be suspected. Clinically, osteoarthropathy occurs in a midfoot location and is polyarticular in nature, whereas osteomyelitis is found most frequently as a focal cortical lesion in the toes or metatarsal heads. If x-ray imaging is negative, MRI may be helpful and has high sensitivity and a high negative predictive value. However, the presence of neuroarthropathy or chronic bone changes due to trauma, surgery, or arthritis will adversely affect the sensitivity and specificity of MRI. Other diagnostic modalities include tagged white blood cell scanning and CT imaging, but the authors would recommend open or image-guided bone biopsy as the next diagnostic step if the presence of

osteomyelitis remains in doubt.

TREATMENT

The Team Approach

The core team consists of a vascular surgeon and a podiatrist trained in the management of complex foot wounds, although often general surgeons, plastic surgeons, and orthopedic surgeons contribute. Rehabilitation specialists and prosthetists are invaluable postoperatively. Screening and referral to a multispecialty foot care clinic has shown to be the most effective method for preventing amputation in high-risk individuals.

Avoiding Amputation

With a properly executed treatment plan, most noninfected, nonischemic wounds will heal without amputation. The first step is to perform a sharp debridement of the wound until all margins are healthy, bleeding tissue. After all nonviable tissue is removed, a culture can be taken from the deepest portion. The most common organisms cultured are Gram-positive cocci, but diabetic wounds are known to be polymicrobial with aerobes and anaerobes present. Antibiotics should be administered as appropriate. Failure to clear minor infections within a month or so should alert the physician to underlying osteomyelitis and/or vascular insufficiency. Prolonged IV antibiotics almost never lead to cure.

After debridement the wound should be offloaded with total contact casting or a nonremovable fiberglass cast. These have been demonstrated to be more effective than traditional dressing changes in decreasing infection and promoting ulcer healing. Good evidence is lacking for the use of felted foam or pressure-relief half-shoe.

There is a myriad of adjunctive wound healing techniques that have marginal evidence. Human skin equivalent stimulates tissue growth via cytokine stimulation and dermal matrix components. Its benefit in ulcer healing, limb salvage, and preventing osteomyelitis has been demonstrated over saline and gauze in high-quality randomized controlled trials. Cost and availability limit its use.

TABLE 211.4 Independent Predictors of Limb Loss as Determined by Logistic Regression Analysis

Risk Factor	Wald Test	OR	95% CI
ESRD	$P < 0.01$	1.72	1.12–2.83
TMA[a]	$P < 0.01$	1.62	1.15–1.93
Subsequent bypass[b]	$P < 0.005$	2.11	1.39–4.21

OR, odds ratio; CI, confidence interval; ESRD, end-stage renal disease; TMA, transmetatarsal amputation.
[a]A transmetatarsal as the initial amputation level.
[b]A revascularization performed after the minor amputation, ≤30 days.

Systemic hyperbaric oxygen increases oxygen partial pressure in tissues and is reimbursed by the Center for Medicare and Medicaid Services for a variety of conditions. Studies regarding its use for ulcer healing, however, have been poorly designed and there remains no high-quality evidence for its use in this condition. We currently advocate hyperbaric therapy only in the case of the severely infected diabetic ulcer, and even then only as an adjunct to proper surgical treatment.

Evidence is lacking regarding topical growth factors whether they are platelet-derived, protein-based, or epidermal. Similarly, the use of retinoids and human cultured dermis has not been adequately investigated. We currently encourage practitioners to avoid the use of any of these adjuvants except as part of a randomized, controlled trial.

Timing of Revascularization in Setting of Minor Amputation

The performance of a delayed bypass after amputation was found to independently predict limb loss (Table 211.4). In addition, the patients who converted to a major amputation within 30 days of the original minor amputation had a significantly reduced life expectancy (Fig. 211.1). Though survival and limb salvage are obviously complex outcomes with many confounding variables, these results do stress the importance of accurately predicting healing ability after minor amputation, as failure of minor amputation often leased to major amputation. Any deferment of a necessary bypass is predictive of treatment failure and limb loss. Our protocol for dealing with forefoot ischemia in patients with peripheral vascular disease is as follows:

1. Prompt and complete surgical drainage of any underlying infection. Debridement of uninfected necrotic tissue is not performed initially in ischemic wounds.
2. Institution of broad-spectrum antibiotics pending culture results.
3. If a clearly palpable dorsalis pedis or posterior tibial artery pulse is not

present, angiography is performed.

4. Intra-arterial digital subtraction angiography is then obtained with anterior–posterior and lateral views of the involved foot.
5. Revascularization is then performed either through endovascular means or a bypass to the most proximal vessel that will yield a palpable pulse in the foot.
6. Final debridement, amputation, and wound closure can then be accomplished under conditions of optimal perfusion. This is often done concurrently with the bypass.

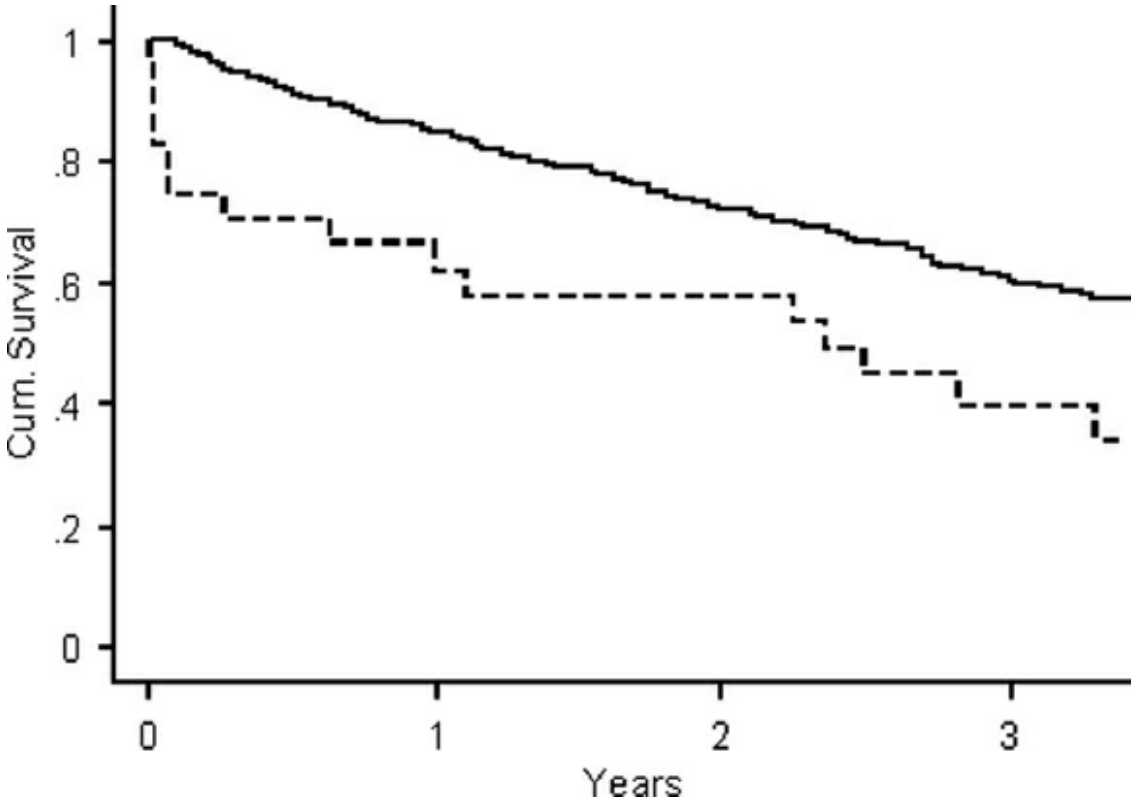

Figure 211.1. Kaplan–Meier analysis demonstrating survival for all individuals in the series. Patients have been divided into two groups representing those who required a major ipsilateral amputation ≤30 days of their initial minor amputation and those who did not. Standard error is <10% in the displayed series. *Solid line*, no early major amputation; *dashed line*, early major amputation ($P < 0.01$).

INDICATIONS

The goals of minor amputation surgery are to:

1. Remove anatomic pressure points and prevent recurrent ulceration.
2. Remove osteomyelitic bone and drain infection.

3. Preserve and restore the foot to optimum ambulatory function.
4. Control and relieve pain.

A simple toe amputation is indicated in the case of irreversible tissue loss or osteomyelitis of one toe distal to the proximal interphalangeal joint. The more extensive ray amputation is performed when gangrene or osteomyelitis extends to the web space, metatarsophalangeal joint, or metatarsal head. Other indications for ray amputation include the need to decompress one deep fascial compartment or extension of skin necrosis past margins acceptable for a simple amputation.

The basic indication for transmetatarsal foot amputation is irreversible tissue loss or infection extending beyond the boundaries of a single-ray amputation but still allowing for the creation of a viable plantar flap. Many patients undergoing TMA have had previous ipsilateral foot procedures such as ray amputation and incision and drainage. Common scenarios include failure of previous toe amputation, the need for multiple-ray amputations, forefoot infection involving multiple deep fascial compartments, forefoot deformity causing severe disability, and intractable pain. As a TMA spares the tibialis anterior, peroneus longus, and peroneus brevis tendon insertions, it is a much more functional amputation than the Lisfranc, Chopart, or Syme. These latter three, in the authors' opinion, provide little to no advantage over a below-knee amputation.

Relative contraindications to a minor forefoot amputation include extensive tissue loss especially on the plantar aspect of the foot, untreatable foot ischemia, knee contractures, and immobility without chance for rehabilitation. These conditions usually necessitate a major amputation. Patients with forefoot sepsis do not have the option to wait for revascularization. They should undergo debridement urgently, as this is a true surgical emergency. This presentation usually includes drainage, cellulitis, hyperglycemia, fever, and leukocytosis and occasionally organ failure. Findings of forefoot sepsis may be more subtle, particularly in the diabetic where we have found that the development of unilateral dorsal forefoot edema in the absence of trauma is pathognomonic for ascending infection and immediate debridement should be considered even in the absence of other objective findings. Stab incisions should be avoided. They do not allow for the proper wide debridement that is necessary in these potentially lethal infections. Delaying debridement can lead to a nonsalvageable foot.

SURGICAL TECHNIQUE

In general, most solitary minor foot amputations can be performed under local or regional block with monitored intravenous sedation. If infection or cellulitis is present, local anesthesia may be ineffective and a block should be performed above the level of infection. Many patients will already have a profound neuropathy. If a concomitant arterial bypass is planned, general anesthesia is preferred.

Transphalangeal Toe Amputation

The foot is prepped and draped to the knee using sterile technique. The incision is made at the level of the midproximal phalanx down to the level of the bone. The incision should be circumferential rather than fish-mouth when possible to avoid compromising blood supply to the flap. In case of the first toe, the approach may be altered to include a plantar flap if possible (Fig. 211.2). The periosteum is stripped with an elevator. The bone is then transected with an oscillating saw at the proximal phalangeal level, ~1 cm proximal to the level of the skin incision. In first toe amputations, the metatarsophalangeal joint should be spared as possible to improve gait stability. The tendons are pulled down, sharply divided, and allowed to retract. After hemostasis is obtained and the wound is irrigated, the skin is closed without tension in an anterior–posterior orientation. Interrupted monofilament sutures are preferred. Dry gauze dressing is applied and full weight bearing is avoided until wound healing has occurred.

Transmetatarsal (Ray) Toe Amputation

The foot and leg are prepped to the thigh and draped using a sterile technique. A racquet-type longitudinal incision is made on the dorsum of the foot parallel to the metatarsal bone extending on each side of the toe as a semielliptical incision converging on the plantar surface of the foot. This so-called racquet incision with wedge resection of the involved toe and metatarsal bone is demonstrated in Figure 211.3. A circular-type incision should be avoided if primary closure is to be attempted, as there will be less tension in the closure of an elliptical incision, and therefore greater chance of wound healing. A ratio of incision length to width of at least 3:1 will aid primary closure. If ulceration is present on the plantar surface at the level of the metatarsal head, this may be included in the excision as

well. Preoperative assurance of adequate circulation is critical to the healing of this amputation type, and is often the longest duration to heal.

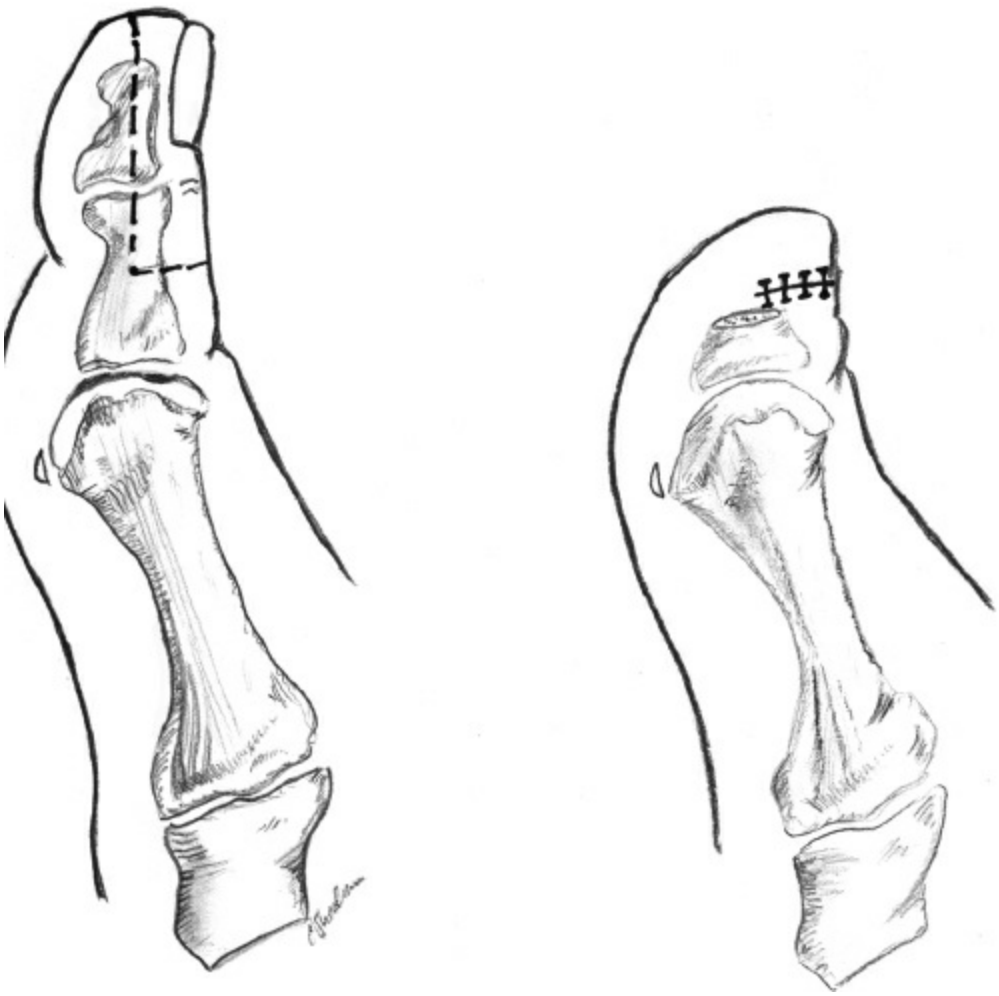

Figure 211.2. Digital amputation of the first toe demonstrating an alternative skin incision yielding a plantar flap.

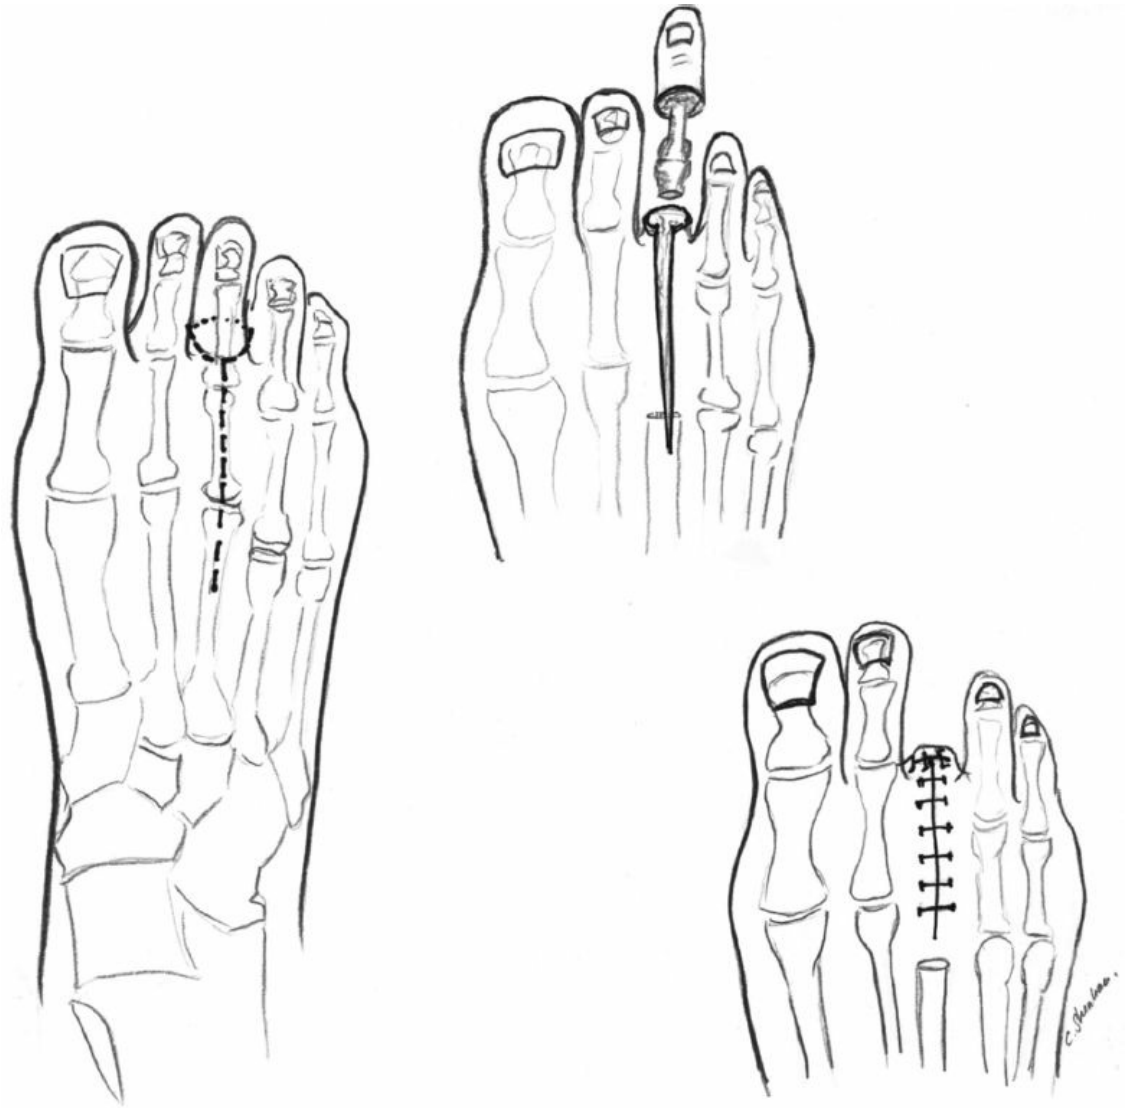

Figure 211.3. Ray amputation of the third toe with a “racquet” incision.

The initial incision is carried down to bone and the toe is disarticulated at the metatarsophalangeal joint. The periosteum is elevated circumferentially down the shaft of the metatarsal bone as far proximally as necessary. This is determined based on preoperative imaging of bony involvement of infection as well as intraoperative inspection of the quality of the viable tissue and extent of infection. It is only rarely necessary to extend this to the level of the metatarsal–cuneiform joint. In the case of the second, third, or fourth toe, removal of the entire metatarsal disrupts the Lisfranc joint, leading to foot instability. The bone is then transected at the proximal diaphysis or the diaphyseal–metatarsal junction. This is best accomplished using an oscillating saw rather than rongeur as splintering is sure to occur with the latter. The bone is passed off, and if wound healing

parameters are found to be adequate, primary closure may be performed after irrigation. Interrupted monofilament sutures are placed in the skin. There is no role subcuticular sutures in these wounds. Dry gauze dressing is applied taking care to avoid contact of tape with the skin. Full weight bearing should be avoided until wound healing has occurred, generally about a month.

If the amputation is being performed for control of forefoot sepsis, the wound is left open. Special considerations should be made in this setting when making the initial incision to protect the future plantar flap for TMA closure. If ischemic eschar is present that is not part of the immediate infectious process, it should not be debrided at the initial drainage procedure as this can ultimately hurt the chances of creating a functional foot. After removing the head of the metatarsal, the foot is then assessed for ascending infection. In compressing the foot if pus is noted along the extensor or flexor tendons, these compartments are opened for more aggressive drainage. After draining all purulence and debridement of all involved tissue, aggressive irrigation is undertaken. We use a power irrigation and suction system with 3 L of antibiotic mixture. The wound is then left open to either heal by secondary intention or delayed primary closure. Postoperative care of the open wound should include moist saline gauze dressings changed twice daily. Cultures are obtained during the debridement and appropriate antibiotics are administered until all objective parameters of infection have resolved. If osteomyelitis was present, intravenous antibiotics are continued for a total of 6 weeks after debridement.

In the case of a first-ray amputation, the incision is made as two curvilinear lines on both the dorsum and plantar surfaces of the foot, extending down to the level of the bone, exposing the metatarsal head. The flexor hallucis tendon will be visible and is usually sacrificed to prevent recurrence of infection. The sesamoids should now be apparent and are resected as well. When transecting the first metatarsal head, as much of the metatarsal should be left behind as possible to maintain function without leaving infected bone. The shaft is cut obliquely to prevent prominence of the bone afterward which could lead to pressure ulceration. The skin is closed with interrupted, nonabsorbable, monofilament sutures. Deep sutures are avoided due to the risk of retained infection. Often, first-ray amputations do not allow for primary closure given the extensive tissue loss. Again, these may be left to heal by secondary intention or delayed

primary closure with skin grafting in some cases.

For a fifth-ray amputation, an incision is made directly over the metatarsal shaft and extended down to encircle the fifth toe. Again, as in the first-ray amputation, the cut in the metatarsal shaft is made obliquely to avoid protrusion of bone.

Transmetatarsal Foot Amputation

The entire leg and foot are prepped and draped using sterile technique. If the blood supply to the foot is normal, exsanguination and a tourniquet may be desired. First, a transverse incision is made on the dorsum of the foot at the midmetatarsal level. A right-angle turn is performed at the medial aspect and the incision is extended around the foot to the plantar surface at the level of the metatarsophalangeal joints (Fig. 211.4). The incision is sharply carried through the tendons and neurovascular structures to the bone. Large vessels, such as the dorsalis pedis artery, should be ligated. The extensor tendons are pulled out, sharply divided, and allowed to retract. Examine the tendon sheaths for pockets of infection. The plantar fascia and fat pad are included in the flap. As Dr. Sanders demonstrated in 1997, the plantar incision line can be modified to include excision of an ulcer (Fig. 211.5). The periosteum of the metatarsal shafts is elevated circumferentially to the level of the intended transection. Retract the skin flaps carefully and transect the bones with an oscillating or Gigli saw at the midmetatarsal level, ~2 cm proximal to the skin incision, thereby preserving the insertions of the peroneus longus, peroneus brevis, and tibialis anterior tendons. Manual bone cutters are to be avoided as they cause bone splintering and may also lead to unwanted bone regrowth which can precipitate late ulceration. The first and fifth metatarsal bones are transected in an oblique fashion to avoid bone protrusion, the first in a medial and plantar direction, the fifth laterally and plantar. Any sesamoids should be resected. The second through fourth metatarsals should be divided in a parabolic manner with a longer cut on the dorsal aspect, beveling in the plantar direction. Care must be taken to divide all of the metatarsals at the same length. The divided bones are reflected upward proximally to distally and the amputation is completed at the level of the plantar flap. All neurovascular structures are ligated. Carefully remove all nonviable tissue. Resect the flexor tendons in a similar manner to the extensors, again inspecting the sheaths for residual infection. The key to success in this procedure is a thick, well-vascularized plantar flap that can

be closed without tension. Release the tourniquet if one was placed. Irrigate copiously with normal saline solution. Allow at least 2 to 3 minutes after tourniquet release to assure hemostasis. A drain can be placed if prolonged bleeding is encountered, but this is not our usual practice. The skin is closed with interrupted vertical mattress monofilament sutures. Just enough tension is applied to barely approximate the skin edges as postoperative edema will occur. Skin is at a premium here and great care should be used in its handling. Potentially ischemic wounds are closed once infection is controlled as the limited circulation will not lend itself to effective granulation of the wound. The foot is dressed with a soft, circumferential dressing from the stump to the midshin. If the incision was not left open, we splint the foot in neutral position to prevent equinus contracture.

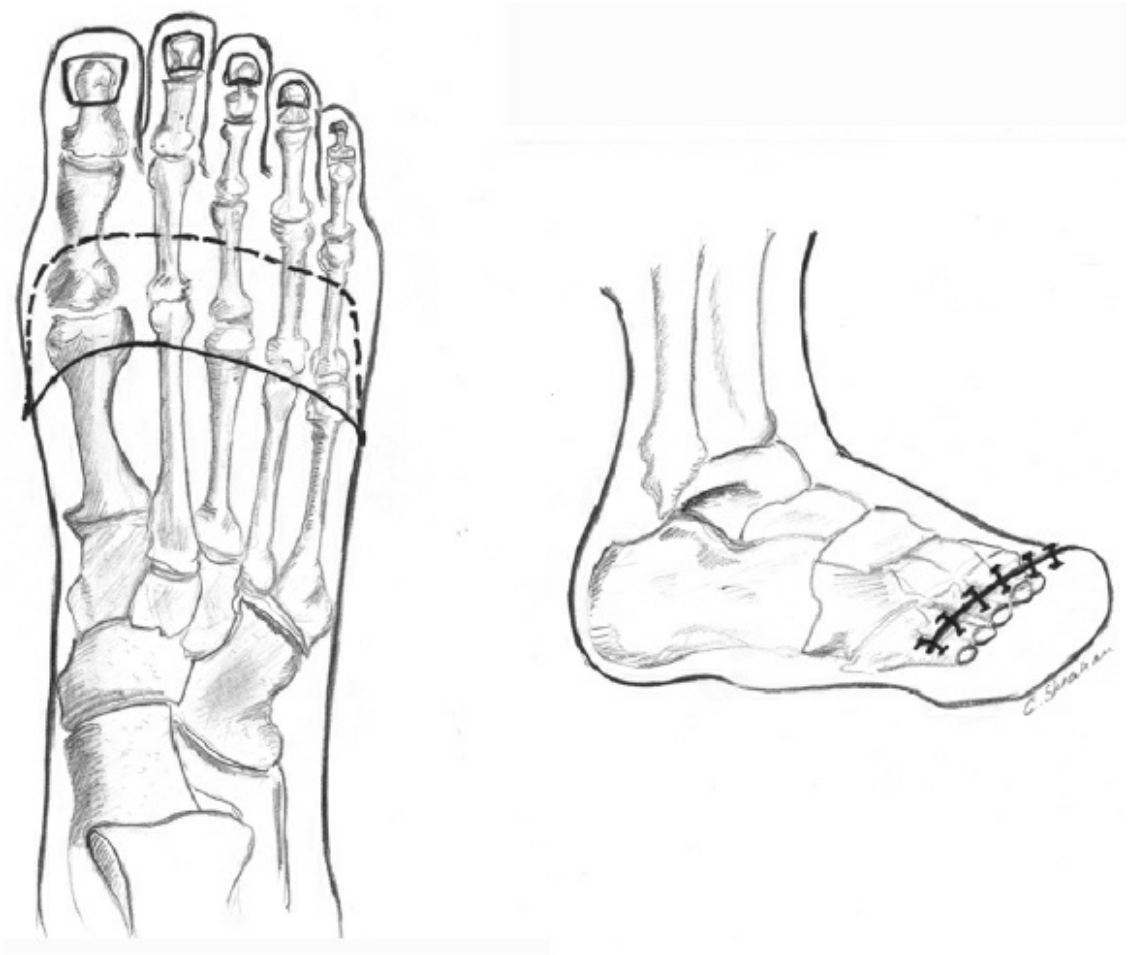

Figure 211.4. TMA with long plantar flap.

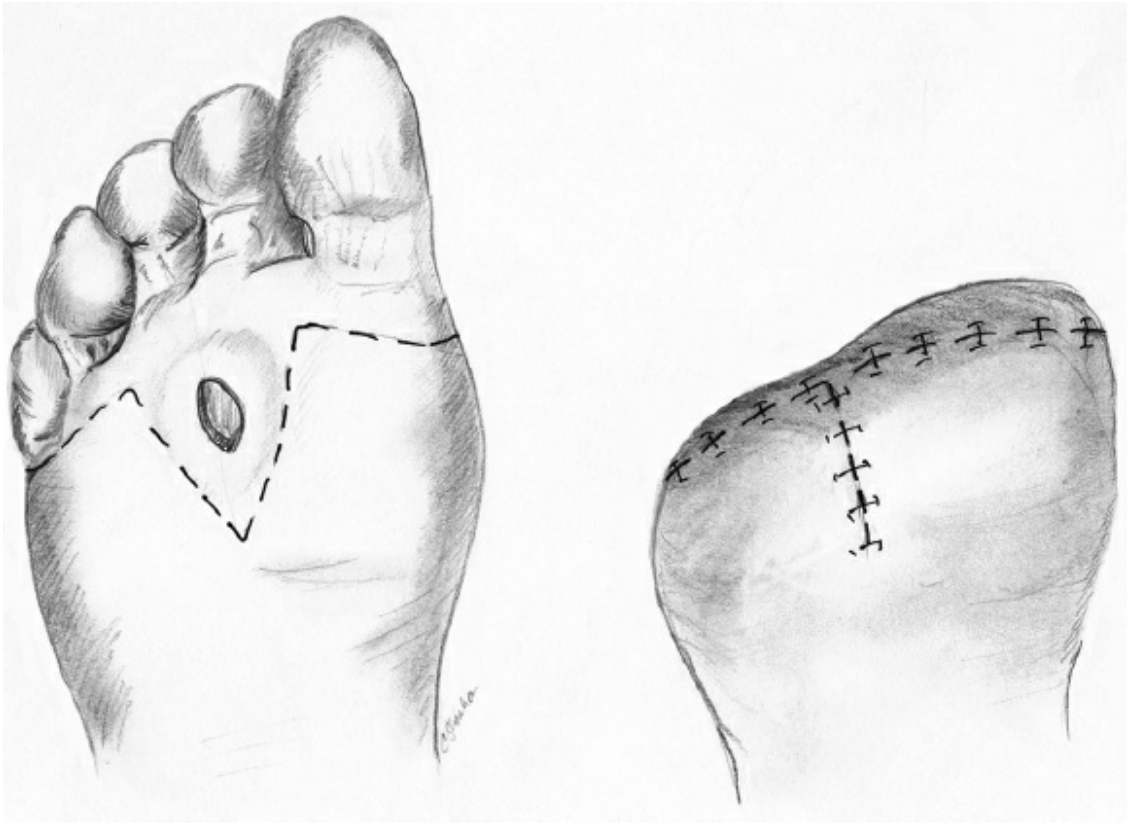

Figure 211.5. An alternative incision for TMA allowing for the excision of a plantar ulcer.

Postoperative Management

In the case of a simple toe or ray amputation, an early evaluation by a prosthetist for shoe fitting is vital. Cane-assisted ambulation can begin early, usually within 24 hours. If the wound was left open, dressing changes should be provided twice a day with normal saline and sterile gauze. If packing was required, this should be reduced on a daily basis to allow for wound contraction. Full weight bearing should be delayed until complete wound healing. Culture-directed antibiotics are administered as indicated and the sutures are left for at least 14 days, but there is no evidence for duration of antibiotics once the osteomyelitic bone is removed.

After a transmetatarsal foot amputation, the patient remains strictly non–weight bearing until the incision is completely healed. If a drain was placed, it should be removed within 24 to 48 hours. The foot and ankle are elevated as often as possible, especially in the early postoperative period. Sutures are left in place for 2 to 4 weeks. If the incision was not left open, we prefer to splint the foot in neutral position until ambulation. In preparation for ambulation, a prosthetist should evaluate for appropriate

footwear. Some patients will require a functional brace or molded footwear, but most will need only a shoe with insert. After ambulation, the patient should be monitored for transfer ulcers.

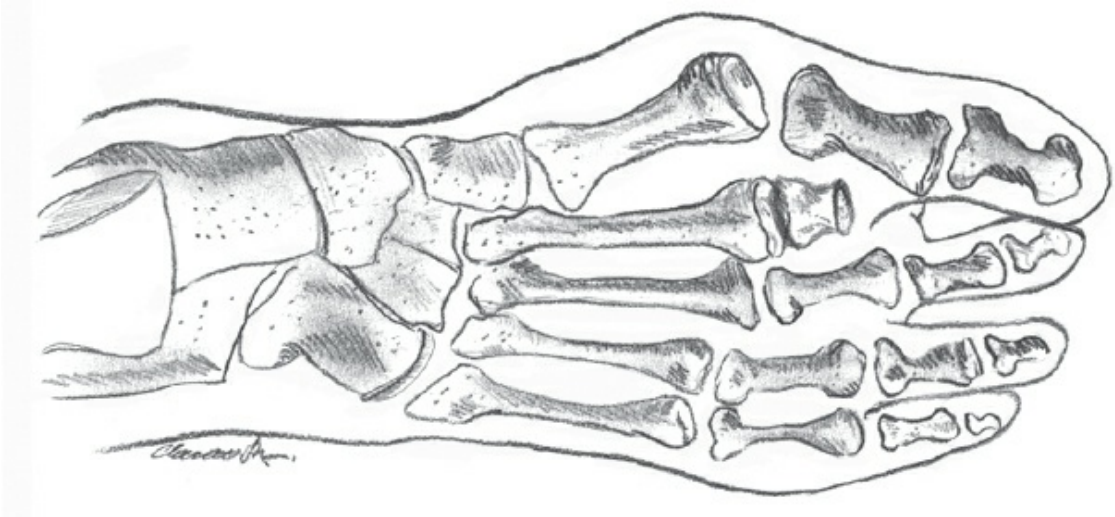

Figure 211.6. Hallux valgus deformity of the first toe after second toe amputation.

COMPLICATIONS

Failure to heal suggests vascular insufficiency, persistent infection, or malnutrition. Premature weight bearing is another culprit. Most simple toe amputations are tolerated well with few gait disturbances. Resection of a lesser toe rarely results in long-term disability with the exception of the second toe which may precipitate a hallux valgus deformity (Fig. 211.6). A spacer can prevent this medial deviation of the first toe.

The first toe is important for propulsion and even a simple amputation can cause problems in this regard. In addition, abnormal pressure may be placed on the plantar aspect of the second or even first metatarsal head after first toe amputation. These issues can be prevented or corrected with orthotics. A ray amputation of the first toe is even more likely to cause a transfer lesion to the second metatarsal head or occasionally the tip of the second toe. This can be severe enough to require conversion to TMA. Other mechanical complications of first-ray amputation include increased pronation during ambulation and midtarsal Charcot deformity.

Ray amputations of the other toes are usually well tolerated. The fewest complications occur when the third metatarsal is amputated. Again, occult sources of deep space infection should always be suspected when poor wound healing is displayed.

Soft tissue contracture after transmetatarsal foot amputation often leads to an abnormal plantar flexion or equinus deformity. Achilles tendon lengthening procedures are a reasonable option to correct this condition. Improper bone resection can cause pressure points in the stump leading to skin breakdown and ulceration. Treatment is usually reoperation with resection of the involved metatarsal. Intractable pain will require conversion to a major amputation. Because of the prolonged non–weight-bearing status after a TMA, these patients are at increased risk for deep venous thrombosis and pulmonary embolus.

Outcomes

There are surprisingly few studies in the literature addressing long-term outcomes after lower-extremity minor amputation. In our mainly diabetic series of 670 patients, limb salvage was 89.8% at 1 year and 82.3% at 5 years. Limb loss was associated with ESRD and the need for an initial amputation at the transmetatarsal level. As mentioned earlier, the need to perform a bypass subsequent to the amputation was an independent predictor of limb loss. Overall patient survival was 83.9% at 1 year and 43.5% at 5 years. Renal insufficiency and conversion to major amputation (Fig. 211.1) were associated with adverse long-term survival.

ACKNOWLEDGMENT

We acknowledge Drs. Malichai and Claudie Sheahan for all their work on the 6th Edition Chapter.

EDITOR'S COMMENT

In this chapter by Dr. Henke entitled "minor amputations," I have to beg the question, is any amputation really minor? Both the physical and mental ramifications of even a minor amputation are often real, impacting ambulation and overall body image. The idea of better foot care following an amputation speaks to the question: What is the likelihood that a patient who necessitated an amputation to begin with can now control their blood glucose, stop smoking, and get some better foot care?

There is little doubt that multidisciplinary care is critical in providing, especially diabetics, better care. In a recent review, Salvo and coauthors state that "it makes inherent sense that a multidisciplinary team approach to these patients is necessary." (Salvo NL, Walsh MD, Brewster LP. Promoting limb salvage through multi-disciplinary care of the diabetic patient. *Curr Treat Options Cardiovasc Med* 2017;19(7):55). In this review, they suggest that the fields of podiatric surgery/medicine, vascular and plastic surgery, all be used in combination to introduce a multidisciplinary limb salvage center that can result in saving lives and limbs of patients, especially those with diabetes.

In an interesting article published by the Vascular-Independent Research and Education-European Organization 9, the authors clearly state that our renewed goal should be to eliminate amputations (Kolossváry E, Farkas K, Colgan MP, et al. "No more amputations": a complex scientific problem and a challenge for effective preventive strategy implementation on vascular field. *Int Angiol* 2017;36(2):107–15). This means shifting the focus from the performance of

minor amputations to a more intense program of diabetes and risk factor modification. They state that “as a consequence of critical limb ischemia, often associated with diabetes, it is highly critical to health care service aiming at prevention of limb loss. Understanding of the nature and complexity of amputation scenarios is paramount for the effective preventive strategy planning and implementation. Lower limb vascular amputations represent a lifetime risk; therefore, not only the effective revascularization is to be achieved, but the importance of the early recognition of peripheral arterial disease, no delay in referral to special vascular care, effective vascular risk prevention, and collaboration in multidisciplinary teams should be also emphasized.” I think this statement very eloquently suggests that we should manage these patients’ risk factors better.

The question is always what patient starts with a minor amputation and then progress to a major amputation. In an article from the Orthopedic Surgery literature, the authors examined risk factors for major lower extremity amputation (LEA) after minor foot amputation in diabetic patients. A total of 163 diabetic patients had undergone an initial minor foot amputation and then had undergone at least one subsequent major or minor LEA. Among the many risk factors examined, there were no statistical differences found between the two groups in terms of hemoglobin A1c, smoking status, chronic kidney disease, end-stage renal disease requiring dialysis, kidney or kidney–pancreas transplantation, or vascular intervention (peripheral arterial bypass). Interestingly, there was a significant difference in the minor group (22.2%) versus the major group (71.2%) in terms of severe peripheral arterial disease (PAD, $p < 0.001$). The take-home message demonstrates the importance of assessing peripheral vascular disease in all diabetic patients with minor LEA. The authors conclude by suggesting that “early referral to a vascular surgeon might delay (or prevent) major LEA.” (Nerone VS, Springer KD, Woodruff DM, et al. Reamputation after minor foot amputation in diabetic patients: risk factors leading to limb loss. *J Foot Ankle Surg* 2013;52(2):184–7.)

Finally, based on the above and a lifetime of practicing vascular surgery, I just have to make a plea for vascular surgeons to continue to stay at the forefront of vascular care in patients with diabetes and peripheral arterial disease. Especially following endovascular therapy, there are a myriad of patients who get an intervention from a nonvascular surgeon and then sent to a vascular surgeon for a minor amputation. Really, no other specialties other than vascular surgeons have the full tool kit to manage these complex patients from risk factor modification to amputation (Robinson WP, Loretz L, Hanesian C, et al. Society for Vascular Surgery Wound, Ischemia, foot Infection (WIfI) score correlates with the intensity of multimodal limb treatment and patient-centered outcomes in patients with threatened limbs managed in a limb preservation center. *J Vasc Surg* 2017; pii: S0741–5214(17)30375–0 [Epub ahead of print]).

Please stay involved and lead the way in preventing amputations, even “minor amputations.”

212 Major Lower Extremity Amputation

Mark R. Nehler

INTRODUCTION

The exponential increase in various endovascular techniques for limb salvage in critical limb ischemia (CLI) has changed the patient population undergoing amputation. Historically, many patients needing amputation had undergone multiple failed open procedures with substantial morbidity. Prior incisions made subsequent amputation more difficult and retarded primary flap healing. However, despite these advances in revascularization, large registries including the Department of Veterans Affairs National Surgical Quality Improvement Program (NSQIP) and the National Hospital Discharge Survey (NHDS) show minimal reduction in major lower extremity amputations in the United States. The aging of the US population, uneven access to care, continued increase in patients with end-stage renal disease, and the relatively short patency of many endovascular interventions are major reasons for this. Therefore, major lower extremity amputation will continue to be a common operative procedure for the general and vascular surgeon.

INDICATIONS

The three most common indications for major lower extremity amputation are chronic CLI, major infection due to diabetic malperforans ulcers with normal arterial circulation, and acute limb ischemia. The first two have significant clinical overlap, with many diabetic patients having poor or marginal circulation suffering neuropathy and malperforans ulcers as an initiating event leading to eventual limb loss. Failure to recognize the arterial ischemia leads to a significant amount of unnecessary limb loss due to delay in referral for potential revascularization often following failed forefoot directed amputations. This ultimately leads to limbs not considered salvageable due to extensive pedal necrosis or who fail to salvage despite successful revascularization due to the same. Recent trends

in a primary endovascular approach to revascularization have helped this issue twofold: (1) Patients with comorbidities who would not be considered for bypass are undergoing endovascular revascularization, and (2) there is a larger group of clinicians from different specialties with endovascular skills who are providing care for the population.

Acute Limb Ischemia

Most occlusions in acute limb ischemia involve the popliteal or more proximal arteries, and therefore significant muscle beds are usually threatened. The majority of acutely threatened limbs have some attempt at salvage, so the majority of amputations in acute limb ischemia occur in patients suffering from the morbidity of a revascularization procedure and often significant reperfusion injury with rhabdomyolysis and renal damage. Because of the proximal nature of the ischemia, most major amputations are at the knee level or above. Currently in the United States, many patients with acute limb ischemia also undergo primary endovascular therapy; however, prior incisions can complicate amputation flaps. Acute limb ischemia patients are often receiving anticoagulants for therapy of the underlying thrombotic or embolic event, further increasing the risk of hematoma and wound complications. Finally, increasing numbers of acute limb ischemia involve iatrogenic vascular injury or delay in diagnosis/referral, increasing the psychological complexity of the care and having medical legal implications. The need to perform a major amputation in that setting is especially problematic.

Chronic Critical Limb Ischemia

The majority of major lower extremity amputations are due CLI. Accurate guidelines on potential salvage of limbs based on revascularization potential and extent of necrosis are lacking in CLI, contrary to the care of aneurysm and carotid disease where practice patterns have been established with level 1 evidence. This leads to significant differences in limb salvage based on geography, access to revascularization and vascular imaging, and clinician experience in the use of open or endovascular techniques. There is a more granular scoring system for CLI—the Wound Ischemia foot Infection (WIfI) system proposed by the Society of Vascular Surgery that may help to stratify patients more accurately in the future. Unlike cardiac disease, there is no established route of access for suspected CLI to revascularization in modern health care systems, leading to

potential delays in referral and diagnosis, wide differences in practice patterns, and ultimately greater costs. Therefore, eventual amputees with CLI fall into two categories: (1) patients who are not offered revascularization either due to the extent of pedal necrosis on vascular presentation, failure to recognize CLI and futile forefoot amputations, and/or comorbidities (medical and/or functional) that would preclude same, or very rarely, anatomy not amenable to revascularization; and (2) patients who fail revascularization (either ongoing occlusion or ongoing pedal necrosis despite improved circulation). Most centers with aggressive limb salvage practice perform far fewer primary amputations than revascularizations, so that many patients with CLI who require amputation have had prior endo- or open revascularizations that have failed. Although several studies have demonstrated no effect of a failed infrainguinal revascularization on amputation level, below-knee amputations (BKA) after failed infrainguinal bypasses have greater wound complications and prolonged healing times. With the increase in endovascular techniques for CLI, these wound issues from prior bypass have been reduced.

Malperforans Ulcer/Normal Circulation

Patients with diabetes with normal circulation who develop overwhelming foot infections are another major amputee group. Typical patterns include first or fifth metatarsal osteomyelitis from a chronic malperforans ulcer in that location. Patients with Charcot foot can have chronic ulceration at the midplantar area due to chronic midfoot fracture, leading to osteophytes and pressure points. Many of these diabetic amputees have had prior digit or ray amputations that may have healed, only to have another malperforans ulcer occur in the adjacent digit as the initial amputation destabilizes the distribution of pressure on the remaining metatarsal heads. The cause of eventual limb loss in these patients is multifactorial. Poor compliance (often demonstrated in significantly elevated glycosylated hemoglobin values), obesity (increasing the pressure on the neuropathic foot when ambulatory), and inadequate footwear are major contributors. A less recognized but equally important cause is patient education. Many poorly educated diabetic patients assume that seeking health care for foot lesions will lead to a major amputation, and therefore delay care until a major amputation is inevitable, which continues to perpetuate this widespread fear. Another issue is access to care as many of these patients are in lower socioeconomic settings.

PREOPERATIVE PLANNING

General

Fewer vascular surgery procedures have the psychological and functional impact of a major lower extremity amputation. Amputation-free survival is considered the primary end point for any clinical trial for patients with CLI. However, in clinical practice, a number of variables can markedly change this end point that has no relationship to efficacy of therapy. Understandably, patients often adamantly refuse amputation. CLI (the most common indication for amputation worldwide) rarely results in overwhelming infection and imminent patient death if left untreated. Therefore, patient pain tolerance is often the deciding variable. Many patients turn to unproven therapies in desperation. The widespread use/advertising of wound centers gives patients hope that all wounds can ultimately be healed, but the reality is some wounds need to be removed. All of these issues increase amputation-free survival. Therefore, for many patients, the first step in preoperative preparation is the acceptance of the procedure—which frequently takes days to weeks and sometimes multiple visits to answer questions and work through the various stages of grief and loss—for the patient and family members. Often consultation with rehabilitation medicine, physical therapy, prosthetics, and even other amputees is very helpful in preparing the patient and family for the realities of life as an amputee.

Standard evaluation with a thorough history and physical examination should be performed in all patients. Active congestive heart failure, unstable angina, or concurrent myocardial infarction must be addressed. In the absence of active cardiac symptoms, evidence of congestive heart failure on history or physical examination, or acute changes on electrocardiogram, thorough cardiac evaluation is not routinely performed. It is important to recognize that most patients presenting for amputation have had limited activity and may not manifest covert cardiac disease due to the lack of physiologic stress, so even minor symptoms should be very concerning.

Beta-blockade prior to vascular surgery has become very controversial. Although a reduction in nonfatal myocardial infarction has been shown, increased risk of mortality and stroke is also felt to be a consequence. Therefore, the use of beta-blockade prior to amputation is not advocated. Management of associated hypertension, diabetes, and renal failure should be optimized. An aggressive approach to normalize glucose levels is

essential to ensure proper wound healing. The timing of hemodialysis in relation to operation is important in managing fluids and electrolytes in the perioperative period. Perioperative nutrition is critical, as many patients are depressed, manifested by severe emaciation. Depressed patients who are not eating or participating in their postoperative rehabilitation programs are at risk for a host of complications, including further nutritional depletion, incisional wound complications, decubitus ulcers, contractures, and deep venous thrombosis (DVT).

Finally, because of relative inactivity and frequent hypercoagulable states in the amputation population, venous thromboembolism is a major source of postoperative morbidity/mortality. Recent data would indicate the incidence is 15%. In addition to the risk of fatal pulmonary embolism, postoperative DVT may cause severe stump swelling and impaired primary healing of the amputation. Routine DVT prophylaxis and/or careful perioperative screening for DVT with duplex scanning in amputation patients appears prudent.

Determination of Amputation Level

The goals of major lower extremity amputation are several: to eliminate the nonviable tissue, to provide a stump that has the best chance to heal, and to provide a stump with the best chance of long-term function—ambulation with a prosthesis. However, which of these factors is the priority often depends on the age, baseline function, and comorbidities of the patient. On balance, it is important to avoid additional operative procedures in this compromised group of patients. In all reported series, healing of an above-knee amputation (AKA) is more rapid and involves less incisional complications than healing a BKA. However, any chance at rehabilitation and prosthetic use in older vascular patients requires the knee joint. Importantly, physicians and patients wish to preserve as much limb length as possible. More recently, the through-knee amputation has been advocated. With the use of a computerized C-leg prosthesis, patients have a much better return to ambulation than with an above knee ambulation due to the longer lever arm for mechanical advantage and balance. In addition, a through knee amputation has minimal muscle transaction and is considered to be faster and with less blood loss.

Worldwide, the ratio of AKAs to BKAs performed is 1. Many AKAs are performed in patients with limited rehabilitation potential and significant comorbidities, as the primary healing is better and there is a

risk of knee contracture in BKAs done in patients who are unable to participate in postoperative physical therapy. Despite this, most patients are considered for BKA due to a variety of reasons, and the surgeon needs to determine if a BKA will heal primarily. The arteriographic status of the ipsilateral profunda femoris artery has been a key component for success. A number of studies in the literature describe various circulatory measures to determine amputation level healing. As a general point, many of these techniques are not practical in clinical practice. A palpable pulse at a level immediately proximal to a proposed amputation has been associated with a 100% rate of healing. Most surgeons agree that a BKA without a femoral pulse is unlikely to do well. However, a palpable femoral pulse does not guarantee success. The clinical judgment of the operating surgeon (skin temperature, hair growth, tissue bleeding, viable muscle, and wounds without tension) has been demonstrated to be reasonably accurate (75% to 85%) in several large clinical series (combined, around 1,000 patients). Finally, despite the plethora of research regarding the technical aspects of salvaging the knee joint, the sobering fact is that many vascular patients will take minimal advantage of this in rehabilitation.

Thermography, skin perfusion via radioisotope injection, and segmental pulse volume recordings (PVRs)/limb pressures have been used to try to improve on the success of clinical judgment in predicting BKA healing. Each has limitations ranging from clinically impractical (thermography and skin perfusion) to not accurate due to calcified vessels (PVRs and pressures) in many amputees. Arguably the most reproducible noninvasive test used to determine BKA healing is transcutaneous measurement of the partial pressure of oxygen ($TcPO_2$). Measurements are obtained in the supine position by placing an oximetry probe on the skin in question and heating the area to 44°C. The generation of heat results in local skin hyperemia, a decrease in flow resistance, and subsequent arterialization of capillary blood. The probe then records skin oxygen tension reflecting the true arterial oxygen pressure in the area in millimeters of mercury. Absolute measurements, measurements compared to a control location such as the chest, and measurements compared to transcutaneous carbon dioxide values have been reported. Various studies have shown that $TcPO_2$ measurements of ≥30 mm Hg have an accuracy of 87% to 100% in predicting BKA healing. In addition, this technique can be used in patients with arterial calcification. However, supplemental oxygen can falsely elevate $TcPO_2$, and edema can falsely reduce $TcPO_2$.

SURGICAL TECHNIQUE

Basic Principles

The authors follow several general principles in amputation surgery. When at all possible, Esmarche bandages and tourniquets are used to minimize blood loss despite liberal use of the knife for dissection—supported by a single small comparative trial in the United Kingdom. The exceptions are diabetic patients with significant calcification where all is accomplished in reducing venous outflow and actually increasing venous bleeding. All major vessels are suture ligated. We do not use bone wax for control of any bone marrow bleeding, for concern of leaving a foreign body and potential infection. We transect both the tibia and the fibula with a saw, to avoid any spiral fracture of the fibula. Major nerves are transected short under tension, with minimal use of chromic ligatures to avoid excessive neuroma formation later and accepting some bleeding as a consequence. Care is taken to débride as much soleus from the BKA muscle flap to avoid a bulbous stump, as this is a difficult prosthetic fit. Some have recommended myodesis, with muscle flaps sutured to the bone, but currently that has not been our practice. Skin is closed with nylon suture in a vertical mattress with long ends, as we often leave the sutures in for several weeks (due to edema and concern for wound separation in patients who are often malnourished) and it helps with later removal in the clinic. We plan plaster casting of BKAs, usually within a few days. We have not done this with AKAs. We have also used subcutaneous and sub-fascial fenestrated catheters to deliver local analgesia via a computerized pump for 48 hours postoperatively with success.

Guillotine Amputation

If there is any question regarding uncontrolled pedal sepsis, a two-staged amputation should be considered. We have found that many diabetic patients in our practice present acutely with unsalvageable pedal sepsis and the majority of our BKAs end up being done in a two-stage manner. These are compromised patients with significant perioperative morbidity/mortality—much of which can be septic. Guillotine amputations offer the ability to remove the septic focus relatively quickly and also provide direct examination of the calf muscle compartments for septic extension. If discovered, a longitudinal incision either medially or laterally in the leg (similar to a fasciotomy) drains the affected compartment and

allows for debridement of nonviable muscle. The patient can be returned to the operating room for the BKA once the edema, fever, and leukocytosis have resolved (usually 3 to 5 days).

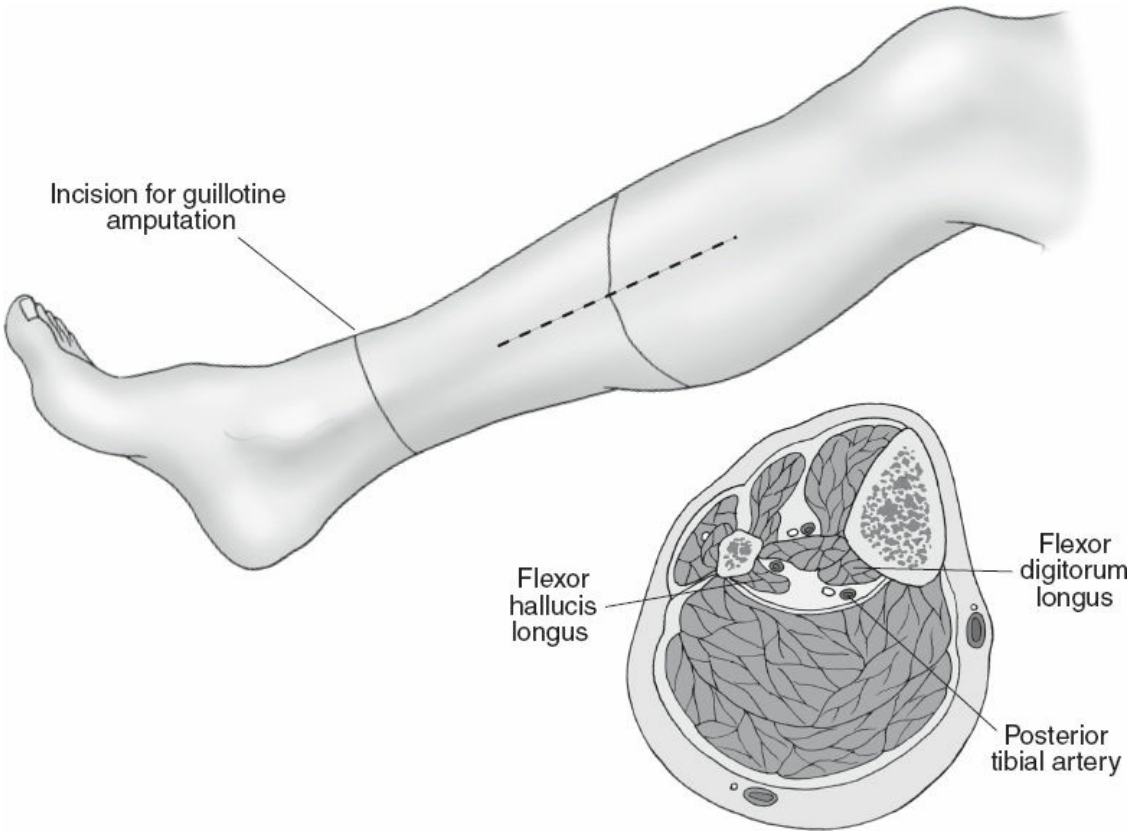

Figure 212.1. Skin incision for guillotine amputation.

The guillotine amputation is relatively straightforward. The limb is prepped to the knee level in case an incision in the calf is needed to drain purulence/necrosis proximally (most commonly the anterior compartment). The authors do not find tourniquets for guillotine necessary, as the assistant can provide some level of arterial control with a firm grip at the distal calf. In addition, Esmarch exsanguination in a septic foot would be contraindicated. The knife is used to make a circular incision just above the malleolus down to the tibia and fibula (Fig. 212.1). Electrocautery is often not useful due to significant edema. Either a power saw or a Gigli saw is used to transect the distal tibia and fibula. The three major vascular bundles are oversewn with silk (Fig. 212.2). Of the three, the peroneal artery is the most difficult to control as it is between the fibula and tibia, making exposure a problem. All of the arteries retract after transection adding to exposure issues. The calf is compressed to check for purulence in the compartments. Finally, the authors place a large piece of

thrombin-soaked Gelfoam over the stump to assist in hemostasis postoperatively. A bulky dressing is applied over this and then an ace wrap over this. It is our practice to not examine the stump for a day or two if there was no sign of proximal infection, as the patient's clinical course is often adequate to gauge therapy, and early dressing changes in a patient with relatively normal circulation at the ankle (as is often the case) risk hemorrhage.

Below-Knee Amputation

Long Posterior Myocutaneous Flap (Burgess)

The Burgess technique is the most frequently used technique in BKA. It takes advantage of the well-vascularized myocutaneous flap consisting of the gastrocnemius muscle, partial soleus muscle, and posterior skin. The disadvantage is that the tibia is directly over the incisional closure, and any trauma to that area can cause dehiscence and exposure of bone. In addition, it requires reasonable distal skin posteriorly, which can be an issue if the patient has chronic venous skin changes.

The patient is positioned supine with some padding at the level of the thigh to assist in elevation of the extremity. The leg is prepped to the groin level. We often use a tourniquet with Esmarch exsanguination of the leg (see comments above). The anterior skin incision should be located 12 cm (roughly one handbreadth) below the tibial tuberosity. The skin incision should then be continued transversely for a distance approximately one third of the calf circumference to minimize the formation of redundant tissue at the stump edges ("dog ears"), which make prosthetic fit more difficult. The incision is then extended along the vertical axis of the extremity for a length ~1.5 times of the length of the transverse incision. The posterior flap is then completed with a transverse incision at this level (Fig. 212.3). The skin incision is then extended sharply through the fascia throughout, with division of the greater saphenous vein.

Initial attention is to the anterior compartment. The anterior compartment muscles (tibialis anterior, extensor hallucis longus, extensor digitorum longus, and fibularis longus) are divided at the same level as the anterior incision. Central in the anterior compartment is the anterior tibial artery and vein and the deep peroneal nerve. The vessels are suture ligated, and the nerve is transected under tension, as outlined above (Fig. 212.4). The tibia is then cleared of lateral and posterior attachments with the periosteal elevator and the interosseous membrane is incised sharply. The

tibia is divided at or just proximal to the skin incision with an anterior bevel. The lateral compartment muscles (fibularis longus and brevis) are divided to expose the fibula. A periosteal elevator is then used to carefully clear the fibula 1 to 2 cm proximal to the level of the tibial transection where it is transected (Fig. 212.5).

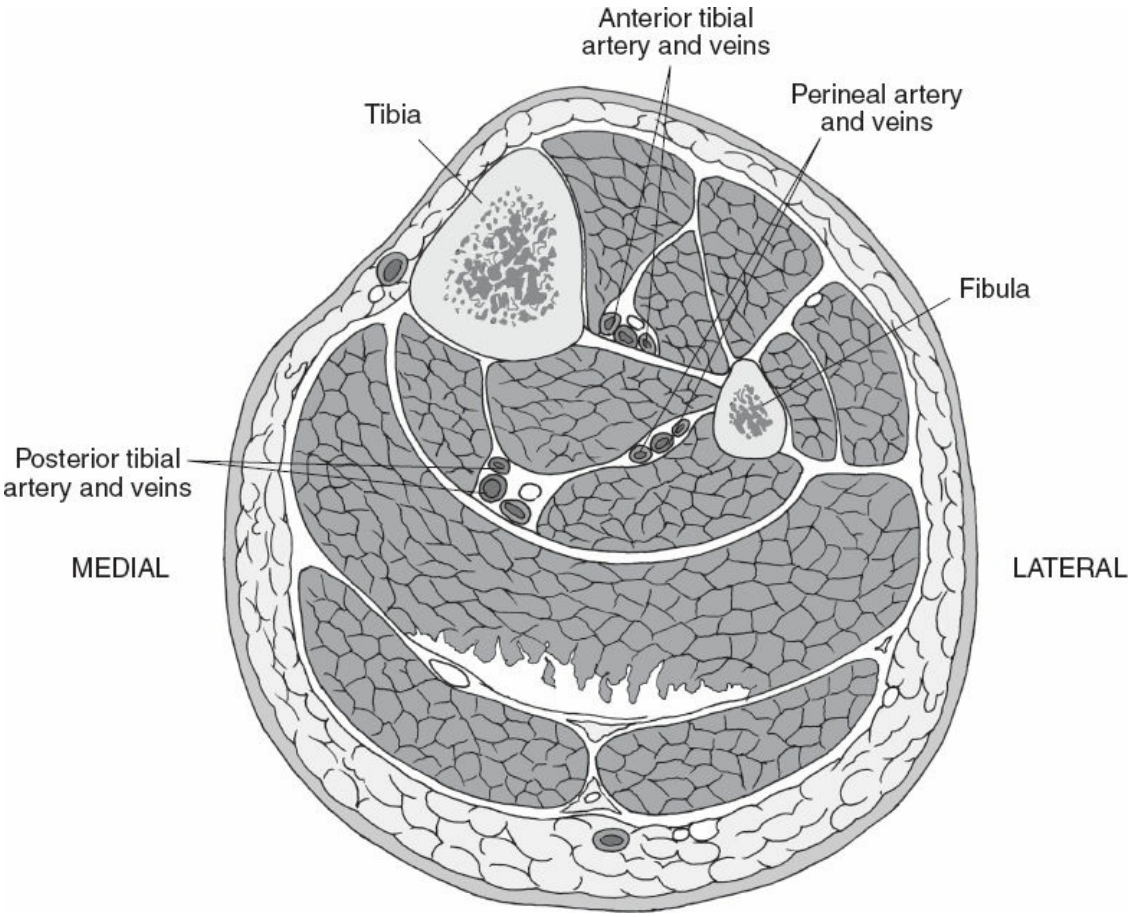

Figure 212.2. Locations of the anterior tibial, posterior tibial, and peroneal vasculature.

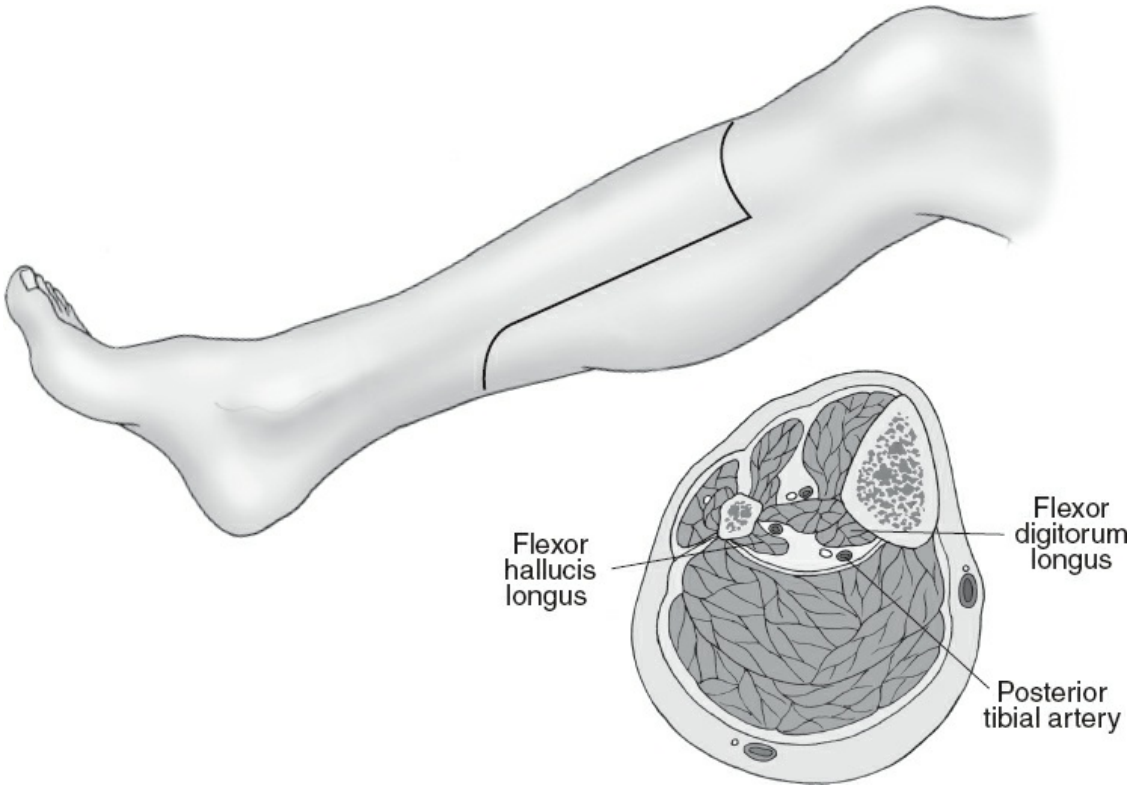

Figure 212.3. Skin incision for Burgess below-knee amputation.

The posterior compartment muscles (soleus and gastrocnemius) are then divided obliquely to create a posterior muscle flap. In general, enough soleus needs to be removed to allow for flap closure without excessive bulk and tension (Fig. 212.6A) but not so much that the end of the soft tissue is not flush with the transected tibia when closed. The posterior tibial and peroneal vessels are suture ligated, as are the extensive venous plexus in the remaining soleus. Prior to the closure of the flaps, bone edges are contoured smoothly. The fascial edges are closed with interrupted absorbable sutures, followed by interrupted vertical mattress nylons for skin closure (Fig. 212.6B).

Skew Flap Transtibial Amputation

A modification of the long posterior myocutaneous flap technique is the skew flap technique. The advantage of this technique is placement of the skin incision lateral to the tibial stump to avoid wound complications caused by tension and to facilitate closure of the incision without redundant tissue or a dog-ear deformity (and therefore improved prosthetic fit). Creation of the skin flaps again involves marking the anterior incision one handbreadth below the tibia. A point in this incision 2 cm lateral to midline over the anterior muscle compartment is then identified as the

anterior junction of the proposed flaps. A string or tape is used to measure the calf circumference at this level. Half of this tape length can then be used to determine the length of the base of the flaps and also to determine the posterior junction of the flaps. Once this is completed, one fourth of the tape length or string should be used to mark the midpoint of each flap. From this point, the most distal extent of the flaps should be marked in a circular fashion at a distance consistent with one fourth of the tape length (Fig. 212.7). Once the flaps are marked, the skin incision may be extended to the level of the fascia. Deep to the fascia, the amputation is performed with the same technique as the long posterior flap. With the skew technique, the posterior muscle compartment is divided 5 cm distally to the previously created posterior skin flap. After appropriate narrowing of the gastrocnemius muscle, it is brought forward and used to cover the anterior tibial periosteum (Fig. 212.8). The skin is then approximated as previously described. Ultimately, this technique results in the creation of two distinct flap coverages for the stump—a deep myofascial flap covering the tibia and anteromedial and posterolateral fasciocutaneous flaps covering the deeper flap (Fig. 212.9).

Above-Knee Amputation

Through Knee or Knee Disarticulation

This technique is advocated for several reasons: (a) Minimal muscle is transected and therefore postoperative bleeding and operative time are minimized; (b) it preserves more limb length than a transfemoral amputation for transfers; (c) although historically it has been a difficult prosthetic fit, excision of the femoral condyles/patella and use of the C-limb prosthesis have improved fitting dramatically; and (d) it avoids any flexion contractures. However, synovial fluid can accumulate, and the flaps can break down due to tension from the underlying femoral condyles.

Equal anterior and posterior fasciocutaneous flaps extending approximately two thirds of the diameter of the leg in length are created (Fig. 212.10). The incision is then extended through the collateral, medial, lateral, and cruciate ligaments, and the hamstring tendons are transected. The tibial nerve, the peroneal nerve, and the popliteal artery and vein should then be identified. The nerves should be transected proximally under tension to avoid neuroma formation, and the vessels should be suture ligated. The patellar tendon can then be separated from the tibia and sutured to the cruciate ligaments and hamstring tendons over the femoral

condyles (Fig. 212.11). The fascial layers are closed with absorbable sutures and the skin with interrupted nylon sutures as described above.

Transfemoral Amputation

The decision to perform a transfemoral amputation (AKA) is influenced by the determination that a patient will be unable to heal a BKA or is unlikely to mobilize after an amputation, or in the patient who has a significant knee contracture. Several vascular centers are now advocating a through-knee amputation over an AKA in most patients to preserve limb length; however, widespread adoption of this practice has yet to occur. Important technical considerations include preserving as much femoral shaft length as possible to improve prosthetic fitting and lever function of the shaft. Creation of equal anterior and posterior flaps involves marking the point of femoral shaft transection ~12 cm from the knee joint. The circumference of the extremity should be estimated at this point, and the intersection of the anterior and posterior flaps should be one half of this. In addition, the distal aspect of the flaps should then extend to a distance two fingerbreadths proximal to the patella (Fig. 212.12). After determining the extent of the flaps, the skin and subcutaneous tissue may then be sharply divided at this level. The quadriceps and the hamstrings (semitendinosus, biceps femoris, and semimembranosus) should then be divided sharply two fingerbreadths distally to the point of femoral shaft division and the vastus lateralis and adductor muscles may be divided at the level of femoral shaft division (Fig. 212.13). Next, the bone is transected with a power saw or Gigli saw, and the edges are contoured with a rasp. As the femoral artery and vein are identified, these should be suture ligated and the sciatic nerve should be divided sharply under tension. After hemostasis is achieved, the fascial edges of the muscles should then be closed over the remaining femoral shaft with interrupted absorbable sutures, and the skin edges should be opposed with interrupted nylon sutures.

POSTOPERATIVE MANAGEMENT/COMPLICATIONS

Based on results, major lower extremity amputations are arguably one of the most difficult procedures the modern vascular surgeon will perform. Perioperative mortality rates of 5% to 7% for BKA and 10% to 15% for AKA are typical. Compare this with the 3% perioperative mortality rate published in the recent Veterans Affairs multicenter open versus endovascular repair aneurysm trial. The potential lethal nature of amputations is not due to the complexity of the procedure, but rather to the patient population requiring it. Available data would indicate significant medical comorbidities, poor nutrition, anemia, and generally a severely deconditioned state secondary to the immobility enforced secondary to the nature of the presenting foot lesions and/or prior forefoot procedures. Many patients are in the last months of their lives, and could be described as dying from the periphery inward. An episode of aspiration pneumonitis, subendocardial infarct, or exacerbation of congestive failure can easily prove to be fatal. Compounding the problem, amputations are rarely considered by anesthesia and/or surgeons as a case of the same magnitude as a major vascular reconstruction or cardiac case.

In addition to the typical cardiovascular morbidities, patients undergoing major amputation are immobile in both the preoperative and perioperative periods. Not surprisingly, the incidence of DVT is high in this population, mandating some level of prophylaxis. As many of these patients have underlying hypercoagulable states or undergo amputation for acute arterial thrombosis, anticoagulation is frequent, which often leads to bleeding complications. Finally, many diabetic patients require amputation for severe forefoot sepsis. These patients can suffer septic complications from delay in definitive removal of the septic focus and/or bacteremia at the time of the procedure.

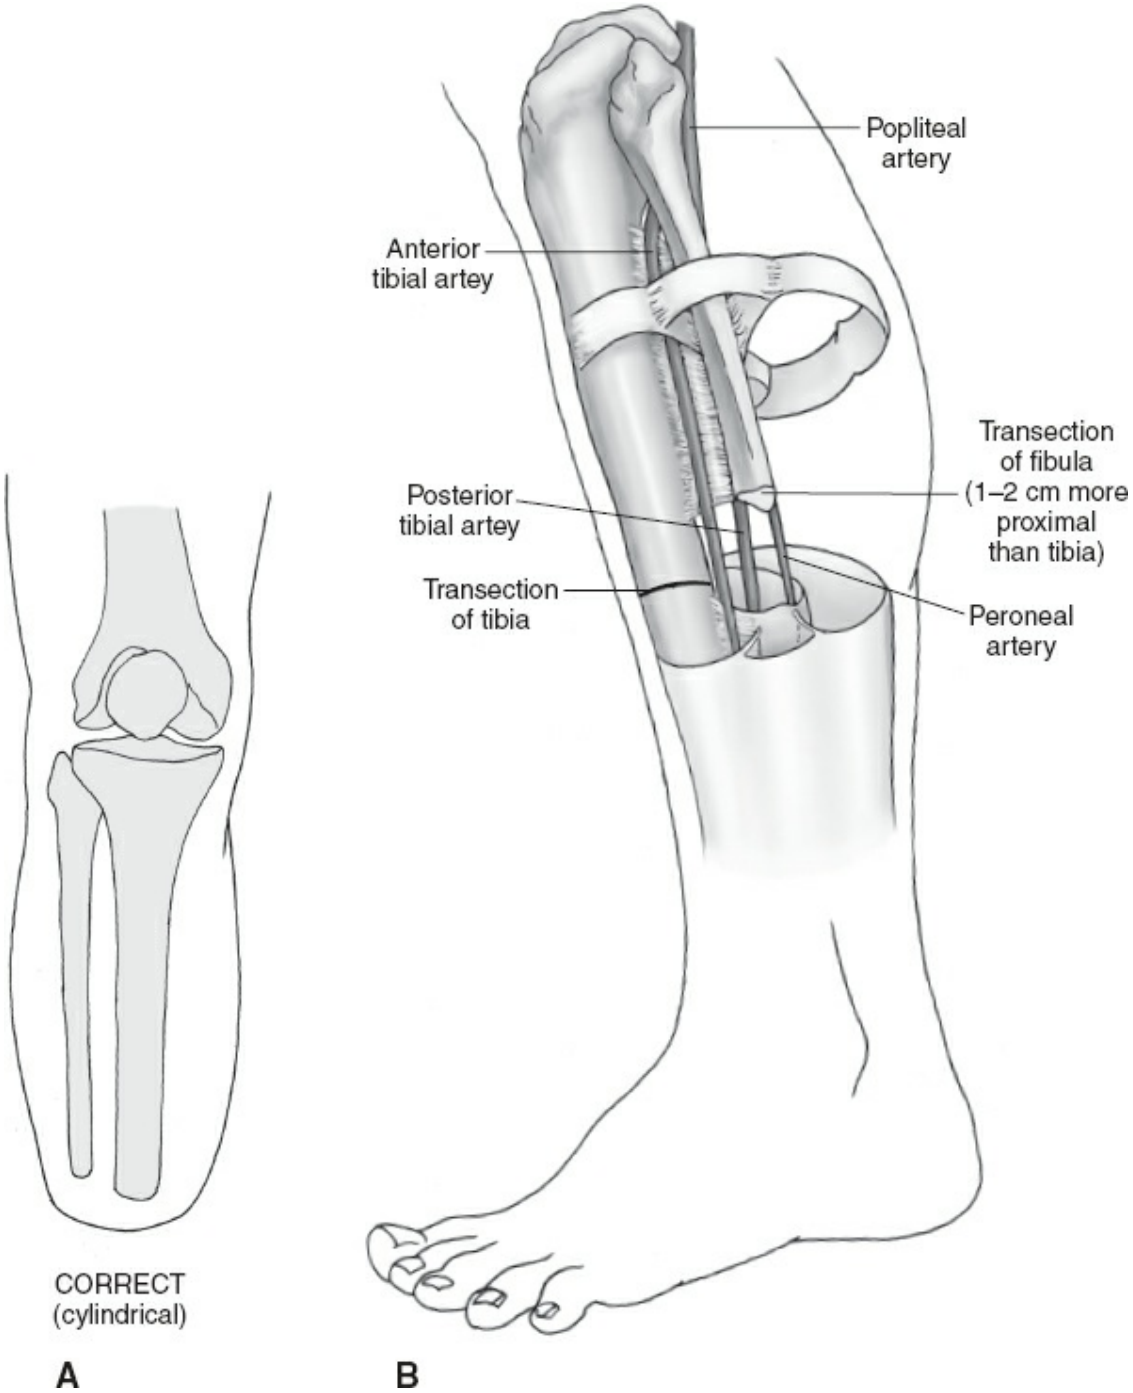

Figure 212.5. Relationship between tibial and fibula transection in the Burgess below-knee amputation.

Healing rates of BKA vary, but failure in 10% to 20% is widely reported. These patients often have one or more operations attempting to salvage the knee joint, followed by an eventual AKA. Amputation healing times are often measured in months rather than weeks. Part of the difficulty in wound healing is related to falls and stump trauma. However, even without postoperative trauma, CLI patients heal incisions below the

knee poorly. Casting the BKA stump appears useful to reduce trauma and edema, but the single small trial using these devices did not demonstrate efficacy compared to standard protective bandages.

From the patient perspective, one of the most important morbidities of amputation is postoperative pain. Chronic postoperative amputation pain can be divided into two groups—residual limb (stump pain) and phantom limb pain. The prevalence is in the range of 50% to 80% of amputees. Both central and peripheral pain mechanisms appear to be involved, including ectopic activity originating from afferent fibers in a neuroma and cortical reorganization/spinal cord sensitization. For most patients, the pain is episodic in nature and not particularly troublesome. In approximately one in four of patients, however, the symptoms are very disabling. In addition, some data suggest that the duration and intensity of preamputation limb pain play a role in early post amputation residual limb and phantom limb pain.

FUNCTIONAL OUTCOMES

A substantial amount of research has focused on preoperative evaluations to determine if a BKA will heal, with preservation of the knee joint and improved function and potential mobility. This is extremely relevant in the younger amputee population. However, the sobering fact is that many elderly patients will not be able to complete an arduous rehabilitation program to ambulate to any extent with a prosthesis. Much of this is related to the comorbidities in the population as previously stated with regard to perioperative mortality. However, in the United States, the passage of the Americans with Disability Act in 1990 has improved wheelchair access by mandating it for public buildings. Frequently, elderly amputees choose to focus effort toward modifying the home to allow at least some mobility in a wheelchair. A review at our institution demonstrated that less than half of amputees were ambulatory postoperatively, but relatively few required transition to a care facility—a more recent study from Sweden demonstrated similar findings in a BKA population as did studies from the United Kingdom and Singapore. A patient with a healed amputation (AKA or BKA) who can independently transfer and take a few limited steps but remains in the community is the end result for many elderly amputees. The prevalence of vascular

amputees who ambulate postoperatively declines over time due to a variety of issues, such as mortality, contralateral limb loss, and clinical events. Finally, the occasional patient will fall and suffer a major fracture during prosthetic use.

Conversely, if patients are to have any realistic hope of extensive prosthetic ambulation postoperatively, the knee joint must be spared. Many of the AKAs performed are done so based on the lack of rehabilitation potential rather than inability to eventually heal a BKA—with some recent movement toward more through-knee amputations. One obvious question is the potential benefit of the knee joint in the nonambulatory patient. Although statements regarding improved transfer potential and balance are frequently made, the available data to support this are lacking. Thigh muscle atrophy has been noted to correlate with the length of the AKA stump. Balance is clearly an issue with prosthetic use, and has been widely studied. However, similar data regarding balance and wheelchair use are lacking. Finally, small series of the bilateral amputee (both above and below knee) have been reported. Ambulation is unusual, but pressure ulcers as seen in neurologically impaired patients do not appear to be a long-term issue.

NATURAL HISTORY

Patient survival in the NSQIP amputation series for BKA and AKA was 57% and 39% at 3 years, respectively, again emphasizing the palliative nature of these procedures in most patients. This significant long-term mortality has been confirmed in studies outside the United States as well. In addition to mortality, significant ongoing morbidity occurs in both the remaining stump (BKA) and contralateral limb following major lower extremity amputation. At 2 years, 15% of patients with an initially successful BKA will convert to an AKA, and another 15% will suffer a major contralateral amputation.

EDITOR'S COMMENT

Dr. Mark Nehler's comprehensive and thoughtful chapter highlights a very common surgical operation, the lower extremity amputation. Few textbooks pay attention to the fine operative points of amputations, and this chapter accomplishes that.

Amputations are often the end stage of peripheral vascular occlusive disease (PVOD) and/or severe foot infection, and performed frequently by orthopedics, plastic, vascular, and general surgeons. Amputations are generally low morbidity and mortality operations, but medium and long-term mortality is high given the patients' underlying comorbidities, as pointed out by the authors. For example, long-term mortality after amputation is worsened with older age, high American Society of Anesthesia score, and chronic kidney disease; all of which are not modifiable (Scott SW, Bowrey S, Clarke D, et al. Factors influencing short- and long-term mortality after lower limb amputation. *Anaesthesia* 2014;69:249–58).

It is not uncommon that patients have had numerous prior endoluminal and sometimes open operations for management of severe PVOD, although the intensity of therapies is dependent on region, socioeconomic, and racial status (Goodney PP, Holman K, Henke PK, et al. Regional intensity of vascular care and lower extremity amputation rates. *J Vasc Surg* 2013;57:1471–9, 1480 e1471–3; discussion 1479–80). How aggressive to be in the setting of PVOD is not well defined by evidence. However, one of the primary considerations is the patients' functional status, and while many technical arterial interventions are possible, the quality of life, frailty, and mobility of the patient are important when considering an amputation as compared to very aggressive limb salvage procedures. Sometimes, the safest and most beneficial procedure is an

amputation.

In terms of preoperative preparation, most of these patients should proceed with surgery and an extensive cardiovascular assessment usually is not required. Indeed, these patients can undergo regional or epidural anesthesia, with less pulmonary risk. I would partially agree with the authors that specifically prescribing beta-blockade prior to amputation is not needed. However, if the patient is on beta-blocker therapy, they should remain on this to avoid tachycardia and rebound hypertension. It also is important to make sure these patients are on statin and antiplatelet therapy for general cardiovascular health if they have significant underlying PVOD.

Determining the level of amputation is critical, and the most distal level that heals allows the most function. Whereas in the past, popliteal pressures or doppler wave forms were used to determine an above the knee versus below the knee amputation site, now transcutaneous partial oxygen level ($TcPO_2$) offers a more sensitive way to determine healing for below the knee amputations (Poredos P, Rakovec S, Guzic-Salobir B. Determination of amputation level in ischaemic limbs using $tcPO_2$ measurement. *Vasa* 2005;34:108–12). Data suggest the $TcPO_2$ levels >40 mm Hg at the ankle are associated with the best chance of healing a below the knee amputation.

Several important technical aspects are well highlighted by the authors, including constructing a good posterior muscle flap. It is critical to create a full but not too bulky posterior muscle bundle as stuffing in too much muscle will lead to ischemia and flap loss. Ligation of the vascular bundles is straightforward, and allowing the nerve to retract to decrease neuroma formation is key. I usually inject the nerve at the time with Marcaine for additional analgesia. For closure, I use staples rather than sutures to close the skin as these are easier to remove at 4- to 6-week timepoint than sutures. I must admit I have no experience with through-the-knee amputation, although Dr. Nehler suggests that with new prosthesis these may be a reasonable or better alternative than a transfemoral amputation. Further study will determine whether this is a useful level of amputation, but mixed evidence of low quality is available (Murakami T, Murray K. Outcomes of knee disarticulation and the influence of surgical techniques in dysvascular patients: a systematic review. *Prosthet Orthot Int* 2016;40(4):423–35).

I disagree that patients with a transfemoral amputation are rarely ambulatory. I have had numerous patients, albeit slightly on the more robust and younger side, fitted with a prosthesis and attain mobility if their other leg is functional. However, if any chance of a below the knee site, it should be pursued. It is common that frail and debilitated patients with a transfemoral amputation will often be bedbound; hence, preoperative discussion of quality of life issues is critical.

Lastly, one of the tougher clinical scenarios is a patient with significant aorto-iliac occlusive disease and who requires an amputation. For example, will a patient who needs a proximal amputation but has an occluded iliofemoral

system heal his or her stump? Proceeding with an endoluminal or an open endarterectomy and angioplasty or bypass to allow a high amputation to heal is controversial. Outside of clinical judgment, little data are present to guide the surgeon. I usually find if their thigh is warm, it will heal at the proximal site even if there is no palpable femoral pulse, although sometimes very slowly, and require debridement, dressing changes, etc. Conversely, if improving aortoiliac blood flow via endoluminal or open surgery will improve the potential healing of a below the knee as compared to a proximal level, I think this is reasonable.

Peter Henke

213 The Prevention and Treatment of Problems With the Diabetic Foot

Norman J. Galbraith, T. Jeffrey Wieman, and Hiram C. Polk, Jr.

INTRODUCTION

Diabetes mellitus remains a growing problem in the Western world, as do the various manifestations of this disease; we focus here upon the diabetic foot. In 2012, 29.1 million Americans were diagnosed with diabetes, with 1.25 million of these diagnosed with type I diabetes and it remains one of the top ten killers in the United States. More concerning is the massive prevalence of prediabetes, counted at 86 million Americans in 2012 with a growing number of undiagnosed cases, to which the ongoing obesity epidemic is almost certainly the key contributor to the growing number of prediabetic and type II diabetic patients. The total cost of diagnosed diabetes in the United States has been estimated at $245 billion per year. Direct medical costs, as well as loss of productivity, can result from many of the common manifestations such as myocardial infarction and stroke from large vessel disease, as well as renal impairment, retinopathy, and of course peripheral neuropathy associated with microvascular disease. Both type I and type II diabetics can suffer from all microvascular complications; thus it is common for diabetic foot patients to have decreased visual acuity, which will impair their ability to see early warning signs in their legs and feet of impending problems.

Furthermore, neuropathy can not only interfere with the autonomic control of the blood supply to the skin, but will decrease light touch and pain sensation as well as proprioception, abetted by diabetic myopathy which accounts for 25% of weakness when compared to nondiabetics. This multiplies the additional risk in allowing a small ulcer to progress to limb-threatening disease. The surgeon must notice these subtleties during the consultation in order to improve early recognition. Educating and instigating the crucial role of the spouse/caregiver helps in close monitoring of the feet. Specific examination of the feet with shoes and socks off in every consultation lessens the likelihood that missed injuries

or ulcers will occur and is probably far more important than the focus on hemoglobin A1c. Notably, numerous papers studying the diabetic gait with remote sensors shows that patients tend to strike the same location of the plantar surface with every step, a de facto decubitus-type injury.

The surgeon can play important roles in the multidisciplinary approach to the diabetic foot. This includes assessment and improvement of the vascular supply to the periphery, procedures to off-load bony prominences at risk, and of course multiple levels of amputation in the elective and emergency setting if prevention fails. However, approximately 1 in 10 diabetics will have a diabetic foot ulcer (DFU) at some point in their life. Diabetes continues to be the most common cause of nontraumatic limb amputation and diabetic foot ulceration precedes more than 80% of amputations. In fact, half of patients who develop a DFU will be dead in 5 years. Therefore, we unapologetically focus on the role of *prevention* in the diabetic foot, in order to try and limit the downward spiral that can arise from first consultation to amputation.

PATHOPHYSIOLOGY

The foot is a complex structure of 26 bones, 33 joints and various larger muscles controlling movements such as dorsi- and plantar-flexion, and small internal muscles controlling finer movements of the foot and toes. The principle role of the foot is balance, weight bearing, weight distribution, and bipedal locomotion. In order to carry out these roles, we all rely heavily on the afferent nerves from the periphery to detect fine touch, pain, changes in temperature, and of course proprioception. Loss of sweating and skin lubrication in autonomic neuropathy are major causes of pathologic callus formation. The autonomic dysfunction also produces subnormal capillary shunting and fragility of vessels at the dermal–subdermal interface, making these vessels more susceptible to disruption which is the original cause of bleeding and ulcer formation beneath callus. DFUs are classified into three types:

Neuropathic: Pink with granulation tissue, classically on plantar surfaces at sites of high plantar pressures
Ischemic: Often distal including between digits, can be dorsal, edges are pale without granulation tissue
Mixed: (50%) are both ischemic-neuropathic

Peripheral neuropathy results from persistently high blood glucose

levels through various poorly understood molecular mechanisms. Hyperglycemia causes increased intracellular glucose levels within peripheral nerves, saturating the normal glucose metabolism pathways. This results in the activation of the polyol pathway, with glucose being converted to sorbitol and fructose. Resulting impairment of sodium–potassium–ATPase pumps leads to structural breakdown and impaired axonal transport. Glucose further interferes with proteins, nucleotides, and lipids resulting in the accumulation of advanced glycation end (AGE) products, which further impair nerve metabolism and function. Oxidative stress further contributes to neuropathy due to increased mitochondrial production of free radicals due to the saturation of neurons by elevated glucose. Peripheral nerves can be damaged due to glycosylation of the vasa nervosum, causing capillary basement membrane thickening and endothelial hyperplasia. Resulting chronic hypoxia to nerves lead to decreased function, beginning with the smallest, unmyelinated fibers such as light touch and temperature which are most readily affected. Finally, nerve entrapment occurs beneath tendon retinacula which exacerbate edema of the nerves, especially the posterior tibial nerve and diminishes its function; under certain circumstances surgical release re-establishes neural function. These nerve changes are intimately linked to microvascular changes in the local small vessels supplying the skin. The process of diabetic neuropathy affects sensory, motor, and autonomic tracts of the nervous system. The decreased function of the afferent **sensory fibers** promotes the glove and stocking distribution of numbness, loss of sensation, and sometimes paraesthesia and pain.

Diabetic ulceration is far from a spontaneous event, and patients influenced by such changes often do not notice even the most minor injury or cut to their feet. Furthermore, bony prominences that bear weight would normally be off-loaded to prevent repeated friction, but without normal proprioceptive function thick callus will develop, with eventually ulceration (Fig. 213.1). Hyperglycosylation of callus makes it stiff and increases plantar pressures at “at-risk” sites.

Figure 213.1. These images show classic neuropathic ulcers (*arrows*) in a diabetic. Areas of high plantar pressure such as the heels and the metatarsal heads on the plantar surface are at special risk. (With permission from Smeltzer SC, Bare BG. *Textbook of Medical-Surgical Nursing,* 9th ed. Lippincott Williams & Wilkins, 2000.)

Autonomic nerves provide control of the blood supply to the skin of the peripheries, a further target of neuropathy. This can result in abnormal distribution of blood to the skin which leads to dry, cracked skin with fissuring, especially at the heel.

Motor neuropathy leads to intrinsic foot muscle wasting, and to claw foot and hammer toe deformities. This change in plantar architecture results in increased plantar pressures, known to be a major risk factor in the development of ulceration. Indeed, peak plantar pressures are higher at sites of established ulcers and at risk sites, which is predictable and not surprising. Diabetic patients, particularly those with neuropathy, experience various **gait abnormalities**. Gait analysis reveals increased step width and less step variability, poor balance, and walking is slower in general. Decreased shock absorption during heel strike results in increased anterior displacement of weight bearing. Subsequently, higher plantar

pressures are seen in the forefoot compared with nondiabetics, maximally at the great toe and 5th metatarsal. This is confounded by direct muscle dysfunction from hyperglycemia, and higher body weight by the average diabetic patient. Therefore, a patients gait must also be examined during a consultation to detect abnormal weight loading. If there are areas of concern, such as ulceration, callus, or evidence of abnormal weight loading then the patient should be prescribed orthotic shoes that will protect and off-load weight from areas of concern, but only after calluses have been completely sanded. Frequently, there is a new ulcer beneath it which must be diagnosed and removed. In fact, as a rule of thumb, all diabetics must wear comfortable, well-cushioned sports shoes, preferably fitted by an orthotist that can decrease the pressure on bony prominences in the foot. The periodicity of reassessment of shoes is uncertain but needs to be discussed by the surgeon with the patient. A weekly examination of both feet of the patient by their caregiver must be instigated, allowing a second pair of eyes to detect early signs of diabetic foot disease. Beware of the elderly couple that both have poor eyesight! Good education of the patient and caregivers should inform that any areas of concern should expedite an appointment with a physician and prevent the downward spiral into an ulcer.

Peripheral vascular disease can occur in the diabetic patient, with hyperglycemic tissue damage and ischemia often coexisting. Peripheral arterial disease in the lower limbs can be present in at least one fourth of all diabetic foot patients, and carries an additional poor prognosis. It is often inadequately addressed in this setting. Specifically, large-vessel disease must be assessed at least by Doppler examination as a vital part of a first visit. In diabetics, the femoro-popliteal and tibial vessels are more commonly affected, compared to aortoiliofemoral vessels in nondiabetics. The clinical aspects of addressing large vessel ischemia will be dealt with later, but young surgeons must remember to consider the potential contribution, and therefore therapeutic avenue, of peripheral artery disease in the diabetic neuropathic foot.

Doppler ultrasound of the dorsalis pedis and anterior tibial artery pulses in both feet, and the calculation of an ankle–brachial pressure index (ABPI) aids the clinical assessment. Do not forget that diabetic vessels are prone to calcification, thus can potentially give misleading readings. If concerned, CT angiography to give an accurate assessment of the arterial

tree can rule out significant stenosis, should renal function tolerate intravenous contrast.

THE SKILLED PROFESSIONAL TEAM IN DIABETIC FOOT CARE

The diabetic foot is a perfect example of a condition that can greatly benefit from a multidisciplinary team approach. The team begins with the patient themselves and their spouse/caregiver—who must be present at first consultation. Prompt and reinforced education of the early warning signs of diabetic foot disease and emphasis of the importance and risks therein is crucial. The delayed presentation of an infected, advanced, and progressing lesion is a prelude to amputation and death.

The internal medicine physician or family physician should lead the care in parallel with surgeon, and is often the source for referral, but are also important in instigating treatment and monitoring diabetic control. Should a patient present with new diabetic foot disease or have elevated HbA1c either in clinic or in hospital, they should continue to see their primary physician to ensure an optimum oral hypoglycemic and/or insulin regime.

The general or vascular surgeon has to determine whether there are elements of large vessel peripheral vascular disease, which could potentially be amenable to reconstruction and enhance healing. Furthermore, they will often be consulted in the emergency setting in the context of invasive infection. The role here is looking at three levels of assessment: the wound, the foot, and the patient as a whole. The surgeon must aim to drain infection and prevent the progression to sepsis, while preserving as much function as possible. Later, optimizing proper footwear designed for the patient in terms of prevention is essential whether by an orthotist, a podiatrist, or a skilled shoemaker. Secondly, should an ulcer arise, they need to ensure optimum off-loading either with specialist shoes or, infrequently, a temporary cast. The surgeon also plays an important role in maintenance of good foot hygiene including sanding down callus, debridement, trimming of toenails, and education. Added skin care with lanolin coconut oil should be done daily. Photographs with smart phones should be taken at each visit. All patients should have a digital plantar pressure measurement taken initially and once a year for comparison of changes. It is highly predictive and should always precede metatarsal head resection (MHR). It will demonstrate other high pressure points and

minimize the risk of a transfer ulcer.

The surgeon can play a vital role in surgical off-loading (through a variety of procedures depending on the location of the lesion), as well as fore- and mid-foot amputation, selected arthrodesis, and in Charcot arthropathy. Other important roles can be played by the family physician in coordinating care, visiting nurses for patients who cannot adequately care for themselves, and diabetic nurse specialists who can closely monitor all aspects of diabetic care. Dieticians, biomechanics/orthotist services, and tissue viability nurses can play an important role but this is often best orchestrated by an informed surgeon.

With any multidisciplinary team, important *leadership*, accountability, and good communication can eliminate preventable amputations. In areas where most patients do not have access to a specialized diabetic foot multidisciplinary team, a patient's prognosis can depend on the surgeon's knowledge, expertise, and commitment to long-term care. Fascinatingly in the United States, in Medicare patients these sessions are well paid but require specific coding, perhaps on a special diabetic foot page in the chart. An example of appropriate documentation would be:

"Sanded two plantar calluses plus evolving cutaneous horn; trimmed all ten toes, especially watch left great toe for ingrowing nail next visit; return 2 months or sooner PRN" becomes a very important communication to other members of the team and, with associated codes, as basis for payments.

PREVENTION OF OCCULT INJURY TO THE DIABETIC FOOT

Undoubtedly, the most important take home message of this chapter is preventing the development of the first DFU. The first opportunity in educating the patient about the risks of the diabetic foot should happen at first diagnosis of diabetes mellitus (Table 213.1). This can be an overwhelming time for a patient with information overload, but both verbal and written information such as a booklet about the warning signs, potential risks, and consequences of the diabetic foot should be delivered in an easy to understand format, combined with early follow-up to see how such instructions have been assimilated.

At every visit thereafter, whether it is with the family physician or surgeon, the consultation must include:

Socks-off examination of both feet
Skin assessment and lubrication
Check for bony prominences and callus with sanding down as appropriate
Re-emphasis of the importance of foot hygiene, nail care, and a weekly examination by a spouse/caregiver
Consideration of diabetic control—such as plasma glucose and HbA1c with referral to the diabetologist as need if this is consistently elevated
Orthotic evaluation
A follow-up plan

- We recommend at least 3 weekly visits initially, then 3 monthly, and then 6 monthly intervals if no complications supervene

Patients should be given specific phone numbers they can call, such as a diabetic nurse who can examine the foot and will expedite care as required, should they have any concerns.

Any wound, callus, skin breakdown, or ulceration should be taken seriously and patients referred to a surgeon ideally with an interest in diabetic foot disease. Clinics such as these can offer an intense program up to 10 weeks that can avoid an amputation (Fig. 213.2).

Numerous nonsurgical options for off-loading bony prominences at risk can range from comfortable, well-cushioned orthotic shoes with personalized in-soles, to a specialist for removable boots and/or nonweight bearing fitted plaster cast. There cannot be enough emphasis placed on the role of proper footwear. Like any intervention in medicine, there must be a follow-up within 4 weeks after new footwear has been initiated to check that the condition of the foot has improved. Bed rest and/or constant foot elevation may be required at home but is seldom actually done; orthotic intervention is more desirable.

TABLE 213.1 Clinical Assessment of the Diabetic Foot

Proper assessment of all diabetic ulcers include:

- Ulcer location, depth, and width
- History of neuropathic foot ulcer or the presence of synchronous ulceration
- Overt ulcer infection (been shown to be present in half of all ulcers). Associated calluses completely removed
- Exudate/purulence/new malodor
- Tissue loss especially necrosis/gangrene distally
- Systemic signs of infection such as chills, fever, nausea/vomiting, and malaise
- Sensation in all plantar areas of the foot should be assessed using a monofilament perpendicular to the skin—note areas of callus might give false positives
- Vascular assessment
  - Absence of both pulses by an experienced clinician is suggestive of vascular disease but must be accompanied by Doppler examination
- Digital plantar pressure measurements
- Transcutaneous oxygen measurements, where available, suggest a loss of perfusion in an affected limb
- Skin assessment and plans for ongoing lubrication
- Warmth can give false reassurance of good perfusion due to arteriovenous shunting in the skin, assuming it is nontender and does not represent invasive infection. However, a difference in temperature between feet is a crude but useful sign of large vessel disease.
- Consider acute Charcot degeneration, easily confused with infection

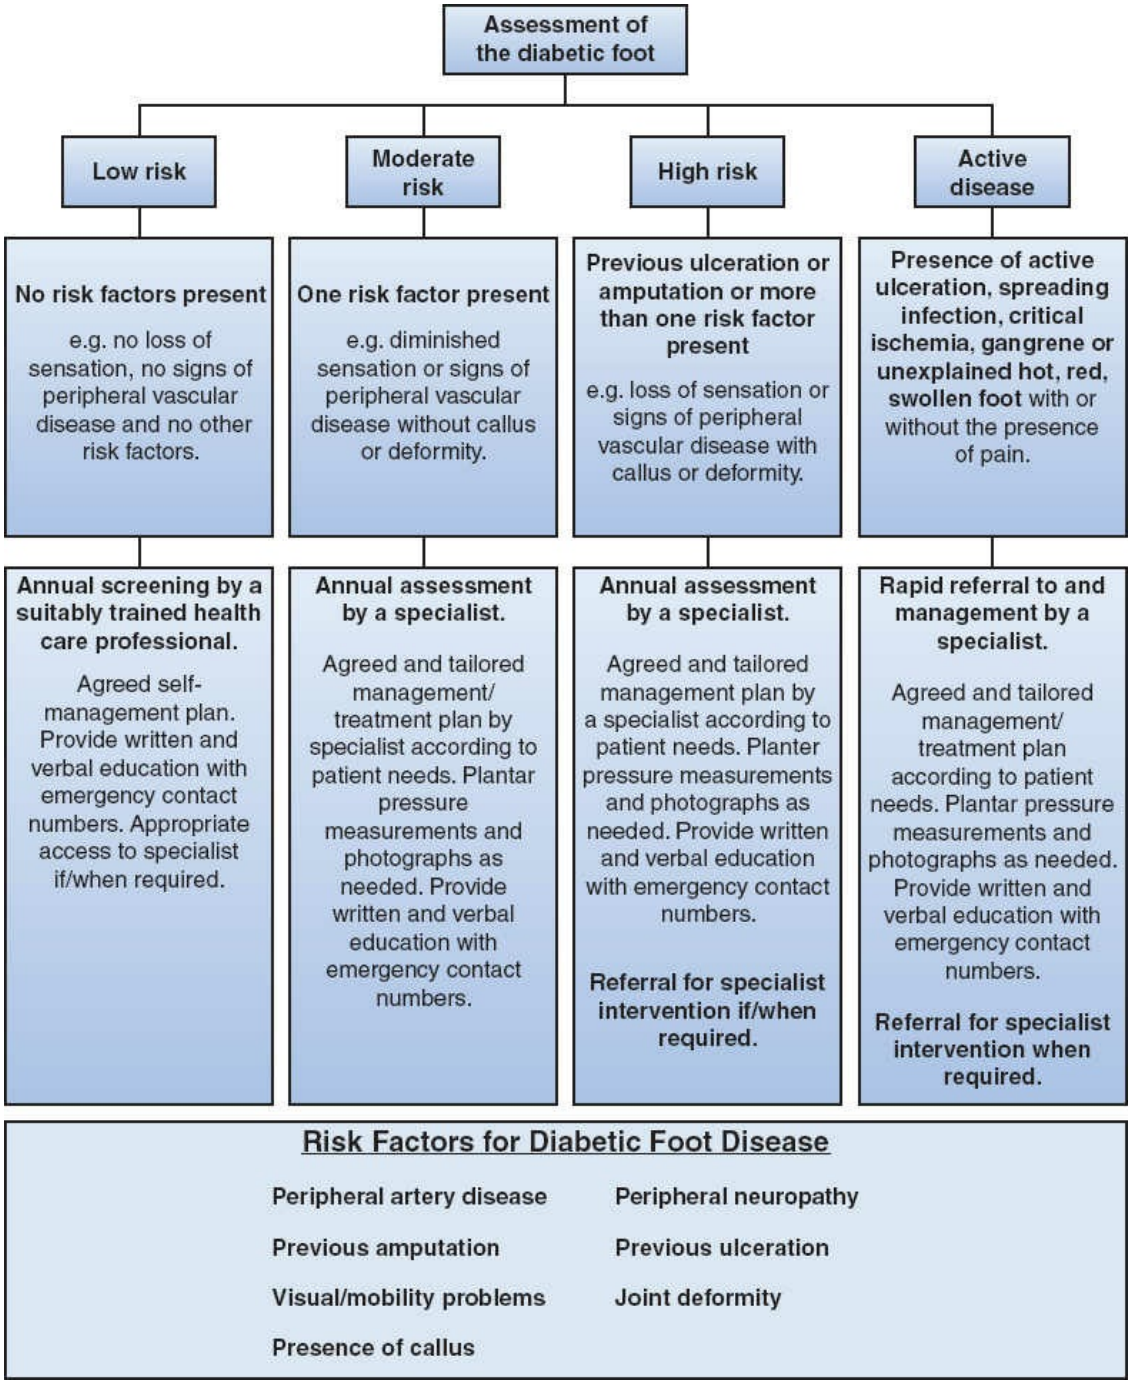

Figure 213.2. Risk stratification and triage of the diabetic foot. Risk factors are also noted.

In the presence of any DFU, the surgeon must ensure ongoing proper assessment of vascular status of the affected and contralateral limb. This can be a reversible factor in the pathogenesis of ulceration, through an endovascular (such as percutaneous transluminal angioplasty) or open (bypass) arterial reconstruction depending on the lesion(s) and the patient. Indications for percutaneous transcutaneous or open angioplasty for

diabetic peripheral artery disease are usually disabling claudication and critical limb ischemia (<30 mm Hg). The former can be very useful when open bypass surgery is contraindicated, and in lesions with a stenosis less than 4 cm long, and occlusions shorter than 10 cm. Even in the absence of the above signs, if there is proven peripheral arterial disease and a nonhealing ulcer despite best medical management, revascularization should be considered.

While many patients may have lost sensation and are pain-free, this is not always the case. For ischemic rest pain, lumbar sympathectomy may still have a minimal and transient role in symptom management. In the context of neuropathic pain, tricyclic drugs such as paroxetine, as well as gabapentin, may be emerging as effective analgesics. At present, they seem modest in effect with substantial side effects. Biofeedback schemes may be helpful.

Ideally, all DFUs, and especially infected diabetic feet, should have photographic documentation (**smartphones**) at the time of examination. This allows for serial comparisons and is particularly helpful when team members alternate care.

Topical Therapies

Emollients should be prescribed and used frequently in patients with dried, cracked skin to lessen other injuries. The choice of dressings can be overwhelming but should be kept simple. If there is active infection, topical antimicrobial dressings such as mafenide or silver sulfadiazine, iodine, honey, or polyhexamethylene biguanide (PHMB) can increase local antimicrobial action. Removal of the biofilm with proper wound bed preparation, consideration for moisture balance, and a suitable secondary dressing such as crepe bandaging should be individualized to the lesion and the patient. The key is to see the patient again promptly. Topical antimicrobials such as silver impregnated dressings can have a role to play, particularly in patients without heavy commensal load or poor vascular supply; only mafenide (Sulfamylon) has the capacity to be absorbed transcutaneously.

In general, in situ dressings designed for 5 days or longer should not be used for the diabetic foot (inviting neglect) due to the risk of rapid progression of infection that necessitates more frequent exposure and examination.

TREATMENTS FOR DIABETIC FOOT ULCERS

Surgical Offloading for Diabetic Foot Ulcers

MHR in the context of an ulcer has been shown to decrease the plantar pressures at the affected site, and often leads to the resolution of the ulcer. Where possible, incisions should be longitudinal over the affected metatarsal and must be on the dorsal surface of the foot through healthy, soft tissues free of inflammation (see Fig. 213.3). Creating new wounds on the poor healing plantar surface, near the affected ulcer itself is asking for trouble. Some concerns exist that by off-loading one ulcerated area of the foot, can lead to weight being transferred to another bony prominence and lead to a so called “transfer ulcer.”

In patients treated without MHR the rate of ulcer recurrence is 60% within 6 months and transfer ulcer rate is 60% to 70% in 5 years. With MHR the transfer ulcer rate is 10% at 5 years and recurrence rate after MHR at the same site is about 5% over 5 years. It is important to have digital plantar pressure measurements done after MHR to predict and prevent future ulceration.

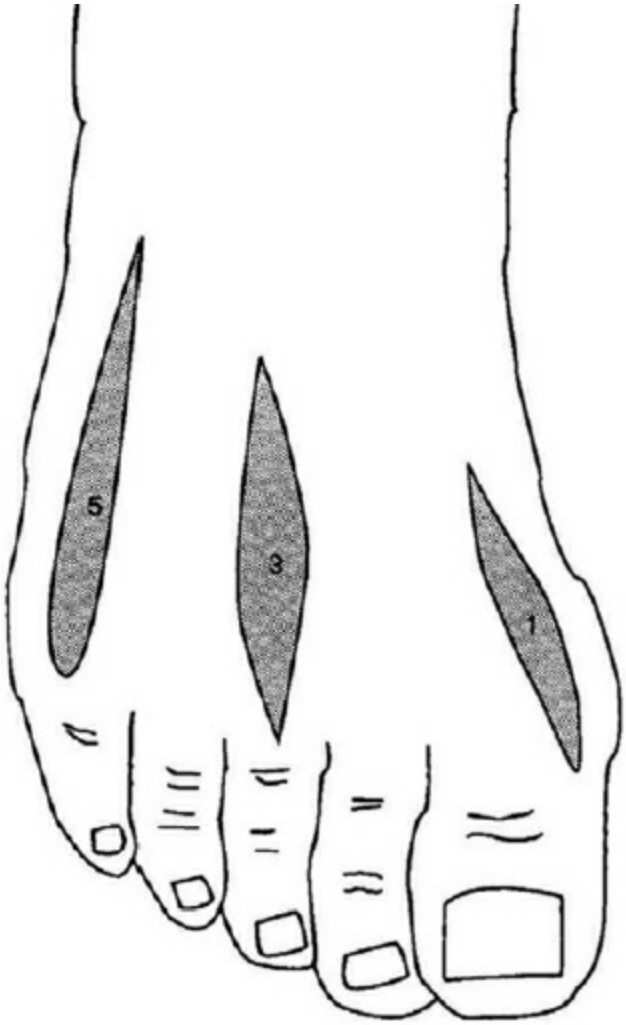

Figure 213.3. Dorsal incisions are preferable for operations on the diabetic foot. Incisions *1, 3,* and *5* would be appropriate for a metatarsal head resection for the corresponding metatarsal from right to left. Some have been concerned that it alters gait, it does—by improving it! These people do not have normal gaits to begin with, so the typical argument does not hold water as it would in nonneuropathic patients. Healing is prompt and complete if the procedure is done properly. Healing time is proportionate to the initial ulcer size. Weight bearing is permissible as soon as the drain is removed. Metatarsal head resection is simpler, faster, and less morbid than traditional transmetatarsal amputation. (With permission from Wieman TJ. Principles of management: the diabetic foot. *Am J Surg* 2005;190:295–9; permission conveyed through Copyright Clearance Center, Inc.)

Treatment of the Diabetic Patient With Lower-Extremity Infection

Although mild infection in a superficial ulcer can be referred to a specialist

within 1 working day, many are more urgent. The presence of infection of the diabetic foot should be considered a medical emergency and patients should be admitted to the hospital. The presentation of this is often delayed, with the classic signs of pain, redness, and fever potentially missed or blunted due to autonomic and sensory neuropathy, poor eyesight, and immune suppression (such as after organ transplantation), respectively (Table 213.2).

When infection is suspected, important aspects of the initial assessment should include: complete debridement of the wound/ulcer, microbiologic culture of the deepest part of the ulcer, blood tests including leukocyte count with a differential count, random plasma glucose, HbA1c, and possible use of inflammatory markers such as C-reactive protein.

Depending on depth of the ulcer, consider **radiographic assessment** for osteomyelitis. The presence of this can be confirmed by plain radiographs of the foot; however, this is not very sensitive and sometimes MRI or even a nuclear imaging white cell scan may be required to rule out osteomyelitis. However, the gold standard for diagnosing osteomyelitis is bone biopsy.
Urgent surgical review to determine the presence of abscess, deep seated infection including fascial compartments, and to determine the presence of wet gangrene, warranting hospitalization.
Subsequent assessment of the biomechanics of the foot and **off-loading treatments** as appropriate, is warranted when acute infection is controlled and amputation anticipated
Early and frequent **reassessment**—to rule out ascending and progressive limb- and life-threatening infection
Tissue viability assessment for consideration of exotic treatments such as negative pressure dressings, larval therapy, or hyperbaric oxygen therapy

The key steps of **therapy** in the presence of infection should include:

Cleaning and complete debridement of the wound
Appropriate wet dressings with coarse mesh gauze, either saline or consider topical antimicrobials such as silver impregnated dressings if there is a significant biofilm of contaminating bacteria
Elevation
Adequate and prompt surgical drainage of abscess/purulence; emergency operation on some occasions is required on the day of admission
Off-loading with custom orthotics or new fitted shoes as recovery

evolves

Close monitoring and follow-up is essential which includes examination of the wound (including photographic documentation) and a footwear specialist assessment to assess the response to altered bone structure or shoes.

In elderly and disabled patients, the role of home health monitoring to deliver regular wound inspection and dressing changes should flag any concerns in a timely fashion. Use of internet communication sent to the lead physician by patients or nurses can be very helpful, as is direct phone calls to the surgeon when invasive infection is thought to be present or to be recurrent and/or worsening.

Early follow up with the surgeon is also important to determine whether surgical intervention was adequate, or if further debridement or amputation is required (Table 213.3).

Debridement

Sharp debridement by an experienced practitioner will aid healing, and can be done in the clinic or by the bedside. However, formal sharp debridement should be cautioned if there is known, treatable peripheral vascular disease. Larval (maggot) therapy is an underrated form of debridement, and is relatively easy to use. Note that they cannot remove callus, so it should not be the sole method of debridement. Debridement should precede a vascular procedure by 24 hours if a prosthetic graft is possible.

CLINICAL SITUATIONS

Tissue Loss

Dry gangrene usually does not require surgical intervention, and can be monitored allowing for autoamputation. However, wet gangrene necessitates urgent surgical intervention and usually warrants leaving the amputation site open, with topical antimicrobials treatment applied.

Microbiology

Most diabetic foot infections are polymicrobial, with aerobic gram positive staphylococci being the most common causative organisms. Oral antistaphylococcal agents have been described as taking special advantage but can be very expensive. Gram negative bacilli and obligate anaerobes are frequent copathogens and seldom warrant systemic antibiotics.

Antimicrobial therapy should depend on local guidelines based on resistance, but should consider co-pathogens as noted above. Superficial swabs can often grow misleading skin commensals or contamination. Note that while infection is common, swab testing of clinically uninfected ulcers should be avoided as this leads to confusing results and inappropriate antibiotic therapy. When infection is present, **always ascertain recent bacteriology culture and sensitivity results** from that patient to guide antibiotic choice. Failure to optimize antibiotics is a missed opportunity to help your patient, but at the same time increase resistant bacterial forms.

It is common for many diabetic foot patients to have had multiple recent courses of antibiotics. Therefore, the possibility of methicillin-resistant *Staphylococcus aureus* (MRSA) may warrant adjunctive agents such as vancomycin to address this. To the same end, many older diabetics might be at risk of *Clostridium difficile*, so this should be taken into account if a prolonged, broad spectrum agent has been or is being used. Diarrhea in patients with prolonged antibiotics is a worrisome sign.

TABLE 213.2 Clinical Classification of Infection, With Definitions

	IWGDF/IDSA Classification
Uninfected: No systemic or local symptoms or signs of infection	1 (Uninfected)
Infected At least 2 of the following items are present: ■ Local swelling or induration ■ Erythema >0.5 cm[a] around the wound ■ Local tenderness or pain ■ Local warmth ■ Purulent discharge Other causes of an inflammatory response of the skin should be excluded (e.g., trauma, gout, acute Charcot neuro-osteoarthropathy, fracture, thrombosis, venous stasis).	
Infection involving only the skin or subcutaneous tissue (without involvement of deeper tissues and without systemic manifestations as described below). Any erythema present extends <2 cm[a] around the wound No systemic signs or symptoms of infection (see below).	2 (Mild infection)

Infection involving structures deeper than skin and subcutaneous tissues (e.g., bone, joint, tendon, muscle) or erythema extending >2 cm[a] from the wound margin. No systemic signs or symptoms of infection (see below).	3 (Moderate infection)
Any foot infection with the systemic inflammatory response syndrome (SIRS), as manifested by ≥2 of the following: ■ Temperature >38°C or <36°C ■ Heart rate >90 beats/minute ■ Respiratory rate >20 breaths/minute or $PaCO_2$ <4.3 kPa (32 mm Hg) ■ White blood cell count >12,000 or <4,000/mm^3, or >10% immature (band) forms	4 (Severe infection)

[a]In any direction, from the rim of the wound; the presence of clinically significant foot ischemia makes both diagnosis and treatment of infection considerably more difficult.
From Lipsky B, Berendt A, Cornia PB. 2012 Infectious Diseases Society of America clinical practice guideline for the diagnosis and treatment of diabetic foot infections. IDSA guidelines. *Clin Infect Dis* 2012;54(12):e132–73; by permission of Oxford University Press.

Osteomyelitis

If osteomyelitis is suspected, cultures of actually involved bone are the gold standard for diagnosis and microbial culture and sensitivity testing. It is imperative to excise the infected bone with a margin of healthy cortex. This can easily be done because healthy cortex is hard and infected bone is demineralized and therefore soft, and easily felt.

NOTE: An infection going down to the bone is not automatically osteomyelitis; that occurs when the bony tissue is invaded or necrotic and requires resection of the involved bone.

If one can probe from an ulcer down to the level of the bone, the patient is at increased risk of future amputation. Other risk factors include the combination of infection and ischemia, and osteomyelitis (especially at the heel) carries an increased risk of major amputation.

TABLE 213.3 Indications for Surgical Over Medical Management of the Infected Diabetic Foot

Presence of ulcer
Crepitus
Bone involvement (confirmed osteomyelitis by plain radiograph/MRI)
Joint involvement (including septic arthritis)
Necrotizing fasciitis
Abscess
Substantial skin/muscle necrosis
Gangrene

In some settings of documented osteomyelitis, particularly if there is adequate blood supply to allow for good intravenous antibiotic penetrance in a compliant patient with reasonable glucose control, they may be eligible for conservative therapy with 6 weeks of intravenous antibiotics guided by cultures and sensitivities from bone biopsy with close monitoring. Medical treatment is protracted, complex, hard to administer, expensive, and prone to failure. Surgical resection is definitive, without complications of long-term antibiotic therapy and is simple and inexpensive compared to medical treatment. If there is clinical and biochemical resolution, and in the absence of systemic signs of infection, it is reasonable to step down to oral antibiotics if the cultures suggest sensitivity to an appropriate agent.

However, in the patient with poor compliance, progressive infection and poor vascular supply (or a failure of the above treatment), then surgical debridement is usually indicated. The approach will depend on the location and extent of infection. This may require only a single incision and drainage, but if infection is deep seated along fascial planes, filleting of the affected area is appropriate followed by specific systemic and topical antibiotics. Ray amputations often heal reasonably well, with the space filled with granulation tissue thus ultimately limiting functional loss. In the context of osteomyelitis, the metatarsal bone and the metatarsophalangeal joint can be excised, similar to a Keller procedure common for hallux valgus. MHR as described is much preferable. In these cases, it is important to dissect close to the bone itself to minimize disruption to the neurovascular bundles.

Surgical principles must be obeyed including removal of any foreign bodies, debridement of all devitalized tissues, and deep tissue culture for

bacterial identification and sensitivities. After thorough irrigation, the wound may be left open with negative pressure (V.A.C.) dressings, or closed with interrupted sutures over a corrugated drain. Prior to discharge, the patient must have competed at least 5 days of antibiotic therapy, been reviewed by physiotherapy, have clean wounds and a clear plan for dressing changes and early follow-up including limits for ambulation.

NOTE: Signs of ascending infection include spreading intense erythema, increasing induration, rigors, lymphangitis, regional palpable lymphadenitis, or hypotension.

Indications for a more **conservative** surgical approach with aggressive debridement or minor amputation, over primary amputation include:

A good blood supply to the foot
Small vessel disease and gangrenous toes
Successful arterial bypass
Neuropathic foot with little arterial disease
Osteomyelitis with little arterial disease

Debridement should go back to healthy bleeding tissue. However, the presence of wet gangrene, life-threatening sepsis, extensive muscle necrosis, and, when revascularization is technically impossible or the patient is bedridden, primary proximal amputation is preferred.

Amputation

In general, amputation can potentially result in a loss of function, loss of independence, and significant psychosocial comorbidity. However, there are circumstances when this option is in the ultimate best interests of the patient. These include:

Intractable ischemic rest pain which cannot be managed by analgesia or revascularization
Life-threatening limb infection that cannot be managed by lesser measures
Nonhealing ulcer that is accompanied by a higher burden of disease than would result from amputation, that is, a well-performed below-the-knee amputation may be better than a **nonfunctional limb**. Prostheses are always a partial answer but in fact, are seldom really used in the older aged diabetic.

Early definitive management of the problem in the absence of gangrene or vascular disease almost completely eliminates the need for amputation

when combined with regular preventive care for the remainder of the patient's life.

One should aim to eliminate infection, while preserving as much normal anatomy and function as possible. From distal to proximal, amputation can occur at the level of metatarsophalangeal, transmetatarsal (Lisfranc), mid foot, and through the ankle joint itself (Syme procedure). Where possible, a pan-MHR can avoid the biomechanical pitfalls of the transmetatarsal amputation. However, below-the-knee amputation is most amenable to a good fitting prosthesis allowing a return of function. This is especially the case compared to an above-the-knee amputation, which sacrifices the important role of the knee joint itself. For below-the-knee amputation, the authors generally prefer leaving a longer posterior skin flap (Burgess method), thus avoiding a suture line over the stump (Fig. 213.4).

Patients who have undergone amputation should remain under regular review, not just for monitoring of the stump, but half of these patients will develop an ulcer in the contralateral limb within 18 months if not under proper and active surveillance.

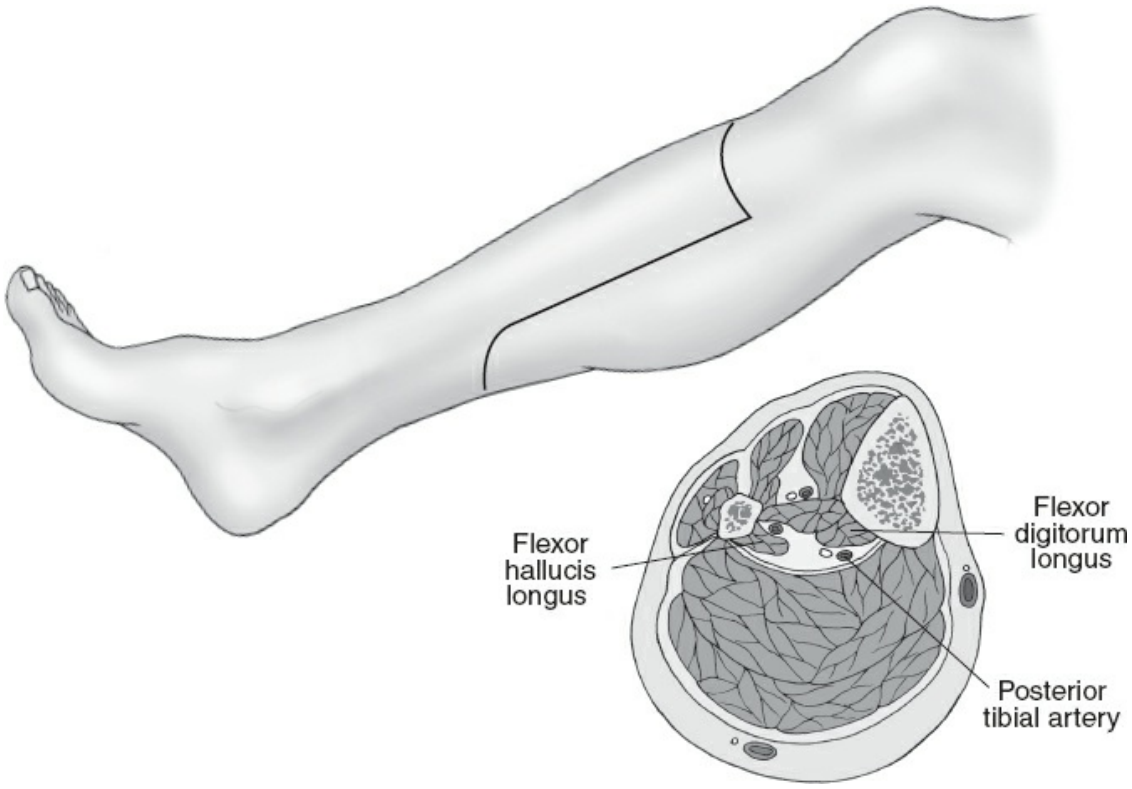

Figure 213.4. Below-the-knee (transtibial) amputation offers better function with prosthesis compared to above-the-knee amputation. The longer posterior flap can be wrapped anteriorly,

which prevents the suture line lying over the weight bearing area. (From Fischer JE, Bland KI, eds. *Mastery of Surgery.* 6th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2012. Fig. 3, Chapter 232.)

Charcot Arthropathy

Charcot joint occurs in only 0.2% of diabetics, but is very important to recognize. Joint destruction occurs due to a mixture of peripheral and/or autonomic neuropathy, osteopenia, or often repetitive trauma. The acute phase is characterized by a red, hot, swollen joint which is often painless. Sometimes this can be difficult to distinguish from osteomyelitis, and MRI can be misleading. Once recognized, initial treatment is by immobilization by nonweight bearing casting. A well-trained orthotist can construct a brace and orthotic, combined with autoinflammatory regime. **Remember: all red, hot ankle joints in a diabetic should be treated as Charcot joint until proven otherwise.**

HOLISTIC CARE OF THE DIABETIC PATIENT

Although the key responsibility of the surgeon is ensuring adequate blood supply and eliminating infection, consultation allows opportunistic assessment of all aspects of care of the diabetic. Ensure that their glycemic control is adequate and that they manage their own regimen effectively and self-monitor their glucose levels. The fact that they may be considered for surgical intervention itself is a sign of poor disease control and a failure of preventive measures. They remain at elevated risk of cardiovascular events such as stroke and ischemic heart disease. Should your patient be on special medications to those ends?

One must remember that the extremely high 5-year mortality in patients with diabetic foot disease is partly due to high rates of myocardial infarction and stroke in this population. At every opportunity smoking cessation should be encouraged, and treatments such as nicotine replacement therapy considered.

Federal pay-schemes are available for the management of the diabetic foot. Medicare pays for 6 monthly medical assessments if a formal diagnosis of diabetic sensory neuropathy is made. In addition, routine foot-care, including sanding and debridement of corns and calluses, and trimming of nails are also covered.

SUMMARY

The diabetic foot continues to carry significant morbidity for our patients, creating a huge socio-economic burden. Yet the spiral toward amputation is all too common, and frustratingly, often preventable. Patient education and empowerment in the prevention of DFUs should begin at the time of their first diagnosis of diabetes mellitus. Every consultation is an opportunity to re-educate both the patient and their caregiver about the importance of proper footwear, good foot hygiene, and close, regular self-examination for ulcers and wounds. The role of the attending surgeon is crucial and the secret to the management of diabetic foot problems is their prevention. Due to neuropathy and poor eye-sight, many patients will present relatively late with ulceration. Sanding or debridement of callus and enrollment of the patient in a skilled professional team that includes an interested and informed surgeon, are keystones in preventing progression. The surgeon must determine if there is an ischemic component to the pathology, and consider correction when at all possible. In the event of infection, one must ensure adequate drainage of abscess when required, and debridement of necrotic or diseased tissue. Should the patient require it, such as limb- or life-threatening infection, amputation should be done in a timely fashion aiming to preserve function as much as possible, while ensuring adequate source control of the infective source. Prevention, good communication with the patient and other doctors and health specialists, with close follow-up should minimize the not inevitable outcome of amputation.

EDITOR'S COMMENT

The chapter by Galbraith et al. focuses on an extremely common and troubling problem in general and vascular surgery, namely, prevention and treatment of the diabetic foot. Notably, diabetes mellitus has increased to epidemic levels, particularly type II diabetes (Mathers CD, Loncar D. Projections of global mortality and burden of disease from 2002 to 2030. *PLoS Med* 2006;3(11):e442). Foot and leg complications are a major source of morbidity and mortality for these patients. Certainly, prevention of initial foot injury is the key and the authors emphasize that fact throughout the chapter. A multidisciplinary approach seems best, and includes physical therapy, orthotics, podiatry, and vascular or general surgery. It requires the engagement and an informed patient as well. These efforts can decrease foot calluses and ulcers that directly lead to infection and subsequent amputations. The pathophysiology underlying the numerous clinical issues is cogently discussed, as are the pathobiologic processes underlying diabetic foot ulcers (DFUs).

Recently published SVS guidelines on diabetic foot care emphasize similar strategies as discussed in this chapter with regard to prevention (Hingorani A, LaMuraglia GM, Henke P, et al. The management of diabetic foot: A clinical practice guideline by the society for vascular surgery in collaboration with the American podiatric medical association and the society for vascular medicine. *J Vasc Surg* 2016;63:3S–21S). For example, annual foot inspections, physical examination with neuropathy testing, custom footwear in high-risk patients, and adequate glycemic control are evidence-based preventative measures. These measures are also likely cost effective.

The authors provide detailed recommendations to prevent injury to the diabetic foot, emphasizing good history and physical examination points. One thing that is missing is the use of the Semmes Weinstein multifilament test, which allows accurate delineation of peripheral neuropathy, and can direct these patients to prophylactic orthotic foot ware (Feng Y, Schlosser FJ, Sumpio BE. The Semmes Weinstein monofilament examination as a screening tool for diabetic peripheral neuropathy. *J Vasc Surg* 2009;50:675–82, 682 e1). The other noted absence is the use of nerve release to treat lower-extremity neuropathy.

Evidence supports the benefit of this approach for prevention of DFU and amputation (Dellon AL, Muse VL, Nickerson DS, et al. Prevention of ulceration, amputation, and reduction of hospitalization: outcomes of a prospective multicenter trial of tibial neurolysis in patients with diabetic neuropathy. *J Reconstr Microsurg* 2012;28:241–6).

Adequate arterial blood flow to promote DFU healing is critical for amputation prevention. Many times, patients with DFU have been treated for months with no improvement and no assessment of blood flow has been made. It is noted by the authors that measuring the ankle brachial index may aide assessment of perfusion and healing potential. However, as they rightly note, tibial arteries are prone to calcification and falsely elevated readings. We tend to use the toe–brachial index or better yet, transcutaneous partial pressure oxygen measure, particularly if an amputation is planned. The use of peripheral bypass and/or endovascular therapies to improve blood flow is also central in the treatment of patients who have DFU, gangrene, and so forth, and who have insufficient blood flow. Standard dogma is that pulsatile blood flow to the foot is requisite for successfully healing any type of significant tissue loss. While the techniques of revascularization may be debated and dependent on multiple factors such as anatomic location of the lesions, their extent, and patient comorbidities (Mills JL, Sr. Open bypass and endoluminal therapy: complementary techniques for revascularization in diabetic patients with critical limb ischaemia. *Diabetes Metab Res Rev* 2008;24 Suppl 1:S34–9), it is reasonable to be aggressive with these patients to prevent limb loss once an open wound is present. Patients with DFU are often younger than the more elderly arterial disease patients, and limb loss may impact the ability to keep a job.

There is evidence that tight glycemic control can decrease foot and leg problems in diabetics. In particular, a meta-analysis showed that tight as compared with standard glycemic control is associated with a decrease in major limb amputation (Hasan R, Firwana B, Elraiyah T, et al. A systematic review and meta-analysis of glycemic control for the prevention of diabetic foot syndrome. *J Vasc Surg* 2016;63:22S–28S.e1–2). For example, intensive glycemic control (HbA1c <7.5%) as compared with less intensive control is associated with a 35% reduction in amputation. This strategy should be standard.

Patients with a diabetic foot infection need to be treated as an emergency. This is well highlighted by the authors, as these patients can often have an invasive infection that if it is delayed in terms of operative drainage, may progress to a nonsalvageable foot. The so-called “septic foot” can sometimes be subtle and requires a high index of suspicion so that rapid care can be given to prevent loss of limb and potentially life. It is important to pay attention to planter tenderness in particular, as that suggests advanced infection.

It is often not clear how best to treat osteomyelitis related to a DFU. The authors note that when osteomyelitis of the foot bones is suspected, the use of

plain films may not be very sensitive. I certainly agree with this. The diagnostic test that I would add is using the Westergren sedimentation rate, which is sensitive but not specific to increase or decrease the pretest probability. The MRI is certainly the best test to diagnose osteomyelitis (Dinh T, Snyder G, Veves A. Current techniques to detect foot infection in the diabetic patient. *Int J Low Extrem Wounds* 2010;9(1):24–30) and I feel is better than radio-labeled leukocyte imaging. Use of broad spectrum antibiotics is standard and obtaining a bone culture to narrow the antibiotics is much favored as compared to using a wound swab; a practice to be discouraged. The latter practice actually may misguide antibiotic therapy, as well as waste money.

Few areas in surgery are less glamorous but as common and important as diabetic foot care. Much research is needed to produce evidence to guide prevention and treatment. Prevention of wounds are critical, and the surgeon is at the center of prevention to proper treatment for limb salvage.

Peter Henke

D ACUTE LOWER EXTREMITY ISCHEMIA

214 Embolectomy

Peter Henke

EPIDEMIOLOGY AND BRIEF PATHOPHYSIOLOGY

Acute limb ischemia (ALI), for which embolectomy remains a standard therapy, is one of the most common vascular emergencies that surgeons encounter. The incidence remains significant, but the estimated incidence has decreased from 42.4 to 23.3 per 100,000 persons between 1988 and 2007. Prompt recognition and diagnosis followed by rapid restoration of blood flow to the ischemic extremity will decrease limb loss and subsequent reperfusion-related local and remote organ injury. This disease most often occurs in aged or critically ill patients, who often have significant comorbidities, which can lead to their demise even after successful revascularization of a limb.

A useful limb ischemia categorization system is the Society for Vascular Surgery/International Society for Cardiovascular Surgery (SVS/ISCVS) joint consensus document (Table 214.1). Class I is a viable limb that is not immediately threatened, no sensory or muscle weakness is present, and arterial Doppler and venous Doppler signals are audible. Category II is a threatened limb, with IIa being marginally threatened if promptly treated, with minimal to no sensory loss, inaudible arterial Doppler signals, but audible venous Doppler signals present. Category IIb is an immediately threatened limb, which requires rapid revascularization, and is associated with sensory loss and associated mild muscle weakness with inaudible arterial and venous signals. Category III is irreversible limb ischemia, with major tissue loss or permanent nerve damage, a profoundly anesthetic and paralyzed limb, with rigor and inaudible signals. The patient whose disease falls into this category almost always requires amputation.

The pathophysiology of ALI is due to an abrupt and complete blockage

of the main arterial supply to the extremity. Unlike chronic limb ischemia, collaterals are not well developed. The distal tissue bed in the limb becomes ischemic with energy metabolism shifting from an aerobic to an anaerobic process. Progressive ischemia leads to cell dysfunction and death. Nerve cells, followed by muscle cells, are most susceptible. A patient without underlying vascular disease and an acute arterial blockage has approximately 5 to 7 hours for revascularization before irreversible functional tissue damage occurs. Upon reperfusion, release of cellular products may cause systemic organ injury, such as renal and pulmonary failure. Both these factors need to be kept in mind when treating these patients.

ANATOMY, DIAGNOSIS, AND INDICATIONS

The etiology of ALI is often an embolic process, usually a thromboembolism, and commonly from a cardiac source. This is typically observed after a patient develops atrial fibrillation with a left atrial thrombus or after a myocardial infarction with a left ventricular thrombus. Common locations of embolic lodgment are at arterial bifurcations where the artery size changes, such as the aortic bifurcation, femoral bifurcation, or popliteal artery, and less frequently at other locations (Fig. 214.1).

The diagnosis is made with a combination of history and physical examination findings. The classical findings are the six P's; pain, pulselessness, poikilothermia, pallor, parathesis, and paralysis. The clues important for determining the etiology of ALI are readily obtainable by the history and physical features (Table 214.2). Often, the location of the embolism can be determined by physical examination. For example, in a patient with new onset atrial fibrillation and right leg ALI, a nonpalpable right femoral pulse and normal left lower extremity pulse examination suggests thromboembolism, for which embolectomy would be appropriate. Conversely, an aged patient with longstanding peripheral arterial disease and claudication, who presents with a cool right lower extremity and a weakly palpable femoral pulse and only dopplerable signals in the contralateral nonaffected side, probably does not have an embolic etiology causing their limb ischemia. This patient would be best addressed with an arteriogram or computed tomography angiogram (CT angiogram) and possible endoluminal intervention.

TABLE 214.1 SVS Grade Acute Limb Ischemia

Category	Description	Neuromuscular Findings	Doppler	Intervention
I	Viable	No sensory or muscle weakness	Audible arterial and venous	Elective
IIa	Threatened (marginally)	Minimal	Often inaudible arterial, audible venous	Urgent
IIb	Threatened (immediately)	Mild to moderate, associated with pain	Usually inaudible arterial, audible venous	Emergent
III	Irreversible	Profound deficit	No signals	Emergent

Adapted from Rutherford R, Baker JD, Ernst C, et al. Recommended standards for reports dealing with lower extremity ischemia: revised version. *J Vasc Surg* 1997;26:517–38.

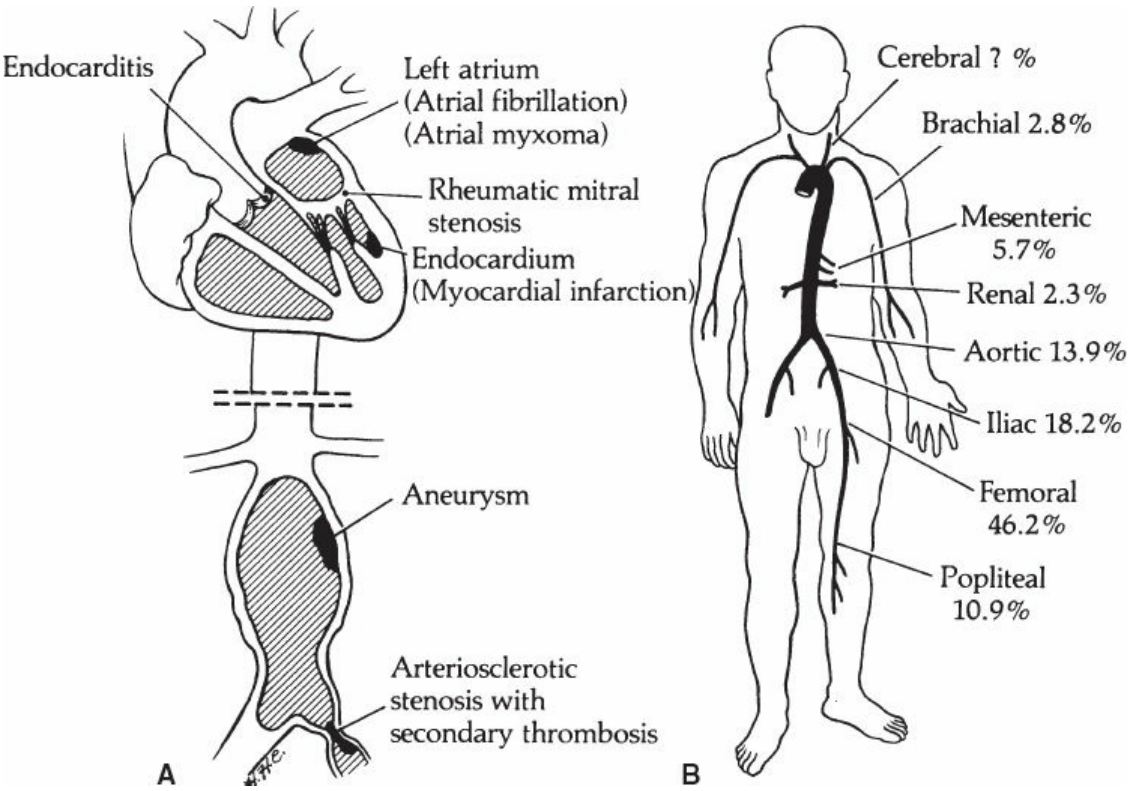

Figure 214.1. The source (**A**) and distribution (**B**) of clinically significant arterial emboli.

Other etiologies of ALI include in situ arterial thrombosis, peripheral bypass thrombosis, peripheral arterial aneurysms, trauma (popliteal artery disruption or penetrating injury), or acute aortic dissection with occlusion of the aorta or iliac arteries. These need to be considered in the differential, but will not be discussed in this chapter as they are not primarily treated with embolectomy.

Men and women are equally affected by ALI. Modern series amputation rate is 13%, mortality is approximately 7% to 10%, and the average hospital length of stay estimated for these patients is approximately 10 days. Generally, ALI does not occur in young people outside of trauma, but it may occur in young patients due to unusual

circumstances, such as paradoxical emboli, hypercoagulable disorders, popliteal artery entrapment syndrome, or in those with severe early onset cardiac disease.

TABLE 214.2 History and Physical Features of Acute Limb Ischemia

	Embolism	Others
History	Rapid onset Prior cardiac event No prior PVOD history	Vague onset or trauma No recent cardiac event History of PVOD
Physical examination	Cold, mottled, paralyzed Normal contralateral limb Clear demarcation	Cool, bluish, paresthesias Abnormal contralateral pulse examination No distinct demarcation
Etiology	Cardiac thrombus Arch plaque	Plaque rupture Hypercoagulable state Cardiac failure
Prior vascular surgery	Usually no	Often yes
Typical location	Arterial bifurcations	Long segment occlusions, diffuse
Most common ischemic class	IIb	IIa

PVOD, peripheral vascular occlusive disease.

Excellent judgment is needed for late SVS grade III limb ischemia. While perhaps obvious, it is important not to attempt embolectomy in those with nonrecoverable ischemia, as the tissue is not viable. Sometimes, the limb examination is marginal, and revascularization with reassessment of tissue viability is reasonable with close observation and a low threshold to amputate if warranted by clinical status. Frank discussion with the patient and their family is important, as there is high potential for limb loss, and setting expectations is critical.

Two primary factors underlie the morbidity and mortality that result from ALI: the patients' underlying comorbid illness and delay in recognition and revascularization of the limb(s). It is uncommon that embolectomy itself will directly cause death. In a mixed etiology of ALI, factors associated with amputation-free survival (AFS) have been evaluated. Decreased AFS is associated with non-Caucasian race, older age, a history of neurologic disease, malignancy, congestive heart failure, and low body weight. Not surprisingly, skin mottling and rest pain are

associated with increased risk of amputation. Another study suggested that ALI-related mortality was increased with delay in treatment of ischemia, significant underlying atherosclerosis, and poor arterial back bleeding at operation.

Selection of appropriate therapy is also an important factor to decrease amputation occurrence and mortality. While strong evidence suggests equivalence of endovascular or surgical therapies, as measured by mortality and amputation, the etiology of the ALI needs to be factored into this equation. Two landmark articles were published in the 1990s, which suggested that thrombolytic therapy had equivalent outcomes to surgical therapy in patients with ALI. These were the Surgery or Thrombolysis in Lower Extremity Ischemia (STILE) and Thrombolysis or Peripheral Artery Surgery (TOPAS) trials, which randomized patients to arteriography and thrombolytic therapy with urokinase, versus arteriography and embolectomy or urgent bypass. While these data are compelling, a majority of patients in both of these trials had class I and IIa ischemia, with <25% having class IIb or III limb ischemia, for which embolectomy is most commonly performed. A large national database study suggested that in those patients with an embolic etiology (generally stage IIb ischemia), amputation is significantly less likely with embolectomy, but not thrombolytic therapy. Importantly, patients who failed thrombolytic therapy had a significantly greater risk of amputation and death. The bottom line is that providers must choose the appropriate therapy very carefully for patients with ALI.

PERI- AND POSTOPERATIVE MEDICAL THERAPY FOR ACUTE LIMB ISCHEMIA

Patient management includes intravenous fluid resuscitation, without potassium, immediate anticoagulation (if no contraindications), and all patients should receive per oral or per rectum aspirin (Fig. 214.2). Standard chemistry and hematology laboratory screening should be done, including a type and screen. Consideration of intravenous mannitol to induce a diuresis, as well as yielding some oxygen radical protection, should be given. It is also reasonable to alkalinize the urine if myoglobinuria is present. Similarly, while no level I evidence exists, use of extracorporeal renal support with CVVHD in patients who have significant tissue ischemia and acute renal insufficiency makes sense to decrease potentially fatal reperfusion hyperkalemia that may result. This

therapy can be ongoing with the patient in the operating room.

It cannot be emphasized strongly enough that all patients with ALI receive rapid, full anticoagulation (except if actively bleeding). This is typically with heparin, with an intravenous bolus of 100 to 150 U/kg, and then titrated to maintain an activated partial thromboplastin time (aPTT) of two to two-and-a-half times baseline. If the patient has a known history of heparin-induced thrombocytopenia or an anti-thrombin deficiency, alternative agents, such as direct thrombin inhibitors (lepirudin or argatroban), can be used and aPTT can be used to guide dosage.

Laboratory markers may help predict major amputation risk in those with ALI. For example, creatinine phosphokinase (CPK) elevation and neutrophilia upon presentation confer a tenfold increased risk of amputation, as compared to those without CPK elevation. It is not clear if CPK elevation after revascularization carries the same prognosis, but is unlikely, as washout of the ischemic tissue bed normally occurs.

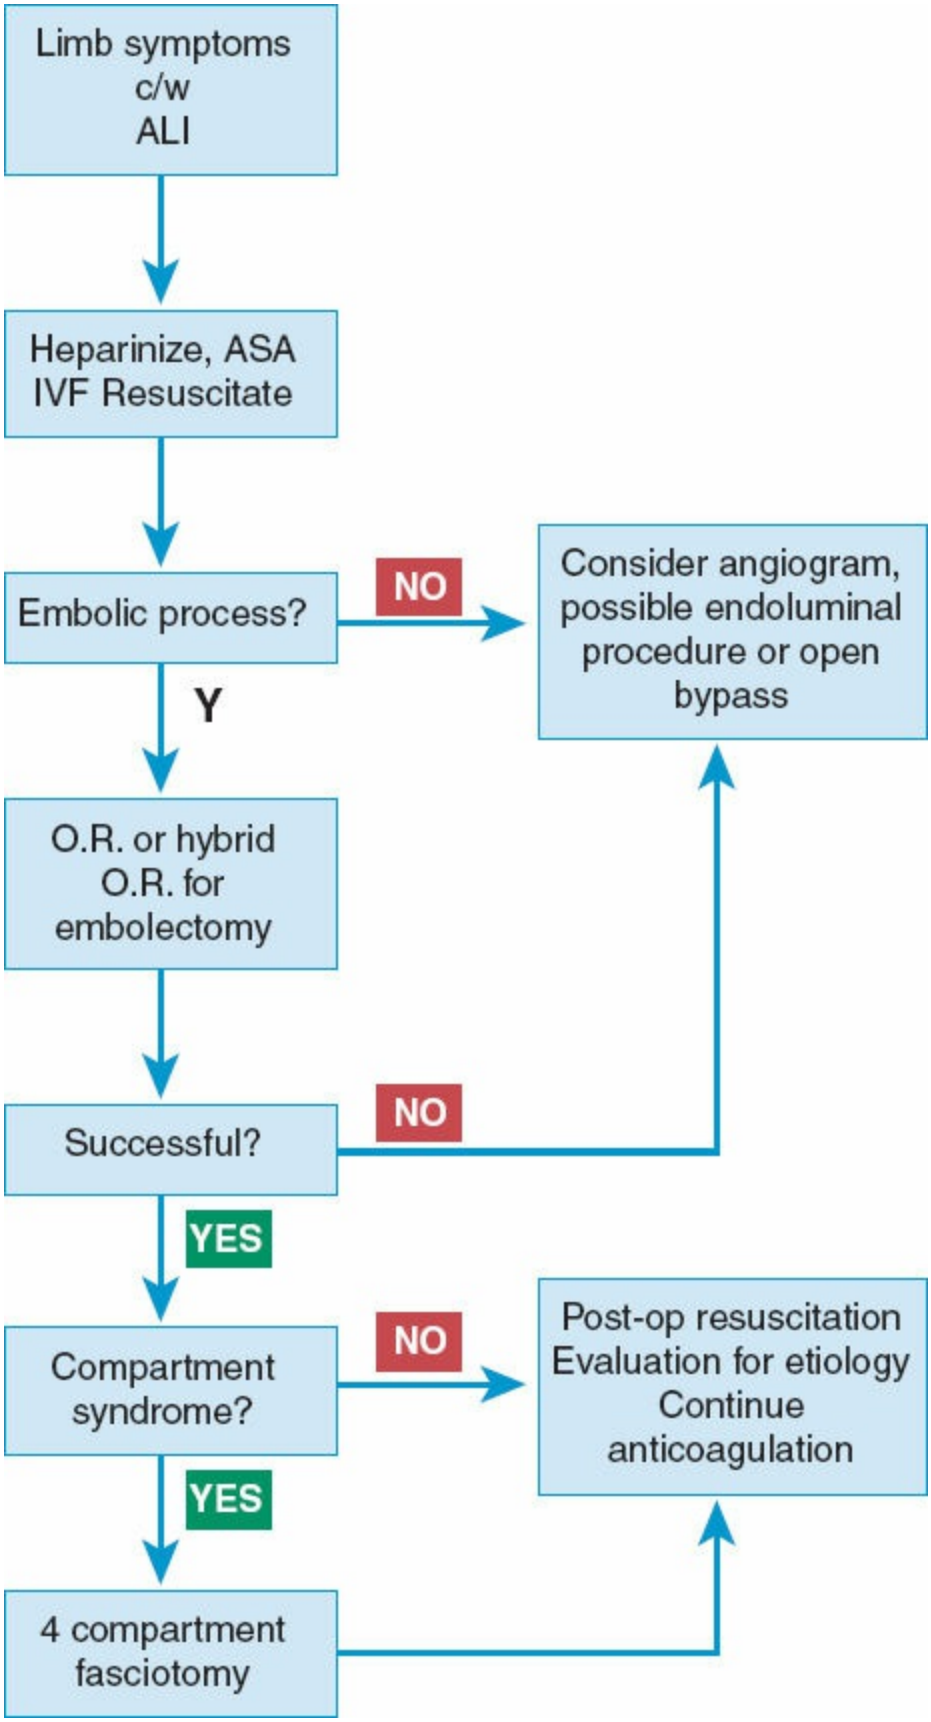

Figure 214.2. Algorithm of treatment for acute limb ischemia (ALI) and catheter embolectomy. ASA, aspirin; OR, operating room.

OPERATIVE SETTING, TECHNIQUES, AND EXPOSURE

Most modern hybrid operating suites have endovascular capabilities with either fixed equipment or a high-quality C-arm and a full array of catheters, wires, and balloons. Rigid distinction between endoluminal and surgical revascularization for ALI is outdated, but is presented below for purposes of clarity and for those surgeons without these resources.

Embolectomy Catheter Basics

The standard embolectomy catheter is a hollow, pliable catheter body with a soft, distensible balloon placed at its tip. It is available in graduated sizes from No. 2 to 7 Fr. A syringe fitting at the proximal end allows controlled inflation and deflation of the balloon. The smaller catheters are constructed with a flexible spring tip to decrease the chance of intimal damage or arterial perforation. Each catheter size has an optimal level of balloon distention, and that recommended volume should not be exceeded.

Saline solution is the routine used for balloon inflation; however, air is more appropriately used with the No. 2 and 3 French catheters. Because air is considerably more compressible than saline solution, the balloon exerts less force on, and is less likely to cause damage to, the smaller vessels.

The general aspects of embolectomy catheter use are as follows: The instrument is threaded into the artery and passed either through the thrombus or between the thrombus and the vessel wall. Although the pliability of the catheter tip is designed to facilitate safe proximal or distal passage, forceful probing at sites of nonembolic obstruction can lead to vessel wall dissection or perforation. When the appropriately sized catheter has been gently advanced as far as possible, the balloon is progressively inflated while the catheter is being slowly withdrawn all in a single continuous motion. Inflating the balloon while static can damage or rupture the artery (Fig. 214.3). The surgeon who withdraws the catheter should also control balloon size because the “feel” is an important factor in ensuring complete clot retrieval and preventing vessel damage. When pull-back catheter resistance appears excessive, it is imperative to allow sufficient balloon deflation to permit smooth passage across segments of atherosclerotic luminal narrowing. As catheter withdrawal continues, reinflation of the balloon should occur to maintain gentle wall contact (Fig. 214.4). Embolic material and associated thrombus do not offer significant resistance to catheter advancement. Usually two to three passes with no further clot suggest complete clearance.

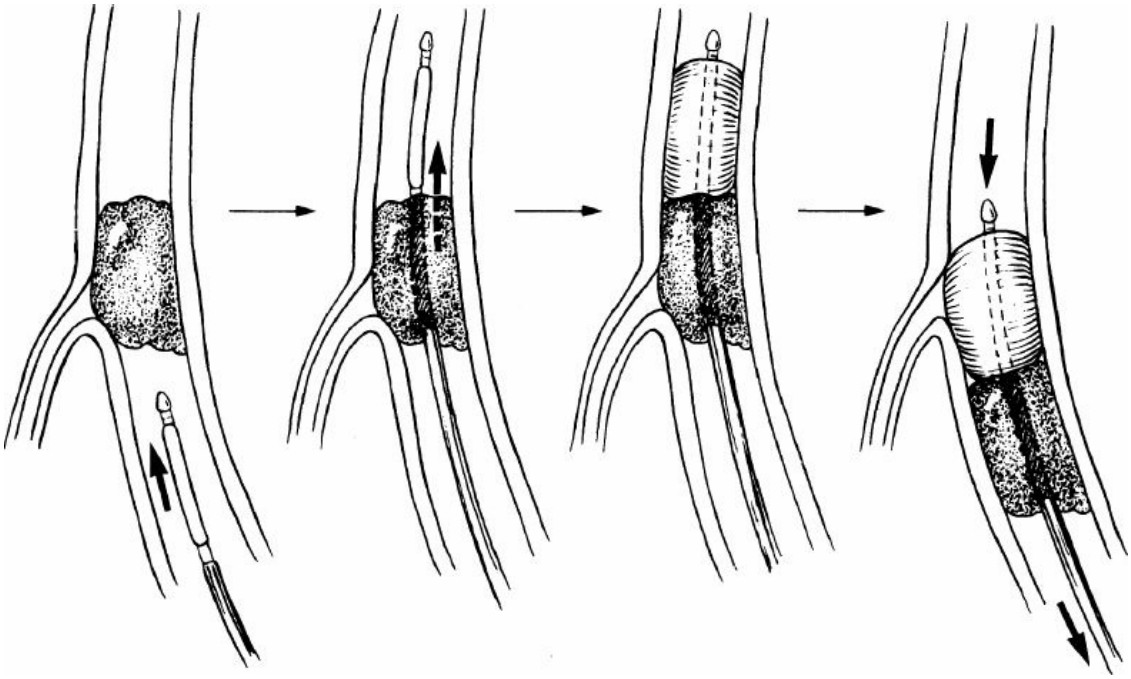

Figure 214.3. The technique of balloon catheter embolectomy with catheter insertion in the distal vessel.

Passage of the catheter may be hindered by angulation at bifurcations or by vessel tortuosity. Maneuvers often helpful in these circumstances include preforming the tip of the catheter at an angle, followed by the rotation of the catheter at the site of obstruction, the simultaneous introduction of more than one catheter, or the progressive flexion of a nearby joint to alter the advancement angle of the catheter tip. An additional technique particularly useful in passing an eccentric plaque involves gentle balloon inflation at the site of the difficult catheter passage, followed by gentle advancement of the catheter during deflation. This maneuver brings the catheter tip away from the wall and toward the residual lumen.

Removal of Mature Adherent Thrombotic Material

The standard fluid or air-filled Fogarty balloon catheter is usually sufficient for removing soft, fresh thrombus, but it is limited in its ability to remove more adherent material, such as older clot of thrombotic origin. Two devices can be used for tenacious clot: the adherent clot catheter (ACC) and the graft thrombectomy catheter (GTC).

The ACC consists of a No. 4 or 6 French flexible catheter body with an adjustable-pitch, corkscrew-shaped distal tip. The corkscrew balloon consists of a latex balloon membrane covering an outer cable that is

loosely spiraled around an inner wire, running the length of the catheter to a control handle at the proximal end. The control handle allows the surgeon to adjust the pitch and diameter of the corkscrew from straight to fully spiraled.

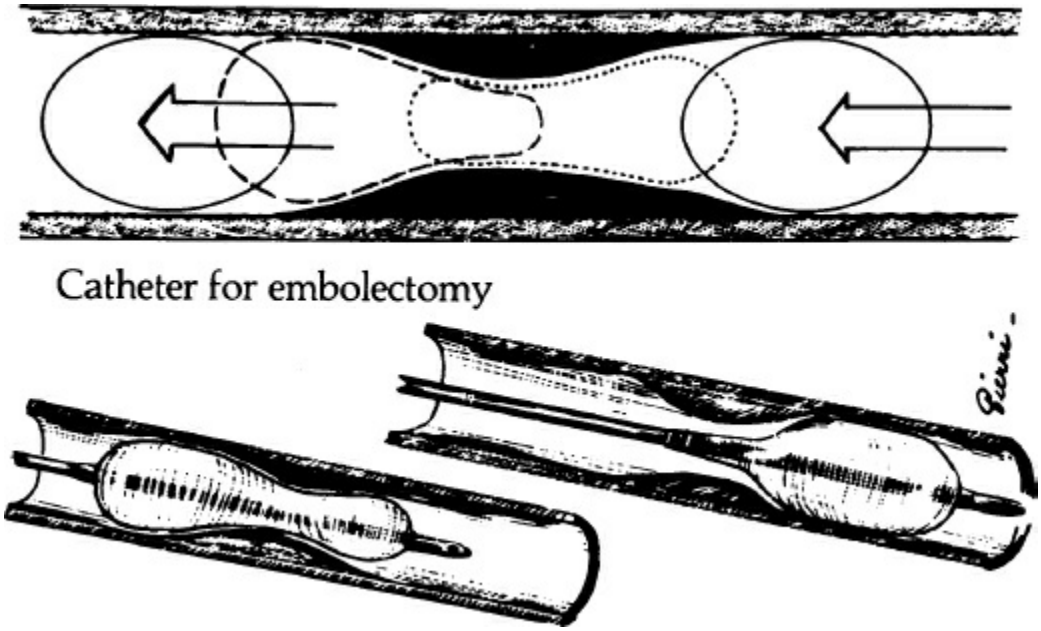

Figure 214.4. Fluid displacement in the specially designed balloon maintains wall contact while minimizing the potential for vessel wall injury.

The ACC is used like the conventional balloon embolectomy catheter. After initial exploration with the standard balloon catheter, the ACC tip is collapsed to its low-profile position and passed into the vessel and beyond the thrombus. The knob on the control handle is then retracted until the spiral is enlarged to the desired diameter, thereby engaging the thrombotic material within the interstices of the spiral. Subsequently, the catheter is drawn slowly back along the vessel and the material is removed through the arteriotomy. The diameter of the spiral can be adjusted according to "feel" in response to resistance within the vessel. The catheter system is appropriate for vessels whose diameters range from 4 to 10 mm, but care is essential for minimizing vessel damage.

The GTC is similar to the ACC, but only for use in synthetic grafts. It consists of a No. 5 or 6 French flexible catheter body; a noninflating, adjustable-diameter, spiral-wire retrieval region with a flexible tip; and a control handle. Unlike the ACC, however, the double-helix-wire region of the GTC is shorter and sturdier, and its wires are not covered by latex. The

exposed spiral wires collapse to ~4 mm and can expand to >16 mm.

Surgical Technique: Extraction of Aortic and Iliac Emboli

The patient is widely prepped and draped as the need for an operative inflow bypass (e.g., femoral to femoral or axillofemoral bypass) may need to be done if embolectomy to restore inflow is unsuccessful and endovascular options are not readily available.

The presence of back bleeding is no assurance that distal patency has been established, because collateral circulation may result in vigorous back bleeding, even in the presence of distal arterial thrombus. If the status of the distal arterial tree is uncertain, intraoperative angiography should be performed. Similarly, if the patient has obstructed outflow or signals are not present at the ankle after retrieval of thrombus, an angiogram should be performed to document any residual thrombi or native arterial lesions that may cause recurrent limb ischemia.

In the surgical management of an aortic embolus, bilateral vertical groin incisions are made and the common, superficial, and deep femoral (profunda femoris) arteries are isolated and looped with silastic (polymeric silicone) tapes. Use of intraoperative handheld duplex or Doppler can speed directed dissection for the femoral artery when a pulse is not present.

After positioning of the clamp high on the common femoral artery, the arteriotomy should be made in the common femoral artery, just proximal to its bifurcation, to allow direct visualization of the superficial and deep femoral orifices. The vessel should be carefully palpated and the location of plaque should be noted. Although it is standard to perform a transverse arteriotomy to avoid narrowing the artery during closure, the presence and location of plaque may dictate tangential or longitudinal incision. At the time of closure, if luminal narrowing results from a primary repair, one should plan to perform a vein or bovine pericardium patch angioplasty. Often, thrombus can be directly removed with forceps at arterial entry to aid proper catheter placement in the lumen.

The distal embolectomy of the superficial femoral artery is usually done first (Fig. 214.5). Depending on the size of the vessel, a No. 3 or 4 French catheter is gently introduced into the superficial femoral artery as far as possible distally and inflated until the arterial wall presents mild resistance. The catheter is then extracted, with the balloon in the inflated position. The material is extracted and should be sent to pathology. The

deep femoral artery is explored in a similar manner, but the No. 3 French catheter in this vessel rarely passes beyond a distance of 25 cm. Care must be taken so that the catheter is introduced into the deep femoral artery and not into one of the large circumflex branches, which has an early origin from this vessel.

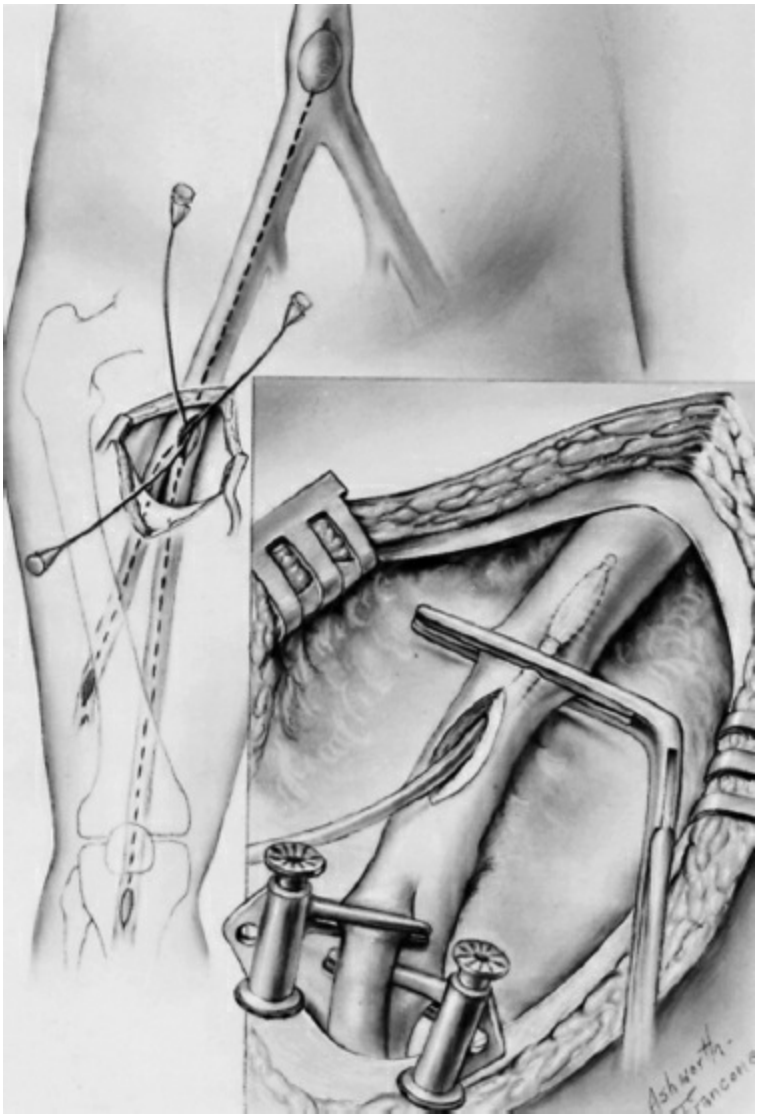

Figure 214.5. Technique of catheter arterial embolectomy of the iliofemoral system.

After successful exploration of the distal arteries as suggested by back bleeding and no further clot, 25 to 50 mL of heparinized solution (5,000 units of heparin in 250 mL of injectable saline solution) is injected into the distal artery. Occasionally, direct injection of 10 mg tissue plasminogen activator with controlled inflow is helpful for small artery distal branch thrombi. Similarly, injection of nitroglycerine (100 to 200 mcg) or

papaverine (10/mg) may help with arterial spasm. A No. 5 to 6 French embolectomy catheter is placed in the common femoral artery and threaded into the aorta. The balloon is inflated with the appropriate amount of fluid and extracted in the inflated position. During the process of extraction, the balloon can be deflated to accommodate a narrowed vessel. The procedure should be repeated if forceful, pulsatile flow is not obtained on the first passage. Significant bleeding, even somewhat pulsatile, may occur from the proximal common femoral artery in the presence of partial continued obstruction, and repeated passes should be made until one is confident that all obstructing thrombi have been removed. After adequate extraction of the clot from one side, a similar procedure is performed on the opposite limb. Both arteriotomies are closed with polypropylene suture after ensuring bilateral simultaneous pulsatile flow. The groins are closed in layers and the skin with subcuticular suture.

In the removal of an isolated iliac or proximal femoral artery embolus, the incision is made only on the affected side in the same manner as described above. Both limbs are prepared for surgical incision because of the small, but real possibility of dislodging a high iliac embolus, with subsequent occlusion of the previously unaffected contralateral vessel.

Extraction of Femoral and Popliteal Emboli

When thrombus remains in the distal popliteal and/or tibial vessels and efforts to remove it from the common femoral artery (CFA) approach prove unsuccessful, a direct approach to the below the knee popliteal artery is required. This is done through a second incision made medially just below the knee. The distal popliteal artery is exposed, and the proximal portions of the anterior and posterior tibial arteries as well as the peroneal artery are looped with Silastic tapes (Fig. 214.6). Note that division of a large crossing tibial vein may be necessary. Through a transverse incision in the distal popliteal artery, No. 2 or 3 French embolectomy catheters should be directly introduced into the anterior, peroneal, and posterior tibial arteries, respectively. If these vessels were previously patent and uninvolved in an arteriosclerotic process, the No. 2 French catheter should be passed beyond the ankle joint. The course of the catheter can be felt by placing the fingers over the distribution of the anterior and posterior tibial arteries. If the catheter is hindered at the ankle joint, it can frequently be passed farther by plantar flexion of the foot.

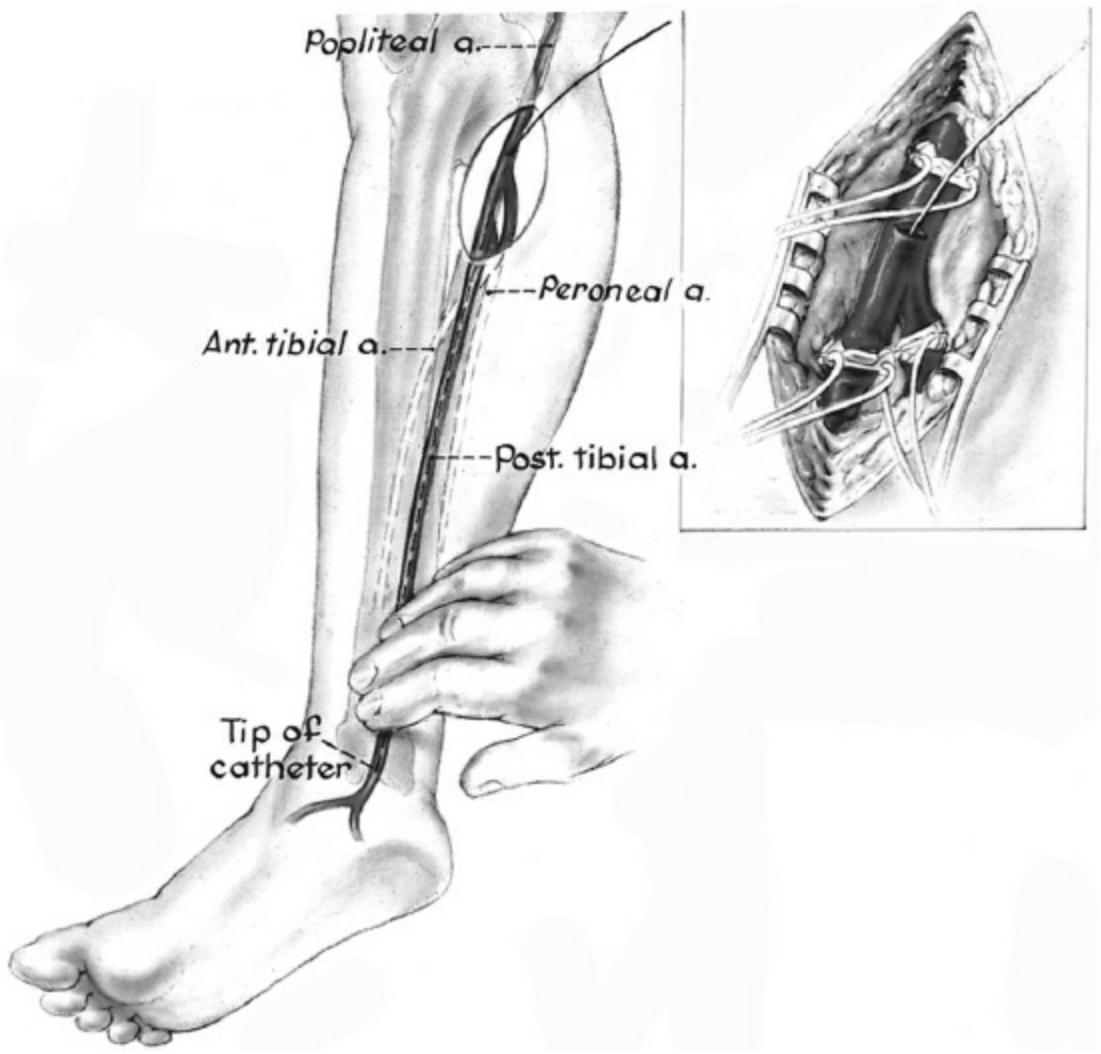

Figure 214.6. Technique of popliteotibial exploration and embolectomy.

Inability to pass a No. 2 French catheter beyond the ankle joint in the presence of angiographic evidence of obstruction beyond this point necessitates direct exposure of the anterior and posterior tibial arteries at the ankle. By direct manipulation of the vessel, combined with gentle simultaneous probing of the catheter from the proximal end, the catheter often passes beyond the point of obstruction without the necessity of an arteriotomy. If an arteriotomy at the ankle level in either of these vessels is required, a transverse arteriotomy—only large enough to allow the introduction of the No. 2 French catheter—is made. The catheter is threaded distally, inflated, and withdrawn in the inflated condition. This maneuver frequently brings the thrombotic material above the small arteriotomy. Additional attempts to extract this thrombotic material should be made by introducing a No. 2 or 3 French catheter into either the anterior

or posterior vessels at the level of the popliteal arteriotomy. This maneuver avoids the necessity of enlarging the arteriotomy at the ankle joint and decreases the possibility of reocclusion. After removal of the thrombotic material, copious irrigation of the distal arterial system should be carried out with a heparinized solution. Once successful, arteriotomies are closed with interrupted monofilament polypropylene suture.

Extraction of Upper Limb Emboli

The technique for embolectomy of the upper limb arteries is identical to that described for the lower limb. Proximal subclavian artery emboli can be routinely removed under local anesthesia by retrograde extraction from a brachial arteriotomy. The standard approach is operative exposure at the distal brachial artery in the proximal forearm, with a transverse or S-shaped incision. Here, the brachial, radial, and ulnar arteries can be encircled and accessed with the balloon catheters. Care must be maintained that if the embolus resides in proximity to the origin of the cranial vessels, fragmentation of the embolus may occur during manipulation, resulting in stroke.

Endovascular Therapy

Arteriography and thrombolysis should be considered in patients in whom the etiology of ALI is unclear or the history and physical examination strongly suggest a diagnosis of arterial or graft thrombosis in situ (Table 214.3). Endovascular therapy is also appropriate in most instances of nonembolic ALI (stage IIa), as mean thrombus lysis times may be 12 to 24 hours.

The technique itself is consistent with standard catheter etiquette and principles. Usually, the unaffected contralateral femoral artery is cannulated and an aortic outflow arteriogram performed to define the exact location and extent of blockage. A guide wire, such as one with a Teflon coating, is passed through the segmental thrombus. A multisidehole catheter follows and the entire thrombus is laced with the lytic agent. Heparin is given at a low dose (e.g., ~300 U/h) through the side port of the sheath to prevent catheter-associated thrombus development. The infusion (usually 1 mg/h of tPA) is maintained for at least 12 hours and reimaging is done to determine success of thrombus dissolution. Thrombolytic success can be followed by clinical examination as evidenced by improvement in limb temperature, capillary refill, pulses,

and patient symptoms. It is quite common for the patient to have significantly more pain with early lysis that over several hours improves that the distal thrombus shower resolves.

TABLE 214.3 Take Home Points

Caveats:

1. Pull the embolectomy catheter as you inflate the balloon, and make it one continuous motion; do not force the catheter
2. Always systemically and fully anti-coagulate (unless active bleeding)
3. If you think about the need for a fasciotomy, then you should do it
4. For massive lower extremity ischemia and acute renal failure, consider active ongoing CVVHD while in the OR during the embolectomy and reperfusion
5. Arteries that reclot intraoperatively or immediately postembolectomy have an uncontrolled and untreated embolic source; consider angiography and intervention
6. Do not perform embolectomy on patients with advanced grade III ischemia; save life over limb and amputate
7. If you have access to a hybrid OR, consider using this for all cases

While an over-the-wire embolectomy balloon catheter is available and useful in situations where occlusive disease is present, newer endovascular mechanical thrombolytic techniques and devices, including catheter suction thrombectomy, thrombus fragmentation/aspiration (rheolytic), and ultrasound energized wires are becoming more commonly used. Promising early results have been published with techniques done in native arteries, the pulmonary artery circulation, and arteriovenous prosthetic access

grafts. Many of these catheter devices also allow concurrent pulse spray of the lytic agent. Larger clinical experience will better define their role in patients with ALI, but this technology has the potential to minimize the two main drawbacks of endovascular ALI therapy: long duration of thrombolytic infusion needed to reestablish arterial perfusion and hemorrhagic complications.

POSTOPERATIVE MANAGEMENT AND COMPLICATIONS

Patients who are critically ill may undergo a thromboembolectomy under local anesthesia if necessary. Typical complications from a surgical thromboembolectomy include infectious, hemorrhagic, and cardiac events. The severity of postoperative complications is often determined by the patient's premorbid state. Groin incision complications are most frequent.

In almost all instances, anticoagulation with intravenous heparin should be continued through the procedure and until the patient is fully anticoagulated with a vitamin K antagonist (VKA), started ~24 hours after the procedure. Hematomas are not uncommon, and a drain for 24 to 48 hours may be useful. The VKA is continued for at least 6 months. If the patient has a major bleed not related to the surgical site, anticoagulation must be stopped and only restarted once the bleeding source is identified and treated. Needless to say, this is a hazardous state for the patient as early recurrent thrombosis increases if anticoagulation is not provided for.

Early ambulation is encouraged, and ACE wraps may be helpful for edema. During the early postoperative period, an echo and CT angiography (CTA) of the chest, abdomen, and pelvis should be done to find the source of the embolus. If this occurs in a younger patient without a source, a thrombophilia workup should commence, including a deep venous thrombosis (DVT) scan to search for a paradoxical embolism.

Repeated procedures after embolectomy are not uncommon. These include need for repeat thrombectomy, exploration for bleeding, fasciotomy, or other procedures. Recurrent loss of pulses often signals a proximal lesion exists that can be treated with an endoluminal procedure if not diagnosed ahead of embolectomy. Hybrid operating suites are valuable for these situations, particularly with upper extremity emboli. If a vascular reconstruction is warranted, it should be performed early. A high incidence of limb loss and mortality accompanies subsequent episodes of rethrombosis, as does a sicker patient.

As a cause of ALI, an occluded aortofemoral limb is not an uncommon problem. In this situation, the ACC is useful for thromboembolus extraction. However, an arteriogram with proximal stent or a covered stent graft limb relining is often necessary if the proximal limbs are kinked or if a stenosis is found proximally. These patients too should be anticoagulated.

Whether long-term anticoagulation is required after acute thromboembolic limb ischemia is not clear if the underlying cause has been corrected. Our practice has been to continue the VKA for at least 6 months if bleeding risk is not excessive. Certainly, there are risks with prolonged anticoagulation, and these must be balanced against recurrent embolism. Non-vitamin K oral antagonists may be safer and easier to administer than coumadin, and thus should be considered once trials show safety and efficacy, although no data yet exist.

Lower extremity four-compartment fasciotomies are routinely performed to prevent a postreperfusion compartment syndrome, in the setting of class IIb and III ischemia with surgical thromboembolectomy. Fasciotomy may need to be done after successful thrombolysis as well (see Chapter 215 for fasciotomy description). Thus, frequent neurovascular extremity examinations are essential during ongoing lytic therapy.

EDITOR'S COMMENT

In this chapter, Peter Henke does a nice job of describing the standard surgical technique of open embolectomy. This advance made possible by the creation of the Fogarty balloon (Green RM, DeWeese JA, Rob CG. Arterial embolectomy before and after the Fogarty catheter. *Surgery* 1975;77:24–33) has clearly saved thousands of limbs and is a significant advance on the use of systemic heparin alone. Having practiced with Dr. Henke for a decade, I know he is dogmatic about the use of high doses of heparin being given to the patient even in transport prior to going to the operating room (OR) or endosuite. This is meant to ameliorate further clot propagation, but also usually has some vasodilatory properties that make the patient feel better.

While the performance of this operation is well described in this chapter, it is amazingly clear to me that these patients are anything but straightforward. The patients almost always present with multiple comorbidities that just make taking them to the OR for a "quick little embolectomy" anything but quick and little. Multiple questions arise on these patients including—where was the source of the embolus, is this an embolus or thrombosis in situ, and should we try a course of thrombolytics first?

Little is written on the above questions, but there are some useful data worth reviewing. A paper from 2008 tried to determine the clinical and echocardiographic measures governing thromboembolism destination in patients with nonvalvular atrial fibrillation (McBane RD, Hodge DO, Wysokinski WE. Clinical and echocardiographic measures governing thrombolembolism destination in atrial fibrillation. *Thromb Haemost*

2008;99:951–5). Embolism occurred to the periphery 85% of the time, as opposed to the cerebral vasculature. In addition, lower extremity involvement was twice as common as the upper extremity. Severe left ventricular dysfunction, spontaneous echo contrast, and left atrial thrombus were two- to threefold more common in peripheral embolism patients, while mean CHADS-2 scores were low and comparable for both groups. This of course does not answer the question as to whether patients with peripheral emboli should get an echo or not before they go to the OR. I think it is always prudent to get one, but I note that some thin slice CT scanners can also determine if thrombus is present in the atrium or ventricle, and in these circumstances an echo may not be needed.

Part of the workup for patients with evidence of peripheral emboli, in addition to an echocardiogram and electrocardiogram, is a CTA of the chest, abdomen, and pelvis. Therefore, we are also often asked to look at CT scans with aortic pathology that looks like a source of peripheral emboli. These lesions are almost always in the descending thoracic aorta and very scary looking (I know that is not really scientific, but how else do you best describe a pedunculated mass floating in the descending thoracic aorta). A recent paper from the group at Pittsburgh I believe is the largest series to look at these lesions (Jeyabalan G, Wallace JR, Chaer RA, et al. Endovascular strategies for treatment of embolizing thoracoabdominal aortic lesions. *J Vasc Surg* 2014;59:1256–64). In their series of 25 embolizing aortic lesions, 16 (64%) presented with peripheral embolic events and 6 with renal emboli. While only 8 patients were tested, 4 of them had a hypercoagulable state. Twenty-four percent of patients had aneurysm disease present. Importantly, the majority of the patients (19) had chronic kidney disease. The 1-year mortality of this group was 25%!

Dr. Henke in his chapter originally suggested that *most* of these cases should be done in a hybrid OR. I have to say that I edited that to read **all** cases should be done in a hybrid OR. There are multiple modalities that can be used during these cases, and therefore being in a hybrid OR allows you do an over-the-wire embolectomy, suction embolectomy, as well as completion angiogram. While the dogma used to be that one needed a palpable pulse to leave the OR following an embolectomy, it is very reassuring to leave the OR with angiographic evidence of flow to the foot *and* a palpable pulse in the foot.

Finally, after reviewing this chapter my thoughts were how long do we leave patients on anticoagulation following a peripheral arterial embolus. There is a lot written about this related to deep venous thrombosis (DVT) and pulmonary embolus, as well as in peripheral arterial disease (Kearon C, Akl EA, Comerota AJ, et al.; American College of Chest Physicians. Antithrombotic therapy for VTE disease: Antithrombotic Therapy and Prevention of Thrombosis, 9th ed: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines. *Chest* 2012;141(2 Suppl):e419S–94S; Alonso-Coello P, Bellmunt S, McGorrian C, et al.; American College of Chest Physicians. Antithrombotic

therapy in peripheral artery disease: Antithrombotic Therapy and Prevention of Thrombosis, 9th ed: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines. *Chest* 2012;141(2 Suppl):e669S–90S) but little about peripheral arterial emboli. I think my answer rests on the DVT literature, but also has to do with the root cause of the peripheral emboli and whether it has been adequately managed (i.e., atrial fibrillation now in sinus rhythm for some time, etc.). I suspect a minimum of 6 months of anticoagulation is reasonable, but I really only base that on our current management of DVT.

Gilbert R. Upchurch

215 Fasciotomy

Jonathan L. Eliason

ETIOLOGY AND PATHOPHYSIOLOGY

A discussion of the surgical procedure known as fasciotomy cannot occur without understanding the underlying pathophysiologic changes that necessitate its use. Compartment syndrome (CS) is the condition that results in the need for fasciotomy, and although CS can occur in the abdomen, upper extremity, or lower extremity, the scope of this chapter will be restricted to the lower extremity. The principles discussed here apply to other anatomical compartments within the body, however. Osseofascial boundaries within the leg that surround muscles, nerves, and blood vessels are nonelastic and form compartments. When the pressure within a given compartment impairs perfusion across tissue capillary beds, CS will ensue. Although the etiologies of CS are varied (trauma, ischemia-reperfusion injury with muscle swelling, etc.), the common pathway for injury is anoxia on a cellular level. If left untreated, a stepwise progression of nerve dysfunction, rhabdomyolysis, and blood vessel compression will occur, ultimately resulting in ischemic necrosis of the tissues within that compartment. The ensuing chapter will include discussion of fasciotomies performed for the prevention and/or treatment of CS in the gluteal region, thigh, and leg.

A thorough understanding of the compartments of the lower extremity is necessary to recognize CS and inform appropriate diagnostic and therapeutic treatments, including the gluteal, thigh, and leg regions. The gluteal region is commonly thought of as a single compartment. However, the fascial boundaries really form three distinct compartments, each surrounding a primary muscle group. The largest compartment surrounds the gluteus maximus. The next compartment surrounds both the gluteus medius and minimus muscles. Finally, a third smaller compartment includes only the tensor fascia lata (Fig. 215.1). The sciatic nerve is the most notable neurovascular structure affected by gluteal CS, and it lies under the gluteus maximus muscle, exiting from the inferior border of the piriformis muscle. The inferior gluteal artery and nerve, which supply the

gluteus maximus muscle, and superior gluteal artery and nerve, which through a complex branching pattern supply the remaining compartments, are also noteworthy (Fig. 215.2).

Three functional and osseofascial boundaries are present in the thigh as well. The anterior compartment contains the quadriceps, sartorius, iliopsoas, and pectineus muscles. This compartment also contains the femoral artery and vein, as well as the femoral, and lateral femoral cutaneous nerves. The posterior compartment contains the biceps femoris, semimembranosus, and semitendinosus muscles, as well as the posterior portion of the adductor magnus muscle. The sciatic nerve lies within this compartment. The medial compartment includes the gracilis, adductor longus, adductor brevis, most of the adductor magnus, and the obturator externus muscles. The obturator artery and vein and obturator nerve lie within this compartment (Fig. 215.3).

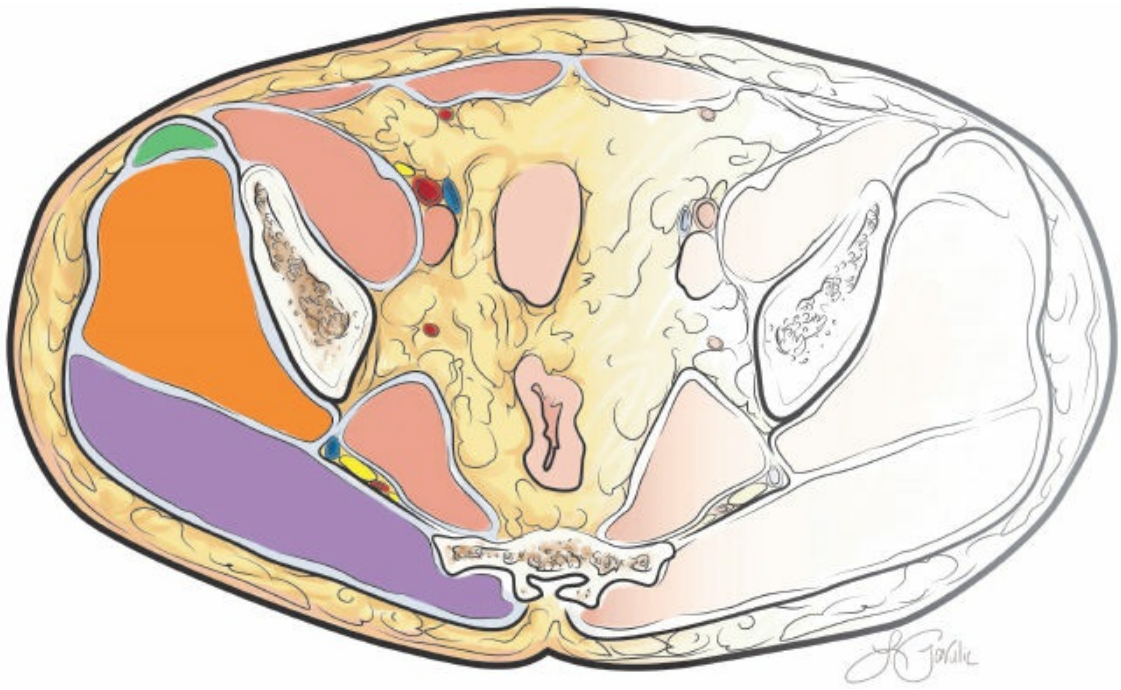

Figure 215.1. Axial view of the pelvis denoting the gluteus maximus compartment in purple, gluteus medius/minimus compartment in orange, and tensor fascia lata compartment in green.

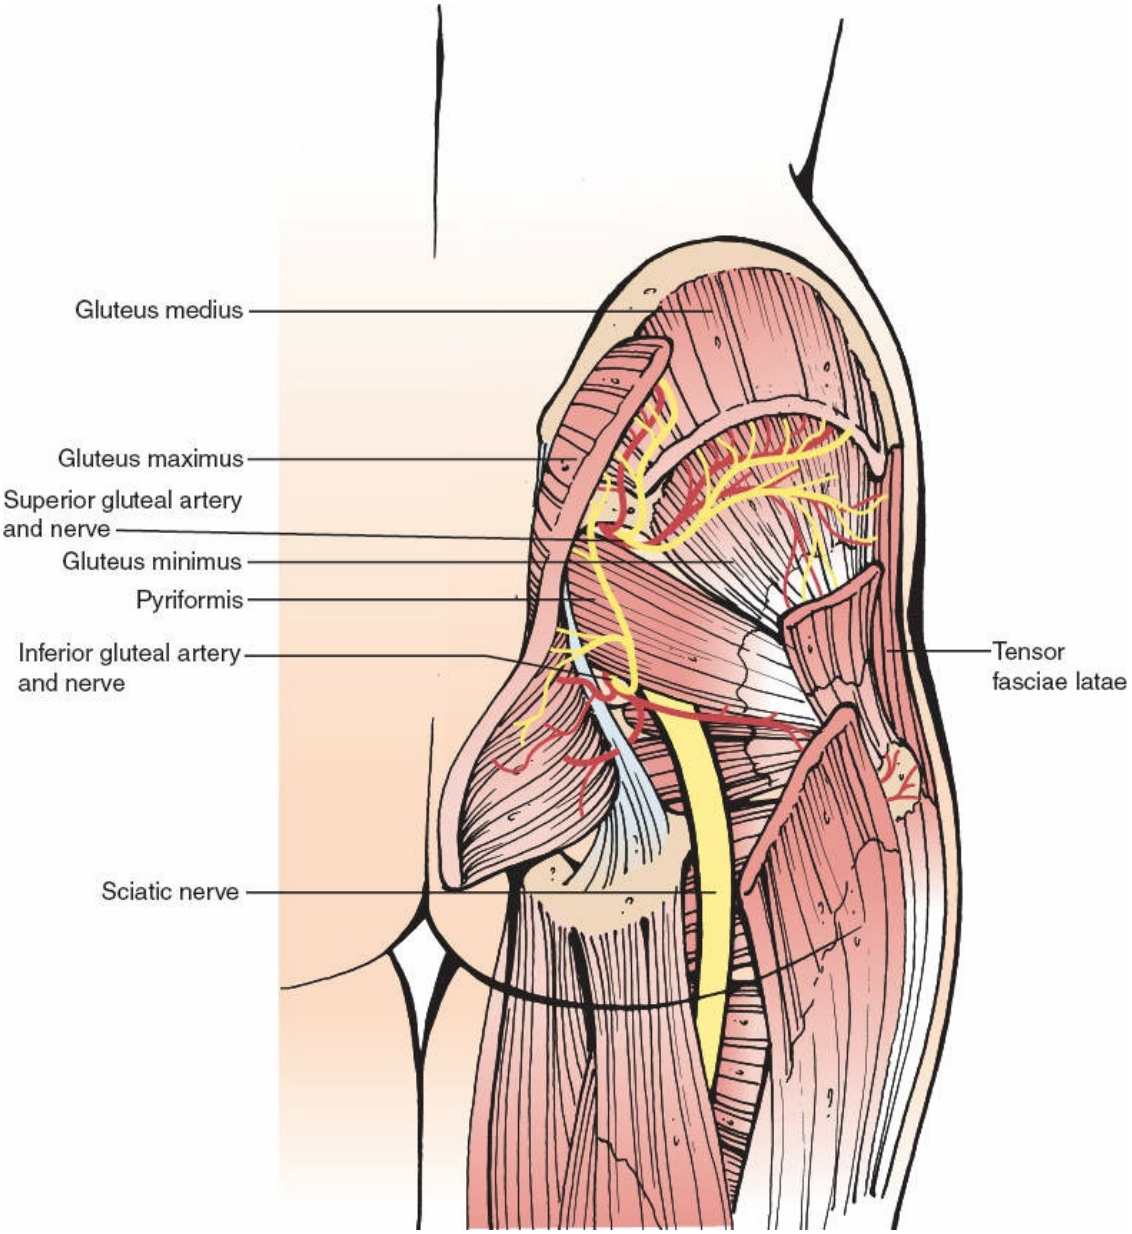

Figure 215.2. Illustration demonstrating major neurovascular structures within the gluteal compartments.

Finally, the leg consists of four distinct compartments described as anterior, lateral, superficial posterior, and deep posterior. The anterior compartment is bordered by the lateral aspect of the tibia, the interosseous membrane, and the intermuscular septum between the anterior and lateral compartments, which is partially contiguous with the fibula. The muscles that produce dorsiflexion of the foot and toes are contained within this compartment. Neurovascular structures in the anterior compartment include the anterior tibial artery and veins, and the deep peroneal nerve. The lateral compartment boundaries include the anterior intermuscular septum, the fibula medially, and the posterior intermuscular septum. The

muscles controlling eversion of the foot are contained within this compartment. The superficial branch of the peroneal nerve courses through the lateral compartment until it exits the fascia typically 10 to 12 cm superior to the lateral malleolus (Fig. 215.4). This nerve is particularly susceptible to harm during fasciotomy, and results in altered sensation over the dorsum of the foot if injured. The superficial posterior compartment contains the gastrocnemius muscle and soleus muscle, and is surrounded by the deep fascia of the leg, with the exception of anteriorly, where this fascial plain joins the posterior intermuscular septum. The deep posterior compartment is the most difficult anatomic compartment in the leg to surgically expose. It is bounded by the tibia, interosseous membrane, and fibula along its anteromedial and anterolateral extent. A small component is bounded medially by the deep fascia of the leg, with the remainder posteriorly being surrounded by the posterior intermuscular septum. The long flexors of the toes are included in this compartment, as well as the posterior tibial and peroneal vessels. The tibial nerve also lies within this compartment (Fig. 215.5).

CLINICAL PRESENTATION

Gluteal Compartment Syndrome

Within the lower extremity, the gluteal region is the least frequently reported location for CS. The most common cause for CS in this location is a patient with prolonged pressure over the gluteal region, such as an unconscious or severely traumatized patient, or a patient with prolonged positioning for a surgical procedure. Musculoskeletal trauma is the next most common cause of this rare syndrome, with motor vehicle collisions and explosive/concussive mechanisms being included in this category. Vascular specific causes may also occur, such as an Ehlers-Danlos patient with spontaneous bleeding from a gluteal artery aneurysm, or gluteal CS following open abdominal aortic aneurysm repair.

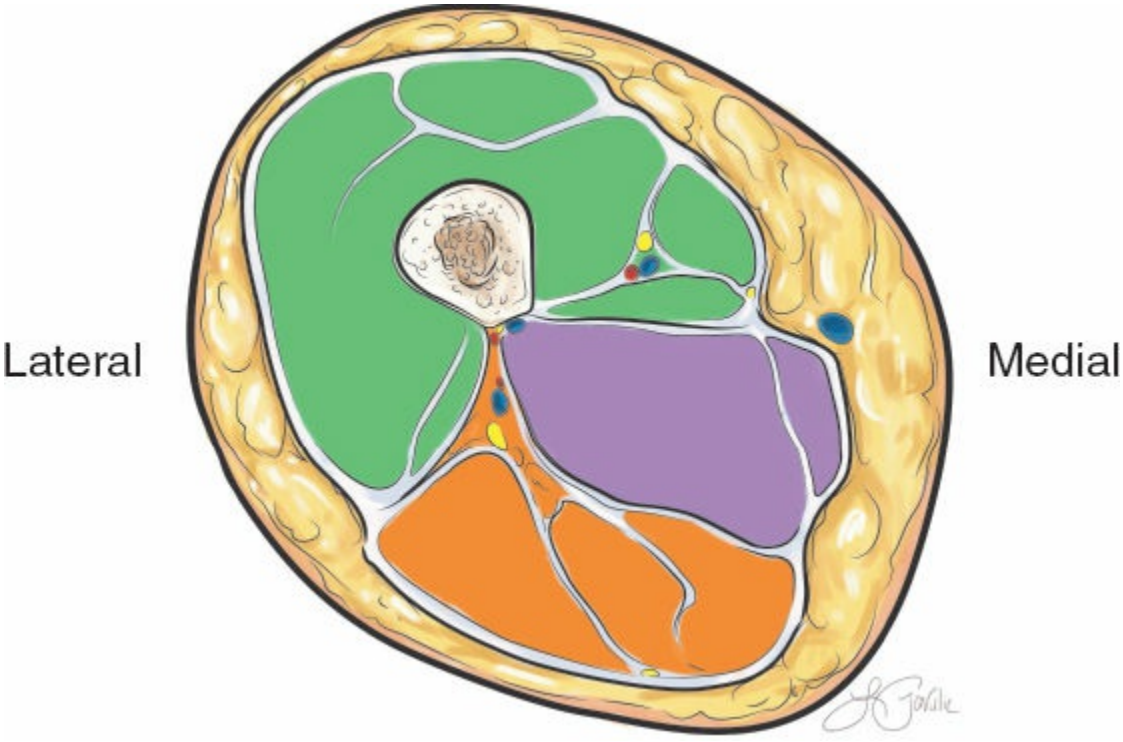

Figure 215.3. Axial view of the thigh denoting the medial compartment in purple, posterior compartment in orange, and anterior compartment in green.

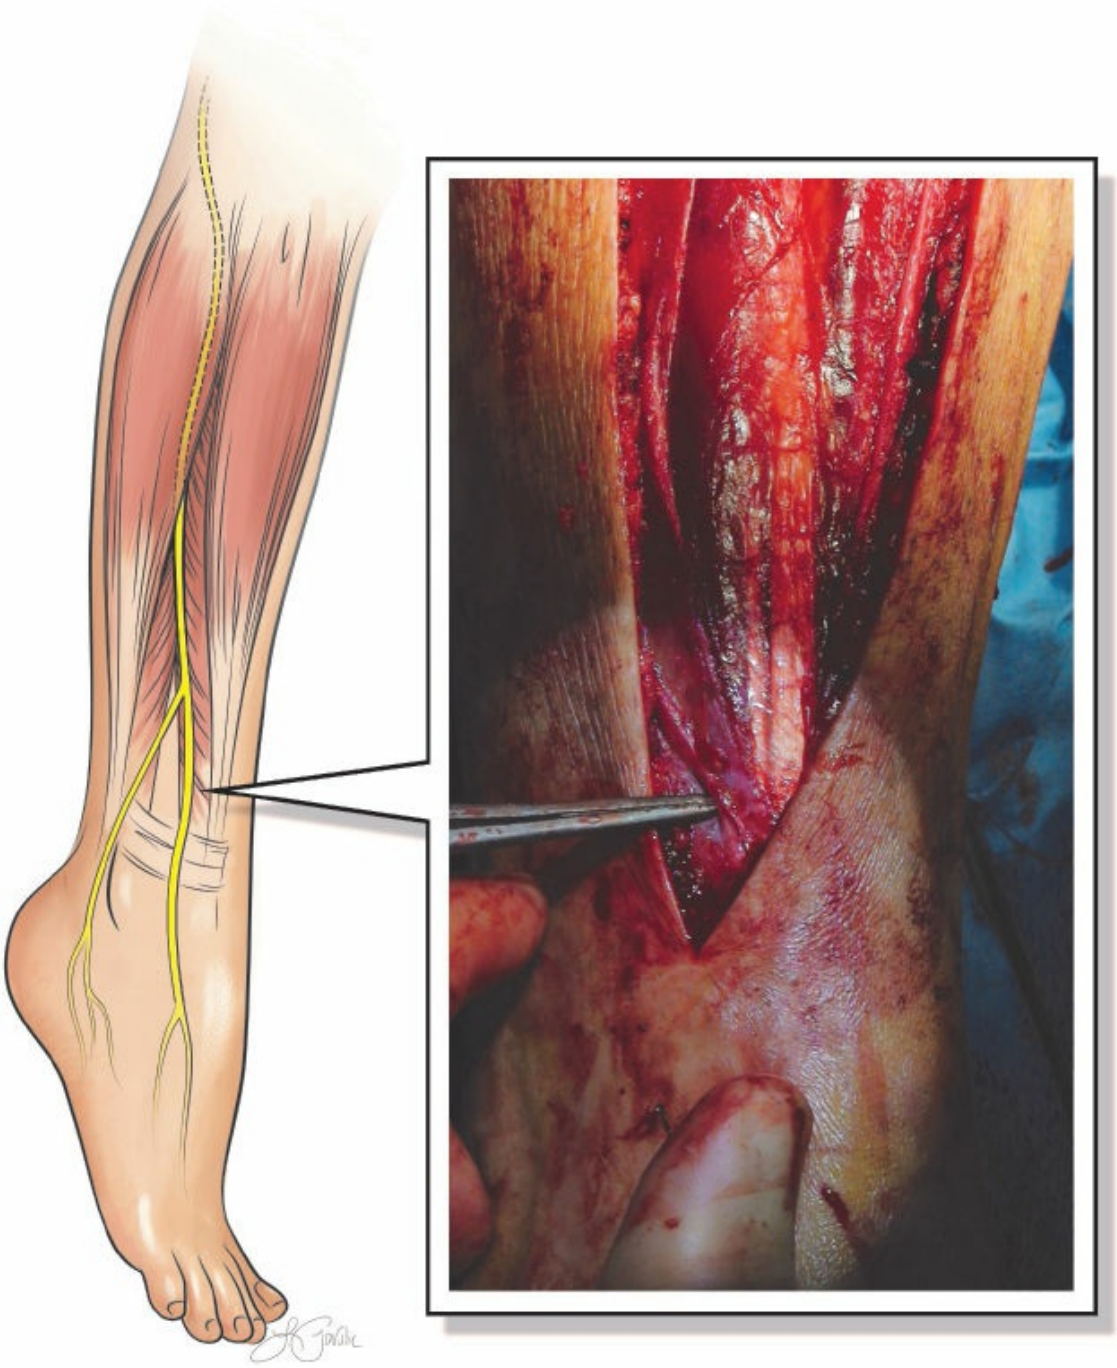

Figure 215.4. Lateral exposure from a two-incision leg fasciotomy demonstrating the superficial peroneal nerve branch coursing toward the foot after exiting the fascia of the lateral compartment.

The majority of patients presenting with this syndrome are unable to give a history, so physical examination findings become extremely important. Almost uniformly, patients with gluteal CS have a massively swollen and extremely firm buttock as part of their presentation (Fig. 215.6). If the patient is able to give a history, symptoms may include

hypesthesia or increasing pain in the region of the injury, or a nerve deficit in the leg correlating to the sciatic nerve distribution. Finally, because of the large mass of muscle in the gluteal compartments, if elevated compartment pressures and/or the injury itself results in significant muscle injury, laboratory findings typically include marked elevation of creatine phosphokinase (CPK) enzyme levels and myoglobinuria from rhabdomyolysis, with the subsequent potential for renal failure.

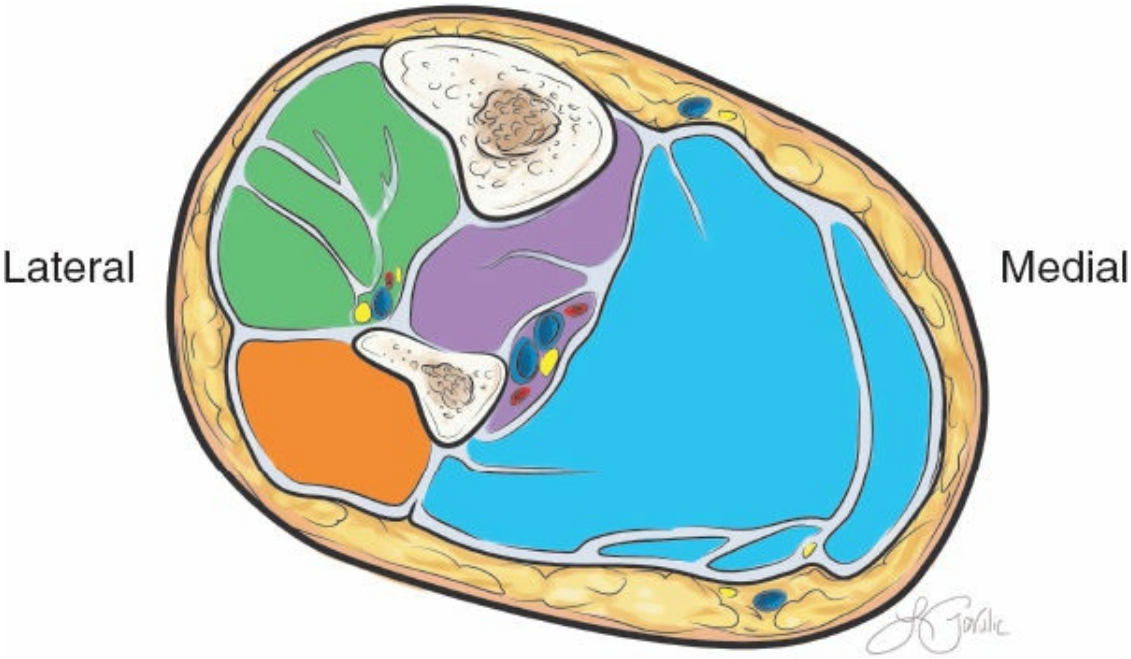

Figure 215.5. Axial view of the right calf denoting the anterior compartment in green, lateral compartment in orange, deep posterior compartment in purple, and superficial posterior compartment in blue.

Thigh Compartment Syndrome

Acute CS of the thigh is also rare. Blunt trauma is the most common cause, with nearly half of the patients with thigh CS having an associated femur fracture. Penetrating trauma, vascular injury, prolonged intraoperative positioning, or external compression from a comatose patient may also cause this syndrome. All patients present with a tensely swollen thigh. Noncomatose patients complain of intolerable pain, with focal paresthesias or paresis also being common. A pulseless extremity may also be a component of the patient presentation for thigh CS in the acute setting, occurring in 1 out of 5 patients. As one would expect, a pulseless extremity occurs more commonly when CS includes a femur fracture.

High CPK levels are less common in thigh CS than gluteal CS, but can certainly be a component of the presentation.

Leg Compartment Syndrome

The leg is the most common site for CS of the lower extremity. Blunt and penetrating trauma are common causes, again being frequently associated with tibia fractures, but ischemia reperfusion also contributes significantly to the prevalence of this disease process. National data suggest that >4% of patients presenting to US hospitals with diagnosis codes consistent with acute limb ischemia undergo a fasciotomy. A high index of suspicion is critical in making the clinical diagnosis of CS. In the obtunded patient, firmness of the compartment is the earliest sign of his syndrome, with loss of pulses being rare and a late finding. In the awake patient, excessive pain, palpable tightness, and severe pain with passive stretch of the muscles are common early findings, with paresthesias, progressive paralysis, and changes in pulse exam being late findings. Understanding which muscles and nerves travel within each of the four different compartments can aid in making the clinical diagnosis of which compartments are affected. Although rhabdomyolysis can occur with this syndrome, it is quite rare. History has shown that revascularization of a densely ischemic leg, especially in the setting of neurologic changes, will likely result in significant reperfusion injury, muscle edema, and CS. In such a patient, prophylactic fasciotomy is often performed in order to prevent this syndrome.

Figure 215.6. Blunt trauma causing gluteal compartment syndrome. Ecchymosis is clearly visible in the region of tense swelling and hematoma.

INDICATIONS AND CONTRAINDICATIONS

Fasciotomy is performed in a prophylactic fashion for those patients at high risk for developing elevated intracompartmental pressures and CS. The most common scenario for prophylactic fasciotomy is the patient with prolonged limb ischemia who has undergone revascularization and will subsequently experience increased muscle swelling from reperfusion injury. Wisdom is found in the surgical dictum stating, “if one thinks about doing a fasciotomy for limb ischemia, one should do one.” The indication for performing a therapeutic fasciotomy is the recognition of the early signs and symptoms of CS. A delay in diagnosis may have devastating consequences. Increased compartment pressure measurements may provide additional objective information and aid in the decision-making process. There are no absolute contraindications to performing a fasciotomy if deemed necessary. However, severe coagulopathy should be corrected prior to fasciotomy if possible.

Although the diagnosis of CS, whether in the gluteal, thigh, or leg compartments, is based upon clinical presentation, there are many clinical scenarios in which the diagnosis is not absolute or is quite difficult to make. In the preoperative period, a patient may be unable to give an accurate history or a reliable response to physical examination due to neurologic impairment, heavy sedation, or other reasons. Even if the patient is awake and alert, there are many other potential confounding reasons for severe pain and a swollen compartment such as long bone fracture, vascular injury with intracompartmental bleeding, or severe contusion. Determining when such an injury has crossed the threshold where elevated compartment pressures are additive to the underlying injury can be extremely challenging. Early CS is not detectable with laboratory evaluation. Elevated CPK and myoglobinuria are found later in the presentation and are unhelpful for making an early diagnosis, although they may be useful in determining the severity of injury or for continuous monitoring during injury recovery, if they are found to be elevated.

When clinical cues are insufficient to make a diagnosis of a CS, direct measurement of the compartment pressures may be necessary. This can be performed using a variety of instruments; however, a handheld monitor

using built-in microchip technology and a side-ported, noncoring needle for pressure measurements have become standard (Fig. 215.7). It is important to remember that safe needle insertion is critical in sampling compartment pressures. A thorough understanding of the anatomy in the compartment being tested is vital. Inadvertent puncture of vascular structures may result in increased bleeding and further tissue injury. Measurement of compartment pressures in patients with coagulopathy or who are receiving systemic anticoagulation should be performed with great caution.

Pressure measurements within the gluteal compartments are performed infrequently, but careful cadaveric studies have demonstrated the locations for proper placement of needles in order to avoid the neurovascular bundles. For the gluteus maximus compartment, the posterior superior iliac spine is the primary landmark, with the needle inserted perpendicular to the surface of the iliac wing 2 cm inferior and lateral to the posterior superior iliac spine. This is in the proximal and inner quadrant of the buttock. For the gluteus medius and minimus compartment, the needle should be placed 2 cm inferior to the iliac crest within the middle third of the iliac wing. Finally, for the tensor fascia lata compartment, the greater trochanter is the bony landmark, and the needle should be inserted 3 cm distal and 2 cm anterior to the tip of the trochanter (Fig. 215.8). Pressures ≥30 mm Hg in the appropriate clinical scenario are considered an indication for fasciotomy, while normal pressures in the gluteal compartment are ~13 to 14 mm Hg.

The upper limit of normal for compartment pressures in the thigh is debatable, but is typically considered to be 30 to 45 mm Hg, although some authors recommend a much higher threshold due to risk of infection. Sampling of compartment pressures should be performed in the mid-thigh. Needle insertion should only be deep enough to access the compartments, without injuring vascular structures. The anterior compartment should be accessed slightly lateral to the midline anteriorly, while the posterior compartment should be accessed slightly medial to the midline posteriorly. The medial compartment is sampled infrequently, but access to this compartment requires a true medial insertion of the needle with the patient in anatomic position (Fig. 215.9).

Figure 215.7. Stryker handheld compartment pressure monitor uses a noncoring needle with a side port for more accurate compartment pressure measurements.

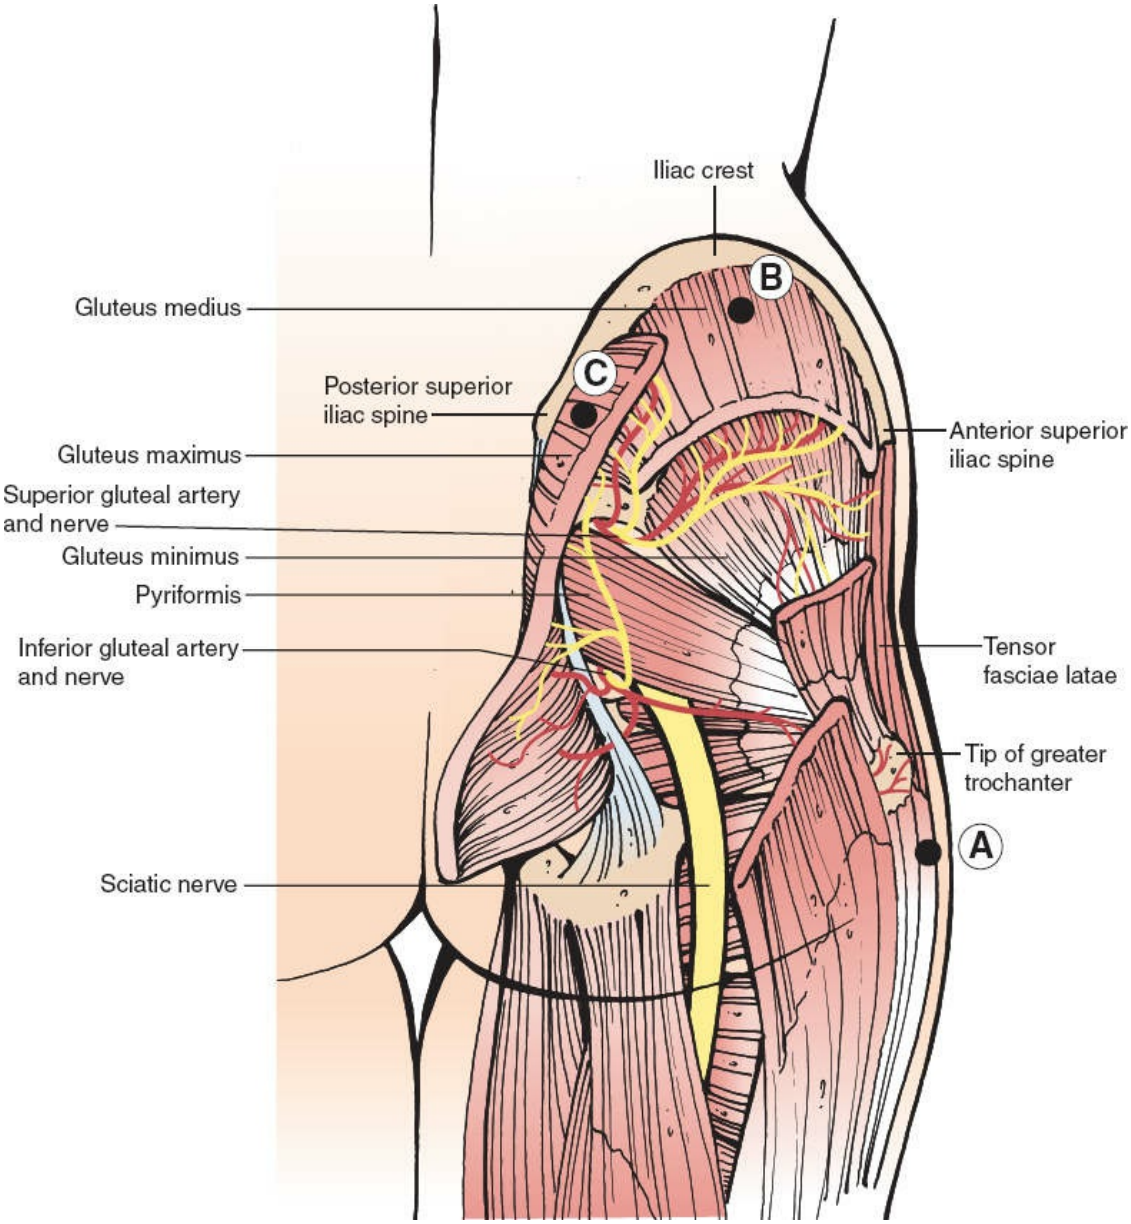

Figure 215.8. Illustration demonstrating the safe regions for obtaining gluteal compartment pressures. (Adapted from Figure 2.)

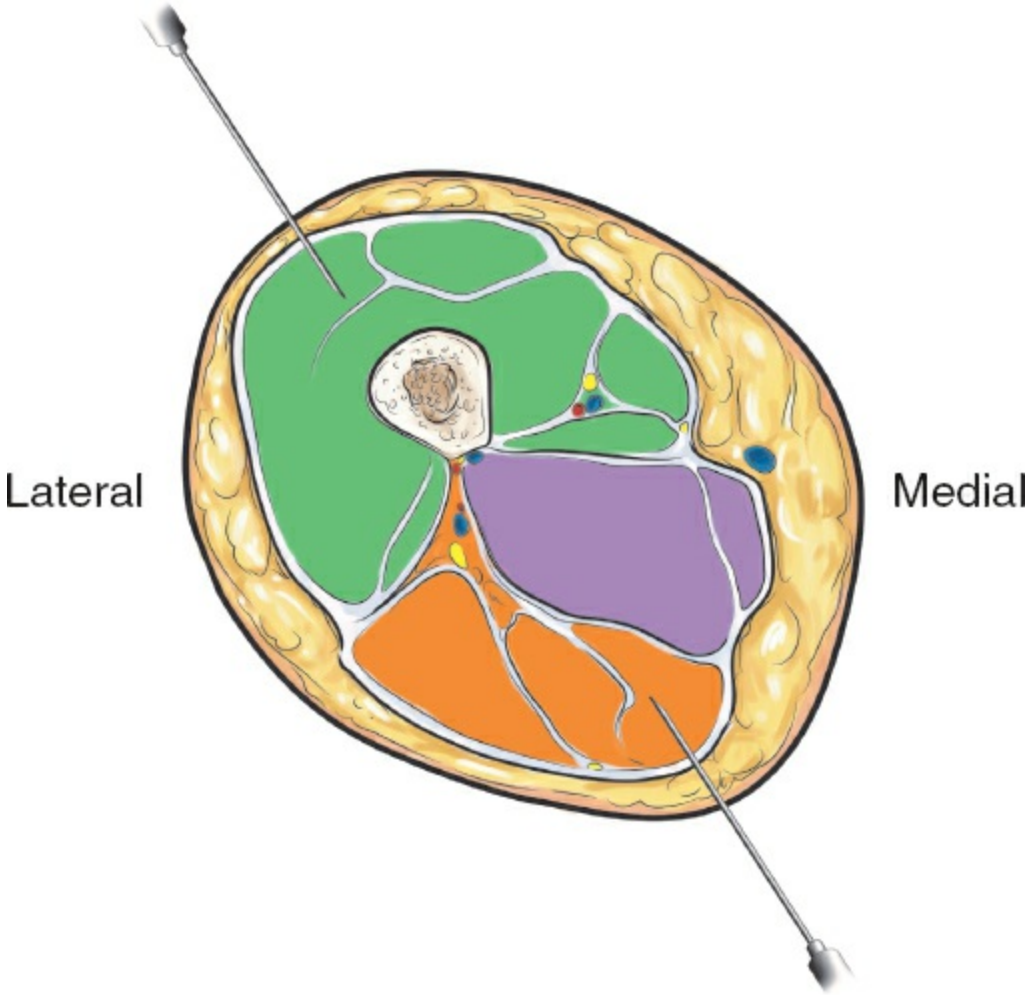

Figure 215.9. Illustration demonstrating the typical compartment pressure measurement locations in the thigh.

Compartment pressure measurements for the leg are commonly performed compared to the thigh and gluteal regions. Compartment pressures >30 mm of mercury are generally considered to be elevated and consistent with CS. However, it is important to remember that clinical evidence of muscle and nerve ischemia is a more reliable indicator of CS than an absolute number. Nevertheless, if there is a clinical indication to obtain compartment pressure measurements, the anterior compartment should be sampled in the mid-calf ~1 to 2 fingerbreadth lateral to the tibia, while the lateral compartment is sampled just lateral to the fibula. The deep posterior compartment is accessed in the mid-calf just posterior to the tibia, with the knowledge that the posterior tibial artery and vein will lie just posterior to this access site. The superficial posterior compartment may be accessed safely from the true posterior position of the mid-calf (Fig. 215.10).

PREOPERATIVE PLANNING

Fasciotomy should be performed without delay once the indication for intervention is recognized. It may be necessary to type and cross-match blood products for reversal of coagulopathy at the time of surgery in order to limit excessive blood loss. An operative suite is preferential for maintaining sterile technique for this procedure, although fasciotomies can be performed at the bedside. The choice of anesthesia includes local, regional, or general. Regional or general anesthesia is preferred unless a single compartment release in the leg is being performed, in which case local anesthesia may be adequate.

SURGICAL TECHNIQUE

The appropriate treatment for all CS is implied in the name "fasciotomy." The Latin root word "*fascia*" literally means band, while the root word "*-tomy*" is Greek for cut. The objective for CS treatment is to normalize compartment pressures and restore tissue perfusion. This requires access via the skin and subcutaneous tissues through a surgical incision, with a wide release of the fascial boundary encircling the affected compartment.

Gluteal Compartment Release

The gluteal compartments are released through a surgical exposure similar to a posterior approach to the hip, utilizing the greater trochanter as a landmark. A curvilinear incision is made in a gentle curve over the buttock, following the arc of the iliac crest (Fig. 215.11). The fascia overlying the gluteus maximus muscle is divided, and the fibers of this muscle split to expose the gluteus medius and minimus muscles. The inferior aspect of the incision may need to be carried onto the proximal thigh near the gluteal fold to access the tensor fascia lata compartment.

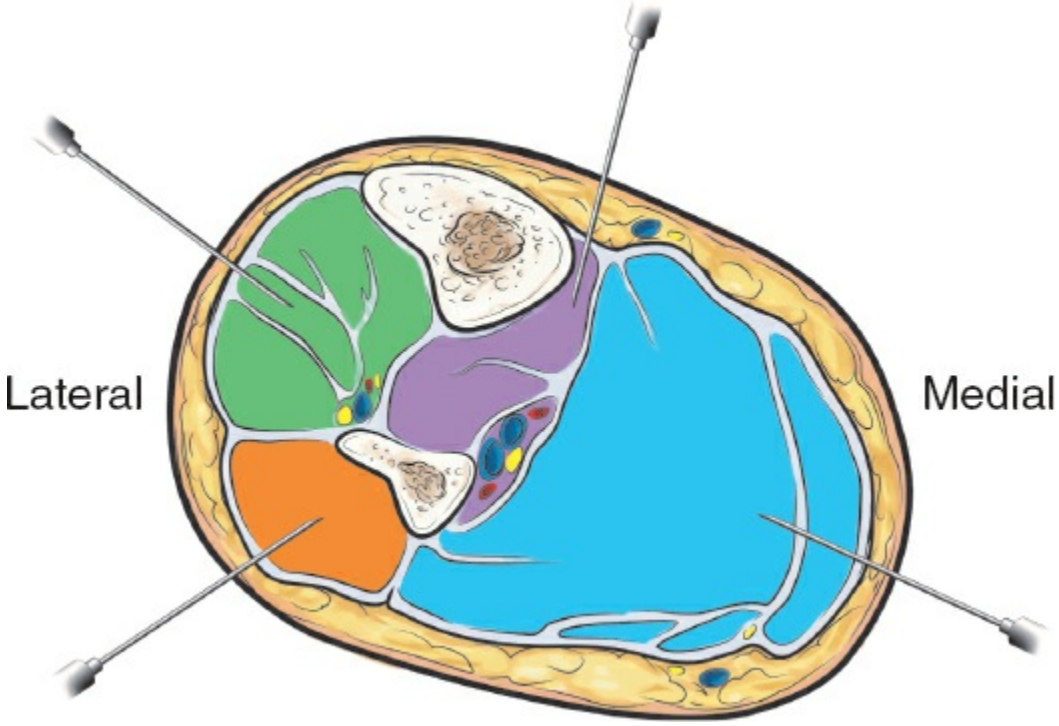

Figure 215.10. Illustration demonstrating the typical compartment pressure measurement locations in the leg.

Thigh Compartment Release

Decompression of the anterior and posterior thigh compartments is performed through a posterolateral approach (Fig. 215.12). The anterior compartment is decompressed first, with a longitudinal incision in the muscular fascia exposing the vastus lateralis. Once anterior decompression is accomplished, the vastus lateralis is retracted medially. The lateral intermuscular septum is then identified, and incised through the anterior compartment, thus decompressing the posterior compartment.

Figure 215.11. Illustration with *dashed line* demonstrating the typical skin incision location for gluteal compartment release. The skin incision may need to be extended across the greater trochanter to allow access to tensor fascia lata compartment.

Leg Compartment Release

A two-incision technique is most commonly employed to release the compartments of the leg (Fig. 215.13A,B). A generous medial calf skin incision is made ~1 fingerbreadth posterior to the medial portion of the tibia. The greater saphenous vein and saphenous nerve often run in this position, parallel to the incision, and injury to this vessel and nerve should be avoided if possible to maximize venous drainage of the lower extremity and limit postoperative neuralgia. The superficial posterior compartment is

released by longitudinally incising the fascia overlying the gastrocnemius muscle. In the mid-calf, the fibers of the soleus muscle running transversely will be exposed. Soleal attachments to the tibia are divided with electrocautery exposing the fascia of the deep posterior compartment. This fascia is incised longitudinally for release of this compartment.

For the lateral and anterior compartment release, a single longitudinal skin incision is made ~2 to 3 fingerbreadths lateral to the tibia. Once the skin and subcutaneous tissues are divided, the fascia is exposed, and separate longitudinal fascial incisions are created on either side of the intermuscular septum that runs between the anterior and lateral compartments. Care should be taken to avoid injury to the superficial branch of the peroneal nerve in the lateral compartment as it exits the fascia ~10 to 12 cm superior to the lateral malleolus.

Figure 215.12. Illustration with dashed line demonstrating the typical skin incision location for a posterolateral, single-incision, two compartment release of the thigh.

POSTOPERATIVE CARE

The performance of appropriate fasciotomies relies on wide surgical exposure of skin, subcutaneous fat, and fascia. These large wounds can be difficult to manage, and the surgeon is often considering how these wounds will be closed by the time the fasciotomy is completed. Immediate closure of the skin is not recommended, as ongoing swelling of the underlying tissues may result in continued elevation of compartment pressures. However, several methods have been employed to facilitate early closure of the skin and subcutaneous tissues. These have included: (1) immediate placement of monofilament nonabsorbable sutures that can be tightened to reapproximate the tissues in a delayed primary fashion, (2) utilization of skin staples along the edges of the wound and lacing vessel loops or tapes back and forth between them for delayed reapproximation (“shoe-lace” or “Roman Sandal” technique), and (3) more recently, utilization of closed suction vacuum-assisted dressings, among others. Each of these therapies is designed to obviate the need for split-thickness skin grafting. If early wound reapproximation is not possible without creating undue tension on soft tissues, however, a split-thickness skin graft is indicated.

Illustration with *dashed lines* demonstrating generous longitudinal skin incisions on the medial and lateral calf approximately one and three fingerbreadths from the tibia, respectively. **B.** Illustration of an axial view of the leg with *arrows* demonstrating the locations of skin incisions for medial and lateral calf compartment release.

COMPLICATIONS AND THEIR MANAGEMENT

Complications are common following fasciotomy. A careful review of patients undergoing leg fasciotomy via two incisions in the setting of trauma reflected an overall fasciotomy-related complication rate of 31%. Skin, soft tissue, or deep infections occur with variable rates, but are higher with delay in fasciotomy of the leg, and have been reported to be as high as 67% for fasciotomy of the thigh. Antibiotics are not indicated unless a documented infection is present. Any necrotic muscle or tissue should be debrided at the time of initial fasciotomy in order to minimize infectious complications. Reexploration of fasciotomy wounds in which necrotic tissue was identified may be necessary at 48- to 72-hour intervals, with serial debridement as needed. Obviously, wounds in which significant necrosis or documented infection have occurred should be left open despite the potential negative cosmetic and functional results.

The most significant complication related to fasciotomies results from a

delay in their implementation. Postponed treatment of CS, or inadequate decompression at the time of fasciotomy, will both result in poor outcomes. A high index of suspicion, serial physical examinations, and timely assessment of compartment pressures when appropriate are keys to preventing such complications.

OUTCOMES

Outcomes following fasciotomy for CS may be classified by cosmetic, functional, and limb-salvage, but overall data are limited. Cosmetic disfigurement following fasciotomy, although important to patients, is a natural consequence of this procedure. Delayed primary closure often results in retracted and thickened scars, while skin grafts have obvious cosmetic effects. Avoiding infection, appropriate debridement of necrotic muscle (best achieved through prompt recognition and treatment of CS aligned with serial operative debridement when necessary), and split-thickness skin grafting by experienced practitioners may limit cosmetic disfigurement. Functional outcomes and limb-salvage rates may be measured objectively, but heterogeneity in etiology makes measuring these outcomes challenging.

While functional outcomes for gluteal CS outcomes are very difficult to assess because of low incidence and sporadic reports in the literature, one review of 18 patients with acute CS of the thigh demonstrated long-term functional deficits in 8 patients. Prolonged interval to decompression, among other factors, was associated with poorer functional outcomes. Perhaps the most robust data regarding frequency of fasciotomy with severe injury have resulted from recent military conflict. Analysis of wartime injured from 2001 to 2010 identified 25,731 casualties in the registry with wounds in any body region, of which 17,166 had limb trauma. Nineteen percent of the limb-trauma group underwent fasciotomy. Unfortunately, functional outcomes were not able to be assessed in this report. The incidence of fasciotomy was higher in those undergoing amputation than those with nonamputation injury, as expected. Another historical report assessing outcomes for leg and forearm fasciotomy identified that fasciotomy performed <12 hours after the onset of symptoms resulted in normal function in 68%, while delayed treatment had only 8% normal function. Regardless of the site of fasciotomy, the most important determinate of functional outcome is the minimizing delay in treating CS.

EDITOR'S COMMENT

The chapter by Dr. Eliason describing many key points of fasciotomy represents a straightforward treatise on an important adjunctive procedure for many of our ill and injured patients who develop compartment syndrome. This chapter includes several anatomical locations beyond that typically performed in the lower leg. I fully agree with the author that "if fasciotomy is thought about, it

should be done," and is akin to "thinking that a patient should be intubated, they probably should be." The morbidity with this adjunctive procedure is low, and missing the diagnosis, even if it is recognized rapidly, results in a repeat operation, time, and hassle for both the patient and the surgeon. Typically, the technical performance of fasciotomy is fairly straightforward, but recognition of when it is required is key as overall amputation rates are ~13% (Lollo L, Grabinsky A. Clinical and functional outcomes of acute lower extremity compartment syndrome at a Major Trauma Hospital. *Int J Crit Illn Inj Sci* 2016;6:133–42).

The primary reason fasciotomy is done is to relieve tissue compartmental pressure, which negatively impacts the neuromuscular function of a limb. Missing the primary diagnosis of a compartment syndrome is not only devastating to the patient long term, but is also a major medical legal liability. Leg pain and neurologic changes are sensitive and specific in the right clinical scenario. The anterior compartment in the lower leg, housing the deep peroneal nerve, is most sensitive to elevated compartment pressure and often the first symptomatically involved compartment. Nerve tissue is most sensitive to ischemia, so by the time arterial flow is impaired, the nerve damage may be permanent. Even with rapid treatment, the neuropathy that results from compartment syndrome, unless it's done prophylactically, often takes month to improve.

The occurrence of a gluteal compartment syndrome is rare but important to consider in the right settings. Examining the buttocks in a patient who has had massive reperfusion injury as well as patients who have had atheroembolism to the internal iliac artery system is important, and may direct one to this diagnosis. The description as put forth is straightforward, and as with most fasciotomies, the morbidity is low.

The most common type of fasciotomy is the four-compartment release of the lower leg. One thing to keep in mind is that the skin and fascial incision needs to be generous enough that you fully release the compartments to allow the muscle release. From my own experience (inadvertently), performing a limited fasciotomy has resulted in the need to take the patient back for further release of the compartments. This may be more common in those younger patients with marked and massive reperfusion, and they often have persistently elevated CPK and myoglobinuria. In the lower extremity four-compartment fasciotomy in a large leg or with extensive trauma, it is important to make sure that you open the anterior compartment and not mistake for the lateral. That is, if you place the incision too far laterally over the fibula, you may incise the lateral compartment twice and miss the anterior compartment. This results in a dead anterior muscle compartment and a need for an above the knee amputation. Need for fasciotomy revision is also associated with a significant increase in muscle necrosis and mortality (Ritenour AE, Dorlac WC, Fang R, et al. Complications after fasciotomy revision and delayed compartment release in combat patients. *J Trauma* 2008;64:S153–61, discussion S161–2).

A common complication that often accompanies fasciotomies is significant bleeding. Patients who had an acute embolic process or thrombotic process usually need to be kept on anticoagulation periprocedurally. However, the open wound beds, skin, and venous tributaries often bleed quite extensively. Wrapping and elevating the patient's limb and at times reversing the systemic anticoagulation are necessary. However, this needs to be balanced against recurrent thrombosis. Furthermore, patients who are on dual antiplatelet therapy, particularly with the newer agents, may also have a greater risk of bleeding. Again, ongoing antiplatelet therapy needs to be balanced for cardiac protection against persistent bleeding. Making sure adequate cautery of the skin bleeders, oversewing of small veins, and the like are done and can help decrease this problem.

E MESENTERIC AND RENAL ARTERY DISEASE

216 Renal Artery Occlusive Disease: Open and Endovascular Management

Laura A. Peterson and Matthew Edwards

ETIOLOGY AND PATHOPHYSIOLOGY

Etiology

The etiology of occlusive renovascular disease in adults can be divided into essentially two main categories: atherosclerosis and fibromuscular dysplasia (FMD), with the vast majority of cases secondary to atherosclerosis. Population-based studies and other reports from the medical literature would suggest that >90% of treated renovascular occlusive lesions arise from atherosclerosis and the majority of the remaining treated lesions are fibrodysplastic (most commonly medial fibroplasia) in nature. Other conditions do cause renal artery occlusive disease, including arteritis (most commonly Takayasu's) and complications of arterial dissections, but these conditions are rarely recognized and treated outside of specialized referral centers.

Children can also be affected by renal artery occlusive disease. In fact, renovascular disease is one of the most common causes of secondary hypertension in young patients. In children, the most common culprit pathologies are congenital lesions, hypoplastic lesions, and variants of fibrodysplasia.

Pathophysiology: Renovascular Hypertension

Atherosclerotic disease of the renal artery primarily affects the renal ostia, usually as an extension of aortic atheroma. Atherosclerotic disease may

also involve any level of the renal vasculature including the small intraparenchymal vessels, but such distal extension of disease is quite uncommon. Histologic evaluation of renal artery plaques has demonstrated features consistent with atherosclerotic plaques in other vascular beds, with typical cholesterol rich lipid containing plaque and disruption of normal intimal and medial histologic architecture and frequent central plaque degeneration and (very frequently) lesion calcification. Contributing factors to the development of renal artery atherosclerosis are essentially the same conditions associated with atherosclerosis elsewhere in the body.

One consideration that is unique to the renal and visceral artery ostial lesions is the continuous nature of the ostial plaque with a sheet of aortic plaque. This characteristic makes these lesions more resistant to balloon dilation than isolated vascular lesions. As a result, balloon angioplasty for the treatment of atherosclerotic lesions of the renal vasculature has largely been abandoned as a stand-alone therapy in favor of balloon-expandable stents when an endovascular repair is indicated.

FMD is the second most common cause of renal artery stenosis (RAS). FMD is actually a group of nonatherosclerotic and noninflammatory conditions, which result from abnormal cell growth, and frequently fibrosis, within the histologic architecture of the arterial wall, especially the media. Multiple variants of FMD occur, but the medial fibroplasia variant is the most common cause of occlusive lesions in adults, with younger females being disproportionately affected. Medial fibroplasia is most commonly identified secondary to a pathognomonic “string of beads” appearance on arteriography resulting from alternating areas of stenosis and poststenotic dilation. The majority of cases demonstrate involvement of both renal arteries. In cases isolated to one kidney, the right renal artery is affected more frequently than the left. The underlying cause of FMD is unknown.

In patients with significant decreases in renal perfusion secondary to occlusive lesions, there are neuroendocrine effects that result in a multitude of downstream issues increasing the patient’s risk of adverse cardiac, neurologic, and renal events, most notably severe, secondary hypertension. The hormonal regulation underlying renovascular hypertension is complex and involves activation of the neuroendocrine–renin–angiotensin–aldosterone system. The stenotic renal artery creates a situation of relative hypoperfusion in the affected kidney. Not all stenotic

lesions are capable of producing impaired blood flow of sufficient magnitude to create a pressure gradient prompting hormonal response. In investigational work, the degree of arterial occlusion requires between a 60% and 80% decrease in cross-sectional area. However, once renal hypoperfusion does occur, a predictable and reproducible physiologic response occurs. First, the juxtaglomerular cells of the renal parenchyma release renin, which enzymatically converts angiotensinogen into angiotensin I. Angiotensin I is converted into angiotensin II by angiotensin converting enzyme (ACE). Angiotensin II is the primary hormonal driver of renin induced hypertension, through effects that are mediated by the activation of downstream receptors: angiotensin type I receptor (ATR1) and angiotensin type 2 receptor (ATR2).

Clinical pathophysiology differs according to whether a single kidney or both kidneys (or a solitary kidney) are affected. In unilateral lesions, compensatory natriuresis and excretion of other metabolites can occur through the unaffected kidney reducing the degree of volume expansion experienced by the patient. Unilateral renovascular hypertension is often treated quite effectively using ACE inhibitors or angiotensin receptor antagonists for this reason, and affected patients are less likely to experience volume-dependent cardiac disturbance issues and measurable decline in excretory renal function. When both kidneys (or a solitary kidney) are affected, the resulting hypertension requires diuretic management of the volume expansion for hypertension control and the decreased excretory function operates across the entire functional nephron mass, increasing the likelihood of clinically apparent renal dysfunction (ischemic nephropathy).

It is important to note that these initial mechanisms of hypertension in renovascular disease are mediated mainly by the effects of angiotensin II. However, over time remodeling both the heart and peripheral vessels occurs, which can lead to hypertension that is more difficult to treat and that may not respond favorably or completely to renal artery revascularization. This cardiovascular remodeling that occurs in renovascular hypertension is distinct from that seen in essential hypertension. In essential hypertension, there is no significant change in the arterial wall mass. In patients who exhibit chronic hyperreninemia, such as in renovascular hypertension, there is a hypertrophic remodeling of the arterial wall with notable expansion of the medial layer.

Pathophysiology: Ischemic Nephropathy

Although the underlying mechanisms leading to renovascular hypertension are well understood, the basis for renal insufficiency secondary to RAS remains poorly defined. The decreased blood flow leads to impaired glomerular filtration, but the role of frank ischemia is less well established. Acute renal artery occlusion leads to dramatic ischemia within minutes and necrosis within hours, but the gradual chronic decrease in blood flow impairs renal function in a more insidious way. In this pathway, as in renovascular hypertension, it is apparent that angiotensin II plays a key role. Angiotensin II increases efferent arteriole pressure and thus glomerular capillary pressure to maintain filtration in the setting of reduced renal blood flow secondary to more proximal renal vasculature obstruction. Through the perirenal effects mediated by ATR1, there is increased transforming growth factor β (TGFβ), PDGF, and nuclear factor-κB. These local regulators create a profibrotic state and lead to both glomerulosclerosis and tubulointerstitial injury. There is also evidence to support that the atheromatous plaque involved in some renal artery stenotic lesions can contribute to ischemic nephropathy by releasing atheroembolic debris leading to microvascular occlusion and associated renal parenchymal loss.

CLINICAL PRESENTATION

Epidemiology

In adults, the most common cause of RAS is atherosclerosis. The presence of atherosclerotic lesions in another vascular bed increases the chance that a patient will have concomitant RAS. The baseline prevalence of RAS depends on the population screened. A community screening program of 834 adults over the age of 65 demonstrated that 6.8% of the population had >60% RAS by renal duplex ultrasonography (DUS). In that study, RAS was almost twice as common in men compared with women (9.1% vs. 5.5%), but there was no difference noted between Caucasian and African-American individuals. Other studies have identified risk factors for RAS including age, systolic hypertension, and reduced high-density lipoprotein cholesterol level. Autopsy data from the 1960s looking at the prevalence of RAS in the general population in comparison to the hypertensive population demonstrated that 27% of patients over the age of 50 had RAS (defined as >50%) and this increased to 53% in those who had a medical

history of diastolic hypertension. A further study, reviewing 154 consecutive autopsies found that the prevalence of RAS in those younger than 55 years of age was only 6% but the prevalence dramatically increased in those over the age of 75 to 40%.

History and Physical Examination

The majority of patients with RAS are asymptomatic. Patients with symptomatic disease will in general present with severe hypertension with or without impaired renal function. In young patients, particularly children, a new diagnosis of hypertension should prompt further evaluation for a secondary cause.

Physical examination findings and laboratory abnormalities are nonspecific. The physician must take care to consider which patients are at greatest risk of having underlying renovascular disease prior to subjecting the patient to further testing. Patients with advanced age, uncontrolled hypertension, or a history of atherosclerotic disease in other vascular beds are at higher risk. Almost all patients, in our experience, with ischemic nephropathy have synchronous severe hypertension. This represents the fact that hypoperfusion severe enough to impair excretory function will also be severe enough to activate the renin-based neurohumoral cascade discussed previously. Therefore, renal insufficiency without hypertension should prompt further evaluation for other intrinsic renal disease. It is important to state, though, that blood pressure may be well controlled on medications and it is important to factor in the degree of antihypertensive treatment into one’s consideration of the severity of the underlying hypertension.

Physical examination may prove a useful if nonspecific evaluation in patients with renovascular disease. The patient may have severe hypertension, abdominal bruits, or nonspecific signs of cardiovascular disease, including diminished or absent peripheral pulses. A diminished lower extremity pulse exam may be present in children presenting with congenital abnormalities, aortic coarctation, or in adults with Takayasu arteritis.

Patients may present with acute worsening of their renal function after initiation of treatment with either an ACEI or ARB. This occurs most frequently in the setting of bilateral RAS due to the functional dependence on the increased efferent arteriolar tone maintained by angiotensin II to maintain glomerular filtration. Once pharmacologic blockage of this

compensatory mechanism occurs, there is an acute decompensation. If this effect is recognized early, and the medication discontinued, then return to baseline renal function usually occurs. Confirmation of RAS by renal artery duplex may be indicated and a different medical regimen prescribed.

A patient who presents with hypertensive urgency or emergency must be carefully evaluated. These hypertensive crises are most common when the patient has long-standing hypertension that has led to compensatory end-organ remodeling. Of particular concern is the patient who presents in congestive heart failure with pulmonary edema. Patients who present with such “flash” pulmonary edema as result of congestive heart failure and hypertension are more likely to have bilateral RAS with expanded intravascular volume, increased left ventricular mass, and diastolic dysfunction. Patients may also present with neurologic symptoms ranging from headache to stroke. The underlying physiology of this presentation is a severe increase in hydrostatic pressure, which drives fluid into the interstitial space causing generalized edema of both the organs and extremities. Hypertensive crisis can also cause transient damage to the kidney. Individuals may have proteinuria and elevated creatinine. As blood pressure is controlled and symptoms managed, there is a trend toward normalization to baseline of both proteinuria and renal insufficiency. Although prompt evaluation of RAS may be desired by the clinician, it is critical to allow sufficient time for renal function to recover prior to initiation of contrast studies or associated interventions that may involve renal ischemia, if possible.

Initial Laboratory Findings

Basic laboratory evaluation is nonspecific in the evaluation of renovascular disease. There may be elevations in blood urea nitrogen or, more commonly, serum creatinine. It is important to note that estimations of GFR are merely measures of total renal excretory function and are not representative directly of the changes in each kidney. These values can be influenced by a multitude of factors, including age, body mass, and protein intake. Historically, there was a call for “split” renal function studies to evaluate the importance of each kidney in the progression of the patient’s renovascular disease. This used a complex system of separate ureteral catheters to collect individual urine specimens and measure values from each kidney. Although very useful in predicting response to therapy, these studies have been abandoned in favor of less invasive radionuclide testing

to estimate fractional blood flow and filtration to each kidney.

If the patient has been suffering from the disease process for a protracted period of time, there may be nonspecific electrocardiogram changes demonstrating a strain pattern with increased voltages suggestive of ventricular wall thickening. An echocardiogram may demonstrate ventricular hypertrophy with poor diastolic relaxation. These findings are particularly common in children, and are reversible in young patients with timely revascularization. If a patient has hypokalemia, a plasma aldosterone level may prove useful in differentiating a diagnosis of primary hyperaldosteronism from RAS. Furthermore, urine metanephrines or serum catecholamines can identify other biochemically active adrenal tumors that can cause secondary hypertension.

Natural History

Once the clinician has identified a patient with RAS, it is important to further understand the natural history of the lesions involved as well as the role of expectant management. In patients with asymptomatic RAS or well-controlled hypertension, there is no roll for invasive treatment. Even in patients who have more severe hypertension and renal insufficiency, an understanding of anatomic lesion progression is necessary in order to best assess which patients require invasive therapy. Historical studies performed in the late 1960s through early 1980s demonstrated dramatic progression of renovascular disease in 11% to 35% of patients as measured by invasive arteriography. In these studies, there was up to a 10% progression to complete arterial occlusion. Although these results would seem to warrant aggressive intervention, it is important to note that the selected population studied had disease with preexisting severe stenosis warranting serial invasive imaging. More recent studies used duplex ultrasonography to evaluate a high-risk patient population and demonstrated an extremely low rate of lesion progression, with a rate of progression to occlusion of <0.5% per year. The reasons for the difference are incompletely understood, but likely stem from better medical management, among other factors. Patient factors that were associated with progression of disease in that cohort were age, uncontrolled hypertension, and continued smoking.

PREOPERATIVE PLANNING

Diagnostic Evaluation: Functional Studies

In the past, measurements of renal vein renin levels were used in order to plan surgical revascularization for hypertension. These measurements were obtained by sampling the renal vein, vena cava, and each individual main renal artery. This allowed the clinician to estimate the contribution of each kidney to the total circulating levels of renin with a ratio of 1.5 compared to the contralateral kidney being accepted as proof of renin hyperproduction from a hypoperfused kidney with RAS. These tests are of little or no value in patients with bilateral RAS. In patients with unilateral lesions, the prognostic value of lateralizing renin values is controversial with proponents and detractors. These studies are also notoriously difficult to perform in terms of medical management, need for prolonged patient recumbence, and patient discomfort/tolerance. For these reasons, renal vein renin analysis is an infrequently used test in contemporary practice. Other functional tests, including captopril renography, have also fallen out of favor.

Diagnostic Evaluation: Noninvasive Imaging

Duplex Ultrasonography

Duplex ultrasonography is an inexpensive test with excellent diagnostic accuracy when performed by experienced operators. Duplex also has the additional benefit of requiring no contrast agents or ionizing radiation exposure. Because of these factors, it is often used to initially diagnose RAS and monitor renovascular occlusive disease at sequential time points to evaluate for progression of disease. The reliability of renal duplex ultrasound, however, is heavily dependent on the expertise of the technician obtaining the images. Furthermore, study times can be considerable requiring appropriate resources. Patient barriers also exist as bowel gas can obscure adequate imaging so the patient must be fasting for a minimum of 8 hours prior to the examination to maximize the likelihood of obtaining the best images and Doppler samples possible. Obese patients also provide a significant challenge. At our institution, these factors can lead to an incomplete examination in up to 4% of the population.

Despite the fact that duplex ultrasonography has more technical considerations than other forms of noninvasive diagnostic testing, its accuracy can exceed 90% when compared to catheter-based arteriography. Several criteria have been used in the literature to predict a critical stenosis. In our laboratory, we employ peak systolic velocity (PSV) of 180 cm/s as a validated indicator of 60% or greater RAS. Other institutions

employ PSV, but also place emphasis on the renal to aortic ratio (RAR) of PSV in order to identify hemodynamically significant RAS. A RAR >3.5 is another indicator of >60% RAS.

Magnetic Resonance Angiography

Magnetic Resonance Angiography (MRA) is also frequently used in the evaluation of occlusive lesions of the renal arteries. Multiple studies have specifically examined its use in evaluation of the renal arteries. A meta-analysis published in 2001 demonstrated that the sensitivity and specificity of contrast enhanced MRA ranged from 88% to 100% as compared to angiography in evaluation of the renal arteries. Multiple studies, however, have demonstrated that there is frequently overestimation of the degree of RAS by contrast enhanced MRA, up to 30% in some series. Nonetheless, there are advantages of MRA over other imaging modalities. It does not require radiation or iodinated contrast agents as with computer tomographic angiography nor does it require the operator skill of duplex ultrasonography. There are drawbacks as well including long scan times, enclosed scanners, and the concern for nephrogenic systemic fibrosis if gadolinium is used in patients with excretory renal dysfunction. Any metal structure, including previously placed vascular stents, can also cause image distortion.

Computer Tomographic Angiography

Computed Tomographic Angiograph (CTA) is another frequently utilized test for defining renal artery occlusive disease. CTA can provide precise three-dimensional visualization and evaluation. Furthermore, there are fewer technical demands in terms of image acquisition and processing compared to the other imaging modalities when evaluating the renal arteries. CTA does however expose the patient to ionizing radiation and iodinated contrast agents with their attendant risks. CTA is less accurate at identifying stenosis of accessory and polar vessels as compared to conventional catheter-based angiography, may provide incomplete definition of changes consistent with FMD, and may provide incomplete luminal characteristic information in the presence of frequent dense perirenal vascular calcification.

Diagnostic Evaluation: Invasive Imaging

Digital Subtraction Angiography

Digital subtraction angiography (DSA) is the historic gold standard by which all other diagnostic imaging modalities in renovascular disease are measured; however, we view angiography as a therapeutic modality, and not a diagnostic modality per se, in contemporary practice. It is highly accurate in delineating renal anatomy and providing clear understanding of the diseased segment and provides an opportunity to treat many variants of renovascular pathology at the time of its performance. There are of course liabilities with DSA: it is invasive, costly, associated with potential access site complications, and requires exposure to radiation and potentially nephrotoxic contrast agents.

ENDOVASCULAR REPAIR

Indications and Contraindications

Indications for endovascular (and open) treatment of RAS have come under scrutiny in the previous decade. With the results of the CORAL, ASTRAL, and STAR, more stringent criteria have been considered for patient selection as none of these trials demonstrated any evidence for significant renal, cardiovascular, or survival benefit with endovascular renal revascularization. However, as with all clinical trials, these investigations had limitations, most notably a relatively limited study sample of patients who would be considered severely affected by RAS with renal insufficiency, bilateral disease, and/or truly difficult to control or uncontrollable hypertension. Given these points, contemporary use of renal revascularization is controversial, but there is expert consensus that the following patient groups represent the populations requiring further study and groups with the highest potential to achieve a beneficial clinical response.

Patients with truly uncontrollable or poorly controlled hypertension on multiple medications, especially if their course is complicated by symptoms or cardiac disturbance (i.e., flash pulmonary edema, symptomatic hypertension, etc.)
Patients with an observed rapid decline in renal function, especially in the setting of RAS involving the entire renal mass (i.e., bilateral disease or unilateral disease to a solitary kidney)

For patients selected for renal revascularization, endovascular methods represent the contemporary standard of care. In general, revascularization with balloon mounted stents rather than stand-alone angioplasty or

angioplasty with selective secondary stenting is recommended for initial treatment. However, there are anatomic characteristics that are relative contraindications for endovascular repair. These include a short main renal artery, multiple small renal arteries, concomitant need for aortic replacement secondary to aneurysmal or occlusive disease, presence of a coral reef atheromas, disease in close proximity to branch points, and congenital or hypoplastic lesions in children.

Preoperative Management

In addition to the preoperative measures described for open repair, preparation for endovascular intervention includes saline hydration. Those patients at risk for contrast nephropathy (i.e., diabetes mellitus, excretory renal insufficiency) receive iso-osmolar iodinated contrast agents. In these cases, carbon dioxide may be employed as a contrast agent to reduce the volume of iodinated materials.

Arteriography

Detailed arteriographic images of the renal arteries and perirenal aorta are essential to endovascular renal revascularization. Common femoral artery access is the most versatile access with the least risk. The femoral artery contralateral to the renal artery considered for endoluminal therapy is preferentially selected. If femoral artery access is not available, left brachial artery access is chosen. In this latter instance, an open approach to the brachial artery can be made through a small incision at the antecubital fossa or it may be percutaneously accessed if the vessel is large. Arteriography is obtained through a multisided hole flush catheter positioned at the L1 to L2 interspace. Initial anteroposterior views are supplemented with oblique views as necessary to visualize the renal artery ostia. A 15-degree left anterior lateral oblique view is often helpful in visualizing ostia orthogonally

Percutaneous Transluminal Angioplasty and Endoluminal Stenting (PTAS)

A variety of guidewires, catheters, sheaths, balloons, and stents exist that are used for renal artery endovascular intervention. Familiarity with individual institution stock supply is necessary for the surgeon. Most devices in current practice will pass through a 6-Fr sheath or guide

catheter. Guide sheaths and guide catheters are used to provide mechanical support for stable guide wire placement into the renal artery and for easy passage of therapeutic devices. They are configured to facilitate access to the renal artery orifices. After arteriography has delineated the renal artery lesion, an appropriately configured 6-Fr guide catheter is positioned at or just within the renal artery orifice (Fig. 216.1). The patient is systemically heparinized prior to cannulation of the renal artery lesion. It is our preference to select the renal artery with a 0.014-inch guide wire. In the presence of renal insufficiency, an embolic protective device may be considered, but data supporting this are lacking.

With the guide wire secured distal to the lesion, a pressure measurement may be obtained. After a significant gradient is defined, a coaxial or rapid exchange balloon mounted stent is chosen. Preferred balloon size is chosen based on quantitative angiographic images. If predilatation is necessary prior to endoluminal stent placement, a low profile 3-mm angioplasty balloon is chosen. Stent size for definitive treatment should be of the same or only slightly larger diameter than the adjacent normal artery for primary treatment. For treatment of ostial atherosclerosis, the stent is positioned with 1- to 2-mm extension into the aorta. Once in position, the balloon is inflated slowly to full profile at the rated nominal pressure before deflation. Once fully deflated, the balloon is removed, selective angiography is repeated, and the pressure measurements are repeated. A residual gradient of >10 mm Hg is considered significant. This is usually treated by additional balloon angioplasty.

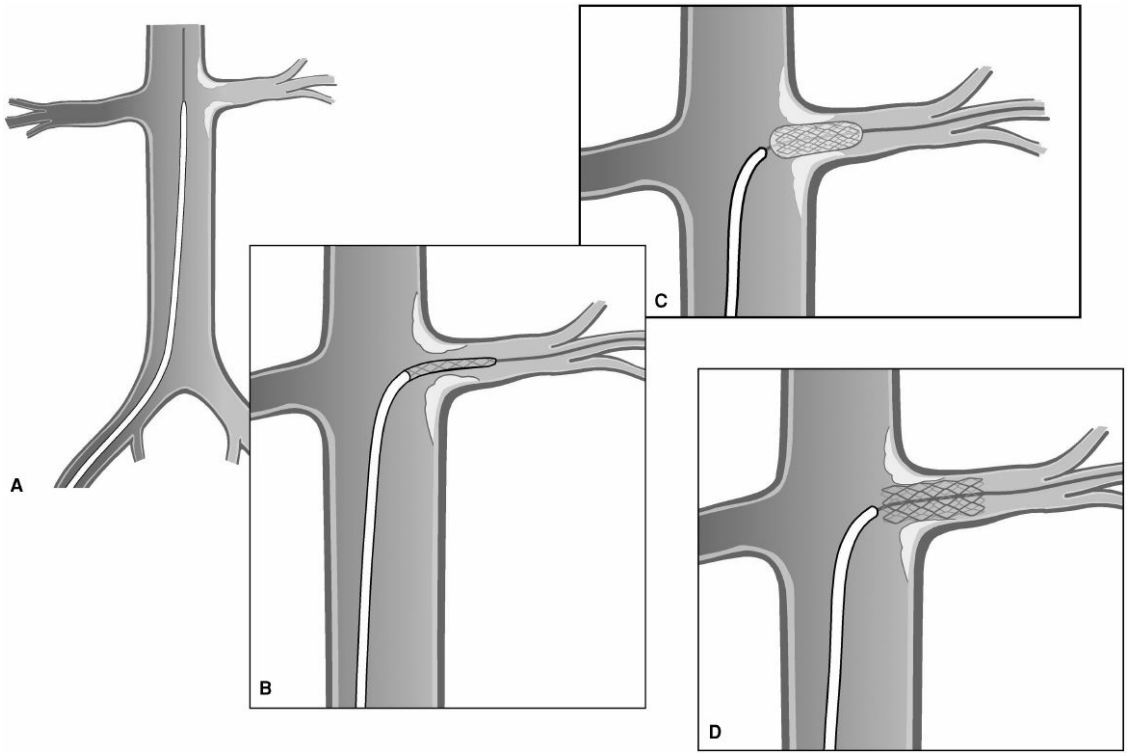

Figure 216.1. Left renal artery angioplasty and endovascular stenting of an ostial atherosclerotic stenosis. **A.** Femoral access contralateral to the renal artery for intervention with guidewire and No. 6-Fr guiding sheath. **B.** Selective placement of a soft tip guidewire to the level of the second-order renal artery branches. **C, D.** Balloon dilatation and deployment of endoluminal stent with complete stent overlap of the aortic atheroma.

OPEN REPAIR

Indications and Contraindications

With the advent of endovascular therapy in RAS, there has been reconsideration for the role of open surgical repair. General indications for open repair should be the same as those for endovascular intervention. Because of the less invasive nature of endovascular treatment of RAS, open surgical repair is now reserved for patients who have more complex anatomic lesions described previously, for failed endovascular treatments, and for aneurysmal disease.

Preoperative Management

There are key periprocedural steps that are common to every open renovascular surgical operation. Patients who require multiple medications for hypertension may experience reduced medication requirements while

hospitalized and at bed rest. Both converting enzyme inhibitors and angiotensin receptor antagonists are discontinued. Perioperative and postoperative medical therapy for blood pressure control includes vasodilators (e.g., amlodipine, nicardipine) and selective β-adrenergic blocking agents (e.g., atenolol, metoprolol). Patients with significant heart disease in combination with sever renal insufficiency may require preoperative placement of invasive monitoring to optimize cardiac index and intravascular volume prior to operation.

Certain steps are common to almost every open renal artery procedure. Intravenous mannitol is administered during periods of aortic and perirenal dissection, as well as before and after periods of renal ischemia. Small repeated intravenous doses are administered up to a total dose of 1 g/kg body weight. Prior to aortic or renal artery cross clamp, 100 units of heparin per kilogram of body weight are administered intravenously and systemic anticoagulation is verified by activated clotting time. During periods of aortic or renal cross-clamp, measurement of activated clotting time is repeated every 45 minutes and additional intravenous heparin is administered as necessary. Protamine is not routinely administered at the conclusion of the procedure unless required for hemostasis.

Renal Artery Exposure

Open repair of RAS is most commonly approached through an abdominal midline incision. Extension of the proximal incision 1 to 2 cm lateral to the xiphoid is critical in obtaining exposure of the proximal abdominal aorta and the renal branches. Mechanical retraction is put in place, and the abdominal exposure and dissection is continued. The posterior peritoneum overlying the aorta is incised longitudinally. Care is taken to mobilize the ligament of Trietz identifying collateral veins that may run in course with the inferior mesenteric vein at this level (Fig. 216.2). The duodenum is retracted gently to the right to allow for exposure of the renal vein (Fig. 216.3A). The renal vein must be mobilized from the inferior vena cava to the renal hilum (Fig. 216.3B). The inferior border of the pancreas is mobilized with this maneuver in the avascular plane. The left gonadal, adrenal, and lumbar branches of the left renal vein may be ligated to allow for retraction of the renal vein to provide better exposure. Often a lumbar branch of the left renal vein enters posteriorly. This can be readily avulsed unless special care is taken when mobilizing the left renal vein. The proximal portion of the right renal artery may be exposed through the base of the mesentery by ligating lumbar branches of the vena cava and

retracting the left renal vein cephalad and the vena cava to the right (Fig. 216.3C). The exposure of the distal aspect of the right renal vein requires mobilization of both the duodenum and right colon medially with the right renal vein being retracted cephalad (Figs. 216.4 and 216.5). Accessory renal arteries occur in 15% to 20% of patients and provide an additional technical challenge. All arteries that course anterior to the vena cava should be considered accessory or polar arteries and should be carefully preserved if of significant size.

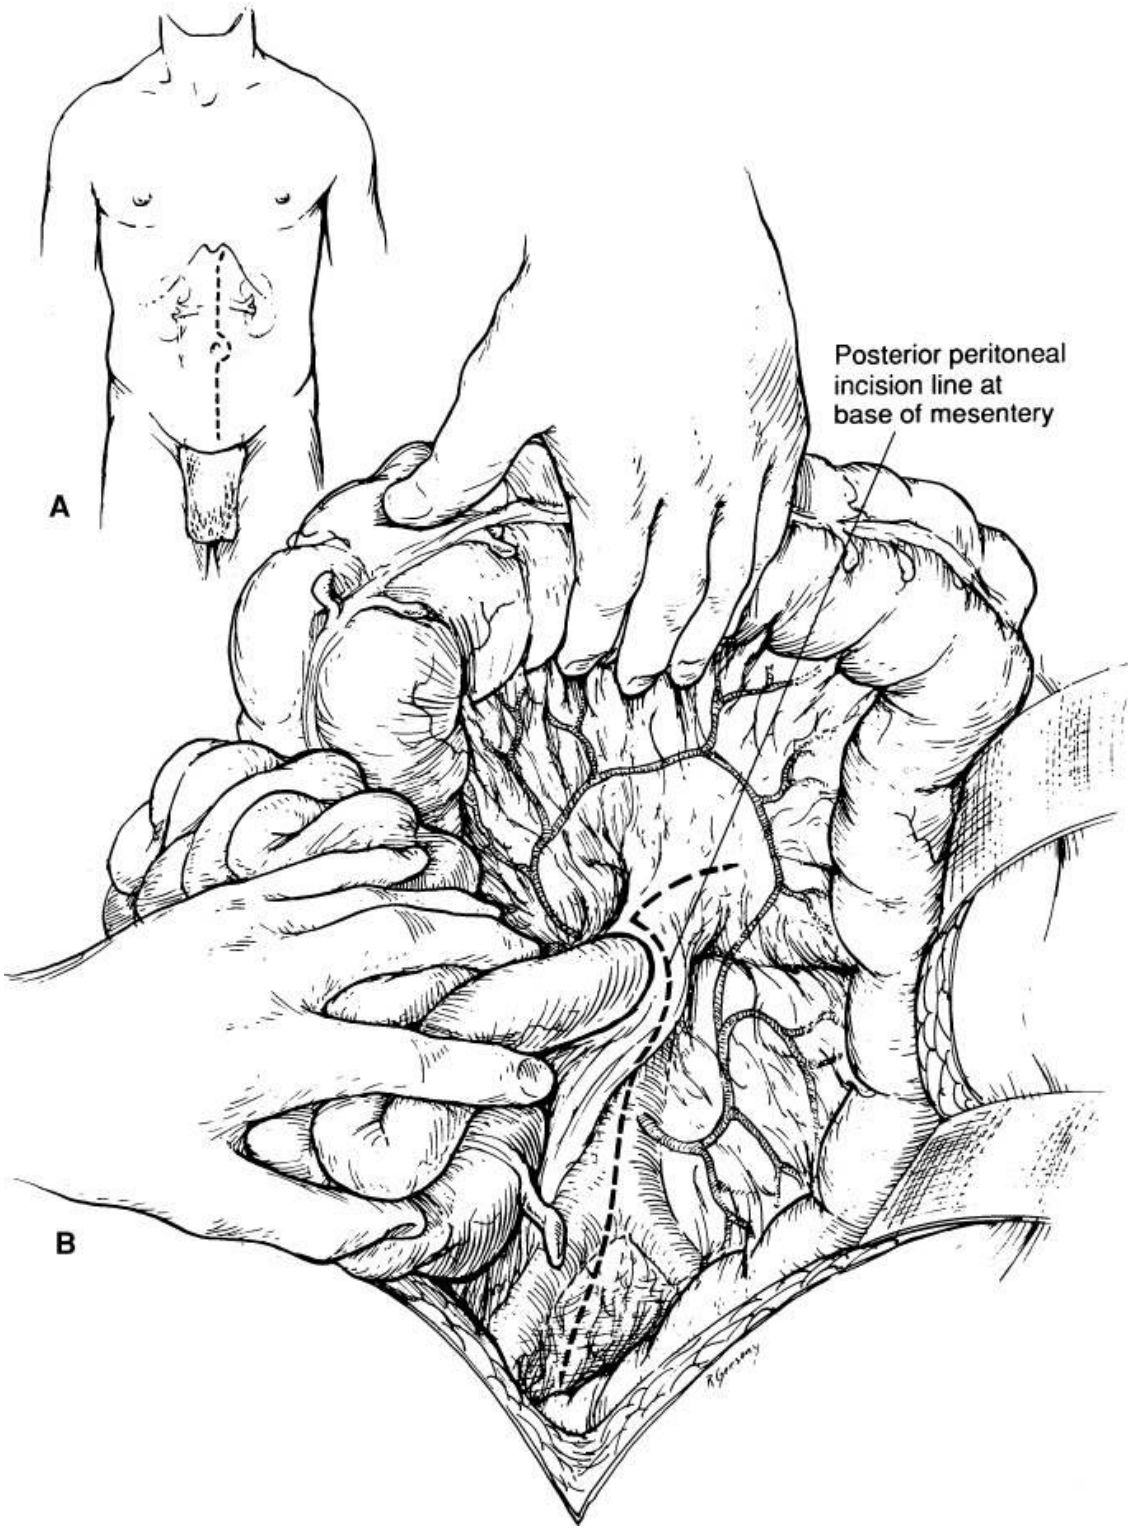

Figure 216.2. A, B. Exposure of the aorta and left renal hilum through the base of the mesentery. Extension of the posterior peritoneal incision to the left, along the inferior border of the pancreas, provides entry to an avascular plane behind the pancreas. This allows excellent exposure of the entire left renal hilum as well as the proximal right renal artery. (Reprinted from Benjamin ME, Dean RH. Techniques in renal artery

reconstruction: part I. *Ann Vasc Surg* 1996;10(3):306–14, with permission from Elsevier.)

In cases where the supraceliac aorta is used as an inflow, combined visceral-renal artery revascularization, or ex vivo branch renal artery repair is required, a generous transverse incision is planned from the contralateral semilunar line, bisecting the ipsilateral costal margin and extending to the pelvic crest. In these cases, the ipsilateral flank is elevated with either a rolled sheet or similar padding. A left visceral mobilization allows the surgeon access to the renal arteries, celiac axis, superior mesenteric artery, and supraceliac aorta. If needed, the diaphragmatic crus may be divided allowing further dissection and access to the extrapleural aorta up to the T10 level of the descending thoracic aorta.

If bilateral renal artery revascularization is required, the exposure technique can be modified. The base of the small bowel mesentery may be mobilized to allow for evisceration of the small bowel, right and transverse colon. In this exposure, the ligament of Treitz is divided and the posterior peritoneal incision proceeds along the base of the mesentery to the cecum then up the lateral gutter to the foramen of Winslow. The inferior border of the pancreas is fully mobilized, which exposes the aorta above the superior mesenteric artery. This latter exposure can be complicated postoperatively by chylous ascites, which can prove quite problematic.

Open Renal Arterial Reconstructions

There is no single operative method of renal artery reconstruction that provides optimal surgical reconstruction for all renal artery lesions. Patient anatomy, disease morphology, and surgeon preference must each be weighed when considering operative technique. There are three basic methods of repair: renal bypass, renal artery thromboendarterectomy, and renal artery reimplantation. Of these methods, renal bypass is the most common and versatile. Saphenous vein is the preferred conduit for an isolated renal artery bypass in an adult. Hypogastric artery is selected for renal reconstruction in the child and adolescent. In the absence of satisfactory autogenous material and a renal artery of <4 mm in diameter, a 6-mm thin walled polytetrafluoroethylene graft provides patency equivalent to autogenous reconstruction.

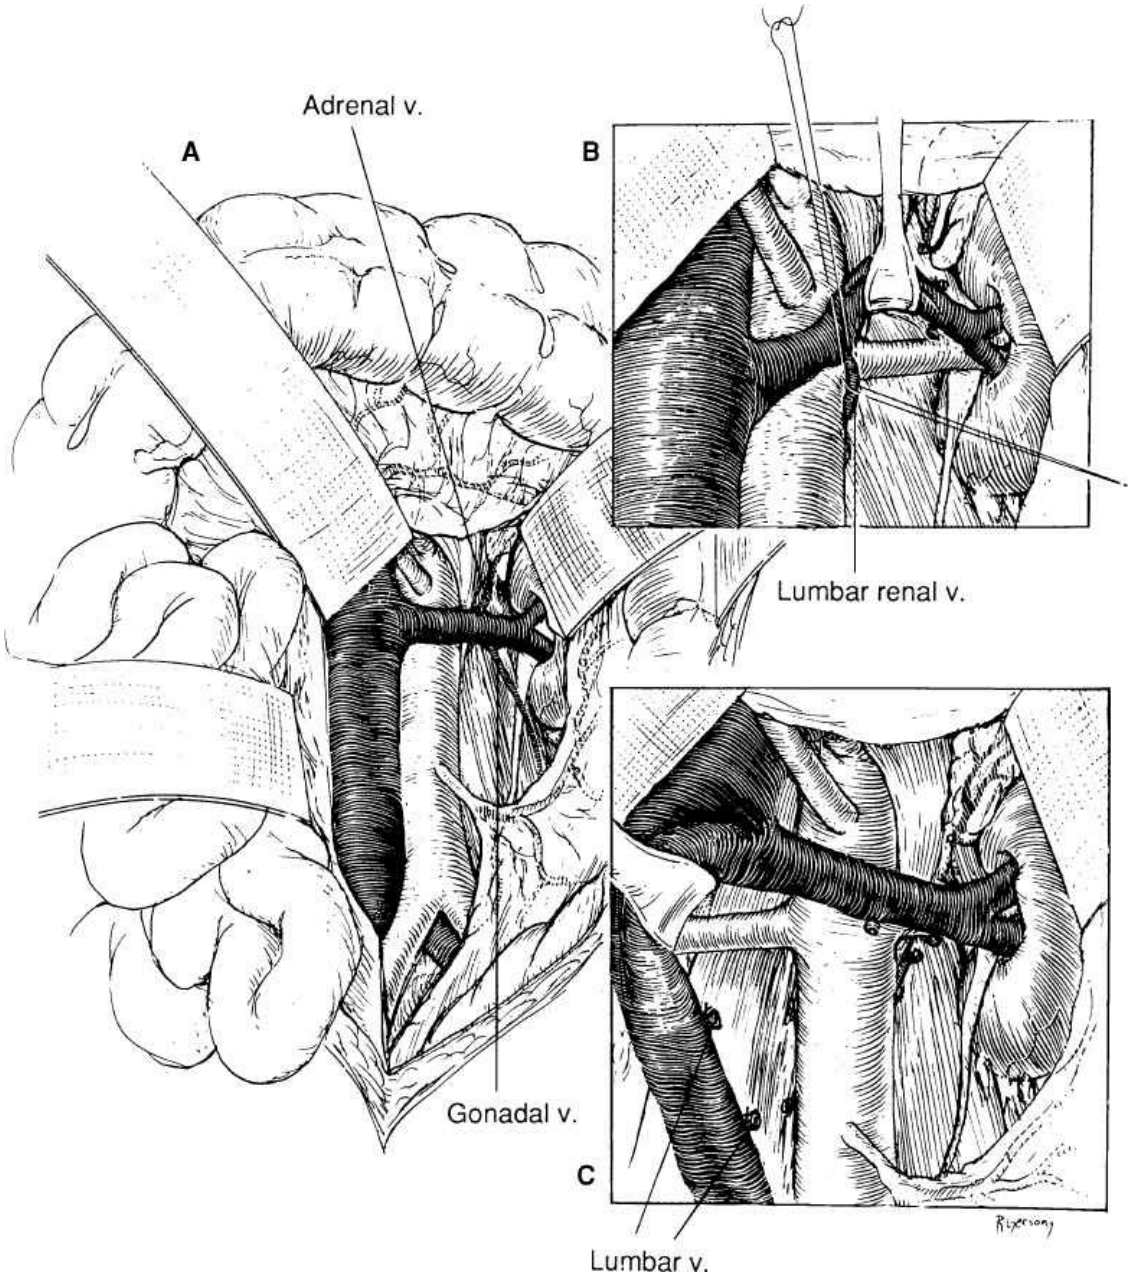

Figure 216.3. **A.** Exposure of the proximal right renal artery through the base of the mesentery. **B.** Mobilization of the left renal vein by ligation and division of the adrenal, gonadal, and lumbar–renal veins allows exposure of the entire left renal artery to the hilum. **C.** Two pairs of lumbar vessels have been ligated and divided to allow retraction of the vena cava to the right, revealing adequate exposure of the proximal renal artery disease. (Reprinted from Benjamin ME, Dean RH. Techniques in renal artery reconstruction: part I. *Ann Vasc Surg* 1996;10(3):306–14, with permission from Elsevier.)

Aortorenal Bypass

Regardless of the conduit chosen, proximal aortorenal anastomosis is

performed first to minimize warm ischemic time. A segment of infrarenal aorta proximal to the inferior mesenteric artery is controlled and an aortotomy created along the anterolateral aspect of the aorta. It is important to excise an ellipse of aorta with the length of the aortotomy at least three times the diameter of the renal artery conduit. Several applications of a 4.8-mm aortic punch can be used to create this ellipse. The proximal anastomosis is performed with a continuous 6-0 polypropylene suture (Fig. 216.6).

In the past, the distal graft to renal artery anastomoses were frequently created in an end-to-side fashion; however, distal end-to-end anastomosis is preferred. In this case, both conduit and renal artery are spatulated widely (two to three times the diameter of the renal artery) and the anastomosis accomplished with a continuous 7-0 polypropylene suture. Prior to the completion of the anastomosis, the graft is flushed of air and debris and blood flow reestablished to the kidney. In most instances, the warm renal ischemia time can be limited to 20 minutes or less.

Thromboendarterectomy

Transaortic thromboendarterectomy is particularly useful in patients with multiple renal arteries that demonstrate orificial atherosclerotic stenosis. Prior to undertaking thromboendarterectomy, the extent of atherosclerotic disease should be clearly defined. All visible and palpable renal artery atheroma should end within 1 to 1.5 cm of the aortic origin. Thromboendarterectomy requires more extensive aortic exposure than aortorenal bypass (Fig. 216.7A). The aorta proximal to the superior mesenteric artery should be exposed for control at this level (Fig. 216.7B). As discussed previously, exposure is facilitated by partial division of the diaphragmatic crura. The superior mesenteric artery origin is exposed and controlled with an elastic vessel loop. After preliminary control of each renal artery and the proximal and distal aorta, the aorta is opened longitudinally to the base of the superior mesenteric artery. First a sleeve endarterectomy of the aorta is performed. The correct endarterectomy plane is best defined at the site of the most advanced atherosclerotic disease. The aortic atheroma is divided sharply at the proximal and distal end points flush with the residual adventitia. Distal tacking sutures may be applied if necessary. Following sleeve endarterectomy of the aorta, an eversion endarterectomy of each renal artery is performed. The renal artery is everted into the aorta to allow the distal end point of the endarterectomy to be visualized. The aortic arteriotomy is then closed primarily with a

continuous 5-0 polypropylene suture.

As with thromboendarterectomy at all anatomic sites, this procedure is contraindicated by the presence of degenerative aneurysmal changes of the aortic wall and aortic atheroma complicated by transmural calcification. This later condition is defined by gentle palpation of the aorta. Transmural calcification may feel like fine grade sandpaper on palpation. When thromboendartectomy is performed in this setting, multiple, difficult to control, defects may be created within the adventitia, which are apparent only after blood flow is restored.

Renal Artery Reimplantation

If after extensive mobilization of the renal artery there is sufficient redundancy in the vessel, an aortic reimplantation may be considered. As with aortorenal bypass, the procedure requires that an ellipse of the aorta be taken and that the renal artery be spatulated two to three times its normal diameter and then reimplanted into the aorta at the anatomic level (Fig. 216.8). This technique is particularly appealing in children and adolescents as it obviates concerns regarding renal artery conduit in these age groups.

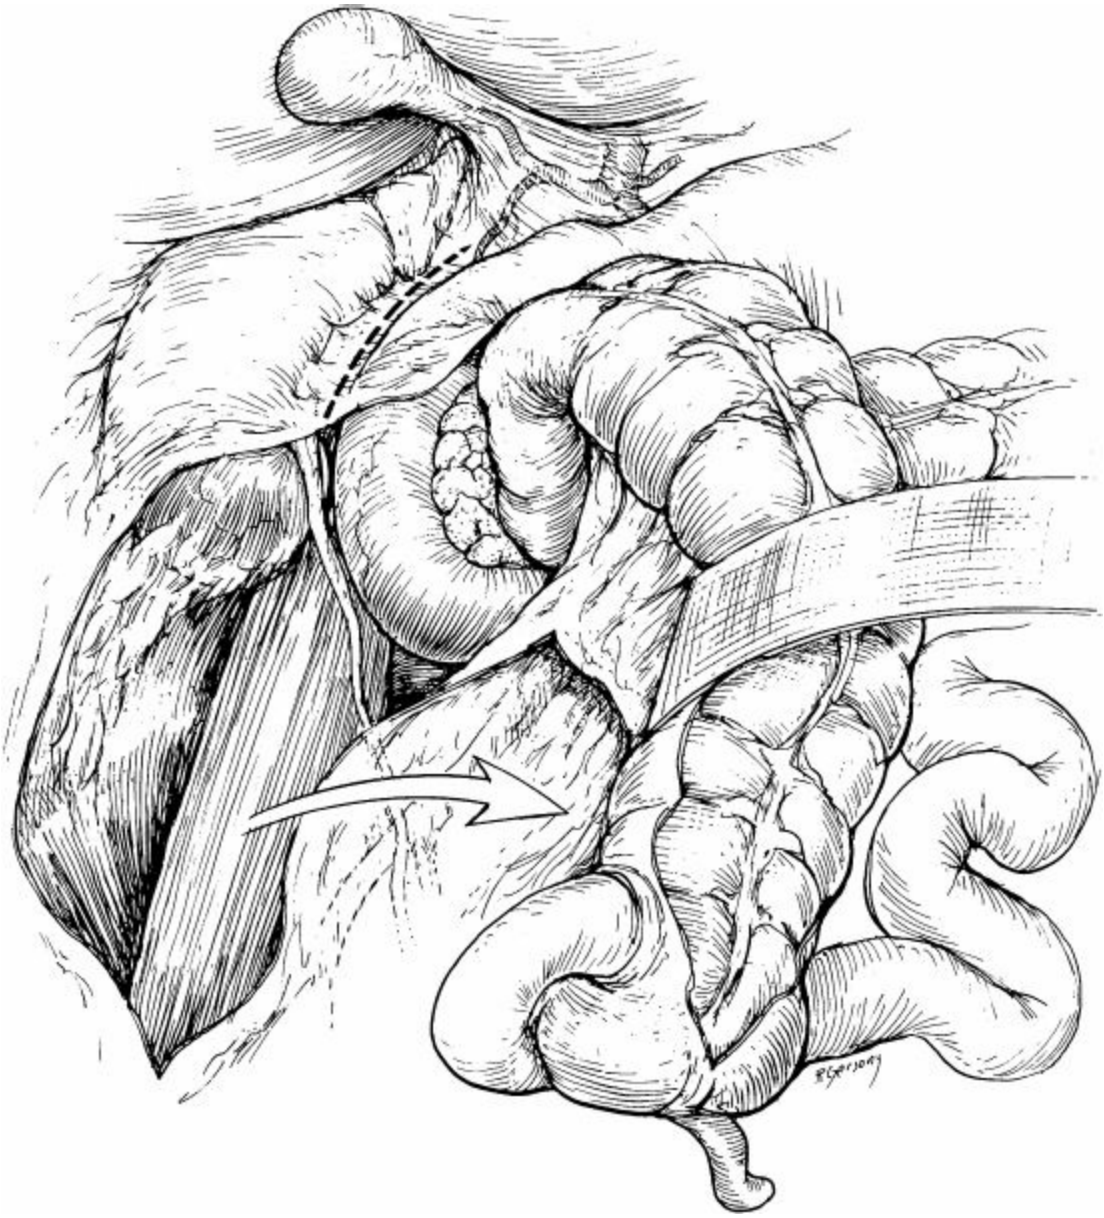

Figure 216.4. With the right colon mobilized medially, a Kocher maneuver exposes the right renal hilum. (Reprinted from Benjamin ME, Dean RH. Techniques in renal artery reconstruction: part I. *Ann Vasc Surg* 1996;10(3):306–14, with permission from Elsevier.)

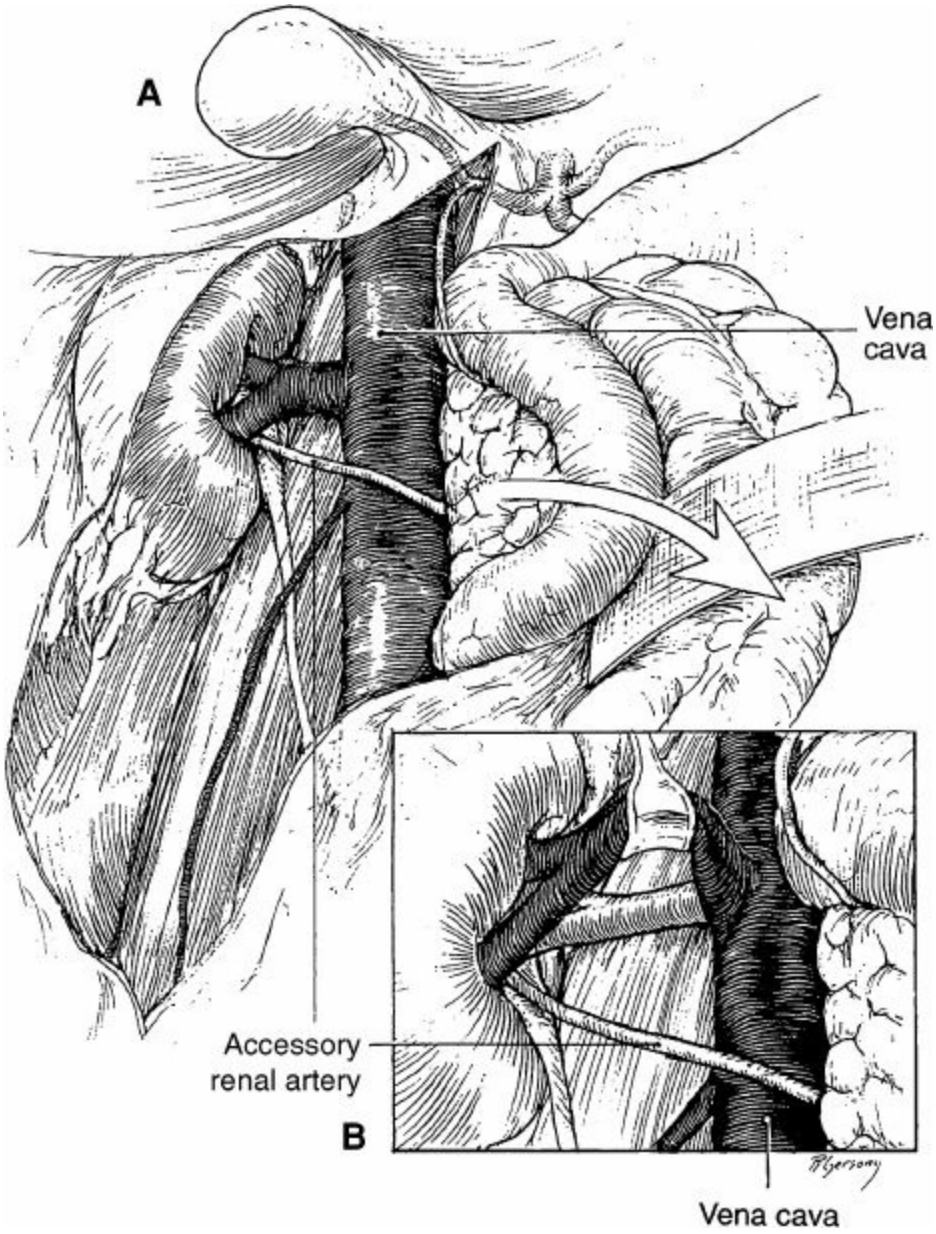

Figure 216.5. **A.** Not uncommonly, an accessory right renal artery arises from the anterior aorta and crosses anterior to the vena cava. **B.** The right renal vein is typically mobilized superiorly for exposure of the distal right renal artery. (Reprinted from Benjamin ME, Dean RH. Techniques in renal artery reconstruction: part I. *Ann Vasc Surg* 1996;10(3):306–14, with permission from Elsevier.)

Splanchnorenal Bypasses

Splanchnorenal bypasses have been used as an alternative method for renal revascularization. It is essential that the celiac axis and its branches be free of hemodynamically significant disease prior to reconstruction. In addition, significant compression during respiratory motion by the arcuate

ligament must be excluded. The exposure for a hepatorenal bypass is obtained through a right subcostal incision (Fig. 216.9). The common hepatic artery is exposed after incising the lesser omentum. A Kocher maneuver is performed to identify the inferior vena cava, the right renal vein, and the right renal artery (Fig. 216.10). A greater saphenous vein segment is ideally used to construct the bypass. The proximal anastomosis is made to the common hepatic artery in an end-to-side fashion with a continuous 6-0 polypropylene suture. The vein craft courses through the foramen of Winslow anterior to the vena cava. The distal renal artery anastomosis is constructed in an end-to-end fashion as described previously.

The splenorenal bypass is usually undertaken through a left subcostal incision. The splenic flexure of the colon is mobilized and the lateral attachments of the descending colon are transected and the dissection plane is carried just anteriorly to Gerota fascia to identify the left renal vein. This anatomic landmark serves as reference to identify the left renal artery. The inferior and lateral border of the pancreas is mobilized in order to expose the splenic artery (Fig. 216.11). In the majority of cases, the proximal most splenic artery is preferable as a point of inflow. Ideally, a greater saphenous vein segment is used to create a proximal end-to-side anastomosis to the splenic artery with a continuous 6-0 polypropylene suture. The distal anastomosis is made in an end-to-end fashion after spatulation of both the renal artery and the vein graft. Alternatively, the splenic artery may be divided in its proximal portion and sewn in an end-to-end fashion to the renal artery avoiding the need for a conduit. Rarely, the left renal artery is redundant and can be reimplanted into the splenic artery.

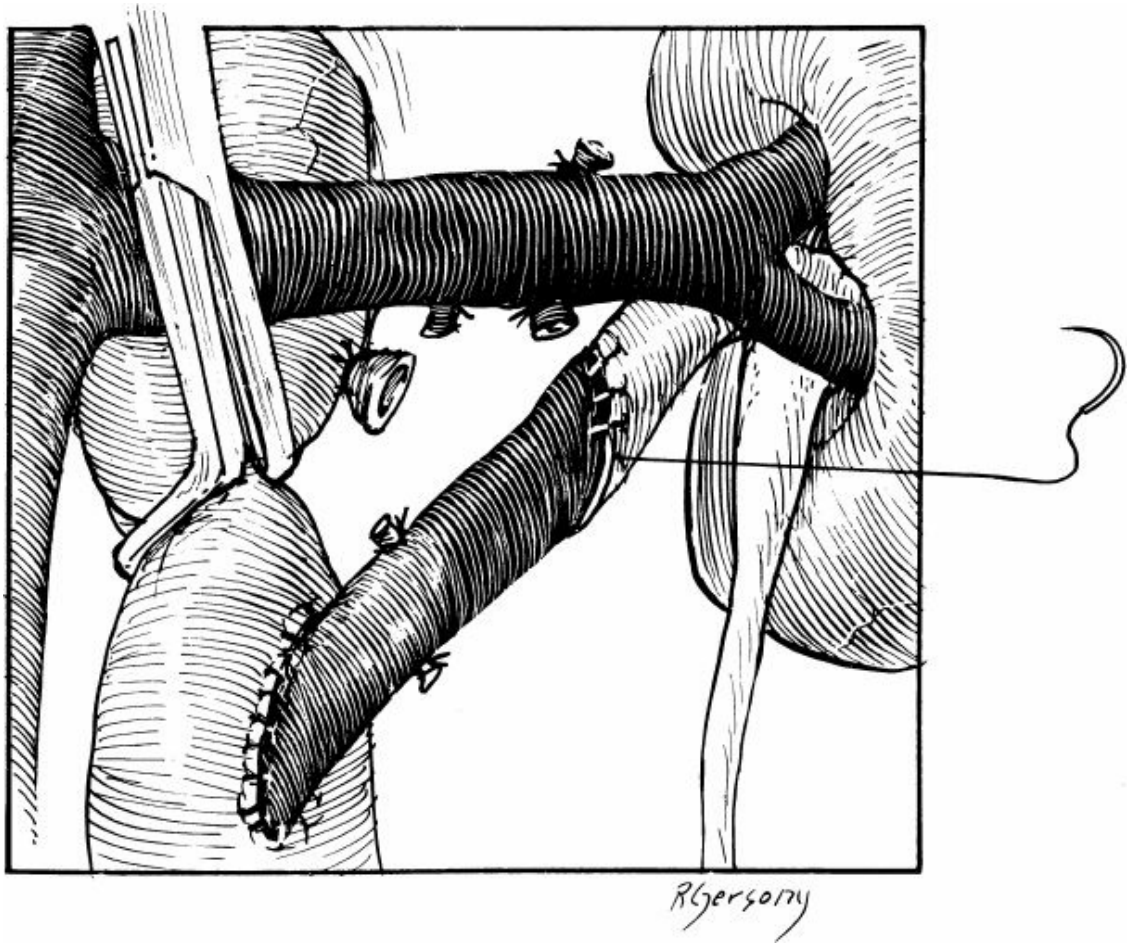

Figure 216.6. Technique for end-to-end aortorenal bypass grafting. The length of arteriotomy is at least three times the diameter of the artery to prevent recurrent anastomotic stenosis. For the anastomosis, 6-0 or 7-0 monofilament polypropylene sutures are used in continuous fashion, under loupe magnification. If the apex sutures are placed too deeply or with excess advancement, stenosis can be created, posing a risk of late graft thrombosis. (Reprinted from Benjamin ME, Dean RH. Techniques in renal artery reconstruction: part I. *Ann Vasc Surg* 1996;10(3):306–14, with permission from Elsevier.)

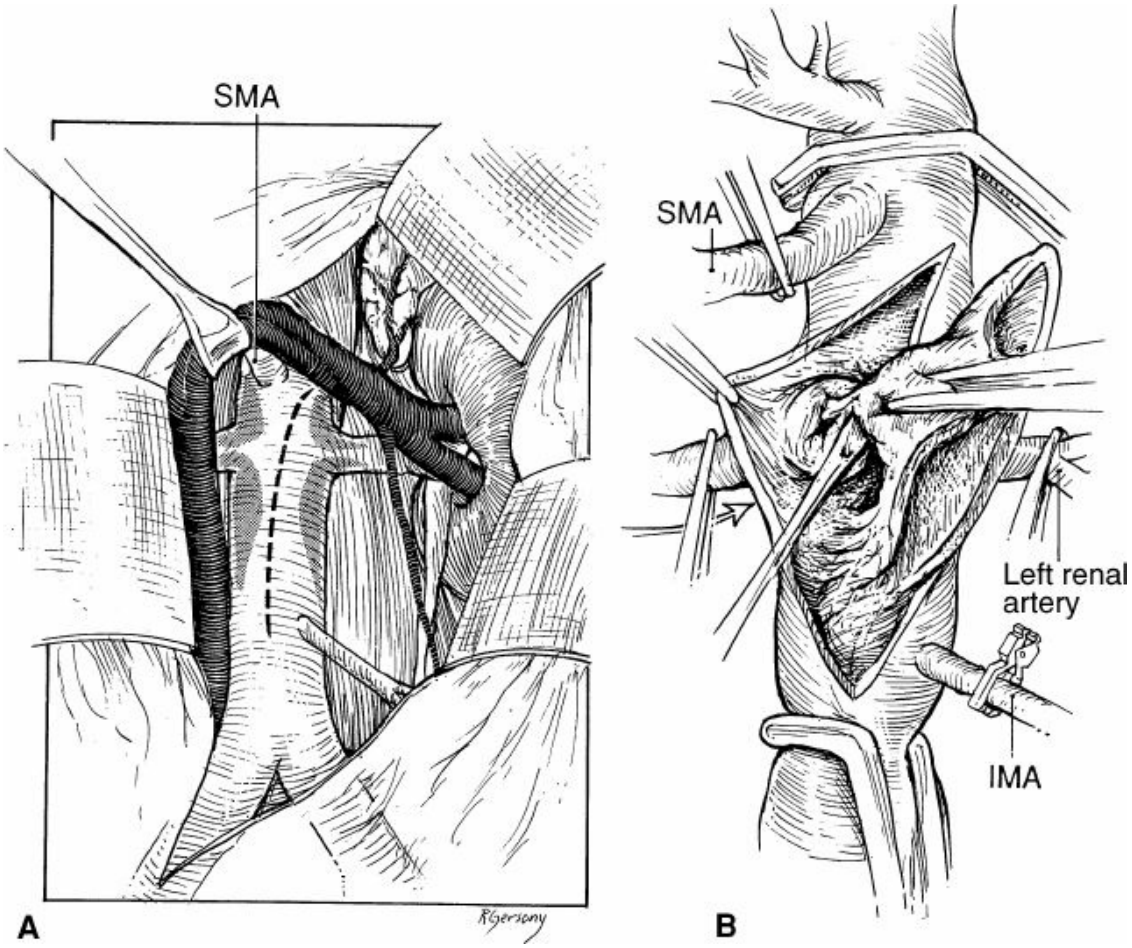

Figure 216.7. Exposure for a longitudinal transaortic endarterectomy is through the standard transperitoneal approach. The duodenum is mobilized from the aorta laterally in standard fashion or, for more complete exposure, the ascending colon and small bowel are mobilized. **A.** *Dotted line* shows the location of the aortotomy. SMA, superior mesenteric artery. **B.** The plaque is transected proximally and distally, and with eversion of the renal arteries, the atherosclerotic plaque is removed from each renal ostium. The aortotomy is typically closed with a running 4-0 or 5-0 polypropylene suture. IMA, inferior mesenteric artery. (Reprinted from Benjamin ME, Dean RH. Techniques in renal artery reconstruction: part I. *Ann Vasc Surg* 1996;10(3):306–14, with permission from Elsevier.)

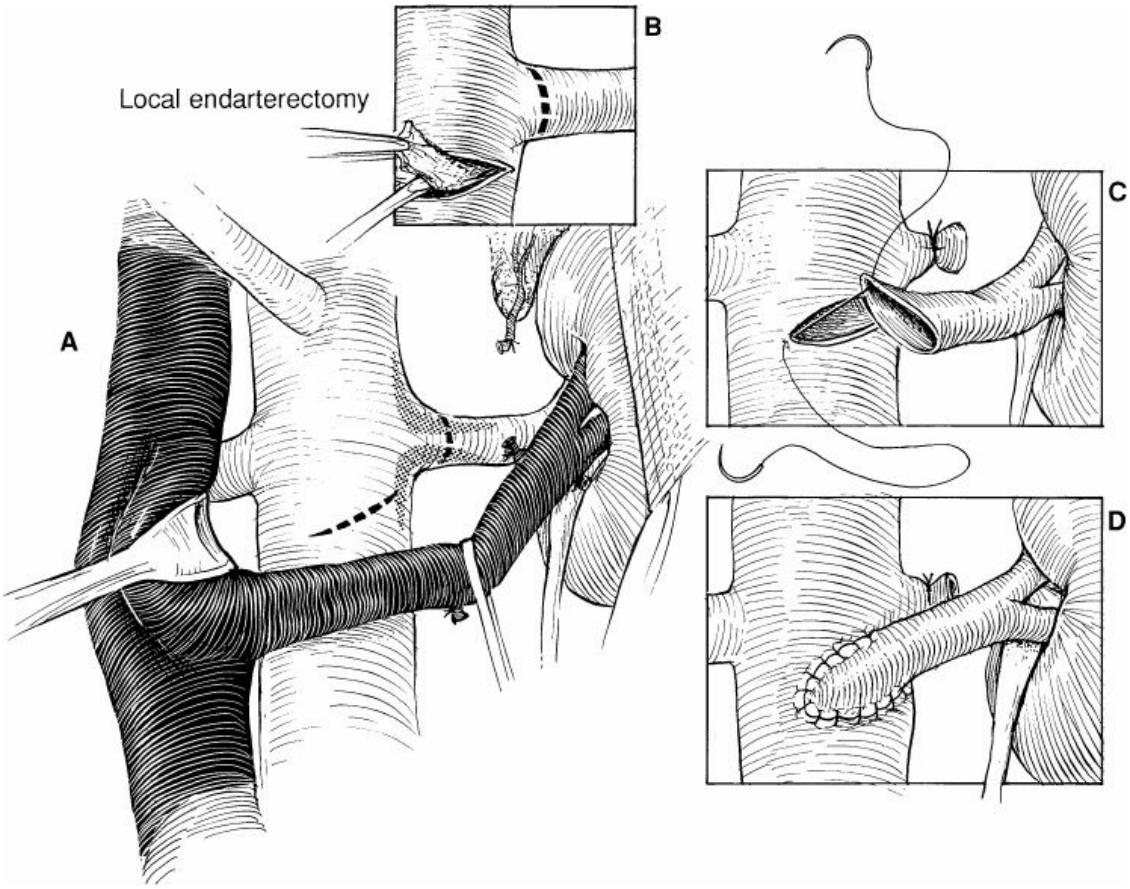

Figure 216.8. When the renal artery is redundant and the disease orificial, the vessel usually can be reimplanted at a lower level (**A**). Local endarterectomy (**B**) allows for placement of the monofilament suture in the aortic wall (**C**). The native renal artery is then ligated, proximally spatulated, and reimplanted (**D**). (Reprinted from Benjamin ME, Dean RH. Techniques in renal artery reconstruction: part I. *Ann Vasc Surg* 1996;10(3):306–14, with permission from Elsevier.)

Ex Vivo Reconstruction

Ex vivo reconstruction should be considered when satisfactory exposure of the distal renal artery and its branches is inadequate or if warm ischemia is projected to be >40 minutes due to the technical complexities of repair. When undertaking this approach, measures to provide protection to the kidney should be employed. Cold perfusion preservation of the kidney, including topical ice slush, can be used to safely extend the ischemic period. This technique is increasingly being used in management of failed endovascular stent placement in which endoluminal stents have been placed into the distal most renal artery and its branches. An ex vivo reconstruction is also employed in management of renal artery aneurysms involving the renal artery branches.

When a branch renal artery reconstruction is planned, the kidney is exposed through an ipsilateral flank incision (Fig. 216.12). The ureter is mobilized to the pelvic brim, but care is taken not to skeletonize it by preserving the periureteric retroperitoneal tissue. At this location, the ureter is looped with an elastic sling. This controls renal perfusion from periureteric collateral present when significant occlusive disease involves the main renal artery. The kidney is mobilized from Gerota space after the fascia is opened anteriorly in cruciate fashion. The kidney is then completely mobilized within the avascular plane of Gerota space. The key to this portion of the procedure is early mobilization of the superior pole of the kidney, which facilitates the remainder of the dissection. The renal artery and renal vein are mobilized in their entirety, and systemic anticoagulation with intravenous heparin is achieved.

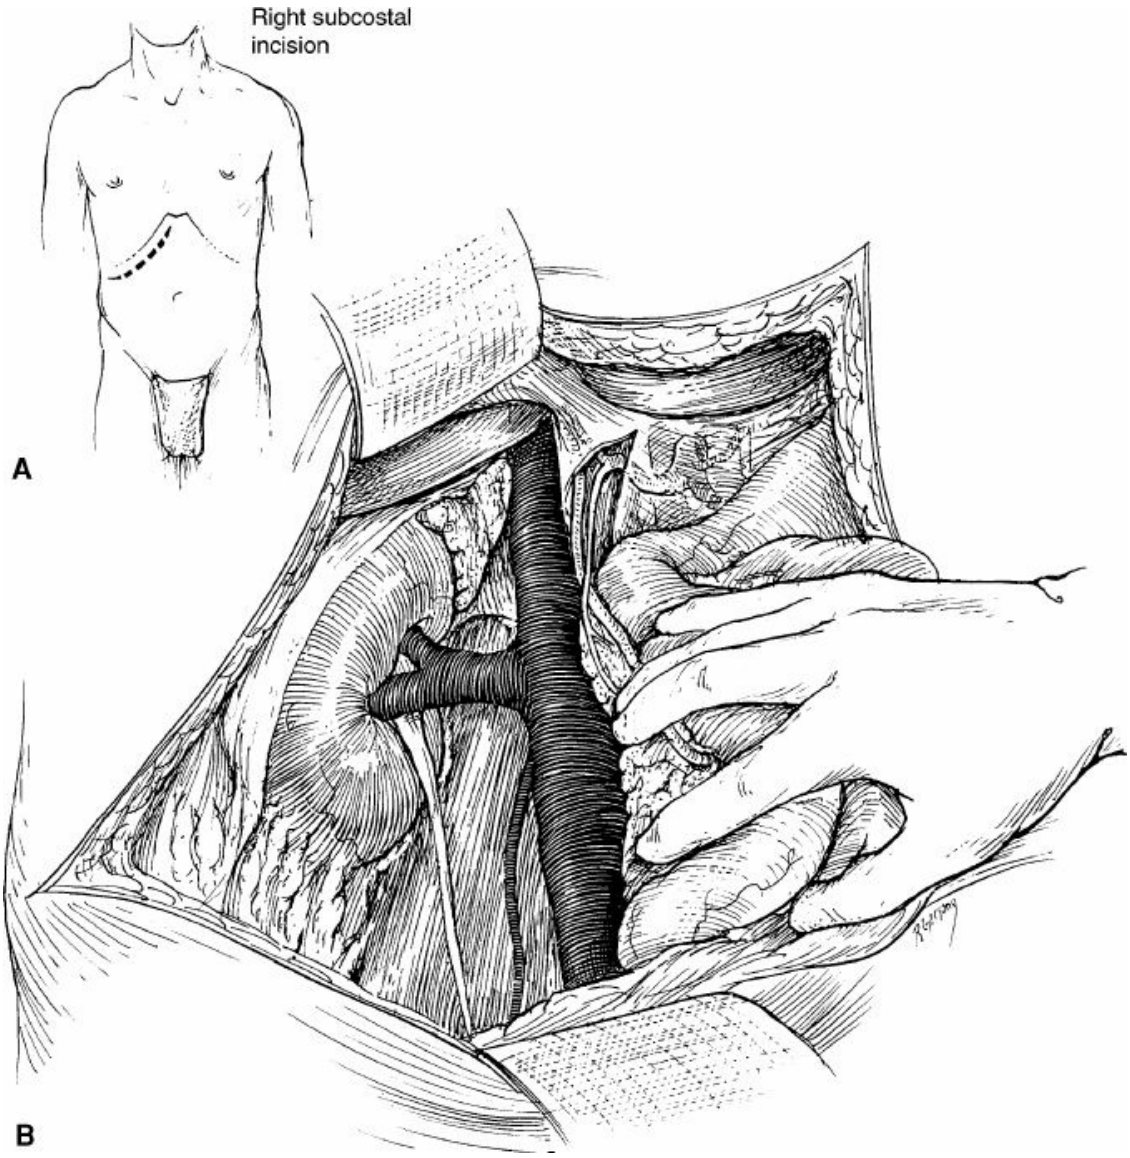

Figure 216.9. A, B. In preparation for extra-anatomic reconstruction of the right renal artery, the common hepatic artery and the proximal gastroduodenal artery are exposed in the hepatoduodenal ligament. Exposure would typically be through a right subcostal skin incision. (Reprinted from Benjamin ME, Dean RH. Techniques in renal artery reconstruction: part I. *Ann Vasc Surg* 1996;10(3):306–14, with permission from Elsevier.)

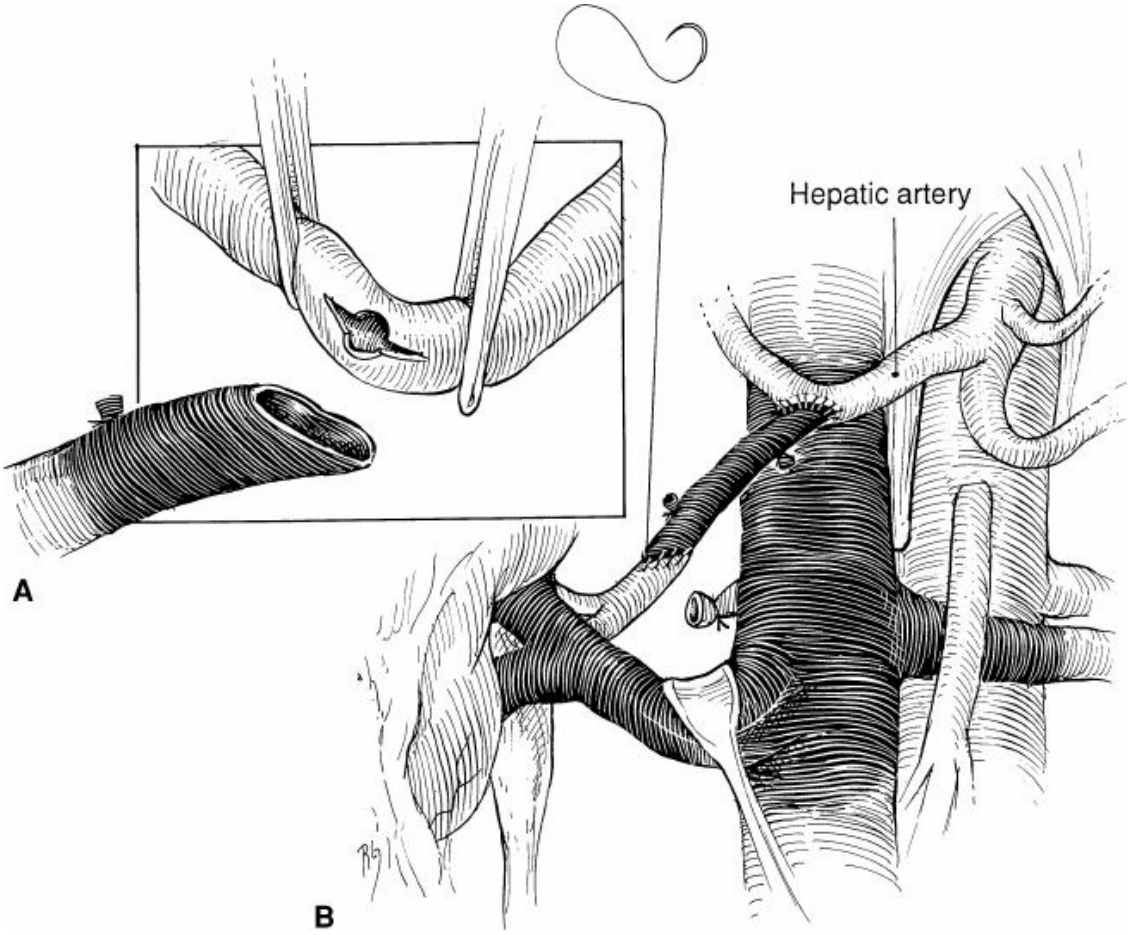

Figure 216.10. The reconstruction is completed using a saphenous vein interposition graft between the side of the hepatic artery (**A**) and the distal end of the transected right renal artery (**B**). (Reprinted from Benjamin ME, Dean RH. Techniques in renal artery reconstruction: part I. *Ann Vasc Surg* 1996;10(3):306–14, with permission from Elsevier.)

When arterial exposure is satisfactory, the renal vein may be left intact but controlled with an atraumatic clamp. A small venotomy is made and the kidney is perfused using a chilled (5°C) solution with an intracellular composition. This should be held at a height of approximately 1 to 2m above the operating table. If arterial exposure is insufficient with the vein

intact, a partial occluding clamp is placed at the caval origin and the vein is divided with a caval cuff. In either instance, the kidney is perfused with 300 to 500 mL of chilled perfusate and placed on a plastic sheet covered with ice slush. Only the vascular hilum is exposed while the remainder of the kidney remains surrounded by ice slush to serve as a supplement to cold perfusion. The aortorenal anastomosis is performed at an infrarenal level as previously described. When the vein is divided, the kidney is returned to the renal fossa after arterial reconstruction. The venous anastomosis is created at its original site. Autotransplantation is not usually necessary. A semicontinous 6-0 polypropylene suture is used to avoid constriction of the venous anastomosis.

Intraoperative Assessment

The short course and high blood flow rates of direct aortorenal reconstructions favor their patency. A flawless technique plays a dominant role in determining postoperative patency of repair. Regardless of the method of reconstruction, each renal artery repair is assessed with intraoperative duplex sonography. The operative site is filled with warm saline. A 18 MHz compact linear array probe with Doppler color flow imaging designed for intraoperative assessment is placed within a sterile sheath with the latex tip containing the sterile gel. A B-scan image is obtained at all sites of aortic control and vascular reconstruction. These sites are imaged in both longitudinal and transverse projection. Doppler samples are obtained proximal and distal to B scan lesions in longitudinal projection to determine their hemodynamic significance. Focal increases in renal artery PSV of >1.8 m/sec associated with distal turbulent wave form are considered major defects, and these are revised immediately. In more than 1,300 renal artery reconstructions, major B scan defects requiring immediate revision have been observed in 10% to 12% of cases. A disproportionate number of these defects occur after transaortic renal endarterectomy

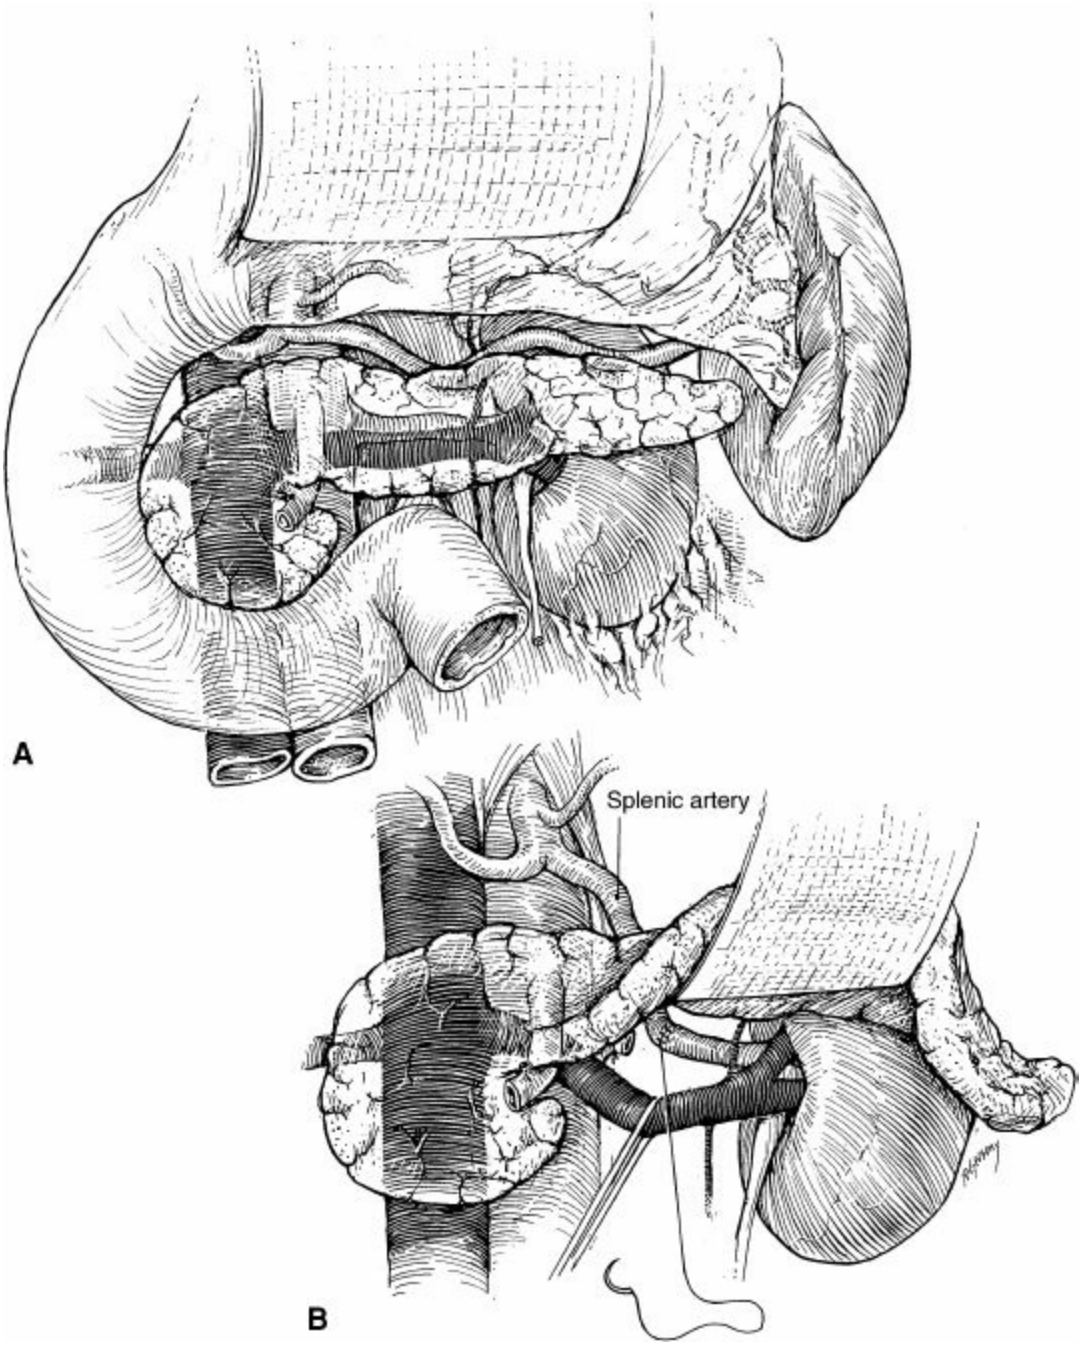

Figure 216.11. A. Exposure of the left renal hilum in preparation for splenorenal bypass. The pancreas has been mobilized along its inferior margin and retracted superiorly. **B.** The transected splenic artery is anastomosed end-to-end to the transected left renal artery. A splenectomy is not routinely performed. (Reprinted from Benjamin ME, Dean RH. Techniques in renal artery reconstruction: part I. *Ann Vasc Surg* 1996;10(3):306–14, with permission from Elsevier.)

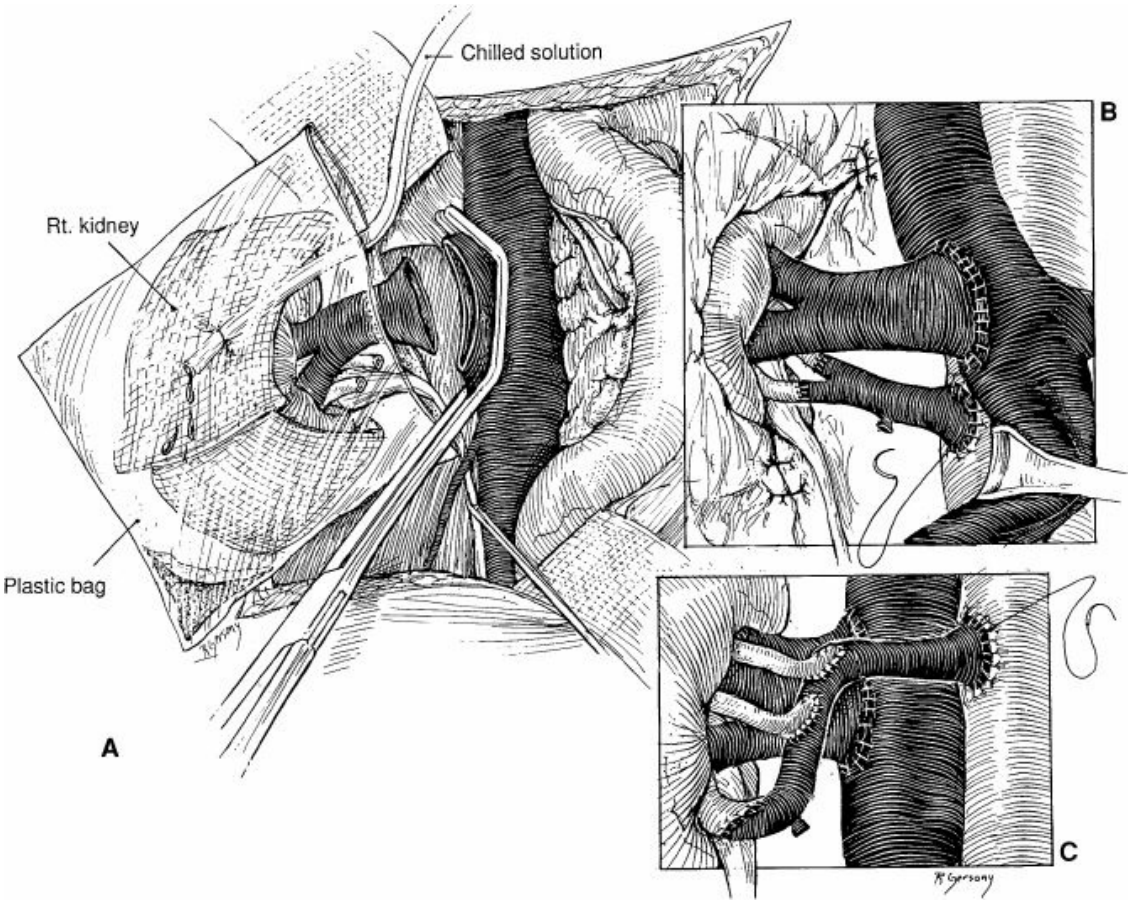

Figure 216.12. A. An ellipse of the vena cava containing the renal vein origin is excised by placement of a large partially occluding clamp. After ex vivo branch repair, the renal vein can then be reattached without risk of anastomotic stricture. **B.** The kidney is repositioned in its native bed after ex vivo repair. Gerota fascia is reattached to provide stability to the replaced kidney. **C.** Arterial reconstruction can be accomplished via end-to-end anastomoses (as in **B**) or occasionally with a combination of end-to-end and end-to-side anastomoses. (Reprinted from Benjamin ME, Dean RH. Techniques in renal artery reconstruction: part I. *Ann Vasc Surg* 1996;10(3):306–14, with permission from Elsevier.)

RESULTS OF RENAL ARTERY INTERVENTION AND OUTCOMES

Open renal artery reconstruction has proven anatomic durability in the treatment of renovascular hypertension and renovascular renal insufficiency (i.e., ischemic nephropathy). However, the morbidity and mortality associated with open reconstruction have favored the application of percutaneous transluminal angioplasty and endoluminal stent placement

(PTAS). Although the hypertension and renal function benefit of PTAS is less well documented than open surgical repair, the procedure offers the benefit of decreased morbidity and mortality, reduced hospitalization, and brief recovery time. These benefits are countered by increased rates of restenosis and a lack of level 1 evidence demonstrating any improved event-free survival after PTAS. Indeed recent randomized trials have demonstrated no benefit in reduction of hypertension or renal insufficiency with PTAS.

Morbidity and mortality associated with open surgical reconstruction for atherosclerotic renovascular disease vary with the patient's age, associated renal insufficiency, left ventricular cardiac performance, and magnitude of the operation. Large contemporary series have demonstrated perioperative mortality <1% for unilateral renal artery reconstruction in good risk patients compared with more than 7% perioperative mortality in patients of advanced age, requiring complex reconstruction for excretory renal insufficiency. These same series suggest that when open operations are undertaken in patients with severe hypertension, a blood pressure benefit (hypertension cured or improved) is observed in 85% of patients. In patients with severe hypertension associated with excretory renal insufficiency, 60% have demonstrated >20% improvement in glomerular infiltration rate after open operation. When direct aortorenal methods of reconstruction are used in combination with intraoperative duplex sonography, 97% of repairs should demonstrate primary patency at 10 years. Recurrent stenosis or occlusion after open repair has demonstrated significant and independent associations with eventual dialysis dependence.

Table 216.1 summarizes the technical success, renal function and blood pressure response, restenosis rate, and rate of major complications from 25 reports after PTAS for atherosclerotic renovascular disease. Overall, 98% of procedures were technically successful. Blood pressure benefit was observed in 61% and renal function was improved in 22% of patients with ischemic nephropathy. Among those studies with objective measures of patency, recurrent stenosis was noted in 19% with major periprocedural complications in 9%. It is important to recall that PTAS has not been shown to reduce the occurrence of subsequent adverse cardiovascular events, renal events, or mortality in large clinical trials. This creates the present controversy currently surrounding this topic and provides grounds for further avenues of study.

EDITOR'S COMMENT

In the peak of open vascular surgery, renal artery reconstructions were one of the most common operations performed. Multiple sophisticated diagnostic studies were developed and used, including invasive procedures such as renal vein renin sampling, to confirm that renal artery stenosis (RAS) was leading to renovascular hypertension. Creative surgeons, like the groups from Wake Forest University headed by Dr. Dean and the group from the University of Michigan headed by Dr. Stanley, were able to offer patients bypasses, reimplantations, and thromboendarterectomies to often cure renovascular hypertension secondary to RAS. Fortunately, two major developments occurred over the last 20 years to make renal artery stenting/surgery for RAS leading to renovascular hypertension almost a thing of the past.

First, renal artery stenting exploded in the treatment of renal artery stenosis, not necessarily in the treatment of renovascular hypertension. We documented back in 2004 using a large nationally representative database from 1998 to 2001, that combined aortic and renal, as well as isolated renal revascularizations, decreased by 73% and 56%, respectively (Knipp BS, Dimick JB, Eliason JL, et al. Diffusion of new technology for the treatment of renovascular hypertension in the United States: surgical revascularization versus catheter-based therapy, 1988–2001. *J Vasc Surg* 2004;40(4):717–23). During this same time period, the number of catheter-based procedures exploded by 173%. "Drive by" renal artery stenting for renal artery stenosis was rampant for even moderate <60% renal artery stenosis. Renal artery stenting became so widespread with such large expenditures in the setting of no real increase in the diagnosis of renovascular hypertension that multiple randomized controlled trials were performed to sort out whether renal artery stenting really impacted the natural history of the disease.

While none of the renal artery stenting trials were really ever compared with surgery, they have for the most part showed noninferiority of medical therapy alone compared with renal artery stenting and medical therapy. The best of the trials in my opinion was the so-called CORAL trial (Cooper CJ, Murphy TP, Cutlip DE, et al.; CORAL Investigators. Stenting and medical therapy for atherosclerotic renal-artery stenosis. *N Engl J Med* 2014;370(1):13–22). The authors randomized 947 patients who had atherosclerotic RAS (defined by multiple and various methods, and not always severe RAS), systolic hypertension, and were taking two more blood pressure medications. Over a median follow-up of 43 months, the rate of the primary composite end point did not differ between the stented group (and best medical therapy) and best medical therapy group. During follow-up, there was a consistent difference in systolic blood pressure favoring the stent group. However, in long-term follow-

up, renal artery stenting did not confer benefit in relation to clinical events when added to best medical therapy. Which brings me around to my second point relevant to renal artery stenosis from atherosclerosis and associated with renovascular hypertension; namely, that the pharmacologic therapies improved significantly over time with entire new classes of medications, including direct renin inhibitors, now available.

As with everything, let's not throw out the baby with the bath water (i.e., there are still some surgical indications for isolated renal artery surgery or endovascular approaches). Clearly, patients with fibromuscular dysplasia (FMD) benefit from percutaneous angioplasty. In addition, pediatric patients with renal artery stenosis are much better treated with surgery (Stanley JC, Criado E, Upchurch GR Jr, et al.; Michigan Pediatric Renovascular Group, Kershaw DB, Williams DM, Berguer R, et al. Pediatric renovascular hypertension: 132 primary and 30 secondary operations in 97 children. *J Vasc Surg* 2006;44(6):1219–28; discussion 1228–9) rather than an endovascular approach. In fact, multiple people have tried treating pediatric renovascular hypertension with stenting with pretty woeful results (Eliason JL, Coleman DM, Criado E, et al. Remedial operations for failed endovascular therapy of 32 renal artery stenoses in 24 children. *Pediatr Nephrol* 2016;31(5):809–17) even though stenting may be indicated when the child is extremely young (and small) or to aid in getting a child through a hypertensive emergency.

Finally, most of the renal artery surgery we do now in my practice is associated with thoracoabdominal aortic aneurysm (TAAA) repair. While the situations are not exactly parallel, talking about renal artery surgery associated with TAAA is sort of like talking about results from combined CABG and carotid endarterectomy versus carotid endarterectomy alone. The operations are really not the same as doing a bypass for renal artery stenosis secondary to atherosclerosis with the renal artery bypass always playing second fiddle to repairing the TAAA. On the other hand, at least the trainees get to expose and sew to the renal artery.

Gilbert R. Upchurch

217 Acute Mesenteric Artery Ischemia: Open and Endovascular

James T. McPhee, Edward Kelly, and C. Keith Ozaki

ETIOLOGY AND PATHOPHYSIOLOGY

Management of the patient facing life-threatening acute mesenteric ischemia maximally challenges the intellectual, technical, clinical, and team leadership skills of the surgeon. Several pathologic mechanisms can result in acute mesenteric ischemic syndromes, including embolism to the superior mesenteric artery (SMA), mesenteric arterial thrombosis (e.g., acute thrombosis of a chronic SMA atherosclerotic lesion), arterial dissections, low-flow nonocclusive mesenteric ischemia (usually with splanchnic vasoconstriction), and mesenteric venous thrombosis. The heart stands as the most common source for emboli, and cardiac pathologies that predispose to thrombus formation include atrial fibrillation (especially in patients with anatomic abnormalities, such as atrial dilation who are not anticoagulated or are underanticoagulated), recent myocardial infarction with mural thrombus formation, and ventricular aneurysm. SMA thromboembolism and acute-on-chronic thrombosis together account for the majority (~75%) of acute mesenteric ischemia cases.

The SMA serves as the primary supplier of blood to the bowel. Anatomically the SMA arises from the anterior aorta typically 1 to 2 cm below the celiac artery, and 1 to 2 cm cephalad to the takeoff of the renal arteries. It usually originates at the level of the first lumbar vertebral body and passes inferiorly and to the right, posterior to the pancreas, and anterior to the fourth portion of the duodenum. This blood vessel, which in the adult is about the size of the fifth finger in diameter, supplies the distal duodenum, the small intestine, and the ascending and transverse colon. Early branches off of the SMA are the pancreaticoduodenal artery (which can serve as a major collateral network between the SMA and celiac axis in occlusive ostial lesions that develop slowly) and the middle colic artery. Since the blood vessel changes caliber with the takeoff of these early

branches, most clinically apparent emboli lodge near the origin of the middle colic, leading to ischemia from the proximal jejunum to the splenic flexure (Fig. 217.1). In 10% to 20% of the population, the right hepatic artery has a replaced origin from the SMA. The SMA terminates as the ileocolic artery. While acute occlusion of the celiac or the inferior mesenteric arteries is usually well tolerated, acute SMA occlusion produces widespread infarction throughout the small bowel and colon.

With abrupt cessation of SMA inflow, small intestinal ischemia rapidly initiates within the usually well-vascularized bowel mucosa, where epithelial and endothelial cell damage lowers mucosal barrier function, leading to bacterial invasion, susceptibility to degrading enzymes, microcirculatory stasis, edema, and intravascular thrombosis. Bacterial toxins and host-derived damage-associated molecular pattern (DAMP) molecules, such as cytokines and particles from cellular death, are released into the portal venous circulation and beyond, and drive systemic effects such as increased capillary permeability with edema formation and shock. Even after restoration of organ perfusion, the endothelial cell dysfunction often persists. The resultant ischemia–reperfusion syndrome drives distant multiple organ insufficiency or failure.

CLINICAL PRESENTATION

The key factor limiting clinical progress in lowering the high morbidity and mortality in acute mesenteric ischemia remains prompt diagnosis; thus, symptoms and signs require careful scrutiny. A key to diagnosis is a high index of clinical suspicion in high-risk patients, especially those with advanced age, cardiac dysrhythmias, recent myocardial infarction, valvular heart disease, congestive heart failure, systemic atherosclerosis, and hypercoagulable states, such as malignancy. Patients with acute mesenteric arterial occlusion typically note abrupt onset of severe, constant epigastric or midabdominal pain, followed soon after by defecation (sometimes diarrhea and/or rarely blood per rectum) and vomiting. The surgeon should also inquire about evidence of chronic symptoms such as postprandial cramping pain with “food fear,” change in bowel habits, and weight loss, since the distinction between acute versus acute-on-chronic disease may impact technical approaches to bowel revascularization. Finally, in the case of SMA embolization, approximately 25% of patients reveal a history of prior embolic events (cerebral, extremity, visceral, etc.).

Figure 217.1. CTA reconstruction showing lateral view of the abdomen. *Red arrow* points to filling defect in the distal superior mesenteric artery (SMA), corresponding to an embolus.

Physical findings in acute mesenteric thromboembolism can be subtle and nonspecific. The abdomen may be distended with diminished intestinal peristaltic sounds. Classically, abdominal tenderness is less than expected from the patient's complaints of severe pain. Document a thorough pulse examination to aid in subsequent bypass graft inflow artery selection or vessel cannulation. Bloody fluid may be retrieved from a nasogastric tube and on rectal examination. Later in the clinical course, as the bowel progresses to infarction, the patient will appear toxic, with shock and peritonitis.

Laboratory tests also yield little sensitivity and specificity. Notable findings may include a leukocytosis with a predominance of immature

white blood cells and a metabolic acidosis. D-dimer has been noted to have a high sensitivity for SMA occlusion, but the specificity of this test is low.

Plain roentgenograms are usually normal but occasionally demonstrate thickened intestinal walls, and in late stages gas in the intestinal wall, or in the portal vein or peritoneum. While emerging as a useful modality in chronic mesenteric occlusive disease, duplex is of limited benefit in the acute setting due to dilated, air-filled loops of bowel. In cases of diagnostic uncertainty and a clinically stable patient, thin-cut computed tomography (CT) scan with intravenous contrast screens for other pathologies. Relevant acute findings on CT scan include whether the contrast-filled SMA can be identified out to its peripheral branches, and bowel abnormalities such as segmental bowel wall thickening. The diagnosis of mesenteric venous obstruction (which is managed primarily with anticoagulation and nutritional support unless it has progressed to significant bowel complications) is made via CT scan—a “halo” or “target” sign can be identified in the superior mesenteric vein. Finally, magnetic resonance angiography can provide anatomic proximal mesenteric vasculature anatomy, although availability and timing limit this modality’s utility in most circumstances.

Visceral biplanar digital subtraction arteriography best defines mesenteric anatomic occlusive lesions. However, angiography is not mandatory, and can result in revascularization delays that adversely affect outcome. In addition to anterior-posterior views, a lateral view starting at the first lumbar artery can demonstrate the characteristic appearance of an embolus with a meniscus sign. Nonocclusive mesenteric ischemia (resulting from a depressed cardiac output and oxygen delivery) findings on angiogram include narrowing at the origin of branches of the SMA, spasm of arcade vessels, and impaired filling of intramural vessels. This syndrome is managed nonoperatively by intra-arterial instillation of dilating compounds (papaverine bolus dose of 60 mg directly into the SMA, followed by a constant infusion of 30 to 60 mg/h until the next angiogram) and correction of the underlying cause of impaired delivery.

INDICATIONS AND CONTRAINDICATIONS

In patients where there has been a clear intra-abdominal catastrophe (which is often the case with acute mesenteric ischemic), extensive laboratory and radiographic testing unnecessarily delays bowel

revascularization, leading to increased bowel loss and higher rates of patient mortality. Resuscitation must proceed expeditiously as the patient is prepared for emergency laparotomy. Surgeons may reasonably immediately move to operative exploration in patients presenting with classical history and physical findings with minimal laboratory testing and no preoperative imaging. That said, in most facilities with high acuity capabilities, a CT angiogram can be obtained within minutes and can greatly impact the approach to revascularization. Terse preoperative frank yet sensitive discussions with the patient and family can reinforce the life-threatening nature of acute mesenteric ischemia, and this may also serve as a time to introduce the concept of “inoperable” circumstances, such as massive bowel infarction. Determination of ischemic versus infarcted bowel remains difficult with currently available clinical and imaging tools, so exploration is most often necessary for assessment. With less dramatic clinical presentations, symptomatic acute mesenteric embolus or thrombosis diagnosed by way of the algorithms outlined above also usually warrants emergency exploration and bowel revascularization.

PREOPERATIVE PLANNING

The surgeon’s focus on timely clinical diagnosis, immediate laparotomy, and urgent bowel reperfusion via surgical interventions builds from the report of Klass from almost 60 years ago. Patients suffering acute SMA obstruction require multiple parallel interventions in preparation for the operating room. Yet none of these should stand as a rate-limiting step toward skin incision, since these patients can deteriorate rapidly and every minute of delay jeopardizes outcome. Upon diagnosis of acute mesenteric ischemia, the patient is systemically heparinized to minimize clot propagation. Activated clotting times (ACT) throughout the operative period ensures adequate systemic anticoagulation. Empiric broad spectrum antibiotics are commonly employed since many of these patients have early sepsis, and they additionally serve as some surgical wound prophylaxis (third-generation cephalosporin, such as ceftriaxone and metronidazole and in the penicillin-allergic patient a fluoroquinolone and metronidazole). Patients who are health care experienced (recent hospital/nursing home stay, regular visits to hemodialysis centers, etc.) should have their coverage tailored based on local antibiograms. As many of these patients are hypovolemic and have electrolyte abnormalities, fluid volume resuscitation is almost always indicated. Fluid infusion should be

targeted to clinical endpoints such as urinary output, skin turgor, and capillary refill; electrolyte abnormalities (especially hypokalemia, hypomagnesemia, and hypophosphatemia) should be corrected as resuscitation proceeds. There is ongoing debate over the optimal type of fluid to use for resuscitation. While the evidence does not support one type of fluid over another, it is best to keep in mind that no matter what type of fluid is used, the clinical response to resuscitation should be closely monitored to prevent both underresuscitation (which can lead to organ failure) and overresuscitation (which can stress the heart and lungs and precipitate myocardial ischemia). All available personnel should work in parallel to place hemodynamic monitors such as arterial lines, secure venous access, a Foley catheter, and a nasogastric tube. Simultaneously, the status of lower extremity pulses is again documented since this patient subset often holds risk factors for lower extremity occlusive disease and may have embolized to the lower extremity arteries.

When endovascular approaches may be a component of the care plan, then an appropriate operating room table and equipment are secured. In a warmed operating room, the patient is prepped from the nipples to the toes bilaterally since veins may be required for patch or conduit (a large greater saphenous vein or the femoral vein functions well for bypass conduit in the setting of peritoneal contamination from gastrointestinal contents). Once the airway is secured, intraoperative transesophageal echocardiogram can assess volume status and ventricular function, and delineate cardiac anatomic abnormalities that may predispose to clot formation and embolization.

SURGICAL TECHNIQUE—OPEN

Typically the incision is made from the xiphoid bone to the pubis in the midline. Gangrenous or perforated bowel is immediately resected or oversewn to reduce soilage. It must be emphasized that intestinal resection alone is not acceptable therapy when ischemic or infarcted bowel is found at laparotomy, and a systematic interrogation into the potential cause of the bowel loss must be conducted. The pattern of ischemia is important to establishing diagnosis. Vascular compromise of the entire jejunum, ileum, and portions of colon stands as the hallmark of SMA occlusion at the origin. With an embolus to the SMA, there is often sparing of the first portion of jejunum due to some perfusion from the celiac branches via the pancreaticoduodenal artery. Patchy, segmental small bowel

ischemia/infarction is consistent with showers of emboli or the vasospasm associated with nonocclusive mesenteric ischemia.

If gut vascular compromise is suspected, steps are initiated to assess the cause of impaired blood supply. Tilt of the operating room table to the right helps keep the small bowel out of the surgical field, and self-retaining retractor systems such as the Bookwalter or Omni-Tract facilitate exposure. To evaluate the SMA, the omentum and transverse colon are lifted cephalad. All small bowel is then retracted to the right, and the sigmoid colon is packed to the left (Fig. 217.2). The ligament of Treitz and the superior attachments of the duodenum are then sharply divided, with the goal of mobilizing the last portion of the duodenum to the right. Then, with four fingers behind the small bowel mesentery and with the thumb anteriorly, the SMA should be palpable at the base of the transverse colon mesentery. This maneuver has been described as “shaking hands with the root of the mesentery.” If a pulse is palpable, then continuous-wave handheld Doppler is used to ensure that there is diastolic flow and not just a water hammer pulse proximal to an occlusion.

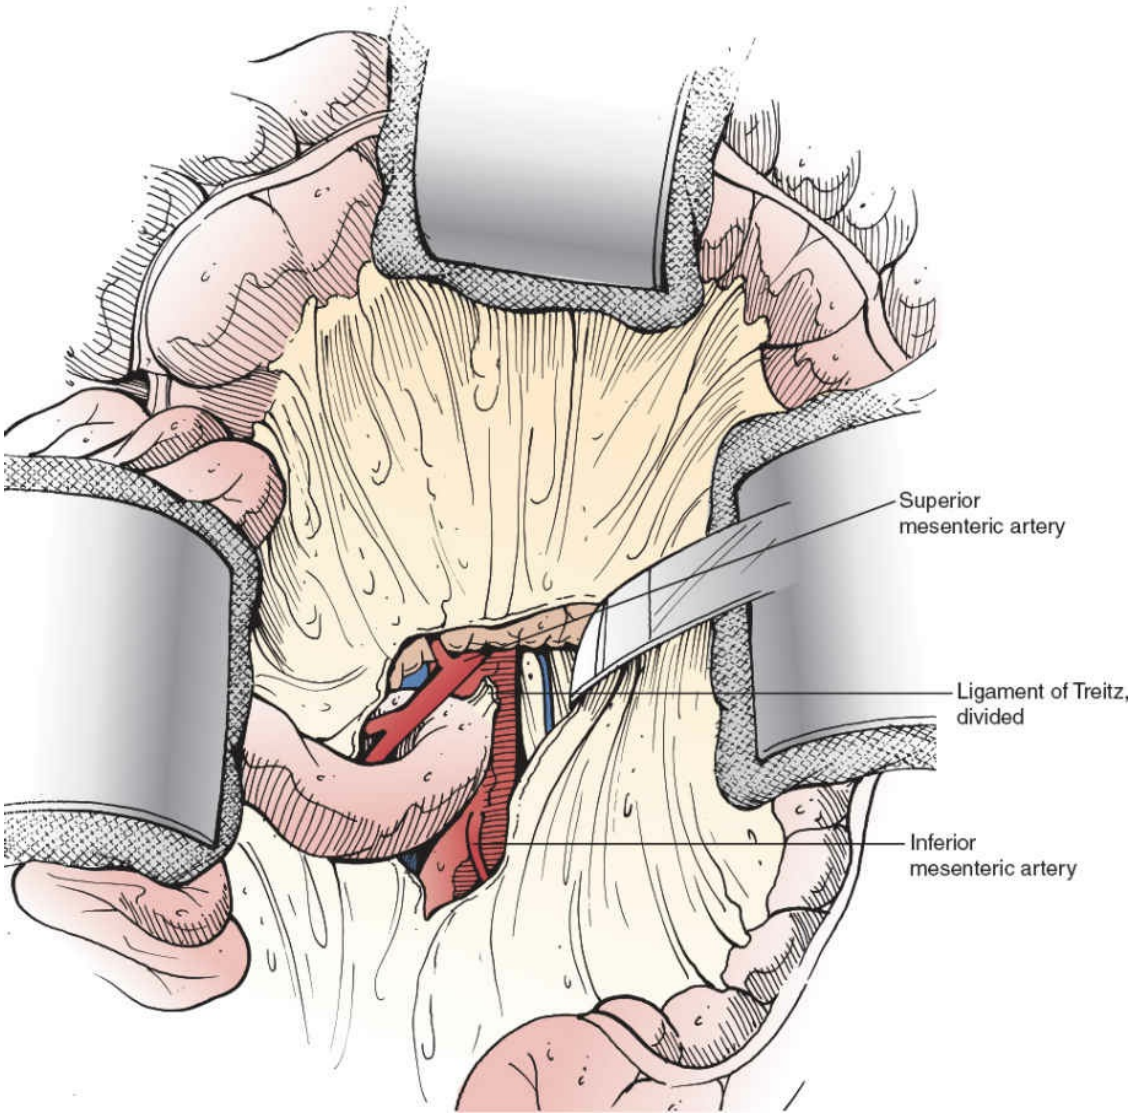

Figure 217.2. Exposure of the superior mesenteric artery (SMA) for embolectomy. The omentum and transverse colon are lifted cephalad. All small bowel is retracted to the right, and the sigmoid colon packed to the left. The ligament of Treitz and the superior attachments of the duodenum are sharply divided, with the goal of mobilizing the last portion of the duodenum to the right. Then, with four fingers behind the small bowel mesentery and with the thumb anteriorly, the SMA should be palpable near the base of the transverse colon mesentery.

If normal blood supply via the SMA cannot be confirmed via these algorithms, then the artery should be surgically exposed. Continuing the maneuvers above at the level of the transverse mesocolon base, the soft tissues overlying the artery are carefully dissected, including ligation of overlying small blood vessels, neural tissue, and lymphatics; and avoiding damage to the superior mesenteric vein, which usually lies to the right of

the SMA (Fig. 217.3). The SMA has a larger caliber proximal to the middle colic origin, making for technically easier arteriotomy. An approximately 3- to 4-cm length of artery is exposed and elastic vessel loops placed for proximal and distal control. If large in caliber and if an embolus is suspected, transverse arteriotomy offers the potential for simple closure. Conversely, if bypass for occlusive disease may be necessary (based on palpation of substantial atherosclerosis in the proximal SMA), the arteriotomy is best made longitudinally in the event that this site is needed as the distal anastomosis location for a bypass graft.

Open mechanical thrombectomy is completed using appropriately sized Fogarty balloon catheters passed proximally and distally. To minimize trauma, the devices are passed into the large portion of the SMA and pulled back gently until one pass retrieves no further clot material. Extreme care must be taken to avoid blood vessel disruption in the peripheral SMA branches, which are soft and small. The radial balloon force on the blood vessel wall can only be inferred by resistance (tactile feedback as the balloon is moved along the intima). Thus, the balloon should never be inflated while the catheter is stationary, but rather as it is withdrawn.

Assuming a normal-caliber vessel, a transverse arteriotomy is closed via a simple interrupted closure using double-armed monofilament sutures so that the intima is retacked up from within. Longitudinal arteriotomy usually requires a patch closure to prevent stenosis with the closure.

If adequate inflow is not attained with thromboembolectomy, then bypass grafting is appropriate (Fig. 217.4). In a recent report from Schermerhorn et al. on surgical revascularizations from 2000 to 2006 for acute mesenteric ischemia, embolectomy was utilized in 49% of cases and bypass in 44%. In the emergency setting externally supported prosthetic bypass conduits are reasonable, assuming there is no enterotomy or enterectomy. Woven fabrics such as Dacron have the largely theoretical added benefit of absorbing a concentrated rifampin solution in the case of very minor contamination. The common iliac arteries, infrarenal aorta, or supraceliac aorta (which tends to be spared from extensive atherosclerosis, though rarely appropriate for the acute setting) may serve as inflow sites for such a bypass. If frank bowel infarction has occurred, then autogenous conduit lessens the chance of infectious complications. Femoral vein serves as a durable bypass material; however is timely to expose and remove, and the conduit lies best with less opportunity for kinking if the

proximal anastomosis is completed at the supraceliac aorta, allowing for antegrade blood flow to the SMA. Because of more difficult exposure and longer dissection time in the often obese body habitus acute mesenteric ischemia patient, the supraceliac aorta should rarely be utilized for inflow in the emergency situation and the common iliac is preferred (retrograde). While revascularization of both the celiac and SMA stands as a standard in operations for chronic mesenteric ischemia, it is reasonable to limit the procedure to the SMA alone in the acute setting to minimize operative duration and trauma.

SURGICAL TECHNIQUE—ENDOVASCULAR

Endovascular approaches including angioplasty (with and without stenting) and thrombolysis (chemical and mechanical) are being used with increasing frequency for revascularization of acute mesenteric ischemia, though open explorations and repairs still predominate. It is emphasized that while less invasive endovascular approaches have substantially positively impacted patient care in many areas of vascular surgery, the role of such strategies in acute SMA embolism and thrombosis has not been well defined. While the results of reports to date summarily compare favorably with open surgical approaches, the small number of patients, enormous bias due to patient selection, and potential for reporting only cases with favorable outcomes limit the applicability of this literature to an evidence-based practice. Since thrombolysis often takes significant amounts of time to achieve end organ perfusion, the bowel may progress to infarction during treatment. Choice between an open versus endovascular first strategy requires thoughtful patient selection. The tenets of management of acute mesenteric ischemia remain revascularization and assessment of bowel in a timely fashion; therefore if any aspect of the endovascular technique will cause significant delay, then standard surgical approaches are preferred.

Technical experience with endovascular approaches to chronic mesenteric ischemia in conjunction with techniques from acute arterial occlusions in other vascular beds has allowed for the adoption of these techniques in the approach to acute mesenteric ischemia. A recent administrative-based national cohort study demonstrated a significant increase in the use of endovascular approaches for acute mesenteric ischemia, the rate of which increased from 11% in 2005 to 30% in 2009. Likewise, a recent institutional review from the Cleveland Clinic found

that an endovascular approach was technically successful 87% of the time when attempted. Compared with their open cohort, endovascular patients had significantly lower rates of mortality, abdominal exploration, and mean length of bowel resected.

Endovascular Access

Appropriate assessment of vascular access is prudent as many patients will have had prior procedures and may have occlusive disease in other beds. Bilateral upper and lower extremity pulse exams will help to inform the best site of vascular access for the intervention. In general, the approach to the mesenteric vasculature is with upper extremity access, as this allows for more favorable cannulation of the celiac as well as the SMA based on the natural contour of these vessels. However, femoral access is an acceptable choice for mesenteric interventions as well. As in other upper extremity cases, an appropriate pulse exam as well as bilateral blood pressure measurements should be performed to assess for subclinical supra-aortic arch branch vessel occlusive disease. Typically left-sided upper extremity access is preferred to minimize wire and catheter manipulation in the arch with its attendant risk of cerebrovascular embolization seen with traversing the cerebrovascular vessels with a right-sided approach.

Left brachial arterial access is achieved either percutaneously or via cutdown depending on patient factors, surgeon preference, and logistic considerations such as availability of a hybrid OR suite. Known risks of percutaneous brachial access include vessel thrombosis, brachial sheath hematoma, and pseudoaneurysm formation. Complication rates range from 3% to 15% depending on sheath size and indication for the procedure and typically require surgical correction when they occur. In the case of acute mesenteric ischemia, most of these patients will be systemically heparinized at the outset and throughout the duration of the procedure, which may have implications for percutaneous brachial access as well as planned sheath removal at the conclusion of the case. While the use of closure devices in the brachial artery has been described, more typically manual compression is employed.

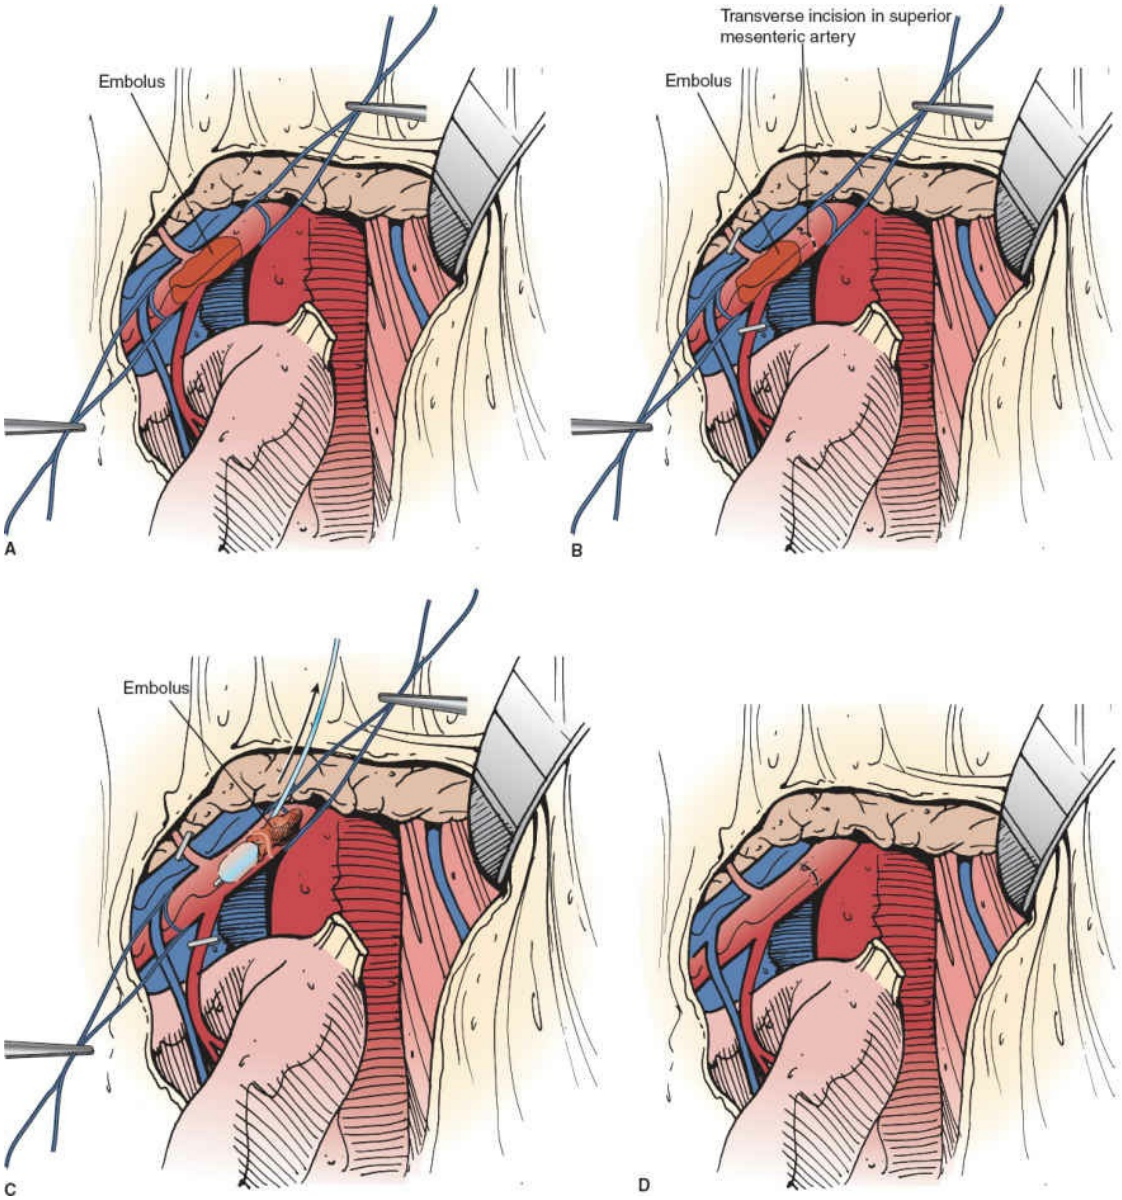

Figure 217.3. Technique of superior mesenteric artery (SMA) embolectomy using Fogarty balloon catheter. If normal blood supply via the SMA cannot be confirmed by palpation and Doppler examination, then the artery is surgically exposed, including ligation of overlying small blood vessels and lymphatics (**A**). If large in caliber and an embolus is suspected, transverse arteriotomy offers the potential for simple closure (**B**). Conversely, if small (will need patch angioplasty closure) or if bypass for occlusive disease is potentially necessary, then the arteriotomy is best made longitudinally in the event that this site is needed as the distal anastomosis site for a bypass graft. Mechanical thrombectomy is completed using Fogarty balloon catheters (**C**). The transverse arteriotomy is closed via simple interrupted closure using double-armed monofilament sutures so that the intima is retacked up from within (**D**).

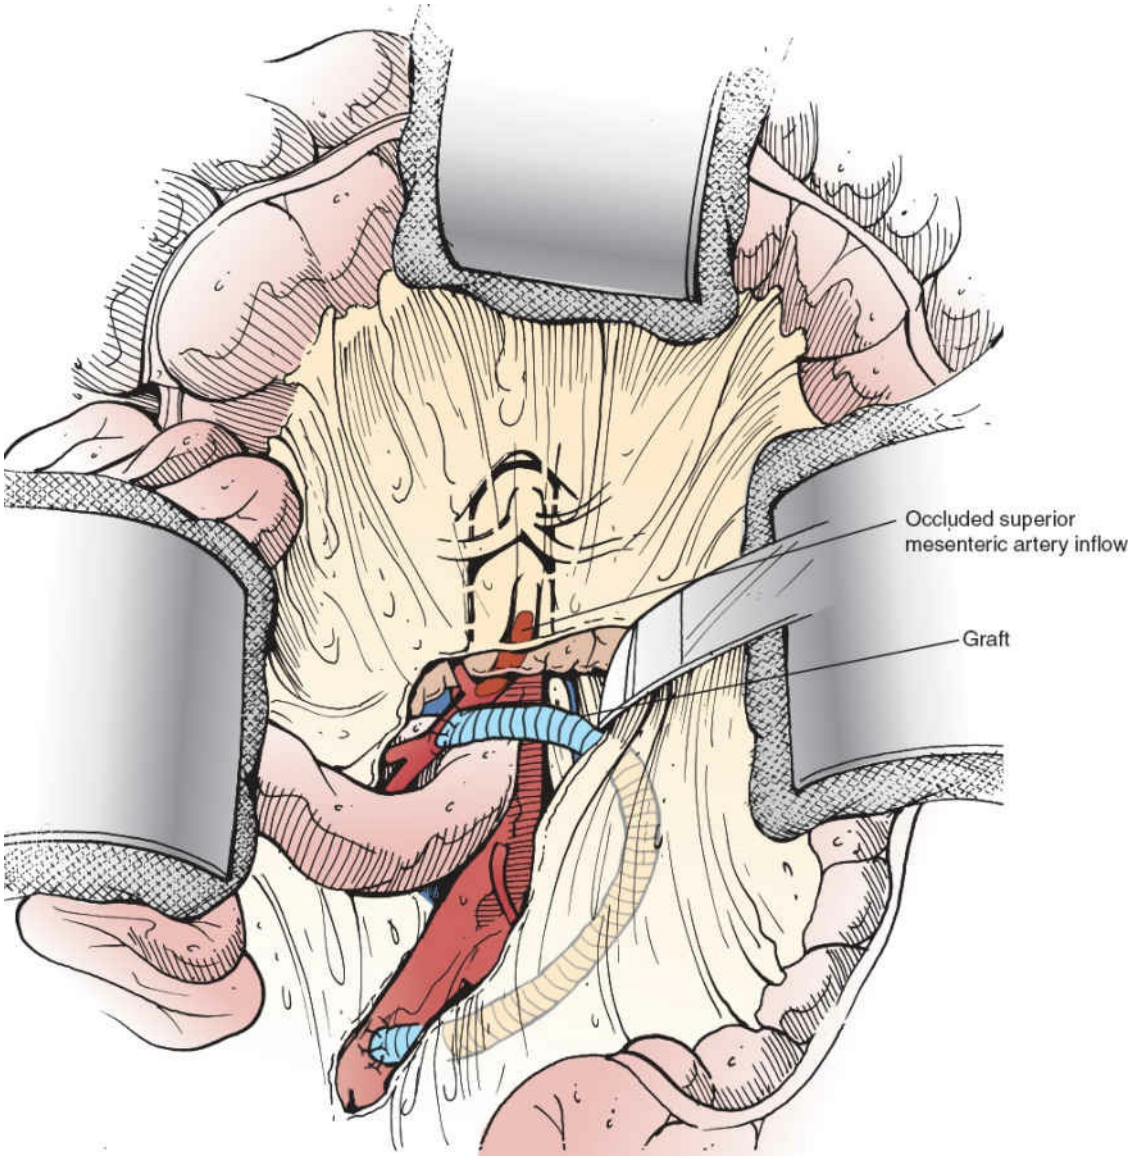

Figure 217.4. Bypass grafting for acute mesenteric ischemia, ileomesenteric as representative image.

Increasing experience with radial artery access has allowed for broadening of its use to include the mesenteric vasculature. Radial access will allow for up to 6-Fr sheath access and may be prone to fewer thrombotic and hemorrhagic complications when compared to femoral and brachial access. Prior to proceeding with radial access, a bedside or formal duplex arterial Allen's test can be performed to ensure the presence of a complete palmar arch and adequate collateral ulnar flow. Typically a bedside duplex is performed with the probe over the palmar arch; reversal of flow with manual radial artery compression is typically adequate confirmation that the patient can tolerate radial occlusion if that were to occur. Further consideration for the radial approach is that currently

hydrophilic sheaths are limited to 25-cm lengths; therefore, familiarity and comfort with guiding catheters through the 6-Fr hydrophilic sheath will be necessary. Using a standard long 6-Fr sheath without hydrophilic coating is not recommended, as it may lead to vessel thrombosis, dissection and/or rupture upon removal. The 0.014 wire platforms may be necessary through the guiding catheter, and 0.014 platform 6- and 7-mm balloon expandable stents are available. Closure of radial access can be safely performed with "patent hemostasis" with the use of the TR Band. A cuffed compression device is placed over the access point and inflated to allow for radial artery hemostasis with preserved downstream perfusion. Typically it can slowly be removed over 1 to 2 hours depending on extent of anticoagulation and reversal thereof. A pulse oximeter is placed on the ipsilateral thumb to ensure adequate perfusion to the hand during compression.

Femoral access is obtained in a standard fashion as for aortography. Ultrasound-guided access allows safe entry into a calcium-free segment of the vessel, and decreases the rate of access complications. Most predilate the tract (also under ultrasound guidance) to facilitate the use of a closure device. After aortagram is performed in the lateral projection, a long 6-Fr (90-cm) sheath can be advanced to the visceral segment of the aorta. The SMA can be cannulated with a selective catheter and the intervention follows.

Endovascular Diagnostic and Revascularization Techniques

For the upper extremity, the left arm is circumferentially prepped from axilla to the hand with an alcohol-based preparation solution. A micropuncture system with ultrasound guidance is employed to gain initial access just above the antecubital fossa where the brachial artery is superficial and can be easily compressed against the medial epicondyle of the humerus at the conclusion of the case. If radial access is selected, ultrasound-guided access is obtained 2 to 3 cm proximal to the wrist where the vessel has a straighter course. This also allows for adequate space to place the TR band upon completion. A short 4-Fr or 5-Fr diagnostic sheath can be placed. Therapeutic heparinization is maintained throughout the case. If time allows, a diagnostic sheath injection can be performed to assess the runoff distal to the elbow as a baseline assessment. If the vessel is small and/or the sheath is potentially occlusive, we will commonly give intra-arterial nitroglycerin (100 to 200 mcg) and/or verapamil (2.5 to 5 mg) through the sheath if the patient's hemodynamics allows to minimize the

extent of vasospasm around the sheath.

When a therapeutic ACT has been confirmed (>250 seconds), a 0.035 glidewire can be navigated proximally toward the arch with a 4-Fr or 5-Fr angled support catheter. We typically favor using exchange length wires (260 cm) and longer catheters (100 cm) to limit the number of exchanges. In left anterior oblique projection, a hydrophilic wire and angled support catheter or other selective catheter are used to direct the wire toward the descending thoracic aorta. On occasion with a type II or III arch, if the origin of the left subclavian is unfavorably low on the arch, then a reverse-angle catheter may be necessary to direct the wire into the descending thoracic aorta. With wire access in the distal abdominal aorta, a flush diagnostic catheter can be advanced to the visceral segment of the aorta for an aortogram (usually a lateral projection angiogram at this point for diagnostic angiography).

Based on diagnostic angiography, if the decision is made to proceed with endovascular treatment, long sheath access at the level of the visceral segment will be necessary. An exchange-length (260 cm) stiff wire is advanced through the diagnostic catheter to the abdominal aorta. A long (90 cm) 6-Fr hyperflexible sheath can be advanced to the visceral segment over the stiff wire. If there was difficulty negotiating the arch, one often advances the sheath under direct fluoroscopic visualization from the arm to the abdominal aorta.

The patient’s clinical condition dictates to what extent endovascular approaches will be utilized. In the acute setting, revascularization of the SMA will be the priority. The clinical presentation and CT angiogram should give some additional information as to the etiology of the acute mesenteric condition, which in turn informs the planned intervention. If an adequate CT angiogram was performed preoperatively, in the interest of minimizing the contrast load a diagnostic aortagram can be skipped in favor of direct vessel cannulation based on bony landmarks.

Acute Embolus

In the case of acute arterial embolus to the SMA, the characteristic finding of an abrupt cutoff will be seen on lateral projection angiogram, and on the preoperative CT angiogram the SMA itself may be a normal vessel with absence of calcific disease. Classically embolization occurs not at the origin of the SMA but rather beyond the first jejunal branches and/or takeoff of the middle colic at the site of vessel caliber decrease. Options

for embolectomy include direct thrombolytic agent injection (e.g., tissue plasminogen activator [TPA]), suction thrombectomy, pharmacomechanical thrombectomy, and TPA infusion. Typically a combination of these techniques is employed. With the patient fully heparinized, a combination of hydrophilic wire and low-profile crossing catheter can be used to select the SMA and traverse the embolus. A stiffer wire with atraumatic tip is then placed in the more distal SMA. Either a 6-Fr sheath or a 6-Fr guiding catheter is advanced across the thrombosed segment. Pre-instillation of TPA into the clot serves to soften the clot in order to facilitate embolectomy. The wire is removed and the guiding catheter, sheath, or aspiration catheter is pulled back using a large (60 mL) syringe on the end of the catheter or side-port of the sheath. Multiple passes can be performed by repeating the above steps.

In the case of incomplete embolic/thrombotic removal, reports of using pharmacomechanical thrombectomy with either the Angiojet (Medrad, Minneapolis, MN) or EKOS (EKOS, Bothell, WA) catheter have also been reported. More typically (as in peripheral arterial thrombosis when residual clot lines the vessel or if there is side branch/terminal branch occlusion), a multiple side hole TPA infusion catheter can be left in the SMA across the residual thrombus, and TPA is infused in a controlled fashion at typically 1 mg/h. Intra-arterial heparin is also infused through the sideport of the access sheath.

The patient is taken to the surgical ICU for close serial monitoring of clinical status, abdominal examination, access site bleeding, coagulation labs, strict blood pressure control, and neurovascular examination. Proponents of endovascular approaches utilize selective rather than routine laparotomy/laparoscopy based on the patient’s clinical status. Patients undergoing catheter-directed thrombolysis are taken for repeat angiogram within 12 hours or sooner if clinical status were to change. If clot resolution is seen, the patient may be systemically anticoagulated and abdominal exploration is dictated by clinical status. If incomplete clot resolution is seen, either ongoing lytic infusion, mechanical catheter thrombectomy, or open surgical thrombectomy/bypass can then be considered depending on the clinical situation and extent of patient’s symptoms. Frequently additional periods of lysis will be needed to adequately clear the clot burden. Adjunctive angioplasty and stenting can be used as needed if underlying SMA stenosis is seen upon clearance of the clot burden.

Primary angioplasty and stenting in the setting of acute SMA embolus is unlikely to be a successful stand-alone treatment, and has the potential to lead to downstream embolization that will necessitate further intervention.

Acute Thrombosis in the Setting of Chronic Occlusive Disease

Managing the patient with in-situ thrombosis of the mesenteric vasculature is akin to managing chronic mesenteric ischemia. The technical aspects are similar to chronic disease interventions, and are predicated on the ability to successfully cross the lesion. Most patients can be adequately treated with primary angioplasty and stenting. A recent institutional retrospective study from Finland noted that of 50 patients with acute mesenteric ischemia, 32 were thrombotic, and of those, 29 (91%) were treated with primary angioplasty and stenting, while the minority (9%) required mechanical thrombectomy. A similar approach is taken as described above. Long-sheath access to the visceral segment of the aorta will be necessary. A hydrophilic wire (0.014/0.035) with appropriate low-profile support catheter is used to traverse the occlusion. Predilatation with a semi-compliant balloon allows for sheath insertion into the mesenteric branch. A balloon expandable stent or stent graft can then be placed and unsheathed in its desired location. As in chronic disease interventions, it is customary to have a small portion of the stent protrude into the aorta to decrease the spillover effect of aortic calcification into the vessel origin.

Retrograde Open Mesenteric Stenting

In the event that antegrade recanalization of an acutely thrombosed SMA is not technically possible or if the patient has already been taken to the operating room for rapid operative exploration, retrograde approaches to the SMA are feasible. Operative exposure of the SMA at the base of the transverse mesocolon is performed as described above. The Dartmouth group advocates performing a longitudinal arteriotomy of the SMA with patch angioplasty (vein or bioprosthetic) and intervening through the patched segment. This allows for focal SMA thrombectomy if needed but also allows for preserved angiographic visualization of the SMA downstream from the intervention without losing intraluminal access. Other authors advocate for direct puncture/wire insertion of the SMA. A 6-Fr sheath is inserted and a hydrophilic glidewire is advanced to the aorta (Fig. 217.5). Full-lateral angiography is performed. It is recommended that

alternative arterial access (brachial or femoral) be established to allow for a landmark/endpoint for the intervention by way of a catheter placed in the aorta at the visceral segment. Again, predilation of the diseased/occluded segment is performed, and a balloon expandable stent/stents are deployed with minimal overhang (2 to 3 mm) into the aortic lumen. Completion angiogram can be performed to assess the SMA run-off at that point. The arteriotomy is closed with interrupted 6-0 Prolene suture.

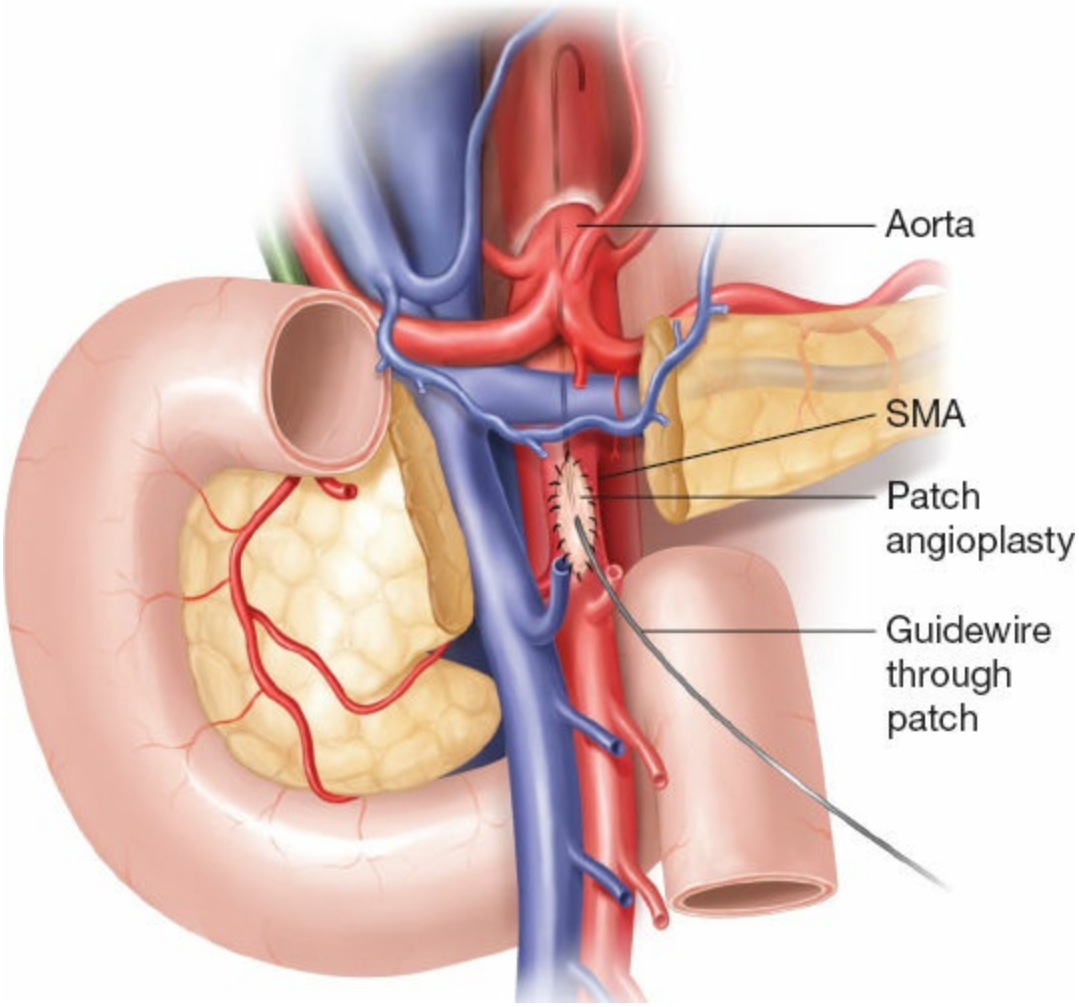

Figure 217.5. Retrograde endovascular (via open SMA exposure) treatment of proximal SMA occlusive disease. Longitudinal arteriotomy of the SMA with patch is performed. A 6-Fr sheath is inserted, and a hydrophilic glidewire is advanced to the aorta. Full-lateral angiography is performed. It is recommended that alternative arterial access (brachial or femoral) be established to allow for a landmark/endpoint for the intervention by way of a catheter placed in the aorta at the visceral segment. Predilation of the diseased/occluded segment is performed, and a balloon expandable stent/stents are deployed

with minimal overhang (2 to 3 mm) into the aortic lumen in the setting of orificial SMA occlusive disease. Intervening through the patch allows for continual flow to the SMA branches and angiographic assessment of run-off patency.

POSTOPERATIVE CARE

Immediately after open setting revascularization, 15 to 30 minutes should pass prior to determination of bowel viability. Clearly dead bowel is resected. Return of color and peristalsis and lack of venous thrombosis indicate viable bowel. However, this clinical judgment can be quite difficult, and adjuncts in addition to close bowel inspection include listening for Doppler signals at the antimesenteric border and bowel fluorescence under Wood's (ultraviolet) lamp examination after intravenous fluorescein infusion. Occasionally, SMA injection of vasodilators (papaverine 30 to 60 mg) and glucagon (0.25 to 0.5 mg) may be of benefit.

Despite these maneuvers, delineation of salvageable versus unsalvageable bowel often remains obscure. In this setting, bowel ends can be stapled off or brought up as ostomies, and the abdomen closed in a temporary fashion of the surgeon's choice (e.g., vacuum-assisted closure dressing, Bogota bag, skin level closure). A second-look operation is planned and carried out in 24 to 48 hours. During this time frame, the patient's oxygen delivery and metabolic status are optimized. A second-look strategy commits the operative team to another procedure in 24 to 48 hours (even if the patient's clinical status improves dramatically); however, in 50% of second-look procedures, additional necrotic bowel will be present, requiring re-resection. Thus, the threshold for second look should be fairly low. Conversely, if the patient's status deteriorates during this early operative period, further interrogation (such as angiogram to ensure optimal intestinal revascularization) and reexploration (for signs of progression to transmural bowel infarction with subsequent complications) may be warranted sooner. Since these patients are often quite ill and the bowel viability may be in question, construction of a primary anastomosis may lead to subsequent anastomotic dehiscence and enteric contents spillage in a critically ill patient. Exteriorizing questionable bowel as stomas enables direct observation postoperatively for viability. One important caveat to this rule is that very proximal jejunostomies (within 20 cm to the ligament of Treitz) can lead to severe losses of fluid,

electrolytes, and other nutrients. Multiple trips (e.g., third looks) to the operating room are not infrequently required to care for the bowel complications of SMA occlusion and revascularization.

Results of published reports vary depending on patient characteristics such as age, comorbidity, and cause for ischemia, but as a rule at least 50 cm of bowel is required to maintain enteral nutrition long term. The ileocecal valve is important to preserve if possible, as shorter segments of bowel have been shown to support enteral nutrition if the ileocecal valve is functional. In cases where the remaining bowel is short and the ileocecal valve is dusky or otherwise questionable, it may be more acceptable to risk a fistula with an anastomosis than to resect the cecum and risk permanent intestinal insufficiency. In patients without advanced comorbidities, long-term survival can be achieved through parenteral support, intestinal adaptation, and, potentially, small intestinal transplantation. The surgeon is occasionally faced with catastrophic complete small bowel infarction, which would leave inadequate intestinal length to nutritionally support life in this often elderly patient population. In this inoperable setting, the abdomen is closed and patient care, in partnership with the available family, transitions to focus on comfort measures only.

COMPLICATIONS AND THEIR MANAGEMENT

The reperfusion syndrome after visceral revascularzation for acute ischemia is largely managed by usual supportive critical care measures. These will be tailored to the individual patient's comorbidities and risks, but the systemic inflammatory syndrome observed in a large majority of these patients requires judicious fluid resuscitation with attention to electrolyte balance, particularly with respect to hyperkalemia. Acute kidney injury is frequently encountered and may be severe enough to require renal replacement therapy. Myocardial function is often impaired due to the combined influences of hypovolemia, acidosis, and mediators with negative inotropic or vasodilatory effects, and invasive monitoring is frequently employed when heart failure develops. Cardiac dysrhythmia may be the underlying cause for embolism and may require advanced management strategies including cardioversion. In cases where cardioversion is indicated, it is crucial to verify that thrombus is not present in the cardiac chambers, usually with transesophageal echocardiography, prior to conversion in order to prevent recurrent embolism.

Patients who have suffered SMA occlusion from an embolus are at high risk for recurrent thromboemboli. Therefore, they should be anticoagulated with heparin, followed by warfarin. Fortunately, these patients are usually well nourished at the onset, so in the early postoperative period nutritional support may usually be safely deferred. Once the acute phase resolves, enteral nutrition should be used as tolerated, as enteral delivery of nutritional factors improves mucosal recovery and promotes intestinal adaptation to intestinal insufficiency. If the patient does not tolerate full enteral feeding, parenteral support should be initiated to prevent malnutrition, which retards intestinal adaptation.

OUTCOMES

Acute mesenteric ischemia remains a highly lethal clinical event, with mortality averaging around 70% from several series. Markers for delayed diagnosis and advanced bowel infarction (such as preoperative presence of peritonitis and need for bowel resection) stand as independent predictors of perioperative mortality or survival dependent on total parental nutrition.

While uncommon, the incidence of this problem may be increasing in the aging population and with the rising incidence of the metabolic syndrome, defined as the accumulation of atherogenic risk factors (e.g., obesity, dyslipidemia, hypertension, glucose intolerance), resulting in pro-atherogenic, prothrombotic, and proinflammatory states. It is also possible that the contribution of the metabolic syndrome to the incidence of acute mesenteric ischemia may be offset by increasing use of anticoagulation for other diagnoses, such as dysrhythmias. A recent population-based series cites an incidence rate as high as 5.3 cases per 100,000 inhabitants per year.

EDITOR'S COMMENT

I was walking down the hall last week, and a high-ranking administrator who is a supporter of vascular surgery remarked, "We sure have a lot of dead bowel (mesenteric ischemia) at our institution." While for a second I of course felt personally attacked for operations gone bad, I quickly realized that his observation was indeed true and for the most part he was not talking about failed surgical or endovascular interventions. I also harkened back to my old institution and remembered our quality officer showing us that we had more deaths from mesenteric ischemia on our service than we did from ruptured aortic aneurysms. Acute mesenteric ischemia kills patients.

In this chapter by McPhee and colleagues, the authors nicely describe the pathophysiology of acute mesenteric ischemia and the subsequent reperfusion injury that occurs following treatment of acute mesenteric ischemia. I have been overwhelmed recently with the injury the liver sustains even after retrograde or antegrade revascularization procedures to the isolated SMA. I know treatment of this disease is not completely like chronic mesenteric ischemia (Hollier LH, Bernatz PE, Pairolero PC, et al. Surgical management of chronic intestinal ischemia: a reappraisal. *Surgery* 1981;90(6):940–6) especially in the setting of embolic disease, but maybe with acute on chronic mesenteric disease, we should be revascularizing both the SMA and the celiac more aggressively.

The authors are correct to point out that any comparison of endovascular and open revascularization is fraught with biases. Maybe the patients committed to an endovascular approach have less suspicious dead bowel or are "less sick" and therefore have more time before frank dead bowel occurs. However, a recent paper using the NSQIP database suggests that patients who undergo an endovascular approach have a lower mortality rate (2.5 times lower than open)

and a decreased need for laparotomy compared with open surgery. In addition, postoperative complications were much lower in the endovascular group (Branco BC, Montero-Baker MF, Aziz H, et al. Endovascular therapy for acute mesenteric ischemia: an NSQIP analysis. *Am Surg* 2015;81(11):1170–6). This suggests to me that perhaps all patients with a suspicion for dead bowel should be placed in a hybrid operating room where endovascular therapy is an option. Others have advocated for an endovascular first approach for all acute mesenteric ischemia (Naylor AR, Forbes TL. Trans-Atlantic debate: Is an "endovascular first" strategy the optimal approach for treating acute mesenteric ischemia? *Eur J Vasc Endovasc Surg* 2015;50(3):279–80). I am not sure that is correct either especially in the setting that typically ends in a "peak" and closes the abdomen without bowel resection scenario when the entire small bowel is dead. It seems like spending hours revascularizing frankly dead bowel is to no one's benefit.

The truth is the management of acute mesenteric ischemia takes great communication between the "bowel resection" team and the "blood flow revascularization" team. Optimal management of these patients also requires a high index of suspicion by our emergency room colleagues on the front line seeing these patients. Embolic disease to the SMA is the great masquerader and often the surgeon will get called in after the diagnosis of acute mesenteric ischemia is no longer in question when pneumatosis in the small bowel or portal vein gas is seen on CT. While both of these signs on imaging can be omnious, it is important to realize that there are some patients without an abdominal catastrophe with benign causes of pneumatosis intestinalis and portal vein gas, and therefore it is important to have an algorithm in working these patients up (Wayne E, Ough M, Wu A, et al. Management algorithm for pneumatosis intestinalis and portal venous gas: treatment and outcome of 88 consecutive cases. *J Gastrointest Surg* 2010;14(3):437–48).

Finally, while this chapter primarily focuses on embolic and acute on chronic mesenteric ischemia, we are seeing an increasing number of patients with both acute type A and B dissections with acute mesenteric ischemia. Some believe that mesenteric ischemia can be managed percutaneously prior to type A repair, (Deeb GM, Patel HJ, Williams DM. Treatment for malperfusion syndrome in acute type A and B aortic dissection: a long-term analysis. *J Thorac Cardiovasc Surg* 2010;140(6 Suppl):S98–S100) while others just proceed to type A repair. This is an ongoing argument among cardiac surgeons. Since I primarily see type B dissections (Lombardi JV, Cambria RP, Nienaber CA, et al. STABLE investigators. Prospective multicenter clinical trial (STABLE) on the endovascular treatment of complicated type B aortic dissection using a composite device design. *J Vasc Surg* 2012;55(3):629–40), I am hoping that new endovascular stent graft systems will also serve to decrease the mortality associated with acute mesenteric ischemia in these ill patients who do not tolerate mesenteric ischemia very well and who also have very few good revascularization options available as the inflow for most bypasses is dissected.

Gilbert R Upchurch Jr.

218 Techniques of Open and Endovascular Revascularization to Treat Chronic Mesenteric Ischemia

Thomas C. Bower and Gustavo S. Oderich

BACKGROUND

The first clinical and anatomical descriptions of intestinal ischemia were recognized in the late 1800s. In 1938, Dunphy described a correlation between recurrent abdominal pain, fatal intestinal infarction, and mesenteric artery occlusive disease. *Intestinal angina* was coined to describe the classic symptom of chronic abdominal pain after meals, the cardinal symptom of *chronic mesenteric ischemia* (CMI).

Shaw and Maynard introduced mesenteric endarterectomy as surgical treatment in 1958. Since then, revascularization has evolved to antegrade or retrograde bypass, and now endovascular therapy. The latter came into vogue in 1980, and over the last decade, the use of endovascular techniques to treat patients with CMI has surged. Mesenteric artery stenting is now first-line treatment at most centers. Open surgery generally is relegated to patients who have complex lesions unsuitable to stenting, those who fail endovascular therapy, and the small subset of patients with inflammatory disorders. This chapter will briefly review the pathophysiology, etiology, clinical presentation, and indications for treatment and outcomes in CMI, but the primary focus is on open surgical and endovascular techniques.

PATHOPHYSIOLOGY, ETIOLOGY, AND NATURAL HISTORY

The mesenteric circulation accounts for approximately 20% of the cardiac output, but blood flow increases to 1 to 2 L/min over 3 to 6 hours after a meal. Patients with mesenteric ischemia are unable to meet the postprandial blood flow and oxygen demands for intestinal secretion and

absorption. In general, at least two of the three arteries need to be occluded or severely stenotic to have symptoms because of the rich collateral network between the celiac artery (CA), superior mesenteric (SMA), inferior mesenteric (IMA), and internal iliac arteries (Fig. 218.1).

Atherosclerotic disease is the cause of CMI in 90% of patients, and is usually isolated to the first 2 to 3 cm of the CA and SMA. Associated aortic, iliac, and renal artery disease is common. Nonatherosclerotic mesenteric lesions include vasculitis (Giant cell arteritis, Takayasu disease, and polyarteritis nodosa), systemic lupus, Buerger disease, spontaneous dissection, fibromuscular dysplasia, neurofibromatosis, radiation arteritis, drug-induced arteriopathy from cocaine or ergot use, and mesenteric venous thrombosis. Patients with abdominal aortic coarctation or mid-aortic syndrome may have concomitant mesenteric stenoses, with or without symptoms. As a broad group, these patients are younger than those with atherosclerosis.

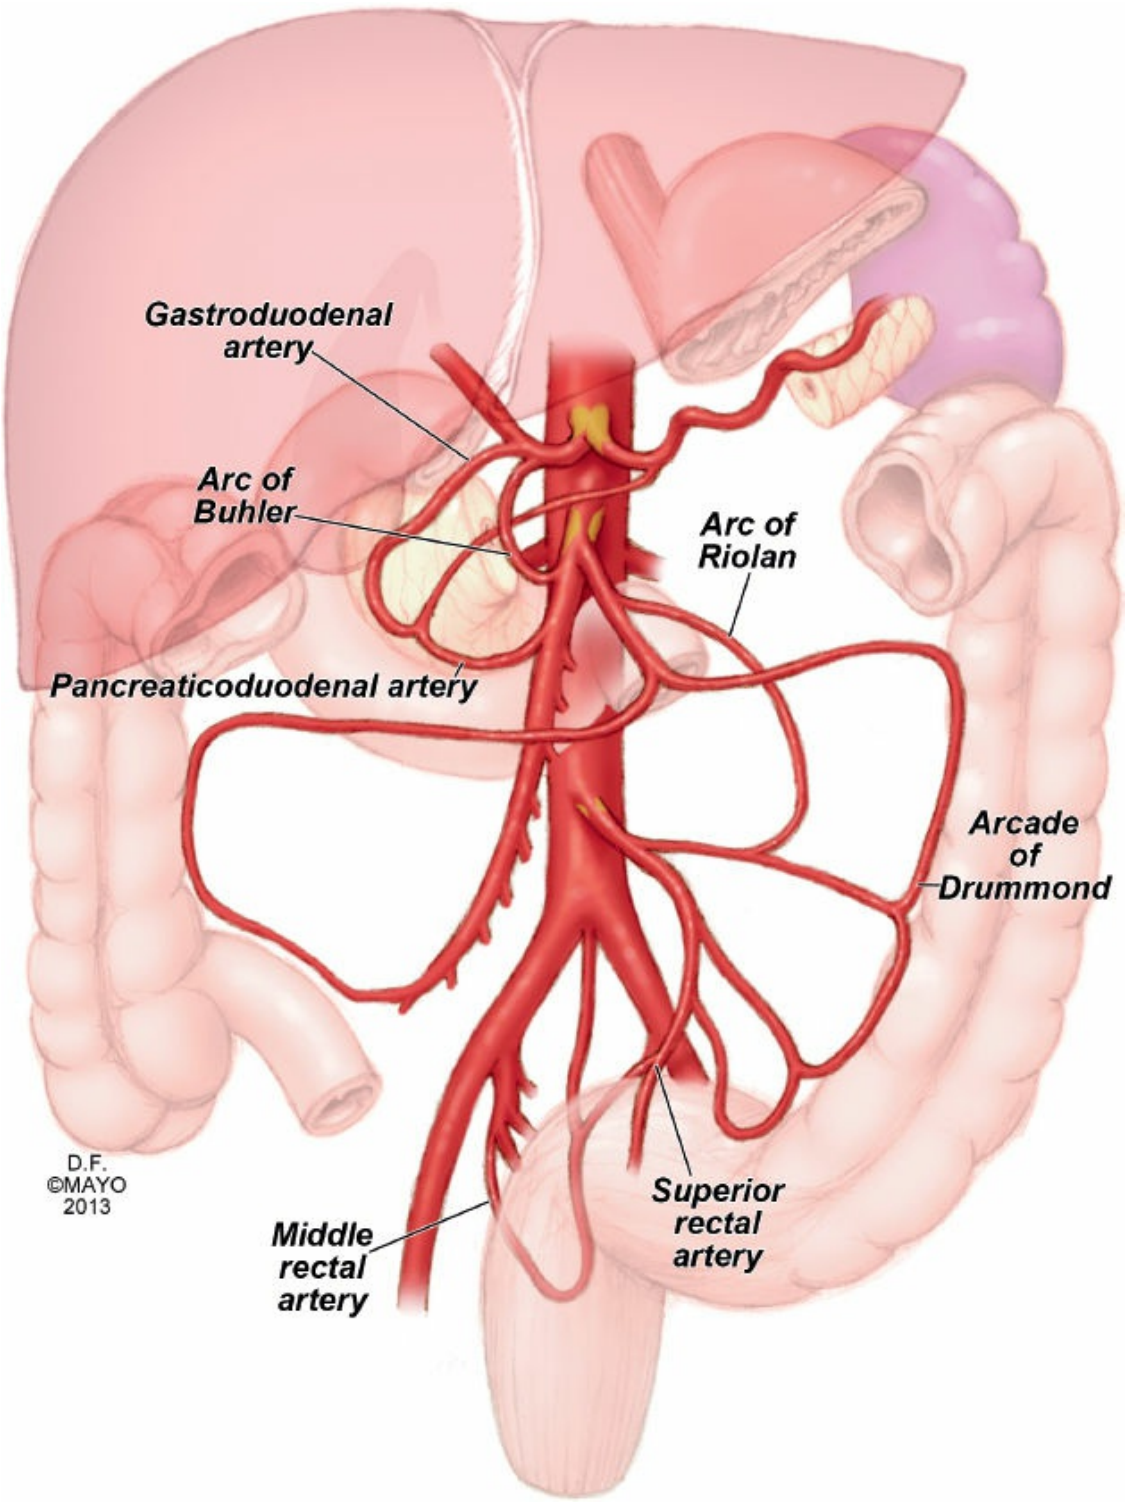

Figure 218.1. Schematic representation of the collateral circulation between the celiac axis, superior mesenteric, inferior mesenteric, and internal iliac arteries. (Image © Mayo 2013.)

The natural history of mesenteric artery disease is not fully understood. Asymptomatic patients have a low risk of bowel infarction if there is non-SMA single vessel involvement. However, 15% to 50% of patients with

bowel gangrene due to in situ arterial thrombosis have no antecedent warning signs. Such patients either have an SMA thrombosis with poorly developed collaterals or have severe three vessel disease.

CLINICAL PRESENTATION

The classic patient with CMI from atherosclerosis is a female smoker between 50 and 70 years of age who has postprandial mid abdominal pain, weight loss, and “food fear.” Pain is present in over 90% of patients, is crampy or dull, begins within a few minutes to 30 minutes after meals, and may persist for several hours. As compensatory collateral blood flow worsens, pain progresses to be near constant and unrelenting. A rare patient has little if any pain because of adaptive strategies to tolerate it. Patients alter eating habits to avoid foods that precipitate symptoms. Unintentional weight loss occurs in more than three fourths of patients, and leads to malnutrition and cachexia in the late stage of disease. Duration of symptoms prior to revascularization averages 15 months. Not every patient has “classic” symptoms. At times, abdominal pain is vague, nausea and vomiting is present, or there is a change in bowel habits. Tobacco use, hypertension, and hyperlipidemia are noted in over 60% to 70%. Physical examination is nonspecific. Most individuals are thin, have a scaphoid abdomen, and at advanced stages have muscle wasting. Laboratory tests are nonspecific, even in acute situations. A low serum albumin, pre-albumin, or transferrin is a marker of malnutrition, while an increase in inflammatory markers, such as sedimentation rate and C-reactive protein suggests systemic inflammation. Diffuse stomach or duodenal ulcers, liver function abnormalities, or patchy areas of ischemia in the colon occur, and should raise suspicion of CMI.

DIAGNOSTIC IMAGING

The diagnosis of CMI is suggested by clinical history and confirmed by imaging studies after other causes of chronic abdominal pain and weight loss such as inflammatory, infectious, and malignant diseases have been excluded. Upper and lower gastrointestinal endoscopy, duplex ultrasonography (DUS), computed tomography (CT), and magnetic resonance imaging (MRI) of the abdomen are common investigative studies. A negative DUS essentially excludes mesenteric artery disease. CT or MR imaging of the abdomen excludes causes of abdominal pain and provides anatomical detail to plan revascularization. Multidetector CT is

considered the best study to evaluate lesion characteristics (calcification, thrombus, diameters, and lengths) and anatomy. The bane of CT angiography is dense arterial calcification. Gadolinium-enhanced MRA has improved with shorter acquisition times. Catheter-based arteriography is rarely used for diagnosis because of improvements in CTA and MRA, except for patients with suboptimal imaging due to dense calcification or metallic artifact from prior stents.

TREATMENT STRATEGIES

There is no role for long-term parenteral nutrition in patients with symptomatic mesenteric artery disease. Delay in treatment leads to clinical deterioration, bowel infarction, and risk of sepsis from catheter-related complications. Revascularization is necessary in all patients with CMI, either by endovascular or open techniques, unless the patient refuses treatment.

Goals of treatment are to alleviate symptoms, improve nutrition to allow weight gain, and prevent bowel infarction. Prophylactic intervention in asymptomatic patients remains controversial. Mesenteric reconstruction sometimes is needed during open aortic reconstruction to prevent perioperative bowel ischemia, and is rarely considered in asymptomatic patients with severe three-vessel disease who live in remote areas. These latter patients are counseled about warning symptoms and monitored closely.

Endovascular therapy has changed treatment approach and patient selection at most centers, and its use increased 10-fold in the United States in the last decade, largely due to improved outcomes. Angioplasty and stenting is now utilized in over 70% to 80% of patients treated for CMI, and is first-line therapy for patients with suitable lesions, regardless of clinical risk.

The SMA is the primary target for revascularization, whether treatment is rendered by endovascular or open techniques. We found no clinical benefit to stent both the SMA and celiac artery, though prefer two vessel bypasses for open repair in most patients. The SMA anatomy is critical if endovascular treatment is to be successful and durable. The ideal lesion for SMA angioplasty and stenting is a short, focal stenosis or occlusion with minimal calcification or thrombus. Stenting of CA lesions carries high rates of restenosis because of external compression by the median arcuate ligament. Severe eccentric SMA calcification, flush occlusion at the aorta,

long lesions (>2 to 3 cm), small target vessel, and tandem lesions increase the difficulty and success of endovascular therapy. Although such anatomy does not preclude stenting, the results of treatment are poorer compared to "ideal lesions," and complications such as distal embolization, dissection, and restenosis are higher.

Preoperative Evaluation

In addition to visceral, aortic, and iliac artery anatomy, preoperative evaluation focuses on surgical risk and assessment of nutritional status. Cardiac, pulmonary, and renal functional assessments are important, and noninvasive cardiac stress and pulmonary function tests are the cornerstones of medical evaluation. Optimal medical therapy is needed before and after operation, and includes smoking cessation, aspirin, a beta-blocker, and statins if tolerated. Patients with severe cachexia, dehydration, and stable symptoms may benefit from intravenous (IV) hydration and a brief period of parenteral nutrition before operation.

OPEN SURGICAL REVASCULARIZATION

Our preference for low-risk patients who either fail stenting or are not considered candidates for it is open revascularization. Mesenteric bypass also becomes necessary for symptomatic patients with chronic stent occlusion not suitable to recanalization, and is the preferred option to treat patients with nonatherosclerotic lesions. Key issues include choice of inflow, status of the target arteries, and graft configuration.

Mesenteric bypass may be antegrade or retrograde to the SMA only, or to both the SMA and celiac. Rarely, are all three visceral vessels reconstructed. Antegrade bypass implies graft origin from the supraceliac aorta. Retrograde bypass originates from the infrarenal aorta, common or external iliac arteries, and is used as a straight graft or placed in a C-shape. Choice of reconstruction is based on patient risk and anatomy. Outcomes are equally good, regardless of graft origin, the number of arteries reconstructed, or graft configuration. Prosthetic is the preferred conduit except in contaminated fields or in a patient with a small target artery. Saphenous vein, femoral vein, cryopreserved artery, or endarterectomy is an alternative to prosthetic in such cases.

In our practice, most patients undergo antegrade bypass from the supraceliac aorta. High-risk patients or those with calcification of the supraceliac aorta are better treated with a retrograde bypass from the

common iliac artery, more often the right one because the graft lays better in the retroperitoneum. If the common iliac arteries are heavily calcified, the external iliac artery can be used for inflow. A rare high-risk patient with iliac disease, who is not a candidate for mesenteric stenting, can be managed with iliac artery stents followed by a retrograde single limb SMA bypass from the external iliac.

Technique and Exposure

Exposure is everything in open vascular surgery, and choice of incision is paramount to success. The supraceliac aorta is approached through an upper midline or bilateral subcostal incision, depending on body habitus. Either incision allows for transperitoneal exposure of the aorta and visceral arteries. For a midline approach, a 2-cm incision along the side of the xiphoid process releases six muscular and aponeurotic attachments and allows for upward and lateral retraction of the body wall (Fig. 218.2). If medial visceral rotation is planned, a small bump placed under the left side of the patient with the knees secured allows rotation of the operating table to facilitate exposure. Once the incision is made, the patient is placed slightly head up, which allows the small bowel to fall caudally. Isolation of the supraceliac aorta begins by take down of the left triangular ligament of the liver. The lesser sac is opened, the crura of the diaphragm is divided or resected, and the aorta is isolated (Fig. 218.3). Care must be taken to protect the esophagus, and having a nasogastric (NG) tube in place is helpful. As much as 5 to 6 cm of the lower descending thoracic or supraceliac aorta can be dissected free, though it is easy to enter the left pleural space in thin patients.

Exposure of the CA is done before the SMA if an antegrade two-vessel bypass is planned. Laparotomy pads or a folded moist towel is laid over the pancreas and bowel, which allows them to be retracted caudally. The artery can be identified at its origin and circumferentially dissected free toward its bifurcation. At times, there are one or more small arterial branches near the celiac origin, which cause troublesome bleeding if not identified and ligated. Peri-arterial ganglionic and fibrous tissue requires resection to free up the celiac trunk. Often, the left gastric artery is ligated and divided, which helps when creating a retro-pancreatic tunnel for the SMA graft limb. Alternatively, if there is scarring around the CA or it is occluded, the common hepatic artery is dissected free and used as the target. One or more small veins alongside the artery may need ligation.

The SMA is isolated above the pancreas if disease is confined to the first centimeter or two of the artery, or at the base of the transverse mesocolon, which is the more common exposure (Fig. 218.3). For the latter, the transverse colon is lifted upward and the small intestine is retracted toward the right side except for the duodenal sweep. The ligament of Treitz is taken down so that the SMA can be palpated in the mesentery. Lymphatic and fibro fatty tissues are ligated and divided along the left side of the duodenal mesentery, which allows the SMA limb to lay better. Care should be taken when isolating the jejunal branches along the side and posterior wall of the SMA, as they tear easily. If a replaced right hepatic artery is present, it needs to be preserved. Extensive calcification and long segment stenosis may be present in heavy smokers, patients with prior radiation or in reoperative cases. In these cases, the surgeon must dissect free the SMA and its branches further distally into the mesentery to find a suitable site for an anastomosis. This maneuver requires ligation and division of crossing mesenteric vein branches. A retropancreatic tunnel is created by blunt and sharp dissection from the supraceliac aorta to the exposed SMA, and is made anterior to the left renal vein and along the left anterolateral aorta. The tunnel must be free of fibrous bands and large enough to avoid compression of the graft. Plasma tubing is passed through the tunnel to simplify passage of the SMA limb.

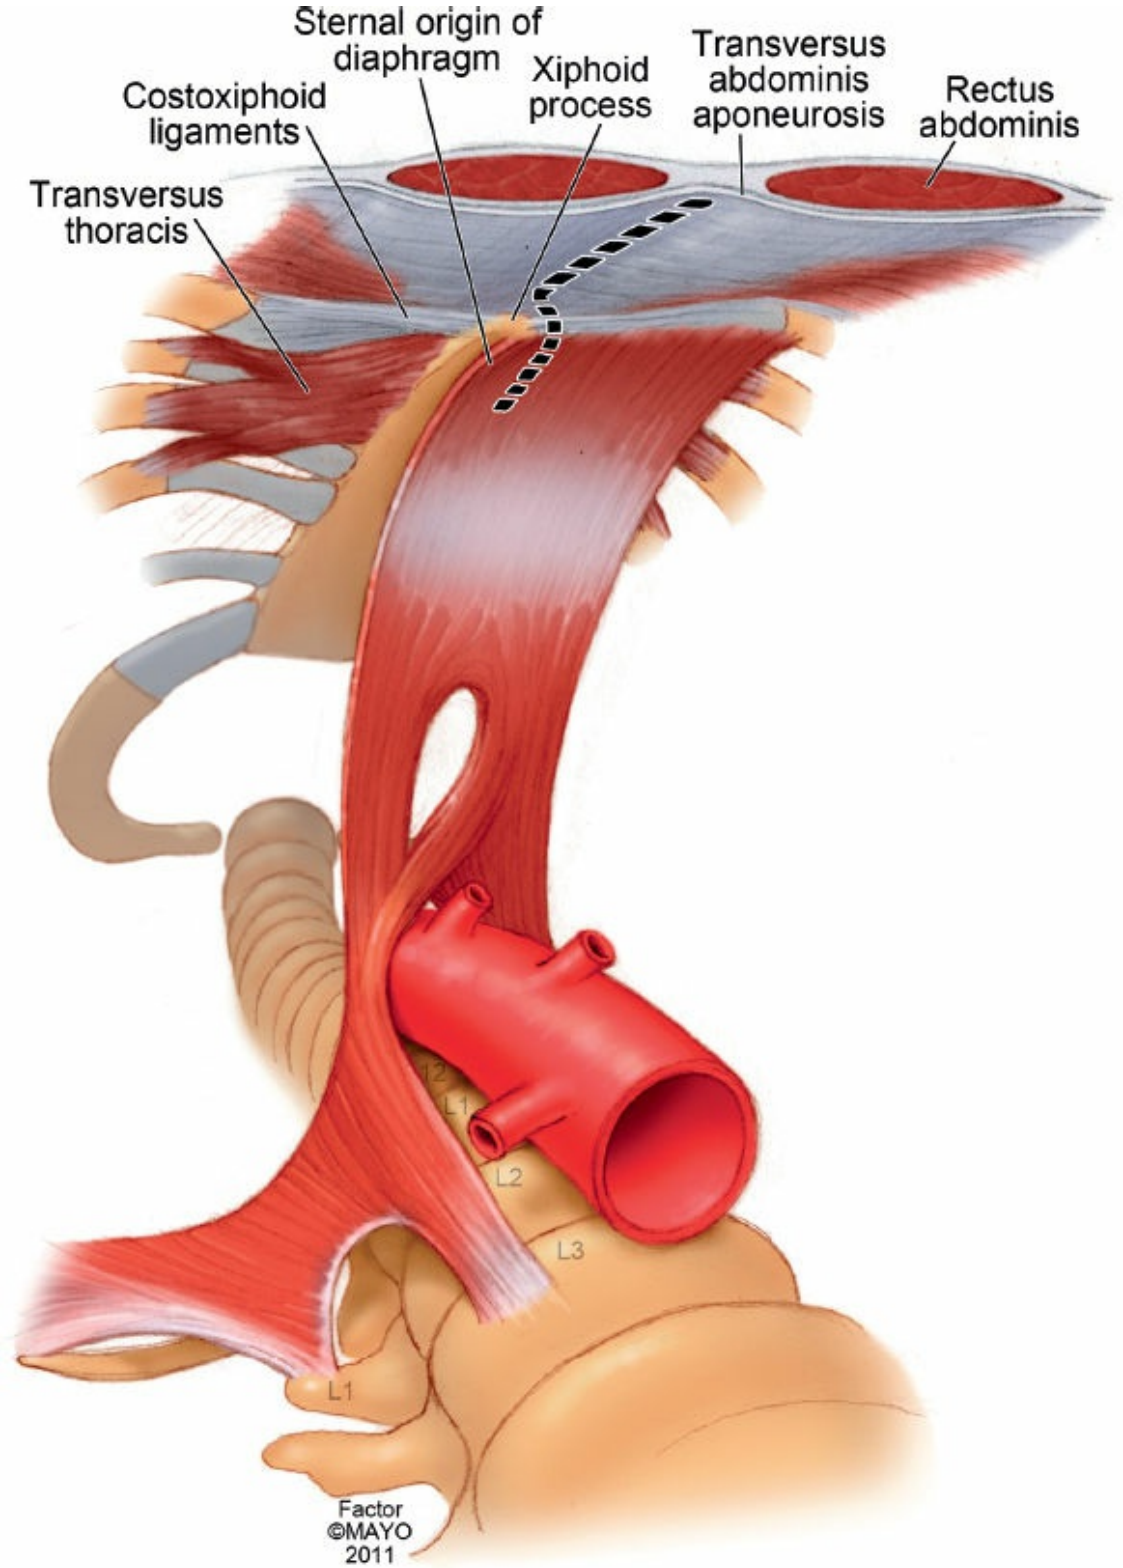

Figure 218.2. Upward and lateral retraction of the body wall aids in exposure of the upper abdominal aorta and visceral arteries. This is enhanced with a midline incision by incising alongside the xiphoid process, which releases six muscular and aponeurotic attachments. (Image © Mayo 2011.)

For supraceliac aorta-based bypass, patients are given between 50 and 100 units per kg of IV heparin and 12.5 g of mannitol before placement of the aortic cross clamp. A partial occlusion clamp allows for distal perfusion during the aortic anastomosis, and the authors have found the all-purpose aortic clamp to work well if the aorta is 18 mm or larger in diameter and not calcified. Deep patients or those with a thick aortic wall are better served with a double clamp technique to allow better visualization for suturing the graft (Fig. 218.4). It is preferable to fully cross-clamp the aorta than to struggle using a partial occlusion clamp and risk an imperfect anastomosis, which has to be redone. A straight aortic clamp is used on the proximal supraceliac aorta. A hypogastric clamp is placed on the distal supraceliac aorta or across it from behind the celiac artery so that it occludes the aorta and the lumbar arteries. Close communication with the anesthesiology team lessens the adverse effects of increased cardiac afterload during aortic clamping, and declamping hypotension when blood flow is restored to the kidneys and lower extremities. A straight or slightly oblique aortotomy is made on the anterior or left anterolateral wall. A stay stitch can be placed, or a small ellipse of wall excised to facilitate the proximal graft anastomosis. Two vessel reconstructions are done with a 12 × 7 mm or 14 × 7 mm knitted polyester graft. Smaller diameter limbs seem more prone to failure from pseudo intima in our experience. The bifurcated graft body is fashioned with the limbs side by side or on top of one another, based on patient anatomy. If a single antegrade bypass is done, the body of the bifurcated graft is cut near the origin of the limb to create a flange. This allows the graft to “sit up from the aorta,” which avoids flattening of graft at the heel that may result in stenosis or graft failure. The latter is why we abandoned the use of saphenous vein in this position unless it is in a pantaloon configuration. Once the aortic graft anastomosis is completed, it is tested by infusing saline into the limbs with clamps still in place. This maneuver allows repair sutures to be placed without having to reclamp the aorta, thereby lowering the risk of clamp injury. If hemostatic, blood flow is slowly restored through the native aorta after back-bleeding and fore-bleeding through the limbs has been done. The body of the graft is clamped at its origin, and blood is suctioned from the limbs so they are clean. A coarctation clamp is placed at the origin of the celiac limb. If ischemia time exceeds 20 minutes during complete aortic crossclamp, additional mannitol and Lasix are given to stimulate urine output.

The distal anastomosis to the celiac artery can be done end-to-end or end-to-side. An end-to-end celiac anastomosis is challenging in two ways. First, the graft can be cut too long if retraction is not temporarily released to gauge the length. This mistake causes a kink or buckle when bowel retraction is relaxed. Second, the artery may be fragile, so if the graft is too taught, the artery will tear. Both necessitate revision. For these reasons, the authors favor an end-to-side celiac anastomosis as it simplifies assessing graft length because the CA is in fixed position. The artery is ligated immediately proximal to the heel to create a functional end-to-end anastomosis (Fig. 218.5). If the celiac is occluded or severely calcified, the bypass target is the common hepatic artery. The graft is sewn to the hepatic end-to-side. Back-bleeding is allowed prior to completion of the anastomosis. Fore-bleeding is done through the SMA graft limb by temporary release of the clamp on the graft body. This limb is irrigated and suctioned to be sure it is clean. The coarctation clamp at the origin of the celiac limb is transferred to the origin of the SMA limb. Clamps on the graft body and CA are released to allow blood flow into the celiac branches.

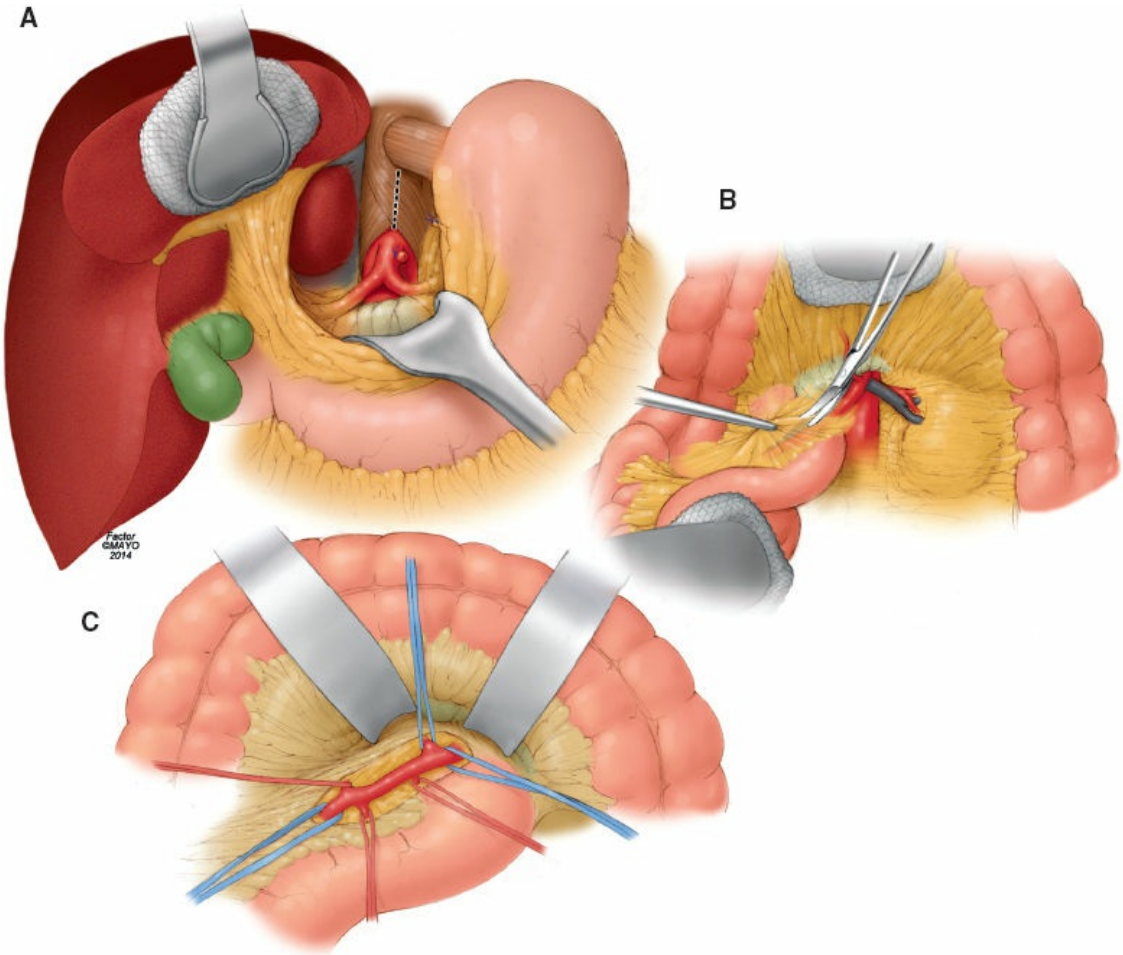

Figure 218.3. Transperitoneal exposure of the supraceliac aorta and celiac artery involves takedown of the left triangular ligament of the liver, opening of the lesser sac, and division of the crura of the diaphragm (**A**). The supraceliac aorta can be isolated first, followed by identification of the celiac trunk, or the common hepatic artery can be identified to guide dissection proximally to the celiac. For antegrade bypass, the left gastric artery often is divided to make it easier to create a retropancreatic tunnel for the SMA graft limb. The SMA usually is isolated at the base of the transverse colon (**B**), and side branches are controlled with silastic loops (**C**). (Image © Mayo 2014.)

A ringed forceps is placed on the caudal end of the plasma tubing that had been passed through the retropancreatic tunnel (Fig. 218.5). The transverse colon is lifted upward, the tubing is pulled cranially, and the clamp guided through the tunnel. The SMA graft limb is grasped, brought through the tunnel, straightened, and secured with a clamp at the base of the transverse mesocolon in an infracolic position. This maneuver fixes graft length and keeps blood or debris from getting into the limb during the

distal anastomosis. This tunnel is remarkably short in length. The retractors on the liver and intestine are released, and exposure reset for the SMA anastomosis. The SMA is opened vertically on its left lateral or anterolateral side in preparation for an end-to-side anastomosis. If there is SMA plaque that requires focal endarterectomy, the arteriotomy is closed with a patch. This facilitates the graft anastomosis and lessens the risk of anastomotic stenosis, particularly in women whose SMA diameter is small. The graft is cut to length after retraction on the small bowel is relaxed. Backbleeding is allowed, the anastomosis completed, and clamps are released to allow blood flow into the SMA.

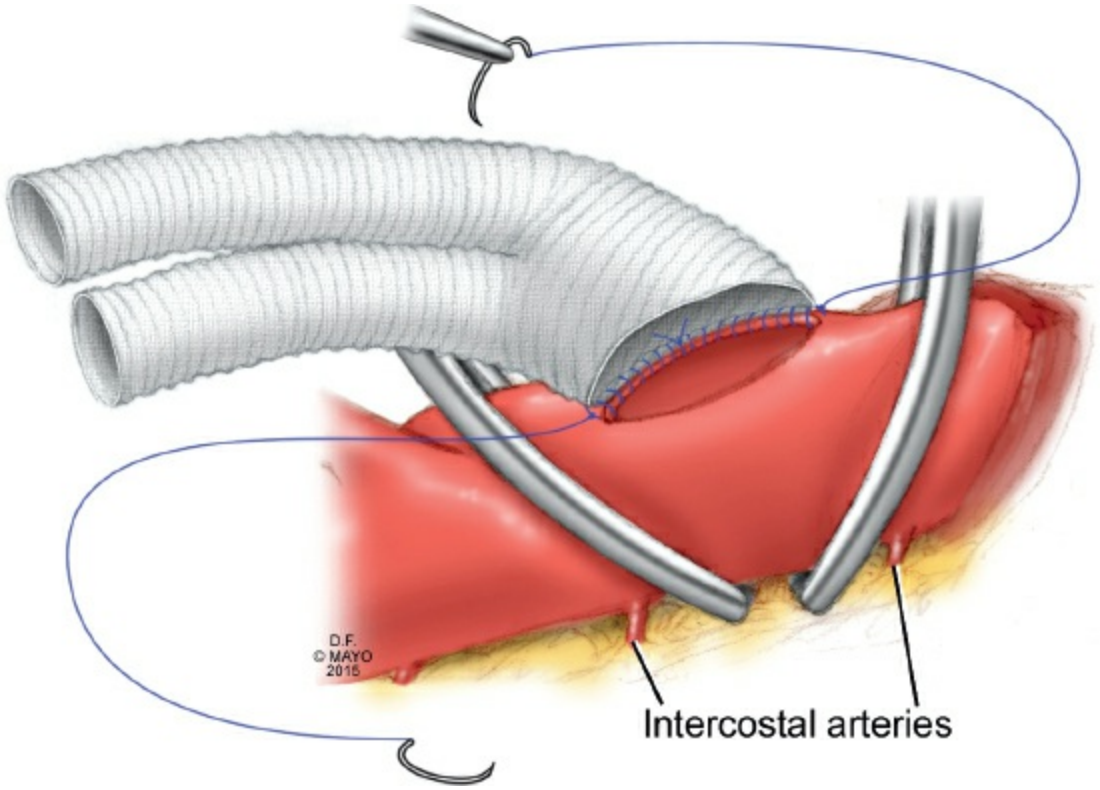

Figure 218.4. The supraceliac aortic-graft anastomosis can be done using a side-biting clamp or a two-clamp technique as shown here. For a two-vessel bypass, the graft limbs can be placed side-by-side, or on top of one another, depending on patient anatomy. (Image © Mayo 2015.)

Retrograde bypass from an iliac artery is done with prosthetic to the SMA alone, or to the SMA and common hepatic (Fig. 218.6). If both arteries are reconstructed, which rarely is needed, a side-to-side anastomosis is done to the SMA. The bypass then is gently curved behind the pancreas or on top of it, and sewn end-to-side to the common hepatic.

Patient anatomy determines the graft course so that it does not kink. Conduit size is chosen by the size of the target artery, with 7-mm or 8-mm prosthetic preferred over vein in most cases. The graft seems to lie better if inflow can be obtained from the right common iliac artery, whether the graft is done in a straight or C-shape configuration (Fig. 218.6). The latter allows antegrade blood flow vis-à-vis the SMA. If the common iliacs are circumferentially calcified but not stenotic, the external iliac artery is used for inflow. For a straight iliac to SMA bypass, the iliac artery anastomosis is done first. If a C-shape is chosen, either the iliac or SMA anastomosis can be done first based on surgeon preference. In this situation, we prefer to do the SMA anastomosis first, clamp the graft flush at its anastomosis and fill it with saline, let the bowel relax, and then lay the graft in a C-shape so that there is no redundancy when sewn to the iliac.

Inflow from the infrarenal aorta is used less often than the iliac artery because it is difficult to gauge graft length when the small bowel returns to its normal position. The graft has a tendency to buckle or kink. The use of a short stove-pipe bypass graft between the aorta and SMA obviates this risk and works well in select high-risk patients who may not tolerate a supraceliac clamp, or those who have calcification of the supraceliac aorta and/or iliac arteries (Fig. 218.7). The graft is first sewn to the posterior or left posterolateral side of the SMA. Retraction on the mesentery and bowel is relaxed, and the aorta is marked where the graft wants to sit. The infrarenal aorta is fully or partially cross-clamped, and the anterior wall is opened vertically. If the anterior wall is thick, a coronary punch or a small curved scissors is used to create an elliptical opening. The graft is cut short and beveled according to whether it will sit in a slight retrograde or antegrade position. The right lateral wall of the aorta and graft are sewn with running polypropylene suture using a parachute technique. The suture begins at the center and extends to the cranial and caudal end. The bowel is relaxed and the suture tightened. A double armed corner suture is placed at each end, tied and secured to the running suture. The left side of the anastomosis is completed by running each new suture toward the center, or by using interrupted sutures.

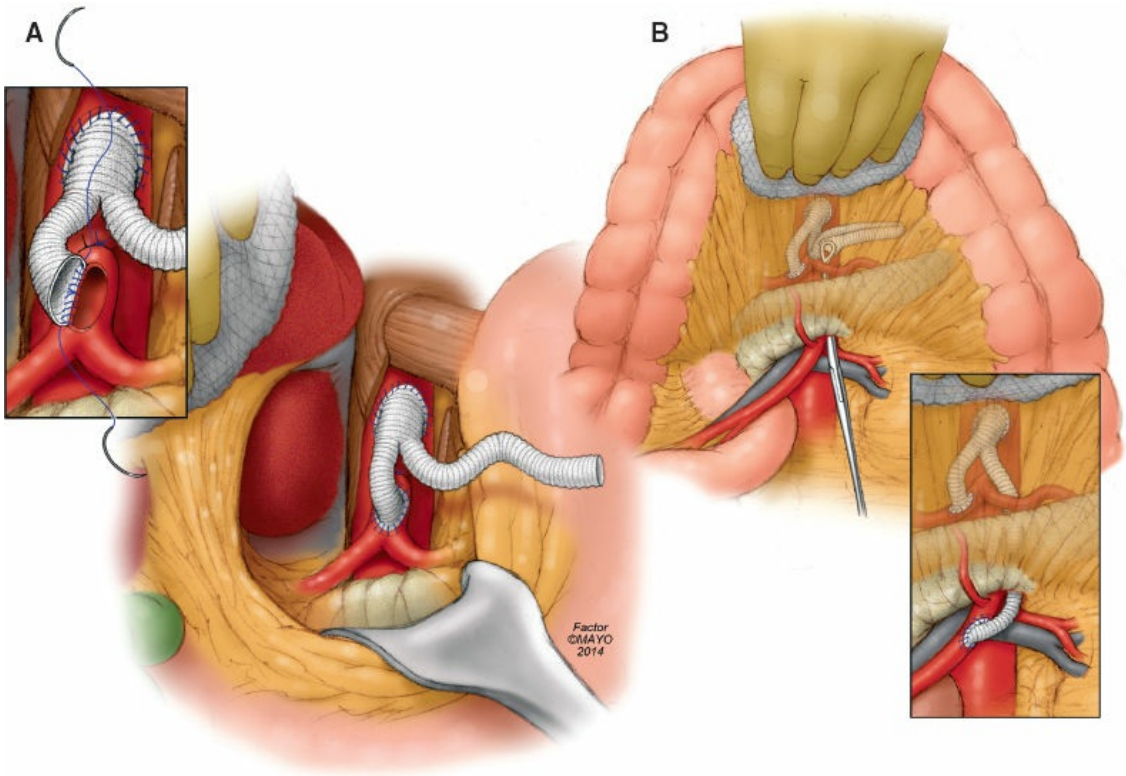

Figure 218.5. Anastomosis to the celiac can be done end-to-end, or configured as a functional end-to-end anastomosis, as illustrated in **A.** The latter simplifies cutting the graft to length and creating an anastomosis without tension. The graft limb is sewn end-to-side to the celiac, and the celiac trunk is ligated immediately proximal to the anastomosis. The SMA graft limb is passed through a retropancreatic tunnel; tension on the limb is fixed with a clamp at the base of the transverse colon, and the graft cut to length and sewn end-to-side to the artery as shown in **B.** (Image © Mayo 2014.)

Transaortic visceral endarterectomy is infrequently used, but works well for patients with atherosclerotic disease confined to the origin or first 2 cm of the SMA and CA. This technique is also useful for select patients with acute mesenteric ischemia and feculent spillage, which obviates the need for prosthetic, or for the rare patient who has concomitant symptomatic renal artery disease amenable to endarterectomy. The aorta and visceral arteries are isolated via left medial visceral rotation with the kidney kept down (Fig. 218.8). The spleen and pancreas are carefully mobilized, padded, and gently retracted. The crura is divided and the aorta is dissected free from its supraceliac to the juxtarenal segment. The adrenal vein is ligated and divided so that the renal vein can be retracted caudally. The renal artery origins are identified to ascertain distal aortic clamp

position, which often is the upper infrarenal aorta. Several centimeters of the celiac and SMA are circumferentially dissected free from their origins to allow for an eversion endarterectomy. Similar mobilization of the renal arteries is done if they require endarterectomy. Left phrenic and other small side branches may require ligation and division. The reconstruction begins by occlusion of the CA, SMA, and sometimes the renal arteries with vessel loops or atraumatic clamps, followed by application of distal and proximal aortic clamps. Lumbar arteries are controlled with small vessel loops or bull dog clamps. A curvilinear or trapdoor aortotomy is made from above the celiac to below the SMA. An endarterectomy plane is developed, and the aortic plaque is circumferentially freed from around the orifices of the SMA and celiac. The plaque is trimmed across the proximal and distal aorta, which facilitates eversion endarterectomy of the visceral arteries. At times, it is easier to evert the plaque from each artery by creating separate buttons, rather than trying to remove the endarterectomy specimen as one piece. The distal aortic endpoint is secured as necessary, and the aortotomy closed with running polypropylene suture. Back-bleeding and fore-bleeding are allowed prior to removal of the aortic and visceral clamps. If concomitant renal endarterectomy is needed, the aortotomy is carried distally on the anterior wall beyond the renal artery origins. An eversion technique is used to remove the occlusive plaque from them. Diuresis is induced with Lasix and mannitol after the cross clamp. Completion endarterectomy is needed in some patients if there is residual plaque or loose intima, which occurs more often in the SMA than the CA. The affected artery is gently clamped at its origin. A transverse or longitudinal arteriotomy is made in the artery, the plaque or intima is removed, and the endpoint secured. If the artery is opened transversely, it is closed primarily with interrupted sutures. If a longitudinal arteriotomy is made, a patch closure is done (Fig. 218.8).

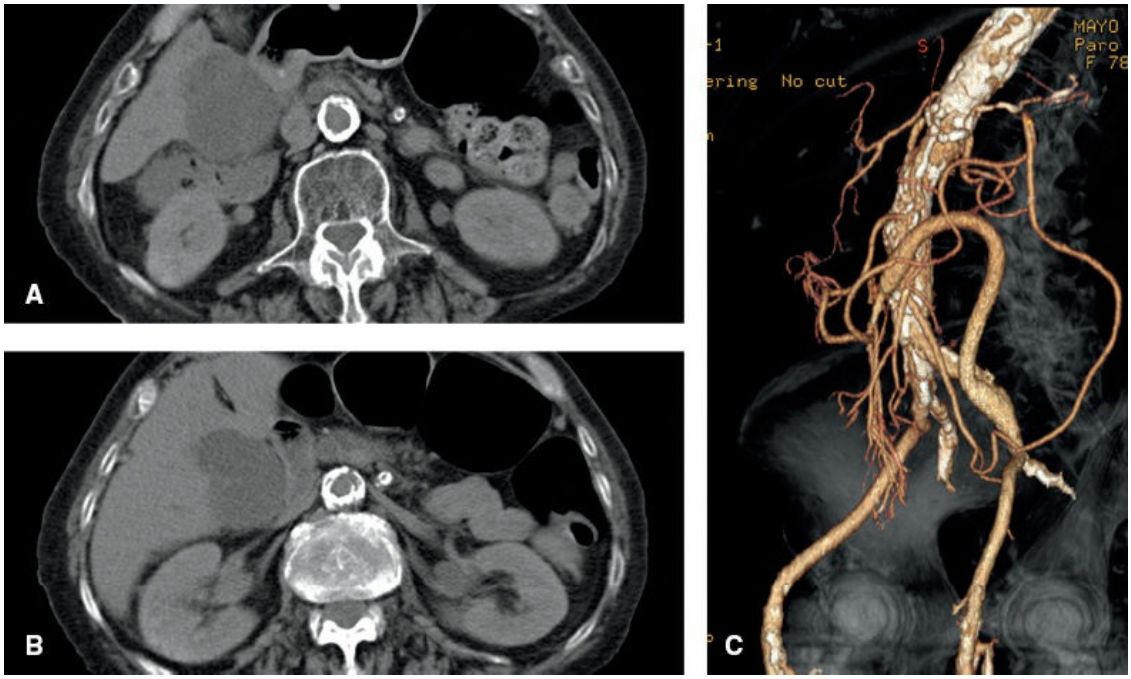

Figure 218.6. Retrograde bypass from the iliac artery can be done as a straight graft to the SMA, or more commonly in a C-shape. A retrograde configuration is used for high-risk patients, or those with severe calcification of the aorta as shown in both CT scan images (**A, B**). In this example, the left iliac artery was used for inflow, and the postoperative CTA shows a widely patent graft (**C**).

Figure 218.7. The challenge with a retrograde graft originating from the infrarenal aorta is kinking or buckling of the graft when the viscera are laid back in place. While rarely used, a short stove pipe graft (~2 cm) between the aorta and SMA obviates this problem. The SMA graft anastomosis is done first to the posterior or left posterolateral wall of the artery. The position of the aortic anastomosis is marked by relaxing retraction on the bowel. A button is cut from the anterior aortic wall, and the right lateral aortic suture line (back wall) is done with a parachute technique. The suture line is pulled tight as the bowel is relaxed. The left lateral suture line (front wall) is completed as a running or interrupted suture line. (Image © Mayo 2002.)

Redo open reconstruction for symptomatic patients with a failed bypass graft poses several challenges. Bowel adhesions and periarterial scar tissue make reoperation technically more difficult, as patients with a chronic graft occlusion can rarely be rescued by endovascular techniques. The burden of atherosclerotic disease may be greater in the SMA, so dissection must be carried further distally along the artery, which risks injury to arterial collaterals. Moreover, long length of disease may necessitate endarterectomy and patch angioplasty to facilitate the distal graft

anastomosis, which technically complicates the reconstruction. If a supraceliac aorta based bypass was done, a bypass from the iliac artery should be considered. If that is not possible because the infrarenal aorta and iliac arteries are too calcified to clamp or are diffusely stenotic, a bypass from the lower thoracic aorta may be needed if the supraceliac aorta cannot be easily isolated.

Completion intraoperative DUS is routinely used to assess technical outcome after mesenteric reconstruction. Bowel retraction is relaxed before the imaging is done to alleviate stretch on the CA and SMA, which otherwise may cause false elevation in blood flow velocities. Identification and immediate correction of technical defects in the operating room lowers early graft failure or arterial thrombosis.

Postoperative care

Postoperative fluid shifts are common during the first 48 postoperative hours because of the loss of mesenteric arteriolar autoregulation. This phenomenon is especially true for patients with subacute on CMI, who not only need fluid support, but may also need IV pressors to maintain adequate perfusion pressure because of a systemic inflammatory response. Adequate volume resuscitation is imperative before pressors are used, to avoid irreversible splanchnic vasoconstriction and bowel infarction that may occur if the central or pulmonary venous pressure is low. Close monitoring of the intravascular volume, cardiac function, and acid-base status is best done in an intensive care unit. Perioperative graft occlusion is rare if the intraoperative DUS shows a widely patent reconstruction. Nonetheless, an increase in fluid requirements, reduction in urine output, thrombocytopenia and/or leukocytosis, and subtle but steady narrowing of the A-aO_2 gradient or pulse pressure are harbingers of bowel ischemia. Metabolic acidosis is a late finding. These signs should prompt CT angiography, as ultrasound imaging of the bypass graft may be hampered by bowel gas. If the graft proves widely patent, abdominal exploration may still be needed if the clinical course worsens. An occluded graft warrants abdominal exploration and thrombectomy. If no technical cause of graft occlusion is found, a hypercoagulable state may be the culprit.

Perioperative complications range between 20% and 40% in most reports, and were listed as 36% in a Mayo Clinic study. The most common problems are pulmonary (15%) because these patients often are smokers with chronic obstructive pulmonary disease (COPD) and susceptible to

lung infection or pulmonary edema; gastrointestinal (14%), including prolonged ileus; and cardiac (10%) or renal (4%). Incisional problems occur in 4% to 8% of patients. Ascites is rare, but may develop in patients with subacute on chronic ischemia because the bowel weeps fluid for several days after surgery, IV requirements are high during this time, and the patients may be hypoproteinemic. Abdominal compartment syndrome is uncommon.

Intravenous nutrition supplemented with vitamins and trace elements is administered to malnourished patients until bowel function returns and caloric goals are met. Some patients benefit from oral nutritional supplements or six small daily meals to reach caloric goal. Diarrhea occurs in some patients and may last days to weeks until intestinal autoregulation improves. This problem can prove difficult to treat, even with antimotility and stool thickening agents. Monitoring of outpatient weight and volume status and involvement of a nutrition team are needed in these cases. Hospital length of stay ranges between 7 and 14 days after open revascularization. DUS surveillance is done at 6-month intervals for the first 2 years, then annually thereafter if the arteries and graft remain widely patent.

ENDOVASCULAR REVASCULARIZATION

The primary goal of percutaneous treatment is to restore antegrade flow into at least one of the three mesenteric arteries, preferentially the SMA. Early reports described successful results with balloon angioplasty alone, but elastic recoil and restenosis have limited its utility when used for ostial lesions. Most experts agree that primary stenting using a balloon-expandable stent offers the best chance for technical success and long-term patency. There is no proven benefit that routine two-vessel stenting provides more durable symptom relief or patency, and a second intervention adds cost and potential risk of complications.

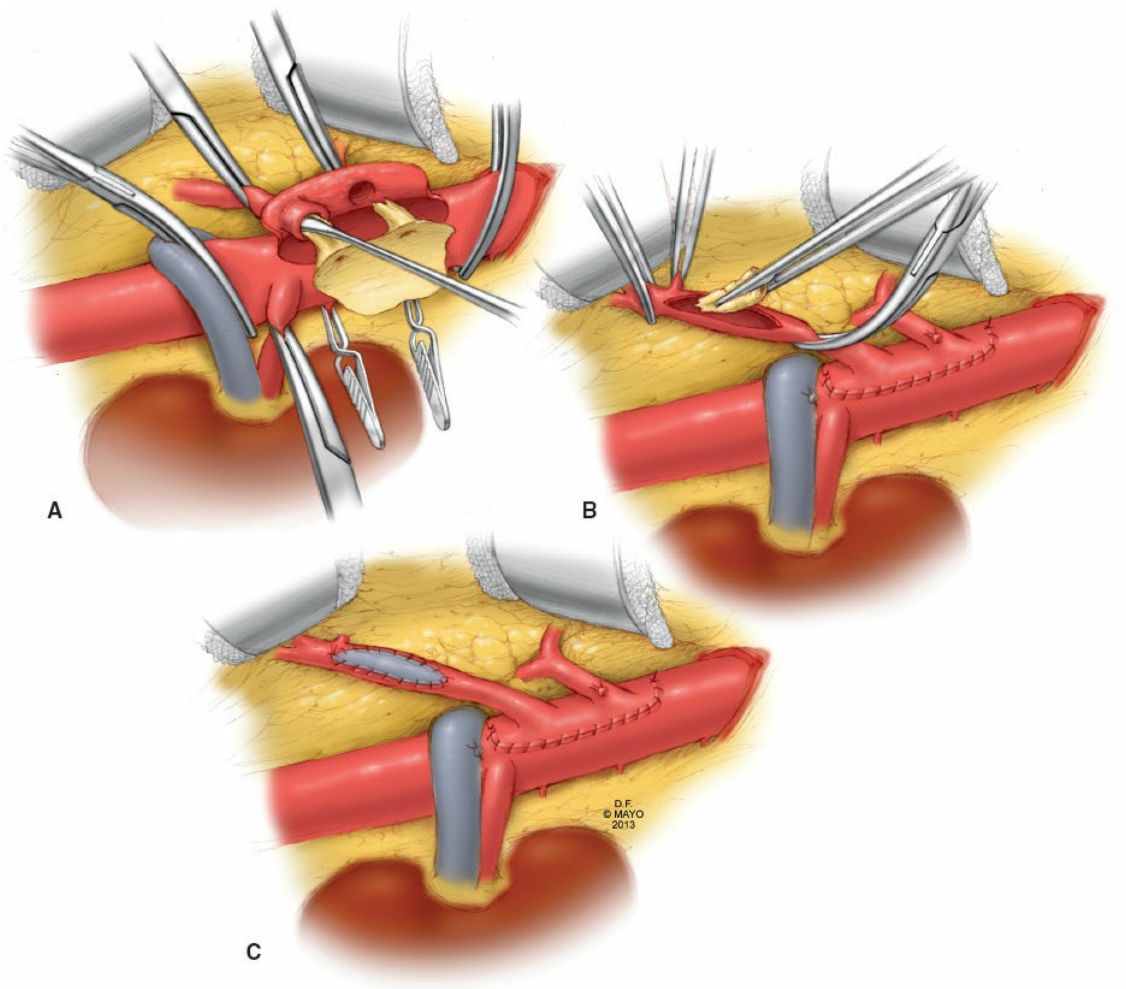

Figure 218.8. Transaortic visceral artery endarterectomy is applicable to patients with chronic, or acute on chronic, mesenteric ischemia who have short segment celiac and SMA occlusions or stenoses. Isolation of the supraceliac and juxtarenal aorta, and the celiac and SMA is done with a left medial visceral rotation, leaving the left kidney down. The visceral and/or renal arteries are clamped before the aortic clamps are placed. An eversion endarterectomy is done through a trapdoor or curvilinear incision as shown (**A**). Here, the entire specimen is shown being removed in one piece. Creation of separate buttons of plaque around the origin of each artery facilitates the eversion endarterectomy in some patients. Sometimes a completion endarterectomy and patch are needed for the SMA (**B, C**). (Image © Mayo 2013.)

Diagnostic Angiography

A diagnostic study includes a biplane abdominal aortography with anterior-posterior and lateral projections. A lateral view is imperative to provide visualization of the origins of the CA and SMA. A right anterior

oblique view demonstrates the origin of the IMA. For better visualization of ostial lesions and quantification of the degree of stenosis, selective catheterization of the visceral arteries is necessary. In patients who had prior CTA or MRA, abdominal aortography may be avoided, unless it is needed to identify the origin of a vessel prior to selective catheterization.

Access is established using ultrasound guidance and 0.035-in guidewire system. A 5-Fr sheath is positioned in the external iliac artery and 5-Fr diagnostic flush catheter is advanced to T12 level over a 0.035-in guidewire. Modest IV heparinization (40 units/kg) is recommended prior to selective catheterization of the mesenteric arteries. Low-osmolar contrast (e.g., Visipaque) minimizes abdominal discomfort during selective injections. Choice of catheter shape is dependent upon access site, angle of origin, and individual preference. MPA catheter is ideal for selective catheterization via brachial approach, whereas a secondary curve catheter (e.g., SOS or Simmons) or a catheter with more acute curve (e.g., Cobra 2) can be used for interventions done via femoral approach. Selective angiography is necessary to confirm the severity of disease and to identify tandem lesions and collateral patterns. In patients with questionable lesions, pressure gradients can be measured using pressure wire, “pull-back” or simultaneous pressure measurement technique.

Technique

A brachial artery approach is preferred for patients with a very angulated origin of the aorta and in those with occlusions or longer lesions (Fig. 218.9). It offers excellent support with small profile systems and allows precise stent deployment in patients with acute SMA angles. Although the risk of puncture-related complications is higher using percutaneous technique, the risk of complications is low using a small 1- to 2-cm incision under local anesthesia to expose and repair of the brachial artery.

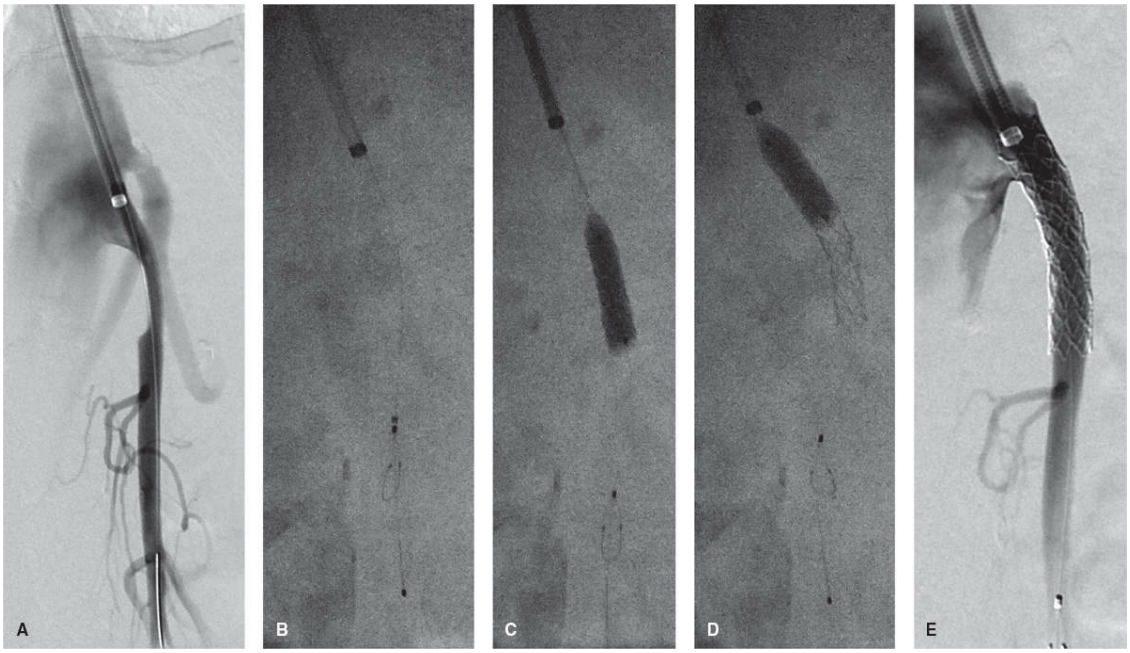

Figure 218.9. Selective angiography of the superior mesenteric artery (SMA) using brachial approach demonstrates high-grade stenosis (**A**). The lesion was crossed using a filter wire (**B**) and stented with balloon-expandable stents (**C, D**). Completion angiography shows widely patent SMA.

Arterial access is established with a 0.018-in micro-puncture set using ultrasound guidance, after which the system is exchanged to 0.035 in. Full systemic heparinization (80 mg/kg) is administered prior to catheter manipulations to achieve an activated clotting time of >250 seconds. A 6- or 7-Fr 90-cm hydrophilic sheath is positioned in the descending thoracic aorta above the CA origin. A 5-Fr MPA catheter is ideal for selective catheterization of the mesenteric arteries using the brachial approach, whereas an SOS or VS1 catheter can be used from the femoral approach. The initial selective angiography should demonstrate the origin of the vessel from the aortic wall, the severity of the stenosis, and should document the distal branches for comparison with postintervention views. The target lesion is initially crossed using a 0.035-in soft angled glide-wire, which is exchanged for the interventional wire after confirmation of true lumen access. Most patients are treated using 0.014- or 0.018-in guide-wire system, which should be visualized and positioned within the main trunk of the SMA, rather than within small jejunal branches, which are prone to perforate or dissect. Embolic protection devices can be useful in patients with occlusions, severe calcification, or acute thrombus, such as in patients with acute or subacute symptoms. Our preference is to use a

320-cm working length 0.014-in filter wire (Spider RX, Medtronic, Plymouth, MN) coupled with a 0.018-in “buddy wire”; the 0.035-in stent is introduced via both wires for better support and to facilitate subsequent retrieval of the embolic protection device. Predilatation is recommended for tight stenosis, occlusions, severe calcification, and to size stents. A balloon-expandable stent with diameters ranging from 5 to 8 mm is used in >95% of cases, allowing precise deployment and greater radial force. Our preference has been to use a covered stent in most patients with proximal lesions that do not extend beyond branches. The stent is positioned under protection of the sheath, covering slightly more than the entire length of the lesion. Positioning the stent in the aortic lumen is critical to avoid missing the proximal portion of the lesion. It is important to position the stent 1 to 2 mm into the aortic lumen. Ideally, the stent should be flared gently into the aorta, which prevents missing the ostia and facilitates recatheterization if needed. Occasionally, a self-expandable stent is needed to treat a nonostial lesion or segments with excessive tortuosity, extending beyond the angulated portion of the SMA.

The technique is slightly modified in patients with occlusions (Fig. 218.10). In these difficult cases, it is of paramount importance to use the brachial approach and a stiff support system, which is accomplished by combining a 7-Fr sheath, 7-Fr MPA guide-catheter, and 5-Fr MPA catheter (Fig. 218.10). Ideally, the tip of the MPA catheter is used to engage the stump of the occluded SMA, and sufficient support is provided by the combination of the sheath and guide-catheter. The lesion is crossed using a straight tip, hydrophilic, soft 0.035-in glide-wire, but also using 0.018-in or 0.014-in guide-wires if needed. It is ideal to avoid the subintimal plane, which is best achieved by using straight tip guide-wires. A Quick-cross (Spectranetics, Colorado Springs, CO) or an alternative support catheter, or even a small coronary balloon may be needed to cross a tight lesion. Once the lesion is crossed, access into the true lumen should be confirmed. Our preference has been to use embolic protection device (e.g., Spider RX, Covidien, Plymouth, MN) with two-wire technique routinely in cases of total occlusion.

Following deployment and flaring of the stent, the embolic protection device is retrieved with careful attention to avoid entrapment into the stent. The basket is examined for debris. A formal completion angiography should be obtained, including a focal magnified view of the stent with the sheath into the aorta to demonstrate the vessel origin and a panoramic view

of the entire SMA and its branches to rule out embolization or perforation. The stiff guide-wire should be retracted and nitroglycerin may be administered via the sheath to minimize spasm or kinks caused by the guide-wire tip. It is particularly important to note the presence of distal embolization, dissection, thrombus, or branch perforation. These complications occur in 5% to 10% of patients and remain a major source of morbidity and mortality if not immediately recognized.

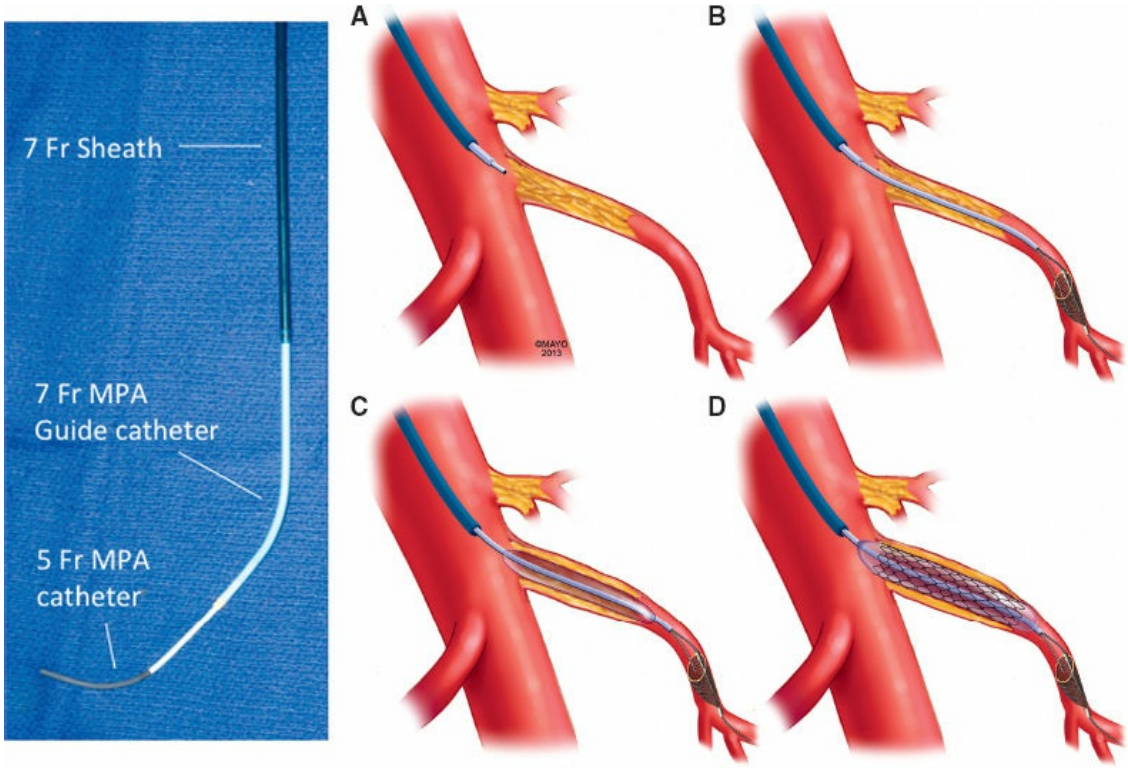

Figure 218.10. Technique of recanalization using co-axial system with 7-Fr sheath, 7-Fr guide catheter, and 5-Fr MPA catheter. The occluded superior mesenteric artery (SMA) stump is engaged with the co-axial system (**A**). The lesion is crossed using a glidewire and catheter (**B**), followed by predilatation (**C**) and stent placement (**D**). (Image © Mayo 2013.)

A number of adjunctive techniques can be used to optimize results of mesenteric stents in patients with complex lesions, but the authors acknowledge that these techniques are anecdotal or supported by a limited number of case reports. The presence of acute and subacute symptom presentation suggests fresh thrombus or complicated plaque. In these cases, local administration of t-PA into the diseased segment 20 to 30 minutes prior to stent placement may improve technical success. For eccentric, calcified lesions, percutaneous atherectomy has been carefully

used in very select cases. It is critical to have an appreciation of the limitations of this technique when applied as off-label use in the mesenteric arteries.

Hybrid Revascularization

The term retrograde open mesenteric stenting (ROMS) has been coined to describe a hybrid approach using a midline laparotomy to expose the SMA and endovascular technique to place a retrograde SMA stent. This was first reported by Milner and colleagues from the University of Pennsylvania and Dartmouth Group. ROMS avoids the need for extensive dissection, vein harvesting, and use of a prosthetic graft. Its utility is for patients with extensive aortoiliac disease and no good source of inflow, or in those with acute mesenteric ischemia, bowel gangrene, and contamination (Fig. 218.11).

The SMA is dissected below the pancreas as previously described. Several jejunal branches are controlled with silastic vessel loops and occluded prior to manipulation to avoid distal embolization. Retrograde SMA access is established using a micro-puncture set with 0.018-in guide-wire. This is exchanged for a 0.035-in guide-wire system and a 6- to 7-Fr sheath is advance to the SMA. Retrograde angiography is obtained and the SMA occlusion or stenosis is crossed, predilated and stented with a balloon-expandable stent. Prior to restoring antegrade flow to the SMA, the sheath is flushed to prevent distal embolization. The puncture site may be closed with interrupted sutures or opened longitudinally and closed over a patch if severely diseased.

Postprocedure Management

The postprocedure care after mesenteric interventions is comparable to that of other peripheral endovascular procedures. All patients are admitted for observation overnight. Worsening abdominal pain after the procedure is unusual and warrants evaluation to rule out thrombosis, embolization, or a mesenteric hematoma from jejunal branch perforation. Patients are allowed to resume a regular diet within 6 to 8 hours. Antiplatelet therapy is typically started prior to the intervention with acetylsalicylic acid, and continued indefinitely thereafter. Clopidogrel is started the day of the intervention with a loading dose of 300 mg, and continued for 6 to 8 weeks as a dual antiplatelet agent, after which patients are kept on acetylsalicylic acid alone. The author’s preference is to obtain a duplex ultrasound scan

prior to discharge or within the first few days after the procedure to serve as a baseline for future comparison. The presence of elevated velocity on duplex ultrasound may be due to inadequate stenting with missed lesion proximal or distal to the stent. Follow-up includes clinical examination and duplex ultrasound every 6 months during the first year and annually thereafter.

RESULTS

Outcome measures for open and endovascular treatment include mortality and morbidity, symptom relief, freedom from restenosis, and symptom recurrence and reintervention. Anatomy, patient age, comorbidities and frailty, surgeon experience, and intraoperative and perioperative management are all influential to outcome. Interpretation of outcomes between centers is hampered by a mix of patients with acute and chronic presentations, those with median arcuate ligament syndrome, and inconsistent reporting of disease severity, clinical and imaging follow-up for patency, and the aforementioned outcome measures. Standards in reporting and risk stratification are needed to compare effectiveness of treatment. Similar to outcome for other open vascular operations, the lowest mortality rates for mesenteric bypass are reported by high-volume surgeons at high-volume centers. Mortality rates of 10% or more reported at some hospitals are excessive in our opinion. Isolated bypass performed by experienced surgeons can be done safely, even for redo reconstructions.

A Mayo Clinic report assessed risk-stratified outcomes in 229 CMI patients treated by open bypass or endovascular procedures, using the Society for Vascular Surgery comorbidity scoring system. The data from this paper can be used to gauge treatment. Patients were categorized into high- or low-risk open and endovascular groups. Overall mortality was similar between the open (2.7%) and endovascular (2.4%) groups. However, low-risk patients treated with open bypass had a perioperative mortality rate of only 1% compared with 6.7% for high-risk patients. Operative mortality varied based on the number of high-risk criteria present. Patients with no high-risk factors had a 30-day mortality rate of 0.7%. This sharply contrasted to mortality rates of 3.1% if one high-risk criterion was present, to more than 25% if four criteria were present. Moreover, concomitant aortic reconstruction carried an 8.9% mortality rate. Therefore, mesenteric revascularization should be the sole goal of therapy, and the type of revascularization tailored to what patient risk and

anatomy allow. Aortic replacement should only be done if inflow cannot be otherwise obtained, or if the patient has a large aneurysm. Old sick or malnourished patients are at high risk for perioperative problems, and are better served by the least stressful procedure possible. Mortality and morbidity of open revascularization are higher compared to endovascular approach in review of large datasets.

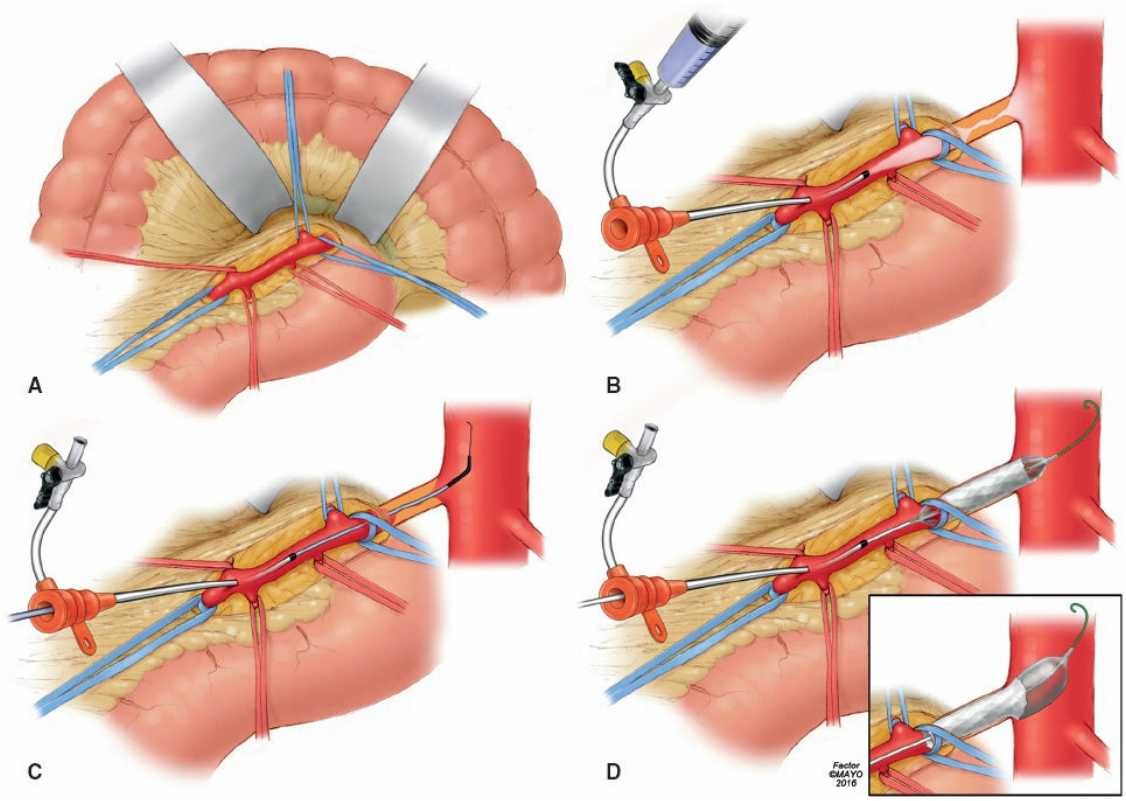

Figure 218.11. Technique of retrograde open mesenteric stenting (ROMS) requires exposure of the SMA via laparotomy (**A**). The SMA is accessed in a retrograde fashion with a 7-Fr sheath (**B**). Retrograde angiography demonstrates near occlusion of the SMA, which is crossed using glidewire and catheter (**C**). The stenotic SMA is stented using a balloon expandable covered stent (**D**). (Image © Mayo 2016.)

Both methods of revascularization are highly effective, with symptom improvement averaging 88% with endovascular and 93% with open revascularization. Most single center series show mesenteric bypass to carry a higher patency rate, lower risk of restenosis, better freedom from recurrent symptoms, and fewer reinterventions than patients treated with angioplasty and stenting. Primary patency 5 years after open bypass averages almost 90% in a review of the pooled literature (range 57% to

92%), and reintervention is needed in less than 10% of cases. One theoretic advantage of two-vessel bypass is that occlusion of one graft limb does not always necessitate reintervention or cause recurrent symptoms.

Endovascular treatment is offered over open revascularization at most centers, because of its low mortality, morbidity, and short hospital stay. Recurrent stenosis may occur at the edges of the stent in 50% or more of the patients, with in-stent stenosis in the remainder. Patency can be maintained with another endovascular intervention, such as cutting or cryo-balloon angioplasty, redo stenting with bare metal or drug-eluting stents, atherectomy or covered stents. To date, while none has been proven better than standard angioplasty, our preference is to treat restenosis with a balloon expandable covered stent. Some data suggest that primary use of a covered stent may be better than placing a bare metal stent. This paradigm shift in treatment has relegated open bypass to patients with more challenging anatomy and for endovascular failures. Even in these circumstances, nearly three fourths of bypass grafts remain patent at 5 years.

PATIENT SURVIVAL

Many factors affect long-term survival after mesenteric revascularization, including advanced age, impaired cardiac, pulmonary or renal function, and type of therapy. The use of propensity matched scores among a cohort of 343 patients treated for CMI by endovascular techniques and open bypass at Mayo Clinic sheds some light on survival trends. The 5-year survival rates were nearly identical in patients treated by open (57%) or endovascular techniques (60%), yet patient comorbidity and risk score impacted survival. For example, 5-year patient survival was approximately 71% for low-risk patients, 49% for intermediate-risk ones, and 38% for high-risk patients. Open bypass and endovascular treatment provided excellent 5-year freedom from mesenteric-related death, over 90% in each group. Age over 80 years, home oxygen therapy, advanced chronic kidney disease, and diabetes increased all-cause mortality, whereas the latter two problems influenced mesenteric-related death. The most common cause of late death is cardiac events, which suggests the need for long-term monitoring of cardiovascular risk factors in these patients.

NONATHEROMATOUS PROBLEMS

Mesenteric vasculitis is the second most common cause of CMI after atherosclerosis, but the literature is sparse. Medical treatment with steroids or other immunosuppressants is initiated first. Stenting does not work well, and operation should be avoided in the active phase of disease unless absolutely necessary to treat an acute event because of the high risk of graft occlusion. For symptomatic patients with mesenteric stenoses whose arteritis is quiescent or chronically controlled by steroids, bypass is effective. Arterial outflow and inflow must be done to and from healthy vessels to achieve the best durability. Long-term survival is similar to the general population. Reconstructions are safe, and provide similar graft patency (83% vs. 84%) and freedom from recurrent symptoms (83% vs. 75%) as patients treated for atherosclerotic disease. The reader is referred to other literature for the management of mesenteric ischemia caused by aortic or isolated visceral dissection, coarctation, neurofibromatosis, and radiation injury.

SUMMARY

Intervention for patients with CMI is done with endovascular techniques as first-line therapy at most centers. Even patients with difficult lesions are considered for angioplasty and stenting, accepting a higher rate of technical failure and reintervention in those with long occlusions or severe calcification. Primary stenting using a balloon-expandable covered stent seems to afford the best technical result and long-term patency rate. Open mesenteric revascularization is done for low-risk patients with flush SMA occlusion, long segment calcified stenoses not amenable to stenting, women with small vessels, and for nonatheromatous diseases. Our preference is to use the supraceliac aorta for inflow, and to reconstruct both the CA and SMA when possible. However, SMA bypass alone works well, whether done antegrade or retrograde. Mesenteric bypass can be performed safely by experienced surgeons, even for reoperation. Surgical treatment should focus on mesenteric artery revascularization as the primary goal, and concomitant aortic replacement should be avoided.

EDITOR'S COMMENT

This chapter by Bower and Oderich serves as the master's guide on how to define and manage chronic mesenteric ischemia and really helps to remind me why this book is important for our readers. Dr. Tom Bower is a master open surgeon who has spent his entire career at the Mayo Clinic really performing open surgery on all comers, but really mainly on people who could not have an endovascular approach who has already had an open/endovascular approach that failed. Dr. Gustavo Oderich is an expert endovascular specialist, who has developed novel endovascular techniques to make stenting of previously nonstentable lesions (i.e., occlusions) safely treatable via endovascular techniques.

The description of open surgery using the supraceliac aorta or an iliac artery is spot on. I, likely because I used to do a lot of abdominal aortic debranchings, am more comfortable with the iliac as the inflow source (Kabbani LS, Criado E, Upchurch GR Jr, et al. Hybrid repair of aortic aneurysms involving the visceral and renal vessels. *Ann Vasc Surg* 2010;24(2):219–24). It seems like many of the patients I have taken care of always have diseased supraceliac aortas, making the idea of clamping in this region less than attractive. My old partner Ramon Berguer used to love doing supraceliac aortic bypasses. However, he used a single graft off the aorta that he then sewed on another graft in a y-configuration, rather than a bifurcated aortic graft. His results paralleled those of the Mayo Clinic presented in this chapter.

I should comment on the idea of getting chronic mesenteric arteries that are occluded open. Dr. Oderich describes using a filter wire and a buddy 0.035 wire

to both protect the distal SMA and also deliver the balloon expandable covered stent. This makes sense but seems pretty cumbersome and makes one wonder why a company doesn't make a 0.035 filter wire that can be used in such a situation.

There are data in open mesenteric revascularization surgery to support an approach that supports revascularizing as many mesenteric vessels as one can (Hollier LH, Bernatz PE, Pairolero PC, et al. Surgical management of chronic intestinal ischemia: a reappraisal. *Surgery* 1981;90(6):940–6). I believe this suggestion has stood the test of time and remains true. However, it is interesting to note that most endovascular enthusiasts don't support this approach when it comes to endovascular revascularization in patients with CMI. Almost universally people only stent the SMA and I don't really understand it other than the fact that I recognize that celiac stents can be crunched and I personally don't think they work that well (Ahanchi SS, Stout CL, Dahl TJ, et al. Comparative analysis of celiac versus mesenteric artery outcomes after angioplasty and stenting. *J Vasc Surg* 2013;57(4):1062–6). Some have even suggested that celiac stenting be abandoned, especially in the setting of suspected median arcuate ligament compression of the celiac (Delis KT, Gloviczki P, Altuwaijri M, et al. Median arcuate ligament syndrome: open celiac artery reconstruction and ligament division after endovascular failure. *J Vasc Surg* 2007;46(4):799–802). It also sort of suggests that important collaterals are lost when open surgery is performed. I have gone to using a retrocolic, retrogastic tunnel, not a retropancreatic tunnel for bypasses as I worry about the creating the retropancreatic tunnel (and have seen some serious misfortune while creating that tunnel!) In contrast, others have stented the inferior mesenteric artery in the setting of an occluded celiac and SMA stent and the patients benefited (Wohlauer M, Kobeiter H, Desgranges P, et al. Inferior mesenteric artery stenting as a novel treatment for chronic mesenteric ischemia in patients with an occluded superior mesenteric artery and celiac trunk. *Eur J Vasc Endovasc Surg* 2014;27(3):e21–e23). Really hard to make sense of what the right thing to do in a one-size-fits-all type of algorithm. It is best to recognize that one needs to approach every patient individually and trying to figure out a revascularization strategy that works best for their patient.

Finally, it is sort of interesting to me that when patients have SMA stents go down, especially in the chronic setting, they seem to tolerate it and don't have complete collapse from an entirely ischemic small bowel. Of course this is completely anecdotal, but I have seen a number of these occluded stents rescued with posis and restenting. Having said that, I would still treat this like a surgical emergency and be quick to get the patient to the hybrid endosuite. Dr. Oderich is probably right in this in this setting similar to the native occluded SMA, the use of a filter wire is likely indicated.

Gilbert R. Upchurch

F VASCULAR INFECTION

219 Mycotic Aneurysms

Cheong J. Lee

Originally introduced by Osler in 1885 to describe peripheral arterial aneurysms initiated by septic embolization from bacterial endocarditis, the term “mycotic aneurysm” is now generally applied to aneurysmal degeneration of an artery from infection. Although the term “mycotic” implies fungal etiology, the majority of these aneurysms are caused by bacteria. Mycotic aneurysms can be found in any peripheral vascular bed, and within this spectrum, aortic infections or aortitis represents one of the most challenging entities to manage surgically.

Aortitis as a clinical entity is generally viewed as the early stage of a mycotic aortic aneurysm. The dilemma of aortitis lies in how to differentiate between infectious versus noninfectious causes, since infectious aortitis without intervention often leads to aortic rupture and death. Aortitis account for approximately 1% to 2% of all cases of abdominal aortic aneurysms. Aseptic or inflammatory aortitis is more commonly encountered; however, the majority of surgically relevant aortitis and mycotic aortic aneurysms result from arterial wall degradation by pathogenic organisms. Infective aortitis is associated with substantial morbidity and mortality. As such, high index of suspicion is required for confirming the diagnosis, which is often based on morphologic changes of the aortic wall that range from thickening, endarteritis, emphysema, ectasia, ulcerations, to ultimately aneurysms. Once aortitis has been confirmed radiographically, its nature should be considered infectious until proven otherwise.

ETIOLOGY AND PATHOPHYSIOLOGY

Mechanisms by which mycotic aneurysms form are by direct pathogenic inoculation of the arterial wall, bacteremia, local contamination by

infection, and septic embolism. Underlying risk factors of patients that increase vulnerability to arteritis and subsequent mycotic aneurysm development include patients with direct arterial injury, those with history of an antecedent infection, patients with impaired immunity, and preexisting disease of the arterial intima, such as atherosclerosis and aneurysms.

The most common pathways behind the development of mycotic aneurysms are via direct bacterial inoculation and bacteremia from an antecedent infection. Seeding of the arterial wall can occur at the time of vascular injury by mode of self-inflicted processes (intravenous drug use), iatrogenic (contaminated instrumentation), or due to penetrating trauma leading to the development of mycotic pseudoaneurysms in which there is complete degradation of arterial wall integrity. Contaminated needle sharing is probably the most common mode of peripheral mycotic aneurysm development. With regard to iatrogenic causes, recently there have been increasing reports of mycotic aneurysms developing in patients who have had intravesicular Bacillus Calmette-Guérin (BCG) instillation for treatment of bladder cancer. BCG is a strain of *Mycobacterium bovis* that elicits a local granulomatous inflammation to temper progression of bladder tumor cells. It is thought that septic dissemination of BCG via the vasa vasorum leads to mycotic arteritis and aneurysms. BCG-associated mycotic aneurysms can develop in any vascular bed in this inherently immunocompromised patient population. Although cases seem exceptional and rare, the author of this chapter has treated two patients with tubercular mycotic aneurysms that formed in the carotid, femoral, popliteal, aortoiliac, and coronary arterial beds following long-term BCG use.

Extension of a focus of infection is another means for direct arterial contamination. Infected aortoiliac aneurysms have been reported as a result of local sepsis caused by gastrointestinal perforations and colorectal infections. Pancreatitis and vertebral osteomyelitis have been reported to cause mycotic visceral artery and aortic aneurysms. Infected orthopedic hardware and other prosthetic implants adjacent to a vascular bed can also conceive arterial infections.

Septic embolism from endocarditis (from which the term “mycotic aneurysm” originates) can evolve into arteritis and on to infected aneurysms. In the pre-antibiotic era, the majority of infected aneurysms were due to endocarditis. Typically, emboli lodge at arterial bifurcations and as such mycotic aneurysms from septic emboli most commonly

develop in the peripheral arterial bed. Intracranial arteries, followed by visceral arteries, and upper or lower extremity arteries are the most commonly involved sites.

Although normally resistant to infection, a diseased intima, such as in atherosclerotic plaques or preexisting aneurysms, allows pathogens into deeper layers of the arterial wall. Aorta is the most commonly involved arterial bed by bacteremic seeding and inoculation given that it is burdened with the greatest amount of atherosclerosis. Preexisting aortic aneurysms are also at risk for infection. When cultured, a significant number of aortic aneurysms are found to have bacterial colonization in the aortic tissue, although the majority of patients go on to have no known negative sequelae.

The microbiology of mycotic aneurysms continues to change over time. In most cases, blood and tissue cultures are positive in over 50% of patients with the diagnosis; however, no pathogen is isolated in up to 25% of cases. The organisms classically known to have the greatest affinity for the vascular wall are *Staphylococcus* and *Salmonella*. In the western hemisphere, *Staphylococcus aureus* and *Streptococcal* species are typically the most common pathogens reported in infected arterial beds. Salmonella is the most common organism seen in the eastern hemisphere. Gram-negative organisms overall are associated with higher incidence of aneurysm rupture and associated mortality. More rare are anaerobic and fungal pathogens, along with mycobacterial causes as mentioned previously.

CLINICAL PRESENTATION

The presentation of patients with mycotic aneurysms varies depending on the arterial bed involved. For more peripheral or superficial arterial segments, the classic presentation of a mycotic aneurysm is a painful, pulsatile, enlarging mass in the setting of systemic responses, such as fever and malaise. Nonaortic peripheral aneurysms that deviate from their natural history and present with rupture should raise suspicion for underlying infection. In general, aseptic peripheral aneurysms (e.g., popliteal and brachial) more commonly present with distal embolization and not rupture. Unless the process is an acute pseudoaneurysm from recent trauma, it is atypical for true peripheral aneurysms to be tender and symptomatic, or present with rupture (Fig. 219.1). Infected aneurysms may be masked by overlying inflammation and presence of a soft tissue

infection adjacent to a major blood vessel should raise suspicion for a mycotic process. The process can be easily misdiagnosed as cellulitis, abscess, or thrombophlebitis.

Deeper seeded arterial infections may present with more nonspecific systemic symptoms. Mycotic aneurysms involving the aorta or iliac arteries may be accompanied by abdominal or back pain but vague systemic symptoms such as fever, chills, and night sweats are more common. As such, the diagnosis may not be apparent until the aneurysm has ruptured. Mycotic aortic aneurysms can occur throughout the aorta. The most common location is thought to be the infrarenal aortic segment, which is seen in up to 50% of the cases. The descending thoracic aorta is the next most common (~25%), followed by paravisceral (16%), and ascending (10%) segments. A recent report from Northwestern Memorial Hospital (Chicago, IL), however, suggests that the paravisceral aorta maybe involved more frequently. Of 13 patients treated over a 10-year span with primary infectious aortitis, 8 (61%) involved the paravisceral aortic segment.

Profound mass effect or erosion of a mycotic aneurysm can result in enterobiliary and at times pulmonic erosion and fistulae. Gastrointestinal bleeing or hemoptysis as a result of arterial erosion can have catastrophic outcomes and expedient management is required. Similarly, arteriovenous communications have been reported following rupture of an infected aneurysm to an adjacent major venous bed. Such events can lead to high-output cardiac failure. At times, mass effect of aneurysms can result in neurologic sequelae. Mycotic aneurysms of the carotid artery can present with hoarseness due to vagus nerve compression, aortoiliac processes can result in femorosciatic radiculopathy, and intracranial mycotic aneurysms can present as acute stroke.

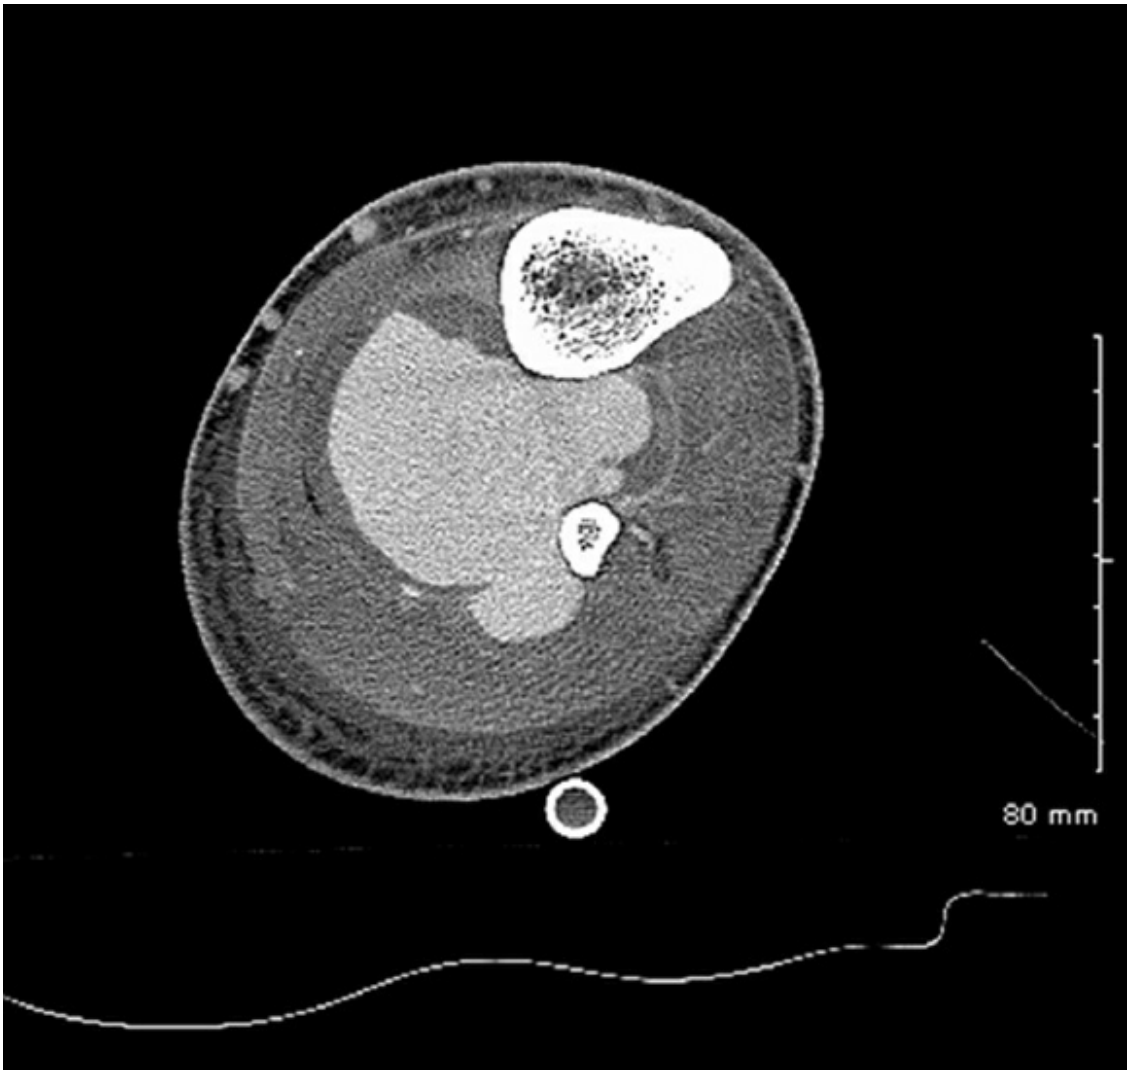

Figure 219.1. CT scan of a ruptured mycotic popliteal artery aneurysm that developed in an IV drug user with bacterial endocarditis. Infectious etiology should be considered when nonaortic peripheral aneurysms deviate from their natural history, which is generally distal embolization and occlusion.

DIAGNOSIS

Imaging plays a critical role in the diagnosis of mycotic aneurysms. In cases of aortitis, it is difficult to distinguish mycotic aortic aneurysms from inflammatory aortic aneurysms as clinical presentation is similar. Both processes can present with a spectrum of symptoms suggestive of systemic inflammatory response syndrome (SIRS), such as fever, weight loss, nonspecific abdominal pain, and elevated serum inflammatory markers including leukocytosis, C-reactive protein, and sedimentation rate. Both entities involve the arterial wall, but inflammatory aortitis is primarily characterized by adventitial thickening and fibrosis. Indistinct

retroperitoneal tissue planes between structures, such as the duodenum, ureter, and vena cava, can be seen on imaging. Wall thickening does occur with infective aortitis, but notable morphologic deterioration can ensue ranging from thickening, edema, endarteritis, emphysema, ectasia, ulcerations, to ultimately aneurysmal development and frank rupture (Fig. 219.2).

Contrast-enhanced computed tomography (CT) scan is probably the most useful modality in differentiating the types of aortitis and other peripheral mycotic aneurysms. Magnetic resonance imaging (MRI) can be helpful in cases where intravenous contrast is contraindicated. Saccular or multilobular type aneurysm or eccentric irregularity of an arterial wall with ulcerations is suspicious for a mycotic aneurysm (Fig. 219.3). Presence of perivascular fluid or edema, intramural air or extraluminal air surrounding the vessel and stranding are additional features to help confirm the diagnosis. Interval imaging to mark evolution and rapid enlargement of a possible infected aneurysm is beneficial in cases where the diagnosis is uncertain. Other modalities including ultrasound and conventional angiography are not as beneficial as arterial wall characterization is not as easily made. Nuclear imaging including indium-111 tagged white blood cell scan can be beneficial in confirming the diagnosis if conventional axial imaging demonstrates uncertainty but suspicion for an infectious process remains high.

MANAGEMENT

Once the diagnosis is suspected, regardless of the underlying etiology, expedient treatment of the infected artery is required as rapid degeneration of the arterial wall will occur leading inevitably to rupture, even in cases without aneurysms. If diagnosed correctly, noninfectious, immune-mediated aortitis will respond to immunosuppressive therapy, whereas infectious aortitis requires appropriate antimicrobial therapy in conjunction with surgical debridement and revascularization. Antimicrobial therapy alone in the setting of infectious aortitis demonstrates mortality rates that approach 100%. Similarly, medical therapy alone for infectious peripheral aneurysms will result in eventual catastrophic bleeding and end organ loss.

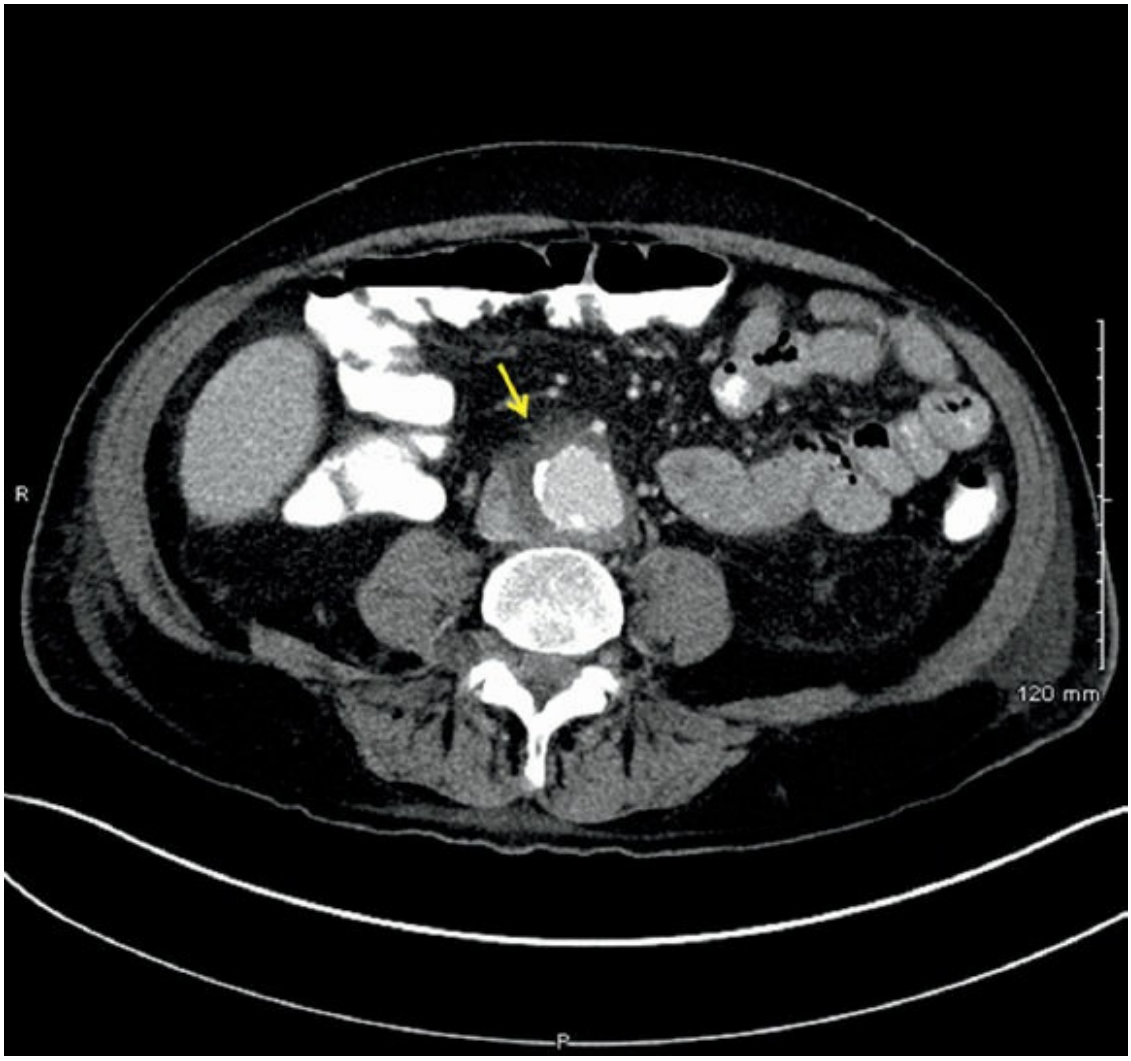

Figure 219.2. Contrast-enhanced computed tomography (CT) scan of the abdominal aorta demonstrating irregular wall thickening (*arrow*) and ectasia suggestive of aortitis.

The initial antimicrobial therapy should be broad spectrum, but dependent on the most likely infecting organism based on clinical circumstance. A combination of Vancomycin to treat an array of gram-positive organisms with a good broad enteric gram-negative agent such as piperacillin-tazobactam or third- and fourth-generation cephalosporins (e.g., cefipime, ceftriaxone) is recommended. Following culture results and susceptibility findings, the antibiotics should be appropriately tailored.

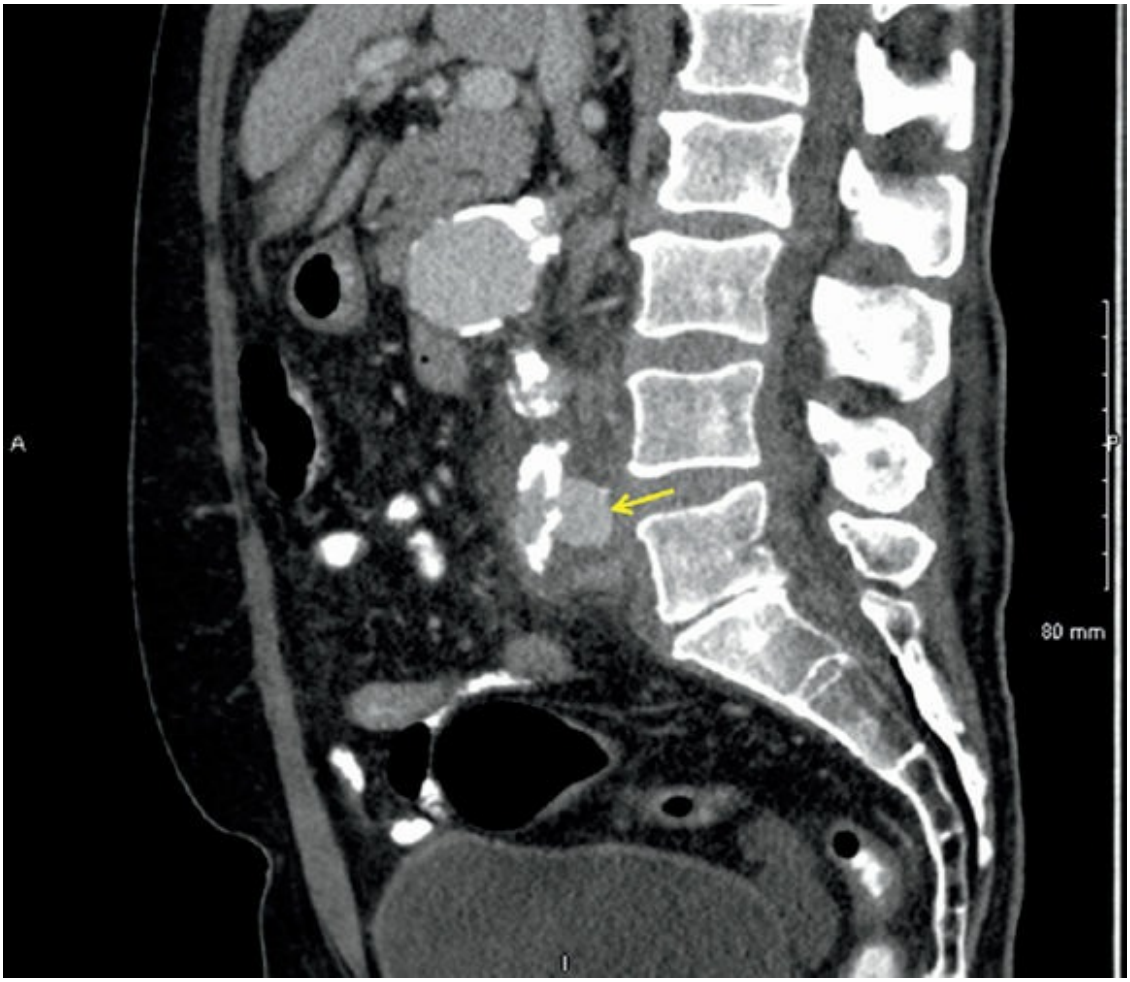

Figure 219.3. CT scan of a mycotic, saccular common iliac artery aneurysm demonstrating an atherosclerotic nidus (*arrow*), arterial wall enhancement and thickening, and retroperitoneal soft tissue stranding.

There are no data on the optimal duration of antibiotic therapy, but it is recommended that the patient should receive, at a minimum, a 6- to 8-week course. The duration of antimicrobial therapy should be guided by patient factors, including the location of the infection, specific bacteria (resistant or biofilm producing organisms), type of vascular reconstruction performed (autogenous versus prosthetic), and levels of observed systemic inflammatory markers (e.g., erythrocyte sedimentation rate, C-reactive protein). Chronic suppressive therapy may be warranted in cases where persistent positive cultures are seen or in cases where prosthetic graft material is used in situ for revascularization or aneurysm exclusion.

NONAORTIC ANEURYSMS

Surgical management of mycotic aneurysms in the periphery follows the

general principles of source control—wide debridement and drainage of infected or inflammatory tissue, and vascular control. Revascularization to address the end organ ischemia following radical debridement should be attempted in most situations; however, in some cases definitive ligation of the artery followed by amputation of the ischemic organ or limb may be the best option. Depending on the end organ, the timing of revascularization could be staged and may be warranted to prevent recurrent infection in the new reconstruction. In general, the artery involved should be debrided back to healthy tissue. Whether ligation or anastomosis is to be performed, permanent suture should be used.

When possible, vascular reconstructions in situ should be performed with autologous tissue. In most peripheral arteries, the saphenous vein is a good conduit to use for replacing the involved arterial segment. Upper arm veins are options, but may demonstrate inferior patency. In cases where larger caliber conduits are required, creation of panel grafts using saphenous vein or procurement of the deep femoral and jugular veins has been described. If no autologous conduits are available, the options available are use of either antibiotic-impregnated prosthetic grafts and cadaveric grafts. One word of caution about using cadaveric vein grafts in infected beds, the author has experienced several anastomotic blowouts of cadaveric saphenous vein in grossly infected beds, particularly with gram-negative infection. If gram-negative infection is suspected, antibiotic-impregnated prosthetic conduits may be more preferable over cadaveric vein grafts. When possible, all suture lines should be covered with vascularized tissue (i.e., adjacent muscle, omentum) following completion of the vascular reconstruction. For further local eradication of infective biofilms, the use of antibiotic-loaded methyl methacrylate cement, which elutes strong local concentration of antibiotics, has shown some benefit (Fig. 219.4).

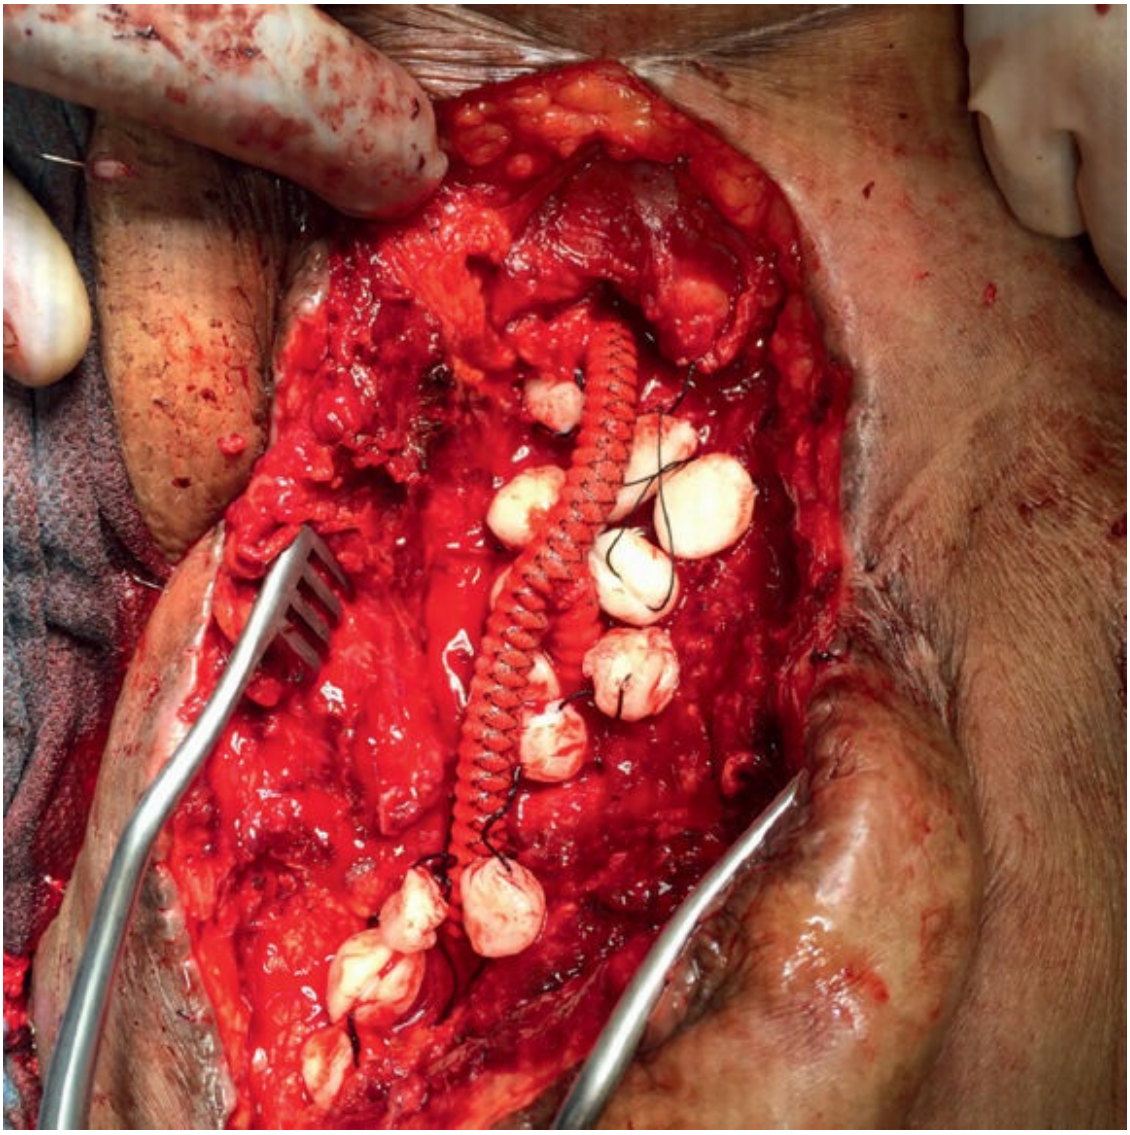

Figure 219.4. Intraoperative photo demonstrating in situ reconstruction of the femoral artery bifurcation with Rifampin-soaked Dacron grafts and placement of Tobramycin-impregnated methyl methacrylate cement beads following wide local debridement of an infected common femoral artery.

MANAGEMENT OF AORTITIS AND MYCOTIC AORTIC ANEURYSMS

"There is no disease more conducive to humility than aneurysm of the aorta."

– William Osler

Aortic infections present a particularly challenging surgical problem as management paradigms shift depending on the aortic segment involved. Generous exposure should be obtained, and aortic clamping should occur

well away from the infected segments. Following radical debridement of infected tissue, approaches in aortic replacement include in situ reconstruction with antibiotic-impregnated grafts (rifampin-soaked dacron), cryopreserved aortic homograft, autologous deep femoral vein-constructed neo-aortoiliac system (NAIS) championed by Clagett and colleagues, or extra-anatomic bypass. The purported advantage of aortic homograft over prosthetic grafts is its relative resistance to reinfection. The NAIS procedure offers a durable option for aortic replacement with lowest rates of reinfection and excellent long-term patency; however, the procedure should be reserved for stable patient. The procedures can be long and become a burden on patients who present with relative instability. The disadvantage of immediate in situ reconstruction is the potential for recurrent infection and subsequent breakdown of the anastomoses leading to hemorrhage. Suprarenal aortic involvement, however, precludes extra-anatomic bypass.

The decision to perform in situ repair or extra-anatomic bypass also depends upon the severity of the patient's underlying peripheral occlusive disease, patient's hemodynamic stability, and virulence of the infection involved. Severe atherosclerotic occlusive disease of the aortoiliac segments requiring long segment reconstruction may be better served with extra-anatomic bypass. Aortofemoral reconstructions are not recommended as it would require creation of anatomic tunnels that originate from a contaminated field. If the patient is hemodynamically unstable due to shock, the operation may be expedited with an in situ repair rather than prolong ischemia time with performing a separate exposure. Highly virulent organisms such as *Pseudomonas* and aerobes result in greater potential for reinfection and anastomotic complications, thus obviate in situ repairs. The character and degree of aortic degradation should be assessed at the time of aortic debridement. High degree of wall and tissue friability and loss of integrity and gross area of involvement should be informative of organism's virility,

Suprarenal and paravisceral involvement requires in situ reconstructions through either thoracoabdominal or transperitoneal approaches. If the aortitis is seen involving the base of the celiac artery, the author recommends a retroperitoneal or thoracoabdominal exposure. The visceral arteries can be reimplanted either individually to the graft or as an island pedicle. It cannot be stressed enough that all anastomosis should be created onto healthy aortic segments. There are key technical considerations when

cryopreserved aortic homografts are used for aortic replacement. The most important maneuver is to avoid direct clamping of the graft. The graft should also be sewn in with the posterior of the graft facing anteriorly (the sutured lumbar arteries should be facing up). Allografts are essentially decelluarized scaffolding that do not have robust structural integrity; direct clamping can result in aneurysmal degeneration and blowout at these sites. The aortic branches, namely the posterior lumbar arteries, are suture ligated and these areas are susceptible to degradation following preservation processes. Procurement and preparation of the aorta are also never perfect. When the graft is sewn in with the posterior side facing up, the potential imperfections are readily accessible for repair.

Extra-anatomic bypass with inflow from the axillary arteries for distal perfusion (Fig. 219.5) has advantages over in situ reconstruction in the setting of severe septic shock, large infected retroperitoneal hematoma, significant aortoiliac atherosclerosis and calcification, and adjacent infections such as vertebral osteomyelitis or enteric compromise. A staged approach of extra-anatomic bypass first with subsequent wide debridement and aneurysm excision is preferred. Physiologically, the patient endures less lower extremity ischemia time if extra-anatomic bypass is performed first. It is also preferable to create sterile incisions first for the bypass rather than follow exploration of a contaminated field. Typically, a right axillobifemoral bypass is performed. The right axillary artery is preferable for inflow if brachial pressures are equivocal between the two arms in the event some need arises for a left thoracotomy for aortic control. After completing the bypass and the incisions are closed and sterilely covered, a laparotomy is performed with the goals of radical debridement of infected aortic tissue and closure of the aortic stump proximally and distally at healthy segments. It is highly recommended to mobilize a well-vascularized pedicle of omentum to reinforce the aortic suture line and the aortic bed. Drains are then placed in the retroperitoneum.

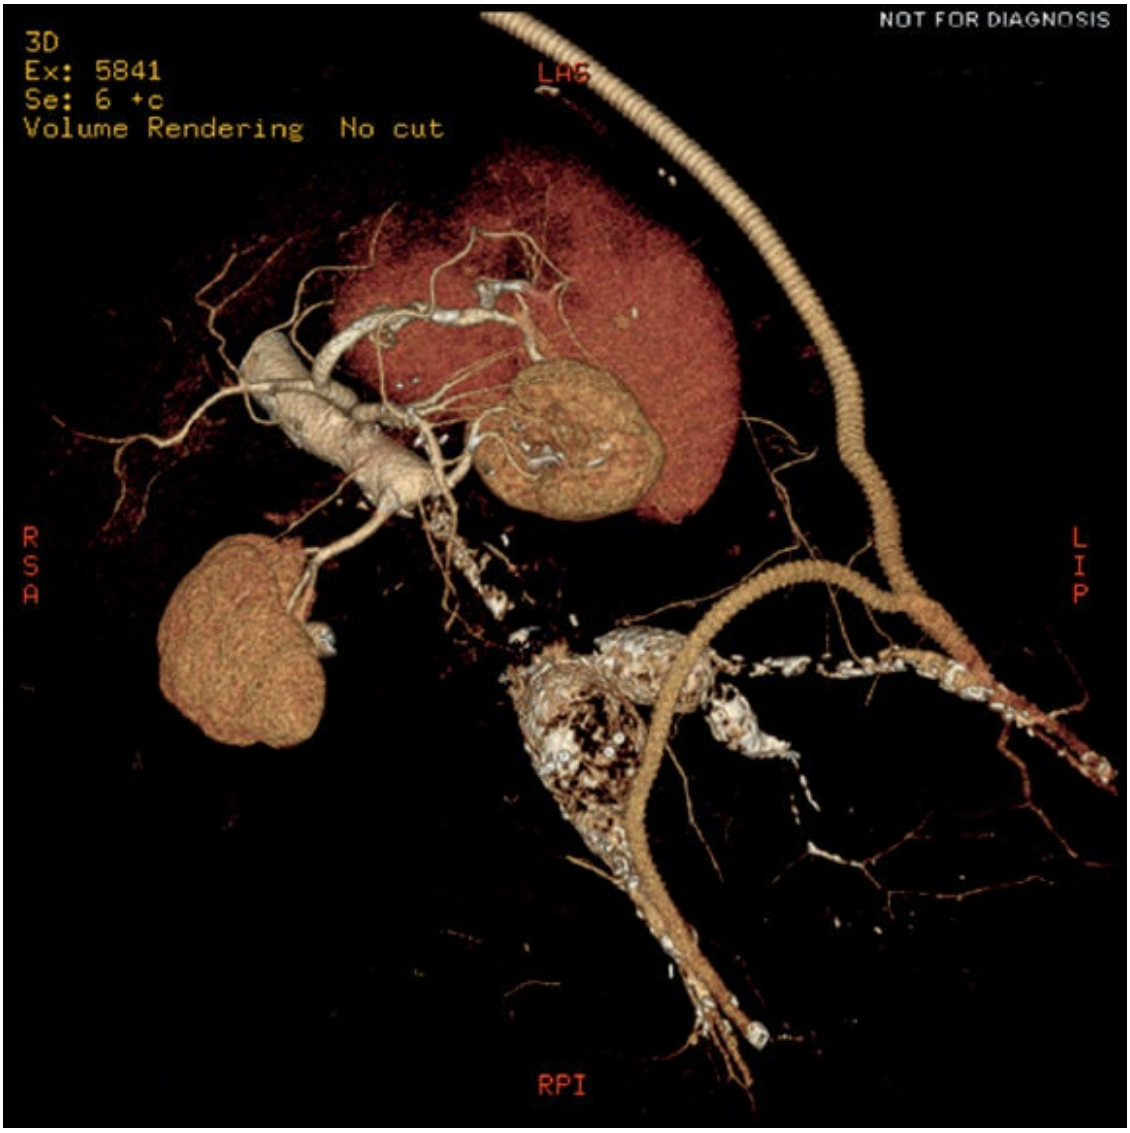

Figure 219.5. Volume-rendered CT scan of a patient status post ligation and wide excision of an infected infrarenal abdominal aorta and extra-anatomic bypass (left axillary artery to bilateral common femoral artery bypass).

ROLE OF ENDOVASCULAR TECHNIQUES

Employing an endovascular graft in an infected environment is controversial but may provide an option for patients who are unfit for conventional surgery. Covered stent grafts have been utilized for rapid control of ruptured aneurysms in many arterial beds, including the carotid and popliteal territories with good short-term results. Late reinfection is common, and can be associated with end organ or limb loss. With infected aneurysms of the aorta, endovascular repair is gaining more popularity. The primary purpose of endovascular aortic repair (EVAR) in infected aneurysms is to exclude the aneurysm in the setting of rupture or rapid

aneurysm instability in whom morbidity and mortality of open surgery would be prohibitive. Anatomic location of the aneurysm, as discussed previously, can make conventional surgical repair demanding. For infected thoracic aortic aneurysms for instance, endovascular repair provides a significantly less invasive means for aortic control.

Debridement of the infected tissues, however, is not accomplished with EVAR and reinfection and late failure rates are expected even with antibiotics. As such, EVAR for mycotic aortic aneurysms may be considered as the definitive therapy, in essence for palliation or as a bridge to definitive therapy. EVAR allows time for the patient to stabilize so that debridement and reconstruction can be performed under more elective circumstances.

Long-term, and in many incidences, life-long antibiotics accompany the use of EVAR in the treatment of mycotic aneurysms. Some argue to institute broad spectrum antibiotics to a point of negative blood cultures prior to EVAR with hopes of minimizing complications related to late infection. Limited or percutaneous drainage of infected fluid associated with the arteritis in combination with antibiotics may further assist long-term stability with EVAR in infected aneurysms. Coating the stent graft directly with antibiotics prior to its deployment in the aneurysm has been done, but no data exist on the efficacy of this technique.

Imaging follow-up is essential when EVAR is employed for treatment of mycotic aneurysms. CT is the best imaging modality to use compared to ultrasound or MRI. Manifestations of EVAR complications include new fluid or stranding at areas of repair, proximal or distal seal zone degeneration with subsequent endoleak, new endoleak, device movement and migration due to progressive wall degeneration, and graft occlusion. There is no set interval for imaging from the time of EVAR; however, surveillance should be performed more frequently in comparison to conventional EVAR.

OUTCOMES

Nonaortic Aneurysms

The major morbidity of nonaortic, peripheral mycotic aneurysms is high rates of end organ loss. In the distal extremity, infected femoral and popliteal aneurysms are associated with amputation rates as high as 30% despite repair and revascularization owing to distal embolization at time of presentation. Upper extremities often tolerate interruption of arteries

without significant ischemic consequence, owing to robust collateral networks around the shoulder and elbow, and have lower rates of limb loss. Infected aneurysms of visceral arteries have significant morbidity and mortality. Ruptured visceral arteries carry mortality rates as high as 20%. Intestinal ischemia resulting from ligation and aneurysm excision carry high morbidity and mortality as high as 40%. Interruption of the carotid or vertebral arteries without revascularization carries a risk of stroke as high as 30%.

Aortitis and Mycotic Aortic Aneurysms

Generally, short-term mortality of conventional open repair for mycotic aortic aneurysms ranges from 20% to 40%. The overall long-term survival following repair approaches 30% to 60% at 5 years. Early surgical management of aortitis before its evolution into an aneurysm may be associated with improved outcomes as overall morbidity and mortality are compounded by both progression of the aortic infection and the technical difficulty of the surgical procedure. In most large series, the location of the mycotic aneurysm is a determinant of mortality. Paravisceral or thoracoabdominal involvement can be common and is associated with operative mortality as high as 50%. Surprisingly, rupture status was not a significant determinant of overall mortality in most recent large studies. Overall surgical morbidity and mortality do not differ between extra-anatomic and in situ repair techniques. Reinfection, however, is more common with in situ reconstructions, while graft-limb occlusion is more common with extra-anatomic bypass.

Reinfection rates after in situ repair of mycotic aneurysms are between 2% and 10%. Late reinfections are associated with high mortality nearing 100%, related to uncontrollable sepsis or rupture. The NAIS procedure has the lowest reported reinfection rate of about 2% with long-term (5-year) patency of the graft approaching 90%; however, it is associated with long operative times. Aortic reconstruction using cryopreserved aortic homografts has reinfection rates of 7% with graft-related complications approaching 19%, including allograft limb occlusions. Antibiotic-impregnated grafts for aortic replacement have reinfections rates of 4% to 10%. Gram-negative organisms are associated with higher rates of graft infection, which is the culprit behind 60% of reoperations that are performed for graft reinfection.

EVAR outcomes generally show more favorable short-term mortality in

comparison to open surgery with a 30-day mortality of 10%. Long-term survival at 5 years approaches 55%, which is comparable to the outcomes reported following conventional open surgery. As expected, however, the reinfection rates are as high as 20% following endovascular repair. Late reinfection develops when antibiotic therapy is discontinued, and many authors recommend long-term and possibly life-long therapy as a prerequisite for EVAR in the treatment of mycotic aneurysms. Majority of the patients following reinfection of their EVAR graft die (70%). In addition to reinfection, the rates of secondary operations are also high following EVAR due to graft-related issues. In the largest current report, conversion to open repair from EVAR occurred in 5% of patients in the perioperative period and cumulative incidence of intervention for EVAR graft complications occurred in 17% of patients.

EDITOR'S COMMENT

Mycotic aneurysms remain one of the most dreaded and perhaps least well-understood of all the diseases surgeons take care of. In the present chapter by Lee, he has elaborated on the etiology, diagnosis, and treatment strategies for both aortic and nonaortic mycotic aneurysms. Clearly, a strategy of obliteration in the case of complicated mycotic femoral artery aneurysms from intravenous drug injection has more or less stood the test time in terms of the saving the patient's life, but not always the limb (Feldman AJ, Berguer R. Management of an infected aneurysm of the groin secondary to drug abuse. *Surg Gynecol Obstet* 1983;157(6):519–22). This scenario at least historically has some point of reference in the literature.

When patients present with a clear-cut scenario as described above, the diagnosis of a mycotic aneurysm is never really in doubt. Unfortunately, it seems like the patient with a mycotic aneurysm, especially aortic aneurysm, often presents a diagnostic conundrum. Patients will present with low-grade fevers, vague abdominal or back pain, with an overall chronic course of overall health decline. The patient may have seen multiple other specialists prior to seeing a surgeon for this problem. While the diagnosis is more easily confirmed following the attaining of positive blood cultures, often we fail to have positive cultures prior to operating on patients (Lee CJ, Kibbe MR, Eskandari MK, et al. Surgical management of aortitis with early aneurysmal dilation. *Ann Vasc Surg* 2014;28(3):568–74). I am not sure there is good science to support this practice, but I always like to treat patients with intravenous antibiotics for at least 48 hours prior to operating on them. If the aneurysm is not ruptured, some also advocate placement of a percutaneous drain to both attempt to have culture-directed data for antibiotics and also perhaps decrease the pain associated with "pus under pressure."

In general, imaging is the key to confirming the diagnosis (Deipolyi AR, Rho J, Khademhosseini A, et al. Diagnosis and management of mycotic aneurysms. *Clin Imaging* 2016;40(2):256–62). A fine-cut computed tomography angiography almost always suggests either an atypical or saccular aneurysm and may document a surrounding phlegmon around the aneurysm. Others have recommended MRI/A as a better in terms of cross-sectional imaging. Finally, the use of nuclear medicine scans, in particular CT-PET scans with fludeoxyglucose (18F) or labeled white blood cell scans, as a method to confirm an atypical aneurysm is mycotic (Sörelius K, Mani K, Björck M, et al. European MAA collaborators. Endovascular treatment of mycotic aortic aneurysms: a European multicenter study. *Circulation* 2014;130(24):2136–42). These scans can be useful if they are positive, but a negative scan by no means rules out a mycotic aneurysm.

In terms of treatments, Dr. Lee has done a nice job of describing the multiple options for managing a mycotic aneurysm. For the readers of this chapter, I

would like to clearly delineate the difference between a mycotic native aneurysm and a graft infection (chapter to follow). The reason this is important to clearly define is because of what some might say that what I am about to espouse is heresy. Over time and having seen a number of these patients, especially with complex aortic aneurysms, I believe consideration for a primary endovascular management of these true mycotic aneurysms may be called for (Murakami M, Morikage N, Samura M, et al. Fluorine-18-fluorodeoxyglucose positron emission tomography-computed tomography for diagnosis of infected aortic aneurysms. *Ann Vasc Surg* 2014;28(3):575–8). The reason I believe this strategy may be best is that when an aneurysm is mycotic, the intima and most importantly the adventia of the vessel wall are still intact, just infected. This is very different from a graft infection. I think this type of approach is most justified in the thoracic aorta, and there are data to suggest that this approach is justified.

The issue of whether an endovascular approach is just a temporizing maneuver is also controversial. I do note that if lung, bowel, ureter, etc. are still attached to the mycotic aneurysm, this connection or fistulae need to be taken down, preferably after placement of an endovascular prosthesis (Setacci C, de Donato G, Setacci F. Endografts for the treatment of aortic infection. *Semin Vasc Surg* 2011;24(4):242–9). Failure to remove the offending source of the infection, almost always dooms an open or endovascular approach to reinfection and likely patient's demise. Likewise, lifelong antibiotics are required in all of these patients. While there are no level 1 data to support or refute this approach (and likely never will be), we have a series of mycotic thoracic aortic aneurysms that we are writing up for publication in which the patients, after a period of relatively good health and an endograft in place, stopped their suppressive oral antibiotics. Two of the patients reinfected their stent grafts and expired. I therefore strongly suggest continued lifelong oral antibiotics.

Finally, a word on mycotic aneurysms that occur secondary to infected embolic material from a remote cardiac source, often a valve or valve prosthesis (Rega FR, Nevelsteen A, Peetermans WE, et al. Simultaneous valve replacement and venous patch repair of superior mesenteric artery aneurysm due to infective endocarditis: a case report. *Heart Surg Forum* 2006;9(5):E741–3). As with all patients with mycotic aneurysms, these patients are often difficult to manage. Which pathology gets treated first is always a debate with your cardiac colleagues, and as a rule unless end organ damage or limb loss is pending, we typically like to have the cardiac source adequately treated first prior to operating on a patients with a septic embolic and a potential mycotic aneurysm. Historically, superior mesenteric artery aneurysms were always secondary to septic emboli from a cardiac source (Sharma G, Semel ME, McGillicuddy EA, et al. Ruptured and unruptured mycotic superior mesenteric artery aneurysms. *Ann Vasc Surg* 2014;28(8):1931.e5–8). That fact may be worth remembering for in service or qualifying exams!

Gilbert R. Upchurch Jr.

220 Surgical Management of Aortic Graft Infections

Manuel Garcia-Toca and Guillermo A. Escobar

INTRODUCTION

The management of aortic graft infections remains one of the greatest challenges to the vascular surgeon, with amputation and mortality rates exceeding 11% and 40%, respectively. The incidence varies from 0.2% to 3%, depending on whether the prosthesis is entirely intrathoracic (1% to 2%), aortoiliac (<1%), extends to the femoral arteries (1% to 3%), or is an endovascular stentgraft (<1%). Keys to a successful management of these infections include accurate and timely diagnosis of the infection, the extent of the graft infection, administration of appropriate antibiotic therapy, and a well-planned and executed surgical intervention.

ETIOLOGY AND PATHOPHYSIOLOGY

Infections of aortic prosthesis occur by perioperative contamination at the time of implantation, translocation and seeding from bacteremia, mechanical erosion of the graft into the bowel or genitourinary tract, and/or direct contact of the graft with a contiguous infectious process (like a spine infection or retroperitoneal abscess). Underlying immunosuppression can further increase the risk for infection.

Bacteriology

Cultures may be negative in as many as half of cases, and virtually any microorganism can infect a graft. In addition, the offending organism or organisms will vary, depending on the mechanism of infection, such as bacteremia or enteric erosion. This explains the wide variability in the infectious agents reported in series that combine all organisms they cultured in primary and secondary graft infections.

Staphylococcus aureus is historically the most prevalent pathogen of primary graft infections, and accounts for about 20% to 30% of graft infections. However, individual case series also have reported

Streptococcus viridans accounting for approximately 40% of cases, while other series find graft infections from *S. epidermidis* or gram-negative bacteria, which are becoming more prevalent.

Graft-enteric erosions and graft-enteric fistulae are typically polymicrobial and often include fungi like *Candida* sp. Among gram-negative organisms recovered from infected grafts, the most common are *Escherichia coli, Klebsiella, Proteus, Enterobacter, Pseudomonas, Bacteroides,* and non-hemolytic streptococci. Infections associated with negative culture results can be due to systemic antibiotics started empirically prior to a culturing, low virulence organisms with low rates of bacteremia, or on occasion not using the correct cultures in cases of fungus or even rare organisms, such as mycobacteria.

The outcomes after surgery can be dramatically affected depending on what organisms are detected in the blood or intraoperative cultures. The odds ratio for perioperative mortality after an aortic graft infection treated with a femoral vein reconstruction is highest with positive cultures for Candida (any *Candida* OR 3.4 and *C. glabrata* OR 7.6), *Klebsiella pneumonia* (OR 3.5), and *Bacteroides fragilis* (OR 4.1). Conversely, the results of cultures might impact what type of conduit should be used or avoided in the reconstruction. For example, *Enterococcus faecium* is very frequently resistant to rifampin, so rifampin-treated Dacron grafts should not be used for these infections; while this technique may be ideal for a *Mycobacterium* or susceptible *Staphylococcus* infection.

Primary fungal (e.g., *Candida*, and *Aspergillus* species) or *Mycobacterium* graft infections are rare. Most cases are associated with severe immunosuppression, have an established fungal infection elsewhere (usually other prosthetics), or the patients were exposed to the organism iatrogenically (e.g., after *Mycobacterium bovis* treatments for transitional bladder cancer). These organisms should be sought out using their atypical culture media, especially when there is clear evidence of a graft infection, but traditional (bacteriologic) cultures appear negative. Even if these organisms are only diagnosed after repair, it will assist long-term antibiotic management and identify resistant strains (especially in multidrug-resistant organisms like *Pseudomonas* and *Mycobacterium*).

CLINICAL PRESENTATION AND DIAGNOSIS

The clinical manifestations of an aortic graft infection depend on the interval between graft implantation and the onset of the infection, the

nature of the organism, and the anatomic location of the prosthesis. Early graft infections (less than 4 months after implantation) are more likely to involve the graft diffusely and usually have systemic manifestations and more intra-abdominal manifestations. Some early infections may manifest only with pseudoaneurysm and disruption of the anastomosis leading to tragic outcomes.

In general, aortic graft infections tend to manifest remotely from implantation and have a broader spectrum of nonspecific symptoms. These can be subtle with malaise, fever of unknown origin, discomfort and/or weight loss alone. In contrast, there are patients who present with a high fever, leukocytosis, and severe shock from systemic sepsis or from uncontrolled bleeding either into the bowel (aortoenteric fistulae) or into free ruptures (anastomotic pseudoaneurysms). Low-virulence organisms can also create indolent fluid collections, where the abscesses can grow to compress neighboring structures (i.e., ureters, vena cava, and femoral nerve) and can even necessitate out of the skin. The latter present as subacute wound infections or draining sinus tracts (usually in the groin incisions).

The most common site for the graft to erode into the bowel is into the small intestine, especially near the level of the fourth portion of the duodenum, usually overlying the proximal aortic anastomosis. This notwithstanding, any portion of a prosthetic graft that comes in direct contact with the small or large bowel will eventually erode into it. These erosions are not the same as graft-enteric (or “aortoenteric”) fistulae, which is when the graft disrupts and bleeds into the intestinal lumen. They will typically present with a bout of severe hematemesis and/or hematochezia. Any indication of this “sentinel bleed” in the setting of previous aortic surgery should mandate aggressive investigation and early intervention to treat the fistula as the subsequent hemorrhage may be fatal. Graft-ureteral fistulae are also well described, typically after injuries to the ureter lead to disruption and pseudoaneurysms at the anastomosis of the graft to the iliac arteries.

Isolated pseudoaneurysms occur spontaneously, or when infections disrupt the graft-arterial anastomosis. The aortic anastomosis can sometimes be disrupted in absence of enteric leaks, but pseudoaneurysms are far more common at the level of the femoral anastomosis. Infection and disruption of aortic patch angioplasties used for aortoiliac endarterectomies can also lead to large pseudoaneurysms on the anterior

wall of the aorta and iliac arteries. These pseudoaneurysms can be contained in the retroperitoneum or within scar tissue in the groin, presenting with nonspecific pain and compression symptoms.

Graft infections can also manifest as acute graft occlusions, particularly in aortofemoral bypass limbs. Thus, a suspicious review of the incisions and all imaging studies looking for any signs of infection are important to avoid discovering a graft infection in the operating room.

The diagnosis of aortic graft infection is the first of many challenges, and commonly requires multiple diagnostic modalities:

Computed Tomography (CT) Imaging

The current gold standard for the initial diagnosis is CT angiography because it can assess of the extent of graft infection and native vascular involvement, establish patency, and help determine the ideal locations needed for vascular control during the reconstruction. CT also provides information to help determine if percutaneous aspiration of a fluid collection for microbial analysis or if a conservative approach is contemplated. CT scanning can identify aortic graft infections with a sensitivity of up to 94% and a specificity of 85%. Characteristic CT findings suggesting the presence of late aortic prosthetic graft infection include periprosthetic gas or fluid (Fig. 220.1), soft tissue thickening, hydronephrosis from compression, vertebral body degeneration/infection, bowel wall thickening in proximity to the graft (suggesting aortoenteric erosions), and locating pseudoaneurysms. Although the presence of fluid or loculated air around the graft is common in the early postoperative period after graft implantation, gas seen around the graft more than 2 months after initial aortic surgery is strongly suggestive of graft infection. Any patient with signs and symptoms of infection with suspicious CT findings should be treated as a graft infection until proven otherwise.

Nuclear Tagged White Blood Cell Imaging

These techniques allow infections to be detected using labeled white cell scans (usually using ^{111}Indium). When used alone, studies report variable sensitivities and specificities ranging from 75% to even 100%. Generally, it should be considered a useful adjunct to clinical suspicion and other imaging techniques, but not as a stand-alone method for diagnosis or exclusion.

Fluorodeoxyglucose-Positron Emission Tomography (FDG-PET)

This has a high sensitivity derived from the increase FDG uptake observed in inflammatory cells, but has low specificity. As it is the most expensive imaging technique, its use should potentially be considered when a more sensitive analysis of the extent of involvement of the infection, or when infection is suspected, but the above-mentioned techniques are not demonstrative of infection.

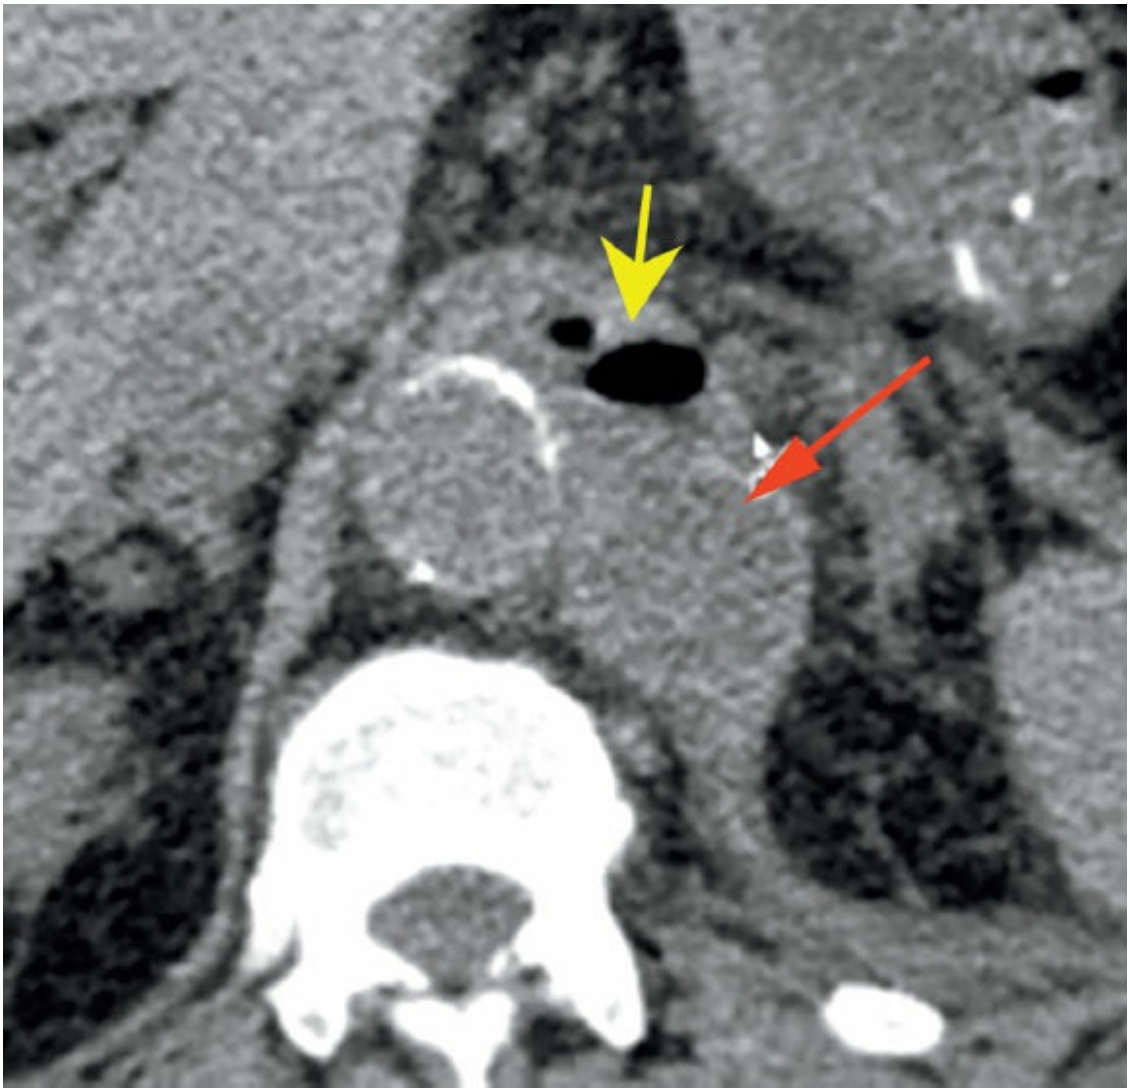

Figure 220.1. Noncontrast CT demonstrating an abscess in the psoas muscle on the left of the aorta (*long red arrow*) and gas seen around aortic graft (*short yellow arrow*).

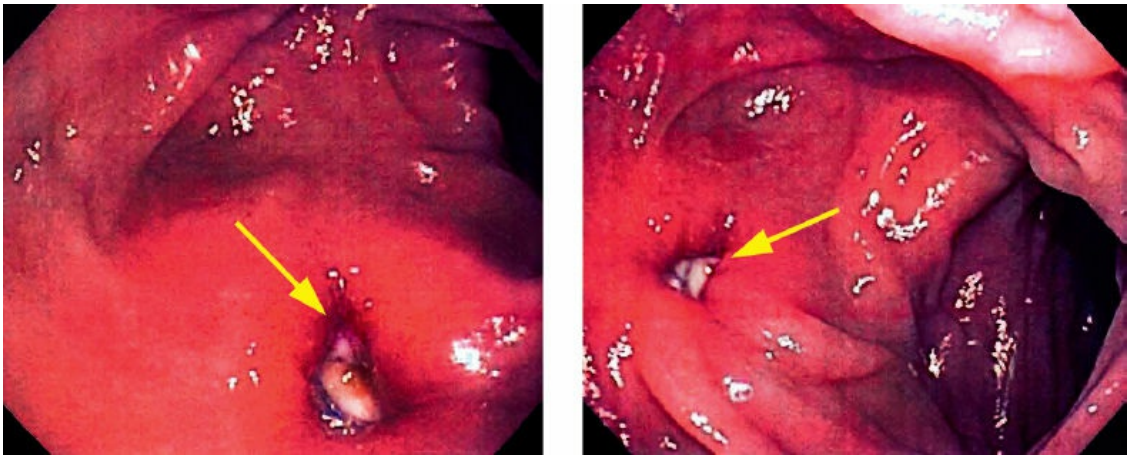

Figure 220.2. Endoscopic view of an aortoenteric fistula. This patient presented with hemorrhagic shock from and was treated with an axillary–femoral bypass and removal of all infected graft material. *Arrows* identify the ulcer in the fourth portion of the duodenum with the white graft material seen at the base.

Gastrointestinal Endoscopy

This modality is often how the graft erosion is first discovered when an endoscopist is asked to evaluate someone with cryptogenic upper gastrointestinal bleeding (Fig. 220.2). The authors only use it secondarily when there is a low suspicion of a graft-enteric erosion by CT scan, but surgical planning is needed to determine the need for a complex intestinal reconstruction in addition to a vascular reconstruction. Endoscopy can miss graft-enteric erosions if they are distal to the fourth portion of the duodenum, where push-endoscopy may be needed. Careful communication with the endoscopist prior to the procedure is paramount. The goal of the test should be clear to both parties and avoid performing biopsies near the ulcer for any reason.

PREOPERATIVE PLANNING

Regardless of the technique used to eradicate the graft infection, success is measured by patient survival, freedom from recurrent infection, patency of the revascularization, and avoidance of major morbidity including amputation. We highly recommend treatment with targeted or broad-spectrum antimicrobials for several days prior to reconstruction whenever possible. This may mitigate the systemic infection, improve the patient's anorexia from illness, and minimize re-infection rates after reconstruction (especially when prosthetics are used in the reconstruction).

Extent of Graft Infection

Determination of the extent of graft infection is important to successful treatment planning. In order to be fully prepared in the operating room, one should always assume that the entire graft in infected, and then work backwards. One should always plan for more extensive graft involvement than what was expected from the imaging tests, and be prepared to obtain a more proximal site for vascular control. If the aortic neck looks tenuous and inflamed near the renal or mesenteric arteries, plan for a prolonged supra-renal clamp, and the possibility of even needing preemptive bypasses to the renal or mesenteric arteries to maintain perfusion after graft removal (especially when explanting aortic endografts with supra-renal fixation barbs). If the entire graft is involved, it will require removal in its entirety when possible. However, if only one portion/limb of an aortobifemoral graft is involved, it may be possible to remove only the infected portion and salvage the remaining, uninfected graft. Complete graft excision is usually required in early infections, because the graft is not incorporated into the tissue. However, late infections with limb involvement limited to the groin can often be treated with unilateral graft excision.

Nutritional and Constitutional Assessment

Patients with aortic graft infection are often elderly and debilitated, especially if the diagnosis was delayed and the process is chronic. Adequate nutritional support is critical to meet the metabolic demands of sepsis and a prolonged operative and postoperative course. If the infection is stable and indolent, it may be wise to postpone the surgery for weeks or months to augment the patient's nutrition and activity in the interim. An elderly, deconditioned, and malnourished patient will be unlikely to survive surgery, regardless of the surgeons' technique or skill.

In the presence of aortoenteric fistula, enteral nutrition may need to be delayed for a lengthy period of time. Transition to enteral nutrition may be facilitated by the use of feeding gastrostomy or jejunostomy after surgical intervention. Parenteral nutrition may be needed, although it should be avoided when possible to minimize the risk of infection.

Preoperative Cardiovascular Risk Assessment

As previously mentioned, the morbidity and mortality of these cases are

some of the highest in the surgical literature. Therefore, patient selection and preparation are critical. In cases of emergent need for intervention (hemorrhagic or septic shock), then the decision to proceed depends on the surgeon's best assessment of survival. Placement of temporary, rifampin-soaked endografts may assist in some cases until optimal conditions are achieved. Otherwise, careful risk-assessment and cardiovascular optimization should be sought prior to revascularization when possible in order to adequately select (or exclude) patients for surgery. Conservative modalities for patients deemed too high risk for any reason include antibiotics alone, percutaneous drainage, and antibiotic lavage or use of "destination" rifampin-soaked endografts to treat pseudoaneurysms.

Assessment of Lower Extremity Perfusion

Preoperative assessment of lower extremity perfusion is necessary to plan treatment and may be based on physical examination and lower extremity noninvasive studies. If the infected prosthesis is occluded and the lower extremities are viable, excision of the infected graft material alone should be adequate, and vascular procedures to improve lifestyle can be done at a later time. However, if lower extremity perfusion depends on the involved graft, extra-anatomic bypass or in situ reconstruction will be required to avoid amputation once the infected graft is removed. Meticulous evaluation of CT or conventional arteriography can identify patent vessels available for revascularization of the lower extremities. Low arterial-brachial indices or toe pressures may also predict the need for fasciotomy after reconstruction in cases where prolonged perioperative ischemia will be present.

Vein Mapping

Venous duplex ultrasonography is essential in planning reconstruction when the saphenous or femoral veins are considered as conduit. Examination of the lower extremity venous system establishes the diameter and available length of the deep veins. In addition, duplex ultrasonography can evaluate acute or chronic thrombosis, recanalization changes, and congenital venous abnormalities that may dissuade from using these veins. Femoral or saphenous veins that are less than 5 mm in diameter may not be useful for aortic conduits unless two veins are sewn together (which will ultimately limit potential length of the final venous conduit), and other conduits or approaches may be needed. Conversely,

even saphenous veins may be used as conduits in some women if the native vessels are small and the saphenous veins are large (4 to 5 mm) at the thigh (Fig. 220.3).

Figure 220.3. Saphenous vein used as conduit for aortic reconstruction.

SURGICAL TECHNIQUE

Selection of the surgical approach is based on two major principles. The

first focuses on eradication of the infection and its sequelae by removal of the affected graft and debridement of all infected tissue with minimal morbidity. The second principle focuses on maintaining or restoring perfusion to the lower extremities.

Considerations influencing the choice and timing of reconstruction in aortic prosthetic graft infections include the stability of the patient, extent of the graft infection, the offending organism, the potential consequence to the visceral organs or limbs from ischemia, and the patient's comorbidities. Always consider a staged approach for extra-anatomic and venous reconstructions to lessen the burden on the patient and the surgical team. Appropriate antibiotic therapy for the primary infection and to prevent secondary infection in the new reconstruction is fundamental; preoperative aspiration/sampling may be useful when fluid can be obtained safely.

Exposure of the Aorta and Graft Excision

Complete removal of an infected aortofemoral graft begins with the femoral exposures to minimize the time the abdomen is open. Aortic exposure can then be done through the previous incision, but sometimes using an alternative approach (retroperitoneal or celiotomy) than the one used for the initial implantation may facilitate access to the aorta and iliac arteries. Preoperative placement of ureteral stents may be helpful to avoid/treat any injury, especially when hydronephrosis or extensive left sided-retroperitoneal inflammation is present.

Access to the aorta can be done via celiotomy or retroperitoneal approach. Celiotomy allows for good exposure of the bowel and most of the aorta from the superior mesenteric artery to the external iliac arteries, but is limited in visibility of the aorta near the celiac artery. Any intra-abdominal adhesions may slow down access to the infected graft. A retroperitoneal avoids adhesions and allows for greater access to the supraceliac and thoracic aorta, as well as all the proximal portions of the visceral arteries. This approach may be preferred if the inflammation/infection seems to extend to the visceral segments of the aorta. However, retroperitoneal exposure has limited visibility and access to the more distal portions of the right iliac artery, renal artery, and tunneled grafts. In addition, access to the bowel to perform a complex repair of a graft-enteric erosion in retroperitoneal exposures can be more challenging.

Early control of the supraceliac aorta should always be considered for infections involving the aortic neck, and done prior to exposing an infected aortic anastomosis, especially if there is significant periaortic inflammation or pseudoaneurysm. Sudden graft disruption during vascular dissection can be a disastrous and potentially unsurmountable complication without adequate vascular control. Although intraluminal balloon occlusion of the aorta and iliac arteries may be possible, there is greater potential for large-volume blood loss and inability to maintain a dry surgical field during reconstruction. Thus, direct dissection and clamping of uninvolved iliac and mesenteric vessels distal to the infected segments may be safer. Only expose the portion of the infected vessel needed for vascular control. Trying to completely encircle scarred and inflamed arteries may lead to their injury and/or large-volume hemorrhage from puncturing adhered veins.

The perirenal aorta should be exposed from proximal to distal, starting above the area of concern to identify the best place for a proximal clamp, and then move caudal toward the infected aorta. The iliacs should also be identified far from the area of concern and then work caudally. If the left renal vein is patent, its location can be difficult to locate within the inflamed periaortic lymphatic tissue. This can lead to bleeding that is difficult to control. Using a vascular-load automatic stapler to sequentially ligate and expose the anterior aorta may decrease bleeding and expedite access to the suprarenal aorta. Care must be taken to ensure the location of the mesenteric and renal vessels as this is done to avoid injury to them with the stapler.

After gross removal of the infected graft, the vessel is debrided back to normal-appearing aortic wall. All graft material should be removed, taking care to remove the entire suture line that can be hard to see in the thickened aortic wall. Identification of the suture material while cutting out the anastomosis is important to ensure all prosthetic is removed. After debridement, the residual vascular bed is often topically “sterilized” with local lavage using antibiotic solutions or treating the area with high-energy surface cautery. While not evidence-based, it seems irresistible to most surgeons to try and treat spilled purulent material. Pledgets using prosthetic material should be avoided as they are nidus for recurrent infection. In critical cases, reinforcements for sutures can be made from fascia lata as a form of autologous pledget (obtained from an incision on the lateral thigh), or cut pieces of rifampin-soaked Dacron.

Figure 220.4. Endograft transected with high energy electrocautery.

Removing infected aortic endografts can pose significant difficulties when they have supra-renal fixation, and should be done only by very experienced aortic surgeons. These barbs are specifically designed to stay attached to the aortic wall under caudal traction, and they usually affix to the aorta at (or above) the superior mesenteric artery origin. Supraceliac clamping is critical in these cases, as is control and clamping of all renal and mesenteric branches to minimize the inevitable acute blood loss that follows. Placing clips on all visible lumbar arteries before entering the aortic sac is advised to avoid subsequent bleeding. In order to cross-clamp an aortic endograft, we use two soft-jaw Fogarty clamps because traditional aortic clamps may not be hemostatic. Access to powerful scissors and wire cutters is imperative to be able to cut and remove the graft. However, cutting across the endograft can be very difficult, time-consuming, and accompanied by voluminous, life-threatening bleeding. One author routinely transects the main body of the graft using high-

energy electrocautery that effectively melts the fabric off the metallic stent skeleton. This allows for easier transection and allows it to be clamped and removed. This technique is especially useful when there are multiple endograft cuffs, making cutting through them nearly impossible (Fig. 220.4). Any attempts to simply oversew an infected aortic endograft and leave it in place will lead to uncontrolled infection, and potential pseudoaneurysm that will ascend the periaortic region.

CHOICE OF RECONSTRUCTION

Extra-Anatomic Axillary–Femoral Revascularization

The primary benefit of an extra-anatomical revascularization is that it poses the lowest morbidity from the reconstruction itself, and subsequent graft excision can be performed at a later stage (or done simultaneously, ideally with a two-team approach). It also allows for minimal ischemic time to the limbs as they are perfused at all times by the bypass, unlike when techniques are used to reconstruct the aorta. The axillary–femoral bypasses can also be done entirely under local anesthesia and sedation if needed. The extra-anatomic configurations for the bypasses can be created using a single, "Y" shaped axillary–bifemoral graft, a single axillary–femoral bypass, followed by a femoral–femoral bypass, or two separate axillary–femoral bypasses.

While often considered otherwise, the complete procedure is certainly not "low risk." The reality is that independent of the extra-anatomic bypass, the aortic graft excision remains a formidable procedure and mortality remains significant. In clinically stable patients, staged management with an initial axillary–femoral bypass, followed 1 to 2 days later by the excision of the aortic graft, has a significantly lower perioperative mortality than doing everything in a single surgery. Simultaneous ex situ bypass with graft excision (ideally using two surgical teams) may be necessary in more unstable patients with systemic sepsis, intra-abdominal hemorrhage, or aortoenteric fistula.

The procedure consists of first exposing all vessels, followed by the tunneling of the graft material before any anastomosis is done. This will ensure adequate angles are chosen for the anastomosis of the grafts and avoid kinking. It is not uncommon for the end-to-side anastomosis of the graft to the axillary artery to be at nearly a 90-degree angle off the anterior wall. This is especially true in larger or obese patients where the distance from the subcutaneous tunnel to the axillary artery is far.

Axillary–bifemoral bypasses typically originate from the first (proximal/medial) portion of the right axillary artery. The axillary artery is more mobile distally and moves in conjugation with the elevation of the arm, leading to less injury and kinking. Ideally, the right side is preferred as it is statistically less likely to have atherosclerotic disease of the subclavian artery, and allows for future access to the left chest for retroperitoneal or thoracic approaches to the aorta. Bilateral blood pressures are obtained; and if there is more than 10 mm Hg difference, then the better side is chosen.

A transverse incision is made about one fingerbreadth below the clavicle, and taken down through the fascia of the pectoralis major. Difficulties finding the artery in obese patients can be aided by a Doppler during the exposure, and by identification of the thoracoacromial or superior thoracic arteries and following them posteriorly. We prefer the proximal inflow graft to be reinforced polytetrafluoroethylene (PTFE), at least 7 mm in diameter (preferably 8 mm). Rifampin-soaked Dacron grafts are sometimes used when the distal anastomosis must land in nonsterile femoral arteries. To obtain good visibility into the lumen of the fragile axillary artery, we use an arterial punch to widen the orifice. Small distal vessels can be accommodating larger grafts by making a wide mouth arterial anastomosis, or joining a smaller graft to it at the groin. This is preferable to using a small, long, high-resistance graft for the inflow feeding both legs.

If the infected graft involves the common femoral artery, then the new anastomosis should be beyond the inguinal region (onto profunda femoris branch artery, superficial femoral artery, or even popliteal). This is done through a lateral incision, distal to the original femoral anastomosis, and the axillofemoral graft is routed lateral to the anterior superior iliac spine. In cases of minimal groin sepsis, a prosthetic femoral–femoral graft may be routed in a subcutaneous tunnel medial to the original femoral incisions, avoiding the areas of infection. In selected cases with extensive femoral abscess/infection or extreme obesity, bilateral axillofemoral prosthetic grafts can be utilized. In addition to a typical axillary–bifemoral bypass, an axillary–unifemoral bypass with prosthetic can be used, followed by a femoral–femoral bypass with saphenous or femoral vein, especially in cases with unilateral femoral graft infections (Fig. 220.5).

Proximal vascular control in the groin is obtained well away from the femoral anastomosis, and may need a suprainguinal retroperitoneal

exposure for large pseudoaneurysms near the inguinal ligament. Once the femoral vessel and infected graft are exposed, it is debrided and either closed (primary lateral closure or autogenous vein patch closure), or it is used for the anastomosis if an autologous vein is the conduit. We routinely use muscle flaps to cover the repair, and the skin may be left open (with or without a negative-pressure dressing) in cases of severe infection. The authors prefer a sartorius muscle flap or rotating the gracilus muscle if the groin is too scarred. This is particularly important in cases where autologous tissue is not used as part of the femoral artery repair.

If a two-stage approach is used, function and adequacy of the extra-anatomic arterial reconstruction should be assessed prior to the second stage. A pulse examination, ankle-brachial pressure indexes, and/or duplex scanning are critical. The patient should return to the operating room within 4 days for the resection of the aortofemoral prosthetic, debridement of the infected retroperitoneal tissues, and oversewing of the infrarenal aortic stump. It is important to minimize this time period to avoid a new infection, but also to avoid thrombosis of the extra-anatomic bypass due to poor, “competitive flow” to the legs from both conduits (infected aortic graft and extra-anatomic grafts). Once the aortic graft has been removed, it is imperative to again ensure patency of the axillary–femoral limbs prior to leaving the operating room.

Adequate closure of the aortic stump after graft excision is essential, but can pose quite a challenge because of the inflamed aortic tissue and fragile aortic wall. Various techniques have been proposed to ensure stump integrity. These include a double layer of Prolene sutures using a reinforcement using various “pledgets” made from vein, fascia (from spine or lateral thigh), rifampin-soaked Dacron or felt, double-plane sutures, and vascular stapler devices. A similar, two-layer closure technique should be used for the distal aortic or iliac arteries should be performed to maintain retrograde flow from extra-anatomic bypasses at the femoral level into at least one pelvic artery system (external iliac and hypogastric) to avoid distal colonic, pelvic, and lower spinal cord ischemia. Careful vigilance for signs of aortic stump disruption should be maintained.

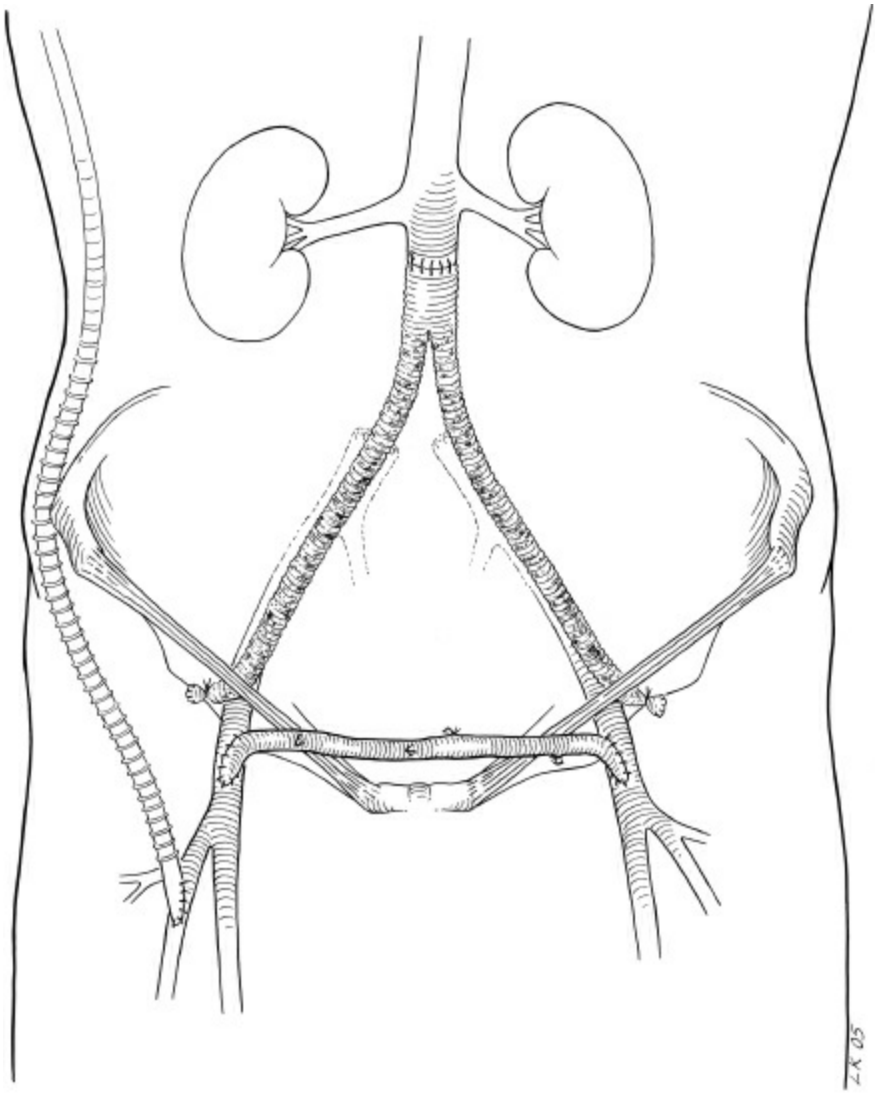

Figure 220.5. Right axillofemoral prosthetic bypass and femoral–femoral bypass using autogenous femoral vein. Axillofemoral prosthetic bypass routed lateral to the anterior superior iliac spine with distal anastomosis at the midprofunda femoral artery.

IN SITU VEIN RECONSTRUCTION

Neoaortic Iliac System With Femoral Vein (NAIS)

This technique was championed by Dr. Patrick Clagett, demonstrating outstanding durability with low amputation rates. Its primary benefit is that these patients do not require treatment with lifelong anticoagulants or antibiotic therapy when successful. The disadvantage of the NAIS reconstruction is that the procedure is time-consuming (mean operating time >8 hours), technically demanding (especially when there is significant size-mismatch or length discrepancies of the conduits), and can lead to significant morbidity to the legs from the venous harvesting (10% to 20%

need fasciotomies and many have significant swelling long-term). The NAIS procedure is sequenced into major steps designed to minimize lower extremity ischemia time and time that the abdomen is left open. The sequence is as follows: (1) dissection of the femoropopliteal veins (FPVs), which are left in situ until needed (and you may stop here, when staging the procedure); (2) isolation and control of the femoral vessels; (3) entry into the abdomen and dissection and control of the aorta above the anastomotic site (may involve suprarenal dissection); (4) removal and preparation of measured lengths of FPVs that will be required for the reconstruction; (5) application of aortic and femoral cross-clamps with removal of the infected prosthesis; and (6) reconstruction with FPV grafts.

Exposure begins via an incision that follows the anterolateral border of the Sartorius. The common femoral vein is identified and followed until the division of the deep femoral vein and FPV is identified; the latter will be the conduit and the deep femoral vein must be left intact. The profunda femoris vein is easily recognized as a large posteriorly penetrating vein in the proximal thigh with multiple, large branches. The femoral vein is then dissected parallel to the superficial femoral artery, through the adductor hiatus to the proximal portion of the popliteal vein. The segment in the adductor canal has multiple large branches, which must be carefully ligated. The dissection can easily be taken down to the level of the knee joint. The veins are left in situ and measured to determine length of the conduit needed from the aortic anastomosis to the distal anastomotic site. Measure the vein while in situ as it will dramatically shorten when cut, and return to its original length or longer when pressurized with aortic pressure.

The FPV has many large and small side branches. Careful, meticulous suture ligation of these branches with prolene is critical. Failure to ligate a branch adequately will result in exsanguinating hemorrhage if a tie pops off when exposed to aortic pressure, or when tunneled. Although the FPV is larger and sturdier than the typical great saphenous vein, it is thin walled in some areas where valves and branches are present. If a branch is avulsed during dissection, suture repair with 6-0 or 7-0 polypropylene is necessary. Unlike saphenous veins, these branches are ligated close to their bases because this is where the vein wall tends to be thin; the larger caliber of the FPV allows this to maintain a large caliber lumen.

The femoral vein is divided and suture-ligated flush with the profunda femoris vein. The grafts are then distended in a heparin-blood solution and

leaks are repaired with sutures. Next, the valves in the vein grafts are lysed. This is a critical step because the grafts are usually placed in a nonreversed fashion to optimize size matching with the aorta for the proximal anastomosis. You must evert the vein grafts and excise all valves with scissors under direct vision, and valve lysis with valvulotomes will be invariably incomplete, may tear the vein, and the remnants of the valves may become sites of graft stenosis and failure.

Multiple configurations have been successfully employed to reconstruct the aortoiliac/femoral vasculature (Fig. 220.6). The proximal anastomosis is performed with a continuous 4-0 prolene suture. The diameter of the FPV graft is typically about 1.5 cm or greater, and the mismatch in diameter between the graft and the aorta is dealt with by taking slightly more advancement on the aortic wall than on the graft wall. If the caliber discrepancy between the two structures is excessively large, another technique must be employed, such as plication of the aorta, joining the venous grafts in a pantaloon configuration, or placement of a triangular patch at the proximal aspect of the graft (Fig. 220.7). After the proximal anastomosis is complete, the venous graft is distended under aortic pressure, and the side branches are carefully examined to confirm that all ligatures are securely placed. Any questionable areas are repaired. Measurement usually demonstrates an even longer graft than when in situ. Anastomotic leaks are repaired with the aorta clamped again to ensure that the venous graft is not torn by the needle during repair. Extending the graft into the groins should be done by an end-to-end anastomosis of the entire contralateral vein and allowing it to fully distend as one long tube. The vein is tunneled and anastomosed into the femoral artery with the infection first. The remnant femoral vein is then anastomosed end to side as distal as possible on the aortofemoral conduit to shorten the distance for the next tunnel to the femoral artery. If concern arises as to the length of the last segment, then a rifampin-soaked Dacron graft can be anastomosed end to end to the FPV and pulled in the tunnel toward the femoral artery. Once the rifampin-treated graft is brought to the groin and allowed to pressurize, there usually is minimal prosthetic needed to be left in the groin. By using prosthetic only in the groin, if it gets infected later, it can be more easily managed than if prosthetic is left in the abdomen.

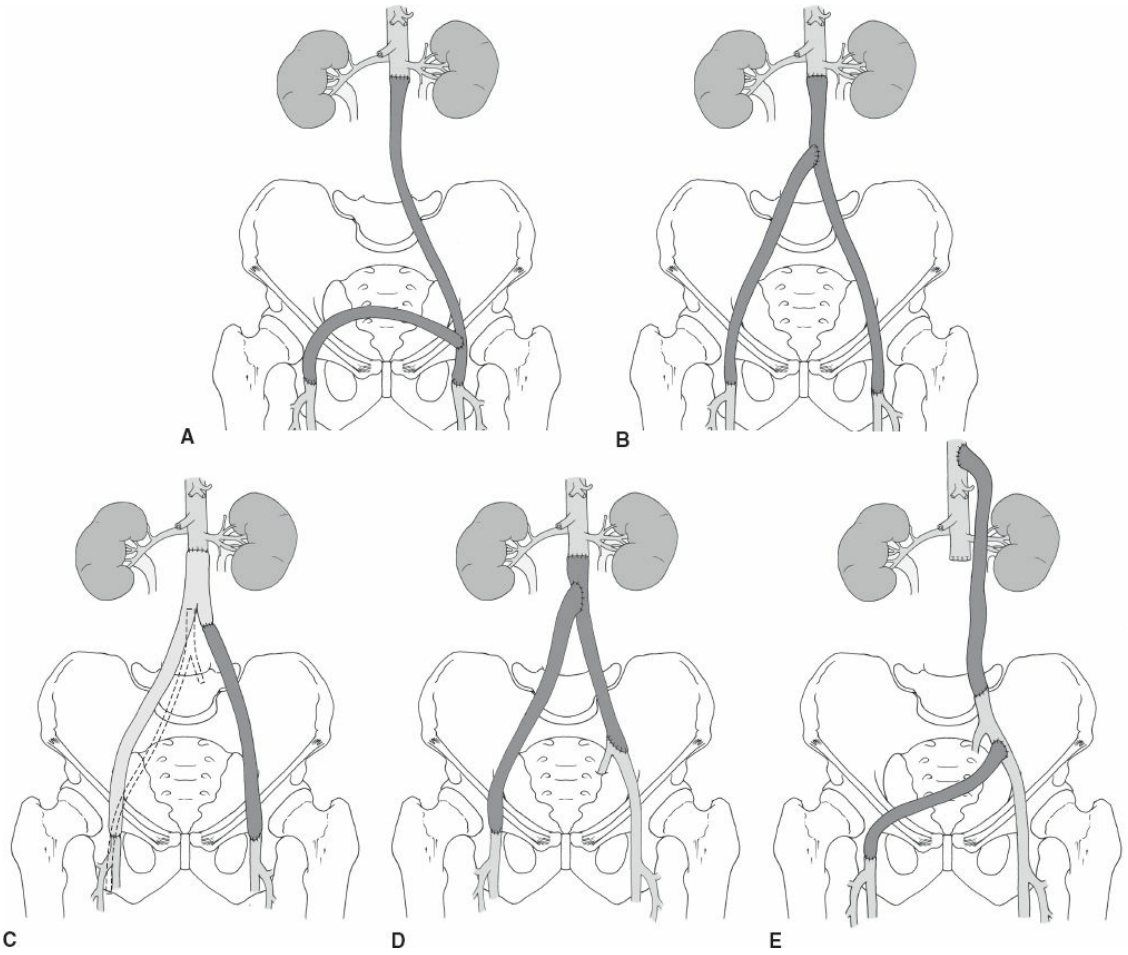

Figure 220.6. **A.** An aortofemoral bypass is fashioned on the left side with the femoropopliteal vein (FPV) graft. Another FPV graft is used to cross over to the right femoral region. **B.** Instead of a crossover femoral bypass, the right limb is connected to the left aortofemoral bypass using an end-to-side anastomosis. In both A and B, a shorter length of FPV graft is required for the right side of the reconstruction. **C.** In this example, infection was limited to the femoral region and the distal limb was replaced with an FPV graft. Care must be taken to prevent cross-contamination and the FPV graft routed lateral to the infected area or via a transobturator route. **D.** In this circumstance, a left common aortoiliac bypass is fashioned from one third to one half of an FPV graft and the right limb is fashioned from the remainder of the graft. This technique allows harvest of only a single FPV graft. **E.** In some circumstances, it is easier to approach the paraceliac aorta via a retroperitoneal approach and use this area for proximal anastomosis as shown in this figure. Although the distal anastomosis is to the common iliac artery in this case, additional length of FPV graft can be harvested to reach the femoral vessels if necessary

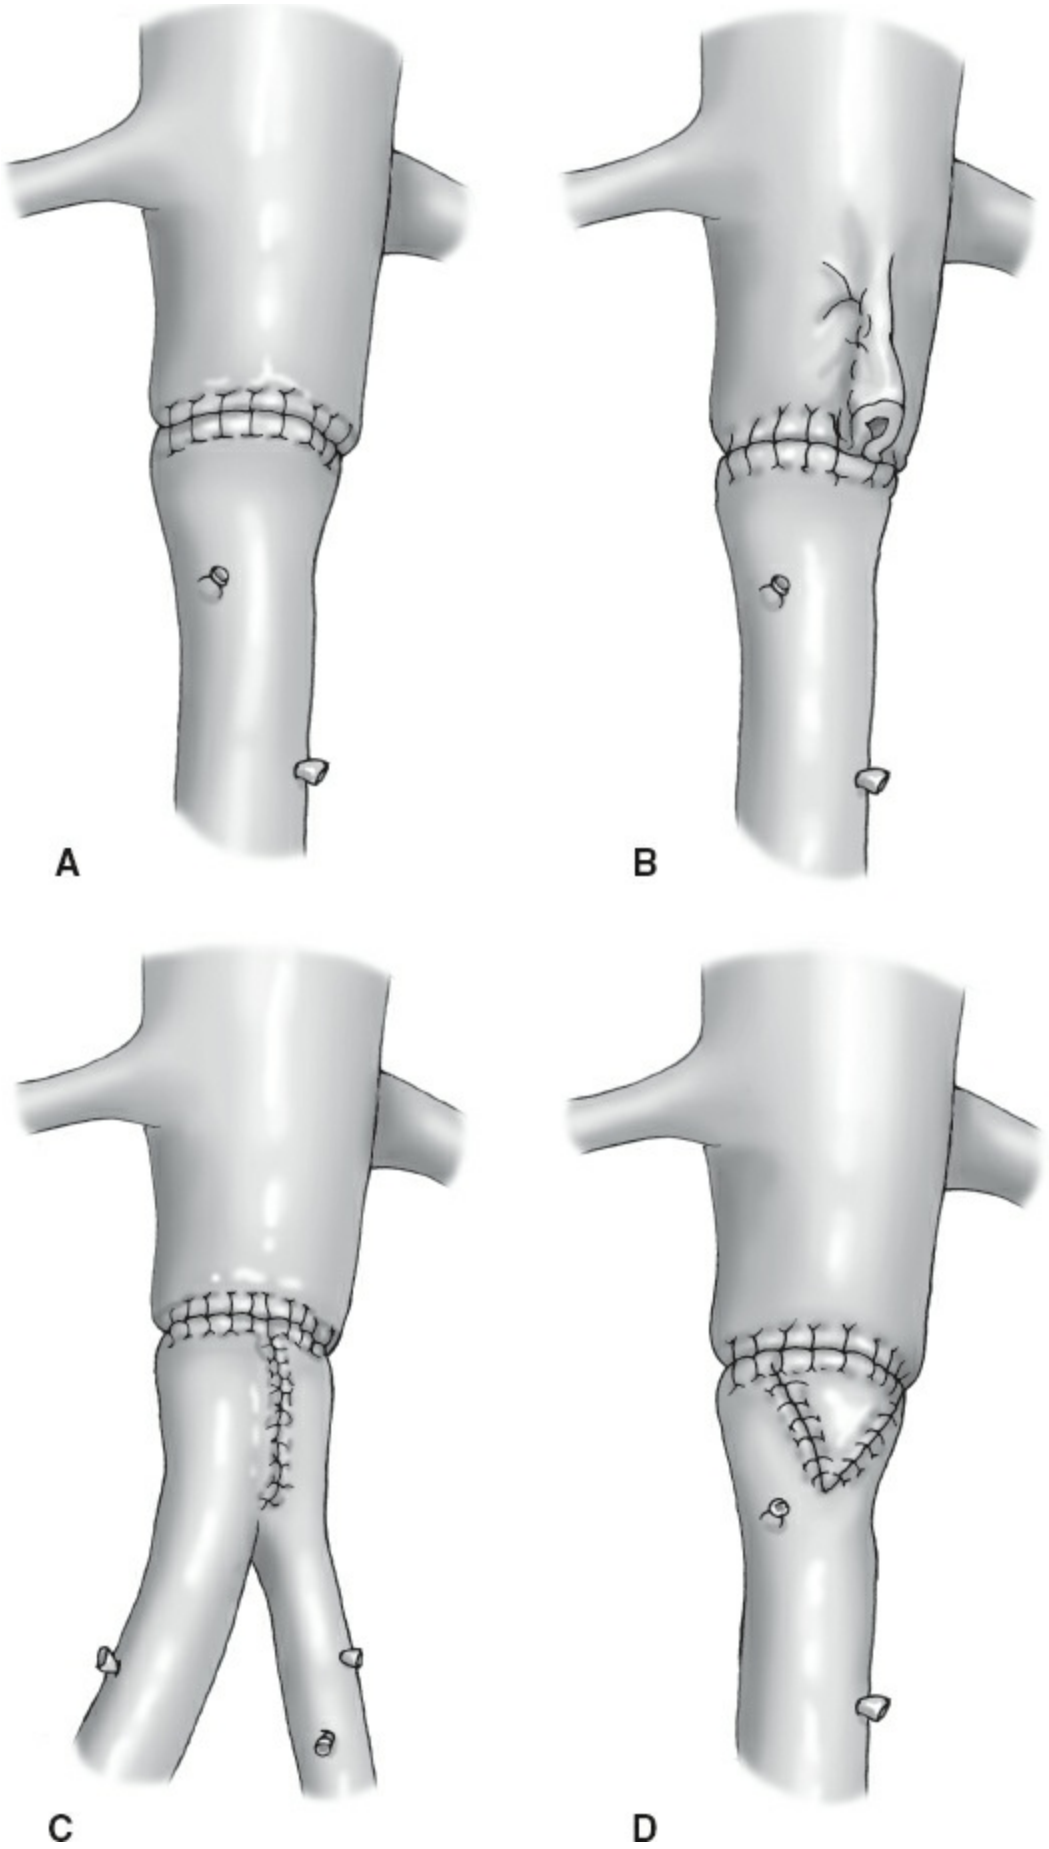

A
B
C
D

Figure 220.7. A. When the aorta is of normal size, the proximal end of the femoropopliteal vein (FPV) graft is anastomosed end to end. **B.** Simple plication of a portion of the aorta can be performed to allow comfortable end-to-end anastomosis when the aorta is either larger than normal or the FPV graft is comparatively small. **C.** In this example, two FPV grafts are joined together (pantaloon technique) and sewn end to end to the aorta. This effectively doubles the circumference of the vein graft and is used to accommodate very large aortas. **D.** In this case, a wedge-shaped portion of vein is incorporated into the proximal end to increase the circumference of the FPV graft.

RECONSTRUCTION USING NONAUTOLOGOUS MATERIALS

Cryopreserved Allografts

The versatility of cryopreserved allografts rapidly extended the indication for its use in the treatment of graft infection involving patients who need major concomitant surgery due to infective destruction or associated comorbidities.

These grafts allow safe in situ replacement of infected vascular or prosthetic segments, limit extended debridement at the site of infection, and obviate the need for complex extra-anatomic reconstructions with their distinct disadvantages (e.g., aortic stump blowout syndrome, suture line rupture, anastomotic aneurysms, and reinfection of the extra-anatomic grafts leading to multiple reoperations, distal amputations, and prolonged, even lifelong antibiotic treatment). A distinct advantage of allografts is the possibility to partially replace a graft when the vascular prosthetic infection is limited (involving only a small portion of the graft or the anastomosis itself, e.g., a false aneurysm of the proximal anastomosis or, in the case of groin infection, in a patient with aortobifemoral bifurcation prosthesis). Preparation of cryopreserved allografts is critical, as thawing and washing before implantation require a defined protocol. Sound surgical technique is critical—critical selection of allografts, eliminating those that are particularly friable, proper timing of allograft thawing, appropriate length and anastomosis without the slightest tension, proper ligature of allograft side branches using a through-and-through polypropylene suture (Fig. 220.8), avoidance of any exudate collection around the allograft by means of aggressive wound drainage, circumferential anastomotic reinforcement with allograft strips,

gentamycin-impregnated fibrin glue covering all anastomosis, and prolongation of antifungal treatment to 3 months postoperatively. A major drawback of allografts is the timely acquisition of an adequate allograft covering the individual patient's need. This is particularly true for those hospitals without an in-hospital allograft bank. They are stored in a –70°C freezer (or flown in just for the case), and the dimensions of the available grafts are limited and variable as they are obtained sporadically from cadavers. Furthermore, allografts may be more expensive than conventional prosthetic grafts. Allograft-related technical problems include intraoperative rupture caused by allograft friability, late allograft rupture from ligated allograft side branches, anastomotic stricture after partial graft replacement, anastomotic failure caused by inappropriate mechanical stress, allograft failure caused by inappropriate wound drainage, and recurrence of infection after inappropriate duration of antifungal treatment.

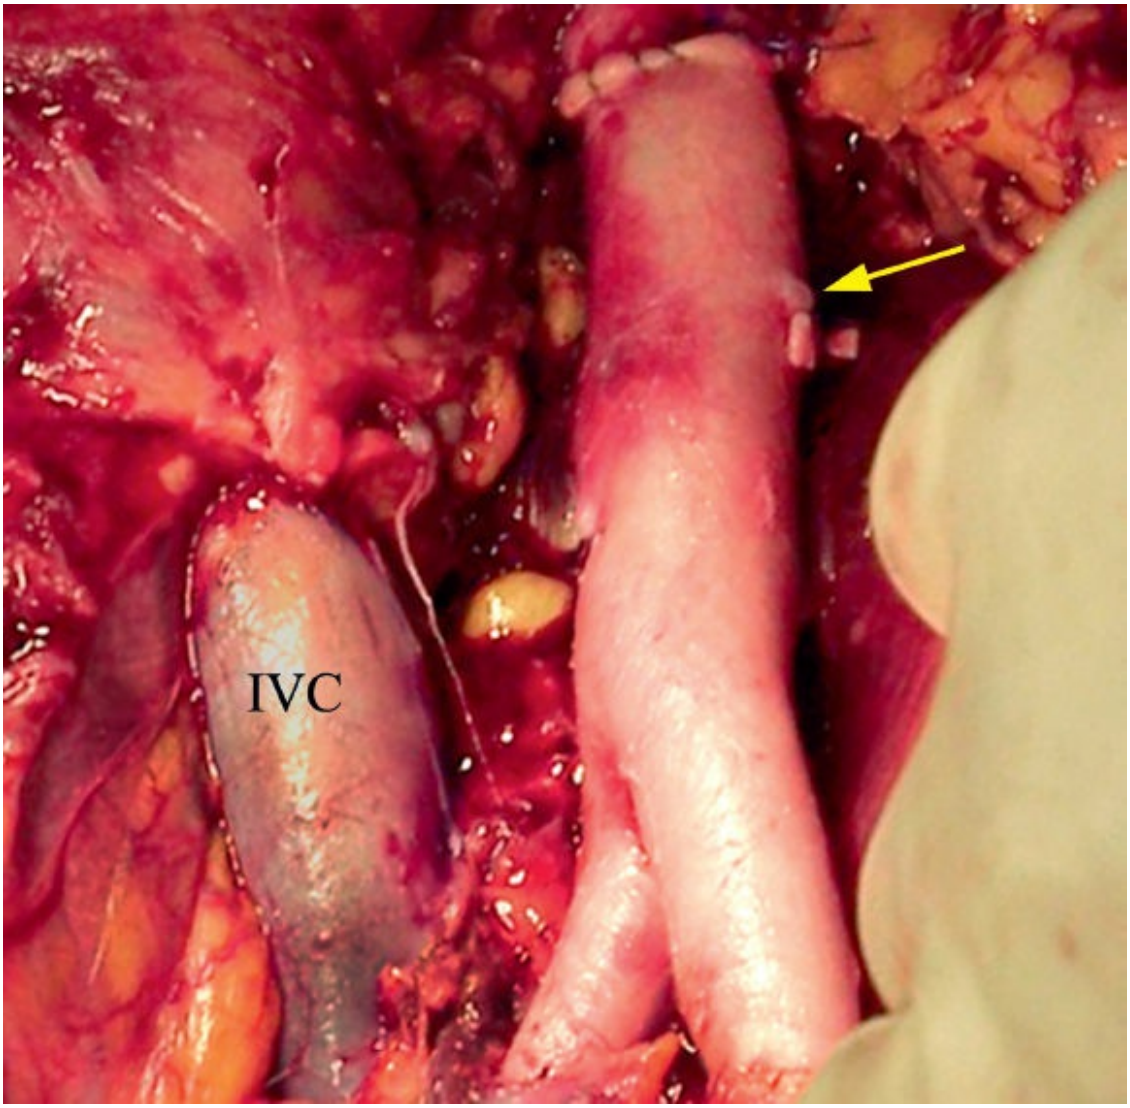

Figure 220.8. Aortic homograft used to replace an infected aortic graft. *Arrow* identifies ligated lumbar artery on the homograft. Inferior vena cava (IVC).

Antibiotic Impregnated Dacron Graft

Graft excision and in situ replacement using rifampin-treated Dacron grafts has been well documented since the late 1980s. It was most studied in-vivo for infections involving *Staphylococcus aureus* and *S. epidermidis* with a reported graft reinfection rate of 5% to 20% and limited morbidity.

Recurrent infections are usually due to from inadequate removal of all prosthetic at the first operation, or due to rifampin-resistant organisms (most notably *Enterococcus* sp.). Dacron grafts are soaked in Rifampin (60 mg/mL) for approximately 15 minutes prior to implantation. They have been found to retain their antibacterial effects for at least 2 to 3 days after implantation without additional antibiotics, depending on the organism.

Other antibiotics found to resist graft colonization *in vitro* include Daptomycin and nebacetin, as well as silver-woven grafts; but none of these have the extensive in-vivo experience that is reported with Rifampin. The authors also recommend the use of a pedicled omental flap to wrap the entirety of the rifampin graft after it is implanted. This is facilitated by allowing the graft to be a little more lax than usual when completing all the anastomosis. This leaves some room posterior to the graft to allow you to completely wrap the omentum behind and in front of the graft. This isolates the graft from the infected bed, potentially allows antibiotics to be circulating locally, and isolates it from the bowel. The largest series reported from the Mayo Clinic found a 5-year patient survival, primary graft patency, and limb salvage rates ranges are 60%, 92%, and 100%, respectively. Perioperative survival is overall 90%, but worse in unstable patients (～40%).

We recommend at least 6 weeks of intravenous antibiotics after implantation of all nonautologous grafts, followed by lifelong oral antibiotic suppressive therapy.

OUTCOMES

The optimal treatment for an infected aorta has historically been extra-anatomical bypass and removal of the infected graft. This is now being challenged. In a meta-analysis of treatments for infected aortic grafts, extra-anatomical bypass was compared to in situ rifampin-soaked Dacron, cryopreserved allografts, or autogenous veins using studies dating back to 1985.

Mean event rates for all outcomes combined (i.e., amputations, conduit failures, reinfections, <30-day mortalities, and >30-day mortalities) were calculated for each treatment modality. The results were 0.16 for extra-anatomic bypass, 0.07 for rifampin-bonded prostheses, 0.09 for cryopreserved allografts, and 0.10 for autogenous vein. A lower value meant fewer overall events. Despite the inherent weakness of a meta-analysis, in situ aortic reconstruction with rifampin-bonded prosthesis had the best outcomes. The authors questioned whether extra-anatomic bypass should remain the gold standard for treatment of aortic graft infection. The Society for Vascular Surgery Low Frequency Diseases Consortium studied outcomes of the use of cryopreserved grafts and found that in 220 patients the outcomes were comparable to femoral vein and only 10 (5%) patients required allograft explant.

Rifampin-treated Dacron with omental wrapping has a reinfection rate of about 12% and was not associated with procedure-related death. Comparing the procedure-related death rate for patients treated with this technique was slightly lower, but not significantly different than those treated with axillobifemoral bypass (9% vs. 23%; $P = 0.11$). However, there was a significant improvement in the primary patency 5 years (89% in Rifampin-treated grafts vs. 48% in the extra-anatomic group; $P = 0.01$), and a higher rate of major complications or procedure-related death in the axillobifemoral group (30% vs. 60%, respectively, $P < 0.04$).

Thus, in order to offer patients with this complex problem the optimal outcome possible, we stress that the approach be individually tailored to each case. They should be ideally managed by surgeons who are facile with each of the above-mentioned approaches, taking into consideration the risks and benefits of each technique.

EDITOR'S COMMENT

While mycotic aneurysms are difficult to deal with, graft infections in my mind remain the most confusing and life-threatening conditions we treat as surgeons. Plagued with the concept as suggested in this chapter by Garcia-Toca and Escobar that there is not a "one size fits all" when it comes to graft infections, the challenges of taking care of patients with this condition are multiple.

Importantly, one needs to first admit or decide that a graft infection is present. While the graft infection that shows up with air around it usually is clear, as most graft infections are *Staph* species, graft infections can also be indolent and smolder for years. It is clear that a good history is important as one needs to know what previous surgery has been done and what graft material has been used. I so remember a graft infection I was managing when all of the operative notes from a complicated aortic and groin graft infection were not received. I so remember discovering that a jump graft had been performed under the inguinal ligament to the very distal external iliac artery and then to the femoral, rather than just straight to the groin. The patient did fine, but the amount of bleeding that occurred during that operation was more than it should have been.

Imaging is once again key in the setting of graft infections, especially aortic graft infections (Bruggink JL, Slart RH, Pol JA, et al. Current role of imaging in diagnosing aortic graft infections. *Semin Vasc Surg* 2011;24(4):182–90). Remember that sometimes infected grafts present with occlusion. In addition, noticing on an angiogram that one can still see the waves or ripples in a Dacron graft is a subtle sign that a graft is not well incorporated and thus may be infected. Cross-sectional imaging with computed tomography angiography (CTA) or magnetic resonance angiography (MRA) remains the mainstay of diagnosis with nuclear imaging only required if the diagnosis is not clear cut (Keidar Z, Nitecki S. FDG-PET in prosthetic graft infections. *Semin Nucl Med* 2013;43(5):396–402).

As described in the present chapter, there are literally a myriad of ways to treat a graft infection. The general tenet has changed somewhat in that cryopreserved and antibiotic-soaked grafts are now commonly used; however, historically the treatment was to remove in total the offending infected graft and replace it through a noninfected field. This would typically involve performing the clean portion of the operation first (axillary to bifemoral bypass, obturator bypass, etc.) first, closing, and then performing the removal of the infected graft (Berger P, Moll FL. Aortic graft infections: is there still a role for axillobifemoral reconstruction? *Semin Vasc Surg* 2011;24(4):205–10). If this

can be done, I can't help but believe this type of approach is still the best for gram-negative and fungal infections or those associated with lung, bowel, or urine fistulae. My guess is that recurrent infection will always be less when this approach is used.

The use of autogenous vein, namely the femoral vein (used to be called the superficial femoral vein), for graft infections sort of changed the way we think about and manage graft infections (Chung J, Clagett GP. Neoaortoiliac System [NAIS] procedure for the treatment of the infected aortic graft. *Semin Vasc Surg* 2011;24(4):220–6). I personally like a direct approach to this problem and think the extra-anatomic bypasses we perform for graft infections are really not that durable and don't show great long-term patency. I just don't see how bilateral axillary to distal superficial or proximal above knee popliteal arteries are ever a solution for anything. While I have performed multiple neo-aortic replacements, these long procedures are brutal on patients who typically are already chronically ill. The literature now supports the use of two teams (one harvest, one performing graft explanation and repair) for these long surgeries, or to break the surgery up into two settings (one where the veins are exposed), followed a day later by vein excision and infected graft replacement (Budtz-Lilly J, Eldrup N, Vammen S, et al. Femoral vein repair of arterial infections: technical tips to reduce procedure time. *Vasc Endovascular Surg* 2014;48(5–6):367–71).

I also have on multiple occasion used Rifampin-soaked grafts with antibiotics beads, as well as the creation of an omental or muscle flap (Davila VJ, Stone W, Duncan AA, et al. A multicenter experience with the surgical treatment of infected abdominal aortic endografts. *J Vasc Surg* 2015;62(4):877–83). One can use this sort of approach when the bacteria involved in the aortic graft infection are a gram-positive species. However, the key is removing the previous graft, debriding the infected area, and finally and importantly making sure some real and substantial autogenous tissue coverage is placed around the rifampin-soaked graft. Others have used cryografts in a similar fashion and they seem to work just about as well (Noel AA, Gloviczki P, Cherry KJ Jr, et al.; United States Cryopreserved Aortic Allograft Registry. Abdominal aortic reconstruction in infected fields: early results of the United States cryopreserved aortic allograft registry. *J Vasc Surg* 2002;35(5):847–52).

Finally, I need to provide just a thought on the "conservative management" of these patients with graft infections, namely those that have an indolent where the patient is not septic from their graft infection, and the patient is not fit for repair. Others much more commonly use this approach, even though I am sure that my infectious disease colleagues would never go along with this approach. One of my senior partners Dr. Ken Cherry once suggested to me that an alive patient with or without a drain on chronic lifetime suppressive antibiotics is better than a dead patient who underwent a heroic attempt at an operation that ultimately failed.

G VENOUS DISORDERS

221 Contemporary Operative Venous Thrombectomy

Anthony J. Comerota and Faisal Aziz

INTRODUCTION

The controversial history of operative venous thrombectomy necessitates a background discussion before embarking upon a description of the technique. Patients with multilevel deep venous thrombosis (DVT) are at increased risk for severe postthrombotic syndrome, and those with iliofemoral DVT represent the highest risk subset. Therefore, it is appropriate to approach patients with iliofemoral DVT with an initial treatment strategy to eliminate their thrombus. Occasionally, catheter-based techniques will not be an appropriate option. Therefore, the option remaining to restore venous patency is operative venous thrombectomy.

Postthrombotic syndrome results from valve reflux or luminal obstruction. It is increasingly severe with combined reflux and obstruction, and most severe in patients with postthrombotic iliofemoral venous obstruction. Intuitively, if unobstructed venous drainage from the leg into the vena cava can be restored, patients should enjoy a significantly better quality of life as a result of fewer postthrombotic sequelae. This has been shown with catheter-directed thrombolysis, as well as a randomized trial of operative venous thrombectomy versus anticoagulation. Adopting a strategy of thrombus removal is an important first step in the management of these patients (Fig. 221.1).

Venous thrombectomy was largely abandoned in the United States because of two early reports. Interestingly, the procedures were performed approximately 50 years ago at a time when true “vascular” techniques did not exist. Vascular imaging was in its infancy, and anticoagulation was inconsistent. Unfortunately, some guidelines on the management of venous thromboembolism (VTE) continue to focus on the outdated retrospective

reports and overlook more recent studies showing improved outcomes using contemporary vascular techniques. Until 2008, guideline authors overlooked a multicenter *randomized* trial evaluating contemporary venous thrombectomy versus standard anticoagulation. A Scandinavian randomized trial demonstrated significant benefit to those undergoing operative venous thrombectomy, with fewer postthrombotic sequelae, increased iliac vein patency, lower venous pressures, and improved valvular function, compared to those treated with anticoagulation alone.

The technique of contemporary venous thrombectomy reviewed here is designed to maximize the chance of a favorable outcome (Table 221.1) and is significantly different compared to the technique used in earlier reports (Table 221.2).

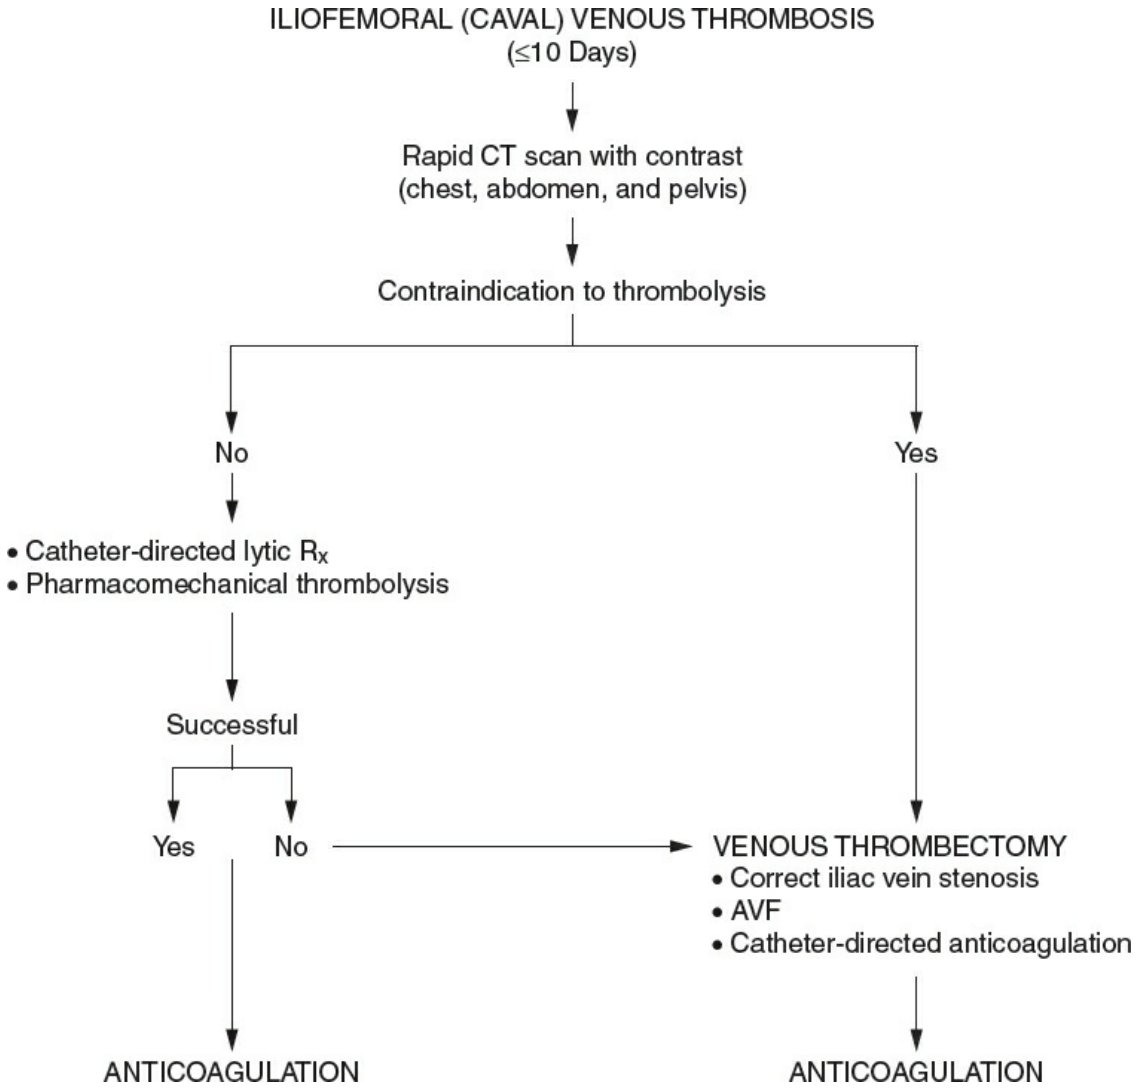

Figure 221.1. Algorithm for the recommended treatment for iliofemoral venous thrombosis. CT, computed tomography; AVF, arteriovenous fistula.

TABLE 221.1 Technique of Contemporary Venous Thrombectomy

1. **Define full extent of thrombus**
   a. Venous duplex examination
   b. Rapid CT scan of head, chest, abdomen, and pelvis
   c. Contralateral iliocavagram
2. **Prevent pulmonary embolism (numerous techniques)**
   a. Initiate nticoagulation
   b. Vena caval filter (if nonocclusive clot in vena cava), or
   c. Balloon occlusion of vena cava cephalad to nonocclusive caval thrombus during iliocaval thrombectomy
   d. Positive end-expiratory pressure during thrombectomy of iliocaval segment
3. **Perform a complete thrombectomy**
   a. Iliofemoral (vena cava) thrombectomy
   b. Infrainguinal venous thrombectomy (if required) using compression. If compression techniques fail direct balloon catheter thrombectomy from distal to proximal is recommended.
4. **Prevent recurrent thrombosis**
   a. Correct iliav veni stenosis if present
   b. Construct arteriovenous fistula (saphenofemoral)
   c. Maintain continuous therapeutic anticoagulation
   d. Catheter-directed postoperative anticoagulation (if infrainguinal venous thrombectomy was performed) via catheter in posterior tibial vein
   e. Extended oral anticoagulation

TECHNIQUE OF OPERATIVE VENOUS THROMBECTOMY

The principles of successful venous thrombectomy are briefly summarized in Table 221.1. The important conceptual elements of the procedure are numbered sequentially, with methods to achieve these goals listed beneath each numbered item.

PREOPERATIVE PATIENT EVALUATION AND PLANNING

Of all the patients presenting with lower extremity DVT, those with iliofemoral DVT represent the patient population with the highest thrombus burden. Often, there is a reason for this degree of extensive thrombosis, which may include an underlying thrombophilia or malignancy.

It is crucial to determine the proximal and distal extent of thrombus. The infrainguinal veins are well examined by venous duplex. We prefer a contralateral iliocavagram to evaluate the vena cava and iliac veins. Magnetic resonance venography or spiral computerized tomography (CT)

with contrast may obviate the cavagram.

A rapid CT scan with intravenous contrast of the head, chest, abdomen, and pelvis is performed. Asymptomatic pulmonary emboli (PE) are found in approximately 50% of cases. Extending imaging from the head and chest to the abdomen and pelvis is an effective way to rapidly screen for other pathology. In addition to identifying the proximal extent of thrombus and PE, CT scans have revealed new findings of renal cell carcinoma, adrenal tumors, hepatic metastases, retroperitoneal lymphoma, iliac vein aneurysms, and congenital absence of the vena cava. Each of these findings can have important implications for immediate and long-term patient care.

TABLE 221.2 Venousthrombectomy: Comparison of Old and Contemporary Techniques

Technique	Old	Contemporary
Pretreatment phlebography/computed tomography scan	Occasionally	Always
Venous thrombectomy catheter	No	Yes
Operative fluoroscopy/phlebography	No	Yes
Correct iliac vein stenosis (stent)	No	Yes
Arteriovenous fistula	No	Yes
Infrainguinal thrombectomy	No	Yes
Full postoperative anticoagulation	Occasionally	Yes
Catheter-directed anticoagulation	No	Yes
Intermittent pneumatic compression postoperatively	No	Yes

Adapted from Comerota AJ, Gale SS. Surgical venous thrombectomy for iliofemoral deep vein thrombosis. In: Greenhalgh RM, ed. *Towards Vascular and Endovascular Consensus.* London: BIBA Publishing; 2005.

While a hereditary thrombophilia evaluation was performed early in our experience, it has been recognized that it is no longer necessary as the patient's existing thrombosis is a higher risk for recurrence than any detected hereditary thrombophilia. Furthermore, a negative panel may mistakenly mislead the physician into thinking the patient is at a low risk for rethrombosis. In general, the risk of rethrombosis associated with extensive DVT is greater than the risk associated with a hereditary thrombophilic condition. We recommend that first-degree female relatives of child-bearing potential be studied for Factor V Leiden, prothrombic gene mutation and antithrombic deficiency, as a positive test may affect

treatment during subsequent pregnancy. Antiphospholipid antibodies are obtained in all patients.

Therapeutic anticoagulation with unfractionated heparin (UFH) or low–molecular-weight heparin (LMWH) is initiated and the patient fully anticoagulated. UFH is used during the procedure and early postoperative period. Intravenous UFH offers temporal control of the degree of anticoagulation, and of course is the agent used for postoperative catheter-directed anticoagulation.

Vena caval filtration is generally not required; however, an exception may be the patient with nonocclusive thrombus in the vena cava or those with symptomatic PE. Also, patients can be protected from intraoperative PE by balloon occlusion of the proximal vena cava during the operative procedure (Fig. 221.2). The vena caval balloon can be positioned from the contralateral femoral vein using fluoroscopic guidance during preoperative iliocavagraphy. Once the balloon is properly positioned, it remains deflated until the time of thrombus extraction. During thrombectomy, the caval balloon is inflated and the thrombectomy performed under fluoroscopic guidance, inflating all balloons with contrast mixed with saline. If fixed imaging is not available, the operating room is prepared for fluoroscopy with any necessary modifications in operating room table positioning. An autotransfusion device is also available during the procedure.

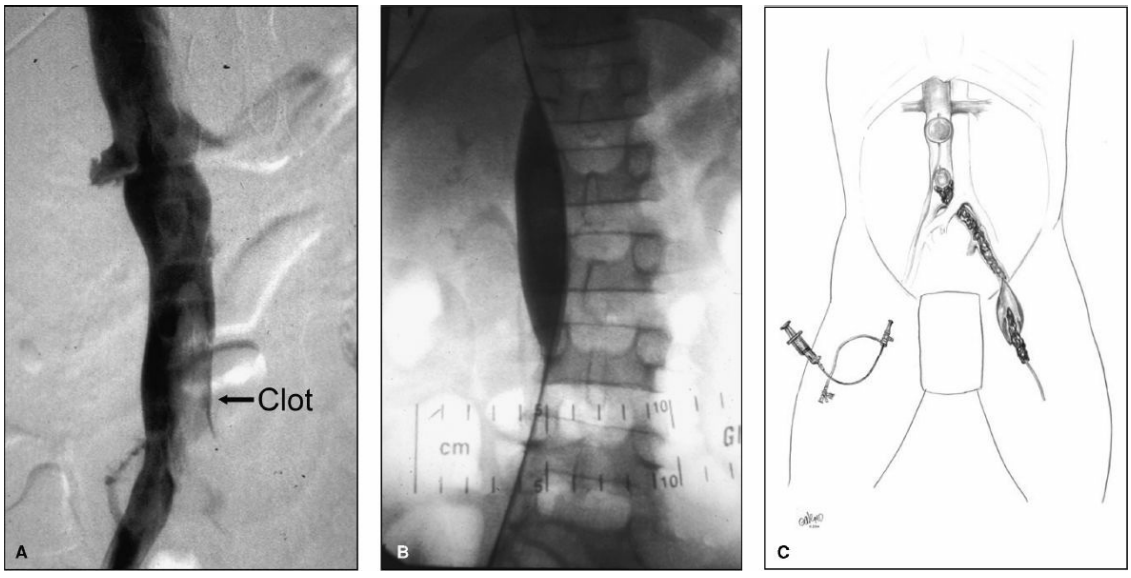

Figure 221.2. A. Preoperative iliocavagram shows nonocclusive thrombus extending from the left iliofemoral venous system into the vena cava. Insert to left of vena cava shows caval thrombus was removed in its entirety. **B.** A balloon catheter was placed

from the contralateral femoral vein and inserted under fluoroscopy; positioned above the caval thrombus. The caval balloon is inflated at the time of thrombectomy. **C.** Schematic of iliocaval thrombectomy performed with the double balloon catheter technique, protecting the patient from pulmonary embolism.

SURGICAL TECHNIQUE

Following the induction of general anesthesia, the entire involved leg, lower abdomen, and opposite leg to the knee are prepped into the field. If there is any doubt that successful iliac vein patency can be restored, both legs are prepped into the operative field, in the event that an autogenous cross-pubic venous bypass is required. A longitudinal inguinal incision is made in the groin, exposing the common femoral vein to the inguinal ligament, the saphenofemoral junction, the origin of the profunda femoris vein and the proximal femoral vein (Fig. 221.3A). A longitudinal venotomy is performed near the saphenofemoral junction. The exact location of the venotomy will depend upon the extent and location of the thrombosis. Since the femoral vein is distended, a longitudinal venotomy is preferred and can be closed primarily without compromising vein lumen.

In patients with infrainguinal thrombosis, an infrainguinal venous thrombectomy is performed first. Initially the leg is elevated and wrapped tightly with an elastic bandage. The leg is squeezed and the foot dorsiflexed, and the leg is milked in an effort to remove clot from below. If these maneuvers are successful, the femoral vein below the venotomy is clamped. The distal posterior tibial vein is exposed to perform an infrainguinal venous thrombectomy (Fig. 221.3B). A No. 3 balloon catheter is passed proximally from below to exit the common femoral venotomy (Fig. 221.4A). The silastic sheath of a large intravenous catheter (12 to 14 gauge) is cut from its hub and slid halfway onto the balloon catheter that was passed from below. Another No. 4 balloon catheter is placed into the proximal end of the silastic sheath. A single operator applies pressure to the syringes attached to the two catheters, which firmly secures the balloons inside of the sheath, providing protective passage distally through the clotted venous system and valves (Fig. 221.4B). The catheters exit the posterior tibial venotomy (Fig. 221.4C). A standard balloon catheter thrombectomy can then be performed in the direction of the venous valves (Fig. 221.4D,E). Repeated balloon thrombectomy (with

a larger catheter if necessary) can be performed until no further thrombus is extracted. The infrainguinal venous system is then vigorously flushed with a heparin-saline solution to hydraulically force residual thrombus from the deep venous system (Fig. 221.5). This is accomplished by placing a No. 14 to 16 red rubber catheter into the proximal posterior tibial vein and flushing with a bulb syringe. It is often surprising to see the amount of additional thrombus flushed. After flushing, a vascular clamp is applied below the femoral venotomy and the infrainguinal venous system is then filled with a large volume of dilute plasminogen activator solution. Commonly, 3 to 4 mg of rt-PA is diluted in 200 mL of saline and injected into the infrainguinal venous system. If the infrainguinal thrombectomy is not successful due to chronic disease in the femoral vein, or if there is multichannel recanalization of the femoral vein, it is ligated and divided just below its junction with the profunda. Patency of the profunda femoris vein must be ensured prior to ligation of the femoral vein. This maneuver prevents the inevitable venous reflux through the diseased femoral vein. Venous drainage through an unobstructed profunda system, which may have competent valves, offers a better chance at reducing postthrombotic sequelae.

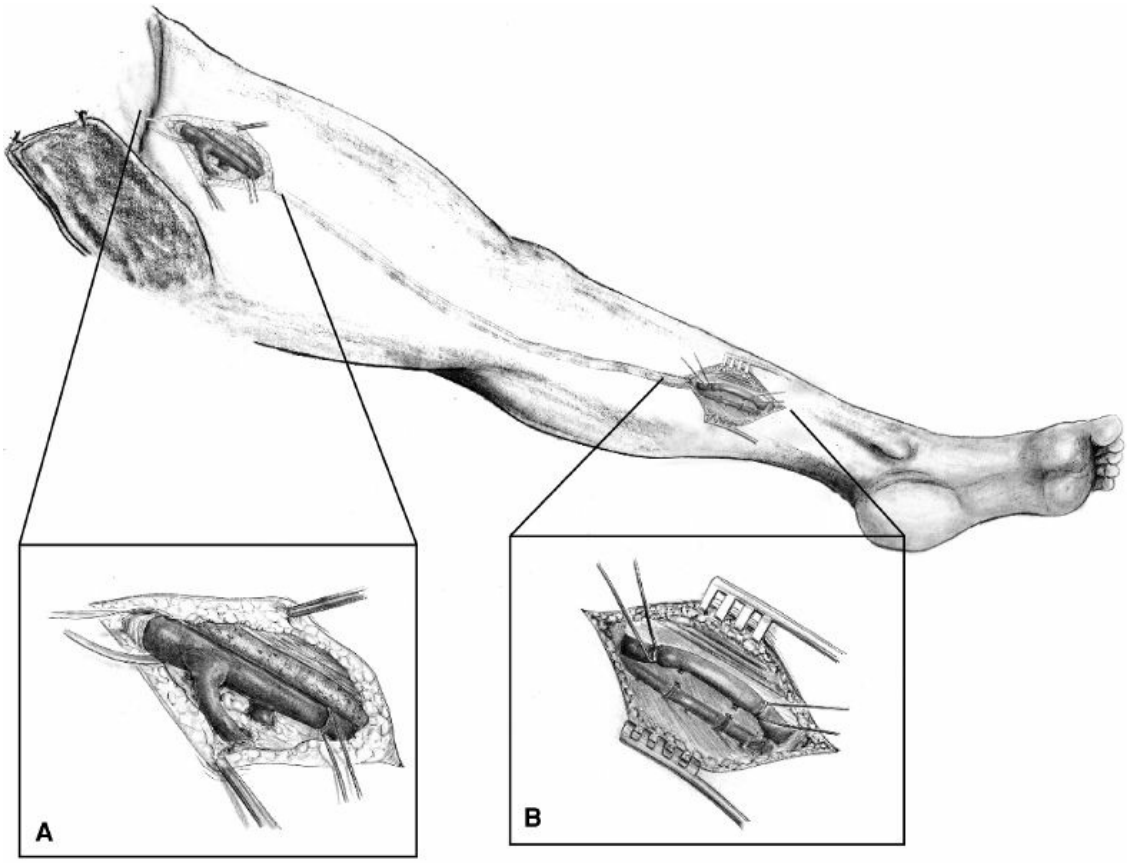

Figure 221.3. **A.** Exposure of the common femoral, femoral, and profunda femoris veins. **B.** Exposure of the posterior tibial vein.

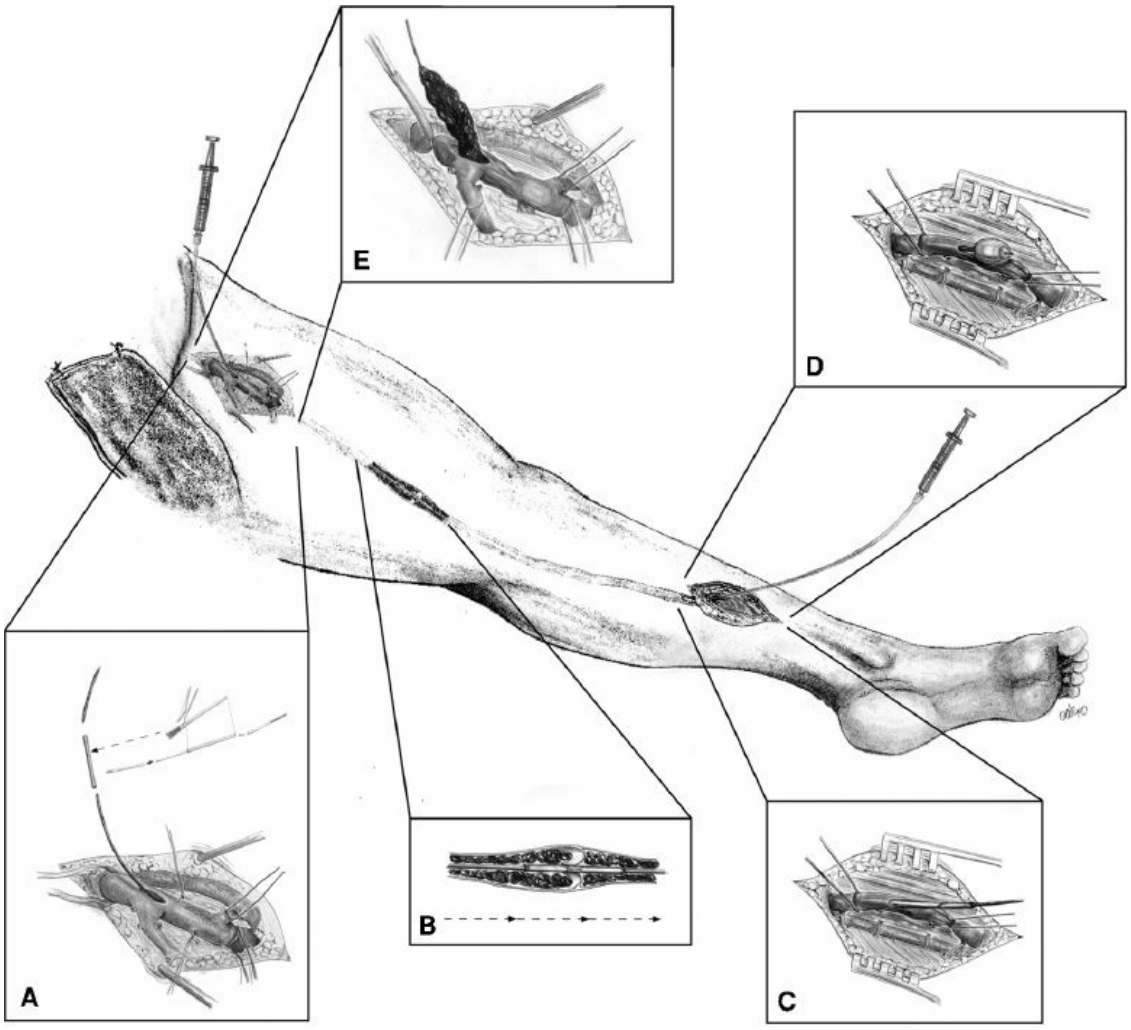

Figure 221.4. Technique of infrainguinal balloon catheter venous thrombectomy begins with passage of a No. 3 balloon catheter from the posterior tibial vein proximally (**A**), exiting the femoral venotomy. A silastic IV sheath is placed halfway onto the No. 3 catheter, and a second No. 4 balloon catheter inserted into the cephalad end of the sheath. **B.** The balloons are pressurized to fix the catheter tips inside of the sheath, with the pressure applied by a single individual guiding them distally through the clotted veins and venous valves no resistance to catheter passage should be encountered. **C.** Catheters and sheath exit the posterior tibial venotomy. **D.** The No. 4 thrombectomy catheter balloon is gently inflated as the catheter is pulled proximally (**E**) to exit the femoral venotomy, extracting thrombus. This is repeated several times until not thrombus is retrieved.

The iliofemoral and caval thrombectomy is performed using a No. 8 or 10 *venous* thrombectomy catheter. The catheter is passed partway into the iliac vein several times to remove the majority of the iliac vein thrombus before advancing into the vena cava. The proximal thrombectomy is performed under fluoroscopy using a contrast-saline solution to expand the balloon. This is especially important if a vena caval filter is present, if there is clot in the vena cava, or if the surgeon experiences resistance to catheter passage. The anesthesiologist applies positive end-expiratory pressure during the iliocaval thrombectomy to further reduce the risk of intraoperative PE.

Following completion of the iliofemoral and vena caval thrombectomy, the iliofemoral system and vena cava are examined with a biplane intraoperative venogram to ensure unobstructed venous drainage into and through the vena cava. If there is any question about an iliac stenosis, intravascular ultrasound is used to examine the iliac veins. An underlying iliac vein stenosis is corrected with balloon angioplasty and, if necessary, a stent to maintain the desired luminal diameter (Fig. 221.6). If a stent is placed into the common iliac vein, it should be no smaller than 14 mm in diameter, with most being larger.

The importance of correcting an underlying venous stenosis at the time of venous thrombectomy cannot be overstated (Fig. 221.6). Long-term patency with this approach has been reported to be 84% to 86%. If early rethrombosis is avoided, this has proven to be a durable and worthwhile procedure.

The venotomy is closed with a running fine monofilament suture. The proximal saphenous vein is exposed and may require thrombectomy in anticipation of constructing an arteriovenous fistula (AVF). The AVF is constructed by anastomosing the end of the transected proximal saphenous vein (or a large proximal side branch of the saphenous vein) to the side of the proximal superficial femoral artery. The anastomosis should be no greater than 3.5 to 4.0 mm in diameter. A small piece of bovine pericardium or PTFE is placed around the saphenous AVF, and a large permanent monofilament suture is looped around the PTFE graft and clipped, leaving approximately 2 to 3 cm in the subcutaneous tissue (Fig. 221.7A). This maneuver is performed in the event that operative closure of the AVF becomes necessary. Although others have used the AVF as temporary and report closure by percutaneous or open occlusion, we view the AVF as permanent, since it is small and cannot enlarge there has been

no hemodynamic consequence. Most patients tolerate the AVF well, and the flow through this small channel often diminishes with time due to neointimal fibroplasia. Since approximately 15% of patients with early closure of AVFs have early recurrent thrombosis, and since our patients have tolerated the AVF without difficulty, we believe that routine, elective closure of this small AVF is not warranted. However, if the AVF is large (≥6 mm), it will produce arterial and venous dilation. In this instance, the AVF should be closed.

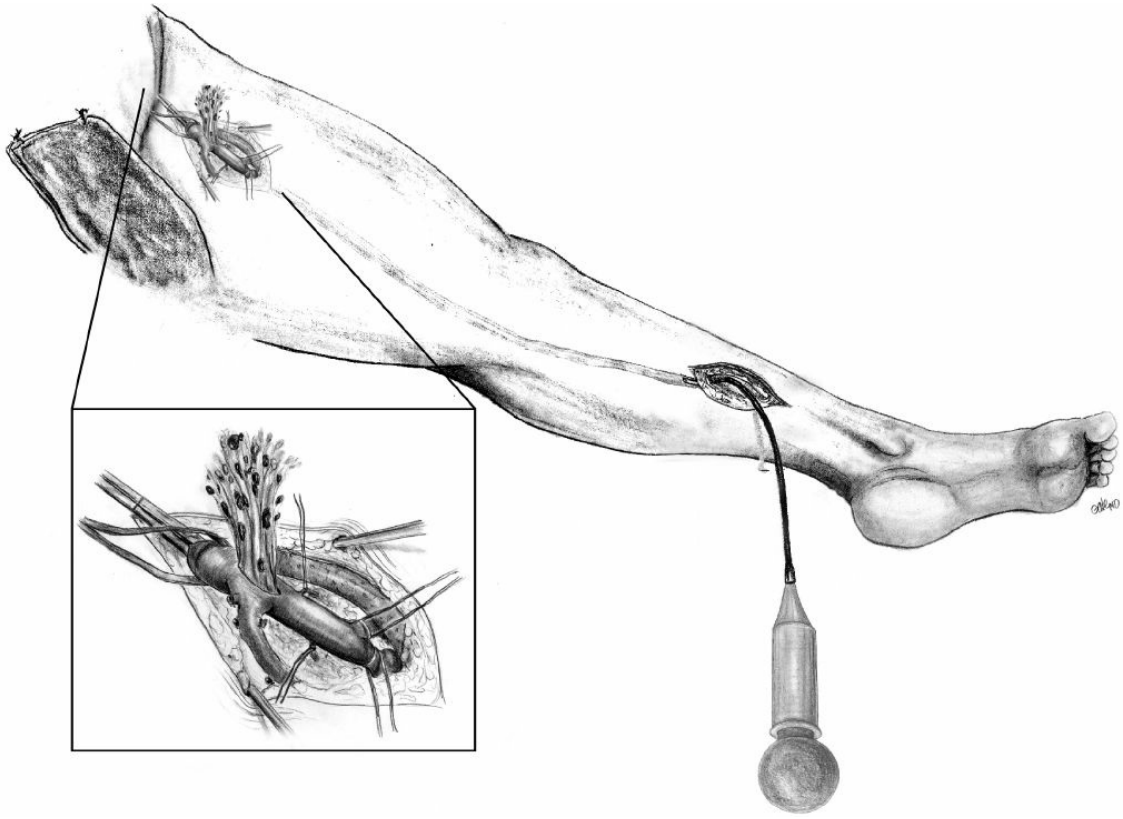

Figure 221.5. A red rubber catheter (largest diameter possible) is placed into the posterior tibial vein and vigorously injected with a heparin-saline solution using a bulb syringe to flush residual thrombus. After flushing, the femoral vein is clamped and the leg veins injected with 150 to 200 mL of a dilute 2- to 3-mg rt-PA solution.

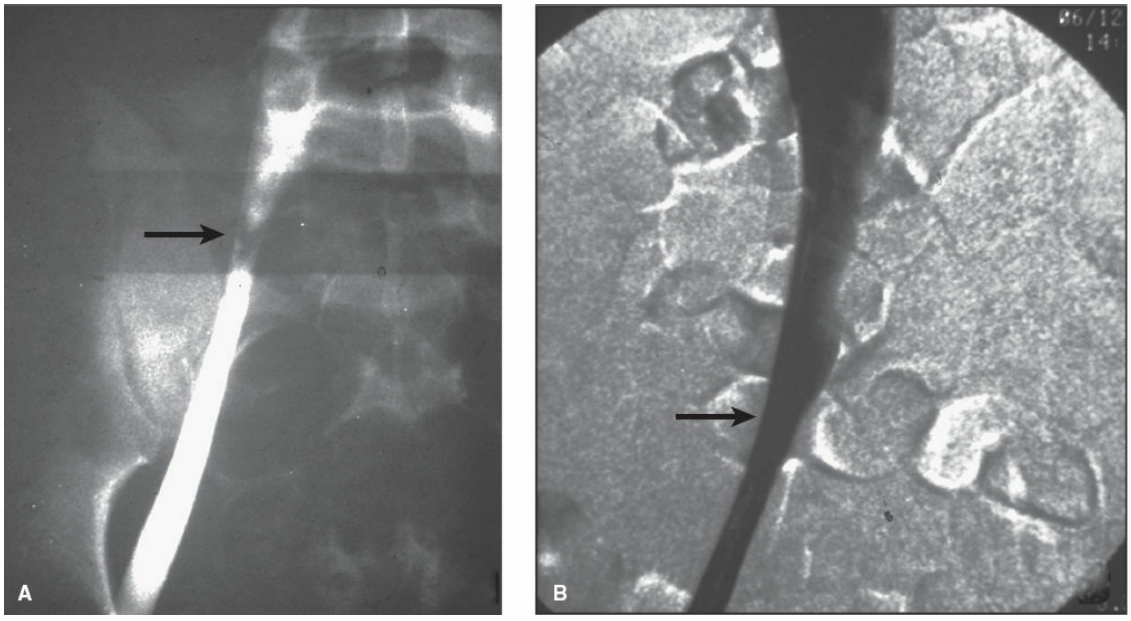

Figure 221.6. **A.** After iliac vein thrombectomy, a completion phlebogram of the right common iliac vein shows a residual stenosis (*arrow*). **B.** Following iliac vein venoplasty, the stenosis is corrected (*arrow*), restoring unobstructed venous drainage into the vena cava. Most patients will require stenting to correct their stenosis.

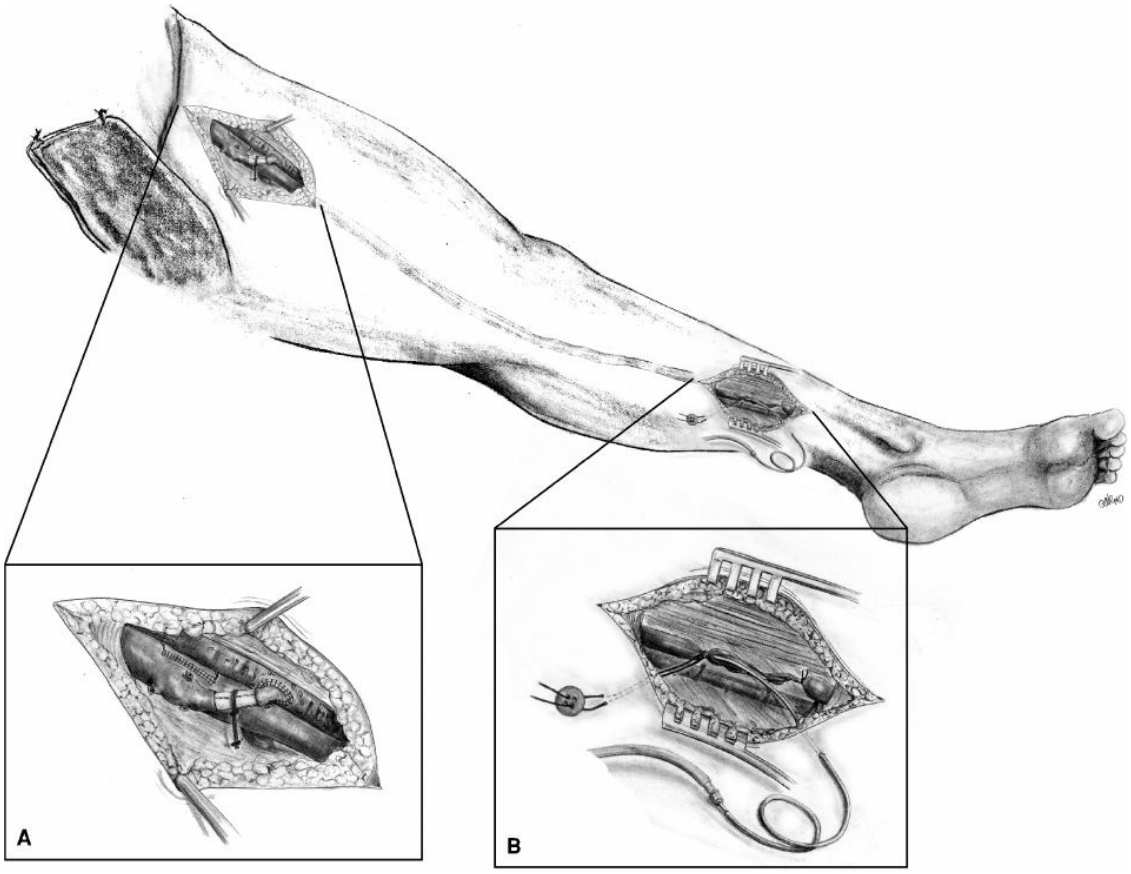

Figure 221.7. **A.** The venotomy is closed with fine monofilament

suture, and a 3.5- to 4.0-mm arteriovenous fistula (AVF) is constructed sewing the transected end of the saphenous vein to the side of the superficial femoral artery. A piece of bovine pericardial patch is placed around the saphenous AVF, looped with No. 0 monofilament suture, and the ends clipped, leaving approximately 2 to 2.5 cm in the subcutaneous tissue. This eliminates the risk of the AVF enlarging and serves to guide surgical closure of the AVF, should it become necessary. **B.** The distal posterior tibial vein is ligated. An infusion catheter (pediatric nasogastric tube) is brought into the wound through a separate stab wound in the skin and inserted and fixed in the proximal posterior tibial vein. The proximal posterior tibial vein and catheter are looped with No. 0 monofilament suture and fixed to the skin through a sterile button, which is used to snugly occlude the posterior tibial vein at the time of catheter removal.

Common femoral vein pressures are measured before and after the AVF is opened (Fig. 221.8), the pressure should not change. If the femoral vein pressure increases when the AVF is opened, the iliac veins should be reevaluated for residual stenosis or obstruction and the proximal lesion corrected. If the pressure remains elevated in the absence of proximal disease, the AVF should be constricted to decrease flow and normalize pressure.

If there appears to be notable serous fluid in the wound, a careful search for transected lymphatics is performed and they are ligated. A closed suction drain is placed in the wound to evacuate blood and serous fluid that may accumulate postoperatively in an effort to reduce hematoma or seroma formation. The drain exits through a separate puncture site adjacent to the incision, and the wound is closed with multilayered running absorbable sutures to obliterate dead space and achieve hemostatic and lymphostatic wound closure.

Before closing the distal incision, the distal posterior tibial vein is ligated. A small infusion catheter is brought into the wound via a separate stab incision in the skin and inserted into the proximal posterior tibial vein. We frequently use a pediatric feeding tube (Fig. 221.7B). This catheter is used for postoperative therapeutic anticoagulation, with continuous infusion of UFH directly into the previously thrombosed venous system, which is continued for 4 to 5 days until the patient is therapeutic on warfarin. Prior to catheter removal, a phlebogram is performed. Postoperative heparin infusion through this catheter ensures

supratherapeutic heparin concentration into the affected venous segment. Heparin binds to endothelium, smooth muscle cells, and subendothelial collagen. We believe this to be a valuable addition to this procedure. A 2-0 monofilament suture is looped around the posterior tibial vein (and catheter) with both ends exiting the skin adjacent to the wound. Both ends of the suture are passed through adjacent holes of a sterile button, which is secured to the skin snugly when the catheter is removed. This maneuver obliterates the proximal posterior tibial vein and eliminates any risk of bleeding following catheter removal.

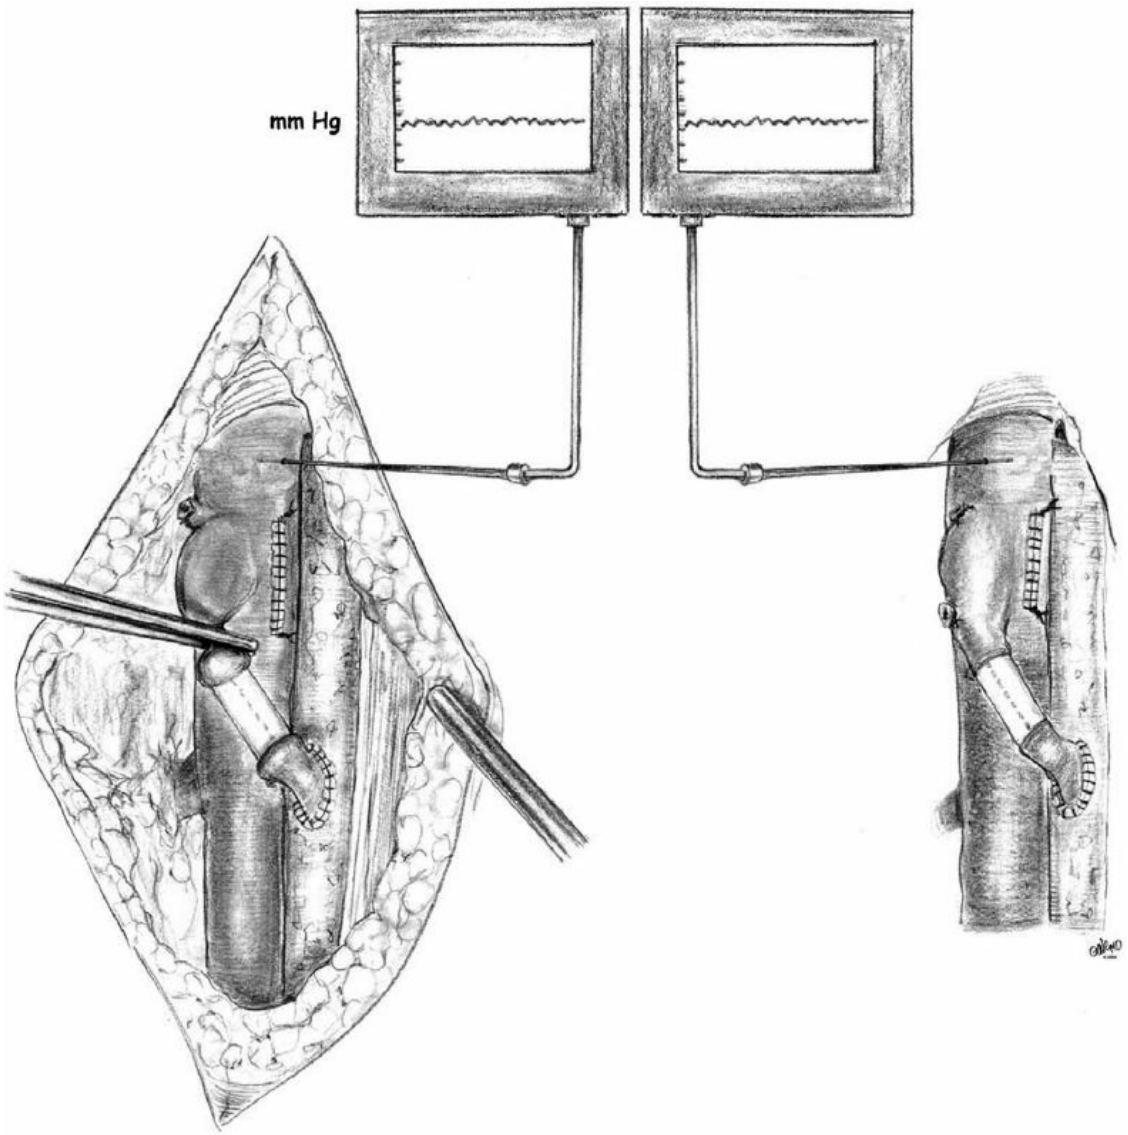

Figure 221.8. The common femoral vein pressure is measured before and after the arteriovenous fistula is opened; the pressure should not change.

Figure 221.9. An ascending phlebogram evaluates venous patency prior to catheter removal, after the patient is therapeutic on warfarin.

POSTOPERATIVE MANAGEMENT

After wound closure, antibiotic ointment and sterile gauze are applied to the wounds. The patient's leg is wrapped from the base of the toes to the inguinal area with cotton gauze and elastic bandages. Full anticoagulation is continued postoperatively with UFH infused through the catheter secured in the posterior tibial vein (as mentioned previously). The patient is encouraged to ambulate beginning the first postoperative day. Oral anticoagulation is begun immediately postoperatively when the patient resumes oral intake. The heparin infusion is continued for a minimum of 4 to 5 days and the international normalized ratio reaches 2.0 to 3.0, if the patient is treated with a VKA. Intermittent pneumatic compression garments are used on both legs during the postoperative period when the patient is not ambulating. While the direct oral IIa and Xa inhibitors are as effective as heparin/warfarin treatment for the majority of patients with acute DVT, we prefer to manage these patients with heparin and warfarin,

at least for the first 6 to 12 months.

Prior to removing the posterior tibial vein catheter, an ascending venogram is obtained to evaluate venous patency (Fig. 221.9). The femoropopliteal veins are well visualized; however, the iliofemoral venous system may not be adequately imaged due to washout and dilution of contrast by the AVF. If imaging of the iliofemoral venous system is required, alternative techniques such as direct femoral vein puncture, contrast injection into the artery, or a CT scan with IV contrast may be used. Any significant stenosis or occlusion in the iliofemoral segment should be promptly treated to provide unobstructed venous drainage into the vena cava.

Oral anticoagulation is recommended for an extended period of time. Patients are anticoagulated for a minimum of 1 year, with most treated longer. Elastic compression stockings with a 30- to 40-mm ankle gradient are used in all patients and have been found to further reduce postthrombotic sequelae. However, if patents have no swelling without the use of elastic compression stockings, they generally will receive no benefit from their use.

SUMMARY

The technique of contemporary operative venous thrombectomy has been refined and the early and long-term results have been considerably improved compared to initial reports. Operative morbidity is low, with fewer, if any, reports documenting an operative mortality. Fatal PE has not occurred in the contemporary experience, and in fact no patient in the author's experience has suffered from a symptomatic pulmonary embolism in association with operative venous thrombectomy, even when thrombus extended into the vena cava.

Adapted from Comerota AJ, Gale SS. Surgical venous thrombectomy for iliofemoral deep vein thrombosis. In: Greenhalgh RM, ed. *Towards Vascular and Endovascular Consensus.* London: BIBA Publishing; 2005.

Operative venous thrombectomy follows basic vascular surgical principles. By achieving complete or near-complete thrombus extraction from the deep venous system and preventing rethrombosis, significant morbidity from postthrombotic sequelae can be avoided. Basic strategies to minimize rethrombosis include:

(a) Ensuring that thrombus removal is optima

(b) Dilating and stenting any residual iliac vein stenosis

(c) Increasing the velocity of blood flow in the iliofemoral venous system with a small AVF

(d) Postoperative catheter-directed anticoagulation in the thrombectomized infrainguinal venous system (if an infrainguinal venous thrombectomy is required)

(e) Therapeutic and prolonged anticoagu-lation

Meissner et al., 1996	27	60	30
TOTAL	**352**	**45 mo (mean)**	**63% (mean)**

Cumulative results in reports published within the past 25 years demonstrate that in patients followed for a mean of 41 months, 76% of the iliac veins remained patent and 63% of the femoropopliteal segments maintained competent valves (Tables 221.3 and 221.4). These good results can be improved by incorporating more of the details described herein. In the author's 43-patient experience, 3 patients suffered recurrent iliac vein thrombosis—the first due to chronic disease, the second due to an uncorrected iliac vein stenosis (early in the experience), and the third rethrombosed the vena cava because anticoagulation could not be given secondary to an intracranial malignancy.

In summary, active individuals with iliofemoral DVT have better long-term outcomes if treated with strategy of thrombus removal. If the patient has a contraindication to or failed catheter-based techniques, operative venous thrombectomy should be recommended. Since the benefit to patients is well-established, surgeons who manage patients with venous disease should include contemporary venous thrombectomy as part of their therapeutic armamentarium.

EDITOR'S COMMENT

The nicely detailed chapter by Aziz and Comerota highlights a rarely performed, but occasionally necessary procedure for potential limb salvage in the setting of extensive deep venous thrombosis (DVT). Most commonly, an

open venous thrombectomy is utilized when the patient has either failed or cannot undergo catheter-based pharmacomechanical thrombolysis for opening up the deep venous system in patients with either phlegmasia or a very large thrombus burden for which decreasing the risk of postthrombotic syndrome is the indication. Interestingly, a prospective randomized trial data support this procedure as compared with medical therapy with the endpoint of significantly reduced postthrombotic syndrome, but it is still rarely done (Plate G. Venous thrombectomy for iliofemoral vein thrombosis—10-year results of a prospective randomized study. *European J Vasc Endovasc Surg* 1997;14:367–734). The technique described is logical and clearly derived from operative experience.

General venous exposure and vascular control are well described, but whether an arteriovenous fistula should be constructed postthrombectomy is more controversial. The idea behind an arteriovenous fistula is to create a venturi flow effect and prevent blood stasis in the iliac vein segments. At our institution, we typically perform a prophylactic arteriovenous fistula more often than not. However, if the deep femoral vein is widely patent and provides a good venous inflow, we may not create an arteriovenous fistula. The use of a small prosthetic graft for an arteriovenous fistula is reasonable as is the ability to close this with a small percutaneous incision or using endovascular techniques as described by the authors. The idea to use a pedal vein catheter to allow direct heparinization infusion is a neat idea, and whether it's an improvement over systemic heparinization is not clear, but is unlikely to hurt.

Although heparin followed by warfarin anticoagulation is standard, the non-vitamin K oral antagonists are a reasonable alternative and will become more commonplace as reversal agents become available (Weitz JI, Bates SM. New anticoagulants. *J Thromb Haemost* 2005;3:1843–53.) Several are FDA-approved for treating DVT. The major bleeding complications are lower with most of these agents. If the patient has evidence of heparin-induced thrombocytopenia, these new agents offer a safe and effective alternative for long-term anticoagulation. In patients with extensive iliofemoral DVT, we typically recommend lifelong anticoagulation as the benefits generally outweigh the risk, unless they have a high bleeding risk.

One of the more difficult patient groups to treat are those who have a significant cancer burden and/or cannot be directly anticoagulated postprocedure and require open venous thrombectomy. These patients may have small amounts of heparin used locally, and generally will not increase bleeding risk. Even if the patient cannot be anticoagulated postprocedurally, it is not unreasonable to clear out the thrombus via thrombectomy, as the recurrent thrombus is often less firmly formed, and is easier with compression to allow salvage of the limb, despite rethrombosis. Frank discussion on endpoints with the patient and family is important with these difficult situations.

222 Acute Deep Venous Thrombosis: Endovascular

Moon O. Kwoun

INTRODUCTION

Approximately 600,000 cases of acute deep vein thrombosis (DVT) are diagnosed in the United States annually. Pulmonary embolization, its most serious acute complication, has a 3-month all-cause mortality of 15% to 30%, making it the third most common cardiovascular-related mortality after myocardial infarction and cerebral vascular accident.

One of the most serious, long-term sequelae of DVT is postthrombotic syndrome (PTS), affecting between 25% and 46% of individuals with DVT over a 5-year period. The symptoms are often characterized by chronic pain and swelling of the affected limb, and sometimes progressing to chronic ulcerations. The estimated annual direct care cost in the United States for patients with DVT is over $200 million. PTS impairs quality of life (QOL), as the Venous Thrombosis Outcomes cohort study clearly demonstrates, showing that the presence and severity of PTS to be the leading predictor of health-related QOL, 2 years after a DVT. The indirect cost of PTS is 2 million workdays lost annually, mainly due to chronic pain from venous claudication, as well as chronic venous ulcers and their sequelae.

Treatment to prevent pulmonary embolization, thrombus progression, and recurrence obviously remains important in the overall care of those patients who sustain venous thromboembolism (VTE). More specifically, several studies have clearly delineated the significance of proximal versus distal limb DVT, in terms of the increased risk for pulmonary embolization, decreased restoration of flow, and the higher incidence of PTS in the patients with iliofemoral thrombosis, ranging from 50% to 82%. Thus, the importance of aggressive treatment for proximal iliofemoral thrombosis will be highlighted in this chapter.

The most recent guidelines for treatment of VTE established by the American College of Chest Physicians (ACCP), in 2012, softened their

stance on treatment of DVTs in the iliofemoral veins, in contrast to previous guidelines established by the same group in 2008. Their guidelines now favor anticoagulation alone versus catheter-directed thrombolysis (CDT) or pharmacomechanical thrombolysis (PMT). Nonetheless, the Society of Interventional Radiology (SIR) and the Society for Vascular Surgery (SVS) both suggest CDT or PMT as a viable option in select patients, pointing to the growing number of studies supporting a more rapid and efficacious method of reducing thrombus burden. More recent randomized studies, evaluating the efficacy and safety of CDT and PMT, are currently underway to assess their role in patients with proximal symptomatic iliofemoral DVTs.

ETIOLOGY AND PATHOPHYSIOLOGY

Etiology

There are numerous risk factors for the development of VTE (Table 222.1), all of which stem from Virchow Triad: hypercoagulability, stasis, and endothelial injury. A single abnormality may be sufficient to induce a thrombotic event, but in the majority of cases, there is more than one defect of the triad identified. The most common site of DVT is in the legs, followed by DVTs in the pelvic veins, the vena cava, the right side of the heart, and then the arms.

TABLE 222.1 Risk Factor for Venous Thromboembolism

Plasma coagulation factors are usually in a nonactivated state. Intrinsic regulatory systems maintain a coagulation balance and prevent excessive activation. Significant abnormalities in clotting levels, mutations in intrinsic protein structure, or circulating antibodies can result in hypercoagulability, of which there are inherited or acquired forms of thrombophilia. Of the inherited type, factor V Leiden mutation is the most common. Others include factor II G20210A mutation, elevated factor VIII, protein C and S deficiencies, and hyperhomocysteinemia. Acquired hypercoagulability usually occurs with known or occult malignancies and may be a factor after recent trauma.

Stasis is a predominant factor in the development of thrombosis. The initial site for thrombus formation is the vein valve sinuses, usually due to turbulence and eddy of flow. Any condition that hampers flow, either through increased venous resistance, reduced cardiac output, diminished muscular contraction, or commonly due to immobilization, may diminish flow in the veins, allowing for thrombus formation.

Endothelial injury is probably the least important of the factors for development of thrombus. This is usually caused from direct trauma sustained to the vessel wall that leads to adherence of platelets to the vessel wall leading to a coagulation cascade. Immune complex deposition

from autoimmune disease or bacterial septicemia may also lead to an acute vasculitis, generating a venous thrombosis. Chronic vessel injury from previous DVT holds the greatest risk factor for DVT recurrence with a likelihood approaching 30% at 8 years.

Pathophysiology

The pathogenesis of PTS is complex and incompletely understood. Studies have demonstrated that an initial inflammatory response to thrombosis strongly influences thrombus resolution, organization, and subsequent wall injury. Factors that play a role include inflammatory and growth factor mediators, chemokines, extracellular matrix-derived factors, blood-borne elements, and endothelial factors. Ultimately, the result of this process is thickening of the vessel wall and reduction in compliance. Macroscopically, there is incomplete clearance of thrombus, as the inflammatory response directly damages the venous valves and alters the wall, leading to venous reflux. Existing clot burden can cause increased venous hypertension from vessel occlusion, causing further damage to venous valves distally by disrupting the calf muscle pump function. Studies have consistently found that patients with chronic venous obstruction have the most severe PTS, with occlusion of the iliofemoral segment causing the most profound morbidity. A paracrine-like scarring process in the adjacent wall and subsequent fibrosis lead to valve failure, which in turn will allow for venous hypertension. The inflammatory process also incites a localized action of leukocytes that express multiple matrix metalloproteinases (MMPs), which play a role in collagen degradation. The mechanism causing nonhealing skin ulcers is likely due to increased ambulatory venous hypertension caused by superficial and deep venous incompetence, and subsequent alteration of the skin microcirculation. Capillaries become dilated and tortuous as they respond to the increased hydrostatic pressures. They begin leaking plasma, proteins, and erythrocytes. Chronic leakage of fibrinogen leads to formation of extravascular cross-linked fibrin around capillaries, fibrin cuffs. This pericapillary protein acts as a barrier to decrease oxygen diffusion contributing to tissue hypoxia despite adequate arterial supply.

CLINICAL PRESENTATION

Clinical features of DVT can be divided into local, distant, and systemic. The classic local symptoms of the leg are swelling of the leg or along a

vein in the leg, pain with associated increased warmth, and red or blue skin discoloration on the affected leg. The more proximal and severe the thrombosis, the more pronounced the symptom and signs. Distant clinical signs are pulmonary embolism (PE) and very rarely paradoxical embolization through a congenital atrioseptal defect (ASD) or pulmonary arteriovenous malformation (AVM). The most common systemic effect is fever. Unfortunately, the diagnostic accuracy of clinical signs of DVT is <40%.

The manifestations of PTS can vary from minimal to extreme, ranging from venous varicosities, leg pain, swelling, lifestyle-limiting venous claudication, skin hyperpigmentation, to, in some cases, venous stasis ulcers.

STANDARD OF CARE FOR DEEP VENOUS THROMBOSIS

Anticoagulation and Elastic Compressive Stocking Therapy

There have been great advancement in and usage of anticoagulants in recent years. Low–molecular-weight heparins, factor Xa inhibitors, as well as the availability of direct thrombin inhibitors, are used to arrest the progression of thrombus, reduce the rate of recurrence, and aid in managing patients with a history of heparin-induced thrombocytopenia. However, anticoagulation alone has proven ineffective for clot removal in the majority of cases, with complete resolution in <10% of patients. Placebo-controlled, multicenter randomized trials, such as the SOX Trial, have failed to show the efficacy of anticoagulation in conjunction with elastic stocking therapy (even when used for 2 years) to decrease the incidence of PTS in patients with proximal DVT.

Open Vein Concept

The strategy of early thrombus removal, to reduce the incidence of PTS long term, comes from natural history studies of acute DVT, venous thrombectomy data, and studies of systemic thrombolysis and CDT.

Pooled analyses indicate that only 4% of patients treated with anticoagulation alone had significant or complete lysis, with an additional 14% having partial lysis. Most patients (82%) had either no objective phlebographic clearing or actually had extension of their thrombus. Recanalization rates in iliofemoral thromboses are much lower than

extremities with distal clot.

In a randomized, controlled study, Prandoni found that patients who had residual thrombus developed more frequent PTS at the initial 6-month follow-up. A separate, published randomized trial found that surgical venous thrombectomy with anticoagulation resulted in better venous patency and reduced PTS than when patients were treated with anticoagulation alone. In the Cochrane group analysis of 12 randomized trials, evaluating systemic thrombolysis versus anticoagulation, PTS was significantly lower in the lysis group (with a relative risk of 0.66).

Open Surgical Thrombectomy

Venous thrombectomy is effective in relieving iliofemoral obstruction and may preserve distal valvular function. In a randomized trial of patients with acute iliofemoral DVT, as well as pooled analysis, patients treated with contemporary surgical thrombectomy along with anticoagulation therapy experienced better long-term limb outcomes than patients treated with anticoagulation therapy alone. The techniques and adjuvant treatments are largely guided by case series and expert opinion rather than comparative trials. Although thrombectomy does appear to be associated with improved long-term outcomes, open thrombectomy has fallen out of favor due to excessive bleeding, morbidity, and its invasiveness, especially as the rationale for the use of modern endovascular thrombus removal therapies for DVT is now being widely accepted and trialed.

INDICATIONS AND CONTRAINDICATIONS TO THROMBOLYSIS

Because the effectiveness of endovascular therapy depends on multiple factors, including predisposing risks, symptom duration, extent of thrombus, technical approaches, and interventional success, accurate identification and timing are critical to maximize treatment benefits, while minimizing the risks to the patient.

Systemic Thrombolysis Therapy

The basic mechanism of thrombolysis is the activation of fibrin-bound plasminogen to the active enzyme plasmin, which dissolves clot. During thrombolysis, circulating Glu-plasminogen binds to fibrin and is converted to Lys-plasminogen, which has more binding sites for plasminogen

activators and is more efficiently activated to plasmin than Glu-plasminogen.

The use of systemically administered (i.e., via a peripheral intravenous line distant from the affected limb) thrombolytic agents to treat acute proximal DVT has been systematically assessed in randomized clinical trials. In patients treated with systemic thrombolysis, 45% had significant or complete clot resolution, 18% had partial clearing, and 37% failed to improve or worsened. Whereas, anticoagulation alone showed <5% complete lysis and 15% to 20% partial lysis.

By directing the lytic agent directly into the thrombus, catheter-directed lysis should improve lytic efficacy. Intrathrombus delivery naturally protects plasminogen activators from neutralization by circulating plasminogen activator inhibitor (PAI-1) and also protects the resultant active enzyme plasmin from instantaneous neutralization by circulating antiplasmins. Several studies report an initial success rate of >80%. Those with successful lytic outcome reported a significantly better health utilities index, increased physical functioning, less stigmata of chronic venous disease, less health distress, and fewer overall postthrombotic symptoms.

Who Should Be Treated?

There is a great heterogeneity in the clinical and biologic phenotypes with the patient population with DVT. Given the clinical importance of PTS to the long-term health of the patient and the invasiveness, risks, and costs of thrombolytic therapy, it is important for clinical decision making to be guided by rigorously performed randomized trials. While these studies are ongoing, we must be thoughtful to use these procedures in those patients who are most likely to benefit and least likely to be harmed.

1. Assessment of risk of bleeding

   Patients must undergo careful evaluation for factors that may increase the risk of bleeding, including recent major surgery, trauma, pregnancy, cardiopulmonary resuscitation, or other invasive procedures. Patients with lesions that may have potential for bleeding in critical areas such as the CNS will likely need to be excluded.
2. Clinical severity of the DVT

   Urgent endovascular thrombolysis is indicated to prevent life-, limb-, or organ-threatening complications of acute DVT, such as phlegmasia cerulea dolens or extensive inferior vena cava (IVC) thrombus (especially with suprarenal extension that may lead to fatal

PE or renal failure). These techniques may be the only viable option and may be necessary even when moderate risk factors for bleeding exist.

3. Anatomic extension of DVT

   Patients with iliofemoral DVT, defined as involving the iliac vein or common femoral vein, are at significantly increased risk for both PTS and recurrent VTE. Patients should be given a thorough and balanced discussion of the risks and possible benefits of nonurgent first-line endovascular thrombolytic therapy for the purpose of PTS prevention.

4. Assessment of life expectancy, functional status, and comorbidities

   Patients who are chronically unable to walk or have a very short life expectancy are less likely to benefit meaningfully for aggressive therapy to prevent PTS.

5. Patient preference

   For therapy whose benefits have not been conclusively established, it is important for the patient to receive a balanced discussion regarding the rationale, intended benefits and inconveniences, and treatment alternatives.

Successful thrombolysis of acute DVT is most likely to be achieved in patients with recently formed thrombus, of <10 to 14 days. Patients with symptoms of 14 to 28 days usually also experience significant thrombolysis, but such patients often require adjunctive iliac vein stent placement for maximum benefit of treatment.

Patients with short life expectancy, those who do not ambulate, and those with factors predisposing them to bleeding complications are poor candidates as are those fitting three subsets: (1) patients with chronic DVT (>28 days) limited to the femoropopliteal segment, since thrombolytic therapy tends to be ineffective for them; (2) patients with isolated calf vein DVT, as they tend to be less symptomatic and develop PTS less frequently; and (3) patients with asymptomatic DVT, who rarely develop PTS.

PREOPERATIVE PLANNING

Early Identification

Early identification and confirmation of VTE are vital for life- or limb-saving therapy. Past studies have demonstrated that >50% of patients with symptomatic DVT will have a PE (symptomatic or asymptomatic), and

approximately 70% of those patients with symptomatic PE will also have DVT (symptomatic or asymptomatic). The risk of early death from VTE due to either the initial acute episode or recurrent VTE is much greater after presenting with PE than with DVT, thus the treatment plan must be set in motion more rapidly and aggressively. Recurrent episodes of DVT are three times as likely to present as a PE after an initial PE than after an initial DVT.

Diagnostic Techniques for Full Assessment of Length and Location of Thrombosis

Venous Duplex

A comprehensive study utilizing real-time B-mode ultrasonography as well as color Doppler imaging, venous compression under direct visualization, assessment of venous respirophasic flow, and response to Valsalva maneuvers is widely accepted as the first-line investigation for DVT. The weighted mean sensitivity and specificity of venous ultrasonography (including all types) for the diagnosis of symptomatic proximal DVT are 97% and 94%, respectively. A negative single, complete duplex color ultrasound of the entire lower extremity to assess for suspected DVT has a negative predictive value of 99.5% (Fig. 222.1).

Specific findings include the following:

Incompressibility: A thrombosed vein does not compress.
Loss of augmentation: Loss of appropriate increased flow when the lower extremity is compressed implies an obstruction (clot) between the transducer and the compressed area.
Visualization: DVT may be directly visualized as moderately echoic to hyperechoic masses separate from anechoic fluid.
Doppler flow: Doppler color-flow imaging can depict absent or abnormal flow in an area where isoechoic clot might not be visible.
Below-the-knee thrombus: A clot below the popliteal vein level remains an elusive area in duplex scanning. It is challenging to detect, and detection is operator-dependent.

Visualization of iliac or proximal thrombus is often difficult. In the presence of thigh swelling or an abnormal common femoral vein, the central iliocaval veins may warrant evaluation by other diagnostic modalities. Interposed bowel gas may also compromise duplex ultrasonography, for which CT venogram (CTV) or MRI venous phase (MRV) has been useful adjunct.

Multidetector CTV or MRV

Either diagnostic studies are feasible second-line options or additional information is required. Studies of multidetector CTV showed that venous-phase scanning after arterial-phase scanning is feasible and possibly cost-effective. By adding the indirect CTV to standard computed tomography (CT) pulmonary arteriography for suspected PE allows for an increase of 15% to 38% in the diagnosis of VTE. CTV reliably depicts the extent of the thrombus and underlying anatomic abnormalities, and may help in defining the chronicity of the lesion. Increased attenuation of the thrombus (>60 HU) and an increased diameter of the vessel (>150% the diameter of the contralateral normal vein) are correlated with higher acuity, and may, therefore, be predictors of successful CDT (Fig. 222.2). However, CTV deals with irradiation and contrast, with its potential allergies and nephropathy. Studies in which indirect CTV was compared with venography showed 95.9% sensitivity and 95.2% specificity. The clear advantage is visualization of the entire venous system with one diagnostic study. The radiation dose, cost, and scanning time may make it prohibitive to use CT to evaluate extremity DVT alone.

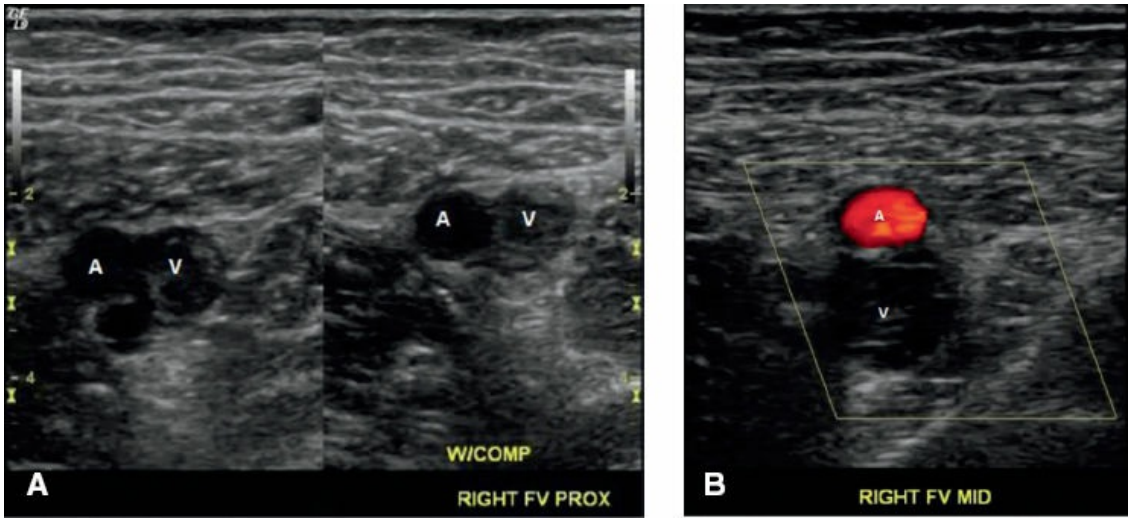

Figure 222.1. A, B. Ultrasound Duplex demonstrating occlusive thrombus of right femoral vein (FV) in 38-year-old female with acute onset of leg pain and swelling. **A.** Transverse aspect of thrombosed vein without and with compression (noncompressible). **B.** Transverse view of femoral artery and vein with color flow Doppler. No flow noted in femoral vein.

MRV (Fig. 222.3) is effective and accurate, with a sensitivity and specificity for iliac and femoral DVT 95.7% and 92.9%, respectively,

compared with venography and a 92% sensitivity in detecting isolated calf-vein thrombus. In addition, pelvic veins that are nearly impossible to visualize on ultrasound and difficult to view by other means are consistently imaged well with either CTV or MRV. However, MR tends to be subject to more artifacts that simulate vascular disease.

Figure 222.2. CT venous phase of patients with extensive IVC and iliofemoral thrombus, with associated pulmonary embolus.

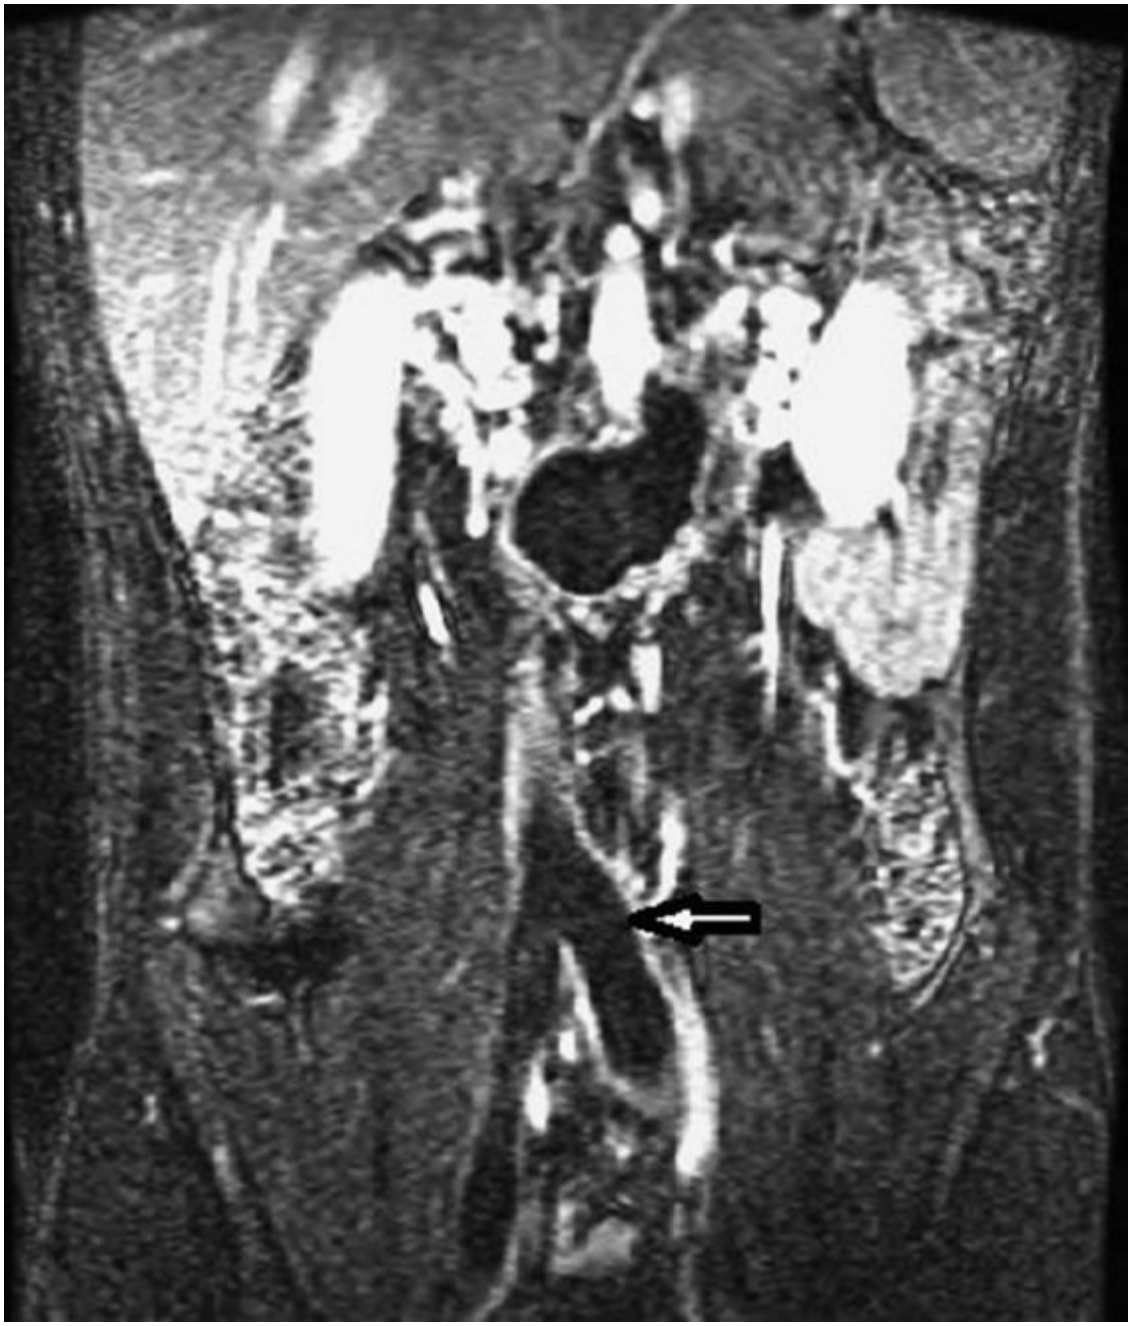

Figure 222.3. MRV illustrating extensive clot burden in the iliac veins and IVC.

Although MRV is highly sensitive and relatively specific, the cost of the examination, the technical complexity, and the lack of general availability limit the use of MRV as a screening tool. Specific indications for MRV are primarily as an alternative to CT (particularly in patients with an allergy to contrast material, in those with renal failure, and those in whom an evaluation of the iliocaval veins is required for questionable sonographic findings) or for an evaluation of the extent of a thrombus in preparation of an intervention.

Limitations include those patients with ferromagnetic implants or in those who depend on metallic devices that cannot be placed in the imaging unit. Relative contraindications include claustrophobia, extreme patient girth, certain metallic implants, or an inability to remain immobile that can produce nondiagnostic studies.

Venography

Before the 1990s, venography was considered the gold standard for evaluation of venous thrombus. With the advancement and evolution of newer and better technology, as well as issues of patient discomfort from needle puncture, the potential for infiltration of contrast agent at the injection site or allergy to the product, plus the cost in time and necessary infrastructure, its use is now relegated to specific indications. Venography remains the examination of choice when absolute determination of the presence and extent of thrombus is needed or in conjunction with a therapeutic treatment option (Fig. 222.4).

Technical limitations include poor intravenous access in the foot, poor contrast opacification of the deep veins (contrast material shunted to superficial veins, injection too slow, poor tourniquet compression), motion artifact, and excessive muscular contractions or spasms. Also, the internal iliac vein in the pelvis is not imaged, and a clot in this area cannot be excluded.

SURGICAL TECHNIQUE

Inferior Vena Cava Filter Placement

The goal of IVC filter placement is to prevent pulmonary emboli or recurrence of emboli. Indications and candidacy for IVC filter placement are beyond the scope of this chapter.

CDT has not demonstrated an added risk of PE to warrant routine filter placement. However, for patients with contraindications to pharmacologic lysis in whom a percutaneous mechanical thrombectomy device is to be used, a filter may be a useful adjunct.

Figure 222.4. Venogram of the iliofemoral demonstrating significant DVT in the left lower extremity.

SITE-SPECIFIC TREATMENT OF DEEP VENOUS THROMBOSIS

Catheter-Directed Thrombolysis (CDT)

A fibrinolytic agent, such as tissue plasminogen activator (tPA) or its derivative, is infused continuously and directly at low dose (0.5 to 1 mg/h), with an adjuvant infusion of intravenous heparin at subtherapeutic levels. The technical aspects, as with any interventional procedures, involve remote location access either from a patent ipsilateral popliteal vein with the patient in a prone position or from the contralateral limb. Maneuvering and positioning of a thrombolytic catheter into the proximal segment of the

clot burden is required to allow for maximal infusion of the lytic drug for several hours, with postprocedure evaluation and care, usually in the intensive care unit. We typically utilize a Uni*fuse infusion catheter (Angiodynamics) (Fig. 222.5) in a majority of our directed lysis cases, primarily due to its ease of use, uniformity of lytic distribution, and compatibility with a 0.035 system. Repeat venography is performed every 12 to 24 hours to assess for complete lysis.

The theoretical advantage of using image-guided, catheter-directed, intrathrombus drug delivery is recognized as potential avenue to safely and efficiently lysis of thrombus with (1) an ability to achieve a high intrathrombus drug concentration and to avoid bypass of the drug around the occluded venous segments; (2) the ability to reduce thrombolytic agent dose, treatment time, hospital resource utilization, and bleeding complications by achieving more efficient thrombolysis; and (3) an ability to prevent recurrent DVT episodes by concomitantly using adjunctive catheter-based techniques, such as stents, to treat anatomic venous abnormalities. The significant disadvantage is the need for a prolonged ICU stay during infusion, often ranging from 36 to 72 hours. This infusion technique may become costly if the infusion time extends into days. Bleeding complications continue to be a major concern; therefore, strict protocols and laboratory evaluations must be maintained and monitored to minimize these risks.

Figure 222.5. Uni*fuse thrombolysis catheter with occluding ball wire in place.

Mechanical Thrombectomy (MT)

The Trerotola Arrow is a catheter-based rotational fragmentation cage that is pulled through the vein as it macerates and strips the thrombus from the vein walls. The technical success has been reported to approach 99%, but also has an increased chance for pulmonary embolization without an adjunct IVC filter in place. Vessel wall damage has also been identified

with this and similar devices, such as the Amplatz thrombectomy device, that may attribute to potential complications in the future.

This technique has largely grown out of favor due to the significant number of complications, including an increased risk of embolization, and largely replaced by a pharmacomechanical technique.

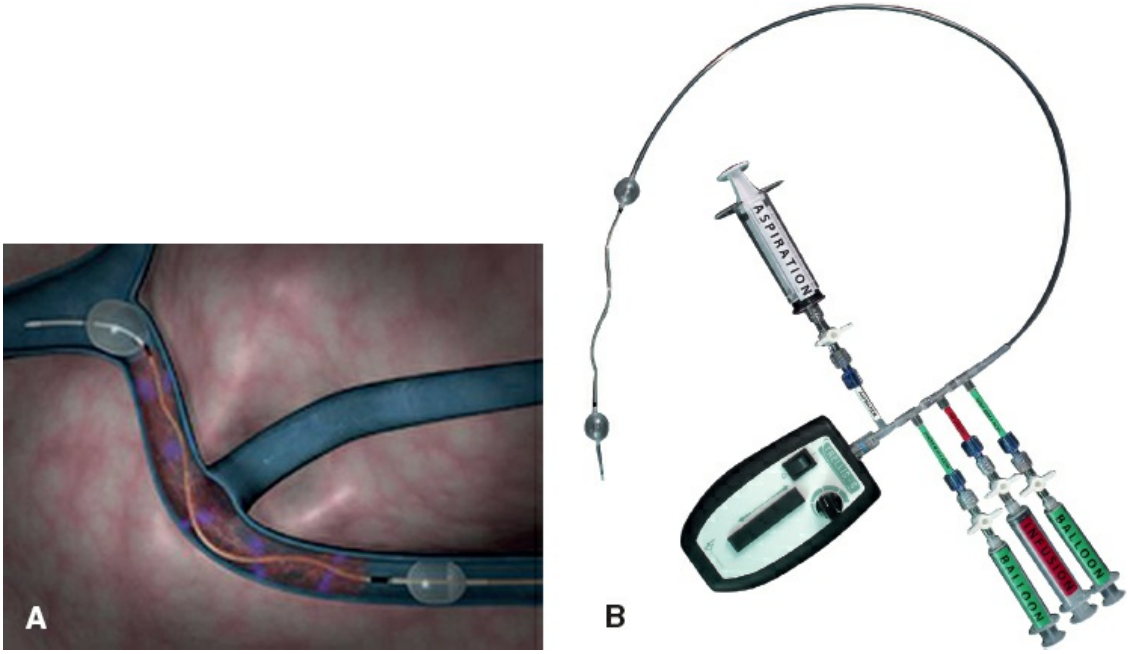

Figure 222.6. A, B. Trellis-8 peripheral infusion system for single use treatment of DVT. (Courtesy of Covidien.)

Pharmacomechanical Thrombolysis (PMT)

As the most effective modality for endovascular thrombus removal, it utilizes the combination of intrathrombus drug delivery with the use of percutaneous mechanical thrombectomy. Various devices have been manufactured and marketed, with new products currently undergoing clinical trials.

Isolated Segmental Pharmacomechanical Thrombolysis

The Trellis device (TPM) is a single-use catheter that features a multilumen catheter with two occluding balloons and a dispersion wire attached to the drive unit (Fig. 222.6). The device disintegrates the thrombus with a sinusoidal Nitinol wire rotating at high speed (1,500 revs/min) between the two occlusion balloons, 15 to 30 cm apart, in a zone where the tPA is injected (Trellis system: Bacchus Vascular). The Trellis system is activated for periods of 10 to 15 minutes, interspersed with infusions of 5 to 10 mg of tPA (1 mg/min and up to 10 mg) followed by

manual thromboaspiration. An auto-expanding stent may be inserted if any underlying anomaly is discovered. An optional IVC filter is not always inserted unless there is a PE or extensive clot in the vena cava. The initial reports through the Galway Trellis Experience, reported by O'Sullivan 2007, demonstrated in 36 patients presenting with acute DVT, reporting 100% technical success with 96% clearance of at least 50% of the clot burden, effectiveness achieved in <2 hours, and primary permeability after 2 days of 85%. No bleeding was observed with his experience (Fig. 222.7).

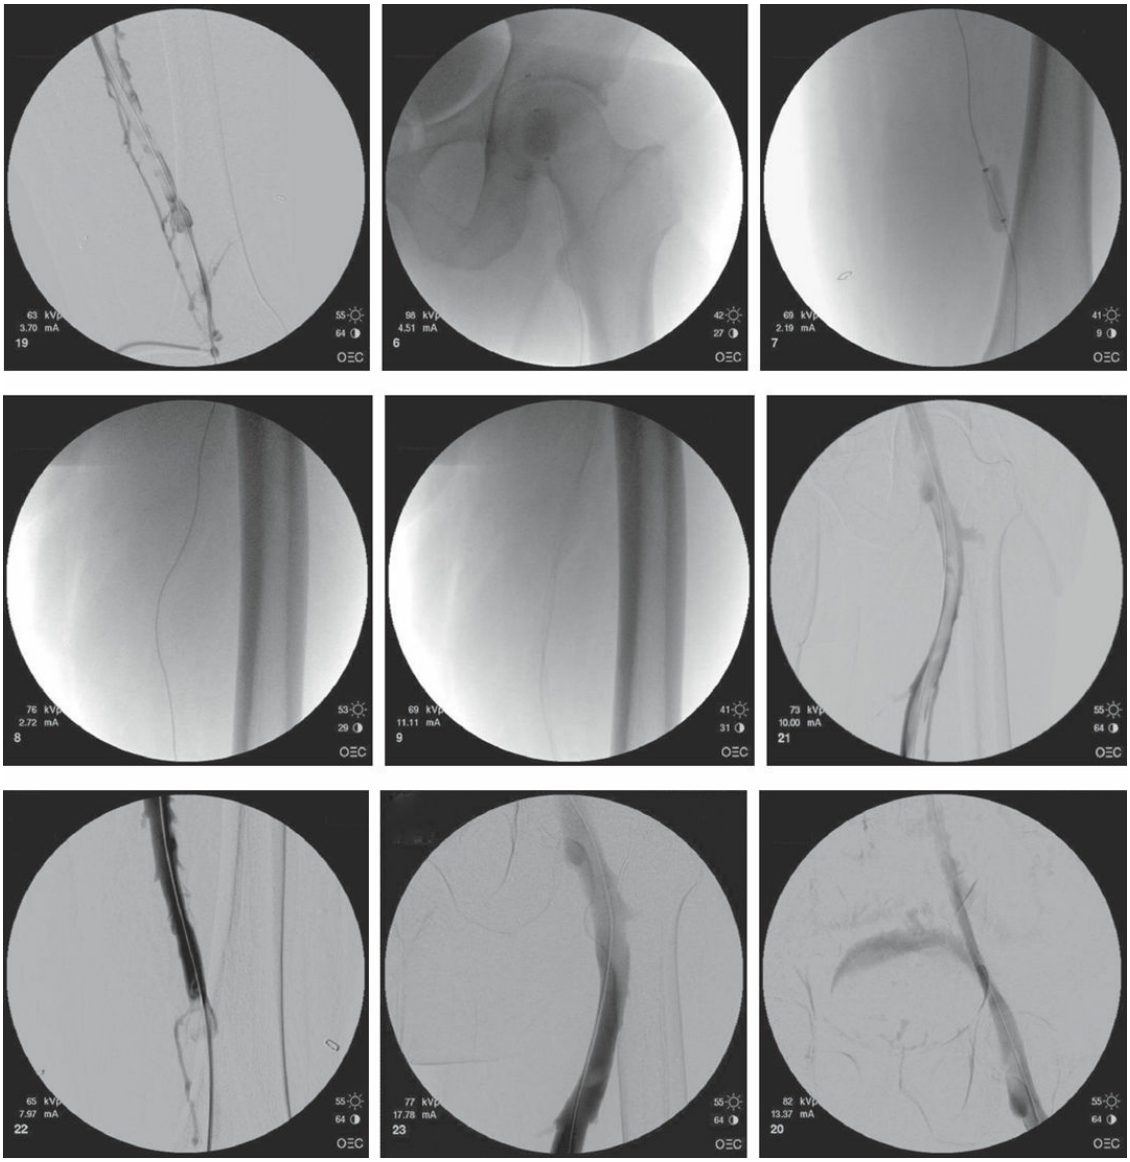

Figure 222.7. Case of a symptomatic DVT in left lower extremity. Top row, from left to right: venogram showing a thrombosed segment of the venous system; inflated proximal occluding balloon; inflated distal occluding balloon. Middle row, from left to right: Trellis dispersion wire within the balloon catheter; sine wave of the Trellis wire; SFV during clot dispersion and aspiration of the remnant material through the Trellis catheter. Bottom row, from left to right: SFV after mechanical thrombectomy; CFV after mechanical thrombectomy.

"Rheolytic" instruments can also be used (Angiojet; Possis; Hydroliser; Cordis, Oasis Thrombectomy System Boston Scientific) (Fig. 222.8). With the "powerpulse" technique, the thrombus is initially sprayed with fibrinolytic agent, then after an appropriate time for the tPA to interact with the thrombus, very high velocity jets (400 km/h) of saline are applied,

thereby creating a depression by way of a Venturi effect, so that the fragmented thrombotic material can be aspirated. The device does not come in contact with the vessel wall, but there is theoretical risk of hemolysis. The results of 160 patients from the PEARL register showed that lysis was achieved in 93% of segments treated, achieved in almost 100% of cases in under 48 hours, and in two thirds of cases, in under 6 hours. Major bleeds are estimated to occur in 2% to 4% of patients receiving pharmacomechanical catheter-directed thrombolysis (PCDT) (Fig. 222.9).

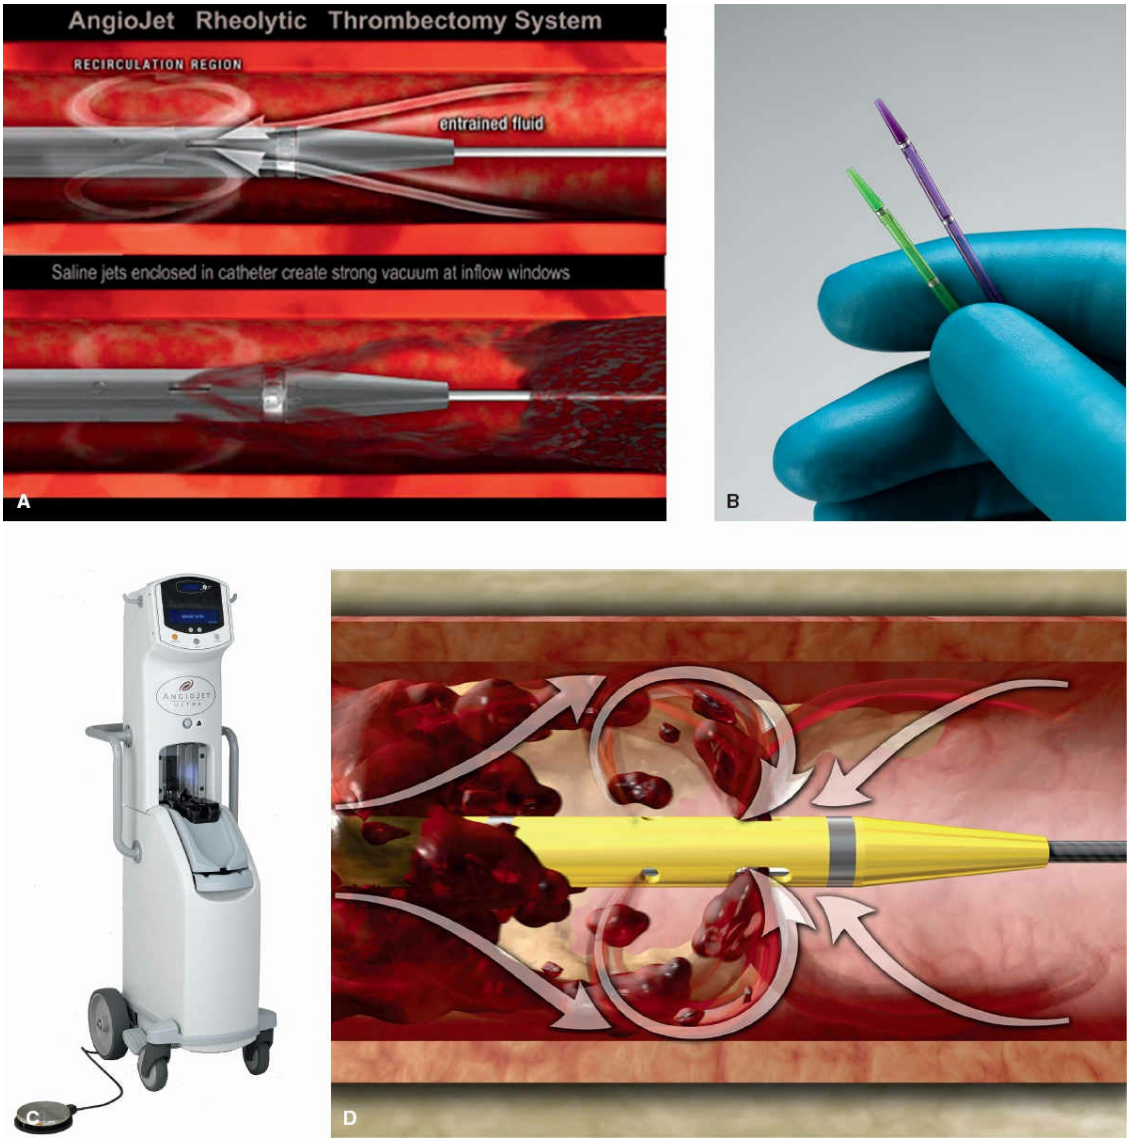

Figure 222.8. **A.** Angiojet rheolytic thrombectomy system. **B.** Various tips utilized for the pulse power spray technique. **C.** Drive unit with single use pump set. **D.** Active jet of saline and aspiration to retrieve thrombus. (Courtesy of Boston Scientific.)

Another technique, described as a "rapid lysis technique," utilizes the rotation of an angled 8-Fr hockey stick angled catheter with the Angiojet protruding from its end, and with the outflow set open. By spiralling the catheter and Angiojet in tandem as there is gentle retraction from central to peripheral, there is a larger area of potential clot clearance. Because the vacuum phenomenon is active, the possibility of embolization is minimized.

Finally, the concept based on boosting the effectiveness of the thrombolytic drug with ultrasound (Ekos Endowave; Ekos Corporation, Omniwave; OmniSonics Corp) (Fig. 222.10) comes in the form of a triple

lumen catheter with multiple ultrasonic transducers that emit high-frequency, low-energy ultrasound that destroys the strands of fibrin of the thrombus, thereby helping to expose the plasminogen receptors to the locally injected fibrinolytic drug. There is no mechanical effect, and the infusion time will be longer. The fibrinolytic drug used is rtPA at a dose of 2 mg/h for 5 hours, then 1 mg/h up to a maximum of 20 mg. Its major drawbacks include longer initial procedure time and expense primarily due to device cost.

Adjunctive Use of Venous Stents

There is an intermediate recommendation to use self-expanding metallic stents for the treatment of chronic iliocaval compression or obstructive lesions discovered during removal, and is considered a grade 1C recommendation, where the benefit to risk ratio is clear, but the quality of evidence is low.

Figure 222.9. Angiojet treatment.

POSTOPERATIVE CARE

Complications and Their Management

Major bleeding is the most frequent major complication of endovascular DVT thrombus removal. The bleeding risk is almost always dependent on duration and concentration of the treatment and medications, respectively. In patients undergoing CDT, major bleeding risk, in a prospective registry, was observed in 11.4% of patients, a very low 0.4% suffering intracranial bleeding. More recent series and multicenter RCT utilizing low-dose rtPA have demonstrated a much lower rate of bleeding at 3%. Venous access with ultrasound guidance and use of micropuncture systems (Fig. 222.11) should help contribute to minimizing local trauma during the access procedure. Although there is no conclusive evidence to support the

relationship between fibrinogen levels and bleeding, the majority opinion is that serial monitoring of fibrinogen levels during venous CDT may help prevent complications. Levels at or below 150 mg/dL demonstrated a significantly higher rate of major bleeding, leading to extended or unexpected hospitalization, surgery, or blood transfusions.

Complete Lysis Versus Partial Clearance

Success rates with catheter-directed PMT vary depending on the age of the thrombus and the proximity to the IVC. Success with this technique in acute iliofemoral venous thrombosis has been reported to be 80% to 85%, with 1-year patency at 60% to 65%. Major bleeding complication rates vary from 3% to 11%; most bleeding occurs at the puncture site.

Large observational studies have underscored the importance of recurrent DVT being associated with severe PTS. It has also been shown that patients with residual venous thrombus and increasing thrombus activity have a significant rate of recurrence. Aziz et al. reported that recurrent DVT following CDT correlated with the amount of residual thrombus at the end of their initial lysis. Failures were predicted with <50% lysis or malignant disease.

The SIR has graded procedural success in relation to luminal patency:

Grade 1 SIR thrombolysis – <50% thrombus removal
Grade 2 SIR thrombolysis – 50% to 95% thrombus removal
Grade 3 SIR thrombolysis – >95%

The Thrombus Obliteration by Rapid Percutaneous Endovenous Intervention in Deep Venous Occlusion (TORPEDO) study, a randomized trial, compared anticoagulation alone versus pharmacomechanical treatment: a combination of mechanical thrombectomy, angioplasty, stenting, and rtPA. While it did not use validated measurements to define the extent of patient suffering, it revealed a significant reduction in the incidence of cases of weak or moderate PTS after 6 months, when compared to the traditional treatment (3.4% vs. 27.2%). Even more compelling was that the recurrent DVT developed in 2.3% of the endovascular patients versus 14.8% of the control patients (P = 0.003), without an increase in the risk of hemorrhage, which was estimated to be 2%.

TABLE 222.2 Villalta Scale

Symptoms/Clinical Signs	None	Mild	Moderate	Severe
Symptoms				
Pain	0 points	1 point	2 points	3 points
Cramps	0 points	1 point	2 points	3 points

Venous ectasia	0 points	1 point	2 points	3 points
Pain on calf compression	0 points	1 point	2 points	3 points
Venous ulcer	Absent			Present

PTS, postthrombotic syndrome.

OUTCOMES

Kahn analysis showed that the strongest predictor of PTS within 2 years' follow-up is the severity of residual venous symptoms and signs 1 month after the diagnosis of the DVT. About 3% of patients develop severe postthrombotic symptoms, including venous stasis ulcers. Quite interestingly, in their findings, factor V Leiden and prothrombin mutations seemed to protect against the PTS.

Ultimately, we must gauge the success of our treatments by looking at the long-term sequelae of PTS, which can be validated by the Villalta PTS scale (Table 222.2), and endorsed by the International Society of Thrombosis and Hemostasis or the VSCS scale. The Villalta Scale incorporates patient self-assessment of five common symptoms of PTS along with a blinded clinician's assessment of six common PTS signs on physical examination. Secondary outcomes may be assessed, and include venous disease-specific and generic QOL, using the Venous Insufficiency Epidemiological and Economic Study-QOL and SF-36 measures.

Upcoming Trials

The National Heart, Lung, and Blood Institute is sponsoring an "Acute Venous Thrombosis: Thrombus Removal with Adjunctive Catheter-Directed Thrombolysis (ATTRACT) Trial," with a 2016 target completion date. It is a randomized, double-blind, multicenter study with two parallel arms. Carried out in 60 centers throughout North America on 692 patients

with symptomatic DVT, patients will receive either pharmacomechanical treatment combined with standard traditional treatment or the standard traditional treatment. The endovascular arm use either rtPA alone at a dose of 0.01 mg/kg per hour for a maximum of 24 hours with a maximum of 3 mg, or rtPA delivered in one-spot via Trellis system or AngioJet, with up to a maximum of 25 mg administered. The study is to ascertain whether using pharmacomechanical techniques might reduce the occurrence of PTS by a third after 2 years of follow-up. PTS is assessed every 6 months against the Villalta scale, quantifying quality of life, symptom relief cost, and safety.

SUMMARY

Thrombus recurrence and postthrombotic syndrome are critical factors to consider when treating an acute proximal DVT. Despite the guidelines presented by the ACCP in 2012, where CDT and PMT are more secondary treatment options, the benefit of early clot removal via endovascular means, when done safely and efficiently, has become apparent. The ATTRACT study should provide the necessary information to qualify the safety and efficacy of PMT. By utilizing these newer techniques, the systemic circulation of the lytic agent can be greatly diminished, thus lowering the bleeding complications of nondirected therapy and allow for a speedier, and more effective, recovery. This evolution in our approach to treat extensive DVT, from catheter-directed lysis to a pharmacomechanical one, will allow for early restoration of patency in these veins, thus reducing the incidence of PTS, and recurrence, and improving overall QOL.

EDITOR'S COMMENT

The endovascular management for acute deep vein thrombosis (DVT), sometimes called pharmacomechanical thrombolysis (PMT), is now much more commonplace, although it is still controversial based on the current 2012 *Chest* guidelines. The basics of DVT treatment are well stated in this chapter. As detailed by Dr. Kwoun, anticoagulation, ambulation, compression, and assessment for risk factors for recurrence are the cornerstones of DVT therapy. Herein, the authors nicely detail aspects of DVT pathophysiology with regard to the inflammatory vicious cycle. It is well known that inflammation can both promulgate DVT, and that DVT itself is an inflammatory nidus. Indeed, the DVT sets up an inflammatory response for which the vein wall is injured and the thrombus must resolve via thrombolysis, fibrosis, and neovascularization (Wakefield TW, Myers DD, Henke PK. Mechanisms of venous thrombosis and resolution. *Arterioscler Thromb Vasc Biol* 2008;28:387–91). It is the extent to which the body naturally dissolves (lyses) the clot that directly portends whether a venous obstruction remains, and if so, increases the risk of postthrombotic syndrome. Endovascular methods to remove the DVT may thus

decrease this sequlae.

Hypercoagulable states are often evaluated for, but the diagnostic yield is low. Regardless, most patients with an extensive DVT or one of idiopathic nature support lifelong anticoagulation. The patient's duration of therapy can be modified by two things: first, if persistent "clot" is present on duplex ultrasonography of the veins affected, and second, persistent elevation of d-Dimer. For example, if d-Dimer is elevated 1 month after ceasing 3 months of anticoagulation, then they should be restarted and continue on anticoagulation indefinitely (Palareti G, Cosmi B, Legnani C, et al. D-dimer testing to determine the duration of anticoagulation therapy. *N Engl J Med* 2006;355:1780–9). If the d-Dimer value is in the normal range, the patient can usually safely stop anticoagulation. It is important to remember in patients who cannot undergo PMT that extended use of low–molecular-weight heparin (LMWH) with compression significantly decreases risk of PTS, as compared with standard oral anticoagulation (Hull RD, Pineo GF, Brant R, et al. Home therapy of venous thrombosis with long-term LMWH versus usual care: patient satisfaction and post-thrombotic syndrome. *Am J Med* 2009;122:762–9 e763). It is likely that LMWH confers a distinct advantage over coumadin with anti-inflammatory and pro-thrombus resolution activities. It may also be that LMWH enhances endothelial recovery after thrombus juxtaposition with the vein wall (Moaveni DK, Lynch EM, Luke C, et al. Vein wall re-endothelialization after deep vein thrombosis is improved with low-molecular-weight heparin. *J Vasc Surg* 2008;47:616–24).

The use of the techniques described in this chapter is fairly well established and for which numerous devices are detailed. Clinically, whether aggressive endovascular removal of the DVT decreases incident postthrombotic syndrome is beginning to be answered from trials. For example, the CaVenT trial suggested a modest benefit of aggressive endoluminal techniques to clear iliofemoral thrombosis over standard medical therapy (Enden T, Haig Y, Klow NE, et al. Long-term outcome after additional catheter-directed thrombolysis versus standard treatment for acute iliofemoral deep vein thrombosis (the cavent study): a randomised controlled trial. *Lancet.* 2012;379:31–8). However, the larger ATTRACT trial will answer this question and hopefully suggest patients who are best treated with PMT as compared with those who are best treated with medical therapy.

One particularly vexing problem is DVT age determination and its relation to the effectiveness of PMT. The older the DVT, the less successful the clearance. For example, a patient presents with an apparent acute DVT by history, but is actually older and more fibrotic, and not able to be cleared with PMT. In other words, the thrombus age is imprecisely known and methods to define this are not widely available in humans. The use of MR scanning may be beneficial as suggested by experimental data (Saha P, Andia ME, Modarai B, et al. Magnetic resonance t1 relaxation time of venous thrombus is determined by iron processing and predicts susceptibility to lysis. *Circulation* 2013;128:729–36)

and enhanced ultrasound diagnostic techniques or PET scanning may also be helpful. Further research will define this critical parameter to direct patients to the best therapeutic option.

Peter Henke

223 Chronic Deep Vein Thrombosis/Postthrombotic Syndrome: Open and Endovascular Treatment

Peter Gloviczki and Arjun Jayaraj

INTRODUCTION

Reconstruction of the obstructed iliofemoral vein or the inferior vena cava (IVC) may be required in patients with chronic venous insufficiency (CVI), who present with primary nonthrombotic iliac vein obstruction (NIVO) or with secondary, postthrombotic obstruction. Venous reconstruction may also be beneficial in those patients who undergo excision of primary or metastatic malignant tumors invading large veins like the IVC or the iliac veins and in those with acute traumatic or iatrogenic venous injury.

Chronic NIVO-like May–Thurner syndrome (MTS) is responsible for the symptoms in up to one third of the patients with CVI. Endovascular treatment for iliocaval obstruction has progressed rapidly, and today venous stenting is the primary choice for treatment of benign iliac, iliofemoral or iliocaval venous occlusions in patients who fail conservative compression therapy. Venous stenting is used for patients with malignancy only in those cases when excision of the tumor is not possible and the goal of therapy is palliation. Hybrid procedures are performed occasionally when femoral vein exposure and endophlebectomy are added to improve inflow for venous stenting. In the last two decades, results of open surgical reconstructions have improved, and symptomatic patients who are not candidates for or who failed endovascular reconstructions can be treated with venous bypasses to relieve venous outflow obstruction. A thorough preoperative evaluation to identify significant venous outflow obstruction and establish adequate inflow and outflow to the bypass in these patients is essential.

Etiology

Chronic deep venous obstruction is usually the result of a previous acute deep venous thrombosis (DVT) leading to postthrombotic syndrome (PTS). PTS develops in 20% to 50% of patients who develop DVT. MTS where compression of the left common iliac vein (CIV) by the overriding right common iliac artery occurs has been recognized now as the most frequent cause of left iliofemoral venous thrombosis. May and Thurner observed secondary changes, such as an intraluminal web or “spur,” in the proximal left CIV in 20% of 430 autopsies. While MTS is the most frequent form of NIVO, obstruction can also occur in the right CIV or in one of the external iliac veins (EIVs), although these conditions are less frequent. Acute symptoms generally are more common (73%) than a chronic presentation with MTS. Compression of the left iliac vein without coexistent DVT is an important etiology of symptomatic chronic venous outflow obstruction. In a series of 982 patients who underwent venous stenting, 53% of the femoro-ilio-caval lesions were of primary and not postthrombotic etiology.

Iliofemoral or IVC obstruction can also be caused by retroperitoneal fibrosis; iatrogenic, blunt, or penetrating trauma; congenital venous anomalies; or benign or malignant tumors (Fig. 223.1). The most frequent primary malignant tumor originating from large veins is primary venous leiomyosarcoma; secondary tumors invading the vena cava include adenocarcinoma or liposarcoma. Renal carcinoma may extend into the IVC, and the tumor thrombus in some patients may reach all the way up into the right atrium. Rarely, congenital suprarenal IVC occlusion can occur due to webs or caval coarctation that may also present with associated hepatic vein occlusion (Budd–Chiari syndrome).

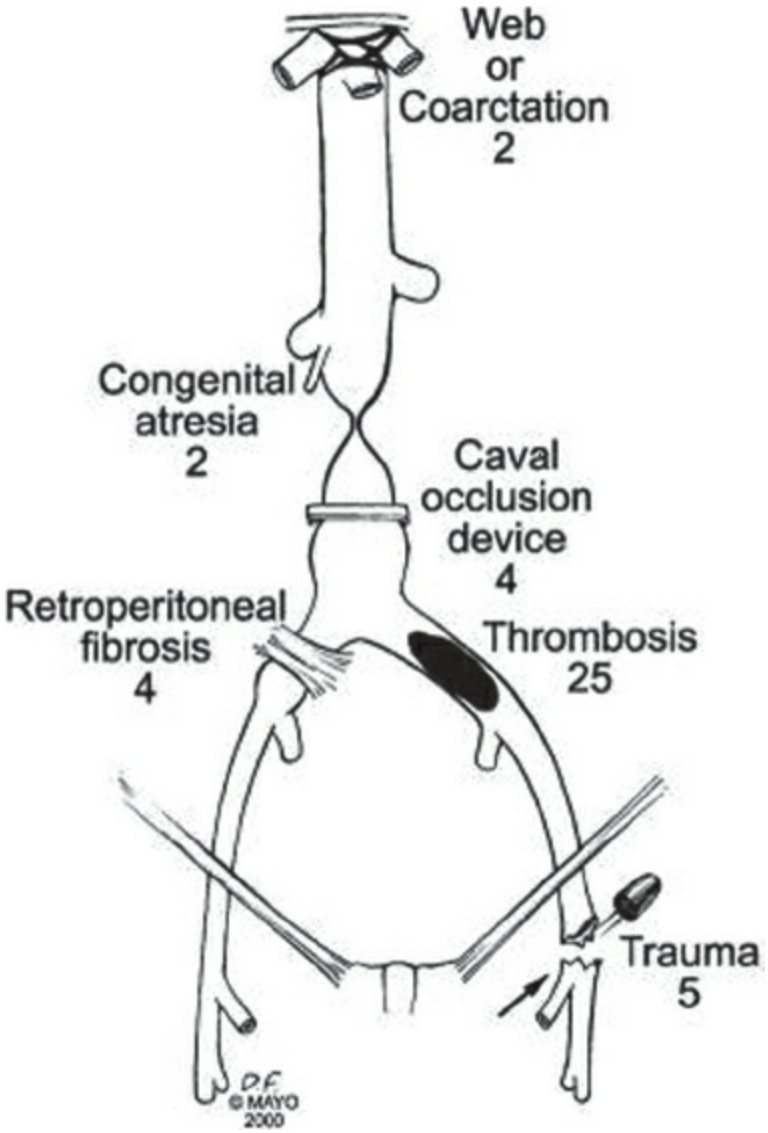

Figure 223.1. Cause of venous occlusion in 42 patients who underwent open surgical reconstruction for nonmalignant venous occlusive disease. (Reprinted with permission from the Mayo Foundation.)

Pathophysiology

During the acute phase of DVT, the thrombus in the vein activates the inflammatory cascade, which in turn promotes partial lysis of the thrombus and leads to recanalization. However, these processes are also responsible for damage to the vein wall and to the venous valves, leading to chronic obstruction and valvular incompetence. If collateral venous circulation in iliofemoral venous occlusion is inadequate, ambulatory venous hypertension develops due to a functional venous outflow obstruction. In PTS, deep reflux and obstruction of multiple venous segments often coexist.

Diagnosis

Patients with chronic iliofemoral vein or iliocaval obstruction present with signs and symptoms of CVI. These include pelvic, thigh, or hip pain that frequently develops after exercise (venous claudication), swelling, varicosity, pigmentation, skin, and subcutaneous inflammatory changes (eczema, induration, lipodermatosclerosis, dermatitis, and venous ulcerations) of the affected limb. In the Mayo Clinic experience with 64 open venous reconstructions, performed in 60 patients with benign disease, mean duration of symptoms was 6 years; 94% of patients presented with swelling, 90% with venous claudication, and 84% with both. Leg ulcers were present in 12 patients (19%) and 12% had healed ulcerations.

Preoperative evaluation of CVI must focus on two major issues: confirming the cause of chronic iliofemoral venous occlusion and establishing the presence and significance of poor venous outflow due to venous obstruction. In addition, careful attention must be paid to inflow and outflow that would determine outcome of any intervention, open or endovascular. The physician must exclude any abdominal or pelvic malignancy and consider MTS or other NIVOs as the cause of benign left iliac vein thrombosis.

Venous duplex scanning should be performed in all patients with symptoms of CVI to help define the location, cause, and severity of the underlying problem. Duplex scanning will diagnose both valvular incompetence and venous obstruction. Typical appearance of a postthrombotic vein at duplex scanning is that of a thickened, hardly compressible vessel with damaged, incompetent valves and variable degrees of venous flow due to partial recanalization. Obesity and bowel gas may prevent good visualization of the common hepatic veins and the IVC with ultrasound.

Air or strain gauge plethysmography is designed to evaluate the global leg hemodynamics by measuring reflux, obstruction, and calf pump function. Decreased vein wall compliance in patients with PTS may interfere with proper evaluation of calf muscle pump function. Unfortunately, the site and the level of reflux cannot be localized with plethysmography, and this test is absent today from many vascular laboratories. Plethysmography, however, is suitable to confirm functional venous outflow obstruction.

Magnetic resonance (MR) imaging, MR venography, and computed tomographic (CT) venography will identify any obstructing mass or tumor,

and provide sufficient information in most patients about venous anatomy, collateral circulation, occlusion, or stenosis. Contrast venography is useful in some patients before open surgical deep venous reconstructions, and it is routinely done in those who have endovascular intervention. Ascending venography provides a “road map” of the deep veins of the limb; it defines the sites of obstruction, images the collateral venous circulation, and the patterns of preferential flow. This is typically done by cannulation of the dorsal vein of the foot to assess the veins of the leg and through separate access of the common femoral vein (CFV) to assess the iliocaval system. Descending venography under fluoroscopy permits evaluation of sites of reflux in the saphenous and deep system. Contrast venography is combined with direct venous pressure measurement to document a pressure difference between the femoral vein and the vena cava. A resting pressure differential of 5 mm Hg or greater is considered evidence for significant obstruction. A lower pressure at rest but an increase to 10 mm Hg after exercise is also a sign of functional obstruction. Exercise consists of 10 dorsiflexions of the ankle or 20 isometric contractions of the calf muscle. Ambulatory venous pressure measurement by venous cannulation in the foot will help quantify venous hypertension and guide follow-up post intervention. Intravascular ultrasound (IVUS) is used frequently today to assess the degree of iliac vein stenosis before stenting, but in patients with complete venous occlusions IVUS has a limited role.

TREATMENT

Conservative Management

Symptoms of chronic deep venous obstruction should be first treated with frequent leg elevation, graduated compression stockings (30 to 40 mm Hg), and local wound care of venous ulcerations, if there are any. Compression garments result in variable degrees of success and mandate strict patients’ compliance, which in a hot climate can be both distressing and difficult. The benefits of graduated compression stockings reside in their theoretic effects on venous hemodynamics, skin circulation, and calf muscle pump function. Patients with persistent disabling symptoms, such as venous claudication, severe swelling, and nonhealing or recurrent ulcers not responding to conservative treatment, should be considered for endovascular or open surgical reconstruction.

Endovascular Treatment

Iliac or iliocaval stenting has become the primary treatment for chronic nonmalignant venous occlusions. The approach is most frequently through ultrasound-guided percutaneous access of the common femoral or mid-thigh femoral vein. A retrograde access through the right internal jugular vein is also used if the obstruction cannot be crossed from the femoral access. Access is obtained with an 18-gauge needle (some use a 21-gauge micropuncture set first) and a floppy tip or J tip 0.35-in guidewire. A 6-Fr short sheath (11 cm) is placed first and a venogram is performed to delineate anatomy if not done previously and provided the patient does not have significant renal dysfunction. The sheath is then upsized to a 9- to 11-Fr short sheath for the remainder of the procedure, depending on the size of the stent used. An IVUS exam is then carried out to assess diameters and luminal surface areas in the CFV, EIV, and CIV. Using planimetry, the normal luminal cut off areas are 125 mm^2, 150 mm^2, and 200 mm^2 respectively for the CFV, EIV, and CIV respectively. Predilation of any areas of narrowing is performed by using a 14- to 18-mm angioplasty balloon, and stent sizes of 14 mm for the external iliac vein and 16 to 18 mm for the CIVs are selected. Our preference is for the self-expanding Wall stents (Boston Scientific, Marlborough, MA) (Fig. 223.2A–D). Raju et al. uses extra support of the iliac confluence by Gianturco stents (Cook Medical, Bloomington, IN). The advantage of the Gianturco stent in addition to radial strength is the wide distance between the stent struts, preventing development of a continuous pseudointima, that favors thrombosis of the contralateral CIV, if the stent extends too much into the IVC. Any residual narrowing on IVUS interrogation is overcome by post dilation using an 18-mm or 20-mm angioplasty balloon, but excessive overdilatation and stents beyond 18 mm of diameter should be done selectively.

Kurlinksky et al. reported the Mayo Clinic experience with stenting 91 postthrombotic iliac or iliofemoral veins. Primary, primary-assisted, and secondary patencies at 3 years were 71%, 90%, and 95%, respectively. In the largest study from a single institution, 6-year follow-up data of 982 stents placed by Neglen et al. for chronic nonmalignant obstructive lesions of the femoro-ilio-caval vein demonstrated a primary, primary-assisted, and secondary patency rates of 79%, 100%, and 100% in nonthrombotic disease and 57%, 80%, and 86% in postthrombotic disease, respectively. Venous stenting was performed with no mortality and low morbidity. Risk factors for restenosis/stent occlusion after venous stenting were the

presence and severity of thrombotic disease; thrombophilia by itself was not a risk factor.

Hybrid Treatment

Patients with CFV, iliac, or iliocaval obstruction are candidates. Venous stents are combined with femoral vein endophlebectomy and patch angioplasty to improve inflow to the stents. The stent may be placed only proximal to the patch, or it can also be placed into the venous patch. In our practice, we perform these procedures rarely, as the last resort. The groups of Comerota and Wittens reported improved patency when a femoral arteriovenous fistula was used for this procedure.

Open Surgical Treatment

Patients who are not candidates or who failed endovascular reconstructions can be treated with venous bypasses to relieve symptomatic venous outflow obstruction. Venous reconstruction is also performed in those patients who undergo excision of malignant tumors invading the vena cava or iliac veins.

Crossover Saphenous Vein Transposition (Palma Procedure)

Patients with symptomatic unilateral iliac vein obstruction are candidates for saphenous vein transposition (Palma procedure) (Fig. 223.3). With this technique, the contralateral saphenous vein is used for a crossover bypass to decompress venous congestion in the affected limb. The CFV on the affected side is exposed first through a 6- to 8-cm long longitudinal groin incision. The collateral veins should be preserved if possible. The great saphenous vein of the contralateral leg is dissected through a 3- to 5-cm incision made in the groin crease, starting just medial to the femoral artery pulse. Tributaries of the saphenous vein are ligated and divided and the saphenous vein is mobilized in a length of about 10 to 12 cm. A short second upper-thigh incision is made to dissect a 20- to 25-cm long portion of the saphenous vein. Distally the vein is ligated, and proximal to the ligature it is divided and pulled up to the groin incision. Alternatively, endoscopic harvesting of the saphenous vein can also be performed, but the vein proximally should not be divided. It is essential to free up the saphenofemoral junction completely and dissect at least the anterior wall of the CFV around the saphenous vein so that there is no kink or buckle when the saphenous vein is pulled into the suprapubic tunnel. In some

patients with a low saphenofemoral junction, a kink is unavoidable. Excision of the saphenous vein with a 2-mm cuff from the CFV and reanastomosis to the femoral vein with running 6-0 polypropylene suture, after turning the junction upward 180 degrees, is the way to solve this problem. Before tunneling, a small Satinsky clamp is placed on the CFV to allow distention of the saphenous vein and the saphenofemoral junction under gentle pressure using heparinized papaverine-saline solution. The vein is then tunneled subcutaneously in the suprapubic space over to the contralateral side using an aortic clamp to ensure a large tunnel without any constriction of the graft whatsoever. Saphenous vein graft in morbidly obese patients is not recommended because of the high chance of external compression of the vein. The CFV is cross-clamped with small vascular clamps or bulldogs and the vein is opened longitudinally in a length of about 2 cm. The anastomosis between the saphenous vein and the femoral vein is performed with running 6-0 polypropylene suture. A vein at least 5 mm in diameter is required to achieve a satisfactory result and provide high venous flow to treat the basic problem in these patients, which is poor venous emptying. For a smaller vein, a temporary arteriovenous fistula (AVF) can be added between the superficial femoral artery and the saphenous or CFV using a 4- to 5-mm polytetrafluoroethylene (PTFE) graft or a large tributary of the saphenous vein. This fistula must be taken down at 3 months to enjoy the full benefit of the saphenous bypass. Endovascular occlusion of the fistula with coils or a plug should be considered. The Palma procedure, however, should not be performed with veins 4 mm or smaller.

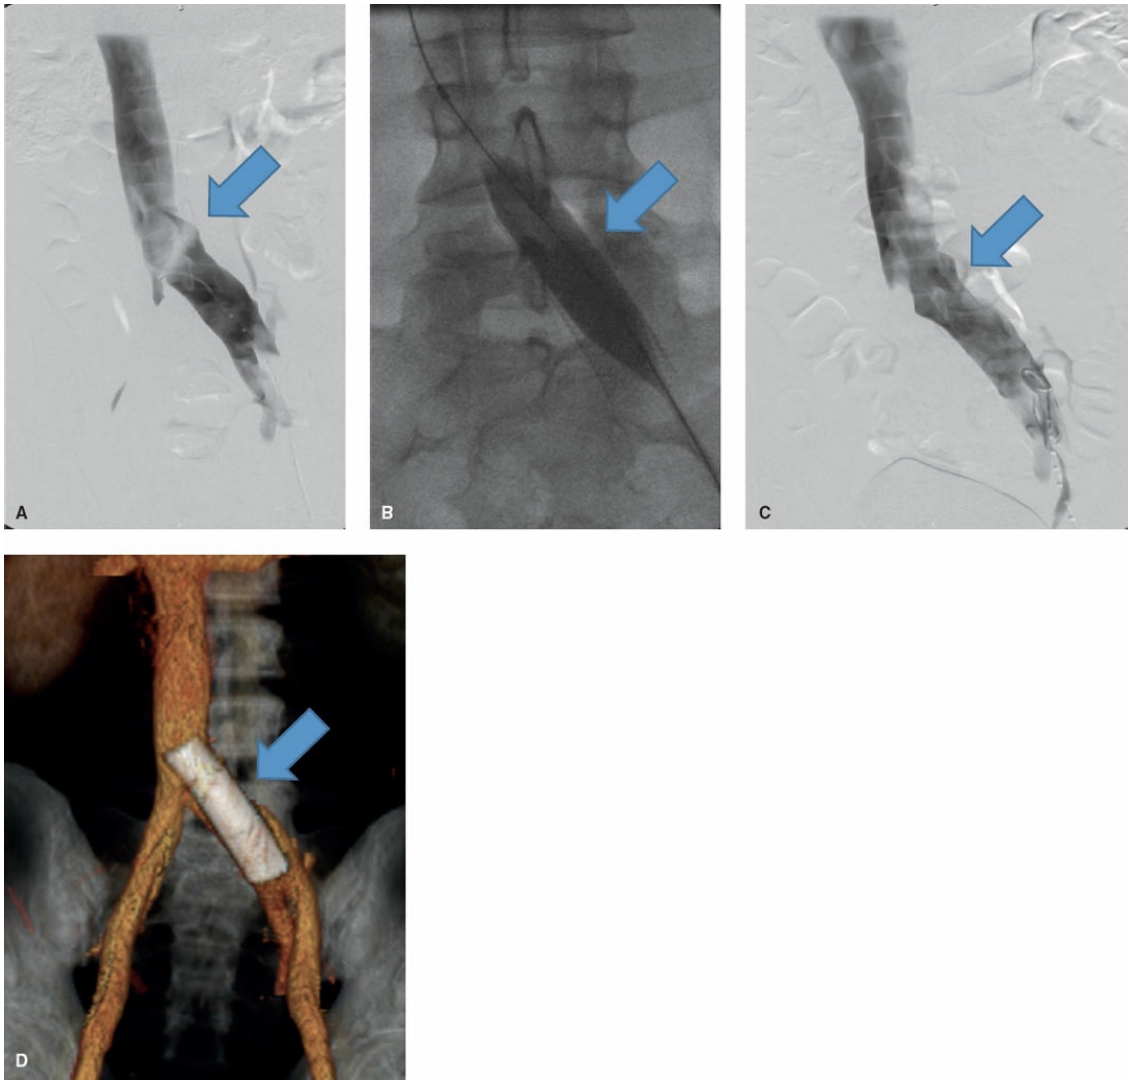

Figure 223.2. **A.** Venogram before stenting the narrowed left iliac vein (*arrow*) in May–Thurner syndrome. **B.** Balloon angioplasty of the stented (self expanding stent) left iliac vein. **C.** Poststent venogram shows excellent flow in the widely patent stent. **D.** Postoperative computed tomographic venogram confirms successful stenting. (Reprinted with permission from the Mayo Foundation.)

Although fewer large series have been reported, overall patency of Palma grafts in nine series including 412 operations ranged between 70% and 83% at 3 to 5 years. Results were better in patients who had no or minimal infrainguinal venous disease and in those with MTS without previous deep vein thrombosis. We observed a 70% primary and a 78% secondary patency rate at 5 years in 25 Palma vein grafts. Endoscopic vein harvest was associated with decreased primary but not secondary patency rates.

Crossover Femoral Venous Prosthetic Bypass

When the saphenous vein is small or not available, a crossover femoral venous prosthetic bypass with an 8- or 10-mm externally supported expanded PTFE (ePTFE) graft is a good alternative (Fig. 223.4). Similar to the autologous femoral suprapubic bypass, the femoral veins are exposed bilaterally, the ePTFE graft is positioned in the subcutaneous suprapubic tunnel, and an end-to-side anastomosis is performed to the CFVs at each side. A distal AVF on the affected side is routinely added to the procedure using a 4- to 5-mm PTFE graft for the fistula between the PTFE graft and the superficial femoral artery. Satturai recommended cutting out a small window rather than just making a longitudinal cut in cross-femoral graft at the hood of the femoral anastomosis to optimize inflow and decrease intimal hyperplasia of the AVF.

Variable patency rates of ePTFE grafts in this location have been reported and range between 0% and 100%, with data from one large series quoting a 100% (19 of 19) patency rate at long-term follow-up. Gruss and Hiemer observed 77% patency at 5 years in 27 PTFE Palma grafts. In the authors' experience, long-term patency is about 50% and preference still should be given to saphenous crossover grafts.

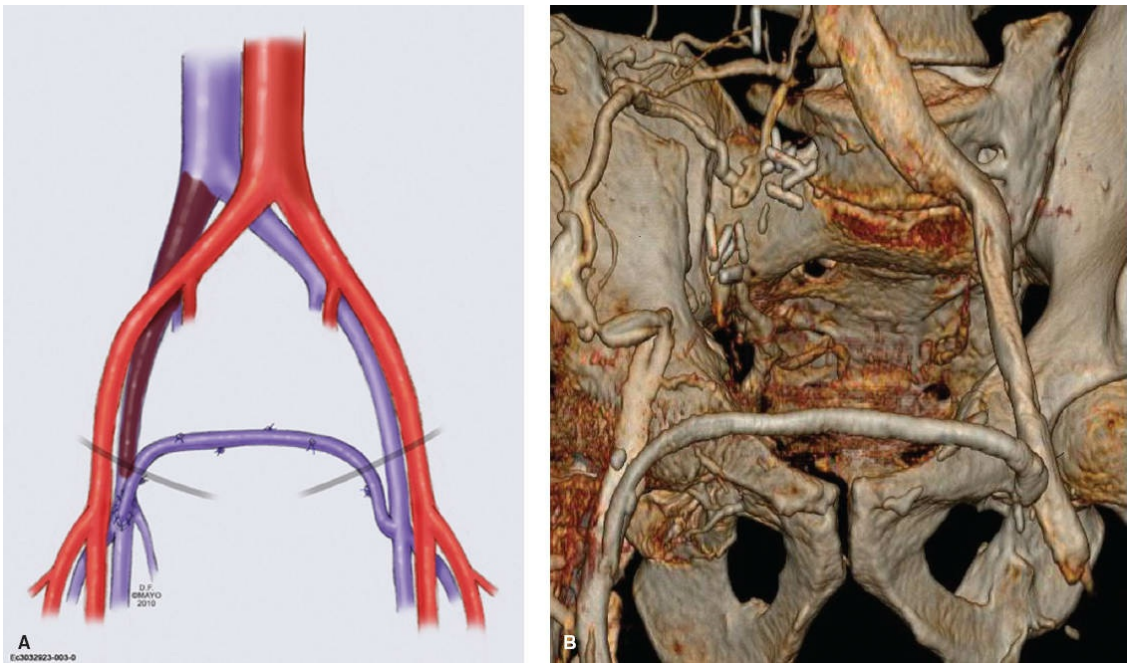

Figure 223.3. A. Suprapubic saphenous vein transposition (Palma procedure) for chronic thrombosis of the right common and external iliac vein and portion of the right common femoral vein. Bilateral groin incisions were performed to expose the right femoral vein and the left saphenofemoral junction. The left

saphenous vein was harvested open through two short incisions in the thigh. The saphenous vein was anastomosed to the right femoral vein using 6-0 running polypropylene suture. (Reprinted with permission from the Mayo Foundation.) **B.** CT venography confirmed patency at 2 months after surgery.

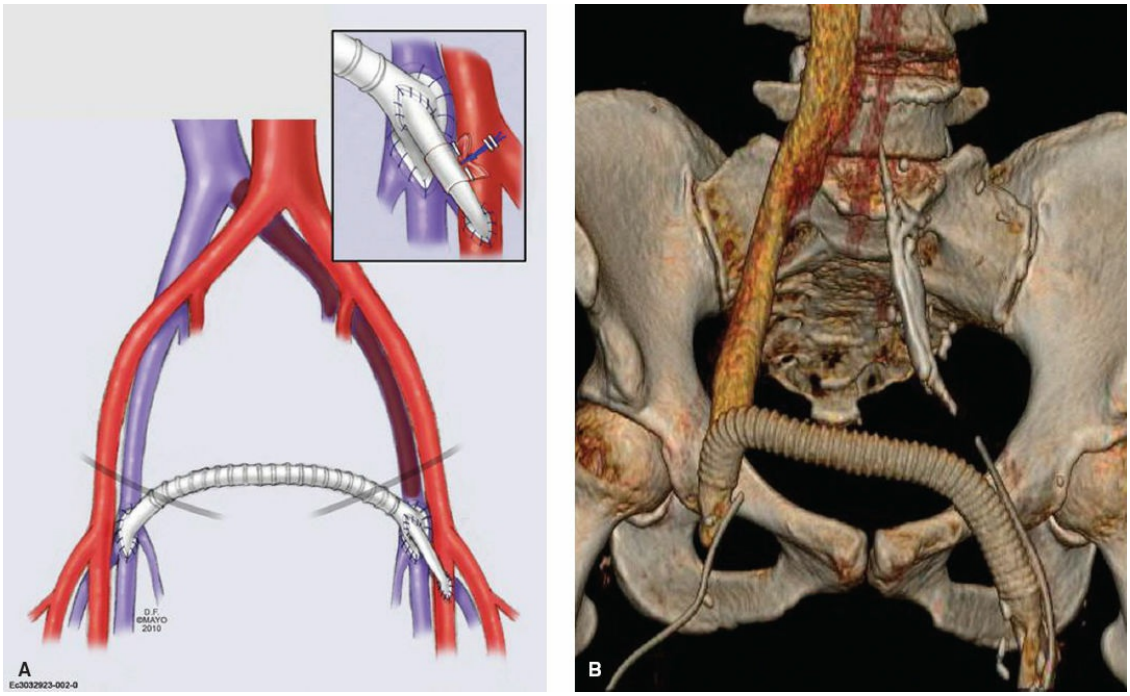

Figure 223.4. A. Polytetrafluoroethylene femorofemoral bypass with a left femoral arteriovenous fistula. A silastic sheath was placed around the fistula to avoid tissue ingrowth and easy ligation of the fistula, if needed. (Reprinted with permission from the Mayo Foundation.) **B.** Computed tomographic venogram at 1 year shows patent bypass and patent fistula.

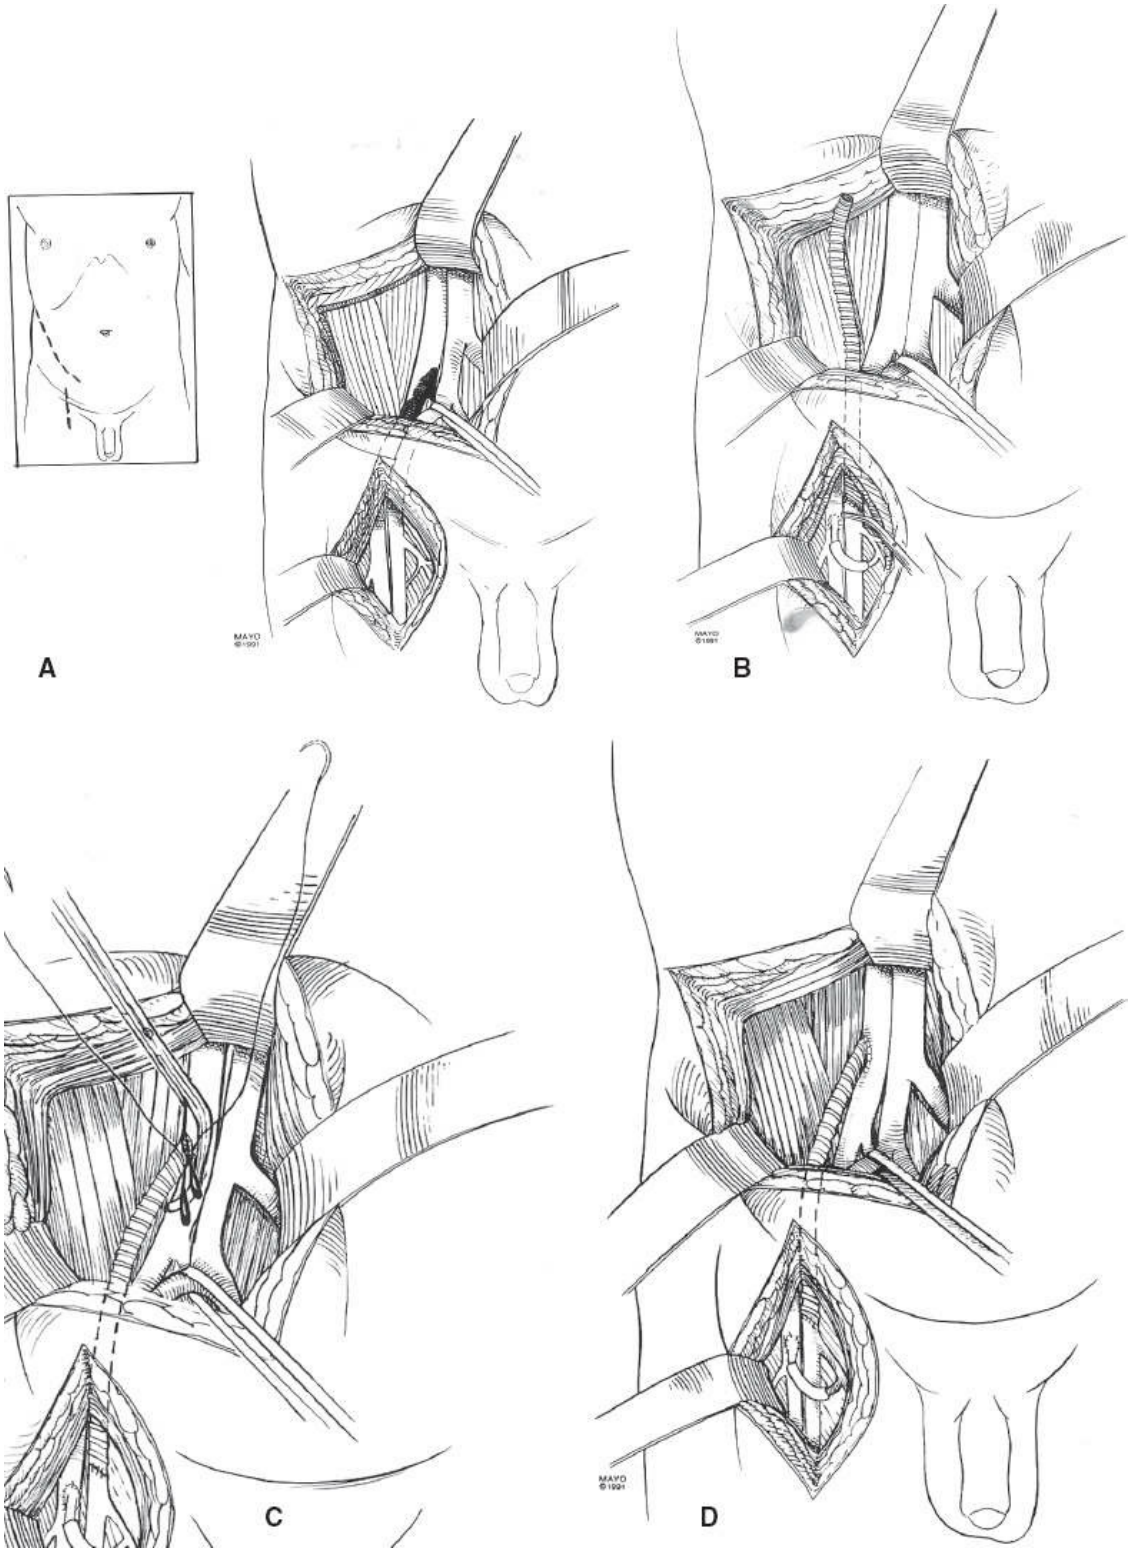

Figure 223.5. A. Location of the incisions of a right femorocaval bypass. The common femoral and the proximal saphenous veins are exposed through a 6- to 8-cm vertical incision at the groin. The distal inferior vena cava (IVC) is exposed retroperitoneally through a right oblique anterolateral flank incision, transecting the abdominal muscles and the transversalis fascia. The ureter is retracted medially. **B.** The femoral arteriovenous fistula is

performed first in this case with a large tributary of the saphenous vein and the femoral artery. A silastic sheath is wrapped around the vein for easy late identification. The distal anastomosis is performed then in an end-to-end fashion between the common femoral vein and the 10-mm externally supported polytetrafluoroethylene graft. **C.** The anastomosis between the graft and the IVC is performed in an end-to-end fashion using 5-0 polypropylene suture. Air is carefully flushed from the graft before removing the clamp from the IVC. **D.** Completed femorocaval bypass with a saphenofemoral arteriovenous fistula. (Reprinted with permission from the Mayo Foundation.)

Iliocaval and Femorocaval Bypass

Low-risk patients with bilateral iliac obstructions or with iliocaval obstruction that cannot be treated with stents or who have failed stents should be considered for an in-line femorocaval (Fig. 223.5A–D) or iliocaval (Fig. 223.6) bypass. For in-line reconstruction of iliocaval or caval occlusions, an ePTFE graft with external support is the preferred conduit (Fig. 223.7). Short, large-diameter (12-mm) grafts are used most frequently; a diameter of 12 to 14 mm is used for iliocaval bypasses and at least 10 mm for femorocaval bypass. The upper portion of the infrarenal IVC at and immediately distal to the renal veins is best approached transperitoneally through a midline incision, reflecting the ascending colon medially and mobilizing the duodenum using the Kocher maneuver. The low IVC just above the iliac bifurcation is well approachable through a right flank incision retroperitoneally (Fig. 223.5A). If the occlusion is limited to the right CIV, the same incision is used to expose the external iliac vein for the distal anastomosis. The graft is tunneled under the ureter.

If a femorocaval graft is placed, a separate 8-cm long vertical groin incision is made on the affected side and the graft is tunneled under the inguinal ligament (Fig. 223.5A). To all grafts originating from the femoral vein and to most long iliocaval grafts, an AVF is added at the groin (Fig. 223.5B). To start local heparin therapy (500 units/hr), a 20-gauge catheter is introduced through a tributary of the saphenous vein (Fig. 223.6) and advanced to the distal anastomosis. This catheter can be used for completion venography 24 to 48 hours after reconstruction and removed the 3rd postoperative day, when full anticoagulation is started. Early clinical improvement can be expected in the majority of patients, but presence of coexisting femoropopliteal reflux can still be the cause of

significant disability.

The use of autologous vein for femoroiliac or femorocaval reconstruction is also an option. Because of a relatively small size, saphenous vein in this location can only rarely be used. If short segment of the common femoral or iliac vein has to be reconstructed, a better size match is a spiral saphenous vein graft, prepared using the contralateral saphenous vein (Fig. 223.8). The excised vein is opened longitudinally, the valves are excised, and the graft is wrapped around a 28- or 32-mm argyle chest tube. The edges are approximated with running 6-0 polypropylene sutures or with stainless steel nonpenetrating vascular clips. The internal or external jugular veins are other conduits that can be considered for venous reconstruction. The femoral vein is also an alternative for reconstruction of abdominal veins, although morbidity of removing this vein in many of these patients with underlying thrombophilia or PTS is high and other options are recommended. Cryopreserved saphenous or femoral vein has also been reported for venous reconstruction, but long-term patency of these grafts for venous replacement in our experience has been poor.

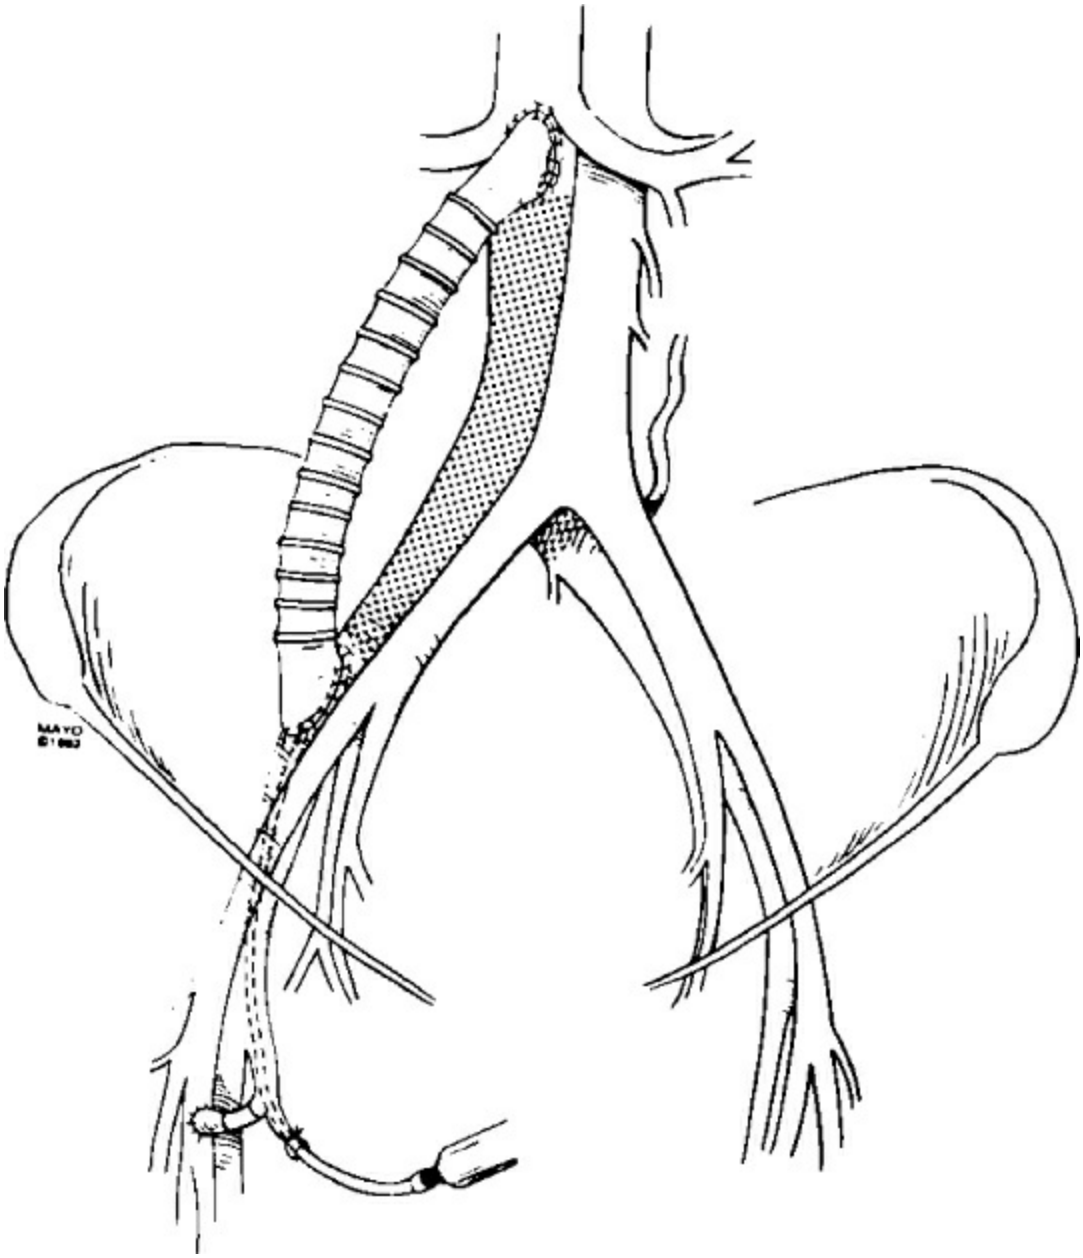

Figure 223.6. Iliocaval polytetrafluoroethylene bypass between the right external iliac vein and the infrarenal inferior vena cava. Note the saphenofemoral arteriovenous fistula and placement of a 20-gauge pediatric central line into the saphenous vein and advanced up to the graft to perfuse heparin to prevent early thrombus formation on the graft surface. (Reprinted with permission from the Mayo Foundation.)

Experience with femorocaval or iliocaval PTFE bypass grafts for benign disease has been limited; reported primary and secondary patency rates at 2 years were 37% and 54%, respectively. In one series, published by Satturai, long-term patency of 77% (10 of 13) was reported. We observed an 86% 5-year patency in short femoroiliac or iliocaval grafts

and a 57% patency of long femorocaval bypasses.

Cavoatrial Bypass

Patients with symptomatic short membranous occlusion of the IVC or longer congenital or acquired narrowing (caval coarctation) without or with hepatic venous outflow obstruction (Budd–Chiari syndrome) can be treated by cavoatrial bypass when attempts at percutaneous angioplasty or stenting have failed, or if transcardiac membranotomy is not feasible.

The suprahepatic IVC or right atrium is approached through an anterolateral right thoracotomy (Fig. 223.9A–D). The pericardium is opened anterior to the phrenic nerve. If the membranous occlusion is short and is located to this area, a short PTFE interposition graft can be performed from this exposure. If the occlusion extends distal to the hepatic veins, the abdomen is entered through the same thoracotomy, transecting the diaphragm circumferentially and mobilizing the liver forward and medially. Division of the triangular and the right coronary ligament will help mobilization of the liver. The adrenal gland and the kidney are left in their bed and dissection is moved more medially. Excellent exposure of the suprarenal IVC can be achieved through this approach. If the distal anastomosis has to be made more distally, a separate right subcostal or midline incision can be performed as previously described.

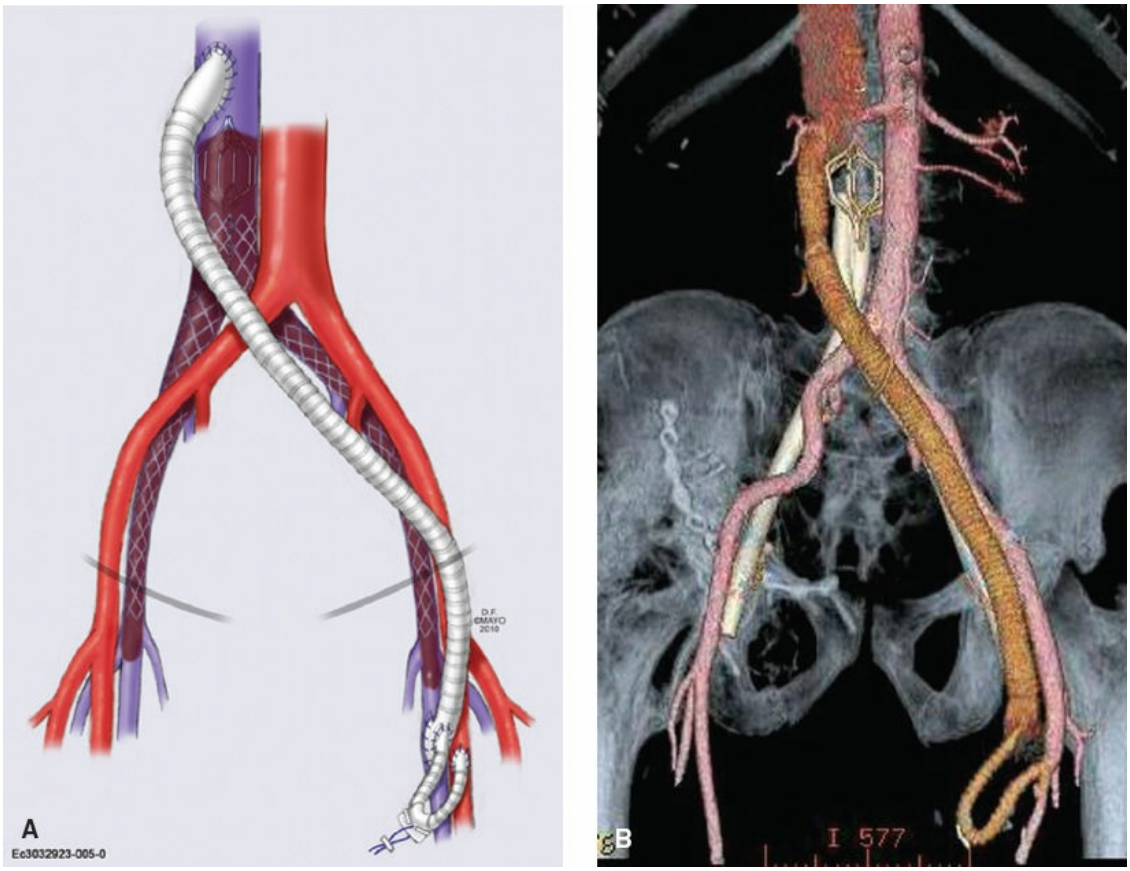

Figure 223.7. **A.** Femorocaval polytetrafluoroethylene (PTFE) bypass in a 42-year-old male who had inferior vena cava (IVC) and bilateral iliac vein stent thrombosis after placement of an IVC filter. The left femoral–suprarenal IVC bypass was performed with a 12-mm PTFE graft and a left femoral loop arteriovenous fistula. **B.** Computed tomographic venogram at 7 months shows patent graft and a patent fistula. The patient had excellent clinical improvement after surgery. (Reprinted with permission from the Mayo Foundation.)

Figure 223.8. Technique to prepare a spiral saphenous vein graft. The vein is cut open longitudinally, valves are excised, and the vein is wrapped around a 28- or 32-gauge argyle chest tube. The edges are approximated with running 6-0 polypropylene sutures, making interrupted stitches after each circle to minimize purse stringing. Alternatively, nonpenetrating vascular clips can be used for this purpose. (Reprinted with permission from the Mayo Foundation.)

For a cavoatrial bypass, an end-to-side anastomosis to the IVC is performed and the graft is routed under the liver parallel to the IVC. The graft is then anastomosed end to side to the suprarenal IVC or the lower portion of the right atrium. Partially occluding clamps are used to perform the anastomoses, and cardiopulmonary bypass is not needed. Traumatic or iatrogenic occlusions can also be managed by this technique. The use of a 16- to 20-mm externally supported PTFE graft is recommended.

The reported clinical success rate with cavoatrial grafts is about 77%, with a perioperative mortality of 3% and 2-, 5-, and 10-year patency rates of 86%, 78%, and 57%, respectively. Kieffer's group reported on long-

term patency in five of six grafts placed for membranous occlusion of the vena cava. Victor and co-workers reported patent grafts at 21 months to 6 years after the operation in five patients. Three cavoatrial grafts placed for nonmalignant disease were reported by our group: the patient with an ePTFE graft was asymptomatic at 10 years, the long Dacron graft failed at 3 years, and the spiral vein graft occluded within 1 year.

Inferior Vena Cava Reconstruction Following Excision of Malignant Tumors

Primary venous leiomyosarcoma or secondary tumors invading the vena cava, such as hepatic tumors, retroperitoneal sarcomas, or adrenal tumors, are the most frequent indications. Most renal carcinomas that extend into the vena cava do not invade the wall of the vessel and the tumor thrombus can frequently be removed from the IVC without the need for venous reconstruction. Attention must be paid to avoid tumor embolization into the pulmonary arteries. Patients with extension of the tumor thrombus into the right atrium need cardiopulmonary bypass to permit safe removal of the tumor.

The incision for resection of primary IVC tumors is transperitoneal, usually midline or right subcostal. Hepatic tumor resection may require a right thoracolaparotomy (Fig. 223.10A–D). The IVC is exposed by mobilizing the ascending colon and performing the Kocher maneuver to mobilize the second portion of the duodenum medially, as described before. PTFE grafts (14 to 20 mm) with external support provide excellent patency of the reconstructed suprarenal or infrarenal IVC, since inflow is usually excellent and there is no associated iliac vein thrombosis. Short, 8- or 10-mm wide, externally supported PTFE grafts can also be used to reconstruct the renal veins if nephrectomy for treatment of the tumor does not have to be performed. For partial invasion of the IVC, wide excision of the wall and direct suture or a PTFE or bovine pericardial patch are options for reconstruction.

A venovenous bypass between the IVC or iliac vein and the axillary or internal jugular vein using a mechanical (Biomedicus) pump is only rarely needed in patients with poor cardiac function who cannot maintain a systolic blood pressure above 100 mm Hg when both the IVC and the hepatic veins are occluded for an anastomosis. When resection of the retrohepatic suprarenal vena cava has to be performed, the proximal anastomosis is performed first to allow early restoration of hepatic venous outflow (Fig. 223.10C,D). A femoral AVF is usually not required because

of the excellent venous inflow.

Perioperative complications are frequent (43%), and operative mortality because of the associated liver resection can be high (7%). Graft patency is excellent, 93% at 3 years. Survival in many patients, however, is limited due to recurrent local tumor or distant metastases. Nevertheless, aggressive surgical management may offer the only chance for cure or palliation of symptoms for patients with primary or secondary IVC tumors. Caval reconstruction may result in significant improvement of the quality of life in these patients, even if their survival is short due to the underlying malignant disease.

Special Considerations

Endophlebectomy

Postthrombotic femoral veins frequently have multiple lumens due to partial recanalization of the thrombus. Excision of the organized and fibrotic thrombus will enlarge the lumen, although the exposed collagen in the media of the vein wall is more thrombogenic than the intact venous wall. Still, careful endophlebectomy will improve inflow to a great extent; attention, however, must be paid to avoid injury to the thin residual venous wall. This procedure has also been performed combined with deep venous valve transplantation in patients with PTS. In patients who have localized high-grade stenosis of the CFV, this operation alone is sufficient to improve venous outflow. The defect is closed with a patch using a segment of the saphenous vein or bovine pericardium. The endophlebectomized segment can also be used to improve inflow for iliocaval stenting (see hybrid procedures) or for a cross-femoral or femorocaval bypass. In a series of 10 patients who underwent endophlebectomy alone, early results showed 77% patency of the operated segments at 8 months.

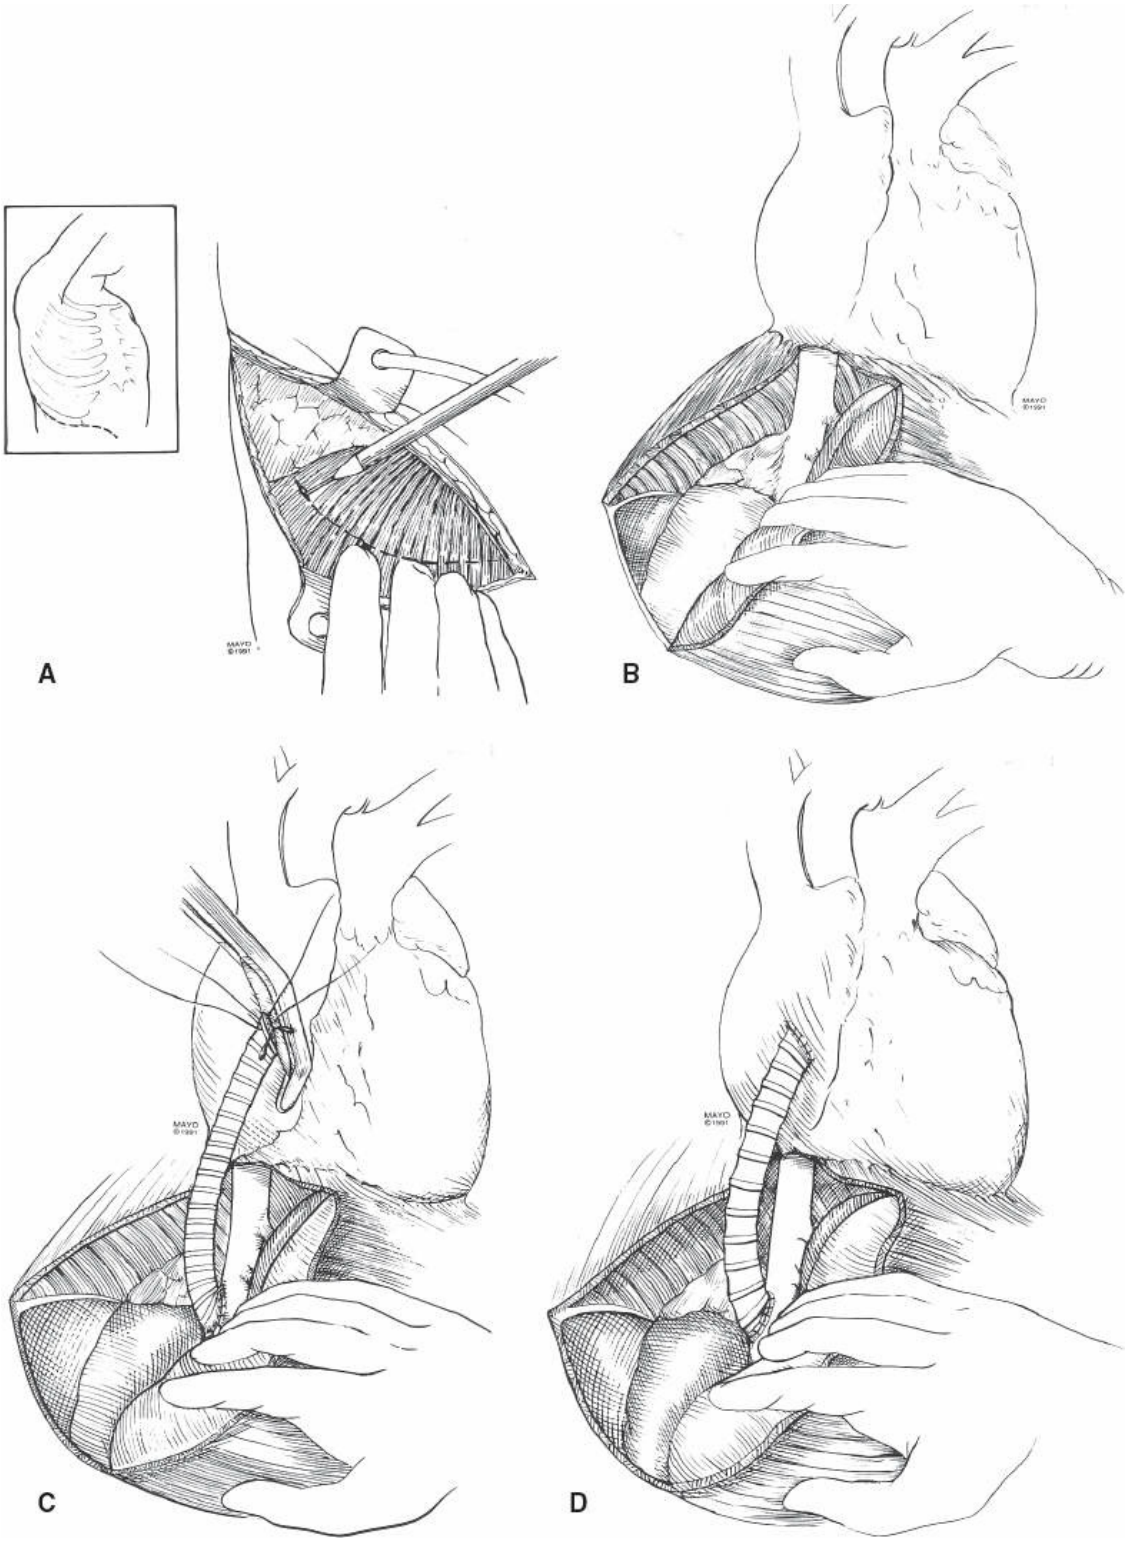

Figure 223.9. A. For a cavoatrial bypass, the thorax is entered through the eighth intercostal space performing an anterolateral thoracotomy. The costal arch is sharply divided through the eight and ninth ribs, but the abdomen is not entered. The inferior pulmonary ligament is divided and the diaphragm is circumferentially incised and the abdomen is entered. (Reprinted with permission from the Mayo Foundation.) **B.** The triangular

and right coronary ligament is divided and the right lobe of the liver is mobilized medially and anteriorly. (Reprinted with permission from the Mayo Foundation.) **C.** The suprarenal inferior vena cava is dissected and partially cross-clamped. A 14- or 16-mm externally supported polytetrafluoroethylene graft is anastomosed first to the cava, then to the right atrium. Air is carefully flushed before opening up flow in the graft. **D.** Completed cavoatrial PTFE bypass. (Reprinted with permission from the Mayo Foundation.)

Adjunctive Procedures

With the exception of caval reconstructions or short iliocaval grafts, prosthetic bypasses used for venous outflow obstruction of the legs need an adjunctive temporary AVF to maintain patency. The best technique is a 4- to 5-mm PTFE graft that is about 2-cm long and is placed between the superficial femoral artery and the lower portion of the PTFE venous graft. The authors use a tapered 4- × 7-mm PTFE graft to obtain a segment suitable for AVF. Short straight graft or a small loop fistula can be created. Both anastomoses are performed with 6-0 polypropylene sutures. A small silastic sheet is wrapped around the bypass to avoid healing and permit easy identification later when the fistula is closed. A 2-0 polypropylene suture is then tied to this silastic sheath and positioned under the skin incision for easy identification. A longer PTFE straight or loop graft used for the fistula can also be closed later percutaneously, using an Amplatz plug. Patients who have saphenous Palma grafts undergo takedown of the fistula at 3 months, with endovascular or open procedure. Patients who have PTFE grafts will keep the AVF longer, if possible. The AVF increases flow through the graft, decreases platelet and fibrin deposition, and contributes to improved patency. It also provides time for pannus formation over the anastomoses during the initial period when the graft surface is most thrombogenic. Potential side effects are a high cardiac output, functional outflow obstruction resulting in high distal venous pressures, and accelerated intimal hyperplasia.

Prevention of Complications

In general, large vein reconstructions for benign disease are performed in good surgical candidates only, with a low risk of systemic complications. Of the local, nonvascular complications, wound infection, hematoma, and lymphatic leaks (fistula, lymphocele) are the most frequent, and atraumatic

surgical technique, antibiotic prophylaxis, and standard surgical principles are helpful in prevention.

Intraoperative air embolism, especially during caval reconstruction, is a potentially fatal complication and may be prevented by meticulous flushing of the grafts before reestablishment of the circulation and passive Valsalva maneuver (30 mm Hg) as well as Trendelenburg position before release of the proximal clamp.

DVT and pulmonary embolism are serious systemic vascular complications. During 64 procedures that we performed for nonmalignant disease, there were no mortality and pulmonary embolism. Although early thrombosis rate was high (20%), and reinterventions were needed, 96% of the patients left the hospital with a patent graft after open surgical bypass. In a recent review of 65 patients who underwent IVC reconstruction, mostly for renal cell cancer and retroperitoneal sarcoma, Hicks et al. reported a perioperative VTE rate of 22% (n = 14), including pulmonary embolism in 12%. Perioperative anticoagulation with heparin and warfarin, the use of elastic stockings, intermittent pneumatic compression pumps, and early ambulation help prevent thromboembolic complications. Local vascular complications are rare; they are specific to venous reconstructions and include graft stenosis or thrombosis, perioperative bleeding, graft infection, and injury to the surrounding vascular and nonvascular structures.

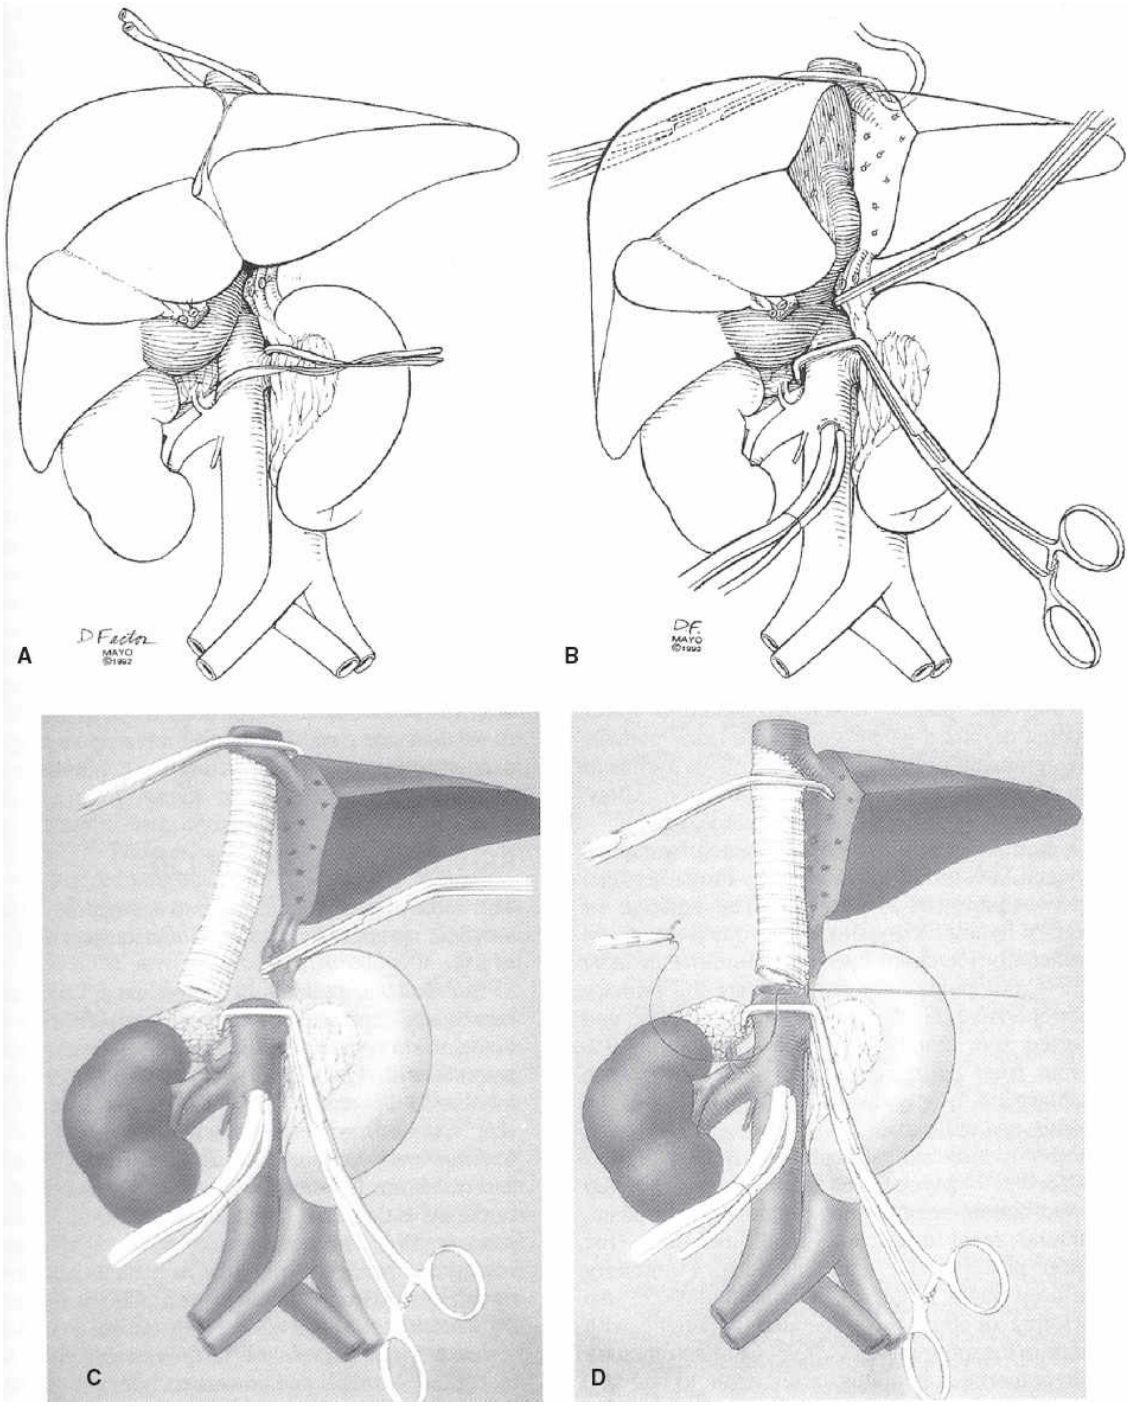

Figure 223.10. Technique for polytetrafluoroethylene graft replacement of the suprarenal inferior vena cava following right hepatic lobectomy for a malignant tumor with caval invasion. **A.** Isolation of the suprahepatic and suprarenal segments of the vena cava and division of the right hepatic artery and portal vein branches. **B.** Hepatic vascular exclusion used to complete resection of the liver, tumor, and retrohepatic vena cava. If necessary, venovenous bypass via an infrarenal cannula is used. **C.** The upper caval anastomosis is performed first to minimize hepatic ischemia. **D.** The suprahepatic caval clamp is transferred

across the graft after acid metabolites have been flushed from the liver. The lower caval anastomosis is completed. (From Bower TC, Nagorney DM, Toomey BJ, et al. Vena cava replacement for malignant disease: is there a role? *Ann Vasc Surg* 1993;7(1):51–62. Copyright © 1993 Annals of Vascular Surgery, Inc., with permission.)

Anticoagulation

Grafts placed in the venous system have a higher rate of thrombosis than arterial grafts due to relatively slower venous velocities. Infrainguinal venous obstruction and valvular incompetence further decrease inflow to the graft, and it is a major contributing factor to failure. Thrombophilia is prevalent among patients undergoing venous reconstructions, and many patients have absent circulating anticoagulants such as protein factor C, protein factor S, and Antithrombin, or have factor V Leiden mutation. The thrombogenic surface of any prosthetic graft also increases the risk of graft failure. For these reasons, perioperative anticoagulation is indicated in patients undergoing reconstructive venous surgery for deep venous obstruction.

The patient is fully heparinized during reconstruction and protamine is avoided at the completion of the procedure. Heparin at a dose of 500 units/hr is started in the operating room through a 20-gauge pediatric central line that is placed through the saphenous vein of the affected limb and advanced to the distal anastomosis of the prosthetic graft. Complete postoperative systemic heparinization is achieved by 48 hours, and full-dose low–molecular-weight heparin is continued subcutaneously for another 3 to 5 days, given simultaneously with warfarin. The incidence of postoperative bleeding has been between 5% and 10%, mainly as a result of anticoagulation. Warfarin is continued indefinitely in most patients with prosthetic grafts and in all with a known underlying coagulation abnormality.

Following iliocaval stenting for postthrombotic disease or in those with thrombophilia, we recommend anticoagulation for at least 3 months. In nonthrombotic patients, antiplatelet treatment with clopidogrel (75 mg daily) or a combination of aspirin (81 mg) and Cilastazol (50 mg twice daily) is used. There is some evidence that the latter retards instent restenosis/neointimal hyperplasia. In the presence of significant instent restenosis, but lack of symptom recurrence we use low-dose Coumadin (1 mg)/Apixaban (2.5 mg) on a daily basis. Recurrence of symptoms is an

indication to repeat IVUS and perform balloon angioplasty. Raju et al. reported on benefit from dilation using a balloon with a larger diameter than that of the stent.

Follow-Up and Reinterventions

Duplex scan on the first postoperative day or contrast CT/MR venography is performed to confirm graft patency. Stenosis or thrombosis is corrected immediately after recognition. If thrombosis occurred in a graft without fistula, thrombectomy is done with addition of a fistula. Graft stenosis discovered during surveillance in the late postoperative period is treated first with angioplasty or venous stenting. Late graft thrombosis is treated with thrombolysis, angioplasty, and stenting. Surgical revision is usually limited to patch angioplasty of the stenotic portion of the graft, although occasionally aneurysmal dilation of the saphenous crossover graft may also need surgical correction. For stent, postoperative duplex is performed on day 1 with repeat duplex exam being performed 2 and 6 weeks post procedure to ensure adequacy of symptom relief and stent patency. Annual follow-up is required subsequently.

EDITOR'S COMMENT

The chapter by Gloviczki and Jayaraj describes, based on extensive institutional experience, endoluminal and open treatment of chronic venous occlusive

disease (CVD). The workup and planning as written in the chapter are well supported. We typically will use CT scanning and then contrast venography for patients in whom a stent and/or possibly bypass procedure is planned. We have less expertise with regard to MRI. To my knowledge, each has some advantages and disadvantages, but no head-to-head comparisons for which imaging modality is better. Probably the most accurate is intravascular ultrasound, which can determine apposition of the stented vein wall with sizing and post ballooning of the vein. Moreover, intravascular ultrasound is most accurate for determining stenosis severity. For example, single plane venography had only 45% sensitivity and a 49% negative predictive value as compared with intravascular ultrasound (Neglen P, Raju S. Intravascular ultrasound scan evaluation of the obstructed vein. *J Vasc Surg* 2002;35:694–700).

The patients for whom these types of procedures are most applicable are those with severe venous insufficiency, such as CEAP class 5 and 6. In particular, the patient with recalcitrant ulcerations or venous claudication and severe disability should be considered for invasive therapy. Much experience of CVD treatment comes from Dr. Raju's group in Mississippi. Durability of the iliac venous stenting seems good, as about 13% may need re-intervention, with good secondary success (Raju S, Tackett P Jr., Neglen P. Reinterventions for nonocclusive iliofemoral venous stent malfunctions. *J Vasc Surg* 2009;49:511–8). Specifically, certain aspects such as stenting into the IVC, use of oversized self-expanding stents, as well as stenting into common femoral vein seem to be efficacious and supported by their data. Similarly, the published Mayo data support similar endovascular approaches as described in this chapter.

As noted by the authors, hybrid procedures with endoluminal treatment are more common today, particularly an endophlebectomy of the common femoral segment followed by a retrograde iliac venous stenting procedure. Indeed, significant symptomatic and durable improvement in symptoms is likely utilizing the hybrid approach (Vogel D, Comerota AJ, Al-Jabouri M, et al. Common femoral endovenectomy with iliocaval endoluminal recanalization improves symptoms and quality of life in patients with postthrombotic iliofemoral obstruction. *J Vasc Surg* 2012;55:129–35). This allows the establishment of venous inflow and outflow into the iliac and the vena cava with angioplasty and stenting, providing revascularization to the anatomical segments most causative of severe CVD.

In our own series, we found iliac vein stenting patency was diminished in males and younger aged patients, but not in those with hypercoagulability (Knipp BS, Ferguson E, Williams DM, et al. Factors associated with outcome after interventional treatment of symptomatic iliac vein compression syndrome. *J Vasc Surg* 2007;46:743–9). Moreover, non-occlusive May–Thurner disease usually has excellent long-term stent patency, whereas those patients with diffuse iliac occlusive disease after a DVT are significantly less successful long term.

Open venous bypass procedures are rare. For example, the Palma procedure

using a saphenous vein crossover is likely to be rarely performed by most surgeons, but the critical technical points are clearly described herein. Several technical aspects that are well established to prevent kinking are well described. Use of an arteriovenous fistula may be beneficial in those patients in whom poor venous inflow is noted. These arteriovenous fistulas can be occluded 6 to 12 months afterwards or remain open indefinitely. Rarely does this lead to leg swelling or congestive heart failure.

We find that most of these patients with postthrombotic syndrome do need to be anticoagulated for life. We continue anticoagulation perioperatively, whereas those patients without postthrombotic syndrome aspirin and plavix will usually suffice. Whether the new, more potent, antiplatelet therapies will better requires further study. Interestingly, Vorapaxar, a direct protease activated receptor-1 inhibitor, may be useful in this regard as it seems to be associated with less native arterial thrombosis (Bonaca MP, Gutierrez JA, Creager MA, et al. Acute limb ischemia and outcomes with vorapaxar in patients with peripheral artery disease: results from the trial to assess the effects of vorapaxar in preventing heart attack and stroke in patients with atherosclerosis-thrombolysis in myocardial infarction 50 (tra2 degrees p-timi 50). *Circulation* 2016;133:997–1005) and this may translate well into preventing recurrent venous thrombosis in the stented segments. Certainly, these questions are ripe for a controlled trial to answer.

224 Vena Cava Filter Placement

Mark Levin and John E. Rectenwald

INTRODUCTION

Deep venous thrombosis (DVT) and pulmonary embolism (PE) together comprise venous thromboembolic disease (VTE), and occur with an annual incidence of 1 per 1,000 adults. Each year in the United States, an estimated 350,000 to 600,000 individuals develop VTE and 100,000 to 180,000 people die of PE. With an aging population, an increased disease burden is expected as VTE rates are nearly 13-fold higher in octogenarians. Moreover, elderly individuals are more susceptible to adverse outcomes associated with VTE, highlighting the importance of both management and prevention. Although anticoagulation with Lovenox, Coumadin, or more recent novel oral agents remains the mainstay of therapy, situations arise when these medications are contraindicated or inadequate. In these instances, vena cava filters are used to prevent PE.

INDICATIONS FOR FILTER PLACEMENT

The impetus for placing an inferior vena cava (IVC) filter is to prevent a potentially fatal pulmonary embolus, and indications fall into three general categories: absolute, relative, and extended. Absolute indications for filter placement are as follows:

1. The presence of a VTE when anticoagulation is contraindicated
2. Failure of anticoagulation in the setting of VTE
3. Emergency treatment following massive PE
4. Chronic, recurrent PE when anticoagulation has failed or is contraindicated

Table 224.1 highlights all of the indications for filter placement. Although seemingly straightforward, the decision to place a vena cava filter should not be made lightly as its use has recently fallen under intense scrutiny by the U.S. Food and Drug Administration (FDA) and in medicolegal circles given the propensity for filters to fracture, migrate,

perforate the IVC, or embolize to the heart or lungs. At the same time, the occurrence of perioperative VTE is a measure of quality, and well-intended attempts at risk mitigation may influence the decision to place a filter using more lenient or extended criteria. Nevertheless, in 2013 the FDA issued a position statement advocating that the prophylactic use of IVC filters in patients without PE is off-label. Despite this recommendation, off-label or prophylactic use has become more prevalent as clinicians recognize that certain subsets of patients, including those with multisystem trauma, bariatric patients, immobile patients, and cancer patients all have increased risk for VTE. While patients with absolute and relative indications for filter placement have existing thromboembolic disease and either a contraindication to anticoagulation, complications relating to anticoagulation, or overt failure of anticoagulation, placing filters utilizing extended criteria should be tailored to each patient after thorough discussion of the risks and benefits of the procedure, and with the understanding that off-label use may pose a liability risk to the physician. In addition, every attempt should be made to remove these filters when the risk of VTE has decreased or the patient can be safely anticoagulated.

TABLE 224.1 Indications for Vena Cava Filter Placement

I. Absolute indications
   VTE with
      Contraindication to anticoagulation
      Recurrent thromboembolic disease despite adequate anticoagulation therapy
      Significant bleeding complications of anticoagulation therapy
II. Relative indications
   VTE with
      Large, free-floating iliocaval thrombus (>6 cm in length)
      Pre- or postpulmonary thromboembolectomy
      Thromboembolic disease with limited cardiopulmonary reserve
      Poor compliance with medications
      Thrombolysis of iliocaval thrombus
      Patients with ataxia or significant fall risk
III. Extended indications (No requirement for VTE)
   High-risk trauma patients
      Head or spine injury
      Spine, pelvis, or long bone fracture
   Bariatric surgery
   Preoperative patients with multiple risk factors for VTE
   High-risk immobilized patients

The only absolute contraindications to filter placement are complete thrombosis of the IVC and lack of caval access due to extensive thrombosis. Caution is advised in the setting of coagulopathy and in children and pregnant patients.

TYPES OF AVAILABLE VENA CAVA FILTERS

The stainless steel Greenfield filter, introduced in 1972 and deployed using an open venotomy and 24-French sheath, was the original endoluminal caval interruption device. It consisted of a cone of six steel wires ending in tethering hooks. Two thirds of the filter cone could be filled with thrombus while leaving 50% of the caval diameter patent to allow for the native fibrinolytic system to lyse the clot. Percutaneous introduction techniques evolved 12 years later, followed by multiple iterations of other lower profile devices, and ultimately retrievable filters (Table 224.2).

An ideal filter would be securely fixed within the vena cava, biocompatible, nonthrombogenic, low profile, easy to deploy and retrieve, and have a low complication rate. While newer devices have some of these characteristics, the perfect filter does not exist. Retrievable devices, by definition, must be less secure than permanent filters. Access-related complications persist, despite lower profile deployment systems. Caval thrombosis, recurrent PE, and fracture are still major concerns to be dealt with. Table 224.3 depicts features of an ideal IVC filter.

TABLE 224.2 Characteristics of Available Vena Cava Filters

Filter	Introducer Size (FR)	Maximal Caval Diameter (mm)	Magnetic Resonance Compatibility	Other
Greenfield	14	28	Safe	Greatest clinical experience
Bird's nest	12	40	Not recommended	IVCs >30 mm
Simon nitinol	7	28	Safe	
Vena Tech LP	7	28	Safe	
TrapEase/ OptEase	6	30	Safe	OptEase is retrievable within 23 days
Gunther-Tulip/ Celect	8.5 Femoral 7 Jugular	30	Safe	Nonspecific retrievable window
Denali	8.4	28	Safe	Nonspecific retrievable window
Option	6.5	30	Safe	Nonspecific retrievable window

IVC, inferior vena cava.

TABLE 224.3 Characteristics of an Ideal Vena Cava Filter

Nonthrombogenic, biocompatible
High filtering efficiency with no flow impedance
Secure fixation within vena cava
Ease of insertion
Low profile
Simple deployment
Able to reposition
Magnetic resonance imaging compatibility
Low incidence of complications (migration, fracture, occlusion, perforation, insertion-site thrombosis)
Retrievable, with no time limit
Low cost

PREPROCEDURE EVALUATION

Once indications are confirmed and the decision made to place a filter, preparation includes a thorough physical exam, review of basic laboratory data, and evaluation of pertinent imaging. With fewer exceptions, IVC filters should be placed with the intent for removal; however, all currently available temporary filters carry approval for permanent use. Access for an infrarenal filter is most easily obtained via the right common femoral vein, as this provides the most direct route for device deployment and comfort for the operator. If right common femoral venous access is precluded, the right internal jugular vein is a reasonable second choice. The left common femoral vein, although feasible, is less desirable as the left common iliac vein drains into the IVC via an acute angle that may direct the filter delivery system into the right lateral wall of the IVC, causing the filter to tilt. Lab data including creatinine and a coagulation profile should be obtained. Anticoagulation should be held for 2 to 4 hours prior to the procedure. Imaging, including venous duplex studies, computed tomography (CT) venogram, or magnetic resonance venography (MRV) should be reviewed with specific attention focused on determining patency of the iliofemoral veins and vena cava. If CT or magnetic resonance imaging is available in the preoperative period, these studies may help

delineate anatomic features of the IVC that may alter the surgical plan by identifying the location of the renal veins, caval diameter, the presence of a circumaortic or retroaortic left renal vein, or duplicated IVC.

ANATOMIC VARIATIONS OF THE IVC AFFECTING FILTER PLACEMENT

The IVC develops between the 6th and 8th week of gestation from growth and regression of three paired cardinal veins. Anatomic variants arise due to abnormalities in the process and become relevant in patients requiring a filter as their presence may necessitate alteration of the surgical plan in up to 3% to 15% of cases.

Duplication of the IVC

With an incidence of 0.2% to 3%, duplication of the IVC occurs when the right and left supracardinal veins persist, leading to a double IVC to the level of the left renal vein. The left IVC drains into the left renal vein, which subsequently drains into the right IVC. Filter placement in one side, while leaving the other uninterrupted, is inadequate prophylaxis for PE. To rule out this anomaly, during venography through a flush catheter, one should visualize contrast refluxing into the contralateral common iliac vein. In the absence of this finding, duplicated IVC should be suspected and confirmed by accessing the contralateral side and performing venography to identify contrast filling the left renal vein. Additional clues hinting at the presence of a duplicated IVC would be a diminutive right IVC, or a high volume of nonopacified blood filling the right IVC above the level of the left renal vein.

Circumaortic and Retroaortic Left Renal Vein

Circumaortic renal veins occur in 1.6% to 14.0% of the population and carry significance for filter placement as the hilar junction of these veins with the IVC may be quite large, allowing for an alternative pathway for thrombi to escape the filter. To mitigate this risk, filters should be placed inferior to the entire circumaortic venous complex, where the overall diameter of the IVC is smaller, or in the suprarenal IVC. The presence of a retroaortic left renal vein should be noted, but does not carry an increased risk of embolism.

Left IVC

Persistence of the left supracardinal vein and regression of the right supracardinal vein results in a left-sided IVC in 0.2% to 0.5% of the population. In this situation, the infrarenal IVC lies on left, and the suprarenal IVC lies on the right. Generally, the left IVC crosses anterior to the aorta to join the right at the level of the renal veins; however, retroaortic left IVC has also been described. With left IVC, venous anatomy may be reversed whereby the left gonadal and adrenal veins drain directly into the IVC and the right gonadal and adrenal veins drain into the right renal vein. In addition, patients with a left IVC frequently have multiple renal veins. In this situation, a suprarenal filter may be necessary.

Megacava

Megacava, defined as an IVC diameter of >28 mm, is an important entity to identify prior to placing a filter. Currently, all commercially available devices can be used with caval diameters up to 28 mm; however, only a few (Gunteher-Tulip/Celect, the TrapEase/OptEase, and the Option filter) can be used for diameters up to 30 mm, and only one device (the Bird's Nest filter) is approved for megacava up to 40 mm. Alternatively, two IVC filters can be placed in both iliac veins or a single suprarenal IVC filter can be positioned in the suprarenal cava if it is of appropriate diameter. Filters are secured in place either with lateral force exerted by the legs, active fixation via tethering hooks, or a combination of both. As caval diameters increase, the legs of an undersized filter may not exert enough force on the wall to maintain position or sink the hooks, thereby resulting in migration. Obtaining accurate measurements, either with contrast venography or intravascular ultrasound (IVUS), is critical when choosing a device of appropriate size.

FLUOROSCOPICALLY GUIDED INFERIOR VENA CAVA FILTER PLACEMENT

The common femoral vein is identified using ultrasound. Obtaining access over the femoral head is critical to facilitate gentle manual compression at the conclusion of the case. Overaggressive compression of the femoral vein has been cited as one possible cause for perioperative venous thrombosis. Appropriate position is confirmed by placing a clamp at the intended access site and shooting a spot view under fluoroscopy. The groin

is then anesthetized and a 2- to 3-mm skin incision is made with an 11-blade scalpel. The common femoral vein is percutaneously cannulated with a double-wall needle, and a soft wire (Glidewire, Bentson, or J-wire) is advanced into the IVC under continuous fluoroscopic guidance. A 10-cm No. 5-French sheath is then advanced over the wire, into the common femoral vein, using Seldinger technique. A flush catheter is then advanced over the wire and an iliocavagram obtained (Fig. 224.1). At this point, the surgeon should take note of several key factors:

1. The presence of iliac and vena cava thrombus should be ruled out. Distal IVC thrombus generally necessitates jugular access.
2. Anomalous venous anatomy should be noted, and the surgical plan altered as necessary.
3. The location of the renal veins (particularly the lowest renal vein) should be documented.
4. The diameter of the infrarenal IVC should be determined. If megacava with diameters between 30 and 40 mm is identified, either a bird's nest, bilateral iliac vein filters, or a suprarenal IVC filter may be required.
5. The distance between the lowest renal vein and the confluence of iliac veins should be documented.

Occasionally, venacavagram may fail to clearly identify the renal veins. In this instance, the renal veins should be selectively catheterized (with a LIMA, RDC, Bernstein, or C2 Cobra catheter) and injected to eliminate any ambiguity in their location (Fig. 224.2). Most available filters are 60 mm in length or shorter, except the bird's nest filter, which is 80 mm long.

Figure 224.1. Iliovenacavagram showing the absence of thrombus in the vena cava and visualized iliac veins, the diameter of the infrarenal vena cava, the level of the lowest renal vein, and normal caval anatomy.

Once the anatomy is confirmed and measurements are taken, the device is opened and prepared on the back table. The 5-French sheath is exchanged for the long delivery sheath that accompanies each filter. In general, IVC filters have similar deployment systems; however, each device has its own idiosyncrasies that the surgeon must take into account. Deployment typically involves advancing the delivery sheath, under

fluoroscopic guidance, to a point just below the lowest renal vein. Deploying the device as close to the renal veins as possible is important to avoid creating a low-flow zone above the filter and below the vein that could create a nidus for thrombosis outside the filter. The dilator and wire are then removed while precisely maintaining sheath position in the IVC. The filter is then inserted in the back of the delivery sheath and advanced to the end under fluoroscopic surveillance. To deploy the filter, the delivery system is immobilized with one hand, while the other pulls the sheath back. Most filters deploy fully with this technique, but some have additional steps to facilitate more precise delivery and to avoid tilting and uncontrolled forward advancement of the filter (the so-called “watermelon seed” effect). Once deployed, completion venography is performed to document the final position and ensure patency of the IVC and renal veins. The device is removed from the common femoral vein and manual compression is held to achieve hemostasis. A completion spot film is then obtained to document the final position of the IVC filter (Fig. 224.3) for future reference if needed.

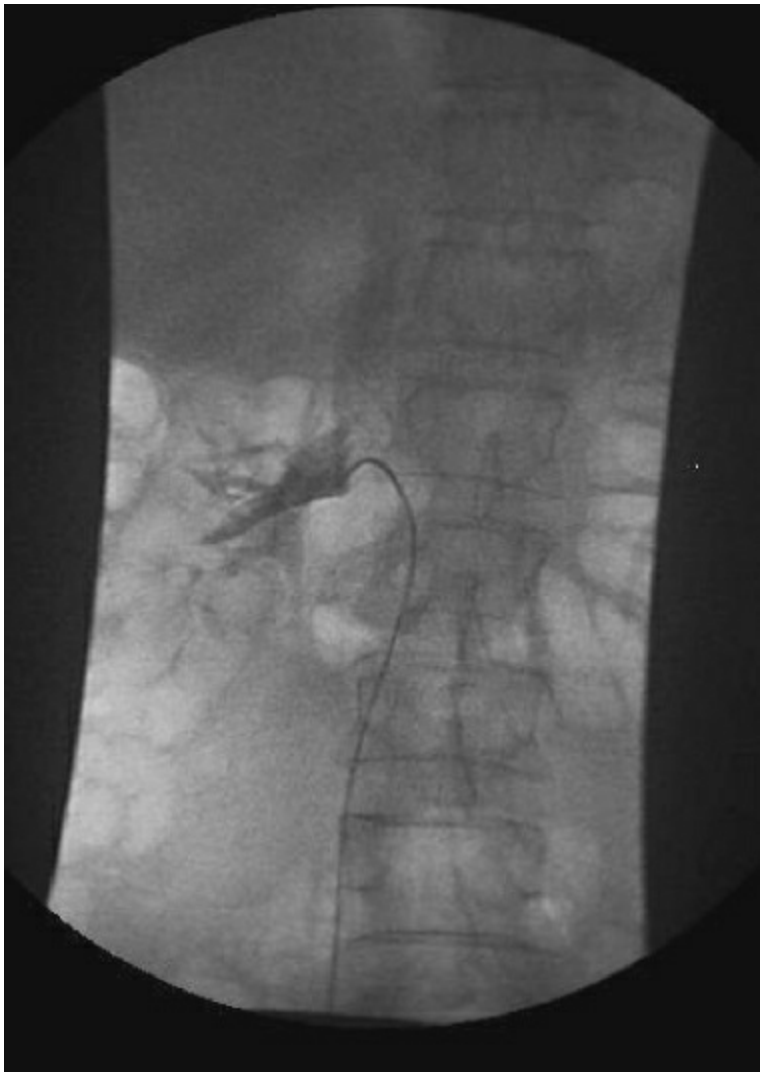

Figure 224.2. Selective cannulation of the right renal vein with a C2 Cobra catheter to confirm its location.

Figure 224.3. Completion spot film documenting adequate placement of the filter and filter position in relation to bony landmarks.

ULTRASOUND-GUIDED INFERIOR VENA CAVA FILTER PLACEMENT

Some patients may be poor candidates for fluoroscopically guided IVC filter placement due to clinical instability and inability to transfer to an operating room, or have prohibitively elevated creatinine levels precluding the use of contrast media. Under such circumstances, placing an IVC filter is still possible with the aid of a portable IVUS system brought to the bedside. IVUS allows for precise device deployment without the use of contrast, and data suggest that IVUS measurements are more accurate than those obtained with traditional contrast venography, which tends to overestimate IVC diameter. Despite these advantages, there are several caveats to this technique. The learning curve is steep and rates of filter malposition range from 2% to 8%, attributable primarily to inexperience

leading to misidentification of normal anatomy, and failure to appreciate abnormal anatomy. Familiarity with basic wires and IVUS interpretation is a prerequisite to any attempt at IVUS-guided IVC filter placement.

The first IVUS-guided filter was placed in 1999, but the technique was initially met with some resistance as bilateral access was required to maintain real-time ultrasound imaging during deployment. The IVUS catheter was advanced into the IVC via one common femoral vein, and the delivery device was placed via the contralateral side. With both the IVUS catheter and delivery system in the IVC, deployment is directly observable. An alternative technique, utilizing a single-puncture, involved mapping the IVC with IVUS, measuring the distance from the puncture site to the renal vein, removing the IVUS catheter, and then advancing and deploying the filter blindly.

With this technique, common femoral access is obtained and the delivery sheath for the filter is advanced a few centimeters into the vein over a wire. A No. 8-French sheath and an IVUS catheter are then inserted and advanced with the wire to the level of the heart, verified by visualizing cardiac motion. The IVUS catheter is then withdrawn to map the anatomy of the entire IVC. Renal vein identification is aided by noting the location of the right renal artery posterior to the vena cava just below the level of the renal veins. Once the IVUS catheter is in position below the renal vein, the No. 8-French sheath is advanced until its tip just overshadows the IVUS probe. The wire and IVUS catheter are then removed, maintaining sheath position. The filter is then loaded with its obturator through the No. 8-French sheath and advanced until the shaft reaches the level of sheath diaphragm. The filter is now at the end of the sheath, ready for deployment. The obturator is then removed using a “pin-and-pull” technique to deploy the filter. Position can be confirmed either with an abdominal plain film, or by reinserting the IVUS catheter over a wire and evaluating the IVC directly.

Single puncture methods involving the use of transabdominal ultrasound for real-time guidance during deployment have been described in the literature and appear to be a promising technique.

SUPRARENAL AND SUPERIOR VENA CAVA FILTER PLACEMENT

Placing a filter in an infrarenal location is preferable whenever possible, but situations do arise that require placement in the suprarenal vena cava.

Heavy thrombus burden in the IVC, thrombus extending to the renal veins, renal or gonadal vein thrombosis, pregnancy, and a duplicated IVC may all necessitate a suprarenal filter. The suprarenal IVC tends to have a larger diameter than the infrarenal IVC; thus, filters may be more prone to migration in this segment. In 2008, Kalva et al. published their 20-year experience with 70 with suprarenal filters and found no occurrences of caval thrombosis, 3 patients had CT evidence of thrombus in the filter, there was one incidence of filter fracture, and asymptomatic filter penetration of the IVC wall occurred in 2 patients. Postfilter PE was suspected in 10 patients (11.5%), 8 of whom underwent CT, but only 1 of those patients had radiographic evidence of a new PE. They concluded that the safety and efficacy of suprarenal IVC filters are comparable to that of filters placed below the renal veins.

If a superior vena cava filter is to be placed for the prevention of PE from upper extremity DVT, placement proceeds following the steps described for the IVC filter. The ideal location is immediately proximal to the innominate vein. It is important to remember that, in this case, the orientation of the filter must be reversed in comparison to a standard IVC filter. Therefore, a femoral IVC filter kit must be used from a jugular approach or, more commonly a jugular kit from the femoral approach. Care must be taken to avoid extension of the IVC filter into the right atrium.

THE PREPIC TRIALS

To date, there has only been one long-term randomized study evaluating the roll of IVC filters in the prevention of PE. The PREPIC (Prevention du Risque d'Embolie Pulmonaire par Interruption Cave) study, whose initial 2-year results were published in 1998, and whose 8-year long-term follow-up results were published in 2005, randomized 400 patients with proximal DVT to treatment with anticoagulation alone (with low–molecular-weight heparin for 8 to 12 days, followed by a vitamin K antagonist for a minimum of 3 months) versus anticoagulation and a permanent vena cava filter. At 12 days, 2 PEs occurred in the filter group (1.1%) versus 9 PEs in the nonfilter group (4.8%) ($P = 0.03$). At 2 years, there were 6 PEs (3.4%) in the filter cohort and 12 PEs (6.3%) ($P = 0.16$) in the nonfilter group. Recurrent DVT occurred in 37 (20.8%) patients in the filter group and 21 (11.6%) patients in the nonfilter group ($P = 0.02$). The 2-year results suggest that IVC filters provide significant short-term protection from PE

compared with anticoagulation alone, but this benefit wanes over time and that filters are associated with an increased risk of recurrent DVT.

Eight-year results of the PREPIC trial demonstrated 9 PEs in the filter group (6.2%) versus 24 PEs in the nonfilter group (15.1%) ($P = 0.08$). The filter group had 57 patients with DVT (35.7%) versus 41 (27.5%) in the nonfilter group ($P = 0.042$). Postthrombotic syndrome (PTS) occurred at similar rates in both groups, and was found in 109 (70.3%) patients in the filter group and 107 (69.7%) in the nonfilter group. This rate is substantially higher than other rates reported in the literature; however, it should be noted that 24% of patients in the PREPIC trial had PTS at the time of inclusion in the study. Mortality rates between the groups did not differ as there were 98 (48.1%) deaths in the filter group and 103 (51.0%) deaths in the nonfilter group. Of note, the predominant cause of death was cancer (in 49 patients), followed by cardiovascular-related mortality (32 patients), cardiac disease (22 patients), and bleeding (17 patients).

PREPIC results suggest that at 8 years, vena cava filters reduce the risk of PE but increase the incidence of DVT. IVC filters have no effect on the incidence of PTS or on survival.

The results of the PREPIC 2 trial were recently published. This extension of the PREPIC trial looked at the effect of routine placement of IVC filters on rates of recurrent PE in high-risk patients compared to anticoagulation alone. This multicenter, controlled trial randomized 399 patients to IVC filter ($n = 200$) and anticoagulation or anticoagulation alone ($n = 199$) at 17 centers in France from 2006 to 2012. Follow-up was at 3 and 6 months and the primary outcome was recurrent symptomatic PE at 3 months. The study reported rates of symptomatic or fatal recurrent PE were 3% in the IVC filter group versus 1.5% in the group with anticoagulation alone (RR 1.4, $p = 0.29$). Recurrent PE at 6 months was similar (3.5% filter group vs. 2% anticoagulation alone, RR 1.75, $p = 0.54$). There was no difference in all-cause mortality or major bleeding events between both groups at any time point. The PREPIC 2 study suggests that in patients with PE, at high risk of recurrence, the routine placement of IVC filters does not reduce the risk of recurrent PE when compared to anticoagulation alone.

Despite their longstanding and widespread use, long-term data on the safety and efficacy of vena cava filters are lacking. The PRESERVE trial (Predicting the Safety and Effectiveness of Inferior Vena Cava Filters), a joint venture between the Society for Vascular Surgery, the Society of

Interventional Radiology, and the FDA, began enrolling patients in 2015 in the first large-scale multispecialty prospective study designed to evaluate the use of IVC filters and follow-up. The trial aims to evaluate 2,100 patients at 60 centers in the United States, with 300 patients enrolled from each of the major filter manufacturers. Results will likely be available in the years to come and may answer many of the questions about IVC filter use and performance in the real-world environment.

RETRIEVABLE FILTERS

The intent of a retrievable filter is risk mitigation for patients with a transiently increased risk of PE. However, when retrievable filters are placed prophylactically in a patient without a DVT or PE, it is considered off-label use of the device. The FDA estimates that nearly 50% of filters are placed using extended criteria. Retrievable filters are placed in a manner identical to permanent filters, but have design features allowing for recapture and removal during a second procedure from a jugular approach. Ironically, key features of the filter that allow for recapture may also lower the safety profile of these devices, promoting fracture or migration. Ease of retrieval requires less secure fixation, more shallow or flexible anchoring hooks, and reduced endothelialization of the anchoring portion of the filter. Nevertheless, all currently available retrievable filters carry dual FDA approval for either temporary placement or permanent use. Although the option of retrieval is appealing at face value, in real-world clinical practice, there are no defined follow-up criteria and only a paucity of these devices is ever removed.

TABLE 224.4 Factors to Consider Before Discontinuing a Retrievable Filter

1. No indication for a permanent filter
2. Expected period of increased VTE risk has passed and the patient will not return to a high-risk state
3. Risk of PE is low
4. Life expectancy is long enough for the patient to derive benefit from removal
5. Filter retrieval is safe and technically feasible

The development of retrievable filters was spurred by several factors. Data obtained from the PREPIC trial suggested that IVC filters, left in place long-term, increase the risk of recurrent DVT. Second, physicians across multiple specialties are implanting ever-increasing numbers of filters using off-label extended criteria as certain subsets of patients were perceived to have an increased risk of thromboembolism in temporal relation to their condition or procedure and a relative contraindication to standard primary VTE chemoprophylaxis. Multisystem trauma patients, orthopedic patients, bariatric patients, and pregnant patients all represent higher-risk cohorts for whom these filters are used in an off-label prophylactic fashion.

Currently available retrievable filters are shown in Figure 224.4. All of these filters have a window of time during which they can safely be removed and retrieval times may vary between filter designs. There are no strict criteria to guide the decision-making process for removal, but several factors should be considered, as seen in Table 224.4. Well-controlled clinical trials evaluating the impact of retrieval versus permanence are lacking; however, mathematical modeling suggests an optimal time frame for removal lies between 29 and 54 days after the VTE risk subsides.

Several iterations of retrievable filters have come and gone from the market, but the majority share similar design features, including a hook at the top allowing for capture with a gooseneck snare and recovery through a sheath. Figure 224.5 demonstrates the recapture and filter retrieval process.

COMPLICATIONS

Although a myriad of filter-related complications have been described,

major adverse events fortunately are rare. During the procedure or immediately thereafter, filter malposition, migration, access site hematoma, and femoral vein thrombosis are most frequent. New femoral vein thrombosis on the side ipsilateral to the procedure and after insertion is common, occurring in up to 20% to 40% of patients by 1 to 2 weeks in some series. In general however, less than half of these new DVTs are symptomatic. Disappointingly, new lower profile devices have not been shown to lower this rate. Recurrent PE, perhaps the most important measure of a filter's efficacy, occurs in an estimated 2% to 5% of patients. However, these data may underreport the true incidence as the number of asymptomatic recurrences is difficult to quantify.

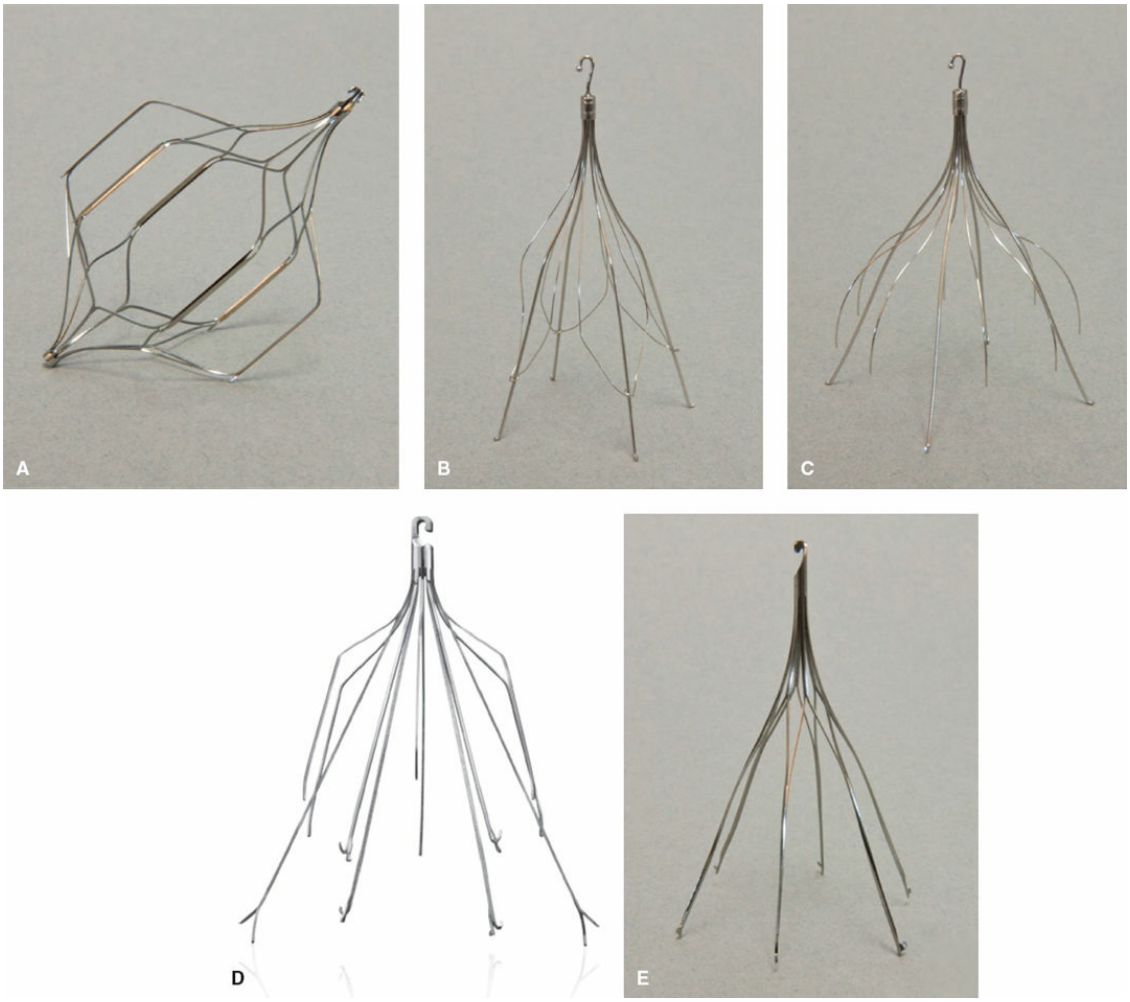

Figure 224.4. Examples of currently available retrievable IVC filters. (**A**) Optease, (**B**) Günther Tulip, (**C**) Celect, (**D**) Denali, and (**E**) Option filters.

Asymptomatic perforation of the IVC with a chronically indwelling filter is one of the most common findings observed in patients who undergo abdominal imaging for other indications. Durack and colleagues reported a retrospective series of 50 patients with either the Gunther Tulip or Celect filters who had abdominal CT scans obtained between 1 and 880 days after insertion. Forty-three (86%) of these filters had at least one component perforating the vena cava. By 71 days, all filters imaged demonstrated some degree of caval perforation. Isolated reports of filters perforating the vena cava and injuring surrounding organs, including the aorta, duodenum, or small bowel have been reported, but the true incidence of these rare events is unknown.

Filter fracture and embolization are common events, the incidence of which increases with longer dwell time; but whose clinical significance remains unclear. Data suggest that between 6% and 25% of filters left in

place longer than 2 years will fracture. But the clinical consequences when a portion of a filter dislodges are highly variable, ranging from asymptomatic to immediately life-threatening. The majority of embolized fragments lodge harmlessly in distal pulmonary arteries. However, a minority of events have led to lethal cardiac arrhythmias and cardiac tamponade (Fig. 224.6).

The importance of removal of retrievable IVC filter has recently been underscored by two safety alert communications from the FDA. Currently, very few retrievable IVC filters are actually removed with published retrieval rates ranging from as low as 13% to 18%. In 2009, in a review of the FDA's Manufacturer and User Facility Device Experience (MAUDE) data base, the FDA noted 951 IVC filter complications over a 5-year period documented in the database and that a significant majority of these were occurring with retrievable IVC filters. This resulted in an FDA alert communication in August of 2010 recommending "that implanting physicians and clinicians responsible for the ongoing care of patients with retrievable IVC filters consider removing the filter as soon as protection from PE is no longer needed." This communication was followed by a second update on the original safety alert in May of 2014 "encouraging all physicians involved in the treatment and follow up of patients receiving IVC filter to consider the risk and benefits of filter removal for each patient. A patient should be referred for IVC filter removal when the risk/benefit profile favors removal and the procedure is feasible given the patient' health status." According to a decision analysis published by representatives of the FDA, patients without PE should have their filters removed between 29 and 54 days after the time their filters were placed as the transient risk of PE has passed and the benefit/risk profile favors filter removal.

EDITOR'S COMMENT

The cogently written chapter by Levin and Rectenwald highlights inferior vena cava (IVC) filter placement, a straightforward and common procedure to prevent pulmonary embolism in those who cannot have anticoagulation, or have had complications related to anticoagulation. IVC filter placement is ubiquitous because it is technically straightforward, effective, and is associated with a low number of complications. However, recently filter design changes have rendered them less safe with regard to potential stent fracture and embolization, as well as trans-caval perforation.

First, the proper indication for an IVC filter cannot be overemphasized, as the authors state. It serves to reiterate here the absolute indications for an IVC filter. These are when anticoagulation is contraindicated in the presence of a venous thromboembolism (VTE), the failure of anticoagulation in the presence of a VTE, an emergency treatment following massive PE, or chronic recurrent PE when anticoagulation has failed. These indications are well established and also included in the 2016 *Chest American College of Chest Physicians Venous Thromboembolism* guidelines (Kearon C, Akl EA, Ornelas J, et al. Antithrombotic therapy for VTE disease: CHEST guideline and expert panel report. *Chest* 2016;149:315–52). Unfortunately, over the recent years, prophylactic IVC filter indications have liberalized and now account for the majority of filters placed (Stein PD, Matta F, Hull RD. Increasing use of vena cava filters for prevention of pulmonary embolism. *Am J Med* 2011;124:655–61). Although filters are quite safe, they are still associated with complications, and are costly. For example, patients who undergo bariatric surgical procedures have been found to have no benefit from prophylactically placed IVC filters (Birkmeyer NJ, Share D, Baser O; Michigan Bariatric Surgery C. Preoperative placement of inferior vena cava filters and outcomes after gastric bypass surgery. *Ann Surg* 2010;252:313–8) despite the fact that obesity remains a major risk factor for venous thromboembolism (Heit JA, Ashrani AA, Crusan DJ, et al. Reasons for the persistent incidence of venous thromboembolism. *Thromb Haemost* 2017;117(2):390–400).

Another common IVC filter prophylactic indication is for the poly-trauma patient. However, the risk of death in trauma patients is not reduced with a prophylactic IVC filter. Specifically, data from a large statewide trauma registry showed that those patients who underwent a prophylactic IVC filter placement as compared with those who did not had no change in overall mortality, despite risk stratification (Hemmila MR, Osborne NH, Henke PK, et al. Prophylactic inferior vena cava filter placement does not result in a survival benefit for trauma patients. *Ann Surg* 2015;262:577–85).

Multiple types of filters now exist, and I would say that based on both basic research and clinical experience, the conical design makes most sense. This allows an embolus to be trapped in the center, and provides for perithrombus

flow to be maintained. Filter designs that are not of that geometry tend not to be as effective, particularly with regard to filter thrombosis. This was highlighted in a comparative trial of the Trapeze filter design (nonconical) versus the Greenfield filter (Usoh F, Hingorani A, Ascher E, et al. Prospective randomized study comparing the clinical outcomes between inferior vena cava Greenfield and TrapEase filters. *J Vasc Surg* 2010;52:S394–9).

There are numerous routes by which to place a filter, although fluoroscopic guidance is most common and is generally quite safe. Transabdominal and intravascular ultrasound-related filter placement takes additional skills and experience, although it is used at some institutions quite frequently. For critically ill patients, this option may be particularly useful.

It should be noted that suprarenal and superior vena cava IVC filter placements are quite different. Suprarenal placements rely on the same principals, and are as efficacious and safe as infrarenal IVC filter. They are of particular use in those patients who may become pregnant or have a duplicated IVC system. It is unclear if a superior vena cava filters are indicated; based on the high mortality, many of these patients have due to their underlying diseases (Ascher E, Hingorani A, Tsemekhin B, et al. Lessons learned from a 6-year clinical experience with superior vena cava Greenfield filters. *J Vasc Surg* 2000;32:881–7). Moreover, it is difficult to discern if upper extremity DVT really accounts for large pulmonary emboli that would lead to right heart strain and potentially death. Thus, we rarely recommend them.

The lack of actual filter retrieval in the optional retrieval IVC filters is quite striking. This has been documented in several studies and the FDA is aware. Maintaining a patient registry and patient call backs for retrieval of their IVC filter is laudable and hopefully will increase the retrieval rates as the authors' highlight. This will also be better defined with the ongoing PRESERVE trial.

The complications that occur with filters are rare but once in a while do require a late IVC filter removal. There are now numerous endovascular techniques, including using a bronchial forceps, large sheaths, multiple snare wires, and laser cutting of stents for late removable of a retrievable IVC filter. Open surgical removal can be morbid and associated with significant blood loss, although with some patients who have perforation of either their aorta or the duodenum, this can be effective therapy relieving chronic abdominal pain.

Peter Henke

225 Venous Insufficiency

Megan Tracci

Superficial venous insufficiency is perhaps the most prevalent of vascular disorders. The range of reported prevalence is attributable to the use of a variety of clinical and functional definitions, ranging from the presence of any visible manifestation of venous disease (from spider veins to severe trophic changes) to the demonstration of significant reflux on duplex ultrasound. Nevertheless, in a large population study, 28% of patients (30%) of women were found to have either deep or superficial reflux exceeding 0.5 second on duplex ultrasound and far more to manifest visible changes typically associated with venous insufficiency. More than 5% demonstrated trophic skin changes, consistent with prior findings that approximately 0.5% of the population suffers from active ulcers and 0.6% to 1.5% have healed ulcers. Venous insufficiency is two to three times more common in women than men and also seems to occur more frequently in non-Hispanic whites than in other ethnic populations. The incidence of symptomatic venous insufficiency also rises with age, pregnancy and parity, obesity, heredity, venous thromboembolic disease, and the presence of certain genetic disorders.

ETIOLOGY AND PATHOPHYSIOLOGY

Familiarity with the venous anatomy of the lower extremity is essential to understanding the pathophysiology of venous insufficiency (Fig. 225.1). The superficial veins of the leg travel above the muscular fascia. The great saphenous vein (GSV) and small saphenous vein (SSV) are the primary axial superficial veins and may give rise to anterior and posterior accessory veins that cross the thigh in an oblique fashion, to a posterior accessory vein termed the “posterior arch vein” arising from the GSV in the leg, and to a vein providing communication between GSV and SSV systems. The GSV joins the femoral vein at the groin, in a region termed the saphenofemoral junction (SFJ). The SSV most commonly joins the popliteal vein behind the knee, though its anatomy is more variable and this junction may occur as high as the midthigh femoral vein. As with the

saphenofemoral junction, the initial portion is termed the saphenopopliteal junction (SPJ), referring to the segment from the orifice of the vein to the penultimate valve. The deep system comprises the common femoral, profunda or deep femoral, and femoral (previously termed “superficial femoral”) veins, the popliteal vein, and the paired tibial veins. While the deep and superficial system are assessed separately, they communicate via numerous perforating veins and form an interconnected physiologic system. The veins of the lower extremity are endowed with delicate, bicuspid endothelial valves designed to promote unidirectional, central flow and to resist gravity in preventing reflux of blood. Valve dysfunction may be either primary or secondary to damage associated with thromboembolic disease, injury, or distension associated with conditions such as central obstructive disease or pregnancy, which combines hormonal, volume, and obstructive components. The venous hypertension associated with valve dysfunction contributes to the development of visible and/or symptomatic venous disease. Outflow obstruction within the venous system may also contribute to the progression of disease in a number of ways. Thromboembolic disease may either directly damage involved valves or lead to chronic obstruction, particularly in the deep venous system. Obstruction may also result from direct venous trauma or from external compression, such as compression of the left iliac vein by the iliac artery in May–Thurner syndrome.

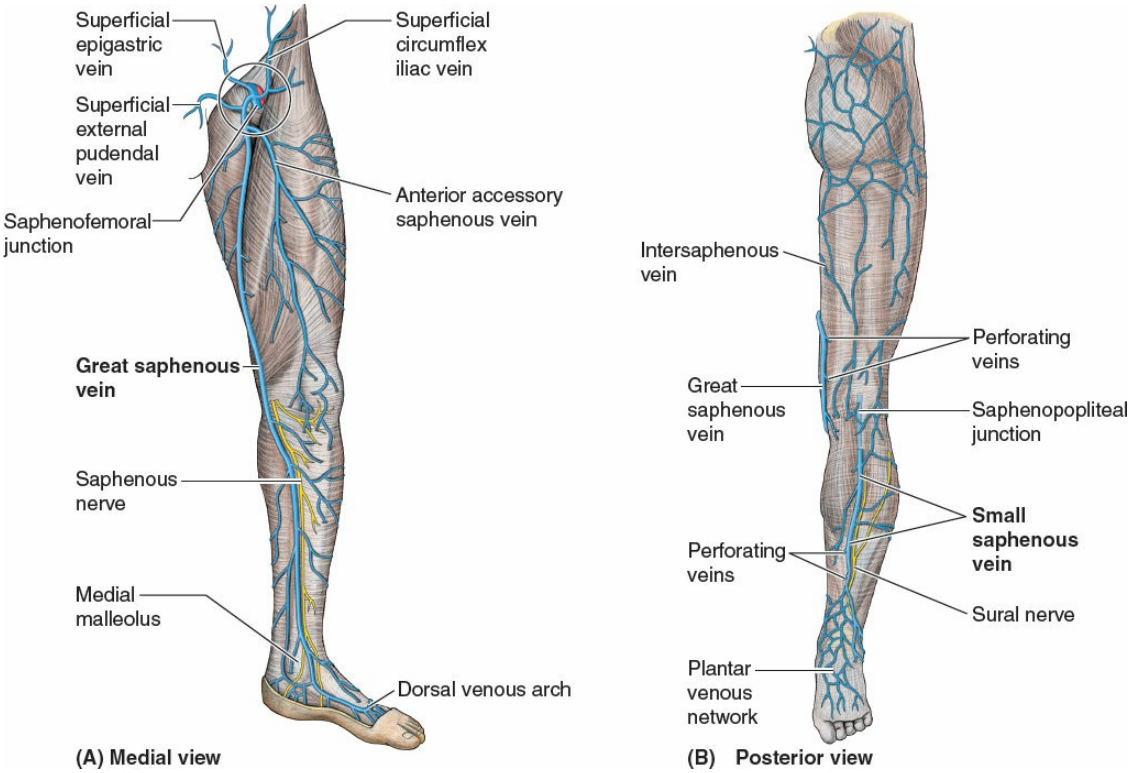

Figure 225.1. Superficial venous anatomy of the lower extremity is highly variable. **A.** Medial view; **B.** Posterior view. Generally, one should be aware of the great saphenous, accessory saphenous, small saphenous, and intersaphenous veins, and their zones of influence in the leg. (Modified from Moore KL, Dalley AF II. *Clinical Oriented Anatomy,* 4th ed. Baltimore, MD: Lippincott Williams & Wilkins; 1999.)

CLINICAL PRESENTATION

The clinical presentation of mild to moderate venous insufficiency is widely variable, ranging from asymptomatic visible manifestations such as telangiectasia (spider veins) or varicosities to disease that causes symptoms ranging from aching, edema of the foot and ankle, itching, dermatitis, or heaviness, to trophic changes such as ulceration. These symptoms typically progress over the course of the day or with prolonged standing and may be relieved by leg elevation. The severity of symptoms varies widely and often correlates poorly with the visible appearance of varicosities or with physiologic findings. In more advanced disease, venous hypertension contributes to microangiopathy, with elongation and dilatation of small vessels, endothelial damage, pericapillary edema, hemosiderin deposition, and fibrin cuff formation, culminating in lipodermatosclerosis, with its characteristic fibrotic changes to the dermis

and subcutaneous tissue. These trophic skin changes herald the formation of venous ulcers, typically in a perimalleolar position.

An important tool in the assessment and documentation of venous disease is the CEAP classification, which characterizes venous disorders based on clinical, etiologic, anatomic, and pathophysiologic characteristics (Table 225.1).

In addition to ulcers, venous disease may give rise to other troublesome complications. Varicosities may be prone to thrombus formation giving rise to superficial thrombophlebitis, which manifests as a tender, warm, inflamed region associated with the affected vein segment, which may itself form a palpable cord. Thrombosis within large, axial veins may predispose patients to deep vein thrombosis and further thromboembolic complications through propagation of clot centrally. Varicosities may also rupture and bleed either spontaneously or as a result of local trauma, resulting in significant blood loss.

TABLE 225.1 CEAP Classification of Venous Disease[a]

Class	Description
0	No visible or palpable signs of venous disease
1	Telangiectasias or reticular veins
2	Varicose veins
3	Edema
4	Skin changes such as pigmentation, eczema, lipodermatosclerosis
5	Skin changes with healed ulceration
6	Skin changes with active ulceration

[a]CEAP, clinical etiologic, anatomic, and pathologic signs.

TREATMENT OF SUPERFICIAL VENOUS INSUFFICIENCY

Conservative and Medical Therapy

Graduated compression garments are available in a variety of configurations, from knee- and thigh-high stockings through full compression hose, as well as a range of degrees of compression. Patients with symptomatic superficial venous insufficiency may benefit from moderate compression (20 to 30 mm Hg) for symptom management, though compression has not been demonstrated to affect the progression of disease, including the development of future varices. Compliance with compression therapy is often a challenge, as patients may find the garments themselves uncomfortable or may have physical difficulty donning stockings, even with the use of commercially available donning aids. Compression therapy is considered the mainstay of treatment for patients with venous ulcers, with multilayer dressings preferred for ulcer healing and stockings utilized for maintenance therapy and the prevention of new ulcers. A number of vasoactive medications, many of which are commercially available in the United States as nutritional supplements rather than FDA-approved drugs, have also shown utility in the relief of symptoms (diosmin, hesperidin, horse chestnut seed extract, rutosides, sulodexide, and micronized purified flavonoid fraction) or the healing of venous ulcers (pentoxifylline, micronized purified flavonoid fraction).

Endovascular Therapy

Indications and Contraindications

Endovenous thermal ablation using either radiofrequency or laser energy may be used for closure of axial superficial veins (GSV or SSV) and is indicated when axial reflux is present either for the treatment of symptomatic varicose veins, including to aid the healing or prevent recurrence of a venous ulcer. There are few true contraindications to these procedures. Historically, the presence of a patent deep vein system was viewed as a prerequisite for saphenous vein removal or closure. However, it has become apparent that the multitude of collateral pathways in the venous system preserve adequate venous outflow after ablation of a refluxing superficial axial vein. Similarly, the presence of thrombus in a saphenous vein, typically as a sequella of prior phlebitis, does not preclude treatment. Multiple authors report successful treatment of large diameter saphenous veins (>1 to 1.5 cm), though it is noted that treating surgeons often utilize more energy/cm in the closure of these vessels. Tortuous veins or those with stenotic segments may often be traversed with the

assistance of a hydrophilic guidewire, or the operator may elect more than one access point in order to treat the entire segment. Ultimately, contraindications comprise patient factors such as pregnancy and uncorrectable coagulopathy.

Preoperative Planning

Preoperative planning should include a focused history, including personal or family history of thrombophilia or disorders of hemostasis, the use of relevant drugs such as anticoagulants, and drug allergies or intolerances that might interfere with anesthesia or analgesia. If intravenous sedation is planned, factors such as obesity and the presence of sleep apnea are relevant. A thorough duplex ultrasound should be performed to delineate anatomy, including vein diameters and branching patterns and to evaluate for the presence, severity, and location of occlusive disease or reflux. Attention should be paid to the anatomy of junctional areas such as the saphenofemoral and saphenopopliteal junctions and to the anatomy of the veins to be treated, including tortuosity or segmental disease that may interfere with passage of guidewire or catheter (see Fig. 225.1).

Surgical Technique (Including Diagrams)

This procedure may, at the surgeon's discretion, be performed under general anesthesia, monitored IV sedation, or with oral medications only. For ablation of the GSV, the patient is placed either supine or in a slight reverse Trendelenburg position. The leg is sterilely prepped from ankle to groin and draped. Ultrasound is used to localize the desired point of access, which is typically at the level of the knee or proximal calf, but may be selected further distally based on anatomic considerations. The skin and subcutaneous tissue overlying the access point are infiltrated with 1% lidocaine and the vein accessed under ultrasound guidance using a 21-gauge micropuncture needle. The 0.018″ micropuncture guidewire is carefully advanced and a small skin nick created with a No. 11 blade. The needle is removed and replaced with a 4-Fr microsheath. The inner dilator and microwire are removed and a 0.35″ guidewire, typically either a J- or Bentson configuration, is advanced across the SFJ. The 4-Fr microsheath is then exchanged for a 5-Fr long sheath (typically available in 45, 60, and 90 cm configurations), which is also advanced across the SFJ. The wire and inner dilator are then removed and the laser fiber or RF probe advanced through the sheath. Ultrasound is used to guide careful tip placement, typically 1 to 2 cm distal to the SFJ.

Both laser and RF techniques require perivenous infiltration using a dilute lidocaine solution (445 mL of 0.9N saline, 50 mL of 1% lidocaine, and 5 mL of 8.5% sodium bicarbonate). The infiltration is performed under ultrasound visualization, with a goal of achieving circumferential infiltration within the saphenous compartment along the entire treated length of the vein. This infiltration should ideally provide 1 cm of buffer around the vein and, in particular, between treated vein and skin. Special attention should also be paid to careful infiltration of any below-knee segment treated, due to the proximity of the saphenous nerve. The tumescent solution creates a heat sink, buffering the nerve, skin, and surrounding tissues from thermal injury, as well as compressing the vein around the catheter, reducing vein volume and aiding in effective thermal ablation. For large-diameter veins, this compressive effect may be aided by placing the patient in the Trendelenburg position or by aspirating on the side port of the sheath.

If laser is used, the operator, patient, and other staff present must don protective glasses rated to the appropriate wavelength. The proper location of the fiber tip should be confirmed once again by ultrasound prior to initiating therapy. The vein is then ablated by activation of the energy source during catheter pullback. The laser systems utilize continuous pullback of 2 to 3 mm/s, with a goal of delivering 30 to 50 J/cm energy. Most operators have slightly modified this technique to deliver higher energy (up to 80 J/cm) for the first 10 cm below the SFJ by slowing the pullback rate to 1 to 2 mm/s. The literature describing successful closure of large diameter veins does also note a slightly higher average energy delivery by operators in these cases.

The RF system utilizes sequential treatment of overlapping 7 cm segments of vein for 20-second cycles. As with laser, more energy is delivered to the first segment below the SFJ, in this case by applying two cycles of heating before pulling the catheter back to the next station.

At the conclusion of the procedure, the catheter and sheath are removed and gentle pressure applied to the access site. Completion imaging at the SFJ should confirm cessation of flow in the saphenous vein beyond the first 1 to 2 cm and, more importantly, note the absence of thrombus extending into the deep (common femoral or popliteal) vein.

Minor variations apply when treating the SSV or accessory/branch veins. When treating the SSV, careful attention must be paid to appropriate catheter tip placement, as there is significant anatomic variability in the

junction of the SSV and the deep system. Furthermore, the potential proximity of the tibial and common peroneal nerves (in the proximal/saphenopopliteal region) and the sural nerve (in the distal lower leg) should prompt thorough infiltration of these areas with tumescent solution and careful catheter placement with avoidance of the saphenopopliteal junction and the more distal lower leg. The origin of the anterior accessory saphenous vein in the thigh may also be variable, with this vein emptying either into the proximal portion of the GSV or directly into the femoral vein. Ablation typically begins just distal of the junction of the GSV in the former case or 1 to 2 cm distal to the junction with the deep vein in the latter.

Of note, cyanoacrylate adhesive and combined mechanical–chemical endovenous ablation techniques which do not require the use of tumescent have been reported within the past 5 years, though these have not yet been widely adopted in the United States.

Postoperative Care

Waist high (GSV) or thigh high (SSV) graduated compression stockings providing 30 to 40 mm Hg compression are then placed. Surgeon practice is highly variable with regard to need for or duration of compression therapy. However, the majority of operators continue to recommend compression with a range of 2 to 14 days reported. Durations of therapy from 7 to 14 days have been associated with some reduction in pain and analgesic use. There is no strong data suggesting a benefit with regard to therapeutic effectiveness or the incidence of VTE. Although some argue that the very low rate of PE (thought to be <0.01%) following endothermal ablation obviates the need for routine postprocedure screening of asymptomatic patients, duplex ultrasound screening for DVT remains common practice at intervals of 48 hours to 2 weeks postprocedure.

COMPLICATIONS AND THEIR MANAGEMENT

The most commonly observed form of thrombus has been termed endothermal heat-induced thrombosis (EHIT), and classified as EHIT 1 to 6 based on the degree of extension into the femoral vein. In general, levels 1 to 4 are managed with observation with serial duplex ultrasonography or without the addition of antiplatelet therapy. Levels 5 and 6 are frequently treated with observation and a short course (1 to 6 weeks) of anticoagulation.

Open Surgical Therapy

Surgical Saphenectomy

Indications and Contraindications

The indications for surgical treatment of the saphenous vein by high ligation, division, and invagination saphenectomy ("stripping") parallel those for the endovenous thermal ablation procedures that have largely supplanted this technique. Ligation alone at the SFJ is ineffective and associated with a high rate of persistent or recurrent symptoms. The procedure may be carried out under general anesthesia or under local tumescent anesthesia with or without moderate IV sedation. Once again, contraindications relate to patient characteristics that may preclude safe anesthesia, analgesia, or surgical intervention. Preoperative evaluation should encompass the same factors as for endovenous intervention as well as further investigation warranted based on the choice of anesthesia techniques. While endovenous therapy may be undertaken without interrupting antiplatelet or anticoagulant regimens, the potential for significant bruising and discomfort dictate a period of abstinence prior to open venous surgery. Careful duplex ultrasonography is important prior to saphenectomy and can alert the surgeon to the presence of accessory veins or atypical anatomy, as well as to diseased or tortuous segments of the saphenous veins that may not be amenable to passage of the stripper.

Surgical Technique (Including Diagrams)

The patient is laid supine. A prophylactic single dose of subcutaneous heparin or low molecular weight heparin is administered. A 2- to 3-cm incision is made in the groin crease overlying the SFJ. In an obese patient, the use of ultrasound to localize the SFJ can minimize both the size of the incision and the extent of dissection with attendant risk of lymph leak. In addition, careful sonography can identify accessory veins, typically arising within several centimeters of the SFJ that should, if incompetent, be addressed at the time of operation to prevent recurrent symptoms. Dissection is limited to that required to provide sufficient visualization of femoral vein at the junction, permitting ligation of the saphenous vein with nonabsorbable suture and division at this level. Care should be taken to avoid injury to the femoral vein, but also to achieve a relatively flush ligation to avoid leaving an extensive blind stump of saphenous vein. A flexible stripper is then passed down the saphenous vein through a small venotomy. The stripper should be palpable, and is often visible, at the level

of the knee. A small counterincision is performed to permit circumferential dissection of a short segment of the saphenous vein at this level. The vein is ligated distally and divided. The proximal end of the saphenous vein is affixed to the stripper either using a 0 silk or by utilizing the removable tip provided with the stripper. It is then invaginated on itself and removed in a proximal to distal direction and removed via the distal incision. Surgical saphenectomy should typically be limited to the thigh segment, with the distal incision at or just below the knee, in order to minimize trauma to the saphenous nerve, which is closely associated with the vein below the knee.

Several approaches to hemostasis are frequently utilized. Use of a tourniquet may require general anesthesia and is of greatest utility when additional phlebectomy, particularly of sizeable veins, is anticipated. In this case, an appropriately sized tourniquet should be placed over soft webbed dressing on the high thigh and the leg elevated, exsanguinated from foot to groin with an Esmarch bandage, and the tourniquet inflated prior to additional phlebectomy. This technique is not effective in patients whose femoral arteries are noncompressible. The use of tumescent anesthesia with a dilute lidocaine solution to infiltrate along the course of the saphenous vein may permit the performance of this operation without general anesthesia and is also helpful in reducing the degree of bruising, swelling, and discomfort associated with accumulation of blood in the saphenous tunnel. In any case, immediate compression of the saphenous tunnel aids with this. The incisions are closed in layers, reinforced with surgical strips or a dermal adhesive, and sterilely dressed before placement of gauze fluffs dressings over the course of the saphenous vein and the application of a compressive elastic dressing.

The Small Saphenous Vein

As noted in the discussion of endovenous ablation, the anatomy of the saphenopopliteal junction may be variable and the SSV, itself, in proximity to motor as well as sensory nerves.

Postoperative Care

The compressive dressing is left in place for 48 hours, then removed. This dressing may be left in place for up to 4 days when more extensive phlebectomy has been performed. Patients are instructed that they may benefit from wearing either an elastic compressive dressing or compression stockings for comfort for the first postoperative week. Once

the dressing is removed, bathing is permitted and activity advanced as tolerated. A postoperative visit is scheduled at 4 weeks.

Ambulatory Phlebectomy

Phlebectomy yields gratifying results in the management of isolated, pressurized varicosities and those that persist following successful treatment of axial reflux. It can be performed awake with local tumescent anesthesia alone, with mild to moderate sedation as an adjunct, or under general anesthesia, based on the extent of disease and patient and surgeon preference. The selection of ambulatory phlebectomy may incorporate a number of factors, including the characteristics of the targeted veins, with large and pressurized veins often proving somewhat resistant to percutaneous sclerotherapy, patient preference, surgeon experience, and the potential to stage later percutaneous therapy.

Surgical Technique

The veins to be treated are marked with the patient well hydrated and standing. The patient is then positioned for optimal access to the target veins and the skin sterilely prepped and draped. If local tumescent anesthesia is used, the area to be treated is infiltrated and treatment proceeds to contiguous areas to minimize patient discomfort. If the veins to be treated are large and extensive and general anesthesia is used, utilization of a tourniquet and exsanguination of the leg using an Esmarch bandage can afford hemostasis and minimize postprocedure pain and bruising. A 1- to 3-mm skin incision is made over the target vein, typically in a longitudinal orientation, except in flexural areas, where the incision should be oriented with the lines of skin tension (Langer lines). For very small, dermal veins, this incision may be made using an 18-gauge needle or the tip of a No. 11 blade. Small veins may be elevated using a fine vein hook, which minimizes stretching of the incision. These are available in a variety of configurations. Larger veins may be grasped and elevated more effectively using a fine, curved hemostat. The vein is then grasped between two hemostats, divided, and the hemostats are gently rotated in order to extract the greatest length possible, often several centimeters, in each direction. Occasionally, larger tethering branches will become visible. These can be grasped, divided from the main trunk, and avulsed in a similar fashion. Typically, the compression afforded by tumescent infiltration along with a minute or two of gentle manual pressure are

adequate for hemostasis. In this fashion, the marked veins may be removed using as few incisions as possible. Vein ligation is rarely indicated, except in the relatively infrequent circumstance of varices arising directly from intact axial veins or the use of ultrasound localization to focally ligate a perforating vein associated with a cluster of varices. At the conclusion of the procedure, the incisions are cleaned and either sterile surgical strips or a dermal adhesive applied. As with saphenectomy, a layered gauze and compressive dressing is then applied and left in place for 48 hours.

Complications and Their Management

The most common complaints following surgical phlebectomy are pain and bruising. Patients not infrequently benefit from several days of prescription pain medication following saphenectomy or particularly extensive phlebectomy. Subsequently, and for typical microphlebectomy, NSAIDs or acetaminophen provide sufficient analgesia. Bruising is more common with extensive phlebectomy, impaired platelet function, or anticoagulation and may take several weeks to resolve completely. Compliance with compression following the procedure can help to minimize the duration and severity. Wound complications such as significant bleeding, hematoma, or infection occur infrequently.

Deep vein thrombosis following saphenectomy is likely both underreported and infrequently clinically symptomatic. Surveillance duplex following saphenectomy or phlebectomy is not standard in most practices. However, new onset symptoms consistent with DVT should be promptly evaluated.

Nerve injury presenting with numbness, paresthesia, or pain may also occur. These typically improve over time, though complete resolution may not be achieved. Persistent pain may necessitate targeted therapy. The saphenous nerve distribution results in symptoms along the medial calf, malleolus, and a portion of the medial foot. The nerve is more closely associated with the saphenous vein distal to the tibial tuberosity, supporting the modern practice of limiting stripping to the segment cephalad to this region. Due to the variable anatomic relationship of the SSV with the nerves of the popliteal fossa, dissection in this area may affect the sural, peroneal, or tibial nerves.

Neovascularization and recurrent varicose veins may also result in late recurrence of symptoms. In some instances, extensive dissection, particularly at the SFJ, is thought to contribute to neovascularization. In the popliteal fossa and distribution of the SSV, it is most likely that

recurrent symptoms are attributable to the multiple collateral pathways from the popliteal vein to the proximal SSV via perforating veins or large medial gastrocnemius veins. On occasion, communication may also be found with the greater saphenous vein.

Percutaneous Therapy (Sclerotherapy)

Indications and Contraindications

Percutaneous sclerotherapy using, most commonly, polidocanol (Asclera, BioForm Medical Inc) or Sotradecol can be quite effective in the treatment of varicose and reticular veins (1 to 3 mm) and telangiectasias. Both agents are detergents that act on the intima to promote vein closure. Polidocanol is available in 0.5% and 1% formulations in 2 mL ampules and is FDA approved for the treatment of reticular veins and telangiectasias. Sodium tetradecyl sulfate/STS (Sotradecol, Bioniche Pharma Group) is manufactured in 3% and 1% concentrations and is approved for the treatment of small, uncomplicated varicose veins.

Both agents have favorable safety profiles, with polidocanol exhibiting a slightly lower incidence of allergic reaction, of extravasation necrosis, and of posttreatment hyperpigmentation. Thrombotic complications may be seen and these sclerosants should not be used in the setting of acute venous thrombosis. Osmotic agents such as hypertonic saline and irritants such as glycerine or alcohol have less favorable safety and side-effect profiles and are infrequently used in modern venous practice.

Preoperative Planning

Understanding of vessel size and underlying patterns of venous hypertension are critical to achieving optimal results. Appropriate duplex ultrasound imaging should be obtained when axial reflux is suspected and patients should be appropriately advised that untreated reflux of saphenous or perforating veins will render visible varicosities, reticular veins, or telangiectasias more resistant to sclerotherapy and that, similarly, deep reflux will tend to contribute to persistent or recurrent veins. The agent and concentration should be selected based on vein size. Telangiectasias of 1 mm or less in diameter can be treated effectively with liquid 0.5% polidocanol or 0.2% to 0.3% Sotradecol. Typical blue–purple reticular veins of 2 to 3 mm in diameter are effectively treated with 0.5% to 1% polidocanol or concentrations up to 0.5% Sotradecol. At this size, many clinicians find that utilizing these solutions off-label as a room air or

carbon dioxide microfoam is quite effective. Veins larger than 3 mm may be treated with concentrations up to 1% polidocanol or 3% Sotradecol, typically in microfoam form.

Higher concentrations and more aggressive therapy are associated with an increased incidence of posttreatment hyperpigmentation. The maximum recommended volume per treatment session of either agent is 10 mL.

Surgical Technique (Including Diagrams)

Treatment of telangiectasias is best accomplished using a very dilute solution injected at a low angle to the skin using a 1- to 3-cc syringe and either a 27- or 30-gauge short needle. Visualization may be aided by the use of dedicated lighting and surgical loupes for magnification. Each injection is performed slowly with minimal pressure to prevent or quickly detect any extravasation and typically totals only 0.2 to 0.3 cc in volume. The course of the sclerosant is apparent due to visible, transient blanching of the treated portion of the vein. Reticular veins may be treated in a similar fashion with slightly higher sclerosant concentrations and volumes.

Veins larger than the 2 to 3 mm blue reticular form are often addressed using a microfoam technique. If foam is used, it is created using the Tessari method of agitation of a 1:4 to 1:5 mixture of sclerosant and either air or carbon dioxide using two syringes and either a Luer connecter or three-way stopcock. The fine foam created by vigorous to-and-fro agitation between syringes is typically stable for several minutes.

The treatment of larger, deeper varicosities or saphenous veins is best accomplished using ultrasound guidance by an experienced operator using a probe with sterile cover to ensure intravenous instillation, observe the course of the sclerosant, and guide the termination of injection once the microfoam is observed approaching or entering the deep system. The point of communication can be compressed manually or with the probe to prolong contact with the target segment and minimize exposure of the deep system. When treating axial veins, this is accompanied by elevation of the limb to decrease drainage centrally into the deep system, using a maximum of 15 to 20 mL of foam. Successful therapy of relatively large axial (great, small, or accessory saphenous) veins by this technique has been reported. This can be a helpful adjunctive technique when very tortuous segments not amenable to catheter passage are encountered when using laser or radiofrequency techniques for saphenous vein closure.

Postoperative Care

The injection sites are covered with folded 2 × 2 gauze and a compressive wrap or stocking to provide moderate compression. The patient is briefly observed to detect any allergic or anaphylactic reaction. Compression is recommended following sclerotherapy to reduce the risk of deep vein thrombosis and to optimize cosmetic results. The duration and method are widely variable among providers, but are typically 2 to 3 days for telangiectasias and small reticular veins and up to 7 days for extensive reticular veins or larger varicosities using 20–30 mm Hg stockings or an elastic wrap.

Complications and Their Management

It is typical for patients to notice some increase in discoloration in the first few days postprocedure. When this is associated tenderness, local firmness, and dark pigmentation in the region of a small thrombosed vein, recovery may be enhanced by local microthrombectomy, typically using an 18-gauge needle and gentle pressure to express retained clot. Phlebitis may otherwise be relieved by traditional methods of warm compresses, gentle compression, and the use of NSAIDs. Where it is associated with partial vein thrombosis, additional treatment to induce complete vein closure is helpful. Some degree of brown hyperpigmentation may affect up to 20% to 30% of patients treated with Sotradecol and a somewhat smaller proportion of those treated with polidocanol. This is associated with the use of higher concentration solutions and more extensive treatment. This hyperpigmentation will tend to fade on its own over the course of several months, though some patients will elect cutaneous laser treatment to accelerate this process. Neovascularization or telangiectatic matting describes the development of new, fine networks of red capillaries that can appear like a bruise in the area of treatment. Again, this tends to resolve over a matter of months postprocedure, but further sclerotherapy should be carefully considered in a patient prone to this complication. Nd:YAG laser or Intense Pulsed Light (IPL) treatment can be effective in treating persistent matting and may be an alternative for the management of remaining telangiectasias in a patient prone to matting postinjection.

Significant complications may also be associated with inadvertent extravascular or intra-arterial injection of sclerosant, which may, in the former case lead to focal skin necrosis and in the latter to more extensive and severe tissue loss. Small volume extravasation is generally well tolerated with the detergent agents.

It must be noted that while commonly practiced, the creation and

injection of microfoam is an off-label use of the detergent agents and that stroke in the setting of foam injection in a patient with patent foramen ovale and associated shunting has been reported. Less marked symptoms such as headache and transient visual symptoms have also been described. The use of carbon dioxide as a mixing agent may reduce the risk of these complications.

TREATMENT FOR DEEP VENOUS INSUFFICIENCY

While the majority of the treatment of venous insufficiency focuses on management of the superficial veins, there are several surgical methods that continue to find application in the repair or replacement of dysfunctional valves of the deep venous system.

Indications and Contraindications

Valve reconstruction by replacement or repair is indicated when severe symptoms (CEAP 4b to 6) are unrelieved by compression and treatment of superficial insufficiency or where deep insufficiency occurs in isolation. Results are compromised by the presence of extensive postphlebitic changes with scarring or occlusion in the distal vein segment.

Preoperative Planning

A thorough evaluation by duplex ultrasonography should demonstrate the location and function of the lower extremity valves, the anatomy of the incompetent segments and relationship varicosities, skin changes, or ulcers present on examination. The presence of any concomitant occlusive disease must also be documented. Reconstruction is focused on the most proximal dysfunctional segment. The structure and function of these valves must be carefully assessed. Primary valve dysfunction is less likely to be associated with thickened, damaged leaflets than postphlebitic dysfunction. A handful of surgeons have developed successful techniques of open/internal or “closed”/external repair of valves with preserved leaflet structure to bring the leaflets back into appropriate apposition and restore function. These valves may also be replaced through valve transplantation, most commonly using a segment of axillary vein that has been similarly assessed ultrasonographically and found to have healthy, functioning valves. Finally, in vein relocation/transposition, a functioning valve is present within a collateral system, such as a competent SFJ and proximal

greater saphenous vein in the presence of severe femoral vein reflux, and the incompetent vein can be transposed below the competent valves of the collateral system.

Surgical Technique (With Figures)

Open Valve Repair

The femoral vein is exposed and duplex ultrasound used to locate the most proximal incompetent valve. The vein is controlled proximally and distally with atraumatic clamps and a “T”-shaped venotomy performed at the level of the valve to permit exposure of the cusps without excessive distortion of the valve’s structure. Interrupted 7-0 or 8-0 Prolene sutures are placed from the corners of the valve cusps to improve apposition. Great care must be taken in handling the cusps both during repair and in assessment of apposition to avoid injury to these delicate structures. The venotomy is then closed in a running fashion after purging of air and the function of the repaired valve is assessed using duplex ultrasound and provocative maneuvers.

Closed Valve Repair

A similar repair may, in skilled hands, be effected by location of the valve using ultrasound and placement of commissural sutures transmurally through the external vein wall. These sutures are then retracted and their effect assessed using duplex ultrasound and provocative compression of the distal vein to induce reflux. If the suture improves apposition and function, it is carefully tied externally. The ability to assess valve function and cusp orientation in situ avoids the need, in open repair, of visually assessing the valve in its exposed state and delaying full function assessment until closure of the venotomy. The use of angioscopy, though not widely available, has been described as a helpful adjunct to aid in the placement and assessment of these external sutures, particularly early in the surgeon’s experience with this technique.

Both valve repair techniques may be accompanied by placement of a reinforcing external cuff to prevent subsequent dilation and recurrent failure of cusp apposition.

Valve Transplantation

The arm is abducted and an incision made along the course of the axillobrachial vein in the superior axilla. At this level, collateral pathways

provide adequate venous drainage to avoid significant postharvest swelling of the upper extremity. The donor segment of the axillary vein is resected after careful ultrasound confirmation of valve location and ligation and division of tributaries. The donor segment is inserted as an interposition graft in the proximal femoral vein. Valve function is assessed by duplex ultrasound and additional suture modification of the valve or external cuff reinforcement performed at the surgeon's discretion.

Valve Transposition

An incompetent tributary may be transposed below a competent valve within a collateral vessel in either and end-to-side or, less frequently, end-to-end configuration. Care must be taken to avoid kinking that would compromise either patency or valve function. The end-to-side configuration permits outflow from both veins, greater latitude with regard to the "lie" of the veins, and addresses size mismatches between transposed and outflow veins.

Complications and Management

The postoperative course of valve reconstruction is marked by a close balancing of the prothrombotic milieu of the vein and the potential for bleeding complications associated with the necessary perioperative course of anticoagulation, which is typically initiated immediately and extended from 8 to 12 weeks postprocedure.

OUTCOMES

In recent years, the latest generation endovenous ablation techniques using either laser or radiofrequency technology have yielded results equivalent to gold-standard high ligation and saphenectomy with a favorable complication profile. Deep venous reconstruction, in the hands of the relatively few, experienced operators reporting in the literature can also benefit the selected group of patients suffering severe complications of deep venous insufficiency using valvuloplasty, autogenous vein valve transplantation, and transposition techniques. Reconstruction using artificial, tissue-engineered, or cryopreserved vein valves has not, to date, yielded comparable results. Assessment of outcomes will increasingly incorporate quality of life and other patient-reported outcomes in addition to traditional clinical endpoints.

EDITOR'S COMMENT

Superficial venous insufficiency is, as Dr. Tracci states, the most prevalent vascular disorder in humans. This primarily encompasses varicose veins and related superficial venous reflux. The venous reflux is a major contributor to hydrostatic hypertension, of which the limb complications are swelling, pain, pruritus, and occasionally ulcers. While rarely limb- or life-threatening, it is a source of significant disability, particularly in the severe stages (Gloviczki P. The changing face of care for venous disease. *J Vasc Surg* 2011;53:1S). This nicely organized chapter highlights the primary etiologies, pathophysiology, and treatments for this disease.

Several important points bear discussion. First, there has been a rapid explosion of new techniques and devices to treat superficial venous insufficiency. In fact, the number of procedures that are related to superficial

venous disease treatment has exploded by approximately 4,000%, as cited by Dr. Lawrence in his Society for Vascular Surgery Presidential talk (Lawrence PF. “Better” (sometimes) in vascular disease management. *J Vasc Surg* 2016;63:260–9). This reflects not only improved physician recognition, but new devices, industry involvement, and more physicians treating these patients. Selection and appropriate indications for treating patients with superficial venous disease is paramount, and nicely highlighted by the author.

Second, it is important to use a consistent venous insufficiency classification system as highlighted. The clinical etiologic anatomic pathophysiology (CEAP) classification system is very useful, and widely accepted. The most common class of disease for patients with superficial venous insufficiency is usually C2 to C3. This is primarily leg heaviness, fullness, and occasional pain with the varicosities. The higher the category, such as C4B, C5, and C6, the more disabling it is due to chronic wounds, rash, swelling, and inability to ambulate as one desires.

Third, a major controversy is the recommendation or stipulation from health payers that compression therapy should be instituted for at least 3 to 6 months prior to any invasive therapy. However, the REACTIV trial has shown that this is of no benefit and proceeding with an invasive procedure for properly selected patients who are symptomatic and otherwise is warranted (Michaels JA, Brazier JE, Campbell WB, et al. Randomized clinical trial comparing surgery with conservative treatment for uncomplicated varicose veins. *Br J Surg* 2006;93:175–81). There are many options to treat superficial venous insufficiency, including foam sclerotherapy (now FDA approved, called Verathina), as well as surgical striping (much out of favor), and endoluminal venous ablation whether by radio frequency or laser catheters, glue, or other nonheat-related devices (Gloviczki P. The changing face of care for venous disease. *J Vasc Surg* 2011;53:1S). These procedures are often done in the office, and in part related to reimbursement from professional and facility fees, is the reason these procedural numbers have increased. Despite this, the outpatient setting seems most appropriate and is likely less costly than performing these procedures in the hospital setting. Interestingly, a randomized controlled trial showed most major techniques were nearly equivalent in outcomes, including quality-of-life measures (Brittenden J, Cotton SC, Elders A, et al. A randomized trial comparing treatments for varicose veins. *N Engl J Med* 2014;371:1218–27).

Fourth, endovascular heat-induced deep vein thrombosis, unique to these new endoluminal techniques are caused by endothermal heat-induced vein injury, occurring at the saphenous femoral junction after ablation. E-Hits are the primary complication outside of nerve and wound complications, and sometimes mandate limited treatment anticoagulation if protruding into the common femoral vein. A classification system of types is well described but whether routine postprocedure duplex should be performed is questionable (Suarez L, Tangney E, O’Donnell TF, et al. Cost analysis and implications of

routine deep venous thrombosis duplex ultrasound scanning after endovenous ablation. *J Vasc Surg Venous Lymphat Disord* 2017;5:126–33). Very rarely are these to a true DVT as the pathophysiology is different. Nonetheless, we recommend all patients should be stratified preoperatively by the Caprini venous thromboembolism risk scoring system to determine the risk for DVT. Some patients may benefit from unfractionated heparin periprocedurally.

Lastly, the procedural sequence of whether stab phlebectomy should be performed at the same time as endovenous ablation, or should be done in a staged setting is up in the air. However, most surgeons opt to do these procedures at the same time as many patients return with continued symptoms. Further research is needed in all aspects of superficial venous disease treatments.

Peter Henke

H DIALYSIS ACCESS

226 Autogenous Arteriovenous Hemodialysis Access

Robert J. Feezor and Thomas S. Huber

INTRODUCTION

End-stage renal disease (ESRD), and the maintenance of hemodialysis access, is a tremendous public health problem that has reached near epidemic proportions in the United States. In 2013, there were 661,648 prevalent (prevalence—patient count at a single point in time) and 117,162 incident (incidence—new patients over a time interval) ESRD patients. Although the number of incident cases has remained relatively stable since 2010, the number of prevalent cases has increased approximately 20,000 per year. It has been estimated that the prevalent and incident patient counts will be 784,613 and 150,772 respectively by 2020. The majority of patients with ESRD are on hemodialysis (hemodialysis, 64%; transplant, 29%; peritoneal dialysis, 7%). There was a record 18,000 kidney transplants performed in 2006, largely due to an increase in the number of deceased donors, but the annual volume has been somewhat stable since then with 17,600 kidney transplants being performed in 2013. Unfortunately, the number of patients on the transplant list has continued to increase and has outstripped the number of available organs. For candidates listed or relisted for renal transplantation in 2009, the median waiting time was 3.9 years. The Medicare costs associated with ESRD are staggering. Although ESRD patients account for <1% of the general Medicare population, dialysis-related expenditures accounted for 7% ($30.9 billion) of the general Medicare costs in 2013. The Medicare expenditure per ESRD patient per year is greatest for patients on hemodialysis (hemodialysis, $84,550; peritoneal, $69,919; transplant, $29,920). Not surprisingly, maintaining hemodialysis access is a significant burden for most health care providers. This is compounded by

the limited functional patency rates for the various access options and, almost paradoxically, the improved patient survival.

The National Kidney Foundation Dialysis Outcome Quality Initiative (KDOQI) has emphasized the importance of autogenous access, commonly referred to as an arteriovenous fistula or simply a fistula. Their "preferred" access choices include the radiocephalic, brachiocephalic, and brachiobasilic autogenous access, although they concede that prosthetic or biologic accesses are acceptable. It is interesting to note that there has been an evolution in the guidelines with a change in the emphasis from an "autogenous" to a "functional" access (i.e., both autogenous and prosthetic access acceptable). Not surprisingly, they recommend that long-term dialysis catheters should be avoided. The guidelines have a set an autogenous access target rate of >65% with a catheter rate of <10%. The Center for Medicare and Medicaid Services' (CMS) National Vascular Access Improvement Initiative or "Fistula First Breakthrough Initiative" was implemented to attain the initial KDOQI targets or specifically to "increase the proportion of hemodialysis patients who use arteriovenous fistulas as the primary mode of vascular access." This multidisciplinary approach was defined by 11 original concepts designed to impact practice patterns (Table 226.1). Notably, a significant proportion of the "Fistula First" effort was targeted at access surgeons. The "Fistula First" effort was largely successful as reflected by the prevalence of autogenous access across the country relative to the 2003 baseline year (Fig. 226.1). Despite these national initiatives, the prevalence of autogenous accesses in the United States remains well below the 80% rate reported from Europe (France, Germany, Italy, United Kingdom, Spain).

The KDOQI recommendations for autogenous accesses are based partly upon the presumption that the patency rates for autogenous access are superior to their prosthetic counterparts. However, the data in the KDOQI cited to justify the superiority of autogenous accesses were limited by Evidence-Based Medicine Standards and included retrospective case series and expert opinion. Murad et al. performed a systematic review and meta-analysis to compare autogenous and prosthetic hemodialysis access as part of the Society for Vascular Surgery Clinical Practice Guidelines and concluded that the autogenous accesses had better patency rates at both 12 and 36 months. However, they stated that these conclusions were based upon "low-quality evidence from inconsistent studies with limited protection against bias." Our group published a formal systematic review

of the literature comparing the patency rates of upper extremity polytetrafluoroethylene (PTFE) and autogenous accesses in adults. Studies were considered acceptable for inclusion if patency was reported using either the life table or Kaplan-Meier methods and included the number of patients at risk. Unfortunately, there were only 34 studies at that time that satisfied the inclusion criteria with the majority composed of cases series or nonrandomized controlled studies with the data collected in a retrospective fashion. The primary annual patency rates for the autogenous and PTFE accesses were approximately 60% and 40% respectively, while the corresponding secondary patency rates were 80% and 60% (Fig. 226.2). Al-Jaishi et al. reported comparable results in a more recent systematic review of autogenous access with primary and secondary patency rates at 1 year of 60% and 71%, respectively. Notably, these secondary patency rates are significantly lower than the outcome targets defined by KDOQI (autogenous access—thrombosis rate 0.25 episodes/patient year at risk, patency rate >3 years; prosthetic access—thrombosis rate 0.5 episodes/patient year at risk, patency rate >2 years).

TABLE 226.1 Fistula First Breakthrough Initiative Practice Recommendations

1. Routine quality review for vascular access
2. Timely referral to a nephrologist
3. Early referral to a surgeon for "AVF" (AVF—autogenous arteriovenous hemodialysis access) evaluation and timely placement
4. Surgeon selection based on best outcomes, willingness, and ability to provide access services
5. Full range of appropriate surgical approaches for AVF evaluation and placement
6. Secondary AVF placement in patients with AV grafts (AV grafts—prosthetic arteriovenous hemodialysis access)
7. AVF placement in patients with catheters when indicated
8. Cannulation training for AVFs
9. Monitoring and maintenance to ensure adequate access function
10. Education for care givers and patients
11. Outcome feedback to guide practice

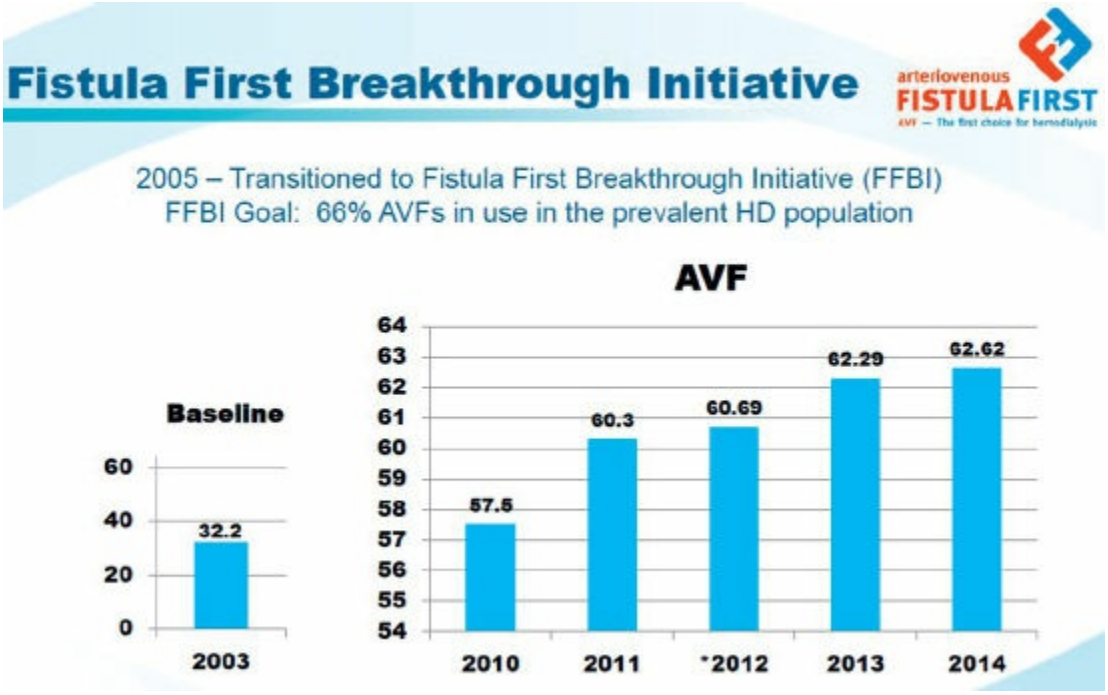

Figure 226.1. The percentage (%) of AVFs (arteriovenous fistulas) or autogenous hemodialysis accesses is shown across the United States from 2010 to 2014 relative to the baseline year in 2003. Note the dramatic improvement in the overall autogenous utilization rate that approaches the KDOQI (65%) and Fistula First (66%) goals. (With permission from the End Stage Renal Disease National Coordinating Center (ESRD NCC).)

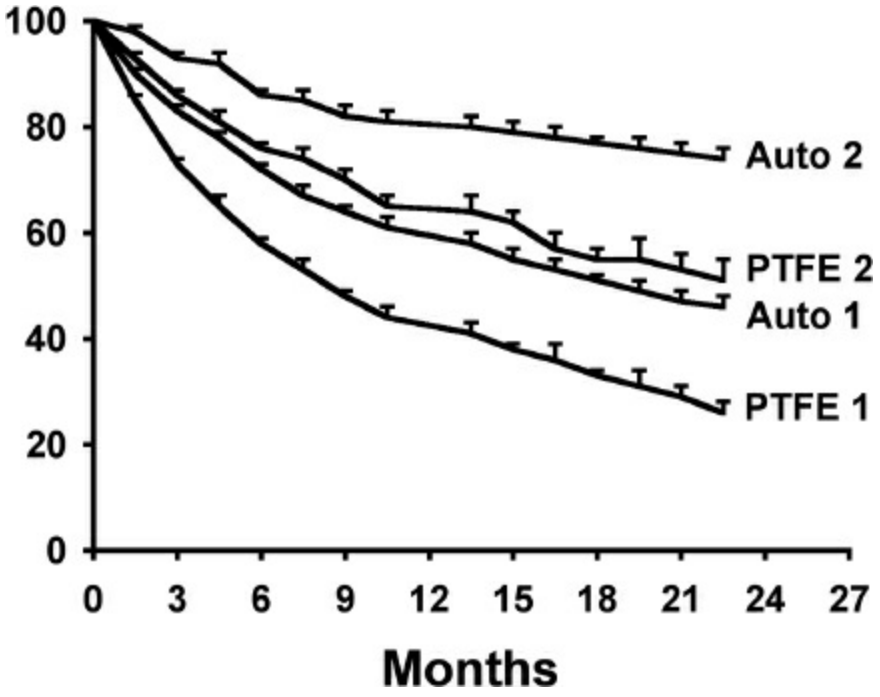

Figure 226.2. The patency rates (percent patent) for the

autogenous (**Auto**) and PTFE (**PTFE**) upper extremity hemodialysis accesses are plotted against time (months) with the positive standard error bars. Both the primary (**Auto 1, PTFE 1**) and secondary (**Auto 2, PTFE 2**) patency rates for the two access types are shown. The patency rates for the autogenous accesses were better than their corresponding PTFE counterparts with the one exception of the initial (1.5 mos) time point for the primary patency comparison. (From Huber TS, et al. Patency of autogenous and PTFE upper extremity arteriovenous hemodialysis accesses: a systematic review. *J Vasc Surg* 2003;38:1005–11.)

The KDOQI also justified the use of autogenous accesses based upon their lower complication rates. Notably, Murad et al. reported that autogenous accesses were associated with a lower infectious risk in their systematic review, although there was no difference in the other complication rates. We were unable to determine accurate complication rates in our systematic review of the literature either because the complications were not described in the individual studies, the descriptions were not standardized, or the means of reporting were not amenable to meta-analysis. However, the results from the individual studies suggest that the perioperative mortality rate was essentially 0 (median—0, range 0% to 1%), while the incidence of hand ischemia (median—2%, range 0% to 14%), access infection (median—7%, range 0% to 30%), and aneurysm/pseudoaneurysm formation (median—4%, range 0% to 6%) was low for both autogenous and PTFE accesses. Not surprisingly, the overwhelming majority of the access infections were seen in the PTFE accesses. Ravani et al. performed a more recent systematic review of the literature to look at the association between complications and access type. Not surprisingly, they concluded that tunneled dialysis catheters were associated with the highest risk of death, infections, and cardiovascular events, while autogenous accesses were associated with the lowest risk.

The annual mortality rate associated with dialysis catheters and prosthetic accesses has been consistently shown to exceed those for autogenous accesses. Notably, Dhingra et al. reported from the United States Renal Data System that the relative mortality risk (reference group autogenous accesses) was 1.41 and 1.54 for diabetic patients dialyzed with prosthetic accesses and catheters respectively while the corresponding values were 1.08 and 1.70 respectively among nondiabetics. Indeed, the annual unadjusted mortality rate for all hemodialysis patients across the

United States was a staggering 21.7% in the Dialysis Outcomes and Practice Patterns Study (DOPPS) and was significantly greater than those reported from Europe (15.6%) and Japan (6.6%). Although the mean patient age and the burden of comorbidities were greater in the United States, the adjusted relative risk of mortality was 1.33 greater in the United States relative to Europe and 3.78 relative to Japan. It is likely that the discrepancy in the prevalence of the autogenous accesses between the three continents contributed.

There are a few distinct disadvantages to autogenous accesses. The obligatory period to allow the autogenous access to mature usually exceeds the corresponding “maturation” time for prosthetic access. Notably, prosthetic accesses have traditionally not been cannulated for 3 to 6 weeks after creation to allow incorporation of the graft into the surrounding tissue. However, there are several newer prosthetic grafts that allow immediate cannulation. Rayner et al. reported from the DOPPS that the median duration from autogenous access creation to cannulation in the United States was 98 days. This obligatory period usually requires the use of dialysis catheters as a “bridge” and subjects the patients to all the potential catheter-related complications. Admittedly, the use of dialysis catheters in this setting may be reduced by early patient referral to an access surgeon prior to the initiation of dialysis although this has not been particularly successful across the country. Furthermore, a significant proportion of the autogenous accesses fail to mature sufficient for cannulation. Dember et al. reported from the Dialysis Access Consortium, a multicenter randomized trial evaluating the role of clopidogrel on access maturation, that the failure to mature rate for autogenous accesses was >60%. Lok et al. developed a scoring system to predict maturation and found that age, race, peripheral arterial occlusive disease, and coronary artery occlusive disease were all associated with failure. Using their system, the predicted “failure to mature” rate for an autogenous access in a 70-year-old African American with both coronary artery and peripheral vascular disease was approximately 70%. Lastly, approximately 25% of the initial autogenous accesses need some type of remedial imaging or procedure to facilitate maturation, potentially further prolonging the obligatory catheter time for patients already on dialysis.

Despite these limitations, it is generally well accepted that a “mature” autogenous access is the optimal choice for permanent hemodialysis access as recommended by the national initiatives. We have attempted to

optimize the use of autogenous access in our own practice, but would concede that an autogenous access is not possible and/or appropriate for all clinical settings and believe that the ultimate goal should be a “functional” permanent access as emphasized by the evolution in the national guidelines. We currently construct prosthetic accesses for patients without autogenous options on the preoperative imaging, those with limited life expectancy, and those with marginal autogenous access options in which previous autogenous access attempts have not matured sufficiently for cannulation. These indications are consistent with the thoughtful review about the role of prosthetic access in the Fistula First era.

DETERMINATION OF AUTOGENOUS ACCESS CONFIGURATION

General Principles (Fig. 226.3)

The overwhelming majority of patients presenting for permanent access are candidates for an autogenous access. Our approach, designed to optimize the use of autogenous upper extremity accesses, is predicated upon the standard principles of vascular surgery, including adequate arterial inflow, adequate venous outflow, and a suitable conduit. Furthermore, it is based upon the use of dialysis catheters as a “bridge” or temporary access until the permanent access is suitable for cannulation and an aggressive approach to “failing” or “nonmatured” accesses. Despite our use of the catheters as a “bridge,” we have made every attempt to limit the use of these catheters, in accordance with the national guidelines, because of their limited patency, infectious complications, and potential to cause central vein stenoses and/or occlusions.

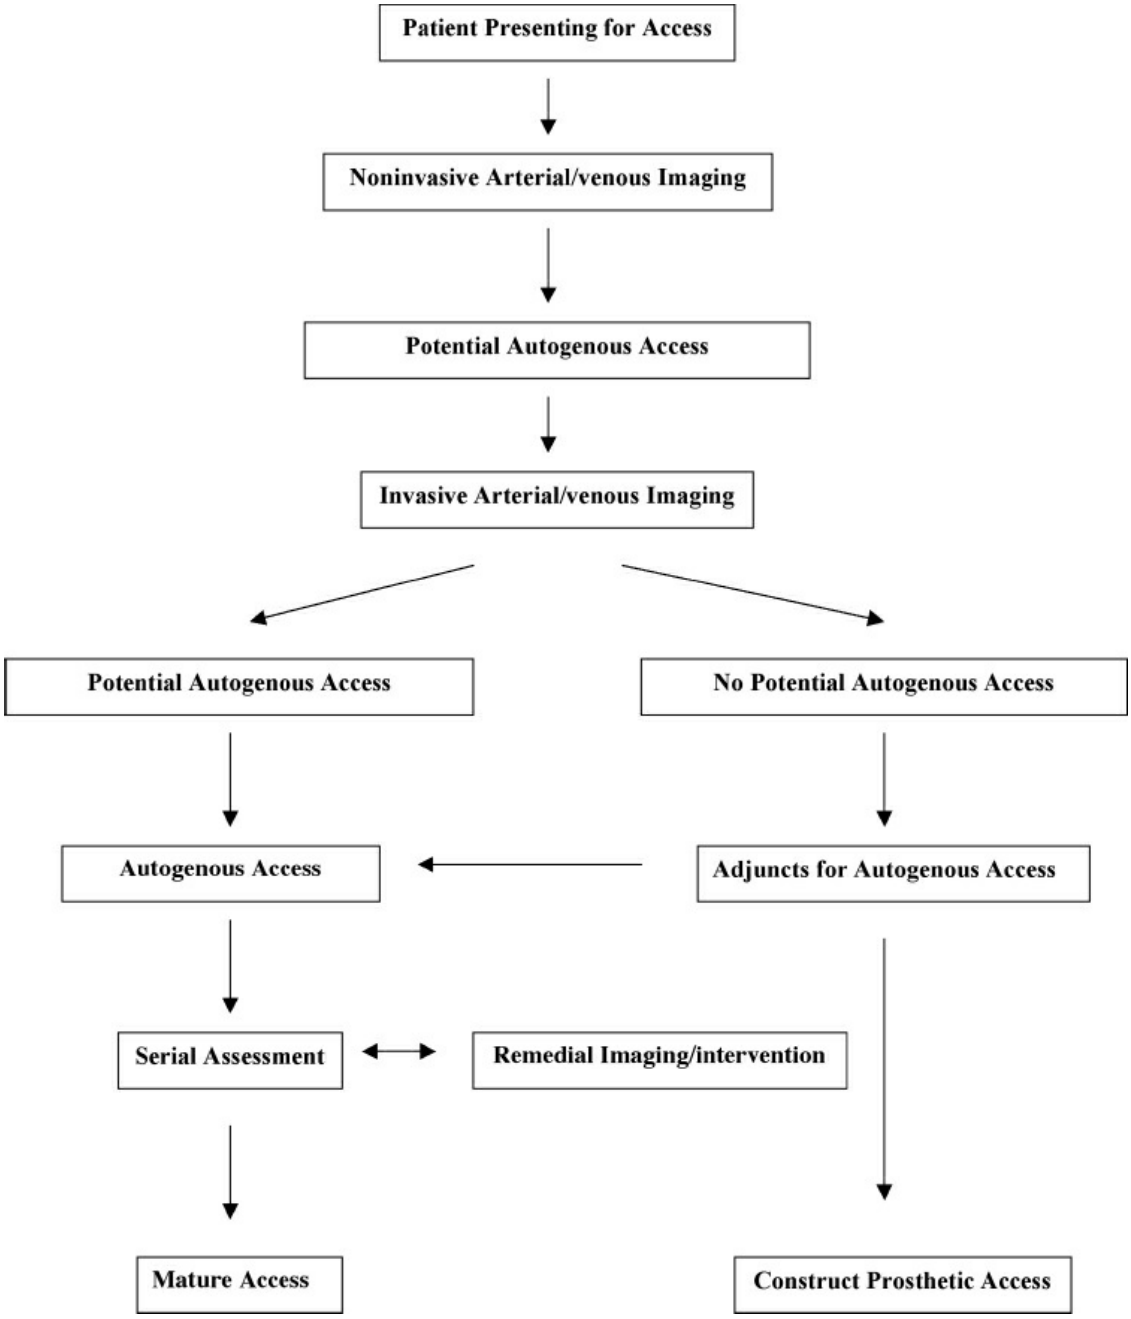

Figure 226.3. The algorithm for patients presenting for permanent hemodialysis access is shown. The individual steps are outlined within the text. Patients who fall into the group **No Potential Autogenous Access** due to peripheral veins that are insufficient diameter (<3 mm) are either reimaged in the operating room after induction of anesthesia and the resultant vasodilation or the veins are dissected and explored directly. **Adjuncts for Autogenous Access** include endovascular treatment of arterial inflow/venous outflow lesions and composite access configuration with saphenous vein. (Reprinted from Huber TS, Ozaki CK, Flynn TC, et al. Prospective validation of an algorithm to maximize arteriovenous fistulae for chronic

hemodialysis access, *J Vasc Surg* 2002;36(3):452–9. Copyright © 2002 The Society for Vascular Surgery and The American Association for Vascular Surgery, with permission.)

History/Physical Examination

The initial evaluation of patents presenting for permanent hemodialysis access includes a focused history and physical examination. Special attention should be directed at documenting the access history, including procedures, revisions, and associated complications. This should include any history of central vein cannulation, arm edema, and hand ischemia. Physical examination should include a detailed pulse examination with an Allen test to determine the forearm vessel responsible for the dominant arterial supply to the hand and examination of the neck and chest to look for venous collaterals.

Noninvasive Imaging

Noninvasive testing in the diagnostic vascular laboratory is the cornerstone of our algorithm. The examinations involve interrogation of both the arterial and venous circulation. The arterial studies include blood pressure measurements of the brachial, radial, ulnar, and digital arteries along with the corresponding Doppler waveforms of all but the digital vessels (Fig. 226.4). Additionally, the Allen test is repeated and the diameters of both the radial (wrist) and brachial (antecubital fossa) arteries are measured. Venous imaging includes the interrogation of the cephalic and basilic veins from the wrist to the axilla to assess their patency, quality (e.g., evidence of prior thrombosis), and size (i.e., diameter), similar to the preoperative vein survey obtained prior to infrainguinal arterial revascularization (Fig. 226.5). Additionally, the upper extremity and central veins are examined for the presence of deep venous thrombosis, although the interrogation of the veins within the thoracic cavity is somewhat limited due to the bony structures.

Potential Autogenous Access Configuration

A preliminary operative plan is then generated based upon the results of the history/physical and noninvasive imaging. Our objective has been to select the combination of artery and vein that would most likely result in a successful autogenous access. We have not felt constrained by the usual conventions of using the nondominant more than dominant extremity and

the forearm more than arm, although we have followed these standard approaches when the choices are equivocal. The criteria for an adequate artery and vein include no hemodynamically significant arterial inflow stenoses, no venous outflow stenoses, and a peripheral vein segment of suitable length and diameter (Table 226.2). Our preferences in descending order include the radiocephalic, radiobasilic, brachiocephalic, and brachiobasilic autogenous accesses prior to use of prosthetic material (Table 226.3). Notably, these preferences are consistent with the current KDOQI guidelines. We have had particularly good results with the autogenous brachiobasilic configuration. Indeed, the basilic vein is an excellent conduit for an autogenous access since it is usually relatively thick-walled, large in diameter, and well preserved in terms of cannulation for venipunctures and intravenous catheters due to its relatively deep course.

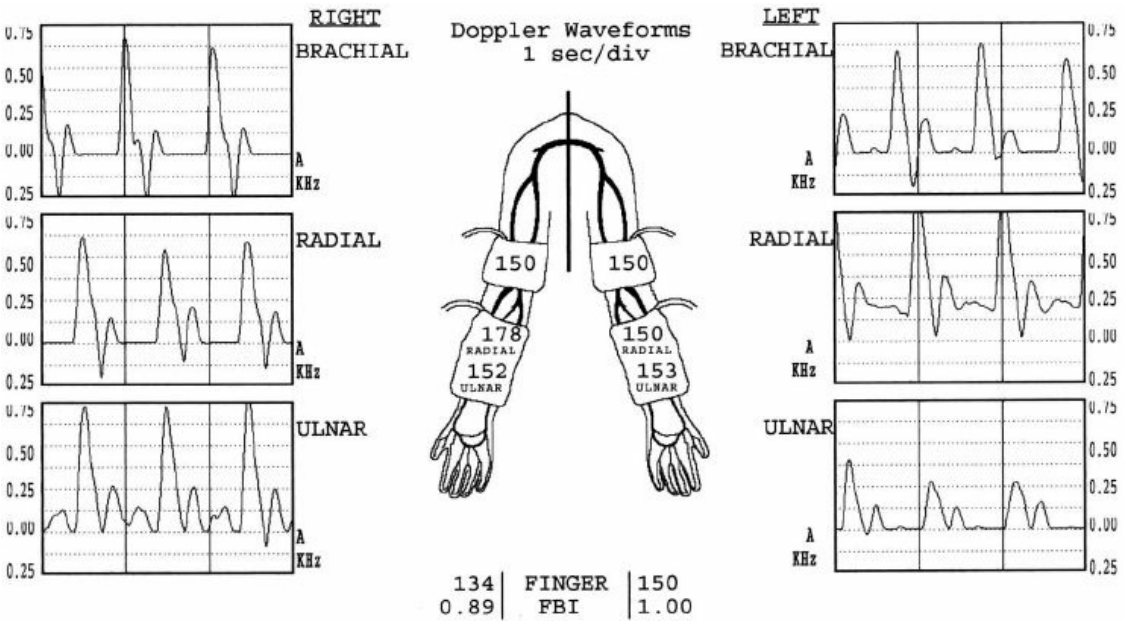

Figure 226.4. Part of the preoperative noninvasive arterial imaging studies is shown. The brachial, radial, and ulnar arterial pressures (mm Hg) are shown on the diagram of the upper extremities, while the finger pressures are shown in the center of the figure at the bottom. The corresponding Doppler waveforms (sec/div) are shown for the brachial, radial, and ulnar arteries. The FBI denotes the finger/brachial index and is the ratio of the finger pressure to the ipsilateral brachial artery pressure. Note the symmetric brachial artery pressures and the corresponding normal appearing triphasic velocity waveforms. (From Huber TS, Seeger JM. Approach to patients with “complex” hemodialysis access problems. *Semin Dial* 2003;16(1):22–9. Copyright © 2003

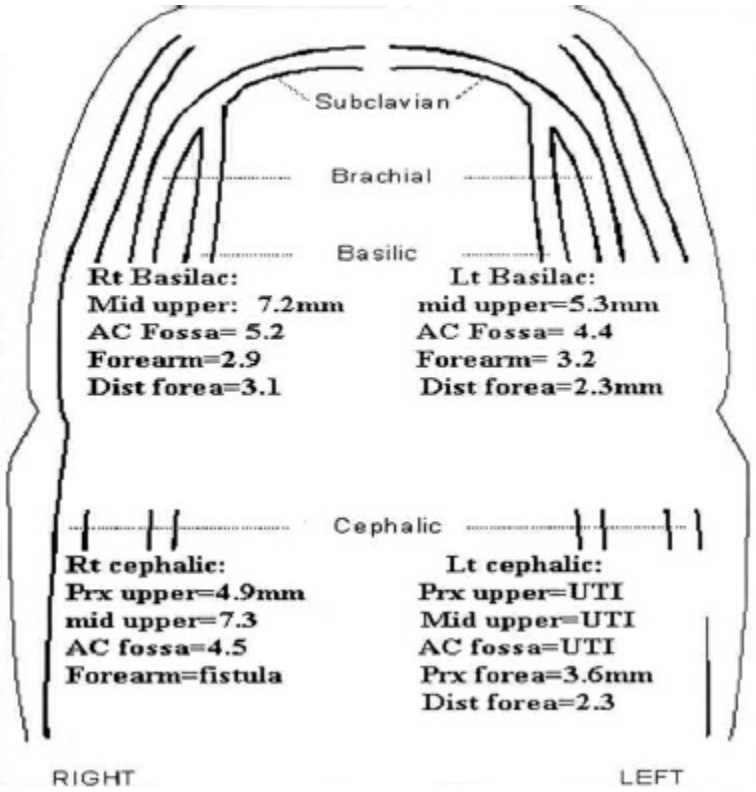

Figure 226.5. Part of the preoperative noninvasive venous imaging studies is shown. The diameters (mm) of both the basilic and cephalic veins are shown on the diagram of the upper extremities. The diameters are reported for the corresponding anatomic segment (prx upper—proximal upper arm, mid upper—mid upper arm, ac fossa—antecubital fossa, dista forea—distal forearm). Note that the basilic vein segments in both upper arms and the cephalic vein in the right upper arm are suitable for arteriovenous fistula using the diameter criteria (≥3 mm). The cephalic vein in the left upper arm was unable to be imaged (UTI). Additionally, the patient has a patent fistula in the right forearm that was not imaged. (From Huber TS, Seeger, JM. Approach to patients with complex hemodialysis access problems. *Semin Dial* 2003;16:22–9; with permission of John Wiley and Sons.)

TABLE 226.2 Criteria to Determine Suitability of Artery and Vein for Autogenous Access

Vein
Diameter >3 mm without evidence of significant stenosis
Suitable segment from wrist to antecubital fossa (forearm access) or antecubital fossa to axilla (upper arm access)
Absence of significant central vein stenosis in the ipsilateral extremity
Artery
Diameter 2 mm
Absence of hemodynamically significant inflow stenosis[a]
Nondominant radial artery for wrist access

[a]≥15 mm Hg pressure gradient between the brachial arteries for proposed arm accesses or between the ipsilateral brachial and radial arteries for proposed forearm accesses.
From Huber TS, Ozaki CK, Flynn TC, et al. Prospective validation of an algorithm to maximize arteriovenous fistulae for chronic hemodialysis access. *J Vasc Surg* 2002;36:452–9.

Additional Imaging

Contrast arteriography and venography can be used to confirm the preliminary access choice. Although we have previously used these modalities more routinely, we now reserve them for select indications. The potential indications for arteriography (i.e., catheter-based or computed tomography [CT] arteriography) include the presence of peripheral arterial occlusive disease, diabetes mellitus, complex access procedures, multiple failed access procedures, abnormal noninvasive studies, and prior episodes of access-related hand ischemia. The potential indications for venography (i.e., catheter-based or CT venography) include arm edema, multiple venous collaterals, pacemakers, multiple central venous catheters, multiple prior access procedures, and complex reconstructions. A catheter-based venogram can be performed simply by cannulating a superficial vein in the forearm with a 20-gauge intravenous catheter and injecting a bolus of 20 mL of contrast followed by an equal volume of saline. Hemodynamically significant stenoses are suggested by the presence of collaterals. Although the catheter-based venogram has not been particularly helpful as a means to interrogate the more superficial basilic and cephalic veins, we have found it to be more reliable than CT venography in determining central vein stenoses or occlusions. An ipsilateral catheter-based arteriogram can be performed, as necessary, if no central vein problems are identified. The

arteriogram is typically performed using a retrograde femoral approach with complete visualization of the arterial tree from the aortic arch to the digits. This requires a flush catheter arteriogram of the thoracic aortic arch followed by selective cannulation of the extremity and contrast arteriography with the arm abducted at 90 degrees relative to the torso. If a significant central vein problem is identified, a venogram on the contralateral extremity is performed before proceeding with the arteriogram. Endovascular treatment, either angioplasty alone or in combination with an intraluminal stent, may be performed at the same time of the invasive imaging studies or at the time of the access procedure itself. However, the decision to proceed with intervention is contingent upon the clinical scenario and the other potential access options identified by the noninvasive testing. Iodinated contrast is nephrotoxic and relatively contraindicated in patients with chronic kidney disease (i.e., those patients not on dialysis). The contrast-associated nephrotoxicity may be reduced with a combination of hydration, acetylcysteine, and sodium bicarbonate. Unfortunately, the alternative contrast agent gadolinium is absolutely contraindicated for patients with chronic kidney disease and ESRD because of the risk of nephrogenic systemic fibrosis. Similarly, the use of carbon dioxide in the upper extremity is also contraindicated because of the potential to enter the cerebral circulation. In the event that the invasive imaging does not support the initial access configuration, a second choice is made based upon the same principles (i.e., artery/vein requirements, imaging studies, hierarchy of procedures, conventions).

Urgent Need for Dialysis

Catheters are used for patients needing urgent dialysis. Indeed, these “temporary” catheters afford the luxury of time to allow the autogenous accesses to mature. The complications associated with these catheters are well known, and every attempt is made to minimize their use. Ideally, patients should have their access procedures well in advance of their anticipated dialysis start date. However, <20% of patients in the United States actually start dialysis with a permanent access (i.e., autogenous or prosthetic access).

Validation of the Algorithm

During the prospective validation of our algorithm, we were able to construct a successful autogenous upper extremity access in 70% of the

patients referred for permanent access. Notably, 83% of the 139 consecutive patients were candidates for an autogenous upper extremity access using the criteria defined above with a mean of 2.7 ± 2.1 possible configurations per patient. Among the subset of patients who had previously undergone a permanent hemodialysis procedure, 75% were candidates for an upper extremity autogenous access with a mean of 2.1 ± 2.0 possible configurations. The invasive imaging demonstrated some type of abnormal finding in approximately 40% of the cases, and these findings impacted the operative plan generated by the noninvasive studies alone almost 20% of the time. The accesses were suitable for cannulation in a mean of 3 months, although almost 25% of the patients required some type of remedial procedure to facilitation maturation. Although it has been a few years since our original publication, our approach has remained essentially the same with the noted exception that the invasive imaging is used selectively.

PREOPERATIVE EVALUATION

Patients with ESRD usually have multiple comorbidities and represent a significant operative risk. Although the access procedures are relatively minor compared to most general and vascular operations and not associated with significant bleeding or fluid shifts, our perioperative mortality over the past few years (encompassing >2,000 procedures) has been approximately 3% and the annual mortality rate for all ESRD patients in the United States is approximately 22% as noted above. In light of these concerns, the preoperative evaluation should be essentially the same as that for any major vascular surgical procedure. It is important to coordinate the hemodialysis schedule with the operative procedure. We prefer to operate on nondialysis days for both medical and logistical reasons. Patients are usually tired and volume contracted immediately after dialysis. Furthermore, dialyzing patients immediately postoperatively may increase the incidence of wound hematomas. The superficial arm veins selected for the planned access may be marked on the skin in the noninvasive vascular laboratory during the preoperative evaluation in an effort to minimize the tissue trauma associated with the exploration of the vein. Alternatively, the vein can be marked by the surgeon immediately before the start of the case using ultrasound as detailed below.

OPERATIVE TECHNIQUE

General

Regional anesthesia is used preferentially for the forearm, brachiocephalic, and first-stage brachiobasilic autogenous accesses, while general anesthesia is used for the transposed brachiobasilic autogenous accesses (both the single- and second-stage procedures). Patients with peripheral veins that are deemed too small (<3 mm) for autogenous accesses by the preoperative noninvasive imaging are reimaged preoperatively in the vascular laboratory or intraoperatively after induction of anesthesia using ultrasound. We have been impressed with the variability in the vein diameter measurements during serial imaging performed on different days and have attributed it to the volume changes associated with hemodialysis. The general and regional anesthetic agents seem to act as vasodilators, occasionally leading to the identification of a suitable peripheral vein that was deemed too small based upon the initial noninvasive imaging. Alternatively, the veins can be dissected and examined directly. The upper extremity from the wrist to the axilla is included in the operative field and positioned on a hand table attached to the standard operating room table.

Autogenous Radiocephalic Access (Fig. 226.6A,B)

The autogenous radiocephalic access is constructed using a 3-cm longitudinal incision in the distal forearm midway between the radial artery and the cephalic vein. Alternatively, the artery and vein can be exposed using an incision in the anatomic snuffbox, although the caliber of the vessels is somewhat smaller in this location. A small skin flap is elevated and the cephalic vein dissected free from the surrounding tissue. Two small spring retractors can be oriented diagonally across the wound to facilitate exposure. The vein should be dissected beyond the distal extent of the incision to assure a sufficient length (~3 cm) to transpose onto the artery. A second small skin flap is created to expose the course of the radial artery. The investing soft tissue is excised and a 2-cm segment of the artery is exposed. The desired segment of the artery usually has a few small branches that need to be ligated or occluded with surgical clips. The transected vein is distended with saline using a small olive tipped cannula and its terminal aspect spatulated. We routinely administer 5,000 units of heparin intravenously prior to occluding the radial artery, although we do not monitor the activated clotting time. The artery is occluded with two small microvascular clamps (e.g., Cooley microvascular clamps), and a 0.75-cm arteriotomy is created using a No. 11 scalpel blade and fine

arteriotomy scissors (e.g., Pott scissors). The anastomosis is performed in an end-side fashion using a running 6-0 monofilament vascular suture. Other anastomotic configurations have been reported (i.e., side–side, end artery–end vein, end artery–side vein), although it is the general impression that the end of vein–side of artery is associated with the greatest long-term patency and the lowest incidence of venous hypertension in the hand. The arteriovenous fistula and the arterial perfusion of the hand should be interrogated with continuous wave Doppler. Although a thrill may not be detected in the cephalic vein immediately upon completing the anastomosis (presumably due to arterial spasm), a continuous signal throughout systole and diastole should be detected. A pulsatile or arterial signal in the cephalic vein suggests an outflow obstruction and mandates further investigation with a fistulagram or revision of the anastomosis. Occasionally, it may be necessary to mobilize the cephalic vein more proximal on the forearm to facilitate the proper orientation of the vein/artery. It is rarely necessary to reverse the anticoagulation with protamine. The wounds are closed using an interrupted 3-0 braided, absorbable suture placed into the deep dermis, and the skin is closed using a running 4-0 monofilament, absorbable suture in a subcuticular fashion.

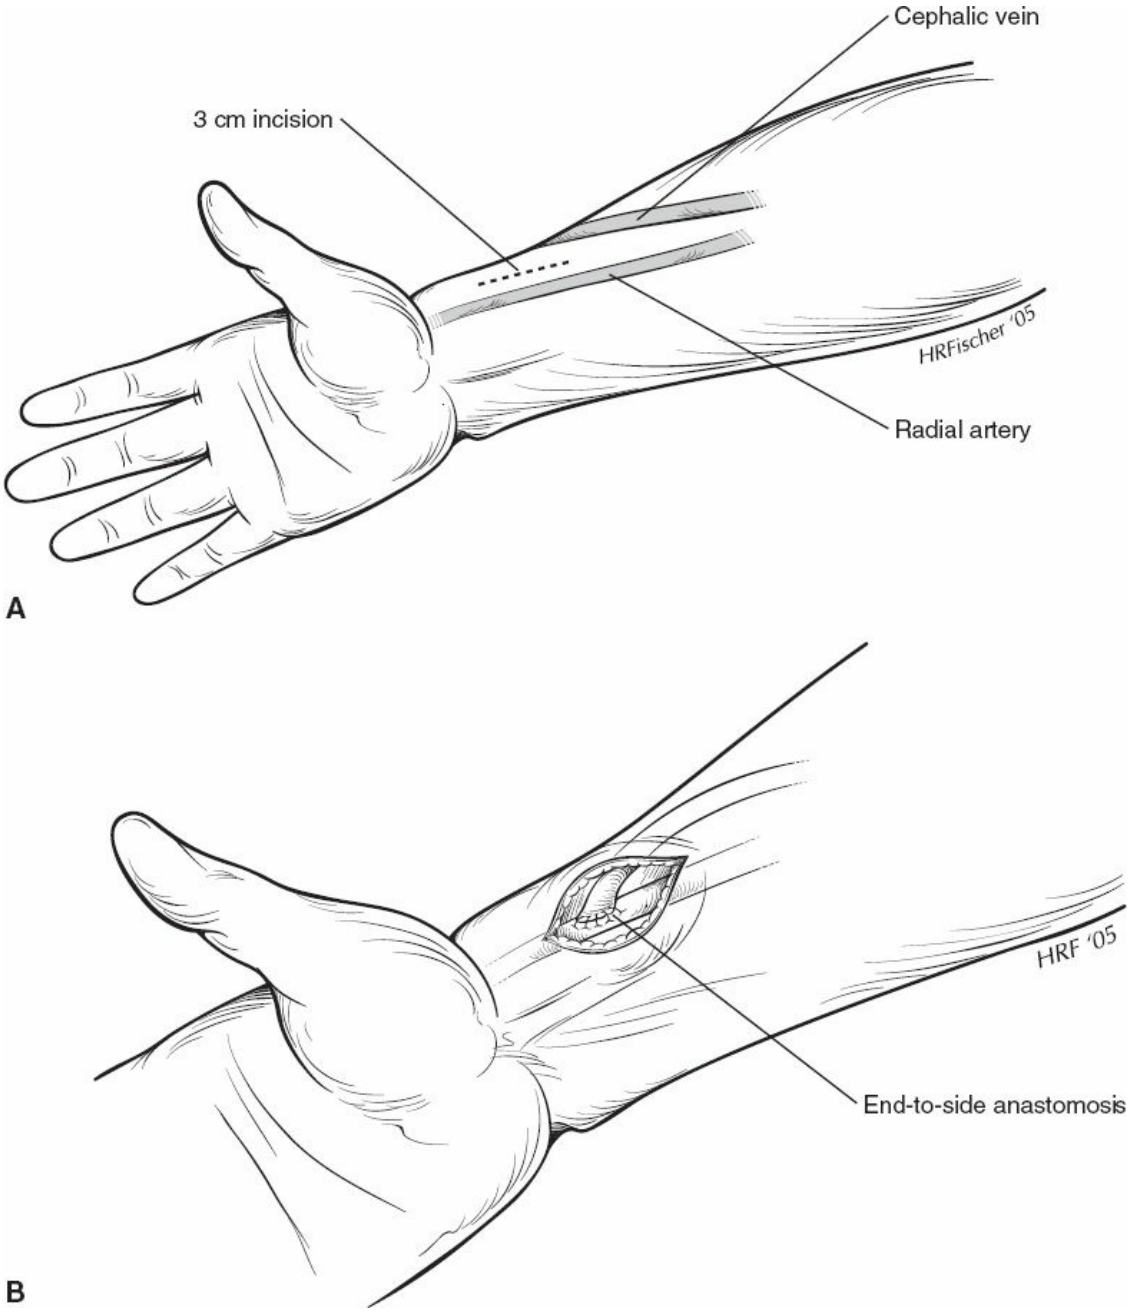

Figure 226.6. Radiocephalic autogenous access. **A.** Approximately a 3-cm longitudinal incision is made between the cephalic vein and the radial artery proximal to the skin crease at the wrist. **B.** The cephalic vein is transected and anastomosed in an end of vein—side of artery fashion. (From Englesbe MJ, Campbell DA. Upper extremity arteriovenous hemodialysis access. In: Zelenock GB, Huber TS, Lumsden A, et al., eds. *Mastery of Vascular and Endovascular Surgery*. Philadelphia, PA: Lippincott Williams & Wilkins; 2006.)

Autogenous Radiobasilic Access (Fig. 226.7A,B)

Although rarely feasible, the transposed autogenous radiobasilic access is

an excellent option. The radial artery is exposed using a 3-cm incision directly over the vessel immediately proximal to the wrist. The basilic vein is exposed using an incision extending from the antecubital fossa to the wrist and the branches are ligated. The vein is transected at the wrist and the residual stump suture ligated. The vein is distended with saline using the olive-tipped cannula and any defects are repaired. The vein is tunneled across the volar aspect of the forearm to the radial artery incision using a vascular clamp (e.g., Debakey aortic, Kelly) or a hollow graft-tunneling device. The vein should be tunneled immediately deep to the dermis, particularly in patients with considerable subcutaneous fat. The proper orientation of the vein can be maintained by marking one side and passing it through the tunnel while distended. The remaining portions of the procedure, with the exception of the basilic vein closure, are identical to that outlined above for the radiocephalic access. The basilic vein harvest incision can be closed with a running 3-0 braided, absorbable suture in the subcutaneous layer and 4-0 monofilament, absorbable suture for the skin.

Autogenous Brachiocephalic Access (Fig. 226.8A–C)

The incision for the autogenous brachiocephalic access is dictated by the patient's body habitus and the specific location of the cephalic/median antecubital vein and the brachial artery. Three incisions are acceptable: a transverse incision across the antecubital fossa, a sigmoid incision coursing medially in the upper arm across the antecubital fossa and along the cephalic vein in the forearm, and separate incisions over the brachial artery and cephalic vein in the upper arm. The sigmoid incision will be used to illustrate the technique, although more recently we have favored the transverse incision. The brachial artery is palpated in the distal upper arm and its course is marked on the skin. The sigmoid incision is started at this point and extended across the antecubital crease and onto the forearm incorporating the previously marked cephalic vein. It can be helpful to place marks transversely across the course of the planned incision to facilitate the appropriate alignment of the skin at the closure. Care should be exercised during the skin incision since the cephalic and median antecubital veins are very superficial and can be inadvertently injured. Exposure can be facilitated with two large spring retractors—one directed along the longitudinal axis of the arm and the other transversely across the antecubital crease. The cephalic vein is dissected free for approximately 4 cm by creating superior and inferior skin flaps. The cephalic, and its

continuation as the median antecubital vein, bifurcates or trifurcates in the antecubital fossa. It can be helpful to preserve the proximal aspects of these branches to help create a generous hood for the anastomosis. These large, deep branches should be suture-ligated since they tend to retract into to muscle and soft tissue. The brachial artery is exposed by incising the overlying bicipital aponeurosis and approximately 2 to 3 cm of the artery is dissected free. A pair of deep brachial veins flanks the artery, and they communicate via crossing branches that overlie the artery. These delicate branches must be dissected to allow exposure of the artery. The vein is distended with saline using an olive tipped catheter, spatulated, and all defects are repaired. Patients are administered 5,000 units of heparin intravenously and the brachial artery is occluded proximally and distally with the appropriate-sized vascular clamps (e.g., Cooley microvascular or Gregory bulldogs). A 0.75- to 1-cm incision is created in the artery using a No. 11 blade scalpel blade and arteriotomy scissors. The anastomosis is performed using a 6-0 monofilament vascular suture and standard surgical technique. Upon completion, the fistula and the arterial signals at the wrist are interrogated with the continuous wave Doppler. Unlike the radial artery-based autogenous accesses, a thrill should be detected in the proximal aspect of the fistula. The absence of a thrill or a pulsatile Doppler signal merits further investigation. This may be as simple as dissecting the vein more proximal on the arm to assure that it takes a gentle, unobstructed course. A diminished or monophasic Doppler signal at the wrist suggests that the hand may be ischemic. It is impossible to determine at this point whether this is due to reversible vasospasm or frank hand ischemia. All patients with suspected hand ischemia merit very close observation throughout the immediate postoperative period with aggressive remedial treatment as necessary. As detailed below, access-related hand ischemia is one of the most worrisome complications and we usually challenge our trainees at this point in the procedure to devise a strategy to address the potential future phone call from the recovery room nurse stating that the patient’s hand is severely ischemic. The wound edges are reapproximated with an interrupted 3-0 braided, absorbable suture and the skin is closed with a subcuticular stitch (e.g., 4-0 monofilament, absorbable) to complete the procedure. Unfortunately, there is not a lot of soft tissue to cover the anastomosis, and, thus, a wound breakdown potentially places the anastomosis at risk.

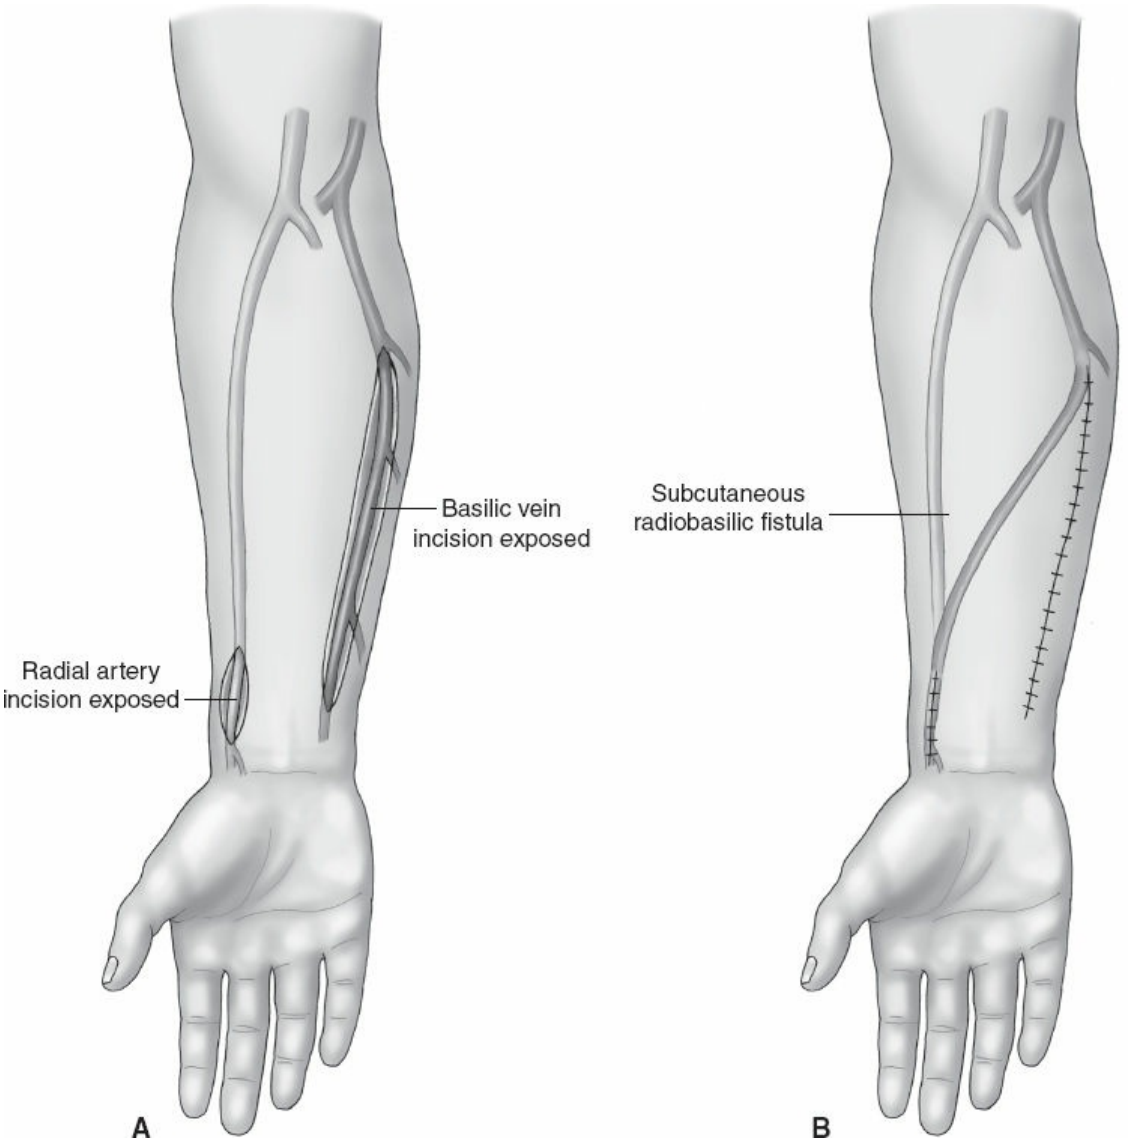

Figure 226.7. Radiobasilic autogenous access. **A.** Approximately a 3-cm longitudinal incision is made overlying the radial artery immediately proximal to the wrist. The basilic vein is exposed using an incision extending from the antecubital fossa to the wrist. The vein is tunneled across the volar aspect of the forearm using a clamp or a tunneling device. **B.** The completed access is shown. Note the course of the access across the forearm.

Figure 226.8. Brachiocephalic autogenous access. **A.** The possible incisions for the autogenous brachiocephalic access are shown. The simple horizontal or transverse incision is our current preferred approach, but the choice is usually dictated by the patient's body habitus. **B.** A sigmoid incision is started over the brachial artery in the proximal arm and extended across the antecubital crease and along the forearm incorporating the previously marked cephalic vein. Approximately 4 to 6 cm of the cephalic vein is dissected free to facilitate rotating it medially onto to the artery to construct the anastomosis. **C.** The cephalic vein is transected and anastomosed in an end of vein—side of artery fashion. (Figures **B** and **C** from Englesbe MJ, Campbell DA. Upper extremity arteriovenous hemodialysis access. In: Zelenock GB, Huber TS, Lumsden A, et al., eds. *Mastery of Vascular and Endovascular Surgery*. Philadelphia, PA: Lippincott Williams & Wilkins; 2006.)

The proximal radial artery can be used as an alternative arterial inflow source for upper arm cephalic- or basilic-based autogenous access procedures. The potential advantages of using the proximal radial artery include a lower access flow rate that may result in less venous hypertension and potentially a lower incidence of access-related hand ischemia. The proximal radial artery can be exposed by dissecting further distal on the brachial artery than outlined above, and this is facilitated by the sigmoid incision demonstrated in the figures. The median antecubital vein and its deep branches should be preserved and can be used for the anastomosis.

Autogenous Brachiobasilic Access—Single-Stage Procedure (Fig. 226.9A,B)

An incision is made in the distal upper arm along the course of the previously marked basilic vein. Alternatively, surgeon-directed ultrasound immediately prior to the procedure can be used to guide the location of the incision as noted above. We prefer to make a limited incision initially and identify the vein prior to making the full incision in an attempt to minimize the extent of the skin flaps. The basilic vein courses deep to the subcutaneous tissue and can actually be quite deep relative to the skin in obese patients. It courses adjacent to the medial antecubital cutaneous nerve in the distal upper arm, and this nerve can serve as a landmark. The skin incision and the dissection should extend proximally to the axilla and

distally to at least the antecubital crease. Notably, the forearm basilic vein is joined by the median antecubital vein at the level of the antecubital crease. We usually extend the incision across the antecubital crease or onto the proximal forearm and dissect the largest branch of the vein (i.e., median antecubital or forearm basilic vein). Indeed, the “longer the vein the better” since a longer segment facilitates a more lateral subcutaneous course for the transposition. The basilic vein should be dissected throughout its course and the branches ligated. It is imperative to mobilize the basilic vein in the proximal arm at the level of the axilla to prevent any undo tension on the vein at the swing segment for the transposition. Indeed, it has been our anecdotal impression that the tension on this segment resulting from inadequate mobilization leads to focal intimal hyperplasia, a common mechanism of failure for brachiobasilic accesses. We frequently suture-ligate the larger, broad-based branches with a 5-0 monofilament vascular suture. After the proximal end of the vein is transected (antecubital end), it is distended and all defects are repaired. The distended vein is then gently draped over the upper arm in an arc and the future course of the transposed vein is marked on the skin. The brachial artery is dissected free in the distal upper arm at the site of the planned anastomosis. The brachial artery courses in the groove formed between the triceps and biceps muscles beneath the deep fascia. The brachial artery lies deep to the median nerve, adjacent to the paired brachial veins and on top of the ulnar nerve. Approximately a 3-cm segment of artery is dissected free to facilitate the anastomosis. A tunnel is then created along the course marked on the skin using a semicircular, hollow tunneling device, and we prefer to pass the tunnel from the antecubital crease to the axilla. The tunneler is passed deep to the subcutaneous tissue near the antecubital fossa and the axilla, but immediately below the dermis throughout the region that will actually be used for cannulation. A sharp-tipped or pointed-tipped tunneler is particularly helpful because it facilitates passing the device in the correct plane. This helps assure that the access can be easily identified by the technologists, and this concern is particularly relevant for obese patients. Patients are heparinized with 5,000 units after the tunnel is created and the anastomosis is performed as outlined above for the brachiocephalic access. A thrill should be detected in the proximal aspect of the access. A closed suction drain (e.g., No. 10 Jackson-Pratt) is placed in the bed of the basilic vein harvest and brought out through a separate stab wound on the distal upper arm. The wound is closed in two

layers with a running 2-0 braided, absorbable suture and the skin is reapproximated with a subcuticular suture. It is important to examine the access (i.e., the thrill) during the closure to assure that it has not been inadvertently narrowed or kinked.

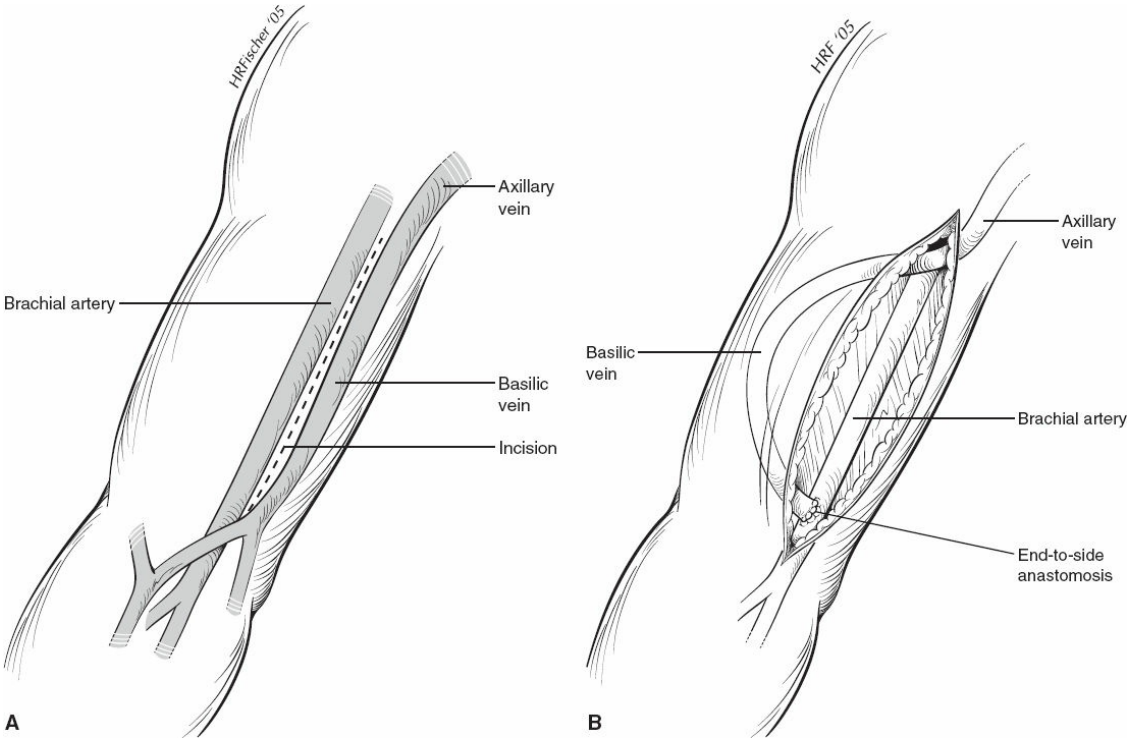

Figure 226.9. Brachiobasilic autogenous access. **A.** An incision is made extending from the antecubital fossa to the axilla. The basilic vein is dissected completely free and the multiple branches are ligated. **B.** The vein is tunneled laterally over the biceps muscle in the subcutaneous plane using the semicircular vascular tunneler and anastomosed to the brachial artery proximal to the antecubital fossa in an end of vein—side of artery configuration. (From Englesbe MJ, Campbell DA. Upper extremity arteriovenous hemodialysis access. In: Zelenock GB, Huber TS, Lumsden A, et al., eds. *Mastery of Vascular and Endovascular Surgery*. Philadelphia, PA: Lippincott Williams & Wilkins; 2006.)

Autogenous Brachiobasilic Access—Two-Stage Procedure

The brachiobasilic autogenous access can be created as a two-stage procedure. Indeed, it has been our preference over the past several years to use the two-stage approach. The theoretical benefit to this approach is that the vein may dilate or mature better in situ (vs. the transposed location) and that it doesn't subject the patient to a more involved operation (and

potential for wound complications) unless the vein has matured and is, thus, likely to be successfully used for cannulation. Unfortunately, the literature supporting the two-stage procedure is somewhat equivocal with Cooper et al. reporting from their meta-analysis that there was no difference in failure and primary patency rates despite the two-stage procedure being used in patients with smaller basilic veins.

The principles for the two-stage procedure are similar to those outlined above for the single-stage procedure with a few notable differences. The first-stage procedure is typically done as an outpatient procedure under regional anesthesia and a drain is not required. A limited, 4-cm incision is made over the basilic vein in the distal upper arm, although the incision can be extended across the antecubital crease if the vein is suitable. Patients are seen in clinic on a monthly basis until the vein is deemed suitable in size for the second-stage procedure, and we use a diameter measurement of 6 mm, based on ultrasound, as our criteria. The mobilization of the basilic vein that comprises the fistula is similar to the single-stage procedure, although there is additional scar tissue near the anastomosis and an element of venous hypertension. We traditionally dissect the basilic vein all the way up to the anastomosis to optimize the available length of vein. There are several reported techniques to handle the vein in terms of creating a usable segment for cannulation. Specifically, the vein can be simply elevated with the anastomosis left intact and the subcutaneous tissue reapproximated below the vein, thus, “elevating” the vein to the level of the skin. This technique has some appeal because it avoids having to revise the anastomosis, but requires transecting the antecubital cutaneous nerve. Furthermore, the fistula sits immediately below the incision and is at risk if the wound were to break down while the ultimate course of the fistula and the usable segment of the fistula sits very medial on the upper arm and is somewhat awkward to cannulate when the patient is in the dialysis chair. Alternatively, a subcutaneous pocket can be created by undermining the skin, and the mobilized segment of the vein can be “tucked” into the pocket to avoid having the vein course immediately below the harvest incision. Lastly, the anastomosis can be completely dissembled and vein tunneled as outlined above for the single-stage procedure. This requires re-siting the anastomosis more proximal on the brachial artery. The original fistula anastomosis on the brachial artery can be repaired with a vein patch or the proximal part of the fistula can be transected and simply oversewn. This

approach overcomes the limitations of simply elevating the vein and facilitates tunneling the vein in a more lateral course away from the harvest incision. It has been our anecdotal impression that the basilic veins tend to elongate in addition to just dilate after the first-stage procedure, thus facilitating a more lateral tunnel. This final technique has been our preferred approach, and we have found that re-siting the anastomosis is not particularly difficult nor does it add too much to the duration and complexity of the procedure.

POSTOPERATIVE MANAGEMENT

Patients undergoing a forearm, brachiocephalic, or first-stage brachiobasilic autogenous access are usually discharged home from the recovery room, while those undergoing a brachiobasilic autogenous access are admitted overnight. It is imperative to confirm that the hand is not ischemic before patients are discharged. The adequacy of the hand perfusion can usually be determined by the absence of any subjective complaints and a focused motor and sensory examination. Admittedly, this can be confounded by any regional anesthesia, although the underlying neurologic deficits are usually different. Notably, we specifically use short-acting regional anesthetic agents to allow accurate assessment of the hand in the early postoperative period. We routinely check a set of serum electrolytes to confirm that the patients do not need to dialyze. As noted above, we try to schedule the access procedures on days between dialysis sessions. Patients admitted to the hospital are placed on telemetry with a pulse oximeter. Although these precautions may seem unnecessary, we have had a few patients die in the immediate postoperative period without an identifiable cause. The closed suction drain is removed on the first postoperative day, provided that the drainage is minimal, and patients are discharged home after their regular dialysis session. All patients discharged from the recovery room (i.e., outpatient procedure) are contacted the day after their procedure to make sure that they are doing well and, specifically, that their hand is not ischemic.

Patients are seen in the outpatient clinic within 2 weeks after their operative procedure and at monthly intervals thereafter until their accesses are usable for dialysis. During the prospective validation of our algorithm, it took a mean of 3 months until the autogenous accesses were suitable for cannulation, although it has been our anecdotal impression that the time course is now closer to 4 months. The access must be sufficiently dilated

before the technologists can consistently cannulate the lumen and must be “arterialized” to sustain the repeated trauma of cannulation. We have used the KDOQI “rule of 6s” to determine whether the access is suitable for cannulation: 6 mm in diameter, 6 mm depth below the skin, 600 mL/min. Unfortunately, there are no means to assess the integrity of the access wall. During the follow-up period, we obtain ultrasounds of any accesses that do not appear to be maturing or dilating. We have found the ultrasound-based diameter measurements of the accesses to be particularly helpful, although the absolute velocity measurements have not been particularly informative, unlike the scenario of lower extremity bypass graft surveillance. The accesses that fail to dilate and those without a thrill are imaged with either a catheter-based fistulagram or an arteriogram in an attempt to identify the specific problem and facilitate maturation. The choice of procedures is contingent upon the clinical suspicion with the latter reserved for those patients in which an arterial inflow problem is suspected since the full extent of the access (including the arterial anastomosis and central venous runoff) can usually be imaged with a fistulagram. Additional open, surgical, or endovascular procedures are performed as necessary. Balloon angioplasty is our preferred initial approach, and it has proven quite effective for focal lesions. Furthermore, failure of the endovascular approach does not usually preclude a remedial open procedure. When the accesses are ultimately deemed suitable for cannulation, the patients are provided with a diagram of the specific configuration and instructions for cannulation while an identical facsimile is sent to their dialysis unit. Notably, we have become very conservative about releasing the autogenous accesses for cannulation based upon a few bad experiences in which accesses were damaged from premature cannulation. We have established a relationship with the patients and nephrologists such that the accesses are not cannulated until released from our clinic. It is important to remember that the ultimate goal is long-term access patency and a few additional weeks delay on the front end is likely irrelevant.

COMPLICATIONS

Many of the postoperative complications after autogenous hemodialysis access procedures are generic to all vascular surgical procedures and include both local (i.e., thrombosis, infection, and wound complications) and systemic problems (i.e., myocardial ischemia, dysrhythmias, cerebrovascular accidents). As noted above, many of these adverse

outcomes have been used to justify the choice of autogenous accesses. The KDOQI Clinical Outcome Goals include a thrombosis rate of 0.25 episodes/patient year and life expectancy of >3 years for autogenous accesses and a thrombosis rate of 0.5 episodes/patient year and a life expectancy of >2 years for prosthetic accesses. In our own meta-analysis, the primary and secondary annual patency rates for the autogenous accesses were 80% and 60% respectively as noted above (see Fig. 226.2). Furthermore, KDOQI stated that the infectious complication rates should not exceed 1% and 10% over the functional life of an autogenous and prosthetic access respectively. In the prospective validation of our algorithm, the perioperative complication rate was approximately 20% with half of these due to wound problems. Fortunately, the majority of the wound complications after autogenous access are self-limited and do not translate into access loss.

Postoperative hand ischemia is specific to hemodialysis access procedures and represents one of the most worrisome complications. This access-related hand ischemia or “steal” results from the diversion of blood from one anatomic bed to another. Despite the colorful label, there is nothing “illegal” about the condition since the blood flow simply follows pressure gradients. An arteriovenous fistula is a low resistance circuit that causes a decrease in both blood flow and perfusion in the arteries distal to the anastomosis. Hand ischemia occurs when the compensatory changes (i.e., vasodilation, increased cardiac output, collateral flow through the profunda brachial) are inadequate to maintain tissue perfusion. Predictably, the decrease in perfusion (and potential symptoms) is further exacerbated by the presence of arterial occlusive disease in the inflow (i.e., axillary, subclavian) and the forearm arteries distal to the anastomosis. Some type of “steal” phenomenon is common after all access procedures, although symptomatic “steal” or hand ischemia is relatively rare with an incidence of 2% and 10% after radial and brachial artery based procedures respectively. Unfortunately, there are no preoperative tests to predict which patients will absolutely develop hand ischemia (and therefore the access procedure should be avoided). However, several clinical predictors have been identified, including female gender, advanced age (i.e., ≥60 years), diabetes, peripheral arterial occlusive disease, large conduits (e.g., femoral vein), brachial artery based procedures, autogenous accesses, and a previous episode of access-related hand ischemia. Indeed, it has been our anecdotal impression that patients with a previous episode of hand

ischemia have almost a 100% incidence of developing the same during subsequent procedures regardless of the upper extremity (i.e., ipsilateral or contralateral).

The diagnosis of hand ischemia is predominantly a clinical one. Indeed, all hand complaints after a prosthetic or autogenous hemodialysis access should be attributed to hand ischemia until proven otherwise. Importantly, patients can have access-related hand ischemia despite having a weakly palpable pulse. Both noninvasive (i.e., upper extremity arterial pressures and waveforms) and invasive (i.e., catheter-based arteriography) imaging can be used to confirm the diagnosis and are helpful in equivocal cases, but the clinical symptoms should take precedence over the imaging findings. Diminished wrist and digital pressures and the inability to visualize the forearm vessels are suggestive of the diagnosis on the noninvasive and invasive imaging respectively. Hand ischemia may develop either early (i.e., immediate postoperative) or late (i.e., weeks/months postoperative) relative to the index access procedure. Patients who present with delayed hand ischemia usually complain of their initial symptoms during dialysis due to the concomitant decrease in blood pressure.

The treatment goals for patients with hand ischemia are to relieve the symptoms and preserve the access, although the primary objective is to maintain normal hand function. A variety of treatment options have been proposed, including access ligation, proximal revascularization, proximalization of the arterial inflow (PAI) narrowing of the anastomosis or access outflow (i.e., “banding”), revision using distal inflow (RUDI), and distal revascularization/interval ligation (DRIL). The most appropriate treatment is usually dictated by the clinical scenario with the treatment considerations, including the severity of the symptoms, the long-term potential of the access, the available autogenous conduit, and the other potential access options. Importantly, the various remedial procedures should be viewed as complementary since they all serve a potential role in the treatment algorithm. Access ligation is the simplest and most definitive treatment to relieve the symptoms, although, needless to say, the access is sacrificed. The DRIL procedure (Fig. 226.10) is very effective in terms of achieving both objectives (i.e., relief of symptoms, access preservation), although it is a moderate undertaking, requires a segment of autogenous vein (usually saphenous), and creates a scenario in which the perfusion of the hand is dependent upon the integrity of the bypass. In our own

experience, the DRIL procedure salvaged the access and reversed the presenting symptoms in the overwhelming majority of the cases. Patients with a presumed inflow stenosis as the source of their hand ischemia should undergo an arteriogram and remedial therapy as indicated. However, this scenario is somewhat unusual in our practice given the noninvasive arterial imaging described in the algorithm and our liberal use of preoperative arteriography. Limiting the flow through the access (i.e., “banding”) such that it is adequate to sustain dialysis yet sufficient to maintain hand function may be difficult, although there has been a resurgence in the technique. This technique usually requires some type of objective measurement intraoperatively to confirm that the distal perfusion has been augmented. The proximalization of the arterial inflow likely represents a variant of the flow limiting procedures, although it can be helpful in patients who don’t have a suitable segment of autogenous conduit for a DRIL procedure. Furthermore, the technique essentially converts an autogenous access to a composite access since the described technique uses a prosthetic graft as the conduit, although it is possible to use an autogenous conduit. The revision using distal inflow may be helpful for “high flow” autogenous access and essentially converts a brachial artery-based access to a radial artery-based one.

In our practice, the usual clinical decision is whether to simply ligate the access or perform a DRIL procedure. We have elected to perform DRIL procedures on good-risk patients with an autogenous access that is likely to mature sufficiently for cannulation. Indeed, it has been our anecdotal impression that the larger diameter veins (i.e., those more desirable in terms of their potential to develop into a mature autogenous access) are more likely to cause hand ischemia. Furthermore, we usually make the decision about the most appropriate remedial treatment (i.e., ligation vs. DRIL) at the time of the original access procedure.

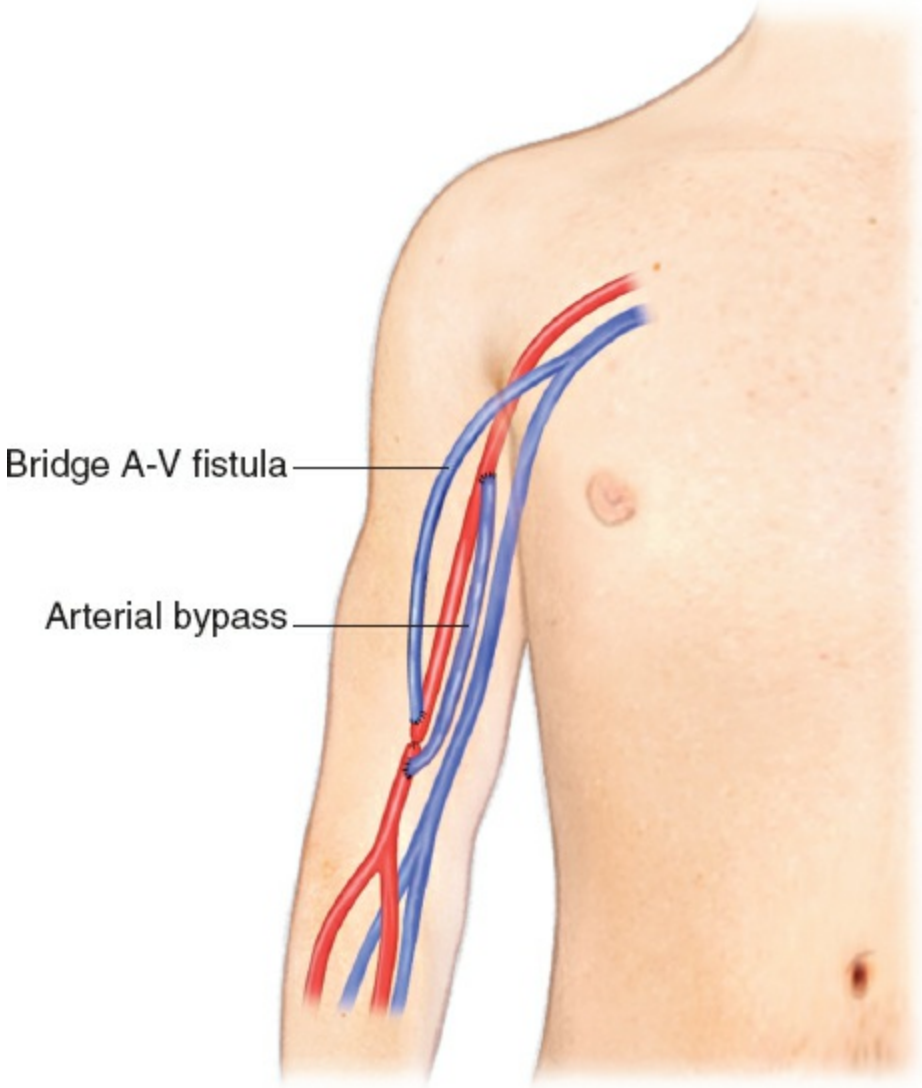

Figure 226.10. The configuration of the DRIL (distal revascularization and interval ligation) procedure is illustrated. A brachial artery–brachial artery bypass is performed using saphenous vein with the proximal anastomosis sited 7 to 10 cm above the arteriovenous fistula anastomosis. The brachial artery immediately distal to the arteriovenous fistula anastomosis is ligated.

EVALUATION OF PATIENTS WITH COMPLEX ACCESS PROBLEMS

General

The majority of patients labeled with “complex” or “tertiary” access problems are candidates for upper extremity autogenous accesses using the outlined algorithm. However, there are subsets of patients who pose additional challenges within this framework. Analysis of the reasons that

they are not candidates for the algorithm suggests potential solutions and treatment options, albeit not always autogenous accesses.

Inadequate Ipsilateral Arm Vein

Autogenous vein is the optimal conduit, but prosthetic accesses are acceptable when autogenous accesses are not feasible. Thus, inadequate ipsilateral arm vein should rarely comprise a legitimate contraindication to constructing an access provided there is a suitable arterial inflow and venous outflow. Indeed, it is possible to construct numerous brachial artery-based prosthetic accesses with the venous anastomosis sited anywhere along the axillary, subclavian, or internal jugular veins. The options for constructing autogenous accesses with upper extremity veins that are of adequate diameter (≥3 mm) but *inadequate length* include composite saphenous—arm vein configurations. When the ipsilateral veins are of *inadequate diameter*, the autogenous options include a translocated transposed femoral/popliteal vein. Indeed, we have had particularly good success with the translocated femoral/popliteal vein used in the brachioaxillary configuration, although the magnitude of the procedure is significant and the configuration associated with a moderate amount of hand ischemia given the large conduit. A variety of alternative or more heroic (e.g., brachial artery–brachial vein) autogenous accesses have been reported, although their success rates and longer-term durability remain undefined.

Inadequate Arterial Inflow

Inadequate arterial inflow can complicate the choice of an access configuration in a patient with a reasonable peripheral vein and patent central runoff. This scenario is relatively common and frequently due to the presence of an orificial subclavian artery stenosis or occlusion. A variety of endovascular and surgical options are available with the choice contingent upon the location and extent of the lesion. Balloon angioplasty in combination with an endoluminal stent is an ideal solution for most orificial subclavian lesions and can be performed simultaneous with the access procedure working retrograde through the brachial artery, oftentimes through the site chosen for the anastomosis.

Central Vein Stenosis/Occlusion

The presence of a significant central vein stenosis or occlusion is a *relative* contraindication to an ipsilateral permanent hemodialysis access due to the potential to develop significant venous hypertension and arm edema with the *absolute* contraindications being patients with superior vena cava syndrome or prolonged arm edema. Central vein stenoses and occlusions have become the most common complex or tertiary access-related complication, likely the sequelae of prior central venous catheters (including tunneled dialysis catheters), prior permanent accesses, and deep venous thromboses. Occasionally, a patient's only upper extremity access options are ipsilateral to a significant central vein lesion. The potential options in this setting include abandoning the upper extremities in favor of a lower extremity site, correcting the ipsilateral central vein lesion prior to placing the permanent access, or placing the permanent access and correcting the vein lesion if the patient develops significant, sustained arm edema. Our preferred approach is the latter, and we have been anecdotally impressed that not all of the patients with a central vein lesion develop significant edema after the procedure. The likely explanation for this finding is that a significant collateral network develops that reduces the venous hypertension, thereby preventing the edema. The invasive treatment options (i.e., endovascular or surgical) are the same whether they are performed before or after the access and they are not particularly complicated by the procedure itself. Indeed, the high flow in the access may improve the initial patency after central vein angioplasty or stenting so that there may be a theoretical advantage to performing these interventions postoperatively. Unfortunately, the long-term durability of central vein angioplasty is only fair with primary patency rates ranging from 20% to 30% at 12 months. However, the majority of the lesions are amenable to remedial angioplasty procedures either alone or in combination with an intraluminal stent. Notably, the recurrent central vein stenoses after endovascular (or open surgical) revascularization may not necessary result in recurrent arm edema if additional collateral pathways develop. The reported, open surgical options include jugular vein turn down, axillary/subclavian–jugular vein bypass, axillary/subclavian–contralateral axillary/subclavian vein bypass, axillary–common femoral vein bypass, and central vein–atrial bypass. The choice of procedures, obviously, is dictated by the patent central veins, and we have found CT venography particularly helpful to delineate their status.

The HeRO Graft (Merit Medical, South Jordan, UT) is a novel hybrid

catheter-graft combination that may play a role in patients with refractory central vein stenoses or occlusions. It is composed of a 6-mm PTFE graft that is coupled to a 6.3-mm outflow catheter and functions essentially as a prosthetic access hooked to a dialysis catheter. Notably, the graft and catheter components are all implanted beneath the skin, and thus it has the appearance of a prosthetic access. The initial results are somewhat encouraging, although the patency and infectious complication rates remain concerning. Implantation requires crossing the central vein stenosis or occlusion with the relatively large catheter component (OD 6.3 mm, 19 Fr) and can be challenging. We have used the HeRO graft both as the initial access for patients with known central vein occlusions and as remedial treatment for patients with a functional access and refractory arm edema secondary to a central vein lesion.

Multiple Prosthetic Access Failure

There is a subset of patients in which prosthetic accesses do not appear to work. In the typical scenario, patients are referred for access after multiple previous prosthetic accesses (and revisions) have failed to function for any appreciable length of time. Although it is conceivable that this subset of patients is hypercoagulable, formal hypercoagulable evaluations and medical therapies (i.e., anticoagulants, antiplatelet agents) have not been particularly beneficial. The optimal treatment in this setting is to construct an autogenous access. For those patients with limited autogenous conduit, there are several alternatives as noted above.

Obesity

Similar to most surgical problems, obesity complicates the challenges of constructing permanent hemodialysis access due to the depth of the “superficial” veins below the surface of the skin and the increased incidence of wound complications. Notably, obese patients have been shown to have comparable number of autogenous access configurations, similar revision/failure rates, but a lower maturation rate among those considered morbidly obese (i.e., highest quartile). The deep course of the “superficial” veins can be overcome by transposing or elevating the veins such that they course immediately beneath the skin or by excising the adipose tissue (i.e., “lipectomy”). We have had good results with the elevation procedure and prefer to do this as part of a two-stage procedure (first stage—access construction, second stage—elevation) since it has

been our anecdotal impression that the veins mature better in situ. An incision is made over the course of the dilated vein that comprises the fistula and the vein is dissected free. The subcutaneous tissue is then reapproximated underneath the vein with interrupted absorbable sutures, thereby elevating it to the level of the skin. This requires a little trial and error to assure that the vein is elevated sufficient to facilitate easy cannulation, yet there is an adequate amount of soft tissue overlying the vein and the skin is not closer under undue tension. The healed incision helps identify the ultimate course of the fistula for the technologist and the scar if fairly insensate, and thus, cannulation is well tolerated by the patients. Bourquelot et al. have reported a novel “lipectomy” technique that involves making a series of parallel transverse incisions over the access and then excising the excess adipose tissue below the skin, thereby “elevating” the vein. Alternatively, implantable guides (VWing, Vital Access, Salt Lake City, UT) have been described that direct the needle through the subcutaneous tissue into the vein that comprises the access.

Thin Skin

Patients with thin skin such as the elderly and those on chronic steroids present a problem because any breakdown of the skin over the access can lead to an access infection or bleeding. This is particularly a concerning in the immediate postoperative period for the incision adjacent to the anastomosis. We have approached patients with thin skin using our same algorithm, but have attempted to tunnel the prosthetic grafts or autogenous vein as deep beneath the skin and subcutaneous tissue as possible. We have been anecdotally impressed that the repeated trauma from accessing the conduit can lead to fibrosis over the conduit that can be protective.

Human Immunodeficiency Virus

The life expectancy for patients infected with human immunodeficiency virus (HIV) is quite good given the recent advances in medical therapy and, thus, it is essentially a chronic illness with a reasonable life expectancy. Indeed, the decision to offer patients hemodialysis or permanent hemodialysis access is no longer relevant given these advances. The patency rates for prosthetic accesses may be reduced among patients with HIV while the associated infectious complications may be increased. Because of these concerns, autogenous access is likely the most ideal choice for patients with HIV and every option in the algorithm outlined

above should be exhausted prior to considering a prosthetic access.

Elderly Patients

The elderly represent one of the most rapidly expanding cohort of patients on dialysis. Although there is no specific age cutoff to define the elderly population, the generic concerns are consistent across patients of advanced age. These concerns advanced comorbidities, decreased functional status, generalized frailty, limited life expectancy, and increased morbidity/mortality associated with interventions. There is no consensus across the literature for elderly patients, although concerns have been expressed that the autogenous maturation rate is lower and that a large percentage of patients with chronic kidney disease who undergo placement of an autogenous access never use it for dialysis. Our approach for elderly patients is essentially the same as outlined above, and we have attempted to construct autogenous access in the majority of patients. However, our threshold for constructing a prosthetic access is somewhat lower and we frequently delay intervention until the patients are closer to dialysis with the overarching goal of achieving a functional access, not necessary an autogenous access.

Prior Hand Ischemia

A history of access-related hand ischemia is problematic and predictive of future ischemic events regardless of the extremity (i.e., contralateral or ipsilateral). A catheter-based or CT arteriogram is mandatory during the preoperative evaluation in this setting, independent of the noninvasive studies. An arterial inflow lesion may not become hemodynamically significant until an arteriovenous fistula is constructed and it has been estimated that up to one third of all access-related ischemic events are due to inflow stenoses or occlusions. All arterial inflow lesions should be corrected prior to constructing a new access and a remedial plan should be generated *preoperatively* to address any *postoperative* hand ischemia. We have had very good results with the DRIL procedure as noted above and have performed a few preemptive DRIL procedures (planned simultaneous access, DRIL). We routinely survey the saphenous vein during the preoperative evaluation in these patients. Alternatively, the arterial anastomosis for the access can be sited more proximal (e.g., proximal brachial artery) or distal (e.g., proximal radial artery) on the arterial tree relative to the brachial artery at the antecubital fossa. This has been shown

to have a favorable hemodynamic benefit in terms of the distal perfusion or magnitude of the “steal” phenomenon. Indeed, these approaches are the basis of the “proximalization of the arterial inflow” and “revision using distal inflow” that comprise two of the remedial treatments for access-related hand ischemia. The typical example is a prosthetic brachioaxillary access in which the arterial anastomosis is performed on the proximal brachial artery rather than the segment near the antecubital fossa.

Upper Extremity Access Precluded

Permanent lower extremity hemodialysis accesses are only indicated for patients who are truly precluded from any upper extremity procedures (i.e., superior vena cava syndrome, refractory arm edema, uncorrectable access-related hand ischemia). The complication rates (particularly the infectious complications) associated with lower extremity accesses are significant and rival those for catheters. We routinely obtain preoperative ankle/brachial indices and lower extremity vein survey (i.e., duplex ultrasound) of the saphenous and femoral system in addition to the CT venogram noted above in patients with complex access issues who are being considered for lower extremity access. Both the autogenous and prosthetic options in the lower extremity are somewhat limited. Several studies have reported reasonable results using the femoral vein as an autogenous access, but we have had a hard time reproducing these experiences (largely due to the development of significant wound complications) despite multiple attempts and various modifications of the technique (e.g., skip incisions, composite configurations with prosthetic or cadaveric grafts). Alcoer et al. have reported a technique that involves a limited incision in the mid third of the thigh, mobilization of the femoral vein from the adductor canal to the confluence of the profunda vein, and then elevation of the vein to the level of the skin incision. We have had some success with this approach, but its use is limited to thin patients because of the limited length of the femoral vein and the need to elevate it to the level of the skin. Our preferred lower extremity prosthetic access is the thigh loop based off the common femoral artery and vein. It is certainly possible to use the proximal superficial femoral artery for the inflow and the saphenous vein for the venous outflow, although we have favored the common femoral artery and vein because of their larger size. Flarup and Hadimeri have reported using the superficial femoral artery and vein in the distal thigh, although it is not clear whether the wound complications are

lower and the configuration may be precluded in patients with lower extremity occlusive disease.

STRATEGIES TO MAINTAIN ACCESS

It is important to emphasize that maintaining adequate access is a lifelong process that requires a lifelong plan. Strategies should be designed to preserve all possible access options, select the access most likely to have the best long-term patency, and sustain each individual access as long as is possible. Specifically, the cephalic and basilic veins should be preserved. They should not be used for blood draws, intravenous catheters, peripherally inserted central catheters (i.e., PICC lines) or conduits for lower extremity arterial bypass if at all possible. For the inpatients, we traditionally post a sign over the head of their bed, although it is likely more effective to counsel the patients about the importance of preserving these potential conduits and allow them to serve as their own advocate. The subclavian vein should not be used for dialysis access catheters, and, ideally, not for any other type of central vein catheter. Notably, subclavian vein dialysis catheters are associated with approximately a 30% incidence of subclavian vein stenosis or occlusion that precludes permanent hemodialysis access on the ipsilateral extremity. Every effort should be made to construct autogenous accesses as emphasized by KDOQI due to their better long-term patency rates. An aggressive surveillance protocol should be devised to identify “failing” accesses and appropriate remedial procedures performed. Admittedly, the ideal surveillance technique remains to be identified, and it is likely that a variety of different ones are suitable. Lastly, attempts should be made to salvage all thrombosed accesses. The treatment algorithms have been worked out reasonably well for thrombosed prosthetic accesses, although the guidelines are less clear for thrombosed autogenous accesses. It has been our anecdotal impression that the same treatment options (i.e., chemical lyses, mechanical thrombectomy) are appropriate for thrombosed autogenous accesses, although the success rates may not be as good as those for prosthetic accesses.

ALTERNATIVE STRATEGIES FOR RENAL REPLACEMENT THERAPY

Despite our aggressive algorithm, there is a very small subset of patients

who are not candidates for permanent hemodialysis access due to anatomic restrictions, limited life expectancy, or prohibitive comorbidities. Fortunately, we have been able to obtain some type of access or use other strategies for renal replacement therapy in these difficult patients. However, most nephrologists have had patients in their practices who have succumbed due to the inability to obtain long-term dialysis access. We have used tunneled "temporary" catheters as the permanent hemodialysis access in this group of patients. Fortunately, the interventional radiologists at our institution have shared our dedication to these patients. Admittedly, these tunneled catheters are associated with significant complication rates and need to be changed frequently. Furthermore, we have aggressively explored the alternative options for renal replacement therapy, including peritoneal dialysis and transplantation.

EDITOR'S COMMENT

The need for hemodialysis access creation has markedly increased over the last 20 years and will likely to continue to do so as patients generally live longer due to improvement in cardiovascular health. Indeed, elderly patients were once defined as over 65, but now make up the bulk of all hemodialysis access procedures. Several important points are brought up in this very comprehensive and detailed chapter by a group with much experience and outstanding published outcomes.

One of the primary benefits of timely autologous access creation is to avoid a tunneled catheter. Tunneled catheters are associated with numerous problems, but most concerning is bloodstream infection (Napalkov P, Felici DM, Chu LK, et al. Incidence of catheter-related complications in patients with central venous or hemodialysis catheters: a health care claims database analysis. *BMC Cardiovasc Disord* 2013;13:86). Indeed, septicemia related to catheter use contributes to endocarditis and potential significant mortality. Hemodialysis access created with autogenous tissue is ideal because it avoids the risk of infection associated with a prosthetic, and, if the fistula matures, has an excellent long-term patency rate of ~60% to 70% (Al-Jaishi AA, Oliver MJ, Thomas SM, et al. Patency rates of the arteriovenous fistula for hemodialysis: a systematic review and meta-analysis. *Am J Kidney Dis* 2014;63:464–78). However, the "Achilles heel" of autogenous access is fistula maturation. While

the technical aspects of fistula creation are straightforward, and actual fistula thromboses are low, incomplete fistula maturation is a problem that effects up to 30% or 40% of all hemodialysis access cases (Patel ST, Hughes J, Mills JL, Sr. Failure of arteriovenous fistula maturation: an unintended consequence of exceeding dialysis outcome quality Initiative guidelines for hemodialysis access. *J Vasc Surg* 2003;38:439–45; discussion 445). Research to define and improve this is ongoing, including a large prospective multicenter trial sponsored by the NIH to look at access fistula maturation factors. However, in my experience, the conduit size and quality are most important for early success. This of course assumes an adequate inflow arterial source, readily confirmed in the vascular lab and by checking bilateral blood pressures.

Another major issue is predicting when a patient should have an autogenous access created, in relation to when they will start hemodialysis (Shechter SM, Skandari MR, Zalunardo N. Timing of arteriovenous fistula creation in patients with CKD: a decision analysis. *Am J Kidney Dis* 2014;63:95–103). This has still not been devised with good prognostic certainty; however, patients with lower glomerular filtration rate, diabetes, and significant proteinuria all have a more accelerated rate of requiring hemodialysis for renal replacement. A concern is that creating a fistula too early means the patient may undergo an unneeded surgery, but more so that when the fistula is needed, it may now have a diminished lifespan because it has been in place for months to years. Placing a fistula after the patient is on hemodialysis is fraught with an increased failure rate and the need for a temporary tunneled catheter, with all its attendant problems.

Salvage of autogenous arteriovenous access is now more commonly successful, and effectively done using covered endoluminal stents for areas of long segment stenosis, stricture, and sometimes pseudoaneurysms. Indeed, prosthetic-covered stents are well utilized in this regard and seem to have less risk of neointimal hyperplasia than a primary prosthetic arteriovenous fistula graft configuration. However, infection risk does remain, occasionally necessitating stent removal with loss of access.

Whether post procedure duplex ultrasound can help define those fistulas at increased risk of failure has recently been shown in a retrospective study (Itoga NK, Ullery BW, Tran K, et al. Use of a proactive duplex ultrasound protocol for hemodialysis access. *J Vasc Surg* 2016;64:1042–9.e1). One of my partners uses this strategy to detect potentially failing grafts and uses the balloon-assisted maturation technique that has been popularized over the last several years (Roy-Chaudhury P, Lee T, Woodle B, et al. Balloon-assisted maturation (BAM) of the arteriovenous fistula: the good, the bad, and the ugly. *Semin Nephrol* 2012;32:558–63). Whether this leads to actual increase fistula utilization or increased fistula life has yet to be proven.

The operative techniques are well described in this chapter, including the diagrams and technical points. I would only differ in that I see no benefit to a staged brachial-basilic access as compared to a single stage. A two-stage

approach subjects the patient to two operations, and often the need to move the fistula up to a more proximal arterial site, as noted by the authors. Given the average size of the basilic vein, maturation is not an issue. However, many disagree with the single-stage procedure, but I have not found a detriment to a single-stage procedure to change my practice.

Complications of arterial steal are real, and are well highlighted in this chapter. Steal needs to be recognized in a rapid manner to prevent critical hand debility issues, such as ischemic changes, neuropathic pain, and inability to use the hand. This can be a devastating complication if unrecognized. The authors lay out useful risk predictors of ischemia related to autogenous arteriovenous fistulas.

Lastly, this topic highlights that novel conduit options for hemodialysis access are needed. A holy grail is to have a prosthetic graft that would be resistant to infection and resistant to neointimal hyperplasia. However, this is unlikely to be seen within the next decade. However, there are biologic grafts that are now being tested for use in the hemodialysis access arena and hold promise that there would be a true biologic construct that rivals or betters human vein.

Peter Henke

227 Hemodialysis Access-Prosthetic Arteriovenous Access

Robyn A. Macsata and Anton N. Sidawy

In 2012, data from the United States Renal Data System (USRDS) showed that 114,813 new patients began therapy for end-stage renal disease (ESRD), whereas the prevalent dialysis population reached 636,905. Of note, after a continuous rise in ESRD patients between 1980 and 2010, for the first time a plateau or even slight decline was seen between 2010 and 2012. Despite this, total Medicare costs for ESRD patients increased by 3.2%, to $28.6 billion, accounting for 5.6% of the total Medicare budget. Not surprising to vascular access surgeons, most of these costs come between the transitions from chronic kidney disease (CKD) to ESRD and are related to dialysis access. With these ongoing numbers and ever increasing cost of care of renal patients, placement of successful permanent arteriovenous (AV) access is essential.

Because of known higher long-term patency rates and lower complication rates of autogenous AV access in comparison with prosthetics, we attempt to place autogenous AV access in all our patients with ESRD. In order to achieve success, we stress early referral of these patients from our nephrologists, a thorough preoperative evaluation including noninvasive vascular laboratory testing, particularly superficial venous mapping, and contrast studies if necessary, and routine postoperative follow-up with secondary procedures if indicated. Unfortunately, even with these efforts, it is sometimes impossible to construct an autogenous AV access, requiring placement of a prosthetic AV access. To achieve success in this population, thorough pre- and postoperative evaluations as well as meticulous surgical technique are even more imperative.

INDICATIONS

The National Kidney Foundation-Disease Outcomes Quality Initiative (NKF-KDOQI) guidelines recommend that patients be referred to a

vascular access surgeon for permanent AV access when their creatinine clearance is less than 25 mL/min. Once preoperative evaluation is complete, if we feel the patient will require a prosthetic AV access, we delay construction of the access until 3 to 6 weeks prior to the initiation of dialysis; this is due to the fact that prosthetic access patency is limited by time of access placement, and not by access use.

PREOPERATIVE PLANNING

History and Physical Examination

A thorough patient history is taken documenting patient's dominant extremity, recent history of peripheral intravenous lines, site of indwelling or previous central venous lines including pacemakers and defibrillators, all previous access procedures, any history of trauma or previous nonaccess surgery to the extremity, and all co-morbid conditions. On physical examination, the brachial, radial, and ulnar arteries are evaluated for compressibility and equality; an Allen test is performed to evaluate for palmar arch patency. With a venous tourniquet in place, the cephalic and basilic veins are evaluated for diameter, distensibility, and continuity; the arm is examined for any signs of central venous stenosis including prominent venous collaterals, edema, or a differential in extremity diameter.

Arterial Assessment

If any abnormality is noted on clinical arterial examination, the patient is further evaluated with segmental pressures and duplex ultrasound. Any abnormalities noted on noninvasive testing, including pressure gradients between the bilateral upper extremities, arterial diameters less than 2.0 mm, and nonpatent palmar arches, are further evaluated with an arteriogram. Any inflow stenosis is treated first with endovascular techniques such as angioplasty and/or stenting, and if not amenable or unsuccessful, open surgical techniques such as patch angioplasty or bypass.

Venous Assessment

If superficial veins cannot be visualized or any abnormality is noted on the superficial venous examination, the patient is further evaluated with superficial venous duplex; using duplex the superficial veins are examined

for diameter, distensibility, and continuity. We only use superficial veins for autogenous access that are greater than 2.5 mm in diameter.

If any central venous stenosis is suspected by history or any abnormality is noted on physical examination, the patient is further evaluated with deep venous duplex; if the deep venous duplex is non-diagnostic or any central venous stenosis is noted, the patient is further evaluated with a venogram. Any central venous stenosis is treated first with endovascular techniques such as angioplasty and/or stenting, and if not amenable or unsuccessful, open surgical techniques such as internal jugular to axillary venous bypass or subclavian vein turndown.

In patients nearing dialysis, the risk of contrast arteriogram or venogram is weighed against the need for an access to mature before beginning dialysis; in this population, we use renal protective agents prearteriogram, including intravenous fluids, *N*-acetylcysteine, and sodium bicarbonate.

ACCESS LOCATION SELECTION

Table 227.1 lists the various types of autogenous and prosthetic AV access available in the upper and lower extremities and body wall; when planning AV access, a few general principles apply.

1. Given their superior patency rates and lower complication rates, autogenous AV accesses are always attempted before a prosthetic AV access.
2. Due to easier accessibility and lower infection rates, upper-extremity access sites are used first, with the nondominant arm given preference over the dominant arm.
3. To preserve proximal sites for future accesses, AV accesses are placed as far distally in the extremity as possible.
4. Autogenous AV access configurations, in order of preference, are direct AV anastomosis, venous transpositions, and venous translocations.

For purposes of this chapter, we will focus on prosthetic AV access.

TABLE 227.1 Arteriovenous Access Configuration

Upper Extremity

Forearm

1. Autogenous
   a. Autogenous posterior radial branch–cephalic wrist direct access (snuffbox fistula)
   b. Autogenous radial–cephalic wrist direct access (Brescia–Cimino–Appel fistula)
   c. Autogenous radial–cephalic forearm transposition
   d. Autogenous brachial (or proximal radial)–cephalic forearm looped transposition
   e. Autogenous radial–basilic forearm transposition
   f. Autogenous ulnar–basilic forearm transposition
   g. Autogenous brachial (or proximal radial)–basilic forearm looped transposition
   h. Autogenous radial–antecubital forearm indirect greater saphenous vein translocation
   i. Autogenous brachial (or proximal radial)–antecubital forearm indirect looped greater saphenous vein translocation
   j. Autogenous radial–antecubital forearm indirect femoral vein translocation
   k. Autogenous brachial (or proximal radial)–antecubital forearm indirect looped femoral vein translocation
2. Prosthetic
   a. Prosthetic radial–antecubital (or brachial) forearm straight access
   b. Prosthetic brachial (or proximal radial)–antecubital (or brachial) forearm looped access

Upperarm

1. Autogenous
   a. Autogenous brachial (or proximal radial)–cephalic upper arm direct access
   b. Autogenous brachial (or proximal radial)–cephalic upper arm transposition
   c. Autogenous brachial (or proximal radial)–basilic upper arm transposition
   d. Autogenous brachial (or proximal radial)–brachial (vein) upper arm transposition
   e. Autogenous brachial (or proximal radial)–axillary (or brachial) upper arm indirect greater saphenous vein translocation
   f. Autogenous brachial (or proximal radial)–axillary (or brachial) upper arm indirect femoral vein translocation
2. Prosthetic
   a. Prosthetic brachial (or proximal radial)–axillary (or brachial) upper arm straight access

Lower Extremity

1. Autogenous
   a. Autogenous femoral–greater saphenous lower-extremity (straight or looped) transposition
   b. Autogenous tibial (anterior or posterior)–greater saphenous lower-extremity direct access
   c. Autogenous femoral–femoral (vein) lower-extremity (straight or looped) transposition
2. Prosthetic
   a. Prosthetic superficial femoral–femoral (vein) lower-extremity straight access
   b. Prosthetic superficial femoral (or common or profunda femoral)–femoral (vein) lower-extremity looped access

Body Wall

1. Prosthetic
   a. Prosthetic axillary–axillary (vein) chest (straight or looped) access
   b. Prosthetic axillary–internal jugular chest looped access
   c. Prosthetic axillary–femoral (vein) body wall access

Adapted from Sidawy AN, Gray R, Besarab A, et al. Recommended standards for reports dealing with arteriovenous hemodialysis accesses. *J Vasc Surg* 2002;35(3):603–10; with permission from Elsevier.

Forearm

In the upper extremity, the cephalic and basilic veins are both options for autogenous AV access; however, when unavailable, we perform a prosthetic upper-extremity access, beginning in the forearm. Sources of arterial inflow include the distal or proximal radial and brachial arteries; we use the most distal artery in the arm felt to be adequate by preoperative evaluation for inflow to preserve more proximal arteries for future accesses. Sources of venous outflow include the antecubital vein or the brachial vein; we prefer to use the superficial system if felt to be adequate on exploration to help with venous dilation of the upper arm superficial veins for future accesses. Therefore, when the distal radial artery is adequate, we perform a prosthetic radial–antecubital (or brachial vein) forearm straight access (Fig. 227.1). If the distal radial artery is inadequate but the brachial or proximal radial artery is adequate, we perform a prosthetic brachial (or proximal radial)–antecubital (or brachial vein) forearm looped access (Fig. 227.2).

One of the interesting debates in this area is whether, after exhausting the forearm autogenous options, the surgeon should recommend a forearm prosthetic access before proceeding to an upper arm autogenous access. We handle this decision by having a discussion with the patient about this alternative option and its advantages and disadvantages, and allow the patient to make an informed decision. If a prosthetic forearm access is chosen, we explain to the patient that this access is used as a "bridge" to an autogenous upper arm access; we minimize attempts to salvage this access to avoid damaging the venous outflow so it can still be used for an autogenous upper arm access.

Upper Arm

When use of the forearm has been exhausted, efforts are directed to the upper arm. Like the forearm, the cephalic and basilic veins are both options for autogenous access; however, when unavailable, we perform a prosthetic upper arm access. Sources of arterial inflow include the proximal radial and brachial arteries; we use the most distal artery in the arm felt to be adequate by preoperative evaluation for inflow to preserve more proximal arteries for future access. Sources of venous outflow include the proximal brachial and axillary vein. Therefore, in patients with no adequate vein, a prosthetic brachial (or proximal radial)–axillary (or brachial vein) upper arm straight access (Fig. 227.3) is performed.

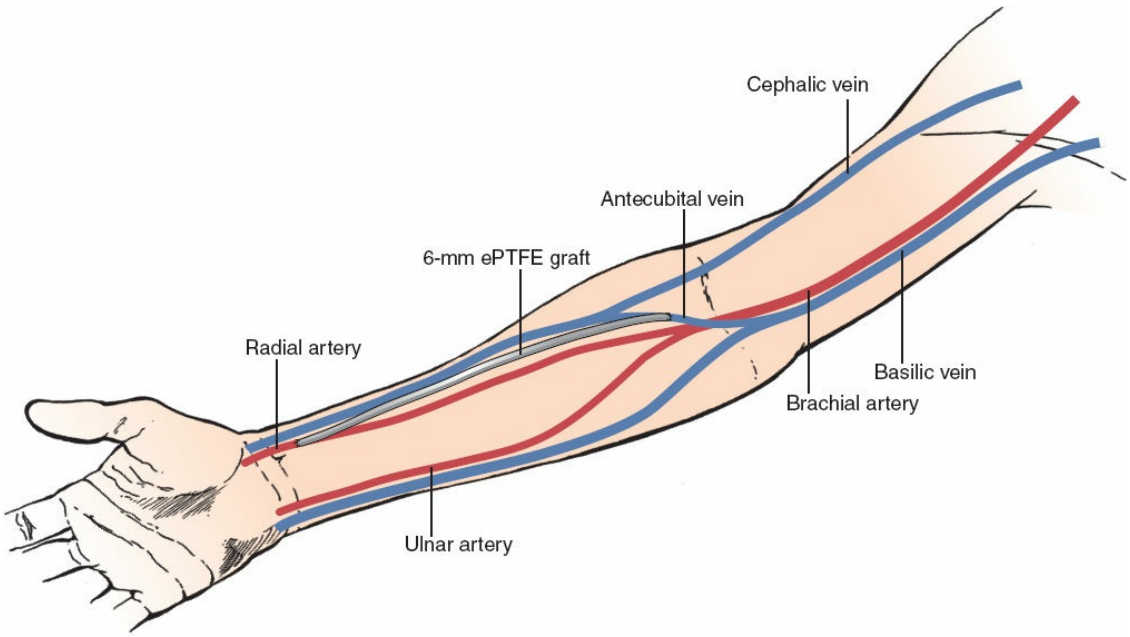

Figure 227.1. Prosthetic radial–antecubital forearm straight access. ePTFE, expanded polytetrafluoroethylene.

Lower Extremity

When use of the bilateral upper extremities has been exhausted, efforts are directed to the lower extremity; this access is less desirable due to the higher incidence of occlusive disease, arterial steal, and infections. As with upper-extremity access, autogenous access is preferred; the greater saphenous and superficial femoral veins are both options for autogenous AV access. When these veins are not available, we perform a prosthetic lower-extremity access. Sources of arterial inflow include the common, proximal and distal superficial, and profunda femoral arteries; we use the most distal artery in the leg felt to be adequate by preoperative evaluation for inflow to preserve more proximal arteries for future access. Sources of venous outflow include the common, superficial, and profunda femoral vein. Therefore, in patients with an adequate distal superficial femoral artery, we perform a prosthetic superficial femoral–femoral (vein) lower-extremity straight graft (Fig. 227.4). In patients with an inadequate distal superficial femoral artery but adequate proximal artery, we perform a prosthetic superficial femoral (or common or profunda femoral)–femoral (vein) lower-extremity loop graft (Fig. 227.5).

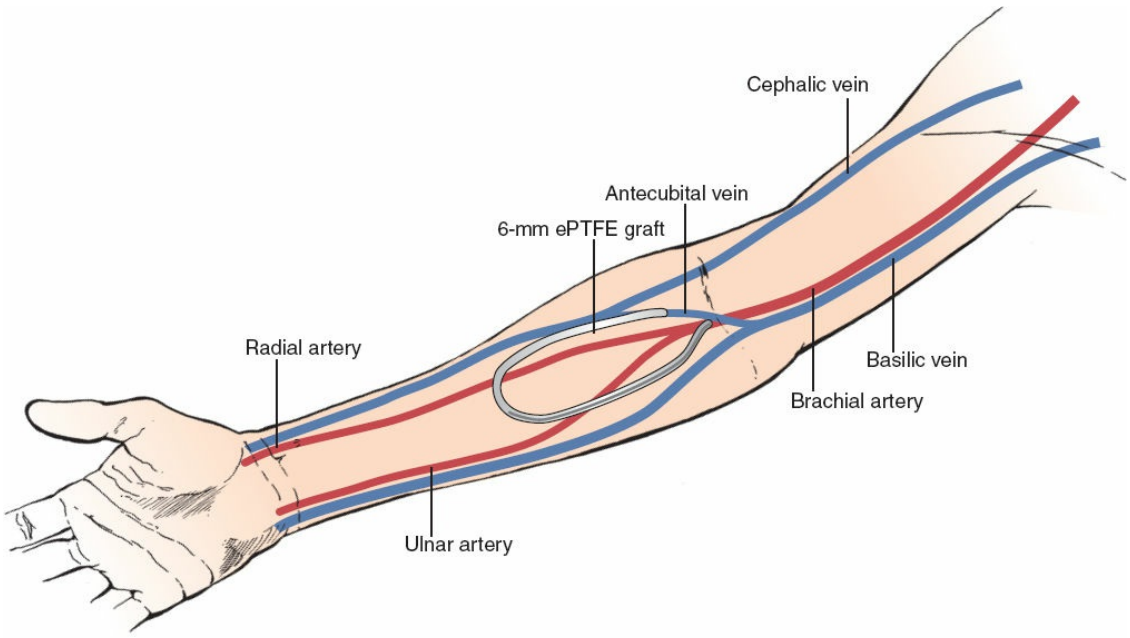

Figure 227.2. Prosthetic brachial–antecubital forearm looped access. ePTFE, expanded polytetrafluoroethylene.

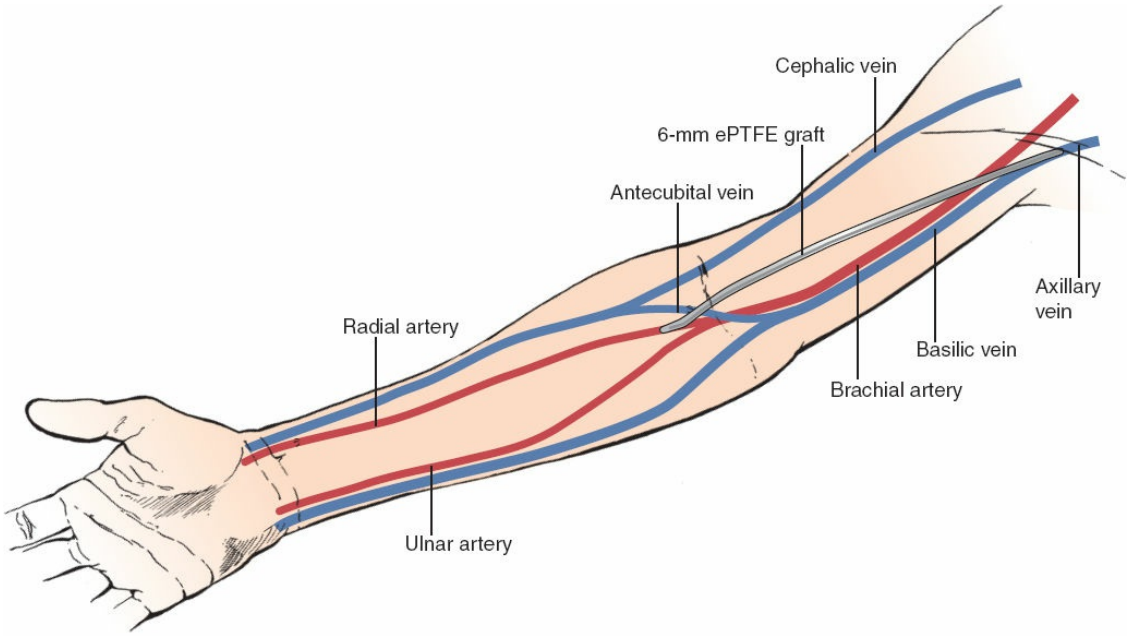

Figure 227.3. Prosthetic proximal radial–axillary upper arm straight access. ePTFE, expanded polytetrafluoroethylene.

Body Wall

After both upper and lower extremities have been exhausted, body wall access is used as a last alternative access site; these accesses almost always require a prosthetic graft. The main source of arterial inflow is the axillary artery. Sources of venous outflow include the axillary, internal jugular, and femoral veins. Appropriate options include a prosthetic axillary–axillary (vein) chest (straight or looped) access, a prosthetic axillary–internal jugular chest looped access, and a prosthetic axillary–femoral (vein) body wall access.

Choice of Graft Material

A standard 6-mm expanded polytetrafluoroethylene (ePTFE) is our choice for graft material for prosthetic AV accesses. Variations of the standard ePTFE graft include thin-walled, extended stretch, external rings, various tapered configurations, and heparin coating, which are all meant to ease handling, provide external support, and improve patency rates. To date, there is only minimal evidence that any of these variations improve long-term results, and therefore, use of any of these variations remains a matter of surgeon preference.

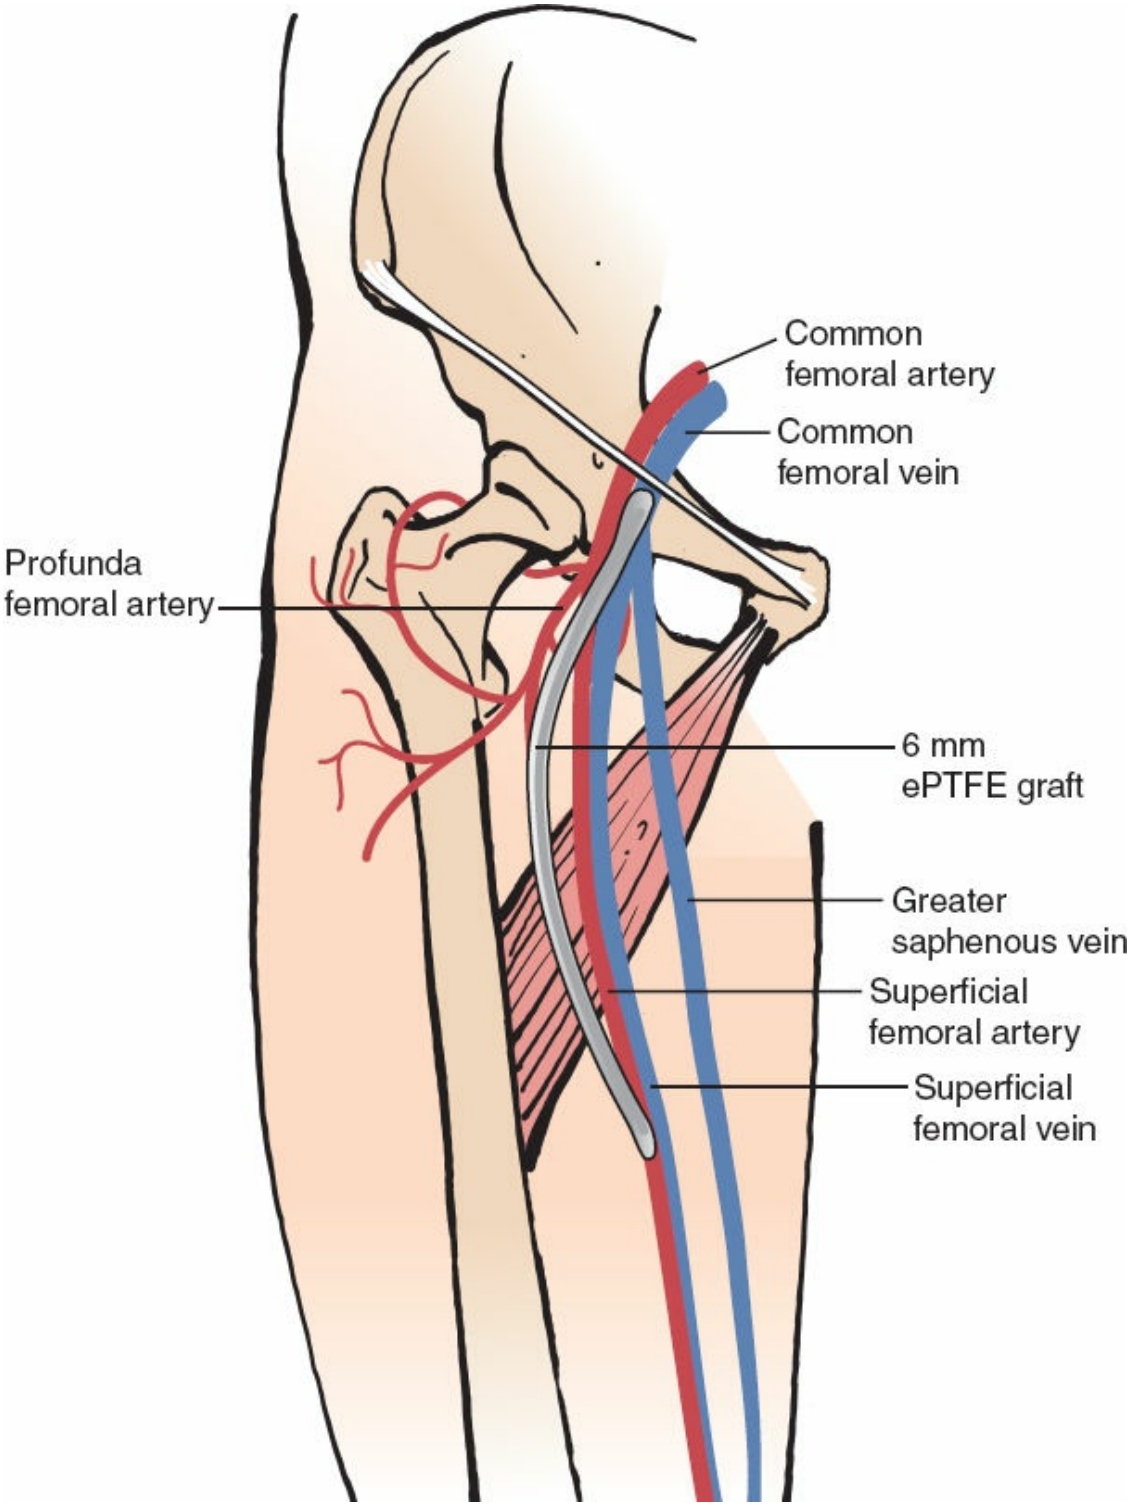

Figure 227.4. Prosthetic superficial femoral–femoral (vein) lower-extremity straight access. ePTFE, expanded polytetrafluoroethylene.

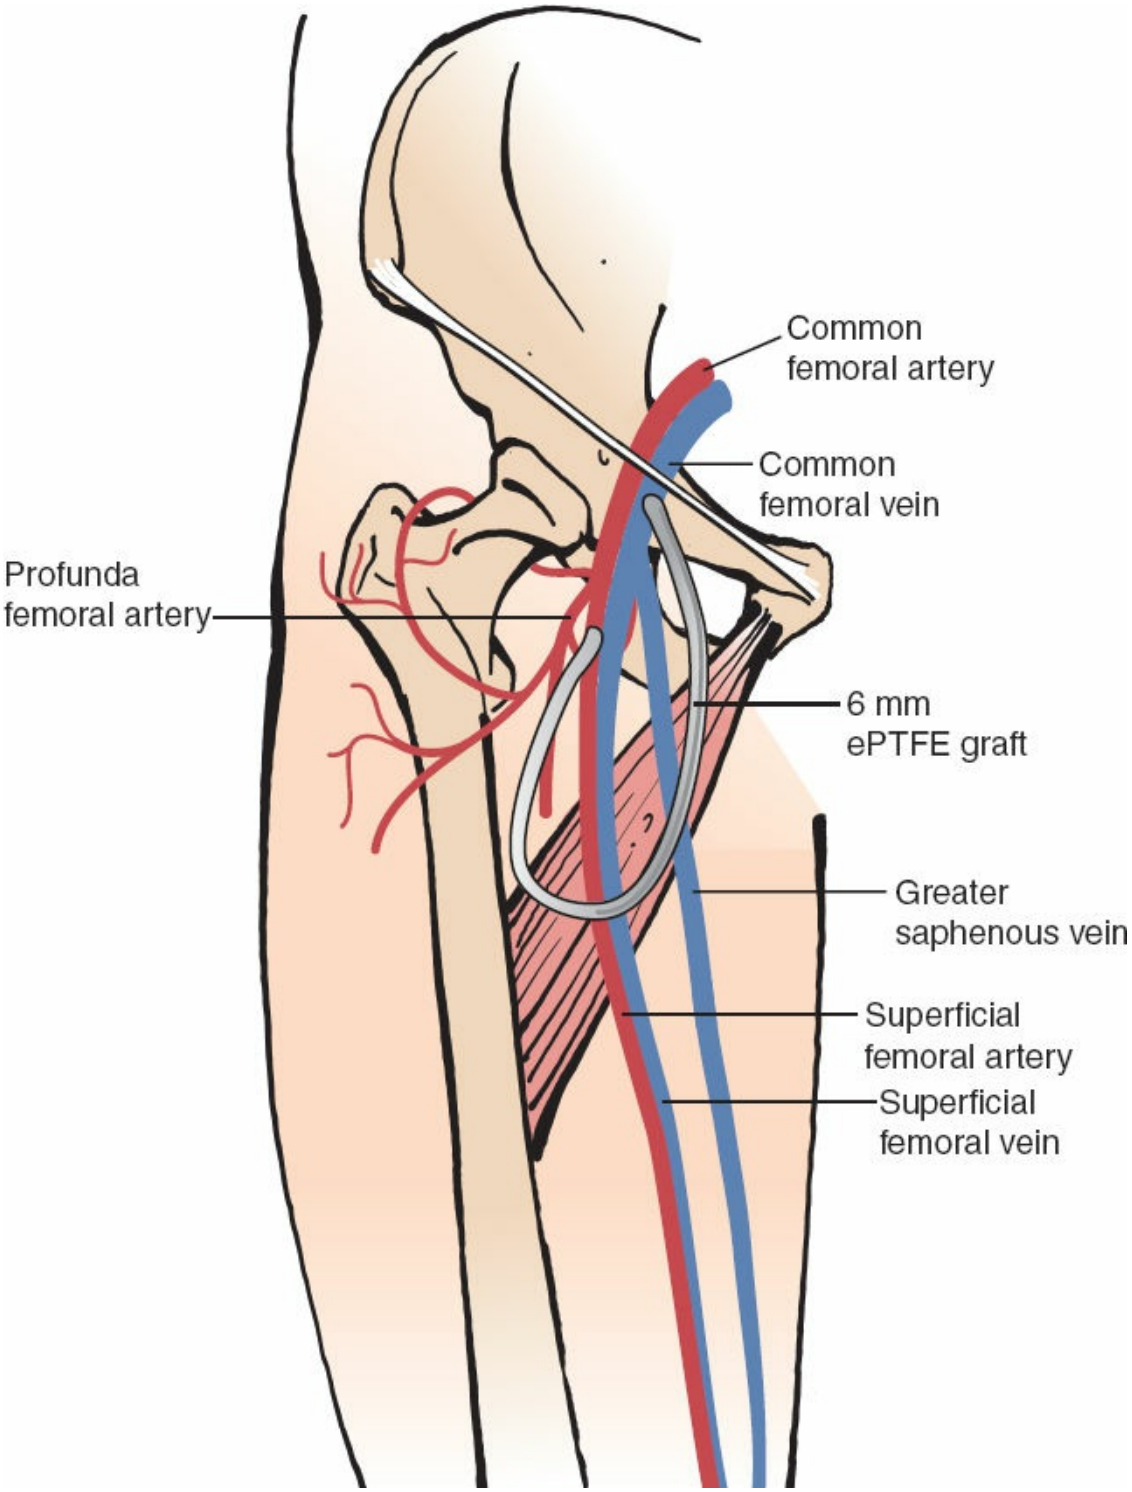

Figure 227.5. Prosthetic superficial femoral–femoral (vein) lower-extremity looped access. ePTFE, expanded polytetrafluoroethylene.

There has also been development of early cannulation prosthetic grafts (Acuseal, W. L. Gore, Flagstaff, AZ, Flixene Maquet-Atrium Medical Rastatt Germany, and Vectra Bard Covington GA), generally constructed

in three layers, with an elastomeric membrane sandwiched in between two layers of ePTFE material. This configuration hinders suture line and dialysis cannulation needle bleeding allowing for early cannulation, reported as soon as 24 hours from implantation. Thus, offering the potential for either avoidance of or early removal of short- and long-term dialysis catheters. Similar to other variations of prosthetic accesses, there is minimal evidence that this variation improves long-term results; therefore, use or this variation remains a matter of surgeon preference.

Hemodialysis Reliable Outflow Graft

The Hemodialysis Reliable Outflow (HeRO) graft (Hemosphere/CryoLife Inc, Eden Prairie, MN) is an innovative approach to obtain permanent AV access in patients with central venous occlusions not amenable to open or endovascular means of recanalization. The HeRO graft has two components: the venous outflow component, which is inserted into the central venous system proximal to any occlusion, similar to a temporary dialysis access line, and the arterial graft component, which is made of 6 mm ePTFE and is tunneled under the skin and sewn into the arterial inflow similar to permanent AV access (Fig. 227.6). Due to its relatively low patency and high complication rates, we generally reserve HeRO grafts for a last resort measure on ESRD patients with central venous occlusions and temporary lines as their only alternative option for dialysis access.

SURGICAL TECHNIQUE

As described above, prosthetic AV access may be performed with multiple different options for arterial inflow, conduit, and venous outflow. Despite these different options, surgical technique is similar. Steps common to all prosthetic AV accesses include the following:

1. Due to the risk of cardiopulmonary complications associated with general anesthesia, we prefer to perform AV accesses with local nerve block.
2. Because most early access failures are due to inadequate venous outflow, the venous outflow is dissected first, to ensure that it is adequate before proceeding further; it is controlled with vessel loops.
3. The arterial inflow is dissected and controlled with vessel loops.
4. A standard 6-mm ePTFE prosthetic graft is used for conduit.
5. The subcutaneous tunnel is made with a Kelly–Wick tunneler; the tunnel is made as superficial as possible to allow easy detection by

dialysis personnel and as long as possible for a large service area to prevent repetitive trauma to the same area of the graft and subsequent pseudoaneurysm (PSA) formation. Of note, early cannulation grafts generally require tunnelers specialized to the manufacturer.

6. If the venous outflow and arterial inflow are located away from each other, a straight prosthetic AV access configuration is performed. If the venous outflow and arterial inflow are located close to each other, a loop prosthetic AV access configuration is performed; this requires a counter-incision at the apex of the loop.
7. The length of the arteriotomy is not limited; the diameter of the graft will limit the incidence of arterial steal.
8. The artery is flushed proximally and distally with heparinized saline to avoid thrombosis during the anastomosis.
9. The arterial anastomosis is performed using a 6-0 or 7-0 monofilament nonabsorbable suture in a continuous manner.
10. As with arteriotomy, the length of the venotomy does not need to be limited.
11. The vein is flushed proximally and distally with heparinized saline to avoid thrombosis during the anastomosis.
12. The venous anastomosis is performed using a 6-0 or 7-0 monofilament non-absorbable suture in a continuous manner.
13. After completing both anastomoses, a thrill should be felt in the prosthetic graft and venous outflow tract.
14. The incision is closed in layers, to provide surface coverage for the graft; careful attention to sterile technique is paramount to avoid graft infections.

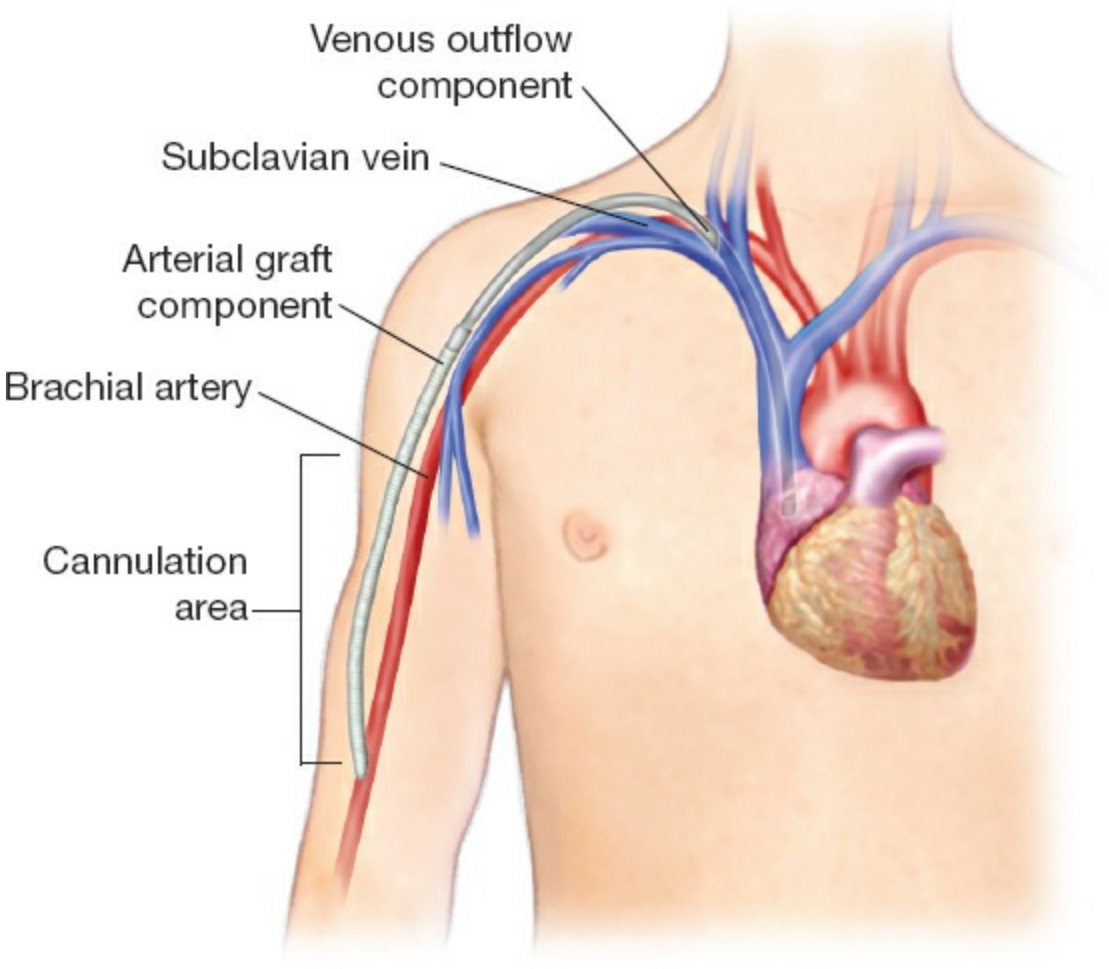

Figure 227.6. HeRO catheter insertion.

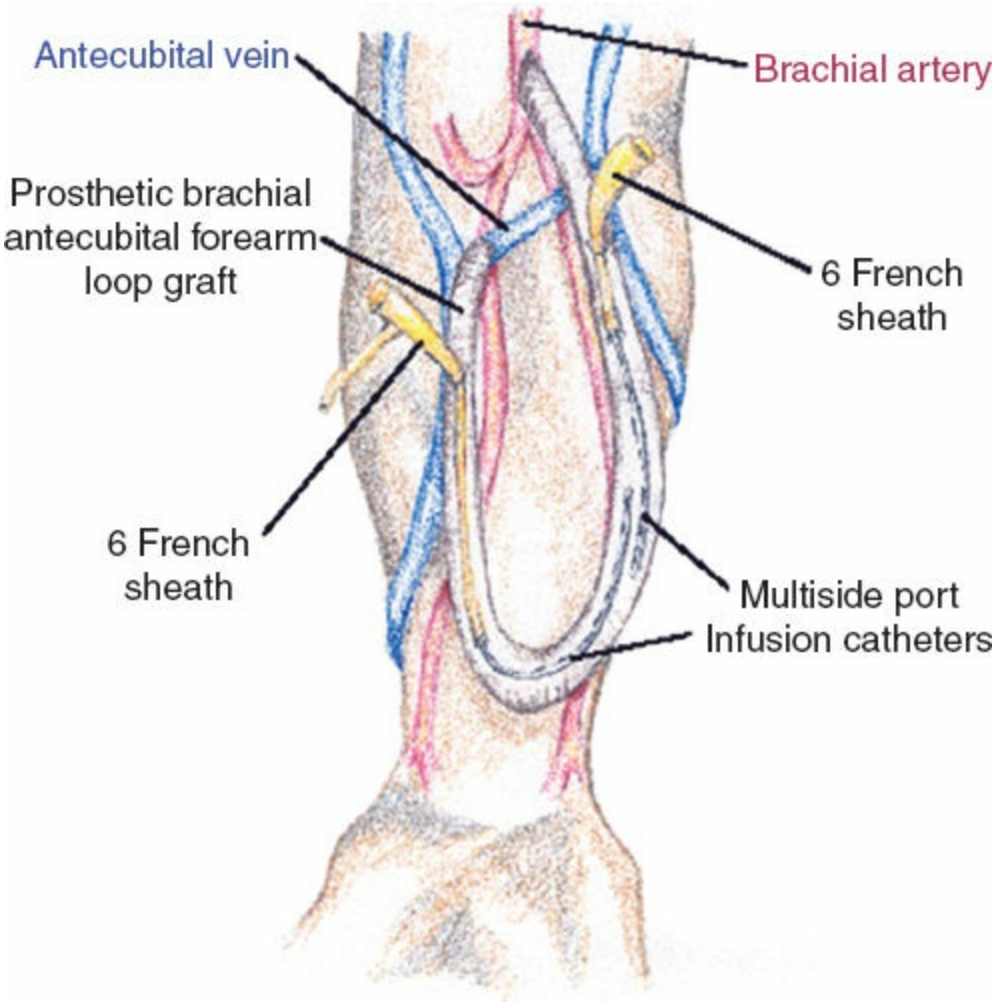

Figure 227.7. Prosthetic brachial-antecubital forearm looped access thrombolysis using cross-catheter technique.

POSTOPERATIVE CARE

We follow up our patients postoperatively until their access is mature and ready for cannulation; for standard prosthetic AV access this may be as soon as 2 weeks and for early cannulation prosthetic AV access immediate. After initial maturation, the AV access is monitored by nephrology while on dialysis. Our preferred method of monitoring is monthly determination of access flow by ultrasound dilution, conductance dilution, thermal dilution, or Doppler technique. Other options include measurement of static venous pressures, measurement of prepump arterial dialysis pressure, measurement of access recirculation using urea concentrations or dilution techniques, evaluation of physical findings such as arm edema, altered characteristics of access thrill, or notation of prolonged bleeding after needle removal. We have found routine duplex surveillance not to be beneficial for long-term patency rates, and therefore,

do not use this method.

COMPLICATIONS AND THEIR MANAGEMENT

For the purposes of this chapter, we will highlight the management of complications more commonly associated with prosthetic accesses.

Late AV Access Thrombosis

Late AV access thrombosis occurs due to intimal hyperplasia; this is most commonly seen at the graft–venous anastomosis but may also occur in the central veins related to catheter use. Treatment options for declotting a prosthetic AV access are either percutaneous techniques including thrombolysis and mechanical thrombectomy or open surgical thrombectomy. Once the prosthetic access is successfully declotted, to avoid repeated thrombosis, it is imperative that the source of thrombosis be identified and appropriately treated.

For endovascular treatment, we prefer thrombolysis using a cross-catheter technique. We perform this by placing two 6-Fr sheaths into the prosthetic access, one placed at the arterial end aimed to the venous end and the other placed at the venous end aimed to the arterial end. Each sheath is accessed with a 0.035-in hydrophilic wire; multi side port infusion catheters are fed over the wires, and left in the thrombosed portion of the AV access (Fig. 227.7). About 5 mg of tPA with 70 IU/kg of heparin is administered via the infusion catheters using a pulse-spray technique balloon; angioplasty (4- to 6-mm balloon) is used to macerate any residual thrombi. After successful declotting, we perform a fistulogram/venogram and balloon angioplasty (6- to 10-mm balloon) for any underlying stenosis identified.

For open surgical treatment, we expose the graft–venous anastomosis and perform a thrombectomy using Fogarty balloons through this anastomosis. After successful declotting, we perform a patch angioplasty to treat any intimal hyperplasia. As with the endovascular technique, we perform a completion fistulogram/venogram and balloon angioplasty (6- to 10-mm balloon) of any other underlying stenosis identified.

TABLE 227.2 Autogenous AV Access Patency Rates

Access Location	Primary Patency (%)	Primary Patency (%)	Secondary Patency (%)	Secondary Patency (%)
	1-year	**2-year**	**1-year**	**2-year**
Upper extremity	43–85	40–69	46–90	62–75
Lower extremity	73	68	86	87–94

Infection

Prosthetic graft infections usually are due to Gram-positive organisms, most commonly *Staphylococcus aureus*, however, up to 25% of infections may involve Gram-negative organisms or be polymicrobial. Infections are seen at a rate to 4% to 20% per year in prosthetic AV access while only at a rate of 0.56% to 5% in autogenous.

Treatment varies based on presentation; if a patient has only a mild cellulitis, we use a trial of broad spectrum antibiotics with close observation. If a patient fails antibiotics or presents with a more severe cellulitis, an abscess, exposed prosthetic material, or sepsis, we remove the infected portion of the graft, leaving all wounds open, and place the patient on broad spectrum antibiotics. If on exploration, either anastomosis is involved, we remove the entire graft to prevent anastomotic disruption.

Pseudoaneurysm

PSAs are due to continuous accessing of the graft in the same location by dialysis personnel; since this requires an arterial and venous puncture with each session, they usually occur in pairs and are located along the length of the access. If they are located at either the arterial or venous anastomosis, they are due to graft infection and are treated as such.

We monitor most puncture site PSAs, instructing dialysis personnel to use alternative sections of the access for cannulation. We repair PSAs that are greater than 3.0 cm, ulcerated, or are noted to be significantly expanding while being monitored. Our preferred method of repair is replacement of the involved section with a new graft; an alternative approach is endovascular treatment with covered stent grafts. With either procedure, postoperative dialysis is continued by accessing the uninvolved portion of the access.

TABLE 227.3 Prosthetic AV Access Patency Rates

Access Location	Primary Patency (%)	Primary Patency (%)	Secondary Patency (%)	Secondary Patency (%)
	1-year	**2-year**	**1-year**	**2-year**
Upper extremity	40–54	18–30	59–65	40–60
Lower extremity	54	18–47	64	18

Seroma

The exact etiology of seromas are unknown, but they are presumed to occur from transudation of serous fluid from the porous graft. They are most commonly seen within 1 month of graft placement and surrounding the arterial anastomosis.

Seromas rarely resolve without intervention and commonly reoccur if treated with aspiration or incision and drainage alone. We find graft replacement, using a different type of graft material routed in a new tunnel, to have the highest likelihood of success.

Steal

Arterial steal occurs secondary to low access tract resistance, creating reversal of blood flow in the arterial outflow tract toward the access and away from the hand. Occurrence rates depend on the site of arterial inflow, with clinically symptomatic steal being seen in 0.25% to 1.8% of wrist accesses and 4% to 9% of upper arm access, regardless of the access being autogenous or prosthetic.

Outflow Venous Obstruction

Venous hypertension occurs secondary to venous outflow stenosis; the outflow obstruction is commonly located in the subclavian vein as a result of intimal hyperplasia associated with venous catheters but may be seen anywhere in the outflow tract. Similar to arterial steal, its occurrence is similar in both autogenous and prosthetic AV access.

OUTCOMES OF AVG

In the upper extremity, prosthetic AV access has consistently been shown to have poorer primary and secondary patency rates when compared to autogenous AV access. Prosthetic AV access 1- and 2-year primary patency rates of 40% to 54% and 18% to 30%, respectively, are clearly inferior to autogenous access 1- and 2-year primary patency rates of 43%

to 85% and 40% to 69%, respectively. Similarly, prosthetic access 1- and 2-year secondary patency rates of 59% to 65% and 40% to 60%, respectively, are also inferior to autogenous AV access 1- and 2-year secondary patency rates of 46% to 90% and 62% to 75%, respectively. Furthermore, to achieve these secondary patency rates, prosthetic AV access requires more interventions (Tables 227.2 and 227.3).

Similar to the upper extremity, lower-extremity prosthetic AV access has consistently been shown to have poorer primary and secondary patency rates then autogenous AV access. Prosthetic AV access 1- and 2-year primary patency rates of 54% and 18% to 47%, respectively, are clearly inferior to autogenous access 1- and 2-year primary patency rates of 73% and 86%, respectively. Similarly, prosthetic access 1- and 2-year secondary patency rates of 64% and 18%, respectively, are also inferior to autogenous AV access 1- and 2-year secondary patency rates of 86% and 87% to 94%. And again, to achieve these secondary patency rates, prosthetic AV access requires more interventions (Tables 227.2 and 227.3).

United States Renal Data System. 2014 USRDS annual data report: *Epidemiology of kidney disease in the United States. National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases,* Bethesda, MD: 2014.

EDITOR'S COMMENT

As noted by the authors, the US Renal Data System suggests a projected dramatic increase in end-stage renal failure patients who will need HD access. This is, in part, because of patients living longer due to good cardiovascular care and other medical innovations. Thus, many patients who would have died of other causes ultimately succumb to renal failure and require renal replacement therapy, and are not able to get a transplant. Herein, the arterial venous graft (AVF) access technique is nicely described.

The AVG access is not the primary HD choice given the durability of native autologous AV access. However, while the NKF-KDOQI guidelines have made a significant impact for increasing autologous access creation, maturation and ultimate usability remain a problem. Further, many patients may not have adequate venous conduit to use for an AVF. The least acceptable HD route is the tunneled central venous catheter that is associated with higher morbidity/mortality primarily related to infectious and thrombotic complications (Astor BC, Eustace JA, Powe NR, et al. Type of vascular access and survival among incident hemodialysis patients: The choices for healthy outcomes in caring for ESRD (choice) study. *J Am Soc Nephrol* 2005;16:1449–55). As noted, many patients ultimately have long periods of time with invasive catheters, prior to AVF maturation or other issues.

There is recently a move toward proceeding with a prosthetic AVG if the vein is marginal as these can be accessed sooner and salvage techniques of AVG are reasonable, often comparable AVF in secondary patency (Disbrow DE, Cull DL, Carsten CG, 3rd, et al. Comparison of AV fistulas and AV grafts in patients with favorable vascular anatomy and equivalent access to health care: Is a reappraisal of the fistula first initiative indicated? *J Am Coll Surg* 2013;216:679–85; discussion 685–6). As noted by the authors, using the forearm and moving up the arm is generally accepted and I agree with that. Loop forearm AVGs at the antecubital site allows good venous outflow through the cephalic and basilic systems as well as the brachial venous system. Whether proceeding with a forearm prosthetic access before an upper arm autologous

access is debatable (Leake AE, Yuo TH, Wu T, et al. AV grafts are associated with earlier catheter removal and fewer catheter days in the united states renal data system population. *J Vasc Surg* 2015;62:123–7), and generally the decision should be based, I believe, on whether the patient is already on HD. If they are not and they are approaching dialysis, an autologous attempt is reasonable as they often have the luxury of time. However, if the patient has imminent need for dialysis, then utilizing an AVF is reasonable, particularly since it can be accessed within a month's time, or less.

Several unusual configurations such as body wall or more exotic inflow and outflow artery vein constructs are noted. Lower-extremity AVF are used rarely as they are at higher risk of infection, and may lead to leg steal that is more common than the upper extremity.

As noted also by the authors, the HeRO graft has been fraught with several reports of significant complications related to this technique and I agree with reserving this for rare occasions. The complications of AVG are nicely delineated in this chapter and include late thrombosis usually due to venous outflow and neointimal hyperplasia. Certainly this is an area where drug-luting balloons, stents, and other technologies may improve the patency. Infection remains a concern, although it is surprising given how often these grafts are accessed percutaneously; they really rarely develop, and salvage techniques are possible.

Peter Henke

I THORACIC

228 Thoracic Outlet Syndrome

Robert Thompson

Thoracic outlet syndrome (TOS) is a group of conditions caused by compression of the neurovascular structures that serve the upper extremity. The thoracic outlet is located within the lower part of the neck, behind the clavicle and above the first rib, and extending into the axilla, and it is often described by several closely related anatomic spaces, including the scalene triangle, the costoclavicular space, and the subcoracoid space (Fig. 228.1). Knowledge of these spaces and the structures that define them is critical toward understanding the clinical manifestations and optimal management of TOS.

ANATOMY

Musculoskeletal Structures and Spaces of the Thoracic Outlet

The scalene fat pad lies deep to the platysma layer in the supraclavicular space of the lower neck where it helps to protect the deeper muscular and neurovascular structures of the thoracic outlet. It attaches adjacent to the internal jugular vein and the undersurface of the clavicle, and contains lymph nodes and lymphatic channels as well as small arteries and veins. The lateral part of the omohyoid muscle also passes through the scalene fat pad as it traverses the lower part of the neck. The anterior scalene muscle (ASM) lies directly behind the scalene fat pad, arising from the transverse processes of the cervical vertebrae and running vertically to attach to the top of the first rib. The middle scalene muscle (MSM) also arises from the cervical spine, runs vertically posterior to the ASM, and attaches to the top of the posterolateral first rib. The narrow vertical space formed between the ASM and MSM, with the first rib at the base, is called the scalene triangle. The major nerves and blood vessels serving the upper extremity lie within or adjacent to the scalene triangle as they pass through the upper

part of the thoracic outlet. The area immediately between the first rib and the clavicle is the costoclavicular space. It is traversed by the subclavius muscle, which runs along the underside of the clavicle to attach to the first rib medial to the ASM. The subclavius muscle forms a band of dense connective tissue immediately lateral to and underneath the sternoclavicular joint, called the costoclavicular ligament. The subcoracoid space lies beyond the first rib and underneath the clavicle and is defined by the pectoralis minor muscle. This muscle lies deep to the pectoralis major muscle in the anterior upper chest, arising from the second, third, and fourth ribs. It runs upward to attach to a protrusion from the scapula known as the coracoid process, to which the short head of the biceps muscle tendon is also attached.

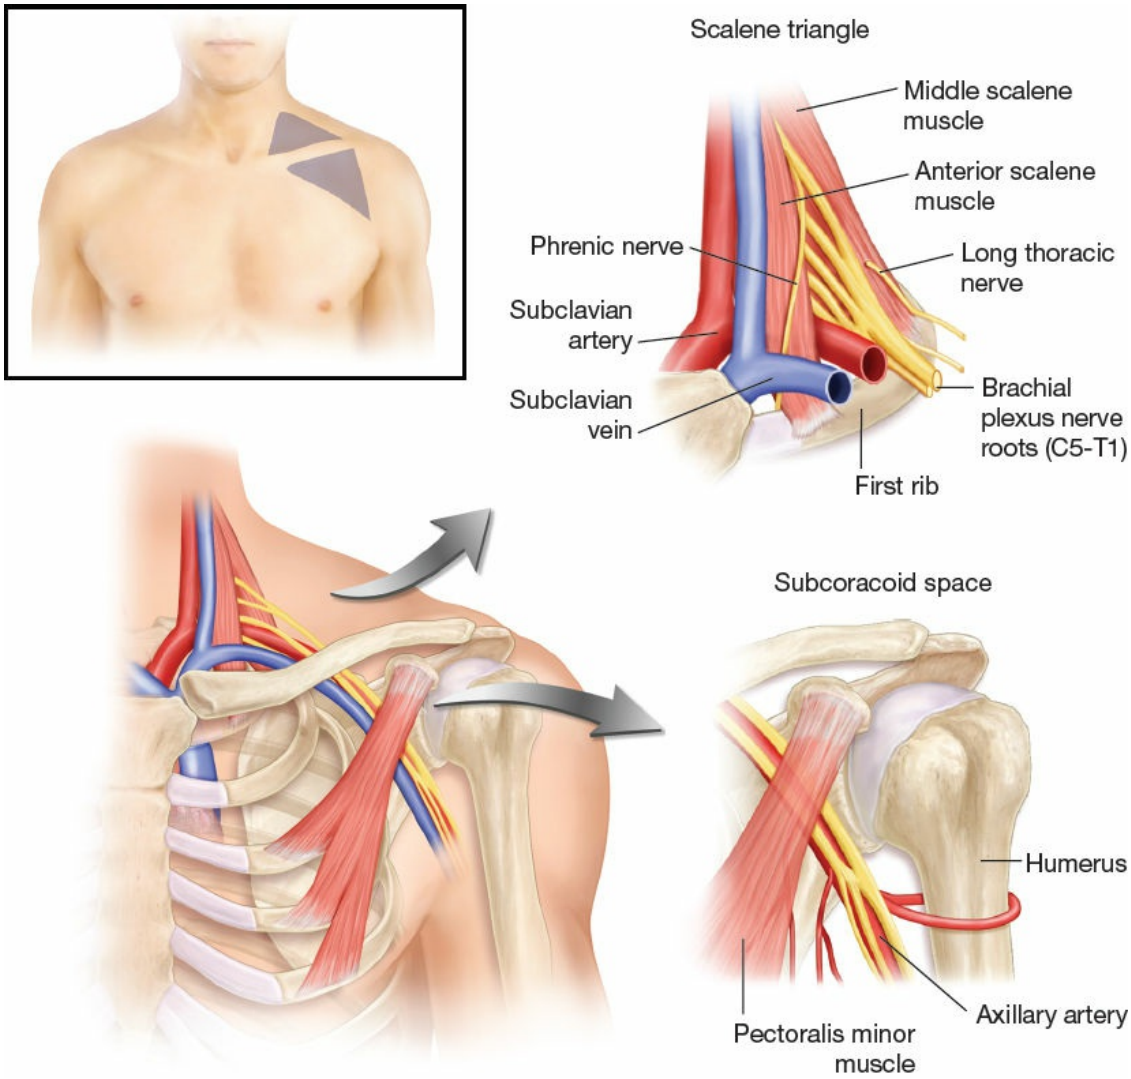

Figure 228.1. Overview of the anatomy of the thoracic outlet, focusing on the scalene triangle and the subcoracoid space. (From Thompson RW, Vemuri C. Neurogenic thoracic outlet

syndrome exposure and decompression: supraclavicular. In: Mulholland MW, Hawn MT, Hughes SJ, et al., eds. *Operative Techniques in Surgery*. Philadelphia, PA: Wolters Kluwer Health; 2015:1848–61.)

Nerves of the Thoracic Outlet

The motor and sensory nerves serving the upper extremity arise from cervical nerve roots C5 through T1. After leaving the spine and passing into the scalene triangle, these nerve roots bundle together and interconnect to form the initial trunks of the brachial plexus. The three trunks of the brachial plexus include the upper trunk (formed by fusion of the C5 and C6 nerve roots), the middle trunk (composed of the C7 nerve root), and the lower trunk (formed by fusion of the C8 and T1 nerve roots). The brachial plexus nerves pass through the scalene triangle and over the lateral first rib, before passing underneath the clavicle and pectoralis minor muscle to the axilla. Further merging and branching result in formation of the divisions, cords, and terminal nerves of the brachial plexus, as well as the peripheral nerves of the upper extremity.

The phrenic nerve forms from C3, C4, and C5 at the lateral border of the ASM, then descends on the muscle surface in a lateral to medial direction. It passes behind the subclavian vein into the superior mediastinum, then on to innervate the ipsilateral hemidiaphragm. The long thoracic nerve arises from C5, C6, and C7 within the body of the MSM, where its three components merge to form a single nerve. It passes through the MSM and over the posterolateral first rib, then descends to supply the serratus anterior muscle underneath the scapula. The cervical sympathetic chain passes vertically between the neck and the upper chest, lying along the posterior inner curve of the ribs. The sympathetic supply to the upper extremity arises from ganglia at T1 to T3, with several ganglia fused at the level of the first rib to form the large stellate ganglion that also supplies part of the face and eye.

Blood Vessels of the Thoracic Outlet

The subclavian artery arises from the innominate artery on the right and from the aorta on the left, in the upper chest and base of the neck. It passes up and over the first rib behind the ASM and immediately in front of the brachial plexus nerve roots, and is therefore within the scalene triangle. The vertebral artery and the internal thoracic artery arise from the

subclavian artery proximal to the scalene triangle, and several smaller branches arise behind the ASM, including the transverse cervical and inferior thyroid arteries (often from a common origin). Beyond the first rib and clavicle, the subclavian artery becomes the axillary artery where it passes underneath the pectoralis minor muscle. The distal axillary artery has a number of branches that serve the shoulder girdle, including the subscapular artery and the (anterior and posterior) circumflex humeral arteries. After passing in front of the shoulder, the axillary artery becomes the brachial artery.

Blood returning from the arm passes through a number of superficial and deep veins, which combine underneath the pectoralis minor muscle to form the axillary vein. The axillary vein passes underneath the clavicle and is joined by the cephalic vein to become the subclavian vein. The subclavian vein crosses over the first rib in front of the ASM (and is therefore not within the scalene triangle). It then passes through the space between the anterior first rib, clavicle, subclavius muscle, and costoclavicular ligament. After passing over the first rib, the subclavian vein joins the internal jugular vein as it descends from the neck, forming the innominate (or brachiocephalic) vein behind the sternoclavicular joint. The innominate vein passes further underneath the sternum to join with its counterpart from the other side, forming the superior vena cava.

Anatomic Variations and Acquired Changes in the Thoracic Outlet

Many natural variations in anatomy are found in the thoracic outlet. The most obvious is a congenital cervical rib, which occurs in approximately 0.5% of the population. Cervical ribs arise from the C7 transverse process and lie within the plane of the MSM. Osseous cervical ribs are readily detected by plain radiographs, but those composed of cartilage may not be easily identified. Complete cervical ribs attach directly to the first rib and act to displace the structures of the scalene triangle anteriorly. Partial cervical ribs can also occur, with a short segment of bony cervical rib and a ligamentous extension that attaches to the first rib; a wide C7 transverse process can also be associated with a ligamentous band in the same manner. Other rare bony anomalies include a partial (hypoplastic) first rib, an unusually high-lying first rib, or a fusion between the first and second ribs. Any of these anomalies may predispose to the development of neurovascular compression.

Soft tissue variations in the thoracic outlet are often too small to be detected by standard imaging (plain x-rays, computed tomography [CT] or magnetic resonance imaging [MRI] scanning), but are frequently seen at the time of surgery. For example, a scalene minimus muscle is a frequent variant in which muscle arising from the plane of the MSM passes between the nerve roots of the brachial plexus, then joins with the ASM to attach to the first rib. A number of different ligamentous or fibrofascial bands may also be present in the thoracic outlet, which frequently pass in front of or between the brachial plexus nerve roots. One of the best described is a fibrous band that runs from the back of the first rib to the front, crossing over (and compressing) the lower nerve roots. Langer's axillary arch is another anomalous fibrous band, which extends from the latissimus dorsi muscle to the coracoid process. When present, any of these soft tissue structural variations can contribute to nerve or blood vessel compression.

Acquired changes in the anatomy of the thoracic outlet often contribute, either directly or indirectly, to compression of the neurovascular structures. The most obvious examples are fractures of the first rib or clavicle. Fractures of the first rib are usually the result of considerable trauma associated with other severe injuries, but evidence of previous first rib fracture is occasionally observed during surgery for TOS, where callous at the fracture site may act to compress the adjacent neurovascular structures. Calcification, osteophytic degeneration, and occult nondisplaced fractures of the anterior first rib are also a frequent observation in patients with venous TOS. Fractures of the clavicle are relatively common and occur with a lesser degree of trauma than overt first rib fractures. Most clavicular fractures heal without consequence, but a large callous from a healed (or unhealed) fracture can protrude posteriorly to compress the underlying neurovascular structures. Anatomic changes can also occur within the soft tissues of the thoracic outlet, particularly when the scalene muscles are subjected to previous stretch injury, chronic strain, and repetitive overuse. In these situations, the scalene muscles undergo an inflammatory healing response that leads to fibrosis and other microscopic changes, making the muscles firm, prone to persistent spasm, and less resilient to positional changes. Localized healing responses can also lead to scarring and fibrosis directly around the brachial plexus nerve roots, which can subsequently contribute to nerve compression, irritation, and production of symptoms.

CLINICAL PRESENTATION

The clinical presentation of patients with TOS depends on the specific structures compressed, giving rise to three distinct conditions: (1) Neurogenic TOS, caused by compression of the brachial plexus nerves; (2) Venous TOS, caused by compression of the axillary and/or subclavian veins; and (3) Arterial TOS, caused by compression of the axillary and/or subclavian arteries. All three types of TOS are considered rare conditions, but clinical recognition and differentiation of these conditions are crucial in planning further steps in diagnosis and treatment.

Neurogenic TOS

Neurogenic TOS (85% to 95% of all patients with TOS) is characterized by compression of the brachial plexus nerve roots within the scalene triangle and/or subpectoralis space. This may be due to a combination of two factors: (a) predisposing variations in anatomy, such as anomalous scalene musculature, aberrant fibrofascial bands, or cervical ribs, and (b) neck or upper extremity injury that has resulted in scalene or pectoralis minor muscle spasm, fibrosis, and other pathologic changes. The symptoms of brachial plexus nerve root compression consist of pain, numbness, and tingling (paresthesias) in the neck, shoulder, arm, and hand. These symptoms can be somewhat variable throughout the day, and they may differ day-to-day, depending on levels of activity. The symptoms are also typically dynamic, with marked positional exacerbation during arm abduction, elevation, and other maneuvers. There are usually localizing tenderness and reproduction of symptoms on palpation over the scalene triangle and/or subpectoralis space. Patients with neurogenic TOS often have gradual development of symptoms, but can have acute exacerbations or a steady progression with increasing disability. The diagnosis of neurogenic TOS is difficult and often elusive, and may involve extensive testing, multiple specialist evaluations, and prolonged attempts at various forms of management.

Venous TOS

Venous TOS (10% to 15% of all patients with TOS) is characterized by subclavian vein compression between the clavicle, subclavius muscle, and first rib. Most patients present with abrupt spontaneous swelling of the entire arm, often with cyanotic discoloration, heaviness, and pain, which

form the characteristic features of axillary–subclavian vein "effort thrombosis." Effort thrombosis (also known as the "Paget–Schroetter" syndrome) is distinct from more common forms of deep venous thrombosis (DVT), in that it occurs in young, active, and otherwise healthy individuals, with no associated central venous catheters or underlying blood clotting disorder. The pathogenesis of effort thrombosis involves repetitive extrinsic compression of the subclavian vein during activities involving arm elevation or exertion, leading in time to chronic venous injury and progressive fibrous stenosis of the vein. This involves scar tissue formation and contraction around the outside of the vein, as well as fibrosis and wall thickening within the wall of the vein itself. The initial phase of venous TOS is usually asymptomatic due to simultaneous expansion of collateral veins passing around the narrowed subclavian vein, but stagnant blood within the narrowed subclavian vein eventually leads to thrombotic occlusion. Growth and extension of this clot into the axillary vein can then result in further obstruction of critical collateral veins, resulting in the acute clinical presentation. Pulmonary embolism from clot within the proximal subclavian vein may also occur, particularly with motion of the arm, but this is infrequent compared to DVT in the lower extremities.

Arterial TOS

Arterial TOS (2% to 5% of all patients with TOS) is caused by subclavian artery compression within the scalene triangle, leading to the development of subclavian artery occlusions or poststenotic subclavian artery aneurysms. These lesions almost always occur in association with a congenital cervical rib or other bony anomaly. Ulcerative subclavian artery lesions and aneurysms are often accompanied by mural thrombus formation, and frequently complicated by distal thromboembolism with hand and/or digital ischemia. Patients with acute thromboembolism present with a sudden onset of hand pain and weakness, numbness and tingling, and cold and pale fingers. Those with more longstanding ischemia may present with chronic arm fatigue or claudication, nonhealing wounds, or ulcerations in the fingers. Subclavian artery occlusions or aneurysms may also be asymptomatic. Occlusions may be identified by a significant blood pressure differential between arms, and aneurysms occasionally present as a nontender pulsatile mass in the anterolateral neck. A second form of arterial TOS is observed almost solely in overhead

throwing athletes, associated with occlusive or aneurysmal lesions of the distal axillary artery. These lesions are caused by repetitive trauma from hyperextension during the throwing motion, in which the axillary artery can be compressed by forward motion (subluxation) of the head of the humerus. The complications of these lesions are similar to those of arterial TOS caused by subclavian artery lesions at the level of the first rib.

DIAGNOSIS

Neurogenic TOS

The diagnosis of neurogenic TOS is based on clinical evaluation according to the criteria listed in Table 228.1, supplemented by relevant testing procedures to exclude alternative conditions. The extent of brachial plexus compression attributable to either the scalene triangle or the subcoracoid space is characterized by physical examination. A chest x-ray can help determine the presence or absence of a cervical rib, but other imaging studies of the brachial plexus are usually not helpful. Although conventional electromyography and nerve conduction studies (EMG/NCS) are often performed to exclude peripheral nerve compression disorders or cervical radiculopathy, these tests are usually negative or nonspecific in neurogenic TOS. Patients with a suspected diagnosis of neurogenic TOS may undergo an image-guided anterior scalene and/or pectoralis minor muscle block with a short-acting local anesthetic, both to support the clinical diagnosis and to help predict the reversibility of symptoms with treatment.

TABLE 228.1 Clinical Diagnostic Criteria for Neurogenic TOS

Upper extremity symptoms that extend beyond the distribution of a single cervical nerve root or peripheral nerve have been present for at least 12 weeks, have not been satisfactorily explained by another condition, and meet at least one criterion in at least four of the following five categories:

Principal Symptoms
1A: Pain in the neck, upper back, shoulder, arm and/or hand
1B: Numbness, paresthesias, and/or weakness in the arm, hand, or digits

Symptom Characteristics
2A: Pain/paresthesias/weakness exacerbated by elevated arm positions
2B: Pain/paresthesias/weakness exacerbated by prolonged or repetitive arm/hand use, including prolonged work on a keyboard or other repetitive strain tasks
2C: Pain/paresthesias radiate down the arm from the supraclavicular or infraclavicular spaces

Clinical History
3A: Symptoms began after occupational, recreational, or accidental injury of the head, neck, or upper extremity, including repetitive upper extremity strain or overuse
3B: Previous ipsilateral clavicle or first rib fracture, or known cervical rib
3C: Previous cervical spine or ipsilateral peripheral nerve surgery without sustained improvement in symptoms
3D: Previous conservative or surgical treatment for ipsilateral TOS

Physical Examination
4A: Local tenderness on palpation over the scalene triangle and/or subcoracoid space
4B: Arm/hand/digit paresthesias on palpation over the scalene triangle and/or subcoracoid space
4C: Objectively weak handgrip, intrinsic muscles, or digit 5, or thenar/hypothenar atrophy

Provocative Maneuvers
5A: Positive upper limb tension test (ULTT)
5B: Positive 3-min elevated arm stress test (EAST)

Exclusion of other conditions typically includes nonspecific or negative findings on physical examination (Spurling's test, axial compression test, Tinel's sign over the carpal tunnel or cubital tunnel, and Phalen's test), imaging studies (MRI of cervical spine and shoulder), and conventional electrophysiologic tests (upper extremity electromyography and nerve conduction studies). Adapted from preliminary consensus diagnostic criteria developed by the Consortium for Research and Education on Thoracic Outlet Syndrome (CORE-TOS).

Venous TOS

The diagnosis of venous TOS is based on the stereotypical clinical presentation of axillary–subclavian vein effort thrombosis. Upper extremity venous Duplex studies may confirm the presence of upper extremity DVT, but Duplex imaging of the subclavian vein is inaccurate and therefore cannot be used to exclude the diagnosis. More definitive information on the location and extent of axillary–subclavian vein thrombosis is obtained by contrast-enhanced imaging studies, such as

computed tomographic angiography, magnetic resonance angiography, or direct catheter-based venography. When there is incomplete subclavian vein obstruction, these studies can also be performed with the arms at rest and in elevation. The advantage of using catheter-based upper extremity venography as the initial diagnostic step is that this can be followed immediately by thrombolytic therapy, with completion venograms typically revealing a focal area of residual subclavian vein stenosis or occlusion at the level of the first rib. Although blood coagulation testing is often performed in patients with upper extremity DVT, these tests are usually negative and add little to the initial diagnosis or management.

Arterial TOS

The diagnosis of arterial TOS is suspected by clinical findings and potentially confirmed by noninvasive vascular laboratory studies, such as Duplex imaging and segmental arterial waveform analysis. Plain radiographs are also used to determine if a cervical rib or first rib anomaly is present. Positional angiography (with either contrast-enhanced MRI, CT, or catheter-based arteriography) is often performed to determine the presence or absence of a subclavian artery aneurysm. Similar imaging studies are performed in patients who have presented with upper extremity arterial thromboembolism to detect a proximal source of embolism in the subclavian or axillary artery.

INITIAL TREATMENT

Neurogenic TOS

Neurogenic TOS is initially treated with physical therapy to relieve scalene/pectoralis muscle spasm, improve postural disturbances, enhance functional limb mobility, strengthen associated shoulder girdle musculature, and diminish repetitive strain exposure in the workplace. It is important that the patient be referred to a therapist with experience, expertise, and interest in TOS, since the management of this condition is different than that of other disorders affecting the neck, shoulder, spine, and upper extremity. Incorrect approaches to physical therapy can result in worsening of symptoms and premature failure of conservative management. After an initial 4- to 6-week course of physical therapy, significant improvement is observed in most patients with mild symptoms of neurogenic TOS or those in whom therapy has been started early after

the onset of symptoms. Therapy is then continued with the expectation that continued benefits will preclude the need to consider surgical treatment. Because neurogenic TOS is considered a chronic condition subject to occasional “flare-ups” of more acute symptoms (often related to overuse activities or new injury), it remains important for the patient to continue regular physical therapy exercises and occasional therapist visits as needed during long-term follow-up.

Venous TOS

Current approaches to venous TOS emphasize early diagnosis by contrast venography and prompt use of catheter-based thrombolytic therapy to reduce the amount of thrombus within the axillary and subclavian veins. This is facilitated by use of pharmacomechanical approaches, where thrombolysis can usually be accomplished in a single setting rather than by infusion over several days. In some cases, balloon angioplasty may be used following thrombolysis, in attempting to reduce the degree of stenosis in the subclavian vein. However, because the residual subclavian vein obstruction is usually caused by external compression between the clavicle and first rib as well as scar tissue within the wall of the vein, balloon angioplasty is often unsuccessful or results in only short-lived improvement. It has also become clear over the past decade that placement of stents within the subclavian vein frequently leads to poor outcomes and should be avoided. Conservative treatment of subclavian vein effort thrombosis consists of chronic anticoagulation, long-term restrictions in arm activity, and intermittent arm elevation and use of compression sleeves to reduce edema, with the hope that increased collateral development will eventually compensate for axillary–subclavian vein occlusion. Even with satisfactory anticoagulation, this approach is associated with recurrent thrombosis or chronic venous congestion in 50% to 70% of patients, and aggravation of symptoms during active use of the arm may require considerable limitations for young active patients. The proper duration of anticoagulation for subclavian vein effort thrombosis is also not known, and because this condition is caused by repetitive mechanical compression of the vein rather than a disorder of blood clotting, lifelong anticoagulation may be required in the absence of surgical treatment. For these reasons, most experts recommend early surgical treatment for almost all patients with venous TOS, to avoid long-term disability from venous obstruction and the need for long-term

anticoagulation, and to permit a prompt return to normal arm activities.

Arterial TOS

In arterial TOS, the necessity of immediate anticoagulation and urgent surgical treatment is undisputed in patients with acute upper extremity ischemia due to thromboembolism. Initial treatment may involve brachial artery exposure and thromboembolectomy to improve the distal circulation in the hand, with or without intra-arterial infusion of thrombolytic and vasodilator agents. In this setting, treatment of the distal circulation should be immediately followed by thorough arteriographic assessment of the axillary and subclavian arteries as proximal sources of thromboembolism. In patients with stable distal circulation found to have arterial TOS during more elective evaluation, direct surgical treatment is recommended. In all patients, therapeutic anticoagulation and anti-platelet therapy are continued from the time of diagnosis until definitive surgical treatment.

INDICATIONS FOR SURGERY AND PREOPERATIVE PLANNING

Neurogenic TOS

Surgical treatment is recommended for patients with neurogenic TOS when the diagnosis is sound, the patient has substantial disability (symptoms interfere with daily activities and/or work), and there has been an insufficient response to a course of physical therapy directed by a therapist with specific expertise with this condition. Surgical treatment is also recommended in selected patients with persistent or recurrent symptoms of neurogenic TOS following a previous operation, when there has been no response to appropriate conservative measures. In each of these situations, we find that supraclavicular decompression—based on complete scalenectomy, first rib resection, and brachial plexus neurolysis—provides the most definitive approach for surgical treatment. Supraclavicular decompression also appears to have a lower rate of recurrence than other approaches used for neurogenic TOS. For patients with symptoms of neurogenic TOS referable to the subcoracoid space, surgical decompression includes pectoralis minor tenotomy as an addition to supraclavicular thoracic outlet decompression, or as an isolated procedure when this site is the dominant location of nerve compression symptoms. In the presence of distinct localizing findings, pectoralis minor

tenotomy may also be performed in patients with persistent or recurrent neurogenic TOS who have previously undergone thoracic outlet decompression by other approaches.

Venous TOS

For patients with venous TOS who have presented with effort thrombosis, anticoagulation is maintained after thrombolytic therapy and surgical treatment is recommended within several weeks, even for those with lengthy venous occlusions. Surgical treatment is also recommended in patients with previous axillary–subclavian vein thrombosis who remain symptomatic despite anticoagulation and restricted activity, as well as for asymptomatic individuals in whom long-term anticoagulation and restrictions on upper extremity activity are undesirable. With the addition of an infraclavicular incision to ensure complete medial first rib resection and to facilitate direct subclavian vein reconstruction, the supraclavicular (paraclavicular) approach is ideal for all of these circumstances.

Arterial TOS

Surgical treatment based on supraclavicular decompression is recommended for all patients with arterial TOS and subclavian artery occlusive lesions or aneurysms. This should include direct arterial reconstruction for subclavian aneurysms that have already produced distal emboli, those associated with imaging evidence of intimal ulceration or mural thrombus, or those larger than twice the diameter of the normal proximal subclavian artery.

SURGICAL TECHNIQUE

Under general anesthesia, the patient is positioned supine with the head of the bed elevated 30 degrees. The neck is turned to the opposite side and an inflatable pillow is placed between the shoulders to help extend the neck. The neck, upper chest, and affected upper extremity are prepped into the field, with the arm wrapped in stockinette and held comfortably across the abdomen (Fig. 228.2). A transverse neck incision is made parallel to and just above the clavicle, beginning at the lateral border of the sternocleidomastoid muscle and extending to the anterior border of the trapezius muscle. The incision is carried through the platysma layer, and the edge of the sternocleidomastoid muscle is not divided but simply

retracted medially. The scalene fat pad is mobilized beginning at the lateral edge of the internal jugular vein, and a short segment of the omohyoid muscle is resected. The scalene fat pad is completely mobilized from its inferior and superior attachments, with ligation of small blood vessels and lymphatic tissues. On the left side, the thoracic duct is usually identified entering the venous system near the inferomedial aspect of the scalene fat pad, where it may be ligated and divided.

The tissue plane underneath the scalene fat pad is gently dissected with a fingertip, exposing the underlying ASM and phrenic nerve. The phrenic nerve is identified by its location and course, and by gentle manipulation resulting in contraction of the diaphragm (a diaphragmatic startle, or "dartle" response). Lateral mobilization of the scalene fat pad further reveals the brachial plexus along the lateral edge of the ASM, followed by the MSM attaching to the upper surface of the first rib behind the brachial plexus. The long thoracic nerve is identified where it emerges from the MSM to pass across the lateral first rib. Direct visualization of these structures within the operative field represents the first "critical view" to be obtained during supraclavicular decompression (Table 228.2). The scalene fat pad is subsequently held in position with several retraction sutures, and the exposure is maintained with a Henley self-retaining retractor, using the third arm to hold the edge of the sternocleidomastoid muscle (Fig. 228.3).

Figure 228.2. Patient position and planned incision(s) for supraclavicular thoracic outlet decompression (left side). The supraclavicular skin incision is made just above and parallel to

the clavicle, extending from the lateral border of the sternocleidomastoid muscle to the anterior border of the trapezius muscle. For pectoralis minor tenotomy, a vertical deltopectoral groove incision is used. (From Thompson RW, Vemuri C. Neurogenic thoracic outlet syndrome exposure and decompression: supraclavicular. In: Mulholland MW, Hawn MT, Hughes SJ, et al., eds. *Operative Techniques in Surgery*. Philadelphia, PA: Wolters Kluwer Health; 2015:1848–61.)

The brachial plexus and subclavian artery are separated from the lower lateral edge of the ASM, gently passing a fingertip behind the muscle just above the first rib. With the neurovascular structures displaced posteriorly, blunt finger dissection is continued behind the ASM toward its medial edge, where the proximal subclavian artery and the phrenic nerve are well visualized and protected. Once the insertion of the ASM onto the first rib has been isolated under direct vision, it is sharply divided using a curved scissors (Fig. 228.4).

The end of the divided ASM is elevated, and any additional slips of muscle, fascia, or tendon are divided, including direct attachments of the muscle to the subclavian artery and the thickened extrapleural fascia. The ASM is passed underneath the phrenic nerve to its medial side and lifted further, with division of its posterior attachments and protection of the upper brachial plexus nerve roots, until it is held on a pedicle from its origin on the transverse process of the cervical spine. The ASM is then sharply divided from its origin, and the entire muscle is removed and weighed (Fig. 228.4).

During resection of the ASM, any scalene minimus muscle anomalies are identified and resected, as represented by fibers that pass between the brachial plexus nerve roots and insert on the extrapleural fascia or first rib (along with or independent of the ASM). Anomalous fibrofascial bands may also be observed after ASM resection, typically passing in front of the lower brachial plexus nerve roots. These structures are also resected as they are encountered to ensure thorough decompression and full mobility of the nerve roots.

TABLE 228.2 Six “Critical Views” During Supraclavicular Thoracic Outlet Decompression

1. View of the operative field after lateral reflection of the scalene fat pad, with visualization of the internal jugular vein, anterior scalene muscle, phrenic nerve, brachial plexus, subclavian artery, middle scalene muscle, and long thoracic nerve.
2. View of the lower part of the anterior scalene muscle where it attaches to the first rib, with space sufficient to allow a finger to pass behind the anterior scalene muscle and in front of the brachial plexus and subclavian artery, prior to division of the anterior scalene muscle from the top of the first rib.
3. View of the upper part of the anterior scalene muscle at the level of the transverse process of the cervical spine, in relation to the C5 and C6 nerve roots, prior to division of the origin of the anterior scalene muscle.
4. View of the insertion of the middle scalene muscle on the first rib, with each of the five nerve roots of the brachial plexus and the subclavian artery retracted medially and the long thoracic nerve retracted posteriorly, prior to division of the middle scalene muscle from the top of the lateral first rib.
5. View of the posterior neck of the first rib, with the T1 nerve root passing from underneath the rib to join the C8 nerve root to form the inferior trunk of the brachial plexus, prior to division of the posterior first rib.
6. View of the anterior portion of the first rib underneath the clavicle, with placement of the rib shears medial to the scalene tubercle, prior to division of the anterior first rib.

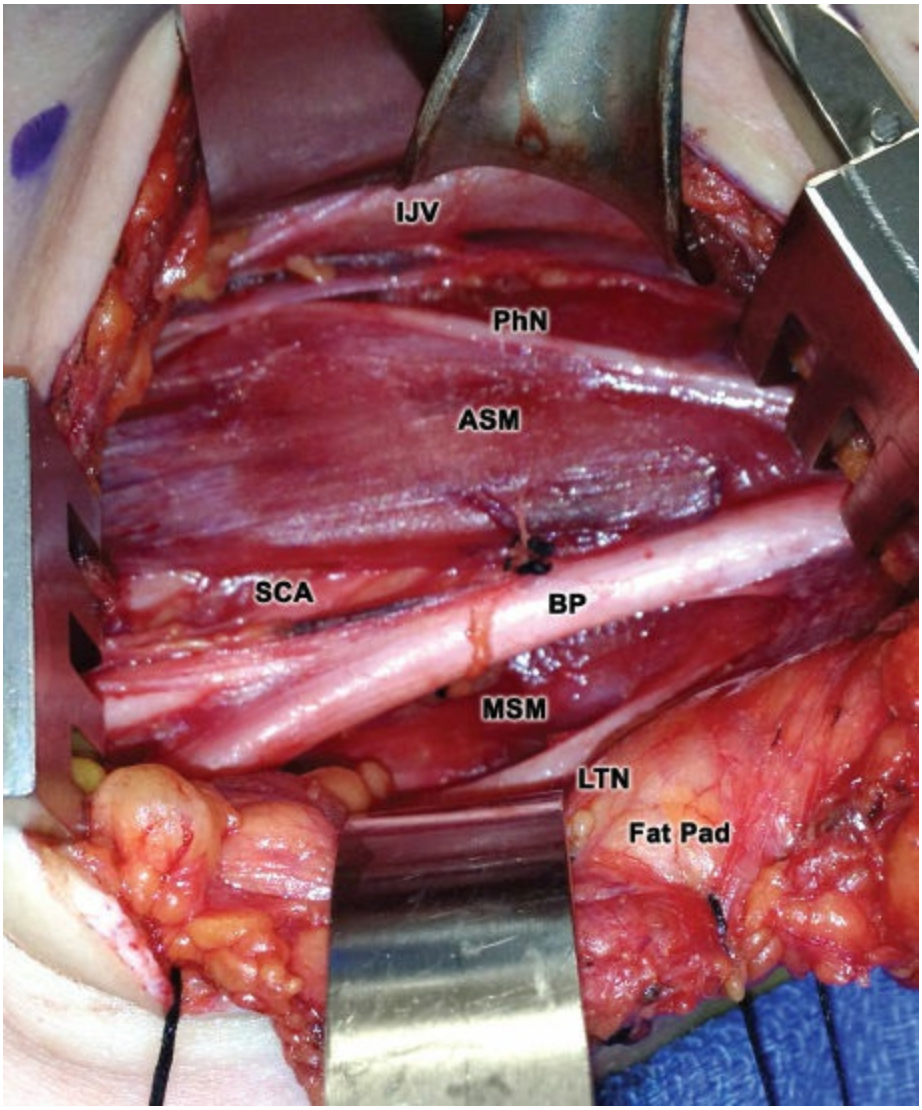

Figure 228.3. Supraclavicular exposure (left side). Following mobilization and lateral reflection of the scalene fat pad, direct visualization is obtained of the internal jugular vein (IJV), anterior scalene muscle (ASM), phrenic nerve (PhN), brachial plexus (BP), subclavian artery (SCA), middle scalene muscle (MSM), and long thoracic nerve (LTN). (From Thompson RW, Vemuri C. Neurogenic thoracic outlet syndrome exposure and decompression: supraclavicular. In: Mulholland MW, Hawn MT, Hughes SJ, et al., eds. *Operative Techniques in Surgery*. Philadelphia, PA: Wolters Kluwer Health; 2015:1848–61.)

The brachial plexus nerve roots are separated from the front edge of the MSM until a small malleable retractor can be placed behind the brachial plexus, and each nerve root from C5 to T1 is sequentially identified. With medial retraction of the brachial plexus and posterolateral retraction of the long thoracic nerve, the attachment of the MSM to the first rib is then

exposed and divided from the rib using the electrocautery (Fig. 228.5). The MSM is further detached along the top of the first rib using a periosteal elevator, extending to a point parallel with the T1 nerve root. The plane separating the MSM and posterior scalene muscles is defined by the long thoracic nerve, and muscle tissue anterior to the nerve is divided to complete the resection of the MSM.

Following complete anterior and middle scalenectomy, intercostal muscle attachments to the lateral first rib are divided using the electrocautery under direct vision. Blunt finger dissection between the brachial plexus and the inner side of the first rib then allows the extrapleural tissues to be swept away from the undersurface of the bone. The posterior neck of the first rib is exposed where the T1 nerve root emerges from underneath the rib to join the C8 nerve root above the rib to form the lower trunk of the brachial plexus. Any remaining intercostal muscle is detached from underneath the rib and the first intercostal nerve is displaced. A modified Giertz-Stille rib shears is inserted around the neck of the first rib with protection of the C8 and T1 nerve roots under direct vision, and after verifying mobility of the nerve roots the bone is divided (Fig. 228.6). A Kerrison bone rongeur is used to remove additional bone as needed, to ensure that the posterior stump of the first rib will not impinge upon the lower nerve roots, and the end of the bone is sealed with bone wax.

Remaining intercostal muscle and fascial attachments to the anterior first rib are divided to the level of the scalene tubercle. The clavicle is elevated with a small Richardson retractor, and the proximal portion of the rib is displaced inferiorly with fingertip pressure, to open the anterior costoclavicular space. The rib shears are placed around the anterior first rib immediately medial to the scalene tubercle under direct vision, and the proximal first rib is then divided (Fig. 228.7). The specimen is extracted from the operative field. The remaining anterior end of the first rib is remodeled to a smooth surface with a Kerrison rongeur.

Cervical ribs arise within the plane of the MSM behind the brachial plexus and subclavian artery, and are therefore encountered, when present, during the course of scalene muscle resection. The anterior end of a cervical rib may be unattached, with a ligamentous extension to the first rib, or it may be attached to the first rib, often forming a true joint. Cervical ribs are carefully exposed along their course while carefully protecting the brachial plexus nerves, and in most cases the posterior

portion is divided before and in the same manner as used for first rib resection. The anterior portion of the cervical rib is then divided, and the bone is removed. When the cervical rib forms a true joint with the first rib, the anterior portion may be left attached while the first rib resection is completed, with the two removed together as a single specimen (Fig. 228.8).

Following scalenectomy and removal of the first rib, attention is returned to the brachial plexus and each of the contributing nerve roots is meticulously dissected free of any perineural fibrous scar tissue. This aspect of the operation ("external neurolysis") is not complete until each nerve root from C5 to T1 is completely dissected throughout its course in the operative field to ensure full mobility (Fig. 228.9).

Reoperations for Neurogenic TOS

Reoperations for neurogenic TOS are optimally performed using the supraclavicular approach, because this provides the most thorough exposure of the anatomy with the greatest margin of safety. Following lateral reflection of the scalene fat pad, the brachial plexus nerve roots are carefully exposed and mobilized. Any structures that were retained at the initial operation are then resected, including the scalene muscles, anomalous fibrofascial bands, and/or the first rib. Fibrous scar tissue is removed by performing a complete brachial plexus neurolysis, with each nerve root fully mobilized. Great care must be taken during this dissection to avoid nerve and blood vessel injury, given the dense fibrous scar tissue usually present within operative field.

Pectoralis Minor Tenotomy

To perform pectoralis minor tenotomy, a short vertical infraclavicular incision is made in the deltopectoral groove, beginning just below the coracoid process. The deltoid and pectoralis major muscles are separated with the plane of dissection kept medial to the cephalic vein. The lateral edge of the pectoralis major muscle is retracted medially and lifted, and the underlying fascia is exposed. The pectoralis minor muscle is identified and encircled near its insertion on the coracoid process, taking care to protect the underlying neurovascular bundle and to avoid the tendon of the short head of the biceps muscle. The pectoralis minor tendon is then divided with electrocautery under direct vision, within 2 cm of the coracoid process, and the medial edge of the divided muscle is oversewn

with sutures to ensure hemostasis. The remaining clavipectoral fascia is opened to the level of the clavicle, but no further dissection of the brachial plexus or axillary vessels is performed once the pectoralis minor muscle has been divided.

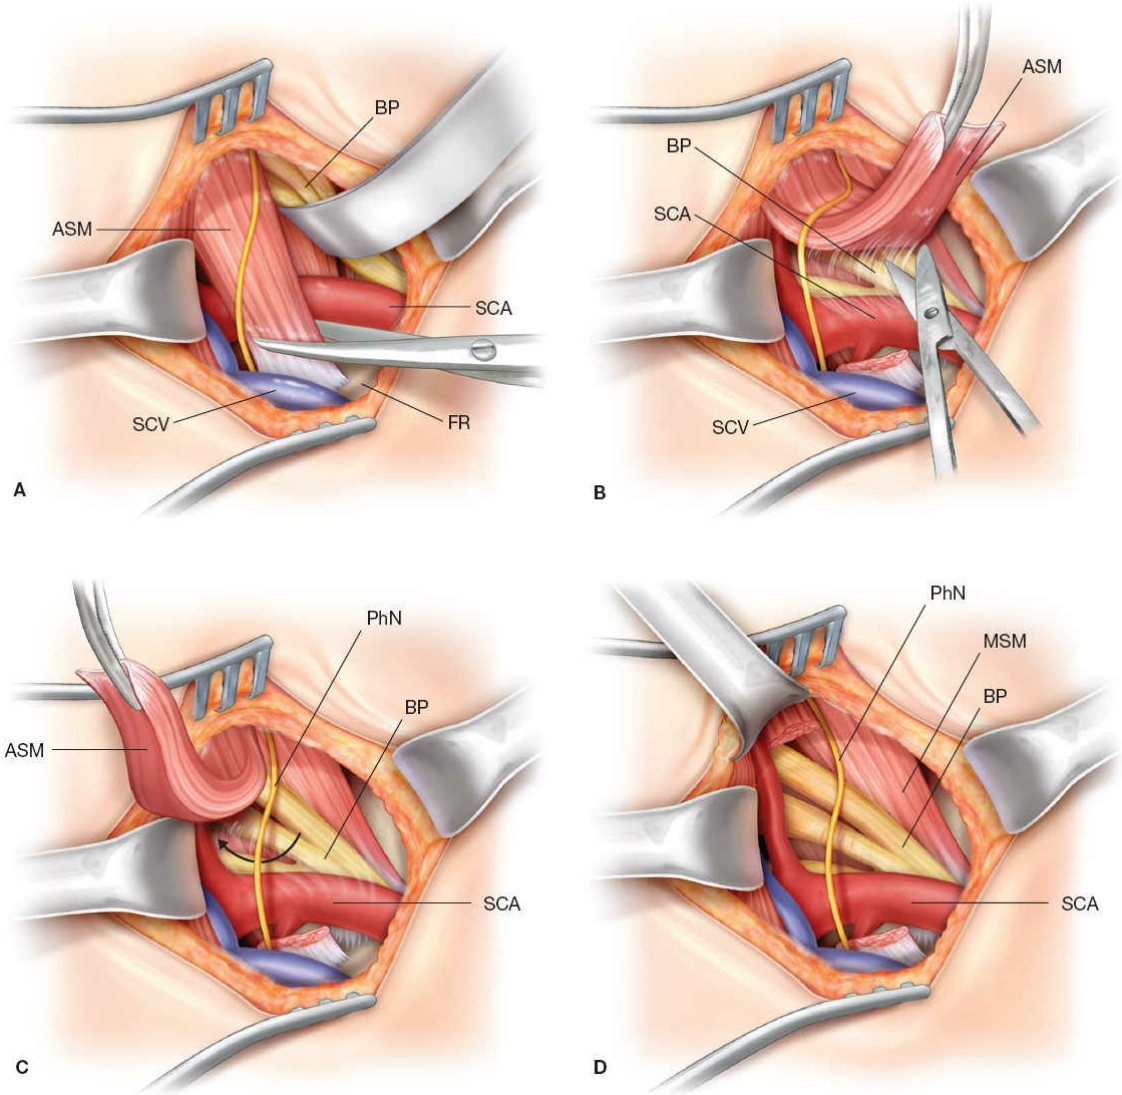

Figure 228.4. Anterior scalene muscle (left side). **A.** The anterior scalene muscle (ASM) insertion is isolated by displacing the underlying subclavian artery (SCA) and brachial plexus (BP), using blunt fingertip dissection behind the muscle, and the muscle is sharply divided from the top of the first rib (FR) behind the subclavian vein (SCV). **B.** The end of the divided anterior scalene muscle is lifted and sharply dissected free of structures lying behind the muscle, including the subclavian artery. **C.** As it is mobilized, the anterior scalene muscle is passed underneath and to the medial side of the phrenic nerve (PhN). **D.** The dissection is carried up to the level of the C6 transverse process where the anterior scalene muscle can be safely divided from its origin and removed. (From Thompson RW, Vemuri C. Neurogenic thoracic outlet syndrome exposure and decompression: supraclavicular. In: Mulholland MW, Hawn MT, Hughes SJ, et al., eds. *Operative Techniques in Surgery*. Philadelphia, PA: Wolters Kluwer Health; 2015:1848–61.)

Upon completion of thoracic outlet decompression, the apex of the pleural membrane is opened and a closed-suction drain is placed into the supraclavicular field, where it is positioned behind the brachial plexus with its tip lying in the upper posterior pleural space. Two multi-hole catheters are placed within the wound, adjacent to the brachial plexus and within the bed of the resected first rib, for postoperative infusion of local anesthetic. A bioresorbable (polylactide) film is wrapped around the brachial plexus to limit development of postoperative perineural fibrosis, and the scalene fat pad is reattached to lie over the brachial plexus. The edges of the platysma muscle are reapproximated, and the procedure is completed with a subcuticular skin closure.

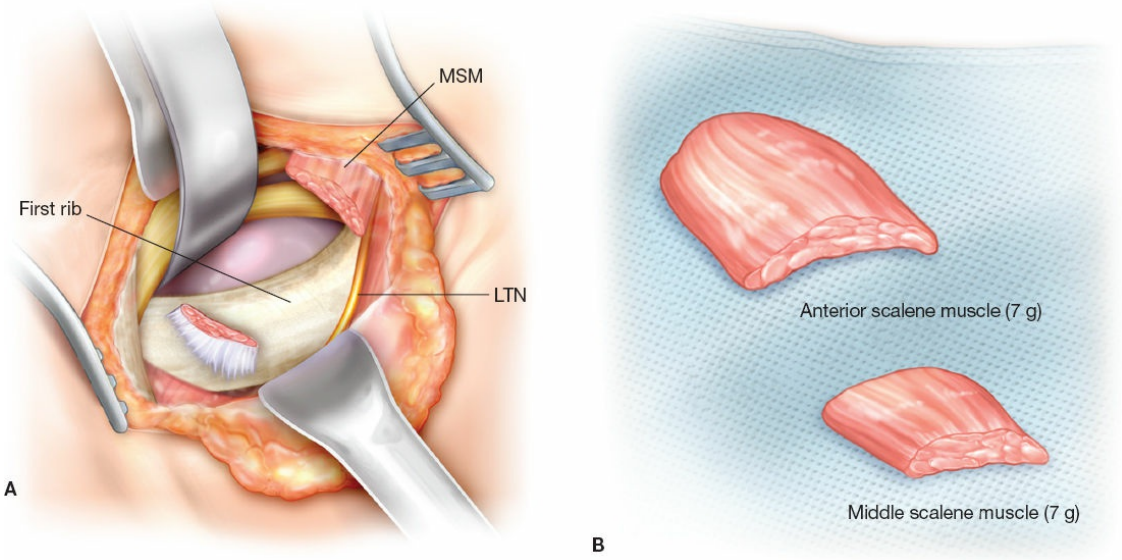

Figure 228.5. Middle scalene muscle (left side). **A.** After detaching the middle scalene muscle (MSM) from the top of the posterolateral first rib using the electrocautery, the muscle tissue lying anterior to the long thoracic nerve (LTN) is excised. **B.** Typical operative specimens of the anterior and middle scalene muscles. (From Thompson RW, Vemuri C. Neurogenic thoracic outlet syndrome exposure and decompression: supraclavicular. In: Mulholland MW, Hawn MT, Hughes SJ, et al., eds. *Operative Techniques in Surgery*. Philadelphia, PA: Wolters Kluwer Health; 2015:1848–61.)

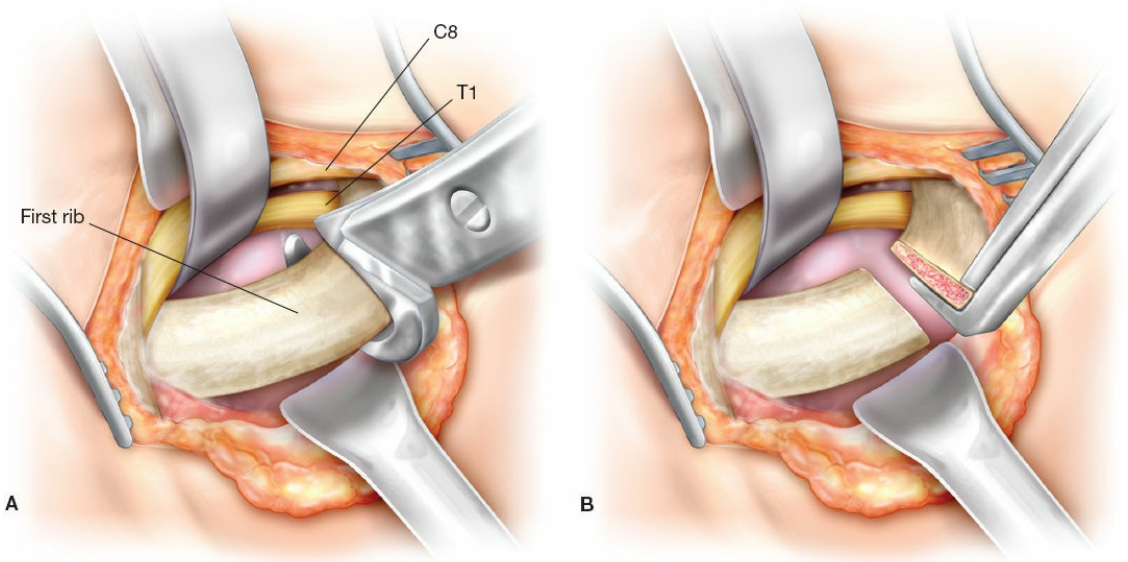

Figure 228.6. First rib resection, posterior (left side). **A.** The posterior portion of the first rib is exposed following removal of the middle scalene muscle, with visualization of the C8 and T1 brachial plexus nerve roots immediately above and below the posterior first rib, respectively. A modified Giertz-Stille rib shears is placed around the posterior portion of the first rib in preparation for division of the bone. **B.** Following application of the rib shears, the remaining posterior first rib is further remodeled with a Kerrison rongeur to obtain a smooth edge immediately medial to the T1 nerve root. (From Thompson RW, Vemuri C. Neurogenic thoracic outlet syndrome exposure and decompression: supraclavicular. In: Mulholland MW, Hawn MT, Hughes SJ, et al., eds. *Operative Techniques in Surgery*. Philadelphia, PA: Wolters Kluwer Health; 2015:1848–61.)

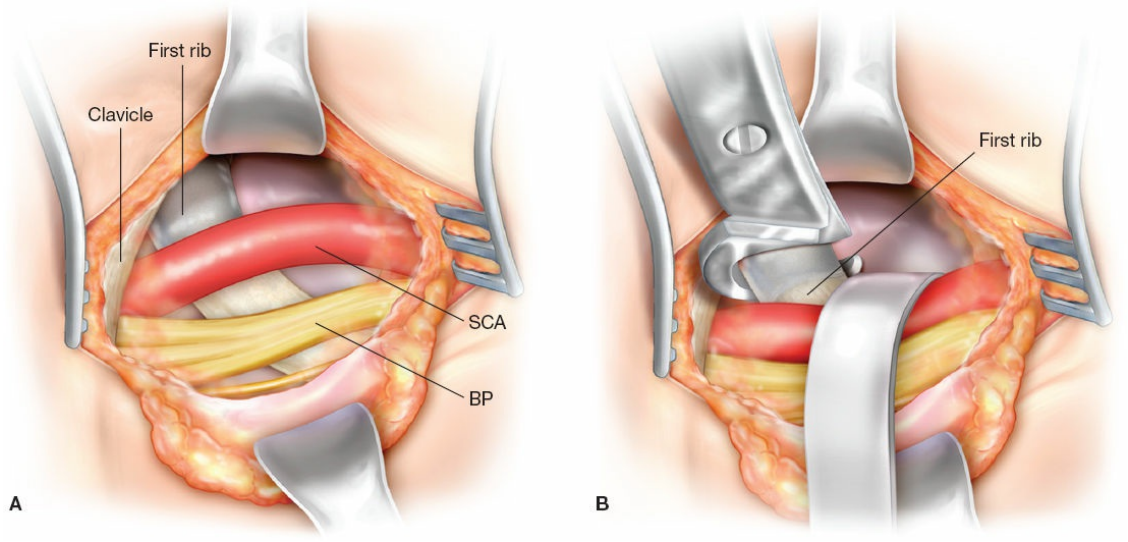

Figure 228.7. First rib resection, anterior (left side). **A.** The

anterior portion of the first rib is exposed underneath the clavicle and subclavian vein, anterior to the subclavian artery (SCA) and brachial plexus (BP), where it will be divided immediately medial to the scalene tubercle. **B.** A Giertz-Stille rib shears is placed around the anterior portion of the first rib for division of the bone. The remaining anterior first rib will be remodeled with a rongeur as needed to obtain a smooth edge. (From Thompson RW, Vemuri C. Neurogenic thoracic outlet syndrome exposure and decompression: supraclavicular. In: Mulholland MW, Hawn MT, Hughes SJ, et al., eds. *Operative Techniques in Surgery*. Philadelphia, PA: Wolters Kluwer Health; 2015:1848–61.)

Management of Venous TOS

Operative management for venous TOS begins with supraclavicular decompression as described above, with the exceptions that the anterior first rib is not yet divided and brachial plexus neurolysis is not performed. To accomplish complete resection of the anteromedial portion of the first rib as needed for venous decompression, a second transverse skin incision is made several centimeters below the medial clavicle. The upper and middle portions of the pectoralis major muscle are spread and the cartilaginous portion of the first rib is identified. This may be facilitated by applying downward fingertip pressure to the divided posterior segment of the first rib from the supraclavicular incision, thereby displacing the attachments between the medial first rib and clavicle. The superior edge of the first rib is then dissected from soft tissue attachments through the infraclavicular incision, and the subclavius muscle tendon, the costoclavicular ligament, and the muscles of the first intercostal space are all divided under direct vision. The anterior first rib is divided adjacent to the sternum with a duckbill rongeur, and the entire first rib is then withdrawn from the operative field as a single specimen.

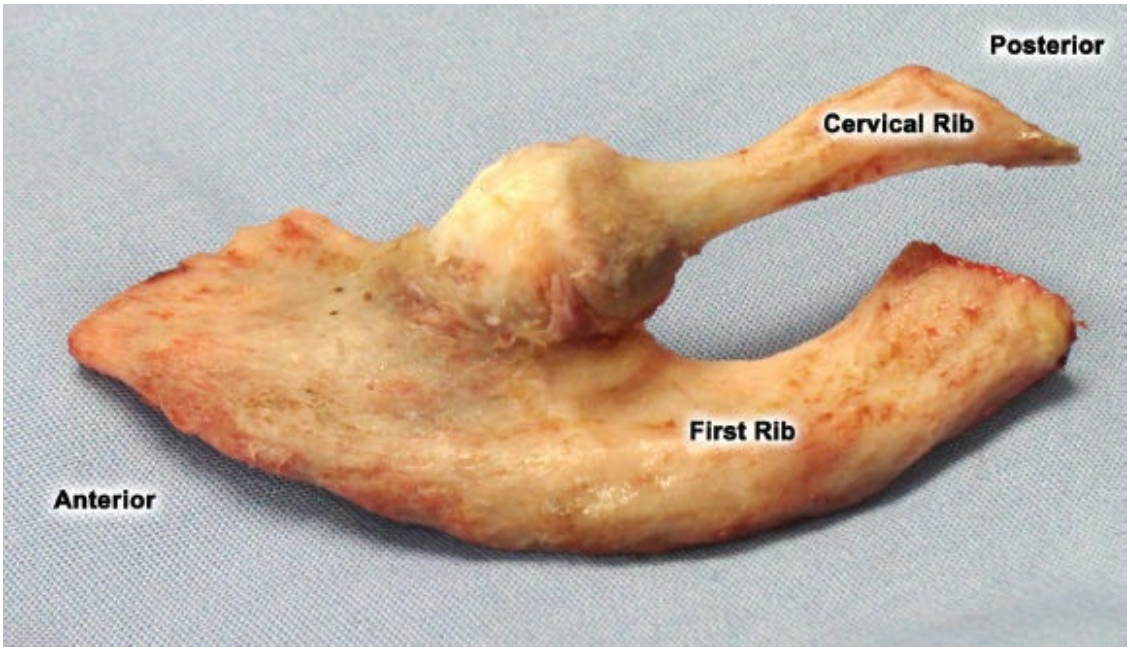

Figure 228.8. Operative specimen following combined resection of the cervical rib and first rib (left side). (From Thompson RW, Vemuri C. Neurogenic thoracic outlet syndrome exposure and decompression: supraclavicular. In: Mulholland MW, Hawn MT, Hughes SJ, et al., eds. *Operative Techniques in Surgery*. Philadelphia, PA: Wolters Kluwer Health; 2015:1848–61.)

The axillary vein is first identified underneath the clavicle through the lateral portion of the infraclavicular incision, where it is carefully separated from the subclavius muscle. Collateral vein branches that enter the subclavian vein are ligated and divided, and the subclavius muscle is completely resected. Further exposure of the subclavian vein is accomplished through the supraclavicular incision, moving medially toward the junction of the subclavian and internal jugular veins to form the innominate vein. The internal jugular vein is circumferentially exposed for several centimeters above its junction with the subclavian vein, and the innominate vein is exposed for several centimeters into the upper mediastinum. There are usually one or two significant venous collaterals to the subclavian vein underneath the medial clavicle, which are ligated and divided to permit the subclavian vein to fall away from the clavicle. The course of the phrenic nerve is noted, and it is protected where it passes underneath the subclavian vein.

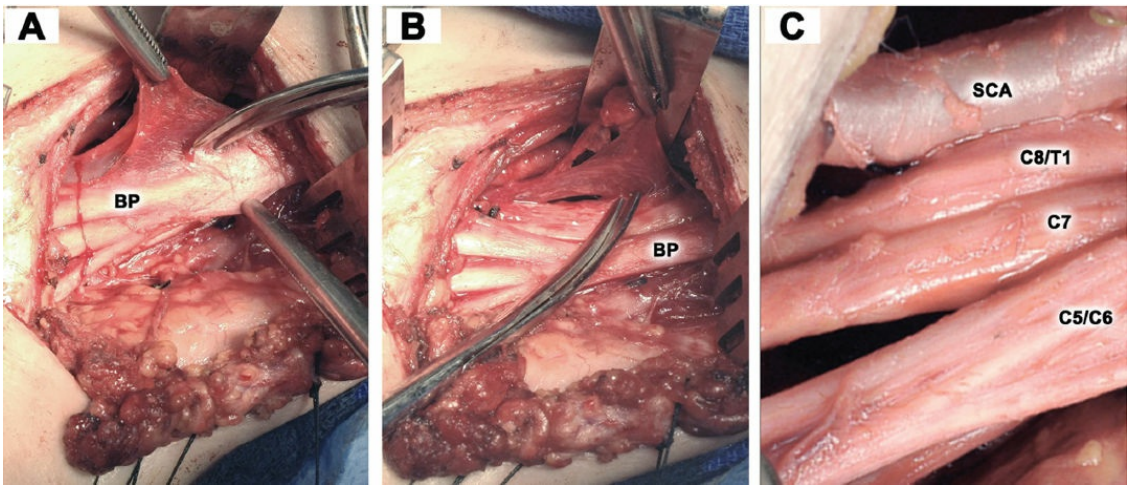

Figure 228.9. Brachial plexus neurolysis. **A–C:** Fibrous scar tissue is sharply removed from each of the brachial plexus (BP) nerve roots by external neurolysis. (From Thompson RW, Vemuri C. Neurogenic thoracic outlet syndrome exposure and decompression: supraclavicular. In: Mulholland MW, Hawn MT, Hughes SJ, et al., eds. *Operative Techniques in Surgery*. Philadelphia, PA: Wolters Kluwer Health; 2015:1848–61.)

Pathologic changes in the medial subclavian vein are assessed both visually and by digital palpation, and any residual scar tissue surrounding the vein is completely excised ("circumferential external venolysis"). In many patients with venous TOS, this allows re-expansion of the previously constricted segment of the vein, and if the underlying vein is soft to palpation and easily compressible, it is likely that no further venous reconstruction will be necessary. Additional venous reconstruction is performed when external venolysis has not eliminated subclavian vein obstruction or when there is residual venous stenosis demonstrated by intraoperative venography. This is accomplished after infusion of low molecular weight Dextran and administration of intravenous heparin, beginning with clamp control of the axillary or distal subclavian vein, the lower portion of the internal jugular vein, and the upper portion of the innominate vein. The anterior aspect of the subclavian vein is opened along its axis and the lumen is thoroughly inspected. If the luminal surface is smooth and free of thrombus, reconstruction is performed with a vein patch angioplasty using a segment of autologous greater saphenous vein, bovine pericardium, or a cryopreserved femoral vein allograft. It is important to construct the patch angioplasty along the entire length of the affected vessel, both proximal and distal to the stenotic segment, including extension into the innominate vein.

When there is dense fibrosis within the wall of the subclavian vein, or ulceration and mural thrombus upon inspection of the luminal surface, the affected segment of the subclavian vein is excised and replaced by an interposition bypass graft. The interposition graft is constructed using a widely beveled end-to-end anastomosis to the unaffected axillary–subclavian vein, and the proximal anastomosis is extended into the anteromedial aspect of the innominate vein. Because the saphenous vein is too small for replacement of the subclavian vein, use of a cryopreserved femoral vein allograft is usually preferred for subclavian vein reconstruction.

At the completion of the procedure, an intraoperative venogram is performed to confirm a satisfactory subclavian vein reconstruction. In patients for whom a long axillary–innominate vein bypass has been performed for chronic axillary–subclavian vein occlusion, construction of a temporary radiocephalic arteriovenous (AV) fistula between the end of the distal cephalic vein and the side of the radial artery at the wrist may also be considered, as a simple and useful adjunct to increase upper extremity venous blood flow. In this event, the AV fistula is maintained until 12 weeks after surgical treatment, at which time it is ligated under local anesthesia and a final follow-up venogram is performed.

Management of Arterial TOS

Following supraclavicular decompression as described above, including removal of the cervical and first ribs, the subclavian artery is mobilized in preparation for interposition graft repair. Satisfactory distal control of the nonaneurysmal subclavian artery can usually be achieved through the supraclavicular incision alone, once the artery has been fully mobilized. When the lesion is more extensive, exposure of the axillary artery for distal vascular control can be accomplished by adding a transverse infraclavicular incision, with division of the pectoralis minor muscle if needed. The proximal subclavian artery is clamped immediately distal to the vertebral artery and the distal subclavian artery is clamped immediately beyond the aneurysm. The aneurysmal segment of subclavian artery is excised and replaced with an interposition bypass graft using slightly beveled end-to-end anastomoses. The distal anastomosis is usually performed first, and the artery is allowed to relax into its normal position. The graft is then measured and cut to an appropriate length for a tension-free proximal anastomosis. Reversed saphenous vein grafts are suitable for

this reconstruction but are often too small in caliber for subclavian artery replacement, in which case reconstruction can be performed with a cryopreserved femoral/popliteal artery allograft, Dacron or PTFE prosthetic grafts, or autologous deep vein (e.g., superficial femoral) or artery (e.g., iliac) grafts. Following reconstruction, a completion arteriogram is performed to evaluate the subclavian artery bypass graft in different positions of the arm, as well as to reassess the distal circulation.

POSTOPERATIVE MANAGEMENT

An upright chest x-ray is performed in the recovery room and daily for 3 days after surgery. Any small air or pleural fluid collections are observed with the expectation of spontaneous resolution. Postoperative analgesia is provided by patient-controlled intravenous opiates until adequate pain control can be achieved by oral medications, and continuous-infusion local anesthesia is discontinued on postoperative day 3. Oral narcotics, a muscle relaxant, and a nonsteroidal anti-inflammatory agent are routinely prescribed upon hospital discharge and for at least several weeks following surgery. Postoperative hospital stay is typically 3 to 4 days and the closed-suction drain is removed when output is less than 50 mL/day, usually 5 to 7 days after surgery. Physical therapy to maintain range-of-motion is resumed the day after surgery and continued upon hospital discharge, with patients advised to avoid excessive reaching overhead or heavy lifting with the affected upper extremity, and with caution against activities that can result in muscle strain, spasm, and significant pain in the sternocleidomastoid, trapezius, and other neck muscles. A gradual return to use of the upper extremity is encouraged, with the majority of patients permitted cautious light-duty work by 4 to 6 weeks. Patients are seen in follow-up every 3 months in the first year to assess long-term results, and physical therapy is continued for as long as necessary to achieve an optimal level of function. For patients who have undergone treatment for venous TOS, anticoagulation and antiplatelet therapy are both continued for 12 weeks after operation, at which time all medications are discontinued and unrestricted activity is allowed. Patients treated for arterial TOS are maintained on daily aspirin but no anticoagulation, and normal activity with the upper extremity is allowed early after recovery from the surgical procedure.

COMPLICATIONS

Symptoms of numbness and tingling in the hand or fingers are common early after any form of thoracic outlet decompression, arising as a result of previous neurologic damage, intraoperative mobilization of the brachial plexus, and postoperative inflammation and perineural wound healing. The use of continuous local anesthetic infusions for postoperative pain control may also result in sensory neurologic symptoms. More pronounced neurologic dysfunctions including motor deficiencies are rarely observed, particularly arm weakness and loss of handgrip strength, but may represent temporary brachial plexus neuropraxia or pain-limited restrictions in mobility. Spontaneous resolution of such symptoms usually occurs within several days to weeks, but may persist for several months. It is notable that patients with longstanding neurogenic TOS can often display residual symptoms that may not be completely eliminated by thoracic outlet decompression. While these symptoms may be tolerable and are expected to gradually improve, the surgeon must provide continuing support and reassurance during the prolonged period of recovery and rehabilitation.

Mild-to-moderate pleural fluid collections are often observed on the side of surgery following supraclavicular decompression, consisting of serosanguinous fluid that can be expected to spontaneously reabsorb within several days to weeks. Although well-tolerated by most patients, some may experience shortness of breath with exertion until the fluid has resolved. In such individuals, chest radiographs are useful to distinguish the presence of a pleural effusion from the effects of diaphragmatic elevation due to phrenic nerve dysfunction.

Postoperative bleeding is rare but can result in wound hematomas, or when substantial, may lead to hemothorax. Early anticoagulation following operations for venous TOS can elevate the risk of bleeding complications. While often self-limited, reexploration of the supraclavicular wound allows the operative site to be directly inspected and any specific site of bleeding to be controlled. Evacuation of hemothorax can usually be achieved through this approach as well, avoiding the need for chest tube placement.

If there is persistent or increasing drain output of lymphatic fluid greater than 250 mL/day, particularly when chylous in appearance and on the left side, a clear liquid diet is maintained along with administration of octreotide to reduce the volume of lymph flow, and removal of the closed-suction drain is deferred until the leak has subsided. Early supraclavicular reexploration is recommended for persistent high-volume lymph leaks

(more than 500 mL/day for more than 5 days) or those resulting in chylothorax.

Elevation of the ipsilateral diaphragm on postoperative chest x-rays indicates the presence of phrenic nerve dysfunction, which may be associated with shortness of breath on exertion or supine positioning, as well as lower lateral chest discomfort. Most individuals with a unilateral phrenic nerve palsy can compensate satisfactorily with the contralateral diaphragm and intercostal muscles and many become asymptomatic within a short period of time, but patients with severe underlying pulmonary disease may be at risk for significant disability. Postoperative phrenic nerve dysfunction is usually temporary, due to intraoperative mobilization of the nerve or postoperative infusion of local anesthetic, but on occasion phrenic neuropraxia can persist for several weeks; in rare situations, phrenic neuropraxia may be prolonged up to 9 to 10 months before signs of reinnervation appear. The vast majority of such patients should be managed expectantly.

Postoperative dysfunction of the long thoracic nerve is occasionally observed following thoracic outlet decompression, resulting in a winged scapula defect due to weakness of the serratus anterior muscle. Scapular dysfunction due to this defect is readily detectable by physical examination, and it may interfere with shoulder girdle mechanics and physical therapy, thereby prolonging full recovery from operation. While there is no specific treatment, long thoracic neurpraxia is usually self-limited and recovery can be expected within several months.

EDITOR'S COMMENT

The beautifully detailed chapter on thoracic outlet syndrome (TOS) is written by one of the masters of these procedures in the world. Dr. Thompson has accrued a very large patient experience and that knowledge is clear with the well-described specifics of this procedure to make it effective and safe. The detailed anatomy of the thoracic outlet is well described, particularly the key landmarks that are important to stay out of trouble with. The pictures and procedural details are clear and relevant throughout the whole chapter. Nonetheless, patients who undergo TOS decompression should see someone who specializes in this technique, as the volume outcome relationship and more so experience is key for good outcomes.

Thoracic outlet syndrome is primarily three syndromes, the least controversial of which to treat surgically are the venous and arterial TOS. These are rare, but for affected patients, the thoracic decompression with often vascular reconstruction is definitely beneficial. The neurogenic type is typically the most common, causing hand- and arm-related pain, but is a little more nebulous with regard to outcomes. However, quality of life and patient-reported outcomes are now more commonly being used as important factors, as noted in the recent report standards document by the Society of Vascular Surgery (Illig KA, Donahue D, Duncan A, et al. Reporting standards of the Society for Vascular Surgery for thoracic outlet syndrome. *J Vasc Surg* 2016;64:e23–e35).

The initial treatment of neurogenic TOS patients should be physical therapy, occupational therapy, and sometimes psychiatry and counseling, particularly if longstanding chronic pain issues are present. Postural strengthening and core muscle conditioning are also important for neurogenic TOS treatment. Neurogenic TOS may sometimes be associated with work injuries, and thus excellent clinical documentation is critical.

Venous TOS manifested by effort thrombosis is typically treated by

thrombolysis acutely, to open the axillary and subclavian vein systems (Vemuri C, Salehi P, Benarroch-Gampel J, et al. Diagnosis and treatment of effort-induced thrombosis of the axillary subclavian vein due to venous thoracic outlet syndrome. *J Vasc Surg Venous Lymph Disord* 2016;4:485–500). Similar to the author's recommendation, at our institution we typically wait 2 to 4 weeks after thrombosis and full anticoagulation and then bring the patient back for decompression to allow some of the perivascular inflammation to resolve. Not all groups agree with this approach (Guzzo JL, Chang K, Demos J, et al. Preoperative thrombolysis and venoplasty affords no benefit in patency following first rib resection and scalenectomy for subacute and chronic subclavian vein thrombosis. *J Vasc Surg* 2010;52:658–62; discussion 662). We also believe the supraclavicular approach is most straightforward. A major caveat is that subclavian venous stenting should not be done after thrombolysis and balloon angioplasty, due to stent crushing. This can make a salvageable vein stenosis very difficult to successfully treat as the authors' note.

The pectoralis minor syndrome is often not considered as a diagnosis, and with release provides good relief for these patients in whom it is diagnosed. Here, clinical history and carefully physical examination are critical, with pain and tenderness over anterior chest wall and axilla, rather than the supraclavicular space (Sanders RJ, Rao NM. The forgotten pectoralis minor syndrome: 100 operations for pectoralis minor syndrome alone or accompanied by neurogenic thoracic outlet syndrome. *Ann Vasc Surg* 2010;24:701–8). Pectoral minor tenotomy is very successful for these patents.

Complications of TOS decompression are few but do need to be watched for, including hemo-pneumothorax, brachial plexus nerve injury, and wound infection. However, there is no prosthetic placed in this area and so the infection risk is fairly low and not catastrophic.

TOS decompression is safe and effective, but experience and focus of the surgeon are essential to excellent outcomes as highlighted in this chapter.

229 Thoracic Aortic Transection

Himanshu J. Patel and Bo Yang

ANATOMY, NATURAL HISTORY, AND CLINICAL PRESENTATION

Blunt thoracic aortic injury (BTAI) is the second leading cause of death from vehicular trauma. The classic autopsy study by Parmley et al. as well as more contemporary studies has suggested that the mortality of BTAI exceeds 85% at the time of injury, while mortality risk beyond 4 hours following presentation remains low at 6%. More recently, selective delayed operative management advocated by our group as well as others suggests that with aggressive antihypertensive therapy, survival rates following admission are higher than those seen in autopsy reports.

Although the location of injury can occur at any site in the aorta, the most frequent location identified in operative series is the segment just distal to the ligamentum arteriosum. Although the pathogenesis remains debated, potential etiologies for disruption include both differential deceleration forces on the aorta relative to surrounding tissues and thoracic compression forces impacting the aorta directly.

BTAI can have a spectrum of injury ranging from complete disruption with a true double barrel aorta, to a partial wall disruption with pseudoaneurysm formation, and finally to an isolated intimal injury without associated mural hematoma. In our estimation, the best grading of injury has been reported by Azzizadeh et al. from Houston describing grade 1 (intimal injury), grade 2 (intramural hematoma), grade 3 (pseudoaneurysm formation), and grade 4 (frank rupture).

This spectrum of disease likely results in disparate trajectories in the natural history. Isolated intimal injury is likely a benign process, and will often heal spontaneously without intervention. Partial wall disruption will often result in pseudoaneurysm formation medially into the mediastinum with associated mediastinal hematoma, and on exploration resembles an entry tear of an acute type B dissection. Those presenting with lateral wall (i.e., projecting into lung parenchyma) involvement are considered by us

to be somewhat more unstable, and are less frequent perhaps because these patients have succumbed to free rupture. Finally, complete disruption is considered by us to be the least stable pathology and at the highest risk for rupture. In general, partial tears and complete disruption transections are often transverse in orientation, and the natural longitudinal tension in the aorta separates the disruption by several centimeters.

Clinical Presentation and Diagnosis

BTAI should be suspected on initial primary survey, based upon both the mechanism of injury and physical signs or imaging findings. High-impact mechanism including vehicular accidents with significant deceleration forces, falls, or blast injuries should prompt evaluation for BTAI. Physical signs such as first or second rib or thoracic spine fractures, shock, dyspnea, or hemothorax are also suggestive.

Imaging studies are of vital importance in confirming the diagnosis of BTAI. Aortography, widely considered the gold standard in evaluation for BTAI, has a near 100% sensitivity and specificity in experienced hands, but is time-consuming and often negative. An often underutilized tool in diagnosis is the transesophageal echocardiogram (TEE). The main advantage of this test is its portability, and its use can be important in those patients presenting requiring immediate surgery for concomitant injuries. At the time of operative repair of concomitant injuries, TEE can be performed safely during the operative procedure to obtain the diagnosis. The previously routine use of aortography in diagnosis of BTAI has now been supplanted by the widespread use of computed tomography (CT), which in the modern era is obtained rapidly and can also be used in aiding diagnosis of concomitant injuries. Suggestive findings on CT scanning include mural and mediastinal hematoma, intimal flaps, or pseudoaneurysm formation. This test is important for multiple reasons, particularly in the endovascular era where endograft sizing is dependent on good thin cut (1.25 to 3 mm) imaging with three-dimensional (3D) reconstruction.

INDICATIONS AND TIMING OF INTERVENTION

In BTAI, the indication for operation is aortic repair for improvement in life expectancy. As was discussed earlier, we believe that not all aortic injuries require operation. While the partial and complete disruptions have a risk for rupture without repair, intimal injuries or mural hematomas

(Azzizadeh grades 1 or 2) likely do not portend the same risk. We and others have noted that a large percentage of patients will spontaneously heal these lesions with aggressive medical therapy. In our experience, these do not subsequently develop pseudoaneurysms without surgery and likely have a relatively low risk for rupture.

Following presentation, patients are immediately treated with parenteral antihypertensive therapy. At our institution, we will aggressively reduce blood pressure for at least a week (goal systolic BP 100 to 120 mm Hg), with beta blockers used as a first-line agent. If repair is delayed by more than 1 week for reasons of comorbidities or associated injuries, we then liberalize control to let systolic pressures rise to no more than 150 mm Hg, and institute oral pharmacotherapy. If operative repair is delayed, we will obtain repeat imaging at 48 hours to be certain that there is no significant change in the injury, such as rapid growth of pseudoaneurysm or increased mediastinal hematoma. It is not unusual for patients to develop pleural effusions that can increase in size over the first 24 to 48 hours with volume resuscitation, and this in and of itself does not represent an indication for more urgent repair.

Repair of the aortic injury is performed as soon as appropriate. However, life-threatening abdominal or neurologic injuries will preclude early repair. In our experience, the most frequent reason for operative delay involves the presence of closed head injury precluding use of heparin for either open or endovascular repair. Another frequent reason is the presence of significant pulmonary contusion, precluding use of single lung ventilation for open descending thoracic aortic repair (DTAR). In the current era, if thoracic endovascular aortic repair (TEVAR) is not felt appropriate, we will delay the open procedure until the time when the patient's pulmonary status allows proceeding with surgery. Finally, in the event that deep hypothermic circulatory arrest is deemed a necessary adjunct (<5%), we will often wait until the patients have been extubated, and have undergone some degree of rehabilitation, as this operative approach requires a significantly increased physiologic reserve.

The determination of the type of repair (i.e., DTAR vs. TEVAR) is based upon several premises. Unlike some institutions that espouse one or another approach exclusively, we take a more conservative strategy understanding that we have an extensive positive experience with both open and endovascular approaches to the descending aorta. There are no long-term data (>15 years) reported with TEVAR for BTAI, and this is an

important consideration in this younger population. Another important consideration is that frequently, follow-up is incomplete making serial imaging that is needed after TEVAR impossible in all patients. A growing concern is also that the serial imaging needed after TEVAR is associated with a large accumulated contrast and radiation exposure over the patient's lifespan, particularly in the younger population. The configuration of the arch is more hazardous in the younger patient population, particularly with the currently available stent graft technology. This is shown in Figure 229.1. Finally, there is a demonstrated natural growth rate of the aorta from the second to eighth decade that can be as much as 1 cm normally. The stability of the stent grafts is uncertain over this time frame.

Certain patient populations such as older patients may benefit from an endovascular approach, both because of the impact of open repair on early recovery, morbidity, and mortality, and because the aortic arch anatomy may be more conducive for TEVAR. We will preferentially use TEVAR in patients over 60 years of age, and in those who have significant or incompletely evaluated comorbid conditions, such as coronary artery disease without known extent, congestive heart failure, chronic renal failure, or emphysema. If TEVAR is not felt suitable, we will then delay the open repair if possible until these conditions have been more adequately evaluated. While we often will consider the gold standard as the open procedure, improvements in device design have led us to use an endovascular paradigm even in younger patients. The potential of branched arch endograft technology may shift the preference further toward TEVAR.

CONVENTIONAL OPEN REPAIR

Preoperative Planning

We rely on CT scan imaging with an aortic protocol as the preoperative test of choice. In performing this test, the contrast bolus is timed to reside within the aortic lumen and thin 1.25- to 2.5-mm cuts are obtained to provide fine details regarding the pathology. Images are obtained starting at the base of the brain and extending to the femoral heads. In this way, we obtain critical information regarding the patency of the Circle of Willis, the extent of mediastinal hematoma, and evaluation of the pelvic vasculature. The performance of 3D reconstructions of the aorta is imperative to better aid in planning for both open and endovascular options.

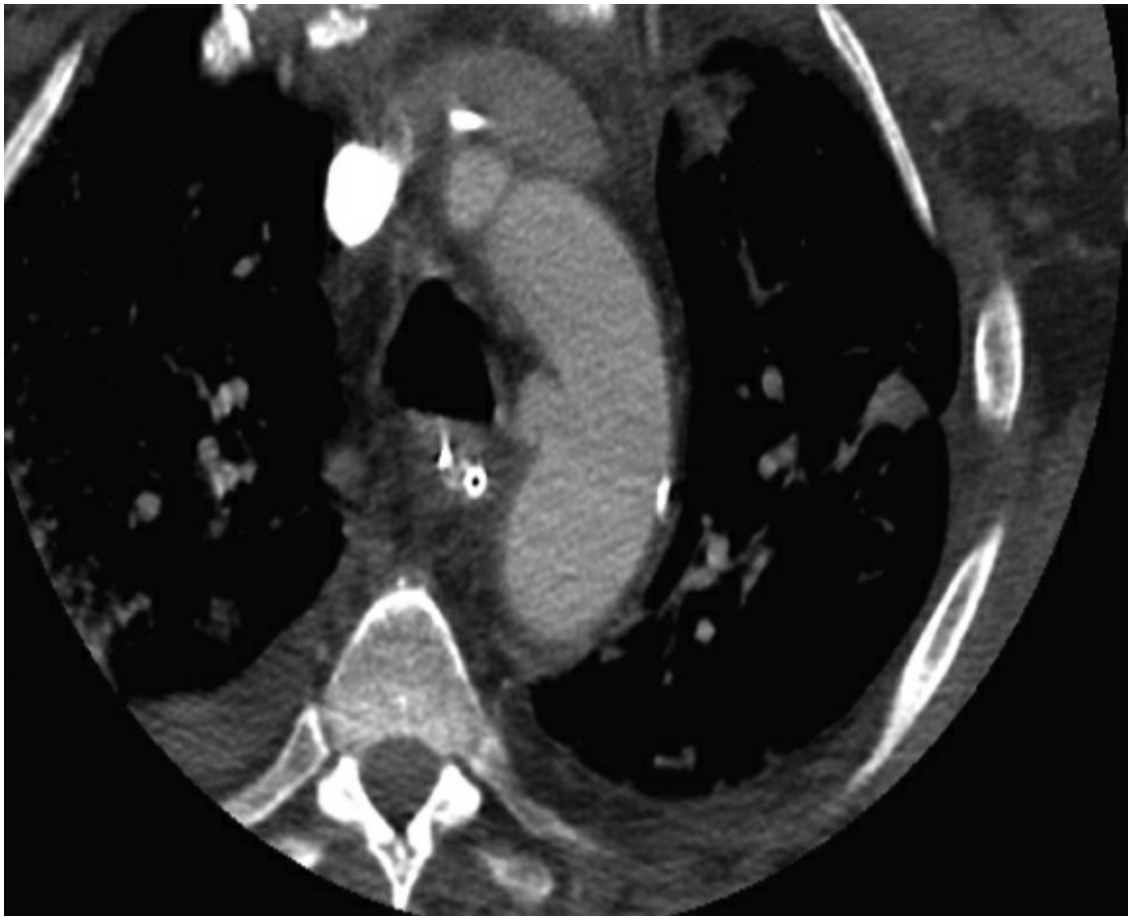

Figure 229.1. This cross-sectional CT scan displays a pseudoaneurysm secondary to blunt traumatic aortic injury. The scan was obtained after a delay period of 7 days, and the periaortic hematoma frequently present on the early scan has now resolved leaving only the grade 3 injury.

Operative Technique

All open repairs (DTAR) are conducted with the use of extracorporeal circulation. The technique of “clamp and sew” is to be avoided as the risks of paraplegia are markedly increased. If a sufficient neck exists for placement of the cross-clamp, left heart bypass with a Carmeda coated system is utilized. The Carmeda coating allows us to reduce the heparin dosing to keep the activated clotting times at about 200 to 250 seconds. Although others have reported safety in using this system without anticoagulation, we have found that even with a lower heparin dosing regimen, clot often forms on the graft itself in the absence of continued flow, and may present a risk for thromboembolism following the release of the distal clamp. Although the procedure can be done without use of an oxygenator, in the acute setting, an oxygenator is preferred as the patient

may have significant right-sided pulmonary contusion impairing gas exchange on one lung ventilation.

The aortic neck in BTAI often exists in the mid-arch aorta, and the placement of the proximal cross-clamp is usually just distal to the left carotid artery. A good rule of thumb is that the inadequacy of a 2 cm neck distal to the left carotid artery prior to the origin of the tear often precludes the use of left heart bypass, cross-clamp application, and still sufficient aorta to which to suture a graft. The use of deep hypothermic circulatory arrest with construction of an open proximal anastomosis is then mandatory. We have found this adjunct needed in less than 5% of our series.

The operative procedure starts with the use of general anesthetic with a double lumen tube to isolate the left lung. A lumbar drain for spinal cord protection is typically not employed for the standard distal arch and proximal descending aortic replacement. A left posterolateral thoracotomy with entrance into the fourth intercostal space is made. We will often preserve the serratus anterior muscle and will try to avoid extending the thoracotomy posteriorly. In this manner, the thoracotomy wound will then not be in a posterior location prone to breakdown with an ill intubated patient. The mediastinal hematoma in the acute injury is usually immediately visible in the posterior mediastinum as a bluish discoloration of the pleura. Particular attention is paid to the preoperative CT scan, as dissection in the area where the rupture is located is avoided until both proximal and distal control are obtained. We initially attempt to obtain distal aortic control first by mobilizing the aortic segment at about the T6 level. If the injury is acute, we mobilize the proximal aorta only after the patient is cannulated for left heart bypass. If the injury is subacute or chronic, dissection is then continued proximally to mobilize the mid-arch aorta prior to cannulation. The phrenic nerve is preserved and serves as a good marker for location of the left carotid artery. Dissection of the mid-arch starts by opening the pleura posteriorly to the phrenic nerve and identifying the aorta. The dissection is best continued superiorly identifying the distal arch vessels. Often in the acute setting, the hematoma often partially dissects the planes, thereby facilitating aortic mobilization. A finger is then used to separate the trachea and left mainstem bronchus medially from the aorta laterally until the inferior edge of the aorta is reached. Then, starting often close to the proximal arch lesser curvature where the pericardial reflection sits, the lesser curve dissection is

continued to the ligamentum arteriosum. Great care should be taken in this region given the proximity of the contained rupture. The left recurrent laryngeal nerve is not usually identified until the aorta is ready to be clamped proximally and the patient is placed on left heart bypass.

Cannulation for left heart bypass is performed with division of the inferior pulmonary ligament and exposure of the left inferior pulmonary vein or by placement in the superior pulmonary vein. A right angle tip cannula is placed through this vessel into the left atrium for venous drainage. Arterial return is accomplished via either the distal aorta (if no hematoma is present) or the left femoral artery (if significant aortic mural hematoma exists down into the infradiaphragmatic aorta). We usually do not cool much more than 33°C to 34°C to avoid the risk of ventricular fibrillation.

Further mobilization of the aorta is then often performed after placing the patient on left heart bypass. Cross-clamps are then applied to isolate the aortic segment ready for resection, and the limited injured segment of aorta is mobilized off the esophagus after incision into the aorta. Any back bleeding intercostal vessels in the region where resection is to occur are ligated. If any intercostal arteries can be preserved but are located within the isolated aortic segment, small occlusion clamps are placed externally, or small Fogarty balloon catheters are placed into their lumina to prevent blood loss from back bleeding. We would previously resect the pseudoaneurysm completely and then interpose a Dacron graft. Now, we will often start with a linear aortotomy along normal aorta to inspect the defect. If there is a partially disrupted wall confined to one side of the aorta, we would consider patching this defect with a Dacron patch sewn on with a 4-0 polypropylene suture. This can even be done endoluminally, running the patch along the rim of the defect, and keeping the pseudoaneurysm intact externally to keep it separate from adjacent viscera such as lung or esophagus. Occasionally, if the defect is not large, the adjacent aorta can be mobilized and the tear primarily repaired with a running 4-0 polypropylene suture to avoid leaving prosthetic material. It is imperative to leave this anastomosis without tension with adequate aortic mobilization.

If there is a spiral tear, we will resect the aorta and construct the proximal anastomosis of aorta to the Dacron graft with a running 4-0 polypropylene suture with or without Teflon felt reinforcement (Fig. 229.2B). The cross-clamp is then moved onto the graft and the proximal

suture line checked for hemostasis. The graft is sized to an appropriate length, and then cut to reach the distal aorta. This anastomosis is then similarly constructed and the clamps removed after de-airing maneuvers are performed (Fig. 229.2C). We then reverse the heparin with protamine and decannulate the patient. Finally, the graft is then separated from the adjacent lung with pleura if available, or with bovine pericardium or separate Dacron graft strips wrapped around the anastomoses.

Postoperative Management and Potential Complications

Routine postoperative care involves management of concomitant injuries and hemodynamic support. In particular, the spinal cord is protected with a regimen of permissive hypertension with maintenance of systolic blood pressures at 120 to 140 mm Hg. As stated previously, routine use of cerebrospinal fluid drains is not necessary as few intercostal vessels are sacrificed in the typical repair and distal aortic perfusion is maintained with left heart bypass. The expected risk for paraplegia after open repair for BTAI should be less than 5%.

We usually remove chest tubes after confirming the absence of a chyle leak by enteral feeding of 80 cc of heavy cream. If a chyle leak is suspected, conservative measures including a no fat diet are employed. Protracted observation of a chyle leak is discouraged, as severe malnutrition can ensue particularly in the multisystem trauma patient. Rather, in that event, a postpyloric enteral feeding tube is inserted and cream instilled continuously 6 hours before and (most importantly) into the operating room to help identify the source of chyle leak on re-exploration via a left thoracotomy. The leaking duct is then ligated with clips or multiple silk ligatures.

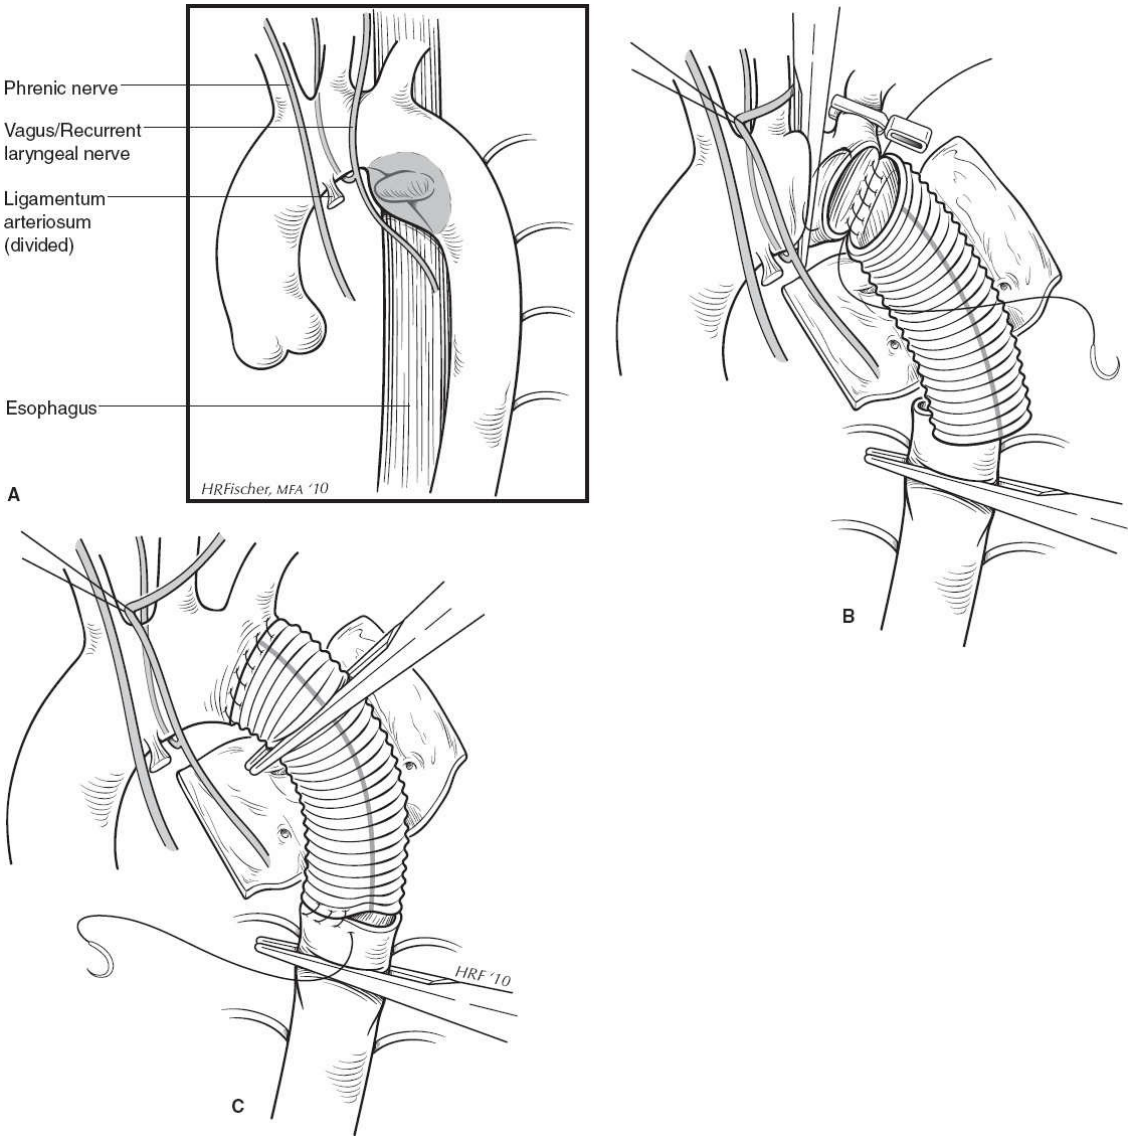

Figure 229.2. *Open repair of the traumatic aortic transaction.* This depicts the usual location of the thoracic aortic transaction. The important anatomical landmarks include the left phrenic, vagus, and recurrent laryngeal nerves as well as the esophagus (**A**). Proper mobilization of the aortic arch and proximal descending aorta is required for complete repair. Note that the ligamentum arteriosum has been divided to allow for proper placement of the proximal cross-clamp that is normally applied proximal to the left subclavian artery. In addition, the left vagus and recurrent laryngeal nerves are mobilized anteriorly to allow for arch exposure. On the medial aspect of the proximal cross-clamp, the trachea is usually palpated (not shown in figure). The extent of injury is usually very localized, and few if any intercostal arteries require sacrifice (**B**). After construction of the proximal anastomosis, the proximal cross-clamp is moved onto the aortic graft to restore antegrade perfusion of the left subclavian artery (**C**). The distal anatomosis is then constructed with 3-0

polyprolene suture.

THORACIC AORTIC ENDOVASCULAR REPAIR (TEVAR)

The recent advent of endoluminal techniques for aortic disease has been applied to the multisystem trauma patient with great success (Figure 229.3). Numerous studies have focused on early outcomes. However, late outcomes (>15 years) remain yet to be defined. Despite the lack of long-term data, this approach has rapidly been applied in the setting of BTAI as a potential means of decreasing early morbidity and mortality. The recent American Association for Surgery of Trauma (AAST) trial suggested that this treatment modality has become much more prevalent than open repair in multiple trauma institutions.

Preoperative Planning

Again, the preoperative imaging modality of choice is the CT scan with 3D reconstruction. Similar to other pathology, the successful use of TEVAR in this setting is critically dependent on preoperative anatomy. The CT scan obtained in this setting is obtained again extending from the base of the brain to the pelvis, with the contrast bolus timed to reside within the aorta itself. In this way, key information regarding the pathology, the circle of Willis, and access vessels is defined. Given the need to access peripheral vessels with large bore sheaths, we will also obtain preoperative ankle-brachial indices to determine a baseline measurement.

With the current second-generation thoracic endografts, certain contraindications to standard TEVAR exist. These include: (1) inadequate (<2 cm) proximal neck defined as the distance from the left carotid artery to the tear, (2) inadequate access vessels to deliver the device, (3) aortic diameters outside of the range of currently available devices, and (4) a “gothic” rather than an “elliptical” aortic arch configuration (Figure 229.4). However, it must be recognized that these represent relative contraindications, as “advanced” TEVAR techniques such as arch debranching for inadequate proximal neck, use of abdominal endograft components in small native aortic diameters, or device delivery via the ascending aorta can be applied to overcome these limitations.

The choice of endograft is then made based upon the 3D reconstructive anatomy. It is important to consider the volume status of the patient at the time of the CT scan, and remember that a properly resuscitated patient

may have an aortic diameter that is up to 10% larger than a patient who acutely arrives in the hospital in the setting of hemorrhagic shock. When aortic repair is delayed, we will consider repeating the CT scan after the patient is volume resuscitated in the event that TEVAR is considered the appropriate therapy. Generally, diameter specification is made first, and this chosen diameter stent graft is oversized by approximately 10%. Next, the treatment length is determined by a centerline of flow assessment of length (i.e., center portion of the 3D reconstructed aorta). We use the shortest possible graft that will allow coverage of the entire length of the pseudoaneurysm, along with the 2 cm length needed for the proximal and distal landing zones.

Need for Adjunctive Left Carotid to Left Subclavian Artery Bypass

Given the location of the typical BTAI injury, the left subclavian artery (LSA) often requires at least partial coverage. Absolute indications for LSA revascularization with either a bypass or a transposition include presence of a pedicled left internal mammary artery to left anterior descending coronary artery bypass graft or a dominant left vertebral artery. We will often include a direct origin of the left vertebral artery from the aortic arch as an important indication for LSA revascularization. There are emerging data suggesting a decrease in the risk of stroke and paraplegia with left subclavian arterial revascularization. On the basis of these data as well as our personal experience, we will routinely perform LSA revascularization prior to complete coverage unless a contraindication exists such as a neck fracture or hemodynamic instability. As branched endograft technology evolves, the need to perform adjunctive maneuvers may diminish.

Finally, a discussion of complex TEVAR with so-called “chimney” or “snorkel” stent grafts for branch vessel is warranted. With this approach, a bare stent or endograft is placed into the branch vessel, and spanned across the landing zone into the more proximal uncovered aorta as a parallel conduit. Branch vessel flow is preserved despite branch vessel origin coverage, and the landing zone is extended without open adjunctive extra-anatomic revascularization. We will reserve this option for emergent procedures where more conventional methods will not be possible, or for other reasons such as inability to turn the neck for performance of the LSA bypass in the setting of an absolute indication for its revascularization.

Operative Technique

The open access vessel (usually femoral artery) is exposed and made ready for isolation. The femoral artery is exposed via a transverse infrainguinal incision. If the caliber of the iliac artery is smaller than what is required, an iliac artery is exposed via a lower quadrant incision and mobilization and exposure of the vessel staying in the preperitoneal and retroperitoneal planes. A Dacron graft is then anatomosed to the common iliac artery in an end-to-side fashion and the open distal end of the graft brought out through the abdominal wound to serve as the conduit for device delivery. Percutaneous access is obtained in the contralateral femoral artery with a 5-Fr sheath. Via the percutaneous access, a marker pigtail catheter is situated into the arch aorta.

The endograft is then advanced over a super-stiff wire via the open arterial access site and placed into the ascending aorta. We will routinely heparinize the patient unless a contraindication exists. Generally, if a contraindication exists (e.g., traumatic brain injury), we delay the operative procedure to a time when heparin administration is considered relatively safe. Although there have been reports of safely performing this procedure without heparin, we find the delivery sheaths for the devices generally occlusive up to the level of the iliac arteries. In this situation, there exists a catastrophic potential for not only iliac artery thrombosis, but also thrombus formation on wires, catheters, and sheaths placed in the ascending and arch aorta.

An arch aortogram is then performed, delineating the pathology and critical branch vessels. In general, the projection of the image intensifier should be in a location whereby all of this information is obtained with one injection. If significant renal failure exists preoperatively, we have performed this procedure with the use of intravascular ultrasound to mark the branch vessels and minimize contrast exposure. Assuming the ileofemoral system has an adequate caliber to accommodate the devices, the stent grafts are advanced into the intended landing zone and then deployed. Gentle balloon dilation of the proximal and distal landing zones can be performed, but is not mandatory. Completion thoracic aortography is performed to determine the presence of endoleaks (usually type I as these repairs usually only need one stent graft component). If they exist, consideration is then given to determine whether a more proximal extension is feasible, or whether these can be left alone. Since there is typically no outflow in the pseudoaneurysm sac, we have found that even

if an endoleak persists despite re-ballooning the aorta, by the time of the first CT scan at 1 month postoperatively, the pseudoaneurysm has collapsed and no endoleak exists.

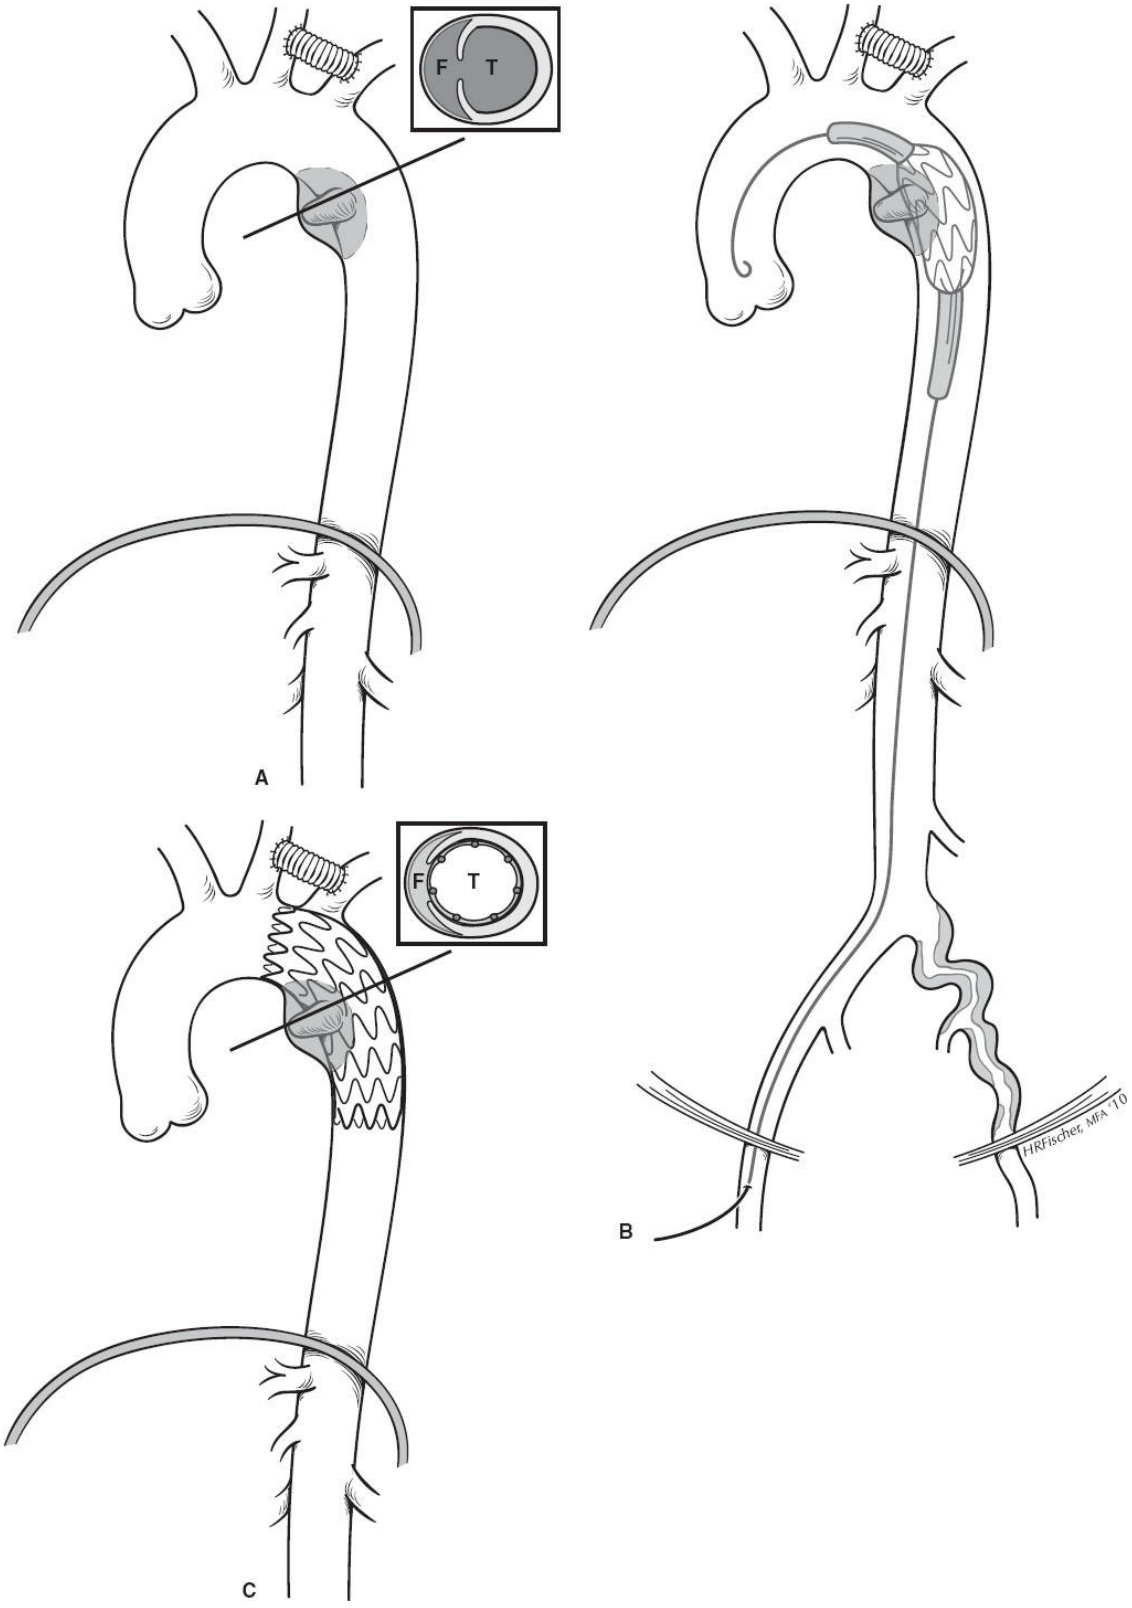

Figure 229.3. *Thoracic endovascular repair of the traumatic aortic injury.* This again depicts the injury in a left anterior oblique projection (**A**), but in preparation for TEVAR, a left carotid to left subclavian artery bypass has been constructed. The stiff wire has been advanced into the ascending aorta (**B**) via the better right femoral access vessel. The endograft is brought toward the base

of the left carotid artery and then subsequently deployed to cover the origin of the left subclavian artery (**C**). In general, we do not preemptively place occlusion devices into the orifice of the subclavian vessel unless the pseudoaneurysm abuts its origin along the greater curvature. Endoleaks that are identified early are rarely seen late, as there is usually no outflow thus promoting sac thrombosis and regression.

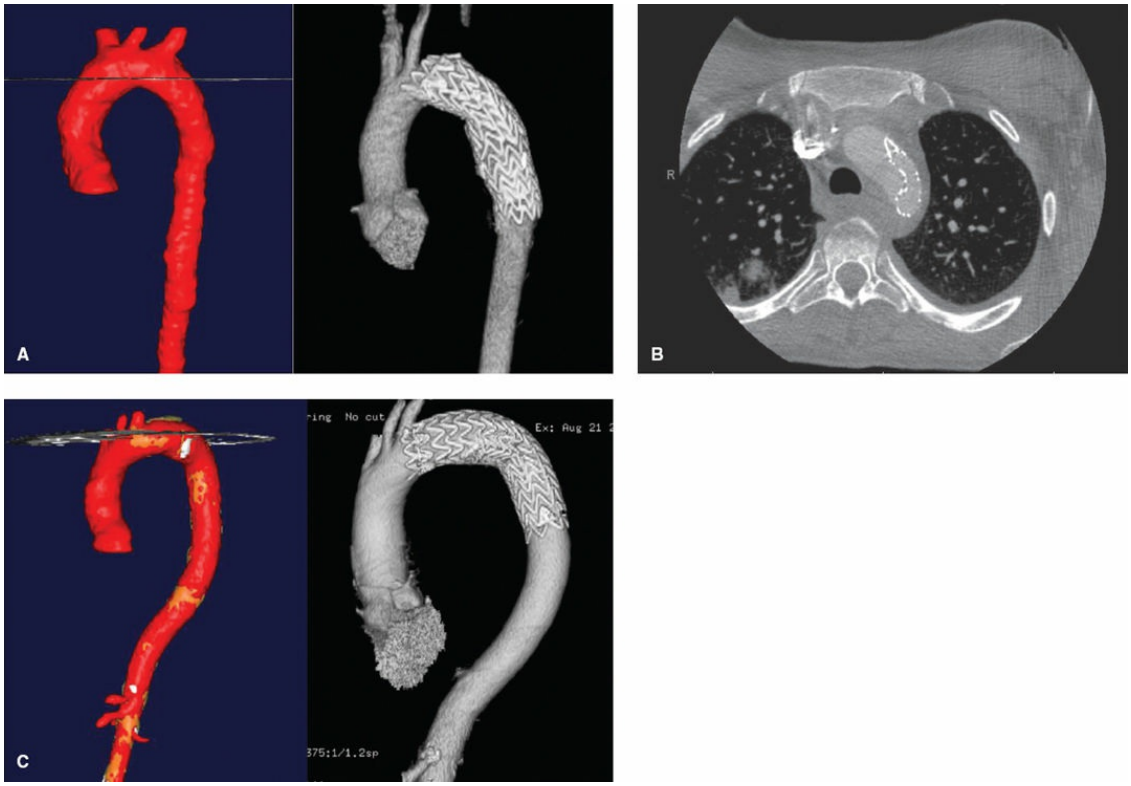

Figure 229.4. (**A**) This 3D reconstruction reveals the typical "gothic arch" in a 23-year-old male with a blunt injury (not shown in this projection). Deployment of the stent graft results in a "bird beak" configuration with incomplete apposition of the stent graft to the lesser curvature. In this setting, there is a possibility of resulting collapse of the endograft (shown in **B**). Maneuvers to diminish this risk include placement of a second endograft or a balloon expandable stent to increase radial force. In contrast in (**C**), this 71-year-old male has a relatively flat arch more amenable to coaxial stent graft alignment and good lesser curvature apposition.

Finally, the discussion of whether to occlude the subclavian artery prior to stent graft deployment often arises. In our experience, it is unusual for the LSA to cause a retrograde type II endoleak as the pseudoaneurysm is typically located along the lesser curvature. In the event that this occurs,

coil embolization from a percutaneous brachial approach is simple and associated with minimal morbidity. Indications for preemptive LSA plug occlusion however include a marginal proximal neck (<2 cm), or the presence of a tear abutting the origin of the subclavian artery.

Following completion of the stent graft deployment, we withdraw the device sheaths from the open arterial access initially maintaining wire access to be certain that iliac rupture has not occurred. The femoral or iliac artery is carefully repaired with interrupted 5-0 polypropylene sutures, taking care to tack down the inevitable flap created by sheath advancement. Protamine is then administered and the percutaneous access then removed with manual hemostasis.

Postoperative Management

The standard postoperative management following TEVAR is similar to that described above for open repair. Vascular system checks are imperative as is the need to evaluate all percutaneous puncture sites for hematoma or pseudoaneurysm formation. We will obtain ankle-brachial indices the next day to be certain that there is no change from preoperative status.

Complications

The complications from open surgery (stroke, paraplegia, renal failure) can still occur following TEVAR. To minimize contrast-induced renal failure, we hydrate the patient both prior to and following the TEVAR procedure. Several complications unique to TEVAR exist. The first is an access related one, namely, iliac artery rupture, which usually occurs at the iliac artery bifurcation following device sheath removal. In our experience, this is a common cause of death after TEVAR for any indication. The best treatment is prevention, and liberal use of iliac conduits when necessary. In the event of rupture, we now repair the artery with an iliac stent graft inserted over the wire used for thoracic device delivery. The importance of maintaining wire access cannot be underemphasized, and we have a “rupture kit” available when access vessels are marginal to start with. The first sign of iliac rupture is not hypotension, but loss of pulse distal to the ruptured artery. In rapid sequence, a 20-Fr sheath is advanced into the iliac artery, followed by an occluding balloon (size selected prior to start of TEVAR procedure) placed just distal to the aortic bifurcation. An angiogram is performed through the sheath, distal to the occluding balloon

confirming the diagnosis and site of rupture. After the patient is volume rescusitated, we then rapidly deflate and withdraw the balloon and advance and deploy the iliac stent graft (also selected prior to start of TEVAR procedure). Return of hemodynamic stability and distal pulses confirms exclusion of rupture, but angiographic control is performed.

The second unique complication is that of endograft collapse following TEVAR. This can result in repressurization of the pseudoaneurysm, or even a coarctation-like presentation if it is occlusive. Prevention is paramount, and the risk is decreased if oversizing or treatment in a "gothic" arch configuration is not performed. In addition, at the conclusion of each TEVAR procedure, we will examine the leading edge of the endograft under magnification views with fluoroscopy to ensure that the lesser curvature segment is not mobile. Also, the postprocedure angiogram provides an idea of potential instability if there is a significant "bird-beaking" effect where the leading edge is separated from the lesser arch curvature by >0.75 cm. If any of these indicators exist, consideration is then given for either placement of a balloon expandable bare metal stent into this segment or a second endograft placed within the first. Both maneuvers will increase the radial force of the graft and minimize risk of collapse. The incidence of this unique occurrence has diminished as second-generation devices have become available, and as its awareness particularly for this pathology has increased.

CONCLUSIONS

The last decade has seen dramatic shifts in the management of blunt thoracic aortic injury. Advances in imaging have reduced the need for invasive angiography for therapy, and have identified the injury in a more rapid and consistent manner. The importance of medical therapy in the early postinjury period has been recognized. Not only has the paradigm shifted from immediate repair for all patients to a selective management toward early intervention, but the type of therapy in the "real world" appears to have shifted favoring an endovascular approach. The surgeon(s) evaluating this lethal injury should be well versed in all of these issues, whether they perform the procedure or not, in order to provide the best care of the complex injured patient.

EDITOR'S COMMENT

Complete aortic transections are almost universally lethal at the scene. While I am not sure of any literature that suggests more people in motor vehicle or motorcycle accidents are surviving with aortic injuries with all the new safety prevention strategies (airbags, etc.), I do know that the diagnosis, as well as the management, of this disease process has changed radically for the better. When I think back to all of the mainly unneeded aortograms we used to perform on trauma patients and then the "clamp and sew" repairs of these injuries when found, I really suspect that few areas of care have been improved more than how we take care of patients with traumatic aortic injuries. Unfortunately, both reporting standards and follow-up of these often young patients are woeful, making comparison of open versus endovascular repair (TEVAR) of the thoracic aorta difficult (Karmy-Jones R, Ferrigno L, Teso D, et al. Endovascular repair compared with operative repair of traumatic rupture of the thoracic aorta: a nonsystematic review and a plea for trauma-specific reporting guidelines. *J Trauma* 2011;71(4):1059–72). I think a good general consensus however is that TEVAR is associated with a lower mortality and paralysis rates, but that comes at the expense of more strokes in the TEVAR group.

First, cross-sectional imaging with high-resolution CTA followed by 3D

immediate reconstructions has given us pause for treating all aortic injuries, short of a complete aortic transection. As Patel and coauthors point out, we now recognize that there are degrees of aortic injury that range from a small intimal tear to an intramural hematoma to a full-blown transection. My guess is that we have become more conservative over time especially with the small intimal tears and localized injuries (Mosquera VX, Marini M, Lopez-Perez JM, et al. Role of conservative management in traumatic aortic injury: comparison of long-term results of conservative, surgical, and endovascular treatment. *J Thorac Cardiovasc Surg* 2011;142(3):614–21). Many of these patients can safely undergo repeat imaging with almost all of them healing their aortic tear. In addition to the grading system around these injuries, I think we have become more comfortable with delaying repair when no blood is present in the mediastinum or chest. I am not advocating a policy of delaying for extended periods of time, even though I am not sure we know a lot about the perfect timing of repair in these patients. I am suggesting that taking these multitrauma's down in the middle of the night with less than the "A team" can probably be delayed long enough to get the appropriate staff and environment, specifically an hybrid operating room with experienced interventional radiology technician's and nursing personnel.

Second, while Dr. Patel has well described open surgery for patients with aortic transections, except for in the rare event where the aortic injury is an isolated injury, almost all of these patients are now treated with endovascular stenting as they typically are multitraumas (i.e., more than one system injured) (Mwipatayi BP, Boyle A, Collin M, et al. Trend of management of traumatic thoracic aortic injuries in a single center. *Vascular* 2014;22(2):134–41). In fact, there are now three endograft companies that manufacture grafts that have traumatic aortic injury as an FDA-approved indication. Most of the endograft companies now have developed thoracic endografts that are smaller profile in terms of the delivery sheath size. These smaller diameter sheaths make for fewer iliac artery injuries when delivering the endograft to the thoracic aorta (that when they occur, you quickly realize upon sheath removal when the blood pressure goes to 0!). They also have recognized the need for smaller diameter aortic endografts to treat smaller aortas in these often young, multitrauma patients. Gone are the days when short aortic cuffs were "shingled" into the thoracic aorta in order to treat aortic transections (Thompson JK, Reed AB, Giglia JS. Novel endovascular treatment of blunt thoracic aortic trauma with a self-expanding stent lined with aortic extender cuffs. *Ann Vasc Surg* 2006;20(2):271–3). This is definitely a good thing.

Finally, I would comment on two other issues that Patel has addressed in this chapter, but I need to add my two cents worth on. I almost always use heparin prior to delivering the thoracic endograft. Recognizing that the incidence of thromboembolic disease to the lower extremities is low, I still believe most patients can tolerate some heparin, say 3,000 to 5,000 units intravenously. I am not talking about giving cardiopulmonary bypass doses, but enough heparin to

potentially prevent what I think is the most devastating complication of stent grafting in the aortic arch (i.e., stroke) (McBride CL, Dubose JJ, Miller CC 3rd, et al. Intentional left subclavian artery coverage during thoracic endovascular aortic repair for traumatic aortic injury. *J Vasc Surg* 2015;61(1):73–9). I think that is especially important in patients you are planning to cover the left subclavian artery, as this is associated with more manipulation of the endograft in the aortic arch. I agree that most patients tolerate left subclavian artery coverage fine, especially in the emergent setting. However, I always get a CTA of the head and neck to make sure of the patients intracerebral anatomy, including the course and dominance of the vertebral arteries (McBride CL, Dubose JJ, Miller CC 3rd, et al. Intentional left subclavian artery coverage during thoracic endovascular aortic repair for traumatic aortic injury. *J Vasc Surg* 2015;61(1):73–9). Obviously, I would not cover the left subclavian artery in a patient who has a LIMA (left internal mammary artery) graft to a coronary artery and would do a left carotid to left subclavian artery bypass for these patients, until branched aortic arch endografts become available (which is not that long from now!).

230 Vascular Injuries to the Neck, Including the Subclavian Vessels

Nam T. Tran

BACKGROUND

The neck is unique in that it contains vital organs from the respiratory, digestive, vascular, neurologic, and endocrine systems. In the severely injured trauma patient, all of these structures must be assessed and treated accordingly. While vascular injuries to the neck only account for 5% of all civilian vascular injuries, rapid management is critical once the airway has been secured to ensure patient survival and optimal outcome. Both penetrating and blunt mechanisms can cause injury to vascular structures in this region. Unlike other anatomic areas of the body, penetrating wounds comprise the majority of vascular injury in the neck in urban trauma centers. While less common, blunt mechanisms can also result in significant injury to vascular structures as well.

HISTORICAL PERSPECTIVE

In 1552, the French surgeon Ambroise Pare ligated both carotid arteries and a jugular vein of a soldier injured in a duel. The soldier survived the operation, but unfortunately was left with hemiplegia and aphasia. Two centuries later, a young naval surgeon, Fleming, ligated the common carotid artery on a suicidal sailor with a successful outcome. The mortality associated with cervical vascular injuries in World War I was approximately 16% to 30% for both nonoperative management and ligation of actively hemorrhaging vessels. In World War II, a more aggressive policy toward routine exploration resulted in a significant reduction in mortality with cervical vascular trauma. The first attempt at surgical repair of a cervical vascular structure, an injured carotid artery,

was performed during the Korean War. Repairs at that time consisted of direct suture, primary anastomosis, and interposition vein graft. Modern-day management has included the addition of endovascular approaches with coil embolization of bleeding vessels and the placement of both covered and bare metal stents.

GENERAL APPROACH—ANATOMIC ZONES

Classically, the management of cervical trauma is dictated by anatomic zones originally described by Monson at the Cook County Hospital in 1969 and still remain in use today (Fig. 230.1). Zone I is defined by the thoracic inlet inferiorly and the cricoid cartilage superiorly. In this area, structures at risk include the subclavian vessels, brachiocephalic vessels, aortic arch, and origins of the carotid artery. Zone II is the midportion of the neck and is demarcated by the cricoid cartilage inferiorly and the angle of the mandible superiorly. This zone contains the carotid arteries, vertebral arteries, and the jugular veins. Lastly, zone III is the highest in the neck and is bound by the angle of the mandible inferiorly and the base of the skull superiorly. In this region, the carotid arteries and jugular veins are at greatest risk. Typically, injuries to structures in zone III are the most difficult to access surgically.

ETIOLOGY/EPIDEMIOLOGY

Overall, gunshot wounds account for the majority of cervical penetrating trauma. Stab wounds often cause injury to the left neck due to the majority of the population being right handed. The common carotid artery is the vessel most often injured followed by the internal carotid and subsequently the external carotid artery. Mortality from penetrating missile wounds ranges anywhere between 2% and 10% and is dependent upon other associated injuries, time between injury and presentation, and the patient’s overall neurologic status. In particular, those with profound neurologic deficits carry the worst prognosis.

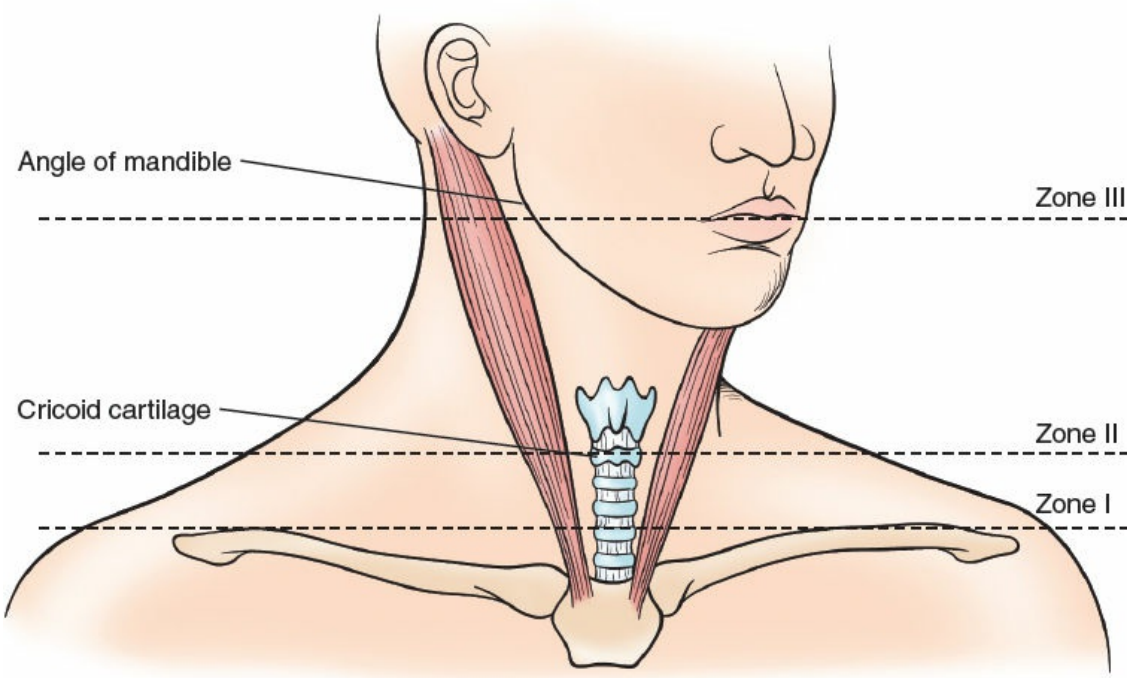

Figure 230.1. Zones of the neck. (Adopted from *Anatomic Exposures in Vascular Surgery*, 2nd ed. Valentine, Wind, LLW Publishing, 2003.)

Penetrating neck injury can be due to direct effect of the projectile resulting in partial or complete vessel transection. Localized effect, such as blast injury, can result in the formation of an intimal flap, dissection, pseudoaneurysm, or arteriovenous (AV) fistula. In 25% to 40% of cases, penetrating trauma results in vessel thrombosis. Of the vascular structures in the neck, the internal jugular vein (95%) and carotid artery (7%) are most often injured.

While penetrating neck trauma is often discussed and written about, the majority of injuries to the neck are caused by blunt force trauma. This can be the result of motor vehicle collision or due to sports-related injury (i.e., clothesline tackle), chiropractic manipulation, blow from the fists or feet, and strangulation.

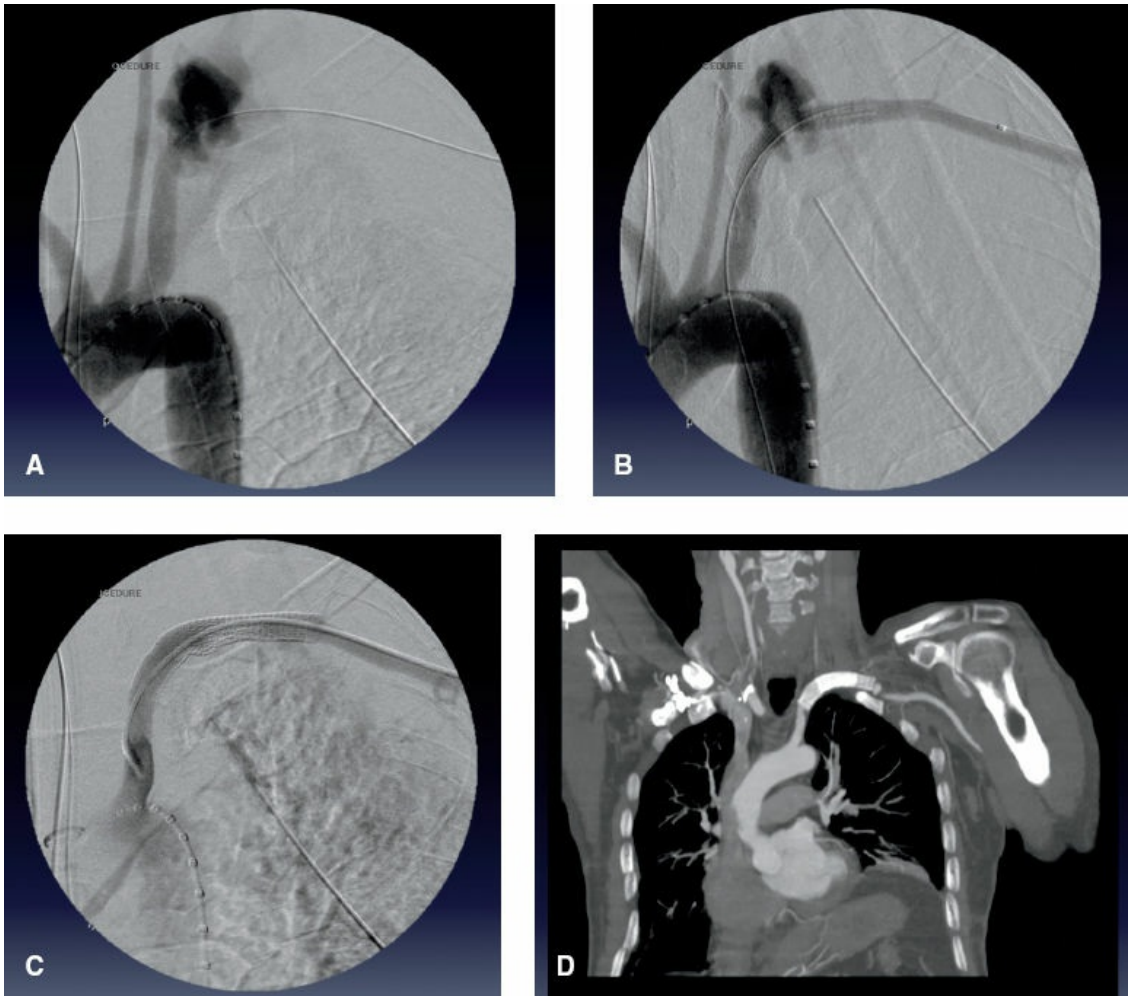

Figure 230.2. (**A**) Initial diagnostic arteriogram showed extravasation from the left subclavian artery secondary to GSW, (**B**) initial placement of a covered stent across the injury, (**C**) completion angiogram demonstrated patency of the subclavian and exclusion of the injury, (**D**) follow-up CT scan at 1 month.

MANAGEMENT—OPERATING ROOM SETUP/HYBRID SETUP

In the past, cervical vascular injury was treated via open surgical approach once the injury was identified. Often, this involved diagnostic imaging in a separate hospital location such as that of a computed tomographic (CT) scanner or the angiographic suite. This paradigm is suboptimal and often prolonged the time to surgical intervention especially in critically ill patients.

With the adoption of endovascular techniques, modern vascular surgeons are able to provide a full range of services to the patient with cervical vascular trauma from diagnosis to surgical intervention.

Furthermore, the adoption of endovascular techniques has allowed most cervical vascular injuries to be treated in a "minimally invasive" manner, thus avoiding the morbidity of a full open exposure and repair (Fig. 230.2).

The modern operating room (OR) needs to be able to function as both an open operating theater and an angiographic suite. This OR needs to be able to allow one to perform a full range of open vascular reconstructions from simple vascular repair to complex aortic reconstruction with the use of cardiopulmonary bypass. At the same time, the use of ceiling-mounted imaging equipment or portable C-arm fluoroscopy enables the surgeon to acquire high-resolution diagnostic imaging of the vascular system and perform life-saving therapeutic interventions.

In the case of cervical trauma, the "hybrid OR" will need to be set up to allow for efficient interactions of all team members involved. Specifically, the anesthesiologist will need to have full access to the patient's airway, as well as one or both upper extremities for invasive hemodynamic monitoring and fluid resuscitation. The OR staff will need adequate space for open surgical trays and endovascular equipment. Finally, the imaging technologist should be able to maneuver the ceiling-mounted or portable imaging equipment with ease and with full access to all the required regions for endovascular intervention.

MANAGEMENT—ZONE I PENETRATING INJURY

Patients presenting with hard signs of arterial injury at the base of the neck should be considered for immediate surgical exploration (Table 230.1). In stable patients, diagnostic studies are usually indicated first to fully define the location and extent of associated vascular injuries. Ultrasound has a limited role in the evaluation of vascular structures in this location due to depth of the vascular structures and the overlying rib cage. Arteriography has been considered to be the gold standard for the diagnosis of vascular injuries in this region. Recently, dynamic contrast-enhanced CT angiography (CTA) has been used with anatomic resolution and accuracy equivalent to that of traditional arteriography. CTA is rapid and allows for identification of associated injuries to the surrounding aerodigestive structures.

TABLE 230.1 Clinical Indications Suggestive of Blunt Cerebrovascular Injury

Open Surgical Approach

Penetrating injury to zone I can result in massive blood loss from injury to the subclavian vessels, brachiocephalic vessels, or proximal portion of the carotids. Rapid control has traditionally been performed via a sternotomy with or without cervical extension.

Vascular injury in zone I usually involves the named arterial vessel's origin, as well as surrounding neurovascular structures. The first structure seen upon entering the mediastinum is the brachiocephalic vein. With superior and inferior retraction, one can visualize the aortic arch. From this exposure, the origins of the innominate artery, the left common carotid artery, and the left subclavian artery can be controlled, usually with vessel loops. Care is taken to identify and protect the left recurrent laryngeal and vagus nerve prior to application of vascular clamps. Partial side-biting clamps can allow for control of the great vessel origin without the need for complete aortic occlusion.

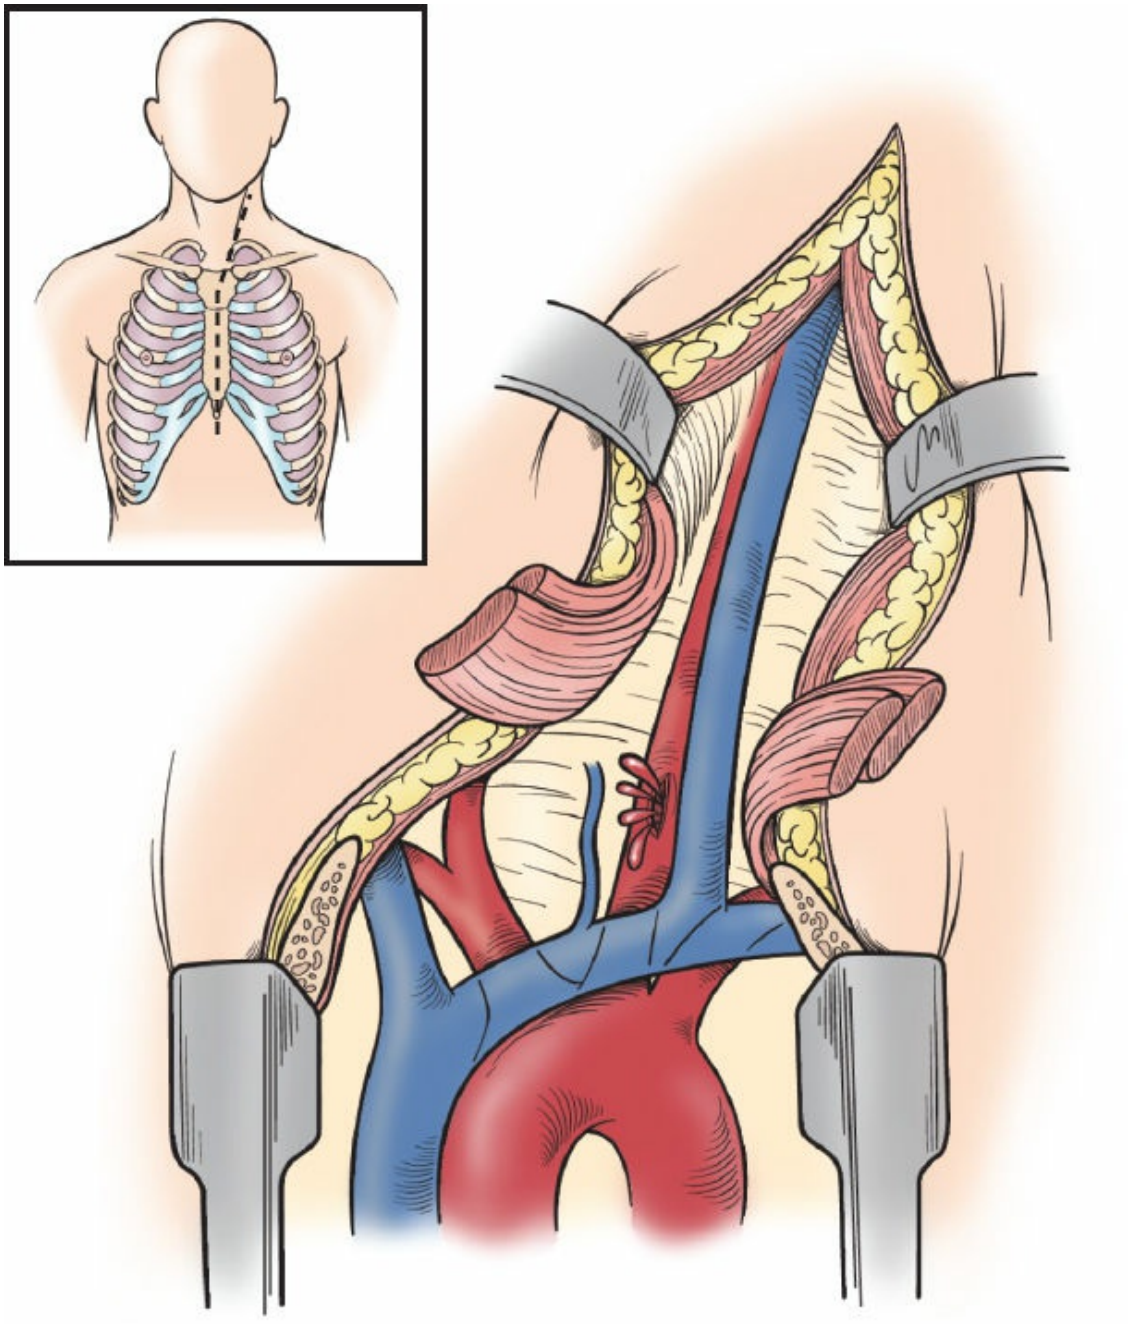

Figure 230.3. Sternotomy with neck extension for control of carotid injury.

Once vascular control has been obtained, primary repair of the injured vessel can be performed. Often, this will require segmental resection to remove the devitalized vessel wall followed by an interposition bypass. Because of the large caliber and flow associated with the vessels in this location, prosthetic conduits are appropriate. Alternatively, panel or spiral grafts can be constructed by using a long segment of saphenous vein incised longitudinally and wrapped around a chest tube of correlating size

and sutured together.

While the origin of the left common carotid artery can be seen through a midline sternotomy, distal control of this artery can be accomplished through oblique extension of the vertical sternotomy incision based on the anterior border of the sternocleidomastoid muscle (SCM) as one traverses toward the cervical region (Fig. 230.3). The carotid sheath is located just underneath the anterior border of the SCM. Once the sheath of connective tissues is divided, one can assess the injury and determine the best plan for operative repair.

The origin of the innominate artery is also often injured in zone I. Usually, surgical repair involves ligation of the origin with a bypass graft based off the ascending aorta. This can be done with partial side-biting clamps and does not require full cardiopulmonary bypass (Fig. 230.4).

In a strictly open approach, the patient should be positioned as shown in Figure 230.5, with both arms tucked. The bilateral neck, entire chest, abdomen, bilateral groin, and upper thighs should be prepped into the field. This allows for extension of the sternotomy to the neck, laparotomy, proximal saphenous vein harvest, as well as femoral cannulation for fluid resuscitation or cardiopulmonary bypass if needed.

A difficult and vexing problem is that of the proximal left subclavian artery. Because of its anterior to posterior course in zone I, the best surgical exposure of this vessel involves both a sternotomy for proximal control and a high anterolateral thoracotomy to gain access to the more distal portion. In this situation, the combination of both endovascular and open surgical techniques can be employed to obtain vascular control and perform the necessary open surgical repair. The patient should be taken directly to the hybrid OR where a diagnostic arteriogram can be performed to define the exact nature of the injury. Subsequent to that, the vascular surgeon can deploy a compliant occlusion balloon for temporizing vascular control via a retrograde femoral approach. With hemorrhage control achieved with the occlusion balloon, a sternotomy is completed and the left subclavian artery exposed, the balloon replaced with a vascular clamp, and the injury repaired or ligated.

In this scenario, the arrangement shown in Figure 230.6 allows the surgical team to perform the initial diagnostic imaging as well as place an occlusion balloon from the femoral artery to obtain vascular control. Once this has been completed, the imaging equipment can be pulled back and the case converted to a routine open procedure.

In zone I, endovascular treatment of penetrating subclavian and axillary arterial injury is extremely attractive as surgical exposure often requires multiple incisions as described above. Vascular control of the injured subclavian artery may be carried out using compliant occlusion balloons inserted from the femoral or retrograde brachial approach. Once balloon vascular control is successful, one can contemplate using a covered stent graft for repair (Fig. 230.2). The stent can easily be delivered via a retrograde brachial approach. In case of vessel transection, a wire may not be able to traverse the hematoma between each end of the vessel. However, the passage of the wire can be overcome by employing wires from both the groin and arm with snaring of the two wires to create a brachio-femoral “through and through” technique.

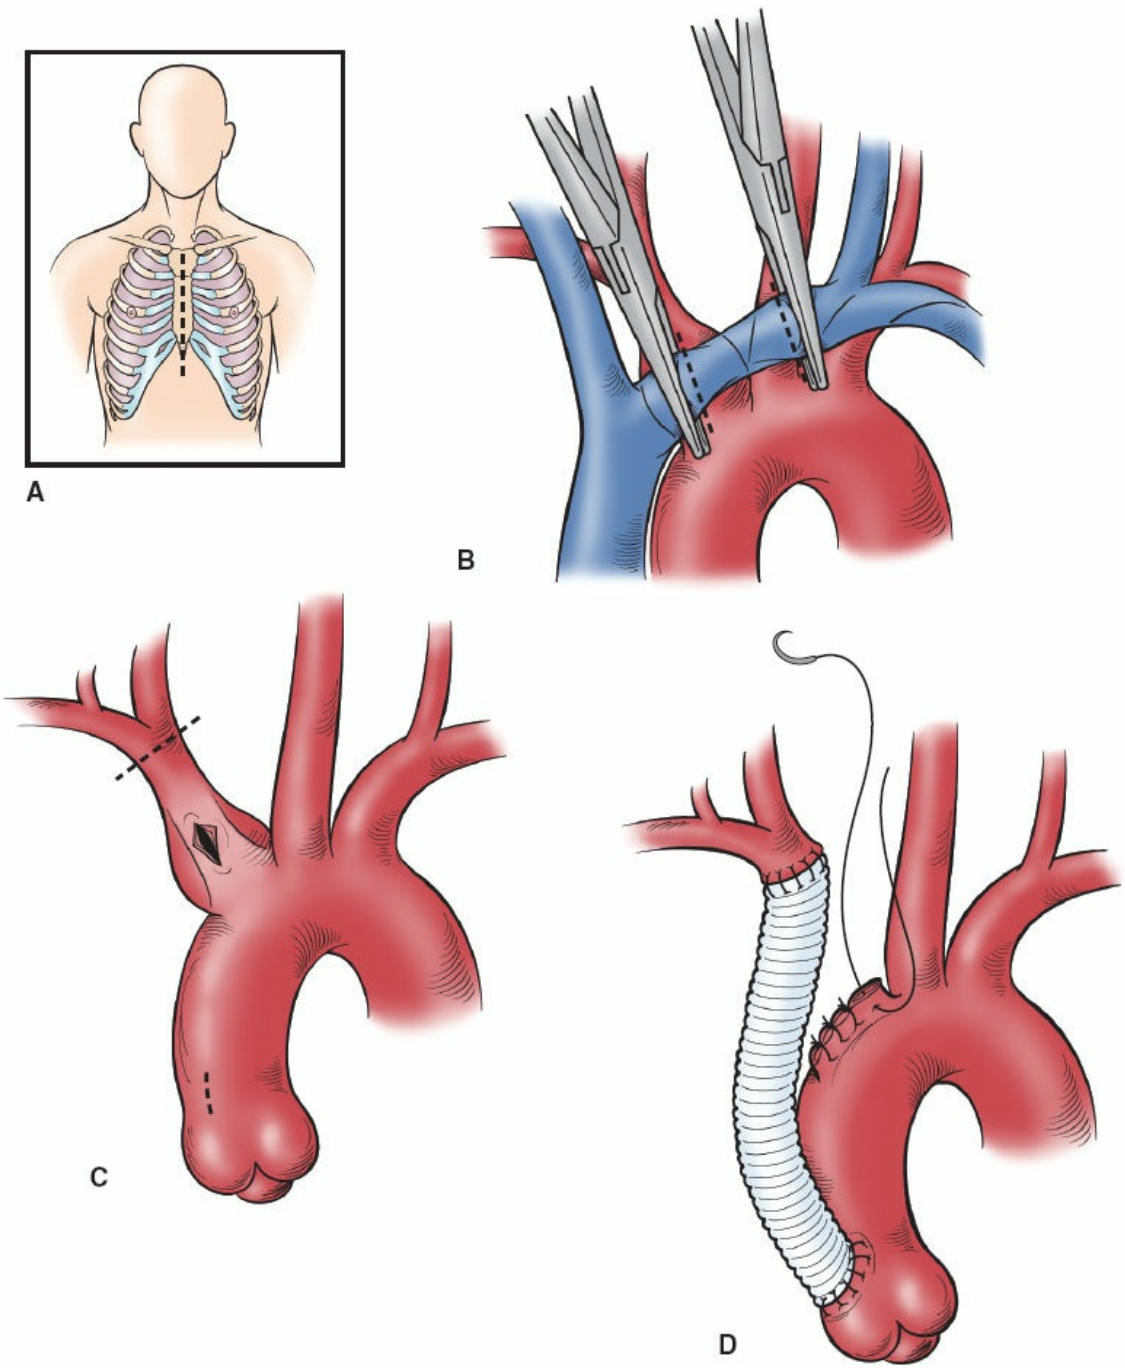

Figure 230.4. Innominate artery repair via sternotomy with interposition graft from the ascending aorta.

In this scenario, the room arrangement adds an arm table to allow for access to the brachial artery (Fig. 230.7). Typically, the brachial artery is surgically exposed. This allows for use of larger vascular sheaths, typically 9 to 11 Fr, to deliver a covered stent in a retrograde manner.

Venous injury in zone I to both the brachiocephalic and internal jugular can be ligated without major consequences.

MANAGEMENT—ZONE II PENETRATING INJURY

Vascular structures in zone II are easily accessible through standard open surgical exposures. In addition, zone II injuries comprise the majority of penetrating trauma to the neck. Those patients with hard signs require immediate exploration. The dilemma is what to do with those patients who are stable or semistable without hard signs of vascular injury. The pendulum has swung from nonoperative management alone, nonoperative management with careful imaging, selective exploration based on physical examination with or without imaging to routine exploration.

In the past, mandatory exploration for all wounds penetrating the platysma was the accepted practice regardless of the presence or absence of hard signs of vascular injury. This approach resulted in a rate of missed injury of only 1% to 2%. However, complications associated with negative exploration can be severe due to inadvertent cranial nerve injury, bleeding, and delay in the treatment of associated injuries. With the widespread use of arteriography, patients without hard signs were being managed by imaging alone with exploration reserved for those with positive findings on angiography.

In the 1990s, Demetriades championed careful physical examination and color flow Doppler imaging in stable patients. Others have advocated physical examination alone with serial observation and no imaging tests. This approach resulted in a missed rate of 0.6% and is no different than other management algorithms.

If one decides on surgical exploration, the patient is prepared similarly as in an elective carotid endarterectomy with the patient supine and the neck hyperextended in a semi-Fowler position. The groin can be prepped in case the greater saphenous vein (GSV) is needed for patch repair or bypass. The carotid artery is best exposed through an oblique cervical incision based on the anterior border of the SCM. The anatomical landmark that guides the surgeon toward the carotid bifurcation is the crossing facial vein. This can be routinely ligated to allow full access to the carotid bifurcation. Often, the external carotid artery will have several branches that will need individual control with vessel loops.

Limited injury can be primarily repaired with interrupted lateral sutures. In most cases, a patch or interposition graft will be required after one has debrided all devitalized tissue. Unlike zone I injury, the GSV is the conduit of choice rather than prosthetic materials. Care is taken to identify intimal flaps, which should be tacked down by incorporation it into the vascular

repair. Useful adjunctive techniques include transposition of the external carotid artery to replace the injured internal carotid artery (ICA) (Fig. 230.8). The injured external carotid artery is usually ligated.

Controversy abounds regarding whether or not one should ligate or repair carotid injury. Careful preoperative neurologic evaluation is critical if the situation permits. If the patient is neurologically intact, then repair or interposition bypass should be carried out. If one needs to clamp the carotid, consideration should be made for carotid shunting. In the Vietnam War, carotid artery repair was carried out safely without use of vascular shunts for up to 60 minutes. Unfortunately, a similar experience with civilian trauma has not been reported. As such, placement of an arterial shunt should be left to individual surgeon preference with critical stump pressure of <50 mm Hg as the cutoff for shunt placement.

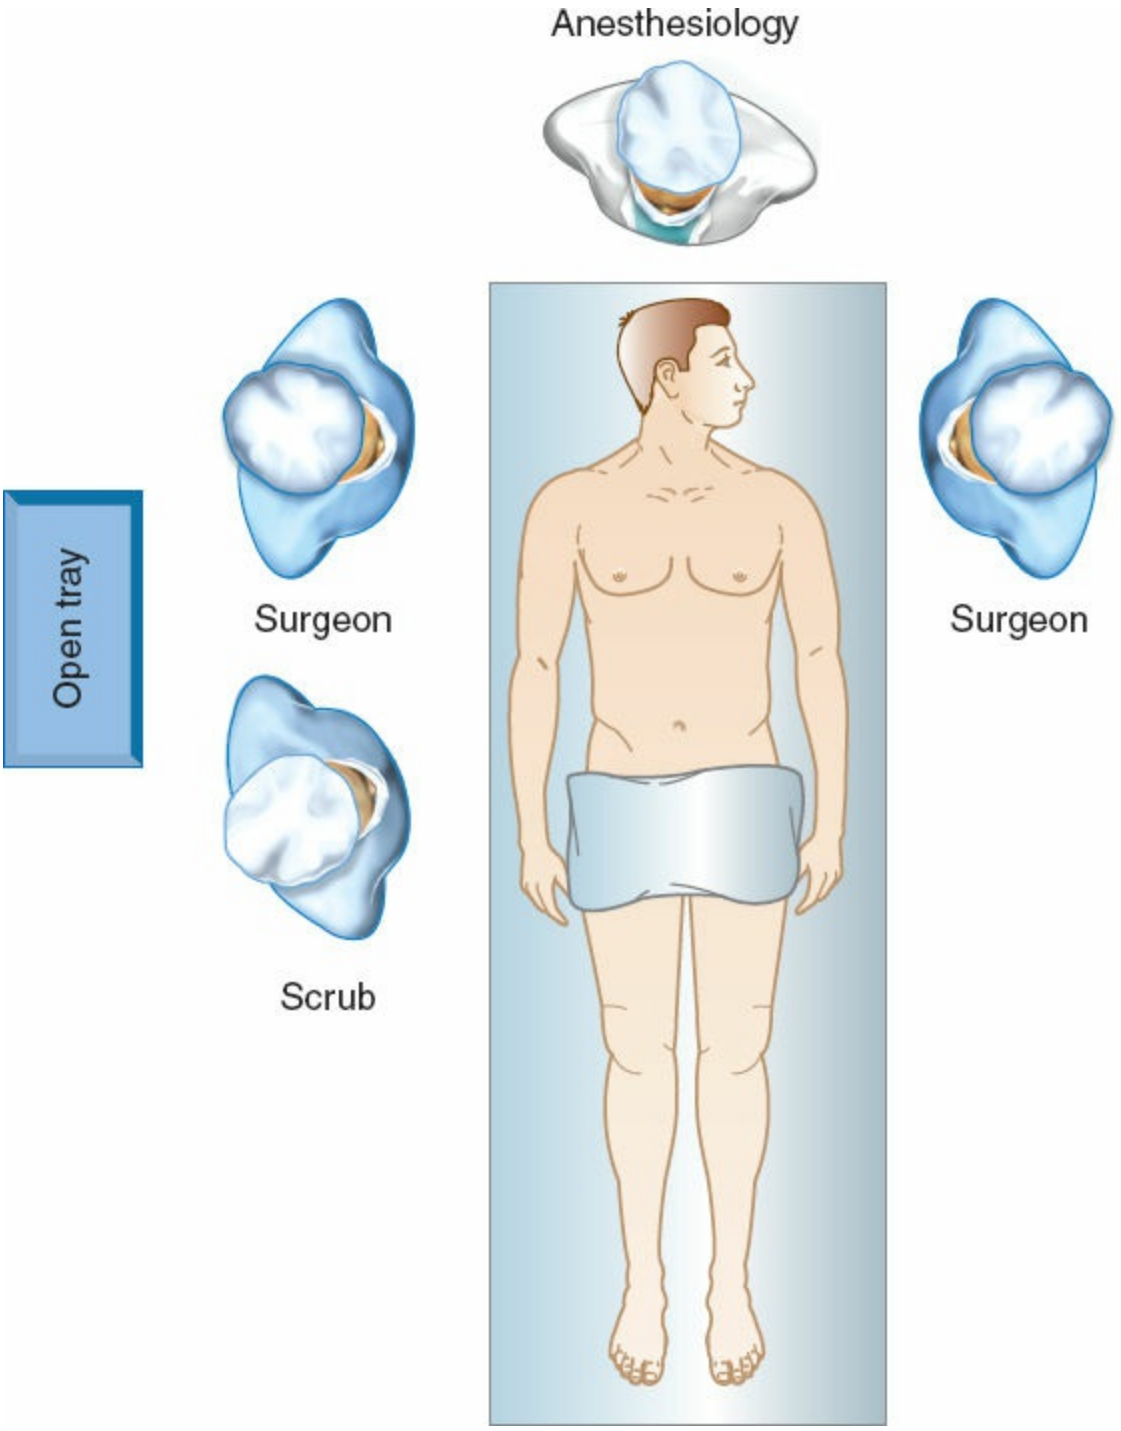

Figure 230.5. Standard room arrangement and patient positioning for an open approach.

MANAGEMENT—ZONE III PENETRATING INJURY

In this region, the distal ICA traverses behind the mandible. As such, surgical exposure is difficult and bleeding can be massive. The unstable, actively hemorrhaging patient should be taken directly to the OR where attempts at direct repair of the ICA can be carried out. In order to gain

adequate visualization of the distal ICA, the oblique cervical incision is extended superiorly toward the posterior aspect of the ear. The posterior belly of the digastric muscle is divided. The vagus, hypoglossal, and glossopharyngeal nerves are carefully identified as they often are closely associated in this region. Useful techniques to improve surgical exposure include anterior mandibular subluxation, osteotomy of the mandibular ramus, and use of a 3-Fr Fogarty balloon catheter for distal control. While often discussed, mandibular manipulation only allows a few more centimeters of distal exposure. Based on the surgeon's experience and comfort with skull-based exposure, the use of a craniofacial specialist can be extremely useful. There have been case reports of cervical ICA to petrous ICA vein bypass in patients with inadequate cross-over cerebral circulation.

If possible, simple direct repair is carried out. Interposition bypass is difficult if not impossible due to lack of adequate visualization of the distal vessel as it enters the base of the skull. In this situation, carotid ligation should be considered even though it is associated with significant stroke risk.

The use of endovascular techniques to access the ICA for balloon tamponade of life-threatening hemorrhage can be much quicker than that of an attempt at surgical exposure. Furthermore, placement of a covered stent can provide for definitive treatment without the morbidity associated with a difficult skull-based exposure.

Thankfully, zone III penetrating vascular injury is uncommon likely due to the protective nature of the overlying mandible. With either direct surgical exposure or an endovascular approach, the threshold for ligation/embolization should be low due to difficulty with surgical access in this region and the lethal consequences of massive hemorrhage.

In the stable patient, zone III penetrating injuries are managed expectantly with imaging such as contrast-enhanced dynamic CTA or arteriography. One often discovers pseudoaneurysm or an AV fistulae formation in these patients. Endovascular treatments of these lesions with self-expanding covered stents carry low morbidity and mortality risk. Other injuries such as intimal flaps can be managed with antiplatelet agents. Over time, most of these lesions heal, but careful imaging follow-up will be required.

MANAGEMENT—BLUNT VASCULAR INJURY

Blunt injuries to the cervical vessels are usually due to motor vehicle crashes (MVC). Other more unusual etiologies include sports-related injuries (the clothes line tackle), strangulation, and aggressive cervical manipulation, such as that of chiropractic treatment.

Unlike penetrating trauma where patients usually present in extremis with active hemorrhage, patients with blunt injury are often stable and asymptomatic. The involved vessel typically sustained an intimal tear that can lead to dissection, distal embolization, pseudoaneurysm formation, thrombosis, or even active extravasation from complete vessel transection.

Because of the benign nature of the initial presentation, the diagnosis of blunt cervical vascular injury can be difficult to uncover as up to 80% of patients are asymptomatic. There is typically a latent period, usually >12 hours, between the time of injury and when the appearance of clinical manifestations is usually seen. Thus, screening for blunt injuries during this time window allows for effective therapy to be initiated and can reduce the rate of permanent neurologic deficits from 21% down to as low as 0.5%.

Imaging modalities, such as CTA, MR angiography, and duplex ultrasonography can all be used in the screening of the trauma patients with suspicion for blunt cerebrovascular injury. Of these, fine-cut CTA (≥16 slices) is the most reliable modality with arteriography reserved for those cases where the CTA is normal but a strong clinical suspicion for injury still exists. By using screening guidelines, especially for those patients who are asymptomatic, blunt cerebrovascular injury can be detected in up to 34% of screened patients (Table 230.2).

The majority of blunt vascular injury occurs at the base of the skull in zone III due to the force exerted on the ICA as it enters the skull base. Typically, the pattern of injury includes intimal flap formation, nonocclusive and occlusive dissection, and vessel thrombosis (Table 230.3). Embolization can occur and can lead to severe neurologic morbidity. The mainstay of treatment of these lesions usually involves anticoagulation. In Fabian's experience, heparin is the single variable independently associated with improved neurologic outcomes. Transcranial Dopplers (TCDs) have been valuable in the detection of cerebral emboli and follow-up of anticoagulation therapy. However, some of these patients are not candidates for anticoagulant therapy due to concomitant injuries. In these instances, there may be a role for endovascular stents to "tack down" the intimal flap and prevent further

embolization.

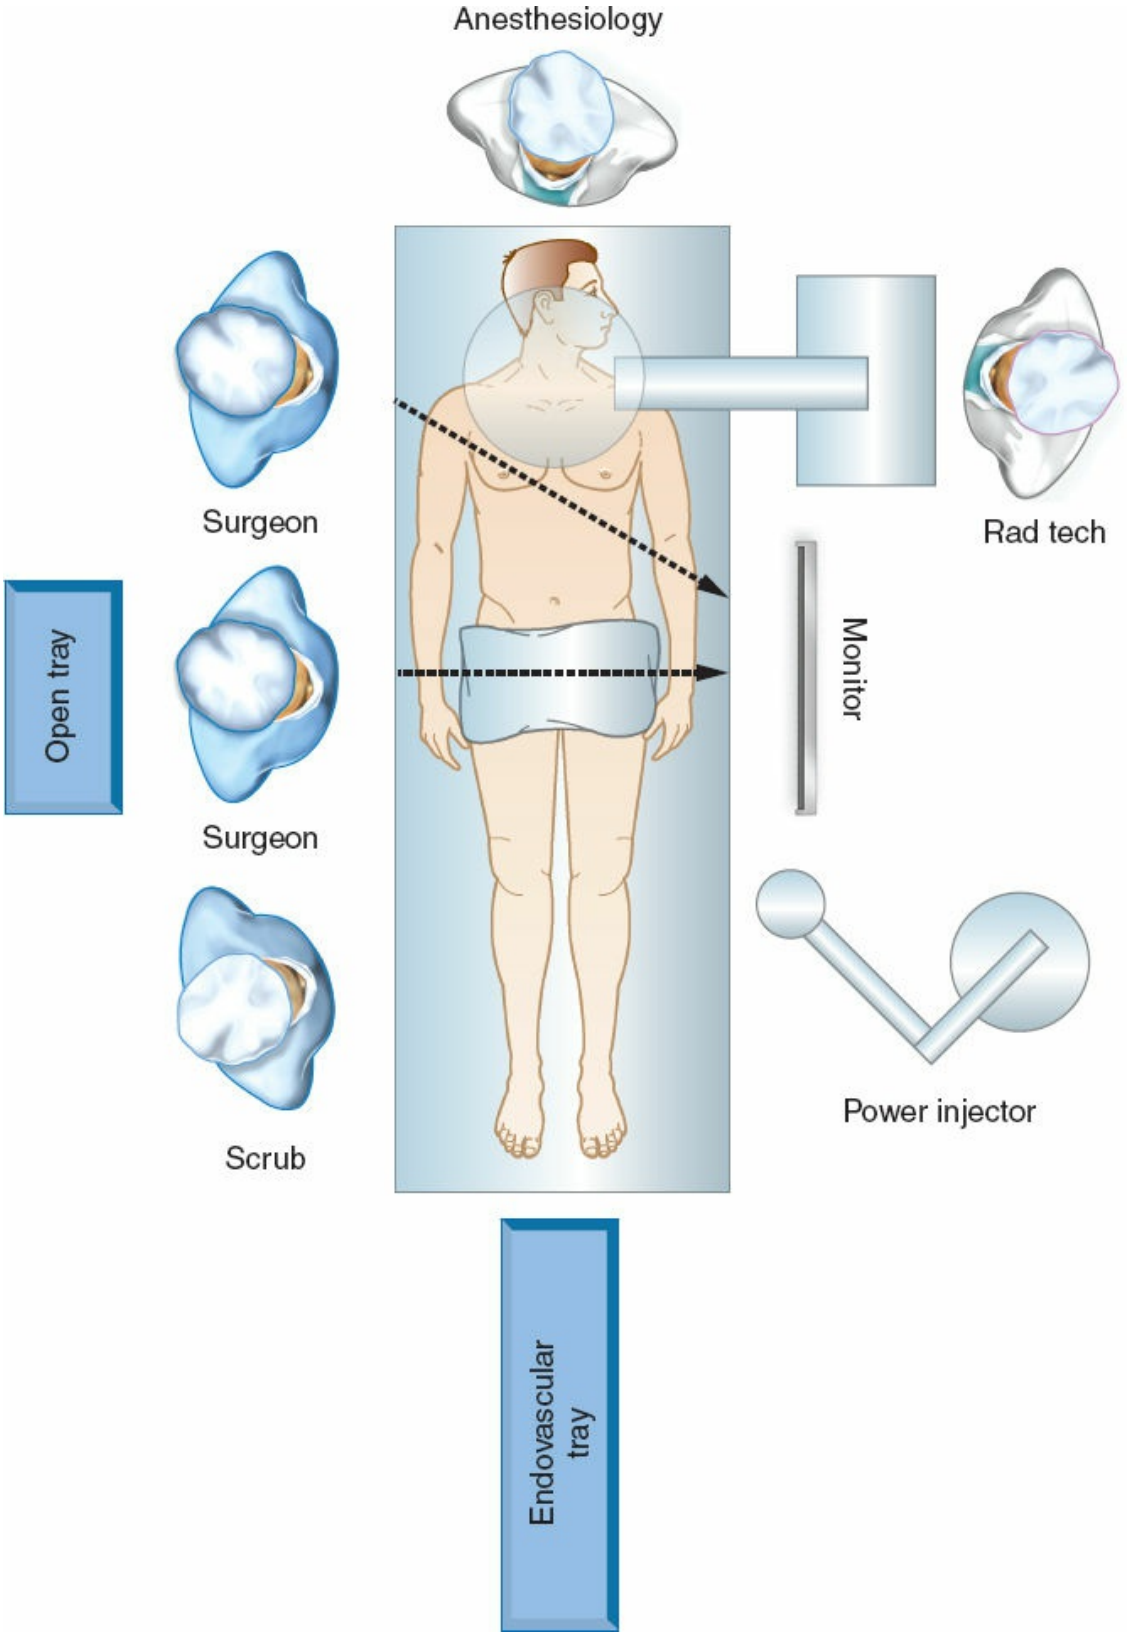

Figure 230.6. Remotely placed occlusion balloon from a femoral approach.

In follow-up studies, most injuries are noted to heal on their own. Of

those requiring intervention, the location of the injured internal carotid in zone III makes open surgical approach a challenge even for the experienced surgeon. Maneuvers described under the previous penetrating carotid injury section can be used. Often, this will lead to limited exposure. As such, endovascular treatment is extremely attractive in this region. Intimal dissection flaps can be tacked down with self-expanding stents delivered percutaneously from the groin. In cases where a pseudoaneurysm develops, multiple authors have reported successful exclusion with bare metal stents. Usually, coverage of the origin of the pseudoaneurysm is sufficient to cause its thrombosis. If not, coil embolization of the pseudoaneurysm can be performed through the interstices of the stents.

VERTEBRAL ARTERY TRAUMA

The incidence of vertebral artery trauma is extremely small, making up only 5% of cervical vascular trauma, with over 95% due to penetrating missile wounds. Blunt trauma is usually the result of a MVC. Injury can occur at any level with zone I being the most common followed by zone III.

TABLE 230.2 Risk Factor for Blunt Cerebrovascular Injury (BCVI)

Displaced mid-face fracture (LeFort II or III) Mandible fracture Basilar skull fracture Occipital condyle fracture Severe traumatic brain injury (TBI) with GCS <6 Cervical spine fracture, subluxation or ligamentous injury at any level Near hanging with anoxic brain injury Clothesline type injury or seat belt abrasion with significant swelling, pain, or altered MS Scalp degloving Major thoracic vascular injury Blunt cardiac injury Upper rib fractures

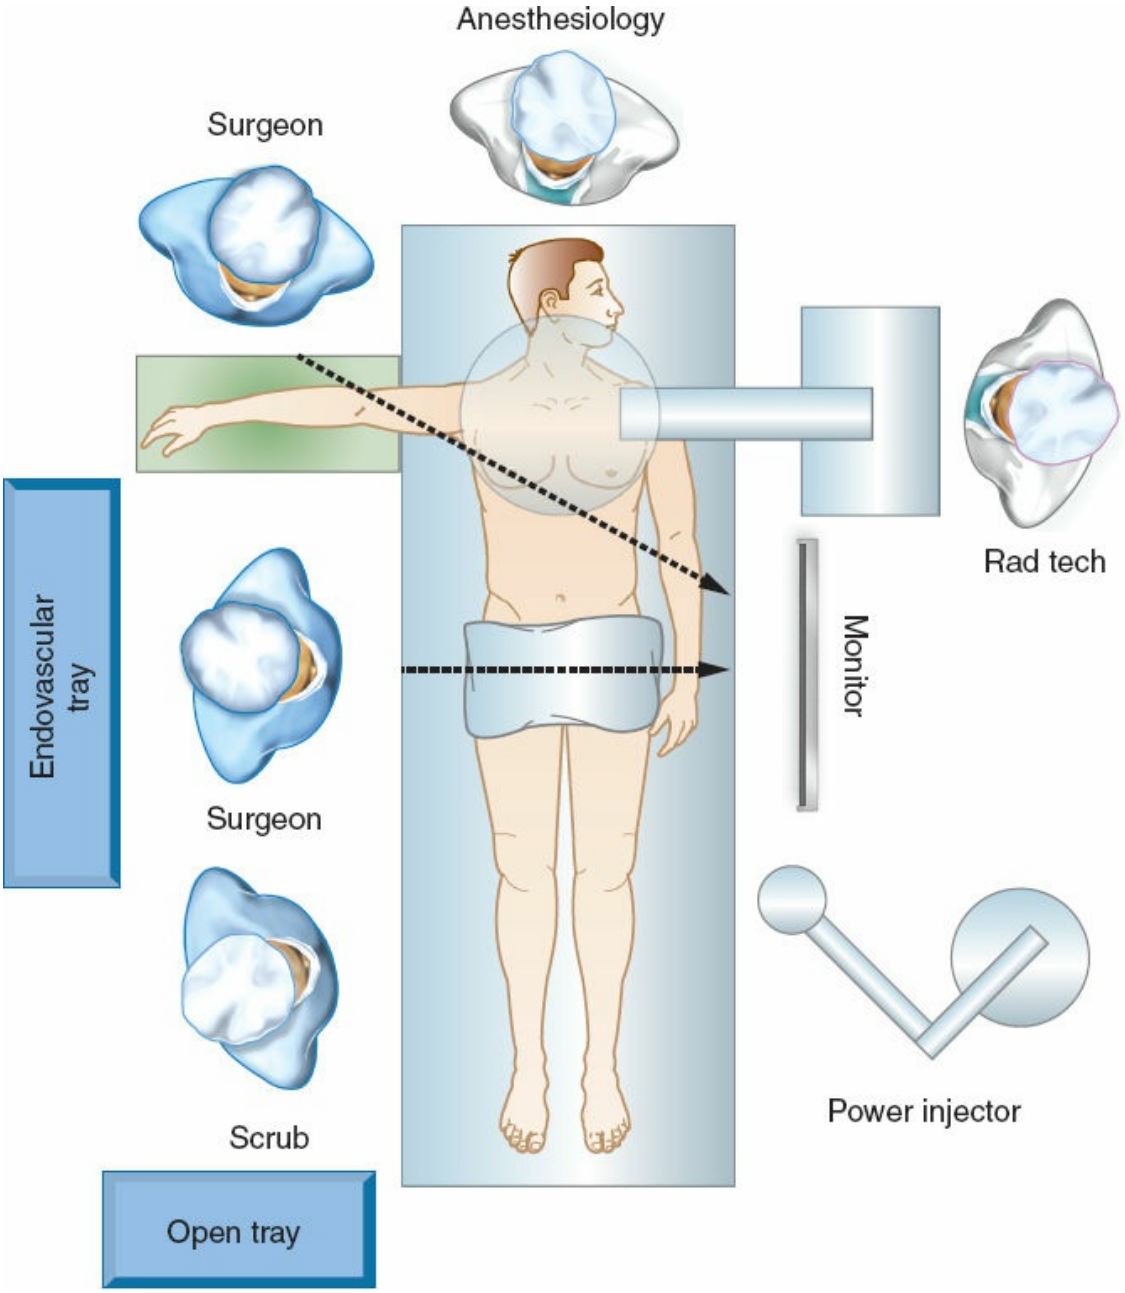

Figure 230.7. Combined endovascular and open approach for repair of subclavian/axillary artery injury.

Anatomically, the vertebral artery is the first branch vessel originating from the subclavian artery. It enters the transverse foramen of the cervical vertebral body at C6 and exits at C2. The two vertebral arteries join together to form the basilar artery at the base of the skull. Generally, one of the vertebral arteries can be ligated without significant consequences. However, in about 15% of cases, the contralateral vertebral artery is small and hypoplastic. In these cases, every attempt should be made to preserve flow in order to avoid a posterior circulation stroke.

Seventy-five percent of patients with vertebral artery injury will not exhibit any overt clinical sign. This is due to the redundancy of the paired vertebral arteries in that flow is needed only through one to maintain flow to the basilar and the posterior cerebral circulation. As such, a high index of suspicion for diagnosis is warranted. Certainly, clinical evidence of vertebral artery injury can manifest as high cervical quadriplegia, Horner syndrome, ataxia, cranial deficit, and respiratory failure to name a few. Proximity to the path of the penetrating missile indicates the need for further workup. Similarly, associated injuries to the cervical spine in the region should raise the index of suspicion for blunt vertebral artery trauma. While four-vessel arteriography was used exclusively in the past, most modern trauma centers now use CTA to work up vertebral artery injury with high degree of specificity and sensitivity. Because of the overlying bony structures, ultrasonography has limited utility in this region.

Once the injury has been identified, the method of treatment is dependent on several factors, such as the nature of the injury (active extravasation, intimal flap, dissection, or thrombosis). As mentioned previously, the clinical status of the patient and the quality of the contralateral vertebral artery are important discriminators.

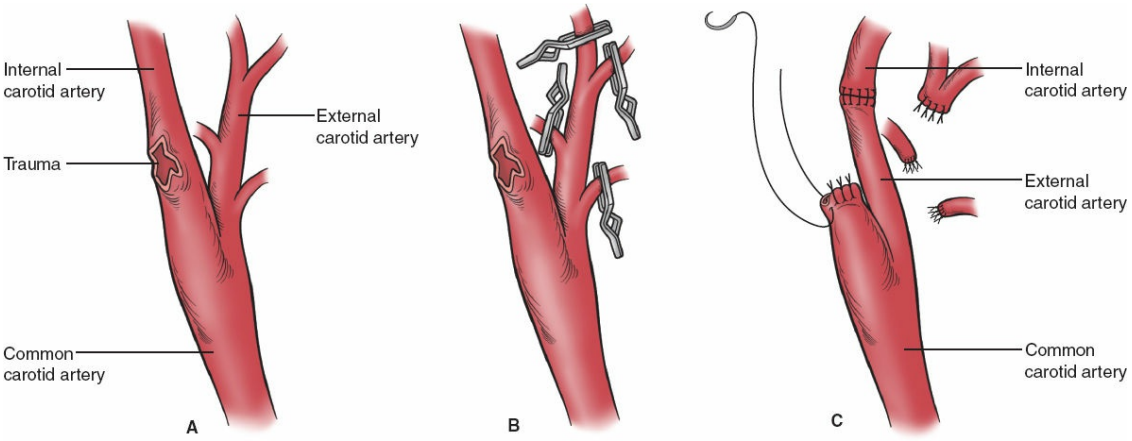

Figure 230.8. Transposition of the external carotid in order to replace the injured proximal segment. The distal ends of the external carotid can usually be ligated.

Active bleeding from the vertebral artery in zone I can be treated with surgical ligation or endovascular embolization. Surgical exposure of the vertebral artery in zone I can be done through the same oblique cervical incision for exposure of the carotid artery. In this situation, the carotid sheath is retracted medially and the anterior scalene is retracted laterally to

exposure the vertebral artery. It can then simply be ligated or an interposition vein bypass performed if patency is required. For endovascular embolization, both proximal and distal ends of the artery should be treated to prevent hemorrhage from backbleeding distally.

Injury to zone II or III can be a challenge due to the difficulty associated with exposure of the vertebral artery in this location. Even in the hands of the most experienced surgeon, the procedure is extremely difficult due to the urgent nature of the case.

If required, the vertebral artery can be approached via an oblique incision, which is carried posteriorly to the ear. Typically, the carotid sheath is retracted medially and the SCM laterally (Henry procedure), or both are retracted medially (modified Henry procedure). In these approaches, the surgeon will see the longus colli muscle as a guide. Dissection deep to this muscle will expose the prevertebral muscles and sympathetic chain. Often, brisk bleeding will be encountered at this point. The most expedient method of hemorrhage control is by placing vascular clips directly on the vertebral artery. Care must be taken to not traverse posteriorly as the neural cervical roots are directly behind the vascular structures.

In zone II and III vertebral artery trauma, application of endovascular technology has been extremely helpful due to difficulty with surgical exposure. Percutaneous vertebral artery embolization (both proximal and distal) can halt nearly all hemorrhage. Others have described endovascular techniques used to treat posttraumatic AV fistula in this region with great success.

Overall, the mortality associated with vertebral artery trauma ranges from 10% to 25%. While actual mortality can be attributed to the injured vertebral artery in <5% of patients, the overall cause of mortality in these cases is due to associated injuries of which the most common is neurologic.

SUMMARY

While rare, the presence of cervical vascular trauma can result in early death from exsanguinating hemorrhage. Late morbidity is usually the result of associated injury to surrounding structures or cerebral infarct. Expedient workup and rapid control of vascular structures is critical. In the stable patient, a detailed assessment and protocol-driven workup can successfully identify and manage most injuries. The role of endovascular

techniques has been expanded in recent years in the treatment of these injuries. Specifically, the application of remote balloon occlusion for proximal control of hemorrhage and subsequent repair with covered stents can result in improved outcomes especially in surgically difficult access areas, such as zone I and III. The surgeon managing these trauma patients should be adept at employing both open and endovascular techniques in the management of cervical vascular injuries. Similarly, the modern OR should be of a hybrid design to allow the full range of therapy from simple diagnostic arteriography to full cardiopulmonary bypass.

EDITOR'S COMMENT

The management of vascular injuries to the neck represents a nice combination of anatomic lessons learned from the past combined with the use of modern endovascular techniques to provide the patient with the best outcome. I was struck by the complexity of injuries affecting so many systems while reviewing this excellent chapter written by Dr. Tran. In addition to most of the vascular injuries now being managed by endovascular means, it is becoming apparent that imaging has gotten so much better such that many patients even with penetrating neck injuries (PNI) can be managed with selective nonoperative management (SNOM). In a large review from a South African trauma service, 510 trauma patients with 452 stab wounds (SW) and 58 gunshot wounds (GSW) were reviewed (Madsen AS, Laing GL, Bruce JL, et al. An audit of penetrating neck injuries in a South African trauma service. *Injury* 2016;47(1):64–9). Injuries occurred to the airway (6%), pharyngo-esophageal area (8%), and vasculature (17%). Of the total, 76% underwent CTA. Of the 70 patients with a suspected vascular injury, catheter-directed therapy confirmed injury in only half the patients. A total of 401 (79%) patients were managed conservatively for PNI, while 109 (21%) were managed with either surgery or endovascular means. Importantly, only 5 patients (1.2%) failed SNOM and required further surgery with no deaths attributed to failure of SNOM. The authors concluded (as do I), that SNOM of PNI is safe and appropriate management strategy even in penetrating neck trauma. Furthermore, the authors suggested that CTA had a pretty significant false positive rate and suggested that clinical assessment remains one of the cornerstones of management of these complex, often multitrauma patients.

Little has really changed in that we still use the same anatomic levels described in 1969 to assess which anatomic structures are most likely to be injured. In contrast, what has evolved is the operative/interventional algorithm that is used in these patients. For example, it appears that the patient with a

knife injury in zone II may safely not undergo emergency surgical exploration of the carotid sheath if an ultrasound or CTA is not suggestive of an injury to the carotid artery or internal jugular vein. I would add that CTA is often used as well to exclude injury to these vessels. A recent study over a 4-year period suggested that even in the presence of clinical hard signs in zone II, CTA in addition to the Western Trauma association (WTA) algorithm significantly decreased the rate of negative neck exploration without a significant increase in the rate of missed injuries (Schroll R, Fontenot T, Lipcsey M, et al. Role of computed tomography angiography in the management of Zone II penetrating neck trauma in patients with clinical hard signs. *J Trauma Acute Care Surg* 2015;79[6]:943–50). In this study of 183 zone II neck traumas, the use of CTA prevented 17 unnecessary neck explorations. The authors called for a prospective study of CTA in addition to the WTA algorithm in zone II PNI.

I would add that one of the things I think that has changed in the management of neck trauma is the management of carotid and vertebral dissections (not of course based on any good literature). When I typed in vertebral artery dissection and trauma into Pubmed.gov, I retrieved 1,668 pieces of literature. Almost all of them are single case reports of a dissection associated with some sort of manipulation. The issues for me are do these need to be anticoagulated or is aspirin adequate, and then do we really need to aggressively treat vertebral artery dissections or pseudoaneurysms. My treatment algorithm has moved toward only anti-platelet therapy and to just follow up these other injuries unless clinically indicated. The same is also true of carotid dissections I think, but they seem to be more symptomatic more often. A large experience by Dr. Greer and coauthors examined vertebral artery injuries (VAI) in a single military institution (Greer LT, Kuehn RB, Gillespie DL, et al. Contemporary management of combat-related vertebral artery injuries. *J Trauma Acute Care Surg* 2013;74(3):818–24). The authors concluded that VAI are infrequent in modern combat and only occur in 3% of casualties. Most of these injuries are discovered incidentally during the secondary evaluation at higher echelons of care. These injuries should be suspected in patients with cervical spine fractures. Like most neck trauma, they recommended treatment with endovascular coils or covered stents if needed.

Gilbert Upchurch

231 Injury to the Abdomen: Open and Endovascular

Dennis Y. Kim and Matthew C. Koopmann

INTRODUCTION

Abdominal vascular injuries are potentially devastating injuries associated with significant morbidity and mortality. The vast majority of these injuries occur following a penetrating mechanism of injury, particularly gunshot wounds (GSWs), and are more commonly encountered in urban civilian versus military settings. Abdominal vascular injuries may occur in up to 10% of patients with abdominal stab wounds and 25% of patients with GSWs. Major abdominal vascular injuries rarely occur in isolation as one third of patients will also have a hollow or solid visceral organ injury. Although the incidence of concomitant vascular injuries varies, combined arterial and venous injuries are the most common.

Because of the overall rarity of abdominal vascular injuries, experience in managing these challenging and life-threatening injuries may be limited. In addition, patients with these injuries often present “in extremis” with minimal physiologic reserve. Surgical access, as well as exposure of the involved retroperitoneal vasculature, may also prove difficult. Therefore, it is incumbent upon surgeons to have an organized and systematic approach to the identification and management of these injuries. Application of damage control surgery techniques, in conjunction with modern hemostatic resuscitation principles, is critical to successful patient outcomes.

ANATOMY AND PATHOPHYSIOLOGY

Abdominal vascular injuries occur as a result of injury to named retroperitoneal, visceral, or mesenteric vessels. The finding of a retroperitoneal hematoma or free hemorrhage originating from the retroperitoneum is consistent with a major abdominal vascular injury. Anatomically, the retroperitoneum is divided into three zones (Fig. 231.1). These zones, in combination with the mechanism of injury, dictate the

surgical approach at the time of laparotomy and should alert surgeons to the potentially injured vessels (Table 231.1).

Zone I extends from the aortic hiatus to the sacral promontory in the midline anterior to the spinal column. Zone I is further divided by the transverse mesocolon into *supramesocolic* and *inframesocolic* regions. The finding of hemorrhage or hematoma in Zone I supramesocolic is consistent with injury to the suprarenal abdominal aorta, celiac and proximal superior mesenteric arteries (SMA), and proximal renal arteries. Venous structures include the suprarenal inferior vena cava (IVC) and proximal superior mesenteric vein (SMV). Major vessels found in the inframesocolic region of Zone I include the infarenal abdominal aorta, distal SMA, and inferior mesenteric artery, as well as infrarenal IVC and distal SMV.

Zone II encompasses the upper lateral retroperitoneum along the pericolic gutters on both the right and left sides. Hematoma or hemorrhage in Zone II is indicative of injury to the distal renal arteries, renal veins, or kidneys.

Zone III begins at the sacral promontory and consists of the pelvic retroperitoneum. Injury to the iliac arteries, veins, or both, should be suspected in patients with hematoma or hemorrhage in this area.

Mechanism

Penetrating injuries due to stab wounds or GSWs account for the vast majority of abdominal vascular injuries. Lateral defects occur more commonly than complete transection of vessels. Both partial and complete transections may present as expanding or pulsatile hematomas or free hemorrhage. Blast effect is common following GSWs and may result in intimal dissection or flaps with secondary thrombosis. Pseudoaneurysms and arteriovenous fistulas may also occur following penetrating mechanisms of injury.

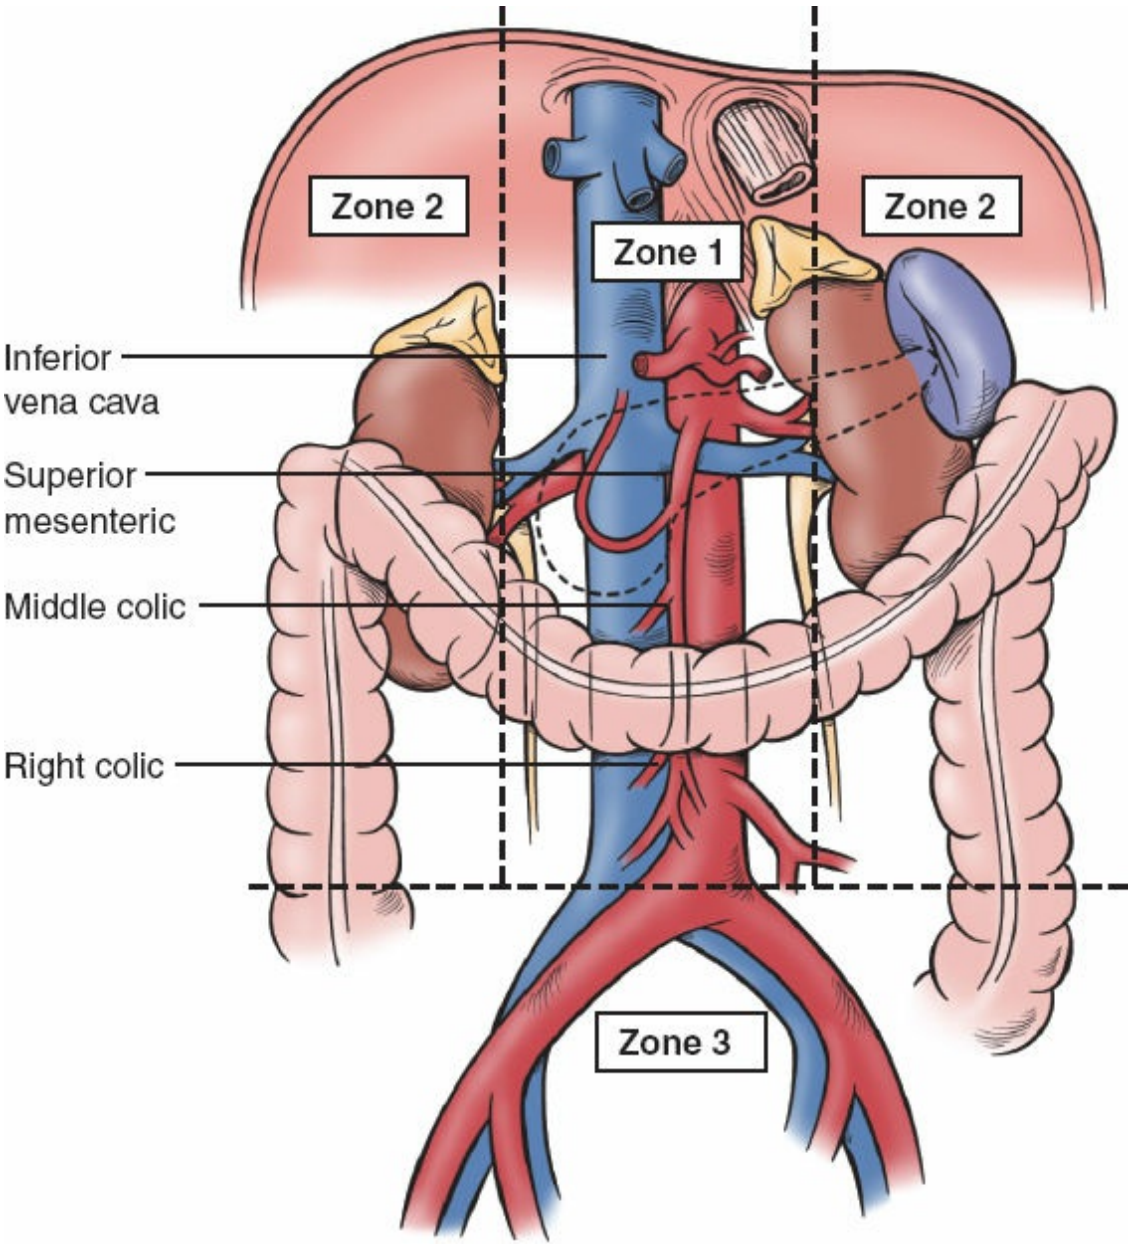

Figure 231.1. Zones of the retroperitoneum.

Blunt mechanisms result in vascular injuries as a result of rapid deceleration, crushing injuries, or direct blows. Deceleration may result in shearing or avulsion of blood vessels with resultant thrombosis or hemorrhage. Avulsion of small branches of major vessels such as the intestinal branches at mesenteric fixation sites may result in thrombosis or pseudoaneurysms. Venous injuries usually occur at the confluence of smaller venous tributaries. Crushing injuries as may occur due to a seatbelt may cause intimal tears or flaps with or without thrombosis. Partial or complete transections may also occur following crushing injuries or direct blows.

CLINICAL PRESENTATION AND DIAGNOSIS

The clinical presentation of patients with abdominal vascular injuries varies based on the nature of injuries sustained. Tachycardia, hypotension, and a narrowed pulse pressure are commonly encountered in patients with abdominal vascular injuries. Responsiveness of these physiologic variables to resuscitative efforts may indicate ongoing bleeding versus the establishment of tamponade or cessation of bleeding. Findings of abdominal distension, tenderness, or generalized peritonitis are dependent on the volume of blood loss and presence of associated injuries. Unilateral absence of a femoral pulse should raise suspicions for an ipsilateral common or external iliac artery injury, particularly among patients with penetrating transpelvic trajectories. Unlike patients presenting with vessel disruption, those with acute traumatic thrombosis may present hemodynamically stable but with abdominal pain and subtle or occult signs of end-organ dysfunction, for example, hematuria in the setting of a blunt renovascular injury.

TABLE 231.1 Operative Management Strategies by Mechanism and Zone of Injury

	Zone I	Zone II	Zone III
Blunt	Explore	Selective	Do not explore
Penetrating	Explore	Explore	Explore

In addition to the history and findings on physical examination, several other diagnostic and adjunctive tests may provide further information regarding the presence and location of an abdominal vascular injury, as well as guide resuscitative and operative planning efforts. Focused assessment with sonography for trauma (FAST) is an accurate and readily available modality for detecting intra-abdominal free fluid as well as associated cardiothoracic injuries, particularly following blunt trauma. Plain film radiographs, with or without radiopaque markers, may be helpful in delineating the trajectory of injury in patients sustaining GSWs.

For patients who present hemodynamically stable without an immediate indication for exploratory laparotomy, contrast-enhanced computed tomography (CT) should be undertaken. Depending upon the findings from physical examination and the initial arterial phase CT, further imaging phases may provide useful information regarding suspected

injuries. Venous and delayed image acquisition may be invaluable in confirming the presence of a blush or other injuries, for example, urinary extravasation in patients with renal injuries.

Although rarely used, diagnostic peritoneal aspiration (DPA) may still play a role in hemodynamically unstable patients presenting with a blunt pelvic fracture and a negative or equivocal FAST examination. Aspiration of gross blood or enteric contents is an indication to proceed with emergent laparotomy.

Finally, laboratory testing rarely provides useful information in the acute management of patients with abdominal vascular injuries. Point of care testing, if available, is performed routinely. A complete blood count (CBC), type and cross, basic metabolic panel, and arterial or venous blood gas may be sent. Serial rapid thromboelastography may provide valuable information regarding dynamic changes in coagulation parameters.

PREOPERATIVE PLANNING

The initial assessment and management of patients with suspected abdominal vascular injuries should be carried out in accordance with the principles of Advanced Trauma Life Support. Establishment of a definitive airway and peripheral intravenous (IV) lines are critical in hemodynamically unstable patients. IVs should be preferentially placed in the upper extremities in patients in whom the potential for major abdominal venous injuries exists. Following penetrating truncal trauma, resuscitative efforts with crystalloids and blood products should be withheld until patients arrive in the operating room (OR) provided that they are conscious and have a palpable pulse. Although permissive or hypotensive resuscitation is a reasonable strategy for victims of penetrating trauma, this concept should not be extended to patients following blunt polytrauma, as the potential for traumatic brain injury remains high. Foley and nasogastric catheter insertion allows for monitoring of urine output and decompression of the stomach.

There should be a low threshold for initiating the institutional massive transfusion protocol, and consideration may be given to the administration of tranexamic acid. Hemostatic or balanced resuscitation in a 1:1:1 ratio of platelets-to-plasma-to-packed red blood cells should be targeted. In addition, the administration of crystalloids should be minimized, and attempts to maintain normothermia should be initiated.

For patients in extremis or who arrive pulseless, resuscitative

thoracotomy should be performed. In addition to cross-clamping the descending thoracic aorta in order to maintain cardiocerebral perfusion, other measures include confirming endotracheal tube placement, direct control of bleeding, relieving cardiac tamponade, open cardiac massage and internal defibrillation, as well as identification and control of bronchovenous embolism. The right hemithorax may also be interrogated for traumatic pathology by passing one's hand across the anterior mediastinum and opening the right pleural space. The finding of a massive right hemothorax may require extension of the anterolateral thoracotomy to a bilateral or clamshell thoracotomy.

INDICATIONS AND INITIAL SURGICAL MANAGEMENT

The two absolute indications for operative intervention or exploratory laparotomy following either blunt or penetrating abdominal trauma are hemodynamic instability and peritonitis. Shock in the setting of trauma is always attributable to bleeding until proven otherwise. Extra-abdominal sources of hemorrhage include the chest, pelvis, extremities, and external blood loss. In addition, causes of obstructive shock including tension pneumothorax and cardiac tamponade should be considered. Clinical examination in conjunction with diagnostic adjuncts such as chest and pelvic radiographs are invaluable in identifying sources of blood loss and shock.

Patients should be placed supine on the OR table and prepped from the chin to knees. This will allow for access to the left chest should a resuscitative thoracotomy be required as well as to the groins to allow for harvesting of saphenous vein, if necessary. If not already intubated, induction should occur while the patient is being prepped as the sympatholysis that accompanies induction may result in significant hypotension. Appropriate perioperative antibiotics should be administered and attention should be directed toward minimizing heat loss through the application of external warming devices and raising of ambient room temperature. Other considerations include, but are not limited to, presence of senior assistants, adequate lighting, appropriate equipment including a vascular tray and sutures, autotransfusion devices, and hemostatic adjuncts.

Access begins through a standard midline incision extending from the xiphoid process to the pubis. The two key objectives upon entry into the peritoneal cavity are temporary hemorrhage control and minimization of

contamination. Following evacuation of clots and pooled blood, the abdominal cavity is surveyed to identify ongoing sources of bleeding. Active hemorrhage is controlled by packing of solid organs and standard vascular techniques with an emphasis on exposure, digital compression, and obtaining proximal and distal vascular control. The use of sponge sticks and kitners is very helpful for obtaining vascular control of venous injuries, particularly of the IVC, renal, and iliac veins. Following temporary vascular control, enteric injuries should be controlled using a combination of temporary clamps, oversewing, or stapling. Once major hemorrhage has been temporarily controlled, attention should be directed toward identifying the source or anatomic location of bleeding according to retroperitoneal zone.

The options and principles for managing abdominal vascular injuries are similar to those for extremity vascular injuries and include damage control techniques such as ligation or temporary intravascular shunting, as well as more definitive repair techniques. These range from simple lateral repair to patch angioplasty and end-to-end or end-to-side anastomosis, with or without the use of an autologous or prosthetic conduit. For the majority of patients with abdominal vascular injuries, simple damage control techniques are favored over definitive repairs so that patients may be brought expeditiously to the intensive care unit (ICU) where ongoing resuscitative efforts may continue with a focus on reversing acidosis, hypothermia, and coagulopathy. In instances where definitive or complex vascular repairs are able to be safely undertaken, meticulous attention should be directed toward gentle handling of vessels, debridement of vessel walls, instillation of heparinized saline, and passing of Fogarty catheters to remove clot and ensure adequate proximal inflow and distal outflow. In the absence of significant concomitant injuries, systemic heparinization should also be employed.

SURGICAL TECHNIQUE—OPEN

Zone I

Following initial access and exposure, the next steps are dictated by operative findings, specifically, the presence of a contained hematoma or active hemorrhage. A contained Zone I supramesocolic hematoma is generally approached via a left-sided medial visceral rotation. This involves incising the lateral retroperitoneal attachments along the avascular line of Toldt starting at the distal left colon and proceeding

cephalad around the spleen toward the gastroesophageal junction. This maneuver will allow for the left colon, distal pancreas, spleen, and stomach to be rotated toward the midline (Fig. 231.2). Occasionally, the left kidney may also be mobilized from the retroperitoneum. Left-sided medial visceral rotation provides complete exposure of the abdominal aorta and its major visceral branches (celiac, SMA, left renal vascular pedicle, IMA) from the aortic hiatus to the bifurcation of the common iliac arteries (Fig. 231.3).

In the case of a contained Zone I inframesocolic hematoma, it may not be necessary to perform a left-sided medial visceral rotation. Rather, with the small bowel reflected to the patient's right and the transverse colon/mesocolon placed on tension cephalad, the ligament of Treitz may be incised and the duodenojejunal junction mobilized along the aorta until the left renal vein is encountered, thereby allowing for exposure of the infrarenal abdominal aorta.

Exposure of the IVC is accomplished by performing a right-sided medial visceral rotation as is done when mobilizing the right colon during the performance of an open right colectomy. A Kocher maneuver is then performed to reflect the C-loop of the duodenum and head of the pancreas medially (Fig. 231.4). Additional exposure of the confluence of the common iliac veins can be achieved by performing a Cattell–Braasch maneuver, whereby the base of the small bowel mesentery is incised starting at the ileocecal junction toward the ligament of Treitz. With the small bowel completely eviscerated, a panoramic view of the major retroperitoneal vasculature is obtained.

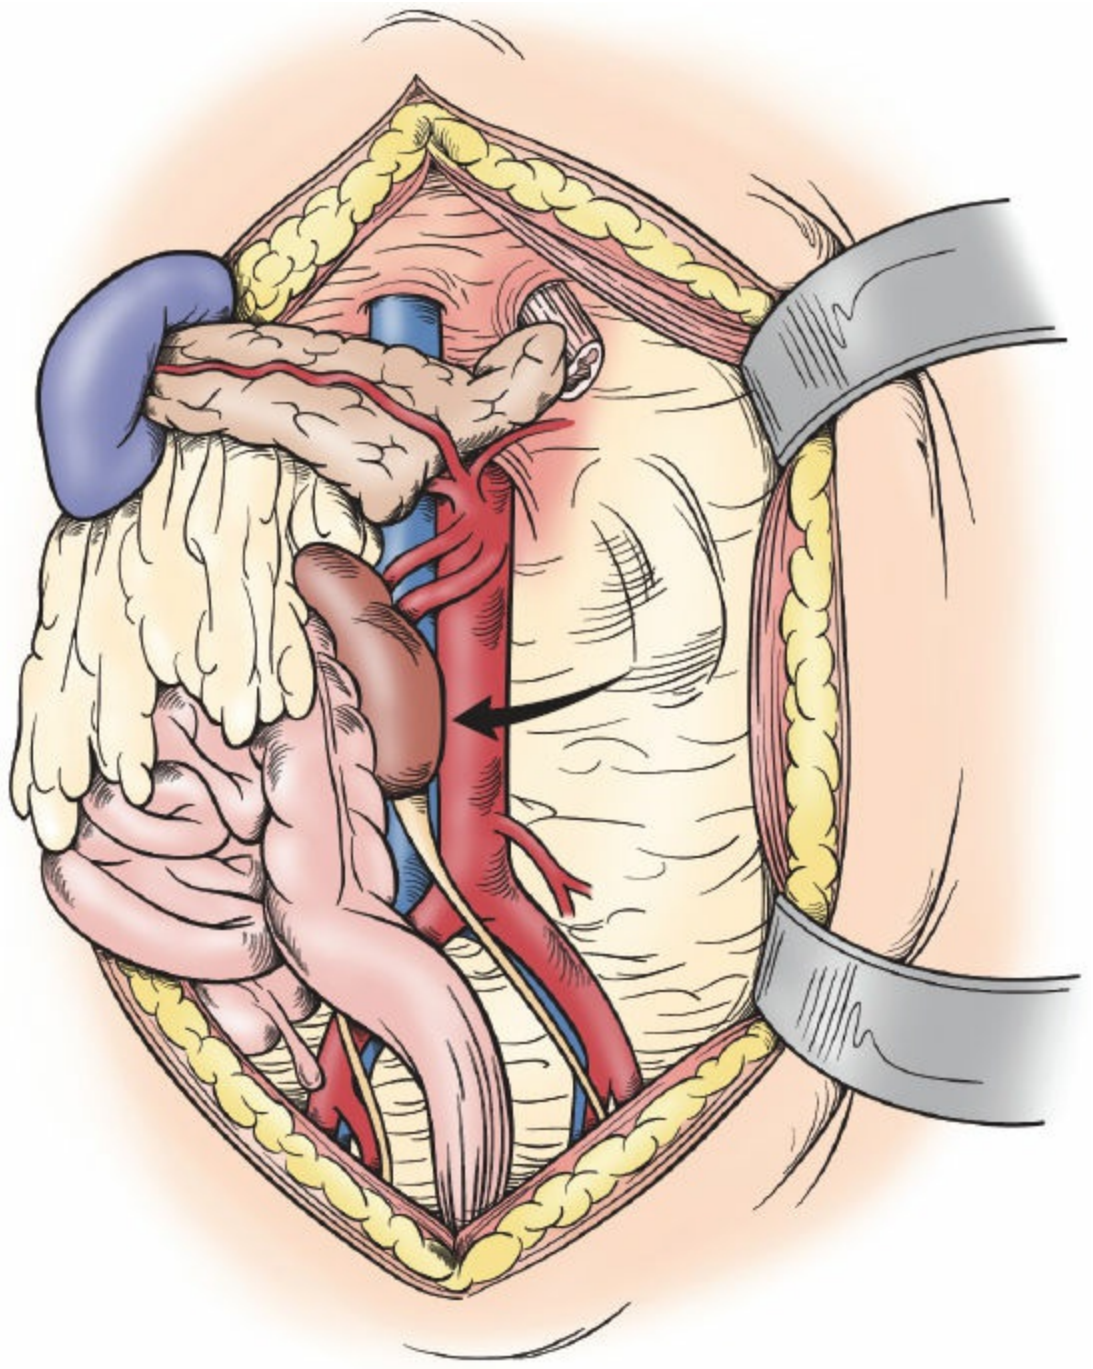

Figure 231.2. Left-sided medical visceral rotation.

If free hemorrhage is encountered, proximal aortic control should be obtained immediately. Supraceliac aortic control may be rapidly achieved using an aortic compressor device or application of digital pressure. Although a rapid means of preventing further blood loss, a major disadvantage of this technique is the need for an assistant's hand and difficulty exposing and working around the device. The authors' preferred approach is to obtain proximal aortic control via supraceliac cross-

clamping of the descending thoracic aorta. To this end, the lesser omentum or gastrohepatic ligament is sharply incised or opened bluntly and lateral traction is placed on the stomach and esophagus. The crura muscle fibers enveloping the aorta may be dissected bluntly using finger dissection on either side of the aorta or sharply by incising the left crura with scissors or electrocautery, typically at the 2 o'clock position, followed by placement of a gently curved aortic vascular clamp.

Injuries of the celiac trunk are managed with simple ligation. Occasionally lateral repair of the common hepatic artery may be undertaken; however, this is not usually possible with the smaller caliber left gastric and splenic arteries. Injuries to the SMA are classified according to the Fullen classification that divides the SMA anatomically into four zones and grades of injury (Table 231.2). For proximal SMA injuries (Zones I and II), lateral repair should be undertaken whenever possible. Insertion of a temporary vascular shunt allows for expeditious management of bleeding while maintaining midgut viability. When the injury is retropancreatic, division of the pancreas may facilitate exposure. The formation of a vascular anastomosis should be tempered against the potential for disastrous anastamotic breakdown in the face of pancreatic injury and leak. For distal SMA injuries, particularly Zones III, lateral or primary repair should be undertaken. Zone IV or segmental injuries can be managed with simple ligation and, if necessary, segmental bowel resection.

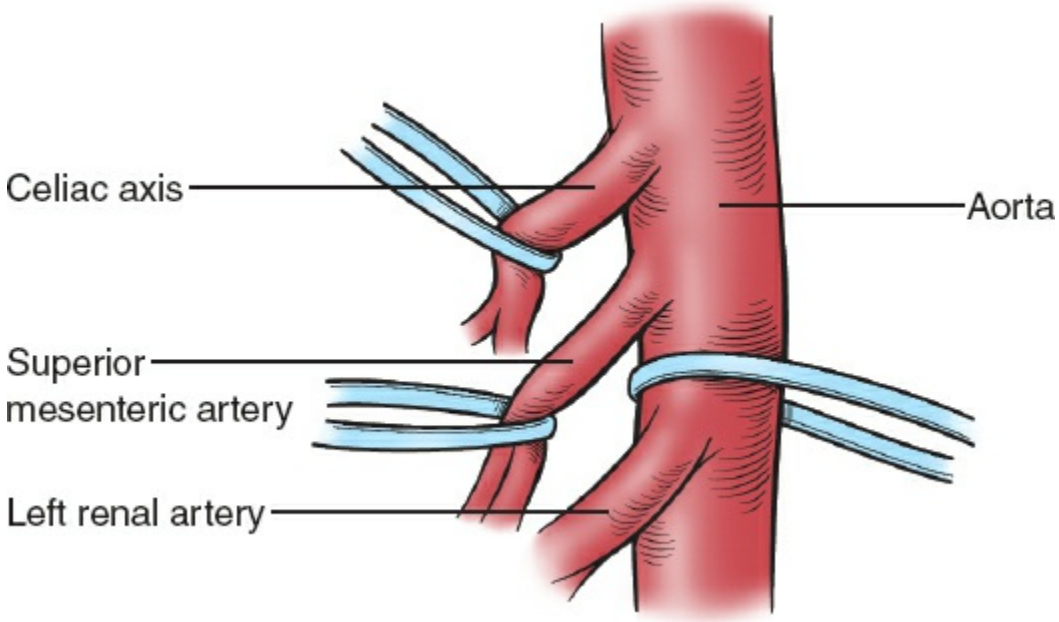

Figure 231.3. Abdominal visceral vessels.

Injuries of the abdominal aorta and IVC are classified anatomically in relation to the renal arteries and liver. Small tears or injuries to the either the supra- or infrarenal aorta can be repaired using 4-0 polypropylene suture. Patch aortoplasty may be performed for larger injuries in order to avoid iatrogenic stenosis. The choice of material will be contingent upon the presence or absence of enteric contamination. In the case of an isolated aortic injury, synthetic graft such as polytetrafluoroethylene (PTFE) or Dacron may be used with minimal risk for infection. In the presence of contamination, native saphenous vein or bovine pericardium should be considered. An end-to-end anastamosis is used for short segmental defects provided a tensionless repair can be performed. Should a prosthetic graft be necessary, a 14–18-mm Dacron or PTFE graft is usually sufficient in the nondiseased adult aorta. Care should be taken to cover the suture lines with pedicled omentum. In the presence of concomitant bowel injury and an extensive infrarenal aortic injury not amenable to repair without a conduit, consideration should be given to ligation of the infrarenal aorta and extra-anatomic bypass via an axillobifemoral bypass.

Management of IVC injuries is dictated by the location and extent of injury, as well as the overall status of the patient. Proximal and distal control can be achieved using digital compression or sponge sticks. Simple lacerations as may occur following a stab wound are usually amenable to lateral venorrhaphy. For larger lacerations, once hemorrhage is controlled and the injury identified, the edges of the laceration may be picked up with atraumatic tissue forceps and a side-biting Satinsky clamp placed to achieve partial occlusion of the IVC, followed by oversewing of the IVC with 4-0 or 5-0 polypropylene suture. Another effective method of preparing the wound for lateral venorrhaphy is to achieve tamponade with a tightly rolled pack followed by serial application of Allis or Babcock clamps as the pack is slowly rolled distally.

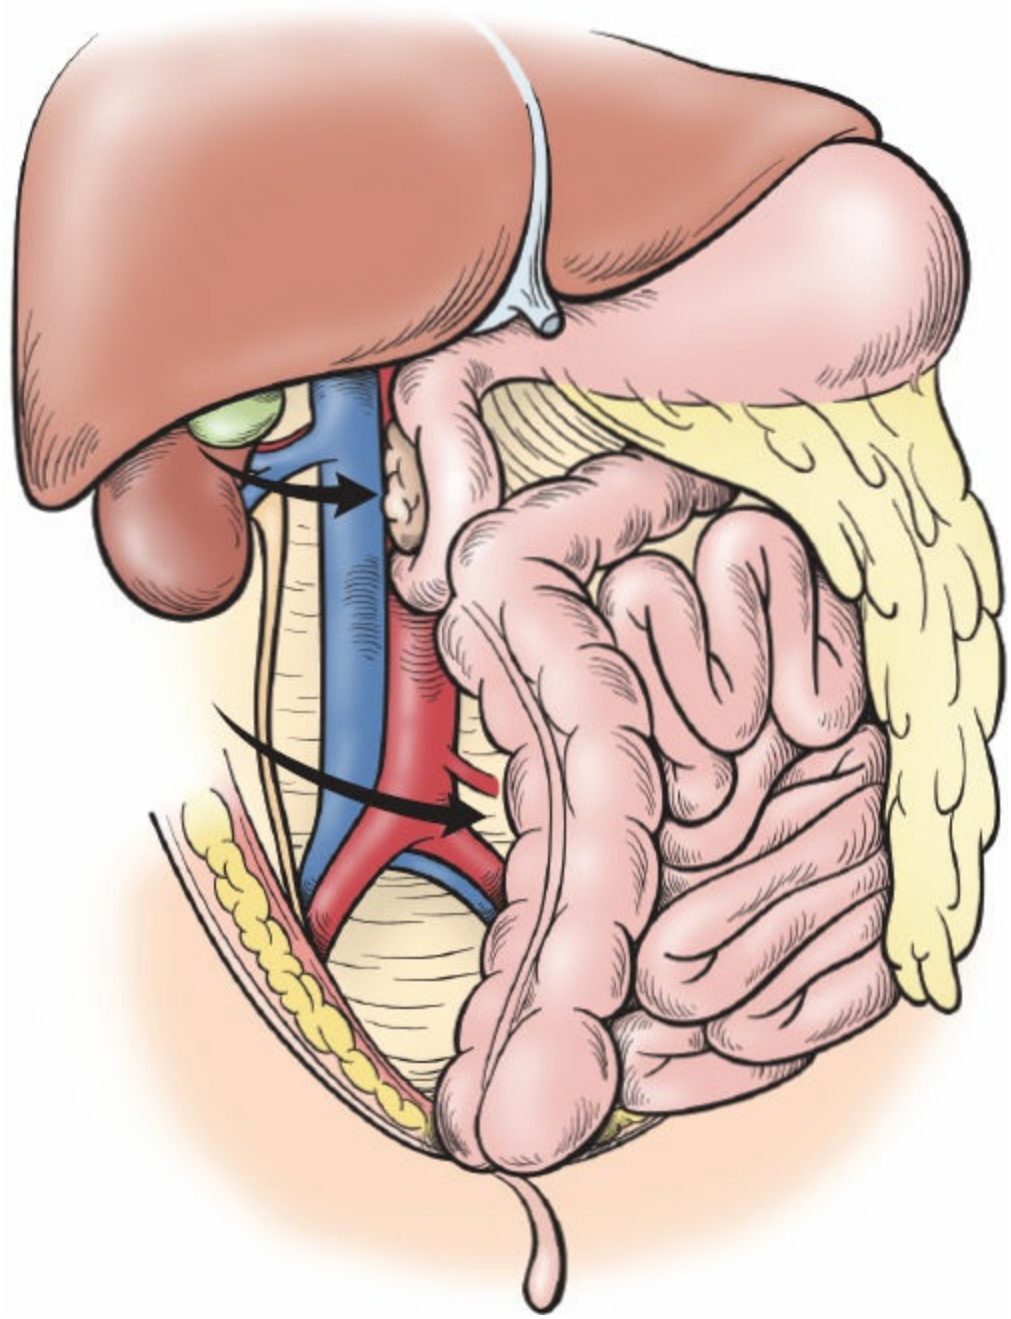

Figure 231.4. Right-sided medical visceral rotation.

It is important to rule out a through-and-through injury to the posterior wall of the IVC. This can usually be performed by rolling or rotating the IVC after freeing it bluntly from its loose surrounding retroperitoneal attachments, being careful not to inadvertently avulse any lumbar veins. Alternatively, the posterior wall may be interrogated by extending the anterior perforation and visualizing the posterior wall from within the lumen of the IVC. This is rarely necessary. For extensive infrarenal IVC injuries accompanied by hemodynamic instability and shock, ligation should be performed without hesitation. Infrahepatic suprarenal injuries

should be repaired whenever possible. In general, ligation of the suprarenal IVC is associated with poor survival. Following ligation of the IVC, massive lower extremity edema should be anticipated. Elevation of the lower extremities in conjunction with early application of circumferential lower extremity elastic bandages or wraps will help to minimize edema.

TABLE 231.2 Fullen Classification for SMA Injuries

Zone	Segment of Superior Mesenteric Artery	Grade	Ischemic Category	Bowel Segments Affected
I	Trunk proximal to inferior pancreaticoduodenal	I	Maximal	Jejunum, ileum, right colon
II	Trunk between inferior pancreaticoduodenal and middle colic	II	Moderate	Major segment, small bowel, right colon
III	Trunk distal to middle colic	III	Minimal	Minor segment or segments, small bowel or right colon
IV	Segmental branches-jejunal, ileal, or colic	IV	None	No ischemic bowel

For patients with evidence of a subhepatic retroperitoneal hematoma immediately below the liver or a retrohepatic hematoma, a retrohepatic IVC injury should be suspected. In such cases, the optimal management strategy is to leave the hematoma alone and to not make any efforts to mobilize that attachment of the liver. Provided that the suspensory ligaments of the liver, posterocentral liver, and diaphragm remain intact, retrohepatic IVC injuries should tamponade. In cases where spontaneous tamponade is not achieved, hemorrhage control may be attempted via direct compression. Other measures to control hemorrhage include total hepatic vascular isolation, insertion of an atriocaval shunt, and institution of venovenous bypass followed by direct suture repair of the IVC. For patients with massive hemorrhage due to a retrohepatic IVC injury, early consideration and application of these more aggressive strategies is paramount to good outcomes.

Zone II

Injuries to the lateral retroperitoneum in Zone II may involve the renal vascular pedicle, renal parenchyma, or both. In stable patients with a blunt mechanism of injury, Zone II hematomas are generally not opened unless

they are pulsatile or expanding. Following a penetrating mechanism, exploration is recommended. An exception to this may be the occasional patient who is hemodynamically stable and who has undergone preoperative imaging, which demonstrates an absence of a high-grade renal injury or active hemorrhage.

In patients who are stable without extensive hemorrhage, control of the ipsilateral renal vessels may be obtained in the midline at the base of the mesocolon. The technique of midline looping is a reasonable option in patients with Zone II hematomas (Fig. 231.5). The alternative and simpler option, particularly among patients who are actively bleeding or hemodynamically unstable, is to simply incise the retroperitoneum and Gerota fascia lateral to the kidney and elevate it to the midline followed by application of a vascular clamp.

Renal artery injuries represent a technical challenge due to their small caliber and location deep in the retroperitoneum. For partial injuries, lateral repair may be undertaken. If lateral repair is not feasible, palpation and confirmation of the presence of a contralateral kidney should be undertaken, followed by nephrectomy. For patients with a solitary kidney, renal salvage via aortorenal interposition grafting with saphenous vein or prosthetic graft may be performed. Less commonly, renovascular reconstruction may be performed by translocating splenic or hepatic arteries to the left or right kidney respectively. Definitive reconstruction is suitable for patients who are hemodynamically stable or in those patients found to have a solitary kidney. Those patients in shock with active hemorrhage due to a kidney or renal vascular pedicle injury, following confirmation of a contralateral kidney, should undergo a nephrectomy. For patients with renal vein injuries, attempts at lateral repair should be undertaken. Left-sided renal vein injuries near the confluence with the IVC may be ligated and observed. Collateral outflow via the left gonadal vein and adrenal veins should preserve renal function.

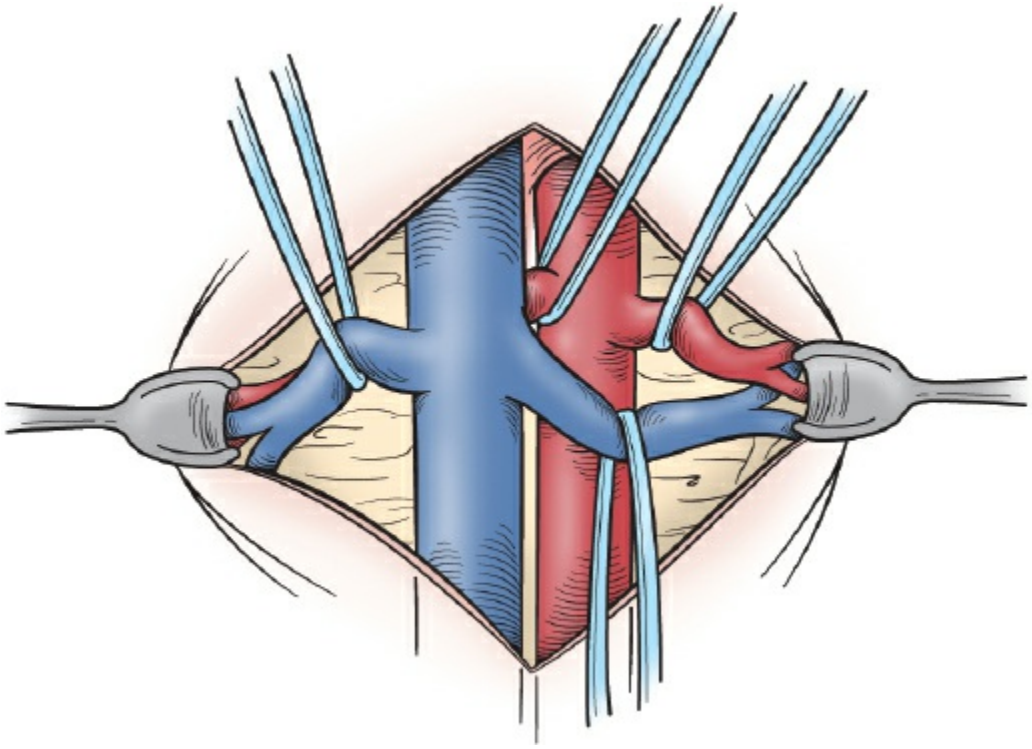

Figure 231.5. Midline looping.

Blunt renovascular injuries continue to be difficult injuries. The majority of these injuries are confirmed by CT scan and occur as a result of an intimal tear and subsequent thrombosis of the distal renal artery, 2 to 4 cm from the aorta. Overall outcomes following attempts at revascularization remain poor. In general, outcomes are dictated by severity of injury and time to revascularization or warm ischemic time. The operative approach involves resection of the involved segment and interposition grafting with saphenous vein or PTFE. Endovascular stenting may play a role in patients with evidence of active extravasation or in those patients with evidence of an intimal tear and downstream emboli. Patients should be followed closely for the delayed development of hypertension or end-stage renal disease.

Zone III

The presence of a Zone III hematoma or active hemorrhage following a penetrating mechanism of injury mandates exploration as the potential for an iliac vessel injury remains high. Exposure of the iliac vessels involves medial mobilization of the cecum on the right or the sigmoid colon on the left by dividing the avascular line of Toldt. For injuries near the aortic bifurcation, confluence of the common iliac veins, or suspected bilateral

injuries, a Cattell–Braasch maneuver should be performed with further caudad dissection of the pelvic peritoneum as necessary. Identification of the ureter as it passes over the ipsilateral common iliac artery proximal to the bifurcation of the external and internal iliac arteries is critical to avoid iatrogenic ureteric injury.

Initial temporary bleeding control should be obtained by direct compression followed by proximal and distal control. In cases where the source of bleeding is apparent, this may be achieved through the application of digital pressure or compression with sponge sticks. More often, the exact site of injury is not readily apparent and attempts at hemorrhage control prove difficult. In these cases, pelvic vascular isolation should be considered, which entails proximal aortic and IVC control combined with distal control at the level of the external iliac vessels bilaterally (Fig. 231.6). Distal control may be obtained intra-abdominally by inserting Deaver retractors and compressing the external iliac vessels against the pubic bones. Alternatively, a separate longitudinal groin incision or oblique incision in continuity with the inferior midline incision, followed by division of the inguinal ligament, may provide access to the distal external iliac artery and proximal common femoral artery. Once proximal and distal control have been obtained, the technique of sequentially “walking the clamps” toward the site of injury should allow for more precise identification of the vascular structure(s) involved.

Common and external iliac artery injuries are usually amenable to lateral repair. For more extensive injuries, an end-to-end anastomosis may be performed with either autogenous or prosthetic graft (size 6 or 8 PTFE). For patients who are in shock, insertion of a temporary intravascular shunt should be performed. Care must be taken to ensure that the shunt is adequately secured. Ligation of the common iliac or external iliac artery is poorly tolerated and associated with a high risk of lower extremity limb loss. Should ligation be performed, consideration for an extra-anatomic (femoral–femoral bypass) should be done, with or without lower extremity fasciotomies. Injuries of the internal iliac artery injuries are generally managed with ligation.

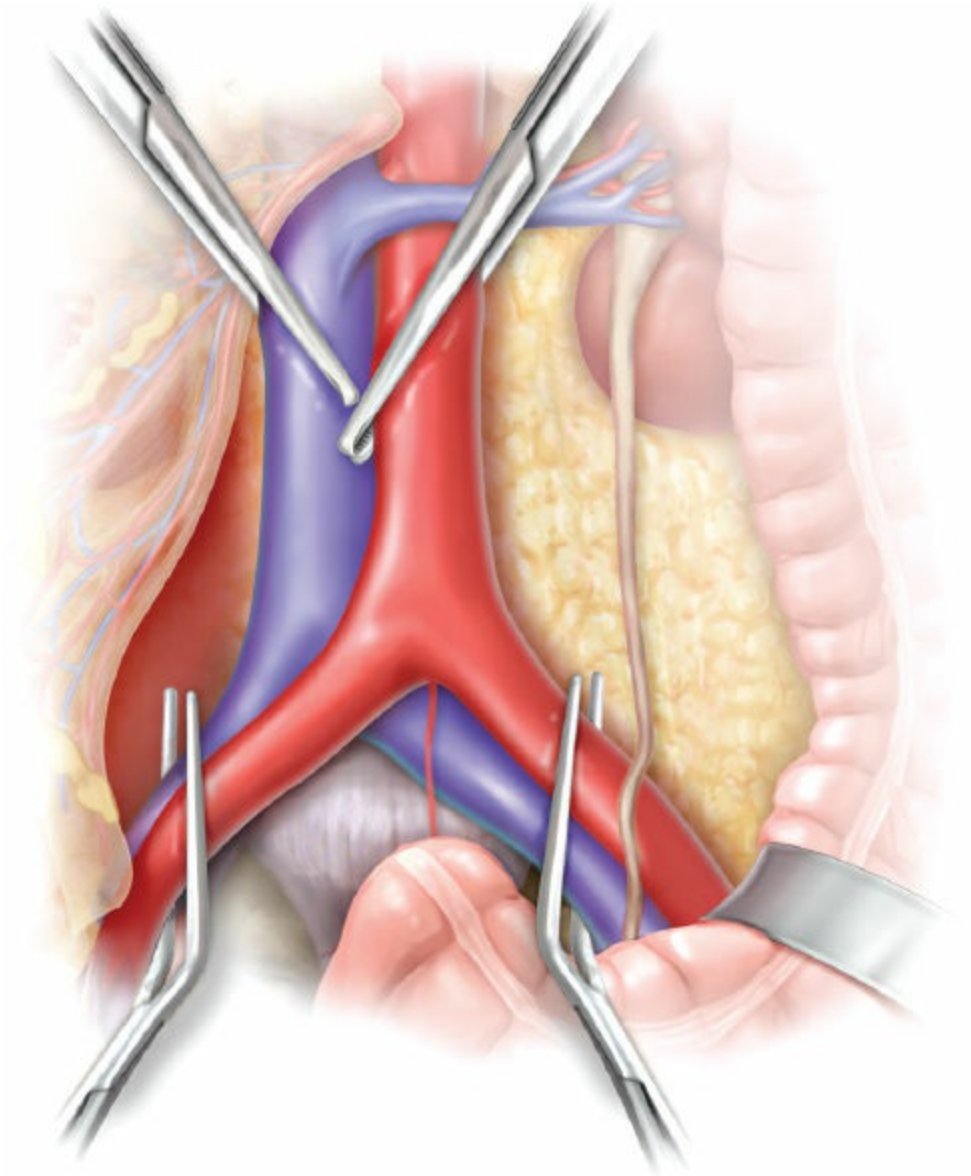

Figure 231.6. Pelvic vascular isolation.

Iliac venous injuries are usually much more difficult to manage owing to their challenging anatomic location in relation to the iliac arteries, which makes exposure technically demanding. This is especially true for the confluence of the common iliac veins located deep to the right common iliac artery. Although transecting the overlying iliac artery is an option for gaining access to an injured iliac vein, this is seldom necessary. Whenever possible, lateral venorrhaphy should be attempted for small venous injuries. Shunting is a viable option, as is ligation. Ligation of the common or external iliac vein is generally well tolerated. Postoperative edema and lower extremity compartment syndrome requiring fasciotomy should be anticipated. Insertion of intravascular balloon catheters is another helpful

adjunct in gaining distal control of external iliac vein injuries.

In patients with extensive iliac vessel injuries associated with concomitant bowel injuries, options for repair include ligation, with or without extra-anatomic bypass, shunting, or insertion of an interposition graft. Provided that there is minimal contamination, insertion of a prosthetic graft is a reasonable and much quicker alternative to using an autologous graft. Prior to grafting, all enteric contents should be removed and the peritoneal cavity thoroughly lavaged. Following repair, the peritoneum should be closed over the graft and antibiotics continued into the postoperative period.

Patients with a Zone III hematoma following a blunt mechanism and a known pelvic fracture should not undergo exploration or unroofing of the pelvic hematoma. Exceptions to this rule include patients who are found to have a pulsatile or expanding hematoma accompanied by hemodynamic instability or an absent femoral pulse. The operative principles for exposure and hemorrhage control are similar for patients with penetrating injuries. Bilateral ligation of the internal iliac arteries is a reasonable option in patients with unstable pelvic fractures and ongoing hemodynamic compromise. The risk for gluteal necrosis is low, particularly among patients without significant associated gluteal soft tissue injuries.

INJURIES IN THE PORTA HEPATIS

Portal vein injuries are among the most lethal of abdominal vascular injuries, and the majority of patients with these injuries succumb to intraoperative exsanguination. Formed by the confluence of the superior mesenteric and splenic veins, the low-pressure portal vein accounts for 80% of the hepatic blood flow. These injuries may present as a hematoma or hemorrhage originating from the hepatoduodenal ligament, upper central retroperitoneum, or root of the mesentery. In general, portal vein injuries rarely occur in isolation and associated IVC, hepatic artery, and pancreaticoduodenal injuries are commonplace.

Anatomically, wounds of the portal vein are classified into *suprapancreatic* and *retropancreatic* locations. For patients found to have a stable hematoma, initial exposure and hemorrhage control should be obtained via right medial visceral rotation and a Kocher maneuver followed by application of a Pringle maneuver and compression of the duodenum and head of the pancreas between lap pads. Precise

identification and characterization of the location and presence of associated injuries will dictate the operative approach. For patients with uncontrolled hemorrhage, direct compression of bleeding in combination with supraceliac crossclamping of the aorta should be performed. Distal aortic control in the infrarenal location may help to further minimize blood loss by decreasing splanchnic circulation and reducing portal venous flow. Backbleeding may be controlled by clamping the portal triad immediately adjacent to the liver or through the insertion of intravascular balloon catheters into the left and right portal veins. Options for repair of suprapancreatic portal vein injuries include lateral venorrhaphy, patch angioplasty, and insertion of an interposition graft. Generally, complex reconstructions are discouraged unless a concomitant irreparable injury of the common hepatic artery is present. Options for repair of retropancreatic portal vein injuries are limited. If lateral repair is not possible, early and immediate consideration should be given to ligation of the portal vein, provided that the proper hepatic artery remains intact. Transection of the pancreas rarely offers additional meaningful exposure. Postoperatively, patents undergoing portal vein or SMV ligation will undergo massive bowel edema due to splanchnic hypervolemia, which is accompanied by a systemic hypovolemia. Aggressive fluid administration and planned second look laparotomy are mandatory in this patient subset.

SURGICAL TECHNIQUE—ENDOVASCULAR

Endovascular management of abdominal trauma in the current era consists of three general modalities: balloon occlusion, angioembolization, and stent-grafting. These techniques can be used percutaneously in the emergency department or endovascular suite. Alternatively, they can be combined with open surgery using a mobile C-arm in a traditional OR or using fixed imaging systems in a “hybrid” OR. The choice of treatment setting depends on the stability of the patient, the types of procedures required, and institutional capabilities and practice patterns.

Endovascular surgery treats the same traumatic pathology as open surgery (hemorrhage, vessel dissection or occlusion, pseudoaneurysm, arteriovenous fistula), only using minimally invasive equipment and techniques. Vessel access, wires, catheters, and sheaths provide the “exposure” for the intervention. Wires can also be viewed as a vascular clamp: once you have a wire across a vascular lesion, you have “control” of the vessel and can treat it. Coils, occluders, and embolic materials (glue,

gelfoam, etc.) are used to embolize, or “ligate,” traumatized vessels. Stents and covered stent-grafts are the endovascular equivalent of primary vessel repair or bypass.

The basic treatment platform is essentially the same for most endovascular interventions. Vessel access is usually via the common femoral artery for arterial interventions and the common femoral or internal jugular vein for venous interventions. Alternative arterial access can be obtained using the axillary or brachial artery, usually from the left arm, although this requires a longer length of wires and catheters to reach vascular structures in the abdomen, retroperitoneum, or pelvis. Access is obtained via an angioaccess needle, using anatomic or fluoroscopic landmarks or ultrasound guidance. Micropuncture kits are available that allow precise ultrasound-guided access with minimal trauma to the vessel. Once the vessel is successfully punctured, a short wire is advanced and then a short sheath with dilator is advanced over the wire. The sheath is flushed with heparinized saline, and then a floppy wire is advanced into the aorta. At this point, a diagnostic catheter with multiple side-holes, such as a pigtail or Omni flush catheter, can be advanced over the wire, and a diagnostic aortoiliac angiogram can be performed using a power injector to delineate the anatomy and the pathology in the area of interest. Once the area of interest is identified, a stiff wire can be placed and a longer sheath advanced close to the area of intervention to provide additional support. The sheath should be of sufficient French size to allow passage of the devices that are anticipated to be used for treatment. Sheaths are sized by their inner diameter, while catheters are sized by their outer diameters (e.g., a 6-Fr sheath will accept a 6-Fr catheter or device). Wires should be at least twice the length of any catheter or sheath that is advanced over it to avoid losing wire access. Once the sheath is in place, a selective catheter coupled with a floppy wire can be used to select the vessels of interest and treatment can begin.

Balloon Occlusion

Noncompressible torso hemorrhage is a leading cause of early mortality in trauma patients, and early aortic occlusion is often necessary before definitive control of the bleeding organ or vessel can be performed. Traditionally this has been managed with thoracotomy or laparotomy with cross-clamping of the descending thoracic or supraceliac aorta. Resuscitative endovascular balloon-occlusion of the aorta (REBOA) can

be used in the emergency department, the angio suite, or the OR to rapidly occlude the aorta proximal to the source of hemorrhage and increase central aortic pressure while definitive hemorrhage control is achieved.

Femoral artery access is obtained and a 5- to 6-Fr short (8 cm) sheath is placed. A stiff wire is advanced into the distal aortic arch under fluoroscopic guidance. The short sheath is exchanged for a longer sheath (45 to 60 cm) large enough to accommodate the aortic occlusion balloon (at least 12 Fr). The sheath is positioned in Zone I (between the origin of the L subclavian artery and the celiac artery) (Fig. 231.7). The dilator of the sheath is removed over the wire, and the balloon is advanced over the wire until it is out of the sheath. A 30-mL syringe filled with a 50–50 mixture of contrast and saline is attached to the balloon stopcock. The balloon is inflated until it forms a cylinder that mimics the contour of the aorta. The stopcock on the balloon is turned off to keep the balloon inflated, and the sheath is either sewn to the skin or held in place by hand to prevent distal migration by aortic pressure. Balloon deflation occurs when hemorrhage control is achieved and, like removing an aortic clamp, should be communicated to the anesthesia team in preparation of the resultant hypotension related to reduced afterload and reperfusion of ischemic organs. The balloon and the wire can be removed from the sheath and the sheath flushed with heparinized saline. The sheath should be removed via a groin cutdown after proximal and distal control of the femoral artery has been achieved and the arteriotomy is closed primarily with permanent monofilament suture. Newer balloon catheters are available that can be placed into the aorta transfemorally without wire or fluoroscopic guidance. These low-profile (7 Fr) catheters are placed using external anatomic landmarks and can be accurately and safely placed in settings without radiographic capabilities. The low-profile catheter allows a smaller sheath and a totally percutaneous approach.

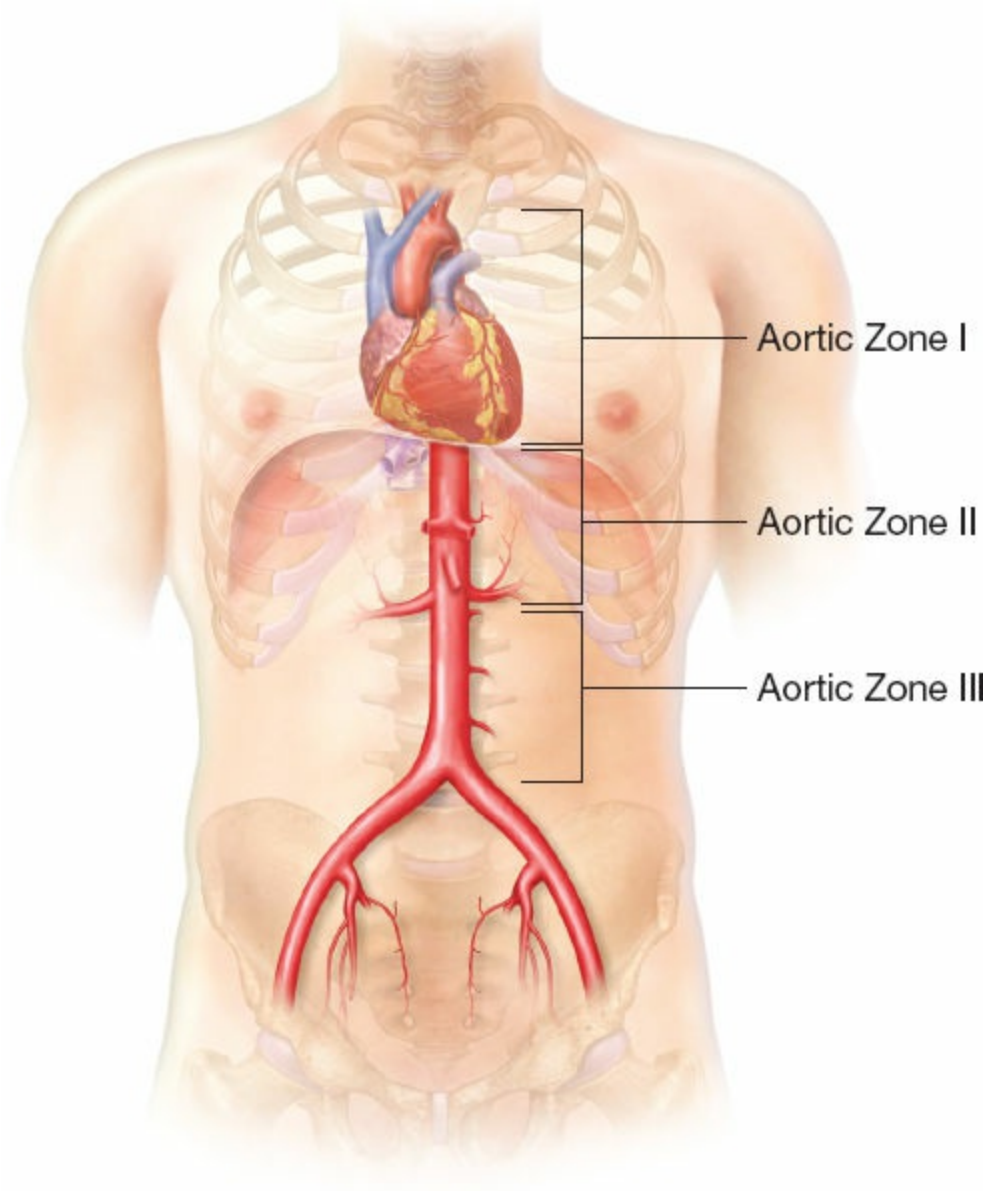

Figure 231.7. Aortic zones related to REBOA.

Angioembolization

Embolization can be performed to treat bleeding abdominal or retroperitoneal vessels or blunt solid organ injury in the absence of peritonitis. Usually, a CT with contrast will show a contrast blush, pseudoaneurysm, or arteriovenous fistula and will guide the angiographic procedure. Femoral access is obtained and selective catheterization of the main aortic branch vessel is performed using a 5-Fr selective catheter. Digital subtraction angiography is performed in multiple projections to identify the vascular lesion. The selective catheter can be used to embolize proximal vessels; but for distal lesions, a coaxial platform using microcatheters telescoped within the selective catheter can allow access to

small branch vessels to deliver embolic agents to a focal area of injury.

Splenic embolization can be performed with either proximal or distal embolization depending on the location and severity of the injury. Multiple injured sites or severe (grade IV or V) injury can be treated with proximal splenic artery embolization with large coils (1 to 2 mm larger than the vessel) or vascular occluders (oversized 40% greater than the vessel) ensuring that the proximal splenic branches supplying the pancreas are spared to avoid postprocedure pancreatitis. Distal embolization is performed using microcatheters to perform superselective catheterization of the branch artery. Small coils, cyanoacrylate, or gelfoam can be used as embolic agents. Coils are a good choice for a single focus of extravasation, while gelfoam and cyanoacrylate are good choices for multifocal extravasation as they can reach multiple areas of distal extravasation from one catheter position. Liver and renal embolization usually requires superselective distal embolization due to the decreased tolerance of the parenchyma to proximal embolization.

Embolization is the treatment of choice for trauma of the pelvis resulting in hemorrhage. Access is usually via the common femoral artery; but if injuries or pelvic devices preclude femoral access, the approach can be made from the arm. If the patient is hemodynamically unstable, an occlusion balloon can be delivered via contralateral access as described above to occlude the aorta until the hemorrhage is definitively treated. While pelvic bleeding usually arises from the internal iliac artery, an initial aortogram should be performed to ensure that alternative bleeding sites are not present, such as the lumbar arteries or the external iliac artery. A pelvic angiogram should then be performed using a contralateral anterior oblique view to image the internal iliac artery. The internal iliac artery is selected with a catheter, and a selective internal iliac angiogram is performed with ipsilateral anterior oblique views to allow visualization of the superior gluteal and the internal pudendal arteries. If the patient is hemodynamically unstable or multiple areas of injury are identified, proximal embolization of the internal iliac artery or its anterior or posterior divisions can be performed with coils or vessel occluders. However, in cases of discrete bleeding, superselective catheterization and embolization are performed using coils or gelfoam, either alone or in combination. Gelfoam is a temporary embolic agent, allowing vessel recanalization over a period of weeks and reperfusion of the embolized area after the injury has healed.

Complications of angioembolization include tissue infarction from vessel occlusion, migration of embolic agents into nontarget vessels, and rebleeding due to unsuccessful embolization or missed injuries. Delayed hemorrhage can occur due to recanalization of occluded vessels or resolution of arterial vasospasm after resuscitation. It is often a good idea to leave the access sheath in place after the initial embolization procedure if there is any concern for incomplete embolization or if the patient needs further resuscitation. This allows repeated attempts at embolization without needing to regain arterial access.

Stent-Grafting

Stents are used to open stenotic or occluded vessels or to cover holes in vessels leading to hemorrhage, pseudoaneurysm, or arteriovenous fistula. Stent types are defined by whether they are self-expanding or balloon-expandable and whether they are bare-metal or covered (stent-grafts). Self-expanding stents are deployed by retracting the sheath they are housed in. They are usually oversized by 10% to 20% greater than the diameter of the vessel. Self-expanding stents can be used in any location, but are particularly well suited to superficial locations and in mobile arteries near joints since they elastically recover when externally compressed. Balloon-expandable stents are mounted on an angioplasty balloon and are deployed by inflating the balloon to expand the stent. They are usually sized to the actual diameter of the vessel. Balloon-expandable stents can collapse with external pressure, so are not well suited for superficial locations or in mobile arteries such as those that cross joints. Stent-grafts can be delivered over a wire and deployed to treat arterial injuries in the aorta and iliac vessels as well as branch vessels such as the renal arteries. Complications include vessel rupture from aggressive balloon angioplasty, acute thrombosis, and stent migration due to inaccurate sizing or deployment. Long-term complications include stent fracture, migration, in-stent stenosis, thrombosis, and infection.

POSTOPERATIVE CARE

Following damage control surgery in patients with abdominal vascular injuries, patients should be brought expeditiously to the ICU where further resuscitation and invasive monitoring efforts are continued. On occasion, it may be helpful to obtain a torso CT scan en route to the ICU to identify potential sources of ongoing bleeding, missed injuries, or previously

undefined wound trajectories. The majority of patients will undergo temporary abdominal closure, with or without the use of drains, and close attention to both the quality and quantity of abdominal outputs is critical in determining the need for a return trip to the OR. Serial monitoring of abdominal compartment pressures, in conjunction with other physiologic variables, should allow for the early identification of intra-abdominal hypertension and the abdominal compartment syndrome. Reversal of the acute coagulopathy of trauma, hypothermia, and metabolic acidosis is essential for optimal outcomes and patient survival. Serial neurovascular checks and balanced resuscitation, with or without the use of invasive hemodynamic monitoring such as pulmonary artery catheters, are key components in the postoperative management of patients with abdominal vascular injuries. Timing of reoperation and attempts at definitive repair and closure should be dictated by patient physiology.

COMPLICATIONS AND THEIR MANAGEMENT

Abdominal vascular injuries are associated with numerous complications that may be directly related to the injuries inflicted or the interventions undertaken to control hemorrhage and restore physiologic stability. Because of the severity of blood loss and shock that accompany vascular injuries, multiorgan system involvement is the rule rather than the exception. In the immediate postoperative period, ongoing or recurrent hemorrhage usually signifies uncontrolled bleeding requiring reoperation in conjunction with optimization of coagulation parameters. Missed injuries, dislodgement of intravascular shunts, and dehiscence or anastamotic breakdown are but a few of the potential causes of early postoperative bleeding. Thrombosis or distal embolism may also occur in an early or delayed fashion. Therefore, careful monitoring of abdominal outputs, serial abdominal and neurovascular examinations, and trending of endpoints of resuscitation are mandatory. The decision to administer anticoagulation should be made on an individual basis. The development of abdominal compartment syndrome usually mandates decompression either at the bedside or in the OR. Venous vascular injuries treated with ligation are invariably associated with venous hypertension, edema, and fluid sequestration. In the extremities, this may mandate lower extremity fasciotomies. An uncommon but feared delayed complication of vascular repairs is the development of a vascular enteric fistula. The decision to proceed with an open or endovascular operative approach is based on

patient stability, anatomy, and institutional capabilities. Arteriovenous fistulas and pseudoaneurysms can usually be managed using endovascular stents. The risk for surgical site infection is related to a variety of factors, including administration of appropriate perioperative antibiotics, patient comorbidities, and associated injuries. Source control and administration of appropriate broad spectrum antibiotics form the cornerstone of sepsis management.

EDITOR’S COMMENT

I will use this chapter by Kim and Koopmann on injury to vessels in the abdomen every time in the next 5 years or so that I need a refresher on how to manage this problem, which fortunately is not that frequently as I practice in a

small college town. The classic description of the zones of the abdomen associated with trauma and how they are managed are textbook perfect. However, realistically it seems to me that the management of trauma has evolved somewhat away from management by zones to an algorithm that begins with a computed tomographic angiography (CTA) from the head to the toes, and then is quickly followed by endovascular management of trauma to almost all vascular beds. Originally this approach was felt to be most suitable for patients with hemodynamic stability, but now it appears that even unstable patients with retroperitoneal trauma can undergo an expeditious endovascular approach (Boufi M, Bordon S, Dona B, et al. Unstable patients with retroperitoneal vascular trauma: an endovascular approach. *Ann Vasc Surg* 2011;25(3):352–8). The use of endovascular approaches to repair vascular injuries following trauma has become so common that courses have been developed to teach this approach (Villamaria CY, Eliason JL, Napolitano LM, et al. Endovascular Skills for Trauma and Resuscitative Surgery [ESTARS] course: curriculum development, content validation, and program assessment. *J Trauma Acute Care Surg* 2014;76(4):929–35; discussion 935–6).

While an endovascular solution may not always be the primary means by which vascular injuries are repaired, endovascular approaches can often be used as an adjunct allowing for concurrent repair performed in a safer fashion (Beyer C, Zakaluzny S, Humphries M, et al. Multidisciplinary management of blunt renal artery injury with endovascular therapy in the setting of polytrauma: a case report and review of the literature. *Ann Vasc Surg* 2017;38:318.e11–318.e16). In a recent study by Abe et al. examining a nationwide trauma registry in Japan, patients with critical trauma were compared who had their aorta cross-clamped with those who underwent resuscitative endovascular occlusion of the aorta (REBOA). When a total of 903 patients were compared, only 67% of patients who underwent REBOA died (odd ratio 0.26), while 90% of those who had their aorta cross-clamped died, suggesting that REBOA was protective. While the authors admit there was clearly a risk of selection bias, they concluded by suggesting that REBOA might be a favorable alternative method to resuscitative cross-clamping of the aorta for severe trauma. Thus, even when used in a hybrid manner, endovascular approaches in trauma offer selective advantages. This is true not only for aortic injury but also really for almost all vascular beds, including the renals (Abe T, Uchida M, Nagata I, et al. Resuscitative endovascular balloon occlusion of the aorta versus aortic cross clamping among patients with critical trauma: a nationwide cohort study in Japan. *Crit Care* 2016;20(1):400). A recent review senior authored by Dr Rasmussen is highly recommended (Brenner M, Hoehn M, Rasmussen TE. Endovascular therapy in trauma. *Eur J Trauma Emerg Surg* 2014;40(6):671–8).

Clearly, the military has been a leader in the management of vascular trauma, but also in its evolution to include more endovascular approaches, as well as the expanding use of shunts. The newly created American Association for the Surgery of Trauma PROspective Observational Vascular Injury Treatment

(PROOVIT) registry focusing on modern vascular injury diagnosis, management, and outcomes will clearly serve as a repository that can be used to help us better understand how we manage vascular trauma (DuBose JJ, Savage SA, Fabian TC, et al.; AAST PROOVIT Study Group. The American Association for the Surgery of Trauma PROspective Observational Vascular Injury Treatment [PROOVIT] registry: multicenter data on modern vascular injury diagnosis, management, and outcomes. *J Trauma Acute Care Surg* 2015;78(2):215–22; discussion 222–3). Whereas in many civilian trauma series patient follow-up is limited after discharge as many trauma patients are young and follow-up is lacking, this registry will hopefully help us to define a new treatment paradigm based on long-term outcomes about how best to manage patients with intra-abdominal vascular trauma.

Gilbert Upchurch Jr.

232 Injury to the Extremities: Open and Endovascular Management

W. Darrin Clouse

CLINICAL PRESENTATION, DIAGNOSIS, AND ASSESSMENT

Extremity vascular injury typically presents with hemorrhage, ischemia, or soft signs thereof. The principles of initial limb evaluation and examination have remained constant. Hard signs of vascular injury include absent pulses, active bleeding, clinically evident ischemia, expanding hematomas, and palpable thrills or audible bruits. These are clear indications for immediate assessment and intervention. When more subtle or "soft" signs of vascular injury are present, a more deliberate thought process in assessment can occur. These soft signs may include asymmetric/diminished pulse examination, a history of hemorrhage, stable hematoma, neurologic deficits, or wound proximity and character whereby vascular injury may have occurred.

Continuous wave Doppler utilization with ankle-brachial indices (ABI), or arm contralateral brachial index in upper extremity injuries, can be invaluable. Reduction of bony injury with restoration of length should be done prior to pulse examination and ABI. An ABI of <0.9 is highly suggestive of injury and is a quick and simple tool. Studies have indicated sensitivities of 80% to 97% for arterial injury, but specificities in the 40% to 100% range due to a noteworthy false positive rate. However, negative predictive values are well over 80%. Thus, if no hard signs are present but either soft signs are present or injury is suspected, a critical pulse examination and ABI performance are indicated. In those with a normal examination and ABI, observation is appropriate, while reduction in ABI below 0.9 indicates the need for further localization, definition, and imaging. Some minor injuries may not be recognized by ABI, yet these are generally rare. Minor injuries infrequently evolve and rarely declare themselves by clinical deterioration. Only 1% to 2% of those with minimal or soft signs and normal examination come to operation for an

unrecognized injury. Indeed, in those with wounds in proximity to major axial arteries but no pulse or perfusion abnormalities and no signs of vessel injury, the occurrence of occult abnormal findings on imaging is 10% to 12% with only 1.4% ultimately proceeding to need for intervention. In assessing 300 patients with penetrating extremity injury, proximity wound, and otherwise normal physical examination and ABI, Conrad and colleagues found no missed injuries in 51% of the cohort with follow-up available between 1 and 48 months. Thus, there is plain support for no further assessment in patients with normal examination and ABI.

Computed tomographic angiography (CTA) has largely replaced catheter-based angiography in the diagnosis and definition of arterial and venous injury in the extremity. Sensitivities and specificities of over 90% have been reported (Fig. 232.1). It is quickly performed in minutes after presentation with most patients requiring CT for other indications in today's trauma environment. CTA provides information on soft tissue and bony injuries as well. It can be particularly helpful when several levels of injury are suspected viz blunt injury or multiple penetrating injuries. It is relatively inexpensive compared to angiography, and its performance over the last two decades in this fashion has created familiarity with its use. Limitations include dependence on proper bolus timing, poor luminal definition in those with atherosclerosis and significant arterial calcification, and artifact with foreign bodies and metal fragments including bullets or projectiles. Indeed, a remaining indication for initial diagnostic catheter-based arteriography in extremity injury is the limb with multiple retained metallic fragments over a large region such as shot-gun blasts with requirement for anatomic imaging. Arteriography has principally been relegated to performance as part of endovascular therapy.

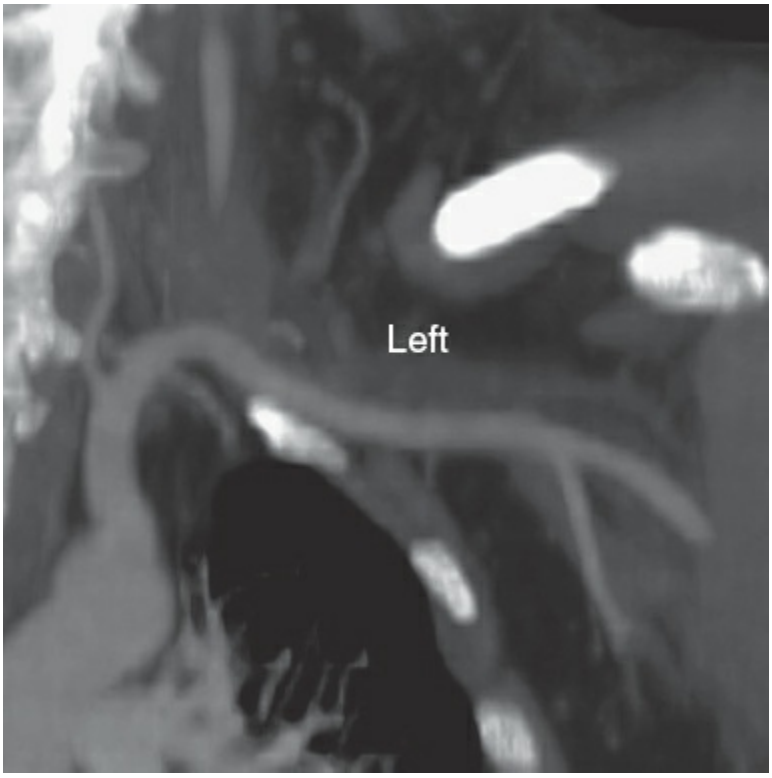

Figure 232.1. Computed tomographic angiography (CTA) reconstruction showing normal left subclavian artery with injury at the distal axillary, proximal brachial artery and absence of arterial flow.

Duplex ultrasound (DUS) has been shown to be a reasonable first-line diagnostic modality. However, it has a broader range of sensitivity and specificity than CTA. It is user-dependent and does not afford the degree of definition of inflow, outflow, and extent of injury that CTA provides. It is also limited anatomically and can only be realistically considered in evaluation beyond the junctional zones of the thoracic inlet and lower pelvis. Yet, it does have some decidedly useful applications in extremity injury. Minimal vascular injuries such as intimal flaps, pseudoaneurysms, arteriovenous fistulas, and nonspecific narrowings ("spasm") can be further physiologically defined and serially imaged with Duplex. In this regard, DUS has an additional adjunctive surveillance role. It is the initial modality of choice in iatrogenic injury. Another arena where DUS may be helpful diagnostically is knee dislocation and assessment of the popliteal artery. These injuries carry a 10% to 40% risk of popliteal artery injury. Pulse examination and ABI performance are, of course, first-line assessment, and Duplex is easy and quick to assess this focal area after reduction. Yet, as noted above, the anatomic benefits of CTA are apparent

if repair is needed. Duplex's role in most centers is relegated to confirmation of normalcy, recognition, and surveillance of minor injury, or when hardware makes CT impractical or uninterpretable.

TABLE 232.1 Mangled Extremity Severity Score (MESS)

Variable	Injury Assessment	Points
Skeletal	Low Energy (stab; simple fracture; "civilian" GSW)	1
	Medium Energy (open or multiple Fxs, dislocation)	2
	High Energy (close-range shotgun or "military" GSW; crush injury)	3
	Very High Energy (above + gross contamination; soft tissue avulsion)	4
Limb Ischemia	Pulse Reduced or Absent but Perfusion Intact	1[a]
	Pulseless; Paresthesias; Diminished Capillary Refill	2[a]
	Cool; Paralyzed; Insensate; Numb	3[a]
Shock	SBP always >90 mm Hg	0
	Transient Hypotension	1
	Persistent Hypotension	2
Age (yrs)	<30	0
	30–50	1
	>50	2

Adapted from Johansen K, Daines M, Howey T, et al. Objective criteria accurately predict amputation following lower extremity trauma. *J Trauma* 1990;30(5):568–73. Wolters Kluwer Health, Inc.
[a]Score doubled for ischemia time >6 hours.

A mangled extremity is defined as a complex injury involving soft tissue, bone, nerve, and vasculature. Determining which patients and mangled extremities will benefit from aggressive attempts at limb salvage, or which would be better served with primary amputation in the early stages of management can be challenging. Exhaustive efforts at limb salvage in severely injured patients may result in misdirection of care, whereas premature extremity amputation may preclude optimal functional outcome.

Scoring systems have been developed to take into consideration concomitant injuries, as well as the degree and nature of the bony, soft tissue, nerve, and vessel features of extremity injury. These systems are designed to assist the surgeon in decision making during the early phases of mangled limb management and also provide a mechanism to do comparative retrospective study of extremity injury. Application of

different scoring systems such as the Mangled Extremity Severity Score (MESS), Mangled Extremity Syndrome Index (MESI), Predictive Salvage Index (PSI), and Limb Salvage Index (LSI) has been evaluated regarding their ability to predict limb salvage and long-term functional outcome.

The most robust validation studies of mangled extremity scores focused on the lower extremity, and caution was proposed in applying MESS to upper extremity injury by the original authors Johansen et al. (Table 232.1). Recommendations against its relevance for upper extremities are found. Yet, the simplicity of determining the 4 clinical variables in MESS has resulted in its application in upper extremities. Slauterbeck et al. reported on 43 mangled upper extremities, and found all 9 arms with a MESS of ≥7 were primarily amputated, whereas a score of <7, found in 34 upper extremities, resulted in salvage. Durham et al. also retrospectively evaluated the application of limb salvage scores independently for both upper and lower mangled extremities and concluded MESS and MESI both decently predicted limb salvage. Interestingly, these authors concluded that these scores did not accurately predict functional outcome, iterating limb viability and function are related but not identical.

In Iraq, using a combination of 17 upper and 43 lower extremity injuries, Rush and colleagues suggested a MESS of 7 or greater predicted limb loss. In our propensity-adjusted, multivariate analysis of 64 shunted versus 61 matched, un-shunted arterial extremity injuries with nearly 2-year mean follow-up Gifford confirmed the seeming fidelity of MESS. This case control study included 35 upper extremities along with 90 lower extremity injuries. Proportional hazards modeling showed significant prediction of amputation using MESS (MESS 5–7 [RR 3.5; 95% CI 0.97–12.4; $p = 0.06$] and MESS 8–12 [RR16.4; 95% CI 3.79–70.98; $p < 0.001$]) (Table 232.2).

The general sentiment regarding mangled extremity scores suggests they serve as an objective reminder of subjective clinical experience. They provide cues to the nuances leading to either limb salvage or limb loss in significantly injured extremities, and provide a broad framework of important considerations. Yet, their clear and unquestioned use as an indicator of whether an extremity should be primarily amputated in the acute setting, or aggressive salvage pursued, remains to be proven. The expertise and opinion of the evaluating surgeon remain most essential in determining management approach.

Use of tourniquets in modern day civilian trauma has not been

systematically endorsed, but the effectiveness of tourniquets has been recently demonstrated in the combat environment. This has led to some provocative dialogue in the trauma community. Early application of tourniquets in Operation Iraqi Freedom (OIF)/Operation Enduring Freedom (OEF) has proven effective and life saving in patients with extremity injuries. In 2009, Kragh and colleagues reported on application of an extremity tourniquet in casualties in Iraq. Among 2,838 civilian and military casualties with major limb trauma, survival among 232 (8%) casualties with emergency tourniquet use was investigated. Casualties were evaluated for shock and prehospital versus emergency department (ED) tourniquet placement. There were 31 deaths (13%). Tourniquet use when shock was absent was strongly associated with survival (90% vs. 10%; $P < 0.001$). Prehospital tourniquets were applied in 194 casualties of which 22 died (11% mortality), whereas 38 patients had ED application of which 9 died (24% mortality; $P = 0.05$). The authors concluded that tourniquet use overall and particularly prehospital use was strongly associated with survival in major limb injury. A small percentage (1.7%) experienced nerve palsy at the level of application, but no amputations resulted from tourniquet use.

TABLE 232.2 Multivariate Proportional Hazards Regression Modeling for Factors Independently Affecting Time-to-Amputation in 125 Extremity Arterial Injuries (64 Shunted; 61 Unshunted)

Proportional Hazards Model			
Effect	Relative Risk	95% CI	*P* Value
TVS Group[a]	0.47	(0.18,1.19)	0.11
MESS Score (5–7)[b]	3.46	(0.97,12.36)	0.06
MESS Score (8–12)[b]	16.37	(3.79,70.79)	<0.001
Venous repair[c]	0.2	(0.04,0.99)	0.05
Associated bone injury	5.01	(1.45,17.28)	0.01

Propensity score adjustment was used to account for the differences noted in the comparison of the TVS and control group concerning Injury Severity Score and Level 2 care.
[a]Compared with no shunting control group.
[b]Compared with MESS of 1–4.
[c]Compared with venous ligation where venous injury was present.
CI, confidence interval; MESS, mangled extremity severity score; TVS, temporary vascular shunting.
Reprinted from Gifford SM, Aidinian G, Clouse WD, et al. Effect of temporary shunting on extremity vascular injury: an outcome analysis from the Global War on Terror vascular injury initiative. *J Vasc Surg* 2009;50(3):549–55, with permission from Elsevier.

In another evaluation over a 4-year period by Israeli Defense Forces, 110 tourniquets were applied to all extremity injuries. The 35 applied to the upper extremities were effective in controlling hemorrhage in 94% of the injuries as compared to 74% of tourniquets applied to the lower extremity injuries. Neurologic complications developed in 7 limbs (6%). Recent data from Davidson and the group at Oregon Health and Science University indicate that with tourniquet occlusion of the common femoral artery (CFA) in human subjects, there remained 25% to 35% residual arterial perfusion via collaterals as measured by contrast-enhanced ultrasound perfusion imaging. This information is obviously encouraging and supportive as renewed civilian interest in tourniquet applications is appearing. It seems likely that tourniquet use will be further studied and incorporated into civilian care systems in some way. Current experience supports their use for initial control of extremity vascular injury to proceed in assessment and management.

ETIOLOGY AND PATHOPHYSIOLOGY

Vascular injury of the extremities occurs in a spectrum depending upon mechanism, anatomic location, temporal circumstances, and concomitant injuries. Vessel laceration, complete and partial transection, contusion with or without secondary wall or intimal defect, secondary thrombosis or aneurysm, pseudoaneurysm, arteriovenous fistula, tapered lesions, and external compression in the perivascular space may all be at play. These may be the result of low- or high-powered blunt or penetrating mechanisms, including blast or combined, multimodal trauma. Direct damage to the blood vessel may occur, or it may be secondary to cavitation effects. Life-threatening hemorrhage may occur. Tissue ischemia, particularly if prolonged, may lead to ischemic neuropathy/plexopathy, compartment syndromes, soft tissue and muscular necrosis, and contractures. Venous congestion can contribute to relative tissue ischemia and inflammation. Associated direct injuries to the nerves, bones, and soft tissues also contribute to pain and dysfunction.

EPIDEMIOLOGY, AMPUTATION, AND MORTALITY

Civilian

Within civilian series, the overall rate of vascular injury remains low representing a mere 1% to 4% of injured patients. The extremities have

long been known as the location most often affected by vascular injury accounting for 40% to 80% of arterial injuries identified depending upon the circumstances of the reported series. Extremity injury appears to occur relatively equally in the upper and lower extremities with perhaps a slight increase in upper extremity injury recently. Mortality from extremity vascular injury, even in isolated cases, can approach 5% to 10% depending upon the vessels injured. Kauvar and colleagues queried the National Trauma Data Bank (NTDB) from January 2002 to December 2005 and identified 651 isolated lower extremity vascular injuries and found a mortality of 2.8% with amputation occurring in 6.5%. The more proximal the arterial injury, the higher the mortality as CFA injuries led to an 8% mortality. Mortality was significantly higher with injury to common femoral and superficial femoral arteries compared to popliteal and distal vessels (4.8% vs. 1.4%; $p = 0.02$) (Fig. 232.2A). Nearly 80% of deaths were from penetrating injury. On the other hand, amputation occurred more commonly with injury to the popliteal and tibial arteries compared to the femoral arteries (8.3% vs. 4.1%; $p = 0.03$). Amputation occurred twice as often when the mechanism of injury was blunt (9.1% vs. 5.1%; $p = 0.05$) (Fig. 232.2B).

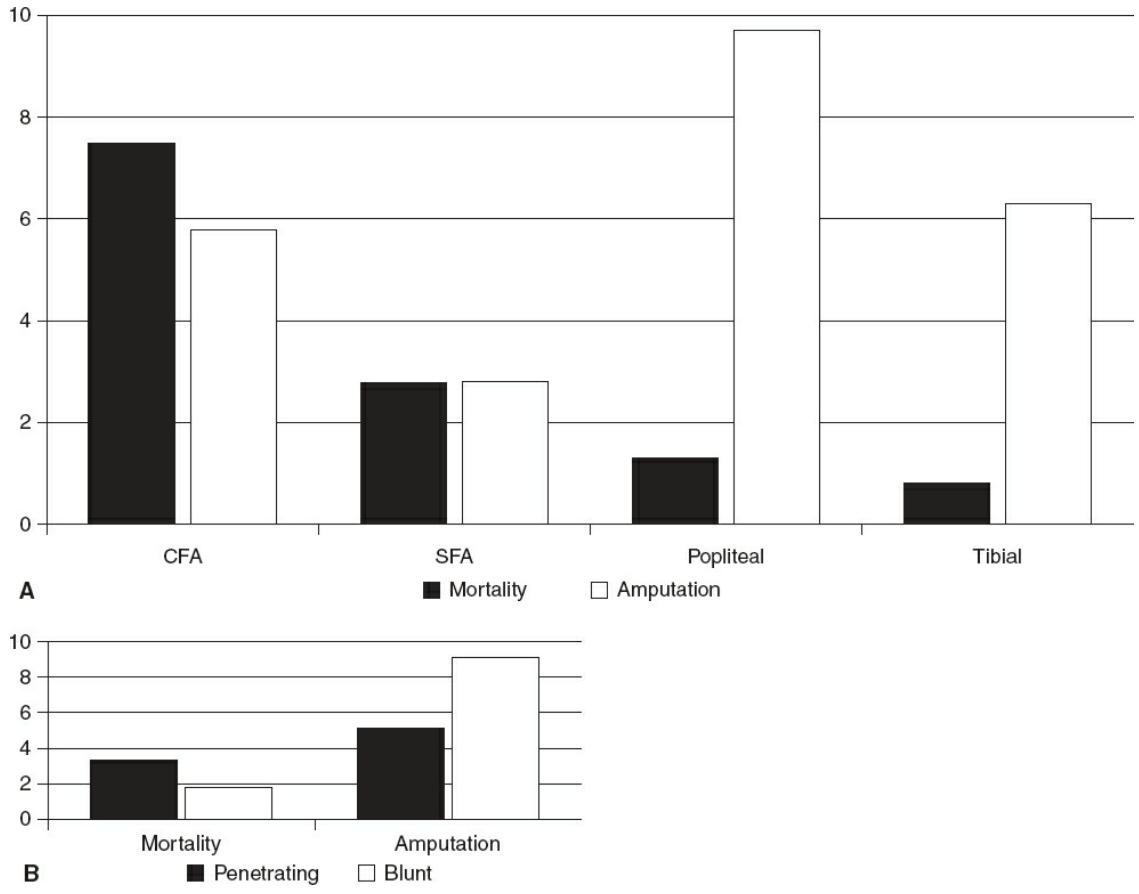

Figure 232.2. **A.** Mortality rates and amputation rates by anatomic injury level in isolated lower extremity arterial injuries. **B.** In these patients, mortality and amputation rates by general mechanism of injury. (Reprinted from Kauvar DS, Sarfati MR, Kraiss LW. National trauma databank analysis of mortality and limb loss in isolated lower extremity vascular trauma. *J Vasc Surg* 2011;53(6):1598–603. Copyright © 2011 Society for Vascular Surgery, with permission.)

Perkins and colleagues provided a recent meta-analysis of almost 3,200 lower extremity vascular injuries, which reported factors associated with secondary amputation after arterial repair. Significant prognostic factors heightening amputation risk were soft tissue injury (26% vs. 8%; OR 5.8), compartment syndrome (28% vs. 6%; OR 5.1), multiple arterial injuries (18% vs. 9%; OR 4.9), and ischemia over 6 hours (24% vs. 5%; OR 4.4). Mechanism of injury was also significant as blast and blunt injuries led to amputation more than penetrating injury (19% vs. 15% vs. 5%, respectively). Age over 55 was also an important characteristic as was the central proximity of injury. Secondary amputation occurred in 18% of iliac, 14% of popliteal, and 10% of tibial injuries while femoral artery injuries led to amputation in only 4%. Most of these factors are indeed what is appreciated experientially across trauma centers.

Injuries to upper extremity arteries in the civilian setting less commonly lead to death or amputation. The more proximal the injury, the higher the risk of amputation or death. Tan and colleagues queried the NTDB investigating over 8,000 civilian extremity arterial injuries to compare lower extremity and upper extremity outcomes. They describe lower extremity injury more commonly resulting from blunt mechanisms, and upper extremity injury more likely penetrating in nature. Lower extremity injury was independently associated with increased mortality (OR 2.2; $p < 0.0001$) and risk for amputation (OR 4.3; $p < 0.0001$). This relationship was maintained when stratified by type of mechanism. Blunt mechanism portended higher mortality and amputation (Fig. 232.3). Overall, mortality was 2.2% in upper extremity injuries versus 7.7% in those of the lower extremity ($p < 0$ .0001). Amputation occurred in 7.8% of lower extremity injuries compared to only 1.3% of upper extremity arterial injuries ($p < 0.0001$).

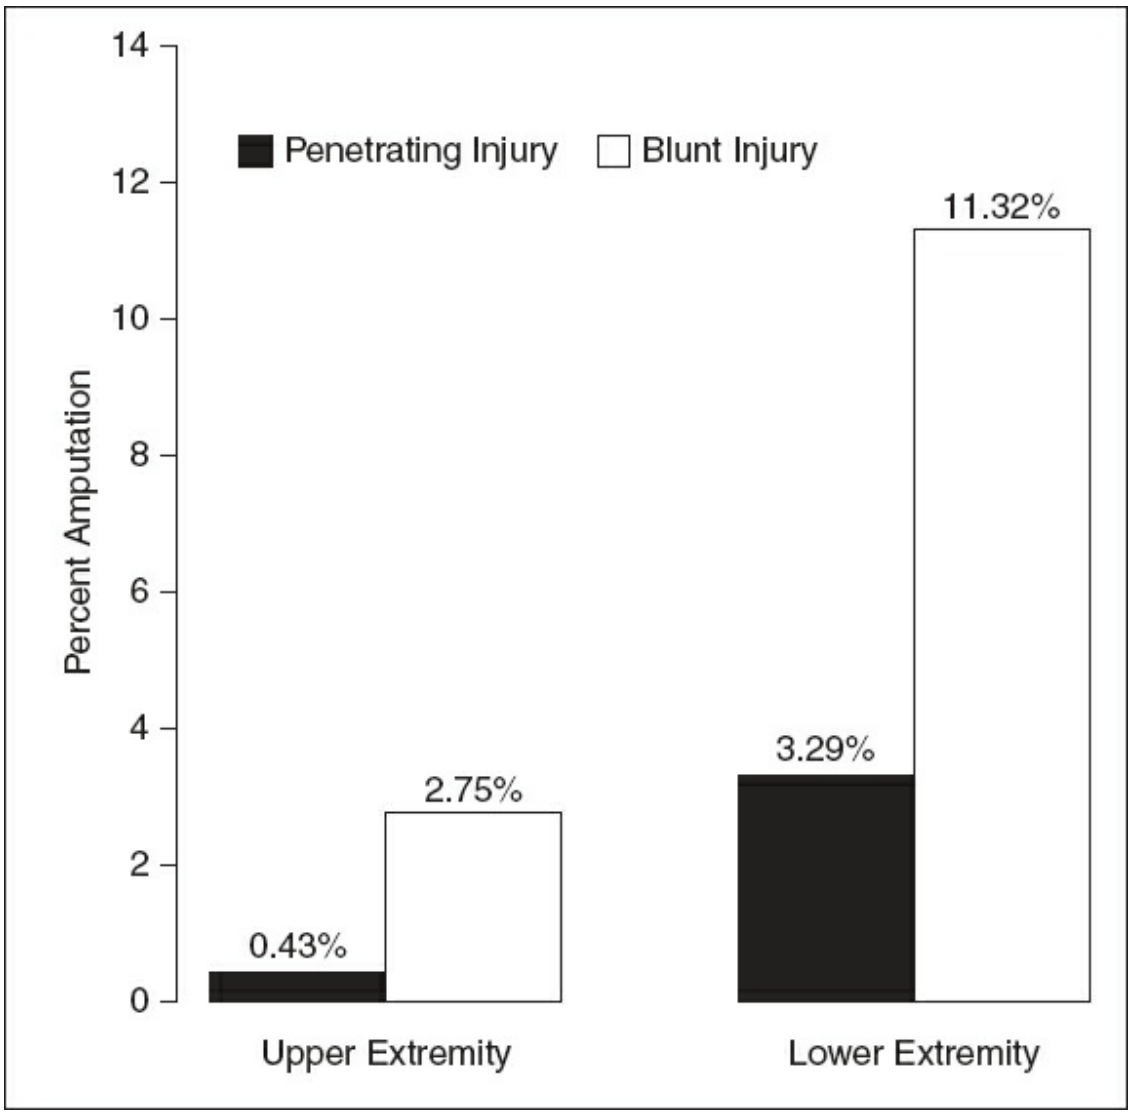

Figure 232.3. Comparative amputation rates by upper and lower extremity arterial injury stratified by mechanism of injury. (From Tan TW, Joglar FL, Hamburg NM, et al. Limb outcome and mortality in lower and upper extremity arterial injury: a comparison using the National Trauma Data Bank. *Vasc Endovasc Surg* 2011;45:592–7. Copyright © 2011 SAGE Publications Ltd, All rights reserved.)

Military

Rates of vascular injury during military operations have been a point of interest throughout documented history. Modern assessment began when DeBakey and Simeone reported an identified arterial injury rate of 0.96% in World War II. Accounts from the Korean War cited rates of 1% to 3%. Recent data show the rate of vascular injury during war appears to have increased from 2% to 3% of battle-related injuries during the Vietnam War

to 4% to 12% during the wars in Iraq and Afghanistan. Over 2004 to 2006 in Balad, Iraq, using a cohort of 6,800 casualties with nearly 350 vascular injuries, we documented an incidence of vascular injury (4.8%), the accompanying operative mortality (4.3%), and early amputation rate (6.6%). Extremity injuries accounted for 75% of vascular reconstructions performed. This was significantly expanded by White et al. who, using the tools of the Joint Theater Trauma System and the Joint Theater Trauma Registry (JTTS/JTTR), were able to more precisely describe this apparent augmentation in vascular injury rates. Between January 2002 and September 2009, over 13,000 battle-related injuries occurred in U.S. troops. Of these, 12% had identified vascular injuries documented and 9% underwent operative intervention for these injuries. Seventy-nine percent of vascular injuries occurred in the extremities with distal arterial injury in the forearm vessels or tibial vessels accounting for 40% of all identified injuries. Only 12% of injuries were in the torso, and 8% cervical (Fig. 232.4). Mortality in OIF/OEF extremity wartime injuries has been determined to be 2% to 4%. This clear temporal uptick in vascular injury identification is most likely due to modern casualty care strategy and tactics with better battlefield evacuation, forward surgical assets, and newer diagnostic modalities.

REPAIR INDICATIONS AND NONOPERATIVE MANAGEMENT

Identification of extremity arterial injury associated with hemorrhage or ischemia is an indication for repair. The goal of course is to prevent exsanguination, restore appropriate axial arterial perfusion, and perhaps maintain venous continuity. When identified extremity arterial injuries are minimal and there is no active hemorrhage or critical diminution in distal perfusion, observation may be considered. These lesions are clinically silent. They include intimal flaps and defects, tapered narrowings, small pseudoaneurysms, and arteriovenous fistulae as noted previously. This discussion has become even more relevant due to the continual, significant improvements in arterial imaging techniques leading to more sensitive recognition of these injuries. Yet, only 1% to 2% of minimal injuries will re-present requiring repair, and in available series no interventions have been required after 3 months in identified and observed minimal extremity injuries. A mature, but small body of descriptive literature, including animal intimal injury models, has indicated that the most benign of these

lesions are small intimal flaps, and nonspecific taperings (i.e., spasm in otherwise normal vessels) that heal at rates well over 90%. It has been suggested that intimal flaps producing over 75% luminal stenosis are more problematic and repair considered. Small pseudoaneurysms (<5 mm) also spontaneously heal but may require intervention in up to 30% to 40%. Arteriovenous fistulas, which are least common, may also spontaneously close when small (<5 mm). Initial nonoperative surveillance is appropriate. Larger ones are probably best served with repair. When surveillance of these lesions shows progression or enlargement, repair is indicated. Aspirin in minimal lesions appears beneficial and improves patency. How endovascular intervention may impact these minimal injuries is unclear, and must be considered on a case-by-case basis. When repair is pursued, endovascular methods logically may simplify this technically. Given the historical rates of resolution and the complication profile of endovascular therapies, this decision is likely to remain left to clinical intuition.

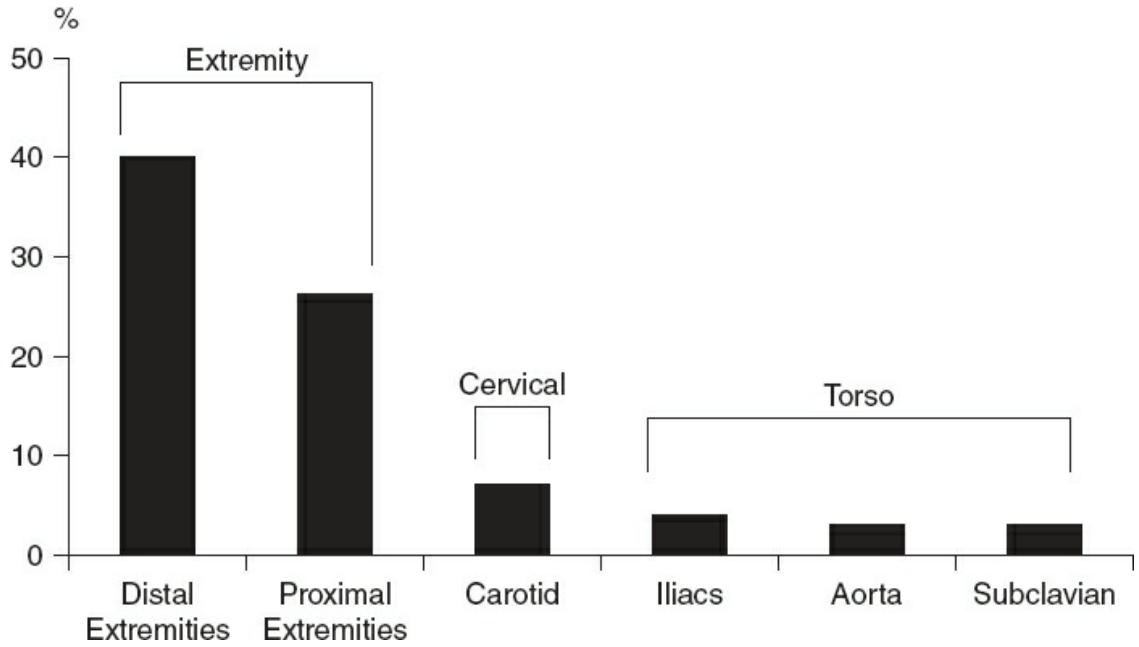

Figure 232.4. Distribution of identified vascular injury in U.S. forces during Operation Iraqi Freedom and Operation Enduring Freedom noting the high prominence of extremity injury. (From White JM, Stannard A, Burkhardt GE, et al. The epidemiology of vascular injury in the wars in Iraq and Afghanistan. *Ann Surg* 2011;253(6):1184–9.)

Because of vessel size and reactivity, nonoperative management may be considered in young children if the limb appears viable or distal flow can

be documented. In newborns and infants, nonoperative management is preferred and use of a systemic antithrombotic therapy, topical vasodilators, warming mechanisms, and plastic covers on the limb to augment vasodilation and flow logical options. In the severely injured patient with poor prognosis or a prohibitive risk, a nonoperative approach to nonhemorrhaging lesions can be considered.

PREOPERATIVE PLANNING

Depending upon injury location, active hemorrhage may require digital control from an assistant, or placement of an available windlass tourniquet or pneumatic tourniquet to prevent exsanguination. The patient should be placed on a fluoroscopically compatible table to allow for endovascular control and angiography. Today, utilizing hybrid, fixed imaging operating rooms permits the full management spectrum of open surgical and endovascular therapeutic options and comprehensive flexibility. Prepping and draping should be circumferential with extension extended contiguously onto the torso to allow for any conceivable control option. Other extremities in which autogenous conduit may be harvested should be prepared. Not uncommonly, to avoid thermal loss as possible, prepping widely with sterile sheets placed over areas until or if they are required is prudent.

SURGICAL TECHNIQUE (INCLUDING DIAGRAMS)

General Operative Topics

There are several general operative considerations that should be reviewed in the care of the patient with an extremity vascular injury. These include the proper role for shunting techniques, vein repair, conduit selection, wound management, as well as the impact of fasciotomy.

Temporary Vascular Shunting (TVS)

Temporary intravascular shunts can allow for rapid restoration of distal limb perfusion when immediate vascular reconstruction is not possible (Fig. 232.5). This may be due to delays involving orthopedic fixation, major wound debridement and definition, vein harvest, lack of clinical expertise at the initial treating facility, or addressing more life-threatening injuries. Arterial injury identification, thrombectomy, regional heparin, and selective intra-arterial vasodilators with temporary shunt placement

provide reperfusion and time. This has become known as vascular damage control. Use of intravascular shunting has been specifically applied as a method to stabilize and temporize peripheral vascular injuries, avoid vascular reconstructions in austere environments with limited resources and time, and allow for restitution and preservation of extremity perfusion during transport to definitive care. Furthermore, shunting has been used during mass casualty events and during damage control in those with significantly adverse physiology or concomitant injuries. Patency reports for temporary shunts have refuted the obligatory need for systemic anticoagulation for maintenance in the first 24 to 48 hours after placement.

We chronicled descriptive data from the Balad Vascular Registry demonstrating that shunts placed for proximal vascular injuries (at or proximal to the knee or elbow) had a significantly greater patency (86%, n = 22) than shunts placed in distal vascular injuries (distal to the knee or elbow) (12%, n = 8). However, no difference in early limb viability was identified between the groups (95% and 88%, respectively; p = NS). Thus failure of the distal shunts did not result in decreased limb viability. Our experience with shunt use in 126 femoropopliteal arterial injuries specifically described that 43% were shunted. Of these, 93% were patent on arrival to us with only two (4.7%) shunts dislodged during evacuation. Stability in mobility was confirmed.

In 2009, Gifford presented longer-term outcome analysis in a case-controlled, propensity matching fashion with a time-to-event analysis portraying TVS's impact on freedom from amputation using data collected from the Joint Theater Trauma Registry (JTTR), including the Balad Vascular Registry (BVR), and the Walter Reed Vascular Registry (WRVR). Cases and controls consisting of 64 and 61 extremity arterial injuries, respectively, had a mean follow-up of 22 months. While the shunted group showed significant higher mean injury severity scores when compared with the control group (18 vs. 15, p = 0.05), after propensity score adjustment, use of TVS suggested a reduced risk of amputation, but was not statistically significant (RR = 0.47; 95% CI [0.18–1.19]; p = 0.11) (Table 232.2). Similar freedom from amputation was identified in both shunted and nonshunted extremities after definitive reconstruction (78% vs. 77% at 3 years; p = 0.5), but relative, graduated improvement in limb salvage with shunting as the severity of extremity injury increased was noted (Fig. 232.6A,B).

Civilian series report similar results and considerations regarding use of

shunts and corroborate potential benefits. Animal study evidence, both physiologic and histologic, in support of venous shunting in combined arterial/venous extremity injuries is scant but available. The generally beneficial effects in these experiments speak to the potential of venous repair. The theoretic benefits of venous shunting, as well as those of arterial therapeutic, or pharmacologic, shunting remain to be further studied and defined. As this information develops, the posture of shunting in civilian settings should be clarified.

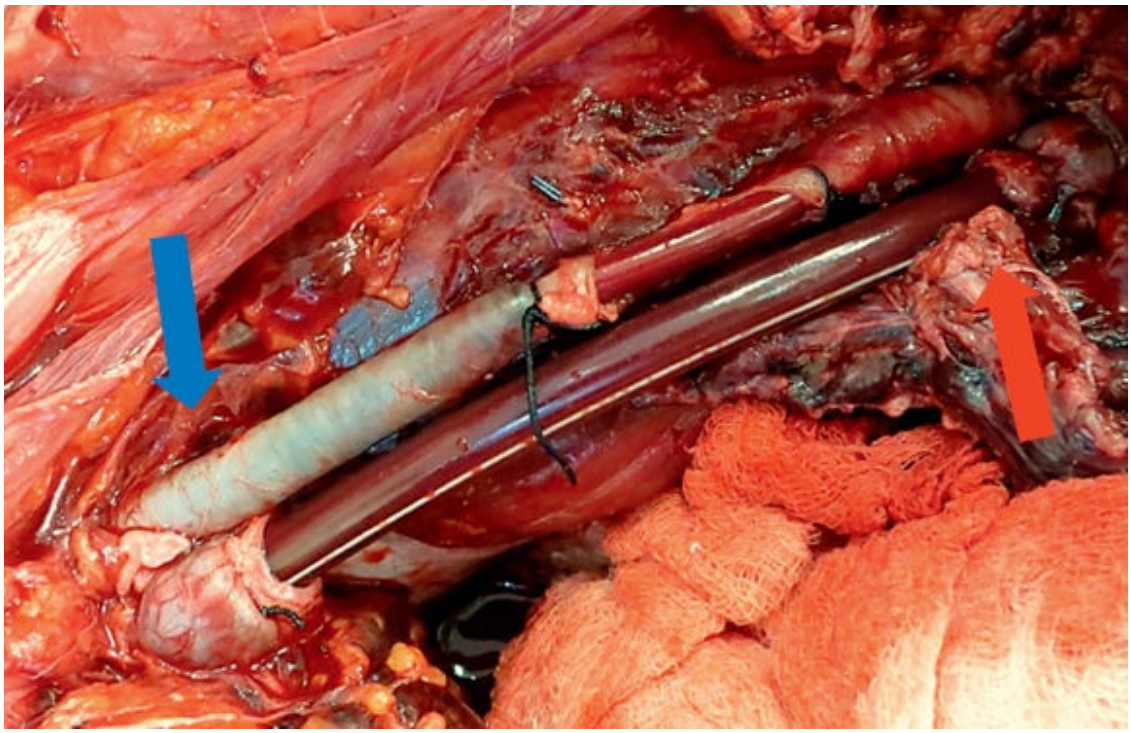

Figure 232.5. Arterial and venous shunting of proximal superficial femoral artery and femoral vein in major multimechanistic injury to the right upper thigh. Note the difference in color and apparent viability of the blood vessels (*red arrow*) versus the lack of perfusion and viability distally (*blue arrow*).

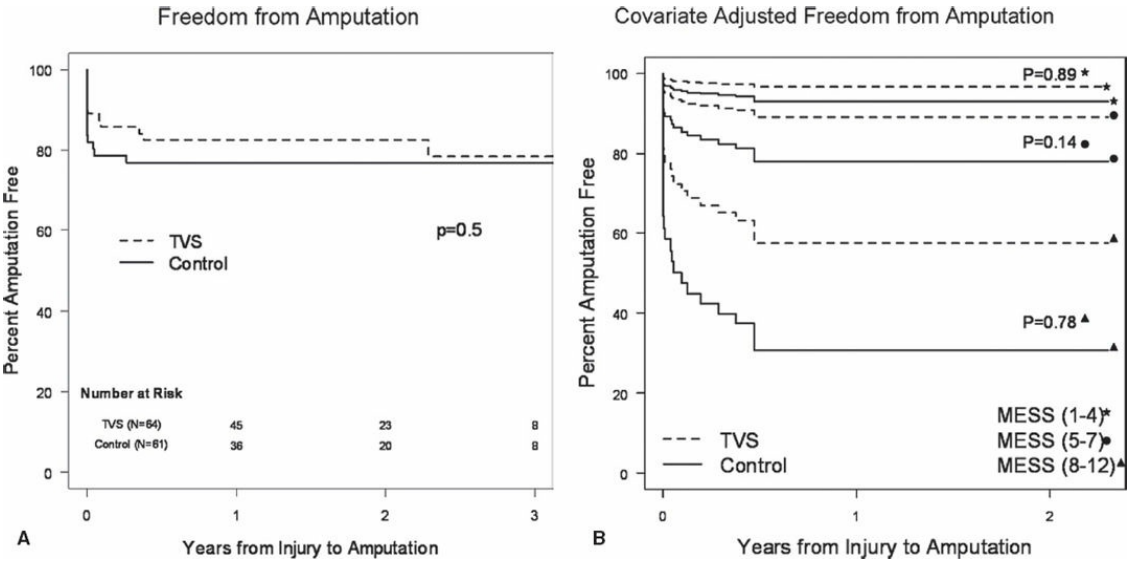

Figure 232.6. **A.** Freedom from amputation in shunted versus matched unshunted extremity arterial injury cohorts showing no difference in long-term outcome but no detriment to shunting. **B.** Graduated, relative benefit of shunting as the severity of extremity injury worsens. (Reprinted from Gifford SM, Aidinian G, Clouse WD, et al. Effect of temporary shunting on extremity vascular injury: an outcome analysis from the Global War on Terror vascular injury initiative. *J Vasc Surg* 2009;50(3):549–56. Copyright © 2009 Elsevier, with permission.)

Potential drawbacks of TVS such as unrecognized iatrogenic vessel injury, or necessity for more extensive repair owing to securing mechanisms seem negligible overall. Even when faced with primary vascular injury at the time of definitive management, the author finds initial shunt use can be quite effective in providing time for operative planning and optimization in the operating room. This simple strategy may create an environment for a more precise and durable final revascularization with improved neuromuscular outcome.

Traditional surgical teaching, based upon simple muscle histology evidence, promulgated 6 hours as the ischemic threshold beyond which functional recovery was likely not possible. However, a new porcine model has provided more scientifically rigorous assessment. Our initial model reported by Gifford describing the biochemical effects of various temporal profiles of ischemia confirmed TVS reversed ischemia. Utilizing this model and allowing for survival, Burkhardt studied neuromuscular recovery by electromyography and modified Tarlov functional scores. Just under 5 hours of ischemia was identified as the breakpoint after which neuromuscular recovery was worse than initial ligation at 14 days after

injury. This was then taken one step further and Hancock reported this threshold was reduced to 3 hours of ischemia with 35% hemorrhage and class III shock. Exactly how this animal model reflects the physiology of human traumatic ischemia is not certain, but it seems clear 6 hours of ischemia is indeed an extreme regarding the functional recovery potential of the limb, and in most injuries, it is likely less. The clinical physiology and shock status of the patient is, as one would anticipate, important, and may reduce this threshold.

Conduit Selection

Primary repair and interposition grafting are the technical open methods used in most arterial repairs for extremity injury. The decision for and knowledge of proper conduit use are therefore essential. Autogenous venous conduit should generally be procured from an uninjured extremity so as not to further disrupt venous return. This is usually the great saphenous vein (GSV). However, for shorter interposition grafts, a single segment of arm vein is acceptable. Also, should the injury in the extremity not lead to substantial soft tissue injury and no associated axial venous injury is present, a short segment of ipsilateral great saphenous vein, or superficial arm vein in upper extremities, can be considered. When multiple extremities are involved, autogenous vein harvest from the extremity with the least amount of injury is proper. Occasionally, femoral vein, jugular vein, or hypogastric artery may be rational. We have also used both autogenous venous and arterial conduit from other primarily amputated limbs.

The use of prosthetic grafts for reconstruction of military extremity vascular trauma has been consistently discouraged. In a report from the Vietnam Vascular Registry, only four (0.4%) patients with arterial injuries were managed using prosthetic graft interposition grafts. The importance of autogenous conduit for contaminated war wounds has also been encouraged and emphasized in OIF/OEF. Among 301 arterial injuries in OIF, only 8 (2.7%) were repaired using a prosthetic graft and 3 of these were in the abdomen or chest.

Vertrees and colleagues underscored the need for surgical judgment in knowing when a prosthetic graft may be useful. As of 2010, the Walter Reed Vascular Registry only had 17 (4.6%) casualties who had undergone emergent vascular reconstruction using polytetrafluoroethylene (PTFE) grafts. Despite a prosthetic graft being emergently placed into large

contaminated soft tissue wounds, 79% of these prosthetic grafts were patent in the short term. This strategy allowed for patient stabilization, transport to stateside facility, and elective rather than emergent revascularization with remaining autologous (arm or leg) vein. There were no prosthetic graft disruptions or amputations performed because of prosthetic graft failure. The authors concluded for complex repairs, when autologous conduit is limited, a temporary prosthetic graft followed by staged, definitive autogenous reconstruction may be a reasonable option. Recently, Watson and colleagues performed a small, retrospective cohort matched study assessing PTFE (n = 25) versus autogenous vein (n = 24) in arterial injury in the JTTR. Mean follow-up was over 5 years. While PTFE in the carotid-subclavian domain performed equal to vein, PTFE in the extremity performed poorly. The 8-year freedom from complication was significantly worse for prosthetic (77% vs. 31%; p = 0.044). These PTFE failures were evenly distributed among thrombosis, infection, and restenosis and were distributed throughout the follow-up timeframe. Autogenous failure did not occur after the first few months.

Civilian literature has also espoused the use of PTFE prosthetic as a reasonable alternative conduit. This is most logical and successful in proximal, larger vessels for appropriate size match in low impact injuries with little soft tissue injury. Patency in PTFE grafts for extremity vascular injury, generally however, has not been encouraging. In a recent meta-analysis of almost 1,200 lower extremity injuries repaired by interposition grafts, the use of PTFE was associated with a nearly twofold higher risk of secondary amputation (OR 1.88; CI 0.55–5.83, p = 0.88). This likely reflects two features of extremity injury grafting. The available data indicate autogenous conduit is preferred, particularly in high-impact, high-velocity injuries leading to major soft tissue destruction. Yet, even in this considerable number of patients, statistical superiority was not realized indicating that when clinical reasoning dictates, PTFE can logically be used.

Arterial Repair

Wide exposure of the injured artery with local control is accompanied by assessment of surrounding soft tissue. Once local control is achieved, release of more global control, if utilized, should be a priority to diminish ischemia. Debridement of devitalized tissue with an eye toward reconstruction coverage is necessary. Revascularization is usually able to

be accomplished in an anatomic way, but in extensive injury with severe tissue destruction and debridement, creative graft tunneling in septal planes may be needed and is essential. Prior to repair, vessel debridement should also be performed. While it is easy to say this should be done to "healthy" vessel, this is sometimes difficult and subjective. In the author's experience, the color of the vessel is key (Figs. 232.5 and 232.7). Arterial appearance should be bright with red vasa vasorum indicating their patency. When the artery is opened, the intima should not only be intact, but moist and tan, not hemorrhagic, contused, or gray. More debridement is usually safer than too little within reason. The author tends to debride to areas for anastomosis while leaving the back wall intact when the artery is not fully transected in order to maintain length and tension. Identified major nerve injuries can either be repaired early or in a delayed fashion depending upon wound and mechanism, but discussion regarding this disposition is essential during operative management.

Systemic use of heparin should be considered when other injuries do not afford undue risk. In isolated injuries, standard doses can normally be given. Graduated use based upon other injuries is reasonable, and in those with systemic use contraindicated, regional heparin saline is particularly important. The general approach to arterial injury repair should include gentle Fogarty balloon thromboembolectomy proximally and distally starting for just a few centimeters looking for strong, thrombus-free inflow and patent outflow. Too vigorous of embolectomy can cause irritation and spasm. Further thrombectomy is only occasionally necessary. Regional heparin should be instilled after judgment of distal and proximal patency. Vasodilators such as nitroglycerine should be considered both topically and instilled into the inflow and outflow. In low-velocity, penetrating trauma, with laceration, primary repair or patch angioplasty is occasionally feasible. With blunt injury, gunshot wounds, or extensive blast injury, interposition or bypass grafting is the correct construct. The size, quality, and reactivity of arteries in children require a specific comment. These features make them quite difficult to adequately repair. Should repair be necessary, liberal use of topical and infused vasodilators can be helpful. Interrupted anastomoses are important to allow for radial growth of the vessels. In children, the great saphenous vein can be a reasonable conduit, but femoral vein, internal jugular vein, and hypogastric artery are important considerations.

Vein Repair

The optimal management of extremity venous injury remains a controversial topic. Ligation of the named veins of the extremity can be performed in austere conditions, when another life-threatening injury takes precedence, or when the patient's physiology will not allow extended operation with relatively low acute morbidity. It has been previously recommended that venous injuries ideally should be repaired when the patient's condition permits. Extremity venous repair gained prominence during the Vietnam War with Rich reporting 377 venous injuries, in which 124 (32.9%) were repaired. Lateral suture was the most common repair performed (n = 106) followed by end-to-end anastomosis (n = 10), vein interposition graft (n = 5), and vein patch graft (n = 3). It was noted in this report, and further emphasized later from the Vietnam Vascular Registry, that concern for thromboembolic complications did not materialize as was historically expected with venous repair. Rich went on to also suggest that extremity venous repair may be important to limb salvage, and although many repairs fail, a major proportion of these may recanalize without higher risk. How recanalization relates to meaningful venous return and later insufficiency has not been defined. It was further work by Rich and Hobson that identified the negative impact of proximal femoral venous ligation on arterial flow in a canine model and formed the foundation of the current venous shunting and repair mindset. This also established the premise that vein repair might facilitate arterial flow and serve as an important component in arterial reconstruction durability.

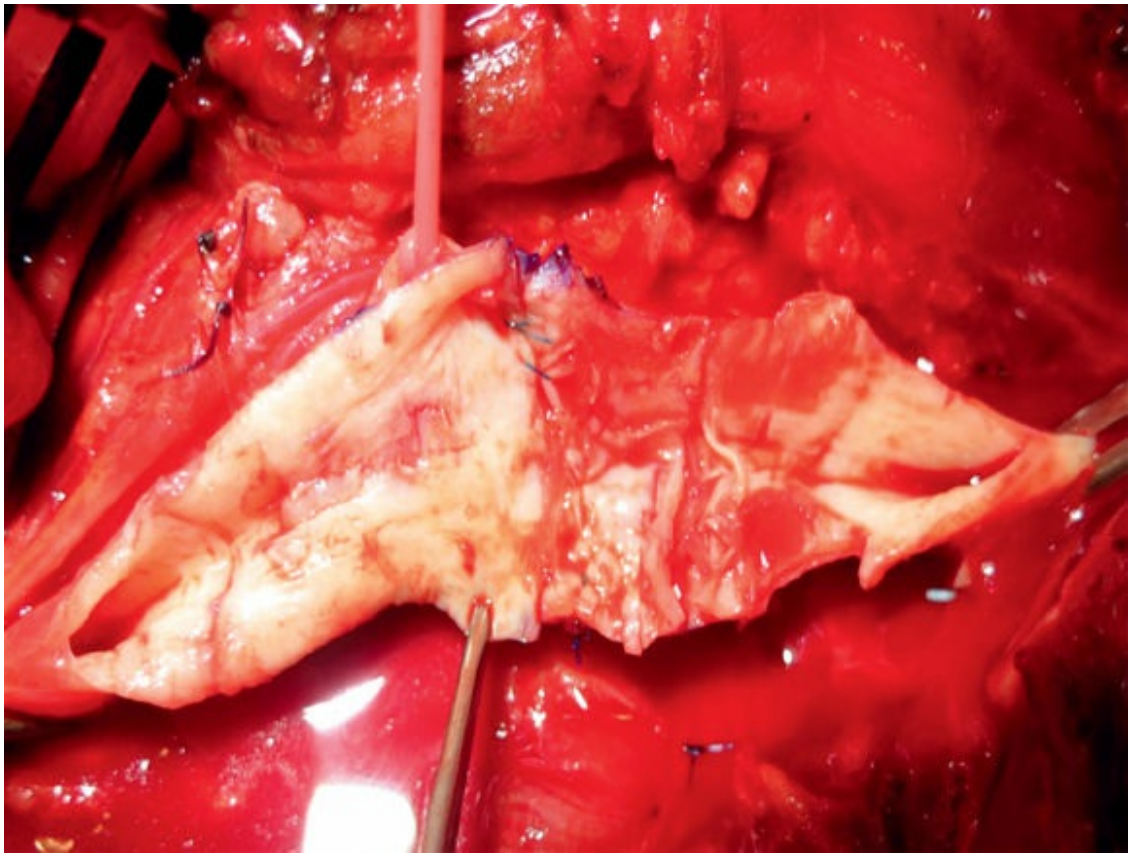

Figure 232.7. Inspection of injured superficial femoral artery shows disrupted vessel wall and the artery opened to healthy, normal appearing intima.

In another large, more recent military series, Quan et al. retrospectively reviewed 82 patients with 103 venous injuries. While a majority of patients (63%) were treated with ligation, no significant difference in postoperative thromboembolic complications was seen between the group that had ligation and the group that underwent venous repair. In 2009, our reported cohort matched shunting evaluation identified venous repair as independently protective against amputation (RR = 0.2; 95% CI [0.04–0.99], $P = 0.05$) during evaluation of 125 combat extremity vascular injuries (Table 232.2). Most recently, a comprehensive meta-analysis of the world's literature on lower extremity vascular injury was conducted by Perkins and colleagues. They were able to identify 904 venous injuries associated with arterial injury along with described limb outcomes. Astoundingly, venous repair provided a six times lower risk of secondary amputation compared to ligation (OR 0.17 [95% CI: 0.06–0.39]; $p < 0.01$). It seems to be becoming clearer the advantages of venous repair do extend to limb salvage particularly in combined arterial and venous injuries.

Civilian series evaluating extremity venous repair are small,

descriptive, and without consensus. These have indicated a significant early repair thrombosis rate, but have confirmed recanalization with generally low morbidity rates in civilian environments. There has been no identifiable difference in outcomes with repair versus ligation or formal associations with amputation based upon management. Smith and coworkers reported that in 20 major extremity venous injury repairs, patency at 72 hours was 55% but increased to 85% at 6 weeks with little morbidity. Meyer et al. reported 34 patients with venous injury (26 lower extremity, 8 upper extremity), and showed 61% early patency for all venous repairs with a 40% early patency for interposition vein grafts. Nypaver and colleagues reviewed longer-term follow-up (mean 49 months; range 6 to 108 months) for 32 patients who had venous reconstruction, and found long-term patency to be 90% as determined by duplex ultrasound. Yet, in 74 patients with extremity venous injury, Yelon and Scalea concluded that ligation was a safe and reasonable option as no differences in outcomes were identified between the 44 ligated and the 30 repaired. Finally, Timberlake and Kerstein reported on 322 patients with venous injury—83 injuries were isolated venous injuries, while 239 were combined arterial and venous. With mean follow-up of 34 months, only 4 patients (1.2%) had long-term edema. All four had arterial and venous injury at the popliteal level. This seems to speak to the wide variability in civilian extremity trauma severity and mechanism. Arguments against venous repair surround time required, difficulty in repair, the patient's associated injuries and general condition, and unidentified long-term benefit.

TABLE 232.3 Triage Categories of Extremity Venous Injury Management

Triage Category	Injury Characteristic	Recommendation on Vein Repair
1.	Isolated extremity injury	Vein repair
2.	Vascular injury with other Non–life-threatening injuries	Vein repair
3.	Multiple vascular injuries	Vein repair if simple. Based on location and patient condition. Consider shunting/ delayed decision in OR
4.	Vascular injury with other life-threatening injuries	Diminished role. No vein Consider shunting/delayed repair
5.	Vascular injury and instability	No vein repair. Ligation Consider delayed repair if reasonable

From Williams TK, Clouse WD. Current concepts in repair of extremity venous injury. *J Vasc Surg: Venous Lym Dis* 2016;4:238–47.

These thoughts have collectively led to the author's relatively aggressive stance to repair veins particularly in the proximal limb and in confluence veins where larger veins represent watershed areas of venous drainage such as in the axillosubclavian venous segment, common femoral vein, or a single popliteal vein. Contemplative of Rich's Vietnam work, our initial OIF reports characterized a 60% to 70% repair rate for identified extremity venous injury. Furthermore, we have suggested five triage categories for extremity venous injury along with management considerations (Table 232.3). Duplicate venous systems can be present, and should be identified. For instance, a duplicate popliteal venous system can be present in up to 30% to 40% of individuals.

Extremity vein repair should also be heavily considered in instances where there is multimechanistic injury resulting in a soft tissue defect likely to compromise venous collateral network return. Rich, in his experimental work, suggested each limb has many collateral venous channel networks, and these are important in limb drainage when the main axial channel is disrupted. With extensive soft tissue injury, these are also compromised, and repair's significance is likely more robust. In these instances it is the author's observation that maintenance or reestablishment of the main axial venous outflow is important in quality limb salvage. The caveat, of course, is that the patient should be in a physiologic state in which repair can be tolerated and no other life-threatening injuries should take precedence. Ligation is logical and appropriate in this situation. As noted, the role of venous shunting is undefined but intriguing. The general goals of venous repair are acute decompression of the congested, injured

limb decreasing venous blood loss, to permit venous collateral development or maturation, enhance arterial repair durability, and to reduce edema and long-term postphlebitic changes.

Debridement for venous repair is quite challenging as these veins usually have some element of thrombosis, but similar principles should apply with normal appearing intima and external features after preparation. Vein repair, when performed, is initiated by ESMARCH exsanguination of the elevated distal limb with the distal aspect of the vein widely free and open without occluding control in order to clear distal thrombus as possible. Gentle thromboembolecotmy with Fogarty balloons smaller than the veins can be helpful in catching strands of thrombus. Regional heparin should be instilled. Depending upon mechanism and destruction, primary repair, patch angioplasty, interposition grafting or panel grafting can be performed (Fig. 232.8A,B). It is difficult to gauge what the allowable size mismatch is for venous repair. The author's tact in repair has been to accept up to a 50% decrease in diameter using interposition grafts, as long as the distended autogenous graft diameter is 5 mm or more. Anything less requires panel grafting. Spiral grafting is described but requires more time and is technically demanding to fashion appropriately and secure. A panel graft allows for placement in situ with appropriate tension to assist construction when each panel is first secured to the proximal and distal ends of the vein. Panel grafting much more than 10 cm of venous defect is simply too time demanding in these acute situations to be normally justifiable. The author has tended to repair venous injury prior to arterial repair when (1) TVS normalizes distal flow with either palpable pedal pulses or brisk continuous wave Doppler signals, (2) the extremity injury is isolated or there are only minor concomitant injuries, (3) autogenous conduit is adequate and generous, and (4) there is substantial soft tissue injury. As noted, this latter scenario often leads to rapid tissue edema and venous oozing with significant ongoing blood loss. Restoration of venous outflow prior to definitive arterial reconstruction can impressively reduce bleeding and the appearance of venous congestion.

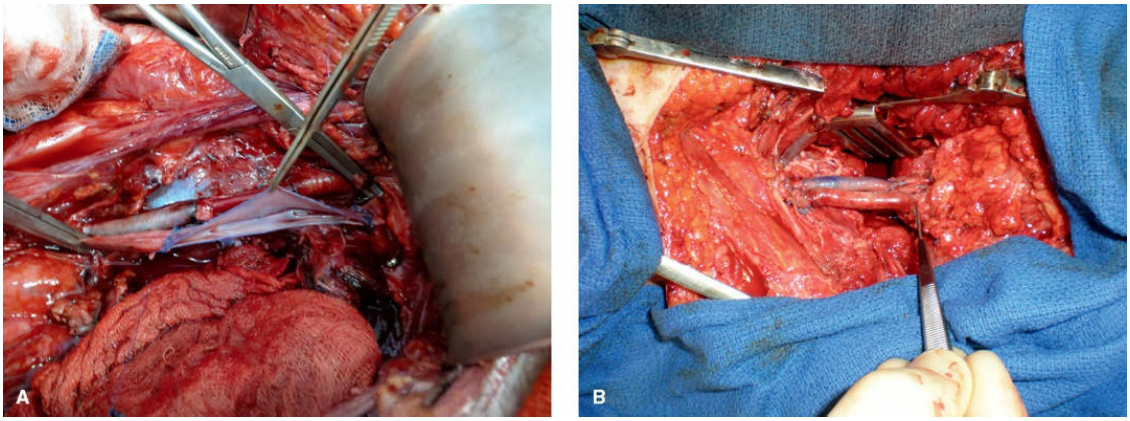

Figure 232.8. Constructs of extremity vein repair. **A.** Creation of a panel vein graft with two panels of great saphenous vein to repair the proximal femoral vein. **B.** Interposition vein grafts of the popliteal artery and vein above-knee.

Fasciotomy

The traditional indications for fasciotomy in extremity injury include ischemia over 4 hours, significant blast, soft tissue or crush injury, patient evacuation scenarios, and inability of the patient to subjectively participate in examination (i.e., head injury). In reality, fasciotomies are best done whenever they are considered and remain an integral component of the surgical treatment of extremity vascular injury. The argument for selective fasciotomies stems from small series touting long-term pain and reduction in calf-pump efficiency. However, the flaw in this logic is noted by recent assessments of delayed fasciotomy and missed release. Ritenour and colleagues reported on 336 U.S. combat wounded undergoing fasciotomy for major limb trauma. They found those with fasciotomies needing revision had significantly more muscle excision and higher overall mortality (20% vs. 6%; $p < 0.01$). Furthermore, they noted statistically significant increases in muscle excision, amputation (31% vs. 15%; $p < 0.01$), and mortality (19% vs. 5%; $p < 0.01$) if fasciotomies were performed after evacuation, or delayed, than if done in theater. This theme was reiterated by Farber et al. who recently reviewed outcomes of civilian patients with fasciotomies and lower extremity arterial injury repair in the NTDB. Compared to those who had fasciotomies accomplished beyond 8 hours of repair, those within 8 hours of repair had a significantly lower amputation rate (8.5% vs. 24.6%; $p < 0.001$), infection rate (6.6% vs. 14.5%; $p = 0.028$), and shorter hospital stay (18.5 ± 20.7 days vs. 24.2 ±1 4.7 days, $p = .007$). On multivariate analysis, early fasciotomy was protective against amputation (OR 0.26, 95% CI 0.14–0.50; $p < 0.0001$)

and led to a 23% shorter stay ($p = 0.01$).

Two-incision lower extremity compartment release is recommended. Via the medial incision, the posterior superficial compartment is opened with initial fascial incision. The posterior deep compartment is entered by release of the fibrous attachment of the soleus on the tibia for its length. The lateral incision is performed 2 to 3 fingerbreadths lateral to the tibial edge. The anterior compartment is opened by fascial incision in this plane. The lateral compartment is either entered via separation of the intercompartmental septum as viewed in the anterior compartment, or it may be entered separately by posterior retraction of the skin and subcutaneous tissue of the incision to expose the lateral compartment external fascia. The skin incisions should be generous and fascia of these compartments separated from just below the knee to the ankle.

Upper extremity fasciotomy can be more complex. Performance of upper extremity fasciotomy should begin medially in the arm, and become sinusoidal from medial to lateral at the antecubital fossa incorporating the bicipital aponeurosis. Extension must be sufficiently lateral to open the fascia over the extensor wad. Rarely, a second dorsal fasciotomy incision over the dorsal wad extensor muscles is necessary. Gentle incision back to the volar fascia will help to also release this aspect (Fig. 232.9). Depending upon the severity of soft tissue damage and mechanism, this may need to be lengthened into a concomitant carpal tunnel release.

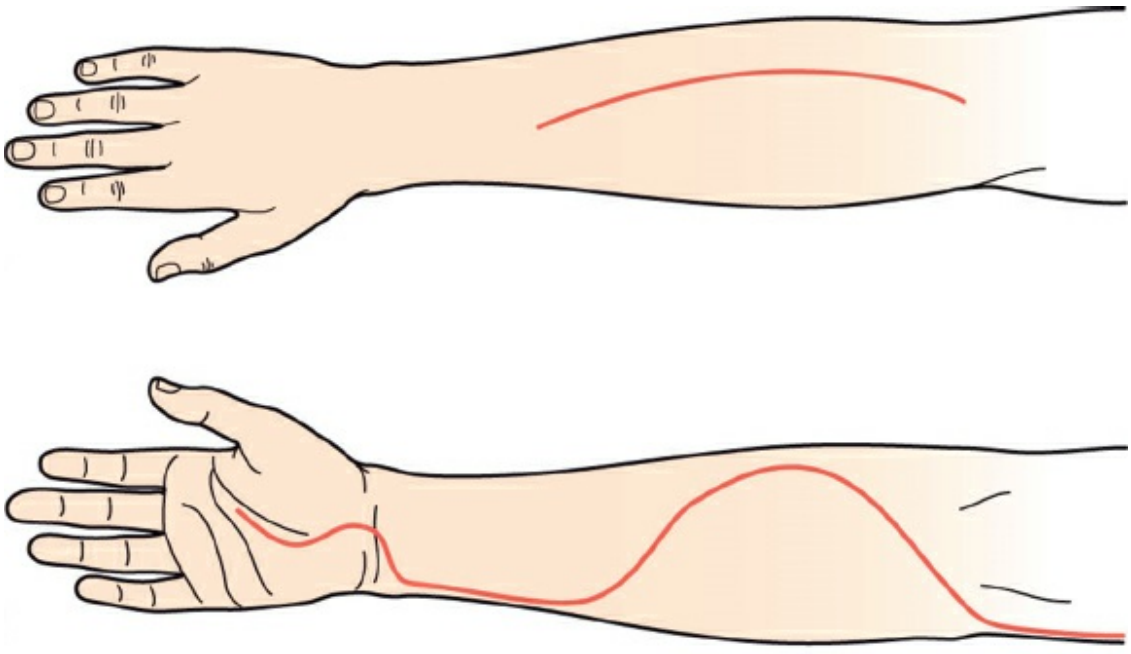

Figure 232.9. Incision lines for performance of upper extremity fasciotomy with mid-medial arm proceeding to S-shaped

antecubial fossa incision opening bicipital aponeurosis then laterally the extensor muscle wad back medially to the forearm muscles and finally through a carpal tunnel release if necessary. A separate dorsal incision to further release the extensor muscles can be created if required.

Wound Management

Contemporary wound care strategies and definitive reconstructive surgery for casualties with vascular injury have also influenced limb salvage rates. Large cavitary wounds require continual assessment and periodic debridement of devitalized tissue to ensure grafts remain covered with healthy muscle tissue. The use of closed negative pressure wound therapy has advanced the practice of closing deep soft tissue wounds to achieve sufficient muscle coverage. The impact of this technology is now used every day in every trauma environment and cannot be underemphasized. Some benefits of negative pressure therapy include wound splinting, perfusion enhancement, stimulation of cell division, wicking of edema and lymph, decreasing bacteriophilic exudate, and downregulation of adverse molecular regulators. Peck described our experience with 134 extremity vascular injuries with extensive soft tissue wounds undergoing repair, serial debridement, negative pressure therapy, and delayed closure. Of these, 57% were able to be managed with early delayed primary closure, confirming the effective use of negative pressure with vascular reconstruction. For wounds that cannot be closed easily, repeated debridements, wound washouts, and changes of negative pressure dressing can properly prepare the site for a split thickness skin graft. Early complications did occur, some requiring alternative revascularization routing. Wound infection occurred in 3.7%, anastomotic disruption in 3%, graft thrombosis in 4.5%, with amputation and mortality rates of 3% and 1.5%, respectively. Thus, a closure strategy must evolve as promptly as feasible and prudent use of extra-anatomic graft routing in large defects must be contemplated and prepared for. Definitive reconstructive surgery has also expanded horizons and demonstrated the effectiveness of both local rotational and microvascular free tissue transfers to salvage extremity wounds in those with vascular injury. This should also be considered in the closure strategy, and expertise sought early in the patient’s management should this be potentially relevant.

UPPER EXTREMITY

Subclavian Artery Injuries

Subclavian artery injuries are rare. They account for <8% of upper extremity arterial injury and 2% of all arterial injury. The right subclavian artery origin can be exposed via a median sternotomy. Further mid-portion exposure may require a clavicular extension with or without clavicular resection. The origin of the left subclavian artery is in a more posterior location on the aortic arch and is exposed through a left anterolateral thoracotomy. The left subclavian artery can be controlled through a median sternotomy with a supraclavicular or cervical extension, but is more classically described with origin control in an anterolateral thoracotomy and separate supraclavicular exposure as the former exposure is deep and can be challenging. A scapular/shoulder roll can be quite helpful. When exposure is difficult, particularly in large, muscular individuals, the clavicle can be resected in a subperiosteal fashion to aid exposure. When the goal is to expose the mid-portion of the subclavian artery in stable patients, a combined supraclavicular/infraclavicular two-incision technique has also been described, but in the authors' experience a single incision approach with subperiosteal clavicular resection used liberally with or without contemporaneous reconstruction of the clavicle seems most expeditious and flexible. The distal subclavian artery and proximal axillary artery are potentially treatable from a two-incision approach, but injury management may require a lateral clavicular resection, again with or without bony replacement. In our experience, longer-term issues with clavicle resection have been minimal. Others, however, do not share this view, and concerns over shoulder stability and use do exist.

Dissection in the area of the subclavian artery and vein should be performed with care given the abundance of adjacent nerve structures at risk for inadvertent injury. Aside from the brachial plexus and vagus nerve, the phrenic nerve sits on the anterior scalene muscle and should be identified and avoided. The anterior scalene muscle can be divided sharply once phrenic nerve identification occurs. Care must be taken to avoid the thoracic duct on the left and right lymph duct as they enter the jugulosubclavian venous confluence. The abundance of collaterals around the shoulder and neck may allow for ligation of the subclavian artery in emergency situations with the upper extremity remaining viable. Temporary shunting, however, may be considered, and in the author's

opinion provides a better expeditious alternative to ligation with delayed reconstruction possible. Tension-free repair of the subclavian artery cannot be overemphasized as the vessel is relatively thin, and delicate. Because of this, primary repair and patch angioplasty are challenging. If these are entertained, use of pledgets can be helpful. Prosthetic material can be used as an interposition graft for these larger, more proximal great vessel and upper extremity reconstructions. Autologous conduit such as saphenous vein, paneled saphenous vein, internal jugular vein, or even femoral vein can be entertained depending upon size, length, injury, and patient considerations. In more extensive injuries, ligation and revascularization using bypass with inflow based more proximally from the ascending aorta, innominate artery, or common carotid may also be an option.

Axillary Artery Injuries

Axillary artery injury occurs slightly more frequently than subclavian injury but is still rare compared to more distal vessels. It represents 2% to 8% of upper extremity and 2% to 3% of arterial injury. Sterile preparation of the ipsilateral neck, chest, supraclavicular fossa, and the circumferential arm is essential in order to fully prepare for optimal exposure and ease repair.

An infraclavicular incision made 2 fingerbreadths below and parallel to the clavicle will allow for access to the proximal axillary artery. Again, a scapular/shoulder roll can be useful. The clavipectoral fascia is next divided through the superior aspect of this incision opening a space, which allows visualization of the proximal most axillary artery. Identification and division of the pectoralis minor muscle through this exposure are frequently necessary to show the entire axillary artery. Exposure of the subclavian artery as discussed may also be required for more proximal axillary artery injuries. Precise clamping is essential given the proximity to the axillary vein and brachial plexus cords. Most axillary artery injuries require interposition grafting. Wide mobilization with side branch division for primary repair disrupts collateral flow and the author avoids it. Conduit concerns are similar to subclavian injury.

Brachial Artery Injuries

The brachial artery is frequently injured and represents 14% to 30% of arterial injuries and up to 60% of those in the upper extremity. Proximal control can often be obtained by manual compression of the brachial artery

against the humerus should ongoing hemorrhage be present. However, brachial artery contraction and local thrombosis after development of hematoma are not uncommon. A wide prep and drape including the ipsilateral neck and chest should be performed in case more proximal exposure is required. Access to the hand and wrist for palpation and Doppler interrogation of radial and ulnar arteries is also an important consideration in draping.

A longitudinal incision is made in the palpable groove on the medial side of the upper arm between the biceps and the triceps. This incision can be extended proximally and distally as needed. With retraction of the pectoralis muscles, exposure as high as the distal axillary artery is possible. The median nerve and ulnar nerve are in close proximity to the artery, and dissection should be performed with this in mind avoiding excessive retraction. The basilic vein should be preserved if possible, and ligation of side branches can aid with mobilization to allow for easier retraction. Distally, the bicipital aponeurosis must be divided to expose the brachial artery. The median nerve will be located deep and lateral to the artery proximal in the arm with the ulnar nerve medial. The median nerve crosses the brachial artery distally in the arm and will lie medial and deep to the artery in the antecubital fossa.

Brachial artery injuries resulting from low-velocity mechanisms may be repaired primarily if there is not a segment of devitalized artery. Injuries resulting from higher velocity mechanisms with or without soft tissue involvement, as well as blunt injuries, require a more extensive reconstruction. With any anastomosis on the brachial artery, spatulation is necessary to avoid narrowing. In some instances, an interrupted suture technique should be used given the relative small size of the artery and its tendency to spasm. Injuries to the brachial artery that occur distal to the profunda brachii origin may or may not present with critical ischemia depending upon the type of injury and the amount of associated damage to the collateral circulation from soft tissue wound or fracture.

Radial and Ulnar Artery Injuries

Forearm vascular injuries account for the majority of upper extremity arterial injury. Typically, control of forearm hemorrhage can be obtained with direct pressure or tourniquet. The proximal portion of the arm, hand, and fingers should be prepped and draped in a circumferential manner in order to allow for adequate proximal and distal control and adequate operative exposure and assessment of the radial and ulnar arteries. An S-

shaped incision over the antecubital fossa will allow for proximal exposure of both the radial and ulnar arteries. Identifying the brachial artery as described above and then tracing it distally may aid in identifying the ulnar and radial arteries. The radial artery follows the medial border of the brachioradialis muscle, and the medial groove of this muscle can be used as a landmark to make an incision in the mid forearm. In the distal wrist, the radial artery can be exposed by a longitudinal incision slightly lateral to the artery. The ulnar artery dives deep to the pronator teres slightly beyond the bifurcation and remains deep to the flexor muscles of the proximal forearm before emerging to a more superficial position in the midpoint of the arm that makes proximal exposure more difficult. A longitudinal incision is made on the medial side of the arm about 4 fingerbreadths distal to the medial epicondyle, and the artery can be identified between the flexor carpi ulnaris and flexor digitorum superficialis. In the wrist, the ulnar artery can be exposed through a longitudinal incision on the radial side of the flexor carpi ulnaris muscle in order to avoid the ulnar nerve, which runs medial to the ulnar artery.

Typically, the management of forearm artery injury is dependent upon whether or not there is a satisfactory continuous wave Doppler signal at the wrist and/or in the palmar arch of the hand. Should a reasonable signal be present with the injured vessel occluded, ligation is a viable alternative. With simple lacerations, primary repair using fine, permanent sutures is also reasonable. Vasodilators may be needed. Spatulation is required because of the small size of the vessel. Interrupted technique is useful. In significant forearm injuries with critical ischemia, vein graft interposition or bypass based from the more proximal brachial artery may be necessary. For reconstructions at the wrist, it may be helpful to have a hand surgeon present. Conduits for wrist/hand level reconstruction can include forearm or foot vein as well as various other autogenous arterial conduits.

LOWER EXTREMITY

Femoral Artery Injuries

The femoral arteries are the most commonly injured lower extremity arteries accounting for 25% to 50%. The superficial femoral artery (SFA) is injured most frequently. Control for common CFA injuries can be accomplished in several ways. First, if the patient is not doing well with ongoing hemorrhage or growing hematoma, it may be most expeditious to perform a lower laparotomy and control the distal external iliac artery in

the abdomen. Alternatively, if time allows but the groin morphology is obscure, retroperitoneal exposure of the distal external iliac artery for control is reasonable. This can be accomplished either by extending the traditional longitudinal incision over the groin obliquely onto the abdomen and entering the retroperitoneum with fascial incision parallel to the external oblique fibers (Fig. 232.10), or via a separate oblique lower abdominal incision. If the patient is stable and the situation permits, consideration for standard, longitudinal femoral exposure with control at the inguinal ligament can be appropriate if the mechanism is stab or puncture and the groin is stable. If there is any concern for any reason, more extensive exposure and control are encouraged rather than needing to seek further proximal control after hemorrhage control is less stable. Use of self-retaining retractor systems can be essential. The author prefers the pediatric OMNI system, but others can suffice. Selective iliac endovascular balloon control from the contralateral femoral artery or the arm can also be performed. Nonselective resuscitative endovascular balloon aortic control (REBOA) can be considered in unstable patients, but should be replaced by open control or selective iliac balloon control as soon as possible. Endovascular control is particularly useful when the clinical situation requires manual hemorrhage control in the groin. When the injury is proximal, division of the inguinal ligament has been espoused. This can be frequently avoided with endovascular control, or peritoneal or retroperitoneal exposures. These allow for broader control away from the femoral artery that makes repair easier with the extent of hematoma and edema in the groin.

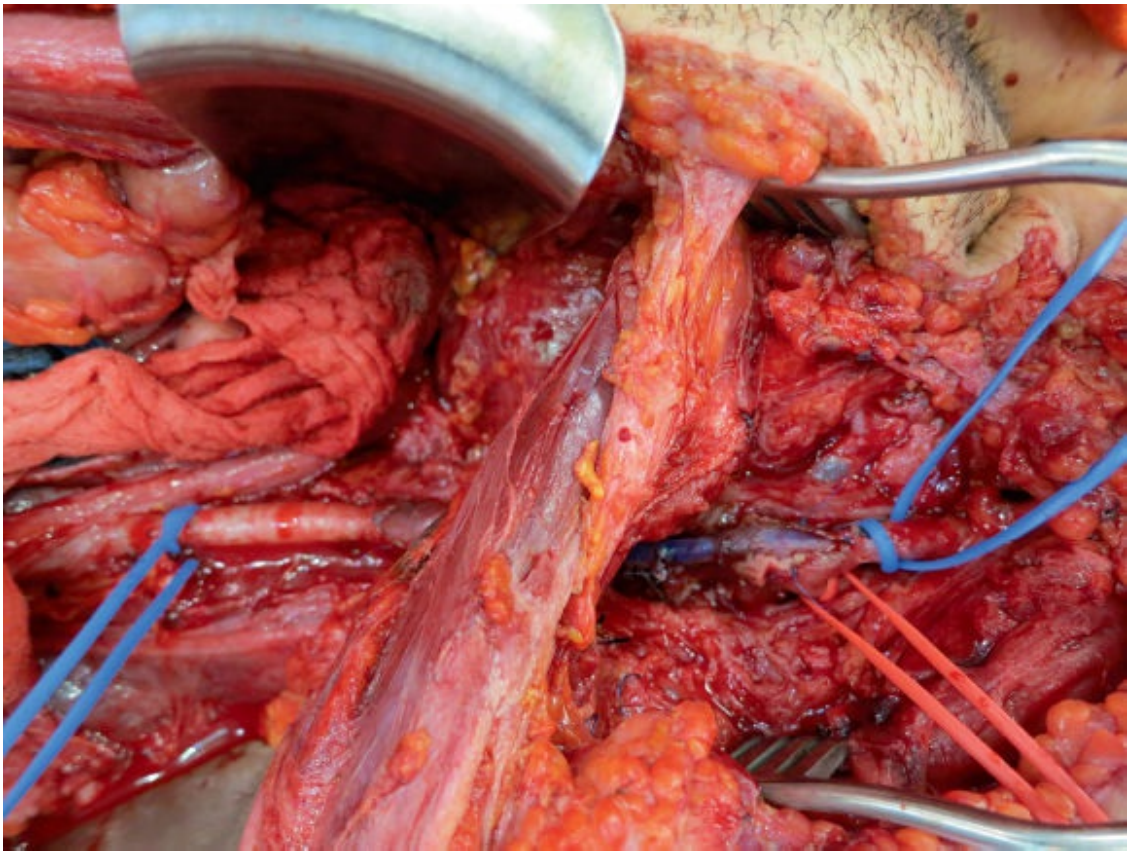

Figure 232.10. Vein graft repair of a common femoral artery injury preserving the bifurcation by beveling of the graft. The distal external iliac artery and common femoral artery are exposed through a single incision with both groin and retroperitoneal exposure. The retroperitoneum has been entered via an oblique fascial incision above the groin.

Repair of CFA injuries requires judgment. Arterial debridement and primary repair, autogenous or prosthetic patch angioplasty can be performed. These should not narrow the artery's original diameter. In more extensive injuries, interposition grafts are necessary. Autogenous saphenous vein interposition, prosthetic grafts, femoral vein, internal jugular vein, arm veins, or panel vein grafts can be considered. Proximal basilic vein is often a good option. It can be formidable to determine if simple vein interposition is adequate in the CFA. As the vein will enlarge over time, it has been the author's practice to accept vein sizes of at least two thirds the normal CFA size that is mostly in the 5 to 8 mm range. Salvage of the femoral bifurcation allowing flow into not only the SFA but also the profunda femoris artery (PFA), the major collateral supply to the limb, is important and repair should be purposeful in this regard. This can be accomplished with beveling of the femoral bifurcation, reimplantation

of the PFA origin onto the graft or the SFA, or separate bypass graft to the PFA. In damage control scenarios, separate parallel TVS or an inverted and cut hemodialysis catheter from the external iliac artery (EIA) to the SFA and PFA have been used with a well-planned full revascularization after resuscitation. Isolated SFA injury is largely repairable with GSV or prosthetic. PFA injuries can be ligated if necessary.

Popliteal Artery Injuries

The popliteal artery is injured frequently and accounts for some 12% to 25% of lower extremity arterial injuries. Combined popliteal venous injury is not uncommon and occurs in 30% to 60% of injuries. The tibial nerve is involved in 10% to 30% irrespective of the clinical mechanism. This milieu establishes popliteal artery injury as the arterial level carrying the highest risk of amputation in the extremities. Surgical approach to the popliteal vessels is usually medially that can utilize both traditional above and below knee incisions. This provides the freedom to exposure further proximally or distally as needed. Proximal control may be at the common femoral, or SFA level should above-knee popliteal artery control be impractical. The posterior approach should be reserved for only patients in whom the injury is isolated, are physiologically normal, and injury contained within a very focal area of the artery with little soft tissue injury. The prone position limits the overall systemic care of the trauma patient. The posterior approach may be more applicable in focal injury evolution late after injury event in a more elective situation. Occasionally, mostly in later, chronic scenarios or in cases of major tissue destruction or infection the lateral approach to the popliteal artery can be useful. Above knee, the incision is made at the posterior aspect of the iliotibial band with dissection between the vastus lateralis muscle anteriorly and the biceps femoris posteriorly. Below the knee, resection of the proximal fibula is required with protection of the common peroneal nerve. With the fibular periosteum retracted anteriorly, the vessels are found anterior to the gastrocsoleus complex. The lateral soleal arch must be divided.

With the medial approach, most injuries can be defined, and exposed. Yet, some 5 cm of retrogeniculate artery is inaccessible and when injured, must simply be ligated above and below with bypass performed. Late problems, such as bleeding or false aneurysm formation, in this segment due to residual branch flow are not reported but are ostensibly possible. With soft tissue injury, edema, and hematoma, exposure becomes more difficult and increases the length of this poorly exposable area. In many

multisystem injuries, proper exposure and repair require external fixation devices to either be loosened and then repositioned after vascular repair, or simply accomplished after vascular repair. It can be difficult to appropriately estimate graft length in these circumstances. A helpful method to address this is to expose and control the injury, shunt, and then allow proper reduction and placement of the external fixator pins. If necessary, measure the projected length of graft needed when reduced. Then, loosen the fixator, repair the vessel, and re-reduce appropriately and secure. This requires multidisciplinary team coordination. Leg exsanguination with tourniquet control can be considered in limbs with minimal deformity, and no major bony or soft tissue injury, but in the author's experience has not been utilized.

Tibial Artery Injuries

Tibial artery injuries represent 25% to 40% of lower extremity arterial injuries. The surgical approach to the tibial arteries is standard. The mid-distal anterior tibial artery (ATA) is approached through an incision 2 to 3 fingerbreadths lateral to the anterior tibial edge. It is identified on the interosseous membrane in the raphe lateral to the anterior tibialis muscle and medial to the extensor digitorum longus and extensor hallucis longus muscles. The posterior tibial artery (PTA) is approached medially via an incision 1 to 2 fingerbreadths posterior to the medial border of the tibia. Proximally, it runs underneath the soleal arch and this should be divided after identification of the below-knee popliteal artery taking care to stay superficial to the arteries (Fig. 232.11). The origin of the ATA is just distal to the soleal arch attachment. The tibioperoneal trunk and its bifurcation can be identified with distal dissection from the arch providing exposure of the proximal PTA. Distal to this, the PTA is found between the soleus and the flexor digitorum longus muscle and posterior to the flexor tendon just at and above the medial malleolus. The peroneal artery is more challenging and is usually approached medially with further dissection anterior to the posterior tibial vessels and nerve in the raphe behind the tibialis posterior. The lateral approach to the peroneal with excision of the fibula is rarely used in traumatic injury. These incisions, in standard positions, allow for simultaneous four-compartment fasciotomy.

Figure 232.11. Vein graft from the above-knee popliteal artery to the proximal posterior tibial artery. The soleal arch has been taken off the tibial edge to expose the proximal infrageniculate arterial system.

Similar to the forearm arterial injuries, the redundant perfusion to the foot allows for simple ligation of identified injuries should reasonable perfusion be appreciated. Continuous wave Doppler examination or on-table Duplex can be invaluable in determining tibial vessel patency and perfusion with ligation. The experiential dictum that one tibial vessel in continuity with the foot is acceptable should be followed. Patients with tibial level injury frequently have other injuries or reasons to be in shock making clinical assessment difficult. Furthermore, tibial reconstruction for traumatic injury is quite challenging and time-consuming, thus making selection of those who need revascularization thought-provoking and vital. Tibial reconstruction should only be pursued in true critical ischemia without viable distal perfusion, in those who do not have significant other life-threatening injuries and have a reasonable salvage potential with little soft tissue loss or foot deformities. We have recently shown statistically that this selective posture toward tibial injury repair results in similar amputation-free survival in those receiving tibial bypass versus those not,

and is a reasonable stance. When otherwise normal, these muscular arteries can easily develop spasm and resuscitation after addressing other life-threatening injuries with vigilant reassessment is prudent without hard indication of disruption. Anecdotally, the author has operated on infrageniculate injuries and been nearly unable to identify the tibial arteries due to this process. Yet, 12 to 24 hours later a palpable pulse is present with a warm foot in a vessel not intervened upon. Because of spasm, and the points above, it is wise to perform end-to-side anastomoses proximally to maintain axial flow to any vessels remaining inline distal.

ENDOVASCULAR TREATMENT

Application of endovascular techniques in the diagnosis and treatment of vascular trauma has become common. Yet, addressing arterial injury with endovascular methods remains relatively rare today as it is utilized in <8% of injuries. For obvious reasons, aortic and torso injuries have been the focus while the majority of reports delineating extremity use involve the junctional zones. Catheter-based techniques offer advantages in both acute vessel injuries and less urgent traumatic sequelae such as arteriovenous fistula and pseudoaneurysm particularly in junctional zones as they avoid operative dissection. Furthermore, use of covered stents is becoming recognized as a feasible alternative in definitive management in both penetrating and blunt trauma. These should be sized in a similar way to that of age-related vascular disease; however, the generally healthy arteries in trauma are smaller than atherosclerotic vessels and more like 20% to 30% oversizing may be needed for self-expanding devices. Even in the presence of hard signs of vascular injury (pulsatile bleeding, absent distal pulses, expanding hematoma, bruit or thrill) and hemodynamic instability, patients now may be considered for emergent endovascular balloon control and repair by either open or endovascular methodologies in the operating room with open conversion possible. Endovascular management requires endovascular expertise is available and the operating room is capable of timely endovascular proficiency. Today, as fixed hybrid operating room technology with state-of-the-art imaging becomes more commonplace, this is more and more realistic. In stable patients, today’s use of noninvasive anatomic imaging, usually CTA, allows for injury definition and endovascular treatment planning.

Upper Extremity

Control and definitive endovascular management of axillo-subclavian artery injuries is arguably the arena in which there is the most experience currently. These may require femoral access, retrograde ipsilateral brachial access, or both. Passing the wire under fluoroscopic guidance across vessel disruption from either the retrograde femoral or brachial approach may be challenging. Because of the shorter distance from the access site to the injury, many prefer the retrograde brachial approach. Directional catheters, balloon centering guidance, as well as combined femoral and brachial access with snare capture of the wire through the injury are techniques used to achieve wire access across the upper extremity vessel injury. Endovascular control and repair allow the surgical team to address other life-threating injuries avoiding the time and morbidity of median sternotomy, thoracotomy, or junctional zone open exposure.

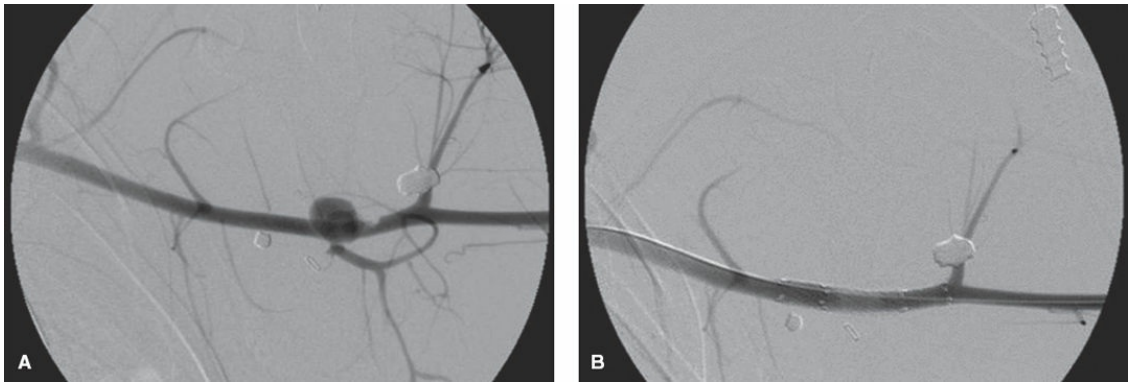

Figure 232.12. A. Retrograde left brachial artery access with arteriography showing a proximal brachial artery penetrating injury. **B.** Covered stent repair of the injury using two short segment self-expanding covered stents to exclude the injury and maintain axial brachial artery perfusion.

Either self-expanding or balloon expandable covered stents have been effective in managing select innominate and axillosubclavian injuries. In contrast, bare metal stents have been more commonly reported with treatment of small dissections or intimal flaps. One multicenter trial evaluating use of the self-expanding Wallgraft Endoprothesis (Boston Scientific; Natick, MA) for the treatment of 62 iliac, femoral, or subclavian arterial injuries showed the endoprosthesis achieved exclusion of the injury in 93.5% of cases and 90% of the subclavian artery injuries. Freedom from bypass was achieved in 100% of the subclavian injuries. Overall early mortality was 6.5%, but no procedure-related mortalities were reported and the most common post procedure complication involved

stenosis or occlusion. While the data support use of endovascular management of arterial injury, most procedures in this series were performed for iatrogenic injury (78%) and comparison of this study population with major accidental traumatic vascular injuries should be done with caution. Du Toit and colleagues reported 57 patients with penetrating subclavian artery injury who underwent stent graft repair during a 10-year period. One patient in this series died due to other injuries, and 3 (5%) developed early, non–limb-threatening stent graft occlusion. Complete follow-up data were available for 16 patients at a mean of 61 months (range 8 to 104 months), which showed that 5 patients had claudication and >50% in-stent stenosis on arteriogram. These patients were successfully re-treated with balloon angioplasty. Three additional asymptomatic patients in the follow-up cohort had stent occlusion, but did not require reintervention. There are also multiple case reports exhibiting use of endografts in the setting of upper extremity arterial trauma. Hershberger et al. reviewed 195 studies published between 1995 and 2007 and suggested the overall treatment success rate for supradiaphragmatic extremity arterial injury was 96%. When all reports reviewing endovascular treatment of innominate (n = 7), subclavian (n = 91), and axillary (n = 12) artery injuries were assessed, technical success rates were 85.7%, 96.7%, and 100%; periprocedural morbidity was 0%, 12.1%, and 8.3%; and mortality 0%, 3%, and 0%, respectively for each segment. The infrequent complications that were reported following endovascular repair of upper extremity vascular injury include access site pseudoaneurysm, arm claudication due to restenosis or thrombosis, and stent fracture.

While short-term durability has been suggested to be equivalent to operative repair, long-term durability of endovascular stents in upper extremity traumatic injuries has not been completely defined. Current results are encouraging. Specifically, patency rates appear to be acceptable with fewer reports describing the need to revascularize following upper extremity stent graft occlusion. Although the possibility of infection remains a legitimate concern, there is no suggestion that use of today's covered stents in trauma patients poses an undue risk. In our review of available literature on axillosubclavian arterial injury handled with endovascular repair, of 160 cases, no infections were noted, 3% underwent open conversion, and 8.5% required reintervention. Thus, use of endovascular stenting does not preclude either future open repair or catheter-based reintervention. Longer follow-up periods and larger

experiences are needed before definitive durability of these interventions can be appreciated. Reports describing endovascular intervention for successful management of brachial artery injury and transection are appearing (Fig. 232.12A,B). Whether this technique becomes widely applicable remains to be seen.

Lower Extremity

Description of lower extremity arterial endovascular repair is much less mature than that of the proximal upper extremity. As early as 1994, lower extremity trauma has been approached with endovascular methods when Marin and the Montefiore group in New York described three patients with homemade stent grafts in the SFA location for pseudoaneurysms and arteriovenous fistulas. However, since then most communications are case reports with many describing embolization of branch vessel bleeding and fewer axial endografts. As noted above, White and coworkers described use of axial stent grafts at the femoral and iliac levels. Early injury exclusion failures were most common in the femoral artery, and early mortality was not endograft related. Exclusion success at 1 year was 91.3% for iliac arteries but only 62.3% at the femoral level. No femoral failure required reintervention. Recent assessment of lower extremity arterial injury at a level I trauma center from 2005 to 2010 indicated endovascular methods for repair of infrainguinal arterial injury occurred in four femoral level injuries representing only 7.5% of injuries. An initial report from the multicenter Prospective Observational Vascular Injury Treatment Registry (PROOVIT) describing over 500 arterial injuries at 13 trauma centers over 1 year indicated only 3 endovascular interventions in the lower extremity. Practice Guidelines on lower extremity arterial injury from the Eastern Association for the Surgery of Trauma were provided in 2012, and they decried the lack of series and data describing stent grafting for axial vessel injury. They recommended case-by-case selection. The general technical approach to arterial injury in the lower extremity is similar to that of the upper extremity. The caveat being combined antegrade and retrograde access for transection traversal is more difficult, or may be simply contraindicated. Infrageniculate injuries can be approached via a contralateral, retrograde “up and over” method, or percutaneous or open antegrade access. Proximal extremity injuries may be approached from brachial access. More information is unmistakably needed in order to better define the rolls and outcomes of endovascular

repair of axial lower extremity arterial injury. At this point, feasibility and safety are discernable.

POSTOPERATIVE CARE AND COMPLICATIONS

Postrepair antiplatelet therapy should be utilized in arterial repair unless contraindicated due to other injuries. The use of inferior vena cava (IVC) filters in venous repair or ligation is debated with no clear consensus, but consideration is justifiably important when other injuries preclude antithrombotic use. To this end, the proper antithrombotic regimen indicated with extremity venous repair or ligation is also debated. It would make sense that in isolated extremity injury, anticoagulants should be considered with venous ligation or repair. When concomitant injuries preclude this, the maximal antiplatelet regimen reasonable should be instituted as soon as feasible. When combined arterial and venous injuries occur, low-intensity antiplatelet therapy, such as aspirin, with anticoagulants should be contemplated. These obviously must be tempered with the degrees of soft tissue injury, neuroaxial injury, or cavitary injury. However, as noted above Quan and colleagues have recently reconfirmed that the incidence of clinically important pulmonary embolism after either venous repair or ligation in combat injuries with selective use of antithrombotic regimens is <5%. Elevation and compression postoperatively are essential. Standard postoperative surgical care surrounds graft monitoring surveillance with physical examination and duplex ultrasound. Wound care for operative wounds, traumatic wounds, and fasciotomies is paramount. As noted, this may include serial washout, debridement, and negative pressure therapy. Aggressive physical therapy is important. Wound infection occurs in 3% to 5%, anastomotic disruption in 3% to 5%, early graft thrombosis in up to 5%, with in-hospital amputation and mortality rates of 3% to 5% and 1% to 2%, respectively. Anastomotic disruption may occur due to poor coverage, infection or prolonged negative pressure therapy and desiccation. Reoperation for re-grafting, rerouting or coverage improvement thus occurs in this minority of patients. Compartment syndrome may occur depending upon vascular and orthopedic concerns and injury mechanisms. It may be present in over 50% of extremity injuries associated with ischemia and fracture. Venous injury can play a role. Thus, as noted, fasciotomy is a key component of the care of the patient with extremity vascular injury. Neuromuscular recovery dictates long-term limb salvage that is estimated at roughly 80%

at 3 years.

EDITOR'S COMMENT

Dr. Clouse in this chapter draws extensively on his long and decorated experience in the Air Force, especially during the Iraqi conflict. After reading this chapter on injury to the lower extremities, I believe it represents what this book is intended to provide for its readers, namely, detailed coverage of a topic written by a master clinician in the field. Two things are true of the management of extremity trauma for sure. There is little doubt that endovascular therapy has positively impacted outcomes from lower and upper extremity trauma (Scott AR, Gilani R, Tapia NM, et al. Endovascular management of traumatic peripheral arterial injuries. *J Surg Res* 2015;199(2):557–63). Second, the concept of damage control continues to work, even though at times it is hard to leave the operating room, while the salient outcome rendered in the operating room is not perfect, but acceptable (DuBose JJ, Savage SA, Fabian TC, et al.; AAST PROOVIT Study Group. The American Association for the Surgery of Trauma PROspective Observational Vascular Injury Treatment (PROOVIT) registry: multicenter data on modern vascular injury diagnosis, management, and outcomes. *J Trauma Acute Care Surg* 2015;78(2):215–22; discussion 222–3).

I learned a number of things from reading this chapter. One is that those of us managing civilian trauma would do well to use more shunts in injured extremities with arterial and venous injuries (Hornez E, Boddaert G, Ngabou UD, et al. Temporary vascular shunt for damage control of extremity vascular injury: a toolbox for trauma surgeons. *J Vasc Surg* 2015;152(6):363–8). The age-old dilemma when managing extremity trauma has to do with who goes first: orthopedics with the external fixators or surgery with restoration of blood flow. I know that the ABC's should necessitate that circulation is before orthopedics, but who hasn't done a bypass without the bone extracted only to find the vascular reconstruction has failed because of tension, compression, etc. The data are pretty strong suggesting that shunts save limbs, remarkably even when they thrombose (Hornez E, Boddaert G, Ngabou UD, et al. Temporary vascular shunt for damage control of extremity vascular injury: a toolbox for trauma surgeons. *J Vasc Surg* 2015;152(6):363–8). We need to use more shunts in civilian lower extremity trauma.

In addition, the use of wound management systems has also improved the outcomes of extremity trauma (Fang R, Dorlac WC, Flaherty SF, et al. Feasibility of negative pressure wound therapy during intercontinental aeromedical evacuation of combat casualties. *J Trauma* 2010;69(Suppl 1):S140–5; Kanakaris NK, Thanasas C, Keramaris N. The efficacy of negative pressure wound therapy in the management of lower extremity trauma: review of clinical evidence. *Injury* 2007;38(Suppl 5):S9–18). Often despite performing an eloquent bypass, the wound that is contaminated to begin with is closed. As the wound progresses and becomes frankly infected, bypasses either blow out or

thrombose. The idea that one can perhaps just cover the bypass with nearby viable muscle and come back and wash out the wound using a wound management system has also likely helped to save some limbs.

On that same note, I often find in civilian trauma we are slow to make large incisions for fasciotomies. I have found on more than one occasion an inadequate fasciotomy in a trauma patient. Let me encourage readers of this commentary to make larger incisions and to use wound closure devices/systems to help accelerate healing placed on about day 2 or 3. It would be hard for me to provide objective data on this, but anecdotally it seems like I see fewer foot drops with more complete fasciotomies.

Finally, I am not sure about the use of IVC filters in young trauma patients (Quirke TE, Ritota PC, Swan KG. Inferior vena caval filter use in U.S. trauma centers: a practitioner survey. *J Trauma* 1997;43(2):333–7). I am sure there are data supporting their use, but the placement of IVC filters to prevent pulmonary embolus has been so overperformed largely based on soft indications. Clearly the immobilized, multitrauma patient with long bone fractures who may not be able to be placed on prophylactic heparin may benefit from an IVC filter. However, we now on a routine basis see patients with complications from IVC filters with hooks in the duodenum, aorta, iliacs, etc. Maybe I should make a plea that these filters, if placed temporarily, be removed as soon as these patients who have experienced extremity trauma are up and ambulatory and/or can be placed on prophylactic anticoagulation.

Preface 82
Contents 85
VOLUME I 103
SECTION I PERIOPERATIVE CARE OF THE SURGICAL PATIENT 103
CHAPTER 1: Metabolic and Inflammatory Responses to Trauma and Infection 104
CHAPTER 2: Perioperative Management: Practical Principles, Molecular Basis of Risk, and Future Directions 162
CHAPTER 3: Enteral Nutrition Support 254
CHAPTER 4: Cardiovascular Monitoring and Support 290
CHAPTER 5: Pulmonary Risk and Ventilatory Support 342
CHAPTER 6: Hemorrhagic Risk and Blood Components 393
CHAPTER 7: Perioperative Antimicrobial Prophylaxis and Treatment of Surgical Infection 414
CHAPTER 8: Multiple Organ Dysfunction Syndrome: Prevention and Clinical Management 462
CHAPTER 9: Immunosuppression in Organ Transplantation 490
CHAPTER 10: Surgeons and the Opioid Epidemic 515
SECTION II BASIC SURGICAL SKILLS: NEW AND EMERGING TECHNOLOGY 537
CHAPTER 11: Ventral Abdominal Hernia: Open and Minimally Invasive and Component Separation Release 538
CHAPTER 12: Laparoscopic Suturing and Stapling 583
CHAPTER 13: Ultrasonography by Surgeons 603
CHAPTER 14: Tumor Ablation: Technologies and Clinical Applications 652

CHAPTER 15: Upper and Lower Gastrointestinal Endoscopy 685
CHAPTER 16: Soft Tissue Reconstruction With Flap Techniques 712
CHAPTER 17: Hand Surgery: Traumatic and Infectious Emergencies 795
CHAPTER 18: Robotic Surgery 832
CHAPTER 19: Surgical Energy 867
SECTION III THE HEAD AND NECK 895
CHAPTER 20: Anatomy of the Head and Neck 896
CHAPTER 21: Surgery of the Major Salivary Glands 968
CHAPTER 22: Anatomy of the Parotid Gland, Submandibular Triangle, and Floor of the Mouth 991
CHAPTER 23: Lip Reconstruction 1017
CHAPTER 24: Surgery for Cancer of the Oral Cavity 1040
CHAPTER 25: Neck Dissection 1071
CHAPTER 26: Congenital Lesions: Thyroglossal Duct Cysts, Branchial Cleft Anomalies, and Cystic Hygromas 1119
CHAPTER 27: Vascular Anomalies of Infancy and Childhood 1142
CHAPTER 28: Surgical Treatment of Laryngeal Cancer: A Legacy of Minimally Invasive Innovation and the Preservation of Airway, Swallowing, and Vocal Function 1173
CHAPTER 29: Surgical Treatment of Pharyngeal Cancer 1212
CHAPTER 30: Malignant Melanoma and Skin Cancer 1247
CHAPTER 31: Melanoma 1270
CHAPTER 32: Inguinal Lymph Node Dissection: Indications and Surgical Technique 1302
CHAPTER 33: Evaluation and Repair of Common Facial Injuries 1312
CHAPTER 34: Resection and Reconstruction of the Trachea 1352
CHAPTER 35: Penetrating Neck Injuries 1390
CHAPTER 36: Neurosurgical and Neurologic Emergencies for Surgeons 1420
CHAPTER 37: Tracheotomy 1461

SECTION IV ENDOCRINE SURGERY 1486
CHAPTER 38: Surgical Anatomy of the Thyroid, Parathyroid, and Adrenal Glands 1487
CHAPTER 39: Biopsy, Lobectomy, Total Thyroidectomy, and Lymph Node Dissection for Thyroid Cancer 1534
CHAPTER 40: Comprehensive Parathyroidectomy for the Treatment of PHPT, Including Intraoperative Parathyroid Hormone Assay–Guided Parathyroidectomy 1577
CHAPTER 41: Minimally Invasive Parathyroidectomy 1610
CHAPTER 42: Secondary and Tertiary Hyperparathyroidism 1633
CHAPTER 43: Transsternal, Transcervical, and Minimally Invasive Thymectomy for Benign and Malignant Disease 1648
CHAPTER 44: Adrenalectomy—Minimally Invasive and Open 1688
CHAPTER 45: Pancreatic Neuroendocrine Tumors 1725
SECTION V THE BREAST, CHEST, AND MEDIASTINUM 1753
CHAPTER 46: Embryology and Anatomy of the Breast 1754
CHAPTER 47: Benign Disease and Breast Pain 1780
CHAPTER 48: Diagnostic Approach to Breast Abnormalities 1801
CHAPTER 49: Breast-Conserving Surgery 1843
CHAPTER 50: Radiation Treatment, Whole and Partial Breast and Intraoperative Irradiation 1905
CHAPTER 51: Ablative Techniques for Benign and Malignant Breast Tumors 1933
CHAPTER 52: Sentinel Lymph Node Biopsy in Breast Cancer 1969
CHAPTER 53: Lymphedema—Pathophysiology, Prevention, and Treatment 1986
CHAPTER 54: Modified Radical Mastectomy and Radical Mastectomy 2022
CHAPTER 55: Oncoplastic Techniques for Breast Conservation Surgery 2086
CHAPTER 56: Breast Reconstruction Following Mastectomy 2109

CHAPTER 57: Chest Wall Resection and Reconstruction for Advanced/Recurrent Carcinoma of the Breast 2160
CHAPTER 58: Clinical Trials and Follow-Up for Breast Cancer 2192
CHAPTER 59: The Deep Inferior Epigastric Perforator Flap for Breast Reconstruction 2216
CHAPTER 60: Applied Anatomy of the Chest Wall and Mediastinum 2239
CHAPTER 61: Thoracic Trauma 2278
CHAPTER 62: Pulmonary Resection 2310
SECTION VI THE DIAPHRAGM 2365
CHAPTER 63: Surgical Anatomy of the Diaphragm 2366
CHAPTER 64: Congenital Diaphragmatic Hernia 2420
CHAPTER 65: Eventration of the Diaphragm 2442
CHAPTER 66: Traumatic Injury to the Diaphragm 2467
CHAPTER 67: Paraesophageal Hernia—Open Repair 2492
CHAPTER 68: Gastroesophageal Reflux Disease in Infants and Children 2518
SECTION VII THE GASTROINTESTINAL TRACT 2549
Part A: The Esophagus 2550
CHAPTER 69: The Anatomy of the Esophagus 2550
CHAPTER 70: Transthoracic Antireflux Procedures 2597
CHAPTER 71: Laparoscopic Esophagectomy 2636
CHAPTER 72: Nissen–Rossetti Antireflux Fundoplication (Open Procedure) 2667
CHAPTER 73: Modified Hill Repair for Gastroesophageal Reflux 2689
CHAPTER 74: Laparoscopic Antireflux Surgery 2714
CHAPTER 75: Peroral Endoscopic Myotomy for Achalasia and Endoluminal Approaches for GERD 2763
CHAPTER 76: Minimally Invasive Treatment of Achalasia and Other Esophageal Dysmotility 2784
CHAPTER 77: Esophagogastrectomy for Carcinoma of the Esophagus 2827
CHAPTER 78: Transhiatal Esophagectomy Without Thoracotomy 2875

CHAPTER 79: Esophageal Perforation 2936
CHAPTER 80: Repair of Esophageal Atresia and Tracheoesophageal Fistula 2972
CHAPTER 81: Pathology and Treatment of Zenker Diverticulum 3007
Part B: The Stomach and Duodenum 3023
CHAPTER 82: Anatomic Considerations in Gastroduodenal Surgery 3023
CHAPTER 83: Percutaneous Endoscopic Gastrostomy 3097
CHAPTER 84: Distal Gastrectomy With Billroth I or Billroth II Reconstruction 3117
CHAPTER 85: Selective Vagotomy, Antrectomy, and Gastroduodenostomy for the Treatment of Duodenal Ulcer 3151
CHAPTER 86: Selective and Nonselective Vagotomies 3185
CHAPTER 87: Duodenal Ulcer Disease: Pathogenesis and Management of Complications 3208
CHAPTER 88: Gastric Cancer 3276
CHAPTER 89: Distal Gastrectomy With Roux-en-Y Reconstruction and Laparoscopic Gastrectomy 3313
CHAPTER 90: Postgastrectomy Syndromes in the Current Era 3332
CHAPTER 91: Congenital Pyloric Stenosis and Duodenal Obstruction 3379
CHAPTER 92: Diabetes and Other Metabolic Diseases 3408
CHAPTER 93: Vascular Compression of the Duodenum 3433
Part C: Bariatric and Metabolic Diseases 3454
CHAPTER 94: Gastrointestinal Stromal Tumors 3454
CHAPTER 95: The Laparoscopic Gastric Band Technique of Placement 3468
CHAPTER 96: Revision and Conversion of Vertical Banded Gastroplasty 3484
CHAPTER 97: Laparoscopic Gastric Bypass 3501
CHAPTER 98: Laparoscopic Gastric Sleeve 3525
CHAPTER 99: Laparoscopic Biliopancreatic Diversion With Duodenal Switch 3547

CHAPTER 100: EndoBarrier for the Treatment of Morbid Obesity and Type II Diabetes 3572
CHAPTER 101: Revisional Bariatric Surgery 3594
CHAPTER 102: Management of Complications of Gastric Bypass and Repair 3624
VOLUME II 3647
Part D: The Liver and Biliary Tract 3647
CHAPTER 103: Surgical Anatomy of the Liver and Bile Ducts 3647
CHAPTER 104: Diagnostic Considerations in Biliary and Liver Disease 3681
CHAPTER 105: Approaches to Drainage of Hepatic, Perihepatic, and Subhepatic Abscesses 3719
CHAPTER 106: Echinococcal Cyst—Open and Laparoscopic Approach 3740
CHAPTER 107: Hepatic Resection for Primary and Metastatic Tumors 3796
CHAPTER 108: Treatment of Major Hepatic Trauma 3834
CHAPTER 109: Cholecystostomy, Cholecystectomy, and Intraoperative Evaluation of the Biliary Tree 3878
CHAPTER 110: Laparoscopic Cholecystectomy, Intraoperative Cholangiography, and Common Bile Duct Exploration 3907
CHAPTER 111: Reconstruction of the Bile Duct: Anatomic Principles and Surgical Techniques 3951
CHAPTER 112: Current Application of Endoscopic Sphincterotomy, Lateral Choledochoduodenostomy, and Transduodenal Sphincteroplasty 3990
CHAPTER 113: Primary Sclerosing Cholangitis 4022
CHAPTER 114: High Malignant Biliary Tract Obstruction 4049
CHAPTER 115: Cholecystojejunostomy and Choledocho/Hepaticojejunostomy 4072
CHAPTER 116: Operative Treatment for Choledochal Cysts 4095
CHAPTER 117: Biliary Atresia—Portoenterostomy 4116
CHAPTER 118: Liver Transplantation 4138

CHAPTER 119: Special Comment: The Unfinished Legacy of Liver Transplantation 4184
CHAPTER 120: The Associating Liver Partition and Portal Vein Ligation for Staged Hepatectomy (ALPPS) Approach 4211
Part E: The Pancreas 4237
CHAPTER 121: Surgical Anatomy of the Pancreas 4237
CHAPTER 122: Selection of Surgical Therapy for Chronic Pancreatitis 4299
CHAPTER 123: Operative Interventions for Chronic Pancreatitis 4332
CHAPTER 124: Parenchyma-Sparing, Limited Partial and Total Pancreatic Head Resection for Inflammatory Tumor, Cystic Neoplasia, Neuroendocrine Adenoma, and Low-Risk Periampullary Malignant Tumor 4359
CHAPTER 125: Necrosectomy for Acute Necrotizing Pancreatitis 4383
CHAPTER 126: Management of Complications of Acute and Chronic Pancreatitis: Endoscopic, Laparoscopic, and Open Approaches to Pancreatic Pseudocysts and Pancreatic Necrosis 4414
CHAPTER 127: Pancreaticoduodenectomy and Total Pancreatectomy for Cancer 4459
CHAPTER 128: Operative Management of Pancreatic Trauma 4516
CHAPTER 129: Splanchnic Denervation of the Pancreas for Intractable Pain 4537
Part F: Introduction to Portal Hypertension 4556
CHAPTER 130: Anatomy of the Portal System and Experience With Portacaval Shunt 4561
CHAPTER 131: Small-Diameter Prosthetic Interposition Shunt 4608
CHAPTER 132: Distal Splenorenal Shunts: Hemodynamics of Total Versus Selective Shunting 4632
CHAPTER 133: Central Splenorenal Shunts 4660
CHAPTER 134: Endoscopic Therapy in the Management of Esophageal Varices 4675
Part G: Surgery of the Small Intestine 4715

CHAPTER 135: Small Bowel Obstruction 4715
CHAPTER 136: Metabolic Surgery and Intestinal Bypass for Hypercholesterolemia 4738
CHAPTER 137: The Continent Ileostomy 4764
CHAPTER 138: Technique of Ileostomy Construction and Closure 4785
CHAPTER 139: Gastrointestinal-Cutaneous Fistulas 4814
CHAPTER 140: Surgical Treatment of Small Bowel Crohn Disease 4845
Part H: Surgery of the Colon 4885
CHAPTER 141: Clinical Anatomy for Procedures Involving the Small Bowel, Colon, Rectum, and Anus 4885
CHAPTER 142: The Appendix 4916
CHAPTER 143: Large Bowel Obstruction 4949
CHAPTER 144: Surgical Treatment of Colonic and Perianal Crohn Disease 4977
CHAPTER 145: Surgery for Toxic Megacolon 5006
CHAPTER 146: Total Proctocolectomy and Inter-Sphincteric Proctectomy for Benign Disease 5026
CHAPTER 147: Ileoanal Pouch Procedure for Ulcerative Colitis and Familial Adenomatous Polyposis 5042
CHAPTER 148: Total Colectomy and Ileorectal Anastomosis 5067
CHAPTER 149: Surgery for Diverticulitis 5107
CHAPTER 150: Technique of Colostomy Construction and Closure 5138
CHAPTER 151: Care of Stomas 5164
CHAPTER 152: Open and Minimally Invasive Right Hemicolectomy for Cancer 5187
CHAPTER 153: Open and Minimally Invasive Left Hemicolectomy for Neoplasms of the Descending Colon, Sigmoid, and Upper Rectum 5211
CHAPTER 154: Historical Perspectives on Total Mesorectal Excision 5234
CHAPTER 154A: Advances in Total Mesorectal Excision 5284
CHAPTER 155: Open and Minimally Invasive Sphincter-

Preserving Radical Resection for Malignant Disease of the Middle and Lower Thirds of the Rectum 5311
CHAPTER 156: Abdominoperineal Resection for Rectal Cancer 5354
CHAPTER 157: Abdominoperineal Resection for Rectal Cancer 5387
CHAPTER 158: The Approach to Reoperative Pelvic Surgery in Rectal Cancer 5412
CHAPTER 159: Sacral Resection for Recurrent Rectal Cancers 5429
CHAPTER 160: Cytoreductive Surgery and Hyperthermic Intraperitoneal Chemotherapy for Cancers of the Appendix and Colon 5457
CHAPTER 161: Management of Retrorectal Tumors 5471
CHAPTER 162: Rectal Prolapse: The Open Abdominal Approach 5504
CHAPTER 163: Rectal Prolapse 5535
CHAPTER 164: Anorectal Disorders 5562
CHAPTER 165: Transanal Excision of Rectal Neoplasms 5637
CHAPTER 166: Functional Bowel Disorders 5669
CHAPTER 167: Groin Dissection 5714
CHAPTER 168: Transanal Pull-Through for Hirschsprung Disease 5735
CHAPTER 169: Neonatal Enterocolitis and Short Bowel Syndrome 5749
SECTION VIII NONGASTROINTESTINAL TRANSABDOMINAL SURGERY 5771
Part A: The Spleen 5772
CHAPTER 170: Laparoscopic Splenectomy 5772
Part B: The Urinary Tract and Bladder 5811
CHAPTER 171: Anatomy of the Kidneys, Ureter, and Bladder 5811
CHAPTER 172: Surgical Management of Nephrolithiasis 5833
CHAPTER 173: Operations on the Ureteropelvic Junction 5855
CHAPTER 174: Radical Nephrectomy for Renal Cell 5872

Cancer 5872

CHAPTER 175: Radical Cystectomy and Orthotopic Urinary Diversion for Bladder Cancer 5912

CHAPTER 176: Laparoscopic Pelvic and Retroperitoneal Lymph Node Dissection 5975

CHAPTER 177: Robot-Assisted Radical Prostatectomy 6020

CHAPTER 178: The Undescended Testis 6032

CHAPTER 179: Surgical Management of Wilms Tumor 6049

CHAPTER 180: Genitourinary Tract Trauma 6077

CHAPTER 181: Supravesical Urinary Diversion 6121

Part C: Gynecologic Surgery 6156

CHAPTER 182: Cesarean Delivery 6156

CHAPTER 183: Abdominal Hysterectomy 6183

CHAPTER 184: Radical Hysterectomy 6204

CHAPTER 185: Surgical Management of Ovarian Carcinoma 6237

CHAPTER 186: Anterior and Posterior Colporrhaphy 6294

Part D: Surgery of the Hernia 6348

CHAPTER 187: Surgical Anatomy of the Hernial Rings 6348

CHAPTER 188: Overview of Inguinal and Femoral Hernia Repairs 6417

CHAPTER 189: The Shouldice Method of Inguinal Herniorrhaphy 6463

CHAPTER 190: Iliopubic Tract Repair of Inguinal Hernia: The Anterior (Inguinal Canal) Approach 6498

CHAPTER 191: Iliopubic Tract Repair of Inguinal and Femoral Hernia: The Posterior (Preperitoneal) Approach 6526

CHAPTER 192: Kugel Technique of Groin Hernia Repair 6550

CHAPTER 193: Generations of the Plug-and-Patch Repair: Its Development and Lessons From History 6569

CHAPTER 194: Postherniorrhaphy Inguinodynia: Causes, Prevention, and Surgical Treatment: Triple Neurectomy 6603

SECTION IX VASCULAR SURGERY 6619

CHAPTER 195: Carotid Bifurcation Disease: Carotid Endarterectomy and Stenting 6620
CHAPTER 196: Brachiocephalic Reconstruction: Open and Endovascular 6659
CHAPTER 197: Carotid Body Tumors 6678
Part B: Aneurysmal Disease 6711
CHAPTER 198: Open Thoracoabdominal Aortic Aneurysm Repair 6711
CHAPTER 199: Open Infrarenal and Pararenal Aortic Aneurysm Repair 6739
CHAPTER 200: Endovascular Repair of Abdominal Aortic Aneurysms 6763
CHAPTER 201: Ruptured Abdominal Aortic Aneurysms 6778
CHAPTER 202: Femoral and Popliteal Artery Aneurysms 6819
CHAPTER 203: Treatment of Splenic Artery Aneurysms: Open and Endovascular 6846
Part C: Chronic Lower Extremity Occlusive Disease 6859
CHAPTER 204: Aortofemoral Bypass 6859
CHAPTER 205: Aortoiliac Occlusive Disease: Extraanatomic Bypass 6892
CHAPTER 206: Endovascular Procedures for Aortoiliac Occlusive Disease 6913
CHAPTER 207: Reversed Vein Bypass Grafts to Popliteal, Tibial, and Peroneal Arteries 6932
CHAPTER 208: Peripheral Arterial Disease: Prosthetic Bypass 6960
CHAPTER 209: Dorsalis Pedis, Tarsal, and Plantar Artery Bypass 6982
CHAPTER 210: Peripheral Vascular Occlusive Disease: Endovascular 7006
CHAPTER 211: Minor Amputations 7024
CHAPTER 212: Major Lower Extremity Amputation 7046
CHAPTER 213: The Prevention and Treatment of Problems With the Diabetic Foot 7072
Part D: Acute Lower Extremity Ischemia 7097

Part D: Acute Lower Extremity Ischemia 7097
CHAPTER 214: Embolectomy 7097
CHAPTER 215: Fasciotomy 7118
Part E: Mesenteric and Renal Artery Disease 7141
CHAPTER 216: Renal Artery Occlusive Disease: Open and Endovascular Management 7141
CHAPTER 217: Acute Mesenteric Artery Ischemia: Open and Endovascular 7176
CHAPTER 218: Techniques of Open and Endovascular Revascularization to Treat Chronic Mesenteric Ischemia 7200
Part F: Vascular Infection 7232
CHAPTER 219: Mycotic Aneurysms 7232
CHAPTER 220: Surgical Management of Aortic Graft Infections 7251
Part G: Venous Disorders 7279
CHAPTER 221: Contemporary Operative Venous Thrombectomy 7279
CHAPTER 222: Acute Deep Venous Thrombosis: Endovascular 7298
CHAPTER 223: Chronic Deep Vein Thrombosis/Postthrombotic Syndrome: Open and Endovascular Treatment 7328
CHAPTER 224: Vena Cava Filter Placement 7356
CHAPTER 225: Venous Insufficiency 7381
Part H: Dialysis Access 7402
CHAPTER 226: Autogenous Arteriovenous Hemodialysis Access 7402
CHAPTER 227: Hemodialysis Access-Prosthetic Arteriovenous Access 7446
Part I: Thoracic 7465
CHAPTER 228: Thoracic Outlet Syndrome 7465
CHAPTER 229: Thoracic Aortic Transection 7497
Part J: Trauma 7517
CHAPTER 230: Vascular Injuries to the Neck, Including the Subclavian Vessels 7517
CHAPTER 231: Injury to the Abdomen: Open and

CHAPTER 232: Injury to the Extremities: Open and Endovascular Management 7571

Index 7615
